Nucleophile-to-electrophile attacks are the most common protein conjugation reactions. The strongest nucleophile present in natural proteins is the cysteine thiol group. However, this amino acid is relatively rare, and when it is present in a protein, it is often involved in the catalytic center or in disulfide bridges. Cysteine residues are therefore not always optimal as sites for conjugation reactions. Consequently, the main targets of protein conjugation are the ε-lysil amino groups (together with the N-terminal (α-) amino group). The natural occurrence of lysine residues in mammalian proteins is around 6% (*13*). Therefore, site-specificity can be difficult to achieve. When there are no lysine residues available, or lysine residues form part of the active site of a protein, conjugation to carboxylic acid groups can be considered. However, it is then difficult to avoid cross-linking with the amino groups of the protein itself (*1*).

In nature, the range of functions of proteins is extended by posttranslational modifications of amino acid residues. Other functional groups, peptides, or proteins can be attached and structural changes can be made. Even the very chemical nature of an amino acid residue can be changed (*14*). The enzymes that naturally induce such posttranslational modifications can be used for bioconjugation as well. Transglutaminase can, for example, be used for polyamination (*15*); farnesyltransferase and geranylgeranyltransferase can be used for prenylation (*16, 17*); and *N*-myristoyltransferase can be used for myristoylation (*18, 19*). Once again, the limitation of these reactions is that the essential amino acid residues must be available and the modification of an amino acid residue should not induce loss of structural integrity and functionality.

In general, due to the abundance of amino acids containing functional side groups within proteins, site-specific conjugation reactions to canonical amino acids are often difficult to achieve. Conjugations at undesired sites within the protein may induce loss of structural integrity and functionality.

TRANSLATIONAL INCORPORATION OF NONNATURAL AMINO ACIDS

With the recent developments in synthetic biology, it has become possible to engineer bacteria and yeast in such a way that they can incorporate nonnatural amino acids with selective reactivities into proteins. With this technique, the possibilities for site-specific conjugation to functionally active proteins can be substantially increased. Several methods that currently exist for the translational incorporation of nonnatural amino acids are discussed here.

Use of Auxotrophic Strains. The simplest and oldest method for incorporation of nonnatural amino acids into recombinantly produced proteins makes use of *Escherichia coli* strains that are auxotrophic for a certain amino acid. This means they are unable to synthesize it and therefore dependent on uptake from the growth medium. In the growth medium, this particular amino acid can be replaced by a structurally similar nonnatural analogue. The bacteria then build in this analogue. For this substitution method, the gene encoding the protein of interest has to be under tight inducible control. The bacteria can then first be grown in normal medium, followed by washing and transfer to medium containing the nonnatural analogue instead of the natural amino acid. After allowing the bacteria some time to deplete their intracellular stocks of the natural amino acid, production of the target protein is induced. Virtually, all copies of the target protein will then contain the nonnatural amino acid.

Incorporation efficiency can be greatly enhanced by overexpressing the relevant aminoacyl tRNA transferase and by somewhat relaxing the substrate specificity of its synthetase and proofreading active sites (*20*−*23*).

Codons for leucine (*24*), isoleucine (*25*), phenylalanine (*26*), tryptophan (*27, 28*), proline (*29*), and especially methionine (*20, 30*−*35*) have been reassigned in order to incorporate nonnatural amino acids using this method. Methionine is a frequently used amino acid for this technique, since it is one of the least common natural amino acids. Global replacement of methionine by nonnatural amino acids can therefore be expected

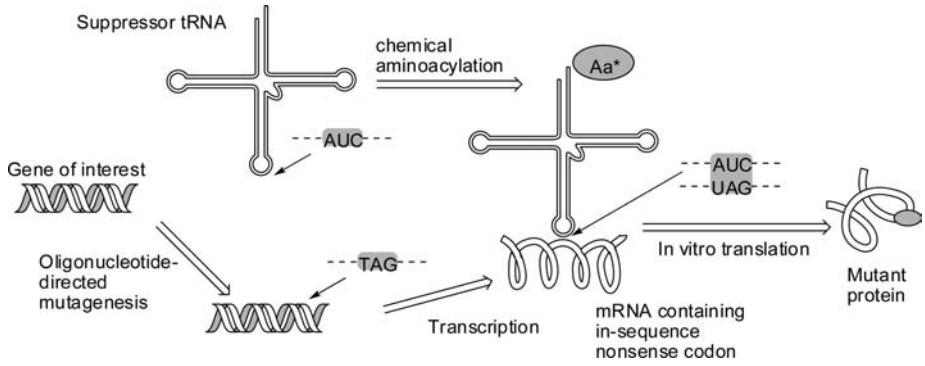

Figure 1. tRNA suppressing the amber codon.

to have less impact on protein structure and function than substitution of other amino acids. Furthermore, due to its hydrophobicity methionine is usually not located at the surface of natural proteins. This makes it possible to introduce, e.g., an alkyne or azide methionine analogue in a unique and well-defined place on the outside of a protein, accessible for subsequent modification by the azide/alkyne 'click' reaction.

Obviously, the major drawback of the substitution technique is that it leads to incorporation of the nonnatural amino acid at *every* site where the substituted amino acid is encoded. This may impair the protein's structure and function. Furthermore, incorporation in the cell's own proteins may lead to toxic effects. Finally, it is not possible to incorporate both the nonnatural amino acid and the substituted natural amino acid.

Stop Codon Suppressor tRNAs. To overcome the above-mentioned problems, Noren et al. (1989) developed a different method to translationally incorporate nonnatural amino acids into proteins. They used a tRNA that specifically recognizes one of the three stop codons. By chemically aminoacylating this tRNA and injecting it into *Xenopus* oocytes, a nonnatural 21st amino acid could be incorporated into proteins in response to the stop codon (*36*) (Figure 1).

tRNAs that efficiently recognize the amber (UAG) stop codon occur naturally in yeast. Such amber-suppressor tRNAs prevent release factor I (RF-I) from binding to the UAG codon. Therefore, the ribosome will continue elongating the protein. Because the ribosome does not proofread amino acids during translation, the cell does not recognize this "error" in the protein and therefore does not destroy it (*37*). By aminoacylating such a suppressor tRNA with a desired nonnatural amino acid (e.g., through chemical aminoacylation), it becomes possible to site-specifically incorporate a 21st amino acid in response to the amber codon (*36*−*39*).

The main advantage of the termination readthrough mechanism is that nonnatural amino acids are only incorporated at the amber codon and therefore can be incorporated *in addition to* the 20 standard amino acids. Due to this characteristic, amber suppression has become a popular tool for incorporation of nonnatural amino acids (*40*). Since the elongation factor and peptidyltransferase show relatively broad substrate specificity, site-specific insertion of any desired amino acid may in principle be achieved (*36*).

To achieve high product yield and homogeneity, the suppressor tRNA must efficiently insert the amino acid in response to the UAG codon. Furthermore, it must be neither acylated nor deacylated by any of the naturally occurring aminoacyl-tRNA synthetases (AARS) of the host organism (*36, 37*).

Orthogonal Aminoacyl-tRNA Synthetases. A major drawback of the above-mentioned approach is that tRNAs are too large to be taken up by the host cell after chemical aminoacylation. Therefore, they have to be microinjected (*41, 42*). This limits the applicability of this technique to large cells such as

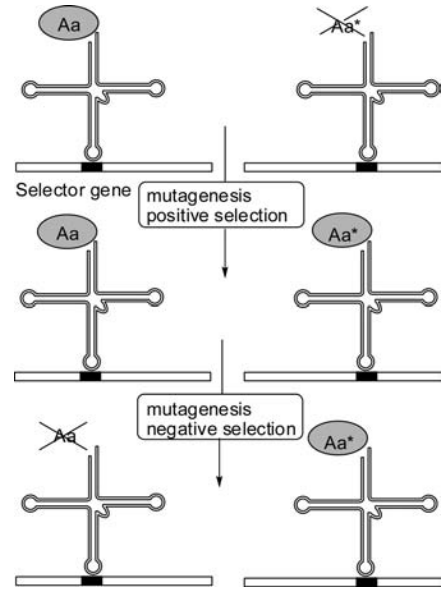

Figure 2. Strategy to select for an orthogonal AARS pair. (A) The starting AARS charges the suppressor tRNA with a natural amino acid Aa but not with the nonnatural amino acid Aa*. An amber codon (UAG) is inserted into a gene that codes for a selectable marker such as antibiotic resistance, GFP, or the Gal4 repressor. (B) A positive selection yields AARS* variants that incorporate both the natural and nonnatural amino acids. (C) Negative screening or selection yields an AARS** variant that rejects the natural amino acid.

Xenopus oocytes (*43, 44*). A variant to this approach is in vitro protein translation in cell free extracts (*45, 46*). However, these two methods are only applicable on a very small scale. To overcome this problem, the host cell can be genetically engineered to produce the suppressor tRNA and a corresponding AARS itself (*47*). This AARS/tRNA pair has to be orthogonal to the host AARS/tRNA pairs. This means that the introduced tRNA should function efficiently in protein translation but should not be a substrate for any of the host AARS. Furthermore, the introduced AARS should not aminoacylate any of the endogenous host tRNAs (*37, 40*). There are two methods to develop an orthogonal AARS/tRNA pair: it can be borrowed from unrelated organisms (*48*), or it can be designed (*37, 49*). Figure 2 illustrates the general selection method to develop orthogonal AARS/tRNA pairs (*37*).

When using orthogonal AARS/tRNA pairs, the nonnatural amino acid has to be available in the cytoplasm of the host. Therefore, the nonnatural amino acid has to be designed such that it can be passively or actively transported into the host cell. It is even possible to genetically modify *E. coli*, giving it the capability of biosynthesizing a nonnatural amino acid itself (*50*).

Although successful, incorporating nonnatural amino acids by tRNA suppression of nonsense codons is somewhat limited

by its low efficiency. The efficiency of the incorporation of one nonnatural amino acid per protein by amber suppression is dependent on the host organism, but on average, an efficiency of 20−30% (defined as the ratio of full-length protein to truncated protein) can be achieved. The low efficiency is a result of two factors. First, the acylation of suppressor tRNAs is sometimes a problem. Second, RF-1 will always compete with the suppressor tRNA for the stop codon (*37, 38, 40, 51*). If the number of amber codons in a gene increases, the efficiency decreases multiplicatively (*51*). Consequently, multiple incorporations of nonnatural amino acids by using more than one amber codon are not feasible. Combining the suppression of another stop codon with amber codon supression is not feasible either, since the suppression efficiency of the other stop codons (UAA and UGA) is even smaller (*52*). Apart from these limitations, it has also been observed that charged amino acids are incorporated less efficiently than hydrophobic ones. D- and β-amino acids are not compatible with stop codon suppression (*53*).

Apart from bacteria, mammalian cells are also used for the production of certain proteins. Whether the method of stop codon suppression can ever be exploited for the introduction of nonnatural amino acids in these systems is uncertain, because the occurrence of the amber termination codon is higher in mammals then in *E. coli.* In human genes, for example, 23% of stop codons is UAG. It is therefore likely that amber suppression will be toxic, since essential proteins are not terminated correctly. The use of the other termination codons seems even less promising because their occurrence is even higher (UAA, 30%; UGA, 47%) (*51, 54*).

An exciting recent variation to stop codon reassignment is the reassignment of degenerate *sense* codons. Kwon et al. (2003) demonstrated the feasibility of this approach by breaking the degeneracy of the phenylalanine codons UUU and UUC. The anticodon sequence of $tRNA^{Phe}$ is AAG, but this tRNA also binds to the UUU codon by "wobbling". Kwon et al. introduced a heterologous tRNA having the anticodon AAA into an *E. coli* host. At the same time, they introduced an AARS that specifically loaded this tRNA with 2-naphtylalanine. By doing so, they were able to reach an incorporation efficiency of 80% for 2-naphtylalanine in response to UUU, while all UUC was still translated as phenylalanine (*55*).

Another recent addition to the technique of stop codon suppression is the development of an orthogonal ribosome−mRNA pair (*51, 56*). In this technique, the mRNA encoding for the protein of interest is given a modified Shine−Dalgarno (SD) sequence. The SD sequence is the part of the mRNA that initiates binding to the ribosome. The modified SD sequence is not recognized by natural ribosomes. The used expression strain is therefore given two sets of ribosomes: one that only recognizes normal SD sequences and one that only recognizes the modified SD sequence. In this way, the production of the cell's own proteins is separated from the production of the desired protein containing the nonnatural amino acid. Furthermore, the mutant ribosome has an adjusted structure that rejects RF-1 (Figure 3). The use of such an orthogonal ribosome−mRNA pair therefore increases the suppression efficiency. Using this technique, a readthrough efficiency of 60% has been achieved (*51*).

Expanding Size of Codons. The number of different amino acids that can be incorporated into one protein is ultimately limited by the fact that natural codons consist of only three bases. The discovery of frameshift suppressor tRNAs, together with the ability of ribosomes to handle a wide variety of codon/anticodon pairs, has made it possible to create new codons by expanding the size of codons from triplets to quadruplets or even quintets (*52, 57, 58*). This method was pioneered by

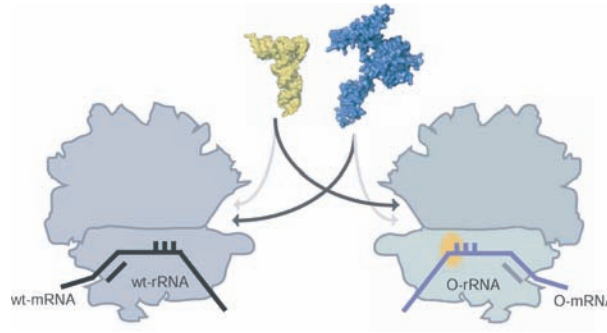

Figure 3. Orthogonal ribosome−tRNA pairs. The natural ribosome (left) and the orthogonal ribosome (right) translate wild-type (black) and orthogonal (purple) mRNAs, respectively. RF-1 (blue) cannot compete efficiently for UAG codons in the modified A-site (orange) of the orthogonal ribosome. Therefore, the orthogonal ribosome efficiently accepts the suppressor tRNA (yellow). Translation of the cell's own mRNAs is unaffected because the orthogonal ribosome does not read mRNAs with a normal SD sequence, but the natural ribosome is unaltered. Reprinted by permission from Macmillan Publishers Ltd.: *Nature Biotechnology* 25(7) p771, copyright 2007.

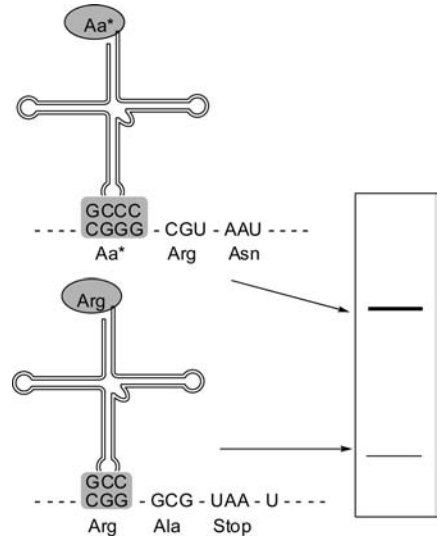

Figure 4. Principle of the four-base codon strategy. The target protein (right, upper band) can easily be separated by gel electrophoresis from the byproduct resulting from insertion of a natural amino acid (lower band).

Hohsaka and Sisido (2000) (*57*). It has created the possibility to develop additional codons and thereby has made incorporation of several different nonnatural amino acids at a time possible (*59*).

Figure 4 illustrates the basic principle of this frameshift suppressor tRNA strategy. The gene containing the quadruplet or the quintet is generated by PCR (*57*). During this process, an extra nucleotide is inserted at a specific place to create the quadruplet codon. In the case of a quintet, two nucleotides are inserted. Besides the modified DNA, the relevant orthogonal tRNA as well as a corresponding AARS are required for this method. When the frameshift suppressor tRNA successfully reads the concerning quadruplet/quintet, a frameshift will take place as planned and the protein will be completed to a full-length protein containing the nonnatural amino acid. However, if the concerning sequence is read by a naturally occurring tRNA, the planned frameshift does not occur. The reading frame is then shifted backward by one or two bases, which results in truncation of the protein at the next occurring stop codon (*52, 57*).

Many four-base codons have been examined in *E. coli*. Hohsaka et al. (2001) found that five quadruplet codon/anticodon

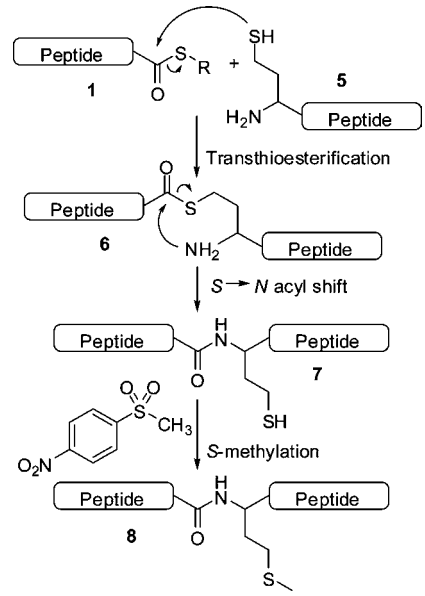
pairs (AGGU, CGGU, CCCU, CUCU, and GGGU) are orthogonal and very efficient (e.g., GGGU has an efficiency of 80% with respect to the wild-type protein) (*58*). Several different quadruplets can in principle be used to incorporate more than one nonnatural amino acid into one protein. Hohsaka and Sisido (2000) also examined the quintet codons $CGGN_1N_2$. The suppression efficiency was comparable for all the different quintets and was estimated at 16% for the incorporation of nitrophenylalanine in cell-free extracts. This is comparable to the efficiency of the amber suppression method with the same nonnatural amino acid (*57*). Other amino acid analogues that have been introduced using this technique are homoglycine (*59*) and 2-hydroxy-3-(4-hydroxyphenyl)propionic acid, which introduces a hydrolyzable ester bond instead of an amide bond into the protein backbone (*60*).

Efforts have been undertaken to use frameshift suppression in vivo, but these have not been very successful until now (*37, 59*).

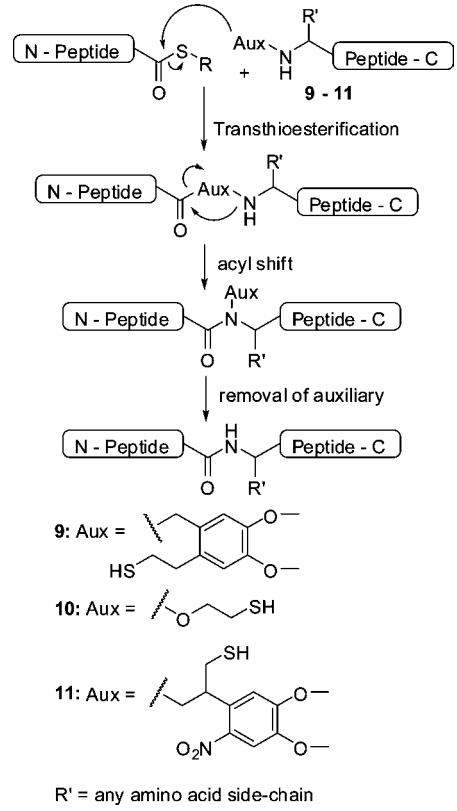
Nonnatural Base Pairs. A challenging method to expand the genetic code is to develop nonnatural base pairs. Creating a new base pair that is orthogonal to the naturally occurring base pairs generates great opportunities. With an additional base pair, the genetic code can be expanded from 64 coding triplets to 216 coding triplets. The basic principle behind this approach is illustrated in Figure 5.

Switzer et al. developed the first new base pair and thereby a 65th codon in 1989 (*61*). They incorporated the base pair

Scheme 2. Native Chemical Ligation with Homocysteine



Scheme 3. Chemical Ligation Using Removable Auxiliaries



isoC and isoG into DNA and managed to transcribe the DNA containing these nonnatural bases into mRNA, which in turn was successfully translated with the help of a synthetic tRNA into a protein containing a nonnatural amino acid. This approach seemed very promising, but the main problem was that the DNA containing the nonnatural base pairs had a limited stability (*62*). Apart from the stability of the DNA, the success of a nonnatural nucleotide base pair is dependent on many other factors. The base pair must be completely orthogonal to the other nucleotide bases, but they must couple to each other with high affinity and high fidelity. In addition, the artificial base pair must be accepted and recognized by

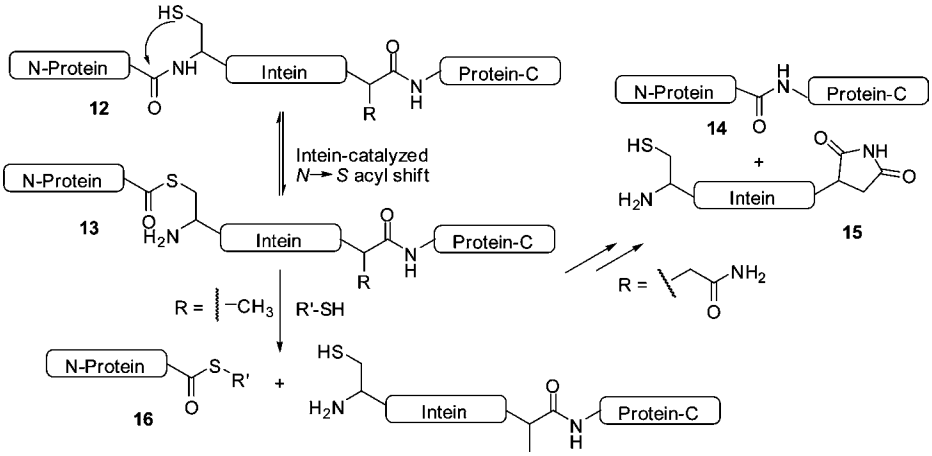
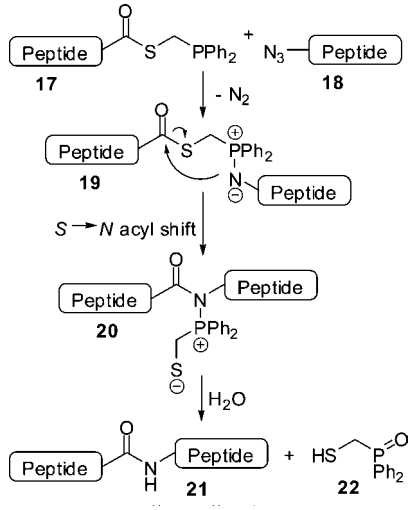
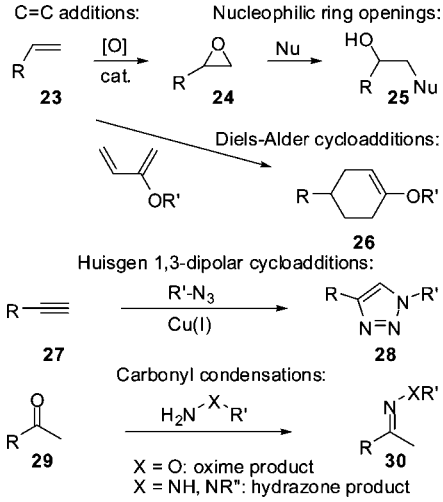


Scheme 5. Staudinger Ligation



Scheme 6. A Selection of 'Click' Reactions



the DNA polymerase and RNA polymerase to make replication and transcription possible (*52, 63, 64*). Despite the fact that it is not easy to satisfy these requirements, Ohtsuki et al. (*65*), Hirao et al. (*66, 67*), and the group of Romesberg (*63, 64*) succeeded to develop several nonnatural nucleotide base pairs which are promising candidates for expanding the genetic code. However, the orthogonality, fidelity, and DNA synthesis efficiency of these nonnatural base pairs is still insufficient for practical application.

SEMISYNTHETIC INCORPORATION OF NONNATURAL AMINO ACIDS

Through the progression in solid-phase peptide synthesis (SPPS) methodology, the synthesis of peptides and small proteins has become routine. With SPPS, it is easy to incorporate all sorts of nonnatural amino acids into peptides. However, the solid-phase methodology has some drawbacks. These include accumulation of side products arising from incomplete deprotection or coupling reactions, the difficulty of synthesizing highly hydrophobic peptides, and nonnative folding of the products. Therefore, the method is limited to the synthesis of polypeptides not larger than 50 amino acid residues. In contrast, the average length of a natural protein is about 250 amino acid residues.

To circumvent these size limitations of the solid-phase methodology, several semisynthetic approaches have been developed to incorporate nonnatural amino acids (*68*). The principal strategy encompasses synthesizing the desired protein in two parts. The part that contains the nonnatural amino acid(s) is synthesized by SPPS. The rest of the target protein is produced by recombinant techniques. The two fragments are then modified at their termini with mutually reactive, bio-orthogonal groups. Finally, the two fragments are linked to each other to yield a full-length semisynthetic protein containing one or more nonnatural amino acids (*69*). Schnolzer and Kent (1992) were among the first to prove this powerful concept through the chemoselective synthesis of a human immunodeficiency virus 1 (HIV-1) protease analogue having a modified backbone. They used this analogue for the study of backbone involvement in inhibitor binding (*70, 71*).

A variety of chemoselective protein ligation reactions have been developed (*70*). Some of these reactions generate a nonnatural structure at the ligation site. Examples include the thioester and thioether ligations (*72*−*75*) and the imine/pseudoproline ligation (discussed below). In addition to these, there are now a number of ligation reactions available that generate a native peptide bond. Generally, these consist of a two-step sequence (Scheme 1). The first step is a chemoselective capture between an electrophile at the C-terminus of peptide **1** and a nucleophile at the N-terminus of peptide **2**. The type of bond that is formed depends on the nucleophile and electrophile used in the capture reaction. If the formed bond is an ester or a thioester, a spontaneous intramolecular acyl shift will occur (through the five-membered intermediate **3**) to form an amide bond in the product **4** (*69, 76*).

Native Chemical Ligation. The native chemical ligation approach of Dawson et al. (1994) was the first approach that

did not cause a nonnatural structure at the ligation site (*77*). The principle behind this method is that each peptide fragment has a unique, mutually reactive functionality which enables a chemoselective reaction. Because of this chemoselectivity, the ligation can take place with unprotected peptide fragments in aqueous solution. In the native chemical ligation approach, the peptide **2** bears an N-terminal cysteine and the peptide **1** bears a C-terminal thioester. There are several solid-phase methods and recombinant strategies based on protein splicing to synthesize a C-terminal thioester (*77, 78*). The first step of the ligation is a chemoselective transthioesterification reaction involving the thiol group of the N-terminal cysteine of peptide **2** and the C-terminal thioester moiety of peptide **1**. The intermediate product **3** then undergoes a rapid intramolecular S→N acyl shift, which results in an amide bond at the ligation site in the final product **4** (*68*).

This reaction is applicable to peptides with all (non-) canonical amino acid residues, as long as one of the peptides bears a thioester at the C-terminus and the other peptide has an N-terminal cysteine residue. The nature of the thioester leaving group and the pH both influence the rate and the efficiency of the reaction (*68*). The most important limitation of this method is that a cysteine residue always results at the ligation site. In a semisynthetic approach, the location of cysteines in the desired product therefore dictates the length of the recombinantly and synthetically produced parts. Since the occurrence of cysteine is only 1.7%, this can lead to impractically long sequences that have to be produced by SPPS.

Several alternative methods have been developed to overcome this problem (*79*). For example, Tam and Yu (1998) devised a route that leads to a methionine at the ligation site (*80*). This approach is illustrated in Scheme 3. Instead of a cysteine, the peptide **5** has an N-terminal homocysteine residue. The start of the reaction is the same as for the native chemical ligation, but the intermediate product **6** is different: the intramolecular S→N acyl shift occurs through a six-membered ring instead of a five-membered ring. After the ligation reaction, the homocysteine residue can be converted to a methionine by methylation. Comparable ligation reactions can be executed with selenocysteine and the imidazole side chain of histidine (*68*). Another versatile method to overcome the requirement of an N-terminal cysteine residue is to mimic the characteristics of the cysteine residue through the use of a removable auxiliary. Several types of auxiliaries have been developed. These are shown in Scheme 3. Several researchers have replaced the N-terminal cysteine residue by 2-mercaptobenzylamine **9** (*68, 81*). Canne et al. (1996) used oxyethanethiol **10** (*82*) and Kawakami and Aimoto (2003) used the photoremovable *o*-nitrobenzyl scaffold **11** to substitute the N-terminal cysteine residue (*83*). The principle behind this method is that, by mimicking the characteristics of the cysteine residue, it is possible to ligate the peptides by native chemical ligation regardless of the kind of amino acid residue at the N-terminus of peptides **9**−**11**. The reaction is the same except that there is one additional step at the end to remove the N-terminal substitute (*83*). A significant limitation of all

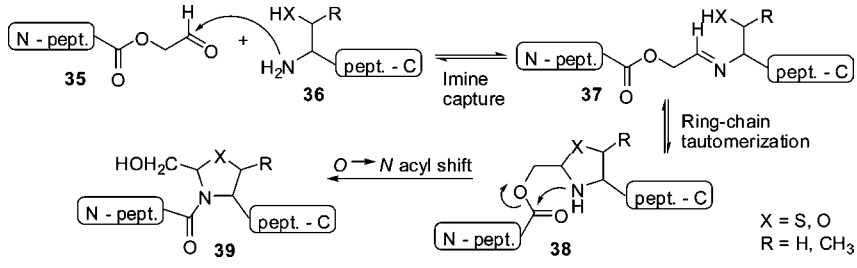

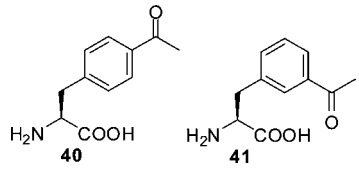

Figure 7. Nonnatural amino acids having carbonyl functionalities.

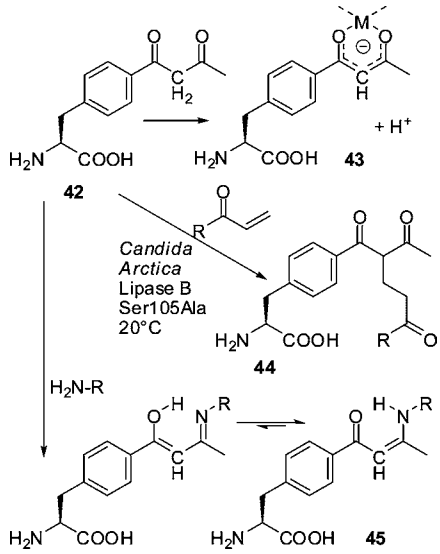
Scheme 8. Possible Bioconjugation Reactions to the Diketone-Containing Nonnatural Amino Acid 42



auxiliaries is, however, that they are currently only applicable to synthetic C-terminal peptides (*84*).

Use of recombinantly produced protein fragments in (native) chemical ligation reactions requires that they possess either an N-terminal cysteine residue or a C-terminal thioester. The latter has become possible due to the expressed protein ligation method developed by Muir and co-workers. They used intein-mediated posttranscriptional protein splicing (Scheme 4). This is a naturally occurring process whereby a protein **12** undergoes an intramolecular rearrangement resulting in the extrusion of an internal sequence (intein **15**) and the joining of the lateral sequences (exteins) to form the protein **14**. This reaction is autocatalyzed by the intein domain. An intermediate product of the reaction is thioester **13**. By mutating the site between the intein and the C-terminal protein from arginine to alanine, the splicing reaction can be stopped halfway. Addition of a thiol then results in the natural protein **16** having a C-terminal thioester (*78, 85, 86*). This product can subsequently be used for native chemical ligation (*87*).

Staudinger Ligation. The groups of Raines and Bertozzi independently developed an elegant method to overcome the limitation of the original native chemical ligation method (*88, 89*). Their approach is based on the Staudinger reaction (*90*). Scheme 5 illustrates the ligation of two peptides by this modified Staudinger reaction. The C-terminus of peptide **17** needs to bear a phophinothioester group, and the second peptide **18** needs to bear an N-terminal azide group.

Like in the classical Staudinger reaction, the first step is the reaction between the C-terminal phophinothioester **17** and the N-terminal azide **18** to form the intermediate iminophosphorane **19**. **19** then undergoes an intramolecular S→N acyl shift leading to the amidophosphonium salt **20**. Through hydrolysis, this salt is converted to the amide product **21** and the phosphine **22**.

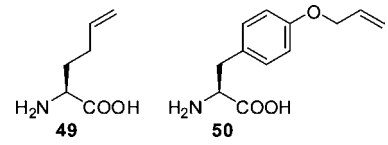


Figure 8. Nonnatural amino acids having vinyl functionalities.

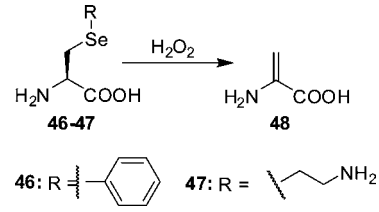
Scheme 9. Conversion of Selenium-Containing Nonnatural Amino Acids into Dehydroalanine



The disadvantages of this method are that the peptide chains must be fully protected because of the high reactivity of the intermediate aza-ylide and that diphenyl phosphine oxide traces always remain in the product (*68, 91*). To overcome the latter disadvantage, a "traceless" Staudinger ligation has also been developed (*89, 91*).

In biochemistry, these reactions are particularly valuable because the azide function is (i) virtually absent in biological macromolecules, (ii) exhibits a high intrinsic reactivity with a very limited number of reactants, and (iii) can be easily introduced in peptides or proteins using either organic chemistry or recombinant techniques (*91*).

BIO-ORTHOGONAL CONJUGATION TO NONNATURAL AMINO ACIDS

Several classes of nonnatural amino acids have been successfully incorporated into proteins by the methods described above. The following section describes the nonnatural amino acids that have bio-orthogonal reactivities which can be used in bioconjugation reactions. Most of these nonnatural amino acids have been incorporated using either the substitution method or the termination readthrough method (*92*).

'Click' Chemistry. Many of the bioconjugation reactions that are discussed below can be referred to as 'click' reactions. In a narrow sense, this term is often used specifically for the Huisgen 1,3-dipolar cycloaddition (discussed below). However, the term is used here in its original, much broader sense. 'Click' chemistry is a synthetic approach inspired by the simplicity and efficiency of the chemistry of nature (*91*). Nature prefers building its products from simple building blocks linked by carbon-heteroatom bonds rather than carbon−carbon bonds (*93, 94*). The Sharpless group has identified a set of reactions that they termed 'click' reactions. These reactions mimic nature in "[being] modular, wide in scope, give very high yields, generate only inoffensive byproducts that can be removed by nonchromatographic methods, and [being] stereo-specific (but not necessarily enantioselective)" (*94*). Furthermore, the process should have simple reaction conditions, have readily available starting materials and reagents, and require no or easily removable solvents. The term 'click' reaction refers to the high rate and high selectivity of these reactions (*94*). Examples of such reactions are given in Scheme 6 and Table 2.

Alkyne and Azide Functionalities. The most frequently applied 'click' reaction is the Huisgen 1,3-dipolar cycloaddition reaction of alkynes and azides catalyzed by copper(I) (*93*). The general principle of this reaction is outlined in Scheme 6 (**27** to **28**). This is a straightforward reaction which can be performed

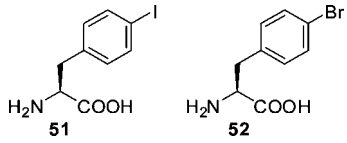


Figure 9. Nonnatural amino acids having aryl halide functionalities.

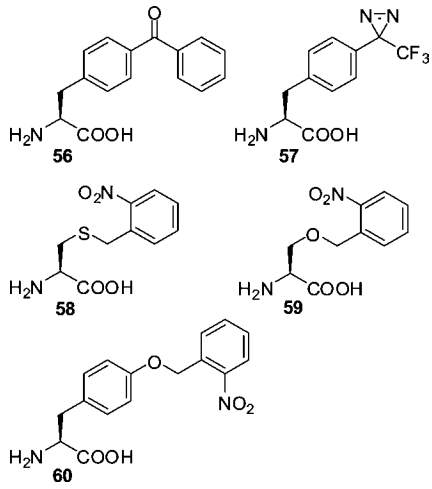

Figure 11. Nonnatural amino acids carrying photoreactive groups.

at room or body temperature and in a variety of solvents. Furthermore, the reaction is compatible with several other functional groups (*91*).

As a result of the popularity of the azide/alkyne 'click' reaction, many attempts have been undertaken to incorporate nonnatural amino acids containing azide or alkyne functionalities into proteins. The nonnatural amino acids azidohomoalanine **31** and homopropargylglycine **33** have been designed to closely mimic the natural amino acid methionine. Indeed, they have been shown to be effectively introduced into proteins by methionine auxotrophic bacterial strains. Strable et al. (2008) proved this concept by first incorporating **31** or **33** into hepatitis B virus by reassigning the methionine sense codon. Subsequently, the azide or alkyne containing virus particles were successfully labeled using alkyne or azide functionalized fluorescein, rhodamine, biotin, or gadolinium-tetraazacyclododecanetetraacetic acid (Gd-DOTA) (*104*). 'Click' reactions to incorporated nonnatural amino acids **31** and **33** have also been successfully used to PEGylate proteins (*105*), glycosylate proteins (*106, 107*), label proteins with fluorophore tags (*108, 109*), and cross-link several proteins into supramolecular structures (*33, 104*). Even live *E. coli* cells have been biotinylated at their outer membrane proteins using this method (*110*).

The aromatic amino acids *p*-azidophenylalanine **32** and *p*-propargyloxyphenylalanine **34** have been incorporated site-

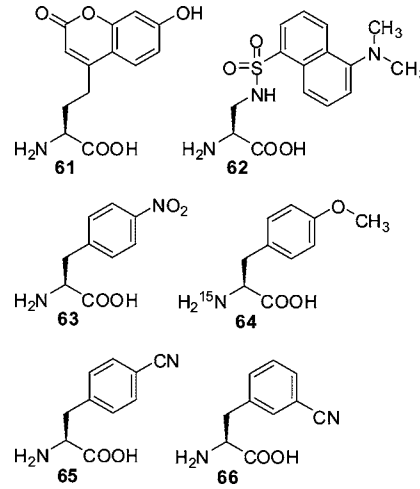

Figure 12. Nonnatural amino acids carrying biophysical probes.

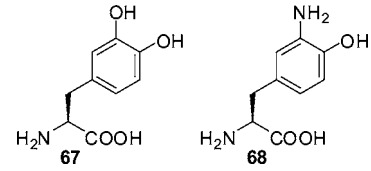

Figure 13. Redox-active nonnatural amino acids.

specifically into proteins by reassigning the UAG stop codon. In *Saccharomyces cerevisiae*, this has been achieved by introducing an *E. coli* mutant tyrosyl-tRNA synthetase (*111*) and in *E. coli* by using a mutant *Methanococcus jannaschii* tyrosyl-tRNA synthetase (*112*). By means of the azide/alkyne 'click' reaction, **34** has been used to site-specifically functionalize cytochrome c3 with the electron donor azidoviologen (*113*). **32** has been used for site-specific PEGylation of proteins by reaction with alkyne-functionalized PEG segments (*114*).

Apart from azide/alkyne 'click' chemistry, bio-orthogonal conjugation to peptides can also be achieved using Staudinger ligation at azide-containing nonnatural amino acids such as **31** and **32** (*115, 116*). Another interesting application of **31** is its ability to be cleaved by a phosphine or dithiol. This reaction yields a reactive C-terminal homoserine lactone in a fashion similar to cyanogen bromide cleavage but under very mild conditions (*117*).

Keto/aldehyde Functionalities. Another class of 'click' reactions that are gaining interest are certain nucleophilic additions to carbonyl groups. Carbonyl groups do not occur in natural proteins. They have a slightly acidic α-hydrogen due to keto−enol tautomerization and are easily attacked by nucleophiles (Scheme 6: **29**−**30**). If carbonyl groups are introduced into recombinant proteins, some imine formation with the ε-amino groups of lysine residues will therefore occur. However, this reaction is reversible and at physiological pH the equilibrium lies toward the free carbonyl and amine (*118*).

Hydrazides, alkoxyamines, and semicarbazides react rapidly and quantitatively with carbonyl groups to form hydrazones, oximes, and semicarbazones, respectively (*119*−*121*). These reaction products are stable under physiological conditions. An additional advantage of these reactions is that they occur in only slightly acidic aqueous medium and require no auxiliaries or catalysts.

The oxime ligation method involves an imine capture between an ester, an aldehyde, or a ketone **29** and an aminooxy nucleophile, yielding the oxime **30** (*122, 123*). The hydrazone ligation method is one of the oldest ligation methods and is

comparable with the oxime ligation method. However, a hydrazide rather than an aminooxy is used for the ligation, and therefore, a hydrazone bond is formed in the product **30** (*124*). No side chain protection is needed for these ligation methods, because on one hand aminooxy and hydrazide groups are more nucleophilic than natural amino acid side chains, and on the other hand the carbonyl groups are more electrophilic than natural side chains.

Another useful carbonyl reaction is imine ligation (Scheme 7), which produces a proline-like structure at the ligation site. This reaction can be used for conjugation to a nucleophilic N-terminal amino acid **36**. The carbonyl group of the conjugating agent **35** is attacked by the nucleophilic N-terminal amino acid **36**, forming the imine **37**. **37** subsequently undergoes a rapid ring−chain tautomerization, which results in the heterocycle **38**. This intermediate product facilitates an acyl transfer, forming a proline-like imidic bond in the product **39**. This reaction is well-represented by ligation methods using cysteine, threonine, tryptophan, histidine, or asparagine as N-terminal nucleophiles, yielding a variety of mono-, bi-, and tricyclic side chains at the ligation site (*76*). The ring−chain tautomerization in the formation of the heterocyclic ring **38** affords the specificity of the imine ligation (*122*). The central feature of imine capture is that the reaction is driven by the weakly basic N-terminus of **36**, which induces the formation of a heterocyclic ring. Given that imine ligation is performed under slightly acidic aqueous conditions, lysine and arginine side chains will be protonated and are therefore not reactive (*122*).

Although the ketones and aldehydes that are required for these reactions do not occur in natural proteins, they can be introduced into proteins by sodium periodate oxidation of an N-terminal threonine or serine, respectively. Serine-derived aldehydes have been used to attach a hydrazide-functionalized biotin tag and aminooxy-functionalized PEG chain to the N-terminus of proteins (*119, 125*). Furthermore, they have been used to couple two peptide or protein segments by hydrazone or oxime linkages (*120, 121, 126, 127*).

The method of sodium periodate oxidation is, however, hampered by the fact that it is only applicable to the N-terminus of a protein. Therefore, several groups have developed carbonyl-containing nonnatural amino acids. The nonnatural amino acids *p*-acetylphenylalanine **40** and *m*-acetylphenylalanine **41** have been introduced site-specifically into recombinantly produced proteins by the amber suppression method (*129*−*133*). In addition, **40** has also been introduced using a phenylalanine auxotrophic bacterial strain (*128*). The resulting proteins were successfully reacted in vitro and in vivo with biotin hydrazide (*128*−*130*) or fluorescein hydrazide (*129*−*131*). In addition, **40** has also been coupled to aminooxy-functionalized biotin (*132*). Another published application of **40** involves recombinant incorporation followed by reaction with aminooxy-functionalized saccharides. In this way, proteins have been site-specifically glycosylated (*133*).

The β-diketone analogue **42** has also been genetically incorporated into proteins using stop codon suppression. Subsequently, it was labeled with aminooxy-functionalized biotin and Alexa Fluor 488 (*127*). Furthermore, **42** is expected to have a number of other reactivities (Scheme 8). For example, the hydrogen atoms between the two keto groups are relatively acidic. The deprotonated **43** may therefore be able to chelate metal ions. **42** is also expected to react enzymatically with α,β-unsaturated carbonyl compounds in a carbon−carbon bond forming Michael reaction yielding **44** (*127, 134*). Finally, **42** can form the enamine adduct **45** by reacting with a primary amine. **45** is stable at physiological pH due to a six-membered intramolecular hydrogen bridge (*127, 135*).

Alkenes. A fourth functional group that is very common to synthetic organic and polymer chemistry but rare in natural proteins is the carbon−carbon double bond. The simplest amino acid containing an alkene functionality is dehydroalanine **48**, which occurs sometimes as a posttranslational modification of cysteine (*136*). This amino acid has not been introduced directly into recombinant proteins. Instead, its precursors phenylselenocysteine **46** and selenalysine **47** have been used. For the incorporation of **46**, the amber suppression strategy was used (*138*). **47** was substituted for lysine in a cell-free translation system (*137*). Upon mild oxidative elimination, these two nonnatural amino acids yield **48**, which has been reacted in a Michael addition reaction with various thiol reagents (*137, 138*).

Two alkene-containing amino acids that have been directly incorporated into proteins are homoallylglycine **49** (*34*) and *O*-allyltyrosine **50** (*139*). **49** was incorporated by a methionine auxotrophic strain. In another experiment, it was used for cyclization of peptides by ruthenium-catalyzed alkene metathesis (*140*). **50** was incorporated by stop codon suppression. Bioconjugation reactions involving **50** have not yet been described to our knowledge. However, it can be expected to have the same reactivity as the other alkene-containing amino acids.

***p*-Halophenylalanines.** Using a palladium catalyst in aqueous environment, aryl halides can undergo a Mizoroki−Heck substitution reaction with alkenes or alkynes. This has been exploited by the incorporation of *p*-iodophenylalanine **51** into proteins in a cell-free translation system, followed by reaction with vinylated biotin (*141*). *p*-Bromophenylalanine **52** has been incorporated into recombinant proteins by both the stop codon suppression method and the substitution method, using a phenylalanine auxotrophic *E. coli* strain (*22, 142*). However, a subsequent coupling to an alkene or alkyne has, to our knowledge, not yet been described for this amino acid.

Radical Polymerization Initiators and Chain Transfer Agents. One particularly challenging field of bioconjugation chemistry is the chemical synthesis of polymers starting from a protein as macroinitiator or macro-chain-transfer agent (the so-called "grafting from" approach) (*143*). The ribosomal incorporation of nonnatural amino acids that can give proteins these functionalities would give this field of research a considerable impulse.

Recent progress in this direction is the successful use of *p*-(1-chloroethyl)phenylalanine **53** and *O*-(2-bromoisubutyryl)serine **54** as ATRP initiators. However, these have at present only been incorporated into solid-phase synthesized peptides (*144*). The depicted stable radical containing cysteine derivative **55** has been incorporated into proteins by stop codon suppression in *E. coli* and *Xenopus* oocytes (*145, 146*). In these experiments, it was used as a spin label. However, **55** might also be used as a chain transfer agent in nitroxide-mediated controlled radical polymerization.

Other Functional Nonnatural Amino Acids. Apart from the above-mentioned chemically reactive amino acids, many amino acids with other functionalities have been site-specifically introduced into proteins. This makes it possible to incorporate a certain functionality directly into the protein of interest, without having to perform a bioconjugation reaction after protein production. So, whereas some nonnatural amino acids expand the possibilities for bioconjugation, others even make bioconjugation superfluous. To illustrate this vast potential of nonnatural amino acids, a short overview of the functionalities that have been incorporated is given here.

Amino acids carrying photoreactive groups such as *p*-benzoylphenylalanine **56** and *p*-(3-trifluoromethyl-3*H*-diazirin-3-yl)-phenylalanine **57**, but also *p*-azidophenylalanine **32**,

can be used as probes of protein interactions, protein structure, and protein dynamics in vitro and in vivo. They can therefore be useful in identifying receptors for ligands (*147*−*155*). Other types of photoreactive amino acids are the photocaged cysteine, serine, and tyrosine analogues **58**, **59**, and **60**. Substituted nitrobenzyl groups block the side-chain hydroxy or thiol groups of these amino acids. These protective groups can be cleaved off by irradiation with 365 nm light in vitro or in vivo, making it possible to "switch proteins on" by illumination (*156*, *157*).

The fluorescent probes **61** and **62** (*158*, *159*), the distance probe **63** (a tryptophan autofluorescence quencher) (*160*), the site-selective ^{15}N NMR probe **64** (*161*), and the infrared probes **65** and **66** (*162*) are all examples of recombinantly incorporated nonnatural amino acids carrying biophysical probes. These functional groups can visualize protein conformational changes, localization, protein dynamics, local environment, and intermolecular interactions. The amino acids **51** and **52** also belong to this class, as their heavy halogen atoms induce single-wavelength anomalous diffraction (*163*).

Electron transfers are involved in a large number of biological processes such as enzyme catalysis and the primary charge separation processes in photosynthesis. To aid in studying these phenomena, the redox-active nonnatural amino acids dihydroxyphenylalanine **67** and 3-aminol-tyrosine **68** have been site-specifically incorporated into proteins (*38*, *39*, *164*). Both can be used to probe and manipulate electron-transfer processes in proteins because they can undergo a two-electron oxidation.

CONCLUSION AND FUTURE PROSPECTS

The research areas of bioconjugation to proteins and incorporation of nonnatural amino acids into proteins are both growing at a fast pace. This is driven by the need for innovative ways of probing protein structure and interactions and the rapid increase in the number of potential therapeutic proteins.

The field of recombinant introduction of nonnatural amino acids is relatively new. The possibilities in this field are actively being expanded at present. In the near future, this may lead to the incorporation of metal-chelating amino acids, amino acids carrying electron-transfer mediators, near-infrared probes, and long-chain alkanes, as well as amino acids with altered backbones (e.g., β-amino acids). It might eventually become possible to create biopolymers with ester rather than amide linkages in the backbone or even generate multicellular organisms that contain nonnatural amino acids (*92*). In addition, research into bioconjugation to nonnatural amino acids is currently emerging.

As shown in this review, several reactive nonnatural amino acids have already been incorporated into proteins. A significant number of conjugation reactions to these amino acids have been described. These include the alkyne/azide 'click' reaction, carbonyl condensations, Michael-type additions, and Mizoroki−Heck substitutions. More examples can be expected in the near future. Further elaboration of this field will lead to the creation of powerful strategies to synthesize complex nonnatural proteins by combining methods to incorporate nonnatural amino acids with bio-orthogonal conjugation methods.

We anticipate that this as-yet relatively unexplored field of bioconjugation holds a great potential and will fast-forward developments in the design of, e.g., therapeutic protein derivatives and semisynthetic biomaterials.

Fluorescence Emission and Polarization for Analyzing Binding of Ruthenium Metalloglycocluster to Lectin and Tetanus Toxin C-Fragment

Tomoko Okada,* Taro Makino, and Norihiko Minoura

Graduate School of Bionics, Tokyo University of Technology, Katakura, Hachioji, Tokyo 192-0982, Japan. Received March 6, 2009; Revised Manuscript Received May 15, 2009

We have designed and synthesized ruthenium complexes bearing clustered galactose Ru(bpy-2Gal)$_3$ and glucose Ru(bpy-2Glc)$_3$. Changes in fluorescence emission (FE) and fluorescence polarization (FP) of the metalloglycoclusters were measured by adding each lectin (*peanut agglutinin* (PNA), *Ricinus communis agglutinin 120* (RCA), *concanavalin A* (ConA), or *wheat germ agglutinin* (WGA)) or tetanus toxin c-fragment (TCF). Following the addition of PNA and ConA, the FE spectra of Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$ showed new emission peaks, respectively. In addition, Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$ exclusively increased the FP values by addition of PNA and ConA. Since other combinations of the metalloglycoclusters and lectin caused little change, specific bindings of galactose to PNA and glucose to ConA were confirmed by the FE and FP measurement. From the FP analyses, the dissociation constants (K_d) of Ru(bpy-2Gal)$_3$ to PNA and Ru(bpy-2Glc)$_3$ to ConA were calculated to be ca. 6.1×10^{-6} M and 1.8×10^{-5} M. Furthermore, the FP analyses proved specific binding of Ru(bpy-2Gal)$_3$ to TCF.

Carbohydrates are well-known to play important roles in biological processes. Specific binding between carbohydrate and protein (lectin) can induce serious infections from virus and pathogenic toxins (*1*). Therefore, development of a useful method is desirable to investigate the affinity property of the carbohydrate. Fluorescence polarization (FP) analysis is an effective method to evaluate a binding event of a small carbohydrate molecule and large protein (*2*). Since the FP analysis requires a fluorescent-labeled carbohydrate probe, this study aimed to apply a fluorescent metalloglycocluster as a probe molecule. A metalloglycocluster, a group of a glycocluster containing a metal center, is an especially attractive carbohydrate probe, since the metal center gives characteristic photochemical and electrochemical properties that can be utilized as an indicator. Moreover, the clustered carbohydrate around the metal center would enhance the binding constant of generally weak interaction between carbohydrate and protein. Recently, many researchers reported the enhanced binding constant achieved by clustering the carbohydrate, such as dendrimers modified with carbohydrates at their branches, organic polymers possessing carbohydrate branches at each monomer unit, and ruthenium metalloglycoclusters (*3*−*6*). Since the ruthenium metalloglycocluster possesses characteristic fluorescence emission (FE) property, both the FE and FP analyses are applicable for the affinity evaluation. In this study, we propose the utility of FE and FP analyses using a ruthenium metalloglycocluster for evaluating the affinity property between carbohydrate and lectins.

We designed metalloglycoclusters, Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$, as carbohydrate probes (Figure 1). Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$ have a ruthenium metal center coordinated by three bpy-2Gal and bpy-2Glc. Since the ruthenium(II) complex adopts octahedral geometry, six galactoses or glucoses are clustered around the metal center. These designed metalloglycoclusters were synthesized by chemical synthetic procedures. For the affinity evaluation, both ruthenium complexes were used without isolation of diastereomers (Λ- and Δ-forms).

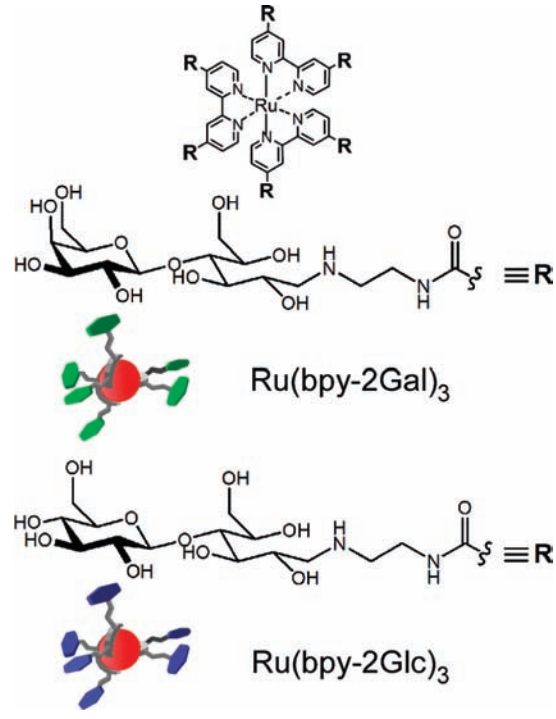

Figure 1. Schematic representation of the metalloglycoclusters Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$.

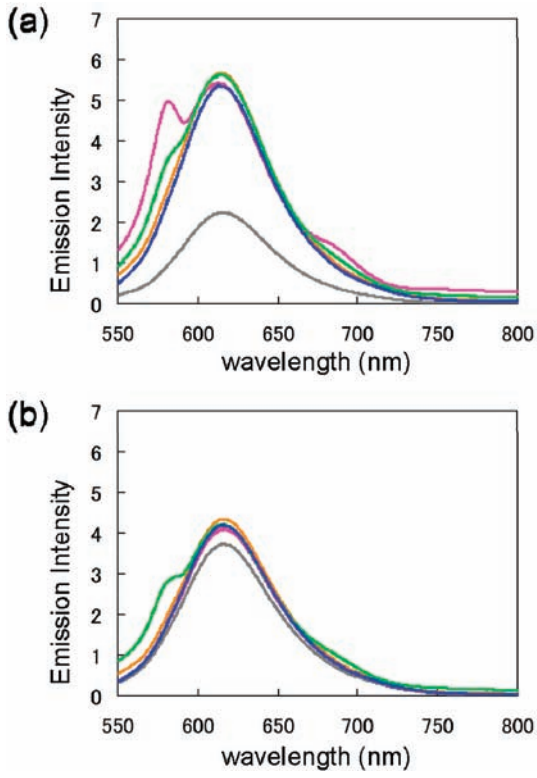

Figure 2. Fluorescence emission spectra of the metalloglycoclusters (20 μM), (a) Ru(bpy-2Gal)$_3$ and (b) Ru(bpy-2Glc)$_3$, with lectin (5 μM) (PNA (pink), RCA (orange), ConA (green), and WGA (blue)) or without lectin (gray). Excitation wavelength was 468 nm.

To examine the binding properties of Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$, fluorescence emission spectra were measured for each probe before and after the addition of each lectin (PNA, RCA, ConA, and WGA). Figure 2a shows the emission spectra of Ru(bpy-2Gal)$_3$ with or without each lectin. Addition of PNA caused the most drastic change to the spectral shape compared with the other lectins (RCA, ConA, and WGA). In particular, a new emission peak appeared at ca. 580 nm, and this new peak disappeared following addition of galactose to the solution. The emission spectral change suggests that Ru(bpy-2Gal)$_3$ specifically binds to PNA, and the local environment of Ru(bpy-2Gal)$_3$ becomes more hydrophobic compared with when the Ru(bpy-2Gal)$_3$ presents alone in PBS (*7*). This assumption is supported by the emission spectrum of Ru(bpy-2Gal)$_3$ in ethanol that is a more hydrophobic solvent than PBS. Following the addition of ethanol to the PBS solution of Ru(bpy-2Gal)$_3$, a new emission peak was observed at 580 nm. Therefore, the new emission peak observed for Ru(bpy-2Gal)$_3$ with PNA is evidence that Ru(bpy-2Gal)$_3$ specifically binds to the hydrophobic binding pocket of PNA. A similar spectral change was observed for Ru(bpy-2Glc)$_3$ with ConA. Since the appearance of the new emission peak was not observed with other lectins (PNA, RCA, and WGA), the FE analysis confirms that Ru(bpy-2Glc)$_3$ specifically binds to ConA. These FE measurements confirmed that galactose and glucose bind specifically to PNA and ConA, respectively. Such a drastic change in emission spectra is unusual during the course of the binding event between the ruthenium metalloglycocluster and lectin.

The affinity evaluation method using the FE spectrum depends on the hydrophobicity of lectin. In contrast, the FP analysis allows direct investigation of the molecular motion (namely, molecular size) in the absence of contributions derived from the environmental conditions that the metalloglycoclusters experience. Therefore, the FP measurement was performed to confirm the affinity property of the metalloglycocluster to lectin.

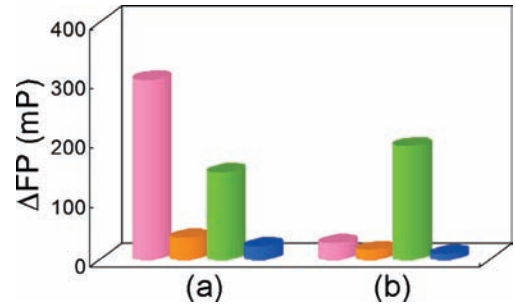

Figure 3. Changes in fluorescence polarization of the metalloglycoclusters (20 μM), (a) Ru(bpy-2Gal)$_3$ and (b) Ru(bpy-2Glc)$_3$, following addition of lectins (5 μM) (PNA (pink), RCA (orange), ConA (green), and WGA (blue)). Excitation wavelength was 468 nm, and polarization values were used at 580 nm.

Figure 3 shows the increased FP values when PNA, RCA, ConA, or WGA was added to each metalloglycocluster. Unlike the other lectins, FP value of Ru(bpy-2Gal)$_3$ increased the most by the addition of PNA. In contrast, Ru(bpy-2Glc)$_3$ showed the greatest increment when ConA was added to the solution. These drastic increments in FP values confirm that Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$ specifically bind to PNA and ConA, respectively. Besides, electrostatic interaction between the divalent metalloglycoclusters and lectin is negligible because the emission spectrum of Ru(bpy)$_3$ showed no changes following addition of each lectin. Therefore, the FE and FP analyses determined specific bindings of galactose to PNA and glucose to ConA, which are consistent with the previous reports showing high affinity of galactose to PNA and glucose to ConA. Changes in the FE and FP of Ru(bpy-2Gal)$_3$ were unexpectedly negligible, suggesting poor affinity of Ru(bpy-2Gal)$_3$ to RCA, despite the previous paper reports high affinity of galactose-bearing metalloglycocluster to RCA (*3*). Surface plasmon resonance analysis also proved that the RCA used in this study showed high affinity to galactose (4-aminophenyl-galactopyranoside) immobilized on a gold surface. Therefore, the low affinity is assumed to have a structural cause of the metalloglycocluster examined in this study, and molecular dynamics calculations are now underway to assess the possible reason.

By varying the concentrations of PNA and ConA, FP values were collected to examine the detailed binding properties of Ru(bpy-2Gal)$_3$ to PNA and Ru(bpy-2Glc)$_3$ to ConA (Figure 4). The horizontal axis represents the concentration of the binding sites from each lectin, which possesses four independent binding sites for every lectin molecule. Ru(bpy-2Gal)$_3$ showed a greater change in polarization than Ru(bpy-2Glc)$_3$ signifying higher affinity of PNA to galactose than glucose. The FP value for Ru(bpy-2Gal)$_3$ increased as the PNA increased and then plateaued. Nonlinear least-squares fitting determines the dissociation constant (K_d) of Ru(bpy-2Gal)$_3$ and PNA as 6.1×10^{-6} M. In a similar manner, Figure 4b shows higher affinity of ConA to glucose than galactose, and the K_d value was estimated to be 1.8×10^{-5} M. These dissociation constants prove that the affinity of clustered galactose and glucose is higher than that of nonclustered galactose and glucose ($K_d \approx 10^{-3}$ to 10^{-4} M) (*1*). To confirm the clustering effect on the lectin binding event, K_d of a metalloglycocluster having two galactose residues, Ru(bpy)$_2$(bpy-2Gal), was examined following the similar FP analysis with Ru(bpy-2Gal)$_3$ (*8*). The K_d of Ru(bpy)$_2$(bpy-2Gal) to PNA was estimated to be more than 10^{-4} M. Since highly clustered Ru(bpy-2Gal)$_3$ showed lower K_d than Ru(bpy)$_2$(bpy-2Gal), the clustered galactose of Ru(bpy-2Gal)$_3$ was confirmed to raise its affinity to PNA.

On the basis of the elucidated FP properties, affinity of the metalloglycoclusters (2 μM), Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$, was examined using 0.05 μM of tetanus toxin c-fragment (TCF).

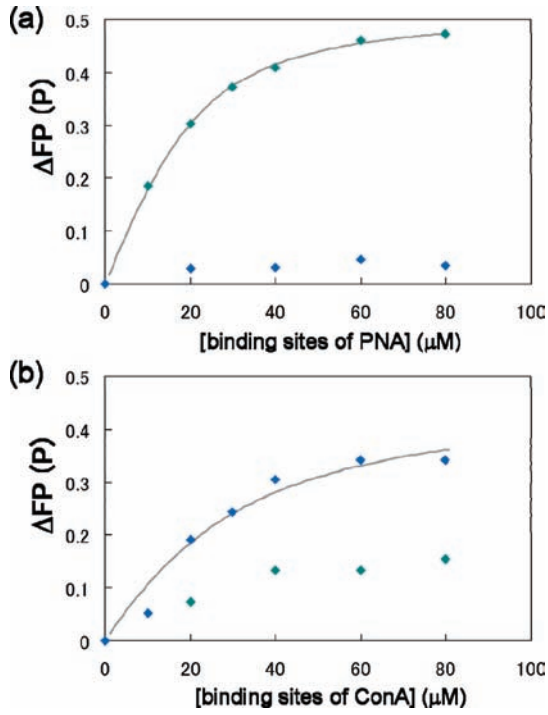

Figure 4. Changes in fluorescence polarization of metalloglycoclusters (20 μM), Ru(bpy-2Gal)$_3$ (green) or Ru(bpy-2Glc)$_3$ (blue), following addition of (a) PNA and (b) ConA. Excitation wavelength was 468 nm and polarization values were used at 580 nm. The gray line represents a fitted curve obtained from nonlinear least-squares fitting.

The TCF reportedly has affinity for galactose (*9, 10*). Following the addition of TCF, Ru(bpy-2Gal)$_3$ increased the polarization value by 47 mP; however, Ru(bpy-2Glc)$_3$ increased only by 7 mP. Because of the distinctive increment of the FP value for Ru(bpy-2Gal)$_3$, specific binding of galactose to TCF was confirmed.

In summary, the FE and FP analyses showed that the synthesized novel metalloglycoclusters, Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$, bind specifically to PNA and ConA, respectively. The results in this report proved that the combination of FE and FP analyses would empower evaluation of affinity properties between carbohydrate and lectins. Ru(bpy-2Gal)$_3$ and Ru(bpy-2Glc)$_3$ with the clustered galactose and glucose were confirmed to raise affinity to the lectin. Moreover, specific binding of Ru(bpy-2Gal)$_3$ to TCF was proven by the FP analysis. These results ensure that the FP analysis using the ruthenium metalloglycocluster is useful for evaluating interactions between carbohydrates and toxins.

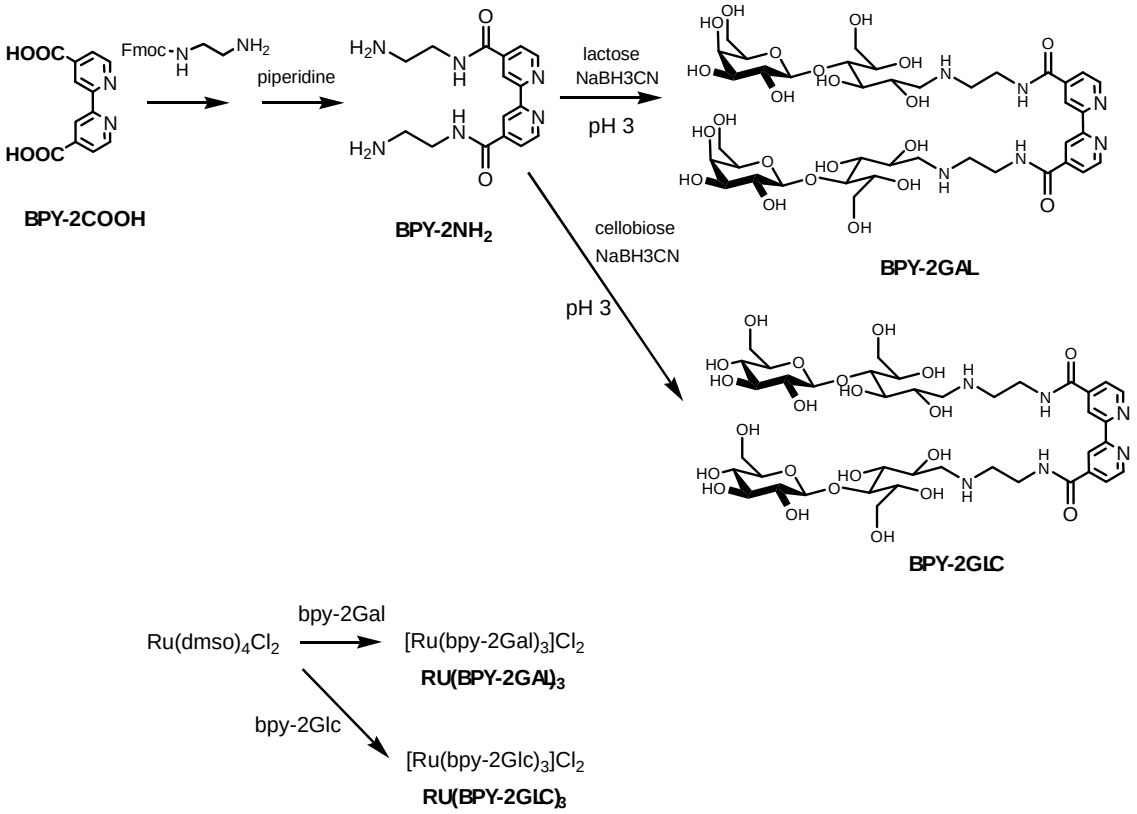
Syntheses and identification of metalloglycoclusters.

Metalloglycoclusters, $Ru(bpy\text{-}2Gal)_3$ and $Ru(bpy\text{-}2Glc)_3$, were synthesized by following the scheme S1.



Scheme S1 Synthetic scheme of the metalloglycoclusters.

Materials. All chemical reagents were purchased from the chemical companies and used without further purification. Ruthenium(III) chloride, 2, 2'-bipyridine-4, 4'-dicarboxylic acid (bpy-2COOH), lactose and cellobiose were obtained from Sigma-Aldrich. Tetanus toxin c-fragment was purchased from Funakoshi and used without further purification. Reversed phase column chromatography (RP-HPLC) was performed on LC-8A and SPD-M10A (Shimadzu). The purified products were identified by electrospray ionization (ESI) time-of-flight (TOF) mass spectrometry performed on a JMS-T100LC (JEOL) and matrix-assisted laser desorption ionization (MALDI) TOF mass Ultraflex III (Bruker). ^{1}H and ^{13}C NMR spectra were recorded on a FT-NMR (Bruker).

bpy-2NH$_2$. Bpy-2COOH (100 mg, 4.1×10^{-4} mol) was added to 10 mL of thionyl chloride and the mixture was

refluxed for 6 h. After the mixture turned into yellow solution, the solution was evaporated. The yellow solid was dissolved to the mixture of THF (10 mL) and CH_2Cl_2 (10 mL). Fmoc-NH-$(CH_2)_2$-NH_2 (325 mg, 10.2×10^{-4} mol) dissolved in THF (5 mL), CH_2Cl_2 (5 mL), and DIEA (2 mL) was added in dropwise to the yellow solutioin and kept overnight. After quenching the reaction by adding methanol, piperidine (9 mL) was added to the crude product dissolved in methanol and stirred at rt for 12 h. The crude product was purified by a silica-gel column chromatography to give colorless solid (67% in yield). ^{1}H NMR (400 MHz, CD_3OD) δ 8.90 (d, *J* = 5.1 Hz, 2H; C*H(bpy)*), 8.69 (s, 2H; C*H(bpy)*), 7.93 (d, *J* = 5.0 Hz, 2H; C*H(bpy))* 3.70 (t, *J* = 6.1 Hz, 4H; CH_2 *(linker moiety)*), 3.14 (t, *J* = 6.8 Hz, 4H; CH_2); ^{13}C NMR (100 MHz, CD_3OD) δ 167.6, 156.5, 155.8 ,150.3, 149.6, 143.0, 122.1, 121.2, 119.5, 44.5, 39.7, 39.5; ESI-MS *m/z* (M = $C_{16}H_{20}N_6O_2$) 329.1 $[M + H]^+$ (calcd: 329.2), 351.1 $[M + Na]^+$ (calcd: 351.2).

bpy-2Gal. Bpy-2NH_2 (80 mg, 2.4×10^{-4} mol) was dissolved in H_2O (10 mL), then β-lactose (1.66 g, 4.9×10^{-5} mol) and DMAC (10 mL) were added to the solution. The solution was stirred in a water bath at 315 K and acetic acid (2 mL) was added to keep acidity of the solution. Sodium cyanoborohydrate (0.772 g, 0.123 mol) was added to the solution and the mixture was stirred until the MS signal for bpy-2NH_2 disappeared. The crude product was purified by a RP-HPLC with CAPCELL PAK C18 MGII column (4.6 mm × 250 mm) (Shiseido) (11% in yield). ^{1}H NMR (400 MHz, D_2O) δ 8.84 (br, 2H; *CH(bpy)*), 8.45 (br, 2H; *CH(bpy)*), 7.85 (br, 2H; *CH(bpy)*), 4.20 – 3.50 (m, 38H; *CH_2 and CH of carbohydrate and linker moieties*); ^{13}C NMR (100 MHz, D_2O) δ 169.1 169.0 158.6 150.4 142.7 122.1 119.9 102.9 102.8 79.0 78.8 78.3 75.4 75.3 72.4 71.0 70.9 70.8 70.6 70.1 68.7 68.6 67.7 66.4 66.3 66.1 61.9 61.8 61.3 61.2 61.1 49.8 47.3; ESI-MS *m/z* (M = $C_{40}H_{64}N_6O_{22}$) 981.3 $[M + H]^+$ (calcd: 981.4), 491.1 $[M + 2H]^{2+}$ (calcd: 491.2).

bpy-2Glc. Using bpy-NH_2 (41 mg, 1.3×10^{-4} mol), β-cellobiose (171 mg, 4.9×10^{-4} mol), and sodium cyanoborohydrate (316 mg, 5.0×10^{-3} mol), bpy-2Gal was synthesized by the same procedure with bpy-2Gal described above (13% in yield). ^{1}H NMR (400 MHz, CD_3OD) δ 8.76 (br, 1H; C*H(bpy)*), 8.38 (br, 1H; C*H(bpy)*), 7.78 (br, 1H; C*H(bpy))* 3.90 – 3.20 (m, 19H; *CH_2 and CH of carbohydrate and linker moieties*); ^{13}C NMR (100 MHz, CD_3OD) δ 168.9, 155.5, 150.3 ,142.6, 122.1, 119.9, 102.3, 78.7, 76.0, 75.4, 73.2, 70.9, 70.6, 69.5, 67.7, 61.9, 60.6, 49.9, 47.3, 36.7; ESI-MS *m/z* (M = $C_{40}H_{64}N_6O_{22}$) 981.3 $[M + H]^+$ (calcd: 981.4), 491.1 $[M + 2H]^{2+}$ (calcd: 491.2).

Ru(bpy-2Gal)$_3$. $[Ru(dmso)_4Cl_2]$ (0.8 mg, 1.7×10^{-6} mol) and 3 equiv. of bpy-2Gal (5.0 mg, 5.0×10^{-6} mol)

were dissolved in H_2O (0.4 mL), then the reaction mixture was refluxed for 13 hours to give a dark red solution. After removing the solvent, the crude product was purified by a RP-HPLC with CAPCELL PAK C18 MGII column (4.6 mm × 250 mm) (Shiseido) with acetonitrile/H_2O (0.1% HCl) to give the titled compound as dark orange solid (quantitative). The compound was used for the binding analysis without purification of diastereomers (Λ- and Δ- forms). ^{1}H NMR (400 MHz, D_2O) δ 8.97 (br, 6H; *CH(bpy)*), 7.92 (br, 6H; *CH(bpy)*), 7.74 (br, 6H; *CH(bpy)*), 4.00 – 3.16 (m, 114H; *CH_2 and CH of carbohydrate and linker moieties*). MALDI-MS *m/z* (M = $C_{120}H_{192}N_{18}O_{66}Ru$) 3042.1 $[M - H]^+$ (calcd: 3042.1).

Ru(bpy-2Glc)$_3$. Using $[Ru(dmso)_4Cl_2]$ (0.8 mg, 1.7×10^{-6} mol) and 3 equiv. of bpy-2Glc (5.0 mg, 5.0×10^{-6} mol), Ru(bpy-2Glc)$_3$ was synthesized by the same procedure with Ru(bpy-2Gal)$_3$ (80% in yield). The compound was used for the binding analysis without purification of diastereomers (Λ- and Δ- forms). ^{1}H NMR (400 MHz, D_2O) δ 9.02 (br, 6H; *CH(bpy)*), 7.93 (br, 6H; *CH(bpy)*), 7.73 (br, 6H; *CH(bpy)*), 4.10 – 3.10 (m, 114H; *CH_2 and CH of carbohydrate and linker moieties*). MALDI-MS *m/z* (M = $C_{120}H_{192}N_{18}O_{66}Ru$) 3042.5 $[M - H]^+$ (calcd: 3042.1).

Ru(bpy)$_2$(bpy-2Gal). Bipyridine (165 mg, 9.6×10^{-4} mol, 2 equiv) and $RuCl_3$ (100 mg, 4.8×10^{-4} mol) were mixed in 5 mL of 1M HCl. The mixture was kept for 1 week, then the precipitation was collected by a suction filtration. The collected dark green solid, Ru(bpy)$_2$Cl$_2$, (5 mg, 1.0×10^{-5} mol) was suspended in 5 mL of H_2O. After adding bpy-2Gal (10 mg, 1.0×10^{-5} mol) and LiCl (3 mg, 7.3×10^{-5} mol), the reaction mixture was refluxed for 20 h. Solution was removed by evaporation to give a crude product. The residue was chromatographed (RP-HPLC) through CAPCELL PAK C18 MGII column (4.6 mm × 250 mm) (Shiseido) with acetonitrile/H_2O (0.1% HCl) as eluent to obtain the titled compound. ^{1}H NMR (400 MHz, D_2O) δ 8.91 (s, 1H; *CH(bpy)*), 8.71 (d, 2H; *CH(bpy)*), 8.15 (m, 3H; *CH(bpy)*), 7.72 (m, 2H; *CH(bpy)*), 7.66 (br, 1H; *CH(bpy)*), 7.35 (t, 2H; *CH(bpy)*), 3.95 - 3.28 (m, 19H; *CH_2 and CH of carbohydrate and linker moieties*); ESI-MS *m/z* (M = $C_{60}H_{80}N_{10}O_{22}Ru$) 697.2 $[M]^{2+}$ (calcd: 697.2).

UV-vis and ^{1}H NMR titration of metal ions to confirm formation of ML$_3$ (M = Fe^{II}, L = bpy-2Gal or bpy-2Glc) complex.

(UV-vis titration) $FeCl_2$ was added to an aqueous solution of bpy-2Gal (1.0×10^{-3} mol/L). At every molar ratio (Fe:bpy-2Gal), UV-vis absorption spectrum was recorded using a quartz cell (path length: 10 mm). Fig. S1 summarizes the absorption spectra. and absorption coefficients following addition of Fe^{II} ions. Since the intensity

change plateued when the molar ratio of Fe:bpy-2Gal reached 1:3, the UV-vis titration experiment supports quantitative formation of ML_3 complex in the examined condition.

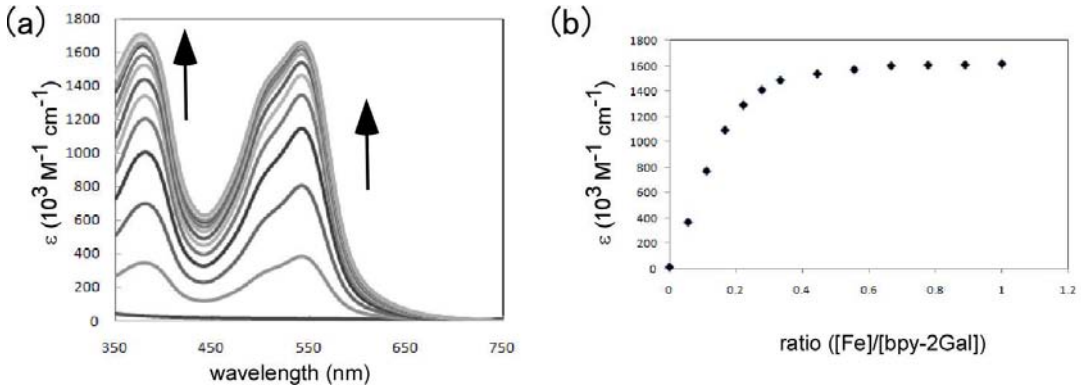


Fig. S1 (a) absorption spectra of bpy-2Gal with Fe^{II} (0 – 1.0×10^{-3} mol/L) and (b) absorption coefficient at 550 nm plotted against the molar ratio (Fe:bpy-2Gal).

(^{1}H NMR titratio) To a solution of bpy-2Gal (1.0×10^{-4} mol/L) in D_2O (0.4 mL), $FeCl_2$ in D_2O was added in stepwise. By addition of $FeCl_2$, a new set of the signals appeared and signals of free ligand decreased. When molar ratio (Fe:bpy-2Gal) reached 1:3, the signals of free ligand disappeared. This titration result supports that bpy-2Gal forms thermodynamically stable ML_3 complex in aqueous solution.

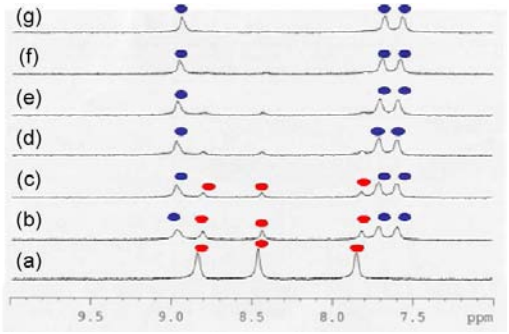

Fig. S2 ^{1}H NMR spectra of bpy-2Gal with Fe^{II} at molar ratio (Fe:bpy-2Gal) (a) 0:3, (b) 1/3:3, (c) 2/3:3, (d) 1:3, (e) 4/3:3, (f) 5/3:3, and (g) 2:3. Red and blue circles represent free bpy-2Gal and $[Fe(bpy\text{-}2Gal)_3]^{2+}$, respectively.

Fluorescence emission intensity and polarization measurements. Emission intensity and fluorescence polarization was recorded on a fluorescence spectrophotometer (HITACHI, F-7000) equipped with an auto-polarization-measurement-system. All spectra of the metalloglycoclusters were measured using 20 μM of the metalloglycocluster with or without 5 μM of lectin in PBS buffer at 298 K. For analyzing binding properties including a dissociation constant, the concentration of the metalloglycocluster was 20 μM and that of PNA or

ConA was varied from 0 – 20 μM. Excitation wavelength was at 468 nm for $Ru(bpy\text{-}2Gal)_3$ and $Ru(bpy\text{-}2Glc)_3$, and at 450 nm for $Ru(bpy)_3$.

Fluorescence polarization (P) was calculated by the equation, $P = (I_{\parallel} - I_{\perp} \times G)/ (I_{\parallel} + I_{\perp} \times G)$, where I is the fluorescence intensity using the polarizer at 0° for excitation ($I_{\parallel}$ and $I_{\perp}$ were observed using the emission polarization filter at 0° and 90°, respectively). The correction factor G was determined by the following equation, $G = i_{\parallel} / i_{\perp}$, where i is the fluorescence intensity using at 90° for excitation ($i_{\parallel}$ and $i_{\perp}$ were observed using the emission polarization filter at 0° and 90°, respectively). For each sample, G factors were defined by measuring $i_{\parallel}$ and $i_{\perp}$ at individual wavelength.

Emission spectral change caused by addition of ethanol.

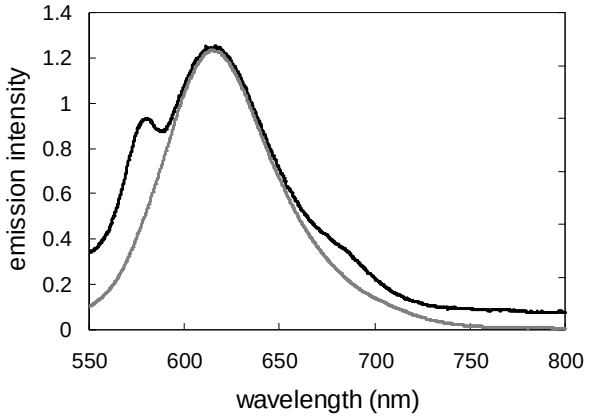

Fig. S3 Emission spectra of 20 μM Ru(bpy-2Gal)$_3$ in PBS (gray) and in PBS with 50% ethanol (black) (λ_{ex}: 468 nm, T: 298 K).

Calculation of the dissociation constant

Dissociation constants (K_d) between PNA and Ru(bpy-2Gal)$_3$, or ConA and Ru(bpy-2Glc)$_3$ were determined with non-linear least squares fitting. Using the fluorescence polarization value, the data was fitted to the following equation, $P/P_{max} = [(K_d + [probe]_{toatal} + [lectin]_{total}) - \{(K_d + [probe]_{total} + [lectin]_{total})^2 - 4[probe]_{total}[lectin]_{total}\}] / 2[probe]_{total}$, where P is the polarization value, P_{max} is the maximum polarization value, $[probe]_{total}$ is the total concentration of Ru(bpy-2Gal)$_3$ or Ru(bpy-2Glc)$_3$, and $[lectin]_{total}$ is the total concentration of PNA or ConA. The simulation results were summarized in Table S1.

Table S1 Results of Non-Linear Squares Fitting using Polarization Value

	P_{max}	K_d (M)	Correlation
Ru(bpy-2Gal)$_3$	0.52	6.1×10^{-6}	0.9996
Ru(bpy-2Glc)$_3$	0.46	1.8×10^{-5}	0.9824

Affinity Evaluation of Tetanus Toxin c-Fragment.

Fluorescence polarization values were recorded on a fluorescence spectrophotometer (HITACHI, F-7000) equipped with an auto-polarization-measurement-system. The metalloglycoclusters, $Ru(bpy\text{-}2Gal)_3$ and $Ru(bpy\text{-}2Glc)_3$, were measured using 2 μM of the PBS solution. Polarization values of the metalloglycocluster with or without 0.05 μM tetanus toxin c-fragment were collected in PBS buffer at 298 K. Excitation wavelength was at 468 nm for $Ru(bpy\text{-}2Gal)_3$ and $Ru(bpy\text{-}2Glc)_3$.

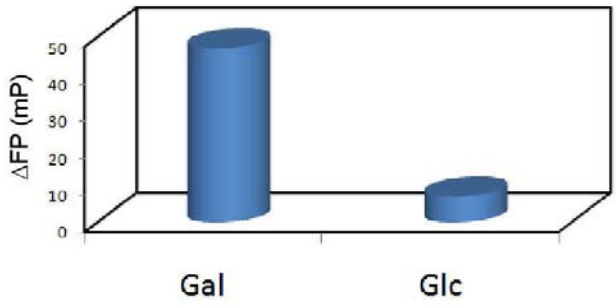

Fig. S4 Changes in fluorescence polarization values of 2 μM $Ru(bpy\text{-}2Gal)_3$ or $Ru(bpy\text{-}2Glc)_3$ in PBS (λ_{ex}: 468 nm, T: 298 K) when 0.05 μM tetanus toxin c-fragment was added.

In Vivo Imaging of Mesenchymal−Epithelial Transition Factor (c-Met) Expression using an Optical Imaging System

Eun-Mi Kim, Eun-Hye Park, Su-Jin Cheong, Chang-Moon Lee, Hwan-Jeong Jeong,* Dong Wook Kim, Seok Tae Lim, and Myung-Hee Sohn

Department of Nuclear Medicine, Research Institute of Clinical Medicine, Cyclotron Research Center, Chonbuk National University Medical School and Hospital, Jeonju, Jeonbuk, Republic of Korea. Received January 6, 2009; Revised Manuscript Received May 12, 2009

Mesenchymal−epithelial transition factor (c-Met) is a receptor tyrosine kinase that has been shown to be overexpressed and mutated in a variety of malignancies, such as glioma. We have recently found that an ^{125}I-radiolabeled Gly-Gly-Gly (GGG)- or 8-aminooctanoic acid (AOC)-containing c-Met binding peptide (cMBP) specifically targets c-Met receptor *in vivo* and *in vitro*. In this report, cyanine dye 5.5 (Cy5.5)-conjugated GGG- or AOC-containing cMBPs were evaluated in human cancer cell xenografts in order to investigate the possibility of c-Met receptor targeting using an optical imaging system. The receptor binding affinity of Cy5.5-conjugated peptides was tested in 96-well plates coated with a c-Met/Fc chimeric protein. Optical imaging studies were performed in U87MG and Ramos bearing athymic mice. The binding affinities of Cy5.5-conjugated GGG- or AOC-containing cMBPs were determined to be 0.318 and 0.342 μM, respectively. Confocal images show that Cy5.5-conjugated peptides bound mainly to the cell surface and that peptide binding was clearly inhibited by free cMBP. Subcutaneous U87MG tumors were clearly visualized with each of the two fluorescent probes. Of the two, cMBP-AOC−Cy5.5 displayed higher tumor uptake and tumor-to-normal tissue ratios at 10 min to 24 h postinjection in the U87MG tumor model. For the *in vivo* blocking study, cMBP-AOC−Cy5.5 (4 nmol) was co-injected with cold cMBP (0.13 μmol) into the U87MG xenograft mice. Image-based tumoral uptake decreased up to approximately 35%. These results suggest that Cy5.5-conjugated cMBP could potentially be used to detect c-Met-positive cancers *in vivo*. However, additional modifications to this optical imaging agent are needed to further improve its efficacy.

INTRODUCTION

As new disease-specific imaging targets (e.g., cell surface receptors) are being identified, demand for targeted imaging agents is increasing. Peptides are receiving much attention for *in vivo* cancer detection because excellent tissue-specific uptake can be achieved (*1*). Mesenchymal−epithelial transition factor (c-Met) is expressed by most carcinomas, and its elevated expression relative to normal tissue has been detected in a number of cancers including lung, breast, colorectal, prostate, pancreatic, head and neck, gastric, hepatocellular, ovarian, renal, glioma, melanoma, and a number of sarcomas (*2*−*5*). Receptor tyrosine kinases are important therapeutic targets for antineoplastic molecularly targeted therapies. In this respect, the c-Met receptor appears to be a good candidate for detection of cancer. Recently, Kim et al. have reported that an epitope-mimicking peptide, NH_2-Lys^1-Ser^2-Leu^3-Ser^4-Arg^5-His^6-Asp^7-His^8-Ile^9-His^{10}-His^{11}-His^{12}-Ac (c-Met binding peptide, cMBP), from a phage display of a combinatorial peptide library, binds to c-Met and inhibits the HGF−c-Met interaction (*6*).

Emerging optical imaging techniques have recently proven to be powerful tools for *in vivo* molecular imaging of specific target structures. Although poor light penetration through tissues makes their utilization in humans difficult, these techniques have been successfully applied in preclinical small animal research (*7*−*9*). Near-infrared (NIR) fluorescence imaging, which uses neither ionizing radiation nor radioactive materials, is emerging as a complement to nuclear imaging methods. A relatively low-cost, safe, and easy-to-use NIR fluorescence imaging system has proven to be a powerful tool for noninvasive imaging of diseases in preclinical models such as rodents (*10*). The NIR fluorescent dye cyanine dye 5.5 (Cy5.5) has proven to be a promising *in vivo* agent. It has an absorbance maximum at 675 nm and emission maximum at 694 nm and can be detected *in vivo* at subnanomole quantities and at depths sufficient for experimental and clinical imaging (*11*−*13*).

We have reported recently that an ^{125}I-radiolabeled cMBP targets c-Met receptor both *in vitro* and *in vivo* (*14*). We were therefore interested in exploring the possibility that tumor-specific optical images could be obtained using optical dye conjugated cMBP. In this study, we report on the targeting of c-Met receptor in human cancer cell xenografted mice using Cy5.5-conjugated cMBPs containing 8-aminooctanoic acid (AOC) or Gly-Gly-Gly (GGG) linkers.

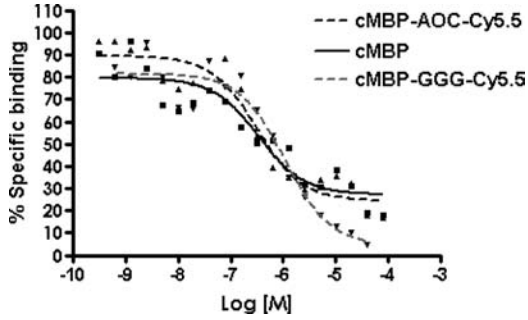

Figure 2. Competitive c-Met receptor assay for cMBP-GGG−Cy5.5, cMBP-AOC−Cy5.5, and cMBP tested with the c-Met/Fc chimeric protein. All experiments were done in duplicate. The IC_{50} values for cMBP-GGG−Cy5.5, cMBP-AOC−Cy5.5, and cMBP were determined to be 318 nM, 342 nM, and 1.5 μM, respectively.

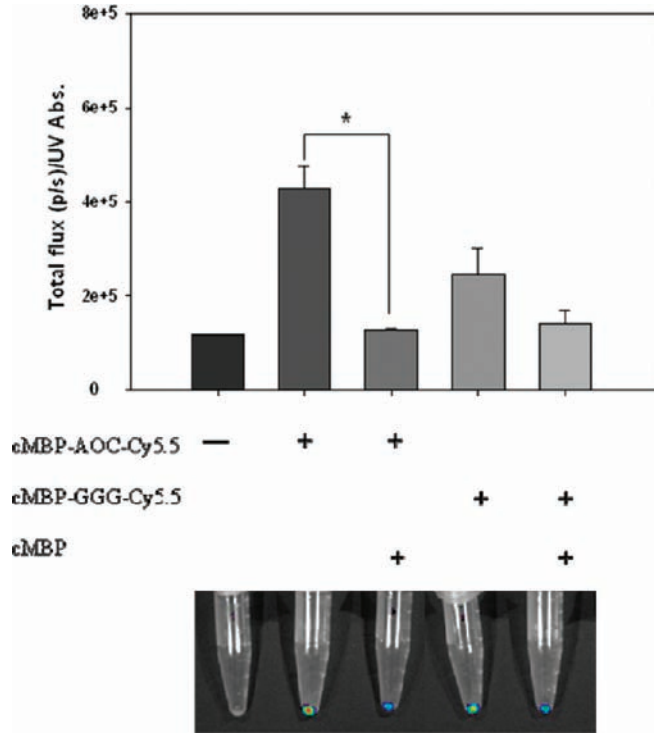

Figure 3. Cellular uptake of cMBP-GGG−Cy5.5 or cMBP-AOC−Cy5.5 in U87MG cells. Cells were incubated with cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 (2 nmol), and cMBP was used as inhibitor (86 nmol). The representative fluorescence images were acquired using an optical imaging system. The data are presented as the mean ± SD (* indicates $P < 0.05$).

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. $Na^{125}I$ was obtained from Perkin-Elmer Life Science, Inc. (Boston, MA). cMBP, cMBP-GGG-SC, and cMBP-AOC-C were synthesized by Peptron using standard Fmoc chemistry (Seoul, Korea). The purity of all samples was over 90%. Cy5.5−maleimide was purchased from GE healthcare (Uppsala, Sweden).

Synthesis and Characterization of cMBP-X−Cy5.5. c-Met binding peptides, cMBP-GGG-SC (1 mg, 0.53 μmol, MW = 1863) and cMBP-AOC-C (1 mg, 0.57 μmol, MW = 1747), dissolved in phosphate-buffered saline (PBS, pH 7.2, EDTA 5 mM) were mixed with Cy5.5−maleimide (0.618 μg, 0.59 μmol, MW = 1152) in the dark at room temperature for 6 h. The final product was lyophilized and dried. Purification of the crude product was carried out on a MWCO 2000 dialysis cassette (Pierce, Rockford, IL). The molecular mass was determined by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) (KBSI, Jeonju, Korea). The analytic reversed-phase high-performance liquid chromatography (RP-HPLC) method was performed with a spectra system SCM100 degasser, a P4000 pump, and an UV/vis 3000 detector (Thermo Scientific, Waltham, MA). The absorbance was monitored at 218 nm and a Hypersil gold column (250 mm × 4.6 mm, Thermo Scientific) was used. ChromQuest 4.2 software was used to record chromatograms. The flow was 1 mL/min, with the mobile phase varying from 97% solvent A (0.1% trifluoroacetic acid in water) and 3% solvent B (0.1% trifluoroacetic acid in acetonitrile; 0−4 min) to 40% solvent B for 10 min, 50% solvent B for 15 min, 40% solvent B for 10 min, and 90% solvent B for 25 min. The final products, cMBP-GGG-

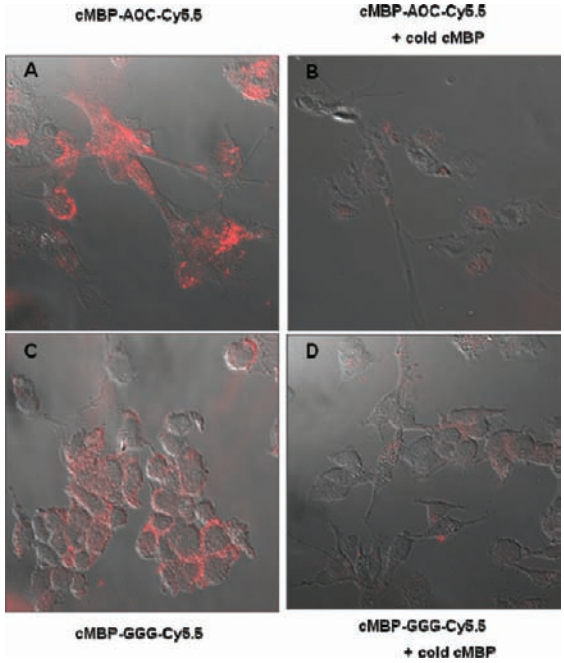

Figure 4. NIR fluorescence images of U87MG cells were obtained after incubation for 1 h in the presence of cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 (2 nmol) with (B, D) or without (A, C) a blocking dose of cMBP peptide (86 nmol). Cellular uptake was blocked by cold peptide. Blocking images demonstrate the high c-Met receptor specificity of Cy5.5-conjugated cMBPs.

SC−Cy5.5 and cMBP-AOC-C−Cy5.5 are referred to as cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5, respectively. The absorption and fluorescence emission characteristics of Cy5.5-conjugated cMBP peptides were measured in H_2O using a UV−vis spectrophotometer (HP8453, Hewlett-Packard, Palo Alto, CA).

Determination of log *P*. Approximately 370 kBq of ^{125}I-cMBP-GGG−Cy5.5 and ^{125}I-cMBP-AOC−Cy5.5 in 500 μL of PBS (pH 7.4) was added to 500 μL of octanol in a microcentrifuge tube. The mixture was vigorously vortexed for 1 min at room temperature. The two phases were separated by centrifugation at 12 500 rpm, and 200 μL aliquots of both layers were counted using a γ-counter (Packard, Meriden, CT). The experiment was carried out five times. The value was expressed as mean ± SD.

Cell Lines. Human glioblastoma cell line U87MG (c-Met receptor positive), nasopharyngeal carcinoma cell line KB (c-Met receptor positive), and B-lymphoma cell line Ramos (c-Met receptor negative) (*15*) were obtained from the Korean cell line bank (Seoul, South Korea) and maintained at 37 °C in a humidified atmosphere containing 5% CO_2 in RPMI-1640 medium with 10% fetal bovine serum (GIBCO, Carlsbad, CA).

***In Vitro* Binding Assay and Cellular Uptake.** cMet/Fc chimeric protein was purchased from R&D Systems (Minneapolis, MN) and dissolved in coating buffer (carbonate buffer, pH 9.75). The cMet/Fc chimeric protein was coated onto 96-well plates (16 h, 4 °C), and plates were blocked with blocking buffer (Pierce, Rockford, IL). After washing with washing buffer (PBS, 0.1% Tween 20), ^{125}I-cMBP was added to the 96-well plates with serially diluted peptides cMBP, cMBP-AOC−Cy5.5, or cMBP-GGG−Cy5.5 at concentrations ranging from 0.04 nM to 150 μM. The plates were then incubated for 2 h at 37 °C and washed and dried before 0.1 mL of 2 N NaOH was added to each well to facilitate cell lysis. Lysates were collected and counted on a γ-counter. The 50% inhibitory concentration (IC_{50}) value for the displacement binding was calculated by nonlinear regression analysis (sigmoidal dose response equation) using the GraphPad Prism 4.0 computer-fitting program (Graph-Pad Software, San Diego, CA). All the experiments were done in duplicate.

For *in vitro* studies, 5×10^5 U87MG cells were seeded into 6 cm dishes. The next day, media was replaced with serum-free media. Cells were incubated with cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 (2 nmol) for 1 h. For blocking studies, cells were cotreated with cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 and nonfluorescent cMBP peptide (86 nmol). After incubation, the cells were detached with trypsin and collected. Cell fluorescence was acquired using an IVIS system (f-stop = 1, binning = 8, field of view = 12.8, exposure time = 1 s; Caliper Lifescience, Hopkinton, MA). Protein amounts were determined by a BCA assay (Pierce, Rockford, IL).

Confocal Microscopy. For laser confocal microscopy, U87MG and KB cells were grown on a 12-mm microscope cover glass (Marlenfeld GmbH, Germany) and incubated at 37 °C in the presence of cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 (2 nmol) for 1 h. For blocking studies, cells were cotreated with cMBP-AOC−Cy5.5 or cMBP-GGG−Cy5.5 and nonfluorescent cMBP peptide (86 nmol). Cells were washed in ice-cold PBS and examined with a HFT405/488/543/633 dichroic beam splitter, with simultaneous 488-nm excitation, 505−530 nm emission for autofluorescence, 633-nm excitation, and ChS1 636−754 nm emission for Cy5.5 and both lasers for (nonconfocal) bright-field transmitted light (LSM 510META, Carl Zeiss, Germany).

Tumor Xenografts. All animal experiments were performed in compliance with the Institutional Animal Care and Use Committee for animal treatment of Chonbuk National University. Female athymic nude mice (4-wk, *nu*/*nu*) were obtained from Orient-Bio (Seoul, Korea). Mice were anesthetized by subcutaneous injection with a mixture of ketamine (50 mg/kg) and xylazine (10 mg/kg). After sedation, glioblastoma (U87MG) and lymphoma (Ramos) tumors were established by subcutaneous injection in the right flank with 5×10^6 tumor cells mixed in Matrigel. When the tumors reached 0.7 or 1 cm in length, the tumor-bearing mice were subjected to *in vivo* imaging studies.

***In Vivo* Optical Imaging.** *In vivo* fluorescence imaging was performed with an IVIS spectrum small-animal *in vivo* imaging system (Caliper Lifescience, Hopkinton, MA), that has both bioluminescence and fluorescence capabilities. U87MG xenograft mice were given injections of cMBP-GGG−Cy5.5 or cMBP-AOC−Cy5.5 (4 nmol) via their tail vein and were anesthetized with 1.5−2% isoflurane before being placed in the camera bed positioned laterally and imaged at various time points postinjection while remaining sedated (f-stop = 2, binning = 8, field of view = 12.8, exposure time = 1 s, sample depth = 1.5 cm). Ramos xenograft mice were given injections of cMBP-AOC−Cy5.5 (4 nmol). For *in vivo* blocking studies, U87MG xenograft mice received an injection of a mixed sample of cMBP-AOC−Cy5.5 (4 nmol) and cold cMBP (0.13 μmol). Images were acquired at various time points after injection. After 2 h, the tumor and major tissue and organs were dissected, and the fluorescence image was obtained (f-stop = 2, binning = 8, field of view = 12.8, exposure time = 1 s, sample depth = 1.5 cm). Excitation filters were 640, 604, and 570 nm, and the emission filter was 700 nm. After three images were acquired, background subtraction was performed using Living Image software (Caliper Lifescience, Hopkinton, MA).

RNA Extraction and Reverse Transcriptase Polymerase Chain Reaction (RT-PCR). Total RNA from cells and tumor tissue was extracted using Trizol reagent according to the manufacturer's instructions (Invitrogen, Carlsbad, CA) and quantified based on the measured absorbance at 260 and 280

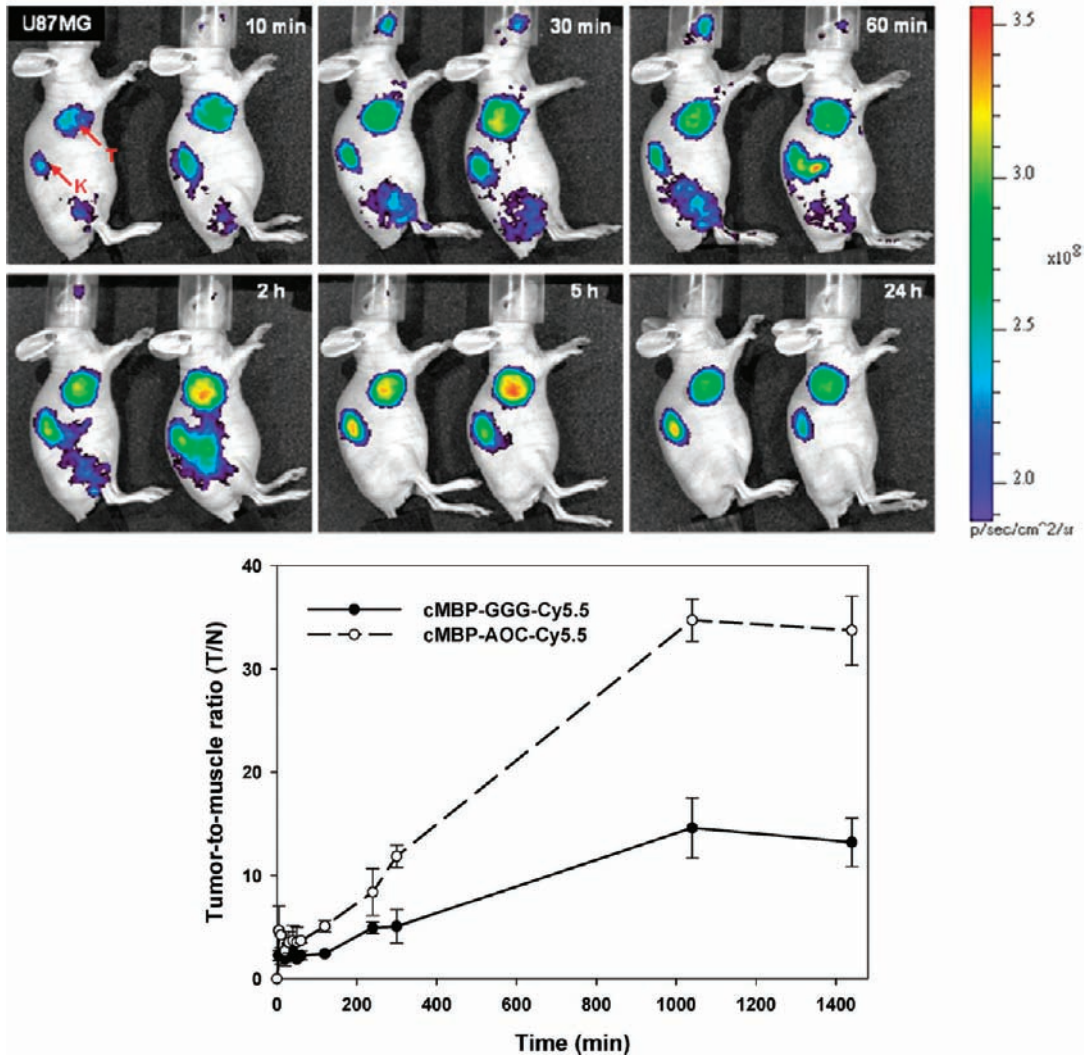

Figure 5. *In vivo* fluorescence imaging of athymic nude mice bearing U87MG xenografts after iv injection of 4 nmol of cMBP-GGG−Cy5.5 (left) or cMBP-AOC−Cy5.5 (right). Red arrows indicate the tumor (T) or kidney (K). All NIR fluorescence images were acquired with a 1-s exposure time at 10 min, 30 min, 60 min, 2 h, 5 h, and 24 h, and background fluorescence was subtracted. Fluorescence signal from Cy5.5 was pseudocolored red. The tumor-to-muscle (T/M) ratio as a function of time postadministration of cMBP-GGG−Cy5.5 (●) or cMBP-AOC−Cy5.5 (○) is shown in the bottom panel.

nm. RT-PCR procedures for c-Met were performed as described previously by Kim et al. (*14*).

Data Processing and Statistics. All data are given as mean ± SD. Statistical analysis was performed using one-way analysis of variance (ANOVA). Statistical significance was assigned for P values <0.05. For determining tumor contrast, mean fluorescence intensities (average radiance, p/(s·cm^2·sr)) of the tumor area, normal muscle area, and kidney were calculated by the region-of-interest (ROI) function of Living Image software.

RESULTS

Synthesis and Characterization of cMBP-X−Cy5.5. The synthesis of cMBP-X−Cy5.5, where X stands for linker, was achieved through conjugation of Cy5.5−maleimide with the thiol group of the cysteine residue of the cMBP-GGG-SC or cMBP-AOC-C peptides. The chemical structures of cMBP-X−Cy5.5 are shown in Figure 1. The final products were purified by dialysis. The purity of Cy5.5-conjugated peptides was over 90% by analytical RP-HPLC. The yield of Cy5.5-labeled peptides were typically over 65%. The retention times on analytical RP-HPLC for cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5 were 9.40 and 9.91 min, respectively. The purified Cy5.5 conjugates were characterized by MALDI-TOF-MS: GGG-containing cMBP-X−Cy5.5, m/z = 2989 for $[M + H]^+$ (calculated MW = 2990); AOC-containing cMBP-X−Cy5.5: m/z = 2874 for $[M + H]^+$ (calculated MW = 2876). The absorption and fluorescence emission characteristics of Cy5.5-labeled cMBP peptide conjugates were identical to those of free Cy5.5; the spectra were measured in H_2O using a UV−vis spectrophotometer (Figure S1, Supporting Information). The octanol−water partition coefficient (log P) for cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5 was −1.028 ± 0.08 and −1.109 ± 0.06.

***In Vitro* Binding Assay and Cellular Uptake.** The receptor binding affinity assay for Cy5.5-conjugated cMBPs for c-Met receptor was carried out using a cMet/Fc chimeric recombinant protein. We compared the receptor binding affinity of the two probes by performing competitive displacement studies with ^{125}I-cMBP as the radioligand (Figure 2). The IC_{50} values for cMBP, cMBP-GGG−Cy5.5, and cMBP-AOC−Cy5.5 were 1.5 μM, 318 nM, and 342 nM, respectively. The binding affinity of the Cy5.5-conjugated cMBPs was in the nanomolar range and lower than nonconjugated cMBPs. The IC_{50} values using U87MG cells

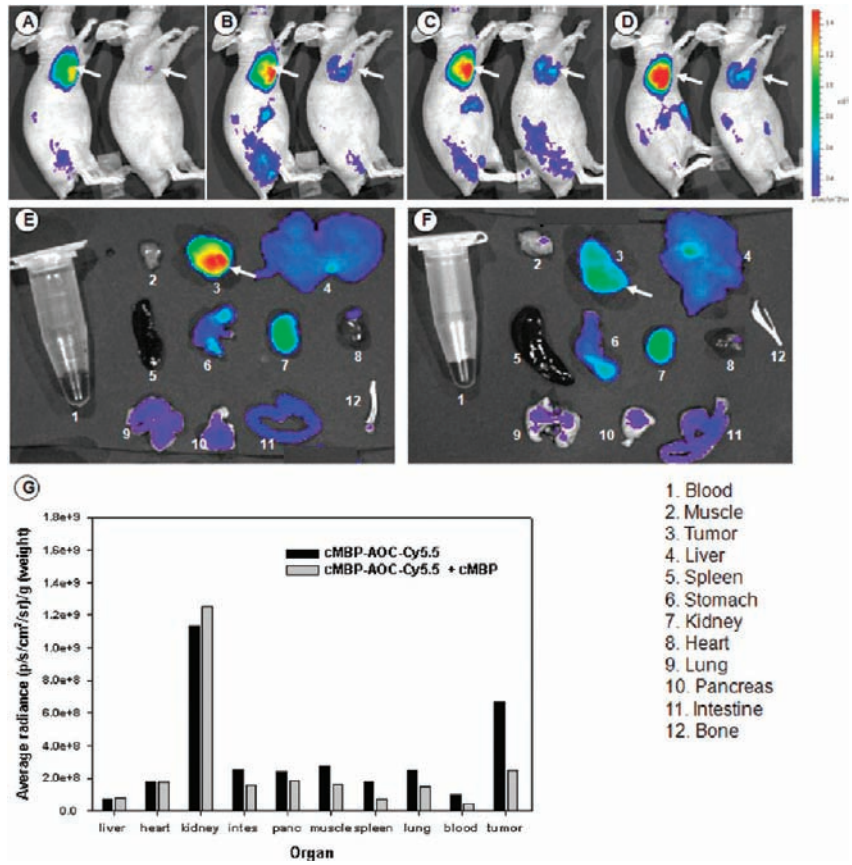

Figure 6. Blocking images in U87MG tumor-bearing nude mice: 10 min (A), 30 min (B), 60 min (C), 120 min (D). The left image shows the result after injection of cMBP-AOC−Cy5.5 (2 nmol), and the right image shows the result after co-injection of cMBP-AOC−Cy5.5 (4 nmol) and cMBP (0.13 μmol). After acquisition, *ex vivo* images also were acquired. Representative images of dissected organs of a cMBP-AOC−Cy5.5-injected mouse (E) and a mouse cotreated with inhibitor (F) are shown. The tumors are indicated with white arrows. Tumoral uptake of cMBP-AOC−Cy5.5 was clearly inhibited by free cMBP peptide. Flux (p/(s·cm^2·sr)) was divided by the weight of organ (G) (intes = intestine, panc = pancreas).

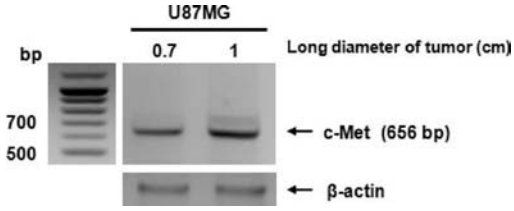

Figure 7. Expression of the c-Met receptor in U87MG tumor tissue was determined by RT-PCR. Fragments of the 656 bp transcript were detected to confirm the expression of c-Met mRNA in U87MG tumor tissue. β-actin was used as an internal loading control. The c-Met-to-actin ratio was 0.74 in the 0.7 cm tumor and 1.24 in the 1 cm tumor ($n = 3$).

of cMBP-GGG-SC, and cMBP-AOC-C were 65 and 85.3 nM, respectively. These values were previously reported elsewhere (*14*).

The cellular uptake is shown in Figure 3. cMBP-AOC−Cy5.5 exhibited a higher total flux/UV absorbance ratio than cMBP-GGG−Cy5.5 in U87MG cells. cMBP-AOC−Cy5.5 was significantly inhibited by nonfluorescent cMBP. cMBP-GGG−Cy5.5 uptake by U87MG cells was not significantly inhibited by cMBP.

Confocal Microscopy. To determine the c-Met receptor specificity and cellular binding of the Cy5.5-conjugated cMBPs, the peptides were incubated with U87MG, and images were taken with a confocal microscope (Figure 4). Cy5.5-conjugated cMBPs were further analyzed in the presence of a blocking dose of free cMBP peptide. cMBP-GGG−Cy5.5 or cMBP-AOC−Cy5.5 bound mainly to the cell surface of U87MG cells (A, C). More cMBP-AOC−Cy5.5 was bound than cMBP-GGG−Cy5.5. This pattern was similar in KB cells and is also correlated with cellular uptake images of Figure 3. The bound peptides on the cell surface were inhibited by cotreatment with peptides (B, D). KB cells also showed specific binding to the cell surface (Figure S2, Supporting Information).

***In Vivo* Optical Imaging.** In U87MG tumor models, cMBP-AOC−Cy5.5 showed a higher tumor-to-muscle ratio than cMBP-GGG−Cy5.5. The tumor-to-kidney (T/N) and tumor-to-muscle (T/M) ratio was calculated and is shown in Figure 5. Receptor specificities of the probes were validated by a blocking experiment. A U87MG tumor xenograft mouse was injected with cMBP-AOC−Cy5.5, and another was injected with a mixture of cMBP-AOC−Cy5.5 and free peptide. As shown in Figure 6, tumoral uptake *in vivo* was clearly inhibited by free peptide. To further characterize the distribution of cMBP-AOC−Cy5.5 in U87MG *in vivo*, the tumor-bearing mice were sacrificed after noninvasive imaging at 2 h. Tumor fluorescence intensity (p/(s·cm^2·sr·g)) was successfully reduced from 6.62×10^8 to 2.4×10^8 (Figures 6E−G). On the other hand, cMBP-AOC−Cy5.5 was not accumulated in the tumor site in the Ramos tumor model (Figure S3, Supporting Information).

RNA Extraction and RT-PCR. The expression of c-Met mRNA in U87MG and Ramos cells was compared (Figure S4, Supporting Information). The expression of c-Met mRNA in Ramos cells was very weak compared with that of U87MG cells. To confirm the expression of c-Met mRNA in U87MG tumor tissue, total RNA was isolated and analyzed. As shown in Figure 7B, c-Met mRNA was expressed in U87MG tumor tissue, as

depicted by the c-Met/actin ratio, which was higher in large size tumors. The ratio correlated well with tumor uptake *in vivo*.

DISCUSSION

Since Met was discovered as an oncogene two decades ago (*16*), the HGF/c-Met signaling pathway has come into the spotlight as a promising therapeutic target for inhibiting tumor growth. Activation or upregulation of c-Met is a negative prognostic indicator in patients with various carcinomas, multiple myeloma, or glioma (*17*−*21*). For these reasons, several strategies to block the activation of Met are under development, such as the use of Met/HGF inhibitors, tyrosine kinase inhibitors, or monoclonal antibodies, and some of these compounds have already been used in clinical trials (*22*−*27*). Together with development of therapeutic agents, noninvasive biomarkers suitable for monitoring and predicting therapeutic response are needed. Recently, other groups showed ^{89}Zr-labeled c-Met antibody for PET imaging (*28*) and gadolinium-labeled c-Met antibody for MRI imaging (*29*). However, optical imaging has not been studied, and in this study, we studied the possibility of the c-Met receptor target using an optical imaging agent.

We reported previously that ^{125}I-radiolabeled cMBP bound specifically to U87MG cells and tumors. This peptide showed unacceptably rapid elimination from the body, so modification was needed to improve its pharmacokinetics. We hypothesized that the introduction of hydrophobic amino acids or aliphatic carbon chain linkers would help reduce radioactive accumulation in the kidney and rapid elimination. GGG or AOC linker was added to the cMBP peptide. This study showed that the GGG linker containing peptide had a higher tumor-to-muscle ratio than the peptide with the AOC linker. Thus, changes in the linker can have a profound effect on tumor uptake (*14*).

On the basis of these results, we also studied whether Cy5.5-conjugated cMBPs can target the c-Met receptor *in vitro* and *in vivo*. The present study demonstrated that the NIR dye Cy5.5-conjugated cMBPs are able to target c-Met receptor *in vitro* and *in vivo* specifically. The molecular mass of Cy5.5 is 1152 g/mol. After conjugation to the peptides, the molecular mass of the product is approximately 3000 g/mol. This is large enough to be separated from free Cy5.5 by the dialysis method. We purified the peptides by dialysis and used RP-HPLC to check the purity of Cy5.5-conjugated cMBPs. RP chromatograms show a single species with retention times of 9.4 min for GGG and 9.91 min for AOC. Free Cy5.5 and unbound peptides were removed effectively by dialysis. Both Cy5.5 conjugates showed similar binding affinity. The IC_{50} of cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5 was 318 and 342 nM, respectively, which is higher than the value for nonconjugated native cMBP peptides (cMBP-GGG-SC = 65 nM; cMBP-AOC-C = 85.3 nM). Although the binding affinities were similar, their pharmacokinetic properties were influenced by the linker. The RP-HPLC retention times reflect the inherent hydrophilic/hydrophobic nature of the two conjugates and correlate well with the *in vivo* distribution.

To demonstrate the c-Met specificity and subcellular localization of cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5, the peptides were incubated with U87MG cells, and images were taken with a fluorescent confocal microscope. cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5 bound predominantly to the cell surface (Figure 4A,C) and were assumed not to be taken up by receptor-mediated endocytosis, despite their large size. These results correlate well with our previous result that ^{125}I-radiolabeled cMBP did not show cellular internalization (*14*). Binding of the peptides was clearly inhibited by free cMBP peptides (86 nmol) (Figure 4B,D). To test whether the cell surface binding phenomenon was general, *in vitro* cellular uptake was also tested in KB nasopharyngeal epidermal carcinoma cell line. This cell line showed c-Met expression like U87MG cells, and similar to U87MG cells, cMBP-GGG−Cy5.5 and cMBP-AOC−Cy5.5 bound specifically to the KB cell surface (Figure S2, Supporting Information).

To acquire NIR fluorescence images, 640, 604, and 570 nm excitation filters and a 700 nm emission filter were used. Even without the optic dye, the mouse body shows autofluorescence. For this reason, 604 and 570 nm excitation filters were used to remove background signal. After three images were acquired, the background subtraction was performed using Living Image software. The background autofluorescence signal was effectively removed to obtain clearer images. NIR fluorescence images in tumor xenograft mice with cMBP-GGG−Cy5.5 or cMBP-AOC−Cy5.5 show apparent tumor uptake. cMBP-AOC−Cy5.5 showed higher tumor uptake than cMBP-GGG−Cy5.5 in U87MG xenograft mice. As shown in Figure 5, the tumor-to-muscle ratio difference of the two Cy5.5-conjugated peptides become more obvious over time (33.71 ± 3.34 for GGG and 13.21 ± 2.33 for AOC, at 24 h). cMBP-GGG−Cy5.5 showed higher kidney uptake than cMBP-AOC−Cy5.5. Both showed fast elimination via the bladder. In a previous study, ^{125}I-radiolabeled cMBP-GGG-SC showed higher tumor uptake than cMBP-AOC-C. However, the tumoral uptake pattern changed after Cy5.5 conjugation. Also ^{125}I-radiolabeled cMBPs showed high pancreatic uptake, but Cy5.5 conjugates did not show this. The differences in tumor and pancreatic retention might be accounted for by factors relating to differences in the size or properties of Cy5.5. Lower pancreas uptake might be caused by Cy5.5 hydrolysis from the peptides but in the case of ^{125}I-radiolabeled cMBPs, the radiolabel taken up by the pancreas was ^{125}I-radiolabeled histidine or histidine as a free amino acids (*14*). Since the octanol−water partition coefficients of the cMBP-GGG-SC and cMBP-AOC−Cy5.5 were similar, the greater tumor uptake of the cMBP-AOC−Cy5.5 could be attributable to the fact that this conjugate showed increased interaction with tumor cells (Figure 5). Tumor uptake was specific, because the signal decreased upon administration of the blocking agent to 2 h as seen in *ex vivo* images with reduced tumor signal. However, there was also a reduction in signal accumulation in noncancerous organs, such as the intestine, pancreas, lungs, liver, muscle, and spleen. The blockage in these organs suggests that the uptake of cMBPs is at least partially c-Met receptor mediated. c-Met receptors are widely expressed in a variety of tissues, and their expression is normally confined to cells of epithelial and mesenchymal origin (*30*, *31*). The glioma uptake of cMBP-AOC−Cy5.5 is significantly higher than its lymphoma tumor uptake. Tumor-to-muscle ratio in lymphoma mice was 1.05, 0.56, 0.51, and 0.21 at 10, 30, 60 min and 2 h, respectively. This is consistent with the result that the U87MG glioma cells have a higher level of c-Met receptor expression than Ramos lymphoma cells (Figures S3 and S4, Supporting Information).

In conclusion, we evaluated the Cy5.5-conjugated c-Met receptor binding peptide analogues with amino acid or aliphatic carbon chain linkers and found that the addition of a lipophilic carbon linker improved their *in vitro* and *in vivo* characteristics. However, additional modifications to the linkers are needed to further improve these optical imaging agents.

Received January 7, 2009; Revised Manuscript Received May 13, 2009

The ability of different synthetic cell penetrating peptides, as Antennapedia (wild and Phe^6 mutated penetratins), flock house virus, and integrin peptides to form complexes with a 25mer antisense oligonucleotide was compared and their conformation was determined by circular dichroism spectroscopy. The efficiency for oligonucleotide delivery into cells was measured using peptides labeled with a coumarin derivative showing blue fluorescence and the fluorescein-labeled antisense oligonucleotide showing green fluorescence. Fluorescence due to the excitation energy transfer confirmed the interaction of the antisense oligonucleotide and cell-penetrating peptides. The most efficient oligonucleotide delivery was found for penetratins. Comparison of the two types of penetratins shows that the wild-type penetratin proved to be more efficient than mutated penetratin. The paper also emphasizes that the attachment of a fluorescent label may have an effect on the conformation and flexibility of cell-penetrating peptides that must be taken into consideration when evaluating biological experiments.

INTRODUCTION

Genomic rearrangements leading to intragenic gene fusion are found in particular types of hematopoietic malignancies and sarcomas. These chimeric genes frequently encode aberrant transcription factors, which are responsible for cellular transformation and in consequence for oncogenesis. The Ewing sarcoma (EWS) family of tumors (ESFT) belongs to this type of translocation-induced cancers (*1*). The EWS-Fli1 protein is an aberrant transcription factor that has been shown by different authors to regulate various genes. In a recent study, it was shown that, when EWS-Fli1 is specifically inhibited by a short interfering RNA (siRNA) in Ewing A673 cells, 80 genes were found up- and down-regulated, respectively, at least 2-fold (*2*). Because chromosome rearrangement occurs in the cancerous cell, the nucleic acid sequence of the junction is present only in the mRNA of tumor cells. It is, therefore, an extremely attractive target for selective therapy of Ewing sarcoma. To our knowledge, no attempts have been made to target the fusion gene at the DNA level, but antisense strategies allow for inhibition of EWS-Fli1 at the mRNA level after splicing. For this purpose, two strategies are useful: siRNA and antisense oligonucleotides (AS-ODNs).

The short interfering RNAs (siRNAs) are double-stranded oligoribonucleotides with a full duplex of 19 bases, and a 2−3-base overhang at the 3′ termini (*3*, *4*). They induce the sequence-specific cleavage of mRNA in the cytoplasm by directing the RNA-induced silencing cleavage complex (RISC) to the complementary sequence on the target RNA. It is a very powerful strategy to inhibit gene expression at the RNA level, and it represents many fields of application for fundamental research. The use of siRNAs as therapeutics is in development, but some recent results show dramatic toxicity on animal models. This will require a modification of their administration ways (*5*, *6*).

Antisense oligonucleotides are short, synthetic strands of DNA (or analogues) that are complementary, or antisense, to a target sequence (DNA or RNA) designed to halt a biological event, such as transcription, translation, or splicing. The mechanism of action of antisense oligonucleotides is enzymatic cleavage of the RNA strand by RNase H (*7*).

Cellular penetration is one of the main challenges to be solved for both strategies to improve their efficiency. Cationic lipids are generally used for cell application, but because of their liver capture and potential toxicity, they are limited to *in vitro* studies. Cell-penetrating virus derivative peptides have been described as molecules able to facilitate the nonendocytic membrane passage of compounds associated to them (*8*−*10*). Nevertheless, depending on the protein origin some cell penetrating peptides (CPPs) use the endocytotic pathways (*8*). The complex formation of antisense oligonucleotides with CPPs may be accomplished either by covalent coupling or by electrostatic interaction.

This paper reports the synthesis and circular dichroism (CD) studies on cell-penetrating peptides as well as epifluorescence microscopic investigation of peptide-mediated delivery of the 5′-fluorescein labeled 25mer EWS-Fli1 antisense oligonucleotide into cells. Antennapedia peptides (wild-type and Trp^6 → Phe^6 mutant penetratins) (*11*, *12*), integrin sequences (*13*), and flock-house virus peptides (*14*) (Table 1) were chosen to probe the cell-penetrating efficiency of CPPs. The peptides were prepared with free N-terminus and in N-terminal fluorescent-labeled form. The 4-(7-hydroxycoumaryl)-acetyl (Hca) group served as fluorescent label (*15*). The direct interactions of the different CPPs with living cells have also been studied. Finally, their ability to deliver the fluorescein labeled AS-ODN into the cells was also measured.

MATERIALS AND METHODS

Materials. Diisopropylcarbodiimide (DIC), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), *N*,*N*′-diisopropylethylamine

(DIEA), hydrogen fluoride (HF), 1-hydroxybenztriazole (HOBt), and trifluoroacetic acid (TFA) were obtained from Fluka. Trifluoroethanol (TFE, Uvasol, Merck, for spectroscopy) was used for CD measurements. Acetonitrile (MeCN), dichloromethane (DCM), and dimethylformamide (DMF) are from Reanal (Budapest, Hungary). Boc-amino acid derivatives and 4-methyl benzhydrylamine resin were from Bachem (Bubendorf, Switzerland). 4-(7-Hydroxycoumaryl)acetic acid (Hca) was prepared by the method of Baker et al. (*15*). Dulbecco's modified Eagle's medium (DMEM), newborn calf serum, and penicillin−streptomycin solution were purchased from Gibco. Trizol was purchased from Invitrogen and RNasin from Promega.

Oligonucleotide. The 5′-fluorescein labeled 25mer EWS-Fli1 AS-ODN is targeted toward the junction sequence between EWS and Fli1 genes as described by Tanaka et al. (*16*) and corresponds to the nucleotides 832−856. EWS-Fli1 AS-ODN inhibits proliferation of human Ewing's sarcoma and primitive neuroectodermal tumor cells (*16*−*18*). To protect it from nuclease degradation, all phosphate groups were changed into phosphorothioate. The AS-ODN sequence 5′-GACTGAGTCATAAGAAGGGTTCTGC-3′ was provided by Eurogentec (Belgium), HPLC-purified and mass spectrometry controlled. A control phosphorothioate sequence (Ct-ODN) was used for the PCR studies with the following sequence: 5′-GCAGAACCCTTCTTATGACTCAGTC-3′

The EWS-Fli1 AS-ODN, without fluorescein label, was synthesized with an Expedite 8909 synthesizer (Applied Biosystems, USA), using solid-supported standard β-cyanoethyl phosphoramidite chemistry at a nominal scale of 1 μmol. Purification was performed by HPLC on a Kromasil 100-C18 250 × 10 mm ID column, using a MeCN 0.1 M triethylammonium acetate (pH 7.0) mixture as eluent. This results in the triethylammonium salt of ODN.

Peptide Synthesis. Peptides (Table 1) were synthesized by manual solid-phase methodology, using Boc/Bzl strategy (*19*) and 4-methyl benzhydrylamine resin (0.7 mmol/g). All amino acids were coupled as Boc-derivatives. The amino acid side chain protection was the following: Boc-Asn(Xan)-OH, Boc-Asp(OcHex)-OH, Boc-Arg(Tos)-OH, Boc-Gln(Xan)-OH, Boc-Glu(OcHex)-OH, Boc-His(Tos)-OH, Boc-Lys-(2ClZ)-OH, Boc-Ser(Bzl)-OH, Boc-Trp(For)-OH [xan (xanthyl), cHex (cyclohexyl), Tos (tosyl), 2ClZ (2-Cl-benzyloxycarbonyl), Bzl (benzyl), For (formyl)]. The Hca coupling was performed by using the DIC/HOBt method (3 equiv of each) (*20*). The coupling efficacy was monitored by the ninhydrin (*21*) assay. Boc-groups were removed by 35% TFA in DCM. Neutralization together with the removal of the formyl-group of Trp was carried out with DBU/piperidine before the final cleavage from the resin with HF containing *p*-cresol as scavenger at 0 °C for 1.5 h. The crude products were analyzed and purified by reverse-phase HPLC as described below.

High-Performance Liquid Chromatography. Analytical RP-HPLC (Jasco, Japan) was performed using an Alltech Alltima C18 WP column (250 × 5 mm) with 5 μm particle size and 300 Å pore size. Depending on peptide composition (Table 1), a linear gradient elution was developed from 5−50% eluent B in 25 min, 15−70% eluent B in 30 min, or 5−60% B in 35 min; eluent A is 0.08% TFA in water and eluent B is 0.064% TFA in acetonitrile−water (95−5%). Detection was performed at 220 and 280 nm. Experiments were carried out at a flow rate of 1 mL/min, at ambient temperature. Samples were applied at 0.1 mg/0.1 mL concentration in eluent A. Purification of peptides was achieved on an Alltech Alltima C18 WP column (250 × 25 mm) with 5 μm particle size and 300 Å pore size using gradient elution with the same eluents, 10 mL/min flow rate, and 20 mg/mL sample concentration. Homogeneity of the pure peptides was confirmed by analytical RP-HPLC.

Electrospray Ionization Mass Spectrometry (ESI-MS). The identification of the peptides was achieved by mass spectrometry (*20*). Electrospray ionization mass spectrometry was performed with a Bruker Daltonics Esquire 3000 Plus (Bremen, Germany) mass spectrometer, operating in continuous sample injection at 4 μL/min flow rate. Samples were dissolved in 50% acetonitrile−water mixture. Mass spectra were recorded in positive mode in the *m*/*z* 200−1500 range. R_f values of purified peptides, calculated, and found masses are listed in Table 1.

Circular Dichroism Spectroscopic Studies. CD spectra were recorded on a Jasco J-810 dichrograph (calibrated with ammonium *d*-10-camphor sulfonate) at room temperature using a 0.02 cm cell for measurements when TFE/water was used as solvent. All measurements are the average of four scans, and the resolution was 0.2 nm. The concentration of the peptides ranged from 0.5 to 1 mM depending on the absorption. The conformational change of penetratins **1** and **2** and the FHV peptide **5** was also monitored in the presence of 5 mM aqueous anionic micelles [L-α-lysophosphatidylcholine (LPC) to L-α-lysophosphatidylserine (LPS) molar ratio (r_M) was 9]. The concentration of the peptides was in this case 40 μM, and a 0.1 cm cell was used.

The CD spectra of AS-ODN and peptide-(AS-ODN) complexes were recorded in the range 250−320 nm in a 0.1 cm cell. The AS-ODN concentration in the samples was in each case 20 μM, and the peptide concentration varied in the interval

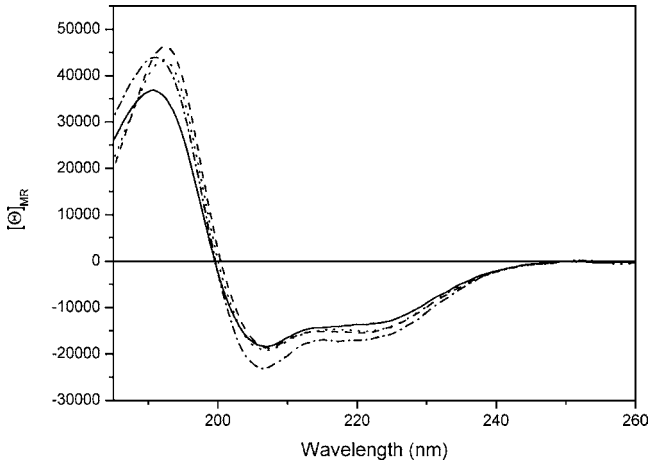

Figure 1. Far-UV CD spectrum of penetratins **1** (—), **1a** (-•-•-), **2** (---), and **2a** (•••) in TFE:water, 9:1 (v/v).

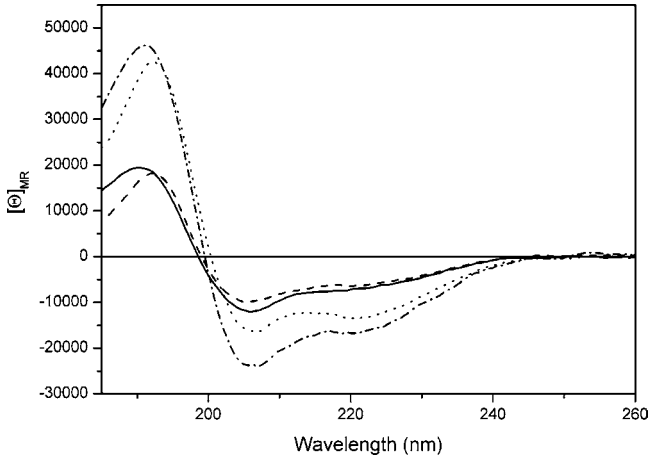

Figure 2. Far-UV CD spectrum of penetratins **1** (—), **1a** (-•-•-), **2** (---), and **2a** (•••) TFE/water, 1:1 (v/v).

20−200 μM. Prior to scanning, the AS-ODN was incubated with the peptides for 1 h. The CD spectra were expressed as mean residue ellipticity $[\Theta]_{MR}$ and were given in units of deg cm^2 $dmol^{-1}$, using a mean residue weight of 114 for the peptides and 306 for the ODN.

Including the free N-terminus, the wild-type (**1**) and mutant penetratin (**2**) comprise eight basic groups but no acidic ones. The Hca-labeled peptides **1a** and **2a** comprise one less basic side-chain group. With this taken into account, the penetratin peptides **1** and **2** bind eight, **1a** and **2a** seven, trifluoroacetic acid molecules that significantly increase their molecular mass. Quantitative amino acid analysis of the penetratin peptides resulted in peptide contents which agreed with the decreased values calculated from the molecular mass of peptide−TFA salts. In the case of peptides **3**−**6**, the TFA content was calculated for the net positive charge (number of basic residues minus number of acidic residues). The $[\Theta]_{MR}$ values were calculated for the increased molecular mass.

AS-ODN Delivery to Cells. NIH/3T3 cells stably transformed by EWS-Flil oncogene (NIH/3T3-EF) were grown in DMEM medium supplemented by 10% heat-inactivated newborn calf serum and penicillin−streptomycin solution. The cells were seeded into 6-well plate at 2×10^5 cell in 1 mL of medium and grown at 37 °C with 5% CO_2 in a moist atmosphere before treatment. Twenty-four hours later, the medium was discarded and replaced by 900 μL of new one. Fluorescein-labeled AS-ODN (0.5 nmol) was incubated for 10 min in 100 μL of 100 mM NaCl, 10 mM Hepes buffer, pH 7.2 containing 17 nmol of

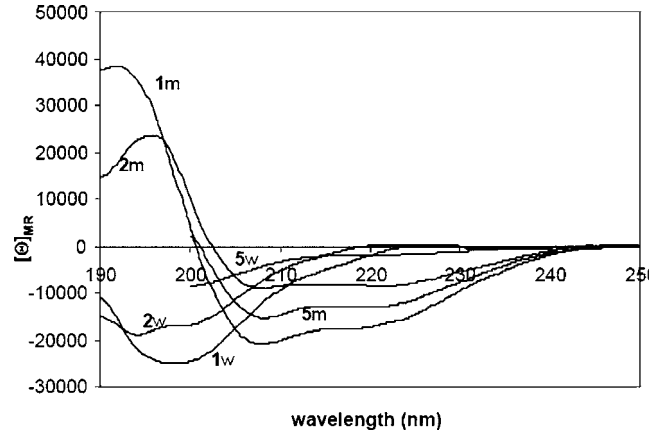

Figure 3. Far-UV CD spectrum of peptides **1**, **2**, and **5** in water (curves 1w, 2w, 5w) and in the presence of 5 mM aqueous anionic micelles (LPC/LPS, $r_M = 9$) (curves 1m, 2m, 5m). Peptide concentration was 40 μM.

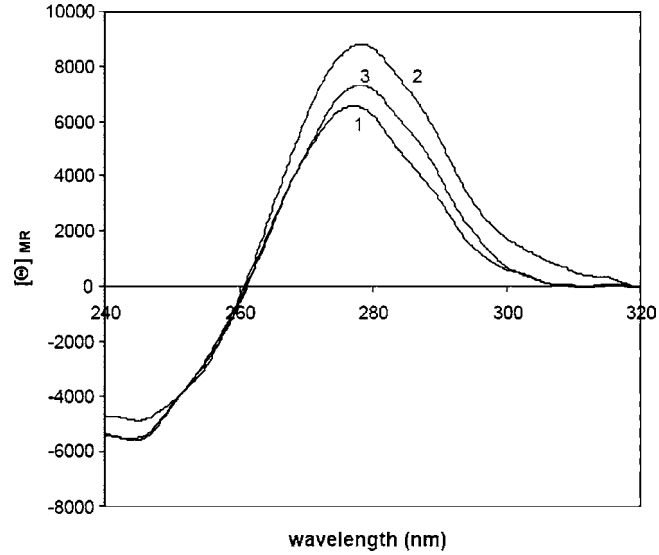

Figure 4. Near-UV CD spectrum of AS-ODN (curve 1), associates of (AS-ODN)-wild-type penetratin (curve 2), and (AS-ODN) mutant penetratin (curve 3) in water. Peptide/ODN, $r_M = 2.5$.

peptide **1a** or **2a**, 15 nmol of peptide **3a**, 30 nmol of peptide **4a**, and 40 nmol of peptide **5a** or **6a** (arbitrary value because these latter peptides do not contain any cationic amino acid) to obtain a charge ratio (r_{CH}) of 5 (positive charges of peptide vs the negative charges of ODN). The charge ratio of 5 has been selected from previous studies (*22*, *23*). The complexes were then added to the cells and incubated for 3 h. The cells were washed two times with a PBS solution, treated with a 4% formaldehyde solution in PBS for 20 min, washed two times with PBS, and observed under epifluorescence microscopy (*24*) (Axiovert 100, Zeiss) with a CCD camera. The same cell treatments were performed with the Hca-peptides alone at 50 μM or the fluorescent AS-ODN alone at 500 nM final concentrations. Fluorescence was observed using an emission multiwavelength filter (460/10, 530/25, 625/50 nm, maximum/band-pass). For the detection of the Hca blue light and the fluorescein green light emission, excitation filters of 365/12 and 494/17 were used, respectively.

Determination of EWS-Fli1 Expression by RT-PCR. The NIH/3T3-EF cells were grown in 6 well plates and seeded one day before the treatment with (AS-ODN)−peptide complexes at 3×10^5 cells/mL in DMEM containing 10% newborn calf serum, 100 U/mL streptomycin, and 100 μg/mL penicillin. After

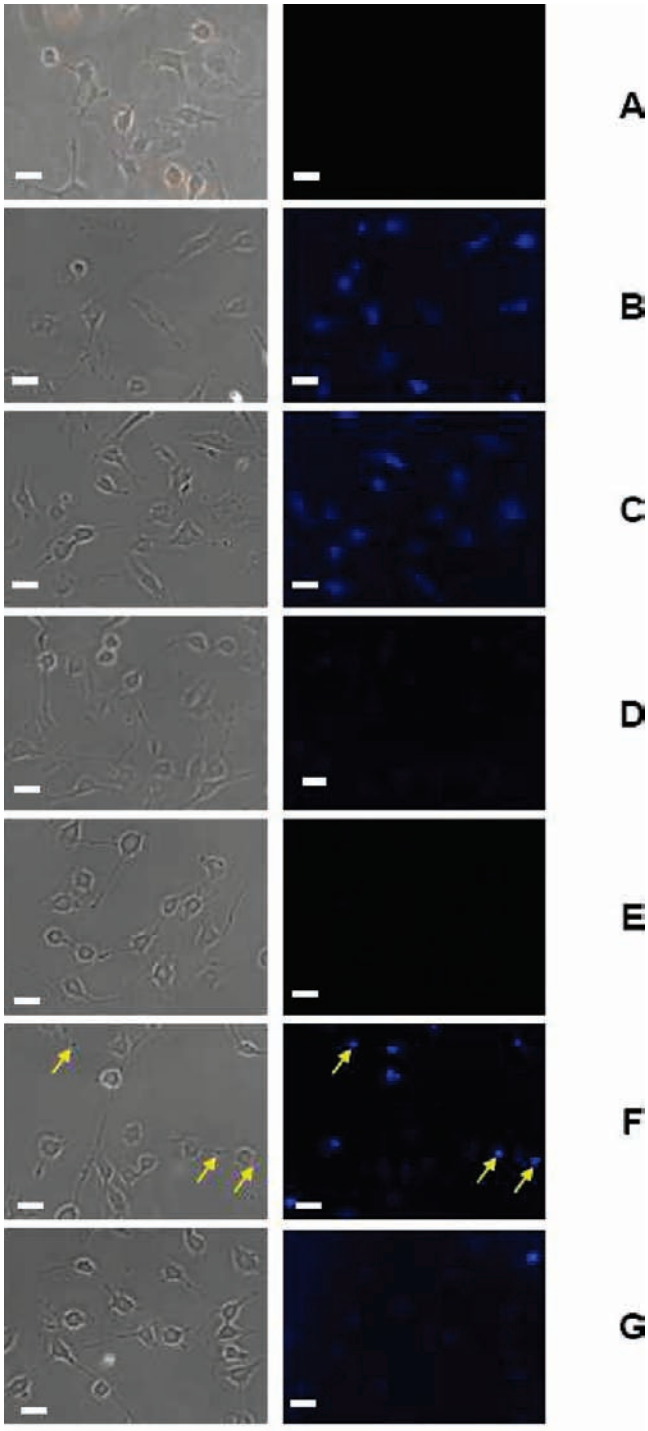

Figure 5. Interaction of peptides with cells. NIH/3T3 cells, incubated for 3 h alone (A) or with 50 μM wild-type penetratin **1a** (B); mutated penetratin **2a** (C); integrin peptide **3a** (D); integrin peptide **4a** (E); FHV peptide **5a** (F); and FHV peptide **6a** (G). The cells were observed with white light (left panel) or excitating Hca at 365 nm (right panel) to detect the different Hca-labeled peptides. Scale bar is 20 μm.

24 h treatment, the cells were washed with PBS buffer (Gibco) and then lysed with 800 μL Trizol, 130 μL of chloroform/isoamylalcohol (49:1, v/v). After centrifugation at 13 000 rpm for 15 min, 350 μL of the aqueous phase was precipitated with an aquivalent volume of isopropanol. Total RNA were then collected by centrifugation at 13 000 rpm for 15 min, washed two times with 75% ethanol solution, and air-dried. The RNA pellet was solved in 10 μL water containing 0.5 U/μL of RNasin, and the solution concentration was determined by absorption spectroscopy. The cDNA was produced on 1 μg of total RNA after hybridization with 2 μL of random primer 50 μg/mL (Promega) in 14.5 μL final volume by heating the solution for 5 min at 65 °C. The cDNA synthesis is performed for 1 h at 42 °C after addition of 4 μL of 5× more concentrated buffer (Biolabs), 0.5 μL 20 mM dNTP, 0.5 μL RNasin 40 U/μL, and 0.5 μL Mo-MuLV reverse transcriptase (Biolabs) 200 U/μL. PCR reaction was performed on 2 μL of cDNA prepared as described above, 5 μL of 10-fold concentrated buffer (Biolabs), 0.5 μL 20 mM dNTP, 0.5 μL of each primer 50 μg/mL, and 0.5 μL of Taq DNA polymerase 5 U/μL (Biolabs). Primer sequences are EWS-Fli1 forward 5′-AGC-AGT-TAC-TCT-CAG-CAG-AAC-AAC-3′ and reverse 5′-CCA-GGA-TCT-GAT-ACG-GAT-CTG-GCT-G-3′. G3PDH was used as the housekeeping gene, and the sequence of the corresponding primers is forward 5′-CAT-TGT-CAT-ACC-AGG-AAA-TC-3′. Amplification conditions were as follows: (i) fusion 94 °C (30 s), (ii) hybridization 56 or 63 °C (30 s) for EWS-Fli1 or G3PDH, respectively, and (iii) elongation 72 °C (50 s). The amplified fragments were detected on 2% agarose gel electrophoresis in TAE buffer and ethidium bromide staining with a CCD camera and corresponding gel analysis system (Ingenius, Syngene).

RESULTS AND DISCUSSION

Circular Dichroism Spectroscopy. The conformational preferences and the effect of fluorescent labeling upon conformation of peptides were probed by CD spectroscopy. The spectra were taken in TFE/water 9:1 (v/v), TFE/water 1:1 (v/v) mixtures, and water. (The wild-type penetratin peptide **1** is not soluble in neat TFE.) TFE is a helix promoting solvent; it is frequently used to mimic cell membranes or their vicinity (*25*). Figure 1 shows the effect of N-terminally coupled Hca-group on the conformation of wild-type (**1**) and mutant (**2**) penetratin in TFE/water, 9:1. The spectrum of **1** is characteristic of peptides featuring high helix content. The phenylalanine-containing mutant peptide **2** also shows a typical helix-type CD spectrum in the same solvent mixture, but the intensity of the positive band at 192.5 nm is higher than that of **1** at 190.5 nm, while the negative bands are less intense. The flock-house virus (FHV) sequence **5** shows a CD spectrum reflecting lower helicity (spectra not shown). As reference, the CD spectra of two integrin sequences **3** and **4** were also measured in TFE. The band amplitudes in the spectrum of the longer sequence **3** are larger as a sign of higher helicity of the 26-mer peptide (spectra not shown).

It is an intriguing question whether or not the attachment of the fluorescent label 4-(7-hydroxycoumaryl)-acetyl (Hca) group has an effect upon the conformation of the peptide. In the far-UV spectrum of 4-(7-hydroxycoumaryl)-acetic acid (Hca-OH), two bands appear at 198 nm ($A = 3.28 \times 10^4$) and 217.5 nm ($A = 1.24 \times 10^4$). Thus, the Hca-group is expected to have a CD spectral effect in the far-UV region if the conformational movement of the N-terminus of the peptide is restricted. As shown in Figure 1, the Hca-group increases the intensity of both the negative and positive bands of wild-type penetratin (**1a**), but it does not have a significant effect upon the spectrum of the mutant penetratin (**2a**). The Hca-group has an effect only on the negative bands in the CD spectrum of the FHV peptide [λ_{nm} ($[\Theta]_{MR}$) values in TFE/water (9:1) for **5**, 218 (−13 240), 207 (−15 200), 190 (26 500), and **5a**, 221 (−11 200), 207 (−12 700), 190.5 (26 200)].

On the basis of the higher band intensities of the exciton couplet in the region of $\pi-\pi^*$ transition, the mutant penetratin **2** shows a more expressed tendency to adopt a helical structure than the wild-type peptide **1**. The attachment of the Hca-group stabilizes the helical conformation of **1** likely through $\pi-\pi$ interaction between the indole ring of tryptophan and the hydroxycoumaryl group at the N-terminus. They are located in

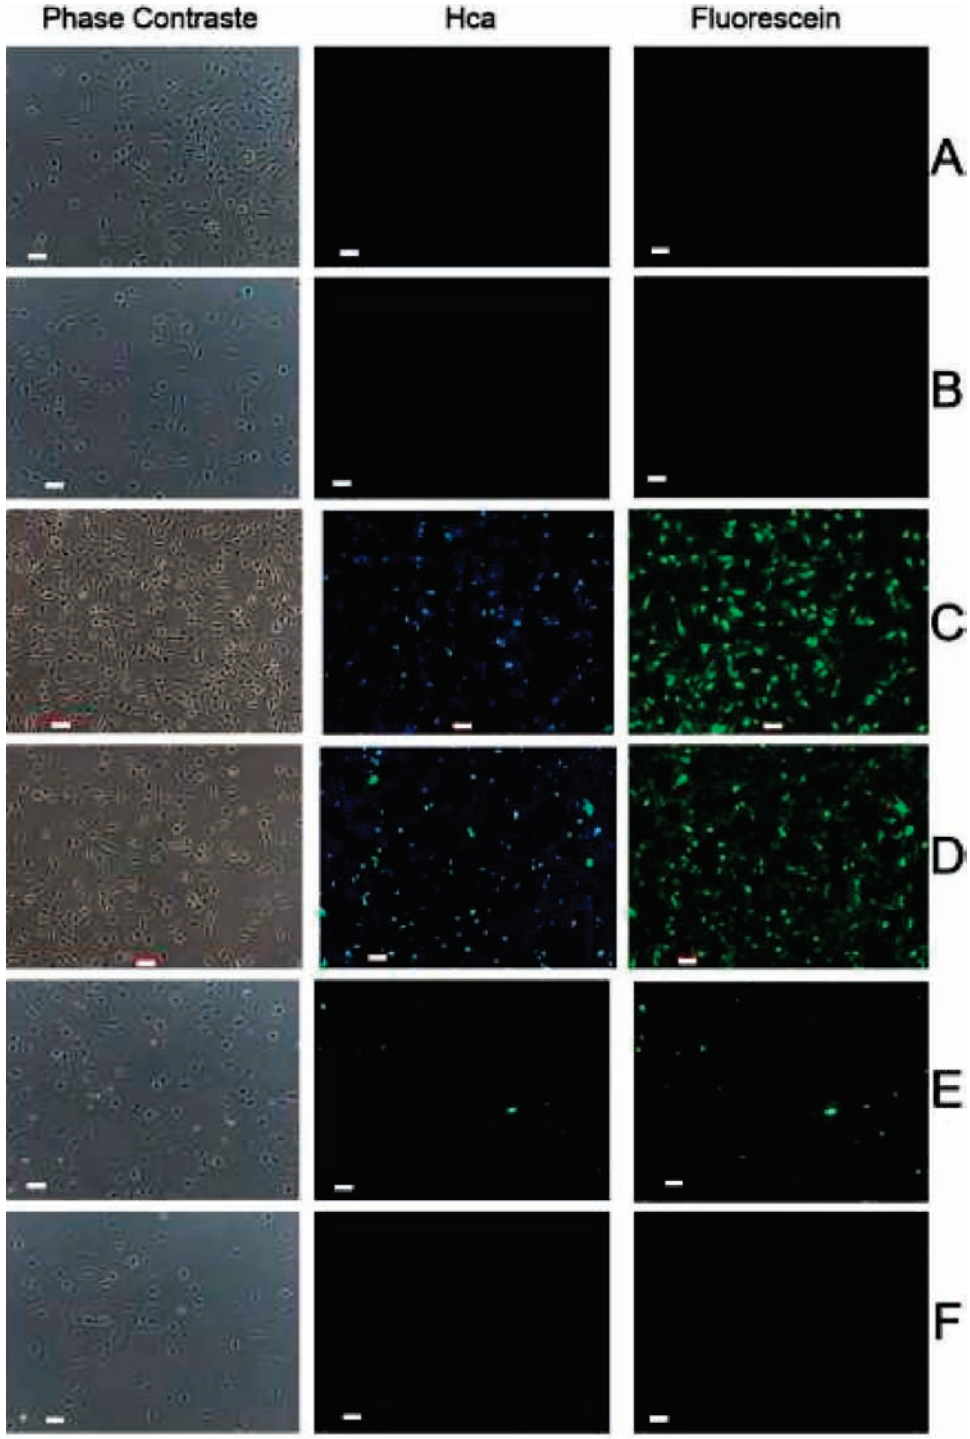

Figure 6. Oligonucleotide interactions with NIH/3T3 cells transformed by EWS-Flil ncogene. Cells incubated for 3 h alone (A); or with 500 nM fluorescein labeled AS-ODN (B); the same labeled AS-ODN complexes to wild-type penetratin **1a** (C); mutated penetratin **2a** (D); FHV peptide **5a** (E); and FHV peptide **6a** (F). The cells were observed with white light (left panel) or exciting Hca at 365 nm (middle panel) and fluorescein at 494 nm (right panel) to detect the interaction between cells and AS-ODN. Fluorescence emission was observed using a three band-pass filter on color camera as described in Materials and Methods. Scale bar is 20 μm.

sterically close position on the same side of the helix cylinder. The phenyl group of phenylalanine in **2** cannot effectively interact with the coumarin ring.

The relative stability of the helices of **1**, **1a**, **2**, and **2a** was probed by measuring their CD spectra in TFE/water 1:1 (v/v). The helical structure of the Hca-penetratins **1a** and **2a** is more resistant to the effect of aqueous environment than that of **1** or **2** (Figure 2). In water, **1**, **2**, and **5** show CD spectra reflecting dominantly unordered conformation (Figure 3). More interestingly, CD spectra in Figure 3 demonstrate that peptides **1**, **2**, and **5** are prompted to adopt α-helical conformation in aqueous solution in the presence of anionic micelles (LPC/LPS, r_M = 9). The induced helicity is more expressed for the wild-type **1** than for the mutant penetratin **2** (Figure 3).

On the basis of CD studies reported earlier, the wild-type penetratin **1** and the FHV peptide **5** interact with an 18-mer AS-ODN in water and in the presence of anionic micelles (*26*). The 25-mer AS-ODN used in this study was found to form complexes with both **1** and **2** (Figure 4). However, the spectral change in the near UV region, characteristic of ODN, is more

pronounced in the presence of **1** than **2** at peptide to ODN molar ratio $r_M = 2.5$. (Above these ratios, the solutions become opaque as a sign of aggregate formation that obscures the measurements of CD.)

Interaction of Hca-Peptides with Cells. NIH/3T3 EWS-Fli1 cells treated by the Hca-peptides were observed under epifluorescence microscopy taking advantage of the blue emission of Hca under UV excitation (365 nm). No fluorescence was observed for untreated cells (Figure 5A) Both the wild-type (**1a**) and mutated (**2a**) penetratin peptides were found to interact strongly with the cells (Figure 5B,C) with a cytoplasmic and nuclear localization. The mutant peptide **2** was earlier described as an inefficient cell-penetrating peptide (*24*). The association of these positively charged peptides to the cells is probably due to electrostatic interaction with the negatively charged cell membrane. Although confocal microscopy could not be used for the detection of Hca fluorescence because of the lack of laser with an emission band corresponding to Hca, the blue fluorescence observed at the nucleus position indicated that the peptides did enter the cell. If the peptides were localized on the cytoplasmic membrane, a pericellular flourescence would have been observed.

The fusogenic region of FHV (**5a**) interacts weakly with the cells with a cytoplasmic localization (Figure 5F). The intense fluorescence spots observed in this case correspond to peptide aggregates located on the external side of membranes as indicated by the yellow arrows on the left panel (bright field) and right panel (fluorescence) slides. The RNA binding peptide sequence (**6a**) of FHV has a low solubility and forms aggregates, which interact unspecifically with dead cells (Figure 5G). The Hca−integrin peptides (**3a** and **4a**) do not interact efficiently with the cells in our experimental conditions (Figure 5D,E).

Peptide-Mediated Delivery of AS-ODN into Cells. To determine the ability of the peptides to facilitate the AS-ODN penetration, cells were incubated for 3 h with fluorescein-labeled AS-ODN (500 nM) alone or in the presence of different peptides ($r_{CH} = 5$; see Materials and Methods). After incubation of AS-ODN with peptides **1a**, **2a**, or **5a**, we observed that the solutions became opalescent, probably due to formation of complexes between the AS-ODN and peptides. No green fluorescence was observed under epifluorescence microscopy of untreated NIH/3T3 cells expressing EWS-Flil oncogene (Figure 6A). After cell treatment with 500 nM AS-ODN for 3 h, a fraction of cells displayed a weak fluorescence (Figure 6B).

The Antennapedia derivative peptides can both make the AS-ODN penetrate into the cells (Figure 6C,D) independently of the mutation. The AS-ODN has mainly a cytoplasmic localization. The higher intensity of the fluorescein emission in Figure 6C compared to Figure 6D indicated that **1a** peptide is much more efficient for AS-ODN delivery than **2a**. This is consistent with an earlier finding where the wild-type penetratin was 2× more efficient for ODN delivery than the Phe^6 mutant penetratin (*25*). The blue fluorescence corresponding to the peptide **1a** and **2a** was still detected on cells after the complex was formed between peptide and AS-ODN. Nevertheless, the fluorescence intensity was much higher compared to that when the cells were treated only with the peptides (compare Figure 5B to Figure 6C and Figure 5C to Figure 6D) suggesting a cooperation between peptides and ODN for interaction with cells.

It can be seen in Figure 6C,D that all the cells present green and blue fluorescence indicating that peptides **1a** and **2a** are very efficient in interaction with the cells and in AS-ODN transfer. Observation of the cells with higher magnification (Figure 7) confirms these results.

Surprisingly, when the slides were illuminated using a filter of 365 nm for exciting Hca we observed green dots in the medium and in the cell membrane level (Figures 6C,D and Figure 7). (This is possible because the emission filter possesses three band passes: blue, green, and red). It is known that if the fluorescence emission spectrum of a donor molecule and the absorption spectrum of an acceptor molecule overlap excitation energy transfer occurs. The intensity of this transfer is inversely proportional to the square of distance between the donor and the acceptor molecules. The wavelength maximum of the emission spectrum of Hca is 460 nm (*20*), and that of the excitation spectrum of fluorescein is 494 nm; hence upon formation of complex between the AS-ODN and the peptide, an increased emission of the fluorescein at 530 nm was observed illuminating the slides at the excitation wavelength (365 nm) of Hca (Figure 6C,D and Figure 7). These complexes are mainly localized on the bottom of the plate (Figure 7, yellow arrow) or on the cell membrane (Figure 7, white arrow). The amount of complex localized on the membrane is higher for peptide **1a** than for **2a**. This means that membrane localization for peptide **1a** is not only of statistical origin. Figure 7 shows that no fluorescence transfer occurs in the cell-bound complex [under Hca fluorescence condition (excitation at 365 nm), the cells are blue]. This result indicates that after interaction with the cell membrane the complexes are dissociated, that is, AS-ODNs and the peptides are located at a large distance that excludes fluorescence transfer. The dissociation is probably favorable for the antisense activity of AS-ODNs.

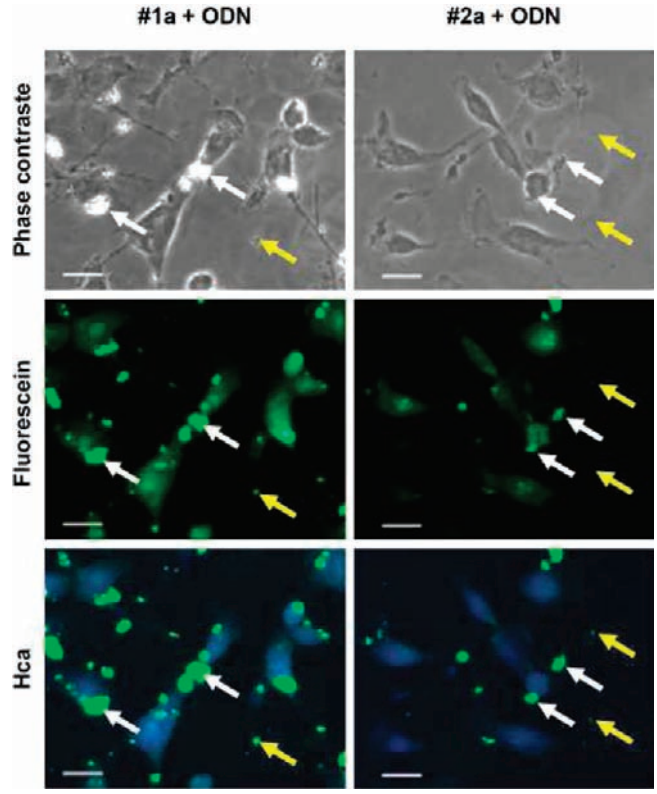

Figure 7. Oligonucleotide interactions with NIH/3T3 cells transformed by EWS-Fli1 oncogene. The cells were incubated for 3 h with 500 nM fluorescein labeled (AS-ODN)-wild-type penetratin **1a** or (AS-ODN)-mutated penetratin **2a** complexes. The cells were observed with white light (top panel) or exciting the fluorescein at 494 nm (middle panel) and Hca at 365 nm (bottom panel) to detect the interaction between cells and AS-ODN. Fluorescence emission was observed using a three band-pass filter on color camera as described in Materials and Methods. Arrows indicate the position of the (AS-ODN)-peptide aggregates: white arrows show aggregates localized on the bottom of the plate; yellow arrows show aggregates localized on cell membrane. Scale bar is 20 μM.

Integrin peptides **3** and **4** are not able to cause efficient penetration of the AS-ODN into cells (results not shown). The

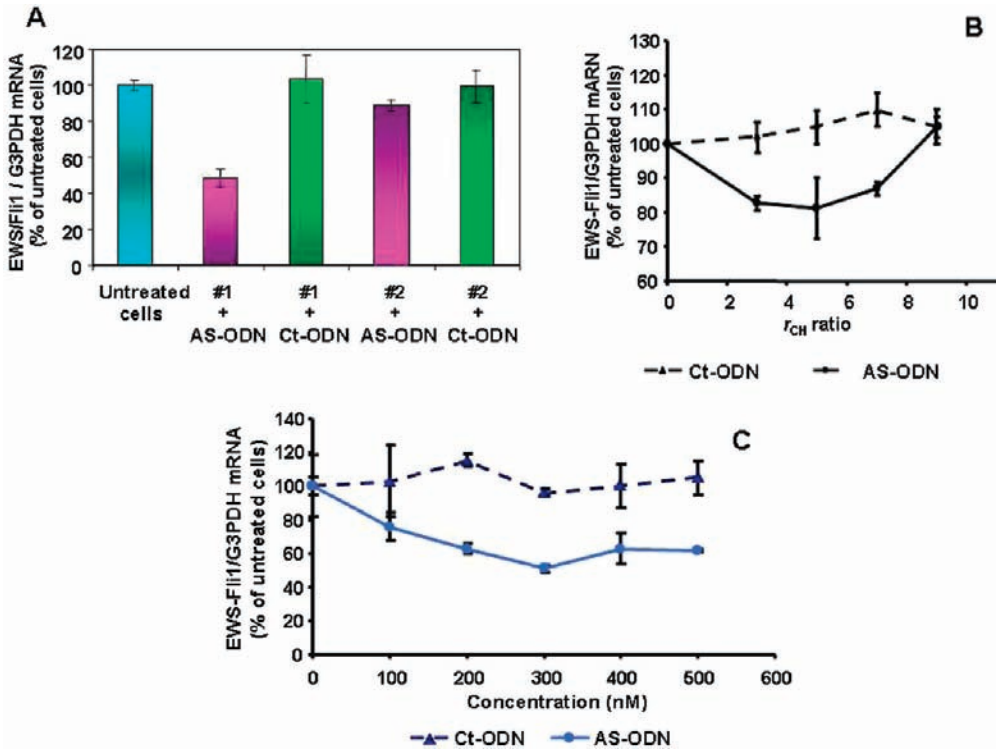

Figure 8. Inhibition of EWS-Fli1 mRNA expression in NIH/3T3-EF cells by antisense ODN (As-ODN) or control sequence (Ct-ODN). (A) The ODN is vectorized by wild-type (**1**) or mutated (**2**) penetratins. Measurement was performed by RT-PCR. ODN concentration was 500 nM and $r_{CH} = 5$. (B) Influence of the r_{CH} ratio on AS-ODN penetration into cell by wild-type penetratin **1**. The cells were treated for 24 h with 200 nM ODN and peptide **1** with r_{CH} varying from 0 to 9. (C) Dose effect of ODN vectorized by wild-type peptide **1** at $r_{CH} = 5$ on EWS-Fli1 expression in cell after 24 h treatment. Gene expression is determined by RT-PCR.

AS-ODN fluorescence intensity is the same that observed for AS-ODN alone and may be attributed to a nonspecific ODN interaction with cell membranes.

The FHV derived peptide **5a** corresponding to the fusogenic part of the protein causes a weak penetration of the AS-ODN into cells (Figure 6E). Fluorescence transfer is observed in aggregates close to the cells (similarly to that found with **1a** and **2a**) indicating the formation of complexes between AS-ODN and peptide **5a** (Figure 6E). The peptide **6**, bearing no positive charges, does not form a complex with the AS-ODN (Figure 6F).

According to CD studies (Figure 1), the attachment of the Hca-group increases the helicity of the wild-type penetratin, while the Hca-group weakly decreases the helicity of the mutant peptide. Anionic micelles induce helicity in the case of both **1** and **2** peptides, which is a more expressed for **1** than **2** (Figure 3). On the basis of CD studies, the wild-type penetratin **1** has a more flexible conformation than the mutant **2**, which is likely more favorable for ODN binding and cell penetration.

Inhibition of EWS-Fli1 Expression by AS-ODN Vectorized by Antennapedia Derivative Peptides. The ability of wild-type and mutated Antennapedia peptides to vectorize efficiently AS-ODN into cells was studied by the measurement of targeted oncogene expression. After cell treatment, total RNA is extracted, and EWS-Fli1 mRNA expression is measured by RT-PCR. It can be seen in Figure 8 that wild-type penetratin is able to inhibit EWS-Fli1 expression only if associated to the AS-ODN. In the same condition, control ODN has no effect. These results indicate that the lower transfection efficiency of mutated penetratin is correlated with the loss of gene inhibition. It has been proposed that association of penetratin peptides to the cell membrane is due to electrostatic interactions. The conformational change of penetratin upon $Trp^6 \rightarrow Phe^6$ mutation must be responsible for the decrease of cell penetration. Indeed, it has been described that the $Gln^8 \rightarrow Pro^8$ change presents a similar effect confirming the key role of this domain for the cell penetration (*27*).

The efficiency of transfection of nucleic acids by noncovalently linked CPP is largely dependent on the ratio of charges (r_{CH}) between the two components. The inhibition of EWS-Fli1 expression determined by PCR was performed for different ODN to CPP charge ratio ($r_{CH} = 0-9$) using the wild-type Antennapedia peptide **1**. Figure 8B shows that maximum inhibition was obtained for r_{CH} ratio of 5 confirming the results obtained previously (*22*, *23*). Dose-dependent treatment (Figure 8C) of the cells shows a maximum inhibition at 300 nM in As-ODN associated to peptide **1**. Under the same conditions, the Ct-ODN displays no inhibition, confirming the specificity of the treatment. For higher concentrations, the efficiency of inhibition was not increased, probably because aggregate formation between the ODN and the peptide might take place. This is unfavorable for ODN delivery and may be associated with a toxic effect.

SUMMARY

Antennapedia peptides were previously described as efficient agents for the delivery of oligonucleotides either by covalent linking or through ionic interaction (*28*, *29*). The action has been attributed to a conformational change of the molecule when interacting with the membrane. The introduction of a mutation inside this peptide was found to result in a dramatic decrease in oligonucleotide delivery. Surprisingly, in our hands both the wild-type and mutated peptides interact strongly with cells (Figure 5). The CD spectra of the wild (**1**) and mutated (**2**) penetratins in TFE solution show that the helicity of the mutated peptide is higher than that of the wild-type, while the Hca-labeled penetratins show similar CD spectra (as a sign of comparable helix content) and interaction with cells (Figure 6). It is likely that the increased helicity of the membrane-bound

wild-type Hca-penetratin (**1a**) explains its improved ability to cross the cell membrane. It should be emphasized here that the attachment of a fluorescent label may have an effect on the conformation and the flexibility of cell-penetrating peptides that must be taken into consideration when evaluating biological experiments.

Molluscan hemocyanins (Hcs) have recently received particular interest due to their significant immunostimulatory properties. This is mainly related to their high carbohydrate content and specific monosaccharide composition. We have now analyzed the oligosaccharides and the carbohydrate linkage sites of the *Rapana venosa* hemocyanin (RvH) using different approaches. We analyzed a number of glycopeptides by LC/ESI-MS/MS and identified the sugar chains and peptide sequences of 12 glycopeptides. Additionally, the potential carbohydrate linkage sites of 2 functional units, RvH-b and RvH-c, were determined by gene sequence analysis. Only RvH-c shows a potential N-glycosylation site. During this study, we discovered a highly conserved linker-intron, separating the coding exons of RVH-b and RvH-c. Following reports on antiviral properties from arthropod hemocyanin, we conducted a preliminary study of the antiviral activity of RvH and the functional units RvH-b and RvH-c. We show that the glycosylated FU RvH-c has antiviral properties against the respiratory syncytial virus (RSV), whereas native RvH and the nonglycosylated FU RvH-b have not. This is the first report of the fact that also molluscan hemocyanin functional units possess antiviral activity.

INTRODUCTION

Hemocyanins (Hcs) are large, oligomeric blue copper-containing glycoproteins that play a role as dioxygen carriers in the hemolymph of most molluscs and several arthropods (*1*−*4*). Despite their common function as dioxygen binding proteins, arthropod and molluscan hemocyanins evolved independently (*3*). The organization and size of molluscan and arthropodan Hc molecules differ significantly in size and oligosaccharide moieties (*5*−*7*).

Carbohydrate structures of hemocyanins from *Helix pomatia* and *Sepia officinalis* and keyhole limpet hemocyanin (KLH) have been identified using different methods (*8*, *9*). Thirteen potential N-glycosylation sites were identified in the gene sequence analysis of one subunit of *Haliotis tuberculata* hemocyanin (HtH1) (*10*) and seven in Nautilus hemocyanin FUs (*11*). Seven potential N-glycosylation sites are present in *Octopus dofleini* hemocyanin (Od) (*12*). A single N-linkage site and three O-linkage sites were found in the arthropod *Carcinus aestuarii* hemocyanin (CaH) (*13*, *14*). Although it is generally accepted that the oligosaccharide constituents of Hc are of prime significance for their antigenicity and biomedical properties, knowledge on the carbohydrate structures of these glycoproteins is still incomplete.

In this work, we focus on the structure and properties of *Rapana venosa* hemocyanin, isolated from the Black Sea. Eight functional units (FUs) with molecular mass of 45−50 kDa, namely, from RvH-a to RvH-h, have been isolated from both structural subunits RvH1 and RvH2 (*5*, *7*, *15*), but the oligosaccharide moieties of only a few of them have been reported (*16*−*19*).

Recently, it was shown that KLH also possesses potential antitumor activity, and this effect was ascribed to the presence of the disaccharide epitope Gal (β1−3)GalNAc, because it is cross-reactive with an equivalent surface epitope of superficial bladder tumor cells (*20*). The KLH dependent cumulative humoral and cellular immune response is expressed as a cytolytic reduction of tumor growth. Further analyses of KLH1 and KLH2 confirmed the multiepitopic potential of these molecules (*21*).

Hcs from other gastropods were considered to be possible substitutes for KLH as immunostimulants. It was found that marine *Haliotis tuberculata* (HtH) (*21*), Chilean gastropod, *Concholepas concholepas* (CcH) (*22*), and *Rapana venosa* (RvH) (*23*, *24*) Hcs have significant antitumor activity against mouse bladder carcinoma cells. The occurrence of xylose in *Helix pomatia* Hc (HpH) is considered to be highly immunogenic in mammalian species (*8*, *25*).

Subsequently, it was found that the arthropodan *Penaeus monodon* hemocyanin has antiviral activity against the spot syndrome virus (WSSV) and Singapore grouper iridovirus (SGIV) (*26*), although the antiviral mechanism is still unclear. The antiviral effect of molluscan Hcs has not been studied yet.

Since the biological effects of hemocyanins on immunostimulatory properties are attributed to their high carbohydrate content and specific monosaccharide composition, we hypothesized that antiviral effects might have a similar origin. We therefore characterized several glycopeptides from *R. venosa* hemocyanin by LC/ESI-MS/MS and investigated their antiviral effects.

MATERIALS AND METHODS

Materials. *Rapana venosa* Hc was isolated from marine snails living in the Black Sea as described before (*4*). Two structural subunits RvH1 and RvH2 were separated on a Resource Q column using an FPLC system. Two functional units RvH2-b and RvH2-c were isolated from structural subunit RvH2 as described by Dolashka et al. (*7, 15*). All other (bio)chemicals, unless noted, were purchased from Sigma-Aldrich.

RNA Extraction and RT-PCR. RNA was extracted using the RNeasy extraction-Kit (Qiagen) according to the manufacturer's instructions using 200 mg of foot tissue. RT-PCR was performed using 1 μg of RNA, Transcriptor reverse transcriptase (Roche), and a degenerated hemocyanin specific oligonucleotide (*27*). PCR was performed using 5 μL of the RT assay. Each PCR was supplied with 1 μM primer, 200 μM dNTP, 3 mM $MgCl_2$, 5 μL of 10× PCR buffer, and 2.5 units of recombinant Taq polymerase (Invitrogen, Germany). Samples were denatured for 2 min at 94 °C, followed by 35 amplification cycles (10 s at 94 °C, 30 s at 55 °C, 2 min at 72 °C) and final extension for 10 min at 72 °C.

Gel Electrophoresis, DNA Purification, and Sequencing Reactions. PCR products were separated by electrophoresis in a 0.8% agarose gel (1× TBE buffer) and extracted using the Peqlab gel extraction kit (Peqlab, Germany). The isolated fragments were either sequenced directly or after being cloned using the StrataClone PCR Cloning Kit (Startagene, USA). Sequencing reactions were performed with the Taq DyeTerminator system (Perkin-Elmer) using standard primers and electrophoretically analyzed by Genterprise (Germany).

Bioinformatics. Alignments were created by *ClustalX* V1.81 (*28*) and optimized manually using *Genedoc* (*29*). Database searches and further analyses were performed using sequence analysis tools [e.g., *Blastn* and *Blastx* (*30*) available at the NCBI (www.ncbi.nlm.nih.gov). 3D models were created using the Swiss PDB viewer (*31*), and phylogenetic analyses were carried out using *Mega* 3.1 (*32*).

Mass Spectrometric Analysis of Glycopeptides by Nanoelectrospray MS/MS. Four milligrams of RvH1 and RvH2 were digested with trypsin, and the glycopeptides were isolated as described by Dolashka-Angelova et al. (*16*). HPLC fractions, detected at a wavelength of $\lambda = 206$ nm, were collected, lyophilized, and analyzed for carbohydrates with orcinol/H_2SO_4 on silica gel plates (*18*). Glycopeptides containing fractions were analyzed by nanoelectrospray ionization (ESI) mass spectrometry (MS) on a hybrid quadrupole orthogonal acceleration time-of-flight tandem mass spectrometer (Q-TOF; Micromass, Manchester, United Kingdom) as described (*33*). Alternatively, glycopeptides were sequenced on a Q-Trap LC/MS/MS system (Applied Biosystems/MDS Sciex, Concord, ON, Canada) equipped with a nanospray ion source (Protana, Odense, Denmark) as described by Sandra et al. (*19*).

Antiviral Effects of the Glycosylated and Nonglycosylated Functional Units. The *in vitro* hemocyanin antiviral effects on the replication of poliovirus type 1 (LSc-2ab), coxsackievirus B1 (CV−B1), and respiratory syncytial virus (RSV) were studied using native RvH and its glycosylated (RvH-c) and nonglycosylated (RvH-b) functional units at a concentration of 1000 μg/mL in 15 mM phosphate buffer, pH 7.1. Polio virus type 1 (LSc-2ab) and CV−B1 were grown in FL cells and RSV was grown in Hep-2 cell cultures. The cultures were grown in a growth medium of DMEM (Gibco BRL, USA), containing 5% fetal calf serum, supplemented with antibiotics (penicillin 100 IU/mL, streptomycin 100 μg/mL, and gentamycin 50 μg/mL) and 20 mM HEPES buffer (Gibko BRL, USA) in a humidified atmosphere at 37 °C and 5% CO_2. Cells were routinely subcultured twice a week. Viruses were replicated on monolayer cells in a maintenance medium of DMEM, supplemented with 0.5% fetal calf serum, 20 mM HEPES buffer, and antibiotics.

Cytotoxicity Test. For cytotoxicity tests, Hep-2 cells were seeded in flat-bottomed 96-well plates by adding 0.2 mL per well of the cell suspension, containing $(1.5-2) \times 10^5$ cells/mL. After formation of a cell monolayer, growth medium was discarded and 0.2 mL containing 0.5 μg serial dilution concentrations of the tested substances, diluted in a maintenance medium, were added, followed by further incubation of cells in a humidified atmosphere at 37 °C and 5% CO_2 and monitoring the microscopic cytotoxic effect after 24 and 48 h. The highest concentration showing no cytotoxic effect was recorded at 48 h post-inoculation and was considered as the maximum of tolerated nontoxic concentration (MTC).

Antiviral Test. The cytopathic effect (CPE) inhibition test was used to measure the antiviral effect of the compounds against the replication of polio virus type 1 (LSc-2ab), CV−B1, and RSV. Briefly, monolayer cells in 96-well plates were inoculated with 0.1 mL virus suspension containing 100 or 10 $CCID_{50}$. After virus adsorption for 1 h at room temperature for polio virus type 1 (LSc-2ab) and CV−B1, and for 2 h at 37 °C and 5% CO_2 for RSV, excessive virus suspension was discarded, and cells were inoculated with 0.2 mL of maintenance medium containing 1 mg/mL RvH-c or RvH-b. Cells were incubated (Hera Cell, 150, Hereaus, Germany) in a humidified atmosphere at 37 °C and 5% CO_2. Virus-induced CPE was scored daily by inverted light microscopy (Olympus CK40, Japan) at 125× and 400× magnification on a 0−4 basis (4 representing total cell destruction and 0 the intact cell monolayer) until the appearance of its maximum in the untreated virus control wells (with no compound in the maintenance medium). This was on the 48th hour for polio virus type and CV−B1 and on the 120th hour for RSV. Virus-induced CPE in treated and nontreated virus control wells was compared, and the percent of CPE inhibition was calculated.

Virucidal Test. The quantitative suspension test was used to detect the virucidal effect of the compounds. Equal volumes of undiluted virus suspension and each of the compounds at their highest initial concentrations were mixed and kept for 1 h at room temperature. The residual infectious virus was determined in monolayer cells by inoculating 0.1 mL of serial 10-fold dilutions of the virus suspension samples, followed by 1 or 2 h adsorption at 37 °C and 5% CO_2. Then, excessive virus was discarded, and cells were inoculated with 0.2 mL of maintenance medium and further incubated at 37 °C and 5% CO_2. The virus CPE was scored daily until its maximum in the virus control wells.

RESULTS AND DISCUSSION

KLH has already been in use for several years as an immunotherapeutic agent in the treatment of bladder carcinoma and other cancer types (*34*). The relevance of specific glycosylation patterns as a differentiating factor for immunostimulatory properties has already been raised in studies on the hemocyanin isoforms KLH1 and KLH2 of *Megathura crenulata* (*20, 21*). Molluscan hemocyanin genes contain several potential N-glycosylation sites, and some of those have been already effectively demonstrated to be glycosylated using a series of analytical strategies (*8, 13*). For a functional unit of *Octopus dofleini* hemocyanin OdH-g, this has been confirmed by X-ray

[a] The exact order of the residues between brackets could not be established, and X represents unknown amino acids.

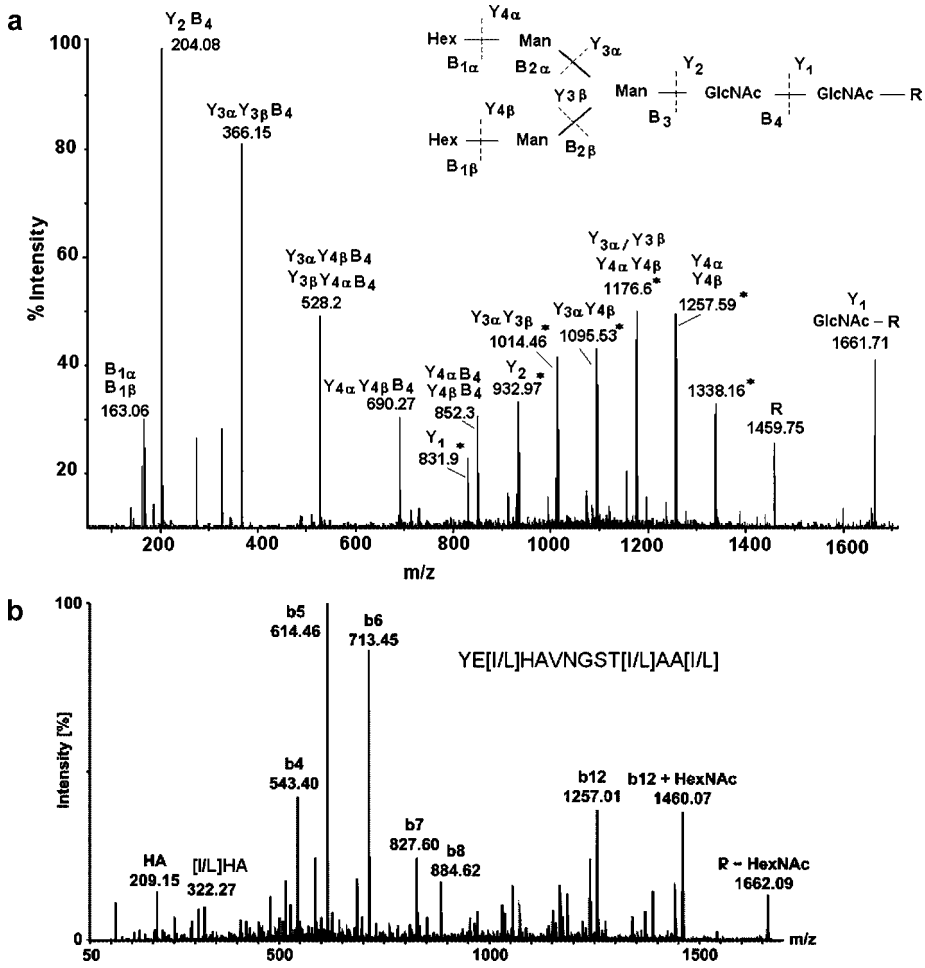

Figure 1. Fragment spectra of the glycopeptide G1 with determined *m/z* 1338.16 $[M+2H]^{2+}$. (a) MS/MS analysis of the sugar moiety, using a collision energy of 37 eV. Annotation of sugar fragments. The insert shows the complete carbohydrate structure and the cleavage points leading to the respective fragments. * corresponds to the doubly charged ions. (b) Pseudo-MS/MS/MS experiment (in-source and collision-induced fragmentation) of the peptide moiety (YEXHAVN*GSTXAAX) still carrying one HexNAc (*m/z* 1662.09, $[M-H]^+$), using a cone voltage of 95 V and a collision energy of 80 eV. R corresponds to the peptide.

crystallography (*35*). Previous analyses of the oligosaccharide moiety of RvH revealed a small set of carbohydrate structures (*16*−*19*). We extended this study here implementing advanced separation and mass spectrometric techniques to analyze the binding sites and the carbohydrate heterogeneity of the structural subunits RvH1 and RvH2.

We used two approaches to analyze the glycosylation sites in *Rapana venosa* hemocyanin. The first approach included the isolation of glycopeptides from structural subunits RvH1 and RvH2, and analysis of their amino acid sequences and structures of the linked oligosaccharides by mass spectrometry. Thirteen glycopeptides, given in Table 1 (No 1−13), were identified using ESI-MS and Q-Trap-LC/MS/MS. Some of them were previously characterized by capillary electrophoresis (*19*) or HPLC/electrospray ionization mass spectrometry (*17*, *18*). The second approach involved identification of the linkage sites by gene sequencing.

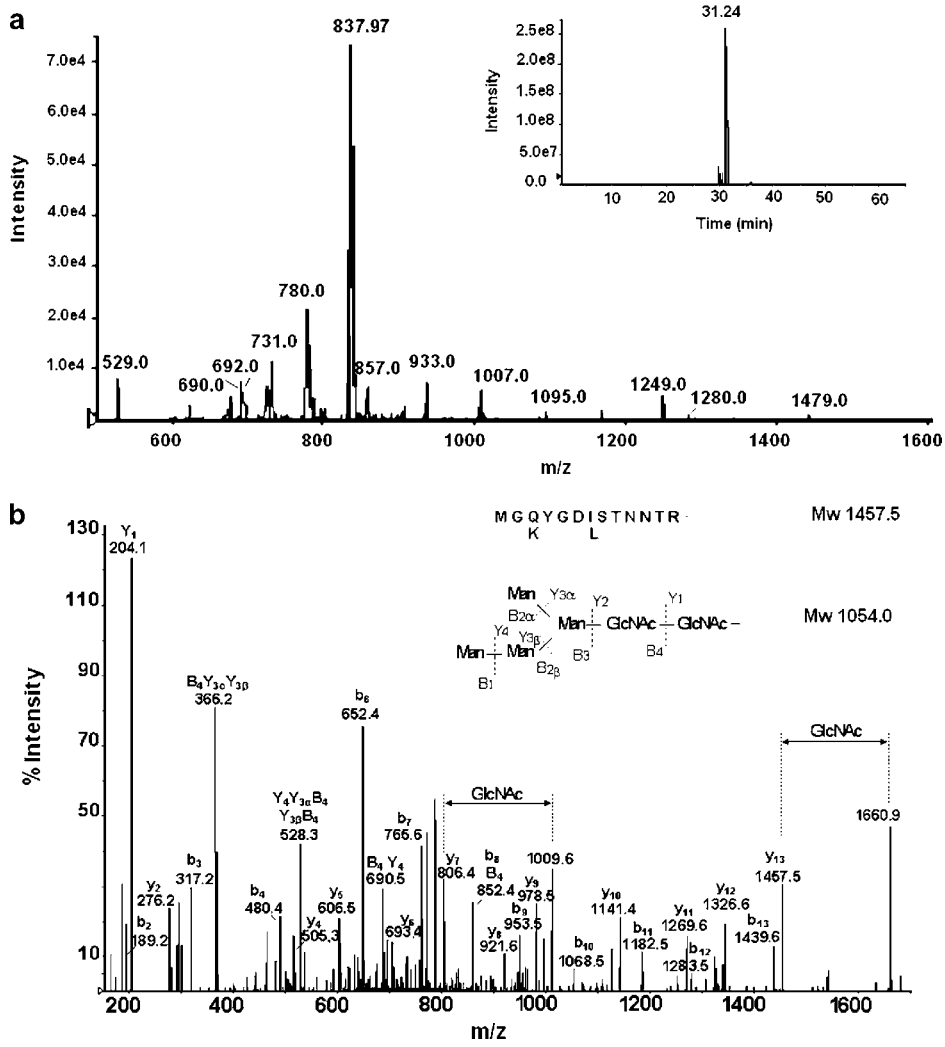

Figure 2. Precursor (a) scan of the ion at time 31.24 min of the chromatographic separation (insert) and enhanced product ion (EPI) scan of the ion (b) at *m*/*z* 837.97.

Glycopeptides were isolated after overnight digestion of the structural subunits RvH1 and RvH2 with trypsin, and the resulting peptides were subjected to reversed phase separation using a Nucleosil 7 C_{18} column. Fractions testing positive in the orcinol test were lyophilized and studied by mass spectrometry.

Characterization of Glycopeptides Using HPLC Fractions Analyzed by Flow Injection Analysis on a Q-TOF ESI-MS. Six glycopeptides were characterized in detail by analyzing the corresponding HPLC fraction by ESI-MS/MS. As an example, we outline here the result of a peptide (Table 1, No 5) that appeared as a doubly protonated molecule of *m*/*z* 1338.16 $[M+2H]^{2+}$ in the MS spectrum (not shown). The MS/MS spectra obtained from this glycopeptide are displayed in Figure 1. Figure 1A shows the MS/MS spectrum after collisional induced dissiocation. The fragment ion at *m*/*z* 1661.71 corresponds to the peptide (designated R-, *m*/*z* 1459.75), which is N-glycosylated, with a single residual GlcNAc residue. The spectrum is further dominated by glycan fragments, which correspond to a classical mannose type of oligosaccharide, consisting of two N-acetylhexosamines (HexNAc) monomers as well as five hexose (Hex) residues. In a pseudo-MS (*3*) experiment, the sugar side chain was removed by in-source fragmentation, and the peptide with one remaining HexNAc residue was further fragmented in the hexapole collision cell. This allowed the sequence analysis of the peptide and the determination of the site to which the sugar chain was attached (Figure 1B). The amino acid sequence of the peptide was revealed to be YEXHAV**N*GS**TXAAX. The glycosylation site N* was identified as part of the typical N-glycosylation motif N-aa-S/T, where aa can be any amino acid except Proline. X represents a leucine or isoleucine residue, which could not be distinguished by the applied MS methods. Five additional glycopeptides (Table 1, peptides 1−6) were characterized in the same way.

Characterization of Glycopeptides Using Q-Trap LC/MS/MS System. The Q-Trap system with its capabilities to perform typical triple quadrupole scans was additionally used for this purpose. Glycopeptides, selectively detected in a proteolytic mixture by the appearance of collisionally induced marker oxonium ions such as *m*/*z* 163 (Hex^+), 204 ($HexNAc^+$), or 366 ($HexHexNAc^+$), were sequenced.

The insert of Figure 2a shows the LC/MS/MS total ion current (TIC) chromatogram of the precursor ion scan (monitoring *m*/*z* 204) of the HPLC fraction at time 31.24 min. The enhanced resolution scan (not shown) showed that the glycopeptide with mass 2511.91 eluting at this moment was triply charged at *m*/*z* 837.97 $[M+3H]^{3+}$. The precursor ion scan at time 31.24 min is presented in Figure 2a. The spectrum is dominated by glycan fragmentation corresponding to the Domon/Costello nomenclature. However, peptide fragmentation (Roepstorff/Biemann cleavages) became more dominant when the collision energy was increased, allowing one to deduce the peptide sequence MGQYGD(I/L)ST*N*NTR from the series of y- and b-ions (Figure 2b). The ion b_{13} (*m*/*z* 1439.6) or y13 (*m*/*z* 1457.5) corresponds to the peptide, which contains two potential linkage

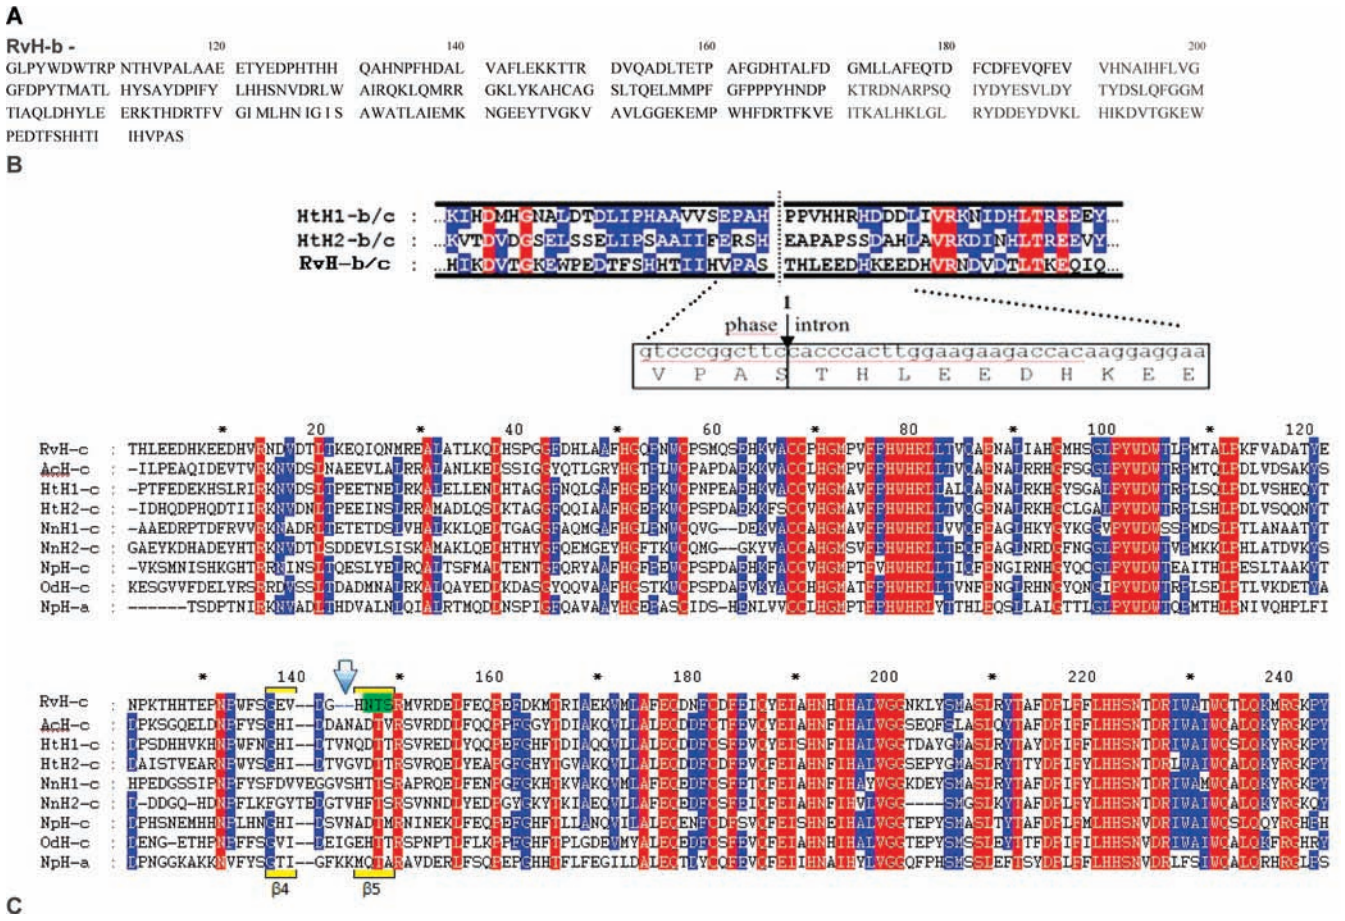

Figure 3. (A) Partially primary structure of functional unit RvH-b, of RvH as predicted from its cDNA sequence. (B-insert) A multiple sequence alignment of the linker intron identified in RvH-c in comparison to *Haliotis tuberculata* (two isoforms: HtH1-b/c, HtH2- b/c). (B) A multiple sequence alignment of the RvH-c with other FUs-c (the N-glycosylated site in RvH-c in green, other such sites are underlined. Residues in red and blue are conserved, or nearly conserved, respectively). Abbreviations of species: RvH, *Rapana venosa* Hc, AcH, *Aplysia californica* Hc, HtH, *Haliotis tuberculata* Hc. The secondary structural elements β4 and β5 are those occurring in the 3D structure of *Octopus dofleini* Hc (*35*).

sites -D(L/I)S- and -NNT-. Normally, D(L/I)S is not expected to be a linkage site, but, just in the unlikely event that deglycosylation of a glycan linked asparagine occurred during sample preparation, we thoroughly investigated this option. The ion y7 at *m/z* 806.4 corresponds to the C-terminal fragment of the peptide -(I/L)STNNTR, and the ion at *m/z* 1009.6 represents the same fragment still containing one GlcNAc moiety. This suggests that only the linkage site -NNT- is glycosylated, most likely via a high mannose-like structure. The ion at *m/z* 1660.9 corresponds to the intact peptide, represented as ion y13 (*m/z* 1457.5), which is N-glycosylated with a single GlcNAc residue. The glycan structure of this peptide could be revealed by this MS/MS spectrum, which displayed the typical ions (represented as Y and B) at *m/z* 204.1 (GlcNAc), *m/z* 366.2 (HexGlcNAc), *m/z* 528.3 ($Hex_2GlcNAc$), 690.5 ($Hex_3GlcNAc$), and 852.4 ($Hex_4GlcNAc$) (Figure 2B). Combining all data, the carbohydrate structure of 1054.0 Da ($Hex_2Man_3GlcNAc_2$) could be suggested.

Additional carbohydrate structures were analyzed in the same way and authentic binding sites could be revealed. The results are summarized in Table 1.

Identification of the Gene Sequence of Two RvH Functional Units. To better frame these results, we sequenced the cDNA of two FUs from RvH. To obtain the complete coding sequence for *R. venosa* hemocyanin (RvH) subunits, we performed RT-PCR using degenerated primers derived from the copper binding site A of *H. tuberculata* hemocyanin (*36*). The obtained fragments were cloned, sequenced, and identified by Blast analysis. We were able to determine the sequence of one hemocyanin coding fragment of 1668 bp in length coding for 556 amino acids, which in fact consisted of two subfragments. Since single functional units (FU) of hemocyanins can be assigned to their orthologs by multiple sequence alignment (*27*), we assume these two fragments partially code for of FU-b (Figure 3A) and FU-c (Figure 3B). The fragment of RvH-b comprises 316 amino acids lacking the first ca. 100 amino acids referring to the complete FU-b of known hemocyanins (*10, 27, 36*). The fragment of the FU-c comprises 240 amino acids, lacking ca. 200 residues of the C-terminus of complete FU-c. However, we can identify 14 amino acids to be part of a conserved phase 1 linker-intron, which exactly corresponds to both the intron phase and the position of the linker introns of functional unit b or c from the first structural subunit of *H. tuberculatos* (HtH1-b/c) and functional unit b or c from the second structural subunit of *H. tuberculatos* (HtH2-b/c) (Figure 3B-insert). The partitioning of the complete fragment into two separate FUs was done according to the known gene structures of *H. tuberculatos*, *O. dofleini*, and *N. pompilius* hemocyanins (*10*−*12, 36*) (Figure 3A,B).

Concerning the intron in the gene region of RvH-bc, we should mention that two types of introns were recognized in each gene of *Haliotis tuberculata* hemocyanin and *Octopus dofleini* hemocyanin: (i) introns positioned within the linker coding region between two functional units, referred to as "linker introns", and (ii) introns within a functional unit exon, consequently termed "internal introns". All hemocyanin linker introns identified so far are strictly phase 1 introns. According to these findings, the intron we observed in RvH is such a linker intron.

A

	HtH1-b	HtH2-b	RvH-b	HtH1-c	HtH2-c	RvH-c
HtH1-b	100	66	52	45	45	46
HtH2-b	66	100	51	42	44	47
RvH-b	52	51	100	43	44	53
HtH1-c	45	42	43	100	69	60
HtH2-c	45	44	44	69	100	57

B

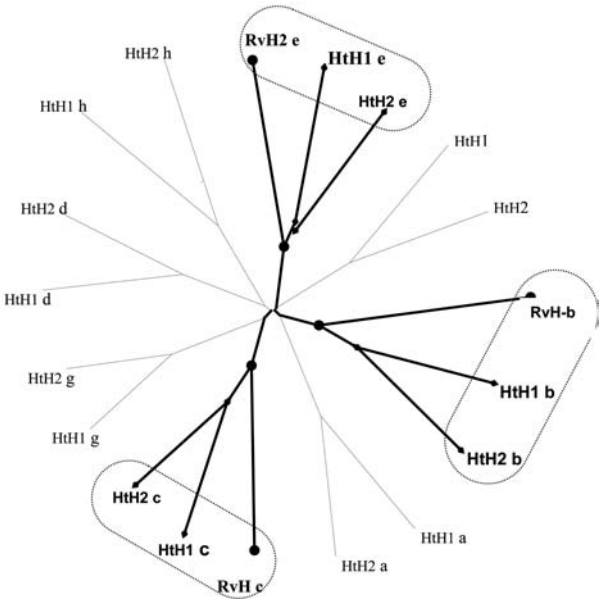

Figure 4. (A) Matrix of percentage identity between known hemocyanin sequences of FUs from *Rapana venosa* and *Haliotis tuberculata*. (B) A radial phylogenetic tree with of molluscan hemocyanin functional units sequences from three FUs from *Rapana venosa* (RvH-a,c,e) and *Haliotis tuberculata* (two isoforms: HtH1, HtH2).

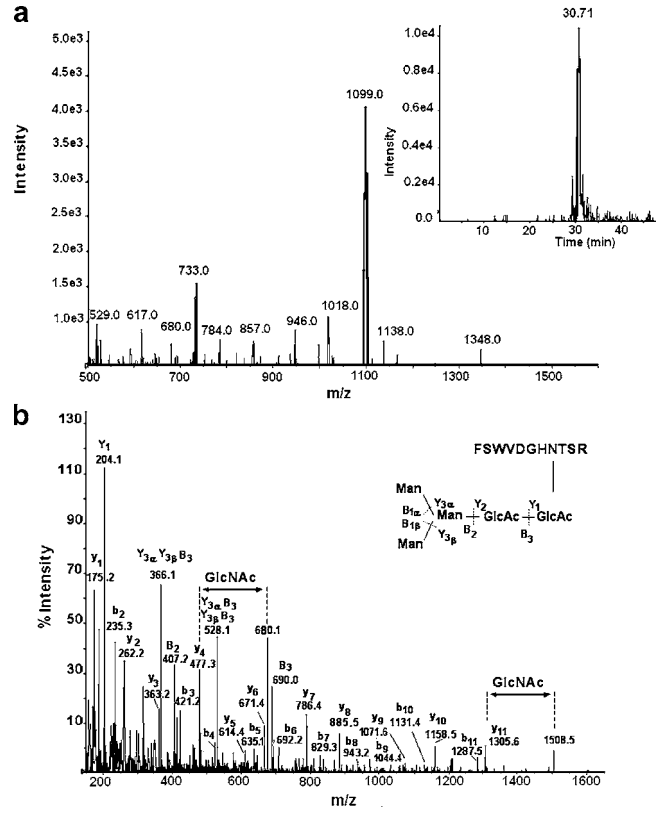

Figure 5. Precursor ion scan (A) at time 30.71 min of the chromatographic separation (insert) and enhanced product ion (EPI) scan of the ion (B) at *m*/*z* 1099.

In addition to the assignment of the orthologous FUs, the multiple sequence alignment of the separated FUs shows that RvH-b shares an identity of 52% and 51% with the vetigastropod hemocyanin isoforms HtH1-b and HtH2-b of *Haliotis tuberculata*, respectively, whereas the corresponding FU-c shares an identity of 57% and 60% with HtH1-c and HtH2-c, respectively (Figure 4A). This clearly suggests a closer relationship of RvH to HtH, which was also suggested by biochemical studies based on immunological assays. Due to the similar identity relationships of HtH1 and HtH2, the closer relationship of RvH and HtH2 cannot be seen in the molecular tree (Figure 4B). Moreover, they do not differ notably from any typical hemocyanin primary structure (Figure 4B) (*27*). No significant similarity to known N-terminal sequence data of isolated RvH1-b/c or RvH2-b/c subunits could be detected (*16*).

Comparisons of RvH-c and the deduced complete primary structures of other molluscan FUs-c shown in Figure 3C (only partial alignments are shown), reveal that only four of the nine c-FUs of *Rapana venosa* (RvH-c), *H. tuberculatos* (HtH2-c), *O. dofleini* (OdH-c), and *N. pompilius* (NpH-c) contain putative N-linkage sites.

Localization of the Carbohydrate Linkage Sites from the Gene Sequence. No carbohydrate linkage site was identified within the 316 amino acids of RvH-b. The finding that the orcinol/H_2SO_4 glycosylation test was negative for FU-b (data not shown) is thus corroborated by the gene sequence data and suggests that the N-terminal region of 100 residues contains no N-glycosylation site. Both isoforms of HtH-b contain at least one potential N-glycosylation site, which cannot be detected within the C-terminal 316 residues of RvH-b.

The finding that RvH-c does react with the reagent likewise corresponds to the gene sequence data, which reveal the presence of a glycosylation site at position 143. This NTS site is unique compared to the other sequences given in Figure 3C and matches perfectly well with the site identified the glycopeptide of mass 1099 $[M+2H]^{2+}$ by mass spectrometry (Table 1, peptides 4 and 9).

Several mass spectral results revealed that the carbohydrate structure $Man_3GlcNAc_2$ is branched to the RvH-c peptide FS**GE**VDGH*N*TSR. The precursor ion scan (monitoring *m*/*z* 204) at time 30.71 min during chromatography, the enhanced resolution (ER) scan of the most dominant ion (973), and the MS/MS spectrum of that ion are presented in Figure 5. It was determined that the glycopeptide has a 2× charge. By subtracting the peptide masses from the molecular ion 1099.19 $[M+2H]^{2+}$ ($[1099.19.2 \times 2] - 1 = 2197.38$), the glycan structure could be derived. The $Man_3GlcNAc_2$ glycan appears to occupy the -**N**TS- glycosylation site. This was confirmed by further investigation of the MS/MS spectrum. The ions at *m*/*z* 680.1 and 1508.5 correspond to the ion y4 (-**N**TSR-) and y11 (peptide), attached with one GlcNAc. The ion y11 at *m*/*z* 1305.6 corresponds to the peptide without the glycan. The *m*/*z* values for y8 and y9 differs by the mass of one tryptophan residue, and the peptide sequence FSWVDGHNTSR was determined. However, it differs by the gene sequence, because mass spectrometric fragmenting around a Gly residue often results in very small peaks and because a glycine-glutamic acid dipeptide is isobaric to a single tryptophan. Therefore, we now conclude that the gene sequence is likely to be correct.

The position, determined by model building, shows that the carbohydrate chain is exposed at the surface of the functional unit (Figure 6), at a similar position within the well-characterized structure of cephalopod *Octopus dofleini* (OdH) hemocyanin (*35*). In addition, it might be essential for establishing or maintaining any contact with other FUs and might contribute to the overall stability of the oligomeric hemocyanin; this remains to be determined.

Figure 6. Presumed 3D structure of FU RvH-c, based on the strongly homologous structure of *Octopus dofleini* Hc (35) and position of carbohydrate structure attached to the polypeptide chain.

Table 2. Testing for Antiviral Activity against the Replication in Vitro of RSV

		CPE score on a 0−4 basis (mean of four wells)			
compounds	concentration (μg/mL)	100 $CCID_{50}$/well	CPE inhibition %	10 $CCID_{50}$/well	CPE inhibition %
RvH	1000	3.5	0	1.5	0
	0	3.5	-	1.5	-
RvH-b	1000	3.5	0	1.5	0
	0	3.5	-	1.5	-
RvH-c	1000	1	71.4	0	100
	0	3.5	-	1.5	-

Antiviral Effect of RvH. Molluscan hemocyanins possess certain inhibitory properties against bacteria, but, so far, it was not shown to have any antiviral potential. We demonstrate here, for the first time, the inhibitory effect of molluscan hemocyanin RvH against viruses. We investigated whether this inhibition effect is linked to the presence of carbohydrate chains in RvH. To study the antiviral effect of RvH-oligosaccharides, polio virus type 1 (LSc-2ab), coxsackie virus B1 (CV−B1), and respiratory syncytial virus (RSV) were treated with native RvH and with nonglycosylated and glycosylated functional units RvH-b and RvH-c (0.45 and 2.0 mg/mL). Cytotoxicity, virucidal, and antiviral effects of glycosylated RvH-c and nonglycosylated FUs RvH-b were studied in FL or HEp-2 monolayer cells depending on the virus tested.

The compounds were nontoxic to monolayer cells even at the highest initial levels of concentration. Monolayer cells, treated with the highest given concentrations of the tested substances, remained completely intact, and no visible changes were detected by inverted light microscopy 24 and 48 h after treatment. Cytotoxicity control was carried out in parallel with the CPE inhibition test. Cells in this case were monitored for signs of toxicity until 120 h p.i. No toxicity was recorded either.

Virucidal and Antiviral Tests. The virucidal quantitative suspension test did not show any virucidal effect against polio virus type 1 (LSc-2ab), CV−B1, and RSV. The cytopathic effect (CPE) inhibition test was used to measure the antiviral effect of hemocyanin against the replication of poliovirus type 1 (LSc-2ab), CV−B1, and RSV. The results showed no antiviral effects of native RvH and of both FUs against polio virus type 1 (LSc-2ab) and CV−B1 (data not shown). However, the results presented in Table 2 show that the glycosylated FU RvH-c possesses some antiviral effect against the replication of RSV, at both viral doses tested. When the effect was tested against the lower virus dose of 10 $CCID_{50}$, the antiviral activity reached even 100% inhibition of the virus-induced cytopathic effect. Although not so strongly expressed, the antiviral effect is evident also at higher virus doses of 100 $CCID_{50}$ (which is the standard virus dose used in the CPE inhibition test), exceeding the 50% inhibition of the virus CPE.

In contrast, non-glycosylated FU RvH-b does not reveal any antiviral activity against the replication of RSV. The compounds also do not show antiviral effect against the replication of poliovirus type 1 (LSc-2ab) and CV−B1.

In conclusion, CPE-inhibition tests of the native RvH and both FUs against the replication of polio virus type 1 (LSc-2ab), CV−B1, and RSV revealed that there is no inhibitory effect on these viruses for native RvH and for non-glycosylated FU-b. However, the glycosylated FU RvH-c does show antiviral effect in the case of RSV replicated in HEp-2 cells. In order to understand the mechanism of this effect, further investigations are under way.

ACKNOWLEDGMENT

This work was supported by a research grant by the Ministry of Sciences and Education through the grant: DAAD-17/2007 (VU-L-310/07) and TK01/496, DFG (Deutsche Forschungsgemeinschaft) (Germany), Fund for Scientific Research-Flanders (FWO-Vlaanderen) through project VS.011.06N and CNR (Italy). Assoc. Prof. P. Dolashka-Angelova also thanks DAAD for granting a scholarship.

Received February 5, 2009; Revised Manuscript Received May 13, 2009

The somatostatin analogue Tyr[3]-octreotide, which has a high binding affinity for the SSTR2 receptor (somatostatin receptor subtype 2) expressed on tumor cells, is used clinically for the diagnosis and treatment of a variety of neuroendocrine tumors and gastrointestinal disorders. There is growing interest in the development of multivalent peptide systems, because they may have enhanced binding affinity compared to monovalent analogues. In this report, we describe the design and synthesis of a series of Tyr[3]-octreotide-containing monomeric, dimeric, and tetrameric dendrimeric conjugates. These multivalent dendrimeric cyclic peptides were obtained using Cu(I)-catalyzed 1,3-dipolar cycloaddition between peptidyl azides and dendrimeric alkynes. Their affinities for the SSTR2 receptor were determined by a competitive binding assay on rat brain sections.

INTRODUCTION

Somatostatin is a cyclic peptide hormone, which circulates in the blood in two biologically active forms: somatostatin-14 and its N-terminally extended form somatostatin-28, consisting of 14 and 28 amino acids, respectively (*1*−*3*). Both hormones exert different biological effects in the gastrointestinal system and in the nervous system. These effects are mediated by high-affinity G protein-coupled somatostatin receptors (SSTRs) and include modulation of hormone release and neurotransmitter release and inhibition of cell proliferation (*4*, *5*). Five different SSTR subtypes have been identified and characterized (SSTR1−5) (*6*). As some of these receptors are overexpressed in several human tumors, especially neuroendocrine tumors and their metastases, there is growing interest in the development of potent analogues to target these receptors. The octapeptide analogues octreotide and octreotate, having high binding affinity for SSTR2-receptor-expressing tumor cells, are used clinically for the diagnosis and treatment of a variety of neuroendocrine tumors and gastrointestinal disorders (*7*−*11*).

Much research has focused on the development of multivalent dendrimeric molecules, because they show interesting properties for enhancing the overall binding affinity compared to monovalent ligands (*12*−*16*). Several research groups have prepared multimers of cyclic Arg-Gly-Asp (RGD) peptides and evaluated their binding characteristics toward the $\alpha_v\beta_3$ integrin receptor (*17*−*19*). Our studies have shown that tumor uptake of a tetrameric RGD dendrimer was significantly higher compared to that of the monomeric and dimeric analogues, presumably due to enhanced statistical rebinding (*20*, *21*). These findings have inspired us to prepare dendrimeric multivalent octreotide-based molecules. On the basis of our experience with previously developed dendrimeric conjugates (*22*−*26*), these octreotide-based dendrimers may have enhanced binding affinity for the SSTR2 receptor. The aim of this study was to synthesize multivalent peptide dendrimers of octreotide, and to compare their in vitro binding characteristics with monovalent congeners.

Especially challenging is the efficient conjugation of these biologically active peptides to the dendrimer. A fast coupling reaction with high efficiency and chemoselectivity is desirable to allow the conjugation of unprotected peptides to dendrimers to obtain well-defined multivalent peptide dendrimers with preservation of receptor binding affinity. Several methodologies have been investigated, and the Huisgen 1,3-dipolar cycloaddition (*27*) of an azide and an alkyne forming a triazole linkage is particularly suitable for chemoselective bioconjugation reactions. The copper-catalyzed variant (*28*, *29*), which regiospecifically gives 1,4-disubstituted 1,2,3-triazoles has led to many applications ranging from therapeutics to macromolecules (*30*−*35*). We recently showed that unprotected peptides could be efficiently attached to an alkyne-derivatized version of our earlier developed dendrimers (*36*−*39*) using the 1,3-dipolar cycloaddition reaction (*21*, *40*). Thus, in this report we describe the synthesis of multivalent dendrimeric octreotide peptides from dendrimeric alkynes and azido peptides. To evaluate the effect of multivalency, the SSTR2 receptor binding characteristics of the corresponding monovalent, divalent, and tetravalent octreotide peptide dendrimers were studied in comparison to octreotide.

EXPERIMENTAL PROCEDURES

Materials and Instruments. Unless stated otherwise, chemicals were obtained from commercial sources and used without purification. Peptide-grade solvents were purchased from Bio-

solve and used directly except for dimethylformamide (DMF), *N*-methylpyrrolidone (NMP), and dichloromethane (DCM), which were dried on 4 Å molecular sieves prior to (solid phase) synthesis. 2-Chlorotrityl chloride resin was purchased from Tianjin Nankai Hecheng Science & Technology Company Ltd. and N^{α}-fluorenylmethyloxycarbonyl (Fmoc) amino acids were purchased from Advanced ChemTech, Alexis, or Novabiochem. Solid-phase synthesis was carried out in plastic syringes with PE frit (20 μm) obtained from Applied Separations Inc. Analytical HPLC runs were carried out on a Shimadzu HPLC system, and preparative HPLC runs were performed on a Kratos HPLC workstation. Analytical HPLC runs were performed on an Alltech Alltima C8 column (250 × 4.6 mm, pore size 90 Å, particle size 5 μm) at a flow rate of 1.0 mL/min using a linear gradient of buffer B (0−100% in 20 min) in buffer A (buffer A: 0.1% trifluoroacetic acid (TFA) in CH_3CN/H_2O 5:95 v/v, buffer B: 0.1% TFA in CH_3CN/H_2O 95:5 v/v). Preparative HPLC runs were performed on an Alltech Adsorbosphere XL C8 column (250 × 22 mm, pore size 90 Å, particle size 10 μm), and semipreparative HPLC runs were performed on an Alltech Adsorbosphere XL C18 column (250 × 10 mm, pore size 90 Å, particle size: 10 μm) at a flow rate of 12.0 mL/min (semipreparative HPLC: 4.8 mL/min) using a linear gradient of buffer B (0−100% in 120 min) in buffer A (buffer A: 0.1% TFA in CH_3CN/H_2O 5:95 v/v, buffer B: 0.1% TFA in CH_3CN/H_2O 95:5 v/v). Electrospray ionization (ESI) mass spectrometry was measured on a Shimadzu QP8000 single quadruple benchtop mass spectrometer operating in a positive ionization mode. MALDI-TOF analysis was performed on a Kratos Axima CFR apparatus with human ACTH(18−39) (monoisotopic $[M+H]^+$ 2465.198), bovine insulin oxidized B chain (monoisotopic $[M+H]^+$ 3494.651), or bovine insulin (monoisotopic $[M+H]^+$ 5730.609) as external references and α-cyano-4-hydroxycinnamic acid as matrix. ^{1}H NMR spectra were recorded on a Varian G-300 (300 MHz) spectrometer, and chemical shifts are given in ppm (δ) relative to TMS. ^{13}C NMR spectra were recorded on a Varian G-300 (75.5 MHz) spectrometer, and chemical shifts are given in ppm (δ) relative to $CDCl_3$ (77.0 ppm). The ^{13}C NMR spectra were recorded using the attached proton test (APT) sequence. Solid-phase synthesis was monitored with the Kaiser (*41, 42*) or the bromophenol blue (BPB) test (*43*). Where needed, the resin loading was determined by measuring the UV absorbance of the piperidine−dibenzofulvene adduct (λ_{max} 300 nm) (*44*) using a Thermo Electron Corporation UV/vis spectrophotometer. Solution-phase reactions were monitored by thin layer chromatography (TLC), and R_f values were determined on Merck precoated silica gel 60 F-254 (0.25 mm) plates. Spots were visualized with UV light or ninhydrin or by staining with chlorine/*N*,*N*,*N*′,*N*′-tetramethyl-4,4′-diaminodiphenylmethane (TDM) (*45*). The syntheses of compounds **1** and **2** are given in the Supporting Information. The syntheses of dendrimers **5**−**10** have been described previously (*21, 40*).

Chemistry. *N_3-Ahx-D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-Threol (3).* The 2-chlorotrityl chloride resin (909 mg, 1.00 mmol) was treated with $SOCl_2$/DCM (1:1 v/v; 2 × 10 mL, 10 min) to convert it completely into the chloride form prior loading of the first amino acid derivative. To remove any residual $SOCl_2$, the resin was extensively washed with DCM (6 × 10 mL, 10 min). Then, Fmoc-Thr(^{t}Bu)Ψ[CH_2OH] **2** (1.53 g, 4.00 mmol) was dissolved in DCM (10 mL), and to this solution *N*,*N*-diisopropylethylamine (DIPEA) (1.42 mL, 8.00 mmol) followed by the 2-chlorotrityl chloride resin were added and the obtained slurry was gently swirled for 2 h at room temperature. The resin was subsequently washed with DCM/CH_3OH/DIPEA (17:2:1 v/v/v; 3 × 10 mL, 10 min) to quench any remaining reactive 2-chlorotrityl chloride, followed by a washing step with DCM (3 × 10 mL, 2 min), DMF (3 × 10 mL, 2 min), and DCM (3 × 10 mL, 2 min). The loading of the resin, as calculated from an Fmoc determination, was 60% (0.66 mmol/g). The linear peptide sequence was synthesized according to Fmoc/^{t}Bu solid-phase peptide synthesis protocols (*32*). In a typical 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluoro phosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt)-coupling procedure, the resin was treated for 3 h with a 4-fold excess of a selected amino acid. After coupling of the N-terminal Fmoc-D-Phe-OH, a portion of the resin (0.60 g, 0.23 mmol) was treated with 20% piperidine/NMP (3 × 5 mL, 10 min) to remove the N-terminal Fmoc group, followed by washing with NMP and DCM. The 6-azido-hexanoic acid **1** (0.15 mg, 0.94 mmol) was dissolved in NMP (4 mL) in the presence of HBTU and HOBt (0.35 mg and 0.14 mg, respectively, 0.94 mmol, 1 equiv), and to this solution DIPEA (0.31 mL, 1.88 mmol, 2 equiv) followed by the peptide resin were added and the obtained slurry was gently swirled for 16 h at room temperature. The resin was subsequently washed (NMP, DCM), dried, suspended in TFA/H_2O/triisopropylsilane (TIS) (95:2.5:2.5 v/v/v; 10 mL) and stirred for 4 h to cleave the peptide alcohol from the resin and to remove the side chain protecting groups. The crude peptide was isolated by precipitation with cold (−20 °C) methyl *tert*-butyl ether (MTBE)/hexane (1:1 v/v). After centrifugation, the pellet was dissolved in CH_3CN/H_2O (1:1 v/v), lyophilized and subsequently purified by HPLC (C8), and fractions collected at 46% buffer B (44% CH_3CN). The linear peptide **3** was obtained in 29% (78 mg) yield. R_t: 20.17 min (C8). ESI-MS: m/z = 1176.30 $[M+H]^+$, 1198.25 $[M+Na]^+$, ($C_{55}H_{77}N_{13}O_{12}S_2$: M = 1175.53).

N_3-Ahx-D-Phe-cyclo(Cys-Tyr-D-Trp-Lys-Thr-Cys)-Threol (4). Compound **4** was obtained by dimethylsulfoxide (DMSO)-mediated oxidation of **3**, according to a procedure of Tam *et al.* (*47*). Peptide **3** (44 mg, 37.4 μmol) was dissolved in aqueous 2.5% acetic acid (50 mL), and the pH was adjusted to 6.0 with aqueous ammonia (25%). To this solution, DMSO (12 mL) was added. After stirring overnight at room temperature, the solution was partially concentrated in vacuo and the remaining DMSO was evaporated. The residue was dissolved in CH_3CN/H_2O, filtered, and purified by HPLC (C8), and fractions of pure peptide were collected at 44% buffer B (42% CH_3CN). The cyclic peptide **4** was obtained in 79% (35 mg) yield. R_t: 20.05 min (C8). ESI-MS: m/z = 1174.00 $[M+H]^+$, 1196.10 $[M+Na]^+$, ($C_{55}H_{75}N_{13}O_{12}S_2$: M = 1173.51).

Monovalent Tyr^3-Octreotide Peptide Conjugate (11). The synthesis of **11** was performed using activated copper-in-charcoal (Cu/C) as the catalyst (*48, 49*). Alkyne **5** (0.5 mg, 2.9 μmol) and azide **4** (3.7 mg, 3.2 μmol, 1.1 equiv) were dissolved in DMF (200 μL). To this solution, Cu/C (10 mg, excess) and triethylamine (TEA) (5 μL) were added. The mixture was allowed to react under microwave conditions (100 °C) for 5−10 min. The cycloaddition reaction was monitored by HPLC. A yellow-brownish solution was formed during the reaction. Following microwave irradiation, the mixture was filtered over Hyflo and concentrated in vacuo. The residue was dissolved in CH_3CN/H_2O (1:1 v/v), lyophilized, and purified by semipreparative HPLC (C18). Yield: 1.8 mg (46%). R_t: 20.48 min (C8). ESI-MS: m/z = 1364.30 $[M+H]^+$, 1386.65 $[M+Na]^+$. MALDI-TOF: 1364.693 $[M+H]^+$, 1386.749 $[M+Na]^+$ ($C_{66}H_{85}N_{13}O_{15}S_2$: M = 1363.573).

Divalent Tyr^3-Octreotide Peptide Dendrimer (12). Alkyne **6** (0.7 mg, 2.8 μmol) and azide **4** (6.9 mg, 5.9 μmol, 2.1 equiv) were dissolved in degassed DMF (200 μL). To this solution CuOAc (0.8 mg, 6.5 μmol, 2.2 equiv) was added, and the mixture was allowed to react under microwave conditions (100 °C) for 20 min. Following microwave irradiation, the obtained yellow mixture was concentrated in vacuo, and the residue was

dissolved in CH_3CN/H_2O (1:1 v/v) and lyophilized. After purification by semipreparative HPLC (C18), compound **12** was obtained in 42% yield (3.1 mg). R_t: 27.33 min (C18). ESI-MS: m/z = 1296.90 $[M+2H]^{2+}$. MALDI-TOF: m/z = 2593.995 $[M+H]_{ave}^{+}$, 2616.045 $[M+Na]_{ave}^{+}$, 2632.121 $[M+K]_{ave}^{+}$, ($C_{124}H_{162}N_{26}O_{28}S_4$: M_{ave} = 2593.074).

*Tetravalent Tyr³-Octreotide Peptide Dendrimer (**13**).* Analogous to the preparation of **12**, alkyne **7** (0.7 mg, 1.0 μmol), azide **4** (5.3 mg, 4.5 μmol, 4.5 equiv), and CuOAc (0.5 mg, 4.1 μmol, 4.1 equiv) were used in DMF (200 μL) as the solvent. After purification by semipreparative HPLC (C18), compound **13** was obtained in 24% yield (1.5 mg). R_t: 29.17 min (C18). MALDI-TOF: m/z = 5375.938 $[M+H]_{ave}^{+}$, 5397.834 $[M+Na]_{ave}^{+}$, 5414.927 $[M+K]_{ave}^{+}$, ($C_{258}H_{334}N_{54}O_{58}S_8$: M_{ave} = 5376.349).

*Monovalent 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-Conjugated Tyr³-Octreotide Construct (**14**).* Synthesis of **14** was performed using a combination of $CuSO_4$ and copper powder as the catalyst (*50*). Alkyne **8** (4.2 mg, 5.4 μmol, 1.1 equiv) and azide **4** (5.5 mg, 4.7 μmol, 1.0 equiv) were dissolved in DMF/H_2O (1:1 v/v; 0.2 mL). To this solution, aqueous 0.1 M $CuSO_4$ (50 μL, 5.0 μmol, 1.1 equiv) and copper powder (5 mg) were added, and the mixture was stirred for 18 h at room temperature. Then, the copper powder was removed by filtration, the solvent was evaporated under reduced pressure, and the residue was taken up in CH_3CN/H_2O (1:1 v/v; 2 mL) and lyophilized. The crude product was purified by semipreparative HPLC (C8, 5→95% CH_3CN in 90 min) to yield *tert*-butyl-protected **14** (lyophilized: 8.0 mg, 87%). The *tert*-butyl esters of the DOTA moiety were cleaved by treatment with $TFA/TIS/H_2O$ (95:2.5:2.5 v/v/v; 2 mL) for 3 h. The solvent was removed under reduced pressure, and the residue was dissolved in CH_3CN/H_2O (1:1 v/v; 2 mL) and lyophilized. After semipreparative HPLC (C8, 5→95% CH_3CN in 90 min) and subsequent lyophilization, **14** (3.4 mg, 1.9 μmol) was isolated in overall yield of 40%. R_t: 18.10 min (C8). MALDI-TOF: m/z = 1780.234 $[M+H]_{ave}^{+}$, 1801.672 $[M+Na]_{ave}^{+}$, 1843.146 $[M+Cu]_{ave}^{+}$, ($C_{83}H_{115}N_{19}O_{21}S_2$: M_{ave} = 1779.05).

*Divalent DOTA-Conjugated Tyr³-Octreotide Dendrimer (**15**).* Alkyne **9** (2.2 mg, 2.7 μmol, 1.0 equiv), azide **4** (6.8 mg, 5.8 μmol, 2.1 equiv), aqueous 0.1 M $CuSO_4$ (55 μL, 5.5 μmol, 2.0 equiv), and copper powder (5 mg) were added to DMF/H_2O (1:1 v/v; 0.2 mL), and the mixture was stirred for 18 h at room temperature. The workup, TFA treatment, and isolation of **15** were similar to that described for **14**. After semipreparative HPLC and subsequent lyophilization, **15** (0.9 mg, 0.3 μmol) was isolated in an overall yield of 12%. R_t: 18.48 min (C8). MALDI-TOF: m/z = 3008.674 $[M+H]_{ave}^{+}$, 3070.520 $[M+Cu]_{ave}^{+}$, ($C_{141}H_{192}N_{32}O_{34}S_4$: M_{ave} = 3007.49).

*Tetravalent DOTA-Conjugated Tyr³-Octreotide Dendrimer (**16**).* Alkyne **10** (1.8 mg, 1.5 μmol, 1.0 equiv), azide **4** (7.6 mg, 6.5 μmol, 4.3 equiv), aqueous 0.1 M $CuSO_4$ (58 μL, 5.8 μmol, 3.9 equiv), and copper powder (10 mg) were added to DMF/H_2O (1:1 v/v; 0.2 mL), and the mixture was stirred for 18 h at room temperature. The workup, TFA treatment, and isolation of **16** were similar to that described for **14**. After semipreparative HPLC and subsequent lyophilization, **16** (0.9 mg, 0.16 μmol) was isolated in overall yield of 11%. R_t: 18.93 min (C8). MALDI-TOF: m/z = 5790.326 $[M+H]_{ave}^{+}$, 5851.068 $[M+Cu]_{ave}^{+}$, ($C_{275}H_{364}N_{60}O_{64}S_8$: M_{ave} = 5790.72).

Receptor Autoradiography. The receptor binding affinity of the peptide dendrimers was determined in a competitive binding assay on rat brain cryostat sections (10 μm) using methods previously described with minor modifications (*51*). The sections were incubated for 1 h at room temperature with 0.1 nM [^{111}In-DOTA^0,Tyr^3]octreotate (135 MBq/nmol) in 167 mM tris(hydroxymethyl)aminoethane (Tris) (pH 7.6), supplemented with 5 mM $MgCl_2$, 1% bovine serum albumin (BSA), and 40 μg/mL bacitracin. To generate the competitive inhibition curves, the sections were incubated in the presence of an increasing amount (10^{-10} to 10^{-5} M) of the nonradioactive dendrimeric octreotide constructs. After incubation, the sections were washed two times for 5 min each in 167 mM Tris (pH 7.6), 5 mM $MgCl_2$, 0.25% BSA, (4 °C), 5 min in 167 mM Tris (pH 7.6), 5 mM $MgCl_2$ (4 °C), and finally rinsed in Milli-Q water (4 °C). The sections were then dried and exposed to phosphor imaging screens (Perkin-Elmer) for 48 h. The imaging screens were read using a Cyclone Storage Phosphor System (Packard), and the autoradiograms were quantified using Optiquant Software (Packard). Fitting of IC_{50} curves and calculation of IC_{50} values were performed with *GraphPad Prism 4.02* (GraphPad Software Inc.).

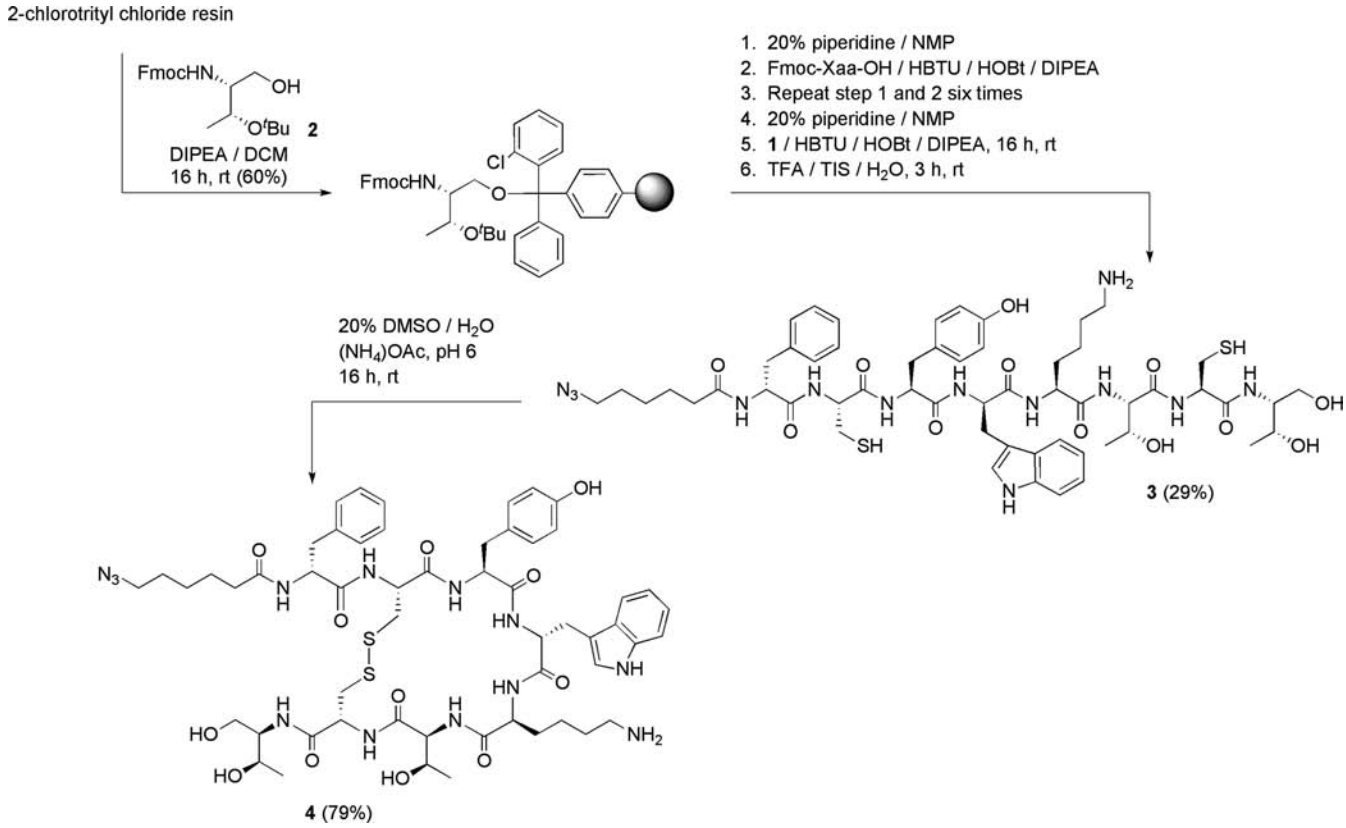
RESULTS AND DISCUSSION

Syntheses of Cyclic Tyr³-Octreotide Azides and Dendrimeric Alkynes. Azido octreotide **4** was prepared on the solid phase via Fmoc/^{t}Bu chemistry protocols (*46*), as depicted in Scheme 1. To enable click chemistry, an N-terminal azide functionality was introduced via 6-azidohexanoic acid **1**, which was prepared from 6-bromohexanoic acid (*52*). The preparation of octreotide required a C-terminal threoninol derivative. For this purpose, Fmoc-protected threonine was reduced to its corresponding alcohol **2** (*53*). Following coupling of the protected threoninol, peptide **3** was prepared on the solid phase, and 6-azidohexanoic acid **1** was coupled to the N-terminal D-phenylalanine before cleavage from the resin. After cleavage and concomitant removal of the side chain protection groups, the unprotected peptide **3** was obtained in an isolated yield of 29%. Despite the fact that the azide is susceptible to reduction in the presence of free thiols as are present in cysteine-2 and cysteine-7, the synthesis and subsequent ring closure by a DMSO-mediated disulfide formation of the peptide proceeded without noticeable side reactions and the azide remained stable throughout this procedure. Thus, linear peptide **3** was oxidized to the cyclic disulfide **4** by treatment with DMSO (*47*). After HPLC purification, the cyclic azido octreotide **4** was obtained in an overall yield of 23%.

Several studies have reported on the convergent synthesis of amino acid based dendrimers with peripheral propargyl groups to enable a 1,3-dipolar cycloaddition ("click") reaction with peptide derived azides (*21, 40*). A similar methodology was used here to prepare alkyne-derivatized dendrimers **5**−**7** and their corresponding DOTA-conjugated derivatives **8**−**10** (Figure 1) as a scaffold for the multimerization of octreotide.

Conjugation of Octreotide to Dendrimers by the Click Cycloaddition Reaction Procedure. After obtaining azide-functionalized octreotide **4** and alkynes **5**−**10**, the stage was set for the preparation of dendrimeric peptide systems using chemoselective "click" chemistry, as shown in Scheme 2. To prove the concept, the first experiments were conducted with alkynes **5**−**7** according to the literature procedure for microwave-assisted cycloaddition chemistry. Azide **4** was reacted with acetylene **5** in the presence of $CuSO_4$/Na-ascorbate in DMF/H_2O (9:1 v/v) for 5−15 min under microwave irradiation. Since the R_f values of the starting material and product were comparable on TLC, HPLC analysis was used to monitor the progress of the click cycloaddition reaction. After 5 min at 100 °C, the monovalent cycloaddition conjugate **11** was formed. Different sources of copper catalyst, including CuOAc and activated copper-in-charcoal (Cu/C) (*48*, *49*), were used for comparison to find the best procedure and to assess the versatility of this approach. Microwave-assisted cycloaddition with any of the three Cu(I)-sources afforded monovalent cycloadducts in yields ranging from 40% to 70%, with Cu/C giving the highest yield. However, the use of CuOAc showed

Scheme 1. Synthesis of the Cyclic *N*-ω-Azido Hexanoyl Octreotide Peptide 4



improved results in attaching peptidyl azide **4** to the divalent alkyne **6** giving divalent octreotide conjugate **12**. Therefore, CuOAc was chosen as the catalyst for the subsequent click conjugation reaction with the tetravalent dendrimeric alkyne **7**. Considerable amount of side products were observed during the reactions toward divalent and especially tetravalent peptide dendrimers, and LC-MS analyses showed most of these to be incomplete cycloadducts. These incomplete conjugates hampered purification by HPLC and resulted into a low isolated yield of the desired product. The formation of **11** and **13** was complete after 5 to 10 min microwave irradiation at 100 °C, whereas the reaction time for **12** had to be extended to 20 min.

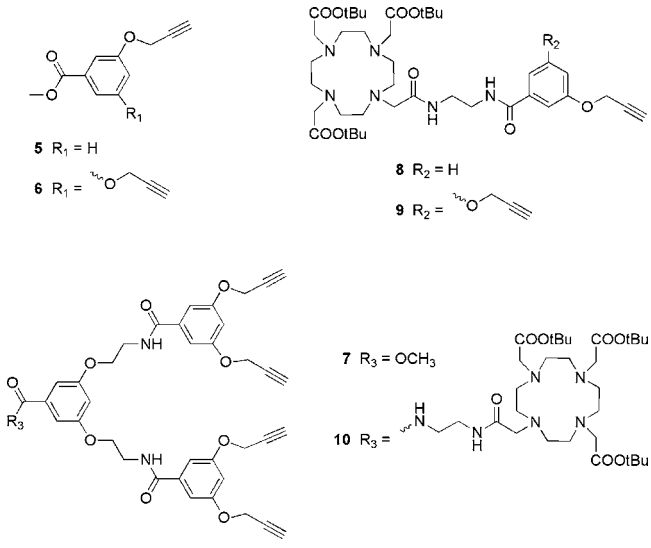


Figure 1. Structures of the mono-, di-, and tetravalent dendrimeric alkynes **5**, **6**, and **7**, and their corresponding DOTA conjugates **8**, **9**, and **10**.

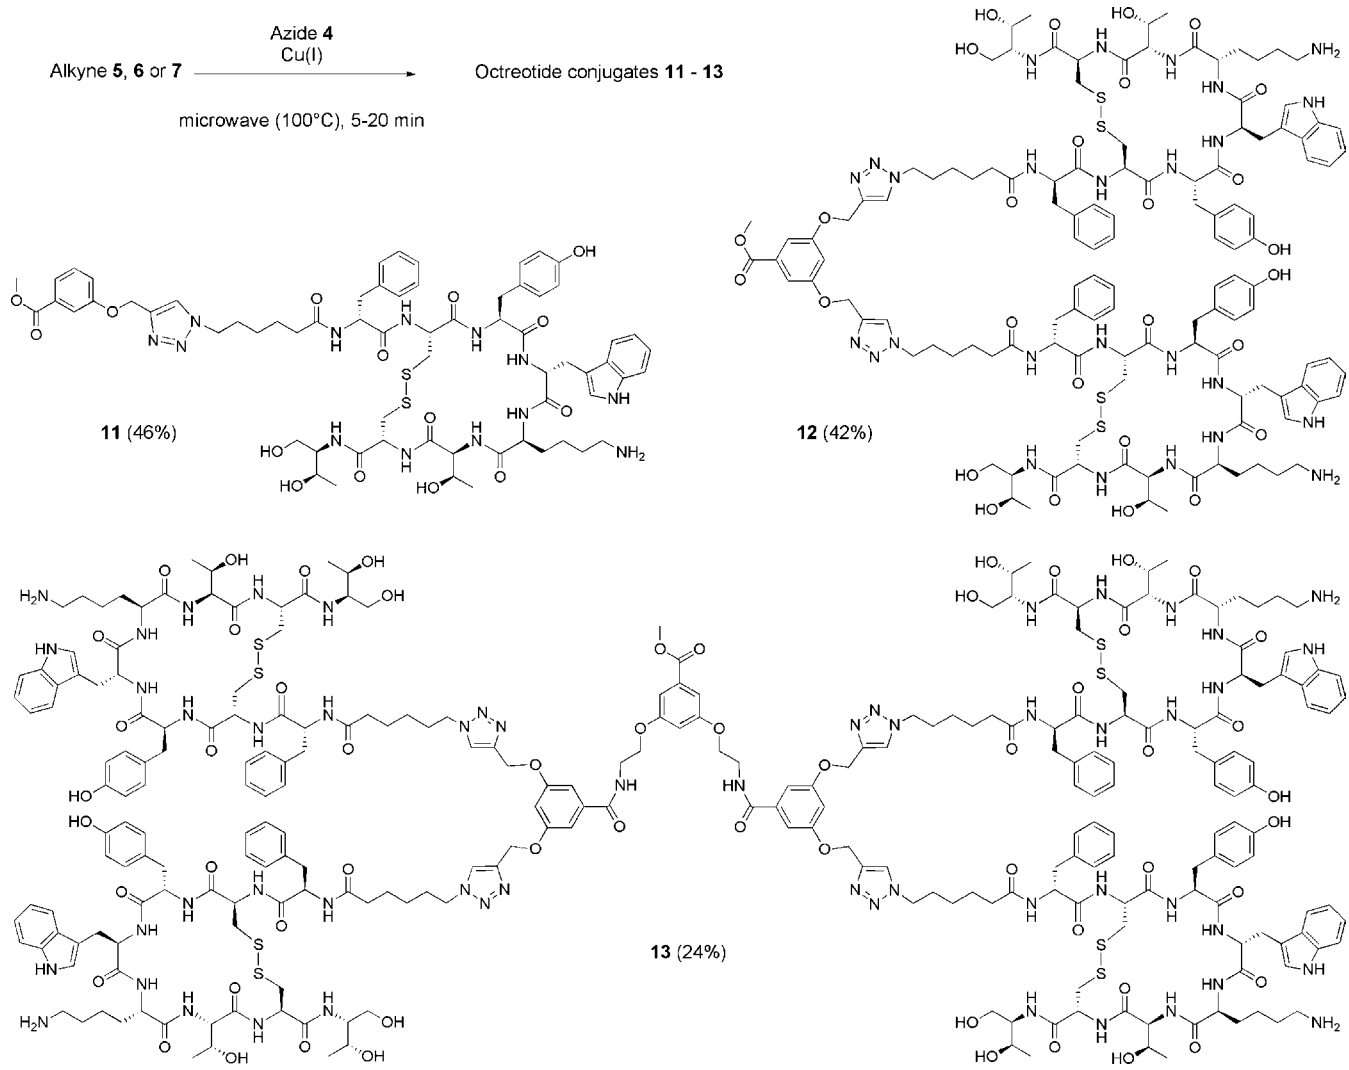
It turned out that using an equimolar amount of CuOAc gave the best result for all cycloaddition reactions. When using more equivalents of copper catalyst, increasing amounts of impurities were detected by HPLC. The identity of the cycloadducts **11**−**13** was confirmed by MALDI-TOF and the spectrum of cyclic octreotide tetramer **13** is shown in Figure 2 as a representative example.

Scheme 3 shows the synthetic route toward DOTA-conjugated octreotide dendrimers **14**, **15**, and **16**. In contrast to the synthesis of conjugated peptide dendrimers **11**−**13**, the DOTA moiety of dendrimers **8**−**10** required a different copper catalyst, since none of the above-mentioned Cu(I)-sources resulted in the desired products. Fortunately, using a combination of $CuSO_4$ and copper powder as described by Kessler and co-workers (*50*) gave the desired conjugates in acceptable yields. Figure 3 shows the analytical HPLC trace of azido octreotide **4** and alkyne **8** (A) and the resulting DOTA-conjugated ^{t}Bu-protected precursor of **14** after the click reaction (B), respectively. Conjugate **14** was obtained in 40% yield after purification. The isolated yields for dimer **15** and tetramer **16** were 12% and 11%, respectively. These relative low values were mainly due to the presence of incomplete coupling products and concomitantly difficult purification to obtain the pure compound.

Since a relatively high amount of copper had to be used during the synthesis of **14**, **15**, and **16**, Cu-DOTA complexes were formed in addition to the desired copper-free products, as was inferred from the mass spectra. To remove residual copper from the DOTA moieties, the product was treated with Na_2S as described in the literature (*50*). This treatment, however, reduced the disulfide bridges in octreotide, which had to be restored by a reoxidation step in aqueous DMSO. Figure 4 shows the mass spectrum of conjugate **14** with no indication of Cu-DOTA complexes. However, mass analysis of either dimer **15** or tetramer **16** still clearly showed copper-bound adducts

Scheme 2. Synthesis of Mono-, Di-, and Tetravalent Octreotide Dendrimeric Constructs 11, 12, and 13



after Na_2S treatment (Supporting Information Figures SI 8,9, respectively).

To avoid copper contamination of the desired end-product, since it is cytotoxic toward mammalian cells and also hampers efficient loading of the DOTA moiety with radioactive metals, approaches toward metal-free azide−alkyne cycloadditions are particularly relevant (*54*). In a recent paper by Rutjes and co-workers (*55*), it was shown that a copper-free tandem 1,3-dipolar cycloaddition retro-Diels−Alder ligation enabled the efficient synthesis of ^{111}In-labeled cyclic RGD−DTPA conjugates. Alternative copper-free "click" approaches to obtain DOTA-conjugated multimeric octreotide dendrimers are currently under investigation in our laboratory.

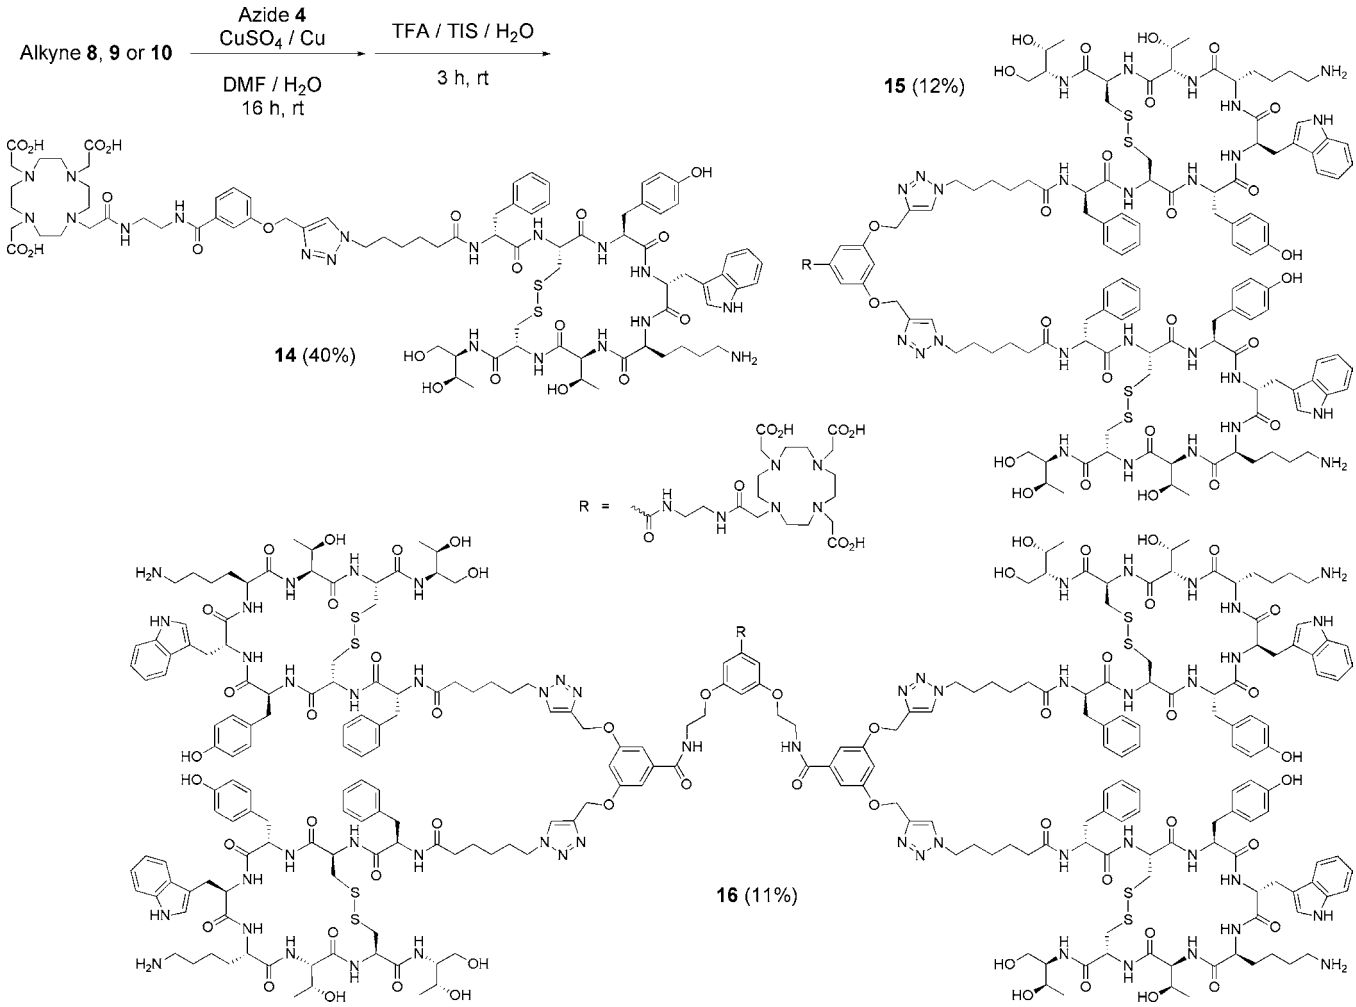
Receptor Binding Assay. Binding affinities toward the somatostatin receptor of the mono-, di-, and tetravalent DOTA conjugates of octreotide **14**, **15**, and **16**, respectively, were determined by a competitive binding assay on rat SSTR2-positive brain cryostat sections, using [^{111}In-DOTA^0,Tyr^3]octreotate as a radiotracer. Figure 5 represents a typical example of an autoradiogram, in which [^{111}In-DOTA^0,Tyr^3]octreotate was displaced by tetravalent octreotide dendrimer **13** (first and second column) and azido octreotide **4** (third and fourth column) in a concentration range from 10^{-10} to 10^{-5} M (from top to bottom) in two independent experiments. The autoradiograms were quantified, and the IC_{50} values were calculated from fitted sigmoidal displacement curves as shown in Figure 6 and summarized in Table 1. On the basis of these data, it became clear that the IC_{50} values of conjugate **14**, dimer **15**, and tetramer **16** were all within the low nanomolar range. However, no significant increase in receptor affinity for the tetramer **16** compared to either dimer **15** or conjugate **14** could be measured. A possible explanation for the absence of the multivalency effect may be found in the nonoptimized spacer-arm length either between the DOTA chelator and the dendrimeric core or between the dendrimer core and the peptide. However, it is known from our earlier work that elongating the spacer-arm length, between the dendrimer core and the carbohydrate moiety of a

Scheme 3. Synthesis of Mono-, Di-, and Tetravalent DOTA-Conjugated Octreotide Dendrimeric Constructs 14, 15, and 16



divalent galabiose derivative, resulted in a 2-fold increase in IC_{50} value for the inhibition of *Streptococcus suis* bacteria (*23*), compared to the analogue without a spacer. Therefore, the present dendrimeric systems of the octreotide cyclic peptide may not be ideal for augmenting receptor binding. Furthermore, the importance of the linker or other solubilizing moieties connected directly to the dendrimer scaffold was also apparent from similar binding experiments using conjugates **11**−**13** without the DOTA-moiety (Supporting Information Table SI 1 and Figure SI 10). The resulting IC_{50} values found for conjugate **11** and dimer **12** were higher than those for their corresponding DOTA conjugates **14** and **15**; probably, a poor aqueous solubility of tetramer **13** prevented even the calculation of a reliable IC_{50} value. Incorporating the DOTA moiety, which contains three hydrophilic carboxylic acid func-

Figure 5. Autoradiograms of tetravalent octreotide peptide dendrimer **13** (first two columns) and azido octreotide **4** (last two columns). Concentrations used (from top to bottom): 10 μM, 1 μM, 100 nM, 50 nM, 10 nM, 5 nM, 1 nM, 0.5 nM, and 0.1 nM, respectively.

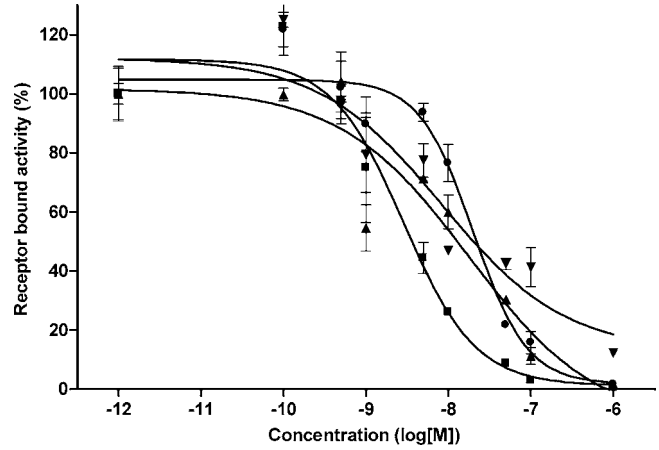

Figure 6. Competitive binding assay of mono-, di-, and tetravalent DOTA-conjugated systems of octreotide **14** (■), **15** (▲), and **16** (▼) displacing [^{111}In-DOTA^0,Tyr^3]octreotate in rat SSTR2-positive brain sections (n = 2 for each data point). [DOTA^0,Tyr^3]-conjugated octreotide **17** (•) was used as reference compound. The error bars indicate the range of the 95% confidence interval.

Table 1. IC_{50} Values for Competitive Binding Assay of Mono-, Di-, and Tetravalent DOTA-Conjugated Systems of Octreotide Displacing [^{111}In-DOTA^0,Tyr^3]octreotate in Rat SSTR2-Positive Brain Sections (n = 2 for each data point)

competing ligand	IC_{50} (nM)	95% CI (nM)
DOTA-conjugate **14**	2.86	1.51−5.41
DOTA-dimer **15**	17.6	2.61−119
DOTA-tetramer **16**	8.34	1.55−44.7
DOTA-octreotide **17**	20.0	10.8−37.1

tionalities, improved the overall solubility, and an IC_{50} value for tetramer **16** could be determined.

CONCLUSIONS

We have reported on the versatile conjugation of octreotide to dendrimers by the Cu(I)-catalyzed 1,3-dipolar cycloaddition ("click") reaction leading to the successful synthesis of multivalent octreotide-based dendrimers, either in the absence or in the presence of the strong metal chelating DOTA moiety. This conjugation method represents a chemoselective approach for the preparation of these dendrimeric peptides from *unprotected cyclic* peptidyl azides and dendrimeric alkynes. We have tested the hypothesis regarding whether functionalization of our DOTA-conjugated dendrimeric alkynes **8**−**10** with octreotide **4** will augment the binding affinity between receptor and multivalent ligand. Competitive binding assays showed no significant increase in receptor affinity for the DOTA-conjugated tetramer **16** or dimer **15** compared to

the monomer **14**. The role of the spacer between the scaffold and the cyclic peptide could play a major role in improving binding affinity of the dimeric and tetrameric conjugates, and this aspect is currently under investigation. Furthermore, to ensure an efficient radiolabeling, alternative copper-free "click" approaches to obtain DOTA-conjugated multimeric octreotide dendrimers are currently being developed in our laboratory.

Synthesis

6-Azidohexanoic acid (1): To a stirred solution of 6-bromohexanoic acid (3.9 g, 20 mmol) in DMF (10 mL) NaN_3 (2.6 g, 40 mmol) was added. The mixture was stirred for 3 h at 85°C. The reaction mixture was diluted with DCM and the obtained solution was washed with 0.1 N aqueous HCl. The organic layer was dried (Na_2SO_4) and concentrated under reduced pressure. Compound **1** was obtained as a colorless oil in 89% yield (2.8 g) and used without further purification. ^{1}H-NMR (300 MHz, $CDCl_3$) δ: 1.44 (m, 2H, γCH_2), 1.65 (m, 4H, $\beta CH_2/\delta CH_2$), 2.38 (m, 2H, αCH_2), 3.28 (m, 2H, εCH_2), 11.5 (broad s, 1H, OH); ^{13}C-NMR (75.5 MHz, $CDCl_3$) δ: 24.3, 26.3, 28.7, 34.0, 51.3, 179.7.

Fmoc-Thr(^{t}Bu)Ψ[CH_2OH] (2): To a cold (−15°C) and stirred solution of Fmoc-Thr(^{t}Bu)-OH (2.0 g, 5.0 mmol) in 1,2-dimethoxyethane (5.0 mL), N-methyl morpholine (0.56 mL, 5.0 mmol) followed by isobutyl chloroformate (0.68 mL, 5.0 mmol) were added. The reaction mixture was stirred overnight under an N_2 atmosphere. The precipitated hydrochloride was removed by filtration over a Hyflo® plug. To the cooled filtrate a solution of $NaBH_4$ (0.50 g, 13 mmol) in H_2O (5 mL) was added as a single portion, followed by the addition of H_2O (200 mL). The reaction mixture was concentrated in vacuo and the residue was redissolved in DCM (100 mL), and this solution was washed with H_2O (100 mL), 1N $KHSO_4$ (100 mL) and brine (100 mL). The organic layer was dried (Na_2SO_4) and concentrated to dryness. The residue was purified by column chromatography (eluens: EtOAc/hexane 1:1 v/v) and **2** was obtained as a clear oil in 94% yield (1.8 g). R_f(EtOAc/hexane 1:1 v/v): 0.32; ^{1}H-NMR (300 MHz, $CDCl_3$) δ: 1.17 (d, 3H, CH_3), 1.22 (s, 9H, $(CH_3)_3$), 2.69 (broad s, 1H, OH), 3.65 (broad m, 3H, NH-C*H*/C*H*$_2$OH), 3.95 (broad d, 1H, C*H*-CH_3), 4.23 (m, 1H, Fmoc CH), 4.42 (broad m, 2H, Fmoc CH_2), 5.23 (broad d, 1H, urethane NH), 7.30-7.78 (m, 8H, arom Fmoc); ^{13}C-NMR (75.5 MHz, $CDCl_3$) δ: 20.3, 28.9, 47.5, 57.4, 63.8, 67.0, 67.3, 74.5, 120.2, 125.3, 127.3, 127.9, 141.6, 144.2, 157.2.

DOTA-D-Phe-*cyclo*(Cys-Tyr-D-Trp-Lys-Thr-Cys)-Threol (17): Resin-bound Fmoc-protected octreotide (60 mg, 0.39 mmol/g, 23 µmol) was treated with 20% piperidine/NMP and subsequently washed with NMP and DCM. DOTA$(OtBu)_3$ (40 mg, 70 µmol, 3.0 equiv) was dissolved in NMP (2 mL) with equivalent amounts of HBTU and HOBt (27 mg and 11 mg, respectively) and DIPEA (24 µL, 140 µmol, 6.0 equiv) was added; this mixture was transferred to the resin-bound peptide and the obtained slurry was gently swirled for 16 h at room temperature. Subsequently, the resin was washed (NMP, DCM), dried and mixed with TFA/TIS/H_2O (10 mL, 95:2.5:2.5 v/v/v) and stirred for 3 h at room temperature. The crude peptide was isolated by precipitation with cold (-20 °C) MTBE/hexane (1:1 v/v). After centrifugation, the pellet was dissolved in CH_3CN/H_2O (1:1 v/v), lyophilized and purified by HPLC (C8). The linear peptide was obtained in 72% yield (24 mg). R_t = 20.45 min (C18); ESI-MS: *m/z* = 1424.19 $[M+H]^+$, 1446.02 $[M+Na]^+$, ($C_{65}H_{94}N_{14}O_{18}S_2$: *M* = 1423.65). The linear peptide (24 mg, 17 µmol) was dissolved in H_2O (26 mL, 2% acetic acid). The pH was adjusted to 6.0 with a 1.0 M ammonium acetate solution. To this solution, DMSO (9 mL) was added. After stirring overnight at room temperature, the solution was partially concentrated in vacuo and the remaining DMSO was evaporated with a rotational vacuum concentrator (Christ, Alpha-RVC). The lyophilized residue was dissolved in CH_3CN/H_2O, filtrated and loaded into a preparative C8 HPLC column. The cyclic peptide was obtained in 10% yield (2.4 mg). R_t: 19.43 min (C18); ESI-MS: *m/z* = 1421.45 $[M+H]^+$, ($C_{65}H_{92}N_{14}O_{18}S_2$: *M* = 1421.64).

Received February 11, 2009; Revised Manuscript Received June 1, 2009

Liposomes have been widely used as a drug delivery vehicle, and currently, more than 10 liposomal formulations are approved by the Food and Drug Administration for clinical use. However, upon targeting, the release of the liposome-encapsulated contents is usually slow. We have recently demonstrated that contents from appropriately formulated liposomes can be rapidly released by the cancer-associated enzyme matrix metalloproteinase-9 (MMP-9). Herein, we report our detailed studies to optimize the liposomal formulations. By properly selecting the lipopeptide, the major lipid component, and their relative amounts, we demonstrate that the contents are rapidly released in the presence of cancer-associated levels of recombinant human MMP-9. We observed that the degree of lipid mismatch between the lipopepides and the major lipid component profoundly affects the release profiles from the liposomes. By utilizing the optimized liposomal formulations, we also demonstrate that cancer cells (HT-29) which secrete low levels of MMP-9 failed to release a significant amount of the liposomal contents. Metastatic cancer cells (MCF7) secreting high levels of the enzyme rapidly release the encapsulated contents from the liposomes.

INTRODUCTION

Liposomes are lipid bilayers encapsulating an aqueous core (*1, 2*). Due to the ease of preparation in a size-controlled manner and biocompatibility, they are widely used as lipid-based nanoparticles for drug delivery (*3, 4*). Hydrophilic molecules are encapsulated in the aqueous interior of the liposomes, and hydrophobic molecules partition into the lipid bilayers (*5, 6*). Incorporation of poly(ethylene glycol) (PEG) containing lipids reduces opsonization and renders the liposomes long-circulating in the bloodstream (*7, 8*). After intravenous administration, long-circulating liposomes passively accumulate in the tumor tissues due to the enhanced permeation and retention effect (*9*). For active targeting, antibodies (*10*), peptides (*11*), and small molecules (*12*) have been conjugated to the surface of the liposomes.

The side effects of anticancer drugs are considerably reduced by encapsulating them in the liposomes (*13*). There are currently about 10 liposomal drug formulations approved by the U.S. Food and Drug Administration (FDA) for human use (*14*). Numerous clinical trials are currently in progress using liposome-encapsulated anticancer drugs (*15*). However, upon targeting, the release of the encapsulated drugs is usually very slow (*16*). An attractive solution to this problem is to formulate liposomes with appropriate lipids such that the contents are released in response to an external trigger. Temperature (*17*), pH (*18*), light (including near-infrared (*19*)), ultrasound (*20*), metal ions (*21*), and enzymes (*22, 23*) have been used as triggers. We have recently demonstrated the release of liposomal contents by the cancer-associated enzyme matrix metalloproteinase-9 (MMP-9) (*24, 25*).

Matrix metalloproteinases (MMPs) are a family of 23 Zn^{2+} and Ca^{2+} dependent extracellular enzymes responsible for the degradation and remodeling of the extracellular matrix (*26, 27*). The expression level and activation of these enzymes are regulated at multiple levels (*28*). Increased expression of MMPs is associated with many diseases, including various types of cancers (*29, 30*). MMP-9 is involved in the progression and metastasis of many cancers (*31, 32*).

Herein, we report our detailed mechanistic and optimization studies on the triggered release of liposomal contents by MMP-9. We have prepared triple helical peptide substrates for MMP-9 and conjugated them with fatty acids to synthesize the corresponding lipopeptides. Liposomes incorporating these lipopeptides released the encapsulated contents in response to cancer-associated levels of recombinant MMP-9. We optimized the system by systematically varying the triple helicity of the lipopeptides, its amount, and the structure of the major lipid component of the liposomes. We observed that the content release is dependent on the degree of mismatch between the fatty acids of the lipopeptides and the major lipid of the liposomes. Using the optimized formulation, we demonstrate that the liposomal contents are released by MMP-9 secreted from the breast adenocarcinoma cells, MCF7. The colorectal adenocarcinoma cells HT29 do not secrete high levels of MMP-9 and failed to release significant amounts of the encapsulated contents from the liposomes.

MATERIALS AND METHODS

Synthesis of the Lipopeptides. The lipopeptides were synthesized by employing a microwave-assisted peptide synthesizer (Liberty, CEM corporation, Matthews, NC) using standard Fmoc-protected amino acids (0.1 mmol scale). The commercially available Fmoc-Gly-CLEAR acid resin was used

as the solid support. The reactions were carried out in a 30 mL reaction vessel housed within the microwave chamber (CEM Discover) of the peptide synthesizer. A mixture of HOBT/HBTU in 5-fold excess was used as the coupling reagent. Each coupling step (with the exception of Arg) was performed at 50 °C under 20 W microwave power for 5 min. The coupling of amino acid Arg was done twice at 25 °C for 25 min without the use of microwave. The N-terminal fatty acid was also subjected to double coupling. The activator base used was 5 equiv of diisopropylethylamine dissolved in *N*-methylpyrrolidone. The Fmoc deprotection was accomplished with 5% (by weight) of piperazine in DMF. Cleavage from the solid support was performed inside the microwave chamber for 35 min using a cocktail of TFA-tri-isopropylsilane and water (95%/2.5%/2.5%). The crude peptides were precipitated as white solids with ice-cold ether, centrifuged, and purified by a semipreparatory RP-HPLC. The monoisotopic masses of purified peptides were determined with an Applied Biosystems/MDS SCIEX 4800 MALDI ToF/ToF analyzer.

Conditions for Analytical HPLC. The analytical HPLC was performed with Vydac analytical diphenyl column (RP219TP5415) with a linear gradient of 0−70% acetonitrile in water as eluant, with each solvent containing 0.1% TFA. The flow rate was maintained at 1.5 mL/min for 25 min. The UV detection wavelength was kept at 214 nm.

Conditions for Semipreparatory HPLC. Vydac diphenyl (RP219TP510) RP HPLC column was used. A linear gradient of 0−70% acetonitrile in water was maintained for 60 min at flow rate 8 mL/min. Each solvent contained 0.1% TFA. The purification was monitored at a detector wavelength of 235 nm.

Liposome Formation. Stock solutions of lipopeptides were prepared by weighing appropriate amounts of the lipopeptide and then dissolving in 5:1 chloroform/methanol to a final concentration of 1 mg/mL. Stock solutions of phospholipids were prepared in chloroform to obtain a final concentration of 2 mg/mL. The lipopeptide and the phospholipid were mixed in appropriate volumes in a 10 mL round-bottom flask. A thin lipid film was obtained by evaporating this mixture in a rotary evaporator at 40 °C. The thin film was kept under high vacuum overnight to remove any residual organic solvents. The dry lipid film was hydrated with 1.5 mL buffer containing 6-carboxyfluorescein at 60 °C for 1−2 h. The hydrated solution was stored for 3−4 h to ensure complete hydration and to allow for proper folding of the lipopeptides into triple helices. In the next step, the large multilamellar vesicles were broken into unilamellar vesicles of appropriate sizes by probe sonication in a heating block for 1 h at 56 °C. After sonication, the liposome solution was centrifuged to remove any suspended metal particles from the probe tip and extruded through a 100 nm polycarbonate filter (Avanti Polar lipids, AL). The unencapsulated carboxyfluorescein was removed from the liposomes by gel filtration through a Sephadex G-100 column. The Sephadex G-100 was hydrated for 24 h at 60 °C and equilibrated with 5 times the volume of the assay buffer before loading of the liposomes. The osmolarity of this eluant buffer was made equal to the osmolarity of the carboxyfluorescein solution used for hydration by adding appropriate amount of NaCl. This ensured minimum background leakage of carboxyfluorescein due to osmotic shock during the actual leakage experiment.

For CD experiments, the thin film prepared in a similar manner as discussed above was hydrated with 1 mL of 5 mM phosphate buffer (pH 8.0) at 60 °C for 1 h. The liposomes after 2 h were subjected to probe sonication for 30 min. The CD spectra were recorded at 25 °C immediately after the probe sonication.

Buffer Solutions. The buffer used in making carboxyfluorescein solution was 25 mM HEPES (pH = 8.0) containing 100 mM carboxyfluorescein, 10 mM $CaCl_2$, 10 μM $ZnCl_2$, and 100 mM NaCl. The buffer used for column equilibration, elution of liposomes from the column, and release experiment consisted of 25 mM HEPES (pH 8.0) with 10 mM $CaCl_2$, 10 μM $ZnCl_2$, and 100−150 mM NaCl. The buffer prepared for the liposome CD experiments was 5 mM phosphate buffer at pH 8.0.

Circular Dichromism Spectroscopy. CD spectra were recorded in a Jasco J815 CD spectrometer using 1 mm path length quartz cuvette. For temperature-dependent CD spectra, the concentration of the lipopeptides used was 1 mg/mL in aqueous solution. The solutions were stored for 12 h at 4 °C before recording the spectra. For each sample, the equilibration time was set for 15 min at each temperature. For each temperature, an average of 3 scans were recorded at a scan speed of 50 nm/min. The response time set was 0.25 s. The melting temperature was obtained by plotting the CD intensity maxima at 225 nm vs temperature. For the liposome CD spectra, the average of 50 scans was recorded with a scan speed of 100 nm/min.

Release Studies. The kinetics of carboxyfluorescence release from the liposomes was monitored by recording the intensity of fluorescence emission at 518 nm using a spectrophotometer (Spectrmax, Molecular Devices) with an excitation wavelength at 480 nm. Each experiment was conducted in triplicate wells on a 96 standard opaque fluorescent well plate. The final reading taken was the average reading from 3 wells. For experiments involving recombinant human MMP-9, the activity of the enzyme was tested with a commercially available fluorogenic substrate prior to the experiment to ensure that the enzyme is fully active. The fluorescence emission was recorded at 20 s interval for 1 h. After 1 h, the liposomes were ruptured using optimized concentration of Triton-X to allow complete leakage of the dye. The fluorescence emission corresponding to this leakage was taken as the maximum emission possible in calculating the percentage release. The percentage release was calculated using a formula reported previously (*25*).

Growth and Maintenance of Cells. All cells were obtained from American type Culture Collection (Manassas, VA, USA). MCF7 (human breast adenocarcinoma) and HT-29 (human colorectal adenocarcinoma) cell lines were cultured in Eagle's Minimum Essential medium and McCoy's 5a medium, respectively, at 37 °C in humidified atmosphere containing 5% CO_2. All media were supplemented with 5% penicillin and streptomycin solution and 10% fetal bovine serum. When the cells achieved 70% of confluency, the old culture media were replaced with fresh culture media without phenol red. The cells were further incubated for 24 h, collected, and centrifuged. The supernatants were collected for further experiments. For cell-based liposomal release experiments, 50 μL of cell media was added to a total volume of 200 μL in each well, and the intensity of emission spectra of carboxyfluorescein at 518 nm ($\lambda_{ex} = 480$ nm) was monitored as discussed in the recombinant MMP-9 release studies.

RESULTS AND DISCUSSION

Synthesis of Lipopeptides. The natural substrate for the MMP-9 is gelatin (*33*). Gelatin and collagen-mimetic triple-helical peptides have been used as models to study substrate selectivity of the MMPs (*34*), as scaffolds and functional biomaterials for tissue engineering (*35*), and as targeting moieties for liposomes (*36*). Structurally, the collagen-mimetic peptides contain repeat units of the amino acid triad Gly-Pro-Hyp (GPO). For these studies, we prepared homotrimeric collagen-mimetic peptides containing the cleavage site for MMP-9 employing a microwave-assisted, solid-phase peptide synthesizer (*37*). The peptides have the general structure of $CH_3(CH_2)_{16}$CONH-GPQGIAGQR$(GPO)_n$GG-COOH, where the

Table 1. Synthesized Lipopeptides, Their Calculated and Observed Molecular Masses, the Calculated Rpn Values at 5 °C, and the Melting Temperatures (T_m)

no.	name	*n*	calcd. M^+	obsd. M^+	Rpn	T_m (°C)
1	**GPO3**	3	2065.06	2066.07	0.08	43
2	**GPO4**	4	2332.24	2332.27	0.11	56
3	**GPO5**	5	2600.37	2599.40	0.13	64

MMP-9 cleavage site is the peptide bond connecting Gly and Ile. In order to vary the triple helicity, the number of GPO repeat units in the peptides (i.e., *n*) were systematically varied (Table 1). We employed the microwave-assisted peptide synthesizer to conjugate the fatty acids to the peptides.

In order to determine the structural resemblance of the synthesized lipopeptides with collagen (and gelatin), we recorded the CD spectra in aqueous solution (1 mg/mL). In CD spectra, the presence of a positive peak at 225 nm and a large negative peak at 195−200 nm confirmed the triple helical structure of the lipopeptides (Figure 1A 38). The calculated Rpn values (*38*) at 5 °C and the melting temperatures (T_m) of the lipopeptides are also shown in Table 1. Since the Rpn value for natural collagen is 0.13 (*38*), we concluded that the lipopeptides adopt triple helical conformation, similar to collagen in aqueous solution. The lipopeptides **GPO3** and **GPO4** showed triple helical conformation in 5 mM phosphate buffer (pH = 8.0). However, the lack of sufficient solubility of the lipopeptides **GPO5** in this buffer prevented us from recording and comparing the spectra for all the lipopeptides at pH = 8.0.

Subsequently, we prepared liposomes containing 30 mol % of the synthesized lipopeptides in 25 mM phosphate buffer, pH = 8.0. The major lipid component of the liposomes was varied among POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine), DOPC (1,2-dioleoyl-*sn*-glycero-3-phosphocholine), and DSPC (1,2-distearoyl-*sn*-glycero-3-phosphocholine), and the CD spectra were recorded. Highest triple helicities for the liposome-incorporated lipopeptides were observed in the POPC liposomes (Figure 1B, red trace), possibly reflecting the mismatch between the fatty acids of the lipopeptides and POPC and the resultant demixing of the major lipid and the lipopeptides. When we incubated these liposomes with 3.0 μM recombinant MMP-9 for 30 min, the triple helicity of the liposome-incorporated lipopeptides was reduced substantially (Figure 1B, blue trace) indicating that the cleavage of the surface-exposed peptide substrates by the enzyme decreases the triple helicity of the lipopeptides.

As an independent measure of the triple helicity of the liposome-incorporated lipopeptides, we synthesized a pyrene-containing analogue of **GPO4** (**PyGPO4**, Scheme 1, synthetic details are included in Supporting Information). The CD spectrum of this lipopeptide in aqueous solution showed a positive peak at 225 nm and a large negative peak at 198 nm, indicating the formation of triple helix (T_m = 36 °C, Supporting Information). Subsequently, we recorded the fluorescence emission spectra (λ_{ex} = 340 nm) of POPC liposomes incorporating 30 mol % of **PyGPO4** in 25 mM HEPES buffer (pH = 8.0). The presence of a strong excimer peak in the emission spectrum (471 nm) indicated the proximity of the pyrene groups in the hydrophobic fatty acids of the lipopeptides (Figure 2, blue trace). Upon incubation of the liposomes with 3 μM MMP-9 for 15 min, we observed that the pyrene excimer emission peak decreased and the monomer emission peaks increased in intensity (Figure 2, red trace). These results indicate that the lipopeptide **PyGPO4** is demixed in the lipid bilayer of the liposomes. Hydrolysis of the peptides by MMP-9 leads to the reorganization of the lipids with increased separation between the pyrene groups.

Next, we proceeded to determine the optimal liposomal formulation for the release methodology. We varied the amounts, the triple helicity of the lipopeptides, and the major lipid component of the liposomes. First, the amount of lipopeptide in the liposomes (30 mol % of **GPO3**) and the concentration of MMP-9 (2.3 μM) were kept constant, and the major lipid component was varied (DOPC, POPC, and DSPC). The rates of release of encapsulated carboxyfluorescein from these liposomal formulations were monitored (λ_{ex} = 480 nm, λ_{em} = 518 nm; Figure 3). When DOPC was the major lipid, we observed complete release of the encapsulated dye within 30 min (Figure 3A). However, these liposomes released about 25% of the contents during the same time in the absence of any enzyme (Figure 3A). For the POPC liposomes, 90% of the encapsulated dye was released by MMP-9 in 30 min (Figure 3B). We were pleased to note that, for these liposomes, no dye released in the absence of MMP-9 (Figure 3B). When DSPC was the major lipid, no significant dye release from the liposomes was observed either in the presence and or in the absence of MMP-9 (data now shown). As discussed before, incorporation of the lipopeptides in the liposomes results in lipid demixing. The degree of this demixing depends on the mismatch between the hydrophobic fatty acid moieties of the lipopeptides and the major lipid component of the liposomes. For the synthesized lipopeptides, the saturated stearoyl moiety does not mix well with the unsaturated oleoyl groups of the lipids POPC and DOPC in the liposomes. However, when DSPC is the major component, the lipopeptides are well-mixed within the lipid bilayer of the liposomes.

Previously, we have observed that the dye release profiles for liposomes incorporating 30 mol % of the lipopeptide **GPO4** were single exponential in nature (*25*). The dye release profiles shown in Figure 3 can be fitted best with a biexponential rate equation: F (release) = $F_0 - (A_1 \times e^{-k1t} + A_2 \times e^{-k2t})$ to obtain the rate constants k_1 and k_2 for the dye release and the amplitudes A_1 and A_2. The calculated rate constants for the dye release from the DOPC and POPC liposomes are shown in Table 2. For the POPC liposomes, both rate constants were faster compared to those for the DOPC liposomes (Table 2). When we prepared liposomes incorporating 30 mol % of the lipopeptide **GPO5** with POPC as the major lipid, encapsulating a sufficient concentration of carboxyfluorescein was found to be very difficult. It should be noted that the triple helices are formed on the outside as well as in the inside of the liposomes. The increased molecular volume of the lipopeptide of **GPO5** possibly hinders the efficient encapsulation of carboxyfluorescein inside the liposomes. When we decreased the amount of **GPO5** to 20 mol % in the POPC liposomes, the dye was encapsulated efficiently. However, the release from these liposomes was inefficient (<40%, Supporting Information) in the presence of 2.3 μM MMP-9. The stability of the triple helices increases with the number of GPO repeat units (Table 1 (*44*)). Increased thermal stability of the triple helices leads to decreased cleavage rates by the MMPs (*44*).

On the basis of these results, we selected POPC as the major lipid component of the liposomes. Our next objective was to determine the amount of lipopeptide needed in the liposomes for optimal release of encapsulated carboxyfluorescein. We have previously observed that 30 mol % of lipopeptide **GPO4** in POPC liposomes exhibited a high amount of contents release (>95%) in the presence of MMP-9 and low amount of background release (<10%) in the absence of the enzyme (*25*). When 30 mol % of the lipopeptide **GPO3** was incorporated in POPC liposomes, 90% of the encapsulated carboxyfluorescein was released in 30 min in the presence of 2.3 μM MMP-9 (Figure 3B). No release of the dye from the liposomes was observed in the absence of the enzyme (Figure 3B). When we reduced the amount of **GPO3** to 20 mol % in the POPC liposomes, 80% of the contents were released in the presence

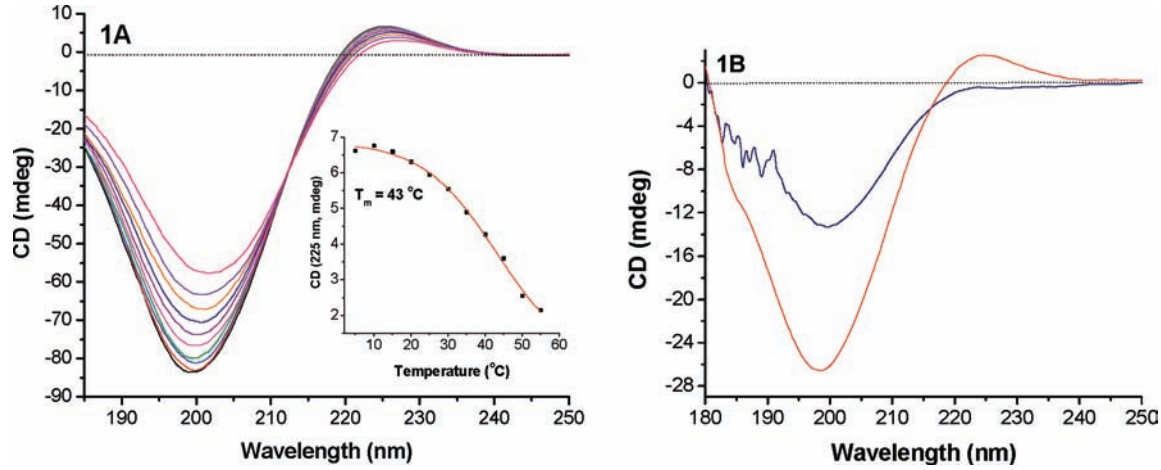

Figure 1. The temperature-dependent CD spectra (5−55 °C) of the lipopeptide **GPO3** in aqueous solution (A) and in POPC liposomes prepared in 5 mM phosphate buffer, pH = 8.0 (B, red trace) are shown. The presence of the positive peak at 225 nm and the large negative peak at 198 nm indicates triple helical structure of this lipopeptide in aqueous solution as well as in liposomes. The inset of (A) shows the melting curve for **GPO3** monitored at 225 nm. When the liposomes were incubated with 2.3 μM recombinant MMP-9 for 30 min, the triple helicity of the liposome-incorporated **GPO3** decreased substantially (B, blue trace). To improve the signal-to-noise ratio, the spectra shown for the liposome-incorporated **GPO3** are the averages of 50 scans. For the last spectrum, the CD spectrum of MMP-9 was subtracted.

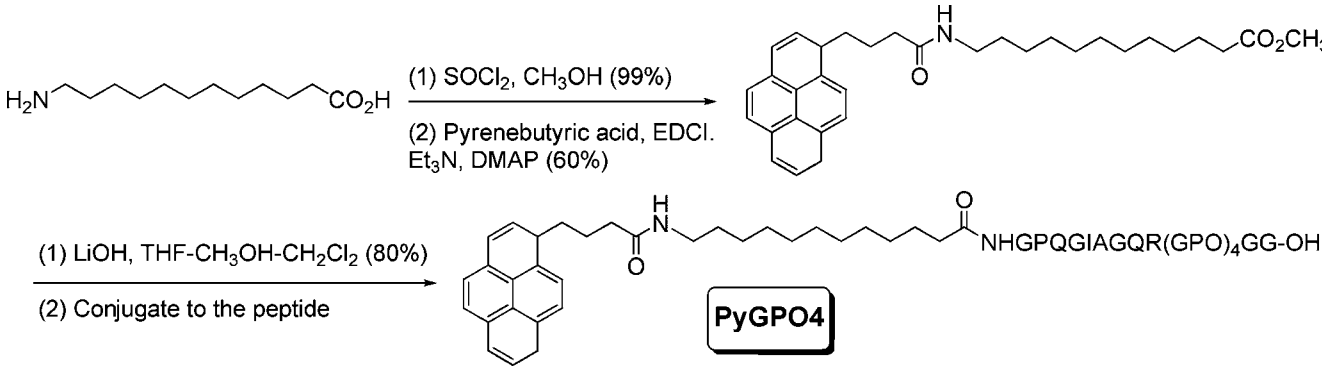
Scheme 1. Synthesis of the Lipopeptide PyGPO4



of 2.3 μM MMP-9 (Figure 4, blue squares). For these liposomes, we observed that 10% of the encapsulated dye was released in the absence of any enzyme (Figure 4, red squares). If the liposomes contained 10 mol % of the lipopeptide **GPO3**, only 38% of the contents were released by MMP-9 (2.3 μM) in 1 h (Figure 4, green circles) with a background release of 10% in the absence of the enzyme (Figure 4, magenta circles). Increasing the amount to **GPO3** to 40 mol % in the liposomes led to a drastic reduction of the release efficiency (<10%, data not shown) in the presence of 2.3 μM of MMP-9. We do not have an explanation for this observation yet. However, this is not due to insufficient peptide cleavage due to shortage of MMP-9, as addition of more enzyme did not improve the release efficiency. Variation of the amount of **GPO5** in the POPC liposomes did not improve the efficiency of the contents release in the presence of the enzyme (Supporting Information).

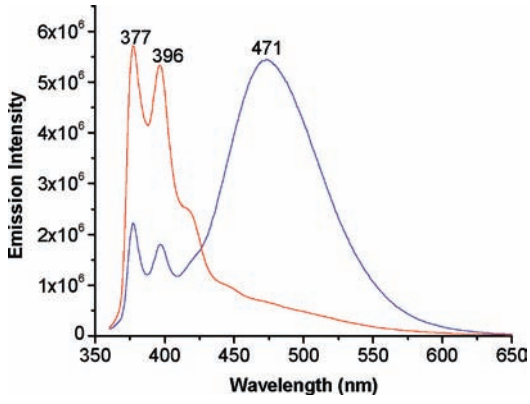


Figure 2. Emission spectra of POPC liposomes incorporating 30 mol % of the lipopeptide **PyGPO4** (blue trace) in 25 mM HEPES buffer, pH = 8.0, containing 100 mM NaCl, 10 mM $CaCl_2$, and 10 μM $ZnCl_2$. The presence of the intense emission at 471 nm indicated the pyrene excimer formation with the lipid bilayer of the liposomes. The emission spectrum of the liposomes after incubation with 2.3 μM MMP-9 for 15 min is shown with the red trace.

Interestingly, these release data also exhibited biexponential rate profiles. The release of the liposomal contents involves several intermediate steps: binding of the enzyme to the exposed peptides, hydrolysis of the peptides, creation of lipid "defects" and lipid reorganization, release of encapsulated carboxyfluorescein, and repairing of the "defects" created in the lipid bilayer. Fitting the observed release data by a biexponential rate equation is clearly an oversimplification of the complex set of steps involved in the triggered release process. Notably, when we decreased the amount of the lipopeptide **GPO3** in the liposomes, the magnitudes of the rate constants for the release remained nearly the same, but the amplitude of the faster rate process progressively increased and the amplitude for the slower step decreased (Table 3). It is possible that the faster of the two steps is the repair of the "defects" created in the lipid bilayer as MMP-9 hydrolyzes the exposed peptides. With less lipopeptide incorporated in the liposomes, it is expected that lower amount of "defects" are created in the bilayers, and hence, they are

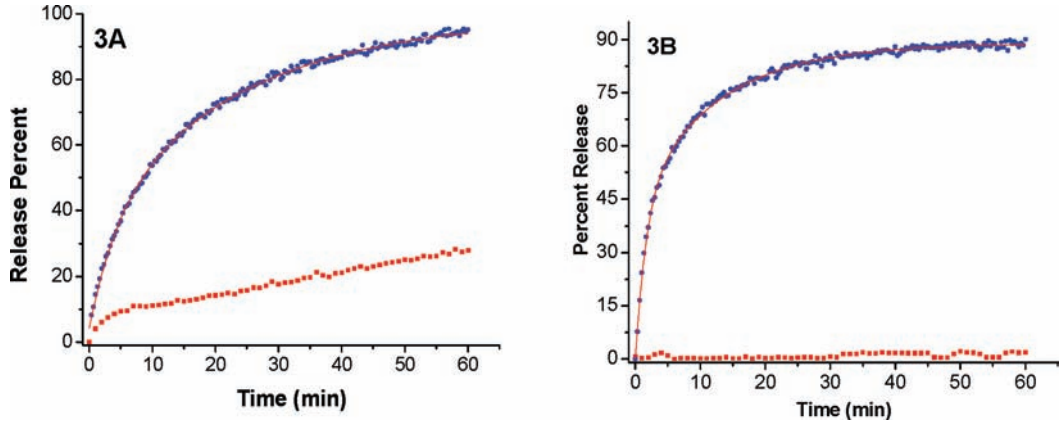

Figure 3. The release profiles for encapsulated carboxyfluorescein (λ_{ex} = 480 nm; λ_{em} = 518 nm) for the liposomes incorporating 30 mol % of the lipopeptide **GPO3** in the presence and absence of MMP-9 in 25 mM HEPES buffer, pH = 8.0 containing 100 mM NaCl, 10 mM $CaCl_2$, and 10 μM $ZnCl_2$. For DOPC liposomes (A), complete dye release was observed (blue circles) in the presence of 2.3 μM MMP-9, and about 25% release was observed in the absence of the enzyme (red squares). For POPC liposomes (B), 90% of the encapsulated dye was released with 2.3 μM MMP-9 (blue circles); in the absence of the enzyme, no dye release was detected (red squares). The lines through the release profiles are the fitted curves using a biexponential rate equation.

Table 2. Calculated Rate Constants (k_1, k_2) and Amplitudes for the Release of Encapsulated Carboxyfluorescein from DOPC and POPC Liposomes Containing 30 mol % of GPO3 in the Presence of 2.3 μM MMP-9 (errors: 3−6%)

repaired quickly. On the basis of these observations, we selected 30 mol % as the optimal amount of lipopeptide in our liposomal formulations.

After optimizing the major lipid component and the amount of lipopeptides in the liposomes, we turned our attention to the response of the release methodology to MMP-9 concentration. It is reported that, in normal tissues, the concentration of the active form of MMP-9 is about 10 nM (*39*). However, for lung cancer patients, the concentration of this enzyme in the bronchial lavage fluid can be as high as 200 nM (*40*). We have previously observed that, for the POPC liposomes containing 30 mol % of the lipopeptide **GPO4**, the rates and the amounts of content release progressively decreased with decreasing concentrations of MMP-9 (*25*). While 2.3 μM MMP-9 completely released the contents within 30 min, 50% of the encapsulated dye release was observed in 1 h in the presence of 200 nM enzyme (*25*). In order to determine if such a desirable property exists for the POPC liposomes containing 30 mol % of the lipopeptide **GPO3**, we added varying concentrations of recombinant human MMP-9 to these liposomes and monitored the release of encapsulated carboxyfluorescein (Figure 5A).

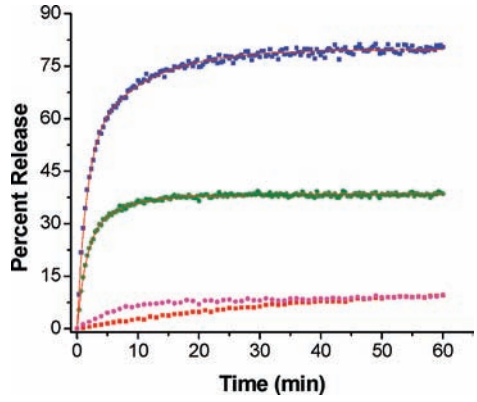

Figure 4. Release profiles for liposome-encapsulated carboxyfluorescein (λ_{ex} = 480 nm; λ_{em} = 518 nm) in the presence and absence of 2.3 μM MMP-9 in 25 mM HEPES buffer, pH = 8.0, containing 100 mM NaCl, 10 mM $CaCl_2$, and 10 μM $ZnCl_2$ for POPC liposomes incorporating 20 mol % (blue squares) and 10 mol % of lipopeptide **GPO3** (green circles). The background releases of the dye in the absence of the enzyme are also shown (red squares, 20 mol % **GPO3**; magenta circles, 10 mol % **GPO3**). The lines through the release profiles are the fitted curved using a biexponential rate equation.

When the concentration of the enzyme was decreased from 2.3 μM to 1.2 μM, we observed a significant reduction in the amount of dye release from the liposomes (Figure 5A). In the presence of 900 nM of MMP-9, only 15% of the encapsulated dye was released. The difference in release profiles between the lipopeptides **GPO4** and **GPO3** may be related to their triple helicity. The Rpn value for **GPO4** is 0.11, while that for **GPO3** is 0.08 (Table 1). Thus, lesser fractions of the lipopeptide **GPO3** exist in triple helical conformation compared to **GPO4**. Upon peptide hydrolysis by MMP-9, the structural perturbation within the lipid bilayer of the liposomes will be more pronounced in the case of the lipopeptide **GPO4** compared to **GPO3**. The liposomes did not release any significant amount of the encapsulated dye in the presence of other MMPs, which cannot hydrolyze triple helical peptides (e.g., MMP-7 and -10; Figure 5B) or in the presence of trypsin (data not shown). Taking into consideration all of these results, we decided to proceed to the cell-based studies employing liposomal formulation incorporating 30 mol % of the lipopepide **GPO3** or **GPO4** with POPC as the major lipid component.

After optimizing the liposomal formulations for contents release triggered by recombinant human MMP-9, we proceeded to determine the release property in the presence of cell-secreted enzyme. We noted, a priori, that our recombinant MMP-9 contains the catalytic and fibronectin domains, but the cell-secreted enzyme has the additional hemopexin domain (*41*). For the cell-based studies, the metastatic breast adenocarcinoma cells MCF7 was selected, as this cell line is known to secrete high amounts of MMP-9 and -2 in the extracellular matrix (*42*). The

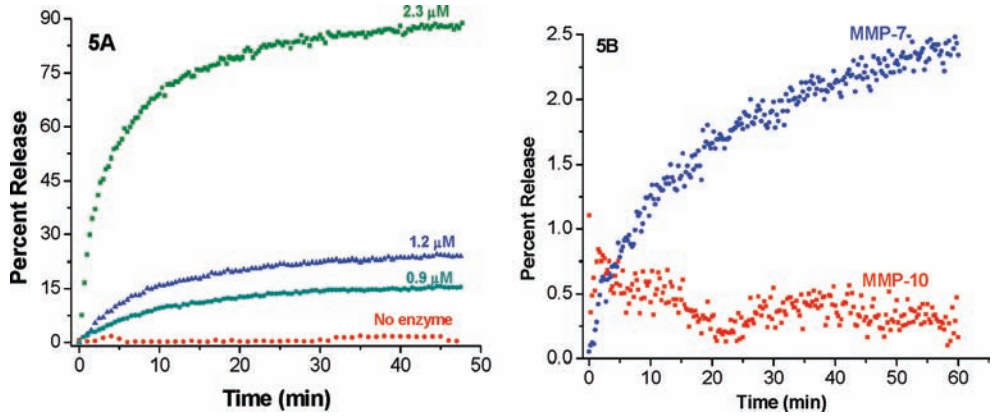

Figure 5. The release profiles for POPC liposome-encapsulated carboxyfluorescein ($\lambda_{ex} = 480$ nm; $\lambda_{em} = 518$ nm) containing 30 mol % of lipopeptide **GPO3** in the presence 2.3 μM (green squares), 1.2 μM (blue triangles), and 900 nM (cyan circles) of MMP-9 in 25 mM HEPES buffer, pH = 8.0, (A) containing 100 mM NaCl, 10 mM $CaCl_2$, and 10 μM $ZnCl_2$. The background release in the absence of any MMP-9 is shown in red circles (A). Part B shows the release of the encapsulated dye from these liposomes in the presence of 2.3 μM MMP-7 (blue circles) and 2.3 μM MMP-10 (red squares) under the same conditions.

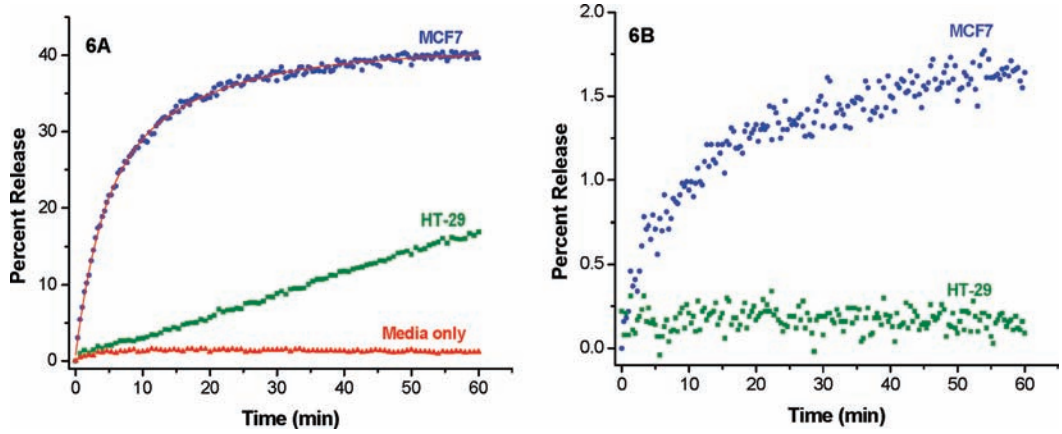

Figure 6. The release profiles for POPC liposome-encapsulated carboxyfluorescein ($\lambda_{ex} = 480$ nm; $\lambda_{em} = 518$ nm) containing 30 mol % of lipopeptide **GPO4** in the presence of cell-secreted MMP-9 in 25 mM HEPES buffer, pH = 8.0, containing 100 mM NaCl, 10 mM $CaCl_2$, and 10 μM $ZnCl_2$ (A). The conditioned media from MCF7 cells released 40% of the encapsulated dye (blue circles) in 30 min; the conditioned media from the HT-29 cells released less than 10% of the contents in 30 min (green squares), and the culture media did not release any contents from the liposomes (red triangles). The line through the blue circles represents the fitted curve using the biexponential rate equation. The liposomes containing 30 mol % of lipopeptide **GPO3** failed to release significant amount of the encapsulated dye under identical experimental conditions with conditioned media from MCF7 (B, blue circles) and HT-29 (B, green squares).

human colorectal adenocarcinoma cells HT-29 were used as the control, since these cells do not secrete high levels of MMP-9 and -2 in the extracellular matrix (*43*). All cells were obtained and cultured following the protocols from American type Culture Collection (Manassas, VA, USA). When the cells achieved 70% of confluency, the old culture medium was replaced with fresh culture medium without phenol red. The cells were further incubated for 24 h, collected, and centrifuged. The supernatants were collected for the release experiments from the liposomes.

For the POPC liposomes containing 30 mol % of the lipopeptide **GPO4**, the conditioned media collected from the cultured MCF7 cells rapidly released 40% of the encapsulated dye within 30 min (Figure 6A). The release data can be fitted with a biexponential rate equation, with $k_1 = 1.0 \times 10^{-3}$ s^{-1} (44% amplitude) and $k_2 = 2.5 \times 10^{-3}$ s^{-1} (56% amplitude). These liposomes in the presence of the conditioned media collected from the HT-29 cells showed a very different profile (linear), slowly releasing less that 10% of the contents in 30 min. The cell culture media (for both cells) did not release any liposome-encapsulated dye during the same period of time (Figure 6A). However, liposomes incorporating 30 mol % lipopeptide **GPO3** failed to release any encapsulated contents in the presence of conditioned media from the MCF7 or the HT-29 cells (Figure 6B).

The concentrations of active MMP-9 and -2 were estimated to be 150 nM in the conditioned media from the MCF7 cells and 25−30 nM for the conditioned media from the HT-29 cells (by employing a fluorogenic MMP-9 activity assay kit from Biomol International). Previously, we observed that POPC liposomes with 30 mol % of lipopeptide **GPO4** released 50% of the encapsulated contents in the presence of 200 nM recombinant, two-domain MMP-9 (*25*). Since the additional hemopexin domain present in the cell-secreted MMP-9 does not participate in unwinding or catalysis of small triple helical peptide substrates (*44*), the results obtained with the recombinant MMP-9 corroborate the results with cell-secreted MMP-9. The substrate selectivities for MMP-9 and -2 are very similar (*34*), and it is expected that the MMP-2 present in the conditioned media will also hydrolyze the triple-helical peptides on the liposome surface and contribute to the release of the encapsulated dye.

The release profile in Figure 6A in the presence of the conditioned media from the MCF7 cells showed an initial linear phase followed by a slowly decreasing phase. The first step in the enzymatic release of the dye from the liposomes is the cleavage of the lipopeptide **GPO4** by the cell-secreted MMP-2 and -9. We estimated the concentration of **GPO4** on the outer lipid layer of the liposomes to be about 100 nM and the

concentration of MMP-2 and -9 in the conditioned media to be about 150 nM. Initially, the lipopeptides are rapidly cleaved by MMP-2 and -9 in the conditioned media, leading to the rapid release of the encapsulated carboxyfluorescein. As the concentration of **GPO4** decreases, the rate of cleavage of this substrate by MMP-2 and -9 is reduced, leading to the slow release of the liposomal contents. On the other hand, the concentration of MMP-2 and -9 in the conditioned media from the HT-29 cells is about 30 nM. Since the concentrations of **GPO4** in the liposomes are higher compared to the MMP concentration, the substrate cleavage by the enzymes proceeds slowly. This is reflected in the slow linear release of the liposome-encapsulated dye in the presence of the conditioned media from the HT-29 cells (Figure 6A).

CONCLUSION

We have demonstrated that, by optimizing the structure and the amount of the lipopeptide substrate and the major lipid component, liposomal contents can be rapidly released in the presence of the extracellular pathogenic enzyme MMP-9. The amount of contents released depends on the mismatch between the fatty acid moieties of the lipopeptide and the major lipid of the liposomal formulations. By utilizing the optimized liposomal formulations, we also demonstrated that, while cancer cells (HT-29) which secrete low levels of MMP-9 failed to release significant amounts of the liposomal contents, metastatic cancer cells (MCF7) secreting high amounts of the enzyme rapidly released the encapsulated contents from the liposomes. We are currently optimizing the liposomal formulations by incorporating 10 mol % of a poly(ethylene glycol)-containing lipid to impart a long-circulating property to the liposomes. These studies and release studies using a mouse model of metastatic breast adenocarcinoma will be reported in the future.

ACKNOWLEDGMENT

This research was supported by the NIH grants 1R01 CA113746, 1 R01 CA 132034 and NSF DMR-0705767 to S.M. and D.K.S. J.S. thanks the support of the proteomics core facility by NIH Grant P20 RR016741 from the INBRE Program of the NCRR.

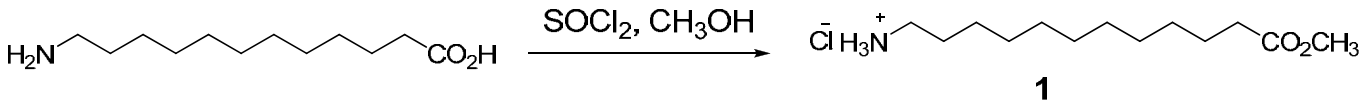
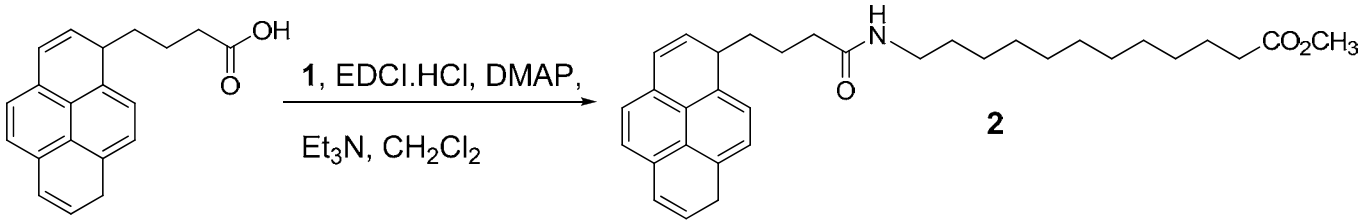
Synthetic details for PyGPO4:

Reagents were purchased from Alfa Aesar or TCI America. EDCI.HCl was purchased from ChemPep, Inc. All organic solvents used were distilled. Melting points were determined using a micro melting point apparatus. ^{1}H and ^{13}C NMR spectra were recorded on 300 or 400 MHz spectrometer. NMR spectra was recorded either using $CDCl_3$ or DMSO-d_6 as solvents with TMS as the internal standard. TLC was performed with Adsorbil plus IP, 20 x 20 cm plate, 250 μm (Altech Associates, Inc). TLC plates were visualized under UV light or in an iodine chamber. Flash column chromatography was carried out with Merck Silica gel 60.



1

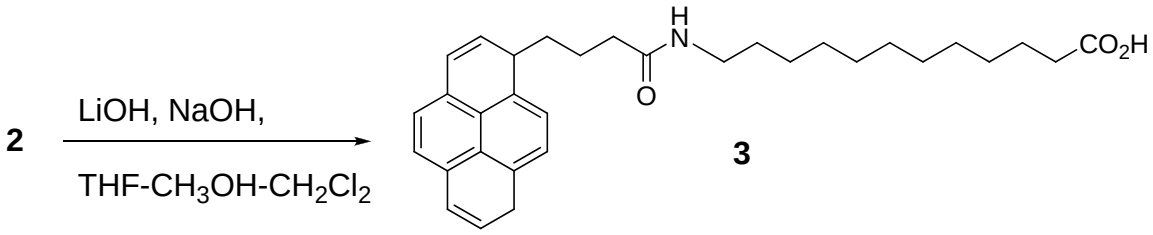
Compound 1: To a suspension of 12-aminolauric acid (5.0 g, 23.2 mmol, 1 equiv) in methanol (50 mL) under nitrogen, thionyl chloride (2.7 mL, 1.6 equiv) was added at 0 ^{o}C. The reaction mixture was stirred under a nitrogen atmosphere at room temperature for 2 h and then heated to reflux for 2 h. After cooling the reaction to room temperature, the organic solvents were evaporated in a rotary evaporator giving a white solid. The white solid was dried under vacuum and used for the next step without further purification. Yield: 5.30 g (99%), mp: 157-160 ^{o}C; ^{1}H NMR ($CDCl_3$, 400 MHz): δ ppm 1.22-1.44 (m, 14H) 1.55-1.66 (m, 2H) 1.76 (quin, J = 7.5 Hz, 2H) 2.30 (t, J = 7.5 Hz, 2H) 2.98 (t, J = 7.7 Hz, 2H) 3.67 (s, 3H) 8.31 (br, s, 3H).



2

Compound 2: To a suspension of pyrenebutyric acid (2.0 g, 6.93 mmol) in CH_2Cl_2 (180 mL) under nitorgen triethylamine (1.32 mL, 9.47 mmol) was added. The resultant mixture was stirred for 5 min, cooled to 0 ^{o}C and compound **1** (1.446 g, 6.30 mmol), 4-(N,N-dimethylamino)pyridine (DMAP; 0.924 g, 7.56 mmol) and EDCI.HCl (1.450 g, 7.56 mmol) were added sequentially. The reaction mixture was stirred at room temperature under nitrogen overnight. The reaction was quenched with water and the organic layer was washed with 1 N HCl, 1 N NaOH and brine respectively. The organic layer was then

dried over $MgSO_4$ and the solvent was removed under reduced pressure. The crude product was purified by silica gel flash chromatography (eluant: 1:1 ethylacetate in hexane, R_f = 0.3) to obtain the pure product as yellowish brown solid. Yield: 2.08 g (60%), mp: 95-97 ^oC; ^1H NMR ($CDCl_3$, 300 MHz): δ ppm 1.24 (br, s, 14H) 1.45 (br, s, 2H) 1.51-1.67 (m, 3H) 2.13-2.33 (m, 6H) 3.17-3.29 (m, 2H) 3.40 (t, J = 7.0 Hz, 2H) 3.66 (s, 3H) 5.34 (br, s, 1H) 7.87 (d, J = 7.7 Hz, 1H) 7.95-8.06 (m, 3H) 8.08-8.20 (m, 4H) 8.31 (d, J = 9.3 Hz, 1H). ^{13}C NMR (DMSO-d_6, 100 MHz): δ ppm 25.05, 27.07, 28.31, 29.07, 29.28, 29.40, 29.50, 29.55, 29.63, 29.82, 32.94, 33.89, 35.76, 39.06, 51.81 124.14, 124.83, 125.43, 125.61, 126.80, 127.18, 127.89, 128.10, 128.85, 129.96, 129.99, 131.11, 131.56, 137.24, 172.31, 174.00.



Compound 3: The ester **2** (1.264 g, 2.52 mmol) was hydrolyzed with LiOH (1.057 g, 25.1 mmol) in MeOH-THF-CH_2Cl_2 (20-10-5 mL). A few drops of 1 N NaOH was also added. The reaction mixture was stirred overnight when a white residue formed. On acidification with 2 N HCl, the white solid dissolved. After evaporation of the solvents, the white solid obtained was washed with water, filtered and lyophilized. Yield: 1.162 g (94%), mp: 129-132 ^oC; ^1H NMR (DMSO-d_6, 300 MHz) δ ppm 1.19 (m, 14H) 1.33-1.48 (m, 4H) 2.02 (d, J = 6.8 Hz, 2H) 2.14 (t, J = 7.0 Hz, 2H) 2.22 (d, J = 6.4 Hz, 2H) 3.06 (d, J = 6.0 Hz, 2H) 3.21-3.32 (m, 2H) 7.83 (br, s, 1H) 7.94 (d, J = 7.7 Hz, 1H) 8.07 (d, J = 7.7 Hz, 1H) 8.14 (s, 2H) 8.19-8.31 (m, 4H) 8.38 (d, J = 9.3 Hz, 1H). ^{13}C NMR (DMSO-d_6, 100 MHz): δ ppm 24.43, 26.39, 27.61, 28.49, 28.68, 28.72, 28.86, 28.90, 28.96, 29.14, 32.24, 33.62, 35.05, 38.38, 38.89, 123.45,124.22, 124.75, 124.89, 126.10, 126.46, 127.16, 127.42, 127.46, 128.13, 129.28, 130.40, 130.87, 136.55, 171.61, 174.45.

Synthesis of pyrene conjuagted lipo-peptide PyGPO4:

The synthesized pyrene conjugated fatty acid (compound **3**) was used in 5 fold excess for coupling with the N-terminus of the peptide under microwave condition, following the same protocol as discussed in the experimental procedure. The purification procedure was the same as described for **GPO4** in the manuscript and characterized by MALDI-ToF mass spectrum. M^+ calculated: 2535.43; observed: 2534.54.

Liposome preparation using PyGPO4:

A stock solution of the lipo-peptide was prepared by dissolving the compound in methanol:chloroform (1:5) mixture to give a final concentration of 1 mg/mL. A lipid thin film was prepared by adding 1.4 mL of this stock solution to 250 μL of POPC solution in $CHCl_3$ and rotary evaporating the organic solvents at 40 ^{0}C. The thin film was dried overnight in vacuum. The dry lipid film was next hydrated with 25 mM HEPES buffer (pH = 8.0) containing 100 mM NaCl, 10 mM $CaCl_2$ and 10 μM $ZnCl_2$ by slow rotation at 60 ^{0}C for 1 h. After storing at 4 ^{0}C for 3 h, the hydrated solution was sonicated by probe sonicator for 1 h followed by 11 cycles of extrusion through a 100 nm polycarbonate membrane. The liposomes were diluted 20 times before recording the fluorescent spectra.

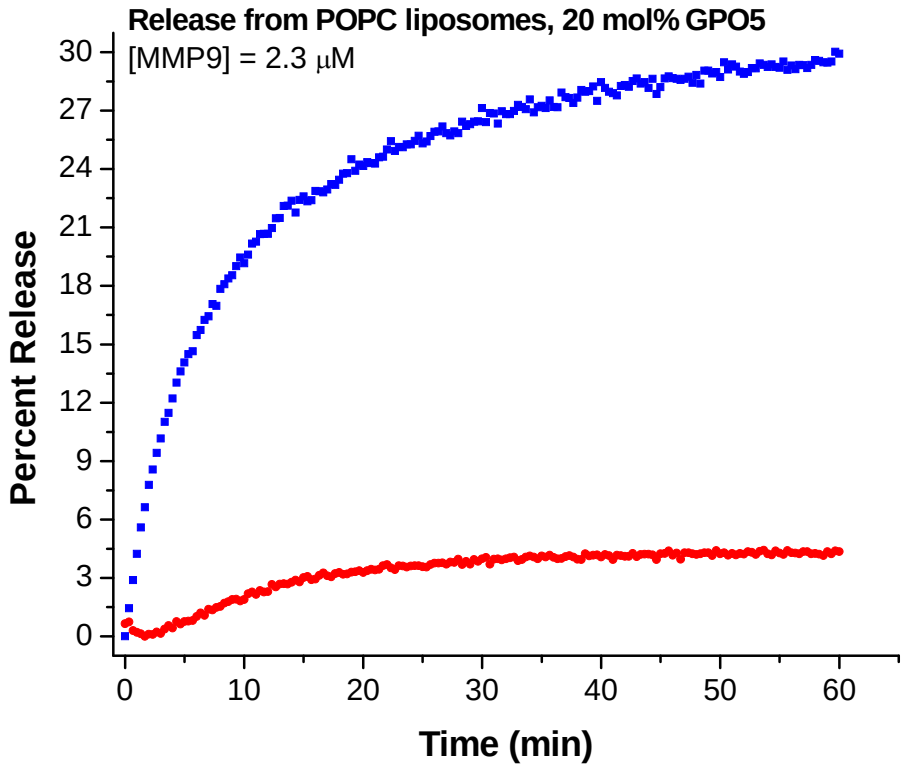


Figure S1. The carboxyfluorescein release profiles from POPC liposome containing 20 mol% of the lipopeptide **GPO5** (λ_{ex} = 480 nm; λ_{em} = 518 nm) in the presence and absence of 2.3 μM MMP-9 in 25 mM HEPES buffer, pH = 8.0 containing 100 mM NaCl, 10 mM $CaCl_2$ and 10 mM $ZnCl_2$. The enzyme released 30% of the dye in 1 h (blue squares). In the absence of MMP-9, <5% of the dye was released in 1 h (red circles).

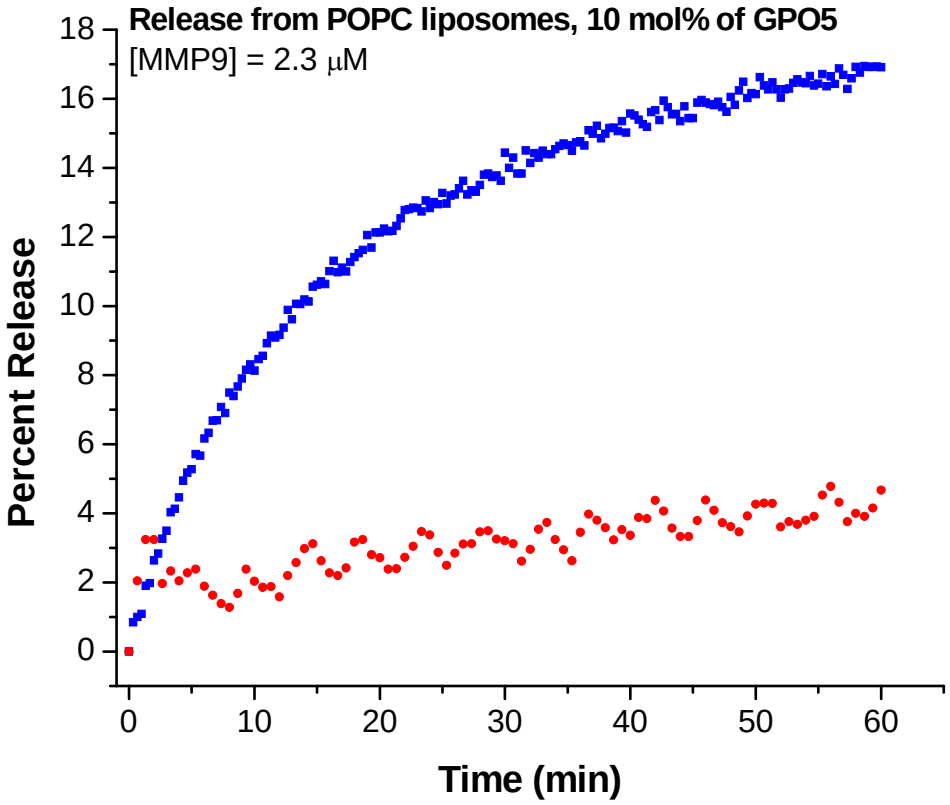

Figure S2. The carboxyfluorescein release profiles from POPC liposome containing 10 mol% of the lipopeptide **GPO5** (λ_{ex} = 480 nm; λ_{em} = 518 nm) in the presence and absence of 2.3 μM MMP-9 in 25 mM HEPES buffer, pH = 8.0 containing 100 mM NaCl, 10 mM $CaCl_2$ and 10 mM $ZnCl_2$. The enzyme released 18% of the dye in 1 h (blue squares). In the absence of MMP-9, <5% of the dye was released in 1 h (red circles).

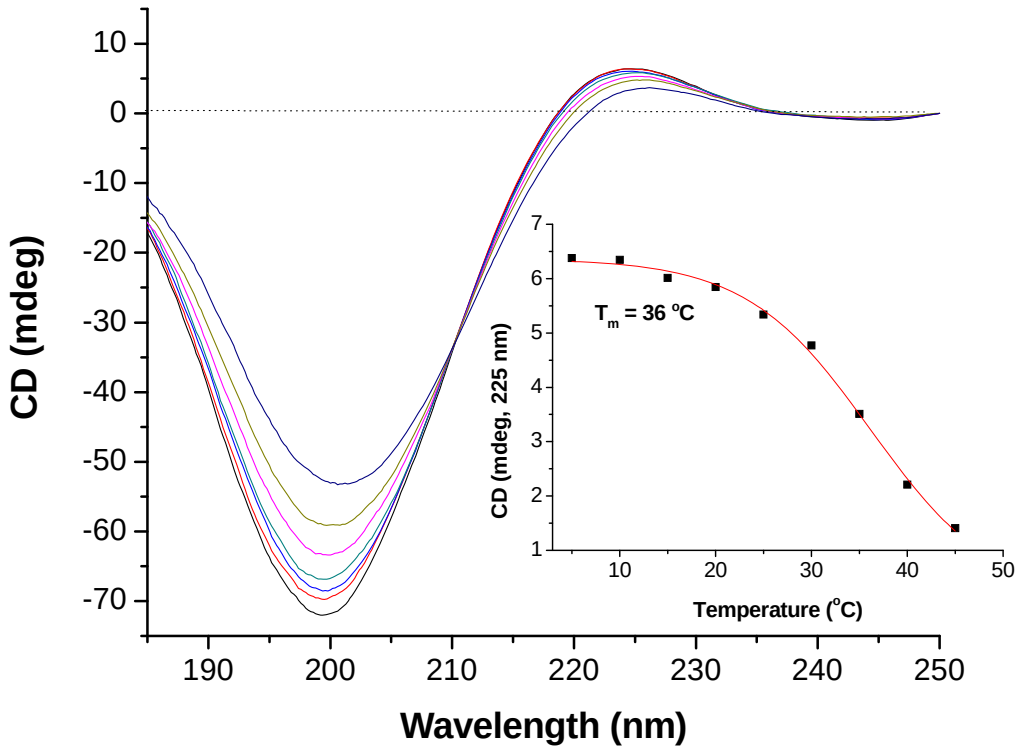

Figure S4. The temperature dependent CD spectra (5 – 45 °C) of the lipopeptide **PyGPO4** in aqueous solution. The presence of the positive peak at 225 nm and the large negative peak at 198 nm indicate triple helical structure of this lipopeptide in aqueous solution. The inset shows the melting curve for **GPO5** monitored at 225 nm. The melting temperature was calculated to be 36 °C.

Radiosynthesis of New [^{90}Y]-DOTA-Based Maleimide Reagents Suitable for the Prelabeling of Thiol-Bearing L-Oligonucleotides and Peptides

Joern Schlesinger,[†] Cindy Fischer,[†] Inge Koezle,[†] Stefan Vonhoff,[‡] Sven Klussmann,[‡] Ralf Bergmann,[†] Hans-Jurgen Pietzsch,*[,†] and Joerg Steinbach[†]

Institute of Radiopharmacy, Forschungszentrum Dresden-Rossendorf, Germany, and NOXXON Pharma AG, Berlin, Germany.
Received March 4, 2009; Revised Manuscript Received June 8, 2009

We describe the radiosynthesis of two new [^{90}Y]-DOTA-based maleimide reagents, suitable for the mild radiolabeling of L-RNAs and peptides modified with thiol-bearing linkers. The synthesis procedure of both maleimide-bearing ^{90}Y complexes, [{(2*S*)-2-[4-(2,5-dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)benzyl]-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl}tetraacetato][^{90}Y]yttrate(1-)([^{90}Y]**3**) and [{(2*S*)-2-(4-{[4-(2,5-dioxo-2,5-dihydro-1*H*-pyrrol-1-yl)butanoyl]amino}benzyl)-1,4,7,10-tetraaza-cyclododecane-1,4,7,10-tetrayl]tetraacetato}[^{90}Y]yttrate(1-)([^{90}Y]**4**), was optimized in terms of an easy purification method via solid-phase extraction (SPE). Application as well as reactivity of both maleimide reagents were initially evaluated by the prelabeling of glutathione (GSH) and a thiol-modified 12mer L-RNA as model substances. In comparison to the *N*-aryl maleimide-bearing complex [^{90}Y]**3**, *N*-alkyl maleimide-bearing complex [^{90}Y]**4** showed an increased hydrolytic stability at pH ≥ 7. A slightly higher reactivity was found for [^{90}Y]**3** by prelabeling of 0.1 and 1 μg glutathione, respectively, in phosphate buffer (pH 7.2) at room temperature. In terms of very high radiochemical yields, the direct radiolabeling of DOTA−L-RNA conjugate with [^{90}Y]YCl_3 proved to be more suitable than the prelabeling of the thiol-modified 12mer L-RNA derivative with [^{90}Y]**4**.

INTRODUCTION

Radioisotopes of yttrium and the lanthanides are increasingly becoming an important component of several medical applications, e.g., for molecular imaging and targeted radionuclide therapy of cancer diseases (*1*, *2*). The trivalent radiometals are routinely conjugated to targeting molecules via the bifunctional chelator (BFC)[1]approach. A frequently utilized chelator for these radiometals is (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl)tetraacetic acid (DOTA). DOTA is known to form thermodynamically stable complexes with lanthanides and yttrium isotopes, and the corresponding radiometal complexes exhibit in many cases high kinetic inertness *in vivo* (*3*). However, the slow complexation rates of trivalent radiometals with DOTA necessitate elevated temperatures (up to 80 °C) to achieve sufficient radiochemical yields (RCYs) (*4*). This may be a drawback, especially for the radiolabeling of thermally sensitive molecules, such as biopharmaceuticals (e.g., DOTA-modified antibodies or antibody fragments). On this account, previous works already focused on optimization of radiolabeling conditions to achieve high RCY without compromising the biological activity (*5*, *6*).

A promising alternative to the "direct" radiolabeling of DOTA-(bio)conjugates ("postlabeling") is the use of so-called "prelabeling" agents. Such a reagent is constituted of the radiometal complex and a reactive coupling moiety, e.g., a bromoacetyl or isothiocyanato group. In such a way, primary amine groups of thermally sensitive molecules can be radiolabeled under mild conditions (≤37 °C) by reaction with the prelabeling agent. However, until now only a few radiometal-DOTA-based prelabeling agents were described (see Figure 1) (*7*−*11*). Another attractive coupling moiety of such a prelabeling agent could be the maleimide group. Maleimide reagents readily react with thiols (e.g., from cysteine residues of proteins or peptides) under physiological conditions (37 °C, pH 7.4) to form thioether bonds (*12*).

In this work, we present the synthesis of two novel [^{90}Y]-DOTA-based maleimide reagents (see Figure 2), suitable for a mild radiolabeling of a peptide or a thiol-modified L-RNA. An L-RNA is a mirror-image oligonucleotide constructed of L-configured riboses and characterized by an extraordinarily high stability against enzymatic degradation (*13*). By using ^{90}Y-labeled L-RNAs as molecular probes, we pursue a strategy for an improved radioimmunotherapy of cancer using pretargeting methods (*14*, *15*). However, the *in vivo* application of the ^{90}Y-labeled L-RNA requires a high effective specific activity (ESA), to prevent unlabeled L-RNA molecules from saturating the complementary L-oligonucleotide strands, which are present in the target tissue. Thus, both prelabeling and postlabeling of an L-RNA have been performed, to compare the two approaches with respect to the achievable RCYs and ESAs. The purpose of this work was to enhance RCY and ESA for ^{90}Y-labeled L-RNAs, by using prelabeling methods. Therefore, application as well as reactivity of both maleimide reagents were initially evaluated by the labeling of glutathione (GSH) as a model substance.

EXPERIMENTAL PROCEDURES

Materials. L-RNA [sequence: 5′-(1-hydroxy-7,8-dithia-tetradecyl) UGACUGACUGAC-3′, MW 4124] was synthesized at NOXXON Pharma AG (Germany). Synthesis of the DOTA-modified 12mer L-RNA **10** was described elsewhere (*16*). Glutathione (reduced) was from Fluka (Germany). (*S*)-2-(4-

[90Y]**4**

Figure 2. Chemical structures of the new [90Y]-DOTA-based maleimide reagents [90Y]**3** and [90Y]**4**.

Aminobenzyl)-1,4,7,10-tetraazacyclododecane-*N*,*N′*,*N″*,*N‴*-tetraacetic acid (**1**) was purchased from Macrocyclics (Dallas, TX, USA). The radionuclide 90Y was purchased as [90Y]YCl_3 in 0.04 M HCl (500 μL) from QSA Global GmbH (Germany) or Polatom (Poland). Measurements of 90Y were done in the 90Y channel of a dose calibrator ISOMED 2000 (Nuklear-Medizintechnik Dresden GmbH, Germany) by measuring the *bremsstrahlung*. Reactions and incubations were performed in 1.5 mL DNA low-binding tubes (Eppendorf, Germany) using a Thermomixer Comfort (Eppendorf, Germany). For evaporation of small sample volumes, a Concentrator 5301 (Eppendorf, Germany) was used. Lyophilization was carried out using an Alpha 2-4 LSC (Christ, Germany). L-RNA concentrations were determined via measurement of the UV absorbance at 260 nm using an Eppendorf (Germany) BIOPhotometer. Measurements of the pH value in small volumes were performed using the pH-sensor Biotrode (Metrohm, Germany).

Chromatographic Purification and Analysis. HPLC analyses were performed with a WellChrom 2700 system (Knauer, Germany), coupled with the radioactivity detector VA-S-968 (Robotron, Germany). HPLC purifications were also performed with a WellChrom K-2201 system. The HPLC columns were as follows: (A) Aqua C_{18} column (Phenomenex, USA) 250 × 4.6 mm i.d., 5 μm, (B) Aqua C_{18} column (Phenomenex, USA) 250 × 10 mm i.d., 5 μm, and (C) XTerra MS C_{18} column (Waters, USA) 3.0 × 50 mm i.d., 2.5 μm. System A(I): flow 1 mL/min, UV 235 nm, 50 mM triethylammonium acetate buffer (TEAA) containing 7% CH_3CN (a) and 50% CH_3CN (b), gradient (a): 0 min 100%, 10 min 80%, 15 min 60%, 20 min 0%. System A(II): flow 1 mL/min, UV 240 or 260 nm, 50 mM NH_4OAc buffer (pH 7.0) containing 5% CH_3CN (a) and 50% CH_3CN (b), gradient (a): 0 min 100%, 30 min 80%, 35 min 60%, 38 min 0%. System A(III): flow 1 mL/min, UV 240 nm, 0−25 min 50 mM TEAA (pH 7.0) containing 7% CH_3CN. System B(I): flow 4 mL/min, UV 240 nm, 50 mM TEAA containing 7% CH_3CN (a) and 50% CH_3CN (b), gradient (a): 0 min 100%, 10 min 90%, 15 min 60%, 20−25 min 0%. System B(II): flow 4 mL/min, UV 240 nm, 50 mM TEAA containing 7% CH_3CN (a) and 50% CH_3CN (b), gradient (*a*): 0−20 min 100%, 40−55 min 0%. System C(I): flow 0.35 mL/min, UV 260 nm, 50 mM TEAA containing 7% CH_3CN (a) and 50% CH_3CN (b), gradient (a): 0 min 100%, 10 min 90%, 15 min 60%, 22 min 0%.

TLC was performed on precoated RP18 plates (Merck, Germany) with System I (50 mM TEAA containing 20% CH_3CN) and System II (MeOH/10% NH_4OAc (9:1 v/v)). The dried TLC plates were exposed to phosphor imaging plates for 10 min and scanned with a Fujix BAS 5000 (Fujifilm Europe, Germany). Radiochemical yields (RCYs) of the reactions and radiochemical purity (RCP) of the compounds were calculated from the activity area of the product peak related to the total activity area using AIDA software (Raytest, Germany). Non-radioactive compounds were visualized under UV-light at 254 nm.

Solid-phase extractions (SPE) were performed on SepPak Plus C_{18} and SepPak QMA Acell Plus cartridges (Waters, USA). Elution profiles of **1**, Y**2**, Y**3**, and Y**4** and the corresponding hydrolysis products Y**12** and Y**13** were initially monitored at 254 nm on the cartridges using an ÄKTAprime plus system (GE Healthcare, Germany). UV-chromatograms were evaluated with PrimeView software (GE Healthcare, Germany).

Gel Electrophoresis. PAGE was performed with vertical electrophoresis unit TV200YK (Biostep, Germany) running native 20% polyacrylamide gels at 10 mA and 10 °C in 1× TBE running buffer. A 10 bp DNA ladder (Fermentas, USA) was applied as a molecular weight standard. After electrophoresis, gels were exposed to phosphor imaging plates for 2−4 min. The plates were scanned and the RCYs of the conjugations and RCP of the radiolabeled L-RNA derivatives were calculated as

described above using AIDA software (Raytest, Germany). Subsequently, the gel was stained using ethidium bromide, and the DNA ladder was visualized under UV-light and photographed (Gene Flash, Syngene, UK).

Mass Spectrometry. Mass spectra were recorded on a Quattro Ultima ESI-MS (Micromass, UK) and on a Daltonics Autoflex II TOF/TOF50 (Bruker). The MALDI-TOF matrix, 3-hydroxypicolinic acid, was purchased from Aldrich. The L-RNA probes were desalted for MALDI-TOF measurements using C_{18} purification tips (ZipTip, Millipore, USA) as described elsewhere (*17*).

Chemistry. Synthesis, purification, and characterization of the $\Delta(\delta\delta\delta\delta)$ (twisted square antiprism, TSAP) and $\Lambda(\delta\delta\delta\delta)$ (square antiprism, SAP) isomers of [(2*S*)-2-(4-aminobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl]tetraacetato}-yttrate(1-) (Y**2**) were described in-depth elsewhere (*13*). Following experimental procedures for synthesis of the TSAP and SAP isomers of Y**3**, Y**4**, Y**6**, Y**7**, and Y**9**, respectively, based on the corresponding TSAP and SAP isomers of Y**2**.

*Preparation of [{(2S)-2-[4-(2,5-Dioxo-2,5-dihydro-1H-pyrrol-1-yl)benzyl]-1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetrayl}tetra-acetato]yttrate(1-) (Y***3***).* The synthesis of Y**3** was adapted and optimized from ref 18. Briefly, *N*-methoxycarbonylmaleimide (15 mg, 96 μmol) was dissolved in 150 μL 1,4-dioxane and added to a solution of Y**2** (3.1 mg, 5.2 μmol) in 300 μL H_2O and 150 μL saturated $NaHCO_3$. The reaction mixture (pH 9.3) was incubated at 25 °C for a maximum reaction time of 15 min. The mixture was diluted with (250 μL) 1 M HCl to adjust pH 2. Subsequently, the mixture was fractionized by HPLC. HPLC fractions containing Y**3** were concentrated by evaporation and lyophilized to obtain 2.9 mg (4.3 μmol) of Y**3** as a white powder. ESI-MS: Y**3** (TSAP and SAP isomer) *m*/*z*: 674 $[M]^-$. HPLC: A(I): R_T(Y**3** TSAP) 17.1 min, R_T(Y**3** SAP) 17.3 min. B(I): R_T(Y**3** TSAP) 17.4 min, R_T(Y**3** SAP) 17.6 min. TLC: (I): R_f(Y**3**) 0.3, (II) R_f(Y**3**) 0.6.

*Preparation of [{(2S)-2-(4-{[4-(2,5-Dioxo-2,5-dihydro-1H-pyrrol-1-yl)butanoyl]amino}benzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl]tetraacetato}yttrate(1-) (Y***4***).* *N*-(γ-Maleimidobutyryloxy)succinimide ester (GMBS, 7.8 mg, 27.8 μmol) was dissolved in 250 μL DMSO and added to a solution of Y**2** (2.6 mg, 4.4 μmol) in (750 μL) 67 mM sodium phosphate buffer (pH 7.2). The reaction mixture (pH 7.9) was incubated at 25 °C for 30 min. Subsequently, the mixture was fractionized by HPLC. HPLC fractions containing Y**4** were concentrated by evaporation and lyophilized to obtain 3.0 mg (4.0 μmol) of Y**4** as a white powder. ESI-MS: Y**4** (TSAP and SAP isomer) *m*/*z*: 761 $[M]^-$. HPLC: A(II): R_T(Y**4** TSAP) 33.5 min, R_T(Y**4** SAP) 35.8 min. B(II): R_T(Y**4** TSAP) 31.4 min, R_T(Y**4** SAP) 31.6 min. TLC: (I): R_f(Y**4**) 0.3, (II) R_f(Y**4**) 0.7.

*Preparation of Y-DID-GSH (Y***6***).* The lyophilized compound Y**3** (1.1 mg, 1.6 μmol) and GSH **5** (2.7 mg, 8.8 μmol) were dissolved in (600 μL) 67 mM sodium phosphate buffer (pH 6.8). The reaction mixture (pH 5.1) was incubated at 25 °C for 25 min. Subsequently, the product Y**6** was fractionized by HPLC and lyophilized to obtain 1.4 mg (1.5 μmol) of Y**6**. ESI-MS: Y**6** (TSAP and SAP isomer) *m*/*z*: 981 $[M]^-$. HPLC: A(I): R_T(Y**6** TSAP) 7.1 min, R_T(Y**6** SAP) 9.0 min. TLC: (II) R_f(Y**6**) 0.1.

*Preparation of Y-DIBD-GSH (Y***7***).* The lyophilized compound Y**4** (1.0 mg, 1.3 μmol) and GSH **5** (3.0 mg, 9.8 μmol) were dissolved in (600 μL) 67 mM sodium phosphate buffer (pH 7.2). The reaction mixture (pH 6.6) was incubated at 25 °C for 25 min. Subsequently, the product Y**7** was fractionized by HPLC and lyophilized to obtain 1.4 mg (1.3 μmol) of Y**7**. ESI-MS: Y**7** (TSAP and SAP isomer) *m*/*z*: 1066 $[M]^-$. HPLC: A(II): R_T(Y**7** TSAP) 27.9 min, R_T(Y**7** SAP) 28.3 min. TLC: (II) R_f(Y**7**) 0.1.

Conjugation of L-RNA 8 with Y4. The thiol-modified L-RNA was protected as a disulfide (5′-(1-hydroxy-7,8-dithia-tetradecyl) UGACUGACUGAC-3′). The protecting group was initially removed by treatment with dithiotreitol (DTT). Briefly, L-RNA (5 mg, 1.2 μmol) and DTT (9.3 mg, 60 μmol) were dissolved in (1.76 mL) 67 mM sodium phosphate buffer (pH 8.0) and incubated for 60 min at 25 °C. Subsequently, 5′-thiolhexyl L-RNA **7** was purified via size exclusion chromatography (SEC) using an ÄKTAprime plus system (GE Healthcare, Germany) with a Superdex 75 HR 10/30 column (GE Healthcare, Germany) and 67 mM sodium phosphate buffer (pH 7.0, saturated with nitrogen) as mobile phase at a flow rate of 30 mL/h. SEC-fractions containing **8** were lyophilized and stored at −24 °C. The identity of the 5′-thiolhexyl L-RNA **7** was verified by mass spectrometry.

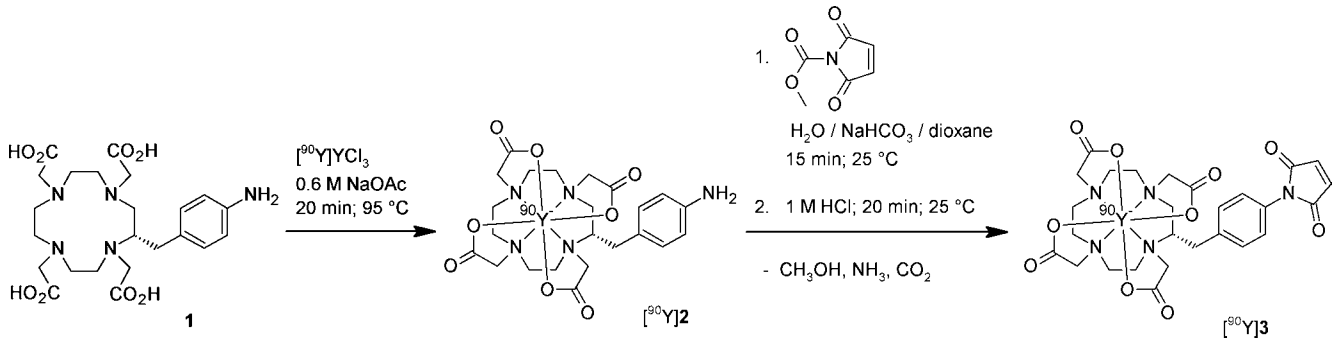
The lyophilized compound Y**4** (0.12 mg, 160 nmol) and L-RNA **8** (0.24 mg, 60 nmol) were dissolved in (250 μL) 67 mM sodium phosphate buffer (pH 7.0). The reaction mixture (pH 6.6) was incubated for 25 min at 25 °C under argon atmosphere. Subsequently, the product Y**9** was fractionized by HPLC and lyophilized to obtain 0.27 mg (57 nmol) of Y**9**. Maldi-TOF: **8** *m*/*z* 3991 $[M + H]^+$, Y**9** (TSAP and SAP isomer) *m*/*z* 4751 $[M + H]^+$. SEC: V_R(**8**) 12.4 mL. HPLC: A(II): R_T(**8**) 25.4 min, R_T(Y**9** TSAP) 28.5 min, R_T(Y**9** SAP) 29.1 min.

Determination of Hydrolytic Stability of Y3 and Y4. First, the corresponding hydrolysis products [(2*Z*)-4-oxo-4-{[4-({(2*S*)-1,4,7,10-tetrakis[(carboxymethyl]-1,4,7,10-tetraazacyclododecan-2-yl}methyl)phenyl]amino}but-2-enoato(4-)]yttrate(1-) (Y**12**) and [(2*Z*)-4-oxo-4-[(4-oxo-4-{[4-({(2*S*)-1,4,7,10-tetrakis[(carboxymethyl]-1,4,7,10-tetraazacyclododecan-2-yl}methyl)phenyl]amino}butyl)amino]but-2-enoato(4-)]yttrate(1-) (Y**13**) of the maleimides Y**3** and Y**4** were synthesized. Briefly, Y**3** and Y**4** were hydrolyzed after their synthesis by the addition of NaOH to the reaction mixtures (pH 9.0). The corresponding maleamic acid derivatives Y**12** and Y**13** were separated via HPLC and analyzed by ESI-MS. To determine the hydrolytic stability of Y**3** and Y**4** depending on time, Y**3** (1 mg, 1.5 μmol) and Y**4** (1 mg, 1.3 μmol) were separately dissolved in (500 μL) 67 mM sodium phosphate buffer (pH 7.0) and incubated at 25 °C for 96 h. Aliquots were sampled after 0, 1, 2, 3, 4, 5, 23, 48, and 96 h, and the samples were analyzed via HPLC. The experiments were repeated three times.

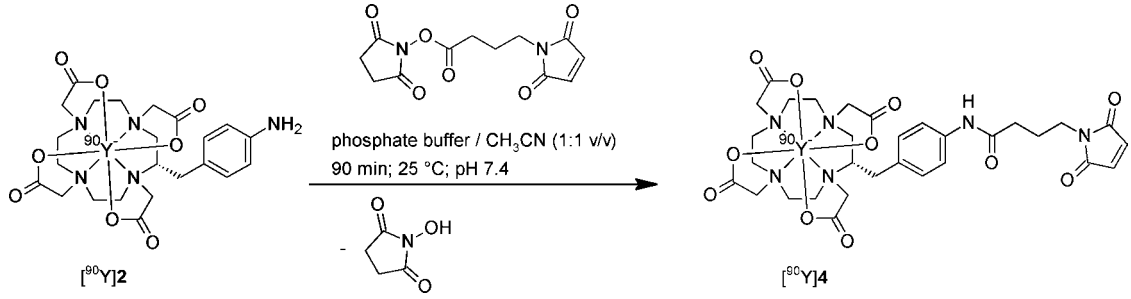
HPLC fractions, containing separately Y**3** and Y**4** in a mixture of 50 mM TEAA/CH_3CN (4:1 v/v, pH 6.25), were adjusted with acetic acid and triethylamine to pH 6.0, 6.6, 7.1, 7.5, 7.8, 8.0, and 8.4, respectively. All mixtures were incubated at 25 °C for 30 min and analyzed via HPLC. ESI-MS: Y**12** (TSAP and SAP isomer) *m*/*z* 694 $[M + 2H]^+$, Y**13** (TSAP and SAP isomer) *m*/*z* 779 $[M + 2H]^+$. HPLC: A(I): R_T(Y**12** TSAP) 10.5 min, R_T(Y**12** SAP) 11.6 min. A(II): R_T(Y**13** TSAP) 12.1 min, R_T(Y**13** SAP) 14.4 min.

Radiochemistry. *Preparation of [(2S)-2-(4-Aminobenzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl]tetra-acetato}[*^{90}*Y]-yttrate(1-) ([*^{90}*Y]***2***).* Chelator **1** (100 μg, 0.15 μmol) in (500 μL) 0.6 M NaOAc buffer (pH 6.8) was added to 80 μL [^{90}Y]YCl_3 (13 MBq) in 0.04 M HCl. The mixture (pH 6.5) was incubated at 95 °C for 20 min. A solution of DTPA (15 μL, 0.45 μmol) was added, and the reaction mixture was incubated at 40 °C for 10 min to complex unreacted [^{90}Y]Y^{3+}. The radiometal complex [^{90}Y]**2** was separated from [^{90}Y]Y-DTPA and **1** using a SepPak Plus C_{18} cartridge (Waters, USA). After elution of **1** and [^{90}Y]Y-DTPA with (10 mL) 67 mM sodium phosphate buffer (pH 7.0), [^{90}Y]**2** was selectively eluted: (a) with 2 mL CH_3CN/H_2O (4:1 v/v) and evaporated to dryness under a stream of nitrogen at 95 °C for 40 min, or (b) fractionized with (2 mL) 67 mM sodium phosphate buffer/CH_3CN (1:1 v/v, pH 8.1). The product [^{90}Y]**2** was found to be >99% radiochemically pure.

Scheme 1. Complexation of $[^{90}Y]Y^{3+}$ with Chelator 1 and Subsequent Synthesis of the Maleimide Reagent [90Y]3 by Reaction of the SPE-Purified Complex [90Y]2 with *N*-Methoxycarbonylmaleimide



Scheme 2. Synthesis of the Maleimide Reagent [90Y]4 by Reaction of [90Y]2 with GMBS



HPLC: A(III): R_T([90Y]**2** TSAP) 9.1 min, R_T([90Y]**2** SAP) 13.3 min. TLC: (I): R_f([90Y]**2**) 0.5, (I) R_f([90Y]**2**) 0.7.

*Preparation of [{(2S)-2-[4-(2,5-Dioxo-2,5-dihydro-1H-pyrrol-1-yl)benzyl]-1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetrayl}tetraacetato][90Y]yttrate(1-) ([90Y]**3**).* The residue of the SPE-purified (scheme a) radiometal complex [90Y]**2** (9.5 MBq) was redissolved in 100 μL H_2O and 50 μL saturated $NaHCO_3$. *N*-Methoxycarbonylmaleimide (5 mg, 32 μmol) was solved in 50 μL 1,4-dioxane and added to the solution of [90Y]**2**. The reaction mixture (pH 9.1) was incubated at 25 °C for 15 min. The mixture was carefully diluted with 1 M HCl (70 μL) to adjust pH < 3, and the tube was left open at room temperature for 20 min. Subsequently, the mixture was diluted with (20 mL) 50 mM NH_4OAc solution (pH 6.0) and applied onto a SepPak Plus C_{18} cartridge. The cartridge was washed with (10 mL) 50 mM NH_4OAc solution (pH 6.0) and (2 mL) 50 mM NH_4OAc/CH_3CN (9:1 v/v, pH 6.5). The final product [90Y]**3** was selectively eluted with (2 mL) 0.1 M NH_4OAc/CH_3CN (1:1 v/v, pH 6.5) and [90Y]**3** was found to be >95% radiochemically pure. HPLC: A(I): R_T([90Y]**3**) 17.4 min. TLC: (I): R_f([90Y]**3**) 0.3, (II) R_f([90Y]**3**) 0.6.

*Preparation of {[(2S)-2-(4-{[4-(2,5-Dioxo-2,5-dihydro-1H-pyrrol-1-yl)butanoyl]amino}benzyl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl]tetraacetato}[90Y]yttrate(1-) ([90Y]**4**).* The SPE eluate, which contained the radiometal complex [90Y]**2** (33.4 MBq) in (0.6 mL) 67 mM sodium phosphate buffer/CH_3CN (1:1 v/v, pH 8.1), was added to GMBS (3 mg, 10.7 μmol). The reaction mixture (pH 7.4) was incubated at 25 °C for 90 min. Subsequently, the mixture was diluted with 20 mL H_2O and applied onto a SepPak QMA cartridge. The cartridge was washed with 10 mL H_2O, and the final product [90Y]**4** was directly eluted on a SepPak Plus C_{18} cartridge with (6 mL) 0.5 M NaCl/CH_3CN (95:5 v/v, pH 3.5). The SepPak Plus C_{18} cartridge was washed with (4 mL) 50 mM NH_4OAc/CH_3CN (9:1 v/v, pH 6.8), and compound [90Y]**4** was selectively eluted with 2 mL H_2O/CH_3CN (4:1 v/v). The product [90Y]**4** was found to be >98% radiochemically pure. HPLC: A(II): R_T([90Y]**4** TSAP) 34.5 min, R_T([90Y]**4** SAP) 36.3 min. TLC: (I): R_f([90Y]**4**) 0.3, (II) R_f([90Y]**4**) 0.7.

Conjugation of Glutathione (GSH) 5 with [90Y]3 and [90Y]4. Dilution series with 1000, 100, 10, 1, and 0.1 μg GSH **5** (corresponding to 3300, 330, 33, 3.3, and 0.33 nmol **5**) in (1 mL) 67 mM sodium phosphate buffer (pH 7.2) were prepared. Both maleimide reagents, [90Y]**3** (0.2 MBq in (150 μL) 0.1 M NH_4OAc/CH_3CN (1:1 v/v, pH 6.5)) and [90Y]**4** (0.2 MBq in 150 μL H_2O/CH_3CN (4:1 v/v, pH 7.0)), were separately added to each solution of **5**. The reaction mixtures were incubated under argon atmosphere at 25 °C for 2 h. For determination of the RCYs, aliquots of the reaction mixtures with the corresponding products [90Y]Y-DID-GSH [90Y]**6** and [90Y]Y-DIBD-GSH [90Y]**7**, respectively, were analyzed after 5, 15, 30, 60, and 120 min by TLC. TLC: (II): R_f([90Y]**6**) 0.1, R_f([90Y]**7**) 0.1.

Conjugation of L-RNA 8 with [90Y]4 via Prelabeling. Dilution series with 400, 200, 100, 40, 20, 8, 2, and 0.4 μg L-RNA **8** (corresponding to 100, 50, 25, 10, 5, 2, 0.5, and 0.1 nmol **8**) in (100 μL) 67 mM sodium phosphate buffer (pH 7.0) were prepared. The maleimide reagent [90Y]**4** (0.5 MBq in 65 μL H_2O/CH_3CN (4:1 v/v, pH 7.0)) was added to each solution of **8**. The reaction mixtures were incubated under argon atmosphere at 25 °C for 2 h. For determination of the RCYs, aliquots of the reaction mixtures with the corresponding product [90Y]Y-DIBD-L-RNA [90Y]**9** were sampled (after 60 and 120 min), evaporated (Concentrator 5314, Eppendorf, Germany), and analyzed via PAGE and HPLC. HPLC: A(II): R_T([90Y]**8** TSAP) 28.6 min, R_T([90Y]**8** SAP) 29.2 min. PAGE: see Supporting Information Figures S3 and S4.

Preparation of the 90Y-Labeled L-RNA [90Y]11 via Postlabeling. Dilution series with 440, 220, 110, 44, 22, 4, 2, and 0.4 μg DOTA−L-RNA **10** (corresponding to 100, 50, 25, 10, 5, 2, 0.5, and 0.1 nmol **10**) in 250 μL NH_4OAc buffer (0.5 M, pH 7.0) were prepared. [90Y]YCl_3 (8 μL, 2.4 MBq) in 0.04 M HCl was added to each solution of **10**. After incubation of the reaction mixtures at 90 °C for 20 min, DTPA (10 μL, 30 mM in 0.5 M NH_4OAc) was added, and the reaction mixtures were kept at room temperature for 10 min to complex unreacted $[^{90}Y]Y^{3+}$ as [90Y]Y-DTPA complex. Aliquots of the reaction mixtures were analyzed via PAGE and HPLC to determine the

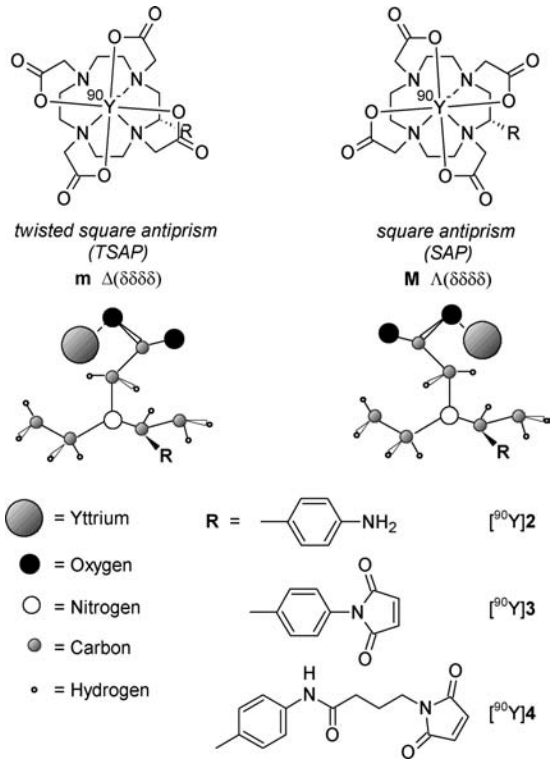


Figure 3. Isomers of the differently substituted [^{90}Y]-DOTA complexes [^{90}Y]**2**, [^{90}Y]**3**, and [^{90}Y]**4** are represented schematically. Only the geometry around the N-CH_2-COO group next to the (*S*)-configured carbon atom is given.

RCYs in dependence of the amount of **10**. HPLC: C(I): R_T([^{90}Y]**11**) 15.3 min. PAGE: see Supporting Information Figure S5.

RESULTS AND DISCUSSION

Synthesis of [^{90}Y]3 and [^{90}Y]4. A straightforward method to synthesize both [^{90}Y]-DOTA-based maleimide reagents [^{90}Y]**3** and [^{90}Y]**4** is to initially complex [^{90}Y]Y^{3+} with chelator **1** and subsequently transform the purified complex [^{90}Y]**2** into the corresponding maleimides, by using activating agents (see Schemes 1 and 2). As previously shown, [^{90}Y]**2** exists as two conformers, adopting the Δ($\delta\delta\delta\delta$) (twisted square antiprism, TSAP) and Λ($\delta\delta\delta\delta$) (square antiprism, SAP) configurations (see Figure 3) (*13*). On this account, two further conformers of [^{90}Y]**3** and [^{90}Y]**4**, respectively, derived from both isomers of [^{90}Y]**1**. Having shown that the differences in the helicity of the carboxylate side arms (Λ or Δ) does not affect the biodistribution of the corresponding radiolabeled L-RNA (*13*), both isomers of [^{90}Y]**2** were used for all radiosyntheses in this work without separation.

*Synthesis and SPE-Purification of [^{90}Y]***2.** The synthesis of [^{90}Y]**2** was performed in an analogous manner as previously described (*13*). By adding DTPA to the solution, unreacted [^{90}Y]Y^{3+} was finally complexed as [^{90}Y]Y-DTPA. Solid-phase extraction (SPE) was used to purify the radiometal complex [^{90}Y]**2** from the excess chelator **1** and [^{90}Y]Y-DTPA complex. In this process, the negatively charged complex [^{90}Y]**1** was retarded on a SepPak Plus C_{18} cartridge applying an aqueous solution of the ion pair reagents TEAA, NH_4OAc, and NaOAc, respectively, whereas **1** and [^{90}Y]Y-DTPA were eluted with these eluents. This observation indicates that triethylammonium, ammonium, and Na^+-cations provide a comparable interaction of [^{90}Y]**2** with the reversed-phase material by masking the negative charge of [^{90}Y]**2**. Furthermore, no differences were observed for these cations in the performance of separation of [^{90}Y]**2** from the side products **1** and [^{90}Y]Y-DTPA. For the synthesis of [^{90}Y]**3**, the radiometal complex [^{90}Y]**2** was selectively eluted from the cartridge with a mixture of CH_3CN and H_2O (4:1 v/v) and evaporated to dryness. To minimize expenditure of time, [^{90}Y]**2** was alternatively eluted with 67 mM sodium phosphate buffer/CH_3CN (1:1 v/v, pH 8.1) and used without any further processing for the radiosynthesis of [^{90}Y]**4**.

*Synthesis of [^{90}Y]***3.** To synthesize [^{90}Y]**3**, the primary amine group of [^{90}Y]**2** reacted with *N*-methoxycarbonylmaleimide (see Scheme 1). This reaction is a comparably mild method for the transformation of amine groups into maleimides. As recently shown with *N*-methoxycarbonylmaleimide (*18*), radiochemical yields (RCYs) greater 90% were already achieved at room temperature after 10 min for a ^{18}F-labeled maleimide reagent. On the basis of this work (*18*), we adapted and optimized these reaction conditions for synthesis of [^{90}Y]**3**. The residue of the SPE-purified radiometal complex [^{90}Y]**2** was redissolved in $NaHCO_3$ solution. After adding *N*-methoxycarbonylmaleimide, the mixture was incubated at room temperature and pH 9.1 for a maximum reaction time of 15 min. In a second step, the pH was lowered from 9.1 to ~2 by addition of 1 M HCl.

*SPE Purification of [^{90}Y]***3.** An efficient purification of [^{90}Y]**3** in regard to short purification time and high RCYs was performed with solid-phase extraction (SPE). For that purpose, elution profiles of **1**, Y**2**, Y**3**, the corresponding hydrolysis product Y**12**, and *N*-methoxycarbonylmaleimide were initially analyzed on a SepPak Plus C_{18} cartridge. On the basis of the elution characteristics of these nonradiolabeled compounds, the following procedure was conducted to purify [^{90}Y]**3** with only

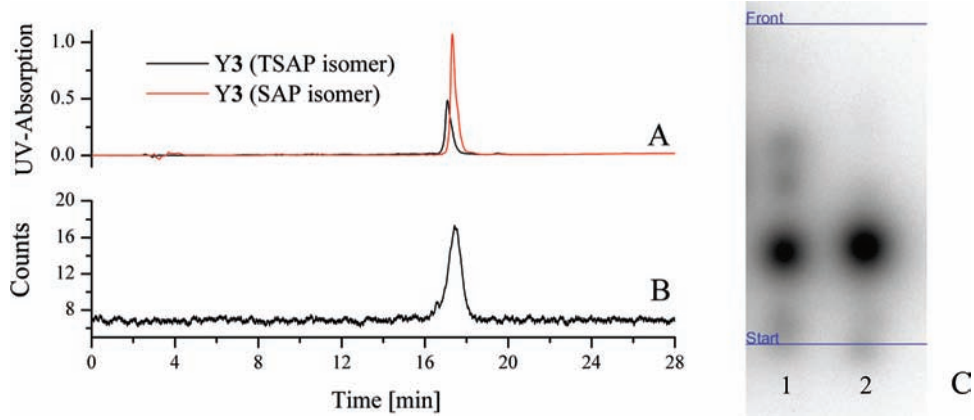

Figure 4. Radio-HPLC and radio-TLC chromatograms of the maleimide reagent [^{90}Y]**3**. (A) Overlay of HPLC profiles of the TSAP and SAP isomer of Y**3** as references. (B) SPE-purified [^{90}Y]**3**. The TSAP and SAP isomer of [^{90}Y]**3** could not be separated under the used HPLC conditions. (C) Radio-TLC analysis of the reaction mixture containing [^{90}Y]**3** (1) and the SPE-purified [^{90}Y]**3** (2) with TLC system **I**.

Table 1. Time-Dependent Radiochemical Yields (RCYs) of [90Y]4 (RCYs Were Determined via Radio-TLC Analysis)

reaction time [min]	15	30	45	60	75	90
RCY [%]	30	38	46	58	62	66

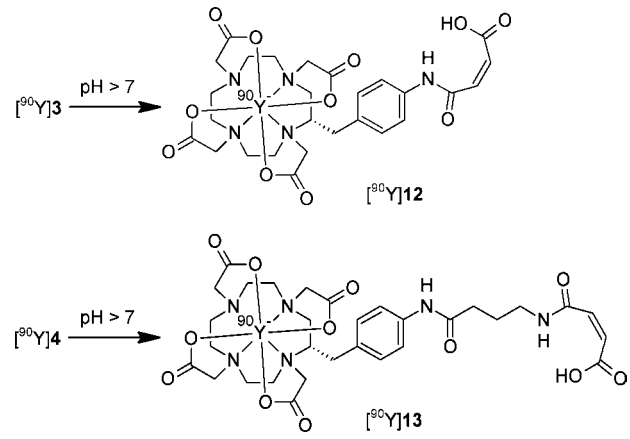
one SepPak Plus C_{18} cartridge: (A) First, the concentration of dioxane was reduced from 25% in the reaction mixture to 0.5% by adding 20 mL NH_4OAc solution. Higher dioxane concentrations would lead to an elution of [90Y]**3**. (B) Subsequently, the cartridge was washed with a solution of 10 mL 50 mM NH_4OAc (pH 6.0) and a mixture of (2 mL) 50 mM NH_4OAc and CH_3CN (9:1 v/v, pH 6.5), to elute both unreacted *N*-methoxycarbonylmaleimide and the hydrolyzed species [90Y]**12** from the cartridge. (C) Finally, compound [90Y]**2** was selectively eluted with a mixture of (2 mL) 0.1 M NH_4OAc and CH_3CN (1:1 v/v, pH 6.5). A pH value of ≤6.5 in the final elution mixture proved to be important for preventing hydrolysis of the maleimide [90Y]**3**. The obtained maleimide reagent [90Y]**3** was used for the prelabeling of GSH **5** without any further processing. Hence, in a typical experiment starting with the complexation of 11 MBq [90Y]YCl_3 with **1**, 3.7 MBq of [90Y]**3** was obtained with a radiochemical purity of >95% within 145 min (Figure 4).

*Synthesis of [90Y]***4.** The transformation of the primary amine [90Y]**2** into a maleimide group can also be conducted with heterobifunctional reagents, e.g., *N*-(γ-maleimidobutyryloxy)-succinimide ester (GMBS). At pH 7.0−7.5, GMBS readily reacts with both primary amines via the chemically reactive succinimidyl group and thiols via the maleimide group. The nucleophilic substitution of the primary amine [90Y]**2**, by reaction with the activated carbonyl carbon in GMBS, leads to the formation of [90Y]**4** (see Scheme 2).

To synthesize [90Y]**4**, SPE-purified [90Y]**2** (33.4 MBq) in 0.6 mL sodium phosphate/CH_3CN (1:1 v/v) was added directly to GMBS. Subsequently, the solution was vigorously mixed at room temperature. The pH value of the reaction mixture (pH 7.4) remained constant over the reaction time of 90 min. The kinetics of the reaction was monitored by radio-TLC analysis. The time-dependent RCYs of the maleimide formation are shown in Table 1. Compound [90Y]**4** was obtained with the maximum RCY of 66% after 90 min. In a competing side reaction, GMBS was hydrolyzed to the corresponding byproduct *N*-hydroxysuccinimide and 4-maleimidobutyric acid, as confirmed by HPLC. Thus, reaction times longer than 90 min would not lead to higher RCYs.

*SPE Purification of [90Y]***4.** Separation of *N*-hydroxysuccinimide, 4-maleimidobutyric acid and the unreacted complex [90Y]**2** from the maleimide reagent [90Y]**4** was performed via SPE. For that purpose, elution profiles of these compounds on different cartridges were initially analyzed. On the basis of their elution characteristics, the following procedure was conducted to purify [90Y]**4** efficiently with an anion-exchanger (SepPak QMA Acell Plus) and a C_{18}-cartridge (SepPak Plus C_{18}): (A) Prior to loading the reaction mixture onto the anion-exchanger the concentration of phosphate ions was reduced from 67 to 6 mM by adding 20 mL H_2O, thus preventing an elution of [90Y]**4** during the loading step. (B) The anion-exchanger was washed with 10 mL H_2O to elute unreacted GMBS. (C) The maleimide reagent [90Y]**4** was eluted directly onto the C_{18}-cartridge with a mixture of (6 mL) 0.5 M NaCl and CH_3CN (95:5 v/v). (D) Subsequently, the C_{18}-cartridge was washed with (4 mL) 50 mM NH_4OAc/CH_3CN (9:1 v/v), to elute all byproduct from the cartridge. Under these conditions, almost 70% of the product [90Y]**4** remained on the C_{18}-cartridge. (E) Finally, compound [90Y]**4** was selectively eluted with 2 mL H_2O/CH_3CN (1:1 v/v, pH 7.0) from the cartridge. Hence, in a typical experiment starting with the complexation of 39 MBq [90Y]YCl_3 with **1**, 8 MBq of [90Y]**4** was obtained with a radiochemical purity of >98% within 170 min (Figure 5).

Scheme 3. Maleamic Acid Derivatives [90Y]12 and [90Y]13 Derived from the Basic Hydrolysis of the Maleimide Reagents [90Y]3 and [90Y]4



Hydrolytic Stability of [90Y]3 and [90Y]4. During the preparation process, the maleimide reagents [90Y]**3** and [90Y]**4** hydrolyzed at pH values greater than 7.0 into the corresponding nonreactive maleamic acids [90Y]**12** and [90Y]**13** (Scheme 3) (*12*, *19*). Differences were found in the hydrolytic stability of the *N*-aryl maleimide [90Y]**3** and the *N*-alkyl maleimide [90Y]**4**. By examining heterobifunctional linkers, Kitagawa et al. observed a higher hydrolytic stability of *N*-alkyl against *N*-aryl maleimides in aqueous solutions at pH 8.0 (*20*). Thus, only 8−12% hydrolysis products were found for *N*-alkyl

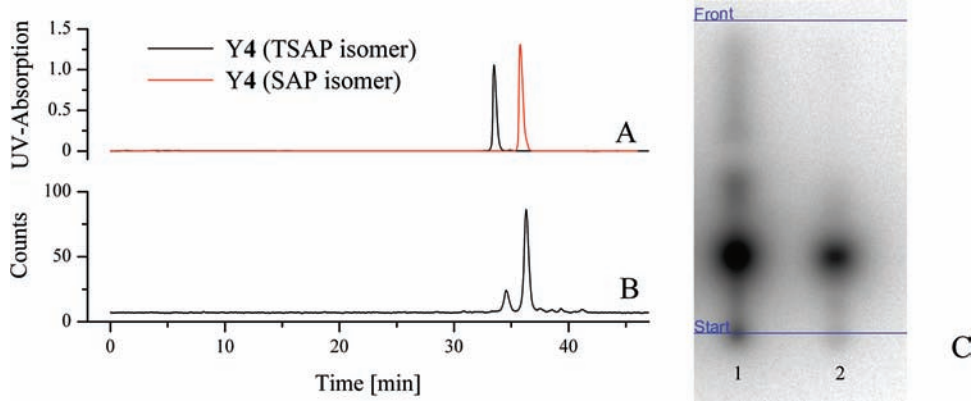


Figure 5. Radio-HPLC and radio-TLC chromatograms of the maleimide reagent [90Y]**4**. (A) Overlay of HPLC profiles of the TSAP and SAP isomer of Y**4** as references. (B) SPE-purified [90Y]**4**. (C) Radio-TLC analysis of the reaction mixture containing [90Y]**4** (1) and the SPE-purified [90Y]**4** (2) with TLC system I.

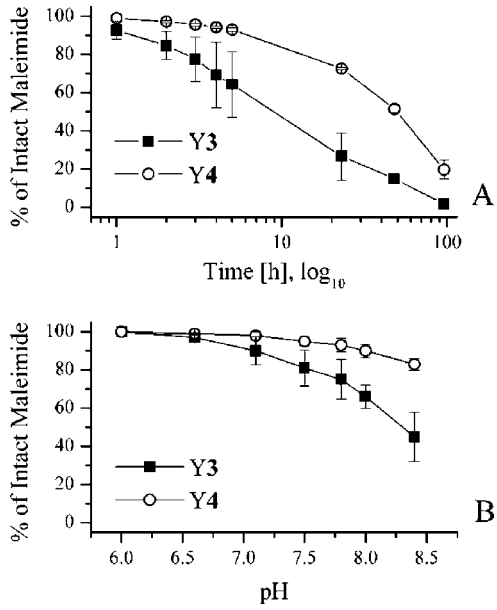

Figure 6. Hydrolytic stability of the maleimides Y**3** and Y**4**: (A) as a function of time at pH 7.0, (B) as a function of pH value for 30 min ($n = 3$).

maleimides, whereas 41−69% of the *N*-aryl maleimides were hydrolyzed under the same conditions (after 30 min at 30 °C). The highest stability was observed for all maleimides in weak acid solutions at pH 6.0.

To verify the hydrolytic stability of the maleimide reagents [^{90}Y]**3** and [^{90}Y]**4**, hydrolysis rates of the nonradioactive maleimides Y**3** and Y**4** were analyzed as a function of time and pH (see Figure 6). In agreement with the previous observations of Kitagawa et al. (*20*), *N*-alkyl maleimide Y**4** showed increased stability at pH 7.0 over a period of 96 h, in comparison to *N*-aryl maleimide Y**3**. Hydrolysis ratios of 73% for Y**3**, but only of 27% for Y**4** were estimated after 23 h incubation time. As expected, Y**4** was more stable than Y**3** at higher pH values (7.8−8.4). Therefore, a careful control of reaction time and pH seems to be important for the synthesis of [^{90}Y]**3**, since the formation of [^{90}Y]**3** competes with the base-catalyzed ring-opening of the maleimide group in the first reaction step (see Scheme 1). HPLC analyses also confirmed that 10% of the corresponding maleamic acid derivative Y**12** was already formed 20 min after addition of *N*-methoxycarbonylmaleimide to the nonradioactive precursor Y**2** (data not shown). Therefore, in order to get higher RCYs a reaction time of 15 min and pH 9 should not be exceeded in the first reaction step.

Prelabeling of GSH as Model Peptide with [^{90}Y]3 and [^{90}Y]4. To evaluate the application and reactivity of both maleimide reagents [^{90}Y]**3** and [^{90}Y]**4**, the prelabeling approach was initially tested with GSH **5** as a model substance. The conjugations of both maleimide reagents [^{90}Y]**3** and [^{90}Y]**4** to **5** were conducted with different amounts of **5** in 1 mL of phosphate buffer (pH 7.2) at room temperature (see Scheme 4). The kinetics of these reactions was monitored via radio-TLC analysis. Time-dependent RCYs of both prelabeling reactions are summarized in Table 2. For [^{90}Y]**6** and [^{90}Y]**7**, RCYs greater than 85% were reached already after 5 min reaction time in batches with 10 to 1000 μg **5**. Slight differences in the obtained RCYs were only observed for both maleimide reagents at amounts of 0.1 and 1 μg **5**. At these low amounts of **5**, higher RCYs were achieved for maleimide reagent [^{90}Y]**3** than for [^{90}Y]**4**. This points to a slightly higher reactivity of [^{90}Y]**3** compared to [^{90}Y]**4**. In contrast, the higher hydrolytic stability of [^{90}Y]**4** showed no influence on the RCYs. In summary, higher RCYs were obtained for both conjugations with increasing amounts of **5** and longer reaction times. Similar results were found for the radiolabeling of GSH **5** with both [^{90}Y]-DOTA-based maleimide reagents [^{90}Y]**3** and [^{90}Y]**4** as already known for a [^{18}F]-based maleimide (*21*).

^{90}Y-Labeling of an L-RNA via the Pre- and Postlabeling Approach. For the evaluation of achievable RCYs and ESAs both pre- and postlabeling were performed with a 12mer L-RNA as model substance. Due to its higher hydrolytic stability, only [^{90}Y]**4** was used for the prelabeling of the 12mer L-RNA **8**. On

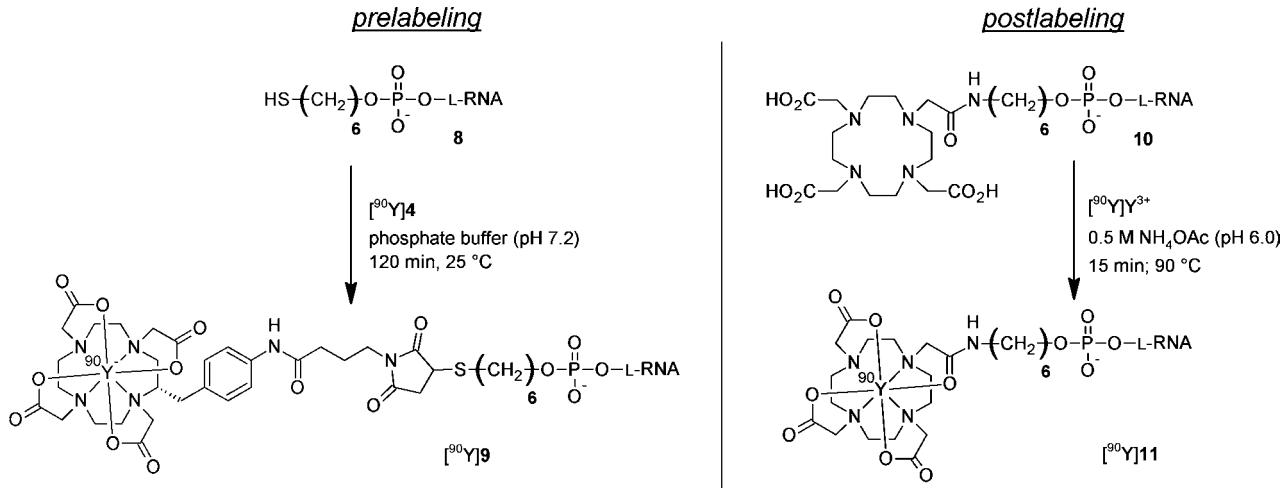
Scheme 5. ^{90}Y-Labeling of L-RNA via the Pre- and Postlabeling Approach[a]



[a] Prelabeling approach: Compound [^{90}Y]**9** was formed by reaction of L-RNA **8** with [^{90}Y]**4** under mild conditions. Postlabeling approach: [^{90}Y]Y^{3+} labeling of DOTA−L-RNA **10** results in formation of [^{90}Y]**11**.

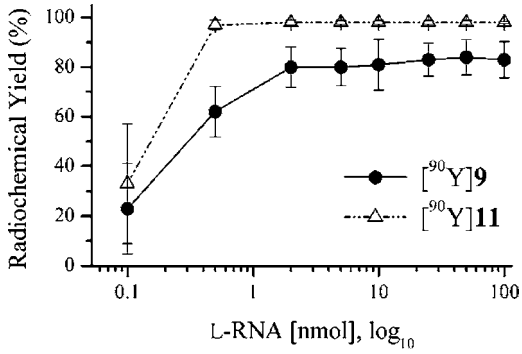


Figure 7. RCYs (%) of [^{90}Y]**9** and [^{90}Y]**11** as a function of the amount of L-RNA derivatives **8** and **10**. The results were obtained by PAGE analysis (n = 4 ([^{90}Y]**9**), n = 3 ([^{90}Y]**11**)).

this account, the prelabeling of **8** with [^{90}Y]**4** was compared with the direct radiolabeling of DOTA-L-RNA **10** with [^{90}Y]YCl_3.

Prelabeling of a Thiol-Modified L-RNA **8** *with [^{90}Y]***4.** The 12mer L-RNA was derivatized with a 5′-hexyl disulfid group, and after removal the protective group, the free thiol group of **8** was used to attach the maleimide reagent [^{90}Y]**4**. The conjugation was performed at room temperature in 0.1 mL phosphate buffer at pH 7.2 (Scheme 5). The dependence of the RCY of the prelabeling reaction on the amount of **8** was estimated in range 0.1−100 nmol of **8**. The progress of the reaction was monitored by gel electrophoresis after 2 h reaction time (Supporting Information Figure S3B). The difference in the retention factor values of [^{90}Y]**4** (R_F 0.39; 0.70) and the product [^{90}Y]**9** (R_F 0.61) allowed a quantitative analysis of the reaction (Supporting Information Figure S4). The obtained RCYs of the conjugation, as a function of the amount of **8**, is shown in Figure 7.

Postlabeling of DOTA−L-RNA **10** *with [^{90}Y]YCl_3.* The ^{90}Y-labeling of DOTA−L-RNA **10** was performed in an analogous manner to that previously described (*16*). The dependence of the RCY of the postlabeling reaction on the amount of **10** was monitored in the range 0.1−100 nmol of **10** and estimated by gel electrophoresis (Supporting Information Figure S5B). Before analyzing the reaction aliquots, unreacted [^{90}Y]Y^{3+} was first complexed as [^{90}Y]Y-DTPA by adding DTPA to the solution. The RCYs of the complexation, obtained from PAGE analyses, are graphically shown in Figure 7.

Comparison of Both Radiolabeling Methods. In the range 0.1−100 nmol of L-RNA, higher RCYs of ^{90}Y-labeling were

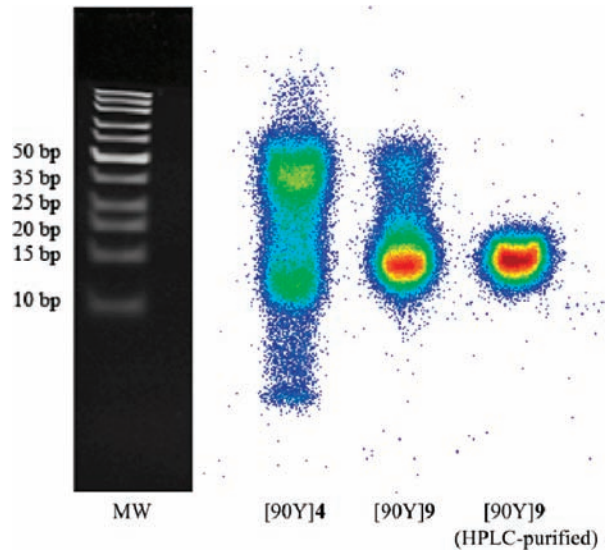

Figure 8. Image fusion of the autoradiogram of the exposed 20% polyacrylamide gel and the photographed 10 bp DNA ladder (MW) after staining with ethidium bromide. Applied samples in the lanes: maleimide reagent [^{90}Y]**4**, ^{90}Y-labeled L-RNA [^{90}Y]**9** before (aliquot of the crude reaction mixture) and after HPLC separation.

obtained by the postlabeling approach. Using 2.4 MBq [^{90}Y]Y^{3+}, RCYs higher than 97% were already achieved with 0.5 nmol **10**. A higher effective specific activity (ESA) of up to 4 GBq/μmol [^{90}Y]**11** was obtained with the postlabeling approach. Furthermore, an additional HPLC separation of [^{90}Y]**11** (R_T 15.3 min) from excess **10** (R_T 16.8 min) would theoretically enhance the ESA to 29 GBq/μmol (Supporting Information Figure S2, HPLC system C(I)).

In contrast, prelabeling experiments with 0.5 MBq [^{90}Y]**4** gave lower RCYs of ^{90}Y-labeling in the range 0.1−100 nmol L-RNA. The maximum RCY of 84% was obtained at 50 nmol **8**. In comparison to 35% and 97% RCY for postlabeling at 0.1 and 0.5 nmol of L-RNA **10**, respectively, 23% and 62% RCY was calculated for prelabeling at the same amounts of L-RNA **8**. HPLC separation of [^{90}Y]**9** resulted in an ESA of 0.7 GBq/μmol [^{90}Y]**9** and a radiochemical purity of 99%, as determined by HPLC and PAGE analysis (Figure 8). The ESA calculated for the HPLC purified [^{90}Y]**9**, was approximately six times lower than the 4 GBq/μmol found for [^{90}Y]**11**. HPLC analysis showed

a ratio of both isomers of [^{90}Y]**9** of 1:5 (TSAP/SAP) after HPLC separation (Supporting Information Figure S1C).

CONCLUSIONS

The purpose of the present work was to investigate the applicability of two new [^{90}Y]-DOTA-based maleimide reagents, the *N*-aryl maleimide [^{90}Y]**3** and *N*-alkyl maleimide [^{90}Y]**4**, for the prelabeling approach. On this account, we were able to radiolabel GSH and a 12mer L-RNA as model substances using these new prelabeling agents. Both maleimide reagents showed a high potential for that purpose. However, concerning high RCYs, the direct labeling of DOTA−L-RNA with [^{90}Y]YCl_3 proved to be more efficient than the prelabeling of the thiol-modified 12mer L-RNA derivative with [^{90}Y]**4** at low activity levels. With regard to ^{90}Y-labelings of thermally sensitive molecules, such as biopharmaceuticals, prelabeling could have more advantages than the direct radiolabeling, due to the milder labeling conditions. To enhance both RCY of the prelabeling approach and ESA of the corresponding ^{90}Y-labeled molecules, further optimizations of the SPE-separation process of both maleimide reagents [^{90}Y]**3** and [^{90}Y]**4** seem to be necessary.

Photoinitiated Coupling of Unmodified Monosaccharides to Iron Oxide Nanoparticles for Sensing Proteins and Bacteria

Li-Hong Liu,[†] Hervé Dietsch,[‡] Peter Schurtenberger,[‡] and Mingdi Yan*[,†]

Department of Chemistry, Portland State University, P.O. Box 751, Portland, Oregon 97207-0751, and Adolphe Merkle Institute and Fribourg Center for Nanomaterials, University of Fribourg, Route de l'ancienne Papeterie CP 209, CH-1723 Marly 1, Switzerland. Received March 12, 2009; Revised Manuscript Received May 13, 2009

We report a versatile approach for the immobilization of unmodified monosaccharides onto iron oxide nanoparticles. Covalent coupling of the carbohydrate onto iron oxide nanoparticle surfaces was accomplished by the CH insertion reaction of photochemically activated phosphate-functionalized perfluorophenylazides (PFPAs), and the resulting glyconanoparticles were characterized by IR, TGA, and TEM. The surface-bound D-mannose showed the recognition ability toward *Concanavalin A* and *Escherichia coli* strain ORN178 that possesses mannose-specific receptor sites. Owing to the simplicity and versatility of the technique, together with the magnetic property of iron oxide nanoparticles, the methodology developed in this study serves as a general approach for the preparation of magnetic glyconanoparticles to be used in clinical diagnosis, sensing, and decontamination.

INTRODUCTION

Naturally occurring carbohydrates and glycoconjugates (glycoproteins, glycolipids) present at the surface of nearly every cell in the living system are known to play crucial roles in biological events as recognition sites between cells and factors. They can trigger various phenomena such as cell growth, inflammatory responses, or viral infections. Surface-exposed carbohydrate moieties that are characteristic of a given microbe may serve as key biomarkers for pathogen and toxin identification, diagnosis, and vaccine development. Carbohydrates as a detection platform have recently emerged and have demonstrated tremendous potential to achieve superior sensitivity and selectivity (*1*−*4*). Compared to antibodies used in immunoassays that are often fragile and unstable, carbohydrates are stable entities. Carbohydrate-based assays have the potential to be an alternative benchmark detection technology for a wide range of biomolecules including proteins, bacteria, pathogens, and toxins (*5*).

A key technology requirement in receptor/ligand-based sensing and detection is the surface conjugation chemistry leading to efficient and effective coupling of ligands to solid substrates (*6*). The performance of the device, the detection sensitivity, and the dynamic range are largely governed by the ligand to be immobilized, the nature of the coupling chemistry, the ligand density, and the presentation. There is a great demand for effective conjugation chemistry that is general, versatile, and can accommodate ligand diversity and give stable interfaces, yet is simple and reproducible. Reported strategies for the covalent immobilization of carbohydrates on surfaces mostly rely on conventional coupling chemistry, such as amines with ester (*7, 8*) thiols with maleimides (*9, 10*), and azide with alkynes (*11, 12*), which requires sometimes laborious synthesis of carbohydrates having a specific functional group or tether. Coupling chemistry that does not require chemical derivatization of carbohydrates is appealing. There are a few methods reported in literature. One approach uses hydrazide-modified gold substrates, where the hydrazide reacts with the terminal aldehyde group of the carbohydrates (*13, 14*). A similar approach employs amine-functionalized surfaces, and the coupling with carbohydrates takes place by reductive amination to yield an amine conjugate (*15, 16*). In both cases, reducing sugars are necessary, and for monosaccharides, the coupled products often become acyclic and lose their binding affinity. Photochemically initiated immobilization and patterning of biological molecules has been explored (*17*), although few reports have focused on carbohydrates (*18, 19*).

We have developed a photochemically initiated coupling chemistry that employs functionalized perfluorophenyl azides (PFPAs) to attach molecules and materials to solid substrate surfaces (*20*−*22*). Upon light activation, the azide moiety converts to a highly reactive nitrene that, notably, inserts into CH and NH bonds, creating highly robust covalent linkages. We have successfully employed PFPAs in surface modification, targeting polymeric materials that lack reactive functional groups for surface coupling (*23, 24*). Carbohydrates, being complex in structure and challenging to chemically derivatize, are another class of compounds that are well-suited for the PFPA photocoupling chemistry. The design of our approach is to prepare PFPA-functionalized iron oxide nanoparticles that can be subsequently used to covalently couple, in principle, any carbohydrate structures by way of the insertion reactions of photochemically activated nitrene species.

Iron oxide nanoparticles are attractive due to their inherent magnetic properties that make them useful for magnetic resonance imaging, magnetic field-assisted transport, as well as sensing and separation (*25*−*27*). In addition, iron oxide nanoparticles are nonporous, which avoid delay due to diffusion, and thus the equilibrium is reached rapidly and fast response can be achieved. A number of methods have been reported for functionalizing iron oxide nanoparticles with organic compounds (*28, 29*) such as silanes (*30, 31*) and phosphoric acids (*32*−*38*). Silanes form robust siloxane bonds with surface −OH groups; the drawback is the self-condensation reaction leading to multilayer formation or deposition of aggregates on the substrate surface. Phosphates, on the other hand, do not undergo self-condensation reactions. These agents couple with surface −OH groups creating the stable Fe−O−P structure (*28, 32*).

Here, we report the synthesis of phosphate-functionalized PFPAs and their uses for the covalent immobilization of monosaccharides on iron oxide nanoparticles. The recognition ability of the surface-bound ligands are tested using *Concanavalin A* (*Con A*), an oligomannose-binding lectin, and *Escherichia coli* (*E. coli*) strain ORN178 that possesses mannose-specific receptor sites (*39*). *Con A* and *E. coli* also serve as the model systems allowing us to test the ability of these carbohydrate-functionalized iron oxide nanoparticles for sensing and detecting proteins and bacteria.

EXPERIMENTAL SECTION

Materials and Instrumentation. Chemicals and solvents were purchased from TCI, Sigma-Aldrich, ACROS, or Fisher Scientific. Methylene chloride was distilled from calcium hydride. Triethylamine was distilled before use. All other solvents and commercial grade reagents were used without further purification. Milli-Q water having a resistivity of 18.2 $mW \cdot cm^{-1}$ was used for the synthesis of spindle-type hematite particles. ^1H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker AMX-400 MHz spectrometer. Chemical shifts were reported in parts per million (ppm) relative to TMS and referenced to the residual solvent. Elemental analysis was performed by Quantitative Technologies Inc. (Whitehouse, NJ). Infrared spectra were obtained on a Perkin-Elmer 2000 series FT-IR spectrometer. TEM images were obtained on a JEOL 100C transmission electron microscope. Photolysis was carried out at the ambient temperature with a 450 W medium pressure Hg lamp (Hanovia). The lamp reached its full power after a 2 min warmup to an intensity of 5.0 mW/cm^2, as measured by a model UVX radiometer and UVX-36 sensor (Upland, CA). A 280 nm optical filter was used during irradiation. Thermogravimetric analysis (TGA) was performed on a Perkin-Elmer TGA7 Analyzer. Samples were combusted in nitrogen flow at a heating rate of 10 °C/min from 50 to 900 °C.

2-(2′-(2″-(4-Azidoethoxy)ethoxy)ethanol (3). 2-(2′-(2″-Chloroethoxy)ethoxy)ethanol (0.5 g, 2.97 mmol), NaI (0.09 g, 0.6 mmol), and NaN_3 (2.0 g, 30 mmol) were dissolved in water (10 mL), and the solution was stirred at 50 °C for 48 h. The reaction mixture was then filtered, and the aqueous phase was extracted with ethyl acetate (4 × 10 mL). The organic extracts were collected and evaporated to give **3** as a light yellow liquid (0.4 g, 77%). ^1H NMR (400 MHz, $CDCl_3$, δ): 3.72 (t, 2H, J = 5.0 Hz), 3.68 (m, 6H), 3.60 (t, 2H, J = 5.0 Hz), 3.40 (t, 2H, J = 5.0 Hz), 3.19 (br, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 72.63, 70.59, 70.34, 69.98, 61.56, 50.61.

2-(2′-(2″-Aminoethoxy)ethoxy)ethanol (4). 2-(2′-(2″-(4-Azidoethoxy)ethoxy)ethanol (**3**) (400 mg, 2.4 mmol) was dissolved in dry THF (10 mL), and the solution was cooled to 0 °C. Triphenyl phosphine (600 mg, 2.4 mmol) was added, and the reaction mixture was stirred at room temperature for 10 h. Water (0.12 mL, 6.7 mmol) was added, and the mixture was stirred for another 5 h. The reaction mixture was diluted with water and washed with toluene (3 × 10 mL). The aqueous layers were collected and evaporated to give **4** as a colorless liquid (240 mg, 70% crude). This compound was used directly in the next step without further purification.

4-Azido-2,3,5,6-tetrafluoro-*N*-(2-(2′-(2″-hydroxyethoxy)-ethoxy)ethyl)benzamide (5). Dry CH_2Cl_2 (10 mL) was added to a mixture of *N*-succinimidyl 4-azidotetrafluorobenzoate (*40*) (400 mg, 1.2 mmol) and 2-(2′-(2″-aminoethoxy)ethoxy)ethanol (**4**) (180 mg, 1.2 mmol) via syringe, and the mixture was purged with argon for 30 min and stirred at room temperature for 6 h. Water (10 mL) was added, and the mixture was extracted by $CHCl_3$ (3 × 10 mL). The organic layers were combined, dried over anhydrous Na_2SO_4, and evaporated in vacuo. The residual was purified by column chromatography (10/4/0.5, ethylacetate/hexanes/methanol) to give **5** as a white waxy solid (180 mg, 41%).^1H NMR (400 MHz, $CDCl_3$, δ): 7.04 (1H), 3.65 (m, 10H), 3.55 (t, 2H, J = 5.0 Hz), 2.69 (br, 1H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 157.93, 145.28, 142.78, 141.74, 139.08, 121.60, 111.85, 72.47, 70.28, 70.23, 69.47, 61.51, 39.99. Anal. Calcd. for $C_{13}H_{14}F_4N_4O_4$: C 42.63; H 3.85; N 15.30. Found: C 42.43; H 3.87; N 15.27.

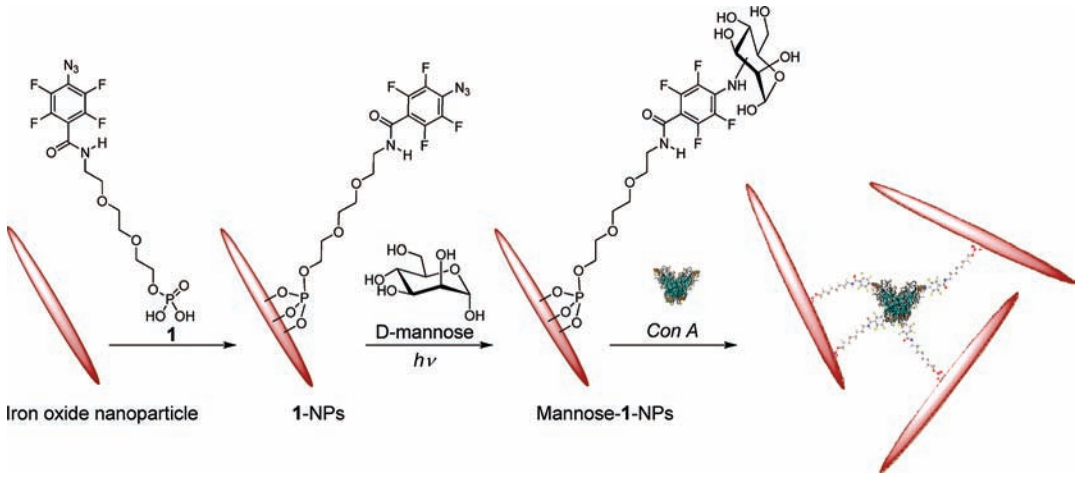
2-(2′-(2″-(4-Azido-2,3,5,6-tetrafluorobenzamido)ethoxy)-ethoxy)ethyl Dihydrogen Phosphate (1). 4-Azido-2,3,5,6-tetrafluoro-*N*-(2-(2′-(2″-hydroxyethoxy)ethoxy)ethyl) benzamide (**5**) (180 mg, 0.49 mol) was dissolved in dry CH_2Cl_2, and the solution was purged with argon. Anhydrous triethylamine (0.1 mL, 0.7 mmol) was added, and the mixture was cooled to 0 °C with an ice bath before $POCl_3$ (0.06 mL, 0.7 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature and stirred for another 6 h. Water (10 mL) was added, and the mixture was stirred for 1 h. The reaction mixture was extracted with $CHCl_3$ (3 × 10 mL). The organic layers were collected, dried over anhydrous Na_2SO_4, and evaporated to give **1** as a light yellow, highly viscous clear liquid (120 mg, 55%). ^1H NMR (400 MHz, $CDCl_3$, δ): 6.94 (br, 1H), 4.44 (m, 2H), 3.80 (m, 2H), 3.67 (m, 8H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 157.94, 145.30, 142.80, 141.76, 139.09, 121.63, 111.82, 71.03, 70.77, 70.32, 69.43, 68.97, 40.01. Anal. Calcd. for $C_{13}H_{15}F_4N_4O_7P$: C 34.99; H 3.39; N 12.56. Found: C 34.72; H 3.18; N 12.23.

4-Azido-2,3,5,6-tetrafluoro-*N*-(8-hydroxyoctyl)benzamide (6). *N*-Succinimidyl 4-azidotetrafluoro benzoate (200 mg, 0.6 mmol) and 8-aminooctan-1-ol (90 mg, 0.6 mmol) were added to dry CH_2Cl_2 (10 mL), and the solution was purged with argon for 30 min and stirred at room temperature for 6 h. Water (10 mL) was then added, and the mixture was extracted with $CHCl_3$ (3 × 10 mL). The organic layers were combined, dried over anhydrous Na_2SO_4, and evaporated in vacuo. The residual was purified by column chromatography (10/4/0.5, ethylacetate/hexanes/methanol) to give **6** as a white power (110 mg, 50%). ^1H NMR (400 MHz, $CDCl_3$, δ): 5.96 (s, 1H), 3.64 (t, 2H, J = 7.0 Hz), 3.45 (q, 2H, J = 7.0 Hz), 1.59 (m, 4H), 1.35 (m, 8H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 157.59, 145.34, 142.79, 141.63, 139.15, 121.82, 111.61, 62.99, 40.33, 32.70, 29.27, 29.23, 29.10, 26.65, 25.61. Anal. Calcd. for $C_{15}H_{18}F_4N_4O_2$: C 49.72; H 5.01; N 15.46. Found: C 49.63; H 5.18; N 15.47.

8-(4-Azido-2,3,5,6-tetrafluorobenzamido)octyl Dihydrogen Phosphate (2). 4-Azido-2,3,5,6- tetrafluoro-*N*-(8-hydroxyoctyl)benzamide (**6**) (250 mg, 0.69 mmol) was dissolved in dry THF (10 mL), and the solution was purged with argon. Anhydrous triethylamine (0.13 mL, 0.9 mmol) was added, and the mixture was cooled to 0 °C with an ice bath before $POCl_3$ (0.08 mL, 0.9 mmol) was added dropwise. The reaction mixture was allowed to warm to room temperature and stirred for another 6 h. Water (10 mL) was added, and the mixture was stirred for another 1 h. The reaction mixture was extracted with $CHCl_3$ (3 × 10 mL). The organic layers were collected, dried over anhydrous Na_2SO_4, and was evaporated to give **2** as a light amber viscous liquid (140 mg, 45%). ^1H NMR (400 MHz, $CDCl_3$, δ): 7.01 (s, 1H), 4.33 (m, 2H), 3.39 (q, 2H, J = 7.0 Hz), 1.81 (m, 2H), 1.59 (t, 2H, J = 7.0 Hz), 1.36 (m, 8H). ^{13}C NMR (100 MHz, $CDCl_3$, δ): 158.05, 145.13, 142.63, 141.69, 139.04, 121.61, 111.73, 72.57, 40.31, 29.42, 29.04, 28.91, 28.76, 26.54, 25.11.

Preparation of Spindle-Type Hematite α-Fe_2O_3. The nanoparticles were synthesized following a slightly modified literature procedure (*41*). In a typical reaction, $Fe(ClO_4)_3 \cdot 6H_2O$ (11.56 g), NaH_2PO_4 (162 mg), and urea (1.50 g) are solubilized into 250 mL of Milli-Q water at room temperature. The obtained solution was sonicated for 2 h, transferred to a preheated oven at 100 °C for 24 h, and then cooled down to room temperature.

Scheme 1. Functionalization of Hematite Nanoparticles with 1 Followed by Coupling of D-Mannose and Subsequent Binding with *Con A*



After settling, half of the supernatant was removed and the rest of the mixture was centrifuged. The solid was cleaned 5 times at 10 000 rpm for 20 min each with Milli-Q water. The obtained brick red hematite nanoparticles were stored in Milli-Q water.

Preparation of Magnetite Fe_3O_4 Nanoparticles. Magnetite Fe_3O_4 nanoparticles were prepared by the coprecipitation method (*4*, *42*). The Fe^{3+} solution (1 M) was prepared by dissolving ferric chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) in 2 M HCl, and the Fe^{2+} solution (1 M) was prepared by dissolving ferrous sulfate heptahydrate ($FeSO_4 \cdot 7H_2O$) in 2 M HCl. The two solutions, 100 mL of Fe^{3+} and 50 mL of Fe^{2+}, were mixed in a degassed flask. NH_4OH (30%) was added dropwise until the solution pH reached 11. The mixture was stirred vigorously for 30 min at room temperature. The resulting black precipitates were isolated by applying a permanent external magnet and washed 3 times with Milli-Q water. The mixture was then centrifuged, and the solid washed copiously with ethanol to give magnetite Fe_3O_4 nanoparticles.

Preparation of PFPA-Functionalized Iron Oxide Nanoparticles. Hematite (α-Fe_2O_3) and supraparamagnetic (Fe_3O_4) nanoparticles were functionalized with PFPA using the following procedure (*33*). PFPA **1** or **2** and nanoparticles (1:1 w/w, 50 mg each) were mixed in $CHCl_3$ (15 mL), and the mixture was sonicated for 30 min until the particles were well-dispersed. Excess **1** or **2** was removed by copiously washing the nanoparticles with ethanol and centrifuging. Functionalized hematite nanoparticles were labeled as **1**-NP and **2**-NP, respectively, and functionalized Fe_3O_4 nanoparticles were labeled as **1**-Fe_3O_4-NPs.

Coupling Carbohydrates to PFPA-Functionalized Nanoparticles. PFPA-functionalized nanoparticles (5 mg) and the carbohydrate solution (50 μL, 1 mg/mL) were added to water/ethanol (1.5 mL), and UV irradiated for 30 min with a medium pressure Hg lamp with a 280 nm long-path optical filter. The irradiation time of 30 min was determined by FTIR when the azide antisymmetric stretch at 2126 cm^{-1} completely disappeared. The resulting nanoparticles were washed 5 times with water and 3 times with ethanol, and stored in ethanol for further uses.

Binding of Con A to Carbohydrate-Functionalized Nanoparticles. Mannose-functionalized hematite nanoparticles (mannose-**1**-NPs) was incubated with a solution of pH 7.4 PBS buffer containing 0.1% Tween 20 and 3% BSA (w/v) for 30 min and washed with pH 7.4 PBS buffer containing 0.1% Tween 20 for 20 min. The nanoparticles (500 μg/mL) were then incubated with a solution of *Con A* (15 mg/mL) in pH 7.4 PBS containing 0.01% Tween 20 for 6 h at room temperature. The resulting nanopartilces were washed thoroughly with the buffer solution followed by five times with Milli-Q water.

Binding of Mannose-1-NPs to *E. coli* K-12 Strains ORN178 and ORN208. *E. coli* ORN178 and ORN208 were grown in the Luria-Bertain Broth medium at 37 °C to an optical density of 0.9 at 600 nm (approximately 10^9 cells per mL) and precipitated by centrifugation at 3000 rpm for 4 min (*43*). After centrifuging-suspending twice with pH 7.4 PBS buffer, the bacteria (500 μL) was mixed with 500 μL mannose-functionalized nanoparticles (500 μg/mL), and the mixture was gently shaken at room temperature for 1 h.

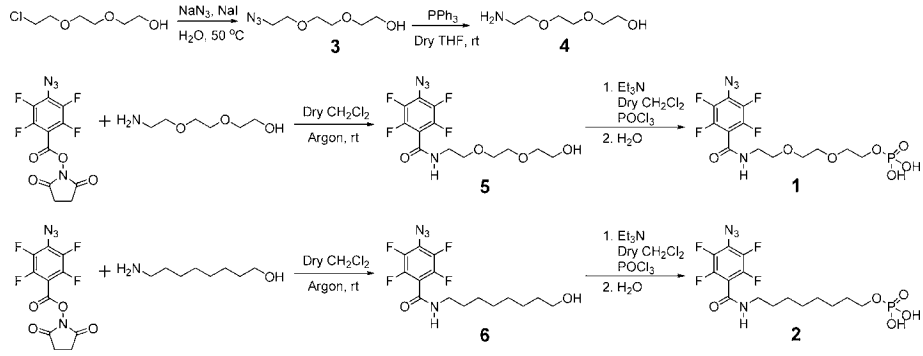
Transmission Electron Microscopy (TEM). Samples of *E. coli* ORN178 and ORN208 treated with mannose-**1**-NPs were placed onto a 200 mesh carbon-coated copper grids, and the suspension was allowed to settle for 1 min, and the excess liquid was removed by a filter paper. A drop of 1% phosphotungstic acid was used to negatively stain the samples for 1 min before they were examined by TEM.

RESULTS AND DISCUSSION

The design of our approach is to prepare PFPA-functionalized iron oxide nanoparticles which can then be used to covalently couple carbohydrates by way of the CH insertion reaction of photochemically activated PFPA (Scheme 1). Phosphate-functionalized PFPA photocoupling agents **1** and **2** were synthesized, where **1** contains ethylene oxide units which are polar and hydrophilic, whereas **2** has methylene units, which are nonpolar and hydrophobic. The ethylene oxide linkage has the additional property of being protein resistant; thus, it has been widely used to create biocompatible and antifouling surfaces (*44*, *45*). Compounds **1** and **2** are prepared following the synthetic sequence shown in Scheme 2.

Spindle-type hematite α-Fe_2O_3 nanoparticles were synthesized by precipitating iron(III) perchlorate in the presence of urea and sodium dihydrogen phosphate, following a modified method by Ocaña (*41*). We found that, by adjusting experimental parameters such as the type of iron salt, the concentration, and the ionic strength of the solution, the size, morphology, and surface functionality of hematite nanoparticles can be controlled (*46*). Nanoparticles of ~250 nm and ~40 nm in equatorial diameters along the *x* and *y* axes, and ~40 nm in the polar diameter along the *z* axis, were synthesized and used in the present study. These particles were functionalized with **1** or **2** following a slightly modified literature method (*33*). In the experiment, nanoparticles were sonicated in the solution of **1** or **2** in $CHCl_3$ for 30 min followed by copious washing to remove the excess coupling

Scheme 2. Synthesis of Photocoupling Agents 1 and 2



agent. The IR spectra of the resulting nanoparticles showed the azide ($-N_3$) antisymmetrical stretch at 2126 cm^{-1}, amide stretch at 1653 cm^{-1}, and P−O−C and P−O−Fe stretches from 1270 to 990 cm^{-1} (*47*), indicating that the nanoparticles have been successfully functionalized with the PFPA-phosphate coupling agent (Figure 1). Control studies were conducted with compounds **5** and **6** that are precursors of **1** and **2** and do not possess the phosphate group. The experiments were carried out following the same preparation procedure for **1**-NPs and **2**-NPs. The IR spectra of the resulting nanoparticles did not show the characeristic azide ($-N_3$) antisymmetrical stretch at 2126 cm^{-1} (Figure S3, Supporting Information), demonstrating that the phosphate group in **1** and **2** is responsible for the attachment of these coupling agents to the nanoparticles.

The successful surface functionalization of the nanoparticles was further supported by a solvent dispersion study. Nanoparticles functionalized with **1** or **2** (**1**-NPs, **2**-NPs) were mixed and sonicated in different solvents of water, ethanol, and acetonitrile. As shown in Figure 2, **1**-NPs dispersed well in water and ethanol but precipitated in acetonitrile. **2**-NPs, however, showed the opposite behavior; the particles precipitated in water and ethanol but dispersed well in acetonitrile. The ethylene oxide linkage in **1** is capable of forming hydrogen bonds with protic solvents of water and ethanol, thus improving the miscibility of the resulting nanoparticles in these media (*48*, *49*). Acetonitrile, lacking the hydrogen bonding ability, is more compatible with the hydrophobic alkyl linkage in **2**. Therefore, depending on the nature of the ligands to be attached, the corresponding coupling agent can be selected, for example, **1** for aqueous-soluble molecules and **2** for organic solvent-soluble compounds. For carbohydrates that are highly polar and water soluble, **1** was used as the coupling agent, and **1**-NPs were used throughout the study.

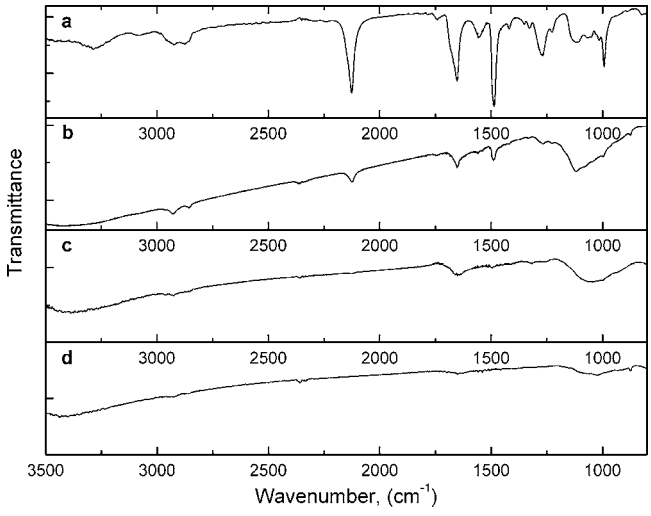


Figure 1. FTIR spectra of (a) PFPA-phosphate ligand **1**; (b) hematite nanoparticles functionalized with **1**; (c) nanoparticles coupled with D-mannose; (d) unfunctionalized hematite nanoparticles.

Subsequent coupling of carbohydrates to **1**-NPs were carried out using D-mannose. Monosaccharides are the smallest carbohydrate structures and the most challenging for this coupling chemistry. The probability of the CH insertion reaction increases as the size of the carbohydrate structure or the number of CH bonds increases. Additionally, monosaccharides are the lowest-affinity ligands, therefore lacking the multivalency effect that can occur in their oligosaccharide counterparts (*50*). Thus, if these monosaccharide ligands can be successfully coupled to NPs, and the resulting conjugated ligands retain their recognition abilities, the methodology developed can be readily applied to other large and more complicated carbohydrate structures. The coupling reaction was carried out by irradiating a mixture of **1**-NPs and the monosaccharide in water/ethanol for 30 min while stirring. The $-N_3$ absorption at 2126 cm^{-1} disappeared in the IR spectrum of the resulting nanoparticles (Figure 1c) indicating that the azide was activated. The surface property of the NPs changed after the monosaccharide coupling. While the as-prepared hematite NPs tend to agglomerate (Figure 3a), NPs coated with D-mannose were well-separated (Figure 3b). In addition, the D-mannose-coated NPs were readily dispersed in water to give a homogeneous dispersion.

The amount of carbohydrate ligands bound to the nanoparticles was determined by the thermogravimetric analysis (TGA). TGA measures the mass loss of the organic materials as they decompose upon heating. When TGA was conducted on **1**-NPs and mannose-**1**-NPs, the percentage mass changes relative to the weight of the hematite NPs were small and within the experimental error of the instrument. To overcome this problem, smaller iron oxide nanoparticles were prepared to increase the percentage of the organic mass relative to that of the nanoparticles. Spherical superparamagnetic Fe_3O_4 nanoparticles of ∼10 nm in diameter were synthesized by the coprecipatation method according to the literature procedure (*4*, *42*). The particles were functionalized with **1**, and the subsequent D-mannose coupling was carried out following the same protocol described above for the hematite NPs. Figure 4 shows the weight loss of each sample as a function of heating temperature. The unfunctionalized NPs showed a decrease in mass up to ∼400 °C, probably due to the presence of volatile residuals trapped inside the nanoparticles. Compared to the unfunctionalized NPs, nanoparticles functionalized with **1** showed a 3.3% weight loss at 600 °C accounting for the mass of the coupling agent. After D-mannose was attached to the nanoparticles, weight loss of

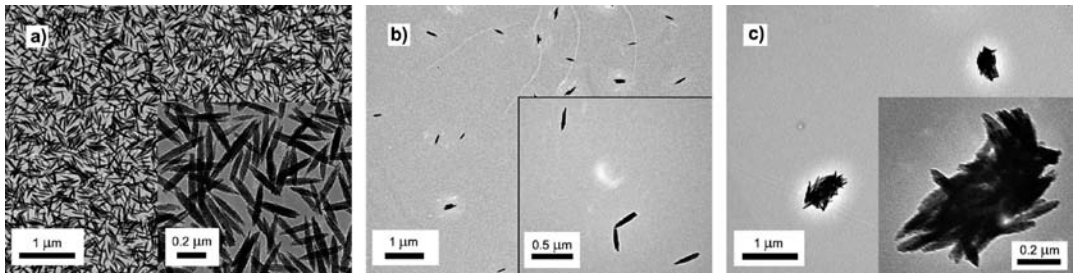

Figure 3. TEM images of (a) hematite nanoparticles, (b) mannose-**1**-NPs (500 μg/mL), and (c) subsequent treatment with *Con A*.

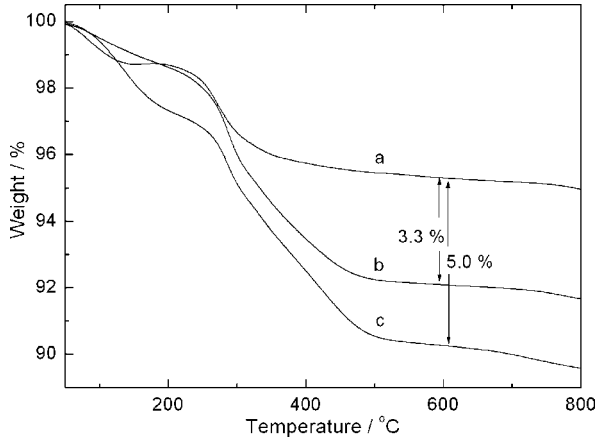

Figure 4. TGA curves of (a) Fe_3O_4 nanoparticles; (b) **1**-Fe_3O_4-NPs; (c) mannose-**1**-Fe_3O_4-NPs.

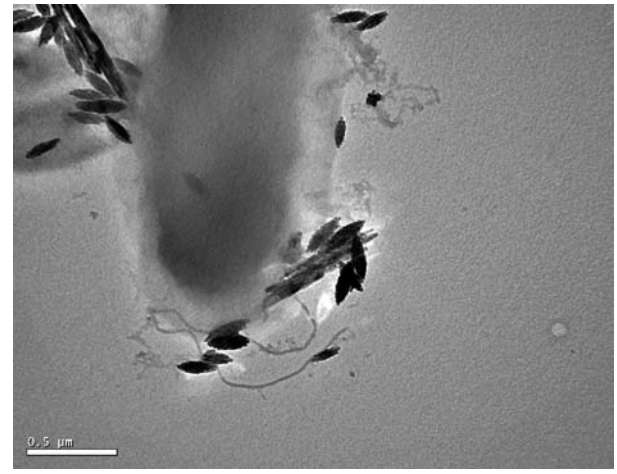

Figure 5. TEM images of *E. coli* ORN178 strain after treating with mannose-functionalized hematite nanoparticles.

5.0% at 600 °C was observed. This corresponds to the combined mass of D-mannose and the coupling agent **1**.

On the basis of these results, the number of organic molecules on each nanoparticle (N) can be calculated from eq 1

$$N = \frac{\frac{4}{3}\pi r^3 \rho w}{\mathrm{MW}} N_\mathrm{A} \qquad (1)$$

where w is the percentage of the weight loss (%), r is the radius of the Fe_3O_4 nanoparticles (averaged 5 nm by TEM), N_A is the Avogadro number, ρ is the density of Fe_3O_4 (5.1 g/cm^3 or 5.1 $\times$ 10^{-21} g/nm^3), and MW is the formula weight of the organic molecule after attaching to the nanoparticle (446 g/mol for **1** and 626 g/mol for mannose-**1** linked to nanoparticle surface). Therefore, weight losses of 3.3% and 5.0% correspond to 119 PFPA-phosphate ligands **1** and 128 mannose-**1** on one nanoparticle surface, respectively. This result means that there are roughly the same number of the coupling agent and the coupled D-mannose on the nanoparticles, indicating that the carbohydrate coupling reaction is fairly efficient.

The mannose-functionalized hematite NPs were subsequently evaluated to test if the conjugated D-mannose retains its recognition ability. *Con A*, a plant lectin that specifically binds mannopyranoside and glucopyranosides (*39*, *50*, *51*), was chosen for this study. Above pH 7, *Con A* exists as a tetramer with each face having two binding sites for the carbohydrate ligand. When mannose-**1**-NPs were treated with *Con A*, they assembled into bundled clusters (Figure 3c). Note that the mannose-**1**-NPs were well-dispersed before binding with *Con A* (Figures 3b). The aggregation can be explained by considering *Con A* as an equivalent of a tetrafunctional cross-linking agent, which upon interacting with D-mannose on NPs, brings together the nanoparticles forming a cross-linked network structure (*52*).

The recognition ability of D-mannose tethered to the hematite NPs was further evaluated in a bacteria binding study. Two *E. coli* strains, ORN178 and ORN208, were selected (*53*). ORN 178 has a mannose specific binding domain, i.e., the FimH lectin on type 1 pili, whereas ORN 208 is deficient of mannose-binding FimH protein (*53*−*57*). After the mannose-**1**-NPs were incubated with ORN 178, spindle nanoparticles were observed attaching themselves at the lateral ends and along the pili of the bacteria (Figure 5) (*53*, *54*, *58*). The strong binding between the nanoparticles

and the pili of ORN178 can be attributed to the multivalent interactions between the surface-confined mannose with the FimH lectin domain on type 1 pili. On the contrary, nanoparticles were absent on the *E. coli* ORN208 strain confirming the FimH-specific binding of the mannose ligands.

CONCLUSIONS

In summary, phosphate-containing PFPA coupling agents were synthesized and applied to functionalize iron oxide nanoparticles. Monosaccharides were successfully coupled to PFPA-functionalized nanoparticles by the photochemically induced CH insertion reaction of PFPA, which does not require chemical derivatization of the carbohydrate structures. The immobilized carbohydrates retained their recognition abilities, as demonstrated by the strong affinity with their corresponding carbohydrate-binding proteins and bacteria. The method developed can be readily applied to other carbohydrate structures including oligosaccharides, polysaccharides, and glycoconjugates. This general coupling chemistry, together with the magnetic properties of iron oxide nanoparticles, offer an attractive platform for rapid qualitative clinical diagnosis, decontamination of biological threats, and biomedical applications.

Received March 26, 2009; Revised Manuscript Received May 19, 2009

Hemoglobin conjugated with poly(ethylene glycol) (PEG) acts as an oxygen carrier free in plasma, substituting red blood cells in supplementing oxygen in hypo-oxygenation pathologies. Given the complexity of oxygen delivery controls, subtle structural and functional differences in PEGylated hemoglobins might be associated with distinct physiological responses and, potentially, adverse effects. We have compared hemoglobin PEGylated under anaerobic conditions, called PEG-Hb^{deoxy}, with hemoglobin PEGylated under aerobic conditions, called PEG-Hb^{oxy}, a product that mimics Hemospan, produced by Sangart, Inc. SDS PAGE and MALDI-TOF analyses demonstrated that PEG conjugation yields products characterized by a broad distribution of PEG/hemoglobin ratios. The elution profiles in size-exclusion chromatography indicate that both products exhibit a more homogeneous distribution of molecular weight/hydrodynamic volume under deoxy conditions and at higher concentrations. PEG-Hb^{oxy} shows high oxygen affinity, low modulation of allosteric effectors, almost no cooperativity, a fast and monophasic CO binding, and a limited dependence of functional properties on concentration, whereas PEG-Hb^{deoxy} exhibits oxygen binding curves that significantly depend on protein concentration, and a slow CO binding, similar to native hemoglobin. PEGylated CO-hemoglobins, probed by flash photolysis, exhibited a lower amplitude for the geminate rebinding phase with respect to native hemoglobin and a negligible T state bimolecular CO rebinding phase. These findings are explained by an increased dissociation of PEGylated hemoglobins into dimers and perturbed T and R states with decreased quaternary transition rates. These features are more pronounced for PEG-Hb^{oxy} than PEG-Hb^{deoxy}. The detected heterogeneity might be a source of adverse effects when PEGylated Hbs are used as blood substitutes.

Hemoglobin-based oxygen carriers (HBOC)[1] (*1*−*4*) are potential therapeutic agents for clinical needs that cannot be fullfilled by blood transfusions, such as (i) acute hemorrhages associated with accidents or weapon wounds in location far from hospitals, (ii) immunoreactivity against all red blood cell determinants, (iii) oxygen supply to patients that do not accept blood transfusions for religious dictates, (iv) oxygenation of ischemic tissues where red blood cells cannot diffuse (*5, 6*), and (v) increase in oxygen concentration in solid tumors for the improvement of radiation therapy (*7, 8*). Moreover, HBOCs can be used for (i) partial substitution of normal transfusion to save blood units during orthopedic surgeries, (ii) reduction of the exposure of preterm infants to adult red cells, potentially causing severe chronic pathologies (*9*), and (iii) safe supply of an oxygen supplier in world countries where blood units from healthy donors are limited. The absence of cross-matching, the room temperature storage, the more than one year shelf life, and the possibility of tuning hemoglobin (Hb) oxygen affinity depending on clinical requirements are other advantages for HBOCs with respect to red blood cell transfusions. Several products have been developed based on approaches aimed at increasing the molecular size of Hb via either subunit cross-linking (*10*−*14*) or conjugation with poly(ethylene glycol) (PEG) (*15*−*18*) to avoid vessel extravasation and renal ultrafiltration. Only a few of these products, manufactured by companies, have progressed and been evaluated in phase II and III trials (*12, 19*−*22*). So far, no products have been approved by the FDA. Moreover, a meta-analysis of the recent clinical trials has evidenced that, to some extent, all products cause medium to severe adverse effects, such as death, myocardial infarction, and pancreatitis (*23*), strongly questioning their safe use. However, companies have expressed concerns on the validity of the meta-analysis (*24, 25*).

It should be fully appreciated that HBOC is a peculiar drug because the amount of product that is injected into the plasma is on the order of grams in comparison to milligrams or micrograms for most other drugs. Thus, even a small amount

species	reaction cycles	total SH	free SH	conjugation (NEM or MAL-PEG)
HbA	–	–	2.3	–
NEM-Hb	2 cycles IMT+NEM	7.7	2.3	5.3 (NEM)
PEG-Hb^{deoxy}	1 cycle IMT+MAL-PEG	9.0	2.3	6.7 (MAL-PEG)
PEG-Hb^{oxy}	1 cycle IMT+MAL-PEG	6.9	1.0	5.9 (MAL-PEG)
PEG-BSA	1 cycle IMT+MAL-PEG	5.9	0.2	5.7 (MAL-PEG)

[a] IMT-modified amino groups before (total SH) and after reaction with NEM or MAL-PEG (free SH) as determined on a tetramer basis by thiol titration with the method of Ampulsky et al. (*39*) The number of residues conjugated with NEM or MAL-PEG was equal to the difference between total SH and free SH. The titre of Cysβ93 of native Hb yielded by the method was 2.3.

of byproduct and heterogeneity generated by the chemical procedures or slight deviation of the functional properties from the physiological needs might be responsible for some of the observed adverse effects. However, so far, no investigation has been carried out to link structural and functional properties of products with the observed adverse effects. One of these products, MP4, trade name Hemospan, is obtained via the conjugation of Hb with an average of 6−7 PEG 5000 (M_r) chains under oxygenated conditions in a two-step procedure: first, oxyHb is thiolated by treatment with iminothiolane (IMT), and then, thiols react with the PEG-maleimido derivative MAL-PEG (*16, 26*). Hemospan has completed phase III clinical trials to test its capacity for prevention and treatment of hypotension during orthopedic surgery (*22, 25, 27*). Hemospan exhibits high oxygen affinity and low cooperativity, which makes it more similar to Hb dimers than to the physiological tetrameric oxygen carrier. These features might have originated from the interference of PEG molecules with Hb amino groups of the organic phosphate binding pocket and the sulfhydryl groups of Cysβ93 (*28*−*31*), which are involved in NO binding (*16, 32, 33*). Recently, it was also demonstrated that PEGylated Hb exhibits an increase in the nitrite reductase activity (*31*).

With the aim of protection from PEGylation function-associated groups, PEGylation of Hb was carried out under anaerobic conditions, in the presence of IHP and Cl^- (*34*). This PEGylated Hb exhibits lower oxygen affinities than Hemospan and normal or moderately reduced response to 2,3-BPG, and retains about 50% of the cooperativity of native Hb (*34, 35*). Otherwise, in transfused rats, retention time, renal filtration, and pressure effects of Hb, PEGylated under anaerobic conditions with seven PEG and seven propionyl groups, called Euro PEG-Hb, were found to be similar to those observed for Hb PEGylated under aerobic conditions (*35*). The altered oxygen affinity and cooperativity of the PEGylated products might not be due solely to lysines modifications. It is known that interface mutants or chemically modified Hbs characterized by an increased oxygen affinity and reduced cooperativity exhibit perturbed tetramer−dimer equilibria, favoring the latter species (*36, 37*). This might also be the effect of PEGylation on Hb.

In the perspective of the use of PEGylated Hb products as a blood substitute and in light of the recently observed adverse effects (*25*), we have carried out a detailed comparison of the structural and functional properties between a product prepared using the procedure reported for Hemospan (*16, 26*), that we named PEG-Hb^{oxy}, that is conjugated with six PEG molecules under aerobic conditions, and Hb, similarly modified with an average of six PEG molecules, under anaerobic conditions, that we named PEG-Hb^{deoxy}. We have studied the molecular weight distribution, physicochemical properties, oxygen binding curves, and time courses of CO binding as a function of protein concentrations, in the absence and presence of allosteric effectors. Results were correlated with elution profiles in size exclusion chromatography under deoxygenated and oxygenated conditions. Our studies suggest that PEG-Hb^{oxy} more than PEG-Hb^{deoxy} exhibits altered tetramer−dimer equilibria, due to slower association rates of the PEGylated dimers as compared with native Hb, thus accounting for most of the observed distinct functional properties. This conclusion is in keeping with a very recent study carried out on Hb PEGylated at both Valα1 and Valβ1 (*38*).

EXPERIMENTAL PROCEDURES

Materials. IMT, IHP, NEM, molecular weight markers, BSA, and MALDI calibration kit were purchased from Sigma Aldrich. Reagents and equipment for SDS-PAGE were from Biorad Laboratories Inc. Ultrafiltration membranes and kits were from Sartorius Stedim and Millipore. MAL-PEG (molecular mass 5.6 kDa) was from Nektar Molecule Engineering (Nektar Therapeutics).

Protein Modification. Conjugated Hbs were prepared by treating HbA in 50 mM Na-phosphate, 100 mM NaCl, 0.5 mM EDTA, pH 7 at 20 °C, with an excess of IMT and MAL-PEG, or NEM, under anaerobic conditions in the presence of IHP, as previously described (*34*) to produce PEG-Hb^{deoxy}. The amount of IMT and the reaction time were adjusted to achieve the desired degree of thiolation and, thus, the number of conjugated PEG molecules. Concentrated and deoxygenated lysine and cysteine solutions were added to stop IMT and MAL-PEG reactions, respectively. PEG-Hb^{deoxy} was then equilibrated with 100 mM NaCl by seven ultrafiltration cycles, under aerobic conditions, at 5 °C, using a 30 kDa cutoff Amicon membrane. The solution was concentrated to one-third of the initial volume before redilution with NaCl solution. The number of conjugated PEG chains was estimated by treating deoxy Hb with IMT under the same conditions without the addition of MAL-PEG. The thiol titer determined by a biochemical method (*39*), corrected for the titer determined after treatment with MAL-PEG, or NEM, yielded the number of conjugated PEG/tetramer, or NEM/tetramer (*34*). PEG-Hb^{oxy} was prepared as described by Vandegriff et al. (*16*). Hb, PEG-Hb^{deoxy}, and PEG-Hb^{oxy} were stored in liquid nitrogen. The ferric Hb content was <2%. Hb concentration is expressed on a heme basis. BSA (68 kDa, 59 lysines) was PEGylated under aerobic conditions by the same procedure described for PEG-Hb^{deoxy} to obtain a protein conjugated with an average number of 6 PEG/molecule. Since the BSA sample was contaminated by 5% IgG immunoglobulin, the product was also contaminated by PEGylated IgG, which showed up in size exclusion chromatography as an inflection of the leading edge of the elution profile of PEG-BSA. The characteristics of the various preparations are summarized in Table 1.

SDS-PAGE and Protein Extraction. SDS-PAGE was carried out according to Laemli (*40*) using acrylamide and piperazine diacrylylamide as the cross-linker. Gels were stained with BioSafe G-250 Coomassie Brilliant Blue compatible with MS analysis and scanned using Quantity One software. Protein bands were excised from the gels and destained with a 40/10 (v/v) mixture of methanol/acetic acid. The proteins were recovered by passive elution at 37 °C using the SDS-PAGE running buffer and concentrated by Vivaspin 2 (Sartorius) centrifugal concentrators, which facilitates SDS removal.

Mass Spectrometry. A layer of sinapinic acid in acetone was spotted onto the sample well before adding 1 μL protein aliquotes diluted with matrix solution containing 30 mg/mL sinapinic acid in 50/50 (v/v) ACN/0.1% TFA. MALDI TOF mass spectra were obtained using a MALDI-LR mass spectrometer (Waters Italia) operated in negative linear mode. External calibration was carried out in the 7−70 kDa mass range using protein standards from the ProteoMass Peptide and Protein MALDI-MS Calibration kit: apomyoglobin (equine) ($M+H^+$: 16 952.27), aldolase ($M+H^+$: 39 212.28), albumin ($M+H^+$: 66 430.09) and High Mass Post Acceleration Linear detector to increase the sensitivity for the PEGylated molecules.

Static and Dynamic Light Scattering. Laser light scattering was carried out with a goniometer (BI-200SM Brookhaven Instrument Corporation) equipped with a BI9K Digital correlator and a solid-state 676 nm light source. Independent SLS and DLS measurements were carried out at 20 °C, under aerobic conditions, on Hb, PEG-Hb^{deoxy}, and PEG-Hb^{deoxy} in a solution containing 50 mM Na-phosphate, 100 mM NaCl, 0.5 mM EDTA, 0.5 mM NaCN, pH 7, at 40−280 μM concentration range. The hydrodynamic radii were determined by Cumulant and Fourier Transform analysis of the intensity correlation function measured by DLS (*41*). Independent SLS measurements provided information about the average molecular weight and concentration of macromolecules after absolute intensity calibration with a 0.02 mg/mL $C_{12}E_8$ solution (*42*).

Size Exclusion Chromatography. Chromatography was carried out in 50 mM Na-phosphate, 100 mM NaCl, 0.5 mM EDTA, pH 7, with an AKTA Prime instrument and a HiLoad Superdex 200 column (≈120 mL bed volume, 600 kDa mass exclusion limit), thermostatted at 20 °C, at flow rate of 1.5 mL/min (Amersham Pharmacia Biotech). The retention time was 40−70 min using 0.5 mL samples of PEGylated Hb. To carry out anaerobic chromatography, the buffer reservoir was kept under nitrogen and 1 mM Na-dithionite was added to the buffer. Samples were loaded after deoxygenation by nitrogen tonometry and addition of Na-dithionite. The eluate from Hb chromatographic analysis was monitored at 436 nm to avoid dithionite interference, whereas the flowthrough of BSA chromatographic analysis was monitored at 280 nm. Chromatograms were normalized to absorbance values versus molecular mass derived from standard proteins calibration.

To determine the tetramer−dimer equilibrium constant of oxy Hb and oxy NES-Hb, a HiLoad Sephacryl S-200 column was used (bed volume ≈79 mL, matrix volume ≈3 mL, according to the manufacturer specifications, and void volume ≈38 mL, as determined by Blue Dextran, 250 kDa mass exclusion limit). Solute saturation was achieved by loading 15 mL samples. The column was run at 0.5 mL/min flow rate at 20 °C. A solute in rapid tetramer−dimer equilibrium, as Hb, loaded on such a column under solute saturating conditions, shows an elution profile characterized by a plateau region between a leading and a trailing edge. The solute elution volume at the inflection point of the leading edge, V, is related to the fraction of dissociated tetramers, α, through eq 1 (*43*):

$$V = V_0 + [\sigma_T + \alpha(\sigma_D - \sigma_T)]V_i \quad (1)$$

where V_0 is the void volume, V_i the internal matrix volume, provided by the manufacturer, and σ_T and σ_D are parameters that characterize the matrix interactions with tetramers and dimers, respectively. These parameters were obtained using enough high and low Hb concentrations to justify the assumption that the protein was in tetrameric and dimeric form, respectively. The gradient of the elution profile was analyzed to precisely determine the elution volume at the inflection point of the leading edge. The dissociation constant is related to α through eq 2:

$$K_d = \alpha^2 C/(1 - \alpha) \quad (2)$$

where C is the solute plateau concentration. Under deoxy conditions, the method could not be used since both normal and NES-Hb require dilution much beyond the limit of concentration detection of the technique and the tetramer−dimer equilibration is not rapid relative to the time scale of the chromatographic run.

Oxygen Affinity Measurements. Oxygen dissociation curves (ODCs) as a function of protein concentration were carried out at 15 °C in a solution containing the enzymatic metHb reducing system (*44*), at pH 7.0, using a novel homemade apparatus (*45*). The gas mixture generated by Environics 200 and 4000 (Environics, Inc.) flows in a thermostatted humidifier and then in the sample chamber consisting of a 2 mm optical path cuvette fused to a 25 mL open-top threaded reservoir with fittings for inlet and outlet gas lines. The chamber is thermostatted in a shaking bath. The sample compartment of a CARY 400 spectrophotometer (Varian, Inc.) is also thermostatted. Fractional oxygen saturations and oxidized hemes were determined by fitting the observed spectra to a linear combination of reference spectra (*46*, *47*). ODCs of PEG-Hb^{deoxy}, in the absence of allosteric effectors, at different protein concentrations, were globally fitted using eq 3, assuming two independent species ***a*** and ***b***, characterized by p50$_a$ and Hill coefficient n_a, and p50$_b$ and Hill coefficient n_b, respectively, varying only the relative fraction of species ***a***, f_a, as a function of concentration:

$$Y = f_a \frac{pO_2^{na}}{pO_2^{na} + p50_a^{na}} + (1 - f_a) \frac{pO_2^{nb}}{pO_2^{nb} + p50_b^{nb}} \quad (3)$$

ODCs in the presence of the allosteric effectors Cl^- and CO_2 were fitted with eq 1, constraining p50$_a$ and n_a to be equal to those calculated in the absence of allosteric effectors. It was assumed that functional properties of species ***a*** are unaffected by effectors because this species corresponds to Hb dimers, whereas functional properties of species ***b*** are affected because this species corresponds to Hb tetramers (see Results). ODCs of PEG-Hb^{oxy} and Hb were fitted to a single species characterized by p50 and Hill coefficient n.

CO Binding Kinetics. CO binding to HbA, PEG-Hb^{deoxy}, and PEG-Hb^{oxy} was followed by stopped-flow apparatus (SX.18 MV, Applied Photophysics) at a single wavelength (435 nm). Two millimolar Na-dithionite was added to deoxygenated protein and ligand solutions to completely remove oxygen. Depending on Hb concentration, a path length of 0.2 or 1 cm was used.

Flash photolysis experiments were performed with a setup described elsewhere (*48*, *49*), following the absorbance change at 436 nm. Photolysis yields for all species were evaluated and found to be similar. The rebinding kinetic traces were first converted to fraction of deoxy-protein as a function of time. The lifetime distribution associated with the observed CO rebinding kinetics was evaluated using the program MemExp (version 3.0) (*50*). The program MemExp uses a maximum entropy method (MEM) and either nonlinear least-squares (NLS) or maximum likelihood (ML) fitting to analyze a general time-dependent signal in terms of distributed and discrete lifetimes. A distribution of effective log-lifetimes, $g(\log(\tau))$, was extracted from the data without restriction to any functional form, as previously described (*51*−*53*).

Stopped-flow and flash photolysis experiments were carried out in a solution containing 1 atm CO, 100 mM Hepes, 1 mM EDTA, pH 7.0, at 15 °C.

RESULTS

Analysis of PEGylated Hbs by SDS-PAGE and Mass Spectrometry. A previous mass spectrometry (MS) study of Hb PEGylated under anaerobic conditions showed that 5 lysines

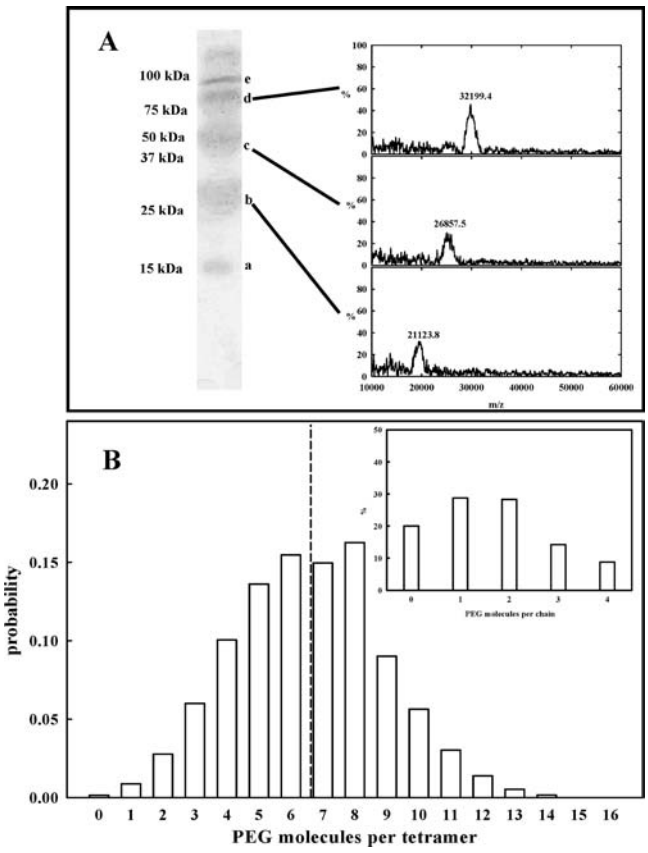

Figure 1. PEG-Hb^{deoxy} heterogeneity. (A) SDS-PAGE and molecular weight determination by MALDI-TOF of PEGylated Hb products. PEG-Hb^{deoxy} was separated by SDS-PAGE (left panel). The molecular weight of species ***a*** was 16 kDa, according to molecular weight markers (not shown). The *m*/*z* values of the species extracted from bands b, c, and d and analyzed by MALDI-TOF MS (right panel) were 21123, 26857, 32199, respectively, indicating the addition of 1, 2, and 3 5.6 kDa PEG molecules. (B) Distribution of unmodified and PEGylated species in a sample of PEG-Hb^{deoxy} calculated from the relative amounts of the various chains determined in Figure 1A. Relative proportions of unmodified and PEGylated chains, as determined by the analysis of the intensities of the stained bands of the SDS-PAGE separations, are reported in Figure 1B, inset.

per subunit were modified by IMT at a significantly higher rate than three additional lysines, both on the α and β chains (*34*). The reactivity differences between these 5 reactive lysines do not allow the preparation of a homogeneous product. Only 6−7 residues per tetramer are PEGylated, showing a significant population of unmodified chains that suppressed the ionization of PEGylated chains in MALDI-TOF MS, thus yielding only a qualitative information on the presence of non-PEGylated Hb chains (*34*). To obtain a quantitative estimate of the proportion of unmodified vs PEGylated tetramers, PEG-Hb^{deoxy} was characterized by SDS-PAGE, which was proven effective in separating nonconjugated and conjugated Hb chains (Figure 1A, left panel). A similar study has recently been carried out for Hemospan (*26*). Since the species in band a runs as HbA chains (data not shown), it was assumed that this species corresponds to the unmodified globin chains. Bands b, c, d, and e migrate with an apparent molecular weight of approximately 25, 45, 75, and 90 kDa, respectively, as calculated using protein molecular weight standards. The species extracted from the bands were individually characterized by MALDI-TOF MS, as shown in Figure 1A, right panel. Bands b, c, and d were assigned to globin chains conjugated with one, two, and three 5.6 kDa PEG molecules, respectively. The protein recovery from the low-intensity band e was not sufficient to collect reliable data in MALDI TOF analysis. However, it is reasonable to assume that this component is conjugated with four PEG molecules per globin chain. The tetramer distribution as a function of the number of conjugated PEG molecules (Figure 1B) was calculated using the densitometric analysis of the stained protein bands (Figure 1B, inset). It displays a wide distribution, spanning from unmodified to 12 PEG molecules per tetramer. The weighted mean is 6.6 PEG molecules/tetramer, in good agreement with the biochemical estimation (see Experimental Procedures, Table 1). Such a distribution indicates that, under these conditions, a wide variety of PEGylated Hb species is present and the probability to find either unmodified or highly PEGylated tetramers (>12−13 PEG molecules) is negligible. Furthermore, samples of PEG-Hb^{oxy} and PEG-Hb^{deoxy} were analyzed by native gel electrophoresis (data not shown). The densitometric profiles indicate that both PEG-Hb^{oxy} and PEG-Hb^{deoxy} are heterogeneous products (see also ref 26).

Analysis of PEGylated Hbs by Static and Dynamic Light Scattering. Solutions containing HbA, PEG-Hb^{oxy}, and PEG-Hb^{deoxy}, at a concentration of 40−280 μM, were characterized by static light scattering (SLS) and dynamic light scattering (DLS) measurements. The observed weight average molecular masses were 68 ± 5, 105 ± 2, and 99 ± 1 kDa, respectively. The average number of PEG chains per tetramer, 6.6 (PEG-Hb^{deoxy}) and 5.6 (PEG-Hb^{oxy}), calculated from these mass values agreed with the values obtained by the biochemical characterization and mass spectroscopy measurements (Table 1). The average hydrodynamic diameters of HbA, PEG-Hb^{deoxy}, and PEG-Hb^{oxy} were 59, 105, and 104 Å, respectively, within 5% error. Using the static and dynamic measurements, it was calculated that Hb hydrodynamic radius agreed with the dimension of a globular particle with 66 kDa molecular mass. In the case of PEG-Hb^{deoxy} and PEG-Hb^{oxy}, PEGylation brought about a significant increase in hydrodynamic radius with respect to the increase in the molecular mass, suggesting a Hb core surrounded by a 15−20 Å thick shell of highly hydrated flexible PEG monomers.

Analysis of PEGylated Hbs by Size Exclusion Chromatography. Column chromatography of oxy Hb and oxy NES-Hb, at 20 °C in 50 mM phosphate, 100 mM NaCl, 0.5 mM EDTA, 0.1 mM NaCN, pH 7, under aerobic conditions and protein column saturation, yielded single plateau regions at all protein concentrations in the 4−4000 μM range. The averaged dimer/tetramer $K_{d(oxy)}$ values were 0.26 ± 0.08 and 0.42 ± 0.07 μM, respectively, comparable to published values of 0.48−1.9 μM for liganded human Hbs under similar conditions (*36, 37*). Under anaerobic conditions, the dimer/tetramer $K_{d(deoxy)}$ values of deoxy NES-Hb could not be obtained by this approach due to the extremely low value of the equilibrium dissociation constant, as already known for Hb (*54*).

The chromatography of PEG-Hb^{deoxy} and PEG-Hb^{oxy}, under aerobic conditions, failed to yield a single plateau because of either the heterogeneity of the PEGylated proteins or the slow equilibration of the species during chromatography. To clarify this issue, we carried out size exclusion chromatography using nonsaturating column conditions. Oxy Hb at all concentrations was eluted as a single, nearly symmetrical peak, which shifted from 65 ± 3 kDa at 800 μM to lower values upon dilution due to the increased fraction of dimers in rapid equilibrium with tetramers (data not shown). Deoxy Hb was eluted as a single, 65 kDa symmetrical peak at all concentrations (data not shown). Chromatography of PEG-BSA (Figure 2A, inset) showed a single main peak with an inflection in the leading edge due to the presence of PEGylated IgG immunoglobulin. This clearly indicates that under the conditions of the chromatography the molecular sieve could not resolve species differing in the number of conjugated PEG chains. However, a shift in the apparent molecular weight from 540 ± 25 to 640 ± 25 kDa occurred

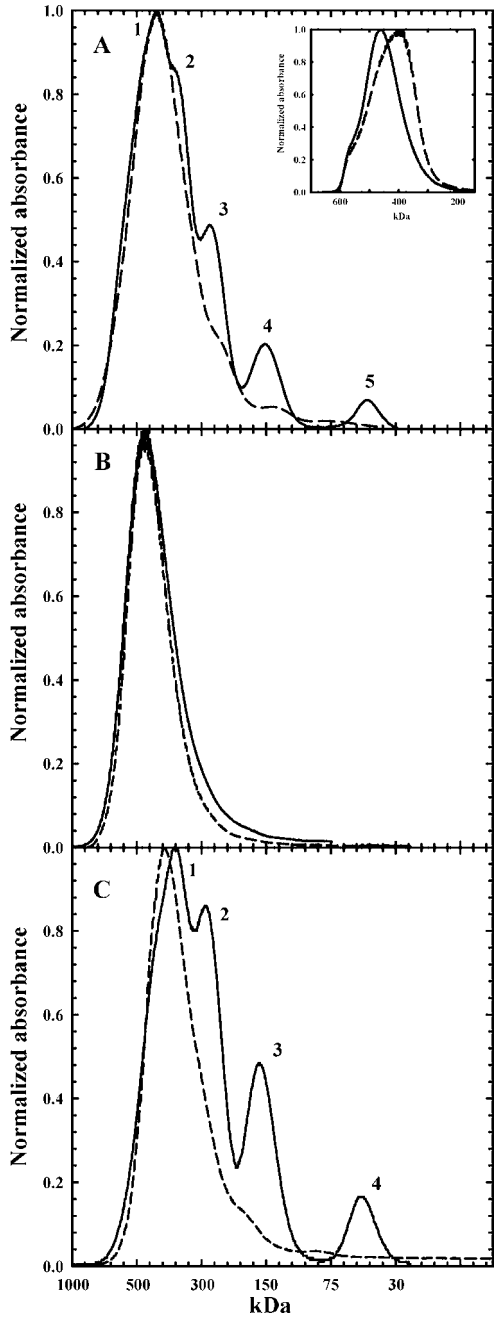

Figure 2. Size exclusion chromatography. A HiLoad Superdex 200 column (about 120 mL bed volume) was equilibrated at 20 °C with 50 mM Na-phosphate, 100 mM NaCl, 0.5 mM Na-EDTA, 0.1 mM NaCN, pH 7. Samples (0.5 mL) were eluted at a 1.5 mL/min flow rate. The elution volumes in the abscissa were transformed into molecular weight units (kDa) by column calibration using known standards. Absorbance values on the ordinate were normalized to the highest value. (A) (dash line) 800 and (solid line) 8 μM oxy PEG-Hb^{deoxy}. The species eluted in peaks 1−5 were not identified. The apparent molecular weight of peak 1 is 460 kDa. Inset: 800 μM (solid line) and 8 μM (dash line) PEG-BSA. The apparent molecular weights are 540 and 640 kDa, respectively. The inflection of the leading edge indicates the presence of PEGylated IgG, which contaminated the native BSA sample (5%). (B) 8 μM deoxy PEG-Hb^{deoxy} in the presence of 1 mM Na-dithionite. (dash line), sample prepared by dilution of a deoxygenated 800 μM solution. (solid line), sample prepared by Na-dithionite addition to a 8 μM oxygenated solution. The apparent molecular weight of the peak is 500 kDa. (C) 8 μM PEG-Hb^{oxy} under aerobic (solid line) and anaerobic (dash line) conditions. The species in peaks 1−4 were not identified. The apparent molecular weight of peak 1 is 380 kDa. The 8 μM deoxy PEG-Hb^{oxy} sample was obtained by the addition of Na-dithionite to a 8 μM oxygenated sample before loading. The apparent molecular weight of the peak is 430 kDa.

upon dilution (Figure 2A, inset), due to non-ideality of the solute−matrix interactions. The non-ideality effect was also observed using Hb at high concentrations where dissociation into dimers is not significant (data not shown). At 800 μM concentration, oxy PEG-Hb^{deoxy} was eluted as a main species with an apparent molecular weight of 460 ± 25 kDa, more than four times the value calculated on the basis of the average PEG/tetramer number (Figure 2A). A trailing edge, however, indicated the presence of small amounts of other components. At 2 μM concentration, four additional unidentified components, partially or completely resolved, were observed (Figure 2A). The formation of low relative molecular mass (M_r) components upon dilution was reversible, since a 8 μM sample of oxy PEG-Hb^{deoxy} reconcentrated to 800 μM was eluted as the original undiluted 800 μM sample (data not shown). PEG-Hb^{deoxy} chromatography under anaerobic conditions, at all concentrations, yielded a single peak with an apparent molecular weight of 500 kDa. However, the slight trailing observed with diluted samples depended on the modality of sample dilution. When a 800 μM oxygenated sample was deoxygenated before dilution to 8 μM, trailing was minimal (Figure 2B). If dilution to 8 μM was carried out under aerobic conditions followed by rapid deoxygenation with Na-dithionite, trailing was more pronounced (Figure 2B). Under aerobic conditions and at 8 μM concentration (Figure 2C), PEG-Hb^{oxy} showed at least a five-component elution pattern with the main component, **1** (Figure 2C), shifted to an apparently lower molecular weight (380 kDa) than component **1** in the PEG-Hb^{deoxy} elution pattern, Figure 2A, and a significant increase in the relative proportions of partially or completely resolved species as compared with PEG-Hb^{deoxy} under the same conditions (Figure 2C). Under anaerobic conditions and when rapid deoxygenation of 8 μM oxy PEG-Hb^{oxy} was carried out by Na-dithionite addition (Figure 2C), the apparent M_r of the main peak was 430 kDa and the presence of incompletely reassociated species was more evident than in the case of PEG-Hb^{deoxy} (Figure 2B).

Oxygen Binding Curves of PEG-Hb^{deoxy} and PEG-Hb^{oxy} as a Function of Protein Concentration, in the Absence and Presence of Allosteric Effectors. ODCs were carried for PEG-Hb^{deoxy} at protein concentrations between 11 and 550 μM, for PEG-Hb^{oxy} at 219 μM and for HbA at 13 and 193 μM in a solution containing 100 mM Hepes, 1 mM EDTA, pH 7, at 15 °C (Figure 3). The apparent oxygen affinity for PEG-Hb^{deoxy} was found to increase as protein concentration decreased. ODCs were globally fitted to two components, ***a*** with $p50_a = 0.80 \pm 0.12$ Torr and $n_a = 1.33 \pm 0.09$ and ***b*** with $p50_b = 3.18 \pm 0.08$ Torr and $n_b = 2.54 \pm 0.19$. The fraction of species ***a***, f_a, decreases with increasing Hb concentration, remaining constant above 200 μM (Figure 3, inset). The dependence of f_a on Hb concentration was fitted to a binding isotherm with a dissociation constant K_d of 21.5 ± 2.3 μM.

ODCs for HbA (Figure 3) do not exhibit variation as a function of protein concentration and were fitted to an equation for a single oxygen binding species with a p50 of 2.65 ± 0.02 Torr and Hill *n* of 2.39 ± 0.05, values very close to those exhibited by species ***b***. ODC for PEG-Hb^{oxy} (Figure 3) was well fitted to a single species with p50 of 0.66 ± 0.03 Torr and Hill *n* of 1.36 ± 0.03, values very close to those exhibited by species ***a***. However, when ODCs were measured for PEG-Hb^{oxy} fractions separated by native PAGE (data not shown), p50 values were found to even 2-fold different between them.

PEGylated Hbs obtained under anaerobic conditions exhibited nearly normal oxygen affinity modulation by 2,3-BPG, due to the organic phosphate binding pocket protection by IHP during the chemical modification and a Bohr effect reduced by 20−25% (*34*). However, more relevant in view of the use of PEG-Hbs as HBOC are the effects of CO_2 and Cl^-, which are allosteric

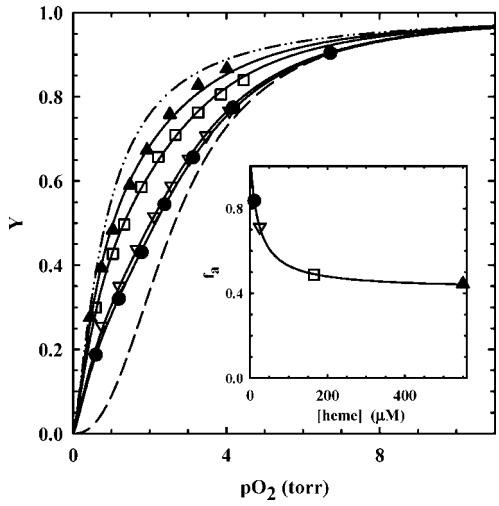

Figure 3. Concentration dependence of oxygen binding to PEG-Hb^{deoxy}, PEG-Hb^{oxy}, and Hb. ODCs at 11 (closed up-triangles), 25 (open squares), 165 (open down-triangles), and 550 μM (closed circles) concentrations of PEG-Hb^{deoxy} were determined in 100 mM Hepes, 1 mM EDTA, pH 7, at 15 °C. ODCs were determined under the same conditions for 193 μM HbA (dash line) and 219 μM PEG-Hb^{oxy}. (dash-dot-dot line). ODCs for PEG-Hb^{deoxy} were globally fitted (solid lines) assuming different fractions of component **a** ($p50_a = 0.80$ Torr and $n_a = 1.33$) and **b** ($p50_b = 3.18$ Torr, $n_b = 2.54$). HbA and PEG-Hb^{oxy} were fitted to a single species with p50 of 2.61 ± 0.05 Torr and Hill n of 2.36 ± 0.06 and p50 of 0.85 ± 0.02 Torr and Hill n of 1.34 ± 0.04, respectively. Inset: dependence of the fraction of component **a** on concentration. The dependence was fitted to a binding isotherm with an apparent tetramer−dimer equilibrium constant $K_d = 21.5 \pm 2.3$ μM.

effectors present in the plasma. The comparison of p50 and Hill n values for Hb, NES-Hb, PEG-Hb^{deoxy}, and PEG-Hb^{oxy}, in the absence and presence of physiological concentrations of CO_2 and saturating concentration of Cl^- (Table 2), shows a decrease in oxygen affinity brought about by the allosteric ligands on both PEGylated Hbs, although to an extent that is less than on HbA.

CO Binding Kinetics to HbA, PEG-Hb^{deoxy}, and PEG-Hb^{oxy}. Binding kinetics of CO to HbA is characterized by an autocatalytic behavior due to the shift of the quaternary T to R state equilibrium as a function of ligand saturation (*55, 56*). The observed log rate constants, expressed as M^{-1} s^{-1} of 0.5 atm CO binding to Hb, determined by stopped-flow measurements (Figure 4), were 5.034 ± 0.001 and 5.776 ± 0.008 at 107 μM HbA, and only slightly higher (5.101 ± 0.002 and 5.782 ± 0.009) at 3.5 μM HbA, in good agreement with previously determined values (*57*). The kinetics of CO binding to 96 and 14 μM PEG-Hb^{oxy} (Figure 4) were monophasic with a log rate constant of ~5.3, independent of protein concentration. The CO binding kinetics to 88 and 6.6 μM PEG-Hb^{deoxy} (Figure 4) were nearly monophasic with log rate constants of 5.073 ± 0.001 and 5.120 ± 0.001, respectively.

The kinetic trace of CO rebinding to HbA after laser flash photolysis (Figure 5A) originates from three distinct processes: a nanosecond geminate rebinding of CO still present in the heme pocket of R state molecules that have not yet relaxed to the T state, a microsecond bimolecular rebinding of CO from the solvent to R state molecules, and a millisecond bimolecular rebinding of CO from solvent to tetramers that have switched to the T quaternary state (*58, 59*). The kinetics is more complex due to the overlapping tertiary and quaternary conformational changes triggered by the ligation state (*59*). The associated lifetime distribution (Figure 5B) exhibits three bands centered at 90 ns, 200 μs, and 6 ms, in good agreement with previously reported data (*59, 60*).

CO rebinding to PEG-Hb^{deoxy} and PEG-Hb^{oxy}, in the absence of IHP, exhibits a lower geminate rebinding amplitude than HbA and an almost negligible T state bimolecular rebinding (Figure 5A). The associated lifetime distributions (Figure 5B) show two major bands centered at ≈ 90 ns and ≈ 200 μs, corresponding to geminate and bimolecular rebinding, respectively. A barely detectable band appears at 10 ms. The amplitude of the band associated with geminate recombination is lower for PEGylated Hbs than in HbA and becomes broader in the case of PEG-Hb^{oxy}. The band centered around 200 μs displays only minimal differences among samples, suggesting that the rate for CO rebinding to R is similar for all samples.

The presence of the allosteric effector IHP leads to a slight decrease in the amplitude of the geminate phase for both PEG-Hb^{deoxy} and PEG-Hb^{oxy} and a concomitant onset of millisecond T state bimolecular rebinding. The comparison of the rebinding kinetics in the absence and presence of IHP for PEG-Hb^{oxy} (Figure 6A) and the corresponding lifetime distributions (Figure 6B) indicates that, in the presence of IHP, the nanosecond and microsecond bands appear to be slightly shifted toward longer times, with the geminate phase becoming a bit smaller, and a clearly distinguishable additional band at ≈ 9 ms. These effects demonstrate for PEG-Hb^{oxy} and, similarly, for PEG-Hb^{deoxy} (data not shown) that the allosteric effectors bias the distribution of molecules toward states with T-like reactivity.

CO rebinding kinetics were measured for 13 and 98 μM PEG-Hb^{deoxy} (Figure 7A). When PEG-Hb^{deoxy} concentration is increased, an additional kinetic phase appears in the millisecond range. Accordingly, three distinct peaks are present in the MEM lifetime distribution (Figure 7B), corresponding to geminate rebinding (100 and 130 ns, at 13 and 98 μM, respectively) and to bimolecular rebinding to R-like structures (230 and 250 μs, at 13 and 98 μM, respectively) and to T-like structures (12 ms at 98 μM; at 13 μM this band is barely detectable and has a maximum at 7 ms). It is worthwhile to notice that the bands become broader when the protein concentration is increased. Analogous results were obtained for PEG-Hb^{oxy} (data not shown).

Variation of the amplitude of the geminate phase and the concomitant increased amplitude of the slow second-order rebinding in the presence of allosteric effectors (Figure 6), increasing protein concentration (Figure 7), and increasing photolysis level (data not shown) indicate that an R to T quaternary conformational change is occurring upon photolysis also for PEG-Hb^{deoxy} and PEG-Hb^{oxy}. However, when compared to rebinding to HbA, the bimolecular rebinding to T-like structures measured for PEG-Hb^{deoxy} and PEG-Hb^{oxy} exhibits a lower amplitude, suggesting that the bias toward a T-like structure is much lower for these products than for HbA due to a higher concentration of the liganded dimers and a slow kinetics of dimer to tetramer association in the unliganded state.

DISCUSSION

PEG-Hb Heterogeneity. The PEGylation procedure yields topologically heterogeneous products because the similar accessibility of the lysine residues (5−7 per Hb chain) reacting with IMT does not allow an absolute selectivity (*34*). In addition, these modifiable sites are not fully saturated by PEG conjugation because the usual HBOC preparation adds only 6−8 PEG per Hb tetramer, which leaves a small fraction of unmodified chains. The MALDI MS analyses carried out on the chains isolated by SDS-PAGE allowed a reliable quantitative determination of unmodified and differently PEGylated chains distribution. The PEG moiety distribution for PEG-Hb^{deoxy} indicates that the bulk of this product (65−70%) consists of tetramers conjugated with a number of PEG chains centered at the value of 6.6 ± 1. Procedures have been developed for the direct coupling to Hb

Table 2. Effects of CO_2 and Cl^- on Oxygen Affinity[a]

[a] p50$_b$ of HbA, NEM-Hb, PEG-Hb^{deoxy}, and PEG-Hb^{oxy}, in the absence and presence of physiological concentrations of CO_2 and saturating concentration of Cl^- (200 mM), in a solution containing 100 mM Hepes, 1 mM EDTA, at 15°C, pH 7.0. The sample concentration is 110−200 μM. [b] For HbA and PEG-Hb^{oxy}, p50 and n were obtained by fitting ODCs to a single species.

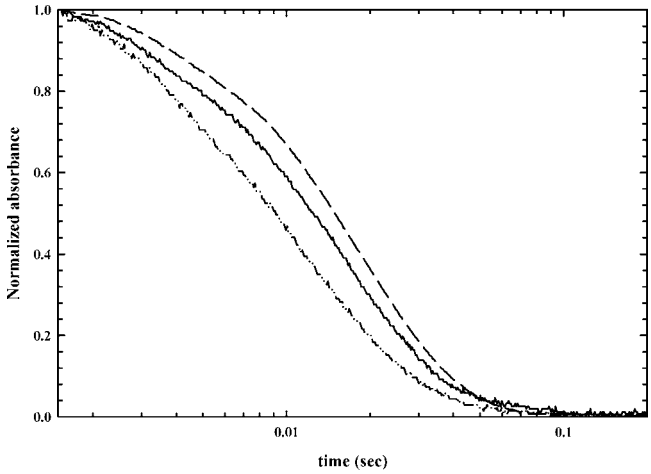

Figure 4. CO binding kinetics to PEG-Hb^{deoxy}, PEG-Hb^{oxy}, and Hb, in the absence of allosteric effectors. Normalized absorbance changes at 435 nm followed upon rapid mixing of deoxy 14 μM PEG-Hb^{oxy} (dash-dot-dot line), 6.6 μM PEG-Hb^{deoxy} (solid line), and 3.5 μM HbA (dash line) in a solution containing 100 mM Hepes, 1 mM EDTA, pH 7, 0.5 atm CO at 15 °C.

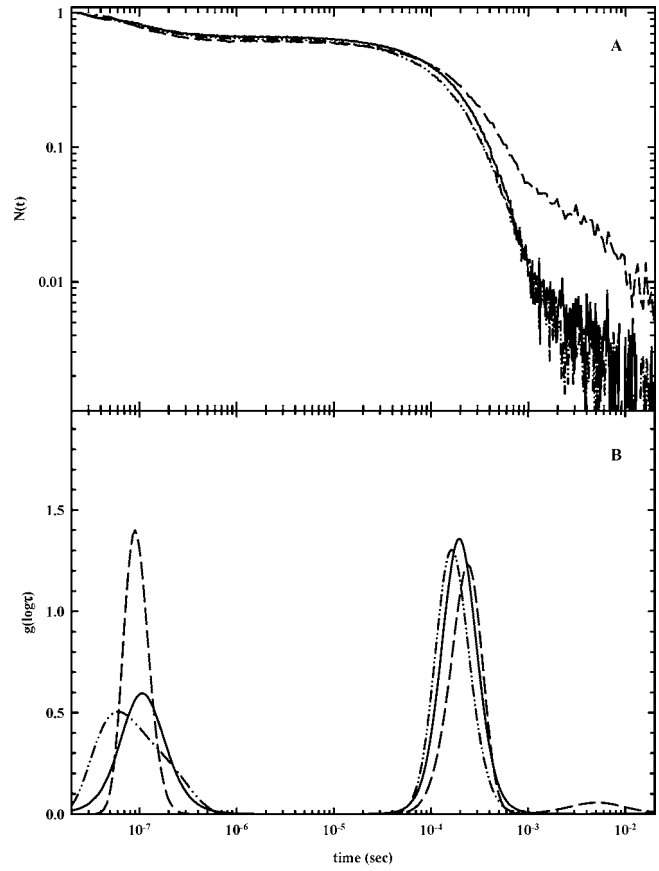

Figure 5. Ligand rebinding kinetics to HbA, PEG-Hb^{deoxy}, and PEG-Hb^{oxy}, after photodissociation of the CO complex. (A) Kinetic progress curves for the fraction of deoxyhemes vs time are reported for HbA (dashed line), PEG-Hb^{deoxy} (solid) and PEG-Hb^{oxy} (dash-dot-dot line) in a solution containing 100 mM Hepes, 1 mM EDTA, pH 7.0, 1 atm CO, at 15 °C, 105 μM HbA, 110 μM PEG-Hb^{deoxy} and 107 μM PEG-Hb^{oxy}. (B) Lifetime distributions associated with the kinetics shown in panel A, calculated using MEM analysis.

of functionalized PEG (*61*, *62*). It cannot be excluded that bound bulky PEG molecules steer the attachment of other PEG molecules leading to products less heterogeneous than those obtained in the two-step PEGylation procedure. However, the issue of molecular weight heterogeneity may also concern these products because of the large number of potential attachment sites, 42 lysines and 4 α-amino groups, with respect to the much lower number, 6−8, of bound PEGs. Thus, it seems unavoidable that PEGylated Hb is a heterogeneous product. This relatively wide species heterogeneity leads to different physicochemical and physiological properties that should be taken into account when in vivo experiments are analyzed and might be responsible for some of the observed adverse effects (*23*).

PEGylated Hb Tetramer Stability. Native Hb undergoes a reversible tetramer−dimer equilibrium as depicted by eq 4:

$$(\alpha\beta)(\alpha\beta) \underset{k_{ass}}{\overset{k_{diss}}{\rightleftharpoons}} 2(\alpha\beta) \qquad (4)$$

where $(\alpha\beta)(\alpha\beta)$ represents the tetrameric form and $(\alpha\beta)$ the dimeric form of the protein.

The rate of dissociation, k_{diss}, is ligation-dependent with $k_{diss(deoxy)} \ll k_{diss(oxy)}$, whereas the rate of association, k_{ass}, is ligation-independent (*37*). The reactions in eq 4 have several important implications for evaluation of the in vitro and in vivo properties of PEGylated Hbs: (i) the exchange of dimers among species differing in the number and distribution of conjugated PEG-Hb yields hybrid species. This phenomenon could contribute in vitro to smoothing out the molecular weight heterogeneity of the species and their properties in solution, such as oxygen affinity, allosteric effects, redox potential; (ii) in the circulation, at the interface with tissues, selective permeation of some species may occur leading to a change in the bulk properties of the PEGylated species confined in the plasma; (iii) the order of magnitude of the equilibrium constants for the dissociation of deoxy Hb and oxy Hb are 10^{-11} and 10^{-6} M, respectively. Most Hb mutants with increased oxygen affinity and decreased cooperativity show an increase in $k_{diss(deoxy)}$, although a few cases are known in which an increase in $k_{diss(oxy)}$ has also been observed (*36*, *37*). Since the tetramer−dimer equilibrium is an oxygen-linked property, it could be involved in the cooperativity reduction of PEGylated Hbs, mimicking mutant species. A direct study of the reactions in eq 4 by various methods, such as haptoglobin binding (*63*) and hybridization techniques (*64*, *65*) was not feasible due to the interference of conjugated PEG.

The equilibrium gel permeation study of NES-Hb showed that the product exhibits the same $K_{diss(oxy)}$ as normal Hb. The $K_{diss(deoxy)}$ value could not be measured because the product was not significantly dissociated under the most dilute conditions, as known for normal Hb. The various PEGylated species in the polydisperse solution of PEG-BSA were not resolved by size

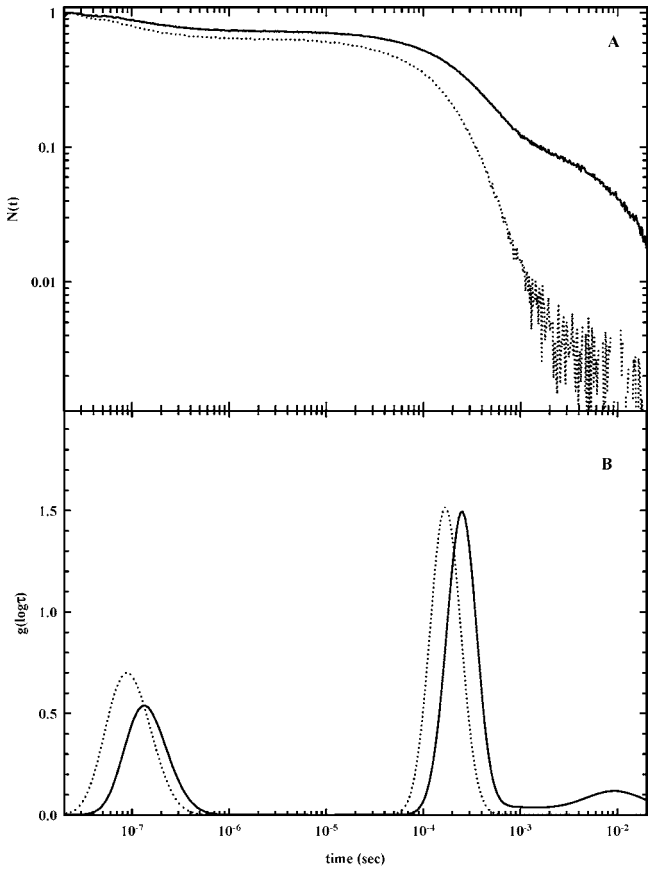

Figure 6. Effect of IHP on PEG-Hb^{oxy} CO rebinding kinetics. (A) CO rebinding kinetics in 100 mM Hepes, 1 mM EDTA, pH 7.0, 1 atm CO, 15 °C, to PEG-Hb^{ox} in the absence (dotted line) and presence (solid line) of 10 mM IHP, at 107 and 100 μM PEG-Hb^{oxy}, respectively. (B) Lifetime distributions associated with the kinetic traces shown in A, calculated using MEM analysis.

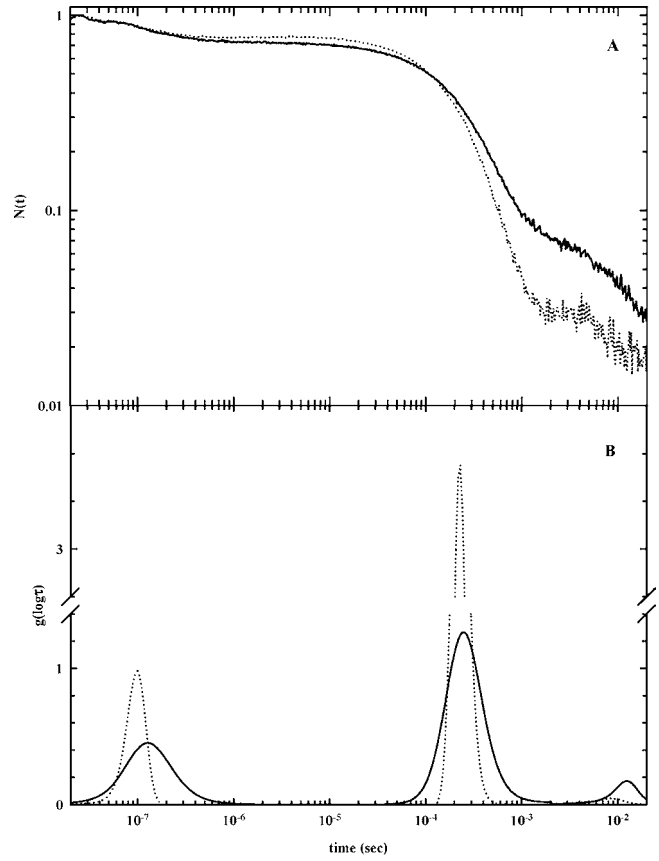

Figure 7. Effect of protein concentration on PEG-Hb^{deoxy} CO rebinding kinetic. (A) CO rebinding kinetics to PEG-Hb^{deoxy} at 13 μM (dotted line) and 98 μM (solid line), 10 mM IHP, 100 mM Hepes, 1 mM EDTA, pH 7.0, 1 atm CO, 15 °C. (B) Lifetime distributions associated with the kinetic traces, shown in A, calculated using MEM analysis.

exclusion chromatography both at high and low product concentration, at which trailing was completely absent. On the contrary, PEG-Hb^{deoxy} under aerobic conditions was resolved into a multiplicity of components upon similar dilution, in agreement with the electrophoretic pattern under native conditions (data not shown). Some of these components had apparent molecular weights consistent with monomeric PEGylated species. Since the phenomenon was completely reversible, the most plausible interpretation is that oxy PEG-Hb^{deoxy} dissociates rapidly into dimers as normal oxy HbA does, but the PEGylated subunits reassociate at a low rate compared with the time scale of the chromatography, in contrast with oxy HbA behavior. This interpretation is consistent with the observation that the slight residual trailing under deoxy conditions was minimal when the sample was obtained by dilution of a deoxygenated solution in which the low molecular weight species had not been given enough time to form (Figure 2B, dashed line). When deoxygenation was carried out rapidly by the addition of dithionite to the diluted oxygenated solution, trailing was more significant because some of the low molecular weight species had not been given enough time to reassociate (Figure 2B, solid line). Two possible explanations for this behavior are the slower translational/rotational coefficient of the PEGylated dimeric species, as suggested by the DLS measurements in dilute solution, also reported by other authors (*32, 66*), and steric interference by PEG in the mechanism of subunit reassociation. The PEG-Hb^{deoxy} chromatography under anaerobic conditions did not show a multiplicity of components. The slight trailing observed at high concentration was not significantly increased upon dilution. This can be attributed to the very slow rate of dissociation of the various PEGylated tetramers as compared with the elution rate.

The size exclusion chromatography studies indicate that under aerobic conditions PEG-Hb^{oxy} was more markedly dissociated into dimers than PEG-Hb^{deoxy} and, under anaerobic conditions, a more pronounced trailing was observed if deoxygenation was achieved by dithionite addition to dilute oxy PEG-Hb^{oxy} (Figure 2C). Fully in keeping with this finding, functional properties of PEG-Hb^{oxy} were found to be less affected by dilution than PEG-Hb^{deoxy} (see below). Therefore, PEGylation carried out under aerobic conditions favors the modification of sites crucial for function and tetramer assembly, likely leading to a very large population of dimeric species. These sites are less severely modified in the anaerobic procedure for PEG-Hb^{deoxy} preparation.

Oxygen Binding Affinity and CO Binding Rate, in the Absence and Presence of Allosteric Effectors. The concentration dependence of the oxygen affinity of PEG-Hb^{deoxy} (Figure 3) and the corresponding analysis (Figure 3, inset) indicates that at least two species are in equilibrium in solution. On the basis of the p50s, Hill coefficients, and responses to allosteric effectors, the more straightforward interpretation is that one species corresponds to PEG-Hb tetramers, characterized by functional properties close to native HbA and the other corresponds to PEG-Hb dimers because its amount increases on dilution. It is interesting to note that the latter species exhibits functional properties very similar to PEG-Hb^{oxy}, that as demonstrated by native electrophoresis and ODC is likely to be composed of heterogeneous highly reactive dimeric species. An alternative interpretation is that the high oxygen affinity species is associated to a perturbed R state tetramer in which the

quaternary transition is either prevented or dramatically slowed down by PEGylation. Such an interpretation is consistent with the hypothesis suggested by Svergun et al. (*33*) that PEG chains may interfere with the T/R transition by binding at the dimer interface, thereby reducing cooperativity. However, the ODC dependence on concentration favors the former interpretation.

PEG-Hb^{deoxy} more than PEG-Hb^{oxy} responds to the physiological concentrations of CO_2 and Cl^- by reducing the oxygen affinity, although not to the same extent as native HbA (Table 2). This can be explained since one of the binding sites common to both ligands involves the α-amino groups of the α chains. PEGylation of Lysα7 likely interferes with the salt bridge formed by Valα1 and removes part of the oxygen-linked CO_2, Cl^-, and Bohr effects involving this site (*34, 67*). However, the protection of the 2,3-BPG binding pocket during PEGylation for PEG-Hb^{deoxy}, but not PEG-Hb^{oxy}, allows CO_2 modulation through binding in the deoxy structure to the amino groups of Val1β, the major site of CO_2 binding (*68*), and Cl^- modulation through binding to Lysβ82 (*69*). These data support the notion that PEGylation of deoxy Hb exhibits a less dramatic impact on protein functional properties.

The comparison of CO binding and rebinding kinetics of PEG-Hb^{deoxy}, PEG-Hb^{oxy}, and HbA, at high and low concentration, in the absence and presence of IHP, allows further identification of functional differences, associated with distinct species. First, it is interesting to note that CO binding to deoxy PEG-Hb^{deoxy} and PEG-Hb^{oxy} is monophasic, lacks the autocatalytic process typical of native Hb, and is concentration-independent over about a 10-fold range of concentrations (10−100 μM). In particular, the observed rate constant for PEG-Hb^{deoxy} exhibits the same value of the rate associated with the slow phase of HbA, whereas the rate constant for CO binding to PEG-Hb^{oxy} is higher but still lower than the rate of the fast phase observed for HbA. These findings suggest that (i) deoxy PEG-Hb^{deoxy} is predominantly present as T state tetramers converting to the R state slower than CO binding, and (ii) deoxy PEG-Hb^{oxy} is present as a mixture of perturbed dimers and T state tetramers, in keeping with the chromatographic measurements, that slowly are converted to the R state. A more detailed analysis is hampered by the fast rate of reaction, leading to the loss of a significant portion of the kinetic traces. Nevertheless, these data provide complementary information with respect to the more robust results generated from flash photolysis experiments. It was found that CO rebinding to both PEGylated samples, in the absence of IHP, did not show significant bimolecular rebinding to T state. This can be explained by either PEGylation reducing the rate of the R to T quaternary transition or the liganded PEGylated Hbs being predominantly present as dimers that, upon deligation, form T state tetramers on a time scale slower than CO rebinding. The reduced amplitude of the geminate rebinding indicates a faster escape to solvent, as observed in myoglobin. The appearance of milliseconds bimolecular rebinding in the presence of IHP, at higher concentrations or higher pulse energy, clearly signals an increased accumulation of T state tetramers. However, their amount is much lower than in native Hb due to a slow quaternary R to T transition and/or dimer association upon deligation.

In a recent paper, CO binding kinetics was measured for Hemospan (*70*), observing a CO rebinding lacking the geminate phase. This discrepancy with respect to our laser flash photolysis data is most probably due to the instrumental setup used in the previous work that did not allow detection of submicrosecond processes.

Overall, results indicate that PEG-Hb^{oxy} is predominantly in a highly reactive state, characterized by high oxygen affinity and a high rate of CO binding. Ligand binding triggers the formation of dimers faster than the quaternary T to R transition. The same picture holds for PEG-Hb^{deoxy}, assuming that the PEG-Hb^{deoxy} tetrameric T state is more stable than PEG-Hb^{oxy} and the T to R quaternary transition efficiently competes with tetramer dissociation. Thus, under physiological conditions, PEG-Hb^{oxy} and PEG-Hb^{deoxy}, in spite of containing the same average number of PEG molecules, are expected to deliver different amounts of oxygen, react with NO and nitrite with different rates, and trigger different regulatory signals because they exhibit distinct functional and structural properties.

CONCLUSIONS

PEGylation affects Hb in distinct ways: (i) perturbation of the T and R states (*31*), (ii) perturbation of the quaternary transitions (*33*), and (iii) influence on the tetramer−dimer equilibrium (*38*). Although animal studies carried out using PEG-Hb^{deoxy} and other similar products showed only moderately adverse pressure and renal filtration effects in the short period (2−3 h), the long-term effects of the stability upon dilution of the various PEGylated tetramers and dimers should be considered with regard to both the physicochemical and physiological properties of the bulk product in the circulation. The observed anomalous equilibrium of the PEGylated tetramers and product heterogeneity should also be considered in the evaluation of the extravasation and renal filtration behavior of these HBOCs. In view of the reported adverse effects of most HBOCs (*23*), it is mandatory to tightly link functional and structural HBOC properties with biochemical and physiological parameters, including proteomic analyses, associated to organ damages, oxidative stress, and inflammatory signals. This is our long-term ongoing challenge.

In vivo fluorescence cancer imaging is an important tool in understanding tumor growth and therapeutic monitoring and can be performed either with endogenously produced fluorescent proteins or with exogenously introduced fluorescent probes bound to targeting molecules. However, endogenous fluorescence proteins cannot be altered after transfection, thus requiring rederivation of cell lines for each desired color, while exogenously targeted fluorescence probes are limited by the heterogeneous expression of naturally occurring cellular targets. In this study, we adapted the dehalogenase-based protein-Tag (HaloTag) system to *in vivo* cancer imaging, by introducing highly expressed HaloTag receptors (HaloTagR) in cancer cells coupled with a range of externally injected fluorophore-conjugated dehalogenase-reactive reactive linkers. Tumor nodules arising from a single transfected cell line were stably labeled with fluorescence varying in emission spectra from green to near-infrared. After establishing and validating a SHIN3 cell line stably transfected with HaloTagR (HaloTagR-SHIN3), *in vivo* spectral fluorescence imaging studies were performed in live animals using a peritoneal dissemination model. The tumor nodules arising from HaloTagR-SHIN3 could be successfully labeled by four different fluorophore-conjugated HaloTag-ligands each emitting light at different wavelengths. These fluorophores could be alternated on serial imaging sessions permitting assessment of interval growth. Fluorescence was retained in histological specimens after fixation. Thus, this tagging system proves versatile both for *in vivo* and *in vitro* imaging without requiring modification of the underlying cell line. Thus, this strategy can overcome some of the limitations associated with the use of endogenous fluorescent proteins and exogenous targeted optical agents in current use.

INTRODUCTION

In vivo fluorescence imaging is performed either with endogenously produced fluorescent proteins (e.g., GFP, RFP) (*1*, *2*) or with exogenously introduced organic or inorganic fluorescent probes (e.g., fluorescein, rhodamine, cyanine) bound to targeting ligands (*3*). Each method has its advantages and disadvantages. Endogenous fluorescent proteins emit strong signals with minimal photobleaching and are consistently produced in stably transfected cells (*2*, *4*). The choice of the encoded fluorescent protein depends on the task to be accomplished and includes considerations such as the depth of the target tissue (due to limited light penetration at lower wavelengths), the tissue-specific spectral characteristics of autofluorescence or other competing fluorescent compounds, and the desired brightness of the fluorescence. However, once a particular fluorescent protein has been selected, the fluorescent properties of the transfected cells cannot be changed; instead, another stable transfection and cloning must be performed. This is not only time-consuming, but may also alter the biologic characteristics of the cell line in ways that introduce new variables into experiments so that each new clone must be extensively validated against prior clones. In contrast, exogenous fluorescent probes utilize a wide range of colors, from blue to near-infrared. These injectable fluorescent probes must be conjugated to targeting moieties to improve their specificity, but are limited to naturally occurring cellular targets that are often heterogeneously expressed in tumors and may be in low abundance compared to background signals.

An alternative approach is to use a gene reporter in which nonfluorescent markers (enzymes, receptors, antigens, etc.) are introduced into cells but are later "tagged" with an exogenous fluorescent ligand unique to that reporter. Such "tag" reporter systems (e.g., Flag-Tag, Snap-Tag, Clip-Tag, or Halo-Tag), have been widely used to label target molecules in cells *in vitro* (*5*, *6*). By introducing highly expressed "Tag" receptors into the target cells, the target to background (TBR) can be markedly improved. This approach increases the flexibility of fluorescence imaging, since many different fluorophores, exhibiting a broad range of emission wavelengths, can be conjugated to the tag-ligand. Therefore, "Tag" methods have the potential to overcome some of the disadvantages of both endogenous fluorescent proteins and exogenous fluorescent probes in *in vivo* fluorescence cancer imaging.

The dehalogenase-based protein-Tag (HaloTag) system is a protein labeling method that uses an enzymatic reaction to covalently tether organic probes directly to a specially designed reporting protein expressed on the membrane surface of live cells (*6*, *7*). This receptor protein is a modified haloalkane dehalogenase that covalently binds to a ligand containing a chloride-terminated reactive linker (HaloTag ligand; HaloTagL).

By genetically fusing this modified haloalkane dehalogenase (HaloTag receptor; HaloTagR) protein with a target protein, the HaloTagL can provide spatial information about target fusion-proteins in live cells. Although the HaloTag system has been employed extensively *in vitro*, it could also be used as an *in vivo* imaging reporter by coupling it with an externally injected fluorescent tag, thus overcoming the disadvantages of both endogenous and exogenous fluorescence. For instance, this would allow conjugation of the tag to a variety of organic fluorophores ranging in emission wavelength from blue to near-infrared, which would create a highly flexible *in vivo* research imaging system that does not require constant modification of the underlying cell lines. Here, we demonstrate the capability of the HaloTag system for multicolor *in vivo* cancer imaging using an established human cell line stably transfected with HaloTagR (HaloTagR-SHIN3) (*8*).

EXPERIMENTAL PROCEDURES

Plasmid Preparation of HaloTag Receptor Protein. The vector encoding β1-Integrin-HaloTag 7 fusion protein (β1Int-HaloTag) was designed according to the protocol described previously (*9*). Briefly, the human β1-Integrin sequence was synthesized (Blue Heron Biotech, Bothell, WA) with a signal peptide (amino acids 1−20), a truncated extracellular domain (amino acids 190−217, 722−730), a transmembrane domain (amino acids 731−756), and a truncated cytoplasmic domain (amino acids 757−762). The HaloTag 7 gene was cloned downstream of the signal peptide and upstream of the extracellular domain. The fusion construct was confirmed by restriction digest analysis and sequencing. DNA was purified using endotoxin free Maxiprep kit (Qiagen, Valencia, CA).

HaloTag Ligands. The HaloTagL-TMR and HaloTagL-Alexa488 are commercially available and were provided by Promega Corporation (Madison, WI). The HaloTagL-Dy633 and HaloTagL-IR800 were synthesized by Promega Inc. The structures of all four ligands are shown in Figure 1, and the synthesis methods for HaloTagL-Dy633 and HaloTagL-IR800 are as follows:

A. HaloTagL-Dy633. To a stirring solution of Dy633 succinimidyl ester (10 mg, 0.012 mmol) (Dyomics GmbH, Jena, Germany) in 1 mL anhydrous DMF (stored over molecular sieves) was added 18-chloro-3,6,9,12-tetraoxaoctadecan-1-amine hydrochloride as a 0.5 M solution in DMF (34 μL, 0.017 mmol) followed by diisopropylethylamine (5 μL, 0.024 mmol). The reaction mixture was allowed to stir for 12 h in the dark, diluted with 1 mL of acetonitrile, and subjected to preparative HPLC purification, giving the product (8.98 mg, 74%) as a dark solid.

MS: *m*/*z* for $C_{51}H_{76}ClN_3O_{12}S_2^+$: 1021 (100%), 1022 (50.8%). Found: 1021.0.

B. HaloTagL-IR800. To a stirring solution of IRDye 800CW succinimidyl ester (5 mg, 0.0043 mmol) (LI-COR Bioscience, Lincoln, NE) in 750 μL anhydrous DMF (stored over molecular sieves) was added 18-chloro-3,6,9,12-tetraoxaoctadecan-1-amine hydrochloride as a 0.5 M solution in DMF (34 μL, 0.017 mmol) followed by a catalytic amount of K_2CO_3. The reaction mixture was allowed to stir for 12 h in the dark, diluted with 1 mL of acetonitrile, and subjected to preparative HPLC purification, giving the product (5 mg, 86%) as a dark solid.

MS: *m*/*z* for $C_{60}H_{83}ClN_3O_{18}S_4^+$: 1296 (100%), 1298 (50.8%). Found: 1298.

Cell Culture. An established ovarian cancer cell line SHIN3 (8) was employed for this study. The cell lines were grown in RPMI 1640 medium (Invitrogen Corporation, Carlsbad, CA) containing 10% fetal bovine serum (FBS) (Invitrogen Inc.), 0.03% L-glutamine at 37 °C, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2.

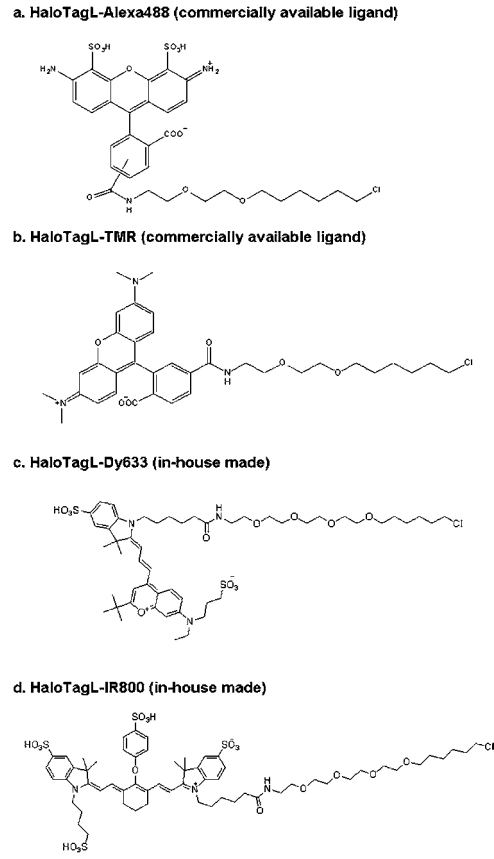

Figure 1. Chemical structures of HaloTag ligands. Chemical structures of all four HaloTagLs, which we used in this study, are shown.

Transfection of HaloTag Receptor Protein to the SHIN3 Cells. The HaloTagR plasmid described above was transfected into SHIN3 cells simultaneously with a neomycin-resistant plasmid (Promega) using the cationic liposome method. Three micrograms of HaloTagR plasmid and 1 μg of neomycin-resistant plasmid were mixed well with 20 μL of cationic liposome solution (DNA fectin, Life Technologies, Rockville, USA) and incubated for 30 min at room temperature. The plasmid-cationic liposome mixture was added to 1×10^5 SHIN3 cells plated in a 25 cm^2 cell culture flask and incubated for 6 h at 37 °C in 5% CO_2 before being placed back into the regular media and kept overnight. The next day, the initial selection of cells was achieved with 1.5 mg/mL neomycin in the regular culture media and colonies were allowed to grow over 2 weeks. HaloTagR-positive colonies were selected by staining with HaloTagL-TMR and spread in culture dishes. This cloning process was repeated twice to derive a stable SHIN3-HaloTagR positive cell line.

Mammalian Cells Culturing, Labeling and Imaging. HaloTagR-SHIN3 cells were maintained in RPMI1640 media supplemented with Hepes, MEM NEAA, Glutamine, and 10% FBS (Invitrogen) at 37 °C and 5% carbon dioxide. For imaging experiments, cells were plated on an 8-well Lab-Tech II chamber cover glass (Thermo Fisher Scientific, Rochester, NY), labeled with HaloTagL, and imaged directly or fixed, permeabilized, and then processed for immunocytochemistry using HaloTag polyclonal Ab (Promega) and Alexa Fluor 594 goat antirabbit IgG Ab (Invitrogen) or Alexa Fluor 488 goat antirabbit IgG Ab (Invitrogen) prior to imaging. All procedures were performed according to the manufacturer's protocol. All imaging was performed sequentially using an Olympus FV500 confocal microscope (Olympus America, Inc., Melville, NY) equipped with appropriate filter sets.

Detection of Halo-Tag Protein by SDS-PAGE. HaloTagR-SHIN3 cells were labeled with either HaloTagL-Alexa488 or HaloTagL-TMR or both ligands. The cells were lysed, and proteins were resolved by SDS-PAGE according to the manufacturer's protocol (Promega). Gels were analyzed on a fluorescence imager Typhoon 9400 (GE Healthcare, Pisctaway, NJ) using appropriate filters for each fluorophore. Quantitation of bands was performed using ImageQuant software (GE Healthcare).

Tumor Model. All procedures were approved by the National Cancer Institute Animal Care and Use Committee. The intraperitoneal tumor implants were established by intraperitoneal injection of 2×10^6 cells suspended in 200 μL of PBS in female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). Experiments with tumor-bearing mice were performed at 14 days for the parent SHIN3 mouse model and 21 days for the HaloTagR-SHIN3 mouse model.

Spectral Fluorescence Imaging Study. *Comparison Study of Parent-SHIN3 and HaloTagR-SHIN3 Bearing Mice.* After establishing peritoneal tumor implants with either the parent-SHIN3 or HaloTagR-SHIN3 cell lines ($n = 5$, each group), 20 nmol of HaloTagL-TMR diluted in 300 μL PBS with 0.4% bovine serum albumin (Sigma Chemical, St. Louis, MO) were injected into the peritoneal cavities of each mouse 24 h prior to imaging. Mice were sacrificed with carbon dioxide, and the abdominal cavities were exposed. Spectral fluorescence images were obtained using the Maestro In-Vivo imaging system (Cambridge Research and Instrumentation, Woburn, MA). Five sets of side-by-side whole abdominal cavity images of animals harboring tumors from the parent-SHIN3 or HaloTagR-SHIN3 cell lines, as well as images of all tumor nodules, were obtained. The brief setting of imaging parameters was described in the Supporting Information.

Comparison Study of Injected Amounts of HaloTag Ligands. Either 10 nmol or 100 nmol of HaloTagL-Alexa488 or HaloTagL-TMR diluted in 300-μL PBS with 0.4% bovine serum albumin (Sigma Chemical) was injected into the peritoneal cavities of each mouse 24 h prior to imaging. Mice were sacrificed with carbon dioxide, and the abdominal cavities were exposed. Spectral fluorescence images were obtained using the Maestro In-Vivo imaging system (CRi). Three sets of side-by-side whole abdominal cavity images of animals harboring tumors, as well as images of tumor nodules, were obtained. The brief setting of imaging parameters were described in the Supporting Information.

Multicolor in Vivo Spectral Fluorescence Imaging. HaloTagL-Alexa488, -TMR, -Dy633, and -IR800 ligands were used for this study. 60 nmol of each ligand diluted in 300-μL PBS with 0.4% bovine serum albumin was injected into the peritoneal cavities of mice with intraperitoneal dissemination of HaloTagR-SHIN3 24 h prior to imaging. Mice were anesthetized with subcutaneously administered 10% pentobarbital sodium (Nembutal; Abbott Laboratories, Abbott Park, IL), followed by *in vivo* spectral fluorescence imaging using the Maestro In-Vivo imaging system. Since the most efficient filter settings varied depending on the characteristics of the fluorophore, a multiexcitation acquisition (*10*) was employed. The imaging parameters are described in the Supporting Information. After obtaining *in vivo* spectral fluorescence images in live mice, all mice were sacrificed with carbon dioxide, and their abdominal cavities were exposed and imaged with the same acquisition settings. Finally, all spectral fluorescence images were unmixed to distinguish autofluorescence from the four different fluorophores using commercial software (*Maestro* software, CRi). This experiment was performed twice with similar results.

Serial in Vivo Spectral Fluorescence Imaging Study. Sixty nanomoles of either HaloTagL-TMR or HaloTagL-IR800 diluted in 300 μL PBS with 0.4% bovine serum albumin was injected into the peritoneal cavities of mice bearing intraperitoneal HaloTagR-SHIN3 tumors. HaloTagL-IR800 was initially injected into the animal, and imaging was performed at 24 and 48 h. After the 48 h image, the same amount of HaloTagL-TMR was administered, and imaging was obtained at 72 and 96 h after initial injection. The order of administration of the two fluorophores was also reversed in another group of two mice. For each imaging session, mice were anesthetized with Isoflurane (IsoFlu; Abbott Laboratories, Abbott Park, IL) and then imaged using the Maestro In-Vivo imaging system. Two single excitation spectral fluorescence images were acquired for each mouse with either green filter settings or near-infrared filter settings. Other settings of the image acquisition were held constant. The spectral fluorescence images consisting of autofluorescence spectra and either TMR or IR800 spectra were obtained and then unmixed, based on their spectral patterns using commercial software (*Maestro* software, CRi). All mice were subsequently sacrificed with carbon dioxide. This experiment was repeated twice.

In Vivo Real-Time Fluorescence Endoscopy. After establishing peritoneal tumor implants with HaloTagR-SHIN3 cell lines, 60 nmol of either HaloTagL-Alexa488 or -TMR diluted in 300-μL PBS with 0.4% bovine serum albumin was injected into the peritoneal cavities 24 h prior to imaging ($n = 3$, each group). *In vivo* fluorescence endoscopy was performed with clinical endoscopic system (EVIS Ecera II CLV-180, Olympus Corporation, Tokyo, Japan) equipped with an in-house developed fluorescence imaging system. A blue filter setting (excitation filter, 465 to 500 nm; emission filter, 516 to 556 nm band-pass) for HaloTagL-Alexa488 and a green filter setting (531 to 556 nm, 570 to 625 nm band-pass) for HaloTagL-TMR were employed for single-excitation acquisition.

Tissue Processing. *Embedding Tissue.* Formalin-fixed tissues were washed in water to remove formalin, then immersed in multiple baths of progressively less concentrated ethanol from 100% to 70%, followed by HistoClear Xylene (Fisher Scientific, Pittsburgh, PA) and then hot molten paraffin wax. Embedded tissue blocks were then cut into very thin (0.5−1 μm) sections using a microtome, and slices were placed on glass slides (*11, 12*).

Dewaxing and Antigen Retrieval. Paraffin sections were dewaxed by immersion in the following solutions, each for 3 min at RT: 3 times in HistoClear xylene, 2 times in 100% ethanol, once in 95% ethanol, and then once in 70% ethanol. Antigen retrieval was done by incubating slides in warm (94−96 °C) 0.01 M citrate buffer pH = 6.0 for 30 min, followed by cooling step at RT (*11*−*13*).

Immunolabeling. All incubation steps were done in a humidified chamber at RT with gentle rocking. Slides were first incubated in a blocking buffer, PBS +60 min; primary Ab to HaloTag (2 μg/mL, Promega Inc.) were applied for overnight incubation at +4 °C and finally Alexa Fluor 594 goat antirabbit IgG Ab (Invitrogen Inc.) or Alexa Fluor 488 goat antirabbit IgG Ab (Invitrogen Inc.) for 60 min. After washing three times in PBS for 5 min, slides were mounted in Vectashield (Vector Laboratories, Burlingame, CA) and stored at 4 °C. All tissue fluorescence and confocal imaging was done using an Olympus BX61 fluorescence and an FV500 confocal microscope (Olympus America Inc.) in sequential mode equipped with appropriate filter sets.

RESULTS

HaloTagR Stably Expresses in SHIN3 Cells Transfected with HaloTagR Protein Gene (HaloTagR-SHIN3) *in Vitro.* SHIN3 cells were transfected with the HaloTagR protein gene fused to β1-integrin-encoding gene, creating a unique cell membrane marker (*9*); cloning was performed using HaloTagL-

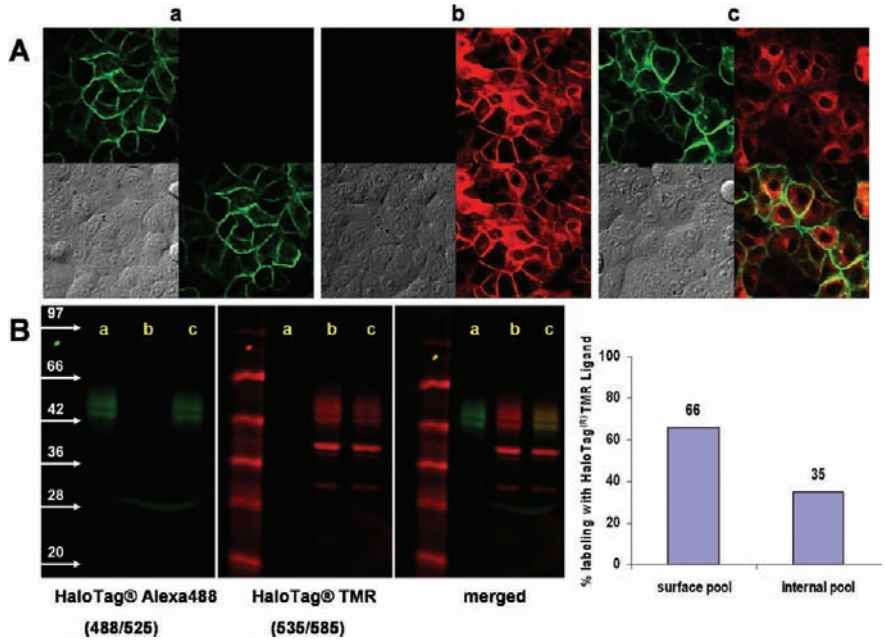

Figure 2. (A) Confocal images of the SHIN3 cells stably expressing HaloTagR (HaloTagR-SHIN3). HaloTagR-SHIN3 cells were labeled with HaloTagL-Alexa488 at 5 μM for 15 min (a) or HaloTagL-TMR at 1 μM for 15 min (b) or pulsed HaloTagL-Alexa488/chased HaloTagL-TMR (c). Images were collected sequentially with appropriate filter sets. Fluorescence images of HaloTagL-Alexa488 (upper left), HaloTag-TMR (upper right), merged image of HaloTag-Alexa488 and TMR (lower right), and DIC images (lower left). (B) SDS-PAGE analysis of the fluorescently labeled β1Int-HaloTag fusion protein stably expressed in the SIHN3 cells. The HaloTagR-SHIN3 cells were labeled as described above. The cells were lysed, cell proteins were resolved on SDS-PAGE, and analyzed on a fluorescence imager Typhoon 9400 using appropriate filter settings. HaloTagL-Alexa488 is cell impermeant and binds only to the surface exposed (glycosylated) HaloTagRS. The HaloTagL-TMR is cell permeant, and binds to the surface exposed (glycosylated) pool and to the intracellular (glycosylated and non-glycosylated) pool of the HaloTagRs. Fluorescence of the protein bands was quantified using ImageQuant software.

TMR to select a colony of cells that stably expressed the HaloTagR on the cell surface and endoplasmic vesicles without interfering with cellular proliferation or tumorigenesis. After establishing the HaloTagR-SHIN3 cell line, the HaloTagR expression was validated by confocal microscopy (Figure 2A), SDS-PAGE (Figure 2B), and immunohistochemical analysis (Supporting Information Figure 1). After validation of HaloTagR-SHIN3, tumor-bearing mice underwent *in vivo* spectral fluorescence imaging.

HaloTagL Specifically Binds to Tumor Nodules Arising from HaloTagR-SHIN3 *in Vivo.* To validate the HaloTag system *in vivo*, spectral fluorescence imaging was performed on HaloTagR-SHIN3 and nontransfected parental SHIN3 tumors after intraperitoneal injection in mice. The SHIN3 tumor model replicates the peritoneal metastases commonly seen in human ovarian cancers. After tumors were established, HaloTagL-TMR was injected intraperitoneally to label the transfected cells. SHIN 3 tumors composed of cells expressing the HaloTagR (HaloTagR-SHIN3) were identified *in vivo* by unmixing the TMR spectrum from background signal. Nontransfected SHIN3 tumors demonstrated no focal fluorescence (Figure 3). These results suggest that the HaloTagL-TMR binds to the HaloTagR-expressing SHIN3 tumors *in vivo* while unbound HaloTagL is cleared from the body within a day.

Larger Amount of HaloTagL Shows Brighter and More Homogeneous HaloTagR-SHIN3 Tumor Staining *in Vivo.* In order to evaluate the dose effect to the HaloTagL to the tumor *in vivo*, a comparative imaging study was performed using HaloTagR-SHIN3 tumor-bearing mice injected with 10 nmol or 100 nmol of either HaloTagL-Alexa488 or HaloTagL-TMR ligands. Tumors in mice, which received 100 nmol HaloTag, showed brighter staining with both fluorophores. These results suggested that an insufficient dose of HaloTagL did not saturate the HaloTagR expressing in the HaloTagR-SHIN3 tumor.

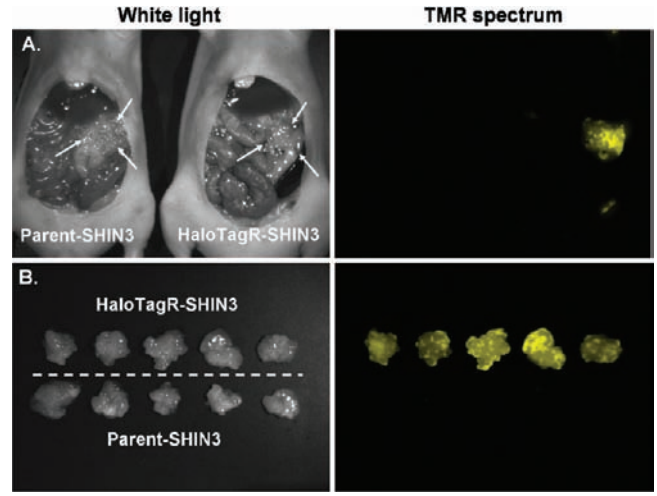

Figure 3. Comparative spectral fluorescence imaging study demonstrated specific binding of HaloTagL to SHIN3 stably expressing stm-HaloTag 7 (HaloTagR-SHIN3) tumor growing in mice. The side-by-side comparative spectral fluorescence images of the representative pair (A) and all excised tumor nodules (B) are shown here. Both mice received the same amount of HaloTagL-TMR ligand 24 h prior to imaging. On the white light images, the same-sized tumors can be identified in both mice (arrows). The unmixed spectral fluorescence images show that HaloTagR-SHIN3 tumor is depicted by the specific wavelength light that corresponded to TMR spectrum with very low background signal, while parent SHIN3 tumor does not. These results support the concept that the HaloTagL specifically binds to HaloTagR expressing SHIN3 tumor.

Tumor Nodules Arising from HaloTagR-SHIN3 Can Be Depicted by Various Fluorophore-Conjugated HaloTagLs *in Vivo.* To demonstrate the ability of this system to accommodate multiple colors, *in vivo* multicolor spectral fluorescence imaging

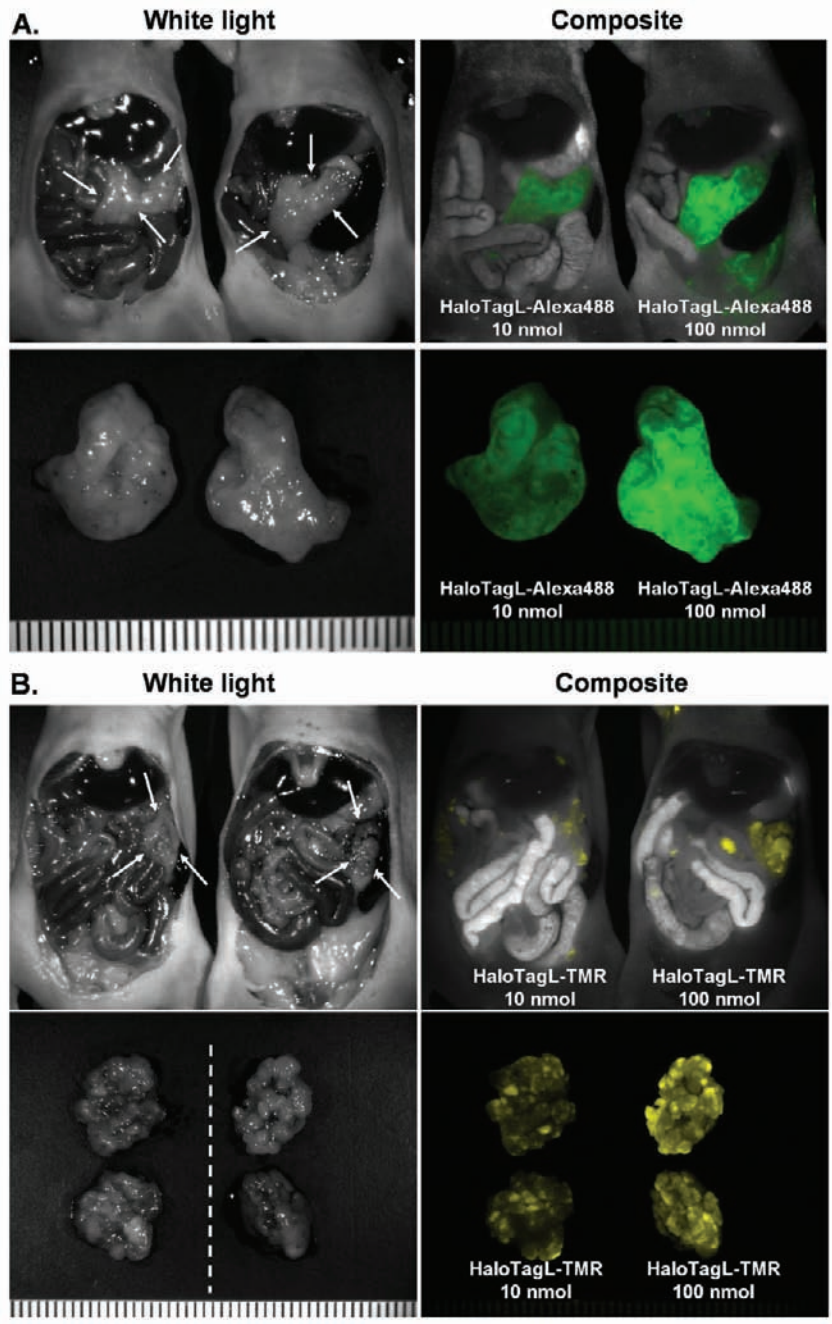

Figure 4. Comparison of injected amounts of HaloTag ligands. A comparative imaging study was performed using HaloTagR-SHIN3 tumor-bearing mice injected with 10 nmol or 100 nmol of either HaloTagL-Alexa488 (A) or HaloTagL-TMR (B) ligands. Tumors in mice, which received 100 nmol HaloTagL-TMR, show brighter and more homogeneous staining with both fluorophores.

was performed after the injection of fluorescent HaloTagLs labeled with several different fluorophores (Alexa488, TMR, Dy633, and IR800) ranging in emission wavelength from green to near-infrared in different tumor-bearing mice. In mice with peritoneal metastases arising from the HaloTagR-SHIN3 cell line, different-colored HaloTagLs resulted in multicolored depiction of the tumors arising from the same transfected cell line (Figure 5A).

Fluorescence Signals Can Be Switched on Alternate Imaging Sessions. The serial *in vivo* spectral fluorescence images showed that the tumor nodules were detected for at least 96 h in the anesthetized live mice after the single administration of either ligand (Figure 5B). Moreover, when two different (e.g., yellow and NIR) fluorophores were used alternately on serial imaging sessions, it was possible to label the interval tumor growth occurring between each imaging session using different colors (Figure 5B). However, the light intensity arising from each ligand-conjugate gradually weakened during the course of observation, probably due to metabolism and photobleaching.

***In Vivo* Real-Time Endoscopy of the HaloTagR-SHIN3 Tumor Labeled by Either HaloTagL-Alexa488 or HaloTagL-TMR.** *In vivo* real-time endoscopy showed that peritoneal tumor implants, which originated from the same HaloTagR-SHIN3 cell lines, emitted different fluorescence signals from preinjected HaloTag-ligands 24 h before imaging (Supporting Information videos, HaloTagL-Alexa488(A) and HaloTagL-TMR(B)). Both real-time endoscopic images specifically depicted small peritoneal implants of HaloTagR-SHIN3 tumors.

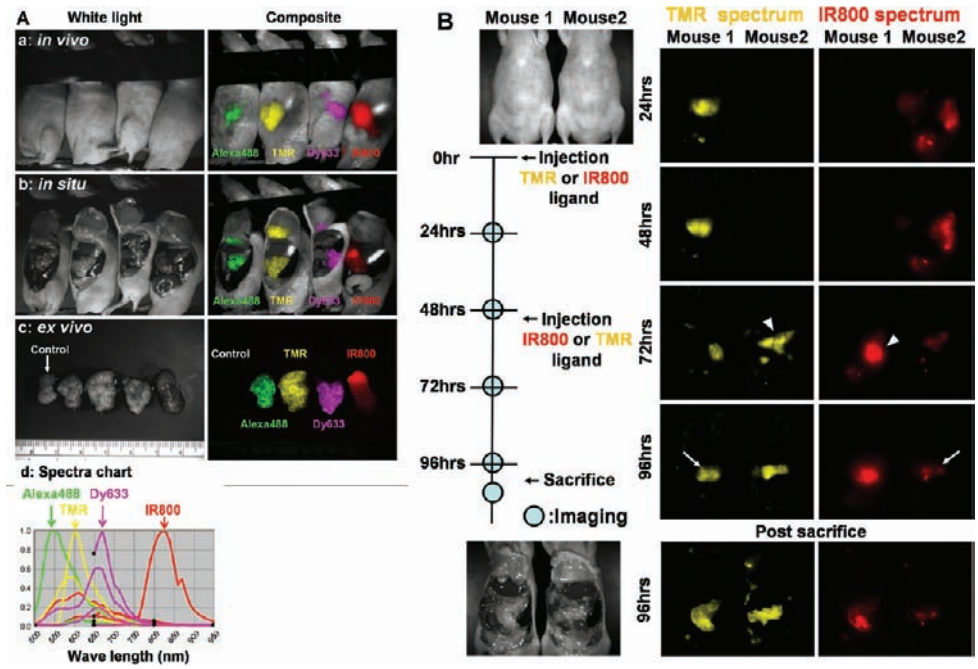

Figure 5. (A) Multiple-colored *in vivo* spectral fluorescence imaging. Unmixed multiple-colored spectral fluorescence images of live, anesthetized mice (a), the exposed abdominal cavities (b), and the excised tumor nodules (c) are shown. All mice were injected i.p. with the HaloTagR-SHIN3 cell line. Twenty-four hours prior to imaging, the mice received HaloTagLs labeled with different fluorophores (left to right: HaloTagL-Alexa488, -TMR, -Dy633, and -IR800 ligands). The tumor nodules are depicted at different wavelengths corresponding to the emission spectra of the fluorophores conjugated to the HaloTagLs. The spectral pattern of each fluorophore (d) is shown. Note that tumors removed from a HaloTagR-SHIN3 mouse, which did not receive ligand, were included as a control (arrow). (B) Serial "pulse-chase" *in vivo* spectral fluorescence imaging. Imaging sessions took place at 24, 48, 72, and 96 h after injection of either HaloTagL-TMR or HaloTagL-IR800. After the images were acquired at 48 h, the same amounts of HaloTagL-TMR were given to the mice in same fashion, and vice versa. The unmixed spectral fluorescence images show that the tumor nodules are detected for at least 96 h in the anesthetized live mice after the single administration of either ligand (arrows). Furthermore, additional colors can be added (arrow heads) and simultaneously spectrally resolved. However, the light intensity arising from each ligand-conjugate gradually weakened during the course of observation, probably due to metabolism and photobleaching.

Histological Validation of HaloTag Receptor Expression in the HaroTagR-SHIN3 Tumor. Formalin-fixed paraffin-embedded tumor tissue specimens, which were obtained from mice shown in Figure 5, were imaged without any additional staining on an Olympus BX61 fluorescence microscope with the appropriate filter sets (Figure 6A). Immunohistochemistry of β1Int-HaloTag fusion protein expressed in HaloTagR-SHIN3 cells, in the same formalin-fixed paraffin-embedded mouse tumor tissue used above, confirmed HaloTagR expression in the HaloTagR-SHIN3 tumor (Figure 6B).

DISCUSSION

The wide range of fluorophores available to bind to the HaloTagL enables the selection of the optimal color to meet the requirements of a particular experiment such as avoiding overlap with the spectrum of an administered drug, avoiding autofluorescence, or adapting to available imaging equipment, without creating new, genetically modified cell lines (*14*). Furthermore, an appropriate near-infrared (NIR) probe may be selected for visualizing deep tumors due to the better tissue penetration and low background signal in the NIR (Figure 5; also see Supporting Information Figure 3), whereas a green fluorophore, with higher quantum efficiency, may be preferred for surface imaging applications such as endoscopy (Supporting Information Videos). Thus, using HaloTagR-transfected tumor cell lines, the tumor can be "painted" with any color as needed without changing the underlying tumor model.

A desirable feature of this system is that the colors could be successfully switched or added on serial *in vivo* imaging sessions. This feature has also been described for injectable target probes including labeled monoclonal antibodies and other receptor ligands, which target naturally occurring receptor proteins. By alternating colors, interval growth can be measured. However, such targeting agents require stably and homogenously expressing endogenous targets on tumor cells as well as sufficient affinity to their respective target antigens. In contrast, the HaloTag system artificially induces sufficient numbers of cell targets by translating the HaloTagR enzyme receptor in the majority of transfected cells, enabling highly specific, stable covalent binding to the tag-ligand which, in turn, can be labeled with a broad range of fluorophores conjugated to HaloTagL.

There are several limitations to this method. First, while HaloTagR was highly expressed in the majority of cells, some tumors were inhomogeneously labeled (Figure 6A) mainly due to inhomogeneous intratumoral distribution of HaloTagL and partly due to variable expression of the HaloTagR protein. The former is overcome by increasing the dose of HaloTagL. When the dose of HaloTagL was increased up to 100 nmol (a 10-fold increase), the brightness of the tumors became more homogeneous compared to the initial dose of 10 nmol (Figure 4). Additionally, deeper tumors were not labeled as effectively as superficial tumors, although HaloTagR expression detected by immunohistochemistry was relatively homogeneous compared with the *in vivo* distribution of HaloTagLs (Figure 6B; also see Supporting Information Figure 2). Since the HaloTagL can bind strongly and quickly to HaloTagR, tumor cells on the surface of tumor implants were more likely to be detected than tumor cells located deeper to the surface (Figure 6A). The brightness of tumors or cells using the HaloTag system was dependent on

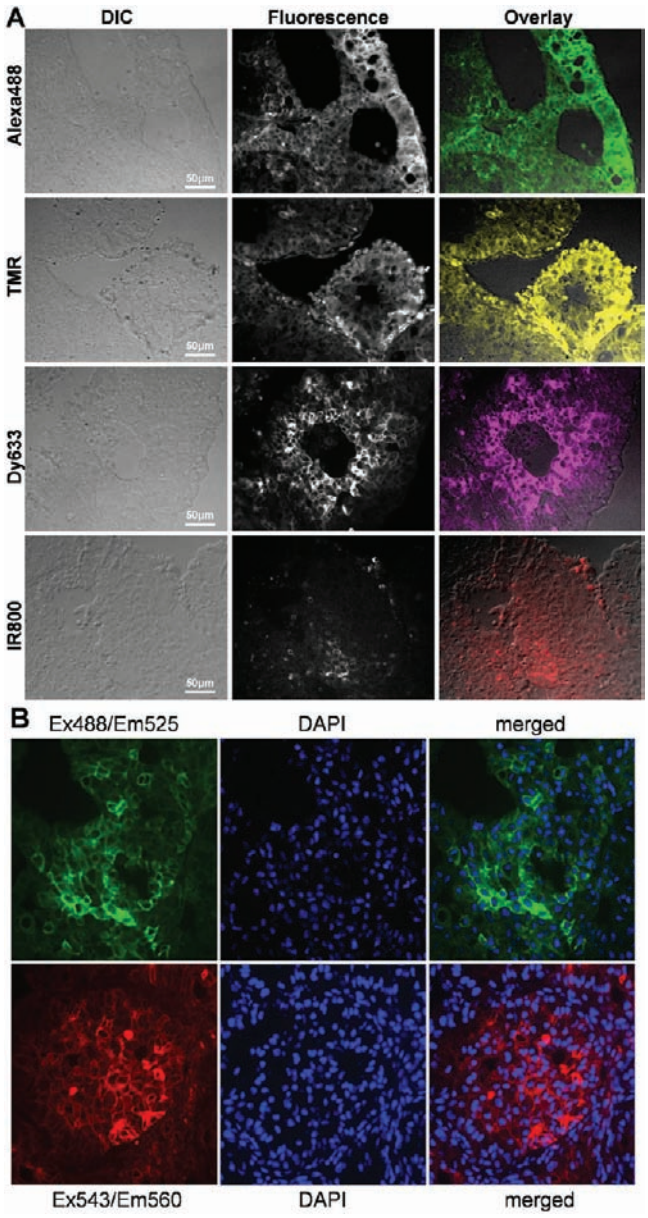

Figure 6. Histological validation of HaloTag receptor expression in the HaroTagR-SHIN3 tumor. (A) Formalin-fixed paraffin-embedded tumor tissue specimens were imaged on an Olympus BX61 fluorescence microscope with the appropriate filter sets for HaloTagL-Alexa488, HaloTagL-TMR, HaloTagL-Dy633, or HaloTagL-IR800. (B) Formalin-fixed paraffin-embedded tumor tissue was processed for immunohistochemistry and probed with anti-HaloTag Ab. Fluorescent signal (secondary Ab) indicates expression of the β1Int-HaloTag fusion protein expressed in the cells forming the HaloTagR-SHIN3 tumor. DAPI stains cell nuclei (blue).

the number of transcripts expressing HaloTagR per cell and the dose of HaloTagL injected into the mouse; however, in our hands the brightness of a green fluorescent HaloTagL was greater than that of a comparable GFP construct both *in vitro* and *in vivo*. Finally, during acquisition of serial *in vivo* images, the intensity of fluorescence gradually diminished especially with the IR800 ligand, possibly due to catabolism or photobleaching (Figure 5B). Therefore, to assess longitudinal tumor growth with this method, multiple injections of ligands with proper timing of the imaging, a use-mode analogous to that of bioluminescence imaging, will be required. In this experiment, despite its shorter emission wavelength, TMR-ligand showed comparable brightness to IR800-ligand probably because TMR-ligand could bind to both membrane and cytoplasmic receptors, while IR800-ligand bound only to the membrane receptors. However, we were still able to validate persistent HaloTagR expression over time in tumor cells by detecting retained fluorescence signal in histological specimens even after fixation (Figure 6). It is possible that *in vivo* imaging of intracellular fusion protein targets could be performed as well by using appropriate permeable ligands such as HaloTagL-TMR as shown in Figure 2B.

In conclusion, we demonstrate the ability of the HaloTag reporter system to successfully perform *in vivo* cancer imaging, and we verify that numerous fluorophores spanning a broad spectrum of emission wavelengths can be used with the same transfected cell line. Thus, the HaloTag reporter system can be used in practically every step of cancer imaging studies including *in vitro* cell-sorting or cloning, *in vitro* validation and quantification of receptor expression, *in vivo* longitudinal animal imaging, and *ex vivo* histological analysis. Furthermore, the system is flexible, because virtually any kind of tumor can be transfected with the HaloTagR protein and imaged with virtually any fluorophore that can be conjugated to HaloTagL. This strategy can overcome some of the limitations associated with the use of endogenous fluorescent proteins or exogenous targeted optical agents, and could become a valuable research approach for *in vivo* cancer imaging in animals.

ACKNOWLEDGMENT

N. Ko. and M. O. equally contributed to this work. We gratefully acknowledge Chad Zimprich and Shana Svendsen for the cloning of β1Int-HaloTag7 and initial characterization of the β1Int-HaloTag 7 fusion protein. This work was supported by the Intramural Research Program of the National Institutes of Health, National Cancer Institute, Center for Cancer Research.

Supporting Information Available: Supplementary videos: *In vivo* real-time endoscopic videos of the HaloTagR-SHIN3 tumor labeled by either HaloTagL-Alexa488 (A) or HaloTagL-TMR (B): These endoscopic videos show that peritoneal tumor implants, which originated from the same HaloTagR-SHIN3 cell lines, emit different fluorescence signals from preinjected HaloTag-ligands (HaloTagL-Alexa488 (A) and HaloTagL-TMR (B)) 24 h before imaging. Both real-time endoscopic images specifically depict small peritoneal implant of HaloTagR-SHIN3 tumors. Left: image without emission filter, right: fluorescence image through an appropriate emission filter. First half: white light image, Second half: excitation light image specific for Alexa488 (A) and TMR (B). Setting of imaging parameter, and additional *in vitro* and histological data are also available. This material is available free of charge via the Internet at http://pubs.acs.org.

Spectral Fluorescence imaging study

Comparison study of parent-SHIN3 and HaloTagR-SHIN3 bearing mice:

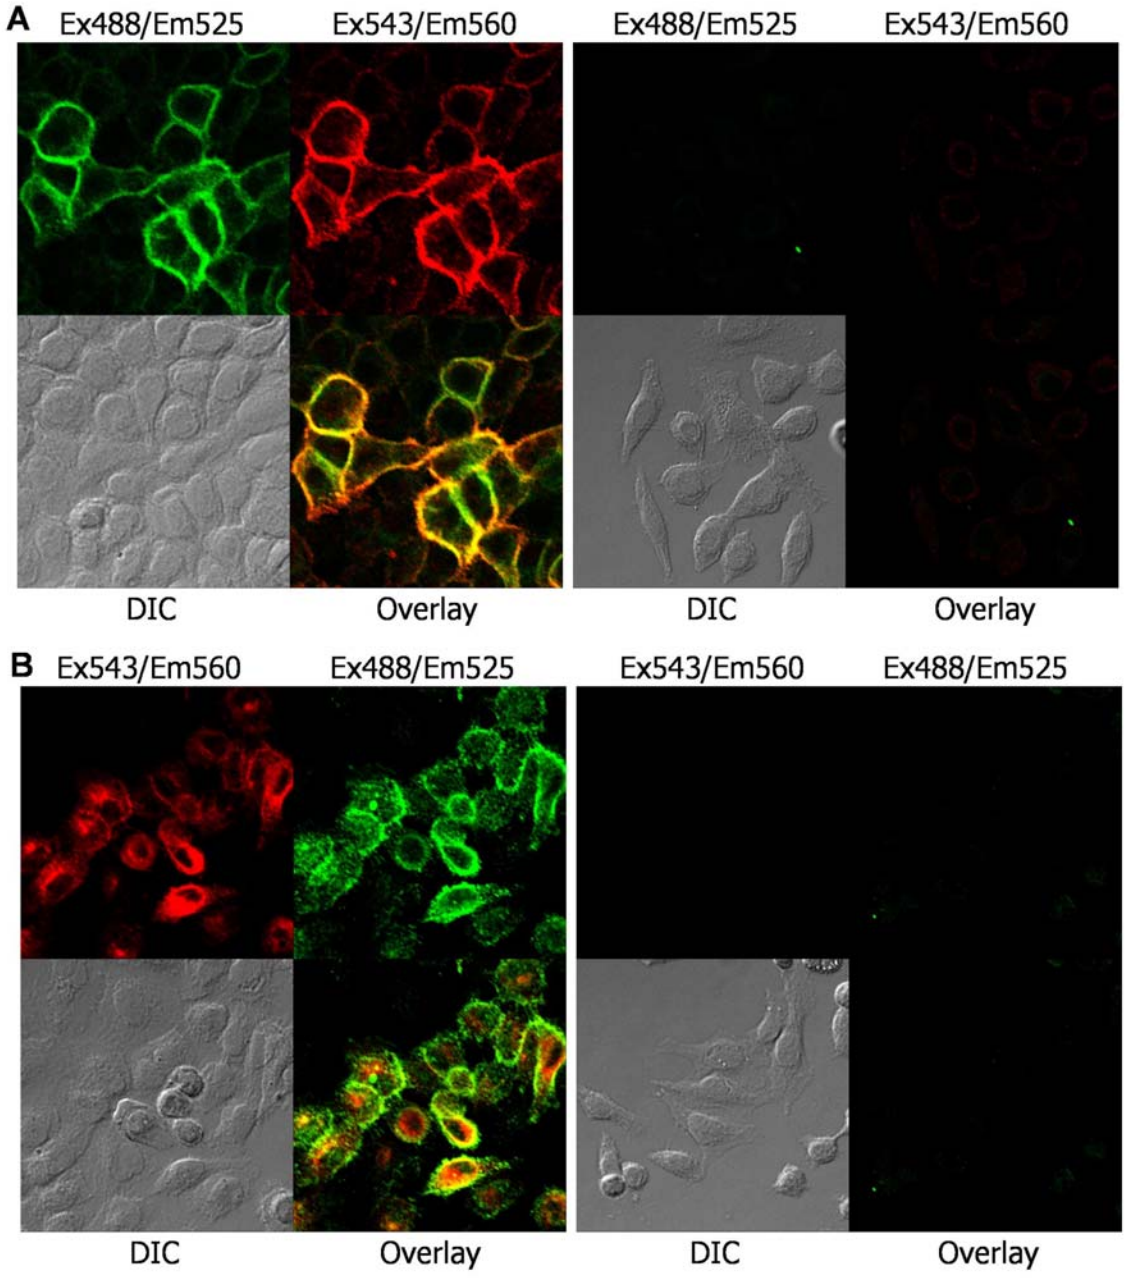
Comparison study of injected amounts of Halotag ligands:

Spectral fluorescence images were obtained using the Maestro In-Vivo imaging system (CRi, Inc., Woburn, MA) with a blue-filter settings (excitation filter: 445 to 490 nm, emission filter: 515 nm long pass) or green-filter setting (excitation filter: 503 to 555 nm, emission filter: 580 nm long pass). The tunable filter was automatically stepped in 10 nm increments from 550 to 800 nm while the camera captured images at each wavelength interval. The spectral fluorescence images consisting of autofluorescence, Alexa488 and TMR spectra were obtained and then unmixed, based on their spectral patterns using commercial software (Maestro software, CRi).

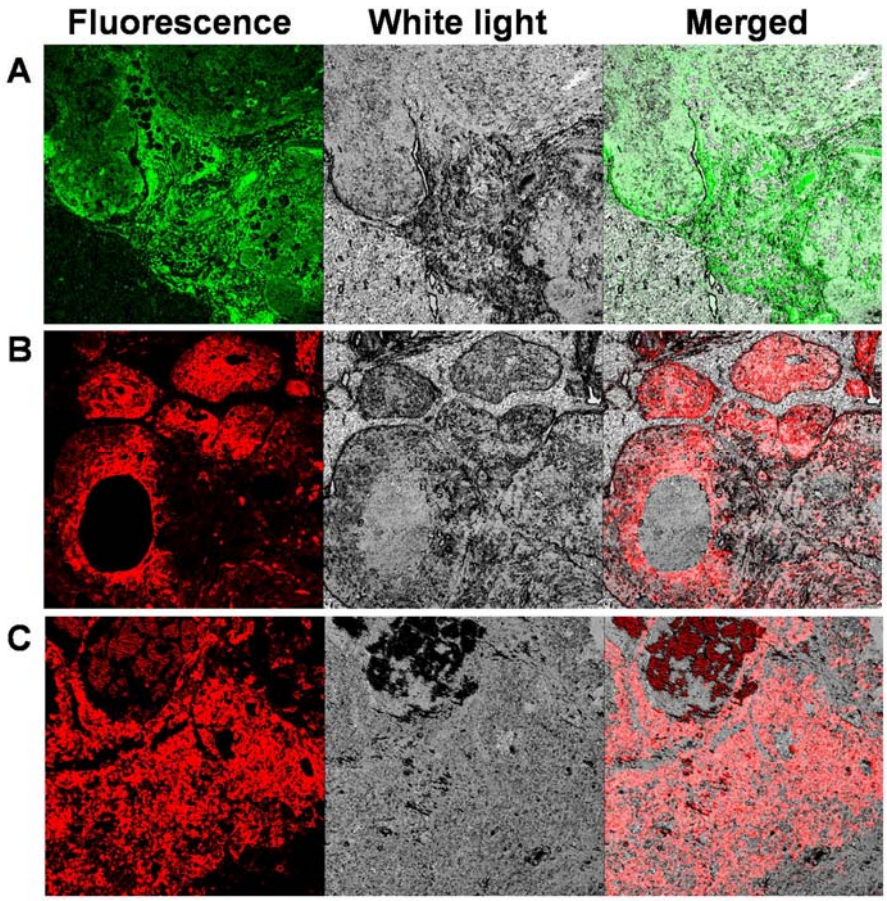
Multi-color in vivo spectral fluorescence imaging:

Multi-excitation spectral fluorescence images were obtained using the Maestro In-Vivo imaging system (CRi, Inc.). Blue filter settings, green-filter settings, yellow-filter settings (575 to 605 nm, 645 nm long pass), and near-infrared-filter settings (710 to 760 nm, 800nm long pass) were employed for multi-excitation acquisition. The tunable filter in the Maestro camera was automatically stepped in 10 nm increments from 550 to 800 nm for blue and green filter settings, 650-950 nm for the yellow and near infrared filter settings while the camera captured images at each wavelength interval.

Supplemental figures

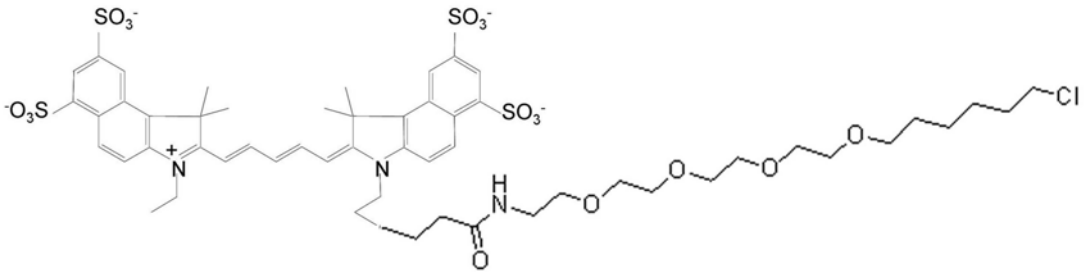


Supplementary Figure 1 Multiplexing live-cell labeling with immunocytochemistry in fixed SHIN3 cells stably expressing stm-HaloTag® 7. SHIN3 cells stably expressing (left panel) or non-expressing (right panel) stm-HaloTag 7 labeled with HaloTagL-Alexa488 (A) or HaloTagL-TMR Ligand (B), fixed with permiabilization and processed for ICC using HaloTag® antibody followed by Alexa Fluor® 594 goat anti-rabbit IgG antibody (Invitrogen). Both HaloTagLs are well co-localized with HaloTagRs, which are detected with HaloTagR antibody.

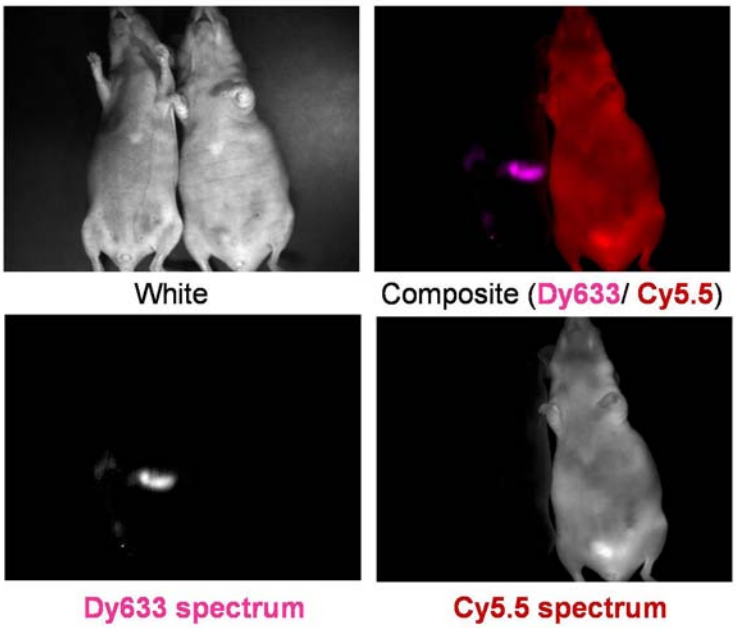


Supplementary Figure 2; Confocal microscopic validation of HaloTagR expression in the HaloTagR-SHIN3 tumor. Formalin-fixed paraffin-embedded of mouse tumor tissue specimens were imaged on Olympus FV500 confocal microscope with the appropriate filter sets for HaloTagL-Alexa488 (A) or HaloTagL-TMR (B) or HaloTagL-Dy633 (C). Since our Olympus FV500 confocal microscope did not have an appropriate filter set for IR800, images taken with HaloTagL-IR800 could not show the signal from the ligand because of low sensitivity.

A. HaloTag-Cy5.5



B.



Supplementary Figure 3; HaloTagL-Cy5.5 demonstrates high non-specific binding, thus reducing the target-to-background. We also synthesized Cy5.5 (GE Healthcare) based HaloTagL (A). However, the pharmacokinetics of HaloTagL-Cy5.5 were quite different from other HaloTagLs (B). HaloTagL-Cy5.5 (right mouse) showed much higher background signal than any other ligand, used in this study, and did not depict the HaloTagR-SHIN3 tumor even 24 hours after i.p. injection. We show side-by-side comparison with HaloTagL-Dy633 (left mouse), which clearly depicted the HaloTagR-SHIN3 tumor with low background.

PARACEST Properties of a Dinuclear Neodymium(III) Complex Bound to DNA or Carbonate

Kido Nwe, Christopher M. Andolina, Ching-Hui Huang, and Janet R. Morrow*

Department of Chemistry, University at Buffalo, State University of New York, Buffalo, New York 14260. Received April 2, 2009; Revised Manuscript Received June 6, 2009

A dinuclear Nd(III) macrocyclic complex of **1** (1,4-bis[1-(4,7,10-tris(carbamoylmethyl)-1,4,7,10-tetraazacyclododecane]-*p*-xylene) and mononuclear complexes of 1,4,7-tris-1,4,7,10-tetraazacyclododecane, **2**, and 1,4,7-tris[(*N*-*N*-diethyl)carbamoylmethyl]-1,4,7,10-tetraazacyclododecane, **3**, are prepared. Complexes of **1** and **2** give rise to a PARACEST (paramagnetic chemical exchange saturation transfer) peak from exchangeable amide protons that resonate approximately 12 ppm downfield from the bulk water proton resonance. The dinuclear Nd(III) complex is promising as a PARACEST contrast agent for MRI applications, because it has an optimal pH of 7.5 and the rate constant for amide proton exchange (2700 s^{-1}) is nearly as large as it can be within slow exchange conditions with bulk water. Dinuclear Ln_2(**1**) complexes (Ln(III) = Nd(III), Eu(III)) bind tightly to anionic ligands including carbonate, diethyl phosphate, and DNA. The CEST amide peak of Nd_2(**1**) is enhanced by certain DNA sequences that contain hairpin loops, but decreases in the presence of diethyl phosphate or carbonate. Direct excitation luminescence studies of Eu_2(**1**) show that double-stranded and hairpin-loop DNA sequences displace one water ligand on each Eu(III) center. DNA displaces carbonate ion despite the low dissociation constant for the Eu_2(**1**) carbonate complex (K_d = 15 μM). Enhancement of the CEST effect of a lanthanide complex by binding to DNA is a promising step toward the preparation of PARACEST agents containing DNA scaffolds.

INTRODUCTION

CEST (chemical exchange saturation transfer) agents are a promising new class of MRI contrast agent. Contrast is produced by applying a presaturation pulse at the resonance frequency of NH or OH protons of an amino acid, sugar, nucleotide, or other metabolite. Transfer of the proton magnetization to the bulk water through chemical exchange results in the reduction of the bulk water signal (*1*). The chemical shifts of the diamagnetic NH or OH protons are only 2−5 ppm different than that of bulk water, which makes it difficult to avoid direct saturation of the bulk water (*2*−*5*). This limitation is overcome by forming complexes with lanthanide ions. Paramagnetic lanthanide CEST agents (PARACEST agents) possess mobile protons such as OH, NH of chelating amide or alcohol ligands or water ligands with resonance frequencies that are often more than 20 ppm away from that of bulk water (*6*−*8*).

For CEST agents, the maximum reduction of the bulk water signal is reached when the magnetization of the nuclei of exchangeable protons are completely saturated and the bulk water protons are not directly irradiated by the presaturation pulse that excites the exchangeable protons (*8*). This condition is met when the presaturation pulse power is optimized and the chemical shift difference between exchangeable protons and bulk water protons ($\Delta\omega$) is large enough so that direct irradiation of the bulk water resonance is negligible. Under these conditions, the saturation transfer percent (ST%) is expressed as shown in eq 1 where I is the signal intensity of the bulk water protons taken immediately after pulse is applied to the exchangeable (mobile) protons of CEST agent, I_0 the initial intensity of bulk water protons in the absence of saturation, k_{ex} is the exchange rate constant, n is the number of saturated protons per CEST molecule, C is the concentration of the CEST agent, and T_1 is the longitudinal relaxation time of bulk water protons (*6*).

$$\mathrm{ST\%} = \left(1 - \frac{I}{I_0}\right)100 = \frac{k_{ex}[C]n}{\frac{111.2}{T_1} + k_{ex}[C]n} \times 100 \qquad (1)$$

An important goal in the development of PARACEST contrast agents is to decrease the concentration of agent required. One option is to increase the number of exchangeable protons (n in eq 1). This has been accomplished through studies on macromolecules with multiple exchangeable groups such as a dendrimers (*9, 10*), albumin (*11*), poly-U (*12*), or peptides (*13*) as CEST agents. Sherry's studies on Yb(III) complexes with pendant amide groups featured eight amide protons in two sets of four equivalent protons (*14*). To further increase the number of exchangeable protons, we linked two macrocyclic complexes together to produce dinuclear Ln(III) complexes with twelve amide protons (Chart 1). A potential drawback in this design is that the amide protons in these complexes are chemically inequivalent. For Ln(**2**), all amide protons for the commonly observed capped square antiprism diastereomer are inequivalent. The presence of an additional diastereomer such as a capped twisted square antiprism would give rise to second set of resonances. For Ln_2(**1**), there are two such Ln(III) centers. In practice, however, the chemical shift of the amide resonances may be sufficiently similar to produce overlapping resonances that increase the efficiency of the CEST agent.

In addition to their large number of exchangeable protons, dinuclear Ln(III) complexes have unique binding properties for small molecules. Such specific binding events may lead to new MRI responsive agents that report on the concentration of metabolites or macromolecules (*15*−*17*). For example, dinuclear complexes of Eu(III) bind more strongly to phosphate esters than do their mononuclear analogues (*18*). Dinuclear Ln(III) complexes of macrocycles related to **1** bind to compounds containing carboxylates (*19*). An anion of primary importance for the application of these dinuclear Ln(III) complexes as PARACEST agents that has not been quantitatively studied is

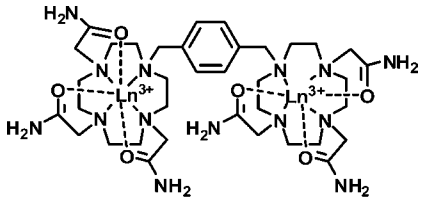
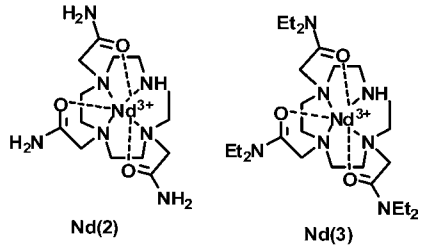
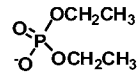
Chart 1







carbonate. Carbonate is present in millimolar concentrations in most tissues in the body and many lanthanide complexes bind carbonate strongly (*20*, *21*). Thus, the influence of carbonate complexes on the CEST properties of these lanthanide complexes is of interest.

Macromolecule binding to Ln(III) complexes modulates their CEST properties by changing the rate of proton exchange and the chemical shift of the mobile protons. This has been demonstrated for Ln(III) complexes of proteins including albumin and ferritin (*11*, *22*). A further example includes a supramolecular Tm(III) complex of poly(L-arginine) that gives rise to an intense CEST effect (*6*). By contrast, the effect of nucleic acid binding to Ln(III) complexes that are PARACEST agents has not yet been reported despite interest in using contrast agents to monitor DNA delivery for gene therapy (*9*, *12*, *23*, *24*) and to use DNA as a scaffold for attaching multiple Ln(III) contrast agents (*25*).

Here, we report on a Nd(III) dinuclear complex that functions as a PARACEST agent through exchange of amide protons. Comparisons are made to two mononuclear complexes. The most efficient CEST agent of these complexes, Nd_2(**1**), binds DNA and certain DNA sequences to give an increased CEST effect. DNA and carbonate binding are further characterized by direct excitation lanthanide luminescence spectroscopy studies of the Eu_2(**1**) analogue.

EXPERIMENTAL SECTION

Materials. $Ln(CF_3SO_3)_3$ salts were purchased from Aldrich. Synthetic DNAs were purchased from Integrated DNA Technologies (IDT) in desalted form and the different oligonucleotides were annealed by heating to 90 °C for 10 min and allowed to cool to room temperature overnight. 1,4-Bis[1-(4,7,10-tris(carbamoylmethyl)-1,4,7,10-tetraazacyclododecane]-*p*-xylene (**1**) was prepared as described previously (*18*). Syntheses of 1,4,7-tris(carbamoylmethyl)-1,4,7,10-tetrazacyclododecane (**2**) and 1,4,7-tris[(*N*-*N*-diethyl)carbamoylmethyl]-1,4,7,10-tetraazacyclododecane (**3**) have been reported elsewhere (*18*). Milli-Q purified water was boiled and bubbled with nitrogen gas for 1 h prior to use in CEST experiments or in luminescence measurements to minimize carbonate concentrations.

Instrumentation. An Orion research digital ionalyzer, model 510, equipped with a temperature compensation probe was used for all pH measurements. All ^1H and ^{13}C NMR were recorded on a Varian Gemini-300, Varian Inova-400, or Inova-500 spectrometer. A Beckman Coulter DU 800 UV−vis spectrophotometer equipped with a high-performance Peltier temperature controller was utilized for all thermal melting experiments. Data were fit by using the *Meltwin 3.5* program. The melting temperatures for HP1 and HP2 (Chart 1) were independent of concentration over the range 40−200 μM DNA, consistent with a hairpin-loop structure. Values of T_m for HP1, HP2, and GGCCGGCC (50 μM) were 60, 63, and 60 °C, respectively, at pH 7.0 with 20 mM HEPES, 50 mM $NaNO_3$. Addition of 1 equiv of Nd_2(**1**) increased the T_m of all sequences by 2−3 °C.

Ln(III) Complexes. The Nd(III) complex was prepared by heating $Nd(CF_3SO_3)_3$ and the macrocyclic ligand (**1**) to reflux in dry methanol for 8 h. In a typical preparation, 0.200 g (0.253 mmol) of ligand and 0.301 g (0.507 mmol) of $Nd(CF_3SO_3)_3$ were heated to reflux in 20 mL of dry methanol for 8 h. The solvent was reduced to 1 mL, and chloroform was slowly added until a precipitate formed at the bottom of the flask. The precipitation was repeated one more time. The supernatant was decanted, and the solid was dried under vacuum to give a white solid. Yield 90%. ^{13}C NMR (300 MHz, D_2O): δ = 19.3, 30.8, 32.5, 34.5, 44.8, 51.8, 60.2, 130.0, 131.8, 175.3. Anal. Cald for $C_{42}H_{64}N_{14}O_{24}F_{18}S_6Nd$: C 23.89, H 2.96, 8.87. Found C 23.78, H 2.88, N 8.75. The synthesis of Eu(III) complex of ligand **1** has been reported elsewhere (*18*). This procedure was modified to reduce the concentration of the carbonate complex. The complex was formed in an aqueous solution by incubation of 1.00 mM ligand **1**, 2.00 mM $Eu(CF_3SO_3)_3$, and 20.0 mM HEPES (pH 7.0) over a period of an hour. Complex formation was verified by Eu(III) luminescence spectroscopy and by ESI-MS spectroscopy. In a few experiments, 25 mM $Pb(NO_3)_2$ was added to the Eu_2(**1**) solution to precipitate adventitious carbonate as $Pb(CO_3)$. To remove the excess Pb(II), 25 mM NaCl followed by 25 mM NaOH (carbonate-free) was added to bring the solution to neutral pH. The solution was vortexed for 30 s and spun in a refrigerated Savant μ-SpeedFuge SFR 13K centrifuge for 60 min at an RFC of 13,000 *g*. The supernatant was removed from the white pellet. Nd(III) complexes of ligands **2** and **3** were prepared by heating $Nd(CF_3SO_3)_3$ and the macrocyclic ligands to reflux in dry methanol for 8 h. The solvent was then reduced to 1 mL and chloroform was slowly added until a precipitate formed at the bottom of the flask. Nd(**2**) Yield 90%. ESI *m*/*e*: 783, 784, 785, 786, 787, 789, 790 ([Nd(**2**)]$(CF_3SO_3)_3$ − $(CF_3SO_3^-)$). ^{13}C NMR (300 MHz, D_2O): δ = 22.1, 23.3, 28.5, 38.3, 40.8, 62.0, 152.5, 176.8. Anal. NMR Measurements. All experiments were carried out on a Varian Inova 500 MHz spectrometer operating at 11.75 T. The saturation transfer experiments were carried out at 298 K by irradiating the sample at 1 ppm incremental steps. The presaturation pulse power was 1000 Hz except where noted. The sample contains 10 mM HEPES buffer (pH 6.5−8.0) and 50 mM $NaNO_3$. An insert coaxial NMR tube was utilized, and the volume of the sample was 100 μL. CEST spectra were measured by recording the bulk water signal intensity as a function of presaturation frequency (in ppm). Studies were conducted using a presaturation pulse irradiation over the range of 20 to −20 ppm with a fixed irradiation time of 3s. CEST

spectra were obtained by plotting the intensity ratio of bulk water signal in the absence of presaturating RF pulse (I_0) and presence of RF irradiation (I) against the frequency of the RF pulse (in ppm). Supporting Information Figure S1 shows CEST spectra as a function of irradiation (saturation) time. The spectra show only minor differences, and the CEST effects are also nearly identical at approximately around 12 ppm where proton exchange occurs. This is an indication that the efficiency of saturation transfer (ST) reaches a steady-state value, and also that the exchange between amide NH and bulk water protons reaches equilibrium with 3 s of irradiation time (*6, 26*), the value used for all CEST data acquisition here.

The longitudinal relaxation time (T_1) of bulk water protons was measured by inversion recovery method. This was done by applying a 180° pulse to invert the magnetization of the bulk water protons followed by a 90° pulse prior to acquisition. Upon completion of the acquisition, Varian Inova software was used to calculate the T_1 value based on the experimental data. Triplicate measurements of T_1 on different samples and different days gave values that were reproducible to ±40%.

Luminescence Spectroscopy. Eu(III) excitation spectra and excited-state lifetimes were obtained using a Spectra-Physics Quanta Ray PRO-270-10 *Q*-switched Nd:YAG pump laser (10 Hz, 60 mJ/pulse) and a MOPO-SL for all luminescence measurements (*27*). The $^7F_0 \rightarrow {}^5D_0$ transition of the Eu(III) ion was scanned between 578 and 581 nm, while the $^5D_0 \rightarrow {}^7F_2$ emission band was monitored at 614 nm using a band-pass filter. Excitation spectra were fit by using the program Peak Fit 4.12 (Jandel). Time-resolved luminescence measurements were collected by using a digital Tektronix TDS 3034B oscilloscope. Five data sets per wavelength were fit to a single exponential decay by using Graphpad *Prism 4* (Graphpad Prism Software, Inc.) and averaged. The number of bound waters, *q*, was estimated by using eq 2 (*28, 29*) where *A* is specific to Eu(III) (1.2 ms), and k_{H2O} and k_{D2O} are the rate constants for luminescence decay in H_2O and D_2O, respectively. The $k_{HNC=O}$ term is for quenching by amides 0.075 ms^{-1}, δ is the number of amide NH groups in the innersphere and α is the total outersphere quenching 0.25 ms^{-1}.

$$q = A(k_{H2O} - k_{D2O} - \delta k_{NHC=O} - \alpha) \qquad (2)$$

DNA binding curves were fit to eq 3 for a simple solution system that involves noncompetitive tight binding of metal complex to multiple binding sites on DNA (*30*). Here, I_0 and I are the luminescence intensity in the absence and presence of nucleic acid, R_b is the luminescence intensity of the bound complex, M is concentration of the complex, K_d is the dissociation constant, n is the number of bases per binding sites, A is the nucleic acid concentration, x is equal to the concentration of DNA times the number of bases in the sequence. The solution includes 25 μM complex, 20 mM HEPES buffered at pH 7.0, 50 mM $NaNO_3$, and 5−50 μM nucleic acid.

$$(I - I_0) = 0.5\left(\frac{R_b}{n}\right)\left\{\frac{n}{K_d} + nM + Ax - \sqrt{\left(\frac{n}{K_d} + nM + Ax\right)^2 - 4nMAx}\right\} \qquad (3)$$

For simple substrates with 1:1 binding stoichiometry, data were fit to eq 4. I_0 and I are the luminescence intensities in the absence and presence of nucleic acid, I_{max} is the maximum luminescence intensity, M is the concentration of Eu_2(**1**), L is the sodium bicarbonate concentration, and K_d is the dissociation constant. The solution includes 20 μM complex, 20 mM HEPES buffer, 50 mM $NaNO_3$, and 20−300 μM concentrations of sodium bicarbonate. This is a method to determine equilibrium binding constant using a nonlinear least-squares fit of the experimental data (*31*).

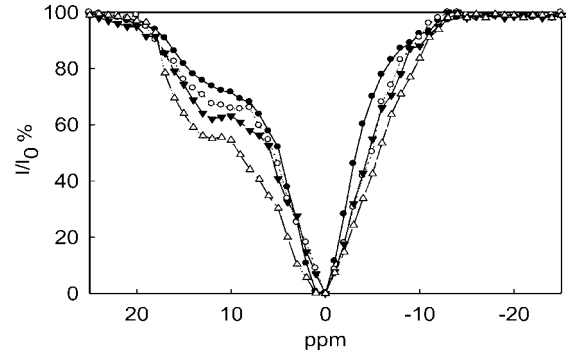

Figure 1. CEST spectra of 5.0 mM (●), 10 mM (○), 15 mM (▼) and 20 mM (△) Nd_2(**1**) at pH 7.0, 10 mM HEPES, 50 mM $NaNO_3$, 25 °C.

$$(I - I_0) = (I_{max})\frac{(M + L + K_d) - \sqrt{(K_d + M + L)^2 - (4 \times M \times L)}}{2 \times L} \qquad (4)$$

RESULTS

CEST Spectra. The CEST spectrum of Nd_2(**1**) is shown in Figure 1. The vertical axis shows the percent reduction of the intensity of the bulk water peak upon irradiation with a presaturation pulse in 1 ppm steps over the range 25 to −25 ppm with the bulk water resonance set at 0 ppm. There is a broad shoulder observed at approximately 12 ppm downfield from the bulk water proton resonance that we attribute to the protons of the NH groups. This assignment was supported by a CEST study of a Nd(III) derivative that lacks NH groups (see below). The only other exchangeable protons are from water ligands, and these are expected to exchange too rapidly to observe a CEST signal. Attempts to assign the NH amide proton resonances by ^1H NMR studies of Nd_2(**1**) in H_2O failed (Supporting Information Figure S2), even at lowered temperatures (5 °C) where slower exchange rate constants may facilitate the observation of these resonances. The absence of a proton resonance in the chemical shift range of the CEST shoulder is attributed to broadening of the NH protons by exchange with water. As discussed below, the rate constants for NH proton exchange are fast in comparison to those of other lanthanide amide complexes, and the observed rate constant suggests that the Nd(III) complex is at the limit of the NMR spectroscopy slow exchange regime.

The CEST spectrum of the Nd_2(**1**) complex was further investigated as a function of concentration and pH (Figures 1 and 2). The CEST enhancement upon increasing pH in the 6.5−7.5 interval is consistent with previously observed enhancements due to base catalysis of the exchange of the amide protons (*32*). A decrease in the CEST enhancement at the 12 ppm shoulder concomitant with a shift of the CEST peak toward the bulk water peak (Supporting Information Figure S3) suggests that exchange becomes even more rapid at pH 8.0, leading to the loss of the CEST peak as the NH peak begins to merge with the bulk water peak at high pH values. The concentration dependence of the CEST spectrum of Nd_2(**1**) is shown in Figure 1.

Figure 3 shows that the dinuclear Nd_2(**1**) complex has a stronger CEST amide NH peak than the mononuclear Nd(**2**) complex at equivalent concentrations. This is presumably due to the larger number of exchangeable amide NH protons in Nd_2(**1**) compared to Nd(**2**), although as noted above, both complexes have several sets of chemically distinct NH protons.

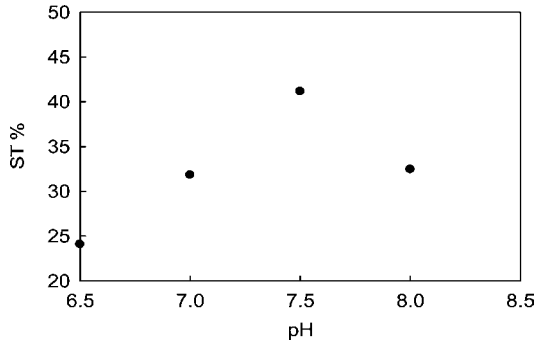

Figure 2. The pH dependence of saturation transfer (ST) efficiency of Nd_2(**1**) at 25 °C, 10 mM buffer, 50 mM $NaNO_3$.

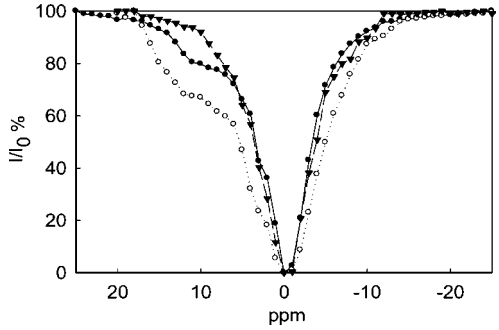

Figure 3. CEST spectra of 5.0 mM Nd_2(**1**) (○), 5.0 mM Nd(**2**)(●) and 5.0 mM Nd(**3**)(▼), B_1 = 1,200 Hz, at pH 7.0, 10 mM HEPES, 50 mM $NaNO_3$, 25 °C.

For comparison, Figure 3 shows a CEST spectrum of the Nd(III) complex of **3**, a ligand lacking NH groups. Nd(**3**) has no discernible CEST peak and only shows a peak for direct irradiation of bulk water. This suggests that the CEST effects centered around 11 ppm for Nd(**2**) and 12 ppm for Nd_2(**1**) are for amide NH protons. Nd(III) macrocyclic complexes with peptide pendant groups have NH CEST peaks with similar chemical shifts (*33*).

By contrast, the Eu_2(**1**) complex has no observable CEST peaks under these conditions (Supporting Information Figure S4). This result is similar to previously reported mononuclear Eu(III) complex analogues that have a barely discernible NH CEST shoulder because their amide NH resonance is very close to the bulk water resonance (*33, 34*).

To estimate the rate constant for NH proton exchange, a concentration study for the saturation transfer of Nd_2(**1**) ranging 5−20 mM was carried out. The plot of the saturation transfer (ST, eq 1) efficiency as a function of concentration is shown in Figure 4. The data are fit to eq 1 to give an exchange rate constant of k_{ex} of 2700 s^{-1} for a measured longitudinal relaxation time (T_1) of bulk water protons of 0.18 s.

Our interest in the design of lanthanide(III) DNA conjugates as MRI contrast agents led us to study the interaction of Nd_2(**1**) with phosphate esters and DNA to determine whether certain DNA structural elements might support or even enhance the CEST effect (Figure 6, Chart 2). Addition of diethyl phosphate (DEP) led to a slight decrease in the CEST peak attributed to the NH group (Supporting Information Figure S5). By contrast, certain structured DNA sequences modestly increased the CEST shoulder at 12 ppm. The hairpin DNA (HP1) was the most efficient (Chart 2) with a 15% enhancement of CEST over the complex alone upon addition of 0.50 mM DNA (Figure 5). Mutation of the closing base pair gives a DNA sequence that enhances the CEST spectrum to a smaller extent at 5%. This suggests that the CEST efficiency is dependent on structural differences in the DNA that are dictated by the closing base

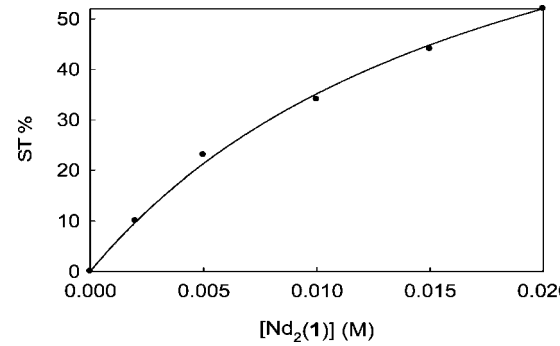

Figure 4. Saturation transfer (ST) effect as a function of Nd_2(**1**) concentration with 50 mM $NaNO_3$ at pH 7.0 and 25 °C. The data were fit to eq 1 to obtain a k_{ex} of 2.7 × 10^3 s^{-1}.

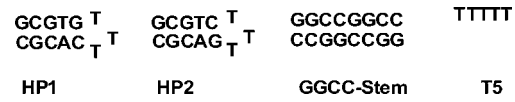
Chart 2



pair. In comparison, neither the self-complementary oligonucleotide GGCCGGCC nor single-stranded T5 measurably affects the CEST spectrum under similar conditions (data not shown).

The effect of carbonate on the CEST spectrum of Nd_2(**1**) was examined. Addition of an equivalent of carbonate to the dinuclear complex at pH 7.4 gave a decrease in the amide CEST peak (Supporting Information Figure S6), consistent with suppression of the NH amide CEST effect for the carbonate complex. Addition of $Pb(NO_3)_2$ to a solution of Nd_2(**1**) to sequester carbonate had little effect on the CEST spectrum. This result suggests that freshly prepared and degassed solutions of Nd_2(**1**) do not contain carbonate complexes in appreciable quantities. Interaction of Ln_2(**1**) with carbonate and DNA was studied quantitatively by using luminescence spectroscopy for the Eu(III) analogue (see below).

Luminescence Spectroscopy. Direct excitation luminescence spectroscopy of the Eu_2(**1**) complex was studied to probe interactions with phosphate esters, DNA and carbonate. The $^7F_0 \rightarrow {}^5D_0$ transition for Eu(III) is between two nondegenerate levels and thus useful for determining the number of species in solution. The $^7F_0 \rightarrow {}^5D_0$ excitation spectrum of Eu_2(**1**) is shown in Figure 6. As shown previously (*18*), the major peak at 579.82 nm is attributed to the dinuclear complex with four bound water ligands (Eu_2(**1**)$(H_2O)_4$), and the red-shifted shoulder and peak at 580.22 and 580.53 nm are attributed to a carbonate complex that forms in water at neutral pH upon exposure of the complex to the atmosphere or upon addition of carbonate ion in buffered solutions. For selected studies, the concentration of carbonate complex was reduced to obtain a solution with predominantly (Eu_2(**1**)$(H_2O)_4$). This was accomplished by treating the Eu_2(**1**)

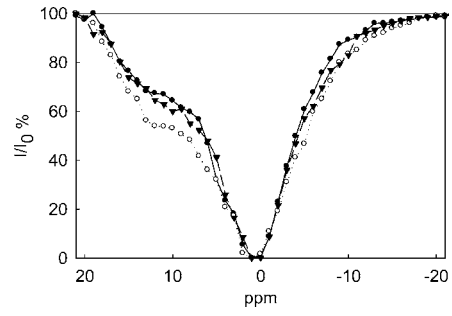


Figure 5. CEST spectra of Nd_2(**1**) 5.0 mM (●) titrated with 0.20 mM (▼) and 0.50 mM (○) HP1 at pH 7.0, 10 mM HEPES, 50 mM $NaNO_3$, 25 °C.

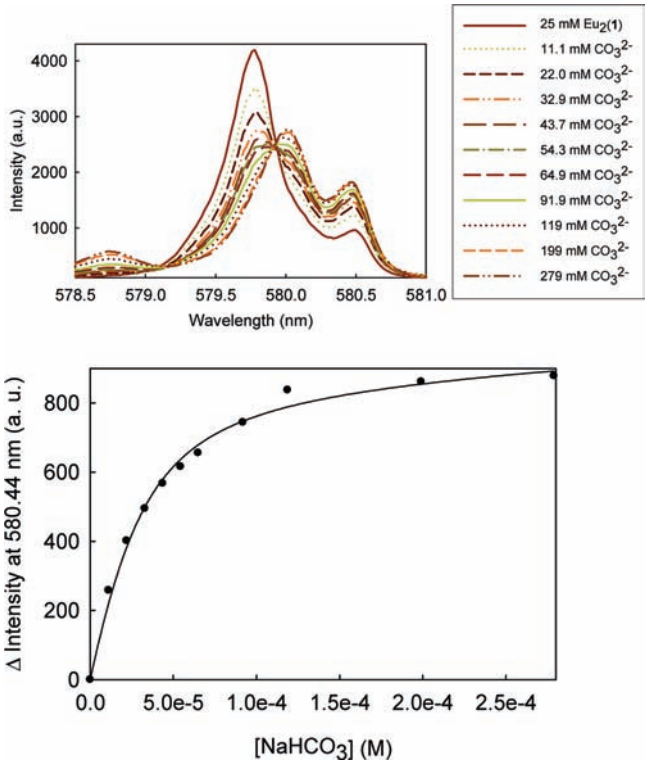

Figure 6. The effect of carbonate on the $^7F_0 \rightarrow {}^5D_0$ excitation band of Eu_2(**1**) for solutions containing 25 μM Eu_2(**1**), 20 mM HEPES, pH 7.0, 50 mM $NaNO_3$ (top). Data are fit to eq 4 with a K_d of 15 uM (bottom).

Table 1. Luminescence Lifetimes of Eu_2(1) upon Binding of DNA or Carbonate[a]

anion	wavelength (nm)	H_2O μs	D_2O μs	anion (μM)	q [b]
HP1	579.64	537	1700	50	0.96
HP2	579.70	512	1630	50	0.93
GGCC	579.70	490	1600	50	1.1
CO_3^{2-}	580.45	608	1330	20	0.50
CO_3^{2-}	580.20	587	1360	20	0.59

[a] Solutions contained 50 mM $NaNO_3$, 20 mM HEPES, pH 7.0, with 25 μM Eu_2(**1**). [b] The number of bound water molecules, q, was calculated by using eq 2. Standard deviations in lifetime values are typically ≤7% in H_2O and ≤3% in D_2O (*27*).

complex with $Pb(NO_3)_2$ to form insoluble $Pb(CO_3)$ followed by precipitation of any remaining Pb(II) with chloride ion.

Addition of carbonate to solutions containing Eu_2(**1**) gives rise to two pronounced excitation peaks at 580.20 and 580.45 nm (Figure 6). These two peaks are attributed to two different isomers, both of which have bound carbonate and have low q values of 0.5 to 0.6 (Table 1). The small peak at 578.74 nm that grows in with increasing carbonate concentration is assigned as the free Eu(III) ion (*27*). A plot of the luminescence intensity as a function of bicarbonate gives a binding isotherm with a K_d of 15 μM by fitting the data to eq 4.

Titration of Eu_2(**1**) with HP1 DNA gives a decrease in the major excitation peak to give a new peak that is slightly blue-shifted (579.69 nm). A plot of the change in luminescence intensity as a function of DNA gives a binding constant of 2.5 μM and $n = 8.2$ (number of bases in binding site) by fitting the data to eq 3 (Figure 7). HP2 DNA and the self-complementary GGCCGGCC DNA give similar excitation peaks and binding curves with dissociation constants of 4.2 μM ($n = 12$) and 28 μM ($n = 6.9$), respectively (Supporting Information Figures S7, S8). By contrast, T5 has only a small effect on luminescence intensity (Supporting Information Figure S9), and a plot of this change in intensity with DNA concentration suggests that

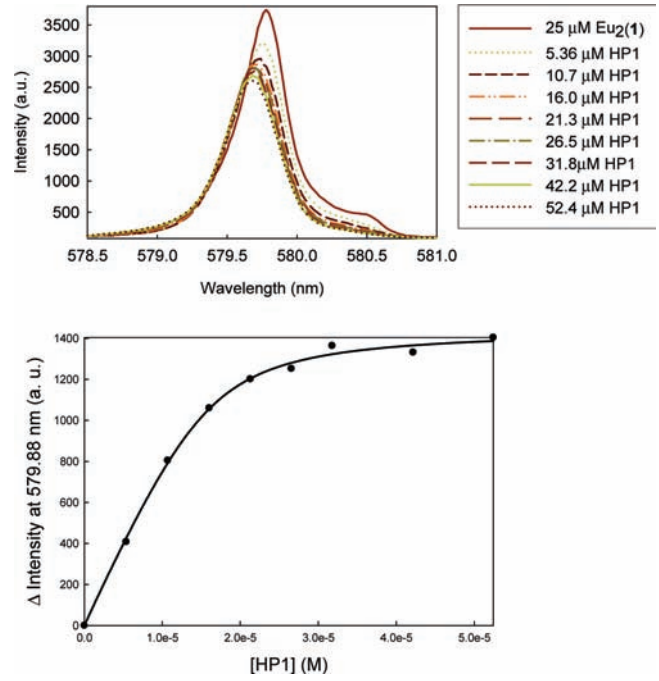

Figure 7. $^7F_0 \rightarrow {}^5D_0$ excitation spectra ($^5D_0 \rightarrow {}^7F_2$ emission) of solutions of 25 μM Eu_2(**1**) titrated with HP1 DNA at pH 7.0, 20 mM HEPES, 50 mM $NaNO_3$ (top). Data are fit to eq 3 with a K_d of 2.5 μM and n of 8.2 (bottom).

binding is weak under conditions of the titration. Luminescence lifetime studies show that there is a reduction in the number of bound waters on each Eu(III) center of the aqua complex (excitation at 579.82 nm) upon DNA binding to hairpin or double-stranded DNA (Table 1). In addition, excitation luminescence studies of the Eu_2(**1**) carbonate complex treated with DNA (Supporting Information Figure S10) show that the carbonate ligand is displaced by DNA.

DISCUSSION

Nd_2(**1**) shows a more pronounced CEST effect than the mononuclear complex Nd(**2**) under the conditions studied here, corresponding to the larger number of mobile amide protons for the dinuclear complex at equal concentrations of complex. In addition, the relatively large exchange rate constant for Nd_2(**1**) amide protons (2700 s^{-1}) contributes favorably to the efficiency of CEST. By comparison, mononuclear Nd(III) complexes have NH proton exchange rate constants that range from 125 s^{-1} to 826 s^{-1} (*14, 32*). The rate constant for Nd_2(**1**) is nearly as large as it can be (6500 s^{-1}) before slow exchange conditions no longer hold $\Delta\omega \cdot \tau \geq 1$. Notably, peaks in the CEST spectrum are observed for mobile protons that approach or even exceed this limit whose resonances are consequently broadened into the baseline (*16*).

The solution chemistry of Ln_2(**1**) complexes is dominated by carbonate complex formation. Indeed, isolation of a carbonate-free complex of Eu_2(**1**) is difficult in aqueous solution without the addition of a carbonate sequestering agent. Eu_2(**1**) binds carbonate more strongly than related monomeric complexes (*18*). This is consistent with the propensity of the dinuclear complex to bind tightly to anions including phosphate esters, carbonate, and sulfonates (*18*). An increased affinity for anions is attributed in part to the aromatic linker which leads to increased Lewis acidity of the Ln(III) centers as well as the possible interaction of anions with both Ln(III) centers. The two distinct excitation peaks for the carbonate complex are attributed to two isomers. One possibility is that the two isomers have similar numbers of bound waters, based on their nearly identical q numbers

derived from luminescence lifetimes. However, the nonintegral q number for the isomers (0.5 and 0.6) suggests an alternate explanation. The two carbonate complex isomers that give rise to two distinct excitation peaks may actually differ by the number of bound water molecules (q values of approximately 1 and 0) but are in rapid exchange on the luminescence emission time scale to give an apparent q that is the average of the two complexes (*35*). This case would be similar to the hydration isomers observed for Eu(EDTA)$(H_2O)_x$ ($x = 2$ or 3) (*27, 36*) that give rise to two excitation peaks but a single luminescence lifetime. For the complexes here, an equilibrium between a bidentate carbonate complex with $q = 0$ (*37*) and a monodentate carbonate complex with a $q = 1$ would be involved. The relatively large difference in the excitation peak frequencies is consistent with this alternative. Also supportive of this assignment is that other carbonate complexes we have reported to date, including both dinuclear and mononuclear Eu(III) complexes of septadentate macrocycles, have two peaks at similar frequencies to those observed here (*18*). These similarities suggest that the isomers do not involve interactions that are specific to dinuclear complexes such as bridging carbonate.

Excitation luminescence studies of complexes related to Eu_2(**1**) show that DEP coordinates to dinuclear Eu(III) complexes with a binding constant of 0.43 mM (*18*). Luminescence lifetime studies are consistent with displacement of one water molecule at each Eu(III) center upon DEP binding (*38*). Assuming a similar binding constant between Nd_2(**1**) and DEP, DEP should be fully bound in the CEST experiment shown in Supporting Information Figure S5. Binding of DEP results in a 10% decrease of the amide CEST peak of the Nd(III) complex. The origin of this decrease may involve a change in the rate constants for amide proton exchange upon binding of DEP mediated by a change in the Lewis acidity of the metal ion center upon complexation of DEP. Alternately, there may be a change in the chemical shift dispersion of the different amide protons for the Nd(III) complex of DEP so that the CEST peak shape is changed. A similar decrease in the CEST amide peak is observed for carbonate binding to Nd_2(**1**). Thus, complexation of either of these two simple anionic ligands leads to a decrease in the CEST amide peak of Nd_2(**1**).

The preparation of biopolymers, polymers, and nanoparticles conjugated to multiple copies of CEST agents is of interest in order to increase the number of CEST agents at a targeted tissue (*15, 39*−*41*). For Ln(III) PARACEST agents, the close proximity of a biopolymer may give rise to changes in the CEST peaks attributed to the influence of the biopolymer environment on the complex (*22*). Thus, it is important to choose an environment that supports or enhances the CEST effect. Typically, interactions of Ln(III) PARACEST agents with other molecules lead to changes in the rate constants for the mobile protons, and this may either enhance or decrease the CEST effect (*16, 17*). In some cases, Ln(III) complexes form supramolecular complexes that induce hyperfine shifting of multiple macromolecular protons to enhance the CEST effect (*6*). In addition to proteins, DNA is of interest for conjugation of lanthanide MRI contrast agents (*24, 25*). Our work here shows that Eu_2(**1**) and Nd_2(**1**) complexes interact strongly with DNA and both binding strength and CEST effect modulation are dependent on DNA secondary structure.

Titration of the Eu_2(**1**) complex with HP1, HP2, and the GGCC stem leads to a decrease in luminescence intensity to form a new complex with a single bound water for each Eu(III) center ($q = 1$, Table 1). Fitting of the data to a binding isotherm for DNA sequences with multiple binding sites shows that all three DNA sequences bind tightly to Eu_2(**1**) with binding constants that are in the micromolar range. The large binding site sizes for the hairpins ($n = 8$−11) are most consistent with a complex involving one to two Eu_2(**1**) bound to DNA. For the GGCC stem, data are most consistent with that of two Eu_2(**1**) binding sites. In any case, these data suggest that, under the conditions of the CEST experiments which contain higher concentrations of Nd(III) complex and DNA, all DNA is bound to the lanthanide complex. Only single-stranded T5 binds weakly to the dinuclear complex, demonstrating that double helical DNA is required for tight binding. The tight binding constants of the hairpin loops and double-stranded DNA led us to initially anticipate that these DNA sequences would have similar effects on the CEST spectrum of Nd_2(**1**).

Modulation of the CEST spectrum is, however, DNA sequence dependent. The CEST peak of Nd_2(**1**) increases upon addition of the hairpin DNA sequences but not with addition of the GGCC stem or T5. At this juncture, it is not known which protons in the Nd_2(**1**) bound DNA complex give rise to the CEST peak. It is likely that, given the large number of amide protons of the Nd(III) complex and the presence of this complex in excess over DNA, the CEST peak results from a favorable increase in the amide proton exchange rate by interaction of the complex with DNA. In addition, it is noteworthy that nucleic acids such as poly-U act as CEST agents through both amide NH and alcohol protons. However, the exchangeable DNA amide protons would have to be hyperfine-shifted by the Nd(III) complex (*12*) to produce the observed CEST peak in our studies. Our data suggest that there is a specific interaction of the Nd_2(**1**) complex with the hairpin loop of HP1 that enhances the CEST peak at 12 ppm. This is supported by the lack of an effect of the GGCC-stem sequence on the CEST spectrum despite strong binding of this DNA to the Ln(III) complex. Even more remarkable is the fact that a change in the hairpin closing base pair (CG to GC) affects the Nd_2(**1**)-DNA complex CEST intensity, although both hairpins bind nearly equally as strongly. Given the important role of the closing base pair on DNA hairpin loop structure (*42*), these data suggest that loop structure is important in the association of the complex. The limited number of DNA secondary structures studied here prevents us from formulating rules for effective enhancement of Ln(III) CEST agents. Our data suggest, however, that secondary structures such as hairpin loops that have been shown to bind lanthanide ions such as the thymidine triloop studied here (*43*) give rise to increased CEST effects. Speculation on the mode of Ln(III) complex DNA interactions is premature, but it is noteworthy that a simple phosphate diester decreases the CEST effect. DNA of a particular sequence and structure gives rise to the modestly enhanced CEST spectrum of the Nd_2(**1**)-DNA complex.

CONCLUSIONS

The presence of a large number of exchangeable amide protons in combination with a relatively rapid amide proton exchange rate in the Nd_2(**1**) complex suggests that further development of dinuclear complexes as PARACEST agents is warranted. Binding of carbonate to complexes of Ln_2(**1**) will influence the solution and PARACEST properties of these complexes in biological systems where carbonate concentrations are high. Interestingly, the carbonate acts as a masking agent that is readily displaced by anionic ligands such as DNA that bind even more strongly than carbonate. This work shows that DNA complexes of PARACEST agents are promising for the design of new nanosized biocompatible systems that use DNA as a carrier or as a scaffold. The position of lanthanide ion complex conjugation to DNA and the secondary structure of the DNA conjugate, however, require further study to optimize the CEST effect. This will require the study of different DNA sequences toward a better understanding of the basis for the modulation of the PARACEST effect by macromolecule binding.

For multiple site-specific conjugations of bioactive molecules to a single-chain antibody (scFv) molecule, we have constructed a human anti HER2 receptor, scFv, with a C-terminal fusion polypeptide containing 1, 3, or 17 threonine (Thr) residues. The C-terminal extended fusion polypeptides of these recombinant scFv fusion proteins are used as the acceptor substrate for human polypeptide-α-N-acetylgalactosaminyltransferase II (h-ppGalNAc-T2) that transfers either GalNAc or 2-keto-Gal, a modified galactose with a chemical handle, from their respective UDP-sugars to the side-chain hydroxyl group of the Thr residue(s). The recombinant scFv fusion proteins are expressed in *E. coli* as inclusion bodies and *in vitro* refolded and glycosylated with h-ppGalNAc-T2. Upon protease cleavage, the MALDI-TOF spectra of the glycosylated C-terminal fusion polypeptides showed that the glycosylated scFv fusion protein with a single Thr residue is fully glycosylated with a single 2-keto-Gal, whereas the glycosylated scFv fusion protein with 3 and 17 Thr residues is found as an equal mixture of 2−3 and 5−8 2-keto-Gal glycosylated fusion proteins, respectively. These fusion scFv proteins with the modified galactose are then conjugated with a fluorescence probe, Alexa488, that carries an orthogonal reactive group. The fluorescence labeled scFv proteins bind specifically to a human breast cancer cell line (SK-BR-3) that overexpresses the HER2 receptor, indicating that the *in vitro* folded scFv fusion proteins are biologically active and the presence of conjugated multiple Alexa488 probes in their C-terminal end does not interfere with their binding to the antigen.

INTRODUCTION

Conjugation of monoclonal antibodies with bioactive molecules such as toxins, drugs, and radioisotopes is an emerging strategy in the treatment and diagnosis of cancer (*1*−*5*). Not only is the conjugation of a multiple number of bioactive molecules to a single antibody molecule desired, but also, site-specific conjugation of these molecules is important. The former enhances the sensitivity of detection and better treatment of cancer, while the latter enables the production of a homogeneous antibody−drug complex that ensures the full activity of both the antibody and the bioactive molecule in an antibody−drug conjugate. Multiple site-specific conjugation has been achieved by engineering the target protein, either by the introduction of free Cys residues (*6*, *7*) or by introducing genetically encoded aldehydes at either terminal end of the protein or by site-directed introduction of azido/alkynyl-tagged methionine analogues into proteins (*8*−*10*). However, protein with free Cys residue(s) needs special handling to prevent its free Cys residues from undergoing undesired oxidation while in the process of introducing the methionine analogue all the methionine residues in the protein are modified. Not many site-specific conjugation methods offer multiple site conjugations.

We have developed a unique, site-specific conjugation method using the mutant galactosyltransferase enzymes, where we first enzymatically transfer 2-acetonyl-2-deoxy-galactose (2-keto-Gal) sugar with a unique chemical handle to a specific sugar moiety, βGlcNAc or βGal1-4GlcNAc, present at the nonreducing end of the glycan of the glycoprotein; then, the chemical handle present in the modified sugar is used for site-specific conjugation with biologically important molecules having a corresponding orthogonal chemical group (*11*−*14*). Using this method, we have recently shown that the biantenary *N*-glycans of a therapeutic IgG molecule have been used as the substrate for the mutant Y298L-Gal-T1 enzyme to transfer 2-keto-Gal sugar and further conjugated with bioactive molecules such as biotin to both arms of the biantenary *N*-glycans, thus producing the native IgG molecule with four biotin molecules site-specifically conjugated (*12*, *14*). However, this method requires the presence of a specific sugar moiety of a glycan chain in the glycoprotein and cannot be used for nonglycosylated proteins, such as single-chain antibodies or bacterial toxins expressed in *E. coli.*

For proteins that lack glycosylation motifs, we have recently developed a method using the human polypeptide-α-*N*-acetylgalactosaminyltransferase II enzyme (h-ppGalNAc-T2), which transfers *N*-acetylgalactosamine sugar (GalNAc) from UDP-GalNAc to Thr/Ser residues on an acceptor polypeptide that is at least 11 amino acids long (*15*, *16*). In this method, we have engineered the acceptor polypeptide substrate of the h-ppGalNAc-T2 with one Thr residue as a fusion peptide at the C-terminus of a bacterial glutathione-*S*-transferase (GST), which is not normally glycosylated. We used this fusion polypeptide moiety as an acceptor substrate for the h-ppGalNAc-T2 to transfer modified Gal with chemical handle such as 2-keto-Gal or GalNAz, thus enabling us to site-specifically conjugate bioactive molecules with a corresponding orthogonal chemical group (*15*). Using this method, in the present study we demonstrate that an anti human HER2 receptor single-chain antibody (anti HER2 scFv) with a fusion peptide containing more than one Thr residue at its C-terminal end can be successfully glycosylated with 2-keto-Gal and then conjugated

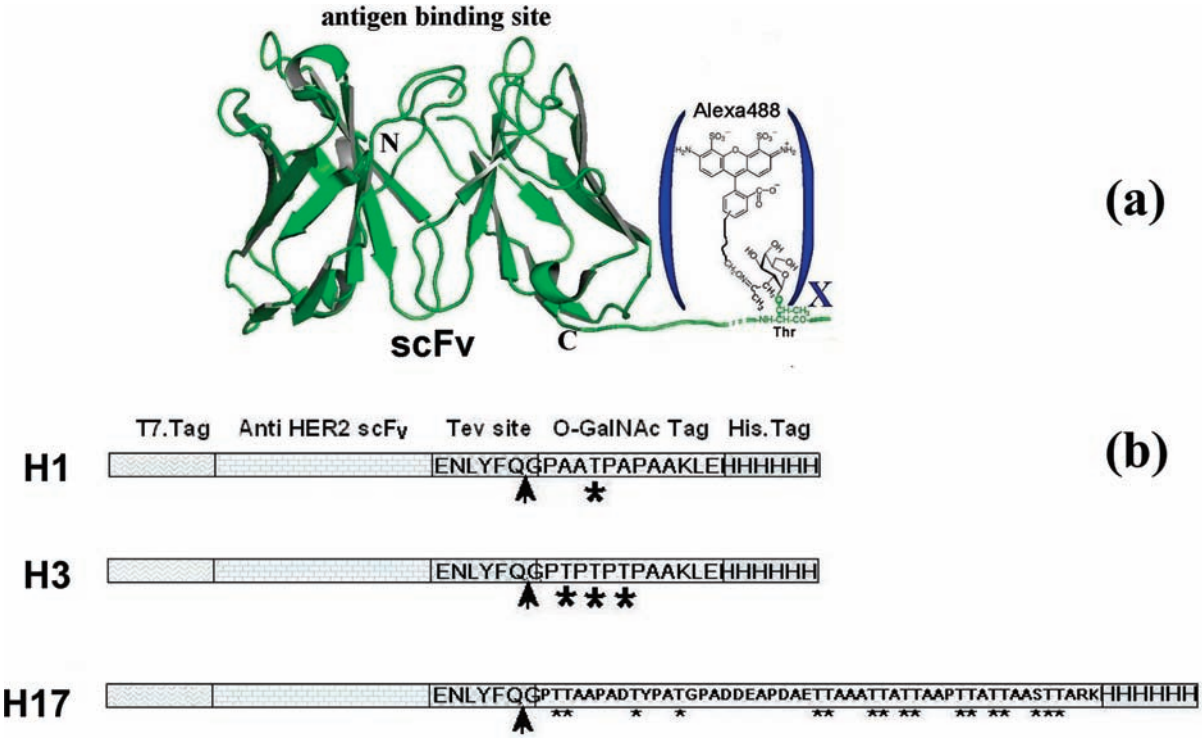

Figure 1. (a) Schematic molecular structure of the Alexa488-conjugated scFv fusion protein. In the present study a single-chain antibody against human HER2 receptor (anti HER2 scFv) with *x* number of Alexa488 molecules conjugated through the modified sugar is named H*x*. The anti HER2 scFv protein has been designed to have specific 1 to 17 O-glycosylation sites. (b) Schematic diagram of the design of anti HER2 scFv proteins with multiple glycosylation sites. The antihuman HER2 receptor single-chain antibody (anti HER2 scFv) expressed in *E. coli* contains a N-terminal T7-tag, a C-terminal Tev protease-cleavable O-glycosylation tag, and an His tag. The proteins with 1, 3, and 17 Thr residues in their O-glycosylation tags (shown as stars at their bottom) are named H1, H3, and H17, respectively. The Tev protease cleavage site is indicated by an arrow. In the presence of Mn^{2+}, the polypeptide-α-*N*-acetylgalactosaminyltransferase II (h-ppGalNAc-T2) enzyme transfers GalNAc or 2-keto-Gal sugar from their UDP derivatives to the side-chain hydroxyl group of the Thr residue present in the O-glycosylation tag.

with Alexa488, a fluorescence probe. Furthermore, our cell surface immunostaining analysis of HER2-receptor expressing SK-BR-3 cells (by fluorescent-activated cell sorting [FACS]) shows that antibody binding to the HER2 receptor is not affected by the one or more Alexa488 molecules present at the C-terminal end of these scFv molecules.

EXPERIMENTAL PROCEDURES

Anti HER2 Single-Chain Antibody Gene Construction and Expression in *E. coli.* The antihuman HER2 scFv gene was constructed from a fully human Fab isolated from a large native phage display Fab library, using HER2 ectodomain as a target (Zhu, Z., and Dmitrov, D., unpublished data). For the construction of H1 and H3 scFv proteins, the anti HER2 scFv gene was repeatedly amplified with the 5-primer, 3-primer-1, and 3-primer2, which introduces a 17-amino-acid peptide as a C-terminal extension following a Tev protease cleavage site. A final PCR amplification with either 3-H(1) or 3-H(3) primer results in a product with a C-terminal O-glycosylation tag without a stop codon, having *Eco*RI and Xho I restriction enzyme sites at their 5′ and 3′ termini, respectively. This construction uses the stop codon at the 3′ terminal in the vector after the His-tag.

5-primer: GCC CCG *GAA TTC* GGG CGC GGC GAA GTG CAG CTG GTG CAG TCT GGA GCA GAG GTG AAA AAG.

3-Primer 1: GCC TTG GAA GTA AAG GTT TTC TAG GAC GGT GAC CTT GGT CCC AGA TCC GAA GAC AGC AAT.

3-H1 Primer: GTG GTG GTG *CTC GAG* TTT AGC TGC CGG TGC GGG ACT AGC TGC AGG GCC.

3-H3 Primer: GTG GTG GTG *CTC GAG* TTT AGC TGC CGG TGT GGG AGT AGG TGT AGG GCC.

The PCR-amplified product was digested with *Eco*RI and Xho I restriction enzymes and ligated with the pET23a vector digested with the same enzymes. The ligated vector was transfected into XL2 supercompetent cells. The ampicillin-resistant clones were screened for the presence of the anti HER2 scFv gene in their plasmid DNA between their *Eco*RI and Xho I restriction sites. The N-terminal T7-tag, which enhances the protein expression in *E. coli* and the C-terminal His × 6 tag, followed by a stop codon, comes from the pET23a vector DNA. For the construction and expression of H17 scFv protein, the cDNA for the scFv protein was first cloned into the pET23a vector between the *Eco*RI and Hind III restricted enzyme sites without the stop codon. This cloning was followed by inserting between the Hind III and Xho I site a cDNA sequence coding for a Tev protease cleavage site and the 50 amino-acid-long polypeptide of the O-glycosylation region of the human small breast epithial mucin protein (BC111421) (*17*) without the stop codon. This construction uses the stop codon at the 3′ terminal in the vector after the His-tag, similar to H1 and H3 scFv gene constructs. The positive clones were sequenced and transfected into Rosetta (DE3) LysS competence cells for expression of the protein.

In Vitro* Folding of Inclusion Bodies of Anti-HER2 scFv Protein from *E. coli. The Rosetta (DE3) LysS cells containing the anti HER2 scFv cDNA sequence in the pET23a vector were grown to an optical density of 0.7−0.8 and then induced with IPTG. The inclusion bodies were purified from the bacterial pellet as described earlier (*18*). From 1 L of bacterial culture, 60 to 70 mg of protein were obtained as inclusion bodies. The *in vitro* folding of anti HER2 scFv was

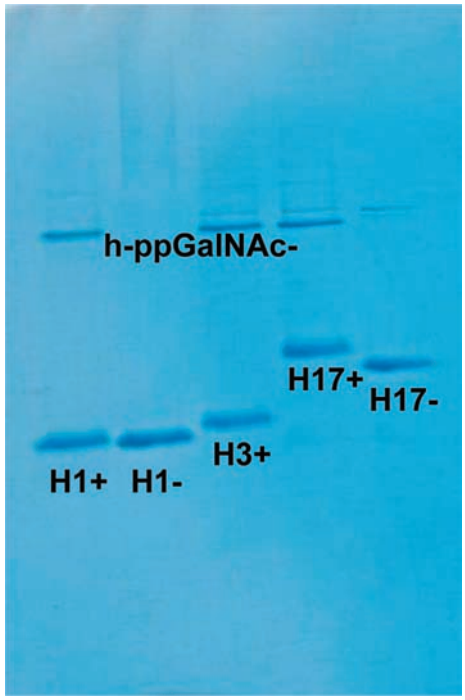

Figure 2. SDS-PAGE gel analysis of the unglysoylated (H1- and H17-) and 2-keto-Gal glycosylated (H1+, H3+, and H17+) proteins: The unglycosylated H1 and H17 proteins are labeled as H1- and H17-, respectively, while the 2-keto-Gal glycosylated H1, H3, and H17 are labeled as H1+, H3+, and H17+, respectively. The h-ppGalNAc-T2 in the glycosylation mixture is also labeled. MALDI-TOF analysis of the H1+, H3+, and H17+ anti HER2 scFv proteins show that these proteins carry 2-keto-Gal (see below). The large difference in the mobility between unglycosylated and glycosylated H17 protein is due to glycosylation, however the microhetrogenity in its glycosylation is not observed (see below). Similarly the mobility difference between the H1 unglycosylated protein and the H1+ and H3+ glycosylated protein may be due to their glycosylation.

carried out in a way similar to that of β4Gal-T1 (*18*). Typically, 100 mg of sulfonated protein was folded for 48 h in 1 L of folding solution that contains oxido-shuffling agents and 500 mM arginine HCl. After refolding the protein, the folding solution was extensively dialyzed against water. During dialysis, the misfolded protein precipitated out, while the folded protein remained soluble. The soluble protein was concentrated to a concentration of 1 mg/mL on an Amicon stirred cell, using a YM-10 membrane, and further purified on a Ni-column. There was no significant loss of protein observed during concentration or during Ni-column purification steps, as estimated by measuring the protein concentration using the Bradford method (BioRad). Nearly 20 mg of folded anti HER2 scFv protein was obtained from 1 L of folding solution. The C-terminal glycosylation peptide tag was released from a 5 μg protein by Tev protease cleavage and analyzed by mass spectrometry.

Glycosylation and Alexa488 Conjugation of Anti HER2 scFv. The cloning, expression, and refolding of the h-ppGalNAc-T2 enzyme has been previously published (*15*). UDP-GalNAc was purchased from Sigma chemicals while the UDP-2-keto-Gal was synthesized in-house. Forty micrograms of anti HER2 scFv fusion protein—H1, H3, or H17—were incubated overnight at room temperature 20 °C with 20 μg of h-ppGalNAc-T2 in the presence of 25 mM Tris-HCl (pH 8.0), 10 mM $MnCl_2$, and 0.5 mM UDP-sugar (UDP-GalNAc, or UDP-2-keto-Gal,) in a total volume of 100 μL (Figure 2). The amount of h-ppGalNAc-T2 enzyme used in these experiments to fully glycosylate the fusion peptide using UDP-GalNAc as the donor substrate was first determined in separate experiments. To remove the entire reaction buffer, the glycosylated anti HER2 scFv protein was precipitated with 40% ammonium sulfate and desalted three times by repeated dilution to 500 μL with water and concentrated each time to 40 μL using microcon centrifuge filters with 10K molecular weight cutoff. The salt-free glycosylated anti HER2 scFv protein was reconstituted in 40 μL water, and an aliquot (2 μL) was cut with Tev protease and analyzed by mass spectrometry (MALDI-TOF).

The entire 40 μg of the desalted 2-keto-Gal glycosylated anti HER2 ScFv protein was conjugated in 60 μL with 75 mM sodium acetate buffer (pH 5.0) and 8 μL *N*-aminoxymethylcarbonylhydrazino-Alexa488 (1 mg/mL in DMSO). Nearly 1000-fold excess of Alexa-488 molecules, more than the manufacturer (Invitrogen) suggested amount, was used in this conjugation reaction. The reaction was carried out in the dark, overnight, at room temperature. The conjugated protein was precipitated with 40% ammonium sulfate, redissolved in water to a 1 μg/μL concentration and used for cell binding. The presence of Alexa488 was confirmed by visualizing as little as 10 ng of protein in SDS-PAGE. The mass spectroscopic analyses were carried out in the Protein Chemistry Laboratory, NCI-Frederick, Frederick, MD.

Cell Binding Assays. The human cancer cell lines SK-BR-3 (HER2 receptor-positive) and MDA-MB-468 (HER2 receptor-negative) were used to test receptor binding activity of the scFv fusion proteins. HER2 receptor expressing human breast adenocarcinoma cells (SKBR-3) and HER2 receptor negative human breast adenocarcinoma cells (MDA-MB-468) were purchased from the American type Culture Collection (ATCC, Manassas, VA). The cells were cultured in McCoy's 5A medium supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) and penicillin/streptomycin as antibiotics at 37 °C in a humidified atmosphere containing 5% CO_2. Other culture reagents were bought from Invitrogen (Carlsbad, CA). In a typical experiment, cells were suspended in enzyme-free cell dissociation buffer (Invitrogen Corp, Carlsbad, CA) and pelleted. The cells were resuspended in phosphate buffer saline (PBS) supplemented with 5% fetal calf serum (PBS-FCS) at a concentration of 10^7 cells per mL. The samples were incubated at room temperature for 15 min to block nonspecific binding sites. The cells were washed twice with cold PBS with 1% bovine serum albumin (PBS-BSA), resuspended in PBS-FCS (10^7 cells /ml), and aliquoted in 0.1 mL samples. Various amounts (0.2, 0.5, and 1 μg) of Alexa-conjugated scFv were added to the cells, and incubations were continued for 45 min on a rotator at 4 °C in the dark. The cells were washed twice with cold PBS-BSA, suspended in PBS-BSA, and analyzed using a FACS caliber flow cytometer (Becton Dickinson, San Jose, CA), analyzing 10 000 events per sample. Herceptin was used as a positive control in these experiments to confirm HER2 expression on SK-BR-3 cells (HER2-positive) and MDA-MB-468 cells (HER2 receptor-negative).

RESULTS AND DISCUSSION

We have previously developed a novel site-specific glycoconjugation of glutathion-S-transferase, by engineering a C-terminal fusion peptide containing one Thr residue that can be glycosylated by h-ppGalNAc-T2 with a modified sugar having a chemical handle (*15*). This site-specific glycan moiety can then be conjugated with bioactive molecules carrying an orthogonal chemical group. Here, we have extended this strategy to engineer, not just one glycosylation site at its C-terminal end, but multiple sites on an antihuman HER2 receptor single-chain antibody (anti HER2 scFv) (Figure 1a). The anti HER2 scFv fusion protein is designed to have a N-terminal T7-tag, which enhances its protein expression in *E. coli* and at the C-terminal end a Tev protease cleavage site, an O-glycosylation peptide followed by a His × 6 tag (Figure 1b). For the present study,

three forms of anti HER2 scFv proteins have been constructed: the H1, H3, and H17, with C-terminal extensions having 1, 3, and 17 Thr residues in their O-glycosylation tag, respectively (Figure 1b). The two C-terminal extension peptides, H1 and H3, were designed based on the preferred acceptor peptide sequence for h-ppGalNAc-T2 enzyme, as described earlier (*15, 16*).

Expression of the Anti Her2 scFv Proteins in *E. coli* and Their *in Vitro* Folding. Although many scFv proteins have been expressed as soluble active proteins in *E. coli*, the anti HER2 scFv proteins, H1, H3, and H17, mostly formed inclusion bodies; and only less than 100 μg of soluble active protein could be obtained from 1 L of bacterial culture. Previously in our laboratory, we have used the *in vitro S*-sulfonation and refolding method to produce large quantities of active β-1,4-galactosyltransferase (β4Gal-T1) enzyme from inclusion bodies (*18*). Using the same method, a large quantity of a soluble form of anti HER2 scFv proteins H1, H3, and H17, with C-terminal extension, has been obtained. The scFv fusion protein has four Cys residues and has two disulfide bonds. The *in vitro* folded protein, nonreduced and reduced with β-mercaptanol, shows in SDS-PAGE a significant mobility difference between the protein bands confirming the presence of disulfide bond(s) in the soluble protein. The yield of the *in vitro* folded protein for H1, H3, and H17 proteins corresponds to 10, 10, and 2.5 mg per liter of bacterial culture. Thus, it seems that the presence of the 17 amino acid C-terminal tag does not interfere with the folding of scFv molecules. Nevertheless, the 50 amino-acid-long tag significantly reduces the folding efficiency. All the refolded proteins can be concentrated to at least 10 to 15 mg/mL concentrations, without any precipitation.

Glycosylation of H1, H3, and H17 anti-HER2 scFv Proteins. As a first step, the H1, H3, and H17 scFv fusion proteins were glycosylated overnight with h-ppGalNAc-T2, using UDP-GalNAc as the donor sugar substrate. The C-terminal fusion polypeptide from these proteins was released by Tev protease digestion and analyzed by mass spectrometry (MALDI-TOF) (Figure 3). The MS analysis of the glycosylated peptide tags from H1 and H3 proteins showed that they carry 1 and 3 GalNAc sugars, respectively (Figure 3a,b), suggesting that the H1 protein has been fully and homogenously glycosylated while the H3 proteins is mostly glycosyled with three GalNAc sugars. However, the polypeptide released from H17 scFv protein by Tev protease was glycosylated with a maximum of 11 sugars instead of 17 sugars (Figure 3c). The catalytic reaction using UDP-α-2-keto-Gal as donor substrate was carried out under the same conditions as the one used for UDP-GalNAc. After the glycosylation, a small amount of the glycoprotein was subjected to the Tev digestion, and the released C-terminal fusion glycopeptides was analyzed by MALDI-TOF analysis. The glycopeptide from the H1 protein was found fully glycosylated with a single 2-keto-Gal sugar, whereas the glycopeptide from H3 and H17 was found to be a mixture of peptides with 2 to 3 and 5 to 8 2-keto-Gal sugars, respectively (Figure 3d,e,f). These results show that all the Thr residues present in the O-glycosylation tag of the H3 and H17 scFv proteins are not homogenously glycosylated by the h-ppGalNAc-T2, particularly with the modified sugar.

In humans, the h-ppGalNAc-T2 enzyme exists as a family of 17 enzymes, namely, ppGalNAc-T1 to ppGalNAc-T17 (*19*). It is well-known that h-ppGalNAc-T2 efficiently glycosylates nonconsecutive Thr residues, while ppGalNAc-T10 uses glycopeptide as the substrate and efficiently glycosylates the consecutive Thr residues if either one is glycosylated (*16, 20*). The O-glycosylation tag of the H17 fusion protein has 10 nonconsecutive Thr residues. Thus, it is not surprising to observe that its tag is glycosylated by h-ppGalNAc-T2 with only 11 GalNAc sugars, and to fully glycosylate this tag, it may be essential to use the ppGalNAc-T10 enzyme, in addition to h-ppGalNAc-T2. Even though the 2-keto moiety in the 2-keto-Gal resembles the N-acetyl moiety in GalNAc, due to its conformational flexibility, the 2-keto-Gal sugar may not be as preferred a donor sugar substrate as is GalNAc by the h-ppGalNAc-T2 enzyme; therefore, the catalytic efficiency of h-ppGalNAc-T2 is expected to be slightly poorer for the 2-keto-Gal transfer than for GalNAc.

Preparation of Alexa488-Anti-Her2ScFv Conjugates and Their Binding to HER2-Receptor-Expressing Cells. To demonstrate a site-specific conjugation, the H1, H3, and H17 scFv proteins with 2-keto-Gal sugars were conjugated with a fluorescence probe, Alexa488, with an orthogonal chemical group, the aminoxy group. The Alexa488-conjugated H1, H3, and H17 scFv proteins can be detected on an SDS-PAGE by their fluorescence emission, even at nanogram amounts (Figure 4a). Interestingly, the H3 and H17 scFv proteins that carry more than one Alexa488 molecule are observed as sharp protein bands in the SDS-PAGE. This is in contrast to limited but random conjugated proteins, where the conjugated proteins are often observed as a smeared broad band in SDS-PAGE. For example, the streptavidin-Alexa488 conjugate protein from Invitrogen is observed as a broad band in SDS-PAGE (Figure 4b). Thus, observation of a sharp protein band on the gel indicates conjugation of the fluoroprobes to unique site(s) on the protein molecules. The observation that the fluorescence emission from H17 protein was not significantly enhanced, compared to the H1 scFv protein, may be due to self-quenching of conjugated Alexa488 molecules. It is known that multiple fluorescence probes conjugated to protein molecules show self-quenching. It is interesting to observe that even though the H3 and H17 protein-Alexa488 conjugates are heterogeneous, arising from their glycosylation with 2-keto-Gal, the protein bands in the SDP-PAGE gel remain sharp. Although the actual number of Alexa-488 molecules that are conjugated to the 2-Keto-galactosylated scFv molecules could not be determined by conventional MALDI-TOF analysis, in our previous studies it was shown that when, instead of Alexa488, biotin molecule was used for conjugation under similar reaction condition, all the 2-keto-Gal sugar molecules were completely biotinylated as determined by MALDI-TOF analysis (*14, 15*). Since we have used nearly 1000-fold excess of Alexa488 molecules in the conjugation reaction, all the 2-keto-Gal sugar molecules are expected to be conjugated with Alexa488 molecules.

Cell-binding assay by FACS methodology analysis shows that Alexa488-conjugated scFv fusion proteins H1, H3, and H17 bind specifically to cells that express HER2 receptors on the cell surface (Figure 5). We did not observe any binding of these modified scFv molecules above background levels when MDA-MB-468 cells (HER2 receptor-negative) were used (Figure 5b). In these experiments, FACS spectra using various amount of scFv fusion proteins ranging from 200 ng to 2.5 μg showed no significant difference, suggesting that even a nanogram quantity of the H1, H3, or H17 protein was sufficient for the detection of HER2 receptor. Although there is enhanced fluorescence emission (FL1-H) with H3 and H17, compared to H1, it is not linearly proportional to the number of additional fluorescence probes conjugated to these proteins (Figure 5a, insert table). This kind of observation for the multiple conjugations of protein probes to proteins is known due to the internal quenching. However, our technology is likely to yield similar conjugates with multiple numbers of MRI image contrast agents (on a single protein molecule), since there is no quenching effect in MRI. The present results suggest that the *in vitro* folded scFv is biologically active and the incorporation of the sugar and the Alexa488 moieties at the C-terminal end had no or little effect on their affinity for the HER2 receptor, thus demonstrating that

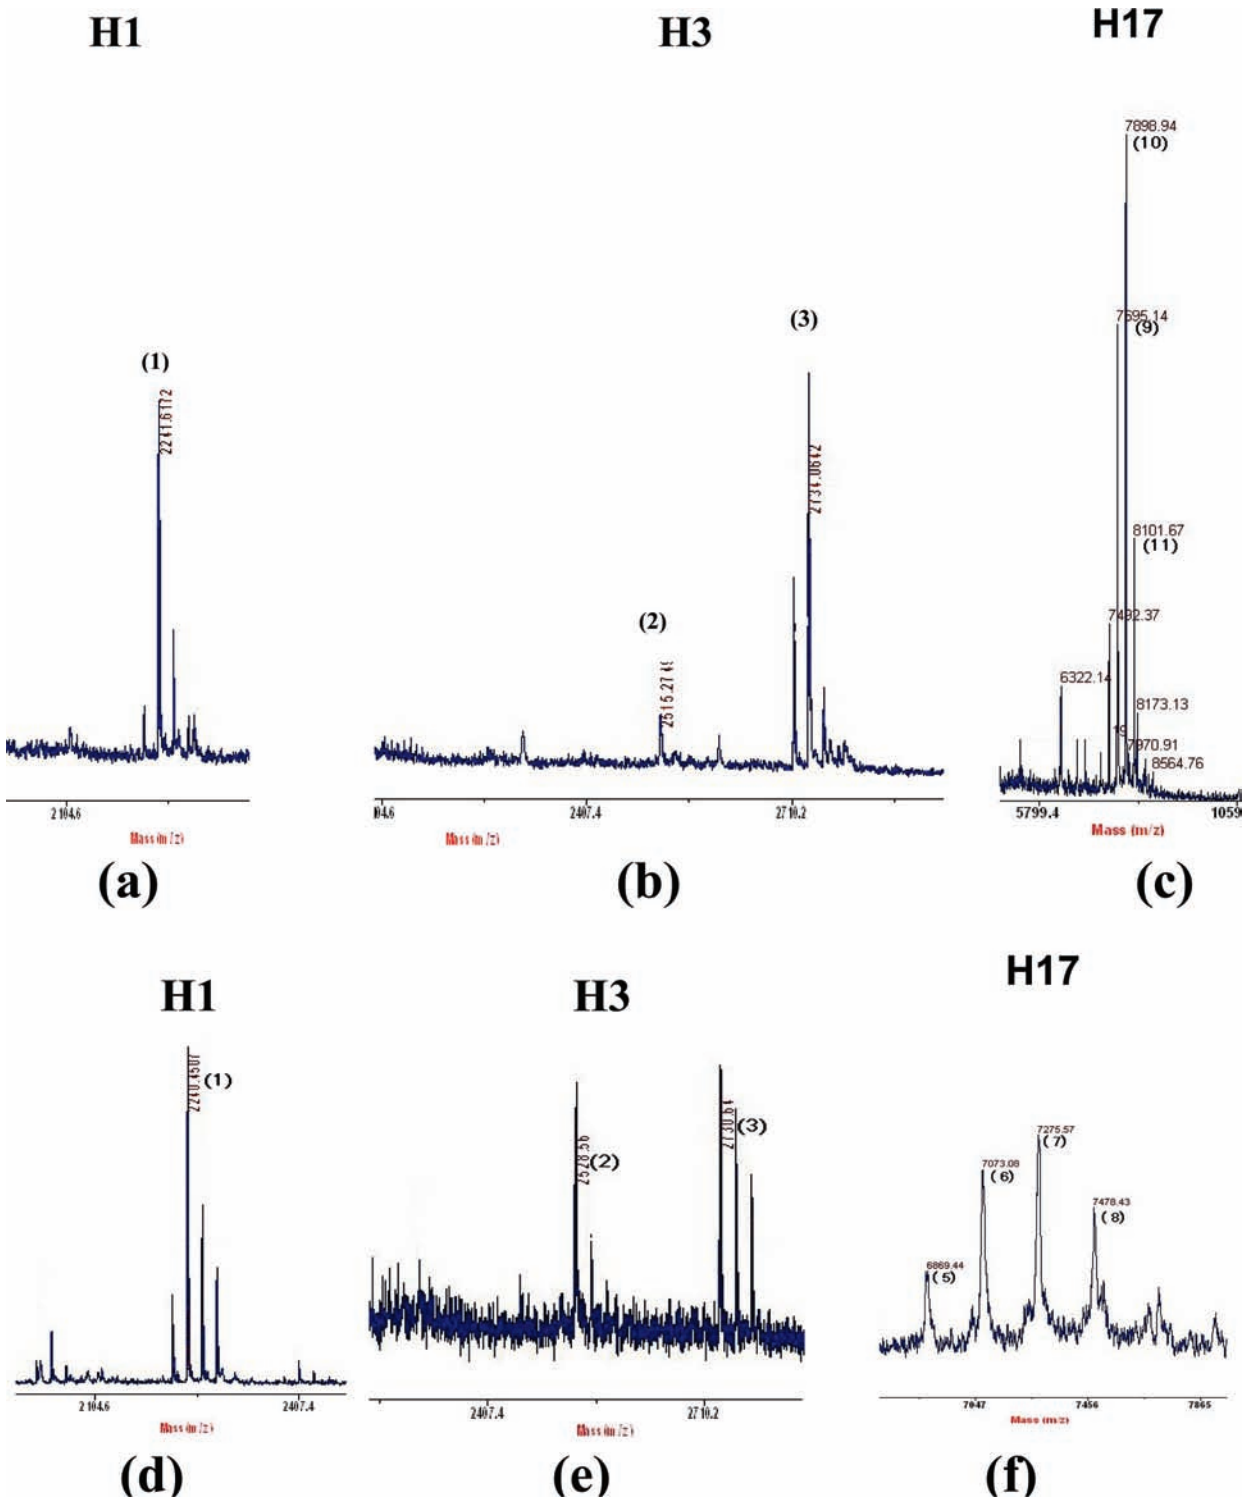

Figure 3. The mass spectrum (MALDI-TOF) of the Tev protease cleaved glycosylated polypeptides with GalNAc (a,b,c) and 2-keto-Gal (d,e,f) from H1, H3, and H17 anti HER2 scFv fusion proteins, respectively. The number of sugar molecules present in the peptide is shown in the parentheses next to the mass value of the corresponding peptide peak. The H1 protein is fully glycosylated with GalNAc sugar (a) while a small trace amount of unglycosylated peptide is observed when 2-keto-Gal was used (d). Although all three Thr residues in the fusion peptide from H3 have been mostly glycosylated with GalNAc, a small trace amount of mono- and diglycosylated forms are observed (b). However, under the same glycosylation condition, a mixture of fusion peptides with two and three 2-keto-Gal has been observed (e) for the H3 protein. Similarly, the H17 fusion protein is glycosylated to a maximum of 11 Thr residues with GalNAc sugar (c), compared to eight with 2-keto-Gal (f).

even a large fusion protein with many conjugated fluorescence probes does not affect the affinity of the scFv to its antigen.

CONCLUSION

Our current method offers a unique possibility not only for site-specific conjugation but also for multiple site conjugations of bioactive molecules at the C-terminal end of the scFv molecule through modified sugars. The proteolysis of the fusion peptide is an important factor for *in vivo* studies. The presence of glycosylation is known to hinder the proteolysis of peptides, and furthermore, the modified sugars are conjugated with bulky bioactive molecules; thus, their susceptibility to proteolysis is

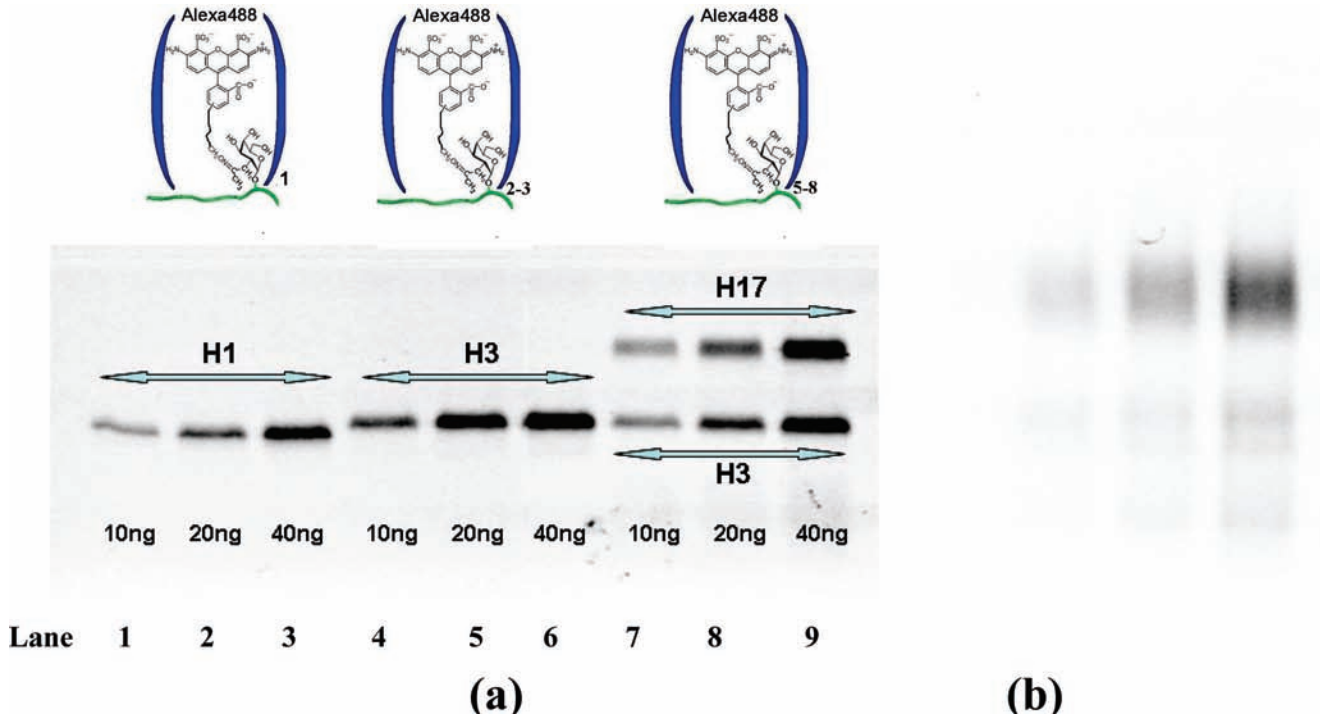

Figure 4. (a) Fluorescence emission of the Alexa488 conjugated H1, H3, and H17 anti HER2 scFv fusion proteins from the nonreduced SDS-PAGE. Lanes 1−3, 3−5, and 7−9 show each 10 ng, 20 ng, and 40 ng of H1, H3, and a mixture of H3 and H17 proteins, respectively. The H17 protein has 5 to 8 conjugated molecules of Alexa488. The fluorescence emission image of the SDS-PAGE gel was scanned using Hitachi FMBIO II fluorescence imaging system. Even 10 ng fusion proteins can be very well detected, and the protein bands are sharp. (b) Fluorescence emission from various amounts of streptavidin-Alexa488 conjugate on nonreduced SDS-PAGE. The protein conjugate from Invitrogen was prepared by a random but limited conjugation method.

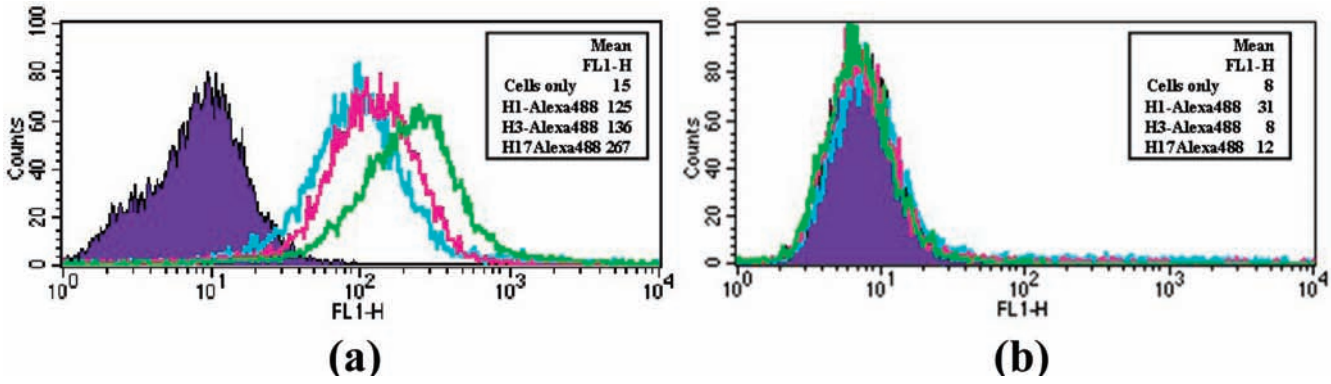

Figure 5. (a) FACS analysis on the binding of Alexa488 conjugated H1, H3, and H17 fusion proteins to SKBR3 cells. 200 ng of the each conjugated protein was used in the assay. (b) Binding of H1, H3, and H17 proteins did not occur with MDAMB-468 cells, since these cells do not express HER2 receptors. The insert table lists the mean FL1-H value for cells without and with bound antibody conjugates. Although the H17 conjugates have nearly seven more fluorescence probes, compared to H1, due to self-quenching there was no linear increase in the fluorescence emission.

expected to be much more limited compared to that of nonglycosylated fusion peptide. Similarly immunogenicity due to the fusion peptide and the modified sugars may be concern. However, it is possible that the fusion peptide may not be well exposed to the environment due to the presence of bulky conjugated bioactive molecules that may reduce the *in vivo* immunogenic effect. Such concerns are associated with most conjugated molecules that are being used or planned for use in *in vivo* studies.

Previously, scFv protein with large protein-like green fluorescence protein fused at its C-terminal end has been found to bind to the antigen without compromising its affinity (*21*). Also, a large mucin protein like, muc6, has been expressed as a soluble protein in *E. coli* and has been *in vitro* glycosylated with more than 50 sugars with GalNAc, using ppGalNAc-T1 (*22*). Therefore, using our present site-specific and multiple site conjugating method, scFv proteins with a C-terminal muc6 fusion protein can be glycosylated with modified sugars and conjugated with bioactive molecules. Such complexes are expected to carry not just a few but several tens of bioactive molecules conjugated to scFv molecules. The methodology described here can generate site-specific and multiple site-conjugated antibody-bioactive molecules that are in great need for the development of targeted MRI image contrast agents and a targeted drug delivery system.

Solid-phase peptide synthesis has been refined to a stage where efficient preparation of long and complex peptides is now achievable. However, the postsynthesis handling of poorly soluble peptides often remains a significant hindrance to their purification and further use. Several synthetic schemes have been developed for the preparation of such peptides containing modifications to aid their solubility. However, these require the use of complex chemistry or yield non-native sequences. We describe a simple approach based on the use of penta-lysine "tags" that are linked to the C-terminus of the peptide of interest via a base-labile linker. After ready purification of the now freely solubilized peptide, the "tag" is removed by simple, brief base treatment giving the native sequence in much higher overall yield. The applicability of the method was demonstrated by the novel preparation of insulin glargine via solid-phase synthesis of each of the two chains—including the notoriously poorly soluble A-chain—followed by their combination in solution via regioselective disulfide bond formation. At the conclusion of the chain combination, the solubilizing peptide tag was removed from the A-chain to provide synthetic human glargine in nearly 10% overall yield. This approach should facilitate the development of new insulin analogues as well as be widely applicable to the improved purification and acquisition of otherwise poorly soluble synthetic peptides.

INTRODUCTION

Solid-phase peptide synthesis (SPPS) has continued to mature and develop to the stage where it is now possible to almost routinely prepare peptides of up to 50 residues. Many of the long-standing problems associated with the methodology, including aspartimide formation, premature loss of peptide from the solid support, incomplete amino acid acylation, and N^{α}-deprotection, have been largely, if not wholly, overcome (*1*). However, the often-vexing issue of postsynthesis handling and purification of poorly soluble synthetic peptides remains generally unresolved. Methods for the solubilization of such peptides include the use of strong solvents such as the toxic hexafluoroisopropanol (HFIP), dimethylformamide (DMF), dimethylsulfoxide (DMSO), and trifluoroethanol (TFE), or strong acids including trifluoroacetic acid (TFA), or chaotropes including urea and guanidinium hydrochloride (*2*−*4*). However, such solutions do not allow convenient purification by, for example, RP-HPLC nor their chemical characterization including by mass spectrometry. The result is that such peptides are obtained in very poor overall yield, if at all.

Alternative approaches to improving the solubility of synthetic peptides have involved temporary chemical modification of the peptide itself. Sheppard and his colleagues showed that peptide backbone secondary amide protection afforded by the *N*-(2-hydroxy-4-methoxy)benzyl (Hmb) group can significantly inhibit intrachain association during solid-phase synthesis that can contribute to failed assembly (*5*). Furthermore, at the completion of synthesis, Hmb *O*-acetylation yields a TFA-stable acetyl-Hmb backbone-protected peptide which, following release from the solid support, possesses significantly enhanced solubility. After conventional purification, the acetyl-Hmb group can be deacetylated by treatment with dilute hydrazine to provide the target peptide. Penta-acetyl-Hmb amyloid-β 1−43 was shown to possess remarkable solubility of greater than 137 mg/mL in 0.1% TFA/acetonitrile compared to the virtually insoluble native peptide (*6*). Similar results were observed for penta-acetyl-Hmb amyloid-β 1−40 (*7*). However, use of Hmb backbone protection as a means for increased solubility has not been popular presumably due to the high cost of the special Fmoc−amino acid derivatives required for the introduction of the Hmb group together with the need for a convenient amino acid sequence for their optimum placement. More recently, the use of *O*-acyl isoacylpeptides has been demonstrated to be a highly effective tool for the synthesis of difficult sequence-containing peptides (*8*−*10*). These consist of a Boc-protected serine or threonine derivative in which the β-hydroxyl group is acylated by an Fmoc−amino acid. Importantly, the resulting depsipeptides obtained directly from the TFA cleavage reaction are often remarkably more soluble than the native target sequence. Following their purification and use, the desired native peptide can be obtained following rearrangement of the isoacyl peptide in neutral to slightly basic buffer. The disadvantages of this approach are the high costs of the isoacyl dipeptide derivatives for use in solid-phase synthesis, the need for convenient serine and/or threonine placements within the target peptide, and the

avoidance of neutral to basic buffers for the purification of the isoacylpeptide intermediate.

Polycationic peptides have long been known to enhance the solubility of peptides and proteins (*11*). Consequently, one of the first attempts to exploit this to address the problem of poor synthetic peptide solubility was undertaken by Englebretsen and his colleagues who used Boc-SPPS to attach a solubilizing poly-(Gly-Arg)-Gly peptide via a base-labile glycolamide linker to the C-terminus of the poorly soluble dodecaalanine (*12*). Following purification of the soluble conjugate, the solubilizing peptide was removed by treatment with mild aqueous base. A urethane linker has also been developed for temporary attachment of solubilizing peptides to the N-terminus of poorly solubilizing peptides via Boc-SPPS (*13*). Again, liberation of the target peptide was achieved following mild aqueous base treatment. Use of both these methods is restricted to Boc-SPPS due to the lability of the linkers to the base employed for N^{α}-deprotection in Fmoc-SPPS. However, this limitation could be avoided by use of an ester linkage based on 4-hydroxymethyl benzoic acid. This enabled tethering of $Gly(Arg\text{-}Gly\text{-}Gly)_3$ as a solubilizing tail peptide to the C-terminus of the target peptide and is stable to the conditions of Fmoc-SPPS. Release of the tail was achieved by brief treatment with aqueous sodium hydroxide (*14*). The favorable solubilizing propensity of polycationic peptides was also demonstrated by the recent work of Aimoto and his colleagues who employed penta-Arg to solubilize one of two segments of the membrane opioid receptor-like 1 for their successful native chemical ligation (*15*). A similar approach was also successfully adapted by Kent for the native chemical ligation of integral membrane proteins (*16*, *17*).

A recent detailed study of the solubilizing propensity of one, three, and five Lys or Arg residues on a low-solubility model protein, BPTI-22 (a BPTI variant containing 22 Ala residues), showed that pronounced solubilization was afforded by five Lys or Arg (more so with six Arg) residues and that the effect was greater if the polycationic peptides were at the C-terminus rather than the N-terminus of the target protein (*18*). Given that lysine derivatives are significantly cheaper and generally less difficult to polyacylate in SPPS compared to arginine derivatives, we sought to exploit this finding in a refinement of Englebretsen's 4-hydroxymethyl benzoic acid linkage procedure as a simpler yet effective means of preparing postsynthesis solubilized peptides via Fmoc-SPPS. This was achieved by utility of efficient solid-phase synthesis protocols together with a base-labile linker that allowed temporary tethering of a pentalysine cationic peptide to the C-terminus of an otherwise poorly soluble peptide. On completion of the purification of the tagged peptide, the linker was cleaved to liberate the native sequence. This was illustrated by the first solid-phase synthesis of human insulin glargine, which possesses a poorly soluble A-chain that has long been problematic for the preparation and study of this essential glucose regulatory hormone.

EXPERIMENTAL PROCEDURES

Materials. 9-Fluorenylmethoxycarbonyl (Fmoc) protected L-α-amino acids and 1-[bis(dimethylamino)methylene]-1*H*-benzotriazolium hexafluorophosphate 3-oxide (HBTU) were purchased from GL Biochem (Shanghai, China). (DMF), piperidine, and (TFA) were obtained from Auspep (Melbourne, Australia). Fmoc-Gly-PAC-PEG-PS, Fmoc-L-Arg(Pmc)-PAC-PEG-PS, and PAL-PEG-PS resins with substitution of ca. 0.20 mmol/g were purchased from Applied Biosystems Inc. (Melbourne, Australia). Methanol, diethyl ether, and dichloromethane were from Merck (Melbourne, Australia), 3,6-Dioxa-1,8-octanedithiol (DODT), triisopropylsilane (TIPS), diisopropylethylamine (DIPEA), and trifluoromethanesulfonic acid (TFMSA) were purchased from Sigma-Aldrich (Sydney, Australia), and 2,2′-dipyridyl disulfide (DPDS) from Fluka (Switzerland). Acetonitrile was obtained from BDH Laboratory Supplies, (Poole, UK). All other reagents were from Sigma-Aldrich (Sydney, Australia). Recombinant derived human glargine (Lantus) was obtained from Sanofi-Aventis (Sydney, Australia).

Methods. *Peptide Synthesis.* All non-solubilizing tagged peptides were solid-phase synthesized as C-terminal acids on PAC-PEG-PS resin. Peptides C-terminally linked to a solubilizing tag were assembled on PAL-PEG-PS such that the polycationic tag itself possessed a C-terminal amide. SPPS employed Fmoc chemistry on one of the following instruments: CEM Liberty microwave peptide synthesizer (Ai Scientific, Queensland, Australia), PerSeptive Biosystems Pioneer continuous-flow peptide synthesizer (Framingham, MA, USA), or Protein Technologies Tribute batchwise peptide synthesizer (Tucson, AZ, USA). The side chain protecting groups of trifunctional amino acids were TFA-labile, except for acetamidomethyl (Acm)-protected cysteines in insulin glargine positions A20 and B19, and *tert*-butyl (tBu)-protected cysteine in position A7. All peptides were synthesized on a 0.1 mmol scale using instrument default protocols with either a 4- or 5-fold molar excess of Fmoc-protected amino acids (0.4 or 0.5 mmol) that were activated by using 4- or 5-fold excess of HBTU in the presence of DIPEA (0.8 or 1.0 mmol). N^{α}-Fmoc protecting groups were removed by treating the resin-attached peptide with piperidine (20% v/v) in DMF. Using the microwave synthesizer, the coupling and deprotection were carried out at 75 °C using 25 W microwave power for 5 min and 60 W microwave power for 3 min, respectively. For the conventional continuous flow (Pioneer) or batch (Tribute) synthesizer, the coupling and deprotection were carried out for 30 and 10 min, respectively.

Preparation of Resin-Bound Base Labile Handle-Linked Solubilizing Tagged Peptide. Fmoc-PAL-PEG-PS (0.1 mmol) was N^{α}-deprotected and then carried through five cycles of acylation with Fmoc-Lys(Boc)-OH and N^{α}-deprotection as described above. The base-labile linker, 4-hydroxymethylbenzoic acid (5 equiv), was attached via a 1 h acylation using 5 equiv of HBTU and DIPEA. The C-terminal residue (in the case of human insulin glargine, Gly) was attached to the resin-bound linker via a double 1 h acylation with the Fmoc−amino acid symmetrical anhydride (5 equiv) in the presence of 0.1 equiv of catalyst, DMAP.

Peptide−Resin Cleavage. On completion of solid-phase synthesis, the peptide (including each of the A- and B-chains of human insulin glargine) was cleaved from the solid support by treatment with (TFA) containing (DODT)/anisole/(TIPS) (94%/1.5%/2.5%/2%, 20 mL) for 90 min. The cleaved product was precipitated in ice-cold diethyl ether and centrifuged at 3000 rpm for 3 min. The pellet was washed by resuspending it in ice-cold diethyl ether and centrifuging it again. This washing process was repeated at least three times.

General Procedure for the Cleavage of the Solubilizing Tag from Target Peptide. To the purified synthetic solubilizing tag-linked peptide (0.25 mmol) was added 1 mL of ice-cold 0.1 N NaOH. The whole was stirred for 2−5 min after which the pH was made acidic by the addition of 0.1% aq TFA. The solution was then applied directly onto an RP-HPLC column for purification as described below.

Synthesis of Human Insulin Glargine. Insulin Glargine A-Chain-Lys_5 Intramolecular Disulfide Bond Formation. The crude [Cys6,11 (S-thiol), Cys7 (tBu), Cys20 (Acm)] A-chain linked to Lys_5 via the base-labile linker (104.6 mg, 32.4 μmol) was dissolved in 100 mL of deionized H_2O. To this was added 10 mL of 4 mM (DPDS) in MeOH, and the stirred reaction progress was monitored by analytical RP-HPLC analysis, which confirmed that the reaction was completed in 20 min at RT. For the purification, the solution was loaded onto a preparative

RP-HPLC column in four lots via the instrument's C-line and purified and freeze−dried to give 27.2 mg of pure, Cys6-Cys11 intramolecularly disulfide-bonded [Cys7 (tBu), Cys20 (Acm)] A-chain C-terminally linked to Lys_5 (8.4 μmol, 25.9%). MALDI-TOF MS showed a single species with *m*/*z* 3227.88 [$(M+H)^+$] (theory: 3226.61).

Insulin Glargine A-Chain-Lys_5 Conversion of Cys7 (tBu) to Cys7 (Pyr). The purified monodisulfide [Cys7 (tBu), Cys20 (Acm)] A-chain (27.0 mg, 8.4 μmol) and 2-DPDS (11.2 mg, 50.8 μmol) were dissolved in 0.6 mL TFA and anisole (9:1 v/v). The solution was chilled on ice before 0.6 mL of (TFMSA)/TFA (1:4 v/v) was added. The reaction was allowed to continue for 1 h at 0 °C before the peptide was collected by diethyl ether precipitation followed by centrifugation, and purified on a preparative RP-HPLC column. The freeze−dried purified product weighed 15.3 mg (4.7 μmol, 55.7%) and was identified as [Cys7(Pyr), Cys20(Acm)] A-chain by MALDI-TOF MS (*m*/*z* 3282.98 [$(M+H)^+$], theory 3280.61).

Combination of Insulin Glargine A-Chain-Lys_5 with Insulin Glargine B-Chain. The [Cys7(Pyr), Cys20(Acm)] A-chain-Lys_5 peptide (10.9 mg, 3.3 μmol) was dissolved in 3 mL of 6 M GnHCl, 0.1 M Gly/NaOH buffer (pH 8.5). The [Cys7(S-thiol), Cys19(Acm)] B-chain (12.7 mg, 3.2 μmol) was dissolved in deionized water (3 mL) and added slowly to the A-chain solution. The reaction was monitored by analytical RP-HPLC analysis and was found to be complete after 30 min at RT as shown by the absence of the starting products and emergence of a new one. The reaction was stopped by the addition of neat TFA, and the product was purified by preparative RP-HPLC and freeze−dried to give 17.7 mg (2.5 μmol, 78.1% relative to B-chain) of [Cys20A(Acm)/Cys19B(Acm)]-A-(Lys_5)-B. MALDI-TOF MS (*m*/*z* 7001.45 [$(M+Na)^+$], calcd. 7002.61.61).

Insulin Glargine with A-Chain C-Terminal Lys_5. The A-(Lys_5)-B peptide [Cys20A(Acm)/Cys19B(Acm)] (13.2 mg, 1.89 μmol) was dissolved in 7 mL of solvent mixture (6.3 mL glacial acetic acid, 0.7 mL of 60 mM HCl). 8.4 mL of 20 mM iodine/acetic acid was then added to the solution. The reaction was monitored by analytical RP-HPLC. After 30 min, the reaction was stopped by precipitation of the peptide following direct addition of ice-cold diethyl ether (*19*). The solubilizing tag-linked insulin glargine was purified by preparative RP-HPLC and freeze−dried to give 2.3 mg (0.34 μmol, 17.9%) (Figure 5A). The peptide was identified by MALDI-TOF MS as a single species (*m*/*z* 6840.01 [$(M+H)^+$], calcd. 6837.96).

Glargine. A-(Lys_5)-B insulin glargine (1.7 mg, 0.25 μmol) was treated with 0.1 N NaOH as described elsewhere in the Methods section. After purification by preparative RP-HPLC and freeze−drying, 0.9 mg (0.15 μmol, 60.0%) of insulin glargine was obtained. The overall yield was 8.5% relative to the B-chain. The peptide was identified by MALDI-TOF MS as a single species (*m*/*z* 6063.92 [$(M+H)^+$], calcd. 6064.12), and the purity was further confirmed by analytical RP-HPLC (Figure 5B).

Peptide Characterization. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) was carried out on a Bruker Ultraflex II instrument (Bruker Daltonics, Bremen, Germany) and used to characterize the peptides at each intermediate step using sinapinic acid (α-cyano-4-hydroxycinnamic acid) or 2,5-dihydroxybenzoic acid (Bruker Daltonics, Germany) as matrix depending upon the molecular size of the peptide. The matrices were made up of 70% acetonitrile containing 0.1% TFA. The peptide content was determined using vapor-phase acid hydrolysis in 6 M HCl containing 2% phenol at 110 °C for 24 h. The individual amino acids were converted to stable, fluorescent derivatives using Waters AccQ.Tag kit (Waters, Sydney, Australia). The derivatized amino acids were separated using a Shim-Pak XR-ODS (3 × 75 mm, 2.2 μm) column on Shimadzu RP-HPLC system (Shimadzu, Victoria, Australia).

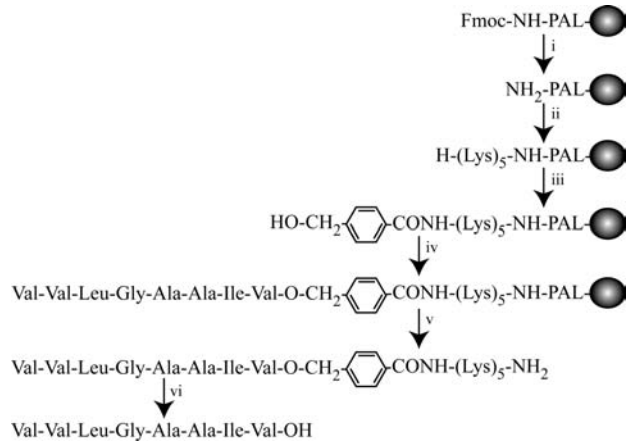

Figure 1. Scheme for the solid-phase synthesis of poorly soluble peptides via a C-terminal-linked penta-Lys "solubilizing tag". (i) 20% piperidine/DMF. (ii) Five successive Fmoc-Lys(Boc)-OH acylations and N^{α}-deprotections. (iii) Acylation with 4-hydroxymethylbenzoic acid. (iv) Double DMAP-mediated 1 h coupling of symmetrical anhydride of C-terminal residue of target sequence followed by solid-phase peptide synthesis. (v) Cleavage of solubilizing tagged peptide from solid support with 95% TFA. (vi) Release of solubilizing tag from target peptide by 2 min treatment with aqueous 0.1 N NaOH. Abbreviation: PAL, 5-(aminomethyl-3,5-dimethoxyphenoxy)valeryl.

Insulin Tolerance Test. Insulin tolerance tests were performed as previously described (*20*). Briefly, fed 8−10-week-old male C57BL/6J mice were anesthetized with sodium pentobarbitone (100 $mg.kg^{-1}$) and injected intraperitoneally with 1 unit of Lantus or synthetic insulin glargine per kg body weight. Blood samples were taken from the tail vein, and glucose concentration was measured using a glucometer (Precision Q.I.D., MediSense, MA, USA).

RESULTS AND DISCUSSION

The concept of use of suitably linked polycationic amino acid tags for temporary solubilization of synthetic peptides was originally developed and exploited by Englebretsen (*14*). His choice of solubilizing peptide tag, poly-(Gly-Arg)-Gly, which was temporarily attached to the C-terminus of the target peptide via a 4-hydroxymethylbenzoic acid linker, is more complex than required. The results of the studies of Kato and colleagues showed that pronounced solubilization could be afforded by attachment of just five consecutive lysine residues at the C-terminus of the peptide of interest (*18*). Thus, we sought to simplify and refine Englebretsen's protocol by the use of a penta-Lys tail and assessed its capacity to solubilize the octapeptide, NH_2-V-V-L-G-A-A-I-V-OH, as outlined in Figure 1. The latter peptide alone is virtually insoluble in water and other aqueous buffers. In contrast, the synthetic C-terminally penta-Lys-linked peptide was freely soluble (results not shown). Removal of the solubilizing tag by 2 min treatment with 0.1 N NaOH resulted in an insoluble mixture (results not shown). Following this proof of concept, the method was then applied to the chemical synthesis of human insulin glargine.

The chemical synthesis of insulin was first achieved by the Shanghai Insulin Research group in 1965 using solution synthesis methods for the assembly of each of the two chains followed by their combination in solution (*21*). This monumental achievement took ten years to complete and required enormous manpower. In contrast, the advent of Merrifield's solid-phase technique enabled the synthesis of the bovine hormone to be completed in a matter of weeks (*22*). However, it was evident from the very early stages of studies on insulin chains that the

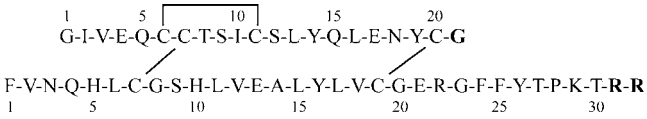

Figure 2. Primary structure of human insulin glargine. The key differences between insulin and glargine are highlighted in bold and are the replacement of A-chain C-terminal Asn with Gly and the addition of two Arg residues to the C-terminus of the B-chain.

A-chain possessed physicochemical properties that hampered both its chemical synthesis and subsequent handling (*23*−*25*). It was thus necessary to convert the S-reduced form of the A-chain into its S-sulfonate in order to improve its solubility and subsequent handling and purification. Despite much effort, no useful alternative to S-sulfonated A-chain and its analogues has been developed, which, in turn, has been a major hindrance to the rational and facile chemical preparation of insulin and its analogues for detailed structure−function relationship analysis and the development of newer generation therapeutics for the treatment of diabetes. Particularly restrictive has been the inability of the conventional chain combination approach to yield insulin analogues with truncated or secondary structure-modified chains which hinder the combination and folding pathway. Nevertheless, there have been some impressive analogue achievements via this synthetic methodology, which have, in turn, significantly contributed to insulin structure−function relationship studies (*26*−*29*). However, the continuing difficulties associated with the need for S-sulfonated chains. together with the generally very low yields of chain-combined products (rarely better than *ca*. 1% overall), have led to the authors of a recent review to state that "a high-yield synthetic route to preparation of insulin analogues remains a high priority yet is seemingly overlooked by the peptide community" (*30*).

Numerous analogues of insulin have been prepared over the past three decades for use in diabetic therapy (*31*). One of the most important of these is human insulin glargine (*32*), which was developed by Sanofi-Aventis and launched in the clinic in 2001 under the trade name of Lantus. It is one of two long-acting (basal) insulins (the other is Levemir; Novo-Nordisk) and is characterized by a substitution of Gly in place of Asn at the C-terminus of the A-chain and an addition of two Arg residues to the C-terminus of the B-chain (Figure 2). These modifications cause a change in the isoelectric point (from pH 5.4 to 6.7), which makes it less soluble at physiological pH than insulin itself. Insulin glargine precipitates in the subcutaneous tissue following injection with the result that its uptake is delayed leading to an extension of duration of activity. In isoglycaemic clamp studies and following subcutaneous injection, insulin glargine plateaus at a concentration 2−3 times lower than human insulin within 6−8 h, remains essentially unchanged for 24 h and is unaffected by the site of injection (*33*). In contrast, insulin peaks within 3−6 h and returns to baseline within 16 h (*34*). Insulin glargine remains one of the most important therapies for type I diabetes today. It is produced by recombinant DNA methods via a single-chain analogue which, upon enzymatic treatment, yields the native two-chain structure. Given that a crucial goal of continued insulin development is the preparation of new generation analogues with improved pharmacokinetic and physiological properties and that insulin glargine is a valuable lead peptide for such study, there is an urgent need for its ready chemical synthesis. In the past decade, our laboratory has developed efficient solid-phase synthesis protocols which, combined with regioselective disulfide bond formation (*35*), have allowed the acquisition of several insulin-like peptides including mouse relaxin and insulin-like peptide 3 in very good overall yields (*36*−*39*). Importantly, such methods of forced and sequential disulfide bond formation have allowed

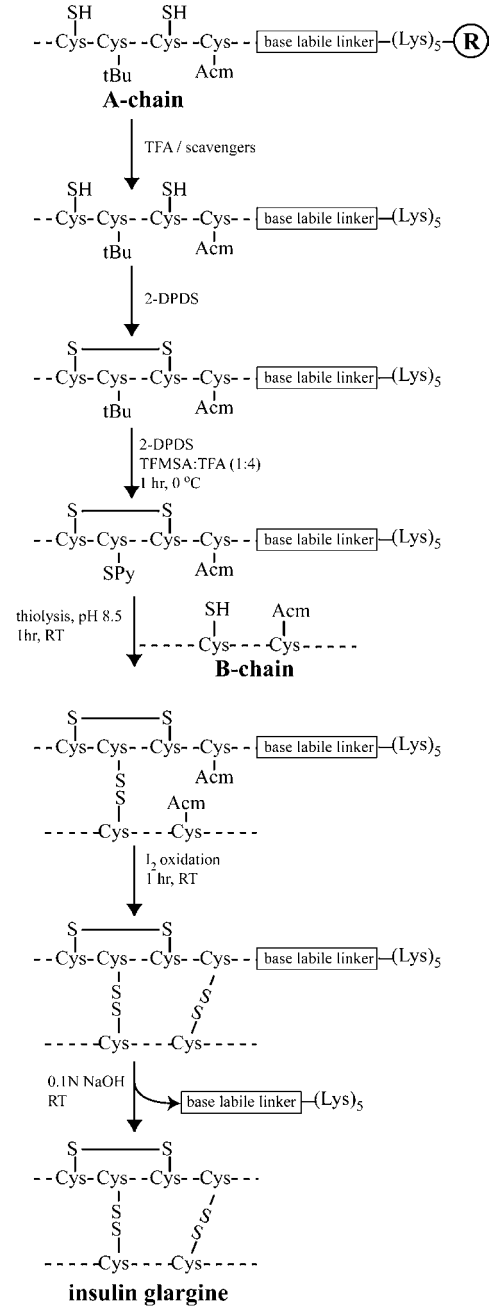

Figure 3. Scheme for the solid-phase synthesis of human glargine via regioselective disulfide bond formation and solubilizing peptide tagged A-chain.

numerous analogues of these peptides to be successfully prepared, which would otherwise not be possible via the conventional chain combination approach. However, application of these methods to the preparation of either human insulin or human insulin glargine did not afford usefully improved yields due to the very poor solubility of the intermediate A-chain peptide, which resulted in little combination with the B-chain (unpublished observations). Consequently, we undertook to assemble insulin glargine via a combination of use of a temporary solubilizing tag on the A-chain and our established regioselective disulfide bond formation protocol (Figure 3).

Solid-phase synthesis of both the nontagged and tagged A-chains as well as B-chain of insulin glargine was achieved without difficulty regardless of the instrumentation or default synthetic protocol employed. The crude selectively S-protected peptides were each of good purity as determined by analytical RP-HPLC and MALDI-TOF MS. Of interest was the curious

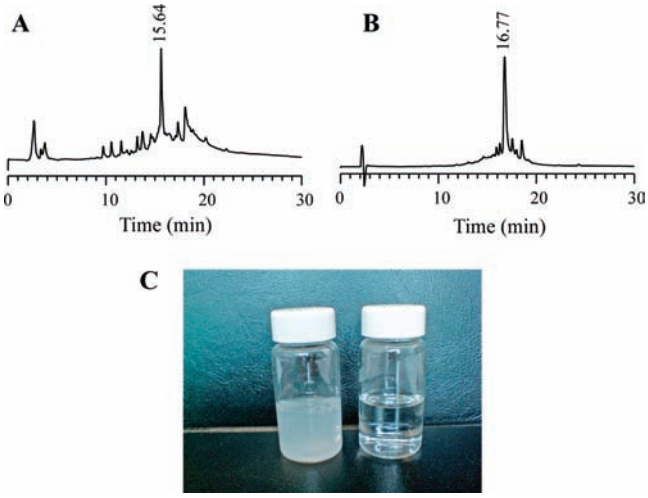

Figure 4. RP-HPLC of crude synthetic human insulin glargine A-chain without (A) and with (B) a C-terminal penta-Lys solubilizing tail. Conditions: Vydac C4 column (4.6 × 250 mm, pore size 300 Å, particle size 5 μ); Buffer A, 0.1% aq. TFA; Buffer B, 0.1% TFA in CH3CN. Gradient = 10−90% B over 30 min. (C) Comparison of relative solubility of the crude synthetic human insulin glargine A-chain without (left) and with (right) a C-terminal penta-Lys solubilizing tail. Peptides added to deionized and distilled water at a concentration of 1.0 mg/mL.

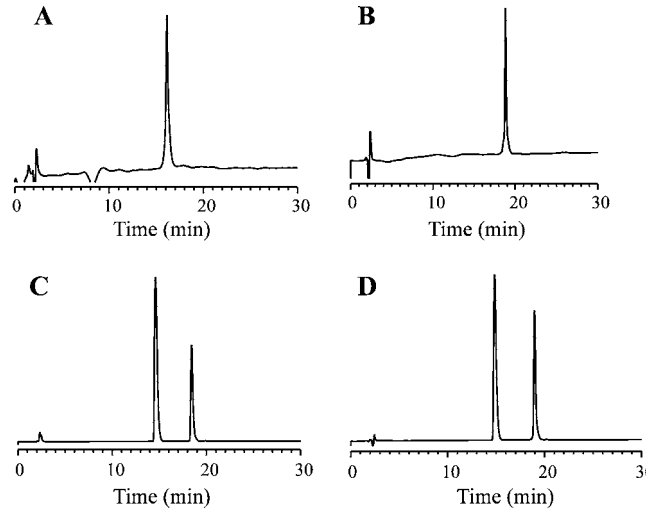

Figure 5. RP-HPLC of (A) synthetic human insulin glargine with solubilizing tail attached to the C-terminus of the A-chain. (B) Synthetic human glargine after removal of solubilizing tail. (C) Commercial Lantus (peak at 14.8 min corresponds to *m*-cresol preservative present in the solution). (D) Coinjection of Lantus and synthetic human insulin glargine. Conditions: Vydac C18 column (4.6 × 250 mm, pore size 300 Å, particle size 5 μ); Buffer A, 0.1% aq. TFA; Buffer B, 0.1% TFA in CH_3CN. Gradient = 20−50% B over 30 min.

observation that the far more hydrophilic tagged A-chain analogue eluted a little later on the RP-HPLC column compared to the nontagged peptide (Figure 4A,B). However, the latter peptide was very poorly soluble, making both its characterization and purification very difficult. Yields of the intramolecular disulfide bonded intermediate were so poor as to deter further effort and subsequent combination with the corresponding B-chain. In contrast, the same peptide containing a C-terminal linked penta-Lys was completely soluble in all aqueous buffers including water alone (Figure 4C) allowing its ready characterization and purification in good yield by RP-HPLC.

The intramolecular disulfide bond within the A-chain was formed by DPDS-mediated oxidation of the free thiol groups of the Cys6 and Cys11 residues (*40*). The Cys7 side chain protecting group (tBu) was then converted to an S-pyridinyl group by reaction of the peptide with DPDS in the presence of TFMSA after which the resulting intermediate was combined with the insulin glargine B-chain. The free thiol group of Cys7 within the B-chain led to thiolysis of the S-pyridinyl group of the A-chain and subsequent formation of the first intermolecular disulfide bond. Following purification by RP-HPLC, the resulting double-disulfide two-chain peptide containing two S-Acm groups on CysA20 and CysB19 was then treated with iodine in hydrochloric acid and acetic acid to generate the second, and final, intermolecular disulfide bond (Figure 5A). The penta-Lys tag was removed from the C-terminal of the insulin glargine by brief base treatment. Following a final RP-HPLC purification step, overall yield of insulin glargine was 8.5% relative to crude starting B-chain, which is satisfactory given the multiple steps involved in its preparation. This compares favorably with the reported yields of other synthetic insulin-like peptides and their analogues with a range of ca. 5−15% (*36*−*39*). Yields of chemically prepared insulin via random chain combination are rarely better than 1%. A solid-phase synthesis of human insulin by an alternative regioselective disulfide bond formation approach but without the aid of a solubilizing tail and involving one fewer step from the initial combination of the two chains resulted in a yield of ca. 1% (*41*).

The synthetic insulin glargine was shown to be highly purified as assessed by analytical RP-HPLC (Figure 5B) and

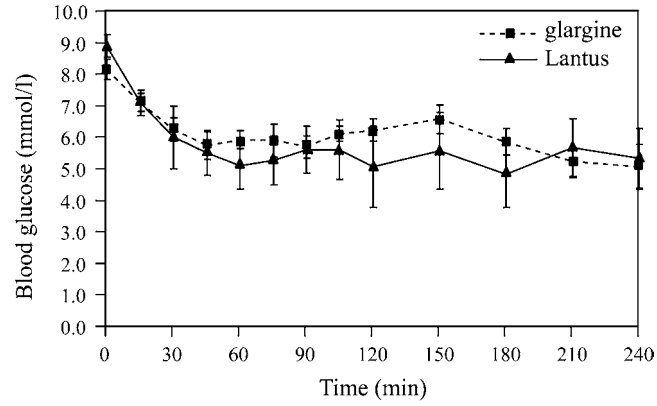

Figure 6. Biological activity of synthetic human insulin glargine in the insulin tolerance test. Synthetic or commercially obtained (Lantus) insulin glargine was injected in 8−10-week-old male C57BL/6 mice at 1 unit/kg body weght and blood glucose levels determined over 240 min. Results are presented as mean ± SEM (n = 4).

MALDI-TOF MS (found MH+ 6063.92; calc. MH+ 6064.12). Coinjection of the peptide with commercially obtained Lantus (which contains *m*-cresol as preservative; see Figure 5C) on RP-HPLC resulted in the two peptides coeluting (Figure 5D). The biological activity of both synthetic and commercial insulin glargine was also assessed using the insulin tolerance test. The synthetic insulin glargine was as effective in reducing glycemia over a 4 h period in mice as the commercially available insulin glargine (Lantus), suggesting equivalent bioactivity (Figure 6).

In conclusion, a simple modification of SPPS methodology has been exploited to enable the preparation of poorly soluble peptides in a form that enables their improved handling and purification. It employs a polylysine solubilizing "tag" temporarily linked to the insoluble peptide via a base-labile handle. Our experience thus far suggests that five Lys residues are adequate for significant solubilization enhancement, although the method readily allows additional Lys residues to be used if necessary. One potential limitation of this approach is that the

base-mediated cleavage step may cause aspartimide formation in sensitive sequences, but this will remain to be investigated. Application of this approach resulted in the acquisition of insulin glargine in nearly 10% overall yield as a consequence of much improved handling of the intractable A-chain. Access to analogues of insulin glargine with potentially improved pharmacological properties should thus be greatly and readily facilitated. Preloaded resins bearing poly-Lys and functionalized linkers may afford an attractive and effective addition to the current armory of methods for handling poorly solubilized synthetic peptides. More broadly, we believe that this simple bioconjugate approach should be more widely employed for the preparation of poorly soluble peptides.

TECHNICAL NOTES

Silver-Catalyzed azaGly Ligation. Application to the Synthesis of Azapeptides and of Lipid−Peptide Conjugates

Nathalie Ollivier, Soizic Besret, Annick Blanpain, and Oleg Melnyk*

UMR 8161 CNRS/Université de Lille 1 et 2, Institut Pasteur de Lille, IFR 142 Institut de Biologie de Lille, 1 rue du Pr Calmette, 59021 Lille Cedex, France. Received January 16, 2009; Revised Manuscript Received May 27, 2009

Glycine is a amino acid frequently found in peptides. Substitution of a glycine residue by an azaglycine allows the modulation of peptide conformation, bioactivity, or stability. Azapeptides are usually prepared using solid-phase synthetic procedures. We show here that azaGly peptides can be assembled chemoselectively and without racemization using unprotected peptide fragments by silver-catalyzed reaction of C-terminal peptide hydrazides with N-terminal phenylthiocarbonyl peptides. The reaction was performed in a *t*BuOH/water mixture and the control of apparent pH permitted the clean formation of the azaGly bond in the presence of lysine residues. We show also that this novel ligation method, called azaGly ligation, can be used for the assembly of lipopeptides. For this, lipid hydrazides were reacted with a phenylthiocarbonyl peptide in the presence of silver ions. This ligation method allows incorporation of acid-sensitive lipid moieties that are incompatible with standard solid-phase peptide synthesis procedures, and more generally should be of interest for the modification of peptides by sensitive acyl moieties.

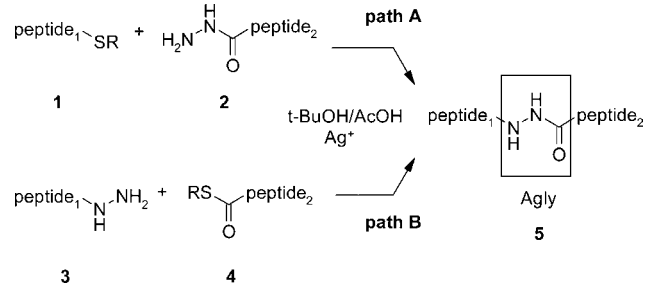
INTRODUCTION

Azapeptides are peptide analogues in which the α-CH moiety of one or more amino acid residues in the peptide chain is replaced by a nitrogen atom (*1*, *2*). This modification has been shown to induce a β-turn geometry due to electronic repulsion between the adjacent nitrogen lone pairs and/or to the formation of intramolecular hydrogen bonds (*3*−*6*). The better stability of azapeptides in biological medium relative to native peptides may be due to the induction of a bent shape by aza-amino acid residue and to the increased chemical stability of urea-type bonds compared to amide bonds. Aza-amino acids can thus be used to improve the stability and bioavailability of peptide drugs (*7*) and also for the design of prodrugs (*8*). Aza-amino acid modification has been exploited also for the design of protease inhibitors (*9*). The inhibition of Ser or Cys proteases is mainly due to the slower hydrolysis of the acyl-enzyme complex by water relative to the native peptide (*9*−*12*).

Gly is a common amino acid in peptides and proteins. Glycine is the most flexible among the 20 coded amino acids due to the absence of a side chain on the α-carbon. Several reports have highlighted the interest of replacing Gly by azaGly (Agly) to improve the stability and/or potency of bioactive peptides. Recently, peptide Z-Arg-Leu-Arg-Agly-Ile-Val-OMe has been described as the strongest ($K(i)$ = 480 pM) and the most selective inhibitor of cathepsin B to date (*11*).

The synthesis of Agly peptides is usually performed using solid-phase methods. One strategy relies on the use of N-protected hydrazine and a peptidyl resin modified on the N-terminus by an isocyanate or active carbamate (*13*). Lubell et al. have recently improved the solid-phase synthesis of azapeptides by coupling N-Boc-aza-dipeptides (*14*) or phosgene-activated N′-alkyl fluoren-9-ylmethyl carbazates (*15*) to the growing peptide chain. More recently, the same group described the preparation of Agly peptides on the solid phase using diphenyl hydrazone protection (*16*).

Scheme 1. Strategies Used for the Chemoselective Assembly of Agly-Peptides



We show in the first part of this article that Agly peptides can be synthesized using a convergent approach by ligating chemoselectively unprotected peptide fragments in solution (Scheme 1). Two strategies have been explored: the reaction between hydrazinocarbonyl peptides and C-terminal peptide thioesters (Scheme 1, path A) or the reaction between C-terminal peptide hydrazides and phenylthiocarbonyl peptides (Scheme 1, path B). Both reactions required the presence of silver ions to activate the alkyl or arylthiocarbonyl groups. In the second part, the utility of azaGly ligation for the synthesis of lipopeptides was examined. For this, a phenylthiocarbonyl peptide was reacted with a series of lipid hydrazides derived from cholesterol or C18 unsaturated fatty acids in the presence of silver ions. Lipopeptides featuring an azaGly residue between the lipid moiety and the peptide chain were isolated successfully.

EXPERIMENTAL PROCEDURES

Synthesis of Thioester Peptides 1a and 1b. The experimental procedure for the synthesis of the thioesters was described in detail elsewhere (*17*). MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for **1a** $C_{52}H_{88}N_{14}O_{15}S_2$ $[M+H]^+$ 1213.6, found 1213.6; calcd for **1b** $C_{53}H_{90}N_{14}O_{15}S_2$ $[M+H]^+$ 1227.6, found 1227.2.

Synthesis of Hydrazinocarbonyl Peptides 2b,c, Typical Experimental Procedure for 2b. Peptide elongation: Peptide elongation was performed on NovaSyn TGR resin (0.38 g, 0.095 mmol, 0.25 mmol/g) using standard Fmoc/*tert*-butyl chemistry on a Pioneer synthesizer (Applied Biosystems) using TBTU/HOBt/DIEA activation in DMF. A capping step was performed after each coupling with Ac_2O/DIEA. At the end of the synthesis, the Fmoc protecting group of the last amino acid was removed using 20% piperidine in DMF. The resin was washed with DMF (4 × 2 min).

Preparation of reagent 7 and coupling to the peptidyl resin: *tert*-Butyl carbazate (125.5 mg, 0.95 mmol) and carbonyldiimidazole (154 mg, 0.95 mmol) were dissolved in dry DMF (4.7 mL) under argon atmosphere. The reaction was complete after 1 h at rt as shown by TLC analysis. This solution was added to the resin and the suspension was agitated at rt for 1 h 30 min. The resin was then washed with DMF (3 × 2 min), CH_2Cl_2 (5 × 2 min), and Et_2O (2 × 2 min) and dried in vacuo.

Deprotection and cleavage: The resin was suspended in TFA/TIS/anisole: 95/2.5/2.5 by vol. (9.5 mL) over a period of 1 h at rt. The peptide was precipitated in Et_2O/pentane 1/1 by vol (95 mL), solubilized in triethylamine acetate buffer (TEAA) (200 mM, pH 6.5, 4 mL), and lyophilized to give 139.9 mg of crude hydrazinocarbonyl peptide **2b**. The crude product was purified by RP-HPLC (C18 hyperprep column, rt, detection at 230 nm, eluent A 10 mM triethylamine acetic acid aqueous buffer (TEAA, pH 6.5), eluent B *i*-PrOH/water 2/3 by vol containing 10 mM TEAA, 0−15% B in 15 min then 15−100% B in 283 min, flow rate 3 mL/min) to give 63.3 mg (54% yield) of peptide **2b**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{47}H_{80}N_{16}O_{13}$ $[M+H]^+$ 1077.6, found 1077.1.

Similarly, peptide **2c** was prepared starting from NovaSyn TGR resin (0.36 g, 0.09 mmol, 0.25 mmol/g). Reaction with **7** was performed overnight to give 69.7 mg (66% yield) of peptide **2c** after RP-HPLC purification (see above). MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{45}H_{77}N_{15}O_{12}$ $[M+H]^+$ 1020.6, found 1020.3.

Synthesis of Hydrazide Peptides 3b,c, Typical Experimental Procedure for 3b. *Coupling of Fmoc-Gly-OH.* Fmoc-Gly-OH (594.6 mg) was solubilized under argon in dry CH_2Cl_2 (7 mL) and anhydrous DMF (700 μL). Diisopropylcarbodiimide (156.6 μL) was added in one portion. The reaction mixture was stirred on ice for 20 min. CH_2Cl_2 was then evaporated. The residue was dissolved in DMF (3 mL) and added on Novasyn TG HMBA resin (869.6 mg, 0.2 mmol, 0.23 mmol/g) swelled in DMF. 4-*N*,*N*-Dimethylaminopyridine (2.44 mg) dissolved in DMF (500 μL) was added to the suspension which was agitated 1 h at rt. The resin was washed with DMF (4 × 2 min) and CH_2Cl_2 (4 × 2 min).

Peptide Elongation. Peptide elongation was performed using standard Fmoc/*tert*-butyl chemistry on a Pioneer synthesizer (Applied Biosystems) using TBTU/HOBt/DIEA activation in DMF. A capping step was performed after each coupling with Ac_2O/DIEA. At the end of the synthesis, the Fmoc protecting group of the last amino acid was removed using 20% piperidine in DMF. The resin was acetylated, washed with CH_2Cl_2 (3 × 2 min) and Et_2O (3 × 2 min), and dried in vacuo.

Deprotection. The dry resin was suspended during 1 h in TFA/H_2O/EDT: 95/2.5/2.5 by vol (20 mL) at rt. The resin was filtered and washed with neat TFA, CH_2Cl_2 (5 × 2 min), DIEA 10% in CH_2Cl_2 (5 × 2 min), and DMF (5 × 2 min).

Hydrazinolysis. The resin was suspended in hydrazine hydrate 5% in DMF (20 mL). After 1 h, the resin was filtered and washed with DMF (2 × 2 min). The combined filtrates were concentrated in vacuo. The peptide was precipitated in Et_2O/heptane 1/1 by vol and purified by RP-HPLC (C3 zorbax column, rt, detection at 230 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, isocratic 0% B, flow rate 6 mL/min) to give 94 mg (31.4% yield) of hydrazide peptide **3b**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{57}H_{89}N_{17}O_{16}$ $[M+H]^+$ 1268.7, found 1268.5.

3c was obtained similarly: 8.5 mg (6% yield) of pure hydrazide peptide **3c**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{58}H_{91}N_{17}O_{16}$ $[M+H]^+$ 1282.7, found 1283.1.

Synthesis of Phenylthiocarbonyl Peptide 4a. *Peptide Elongation.* Peptide elongation was performed on NovaSyn TGR resin (1.304 g, 0.23 mmol/g) using standard Fmoc/*tert*-butyl chemistry on a Pioneer synthesizer (Applied Biosystems) using TBTU/HOBt/DIEA activation in DMF. A capping step was performed after each coupling with Ac_2O/DIEA. At the end of the synthesis, the Fmoc protecting group of the last amino acid was removed using 20% piperidine in DMF. The resin was washed with DMF (3 × 2 min) and anhydrous THF (8 × 2 min).

Phenylthiocarbonyl Functionalization. The resin was suspended in anhydrous THF (12 mL) under argon. Anhydrous Et_3N (154 μL) and phenylthiochloroformate (173 μL) were added to the resin, which was agitated at rt during 1 h 30 min. The resin was washed with anhydrous THF (3 × 2 min), CH_2Cl_2 (2 × 2 min), and Et_2O (2 × 2 min) and dried in vacuo.

Deprotection and cleavage: The dry resin was suspended for 1 h in TFA/H_2O/thioanisole 96.5/2.5/1 by vol (30 mL) at rt. The resin was filtered, and the filtrate was precipitated in Et_2O/pentane 1/1 by vol (300 mL). The crude peptide was purified by RP-HPLC (C18 hyperprep column, rt, detection at 230 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, 0−35% B in 30 min, flow rate 3 mL/min) to give 192.6 mg (55% yield) of peptide **4a**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{53}H_{82}N_{14}O_{13}S_1$ $[M+H]^+$ 1155.6, found 1155.6.

Synthesis of azaGly Peptides. Solvent A is *tert*-BuOH/water 4/1 by vol containing acetic acid (40 mM final concentration). Solvent B is *tert*-BuOH/100 mM pH = 3.9 acetate buffer 4/1 by vol.

Synthesis of Azaglycine Peptide 5a. Dowex 1 × 4 Cl^- resin (12.81 g, Fluka, 100−200 Mesh, 3.5 mequiv/g) was washed with water (150 mL), MeOH (50 mL), 2.24 M sodium acetate (3 × 200 mL, 3 × 15 min), and finally with water (10 × 100 mL) until the pH of the filtrate was 5−6.

Semicarbazide hydrochloride (51.7 mg) dissolved in water (50 mL) was added to the resin. After 1 h, the resin was filtered and washed with water. The filtrates were combined and lyophilized to give 50 mg of semicarbazide **2a** as the hydrochloride salt.

Semicarbazide **2a** (4.4 mg) was dissolved in solvent B (774 μL) and added to thioester peptide **1a** (22 mg). $AgNO_3$ (5.3 mg) was dissolved in solvent B (400 μL) and added to the above reaction mixture. The reaction was stirred 26 h at rt. The mixture was diluted with water (7 mL) and purified by RP-HPLC (C18 Nucleosil column, rt, detection at 230 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, 0−20% B in 20 min, then 20−70% B in 151 min, flow rate 3 mL/min) to give 9 mg (46% yield) of pure peptide **5a**. MALDI-TOF (α-cyano-4-hydroxy-

cinnaminic acid, monoisotopic): calcd for $C_{47}H_{79}N_{15}O_{13}$ $[M+H]^+$ 1062.6, found 1062.7. ^1H NMR (H_2O/D_2O, 300 MHz): selected NMR data $\delta = 8.65$ (d, 1H, $J = 7.5$ Hz, αNH His[7]), $\delta = 8.47$ (t, 1H, $J = 5.7$ Hz, αNH Gly[8]), $\delta = 8.39$ (d, 1H, $J = 5.7$ Hz, αNH Ala[9]), $\delta = 8.31-8.23$ (m, 4H, αNH Lys[3], Leu[2], Glu[4], Ile[1]), $\delta = 8.12$ (d, 1H, $J = 6.9$ Hz, αNH Val[6]).

Synthesis of Azaglycine Peptides 5b,c, Typical Experimental Procedure for 5b. Camphorsulfonic acid (1.24 mg) was dissolved in solvent A (52 μL). This solution was added to hydrazinocarbonyl peptide **2b** (6.7 mg). This solution was then mixed with thioester peptide **1b** (5.2 mg) dissolved in solvent A (52 μL). $AgNO_3$ dissolved in solvent A (253.3 μL, 4.8 mg/mL) was then added to the reaction mixture, which was stirred 25 h at 18 °C. NaCl (10 mM in water, 714 μL) was added to quench silver ions. The reaction mixture was filtered and purified by RP-HPLC (C18 Nucleosil column, rt, detection at 215 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, 0−15% B in 15 min, then 15−100% B in 283 min, flow rate 3 mL/min) to give 2.5 mg (28% yield) of pure Agly peptide **5b**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{93}H_{154}N_{28}O_{25}$ $[M+H]^+$ 2064.2, found 2063.9.

5c was obtained similarly: 2.7 mg (34% yield) of pure Agly peptide **5c**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{91}H_{151}N_{27}O_{24}$ $[M+H]^+$ 2007.1, found 2006.9.

Synthesis of Agly Peptide 5d. Acetic hydrazide **3a** (3.25 mg) was dissolved in solvent A (200 μL) and added to phenylthiocarbonyl peptide **4a** (23.3 mg). $AgNO_3$ (5.74 mg) was dissolved in solvent A (200 μL) and added to the reaction mixture. The reaction was stirred 23 h at rt. NaCl (10 mM, 3.4 mL) was added to quench silver ions. The reaction mixture was filtered and purified by RP-HPLC (C18 Nucleosil column, rt, detection at 215 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, 0−10% B in 10 min, then 10−30% B in 30 min, flow rate 6 mL/min) to give 9.7 mg (43% yield) of peptide **5d**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{49}H_{82}N_{16}O_{14}$ $[M+H]^+$ 1119.6, found 1119.3.

Synthesis of Agly Peptides 5e,f, Typical Experimental Procedure for 5e. Phenylthiocarbonyl peptide **4a** (10.20 mg) and hydrazide peptide **3b** (21.93 mg) were dissolved in solvent A (200 μL for each peptide) and mixed. $AgNO_3$ (2.54 mg) was dissolved in solvent A (323 μL) and was added to the reaction mixture. The reaction was stirred 27 h at 18 °C. NaCl (10 mM, 1.45 mL) was added to quench silver ions. The reaction mixture was filtered and purified by RP-HPLC (C18 Nucleosil column, rt, detection at 215 nm, buffer A 100% water containing 0.05% TFA, buffer B CH_3CN/water 4/1 by vol containing 0.05% TFA, 0−15% B in 15 min, then 15−35% B in 100 min, flow rate 3 mL/min) to give 9.6 mg (48% yield) of azaglycine peptide **5e**. MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{104}H_{165}N_{31}O_{29}$ $[M+H]^+$ 2313.2, found 2313.1.

5f was obtained similarly: 3 mg (41% yield) of pure phenyl azaglycine peptide **5f**. MALDI-TOF (2,5-dihydroxy-benzoic acid, monoisotopic): calcd for $C_{105}H_{167}N_{31}O_{29}$ $[M+H]^+$ 2327.3, found 2327.3.

Synthesis of Lipopeptides. Solvent C is *tert*-BuOH/water/CH_2Cl_2 80/15/5 by vol acetic acid (40 mM final concentration).

Lipopeptide 9a. Cholesterol derivative **8a** (13.6 mg, 30.8 μmol, 4 equiv) was dissolved in solvent C and added to phenylthiocarbonyl peptide **4a** (10.62 mg, 7.68 μmol, 10 mM, 1 equiv). $AgNO_3$ (2.61 mg, 15.36 μmol, 2 equiv) was dissolved in the same solvent, and this solution was added to the reaction mixture. The reaction was stirred at 18 °C for 24 h and monitored by RP-HPLC on a C3 Zorbax column (0−100% B in 30 min, 1 mL/min, 50 °C, detection at 215 nm). The product was purified on a C3 Zorbax column (0−30% B in 10 min, then 30−70% B in 30 min, 6 mL/min, 70 °C, detection at 215 nm) and lyophilized to give 5.1 mg (39%) of lipopeptide **9a** as a white powder.

RP-HPLC purity (C3 Zorbax, 50 °C, detection at 215 nm) >99%, MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{75}H_{124}N_{16}O_{15}$ $[M+H]^+$ 1489.95, found 1490.0, CZE purity citrate buffer (15 min, 15 kV) >99%.

Lipopeptide 9b. Oleyl hydrazide **8b** (9.06 mg, 29.4 μmol, 4 equiv) was dissolved in solvent C and added to phenylthiocarbonyl peptide **4a** (10.17 mg, 7.35 μmol, 10 mM, 1 equiv). $AgNO_3$ (2.54 mg, 14.7 μmol, 2 equiv) was dissolved in the same solvent, and this solution was added to the reaction mixture. The reaction was stirred at 18 °C for 18 h and monitored by RP-HPLC on a C3 Zorbax column (0−100% B in 30 min, 1 mL/min, 50 °C, detection at 215 nm). The product was purified on a C3 Zorbax column (0−30% B in 10 min, then 30−70% B in 30 min, 6 mL/min, 70 °C, detection at 215 nm) and lyophilized to give 4.1 mg (36%) of lipopeptide **9b** as a white powder.

RP-HPLC purity (C3 Zorbax, 50 °C, detection at 215 nm) >99%, MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{65}H_{112}N_{16}O_{14}$ $[M+H]^+$ 1341.86, found 1341.9, CZE purity citrate buffer (15 min, 15 kV) >99%.

Lipopeptide 9c. Linoleyl hydrazide **8c** (9.2 mg, 31.2 μmol, 4 equiv) was dissolved in solvent C and added to phenylthiocarbonyl peptide **4a** (10.78 mg, 7.8 μmol, 10 mM, 1 equiv). $AgNO_3$ (2.65 mg, 15.6 μmol, 2 equiv) was dissolved in the same solvent, and this solution was added to the reaction mixture. The reaction was stirred at 18 °C for 18 h and monitored by RP-HPLC on a C3 Zorbax column (0−100% B in 30 min, 1 mL/min, 50 °C, detection at 215 nm). The product was purified on a C3 Zorbax column (0−30% B in 10 min, then 30−70% B in 30 min, 6 mL/min, 70 °C, detection at 215 nm) to give 4.02 mg (33%) of lipopeptide **9c** as a white powder.

RP-HPLC purity (C3 Zorbax, 50 °C, detection at 215 nm) >99%, MALDI-TOF (α-cyano-4-hydroxycinnaminic acid, monoisotopic): calcd for $C_{65}H_{110}N_{16}O_{14}$ $[M+H]^+$ 1339.84, found 1340.00, CZE purity citrate buffer (15 min, 15 kV) >99%.

RESULTS AND DISCUSSION

The formation of peptide bonds by reaction of α-amino groups with silver ion activated thioacids or thioesters has been studied in detail in the past (*18*−*20*). Thus far, segment couplings were performed essentially with partially protected peptide fragments to avoid competing reactions ε-amino groups of Lys residues (*19*, *20*). In addition, peptide thioesters with a C-terminal Gly residue were the most frequently used ones for segment coupling, because silver ion activation of the thioester usually results in the partial racemization of the C-terminal residue. More recently, Tam et al. reported the synthesis of cyclic peptides using unprotected precursors and silver-activated thioesters for macrocyclization (*21*). The ratio of α/ε-lactamization was highly dependent on the N-terminal amino acid and partial racemization of C-terminal amino acid was also observed.

We hypothesized that the sulfur atom of peptides **1** or **4** and hydrazino group of peptides **2** or **3** (Scheme 1) might simultaneously complex a silver ion. Silver ion was expected to favor Agly bond formation by placing the reactive ends of the peptide fragments in close proximity and by activating the thiocarbonyl moiety. Interestingly, the pK_as of acetylhydrazine and semicarbazide are 3.24 and 3.65, respectively. The reaction could be thus envisaged below pH 5, the threshold pH above which the ε-amino groups of Lys residues usually compete in such reactions (*22*), opening the possibility of forming the Agly bond starting from unprotected peptide precursors. Because silver ion complex formation is known to be favored in apolar solvents,

Table 1. Synthesis of Agly-Peptides by Ligating Peptide Thioesters with Hydrazinocarbonyl Peptides (Path A)[a]

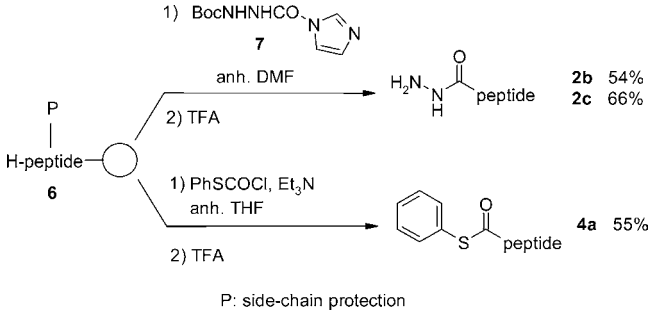
[a] Conditions: Peptide **1** (**1a** 13 mM, **1b** 10 mM), peptide **2** (**2a** 2 equiv, **2b**,**c** 1.5 equiv), and $AgNO_3$ (2 equiv) in tBuOH/water 4/1 by vol containing 40 mM of AcOH (18 °C, 23−27 h). **2b**,**c** were purified by RP-HPLC using a water/acetonitrile gradient buffered at pH 6.5 with triethylamonium acetate. 1.5 equiv of camphorsulfonic acid was added with peptide **2b**,**c** to avoid the increase in pH due to the basicity of peptides **2**. [b] Isolated yield (%) after RP-HPLC purification. [c] Percent of racemization of Ala residue in bold is indicated in parentheses.

Scheme 2. Synthesis of Hydrazinocarbonyl Peptides 2 and of Phenylthiocarbonyl Peptides 4



we examined the interest of *t*BuOH/water mixture for the reaction, since this solvent has been already used for the solubilization of large unprotected peptide fragments (*22*, *23*).

Peptides used in this study feature a Lys residue within their sequence to document the chemoselectivity of the reaction. Thioesters **1** (Table 1) were prepared using the Kenner sulfonamide linker and a solid-phase N,S-acyl shift as described elsewhere (*17*). The synthesis of peptides **2**, i.e., peptides modified at the N-terminus by an Agly residue, was not described to the best of our knowledge (Scheme 2). Usually, once introduced, the Agly residue is acylated on the solid phase before deprotection and cleavage from the resin to give an azapeptide with an internal Agly residue. The synthesis of **2b**,**c** was performed by coupling Boc-Agly imidazole **7** to the peptidyl resin assembled using Fmoc/*t*-Bu strategy (Scheme 2). Hydrazinocarbonyl peptides **2b**,**c** were found to be stable during TFA deprotection and cleavage. Complete hydrolysis of hydrazinoacetyl moiety occurred, however, within minutes during RP-HPLC purification at pH 2 in a water/acetonitrile gradient containing TFA. Alternately, increasing the pH of the eluent from 2 to 6.5 by switching to triethylamonium acetate buffer permitted successful isolation of the target peptides **2b**,**c**. These peptides were stored at −20 °C and were found to be stable for months.

In a first approach, the reaction between thioester **1a** and semicarbazide **2a** (acetate salt) in AcONa pH 3.9/*t*BuOH 1/4 was examined (Table 1, entry 1). The reaction proceeded efficiently and chemoselectively to yield Agly peptide with 46% yield. Hydrolysis of thioester **1a** was negligible. No reaction occurred with semicarbazide hydrochloride, showing the importance of free silver ions for the ligation to proceed. This encouraging result led us to examine the reaction between thioester **1b** and hydrazinocarbonyl peptide **2b**. In this case, similar experimental conditions led to poor results (16% RP-HPLC yield) due to lack of selectivity and significant peptide thioester hydrolysis.

The lower nucleophilicity of the hydrazinocarbonyl moiety of peptide **2b** relative to semicarbazide **2a**, due to the electron withdrawing effect of the peptide chain, might explain this result. Lowering the apparent pH (pH_{app}) of the acetate buffer/*t*BuOH mixture was envisioned as a way to improve the selectivity of the reaction and to minimize thioester hydrolysis. In this context, the influence of *t*BuOH on pH_{app} was examined. The pH_{app} of

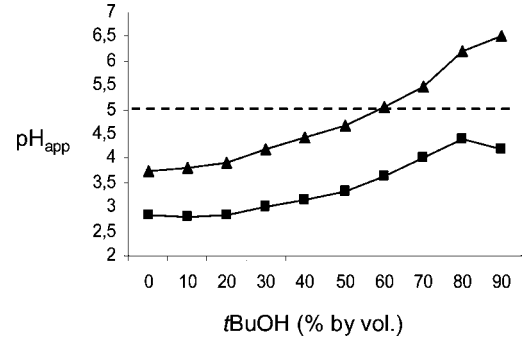


Figure 1. Effect of *t*BuOH on pH_{app} at 18 °C (triangles, 40 mM sodium acetate buffer pH 3.7; squares, 40 mM acetic acid). The horizontal dotted line represents the threshold above which the selectivity of the ligation is affected by the nucleophilicity of ε-amino groups of Lys residues.

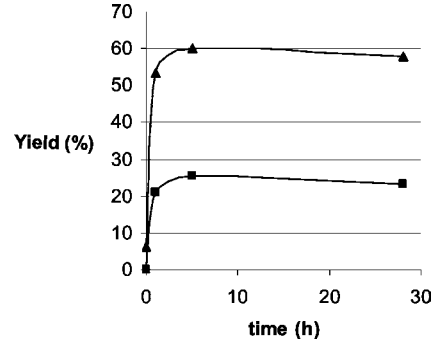

Figure 2. Ligation between peptide hydrazide **3c** and phenylthiocarbonyl peptide **4a** (see Table 2 for experimental conditions). RP-HPLC yield for the ligation product **5f** (triangles) or peptide H-GILKEPVHGA-NH_2 (squares) arising from the hydrolysis of **4a**. RP-HPLC of the crude reaction mixture can be found in Supporting Information.

acetate buffer increases by addition of an organic solvent (*24*, *25*). The impact of the drift of pH_{app} induced by the organic solvent on the selectivity of the silver ion-assisted peptide bond formation has not been discussed in the literature. Figure 1 shows indeed that addition of *t*BuOH up to 80% by vol to a pH 3.7 AcONa buffer results in an increase of pH_{app} of ∼2.5 pH units. Consequently, pH_{app} is ∼1.2 pH units above pH 5, the threshold of selectivity. Obviously such a large increase in pH_{app} might be responsible for the loss of selectivity and thioester hydrolysis observed in the preliminary experiment above.

Alternately, the pH_{app} of a 40 mM acetic acid solution in the presence of *t*BuOH remains below the threshold pH of 5 even for the highest *t*BuOH concentrations tested. This solvent mixture was thus selected for the rest of the study. In addition, 1.5 equiv of camphorsulfonic acid was added with peptide **2b**,**c** to avoid the increase in pH due to the basicity of peptides **2**. Ligation between **1b** and **2b** or **2c** using these optimized experimental conditions proceeded efficiently to give Agly peptides **5b** or **5c** with 28−34% yield after purification. The major side reaction was peptide thioester hydrolysis (15% by RP-HPLC). Peptide **5b** was trypsinized and analyzed by MALDI-TOF spectrometry. Three fragments were detected as

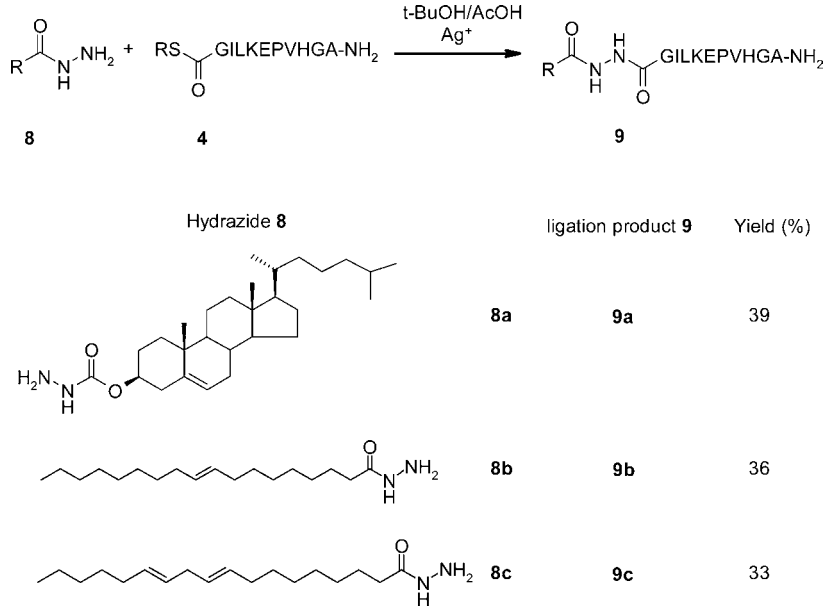
[a] Conditions: **3a**−**c** (2 equiv), peptide **4a** (10 mM), and $AgNO_3$ (2 equiv) in tBuOH/water 4/1 by vol containing 40 mM of AcOH (18 °C, 23−27 h). [b] Isolated yield (%) after RP-HPLC purification. [c] Percent of racemization of Ala residue in bold is indicated in parentheses.

Scheme 3. Synthesis of Lipopeptides Using Agly Ligation between Lipid Hydrazides 8a−c and Phenylthiocarbonyl Peptide 4a



expected. Their sequence was confirmed by postsource decay analysis. GC-MS amino acid analysis of peptides **5b** and **5c** after hydrolysis in 6 N DCl in D_2O showed, however, 30% and 39% of racemization, respectively, for the Ala residue originally at the C-terminus of thioester fragment **1b** (*26*). The extent of racemization using path A (Scheme 1) led us to explore path B as an alternative strategy.

Phenylthiocarbonyl peptide **4a** was prepared as shown in Scheme 2 by reacting commercially available phenylthiochloroformate with the corresponding peptidyl resin assembled using the Fmoc/*t*Bu strategy (*27*). C-terminal peptide hydrazides **3** were synthesized by hydrazinolysis of a deprotected peptide assembled on an HMBA resin (*28*). This method gives access to peptide hydrazides without racemization of the C-terminal amino acid.

In a preliminary experiment, peptide **4a** was reacted with acetylhydrazide **3a** using again 40 mM acetic acid in *t*BuOH/water: 4/1 by vol. as the solvent mixture. Reaction proceeded cleanly to give Agly peptide **5d** with 43% yield. No reaction or degradation occurred in the absence of silver ions, showing as for path A the importance of silver ions for the ligation to proceed. Ligation between peptide hydrazide **3b** and phenylthiocarbonyl peptide **4a** was performed likewise. Because peptide hydrazides were purified using a pH 2 water/acetonitrile gradient, no increase in pH due to peptides **3** was observed, and consequently, addition of camphorsulfonic acid was not required. These experimental conditions led to the chemoselective formation Agly peptide **5e** (48% yield). Likewise, ligation between peptide hydrazides **3c** and **4a** gave Agly peptide **5f** with 41% yield. The unique side reaction observed was the hydrolysis of phenylthiocarbonyl peptide which amounted to 22% (see Supporting Information for RP-HPLC of the crude reaction mixture). Degradation of phenylthiocarbonyl peptide **4a** into the corresponding hydantoin was not observed. Figure 2 shows the time course of the reaction, which was almost complete after 1 h. GC-MS amino acid analysis of **5f** after hydrolysis in 6 N DCl in D_2O confirmed as expected the absence of racemization for Ala residue present originally at the C-terminus of peptide hydrazide **3c**. Finally, all the Agly peptides synthesized in this study were trypsinized and analyzed by MALDI-TOF spectrometry. All the observed fragments were consistent with the proposed structures (see Supporting Information).

AzaGly ligation between a peptide hydrazide and a phenylthiocarbonyl peptide has been shown to be an efficient method for assembling azaGly peptides starting from unprotected peptide fragments. Because a large diversity of hydrazides are commercially available or can be synthesized easily starting from carboxylic acids, azaGly ligation was also envisioned as an interesting method for the modification of peptides by various acyl moieties. The method is particularly useful for incorporating sensitive acyl moieties that cannot survive the experimental conditions used during the solid-phase peptide synthesis. To illustrate the usefulness of azaGly ligation for the synthesis of such conjugates, we have examined the assembly of lipopeptides by reacting phenylthiocarbonyl peptide **4a** with a series of lipid hydrazides derived from cholesterol (**8a**) or C18 unsaturated fatty acids (**8b**,**c**) (Scheme 3). Hydrazides **8a**−**c** feature one or two carbon−carbon double bonds within their structure, which are not compatible with the acid treatment used for deprotecting the peptide chain after the solid-phase peptide elongation step (*22*, *23*, *29*).

Experimental conditions used for the synthesis of Agly peptides were modified to allow the solubilization of the lipid hydrazides. Addition of only 5% by vol of methylene chloride to the *t*BuOH/water solvent mixture permitted the solubilization of both the lipid hydrazides and of the phenylthiocarbonyl peptide **4a**. Ligation proceeded successfully in the presence of silver ions as above. Lipopeptides **9a**−**c** were isolated with a 33−39% yield following RP-HPLC purification. This modest

yield is understandable given the scale of synthesis, the low solubility of lipopeptides in aqueous media, and the known difficulty to purify lipopeptides by RP-HPLC.

CONCLUSIONS

Two strategies were explored for the chemoselective assembly of Agly peptides. The first one, based on the silver ion-assisted reaction between C-terminal peptide thioesters and hydrazinocarbonyl peptides, resulted in the significant racemization of the C-terminal amino acid from the thioester fragment. The second one, based on the silver ion-assisted coupling of C-terminal peptide hydrazides with N-terminal phenylthiocarbonyl peptides, gave better yields and no racemization. The reaction was performed in a *t*BuOH/water mixture, and the control of apparent pH permitted the chemoselective formation of the azaGly bond in the presence of lysine residues. They show also that azaGly ligation can be used for the assembly of lipopeptides, by reacting lipid hydrazides with phenylthiocarbonyl peptides in the presence of silver ions. This ligation method allows incorporation of acid-sensitive lipid moieties that are incompatible with standard solid-phase peptide synthesis procedures.

ACKNOWLEDGMENT

We gratefully acknowledge financial support from CNRS, Université de Lille 1 and 2, Institut Pasteur de Lille, Région Nord Pas de Calais, the European Community, and from Cancéropôle Nord-Ouest. We thank Hervé Drobecq for MALDI-TOF mass spectra and Gérard Montagne for NMR experiments. This research was performed using the Chemistry Systems Biology platform (http://csb.ibl.fr).

The use of targeting ligands to enhance the delivery of liposomal nanoparticles (LNs) has moved slowly toward clinical application. This relative lack of clinical progression is further complicated by the existence of conflicting *in vivo* results in the literature. In this work, we describe new formulations of LNs that are targeted with an arginine-glycine-aspartic acid-containing peptide, cRGDfK, conjugated to the lipid distearoyl phosphatidylethanolamine (DSPE). These formulations may be able to circumvent some of the challenges encountered during the development of targeted-LNs. Of the constructs studied, a fluorescently labeled peptide−lipid conjugate was incorporated into LNs with high yield and accuracy. It is shown that the resulting targeted-LNs bind to human umbilical vein endothelial cells (HUVECs) with increasing avidity as the amount of peptide displayed on the LN surface increases. We specifically demonstrate the ability of targeted-LNs loaded with doxorubicin and incubated with HUVECs to deliver the drug to the cytosol. The cell does not internalize nontargeted LNs, supporting the notion that the RGD motif is associated with internalization of the targeted LN.

INTRODUCTION

In order for liposomal nanoparticles (LNs) to reach cancer cells, they must survive for prolonged amounts of time in the circulatory system (*1*). The addition of a targeting ligand to the surface of an LN is thought to increase the accumulation of the LN by increasing its affinity for a specific target on the surface of diseased cells. Vascular targeting, as opposed to targeting tumor cells themselves, offers the additional advantage of being a relatively general therapy for the treatment of solid tumors, given that all tumors require neovasculature in order to survive (*2*). Cells that make up the tumor vasculature (mainly endothelial cells) are also ideal anticancer targets, as they are not expected to generate drug-resistant variants. The methods described here utilize an arginine-glycine-aspartic acid (RGD) peptide to aid in targeting LNs to endothelial cells containing the molecular target, the $\alpha_v\beta_3$ integrins.

RGD-conjugated drugs have been investigated for their ability to bind to the $\alpha_v\beta_3$ integrins for over fifteen years (*3*). In the late 1990s, medicinal chemists pinpointed a highly selective RGD peptide, which is now an antiangiogenesis drug candidate in phase II clinical trials (*4, 5*). Since the early 2000s, RGD-targeted drugs (*6*), imaging agents (*7*−*9*), antibodies (*10*), and LNs (*11*−*13*) have used cyclic RGD-containing peptides to guide cargo to the tumor-associated vasculature *in vivo*. The timely rate of clinical progression of RGD peptides without cargo and well-defined RGD-imaging agents indicates that RGD-based drugs may be promising new therapies of the future (*9, 14*). RGD-targeted LNs, on the other hand, do not show a sufficient rate of clinical progression.

Targeted-LNs, in general, have held the interest of pharmaceutical innovators since the 1980s (*15*−*17*). RGD-targeted LNs are the most structurally simplified of the known targeting ligands. Despite the relative simplicity of using short peptides as targeting ligands, studies on RGD-LNs tend not to describe the physical and chemical properties of the final product (*11*−*13*). The current theories of the *in vivo* behavior of RGD-LNs are also divergent. While some reports indicate that RGD-LNs share similar *in vivo* circulation lifetimes to nontargeted LNs (*11, 12*), others report the accelerated clearance of RGD-LNs (*13*).

Perhaps the greatest accomplishment toward clinical advancement of targeted-LNs is the first report on the preclinical manufacture of a protein−polymer−lipid micelle, which focuses solely on characterization (*18, 19*). For clinical progression, targeted-LN drug candidates will be required to demonstrate compliance with the regulatory codes of good manufacturing practice. We propose that, in order to move RGD-LN technology toward the clinic, a step backward is necessary to understand what is happening in targeted-LN formulation.

This study focuses on the construction of well-defined RGD-LNs. The RGD-lipid construct with the best formulation properties was purified and qualitatively assessed. A fluorescent label, methoxycoumarin (MCA), was used to track the amount of the purified RGD-lipid construct that is incorporated into an RGD-LN by one of two published methods: either the postinsertion method (*20*) or by classic liposome formulation methods (*21*). Our results also describe the optimal mole fraction of RGD-lipid that enables high target binding and drug delivery via defined RGD-LNs to the cytosol of $\alpha_v\beta_3$-expressing cells.

EXPERIMENTAL PROCEDURES

Materials and Reagents. Unless specified, all reagents were of reagent-grade quality or better. Reversed-phase HPLC (RP-HPLC) was performed using gradients of aqueous acetonitrile containing 0.1% trifluoroacetic acid (TFA) (aqACN) applied to C18 columns. Analytical gradients were run using a 150 mm × 4.6 mm column with a flow rate of 1 mL per minute. Peptides were purified on a preparative scale with a 250 mm × 22 mm column and a flow rate of 10 mL per minute.

Peptide Synthesis. Dimethylformamide (DMF) was the main solvent used for peptide synthesis, unless otherwise specified. The linear sequence D(t-Bu)fK(Z)R(Pbf)G (The RGD-containing peptide) was synthesized by FMOC-based solid-phase peptide synthesis as described previously (*22*). Briefly, peptides were assembled on 0.5 mmol of 2-chlorotrityl resin using 1.3 mol equiv (to carboxylic acid) of the following activating agents:

O-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium hexafluorophosphate (HBTU) and *N*-hydroxybenzotriazole (HOBT). Peptides were activated *in situ* with triethylamine (TEA), then coupled to the resin for at least 1 h. FMOC removal steps were performed upon each amino acid addition by soaking the resin in a solution of 20% piperidine in DMF for 5 min and repeated once. Between each step, the resin was washed with a constant flow of DMF for at least 1 min. Linear peptides were cleaved in 0.1% TFA in dichloromethane (DCM) with 2.5% triisopropyl silane (TIS) and H_2O (v/v). The crude peptide was analyzed by RP-HPLC with a linear gradient of 30−90% aqACN over 30 min (retention time = 16.3 min) and by electrospray mass spectrometry (ESI-MS).

Lyophilized linear peptides were cyclized at 0.5 mM in DMF using benzotriazol-1-yl-oxytripyrrolidiniophosphonium hexafluorophosphate (PyBop) and HOBT to produce cR(Pbf)GD(t-Bu)fK(Z). Cyclization yields were typically greater than 95% and occurred within 30 min, as indicated by RP-HPLC, with a retention time of 19.5 min on the same gradient as the linear peptide and a difference of −18 in the observed molecular weight by ESI-MS. ^{1}H NMR NOE assignments for all α-amide bonds confirmed a head-to-tail cyclic compound.

The benzyl group on the lysine side chain was removed by hydrogenation using a palladium/carbon catalyst. The amine-functionalized peptide, cR(Pbf)GD(t-Bu)K (100 mM in DMF), was modified with 10 mol equiv of succinic anhydride to produce cR(Pbf)GD(t-Bu)fK(succ). The reaction mixture was purified with an RP-HPLC gradient of 10−60% aqACN over 1 h. A 95% pure product eluting after 40 min was characterized both by ESI-MS (MW = 1011.47 ± 1) and by analytical RP-HPLC using a 30−90% aqACN gradient, a product of >95% purity was obtained, with a retention time of 12.1 min.

cR(Pbf)GD(t-Bu)fK-PEG$_2$-K(MCA)-PEG$_2$-COOH Synthesis. Four strategies to synthesize RGD-lipids were investigated (see Supporting Information for a summary of these approaches). We focus on the RGD-lipid construct, which displayed the best characteristics for producing a targeted LN. The synthesis of this chosen construct is described herein.

The spacer−peptide conjugate was assembled as follows: 0.112 mmol 2-chlorotrityl resin was loaded with 2.5 mol equiv of *O*-(*N*-Fmoc-3-aminopropyl)-*O*′-(*N*-diglycoyl-3-aminopropyl)-di(ethylene glycol) (Fmoc-NH-PEG$_2$-COOH) over the course of 3 h, under nitrogen gas with gentle stirring. FMOC was removed by soaking the resin in a solution of 20% piperidine in DMF for 5 min, and repeated once. Ninhydrin assays were used to monitor the success of solid-phase synthesis reactions. 2.5 mol equiv of Fmoc-Lys-(MCA)-OH were then coupled to the free amine using 1.2 mol equiv to carboxylic acid of HOBT, HBTU, and TEA for 1 h, then subsequently, 5 mol equiv of the second Fmoc-NH-PEG$_2$-COOH unit was incorporated over 3 h using 1.2 mol equiv to carboxylic acid of PyBop, HOBT, and TEA. Trial cleavages (performed in a solution of 0.1% TFA in DCM, 2.5% H_2O, 2.5% TIS (v/v)) proved to be more reliable than ninhydrin assays for monitoring the success of each coupling reaction from this point on, presumably due to the shielding effect of PEG. The product (after step d of Figure 1) was retained for 21 min by an analytical RP-HPLC gradient 0−85% aqACN over 30 min. Successful Fmoc removal resulted in a shift in retention time to 14.5 min, using the same gradient. 1.2 mol equiv (to amine) of the cyclic peptide, cR(Pbf)GD(t-Bu)fK(succ), was coupled overnight to the spacer under nitrogen gas using 1.2 mol equiv of PyBop and HOBT and TEA to acid. The product cR(Pbf)GD(t-Bu)fK-PEG$_2$-K(MCA)-PEG$_2$-COOH was purified directly by preparative RP-HPLC (0−85% aqACN) eluting after 40 min.

The dry yield of the peptide−spacer construct was 80 mg. The product was clearly resolved by TLC (chloroform ($CHCl_3$)/methanol (MeOH), 8.8/2.2), R_f = 0.18, and purified to >95% purity as indicated by analytical RP-HPLC (0−85% aqACN). The correct product was validated by ESI-MS.

Synthesis of cRGDfK-PEG$_2$-K(MCA)-PEG$_2$-DSPE. The peptide−spacer construct was conjugated with the lipid anchor, DSPE in a solution. The purified and lyophilized peptide−PEG constructs were dissolved in 2 mL DCM and activated with 5 mol equiv of *N*-hydroxysuccinimide and diisopropylcarbodiimide. The active ester formed within 30 min, and 3.5 mol equiv to acid of distearylphosphatidyl ethanolamine (DSPE) was dissolved in 1 mL $CHCl_3$ at 60 °C. The activated ester was then added to the lipid with 1.2 mol equiv (to ester) of TEA. The reaction occurred within 1 h at 60 °C, and the resulting product was purified on 100 g of silica gel, mobile phase MeOH/$CHCl_3$. The product, cR(Pbf)GD(t-Bu)fK-PEG$_2$-K(MCA)-PEG$_2$-DSPE, eluted between 30−50% methanol in $CHCl_3$ and was identified by TLC ($CHCl_3$/MeOH 8.8/2.2, R_f = 0.74).

The compound was concentrated and redissolved in 95% aqueous TFA to deprotect the arginine and aspartic acid side chains. The product formed within 2 h. TFA was removed by gentle evaporation under a stream of nitrogen, precipitated into ice-cold diethyl ether, centrifuged, rinsed with diethyl ether, and centrifuged again. A yield of 40.8 mg of cRGDfK-SUCC-PEG$_2$(MCA)-PEG$_2$-DSPE (herein, referred to as the RGD-lipid) resulted. The ESI-MS MW for RGD-lipid was 2415.5 ± 1 (predicted MW = 2414.89). Purity of RGD-lipid was confirmed by TLC detected with iodine and UV (MeOH/EtOH/H_2O/TEA (6/3/1/1) R_f = 0.25. Excitation (325 nm) and emission (389 nm) spectra were collected for the construct between 280 and 500 nm using a fluorometer.

Formation of Liposomal Nanoparticles. Dry lipids were dissolved in warm $CHCl_3$ at 60 °C. The solvent was removed under a stream of nitrogen gas to form a thin film, and residual solvent was removed by lyophilization. For empty vesicles, the thin film was hydrated in 100 mM HEPES buffer containing 144 mM NaCl, pH 7.5 (HBS), warmed to 60 °C. The resulting multilamellar vesicles were extruded through two polycarbonate filters with a 100 nm pore size. The vesicles were extruded ten times using an extruder, to form unilamellar LNs.

The mean diameter of the LNs was characterized by dynamic light scattering (DLS) using a Nicomp 370 particle sizer for size distribution analysis. LNs were further characterized by a phosphate assay using the method of Fiske and Subbarow, and by fluorescence emission at 590 nm, upon excitation at 530 nm. RGD-lipids were then incorporated into LNs by one of two methods, either the "post-insertion method" or the "formulation method".

Post-Insertion Method of Incorporating cRGDfK-PEG$_2$-K(MCA)-PEG$_2$-DSPE into Preformed LNs. The post-insertion method of incorporating a ligand-conjugated lipid into preformed LNs has been described previously (*20*). Our LNs were composed of the following lipids: 54 mol % distearylphosphatidylcholine (DSPC)/45 mol % cholesterol (Chol)/0.5 mol % Rhodamine-labeled phosphatidylethanolamine (Rhod:PE). After LNs were prepared as described in the above section, the required amount of RGD-lipid needed to make 1 mol % (RGD-lipid) was prepared as a micelle solution in HBS, at 65 °C. The LNs and RGD-lipid micelles were coincubated together at 65 °C for 2 h. The mixture was purified on a 40 mL Sephadex G50 column. Incorporation of the RGD-lipid into the LN was measured by MCA emission at 389 nm, following excitation at 325 nm in HBS containing 1% Tween 20 and compared against a standard curve made with known amounts of the RGD-lipid.

Formulation Method of Incorporating RGD-Lipids Into LNs. Empty RGD-LNs were also made using the "formulation method". We chose this method to manufacture RGD-LNs for studies on the drug retention characteristics of the LNs and for

all cell-based assays. We varied the amount of RGD per LN by increasing the mol % of the RGD-lipid added before the LNs were formed. The series of RGD-LNs containing different amounts of RGD were formulated as follows: 0.5 mol % RGD-LN was made by incorporating: 54 mol % distearylphosphatidylcholine (DSPC)/45 mol % cholesterol (Chol)/0.5 mol % Rhodamine-labeled phosphatidylethanolamine (Rhod:PE)/0.5 mol % RGD-lipid (i.e., 54:45:0.5:0.5 mol:mol), 1 mol % RGD-LN (53.5:45:0.5:1) mol:mol), 2.5 mol % (52:45:0.5:2.5 mol:mol), and 5 mol % (49.5:45:0.5:5 mol:mol). Nontargeted LNs were formulated as (54.5:45:0.5:0 mol:mol). For drug retention and biological assays on intracellular delivery, 0.5 mol % RGD-LNs were used.

The amount of surface-exposed RGD-lipid per liposome was estimated under the assumption that one LN contains approximately 148 641 lipids (based on the average diameter of the particle being 116 nm, and the average surface area of a lipid headgroup as 0.5 nm^2). For this diameter, the proportion of those lipids residing in the outer leaflet is approximately 57% of the total lipid composition.

Comparison of the Post-Isertion and Formulation Methods for RGD-LN Formation. The postinsertion and formulation methods were compared with regard to their ability to incorporate RGD-lipid into LNs. In order to quantify the amount of the RGD-lipid that was incorporated into the LN by either method, the fluorescence emission and excitation spectra were obtained for the RGD-lipid (Figure 2). The amount of the targeting ligand that was incorporated by either the post-insertion or the formulation method was subsequently measured by fluorometry. Fluorometric measurements were conducted in the presence of 1% Tween 20 in order to disrupt the LN structure. A linear increase in the fluorescence signal corresponded to increasing amounts of RGD-LNs;therefore, a standard curve was established from known amounts of the RGD-lipid in the presence of nontargeted LNs. The amount of RGD-lipid present

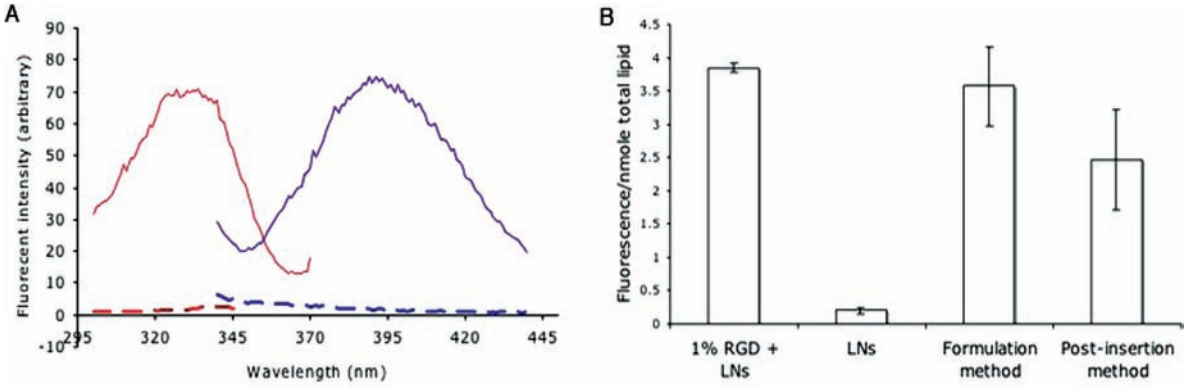

Figure 2. () Excitation (red) and emission (blue) spectra obtained for RGD-LNs with the RGD-lipid embedded in the bilayer. The spectrum for nontargeted LNs is shown by dashed lines. () Fluorescence measurements of the relative amounts of the RGD-lipid in RGD-LNs made by either the formulation method or the postinsertion method. The starting concentrationsof RGD-lipid (1 mol % of the total lipid concentration) plus nontargeted LNs represents the maximum possible RGD-lipid incorporation that was used before the RGD-lipid was incorporated into an LN.

in LNs made by the two different techniques was calculated as shown in Figure 2B.

HPTS Loading. In order to track intracellular delivery of LN contents, the pH-sensitive probe, 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS),was loaded into nontargeted LN and 0.5% RGD-LN (i.e., HPTS/N (55:45:0:0 mol:mol) and HPTS/GD-LN (54.5:45:0:0.5 mol:mol)). LNs were hydrated in 10 mL of HBS containing 40 mM HPTS, extruded,and dialyzed three times for 12 h against 4 L HBS. The resulting HPTS-LNs were characterized by DLS, phosphorus content,and HPTS fluorescence emission at 450 nm following excitation at 395 nm. The contribution from the MCA group of the RGD-lipid was examined and found to be negligible at this wavelength of detection.

Doxorubicin Loading ito the Interior of LNs. Doxorubicin was loaded into preformed nontargeted LNs and 0.5% RGD-LNs using the ammonium sulfate method described previously (*23*). Briefly, LN lipids were dried to a thin film,then hydrated in 10 mL of 300 mM ammonium sulfate, extruded,and dialyzed twice over 12 h against 150 mM NaCl. Phosphate assays were conducted to determine the amount of doxorubicin required to achieve a drug-to-lipid ratio of 0.2 (mol:mol). The appropriate amount of doxorubicin was dissolved in 1 mL of 150 mM NaCl, and the appropriate volume was delivered to each solution of LNs. Doxorubicin and LNs were coincubated at 55 °C for 1 h to load the drug, and then the free drug was removed by size exclusion chromatography, with a 40 mL Sephadex G50 column, equilibrated in 150 mM NaCl. Doxorubicin-encapsulated LNs (Dox:LNs) eluted within the first 10 mL fraction, and free doxorubicin eluted over the following 15 mL fractions. The size of the resulting particles was estimated by dynamic light scattering and assayed for phosphate content. The amount of encapsulated material was determined by RP-HPLC, using a standard curve made from the integrated peak area of doxorubicin's 280 nm UV absorbance. Free doxorubicin elutes on a 0−85% aqACN gradient at 15.8 min.

Doxorubicin Leakage Assay. The amount of doxorubicin that was retained in the LNs was measured over 24 h by the following doxorubicin leakage assay. Doxorubicin-loaded 0.5% RGD-LN and nontargeted LN (i.e., Dox:RGD-LN and Dox:LN), corresponding to an assay-confirmed concentration of 0.25 mM free doxorubicin, were incubated with 30% (v/v) FBS, total volume 1.5 mL, at 37 °C over 24 h. During this time, 100 μL was removed in duplicate at 0 min, 30 min, 1 h, 2 h, 5 h, and 24 h time points. The sample was applied to a spin column composed of 750 μL Sephadex G50 and centrifuged at 100 rpm for 1 min. One milliliter of 10% Triton X-100 (v/v) in 150 mM NaCl was added to the eluent in order to release the LN-entrapped doxorubicin. Doxorubicin content was subsequently assayed using the fluorescence emission of doxorubicin at 590 nm when compared to a standard curve made from free doxorubicin in 10% Triton X-100, 150 mM NaCl.

Cell Culture and LN Binding Assays. HUVEC cells, media, and supplements were obtained from Cascade Biologics (Portland, OR). M21 and M21L melanoma cell lines were obtained from Dr. D. Cheresh and were maintained in Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum (FBS). Rhodamine-labeled LNs varying in their RGD content (i.e., containing between 0 and 5 mol % of the targeting lipid) were added to cells to construct binding isotherms (Figure 3). LNs were adjusted to have equivalent phosphate content by dilution with HBS, then added to cells at concentrations between 0 and 4 mM (total lipid content). The final volume was adjusted to 500 μL with 5% FBS in PBS (PBS/FBS). Cells were incubated with LNs for 1 h at either 4 or 37 °C. After incubation, unbound LNs were removed with 5 mL of PBS/FBS, followed by centrifugation at 1100 rpm for 5 min, repeated twice. Unfixed cells were kept on ice and immediately analyzed by flow cytometry using a BD LSR II flow cytometer equipped with an air-cooled argon laser. Light scattering and fluorescence channels were set to a logarithmic scale and 10 000 events were collected per sample. Data were analyzed using *Flow Joe* (version 4.5.9, Stanford, CA). Electronic gates were established using unstained live cells based on their ability to exclude the uptake of propidium iodide. The mean fluorescence intensity was plotted versus the concentration of LN. Statistical analyses were conducted using *GraphPad Instat*, version 3.0. A Tukey-Kramer multiple comparisons test was used, with n values of 3, representing triplicate data points. P values greater than 0.05 were considered insignificant.

Cellular HPTS Uptake. HPTS:LNs and HPTS:RGD-LNs were added to cells and incubated at 37 °C for 0, 5, 15, 30, and 90 min time points. The cells were rinsed and assayed for cell-associated HPTS fluorescence by flow cytometry. At neutral pH, HPTS fluoresces at 519 nm when excited by light at 488 nm. Acidification of the vesicles (pH ~6.5−7) was monitored by detecting fluorescence emission at 455 nm following excitation at 405 nm. The background binding shown by nontargeted HPTS-containing LNs was low, and this measurement was subtracted from the fluorescence signals produced by RGD-LNs.

Doxorubicin Uptake into Cells as Determined by Flow Cytometry. 80 μM of doxorubicin (either encapsulated within the LN or as the free drug) was added to each aliquot of M21, M21L or HUVEC cells. The mixture was incubated for 90 min

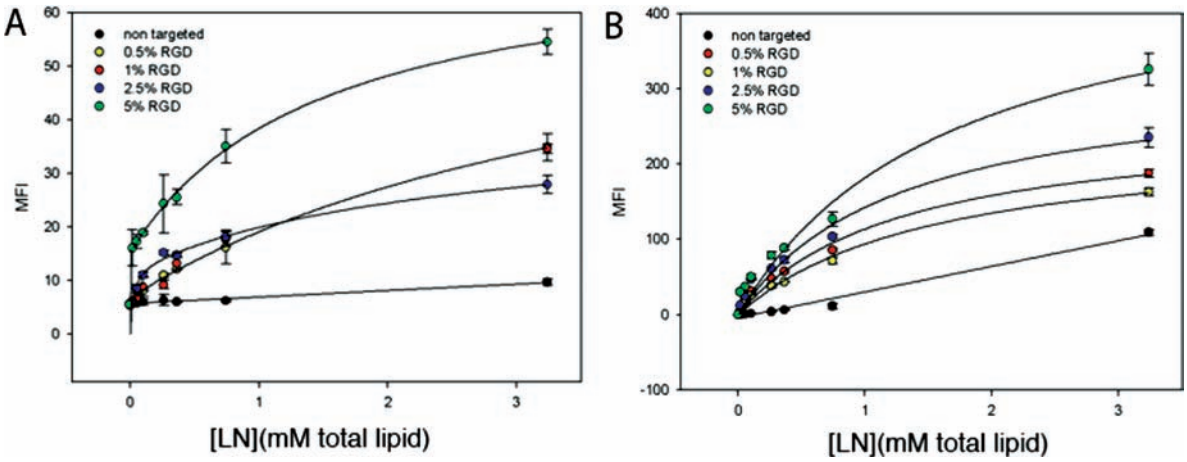

Figure 3. (A) Saturation curves describing the binding of LN to HUVEC following a 1 h incubation at 4 °C (endocytosis is prohibited at low temperatures). The LNs contain between 0 and 5 mol % RGD-lipid. (B) The same binding experiment conducted at endocytosis permissive temperatures (37 °C).

at 37 °C, then assayed for cell-associated doxorubicin fluorescence by flow cytometry as described in the above section.

LN Uptake into Cells as Observed by Fluorescence Microscopy. HUVEC cells were grown to confluence on four chambered glass slides (BD, Franklin Lakes, NJ). Cells were rinsed three times with PBS/FBS. 0.265 mM of doxorubicin was added for a final volume of 125 μL. For HPTS uptake, 1.36 mM (total lipid concentration) was added with a final volume of 200 μL. LNs or free drug were added to the cells; the mixture was incubated at 37 °C for 30 min, rinsed twice with PBS/FBS, and the cells were then fixed with 3.5% paraformaldehyde in PBS for 15 min and rinsed once again with PBS/FBS. Immediately before imaging, chambers were removed and slides were prepared using Vectashield mounting media (Vector Laboratories, Burlingame, USA) containing the blue nuclear stain, 4′,6-diamidino-2-phenylindole (DAPI). Images were captured using a Zeiss Axiovert 200 fluorescence microscope equipped with a Retiga 200R camera. Those acquired under a bright field used a 0.3 s exposure time and in the fluorescence field were acquired using three fluorescence filters with the following exposure times: red 3.5 s, green 5.5 s, DAPI 0.5 s.

RESULTS

Synthesis of Targeting Lipids. We synthesized the RGD-lipid, cRGDfK-SUCC-PEG$_2$(MCA)-PEG$_2$-DSPE using a straightforward solid-phase synthesis procedure, as shown in Figure 1. The final product had a purity of greater than 95% and an overall yield of 42% (or 40.8 mg using our synthesis scale). The peptide showed excellent analytical characteristics due to the presence of the methylcoumarin (MCA) fluorescent label. The MCA fluorophore also facilitated subsequent purification steps, owing to the ability to detect the compound. In our experience, PEG-lipid constructs without a fluorescent label have proven difficult to synthesize and purify (see Supporting Information). The MCA fluorophore was found to be essential once the targeting lipid was incorporated into an LN, as the exact mole percentage of RGD-lipid in LN could then be calculated.

Incorporation of the Targeting Lipid into LNs. The amount of RGD-lipid that was incorporated into RGD-LNs made via the postinsertion method was slightly reduced ($p < 0.05$), when compared to the amount of RGD-lipid that was initially added to the LN (Figure 2). The reason that the RGD-lipid did not fully integrate into the LN bilayer may be due to the adherence of the RGD-lipid micelles to glassware and the relatively small scale of our experiments. No significant decrease in the amount of RGD-lipid was detected for RGD-LNs made by the formulation method ($p > 0.05$). Because the formulation method was more straightforward and had good incorporation yields, it was the method of choice in subsequent experiments.

Table 1. Characterization of RGD-LNs

LN formulation	number of RGD molecules at LN surface[a]	size (nm)	HUVEC binding K_d (nM)[b,c]
nontargeted	0	102.4 ± 27.3	n/a
0.5% RGD	423	102.2 ± 32.0	2.59 ± 0.58
1% RGD	846	94.2 ± 20.7	1.98 ± 0.35
2.5% RGD	2113	128.9 ± 68.0	0.38 ± 0.07
5% RGD	4226	117.4 ± 66.0	0.59 ± 0.02

[a] This value was estimated using the assumptions that 100% of the RGD-lipid was incorporated into the LN and that 57% of the total RGD-lipid resides on the outer leaflet of the LN lipid bilayer. [b] Error is expressed as ± the standard error of the estimate from the nonlinear regression curve for binding. [c] The K_d value is expressed as the concentration of RGD-LN required to achieve half saturation of HUVEC cells and is derived from the data presented in Figure 3.

RGD-LN Characterization. The RGD-lipid was readily incorporated into LNs by the formulation method. When combined with other lipids such as DSPC, cholesterol, and a fluorescently labeled PE (Rhodamine-PE), LNs exhibiting a regular Gaussian size distribution with an average diameter of approximately 100 nm could be formed using up to 5 mol % of the RGD-lipid without obvious signs of aggregation. As summarized in Table 1, the LN particle size increased slightly, with an increase in the standard deviation (an indicator of LN aggregation) when 2.5 or 5 mol % of the RGD-lipid were included in the formulation. The apparent binding constants (expressed as K_d values) shown in Table 1 were calculated from the specific binding at 4 °C (data presented in Figure 3).

RGD-LN Binding Affinities. The apparent K_d values presented in Figure 3 decrease as the proportion of RGD-lipid is increased to 2.5 mol %. It can also be observed from the data in Figure 3A that the B_{max} values observed for the 5 mol % RGD-LNs is higher than the other formulations by 1.7-fold, which could be due to some limited aggregation of the RGD-LNs at these high contents of RGD-lipid. It is important to note that the K_d value observed in Table 1 accounts for a sum of several possible cellular processes and has been simplified here to describe the overall binding of RGD-LNs to live HUVEC cells.

Drug Retention in RGD-Targeted LNs. In some cases, it has been shown that when targeting ligands are incorporated into LNs, the permeability of the LN membrane to the drug

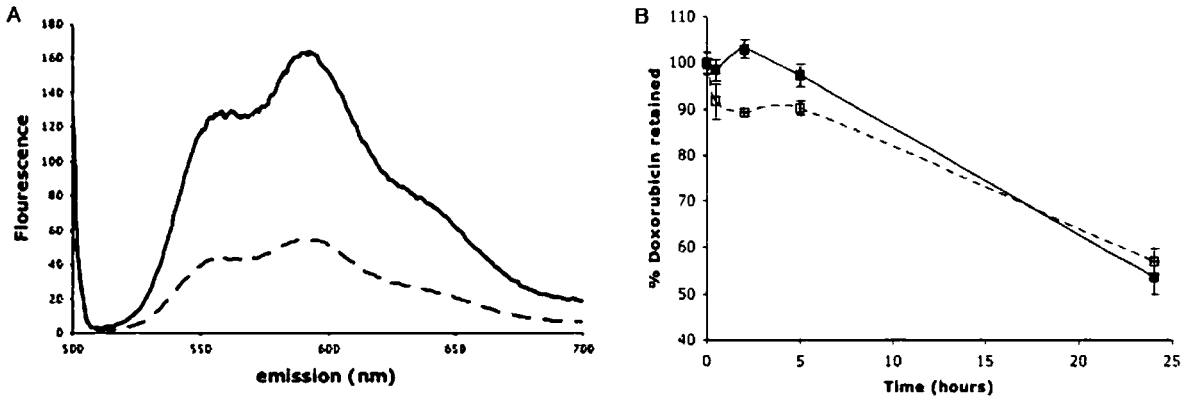

Figure 4. Doxorubicin retention in RGD-LNs versus nontargeted LNs. (A) Emission spectrum (following excitation at 490 nm) of 1.5 μg of doxorubicin dissolved in water (dashed line) or 10% Triton X-100 (solid line). (B) Release of doxorubicin from RGD-LNs made via the formulation method (solid line) and nontargeted LNs (dashed line) in a 10% FBS solution. Error is given as $\pm$ the standard deviation of three data points from the average doxorubicin emission (590 nm) determined in the presence of 10% Triton X-100.

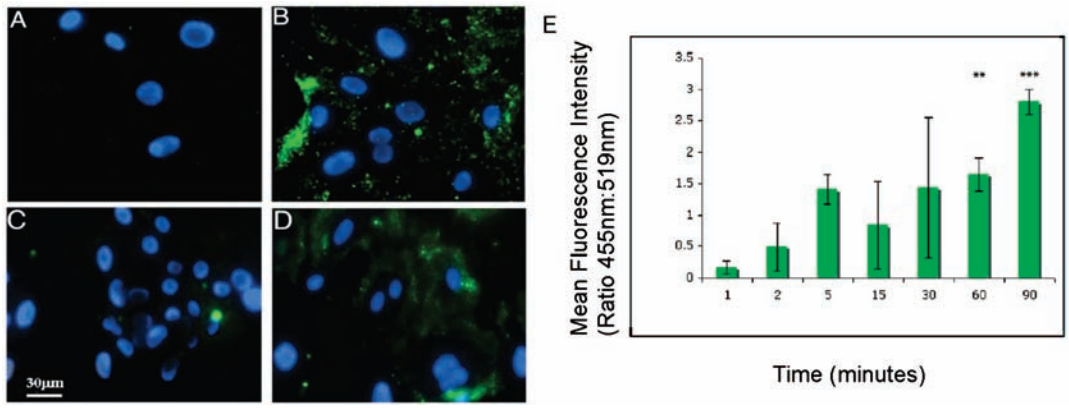

Figure 5. RGD-LNs are internalized and acidified by HUVEC. Panels A−D show fluorescence microscopy images demonstrating LN-associated HPTS uptake by HUVEC, while panel E reflects data obtained by flow cytometry which shows that the LN experiences an increasingly acidic environment as reflected by a progressive shift in the HPTS fluorescence toward fluorescence at 455 nm. LNs loaded with HPTS were coincubated with HUVEC cells at 37 °C. (A) Nontargeted LNs, 10 min incubation; (B) 1% RGD-targeted LNs, 10 min incubation. Panels C and D show HPTS:LNs that were internalized after a 40 min incubation; (C) shows the uptake of HPTS-loaded nontargeted LNs and (D) shows the 40 min uptake of 1% HPTS:RGD-LNs.

may also increase (*24*) (*25*). For this reason, the release of a commonly used anticancer drug, doxorubicin, from LN containing RGD-lipid was investigated.

Doxorubicin was loaded into LN and RGD-LN (containing 1 mol % RGD-lipid, and made by the formulation method) and the LNs were incubated in an aqueous buffer containing blood serum, over 24 h. At specified times, aliquots were withdrawn, free drug removed with a spin column, and the amount of doxorubicin remaining in the LN (upon release with Triton X-100) was assayed (Figure 4A). Little difference could be observed between the release of doxorubicin from RGD-LNs or nontargeted LNs (Figure 4B) indicating that the RGD-lipid did not significantly ($p > 0.05$) enhance the permeability of the LN membrane to doxorubicin over a 24 h period. It should be noted that the loss of nearly 30% of the LN's loaded material over 24 h is somewhat higher than that from the commercial LN formulations of doxorubicin. We attribute the relatively high loss of doxorubicin from the interior of the vesicles to the presence of serum proteins, lack of PEG coating, and incubation at physiological temperatures.

Cellular Uptake and Processing of RGD-LNs. The internalization and subsequent acidification of an RGD-LN within the cell was tracked with the pH-sensitive, membrane-impermeable probe HPTS. When HPTS is acidified, the emission spectrum shifts to shorter wavelengths. HPTS was loaded into LNs as indicated in Experimental Procedures. The LNs were then added to HUVECs and subjected to fluorescence microscopy. Green fluorescence in punctate cytoplasmic vesicles could be observed within 10 min in cells incubated with RGD-LNs, but not in cells incubated with nontargeted LNs (Figure 5A,B). The fluorescent signal detected after a 40 min incubation (Figure 5D) is noticeably more diffuse, suggesting that the fluorophore escapes the endosome at some time between 10 and 40 min following association of the RGD-LN with the HUVEC.

Figure 5E supports the notion that acidification is a function of incubation time. The fluorescence properties of HPTS were investigated with flow cytometry, using the indication of a neutral pH environment (fluorescence emission at 519 nm following excitation at 495 nm) or an acidic environment (emission at 455 nm following excitation at 405 nm). These results indicate that internalization of the particle commenced as early as 5 min. A significant increase in the relative 455 nm fluorescence was observed after 60 min suggesting that the contents within the particle are processed in a manner that coincides with endosomal maturation.

In Vitro Drug Delivery by RGD-LNs. Fluorescence microscope images comparing the delivery of doxorubicin by LNs versus the free drug are presented in Figure 6. Free, unencapsulated doxorubicin has a high affinity for the cell nucleus and rapidly permeates the plasma membrane. Thus, the fluorescence signal for free doxorubicin almost entirely colocalizes with the nuclear stain, DAPI (Figure 6A). Conversely, 1 mol % RGD-LNs deliver doxorubicin to cytoplasmic compartments (Figure 6B). Doxorubicin delivered by nontargeted LNs shows minimal

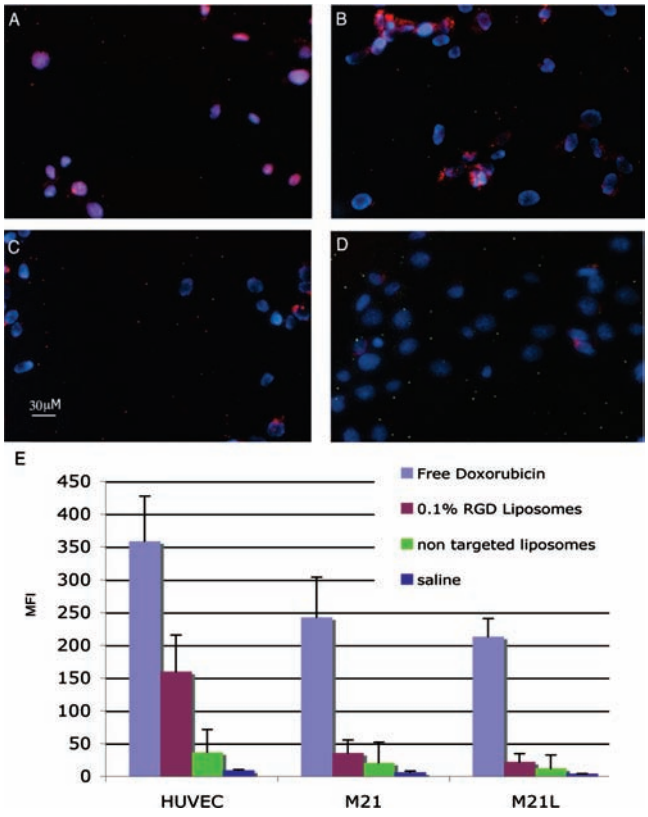

Figure 6. Cellular uptake of doxorubicin as a free drug, encapsulated in nontargeted LNs or in RGD-LNs. Panels A−D: Doxorubicin uptake by HUVEC cells as monitored by fluorescence microscopy following a 30 min incubation at 37 °C with the same amount of doxorubicin (0.265 mM) delivered to cells as (A) free drug, (B) 1% RGD-LN, (C) nontargeted LN, or (D) saline background control. (E) Doxorubicin uptake (as measured by flow cytometry) by three cell lines with different levels of $\alpha_v\beta_3$ expressed on their surface, HUVEC, M21, or M21L. 0.08 mM of doxorubicin was added to cells as either free, RGD-LN, or nontargeted LN formulations and incubated for 1 h at 37 °C prior to analysis.

background staining with uptake levels similar to the saline control (Figure 6C,D).

The ability of RGD-LNs to deliver doxorubicin to $\alpha_v\beta_3$-expressing cells is supported by the flow cytometry experiments shown in Figure 6E. HUVECs express approximately 263 000 $\alpha_v\beta_3$ integrins per cell, whereas M21 and M21L melanoma cells express approximately 56 700 and 1400 integrins per cell, respectively (*22*). RGD-LNs deliver more doxorubicin to HUVECs than nontargeted LN ($p < 0.05$) and appear to deliver modestly higher amounts to M21 cells over the nontargeted LNs; however, this increase is not statistically significant ($p > 0.05$). In contrast, M21L cells that express a relatively low amount of the receptor do not show enhanced uptake of doxorubicin-containing RGD-LNs.

DISCUSSION

This study describes well-defined RGD-lipid formulations that can target anticancer drugs to endothelial cells. Much of our ability to define the RGD-LNs used in this study is attributable to the inclusion of a defined-length, PEG-based spacer. We found that using this spacer improved upon the handling properties of the compound and facilitated analysis by ESI-MS, enabling a defined mass to confirm the identity of the compound. On several occasions, the shielding effect of PEG units was problematic toward the synthesis and purification of the construct. This was particularly important for confirmation of successful couplings while the construct was on a solid phase. In such case, robust qualitative methods (ESI-MS) were required to confirm couplings. The same concern may be raised toward the analysis of a successful purification when the construct was cleaved from the resin.

It is important to note that the PEG−lipid conjugate used in this study differs from commonly used PEG polymers, which are an average molecular weight of PEG repeats. The approximate bond length of the spacer is 75.7 Å. This estimate does not consider the bending and rotation of the spacer in aqueous solutions, which could be more accurately assessed using SPR-based techniques. Such techniques describe the extension of PEG-spacers in water. Using this methodology, it has been shown that PEG_{2000} spacers (commonly used in the manufacture of long-circulating LNs) extend approximately 200 Å from the surface of a lipid bilayer (*26*).

The ability to accurately characterize RGD-LNs is also partly attributable to the use of a fluorescent label within the RGD-lipid architecture. This was found to be essential for the accurate purification and chromatographic identification of the final product. The use of an identifying species such as a fluorescent label may lead to future preclinical targets, which may visualize and treat tumors at the same time. Indeed, RGD-conjugates to deliver imaging agents are quickly progressing through clinical trials (*27*).

Of the different methods employed to produce RGD-LNs, the formulation method was found to be the most straightforward and most effective. In our case, the post-insertion method resulted in incomplete transfer of a lipid particle between the RGD-lipid micelle and the preformed LN. It is generally thought that the post-insertion method of integrating a targeted lipid into the LN bilayer favors the orientation of the targeting lipid toward the outside layer of the LN bilayer (*28*).

A third method exists that is heavily used in the published literature on targeted LNs. This method entails reacting a targeted ligand with a functionalized group on the LN outer surface. Removal of unreacted or nonproduct species from the LN is impossible under these conditions. Furthermore, the measure of the amount of targeting ligand that ends up on the LN surface is generally unknown when using this approach.

Using defined RGD-LNs, we were able to synthesize a series of LNs that were composed of varying densities of the RGD−lipid. When the RGD-LNs were added to HUVECs, we found that an overall decrease in the observed K_d values correlated with an increase in the amount of RGD per LN. This may suggest that the improved binding of the LN can be attributed to the increased RGD valency of the LN. These findings are consistent with results published by Montet and colleagues, who found improved binding for multivalent presentations of their RGD-nanoparticles compared to their monovalent versions (*29*). In our study, we found a modest increase in K_d when the RGD−lipid is incorporated at 5 mol % versus 2.5 mol %. This small increase suggests that the optimal mole percentage of RGD−lipid per LN is within this range. It may also be possible that, after a certain concentration, there is lateral segregation of the RGD−lipid into larger aggregates. The data collected here appear to indicate that a more complex physical association is favored when RGD−lipids are incorporated at higher ratios (i.e., 2.5 and 5 mol % RGD-LNs appeared to have larger variation in particle size) to the other LN lipids. A manuscript which specifically focuses on RGD/HUVEC binding has recently been published by our group (*22*).

The major emphasis of this study is on the synthesis of a pure RGD−lipid and RGD-subsequent formulation into an RGD-LN. Our RGD−lipid is unique since it can be quantitatively formulated into LNs at the time of manufacture. The inclusion of the MCA molecule facilitated this and did not appear to affect the targeting function of the RGD−lipid. We

believe that providing good quantitative analytical data for the RGD-LN is important for *in vitro* analyses as shown in this study and will also be crucial for future *in vivo* characterization.

A New Approach in the Preparation of Dendrimer-Based Bifunctional Diethylenetriaminepentaacetic Acid MR Contrast Agent Derivatives

Kido Nwe,[†] Heng Xu,[†] Celeste Aida S. Regino,[‡] Marcelino Bernardo,[‡,§] Lilia Ileva,[§] Lisa Riffle,[§] Karen J. Wong,[‡] and Martin W. Brechbiel*[,†]

Radioimmune and Inorganic Chemistry Section, Radiation Oncology Branch, and Molecular Imaging Program, National Cancer Institute, 10 Center Drive, Bethesda, Maryland 20892, and Research Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick, Maryland 21702. Received February 4, 2009; Revised Manuscript Received June 7, 2009

In this paper, we report a new method to prepare and characterize a contrast agent based on a fourth-generation (G4) polyamidoamine (PAMAM) dendrimer conjugated to the gadolinium complex of the bifunctional diethylenetriamine pentaacetic acid derivative (1B4M-DTPA). The method involves preforming the metal−ligand chelate in alcohol prior to conjugation to the dendrimer. The dendrimer-based agent was purified by a Sephadex G-25 column and characterized by elemental analysis. The analysis and SE-HPLC data gave a chelate to dendrimer ratio of 30:1 suggesting conjugation at approximately every other amine terminal on the dendrimer. Molar relaxivity of the agent measured at pH 7.4 displayed a higher value than that of the analogous G4 dendrimer based agent prepared by the postmetal incorporation method ($r_1 = 26.9$ vs 13.9 mM^{-1} s^{-1} at 3 T and 22 °C). This is hypothesized to be due to the higher hydrophobicity of this conjugate and the lack of available charged carboxylate groups from noncomplexed free ligands that might coordinate to the metal and thus also reduce water exchange sites. Additionally, the distribution populations of compounds that result from the postmetal incorporation route are eliminated from the current product simplifying characterization as quality control issues pertaining to the production of such agents for clinical use as MR contrast agents. In vivo imaging in mice showed a reasonably fast clearance ($t_{1/2} = 24$ min) suggesting a viable agent for use in clinical application.

INTRODUCTION

The quest for the development of a more efficient contrast agent for magnetic resonance imaging (MRI) is an ongoing process. Although clinically used low molecular weight paramagnetic chelates, such as Gd(III)-diethylenediaminepentaacetic acid (GdDTPA) (Magnevist) and Gd(III)-*N*,*N*′,*N*″,*N*‴-tetracarboxymethyl-1,4,7,10-tetraazacyclododecane (Gd-DOTA) (*1, 2*), are thermodynamically stable within the context of their usage, they suffer from rapid clearance from vascular circulation and renal excretion.

Dendrimer-based macromolecular MR contrast agents in which numerous chelated gadolinium ions (Gd(III)) are covalently attached to a multivalent dendritic architecture are a promising class of diagnostic agents for medical imaging applications (*3*−*6*). There are also growing applications of dendrimers in preparation of macromolecules for radioimmunotherapy (*7*−*9*). Due to their macromolecular size and weight, dendrimer-based MR agents feature higher molar relaxivities along with longer retention and circulation times as compared to the clinically approved Magnevist (Gd(III)-DTPA), thereby resulting in greatly enhanced sensitivity and operational window (*10*). Extensive efforts have been expanded on the preparation and evaluation of these agents in our laboratory along with several other research groups worldwide to study their *in vivo* properties and to eventually reach the goal of producing viable imaging agents that might be translated into clinical use (*4, 11*−*14*). Preclinical results have been promising in animal studies and by virtue of choosing generation size, core elements, and other exterior modifications dendrimer-based MR agents have been successfully employed for the imaging blood pool (*14*), specific organs such as kidney (*4, 5*) and liver, lymphatics (*6*), and tumor vasculature (*12, 13*) in mice with acceptable clearance rates.

The typical procedure for preparation of these agents usually involves three key steps. The first step is conjugation of an isothiocyanate or *N*-hydroxysuccinimidyl active ester form of either 2-(4-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M-DTPA) or 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) derivatives to the multiple periphery functional groups (e.g., $-NH_2$) of various types of polyamino-terminated dendrimers in either aqueous or organic solution. The second step has been complexation of paramagnetic metal Gd(III) ions with the conjugated DTPA or DOTA chelates attached on the dendrimers. The final and highly important step has been the purification of the product to completely remove "free" Gd(III) ions usually by an extensive dialysis technique using appropriate filtration membranes (*3, 5, 6, 10, 15*).

Unlike small molecules, macromolecular agents are usually difficult to define with accurate and precise chemical structures and to characterize their purities by traditional means. This limitation generates real challenges to establishing quality control for reproducible preparation of agents. For instance, even when the same protocol is followed for preparation of these macromolecular dendrimer-based agents, it is exceedingly difficult to ensure that both the same number of conjugated chelates and the same number of Gd(III) ions for each batch will be achieved. This is particularly so when considering that there are potentially hundreds of reactive sites in higher-

generation dendrimers, e.g., a generation 8 PAMAM dendrimer potentially has 1024 terminal primary amines (*16*, *17*). One has to be aware that these products are also effectively a distribution of chelate conjugate products that has been carried forward into another distribution of Gd(III) complexes and that while characterization reports numbers of chelates and Gd(III) those numbers represent average numbers. For clinical use, however, these agents need to have a narrow molecular weight range and the same chemical composition to ensure reproducible expected *in vivo* behavior. The Gd(III) metal content in these dendrimer-based MR contrast agents is a critical factor not only to the level of contrast efficacy, but also to the biological properties (e.g., PD/PK). In our prior synthetic approaches, and to the best of our knowledge of all others, the Gd(III) metal incorporation has always been performed as the last step, following conjugation of bifunctional chelating agents to the dendrimer. In general, by combustion analysis data, this sequence generally results in ~80% of the bifunctional chelating agents being complexed with Gd(III) ions, while the remaining ~20% of those chelates remain vacant of Gd(III) (*18*, *19*).

These 20% "open" chelates possess a significant number of carboxyl groups, which may impact overall hydrophilicity and charge of the agents at the physiological conditions. Accurate determination of what role these vacant or "open" chelates play is an extremely difficult task to perform. Additionally, concerns pertaining to chelation of exogenous biologically relevant metal ions *in vivo* impacting toxicity may be valid when taking into account absolute molar injected amounts versus clearance rates. Lastly, as noted above, these products are actually complex mixtures of products, and elimination of some aspect of that character should strengthen the potential of their clinical translation. With that impetus in hand, we felt it necessary to explore a means to simplify the process while arriving at a more defined product by limiting these variables as much as possible.

With this note, we report a refined synthetic procedure for the preparation of dendrimer-based MR contrast agents, wherein (1B4M-DTPA) is first used to sequester Gd(III) and thereafter the resulting metal complexes are covalently attached to the terminal $-NH_2$ groups in a PAMAM G4 dendrimer. Such an approach allows creation of a simplified standard procedure making small molecule Gd(III) complexes thereby eliminating a manipulation step in preparation of the macromolecular dendrimer molecules while also ensuring full saturation of all of the conjugated chelates with Gd(III) to simultaneously eliminate an entire array of product distribution mixture. The PAMAM generation 4 dendrimer (G4D) with amine surface groups ($-NH_2$) is a convenient building block or core for the conjugation of metal chelates, and the G4D Gd(III) chelate conjugate is known to have moderate blood circulation time and relatively fast excretion via the kidney (*18*).

In order to validate the agent, the molar relaxivity of the generation 4 1B4M-DTPA Gd(III) conjugate (G4-(1B4M-Gd)$_{30}$(CS)) was determined for comparison to the analogous generation 4 dendrimer-based agent, G4-(1B4M)$_{60}$[Gd$_{42}$](CS), prepared in our laboratory using the previously established published synthesis route (*18*). Additionally, sets of mice (n = 2) were imaged with both G4-(1B4M-Gd) $_{30}$(CS) or G4-(1B4M)$_{60}$[Gd$_{42}$](CS) to establish what impact, if any, elimination of the vacant chelators on the exterior of the dendrimer product has on the quality of MR imaging.

EXPERIMENTAL SECTION

Materials and Methods. PAMAM dendrimer generation 4 (G4 dendrimer) with an ethylenediamine core in MeOH (10% w/v) was obtained from Dendritech. Gadolinium nitrate pentahydrate ($Gd(NO_3)_3 \cdot 5H_2O$) was purchased from Aldrich (St. Louis, MO). G4-(1B4M)$_{60}$[Gd$_{42}$](CS) prepared and purified as previously reported was employed in these studies (*18*). Phosphate buffered saline (1× PBS) at pH 7.4 was obtained from Digene (Gaithersburg, MD). Size exclusion HPLC (SE-HPLC) was performed using a Beckman System Gold (Fullerton, CA) equipped with model 126 solvent delivery module and a model 168 UV detector (λ 254 and 280 nm) controlled by 32 Karat software. Size exclusion chromatography was performed on a TSK-gel G2000SW 6 μm, 7.8 mm × 300 mm (Tosoh Bioscience, Montgomeryville, PA), with a TSK-gel 10 μm guard column (Tosoh Bioscience, Montgomeryville, PA) using phosphate buffered saline (1× PBS) solution as the eluent at 0.5 mL/min and 1.0 mL/min, respectively. Reverse-phase HPLC was performed by using a Beckman System Gold HPLC equipped with 165 UV−vis detector with peak detection at 254 and 280 nm and a C_{18} Varian microsorb-mv column (250 × 4.6 mm; 5 um). A gradient system composed of a pH 9.0 buffer (50 mM triethylamine/acetic acid) and methanol (25 min linear gradient from 0% to 100% methanol) with a flow rate of 1 mL/min was employed. All water used was purified using a Hydro Ultrapure Water Purification system (Rockville, MD). The Sephadex G-25 resin was purchased from Pharmacia (Sweden). The resin was pretreated with 1× PBS and loaded to a Pharmacia Biotech column 2.6 × 39.7 cm (Uppsala, Sweden). Elemental analyses were performed by Galbraith Laboratories, Inc. (Knoxville, TN) using combustion analysis method for C, H, and N and inductively coupled plasma-atomic emission spectroscopy (ICP-OES) method for determining the S and Gd. The Bio-Rad's gel filtration standard used to compare the molecular weight of the dendrimer conjugate was purchased from Bio-Rad (Hercules, CA).

Syntheses. *2-(4-Nitrobenzyl)-6-methyl-diethylenetriaminepentaacetic acid·5HCl.* The HCl salt of the bifunctional ligand, 2-(4-nitrobenzyl)-6-methyl-diethylenetriaminepentaacetic acid, **1B4M** from this point on, was prepared as previously described with a brief modification (*20*). Briefly, the pentaester form of the ligand (8.1 g, 9.8 mmol) was treated with HCl (g) saturated 1,4-dioxane (600 mL), and the mixture was stirred for 18 h. The product was precipitated with ethyl ether (400 mL), filtered, and dried to afford a whitish solid (4.8 g, 90%). (See the reference for NMR data.) ESI *m*/*e*: 543 (M+1). Calcd for $C_{22}H_{30}N_4O_{12} \cdot 5HCl$: C, 36.44; H, 4.83; N, 7.72. Found: C, 36.57; H, 5.05; N, 7.89.

*2-(4-Nitrobenzyl)-6-methyl-diethylenetriaminepentaacetic Acid Gadolinium Complex (p-NO$_2$-1B4M-[Gd] (**1**).* 1B4M·5HCl ligand (0.50 g, 0.69 mmol) and $Gd(NO_3)_3 \cdot 5H_2O$ (0.31 g, 0.72 mmol) in 20 mL MeOH were refluxed for 6 h. The solvent was reduced to 1.5 mL, and CH_2Cl_2 was added until a precipitate formed. The supernatant was decanted and the solid was dried. The precipitation process was repeated one more time to yield a pale yellow solid (0.65 g, 80%). ESI *m*/*e*: 700 (M+1). Reverse-phase HPLC t_R = 13.77 min. Calcd for $C_{22}H_{30}N_4O_{12}Gd \cdot 3NO_3 \cdot 5HCl \cdot 2CH_3OH$: C, 25.33; H, 3.78; N, 8.62. Found: C, 25.21; H, 3.67; N, 8.67.

*2-(4-Aminobenzyl)-6-methyl-diethylenetriaminepentaacetic Acid Gadolinium Complex (p-NH$_2$-1B4M-[Gd] (**2**).* A solution of compound **1** (0.50 g, 0.42 mmol) and 10% Pd/C (0.10 g) in H_2O (10 mL) was placed in a Parr hydrogenator at 15 psi. The reaction was allowed to go until the consumption of H_2 gas was completed (~3 h), which was confirmed by HPLC. The mixture was filtered on a glass frit through a pad of Celite (Celite 535 Coarse; Fluka) and washed with H_2O (20 mL). The solvent was evaporated under high vacuum to afford amine **2** (0.41 g, 87%) as a yellowish solid. ESI *m*/*e*: 670 (M+1). Reverse-phase HPLC t_R = 11.32 min. Calcd for $C_{22}H_{32}N_4O_{10}Gd \cdot 3NO_3 \cdot 5HCl$: C, 25.44; H, 3.57; N, 9.44. Found: C, 25.32; H, 3.59; N, 9.57.

*2-(4-Isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic Acid Gadolinium Complex (SCN-1B4M-[Gd] (**3**)).* A solution

of 0.5 mL of thiophosgene in CH_2Cl_2 (3 mL) was added dropwise into a solution of **2** (1.0 g, 0.96 mmol) in H_2O (5 mL). The mixture was continued to stir for 1 h. The aqueous was separated and washed with CH_2Cl_2 (5 mL) and dried to afford compound **3** as a yellow solid (0.81 g, 75%). ESI *m*/*e*: 712 (M+1). Reverse-phase HPLC t_R = 19.17 min. Calcd for $C_{23}H_{30}-N_4SO_{10}Gd\cdot 3NO_3\cdot 5HCl\cdot 2H_2O$: C, 24.69; H, 3.67; N, 8.77. Found: C, 24.61; H, 3.65; N, 8.78.

Conjugation of G4 with **3** *- (G4-(1B4M-Gd)$_{30}$(CS)).* G4 PAMAM dendrimer (1.34 g, 0.0145 mmol; 15.35% w/w) in a 500 mL round-bottom flask was dried under vacuum to remove MeOH. The flask was charged with 350 mL 1× conjugation buffer with EDTA (0.48 M $NaHCO_3$ + 0.02 M Na_2CO_3 + 1.5 M NaCl + 0.005 M EDTA) (pH ~ 8.5) (250 mL). Compound **3** (1.51 g, 1.85 mmol) was added in portions while the pH was adjusted to 8.5 with 1 M NaOH. The mixture was stirred at room temperature for 5 d and 35 °C for 1 d. The solution was cooled to room temperature and filtered. The solvent was reduced under high vacuum to ~30 mL at room temperature. The dendrimer chelate was purified by a Sephadex G-25 column eluted with water (pH 7.5; the pH was adjusted with NaOH). The first band was collected and lyophilized to yield the conjugate as a yellow spongy solid (65% based on dendrimer). SE-HPLC t_R = 14.0. Calcd for $C_{622}H_{1250}N_{250}O_{125}\cdot 30(C_{23}H_{30}N_4SO_{10}Gd)\cdot 49Na\cdot 50H_2O$ [G4-(1B4M-Gd)$_{30}$(CS)$Na_{49}(H_2O)_{50}$]: 41.01 (C), 5.87 (H), 13.51 (N), 2.50 (S), 12.29(Gd). Found: 40.77, 5.94, 13.79, 2.49, 12.03.

Molar Relaxivity Measurements. The molar relaxivity of G4-(1B4M)$_{60}$[Gd_{42}](CS) was measured as reported elsewhere (*18*). Stock solutions of the G4 dendrimer agents, G4-(1B4M-Gd)$_{30}$ (5.0 Mm in Gd), were diluted to concentrations of 0.1, 0.25, 0.50, 0.75, and 1.0 mM in 1× PBS (300 μL). Solutions of Gd(III)-DTPA (Magnevist) at 0.25, 0.50, 0.75, 1.0, 1.25, 1.5, and 2.0 mM were prepared in 1× PBS (300 μL) and used as a reference standard. Relaxivity measurements were obtained at ~22 °C using a 3-T clinical scanner (Signa Excite, GE Medical System, Waukesha, WI) equipped with a rectangular single-loop receiver coil (84 × 126 × 6 mm^3). A series of single-slice 2D inversion recovery (IR) fast spin−echo images of all the solutions were acquired at the same time with a TE around 9 ms and using different inversion recovery times (TI = 50, 100, 350, 750, 1250, 2500, and 5000 ms) followed by a single-slice 8-echo SE image (TE = 9 ms). The R_1 values for each dilution were determined by fitting ROI intensity values from variable IR images using Igor Pro (http://www.wavemetrics.com). R_2 values were measured from ROI values from T_2 maps, which were calculated from the multiecho images in *ImageJ* (http://rsb.info.nih.gov/ij) using the MRI analysis plug-in (http://rsb.info.nih.gov/ij/plugins/mri-analysis.html). The molar relaxivities, r_1 and r_2, were obtained from the slope of $1/T_1$ or $1/T_2$ vs [Gd(III)] plots determined from region of interest measurements.

***In Vivo* Magnetic Resonance Imaging (MRI).** Mice were imaged two at a time to increase throughput using a 3T clinical scanner (Achieva, Philips Healthcare, Best, Holland) equipped with a dual mouse coil comprising two parallel receive-only coils (saddle-shaped Helmholtz coils, 38 mm in diameter × 70 mm in length) connected to independent receiver channels and spaced 43 mm apart. Each mouse was placed in a physical restraint while a catheter line (30 gauge needle on a 0.010 in i.d. × 6 in long Tygon tubing) filled with 1× PBS was inserted into the tail vein, anesthetized using gas mixtures of 3% isoflurane in O_2, and then carefully placed in a mouse bed equipped with a nose cone, respiratory pad, and fiber optic temperature sensor for physiology monitoring. The mice were positioned in the dual mouse coil which was heated with air to maintain the mice at 34 °C. The anesthesia gas was adjusted between 1.5% and 2.5% isoflurane to maintain a respiration rate of ~30 bpm during the acquisition of all images. After acquiring a triplanar gradient echo survey, a coronal-view T_1-weighted 3D-fast spoiled gradient echo image with a low flip angle (repetition time of 14 ms, echo time of 2.4 ms, flip angle of 8°, field of view of 80 mm, matrix size of 512 × 512 pixels, 40 slices, slice thickness of 0.6 mm and 1 average; scan time of 2.3 min) was acquired, followed by a dynamic series using a higher flip angle of 24° repeated every 2.5 min for 1 h. The contrast agent was injected (50 μL of 12 mM Gd(III) in 1× PBS pushed with 50 μL of 1× PBS) after the first dynamic image at a rate of 150 μL/min using a syringe pump (BS-9000-8, Braintree Scientific, Braintree, MA). Blood clearance rates were determined from ROI intensity measurements of the jugular vein in the low flip angle image and high flip angle dynamic images using *ImageJ*. The intensity values during the dynamic scans were then converted to gadolinium concentration, and the resulting [Gd] time curves were fitted to a single exponential function using an Igor Pro (Wavemetrics) macro.

RESULTS AND DISCUSSION

The preparative scheme leading to the formation of the title conjugate G4-(1B4M-Gd)$_{30}$(CS) is shown in Figure 1. The Gd(III) complex **1** was prepared by treatment of the ligand 1B4M with $Gd(NO_3)_3\cdot 5H_2O$ in methanol. Complex **1** could also be prepared by incubation of the ligand with $Gd(NO_3)_3\cdot 5H_2O$ in H_2O with the pH maintained at 5.5, but preparation of the Gd(III) complex in methanol was chosen as a more convenient route, especially for ligands that have limited solubility in water. Previous studies showed that complexes formed in methanol were stable (*21*, *22*). ESI-MS spectrum of the predominant ion for the three complexes showed the presence of carboxylate arm protons. This is in line with the ESI-MS data reported for the commercially available products such as $Gd(DTPA)^{-2}$ and $Gd(DOTA)^{-1}$ (*23*). Other authors have also reported ESI-MS data of lanthanide complexes with numbers of carboxylate protons ranging from 1 to 3 (*24*−*26*). This observation might be due to the nature of the initial electrostatic interaction, instead of covalent bonding, between the cationic metal ion and the anionic carboxylate ion, however having protonated complexes is not unreasonable. Additionally, the complex was isolated as the HCl salt as the starting ligand was in the HCl form also with nitrate as the counterion for the metal ion. Nitrate is known to be a better counterion for lanthanide ions than chloride (*27*−*29*). Lastly, for all the complexes the amount of the free metal ion determined by the UV/vis spectroscopic method was 0.002% (0.2 μM/10 mM) of the total (*30*). Indeed, if one examines the synthesis of the DTPA[Gd(III)] complex directly from DTPA and Gd_2O_3, this route produces a diprotonated complex that requires the addition of 2 equiv of base to make this complex physiologically acceptable (*31*).

For the purpose of comparison, the Gd(III) complex was formed in methanol by refluxing the ligand and the metal salt in the presence of 7 equiv of a solid base (NaOH) for 18 h. The Gd(III) complex was also formed under aqueous condition as previously reported (*26*). The ESI-MS data of both complexes indicated the presence of the complex with two fewer protons (697). However, these two latter complexes were also less stable than that formed in methanol alone. As soon as thiophosgene in CH_2Cl_2 was added to form complex **3** (for the third step), an insoluble precipitate formed when using the Gd(III) complexes formed by the latter means. This result was not observed for the complex formed in methanol without base. The reason for that behavior may reside with those carboxylic acid protons or the fact that the complex is protonated. Once deprotonated by base, the complex becomes vulnerable to attack by acidic

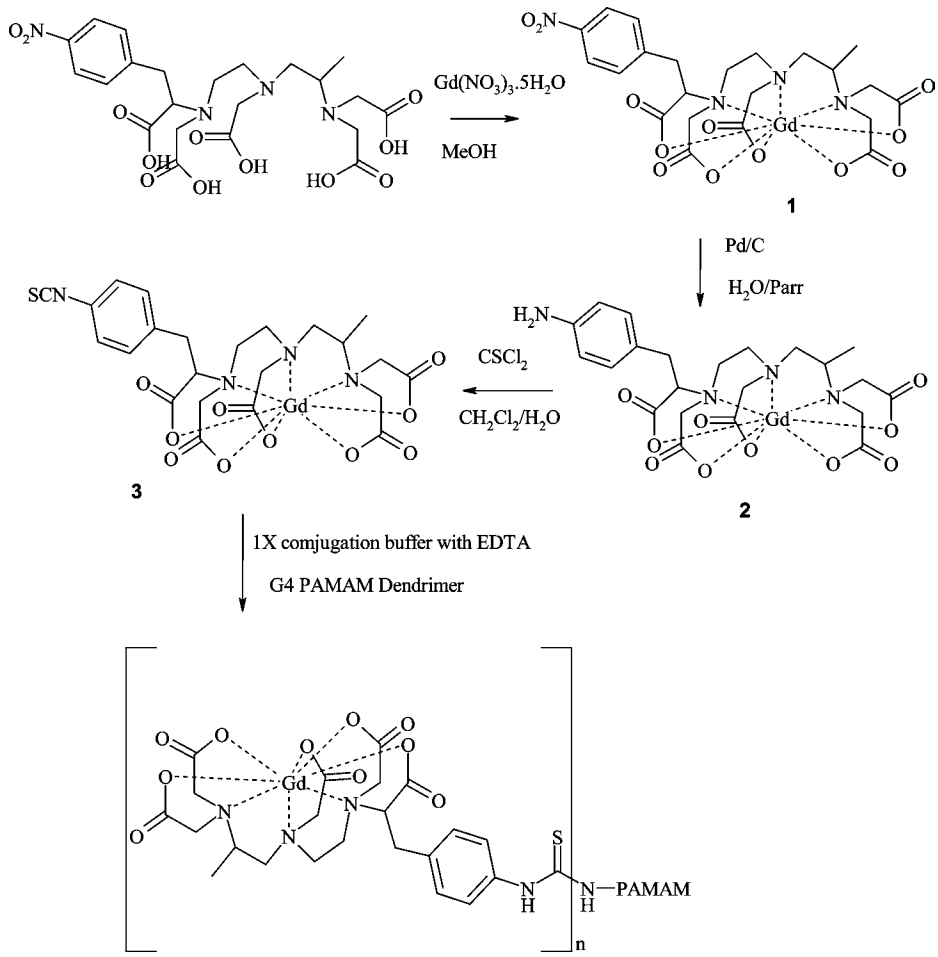

Figure 1. Synthetic scheme of the G4-(1B4M-Gd)$_{30}$(CS).

protons generated by the thiophosgene reaction that could perturb the M−O coordination and cause the metal to dissociate; a protonated complex eliminates this problem. It is also worth noting that the reaction with thiophosgene brought the pH of the solution down to ∼2. For that very reason, we chose to form the complex in methanol without a base. A full and thorough comparative study of the fundamental coordination chemistry of these three complexes will be reported in due course.

The reduction of the nitro group to amine was done using a Parr hydrogenator at 15 psi within a short period of time (∼3 h). The ESI-MS and combustion analysis data did not indicate any sign of the cleavage of the nitrobenzyl group (over-reduction product) or any dissociation of the metal ion from the ligand cavity. For preparation of complex **3**, a mixture of thiophosgene in dichloromethane was added dropwise, and the reaction was allowed to stir for 1 h thereafter, which was sufficient to complete the reaction. This also limits the exposure of the metal complex to low pH (1−2) over an extended period of time, which might induce the dissociation of the Gd(III) from the complex.

The conjugation reaction was done in 1× conjugation buffer (see Experimental Section) with EDTA at pH of 8.5. EDTA was used to sequester the free metal ion (Gd^{3+}), in case it dissociates from the chelate, which is rarely the case under this experimental condition. The dendrimer-based conjugate was purified by a Sephadex G-25 column. This method proved to be more efficient as compared to the exhaustive and time-consuming transverse-flow filtration (TFF) method (*18*). No reasonable MALDI-TOF could be obtained due to extreme broadening of the peak. However, we utilized SE-HPLC to determine the approximate molecular weight of the dendrimer conjugate by comparing with the Bio-Rad gel filtration standard combined with the elemental analysis data. On the basis of the analysis data and the SE-HPLC results, the formula of [G4-(1B4M-Gd)$_{30}$Na$_{49}$(H$_2$O)$_{50}$] was obtained.

To the best of our knowledge, the number of chelates conjugated to dendrimer is sensitive to the method used to append them to the dendrimer. The method used in a previous report to prepare the G4-(1B4M-Gd)$_X$(CS) conjugate, which is under aqueous condition, managed to occupy all of the available sites yielding G4-(1B4M-Gd)$_{64}$(CS)) (*32*). However, a later report, where the conjugation reaction was also done in aqueous condition, but with different buffer, yielded a lower number of chelates (G4-(1B4M$_{60}$-Gd$_{42}$)(CS) (*18*). An even lower number conjugated was achieved when the conjugation reaction was done in methanol followed by the metal chelation under aqueous condition (G4-(1B4M$_{57}$-Gd$_{41}$)(CS)) (*18*). It is worth noting that all these preparations focused on inserting the metal ion (Gd^{3+}) in the final step. In this report, we have inserted the metal ion early on to simplify the solution chemistry and the distribution of the species of the products.

We noticed in these studies that it was not possible to achieve the number of chelates higher than the reported value even in an extended period of time or higher temperature (ca. 45 °C) or even when using large excesses of the Gd(III) complex. On the basis of the number of chelates that we obtained, G4-(1B4M-Gd)$_{30}$(CS)), we hypothesized that the chelate with the metal ion in it may be less soluble and the intermetal or protonated complex interactions might limit the numbers of complexes adjacent to one another, or an equilibrium reaction with the solvent water limits the actual concentration of reactive isothio-

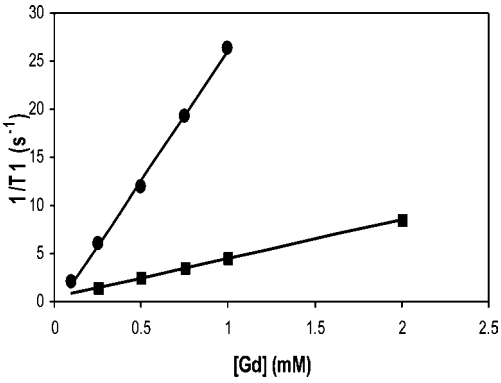

Figure 2. Molar relaxivity plots of G4-(1B4M-Gd)$_{30}$(CS) (•; 26.9 mM^{-1} s^{-1}) and magnevist (■; 4.2 mM^{-1} s^{-1}).

Table 1. Comparison of Results Between G4-(1B4M-Gd)$_{30}$(CS) (A) and G4-(1B4M)$_{60}$[Gd$_{42}$] (CS) (B)

agent	G4:chelate	r_1[a] (mM^{-1} s^{-1})	r_2[a] (mM^{-1}s^{-1})	half life[b] (min)	rate of clearance[c] (min^{-1})
A	1:30	26.9 ± 1.2	56.1 ± 1.4	24.4 ± 4.74	0.029 ± 0.0047
B	1:42	13.9 ± 1.6	33.6 ± 3.1	72.7 ± 17.31	0.010 ± 0.0026

cyanate species present. It is known that the isothiocyanide slowly reacts with water. Nevertheless, the relaxivity of this conjugate prepared by the reported means here is higher than any of the above-mentioned, which is one of the most important factors to be a viable agent. This is clear evidence that higher number of chelates, greater numbers of Gd(III), and thus higher molecular weight does not always translate to higher relaxivity.

Figure 2 shows a plot of inverse longitudinal relaxation time ($1/T_1$) versus gadolinium concentration for G4-(1B4M-Gd)$_{30}$(CS) conjugate (0.1−1 mM) and magnevist (0.25−2 mM). Although G4-(1B4M)$_{60}$[Gd$_{42}$](CS) has a higher dendrimer to metal chelate ratio (1:42), the molar relaxivity of the G4-(1B4M-Gd)$_{30}$(CS) conjugate reported here is almost twice the value reported for the G4-(1B4M)$_{60}$[Gd$_{42}$](CS) (13.9 vs 26.9 mM^{-1} s^{-1}) (Table 1) (*3*, *18*). There are three factors that might have contributed to this higher value. First, the conjugate prepared here does not have any free uncomplexed chelate (chelate without Gd) population of dendrimer conjugation products unlike the former method, G4-(1B4M)$_{60}$[Gd$_{42}$](CS) (Figure 3). This condition eliminates the possibility of a negatively charged carboxylate group from an unoccupied adjacent DTPA to coordinate to the metal ion and thus delete the availability of the water binding site. A reduced number of water-exchangeable sites results in lower relaxivity. A reduced water exchange site through anion binding has been well documented with protein binding (*33*), human serum albumin (*25*), carbonate (*34*), and phosphate (*35*) anions. Second, the conjugate prepared here is more hydrophobic than the G4-(1B4M)$_{60}$[Gd$_{42}$](CS), attributable to the lack of charged noncomplexed chelates. Hydrophobic interaction slows down the tumbling time (τ_R), which results in increasing relaxivity. The rotational correlation time (τ_R) is one of the key parameters contributing to the efficacy of the agent. Such a phenomenon has been reported by Wiener (*11*), Kellar (*36*), and Caravan (*37*). Third, the impact of steric hindrance needs to be taken into consideration, which also contributes to the availability of second sphere water molecules. Because the agent here is not fully saturated, that is, not all the available amino sites (64) are occupied, or lack free noncomplex chelating agents that could either replace

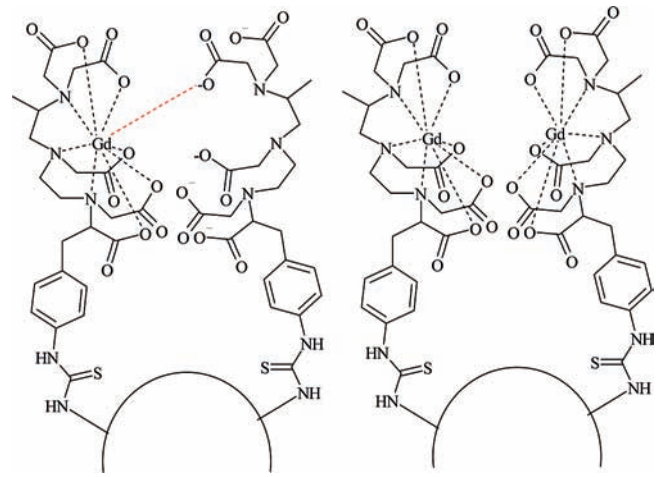

Figure 3. A representation of dendrimers with (left) and without (right) free noncomplexed chelate.

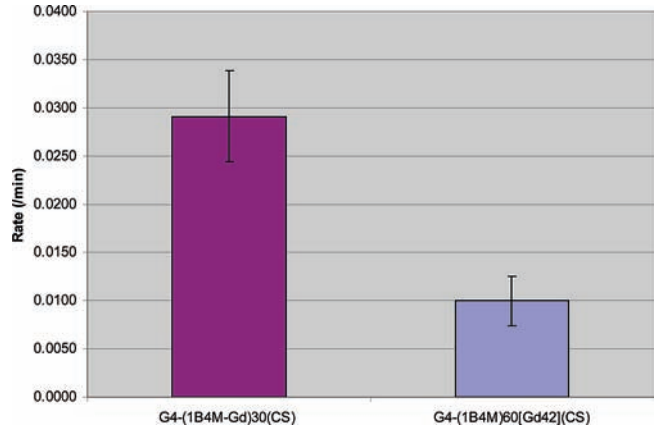

Figure 4. Average blood clearance rates measured at the jugular vein of G4-(1B4M-Gd)$_{30}$(CS) and G4-(1B4M)$_{60}$[Gd$_{42}$](CS).

water binding site or hinder the path of exchanging water molecules, more second-sphere water molecules may be readily available for exchange (*38*). This also helps to explain why previously prepared dendrimer conjugates with high chelate numbers, which are also then more sterically hindered, also have low relaxivity. This is additional evidence that greater numbers of chelates and thus also higher molecular weight may not automatically translate to higher relaxivity.

Table 1 also compares the half-life and rates of clearance between G4(1B4M-DTPA[Gd])$_{30}$(CS) and G4-(1B4M)$_{60}$[Gd$_{42}$]-(CS). The clearance data were fit to a single exponential decay (Figure 4). The rate of clearance of G4-(1B4M)$_{60}$[Gd$_{42}$] (CS) is 2.9 times lower than G4-(1B4M-Gd)$_{30}$(CS). We hypothesize that the agent was cleared mainly through kidneys. The data also indicate that there was a higher tissue uptake for G4-(1B4M-Gd)$_{30}$(CS) that can be useful as a targeting agent. Overall, G4-(1B4M-Gd)$_{30}$(CS) has a faster rate of clearance and a shorter half-life, which is expected for a more positively charged hydrophobic agent. One might be tempted to think that G4-(1B4M-Gd)$_{30}$(CS) is behaving like a small molecule based on the data presented, but the SE-HPLC data clearly indicates that the two agents have about the same size under the same conditions (t_R = 13.2 vs 14.0). This indicates that the charge is the contributing factor in high relaxivity and fast clearance.

Dynamic contrast-enhanced MR images shown in Figure 5 illustrate differences in circulation properties between G4-(1B4M-Gd)$_{30}$(CS) and G4-(1B4M)$_{60}$[Gd$_{42}$](CS). We found that the signal intensity in the kidney increased gradually 10 min after injection due to the high blood flow through this area and

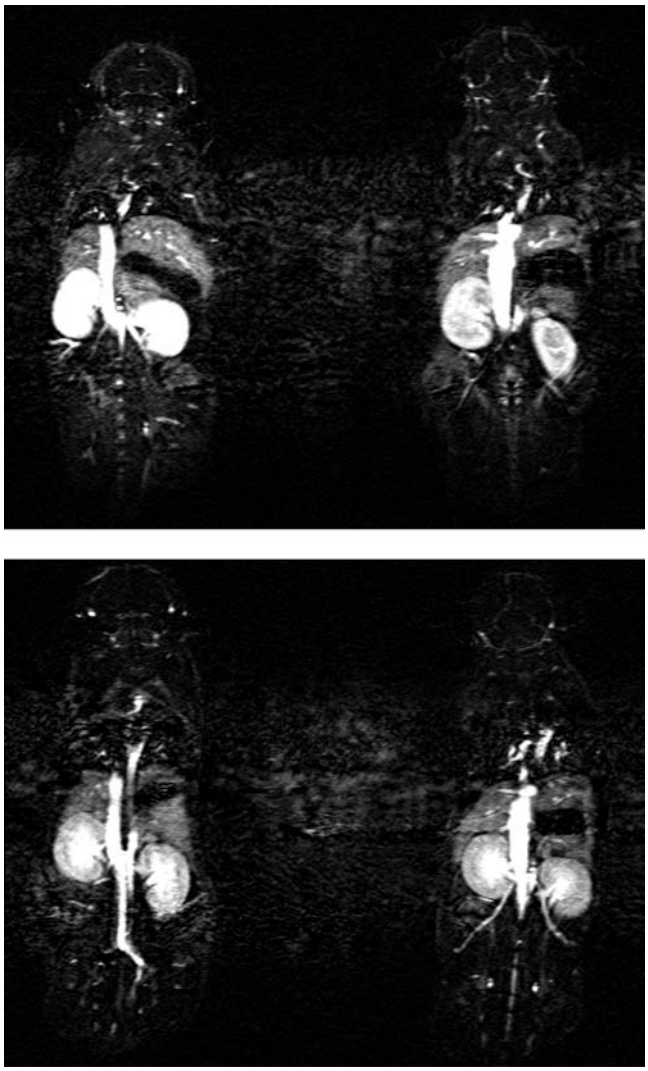

Figure 5. Whole-body 3D-micro-MR images of mice injected with 0.03 mmol/kg of G4-(1B4M-Gd)$_{30}$(CS) (above) and G4-(1B4M)$_{60}$[Gd$_{42}$](CS) (below). Both images were acquired at 30 min postinjection.

fast clearance of the agent. It is also observed that after 40 min postinjection images have no observable signal indicating the total clearance of the agent from the body. The signal intensity is low in kidneys for G4-(1B4M)$_{60}$[Gd$_{42}$](CS) when compared at the same acquisition time. This is expected due to the slow clearance (Table 1) and possible lower tissue uptake.

In conclusion, we herein report an improved synthesis to prepare PAMAM G4 dendrimer-based MR contrast agents, which features full saturation of all of the conjugated chelates with Gd(III) by using preformed Gd(III) complexes as reagents. This better defined chemistry provides less complex products compared to our established published syntheses, which routinely had formed the chelating agent dendrimer conjugate first, followed by addition of Gd(III). We believe that this new chemistry will strengthen the potential of translating these dendrimer-based MR agents into clinical trials by simplifying characterization as quality control issues pertaining to the production of such agents for clinical use as MR contrast agents.

Received October 10, 2008; Revised Manuscript Received December 10, 2008

Hemoglobin (Hb, Mw: 64 500) and albumin (Mw: 66 500) are major protein components in our circulatory system. On the basis of bioconjugate chemistry of these proteins, we have synthesized artificial O_2 carriers of two types, which will be useful as transfusion alternatives in clinical situations. Along with sufficient O_2 transporting capability, they show no pathogen, no blood type antigen, biocompatibility, stability, capability for long-term storage, and prompt degradation in vivo. Herein, we present the latest results from our research on these artificial O_2 carriers, Hb-vesicles (HbV) and albumin−hemes. (i) HbV is a cellular type Hb-based O_2 carrier. Phospholipid vesicles (liposomes, 250 nm diameter) encapsulate highly purified and concentrated human Hb (35 g/dL) to mimic the red blood cell (RBC) structure and eliminate side effects of molecular Hb such as vasoconstriction. The particle surface is modified with PEG-conjugated phospholipids, thereby improving blood compatibility and dispersion stability. Manipulation of physicochemical parameters of HbV, such as O_2 binding affinity and suspension rheology, supports the use of HbV for versatile medical applications. (ii) Human serum albumin (HSA) incorporates synthetic Fe^{2+}porphyrin (FeP) to yield unique albumin-based O_2 carriers. Changing the chemical structure of incorporated FeP controls O_2 binding parameters. In fact, PEG-modified HSA-FeP showed good blood compatibility and O_2 transport in vivo. Furthermore, the genetically engineered heme pocket in HSA can confer O_2 binding ability to the incorporated natural Fe^{2+}protoporphyrin IX (heme). The O_2 binding affinity of the recombinant HSA (rHSA)-heme is adjusted to a similar value to that of RBC through optimization of the amino acid residues around the coordinated O_2.

1. INTRODUCTION

Transfusion of donor blood is currently an indispensable routine procedure in modern medical treatments because the risk of transmission of viral illness has became extremely low. Nevertheless, this level of safety has been achieved at great cost and hepatitis virus or unknown pathogens cannot be excluded completely, even by the nucleic acid amplification test (NAT) system. Furthermore, the transfusion of donor blood necessitates cross matching and compatibility tests to avoid a hemolytic reaction in the recipient, and the donated red blood cells (RBCs) must be refrigerated at 4 °C (up to 3 weeks in Japan). These requirements limit the availability of blood transfusion in disaster or emergency situations.

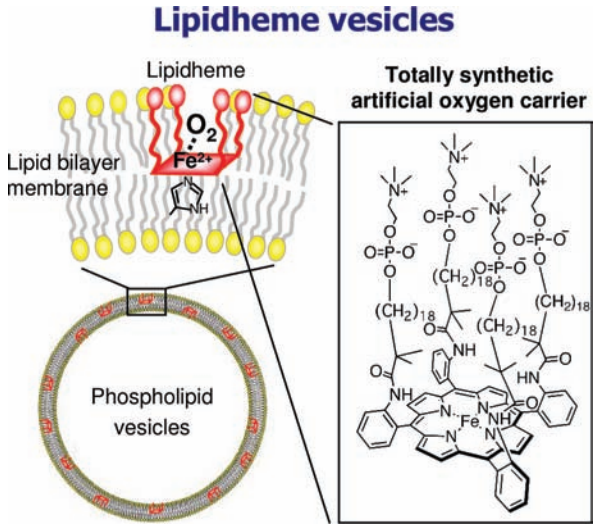

Figure 1. Lipidheme phospholipid vesicles as a totally synthetic artificial O_2 carrier (*7*).

During the past several decades, various artificial O_2 carriers have been synthesized and studied for as RBC substitutes by many scientists in the fields of organic chemistry, inorganic chemistry, biochemistry, and polymer chemistry. These O_2 carriers are classified as perfluorocarbon-based materials, synthetic Fe^{2+}porphyrin-based materials, and Hb-based materials. In this review, we highlight recent developments of our research related to RBC substitutes of the latter two types.

Actually, Hb consists of four polypeptide chains (globin proteins), each of which has an Fe^{2+}protoporphyrin IX (heme) as a prosthetic group. The globin chain forms a compact globular conformation; the heme group is incorporated into the hydrophobic pocket with an axial coordination of histidine (*1*). On exposure of the Hb solution to O_2, the heme forms a stable O_2 adduct complex. However, if the heme is eliminated from the globin wrapping, the heme complex is oxidized immediately and irreversibly to its Fe^{3+} state by proton-driven oxidation or μ-oxo dimer formation (*2*). In the 1970s and 1980s, much research was directed to mimic the O_2 carrier by synthesizing substituted porphyrin derivatives. In aprotic solvents, the proton-driven oxidation is excluded completely. Therefore, the remaining problem is how to suppress irreversible oxidation via dimerization. One successful approach was steric modification of porphyrin. Some superstructured Fe^{2+}porphyrins were prepared using an elegant organic synthesis technique (*2*−*4*). In particular, Collman reported that the tetrakis(α,α,α,α-*o*-pivalamido)phenylporphinatoiron complex with 1-methylimidazole can reversibly bind O_2 in benzene at room temperature (*5, 6*). Nevertheless, these synthetic porphyrins were all oxidized irreversibly in aqueous media.

To create a hydrophobic environment in water, it is possible to use a bilayer membrane of a phospholipid vesicle instead of globin protein. In 1983, we synthesized an amphiphilic Fe^{2+}porphyrin having four alkylphosphocholine groups (lipidheme), which is efficiently embedded into the bilayer of the phospholipid vesicle to yield a homogeneous hybrid. This lipidheme/phospholipid vesicle can bind and release O_2 under physiological conditions (Figure 1) (*7*−*9*). The 10 mM lipidheme/phospholipid vesicle solution dissolves 29 mL O_2/dL compared to 27 mL/dL of human blood. Subsequent to that finding, we synthesized over 60 lipidheme molecules. A new lipidheme having four dialkyl-*sn*-glycerophosphocholine groups is self-organized in water to form self-assembled porphyrin bilayer vesicles without phospholipid (*10*). Furthermore, in 1995, we found that synthetic Fe^{2+} porphyrin bearing a covalently linked proximal base (FeP**1**) is incorporated into human serum albumin (HSA) and the obtained HSA-FeP**1** hybrid coordinates O_2 in aqueous medium (*11*).

In 1985, we began the study of Hb-based O_2 carriers using purified human Hb aiming at the beneficial utilization of outdated RBC to support the present blood donation−transfusion system. This project has been supported for a long time by Japanese Red Cross Society and Ministry of Health and Welfare, Japan. On the basis of a fundamental concept that the cellular structure of RBC is necessary for O_2 transport in the bloodstream, we designed the phospholipid vesicle encapsulating Hb: the so-called Hb-vesicle. It has to be emphasized that the Hb-vesicle comprises a concentrated Hb solution and four kinds of natural and synthetic lipids that assemble to form a hierarchical corpuscle structure (molecular assembly) through the well-regulated secondary interactions, such as hydrophobic and electrostatic interactions. To date, chemically modified Hb of several types have been developed as RBC substitutes or O_2 therapeutic reagents. Herein, we review the latest developments of our research into Hb-vesicles and albumin−hemes.

2. HEMOGLOBIN VESICLES THAT MIMIC THE RBC CELLULAR STRUCTURE

2.1. Physiological Importance of Cellular Structure of RBC for Encapsulated Hb Design. Historically, stroma-free Hb isolated from RBCs were tested as a principal material for carrying O_2. However, the plasma retention time of stroma-free Hb is particularly short (half-life of 0.5−1.5 h) because of the dissociation of the Hb tetramer ($\alpha_2\beta_2$; Mw, 64 500; 6.5 nm diameter) into dimers ($2\alpha\beta$), which are subsequently filtered by the kidney (*12*). Cell-free Hb-based O_2 carriers have been developed to overcome the problems of stroma-free Hb through chemical modification, "bioconjugation", of Hb molecules (Figure 2). They include intramolecularly cross-linked Hb (DCLHb) to prevent dimerization, recombinant cross-linked Hb produced by *E. coli*, polymerized Hb using glutaraldehyde or other cross-linkers, and polymer-conjugated Hb such as PEG-conjugated Hb and polysaccharide-conjugated Hb (*13*−*21*). During the long history of the development of cell-free Hb-based O_2 carriers (HBOCs), the many side effects of stroma-free Hb and chemically modified Hbs have been well-documented: renal toxicity; entrapment of gaseous messenger molecules (NO and CO) inducing vasoconstriction, hypertension, reduced blood flow, and reduced tissue oxygenation at microcirculatory levels (*22*−*25*); neurological disturbances; malfunction of esophageal motor function (*18*); myocardial lesions (*26, 27*); and death (*28*). These side effects of Hb molecules underscore the importance of the large dimension of HBOCs or the RBC cellular structure. Retrospective and recent observations have indicated the main justifications for Hb encapsulation in RBCs: (i) a decreased high colloidal osmotic pressure (*15*); (ii) prevention of the removal of Hb from blood circulation; (iii) prevention of direct contact of toxic Hb molecules and the endothelial lining (*29*); (iv) retardation of reactions with endogenous NO and CO (*24, 25, 30, 31*) (Figure 3); (v) preservation of the chemical environment in cells, such as the concentration of phosphates (2,3-DPG, ATP, etc.) and other electrolytes; (vi) RBCs are the major component that renders blood as non-Newtonian and viscous, which is necessary to pressurize the peripheral artery for homogeneous blood distribution and for maintenance of blood circulation (*32*); (vii) the RBC cellular structure retards O_2-release in comparison to acellular Hb solutions (*33, 34*), thereby retaining O_2 to peripheral tissues where O_2 is required. For those reasons, the optimal structure of Hb-based O_2 carriers might be to mimic the RBC cellular structure.

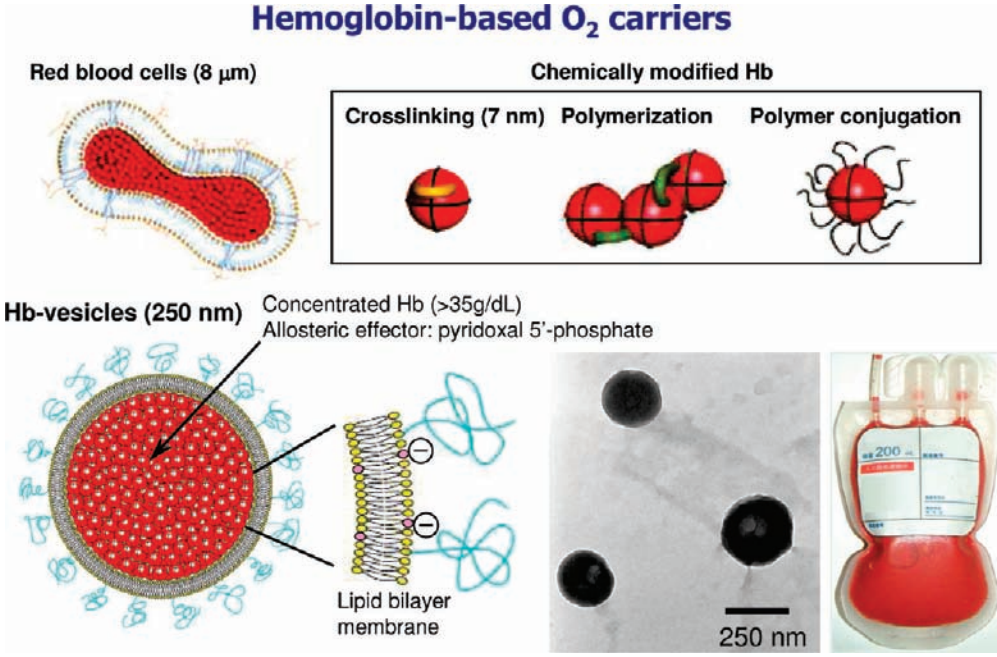

Figure 2. Schematic representation of a series of Hb-based O_2 carriers. Cross-linked Hb, polymerized Hb, and polymer-conjugated Hb are based on the chemical modification of Hb molecules (chemically modified Hbs). In the case of Hb-vesicles, a purified and concentrated Hb solution (35 g/dL) is encapsulated in phospholipid vesicles and the surface is modified using PEG chains. The particle size is well-regulated at 250 nm.

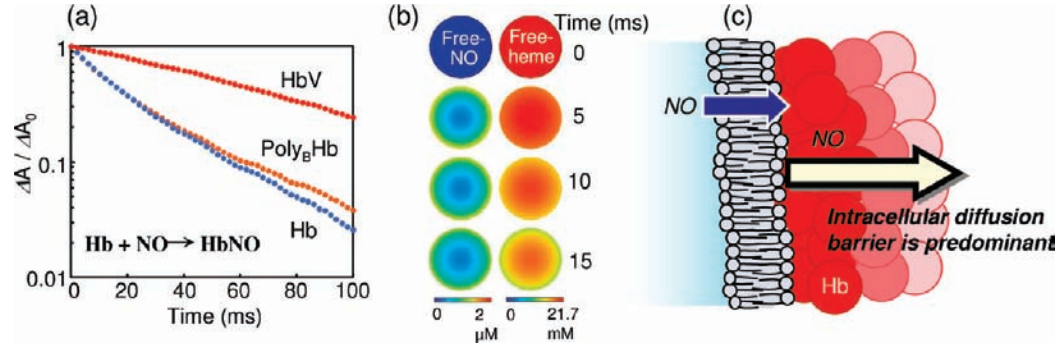

Figure 3. Encapsulation of Hb in vesicles retards NO binding. (a) Time courses of NO binding with HbV, human Hb with PLP (Hb/PLP = 1:2.5 by mol), and polymerized bovine Hb (Poly$_B$Hb) observed by stopped-flow rapid scan spectrophotometry. The level of reaction was plotted on a semilogarithmic graph as a ratio of absorption at 430 nm (ΔA) at time t, to the initial absorption (ΔA_0) at time 0. NO-bubbled PBS ([NO] = 3.8 μM) and deoxygenated-Hb-containing solutions in PBS ([heme] = 3.0 μM) were mixed (*31*). (b) Schematic two-dimensional representation of the simulated time courses of distributions of unbound free NO and unbound free heme in one HbV (250 nm). Both free NO and unbound hemes are distributed heterogeneously. The concentration changes gradually from the surface to the core, indicating formation of the intracellular diffusion barrier (*30*). (c) The phospholipid bilayer membrane cannot have any barrier function to gas diffusion. The determinant factor of retardation of NO-binding should be the intracellular diffusion barrier, which was induced by (i) intrinsically larger binding rate constant of NO to a heme in an Hb molecule, (ii) numerous hemes as sites of gas entrapment at a higher Hb concentration, (iii) a slowed gas diffusion in the intracellular viscous Hb solution, and (iv) a longer gas diffusion distance in a larger capsule.

In 1957, Chang performed the pioneering work of Hb encapsulation to mimic the cellular structure of RBCs (*35*); microcapsules (5 μm) were prepared using nylon, collodion, and other materials. Toyoda in 1965 (*36*) and the Kambara−Kimoto group in 1968 (*37*) also investigated encapsulation of Hbs with gelatin, gum arabic, silicone, and so forth. Nevertheless, results emphasized the extreme difficulty of regulating the particle size to be appropriate for blood flow in the capillaries and to obtain sufficient biocompatibility. After Bangham and Horne reported in 1964 (*38*) that phospholipids assemble to form vesicles in an aqueous medium and encapsulated water-soluble materials in their inner aqueous interior (*39*), it seemed reasonable to use such vesicles for Hb encapsulation. Djordjevich and Miller in 1977 (*40*) prepared liposome-encapsulated Hb (LEH) composed of phospholipids, cholesterol, fatty acids, and so forth. The US Naval Research Laboratories and collaborators demonstrated remarkable progress in the use of LEH (*41*−*43*). Terumo Corp. (Tokyo) developed different LEH, so-called Neo Red Cells (*44*, *45*) (Table 1).

However, some intrinsic issues of encapsulated Hbs remained, which were related mainly to the nature of molecular assembly and particle dispersion. What we call Hb-vesicles (HbV), with their high-efficiency production processes and improved properties, were established by our group based on technologies of molecular assembly in concert with precise analyses of their pharmacological and physiological aspects (*46*−*48*) (Tables 2 and 3). We use stable carbonylhemoglobin (HbCO) for purification with pasteurization at 60 °C for 10 h. The purity of the obtained Hb solution is extremely high (*49*, *50*). Use of the stable and purified HbCO enables concentration of the Hb solution to more than 40 g/dL using ultrafiltration and easy handling of Hb encapsulation using the extrusion method,

Table 1. List of Representative Liposome-Encapsulated Hbs (LEH) Extensively Studied Aiming at Industrialization and Other Potential Encapsulated Hbs Using Biodegradable Polymers

product name	group	characteristics	current status
Hb vesicles (HbV)	Waseda Univ. and Keio Univ.	1. Pasteurization of HbCO at 60 °C for virus inactivation 2. Lipid composition to improve blood compatibility 3. PEG modification and deoxygenation for 2 yr storage 4. [Hb] = 10 g/dL	preclinical
Neo Red Cells (NRC)	Terumo Corp.	1. Inositol hexaphosphate to regulate P_{50} (= 40−50 Torr) 2. Lipids: HSPC/cholesterol/fatty acid/PEG-lipid 3. Storage in a refrigerator for 6 months 4. [Hb] = 6 g/dL	preclinical
artificial red cells (ARC)	NOF Corp. and Waseda Univ.	1. Polymerized lipids (DODPC) for stabilization 2. Storage in powdered or frozen state 3. Difficulty in degradation in RES	suspended
liposome-encapsulated Hb (LEH)	US Naval Research Laboratory	1. Freeze-dried powder with trehalose 2. Low Hb encapsulation efficiency 3. Thrombocytopenia, complement activation	suspended
synthetic erythrocytes	Rush-Presbyterian-St. Luke's Medical Center, Univ. Illinois	1. The first attempt of LEH	suspended
Hb-loaded particles (HbP)	East China Univ. of Science and Technology	1. Hb encapsulation by poly(ε-caprolactone) (PCL) and poly(ε-caprolactone-ethylene glycol) (PCL-PEG) 2. Double emulsion and solvent diffusion/evaporation method 3. Biodegradable	basic study
polymersome-encapsulated Hb (PEH)	The Ohio State Univ.	1. Self-assembly of amphiphilic diblock copolymers composed of poly(ethylene oxide) (PEO), poly(caprolactone) (PCL), and poly(lactide) (PLA) 2. Biodegradable and biocompatible	basic study

Table 2. Physicochemical Characteristics of Hb Vesicles

parameter	
particle diameter	250−280 nm
P_{50} (O_2)[a]	25−28 Torr
[Hb]	10 g/dL
[heme]	6.2 mM
[metHb]	<3%
[HbCO]	<2%
suspending medium	physiologic saline solution (0.9% NaCl)
colloid osmotic pressure	0 Torr
intracellular Hb concentration	ca. 35 g/dL
lipid composition	DPPC/cholesterol/DHSG/DSPE-PEG_{5000}
ζ potential[b]	−18.7 mV
weight ratio of Hb to lipids	1.6−1.9 (w/w)
viscosity[c]	3.8 cP
lamellarity	nearly 1
stability for storage at room temperature	>2 years, purged with N_2
circulation half-life	35 h (rats)

[a] Measured with a Hemox Analyzer (pH 7.4, 37 °C). [b] Measured with a Zeta-Sizer Nano ZS ([NaCl] = 20 mM, pH 7.4). [c] Measured with Anton Parr Rheometer M301 (268 s^{-1}, 25 °C).

Table 3. Characteristics of Hb-Vesicles As a Transfusion Alternative

1. Human derived Hb solution is purified rigorously by pasteurization and ultrafiltration. The blood type antigens and pathogens are eliminated for utmost safety.
2. Encapsulation of concentrated Hb solution (>35 g/dL), like RBCs.
3. Small particle size (250 nm) for homogeneous distribution in the plasma phase of circulating blood.
4. Shielding of the side effects of molecular Hbs by the lipid membrane.
5. PEG modification for dispersion stability for long-term storage and in the bloodstream.
6. Surface properties of HbV (PEG, negative charge, etc.) for blood compatibility.
7. Prompt degradation and excretion of the components after entrapment in RES.
8. Sufficient oxygen transporting capacity ([Hb] = 10 g/dL, *cf*, [Hb] of blood = 12−15 g/dL).
9. Physicochemical properties are easily adjustable because of the nature of the "molecular assembly".

without causing Hb denaturation. It has been confirmed that HbV encapsulates nearly 35 g/dL within a thin bilayer membrane. In final processing, CO of HbCO in HbV is photodissociated by irradiation of visible light under an O_2 atmosphere, and it converts to HbO_2 (*51*).

In fact, Hb autoxidizes to form metHb and loses its O_2-binding ability during storage and during blood circulation (*52*−*56*). For that reason, metHb formation must be prevented. A method exists to preserve deoxygenated Hbs in a liquid state from using intrinsic characteristics of Hb: the Hb oxidation rate in a solution is dependent on the O_2 partial pressure; moreover, deoxyHb is not autoxidized at ambient temperatures (*56*). In the case of HbV, not only the encapsulated Hb but also the capsular structure (liposome) must be physically stabilized to prevent irreversible intervesicular aggregation, fusion, and leakage of the encapsulated Hb.

In addition to HbV, new encapsulated Hbs without liposomes have emerged with the use of recent advanced nanotechnologies, such as polymersome (*57*) and PEG-poly(ε-caprolactone) copolymer nanoparticles (*58*). In vivo evaluation of O_2-carrying capacities of these new materials is anticipated. Encapsulation of Hb can reduce the toxicity of cell-free Hbs. However, numerous hurdles must be surmounted to realize encapsulated Hbs because of the components of the capsules themselves and their structural complexity as a molecular assembly. It is also important to consider the larger dosage requirement of encapsulated Hb for blood substitution than those of conventional drug delivery systems, which require no large dosage.

2.2. Structural Stabilization and Destabilization using Polymerization or PEG Conjugation. Liposomes, as molecular assemblies, have generally been characterized as structurally unstable. The US Naval Research Laboratory tested the addition of cryoprotectants and lyoprotectants such as trehalose to LEH for its preservation as a powder without causing hemolysis after rehydration (*59*, *60*). In addition, many researchers have developed stabilization methods for liposomes that use polymer chains (*61*−*64*). Polymerization of phospholipids that contain two dienoyl groups (1,2-dioctadecadienoyl-*sn*-glycero-3-phosphatidylcholine; DODPC) was studied extensively by our group. For example, gamma-ray irradiation induces radiolysis of water molecules and generates OH radicals that initiate intermolecular polymerization of dienoyl groups in DODPC. This method produces remarkably stable liposomes, resembling rubber balls, which are resistant to freeze−thawing, freeze−drying, and rehydration (*65*, *66*). Actually, the polymerized liposomes were so stable that they were not degraded easily in the macrophages,

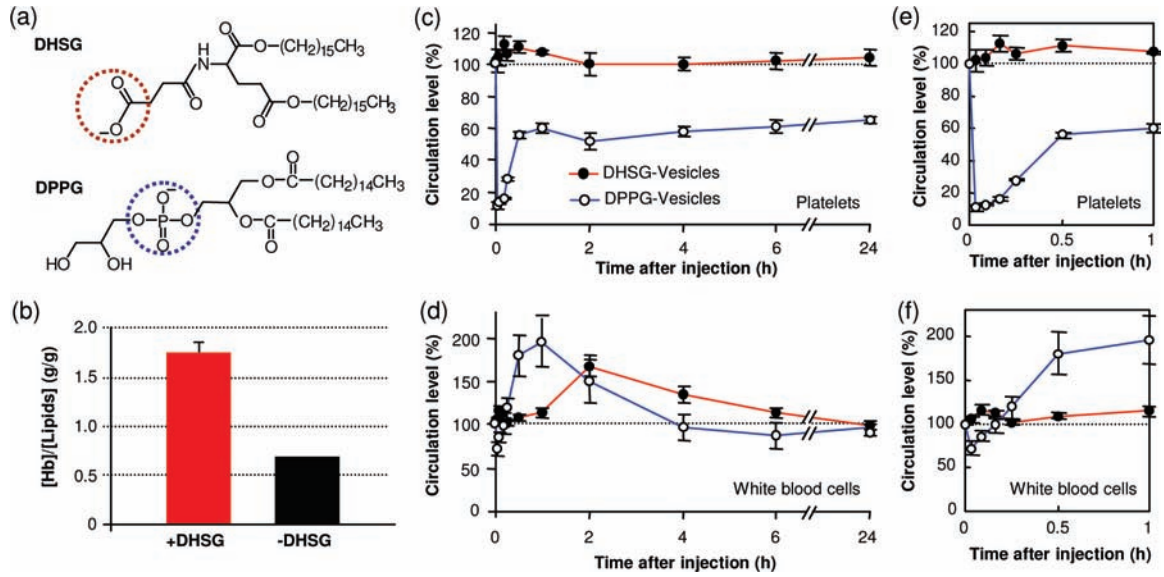

Figure 4. Effect of negatively charged vesicles on encapsulation capability and blood compatibility of HbV. (a) Chemical structures of negatively charged lipids, 1,5-*O*-dihexadecyl-*N*-succinyl-L-glutamate (DHSG) and 1,2-dipalmitoyl-*sn*-glycelo-phosphatidylglycerol (DPPG). (b) Effect of DHSG on encapsulation efficiency of Hb (35 g/dL). (c−f) Circulation levels of platelets (c) and white blood cells (d) after intravenous infusion of vesicles containing 9 mol % DHSG (DHSG-vesicles) or 9 mol % DPPG (DPPG-vesicles) in rats (lipids; 280 mg/kg body weight). The right side graphs show the initial fluctuations in platelets (e) and white blood cells (f).

even 30 days after injection (*67*). It became widely believed that polymerized lipids are inappropriate for intravenous injection because of the difficulty in excretion. Subsequently, it was clarified that selection of appropriate lipids (phospholipid/cholesterol/negatively charged lipid/PEG-conjugated phospholipid) and that their composition is important to enhance the stability of nonpolymerized liposomes (*45, 68*). Surface modification of liposomes with PEG-conjugated lipids is sufficient for dispersion stability (*69*). In fact, in comparison to RBCs, HbV is highly resistant to hypotonic shock, freeze−thawing, and enzymatic attack by phospholipase A_2 (*70*).

We investigated the possibility of long-term preservation of HbV during storage for two years through a combination of deoxygenation and PEG modification (*71*). As little as 0.3 mol % PEG-conjugated lipid stabilizes the dispersion state and prevents aggregation and fusion for two years through steric hindrance (*71*−*73*). The original metHb content (ca. 3%) before preservation decreased gradually to less than 1% after 1 month because of the presence of a reductant, such as homocysteine, inside the vesicles that consumed the residual O_2 and gradually reduced the trace amount of metHb. The rate of metHb formation was strongly dependent on the O_2 partial pressure: a lack of increase in the metHb formation was observed because of the intrinsic stability of the deoxygenated Hb. In fact, the metHb content did not increase for two years. These results suggest the possibility that the HbV suspension can be stored at room temperature for at least two years, which would enable stockpiling of HbV for any emergency.

2.3. Vesicular Surface Modification with PEG and Negative Charges for Blood Compatibility. Liposome is not a solute: it is a particle in a suspension. The particle surface might be recognized, leading to interaction with blood components including complements. The so-called *injection reaction*, or pseudoallergy, results from complement activation, giving rise to anaphylatoxins, which trigger various hypersensitivity reactions. This reaction is observed sometimes not only with liposomal products (*74*), but also with fat emulsions (*75*), and a perfluorocarbon emulsion (*76*). Therefore, examination of blood compatibility of encapsulated Hbs is important for clinical use. Transient thrombocytopenia and pulmonary hypertension in relation to complement activation is an extremely important hematologic effect observed in rodent models after infusion of LEH (containing DPPG: 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylglycerol) developed by the US Naval Research Laboratory (*77, 78*) and other products. In our group, exchange transfusion of prototype HbV (containing DPPG, no PEG modification) in anesthetized rats engendered transient thrombocytopenia and slight hypertension (*79*). Similar effects were also observed for administration of negatively charged liposomes (*80, 81*). The transient reduction in platelet counts caused by complement-bound liposomes was also associated with sequestration of platelets in the lung and liver. Such nonphysiological platelet activation probably engenders initiation and modulation of inflammatory responses because platelets contain several potent proinflammatory substances. A negatively charged lipid is required for encapsulating a large amount of Hb using a minimum amount of lipids (*46*−*48*). Therefore, we had to overcome the problem of conventional negatively charged vesicles to achieve blood compatibility. In the present formation of HbV, we use a negatively charged lipid (DHSG: 1,5-*O*-dihexadecyl-*N*-succinyl-L-glutamate) and confirmed the considerable improvement of Hb encapsulation efficiency (Figure 4a,b**)**. It must be emphasized that the present vesicle formulation for HbV apparently does not induce thrombocytopenia or complement activation in animal experiments (Figure 4c−f) (*82, 83*), probably because the present HbV contains PEG-modification and a different type of negatively charged lipid (DHSG), not DPPG or a fatty acid.

Ikeda and his co-workers (*83*−*86*) thoroughly examined blood compatibility of HbV to human blood in vitro. The present PEG-modified HbV containing DHSG did not affect the extrinsic or intrinsic coagulation activities of human plasma, although HbV containing DPPG and no PEG modification tended to shorten the intrinsic coagulation time. The kallikrein-kinin cascade of the plasma was activated slightly by the prototype DPPG-HbV, but not by the present PEG-DHSG-HbV. The exposure of human platelets to high concentrations of the present HbV (up to 40%) in vitro did not cause platelet activation and did not adversely affect the formation and secretion of prothrombotic substances or proinflammatory substances that are triggered by platelet agonists. These results imply that HbV, at concentrations of up to 40%, has aberrant interactions with neither unstimulated

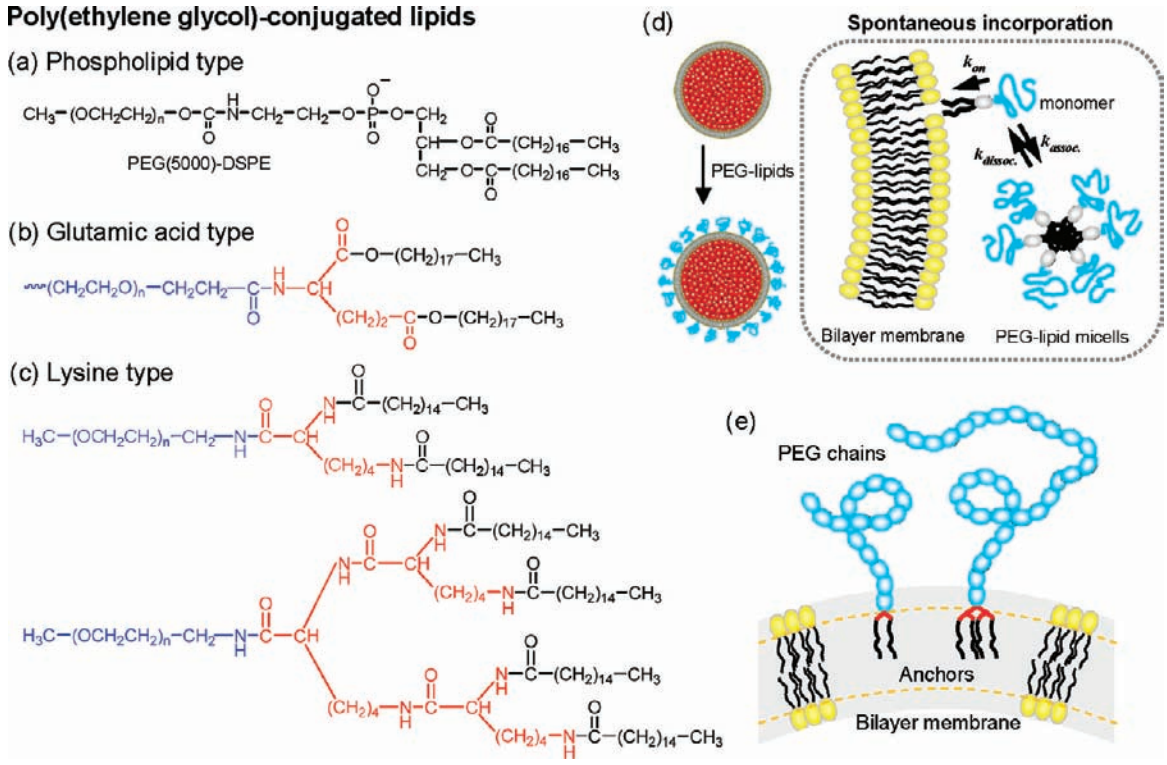

Figure 5. Surface modification of HbV with PEG chains. (a−c) Chemical structures of PEG-conjugated lipids. (a) PEG(5000)-DSPE is commercially available and widely used for surface modification of lipid vesicles. (b) Glutamic acid-type and (c) lysine-type PEG-conjugated lipids were reported previously (*87, 88*). (e) Immobilization of the large water-soluble polymers on the bilayer membranes (*87, 89*).

nor agonist-induced platelets. It can be concluded that the present PEG-DHSG-HbV has higher blood compatibility.

For surface modification of HbV with PEG chains, several PEG-conjugated lipids having amino acid backbone have been synthesized, as presented in Figure 5b,c (*87, 88*). For other applications, these PEG-conjugated lipids are available to modify the surfaces of not only HbV but also lipid vesicles. Because the PEG-lipids having a large hydrophilic group form thermodynamically unstable self-assemblies, called micelles (*73*), they easily dissociate to monomers and spontaneously incorporate only to the outer surface of preformed HbV, as illustrated in Figure 5d (*45, 72*). Using this method, the required amount of PEG-conjugated lipid can be reduced by half or less because only the outer surface of HbV requires PEG chains. In addition, the PEG chains extending from the inner surface are expected to reduce the interior volume for encapsulation because of their exclusion volume effect. Therefore, modification only to the outer surface is important to encapsulate large amounts of Hb in lipid vesicles. To immobilize the hydrophilic macromolecules stably, such as PEG chains and proteins on lipid vesicles, a large hydrophobic anchor having a tetraacyl structure has been synthesized (Figure 5c,e). It has been confirmed that this hydrophobic anchor can stably immobilize PEG chains of high molecular weight (Mw 12 500) or water-soluble proteins (*87, 89*). These surface modification technologies and lipid chemistry have been applied to the development of other functional biomaterials (*87*−*93*).

2.4. Circulation Time, Biodistribution, and Metabolism. The dosage of blood substitutes is expected to be considerably larger than those of other drugs, while their circulation time is considerably shorter than that of RBCs. Therefore, their biodistribution, metabolism, excretion, and side effects must be characterized in detail, especially in relation to the reticuloendothelial system (RES, alternatively, the mononuclear phagocytic system, MPS). Normally, free Hb released from RBCs is bound rapidly to haptoglobin and is consequently removed from circulation by hepatocytes. However, when the Hb concentration is greater than the haptoglobin binding capacity, unbound Hb is filtered through the kidney, where it is actively absorbed. Hemoglobinuria and eventual renal failure occur when the kidney reabsorption capacity is exceeded. The encapsulation of Hb in vesicles completely suppresses renal excretion. However, HbV in the bloodstream is ultimately captured by phagocytes in the RES in much the same manner as senescent RBCs are, as confirmed by radioisotope ^{99m}Tc-labeled HbV injection (*42, 94*). The circulation half-life is dose-dependent: for the dosage of 14 mL/kg body weight, the circulation half-life was 34.8 h in rats and 62.6 h in rabbits (Figure 6a). The HbV are finally distributed mainly in the liver, spleen, and bone marrow (Figure 6b). The species-dependent circulation time is inferred to be dependent upon the species-specific weight balance of phagocyte organs, particularly the liver, spleen, and bone marrow, against body weight (*94*). The circulation half-life in the case of the human body can be estimated as about 2−3 days at the same dosage.

It is generally accepted that the liposome clearance by RES at a small dosage is accelerated by opsonization (absorption of plasma proteins such as antibodies and complements on the liposomal surface). In fact, PEG-modification prevents opsonization for prolonged circulation times (*95*). However, considering a condition in which the dosage of HbV is extremely high and requires a considerable amount of opsonins, and in which HbV does not induce complementary activation (*82, 83*), then opsonin-dependent phagocytosis would not be a major component in the case of HbV with a large dosage. Actually, opsonin-independent phagocytosis, a direct recognition by macrophages, has been clarified in some studies (*96, 97*).

Analysis of the spleen by transmission electron microscopy (TEM) 1 day after infusion of HbV revealed the presence of HbV particles in the phagosomes of macrophages (*98*) (Figure

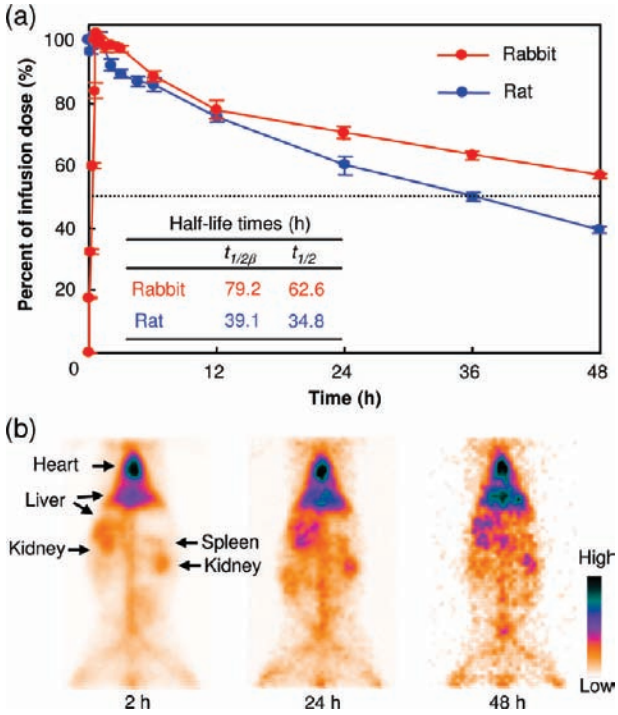

Figure 6. Circulation kinetics and organ distribution of HbV labeled with technetium-99m after top-loading intravenous infusion (14 mL/kg) in rats and rabbits (*94*). (a) Elimination profiles of HbV from blood. (b) Static gamma camera images of a rabbit acquired at 2, 24, and 48 h after HbV infusion.

7). However, after 7 days, the HbV structure cannot be observed. We confirmed transient splenomegaly with no irreversible damage to the organs and complete metabolism within a week. The phagocytic activity transiently, but not completely, decreased 1 day after injection, and it turned to increasing at 3 days. The influence on the defense function and its mechanism has been carefully examined in the ongoing research. Immunochemical staining with a polyclonal anti-human Hb antibody was used as the marker of Hb in the HbV. Results clarified that HbV had almost disappeared in both the spleen and liver after 7 days.

Bilirubin and iron are believed to be released during metabolism of Hb, but our animal experiments of topload infusion, daily repeated infusions, and 40% blood exchange showed that neither of those products increased in the plasma within 14 days (*99*−*101*). Bilirubin would normally be excreted in the bile as a normal pathway; no obstruction or stasis of the bile is expected to occur in the biliary tree. Berlin blue staining revealed considerable deposition of hemosiderin in the liver and spleen, even after 14 days. Moderate splenomegaly and hemosiderin deposition were also confirmed in the spleen after injection of stored RBCs, partly because of the accumulation and degradation of stored RBCs with lowered membrane deformability and shortened circulation half-life (*101*).

As for membrane components of Hb-vesicles, the plasma cholesterol level elevated transiently 3 days after injection: cholesterol was released from macrophages after degradation of HbV in phagosomes (*99, 101*). It was recently clarified using ^{3}H-cholesterol that cholesterol of HbV is released from macrophages to blood; it is ultimately excreted in feces. The PEG chain is widely used for surface modification of liposomal products. The chemical cross-linker succinic acid ester of PEG-conjugated phospholipid is susceptible to hydrolysis to release PEG chains during metabolism. Actually, immunohistochemistry using an anti-methoxy-PEG antibody clarified that PEG had disappeared from the liver and spleen in one week (*102*). The

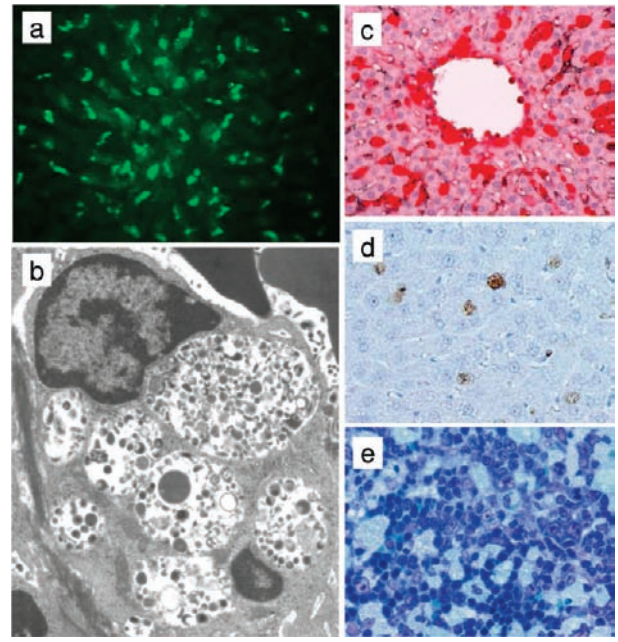

Figure 7. Histopathological examination of livers and spleens of rodents after injection of HbV. (a) Hamster liver 1 h after injection of fluorescence-labeled HbV, observed by a confocal laser scanning microscopy. The strong fluorescence indicates that HbV particles accumulate in Kupffer cells. (b) TEM of rat spleen macrophage 1 day after injection of HbV. The small black dots are HbV particles in phagosomes. The particles disappeared within a week (data not shown) (*98*). (c) Rat liver 1 day after injection of HbV. It was immunohistochemically stained with anti-human Hb antibody. The red parts indicate the presence of human Hb in HbV. It disappeared within a week (data not shown) (*98*). (d) Rat liver 7 day after injection of HbV. It was immunochemically stained with anti-methoxy-PEG antibody. The brown parts indicate the presence of PEG derived from PEG-lipid of HbV during the degradation. Fourteen days after injection, PEG was not detectable (data not shown) (*102*). (e) Rat spleen 3 days after 40% exchange transfusion with HbV. It was stained with Giemsa method. A large amount of blue cells, erythroblasts, are seen, indicating the enhanced hematopoiesis for the complete recovery of hematocrit within one week, while HbV are degraded in RES (*101*).

released PEG chains, which are known as inert macromolecules, are expected to be excreted in urine through the kidneys (*103*).

To determine the physiological capacity of RES for degradation of HbV, we tested massive intravenous doses by daily repeated infusion of 10 mL/kg body weight/day into Wistar rats for 14 days. The cumulative dosage was 140 mL/kg body weight (Hb and lipids, 20 689 mg/kg body weight). The total volume was equal to 2.5 times the total blood volume (56 mL/kg body weight) (*100*). Although splenohepatomegaly was considerable, all rats tolerated the infusions; their body weight increased during the succeeding 14 days until their intended sacrifice. The phagocyted HbV had disappeared, though the considerable hemosiderin deposition was confirmed in the spleen, liver, kidney, adrenal grand, and bone marrow. We were unable to define a lethal dose of HbV in this experiment.

The profile of liposome clearance is species-dependent. More precise data are necessary to extrapolate the phenomena observed in animal experiments to humans. However, these results imply that the metabolism of HbV and excretion are within the physiological capacity that has been well-characterized for the metabolism of senescent RBCs and conventional liposomal products.

2.5. Regulation of O_2 Transporting Capability (MetHb Reduction, $P_{50}(O_2)$). Actually, Hb encapsulation provides a unique opportunity to add new functions to particles by coencapsulation or embedding of functional molecules (*52*−*56, 104*−*106*). MetHb formation of HbV during the

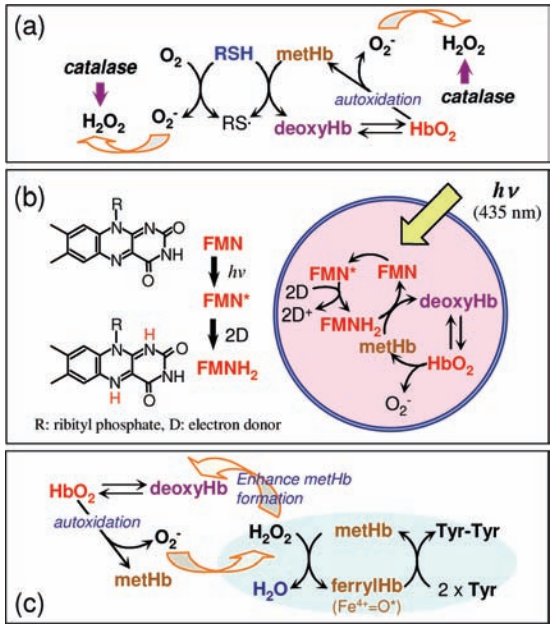

Figure 8. Artificial metHb reduction systems in HbV. (a) Coencapsulation of thiols (RSH), such as glutathione and homocyteine, reduces metHb. However, thiols react with O_2 to generate O_2^- and H_2O_2. A more reactive thiol such as cysteine shows extremely rapid reaction with O_2 and adversely facilitates metHb formation. Coencapsulation of catalase effectively eliminates H_2O_2 and prevent such reactions (*52, 53, 56*). (b) Photoreduction system by coencapsulation of flavin monomucleotide (FMN) and an electron donor such as EDTA and methionine. Visible light irradiation (435 nm) primarily converts FMN to the photoexcited triplet FMN*, and this reacts with two electron donors (D) to generate $FMNH_2$. MetHb is rapidly reduced once $FMNH_2$ is produced (*54*). (c) During autoxidation of Hb and in blood circulation, H_2O_2 is a potent metHb enhancer. A combination of L-tyrosine (Tyr) and metHb effectively eliminates H_2O_2 and prolongs the functional lifetime of HbV (*55*).

preservation is completely prevented simply by deoxygenation. However, autoxidation of HbO_2 is initiated once HbV is administered into the bloodstream because the entire metHb enzymatic system is eliminated during the Hb purification for the utmost safety from infection. An artificial metHb reducing system is required to prolong the O_2-carrying capacity of HbV. We have tested coencapsulation of reductants to directly reduce metHb and a photoreduction system using a photosensitizer such as flavin mononucleotide (FMN). A more practical method is to create an artificial enzymatic system using L-tyrosine (Tyr) and metHb that eliminates H_2O_2 as does catalase (Figure 8).

Without a chemical modification of Hb, O_2 binding affinity (expressed as $P_{50}(O_2)$, O_2 tension at which Hb is half-saturated with O_2) of HbV can be regulated by coencapsulation of an allosteric effector (*105, 106*) (Figure 9a). The $P_{50}(O_2)$ of purified Hb in a saline solution (in the presence of Cl^-) is about 14 Torr; Hb strongly binds O_2 and does not release O_2 at 40 Torr (partial pressure of mixed venous blood). Historically, it has been regarded that the O_2 affinity is expected to be regulated similarly to that of RBC, namely, about 25−30 Torr, using an allosteric effector or by a direct chemical modification of the Hb molecules. This enables sufficient O_2 unloading during blood microcirculation, as evaluated by the arterio-venous difference in the levels of O_2 saturation in accordance with an O_2 equilibrium curve. Pyridoxal 5′-phosphate (PLP) is coencapsulated in HbV as an allosteric effector to regulate $P_{50}(O_2)$ (*105, 106*). The main binding site of PLP is the N-terminal of the α-chain and β-chain and β-82 Lysine within the β-cleft, which is part of the binding site of the natural allosteric effector, 2,3-diphosphoglyceric acid (2,3-DPG). The bound PLP retards the dissociation of the ionic linkage between the β-chains of Hb during conversion of deoxy to oxyHb in the same manner as 2,3-DPG does. Therefore, the O_2 affinity of Hb decreases in the presence of PLP. The $P_{50}(O_2)$ of HbV can be regulated to 8−150 Torr by coencapsulating the appropriate amount of PLP or inositol hexaphosphate as an allosteric effector. Equimolar PLP to Hb (PLP/Hb = 1/1 by mol) was coencapsulated, and $P_{50}(O_2)$ was regulated to 18 Torr. Furthermore, $P_{50}(O_2)$ was regulated to 32 Torr when the molar ratio PLP/Hb was 3/1. The O_2 affinities of HbV can be regulated easily without changing other physical parameters, whereas in the case of the other modified Hb solutions, their chemical structures determine their O_2 binding affinities. Consequently, regulation is difficult. The present HbV contains PLP at PLP/Hb = 2.5 by mol; the resulting $P_{50}(O_2)$ is about 25−28 Torr, which shows sufficient O_2 transporting capacity as a transfusion alternative. Actually, HbV has been shown to provide O_2-transport capacity that is both sufficient and comparable to that of RBCs in experiments related to extreme blood exchange (*68, 69, 79, 105, 107, 108*) and fluid resuscitation from hemorrhagic shock (*102, 109−112*) (Figure 10). A recent experiment of HbV as a priming solution for cardiopulmonary bypass (CPB) in a rat model showed that HbV protects neurocognitive function by transporting O_2 to brain tissue even when the hematocrit is reduced markedly (*113*).

The appropriate O_2 binding affinities for O_2 carriers have not yet been decided completely. However, the easy regulation of the O_2 binding affinity might be useful to meet the requirement of clinical indications such as oxygenation of ischemic tissues. The $P_{50}(O_2)$ of HbV without PLP and Cl^- is 8−9 Torr. This formulation is effective for targeted O_2 delivery to anoxic tissues caused by reduced blood flow (*107, 114, 115*).

2.6. Rheological Properties and Their Physiological Implications for Tissue Oxygenation. The extremely high concentration of the HbV suspension ([Hb] = 10 g/dL; [lipids] = 6 g/dL, volume fraction, ca. 40 vol %) imparts an O_2 carrying capacity that is comparable to that of blood. The HbV suspension does not possess a colloid osmotic pressure (COP), because one HbV particle (ca. 250 nm diameter) contains about 30 000 Hb molecules. In fact, HbV acts as a particle, not as a solute. Therefore, HbV must be suspended in or coinjected with an aqueous solution of a plasma substitutes. This requirement is identical to that for emulsified perfluorocarbon, which does not possess COP (*116, 117*); it contrasts to characteristics of other Hb-based O_2 carriers, intramolecular cross-linked Hbs, polymerized Hbs, and polymer-conjugated Hbs, which all possess very high COP as protein solutions (*15, 118*) (Figure 9b).

Animal tests of HbV suspended in plasma-derived HSA or rHSA showed an O_2 transporting capacity that is comparable to that of blood (*110, 113*). We reported previously that HbV suspended in plasma-derived HSA or rHSA was almost Newtonian: no aggregation was detected microscopically (*68, 69*). In Japan, rHSA was very recently approved for clinical use, in May 2008 (*119*), but various plasma substitutes are used worldwide, such as hydroxylethyl starch (HES), dextran (DEX), and modified fluid gelatin (MFG). The selection among these plasma substitutes is best determined not only according to their safety and efficacy, but also according to their associated price, experience of clinicians, and customs of respective countries. Water-soluble polymers generally interact with particles such as polystyrene beads, liposomes, and RBCs to induce aggregation or flocculation (*120, 121*). For that reason, it is important to determine the compatibility of HbV with these plasma substitutes. With that background, we studied rheological properties of HbV suspended in these plasma substitute solutions using a complex rheometer and a microchannel array (*122*). The rheological property of an Hb-based O_2 carrier is important

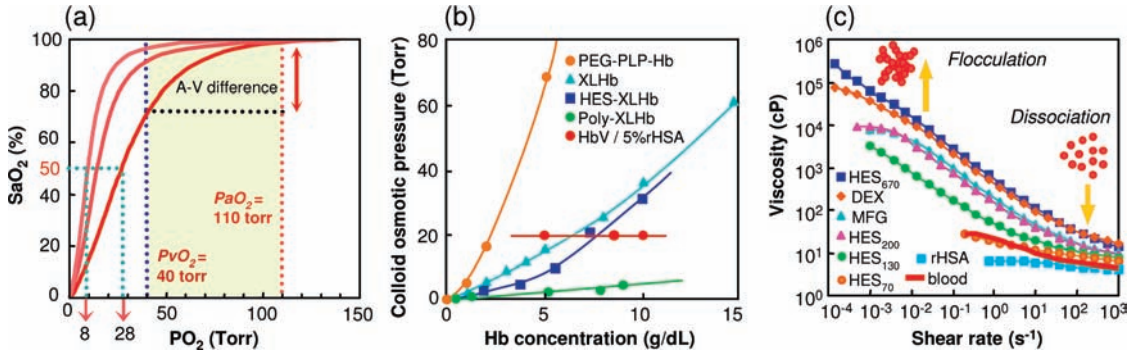

Figure 9. Regulation of physicochemical properties of HbV for versatile applications. (a) Oxygen dissociation curves of HbVs. Oxygen affinity (P_{50}, partial pressure of oxygen at which Hb is half-saturated with oxygen) is regulated by coencapsulation of PLP (*105, 106*). (b) Colloid osmotic pressure (COP) of chemically modified Hb solutions increase with the Hb concentration (*15*). In contrast, HbV particles have no oncotic effect. The figure shows 20 Torr when HbV is suspended in 5% rHSA. XLHb, intramolecularly cross-linked Hb. (c) Rheological properties of HbV suspended in various plasma substitute solutions (*122*). [Hb] = 10 g/dL, 25 °C.

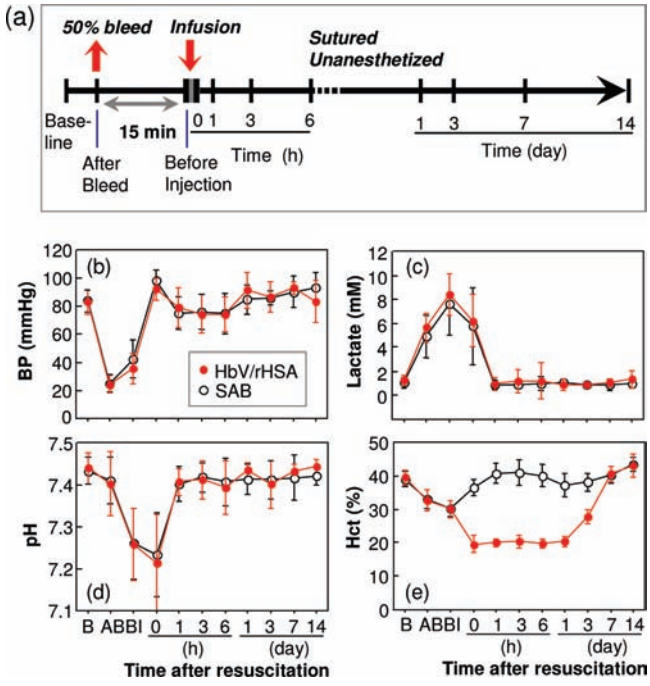

Figure 10. (a) Scheme depicting the experimental protocol of hemorrhagic shock and resuscitation (*102*). Shock was induced by withdrawing 50% of circulating blood volume from Wistar rats. After 15 min, they were resuscitated with either HbV suspended in recombinant human serum albumin (HbV/rHSA) or shed autologous blood (SAB), (b) blood pressure, (c) lactate, (d) pH, and (e) hematocrit (Hct). Mean ± SD. B, Baseline; AB, after bleeding; BI, before injection (B-6 h, n = 24; 1−14 days, n = 5).

because the infusion amount is expected to be considerably large, which might affect the blood viscosity and hemodynamics.

The HbV suspended in rHSA was nearly Newtonian (Figure 9c). Its viscosity was similar to that of blood, and the mixtures with RBCs at various mixing ratios showed viscosities of 3−4 cP. Other polymers, HES, DEX, and MFG, induced flocculation of HbV, possibly by depletion interaction, and rendered the suspensions as non-Newtonian with the *shear-thinning* profile (*122*). These HbV suspensions showed high viscosity and a high storage modulus (G') because of the presence of flocculated HbV. On the other hand, HbV suspended in rHSA exhibited a very low G'. The viscosities of HbV suspended in DEX, MFG, and high-molecular-weight HES solutions responded quickly to rapid step changes of shear rates of 0.1−100 s^{-1} and a return to 0.1 s^{-1}, indicating that flocculation formation is both rapid

and reversible. Microscopically, the flow pattern of the flocculated HbV perfused through microchannels (4.5 μm deep, 7 μm wide, 20 cmH_2O applied pressure) showed no plugging. Furthermore, the time required for passage was directly related to the viscosity.

It has been regarded that lower blood viscosity after hemodilution is effective for tissue perfusion. However, microcirculatory observation shows that, in some cases, lower "plasma viscosity" decreases shear stress on the vascular wall, causing vasoconstriction and reducing the functional capillary density (*123*). Therefore, an appropriate viscosity might exist, which maintains the normal tissue perfusion level. The large molecular dimension of HbV can result in a transfusion fluid with high viscosity. A large molecular dimension is also effective to reduce vascular permeability and to minimize the reaction with NO and CO as vasorelaxation factors (*24, 25, 30, 31*) (see Figure 3). These new concepts suggest reconsideration of the design of artificial O_2 carriers (*124*). Actually, new products are appearing, although they are in the preclinical stage, not only HbV but also zero-link polymerized Hb (*125*) and others with larger molecular dimensions and higher O_2 affinities (*126*). Erni et al. clarified that HbV with a high O_2 binding affinity (low $P_{50}(O_2)$, such as 8−15 Torr) and high viscosity (such as 11 cP) suspended in a high-molecular-weight HES solution was effective for oxygenation of an ischemic skin flap (*115, 127, 128*). That study showed that HbV retains O_2 in the upper arterioles, then perfuses through collateral arteries and delivers O_2 to the targeted ischemic tissues, a concept of targeted O_2 delivery by an Hb-based O_2 carrier (*114*). A high O_2 binding affinity (low $P_{50}(O_2)$) would also be effective to improve the O_2 saturation of Hb in pulmonary capillaries when exposed to a hypoxic atmo-

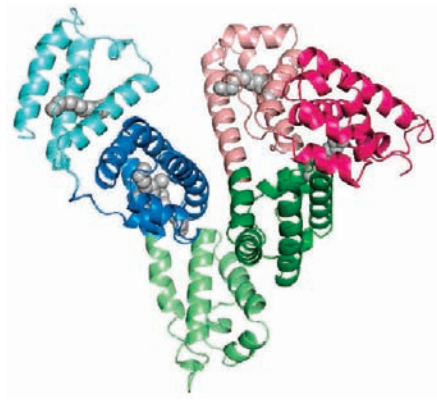

Figure 11. Crystal structure of HSA with myristate (PDB ID: 1BJ5) from ref (*136*).

sphere or with an impaired lung function. Some plasma substitutes cause flocculation of HbV and hyperviscosity. However, reports show that hyperviscosity would not necessarily be deteriorative and might be, in some cases, advantageous in the body (*32*). HbV provides a unique opportunity to manipulate the suspension rheology, $P_{50}(O_2)$, and other physicochemical properties, not only as a transfusion alternative, but also for other clinical applications such as oxygenation of ischemic tissues and ex vivo perfusion systems (*129*−*132*) (Table 4).

3. ALBUMIN-HEMES AS O_2 CARRYING PLASMA PROTEINS

3.1. HSA Incorporating Synthetic Fe^{2+} Porphyrin (HSA-FeP). HSA (Mw: 66 500) has a remarkable ability to bind a wide variety of exogenous compounds in the human circulatory system (*133*). This carrier protein comprises 3 homologue helical domains (I−III) with 9 loops formed by 17 disulfide linkages; each domain contains 2 subdomains (A and B) (Figure 11) (*134*−*137*). It is known that many common drugs such as warfarin, diazepam, and ibuprofen bind to one of the two primary sites (site 1 in subdomain IIA, site 2 in subdomain IIIA) (*138*). In fact, HSA helps to solubilize these compounds to achieve high concentration in the bloodstream; otherwise, they would easily aggregate and be poorly distributed.

In 1995, we found that tetrakis(*o*-pivalamido)phenylporphinatoiron bearing a covalently linked proximal imidazole (FeP**1**, Figure 12) was incorporated into HSA, yielding a red HSA-FeP**1** hybrid (*11*). This synthetic hemoprotein can reversibly bind and release O_2 under physiological conditions (pH 7.4, 37 °C) in much the same way as Hb. The HSA host adsorbs a maximal eight FeP**1** molecules. Their stepwise binding constants (K_1−K_8) range from 1.2×10^6 to 1.2×10^4 (M^{-1}) (Table 3) (*139, 140*). Solution properties of the HSA-FeP**1** solution ([rHSA] = 5 wt %, FeP/HSA=1−8, mol/mol) are almost identical to those of HSA itself: the specific gravity, 1.013; viscosity, 1.1 cP; and COP, 20 Torr. Circular dichroism (CD) spectroscopy and isoelectric focusing measurement revealed that the second-order structure and surface charge distribution of HSA were unaltered after binding of FeP**1**. The obtained solution showed a long shelf-life of over two years at room temperature (*141*). Furthermore, HSA-FeP**1** has no effect on the morphology of blood cell components (*142*) and does not engender immunological reaction and platelet activation (*143*). Upon addition of O_2 gas through this solution, the visible absorption spectrum immediately changed to that of the O_2 adduct complex. After exposure to CO gas, a stable carbonyl complex of HSA-FeP**1** was formed (*139, 140*). The coordination structure of FeP**1** and spin-state of the central ferrous ion was characterized by IR, resonance Raman, and magnetic circular dichroism (MCD) spectroscopy (*139, 140, 144*). The carbonyl HSA-FeP**1** moved to the NO adduct complex after bubbling NO gas (*145*). Subsequent ESR spectroscopy revealed that FeP**1** in albumin formed a six-coordinate nitrosyl complex. The proximal imidazole moiety does not dissociate from the central ferrous ion when NO binds to the trans side (*146*).

The $P_{50}(O_2)$ value of HSA-FeP**1** is always constant (33 Torr, 37 °C) independent of the binding number of FeP**1** (eq 1, Table 5)

$$\text{HSA-FeP} + \text{L} \underset{k_{off}(\text{L})}{\overset{k_{on}(\text{L})}{\rightleftarrows}} \text{HSA-FeP(L)} \quad [\text{L}: \text{O}_2 \text{ or CO}]$$

$$K(\text{L}) = [P_{50}(\text{L})]^{-1} = k_{on}(\text{L})/k_{off}(\text{L}) \quad (1)$$

The O_2 binding equilibrium curve shows no cooperativity. However, the O_2 transporting efficiency between the lungs [$P(O_2)$: ca. 110 Torr] and muscle tissue [$P(O_2)$: ca. 40 Torr] is 22%, which is identical to that for RBC.

The O_2 association and dissociation rate constants [$k_{on}(O_2)$ and $k_{off}(O_2)$] can be measured using laser flash photolysis (*147, 148*). Interestingly, the rebinding process of O_2 to HSA-FeP**1** included two phases (fast and slow phase), perhaps because of the different environment around each FeP**1** in the protein (*149*). The $P_{50}(O_2)$ value can be controlled by tuning the chemical structure of FeP**1**. We have synthesized quantities of Fe(II)porphyrins (Figure 12) and evaluated the O_2 binding parameters of their HSA-FeP hybrids (Table 6).

Actually, FeP**2** has a bulky 1-methylcyclohexanamide group on the porphyrin ring plane (*150*). The O_2 binding affinity of HSA-FeP**2** [$P_{50}(O_2)$: 35 Torr] was almost identical to that of HSA-FeP**1**. However, the stability of the oxygenated complex increased to 4.5 times its usual value [half-life $\tau_{1/2}(O_2)$, 9 h; pH 7.3; 37 °C] (*150*).

In general, the basicity and structure of the proximal base greatly influences the O_2 binding property of Fe^{2+}porphyrin. Both FeP**3** and FeP**4**, similar analogues having an His ligand, showed high O_2 binding affinities [$P_{50}(O_2)$: 3 Torr] (Figure 13, Table 6). Kinetically, substitution of the 2-methylimidazole to His reduces the O_2 dissociation rate constant (*150*). Although one might think that high O_2 binding affinity is not useful as a blood substitute, it can be efficient for oxygenation of hypoxic regions in tumors. Furthermore, the HSA-FeP**4** showed long $\tau_{1/2}(O_2)$ of 25 h (37 °C), which is 13-fold longer than that of HSA-FeP**1**.

Another HSA-FeP**5**, in which the active porphyrin has 3-methyl-L-hisitidine as a proximal base, exhibits an extraordinarily high O_2 binding affinity [$P_{50}(O_2)$: 1 Torr] that approaches those of relaxed-state Hb and Mb (*151*). It is remarkable that replacement of the 3-methyl-L-histidine moiety by 1-methyl-L-histidine isomer (HSA-FeP**6**) reduced O_2 binding affinity to 1/35th of its former level. The low O_2 affinity of FeP**6** is predominantly reflected by the high $k_{off}(O_2)$ value. The axial Fe−N(1-methyl-L-histidine) coordination might be restrained by steric interaction between the 4-methylene group of the His ring and the porphyrin plane (*151*).

The proximal histidyl side chain can be introduced easily into the β-pyrrolic position of the porphyrin via an acyl bond in two steps, FeP**7** (*152*). Although an electron-withdrawing acyl group is bound at the porphyrin periphery, the O_2 binding affinity of HSA-FeP**7** is slightly higher than that of HSA-FeP**4**. The rigid His-Gly(carboxy)butanoyl spacer of FeP**7** probably produces a favorable geometry to fix the imidazole onto the central Fe^{2+} of the porphyrin.

Double-sided porphyrins (FeP**8**, FeP**9**, and FeP**10**) were also incorporated into HSA (*153*). We expected that steric encumbrances on both sides of the porphyrin enable the HSA-FePs to form a stable O_2 adduct complex. Actually, the $\tau_{1/2}(O_2)$ of HSA-

[a] In phosphate buffered solution (pH 7.3), [HSA]: 5 g/dL. [b] At 37 °C. [c] A membrane filter with a cutoff (M_w, 30×10^3) was used. [d] At 25 °C.

FeP**8** was 5 h, which is 2.5-fold longer than that of HSA-FeP**1**. In addition, HSA-FeP**8** showed high stability against hydrogen peroxide. The HSA incorporating double-sided porphyrins would be useful for the synthetic analogue of the oxidation enzyme.

Tailed porphyrins having an α,α,α,*β*-conformer, FeP**11** and FeP**12**, were synthesized easily via four steps from atropisomers of tetrakis(*o*-aminophenyl)porphyrin relative to eight steps of FeP**1** (*154*). Although HSA-FeP**12** binds O_2 reversibly, HSA-FeP**11** was quickly oxidized by O_2. We concluded that the 1-methylcyclohexanamide groups are necessary for the tailed porphyrin to form an O_2 adduct complex under physiological conditions.

Investigations have also revealed that heme [Fe^{2+}protoporphyrin IX; protoheme] derivatives having a proximal base at the propionate side chain (FeP**13**−FeP**16**) were incorporated into HSA (*155, 156*). The oxidation process of HSA-FeP**13**(O_2) to the inactive ferric state obeyed first-order kinetics, suggesting that the *μ*-oxo dimer formation was prevented by the immobilization of FeP**13** into albumin. In fact, HSA-FeP**15** showed lower O_2 binding affinity [high $P_{50}(O_2)$] than the others did. The acetyl groups at the 3,8-positions of FeP**15** decrease the electron density of the porphyrin macrocycle, thereby reducing the O_2 binding affinity. Actually, HSA-FeP**16**, in which the His-Gly tail coordinates to the Fe^{2+} center, showed the most stable O_2 adduct complexes [$\tau_{1/2}(O_2)$, 90 min; pH 7.3; 25 °C] of any of these heme compounds.

3.2. Surface-Modified HSA-FeP with PEG. A remaining defect of HSA-FeP is that the active Fe^{2+} porphyrin sites dissociate slowly from HSA when infused into animals because FeP is bound noncovalently to albumin. One possible solution is to bind the FeP molecule covalently to the protein. We have synthesized FeP**17** having a succinimide side chain; it can react with the Lys amino group of HSA (*157*). The O_2 binding property of HSA-FeP**17** is almost identical to that of HSA-FeP**1**.

Another approach is surface modification with PEG. Actually, PEG decollations of proteins and liposomes are well-known to enhance their plasma half-life, thermostability, nonimmunogenicity, and solubility in organic solvents (*158*−*163*). We surmised that surface modification of HSA-FeP**2** by PEG might help to prolong the circulation lifetime of FeP**2** and retain its O_2 transporting ability in vivo for a long period. Consequently, HSA-FeP**2** (FeP**2**/HSA = 4/1, mol/mol) was modified with maleimide-PEG, and the solution properties, O_2 binding behavior, and circulatory persistence of the PEG-modified HSA-FeP**2** [PEG(HSA-FeP**2**)] were examined (*164*). A thiolation reagent, iminothiolane, first reacted with the Lys amino groups of HSA to create active thiols that bind to α-maleimide-*ω*-methoxy PEG (Figure 14a). Mass spectroscopy measurements and quantification of the mercapro group of PEG(HSA-FeP**2**) revealed the conjugation of six PEG chains on the HSA-FeP**2** surface. The initial FeP**2**/HSA ratio 4/1 (mol/mol) was unchanged after the PEG binding. The adjustment of viscosity is important to design an artificial O_2 carrier. Maintenance of viscosity is necessary to preserve shear stress on the vascular wall that prevents loss of the functional capillary density (*123, 165*). The viscosity and COP of PEG(HSA-FeP**2**) were modulated to some degree by changing the molecular weight of PEG [M_w: 2×10^3 (PEG_{M2}) and 5×10^3 (PEG_{M5})] (Figure 14b). In fact, PEG_{M2}(HSA-FeP**2**) showed almost identical values of viscosity

and COP to those of the nonmodified HSA-FeP**2**. In contrast, PEG_{M5}(HSA-FeP**2**) showed a higher viscosity and more pronounced hyperoncotic property relative to those of HSA-FeP**2**. Nevertheless, PEG_{M5} conjugate may be useful as an efficient plasma expander (*118, 166*).

Under physiological conditions, PEG_{Mn}(HSA-FeP**2**) binds and releases O_2. The $P_{50}(O_2)$ values were almost identical to those of the original HSA-FeP**2**, indicating that the O_2 binding equilibrium was not influenced by the presence of the PEG chains (Figure 14b). Surface modification by PEG delays proton-driven oxidation of the O_2 adduct complex, giving HSA-FeP**2** the $\tau_{1/2}(O_2)$ of 12 h, which is almost equal to that of a natural hemoprotein, Mb [$\tau_{1/2}(O_2)$, 12 h; pH 7, 35 °C] (*167*). The conjugated PEG might change the local proton concentration of the HSA interior compared to the outer aqueous solution.

The circulation persistence of FeP**2** in the bloodstream was measured after administration of PEG_{Mn}(HSA-FeP**2**) to anesthetized rats (*164*). The PEG_{Mn}(HSA-FeP**2**) solution (20% volume of the circulatory blood) was injected intravenously into rats from the tail vein. The concentration decays of PEG_{Mn}(HSA-FeP**2**) in the blood showed single exponentials with half-life [$\tau_{1/2}$(FeP**2**)] of 13−16 h (Figure 14c). These values are considerably longer than those of the corresponding nonmodified HSA-FeP**1** (*168*). Surface modification of HSA-FeP**2** by PEG prevented the rapid clearance of the incorporated FeP**2**. On the basis of these findings, we can conclude that surface modification of HSA-FeP**2** by PEG comprehensively improved its O_2 transporting ability.

We then proceeded to evaluate physiological responses to an exchange transfusion with PEG_{M2}(HSA-FeP**2**) in an acute anemia rat model (*169*) (Figure 15). The animals were first placed in a 65 vol % hemodilution with 5 g/dL HSA. They subsequently underwent a 30 vol % blood replacement with the PEG_{M2}(HSA-FeP**2**) solution. As negative and positive control groups, a 5 g/dL HSA solution (HSA group) and washed RBC suspension (RBC group) were infused, respectively, to similarly operated rats in hemorrhage. The isovolemic 65% hemodilution with HSA reduced the Hb concentration, thereby decreasing the O_2 supply to the tissue. Consequently, the mean arterial pressure (MAP), renal cortical O_2 partial pressure [$PtO_2(R)$], and O_2 partial pressure of muscle tissue [$PtO_2(M)$] were decreased. During hemorrhagic shock by 30% bleeding, significant decreases in the MAP, venous O_2 pressure (PvO_2), $PtO_2(R)$, and $PtO_2(M)$ were observed by the loss of the circulation blood volume. The heart rate (HR) and respiration rate were also decreased. In contrast, arterial O_2 pressure (PaO_2) increased to about 160% of the basal value (b.v.). The arterial CO_2 pressure ($PaCO_2$) decreased to about 62% of the b.v.; the pH increased to 7.55.

The injection of the sample solutions increased the blood volume and improved the circulatory flow. Lactate was washed out from the tissues and into the circulatory system, which decreased the pH to the initial level of 7.43 in all groups. The administration of HSA restored no parameters: death occurred within 41 min. In contrast, the infusion of PEG_{M2}(HSA-FeP**2**) or RBC kept all the rats alive until the end of measurements. After injection of PEG_{M2}(HSA-FeP**2**), the animals showed marked and rapid recovery in MAP, HR, PaO_2, PvO_2, $PaCO_2$, and pH, resembling that shown in the RBC group. These results demonstrate the O_2 transporting capability of the PEG_{M2}(HSA-FeP**2**) solution as a resuscitative fluid. We observed that albumin-based oxygen carrier does not induce hypertensive action, because of its low permeability through the vascular endothelium in comparison with that of Hb molecules. The heart rate responses after the injection were also negligibly small. Visualization of the intestinal microcirculatory changes clearly revealed the widths of the venule and arteriole to be fairly constant (*170*).

Reversible oxygenation of PEG_{M2}(HSA-FeP**2**) was observed even in the solid state (*171*). The aqueous solution of PEG_{M2}(HSA-FeP**2**(CO)) complex was spread on the glass plate and dried overnight at room temperature, producing a red transparent solid membrane (Figure 16a). In contrast, HSA-FeP**2** without PEG decollation yielded a brittle membrane with many cracks. Scanning electron microscopy (SEM) observations of the PEG_{M2}(HSA-FeP**2**) membrane showed a uniform thickness of 15 μm and a smooth surface (Figure 16b). The $\tau_{1/2}(O_2)$ was 40 h, which is three times longer than the value in water. The

Arrows (1), (2), and (3), respectively, indicate the periods of 65% hemodilution, 30% bleeding, and sample infusion. [a]$p < 0.05$ versus HSA group (Tukey-Kramer test), [b]$p < 0.05$ versus PEG_{M2}(HSA-Fe**2**) group (unpaired *t*-test), and [c]$p < 0.05$ versus PEG_{M2}(HSA-FeP**2**) group (Tukey-Kramer test).

O_2 binding affinity was about a half that of the monomeric PEG_{M2}(HSA-FeP**2**).

We subsequently added hyaluronic acid (HA) as a supporting polymer to the protein solution and prepared the solid membrane on a poly(styrene) dish. Actually, HA is known as a glycosaminoglycan component of connective tissues, hyaline bodies, and extracellular matrix (*172*). Water evaporation of the PEG_{M2}(HSA-FeP**2**)/HA mixture ([HSA]: 2.5 wt % and [HA]: 0.2 wt %) produced a uniform red solid membrane that was easily peeled from the dish, yielding a free-standing homogeneous thin film of the PEG(HSA-FeP**2**)/HA hybrid (Figure 16c,d).

The PEG_{M2}(HSA-FeP**2**) solution is useful as a valuable O_2-carrying plasma. Membranes of PEG_{M2}(HSA-FeP**2**) with micrometer thickness can serve as a RBC substitute that can be preserved anywhere and reproduced as a saline solution at any time.

3.3. Recombinant HSA-Heme (rHSA-Heme) Prepared Using Site-Directed Mutagenesis. Hemin [Fe^{3+}protoporphyrin IX] released from metHb during enucleation of RBC or through hemolysis is captured by HSA with a high binding constant ($K \approx 10^8\ M^{-1}$) (*173*). Crystallographic studies have revealed that hemin is bound within a narrow D-shaped hydrophobic cavity in subdomain IB with axial coordination of Tyr-161 to the central ferric ion and electrostatic interactions between the porphyrin propionates and a triad of basic amino acid residues (Arg-114, His-146, and Lys-190) (Figure 17) (*174, 175*). In terms of the general hydrophobicity of this α-helical heme pocket, the subdomain IB of HSA potentially has similar features to the heme binding site of Hb or Mb. However, when one reduces HSA-hemin to obtain the ferrous complex, it is autoxidized rapidly by O_2, even at low temperature (~0 °C), because HSA lacks the proximal His, which, in Hb and Mb, enables the prosthetic heme group to bind O_2. Knowledge of the detailed architecture of the heme binding site in HSA enables us to design mutagenesis experiments to construct a tailor-made heme pocket for stable O_2 binding. Therefore, we used site-directed mutagenesis to introduce an His into the heme binding site that was expected to provide axial coordination to the central Fe^{2+} atom of the heme and thereby promote O_2 binding.

Results of our modeling experiments suggested that a favorable position for the axial imidazole insertion would be Ile-142 (Figure 17). The N_ϵ(His)-Fe distances were estimated as 2.31 Å for H142 (compared to 2.18 Å for Mb). We therefore designed and produced two single mutants I142H and a double mutant I142H/Y161L (HL) (*176*).

In the UV−vis absorption spectrum of rHSA(HL)-hemin, the ligand-to-metal charge transfer band at 625 nm was weakened because of the Y161L mutation. The MCD spectrum of rHSA(HL)-hemin showed a similar S-shaped pattern in the Soret band region resembling that of ferric Mb (*177, 178*). These results suggest that rHSA(HL)-hemin is in a predominantly ferric high-spin complex having a water molecule as the sixth ligand. The rHSA-hemin was easily reduced to the ferrous complex by adding a small molar excess of aqueous sodium dithionite under an Ar atmosphere (Figure 18). A single broad absorption band (λ_{max}: 559 nm) in the visible absorption spectrum and the MCD spectrum of rHSA(HL)-heme indicated the formation of a five-N-coordinate high-spin complex (*176, 177, 179*). The heme therefore appears to be accommodated in the mutated heme pocket with an axial coordination involving His-142. Upon exposure of rHSA(HL)-heme solution to O_2, the UV−vis absorption changed immediately to that of the O_2 adduct complex (Figure 18). It formed a carbonyl complex under a CO atmosphere. The single mutant rHSA(I142H)-heme, which retains Y161, was unable to bind O_2. The polar phenolate residue at the top of the porphyrin plane is likely to accelerate the proton-driven oxidation of the Fe^{2+} center. The replacement of Tyr-161 in rHSA(I142H)-heme by Leu enhanced stabilization of the O_2 adduct complex.

To evaluate the kinetics of O_2 and CO bindings to rHSA-hemes, laser flash photolysis experiments were carried out (Tables 7 and 8). It is noteworthy that the absorbance decay accompanying the CO recombination to rHSA(HL)-heme was composed of double-exponential profiles, which is normally not observed in Mb (the faster phase is defined as species I; the slower phase is defined as species II). The ratio of the amplitude of the species I and the species II was approximately 3:2. On the other hand, the rebinding of O_2 to rHSA(HL)-heme followed a simple monophasic decay. Numerous investigations of synthetic model hemes have helped to reveal the relation between the structure around the hemes and their O_2 and CO binding abilities (*4, 147, 148*). A bending strain in the proximal base coordination to the central Fe^{2+} atom, the "proximal-side steric (proximal pull) effect", is known to be capable of both increasing the dissociation rate for CO and decreasing the association rate. Simultaneously, it increases the O_2 dissociation rate without greatly altering the O_2 association kinetics. Consequently, one possible explanation for the existence of the two phases is that two different geometries of the axial His (His-142) coordination to the central ferrous ion of the heme might exist, each one accounting for a component of the biphasic kinetics of CO rebinding.

3.4. Modulation of O_2 Binding Property of rHSA-(mutant)−Heme. To control the O_2 binding affinity of rHSA-heme, we designed and produced diverse rHSA(mutant)−hemes in which bulky hydrophobic or hydrophilic amino acids were introduced around the O_2 binding site (Tyr-161, Leu-182, Leu-185, and Arg-186) (Figure 17). More recently, the beneficial effect of low-dose CO on the microcirculation by a hemoglobin-based artificial oxygen carrier has been discussed (*132, 182*). Control of the CO binding affinity of rHSA−heme is also tempting.

A. Substitution of Tyr-161 with Leu or Phe. The first, Tyr-161, was substituted to noncoordinating and hydrophobic amino acids (Leu or Phe). The O_2 and CO binding properties of rHSA(HL)−heme and rHSA(I142H/Y161F)−heme [rHSA(HF)−heme] showed that the presence of a Phe rather than a Leu at position 161 results in 6-fold and 4-fold increases in the O_2 binding affinity for species I and II, respectively (Table 7). This enhancement is mainly attributable to an increase in the O_2 association rate constant. The same trend was observed for CO binding [3-fold increase in k_{on}(CO)] (Table 8). The substitution of Leu-161 (102 $Å^3$) by Phe-161 (137 $Å^3$) (*183*) replaces an isopropyl group with a rigid benzyl group within the heme pocket. In rHSA(HL), the small side chain of Leu-161 might enable free rotation of the side chain of neighboring Leu-185, thereby reducing the volume on the distal side of the porphyrin plane (Figure 19a,b). On the other hand, the bulkier aromatic side chain of Phe-161 might prevent rotation of the isopropyl group of Leu-185 and thereby provide greater room of the distal pocket; this effect might provide easier access to the heme Fe^{2+} atom and account for the increased association rates for O_2 and CO.

B. Substitution of Leu-185 with Polar Amino Acid. Leu-185 was substituted with a more hydrophilic amino acid (Asn, Gln, or His), which was expected to interact with the coordinated O_2 by hydrogen bond and to stabilize the O_2 adduct complex similarly to Hb and Mb. In rHSA(mutant)−hemes in which Gln or His was introduced into Leu-185, they formed ferrous six-coordinated low-spin complexes under an Ar atmosphere. That

result suggests that the introduced amino acid coordinates to the heme iron as a sixth ligand under an Ar atmosphere. Upon exposure of the solutions to O_2, they were oxidized. Bis-histidyl hemochromes are known to be oxidized by O_2 rapidly via an outer sphere mechanism (*184*−*186*). On the other hand, rHSA(HL/L185N)−heme and rHSA(HF/L185N)−heme in which Asn was introduced at Leu-185 formed ferrous five-coordinated high-spin complexes under an Ar atmosphere. They formed O_2 adduct complexes under O_2 atmosphere. The introduced Asn is estimated to be too far to coordinate to the heme.

Marked differences were apparent in a comparison of the O_2 and CO binding parameters for rHSA(HL)−heme and rHSA(HL/L185N)−heme. First, the presence of Asn rather than Leu at

position 185 caused 2-fold and 3−6-fold increases, respectively, in the $k_{on}(O_2)$ and $k_{on}(CO)$ values. The Asn might partly rotate upward, which provides somewhat greater space of the distal pocket. Second, Asn-185 induced 18-fold and 10-fold increases in the O_2 binding affinity for species I and II, because the $k_{off}(O_2)$

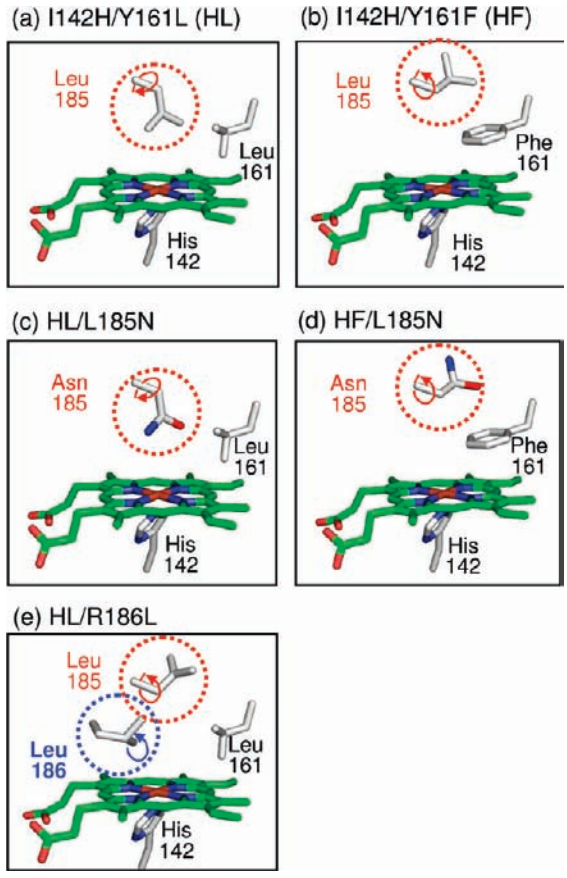

Figure 19. The proposed configuration of Leu-185 in (a) rHSA(HL)−heme and (b) rHSA(HF)−heme, Asn-185 in (c) rHSA(HL/L185N)−heme and (d) rHSA(HF/L185N)−heme, and Leu-186 in (e) rHSA(HL/R186L)–heme.

values were 1/6−1/11 of their former values. This corresponds to a free energy difference of −1.8 kcal mol^{-1} at 22 °C. The magnitude of the effect seems to be reasonable considering that, in HbO_2 and MbO_2, the distal His-64 stabilizes the coordinated O_2 by −0.6 to −1.4 kcal mol^{-1} because of the hydrogen bond (*187*). In contrast, The O_2 and CO binding parameters for rHSA(HF)−heme and rHSA(HF/L185N)−heme showed no significant differences. The bulky benzyl side chain of Phe-161 can prevent rotation of the polar amide group of Asn-185 and thereby decrease the effect of polarity and size on O_2 and CO binding parameters (Figure 19c,d) (*188*).

C. Substitution of Arg-186 with Leu or Phe. For administration into the human circulatory system, it would be better if the affinity were similar to the human RBC [$P_{50}(O_2)$: 8 Torr, 25 °C]. It is expected that providing a certain degree of hydrophobicity into the distal side of the heme by insertion of a nonpolar residue would reduce the O_2 binding affinity of the rHSA−heme complex. The most suitable position for that introduction might be at Arg-186, which is the entrance of the heme pocket and which is rather close to the central Fe(II) ion. Therefore, rHSA(HL/R186L)−hemin and rHSA(HL/R186F)−hemin were prepared. The O_2 dissociation rate constants of rHSA(HL/R186L)−heme and rHSA(HL/R186F)−heme were 3−4-fold higher than that of rHSA(HF)−heme, which reduced the O_2 binding affinities [larger $P_{50}(O_2)$]. This reduction might be attributable to the increased hydrophobicity in the distal pocket. The O_2 binding affinities of rHSA(HL/R186L)−heme [$P_{50}(O_2)$: 10 Torr] and rHSA(HL/R186F)−heme [$P_{50}(O_2)$: 9 Torr] have become equivalent to those of human RBC. The important structural factor in these mutants is Y161L, which enables the rotation of the isopropyl group of Leu-185 above the O_2 coordination site. Unexpectedly, the $k_{on}(O_2)$ and $k_{on}(CO)$ values of rHSA(HL/R186L)−heme and rHSA(HL/R186F)−heme were 3-fold and 3−4-fold higher than those of rHSA(HL)−heme and in the same range as that of rHSA(HF)−heme. In fact, Leu-161 is small, but the hydrophobic Leu-186 or Phe-186 might be integrated into the heme pocket from the entrance and might push up the neighboring Leu-185 residue (Figure 19e) (*188*).

We have engineered mutant rHSA−heme complexes that can bind O_2. Principal modifications to the heme pocket that are necessary to confer reversible O_2 binding are (i) replacement of Tyr-161 by hydrophobic amino acid (Leu or Phe), and (ii) introduction of His as a proximal base at position Ile-142. Furthermore, (iii) modification of the distal amino acid has a considerable effect on the modulation of O_2 and CO binding affinities.

4. CONCLUSIONS

The structures of our artificial O_2 carriers differ greatly from those of sophisticated RBCs. However, clear advantages of simplified artificial O_2 carriers are readily apparent: the absence of blood-type antigens and infectious viruses, stability for long-term storage at room temperature for any emergency, all of which overwhelm the functionality of RBCs. The shorter half-life of artificial O_2 carriers in the bloodstream (ca. 3 days) limits their use, but they are applicable as a transfusion alternative for shorter periods of use. Easy manipulation of physicochemical properties such as $P_{50}(O_2)$ and viscosity supports their possible development of tailor-made O_2 carriers to suit various clinical indications. The achievements of ongoing research described above give us confidence in advancing the further development with the expectation of its eventual realization.

Byproduct with Altered Fluorescent Properties Is Formed during Standard Deprotection Step of Hexachlorofluorescein Labeled Oligonucleotides

A. N Chuvilin,*[,†] M. V. Serebryakova,[†] I. P Smirnov,[†,‡] and G. E. Pozmogova[†,§]

Research Institute of Physical-Chemical Medicine, Moscow, Belozerskii Institute of Physico-Chemical Biology, Moscow State University, Moscow, and Bioengineering Center, Russian Academy of Science, Moscow, Russian Federation. Received February 17, 2009; Revised Manuscript Received June 25, 2009

HEX-labeled oligonucleotides obtained via typical synthetic protocols may contain more than 15% of material with altered spectral characteristics. We discovered hexachlorofluorescein residue transformation unknown earlier for standard DNA ammonolysis step. HEX residue reacts with ammonium hydroxide yielding acridine derivative, which has differed UV−VIS and fluorescent properties compared to HEX. Therefore, for critical bioassays where sensitivity and/or fluorescent signal differentiation (e.g., in quantitative or multiplexed assays) are essential, the careful RP-HPLC purification step is required.

INTRODUCTION

Fluorescently labeled oligonucleotides are now routinely used in molecular biology and medical diagnostics (*1, 2*). Most common methods of such oligomer synthesis assume the introduction of a label during the chain elongation process. In this case, a fluorophore undergoes all deblocking procedures and may be modified. For example, ammonolysis leads to partial conversion of the thiourea fragment of the FITC-label to urea and/or guanidine fragments (*3*).

It is a generally accepted opinion that carefully synthesized RT-PCR probes are not needed in additional purification (*4*). HEX (hexachlorofluorescein), being one of the popular red fluorescent dyes, is widely used in PCR-based assays, including multiplexed RT-PCRs (*5*). We have performed more than 200 HPLC separations of various HEX-labeled oligonucleotides obtained after automated synthesis and purified by PAGE, ion exchange chromatography, or RP cartridges. These oligonucleotides had >95% purity by gel electrophoresis analysis. In all of them, we found the presence of more than 15% full-size oligomers with altered fluorescent and UV−VIS spectral properties. For typical HPLC profiles and separation conditions, please see the Supporting Information. In the case of RT-PCR, the presence of such byproduct may lead to a decline in the sensitivity of RT-PCR assays and may have an impact on quantitation (*6*). Moreover, the fluorescent signal of these byproducts may interfere with signals from other labels, such as fluorescein, leading to a false positive response. Therefore, it is very important to understand the nature of this phenomenon.

RESULTS AND DISCUSSION

As a model object for investigation of the chemical mechanism of HEX-labeled oligonucleotide transmutation, we chose the simplest target oligonucleotide, 5′-HEX-T_{10}. The HPLC profile of the 5′-HEX-T_{10} postammonolysis mixture exhibited two main peaks (Figure 1A), labeled **1** and **2**. Fraction **1** demonstrated spectral properties expected for HEX-derivatives, while **2** had hypochromic shifts both in VIS (42 nm) (Figure 1B) and in fluorescent emission spectra (18 nm) (Figure 1C). Because of a significant shift of the emission maximum, this byproduct interferes with the working range of FITC and FAM labels. This can lead to false positive detection errors of multiplexed fluorescent-based assays.

The ratio of **1**/**2** peak intensities depends on ammonolysis conditions and, as shown on the Figure 1A, varies from 20% to 60% total oligonucleotide content. The yield of compound **1** is reduced with prolongation of time and/or elevation of ammonolysis temperature (see Figure 1A). The highest yields of oligonucleotide **1** were obtained with 25% ammonia either at room temperature/24 h or at 50 °C/5 h. More gentle deblocking conditions enhanced **1**/**2** ratio, but decreased overall yield of oligonucleotide **1** possibly because of incomplete removal of pivalic protection groups from 3,6-positions of the fluorophore.

Repeating ammonolysis of HPLC purified HEX-T_{10} (**1**) led to the appearance of the same compound **2** on the HPLC profile (data not shown). It is noteworthy that the alkaline treatment (1 M NaOH) in the same conditions did not cause such transformations (data not shown). It means that the presence of ammonium hydroxide is essential for change of the HEX label.

We were not able to detect the difference in molecular masses of oligonucleotides **1** and **2** within the mass accuracy of the MALDI TOF linear mode (±1 Da). To obtain better isotopic resolution, the synthesis of low-molecular-weight HEX−isopropylphosphate was undertaken.

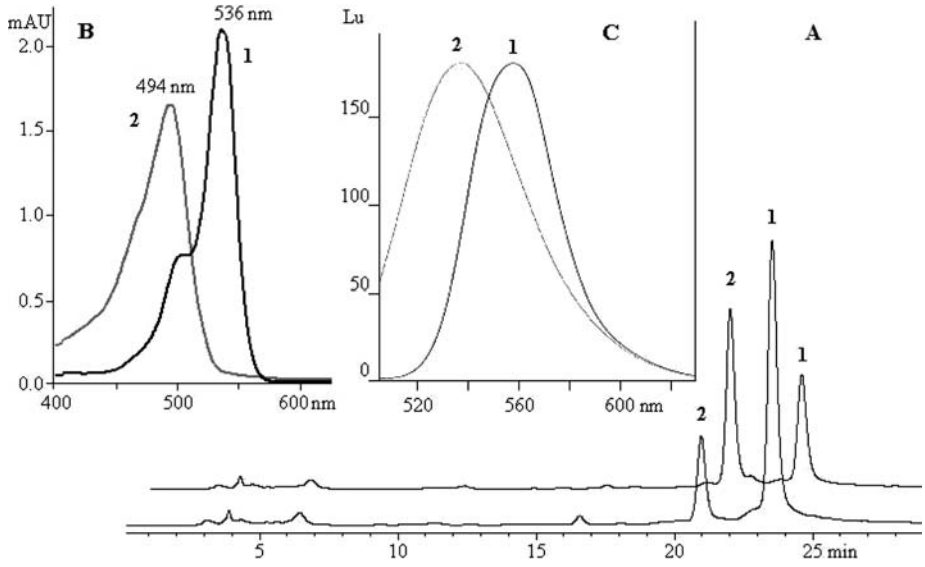

Figure 1. Transformation of 5′-HEX-T_{10} oligonucleotide. A. HPLC profiles of 5′-HEX-T_{10} isolation after ammonolysis at 50 °C/5 h (bottom curve) and at 50 °C/24 h (top curve). Column Diasorb C16T, 0.4 × 25 cm (Elsica, RF). Gradient of acetonitrile (10−20%/35 min) in 0.1 M ammonium acetate, flow 0.8 mL/min, temperature 35 °C. UV detector, λ 260 nm. B. VIS spectra of HEX-T_{10} **1** and of its acridine analogue **2** in 0.1 M NH_4OAc buffer, pH 6.7, normalized to adsorption maximum at 260 nm (UV areas are very similar, not shown). C. Fluorescence emission spectra of HEX-T_{10} **1** and of its acridine analogue **2** in the same buffer, λ_{ex} 480 nm.

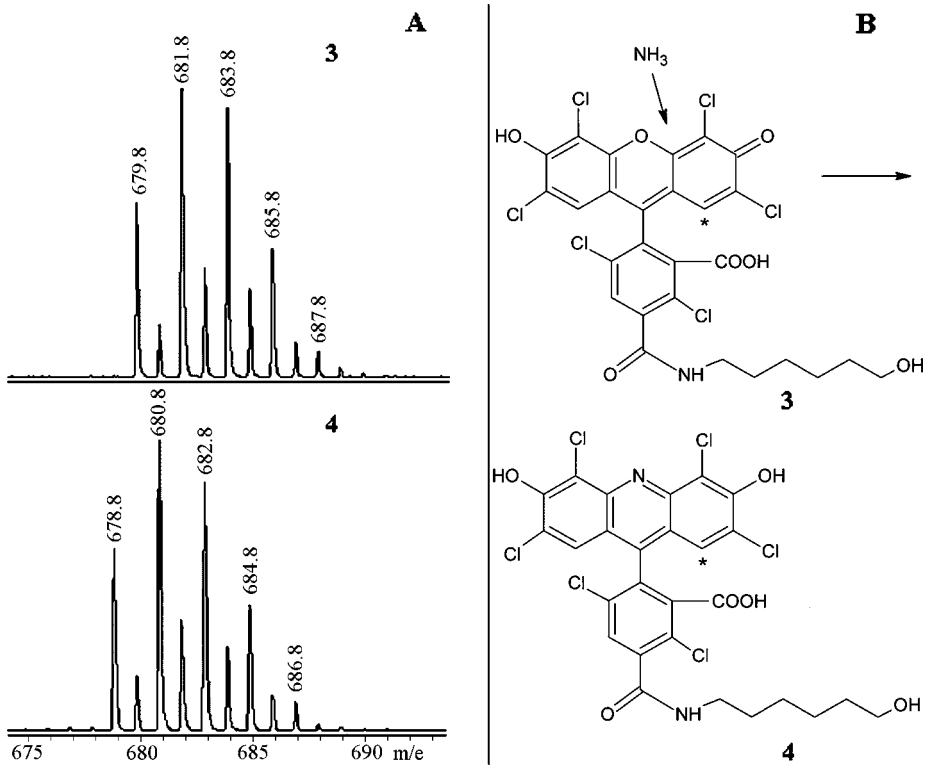

Figure 2. MALDI mass spectra (A) and the structures (B) of model fluorone **3** and acridine **4** derivatives. The arrow marks the interquartile point of ammonia nucleophilic attack. Asterisks mark locations of one of the protons that differed in ^{1}H NMR spectra of **3** and **4**.

Intermediate HEX−cyanoethylisopropylphosphite obtained by condensation of HEX-amidite (Glen Research, USA) with dry isopropyl alcohol in the presence of tetrazole was converted with standard iodine−water−pyridine oxidizer to corresponding phosphotriester, which without isolation was treated with 25% ammonia−tetrahydrofuran (9:1). Since phosphotriester had low solubility in this mixture, ammonolysis time was increased up to 66 h/60 °C. Under these conditions, significant hydrolysis of the phosphoester bonds occurred. HPLC profile of the resulting reaction mixture contained mainly two aromatic nonphosphorylated products, **3** and **4** (Figure 2A) in 7.5:1 integral ratio, according to adsorption at 260 nm. This pair of **3** and **4** had the same differences in fluorescent and VIS spectra as the pair of **1** and **2** (Figure 1B,C).

Mass spectra of compounds containing six chlorine atoms have very specific isotope signal distribution due to the natural abundance of ^{35}Cl and ^{36}Cl. The mass spectrum of **3** exhibits the same shape of the isotopic envelope as theoretically simulated (program *IsoPro* v 3.0 (*7*)) spectrum for 2,4,5,7,2′,5′-hexachloro-4′-(6″-hydroxyhexylaminocarbonyl)-fluorescein (simulation not shown). All signals observed in the mass spectrum (reflectron mode) of **4** were shifted by −1 Da in comparison

with corresponding isotopic signals of compound **3**, while the isotopic distribution remained the same (Figure 2A). These data prove that there are the same number of chlorine atoms in molecules **3** and **4**, and that there is a possibility of single oxygen atom substitution by NH group.

^{1}H NMR spectra of **3** and **4** were practically identical, including the aliphatic proton field (1−3 ppm, 12H) and the peak of the aromatic proton at the phenyl C3′ (7.63 ppm, 1H). The most important similarity is that the signals of both H atoms at C1 and C8 (Figure 2B) in both heterocycles **3** and **4** are singlets (6.96 ppm, 2H, for HEX (**3**), and 6.87 ppm, 2H, for **4**), which suggests preservation of the symmetry of the heterocycle after reaction with ammonia. There exists the sole possibility of symmetric incorporation of ammonia into the fluorone structure, the substitution of heterocyclic O10 with the NH group. Therefore, compound **4** is the acridine derivative—2,4,5,7-tetrachloro-3,6-dihydroxy-9-(2′,5′-dichloro-4′-[6″-hydroxyhexyl-aminocarbonyl]-6′-carboxyphenyl)acridine (see Figure 2B).

We observed a similar reaction of water ammonia with tetrabromo- (eosine) and tribromofluorescein (data not shown) and did not see it for the dibromo derivatives of fluorescein. In agreement with these data, all attempts at long-term ammonolysis (60 °C/6 days) of oligonucleotides labeled with nonhalogenated fluorescein (FAM-label) or with TET-label (containing dichloroxanthene group) also failed to lead to the noticeable formation of acridine structures (like **2** and **4**).

We speculate that the presence of more than two halogen atoms in the xanthene cycle of fluorones at o- and p-positions to carbon atoms near bridge atom O10 significantly facilitates ammonia nucleophilic attack leading to substitution of O10 by NH and formation of acridine structure (see Figure 2B; the most stable tautomer is shown). This effect makes possible the conversion of hexachlorofluoresceins into acridine derivatives (**2**, **4**) and explains the stability of the twice- or non-halogenated xanthene cycle of fluorone residues at the same mild conditions of ammonolysis.

The reaction of fluorone transformation to acridines under very stringent conditions was described a very long time ago, in 1899. Fluorescein ammonium salt in a dry ammonia stream has been converted to 3,6-diaminoacridine derivative at 180−200 °C in 5 days (*8*). However, at lower temperature (110 °C) dry ammonia did not change tetrachloroeosine (*9*). In turn, we did not detect 3,6-hydroxyl substitution with water ammonia at temperatures up to 70 °C.

Here, for the first time we report partial transformation of hexachlorofluorescein derivatives under mild ammonolysis conditions applied in obtaining oligonucleotides.

CONCLUSIONS

There is a possibility of conversion of halogenated fluorone labels of oligonucleotides into their acridine derivatives in mild ammonolysis conditions, which may be useful for future bioconjugate transformations.

During the standard ammonolysis step of hexachlorofluorescein- (HEX-) labeled oligonucleotides, this label undergoes substantial transformation into corresponding acridine derivative.

Post synthetic HPLC purification of HEX-labeled oligonucleotides is essential for demanding applications, where sensitivity and/or fluorescent signal differentiation (e.g., in quantitative and multiplexed assays) are critical and the possibility of false positive response must be minimized.

The examples of HPLC purification of HEX-labeled oligonucleotides.

BHQ2 is "Black Hole 2", a popular quencher of fluorescence.

HPLC were performed in gradient of acetonitrile (MeCN) in 0.1 M water ammonium acetate, pH 6.7, on thermostated columns:

A - Diasorb C16T, 10 mkm, 4*250 mm (Elsica, Russia).

B - Nucleosil 300 C18, 5 mkm, 4.6*250 mm (Teknokroma, Spain).

Peaks I correspond to target oligonucleotide HEX-derivatives, peaks II are acridine ones. We note that example 3 demonsrates not perfect HPLC profile. However, for all often used HEX-oligonucleotides we have found optimal HPLC conditions.

Table of HPLC conditions for HEX-labeled oligonucleotides.

Plate Capture Assay of Fluorescent Oligonucleotide Duplex Reporter−Transcription Factor Complexes

Surong Zhang[†] and Alexei Bogdanov, Jr.*[,†,‡]

Laboratory of Molecular Imaging Probes, Department of Radiology, and Department of Cell Biology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received March 30, 2009; Revised Manuscript Received June 16, 2009

We previously developed prototype oligodeoxyribonucleotide (ODN) duplex fluorescence energy transfer (FRET) reporters for optical sensing of NF-κB transcription factor. We report here a plate-binding assay designed for optimizing the above reporters. Nitrilotriacetate-bearing plates were prepared by using sequential (1) aminosilylation; (2) carboxylation; (3) coupling of *N*α,*N*α-bis(carboxymethyl)-L-lysine or, alternatively, by replacing steps 1 and 2 by treating the glass with 3-(triethoxysilyl)propylsuccinic anhydride. FRET reporters were obtained by covalent linking of Cy5.5 (fluorescence donor) and IRdye800CW (fluorescence acceptor) to complementary ODN strands encoding a high-affinity p50 binding site. Recombinant 6 × His tagged NF-κB p50 was used for immobilizing the protein on glass plates via linked NTA-Ni(II) groups. Imaging and quantification of the fluorescence intensity in the wells was performed in two channels (700 and 800 nm) using a near-infrared scanning device with microscopic resolution. The fluorescence intensity of the ODN duplex reporter was detectible in the plates at the concentration of 5 pM. NF-κB p50-ODN reporter interaction was studied by measuring the ratio of 700 nm (donor) to 800 nm (acceptor) fluorescence intensities. Using the plate assay, we were able to measure p50-mediated interference with FRET at low density of plate binding.

INTRODUCTION

We previously developed probes for optical sensing of NF-κB p50 protein-oligodeoxyribonucleotide (ODN) duplex interactions (*1, 2*). The sensors were based on the effect of fluorescence resonance energy transfer between fluorescence donor (Cy5.5 carbocyanine dye) and acceptor (e.g., IRdye800CW), which were covalently linked to complementary strands encoding a high-affinity transcription factor binding site. We determined that if the donor and acceptor dyes were separated by 8 base pairs the radiative FRET efficiency exceeded 75%. Since the efficiency of FRET between a pair of near-infrared dyes is sensitive to protein binding to ODN duplex-encoded sequence, the reporters can be potentially used for direct sensing protein−DNA interactions (*1, 2*). We initially measured the changes of donor and acceptor fluorescence by using a single-cuvette spectrofluorometer. This testing approach provided high spectral accuracy and precision in determining normalized fluorescence intensity ratios. However, measurements performed in the presence of non-stoichiometric ratios of oligonucleotide probe/transcription factor could also be affected by the excess of free ODN duplex reporter. In addition, the setup lacked multiplexing capabilities and had a low throughput. By using a microtiter assay format, one can potentially achieve high throughputs and better accuracy, since the protein−probe complex can be isolated from the nonbound fluorescence probes by using binding of transcription factor to the plate surface. For isolating such reporter complexes, it is desirable to immobilize them on the microplates using noncovalent, affinity-based strategies (*3*). There are several alternative strategies for achieving the above goal. The alternatives include the use of specific antibodies against transcription factor epitopes (*4, 5*), as well as against fusion peptide tags introduced in the sequence of recombinant transcription factor proteins (*6*). We chose to study ODN duplex reporter-p50 protein complex separation conditions using NTA-Ni(II)-mediated affinity binding of the p50s fusion hexahistidine residue (6 × His) tag (*7*), since commercially available purified transcription factors are usually available as affinity-tagged proteins. We anticipated a potentially high density of 6 × His-tag binding sites that can be covalently linked to the glass surface, in contrast to a less dense coating with antibodies that are prone to activity loss during the storage. Glass has low autofluorescence in red and near-infrared spectral ranges and can be easily modified with sylilation agents affording further chemical modification. We hypothesized that the high efficacy of ODN duplex reporter-p50 protein complex retrieval from the solution could potentially translate into more accurate fluorescence readouts.

Therefore, we compared glass microplate modification protocols and tested the obtained plates for immobilizing NF-κB p50 and for detecting the interactions between NF-κB p50 and ODN duplex.

MATERIALS AND METHODS

Materials. 3-(Triethoxysilyl)propylsuccinic anhydride (TPSA) was purchased from Gelest Inc. (Morrisville PA). 3-Aminopropyltriethoxylsilane (APTS), *N*-(3-dimethylaminopropyl)-*N*′-

ethylcarbodiimide hydrochloride (EDC), *N*-hydroxysulfosuccinimide (sulfo-NHS), ethylenediamine, 2,4,6-trinitrobenzenesulfonic acid (TNBS), and glycine were purchased from Sigma-Aldrich (St. Louis, MO). Tris (2-carboxyethyl)phosphine (TCEP) was obtained from Pierce (Rockford, IL). *N*α,*N*α-bis(carboxymethyl)-L-lysine hydrate (BCML) was purchased from Fluka (Switzerland). Triethylammonium acetate solution (2 M, TEAA), pH 7.0, was purchased from Glen Research (Sterling VA); Cy5.5 maleimide was from GE Healthcare (Piscataway NJ); IRDye 800CW NHS ester was from Li-COR (Lincoln NE). 96-well glass-bottom microplates were purchased from Thermo Fisher Scientific (Hudson, NH).

Oligodeoxyribonucleotide (ODN) Synthesis and Modification. The synthesis, purification, and characterization of the ODNs used in this study were performed as in ref 8. The capped 3′-dithiolinker was introduced by using commercially available CPG derivatives (Glen Research). The conjugation of the donor fluorochrome (Cy5.5 mono maleimide) was achieved after reducing hydroxyethyl dithiopropyl linker on the 3′-end of the oligonucleotide 5′-AGCTATGAGGGACTTTCCG-Y-3′ (ODN1) with DTT. The conjugation of *N*-hydroxysuccinimide ester of IRDye 800CW acceptor fluorochrome was performed by using an internucleoside amino linker positioned between thymidine and cytosine in complementary 5′-CGGAAAGT*CCCTCAT-AGCT-3′ (ODN2), designated by an asterisk. The latter was introduced by using a thymidine phosphoramidite synthon (5′-*O*-DMTr-thymidine-3′-*O*-(2-(2-(2-trifluoroacetamidoethoxy)-ethoxy)ethyl)-*N*,*N*-diisopropylphosphoramidite) with a protected primary amino group linked via a triethylene glycol linker to phosphorus. The separation of donor and acceptor fluorochromes by 8 base pairs resulted in measured radiative FRET efficiency exceeding 75%.

Spectral Measurements. All UV spectral measurements were performed at room temperature unless otherwise stated by using Cary 50 spectrophotometer (Varian). All fluorescence spectral measurements were carried out at room temperature unless otherwise noted in quartz microcuvettes using Cary Eclipse fluorescence spectrophotometer (Varian).

Preparation of ODN Duplexes. Oligodeoxynucleotide (ODN) duplexes were prepared by mixing equimolar amounts of the corresponding ODNs dissolved in 25 mM Hepes, 1 mM $MgCl_2$, 50 mM NaCl, pH 7.4. The duplex mixtures were heated between 90 and 95 °C for 5 min to dissociate any intrastrand secondary structures and allowed to cool at room temperature to attain equilibrium. Each duplex formation was confirmed by measuring UV and fluorescence spectra. Two duplexes were used in this study: (1) FRET duplex: Cy5.5−ODN1/800CW-ODN2; (2) 800 nm fluorescent control duplex: ODN1/800CW−ODN2.

Plate Surface Treatment. For glass surface activation, the following sequence of washes was used: (1) 1 M NaOH, 10 min; (2) water, 5 min; (3) 1 M HCl, 1 h; (3) water, 5 min; (4) H_2SO_4/H_2O (1/1, v/v), 5 min. The plate was then washed in water followed by anhydrous ethanol and dried in a vacuum oven at RT for 1−2 h.

Two-Step Method of NTA Linking to the Glass Surface (Figure 1A). 5% 3-(Triethoxysilyl) propylsuccinic anhydride (TPSA) in anhydrous DMSO was added to the plate and reacted for 1 h followed by washing with DMSO three times; 0.025 mL of 0.2 M *N*α,*N*α-bis(carboxymethyl)-L-lysine (BCML) in 0.2 M Na_2CO_3 (pH 9) and 0.075 mL DMSO were added to each well and incubated for 3 h, followed by washings with water.

Multistep Method of NTA Linking (Figure 1B). Amino sylilation was performed by adding an APTS/DMSO (5/95, v/v) mixture to the plate and incubating for 1 h (*9, 10*). The sylilated plate was then washed three times with DMSO. Plate carboxylation was performed by mixing 0.03 mL 0.1 M succinic anhydride in DMSO with 0.27 mL, 0.2 M $NaHCO_3$, in the wells of the plate, incubated at room temperature for 1−2 h and washed with water three times. Fifty microliters of water was added to each well and the plate was put on ice. To each well, a mixture of 50 mM EDC/20 mM sulfo-NHS in water was added, followed by incubating for 5 min. Then, 0.05 mL of 0.1 M BCML/0.2 M $NaHCO_3$ solution was added. The mixture was incubated with mixing at room temperature for 2 h. The plate was washed three times with water.

Amino Group Titration. For determining amino groups on the glass surface, 0.1 mL of 0.1 M sodium tetraborate pH 9.0, 0.05 mL 0.1% Ipegal, and 0.1 mL 10 mM TNBS were added to the wells. The plate was incubated 1 h at RT, and the absorbance was measured on a SpectraMax M5 microplate reader (Molecular Devices). To test carboxylate-modified plates, ethylenediamine was used for reacting with EDC-activated carboxyl groups in the presence of sulfo-NHS. TNBS/tetraborate/igepal solution was then added to each well. Unmodified plate wells were used as blank controls, and amino group terminated plate wells were used as positive controls. Carboxyl group terminated plate well was used as a negative control.

Ni(II) Chelation. 0.1 mL of 0.1 mM $NiCl_2$/10 mM sodium acetate (pH 5.0) was added to each well, and the plate was incubated at room temperature for 1 h. The plate was washed with 0.05% Tween-20 and then 50 mM Tris HCl, 500 mM NaCl, pH 7.5.

NF-κB p50 Direct Labeling by Fluorochromes and Plate Binding Assay. NF-κB p50 (2 μg in 0.05 mL of 0.1 M $NaHCO_3$, 0.1% Tween-20, pH 8.5) was incubated in the presence of 5-fold molar excess of IRDye800CW-NHS at room temperature for 1 h. The mixture was separated on Micro Bio-Spin P-30 columns (Bio-Rad) equilibrated with plate binding buffer (PPB: 10 mM Tris, 100 mM KCl, 2 mM $MgCl_2$, 0.1 mg/mL tRNA, 10% glycerol, 5 mM TCEP, pH 7.5). The labeled NF-κB p50−800CW protein conjugate was added to the plate in the binding buffer and incubated at room temperature for 1 h. The negative control sample was prepared as above but in the absence of NF-κB p50. The plate was washed with washing buffer (WB: 10 mM Tris HCl, 500 mM NaCl, 0.05% Tween-20, pH 7.5) three times followed by fluorescence readout as described below.

NF-κB p50 Binding Assay. ODN duplex−p50 complex solution in 0.05 mL PPB was prepared by adding 0.4 pmol ODN duplex and 2.4 pmol NF-κB p50 incubated at room temperature for 30 min before being loaded to the plate. The plate was incubated at room temperature for 1 h followed by three washes with WB.

mAb-Coated Plate. According to the manufacturer's instructions, affinity-purified rabbit polyclonal antibody (NFκB p105/p50, Abcam Inc., Cambridge, MA) was adsorbed on a surface of polystyrene 96-well plate at 1 μg/well in 0.01 M carbonate buffer; the plate was washed with PBS-T (0.05% Tween 20) and blocked with BSA. Complexes of ODN and p50 were incubated in the plate for 1 h at room temperature, and fluorescence was determined by using the Odyssey system as described below.

Electrophoretic Mobility Shift Assays (EMSAs). EMSAs were performed using a reaction mixture containing 18 nM ODN duplexes incubated 30 min RT in a volume of 0.01 mL NF-κB p50 solution in PPB. Samples were loaded and run on 10% TBE Ready Gels (Bio-Rad Laboratories, Hercules CA) using 0.5 × TBE buffer. The gels were imaged and digitized using Odyssey Infrared Imaging system (LI-COR Biosciences, Lincoln, NE).

Fluorescence Measurements Using Odyssey Infrared Imaging System. The instrument utilizes simultaneous solid diode excitation of fluorescence at 685 and 785 nm and measures emitted light by using a dichroic mirror transmitting above 810

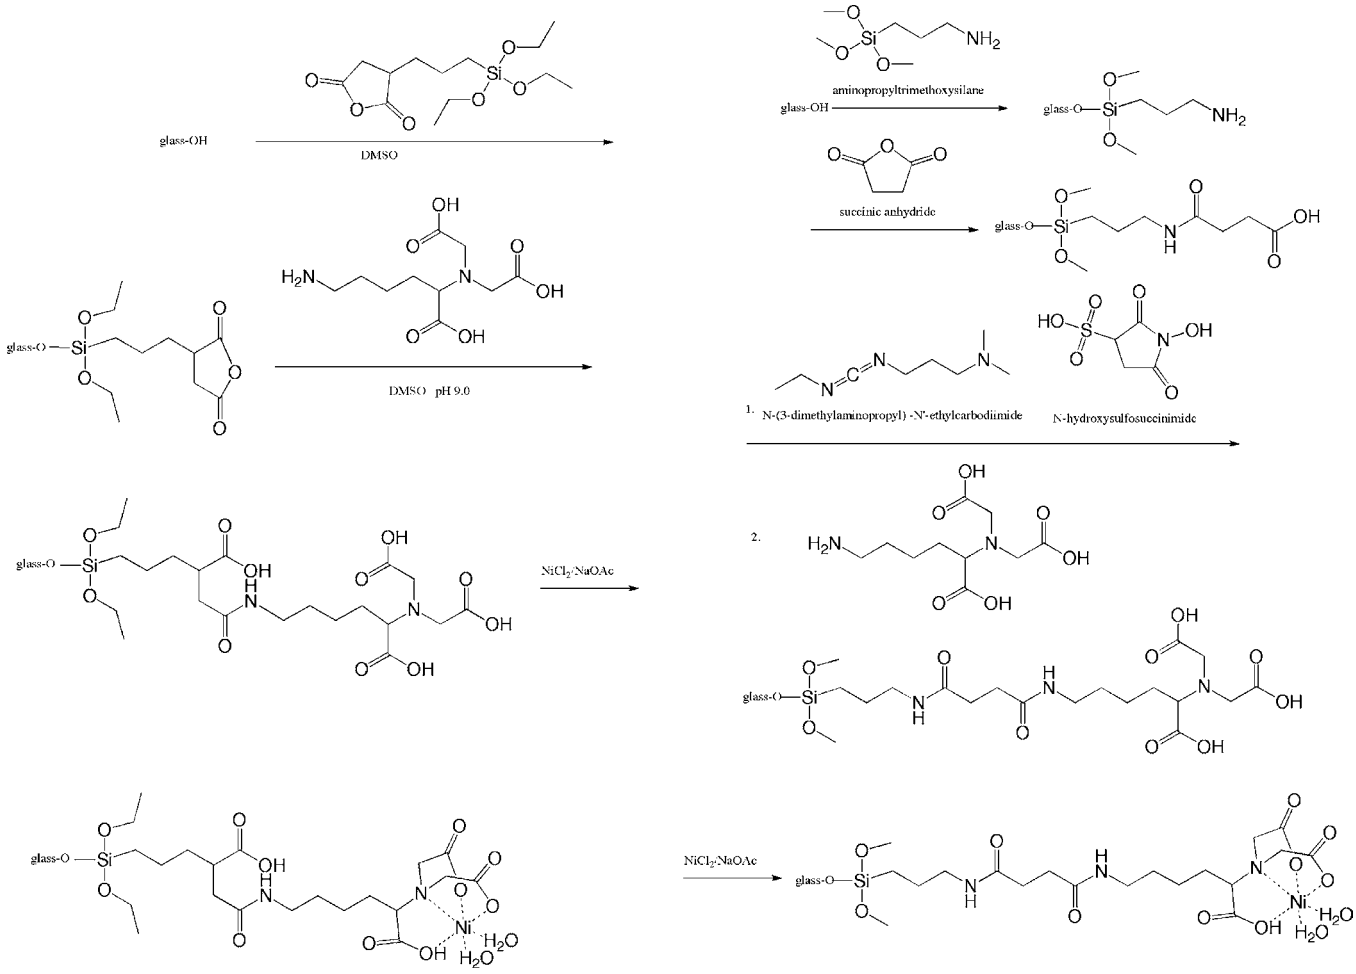

Figure 1. Scheme of NTA-Ni(II) glass plate surface activation. (A) a two-step method including glass surface activation using silylation with 3-(triethoxysilyl) propylsuccinic anhydride (TPSA) followed by coupling of N_α,N_α-bis(carboxymethyl)-L-lysine hydrate (BCML); (B) a multistep synthesis requiring aminosilylation using 3-aminopropyltriethoxylsilane (APTS) with subsequent acylation with succinic anhydride and coupling of BCML in the presence of water-soluble carbodiimide and sulfosuccinimide.

nm ("800 channel" fluorescence band) and reflecting below 750 nm ("700 channel"fluorescence band). Fluorescence signals were processed to filter scattered and stray light. The obtained images (16 bit TIFF) were analyzed, colorized, and fused using *ImageJ 1.38* (NIH).

The standard for measurements in 800 channels was prepared by loading the plate with different concentrations of 800 channel control duplex. FRET duplex was also measured to calculate FRET efficiency.

Statistical Analysis. All experiments were performed in triplicate. Values were expressed as the mean ± the standard deviation (SD) and compared using double-tailed unpaired *t* test with Welch's correction (Prism 4.0, GraphPad).

RESULTS AND DISCUSSION

Preparation and Testing of NTA Glass Plates. We initially compared two strategies of carboxyl group linking to the surface of the glass plates: (1) silylation with 3-(triethoxysilyl) propylsuccinic anhydride and reacting the obtained anhydride group with *N*α,*N*α-bis(carboxymethyl)-L-lysine (Figure 1A); (2) a multistep synthesis requiring aminosilylation using 3-aminopropyltriethoxylsilane (APTS), reacting the glass-linked amino groups with succinic anhydride, and, finally, activating the coupled carboxyls by using water-soluble carbodiimide before adding BCML (Figure 1B). To determine the amounts of amino groups and carboxyl groups on the surface of the plates, we used TNBS as amino group test reagent and measured absorbance of the mixture at 420 nm (*11*).

We used ethylene diamine coupling to either anhydride (first two-step method, Figure 1A) or to EDC/Sulfo-NHS activated carboxyls (Figure 2B) for comparing the efficacy of plate surface modification. By reacting anhydride residues with diamine and treating the conjugated amino groups with TNBS, we showed that at least 60 nmol of reactive carboxyl groups were linked to the surface of each well of a 96-well plate as a result of sylilation with TPSA. In contrast, the multistep approach resulted in 2× less amino groups linked to each well. The multistep conjugation strategy has potential advantages allowing conjugation via longer linker between the glass and chelating group and the absence of additional carboxyl groups in the linker moiety that can potentially weakly bind Ni^{2+} cations. However, the advantage of the first method was in simplicity due to a two-step activation and the higher number of reactive groups linked to the glass. Since the first strategy resulted in 2× more reactive carboxyl groups/well, we used the two-step glass modification approach in the further experiments.

To obtain glass-immobilized quadridentate NTA-Ni(II) chelate and to reduce nonspecific binding, the plate was first blocked with BSA followed by nickel chelation with glass-conjugated NTA groups. To test whether the obtained NTA-Ni(II) plate has 6 × His-tag binding affinity, we labeled NF-κB p50 directly with IRDye800CW fluorochrome and compared binding of labeled protein with the free dye (Figure 2A). No free IRDye800CW binding to the plate was detected, whereas the 800CW-labeled NF-κB p50 showed binding that was directly proportional to the added protein concentration. As shown in

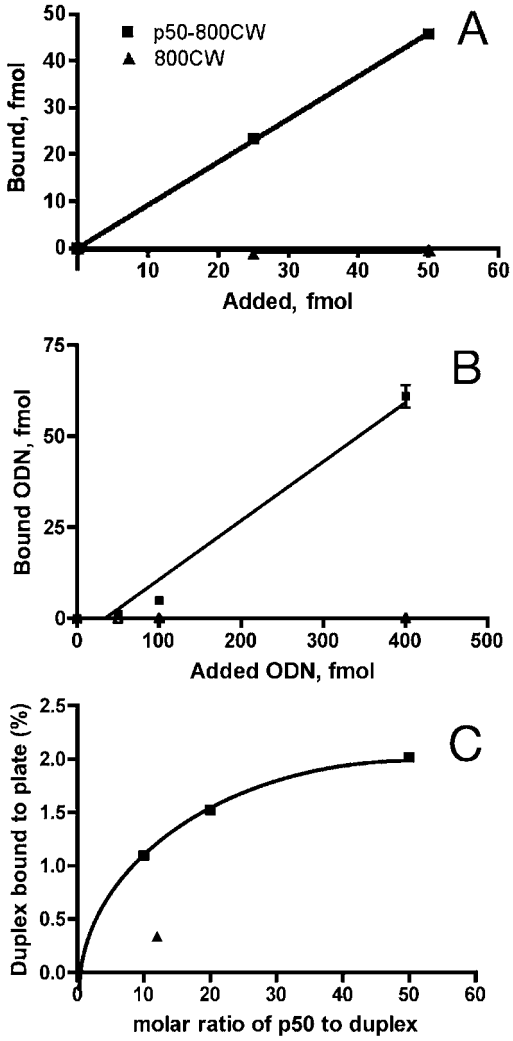

Figure 2. Testing NTA-Ni(II) plate in binding assays. (A) p50 binding to NTA-Ni(II) plate. NF-κB p50 labeled with IRDye800CW (squares), IRDye800CW dye alone (triangles); (B) ODN1/800CW-ODN2 binding to NTA-Ni(II) plate either in the presence of p50 (squares) or in the absence of p50 (diamonds); (C) efficacy of p50−duplex binding to the NTA-Ni(II) plate (squares) at various p50−duplex molar ratios or to anti-p50 antibody-coated plate (triangle) at p50−duplex molar ratio of 12:1.

Figure 2A, in the range below 50 fmol (less than 1 nM p50 added) 90−95% 800CW-p50 was bound to the NTA-Ni plate.

NTA-Ni(II) Plate Binding Assay for Detecting ODN Reporter-p50 Interactions. We tested two types of p50-binding ODN duplexes: a reporter duplex Cy5.5−ODN1/800CW-ODN2 carrying a pair of FRET fluorochromes (Cy5.5, donor and 800CW, acceptor) on complementary strands, as well as non-FRET duplex ODN1/800CW-ODN2 as a standard. According to the results of EMSA, both duplex probes (i.e., reporter and control) were efficiently binding p50 (not shown). ODN duplex ODN1/800CW-ODN2 was initially chosen for testing the binding of ODN duplex probes in the NTA-Ni(II) plate binding assay, since fluorescent signal at 800 nm has a very high signal/background ratio (Figure 2B). ODN1/800CW-ODN2 duplex was first incubated with human recombinant His × 6-tagged p50 at various duplex/p50 molar ratios and then added to the wells of NTA-Ni(II) plates. The measured bound fluorescence values showed that approximately 1−2% of added duplex-p50 complex was bound to the NTA-Ni plate (Figure 2C, squares). Alternatively, ODN duplex−p50 complex (1:12 molar ratio) was captured on the plates using affinity-purified antibody. In contrast to the NTA-Ni(II) strategy, only 0.34% of added duplexes was bound to the plate surface reflecting random immobilization of antibody molecules on the plate and, consequently, a potentially lower density of p50 binding centers (Figure 2C, triangles).

Fluorescence measurements in glass plates demonstrated high sensitivity to the presence of ODN reporter. The limit of FRET ODN duplex reporter detection in solution was 5 pM when fluorescence was measured at 800 nm. To perform testing of ODN duplex probes in the developed NTA-Ni(II) plate binding assay, ODN duplexes (2.4 pmol, 8 nM) were first incubated with human recombinant p50 at the molar ratio of 1:12 at room temperature for 30 min. To test the specificity of p50−ODN duplex recovery from the solution, we added 0−8 nM ODN duplex to the NTA-Ni(II) plate, either in the presence or in the absence of p50 protein. After a 1 h incubation period followed by washings, we measured the fluorescence intensity associated with the plate using a two-channel imaging system (Figure 3A). For quantification of both free and bound duplex, the fluorescence intensity was measured in the 800 nm channel was excited at 785 nm, i.e., the fluorescence intensities of non-FRET duplex ODN1/800CW-ODN2 and FRET duplex Cy5.5−ODN1/800CW-ODN2 measured at 800 nm were treated as unaffected by FRET and plotted on the same scale (Figure 3B). Fluorescence intensities of both Cy5.5 and 800CW fluorochromes measured in the wells after adding FRET ODN duplex−p50 complex showed duplex concentration-dependent increase (Figure 3A,B), whereas free FRET ODN duplex showed no concentration-dependent association with the plate surface (see Figure 3A, upper row). To determine whether FRET efficiency in ODN duplex reporter complex was changing as a result of p50 binding, we performed measurements of fluorescence at 700 nm (donor fluorochrome) to 800 nm (acceptor fluorochrome) and calculated the resultant emission light intensity ratios. Measurements of fluorescence intensity at 800 nm enabled calculation of the duplex amount bound to the plate. By comparing ratiometric measurements performed in the case of free Cy5.5−ODN1/800CW-ODN2 duplex and Cy5.5−ODN1/800CW-ODN2-p50 complex bound to NTA-Ni(II) plate, we showed that in the low range of bound duplex amounts (less than 20 fmol/well) FRET ODN duplex reporter−p50 complex had higher Cy5.5/800CW ratio values than the free duplex (Figure 3C). The above result indicates that p50 partially interferes with the intraduplex FRET effect normally present in p50-free duplex reporter. However, at higher amounts of the duplex bound to the well (>60 fmol/well) we observed a loss of measurable ratiometric difference between duplex reporter−p50 complex bound to the plate and free duplex reporter alone (Figure 3C). This effect can be explained by Cy5.5 fluorochrome partial self-quenching at high local concentrations next to the plate surface (nonemitting FRET).

Therefore, we performed optimization steps for preparing NTA-Ni(II) linked glass plate and used the obtained plates for separating free ODN duplexes from a complex formed between the His × 6-tagged NF-κB p50 protein and fluorescent ODN duplex. This approach enabled reliable ratiometric measurements of FRET effects in ODN reporters bound to the plate surface. The alternative approaches would require coating of the plate with antitranscription factor antibodies or linking the duplexes to the surface as described in refs 5, 12. The antibody-coated plate showed a lower efficacy than the NTA-Ni(II) strategy. The use of covalent conjugation of fluorochrome-linked duplexes to the plate with the subsequent analysis of fluorescence changes after incubating with recombinant NF-κB proteins can be used as a potential alternative. The advantage is that the use of His-tagged proteins, which have a lower DNA-binding affinity (*13*), is not required. However, the latter strategy requires the use of additional linking of reporter ODNs to the glass, for

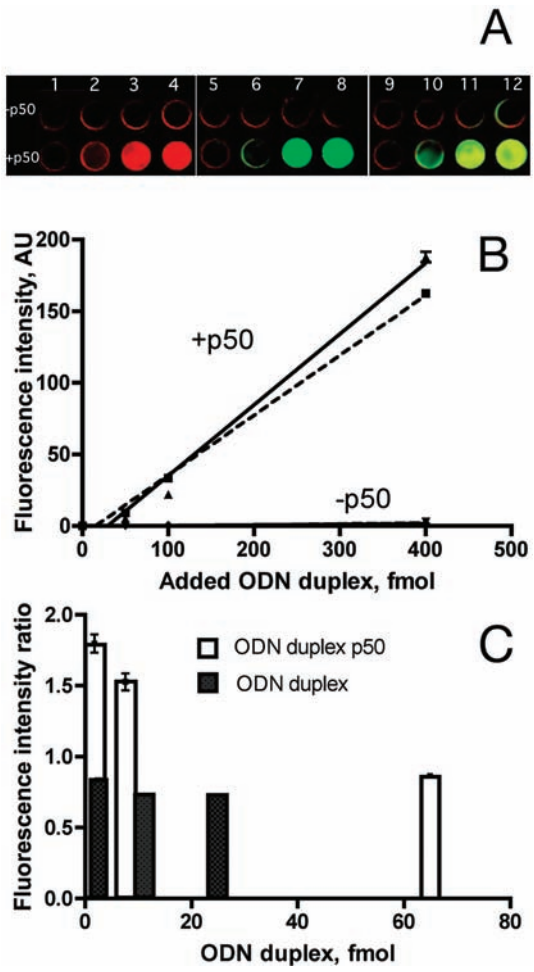

Figure 3. NTA-Ni(II) plate binding of two-fluorochrome labeled FRET reporter duplexes. (A) Dual channel fluorescence imaging of NTA-Ni(II) plate. The upper row, binding of FRET duplex Cy5.5-ODN1/800CW-ODN2 to the plate surface in the absence of p50; the lower row, binding of the FRET duplex to the plate after a complex formation with p50. Lanes 1−8 duplex amounts: lanes 1,5 − control, 0 fmol; lanes 2,6 − 100 fmol; lanes 3,7 − 200 fmol; lanes 4,8 − 400 fmol. Lanes 9−12 show an overlay of images acquired at 700 nm (red) and 800 nm (green). (B) ODN duplex reporters Cy5.5-ODN1/800CW-ODN2 binding to the NTA-Ni(II) plate in the absence or in the presence of p50 protein. Triangles (solid line), fluorescence intensity at 800 nm; squares (hatched line), fluorescence intensity at 700 nm. Results presented as mean ± SD ($n = 3$). (C) Ratiometric measurements (700 channel/800 channel fluorescence intensities) performed using NTA-Ni(II) plate bound Cy5.5-ODN1/800CW-ODN2 ODN duplex reporters in the absence (open bars, free duplex in solution) or in the presence of p50 protein (closed bars, p50-duplex complex bound to the plate).

example, via 3′- or 5′-dithio linkers (*14*), creating potential sterical hindrances for transcriptional factor binding. The assay proposed in our work was specifically designed to capture preformed transcription factor−duplex complexes and allowed selective measurement of FRET in the fraction of protein−ODN duplex complexes. The developed method will be used for optimizing duplex ODN reporter design for potential detection of functional NF-κB components in vitro and in vivo.

Cationic polymers have been of interest and importance as nonviral gene delivery carriers. Herein, well-defined comb-shaped cationic copolymers (HPDs) composed of long biocompatible hydroxypropyl cellulose (or HPC) backbones and short poly((2-dimethyl amino)ethyl methacrylate) (or P(DMAEMA)) side chains were prepared as gene vectors via atom transfer radical polymerization (ATRP) from the bromoisobutyryl-terminated HPC biopolymers. The P(DMAEMA) side chains of HPDs can be further partially quaternized to produce the quaternary ammonium HPDs (QHPDs). HPDs and QHPDs were assessed in vitro for nonviral gene delivery. HPDs exhibit much lower cytotoxicity and better gene transfection yield than high-molecular-weight P(DMAEMA) homopolymers. QHPDs exhibit a stronger ability to complex pDNA, due to increased surface cationic charges. Thus, the approach to well-defined comb-shaped cationic copolymers provides a versatile means for tailoring the functional structure of nonviral gene vectors to meet the requirements of strong DNA-condensing ability and high transfection capability.

INTRODUCTION

Gene therapy shows much promise in tackling various genetic diseases and cancers, viral infection, and cardiovascular disorders (*1*−*3*). Successful gene therapy depends on the design of gene delivery vectors with low cytotoxicity and high transfection efficiency (*4, 5*). In comparison with viral vectors and cationic lipids, cationic polymers have been receiving considerable attention as the major type of nonviral gene delivery vectors, because of their low host immunogenicity, high flexibility, and easy preparation (*6, 7*). Polycations can spontaneously condense negatively charged DNA by electrostatic interaction into compact nanocomplexes and reduce the electrostatic repulsion between DNA and cell surfaces. Polycationic vectors can also protect plasmid DNA from enzymatic degradation by nucleases and facilitate cellular transfection. A great number of polycations, including polyethylenimine (PEI) (*8*), poly((2-dimethyl amino)ethyl methacrylate) (*6, 9, 10*), poly(L-lysine) (*11*), polyamidoamine (*12*), and polysaccharide-based cationic carriers (*5, 13*), have been reported to deliver nucleic acids. Among these cationic polymers, PEI with a molecular weight of 25 kDa is considered the gold standard for polymeric nonviral gene delivery due to its high transfection efficiency (*7*). However, most of them suffer from either low gene transfection efficiency or significant toxicity.

Natural polysaccharides are very suitable candidates for gene delivery, because they are renewable, nontoxic, biodegradable, and excellent biocompatible materials. Hydroxypropyl cellulose (HPC) is a derivative of natural polysaccharide cellulose with both water and organic solubility, where some of the hydroxyl groups of cellulose have been hydroxypropylated to form propylene oxide groups (*14*−*17*). HPC materials have been approved by the United States Food and Drug Administration (FDA) and widely used in food and drug formulations (*15, 18, 19*). Comb-shaped cationic copolymers have been of interest and importance as nonviral gene carriers (*4, 20*−*22*). The reactive hydroxyl groups on HPC can be used as initiation sites for forming side chains to produce the comb-like copolymers via living radical polymerizations (*16, 23*). In the present work, well-defined comb-shaped cationic copolymers (HPDs) of long, biocompatible HPC backbones and short poly((2-dimethyl amino)ethyl methacrylate) (P(DMAEMA)) side chains are prepared via atom transfer radical polymerization (ATRP) (*24*) from the bromoisobutyryl-terminated HPC (HPC-Br) backbones (Scheme 1). The P(DMAEMA) side chains can be further partially quaternized to produce the quaternary ammonium HPDs (QHPDs). HPDs and QHPDs can condense plasmid DNA (pDNA) into complex nanoparticles of 150 to 200 nm in size at nitrogen/phosphate (N/P) ratios of 5 or higher. In comparison with the long P(DMAEMA) homopolymer, HPDs show much lower cytotoxicity and higher gene transfection efficiency. QHPDs exhibit a stronger ability to complex pDNA, due to increased surface cationic charges. The novel HPDs and QHPDs may have potential application as nonviral gene vectors for future gene therapy.

g/mol; from gel permeation chromatography (GPC) with THF as mobile phase: M_n = 28 015 g/mol and M_w = 64 655 g/mol; molar substitution of propylene oxide groups (MS) of about 3 per glucose unit *16, 17*), branched polyethylenimine (PEI, M_w ~25 000 Da), 1,4,7,10,10,-hexamethyl triethylenetetramine (HMTETA, 99%), copper(I) bromide (CuBr, 99%), 2-bromoisobutyryl bromide (BIBB, 98%), and (2-dimethylamino)ethyl methacrylate (DMAEMA, >98%) were obtained from Sigma-Aldrich Chemical Co., St. Louis, MO. DMAEMA was used after removal of the inhibitors in a ready-to-use disposable inhibitor-removal column (Sigma-Aldrich). 3-(4,5-Dimethylthiazol-2yl)-2,5-diphenyl tetrazolium bromide (MTT), penicillin, and streptomycin were purchased from Sigma Chemical Co., St. Louis, MO. HEK293 cell lines were purchased from the American type Culture Collection (ATCC, Rockville, MD). The control P(DMAEMA) homopolymer with about 180 repeat units of DMAEMA was prepared via ATRP, using the reported ethylene glycol di-2-bromoisobutyrate as the initiator (*24*).

Synthesis of Comb-Shaped Cationic Copolymers via ATRP. The starting bromoisobutyryl-terminated HPC (HPC-Br) was synthesized following the procedures. About 2.0 g of HPC was dissolved completely in 100 mL of anhydrous methylene chloride with stirring and then kept in an ice bath. About 0.3 mL of BIBB in 5 mL of methylene chloride was added dropwise into the flask through an equalizing funnel for a period of 10 min at 0 °C. After this addition, the flask was sealed. The reaction was allowed to proceed at room temperature for another 5 h to produce the HPC-Br macroinitiator. The final reaction mixture was precipitated with 1000 mL of diethyl ether. The crude polymer was purified by reprecipitation thrice in diethyl ether. Finally, the HPC-Br for the subsequent ATRP was dried under reduced pressure.

The HPC-*g*-P(DMAEMA) comb-like polymers (HPDs, Scheme 1) were synthesized using a molar feed ratio (DMAEMA (about 1 mL))/(CuBr)/(HMTETA) of 60:1:1.2 at room temperature in 8 mL of isopropanol/water (20/1, v/v) containing 0.2 g of HPC-Br. The reaction was performed in a 25 mL flask equipped with a magnetic stirrer and under the typical conditions for ATRP (*24*). DMAEMA, HPC-Br, and HMTETA were introduced into the flask containing 8 mL of isopropanol/water (20/1, v/v). After HPC-Br had dissolved completely, the reaction mixture was degassed by bubbling argon for 30 min. Then, CuBr was added into the mixture under an argon atmosphere. The reaction mixture was purged with argon for another 10 min. The flask was then sealed with a rubber stopper under an argon atmosphere. The polymerization was allowed to proceed under continuous stirring at room temperature for 2 to 8 h. The reaction was stopped by diluting with THF. The catalyst complex was removed by passing the blue dilute polymer solution through a short aluminum oxide column. A colorless solution was obtained. After removal of THF in a rotary evaporator, the HPDs were precipitated in excess *n*-hexane. The crude polymer was purified by reprecipitation twice in hexane to remove the reactant residues, prior to being dried under reduced pressure. The HPD1 (from ATRP time of 2 h) and HPD2 (from ATRP time of 8 h) yields are about 0.4 and 0.72 g, respectively. The HPC-*g*-QP(DMAEMA) (QHPDs) with partially quaternized P(DMAEMA) side chains were prepared at 50 °C for 24 h in 5 mL of THF containing 0.4 g of HPD2 and 200 or 400 μL of 1-bromohexane. The QHPDs were precipitated in excess *n*-hexane and dried under reduced pressure.

Polymer Characterization. The molecular weights of polymers were determined by gel permeation chromatography (GPC), chemical composition by X-ray photoelectron spectroscopy (XPS), and chemical structure by nuclear magnetic resonance (NMR) spectroscopy. GPC measurements were performed on a Waters GPC system equipped with Waters Styragel columns, a Waters-2487 dual wavelength (λ) UV detector, and a Waters-2414 refractive index detector. THF containing 2 vol % triethylamine was used as the eluent at a low flow rate of 1.0 mL/min. Monodispersed polystyrene standards were used to generate the calibration curve. The XPS measurements were performed on a Kratos AXIS HSi spectrometer equipped with a monochromatized Al Kα X-ray source (1486.6 eV photons), using the same procedures as those described earlier (*24*).^{1}H NMR spectra were measured by accumulation of 1000 scans at a relaxation time of 2 s on a Bruker ARX 300 MHz spectrometer, using $CDCl_3$ or D_2O as the solvent.

Characterization of Polymer/Plasmid DNA Complexes. The plasmid (encoding *Renilla* luciferase) used in this work was pRL-CMV (Promega Co., Cergy Pontoise, France), which was cloned originally from the marine organism *Renilla reniformis*. The plasmid DNA (pDNA) was amplified in *Escherichia coli* and purified according to the supplier's protocol (Qiagen GmbH, Hilden, Germany). The purity and concentration of the purified DNA were determined by absorption at 260 and 280 nm and by agarose gel electrophoresis (*9*). The purified pDNA was resuspended in tris-EDTA (TE) buffer and kept in aliquots of 0.5 mg/mL in concentration. All polymer stock solutions were prepared at a nitrogen concentration of 10 mM in distilled water. Solutions were filtered via sterile membranes (0.2 μm) of average pore size and stored at 4 °C. Comb-like polymers to DNA ratios are expressed as molar ratios of nitrogen (N) in the HPDs and QHPDs to phosphate (P) in DNA (or as N/P ratios). The average mass weight of 325 per phosphate group of DNA was assumed (*8*). All polymer/pDNA complexes were formed by mixing equal volumes of polymer and pDNA solutions to achieve the desired N/P ratio. Each mixture was vortexed and incubated for 30 min at room temperature.

Each cationic polymer was examined for its ability to bind pDNA through agarose gel electrophoresis using the similar procedures as those described earlier (*9*). The polymer/pDNA complexes at various N/P ratios were investigated. Gel electrophoresis was carried out in TAE running buffer (40 mM Tris-acetate, 1 mM EDTA) with a voltage of 110 V for 30 min in a Sub-Cell system (Bio-Rad Lab, Hercules, CA). DNA bands were visualized and photographed by a UV transilluminator and BioDco-It imaging system (UVP Inc., Upland, CA). The particle sizes and zeta potentials of the polymer/pDNA complexes were measured using a Zetasizer Nano ZS (Malvern Instruments, Southborough, MA) and procedures similar to those described earlier (*9*). The polymer/pDNA complexes were also observed with a field-emission scanning electron microscope equipped with a scanning transmission electron microscopy (STEM) detector (JEOL JSM-6700F) and procedures similar to those described earlier (*9*). The complexes were visualized by transmitted electrons (STEM-in-SEM mode) at a low voltage of 15 kV, in comparison to about 200 kV for the conventional TEM. Such low voltage can minimize damage to the polymer/pDNA complex and allow visualization of the complex in the TEM mode at high spatial resolution.

Cell Viability and in Vitro Transfection Assay. The cytotoxicity of the comb-like polymers was evaluated using the MTT assay in HEK293 cell lines. They were cultured in Dulbecco's modified eagle medium (DMEM), supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 units/mL of penicillin, and 100 μg/mL of streptomycin at 37 °C, under 5% CO_2 and 95% relative humidity atmosphere. The cells were seeded in a 96-well microtiter plate at a density of 10^4 cells/well and incubated in 100 μL of DMEM/well for 24 h. The culture media were replaced with fresh culture media containing serial dilutions of polymers, and the cells were incubated for 24 h. Then, 10 μL of sterile-filtered MTT stock solution in PBS (5 mg/mL) was added to each well, reaching a final MTT concentration of 0.5 mg/mL. After 5 h, the unreacted dye was removed by aspiration. The produced formazan crystals were dissolved in DMSO (100 μL/well). The absorbance was measured using a microplate reader (Spectra Plus, Tecan, Zurich, Switzerland) at a wavelength of 570 nm. The cell viability (%) relative to control cells cultured in media without polymers was calculated from $(A)_{test}/(A)_{control} \times 100\%$, where $(A)_{test}$ and $(A)_{control}$ are the absorbance values of the wells (with the polymers) and control wells (without the polymers), respectively. For each sample, the final absorbance was the average of those measured from six wells in parallel.

Transfection assays were performed using plasmid pRL-CMV as the reporter gene in HEK293 cell lines. In brief, the cells were seeded in 24-well plates at a density of 5×10^4 cells in the 500 μL of medium/well and incubated for 24 h. The comb-shaped polymer/pDNA complexes (20 μL/well containing 1.0 μg of pDNA) at various N/P ratios from 7 to 22 were prepared by adding the polymer into the DNA solutions, followed by vortexing and incubation for 30 min at room temperature. At the time of transfection, the medium in each well was replaced with 300 μL of serum-free medium or fresh normal medium (supplemented with 10% FBS). The complexes were added into the transfection medium and incubated with the cells for 4 h under standard incubator conditions. Then, the medium was replaced with 500 μL of the fresh normal medium (supplemented with 10% FBS). The cells were further incubated for an additional 20 h under the same conditions, resulting in a total transfection time of 24 h. The cultured cells were washed with PBS twice and lysed in 100 μL of the cell culture lysis reagent (Promega Co., Cergy Pontoise, France) using the similar procedures as those described earlier (*9*). Luciferase gene expression was quantified using a commercial kit (Promega Co., Cergy Pontoise, France) and a luminometer (Berthold Lumat LB 9507, Berthold Technologies GmbH. KG, Bad Wildbad, Germany). Protein concentration in the cell samples was analyzed using a bicinchoninic acid assay (Biorad Lab, Hercules, CA). Gene expression results were expressed as relative light units (RLUs) per milligram of cell protein lysate (RLU/mg protein).

Statistical Analysis. All experiments were repeated at least three times. The data were collected in triplicate and expressed as mean $\pm$ standard deviation. Error bars represent the standard deviation. The statistical assay was performed using *t*-test, and the differences were considered statistically significant with $p < 0.05$.

RESULTS AND DISCUSSION

Synthesis and Characterization of Comb-Shaped Cationic Copolymers Composed of HPC Backbones and P(DMAEMA) Side Chains. The preparation of functional polymers is usually carried out in organic solvent. Because of its unique characterisitcs of both water and organic solubility, HPC is an ideal substrate for developing novel polysaccharide biopolymer-based cationic carriers. The molecular weight (M_n) of the HPC used in this work from gel permeation chromatography (GPC) is about 2.80×10^4 g/mol, and its corresponding polydispersity index (PDI) is about 2.3. The C 1s core-level X-ray photoelectron spectrum (XPS) (Figure 1a) of the pristine HPC can be curve-fitted by three peak components with binding energies (BEs) at about 284.6, 286.2, and 287.6 eV, attributable to the

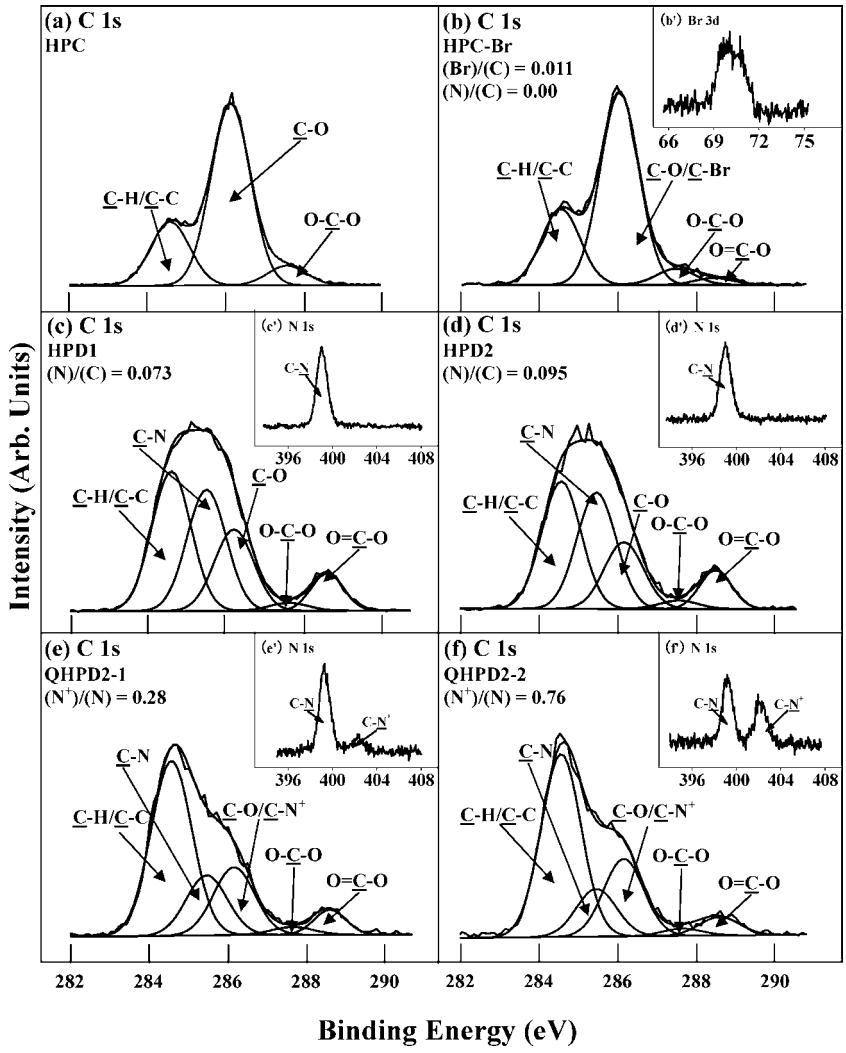

Figure 1. XPS C 1s core-level spectra of (a) HPC, (b) HPC-Br, (c) HPD1, (d) HPD2, (e) QHPD2−1, and (f) QHPD2−2, Br 3d core-level spectrum of (b′) HPC-Br, and N 1s core-level spectra of (c′) HPD1, (d′) HPD2, (e′) QHPD2−1, and (f′) QHPD2−2.

C-H/C-C, C-O, and O-C-O species, respectively (*9*, *24*). From the (C-O)/(O-C-O) ratio of 11, the average number of propylene oxide groups ($-OCH_2CH(OH)CH_3$) per anhydroglucose unit of HPC is about 3, consistent with that (2.9) determined using ^{1}H NMR (*16*, *17*).

In order to prepare comb-shaped copolymers using HPC as a backbone via ATRP, it is essential to introduce alkyl halide into HPC. In this work, the bromoisobutyryl-terminated HPC (HPC-Br) was prepared via the reaction of hydroxyl groups of HPC with 2-bromoisobutyryl bromide (BIBB) (Scheme 1). When ATRP is carried out from a multifunctional backbone with a high local concentration of initiation sites, the radical−radical coupling of the propagating chains will occur and result in a gel. In order to avoid potential gelation and introduce some flexibility onto the comb-like cationic copolymers, the starting HPC-Br with moderate initiation sites is desired for preparing well-defined comb-shaped copolymers. The C 1s core-level XPS spectrum (Figure 1b) of HPC-Br can be curve-fitted by four peak components with BEs at about 284.6, 286.2, 287.6, and 288.4 eV, attributable to the C-H/C-C, C-O/C-Br, O-C-O, and O=C-O species, respectively (*9*, *24*). The new O-C=O peak component is associated with the bromide-capped ester groups of HPC-Br. The corresponding Br 3d core-level spectrum is shown in Figure 1b′. From the (Br)/(C) ratio of 0.011 (determined from the sensitivity factor-corrected Br 3d and C 1s core-level spectral area ratio), it was calculated that about six glucose units of HPC-Br possess one ATRP initiation site. The chemical structure of HPC-Br is also characterized by ^{1}H NMR spectroscopy (Figure 2a). The chemical shift at $\delta = 1.12$ ppm is attributable to the methyl protons of propylene oxide groups (***a***, CH_3). The chemical shift at $\delta = 1.92$ ppm is associated with the methyl protons (***b***, C(Br)-CH_3) of the 2-bromoisobutyryl groups (*24*). The broad chemical shifts in the wide region 2.9−4.3 ppm are mainly associated with the inner methylidyne and methylene protons (***c***, ***c′***, CH and CH_2) on glucose units and propylene oxide groups. From the area ratio of peak ***a*** and peak ***b***, the initiator density of HPC-Br is that every 6.8 glucose units possess one initiation site, fairly consistent with that determined by XPS.

Well-defined comb-shaped copolymers (HPDs) of HPC and P(DMAEMA), or HPC-*g*-P(DMAEMA), were subsequently synthesized via ATRP of DMAEMA from HPC-Br (Scheme 1). The HPDs with different lengths of P(DMAEMA) side chains can be synthesized by varying the ATRP time. Table 1 summarizes the GPC results of HPD1 (from 2 h of ATRP) and HPD2 (from 8 h of ATRP). With the increase in reaction time from 2 to 8 h, the M_n of HPD from GPC using linear polystyrene standards increases from 5.42×10^4 to 8.86×10^4 g/mol, and the total number of DMAEMA repeat units per side chain increases accordingly from 13 to 30. These values are lower than those determined by XPS and ^{1}H NMR (Table 1), probably due to the differences in hydrodynamic volumes between comb-like and linear polymers. In addition, the PDIs of HPDs are comparable to that of the pristine HPC, indicating that the ATRP

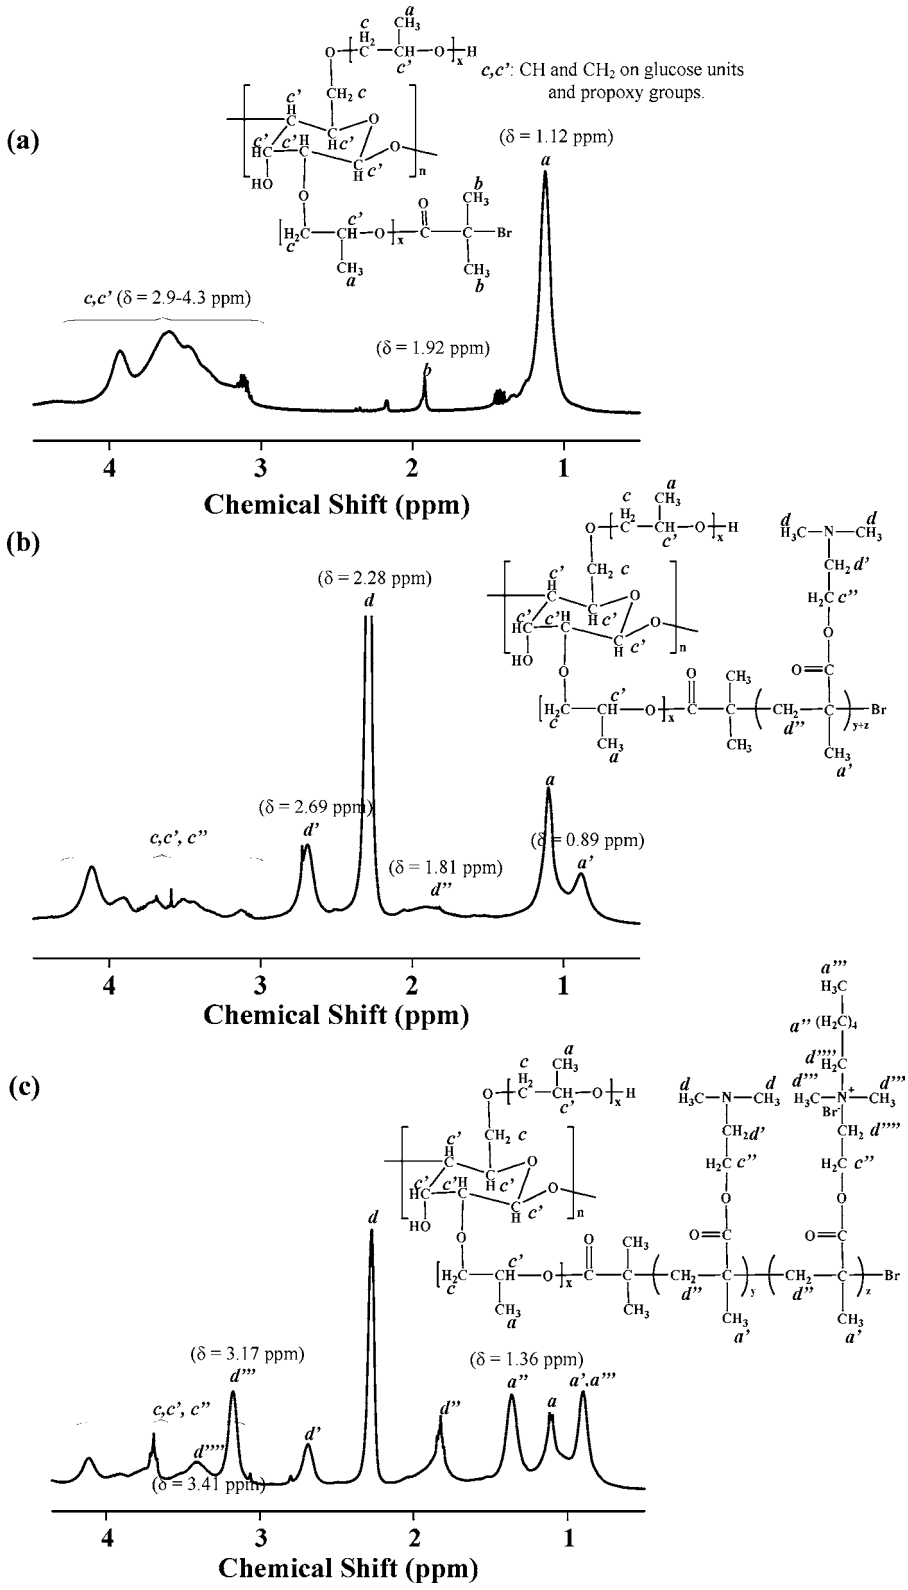

Figure 2. 300 MHz ^{1}H NMR spectra of the (a) HPC-Br, (b) HPD2, and (c) QHPD2−1 polymers.

of DMAEMA is well-controlled. In order to increase the surface cationic charges, the P(DMAEMA) side chains of HPD can be partially quaternized to produce the HPC-*g*-QP(DMAEMA) (QHPD) with quaternary ammonium groups. In this work, the QHPD2−1 and QHPD2−2 with different quaternization contents were prepared by using HPD2 and 1-bromohexane (Scheme 1 and Table 1).

The C 1s core-level spectra of HPD1 and HPD2 (Figure 1c and d) can be curve-fitted into five peak components with BEs of about 284.6, 285.5, 286.2, 287.6, and 288.4 eV, attributable to the C-H/C-C, C-N, C-O, O-C-O, and O=C-O species, respectively. The C-N peak is associated with the P(DMAEMA) side chains. In comparison with the C 1s core-level spectrum (Figure 1b) of HPC-Br, the increase (and decrease) in intensities of the C-N (and C-O) species with ATRP time is consistent with the increase in P(DMAEMA) contents. The corresponding N 1s core-level spectra of HPD1 and HPD2 are shown in Figure 1c′ and d′, respectively. From the (N)/(C) ratios determined by

Table 1. Characterization of the Comb-Shaped Cationic Polymers

sample	reaction time (h)	M_n (g/mol)[c]	PDI[c]	(N)/(C)[d]	$(N^+)/(N)+(N^+)$[d]	DMAEMA repeat units (per side chain)		
HPC	–	2.80×10^4	2.3	–	–		–	
HPC-*g*-P(DMAEMA)1 or HPD1[a]	2	5.42×10^4	2.2	0.073	–	13[e]	16[f]	15[g]
HPC-*g*-P(DMAEMA)2 or HPD2[a]	8	8.86×10^4	1.8	0.095	–	30[e]	35[f]	37[g]
HPC-*g*-QP(DMAEMA)2−1 or QHPD2−1[b]	24	–	–	–	0.22		–	
HPC-*g*-QP(DMAEMA)2−2 or QHPD2−2[b]	24	–	–	–	0.43		–	

[a] Synthesized using a molar feed ratio (DMAEMA (1 mL)):(CuBr):(HMTETA) of 60:1:1:1.2 at room temperature in 8 mL of isopropanol/water (20/1, v/v) containing 0.2 g of HPC-Br. The calculated molecular format of glucose units of HPC is $C_{15}H_{28}O_8$, and about six glucose units of HPC-Br possess one initiation site. [b] Synthesized at 50 °C in 5 mL of THF containing 0.4 g of HPD2 and 200 (for QHPD2−1) or 400 μL (for QHPD2−2) of 1-bromohexane. [c] Determined from GPC results. PDI = Weight average molecular weight/Number average molecular weight, or M_w/M_n. [d] Determined from XPS. [e] Determined from M_n and the molecular weights of DMAEMA (157 g/mol). [f] Determined from (N)/(C) ratio, where $(N)/(C) \approx n_{(DMAEMA)}/((6 \times 15 + 4) + 8n_{(DMAEMA)})$. [g] Determined from the ^{1}H NMR spectroscopy data.

XPS, the P(DMAEMA) contents of HPDs can be calculated (Table 1). After quaternization, the C 1s core-level spectra of QHPD2−1 and QHPD2−2 (Figure 1e and f) can be curve-fitted into five peak components with BEs at about 284.6, 285.5, 286.2, 287.6, and 288.4 eV, attributable to the C-H/C-C, C-N, C-O/C-N^+, O-C-O, and O=C-O species, respectively (*25*). In comparison with the C 1s core-level spectrum (Figure 1d) of the starting HPD2, the increase in intensities of the C-H/C−C and C-O/C-N^+ species of QHPD2−1 and QHPD2−2 indicates that the P(DMAEMA) side chains have been successfully quaternized by 1-bromhexane. In comparison with the monopeak component of the N 1s core-level spectrum (Figure 1d′) of HPD2, the N 1s core-level spectra (Figure 1e′ and f′) of QHPD2−1 and QHPD2−2 can be curve-fitted into two peak components with BEs at about 399 and 402 eV, attributable to the amino (C-N) and positively charged nitrogen (C-N^+) species, respectively (*25*). The quaternization extent of P(DMAEMA) side chains can be expressed as the $(N^+)/((N) + (N^+))$ ratio (determined from the corresponding N^+ peak component and total nitrogen spectral area ratio). The average $(N^+)/((N) + (N^+))$ ratios for QHPD2−1 and QHPD2−2 are about 0.22 and 0.43, respectively (Table 1), indicating that about 1 out of every 4.5 (for QHPD2−1) or 2.3 (for QHPD2−2) DMAEMA repeat units had been quaternized.

Figure 2b and c shows the respective ^{1}H NMR spectra of HPD2 and QHPD2−1 in D_2O. The typical chemical shifts at about 0.89, 1.81, 2.28, and 2.69 ppm are mainly attributable to the (***a′***) C-CH_3 methyl, (***d″***) C-CH_2 methylene, (***d***) N-CH_3 methyl, and (***d′***) N-CH_2 methylene protons of the P(DMAEMA) side chains, respectively. The chemical shift associated with the methylene protons adjacent to the oxygen moieties of the ester linkages (***c″***, CH_2−O−C=O) overlapped completely with glucose peaks of HPC. The signal intensities associated with the HPC backbone (***a***, ***c***, ***c″***) have decreased substantially. From the area ratio of peaks ***d***, ***d′***, ***d″*** and peaks ***a***, ***a′***, the P(DMAEMA) contents of HPDs can be calculated, and the results are comparable to those obtained from XPS (Table 1). After quaternization, the new signals at about 3.17 and 3.41 ppm are attributable to the (***d‴***) N^+-CH_3 methyl and (***d⁗***) N^+-CH_2 methylene protons of the quaternized P(DMAEMA) side chains, respectively (*26*). The chemical shift at about 1.36 ppm corresponds to the methylene protons of hexane (***a″***, CH_2-C). Due to the serious overlaps in the characteristic shifts of the components, it is very difficult to quantify the P(DMAEMA) and QP(DMAEMA) segments by ^{1}H NMR.

Polymer/Plasmid DNA Complexes. For cellular transfection, DNA has to be first condensed by cationic polymers into polymer/plasmid nanoparticles suitable for cellular entry. Thus, the DNA condensation capability is a prerequisite for polymeric gene vectors. In this work, the ability of the comb-shaped cationic copolymers to condense plasmid DNA (pDNA) into particulate structures was confirmed by agarose gel electrophoresis, particle size, and zeta potential measurements, as well as STEM imaging. Figure 3 shows the gel retardation results

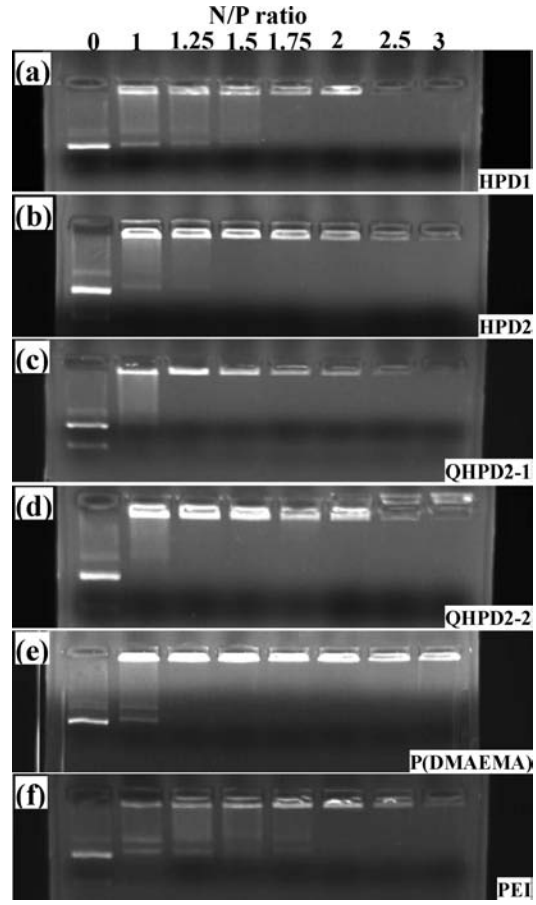

Figure 3. Electrophoretic mobility of plasmid DNA (pDNA) in the complexes of the cationic polymers ((a) HPD1, (b) HPD2, (c) QHPD2−1, (d) QHPD2−1, (e) P(DMAEMA), and (f) PEI at various N/P ratios.

of the cationic comb copolymer (HPD1, HPD2, QHPD2−1, and QHPD2−2)/pDNA complexes with increasing nitrogen (N)/phosphate (P) (or N/P) ratios, in comparison with those of the P(DMAEMA) homepolymer (with about 180 DMAEMA repeat units)/pDNA and branched PEI (25 kDa)/pDNA complexes. HPD1 and HPD2 can compact pDNA effectively at N/P ratios of 1.75 and 1.5, respectively, due to the increasing density of amino groups in the comb-like copolymers (Table 1). The migration of pDNA was completely retarded by QHPD2−1 or QHPD2−2 at an N/P ratio of 1.25, indicating that the increased surface cationic charges from quaternization could enhance the condensation capability of the comb copolymers. The control P(DMAEMA) and PEI could inhibit the migration of pDNA at N/P ratios of 1.25 and 2.0, respectively, indicating that the prepared comb copolymers have good condensation capability.

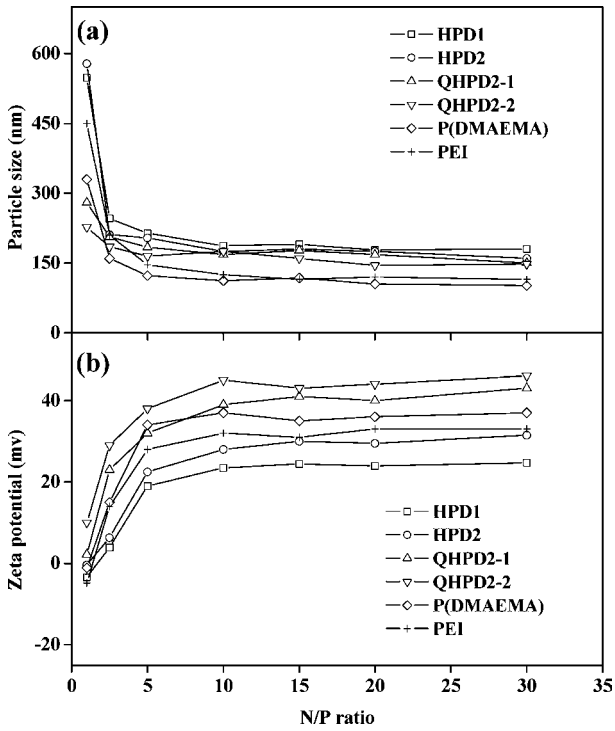

Figure 4. Particle size (a) and zeta potential (b) of the complexes between the cationic polymers (HPD1, HPD2, QHPD2−1, QHPD2−2, P(DMAEMA), and PEI) and pDNA at various N/P ratios.

The (a) particle size and (b) zeta potential of the cationic polymer (HPD1, HPD2, QHPD2−1, and QHPD2−2)/pDNA complexes are compared to those of the P(DMAEMA)/pDNA and PEI/pDNA complexes at various N/P ratios in Figure 4. All the cationic comb copolymers can efficiently compact pDNA into nanoparticles. Generally, the hydrodynamic sizes of the complexes decrease with increasing N/P ratios. After reaching the N/P ratio of 5, all the comb copolymers can condense pDNA into nanoparticles of 150 to 200 nm diameter. The polymer/pDNA complex within this size range can readily undergo endocytosis (*27*). Zeta potential is an indicator of surface charges on the polymer/pDNA naoparticles. A positively charged surface allows electrostatic interaction with negatively charged cell surfaces and facilitates cellular uptake. For the pDNA complexes of HPD1, HPD2, QHPD2−1, QHPD2−2, P(DMAEMA), and PEI, the net surface charge increases dramatically as the N/P ratio increases from 1 to 5, and stabilizes at N/P ratios of 10 and above (Figure 4b). After reaching the N/P ratio of 10, the zeta potentials of the pDNA complexes of all the cationic polymers are strongly positive. Due to the increasing quaternization of the P(DMAEMA) side chains, the pDNA complexes of HPD2, QHPD2−1, and QHPD2−2 show increasing surface cationic charges, indicating that they will produce increasing affinity for anionic cell surfaces. On the other hand, the excess cationic polymers probably do not exert any significant effect on the particle size and zeta potential of the complexes (Figure 4). In addition, the observed N/P ratios for completely retarding the migration of pDNA in the agarose gel electrophoresis (Figure 3) represented the starting points where the polymer/pDNA complexes become positively charged. At such N/P ratios, pDNA cannot be packed tightly. With increasing N/P ratios, the hydrodynamic sizes (or net surface charges) of the complexes decrease (or increase) and stabilize at higher N/P ratios (Figure 4). Therefore, the results from electrophoresis are consistent with those from Figure 4.

Figure 5 shows the representative STEM images of the (a) HPD2/pDNA (at a N/P ratio of 1), (b) HPD2/pDNA (at a N/P ratio of 15), and (c) QHPD2−1/pDNA (at a N/P ratio of 15) complexes. The FESEM equipped with a STEM detector allows the visualization of polymer complexes in the TEM mode at a low voltage of 15 kV to avoid destruction of the polymer/pDNA complex. The images clearly reveal the morphological difference between the polymer/pDNA complexes at different N/P ratios. For the HPD2/pDNA complex at a ratio of 1, loose aggregates (>400 nm), supercoiled pDNA, and compact nanoparticles (<10 nm) are observed at the same time, indicating that pDNA has been partially condensed. At the N/P of 15, pDNA can be packed tightly and condensed completely. The compacted complexes of pDNA with HPD2 and QHPD2−1 exist in the form of spherical nanoparticles (<200 nm in size). No obvious difference was observed among the spherical nanoparticles.

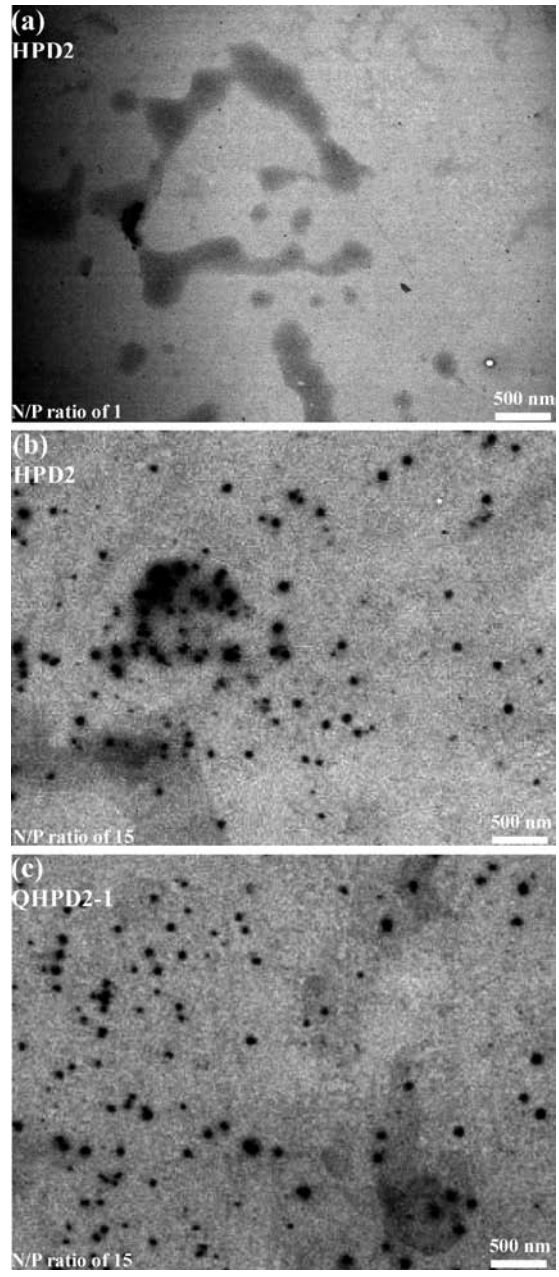

Figure 5. STEM images of the (a) HPD2/pDNA (at a ratio of 1), (b) HPD2/pDNA (at a ratio of 15), and (c) QHPD2−1/pDNA (at a ratio of 15) complexes.

Cytotoxicity of Comb-Shaped Cationic Copolymers. Cytotoxicity is one of the most important factors to be considered in selecting polymeric gene carriers. Figure 6 shows the in vitro MTT assay results of cytotoxicity of HPD1,

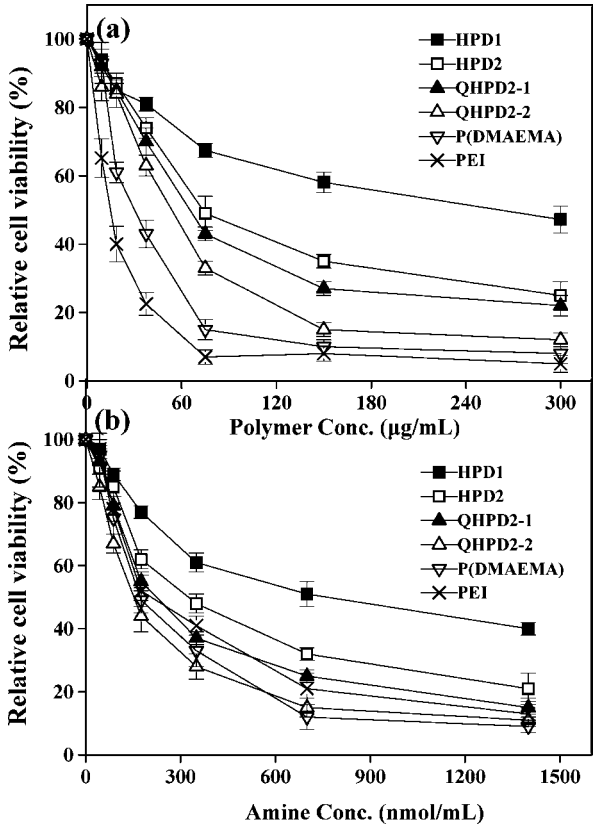

Figure 6. Cell viability assay in HEK293 cells with various concentrations of HPD1, HPD2, QHPD2−1, QHPD2−2, P(DMAEMA), and PEI (a, polymer concentration; b, amine concentration). Cell viability was determined by the MTT assay and expressed as a percentage of the control cell culture. Error bars represent the standard deviation of six measurements.

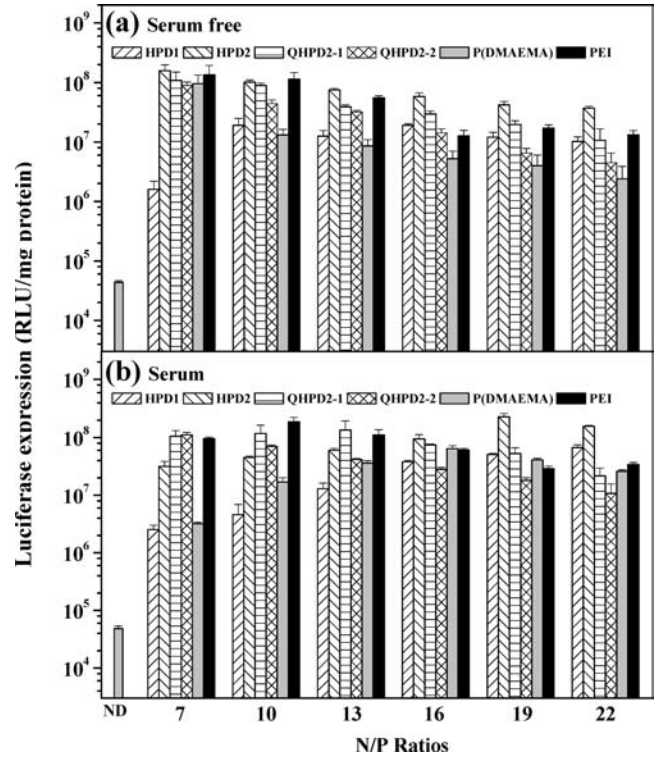

Figure 7. In vitro gene transfection efficiency of the cationic polymers (HPD1, HPD2, QHPD2−1, QHPD2−2, P(DMAEMA), and PEI)/pDNA complexes in comparison with that of naked DNA (ND) at various N/P ratios in HEK293 cells in the absence (a) and presence (b) of serum. Error bars represent the standard deviation of three measurements.

HPD2, QHPD2−1, QHPD2−2, P(DMAEMA), and PEI in HEK293 cells with the vairous polymer (a) and amine (b) concentraions. All of the cationic polymers exhibit a dose-dependent cytotoxicity effect. The slopes of the dose-dependent cytotoxicity curves for P(DMAEMA) are much steeper than those for the HPDs copolymers. The concentrations of amino groups, as well as molecular structure (*27*), are always considered to be important factors affecting cytotoxicity. The introduction of the biocompatible HPC backbones not only results in a lower relative concentration of amino groups, but has also imparted biocompatible characteristics to the cationic carriers. It was also well-known that the cytotoxicity of polycations increases with the molecular weight (*27*). Because of its longer P(DMAMEA) side chains, HPD2 exhibited higher cytotoxicity than HPD1. Both the high-molecular-weight HPD1 and HPD2 produced lower cytotoxicity than P(DMAEMA) homopolymer. The averaged number (about 11 for HPD1 and 34 for HPD2, Table 1) of DMAEMA repeat units per side chain of HPDs is much lower than that (about 180) of the control P(DMAEMA) homopolymer. Therefore, it was indicated that the molecular structure of the high-molecular-weight comb copolymers composed of long biocompatible HPC backbones and low-molecular-weight P(DMAEMA) side chains cannot produce high cytotoxicity. In addition, HPD2, QHPD2−1, and QHPD2−2 exhibit increasing toxicity, indicating that the introduced quaternary ammonium groups can increase the cytotoxicity (*28*), although the quaternization of the P(DMAEMA) side chains could enhance the surface cationic charges and DNA-condensing ability. The above results are also supported by the calculated median inhibitory concentration (IC_{50}). IC_{50} is defined as the polymer concentration of a gene carrier at which the relative cell viability decreases to 50% (*27*). The IC_{50} values of P(DMAEMA) and PEI are about 30 and 24 μg/mL, respectively, in comparison with those of HPD1 (245 μg/mL), HPD2 (70 μg/mL), QHPD2−1 (61 μg/mL), and QHPD2−2 (45 μg/mL).

Gene Transfection Mediated by Comb-Shaped Cationic Copolymers. The in vitro gene transfection efficiency of the cationic polymers/pDNA complexes was assessed using luciferase as a gene reporter in HEK293 cells. Figure 7 shows the gene transfection efficiency of HPD1, HPD2, QHPD2−1, and QHPD2−2 in comparison with those of P(DMAEMA) and PEI at N/P ratio from 7 to 22 in the absence (a) and presence (b) of serum. In the present work, the optimal N/P ratios in the serum (or serum-free) case for HPD1, HPD2, QHPD2−1, and QHPD2−2, and P(DMAEMA) are 22 (or 16), 19 (or 7), 10 (or 7), 7 (or 7), and 16 (or 7), respectively. HPD2, QHPD2−1, and QHPD2−2 exhibit decreasing optimal N/P ratio in the presence of serum, indicating that that the introduced quaternary ammonium groups can increase the DNA-binding ability. The optimal N/P ratio for the control PEI is about 10 at both cases. The transfection efficiency generally increases at lower N/P ratios and then decreases with the increase in N/P ratio. At lower N/P ratios, pDNA cannot be condensed efficiently by the polymers, and the resultant loose polymer/pDNA complex cannot enter the cell easily. At higher polymer/plasmid ratios, the transfection formulation also contains free polymer, besides the compact and positively charged polymer/pDNA complexes. For example, when the N/P ratio was increased to 22, the percentage of free PEI in the PEI/pDNA formulation was at least 55% (=(22 − 10)/22 × 100%) based on the optimal N/P ratio of 10. Due to the presence of an increasing amount of free cationic polymers with the increase in N/P ratios, the increasing cytotoxicity decreases the cell viabilities and results in a reduction in the transfection efficiency. In particular, the

transfection efficiencies mediated by QHPD2−2, P(DMAEMA) and PEI decreases dramatically with the increase in N/P ratios, due to the high cytotoxicity of the three polymers.

As shown in Figure 7, the transfection efficiency mediated by HPD1 is lower than that mediated by HPD2 at various N/P ratios. This observation indicates that the transfection efficiency for HPDs is dependent on the side lengths of P(DMAEMA). The long P(DMAEMA) side chains can increase the binding ability and complex stability, probably leading to a much higher transfection efficiency. It is worth noting that the transfection efficiency mediated by HPD2 is higher than that mediated by the control P(DMAEMA) homopolymer. The averaged number of DMAEMA repeat units per side chain of HPD2 is about 34, much lower than that (about 180) of the P(DMAEMA) homopolymer, indicating that the high-molecular-weight comb copolymers composed of long biocompatible HPC backbones and low-molecular-weight P(DMAEMA) side chains can enhance gene transfection efficiency. One possible reason is that such unique architectures could enhance the interaction of the cationic P(DMAEMA) with pDNA or cellular membranes.

Due to increased surface cationic charges, QHPD2−1 and QHPD2−2 were expected to strongly complex pDNA and result in a higher transfection yield than HPD2. However, at the optimal N/P ratios of HPD2, QHPD2−1, and QHPD2−2, the maximum transfection efficiency follows the order QHPD2−2 < QHPD2−1 < HPD2. This observation indicates that quaternary ammonium groups could not further enhance the transfection efficiency, probably due to the increased cytotoxicity (*28*) and decreased buffering capacity of polymer/DNA complexes. After cellular entry, the polymer/plasmid complexes are transported into the lysosome. The cationic polymers should retain substantial buffering capacity over a wide range of pHs, not only to protect the DNA from degradation inside the lysosome, but it is thought to also lead to lysosomal swelling and rupture via protonization. The latter process in turn provides an escape mechanism for DNA particles into the cytoplasm (*29*, *30*). The released pDNA is subsequently transported into the nucleus for gene expression. The QHPDs with quaternization groups may possess the lower buffering capacity inside the lysosome, which prevents the subsequent release of pDNA from the strongly condensed complexes.

CONCLUSIONS

Well-defined comb-shaped copolymers (HPDs) consisting of long biocompatible HPC backbones and short cationic P(DMAEMA) side chains were prepared via ATRP from the bromoisobutyryl-terminated HPC biopolymers. The P(DMAEMA) side chains can be further partially quaternized to produce the QHPDs with quaternary ammonium groups. At N/P ratios of 5 or higher, HPDs and QHPDs as gene carriers can effectively bind pDNA to form nanoparticle complexes of 150 to 200 nm in size. In comparison with long P(DMAEMA) homopolymers, HPDs exhibit much lower cytotoxicity and better gene transfection efficiency. QHPDs show stronger ability to complex pDNA than HPDs. Thus, structural tailoring of functional comb-shaped cationic copolymers provides a unique and versatile means for designing novel gene carriers.

Received September 16, 2008; Revised Manuscript Received June 17, 2009

RNase A self-associates under certain conditions to form a series of domain-swapped oligomers. These oligomers show high catalytic activity against double-stranded RNA and striking antitumor actions that are lacking in the monomer. However, the dissociation of these metastable oligomers limits their therapeutic potential. Here, a widely used conjugating agent, 1-ethyl-3-(3-dimethylaminoisopropyl) carbodiimide (EDC), has been used to induce the formation of amide bonds between carboxylate and amine groups of different subunits of the RNase A C-dimer. A cross-linked C-dimer which does not dissociate was isolated and was found have augmented enzymatic activity toward double-stranded RNA relative to the unmodified C-dimer. Characterization using chromatography, electrophoresis, mass spectrometry, and NMR spectroscopy revealed that the EDC-treated C-dimer retains its structure and contains one to three novel amide bonds. Moreover, both the EDC-treated C-dimer and EDC-treated RNase A monomer were found to carry an increased number of positive charges (about 6 ± 2 charges per subunit). These additional positive charges are presumably due to adduct formation with EDC, which neutralizes a negatively charged carboxylate group and couples it to a positively charged tertiary amine. The increased net positive charge endowed by EDC adducts likely contributes to the heightened cleavage of double-stranded RNA of the EDC-treated monomer and EDC-treated C-dimer. Further evidence for EDC adduct formation is provided by the reaction of EDC with a dipeptide Ac-Asp-Ala-NH_2 monitored by NMR spectroscopy and mass spectrometry. To determine if EDC adduct formation with proteins is common and how this affects protein net charge, conformation, and activity, four well-characterized proteins, ribonuclease Sa, hen lysozyme, carbonic anhydrase, and hemoglobin, were incubated with EDC and the products were characterized. EDC formed adducts with all these proteins, as judged by mass spectrometry and electrophoresis. Moreover, all suffered conformational changes ranging from slight structural modifications in the case of lysozyme, to denaturation for hemoglobin as measured by NMR spectroscopy and enzyme assays. We conclude that EDC adduct formation with proteins can affect their net charge, conformation, and enzymatic activity.

INTRODUCTION

Bovine pancreatic ribonuclease A (RNase A) is a 124-residue monomeric enzyme that catalyzes the breakdown of single-stranded RNA with specificity for pyrimidines at the 3′-side of the cleavage site. RNase A forms oligomers by a three-dimensional domain swapping mechanism (*1*). Dimers can be formed when two monomers swap their N-terminal α-helices (*2*) or their C-terminal *β*-strands (*3*). These dimers are called the N-dimer and C-dimer, respectively. Higher oligomers form by combinations of N-terminal or C-terminal swapping or both (*4*−*7*). This oligomerization can be induced by lyophilization from 40% glacial acetic acid (*1*) or incubation at elevated temperature at high concentration in water (*8*) or in alcohol/water solution (*9*).

The oligomerization of RNase A has been shown to endow the protein with a marked increased catalytic activity against double-stranded poly(A)·poly(U) or double-stranded viral RNA (dsRNA) (*10*) and, even more remarkably, a potent and selective toxicity *in vivo* against human tumors (*11*). The activity on dsRNA and the cytotoxicity of RNase A oligomers increases with their size (*12*). All RNase oligomers formed are metastable and dissociate over time into monomers. The dissociation of the larger oligomers into smaller ones is markedly faster than the disassociation of the dimers into monomers. The lifetime of the dimers can be as long as months in optimal conditions, namely, 4 °C, pH 7, in phosphate buffer. However, their lifetime is considerably lower at physiological temperatures. RNase S, the product of the mild digestion of RNase A into two fragments which remain associated by noncovalent interactions, forms a 3D domain-swapped C-dimer (*13*). By conjugation of the small fragment with DNA or PNA, it is possible to form semisynthetic RNase S monomers and C-dimers with modulated activities (*14*). However, the study and application of semisynthetic RNase S dimers is impeded by their rather strong tendency to dissociate. Therefore, the addition of cross-links to stabilize RNase A or RNase S oligomers could maintain their novel activity and increase their *in vivo* antitumor activity.

In this paper, we have selected 1-ethyl-3-(3-dimethylaminoisopropyl) carbodiimide (EDC), which induces the formation

of isopeptide bonds between nearby amine and carboxylate groups, as a suitable cross-linking reagent for RNase oligomers. We have identified suitable conditions for obtaining cross-linked RNase A C-dimers. Using these conditions, we have produced and purified cross-linked RNase A C-dimers and determined their enzymatic activities against ssRNA and dsRNA. We also isolated and characterized RNase A monomers carrying EDC adducts which result from a side reaction. The EDC adducts endow RNase A monomers with an increased positive charge and an augmented ribonucleolytic activity on dsRNA.

EDC is a popular reagent for cross-linking two proteins or for activation of carboxylate groups for reaction with other molecules containing amines. The formation of carbodiimide adducts to proteins is well-documented in the literature up until 1995 (*15*−*18*), but the effects of these adducts on protein conformation and function is relatively unexplored. Therefore, a second objective of this work has been to determine how EDC adducts affect protein stucture and activity. To this end, we studied the reaction of EDC with the dipeptide Ac-Asp-Ala-NH_2, and we reacted four well-characterized proteins: ribonuclease Sa (RNase Sa), hen egg white lysozyme, carbonic anhydrase, and hemoglobin with EDC. Using modern biophysical techniques, we show that EDC forms adducts with all four proteins and affects their net charge, conformation, and enzymatic activities to varying degrees.

EXPERIMENTAL PROCEDURES

Materials. Bovine pancreatic ribonuclease A (RNase A) was obtained from Sigma and further purified by cation-exchange chromatography as described previously (*4*). Ribonuclease Sa was expressed in *E. coli* and purified as previously described (*19*). An Asp-Ala dipeptide with the N- and C-termini blocked by acetyl and amide groups, respectively, was purchased from GenScript Corp. It is over 97% pure, and its identity was confirmed by mass spectrometry and NMR spectroscopy. The best grades of hen egg white lysozyme, bovine carbonic anhydrase II, and human hemoglobin were obtained from Sigma and were used without further purification. Yeast single-stranded RNA, synthetic double-stranded poly(A)·poly(U), and 4-methylumbelliforyl D-D-*N*,*N*′,*N*″-triacetylchitotrioside were purchased from Sigma. Sodium dihydrogen phosphate and sodium hydrogen phosphate were obtained from Merck and MES was from Sigma. Sodium azide (99%) was from Panreac. Double-distilled water was deionized using a Milli-Q system. Glacial acetic acid (99.9%) was from Quimipur. 1-Ethyl-3-(3-dimethylaminoisopropyl)carbodiimide (EDC) and *N*-hydroxysulfosuccinimide (sulfo-NHS) were purchased from Pierce.

Structure Analysis and pK_a Prediction. The atomic structures of the RNase A C-dimer (pdb: 1f0v) (*3*) and N-dimer (pdb: 1a2w) (*2*) were examined using the program *Mage* (v 6.30) to measure distances between amine groups and carboxylate groups. The program *MolMol* was used to calculate the percent solvent-accessible surface of carboxylate oxygen atoms in the RNase A C-dimer (*20*). pK_a values in the RNase A C-dimer were predicted using the empirical approach implemented in the program *Propka* (*21*).

Oligomer Formation. RNase A oligomers were obtained by incubation in 40% glacial acetic acid/60% water for 1 h, followed by lyophilization (*1*), and purified as previously described (*4*). Briefly, lyophilized samples were dissolved in sodium phosphate buffer (0.065 M, pH 6.70) containing 0.02% sodium azide, and the C-dimer of RNase A was isolated by cation exchange chromatography with a Source 15S HR 16/10 column using a gradient of 0.09−0.20 M sodium phosphate, pH 6.7, which also contained 0.02% sodium azide. The flow rate was 1.2 mL per min. All chromatography procedures were preformed at room temperature. After isolation, the C-dimer was concentrated using Centriplus concentrators with an M_r cutoff of 3 kDa or 10 kDa.

EDC Reaction. A series of trial reactions were performed at various concentrations of EDC (6 to 180 mM), RNase A (0.2 to 0.7 mg/mL), NaCl (0 to 0.5 M), and different pH values (4.0 to 7.0) with a 2 h reaction time at room temperature. The yield of cross-linked C-dimer was determined by integrating the dimer and monomer peaks after heating the sample to dissociate non-cross-linked C-dimer. Using the paper printout of the chromatogram, integration was performed manually by cutting out the peaks corresponding to cross-linked C-dimer and monomer and weighing them on a high-precision balance. The most satisfactory yields of cross-linked C-dimer were obtained using a concentration of C-dimer of 0.5 mg/mL, in 100 mM MES at pH 5.0 with 68 mM EDC. These same conditions and reactant concentrations were used for the reaction of EDC with RNase Sa, hen lysozyme, carbonic anhydrase, and hemoglobin. Some RNase A reaction trials included 5 mM sulfo-NHS. EDC (∼100 mM) reactions with the dipeptide Ac-Asp-Ala-NH_2 (8 mM) in 20 mM MES buffer were carried out at 25 °C and pH 5.5−5.8 and monitored by NMR spectroscopy and mass spectrometry.

Product Isolation and Characterization. Superdex 75 gel filtration columns, equilibrated with 0.2 M sodium phosphate buffer at pH 6.7 was used at room temperature at a flow rate of 0.5 mL/min to purify and characterize the RNase A reaction products. Further purification and characterization of the product species was performed using cation exchange chromatography using a Mono S column. After reaction with EDC, RNase Sa, hen lysozyme, carbonic anhydrase, and hemoglobin were desalted using a PD-10 column (GE Healthcare) and concentrated using Centricon concentrators with a M_r cutoff of 10 kDa.

Gel Electrophoresis. Denaturing SDS polyacrylamide gel electrophoresis (PAGE) was used for analysis (*22*).Ten percent polyacrylamide gels containing SDS were run at 20 mA for 90 min at room temperature. Cathodic PAGE under nondenaturing conditions was performed according to ref 23 with the slight modification of using β-alanine/acetic acid buffer at pH 4.0 as described previously (*6*). The 12.5% polyacrylamide gels were run at 20 mA for 100−120 min at 4 °C. For both types of gels, fixing and staining were performed with 12.5% trichloroacetic acid and 0.1% Coomassie brilliant blue. Densitometry and molecular weight estimations were performed using the *GeneTools* computer program (v 3.06) from SynGene/SynOptics Ltd., Cambridge, England.

Mass Spectrometry. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra were registered with an Applied Biosystems Voyager System 6214 mass spectrometer as previously described (*24*).

Peptide Mapping using Proteolysis and HPLC/Electrospray Mass Spectrometry. The position of the EDC modified carboxylate groups in RNase A was characterized by proteolysis with subtilisin and trypsin. First, RNase A or EDC modified RNase A was cleaved with subtilisin. The amount of subtilisin added was 1/100th (w/w) that of RNase A. The solution is then incubated at room temperature at pH 8.0 in 25 mM ammonium acetate buffer. This buffer was chosen because it is one of the least interferring salts for mass spectrometry. Small amounts of KOH were added over the course of 3−$3^1/_2$ h to maintain the pH close to 8.0. The reaction was performed at room temperature. After this time, the pH of the solution was reduced to <3 and maintained there for 10 min. This treatment serves to irreversibly denature subtilisin so that it does not make secondary cleavages in RNase S in the presence of trypsin (*25*). Next, the pH of the solution was increased once again to pH 8.0 using KOH and trypsin (1:100 wt/wt relative to RNase A) is added. After incubating the solution for 3 h at RT, the solution

was flash-frozen in liquid nitrogen and maintained at −20 °C until analysis.

Alternatively, pepsin was used to cleave EDC modified RNase A. First, the pH of the protein was lowered to 1.6 with 0.1 M HCl and pepsin (1/100th wt/wt relative to RNase A) was added (*26*). After allowing the reaction to proceed for 30 min at room temperature, the pH of the sample was increased to pH 5 to inactivate pepsin and the samples were flash-frozen in liquid nitrogen and stored at −20 °C until analysis.

For peptide mapping analysis, tandem high-pressure liquid chromatography−electrospray ionization mass spectrometry (HPLC-ESI-MS) experiments were performed using a Finnigan Surveyor pump with quaternary gradient system coupled in-line to a Finnigan LCQ Deca ion trap mass spectrometer using an ESI interface. Sample injections (7 μL) were carried out by a Finnigan Surveyor autosampler. All instruments were from Thermo Fisher Scientific (San José, CA, USA).

The samples were diluted 2:3 with water, and their separation performed at 25 °C on a HyPurity C18(100 mm × 2.1 mm, 3 μm resin beads) column (Thermo Fisher Scientific) at a flow rate of 100 μL min^{-1}. A gradient of two eluents was used: eluent A consisted in 0.05% (v/v) of formic acid (analytical grade, Merck, Darmstadt, Germany) in water (Milli-Q water, Millipore, Bedford, USA), and eluent B in acetonitrile (LC-MS Chromasolv grade, Riedel-de Haën, Seelz, Germany) containing 0.05% formic acid (v/v). The elution program was applied as follows: at the start, 7% B; after 5 min, the percentage of B was linearly increased to 60% in 30 min; 60−95% B linear from 35 to 35 min; 95% B isocratic from 35 to 55 min; ramped to original composition in 1 min; and then equilibrated for 10 min.

The mass spectrometer spray voltage was set at 4.5 kV, the capillary temperature was 200 °C, nitrogen (99.5% purity) was used as the sheath (0.6 L min^{-1}) and the auxiliary (6 L min^{-1}) gas, and helium (99.9990% purity) was employed as the collision gas. The LC-MS system, data acquisition, and processing were managed by *Xcalibur* software (1.2 version, Thermo Fisher Scientific).

NMR Spectroscopy. The reaction of monomeric RNase A with EDC at 25 °C was followed by NMR spectroscopy using a Bruker AV 600 NMR spectrometer with an active shielded *z*-gradient coil and equipped with a cryoprobe for increased sensitivity. The reaction conditions were essentially the same as those indicated previously, except the protein sample used was more concentrated (8 mg/mL) and was recombinant RNase A uniformly labeled with ^{13}C and ^{15}N (*27*). 1D ^{1}H and 2D ^{1}H−^{13}C and ^{1}H−^{15}N HSQC spectra (*28*) were recorded on ^{13}C^{15}N-RNase A samples in 100 mM MES at pH 5.0 or 7.0 dissolved in 90/10 H_2O/D_2O. The ^{1}H−^{15}N HSQC spectra were ^{13}C decoupled. The pH of the MES buffer was altered by varying the relative concentration of the MES acid and sodium MES. The addition of EDC to MES buffer was found to have a negligible effect on the pH. 1D ^{1}H, 1D ^{13}C, and 2D ^{1}H COSY (*29*), NOESY (*30*), ^{1}H−^{13}C HSQC, and 2D ^{1}H−^{15}N HSQC spectra were recorded on EDC, Ac-Asp-Ala-NH_2, and MES solutions individually and mixed to obtain the assignments of EDC and hydrolyzed EDC, the dipeptide and MES, and to follow the reaction of EDC and the dipeptide. 1D ^{1}H NMR spectra on RNase Sa, hen lysozyme, carbonic anhydrase, and hemoglobin were recorded before and after reaction with EDC at 25 °C in 1 to 5 mM sodium phosphate buffer, pH 6.6 in 90/10 H_2O/D_2O. All NMR samples also contained 50 μM sodium-4,4-dimethyl-4-silapentane-1-sulfonate (DSS) as the internal chemical shift reference.

Enzyme Kinetics. The enzymatic activities of Ribonuclease A monomers and dimers, and Ribonuclease Sa and these species modified by EDC were measured against single-stranded yeast RNA (ssRNA) using the assay of Kunitz (*31*) and against double-stranded poly (A)·poly(U) as previously described (*32*). All assays were repeated at least twice, and the uncertainty of these activity values is typically about ±7% and ±15%, against ssRNA and dsRNA, respectively (*4*).

Table 1. Neighboring Amine and Carboxylate Groups in RNase A Swapped Dimers

dimer Species	amine	carboxylate	distance (Å)[a]	INTER- or intra-molecular
C-dimer	Lys 66	Asp 121	3.7	INTERmolecular
C-dimer	Lys 7	Glu 2	5.7	intramolecular
C-dimer	Lys 37	Asp 38	5.4	intramolecular
C-dimer	Lys 104	Asp 83	4.8	intramolecular
C-dimer	Lys 1	Glu 2	11.7	intramolecular
C-dimer	Lys 98	Asp 83	11.7	intramolecular
N-dimer	Lys 66	Asp 121	5.3	intramolecular
N-dimer	Lys 7	Glu 2	8.0	intramolecular
N-dimer	Lys 91	Glu 86	9.5	intramolecular
N-dimer	Lys 104	Asp 83	4.5	intramolecular
N-dimer	Lys 98	Asp 83	7.9	intramolecular

[a] The distance between the Lys ε N atom and the nearest O atom of the carboxylate group.

Carbonic anhydrase activity was assayed using the electrometric method of Wilbur and Anderson (*33*), which monitors the decrease in pH occurring when an alkaline solution of Tris buffer is mixed with water saturated with CO_2. The drop in pH is more rapid when the enzyme catalyzes the conversion of $CO_2 + H_2O$ to carbonic acid. Some modifications in the procedure were implemented. First, a 1.5 mL Eppendorf tube cooled over ice was used instead of a special reaction vessel. Second, rather than mixing the Tris and CO_2 saturated water solutions with syringes, 0.7 mL of 50 mM Tris buffer (pH 9.1), with or without enzyme, was equilibrated over ice, and at time zero, 0.7 mL of ice cold CO_2 saturated water was added and mixed with a pipet. The pH of the resulting solution was recorded every 10 s for 3 min. Third, to determine the activity, a linear function was fit to the decrease in pH vs time between pH 8.5 and 8.0 (controls without enzyme) or pH 8.5 and 7.0 (experiments with enzyme). The activity was calculated using the following equation:

$$\text{activity} = \frac{\Delta\text{pH}/\Delta\text{time(enzyme)} - \Delta\text{pH}/\Delta\text{time(average of controls)}}{\text{concentration of carbonic anhydrase in mg/mL}} \quad (1)$$

Lysozyme activity was measured using the assay of Yang and Hamaguchi (*34*), which is based on the conversion of 4-methylumbelliforyl D-D-*N*,*N*′,*N*″-triacetylchitotrioside into a fluorescent product when it is hydrolyzed. Reactions were performed at 42 °C in a buffer solution composed of 93 mM KCl and 7 mM potassium acetate/acetic acid, pH = 5.0. The substrate concentration was 300 μM and the protein concentration was 0.60 μM for both lysozyme and EDC-modified lysozyme. The apparent activity was measured as the slope of the increase in fluorescence (λ_{ex} = 360 nm, λ_{em} = 450 nm) measured using a Jobin Yvon Fluormax 4 spectrofluorimeter at 25 °C. The assay was repeated twice.

RESULTS

Properties of Possible Target Carboxylate and Amine Groups. We examined the atomic structures of the C-dimer and N-dimer of RNase A to determine if they contain amine and carboxylate groups, which are close enough to form an isopeptide bond (Table 1, Figure 1). Several amine and carboxylate groups are within 10 Å of each other, but almost all are found within the same subunit and therefore would lead to the formation of an intramolecular cross-link. Such a bond

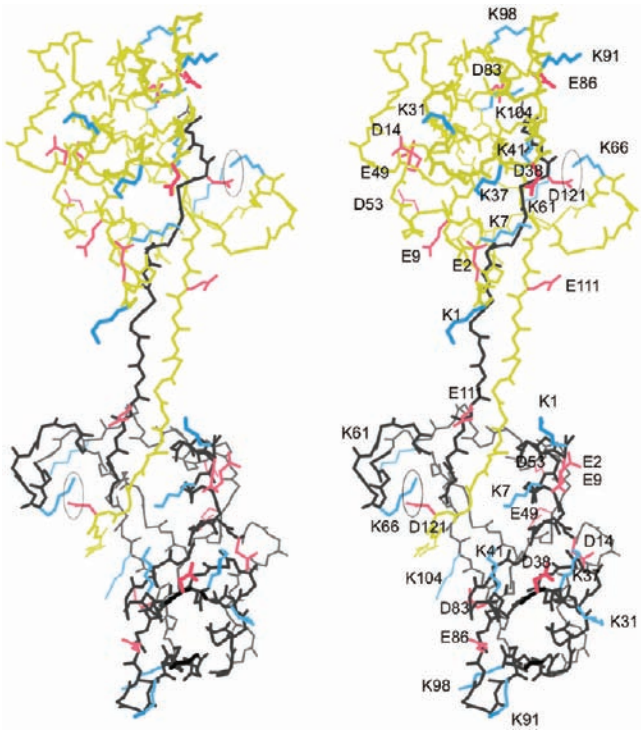

Figure 1. Cross-eyed stereo view of the structure of the RNase A C-dimer (Liu et al. 2001, pdb file 1F0V). The main chains of the two monomers are colored in dark gray and gold. Lysine side chains are shown in blue, while Asp and Glu side chains are colored red. For clarity, all other side chains have been deleted. An ellipse is drawn around the side chains of Lys 66 and Asp 121.

would not be expected to stabilize the metastable dimers against dissociation. However, Lys 66 from one subunit and Asp 121 from the other in the C-dimer are close enough together to form an isopeptide bond, which could stabilize the C-dimer against dissociation.

In order to react with cross-linking agents, carboxylate groups should be solvent-exposed. The percent solvent accessible surface areas are listed in Table 2. It can be seen that Asp 121 is one of the most solvent-exposed groups. Carboxylate groups must be in the charged carboxylate form instead of the neutral carboxylic acid form in order to react with most cross-linking agents. The experimental pK_a values of the carboxylate groups in monomeric RNase A (*35*) are also given in Table 2, along with predicted pK_a values for the same groups in the C-dimer. Asp 121 has a pK_a of about 3.0 in both the monomer and the C-dimer; therefore, about 99% of this residue should be in the charged form at pH 5, the optimal pH for the EDC cross-linking reaction (see below). Asp carboxylate groups typically have a pK_a of 4.0. Asp 121 has a lower pK_a value because the charged carboxylate form is stabilized by electrostatic interactions with Lys 66 and His 119, as inferred by their proximity and detected by the PROPKA program. These interactions might be expected to hinder the reaction of Asp 121 with cross-linking agents. Glu 2, Asp 14, Asp 38, and Asp 83 also have lower than normal pK_a values in the RNase A monomer and C-dimer. These suppressed pK_a values are due to hydrogen bonding and salt bridge formation with Arg 10, Tyr 25, Tyr 92, and Tyr 97, respectively (*36, 37*). These interactions and the lower surface exposure of Glu 2, Asp 14, Asp 38, and Asp 83 can be expected to impede the reaction of their carboxylate groups with cross-linking agents.

Selection of EDC as a Suitable Cross-Linking Reagent. We sought a cross-linking reagent to stabilize RNase A and RNase S domain-swapped oligomers. The ideal reagent would introduce a short, specific cross-link without inactivation or loss of the positive charge density on RNase A. A high net positive charge is crucial for the special biological acitivies of RNase A oligomers. Diethylpyrocarbonate was excluded from consideration, as it aggregates and inactivates RNase A (*38*). Stable cross-linked oligomers have been previously prepared using diimido esters (*39*). These reagents react with Lys amine groups and reduce the net positive charge on the protein and introduce a relatively long cross-link. This leads to a somewhat lower dsRNase activity for these covalent oligomers relative to their swapped counterparts. However, an extraordinary increase in dsRNase activity (*40*) and *in vivo* antitumoral activity (*24*) is obtained by cross-linking these covalent dimers to polyspermine. Two cross-linking reactions, divinylsulfone and 1,5-difluoro-2,4-dinitrobenzene, have been used successfully to covalently cross-link RNase A domain swapped oligomers (*6*). However, these reagents react with catalytic residues at the active site and produce a complete loss of activity. Many other cross-linking agents, i.e., UV light, tetranitromethane, formaldehyde, and so forth, are known (*41*) but also have undesirable properties.

Recently, Hefford and co-workers have discovered and characterized an RNase A dimer formed by heating the lyophilized protein *in vacuo*, which induces the formation of a isopeptide bond between Glu 9 and Lys 66 (*42*). Characterization of this dimer revealed a novel, nonswapped quaternary structure that is resistant to dissociation and ribonuclease inhibitor binding. Its dsRNase activity, although double that of monomeric RNase A, is lower than that of RNase A C-dimer. These results suggest that the formation of an isopeptide bond could be a useful approach for cross-linking RNase A swapped oligomers.

The water-soluble reagent 1-ethyl-3-(3-dimethylaminoisopropyl)carbodiimide (EDC) is capable of promoting the formation isopeptide bonds between the amine group of lysine and the carboxylate group of Glu or Asp in proteins in aqueous solution (*43*). Since EDC introduces no spacer, it is likely to favor the formation of isopeptide bonds between carboxylates and lysines, which are already nearby in the protein structure. The reaction removes both a negatively charged group and a positively charged one and thus does not alter the net charge on the protein. The mechanism of cross-linking with EDC involves formation of an adduct—an O-acylisourea derivate—between the EDC and the carboxylate group of Glu or Asp followed by a nucleophilic substitution with an amine group, most often the ε-NH_2 of lysine (Figure 2). In the absence of amine groups, the active O-acylisourea undergoes rapid hydrolysis regenerating the original carboxylate. A side reaction

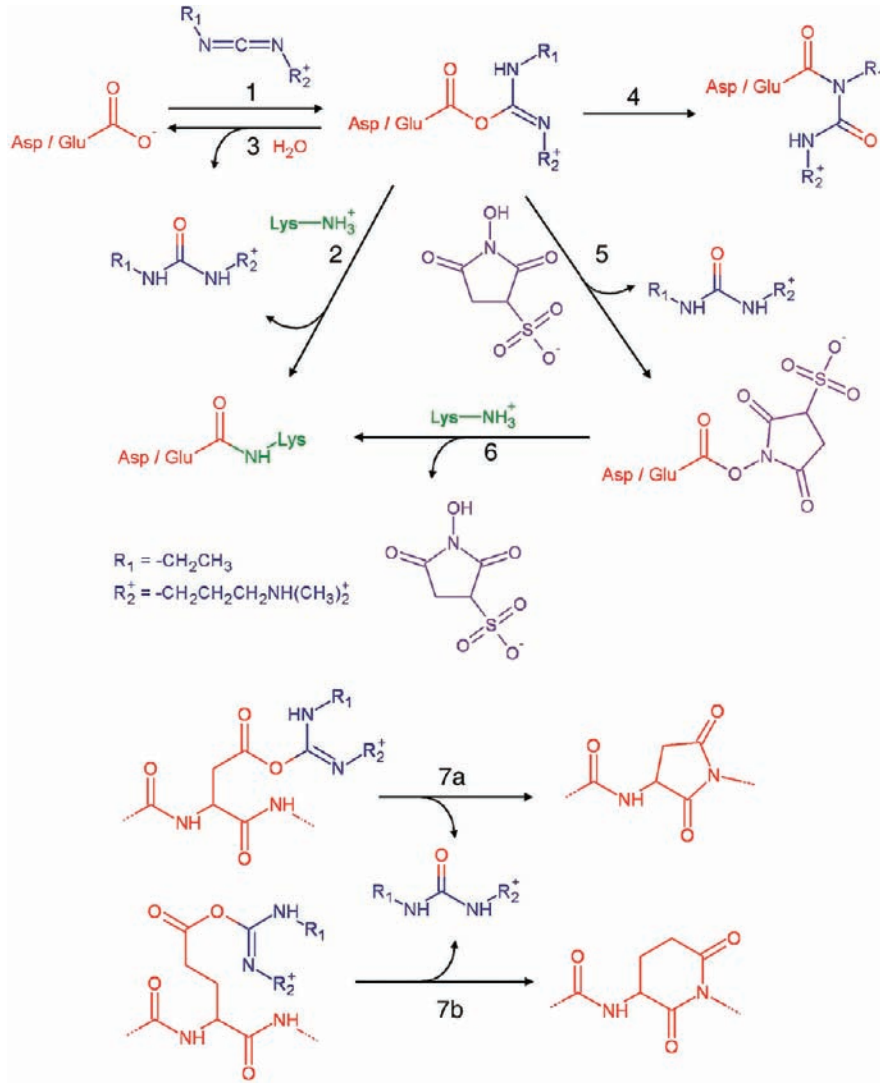

Figure 2. The reactions of EDC with carboxylates: **1**. The carboxylate oxygen (red) attacks the electrophillic carbon of EDC (blue). **2**. The resulting *O*-acylisourea intermediate can react with a nearby Lys amine group (green) to form an amide bond. Note that the formation of the peptide bond eliminates both a positive and a negative charge, so the net charge change is zero. The O-acylisourea, being highly reactive, can readily hydrolyze (**3**) or rearrange to form a relatively stable N-acylisourea (**4**); this side reaction removes a negatively charged carboxylate group and adds a positively charged adduct. The O-acylisourea intermediate can react with added sulfo-NHS (violet) to yield another intermediate (**5**), which has been reported to hydrolyze much more slowly and lead to higher yields of the desired peptide bond (**6**). Finally, another possible side reaction involves the attack of the amide nitrogen of the consecutive residue leading to the formation a cyclic imide with a 5 (Asp: **7a**) or 6 (Glu: **7b**) membered ring and the loss of a negative charge.

which rearranges the O-acylisourea intermediate to produce a more stable N-acylisourea has been observed (*15*, *16*) especially at high EDC concentrations (*18*). The hydrolysis or rearrangement of the O-acylisourea intermediate has been reported to be minimized by the addition of sulfo-NHS (*17*). The same authors found that the addition of sulfo-NHS leads to an increased formation of the desired isopeptide bond.

Reaction of the RNase A C-Dimer with EDC. We found that the most favorable conditions were pH 5.0 in 100 mM MES buffer with no NaCl, 10.6 mg/mL of EDC (68 mM EDC), and 0.5 mg/mL protein. Moreover, no substantial improvement of the yield of a heat stable C_D was obtained by adding sulfo-NHS to the reaction mixture.

Isolation and Characterization of Reaction Products Using Chromatography. A slight shift in elution volume from a gel filtration column of C_D was found after the reaction (Figure 3). The obtained products were heated at 55 °C for 30 min, which is sufficient to fully dissociate un-cross-linked C_D into monomers. A new peak was found at 14 mL and a small one remained at 12.5 mL; their relative peak areas were 93.5% and 6.5%, respectively. On the basis of the elution volumes of unmodified RNase A monomer and C-dimer, these new peaks were designated as EDC-modified monomer (M_{EDC}) and EDC-modified dimer ($C_{D\cdot EDC}$).

We attempted to isolate the products using cationic exchange chromatography, but they elute later, i.e., at higher phosphate concentrations, and did not show enough resolution to achieve their purification. As will be shown below, the M_{EDC} and $C_{D\cdot EDC}$ products contain EDC adducts, which endows them with increased positive charge. Incomplete resolution of cationized RNase species by ion exchange chromatography has been observed previously by Yamada and co-workers (*44*) and Libonati and co-workers (*24*). Considering that cationic exchange chromatography has sufficient resolution to separate RNase species that differ by just a single charge (*45*), the overlapping of the different EDC species is likely due to differences not only in the number of charges but also in the position of the modified carboxylate groups. As the N-acylisourea linkage of the EDC adduct has been reported to be labile to mild alkaline conditions (*15*, *18*), we dialyzed samples

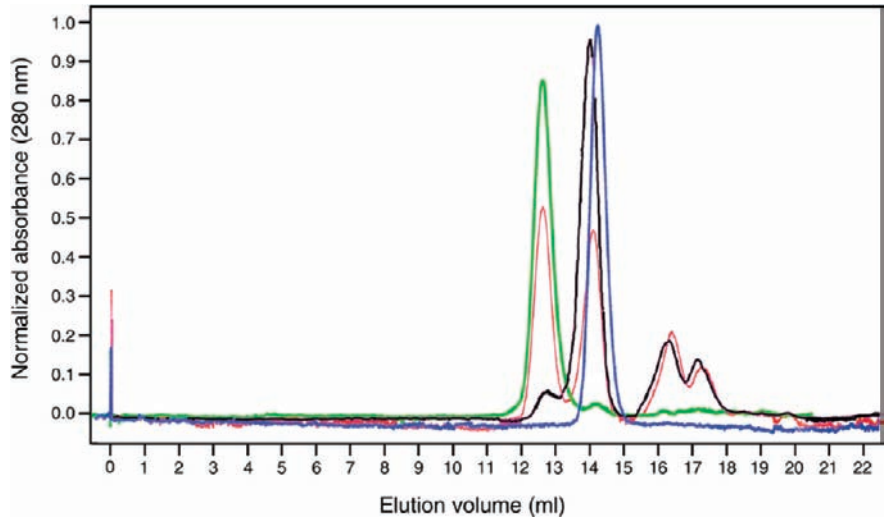

Figure 3. Chromatographic purification and analysis of RNase A EDC reaction products. Gel filtration chromatograms of monomer of RNase A (blue), C-dimer (green), and products of the reaction of RNase A C-dimer with EDC before (red) and after heating (black).

of M_{EDC} overnight against sodium borate buffer at pH 9.00. However, we observed no substantial change in the ion-exchange chromatogram before and after alkaline treatment.

Electrophoretic Characterization of EDC Modified RNase A Monomer and C-Dimer. The M_{EDC} and $C_{D\cdot EDC}$ fractions isolated from gel filtration chromatography were characterized by gel electrophoresis (Figure 4). When subjected to SDS-PAGE, which chiefly separates species according to their size, $C_{D\cdot EDC}$ produced an intense band flanked by two faint bands (Figure 4a). On the basis of the mobility of the molecular weight standards, the two faint bands were estimated to have molecular weights of 43 kDa and 13.5 kDa, which are in fair agreement with the values expected for an RNase A trimer (41 kDa) and monomer (13.7 kDa), respectively. The intense band has an estimated MW is 31 kDa; this is rather close to the value calculated for an RNase A dimer (27.4 kDa). On the basis of the relative intensity of the bands, about 80% of the sample is dimeric, 20% is monomeric, and only a trace (~0.5%) is trimeric. On the basis of these results, we tentatively conclude that $C_{D\cdot EDC}$ is a dimer and contains an intersubunit cross-link, since SDS normally dissociates noncovalent C-dimer into monomers. Turning to the M_{EDC} fraction, it produced a faint band whose mobility corresponds to dimeric RNase A, two faint bands intermediate between dimer and monomer, an intense band with a MW (14.1 kDa) corresponding to monomer, and a broad, fast-moving band corresponding to smaller molecules whose identity is unknown.

Both the M_{EDC} and $C_{D\cdot EDC}$ fractions were also subjected to nondenaturating cathodic PAGE (Figure 4b). In these gels, both the size and the charge of the species affect their mobility, with smaller and more positively charged molecules moving the quickest. Interestingly, $C_{D\cdot EDC}$ was found to migrate faster than unmodified RNase A C-dimer or monomer. As the $C_{D\cdot EDC}$ is a dimer, as tentatively concluded in the preceding paragraph, its faster mobility indicates that it has an increased positive charge. This higher positive charge could result from the side reaction of EDC with carboxylate groups, which removes a negative charge and results in the formation of a positively charged adduct (Figure 2). The broadness of the main $C_{D\cdot EDC}$ band suggests some heterogeneity in the number and position of the new positive charges. The M_{EDC} sample produced a series of fast-moving and overlapping bands (Figure 4b, right-most lane). These bands are assignable to monomeric RNase A species with increased positive charge.

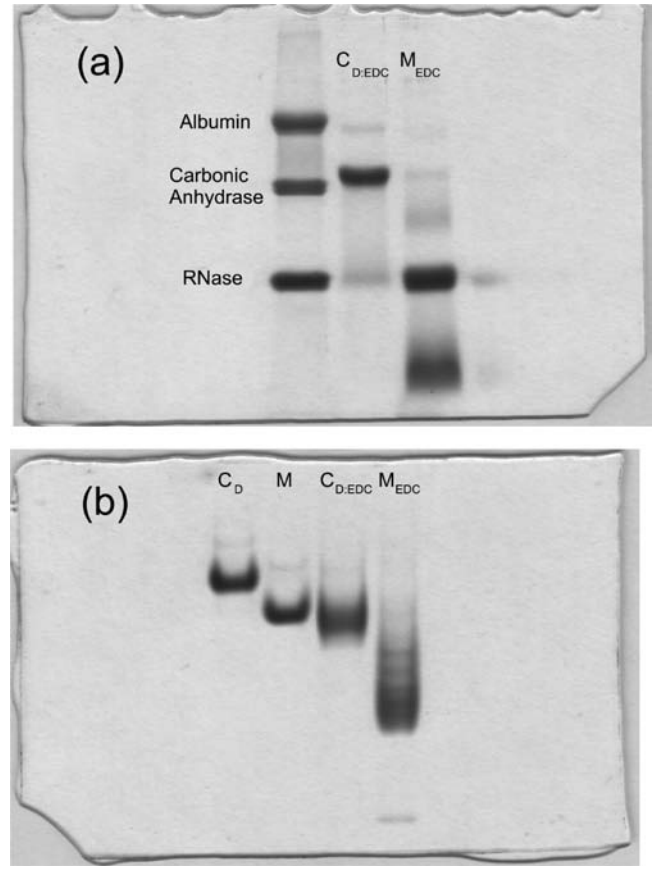

Figure 4. Denaturing and nondenaturing polyacrylamide gel electrophoresis of the products of RNase A C-dimer with EDC. (a) SDS-PAGE: In the first lane, RNase A monomer (14 kDa), carbonic anhydrase (29 kDa), and albumin (45 kDa); in the second lane, $C_{D\cdot EDC}$; and in the third one, M_{EDC}. (b) Cathodic PAGE: From left to right, RNase A C-dimer, RNase A monomer, $C_{D\cdot EDC}$, and M_{EDC}.

Mass Spectra of RNase A Monomer and C-Dimer Modified by EDC. The results of gel electrophoresis indicate that M_{EDC} and $C_{D\cdot EDC}$ contain additional positive charges. If these additional positive charges were due to formation of an N-acylisourea adduct with EDC (Figure 2), then the resulting increase in the molecular weight, 155 Da per EDC adduct, should be detectable by mass spectrometry. The more intense peaks observed have masses expected for monomeric RNase

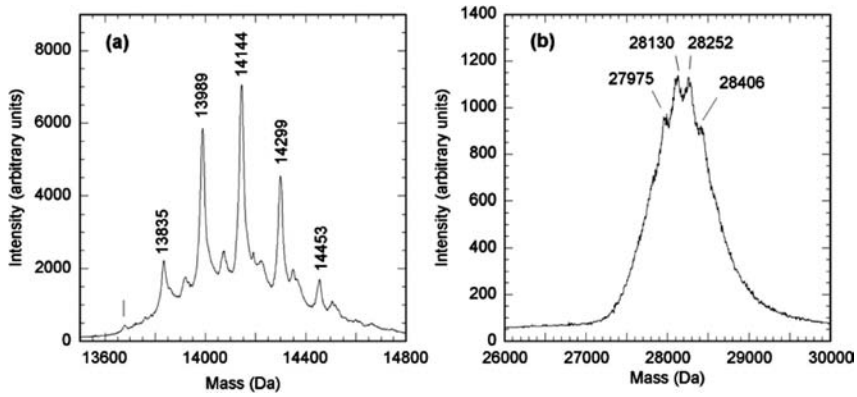

Figure 5. MALDI-TOF mass spectra of (a) M_{EDC} and (b) $C_{D\cdot EDC}$. The minor peaks present in panel (a) and the broadness of the underlying peak in panel (b) could be due to the formation of fragmented EDC adducts and the loss of a water molecule due to cyclization of the polypeptide chain. The dash in (a) marks a tiny peak corresponding to the expected mass (13 679 Da) of monomeric RNase A.

Table 3. Masses Expected and Observed for C-Dimer upon Coupling to EDC and Due to Water Loss[a]

# EDC adducts	−0 H_2O	−1 H_2O	−2 H_2O	−3 H_2O	−4 H_2O
1	27524	27506	27488	27470	27452
2	27680	27662	27644	27626	27608
3	**27836**	*27818*	**27800**	**27782**	27764
4	**27992**	*27974*	**27956**	**27938**	**27920**
5	**28148**	*28130*	**28112**	**28094**	**28076**

8	28616	28597	28579	28561	28543

[a] Masses in italics are observed as discrete peaks in the mass spectrum. Species with masses in boldface could also be present but have a population that is too low or too overlapped with other peaks to be observed individually. Masses in plain text do not appear to be present.

A (13 679 Da) plus one (13 835 Da), two (13 989), three (14 144), four (14 299), and five (14 453 Da) EDC adducts (Figure 5a). No significant change in the number of EDC adducts occurred after overnight incubation in sodium borate buffer, pH 9, as detected by mass spectroscopy (data not shown).

Regarding the mass spectrum of $C_{D\cdot EDC}$ shown in Figure 5b, a series of peaks whose masses correspond to the molecular weights of RNase A dimers with approximately three to seven EDC adducts and having shed one to three water molecules are observed (Table 3). The broadness of these peaks is likely due to the lower resolution of this instrument at higher masses, the possible presence of fragmented EDC adducts (see the description of the reaction of EDC with $AcAspAlaNH_2$ below). and the contribution of isotopes such as ^{13}C. Whereas unmodified C-dimers dissociate into monomers when subjected to MALDI-TOF mass spectroscopy, the observation of peaks with masses expected for RNase A dimers indicates that $C_{D\cdot EDC}$ is a bona fide dimer whose monomers are coupled by one or more covalent bonds. The loss of water molecules is a hallmark of the formation of isopeptide bonds between carboxylate and amine groups (Figure 2). This suggests that isopeptide bonds are the covalent bonds linking the monomers of $C_{D\cdot EDC}$. The species composing $C_{D\cdot EDC}$ could contain up to two additional isopeptide bonds. These are likely to be formed by second pair of Lys 66 and Asp 121 in the other monomers or intramolecular amine and carboxylate groups, which are close together in the same monomer (Table 1). However, water loss is also expected from the formation of intramolecular imide bonds (Figure 2). Therefore, the species of $C_{D\cdot EDC}$ that have lost two or three water molecules might contain one or two intramolecular imide bonds in addition to the amide bond which links the two subunits.

Reaction of EDC with RNase A Observed by NMR Spectroscopy. We used NMR spectroscopy to determine whether or not EDC modifies the three-dimensional structure

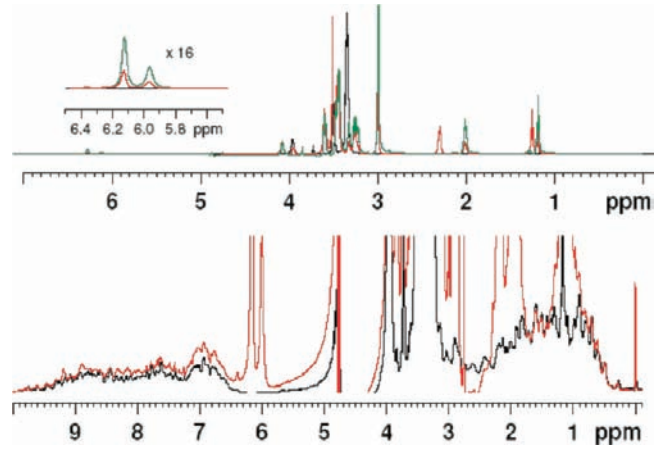

Figure 6. NMR spectra of RNase A, EDC, and EDC modified RNase A. $^{13}C,^{15}N$ labeled RNase A (0.6 mM) at 25 °C in 100 mM MES buffer before (black) and after (red) addition and incubation with EDC. Top panel 1D ^1H spectra. The green spectrum was recorded after 3 h incubation and shows new peaks arising from hydrolyzed EDC. Bottom panel: A 128× view of the 1D ^1H spectra from the top panel revealing the ^1H resonances of RNase A.

of RNase A. The 1D ^1H, 2D $^1H-^{15}N$ HSQC, and $^1H-^{13}C$ HSQC spectra obtained here on RNase A in 100 mM MES buffer at pH 5.0 or 7.0 are very similar to those previously recorded and assigned for RNase A in mildly acidic solutions (*46, 47*) (Figure 6, Supporting Information Figure 1). These spectra indicate that the protein is folded in the native conformation. Upon addition of dry EDC powder to the NMR sample, new resonances corresponding to EDC hydrogens and carbons appear in the 1D ^1H and 2D $^1H-^{13}C$ HSQC spectra. Changes in 1D ^1H signals of EDC over time indicate that it hydrolyzes with a half-life of about 310 min at pH 5 (with no RNase A present) and 90 min at pH 7 (with RNase A present), respectively. Addition of EDC produced a general weakening of the RNase A NMR resonances. This is due to a well-known decreased NMR pulse efficiency at higher ionic strengths. Some new signals near 8.35−7.85 ppm (^1H) and 126−128 ppm (^{15}N) appear in the $^1H-^{15}N$ HSQC spectrum of RNase A after EDC addition. The similarity of these signals' chemical shifts to those appearing in the $^1H-^{15}N$ of $Ac\text{-}Asp\text{-}Ala\text{-}NH_2$ in the presence of EDC suggests that they could result from the reaction of EDC with carboxylate groups near the amide hydrogens. No evidence for protein fragment formation is detected, and no change is observed in the signal arising from the amide group of Lys 66. Essentially, no changes are observed in the ^1H (Figure 6) or ^{13}C (Supporting Information Figure 1) signals of RNase A. Since the magnetic environment of each nucleus is exquisitely sensitive to its local conformation,

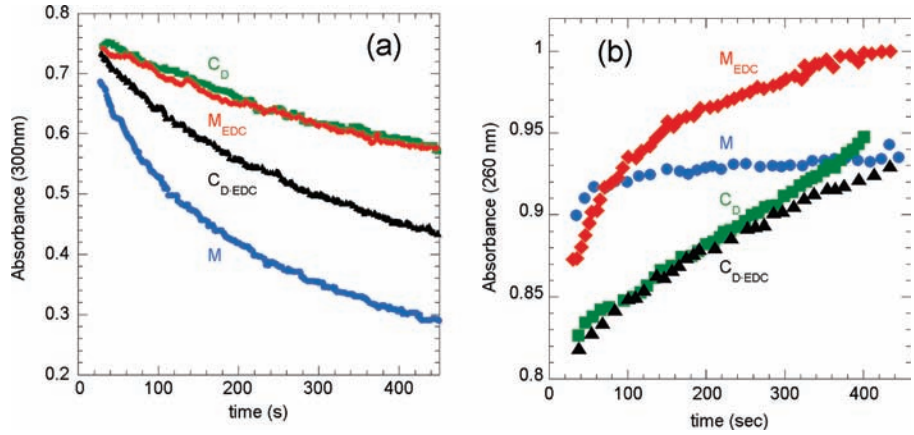

Figure 7. Activity of the products of RNase A C-dimer with EDC against RNA: Activity of RNase A monomer (blue circles), RNase A C-dimer (green squares), M_{EDC} (red diamonds), and $C_{D\cdot EDC}$ (black triangles) against yeast single-stranded RNA (a) and double-stranded poly(A)·poly(U) RNA (b). The protein concentrations were 0.5 μg/mL for all species in the ssRNA assay. Against dsRNA, the concentrations were 12 μg/mL for the RNase A monomer, 6 μg/mL for C_D and M_{EDC}, and 1 μg/mL for $C_{D\cdot EDC}$.

the general absence of change indicates that the conformation of RNase A is not perturbed by reaction with EDC beyond minor alterations near the adduct site.

Ribonucleolytic Activities. We measured the activity of RNase A species against ssRNA and dsRNA (Figure 7a). The activities against single-stranded RNA in Kunitz units normalized to 100 for the RNase A monomer were 100 ± 15 for RNase A monomer, 31 ± 5 for RNase A C-dimer, 47 ± 7 for M_{EDC}, and 37 ± 6 for $C_{D\cdot EDC}$. Relative enzymatic activities against double-stranded poly(A)·poly(U) (Figure 7b) were 1 ± 0.15 for RNase A monomer, 12 ± 2 for RNase A C-dimer, 78 ± 20 for M_{EDC}, and 85 ± 20 for $C_{D\cdot EDC}$.

EDC Reactions with the Dipeptide Ac-Asp-Ala-NH_2. Despite its common use in cross-linking proteins or attaching proteins to substrates for surface plasmon resonance measurements (*48*), the formation of EDC adducts to proteins has not been examined by NMR spectroscopy or mass spectrometry. To better characterize the formation of EDC adducts and other EDC side reactions with proteins, we have studied the reaction of EDC with the dipeptide Ac-Asp-Ala-NH_2, as a simple model for a carboxylate group in a protein. The ^{1}H, ^{13}C, ^{15}N NMR chemical shift assignments of EDC, hydrolyzed EDC, Ac-Asp-Ala-NH_2, and MES were obtained by analysis of 1D and 2D NMR spectra and are reported in Supporting Information Figure 2. Incubation of this dipeptide with excess EDC under reaction conditions similar to those used for proteins (pH 5, 25 °C), namely, 7.72 mM Ac-Asp-Ala-NH_2 in 20 mM MES buffer (pH 6.2) containing 10% D_2O and 50 μM DSS as the chemical shift reference (total volume = 505 μL).

At time = 0, 10.29 mg of EDC (corresponding to a final concentration of about 106 mM) was added to the solution of dipeptide and MES, and the mixture was placed in a 5 mm NMR tube. Over the course of time, the NMR resonances corresponding to the unmodified amide groups of the dipeptide decreased. In the case of the C-terminal $-NH_2$ moiety of the dipeptide, there is a concominant disappearance of the original peaks and an increase of new resonances (Figure 8). For the NH group of Asp, a small peak at 8.71 ppm builds up slowly with time. Essentially all of the original Ala NH peak is gone after 250 min of reaction, and in its place, there is only a series of very small peaks HN with spin systems assignable to Ala in the chemical shift range 8.44−8.25 ppm (Figure 8a,b) and 126 ppm ^{15}N (data not shown). Important spectral changes are also observed in the 1D ^{13}C spectra recorded as a function of time (Supporting Information Figure 3). These spectral changes cannot be accounted for by differences in the chemical shifts of the dipeptide or EDC due to changes in the pH (Supporting Information Figure 4). Therefore, they constitute clear evidence that the dipeptide has indeed reacted with EDC.

Following NMR spectroscopy, the dipeptide/EDC sample was flash-frozen in liquid nitrogen until analysis by HPLC−ESI−MS. A peak whose *m*/*z* value corresponds to the value expected for the dipeptide−EDC adduct is the major peak in this spectrum when recorded in the positive mode (Figure 8c). Also detected are peaks assignable to the cyclized dipeptide, which would result from reaction 7a shown in Figure 1, and to dipeptide adducted to fragments of EDC. The structure of these putative adduct fragments is shown in Supporting Information Figure 5. In agreement with the NMR spectroscopic results, the amount of unreacted dipeptide observed by mass spectrometry is small.

Characterization of EDC Adduct Sites in RNase A. The position of the carboxylate groups in RNase A modified by EDC was characterized by peptide mapping. The results, some representative details of which are shown in Supporting Information Figure 6, strongly suggest that Glu 2, Glu 9, Asp 14, Asp 83, Glu 86, Asp 121, and the C-terminal carboxylate are not modified or are modified in a minority of molecules, whereas Asp 38, Glu 49, Asp 53, and Glu 111 are modified in a relatively large fraction of molecules. These findings are consistent with the observation that Glu 49, Asp 53, and Glu 111 are relatively solvent-exposed and do not interact with other groups in RNase A (Table 2). Except for Glu 9, these results are also in good agreement with the previous results obtained upon reaction of RNase A with different water-soluble carbodiimides under somewhat different conditions (*15*).

How General is EDC Adduct Formation with Protein and What Are Its Effects? We incubated EDC with four well-characterized proteins, namely, RNase Sa, hen lysozyme, carbonic anhydrase, and hemoglobin, under the same reaction conditions as those used to form M_{EDC} and $C_{D\cdot EDC}$ to test for the formation of EDC adducts and to characterize their effects on protein structure and activity. The samples of these proteins, before and after reaction with EDC, were subjected to nondenaturing cathodic PAGE and mass spectrometry to gauge the formation of adducts. Moreover, the proteins and their EDC modified forms were characterized by 1D ^{1}H NMR spectroscopy and enzyme assays to estimate the effect of EDC adducts on their overall structure and activity. The results of all these experiments are summarized in Table 4.

Native cationic gel electrophoresis can provide qualitative data on the extent of protein−EDC adduct formation, since the migration of the protein in the gel increases with its positive charge (Figure 9). Although native RNase Sa is negatively charged and does not enter the gel, EDC treatment of this

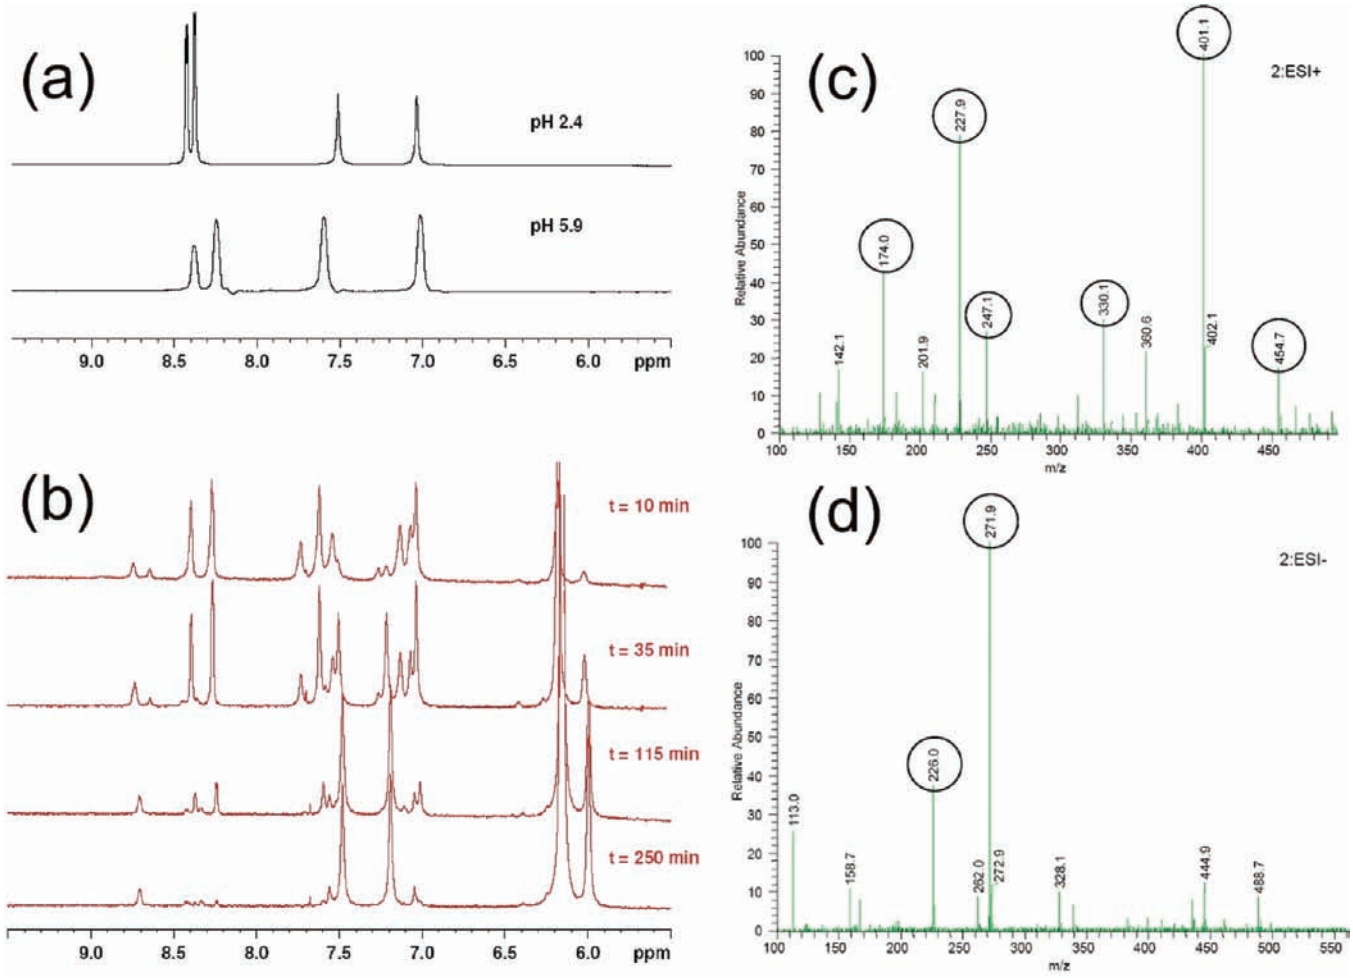

Figure 8. Reaction of the dipeptide Ac-Asp-Ala-NH_2 with EDC. (a) The amide region of the 1D ^{1}H NMR spectrum of the dipeptide at 8 mM concentration at two different pHs and 25 °C. (b) A series of 1D ^{1}H spectra at different times following the addition of 100 mM EDC (final concentration) to the same dipeptide solution. The peaks at 6.00 and 6.15 ppm belong to the amide groups of hydrolyzed EDC. (c) Electrospray mass spectrometry (+ mode) of this sample. The species corresponding to the circled peaks are (*m*/*z* in Da, from left to right) 174.0, EDC + H^+; 227.9, cyclized dipeptide + H^+; 247.1, unreacted dipeptide + H^+; 330.1, dipeptide adducted to a large fragment of EDC + H^+; 401.1, dipeptide adducted to EDC + H^+. 454.7 (cyclized dipeptide)$_2^+$. (d) Electrospray mass spectrometry (− mode) of the same sample. The species corresponding to the circled peaks are 226.0, (cyclized dipeptide − H^+)$^-$; 271.9 (dipeptide adducted to a small fragment of EDC − H^+)$^-$.

Table 4. EDC Adduct Formation by RNase Sa, Lysozyme, Carbonic Anhydrase, and Hemoglobin

protein	native cationic gel electrophoresis	mass spectra[a]	1D ^{1}H NMR	enzyme activity[b]
RNase Sa	no bands	10 570 Da, 10 571 Da	folded	100
RNase Sa·EDC	broad smear with bands at RF = 0.30, 0.49, 0.57, and 0.66	11 195−11 662 Da, 3−7, **5**	folded, but some loss of fine dispersion	40
lysozyme	1 band, RF = 0.76	14 324 Da, 14 293 Da	folded	100
lysozyme·EDC	broad bond, RF = 0.80−0.89	14 451−14 911 Da,1−4, **2**	folded, with only minor changes	50−100
carbonic anhydrase	series of bands, RF = 0.07, 0.13, 0.21, and 0.29	29 121 Da, 29 025 Da	folded	100
carbonic anhydrase·EDC	broad smear with bands, RF = 0.28, 0.37, 0.54, and 0.58	29 100−30 800 Da, 0−12, **6**	substantially unfolded	33
hemoglobin	broad band, RF = 0.39 and 0.47	α 15 261 Da, 15 128 Da β 1 6 111 Da, 15 869 Da	folded	not measured
hemoglobin·EDC	series of broad bands with RF = 0.38, 0.45, 0.54, 0.59, and 0.72	α 15 100−15 400 Da, 0−2, **1** β 16 025−16 400 Da, 1−4, **2**	thoroughly unfolded	

[a] Native: MW calculated from the sequence is given, followed by the MW of the chief peak in the mass spectrum. EDC modified: the approximate MWs of species or range of MWs after EDC treatment is given, followed on the next line by the estimated range of the approximate number of EDC adducts attached per protein molecule. Finally, the most common number of EDC adducts is written in **bold**. [b] In % activity relative to the activity of the unmodified protein.

enzyme produced about four different positively charged species. Gel electrophoresis reveals that lysozyme is also modified by EDC treatment, but to a lesser extent than RNase Sa or carbonic anhydrase. The two bands observed for native hemoglobin could arise from the α and β subunits; EDC treatment endows them with a greater positive charge as inferred from their increased migration in the gel.

Mass spectrometry (Table 4, Figure 10) revealed higher masses for all four proteins after EDC treatment. On the basis of the molecular weight differences of the chief peaks before

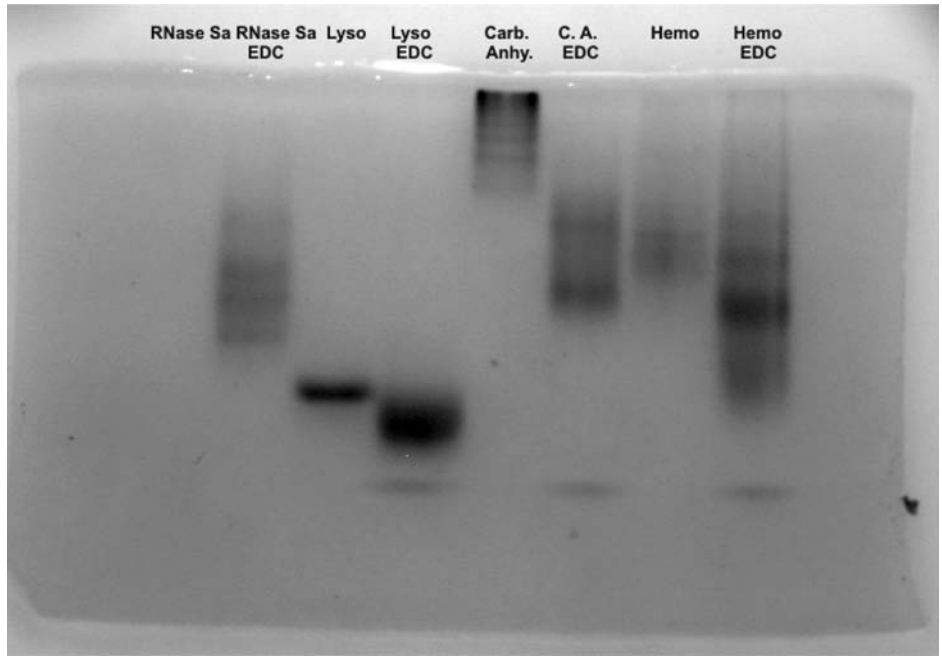

Figure 9. Nondenaturing cationic gel electrophoresis of RNase Sa, lysozyme, carbonic anhydrase, and hemoglobin before and after EDC treatment.

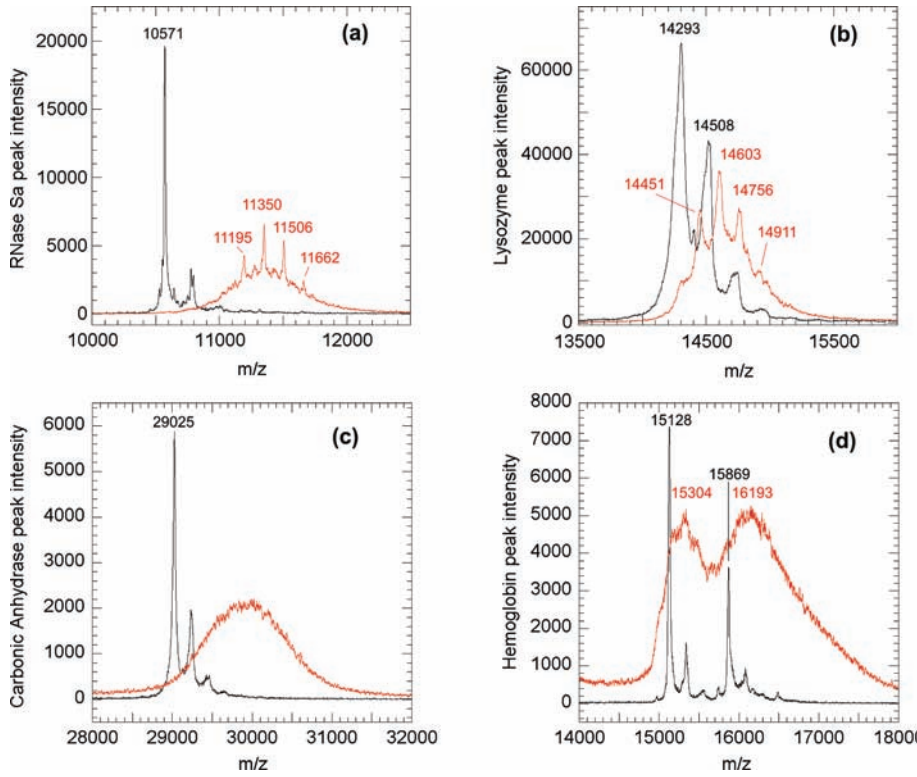

Figure 10. Mass spectra of (a) RNase Sa, (b) lysozyme, (c) carbonic anhydrase, and (d) hemoglobin before (black curves) and after (red) EDC treatment. The increase in the broadness of the peaks after reaction with EDC could result from the formation of EDC adducts, or fragmented EDC adducts, or the loss of a water molecule due to cyclization of the polypeptide chain or combinations of these changes.

and after reaction with EDC, we could estimate that RNase Sa acquired, on average, approximately 5 EDC adducts. This is, in general greater than the number of EDC adducts attached to lysozyme (whose mean value is roughly 2) or the hemoglobin α and β subunits (typically about 1 or 2). Carbonic anhydrase was extensively modified by EDC and acquired, on average, roughly 6 EDC adducts.

1D ^{1}H NMR spectroscopy is commonly used qualitatively to judge if a protein is folded, completely denatured, or in the molten globule state (*49, 50*). The good chemical shift dispersion observed for RNase Sa, lysozyme, carbonic anhydrase, and hemoglobin in their respective 1D ^{1}H NMR spectra reveals that they are in the native, folded conformation (Figure 11) (*51*) (*52*). After EDC treatment, the NMR spectrum of RNase Sa loses some fine dispersion, which can be interpreted as a partial loss of native structure. In contrast, the NMR spectrum of EDC treated lysozyme shows only minor differences as relative to untreated protein. The substantial loss of signal dispersion and

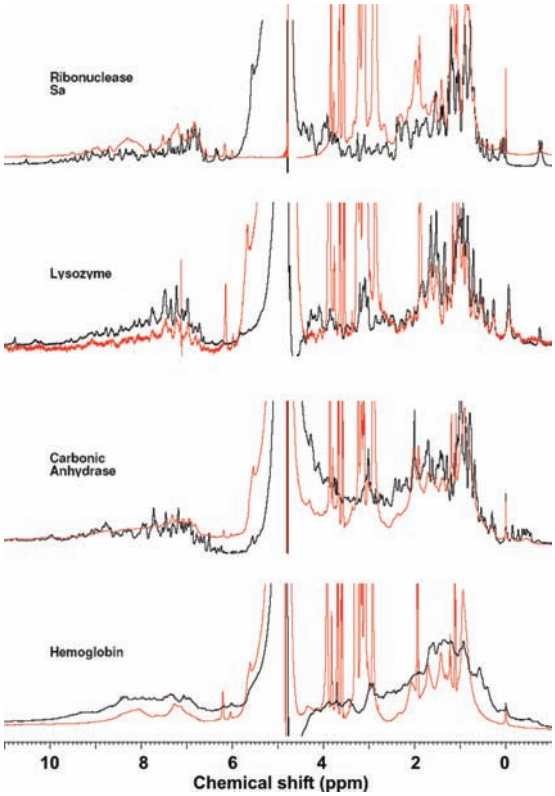

Figure 11. 1D ^{1}H NMR spectra of RNase Sa, hen lysozyme, carbonic anhydrase, and hemoglobin in 1−5 mM sodium phosphate pH 6.6 before (black curves) and after (red curves) EDC modification.

the appearance of a broad NMR peak near 0.90 ppm, which is assignable to unfolded methyl hydrogens, indicates that carbonic anhydrase suffers significant denaturation upon EDC treatment (*52*). Similar, but more drastic spectral changes indicating thorough denaturation are seen for EDC-treated hemoglobin.

Using the Kunitz assay, we found that EDC treatment causes RNase Sa to lose about 60% of the activity of the unmodified protein toward yeast ssRNA (Figure 12a). Neither RNase Sa nor EDC treated RNase Sa showed any detectable activity against double-stranded poly(A)·poly(U); this result is consistent with this enzyme's strict specificity for G. The enzymatic assay for lysozyme and EDC-modified lysozyme indicates that the latter retains most of the enzymatic activity of the former (Figure 12b). The results of the assays of carbonic anhydrase show that EDC treatment reduces the protein's activity by two-thirds (Figure 12c). The mean enzymatic activities were found to be 225 ± 36 for carbonic anhydrase and 72 ± 3 for EDC-modified carbonic anhydrase where the uncertainty given is the standard deviation (1σ).

DISCUSSION

RNase A oligomers, including the C-dimer, show increased ribonucleolytic activity against double-stranded RNAs and potent *in vivo* antitumor activities. These activities are lost as the oligomers slowly disassociate into monomers. In this paper, we have used EDC, a carbodiimide, to cross-link the subunits of the C-dimer. The resulting C-dimer, called $C_{D\cdot EDC}$, is not dissociated by procedures such as heating, SDS PAGE, or MALDI-TOF mass spectroscopy, which do dissociate the unmodified C-dimer. EDC and other carbodiimides induce the formation of amide bonds (also called isopeptide bonds) between nearby carboxylate and amine groups (Figure 2). Although solid evidence is lacking, we infer that Lys 66 and Asp 121 are presumably the residues which form the cross-linking amide

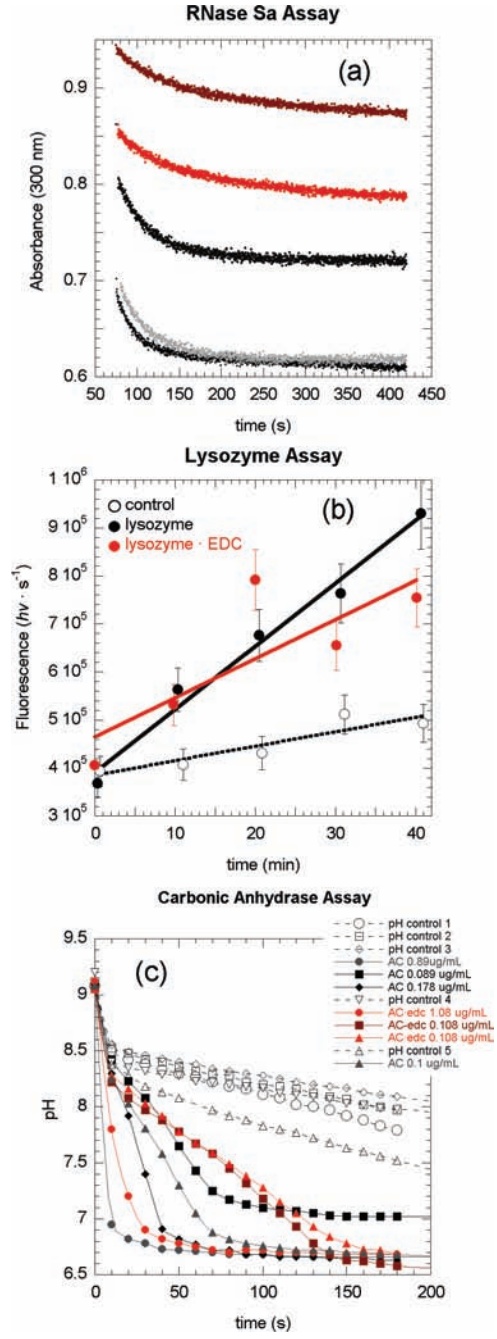

Figure 12. Enzymatic assays of RNase Sa, lysozyme, and carbonic anhydrase and these proteins treated by EDC. (a) Some representative RNase assays against yeast ssRNA are shown. Black curves: RNase Sa 4.4 μg/mL. Red curves: EDC modified RNase Sa 4.9 μg/mL. Curves are offset along the *y*-axis for ease of comparison. (b) Lysozyme assay using 300 μM 4-methylumbelliforyl D-D-*N*,*N*′,*N*″-triacetylchitotrioside and 600 nM lysozyme (solid points), or EDC-modified lysozyme (red solid points). (c) Carbonic anhydrase assays. Open symbols, control experiments; filled symbols, carbonic anhydrase; red-filled circles, EDC-modifed carbonic anhydrase.

bond in $C_{D\cdot EDC}$, since they bear the only amine and carboxylate groups that are in close proximity in the C-dimer structure (Table 1, Figure 1). The yield of the cross-linked C-dimer is rather low (6.5%). This appears to be consistent with the low reactivity of Asp 121 with EDC as detected by peptide mapping as well as the results of Riehm and Scheraga who found this residue to be relatively unreactive toward a water-soluble carbodiimide (*15*).

EDC Forms Adducts with Ribonuclease A. The relatively high concentration of EDC needed to induce C-dimer cross-

linking leads to adduct formation in which EDC is stably linked to a carboxylate group by an N-acylisourea bond (Figure 1). Using MALDI-TOF mass spectrometry, RNase A monomers treated with EDC, called M_{EDC}, were found to carry approximately one to five EDC adducts per molecule, and $C_{D\cdot EDC}$ molecules were observed to bear, in round numbers, three to seven EDC adducts. These mass spectroscopy results and the heterogeneity detected by cation exchange chromatography and nondenaturing cathodic PAGE indicate that M_{EDC} and $C_{D\cdot EDC}$ are rich mixtures of species carrying EDC adducts which vary both in number and in position (*15*) with Asp 38, Glu 49, Asp 53, and Glu 111 being the most heavily modified as gauged by peptide mapping.

Activity of M_{EDC} and $C_{D\cdot EDC}$ against Yeast Single-Stranded RNA. The ribonucleolytic activity against single-stranded RNA decreases somewhat when RNase A is conjugated with EDC. There are three plausible explanations for this loss of activity. First, it is possible that the increased positive charge on the protein surface compromises the conformational stability and thereby decreases the amount of protein present in the native, catalytically active state. However, it has been reported that the substitution of multiple solvent-exposed carboxylate groups by Lys or neutral side chains had modest effects on the conformation stability of T4 Lysozyme (*53*) or RNase Sa (*54*) and on the pKas of their remaining ionizable groups. Moreover, peptides composed chiefly of Ala, Ile, and Lys can form well-folded highly stable four-helix bundle proteins despite the high net charge (+12) conferred by the Lys (*55*). Furthermore, it is striking that RNase 3 (also called eosinophil cationic protein), the mostly positively charged member of the RNase A family, is also the member that has the highest conformational stability (*56*). Finally, NMR spectroscopy shows that the native conformation of RNase A is hardly affected by reaction with EDC. All this evidence points to the conclusion that the low single-strand ribonucleolytic activity of the M_{EDC}, other cationized RNases, and RNase A oligomers is not due to a loss of conformational integrity provoked by electrostatic repulsion. Second, chemical modification of Lys 66 and Asp 121 could affect the activity, since the former participates in RNA binding (*57*) and the latter enhances the activity of the catalytic residue His 119 (*58*). While Lys 66 and Asp 121 are moderately well conserved in the sequences of human ribonucleases (*59*), nevertheless genetic selection experiments have shown that neither is essential for structure or activity in RNase A (*60*). A third possible cause of the loss of activity is that the additional positive charges lead to unproductive binding of RNA to the surface of RNase A away from the active site or retards product release after hydrolysis. This possible explaination has been put forward previously to account for the lower single-strand ribonucleolytic activity of the RNase A oligomers, including the C-dimer (*61*). Lower single-strand ribonucleolytic activity was previously observed for RNase species cationized by chemical coupling (*24*, *44*, *62*).

Reactivity of M_{EDC} and $C_{D\cdot EDC}$ against dsRNA. The increased net positive charge bestowed by the EDC adducts endows both M_{EDC} and $C_{D\cdot EDC}$ with augmented ribonucleolytic activity against the double-stranded poly(A)·poly(U). Increased dsRNase activity, cytotoxicity, and antitumor actions have been observed previously for RNase A species or homologues which carry higher positive charge density, including RNase A oligomers (*32*), variants (*63*−*65*), other cationized RNase A monomers (*40*, *44*, *62*, *66*), cationized RNase A dimers (*24*), BS-RNase (*10*, *67*), and human RNase 1 (*68*). The increase in these activities has been attributed to an improved ability to stabilize transient single-strand regions in double-stranded RNAs (*32*). On the basis of these previous results, we propose that M_{EDC} and $C_{D\cdot EDC}$ might have heightened cytotoxic and/or antitumor activity. An increased positive charge density can promote the intracellular delivery of RNases (*69*, *70*) and augment their capacity to cleave intracellular tRNAs, rRNAs, which are rich in double-stranded regions, and the poly(A) tail of mRNAs, which adopts a double helix (*71*). Raines and co-workers have, however, recently pointed out that an increased positive charge density achieved by site-directed mutagenesis also increases the binding of ribonucleases to the cytoplasmic ribonuclease inhibitor (*70*), and this binding decreases the RNase activity and cytotoxicity. On the other hand, Yamada and co-workers found that the binding of cRI to a series of RNase A species which were cationized by the EDC-mediated coupling of carboxylate groups to ethylenediamine actually *decreased* as the net positive charge of the species increased, an observation which led them to propose that the reduced cytotoxicity of the most cationic RNase A species is due to an increased rate of protein degradation (*44*). Among the carboxylate group carrying residues which are more heavily modified by EDC, Asp 38 and Glu 111 make contact with the cRI (*70*, *72*). It is possible that cRI binding decreases and cytotoxicity increases when these groups were modified by ethylenediamine, thus accounting for the observations of Raines, Yamada, and their co-workers. In support of this possible explanation, the mutation of Asp 38 (*73*) and Glu 111 (*74*) has been shown to reduce cRI binding.

Reaction of EDC with Ac-Asp-Ala-NH_2. The reaction of EDC with a carboxylate containing dipeptide has been monitored for the first time by NMR spectroscopy and mass spectrometry. The reaction produces four detectable dipeptide species, which are putatively the dipeptide−EDC adduct, two species with the dipeptide being adducted to a large or small part of EDC, and the cyclized dipeptide. By mass spectrometry, the dipeptide−EDC adduct seems to be the most populated species. Cyclization reactions due to Asn deamidation are disfavored in folded RNase A (*75*) or its glycosylated form RNase B (*45*) due to the rigidity of the polypeptide chain. This suggests that the cyclization reaction observed here in the dipeptide could be less favored in the context of a folded protein. All of these reactions will remove a negative charge from the modified carboxylate group, and two of them will endow it with a new positive charge.

EDC Adduct Formation in General Alters Protein Net Charge, Conformation, and Activity. Unlike RNase A, RNase Sa is a microbial enzyme endowed with an excess of negative charges. The substitution of five surface carboxylate groups of RNase Sa by Lys causes only very modest effects on the protein's conformational stability and enzymatic activity toward poly(I) (*76*) but confers cytotoxicity (*77*). The modest loss of fine tertiary structure and hydrolytic activity toward ssRNA observed here could arise from the EDC modification of some RNase Sa molecules at Glu 54, which is a catalytic residue, or at Asp 33, Asp 84, or Asp 93, which make important contributions to the conformational stability (*54*).

The neligible to low loss of lysozyme activity upon EDC treatment suggests that the catalytic carboxylate groups, Glu 35 and Asp 52, are not substantially modified by EDC. Previous modifications experiments identified Glu 35 and Asp 52 as being the least reactive carboxylates toward carbodiimide (*78*), whereas Asp 102 is the most reactive (*79*). Although Asp 102 forms part of the first two (A,B) of the six substrate subsites in lysozyme, it would not expected to contribute to binding to the shorter three-residue sugar substrate used in our assay.

Regarding hemoglobin, Acharya and Seetharam (*80*) found using tryptic peptide mapping that EDC readily modifies Glu 22 and Glu 43 of the β chain of human S-hemoglobin. These researchers performed their reaction at conditions similar to ours except they used a slightly higher pH (6.0) and a lower EDC concentration (20 mM). Both bovine carbonic anhydrase II (*81*)

and human hemoglobin (*82*) are known to adopt molten globule or other denatured conformations at pH ≤ 5. It is possible that carboxylate groups that are buried and protected against EDC modification at neutral pH become exposed and react with EDC at pH 5.0 in these partly denatured states. The modification of normally buried carboxylate groups could prevent refolding at pH 6.6 and account for the extensive and severe denaturation observed for these proteins by NMR.

CONCLUSION

The RNase A C-dimer has augmented enzymatic, cytotoxic, and antitumoral activities as compared to the RNase A monomer, but loses these properties upon dissociation. Here, the carbodiimide EDC has been used to induce the formation of isopeptide bonds in the RNase A C-dimer which prevent it from dissociating. This cross-linked C-dimer retains the native protein conformation and shows activity against dsRNA that is even higher than that of the unreacted C-dimer. This further increase in activity is due to the formation of positively charged EDC adducts on the protein surface. Asp 38, Glu 49, Asp 53, and Glu 111 appear to have the carboxylate groups most susceptible to EDC modification. Both the stability against dissociation and the increased positive charge density are likely to be advantageous features for the development of RNase A based therapeutics. EDC is widely used for cross-linking proteins or for activating carboxylate groups for reaction with amines. By using a model dipeptide, EDC adduct formation and peptide cyclization are substantiated for the first time by NMR spectroscopy and mass spectrometry. In this work, these adducts have been found to affect the net charge, conformation, and enzymatic activity of four well-characterized proteins. This side reaction and its consequences should be considered when EDC is used to couple proteins to each other or to substrates for surface plasmon resonance measurements.

ACKNOWLEDGMENT

We thank Dr. Luis Simón for helpful discussion and Prof. Marta Bruix for critically reading the manuscript. We owe our grateful thanks to Dr. David Pantoja and Dr. Plácido Galindo Iranzo for expert technical assistance with NMR spectroscopy and mass spectrometry, respectively. We are especially grateful to D. Alberto Ogbechie Condés for his contribution to the experiments on RNase Sa, Lysozyme, Carbonic Anhydrase and Hemoglobin, and to Prof. C. Nick Pace for his generous gift of RNase Sa. This work was supported by grants CTQ2007-68014-C02-02 and BFU2006-15543-CO2-02 from the Spanish Ministry of Education and Science and ex-60% GOTTE06 from the Italian "M.I.U.R." and the University of Verona. JPLA gratefully acknowledges a fellowship from the Consejería de Educación de la Comunidad de Madrid y el Fondo Social Europeo.

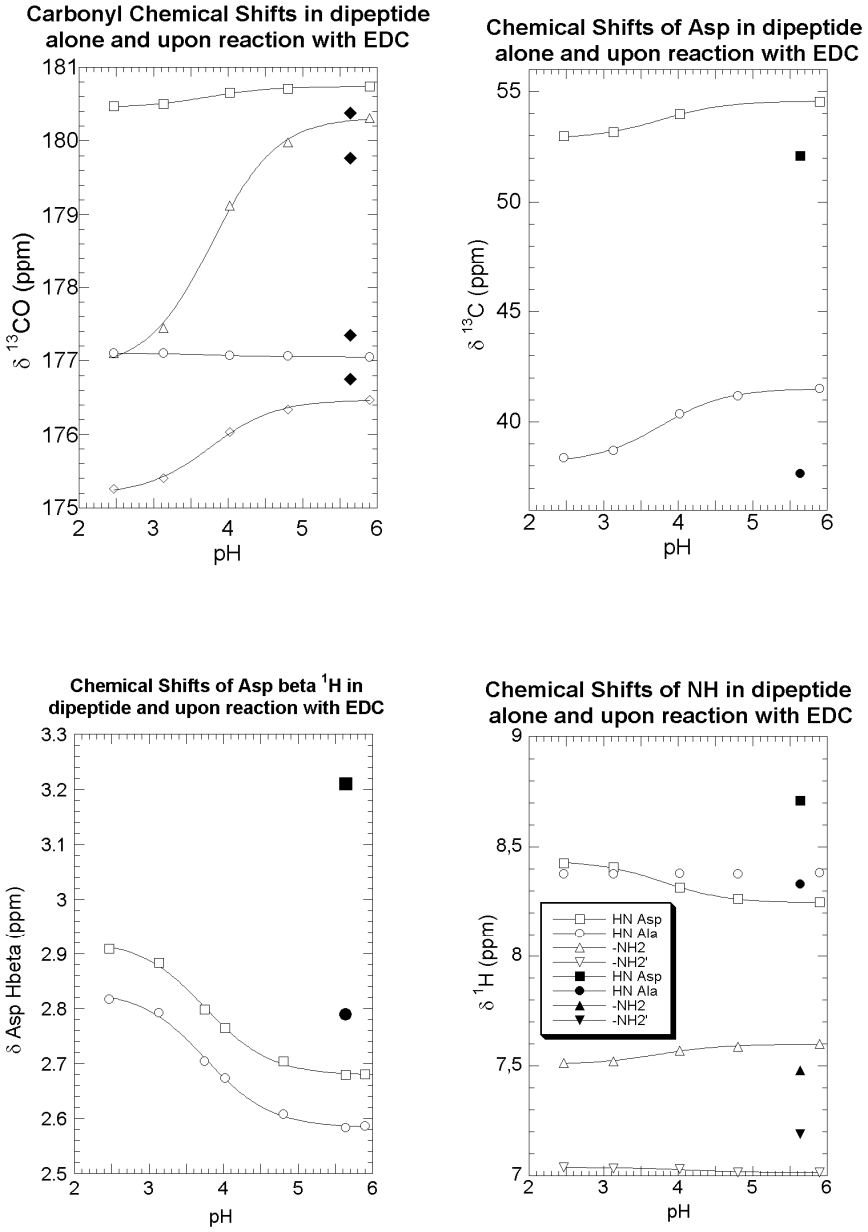
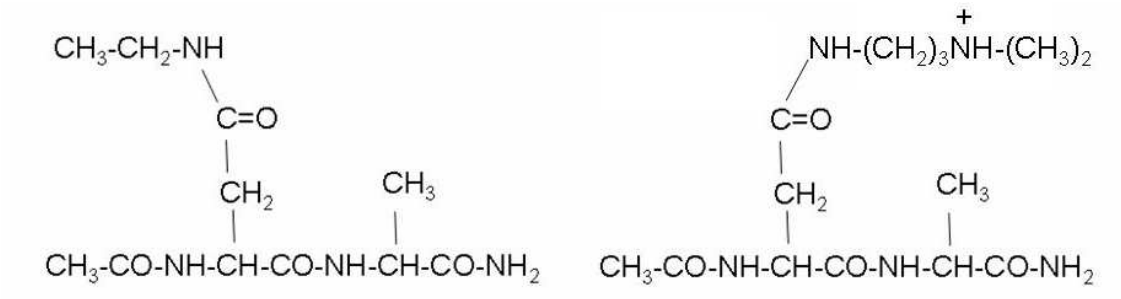
Supporting Figure 4: Comparison of the Chemical Shifts in Ac-Asp-Ala-NH_2 alone and upon incubation with EDC.

In each graph, the chemical shifts of the unmodified dipeptide is shown in open symbols and the chemical shifts of the dipeptide in the EDC reaction mixture is shown in closed symbols. The curve shows the fit of the Henderson-Hasselbach equation to the data. This comparison shows that whereas the chemical shifts of the dipeptide do depend on pH, this pH variation can not account for the new resonances appearing upon incubation with EDC. We therefore conclude that the dipeptide does indeed react with EDC.



Supporting Figure 5

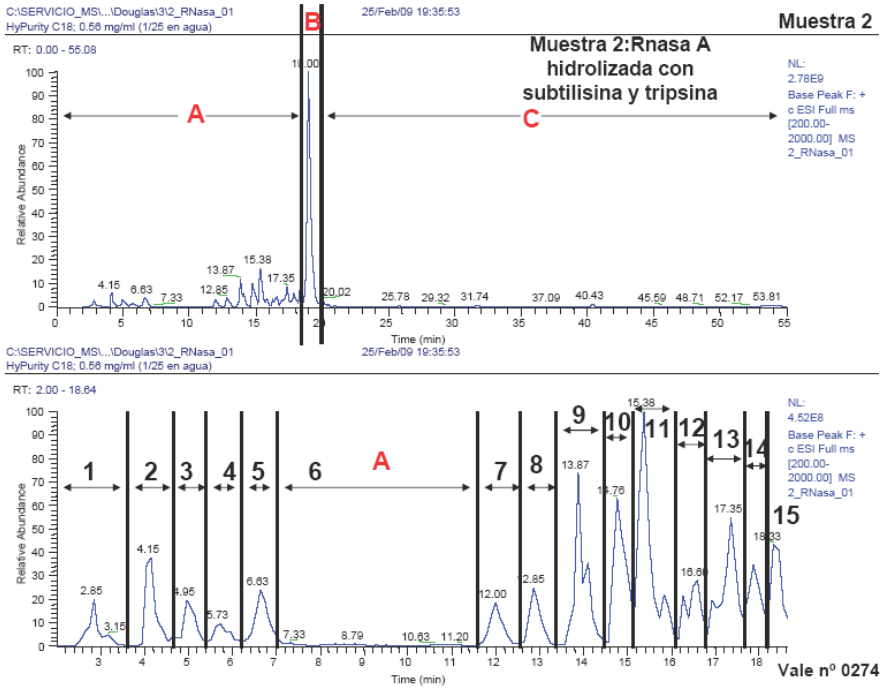
Putative Structure of the Dipeptide – EDC Fragment Adducts Detected by Electrospray Mass Spectrometry



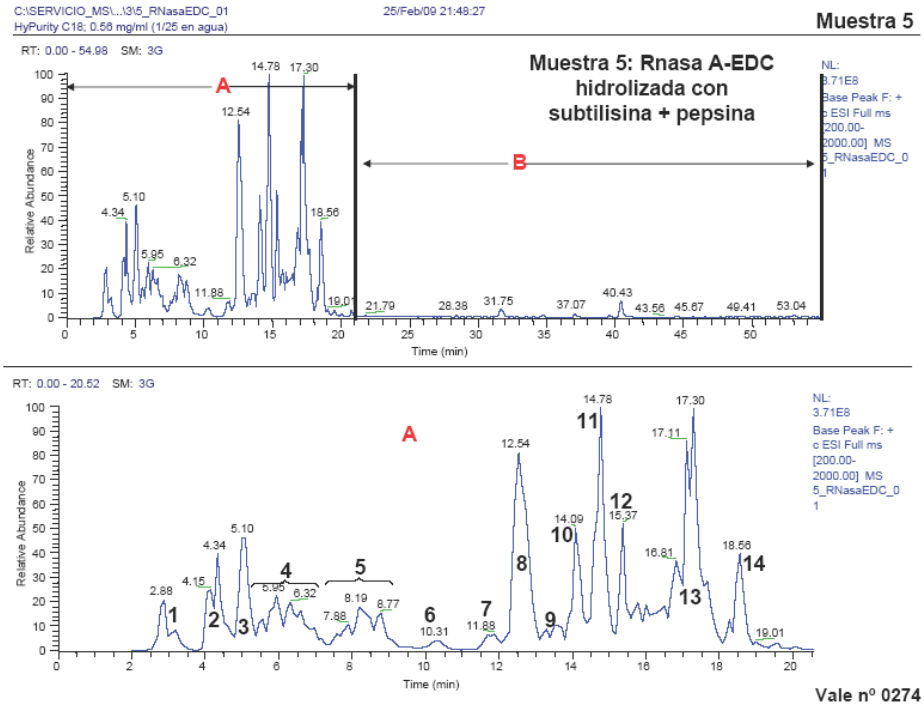
Adduction to a small EDC fragment Adduction to a large EDC fragment

Supporting Figure 6. Representative Peptide Mapping Results

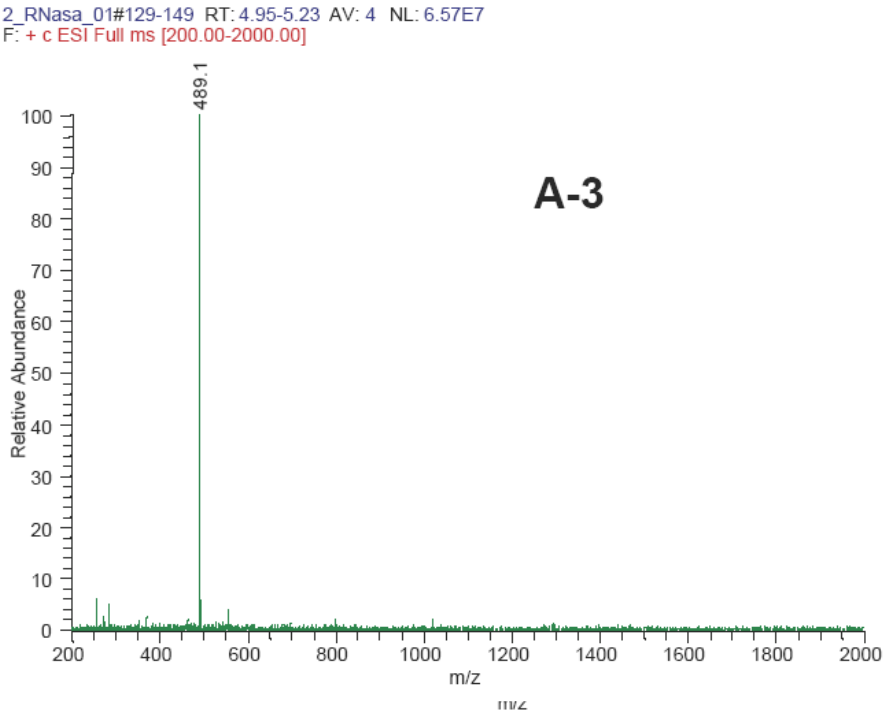
A. HPLC chromatogram of unmodified RNase A digested by subtilisin and trypsin :

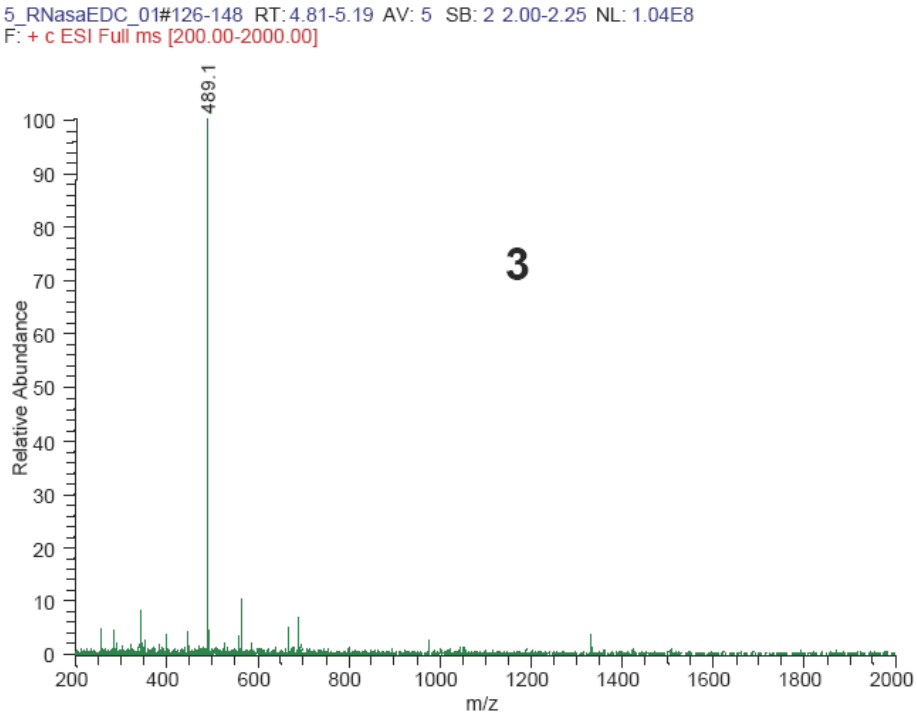


B. HPLC chromatogram of RNase A modified by EDC and digested by subtilisin and trypsin:



C. Observe that peaks A3 (top panel) and 3 (bottom panel) elute in similar positions in both chromatograms. The mass spectra of these peaks:

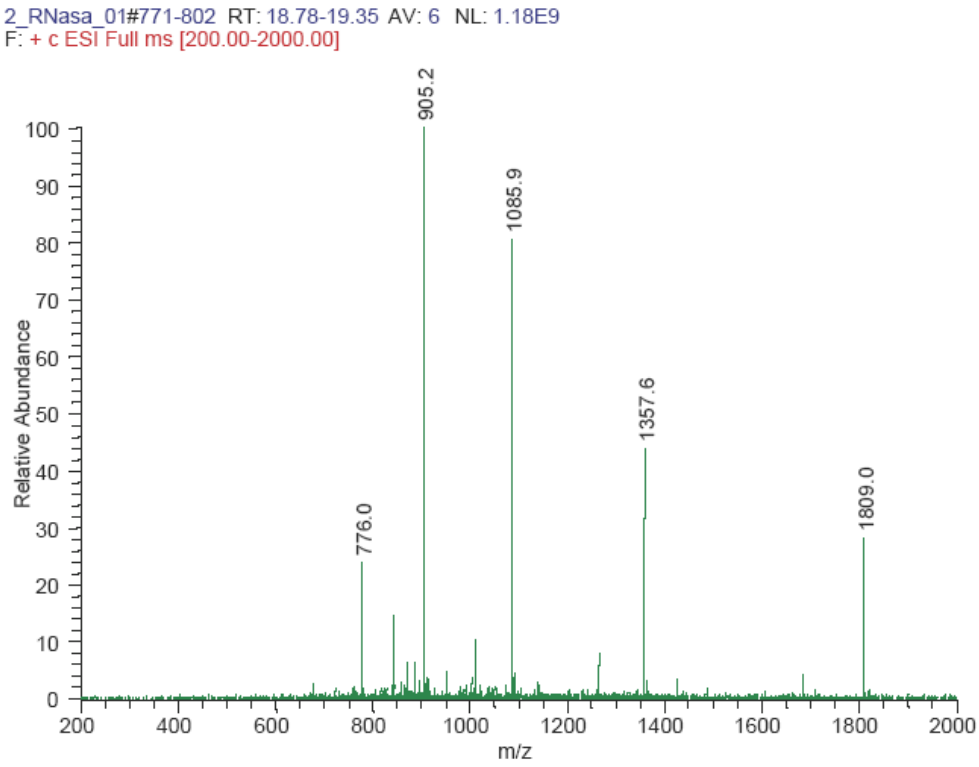




reveal identical peaks corresponding to Fragment II + K^+. Since Fragment II contains Glu 9, these data are good evidence that Glu 9 is not modified or that it is modified in a minority of RNase molecules treated with EDC.

D. Observe that the peak "B" eluting after 18 minutes in the top panel is missing in the bottom panel. The mass spectrum of this peak:

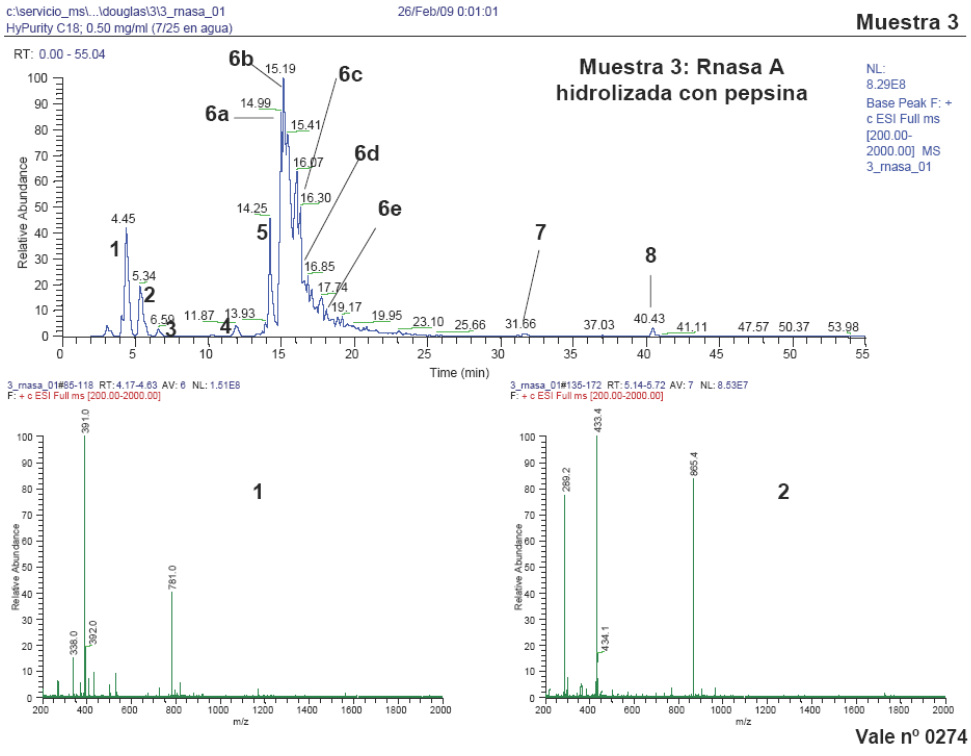
B

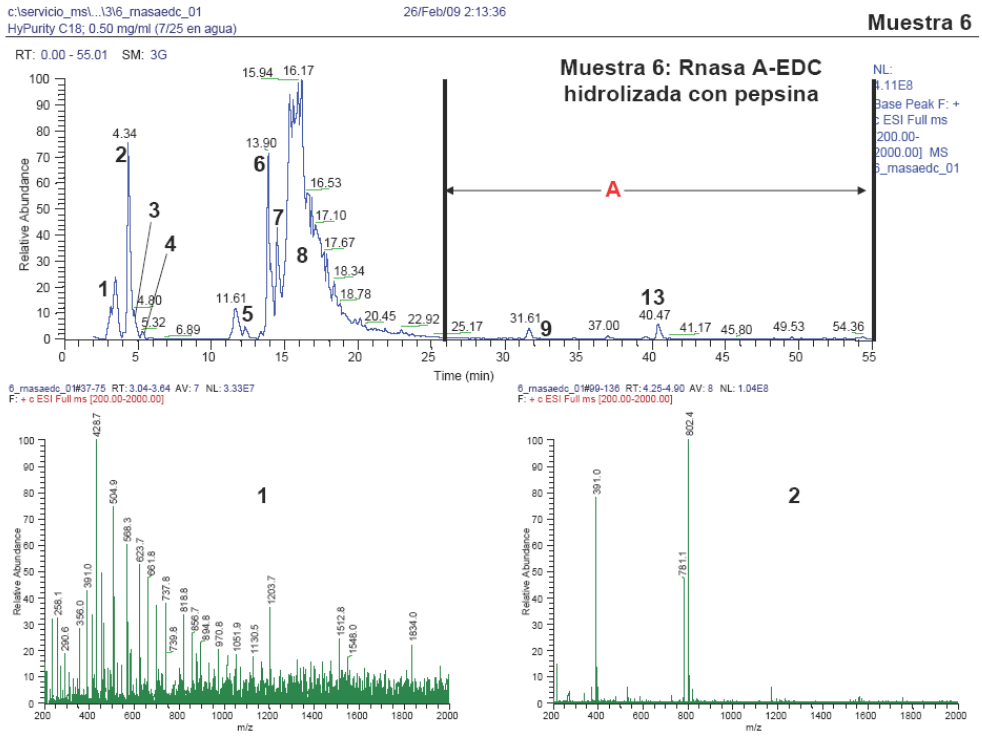


reveals peaks corresponding to fragment XIII + IX (5425.2 Da) with the peaks 1809, 1357.6, 1085.9 and 905.2 carrying 3, 4, 5 and 6 positive charges (H+), respectively. The fact that fragments XIII + IX are not separated is not unexpected as the bond between Lys 41 and Pro 42 is known to be only slowly cleaved by trypsin.

The absence of this peak in the chromatogram of RNaseA · EDC cleaved by trypsin suggests that one or more of the carboxylates in this portion of the protein have been modified by EDC. These carboxylates are Glu 49, Asp 53, Glu 111, Asp 121 and Val 124

E. Regarding the chromatograms of RNase A (top panel) and RNase A · EDC (bottom panel) hydrolyzed by pepsin:





One can see that peak 1 in the chromatogram of RNase A cleaved by pepsin corresponds in elution time to peak 2 in the chromatogram of RNase A · EDC cleaved by pepsin and that both have a peak whose mass corresponds to the C-terminal tetrapeptide Asp121-Ala122-Ser123-Val-124. Therefore, we can conclude that Asp 121 and Val 124 are not modified or that they are modified in a minority of RNase molecules treated with EDC.

On the basis of the other data and a similar way of reasoning, we have reached the following conclusions:

Not modified or modified in a minority of RNase A molecules treated with EDC	Modified in many if not a majority of RNase A molecules treated with EDC
Glu 2	Asp 38
Glu 9	Glu 49
Asp 14	Asp 53
Asp 83	Glu 111
Glu 86	
Asp 121	
Val 124 (C-terminal carboxylate)	

Cys-diabody Quantum Dot Conjugates (ImmunoQdots) for Cancer Marker Detection

Received October 1, 2008; Revised Manuscript Received June 12, 2009

The present work demonstrates the use of small bivalent engineered antibody fragments, cys-diabodies, for biological modification of nanoscale particles such as quantum dots (Qdots) for detection of target antigens. Novel bioconjugated quantum dots known as immunoQdots (iQdots) were developed by thiol-specific oriented coupling of tumor specific cys-diabodies, at a position away from the antigen binding site to amino PEG CdSe/ZnS Qdots. Initially, amino PEG Qdot 655 were coupled with reduced anti-HER2 cys-diabody by amine-sulfhydryl-reactive linker [*N*-ε-maleimidocaproyloxy] succinimide ester (EMCS) to produce anti-HER2 iQdot 655. Spectral characterization of the conjugate revealed that the spectrum was symmetrical and essentially identical to unconjugated Qdot. Specific receptor binding activity of anti-HER2 iQdot 655 was confirmed by flow cytometry on HER2 positive and negative cells. Immunofluorescence results showed homogeneous surface labeling of the cell membrane with Qdot 655 conjugate. In addition, cys-diabodies specific for HER2, as well as prostate stem cell antigen (PSCA), were conjugated successfully with amino PEG Qdot 800. All of these iQdots retain the photoluminescence properties of the unconjugated Qdot 800 as well as the antigen binding specificity of the cys-diabody as demonstrated by flow cytometry. Simultaneous detection of two tumor antigens on LNCaP/PSCA prostate cancer cells (which express PSCA and HER2) in culture was possible using two iQdots, anti-HER2 iQdot 655 and anti-PSCA iQdot 800. Thus, these iQdots are potentially useful as optical probes for sensitive, multiplexed detection of surface markers on tumor cells. The present thiol-specific conjugation method demonstrates a general approach for site-specific oriented coupling of cys-diabodies to a wide variety of nanoparticles without disturbing the antigen binding site and maintaining small size compared to intact antibody.

INTRODUCTION

In recent years, optical imaging has emerged as a sensitive detection method for diagnostic and therapeutic purposes. Quantum dots (Qdots), nanometer-scale semiconductor materials, represent an important class of fluorescent probe for biomolecular and cellular imaging (*1*). Qdots are promising as optical probes because they exhibit high quantum yields, are resistant to photobleaching, have narrow and size-tunable emission wavelengths, and have broad excitation spectra. These unique optical properties of Qdots make them appealing as *in vivo* and *in vitro* fluorophores in a variety of biological investigations. Furthermore, since the emission wavelength is readily tuned by controlling the size of the Qdots, they can be synthesized to emit different colors, allowing multiplex imaging, which is increasingly important in the analysis of complex biological systems (*2*). The use of Qdots as optical probes was originally pioneered by Alivisatos and Weiss and by Nie, in 1998. In the investigations of Alivisatos et al., two different-sized CdSe-CdS core−shell nanocrystals enclosed in a silica shell were prepared for fluorescent imaging of mouse fibroblast cells (*3*). Nie et al. investigated receptor mediated endocytosis of transferrin receptor in cultured HeLa cells using CdSe-ZnS Qdots coupled with transferrin (*4*). By chemically conjugating antibodies and peptides to their surface, quantum dots can specifically target cellular ligands of interest. Biocompatible Qdots have thus been applied for labeling cells (fixed and live) and tissues (*5*−*7*), long-term cell trafficking (*8*), multicolor cell imaging (*9*), tumor cell extravasation tracking (*10, 11*), fluorescence resonance energy transfer (FRET)-based sensing (*12*), bioluminescence resonance energy transfer (BRET)-based imaging (*13*), and sentinel lymph-node mapping (*14*). In addition, semiconductor Qdots have been shown to be suitable for real-time *in vivo* imaging and Qdots surface-modified with poly(ethylene glycol) (PEG) were reported to be biocompatible for *in vivo* cancer targeting and imaging (*15*−*17*).

Antibodies can be engineered into a wide variety of formats that retain binding specificity with target antigen and exhibit optimal properties such as rapid targeting and controlled blood clearance for *in vitro* or *in vivo* applications (*18, 19*). Intact monoclonal antibodies are large (150 kDa) protein molecules. For coupling to Qdots, smaller antibody fragments would be preferable to intact IgGs (Figure 1A); otherwise, the overall size of the antibody−Qdot conjugate becomes quite large. Smaller antibody fragments have been shown to be superior in their

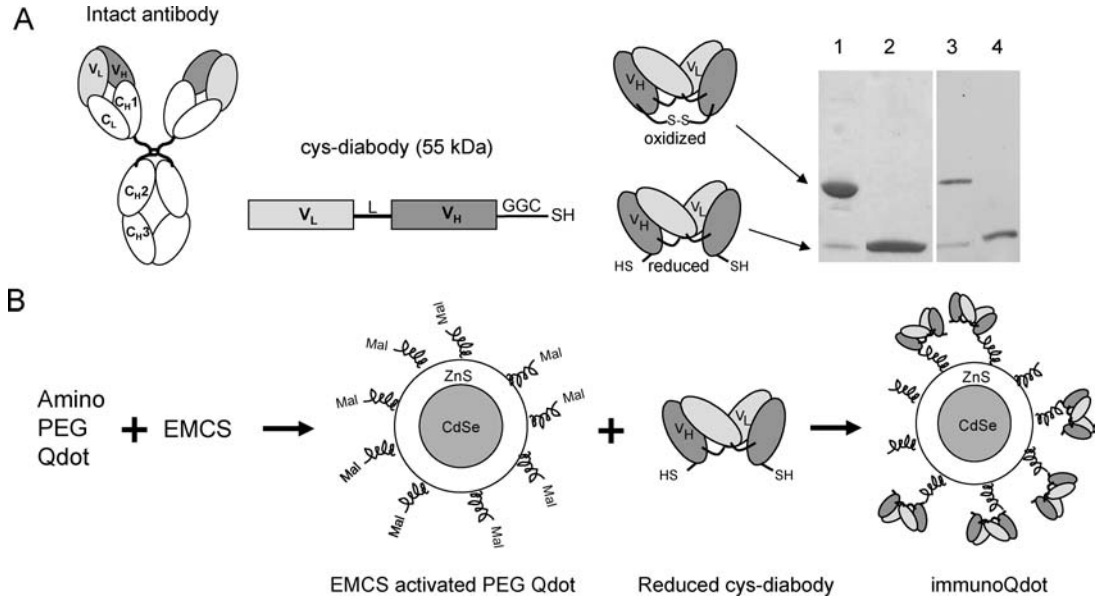

Figure 1. (A) Schematic drawing of an intact antibody showing variable light (V_L) and heavy (V_H) chain regions and constant (C) regions. Cys-diabody was formed by connecting V_L and V_H domains with either 5 or 6 amino acid linker (L) and GGC added to the C-termini for cysteine modification. DNA construct and oxidized and reduced forms of protein are shown. SDS-PAGE of two cys-diabodies: lanes 1 and 2, oxidized and reduced forms of anti-HER2 cys-diabody; 3 and 4, oxidized and reduced forms of anti-PSCA cys-diabody. Nonreduced samples migrate at expected size for covalent dimer (50 kDa), and reduced samples migrate at expected size for monomeric scFv (25 kDa). (B) Schematic illustration of the process of conjugating amino PEG Qdot with cys-diabody. EMCS: [*N*-ε-Maleimidocaproyloxy] succinimide ester. Mal: maleimide group.

ability to extravasate and penetrate solid tumors *in vivo*, when compared with intact antibodies (*20*). Genetically fusing the variable light (V_L) and heavy (V_H) chain domains of a parental antibody through a peptide linker results in the production of a single-chain variable fragments (scFv, 27 kDa), at about 1/6 the size of native antibody, with the same specificity as that of parental intact antibody. Shortening the peptide linker results in formation of noncovalent dimers of scFvs, called diabodies (Db, 55 kDa) which retain full antigen binding activity and specificity in smaller formats (*21*). Our lab has previously demonstrated that radiolabeled diabodies against cell surface cancer antigens efficiently target tumors *in vivo* by microPET (*22, 23*). Their small size (5 × 7 nm) makes these engineered antibody fragments specifically appropriate for conjugation to nanoscale particles.

Conjugation by random chemical modification may be risky for small antibody fragments, due to the possibility of inadvertently disrupting the binding site. Site-specific conjugation is more likely to preserve the binding activity of an antibody. X-ray crystallographic structure of the anti-CEA T84.66 diabody shows that the C-termini of the diabody subunits are almost 70 Å apart and on an alternate face from the antigen-combining site (*24*). Introduction of cysteine residues at the C-termini of scFv fragment has been considered as an approach to allow site-specific, thiol-reactive coupling at a site away from the antigen binding site to a wide variety of agents (Figure 1A) (*25*−*28*). Previous work from our laboratory demonstrated site-specific conjugation and radiolabeling of an anti-CEA diabody with C-terminal cysteine (cys-diabody) for rapid tumor targeting and imaging in CEA-positive xenograft bearing mouse by microPET (*26*).

Numerous studies indicate that the avidity effect of having more than one binding site improves the targeting and retention of antibodies and immunoconjugates. For eventual *in vivo* delivery, an antibody-nanoparticle conjugate needs to be small but also bivalent. Use of a bivalent cys-diabody as the targeting moiety ensures that (at least) two binding sites are attached to the particle, and optimization should allow production of 1:1 conjugates. In contrast, in order to achieve bivalency using monovalent scFv fragments, titration and optimization will be more challenging and yields probably lower, since a broad distribution of conjugation ratios, including monovalent complexes, will be obtained.

The present study demonstrates oriented site-specific coupling of bivalent cys-diabodies specific for well-characterized cancer cell surface antigens, HER2 and prostate stem cell antigen (PSCA) to fluorescent semiconductor amino PEG Qdots using thiol chemistry. Cys-diabody conjugated Qdots are termed immunoQdots (iQdots). Initial biophysical and functional characterization was performed with anti-HER2 iQdot 655. This iQdot demonstrated dual functionality: retention of HER2 antigen binding specificity as well as fluorescence signal of Qdot. Using two iQdots, anti-HER2 iQdot 655 and anti-PSCA iQdot 800, simultaneous detection of two antigens, HER2 and PSCA, on LNCaP/PSCA cells can be possible by *in vitro* optical imaging. This study allows a general approach for biological modification of a variety of nanoscale particles with small bivalent engineered antibody fragments in an oriented fashion without affecting the antigen binding site and maintaining the overall small size compared to intact antibody.

EXPERIMENTAL PROCEDURES

Design, Expression and Purification of Cys-diabodies. The anti-HER2 cys-diabody was constructed from trastuzumab (Herceptin; Genentech, San Francisco, CA) human variable regions using an existing single-chain variable fragment (scFv) gene construct as template (*29*). Affinity matured recombinant scFv fragment, derived from humanized anti-PSCA antibody (hu1G8 mAb) (*30*) was used as a template for anti-PSCA cys-diabody (Lepin, E. unpublished data). Overlap-extension PCR and site-directed mutagenesis (QuickChange XL, Stratagene, La Jolla, CA) were used to generate both of the cys-diabody constructs with the following orientation: V_L-linker-V_H-C-terminal cysteine modification (GGC) (*28*). 5-Amino acid linker, SGGGG, and 6-amino acid linker, SGGGGS, are the linkers used to construct anti-HER2 and anti-PSCA cys-diabodies, respectively. The final PCR product of anti-HER2 cys-diabody was cloned in the pEE12 mammalian expression vector (Lonza

Biologics, Slough, UK) (*28*) containing a mammalian leader sequence for secretion. The anti-PSCA cys diabody was cloned into pSyn1 plasmid for bacterial expression (gift of Dr. James D. Marks, University of California, San Francisco) (*31*).

For expression of anti-HER2 cys-diabody, 2.5×10^6 NS0 cells (*32*) were transfected by electroporation with 10 μg linearized plasmid DNA and selected in glutamine-deficient media as described (*25*). Anti-HER2 cys-diabody expression was screened by Coomassie stained SDS-PAGE precast 4−20% gels (Bio-Rad, Hercules, CA), under reducing and nonreducing conditions. The highest-expressing clones were expanded into triple flasks (Nunclon, Rochester, NY).

For bacterial expression of the anti-PSCA cys-diabody, *Escherichia coli* BL21 cells transformed with the pSyn1 expression vector were grown in Luria-Bertani broth (LB) to an OD_{600} of 0.7, induced with a final concentration of 1 mM IPTG, and grown for 4 h at 37 °C. Periplasmic extracts were prepared using Peripreps Periplasting Kits (Epicenter, Madison, WI).

Both of the cys-diabodies, anti-HER2 and anti-PSCA, were purified by immobilized protein L chromatography according to the manufacturer's instructions (Pierce, Rockford, IL). The final concentration of the purified proteins was determined by $A_{280\ nm}$ using an extinction coefficient $\varepsilon = 1.4$. Purified proteins were analyzed by SDS-PAGE under reducing and nonreducing conditions. Cys-diabodies were also subjected to gel filtration chromatography on a Superdex 75 HR 10/30 column (GE Healthcare, Piscataway, NJ). Final protein yields were 3.0 mg/L of mammalian culture supernatant for anti-HER2 cys-diabody and 0.2 mg/L of bacterial culture supernatant for anti-PSCA cys-diabody.

Coupling of Qdots to Tumor-Specific Cys-diabodies. Cys-diabodies were covalently conjugated to Qdot 655 and Qdot 800 amino (PEG) quantum dots (Invitrogen, Carlsbad, CA). Briefly, Qdots were activated with the heterobifunctional cross-linker[*N*-ε-maleimidocaproyloxy] succinimide ester (EMCS) (Pierce) for 30 min at room temperature in 50 mM borate buffer (pH 7.4), yielding a maleimide-modified particle. In each reaction, 60 μg of cys-diabodies were simultaneously reduced by incubating in 20 mM DTT in PBS at room temperature for 30 min. Excess EMCS and DTT were removed using Bio-Spin 6 (Bio-Rad) desalting columns. Mock conjugation controls were also treated under the same conditions, with no cys-diabody added. Then, activated Qdots were incubated with reduced antibody fragment at room temperature for 1 h in 50 mM borate buffer (pH 7.4). The molar ratio of antibody fragment to Qdot was 22:1. The reaction was quenched by adding 34 μg of *N*-ethyl maleimide (NEM, 10 mg/mL in DMSO, Pierce) per mg of antibody fragment. The uncoupled free cys-diabody and excess NEM were removed by three washes using a 100 KDa ultrafiltration unit, Amicon Ultra-4 (Millipore Corp., Bedford, MA). The final iQdot complex was stored in 10 mM borate buffer at 4 °C.

Cell Lines. NS0 mouse myeloma cells (*32*) and human breast cancer cell lines MCF7 (American type Culture Collection [ATCC], Manassas, VA; #HTB-22) transfected with HER2 (MCF7/HER2 (*33*)) were maintained as described (*29*). Human prostate cancer cell lines LNCaP (American type Culture Collection (ATCC; #CRL-1740) transfected with PSCA (LNCaP/PSCA (*34*)) and human B-cell lymphoma cell line SKW 6.4 (ATCC; #TIB-215) transfected with PSCA (SKW6.4/PSCA) (a generous gift of Dr. Robert Reiter, UCLA) were maintained as described (*35*). SK-OV-3, the human ovarian carcinoma cell line (ATCC; #HTB-77) was maintained in McCoy's 5A medium (Mediatech, Inc., Herndon, VA) supplemented with 10% FBS, and Jurkat helper T cell lines (ATCC # TIB-152) were maintained as recommended by ATCC.

Photoluminescence Spectra. The emissions of unconjugated and conjugated Qdot 655 were determined using a QuantaMaster QM-6 steady state spectrofluorometer (Photon Technology International, Inc., Birmingham, NJ) with a 75 W xenon lamp and a 928R PMT. All NIR emission spectra were recorded on a CCD-array based SPM-002 spectrometer (Photon Control Inc., British Columbia, Canada) with a 532 nm diode pumped laser as pumping source.

Flow Cytometry. MCF7/HER2 cells were incubated with either anti-HER2 iQdot 655 or anti-HER2 iQdot 800 for 1 h at 4 °C in PBS containing 1% FBS. LNCaP/PSCA cells were incubated with anti-PSCA iQdot 800 using the same conditions. Approximately 0.83 pmol of Qdots were used in flow cytometry experiments. The cells were then washed with PBS containing 1% FBS. Antibody fragments binding to tumor cells were quantified by FACSCalibur flow cytometer (Becton Dickinson, UK), and data were analyzed using Cell Quest software (Becton Dickinson). FL3 (λ_{em}: 670 nm long pass) and FL5 (λ_{em}: 740 nm long pass) filters were used for Qdot 655 and Qdot 800, respectively.

For competitive cell binding assays, experiments were performed in triplicate on MCF7/HER2 cells by the addition of a fixed concentration of anti-HER2 iQdot 655 (10 nM) and increasing concentrations of anti-HER2 antibody fragment, minibody (*29*) (0.1−1000 nM) as competitor. Binding of anti-HER2 iQdot 655 on cells was examined by flow cytometry. Result was normalized to the signal obtained in the absence of competitor.

Confocal Microscopy. MCF7/HER2 cells were plated on poly(L-lysine)-coated glass coverslips (BD Biosciences, San Jose, CA) in 12-well plates in DMEM medium containing 5% FBS for 24 h. The next day, cells were incubated with mock conjugated Qdot 655 and anti-HER2 iQdot 655 in PBS/1% FBS on ice for 1 h. Approximately 1.7 pmol of Qdots were used in confocal microscopy experiments. Cells were fixed with 3.7% paraformaldehyde at 4 °C for 30 min. Cell nuclei were counterstained with DAPI. Coverslips were mounted on glass slides and observed using a Zeiss LSM510 META confocal imaging system (excitation: argon laser 488 nm) (Carl Zeiss Inc., Thornwood, NY) equipped with a 100× oil immersion objective lens.

Fluorescence Imaging of Qdot Labeled Cells. LNCaP/PSCA cells were incubated with two different iQdots, anti-HER2 iQdot 655 and anti-PSCA iQdot 800 in microfuge tubes. For control experiment, cells were incubated with mock conjugated Qdot 655 and Qdot 800. Cells with Qdots were incubated for 1 h at 4 °C in PBS containing 1% FBS. Approximately 3.3 pmol of Qdots were used in fluorescence imaging experiments. Cells were then washed twice with PBS (1% FBS) to remove any unbound Qdots. Antibody-conjugated Qdots binding to tumor cells were examined using Maestro *In-vivo* Fluorescence Imaging System (CRI, Inc., Woburn, MA) with a blue filter set (excitation, 445−490 nm; emission, 515 nm long-pass, 515−900 nm). CRI software *Maestro 2p23* was used to analyze the data.

RESULTS

Synthesis and Biophysical Characterization of Anti-HER2 iQdot 655. Anti-HER2 cys-diabody was expressed in mammalian cells and purified successfully. Analysis of the purified proteins on SDS-PAGE showed that the cys-diabody migrated as a monomer consistent with its predicted molecular weight of approximately 25 kDa under reducing conditions and as covalent dimer of 55−60 kDa under nonreducing conditions (Figure 1A). An excess amount of reduced cys-diabody was allowed to react with activated amino PEG CdSe/ZnS Qdot 655 using the heterobifunctional cross-linker EMCS to form anti-HER2 iQdot 655 (Figure 1B).

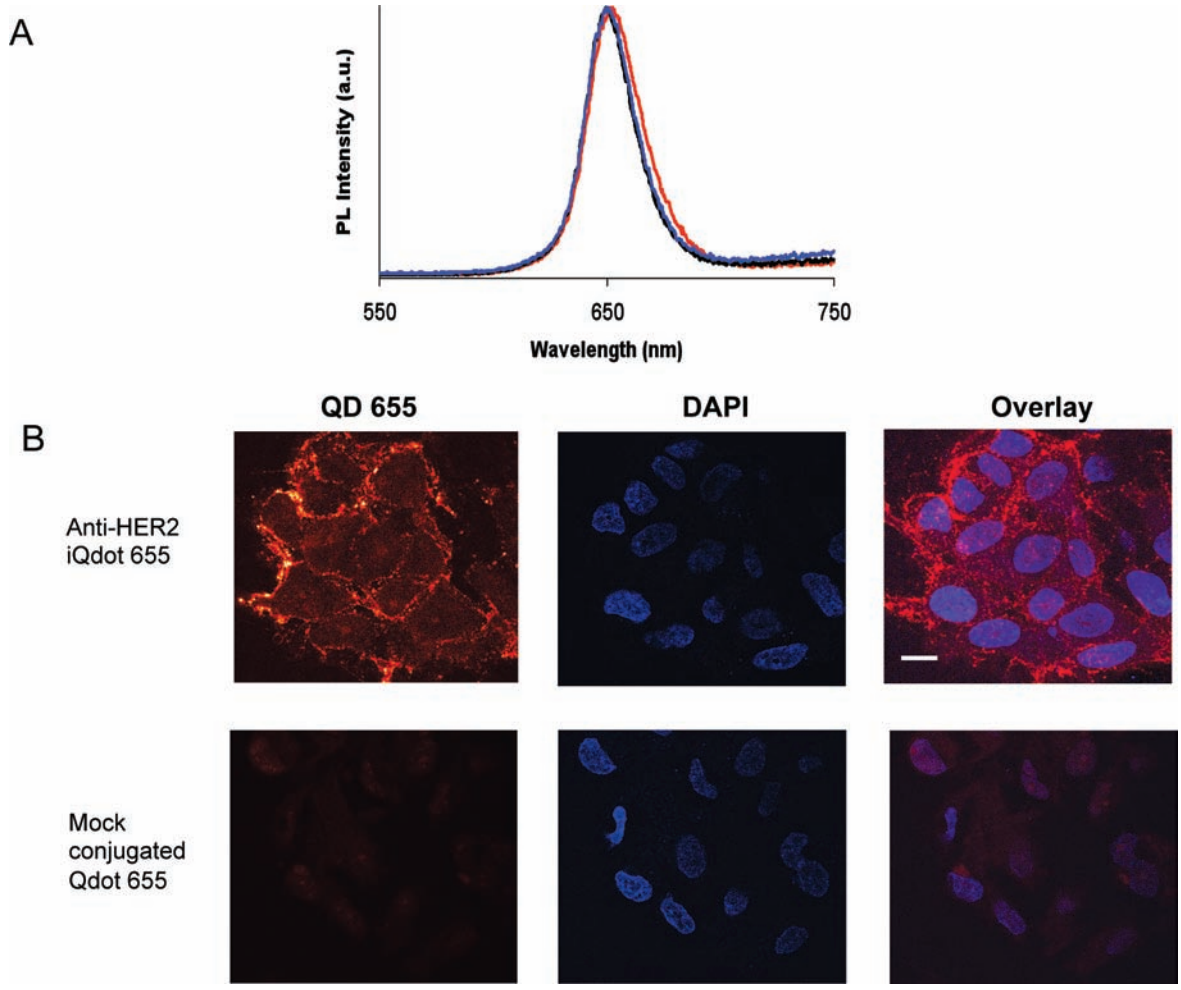

Figure 2. (A) Photoluminescence (emission) spectra of amino PEG Qdot 655 conjugates at excitation wavelength 488 nm. Maximum emission wavelengths are 650.0, 650.5, and 652.5 nm for commercial Qdot 655 (black line), mock conjugated Qdot 655 (blue line), and anti-HER2 iQdot 655 (red line), respectively. All spectra are typically around 30 to 50 nm (full width at half-maximum). (B) Confocal microscopy images of MCF7/HER2 cells stained with anti-HER2 iQdot 655 and mock conjugated Qdot 655. Cell nuclei were counterstained with DAPI and shown in blue. Scale bars: 20 μm.

To visualize the structure of synthesized anti-HER2 iQdot 655, transmission electron microscopy (TEM) was performed on anti-HER2 iQdot 655 and mock conjugated Qdot 655. TEM bright field images revealed that Qdots were uniform in size; prior to and following conjugation, only the inorganic particles are directly visualized at approximately 15 × 5 nm (Supporting Information Figure 1). Negative staining of the conjugates reveals an additional halo, consistent with the conjugation of protein to the particles. Size exclusion chromatography was also performed to evaluate conjugated Qdots. Chromatography on a Superdex 200 HR column showed a single peak eluting at 18.03 min, slightly earlier than that of mock conjugated Qdot 655 (18.28 min) suggesting a relatively uniform preparation without extensive aggregation (Supporting Information Figure 2).

To evaluate whether there was any difference in the photoluminescence (PL) spectrum of Qdots after conjugation to cys-diabody, PL measurements of Qdots were performed by excitation with a 488 nm laser. Figure 2A shows that the spectrum of anti-HER2 iQdot 655 is still symmetrical and almost identical to that of commercial Qdots with only a slight red shift.

Functional Characterization of Anti-HER2 iQdot 655. To determine whether the anti-HER2 iQdot 655 could bind to HER2, HER2 expressing human breast carcinoma MCF7/HER2 cells were incubated with anti-HER2 iQdot 655 and examined by confocal microscopy. The result demonstrated homogeneous surface labeling of the cell membrane with minimal cytoplasmic labeling. Minimal nonspecific binding to the cells was observed with mock conjugated Qdot 655 (Figure 2B).

The anti-HER2 iQdot 655 was also used to assess HER2 expression on MCF7/HER2 cells by flow cytometry. Results showed a strong fluorescent shift of anti-HER2 iQdot 655 with MCF7/HER2 cells (Figure 3A). Control experiments were performed to show the specificity of anti-HER2 iQdot 655. Incubation of MCF7/HER2 cells with mock conjugated Qdot 655 (Figure 3A) or anti-CD20 iQdot 655 (irrelevant iQdot, negative control; data not shown) did not show a shift in fluorescence intensity. Anti-HER2 iQdot 655 also bound efficiently to other HER2 positive cells, i.e., SK-OV-3, ovarian carcinoma cells, and LNCaP/PSCA prostate cancer cells (Figure 3A). No binding was seen to HER2-negative Jurkat cells (Figure 3A).

In order to further evaluate the binding specificity of anti-HER2 iQdot 655, a cell-based competition assay in which Qdot conjugated cys-diabody was incubated simultaneously in the presence of increasing concentrations of competitor, was carried out and analyzed by flow cytometry (Figure 3B). At higher concentrations of the competitor, lower amounts of iQdot were bound. This confirmed that anti-HER2 iQdot 655 retained the same epitope specificity as that of the anti-HER2 antibody fragment.

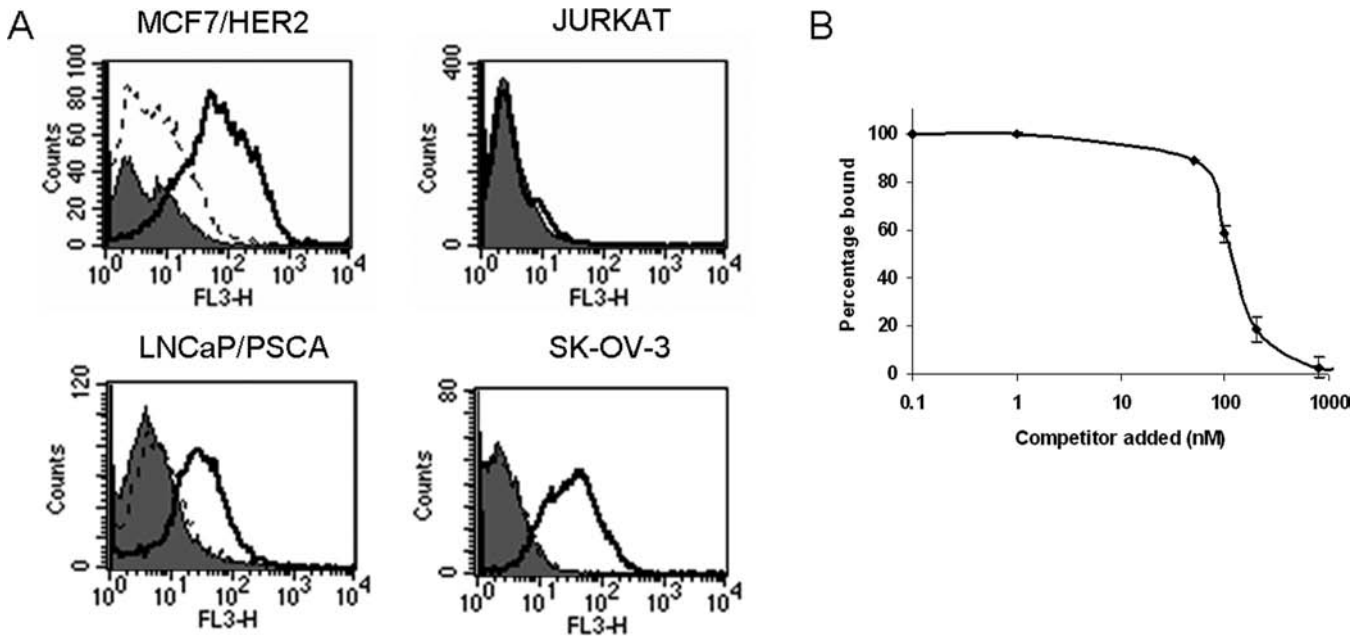

Figure 3. (A) Flow cytometry analysis of cys-diabody conjugated Qdot binding with different tumor cells. Cells were treated with no protein (solid gray), mock conjugated Qdot 655 (dotted black line), and anti-HER2 iQdot 655 (solid black line). FL3 (λ_{em}: 670 nm long pass) was the filter used for Qdot 655. (B) Competitive cell binding assay by flow cytometry. An anti-HER2 antibody fragment, minibody (*29*) was used as competitor. Samples were assayed in triplicate and means ± SEM are shown, normalized to the signal obtained in the absence of competitor.

Functional and Biophysical Characterization of NIR iQdots. In small animals, NIR (700−900 nm) fluorescence imaging is expected to have major utility, because the absorbance spectra for biomolecules reach minima in the NIR region, providing a window for *in vivo* optical imaging. We extended the coupling of anti-HER2 cys-diabody to amino PEG CdSe/ZnS Qdot 800 (emission maximum at 785 nm, anti-HER2 iQdot 800). The specific binding of anti-HER2 iQdot 800 on MCF7/HER2 cells was confirmed by cell binding assay (Figure 4A). In order to demonstrate this oriented thiol-specific coupling of other cys-diabodies specific for cell surface antigens to Qdots, we considered PSCA as an additional target. Applying the same thiol chemistry, we conjugated anti-PSCA cys-diabody with amino PEG Qdot 800 using EMCS (anti-PSCA iQdot 800). Strong binding of anti-PSCA iQdot 800 to LNCaP/PSCA cells was demonstrated by flow cytometry (Figure 4B).

PL measurements of NIR Qdots were performed following excitation with a 532 nm laser. The PL spectra measurements of the Qdots showed maxima at around 785 nm (Figure 4C). There was no significant change observed in mock conjugated and antibody conjugated Qdot spectra.

Duplex Antigen Detection of Prostate Cancer Cells Using Two Colored iQdots. Initially using individual Qdot conjugated cys-diabodies, anti-HER2 iQdot 655 and anti-PSCA iQdot 800, the expression of each target antigen, HER2 and PSCA, was examined on different cancer cells (Table 1). Detection of two individual cancer markers on LNCaP/PSCA prostate cancer cells (which also express HER2) was verified by previous flow cytometry experiments using anti-HER2 iQdot 655 and anti-PSCA iQdot 800 separately (Figure 3A and Figure 4B). Simultaneous detection of the two tumor markers on the same cells was not possible due to lack of proper filters and instrumental settings. To examine the feasibility of multiplex fluorescence imaging, LNCaP/PSCA prostate cancer cells were incubated with two different Qdot conjugates and imaged using a Maestro *In Vivo* optical imaging system (Figure 5A). The spectral analysis shows the presence of two distinct peaks of anti-HER2 iQdot 655 and anti-PSCA iQdot 800 (Figure 5B) verifying that multiplex fluorescence imaging is possible with these iQdots.

DISCUSSION

In this study, we report the site-specific conjugation of engineered antibody fragments with visible/NIR quantum dots for *in vitro* cell labeling and multiplex imaging. A key feature of this approach is the use of cys-diabodies which represent the smallest bivalent antibody fragment that can be generated from intact antibodies. Furthermore, this cys-diabody format enables site-specific, oriented coupling, ideal for applications in nanotechnology. Initial studies showed that Qdots functionalized with anti-HER2 cys-diabody retained antigen-specific cell binding, demonstrated by flow cytometry and fluorescence microscopy. In addition, utilizing the same technique, anti-PSCA cys-diabody was successfully conjugated to Qdots and two-color analysis was possible. The amine modified quantum dots used in this study include a PEG spacer covalently attached to the Qdot surface. We found that the PEG linker gave less nonspecific background compared to the corresponding carboxyl-modified Qdot 655, which does not possess a PEG linker (unpublished data). This characterization is most likely due to the increased hydrophilicity and higher stability resulting from the PEG-coating. The PEGylation reduces the surface charge and as a result, the nonspecific binding is reduced (*16*).

PEGylated Qdots have been used for *in vivo* imaging in mice (*17*). Addition of multiple PEG molecules provides improved biocompatibility and blood retention time. These improved properties of Qdots can facilitate their use as optical imaging probes *in vivo*. Recently, the delivery of Qdot 655 labeled antibody to tumor cells was investigated by *in vivo* real-time tracking (*11*). RGD modified Qdots have also recently been tracked in vasculature by their binding with integrins using intravital microscopy (*36*). PEGylated commercial Qdots had shown slower uptake into liver and spleen and low-level bone uptake in mice compared to un-PEGylated Qdot (*37*), but overall clearance times were still very rapid (6 min vs 2 min).

Use of engineered antibody fragments with Qdots for detection of a specific organic compound, 2,4,6-trinitrotoluene

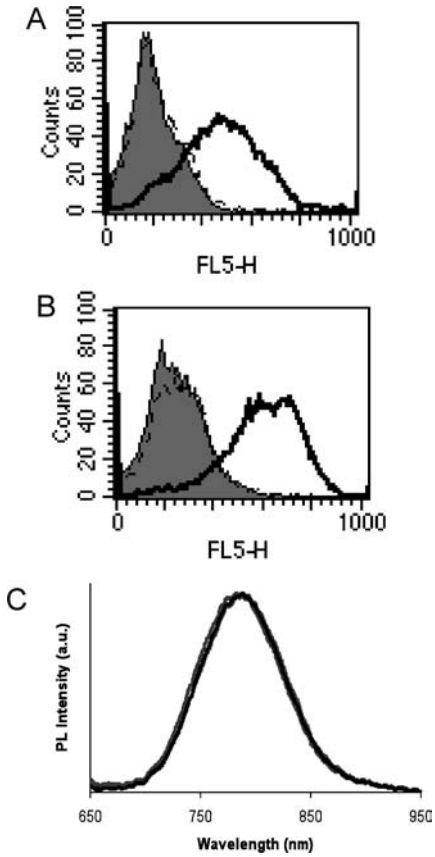

Figure 4. (A) Flow cytometry analysis of cys-diabody conjugated NIR Qdot binding with MCF7/HER2 Cells. Cells were treated with no protein (solid gray), mock conjugated Qdot 800 (dotted black line), and anti-HER2 iQdot 800 (solid black line). (B) LNCaP/PSCA cells stained with no protein (solid gray), mock conjugated Qdot 800 (dotted black line), and anti-PSCA iQdot 800 (solid black line). FL5 (λ_{em}: 740 long pass) was the filter used for Qdot 800. (C) Normalized emission spectra of amino PEG Qdot 800 conjugates. Excitation wavelength was 532 nm. Corresponding emission peaks and associated full-width half-maximum values were 787.9 and 88.95, 785.7 and 89.19, and 789.0 and 89.62 nm for mock conjugated Qdot 655 (black line), anti-HER2 iQdot 800 (red line), and anti-PSCA iQdot 800 (brown line), respectively.

Table 1. Binding Assay of Different ImmunoQdots with Different Tumor Cell Lines

cell line	Anti-HER2 iQdot 655	Anti-PSCA iQdot 800
Jurkat	−	−
MCF7/HER2	+	−
SKW/PSCA	−	+
LNCaP/PSCA	+	+

(TNT) was demonstrated using a scFv fragment (*38*). This study showed the use of luminescent Qdots conjugated to antibody fragments in a solution-phase nanosensor, based on fluorescence resonance energy transfer (FRET) for the specific detection of the explosive TNT in aqueous environments. Attachment of the anti-TNT specific scFv fragments to a hydrophilic Qdot via metal affinity coordination is another example of oriented attachment of small antibody fragments to Qdots. *In vivo* applications may be limited by the size of the overall complexes. In contrast, the present approach to site-specifically label cys-diabodies to any nanoscale particles can be used for *in vitro* as well as *in vivo* applications depending on the size of the conjugated particle.

In contrast to *in vitro* applications, many challenges exist *in vivo*, in particular, when targeting tumor is the goal. Many factors influence the penetration of antibody to areas distal from the blood vessels (*39*). These include antibody affinity, concentrations, antibody size, vascular permeability, and intratumoral pressure. Methodologies for introducing specificities onto Qdots by conjugating intact antibodies specific for HER2 antigen and prostate-specific membrane antigen (PSMA) for *in vivo* study have been developed (*11*, *17*). In mice bearing PSMA expressing tumor xenografts, in addition to tumor uptake, the antibody conjugated Qdots were trapped in the liver and spleen (*17*).

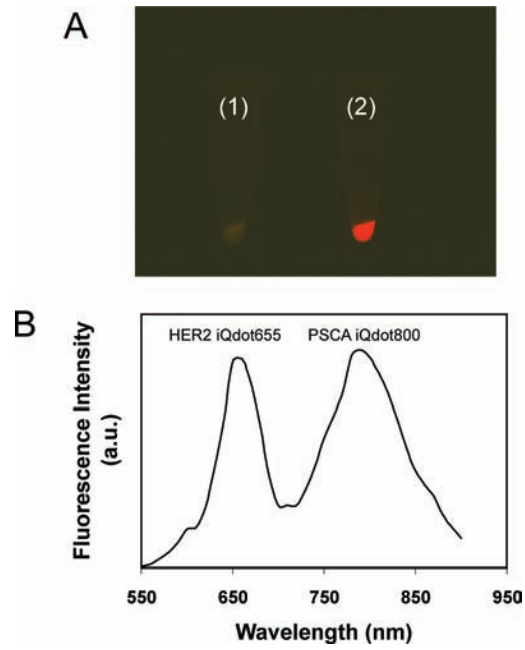

Figure 5. Dual marker Qdot staining of human prostate cancer cells. (A) *In vitro* fluorescence imaging of LNCaP/PSCA cells stained with (1) mock conjugated Qdot 655 and Qdot 800 and (2) anti-HER2 iQdot 655 and anti-PSCA iQdot 800. The raw fluorescence image acquired using a color CCD camera with a 550 to 900 nm filter is shown. (B) Spectral analysis of dual stained cells (sample 2) following background subtraction.

Previous studies of antibodies and antibody fragments have shown rapid and homogeneous tumor penetration by scFv fragments compared to other immunoglobulin forms (*20*). One potential shortcoming of the current Qdot conjugation strategies with biomolecules, especially vis-à-vis *in vivo* applications, is that the Qdot bioconjugates are quite large (∼40−50 nm) once streptavidin or intact antibodies are incorporated. Such large nanoparticles will have difficulty in traversing the endothelium and penetrating into tissues and tumors. In contrast, if smaller antibody fragments such as cys-diabodies are directly labeled to Qdots, the overall smaller size of these iQdots should be more suitable for *in vivo* applications. Further gains can be made by conjugation to even smaller particles such as zwitterionic, cys-coated quantum dots (QD-Cys) having hydrodynamic diameters of about 5.5 nm for rapid and efficient renal clearance and extravasation (*40*). Schipper et al. have further examined the effects of particle size, surface coating, and PEGylation on the biodistribution and clearance of small, near-infrared InAs Qdots, observing a shift toward renal clearance following PEGylation of the smallest, peptide-coated Qdots (*41*).

In conclusion, cys-diabodies are small, bivalent tumor-targeting antibody fragments that retain antigen binding specificity after incorporation of the cysteine-modification at the C-termini. Their small size and favorable pharmacokinetics make them ideal for use in imaging and therapeutic applications. The present study demonstrates site-specific, oriented conjugation of cys-diabodies to commercially available amino PEG quantum dots. The iQdots retain the photoluminescence properties of the unconjugated Qdots as well as the antigen binding

specificity of the cys-diabody. The overall small size of cys-diabody conjugated Qdots should render them suitable for biological applications. The results of Qdot conjugation to cys-diabodies with different tumor specificities opens up new prospects for multiplex imaging in cancer. This thiol-reactive conjugation approach can be used as a generalized platform for site-specific coupling of cys-diabodies with a wide variety of other nanoparticles, such as quantum rods or carbon nanotubes.

Cys-diabody Quantum Dot Conjugates (immunoQdots) for Cancer Marker Detection

TEM Method: Transmission electron microscopy (TEM) specimens were prepared by pipetting 6μl of the sample suspension onto ultrathin Carbon Type-A 400-mesh copper grids (Tedpella Inc., Redding, CA) that had been glow-discharged. After 10 minutes, the grids were rinsed with deionized water to remove any buffer salts that may be present in the samples and wicked to almost dryness with filter paper. Phosphotungstic acid (PTA) of pH 7.0 was then added to the grids to negatively stain the samples. After one minute, the grids were completely dried using filter paper.

All the specimens were analyzed using the Philips CM20 FEG-TEM operating at 200kV. The microscope is also equipped with an energy dispersive x-ray spectrometer (EDS) for compositional analysis.

Size exclusion chromatography: Conjugated Qdots were subjected to size-exclusion chromatography on a Superdex 200 column (GE Healthcare, Piscataway, NJ) in PBS at a flow rate of 0.5 mL/min over one column volume (24 mL) on an AKTA purifier.

We report a highly specific, robust, and generic method for noncovalent labeling of cellular proteins with highly fluorescent core−shell silica nanoparticles termed C dots. Our approach uses short genetically engineered peptides with affinity for silica (GEPS) that are site-specifically introduced at the termini or in loops of cellular proteins. Because GEPS are absent from native cell surface proteins, GEPS-tagged recombinant proteins can be selectively and rapidly labeled with fluorescent C dots. To demonstrate the versatility of our method, we targeted 30 nm C dots to two structurally distinct integral outer membrane proteins in *Escherichia coli*, FhuA and OmpX. Efficient labeling was achieved in 15 min or less and was observed to be highly sensitive and specific. This strategy provides a powerful technique, comparable to other chemical and biological labeling strategies, for efficient and quantitative investigation of protein function in live biological cells.

INTRODUCTION

Visualizing the movement and interactions of cellular proteins is fundamental to our understanding of biochemical networks and for elucidating the structure and function of proteins in their native environment. Numerous biophysical probes (e.g., fluorophores, spin labels, etc.) have been developed for labeling cellular proteins with excellent spatiotemporal resolution (*1, 2*). However, a primary factor limiting the use of many such probes is the technological challenge associated with probe conjugation to target proteins. To address this challenge, a number of general labeling strategies have been reported recently that employ special protein or peptide handles for recruitment of biophysical probes to specific sites within proteins on the surface of living cells (*3*−*6*). For instance, Ting and co-workers have developed a two-step conjugation procedure based on enzymatic biotinylation that enables cell surface protein labeling using different probes, including fluorescent semiconductor nanoparticles known as quantum dots (QDs) (*7*). QDs hold great promise as biophysical probes because of their intense fluorescence emission and remarkable photostability (*8, 9*), as well as their ability to be rendered water-soluble and thus used in biological media and other aqueous environments (*10*). However, although QDs exhibit many desirable photophysical properties, they face significant challenges relating to their toxicity and disposal (*11, 12*).

As an alternative to QDs, organic fluorophores can be incorporated into nanoparticles during synthesis (*13*−*16*). For instance, Wiesner and co-workers recently developed a class of monodisperse fluorescent core−shell silica nanoparticles, termed C dots (Figure 1a), by integrating covalently bound dyes in a sol−gel-derived silica matrix (*17*). The particles are assembled in a core−shell architecture via a modified Stöber synthesis (*18*) with the dye molecules (e.g., tetramethylrhodamine isothiocyanate, TRITC) sequestered within the particle core, which in turn is enclosed in a layer of pure silica. This architecture results in a variety of improved properties, such as reduced photobleaching, minimized solvatochromic shift, and increased fluorescence efficiency relative to free dye in aqueous solution and provides particles with sizes down to the 3−5 nm scale (*19, 20*). The C dot design also allows colocalization of multiple fluorophores within a single particle. This significantly increases per-particle brightness and, because the encapsulated dye molecules are decoupled from each other, reduces intermittent blinking under continuous excitation—a limitation that hinders single-emitter systems such as green fluorescent protein (GFP) (*21*) and QDs (*22*). Importantly, C dots have found use in a broad range of biological imaging applications and are non-cytotoxic at biologically relevant concentrations (*17, 23*). Given the vast diversity of organic dye molecules and the exquisite chemical and photophysical tunability of different encapsulation matrices, this approach should enable the development of nanoparticles with a broad range of precisely controlled fluorescence characteristics.

Here, we present a generic method to rapidly and reversibly label proteins on the surface of living cells with highly fluorescent silica nanoparticles. This was accomplished by exploiting short 12-mer peptide sequences, which we term GEPS (genetically engineered peptides for silica), as recognition elements for site-selective labeling of cell surface proteins with 30 nm C dots. Due to the ability of these peptides to bind biogenic silica (*24*), we hypothesized that they could be used to create a noncovalent linkage between the organosilicate exterior matrix of C dots and proteins of interest. Indeed, we demonstrate that these tags can be genetically encoded into regions of a target protein sequence, such as at the termini or in loops, where they do not disturb the protein's structure and function but are accessible to exogenously added C dots.

EXPERIMENTAL PROCEDURES

Synthesis of C Dots. To achieve the core−shell architecture used for the genetically encoded fluorescent silica nanoparticles, a modified Stöber sol−gel process was used as described

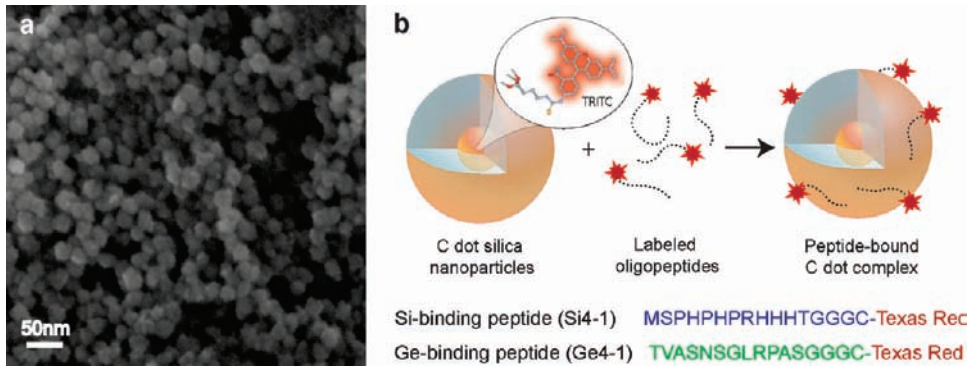

Figure 1. (a) Scanning electron micrograph of 30-nm-diameter TRITC C dots. This size particle was used for all live cell labeling studies. (b) Schematic of binding between C dot and different peptide sequences. Short, purified peptides were used for proof-of-concept binding experiments using orthogonal C dot−peptide pairs. For these experiments, Texas Red conjugated oligopeptides (either silica-binding (Si4−1) or germania-binding (Ge4−1) peptides) were incubated with 60 nm core−shell fluorescent silica nanoparticle C dots that incorporated tetramethylrhodamine isothiocyanate dye (TRITC) as shown.

previously (*17*). Briefly, alkoxysilanes were hydrolyzed and condensed in an aqueous alcohol solution with ammonia acting as catalyst, in the presence of the organic dye TRITC, covalently encapsulating of a silane derivative of the fluorescent dye molecules into the silica matrix (*17, 25, 26*). This dye-rich core formation reaction was followed by a second reaction with further pure silica precursor to form the particle shell. Varying the reaction chemistry allows specific tailoring of the desired nanoparticle size as described (*17*).

Peptide Labeling of C Dots. Proof-of-concept experiments with purified peptides, were performed by incubation of 60 nm C dots with 12-mer oligopeptides (Sigma-Genosys; Ge4−1 - TVASNSGLRPAS and Si4−1 - MSPHPHPRHHHT) conjugated to Texas Red C_2 maleimide (Invitrogen, Inc.) followed by repeated wash steps using water to remove unbound peptide. Following each wash, microcentrifugation was used to pellet the 60 nm particles, and pelleted particles were resuspended in water prior to fluorometric analysis.

Bacterial Strains and Plasmids. *Escherichia coli* strain DH5α (F$^-$ *ϕ80dlacZΔM15 Δ(lacZYA-argF)U169 deoR nupG recA1 endA1 hsdR17*(r_k^-, m_k^+) *phoA glnV44 thi-1 gyrA96 relA1 λ-*) was used for cloning and labeling experiments. *E. coli* strains AB2847 (F$^-$ *aroB thi tsx malT*) and MB97 (as AB2847, but Δ*fhuA*) were used for the albomycin resistance experiments (*27*). All plasmids generated in this study were derivatives of pHIE11 (*28*) or pBAD24. All FhuA constructs were created by inserting DNA encoding the silica- or germania-binding sequences into the *Fse*I-*Not*I multicloning site of plasmid pHIE11 (*28*). This resulted in the placement of each GEPS sequence in extracellular loop 5 of FhuA, just after the proline at position 405. For the OmpX constructs, the *E. coli ompX* gene was PCR-amplified using genomic DNA as template and appended with a C-terminal 6X-histidine tag. The resulting PCR product was cloned in between the *Nco*I and *Sph*I sites of plasmid pBAD24 (*29*) resulting in plasmid pBAD24-OmpX-his. To use extracellular loop 2 in OmpX for the insertion of silica-binding peptides, *Kpn*I and *Spe*I sites were inserted between the serine residues at positions 53 and 54 of OmpX by overlap extension PCR. The resulting PCR product was digested with *Nco*I and *Sph*I and ligated into pBAD24, resulting in pBAD24-OmpX*-his. DNA encoding each of the 12-mer GEPS sequences was cloned in between *Kpn*I and *Spe*I of pBAD24-OmpX*-his. Plasmids pHIE11 and pBAD24-OmpX*-his were modified to include each of the following GEPS primary sequences: Ge4−1 - TVASNSGLRPAS; Si3−3 - APPGHHHWHIHH; Si3−8 - KPSHHHHHTGAN; Si4−8 - APHHHHPHHLSR; and Si4−1 - MSPHPHPRHHHT. All GEPS sequences were codon optimized for expression in *E. coli.* All plasmids were confirmed by sequencing.

Labeling of Living Cells with C Dots. Cells containing FhuA or OmpX plasmids were grown overnight at 37 °C in Luria−Bertani (LB) medium containing appropriate antibiotics (50 μg/mL kanamycin for all FhuA constructs and 100 μg/mL ampicillin for all OmpX constructs). The following day, overnight cells were diluted 10-fold in LB containing antibiotics and allowed to grow for 90 min at 37 °C (OD_{600} ∼0.5). Subcultured cells were induced with 1 mM IPTG for 90 min at 37 °C, at which time the cultures were pelleted via centrifugation for 15 min at 4 °C and 13,200 rpm. Pelleted cells were resuspended in 1 mL of phosphate buffered saline (PBS) and normalized to an OD_{600} of 1.0. Normalized samples were incubated in the dark for 1 h at 4 °C with 30 nm TRITC C dots at a concentration of 8.1×10^8 particles/μL, unless otherwise noted, followed by an additional three washes in PBS.

Fluorescence Microscopy. C dot-labeled cells were imaged using a Carl Zeiss Axioskop 40 optical microscope with a Zeiss 100×/1.30 Oil Plan-NEOFLUAR lens, an EXFO X-Cite Series 120 lamp (Mississauga, Ontario), a TRITC emission filter, and a SPOT FLEX digital camera from Diagnostic Instruments, Inc. (Sterling Heights, MI). A total of 5 μL of live bacterial cells was placed onto a microscope slide and a coverslip placed on top. A drop of oil was added and images were taken using an oil-immersion technique at a magnification of 1000×.

Fluorescence Microplate and Flow Cytometric Analysis. C dot-labeled cells were aliquoted into a 96-well microtiter plate (Corning COSTAR) in triplicate and fluorescence was quantified using a fluorescence microplate reader (Bio-Tek Synergy HT). Cells were excited at a wavelength of 530 nm, and total cell fluorescence was measured at an emission wavelength of 590 nm, parameters that were near-optimal for TRITC (ex, 557 nm; em, 576 nm). Data were reported as an average of three measurements with an error determined as the standard deviation of the mean. For flow cytometric analysis, 5 μL of C dot-labeled cells were diluted into 1 mL of PBS and single-cell fluorescence distributions were measured using a Becton Dickinson FACS-Calibur flow cytometer as described elsewhere (*30*). The excitation/emission filters for this system were configured at 488 and 585 nm, respectively. For TRITC C-dots, a 488 nm excitation wavelength only excites at about 1/6 of the peak absorption and collects at about 80% of the peak emission.

Protein Analysis. To analyze protein expression, soluble fractions were prepared from 10 mL cultures of *E. coli* cells expressing the different FhuA and OmpX constructs as follows. First, cells were pelleted by centrifugation for 15 min at 4 °C and 3500 rpm and then resuspended in 1 mL PBS solution followed by sonication (Branson Sonifier). Then, the sonicant was spun for 15 min at 4 °C and 13,200 rpm, and the resulting supernatant was collected as the soluble fraction. Proteins in

the soluble fractions were separated by SDS-PAGE using 12% Tris−HCl gels (BioRad) and Western blotted as described (*31*). For all pFhuA constructs, anti-FhuA (kindly provided by Dr. Andreas Meinke, InterCell Biomedizinische Forschungs und Entwicklungs AG) was used as the primary antibody at a dilution of 1:100 000 in conjunction with a horseradish peroxidase-conjugated antirabbit secondary antibody (Sigma) diluted 1:5000. For all pOmpX constructs, horseradish peroxidase-conjugated antipolyhistidine antibody (Abcam) was used at a dilution of 1:3000.

Albomycin Resistance Assay. Growth inhibition by albomycin was assayed using a protocol similar to that described by Braun and co-workers (*32*). Briefly, strain MB97 was transformed with plasmids pFhuA, pFhuA-Ge4−1, or pFhuA-Si4−1. Liquid cultures were grown overnight until stationary phase at 37 °C in TY media (1.0% tryptone, 0.5% yeast extract, and 0.5% NaCl). 100 μL of each overnight culture was centrifuged and resuspended in fresh TY media to eliminate any cellular waste and debris. These cells were serial diluted (down to a dilution of 10^6) and spotted on TY/agar plates containing no antibiotics or 25 μg/mL albomycin. Plated cells were grown overnight at 37 °C and subsequently imaged.

RESULTS

Identification of Orthogonal Peptide−Nanoparticle Pairs Using Purified Peptides. The most common approach for targeting QDs and C dots to a protein of interest is to conjugate the nanoparticles with a high-affinity binding protein, such as an immunoglobulin or streptavidin, which mediates binding of the nanoparticle to a specific antigen or biotinylated protein, respectively (*9, 17*). However, the large size of this complex can interfere with membrane protein trafficking and can reduce accessibility of the nanoparticles. Therefore, our goal was to develop a generic method for direct labeling of cell surface proteins with C dots that eliminated the need for bulky binding proteins and provided a genetically encodable linkage between the protein of interest and the C dot. This was accomplished using genetically engineered peptides for silica (GEPS), which are short amino acid sequences that specifically and selectively bind silica. Previous studies using filamentous phage display have isolated genetically engineered peptides that bind to, for example, silica (*24*) and titania (*33*). In the present study, we hypothesized that the silica-binding peptides would electrostatically bind to the surface of C dots. The rationale for this was based on the notion that GEPS selected for strong binding to a specific silica surface of given size and morphology can often bind to another surface of the same material or to a different material but having similar structure or physiochemical properties (*34*).

We first sought to determine whether GEPS sequences that were previously isolated for their ability to bind and precipitate biogenic amorphous silica (*24*) could similarly bind C dots. Proof-of-concept binding experiments were performed to evaluate binding between C dots and different fluorescently labeled peptides (Figure 1b). Specifically, we used two synthetic 12-mer peptides: one with high affinity for silica (Si4−1, MSPHPHPRHHHT) and a second, nonspecific control peptide with affinity for germania (Ge4−1, TVASNSGLRPAS). A GGGC motif was incorporated at the C-terminus of each peptide in order to react the thiol of the C-terminal cysteine with Texas Red C_2 maleimide. Dye-labeled silica- and germania-binding oligopeptides were incubated at various concentrations with 60-nm-diameter TRITC core−shell C dots. Fluorescence spectra and binding curves revealed enhanced binding specificity for the Si4−1 peptides with the silica nanoparticle surface relative to that of the Ge4−1 peptides or to the free dye controls (Figure 2a,b). It should be noted that since silica has its isoelectric point around pH 2−3, at neutral pH the particles are stabilized by eletrostatic repulsive interactions (*19, 20*). At very high salt concentrations (e.g., around 0.1 M aqueous NaCl), these electrostatic repulsions are screened and steric repulsive interactions must be used to stabilize the particles. Hence, the peptide and cell labeling conditions (i.e., PBS at neutral pH) used here are expected to disfavor particle aggregation. It should also be noted that we chose 60 nm C dots for the peptide labeling experiments because of difficulties associated with microcentrifugation of smaller C dots (e.g., 30 nm). In later experiments described below, 30 nm C dots were used because their smaller size was desirable for cell labeling purposes, and due to their specific capture by cells, microcentrifugation was no longer an issue.

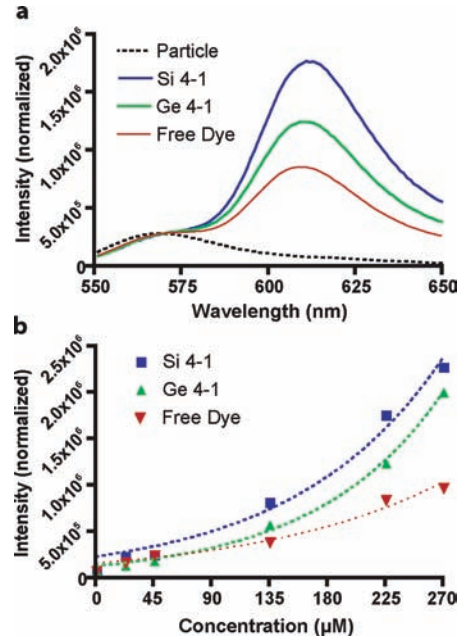

Figure 2. Proof-of-concept binding experiments using C dots and short, fluorescently labeled oligopeptides. (a) Fluorescence spectra and (b) binding curves for the orthogonal C dot−peptide pairs shown in Figure 1b. Texas Red-labeled silica- and germania-binding 12-mer peptides (Si4−1 and Ge4−1, respectively) were incubated with 60 nm TRITC C dot particles and analyzed via a fluorescence spectrometer. Free TRITC dye was used as a control. Data represent the average of three replicate experiments. The standard error in each case was less than 5%.

Rapid, Highly Specific Protein Labeling in Living Cells. We next tested whether the orthogonal C dot−peptide pairs could be used to label cellular proteins. This was achieved by engineering the high- (Si4−1) and low- (Ge4−1) affinity GEPS into a highly exposed extracellular loop of the *E. coli* outer membrane protein, FhuA. FhuA is a ferrichrome and phage T5 receptor that exposes 11 loops to the extracellular milieu and 10 turn regions to the periplasm (*35, 36*). Previous studies demonstrated that extracellular loops 4 and 5 of FhuA are able to tolerate insertions of up to 250 and 166 amino acids, respectively, while still maintaining functionality (*28*). Accordingly, we introduced the Si4−1 and Ge4−1 sequences just after the proline residue at position 405 in the fifth extracellular loop of FhuA (Figure 3a), a site displaying the largest surface area to the extracellular milieu.

To determine the efficacy of this labeling strategy using live cells, the various FhuA constructs were expressed in *E. coli* and analyzed via fluorescence microscopy. Following labeling with 30 nm C dots at a final concentration of 8.1×10^8 particles/μL, cells expressing the FhuA-Si4−1 construct showed a highly fluorescent phenotype, whereas cells expressing FhuA-Ge4−1 or wild-type FhuA with no peptide insert exhibited only minor,

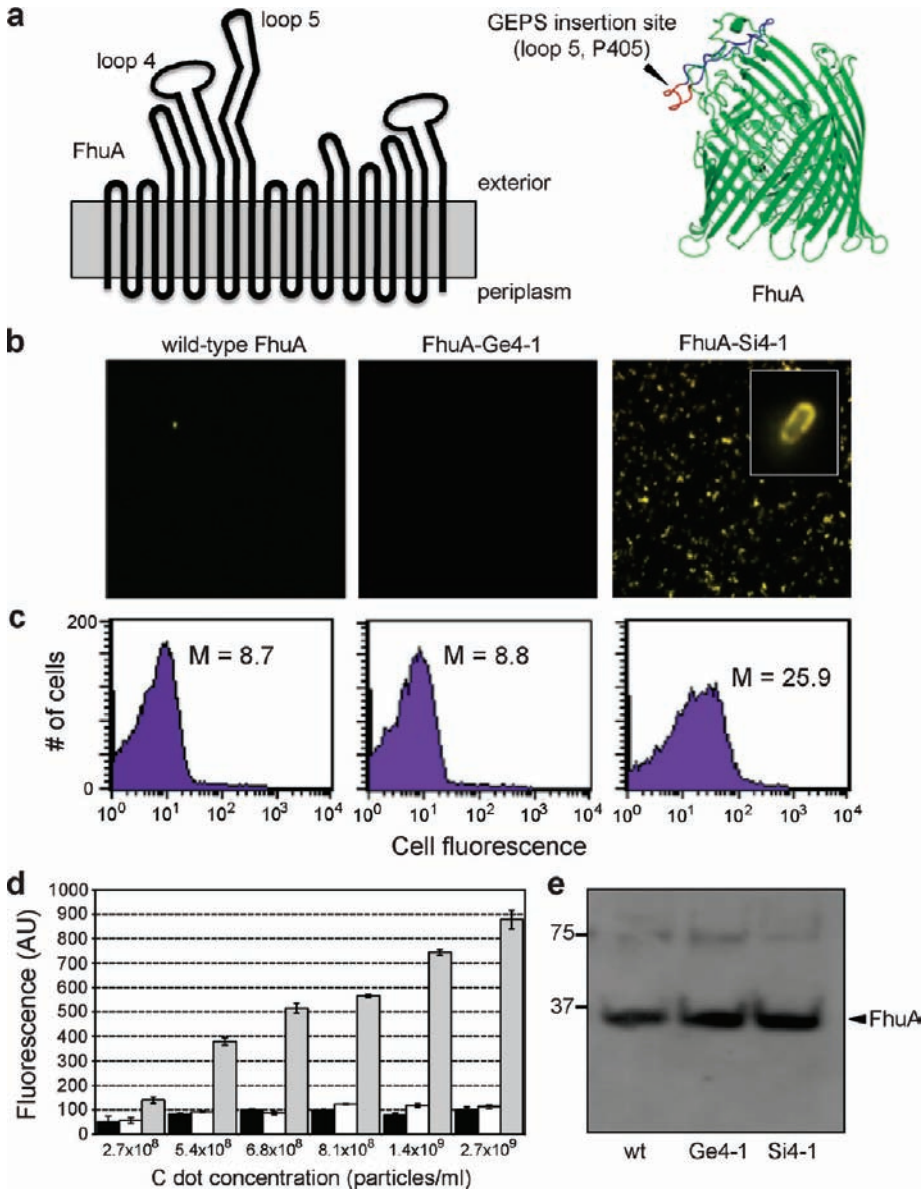

Figure 3. (a) Schematic and three-dimensional structural representations of FhuA depicting the GEPS insertion site in extracellular loop 5, immediately following a proline residue at position 405 (P405). In the FhuA crystal structure (right), loop 5 is highlighted in blue and the GEPS sequence is highlighted in red. (b) Fluorescence microscopy of cells expressing FhuA-Si4−1, FhuA-Ge4−1, or wild-type FhuA with no peptide insert. Following labeling with 30 nm TRITC C dots at a concentration of 8.1×10^8 particles/μL, 5 μL of live bacterial cells were placed onto a microscope slide and a coverslip placed on top. A drop of oil was added and images were taken using an oil immersion technique at a magnification of 1000×. Inset is an enlarged image of a single cell. (c) FACS analysis of the same constructs described in (b). Shown are representative FACS histograms. Mean fluorescence (M) values are the average of three replicate experiments. The error in each case was less than 5%. (d) Quantification of cell fluorescence after C dot labeling. Cells were induced to express FhuA-Si4−1 (gray bars), FhuA-Ge4−1 (white bars), and wild-type FhuA (black bars) and then labeled with a range of C dot concentrations as indicated. Data are the average of three replicate experiments, and error bars represent the standard deviation of the mean. (e) Western blot analysis of soluble fractions generated from cells expressing FhuA-Si4−1, FhuA-Ge4−1, and wild-type FhuA. Soluble proteins from an equivalent number of cells were loaded in each lane and detection was with FhuA antiserum.

static background fluorescence (Figure 3b). Background fluorescence was readily distinguishable from target fluorescence due to both the brightness and localization of the C dots. Characteristic nonspecific background fluorescence appeared as very bright C dot clusters that were not colocalized with *E. coli* cells. In contrast, positive target fluorescence corresponded to a halo-like fluorescent ring that colocalized with the *E. coli* cell body (Figure 3b) and was similar to the fluorescence pattern seen for other cell surface or periplasmic labeling strategies (*37*). The same C dot-treated cells were subjected to fluorescence-activated cell sorting (FACS) analysis. Consistent with the microscopy results, cells expressing FhuA-Si4−1 showed a 3-fold increase in mean cell fluorescence (MF) compared to cells expressing FhuA-Ge4−1 or wild-type FhuA (Figure 3c). When these same cells were analyzed using a fluorescence microplate reader, we observed a 5-fold difference in fluorescence between cells expressing FhuA-Si4−1 and cells expressing FhuA-Ge4−1 or wild-type FhuA (Figure 3d). We attribute the improved signal-to-noise obtained using the microplate reader to the excitation/emission filters (ex, 530; em, 590 nm) of this device, which match the excitation/emission wavelengths of TRITC (ex, 557 nm; em, 576 nm) more closely than our current flow cytometry setup. Moreover, cells expressing FhuA-Si4−1 exhibited a C dot concentration-dependent fluorescence response following labeling with 2.7×10^8 to 2.7×10^9 particles/μL. This was not the case for cells expressing FhuA-Ge4−1 or wild-type FhuA; each of these resulted in only background fluorescence following labeling over the same C dot concentration range (Figure 3d). At the highest concentration of C dots tested (2.7×10^9 particles/μL), the fluorescence signal for FhuA-Si4−1

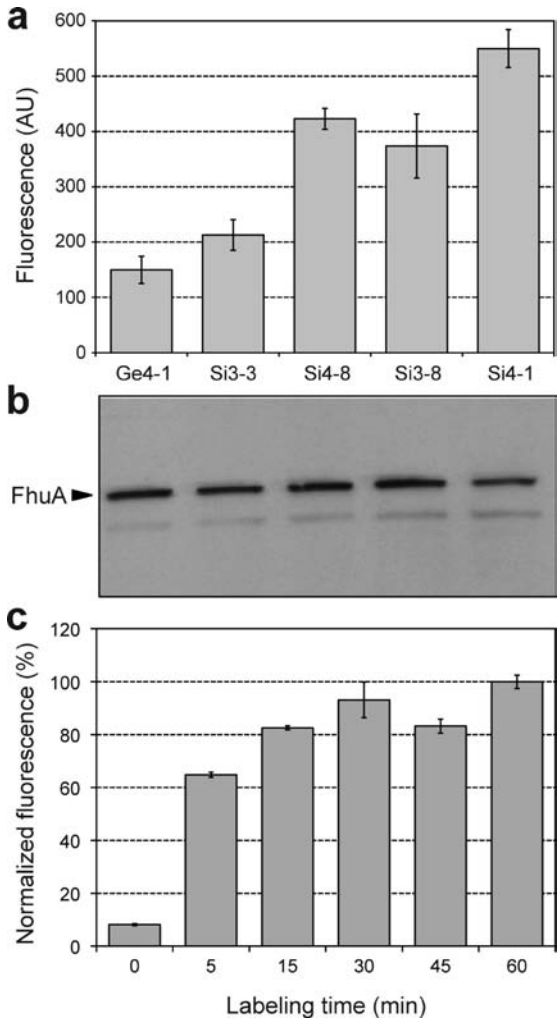

Figure 4. (a) Quantification of cell fluorescence following expression of FhuA constructs modified with different GEPS sequences. All labeling was accomplished with 30 nm particles at a final concentration of 8.1×10^8 particles/mL. Data are the average of three replicate experiments. (b) Western blot analysis of soluble fractions generated from cells expressing the different FhuA constructs as indicated. Soluble proteins from an equivalent number of cells were loaded in each lane and detection was with FhuA antiserum. (c) Effect of C dot incubation time on labeling efficiency. Cells expressing FhuA-Si4−1 were incubated with 30 nm particles at a final concentration of 8.1×10^8 particles/mL for the indicated labeling times. Data are the average of three replicate experiments and are normalized to the florescence signal obtained for FhuA-Si4−1 at 60 min, which was set at 100%. All error bars represent the standard deviation of the mean.

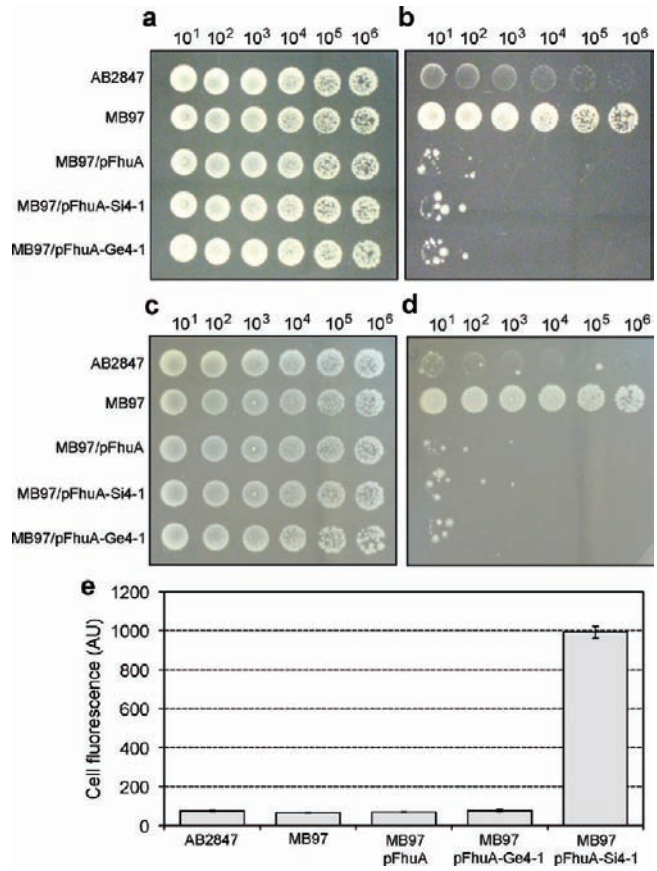

Figure 5. Albomycin resistance phenotype of FhuA-expressing cells. Spot plating of wt AB2847 and isogenic MB97 (Δ*fhuA*) cells on TY/agar plates with (a) no antibiotic or (b) 25 μg/mL albomycin. Plasmid-based complementation of *fhuA* in MB97 cells was from pFhuA, pFhuA-Si4−1, or pFhuA- Ge4−1, as indicated. Spot plating of the same cells in (a,b) following labeling with 30 nm TRITC C dots for 1 h prior to plating on (c) no antibiotic or (d) 25 μg/mL albomycin. Cells were serially diluted as indicated above each panel. (e) Quantification of cell fluorescence after C dot labeling of AB2847 or MB97 cells carrying no plasmids or expressing wild-type FhuA, FhuA-Ge4−1, and FhuA-Si4−1 as indicated. Cells were incubated with 8.1×10^8 C dots/μL for 1 h. Data are the average of three replicate experiments and error bars represent the standard deviation of the mean.

was ∼9× greater than the FhuA-Ge4−1 control, verifying the specificity of the GEPS insert. Finally, it is noteworthy that, even at the highest C dot concentration, there was no measurable growth inhibition for any of the cells tested (data not shown), confirming the biocompatibility of the silica nanoparticles.

We next determined whether the enhanced cellular fluorescence seen for FhuA-Si4−1 versus FhuA-Ge4−1 was due to specificity/affinity of the peptide sequences for the C dots or, instead, differential protein expression. To exclude variations in protein expression, Western blot analysis was performed on samples prepared from cells expressing each of the FhuA constructs. As expected, there was virtually no difference in soluble expression of FhuA-Si4−1 and FhuA-Ge4−1 (Figure 3e), suggesting that the differential fluorescence observed above was attributable to varying degrees of affinity conferred by the peptide inserts. To investigate this in more detail, we constructed several additional FhuA constructs by inserting other silica-specific peptides of varying affinities into extracellular loop 5 of FhuA. These peptides exhibited intermediate binding of silica that was less than the high-affinity Si4−1 clone but greater than the nonspecific Ge4−1 clone, with the relative binding affinity as follows (in order from highest to lowest): Si4−1 ≫ Si3−3 ≈ Si3−8 ≈ Si4−8 ≫ Ge4−1 (*24*). Following C dot labeling of cells, we observed intermediate fluorescence for each of these FhuA constructs that was reproducibly lower than that for FhuA-Si4−1 but significantly higher than that for the FhuA-Ge4−1 construct (Figure 4a). As seen above, similar expression levels were observed for each of these FhuA variants (Figure 4b) indicating that differences in fluorescence were linked to affinity of the displayed peptides for the C dots. A major advantage of this strategy is that high levels of labeling (>80% of the maximum signal) could be achieved in as little as 15 min (Figure 4c).

To determine whether labeling was disruptive to protein function, we next evaluated whether the GEPS-modified FhuA variants retained wild-type activity following labeling with C dots. Native FhuA in the outer membrane of *E. coli* actively transports ferrichrome and the antibiotics albomycin and rifamycin CGP 4832. In the case of albomycin, the antibiotic is internalized through FhuA after which it is cleaved and the antibiotically active moiety is released into the cytoplasm (*27,32*). Cells expressing functional FhuA are sensitive to albomycin,

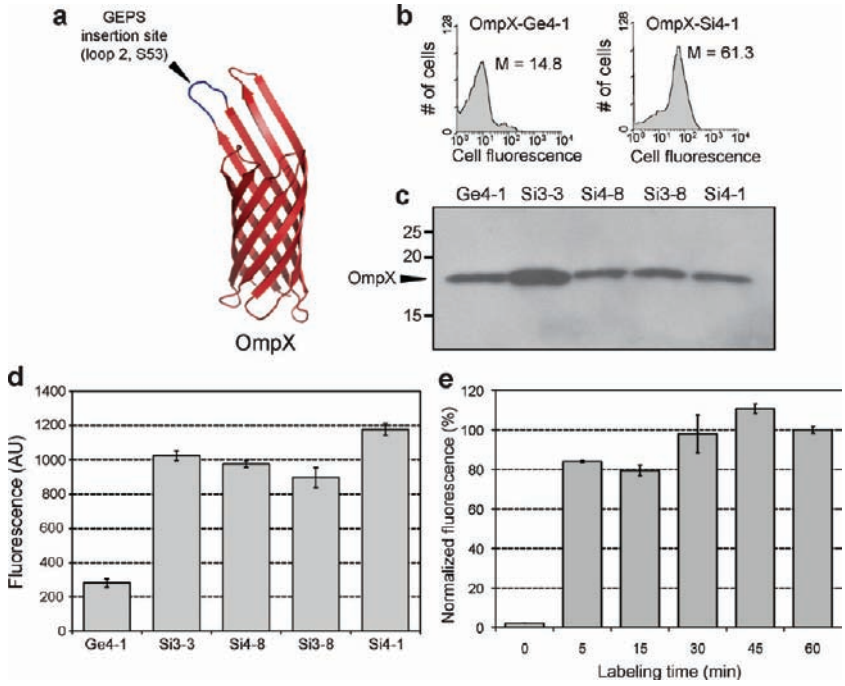

Figure 6. (a) Structural representation of OmpX depicting the GEPS insertion site in extracellular loop 2, immediately after a serine residue at position 53. Loop 2 is highlighted in blue and the GEPS insertion site is indicated by the arrow. (b) FACS analysis of cells induced to express OmpX-Ge4−1 (left) and OmpX-Si4−1 (right) following labeling with 30 nm particles at a final concentration of 8.1×10^8 particles/μL. Shown are representative FACS histograms. Mean fluorescence (*M*) values are the average of three replicate experiments. The error in each case was less than 5%. (c) Western blot analysis of soluble fractions generated from cells expressing different OmpX constructs as indicated. Soluble proteins from an equivalent number of cells were loaded in each lane and detection was with antipolyhistidine antibodies. (d) Quantification of cell fluorescence after C dot labeling of cells expressing OmpX constructs modified with different GEPS sequences. All labeling was accomplished with 30 nm particles at a final concentration of 8.1×10^8 particles/μL. Data are the average of three replicate experiments. (e) Effect of C dot incubation time on labeling efficiency. Cells expressing OmpX-Si4−1 were incubated with 30 nm particles at a final concentration of 8.1×10^8 particles/μL for the indicated labeling times. Data are the average of three replicate experiments and are normalized to the fluorescence signal obtained for FhuA-Si4−1 at 60 min, which was set at 100%. All error bars represent the standard deviation of the mean.

whereas those lacking a functional FhuA protein do not take up albomycin and are resistant to the antibiotic. To determine whether the 12-mer peptide insertions disrupted FhuA function, we evaluated the ability of each FhuA construct to internalize albomycin. As anticipated, AB2847 cells that express an intact copy of wild-type *fhuA* from their genome were highly sensitive to albomycin (Figure 5a,b). In contrast, *E. coli* strain MB97, which carries a complete deletion of the *fhuA* gene (*27*) and thus should not internalize albomycin, grew normally on agar plates supplemented with albomycin. However, when MB97 cells were provided with a plasmid-encoded copy of FhuA, FhuA-Si4−1, or FhuA-Ge4−1, they became highly sensitive to albomycin (Figure 5a,b). Thus, we conclude that the insertion of the peptides in FhuA did not disrupt function because each of the FhuA constructs was capable of internalizing albomycin. Next, to determine whether labeling of FhuA with C dots inhibited function, perhaps by cross-linking FhuA into inactive multimers, we performed a similar experiment as above except now the cells were labeled with C dots for 1 h prior to plating on albomycin. The albomycin resistance behavior of C dot labeled cells was identical to that observed for the same cells that had not been treated with C dots (compare Figure 5c,d with a,b), indicating that C dot labeled FhuA remained functional. It is noteworthy that the fluorescence signal for MB97 cells expressing the FhuA-Si4−1 was nearly 20-fold above the background signal from FhuA-Ge4−1 expressing cells (Figure 5e), which was an improvement over the signal-to-background ratio observed above using DH5α host cells.

Evidence for a Universal Targeting Strategy. To determine whether our C dot binding strategy was generic, we introduced the panel of different GEPS into the *E. coli* integral outer membrane protein OmpX. Like FhuA, OmpX is a β-barrel membrane protein. It contains eight transmembrane β-strands and exposes four extracellular loops (*38*). We introduced each of the different GEPS into extracellular loop 2, just after the serine residue in position 53 (Figure 6a). In agreement with the FhuA results, cells expressing OmpX-Si4−1 were nearly 5 times more fluorescent than their OmpX-Ge4−1-expressing counterparts, as revealed by both FACS and plate reader measurements (Figure 6b,d). Similarly, cells expressing the intermediate peptide sequences exhibited levels of fluorescence that were less than that seen for OmpX-Si4−1 but significantly greater than OmpX-Ge4−1. It is noteworthy that Si3−3 resulted in the lowest fluorescence of the three intermediate binders when inserted in FhuA but was the most fluorescent of the three when cloned in OmpX (Figure 6d). It appears, however, that this unexpectedly high fluorescence was due to a marked increase in OmpX-Si3−3 expression relative to all other OmpX constructs (Figure 6c). For the other two intermediate binders, the relative C dot binding affinity observed with OmpX was the same as FhuA, with Si4−8 showing greater affinity than Si3−8. For these constructs, as well as OmpX-Si4−1 and OmpX-Ge4−1, the soluble expression levels were virtually indistinguishable (Figure 6c), suggesting as above that fluorescence levels were indicative of specificity/affinity for C dots and not gross differences in protein expression levels. Finally, high levels of labeling (>80% of the maximum signal) were observed in as little as 5 min (Figure 6e).

DISCUSSION

In the present study, we report a highly specific, robust, and rapid new method for labeling cell surface proteins with fluorescent nanoparticles, i.e., core−shell silica nanoparticles

referred to as C dots. Our approach uses genetically engineered peptides with affinity for silica (GEPS) as C dot recognition elements that can be site-specifically introduced into cellular proteins. The silica-binding peptides used here were previously isolated for their ability to precipitate silica (*24*) and are enriched in histidine residues, whereas the control germania-binding peptide lacked histidine entirely. Along similar lines, several other groups have reported peptide sequences with affinity for silica and the majority of these appear to be rich in basic and hydroxyl amino acids (*24*, *39*−*41*) as well as proline residues (*40*, *42*). Hence, we believe that C dot binding is due to electrostatic interaction, however, whether other mechanisms are at play cannot be ruled out.

The advantage of GEPS is that they are relatively short peptide sequences that can be genetically encoded at the termini or in loops of proteins without disturbing the protein's structure, function, and subcellular localization. We show here that strategic positioning of GEPS into loops of outer membrane proteins allows for electrostatic capture of 30 nm fluorescent C dots with labeling times as short as 5 min. Because only background fluorescence was observed following C dot labeling of wild-type bacterial cells, we conclude that nonspecific silica-binding activity is largely absent from native cell surfaces. Hence, GEPS-tagged cell surface proteins can be efficiently labeled with fluorescent C dots with signal-to-background ratios of ∼5−20 depending on the target protein, label concentration, and host cell used. It should also be noted that labeling approaches that use peptides rather than proteins are less invasive but typically sacrifice specificity. However, the use of noninvasive silica-binding peptides comprising only 12 residues did not suffer from a lack of specificity as evidenced by the differential binding observed for the different GEPS clones. Since GEPS tags are genetically encodable, we anticipate that the labeling technology described here can be extended to numerous structurally diverse membrane proteins in prokaryotic and also perhaps in eukaryotic cells. Such flexibility should enable visualization of protein dynamics underlying numerous biological processes, especially considering that C dot labeling did not adversely affect protein function. However, a potential concern is that the relatively large 30 nm particles may bind to several genetically modified surface proteins simultaneously in a manner that reduces the mobility of the proteins in the membrane and interferes with dynamic analysis. Therefore, smaller C dot particles may be necessary for performing dynamic analysis. To date, the smallest, stable particles with narrow particle size distributions that we have achieved go down to about 3 nm (*19*).

Interestingly, these peptides not only promoted C dot binding, but different primary sequences resulted in differential binding efficiency. This implies that it may be possible to further optimize GEPS with *increased* affinity for C dots. For instance, cell surface displayed libraries of random Si4−1 variants could be labeled with C dots and screened using FACS to isolate highly fluorescent clones that represent ultrahigh affinity binders. A similar affinity maturation strategy was demonstrated recently by Rozinov and Nolan who used phage display to isolate higher-affinity peptides against small-molecule fluorophores such as Texas Red (*43*). Our studies here show that C dot labeled cells can be visualized with a flow cytometer indicating that FACS could be used to efficiently discriminate binders from nonbinders. Interestingly, while earlier studies reported comparable silica binding for each of these intermediate peptides, our studies show distinct binding differences for these peptides. We suspect that this discrepancy is due to differences in how the peptides were displayed during the binding assays. In the earlier work of Stone and co-workers (*24*), peptides were expressed as unconstrained fusions to the minor coat (pIII) protein of M13 phage, whereas in our studies, the peptides were constrained in the extracellular loops of an outer membrane protein.

A particularly attractive feature of this technology is that it makes possible for the first time a system for genetically tagging cellular proteins with epitopes specific for fluorescent silica nanoparticles. Importantly, the 30 nm diameter variety tested here have already been shown to be 20−30 times brighter on a per particle basis and nearly 20 times more stable than their constituent dyes (*17*, *25*, *44*), offering a robust new avenue for fluorescent labeling. Furthermore, because C dots are multifluorophore systems, at any given time there will still be a portion of the dyes emitting, conferring continuous fluorescence emission. From a practical standpoint, this minimizes the intermittent blinking under continuous excitation suffered by single-emitter systems (*25*). Since many different fluorophores (e.g., TRITC, Oregon Green 488, etc.) and even multiple fluorophores can be localized within a single silica nanoparticle (*25*, *44*), colors and spectral properties, such as peak wavelength and shape, can be chosen at will from a palette of dyes and efficiently coupled to cellular proteins.

In this study, we focused on the integral outer membrane proteins FhuA and OmpX of *E. coli*. These and other β-barrels found in the outer membranes of prokaryotic and eukaryotic organisms constitute an important functional class of proteins. Such proteins play important roles in bacterial pathogenesis, regulating molecular transport, and mitochondrial homeostasis (*45*), and therefore are high-priority targets for structural and functional characterization. For instance, *E. coli* OmpX and its homologues in the human pathogens *Yersinia*, *Enterobacter*, *Klebisiella*, and *Salmonella* promote adherence to and entry into host cells, a key step in the ability of these pathogens to neutralize the host defense system and interfere with the host immune system (*38*, *45*). Thus, we anticipate that site-specific C dot labeling of these membrane proteins in living cells will permit multidimensional time-lapse microscopy and single-molecule analysis of pathogen-host interactions.

ACKNOWLEDGMENT

We thank Dr. Andreas Meinke for plasmid pHIE11 as well as FhuA antiserum. Funding was provided by an NSF CAREER Award CBET-0449080 (to MPD) and a NYSTAR James D. Watson Award (to MPD). We would also like to thank the Cornell Nanobiotechnology Center, an STC Program of the NSF under Agreement No. ECS-9876771 for funding (to UW) and infrastructure.

Received January 15, 2009; Revised Manuscript Received May 18, 2009

In the present work, the possibility to obtain PEGylated nanoparticles from two PBLG derivatives, PEG-*b*-poly(γ-benzyl L-glutamate), PBLG-PEG-60, and poly(γ-benzyl L-glutamate), PBLG-Bnz-50, by nanoprecipitation has been investigated. Particles were prepared not only from one polymer (PBLG-PEG-60 or PBLG-Bnz-50), but also from mixtures of two PBLG derivatives, PBLG-PEG-60 and PBLG-Bnz-50, in different ratios (90/10, 77/23, and 40/60 wt %). Because of the presence of PEG chains, hydrophilic particles were obtained, which was confirmed by ζ potential measurements (ζ from −13 mV and −21 mV) and by isothermal titration microcalorimetry (ITC). This last technique has shown no heat exchange when BSA was added to PEGylated nanoparticles. Further, complement activation has been evaluated by crossed immuno-electrophoresis demonstrating that the introduction of 77 wt % of PEGylated PBLG chains in the particles was enough to ensure a low complement activation activity. This effect was strongly correlated to the ζ potential of the particles, which decreased with an increase of PEG chains content. Interestingly, such properties are of interest for the preparation of degradable stealth nanocarriers. Moreover, it is suggested that the introduction of a reasonable amount (up to 20 wt %) of a second copolymer in the particle composition can be possible without modifying their stealth character. Moreover, the presence of this second copolymer would help to introduce a second functionality to the particles.

INTRODUCTION

Over the past years, nanoparticulate carriers have been developed in order to improve efficiency and site-specificity of drug delivery (*1, 2*). As a result of their small size, this first generation of nanocarriers can be administrated intravenously. However, such small hydrophobic particles are rapidly (half-time of clearance about 1 min) and efficiently (about 90% uptake) cleared from the circulation due to their recognition by opsonins (*3*−*5*). Therefore, to address these limitations, a second generation of nanocarriers is under development taking into account the various parameters which influence carrier recognition by reticuloendothelial system (*3*−*5*). It has been shown that the coating of hydrophobic nanocarrier surfaces by hydrophilic polymers, such as poly(ethylene glycol) (PEG), induces a significant decrease of the opsonisation process (*6*). The coating has to be dense and flexible in order to reduce all types of interactions with hydrophobic nanocarrier surfaces. Moreover, hydrophilic polymer chains, such as PEG, have to be well anchored on nanoparticles to avoid desorption of chains (*4*). Surface modification on hydrophobic nanoparticulate systems has been carried out. Coating or covalent coupling methods (*7, 8*) have been proposed to introduce hydrophilic chains on nanoparticle surface. Hydrophilic polymers such as poly(ethylene glycol), poly(vinyl alcohol), poloxamers, or dextran have been shown to decrease significantly protein adsorption (*4*). In order to obtain a high density of hydrophilic chains on the surface and an efficient anchoring of these chains in the carrier, core−shell type nanoparticles and macromolecular micelles formed in aqueous media by self-assembly of amphiphilic block copolymers have attracted considerable attention for application as drug delivery systems (*9*−*14*). Besides overcoming the rapid recognition of nanoparticles by the reticuloendothelial system, research has been also focused on overcoming the many-faceted problem of biocompatibility. In this context, efforts have been directed toward the use of natural-like materials such as poly(α-amino acids) (*15*). Poly(γ-benzyl L-glutamate), PBLG, a synthetic polypeptide, has attracted attention for biomedical applications (*15*−*21*) because of the presence of a degradable amide bound in the polymer backbone (*21*) and a carboxylic acid function in the side chain, available after hydrolysis of the lateral benzyl ester. Poly(ethylene oxide)-*block*-poly(γ-benzyl L-glutamate) (*22, 23*) allowed macromolecular micelle formation as a result of their amphiphilic nature (*24, 25*). Recently, in response to the need for targeting systems, poly(γ-benzyl L-glutamate) and poly(ethylene glycol) diblock copolymers end-capped with a galactose moiety have been proposed for site-specific drug delivery (*26*). In this context, we focused our interest on the synthesis of PBLG derivatives using initiators allowing the preparation of biocompatible nanoparticulate systems possessing different specific functionalities. For that, PBLG derivatives were synthesized by ring-opening polymerization (ROP) of γ-benzyl L-glutamate *N*-carboxyanhydride (BLG-NCA) using selected amine-terminated initiators (*27*).

In the present work, we report the possibility to obtain PEGylated nanoparticles from two PBLG derivatives, PBLG-PEG-60 and PBLG-Bnz-50, by nanoprecipitation. Composite nanoparticles with different PBLG-PEG-60/PBLG-Bnz-50 ratio

have been prepared and characterized. Interactions of the different nanoparticles with bovine serum albumin (BSA) have been measured by ITC. Moreover, complement activation has been evaluated by crossed immuno-electrophoresis.

MATERIALS AND METHODS

Materials. *N*,*N*-Dimethylformamide (DMF, Acros, 99%) and benzylamine (Janssen Chimica) were distilled under reduced pressure over BaO and KOH, respectively, and stored under argon atmosphere. γ-Benzyl-L-glutamate *N*-carboxyanhydride (γ-BLG-NCA), from ISOCHEM-SNPE, was used as received. Methoxy poly(ethylene glycol) amine (mPEG-NH_2), $\bar{M}w = 5000$ Da from Shearwater Corporation was dried under vacuum over P_2O_5 at 30 °C for 24 h. Bovine serum albumin (BSA) was purchased from Sigma. Water was purified by reverse osmosis (Milli-Q, Millipore). Poloxamer 188 (Lutrol F68), diethyl ether, and other solvents used were analytical grade, and all other chemicals were commercially available reagent grade.

Synthesis and Characterization of PBLG-Derivatives. PBLG-derivatives, PBLG-Bnz-50, and PBLG-PEG-60 were prepared by anionic ring-opening polymerization as described previously (*27*). Briefly, PBLG-Bnz-50 was obtained by anionic ring-opening polymerization of γ-benzyl-L-glutamate *N*-carboxyanhydride initiated by benzylamine in DMF at 30 °C. The reaction mixture was stirred at 30 °C until the characteristic NCA bands disappeared from FT-IR spectrum and then poured into a large volume of cold diethyl ether. The precipitate was dried under vacuum at 35 °C for at least 12 h. This precipitation, purification, and drying procedure was performed twice. The molecular weight of PBLG-Bnz-50 was estimated from intrinsic viscosity measured in DMF at 25 °C using the Mark−Houwink equation for PBLG in DMF at 25 °C (*28*).The molecular weight estimated for the PBLG-Bnz-50 was $\bar{M}w = 45\,000$ g·mol^{-1}. Similarly, PBLG-PEG-60 was obtained by anionic ring-opening polymerization of γ-benzyl-L-glutamate *N*-carboxyanhydride initiated by methoxy poly(ethylene glycol) amine (mPEG-NH_2), average $\bar{M}w = 5000$ g·mol^{-1}, in DMF at 30 °C. The reaction mixture was stirred at 30 °C until the characteristic NCA bands disappeared from FT-IR spectrum and poured into a large volume of cold diethyl ether. The precipitate was filtered, washed with water and diethyl ether, and then dried under vacuum at 35 °C for at least 12 h. A second purification procedure was performed. $\bar{D}Pn$ of the PBLG segment in PBLG-PEG-60 was determined from ^{1}H NMR spectra by the ratio between the peak intensities of methylene protons of the PEG chain, OCH_2CH_2, and the benzyl protons of PBLG chain, $COOCH_2C_6H_5$. A $\bar{D}Pn$ of 231 was found.

Nanoparticles Preparation. Nanoparticles were prepared using a slightly modified nanoprecipitation technique described elsewhere (*29*), in the absence of any surfactant agent, either from one polymer (PBLG-PEG-60 or PBLG-Bnz-50) or from mixtures of these two polymers in different ratios (PBLG-PEG-60/PBLG-Bnz-50 at 90/10, 77/23, and 40/60 wt % ratio and named composite nanoparticles). Briefly, 15 mg of one polymer or a mixture of polymers were dissolved in 5 mL of THF at 30 °C during 18 h, without stirring. The solution was then homogenized under gentle agitation for a few seconds and added, by dripping to 10 mL of Milli-Q water, under magnetic stirring. The mixture was left under magnetic stirring for 15 min and then transferred in a Teflon-coated recipient. The solvent was evaporated, at 30 °C, under a light air flux. In order to eliminate residual solvent, nanoparticles were further diluted with 5 mL of Milli-Q water, and evaporation was carried out to adjust the volume of the nanoparticle suspension to 10 mL. Preparations were kept at 4 °C until characterization.

Nanoparticles Characterization. *Size Distribution.* Mean diameter ($n = 3$) was determined, after suitable dilution of bulk suspensions in Milli-Q water, by dynamic laser light scattering (Nanosizer Coulter N4 Plus, Margency, France).

ζ Potential. ζ potential measurements ($n = 5$) were carried out using a Zetasizer 4, Malvern Instrument after adequate dilution of 200 μL of nanoparticles suspensions into 10 mL of 1 mM KCl filtered through a 0.22 μm filter.

Transmission Electron Microscopy. Nanoparticles were observed by TEM (transmission electron microscope, Philips EM 208). 7 μL of nanoparticles suspension were half-diluted in a 0.125% (w/v) poloxamer solution and placed on a Formvar-carbon film previously coated on a copper grid (400 mesh). After 6 min of deposition at room temperature, nonadherent nanoparticles were eliminated and the sample was stained by phosphotungstic acid (1%) during 30 s. TEM bright field imaging was performed under a 80 kV accelerating voltage.

Isothermal Titration Microcalorimetry (ITC) Studies. ITC experiments were carried out with an VP-ITC, MicrolCal. Interactions between bovine serum albumin (BSA), a model globular protein, and nanoparticles constituted by PBLG-Bnz-50 or PBLG-PEG-60 were evaluated. Solution of BSA at 5.4×10^{-2} mM was placed in a 295 μL continuously rotating (270 rpm) syringe. Nanoparticle suspension at 2.7×10^{-2} mM of polymer was placed in the sample cell of 1.43 mL. A first 2 μL aliquot was injected, without taking into account the observed heat, to remove the effect of solute diffusion across the syringe tip during the equilibration period. Then, injections of 10 μL of the BSA solution were made at intervals of 10 min. Experiments were carried out at 25 °C.

Evaluation of Complement Activation by Crossed Immuno-Electrophoresis. The specific activation of the C3 component of the complement from human serum and induced by the nanoparticle surface was evaluated by comparative measurements of C3 cleavage into C3b. Nanoparticle suspensions (1.5 mg mL^{-1}) were first concentrated by evaporation of part of the water to reach a nanoparticle concentration of 9 mg mL^{-1} or 6 mg mL^{-1} in order to obtain a surface area of 500 cm^2 in a volume $V \leq 100$ μL. The amount of C3 and C3b was measured by crossed immunoelectrophoresis by an adaptation of the method described elsewhere (*7, 30*) after incubation of the nanoparticles with serum. Briefly, human serum obtained from healthy donors was stored at −80 °C until use. Equivalent volumes of nanoparticle suspensions, corresponding to a surface area of 500 cm^2 in 100 μL, were incubated with 50 μL of human serum and 50 μL of veronal-buffered saline containing 0.15 mM Ca^{2+} and 0.5 mM Mg^{2+} in ions (VBS^{2+}), under gentle agitation, for 1 h at 37 °C. Nanoparticle surface area was calculated, assuming that particles were spherical and using the following equations:

$$S = n4\pi r^2 \quad (1)$$

$$V = n4/3\pi r^3 \quad (2)$$

$$\text{leading to} \quad S_{(sp)} = S/V = 6/d\rho \quad (3)$$

where S and V are the surface area and volume, respectively, of n spherical nanoparticles of average radius r. $S_{(sp)}$ is the specific surface area of 1 g of spherical nanoparticles of average diameter d and density ρ (taken as $\rho = 1.2$ g/cm^3 relative to ρ for PBLG).

After incubation with human serum, samples (7 μL) were subjected to a first electrophoresis in 1% agarose gel for about 45 min. The second-dimension electrophoresis was carried out during 18 h with 1% agarose gel on Gelbond films in the presence of a polyclonal antibody to human C3, recognizing both C3 and C3b (complement C3 antiserum developed in goat, Sigma). Buffer used for electrophoresis migration was Tris veronal buffer diluted 1:5 in water and prepared as follow: 44.3 g

Table 1. Physicochemical Characteristics of Nanoparticles Constituted by PBLG-PEG-60 and PBLG-Bnz-50

polymer ratio (wt %)	mean size (nm)[b]	ζ potential (mV)[c]
100/0[a]	58 ± 20	−13.3 ± 0.6
90/10[a]	62 ± 20	−12.6 ± 0.3
77/23[a]	60 ± 21	−13.6 ± 0.3
40/60[a]	54 ± 17	−16.1 ± 0.6
0/100[a]	85 ± 30	−21.1 ± 0.2

[a] PBLG-PEG-60/PBLG-Bnz-50 ratio (in wt %) in the formulation. [b] Measured using dynamic laser light scattering, $n = 3$. [c] Measured using a Zetasizer 4 Instrument, $n = 5$.

of Tris(hydroxy-methyl-amino-methane), 22.4 g of phenobarbital, and 0.53 g of lactate calcium were dissolved in 1 L of water at 50 °C, sodium azide was added to avoid bacterial development, pH was adjusted to pH = 8.6, if necessary. C3 and C3b migration was followed by Coomasie blue staining. The height of the peaks given by the immunoprecipitation of C3 and C3b gave a semiquantitative estimation of the amount of each component in the serum. The complement activation factor (CAF) was expressed as the ratio of the peaks height as follows:

$$\mathrm{CAF} = \mathrm{C3b}/(\mathrm{C3} + \mathrm{C3b}) \quad (4)$$

RESULTS

Nanoparticle Preparation and Characterization. Possibilities to prepare, by nanoprecipitation, nanoparticles, either from one polymer (PBLG-Bnz-50 or PBLG-PEG-60) or from mixtures of these two polymers (composite nanoparticles) in different ratios, have been evaluated. As shown in Table 1, nanoparticles could be easily and reproducibly obtained without any surfactant agents by a slightly modified method described elsewhere (*29*). THF was selected, being both a good solvent of the polymer and miscible to water. Nanoparticle diameter, determined by dynamic laser light scattering, was typically lower than 100 nm. From transmission electron microscopy (Figure 1), it could be seen that nanoparticles prepared from both polymers exhibited ellipsoidal geometries, whose dimensions were compatible with dynamic light scattering measurements. Moreover, it can be seen that particles issued from mixtures of the two polymers were quite homogeneous, suggesting that they formed a single population.

The ζ potential (Table 1) was similar for nanoparticles at 100/0, 90/10, and 77/23 wt % ratio. A weak decrease in the ζ potential was observed for a 40/60 wt % ratio. As expected, the stronger ζ potential value was found for non-PEGylated nanoparticles (0/100 wt % ratio).

Isothermal Titration Microcalorimetry (ITC) Studies. In order to evaluate the capacity of nanoparticles to avoid protein adsorption and, therefore, to confirm the presence of PEG chains at the surface of nanoparticles, isothermal titration microcalorimetry (ITC) has been applied. PEGylated (PBLG-PEG-60) and non-PEGylated (PBLG-Bnz-50) nanoparticle−protein interactions were measured using bovine serum albumin (BSA) as model globular protein. As shown by Figure 2, the interaction of BSA with the nanoparticle surface is an exothermic phenomenon. The area underneath each injection peak is equal to the total heat released for that injection. In the case of nanoparticles constituted by PBLG-Bnz-50 (Figure 2a), signals after each BSA injection were much stronger than signals of nanoparticles constituted by PBLG-PEG-60 (Figure 2b). The corresponding control dilution experiment consisted of BSA injected in water and is shown by Figure 2c.

Evaluation of Complement Activation by Crossed Immuno-Electrophoresis. Figure 3 presents the immuno-electrophoresis patterns of the complement proteins C3 and C3b in serum incubated with the different nanoparticles prepared and of control experiments. The control experiments performed under experimental conditions in the absence of nanoparticles (Figure 3a) showed a major peak of protein C3 and a small peak of protein C3b. It gives the complement activation background under experimental conditions. The CAF value determined for the background activation was 0.16. In the absence of divalent ions (Figure 3b), no C3b peak can be seen on the immuno-electrophoregram in agreement with the fact that activation of the complement system requires divalent cations.

The immuno-electrophoregram of serum incubated with nanoparticles presented both C3 and C3b peaks. The height of the C3b peak was less pronounced for the serum incubated with PEGylated PBLG-PEG-60 nanoparticles (Figure 3d) than the one observed for serum incubated with non-PEGylated PBLG-Bnz-50 nanoparticles (Figure 3c). As reported in Table 2, the CAF was higher for serum incubated with the non-PEGylated nanoparticles (0.40) than the CAF measured for serum incubated with the PEGylated nanoparticles (0.21), indicating that non-PEGylated particles could be rapidly opsonized by serum proteins. The CAF value of the serum incubated with the PEGylated nanoparticles was close to the CAF value of the background activation of the complement under experimental conditions.

The immuno-electrophoresis patterns of the serum incubated with the different composite nanoparticles (Figure 3e,f,g) were very similar to the immuno-electrophoresis pattern shown for PBLG-PEG-60 nanoparticles (Figure 3d). The CAF values reported in Table 2 only showed a slight shift toward a higher value for the serum incubated with the composite nanoparticles containing the lower percentage (40 wt %) of PBLG-PEG-60 polymer. The CAF values obtained for serum incubated with the two other composite nanoparticles were the same than the CAF of serum incubated with nanoparticles prepared with 100 wt % PBLG-PEG-60 polymer.

DISCUSSION

The development of efficient targeting systems necessitates the simultaneous introduction of a set of functionalities within the system itself, regardless of its physical structure. Various polymers have been used to prepare nanoparticles for pharmaceutical applications, and different strategies have been proposed to introduce specific functionalities, e.g., optimized drug encapsulation, controlled release properties, stealthiness in the bloodstream, organ or cell targeting by ligands. It has been shown previously (*27*) that copolymers of poly(γ-benzyl L-glutamate), PBLG, bearing pharmaceutically interesting moieties could be quite easily prepared. Interestingly, mixtures of these copolymers can easily self-associate, which offers a convenient means for introducing by a soft technique desired functionalities within the particles.

In the present work, we investigated the possibility to precisely tune nanoparticle surfaces by introducing an optimal amount of a PEGylated copolymer of PBLG within the structure of nanoparticles. The nanoprecipitation method could be used conveniently to prepare nanoparticles either from one polymer (PBLG-Bnz-50 or PBLG- PEG-60) or from mixtures of these two polymers (composite nanoparticles) in different ratios. Nanoparticles could be easily and reproducibly obtained without any surfactants by a slightly modified method described elsewhere (*29*) as a result of the hydrophobic nature of PBLG. Moreover, DLS and TEM measurements showed that very small particles (lower than 100 nm) could be prepared. In addition, the homogeneous aspect of the particle shapes for the different preparations made from the polymer mixtures suggested that in this case the suspensions were composed of a single population of composite nanoparticles.

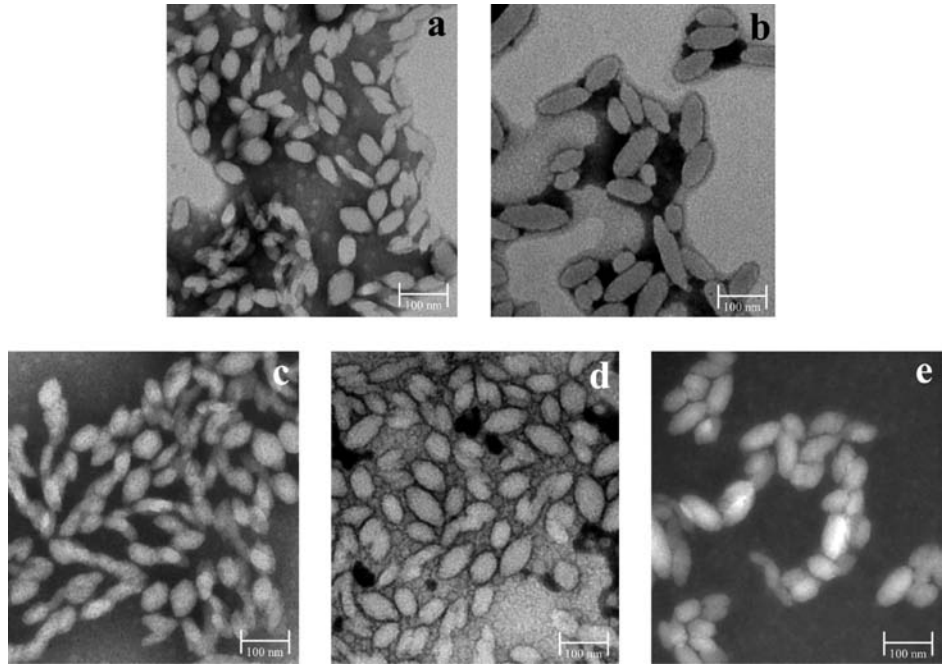

Figure 1. Transmission electron microscope micrographs of the nanoparticles. Simple nanoparticles constituted by (a) PBLG-PEG-60 (100/0 wt %) and (b) PBLG-Bnz-50 (0/100 wt %); Composite nanoparticles constituted by PBLG-PEG-60/PBLG-Bnz-50 at (c) 90/10, (d) 77/23, and (e) 40/60 (wt %), respectively.

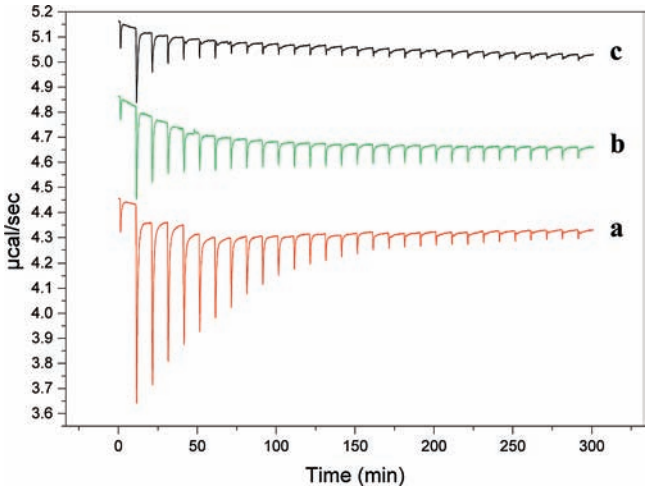

Figure 2. Plots of heat flow vs time of microcalorimetric titration of (a) PBLG-Bnz-50 nanoparticles and (b) PBLG-PEG-60 nanoparticles, by BSA solution. Injections of 10 μL, at 25 °C, of 5.4×10^{-2} mM of BSA solution were made on nanoparticle suspensions (2.7×10^{-2} mM). Control of BSA dilution (c) was carried out by injections of BSA solution in water.

Characterization by ITC of PBLG-PEG-60 or PBLG-Bnz-50 nanoparticle−protein interactions using bovin serum albumin (BSA), a model globular protein, permitted confirmation of the difference in surface properties of PEGylated and non-PEGylated nanoparticle suspensions. Theoretically, PEG chains of PEGylated nanoparticles should avoid or, at least, reduce protein adsorption on the nanoparticle surface as a result of steric repulsions and hydrophilization induced by PEG chains. In the case of nanoparticles constituted by PBLG-Bnz-50 (Figure 2a), signals after each BSA injection were higher than signals observed for nanoparticles constituted by PBLG-PEG-60 (Figure 2b). From this result, it could be concluded that interactions of BSA with nanoparticle surfaces were stronger in the absence of PEG chains.

Quantitative interpretation of observed enthalpy effect after an adsorption process (ΔH_{ads}) could be difficult because various factors can contribute to this effect. For example, Norde and Lyklema (*8*, *31*) took into account several factors while studying adsorption of human plasma albumin and bovin pancreas ribonuclease on negatively charged polystyrene surfaces. Some of these factors were as follows: the structural changes that the protein molecule and other involved molecules (for example, water and electrolyte) can undergo during the adsorption process; the alterations in the hydration state, disruption of the surface/solvent contacts, and simultaneous formation of protein/surface contacts; the modification of protein/solvent interactions due to differences of the chain density between dissolved and adsorbed protein molecules; and the effect of partners dilution.

Because such factors have not yet been elucidated for PBLG-Bnz-50 and PBLG-PEG-60 systems titrated with BSA, interpretation of ΔH_{ads} remains difficult. However, as shown in Figure 2, these studies made possible a qualitative surface characterization of tested nanoparticles. From these results, enthalpies of interactions could be obtained after integration of injection signals and subtraction of control (Figure 2c). Values of $\Delta H_{ads} = 414$ kCal/mol and 83 kCal/mol were obtained for the interaction of BSA with PBLG-Bnz-50 and PBLG-PEG-60 nanoparticles, respectively. Thus, it could be concluded from the existence of this 5-fold factor between adsorption enthalpies that interactions of BSA with non-PEGylated nanoparticles were much important than those observed for PEGylated nanoparticles.

In vitro evaluation of complement activation induced by nanoparticles is a very convenient method that can be used to predict their fate after intravenous injection *in vivo* (*4*, *32*). Indeed, most of the nanoparticles inducing a strong activation of the complement systems are generally rapidly taken up by macrophages of the mononuclear phagocyte systems, while nanoparticles appearing as low or non-activators of the complement systems are not recognized by the macrophages and remain in the bloodstream. In the present work, we have investigated the activation of the complement system induced by both PBLG-PEG-60 nanoparticles and PBLG-Bnz-50 nanoparticles, as well as by composite nanoparticles made from blends of both types of polymers at different composition. The CAF value of PBLG-Bnz-50 nanoparticles was much higher than the CAF value of

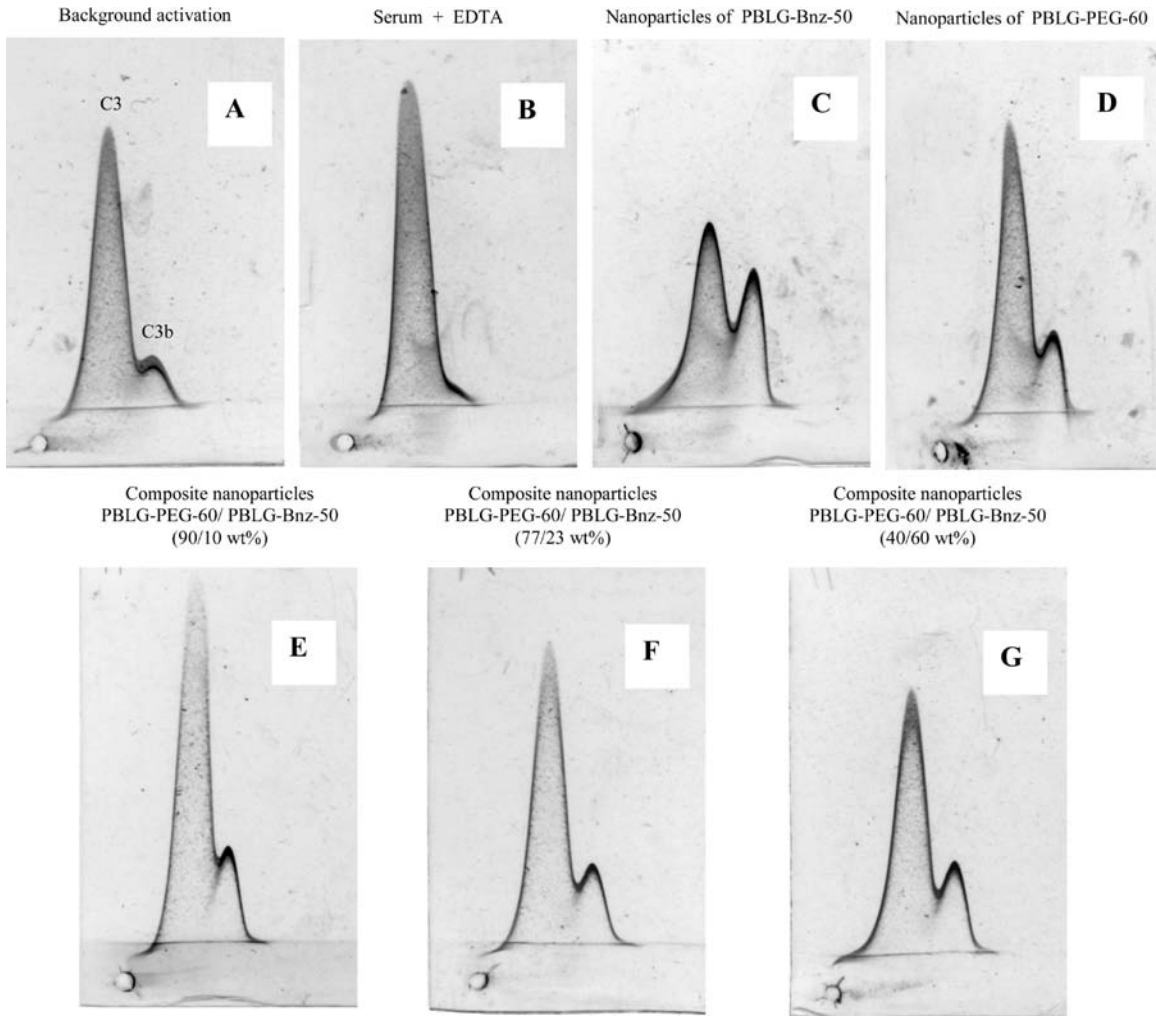

Figure 3. Crossed immunoelectrophoresis of C3 antigens in human serum diluted 1:4 after incubation in the presence of nanoparticles (500 cm^2). (D) Serum/VBS^{2+}/PBLG-PEG-60 nanoparticles. (E) Serum/VBS^{2+}/(PBLG-PEG-60/PBLG-Bnz-50, 90/10 wt %) nanoparticles. (F) Serum/VBS^{2+}/(PBLG-PEG-60/PBLG-Bnz-50, 77/23 wt %) nanoparticles. (G) Serum/VBS^{2+}/(PBLG-PEG-60/PBLG-Bnz-50, 40/60 wt %) nanoparticles.

Table 2. Relationship between PBLG-PEG-60 Content into the PBLG-PEG-60/PBLG-Bnz-50 Nanoparticles and the Complement Activation Factor

	sample	CAF
controls	background activation	0.16
	serum + EDTA	0.05
nanoparticles polymer ratio (wt%)	100/0	0.21
	90/10	0.21
	77/23	0.21
	40/60	0.25
	0/100	0.40

the PBLG-PEG-60 nanoparticles. This result indicated the tendency of uncoated nanoparticles to activate the complement system contrarily to nanoparticles bearing PEG chains. These nanoparticles which gave a CAF value close to the background activation of the serum under experimental conditions appeared as low complement activating nanoparticles. The results observed here are in good agreement with the literature, which reports that nanoparticles prepared with PEG-containing polymers are generally low complement activators due to the presence of PEG chains at the nanoparticle surface (*4*, *5*). Thus, the results also suggested that the organization of PBLG-PEG-60 polymer chains to form the particle was highly efficient to expose PEG moieties at the surface of nanoparticles, ensuring a coating layer able to avoid complement activation. All these results were also in good agreement with the results obtained from the evaluation of PEGylated and non-PEGylated nanoparticle interactions with BSA. Indeed, the nanoparticles showing the lowest adsorption of BSA were also the lowest complement activators in agreement with the fact that surfaces of such nanoparticles are generally less opsonized as a result of the presence of hydrophilic PEG chains. In contrast, non-PEGylated nanoparticles, which adsorbed higher amounts of BSA, appeared as the highest complement activators in agreement with the fact that they are generally strongly opsonized by seric proteins.

Composite nanoparticles also displayed a low capacity to induce activation of the complement system. It is noteworthy that composite nanoparticles containing 90 and 77 wt % of PBLG-PEG-60 showed identical behavior to nanoparticles composed of 100 wt % of this polymer. The PEG coating formed at the surface of these nanoparticles seemed to have identical properties to the one formed on the surfaces of 100 wt % of PBLG-PEG-60 based nanoparticles. Interestingly, the three types of nanoparticles giving the lowest CAF value also showed identical ζ potential suggesting that they showed similar properties (Figure 4).

The composite nanoparticles containing the lowest amount of PBLG-PEG-60 (40 wt %) showed a slightly higher capacity to induce complement activation as suggested by their CAF,

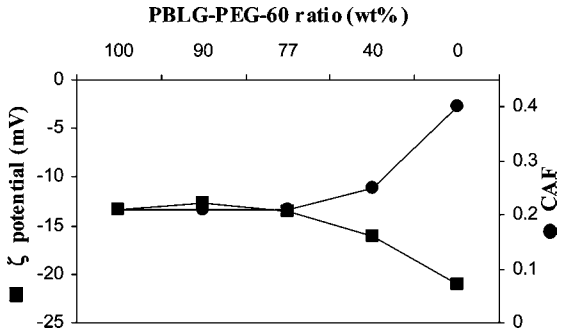

Figure 4. Evolution of ζ potential and complement activation factor as a function of PBLG-PEG-60 ratio (wt %) in nanoparticles constituted of PBLG-PEG-60 and PBLG-Bnz-50. Circle: Complement activation factor. Square symbols: ζ potential.

which was shifted toward higher values. When combining this result with the fact that the ζ potential was also shifted toward the value of the ζ potential measured for nanoparticles composed of 100 wt % non-PEG polymer, it can be suggested that the PEG coating characteristics of the surface of these nanoparticles was modified in such a way that it reduced the effectiveness to prevent complement activation. The lower value of the ζ potential shown by these nanoparticles was in favor of a modification of the surface composition of the nanoparticles, which can be attributed to a decrease in the density of the PEG chains at the nanoparticle surface. Thus, a higher contribution of the core polymer can be associated with the measured ζ potential. This may also contribute to increasing the capacity of inducing complement activation, hence increasing the chance to be taken up by macrophages after intravenous administration in animals.

Finally, from a practical point of view, it is interesting to note that low complement activation characteristics could be obtained with only 77% of PBLG-PEG copolymer chains in the particles, making possible to imagine composite particles containing not only PBLG-PEG copolymer (for ensuring stealth properties in the body), but also other copolymers bearing other chemical moieties, such as recognition ligands, in order to confer simultaneously other properties to the particles.

CONCLUSIONS

The results reported in this contribution permit one to demonstrate that nanoparticles based on PEGylated derivatives of PBLG with a low complement activation pattern can be obtained by nanoprecipitation, an easy and reproducible method. Because of this property, it is strongly expected that these nanoparticles will behave as stealth nanoparticles after *in vivo* administration by the intravenous route. Isothermal titration microcalorimetry and complement activation measurements allowed us to conclude that recognition of PEGylated PBLG-based nanoparticles by proteins is significantly lower than recognition of non-PEGylated nanoparticles. It is worth noting that composite nanoparticles based on a mixture of PBLG-PEG-60 and PBLG polymers have been prepared by nanoprecipitation and present similar properties to PBLG-PEG-60 based nanoparticles, suggesting that it may prove possible to introduce in the particles reasonable amounts of other structurally similar copolymers chains bearing other ligands, without modifying their complement activation properties. This would help to adjunct on demand additional functionalities to the particles.

ACKNOWLEDGMENT

Pr. Denis Labarre is warmly acknowledged for fruitful discussions concerning the discussion of the complement activation experiments. M.EMB would like to thank the CONACyT (Mexico) for the financial support, which enabled her to conduct this study. TEM experiments where performed at the CCME (U. Paris-Sud) facility and authors acknowledge Jeril Degrouard for technical support and fruitful help. The authors would like to acknowledge Laurent Fontaine and Véronique Montembault for their advice and support in the synthesis of the polymers used in the formulation of the nanoparticles.

Received January 22, 2009; Revised Manuscript Received June 6, 2009

Interactions between biomolecules and nanoparticles suggest the use of nanoparticles for various medical interventions. The attachment and entry of herpes simplex virus type 1 (HSV-1) into cells involve interaction between viral envelope glycoproteins and cell surface heparan sulfate (HS). Based on this mechanism, we designed silver nanoparticles that are capped with mercaptoethane sulfonate (Ag−MES). These nanoparticles are predicted to target the virus and to compete for its binding to cellular HS through their sulfonate end groups, leading to the blockage of viral entry into the cell and to the prevention of subsequent infection. Structurally defined Ag−MES nanoparticles that are readily redispersible in water were sonochemically synthesized. No toxic effects of these nanoparticles on host cells were observed. Effective inhibition of HSV-1 infection in cell culture by the capped nanoparticles was demonstrated. However, application of the soluble surfactant MES failed to inhibit viral infection, implying that the antiviral effect of Ag−MES nanoparticles is imparted by their multivalent nature and spatially directed MES on the surface. Our results suggest that capped nanoparticles may serve as useful topical agents for the prevention of infections with pathogens dependent on HS for entry.

INTRODUCTION

The application of nanotechnology in therapeutics, biological imaging, drug delivery, biosensors, and cell labeling is being intensively explored (*1*−*6*). Biologically important entities, such as proteins, antibodies, antigens, and DNA, which possess nanometer size dimensions, may serve as good candidate targets for interactions with such nanoparticles (*1, 7, 8*). Viruses are common nanoelement pathogens that can infect and cause diseases in plants, animals, and humans, while viral diseases present challenging problems with worldwide social and economic implications. Development of antiviral drugs able to target the virus while maintaining host cell viability is challenging (*9, 10*).

Herpes simplex virus type 1 (HSV-1) is a common infectious agent that occurs worldwide and infects humans of all ages (*11*). The outcome of HSV-1 infection includes a wide variety of clinical manifestations, ranging from asymptomatic infection to oral cold sores and severe encephalitis. The HSV-1 virion consists of a 152-kbp double-stranded DNA genome enclosed by an icosahedral capsid, which is surrounded by a lipid bilayer envelope that accommodates 11−12 virally encoded glycoproteins (*11, 12*). The envelope diameter ranges from 170 to 200 nm and contains an array of protruding glycoprotein spikes, making the full diameter of the virion about 225 nm on average. Each virion contains 600−750 spikes, with variable packing densities (*12*). The mechanism of HSV entry into the cell, involving its virus−receptor interaction, is one of the most comprehensively understood routes among members of the Herpesviridae family (*13*). HSV entry occurs when extracellular virions attach to the cell surface via glycoprotein C (gC) and gB, promoting the binding of gD to one of three alternative cellular receptors. In turn, membrane fusion machinery comprised of gB, gH, and gL is activated to mediate fusion with plasma or endocytotic membranes (*11, 14*). During the attachment phase, gC and gB interact independently with cellular heparan sulfate (HS). This reversible interaction likely creates multiple points of adhesion and occurs in both wild-type and laboratory viral strains (*14*). The affinity of the binding of gC to HS is on the order of 10^{-8} M and is considered to be the major binding interaction during attachment (*13*). When gB and gC are absent, viral binding to the cell surface is severely reduced, signifying the important role of this step for viral entry (*11, 15*). Accordingly, cells that are defective in HS exhibit a dramatic reduction in susceptibility to infection (*13*). It is worth noting that the interaction with cell surface HS has been found to be a common pathway for attachment by several other human and animal viruses as well (*15*).

HS is a ubiquitous constituent of cell plasma membranes and extracellular matrices, which mediates various physiological processes, such as development, cell adhesion, tumorigenesis, and viral and bacterial infections (*16*). It is a structurally diverse, highly sulfonated polysaccharide belonging to the family of glycosaminoglycans. HS is composed of alternating sequences of glucosamine and uronic acid. The amino sugars may be N-acetylated or N-sulfated (*17*−*19*). The glucosamine residues may, in some cases, carry O-sulfated groups at C6 or C3, and the uronic acid moieties may be O-sulfated at C2 (*17*). HS is characterized by great structural heterogeneity in terms of chain length and size and the extent of sulfation and epimerization within the modified segments (*19*).

Topical, oral, or intravenous nucleoside derivatives (e.g., acyclovir) have been approved for the treatment of HSV infections and are widely used. However, the emergence of resistant viral strains, mainly after prolonged treatment in immunocompromised patients, is one of the main reasons for the continuous search for new antiviral drugs that can prevent or inhibit infection by both wild-type viruses and drug-resistant strains (*13, 20*). Compounds that mimic HS, such as sulfated polysaccharide (e.g., dextran sulfate, pentosan polysulfate, a

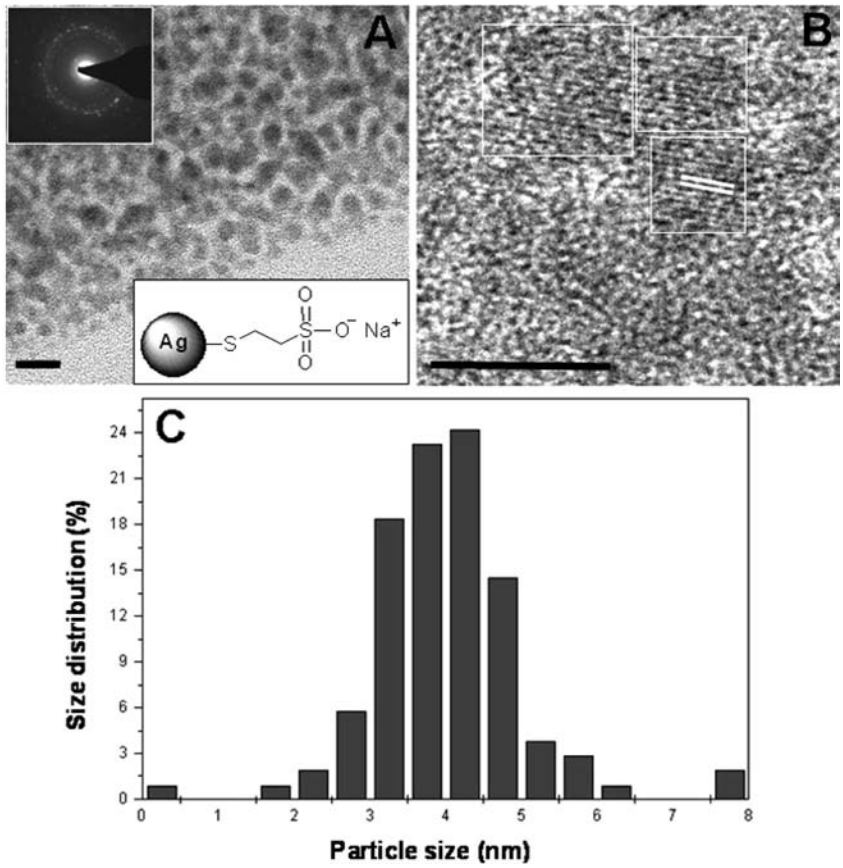

Figure 1. Representative TEM images of Ag−MES nanoparticles. (A, B) with selected area electron diffraction pattern along with the schematic representation of MES binding on the surface of silver nanoparticles (A). The scale bars in TEM images correspond to 10 nm. The size distribution of the Ag−MES nanoparticles was obtained from the TEM analysis and determined by measuring the diameter of 103 Ag−MES nanoparticles (C).

mixture of highly sulfated mannose containing di- to hexasaccharides (PI-88)) and sulfated nonpolysaccharides (e.g., lignin sulfate, poly(sodium 4-styrene sulfonate) (T-PSS)), were shown to inhibit HSV attachment to cells, suggesting that these compounds act via competition with HS chains for the binding to viral post attachment proteins. Interference with post attachment steps by these compounds has also been suggested (*14*, *21*−*24*). Antiviral potencies of candidate compounds are usually enhanced with an increasing degree of sulfation and the size of the oligosaccharide chain. These allow an increased likelihood of successful recognition of the saccharide with the HS-binding domain on the HSV and a simultaneous interaction of the saccharide with numerous copies of viral attachment proteins. Yet, inhibition of HSV during its cell-to-cell spread requires penetration of these compounds into a narrow intercellular space and in this case the size of the inhibitor might be a limiting factor (*14*). Therefore, one should consider the characteristics of the different modes of virus infection and spread during the design of antiviral compounds.

There are only a few reported nanoparticle-based antiviral therapies. Yacaman and co-workers have used silver nanoparticles for the inhibition of human immunodeficiency virus (HIV) infection (*25*), whereas other groups have used modified silver nanoparticles to inhibit monkeypox virus (*26*) and hepatitis B virus (*27*). More recently, Melander and co-workers have used functionalized multivalent gold nanoparticles for the prevention of HIV infection (*28*). Here, we describe the application of a structurally defined aqueous colloidal solution of silver nanoparticles that are capped with mercaptoethane sulfonate group (Ag−MES) as a novel inhibitor of HSV-1 infection. To the best of our knowledge, the antiviral properties of ω-sulfonated nanoparticles remain an undeveloped area, which based on our findings, is of potential medical interest.

EXPERIMENTAL PROCEDURES

Particle Synthesis. Mercaptoethane sulfonate-protected silver nanoparticles (Ag−MES) were synthesized by a modified procedure with a sonochemical reaction based on that described by Zou et al. (*29*). $AgNO_3$ (0.102 g, Aldrich) in 50 mL of ethanol was mixed with 0.25 g of sodium 2-mercaptoethane sulfonate (MES, Fluka Analytical) dissolved in 25 mL of ethanol and 25 mL of a double-distilled water (DDW) solution. After purging the reaction mixture with argon gas for 30 min, sonochemical irradiation (Ti horn from Sonics and Materials VCX 600, 20 kHz, 600 W at 60% efficiency) was applied for 15 min in argon atmosphere. NH_3 (0.1 mL, 25%) was injected into the flask 4 min after the start of the sonication. The reaction was held at a 10 °C, using a water−ice bath.

Characterization of Ag−MES Nanoparticles. The morphology of the nanostructures was characterized with a Philips CM-120 transmission electron microscope (TEM), operating at 120 kV. Images were recorded by a Gatan Ultrascan 1000 2kx2k CCD camera. The nanoparticle size distribution was further characterized using Scion Image software (Alpha 4.0.3.2) based on the TEM images. X-ray photoelectron spectroscopy (XPS) was performed using an Axis HS with monochromatic Al Kα source (Kratos Analytical). Thermogravimetric analysis (TGA) measurements were conducted using a TGA model Q500 (TA Instruments), equipped with a Pt crucible, for the estimation of the amount of the MES surfactant on the surface of the silver nanoparticles.

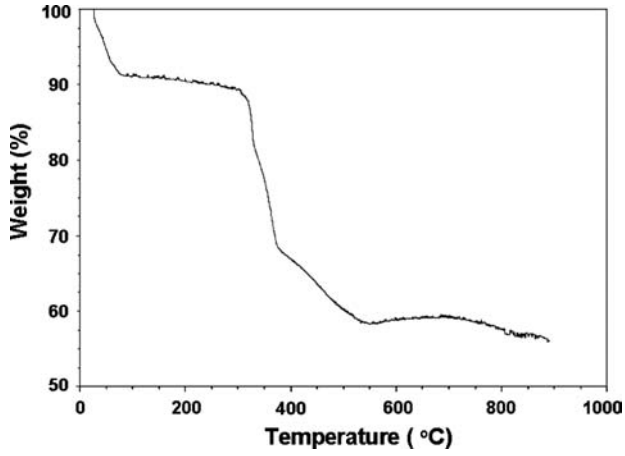

Figure 2. Thermogravimetric analysis (TGA) of Ag−MES nanoparticles depicting percentage weight loss of the sample as a function of temperature.

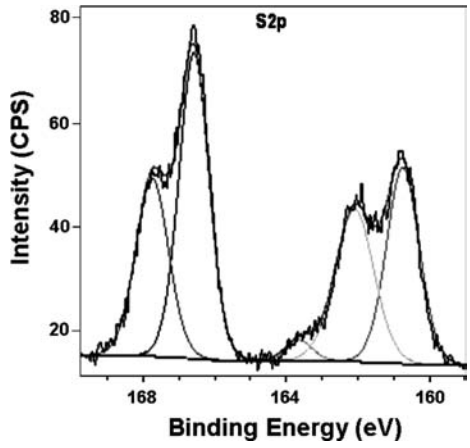

Figure 3. XPS spectra of the S 2p region of Ag−MES nanoparticles. Binding energy (BE) of 161.98 eV corresponds to the thiol group of MES, and BE of 167.77 eV corresponds to the sulfonate group of MES.

Cells and Virus. Vero African green monkey kidney epithelial cells were grown in minimum essential media (MEM)−Eagle's medium (Biological Industries, Israel) supplemented with 10% heat-inactivated fetal calf serum (FCS) (Biological Industries), L-glutamine (Biological Industries), and penicillin−streptomycin−amphotericin (PSA) (Biological Industries). Cells were maintained at 37 °C under 5% CO_2. The virus used was a wild-type HSV-1 McIntyre strain.

Cell Toxicity Assay. The toxicity of the Ag−MES nanoparticles to Vero cells was examined using a cell proliferation kit with an XTT-based colorimetric assay that measures mitochondrial activity, according to the manufacturer's instructions (Biological Industries). Optical density (OD) measurements for calculating cell viability percentage were taken using a TECAN Spectrafluor Plus (NEOTEC Scientific Instrumentation Ltd.) spectrophotometer at 405 nm wavelength.

For the assay, Vero cell monolayers were grown in 96-well plates (2.5×10^4 cells/well) with 5% FCS in MEM−Eagle's medium. Ag−MES nanoparticles were added into each well at different concentrations (25−800 μg/mL in a total volume of 150 μL/well). The control consisted of Vero cell monolayers with no Ag−MES nanoparticles.

HSV-1 in vitro Assays. Viral infection was evaluated by plaque assay on Vero cells. Cells were plated in 24-well dishes (4.5×10^4 cells/well). Confluent monolayers of cells were inoculated with 250 μL of virus suspensions (25, 250, or 2500

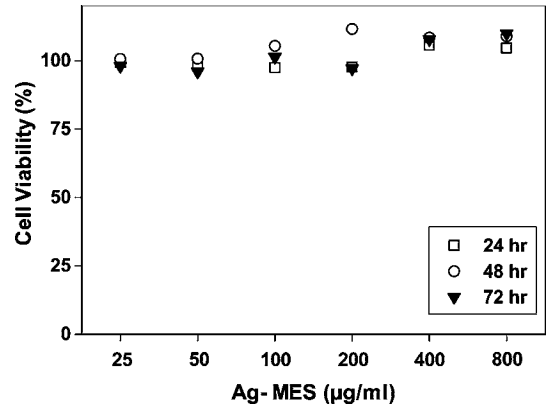

Figure 4. Cell toxicity assay. Cell viability was determined by the XTT assay. The viability of the cells was calculated as percentage relative to control cells, which were not treated with Ag−MES nanoparticles. Average results obtained for control batches were defined as 100% viability, and average values obtained for cells treated with Ag−MES nanoparticles were calculated accordingly. Measurements were taken after 24, 48, and 72 h at different Ag−MES nanoparticle concentrations (25−800 μg/mL). Similar results were obtained in two independent experiments.

plaque forming units (pfu)/well) in the presence of different concentrations of Ag−MES or MES at 37 °C. After 45 min incubation to allow for virus adsorption, the cells were overlaid with 500 μL of MEM−Eagle's medium supplemented with 2% heat-inactivated FCS and 0.1% human γ-globulin (ZLB Behring GmbH, Marburg, Germany) with Ag−MES nanoparticles or MES for maintaining final concentration in each well. Controls included mock-infected cell monolayers with and without Ag−MES nanoparticles or soluble MES. After 2−3 days of incubation, the cell monolayers were stained with Giemsa stain, and the plaques were counted. All determinations were performed in four replicas.

RESULTS AND DISCUSSION

Synthesis and Characterization of Ag−MES Nanoparticles. An aqueous dispersion of silver nanoparticles capped with sodium 2-mercaptoethane sulfonate was synthesized as described in the Experimental Procedures section. Transmission electron microscope (TEM) images of the Ag−MES nanoparticles revealed moderately polydispersed spherical nanoparticles with an average size of 4 ± 1 nm, while the selected area electron diffraction confirmed the presence of metallic silver (Figure 1). MES is expected to bind to the silver surface through the thiol (-SH) group, while the sulfonate end remains free and faces the solvent to target the virus (Figure 1). Thermogravimetric analysis (TGA) measurement on Ag−MES nanoparticles was conducted at a temperature range of 25−900 °C to estimate the amount of the MES on the surface of the silver. Weight loss (%) as a function of the temperature is shown in Figure 2. A total of 10.74% of the initial weight loss was observed over a range of 50−100 °C. We attribute this loss to access of MES molecules that were merely physically adsorbed to the surface of the nanoparticles and to solvent water molecules. A further weight reduction of 30.86% was detected at the temperature range of 320−550 °C. This loss occurred in two main steps: 22% of the weight was lost in the range of 320−370 °C and ~10% between 320 and 550 °C. We assign this weight reduction, at such high temperatures, to the removal of MES molecules that were chemically bonded to the silver core.

Based on the particles size obtained using TEM images and TGA analysis, we calculated that an average single Ag−MES nanoparticle covered with a full monolayer of MES contains 141 MES molecules. These calculations are based on previous

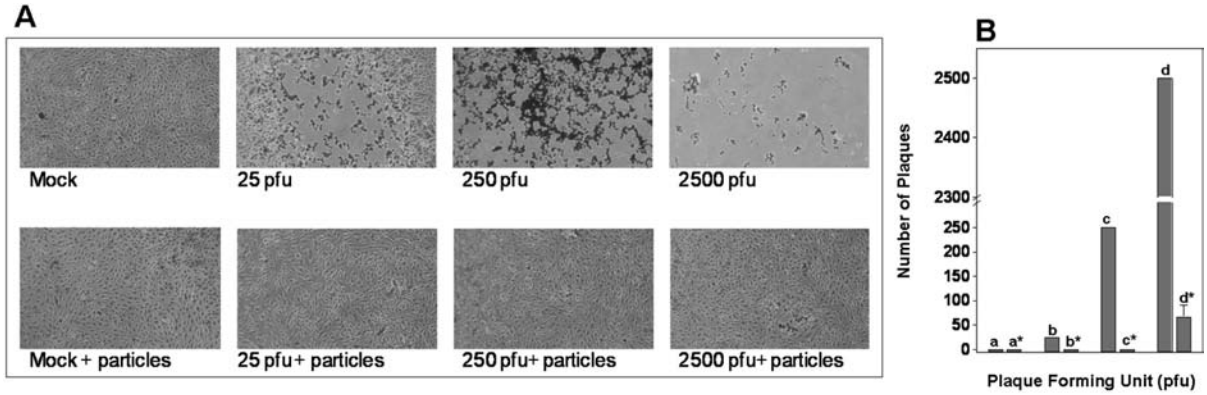

Figure 5. Microscopic and quantitative analysis of effects of Ag−MES nanoparticles toward infection with HSV-1. (A) Optical microscopic image (×10 magnification) demonstrating the effect of Ag−MES nanoparticles on HSV-1 infectivity. Cells were infected with HSV-1 in the absence or the presence of 400 μg/mL Ag−MES nanoparticles. Mock cells were similarly treated, but no virus was added. Pictures were taken 48 h following infection. (B) Quantitative analysis of the Ag−MES inhibition efficiency; a, b, c, and d represent the number of plaques in cell cultures not treated with Ag−MES nanoparticles (mock, 25, 250, and 2500 pfu, respectively); a*, b*, c*, and d* refer to the number of plaques in cell cultures infected with similar viral loads in the presence of 400 μg/mL Ag−MES nanoparticles (mock, 0, 0, and 67 ± 23, respectively).

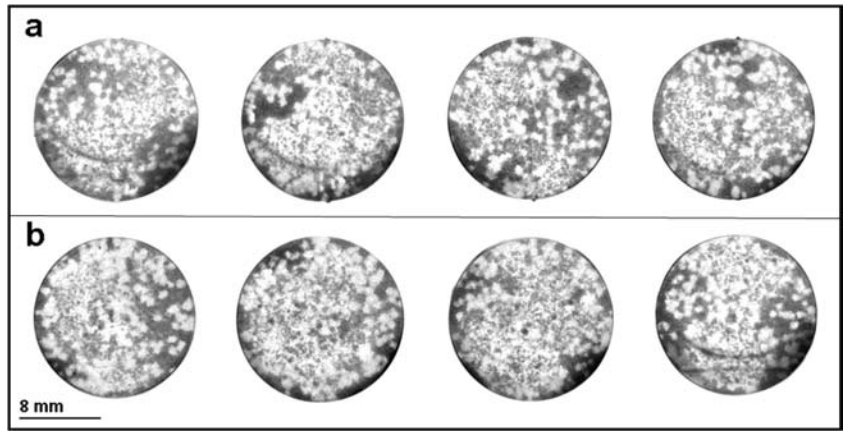

Figure 6. Effect of soluble MES on HSV-1 infection. Cells were infected with HSV-1 in the absence (a) or the presence (b) of 96 μg/mL MES. Pictures were taken 48 h following infection. Results represent four repeats for each condition. A *t* test for the two independent conditions (a and b) showed no significant difference in the diameter of the plaques; $p = 0.372$, $n = 112$.

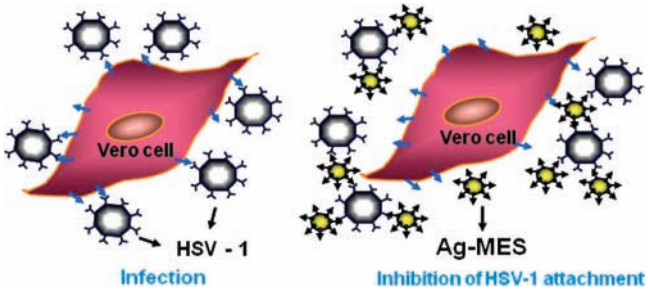

Figure 7. Schematic representation of a proposed mode of HSV-1 inhibition by Ag−MES nanoparticles.

surface coverage measurements carried out with alkanethiolates on metallic nanoclusters (*30*−*32*). The calculated mass percentage of a full MES monolayer on a silver core nanoparticle is therefore 24.1%. TGA measurements showed a 30.86% weight reduction, suggesting that synthesized Ag−MES nanoparticles were fully covered with a MES monolayer.

Figure 3 illustrates the XPS spectrum of S 2p region of Ag−MES nanoparticles. Sulfur appears in two main oxidation states: thiol group binding energy appears as a doublet ($2p_{3/2}$ and $2p_{1/2}$) at 161.98 eV and sulfonate group binding energy appears as a doublet ($2p_{3/2}$ and $2p_{1/2}$) at 167.77 eV. A third, relatively negligible (5.81%), oxidation state appears as well. Assuming that MES molecules were not altered during Ag−MES nanoparticle synthesis, each molecule carries one thiol group and one sulfonate group. Therefore, a 1:1 stoichiometric relation between the two sulfur groups would be expected. However, the XPS spectrum indicates a different ratio, with a larger sulfonate peak area than that of the thiol. This result indicates that most of the MES molecules are bonded to the silver core through thiol groups.

Cytotoxocity Assay. The toxicity of the Ag−MES nanoparticles to mammalian cells was of high concern. We tested the toxicity of the particles on kidney epithelial Vero cells at a concentration range of 25−800 μg/mL using the colorimetric XTT assay. Results were compared with cells that were not treated with Ag−MES nanoparticles (control). Figure 4 presents the results calculated as the percentage of viable cells relative to control cultures for cells incubated with Ag−MES nanoparticles for 24−72 h. As indicated by near 100% cell viability, Ag−MES nanoparticles did not affect the mitochondrial activity of the cells at any time point or concentration.

Inhibition of HSV-1 Infectivity by Ag−MES Nanoparticles. Vero cells show a typical cytopathic effect when infected with HSV-1. Therefore, to evaluate the antiviral activity of the nanoparticles, we used a plaque reduction assay in these cells. Cells were infected with virus suspensions (25−2500 pfu/well) in the absence or presence of different Ag−MES concentrations. Partial inhibition of plaque formation was observed when 200 μg/mL Ag−MES nanoparticles was used. Increased inhibition

was observed in the presence of 400 μg/mL Ag−MES nanoparticles, and no further inhibition was obtained when 800 μg/mL Ag−MES nanoparticles was added. As shown in Figure 5A, infection with HSV-1 was almost completely blocked in the presence of 400 μg/mL nanoparticles. At low virus loads (25 and 250 pfu), infected cell cultures that were treated with Ag−MES nanoparticles demonstrated a similar morphology to control mock infected cells, with no evidence of any plaque formation. In contrast, infected cells that were not treated with Ag−MES nanoparticles demonstrated plaques, with increasing diameters during the experiment. At high virus loads (2500 pfu), very small plaques were observed in cultures treated with Ag−MES nanoparticles, while complete destruction of the culture was observed in the absence of Ag−MES nanoparticles, indicating that Ag−MES nanoparticles act as inhibitors of infection. Figure 5B presents quantitative analysis of the Ag−MES inhibition efficiency calculated according to three independent experiments. The number of plaques was counted in infected cell cultures that were treated with Ag−MES nanoparticles and compared with plaque numbers extrapolated from virus titrations in cell cultures not treated with Ag−MES nanoparticles. It is evident that at low virus loads (25 and 250 pfu), viral infection was completely blocked by the Ag−MES nanoparticles. At higher virus loads (2500 pfu), an average of 67 ± 23 plaques/well was observed, which is nearly a 97% decrease in the number of plaques relative to cell cultures that were not treated with Ag−MES nanoparticles. Furthermore, the observed plaques were tiny compared with the plaques obtained in the absence of Ag−MES nanoparticles. This suggests the efficiency of the Ag−MES particles in blocking HSV-1 infection.

To compare the effect of the soluble MES with that of the nanoparticles, infection was carried out in the presence of 96 μg/mL MES, which is equivalent to the amount of MES incorporated in 400 μg/mL Ag−MES nanoparticles (Figure 6). However, soluble MES was found to be completely ineffective as an HSV-1 inhibitor after 48 or 72 h as indicated by the similarities in the number of plaques and their diameter in comparison to infected cells that were not treated with MES (*t* test for the two independent conditions showed no significant difference in the diameter of the plaques, $p = 0.372$, $n = 112$).

Taken together, using viral plaque reduction assay in Vero cells, we show that infection with HSV-1 was almost completely blocked in the presence of the silver nanoparticles capped with MES. In contrast, equivalent concentration of soluble MES molecules, a clinically approved detoxifying agent for inhibition of hemorrhagic cystitis (*33*), which constitute our nanoparticle capping molecule, was found ineffective in preventing HSV-1 infection.

We believe that the nanoparticles decorated with MES serve as multivalent inhibitors that mimic HS on the host cell membrane and, therefore, that the nanoparticles efficiently interact with HSV-1. This in turn prevents the infection of HSV-1 by blocking viral attachment to the cells as illustrated in Figure 7. Thus, one silver nanoparticle containing numerous functional groups can potentially target more than one virus. This spatial arrangement substantially enhances the effectiveness of the coated nanoparticles. Multivalent particles present the additional advantage of creating a high local concentration of binding molecules, thereby favoring the formation of more virus−particle pairs (*28*, *34*, *35*). In addition, we suggest that the free rotation of the soluble MES considerably reduces the interaction of the sulfonate groups with the target virus, whereas the sulfonate groups in the colloidal solution of the Ag−MES nanoparticles are directed toward the viral glycoproteins. Furthermore, steric effects involving shielding of other viral components that may assist in the attachment process could contribute to the inhibition observed.

The exact inhibitory mechanism will be determined in future studies. Since several pathogens have been shown to exploit cell-surface HS as primary attachment sites during host invasion, Ag−MES nanoparticles may potentially be applied for the topical prevention of other infectious agents, such as genital HSV-2 and HIV. Moreover, alternative nanoparticles constructs, comprised of different core materials and sulfonated surfactants, may be designed based on our prototype and assayed for their antiviral activity.

ACKNOWLEDGMENT

This work will be submitted to Bar Ilan University, Ramat Gan, Israel, by D. Baram-Pinto in partial fulfillment of the degree of Doctor of Philosophy.

Received January 23, 2009; Revised Manuscript Received June 8, 2009

Generation 7 (G7) poly(amidoamine) (PAMAM) dendrimers with amine, acetamide, and carboxylate end groups were prepared to investigate polymer/cell membrane interactions *in vitro*. G7 PAMAM dendrimers were used in this study because higher-generation of dendrimers are more effective in permeabilization of cell plasma membranes and in the formation of nanoscale holes in supported lipid bilayers than smaller, lower-generation dendrimers. Dendrimer-based conjugates were characterized by ^{1}H NMR, UV/vis spectroscopy, GPC, HPLC, and CE. Positively charged amine-terminated G7 dendrimers (G7-NH_2) were observed to internalize into KB, Rat2, and C6 cells at a 200 nM concentration. By way of contrast, neither negatively charged G7 carboxylate-terminated dendrimers (G7-COOH) nor neutral acetamide-terminated G7 dendrimers (G7-Ac) associated with the cell plasma membrane or internalized under similar conditions. A series of *in vitro* experiments employing endocytic markers cholera toxin subunit B (CTB), transferrin, and GM_1-pyrene were performed to further investigate mechanisms of dendrimer internalization into cells. G7-NH_2 dendrimers colocalized with CTB; however, experiments with C6 cells indicated that internalization of G7-NH_2 was not ganglioside GM_1 dependent. The G7/CTB colocalization was thus ascribed to an artifact of direct interaction between the two species. The presence of GM_1 in the membrane also had no effect upon XTT assays of cell viability or lactate dehydrogenase (LDH) assays of membrane permeability.

INTRODUCTION

Polycationic polymers such as poly(lysine)s, poly(ethyleneimine)s, diethylaminoethyl dextrans, and poly(amidoamine) (PAMAM) dendrimers have demonstrated great potential to be exploited as gene transfer and drug delivery vectors (*1*−*9*). Successful *in vitro* biomedical applications of the polycationic polymers have triggered a number of research groups to investigate the internalization mechanism of the macromolecules into cells. Efficient cross-membrane transport and membrane disruption were observed with a strong dependence on size (molecular weight) and surface groups of the polymers, as well as composition of model membranes (*10*−*14*). Among those polycationic polymers, PAMAM dendrimers have attracted great scientific interest in biomedical applications because of their excellent water solubility and well-defined structure, molecular weight, and surface end groups. Demonstrated utility for practical applications, coupled with excellent monodispersity and chemical versatility, make PAMAM dendrimers an ideal material for exploring polymer−membrane interactions in greater detail (*6*, *8*−*10*, *13*, *15*).

The internalization mechanism of amine-terminated PAMAM dendrimers into cells has been explained as polycation-mediated endocytosis or leaky endocytosis (*10*−*14*). In particular, colocalization studies using choleratoxin subunit B (CTB) suggested that ganglioside GM_1 played a major role in the initial interaction with the cell membrane and the subsequent internalization process for EA.hy 926 cells and Chinese hamster ovary (CHO) cells (*16*). Furthermore, inhibition of internalization by methyl-β-cyclodextrin (MβCD) suggested that a lipid-raft mediated process may be a primary pathway for PAMAM dendrimer internalization into the cells. Subsequent studies with HeLa and HepG2 cells did not show an effect from MβCD, but instead, increased uptake and transfection efficiency were observed as a function of caveolin 1 expression (*17*). These results were particularly interesting in light of other studies that had identified an "adsorptive" endocytosis that might involve a specific membrane component for B16f10 melanoma cells (*18*), which are also known to contain GM_1 (*19*). However, the generality of a caveolae-based endocytosis mechanism is called into question by studies on Caco-2 cells which support a clathrin-based mechanism, not a caveolae-mediated mechanism (*20*). In addition, studies on A549 cells indicate that the process is neither clathrin- nor caveolae-based (*21*).

An alternative to endocytic mechanisms of uptake is direct physical disruption of the membrane and the formation of nanoscale holes causing plasma membrane permeability. AFM observations have revealed that polycationic polymers cause nanoscale hole formation, expansion of pre-existing defects, or membrane thinning depending on physical properties of polymers such as structure, size, and terminal groups, as well as

membrane composition and phase (*6, 9, 22*−*25*). Particularly, the efficiency of hole formation in supported lipid bilayers induced by PAMAM dendrimers was concluded to be proportional to molecular weight (G7 > G5 > G3) as well as terminal end groups (amine > acetamide; i.e., charged > uncharged) of the dendrimers. Recent studies across a broad variety of cationic nanomaterials suggests that surface area is the single best correlate (*26*). This observation agrees with *in vivo* studies carried out by Oberdörster et al. (*27*) AFM studies using supported lipid bilayers were consistent with our *in vitro* results exploring cell membrane permeability and dendrimer internalization (*6, 8, 9*). Employing two tumor cell lines, KB and Rat2, cytosolic enzyme (LDH and luciferase) leakage, dendrimer internalization, and small molecule diffusion into and out of the cells were observed as a result of incubation with positively charged G7 PAMAM dendrimers as illustrated in Figure 1. We thus concluded that the cellular-level data for the interaction of cationic PAMAM dendrimers with cell membranes were consistent with induction of nanoscale hole formation and this process may be related to the internalization of these materials into the cell and/or the membrane permeability measured by dye diffusion and LDH assays (*6, 8, 9*).

Considering the recent reports on endocytic internalization (*16*−*21*) and nanoscale hole formation (*6, 8, 9, 26*), we decided to investigate the role of GM_1 in the interaction of PAMAM dendrimers with cells. Experiments were designed probing the roles of GM_1 in endocytosis and/or nanoscale hole formation. Experiments to test other key hypothesis such as clathrin pathways were also explored. For this study, G7 PAMAM conjugates were chosen because of their effectiveness in terms of both endocytosis and cell membrane disruption and because they had been observed to cause membrane permeability even at 4 °C (*6, 8, 9, 28, 29*). Three different types of G7 PAMAM dendrimer−AlexaFluor488 conjugates (amine, acetamide, and carboxylate terminated) were synthesized and characterized (Figure 2). The conjugates were then tested *in vitro* to explore dendrimer−cell interactions. The key findings in this

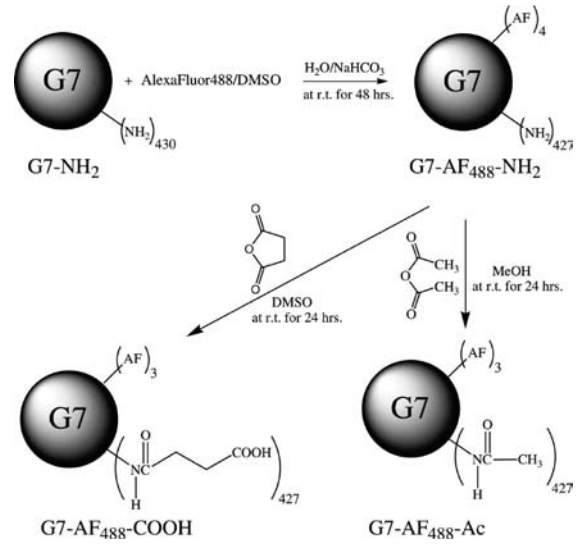

Figure 2. Synthetic routes for G7 PAMAM dendrimer conjugates with various surface end groups.

paper are as follows: (1) no evidence is found for a GM_1 dependence of G7 PAMAM dendrimer with respect to internalization via endocytosis or nanoscale hole formation; (2) the presence of GM_1 in the membrane does not play a role in cell viability assays as measured by XTT; (3) the presence of GM_1 in the membrane does not play a role in plasma membrane permeability assays as measured by LDH.

EXPERIMENTAL SECTION

Materials. G7 and G5 PAMAM dendrimers were synthesized at the Michigan Nanotechnology Institute for Medicine and Biological Sciences and purified using ultrafiltration and dialysis before use. Alexa Fluor488 carboxylated succinimidyl ester (AF488) was supplied by Molecular Probes (Eugene, OR) and

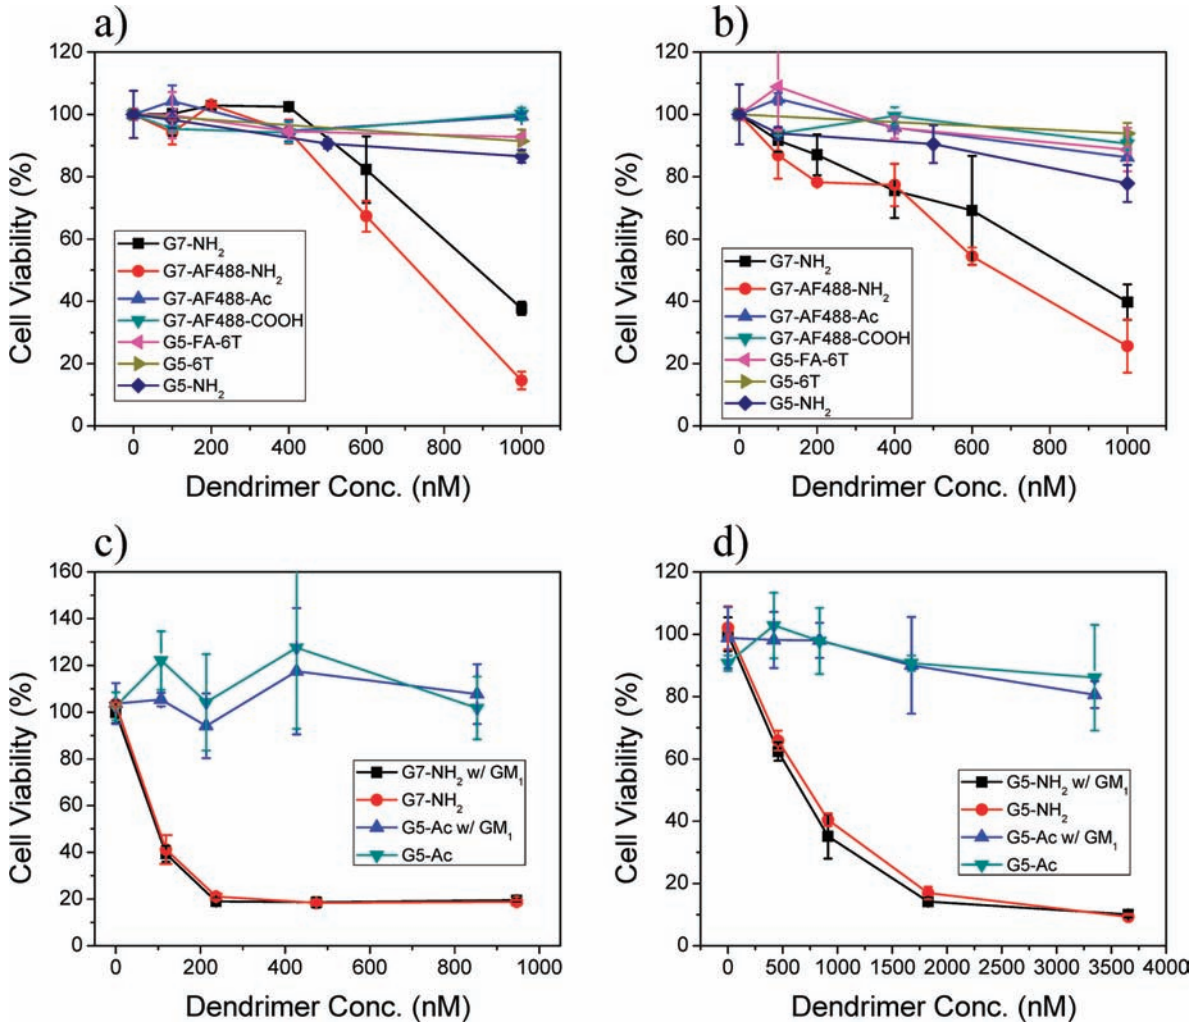

Figure 3. Percentage viability as measured by XTT assay when cells are treated with various G5 and G7 PAMAM dendrimers: (a) KB cells, (b) RAT-2 cells, (c) C6 cells, and (d) C6 cells. FA = folic acid. 6T = 6-Tamra.

used without further purification. Tranferrin from human serum labeled by AlexaFluor546 (TF-AF546), recombinant cholera toxin subunit B-Alexa Fluor647 conjugate (CTB-AF647), and LysoTracker Red DND-99 (LysoTracker) were provided by Molecular Probes. Methyl-β-cyclodextrin (MβCD) and GM_1-pyrene were purchased from Sigma-Aldrich (St. Louis, MO) and used without further purification. Materials for native PAGE were obtained from Invitrogen. All other chemicals were acquired from Aldrich and used as received. Water used in this work was purified by Milli-Q Plus 185 system and had a resistivity higher than 18.0 M$\Omega\cdot$cm.

Preparation of PAMAM Dendrimer Conjugates and Their Surface Modification. Two milligrams of AF488 (6.20 μM, 5× excess to G7) dissolved in 400 μL DMSO were conjugated to 68 mg of the purified G7 PAMAM dendrimers (1.25 μM) under the presence of 2 mL of 1 M $NaHCO_3$ at room temperature for 48 h. The resulting reaction mixture was then dialyzed in water for 2 days and lyophilized for 2 days, followed by 5× ultrafiltration with water using an 80 000 molecular weight cutoff membrane at 21 °C, 5000 rpm, for 30 min each. Sixty milligrams of a yellowish powder (G7-AF488-NH_2) was finally obtained (yield: 86%). The average number of AF488 dye molecules present was determined by ^{1}H NMR and/or GPC. The materials used in these studies varied from 2.4 to 4 AF488 per dendrimer. Twenty-two milligrams of G7-AF488-NH_2 was allowed to react with 12 μL of acetic anhydride (50% mol excess to the conjugate) in 1.5 mL MeOH as a solvent at room temperature for 24 h. The reaction mixture was then purified by ultrafiltration at the same condition above with PBS (w/o Ca^{2+}, Mg^{2+}) and water subsequently 5× each. After lyophilization for 2 days, 16.25 mg of a yellowish powder (G7-AF488-Ac) was obtained (yield: 63%). Twenty milligrams of G7-AF488-NH_2 was also allowed to react with 11 mg succinic anhydride (50% excess to the conjugate) in 1.5 mL DMSO at room temperature for 24 h followed by ultrafiltration and lyophilization at the same condition used for preparation of G7-AF488-Ac. A yellowish powder (18.8 mg) was obtained (G7-AF488-COOH, yield: 67%). The synthetic routes for the three different conjugates are summarized in Figure 2. In addition, G5 PAMAM dendrimers used in the XTT assay (Figure 3) were also conjugated with 6-carboxy-tetramethyl-rhodamine (6-TAMRA) followed by acetylation as described earlier (*30*).

Characterization of the Prepared PAMAM Based Conjugates: UV/vis and ^{1}H NMR Spectroscopy. UV/vis spectra of the G7 PAMAM conjugates were measured on a Perkin-Elmer UV/vis spectrometer Lambda 20 (Wellesley, MA). Molar extinction coefficients of the dendrimer conjugates were also calculated by plotting maximum absorbance values against conjugate concentrations at 20, 40, 60, 80, and 100 μg/mL using the Lambert−Beer law (Table 1). ^{1}H NMR spectra were also taken in D_2O and were used to provide integration values for structural analysis using a Bruker AVANCE DRX 500 instrument (*31*).

Table 1. Molar Extinction Coefficients, Molar Masses, and Polydispersity Indices of the G7 Conjugates

conjugates	molar extinction coeff. ($M^{-1}cm^{-1}$)[a]	theoretical molar mass[b]	molar mass (M_n)[c]	polydispersity (M_w/M_n)	HPLC peak width at half-height[d]
G7-NH_2	N/A	97 020	97 000	1.07 ± 0.02	0.52
G7-AF_{488}-NH_2	171 100	99 137	99 600	1.38 ± 0.03	0.62
G7-AF_{488}-Ac	147 130	116 903	116 300	1.06 ± 0.02	0.49
G7-AF_{488}-COOH	122 520	141 437	138 500	1.08 ± 0.02	0.57

[a] Molar extinction coefficients were obtained from the Lambert−Beer equation by plotting λ_{max} against corresponding concentrations of a conjugate (20, 40, 60, 80, and 100 μg/mL). R^2 values of the linear regressions were 0.9966−0.999. The coefficients were calculated on the basis of UV characteristic peaks of conjugated AF_{488} at 497 nm. [b] Calculated from the measured molecular weight of starting G7-NH_2 by assuming that the G7 PAMAM dendrimers have 4 AF488 moieties per dendrimer and 427 surface terminal groups according to the previously reported curve fit (*30*). [c] Measured by GPC (M_n, Number average molecular weight; M_w, Weight average molecular weight). [d] Obtained from HPLC chromatograms.

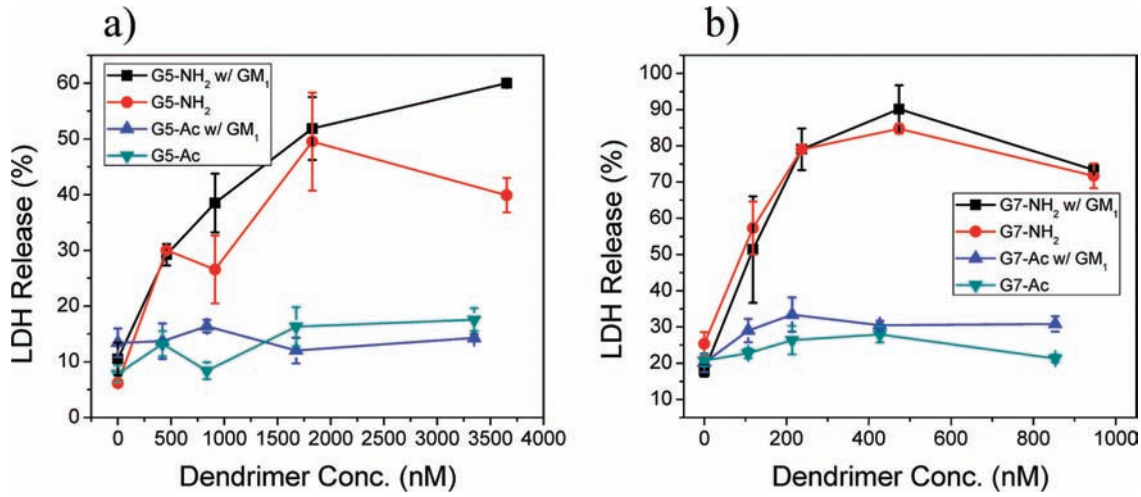

Figure 4. Percentage LDH release of C6 cells when treated with (a) G5 and (b) G7 PAMAM dendrimers.

Characterization of the Prepared PAMAM Based Conjugates: GPC and HPLC. The molar mass moments and molar mass distribution of each polymer sample were measured using gel permeation chromatography (GPC). The number average molecular weight (M_n) and polydispersity index (PDI), a commonly used measure of the breadth of the molar mass distribution defined as the ratio of the weight and number average molecular weights (M_w/M_n), of individual samples are listed in Table 1. GPC experiments were performed using an Alliance Waters 2690 separation module (Waters Corp., Milford, MA) equipped with a Waters 2487 UV absorbance detector (Waters Corp.), a Wyatt Dawn DSP laser photometer (Wyatt Technology Corp., Santa Barbara, CA), an Optilab DSP interferometric refractometer (Wyatt Technology Corp.), and TosoHaas TSK-Gel Guard PHW 06762 (75 × 7.5 mm, 12 μm), G 2000 PW 05761 (300 × 7.5 mm, 10 μm), G 3000 PW 05762 (300 × 7.5 mm, 10 μm), and G 4000 PW (300 × 7.5 mm, 17 μm) columns. A detailed procedure of the GPC measurement was described elsewhere (*9, 31*).

The reverse-phase (RP) HPLC system (Beckman Coulter, Fullerton, CA) consisting of a System GOLD 126 solvent module, a model 507 autosampler equipped with a 100 μL loop, and a model 166 UV detector were used in this study as well. A Jupiter C5 silica-based RP-HPLC column (250 × 4.6 mm, 300 Å) was purchased from Phenomenex (Torrance, CA). Two Phenomenex Widepore C5 safety guards (4 × 3 mm) were also installed ahead of the Jupiter column. The mobile phase for elution of G7-AF488 dendrimer conjugates with different terminal groups was a linear gradient beginning from 100:0 (v/v) water/acetonitrile (ACN) to 50:50 (v/v) water/ACN at a flow rate of 1 mL/min for 40 min. Trifluoroacetic acid (TFA) at 0.14 wt % concentration in water as well as in ACN was used as counterions to make the dendrimer surfaces hydrophobic. All the samples were dissolved into the aqueous mobile phase (water containing 0.14% TFA) at the concentration of 1 mg/mL. The detection of eluted samples was performed at 210 nm. The analysis was performed using Beckman's System GOLD Nouveau software (*32*).

Characterization of the Prepared PAMAM Based Conjugates. *Capillary Electrophoresis (CE).* An Agilent Technologies (Waldbronn, Germany) CE instrument was used in this work. Unmodified quartz capillaries were purchased from Polymicro Technologies (Phoenix, AZ, USA). The voltage was kept at 20 kV. On-capillary UV diode-array detection was used, operating at wavelengths of 210 nm, 250 nm, 280, and 495 nm. Samples were introduced by hydrodynamic injection at a pressure of 50 mbar.

For analysis of G7-AF488 conjugates with amino and acetamide terminal groups, silanized capillaries (i.d. 100 μm) with total length of 48.5 cm and effective length of 40 cm were employed following previous literature (*33*). G7-AF488-NH_2 and G7-AF488-Ac conjugates were dissolved in pH 2.5 phosphate buffer, and the sample solutions were adjusted to pH 2.5 using 0.1 M phosphoric acid to give a concentration of 1 mg/mL. All the conjugates contained 0.05 mg/mL 2,3-diaminopyridine (2,3-DAP) as an internal standard.

For analysis of G7-AF488 conjugate with carboxyl terminal groups, bare silica capillaries (i.d. 75 μm) with total length of 64.5 cm and effective length of 56 cm were used for the characterization of G7-AF488-COOH conjugates. The capillary temperature was maintained at 20 °C. Before use, the uncoated silica capillary was pretreated by rinsing with 1 M NaOH (15 min), deionized water (Purchased from Agilent) (15 min), and running buffer (15 min) (*33*). Before each injection, the capillary was rinsed with a similar sequence of each eluent. Twenty millimolar borate buffer (pH 8.3) was used as the running buffer. G7-AF488-COOH conjugates were dissolved in the running buffer, and the sample's pH was adjusted to 8.3 with 20 mM sodium tetraborate solution to get a final concentration of 1 mg/

mL. 4-Methoxybenzyl alcohol (MBA) (0.05 mg/mL) was used as a neutral marker.

Cell Lines. The KB, Rat2, and C6 cell lines were purchased from the American type Culture Collection (ATCC, Manassas, VA) and grown continuously as a monolayer at 37 °C and 5% CO_2. The KB cells were grown in RPMI 1640 medium (Mediatech, Herndon, VA). The Rat2 and C6 cells were grown in Dulbecco's modified Eagle's medium (DMEM, Gibco, Eggenstein, Germany). The RPMI 1640 and DMEM media were supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% heat-inactivated fetal bovine calf serum (FBS) before use.

XTT Cytotoxicity Assay. Cytotoxicity of the dendrimer conjugates used in this study was assessed by the overall activity of mitochondrial dehydrogenase by 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-*2H*-tetrazolium-5-carboxanilide (XTT) assay (Cell Proliferation Kit II, Roche Molecular Biochemicals, Mannheim, Germany). KB, Rat2, and C6 cell lines (at a concentration of 5×10^4 cells/well) were prepared as monolayers in 96 well plates, followed by incubation with dendrimers in phosphate buffered saline (PBS) with Ca^{2+} and Mg^{2+} at 37 °C under 5% CO_2 for 4.5 h (2 h for C6 cells). Polymer solutions (supernatants) were then removed, followed by washing with PBS twice. Mitochondrial activities of the cells were spectrophotometrically measured at 492 nm using a Spectra Max 340 ELISA Reader (Molecular Devices, Sunnyvale, CA). Cell viability was then calculated on the basis of optical density (OD) from untreated cells.

LDH Membrane Permeability Assay. Membrane permeability was tested via lactate dehydrogenase (LDH) leakage using the LDH assay kit (Promega, Madison, WI). The activity of LDH in extracellular media is taken as a measure of membrane porosity. C6 cells were seeded at a density of 5×10^4 cells/well in 96 well plates for overnight incubation at 37 °C and 5% CO_2. Dendrimers diluted in 100 μL PBS (w/ Ca^{2+}, Mg^{2+}) were added at specified concentrations into the 96 well plates and incubated at 37 °C and 5% CO_2 for 2 h after which the supernatant was removed and 50 μL was taken for the LDH assay (throughout the experiment boundary wells were not used). LDH activity was spectrophotometrically measured at 490 nm using an ELISA reader.

Confocal Laser Scanning Microscopy (CLSM). A concentration of 1×10^5 cells/mL of KB and Rat2 cells was seeded on MatTek glass bottom Petri dishes (35 mm) and incubated at 37 °C under 5% CO_2 for 24 h. The cell culture medium was removed and 2 mL of each dendrimer-AF488 conjugates in PBS (w/ Ca^{2+}, Mg^{2+}) solution was added into the appropriate dish. The dishes were incubated with added solutions either at 37 °C under 5% CO_2 for 1 h or at 4 °C. For the low-temperature experiment, cells were preincubated at 4 °C for 10 min before adding the dendrimer solutions. The conjugate-containing solutions were removed and the resulting cell monolayer was washed with PBS at least three times. Cells were fixed with 2% formaldehyde in the PBS (w/ Ca^{2+}, Mg^{2+}) at room temperature for 10 min, followed by washing with PBS twice.

For colocalization studies of dendrimers with CTB and transferrin on KB and Rat2 cells, dendrimer solutions were premixed with markers, resulting in final concentrations of 200 nM, 10 μg/mL, and 50 μg/mL for G7-AF488-NH_2, CTB-AF647, and TF-AF546, respectively. The mixed solutions were then added to KB and Rat2 cells, and the cells were incubated at 37 °C, 5% CO_2, for 1 h.

For colocalization studies of CTB and G7-NH_2 dendrimers on C6 cells, cells were seeded in Fisherbrand 2 well microscope cover glass #1.5 at 2.5×10^5 cells/mL density, with 1 mL complete media in each well. Cells were allowed to attach to the surface for 4 h after which wells were washed with PBS (w/ Ca^{2+}, Mg^{2+}) and then overnight incubated with media (w/o serum) containing GM_1-pyrene. Cells were then treated with 5 μg/mL CTB-AF647 for 1 h or 500 nM G7-AF488-NH_2- for 2 h, washed with PBS, and imaged in PBS solution.

For coincubation of KB cells with G7-AF488-NH_2 and fully acetylated G5 PAMAM-6-TAMRA conjugates (G5-6T-Ac) (*34*), KB cells were incubated with 100, 200, and 400 nM G7-AF488-NH_2 at 37 °C for 30 min followed by addition of 1 μM G5-6T-Ac with additional incubation for 30 min.

Confocal and differential interference contrast (DIC) images were taken on an Olympus FV-500 confocal microscope using either a 60×, 1.5 NA, or 100×, 1.4 NA oil immersion objective. For the confocal images using three different AlexaFluors, the 488 nm line of an argon ion laser (for dendrimer conjugates), 543 nm line of a HeNeG laser (for transferrin and LysoTracker), or 633 nm line of a HeNeR laser (for cholera toxin) was used for excitation, and the emission was filtered at 505−525, 560−600, 660 IF nm, respectively. Percentages of overlap between two markers in the confocal images were quantified using Metamorph offline software version 6-3r7 provided by Molecular Devices (Downingtown, PA).

RESULTS

Synthesis and Characterization of G7 PAMAM/AlexaFluor 488 Conjugates with Various Surface End Groups. G7 PAMAM dendrimers were conjugated with AF488 dye to allow confocal laser scanning microscopy (CLSM) studies. AF488 was chosen for this study because this fluorophore is known to exhibit brighter fluorescence and greater photostability than other spectrally similar fluorophores (300% more photostable than fluorescein (FITC) at 90 s exposure) as well as greater pH insensitivity between pH 4.0 and 10.0 (*35*). The synthesis scheme for the conjugates is illustrated in Figure 2. ^{1}H NMR spectra for all three conjugates are provided in the Supporting Information (Figure S1). After conjugation with AF488, characteristic peaks for the conjugated dyes molecules appear in the range of δ 6.8−8.4 ppm. The ^{1}H NMR spectrum of G7-AF488-Ac (Figure S1c) is consistent with the previously published spectra using G5 PAMAM (*31*). UV/vis spectra reveal that maximum absorbance of AF488 shifted from 495 to 497 nm after conjugation with the dendrimer. Calculated molar extinction coefficients decrease with the increase of molecular weights of the conjugates providing a rough guide when the surface modification from primary amine end groups to acetamide and carboxylate end groups is successfully performed (see Table 1).

HPLC chromatograms of the prepared G7 PAMAM dendrimer conjugates are provided in Supporting Information (Figure S2). All the conjugates exhibit a single peak and it is notable that no peak is present for free AF488 in the chromatograms. The peak widths at half-height of all the dendrimers range from 0.49 to 0.62 min indicating that the dendrimer conjugates are relatively monodisperse compared to other types of condensation polymers with molecular weights of >100 000 g/mol. This is consistent with GPC results presented in Table 1 (*32*). In order to provide an even more stringent assessment of polymer homogeneity, the same materials were characterized using CE (*9, 33, 36*−*38*). The G7-NH_2 dendrimer exhibits multiple peaks which persist, with a change in relative magnitude, after conjugation with AF488 (Figure S3b). After surface modification with acetamide and carboxylate groups is performed, the dendrimer conjugates produce sharper peaks, although a multiple peak structure is still apparent for G7-AF488-Ac.

Cytotoxicity of Dendrimer Conjugates as Measured by XTT Assays. The cytotoxicity of the G7 PAMAM conjugates on KB, Rat2, and C6 cells *in vitro* was explored using XTT assay (Figure 3). The KB cell line, a variant of the human HeLa

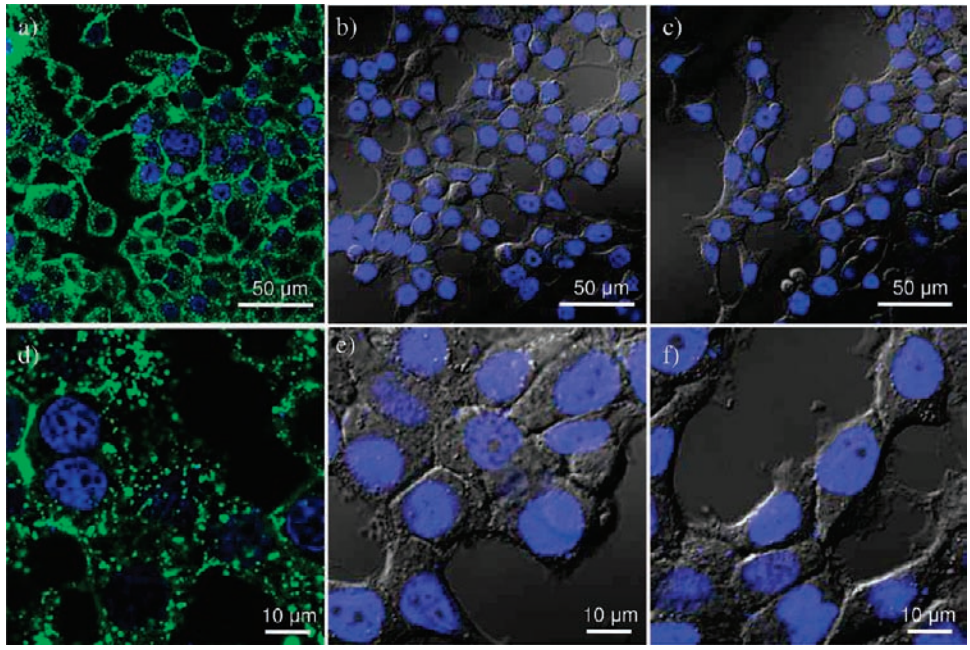

Figure 5. Confocal images of Rat2 cells after exposure to (a) G7-AF488-NH_2, (b) G7-AF488-Ac, and (c) G7-AF488-COOH at 37 °C for 1 h. The concentration of the dendrimer conjugates was at 200 nM. Images e, f, and g are digitally enlarged images of a, b, and c, respectively. Images b, c, e, and f are overlays of confocal and DIC images. Cell nuclei were stained by DAPI resulting in blue fluorescence in the images.

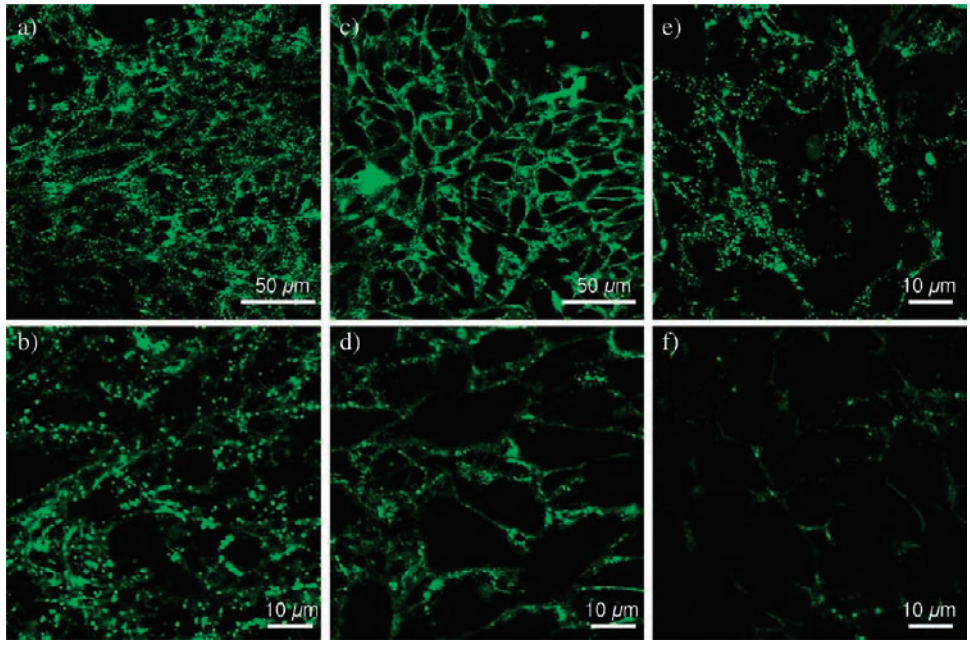

Figure 6. Confocal images of Rat2 cells after incubation with G7-AF488-NH_2 at (a) 37 °C and (c) 4 °C, both for 1 h. Images b and d are enlarged images of a and c, respectively. Concentration of the dendrimer conjugates was 200 nM. Note that G7-AF488-NH_2 penetrates into the cells even at the low temperature. Controls using G5-FITC-NH_2 at (e) 37 °C and (f) 4 °C.

line, and the Rat2 cell line, a dermal fibroblast from Fisher Rat, were selected because they are adherent and robust cell lines enabling us to employ various biological techniques. The C6 cell line was selected because it contains caveolin-1 but lacks GM_1 in the plasma membrane.

Amine-terminated G7 PAMAM dendrimers show a degree of cytotoxicity (~20% toxicity) starting at a concentration of ~400 nM, whereas G5 PAMAMs are not cytotoxic at a concentration as high as 1 μM in both KB and Rat2 cells. These results are consistent with our previous report, which concluded that the cytotoxicity of the PAMAM dendrimers is highly dependent on the size of the macromolecules (9). Surface modification of the starting dendrimers dramatically reduces their cytotoxicity. As shown in Figure 3a,b, G7-AF488-Ac, G7-AF488-COOH, G5-6T-FA (cancer cell targeting dendritic nanodevices), and G5-6T-Ac do not show any significant toxic effect on both cell lines at the concentration range used in the experiment. The effect of the presence of GM_1 in the cell plasma membrane on cytotoxicity was explored using the C6 cell line (Figure 3C,D). The C6 cells exhibited a greater sensitivity to G5-NH_2 and G7-NH_2 exposure, but no differential effect was observed as a function of the presence of GM_1 in the membrane.

Induction of Membrane Permeability as Measured by LDH Assays. The effect of GM_1 on the release of lactate dehydrogenase (LDH) was explored using C6 cells (Figure 4). LDH release was independent of the presence of GM_1 in the

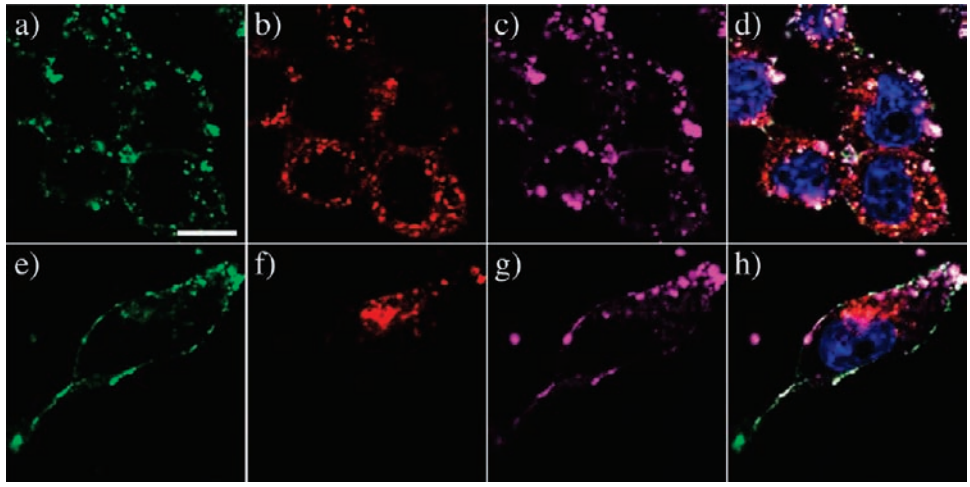

Figure 7. Confocal images of KB cells incubated for 1 h with (a) 200 nM G7-AF488-NH_2, (b) 50 μg/mL transferrin-AlexaFluor 546 (TF-AF546), and (c) 10 μg/mL cholera toxin subunit B-Alexa Fluor 647 (CTB-AF647) conjugates, and (d) a merged image of those. Green, red, and purple fluorescence, respectively, represent G7-AF488-NH_2, TF-AF546, and CTB-AF647. Images e, f, g, and h are a data set of Rat2 cells at the same condition with KB cells. Note that dendrimers are colocalized intracellularly with CTB in both cell lines. Bar: 10 μm.

cell plasma membrane for exposure to G5-NH_2 and G7-NH_2. By way of contrast, the acetylated forms of the dendrimer, G5-Ac and G7-Ac, did not exhibit a concentration-dependent release of LDH.

CLSM Observation: Surface Group Dependence on Dendrimer Internalization. Figure 5 shows confocal images of Rat2 cells after exposure to G7-AF488-NH_2, G7-AF488-Ac, and G7-AF488-COOH at 37 °C, 5% CO_2, for 1 h. The cell nuclei were stained with DAPI and appear as blue fluorescence in the images. Figure 5d,e,f represents digitally enlarged images of Figure 5a,b,c, respectively. As shown in Figure 5a and d, and confirmed by *z*-stack images, G7-AF488-NH_2 readily internalizes into the cells resulting in a punctate distribution of strong green fluorescence. On the other hand, surface-modified dendrimers (G7-AF488-Ac and G7-AF488-COOH) do not interact with the cell membrane or internalize into the cells (Figure 5b,c,e,f). This is consistent with the XTT and LDH assay results shown in Figures 3 and 4 as well as previously published AFM results indicating that G7-NH_2 is the most active with supported lipid bilayers (*24*, *25*). These results stand in stark contrast to CHARM/MD studies that suggest that all three dendrimers should interact strongly with a lipid bilayer (*39*, *40*). To clearly show cell morphology, differential interference contrast (DIC) images of the cells incubated with G7-AF488-Ac and G7-AF488-COOH were overlapped with confocal fluorescence images in those images. Similar results were obtained using KB cells as well (data not shown).

CLSM Observation: Effect of Low-Temperature on G7-NH_2 Internalization. Figure 6 illustrates confocal images of Rat2 cells after incubation with G7-AF488-NH_2 and G5-FITC-NH_2 at both 37 and 4 °C. As shown in Figure 6e,f, G5-FITC-NH_2 penetrates into the cells at 37 °C, whereas they do not internalize but associate with cell plasma membranes at 4 °C, which is in good agreement with previously published images (*9*). Although G7-AF488-NH_2 internalization is reduced at the lowered temperature by ~60% as measured by FACS, the dendrimers internalize into the cells not only at 37 °C, but also at 4 °C as shown in Figure 6a,b. It can be more clearly observed in the enlarged image (Figure 6d). *Z*-stack images of Figure 6d also confirm internalization of the dendrimers (data not shown). The intracellular distribution pattern of fluorescence in Figure 6d is slightly different from that of Figure 6b. Less punctate distribution of the dendrimers in the cytosol is observed in Figure 6d (the low-temperature case) as compared to intracellular distribution of the dendrimers in Figure 6b.

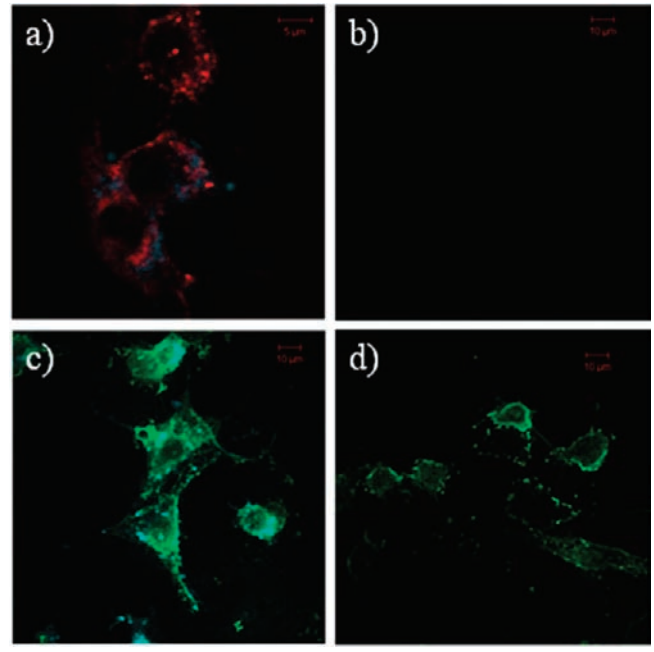

Figure 8. Confocal images of (a) C6 cells having GM_1-pyrene (blue) treated with Cholera toxin subunit B (CTB)-AF647(red), (b) C6 cells without GM_1 treated with CTB, (c) C6 cells having GM_1-pyrene (blue) treated with G7-NH_2-AF488 (green) PAMAM dendrimer, and (d) C6 cells without GM_1 treated with G7 dendrimer. All incubations were for 1 h. CTB is internalized only when GM_1 is present in the cell membrane. G7-NH_2 dendrimer is internalized independent of the presence of GM_1 in the cell membrane.

CLSM Observation: Intracellular Colocalization of G7-NH_2 with Endocytic Markers. The generally reported endocytic pathways for large molecules such as biomedical polymers and cell-penetrating peptides (CPPs) include clathrin-dependent and lipid raft-mediated endocytosis (*2*, *41*). We employed commonly used endocytic markers, transferrin for clathrin-dependent pathways and CTB for lipid raft-mediated endocytosis, to explore the mechanism of dendrimer uptake (*41*, *42*). Direct observation of intracellular localization of the markers using CLSM was enabled by employing markers labeled by different AlexaFluors. As shown in Figure 7, G7-AF488-NH_2 (green fluorescence) is colocalized with CTB-AF647 (purple fluorescence), whereas intracellular localization of TF-AF546 is different from those of dendrimers and CTB in both KB and

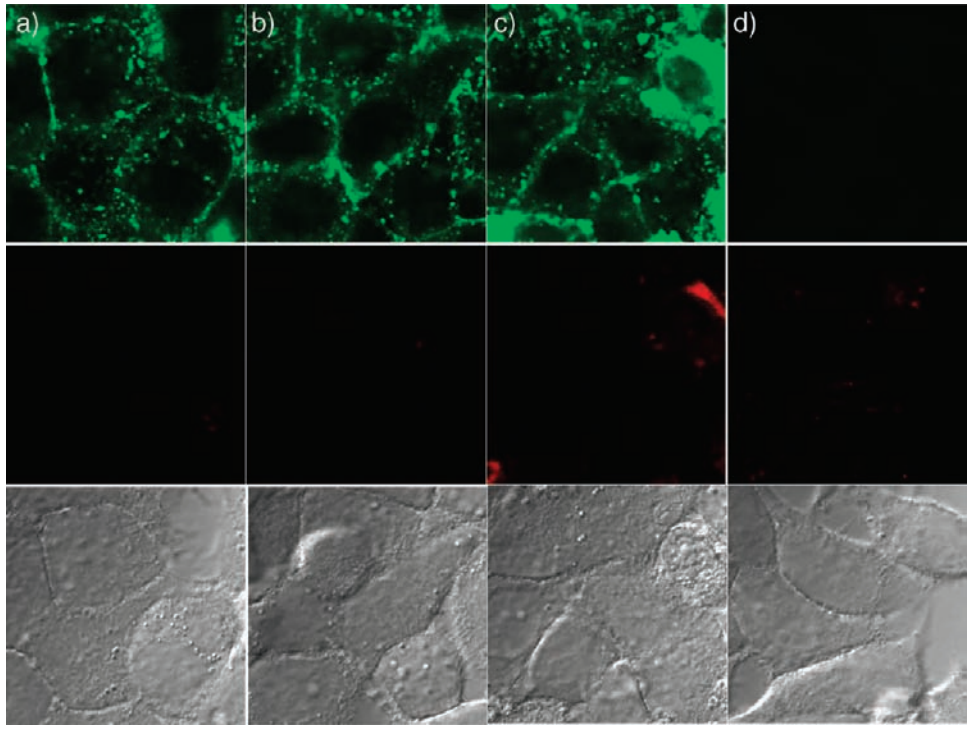

Figure 9. Confocal images of KB cells coincubated for 1 h with (a) 100 nM, (b) 200 nM, and (c) 400 nM G7-AF488-NH_2 and 1 μM G5-6T-Ac. Image d shows KB cells incubated with 1 μM G5−6T-Ac only. Note that red fluorescence should be detected if G7-AF488-NH_2 induces diffusion of G5-6T-Ac into the cells. However, no noticeable signal from G5-6T-Ac is observed. First row, green fluorescence channel detecting G7-AF488-NH_2; second row, red fluorescence channel detecting G5-6T-Ac; and third row, DIC images of each sample. Bar: 50 μm.

Rat2 cells. The quantified pixel counts for overlapped pixels using Metamorph software indicate that the colocalization between G7-AF488-NH_2 and CTB-AF647 is 88% and 68% for KB and Rat2 cells, respectively. In contrast, colocalization as indicated by quantification of overlapped pixels for G7-AF488-NH_2 and TF-AF546 was 10% and 17% for KB and Rat2 cells, respectively.

Colocalization with CTB is commonly taken as evidence for GM_1 interactions and a raft-mediated endocytosis mechanism (*41*). In order to directly test this hypothesis, internalization of CTB and G7-NH_2 was tested using C6 cells. In their native state, these cells contain little GM_1 in the plasma membrane. However, GM_1 can be added to the membrane via incubation. Consistent with previous reports in the literature (*43*), CTB only internalized into C6 cells that had been preincubated with GM_1. However, G7-NH_2 internalized independent of the presence of GM_1 in the plasma membrane (Figure 8). Recall that the results of both the XTT and LDH assays were independent of the presence of GM_1 in the C6 cell plasma membrane (Figures 3 and 4). The interaction of G7-NH_2 dendrimer and CTB was explored using native polyacrylamide gel electrophoresis employing Coommassie blue staining. The band associated with CTB was no longer present upon mixing the dendrimer with the CTB at ratios from 1:5 to 5:1.

CLSM Observation: Diffusion of Neutral Dendrimers into Cell. Neutral dendrimers (G7-Ac and G5-Ac) do not interact with the cell membrane or internalize into the cell as indicated by LDH and XTT assays (Figures 3 and 4) and CLSM experiments (Figure 5). However, if holes of 5−25 nm were created in the membrane, G5-Ac might be expected to enter the cell via passive diffusion processes. Our previous studies have shown that LDH (135−140 kDa, ∼4.3 nm diameter), propidium iodide, and fluorescein all diffuse across the membrane (*6*). However, as illustrated in Figure 9, 100 nM G7-NH_2 is sufficient to give substantial internalization of dendrimer, but 1 μM G5-6T-Ac still gives no detectable internalization. Previous studies indicate the G7-NH_2 should be about 8 nm in diameter and the G5-6T-Ac should be ∼4−7 nm in diameter (*24*, *44*).

DISCUSSION

Dendrimer/Membrane Interactions and Dendrimer Internalization. Amine-terminated (positively charged) G7 PAMAM dendrimers (G7-NH_2) exhibit cytotoxicity (Figure 3), cause LDH leakage (Figure 4), and internalize into cells (Figures 5−8) at <200 nM concentrations whereas charge neutral and negatively charged G7 PAMAM dendrimers do not. This is interesting because negatively charged PAMAM dendrimers (G7-AF488-COOH), suggested as potential drug delivery vectors (*45*), do not bind or internalize into cells at these concentrations (Figure 5c,f). We previously reported that G7-NH_2 PAMAM dendrimers caused more LDH leakage out of cells at 37 °C than G5-NH_2 indicating that G7-NH_2 is more effective in membrane permeabilization or dendroporation. Furthermore, G7-NH_2 induces LDH leakage at 4 °C, whereas G5-NH_2 does not (*9*). Confocal images also illustrate that G7-NH_2 internalizes into the cells at 4 °C but G5-NH_2 does not (Figure 9). One might argue that the enhanced LDH leakage is caused by cell death, since G7-NH_2 appears to be more cytotoxic than G5-NH_2 (Figure 4). In our concentration range (200 nM), however, G7-NH_2 exhibits minimal cytotoxic effects that are ∼100% viability for KB and >80% viability for Rat2. Consequently, the observed LDH assay and confocal data are taken as evidence for membrane permeabilization as opposed to cell death.

Low temperature has been used in a number of studies to investigate energy (or metabolic activities) dependency of proposed internalization mechanisms. Studies have been published for synthetic polymers and for CPPs (*41*, *42*, *46*). The observation of G7-AF488-NH_2 internalization at 4 °C can be explained by a number of possible mechanisms. One would be energy-independent translocation mechanism as previously

proposed for CPP internalization (*47*). However, lowering temperature prevents G5-NH_2 internalization and partially inhibits G7-NH_2 internalization, indicating that dendrimer internalization is an energy-dependent process. A phase change in the cell plasma membrane from the fluid phase (L_α) to low-temperature gel phase (L^*_β) (*48*) would also inhibit nanoscale hole formation. It has recently been demonstrated using supported lipid bilayers that G7-NH_2 dendrimers only cause nanoscale hole formation in fluid-phase membranes (*23*). This is consistent with other reports indicating the membrane fluidity is related to transport properties in epithelial cells (*49*).

There are several energy-dependent pathways proposed for polycationic polymers including endocytosis via clathrin-coated pits (*50, 51*) and endocytosis via lipid rafts or caveolae (*52, 53*). For this study, we employed transferrin which is a commonly used marker for clathrin-mediated endocytosis and CTB which is a commonly used marker for clathrin-independent lipid raft (or caveolae) mediated endocytosis (*41*). G7-AF488-NH_2 did not show substantial colocalization with transferrin (10% and 17% overlapping for KB and Rat2, respectively), indicating that G7-AF488-NH_2 internalization is not related to the clathrin-dependent pathway. Instead, significant colocalization of G7-AF488-NH_2 with CTB-AF647 was observed (88% and 68% overlapping for KB and Rat2, respectively). Colocalization with CTB implies that G7-AF488-NH_2 localizes in the cell with ganglioside GM_1. However, G7-AF488-NH_2 internalized into C6 cells independent of the presence of the GM_1, and G7-AF488-NH_2 did not colocalize with GM_1-pyrene. This indicates that the colocalization observed by us and others (*16*) is probably related to a dendrimer−CTB interaction and is not related to GM_1 interactions or a raft-mediated endocytosis pathway. The LDH assays for C6 cells show no effect upon the presence or absence of GM_1, indicating the GM_1 is also not important for the mechanism of membrane permeabilization and nanoscale hole formation.

A substantial amount of literature exists supporting polycationic endocytosis as a mechanism for the uptake of polycationic polymers into cells (*16, 41, 54−57*). However, many inconclusive and contradictory experiments can be found in the literature, and the details of the internalization mechanisms have remained elusive. In this paper, we provide direct evidence indicating that a GM_1−dendrimer interaction is not involved in G7-AF488-NH_2 internalization. The best evidence supporting raft-mediated endocytosis for dendrimers, colocalization with CTB, is shown to instead result from a CTB−dendrimer interaction. Our results including nanoscale hole formation in supported lipid bilayers (*23−25*), enzyme leakage and small molecule diffusion in and out of cells (*6, 9*), and G7-AF488-NH_2 internalization at 4 °C do provide an alternative mechanism by which polycationic polymers, and nanoparticles more broadly (*26*), may enter cells: the formation of nanoscale holes in the cell plasma membranes (*8*). The data presented here, and published elsewhere by ourselves and others, do not indicate that the nanoscale hole mechanism should be considered as a replacement for endocytosis mechanisms. Rather, it suggests a competitive process in which both mechanisms are operative. The nanoscale hole hypothesis does provide a straightforward explanation for data that is inconsistent with the endocytosis mechanism, both in this paper and in polycationic polymer endocytosis literature more generally.

Inset spectra are enlarged characteristic peaks of AlexaFluor®488.

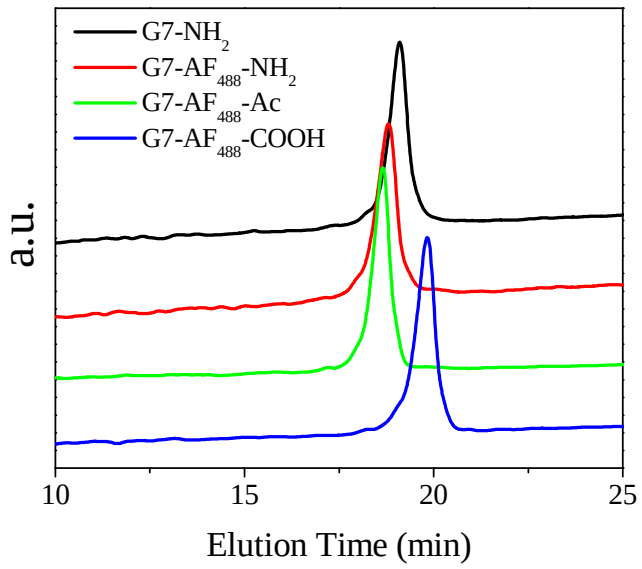

Figure S2. HPLC chromatograms of the dendrimer based conjugates. All the curves are normalized based on the peak intensity of G7-NH_2.

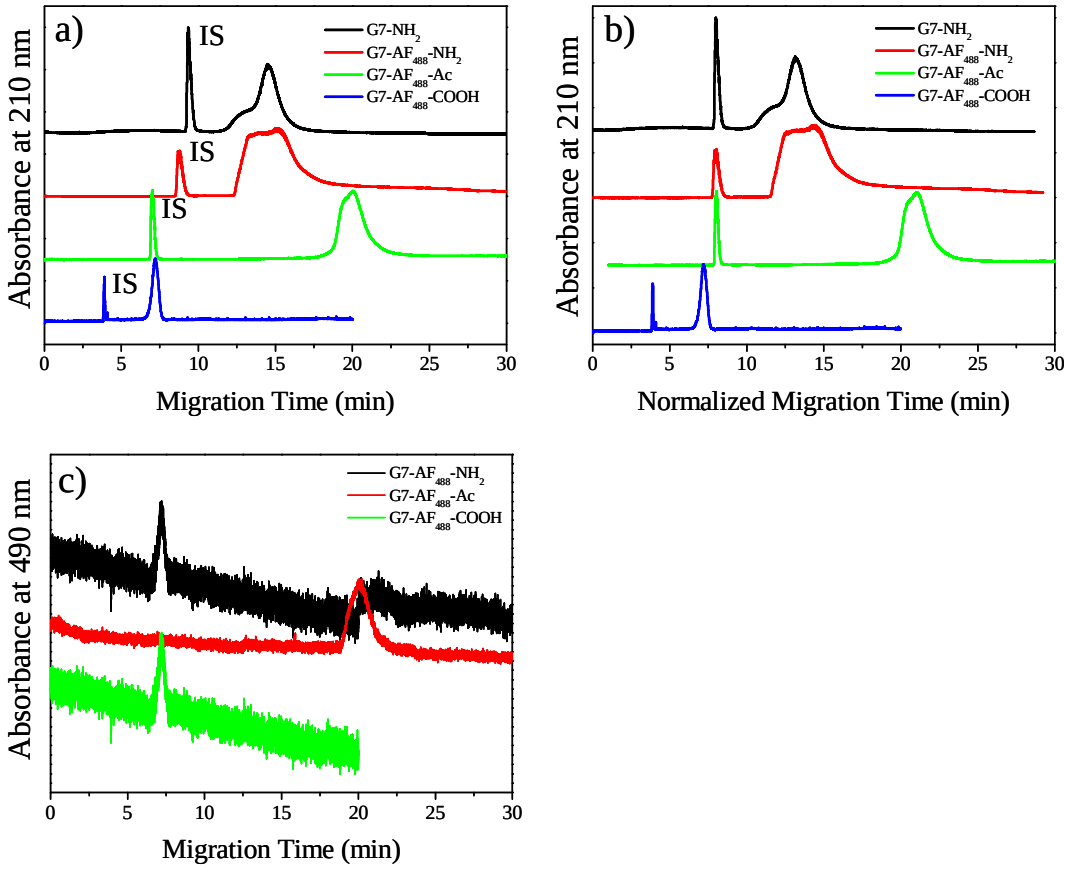

Figure S3. a) CE electropherograms and b) their normalized electropherograms of the dendrimer based conjugates; G7-NH_2, G7-AF488-NH_2, G7-AF488-Ac, and G7-AF488-COOH measured at 210 nm (based on PAMAM dendrimers). Note that 2,3-diaminopyridine (2, 3-DAP) is used as an internal standard (IS) for G7-NH_2, G7-AF488-NH_2, and G7-AF488-Ac. Thus only three curves are normalized in b) based on the IS peak appearance. For G7-AF488-COOH, 4-Methoxybenzyl alcohol (MBA) is used as a neutral marker. Also note that the data of G7-AF488-COOH is shown only up to a 20 min time point because no additional peak was observed thereafter. c) Electropherogram of G7-AF488-NH_2, G7-AF488-Ac, and G7-AF488-COOH measured at 490 nm (based on attached AF488). Peak heights are normalized based on the G7-AF488-NH_2.

Solid Phase 4′-Phosphopantetheinylation: Fungal Thiolation Domains are Targets for Chemoenzymatic Modification

Deirdre Stack, Aisling Frizzell, Karen Tomkins, and Sean Doyle*

National Institute for Cellular Biotechnology, Department of Biology, National University of Ireland Maynooth, Co. Kildare, Ireland. Received February 13, 2009; Revised Manuscript Received June 18, 2009

No data exist on the ability of thiolation domains from fungal non-ribosomal peptide synthetases to undergo 4′-phosphopantetheinylation, using either biotinylated or fluorescently labeled coenzyme A analogues, mediated by 4′-phosphopantetheinyl transferases (PPTase). Yet, this is a key requirement to confirm the amino acid recognition function, and coding potential, of either non-ribosomal peptide synthetases or recombinantly expressed regions of these enzymes (e.g., didomains or modules). Moreover, determination of 4′-phosphopantetheinylation activity remains cumbersome. Here, we demonstrate that a recombinant fungal PPTase catalyzes the solution-phase transfer of either biotin- or fluorescein-labeled 4′-phosphopantetheine region of coenzyme A to a fungal thiolation domain, which is either part of a non-ribosomal peptide synthetase didomain (72 kDa), derived from *Aspergillus fumigatus*, or fused to a non-native protein (glutathione *s*-transferase). Significantly, we demonstrate that this reaction can unexpectedly occur when the target protein (4.4 pmol) is immobilized on a solid surface. These findings (i) confirm that thiolation domains of fungal origin, in native or non-native configuration, can accept modified 4′-phosphopantetheine residues via PPTase-mediated labeling and (ii) illustrate a novel, high-throughput method to determine PPTase activity.

INTRODUCTION

Phosphopantetheinyl transferases (PPTase) catalyze the transfer of 4′-phosphopantetheine from coenzyme A (CoA) to the carrier domain of a range of enzymes involved in non-ribosomal peptide, polyketide, and fatty acid biosynthesis (*1*). Non-ribosomal peptide (NRP) synthetases are produced in the inactive (apo-) form and are post-translationally modified by PPTase to the active (holo-) form by the covalent attachment of CoA-derived 4′-phosphopantetheine to a reactive serine residue in thiolation (T) domains (also referred to as peptidyl carrier protein (PCP)) within the NRP synthetase (*2*). Initial strategies for assaying 4′-phosphopantetheinylation involved the use of [^{3}H]-pantetheine CoA and liquid scintillation counting (*3*), HPLC separation, and analysis of purified proteins (*4*). More recently, the application of protein mass spectrometry for the determination of apoenzyme 4′-phosphopantetheinylation has been reported (*2, 5*). These conventional methods for assaying PPTase activity, however, can be costly and cumbersome and significantly limit high-throughput operations (*6*).

An elegant method of covalently labeling T/PCP domains of NRP synthetases, using biotinylated or fluorescently labeled CoA, and a recombinant *Bacillus subtilis* encoded PPTase, Sfp, in PPTase-mediated reactions has been described (*6*). These authors used Sfp to catalyze modification of carrier proteins with a single fluorescent or affinity reporter, providing a sensitive means of protein visualization, Western blot identification, and affinity purification. This labeling technique also has utility in the identification of carrier protein domains from lysates of native cultures, as a proportion of carrier proteins in the lysate may be present in an unmodified inactive state. Application of the technique to the 6-deoxyerythronolide B synthase (DEBS) pathway from *Saccharapolyspora erythraea* resulted in the identification of a 150 kDa protein indicative of native DEBS (*6*).

The ability of PPTases to post-translationally modify carrier proteins using low molecular mass chemical labels represents a novel and efficient tool for protein labeling and has significant implications in biomolecular research. This approach has been adapted to fluorescence imaging of cellular events involving transferrin-mediated iron uptake (*7*) where the transferrin receptor 1 (TfR1) was fused to a PCP, and the resultant TfR1-PCP fusion specifically labeled with a fluorophore via the action of Sfp. In an independent study, an 11-residue peptide, DSLE-FIASKLA, predicted to be a suitable target for modification by the *B. subtilis* Sfp was fused to the C- and N-termini of target protein and subsequently labeled with a biotin tag by the PPTase (*8*). The majority of reporter labeling of carrier proteins by promiscuous PPTases have been limited to *in vitro* and cell surface protein labeling (*9*−*11*). A chemoenzymatic route to protein modification *in vivo* using a fluorescent marker has also been reported (*12*). This mechanism centered on the ability of native enzymes present in *E. coli*, CoAA, and CoAD and CoAE to sequentially modify a fluorescent pantetheine analogue to result in a fluorescently labeled CoA analogue. Coexpression of the carrier protein *VibB* and the PPTase Sfp in the presence of the fluorescent pantetheine analogue resulted in the fluorescent modification of the VibB carrier protein *in vivo*.

The PPTase-mediated modification of bacterial pyochelin NRP synthetase carrier proteins PchE and PchF using fluorescein (Fl)-CoA analogues has also been reported (*13*). These *in vitro* 4′-phosphopantetheinylation assays used 2 μM *B. subtilis* Sfp, 300 μM Fl-CoA, and PchE/ PchF carrier proteins at concentrations of 10 and 21 μM, respectively. The detection of the modified carrier proteins in this study was enabled by Fourier transform mass spectrometry whereby mass shifts were observed for reporter labeled peptides.

In vitro 4′-phosphopantetheinylation assays have been used to investigate the effect of inhibitors on PPTase activity (*14*).

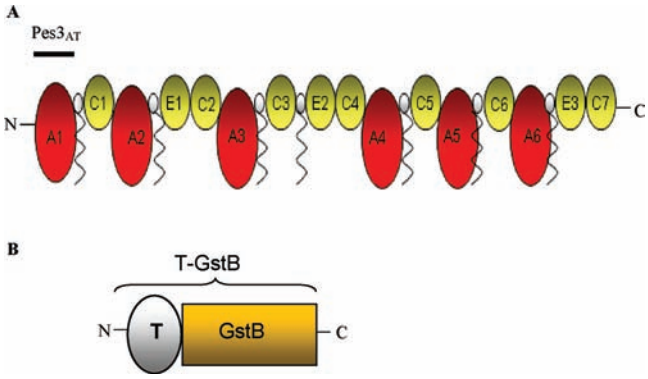

Figure 1. Diagrammatic representation of (A) Pes3 domain architecture, and (B) thiolation (T)-GstB fusion protein. The first adenylation domain and thiolation domain from module 1 of Pes3 ($Pes3_{AT}$) were selected for recombinant protein production. Wavy lines shown in A indicate covalently tethered phosphopantetheine moieties to T domains (shaded). The T-GstB fusion protein is also illustrated showing the Pes3 thiolation domain (T) fused to the GstB protein. The N- and C-termini of both proteins are indicated.

Here, the efficacy of novel anthranilic acid inhibitors of the *B. subtilis* acyl carrier protein synthase (AcpS), which catalyzes the transfer of 4′-phosphopantetheinyl group from CoA onto a conserved serine residue present on an *E. coli* acyl carrier protein (ACP), was assessed and found to exhibit IC_{50} (μM) values of 0.82−32.3. The effect of these inhibitors was determined in a solution phase assay format, which involved incubation of the AcpS (a PPTase) in the presence of a GST-linked ACP carrier protein and a biotin-CoA reporter analogue at room temperature. Detection of the biotin-labeled ACP was achieved by an overnight incubation with streptavidin−allophycocyanin conjugate followed by time-resolved fluorescence detection.

A PPTase from *Aspergillus fumigatus* has recently been expressed in, and purified from, recombinant baculovirus infected *Spodoptera frugiperda*$_9$ (Sf_9) insect cell supernatants. Subsequent mass spectrometric detection of a 4′-phosphopantetheinylated peptide confirmed that this secreted PPTase post-translationally modified a recombinant NRP synthetase T domain from *A. fumigatus* Pes1 in the presence of CoA (*2*). To date, the compatibility of this fungal PPTase has not been demonstrated with modified CoA derivatives; moreover, limited amounts of the secreted PPTase has hindered complete enzyme characterization, and the assay systems for detection of 4′-phosphopantetheinylation are cumbersome and time-consuming.

EXPERIMENTAL METHODS

Bioinformatic Analysis. Preliminary sequence data were obtained from The Institute for Genomic Research Website at http://www.tigr.org. The unannotated genome of *Aspergillus fumigatus* was initially investigated to identify open reading frames corresponding to novel NRP synthetases. One open reading frame, which encoded a putative NRP, was identified and was subsequently termed *pes3* (Figure 1).

Fungal DNA Isolation and PCR Amplification. *A. fumigatus* strain ATCC 26933 was grown (250 mL cultures) at 37 °C in minimal essential medium (MEM) (5% (v/v) containing fetal calf serum (FCS)) for 2 days. Genomic DNA was isolated by crushing fungal mycelia in liquid N_2 followed by phenol/chloroform extraction, washing with 70% (v/v) ethanol and final DNA resuspension in 10 mM Tris-HCl, 1 mM EDTA pH 8.0 (200 μL). PCR was carried out using Accu*Taq* LA polymerase (Sigma) using a total of 5 ng of genomic DNA per PCR reaction. PCR reactions also included 10× Accu*Taq* reaction buffer, 0.25 μM of each dNTP, 1.0 μM forward and reverse primer (Table 1) in a total volume of 20 μL. PCR reactions comprised an initial step of 60 s denaturation at 95 °C, followed by 30 cycles consisting of 60 s at 95 °C, 30 s at 55 °C, 90 s at 72 °C, and finally 360 s at 72 °C. Amplicons were analyzed by agarose gel electrophoresis and visualized using an Eagle-Eye II digital still video system (Stratagene, CA, USA). DNA sequence analysis was carried out on a commercial basis by MWG Biotech (Germany).

Table 1. Oligonucleotide Primers Designed for Directional Cloning of *pes3*$_{AT}$ and *T/PCP* Region Sequences into the pProEx-GstB Expression Vector

Cloning and Expression of the Nonribosomal Peptide Synthetase Gene Fragment, *pes3*$_{AT}$. The *pes3*$_{AT}$ amplicon, which is derived from the 5′ end of the entire *pes3* gene (Figure 1), was initially cloned into the TOPO cloning vector and subsequently cloned into pProEx expression vectors (Invitrogen) according to the manufacturer's instructions. pProEx:*pes3*$_{AT}$, the expression vector containing the region encoding the initial AT didomain of *pes3* (*A. fumigatus pes3*$_{AT}$) (Figure 1), was transformed into *E. coli* according to the manufacturer's guidelines (Invitrogen). Protein expression was induced by the addition of isopropyl β-D-1-thiogalactopyranoside (IPTG; 0.6 mM final concentration) and monitored by SDS-PAGE, Western blot analysis using monoclonal antibody reactivity against a His_6 fusion peptide, and MALDI-ToF mass spectrometry (*15*).

Recombinant $Pes3_{AT}$ Purification and Refolding. Recombinant $Pes3_{AT}$ was purified under denaturing conditions using Ni-NTA metal-chelate affinity chromatography in the presence of 6 M guanidine−HCl. Purified recombinant $Pes3_{AT}$ (250 μg/mL) in 50 mM sodium carbonate pH 9.4 containing 6 M guanidine−HCL was serially dialyzed into 50 mM sodium carbonate pH 9.4 containing 8 M urea, then 4 M urea, followed by dialysis into 50 mM sodium carbonate buffer pH 9.4 to facilitate solubilization.

Generation of Recombinant Fusion Protein (T-GstB) Containing the $Pes3_{AT}$ Derived Thiolation Domain. The region encoding the thiolation (PCP) domain from *pes3*$_{AT}$ was fused to *A. fumigatus* glutathione s-transferase B (*gstB* (*16*)) in order to assess the utility of the domain for non-native protein labeling (Figure 1). PCR cloning primers incorporated *Eco*RI and *Hind*III restriction sites to facilitate PCR amplification and directional subcloning of the T region (Table 1). This amplicon (196 bp) was subsequently digested with *Eco*RI and *Hind*III and ligated to the pProEx-*gstB* expression vector (*16*), which had also been digested with *Eco*RI and *Hind*III. The expression vector containing T-GstB was then transformed into *E. coli* DH5α according to refs 16 and 17. Protein expression was induced by the addition of IPTG (0.6 mM final concentration) and monitored by SDS-PAGE and Western blot analysis. Purification of the T-GstB fusion protein was carried out as previously described (*2*).

PPTase Extraction from Infected (Sf_9) Insect Cells. Sf_9 insect cells (5×10^7), previously infected with recombinant baculovirus encoding PPTase (*2*), were resuspended in Ppant buffer (5 mL; 75 mM Tris-HCl, 5 mM dithiothreitol (DTT), and 10 mM $MgCl_2$ pH 8.0) and sonicated (Bandelin Sonopuls, Progen Scientific Ltd., UK) for 3 × 5 s at a maximum power for 5 min with 30 s second intervals on ice. The resultant cell lysates were centrifuged at 10 000*g* for 10 min at 4 °C. The supernatants were removed and analyzed for the presence of PPTase by Western blot analysis. The concentration of protein present in the cell lysate supernatants was determined by

Bradford analysis and the supernatants divided into 0.5 mL aliquots and stored at −20 °C for further use.

For purification of intracellular PPTase, infected Sf_9 insect cells (5×10^7) were resuspended in lysis buffer (5 mL; 50 mM NaH_2PO_4, 300 mM NaCl, 10 mM imidazole pH 8.0) containing 0.05% (w/v) sodium deoxycholate and sonicated (Bandelin Sonopuls, Progen Scientific Ltd., UK) for 3×5 s at a maximum power for 5 min with 30 s intervals on ice and the resultant lysates centrifuged at 10 000*g* for 10 min at 4 °C. Purification proceeded under native conditions using Ni-NTA metal-chelate affinity chromatography. Optimal protein yields were obtained using an optimized batch purification approach which entailed the incubation of the PPTase lysate to the Ni-NTA resin for 2 h with gentle inversion at 4 °C. Subsequently, the protein/resin complex was packed into a column to facilitate washing and elution steps. Purified PPTase was eluted with 250 mM imidazole and subsequently dialyzed into Ppant buffer.

Coenzyme A Analogue Synthesis and Solution Phase PPTase Activity Analysis. Coenzyme A (CoA) was covalently labeled through an available sulfhydral group by reaction with either maleimido-dPEG$_4$-biotin (MB) (Quanta BioDesign Ltd., Ohio, USA) or 5′-iodoacetamidofluorescein (Sigma-Aldrich) according to ref 6 with modifications (Supporting Information). All reactions were allowed to proceed on ice for 30 min, followed by 10 min incubation at room temperature, and terminated by addition of 1 M DTT (1 μL). 4′-Phosphopantetheinylation reactions using PPTase and recombinant $Pes3_{AT}$ were carried out as follows: Reaction mixtures for the *in vitro* 4′-phosphopantetheinylation assay contained $Pes3_{AT}$ (4.4 μM), PPTase (0.08 μM), biotin-CoA (8.4 μM) in 75 mM Tris-HCL, 5 mM DTT, and 10 mM $MgCl_2$, pH 8.0 (final volume: 100 μL). Reaction mixtures were incubated at 37 °C for 1 h. After incubation, reactions were terminated by the addition of 10% (w/v) trichloroacetic acid (900 μL) and centrifuged at 10 000*g* for 10 min. Pellets were resuspended in 1 M Tris-HCl pH 8.0 and analyzed by SDS-PAGE and Western blot analysis, using direct probing with streptavidin−horseradish peroxidase (HRP) (1/500) and ECL chemiluminescent substrate (Pierce Biotechnology), to visualize biotinylated $Pes3_{AT}$. Fluorescence detection was also undertaken by directly scanning SDS-PAGE gels, when fluorescein-CoA (Fl-CoA) (*6*) was employed instead of biotin-CoA (*6*), using a Typhoon variable mode imager (GE Healthcare) at excitation and emission wavelength at 488 and 520 nm, respectively. Scanned gels were subsequently stained with Coomassie Brilliant Blue R. Alternatively, reaction mixtures were directly added to Nunc Maxisorb microwells (1 h), washed using phosphate buffered saline 0.05% (w/v) Tween-20 (PBST), and fluorescence detected using a plate reader (Bio-Tech, Synergy HT) with excitation and emission values of 490 and 520 nm, respectively.

Microwell Coating with Recombinant $Pes3_{AT}$, T-GstB, or GstB for Use in Solid Phase 4′-Phosphopantetheinylation Assays. Microtiter plates were coated with purified recombinant $Pes3_{AT}$ (2 μg/mL) diluted in 50 mM sodium carbonate buffer pH 9.6 containing 0.01% (w/v) sodium dodecyl sulfate (100 μL/well). Plates were incubated at 37 °C for 2 h and washed twice with PBST (200 μL). Blocking solution (1% (w/v) bovine serum albumin and 10% (w/v) sucrose in 50 mM sodium carbonate buffer pH 9.6; 200 μL/well) was applied to the wells and stored at 4 °C overnight. Blocking solution was decanted from plates, and any residual solution was removed by tapping the plate upside down onto adsorbent paper and transferring the plate to a 37 °C incubator for 1 h prior to use. Microwells were also individually coated with the T-GstB and GstB, respectively (5 μg/mL), for subsequent use in the solid phase 4′-phosphopantetheinylation assays. Microwell coating of T-GstB and GstB and subsequent 4′-phosphopantetheinylation assays were carried out as described for $Pes3_{AT}$.

Solid Phase 4′-Phosphopantetheinylation Using Biotin-CoA. Reactants were prepared in triplicate in 1.5 mL microfuge tubes as outlined in Table 2. Aliquots (100 μL) of each sample were placed in wells of 96-well plates (Nunc Maxisorb) which had been previously coated with $Pes3_{AT}$ (2 μg/mL). Plates were incubated for 1 h at room temperature to facilitate enzymatic reaction. Plates were then washed twice with PBST. Streptavidin−HRP (1/2000 dilution; 100 μL/ well) was added and plates incubated at 37 °C for 1 h. Plates were washed 4 times with PBST. Excess liquid was removed from the wells by tapping the plate out on adsorbent paper. Substrate (3,3′,5,5′-tetramethylbenzidine; TMB; 100 μL/well) was applied to the wells and left to develop for 10 min at room temperature. To terminate the reaction, 1 N H_2SO_4 (100 μL) was added to the wells, and the absorbance values read at 450/630 nm using a plate reader (Bio-Tech, Synergy HT).

Solid Phase 4′-Phosphopantetheinylation Using Fl-CoA. Reactants were prepared in triplicate in 1.5 mL microfuge tubes as outlined in Table 3. Aliquots (100 μL) of each sample were placed in wells of black 96-well plates (Nunc Maxisorb) which had been previously coated with $Pes3_{AT}$ (2 μg/mL). Plates were incubated for 1 h at room temperature in the dark while the enzymatic reaction occurred. Plates were then washed twice with PBST and excess liquid removed by tapping the plates on adsorbent paper. Fluorescence was detected using a plate reader (Bio-Tech, Synergy HT) with excitation and emission values of 490 and 520 nm, respectively.

PPTase Characterization Using Solid Phase 4′-Phosphopantetheinylation Assay. Temperature and pH optima, along with PPTase reaction time, were determined. In addition, the effect of protease inhibitors (phenylmethylsulfonyl fluoride;

PMSF) inclusion on PPTase cell lysate stability was investigated. Student's *t* test was used to assess the statistical significance of relevant results. Absorbance values for control lysate (lacking PPTase) were subtracted from PPTase lysates for calculation of relative PPTase activity (%). The mean absorbance value for purified PPTase was set at 100% with all other values (PPTase lysate and biotin-CoA controls) expressed as a percentage of this.

RESULTS

Recombinant Protein Expression, Purification, and Solubilization. $Pes3_{AT}$ was found to be highly insoluble under nondenaturing conditions (data not shown) and was solubilized by addition of 6 M guanidine−HCl containing 1 mM DTT to a final concentration of 30 mg/mL or 5 mg/g cells. SDS-PAGE analysis and Western blot analysis confirmed the required purity of $Pes3_{AT}$ (Figure 2). The 72 kDa $Pes3_{AT}$ band observed on the Coomassie stained gel was excised and subjected to MALDI-ToF mass spectrometry. Resultant tryptic digest peptide monoisotopic *m*/*z* values (Table 4), compared to those of an *in silico* digest of $Pes3_{AT}$, represented 20% sequence coverage thereby providing conclusive confirmation of $Pes3_{AT}$ identity. $Pes3_{AT}$ was solubilized under nondenaturing conditions by dilution into Ppant buffer containing 8 M urea (4 mL) at 0.5 mg/mL $Pes3_{AT}$ followed by serial dialysis into Ppant buffer (final concentration: 0.41 mg/mL (5.75 μM)). This solubilized $Pes3_{AT}$ preparation was aliquoted and stored at −20 °C for subsequent use. The 36 kDa T-GstB fusion protein was purified from *E. coli* cell lysates resulting in a T-GstB yield of 13 mg/mL or 5 mg/g cells (Figure 2).

Following infection with recombinant baculovirus encoding *A. fumigatus* PPTase, *Spodoptera frugiperda* insect cell lysates were prepared by sonication in the presence of 0.05% (w/v) sodium deoxycholate in Ppant diluent. Purified PPTase was obtained by incubation with Ni-NTA affinity resin for 2 h followed by elution with 250 mM imidazole and dialysis into Ppant diluent (yield: 0.33 mg/10^8 cells) (Figure 3).

Labeled CoA Conjugate Synthesis. Biotin-CoA conjugates were prepared by reacting MB with CoA to form a stable thioether-mediated conjugate for subsequent assay development. Prior to addition of free DTT to scavange any unreacted MB, a new method was deployed to determine the efficiency of biotin−CoA conjugate formation, which involved determination of residual CoA using aldrithiol-4 (4,4′-dithiodipyridine) reagent (Supplementary information). This analysis confirmed ef-

fectively 90%+ efficiency of biotin-CoA conjugate synthesis and extends the utility of aldrithiol-4 and other reagents used for thiol group determination (*18*). Previously, identical biotin-CoA analogues were synthesized, the unincorporated biotin reporter extracted via the use of scavenger resins, and the resultant biotin-CoA reporter subsequently used for the high-sensitivity detection (100 pg) of the biotin labeled recombinant VibB carrier protein domain (*6*). However, we observed minimal background protein modification once DTT was added to biotin-CoA conjugates, which implies that removal of unreacted MB may not always be necessary. A fluorescently linked CoA analogue was also synthesized using 5′-iodoacetamidofluorescein (5′-IAF), which alkylates the sulfhydryl group of CoA. Fluorescent detection offers the potential advantage of direct analysis of labeled proteins without the need for enzyme conjugates and chemiluminescent substrates (*19*). The production of fluorescein-CoA was confirmed by TLC analysis; however, evidence of unreacted 5′-IAF in the fluorescein-CoA sample was also observed (data not shown). As with biotin-CoA conjugates, it was found that subsequent addition of DTT eliminated nonspecific fluorescent labeling of target proteins. In addition, RP-HPLC analysis was also used to detect the production of fluorescein-CoA conjugates with the appearance of a new peak with a lower retention time of 17.0 min for the fluorescein-CoA test specimens which is likely due to the higher polarity of Fl-CoA molecule compared to 5′-IAF (data not shown).

4′-Phosphopantetheinylation of $Pes3_{AT}$ with Biotin- and Fluorescein-CoA is Mediated by PPTase. $Pes3_{AT}$ was subject to specific 4′-phosphopantetheinylation by PPTase present in insect cell lysates (Figure 4a). Here, modification of the $Pes3_{AT}$ (4.4 μM) was clearly detectable using PPTase-containing insect cell lysates (17−1700 μg/mL total protein), with a weak signal, corresponding to specific 4′-phosphopantetheinylation, at 3 μg/mL total cell protein. No 4′-phosphopantetheinylation was detectable in the presence of control insect cell lysate, thereby providing confirmation that modification of $Pes3_{AT}$ with biotin-CoA was mediated specifically by PPTase and not as a result of direct nonspecific labeling of $Pes3_{AT}$ with residual MB. Omission of $Pes3_{AT}$ from the reaction likewise produced a negative result, which confirmed that proteins in the insect cell lysate were not labeled nonspecifically with biotin-CoA (Figure 4a). Replacement of biotin-CoA with fluorescein-CoA as the PPTase substrate also facilitated post-translational modification of $Pes3_{AT}$ (Figure 4b). Here, $Pes3_{AT}$ (4.44 μM) was labeled using both purified PPTase (0.08 μM) and PPTase present in insect cell lysate (34 μg/mL total cell protein). No 4′-phosphopantetheinylation was detectable in the absence of either PPTase or $Pes3_{AT}$. Overall, these observations confirm that the $Pes3_{AT}$ thiolation domain can be post-translationally modified by PPTase with either biotinylated or fluorescently labeled CoA.

High-Throughput Detection of 4′-Phosphopantetheinylation. Reaction mixtures containing combinations of purified PPTase, $Pes3_{AT}$, and fluorescein-CoA were incubated in solution for 1 h and subsequently transferred to black microtiter plates,

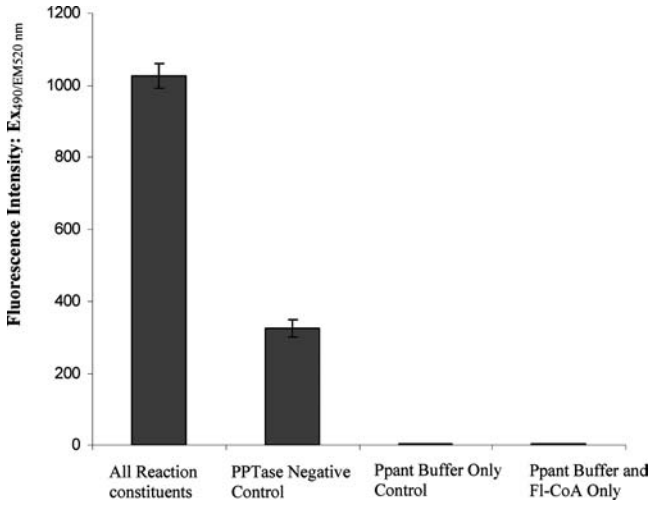

Figure 5. Solid phase 4′-phosphopantetheinylation assay using Fl-CoA. After solution phase incubation, 4′-phosphopantetheinylation reactions (and appropriate controls) were coated on black microtiter plates and subsequently analyzed by fluorescence with excitation and emission at 490 and 520 nm, respectively. Results given represent the mean (±SE) of the experiment performed in triplicate. All reaction constituents: $Pes3_{AT}$; PPTase; Fl-CoA. PPTase negative control: PPTase absent from reactions. Ppant buffer control: Ppant buffer only. Ppant buffer and fluorescein-CoA (Fl-CoA) only: $Pes3_{AT}$ and PPTase absent from reactions.

incubated for a further 1 h, followed by washing with PBST (2×) to remove unbound fluorescein-CoA. Fluorescent analysis at 490/520 nm (ex/em) (Figure 5) indicated that fluorescently labeled $Pes3_{AT}$ had bound to the plate and was detectable by fluorescence analysis. Fluorescence labeling was predominantly mediated by PPTase modification; however, nonspecific labeling was also evident (up to 25%) in the absence of PPTase. No fluorescence was detectable in the absence of $Pes3_{AT}$.

For technical reasons, direct detection of biotinylated $Pes3_{AT}$ on microwells was not possible as described for fluorescent $Pes3_{AT}$ above (data not shown). However, 4′-phosphopantetheinylation was possible using microwells precoated with $Pes3_{AT}$ (4.4 pmol), and stabilized by BSA addition (Figure 6a). To ensure that biotin labeling of the bound $Pes3_{AT}$ protein was the result of PPTase activity and not due to the presence of insect cell proteins present in the crude cell lysate, control reactions were included whereby uninfected insect cell lysates (at identical total protein concentration) were incubated in the $Pes3_{AT}$ coated microwells in the presence of biotin-CoA, and resultant absorbance values compared to those obtained from incubation with PPTase insect cell lysate. Background activity was apparent in uninfected cell lysate controls compared to the biotin-CoA and Ppant buffer controls, but these absorbance values were only 16−25% of those obtained for the wells incubated with PPTase insect cell lysate (mean $A_{450/630\ nm}$: 1.7), thereby confirming that labeling of $Pes3_{AT}$ was due to PPTase present in the insect cell lysate. Consequently, PPTase cell lysate was used for subsequent analysis of PPTase activity using this assay format (Figure 6b). Control insect cell lysate (uninfected cells) was also included in subsequent analysis, and absorbance values obtained for these samples subtracted from the PPTase cell lysate specimens to correct for any nonspecific labeling that may be a result of native insect cell proteins. PPTase-mediated fluorescein-CoA modification of immobilized $Pes3_{AT}$ has also been demonstrated (Figure 6c). Here, nonspecific modification (approximately 25% of the PPTase reaction) was also evident.

Purified PPTase from insect cells lysates also functions in the solid phase 4′-phosphopantetheinylation reaction (Figure 6d). No significant difference was observed between purified PPTase and PPTase cell lysate (at an equivalent dilution; $P = 0.56$), whereas significantly greater 4′-phosphopantetheinylaiton activity was evident compared to biotin-CoA only negative control ($P = 0.00036$).

Fungal Thiolation Domain Facilitates Labeling of Non-Native Substrate Proteins. T-GstB was post-translationally modified by 4′-phosphopantetheinylation with biotinylated 4′-phosphopantetheine when immobilized in microwells (Figure 7). Moreover, background signal arising from GstB negative control was less than 5% of overall T-GstB signal, demonstrating conclusively that the discrete thiolation domain of T-GstB was specifically modified by PPTase activity, even when fused to a non-native protein (i.e., GstB).

Characterization of PPTase Activity. Following the establishment of the *in vitro* 4′-phosphopantetheinylation assay in a solid phase (96 well plate) format using biotin-CoA and PPTase insect cell lysates, temperature, pH optima, and reaction time-course were investigated. Analysis of these data revealed that optimal PPTase activity was evident at 24 °C, with reduced 4′-phosphopantetheinylation observed at 4, 37, and 50 °C (Figure 8a). A statistically significant higher PPTase activity was observed when protease inhibitors were included in the insect cell lysates. This result implies that, in the absence of protease inhibitors, proteases present in the crude insect cell lysate may degrade PPTase and therefore lower the extent of post-translational modification (Figure 8a). The overall affect of pH on PPTase activity is shown in Figure 8b whereby background absorbance values obtained from the insect cell lysate control samples were subtracted from the absorbance values obtained from PPTase lysate reactions. From this analysis, it is clear that pH has an effect on the activity of PPTase with optimal 4′-phosphopantetheinylation occurring at pH 8.0. 4′-Phosphopantetheinylation is 75% complete within 1 h, and complete protein labeling is achieved after 3 h reaction (Figure 8c).

DISCUSSION

Despite recent advances in PPTase-mediated labeling of T/PCP or ACP domains of prokaryotic origin, via biotinylated or fluorescently modified CoA analogues, minimal information on this approach for eukaryotic (fungal) T domain modification is available. Moreover, facile determination of PPTase activity has remained a challenge. Here, data are presented which confirm that T domains of fungal origin can be post-translationally modified, both in solution and when immobilized on a solid surface, using a combination of modified CoA analogues and a functional PPTase. We also demonstrate that T domains can be transferred to a non-native protein (GstB) and that this fusion protein (T-GstB) is also a substrate for PPTase-mediated modification. Finally, it appears that the solid phase assay format presents a new strategy for determination of PPTase activity which is faster than current methods and is compatible with high-throughput functionality.

The gene encoding Pes3 represents the largest NRPS open reading frame in the *A. fumigatus* genome. Here, we have expressed the first AT didomain of Pes3 and a T-GstB fusion protein, in *E. coli* at high yields (5 mg/g cells). We have previously cloned and expressed recombinant PPTase in the baculovirus expression system, purified from PBS washes of intact cells by subsequent Ni-NTA chromatography, and shown it to be capable of transferring the Ppant group from CoA to the T domain derived from a distinct *A. fumigatus* NRPS (*pes1*) (*2*). However, in the present work we utilize PPTase, of intracellular origin, which was extracted in high yields (3.33 mg/10^9 cells) and purified by Ni-NTA affinity chromatography. Interestingly, PPTase activity was detectable in crude cell lysates, indicating that enzyme purification is not always essential.

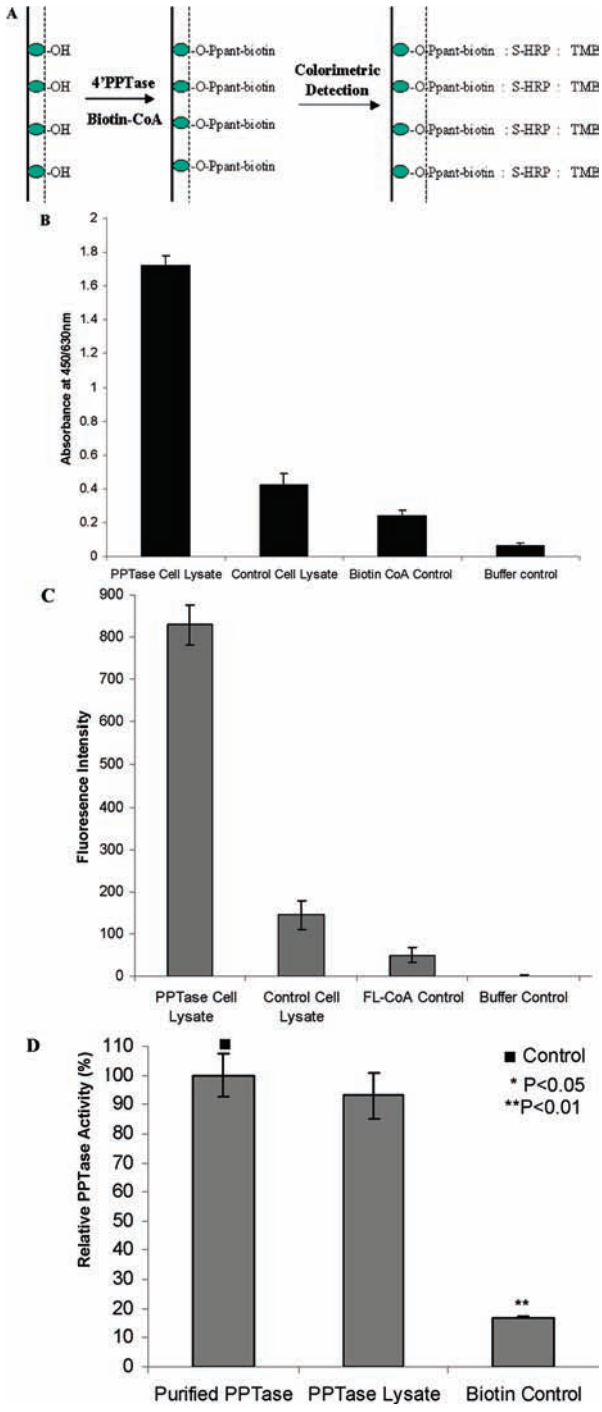

Figure 6. (A) Diagrammatic representation of solid phase 4′-phosphopantetheinylation. Immobilized thiolation domains (e.g., in $Pes3_{AT}$) (green circles) are stabilized by the addition of BSA (dashed line). The reactive serine residue (−OH) on the thiolation domain can then be modified with biotin-CoA in the presence of PPTase. PPTase activity is then indirectly detected by addition of streptavidin−HRP conjugate and TMB substrate. Fluorescein-CoA (Fl-CoA) can be substituted for biotin-CoA followed by subsequent direct fluorescent detection of the labeled thiolation domain. (B) Solid phase 4′-phosphopantetheinylation assay using biotin-CoA. *In vitro* 4′-phosphopantetheinylation assays were carried out on plates coated with $Pes3_{AT}$ (2 μg/mL). Results given represent the mean (±SE) of the experiment performed in triplicate. (C) Solid phase 4′-phosphopantetheinylation assay using fluorescein-CoA. 4′-Phosphopantetheinylation assays were performed in microwells coated with $Pes3_{AT}$ (2 μg/mL). Results given represent the mean (±SE) of the experiment performed in triplicate. (D) Solid phase 4′-phosphopantetheinylation of $Pes3_{AT}$ using purified PPTase (29 μg; 0.7 nmol) and PPTase cell lysate. Results given represent the mean (±SE) of the experiment carried out in triplicate.

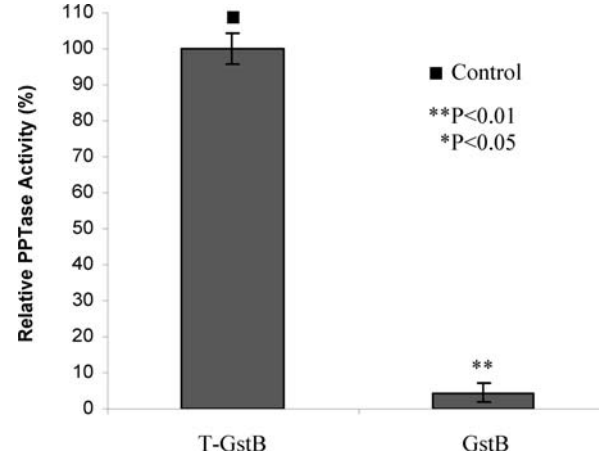

Figure 7. Solid phase 4′-phosphopantetheinylation of T-GstB. Net post-translational modification activity in PPTase cell lysate, toward for T-GstB and GstB, respectively, was calculated by subtracting background signals in control insect cell lysate. Results given represent the mean (±SE) of three individual experiments. Students *t* test was used to calculate *P*-values for the difference between the T-GstB and the GstB ($P = 0.0003$).

To confirm reagent functionality, recombinant $Pes3_{AT}$ was subjected to solution phase biotin- and fluorescein-CoA labeling, respectively, in the presence and absence of PPTase followed by chemiluminescent or direct fluorescence detection (Figure 4). Significantly, $Pes3_{AT}$ (4.4 μM) labeling was observed in all cases in the presence of either purified PPTase or insect cell lysates, which contained impure, but active, preparations of the enzyme. To our knowledge, this is the first demonstration that fungal T domains can be chemoenzymatically labeled with CoA analogues, that crude PPTase preparations can be used to effect *in vitro* 4′-phosphopantetheinylation, and also that the enzyme produced within recombinant baculovirus-infected insect cells is active. Detection of fluorescein-labeled $Pes3_{AT}$ (4.4 μM) was achieved using 7.3 μM fluorescein-CoA and using either 0.08 μM purified PPTase and crude PPTase cell lysate at a concentration of 0.034 mg/mL (estimated to contain 0.92 μM PPTase). Thus, the molar ratios of purified PPTase, carrier protein, and fluorescein-CoA used were approximately 1:55:90. The PPTase mediated modification of the Pyochelin NRP synthetase carrier proteins PchE and PchF using similar fluorescein-CoA analogues has been reported (*13*). The *in vitro* 4′ phosphopantetheinylation assays used in that study, however, used 2 μM *B. subtilis* Sfp, 300 μM fluorescein-CoA, and PchE/PchF carrier proteins at concentrations of 10 and 21 μM, respectively. The molar ratios of PPTase, carrier protein, and fluorescein-CoA in the present study were 1:5−10:150, respectively, similar to fluorescein-CoA-PPTase assay described herein; however, the assay of ref 13 required approximately 5-fold more carrier protein and 25 times more PPTase (Sfp), respectively.

In order to eliminate the time-consuming electrophoretic step associated with labeled carrier protein detection and expedite analysis, we attempted direct immobilization of reaction mixtures to microwells, subsequent to *in vitro* 4′-phosphopantetheinylation followed by visualization and absorbance detection. This approach was unsuitable for use with biotin-CoA reporter analogues as the biotin moiety exhibited high nonspecific binding to microwells thereby masking any possibility of detecting PPTase mediated $Pes3_{AT}$ labeling (data not shown). However, the approach was successfully applied to *in vitro* 4′-phosphopantetheinylation assays using a fluorescein-labeled CoA analogue whereby 3-fold greater fluorescence was detectable in specimens containing PPTase, Fl-CoA and $Pes3_{AT}$ compared to specimens containing Fl-CoA and $Pes3_{AT}$ alone (Figure 5). Although extensive validation of this approach has

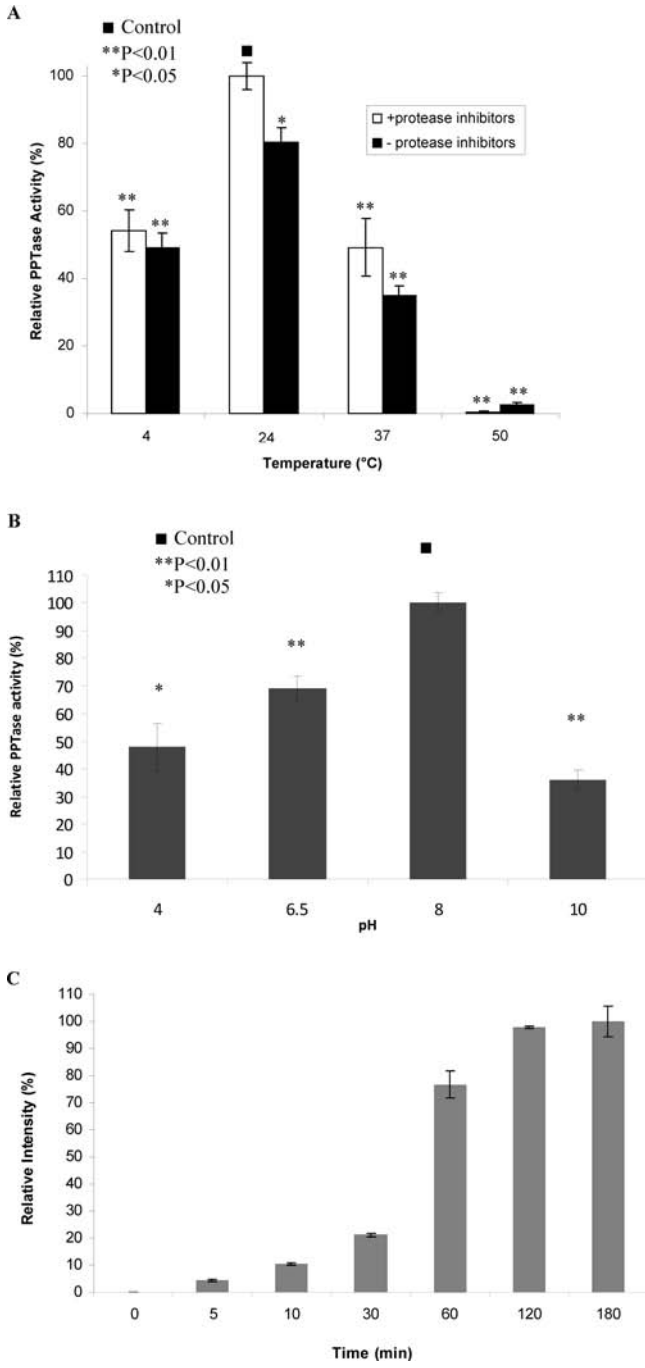

Figure 8. (A) The effect of temperature on PPTase activity in the presence and absence of protease inhibitors. Results given represent the mean (±SE) of three individual experiments. Student's *t* test was used to calculate *P*-values for the difference between the control (24 °C + protease inhibitors) and the following conditions: 4 °C (+/− protease inhibitors ($P = 0.003$; $P = 0.0009$)), 24 °C (− protease inhibitors ($P = 0.03$)), 37 °C (+/− protease inhibitors ($P = 0.005$; $P = 0.0002$)), and 50 °C (± protease inhibitors ($P = 0.00001$; $P = 0.00002$)). (B) The effect of pH on PPTase activity. Results are expressed as percent (%) relative to the highest level, i.e., pH 8.0, and represent the mean (±SE) of three individual experiments. Student's *t* test was used to calculate *P*-values for the difference between the control (pH 8.0) and the following pH conditions: 4.0 ($P = 0.01$), 6.5 ($P = 0.008$), and 10.0 ($P = 0.0003$). (C) The effect of reaction time on PPTase activity. Optimal reaction time is 2 h; however, PPTase-mediated protein modification is up to 75% complete by 1 h.

not been undertaken, we propose that this hybrid assay format, involving solution phase, *in vitro* phosphopantetheinylation and reaction product immobilization for fluorescent detection, may find future application.

A number of groups have confirmed that proteins fused to either T domains of bacterial origin, or peptides derived from phage display, can be covalently tethered to immobilized CoA, and this observation has been proposed as a new strategy for protein array preparation (*9, 20*). However, to date, labeled pantetheine transfer to immobilized T domains, in either native or non-native configuration, has not been demonstrated. The 75 amino acid T domain used in our study is equivalent in size to other fungal and bacterial T domains but considerably longer than ybbR-like tags introduced by other groups (*8*). The use of the T domain of fungal (*A. fumigatus*) origin as a target for C-terminal labeling of $Pes3_{AT}$ and N-terminal labeling of T-GstB, respectively, suggests that domain acceptor function is independent of position in the substrate protein. We have observed that purified $Pes3_{AT}$ or T-GstB can be stably and irreversibly attached to microwells, blocked to minimize nonspecific binding, and followed by PPTase-mediated biotinylation or fluorescent labeling using either biotin-CoA or fluorescein-CoA. This finding represents a new strategy for assessment of both T domain functionality and PPTase activity determination and potentially for the assessment of PPTase/AcpS/Sfp inhibitors, which have been proposed as potential drug targets (*14*).

Our data indicate that 0.33 μg (4.4 pmol) $Pes3_{AT}$ can be detected using 29 μg (0.7 nmol) of recombinant PPTase (in either purified or crude form) in the presence of biotin-CoA via solid phase phosphopantetheinylation. It also suggests that any conformational restriction due to $Pes3_{AT}$ immobilization does not significantly impede phosphopantetheinylation. Moreover, chemoenzymatic detection is statistically significant ($P < 0.05$) over protein labeling in the absence of recombinant PPTase. Importantly, we also demonstrate that the T domain derived from $Pes3_{AT}$ can be fused to an unrelated protein and also be subjected to solid phase phosphopantetheinylation. This confirms the discrete functionality of the T domain and strongly suggests that they can be used as a fusion partners for unrelated proteins to facilitate targeted labeling procedures.

In order to optimise the *in vitro* 4′-phosphopantetheinylation assay and to further characterize PPTase activity, assays were performed at different reaction temperatures. Initial *in vitro* 4′-phosphopantetheinylation assays using the *A. fumigatus* encoded recombinant PPTase (*2*) were carried out at a reaction temperature of 37 °C; however, optimal PPTase activity occurs at 25 °C with 100% increase in the extent of $Pes3_{AT}$ modification observed compared to that at 37 °C. *In vitro* 4′-phosphopantetheinylation assays employing the use of the *B. subtilis* PPTase Sfp, were carried out at room temperature and 30 °C, respectively (*6, 13*). Furthermore, the *in vitro* phosphopantetheinylation assays used to assess the affect of PPTase (AcpS) specific inhibitors on the ability of the *B. subtilis* AcpS to post-translationally modify the ACP carrier protein were also performed at 25 °C (*14*).

Subsequent to determination of optimal PPTase reaction temperature, the effect of pH on PPTase activity was also investigated and revealed that optimal PPTase activity was observed at pH 8.0 (100%), with a significant decrease in PPTase activity to 45%, 65%, and 35% for pH 4.0, pH 6.5, and pH 10.0, respectively. These observations are in accordance with those for the *in vitro* phosphopantetheinylation assays used for *B. subtilis* AcpS type PPTase, which were also carried out at pH 8.0 (*14*). However, a clear pH optimum at pH 6.0 for the *B. subtilis* Sfp type PPTase, with activity reducing to less than 20% of the optimum pH for pH 5.0 and pH 7.0, respectively, has been reported (*3*). Thus, it is clear that optimal reaction conditions should be established for each specific PPTase or equivalent AcpS/Sfp enzyme.

In summary, we have demonstrated that solid phase *in vitro* 4′-phosphopantetheinylation, using either biotin- or fluorescein-CoA substrate analogues, of fungal thiolation domains in native or non-native configuration is possible. Moreover, we have conclusively shown that the solid phase assay format presents a new strategy for determination of PPTase activity, which is superior to current approaches and highly likely to be compatible with high-throughput screening systems for PPTase inhibitor identification. We also suggest that solid phase 4′-phosphopantetheinylation may be compatible with the ongoing search for peptide mimotopes, in part via phage display, of T domain functionality (*21*, *22*).

EXPERIMENTAL METHODS

Determination of thiol availability in Coenzyme A, prior to and post-labeling, using 4,4'-Dithiodipyridine. Coenzyme A solutions were prepared at the following concentrations: 15, 30 and 60 μM. in 50 mM sodium phosphate, 150 mM NaCl, 1 mM EDTA, pH 6.8 (Buffer A). Using Buffer A as a blank at 324 nm, 2 μL aliquot of 4,4'-Dithiodipyridine (11 mg/mL in ethanol) was added to buffer blanks and test specimens respectively. These was slowly mixed by inversion for exactly 1 min and absorbances were determined at 324 nm (A_{324} nm). The same was carried out for labelled CoA preparations (prior to DTT addition). The concentration of thiol (SH) groups was calculated from the A_{324} nm values (Scheme 1). This facilitated the determination of molar ratio of free SH per CoA and this value should theoretically be 1.0. 4,4'-Dithiodipyridine-mediated analysis was also employed to determine residual free thiol groups present in biotin-CoA conjugates (238 μM and 595 μM CoA stock solutions) but diluted to the same CoA concentrations as for free CoA. The molar ratio of free SH per CoA should be 0 assuming conjugation has occurred.

$$[SH]\ (\mu M) = \frac{A_{324}\text{nm (test sample)} - A_{324}\text{nm (blank)}}{0.0198}$$

$$\text{Free SH group per CoA molar ratio} = \frac{\mu M\ SH}{\mu M\ CoA}$$

Scheme 1: Determination of thiol availability in Coenzyme A using 4,4'-Dithiodipyridine.

RESULTS

Biotin-CoA Synthesis and Analysis of the Reaction between Biotin and Coenzyme A. In order to determine biotin-CoA conjugation efficiency, the free thiol group present in CoA was determined. Concentrations of 15 μM, 30 μM and 60 μM

show value approaching 1 free thiol per CoA (Table S1). The same method was used to examine the presence of free thiol groups in biotin-CoA at 1:2 and 1:5 molar ratios of CoA: maleimido-dPEG$_4$-biotin. If 100% conjugation had occurred there should be no free thiol groups present. This was the case for the biotin-CoA at 1:2 and 1:5 molar ratios with reaction efficiency of approximately 95% observed (Table S2; Table S3). Based on the overall results, it appears that the conjugation reaction between maleimido-dPEG$_4$-biotin and CoA is highly efficient, thereby validating the biotin-CoA synthesis method.

Table S1. Determination of thiol/CoA ratio in unconjugated CoA. As expected, one thiol was detectable per CoA.

[CoA]	$A_{324\ nm}$	[SH] (μM)	SH / CoA
60 μm	1.2143	61.32	1.022
30 μm	0.5623	28.39	0.94
15 μm	0.2912	14.70	0.98

Table S2. Determination of thiol/CoA ratio in biotin-CoA prepared with a 1:2 molar ratio of CoA:maleimido-dPEG$_4$-biotin (final CoA concentration: 238 μM). This analysis confirmed 94% efficiency of conjugation.

[CoA]	$A_{324\ nm}$	[SH] (μM)	SH/ Biotin-CoA
60 μm	0.1103	5.57	0.09

EXPERIMENTAL METHODS

Determination of thiol availability in Coenzyme A, prior to and post-labeling, using 4,4'-Dithiodipyridine. Coenzyme A solutions were prepared at the following concentrations: 15, 30 and 60 μM. in 50 mM sodium phosphate, 150 mM NaCl, 1 mM EDTA, pH 6.8 (Buffer A). Using Buffer A as a blank at 324 nm, 2 μL aliquot of 4,4'-Dithiodipyridine (11 mg/mL in ethanol) was added to buffer blanks and test specimens respectively. These was slowly mixed by inversion for exactly 1 min and absorbances were determined at 324 nm (A_{324} nm). The same was carried out for labelled CoA preparations (prior to DTT addition). The concentration of thiol (SH) groups was calculated from the A_{324} nm values (Scheme 1). This facilitated the determination of molar ratio of free SH per CoA and this value should theoretically be 1.0. 4,4'-Dithiodipyridine-mediated analysis was also employed to determine residual free thiol groups present in biotin-CoA conjugates (238 μM and 595 μM CoA stock solutions) but diluted to the same CoA concentrations as for free CoA. The molar ratio of free SH per CoA should be 0 assuming conjugation has occurred.

$$[SH]\ (\mu M) = \frac{A_{324}\text{nm (test sample)} - A_{324}\text{nm (blank)}}{0.0198}$$

$$\text{Free SH group per CoA molar ratio} = \frac{\mu M\ SH}{\mu M\ CoA}$$

Scheme 1: Determination of thiol availability in Coenzyme A using 4,4'-Dithiodipyridine.

RESULTS

Biotin-CoA Synthesis and Analysis of the Reaction between Biotin and Coenzyme A. In order to determine biotin-CoA conjugation efficiency, the free thiol group present in CoA was determined. Concentrations of 15 μM, 30 μM and 60 μM show value approaching 1 free thiol per CoA (Table S1). The same method was used to examine the presence of free thiol groups in biotin-CoA at 1:2 and 1:5 molar ratios of CoA: maleimido-dPEG$_4$-biotin. If 100% conjugation had occurred there should be no free thiol groups present. This was the case for the biotin-CoA at 1:2 and 1:5 molar ratios with reaction efficiency of approximately 95% observed (Table S2; Table S3). Based on the overall results, it appears that the conjugation reaction between maleimido-dPEG$_4$-biotin and CoA is highly efficient, thereby validating the biotin-CoA synthesis method.

Received February 16, 2009; Revised Manuscript Received June 1, 2009

The full therapeutic potential of oligonucleotide (ON)-based agents has been hampered by cellular delivery challenges. Cell-penetrating peptides (CPP) represent promising delivery vectors for nucleic acids, and their potential has recently been evaluated using a functional splicing redirection assay, which capitalizes on the nuclear delivery of splice-correcting steric-block ON analogues such as peptide nucleic acids (PNA). Despite encouraging in vitro and in vivo data with arginine-rich CPP-steric block conjugates, mechanistic studies have shown that entrapment within the endosome/lysosome compartment after endocytosis remains a limiting factor. Previous work from our group has shown that CPP oligomerization greatly improves cellular delivery and increases transfection of plasmid DNA. We now report the chemical synthesis and the evaluation of multivalent CPP−PNA constructs incorporating monomeric ($p53^{mono}$) and dendrimer-like tetrameric ($p53^{tet}$) forms of the p53 tetramerization domain containing peptide, a 10 arginine CPP domain (R10), and a splice redirecting PNA (PNA705). These CPP−PNA conjugates were termed $R10p53^{tet}$-PNA705 and $R10p53^{mono}$-PNA705, referring to their oligomerization state. The present study demonstrates that the splicing redirection efficiency of PNA705 is much greater in the context of the tetrameric $R10p53^{tet}$-PNA705 construct than for the monomeric and occurs at nanomolar concentrations, demonstrating that multivalency is an important factor in delivering PNA into cells.

INTRODUCTION

Oligonucleotide (ON)-based agents have shown great potential in regulating gene expression and are routinely used to carry out functional genomics analyses. However, neither natural nucleic acids nor their chemically modified homologues are taken up efficiently by most cell types. While this challenge is easily circumvented through the use of transfection techniques in cultured cells, the systemic delivery of ONs in experimental animals remains a major limitation. Likewise, clinical trials with antisense ONs have resulted in mixed successes (*1*). Even very potent agents such as siRNAs have led to few clinical trials so far, due to a lack of efficient and nontoxic delivery vectors. Cell-penetrating peptides (CPP) represent good candidates for the intracellular delivery of nucleic acids with short oligoarginine motifs and peptides derived from the HIV Tat protein (Tat 48−60) and the Antennapedia homeodomain (Penetratin) being the most widely cited CPPs. The evaluation of CPPs in delivering functional ONs can best be achieved using the splicing redirection assay proposed by Kole (*2*). The assay is based on the splicing alteration in the β-globin gene in thalassemia. Intronic mutations (such as mutation 705 in intron 2) activate cryptic splice sites in this gene leading to a nonfunctional mRNA. This mutated intron has been introduced into the coding region of a reporter luciferase gene, and the construct has been stably transfected into HeLa cells. Masking the 705 mutated site with an antisense ON results in the reorientation of the splicing machinery toward intron elimination and to luciferase expression. The assay is easy to implement (assessing splicing by luminescence or by RT-PCR) and provides signals covering a high dynamic range. It has now been adopted by many groups in the field of drug delivery as a convenient way to compare the performance of various CPP carriers in delivering ON analogues (*3*−*6*). A broad range of ON analogues has been synthesized to date that do not recruit RNase H. However, peptide nucleic acids (PNA) and phosphorodiamidate morpholino oligomer (PMO) analogues are particularly suited as therapeutic agents since they are RNase H incompetent, are metabolically stable, and hybridize to RNA with high affinity and specificity. Initial assays with a panel of CPPs including Tat 48−60, Penetratin, oligo-Arg, or oligo-Lys have been disappointing, since no efficient splicing correction could be demonstrated in the absence of endosomolytic agents at submicromolar CPP−ON conjugate concentrations. By contrast, encouraging data have been obtained with an arginine-rich peptide named $(RXR)_4$-PNA or -PMO (where X stands for an unnatural aminohexanoyl moiety) (*7*), with R_6-Penetratin-PNA (in which an Arg-rich tail has been appended to Penetratin) (*8*), and with the subsequent serum-stable Pip-PNAs (*9*). Dose-dependent and sequence-specific splicing correction has been achieved at micromolar or slightly lower concentrations in the absence of endosomolytic agents. Importantly, these PMO and PNA conjugates of Arg-rich CPPs also lead to splicing redirection in murine models of Duchenne muscular dystrophy (DMD) (*10*, *11*). Such peptides are being evaluated for clinical applications, such as DMD, but it remains unclear at present whether the CPP-PMO doses required to be administered to humans will avoid potential liver and other toxic effects.

As far as mechanisms are concerned, it is now generally considered that CPP-PNA and PMO conjugates are taken up by endocytosis after binding to cell surface heparan sulfates.

Structure activity (SAR) and mechanistic studies currently in progress with conjugates based on both $(RXR)_4$ and Pip CPP types have confirmed that entrapment within endocytic vesicles remains a major limitation. Studies of $(RXR)_4$-PMO intracellular distribution, in particular, clearly demonstrated that splicing redirection activity was due to the low amount of material that escaped from entrapment within endocytic vesicles.

The multivalent display of peptides harboring arginine- or lysine-containing CPP import sequences has been shown to dramatically enhance the cellular uptake levels of associated cargoes (*12*, *13*). Specifically, synthetic branched peptides incorporating CPP sequences (loligomers) (*12*, *14*, *15*) as well as recombinant peptide constructs containing a self-assembling motif such as the p53 tetramerization domain (*13*, *16*) have been shown to carry more efficiently drugs and chromophores into cells than the equivalent concentration of monomeric CPP homologues (*15*). Similarly, the condensation of such multivalent CPP dendrimers with plasmids results in particle complexes displaying excellent efficiency in entering targeted cells (*14*). In this report, we discuss the chemical assembly and evaluation of multivalent CPP−PNA constructs incorporating monomeric and tetrameric forms of a $p53^{tet}$ domain containing peptide ($p53^{tet}$), a 10 arginine CPP domain (R10), and a splice redirecting PNA (PNA705). These CPP−PNA conjugates were termed R10$p53^{tet}$-PNA705 and R10$p53^{mono}$-PNA705 constructs, referring to their oligomerization state. The present study demonstrates that multivalency is an important factor in delivering PNA into cells.

EXPERIMENTAL PROCEDURES

Synthesis of PNA. The N-terminal nitropyridyl (Npys) cysteine-containing PNA705 (NH_2-Cys(NPys)-Lys-CCTCTTACCTCAGTTACA-Lys-amide) was synthesized on a Liberty microwave peptide synthesizer (CEM) by the Fmoc/Bhoc solid-phase method as previously described using monomers obtained from Link Technologies Ltd. (Lanarkshire, Scotland) or Panagene Inc. (Daejeon, Korea), purified by HPLC, and analyzed by MALDI-TOF mass spectrometry on a Voyager DE Pro BioSpectrometry workstation as previously described (*9*, *17*).

Synthesis and Characterization of R10p53 Peptides. The peptides R10$p53^{tet}$ (R_{10}GEYFTLQIRGRERFEMFRELNEALELKDAQAGCGH$_6$) and R10$p53^{mono}$ (R_{10}GEYFTLQIRGRERFEMFREPNEALELKDAQAGCGH$_6$) were assembled by Fmoc solid-phase peptide synthesis as previously described (*16*). A single mutation of Leucine 344 to Proline (underlined residue) prevents tetramerization. A single cysteine residue was also introduced at their C-terminal end for the subsequent directional coupling of PNA. Peptides were purified to homogeneity by reverse-phase HPLC, and their sequences were confirmed by MALDI-TOF masses: R10$p53^{tet}$, calculated 6363.3, found 6361.2; R10$p53^{mono}$, calculated 6347.2, found 6345.2. The oligomerization status of R10p53 peptides was confirmed by cross-linking these peptides with glutaraldehyde followed by SDS-PAGE, which reveals the presence of a distinctive ladder of protein bands (monomer, dimer, and oligomers of p53 peptides) in the case of tetrameric $p53^{tet}$-containing peptides (Figure 1) as described elsewhere (*18*).

Peptide−PNA Conjugates. Single cysteine residues were inserted in both PNA 705 and R10p53 peptides to covalently link peptide and PNA via a disulfide bond (Table 1) as previously described, using a 2.5-fold excess of peptide component over NPys PNA component. Conjugate purifications were carried out by reverse-phase HPLC and analyzed by MALDI-TOF mass spectrometry as described elsewhere (*9*, *17*). MALDI-TOF masses: R10$p53^{tet}$-PNA705, calculated 11487.3, found 11485.4; R10$p53^{mono}$, calculated 11471.3, found 11467.0.

Cells and Cell Culture. HeLa pLuc705 cells were stably transfected with pLuc/705 plasmid in which the coding sequence of the luciferase gene is interrupted by the mutated intron 2 of the human β globin gene. Cells were cultured at 37 °C, 5% CO_2, as exponentially growing subconfluent monolayers in DMEM medium (Gibco, Cergy-Pontoise, France) supplemented with 10% fetal bovine serum (FBS).

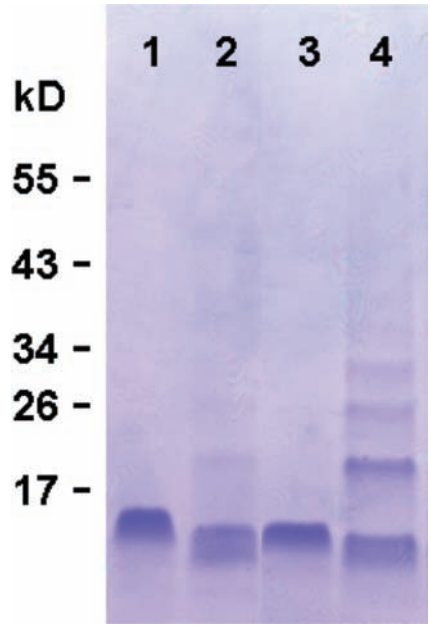

Figure 1. Glutaraldehyde cross-linking of monomeric and tetrametic p53 peptides demonstrating the presence of R10p53 peptide oligomers only for the tetrameric R10$p53^{tet}$ peptide. Coomassie-stained SDS PAGE gel highlights a single protein band migration pattern for unmodified monomeric R10p53 peptide analogue (harboring a L344P mutation; lane 1, $p53^{mono}$) or cross-linked with 0.2% glutharaldehyde for 20 min (lane 2). The unmodified form of the tetrameric R10p53 analogue (lane 3) generates a comparable single band pattern, while the presence of glutaraldehyde results in a characteristic ladder of protein bands associated with the presence of R10$p53^{tet}$ domain oligomers in solution.

Splicing Redirection Assay. The PNA conjugates incorporating either monomeric or tetrameric R10p53 or $(RXR)_4$ were incubated for 1 h at 37 °C in 1 mL optiMEM with exponentially growing HeLa pLuc 705 cells (1.75×10^5 cells/well seeded and cultivated overnight in 24 well plates). Cells were then washed twice with ice-cold PBS and incubation continued for 23 h in complete DMEM supplemented with 10% FBS. Cells were washed twice with ice-cold PBS and lysed with Reporter Lysis Buffer (Promega, Madison, WI, USA). The same protocol was used for HeLa pLuc 705 cells treated with 100 μM chloroquine (Figure 4B). Luciferase activity was measured using a Berthold Centro LB 960 luminometer (Berthold Technologies, Bad Wildbad, Germany) using the Luciferase Assay System substrate (Promega, Madison, WI, USA). Cellular protein concentrations were measured with the BCAProtein Assay Kit (Pierce, Rockford, IL, USA) and read using an ELISA plate reader (Dynatech MR 5000, Dynatech Laboratories, Chantilly,

VA, USA) at 550 nm. Luciferase activities were expressed as relative luminescence units (RLU) per μg protein. All experiments were performed in triplicate. Each data point represents the average of three replicates.

RT-PCR Analysis of Splicing Redirection. Total RNA was extracted from cellular lysates obtained as described in the previous paragraph using the Tri-Reagent kit (Sigma, St. Quentin Fallavier, France) according to manufacturer's instructions. The extracted RNA was amplified by RT-PCR (MJ Research PTC 200 Peltier Thermal Cycler) with forward primer 5′TTG ATA TGT GGA TTT CGA GTC GTC3′ and reverse primer 5′TGT CAA TCA GAG TGC TTT TGG CG3′. The products were analyzed by electrophoresis on a 2% agarose gel.

Saponin Cell Permeabilization. Exponentially growing HeLa pLuc705 cells (1.75×10^5 cells seeded and grown overnight in 24 well plates) were coincubated with the PNA conjugate and with 20 μg/mL of saponin for 30 min. The cells were then washed and incubation continued for 24 h in complete medium (DMEM plus 10% FBS). Cells were washed twice with ice-cold PBS, lysed with reporter lysis buffer, and processed as described above.

RESULTS

Design and Characterization of p53^{tet} Domain-Based PNA Delivery Peptides. As described in the Introduction, the human p53^{tet} tetramerization domain (residues 325−355; GEYFTLQIRGRERFEMFRELNEALELKDAQA) is able to self-assemble into a well-defined tetramer in solution and to enhance the cellular import of conjugated cationic CPPs, as compared to its monomeric counterpart (*13*, *16*). Importantly, the condensation of NLS-R10-p53^{tet} with luciferase reporter plasmid DNA led to complexes that increased the levels of luciferase expression in cells when compared to p53^{mono} constructs (*16*). In terms of designing CPP vectors better able to deliver steric-block ON analogues into cells, we have synthesized a new CPP construct in which an arginine-rich motif (R10) has been attached to the tetramerization domain (residues 325−355) of the human p53 protein. A cysteine was inserted near its C-terminus to covalently attach a PNA, while a short His_6 tag was added for purification purposes (Table 1).

The synthetic peptide was chemically conjugated to a splice-redirecting 18-base-long PNA complementary to the 705 splice site (PNA 705), which we have used extensively in conjugation with other CPPs (*9*). In contrast to our previous CPP-p53^{tet} conjugates designed for plasmid delivery, no nuclear localization signal was included in the construct, since the molecular mass of the conjugate should be small enough to allow diffusion from the cytoplasm to the nuclei through the nuclear pores. R10p53^{tet}-PNA705 conjugates were constructed by forming a disulfide bond between unique cysteine thiol groups present in the p53 peptide and the PNA705 (Table 1) (*17*). A monomeric PNA705 conjugated to a R10p53^{mono} peptide was also synthesized to serve as a control. The monomeric form of the p53 tet domain was generated by introducing a single mutation (L344P) within its sequence: a modification that is known to block tetramer formation (*16*). Both conjugates were purified by reverse-phase HPLC and characterized by MALDI-TOF mass spectral analysis. The oligomerization state of each peptide was confirmed following glutaraldehyde cross-linking experiments with only the tetrameric peptide R10p53^{tet} giving rise to a characteristic ladder of peptide oligomers on SDS PAGE (*18*) (Figure 1). The sequences of the PNA conjugates are presented in Table 1. Light scattering experiments in aqueous solution for the R10p53^{tet}-PNA705 conjugate suggested some level of aggregation, whereas no such signal was observed for the R10p53^{mono}-PNA705 conjugate (data not shown). The exposure of cells to these 10R-p53 peptides did not lead to cell toxicity even at concentrations of up to 25 μM (the highest concentration tested; ref 16).

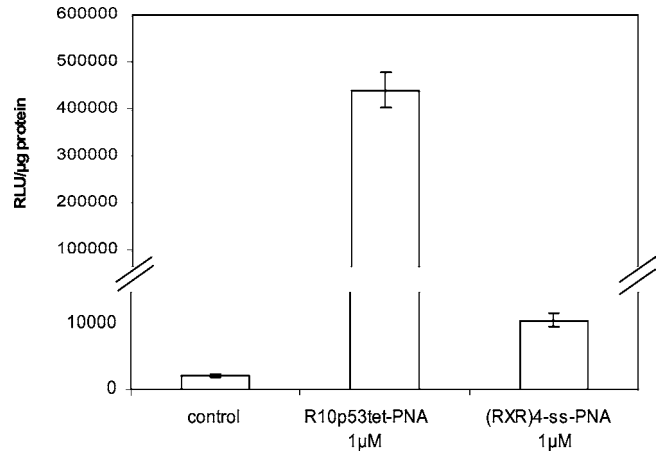

Figure 2. Comparison of R10p53^{tet}-PNA705 with $(RAhxR)_4$-PNA705 in the luciferase assay. Hela pLuc 705 cells were incubated for 4 h with either R10p53^{tet}-PNA705 or $(RAhxR)_4$ PNA705 conjugate at the concentration of 1 μM. After treatment, cells were washed twice with 500 μL PBS, and incubation was continued for 20 h in the presence of complete medium (10% FBS plus DMEM). Luciferase expression was measured 20 h later and was expressed as RLU/μg protein. The control histogram bar represents cells untreated with peptide−PNA conjugates. Each histogram bar represents the averaged RLU/μg protein value with its associated standard deviation derived from experiments performed in triplicate.

R10p53^{tet}-PNA Is Very Effective at Correcting a Defective Luciferase Reporter Gene Located Inside Cells. Our first objective was to establish if the construct R10p53^{tet}-PNA705 CPP could enter HeLa pLuc705 cells and perform the splicing redirection function expected of the conjugated steric-block PNA705 oligomer leading to the expression of active luciferase (*2*). This construct was evaluated and compared to the PNA705 conjugate with the cationic CPP $(RXR)_4$ (data not shown). The conjugate was prepared in OptiMEM medium to avoid technical issues arising from the absorption or proteolytic degradation of CPP peptides in serum. Specifically, the presence of serum has been shown by us and others to generally reduce the in vitro efficiency of CPP conjugates (*5*, *6*, *19*), an effect that does not correlate with their in vivo performance. For instance, $(RAhxR)_4$ PMO conjugates performed poorly in vitro when prepared in serum-containing medium but have been used successfully in vivo in a murine model of Duchenne muscular dystrophy (*9*).

As presented in Figure 2, the treatment of HeLa pLuc705 cells with R10p53^{tet}-PNA705 at 1 μM concentration in the absence of any transfection agent gave rise to an approximately 45-fold higher increase in luciferase signal when compared to the $(RXR)_4$-PNA705 conjugate. In order to monitor whether the increased efficiency of R10p53^{tet}-PNA was due to peptide-based tetramerization, R10p53^{tet}-PNA705 was also compared to its monomeric R10p53^{mono}-PNA counterpart in a dose−response experiment. As expected, the tetrameric form was 10-fold more active in the redirection of luciferase splicing than its monomeric form at nanomolar concentrations (Figure 3A,B). Both peptide conjugates were soluble in the transfection media (OptiMEM), and no signs of toxicity were observed under the tested conditions, as assessed in terms of cell viability and protein levels (data not shown). Using the same experimental samples, it was also demonstrated that the cellular delivery of R10p53^{tet}-PNA705 and R10p53^{mono}-PNA705 constructs at submicromolar concentrations into HeLa pLuc705 cells resulted in

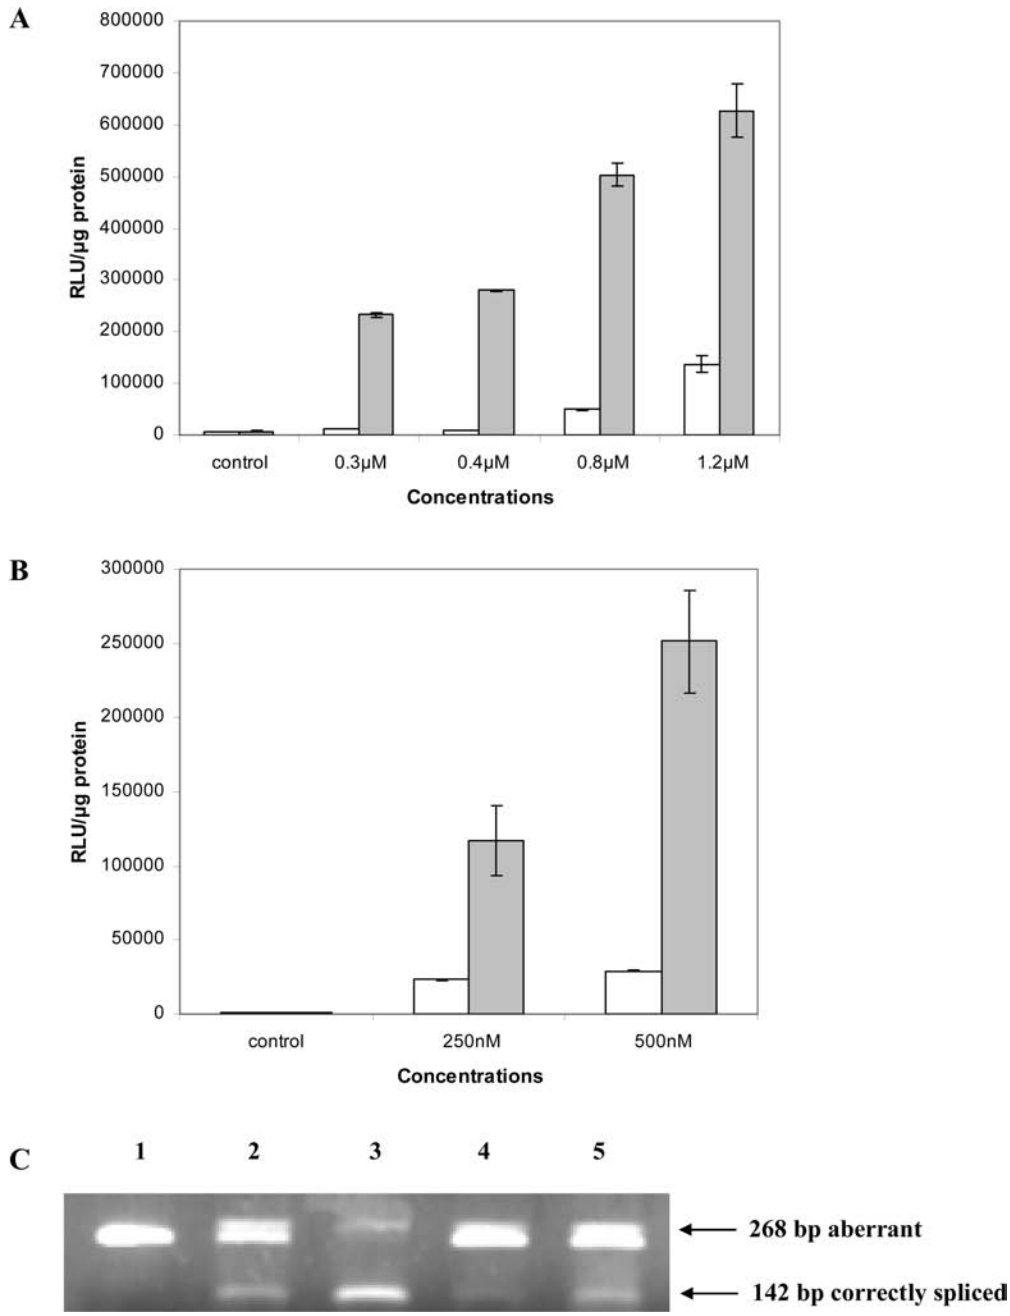

Figure 3. Effect of peptide−PNA concentration on cellular gene correction event. Panels A and B. Dependency of cellular luciferase activity on extracellular peptide−PNA concentration as derived from two separate experiments. HeLa pLuc 705 cells were incubated for 1 h in medium containing R10p53^{tet}-PNA705 (gray bars) or R10p53^{mono}-PNA705 (white bars) conjugates at the indicated concentrations. Luciferase expression was measured 20 h later and expressed as RLU/μg protein. Each histogram bar represents the averaged RLU/μg protein value with its associated standard deviation derived from experiments performed in triplicate. Panel C. RT-PCR detection of correctly spliced transcripts in HeLa pLuc 705 cells at nanomolar concentrations of R10p53-PNA constructs. Lane 1, Nontreated cells (control); Lane 2, R10p53^{tet}-PNA705 250 nM; Lane 3, R10p53^{tet}-PNA705 500 nM; Lane 4, R10p53^{mono}-PNA705 250 nM; Lane 5, R10p53^{mono}-PNA705 500 nM. The RT-PCR experiment was performed with cellular lysates used for generating panel B. The upper band corresponds to the aberrantly spliced luciferase mRNA and the lower band to the correctly spliced mRNA.

the correct splicing of the luciferase transcript at the RNA level (Figure 3C). In brief, treated cells were lysed, and aliquots were processed either for the luciferase luminescence assay or for an RT-PCR assay where the two forms (aberrant and correctly spliced) of luciferase mRNA were amplified. The appearance of the correctly spliced mRNA was dose-dependent and matched the decrease of the aberrantly spliced mRNA. Again, the splicing redirection event was significantly more pronounced for the tetrameric conjugate when compared to its monomeric counterpart.

Mechanism of Cellular Uptake. The mechanism by which cationic CPP−cargo conjugates enter cells is defined by the CPP valency/aggregation state within complexes (*13*, *16*) and the concentration of the CPP/cargoes complexes outside cells. At extracellular CPP concentrations in the 5−100 μM range, cationic CPPs can enter cells via both endocytic and membrane-active mechanisms, which explains the co-observation of both energy-dependent endocytotic and energy-independent entry pathway(s) (*20*). However, the practicality of using CPPs in vivo as delivery vectors would favor their

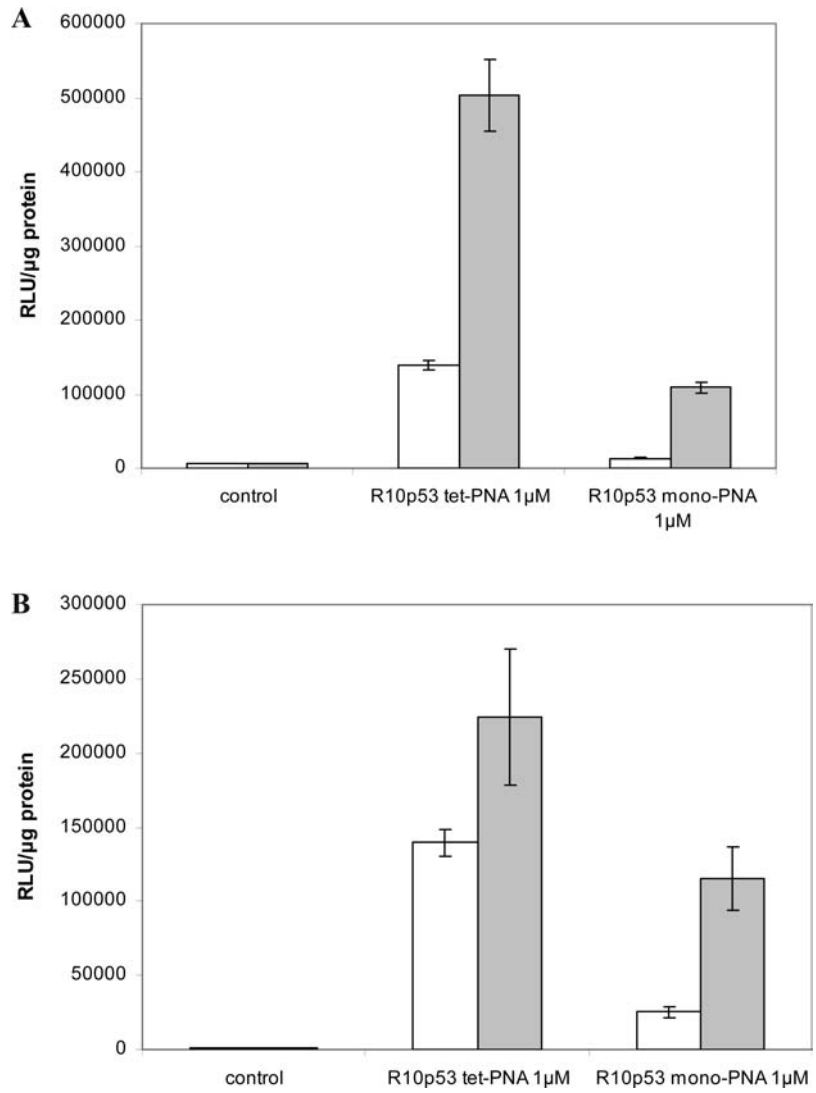

Figure 4. Mechanism of peptide−PNA internalization. Panel A: R10p53^{tet}-PNA and R10p53^{mono}-PNA conjugates are internalized by an energy-dependent mechanism. The splicing correction assay was used to assess the effect of temperature (energy dependency) on peptide−PNA delivery into cells. HeLa pLuc 705 cells were preincubated for 30 min at 4 °C (white bars) or at 37 °C (gray bars) and subsequently exposed to R10p53-PNA conjugates (1 μM) for 1 h under the same conditions. Panel B: Effect of chloroquine on the cytosolic delivery of peptide−PNA constructs leading to luciferase gene correction in HeLa pLuc 705 cells. Cells were incubated for 1 h with either R10p53^{tet} -PNA705 or R10p53^{mono}-PNA705 conjugates (1 μM) in the absence (white bars) or presence (gray bars) of 100 μM chloroquine. Luciferase expression was measured 23 h later and expressed as RLU/μg protein. Each histogram bar represents the averaged RLU/μg protein value with its associated standard deviation derived from experiments performed in triplicate.

use at low micromolar to submicromolar concentrations where their membrane active properties are not observed. Thus, a comparison of the mechanism of cell entry of the tetrameric and monomeric R10p53-PNA705 constructs seemed worthwhile. Therefore, cells were first preincubated at 37 °C or at 4 °C (i.e., at a temperature that prevents any form of endocytosis) before being treated with the conjugates under the same conditions for 1 h. The results (Figure 4A) show a much-reduced splicing redirection activity (as measured by the level of luciferase activity) at low temperature for both monomeric and tetrameric constructs, which suggests an endocytotic mechanism of internalization occurring at a 1 μM concentration.

Since endosomal sequestration remains the principal limitation for the cellular delivery of ONs conjugated to CPPs that pass through the endocytotic route, we incubated cells with each form of R10p53-PNA705 in the presence or absence of chloroquine, a well-known endosomolytic agent (*21, 22*). The splicing redirection efficiency of the PNA conjugate was found to be significantly enhanced (7-fold) in relation to the monomeric conjugate (Figure 4B), which supports the model that entrapment in endocytic vesicles is a limiting step in the cytoplasmic and nuclear release of such conjugates. Interestingly, chloroquine treatment was found to have a much smaller effect on splicing redirection in the case of R10p53^{tet}-PNA705.

Effect of Saponin Treatment. To circumvent the endocytotic pathway, cells were treated under mild conditions with saponin (20 μg/mL), a detergent which transiently permeabilizes the plasma membrane without damaging cells (*23*). Coincubation of R10p-53^{mono}-PNA705 conjugate with saponin gave the expected substantial augmentation of the splicing redirection activity (Figure 5) consistent with other cationic CPP−PNAs previously tested (*7*). However, the observed luciferase expression level remained lower than the value obtained for the tetrameric conjugate without permeabilization. The effect of saponin treatment on the cellular delivery of R10p53^{tet}-PNA705 led to a lower splicing redirection activity comparable to splicing levels observed for the monomeric conjugate. One possible explanation for this result is that the tetrameric conjugate dissociates when coincubated with detergent (loss of valency), behaving the same way as the monomeric

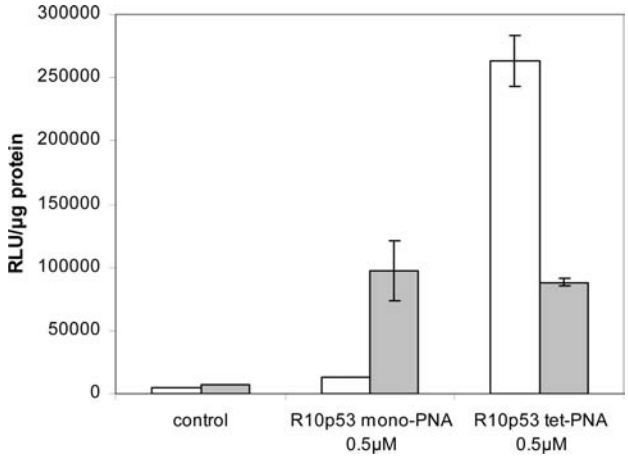

Figure 5. Effect of saponin on delivering peptide−PNA constructs into HeLa pLuc 705 cells. HeLa pLuc705 cells were coincubated with either R10p53^{tet} -PNA705 or R10p53^{mono}-PNA705 conjugates (0.5 μM) in the absence (gray bars) or presence (white bars) of saponin for 30 min. The expression of properly corrected luciferase gene product in HeLa pLuc705 cells was measured as previously described. Each histogram bar represents the averaged RLU/μg protein value with its associated standard deviation derived from experiments performed in triplicate.

conjugate. As shown in Figure 1 (lane C), detergents such as SDS do dissociate the tetramer.

DISCUSSION

Previous work has established that CPP oligomerization through the construction of peptide dendrimers can significantly improve cellular uptake and cytoplasmic delivery of arginine-rich CPPs. The potential of displaying multiple CPPs and their cargoes in the context of the p53 tetramerization domain was evaluated here using a well-characterized splicing redirection assay. The R10p53^{tet}-PNA construct was approximately 45 times more efficient than $(RXR)_4$PNA (Figure 2) and even more active than the Pip2b-PNA construct (ref 9 and data not shown). These results are important, since the Pip series represented until now the most efficient cationic CPP-based PNA delivery vectors.

In order to verify whether the increased efficiency of the R10p53^{tet}-PNA was effectively due to its tetrameric configuration, a monomeric version (R10p53^{mono}-PNA) was engineered through the replacement of leucine 344 by a proline residue, a mutation known to prevent the tetramerization of p53 peptide. Splicing redirection was reduced by a factor of about 10 in keeping with the reduced transfection of a plasmid DNA previously reported by Kawamura and her co-workers (*16*). However, notable differences between the constructs used in these studies should be pointed out. First, the R10p53^{tet}- and R10p53^{mono}- conjugates used in this study do not include a nuclear localization signal (NLS), in contrast to the NLS-10R-P53^{tet} constructs used to condense and transfect luciferase and β-galactosidase reporter plasmids. Also, the number of NLS-10R-p53^{tet} or NLS-10R-p53^{mono} peptides complexed to a single plasmid was not defined in our previous study (*16*). Specifically, the CPP-mediated delivery of DNA plasmids requires that cationic CPPs fulfill more than one role: first, by acting to neutralize the anionic character of plasmid DNA and, second, by condensing the resulting complexes into particles that retain the capacity of CPPs to cause cellular import. By contrast, the role of the present 10Rp53 peptides is limited to the cellular internalization and trafficking of an uncharged PNA cargo. Specifically, the single 18-base-long PNA705 was chemically conjugated to the CPP moiety such that the resulting monomers and tetramers obtained are simple, well-defined structures. Altogether, the present study provides a more direct evaluation of the potential of oligomerization on the nuclear delivery of a cargo.

As highlighted in Figures 2−5, the tetrameric R10p53^{tet}-PNA705 construct represents by far the most effective peptide-PNA705 construct to date in terms of correcting the genetic defect present in HeLa pLuc705 cells. This construct was able to deliver an effective dose of the PNA705 peptide nucleic acid to the cytosol of these cells when present outside HeLa pLuc705 cells at nanomolar concentrations. Somewhat unexpectedly, the R10p53^{mono}-PNA construct remained slightly more active than the $(RXR)_4$PNA conjugate. Clues as to why both R10p53-PNAs are more effective in delivering PNA705 to cells than the $(RXR)_4$PNA conjugate may be linked to two parameters. First, the spacial presentation of CPPs on a p53^{tet} scaffold (branched display where CPPs are equivalently presented) is not identical to that of the $(RXR)_4$PNA conjugate (single CPP consisting of a linear sequence of short internal diarginyl-containing peptide motifs). Second, the p53 constructs possess a higher arginine content (4 × 10 Arg; p53^{tet} scaffold and 10 Arg for the monomeric form) than in the case of the (RXR)4-ss-PNA (4 × 2 Arg) construct. Finally, the presence of the hexahistidine tag in the p53 constructs may also be consequential.

Further studies will be required to identify what features of the p53 peptide and $(His)_6$ domains (see Table 1 for the complete sequence) have a positive impact on PNA delivery.

The mechanism by which CPP−cargo conjugates enter cells remains in part dependent on the steady-state levels of CPP concentration outside cells. Mechanisms involving a direct energy-independent translocation (*20, 23*) as well as various endocytotic pathways (*24*−*27*) have been proposed. Dominance of one or another internalization pathways appears to be linked to the concentration of CPP-conjugates experienced by cells with high local (membrane-bound) concentration of CPP-conjugates (high micromolar range) favoring the aggregation and membrane-active properties of cationic peptides allowing for their direct cell translocation, whereas low CPP concentrations lead to internalization via proteoglycan binding and to endocytic pathways (*28, 29*). As an in vivo drug delivery strategy, CPP concentrations needed to achieve energy-independent translocation are too high (>10 μM) to be effective and may result in cell cytotoxicity.

Internalization of both the tetramer and the monomer R10p53-PNA constructs is energy dependent as previously demonstrated for R10p53 peptides (*16*) and in our functional assay when R10p53 peptides deliver their PNA705 cargo. Specifically, the exposure of HeLa pLuc705 cells to low temperature reduces the expression of functional luciferase driven by the presence of either R10p53 constructs in the medium (Figure 4A). These findings are in accordance with previous work reporting a clathrin-mediated endocytotic pathway of cell uptake for fluorescein-tagged 10R-p53^{tet} peptides (*16*).

Taken together, these observations do not point to differences in the cellular entry mechanism as an explanation for the increased efficiency of R10p53^{tet}-PNA as compared to its monomeric analogue or to $(RXR)_4$PNA. A significant fraction of R10p53 peptides remains trapped in endosomes. As expected, chloroquine treatment, which is known to promote endosomal release of entrapped CPP−cargo conjugates (*30*), indeed causes a significantly more pronounced increase in splicing correction for R10p53^{mono}-PNA compared to R10p53^{tet}-PNA (Figure 4B). Whether this increased ability to escape endocytic vesicles is the only determinant of the increased splice redirecting activity of R10p53^{tet}-PNA as compared to the monomeric form cannot be ascertained on this basis. The presence of chloroquine is thus not essential for cellular delivery using the R10p53^{tet}-PNA

construct. Interestingly, $(RAhxR)_4$ PMO conjugates have been used in vivo (in the absence of the lysosomotropic amine agent chloroquine) and were able to promote exon skipping in the *mdx* mouse model of Duchenne muscular dystrophy (*9*). The constructs used in the present study are more efficient in vitro than these $(RAhxR)_4$ PMO constructs when compared in the same assay in the absence of chloroquine. Thus, we expect that they might be more efficient in vivo in the absence of chloroquine.

We thus attempted to deliberately bypass endocytosis by submitting cells to a brief saponin treatment under mild conditions, known to transiently permeabilize the plasma membrane with minimal alteration of cell physiology (*23*). As expected and in line with previous data from our group for other CPP−PMO/PNA conjugates (*7*), splicing correction by $R10p53^{mono}$-PNA was increased in saponin-treated cells but did not reach the efficiency achieved by $R10p53^{tet}$-PNA in untreated cells. One of the many possible explanations could be that the more bulky $R10p53^{tet}$-PNA construct more efficiently masks the cryptic splice site and reorients the splicing machinery. Unexpectedly, splicing redirection was less efficient in saponin-treated cells for the $R10p53^{tet}$-PNA construct. It might be due to a conversion of the tetrameric form into the monomeric form upon saponin treatment.

Altogether, our results confirm the potential of CPP oligomerization as a strategy to enhance the delivery of conjugated cargoes into cells. Specifically, the cellular delivery and splicing activity of PNA705 observed at nanomolar concentrations for the tetrameric R10p53-PNA construct is remarkable when compared to all other CPP strategies tested to date. This study provides a proof-of-concept for exploiting multivalent CPP strategies in the context of in vivo applications. Future work by our group will include the grafting of CPPs and cargoes onto simpler synthetic dendrimeric scaffolds.

ACKNOWLEDGMENT

TAT Peptide and Its Conjugates: Proteolytic Stability

Jacob Grunwald,[¶,†] Tomas Rejtar,[‡] Rupa Sawant,[†] Zhouxi Wang,[‡,§] and Vladimir P. Torchilin*[,†]

Department of Pharmaceutical Sciences and Center for Pharmaceutical Biotechnology and Nanomedicine, Barnett Institute and Department of Chemistry and Chemical Biology, Northeastern University, Boston, Massachusetts 02115. Received February 20, 2009; Revised Manuscript Received June 19, 2009

The proteolytic cleavage of TATp, TATp-PEG_{1000}-PE conjugate (TATp-conjugate), and TATp as TATp-conjugate in mixed micelles made of TATp-conjugate and PEG_{5000}-PE (2.5% mol of TATp-conjugate, TATp-Mic) were studied by HPLC with fluorescent detection using fluorenylmethyl chloroformate (FMOC) labeling and by MALDI-TOF MS analysis. The cleavage kinetics were analyzed in human blood plasma and in trypsin-containing phosphate buffered saline (PBS), pH 7.4, to simulate the proteolytic activity of human plasma. The trypsinolysis of free TATp, TATp-conjugate, and TATp-Mic revealed that the main initial fragmentation is an endocleavage at the carboxyl terminus resulting in an Arg-Arg (RR) dimer. The trypsinolysis followed pseudo-first-order kinetics. The cleavage of the free TATp was relatively fast with a half-life of a few minutes ($t_{1/2} \sim 3.5$ min). The TATp-conjugate showed more stability with about a 3-fold increase in half-life ($t_{1/2} \sim 10$ min). TATp in TATp-Mic was highly protected against proteolysis with an over 100-fold increase in half-life ($t_{1/2} \sim 430$ min). The shielding of TATp by PEG moieties in the proposed TATp-Mic is of great importance for its potential use as a cell-penetrating moiety for multifunctional "smart" drug delivery systems with detachable PEG.

INTRODUCTION

Cell-penetrating peptides (CPPs) are molecules commonly of a polycationic nature. They readily cross the hydrophobic cell membrane (*1–5*) and can facilitate intracellular delivery of conjugated macromolecules and nanoparticles. The mechanism of their activity is not yet completely elucidated (*6–11*), although it is assumed that CPPs themselves and CPPs with a small-sized cargo cross the cell membrane via a combination of hydrophobic and electrostatic interactions (*12*), while CPPs with a large-sized cargo enter cells via macropinocytosis with subsequent escape from endosomes (*13*). In the past decade, numerous works have been published on the use of CPPs for successful *in vitro* and *in vivo* intracellular delivery of biologically active macromolecules (*14–16*), enzymes (*3*), antibodies (*15*), DNA (*17–19*), liposomes (*20–22*), and imaging probes (*3, 23–25*). The most intensively studied CPP is the transactivating transcriptional activator peptide (TATp) derived from the protein transduction domain (PTD) of HIV-1 (*1, 2, 26, 27*) extending from residues 47 to 57 (YGRKKRRQRRR). The composition of TATp is unique for its predominant content of the positively charged amino acids arginine and lysine. This distinct composition makes it highly susceptible to proteolysis by tryptic enzymes. As pointed out in a recent review (*6*), TATp has six potential trypsin cleavage sites. Since the cell penetration property relies on the integrity of the highly basic TATp sequence (*6, 7*), it is clear that the potential of TATp or similar peptides as mediators of intracellular delivery of therapeutic molecules and drug delivery systems *in vivo* could be significantly limited by their cleavage with proteolytic enzymes (*28–31*).

Despite the enormous number of publications on the use of TATp as a mediator of intracellular delivery, only a few authors have investigated the *in vivo* instability of TATp (*28*) that results from its proteolytic cleavage (*28, 29*). To obtain stable CPPs, an all D-enantiomer peptide was suggested (*30, 31*); another approach offered to overcome proteolytic degradation (*32, 33*) was the replacement of the amino acids, which are particularly susceptible to degradation, with their stable synthetic mimics.

In the study specifically dedicated to the enzymatic cleavage of TATp (*28*), the investigation of furin cleavage of HIV-1 TATp showed that cleavage takes place at the carboxyl terminus and greatly reduces its transactivation activity. However, no studies have been done to determine the kinetics of the proteolysis of TATp or fragment identification by MS.

Our aim was to study the exact pattern of TATp proteolysis and compare the stability against proteolysis (trypsinolysis) of different forms of TATp: native TATp, TATp conjugated with poly(ethylene glycol)-phosphatidyl ethanolamine block copolymer (TATp-PEG-PE), and TATp as TATp-PEG-PE incorporated into PEG-PE micelles with the PEG block in the PEG-PE longer than the PEG block in TATp-PEG-PE conjugate. The kinetics of the proteolytic cleavage of TATp in these forms were investigated using HPLC with fluorescent labeling and MALDI-TOF-MS.

EXPERIMENTAL SECTION

Chemicals. TATp (11-mer: TyrGlyArgLysLysArgArgGlnArgArgArg; molecular mass 1560 Da) and TAT-cysteine peptide (TATp-Cys 12-mer: CysTyrGlyArgLys-LysArgArgGlnArgArgArg; molecular mass 1663 Da, one reactive thiol group) were synthesized by the Tufts University Core Facility (Boston, MA). 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methyl(poly(ethylene glycol))-5000] (PEG_{5000}-PE) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL), NHS-PEG_{1000}-maleimide was purchased from Quanta Biodesign (Powell, OH), and

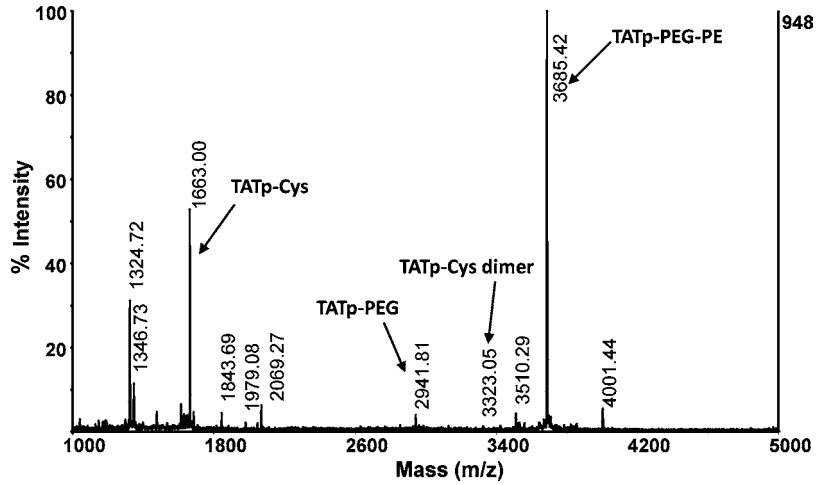

Figure 1. MS spectra of the purified TATp-PEG_{1000}-PE conjugate. The main peak $m/z = 3685.42$ was identified as the conjugate (theoretical $[M+H]^+ = 3685.21$).The intensities of MS peaks do not represent a quantitative ratio. The relative concentration of TATp-Cys did not exceed 7% as determined by HPLC analysis.

TATp-PEG_{1000}-PE (TATp-conjugate) was synthesized in-house (see below). 9-Fluorenylmethyl chloroformate (FMOC-Cl) was purchased from Fluka (Switzerland). Trypsin from porcine pancreas (type IX-S, 13 000−20 000 units/mg), and lyophilized human plasma reconstituted by adding the specified volume of deionized water were purchased from Sigma (St. Louis, MO). All other chemicals and solvents were of analytical grade.

Synthesis of TATp-PEG_{1000}-PE (TATp-Conjugate). TATp-PEG_{1000}-PE conjugate was synthesized as described previously in ref 34 with some modifications. Briefly, an approximately 1.5-fold molar excess of NHS-PEG_{1000}-maleimide was reacted with DOPE-NH_2 by stirring for 4 h in chloroform under argon at room temperature with a 3-fold molar excess of triethylamine. A 2-fold molar excess of TATp-Cys was then added, and the reaction was continued with stirring under argon for an additional 12 h. The excess of TATp-Cys was separated from the product by gel filtration chromatography. The solvent was evaporated, and the product was freeze−dried overnight. The dried product was dissolved in 0.5 mL of water and loaded onto a Sephadex G25 column (length, 10−15 cm; diameter, 0.5−1 cm). The product was eluted with water. Fractions of 0.5−1 mL were collected and monitored by TLC using silica plates and a mobile phase of chloroform/methanol (80:20% v/v). TATp-PEG-PE was visualized by iodine, phosphomolybdic acid, and Dragendorff spray reagents.

The resulting product was freeze−dried, dissolved in chloroform, and stored at −80 °C. The final purified product was identified by MALDI-TOF MS (Figure 1), and its purity as determined by HPLC was above 90%.

Preparation of TATp-Micelles. PEG-PE micelles containing 2.5 mol % of TATp-PEG-PE (TATp-Mic) were prepared as follows: 0.5 mL of PEG_{5000}-PE (10 mg/mL in chloroform) was mixed with 40 μL of TATp-PEG_{1000}-PE (2 mg/mL in chloroform); a PEG-PE film was formed on the bottom of the glass test tube by evaporating the solvent with nitrogen and lyophilization overnight. The film was hydrated in 0.5 mL of PBS, pH 7.4, and vortexed for 2−3 min to yield a clear micelle solution.

A solution of TATp-PEG_{1000}-PE was prepared by a similar procedure, by taking an appropriate volume of the pure TATp-conjugate solution in chloroform (2 mg/mL), evaporating the solvent, and hydrating the residue in PBS, pH 7.4. The hydration required occasional heating to 37 °C and vortexing. Solutions with a conjugate concentration of 0.1 or 1.0 mg/mL were prepared.

TATp Proteolysis in Human Plasma. Plasma samples (100 μL) were spiked with 10 μL of TATp (1 mg/mL, in deionized water) and incubated at 37 °C. To follow the kinetics of TATp proteolysis, the incubation was terminated at specified time points by adding 100 μL of acetone with 2% (v/v) of formic acid. The precipitated proteins were separated by centrifugation (10 000 rpm/10 min); the clear supernatant was lyophilized, dissolved in 100 μL of 0.1% formic acid, and filtered through Amicon centrifugal filters (5 kDa MWCO). The resulting filtrate was transferred for MS analysis. The initial concentration of the intact TATp (at time = 0) was determined by adding 10 μL of the same stock (1 mg/mL) of TATp to plasma in which the proteolytic activity was totally inhibited by phenylmethylsulfonyl fluoride (PMSF).

Trypsinolysis of TATp, TATp-PE-PE, and TATp-Mic. Five microliters of trypsin (0.002 mg/mL, 1.5−1.8 total units) was added to a sample of 100 μL of TATp, TATp-PEG-PE, or TATp-Mic in PBS, pH 7.4, and incubated at 37 °C. The concentration of the different forms of TATp was adjusted to be equivalent to 0.05 mg/mL of TATp (3×10^{-5} M), while the final trypsin concentration was 1×10^{-4}mg/mL (5×10^{-9} M). At prescheduled time intervals, 10 μL aliquots were withdrawn from the sample and immediately used for FMOC-Cl derivatization (see below). It was confirmed that trypsin was completely deactivated by the derivatization conditions, (raising the pH to 10 and 1:1 dilution with FMOC-Cl in acetonitrile). The proteolysis kinetics were determined with HPLC analysis by following the increase in the concentration of the main digest product, the RR fragment.

MS Analysis. The samples resulting from the HPLC or plasma filtrates were spiked with human Glu-fibrinopeptide B to serve as an internal standard for the normalization of signal

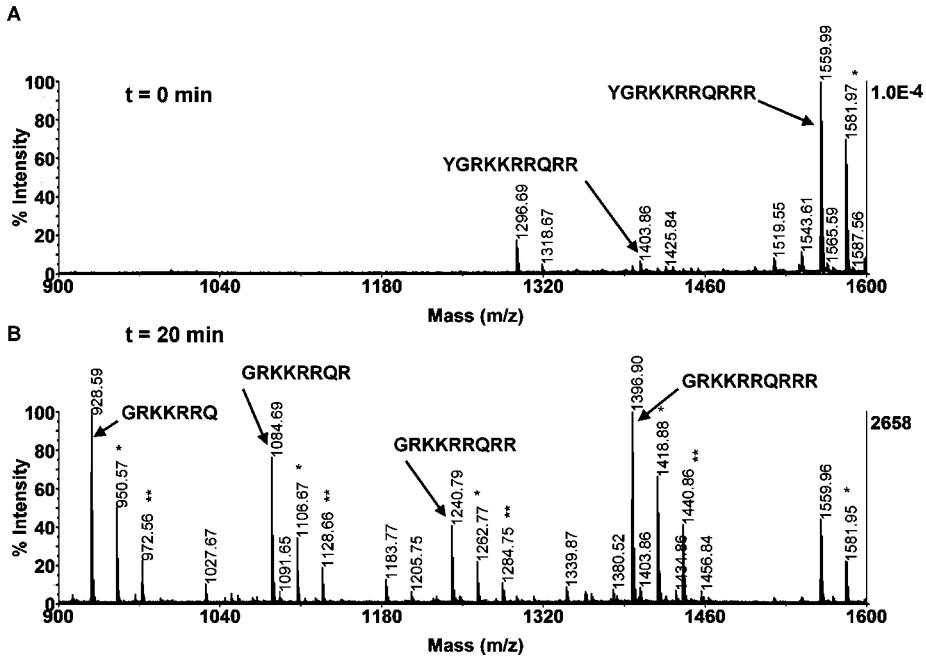

Figure 2. MS spectra of TATp fragments resulting from the incubation of TATp in human plasma at 37 °C. Symbols: * $[M + Na]^+$ and ** $[M + 2Na - H]^+$. (A) $t = 0$ min (determined by spiking TATp into plasma, in which the proteolytic activity was completely inhibited). (B) $t = 20$ min (small peptide fragments were not identified, as they could not be distinguished from the background plasma peptides).

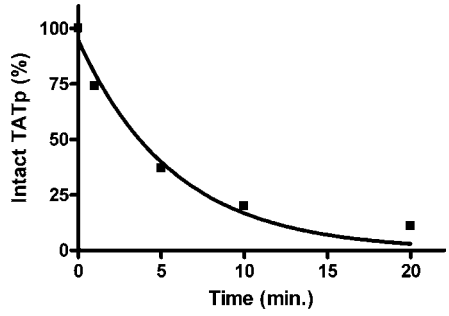

Figure 3. The kinetic of TATp proteolysis in human plasma, described by pseudo-first-order kinetics; $y = 94.84e^{-0.173t}$ (y = % of residual intact TATp); $R^2 = 0.975$.

intensities. Samples were analyzed by MALDI-TOF-MS in a positive reflectron mode with an AB 4700 instrument (Applied Biosystems, Framingham, MA) using 7 mg/mL α-cyano-4-hydroxycinnamic acid or 2,5-dihydroxybenzoic acid in 50% acetonitrile with 0.1% trifluoroacetic acid in water as a matrix solution. The intensity of TATp signal was expressed as a ratio of TATp peak height over the peak height of the spiked standard. For the identification of the chromatographic peaks by MALDI-TOF-MS analysis, the appropriate fractions were collected, lyophilized, and redissolved in 10 μL of 0.1% formic acid.

TATp Derivatization with FMOC-Cl. Samples of TATp, TATp-PEG-PE, TATp-Mic (10 μL), or their trypsin digests in PBS, pH 7.4, were added to a microcentrifuge tube (0.6 mL) containing 2.5 μL of borate buffer (0.4 M, pH 10) followed by addition of 12.5 μL of FMOC-Cl (0.02−0.4 mg/mL) in acetonitrile, then vortexed and incubated for 10 min at room temperature to complete the derivatization. The FMOC-Cl concentration was adjusted in proportion to that of TATp to reach a molar ratio of 1.2–5. Higher excess of FMOC-Cl should be avoided, as highly derivatized TATp tends to aggregate. The 0.4 mg/mL solution of FMOC-Cl was used with trypsin digest samples. Following the fluorescent labeling, the TATp samples were analyzed by HPLC.

HPLC Analysis. The HPLC analysis was performed on a Hitachi Elite Lachrom system (Tokyo, Japan) composed of the

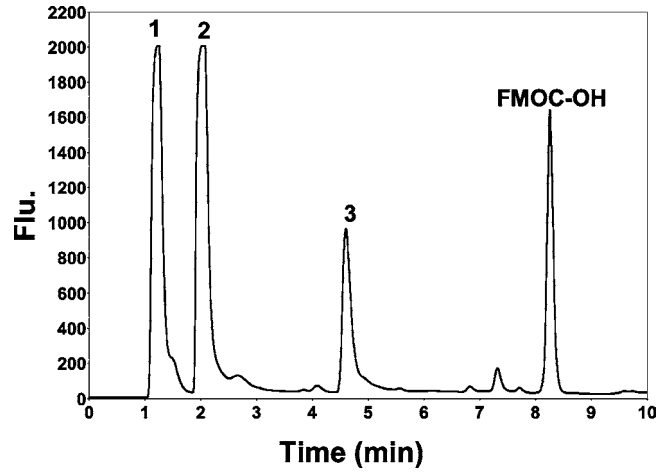

Figure 4. HPLC chromatogram of TATp following FMOC-Cl derivatization. The three separate peaks represent a different extent of derivatization as identified by MALDI-TOF MS (see Figure 5).

following units: a quaternary pump, model L-2130; an automatic sample injector model L-2200; a fluorescence detector, model L-2485, and a Teledyne ISCO fraction collector, Foxy Jr (Lincoln, NE). *EZChrom Elite* (Agilent, Pleasanton, CA) data software was used for the system operation and data processing. The chromatographic separation was performed on a reverse-phase column (Symmetry C18 5 μm, 4.6 × 150 mm, Waters, Milford, MA) using a binary gradient elution. Mobile phase A consisted of 0.1% formic acid in acetonitrile, and B consisted of 0.1% formic acid in deionized water. A constant flow rate of 1 mL/min was used to increase phase A from 30% to 90% within 10 min; this composition (90% A) was held for 5 min and then changed back to the initial composition (30% A). A wait for an additional 5 min was allowed for the column to equilibrate to the initial eluent composition. The FMOC-Cl derivatized samples were diluted 20- to 100-fold with deionized water, and 10 μL volumes were injected for analysis. The

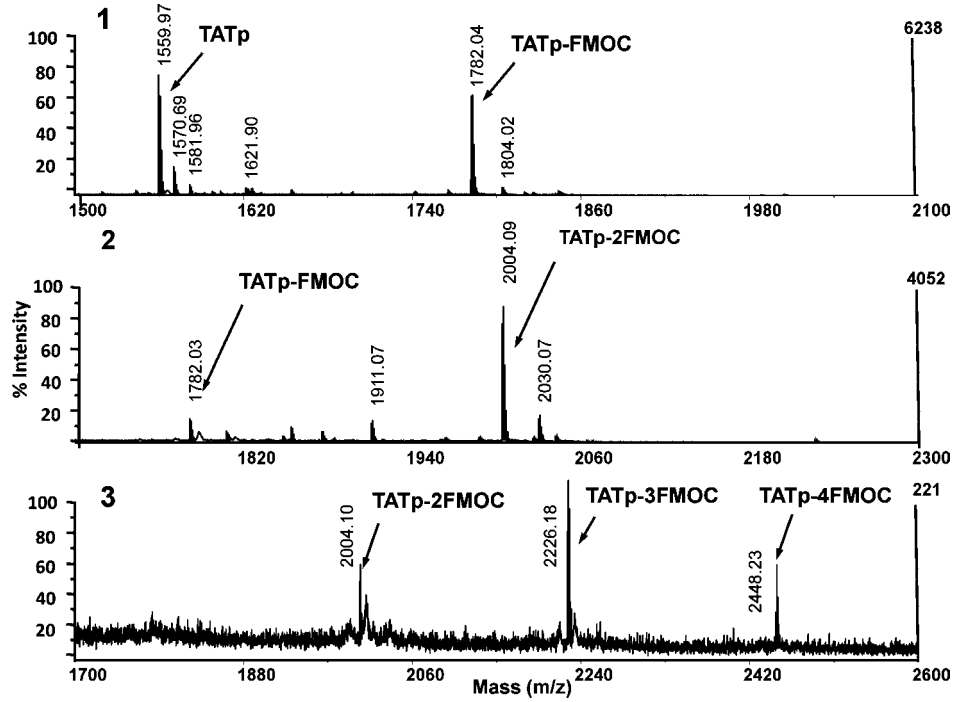

Figure 5. MS identification of the relevant peaks 1−3 (see Figure 4) resulting from FMOC derivatization of TATp. 1, TATp-FMOC and nonderivatized TATp; 2, TATp-2FMOC and traces of TATp-FMOC; 3, TATp-3FMOC and traces of TATp-2FMOC and TATp-4FMOC.

precolumn labeled analytes were detected by the fluorescence detector (ex 263 nm, em 314 nm).

RESULTS

TATp Proteolysis in Human Plasma. The kinetics of TATp proteolysis in human plasma were studied by MALDI-TOF-MS analysis. The main fragments resulting from TATp cleavage were identified as depicted in Figure 2 and summarized in Table 1. The same main fragments were found after 10 and 30 min of plasma incubation, but there was a pronounced change in their relative intensities. The ratio between the most intense fragment resulting from the N-terminal cleavage (GRKKRRQR-RR) and the fragment resulting from C-terminal cleavage (YGRKKRRQRR) increased by 3-fold after 30 min. There was also an increase in the intensity of the smaller fractions with incubation time.

The kinetics of TATp proteolysis were determined by MS analysis by following the decrease in the concentration of the intact TATp as a function of time. As found in other works on peptide proteolysis (*33*), the resulting kinetics (Figure 3) followed a pseudo-first-order rate, described by the following equation: $y = b \cdot e^{-kt}$, where y is the normalized concentration (percentage) of the residual intact peptide at time t; b, the initial peptide concentration; k, the pseudo-first-order rate constant, and t, the incubation time in minutes. The half-life ($t_{1/2}$) calculated from the resulting rate constant equaled 3.5 min. This result points out that the expected lifetime of nonprotected TATp *in vivo* should be on the scale of few minutes.

HPLC Method for TATp Analysis. The analytical method based on HPLC we have developed, with the use of precolumn FMOC derivatization (*35*), RP-chromatography, and fluorescence detection, proved to be a fast and highly sensitive analytical tool to study the proteolytic digestion of TATp.

TATp contains four functional groups which can readily react with FMOC-Cl, three primary amino groups—one at the N-terminal and two at the R-chains of lysine—and the phenol group on tyrosine. As a result, several derivatization products are expected. We found such products separated by HPLC into three peaks (Figure 4) and identified by MS as containing one, two, three, and four FMOC labels per TATp molecule (Figure 5). The FMOC labeling extent could be controlled by adjusting the quantity of the FMOC-Cl used for the derivatization. High molar excesses of FMOC-Cl should be avoided since the highly derivatized peptide tends to aggregate.

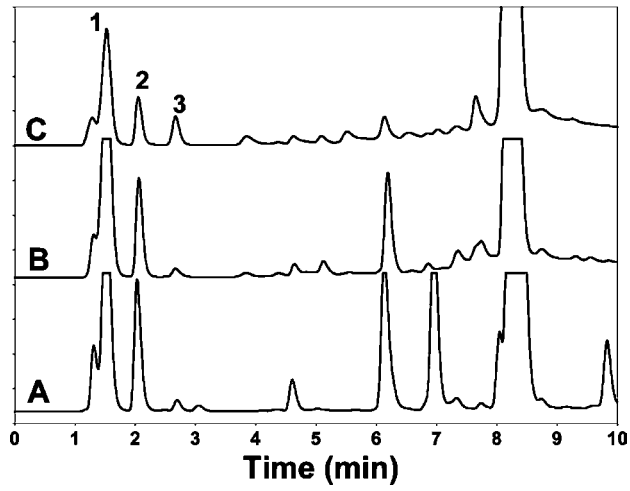

Figure 6. HPLC chromatograms of TATp fragments resulting from the trypsinolysis (1.5 trypsin unit/mL) for 20 min in PBS, pH 7.4, at 37 °C. For the proteolysis of TATp-Mic, 100-fold higher concentration of trypsin was used. Fractions of peaks 1, 2, and 3 were collected and identified by MS. The chromatograms represent free TATp (A), TATp-conjugate (B), TATp-Mic (C).

We found the main derivatization product to be TATp-FMOC, when a molar ratio (FMOC/TATp) of 1.2 was used, and TATp-3FMOC, when a molar ratio of 4.8 was used.

TATp Trypsinolysis in PBS, pH 7.4. For the *in vitro* studies of the proteolysis kinetics of TATp, TATp-conjugate, and TATp-Mic, a solution of trypsin (1×10^{-4} mg/mL, 1.5−1.8 units/mL) in PBS, pH 7.4, was used. This trypsin concentration allowed for TATp proteolysis kinetics similar to those found in human plasma. By using the HPLC analysis to follow the proteolysis of TATp, the same main peptide fragments, peaks

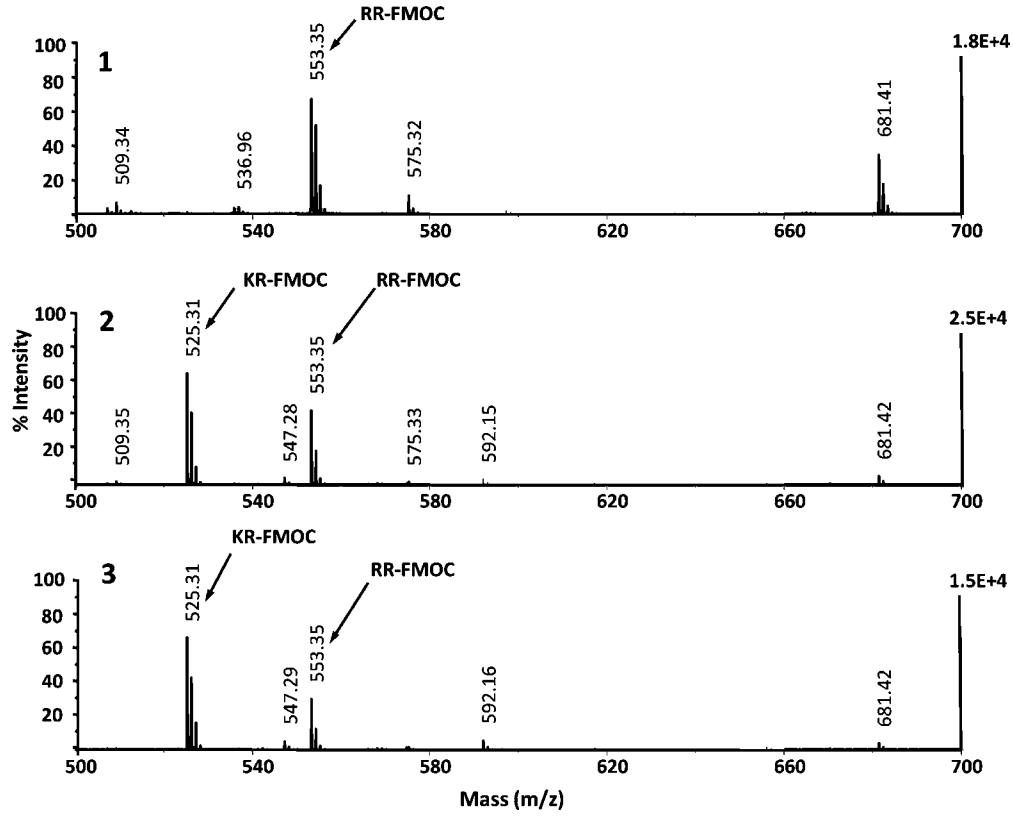

Figure 7. MS identification of the three main fractions (1−3) resulting from TATp proteolysis: (1) RR-FMOC, (2) KR-FMOC, (3) KR-FMOC. The two separate chromatographic peaks of KR-FMOC might result from the two different positions of FMOC labeling: N-terminal or ε-amino group of lysine.

1, 2, and 3 (Figure 6) were detected for the three (A,B,C) different forms of TATp used in this study. The fractions were identified by MS (Figure 7), fraction 1 as RR, and fractions 2 and 3 as KR with individual chromatographic peaks for KR resulting from different positions of FMOC labeling (at N-terminus or ε-amino groups). The RR dimer was the predominant initial proteolysis fragment, which is believed to result from the endocleavage at the carboxyl terminus (YGRKKRRQR↓RR). This finding is in agreement with the cleavage of TATp by furin (*28*).

We found that the chromatographic peak of the RR fragment was the most suitable for the proteolysis kinetics studies since it was the most intense initial fragment and thus easy to detect and analyze quantitatively.

The proteolysis kinetics of TATp were studied either by following the decrease in intact TATp as a function of the incubation time or by following the increase in the main digest fragment (RR). Similar kinetic rates were obtained with both methods (Figure 8). We preferred, however, the method based on the RR fragment, since the same peptide fragment (RR) was found to be the main proteolysis product for all three forms of TATp used in this study. This enabled us to use precisely the same HPLC method for the proteolysis kinetics determination of all the different forms of TATp.

The proteolysis kinetics as determined for the different forms of TATp (Figure 9) fit pseudo-first-order kinetics (R^2 = 0.94−0.98) well, although with quite different proteolysis rates as expressed by the half-lives of TATp: 3.5, 10, and 430 min for TATp, TATp-conjugate, and TATp-Mic, respectively.

DISCUSSION

The studies of the proteolysis of TATp represented in the present work are based on highly precise analytical tools: MALDI-TOF-MS and HPLC. We believe it was important to develop an HPLC method for this study in addition to the MS since most laboratories do not have free access to costly MS instruments. The HPLC analysis developed in this work proved to be a straightforward, highly sensitive, and accurate analytical tool to study the proteolysis kinetics of TATp and TATp conjugates incorporated into PEGylated micelles.

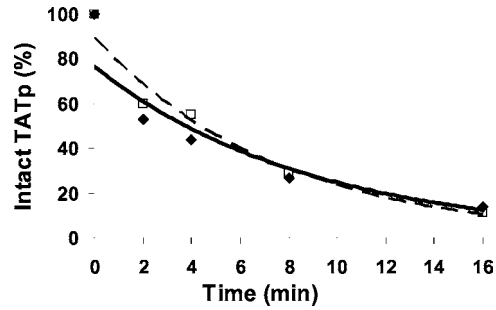

Figure 8. The kinetics of TATp proteolysis by trypsin (1.5 units/mL) in PBS, pH 7.4, at 37 °C. The kinetics was followed by the HPLC based on two different monitoring methods: 1. (—) By determining the decrease in the concentration of the intact TATp. 2. (---) By determining the increase of the RR-fragment normalized to % of the residual intact TATp using the following equation: % Intact TATp = $[A_\infty - A_t/A_\infty] \times 100$; A_∞ = RR concentration at the end of proteolysis; At = RR concentration at time t. The kinetics as determined by both methods fit first-order kinetics (as specified in Figure 2) resulting in a similar half-life ($t_{1/2}$ = ca. 3.5 min).

These kinetics results point out that the expected lifetime *in vivo* of the nonprotected TATp should be on the scale of a few minutes, while highly protected TATp in TATp-Mic can be expected to have a lifetime of several hours. The pronounced differences in the stability against proteolysis among TATp, TATp-conjugate, and TATp-Mic are quite understandable when their structural differences in aqueous medium are taken into

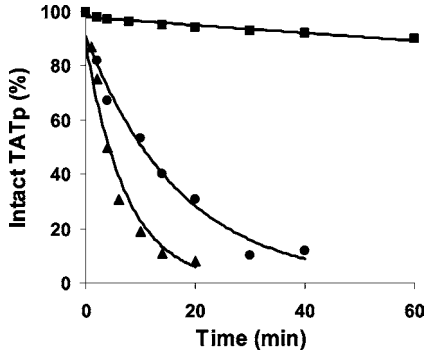

Figure 9. Proteolysis kinetics of different forms of TATp by trypsin (1.5 units/mL) in PBS, pH 7.4, 37 °C, following the RR fragment (as specified in Figure 8). TATp (▲), TATp-conjugate (•), TATp-Mic (■).

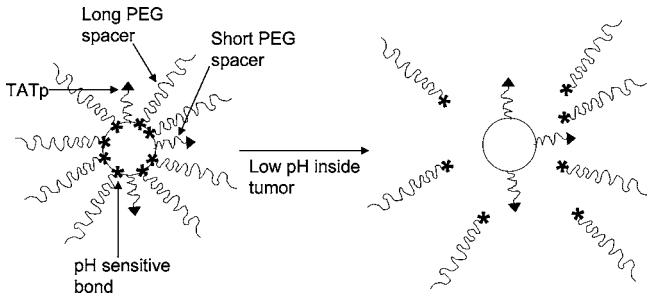

Figure 10. The principal scheme for the action of stimuli-sensitive nanocarriers. The surface of the nanocarrier is modified with TATp (or other CPP) via a relatively short PEG spacer. The TATp is shielded with longer PEG chains, which are attached to the nanocarrier surface via pH-sensitive bonds. The whole system is stable in the blood with TATp moieties protected against proteolytic degradation, and the carrier accumulates in the tumor via the EPR effect. Inside the tumor, protective PEG chains are detached from the surface by rapid hydrolysis of pH-sensitive bonds at the lower intratumoral pH; intact TATp becomes exposed and allows TATp-mediated intracellular delivery.

account. Free TATp can be attacked easily by trypsin and degraded rapidly. The TATp-PEG-PE conjugate, a clearly amphiphilic molecule, can exist in solution as an individual molecule or can form micelles similar to PEG-PE (we did not study the detailed properties of these micelles), but both in free form and in such micelles, the TATp moiety is exposed to the water phase and can still be attacked by trypsin. To some extent, certain steric hindrances for such attacks are created by the presence of PEG or by the micelle surface and will slow down the degradation rate (half-life increased from 3 min for free TATp to 10 min for the TATp-conjugate). By contrast, in TATp-Mic, where the TATp-PEG_{1000}-PE conjugate is located between PEG_{5000}-PE chains, the extended PEG_{5000} chains sterically protect the TATp moiety hidden inside the hydrophilic corona of the mixed micelle from the enzymatic attack and result in a greatly increased lifetime of TATp in TATp-Mic.

These attempts being made to construct "smart" drug delivery systems involve a TATp function hidden under a PEG-based shield, which could be removed, exposing their cell-penetrating function only when the system was in the vicinity of target cells (*22*, *34*, *36*) as depicted in Figure 10. The findings presented clearly show that the hidden TATp function can be well preserved within such "smart" structures for the time required for drug delivery into a target.

CONCLUSIONS

The HPLC analysis based on the FMOC-Cl fluorescent labeling developed in this work is a straightforward, accurate analytical tool for studying the proteolysis kinetics of TATp and TATp conjugates incorporated into PEGylated micelles.

The proteolytic cleavage of free TATp in human plasma or in trypsin-containing medium is relatively fast, with a half-life of approximately 3.5 min. TATp modification with PEG-PE moieties stabilizes TATp only slightly against proteolytic degradation ($t_{1/2}$ = 10 min). High stability of TATp against proteolysis ($t_{1/2}$ > 400 min) can be achieved by incorporating TATp as TATp-PEG-PE conjugates into polymeric micelles formed by PEG-PE if the size of a PEG block is bigger than the PEG fragment in TATp-PEG-PE. Protection of TATp against proteolysis is of great importance for its potential use as a cell-penetrating moiety in multifunctional smart drug delivery systems.

Received March 1, 2009; Revised Manuscript Received May 29, 2009

The synthesis of a conjugated linear organic module containing terminal salicylaldehyde groups and a central activated ester, designed for conjugation to amino-modified oligonucleotides, is presented. The organic module has a phenylene−ethynylene backbone and is highly fluorescent. It is conjugated to oligonucleotide sequences and incorporated into specific locations in a well-defined DNA 4-helix bundle (4-HB). The DNA-nanostructure offers precise location control of the organic modules which allows for selective interhelical coupling reactions. In this study, metal-salen formation as well as dihydrazone formation are used to covalently interlink the organic modules. Both coupling reactions are highly dependent on the distances between the organic modules in the 4-HB. Neighboring modules dimerize easier, whereas more distanced modules are less prone to react, even when the linkers are extended. The dimeric products are characterized by denaturing polyacrylamide gel electrophoresis (PAGE), high performance liquid chromatography (HPLC), and matrix assisted laser desorption/absorption ionization time-of-flight (MALDI TOF) mass spectrometry.

INTRODUCTION

The area of DNA-nanotechnology has evolved over the last 15 years, and an increasing number of impressive two-dimensional (2D) and three-dimensional (3D) nanostructures formed by DNA self-assembly have been described (*1*−*5*). The majority of these self-assembled structures are made of DNA alone; however, convincing results have been reported for the DNA controlled assembly of other materials (*6*). For example, DNA-nanostructures have been used to arrange nanoparticles (*7*−*11*), proteins (*12*−*14*), and RNA (*15*). The use of DNA-programmed assembly of organic building blocks has also been reported (*16*−*21*), but in these cases, only less complex DNA-scaffolds have been applied to template a chemical reaction.

DNA-directed chemistry is a method that offers exclusive control of chemical reactions (*22, 23*). By attachment of functional groups to oligodeoxynucleotides (ODN), the chemical reaction between two or more of such conjugates can be controlled by the ability of the ODNs to self-assemble. The functional groups of choice will typically spontaneously react with each other at millimolar concentrations; however, at micro- to nanomolar concentrations, reactions only happen when DNA-hybridization leads to the formation of a high local concentration, i.e., a pseudointramolecular reaction. Several classical chemical reactions have been applied in DNA-directed chemistry (*22*−*28*). Our interest in DNA-directed chemistry has mainly been in assembling conjugated organic rods into potentially conducting oligomers. We have reported on the direct self-assembly and coupling of ODN−rod conjugates (*29*−*34*) and recently demonstrated DNA-templated assembly of organic rods along the axis of a DNA helix (*35*). These methods were applied to the assembly and coupling of up to four modules; however, they could not be applied to preparing larger structures.

In our continued search for DNA structures that can serve as templates for directed assembly and coupling of organic building blocks, we have investigated interhelical couplings in a DNA 4-helix bundle (4-HB). To the best of our knowledge, the only example of DNA-directed interhelical coupling relies on a short distance amide formation (*36*), and the only two examples of longer distance couplings within the same helix are from Seeman et al. (*27*). and our laboratories (*35*). Furthermore, Mao et al. has described a triplex controlled regioselective formation of an amide (*37*). On the basis of our previous reports on the DNA-directed assembly of organic rods into potentially conducting oligomers (*38*−*41*), we explore the incorporation of organic modules in a 4-HB as a template for organic reactions (*42*).

EXPERIMENTAL DETAILS

General Methods. All organic solvents used in experiments were of high performance liquid chromatography (HPLC) grade purity. THF and triethylamine were distilled over sodium and CaH_2, respectively. Flash chromatography was performed using Merck silica gel 60 (230−400 mesh). Analytical thin layer chromatography (TLC) was performed using precoated aluminum-backed plates (Merck Kieselgel 60 F254) and visualized by ultraviolet irradiation. NMR spectra were acquired on a Varian AS 400 spectrometer, running at 400, 100, and 376 MHz for ^{1}H, ^{13}C and ^{19}F, respectively. Chemical shifts (δ) are reported in ppm relative to solvent signals ($CHCl_3$ at 7.26 ppm for ^{1}H NMR and $CDCl_3$ at 77.0 ppm for ^{13}C NMR). ^{13}C NMR spectra were acquired on a broadband decoupled mode. High resolution mass spectra (HRMS) were recorded on a MicromassLCT spectrometer using electrospray (ES^+) ionization techniques. Matrix assisted laser desorption/absorption ionization time-of-flight (MALDI-TOF) mass spectrometry experiments were performed using a Bruker Daltonics Autoflex spectrometer, an AnchorChip target plate, and one of the following matrixes: saturated dihydroxybenzoic acid (DHB) in methanol for organic

compounds and a 4:1 ratio of 3-hydroxypiccolinic acid (HPA) and diammoniumcitrate (DAC) 10 g/L in water for oligonucleotide containing compounds. The organic compounds were analyzed using a reflective positive mode, and oligonucleotide samples were analyzed using linear negative mode. Water used in oligonucleotide containing experiments was triple distilled. UV−vis absorption spectra were recorded on a Nanodrop ND 1000 spectrophotometer. HPLC analyses were accomplished on a Hewlett-Packard Agilent 1100 series using a Phenomenex Clarity 3u oligo-RP (50 × 4.60 mm 3 μm) column. Oligonucleotides were purchased from DNA technology A/S, Risskov in Denmark and IDT, Coralville, USA.

*Compound **4***. A flame-dried Schlenk flask charged with a magnet, 2-(1,3-dioxan-2-yl)-4-iodophenyl acetate (**3**) (691 mg, 2,79 mmol), $Pd(PPh_3)_2Cl_2$ (98 mg, 5 mol %), and CuI (26 mg, 5 mol %) was left under vacuum for 30 min. Upon turning to an argon atmosphere, we added THF (20 mL), NEt_3 (5 mL), and TMS-acetylene (820 mg, 1.16 mL, 8.36 mmol), and the mixture was stirred at rt overnight. The crude product was concentrated by rotary evaporation and purified by flash chromatography on silica gel (1:1 pentane/CH_2Cl_2) to yield compound **2** as a clear oil (552 mg, 1,73 mmol, 62%).

HRMS $[M + Na]^+$ calc, 341.1185; found, 341.1188. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.77 (s, 1H), 7.44 (d, J = 8.4, 1H), 7.02 (d, J = 8.4, 1H), 5.54 (s, 1H), 4.24 (dd, J = 4.8, 11.0, 2H), 3.93 (t, J = 11.3, 2H), 2.29 (s, 3H), 2.25 − 2.11 (m, 1H), 1.43 (d, J = 13.5, 1H), 0.22 (s, 9H). ^{13}C NMR (101 MHz, CDCl3) δ 168.8, 147.9, 133.0, 131.3, 130.5, 122.7, 121.1, 104.1, 97.3, 94.3, 67.4, 25.6, 20.8, −0.1.

*Compound **5***. A round-bottomed flask with compound **4** (550 mg, 2.57 mmol) in THF (5 mL) was cooled to 0 °C, and TBAF in THF (2.8 mL of 1 M solution) was added dropwise. After 10 min, the mixture was poured into CH_2Cl_2 (40 mL), and the organic phase was washed twice with water (15 mL). The organic phase was dried with Na_2SO_4 (s) and evaporated to dryness by rotary evaporation of the solvent. The crude product was treated with acetyl chloride (0.5 mL) in THF (10 mL) and pyridine (1 mL) for 10 min at rt. The mixture was poured into CH_2Cl_2 (40 mL) and washed with $NaHCO_3$ (aq, sat., 15 mL) and twice with water (15 mL). The organic phase was dried with Na_2SO_4 and evaporated to dryness by rotary distillation. Compound **5** was obtained by flash chromatography on silica gel (1:1 pentane/CH_2Cl_2) as a light yellow crystalline compound (383 mg, 1.56 mmol, 61%).

Mp 93−96 °C, HRMS $[M + Na]^+$ calc, 269.0790; found, 269.0786. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.80 (s, 1H), 7.47 (d, J = 8.2, 1H), 7.04 (d, J = 8.3, 1H), 5.54 (s, 1H), 4.22 (dd, J = 4.6, 11.2, 2H), 3.92 (t, J = 11.5, 2H), 3.05 (s, 1H), 2.29 (s, 3H), 2.25 − 2.11 (m, 1H), 1.40 (d, J = 13.5, 1H). ^{13}C NMR (101 MHz, $CDCl_3$) δ 168.65, 148.07, 133.15, 131.33, 130.62, 122.80, 119.86, 97.07, 82.56, 77.26, 67.27, 25.43, 20.67. Anal. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73. Found: C, 67.44; H 5.93. FTIR (KBr, cm^{-1}): 3271 s, 2849−2961 m, 2110 w, 1773 s, 1756 s, 1608 w, 1486 s.

*Compound **1***. A flame-dried Schlenk flask containing a magnet, pentafluorophenyl-2,5-diiodobenzoate (**7**) (199 mg, 0.37 mmol), $Pd(PPh_3)_2Cl_2$ (8 mg, 2.5 mol %), CuI (2.2 mg, 2.5 mol %), and Cs_2CO_3 (240 mg, 0.74 mmol) was left under vacuum for 30 min. Upon turning to argon atmosphere, we added THF (10 mL) and compound **5** (200 mg, 0.81 mmol), and the mixture was stirred for 1 h at rt. The solvent was removed by rotary distillation, and product **1** was obtained by flash chromatography on silica gel (1:50 Et_2O/ CH_2Cl_2) as a white crystalline product (210 mg, 270 mmol, 73%).

Mp 147−152 °C. HRMS $[M + Na]^+$ calc, 799.1579; found, 799.1591. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.32 (dd, J = 0.5, 1.6, 1H), 7.88 (d, J = 2.1, 1H), 7.81 (d, J = 2.1, 1H), 7.72 (dd, J = 1.7, 8.1, 1H), 7.68 (dd, J = 0.5, 8.1, 1H), 7.57 − 7.50 (m, 2H), 7.10 (d, J = 8.4, 1H), 7.07 (d, J = 8.4, 1H), 5.59 (s, 1H), 5.55 (s, 1H), 4.32 − 4.15 (m, 5H), 4.03 − 3.86 (m, 5H), 2.32 (s, 3H), 2.30 (s, 4H), 2.29 − 2.13 (m, 3H), 1.51 − 1.37 (m, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) δ 168.75, 168.73, 161.04, 148.38, 148.26, 135.78, 134.53, 134.40, 133.05, 132.78, 131.17, 131.12, 130.87, 130.78, 128.21, 124.48, 123.35, 123.06, 123.03, 120.51, 120.28, 97.25, 97.17, 96.93, 91.88, 89.13, 87.64, 87.28, 67.43, 67.40, 25.58, 25.55, 20.79. ^{19}F NMR (376 MHz, $CDCl_3$) δ −152.11 − −152.27 (m, 1H), −158.36 (t, J = 21.8, 0H), −162.61 (dt, J = 11.1, 22.1, 1H). Anal.: Calcd for $C_{41}H_{29}F_5O_{10}$: C, 63.41; H, 3.76. Found: C, 63.39; H, 3.58. FTIR (KBr, cm^{-1}): 2850−2924 m, 2849 m, 2225 w, 1762 s, 1653 w, 1521 s, 1505 s.

*Compound **8***. Compound **8** was synthesized according to a modified literature procedure as follows (*43*). Hydrazine dihydrochloride (5 g, 48 mmol), 1,6-dichlorohexane (1.47 g, 9 mmol), and NaOH (4.2 g, 2.2 equiv) were dissolved in ethanol (40 mL) and heated to reflux for 3 h. The product was obtained upon extraction into EtOAc (40 mL), washing twice with water (20 mL), drying with Na_2SO_4, and evaporating to dryness by rotary evaporation of the solvent. The product was analyzed with ^{1}H NMR, which showed signals identical to those in the literature procedure.

General Procedure for ODNs O1, O2, O3, O4, O7a, O7b, O8a, and O8b. In an Eppendorf tube, a solution of compound **1** in DMF (10 μL, 25 mM) and an aqueous solution of the amino-modified oligonucleotide (10 μL, 0.5 mM) were mixed. Acetonitrile (20−25 μL) was added to produce a clear solution, and finally, NEt_3 (1 μL) was added, and the mixture was left for 2 h at room temperature. The solution was treated with an aqueous solution of ammonia (50 μL, 35% NH_3 in H_2O) for 30 min, and then all solvents were removed on a Speed Vac. A buffer (100 μL, 10% acetic acid adjusted with NEt_3 to pH 4) was added to the dry sample, and the mixture was vortexed carefully and was left at 60 °C for 2 h. Upon centrifugation (13000 rpm) for 1 min, we carefully removed the aqueous phase and injected it into a RP-HPLC column. The column was eluated with TEAA (100 mM, pH 7) and an increasing percentage of acetonitrile. The pure conjugate were eluted from the column with approximately 35% acetonitrile.

Formation of 4-HBs. Each ODN was dissolved in water and diluted to a final concentration of 10 μM. The 9 ODN strands, needed for the 4-HB, were mixed at equimolar concentration. To the resulting solution was added MES-buffer (pH 6.5, 100 mM) and NaCl (aq, 4 M) to a final concentration of 10 mM and 400 mM, respectively. The resulting solution was annealed in a PCR tube cooling from 90 to 25 °C over 2 h, and they were then ready for the coupling reactions.

General Procedure for Ni−Salen Coupling. The coupling was achieved by the addition of $NiCl_2$ and EDA to the 4-HBs obtaining a final concentration of 1 mM and 2 mM, respectively. The mixtures were left to react for 4 h at room temperature. The crude reaction was analyzed by PAGE without further purification.

General Procedure for Dihydrazone Coupling. The coupling was achieved by the addition of dihydrazine (60 mM in a MES buffer (100 mM, pH 5)) to the 4-HBs to obtain a final concentration of 6 mM. The mixtures were left to react for 3 h at room temperature. The crude reaction was analyzed by PAGE without further purification.

RESULTS AND DISCUSSION

The incorporation of organic modules into DNA-nanostructures requires a rational geometrical design to enable the coupling reactions. As illustrated in Figure 1, we aim for a setup where the termini of a 4-HB is functionalized with organic modules. The four DNA helices in the bundle are arranged in

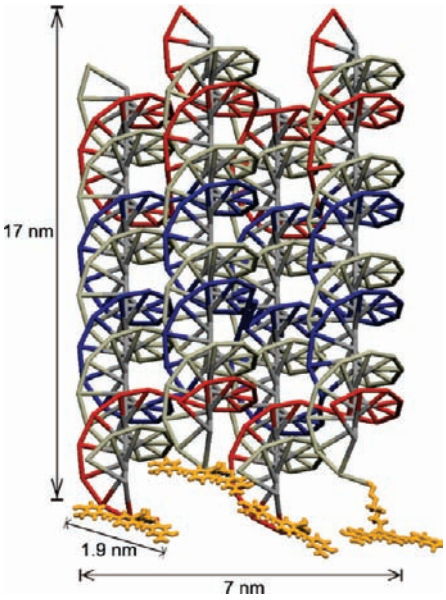

Figure 1. Schematic representation of a 4-HB with four organic modules (yellow) incorporated.

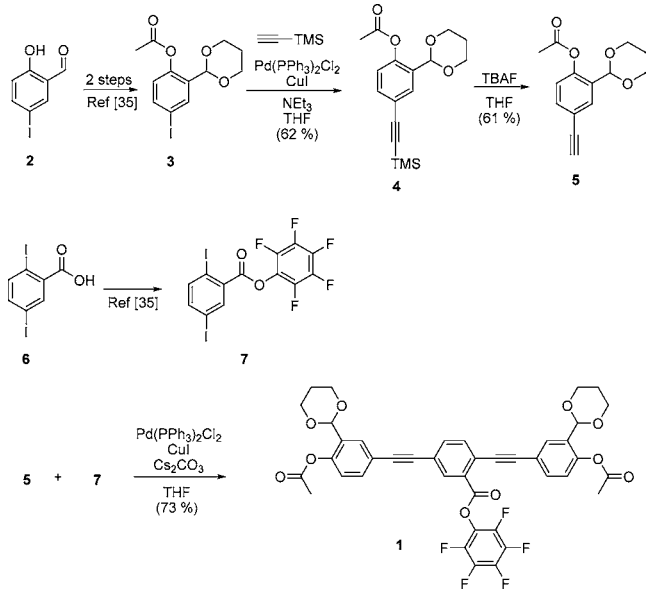
Scheme 1. Synthesis of Organic Module 1[a]



[a] TMS, trimethylsilyl; NEt_3, triethylamine; THF, tetrahydrofuran; TBAF, tetrabutylammonium-fluoride.

parallel, and each helix is coupled to its neighbor with a double crossover giving the 4-HB a well-defined shape. The attachment of organic modules in specific positions allows the 4-HB to serve as a scaffold at which the organic modules are positioned. The organic modules are linked to the 4-HB via spacers that allow the modules to rotate and define the space in which the modules move.

Organic module **1** (Scheme 1) is related to the module applied in a recent report by our laboratories (*35*), however, in a shorter version that fits with an interhelical coupling. It is based on a phenylene−ethynylene backbone with diprotected terminal salicylaldehydes and a central activated pentafluorophenyl ester. The latter functional group allows for the conjugation to amino-modified ODNs. The module has the required solubility in polar media, which is needed for the conjugation to ODNs.

The synthesis of **1**, shown in Scheme 1, is based on 5-iodosalicylaldehyde (**2**) and 2,5-diiodobenzoic acid (**6**).

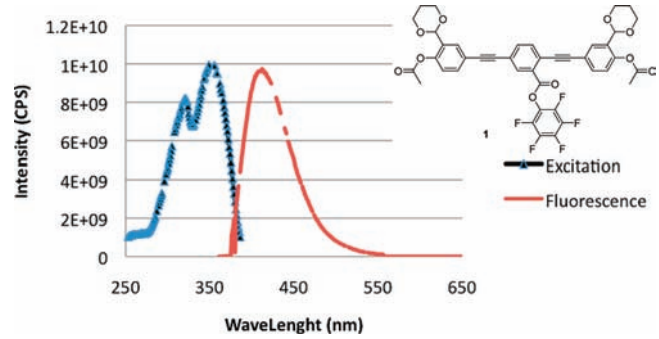


Figure 2. Excitation (blue) and emission (red) spectrum of organic module **1**. The spectra are measured with a solution of 1.66×10^{-4} mg/mL of **1** in 96% ethanol.

The aldehyde in **2** was acetal-protected followed by acetyl-protection of the phenol moiety (*35*). The resulting diprotected 5-iodosalicylaldehyde (**3**) was then ethynylated in a Sonogashira coupling (*44*) by reaction with trimethylsilyl-acetylene to obtain compound **4**. After the TMS group was removed, **5** was obtained in a moderate overall yield. The central aryl moiety (**7**) was prepared from 2,5-diiodobenzoic acid (**6**) by activation of the acid with pentafluorophenol in the presence of dicyclohexyl-carbodiimide (DCC) (*35*). To prevent hydrolysis or cleavage of the labile pentafluoroester (**7**), the final Sonogashira coupling between **5** and **7** was performed using anhydrous Cs_2CO_3 as a base instead of the more common use of secondary or tertiary amines. The coupling reaction gave the desired product **1** in 73% yield.

The excitation and emission spectra of product **1** were measured in ethanol at a concentration of 1.66×10^{-4} mg/mL (2.1×10^{-7} M). The module has two excitation peaks at 321 and 348 nm (Figure 2). After conjugation to an ODN and removal of the protecting groups, the peak at 321 nm disappears (see Supporting Information, Figure S1). When the compound excites at 348 nm, an emission maximum at 412 nm is obtained. It is clear that the organic module is highly fluorescent, and hence, it can be used to track ODNs conjugated to organic module **1**.

The reactive pentafluoroester in **1** serves as a handle for attachment of amino-modified ODNs. As illustrated in Scheme 2, we attached compound **1** to 8 different amino-modified ODNs by mixing the components in a mixture of 25% water, 25% DMF, and 1% triethylamine in acetonitrile. The desired amides were formed within 2 h. It is important that the ratio of water and organic solvent is well balanced since water content that is too high causes the organic module to precipitate, whereas water content that is too low makes the ODN insoluble. After conjugation, the acetyl protecting groups were removed by treatment with aqueous ammonia for 30 min. After evaporation of all solvents, the conjugate could be dissolved in a 10% acetic acid buffer at pH 4. This treatment has a dual purpose: it removes the acetal protecting group, and it causes unreacted organic modules to precipitate, which makes it easy to remove by simple centrifugation.

The conjugates were purified by preparative reverse phase (RP) HPLC. The RP-HPLC chromatograms for the conjugation reaction are shown in the Supporting Information (Figure S1). The product is easily identified because the organic module has a unique absorption peak at 348 nm. Furthermore, the relative height between the calculated extension coefficient of the ODN at 260 nm and the measured extension coefficient of the organic module at 348 nm can verify that exactly one organic module per ODN is present. For all eight conjugates, the product was further characterized by MALDI-TOF mass spectroscopy (see Supporting Information, Figure S2).

[a] Org, conjugated organic module; C6, C_6H_{12} spacer.

The 4-HB applied in this study is built up by 9 DNA strands and is a modification of a 4-HB structure designed by Yan and co-workers (*42*). In the original layout, the 4-HB contained sticky ends for wire formation; however, in this study the sticky ends are omitted. We have, furthermore, applied eight T1-C6 or T3-C6 amino-modified linkers to the organic module, which in different combinations were incorporated into the 4HB bundle. A list of all ODN sequences can be seen in Table 1. Permutations of the oligonucleotides in the 4-HB allow for the construction of 144 possible 4-HBs of which a representative number was prepared.

We have focused on three different designs. The first design has only 3′-modified ODNs, the second has two 3′- and two 5′-modified ODNs, and the third design has alternating 5′- and 3′ modified ODNs (see Figure 3).

All 5′-modified ODNs have one thymine (T) nucleotide (nt) and a C6 linker between the ODN and the organic module. If it is assumed that distance from the 4-HB to the terminal of the organic module is 2.3 nm (measured in ChemDraw 3D), the module can occupy a volume of 26 nm^3, and the concentration in this volume will be 130 mM (two salicylaldehydes in 26 nm^3). The 3′-modified conjugates have three Ts and one C6 linker, and the distance from the last hybridized nucleotide to the terminal position of the organic module is estimated to be 3.5 nm. The volume is calculated to be 90 nm^3 and the concentration of aldehydes 36 mM. The maximum bridging distances will then theoretically be 4.6 and 7.0 nm, respectively. Relating this to the dimensions of the 4-HB dimension reveals that when at least one 3′-modified ODN is incorporated, it should be possible to bridge all the way from the first to the fourth helix and form a dimer. However, if we use the 5′-modified ODNs we have a large actual concentration but a smaller overlapping volume where the two organic compounds can react. Using the long spacer gives a smaller actual concentration but a larger overlapping volume (see Figure 4). However, it should be taken into consideration that the calculated distances are based on the assumption that the 4-HB is rigid and DNA hybridization irreversible. This is of course not the correct picture since DNA is a soft and flexible material that can breathe. Nevertheless, the 4-HB will induce a great increase in the local concentration of the organic module, and the position of the organic modules in the 4-HB highly affects the plausibility for coupling reactions to occur.

The 4-HBs were assembled by heating the nine ODNs of choice to 90 °C followed by cooling to room temperature over 2 h in a MES-buffer (pH 6.5, 10 mM) containing 400 mM NaCl.

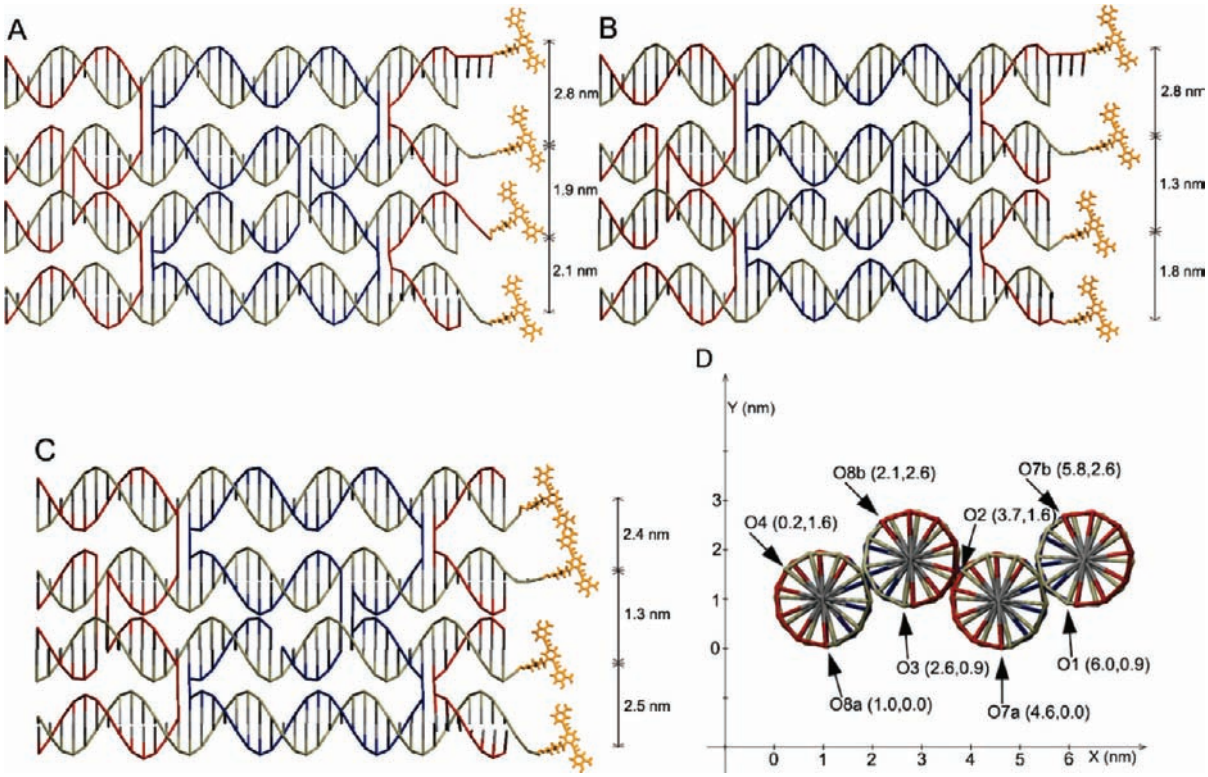

Figure 3. (A) 4-HB with **ODN O7b**, **O2**, **O8b**, and **O4** (all 3′-modified ODNs). (B) 4-HB with **ODN O7b**, **O2**, **O3**, and **O8a** (two 3′- and two 5′-modified ODNs). (C) 4-HB with **ODN O1**, **O2**, **O3**, and **O4** (alternating 5′- and a 3′-modified ODNs). (D) Model of the 4-HB illustrates the position of the eight different organic modified ODNs.

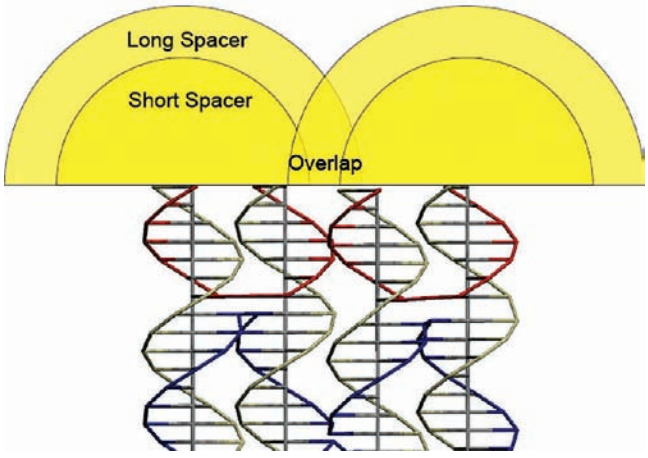

Figure 4. Top of the 4-HB is shown. The yellow spheres placed at helices 1 and 4 indicate the actual volume occupied by the organic modules. The small spheres refer to the short spacer (1 T), and the large spheres refer to the long spacer (3 T). The overlap indicates the chance for coupling.

The resulting 4-HB was analyzed by native polyacrylamide gel electrophoresis (PAGE). As mentioned above, the organic module is highly fluorescent. This enables imaging of the gel without staining with ethidium bromide or other DNA interchelators. Only structures containing the labeled DNA strand are visible, and this greatly simplifies gel analysis. Figure 5a illustrates the stepwise assembly of a 4-HB containing **ODN O1**, and Figure 5b illustrates fully assembled 4-HBs with one or more organic modules incorporated. The fully assembled 4-HBs with one or more organic modules incorporated migrate similarly since the modules constitute a very small fraction of the total molecular mass. The migration of the 4-HBs containing 189 base pairs corresponds to the migration of a linear dsDNA strand of 250 base pairs. The bulk and rigidity of the bundle retards its mobility compared to that of a linear DNA helix.

In this study, we have used two different approaches to perform the interhelical chemical coupling reactions of the terminal salicylaldehydes of the modules. In the first approach, a Ni(II)−salen complex is formed by reaction of Ni(II) chloride and ethylenediamine with two salicylaldehydes (Scheme 3) (*35*). In the other approach, dihydrazine **8**, synthesized according to a modified literature procedure (*43*), reacts with the two salicylaldehydes to form a hydrazone bridge.

In the first approach, the 4-HBs containing organic modules were treated with 1 mM Ni(II) chloride ($NiCl_2$) and 2 mM ethylenediamine (EDA) for 4 h. The products were analyzed with denaturing PAGE. Since two oligonucleotides are covalently coupled, the product of the chemical reactions migrates corresponding to the additive number of nucleotide in the conjugates that react, i.e., as a slower migrating band. We find that product is only observed in cases where the organic modules are incorporated at the right positions in the 4-HB and if structures have been treated with $NiCl_2$ and EDA. A typical denaturing 9% PAGE analysis for the reaction is shown in Figure 6. As Ni−salen complexes have been reported to quench fluorescence (*45*−*47*), the gel has to be stained with ethidium bromide before imaging by UV-light irradiation. Lane 3 is a control, containing a 4-HB with four different organic modified ODNs but without coupling reagents, and as expected, no higher-order structures are observed. In lanes 2 and 5, products arising from the coupling of **ODN O2** and **ODN O3** are observed. The band corresponds well with the 86 nt's of the dimeric product. In lane 2, it is also possible to form other products, but the dimer between helices 2 and 3 seems to be favored. Lanes 1 and 4 illustrate experiments where two shorter dimers containing two organic modules and 59 nt's should be formed. However, this product is not observed in the denaturing PAGE gel, although we do observe the disappearance of starting

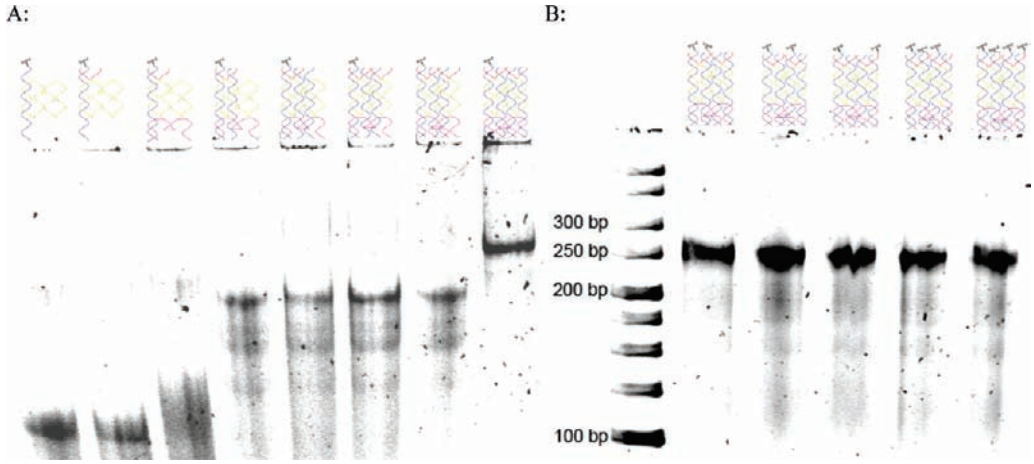

Figure 5. (A) Stepwise assembly of 4-HB. The conjugated DNA strand **ODN O1** is used as the fluorescent probe, and no staining is performed. PAGE (75 V, 2.5 h, 7.5% acrylamide). Lane 1 (**ODN 5** + **ODN O1**), lane 2 (lane 1+ **ODN 7**), lane 3 (lane 2+ **ODN 9**), lane 4 (lane 3+ **ODN 2**), lane 5 (lane 4+ **ODN 3**), lane 6 (lane 5+ **ODN 8**), lane 7 (lane 6+ **ODN 6**), and lane 8 (lane 7+ **ODN 4**). The gel is imaged by UV-irradiation. (B) 4-HBs with one or more organic modules incorporated. PAGE (75 V, 2.5 h, 7.5% acrylamide). The gel is stained with ethidium bromide before imaging. Lane 1 (marker), lane 2 (4-HB with **O1** and **O7a**), lane 3 (**O1** and **O3**), lane 4 (**O1** and **O8a**), lane 5 (**O1**, **O7a**, and **O3**), and lane 6 (**O1**, **O7a**, **O3**, and **O8a**).

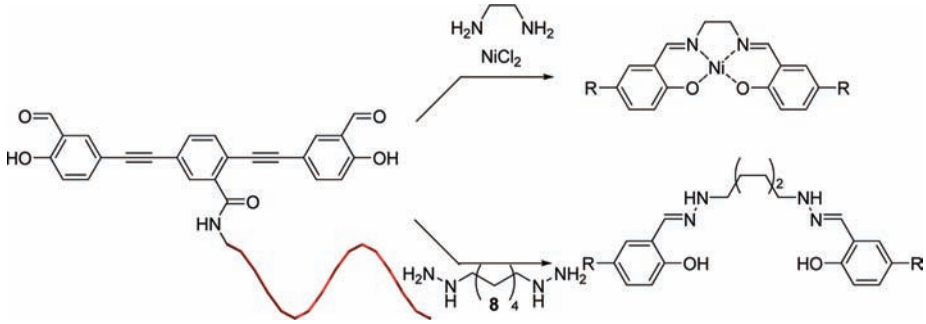
Scheme 3. Two Different Approaches for Interhelical Couplings[a]



[a] Top: aldehyde reacts with dihydrazine to form a dihydrazone. Bottom: salicylaldehydes react with ethylenediamine and Ni^{2+} to form a Ni−salen complex.

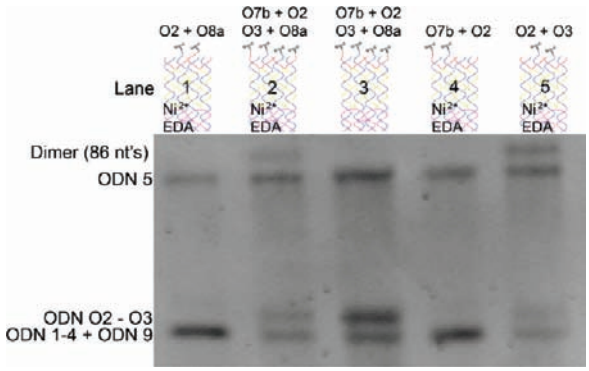


Figure 6. Ethidium bromide stained 9% denaturing PAGE. The 4-HBs with the incorporated organic modules are illustrated on the top of each well. Lane 1 (4-HB with **ODN O2** and **O8b**) treated with Ni^{2+} and ethylene diamine (EDA), lane 2 (4-HB with **ODN O7b**, **O2**, **O3**, and **O8a**) treated with Ni^{2+} and EDA, lane 3 (4-HB with **ODN O7b**, **O2**, **O3**, and **O8b**) not treated with Ni^{2+} and EDA, lane 4 (4-HB with **ODN O7b** and **O2**) treated with Ni^{2+} and EDA, and lane 5 (4-HB with **ODN O2** and **O3**) treated with Ni^{2+} and EDA. The dimer products of the Ni−salen dimer between **ODN O2** and **ODN O3** (organic dimer + 86 nt) are observed. The smaller dimer as well as trimers and tetramer are not observed.

material. We believe that the reason for this is fluorescence quenching by the Ni−salen complex (*45*−*47*). The existence of the small dimer was, however, observed by a number of other techniques. Accumulating the 4-HBs on filter cups before loading onto the polyacrylamide gel gave a weak and smeared dimer band according to PAGE analysis. We also analyzed the reaction mixture by RP-HPLC. The HPLC fractions were analyzed with UV−vis, PAGE analysis and MALDI-TOF mass spectrometry, and the existence of the short dimeric product was confirmed (see Supporting Information, Figure S3). We attribute, in part, the weakness of the bands containing the Ni complexes to be caused by quenching of the ethidium bromide emission (*45*−*47*).

For a further analysis of interhelical Ni−salen couplings, we used 4-HBs containing **ODN O1**−**O4** (42−44 nt) in order to obtain dimers containing at least 84 nt's. We performed PAGE analysis of 8 different 4-HBs, treated with Ni(II) chloride and ethylenediamine, testing the possibility to form interhelical couplings between neighboring helices, across one helix, across two helices, and attempting to form trimers and tetramers. The results are shown in Figure 7. Lane 1 shows the formation of dimer product between helices 1 and 2 (**ODN O1** and **O2**). Lanes 2, 3, and 4 show attempts to form trimer and tetramers, but we only observe increasing amounts of dimer. Lanes 5 and 6 show dimer bands formed between helices 2 and 3 and between helices 3 and 4. Lane 7 shows an attempt to form a dimer across one helix from helix 1 to helix 3. The linker size has only little influence on this result.

Since quenching of ethidium bromide fluorescence by the Ni−salen and other Ni complexes seems to be a serious problem for determining the yields of the experiments, alternative strategies had to be considered. Aldehydes are known to react

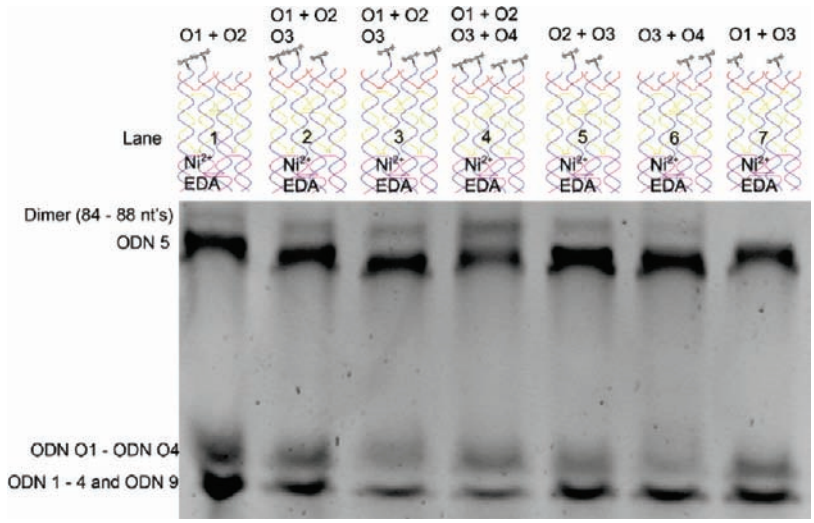

Figure 7. Ethidium bromide stained 9% denaturing PAGE. The 4-HBs with the incorporated organic modules are illustrated on the top of each well. Lane 1 (4-HB with **ODN O1** and **O2**) treated with Ni^{2+} and EDA, lane 2 (4-HB with **ODN O1**, **O2**, and **O3**) treated with Ni^{2+} and EDA, lane 3 (4-HB with **ODN O2**, **O3**, and **O4**) treated with Ni^{2+} and EDA, lane 4 (4-HB with **ODN O1**, **O2**, **O3**, and **O4**) treated with Ni^{2+} and EDA, lane 5 (4-HB with **ODN O2** and **O3**) treated with Ni^{2+} and EDA, lane 6 (4-HB with **ODN O3** and **O4**) treated with Ni^{2+} and EDA, lane 7 (4-HB with **ODN O1** and **O3**) treated with Ni^{2+} and EDA, and lane 8 (4-HB with **ODN O1** and **O4**) treated with Ni^{2+} and EDA. The Ni−salen dimer products of **ODN O1, ODN O2**, **ODN O3**, or **ODN O4** (organic dimer + 84−88 nt) are clearly observed.

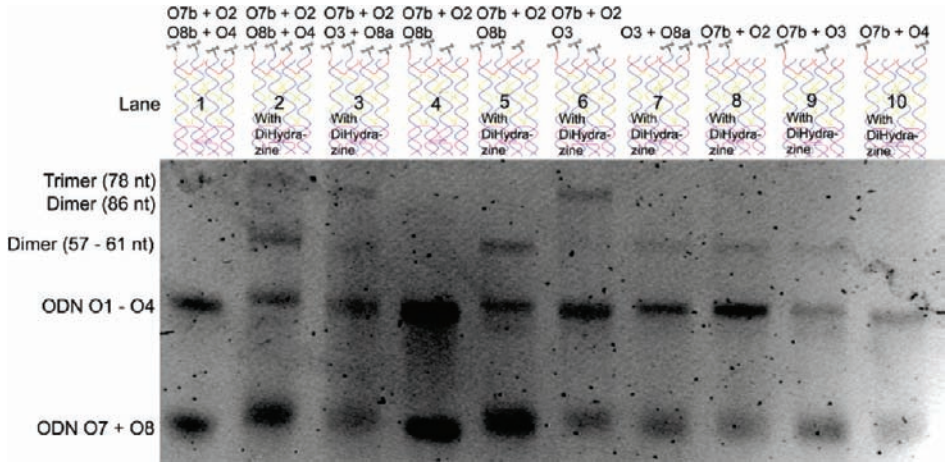

Figure 8. Unstained 9% denaturing PAGE. The 4-HBs with the incorporated organic modules are illustrated on the top of each well. Lane 1 (4-HB with **ODN O7b**, **O2**, **O8b**, and **O4**) with no dihydrazine treatment, lane 2 (4-HB with **ODN O7b**, **O2**, **O8b**, and **O4**) with dihydrazine, lane 3 (4-HB with **ODN O7b**, **O2**, **O3**, and **O8a**) with dihydrazine, lane 4 (4-HB with **ODN O7b**, **O2**, and **O8b**) with no dihydrazine, lane 5 (4-HB with **ODN O7b**, **O2**, and **O8b**) with dihydrazine, lane 6 (4-HB with **ODN O7b**, **O2**, and **O3**) with dihydrazine, lane 7 (4-HB with **ODN O3** and **O8a**) with dihydrazine, lane 8 (4-HB with **ODN O7b** and **O2**) with dihydrazine, lane 9 (4-HB with **ODN O7b** and **O3**) with dihydrazine, and lane 10 (4-HB with **ODN O7b** and **O4**) with dihydrazine. We observe clear dimer bands of both 59−61 nt (dimer 1) and 86 nt (dimer 2), and in lane 2, we observe a trimer with 78 nt.

with hydrazines to form stable hydrazones, and therefore, we developed an approach which is based on this. First, we synthesized the dihydrazine (**8**, Scheme 3) by reacting 1,6-dichlorohexane with hydrazine according to a modified literature procedure (*43*). The modified 4-HB was then treated with 5 mM of the dihydrazine (**8**), which allows the formation of interhelical couplings. Figure 8 illustrates a representative gel, denaturing 9% PAGE, for this approach. One great advantage of this approach is that it allows one to image the gel without staining, which implies that only ODNs with conjugated organic modules are observed, whereas bare ODNs not are visible.

From the PAGE analysis in Figure 8, both the small dimer (with ca. 59 nt) and the large dimer (with 86 nt) are observed in lanes 2, 3, and 5−9. A weak trimeric product is observed in lane 2. Furthermore, it can be seen that no dimer or higher ordered structures are formed in the absence of the dihydrazine (lanes 1 and 4). Important information about the distance dependence can also be derived from this gel image. When the distance between organic modules is increased, the product yield decreases. We do observe a weak band for the coupling between modules attached to helix 1 and helix 3 (across one helix, lane 9).

It is notable that the interhelical couplings are highly specific and rely on the 4-HB template. Both the Ni−salen and the dihydrazone coupling reactions were tested for unspecific couplings where modified ODNs were treated with coupling reagents without the ODNs required for the formation of 4-HB. Here, PAGE analysis (see Supporting Information, Figure S5) revealed that no coupling product was formed, which implies that the interhelical couplings exclusively occur in the 4-HB.

To compare the Ni−salen and the hydrazone couplings, we have repeated the Ni−salen experiments shown in Figure 7, using the same 4-HB and conjugates but applying the dihydrazone coupling instead (see Figure S4, Supporting Information). It is assumed that the results obtained by the Ni−salen couplings shown in Figure 7 are better than they appear from the gel image

since Ni-complexes quench the emission from ethidium bromide (*45*−*47*). The conjugates which have not participated in the formation of a dimer will also react with the diamine and form a complex with nickel (*48*). If it is assumed that the quenching of dimer and the other salicylaldehyde-containing sequences is comparable, then the relative intensities of the **ODN O1**−**O4** and dimer bands in Figure 7 indicate the formation in up to or above 50% yield. For the results obtained for the dihydrazone coupling reactions shown in Figure S4 (Supporting Information), we assume that all aldehyde groups are converted to hydrazones, and therefore, the potential quenching of the starting materials and the dimer is the same. The yields obtained for the dihydrazone couplings appears to be lower than that for the corresponding Ni−salen couplings, but the relative intensity distribution for the different setups are almost identical in the two experiments. The highest dimer yield is obtained when all four organic modules are present, and the lowest yields are obtained when the organic modules are places with a larger distance in between. We also attempted to form trimers and tetramers by placing 3 or 4 modules on 4 neighboring helices. The results from these attempts were in general disappointing since no tetramer was identified. It was possible to form the trimer as verified by PAGE in the dihydrazine reactions, but yields were low.

On the basis of the results presented in Figures 6−8, a consistent picture of the dimerization reactions can be drawn. The efficiency of the coupling reactions is moderate with a maximal yield of around 50% as estimated from relative intensities in the gels. We and others have previously observed that DNA-directed metal−salen couplings can proceed in high yields when the salicylaldehyde moieties are positioned in close proximity (*30, 49*). However, we have also previously observed that increased distance, between the attachment points of the organic module at the DNA-structure, in this case, 3.5 nm, corresponding to one helical turn in a B-DNA helix, gives rise to significantly lower yields. In the 4-HB, the length of the organic module is 1.9 nm and the length distance between neighboring helices around 2 nm, depending on the position of the attachment point in the helix. It is clearly demonstrated that the most favorable positioning of modules for the formation of dimers is where the organic modules are placed closest to a module at neighboring DNA helices (between helices 2 and 3).

CONCLUSIONS

Organic module **1** has been synthesized from 5-iodosalicylaldehyde (**2**) and 2,5-diiodobenzoic acid (**6**) in six synthetic steps closely related to a previously developed compound (*35*). Module **1** was conjugated to 8 different amino-modified oligonucleotides which were applied for the formation of 4-HBs. The stability of the modified DNA-nanostructure has been proved by native PAGE analysis. It is shown for the first time that a more complex DNA-nanostructure (4-HB) is applied to control the formation of a variety of different dimers formed by interhelical coupling of the modules. The bis(salicylaldehyde) terminated molecular rods in the 4-HBs were coupled either by Ni−salen formation or by a dihydrazone linkage developed for this study. The products were analyzed with denaturing PAGE analysis, and a single dimer has also been analyzed with MALDI-TOF analysis (additional gels and MALDI-TOF spectrum are shown in Supporting Information). The yields of the Ni−salen dimers are highly distance dependent. Even though we have designed the modules to be able to couple across one or two helices, we did not observe these long distance coupling. Even at neighboring helices, we observe a significant higher yield when the modules are placed in close proximity. We did not see full conversion of the modified ODNs, but no nontemplated coupling is observed. The dihydrazone coupling is less distance dependent, and the products are much easier to characterize since the fluorescence of the organic modules can be used to images the gel bands. We accomplished coupling across one helix to produce a trimer by this method. In the future, we will aim at improving the yields of interhelical couplings of organic modules and thereby enable the formation of monodisperse macromolecular networks templated by 2D DNA structures.

ACKNOWLEDGMENT

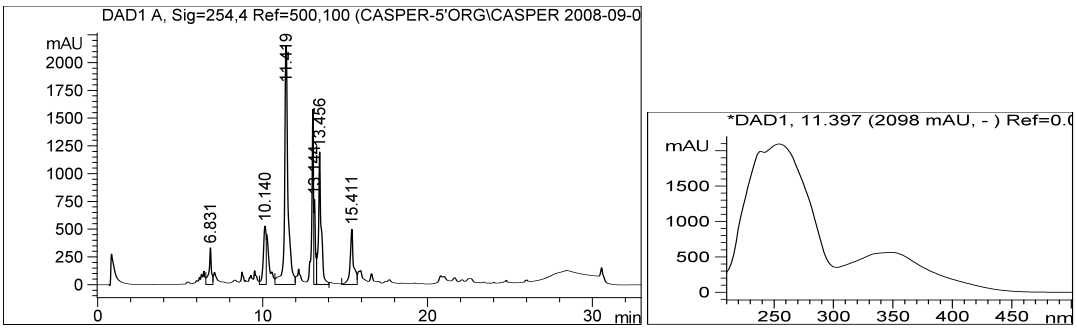

Figure S2. MALDI-TOF MS of the HPLC purified modified ODNs.

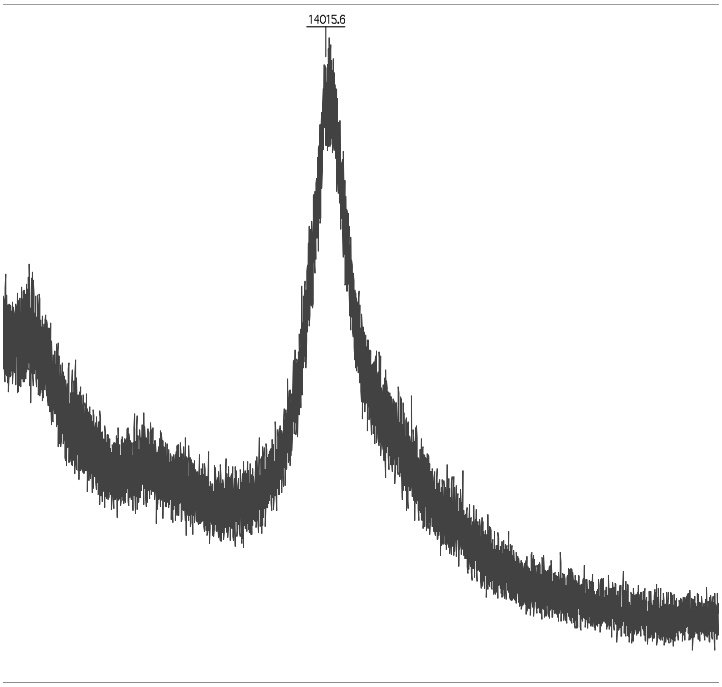
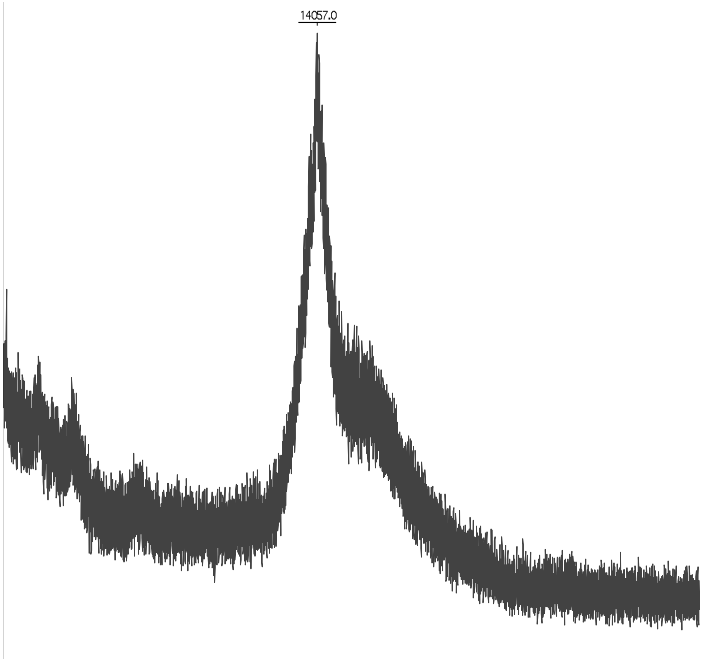
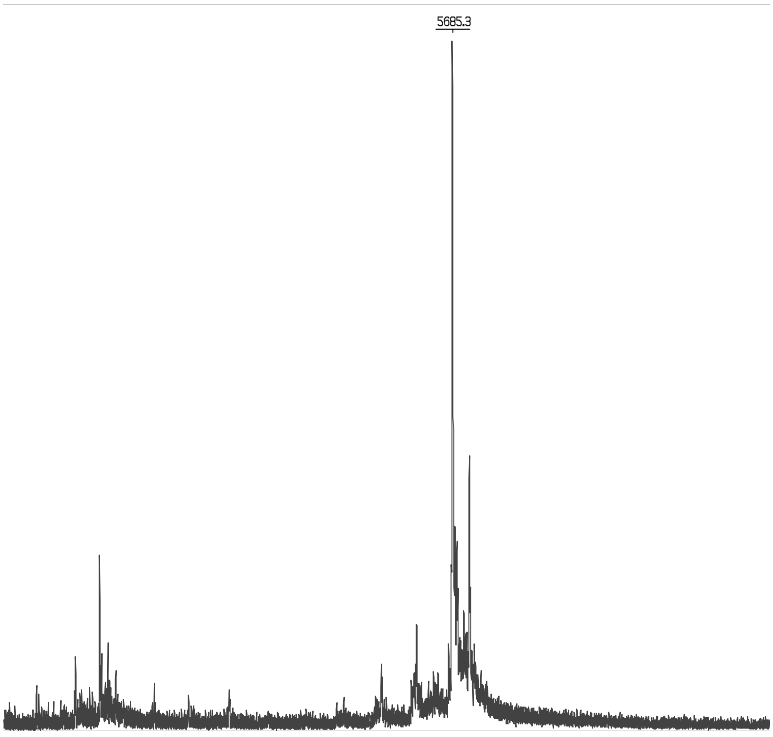
A) Conjugate **O2**: Calcd 14010 Found 14015



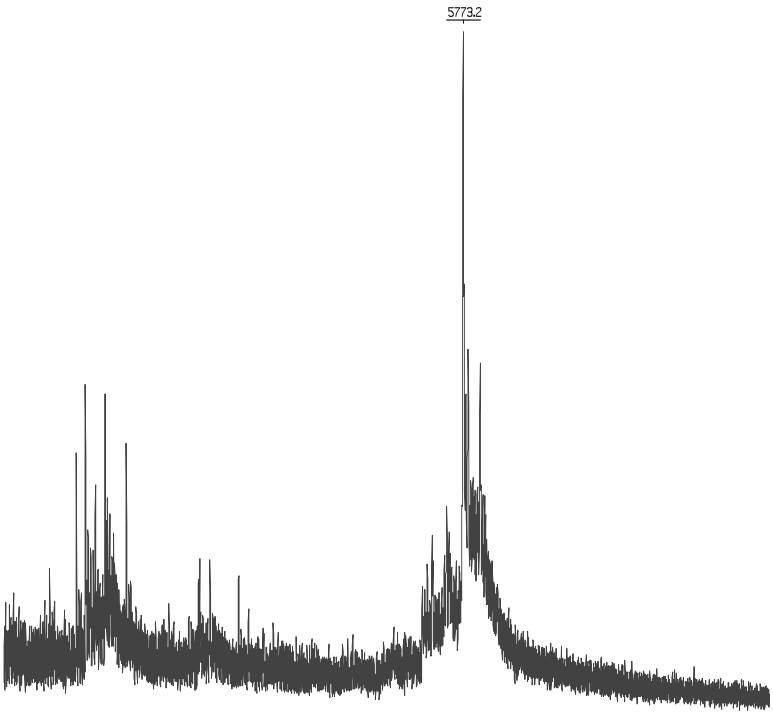
B) Conjugate **O4**: Calcd 14070 Found 14057



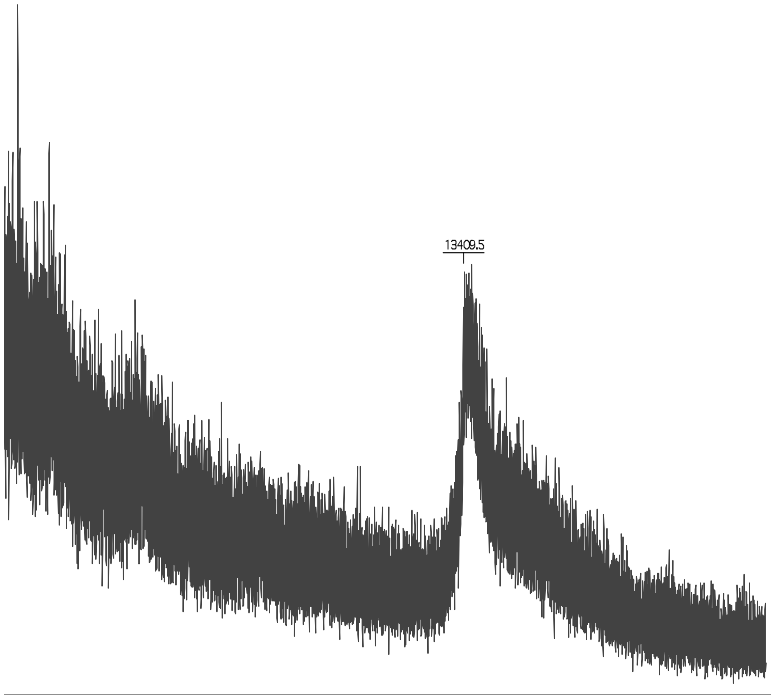
C) Conjugate **O7b**: Calcd 5986 Found 5985. The peak at [M+138] corresponds to the product + one matrix molecule.



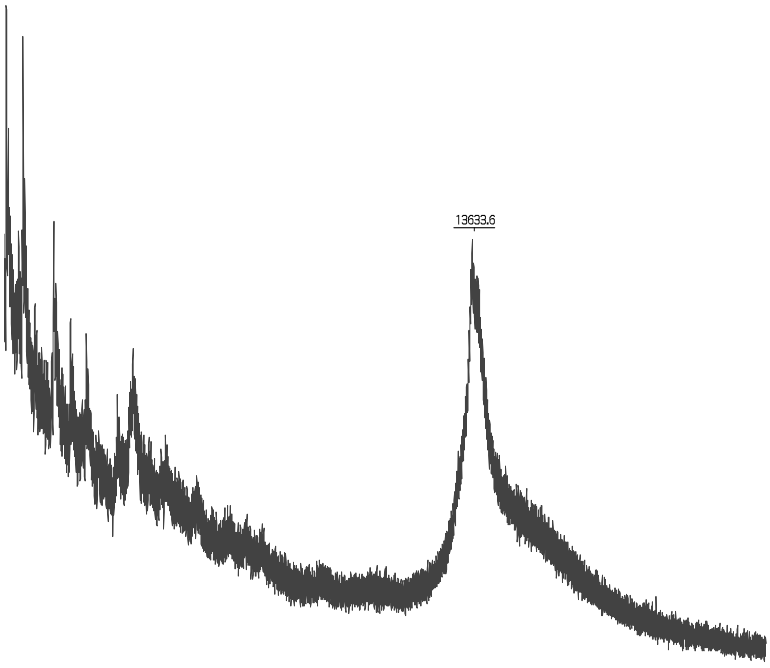
D) Conjugate **O8b**: Calcd 5782 Found 5773. The peak at [M+138] corresponds to the product + one matrix molecule.



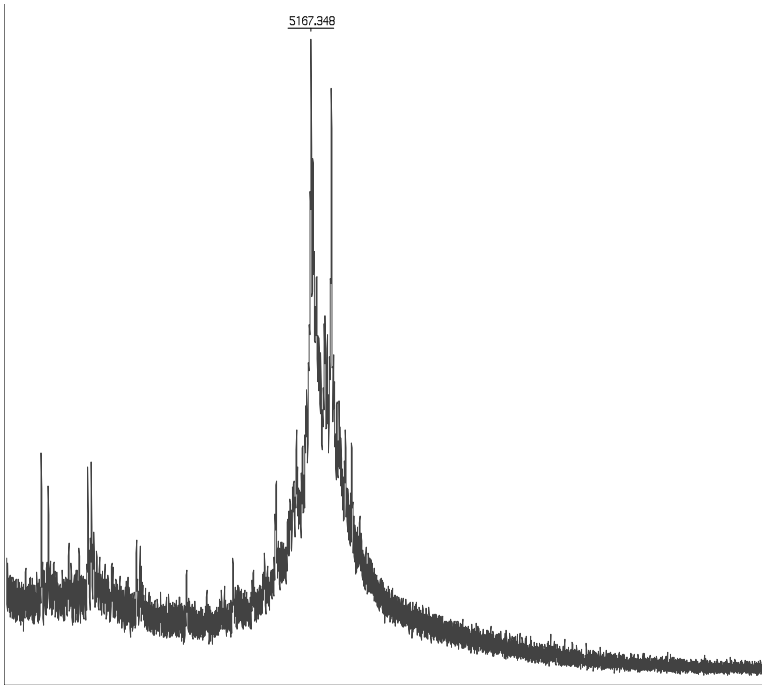
E) Conjugate **O1**: Calcd 13414 Found 13410.



F) Conjugate **O3**: Calcd 13634 Found 13634



G) Conjugate **O7a**: Calcd 5162 Found 5167. The peak at [M+138] corresponds to the product + one matrix molecule.



H) Conjugate **O8a**: Calcd 5258 Found 5258. The peak at [M+138] corresponds to the product + one matrix molecule.

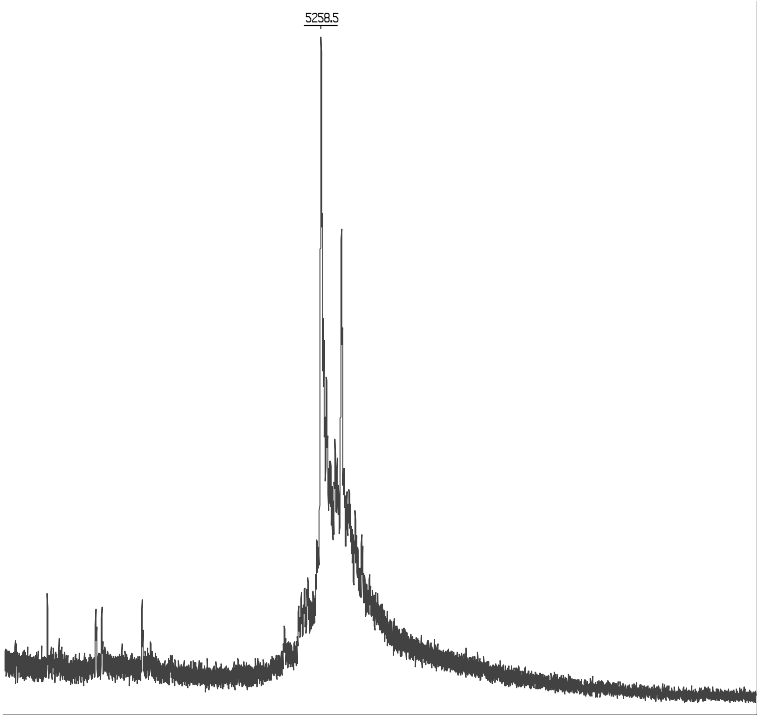


Figure S3. 4-HB templated nickel-salen couplings. (A) 9% denaturative PAGE analysis of 4-HBs, accumulated to one fifth of the original volume on filter cups before gel loading. (B) RP-HPLC chromatogram of the 4-HB with **O1** and **O7a** treated with nickel(II)chloride and EDA. (C) MALDI-TOF analysis of the partly purified dimer. (D) PAGE analysis of the partly purified dimer.

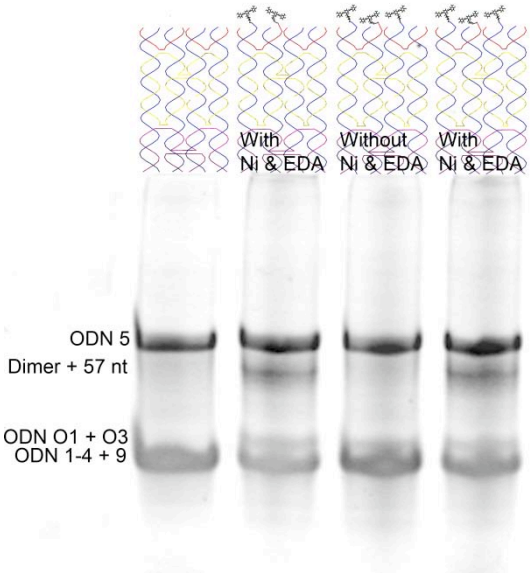
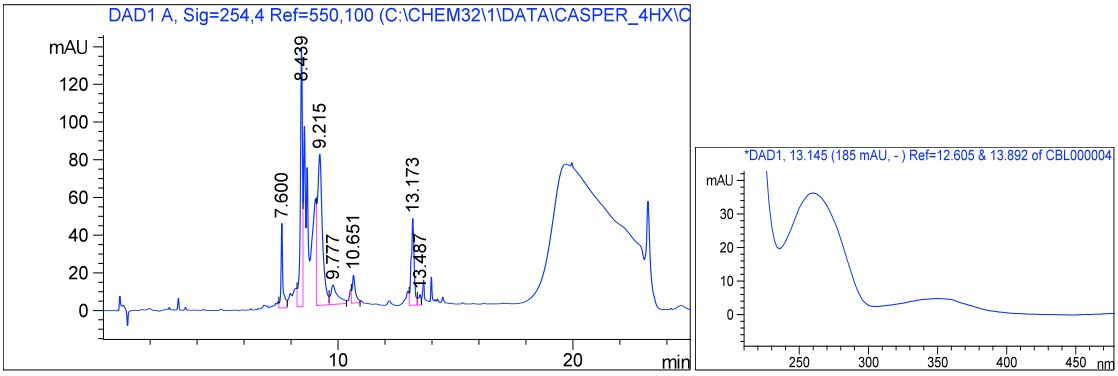
A) Lane 1 (unmodified 4-HB). Lane 2 (4-HB with **ODN O1** and **O7a** without coupling reagents). Lane 3 (4-HB with **ODN O1** and **O7a** without coupling reagents). Lane 4 (4-HB with **ODNO1** and **O7a** with coupling reagents).

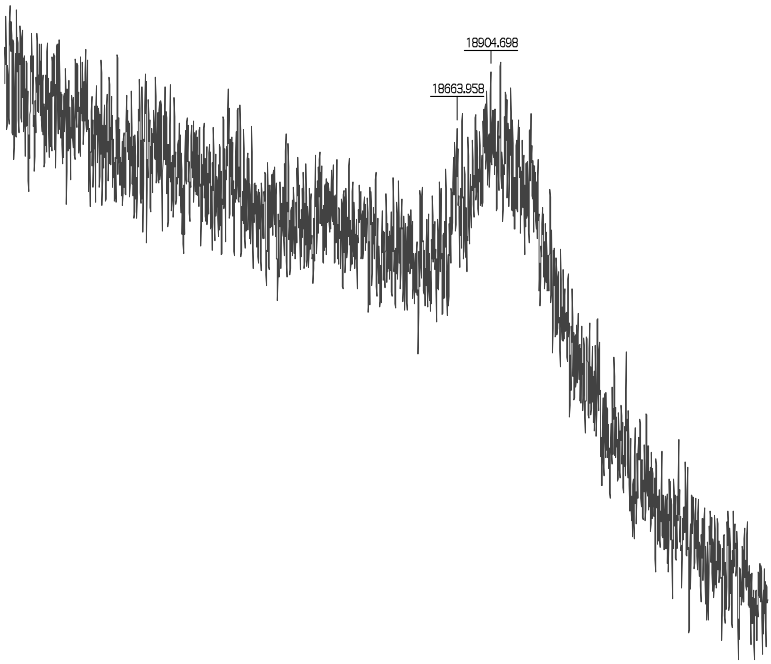


B) RP-HPLC chromatogram of a 4-HB with **ODN O1** and **ODN O7a** treated with nickel(II)chloride and EDA for 4 hours. The initial eluent is pure 0.1 M TEAA and is changed stepwise to separate the unmodified DNA strands (elutes from 7 to 10 minutes) from the organic modified DNA strands (eluted at 13 minutes). The peak at 13 minutes contains a mixture of monomers and the dimer. The UV-VIS spectrum of the collected sample at 13 minutes is shown. The purpose with this stepwise procedure is to remove all unmodified DNA strands and thereby enable the identification of the dimer. The fraction at 13 minutes is analyzed with MALDI-TOF MS and PAGE analysis (see Figure S3C and D)



The stepwise method: The acetonitrile percentage is increased from 0 to 20% in the first 10 minutes. From 10 to 17 minutes is the acetonitrile percentage held constant at 70%.

C) MALDI-TOF analysis of the HPLC fraction collected at 13 minutes, according to the HPLC spectrum in Figure S3B. The peak is very broad and it is therefore difficult to find an exact mass. Expected mass of the **O1**-**O7a** dimer: 18573. Found: 18633.



D) PAGE analysis. An 4-HB with **ODN O1** and **ODN O7a** that has not been treated with coupling reagents was purified by the same stepwise method as described in Figure S3B. Lane 1 contains the resulting fraction at 13 minutes (containing the organic modified DNA strands). Lane 2 contains the fraction at 13 minutes according to the HPLC spectrum in Figure S3B. The short dimer is easily observed because all the unmodifed DNA strand are removed and the SYBr gold stained gel can be images by integrating the fluorescent light for 4 seconds.

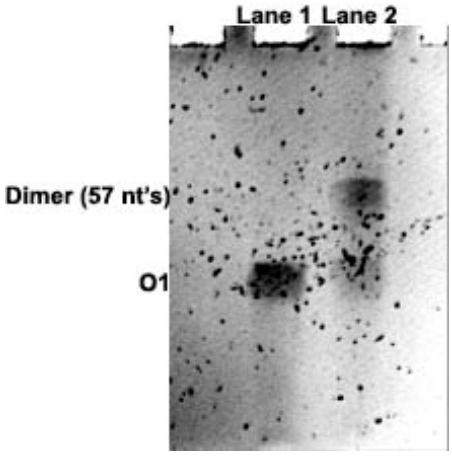


Figure S4. Non-stained 9% denaturing PAGE similar to the gel in Figure 7, but with the dihydrazine as the coupling reagent. The 4-HB incorporating **ODN O1**, **O2**, **O3** and **O4**. Lane 1 (4-HB with **ODN O1**, **O2**, **O3** and **O4** without dihydrazine treatment). Lane 2 (4-HB with **ODNO1** and **O2** treated with dihydrazine). Lane 3 (4-HB with **ODN O1**, **O2** and **O3** treated with dihydrazine). Lane 4 (4-HB with **ODN O2**, **O3** and **O4** treated with dihydrazine). Lane 5 (4-HB with **ODN O1**, **O2**, **O3** and **O4** treated with dihydrazine). Lane 6 (4-HB with **ODN O2** and **O3** treated with dihydrazine). Lane 7 4-HB with **ODN O3** and **O4** treated with dihydrazine). Lane 8 (4-HB with **ODN O1** and **O3** treated with dihydrazine). Lane 9 (4-HB with **ODN O1** and **O4** treated with dihydrazine). The hydrazone dimer consisting of **ODN O1, O2, O3** or **O4** (organic dimer with 84-88 nt) is clearly observed.

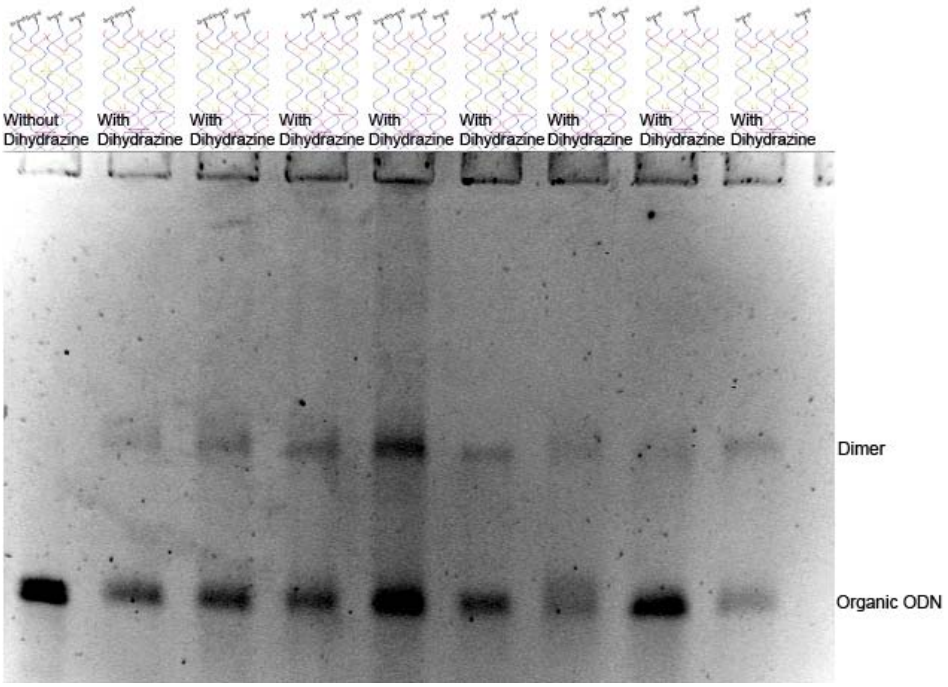

Figure S5. Tests for unspecific couplings in, (A) nickel-salen formation and (B) for dihydrazone formation. (A) Lane 1 (**ODN 1**). Lane 2 (**ODN O1**). Lane 3 (**ODN O1** and **O3**). Lane 4 (**ODN 5**). Lane 5 (4-HB with **O1**). Lane 6 (4-HB). Prior to gel loading was all solutions treated with nickel(II)chloride and EDA. The gel clearly verifies that no intermolecular couplings are observed.

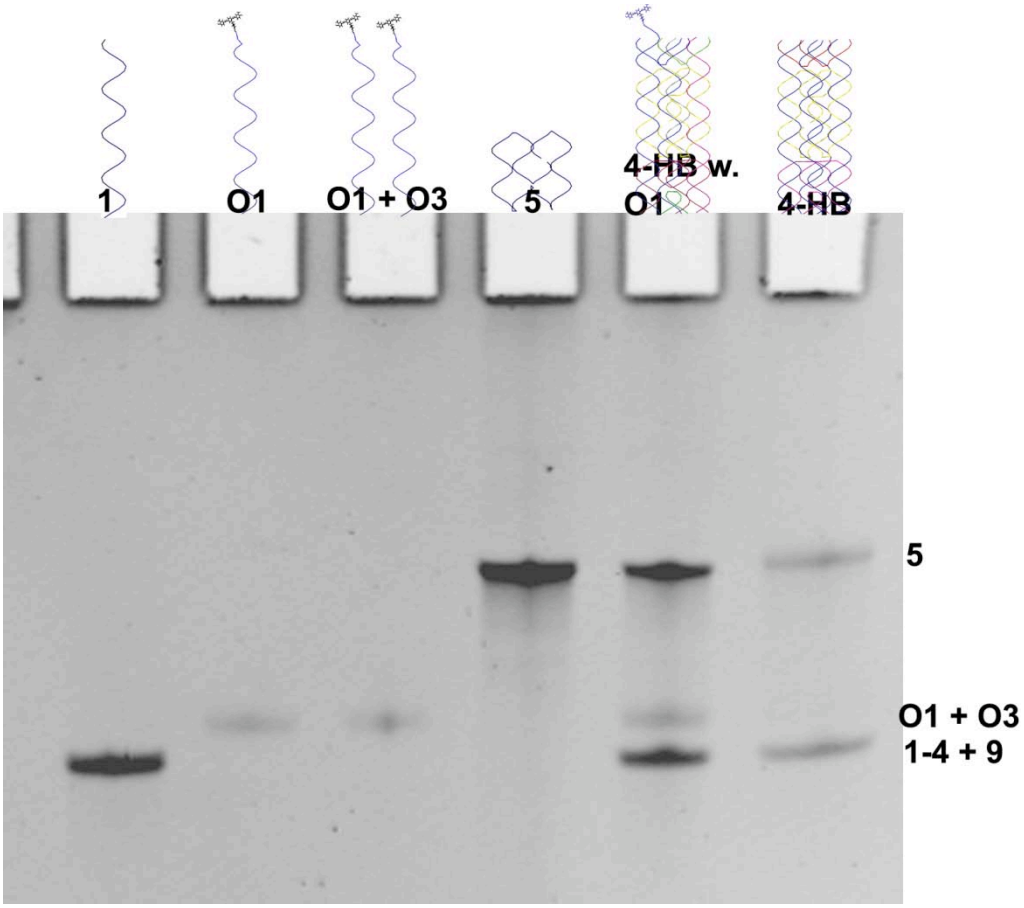

(B) Lane 1 (**ODN 1**). Lane 2 (**ODN O7a**). Lane 3 (**ODN O1** and **O3**). Lane 4 (**ODN O7a** and **O8a**). Lane 5 (4-HB with **O7a**). Prior to gel loading was all solutions treated with dihydrazine for two hours. The gel clearly verifies that no intermolecular couplings are observed.

Optimal ^{99m}Tc Radiolabeling and Uptake of Glucosamine Sulfate by Cartilage. A Potential Tracer for Scintigraphic Detection of Osteoarthritis

Grazyna Sobal,* Johannes Menzel,† and Helmut Sinzinger*

University Clinic of Nuclear Medicine and Institute of Immunology, Medical University of Vienna, Vienna, Austria. Received March 3, 2009; Revised Manuscript Received May 26, 2009

Glucosamine sulfate (GS) is used in treatment of human osteoarthritis, but no data for ^{99m}TcGS scintigraphy are available. Radiolabeling of GS was performed using the $^{99m}TcO_4^-$/tin method. We applied two procedures for separation of free ^{99m}Tc using PD10 and G10 columns. In each eluted fraction, GS content was estimated by the Elson/Morgan method. For optimal radiolabeling, we varied the amount of GS, tin, ^{99m}Tc activity, and pH. For uptake age matched human rib cartilage (males, 78 and 63 years old) and 5−10 μCi/well of ^{99m}TcGS were used. Uptake was monitored up to 72 h. Also, washout of the tracer 3 h and 24 h after uptake was investigated. At pH 2, using PD10 column, the uptake of ^{99m}TcGS amounted to 100.8 ± 2.9%, $n = 6$ at saturation time of 72 h. Uptake was age-dependent; at pH 5, it amounted to 99.8% as compared to 66.1% at 78 vs 63 years old. When the amount of tin was varied at pH 2, the tracer uptake amounted to 21.37% (1 mg) vs 45.99% (2.5 mg) at saturation. At pH 7, the amount of needed tin was much lower and amounted to 42.50 ± 2.50% using 0.1 mg vs 25.11 ± 1.90% using 0.05 mg. Although the uptake at pH 7 (0.1 mg tin) is comparable with that at pH 2 (2.5 mg tin), the washout of the tracer amounted only to 4.10 ± 1.25% and 2.05 ± 0.65% after 3 h and 24 h, respectively. During degeneration of cartilage, incorporation of ^{99m}TcGS is high and could therefore be a promising tracer not only to target osteoarthritis but also to monitor the effects of therapy.

INTRODUCTION

Glucosamine (GA) is a natural sugar and a key component of the extracellular matrix of cartilage. These monomeric sugars possess charged side chains, which absorb water and provide lubrication for cartilage that covers the bones in the joints. With aging or under pathological conditions, GA, like other sugars, declines in concentration and loses the ability to absorb water. Treatment with GA affects the symptoms but not the disease, since after ingestion, GA has been shown to be absorbed in the joints as a component of the cellular matrix of cartilage. Glucosamine sulfate (GS) is the sulfate derivative of the naturally occurring aminomonosaccharide, GA.

GA and chontroitin sulfate (CS) are widely used drugs for treatment of osteoarthritis (*1*−*4*) as symptomatic slow-acting drugs for osteoarthritis (SYSADOA). Osteoarthritis (OA) represents an advanced stage of disease caused in part by injury, loss of cartilage structure, and function and is an inflammatory process. The results of an in vitro study (*5*) indicated that GS and CS can regulate gene expression and synthesis of nitric oxide (NO) and prostaglandin PGE_2, thereby modulating anti-inflammatory activity.

Bone scintigraphy is generally regarded as very sensitive but nonspecific. Because of their sensitivity and advantage over MRI (*6, 7*), noninvasive isotopic methods including SPECT and PET (*8, 9*) play an important role in clinical studies of arthritis. Although imaging techniques using radiolabeled polyphosphonates have been a major clinical tool for imaging osteoblastic activity and tumor involvement of the skeleton during the past decades, radiolabeled probes specific for the pathophysiology of synovium and articular cartilage are just at the early stages of exploration. For this reason, more specific probes for articular cartilage disease would be preferable. GS as an endogenous cartilage component is one of these candidates. GS is widely used for the treatment of human osteoarthritis, but no data on GS labeling with ^{99m}Tc or studies of radiolabeled ^{99m}Tc GS in the cartilage are available.

The aim of this study was to elaborate the optimal radiolabeling of ^{99m}Tc GS for future SPECT analysis by providing the optimal radiolabeling method, quality control of the tracer, its stability, and evaluation of uptake of radiolabeled compound by cartilage and to verify the degree of GS internalization.

EXPERIMENTAL PROCEDURES

Materials. GS was provided by Rottapharm, Monza, Italy. Radiolabeling of GS was performed using $^{99m}TcO_4^-$/stannous chloride according to the methods (*8, 10*) analogous to chondroitin sulfate labeling. We found that, because of colloid formation, pH is a limiting factor for the labeling procedure and tracer uptake.

Radiolabeling Procedure. Briefly, 25 mg of GS was dissolved in 0.75 mL of 0.3 M HCl, pH 2; then, 1 mg of stannous chloride was added followed by the addition of 1−3 mCi (37−121 MBq) of $^{99m}TcO_4^-$/(0.25 mL). We also performed experiments by buffering final reaction mixture with 0.50 M sodium acetate buffer at pH 5.0 or 0.01 M sodium citrate buffer at pH 7 to obtain more physiological conditions. The reaction mixture was gently stirred and incubated for 1 h at room temperature. Thereafter, the radiolabeled product was applied to the Sephadex PD10 chromatography column (Bio-Rad, California, USA) for separation from free technetium. The radiolabeled GS was eluted from the column with 0.3 M HCl in 10% ethanol or buffer in the void volume (3−5 mL), while free technetium was eluted from the column with the total volume (6−10 mL). In parallel, we measured ^{99m}Tc activity in each fraction to obtain the elution profile from the column. For

optimal radiolabeling, we varied the amount of GS (2.5 mg versus 25 mg), tin (1−5 mg), and also ^{99m}Tc activity (1.5−4 mCi, 55.5−148 MBq). We also applied two different procedures for separation of free ^{99m}Tc after radiolabeling by using PD10 and G10 (self-prepared, 15 mL) columns. In each eluted fraction after labeling, GS content was estimated by the Elson and Morgan method (*11*). For each of the radiolabeling variations, the radiolabeling efficiency, maximal uptake, and washout of the tracer were estimated.

Uptake Studies. For uptake studies, human rib cartilage (males, 78 and 63 years old, post mortem) cut into pieces of about 5 mg wet weight was used. For uptake, we incubated with 5−10 μCi/well of ^{99m}TcGS. Uptake was monitored every 10−30 min, and thereafter every few hours until saturation was achieved (up to 72 h).

After each incubation period, the tissue was separated from incubation medium by simple differential centrifugation and rapidly washed twice with PBS buffer. The net (after subtraction of residual activity and activity related to adhesion of tracer to the tubes) cellular uptake of ^{99m}TcGS in vitro was measured by a gamma counter (Packard, Meridien, CT, USA). Also, washout of the tracer after uptake was investigated. The washout of the tracer was performed by incubation of tissue after uptake experiments (3 h and 24 h) with PBS buffer for different times (10 min to 3 h).

Derivatisation of GS. GS measurement was perfomed according to the modified method by Elson and Morgan (*11*). Briefly, 1 mL of column eluent containing GS was mixed with 1 mL of the acetylacetone reagent (2 mL of acetylacetone dissolved in 98 mL of 1 N sodium carbonate) and closed with a cap. The tubes were then placed in a water bath at 90 °C for 45 min. Thereafter, they were cooled in running water. Then, 4 mL of ethanol (95%) was added and tubes were vortexed. Finally, 1 mL of PDMAB (*p*-dimethylaminobenzaldehyde) for derivatization was added. After mixing again, the tubes were allowed to stand at room temperature for 1 h, getting a characteristic pink color. The absorbance was read at 540 nm. GS content of the samples was calculated using a standard curve with defined GS amount (5−50 μg/mL).

Statistical Analysis. The results are expressed as mean values ± SD. Statistical analysis was performed using one-way ANOVA; $p < 0.05$ was considered statistically significant.

RESULTS

Radiolabeling Procedure and Uptake Studies. The radiolabeling yield was strongly influenced by pH because of colloid formation. At higher pH 5, the labeling efficiency was very low (10.1−12.5%) and the colloid content high (31.6−89.9%), detected on Sephadex PD10 chromatography column by separation after labeling. In contrast, at pH 2.0 almost no colloid or only a few percent of colloid was formed (maximal 4.5%; data not shown), and a very high labeling efficiency (72.0−95.6%) was achieved.

During the incubation with ^{99m}TcGS, we observed continuously increasing uptake of tracer over the time up to saturation. At pH 2, after separation on a PD10 column, uptake was very high, amounting to 100.8 ± 2.9%, $n = 6$, at saturation of 72 h (Figure 1A). This means that the obtained saturation of the tracer at this pH was achieved when the total of introduced ^{99m}Tc GS tracer was completely taken up into the cartilage. At pH 5, the uptake was much lower, but increasing with time until saturation amounting to 50.1 ± 5.5%, $n = 6$ (Figure 1A).

After 3 h uptake, the washout of the tracer from cartilage at pH 2 amounted to 45.7 ± 2.5% and was completed after 30 min. After 24 h uptake, the washout was unchanged at 44.1 ± 7.5%, but it was completed after 3 h (Figure 1B). These results indicate that in both experiments more that 55% of the

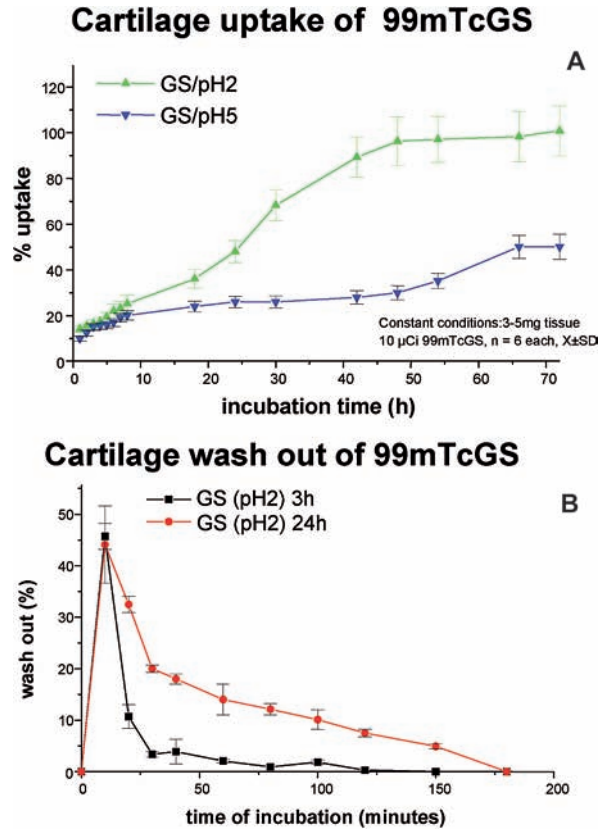

Figure 1. Uptake of ^{99m}TcGS after separation on PD10 column as a function of time, at different pH values (A). The washout of ^{99m}TcGS from cartilage at pH 2, after 3 h and 24 h of uptake as a function of time (B). Each point represents the mean value of three radiolabeling experiments with two measurements each.

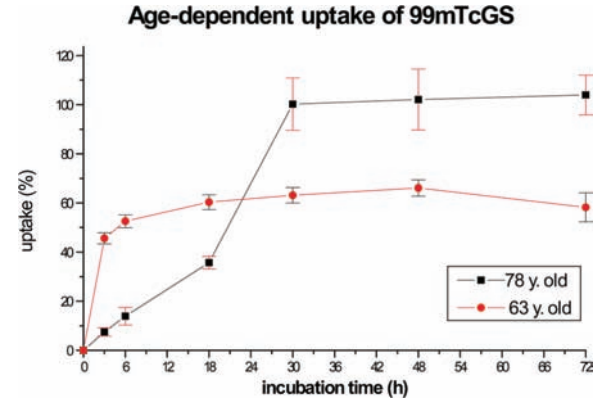

Figure 2. Age-dependent uptake of ^{99m}TcGS at ph 2. Each point represents the mean value of three radiolabeling experiments from two specimens.

introduced tracer is retained in the cartilage and is not eluted. Uptake was age-dependent and amounted to 99.8% as compared to 66.1% at 78- vs 63-year-old individuals at saturation by 72 h (Figure 2). The nonspecific uptake in the presence of a 50-fold excess of cold GS in all experiments increased with time up to a maximum of 12−15% at saturation by 72 h.

Because of similar molecular weights of both components (GS and pertechnetate), the separation of free ^{99m}Tc after radiolabeling by a chromatography column or ITLC-SG chromatography was difficult. For radiolabeling of GS using $^{99m}TcO_4^-$/1 mg tin method at pH 2, we evaluated the separation by PD10 and G10 columns. By estimation of GS content in

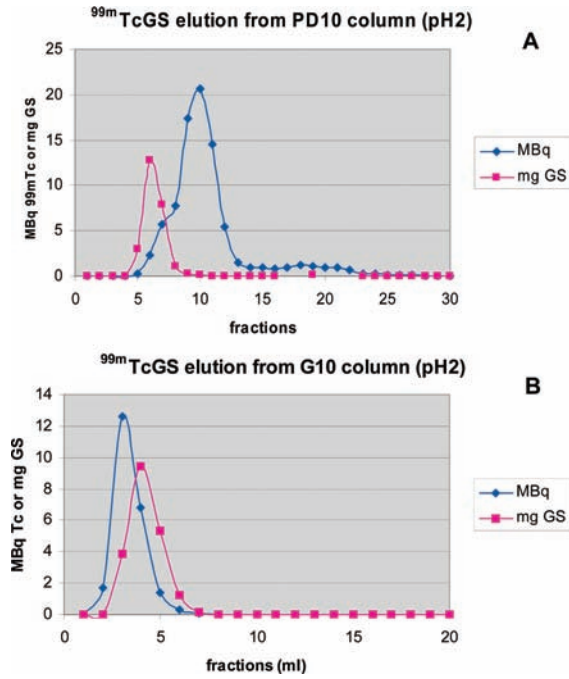

Figure 3. Chromatography procedure on PD10 vs G10 column, after radiolabeling at pH 2. In parallel, GS content in each eluted fraction was estimated.

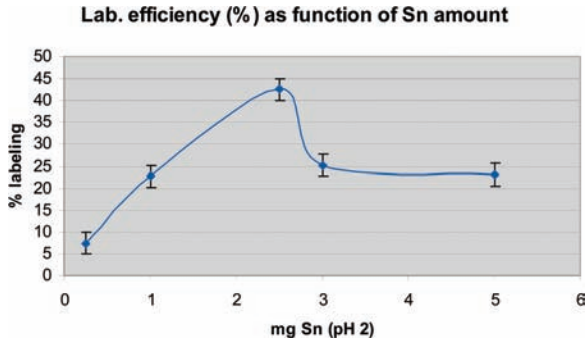

Figure 4. Dose-dependent (tin) estimation of radiolabeling efficiency at pH 2. Each point represents the mean value of three radiolabeling experiments with two measurements each.

each eluted fraction, we found a shift between the maximum of GS content peak and the radioactivity peak by PD10 (Figure 3A); therefore, we applied a G10 column for more precise separation of components after radiolabeling (Figure 3B).

Varying the amount of tin (0.1−5 mg), at pH 2 and using G10 column for separation, we found the optimal conditions at 2.5 mg tin and 25 mg of GS, 4 mCi, for radiolabeling. This factor not only influences the labeling efficiency (22.95−42.73%, 1 mg vs 2.5 mg tin) (Figure 4), but also the ^{99m}TcGS uptake in cartilage. While tracer uptake using 1 mg tin for labeling achieved a maximum of 21.37% at saturation (72 h), in contrast using 2.5 mg tin the maximal uptake amounted to 45.99% at saturation (Figure 5A). However, using 3−5 mg of tin the labeling efficiency and uptake could not be further increased and achieved a comparable amount to that using 1 mg, amounting to 28.13% at saturation at 72 h. Tracer washout after 3 h incubation using 2.5 mg tin for radiolabeling amounted to a maximum of 17.44 ± 6.60% and after 24 h to 4.94 ± 3.60%, respectively (Figure 5B).

Finally, we found that buffering of the radiolabeling mixture with 0.01 M citrate at pH 7, reflecting more closely physiological

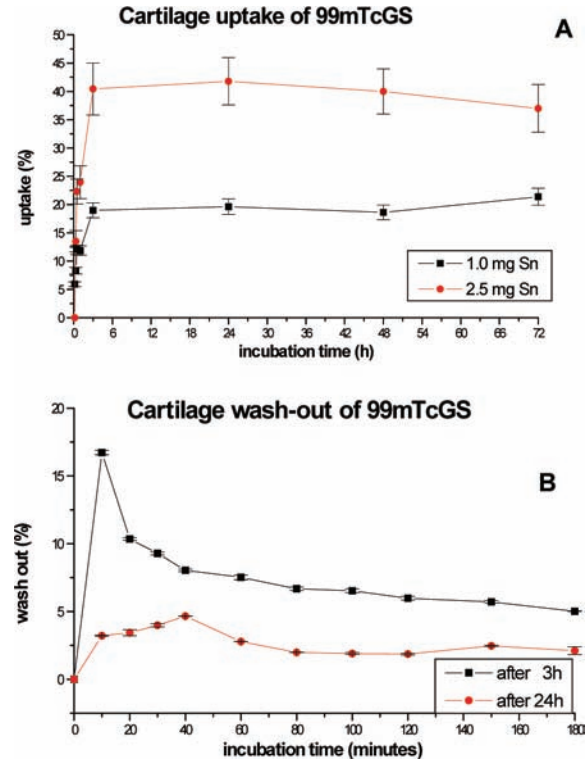

Figure 5. Dose-dependent uptake of ^{99m}TcGS at pH 2 (A) and washout of the tracer 3 h vs 24 h after uptake (B), at constant condition: pH 2, 2.5 mg tin. Each point represents the mean value of three radiolabeling experiments with two measurements each.

conditions, gave the best results of highest labeling efficiency and specific activity of 1.6 MBq/mg GS. However, the amount of tin was much lower than at pH 2. Using 0.1 mg tin for radiolabeling, we get the highest labeling efficiency and specific activity (Figure 6A), followed by 0.05 mg tin, getting slightly worse results (Figure 6B).

Also, the corresponding uptake at this pH 7 (0.1 mg tin) showed a higher uptake (42.50 ± 2.50%) than using 0.05 mg tin for radiolabeling (25.11 ± 1.90%) (Figure 7A). Although the uptake at this pH 7 (0.1 mg thin) is comparable to that at the uptake at pH 2 (2.5 mg tin) (Figure 5A), the washout of the tracer at pH 7 was much lower, amounting only to (4.10 ± 1.25%) and 2.05% ± 0.65%), after 3 h and 24 h, respectively (Figure 7B).

DISCUSSION

GA is an endogenous component of cartilage and is a monomeric part of glucosaminoglycans in cartilage matrix and synovial fluid (*12*). Chondrocytes use it for CS proteoglycan synthesis. GS has been found to be of benefit in OA in a number of studies (*13*−*15*) for the symptomatic treatment beneficially affecting the radiographic progression of OA (*16*−*19*). Therefore, ^{99m}Tc GS could be such a specific tracer for uptake in articular cartilage.

The mechanism of action of GS has not been fully elucidated yet. Cartilage-unrelated effects such as inhibition of superoxide-radical generation (*20*) or the inhibition of nitric oxide synthesis (*21*) have been suggested to explain the fast onset of action on symptoms reported even in short-term clinical trials (*22*). In contrast, the long-term effects of GS reported effects on cartilage metabolism are by stimulation of anabolic activities on proteoglycan synthesis (*23, 24*) and depression of catabolic activity, such as the effect of metalloproteases (*24, 25*).

Clinical studies have shown that GS is fairly safe (*22, 26, 27*) and definitely far more safe than standard nonsteroidal anti-

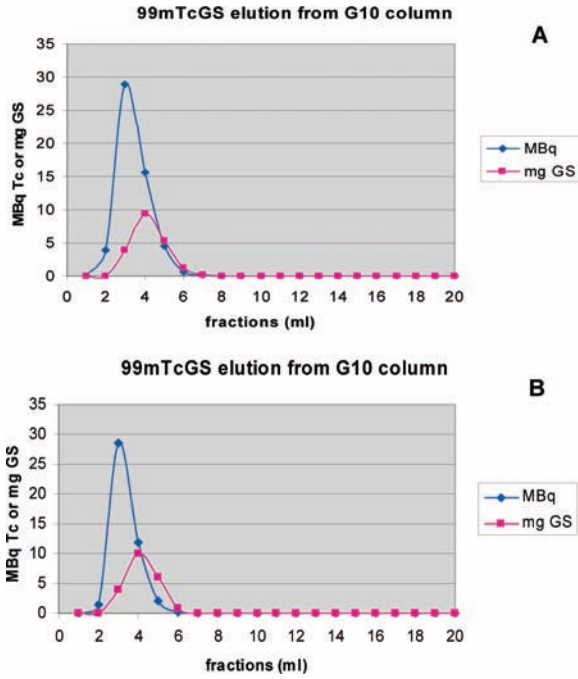

Figure 6. Radiolabeling of GS at pH 7 using 0.1 mg tin (A), as compared to 0.05 mg tin (B). Each point represents the mean value of three radiolabeling experiments with two measurements each.

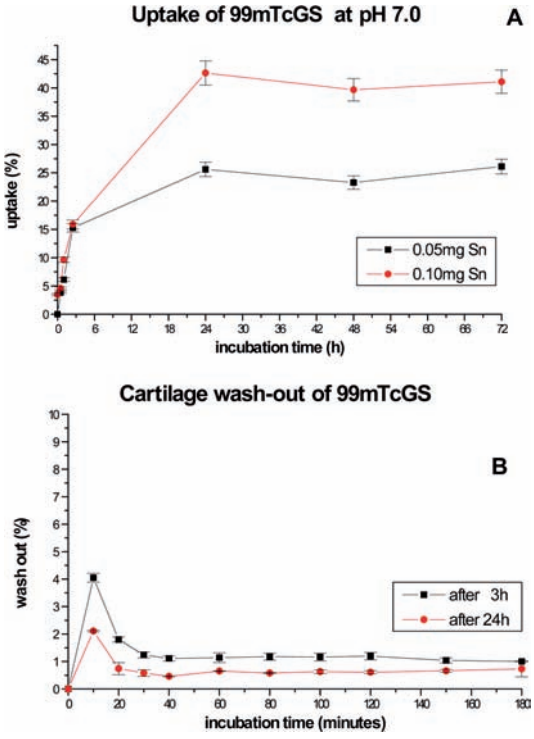

Figure 7. Uptake of ^{99m}TcGS at pH 7 using 0.1 mg tin vs 0.05 mg tin (A) and corresponding minimal washout of the tracer (0.1 mg tin) 3 h vs 24 h after uptake. Each point represents the mean value of three radiolabeling experiments with two measurements each.

inflammatory drugs (NSAIDs), especially concerning the gastrointestinal side effects (*26, 27*). Short-term studies indicate that a daily dose of 1.5 g GS for at least 7 days is sufficient to achieve significant improvement in OA symptoms, being as effective as a 400 mg daily dose of ibuprofen (*27*). Of course, the treatment with GS results in only mild side effects, if any, as compared to ibuprofen. In addition, although the improvements occurred more rapildy with ibuprofen, a more persistent benefit was achieved in patients receiving GS (*28*).

Many studies report that GS is significantly more effective than placebo and even as effective as NSAIDs (*17*). Other studies show that GS has an even significantly greater influence on pain reduction than ibuprofen itself (*18, 19*). In accordance with these findings, a meta-analysis revealed a 40.2% benefit from GS treatment concerning global pain scores or Lequesne's index as compared to placebo (*28*).

Due its low molecular weight, radiolabeling of GS is difficult, as is the separation after radiolabeling from ^{99m}Tc, which also has low molecular weight; in contrast to other GAGs, e.g., chondroitin sulfate with much higher molecular weight. For this reason, it was very important to elaborate the optimal radiolabeling condition considering labeling efficiency, uptake of ^{99m}TcGS in degenerated cartilage itself, and washout of the tracer with time to estimate the net uptake.

It was important and interesting for us to evaluate the in vitro uptake of ^{99m}TcGS by cartilage itself. We found a very high persistent cartilage uptake. The age-dependent uptake of ^{99m}TcGS might reflect the changes in pathologically affected cartilage by dynamic stress during life span. In healthy cartilage, chondrocytes are able to maintain a dynamic equilibrium between anabolic and catabolic processes. However, with increasing age and degeneration this equilibrium is seriously unbalanced causing a dramatic decrease of matrix material, especially of the PG fraction. The major source of structural variation in PG is due to glycosaminoglycan (GAG) chains. They become extended with highly negative charged sulfate and carboxylate groups. With progressing age and degeneration, the number of main and side chains as well as their length and sulfation pattern varies (*29*). This results in a loss of negative charge density and can increase charge-mediated diffusion of GS to compensate this negative charge deficiency. This tendency was also observed in our uptake studies. Of course, this needs to be proven in a higher number of samples.

Apparently, pH plays a very important role not only for the radiolabeling yield, but also with respect to later ^{99m}Tc GS uptake by cartilage. While the radiolabeling at pH 5.0 resulted in very high colloid formation and lower uptake of the tracer, in contrast, at pH 2.0 only few percent colloid were formed and the uptake was very high. The obtained saturation of the tracer at pH 2.0 was achieved when all the ^{99m}Tc GS was completely incorporated into the cartilage. This means that GS has a high tropism for cartilage.

At the physiological condition of pH 7.0, the uptake is comparable to that at pH 2, but the washout is decreased, amounting only to a maximum of 4%. Only experiments undertaken at pH 7.0 are representative for in vivo conditions. The amount of Sn^{2+} influences the labeling procedure of GS. The reason for the highly different uptake depending on the labeling conditions is more complex. For each pH value and each Sn^{2+} amount, there seems to be an optimal reduction state of Tc^{7+} in pertechnetate to $Tc^{+5,+4,+3}$ and the ability to form a more or less stable complex with GS. At pH 7.0, the higher amount of tin (0.1 mg versus 0.05 mg) as a reducing agent influences most likely the efficiency to create the most stable complex with high availability of negatively charged GAG-moieties of cartilage proteoglycans.

Our study supports other findings (*23, 24*) indicating effects of GS on cartilage metabolism including stimulation of anabolic activities such as synthesis of proteglycans. Experimental evidence indicates that GS and CS have a particular effect on cartilage where they serve as substrates in the biosynthesis of glycosaminoglycans (GAGs) (*30*). GS stimulates chondrocytes to synthesize the cartilage GAGs and proteoglycans (PGs), but

also inhibits lysosomal enzymes degrading cartilage (*31*). Animal and human studies have shown that GS after oral administration rapidly appears in the articular cartilage and is retained there for long time periods (*32*−*35*). These findings indicate that endogenous GS has an affinity for cartilage as a substrate for PG biosynthesis. Also, in this respect ^{99m}Tc GS could be used for scintigraphy of joints to monitor effects of therapy by pre- and post-therapy scintigraphy.

CONCLUSION

Using 0.1 mg tin for radiolabeling, at pH 7 (G10 column for separation), we found the highest radiolabeling efficiency and specific activity of GS, a quite high uptake of the tracer, and only a very small washout, resulting in a high "net" uptake of tracer into the degenerated cartilage. Due to high incorporation into cartilage,^{99m}Tc-GS could become a promising tracer to target osteoarthritis, to detect cartilage degeneration, and also to monitor therapeutic effects.

Effect of PEGylation of N-WASP181-200 on the Inhibitory Potency for Renal Aminoglycoside Accumulation

Kenji Fujii, Junya Nagai, Takeshi Sawada, Ryoko Yumoto, and Mikihisa Takano*

Department of Pharmaceutics and Therapeutics, Graduate School of Biomedical Sciences, Hiroshima University, 1-2-3 Kasumi, Minami-ku, Hiroshima 734-8553, Japan. Received March 4, 2009; Revised Manuscript Received May 18, 2009

We previously showed that a 20-residue basic peptide, N-WASP181-200 (NISHTKEKKKGKAKKKRLTK), inhibits renal accumulation of aminoglycoside antibiotics such as gentamicin and arbekacin. The aim of this study is to determine whether PEGylation of N-WASP181-200 enhances its inhibitory potency for renal accumulation of aminoglycosides. N-terminally PEGylated peptide (PEG1k-N-W) was synthesized by conjugating N-WASP181-200 with PEG of approximately 1 kDa using the Fmoc protection/deprotection method. PEG1k-N-W decreased gentamicin binding to isolated rat renal brush-border membrane in a concentration-dependent manner, but the in vitro inhibitory potency of PEG1k-N-W was weaker than that of N-WAP181-200. On the other hand, under in vivo conditions, PEG1k-N-W decreased the renal accumulation of arbekacin more potently than N-WASP181-200. When injected intravenously, PEG1k-N-W showed a 1.7-fold longer plasma half-life relative to N-WASP181-200. In addition, the stability of N-WASP181-200 in renal brush-borer membrane suspension was found to be increased by PEGylation. Our findings suggest that PEGylation of N-WASP181-200 is a useful strategy for reducing dosage of the concomitant with which to decrease renal accumulation in the kidney, leading to prevention of aminoglycoside-induced nephrotoxicity.

INTRODUCTION

Aminoglycoside antibiotics such as gentamicin, amikacin, and arbekacin are widely used for the treatment of Gram-positive and Gram-negative infectious diseases. Aminoglycosides are not metabolized in the body, and most of the injected dose is excreted into the urine. However, a fraction is selectively accumulated in the renal cortex. The concentration of aminoglycoside accumulated in the renal cortex amounts to several times higher than in the plasma. Aminoglycoside taken up by the renal proximal tubular cells stays there with a long-half-life, leading to renal damage such as structural changes and functional impairments (*1*−*3*).

Aminoglycoside binding receptors such as acidic phospholipids and/or megalin are a potential target for preventing aminoglycoside-induced nephrotoxicity (*3, 4*). Early studies reported that acidic phospholipids of the plasma membrane of the proximal tubular cells are the initial binding site (*5, 6*). Subsequently, aminoglycosides including gentamicin were shown to be ligands of megalin (*7*). Megalin (alias LRP-2; low-density lipoprotein receptor-related protein-2) is a multiligand, enodcytic receptor abundantly expressed in the renal proximal tubule (*8, 9*). It was reported that there was little accumulation of gentamicin in the kidney in mice lacking megalin (*10*). In a previous report, we demonstrated that coadministration of cytochrome c, a ligand of megalin, decreased not only renal accumulation of gentamicin but also gentamicin-induced nephrotoxicity (*11*). In addition, several basic peptide fragments with pI values from 10.30 to 11.72, which reportedly bind to phosphoinositides (*12*−*14*), inhibited renal accumulation of gentamicin injected intravenously. Among those peptide fragments examined, a 20-amino-acid peptide N-WASP181-200 from neural Wiskott-Aldrich syndrome protein (N-WASP) was found to be the most effective antagonist under in vitro conditions (*11*).

On the other hand, under in vivo conditions, the inhibitory effect of N-WASP181-200 on renal accumulation of aminoglycosides was much weaker than was expected from the in vitro inhibitory effect; the 50% inhibitory concentration (IC_{50}) value of N-WASP181-200 for gentamicin binding to renal brush-border membrane in vitro (0.041 mM) was much lower than that of cytochrome c (3.20 mM) (*15*), while its IC_{50} value for renal arbekacin accumulation in vivo (19.6 μmol/kg) was found to be higher than that of cytochrome c (1.23 μmol/kg) (*16*). We speculated that one of the main reasons for the apparent inconsistency between in vitro and in vivo studies may be the rapid degradation in the plasma and/or extensive binding to various tissues after intravenous injection of N-WASP181-200.

A number of studies have demonstrated that chemical modification with poly(ethylene glycol) (PEG), PEGylation, is an effective means of improving the in vivo biological potencies of various pharmaceutical peptides/proteins (*17, 18*). The technique is one of the useful strategies to prolong the half-lives of unstable peptides/proteins in the body by reducing proteolysis and renal clearance. In addition, increase in the apparent molecular weight by PEGylation leads to an altered pattern of body distribution of peptide/protein drugs. Furthermore, PEGylation effectively reduces immunogenicity/antigenicity and toxicity, which are caused by injection of peptides/proteins (*17, 18*).

The purpose of this study was to investigate whether PEGylation enhances the in vivo inhibitory effect of N-WASP181-200 on renal accumulation of arbekacin. In addition, the plasma half-life of PEGylated N-WASP181-200 (PEG1k-N-W) intravenously injected was compared with those of N-WASP181-200 and arbekacin. Furthermore, the stabilities of N-WASP181-

200 and PEG1k-N-W in the plasma and renal brush-border membrane suspension were evaluated.

MATERIALS AND METHODS

Materials. N-Fmoc-amido-dPEG$_{24}$ acid was purchased from Quanta Biodesign (Powell, OH, USA). [^{3}H]Gentamicin sulfate (7.4 GBq/g) was obtained from American Radiolabeled Chemicals, Inc. (St. Louis, MO, USA). Arbekacin sulfate was from Meiji Seika Kaisha, Ltd. (Tokyo, Japan). Gentamicin sulfate and 2,4,6,-trinitrobenzene sulfonic acid sodium salt were obtained from Nacalai Tesque (Kyoto, Japan). Trifluoroacetic acid was purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals used for the experiments were of the highest purity available.

Preparation of N-WASP181-200 and Its PEGylated Peptide. N-WASP181-200 (NISHTKEKKKGKAKKKKRLTK) and its N-terminally PEGylated peptide (PEG1k-N-W) were synthesized chemically with the peptide synthesizer (PSSM-8, Shimadzu, Kyoto, Japan) (Figure 1). For N-terminal PEGylation of N-WASP181-200, N-Fmoc-amido-dPEG$_{24}$ acid with molecular weight of 1368.59 was used. After deprotection of the side chain protecting groups, the peptides were precipitated with ice-cold diethyl ether and isolated by centrifugation at 4000 rpm for 5 min. This procedure was repeated twice. The precipitate was dissolved with 0.1% trifluoroacetic acid (TFA) and chromatographed on a Sephadex G-15 column equilibrated with 0.1% TFA. Elution fractions containing peptide were pooled and dialyzed overnight at 4 °C. After lyophilization, the obtained peptides were stored at −30 °C until analysis.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry. The compounds prepared by the synthesizer were confirmed by matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (PerSeptive Biosystems, Tokyo, Japan). Freeze−dried peptides were dissolved with the matrix solution, a saturated solution of α-cyano-4-hydroxycinnamic acid (α-CHCA) in 50% acetonitrile in water with 0.1% TFA. The spectra were recorded with the analyzer in the linear mode at an accelerating voltage of 20 kV.

Preparation of Brush-Border Membrane from Rat Kidney. Experiments with animals were performed in accordance with the Guide for Animal Experimentation, Hiroshima University, and the Committee of Research Facilities for Laboratory Animal Sciences, Graduate School of Biomedical Sciences, Hiroshima University. Renal brush-border membrane (BBM) was isolated from the renal cortex of male Wistar albino rats (190−220 g). The isolation procedure of BBM was based on the Mg/EGTA precipitation method as described previously (*15*). The isolated membranes were suspended in a buffer comprising 100 mM mannitol and 10 mM HEPES/Tris (pH7.5), and stored in liquid nitrogen until use (usually less than 1 month).

Binding Studies Using BBM. [^{3}H]Gentamicin binding to BBM was measured by a rapid filtration technique. In brief, BBM (20 μL) were suspended in a buffer comprising 300 mM mannitol and 10 mM HEPES, adjusted to pH 7.5 with KOH (buffer A). The reaction was initiated by the addition of buffer A (20 μL) containing 20 μM [^{3}H]gentamicin without or with competitor into the membrane suspension at 4 °C. At 60 min, incubation was stopped by diluting the reaction mixture with 1 mL of ice-cold buffer A. The contents of the tube were immediately poured onto Millipore filters (HAWP, 0.45 μm, 2.5 cm diameter), and then the filters were washed once with 5 mL of the ice-cold buffer A. The radioactivity on the filter was determined by liquid scintillation counting. Nonspecific binding was estimated by the addition of unlabeled gentamicin at 1000-fold concentration (10 mM) of [^{3}H]gentamicin. Then, specific binding of gentamicin was determined by subtracting the nonspecific binding from the total binding.

The half-maximal inhibitory concentration (IC_{50}) values of competitors were determined by the Hill equation, as described previously (*15*). The values of the dissociation constant (K_d) and the maximum amounts of the binding (B_{max}) were estimated from the linear regression lines using the double reciprocal analysis based on Klotz equation, as described previously (*15*).

In Vivo Renal Accumulation Study. Male ddy mice weighting 26−33 g were administered arbekacin at a dose of 0.25 mg/kg alone or in combination with the indicated compound via the tail vein. At 24 h after administration, kidneys were excised. The tissues were weighed and then homogenized with an IKA T25 Basic dispenser (IKA Labortechnik, Germany) in 2 mL of 30 mM phosphate buffer (pH 7.5). After shaking for 20 min, the homogenate was mixed with 400 μL of 20% trichloroacetic acid and was further shaken for 40 min. After centrifugation at 3000 rpm for 10 min, arbekacin concentration in the supernatant was determined by HPLC as described below.

In Vivo Pharmacokinetic Study. Male ddy mice (20−30 g) were anesthetized by intraperitoneal injection of pentobarbital. A blood sample was withdrawn through the jugular vein at a stated time after a bolus administration of N-WASP181-200 (100 mg/kg), PEG1k-N-W (100 mg/kg), or arbekacin (4 mg/kg) via the tail vein. Plasma was separated immediately by centrifugation at 10 000 rpm for 5 min. A 100 μL aliquot of plasma sample was mixed with 20 μL of 20% trichloroacetic acid. After centrifugation at 10 000 rpm for 5 min, the concentration of each compound in the supernatant was determined by HPLC as described below.

Proteolytic Stabilities of N-WASP181-200 and PEG1k-N-W. The proteolytic stabilities of N-WASP181-200 and PEG1k-N-W were examined in rat plasma and rat renal brush-border membrane (BBM) suspension. Rat plasma was obtained by centrifuging blood from male Wistar rats. BBM was prepared as described above. For plasma stability assay, 10 mg/mL N-WASP181-200 or PEG1k-N-W (30 μL) were incubated with rat plasma (270 μL) at 37 or 4 °C for 30 min. The incubation was terminated by the addition of 60 μL 20% trichloroacetic acid (TCA). After centrifugation at 10 000 rpm for 10 min, the concentration of N-WASP181-200 or PEG1k-N-W in the supernatant was determined by HPLC as described below. For BBM stability assay, BBM suspension (54 μL) was mixed with a buffer comprising 300 mM mannitol and 10 mM HEPES, adjusted to pH 7.5 with KOH (buffer A). The reaction was initiated by the addition of buffer A (6 μL) containing 10 mg/

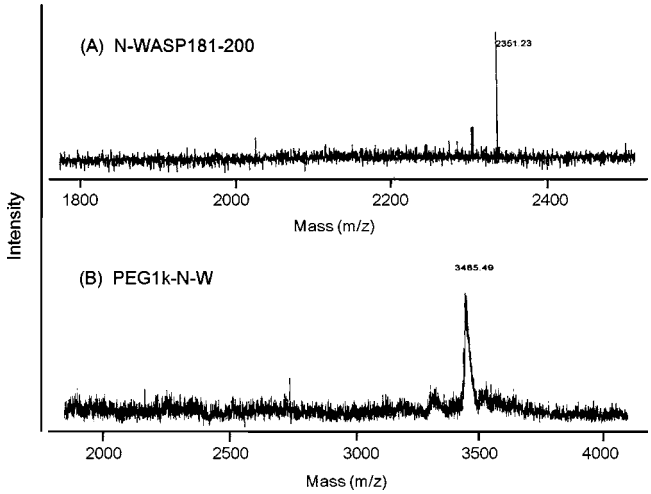

Figure 2. MALDI-TOF mass spectra of N-WASP181-200 (A) and PEG1k-N-W (B).

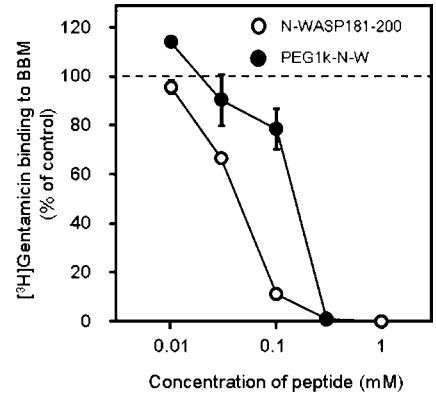

Figure 3. Effects of N-WASP181-200 and PEG1k-N-W on [^{3}H]gentamicin binding to rat renal brush-border membrane (BBM). BBM was incubated for 60 min at 4 °C with the substrate mixture (pH 7.5) including 10 μM [^{3}H]gentamicin with various concentrations of N-WASP181-200 (open circle) or PEG1k-N-W (closed circle). Each symbol represents the mean ± SE of three determinations.

mL N-WASP181-200 and PEG1k-N-W at 37 or 4 °C. At 5, 10, or 15 min, the incubation was terminated by the addition of 12 μL 20% TCA. After centrifugation at 10 000 rpm for 5 min, the concentration of N-WASP181-200 or PEG1k-N-W in the supernatant was determined by HPLC as described below.

HPLC Analysis. Quantitative determinations of N-WASP181-200, PEG1k-N-W, and arbekacin were performed by using high-performance liquid chromatography (PU-980, Jasco, Tokyo, Japan) equipped with an ultraviolet spectrophotometric detector (UV-970, Jasco) with a TSK gel ODS-80TM (4.6 × 100 mm, Tosoh, Tokyo, Japan). For the assay of N-WASP181-200 and PEG-N-W, the mobile phase consisted of 0.1% trifluoroacetic acid (TFA) in distilled water (solvent A) and 0.1% TFA in acetonitrile (solvent B). The mobile phase was run with a linear gradient from 0% to 100% solvent B over 40 min at a flow rate of 1.0 mL/min, and the absorbance of the eluent was monitored at 210 nm at room temperature. For the assay of arbekacin, an isocratic HPLC assay was performed after derivatization of the drug by reaction with 2,4,6-trinitrobenzenesulfonic acid. The conditions were as follows: mobile phase 0.03 M phosphate buffer (pH 7.5)/acetonitrile/methanol (v/v) = 1.1:2:1; flow rate 1.0 mL/min; and room temperature. The absorbance of the eluent was monitored at 350 nm.

Analytical Methods. The elimination rate constant k value was calculated based on the first-order equation. The elimination half-life ($t_{1/2}$) was determined based on the equation $t_{1/2} = 0.693/k$. The *KaleidaGraph* program (version 3.08, Synergy Software, PA, USA) was used for the curve-fitting. Protein concentration was measured by the method of Bradford (*19*) with bovine serum albumin as a standard.

RESULTS

Characterization of PEGylated N-WASP181-200. N-WASP181-200 and its N-terminally PEGylated peptide (PEG1k-N-W) were synthesized using the Fmoc protection/deprotection method. These peptides were identified by mass spectroscopy using MALDI-TOF (Figure 2). The molecular mass of PEG1k-N-W was detected to be 3485 Da, which would be equivalent to N-WASP181-200 (2351 Da) conjugated with 1 unit of $dPEG_{24}$ where the Fmoc group was removed (1368.59 Da as N-Fmoc-amido-$dPEG_{24}$ acid according to the product sheet obtained from the supplier).

In Vitro Inhibitory Efficacy on Gentamicin Binding to Isolated Rat Renal Brush-Border Membrane. To analyze the inhibitory potency of PEG1k-N-W under in vitro conditions, we examined the effect of PEG1k-N-W on [^{3}H]gentamicin binding to isolated rat renal brush-border membrane (BBM). PEG1k-N-W decreased the binding of gentamicin to BBM in a concentration-dependent manner (Figure 3). However, the concentration−response curve of PEG1k-N-W was shifted to the right, compared to that of N-WASP181-200. The IC_{50} value of PEG1k-N-W was 0.128 mM, which was 3.1-fold greater than that of N-WASP181-200 (0.041 mM).

Previously, we showed that N-WASP181-200 inhibits gentamicin binding to BBM in a competitive manner (*15*). In this study, to analyze the nature of the inhibitory effect of PEG1k-N-W on gentamicin binding to BBM, the binding activity at various concentrations of gentamicin was examined at 4 °C in the absence or presence of 200 μM PEG1k-N-W (Figure 4). The double reciprocal plot analysis of the data indicated that the maximum amounts of gentamicin binding (B_{max}) in the absence and presence of PEG1k-N-W were estimated to be 8.4 and 3.3 nmol/mg protein, respectively. In addition, the calculated dissociation constants (K_d) in the absence and presence of PEG1k-N-W were 39.8 μM and 260.1 μM, respectively. Thus, the results of the kinetic analysis (decreased binding capacity and affinity) indicated that PEG1k-N-W gave a mixed-type inhibition against gentamicin binding to BBM.

In Vivo Inhibitory Efficacy on Renal Arbekacin Accumulation in Mice. Next, to analyze the inhibitory potency of PEG1k-N-W under in vivo conditions, the effect of coadministration of PEG1k-N-W on renal accumulation of arbekacin in mice was examined and compared with that of N-WASP181-200 (Figure 5). The accumulation of arbkacin in mouse kidney was inhibited by coadministration of PEG1k-N-W in a dose-dependent fashion, and its dose−response curve was shifted to the left, compared to that of N-WASP181-200. The calculated IC_{50} value of PEG1k-N-W was 17.8 mg/kg, which was 2.6-fold lower than that of N-WASP181-200 (46.1 mg/kg).

Pharmacokinetics of N-WASP181-200 and PEG1k-N-W in Mice. The pharmacokinetics of N-WASP181-200 and PEG1k-N-W were investigated in mice. Figure 6 shows the plasma concentration−time profiles of N-WASP181-200 and PEG1k-N-W after an intravenous bolus injection at a dose of 100 mg/kg into mice. The plasma concentrations of N-WASP181-200 and PEG1k-N-W declined exponentially with time, resulting in half-lives of 2.7 and 4.6 min, respectively. The volumes of distribution of N-WASP181-200 and PEG1k-N-W were 0.40 ± 0.03 L/kg and 0.46 ± 0.03 L/kg, respectively. Figure 7 shows the plasma concentration−time profile of arbekacin after an intravenous bolus injection at 4 mg/kg. The calculated half-life and volume of distribution were 32.4 min and 0.60 ± 0.03 L/kg, respectively.

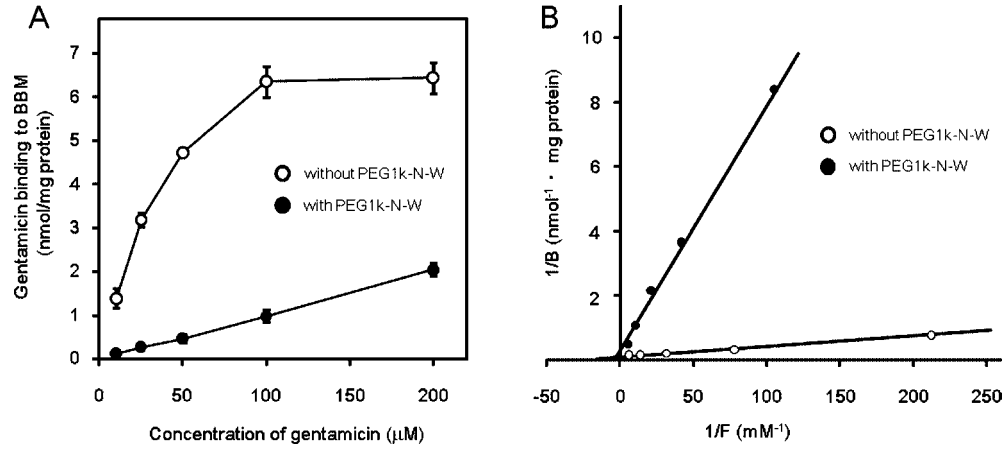

Figure 4. Gentamicin binding to rat renal BBM at various concentrations of gentamicin without or with PEG1k-N-W (A) and its double reciprocal plots (Klotz plots) (B). The BBM binding of various concentrations of [^{3}H]gentamicin in the absence (open circle) or presence (closed circle) of 200 μM PEG1k-N-W was measured as described in Figure 3. Each symbol represents the mean ± SE of three determinations. Abbreviations are as follows: B, the amount of bound gentamicin to BBM; F, the concentration of free gentamicin in the incubation buffer.

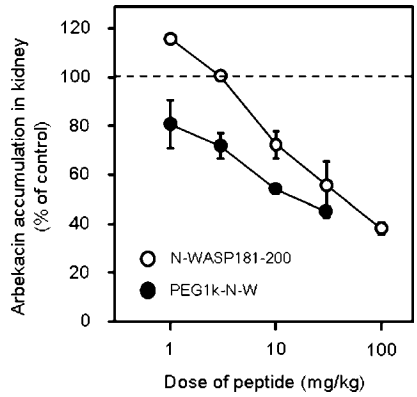

Figure 5. Effect of coadministration of N-WASP181-200 or PEG1k-N-W on arbekacin accumulation. Mice were administered arbekacin alone or in combination with N-WASP181-200 (open circle, 1−100 mg/kg) or PEG1k-N-W (closed circle, 1−30 mg/kg). Each symbol represents the mean ± SE of three mice.

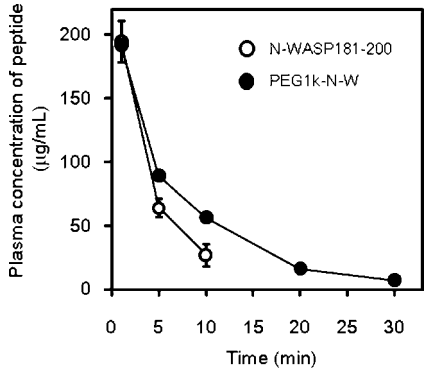

Figure 6. Plasma concentration−time profiles of N-WASP181-200 (open circle) and PEG1k-N-W (closed circle) given intravenously at a dose of 100 mg/kg in mice. Each symbol represents the mean ± SE of three to four mice.

Metabolic Stability. The effect of PEGylation on the stability of N-WASP181-200 was examined in rat plasma and renal brush-border membrane suspension. First, we compared the stability of 1 mg/mL N-WASP181-200 in the plasma between 37 and 4 °C. The concentrations of N-WASP181-200 after 30 min incubation at 37 and 4 °C were 0.76 mg/mL and 0.75 mg/mL, respectively. Thus, it is likely that there was little enzymatic degradation of N-WASP181-200 in the plasma because no

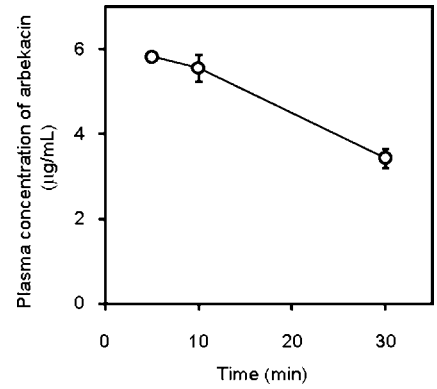

Figure 7. Plasma concentration−time profile of arbekacin given intravenously at a dose of 4 mg/kg in mice. Each symbol represents the mean ± SE of three mice.

temperature-dependent degradation was observed. The decreases in concentration of N-WASP181-200 that were observed at both temperatures might be due to coprecipitation of N-WASP181-200 with plasma proteins during the deproteinization process. Next, the stability of N-WASP181-200 and PEG1k-N-W in renal brush-border membrane suspension was analyzed at 37 or 4 °C (Figure 8). At 37 °C, N-WASP181-200 was rapidly degraded in renal brush-border membrane suspension with a half-life of 6.7 min. The degradation rate of PEG1k-N-W at 37 °C was slower than that of N-WASP181-200, showing an approximately 2-fold longer half-life (12.9 min). At 4 °C, neither N-WASP181-200 nor PEG1k-N-W was degraded up to 15 min incubation.

DISCUSSION

In a previous paper, we found that N-WASP181-200 had a 78-fold higher in vitro inhibitory potency for gentamicin binding to rat renal brush-border membrane than a low molecular weight protein, cytochrome c, when their IC_{50} values were compared (*15*). However, the in vivo inhibitory potency of N-WASP181-200 was 16-fold as low as that of cytochrome c when their IC_{50} values were compared (*16*). One of the main reasons for this disagreement between in vitro and in vivo studies was expected to be a poor delivery of N-WASP181-200 into the renal proximal tubule, where aminoglycosides are taken up. It has been shown that about 90% of the injected dose of cytochrome c was accumulated in the kidney, in particular in the proximal tubular cells through a luminal reabsorption mechanism possibly involving megalin-mediated endocytosis (*20, 21*). Therefore, we

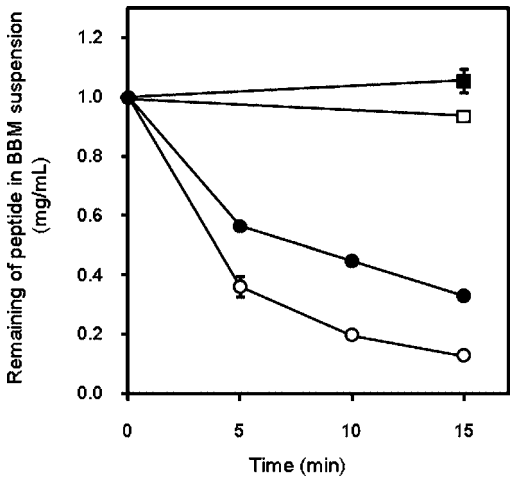

Figure 8. Degradation profiles of N-WASP181-200 and PEG1k-N-W incubated with rat renal brush-border membrane suspension. N-WASP181-200 (open circle and square) and PEG1k-N-W (closed circle and square) were incubated with rat renal brush-border membrane suspension at 37 °C (open and closed circles) or 4 °C (open and closed squares).

expected that more efficient delivery of N-WASP181-200 into the renal proximal tubule might improve the in vivo inhibitory potency for renal accumulation of aminoglycosides. In this study, we tried to investigate whether PEGylation is useful for enhanced delivery of N-WASP181-200 into the renal proximal tubule, resulting in reduced dose requirement of the concomitant for prevention of renal accumulation/toxicity of aminoglycosides.

Since aminoglycosides are taken up in the renal proximal tubular cells after filtration through the glomerulus, a PEGylated compound also needs to be filtered through the glomerulus in order to compete with aminoglycosides for its binding site(s) in the apical membrane of the renal proximal tubule. It has been reported that the ultrafiltration of PEG with molecular size lower than 8 kDa is not restricted, whereas the elimination of PEG in the range 8−30 kDa is governed by the molecular size (*17*, *22*). The elimination of PEG with the molecular sizes exceeding 30 kDa is dramatically decreased, possibly because of molecular sizes beyond the glomerular filtration cutoff (*17*, *22*). Therefore, we selected N-Fmoc-amido-dPEG$_{24}$ acid with a molecular size of 1368.59 Da, which is small enough to be filtered through the glomerulus, for the conjugation with N-WASP181-200. In addition, PEGylation with N-Fmoc-amido-dPEG$_{24}$ acid by the Fmoc solid-phase peptide synthesis had no contamination of unconjugated PEG in the synthesized compound. Furthermore, there was no PEGylation on the ε-amino groups of lysine residues in N-WASP181-200, which would affect the in vitro inhibitory potency for gentamicin binding to renal brush-border membrane (*15*), since N-Fmoc-amido-dPEG$_{24}$ acid is selectively attached to the N-terminal residue of N-WASP181-200 (asparagine). In this study, the purity of the N-terminally mono-PEGylated N-WASP181-200 (PEG1k-N-W) was identified by MALDI-TOF MS analysis.

It is reported that the bioactivities of peptides and proteins in vitro can be reduced by PEGylation (*18*, *23*, *24*). Therefore, we first examined whether or not the inhibitory potency for gentamicin binding to renal brush-border membrane is retained after PEGylation. The in vitro binding study showed that PEGylation decreased the in vitro inhibitory potency by about 3-fold. The reason for the decreased in vitro inhibitory potency by PEGylation is not clear at present, but the steric hindrance effect induced by the flexible PEG chain around the binding site of aminoglycosides may be responsible for a decrease in in vitro inhibitory potency of PEG1k-N-W.

Though PEGylation decreased the in vitro inhibitory potency of N-WASP181-200, it enhanced the in vivo inhibitory potency. To clarify the mechanisms underlying the enhancement of in vivo inhibitory potency by PEGylation, the plasma concentration−time profiles of N-WASP181-200 and PEG1k-N-W after intravenous injection were examined in mice. The plasma half-life of PEG1k-N-W was prolonged by 1.7-fold, as compared to that of N-WASP181-200. There was little change in the distribution volumes between N-WASP181-200 and PEG1k-N-W. However, it is likely that the observed prolongation of the plasma half-life by PEGylation was not due to increased proteolytic resistance in the plasma, since temperature-dependent degradation of N-WASP181-200 in the plasma was not observed. The difference in half-life between N-WASP181-200 and PEG1k-N-W may be due to that inefficiency of glomerular filtration, resulting from small but significantly different molecular sizes (N-WASP181-200, 2351 Da; PEG1k-N-W, 3485 Da). In addition, there might be another possibility that a decrease in nonrenal clearance including hepatic extraction is associated with the prolonged plasma half-life by PEGylation.

The prolongation of plasma half-life was not enough to explain the enhanced in vivo potency by PEGylation, because the plasma half-life of arbekacin was 32.4 min, which is much longer than that of PEG1k-N-W (4.59 min). It has been reported that the membrane-bound peptidases including aminopeptidase A, aminopeptidase M, γ-glutamyltransferase, and dipeptidyl peptidase IV are localized in the brush-border of the renal proximal tubule (*25*, *26*). Therefore, we speculated on the possibility of an increased proteolytic resistance by PEGylation against the peptidases expressed in the renal brush-border membrane, which is the target site for the inhibition of aminoglycoside binding in vivo. Incubation of N-WASP181-200 in renal brush-border membrane suspension at 37 °C induced a disappearance of its peptide with a half-life of 6.7 min, but there was no degradation of N-WASP181-200 when incubation was performed at 4 °C, the temperature at which brush-border enzymes would not work. Thus, the temperature-dependent disappearance indicates the enzymatic degradation of N-WASP181-200 by peptidase(s) in renal brush-border membrane, but not nonenzymatic decomposition. Furthermore, the half-life of PEG1k-N-W for degradation in bush-border membrane suspension at 37 °C was 1.9-fold longer compared to N-WASP181-200. Thus, the resistance to proteolysis in the renal brush-border membrane may be, at least in part, involved in the enhanced in vivo inhibitory effect by PEGylation.

In conclusion, PEGylation enhanced the in vivo inhibitory potency of N-WASP181-200 for renal accumulation of arbekacin in spite of the reduced in vitro inhibitory potency for binding of gentamicin to renal brush-border membrane. Therefore, PEGylation technique is expected to be a useful means with which to develop a more potent peptidic protectant against aminoglycoside-induced nephrotoxicity.

2-Mercaptoacetylglycylglycyl (MAG_2) as a Bifunctional Chelator for ^{99m}Tc-Labeling of Cyclic RGD Dimers: Effect of Technetium Chelate on Tumor Uptake and Pharmacokinetics

Jiyun Shi,[†] Young-Seung Kim,[†] Sudipta Chakraborty,[†] Bing Jia,[‡] Fan Wang,[‡] and Shuang Liu*[,†]

School of Health Sciences, Purdue University, Indiana 47907, and Medical Isotopes Research Center, Peking University, Beijing 100191, China. Received March 4, 2009; Revised Manuscript Received June 10, 2009

This report describes the synthesis of MAG_2-PEG_4-E[c(RGDfK)]$_2$ (MAG_2-P-RGD_2: MAG_2 = *S*-benzoylmercaptoacetylglycylglycyl; PEG_4 = 15-amino-4,7,10,13-tetraoxapentadecanoic acid) and MAG_2-PEG_4-E[PEG_4-c(RGDfK)]$_2$ (MAG_2-3P-RGD_2), and the evaluation of ^{99m}TcO(MAG_2-P-RGD_2) and ^{99m}TcO(MAG_2-3P-RGD_2) as new radiotracers for tumor imaging in the athymic nude mice bearing U87MG human glioma xenografts. We found that MAG_2 is such an efficient bifunctional chelating agent that ^{99m}TcO(MAG_2-P-RGD_2) and ^{99m}TcO(MAG_2-3P-RGD_2) could be prepared in high yield (>90%) with high specific activity (~5 Ci/μmol) using a kit formulation. ^{99m}TcO(MAG_2-P-RGD_2) and ^{99m}TcO(MAG_2-3P-RGD_2) have very high solution stability in the kit matrix. Biodistribution data in athymic nude mice bearing U87MG human glioma xenografts indicated that replacing the highly charged [^{99m}Tc(HYNIC = 6-hydrazinonicotinyl and TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate) with smaller ^{99m}TcO(MAG_2) resulted in a significant increase in the radiotracer uptake in the tumor and normal organs most likely due to the higher lipophilicity of ^{99m}TcO(MAG_2-3P-RGD_2) (log $P = -3.15 \pm 0.10$) than that for [^{99m}Tc(HYNIC-3P-RGD_2)(tricine)(TPPTS)] (^{99m}Tc-3P-RGD_2: log $P = -3.96 \pm 0.05$). Even though ^{99m}TcO(MAG_2-3P-RGD_2) has better tumor uptake (15.36 ± 2.17 %ID/g at 60 min postinjection (p.i.)) than ^{99m}Tc-3P-RGD_2 (9.15 ± 2.13 %ID/g at 60 min p.i.), its tumor-to-background (*T*/B) ratios (tumor/blood = 13.52 ± 4.57; tumor/liver = 4.25 ± 0.88; tumor/lung = 3.17 ± 0.60; and tumor/muscle = 8.34 ± 2.34) are not as good as those of ^{99m}Tc-3P-RGD_2 (tumor/blood = 36.0 ± 11.5; tumor/liver = 5.14 ± 1.46; tumor/lung = 4.36 ± 0.54; and tumor/muscle = 13.70 ± 2.21) at 60 min p.i. On the basis of these results, we believe that ^{99m}Tc-3P-RGD_2 remains a better radiotracer because of its higher T/B ratios.

INTRODUCTION

Radiolabeled cyclic RGD (Arg-Gly-Asp) peptides represent a new class of radiotracers that target the integrin $\alpha_v\beta_3$ overexpressed on both tumor cells and endothelial cells of neovasculature during tumor growth, invasion, and metastasis (*1*−*12*). Many radiolabeled cyclic RGD peptides have been evaluated for imaging integrin $\alpha_v\beta_3$-positive tumors by single photon emission computed tomography (SPECT) or positron emission tomography (PET) over the last several years (*13*−*49*). Among the RGD peptide radiotracers evaluated in different tumor-bearing animal models, [^{18}F]-AH111585, the core peptide sequence discovered from a phage display library (such as ACDRGDCFCG) (*50, 51*), and [^{18}F]Galacto-RGD (2-[^{18}F]fluoropropanamide c(RGDfK(SAA)): SAA = 7-amino-L-glyero-L-galacto-2,6-anhydro-7-deoxyheptanamide) (*52*−*54*) are currently under clinical investigation for noninvasive visualization of integrin $\alpha_v\beta_3$ expression in cancer patients. The imaging studies show that the ^{18}F-labeled RGD peptides are able to target integrin $\alpha_v\beta_3$-positive tumors (*51*−*54*). However, the low tumor uptake, high cost, and lack of preparation modules for ^{18}F-labeled cyclic RGD peptides impose a significant challenge on their continued clinical applications.

To improve integrin $\alpha_v\beta_3$ binding affinity and radiotracer tumor uptake, multimeric cyclic RGD peptides, such as E-[c(RGDfK)]$_2$ and E{E[c(RGDfK)]$_2$}$_2$, were used as targeting biomolecules to carry radionuclide (e.g., ^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) to the integrin $\alpha_v\beta_3$ on tumor cells and endothelial cells of the tumor neovasculature (*20*−*22, 30*−*35, 37*−*49*). The results from in vitro assays, ex vivo biodistribution, and in vivo imaging studies clearly demonstrate that the radiolabeled (^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) multimeric cyclic RGD peptides, such as E{E[c(RGDxK)]$_2$}$_2$ and E[c(RGDxK)]$_2$ (x = f and y), have better tumor targeting capability as evidenced by their higher integrin $\alpha_v\beta_3$ binding affinity and better tumor uptake with longer tumor retention times than their monomeric counterparts (*20*−*22, 30*−*35, 37*−*49*). However, the uptake of radiolabeled (^{99m}Tc, ^{18}F, ^{64}Cu, and ^{111}In) multimeric cyclic RGD peptides in the kidneys and liver is also increased as the peptide multiplicity increases.

Recently, we reported the evaluation of the complex [^{99m}Tc-(HYNIC-3P-RGD_2)(tricine)(TPPTS)] (Figure 1: ^{99m}Tc-3P-RGD_2; HYNIC = 6-hydrazinonicotinyl; TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate; 3P-RGD_2 = PEG_4-E[PEG_4-c(RGDfK)]$_2$ and PEG_4 = 15-amino-4,7,10,13-tetraoxapentadecanoic acid) as radiotracers for imaging integrin $\alpha_v\beta_3$ expression in athymic nude mice bearing U87MG glioma and MDA-MB-435 breast cancer xenografts (*55*). The PEG_4 linkers are used to increase the distance between two cyclic RGD motifs from 6 bonds (excluding side arms of K-residues) in E-[c(RGDfK)]$_2$ to 38 bonds in 3P-RGD_2 so that they are able to achieve the simultaneous integrin $\alpha_v\beta_3$ binding in a bivalent fashion, and to improve radiotracer excretion kinetics from noncancerous organs. Results from the $\alpha_v\beta_3$ integrin binding assay show that the addition of PEG_4 linkers between two cyclic RGD motifs makes it possible for 3P-RGD_2 to become bivalent

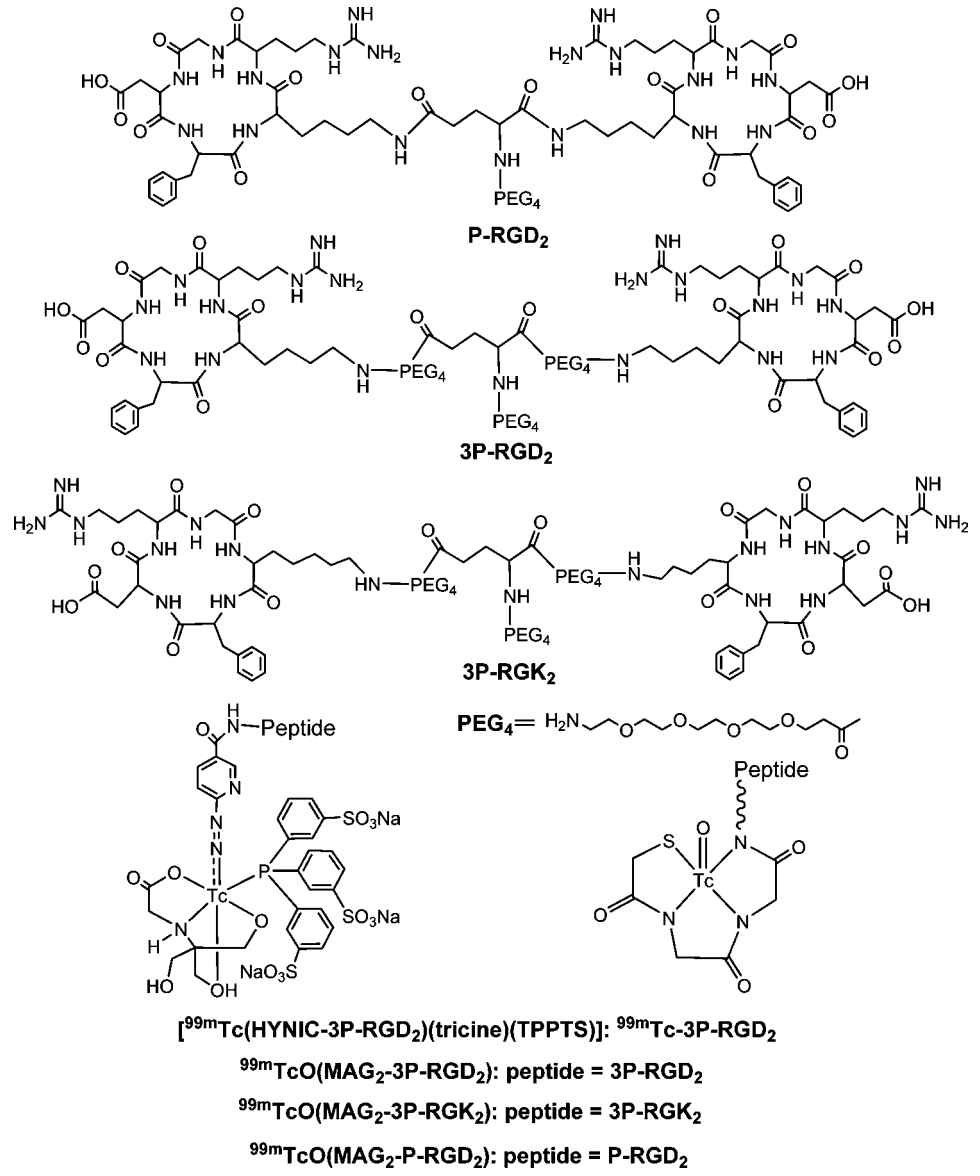

Figure 1. Structures of bivalent cyclic RGD dimers (P-RGD$_2$ and 3P-RGD$_2$) and their ^{99m}Tc complexes: [^{99m}Tc(HYNIC-3P-RGD$_2$)(tricine)(TPPTS)] (^{99m}Tc-3P-RGD$_2$), ^{99m}TcO(MAG$_2$-P-RGD$_2$), and ^{99m}TcO(MAG$_2$-3P-RGD$_2$).

in binding to the integrin $\alpha_v\beta_3$. The results from biodistribution studies clearly demonstrate that PEG$_4$ and G$_3$ linkers are useful for improving the tumor uptake and clearance kinetics of ^{99m}Tc radiotracers from noncancerous organs (*55*, *56*). Similar results were also obtained for [^{99m}Tc(HYNIC-3G-RGD$_2$)(tricine)-(TPPTS)] (^{99m}Tc-3G-RGD$_2$: 3G-RGD$_2$ = G$_3$-E[G$_3$-c(RGDfK)]$_2$ and G$_3$ = Gly-Gly-Gly) (*56*), ^{64}Cu(DOTA-3P-RGD$_2$) (DOTA = 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetracetic acid) and ^{64}Cu(DOTA-3G-RGD$_2$) (*57*).

As a continuation of our interest in radiolabeled cyclic RGD peptides as radiotracers for tumor imaging (*41*−*44*, *55*, *56*), we prepared two novel cyclic RGD conjugates, MAG$_2$-PEG$_4$-E[c(RGDfK)]$_2$ (MAG$_2$-P-RGD$_2$: MAG$_2$ = S-benzoylmercaptoacetylglycylglycyl) and MAG$_2$-3PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (MAG$_2$-3P-RGD$_2$), and their ^{99m}Tc complexes (Figure 1: ^{99m}TcO(MAG$_2$-P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$). MAG$_2$ is of our particular interest as the bifunctional chelator (BFC) because it forms the ^{99m}TcO(MAG$_2$) chelate (molecular weight (MW) ~300 Da) that is much smaller than the bulky and highly charged [^{99m}Tc(HYNIC)(tricine)(TPPTS)] (MW ~900 Da). The integrin $\alpha_v\beta_3$ binding affinities of MAG$_2$-P-RGD$_2$ and MAG$_2$-3P-RGD$_2$ were determined using a displacement assay against ^{125}I-c(RGDyK) bound to U87MG glioma cells. Biodistribution characteristics of ^{99m}TcO(MAG$_2$-P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$) were evaluated in the athymic nude mice bearing U87MG glioma xenografts. The main objective of this study is to demonstrate the usefulness of MAG$_2$ as a BFC for ^{99m}Tc-labeling of small biomolecules and to assess the impact of ^{99m}Tc chelates (^{99m}TcO(MAG$_2$) vs [^{99m}Tc(HYNIC)(tricine)(TPPTS)]) on both tumor uptake and tumor-to-background (*T*/*B*) ratios.

EXPERIMENTAL SECTION

Materials. Chemicals were purchased from Sigma-Aldrich (St. Louis, MO), and were used without further purification. Cyclic RGD peptides, PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (3P-RGD$_2$) and PEG$_4$-E[PEG$_4$-c(RGKfD)]$_2$ (3P-RGK$_2$: a scrambled nonsense peptide), were custom-made by the Peptides International, Inc. (Louisville, KY). MAG$_2$ (*S*-benzoylmercaptoacetylglycylglycine) and PEG$_4$-E[c(RGDfK)]$_2$ (P-RGD$_2$) were prepared according to the literature methods (*43*, *58*). Na^{99m}TcO$_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator (North Billerica, MA). The ESI (electrospray ionization) mass spectral data were collected on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University.

HPLC Methods. HPLC method 1 used a LabAlliance HPLC system equipped with a UV/vis detector (λ = 254 nm) and Zorbax C_{18} semiprep column (9.4 nm × 250 mm, 100 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 2.5 mL/min with the mobile phase starting from 90% A (25 mM NH_4OAc, pH = 6.8) and 10% B (acetonitrile) at 0 min, followed by a gradient mobile phase going from 85% A and 15% B at 5 min to 65% A and 35% B at 30 min. The radio-HPLC method (method 2) used the LabAlliance HPLC system equipped with a β-ram IN/US detector (Tampa, FL) and Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% A (25 mM NH_4OAc, pH = 6.8) and 10% B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% B at 2 min to 15% B at 5 min and to 20% B at 20 min. The radio-ITLC method used GelmanSciences silica-gel paper strips and a 1:1 mixture of acetone and saline as eluant. By this method, ^{99m}Tc-labeled cyclic RGD peptides migrate to the solvent front, while $^{99m}TcO_4^-$ and [^{99m}Tc]colloid remain at the origin.

MAG_2-OSu. To a solution of MAG_2 (310 mg, 1 mmol) and *N*-hydroxysuccinimide (130 mg, 1.1 mmol) in DMF (5 mL) was added dicyclcohexylcarbodiimide (DCC: 230 mg, 1.1 mmol). The mixture was stirred at room temperature for 24 h. After addition of 0.3 mL acetic acid, the resulting mixture was stirred at room temperature for another 5 h. The precipitate was filtered and discarded. The filtrate was evaporated to dryness on a rotary evaporator. The residue was dissolved in dichloromethane (10 mL). After filtration, the filtrate was concentrated to ~2 mL. The solution was added dropwise into diethyl ether (20 mL) to give an off-white precipitate. The solid product was collected, washed with diethyl ether, and dried under vacuum. The yield was 340 mg (83%). ^{1}H NMR ($CDCl_6$, chemical shifts in ppm relative to TMS): 2.81 (s, 4H, $COCH_2CH_2CO$); 3.78 (s, 2H, SCH_2CO); 4.03 (d, 2H, CH_2CO); 4.38 (d, 2H, CH_2CO); 7.13 (dt, 2H, aromatic); 7.47 (t, 2H, aromatic); 7.61 (t, H, aromatic); and 7.96 (d, 2H, NHCO). ESI-MS: m/z = 408.50 for $[M+H]^+$ (408 calcd. for $[C_{17}H_{18}N_3O_7S]^+$).

MAG_2-P-RGD_2. MAG_2-OSu (5.8 mg, 14.2 μmol) and P-RGD_2 (5.4 mg, 3.45 μmol) were dissolved in DMF (2 mL). To the mixture above was added diisopropylethylamine (DIEA, 2 drops). The solution was stirred at room temperature for 2 h. After addition of water (2 mL), the pH was adjusted to 3.0−4.0. The product was separated from the reaction mixture by HPLC (method 1). Fractions at 17.5 min were collected. Lyophilization of combined collections afforded the crude product MAG_2-P-RGD_2 (~75% purity by HPLC), which was then further purified by HPLC (method 1). The yield was 2.7 mg (42%). ESI-MS: m/z = 1858.43 for (1857 calcd for $[C_{83}H_{121}N_{22}O_{25}S]^+$).

MAG_2-3P-RGD_2. MAG_2-3P-RGD_2 was prepared in a similar fashion to that for MAG_2-P-RGD_2 using MAG_2-OSu (4 mg, 9.7 μmol) and 3P-RGD_2 (5 mg, 2.43 μmol). The product was purified by HPLC (method 1). Fractions at ~16 min were collected. Lyophilization of the combined collections afforded the crude product MAG_2-3P-RGD_2 (~77% purity by HPLC), which was further purified by HPLC (method 1). Lyophilization of the combined collections at 20 min afforded MAG_2-3P-RGD_2 with >95% HPLC purity. The yield was 2.0 mg (35%). ESI-MS: m/z = 2351.79 for (2352 calcd. for $[C_{105}H_{163}N_{24}O_{35}S]^+$).

MAG_2-PEG_4-E[PEG_4-c(RGKfD)]$_2$ (MAG_2-3P-RGK_2). MAG_2-3P-RGK_2 was prepared according to the same procedure used for MAG_2-PEG_4-dimer using MAG_2-OSu (12.5 mg, 40 μmol) and 3P-RGK_2 (15 mg, 7.29 μmol). The product was separated from the reaction mixture by HPLC (method 1). Fractions at 16 min were collected. Lyophilization of the combined collections afforded the crude product MAG_2-3P-RGK_2 (~70% purity by HPLC), which was then further purified by HPLC (method 1). Lyophilization of the combined collections at 19 min afforded MAG_2-3P-RGK_2 with >95% HPLC purity. The yield was 6.2 mg (36%). ESI-MS: m/z = 2351.76 for (2351 calcd. for $[C_{105}H_{163}N_{24}O_{35}S]^+$).

^{99m}Tc-Labeling. To a lyophilized vial containing 2.28 mg of NaH_2PO_4, 11.5 mg of Na_2HPO_4, 50 mg of α-D-glucoheptonic acid, 50 μg of $SnCl_2 \cdot 2H_2O$, and 25 μg of the MAG_2-conjugate (MAG_2-P-RGD_2, MAG_2-3P-RGD_2, or MAG_2-3P-RGD_2) was added 1.0 mL of $Na^{99m}TcO_4$ solution (10−50 mCi/mL). The vial was heated at 100 °C for 20−25 min in a lead-shielded water bath. After heating, the vial was placed back into the lead pig and allowed to stand at room temperature for ~10 min. A sample of the resulting solution was analyzed by radio-HPLC (method 2) and radio-ITLC. The radiochemical purity (RCP) was >95% for all three radiotracers, ^{99m}TcO(MAG_2-P-RGD_2), ^{99m}TcO(MAG_2-3P-RGD_2), and ^{99m}TcO(MAG_2-3P-RGK_2), with less than 0.5% of [^{99m}Tc]colloid.

Dose Preparation. For the ex vivo biodistribution studies, the ^{99m}Tc radiotracers were first prepared and then purified by HPLC (method 2). Volatiles in the HPLC mobile phases were removed under vacuum. The dose solution was prepared by dissolving the purified radiotracer in saline to a concentration of 10−25 μCi/mL. In the blocking experiment, E[c(RGDfK)]$_2$ was dissolved in the dose solution to ~3.5 mg/mL. For imaging studies, ^{99m}TcO(MAG_2-3P-RGD_2) was prepared in high yield (RCP > 95%). Doses were made by dissolving the reconstituted kit solution to a concentration of 5 mCi/mL. The solution was filtered with a 0.20 μ Millex-LG filter to remove any particle or precipitate. Each tumor-bearing mouse was injected with ~0.1 mL of the filtered dose solution.

Determination of Log *P* Values. Log P values of were determined using the following procedure: the ^{99m}Tc radiotracer was purified by HPLC. Volatiles were removed completely under vacuum. The residue was dissolved in a equal volume (3 mL/3 mL) mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After stirring vigorously for ~20 min, the mixture was centrifuged at a speed of 8000 rpm for 5 min. Samples (in triplets) from *n*-octanol and aqueous layers were counted in a Perkin-Elmer Wizard 1480 γ-counter (Shelton, CT). The log *P* value was measured three different times and reported as an average of three independent measurements plus the standard deviation.

In vitro Whole-Cell Integrin $\alpha_v\beta_3$ Binding Assay. The in vitro integrin binding affinity of cyclic RGD peptides were assessed by a displacement assay using ^{125}I-c(RGDyK) as the integrin $\alpha_v\beta_3$-specific radioligand. Experiments were performed on U87MG human glioma cells by slight modification of a method previously described (*28, 30*). Briefly, U87MG glioma cells were grown in Gibco's Dulbecco's medium supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co, Carlsbad, CA), at 37 °C in humidified atmosphere containing 5% CO_2. Filter multiscreen DV plates were seeded with 10^5 cells in binding buffer and incubated with ^{125}I-c(RGDyK) in the presence of increasing concentrations of cyclic RGD peptides. After removing the unlabeled c(RGDyK), hydrophilic PVDF filters were collected and the radioactivity was determined using a gamma counter (Packard, Meriden, CT). The IC_{50} values were calculated by fitting the data by nonlinear regression using *GraphPad Prism* (GraphPad Software, Inc., San Diego, CA), and reported as an average plus the standard deviation. Comparison between two radiotracers was made using the two-way ANOVA test (*GraphPad Prism 5.0*, San Diego, CA). The level of significance was set at $p < 0.05$.

Animal Model. Biodistribution studies were performed using the athymic nude mice bearing U87MG human glioma xenografts in compliance the NIH animal experiment guidelines

(Principles of Laboratory Animal Care, NIH Publication No. 86−23, revised 1985). The protocol was approved by Purdue University Animal Care and Use Committee (PACUC). The U87MG human glioma cells were grown at 37 °C in Minimal Essential Medium (Alpha Modification) containing 3.7 g of sodium bicarbonate/L, 10% fetal bovine serum v/v, and 5% penicillin streptomycin (GIBCO, Grand Island, NY) in a humidified atmosphere of 5% carbon dioxide. Female athymic nu/nu mice were purchased from NCI at 4−5 weeks of age. The mice were implanted subcutaneously with ~8 × 10^6 U87MG human glioma cells into the upper left flanks. All procedures will be performed in a laminar flow cabinet using aseptic technique. Two to three weeks after inoculation, the tumor size was 0.1−0.4 g, and animals were used for biodistribution and imaging studies.

Biodistribution Protocol. Fifteen tumor-bearing mice (20 − 25 g) were randomly divided into four groups. Each animal was administered with ^{99m}Tc radiotracer (~2.5 μCi in 0.1 mL saline) via tail vein. Five animals were euthanized by sodium pentobarbital overdose (100−200 mg/kg) at 30, 60, and 120 min postinjection (p.i.). Blood samples were withdrawn from the heart. The tumor and normal organs (brain, eyes, heart, intestine, kidneys, liver, lungs, muscle, and spleen) were excised, washed with saline, dried with absorbent tissue, weighed, and counted on a γ-counter (Perkin-Elmer Wizard 1480). The organ uptake was calculated as the percentage of injected dose per gram of organ tissue (%ID/g). For the blocking experiment to demonstrate the radiotracer integrin $\alpha_v\beta_3$ specificity, each animal was administered ~2 μCi of ^{99m}TcO(MAG_2-3P-RGD_2) along with ~350 μg of E[c(RGDfK)]$_2$ (~14 mg/kg). At 1 h p.i., five animals were sacrificed by sodium pentobarbital overdose (100 mg/kg) for organ biodistribution. The organ uptake (%ID/g) was compared to that obtained in the absence of excess E-[c(RGDfK)]$_2$ at the same time point. For the experiment to demonstrate the radiotracer RGD-specific, each animal was administered with ~2 μCi of ^{99m}TcO(MAG_2-3P-RGD_2) along with ~350 μg of E[c(RGDfK)]$_2$ (~14 mg/kg). At 1 h p.i., five animals were sacrificed by sodium pentobarbital overdose (100 mg/kg) for organ biodistribution. The organ uptake (%ID/g) was compared to that obtained in the absence of excess E[c(RGD-fK)]$_2$ at the same time point.

Scintigraphic Imaging. Three athymic nude mice bearing U87MG glioma xenografts were used for planar imaging studies. Each glioma-bearing mouse was intravenously administered with ~500 μCi of ^{99m}TcO(MAG_2-3P-RGD_2) via tail vein. The animals were anesthetized with intramuscular injection of ketamine (80 mg/kg) and xylazine (19 mg/kg). The animal was placed prone on a single head mini γ-camera (Diagnostic Services Inc., NJ) equipped with a parallel-hole, low-energy, and high-resolution collimator. Static images were acquired at 15, 30, 60, and 120 min p.i. and were stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 500 K. After imaging, the animals were euthanized by sodium pentobarbital overdose (100−200 mg/kg).

Metabolism. Three glioma-bearing mice were used for the in vivo metabolic stability study of ^{99m}TcO(MAG_2-3P-RGD_2), which was intravenously administered at the dose of ~100 μCi per mouse via tail vein. At 120 min p.i., the urine samples were collected and were mixed with equal volume of 20% acetonitrile aqueous solution. The mixture was centrifuged at 8000 rpm for 5 min. The supernatant was collected and filtered through a 0.20 μ Millex-LG filter unit. The feces samples were collected at 120 min p.i. and suspended in a mixture of 20% acetonitrile aqueous solution (2 mL). The resulting mixture was vortexed for 10 min. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and passed through a 0.20 μ Millex-LG filter unit to remove any particles or precipitate. Both the urine and feces samples were analyzed by radio-HPLC (method 2). The tumor, kidney, and liver tissues were harvested at 120 min p.i., counted in a Perkin-Elmer Wizard 1480 γ-counter (Shelton, CT) for total radioactivity, and then homogenized. The homogenate was mixed with 2 mL of 20% acetonitrile aqueous solution. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and counted on a γ-counter to determine the percentage of radioactivity recovery in each organ. After filtration through a 0.20 μm Millex-LG filter unit to remove foreign particles or precipitate, the filtrate was then analyzed by radio-HPLC (method 2).

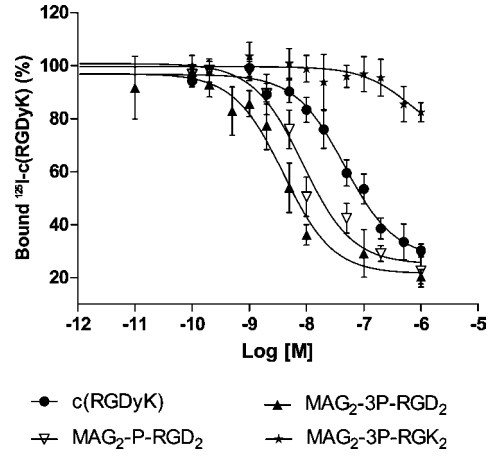

Figure 2. The in vitro inhibition curve of ^{125}I-c(RGDyK) bound to integrin $\alpha_v\beta_3$ on U87MG human glioma cells by c(RGDyK), MAG_2-P-RGD_2, MAG_2-3P-RGD_2, and MAG_2-3P-RGK_2. Their IC_{50} values were calculated to be 46.6 ± 4.5, 8.6 ± 2.8, 3.9 ± 0.4, and 711 ± 128 nM, respectively.

Data and Statistical Analysis. The biodistribution data and target-to-background (*T*/*B*) ratios are reported as an average plus the standard variation based on results from four tumor-bearing mice at each time point. Comparison between two different ^{99m}Tc radiotracers was made using the two-way ANOVA test (*GraphPad Prism 5.0*, San Diego, CA). The level of significance was set at $p < 0.05$.

RESULTS

MAG_2 Conjugate Synthesis. Synthesis of new cyclic RGD peptide conjugates (MAG_2-P-RGD_2 and MAG_2-3P-RGD_2) was straightforward. They were prepared by conjugation of P-RGD_2 and 3P-RGD_2, respectively, with excess MAG_2-NHS in DMF in the presence of a base, such as DIEA. MAG_2-3P-RGK_2 contains two c(RGKfD) motifs instead of c(RGDfK) motifs in MAG_2-3P-RGD_2 and was prepared as a "negative control" to demonstrate the RGD-specificity of ^{99m}TcO(MAG_2-3P-RGD_2). All new peptide conjugates were purified twice by HPLC (method 1) and characterized by ESI-MS. Their HPLC purity was >95% before being used for ^{99m}Tc-labeling and determination of their integrin $\alpha_v\beta_3$ binding affinity.

Integrin $\alpha_v\beta_3$ Binding Affinity. The integrin $\alpha_v\beta_3$ binding affinities of c(RGDyK), MAG_2-3P-RGD_2 and MAG_2-3P-RGD_2 and MAG_2-3P-RGK_2 were determined by a competitive displacement assay. Their IC_{50} values were obtained from curve fitting from Figure 2 and calculated to be 46.6 ± 4.5, 8.6 ± 2.8, 3.9 ± 0.4, and 711 ± 128 nM, respectively.

Radiochemistry. ^{99m}TcO(MAG_2-P-RGD_2) and ^{99m}TcO(MAG_2-3P-RGD_2) were prepared by reacting MAG_2-P-RGD_2 and MAG_2-3P-RGD_2, respectively, with $^{99m}TcO_4^-$ at pH ~8.5 in the presence of excess D-glucoheptonic acid (~50 mg per vial) and stannous chloride. ^{99m}Tc-labeling was accomplished by heating the reaction mixture at 100 °C for 15−20 min. D-Glucoheptonic acid was used to stabilize $SnCl_2$ and the

Table 1. HPLC Retention Time and Log *P* Values for ^{99m}Tc-Labeled Cyclic RGD Peptides

compound	RCP (%)	RT (min)	Log *P*
^{99m}TcO(MAG$_2$-P-RGD$_2$)	>95	17.0	-3.30 ± 0.13
^{99m}TcO(MAG$_2$-3P-RGD$_2$)	>90	16.9	-3.19 ± 0.15
^{99m}TcO(MAG$_2$-3P-RGK$_2$)	>90	17.3	-2.40 ± 0.14
^{99m}Tc-3P-RGD$_2$	>90	16.9	-4.35 ± 0.10[a]

[a] The log *P* value of -3.96 ± 0.05 was reported in our previous communication (*55*). These two values seem to be statistically significant, but they are within the experimental error of the assay.

$[^{99m}TcO]^{3+}$ core and to prevent formation of [^{99m}Tc]colloid during radiolabeling. Their radiochemical purity was >90% with <0.5% of [^{99m}Tc]colloid. In general, 20−25 μg MAG$_2$-3P-RGD$_2$ was sufficient for successful radiolabeling of 50 mCi of $^{99m}TcO_4^-$. The specific activity for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) was ~2.0 mCi/μg (~5 Ci/μmol). ^{99m}TcO(MAG$_2$-3P-RGD$_2$) was stable in the kit matrix for >6 h. All ^{99m}Tc radiotracers were analyzed by the same HPLC method, and their retention times were listed in Table 1. The log *P* values for ^{99m}TcO(MAG$_2$-P-RGD$_2$), ^{99m}TcO(MAG$_2$-3P-RGD$_2$), and ^{99m}TcO(MAG$_2$-3P-RGK$_2$) were determined to be -3.30 ± 0.13, -3.19 ± 0.10, and -2.40 ± 0.14, respectively.

Biodistribution Characteristics. The biodistribution data for ^{99m}TcO(MAG$_2$-P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$) were listed in Tables 2 and 3, respectively. ^{99m}TcO(MAG$_2$-P-RGD$_2$) had the tumor uptake of 9.63 ± 1.39 and 11.95 ± 1.90%ID/g at 30 and 60 min, respectively, but it decreased to 5.90 ± 0.35%ID/g at 120 min p.i. It also had a high kidney uptake with a fast clearance (16.61 ± 5.52 and 3.93 ± 0.60%ID/g at 30 and 120 min p.i., respectively). The liver uptake of ^{99m}TcO(MAG$_2$-P-RGD$_2$) was 4.25 ± 1.53, 2.75 ± 0.76 and 1.47 ± 0.15%ID/g while its tumor/liver ratios were 2.54 ± 0.68, 2.98 ± 0.29 and 3.69 ± 0.58 at 30, 60 and 120 min p.i., respectively. ^{99m}TcO(MAG$_2$-3P-RGD$_2$) also had a high tumor uptake (15.49 ± 5.55, 15.36 ± 2.17 and 14.02 ± 2.20%ID/g at 30, 60 and 120 min p.i., respectively). Its kidney uptake was 16.35 ± 2.20, 11.79 ± 3.98 and 6.07 ± 1.12%ID/g at 30, 60 and 120 min p.i. respectively. Its liver uptake was 4.35 ± 1.51%ID/g at 30 min p.i. and 2.30 ± 0.23%ID/g at 120 min p.i., and its tumor/liver ratio increased steadily from 3.49 ± 1.13 at 30 min p.i. to 5.81 ± 0.65 at 120 min p.i.

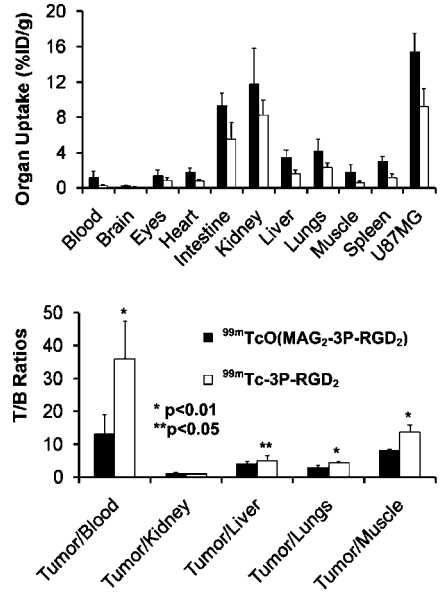

Figure 3. Comparison of the biodistribution data (top) and selected *T*/*B* ratios (bottom) of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) and ^{99m}Tc-3P-RGD$_2$ at 60 min p.i. in the athymic nude mice ($n = 5$) bearing U87MG glioma xenografts.

Effects of Technetium Chelate. To assess the impact of ^{99m}Tc chelates (^{99m}TcO(MAG$_2$) vs [^{99m}Tc(HYNIC)(tricine)-(TPPTS)]) on the radiotracer tumor uptake and T/B ratios, we also obtained the 60-min biodistribution data of ^{99m}Tc-3P-RGD$_2$ using the same animal model with similar tumor size. Figure 3 compares the organ uptake and *T*/*B* ratios for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) and ^{99m}Tc-3P-RGD$_2$ at 60 min p.i. Replacing [^{99m}Tc-(HYNIC)(tricine)(TPPTS)] with the much smaller ^{99m}TcO-(MAG$_2$) resulted in a significant increase in the tumor and normal organ uptake. For example, ^{99m}TcO(MAG$_2$-3P-RGD$_2$) had the 60-min uptake of 15.36 ± 2.17, 1.16 ± 0.78, 9.26 ± 1.50, 11.79 ± 3.98, 3.45 ± 0.86 and 4.17 ± 1.35%ID/g in the tumor, blood, intestine, kidneys, liver and lungs, respectively, while the uptake of ^{99m}Tc-3P-RGD$_2$ in the same organs was 9.15 ± 2.13%ID/g, 0.27 ± 0.08%ID/g, 5.25 ± 1.92%ID/g, 8.22 ± 1.99%ID/g, 1.69 ± 0.46%ID/g, and 2.10 ± 0.54%ID/g at the same time point.

Integrin $\alpha_v\beta_3$ Specificity. Figure 4A compares the organ uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) in the absence/presence of E[c(RGDfK)]$_2$ at 60 min p.i. Coinjection of excess E[c-(RGDfK)]$_2$ almost completely blocked its tumor uptake (0.31 ± 0.07%ID/g with E[c(RGDfK)]$_2$ vs 15.36 ± 2.17%ID/g without E[c(RGDfK)]$_2$). The normal organ uptake of ^{99m}TcO-(MAG$_2$-3P-RGD$_2$) was also almost completely blocked by coinjection of excess E[c(RGDfK)]$_2$.

RGD Specificity. Figure 4B compares the 60 min organ uptake values for ^{99m}TcO(MAG$_2$-3P-RGK$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$). This experiment was designed to demonstrate the RGD specificity of ^{99m}TcO(MAG$_2$-3P-RGD$_2$). ^{99m}TcO(MAG$_2$-3P-RGK$_2$) had much lower tumor uptake (0.70 ± 0.09%ID/g)

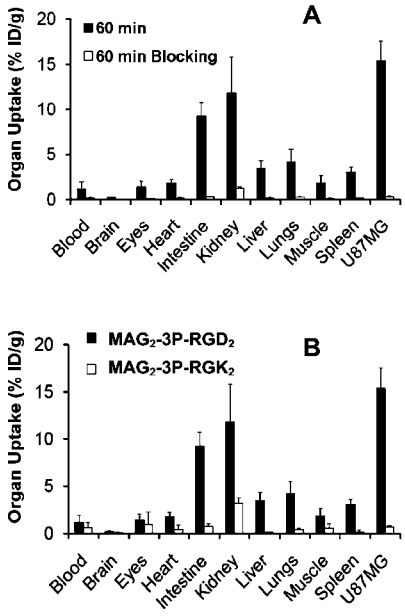

Figure 4. (A) Biodistribution data of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) in athymic nude mice ($n = 5$) bearing U87MG human glioma xenografts in the absence/presence of excess E[c(RGDfK)]$_2$ (14 mg/kg or ~350 μg/mouse) at 60 min p.i. (B) Direct comparison of biodistribution characteristics between ^{99m}TcO(MAG$_2$-3P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGK$_2$) in athymic nude mice ($n = 5$) bearing U87MG human glioma xenografts at 60 min p.i.

than ^{99m}TcO(MAG$_2$-3P-RGD$_2$) (15.36 ± 2.17%ID/g). It also had significantly ($p < 0.01$) lower uptake in normal organs than ^{99m}TcO(MAG$_2$-3P-RGD$_2$). As a result, the radioactivity was excreted much more rapidly (more urine activity at the same time point) from the renal route in the tumor-bearing mice administered with ^{99m}TcO(MAG$_2$-3P-RGK$_2$).

Tumor Size vs Tumor Uptake. In this study, we used a total of 14 glioma-bearing mice to explore the relationship between the tumor size and %ID uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) at 120 min p.i. As illustrated in Figure 5A, there was a linear relationship between the tumor size (0.08−0.4 g; $n = 14$) and the %ID glioma uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) with $R^2 = 0.9226$. Obviously, the %ID tumor uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) increased in a linear fashion as the tumor size became larger.

Planar Imaging. Figure 5B illustrates representative static images of the glioma-bearing mice ($n = 3$) administered with ^{99m}TcO(MAG$_2$-3P-RGD$_2$) at 15, 30, 60, and 120 min p.i. The tumor was clearly seen with excellent contrast as early as 15 min p.i. The tumor radioactivity remained relatively steady over the 2 h study period. The radioactivity accumulation in the blood and muscle disappeared almost completely by 120 min p.i. The most visible organs were tumor, gallbladder, kidneys, and bladder. Because of the radioactivity accumulation in the abdominal region, it was difficult to accurately determine the tumor/kidney and tumor/liver ratios on the basis of planar imaging.

Metabolic Properties. Metabolism studies were performed on ^{99m}TcO(MAG$_2$-3P-RGD$_2$) using athymic nude mice bearing U87MG glioma xenografts. The percentage of radioactivity recovery in the urine and feces samples was very high (>90%); but it was only 45−55% from the homogenates of the tumor, kidney, and liver tissues. Figure 6 shows radio-HPLC chromatograms of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) in saline before injection, in the extracts of urine and feces samples, and in the homogenates from tumor, kidneys, and liver at 120 min p.i. There was no significant metabolism for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) during its excretion from renal and hepatobiliary routes and in the tissues from tumor, liver, and kidneys.

DISCUSSION

In this study, we prepared two cyclic RGD dimer conjugates (MAG$_2$-P-RGD$_2$ and MAG$_2$-3P-RGD$_2$). It is found that both ^{99m}TcO(MAG$_2$-P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$) can be obtained in high yield (>90%) and with high specific activity (~5 Ci/μmol) using a kit formulation, and have very high solution stability in the kit matrix. There are advantages of using small peptides, such as MAG$_2$ (the smallest N_3S triamidethiol chelating unit when conjugated to the peptide), as BFCs. The attachment of BFC can be easily incorporated into solid-phase peptide synthesis. The N_3S chelating units form stable Tc complexes with the $[Tc{=}O]^{3+}$ core. The hydrophilicity of the Tc chelate can be tuned by changing the glycine residues with more hydrophilic amino acids, such as aspartic and glutamic acids.

The integrin $\alpha_v\beta_3$ binding affinity follows the order MAG$_2$-3P-RGD$_2$ ($IC_{50} = 3.9 \pm 0.4$ nM) > MAG$_2$-P-RGD$_2$ ($IC_{50} = 8.6 \pm 2.8$ nM) > c(RGDfK) ($IC_{50} = 46.6 \pm 4.5$ nM), suggesting that bivalency is most likely responsible for the higher integrin $\alpha_v\beta_3$ binding affinity of MAG$_2$-3P-RGD$_2$ as compared to that of MAG$_2$-P-RGD$_2$. This conclusion is well supported by the significantly ($p < 0.01$) higher tumor uptake (Figure 3) of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) than that of ^{99m}TcO(MAG$_2$-P-RGD$_2$). If they were bound to integrin $\alpha_v\beta_3$ in the same fashion, MAG$_2$-3P-RGD$_2$ and MAG$_2$-P-RGD$_2$ would have had the same integrin $\alpha_v\beta_3$ binding affinity, whereas ^{99m}TcO(MAG$_2$-3P-RGD$_2$) and ^{99m}TcO(MAG$_2$-P-RGD$_2$) would have shared the similar tumor uptake in the same tumor-bearing animal model.

The integrin $\alpha_v\beta_3$ binding affinity of MAG$_2$-3P-RGD$_2$ ($IC_{50} = 3.9 \pm 0.4$ nM) is very similar to that of HYNIC-3P-RGD$_2$ ($IC_{50} = 4.1 \pm 0.3$ nM), respectively, suggesting that replacing HYNIC with MAG$_2$ has little impact on the integrin $\alpha_v\beta_3$ binding affinity of 3P-RGD$_2$. It must be noted that this comparison is between the cyclic RGD conjugates, not their ^{99m}Tc radiotracers, the integrin $\alpha_v\beta_3$ binding affinity and biodistribution characteristic of which could be altered significantly depending on the size of ^{99m}Tc chelates (Figure 1: ^{99m}TcO(MAG$_2$) vs [^{99m}Tc(HYNIC)(tricine)(TPPTS)]). ^{99m}TcO-(MAG$_2$) has a molecular weight of ~300 Da and is expected to have minimal impact on integrin $\alpha_v\beta_3$ binding affinity of 3PEG$_4$-dimer. In contrast, [^{99m}Tc(HYNIC)(tricine)(TPPTS)] has a molecular weight of ~1000 Da due to the presence of tricine and TPPTS coligands, and is expected to have much more significant impact on the integrin $\alpha_v\beta_3$ binding affinity of 3P-RGD$_2$. This assumption seems to be supported by the significantly ($p < 0.01$) higher tumor uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) (15.36 ± 2.17%ID/g at 60 min p.i.) than that of ^{99m}Tc-3P-RGD$_2$ (9.15 ± 2.13%ID/g at 60 min p.i.).

Replacing [^{99m}Tc(HYNIC)(tricine)(TPPTS)] with ^{99m}TcO-(MAG$_2$) results in >10× higher lipophilicity for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) ($\log P = -3.19 \pm 0.13$) as compared to ^{99m}Tc-3P-RGD$_2$ ($\log P = -4.35 \pm 0.10$), which is most likely responsible for its higher uptake in tumor, blood, and normal organs (Figure 3: top). For example, the blood radioactivity for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) is 1.16 ± 0.78%ID/g at 60 min p.i. while it is only 0.27 ± 0.08%ID/g for ^{99m}Tc-3P-RGD$_2$ at the same time point. The liver uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) is 3.45 ± 0.86%ID/g whereas ^{99m}Tc-3P-RGD$_2$ has the liver uptake of 2.92 ± 0.77%ID/g at 60 min p.i. ^{99m}TcO(MAG$_2$-3P-RGD$_2$) has the kidney uptake of 11.79 ± 3.98%ID/g while ^{99m}Tc-3PEG$_4$-dimer has the kidney uptake of 8.62 ± 1.99%ID/g at 60 min p.i. The lung uptake is 4.17 ± 1.35%ID/g for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) and 2.10 ± 0.54%ID/g for ^{99m}Tc-3P-RGD$_2$ at 60 min p.i. the tumor/blood, tumor/liver, tumor/lung, and tumor/liver ratios for

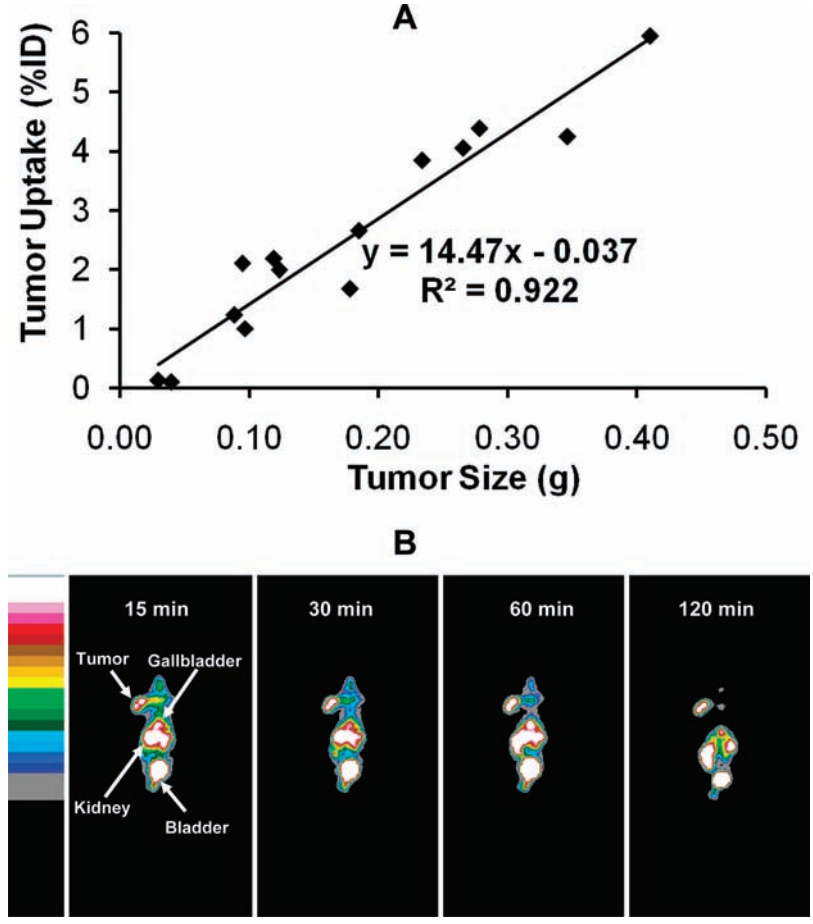

Figure 5. (A) Relationship between tumor size and tumor uptake for ^{99m}TcO(MAG$_2$-3P-RGD$_2$) at 120 min p.i. in the athymic nude mice (n = 14) bearing the U87MG glioma xenografts. The linear relationship between the tumor size and %ID tumor uptake suggests that ^{99m}TcO(MAG$_2$-3P-RGD$_2$) has the potential for noninvasive monitoring of tumor growth or shrinkage during antiangiogenic therapy. (B) Planar images of the athymic nude mice (bearing U87MG glioma xenografts) administered with ~500 μCi of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) at 15, 30, 60, and 120 min p.i. Arrows indicate the presence of the tumor, gallbladder, kidneys, and bladder.

^{99m}TcO(MAG$_2$-3P-RGD$_2$) are not as good as those for ^{99m}Tc-3P-RGD$_2$ (Figure 4: bottom). On the basis of these data, we believe that ^{99m}Tc-3P-RGD$_2$ remains a better SPECT radiotracer for noninvasive imaging of integrin $\alpha_v\beta_3$-positive tumors.

The integrin $\alpha_v\beta_3$-specificity of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) has been demonstrated by the "blocking experiment" (Figure 4A). The blockage of its tumor uptake indicates that ^{99m}TcO(MAG$_2$-3P-RGD$_2$) is integrin $\alpha_v\beta_3$-specific. The uptake blockage in the eyes, heart, intestine, lungs, liver, and spleen suggests that its accumulation in these organs is also integrin $\alpha_v\beta_3$-mediated. This conclusion is supported by the immunohistopathological studies (*34, 35*), which showed a strong positive staining of endothelial cells of small glomeruli vessels in the kidneys and weak staining in branches of the hepatic portal vein. The RGD-specificity of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) is demonstrated by the lower integrin $\alpha_v\beta_3$ binding affinity of MAG$_2$-3P-RGK$_2$ (IC_{50} = 711 ± 128 nM) than that of MAG$_2$-3P-RGD$_2$ (IC_{50} = 3.9 ± 0.4 nM), and the lower tumor uptake of ^{99m}TcO(MAG$_2$-3P-RGK$_2$) than that of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) (Figure 4B). In addition, ^{99m}TcO(MAG$_2$-3PEG$_4$-dimer) is able to maintain its chemical integrity during excretion from both renal and hepatobiliary routes, and in the tumor and liver tissues (Figure 6).

The ability to noninvasively quantify the integrin $\alpha_v\beta_3$ level provides new opportunities to select appropriate patients for antiangiogenic treatment of integrin $\alpha_v\beta_3$-positive cancer patients (*59, 60*). The %ID tumor uptake reflects the total integrin $\alpha_v\beta_3$ level, while the %ID/g tumor uptake reflects the integrin $\alpha_v\beta_3$ density. When tumor is small (<0.05 g or 50 m^3), there is little angiogenesis with low blood flow. As a result, ^{99m}TcO(MAG$_2$-3P-RGD$_2$) has low %ID tumor uptake (Figure 5A). As the tumor grows, the integrin $\alpha_v\beta_3$ level becomes higher, and the %ID tumor uptake of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) increases (Figure 5A). The linear relationship between the tumor size and %ID tumor uptake strongly suggests that ^{99m}TcO-(MAG$_2$-3P-RGD$_2$) has the potential for monitoring the integrin $\alpha_v\beta_3$ expression levels during antiangiogenic therapy. It is important to note that the integrin $\alpha_v\beta_3$ expression is not homogeneous in the tumor tissue. Parts of the tumor tissue may become necrotic when its size is >10 mm in diameter. Therefore, the radiotracer %ID/g uptake values in tumors of different sizes are scattered as previously reported for ^{99m}Tc-3P-RGD$_2$ (*55*), ^{99m}Tc-3G-RGD$_2$ (*56*), and ^{64}Cu(DOTA-3P-RGD$_2$) (*57*).

We must be concerned that the subcutaneous glioma-bearing model used in this study may not reflect the real tumor growth rate in glioma cancer patients, since the tumor growth is too fast in the athymic nude mice bearing U87MG glioma xenografts. However, this tumor-bearing animal model as a screening tool should provide us with sufficient biodistribution data to select an optimal radiotracer for more preclinical evaluations in the future. In addition, we also noticed that the tumor growth rate is largely dependent on the number of U87MG human glioma cells implanted in each animal, and the radiotracer tumor uptake may vary significantly with the tumor growth rate. Whenever possible, the comparison between different radiotracers should be made by using their biodistribution data obtained from the same groups of tumor-bearing

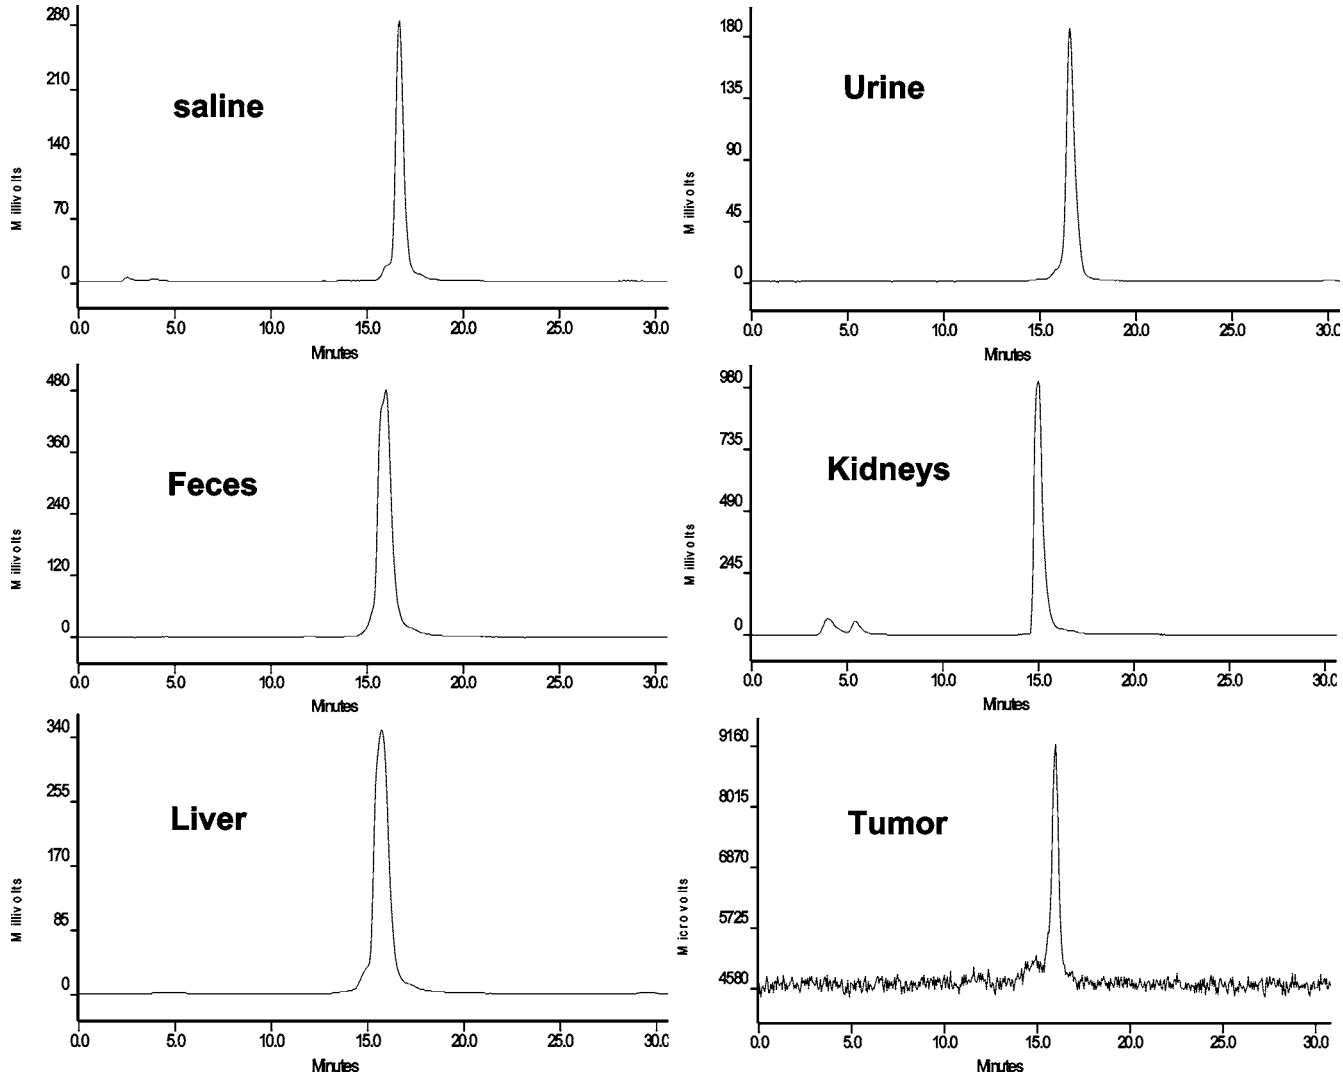

Figure 6. Typical radio-HPLC chromatograms of ^{99m}TcO(MAG$_2$-3P-RGD$_2$) in saline before injection, urine, feces, kidney, liver, and tumor at 120 min p.i. Slight variation in HPLC retention time was probably caused by the presence of 20% acetonitrile in the organ extract.

mice with similar tumor size. That is why in this study we obtained the 60 min biodistribution data of ^{99m}Tc-3PEG$_4$-dimer, instead of using those reported in our previous studies (*55*), to demonstrate the impact of ^{99m}Tc chelates (^{99m}TcO(MAG$_2$) vs [^{99m}Tc(HYNIC)(tricine)(TPPTS)]) on radiotracer tumor uptake and *T*/*B* ratios.

CONCLUSION

In this study, we presented the synthesis of two cyclic RGD peptide conjugates, MAG$_2$-P-RGD$_2$ and MAG$_2$-3P-RGD$_2$, and evaluated ^{99m}TcO(MAG$_2$-P-RGD$_2$) and ^{99m}TcO(MAG$_2$-3P-RGD$_2$) as new radiotracers for noninvasive imaging of integrin $\alpha_v\beta_3$ expression in athymic nude mice bearing U87MG glioma xenografts. The key findings are as follows: (1) MAG$_2$ is such an efficient BFC that ^{99m}TcO(MAG$_2$-3P-RGD$_2$) could be readily prepared in high yield with high specific activity using a single-vial kit formulation; (2) replacing [^{99m}Tc(HYNIC)(tricine)-(TPPTS)] with ^{99m}TcO(MAG$_2$) results in a significant increase in the radiotracer uptake in the tumor, blood, and normal organs due to the increased lipophilicity of ^{99m}TcO(MAG$_2$-3P-RGD$_2$). Even though ^{99m}TcO(MAG$_2$-3P-RGD$_2$) has the better tumor uptake, its tumor/blood, tumor/liver, tumor/lung, and tumor/liver ratios are not as good as those for ^{99m}Tc-3P-RGD$_2$. On the basis of these results, we believe that future research should be directed toward BFC with highly charged amino acid residues, such as aspartic and glutamic acids, instead of glycine in MAG$_2$.

ACKNOWLEDGMENT

Epidermal Growth Factor Tethered through Coiled-Coil Interactions Induces Cell Surface Receptor Phosphorylation

Cyril Boucher,[†,‡] Benoît Liberelle,[†] Mario Jolicoeur,[†] Yves Durocher,[‡] and Gregory De Crescenzo*[,†]

Department of Chemical Engineering, Groupe de Recherche en Sciences et Technologie Biomédicales (GRSTB), Bio-P^2 Research Unit, École Polytechnique de Montréal, P.O. Box 6079, succ. Centre-Ville, Montréal (Qc), Canada H3C 3A7, and Animal Cell Technology Group, Bioprocess Sector, Biotechnology Research Institute, National Research Council Canada, Montréal (Qc), Canada H4P 2R2. Received March 13, 2009; Revised Manuscript Received June 1, 2009

We have elaborated and validated a novel approach for the oriented tethering of proteins such as the epidermal growth factor (EGF) on aminated surfaces. The grafting reactions were optimized to generate a dense and homogeneous EGF layer. Impact of EGF orientation on A-431 cellular response was investigated. Our results demonstrate that, in sharp contrast to responses obtained with soluble EGF supply or with randomly grafted EGF, oriented immobilization of EGF via a de novo designed coiled-coil capture system leads to a sustained phosphorylation of A-431 cell surface EGF receptors. Our results thus indicate that oriented protein immobilization via coiled-coil interactions is an efficient and versatile method to control tethering of bioactive molecules for future applications in the field of regenerative medicine and tissue engineering.

INTRODUCTION

The development of new materials with potential to serve as two- and three-dimensional scaffolds for tissue engineering and regenerative medicine purposes has undergone rapid expansion (*1*). Advances in surface chemistry, much of it propelled by plasma-based polymer modification (*2, 3*) and chemical modification methodologies (*3, 4*) have opened interesting avenues for controlling protein binding as well as cell adhesion and differentiation (*5*). Another level of tailoring may also be added to this new class of materials by tethering specific macromolecules including peptides (*6*) or proteins (*7*) in order to synergistically enhance material intrinsic properties.

In that endeavor, immobilization of the epidermal growth factor (EGF) has already been reported (*7*−*14*). EGF is known to promote the oligomerization and activation of EGF receptors (EGFR) present at the cell surface (*15*), which ultimately leads in a broad spectrum of phenotypic responses such as the proliferation and differentiation of many cell types, including epithelial and mesenchymal cells. The role of soluble EGF in neovascularization and chemotaxis in the wound healing processes has also been documented (*16*). Recently, EGF has also been proposed as a promising candidate for ex vivo expansion of mesenchymal stem cells as well as neuronal stem cells, two attractive cell sources for tissue engineering applications (*12, 17*). Of interest, EGF immobilization has been demonstrated to enhance the EGF mitogenic effect on CHO cells when compared to its soluble form (*18*). On the same note, tethered EGF gradient surfaces were also shown to induce accelerated and polarized migration of keratinocytes, a key issue in the wound closure mechanism (*14*).

The most frequently used method for tethering human or murine EGF on solid supports relies on covalent immobilization through the reactive amine groups present at the EGF N-terminus or on its lysine side chain (at positions 28 and 48 for human EGF; no lysine in murine EGF) or by photoimmobilization. Although unambiguous effects on cell growth and phenotype have been reported with these approaches, it is likely that these immobilization methods are not efficiently transposable to growth factors harboring multiple lysine residues. That is, random amine coupling may not be optimal, since it may negatively impact protein internal conformation, relative molecular orientation, and spatial homogeneity, leading to diminished or even totally abrogated bioactivity (*7*). These concerns have led to the development of alternative strategies for oriented tethering of proteins on various substrates (*11, 19*). For EGF, most of them rely on the design of an EGF fusion protein comprising the Fc region of immunoglobulin G (IgG) or a His tag for their capture onto solid supports that have been previously functionalized with protein A/G or nitrilotriacetate (NTA), respectively (*11, 17*). The use of a hydrophobic tag has also been reported for EGF immobilization on hydrophobic supports (*8*).

In a previous study (*20*), we highlighted the potential of a new capture system based on de novo designed peptides, i.e., the E and K coils (*21, 22*). These two distinct and unstructured 35 amino acid peptides form a stable heterodimeric E/K coiled-coil complex upon binding (*22*). This coiled-coil system was demonstrated to be efficient for the stable and oriented capture of coil tagged proteins (*22*), including fully bioactive N-terminally coil-tagged EGF that had been produced in mammalian cells (*20*) or in bacteria (*23*).

The aim of this work was to further investigate the extent to which coiled-coil oriented immobilization of EGF would promote EGFR activation and, in turn, modulate cell response. Silicon surfaces with native oxide overlayer (Si/SiO_2) harboring primary amines through 3-aminopropyltriethoxysilane (APTES) functionalization were used to characterize and optimize the oriented covalent immobilization of Kcoil peptides and the subsequent capture of Ecoil-tagged EGF proteins (Ecoil-EGF). Dry thickness and water contact angle measurements were achieved to evaluate the amount of end-grafted molecules and the macroscopic homogeneity of the grafted layer, respectively. The optimized experimental conditions were then applied to cell culture-compatible amino-coated glass surfaces. Our study was

then complemented by culturing A-431 cells on these Ecoil-EGF derivatized surfaces. This cell line was selected as a model system since A-431 response to EGF is well-documented. Our in vitro cellular assays demonstrated that oriented EGF immobilization leads to a strong and sustained EGFR autophosphorylation as compared to that observed with randomly immobilized or soluble EGF. Altogether, our results demonstrated that the E/K coiled-coil system is an interesting alternative for the oriented immobilization of EGF, and by extension, of any growth factor, for future applications in the fields of tissue engineering and regenerative medicine.

MATERIALS AND METHODS

Chemicals and Reagents. Native silicon wafers (Prime Si P/Boron) were obtained from University Wafer (South Boston, MA), and amino-coated glass slides (10×10 mm^2) were from Erie Scientific Co. (Portsmouth, NH). Anhydrous 3-aminopropyltriethoxysilane (APTES, 99% purity), ethylenediamine, cysteine (99+% purity), glutaric anhydride (95% purity), and sodium chloride (99.99% purity) were purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON). Succinimidyl 6-[30-(2-pyridyldithio)-propionamido]hexanoate (LC-SPDP, 95+% purity) was obtained from Pierce Biotechnology, Inc. (Rockford, IL). Hydrogen peroxide (30% v/v), chlorhydric acid (37% v/v), chloroform (99.8% purity), sulfuric acid (98% purity), dimethylsulfoxide (DMSO, 99+% purity), and toluene (99.5% purity) were purchased from VWR International Inc. (Mont-Royal, Qc). All solvents were distilled under strict anhydrous conditions prior to use. Milli-Q quality water (18.2 MΩ.cm; total organic compounds (TOC) = 4 ppb) was generated with a Millipore Gradient A 10 purification system. Cysteine-tagged Kcoil peptides were synthesized as previously described (*22*). Untagged human EGF was purchased from R&D Systems (Minneapolis, MN). All the surface plasmon resonance (SPR) experiments were performed using a Biacore 3000 instrument (GE Healthcare, Baie d'Urfe, Qc). CM4 sensor chips and the amine coupling kit containing *N*-hydroxysuccinimide (NHS), ethyl-*N*′-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), and ethanolamine were also purchased from GE Healthcare.

Cell Culture. A human embryonic kidney (HEK) 293 cell line stably expressing EBNA1 (293−6E) was maintained in shake flasks (110 rpm) in F17 medium (Invitrogen, Burlington, ON) supplemented with glutamine (4 mM), Geneticin (25 μg/mL) and pluronic acid (0.1%) in a humidified incubator at 37 °C with 5% CO_2. The A-431 cells were maintained in 175 cm^2 flasks in Dulbecco's modified Eagle's medium (GIBCO/BRL, Burlington, ON) supplemented with 10% fetal bovine serum (Invitrogen, Burlington, ON) in 5% CO_2 incubator until 85−90% confluence.

E/Kcoil-EGF Production. As previously described (*20*), Ecoil and Kcoil-EGF were produced in HEK 293-6E cells and purified by immobilized metal ion affinity chromatography (IMAC). Protein concentration was determined by the Bradford method and analyzed by SDS-PAGE. Purified Ecoil-EGF was then stored at −80 °C until use. Note that the bioactivity of Ecoil-EGF was assayed in solution as described in (*20*) and was found to be equal to that of untagged EGF.

Surface Preparation. All glassware was carefully cleaned by overnight immersion in a bath of KOH-saturated isopropyl alcohol followed by intensive rinsing with Milli-Q water. Glassware was dried in a clean oven at 120 °C under atmospheric pressure. Prior to layer grafting, silicon and amino-coated glass surfaces were washed to remove any adsorbed organic compounds. The silicon surfaces (10×10 mm^2) were cleaned according to the Piranha procedure, i.e., the surfaces were immersed in a 3:1 mixture of sulfuric acid and hydrogen peroxide for 10 min at 100 °C. After intensive rinsing with Milli-Q water, the surfaces were dried in air at room temperature and then introduced in a dried Schlenk. To ensure anhydrous conditions, two cycles of vacuum/dry argon were performed in the Schlenk. The amino-coated glass surfaces (10×10 mm^2) were cleaned in an ultrasonic bath for 1 min in distilled chloroform and then dried in air at room temperature.

Grafting Procedures. *APTES Grafting on Silicon Surfaces.* APTES layers were generated on silicon surfaces using a silanization procedure as previously reported (*24*). Briefly, APTES was first dissolved in anhydrous toluene at a concentration of 10 mM. The solution was injected through a 0.2 μm PTFE filter in dry Schlenk tubes, each containing one silicon surface. After a reaction time of 3 h at room temperature, the surfaces were taken out from the Schlenk tubes, dried in air for 1 min, and placed in an oven at 120 °C for 1.5 h. Then, the surfaces were rinsed by soaking them in freshly distilled toluene for 5 min.

Kcoil Peptides Grafting on APTES-Coated Silicon and Glass Surfaces. Kcoil peptides were immobilized onto APTES-coated surfaces via LC-SPDP linker (*9*). The surfaces were covered with 150 μL of 2 mM LC-SPDP in 100 mM phosphate buffer (10% DMSO) for 2 h at room temperature. The surfaces were rinsed by soaking them in Milli-Q water for 5 min. Then, the thiol-reactive surfaces were covered with 150 μL of 10 μM cysteine-tagged Kcoil peptides (5 heptad repeats (*22*)) in 10 mM phosphate buffer for 2 h at room temperature. The surfaces were finally rinsed by soaking them in 10 mM phosphate buffer (pH 7.4) and in Milli-Q water. Unreacted LC-SPDP sites were blocked using 150 μL of 50 mM cysteine solution (1 M NaCl in 0.1 M sodium acetate, pH 4.0) followed by rinsing with Milli-Q water.

Ecoil-EGF Grafting and Degrafting. To immobilize the Ecoil-EGF on covalently attached Kcoil peptides, the Kcoil-grafted surfaces were covered with 150 μL of 600 nM Ecoil-EGF for 2 h at room temperature. The surfaces were finally rinsed by soaking them in 10 mM phosphate buffer (pH 7.4) and Milli-Q water for 5 min. The detachment of the coil-tagged EGF from the surface was performed by soaking the surfaces in a 5 M guanidium hydrochloride solution, followed by rinses in 10 mM phosphate buffer (pH 7.4) and Milli-Q water for 5 min each.

Nonoriented EGF Grafting. Untagged EGF was covalently grafted onto APTES-coated surfaces using disuccinimide glutarate (DSG) as linker. A glutaric acid solution was prepared by dissolving glutaric anhydride in 10 mM phosphate buffer (pH 7.4) to reach a final concentration of 0.1 mM. Reactive DSG molecules were obtained by mixing 200 μL of 200 mM EDC and 200 μL of 50 mM NHS in 2 mL of the glutaric acid solution. 150 μL of the freshly prepared reactive DSG solution was then deposited on the APTES-coated surfaces for 45 min at room temperature. The surfaces were rinsed in Milli-Q water for 5 min, dried in air, and reacted with 150 μL of 600 nM untagged EGF in Milli-Q water (pH 5.5) for 2 h at room temperature.

SPR Assays. SPR experiments were conducted at 25 °C using HBS-T (10 mM HEPES pH 7.4, 150 mM NaCl, 3.4 mM EDTA, 0.05% Tween 20) as running buffer.

Kcoil Immobilization on Sensorchip. All the steps of the immobilization procedure were carried out at a flow rate of 5 μL/min. The carboxylic groups of CM4 sensorchips were activated by the injection of 50 μL of a mixture containing 0.05 M NHS and 0.2 M EDC. The NHS ester groups were reacted with 50 μL of 1 M ethylenediamine to introduce amino groups on the sensorchip surface (thus mimicking amino-coated glass surfaces). Remaining reactive NHS ester groups were blocked by injecting ethanolamine (50 μL of 1 M ethanolamine). The amino groups were reacted with LC-SPDP (50 μL of 2 mM in

100 mM phosphate buffer, 10% DMSO) to end-graft cysteine-tagged Kcoil (30 μL of 10 μM Kcoil in 100 mM phosphate buffer). Finally, freshly prepared cysteine solution (150 μL of 50 mM cysteine in 0.1 M sodium acetate, 1 M NaCl, pH 4.0) was injected to block any unreacted LC-SPDP sites.

E/Kcoil-EGF Immobilization. Ecoil-EGF proteins were injected 3 times at 10 nM, 100 nM, and 500 nM for 2 min at a flow rate of 10 μL/min. Regeneration of the sensorchip (i.e., removal of Ecoil-EGF) was accomplished by 2 pulses of guanidium hydrochloride (50 μL, 100 μL/min, 5 M). Finally, 100 nM Kcoil-EGF was injected for 2 min at 10 μL/min (control).

Contact Angle Measurements. Contact angle measurements were performed using a FTA200 Dynamic Contact Angle Analyzer (First Ten Angstrom Inc., Portsmouth, VA). All measurements were carried out in equilibrium static mode using Milli-Q quality water as the probe liquid. Equilibrium contact angles θ correspond to the mean values of measurements performed at three different locations on at least two different surfaces. Data analysis was performed using the FTA32 Video software.

Ellipsometric Measurements. Thickness measurements on silicon surfaces were performed with an automatic M2000 ellipsometer (J.A. Woollam Co. Inc., Lincoln, NE). Data were acquired in the wavelength range 245−1650 nm. All measurements were carried out at an angle of incidence of 75°, with air as the ambient medium, at room temperature, and at a normal relative humidity (ca. 50%). The assumed refractive index of the grafted films was $n = 1.465$ (*25*). Effective thickness was computed as the difference between the thickness of modified and unmodified surface. Three measurements were taken on each surface and repeated for at least two samples to obtain average values.

Immobilized EGF Quantification. MicroBCA protein assay kit (Pierce Biotechnology Inc., Rockford, IL) was used to determine the EGF surface density by comparing the EGF concentration in the solution before and after immobilization. The microBCA reaction mixture (50 μL) was added to protein solution (50 μL) in a 96-well plate. Absorbance was measured using a Victor v3 spectrophotometer (562 nm, Perkin-Elmer, Woodbridge, ON) after a 2 h incubation at 37 °C. Bovine serum albumin was used as standard.

Stimulation of A-431 Cells. EGF is known to induce a rapid tyrosine phosphorylation of EGF receptor present at the A-431 cell surface (*26*). To test physiological activity of immobilized EGF, 5 h before experiment, A-431 cells were washed with DMEM medium without serum. Cells were then trypsinized for 5 min at 37 °C, washed by centrifugation, and resuspended in DMEM. A-431 cells were distributed in 24-well plates containing one glass surface at 0.3×10^6 cells/mL, 1 mL/well, and kept at 37 °C in a 5% CO_2 incubator. Five hours after inoculation, Ecoil-EGF was added at 4 nM in the wells corresponding to unmodified glass surfaces (control). This soluble Ecoil-EGF concentration was selected since we previously demonstrated that the EC_{50} related to the phosphorylation of A-431 cell surface EGFR by soluble untagged and Ecoil-tagged EGF was close to 4 nM (*20*).

Adhesion Assays. Medium was removed 5 h after inoculation and immobilized cells were washed 3 times with DMEM (serum-free). Cells were observed using inverted microscope Axiovert S100TV (Carl Zeiss Canada, North York, ON). Images were processed with a QICAM Fast 1394 camera (QImaging), and cell count was operated using Northern Eclipse image acquisition software (Empix imaging).

Phosphorylation Assays by Western Blot. DMEM medium was removed and A-431 cells were washed three times with PBS supplemented with sodium-orthovanadate (1 mM, Sigma) and extracted with lysis buffer (50 mM HEPES pH 7.4), 150 mM NaCl, 1% Thesit, 0.5% Na Deoxycholate, Complete protease inhibitor cocktails (Roche, Laval, QC)) supplemented with 0.1 mM Na_3VO_4, 20 mM β-glycerophosphate, 10 mM $Na_4P_2O_7 \cdot 10H_2O$ and 0.5 μM microcystin) 5 min, 2 h, 3 h, and 4 h after inoculation for wells corresponding to unmodified glass surfaces and 2 h, 3 h, 4 h, and 5 h for wells corresponding to EGF-functionalized surfaces. Insoluble material was removed by centrifugation at $10\,000 \times g$ for 5 min at 4 °C. Western blotting experiments were then performed as previously described (*20*). Briefly, samples were mixed with 4× NuPAGE sample buffer (Invitrogen) containing 50 mM DTT and heated to 70 °C for 10 min. Electrophoresis was performed at 200 V and proteins transferred to nitrocellulose membranes (Schleicher & Schuell) for 1 h at 300 mA. Membranes were incubated in blocking reagent (Roche Diagnostics, Indianapolis, IN), and then probed with phosphotyrosine (PY99) (Santacruz, CA) for 1 h. Detection was performed using BM Chemiluminescence Blotting Substrate (Roche Diagnostics) with a Kodak Digital Science Image Station 440cf equipped with Kodak Digital Science 1D image analysis software version 3.0 (Eastman Kodak, NY).

Statistical Analysis. Values are given as mean value ± standard deviation. Statistical analysis was performed by independent two-sample *t* test with equal variances. Values of $P < 0.05$ and $P < 0.001$ was considered to be statistically significant and are identified by * and **, respectively.

RESULTS

Immobilization of EGF on Surfaces. Silicon substrates with native oxide overlayer (Si/SiO_2), whose surface chemistry is comparable to that of glass, were used to optimize the grafting reactions since high optical contrast at the Si/SiO_2 interface improved the sensitivity of ellipsometric thickness and contact angle measurements. Once optimized on silicon wafers, the experimental conditions for the grafting reactions were then applied to commercially available amino-coated glass surfaces.

Our oriented EGF immobilization strategy consisted of end-grafting cysteine-tagged Kcoil peptides on APTES-coated surfaces using a LC-SPDP linker (Figure 1). Ecoil-EGF proteins were then captured to the Kcoil-modified surface via reversible coiled-coil interaction (*20*).

The APTES, LC-SPDP, and Kcoil layers that were successively grafted on silicon surfaces were each characterized using ellipsometric and contact angle measurements as reported in Figure 2. APTES was self-assembled in solution under strict anhydrous conditions to avoid cross-polymerization of the ethoxysilane groups that might have led to surface heterogeneities and multilayer formation. APTES-deposited layers were heated to promote condensation reactions with the surface and cross-linking of monolayer film. Grafted APTES layers appeared thin and homogeneous with an ellipsometric thickness of 0.9 ± 0.1 nm and a water contact angle of 50 ± 2° (Figure 2, condition a). The bifunctional LC-SPDP linker was then grafted onto the surface via a chemical reaction between its amine-reactive *N*-hydroxysuccinimide ester and the free amino groups of APTES to form a stable amide bond. The resulting films displayed a thickness of 1.2 ± 0.1 nm and a water contact angle of 61 ± 1° (Figure 2, condition b). The other extremity of the LC-SPDP linking agent was terminated in a pyridyl disulfide group that was reacted with thiol groups of cysteine-tagged Kcoil peptides to form a disulfide bond. In order to maximize the Kcoil grafting density, the influence of the pH of the reaction (from 3.0 to 8.5) was studied (Figure 2, conditions c−g). Maximal dry thickness and contact angle values were obtained for Kcoil peptides reacted at pH 7.4 (Figure 2). Of interest, when the same reaction was performed in the absence of LC-SPDP linker, a minor variation of the surface characteristics was observed when

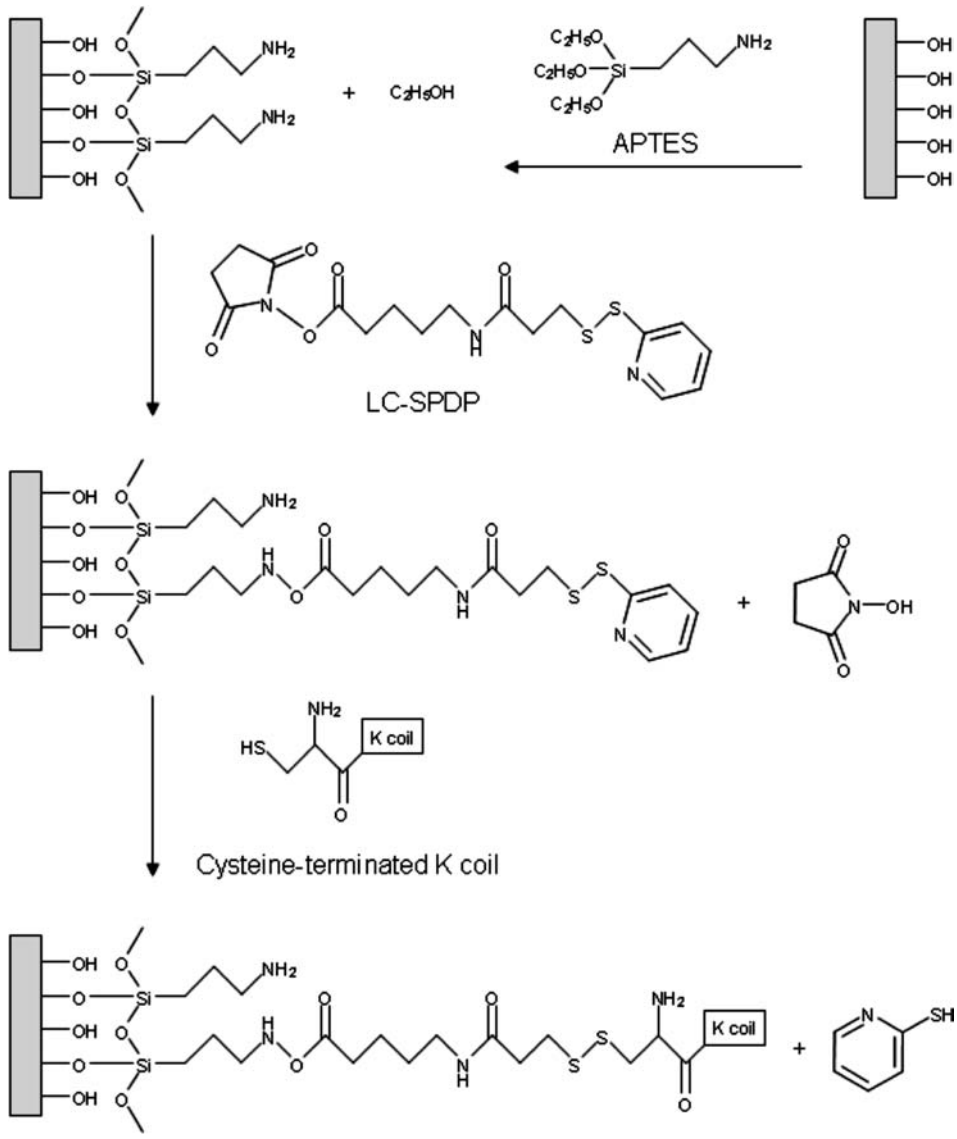

Figure 1. Schematic illustration of the chemical grafting procedure. End-grafting of APTES on silicon surfaces was followed by chemical immobilization of cysteine-tagged Kcoil peptides on APTES-coated surfaces using LC-SPDP as linker.

compared to the APTES layer (+0.1 nm and +1° for dry thickness and contact angle measurements, respectively, Figure 2; compare conditions a and h). This strongly suggested that nonspecific adsorption of Kcoil peptides on the surface was negligible.

After Kcoil grafting, cysteine was used to block the unreacted pyridyl disulfide group of LC-SPDP in order to prevent the attachment of undesired molecules containing thiol groups. No significant changes in the thickness and the water contact angle were observed after cysteine-mediated LC-SPDP deactivation (Figure 2, compare conditions b and f with Figure 3, conditions e and a, respectively). Kcoil-functionalized surfaces were shown to be able to recruit Ecoil-EGF (Figure 3). The resulting film was characterized by a net thickness increase of 0.8 nm and a water contact angle of 61°. The reversibility of the E−K coiled-coil interaction was demonstrated by washing bound Ecoil-EGF with 5 M guanidium hydrochloride. This lead to total thickness and contact angle measurements varying from 3.7 nm and 61° to 3.2 nm and 68°, respectively (Figure 3, conditions b and c). The high specificity of Ecoil-EGF binding to Kcoil surfaces was also demonstrated, since Kcoil-EGF addition onto Kcoil-functionalized surfaces did not lead to any thickness or contact angle variations (Figure 3, condition d). Finally, cysteine-tagged Kcoil or Ecoil-EGF were incubated on LC-SPDP layers previously blocked by cysteine molecules, as reported in Figure 3 (conditions f and g). In both cases, thickness and contact angle values were similar to those measured prior each incubation (Figure 3, condition e), once again demonstrating that nonspecific adsorption was negligible.

The efficiency of the grafting procedure was also evaluated by using a surface plasmon resonance instrument (Figure 4). In order to further demonstrate the adequacy of our chemical strategy, carboxymethylated dextran sensorchip surfaces (CM4) were first chemically modified to present amine groups at their surface (hence mimicking amine groups present on our glass surfaces). Cysteine-tagged Kcoil was covalently immobilized (950 arbitrary resonance units, RUs) on these surfaces using LC-SPDP linker. After Kcoil-oriented covalent coupling, Ecoil-EGF was then injected three times (10 nM, 100 nM, and 500 nM) on Kcoil-functionalized and mock (no immobilized Kcoil on amines) surfaces. This resulted in the net accumulation of 90, 420, and 870 RUs of proteins, respectively. As expected, SPR experiments also demonstrated that the Ecoil-EGF/Kcoil complexes were stable, as almost no dissociation occurred during each buffer injection following each Ecoil-EGF injection. The kinetic profile corresponding to the first Ecoil-EGF injection was found comparable to that already observed when the Kcoil had been covalently coupled using standard thiol-coupling

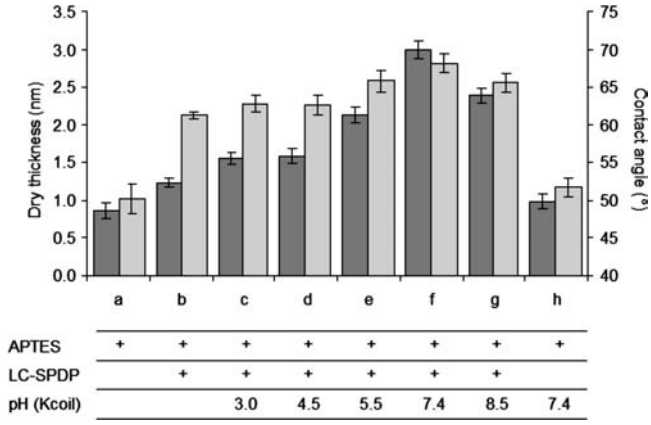

Figure 2. Characterization of the (a) APTES, (b) LC-SPDP, and Cysteine-tagged Kcoil layers grafted on silicon surfaces as illustrated in Figure 1. The dark and light gray bars correspond to dry thickness and contact angle measurements, respectively. The cysteine-tagged Kcoil peptides were reacted on LC-SPDP-coated surfaces at (c) pH 3.0, (d) pH 4.5, (e) pH 5.5, (f) pH 7.4, and (g) pH 8.5. As a comparison, the characterization of Kcoil incubation on APTES-coated surfaces (without LC-SPDP addition), at pH 7.4 is also presented (h). The reference was set as (0 nm, 0°) for a cleaned silicon surface. The successive grafting reactions were performed as described in the Materials and Methods section.

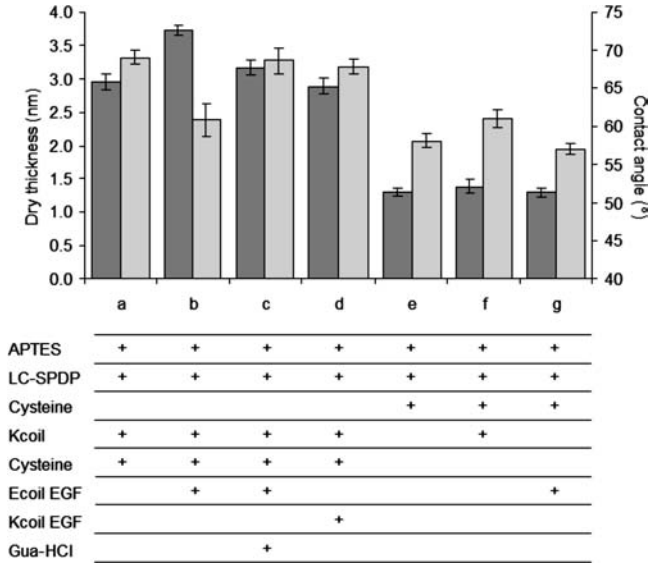

Figure 3. Sequential grafting of Ecoil-EGF via coiled-coil interactions. The dark and the light gray bars correspond to dry thickness and contact angle measurements, respectively. (a) APTES + LC-SPDP + Kcoil + Cysteine, pH 7.4; (b) Ecoil-EGF capture on (a); (c) Ecoil-EGF removal after capture (as in b) with guanidium hydrochloride (5 M). In contrast to Ecoil-EGF, (d) Kcoil-EGF does not bind to Kcoil-functionalized surface (a). As negative controls, the deposition of (f) cysteine-tagged Kcoil peptides and (g) Ecoil-EGF proteins on (e) LC-SPDP layers that had been blocked by cysteine are reported. The reference was set as (0 nm, 0°) for a cleaned silicon wafer surface. The successive grafting reactions were performed as described in the Materials and Methods section.

chemistry (*20*). After Ecoil-EGF dissociation (promoted by injections of guanidium hydrochloride), no Kcoil-EGF binding was observed. This absence of interaction between Kcoil and Kcoil-EGF cannot be attributed to any damage to surface-bound Kcoil by guanidium hydrochloride, since we already demonstrated that guanidium hydrochloride promoted E/K coiled-coil dissociation without affecting surface-bound Kcoil capacity to subsequently recruit Ecoil-tagged proteins (*20*). This once again confirmed the high specificity of the E/K coiled-coil interaction (Figure 4). Altogether, these results unambiguously demonstrated that Ecoil-EGF had been immobilized on APTES-coated surface via stable and specific E/K coiled-coil interactions.

In order to further validate our coiled-coil-based strategy and to compare its efficiency to that of random coupling procedures, EGF proteins were also immobilized on APTES-coated silicon surfaces using disuccinimide glutarate (DSG) as linker. This leads to thickness and contact angle measurements varying from 1.0 ± 0.1 nm and 30 ± 2° (after DSG treatment) to 3.0 ± 0.1 nm and 55 ± 2° (after EGF coupling).

Quantification of Immobilized EGF. 600 nM of Ecoil-EGF were incubated on a Kcoil-coated silicon wafer surface, resulting in the stable capture of 115 ± 8 pmol/cm^2 of Ecoil-EGF (surface density was quantified in a MicroBCA assay). This surface density is at least two times higher than what was previously reported with other protocols for oriented EGF immobilization (*11*, *19*). Combined with dry protein thickness measurements, we then estimated the variation of Ecoil-EGF surface density induced by varying Ecoil-EGF concentration during incubation (Figure 5). Assuming that the Ecoil-EGF/Kcoil interaction followed a Langmuirian isotherm, an apparent thermodynamic dissociation constant (K_D) of 13 nM was determined for the Ecoil-EGF/Kcoil interaction (Figure 5). In parallel, covalent coupling of untagged EGF was performed on APTES-coated silicon wafer surface using DSG as linker. This resulted in the covalent capture of 330 ± 87 pmol/cm^2 of untagged EGF.

EGF Receptor Phosphorylation Assays. EGF mediates its biological effects by binding to EGF receptors (EGFR). Ligand/receptor complex formation leads to cell surface receptor tyrosine autophosphorylation (*27*). Levels of EGFR phosphorylation were assayed for A-431 cells, at different times, by Western Blot analysis. Results corresponding to cells that had been grown on different Kcoil-coated surfaces or on native glass surfaces are presented in Figure 6. As expected, no phosphorylation of EGFR was observed for native surfaces or for Kcoil-functionalized surfaces to which Ecoil peptide had been captured (Figure 6). Of salient interest, we observed that Ecoil-EGF, when immobilized via coiled-coil interactions, induced a sustained phosphorylation of EGFR for at least 5 h (Figure 6). This observation sharply contrasted with EGFR phosphorylation induced by soluble Ecoil-EGF (autophosphorylation was not detectable after 3 h; Figure 6). The influence of EGF orientation, i.e., random versus coiled-coil-oriented, on EGFR phosphorylation was also demonstrated (Figure 6) since EGFR phosphorylation was more intense with coiled-coil oriented EGF compared to randomly coupled EGF.

In Vitro Adhesion Assays. The effect of immobilized EGF on A-431 cell adhesion was also assayed. A-431 cells were incubated on native or Kcoil-coated surfaces (in the presence or absence of soluble EGF), on Ecoil peptides or Ecoil-EGF that had been tethered on Kcoil-coated surfaces, and on covalently immobilized EGF surfaces (random immobilization; Figure 7). An increase of the cell adhesion (+ ca. 65%) was observed for coiled-coil immobilized Ecoil-EGF, whereas a lower increase was observed in the presence of soluble Ecoil-EGF (+ ca. 35%). In contrast, no significant differences from the negative control were observed for surfaces harboring randomly immobilized EGF (Figure 7). These results demonstrate that modified glass surfaces on which Ecoil-EGF had been immobilized via coiled-coil interactions promoted initial A-431 cell adhesion.

DISCUSSION

The development of biocompatible surfaces to promote and sustain tissue regeneration is of great interest for many biomedical applications, including the promotion of the wound healing processes around stent grafts after endovascular aneurysm repair (*5*) or the attachment of epithelial cells to polymeric corneal

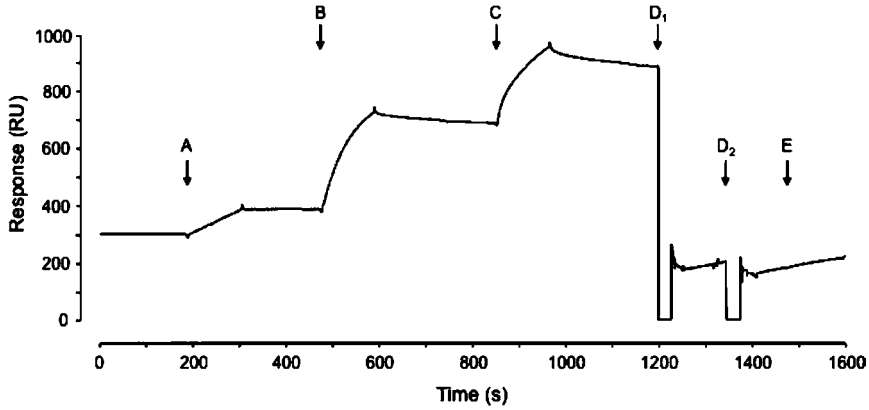

Figure 4. Control-corrected sensograms corresponding to Ecoil-EGF capture via E/K coiled-coil interactions by SPR. Kcoil peptides were immobilized on CM4 sensorchips using the same chemistry strategy (i.e., LC-SPDP as linker) as for silicon wafers and glass surfaces. Ecoil-EGF was then injected three times at 10 nM (A), 100 nM (B), and 500 nM (C). After surface regeneration with 2 pulses of guanidium hydrochloride ($D_{1,2}$), 100 nM Kcoil-EGF were injected (E).

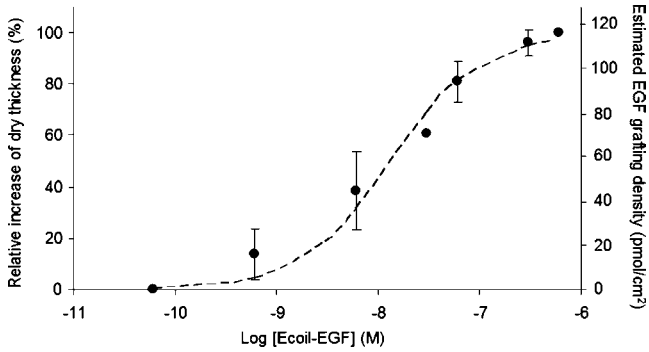

Figure 5. Variation of captured Ecoil-EGF density with Ecoil-EGF concentration during incubation. Various concentrations of Ecoil-EGF ranging from 60 pM to 600 nM were incubated on Kcoil-coated silicon wafer surfaces, as described in the Materials and Methods section, before dry thickness measurements. Surface density (pmol/cm^2) was deduced from the maximum Ecoil-EGF value determined using MicroBCA assay (see text for details). Each black dot corresponds to values obtained for 3 independent measurements while the dotted line corresponds to data fitting using a simple Langmuirian isotherm (K_D = 13 nM).

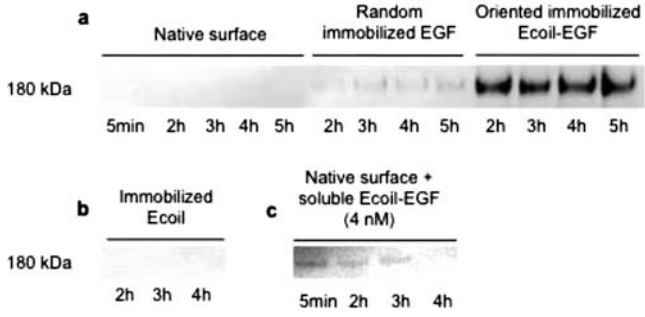

Figure 6. Phosphorylation of A-431 cell surface EGF receptors. The phosphorylation of EGF receptors on A-431 cells was monitored at different times by Western blot (A) on native surface, random immobilized EGF, and oriented immobilized Ecoil-EGF (same membrane); (B) on immobilized Ecoil peptide; and (C) on native surfaces with soluble Ecoil-EGF. The 180 kDa band immunoreactive to anti-pTyr antibody (corresponding to EGFR) was captured using a Kodak 440cf imager.

devices (*10*). Immobilization of specific proteins, such as growth factors, is now acknowledged to improve the potential of these engineered surfaces in stimulating the recruitment of cells and their adhesion and proliferation (*6, 9, 11, 19*). In that context, we have developed a versatile and cell culture-compatible strategy for the oriented immobilization of proteins on surfaces harboring primary amine functionalities. Our experimental approach takes advantage of a de novo designed heterodimerizing peptide system composed of the Ecoil and Kcoil pair. This grafting system has already been used as a tool for different biotechnology applications such as protein capture on biosensor surfaces (*28*), controlled protein dimerization (*17, 29*), or virus targeting (*23*). For the first time, we provide the proof of concept that the E/K coiled-coil system can be used for protein capture, aiming at enhancing material properties with the ultimate goal of developing tailored materials for tissue engineering and regenerative medicine applications.

In that effort, we first optimized Kcoil covalent and oriented immobilization on APTES-functionalized silicon wafers and characterized using dry thickness and water contact angle measurements. Low standard deviations in the measurements indicate that the successive grafted layers are homogeneous and that our protocols are highly reproducible (Figure 2). Nonspecific adsorption on Kcoil-functionalized surfaces was negligible (Figures 2 and 3). Therefore, as previously described (*22*), the protein immobilization via E/K coiled-coil interactions is highly specific, mostly due to the importance of both ionic and hydrophobic interactions during E/K coiled-coil complex formation. Furthermore, additional SPR experiments on sensorchips mimicking the functionalities displayed on our surfaces unambiguously demonstrates that covalently immobilized Kcoil is able to recruit Ecoil-EGF in a highly stable fashion (Figure 4), once again, in excellent agreement with previous studies in which we applied a different Kcoil coupling chemistry (*30, 31*).

Our optimized grafting conditions were then successfully applied to glass surfaces for cell culture. The amount of immobilized EGF was quantified for surfaces supporting the highest EGF grafting density, i.e., 115 and 330 pmol/cm^2 for the coiled-coil oriented capture and nonoriented covalent immobilization, respectively. Dry thicknesses of EGF layers for the corresponding surfaces were 0.7 and 2.0 nm as measured on silicon wafers (Figure 3), thus supporting that dry thickness is directly related to the amount of immobilized EGF (*32*). Ellipsometric measurements were performed on Kcoil-grafted silicon wafers in order to evaluate the influence of soluble Ecoil-EGF concentration upon EGF surface density during the grafting process (Figure 5). Our results underline that varying the concentration of added soluble Ecoil-EGF allows for the controllable modulation of EGF density on Kcoil-derivatized surfaces. The apparent thermodynamic dissociation constant (K_D) between grafted Kcoil peptides and Ecoil-tagged EGF proteins was in the low nanomolar range, in good agreement with previously reported K_D (*28*).

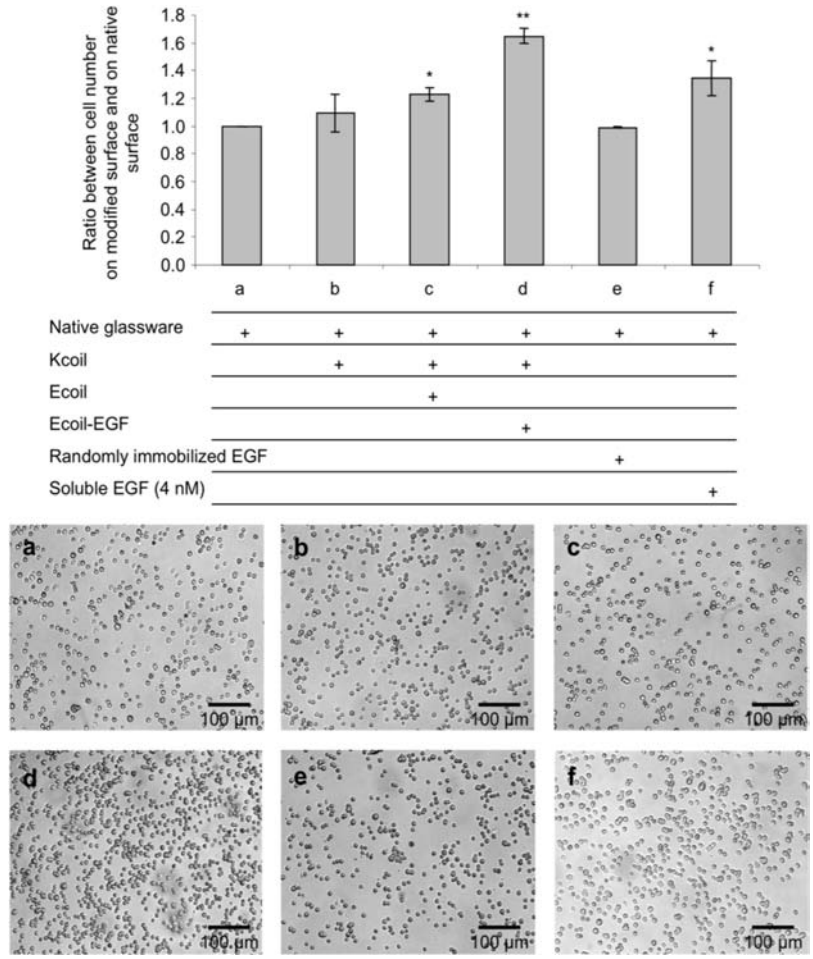

Figure 7. Images of attached cells after 5 h of incubation for adhesion assays. A-431 cells were incubated during 5 h on glass surfaces harboring (a) native amino groups, or coated with (b) grafted Kcoil peptide layer, (c) Ecoil peptides bound to grafted Kcoil peptide layer, (d) Ecoil-EGF bound to grafted Kcoil peptide layer, (e) randomly immobilized EGF layer, and (f) native amino groups with an injection of soluble Ecoil-EGF (4 nM). Differences were significant for $p < 0.05$ (*) and $p < 0.001$ (**).

In order to evaluate the full potential of our grafting strategy, in vitro cellular assays were performed with A-431 cell line. Of interest, after 5 h of incubation with A-431 cells, we noticed an increase of ca. 10%, 20%, and 65% for A-431 cell adhesion for surfaces derivatized with Kcoil alone, Kcoil/Ecoil complexes, and Kcoil/Ecoil-EGF, respectively. In contrast, no increase in cell adhesion was observed for randomly grafted EGF (Figure 7), more likely due to the loss of EGF bioactivity that may have resulted from the random coupling procedure and the absence of linker, as already reported by Kuhl and colleagues (*7*). Altogether, our results suggest that our immobilization strategy per se has a positive effect on cell attachment, a desirable property in tissue engineering. Our results are also in excellent agreement with previous observations by Ogiwara et al. that cultivated 3T3 cells and A-431 cells on surfaces where (i) bioactive EGF fused to the Fc region of an antibody (EGF-Fc) had been photoimmobilized (*11*) and (ii) EGF had been chemically immobilized via an engineered *p*-azido-phenylalanine at its C-terminus, respectively (*13*). More specifically, in both studies, cell adhesion was observed to moderately increase with soluble EGF supply (when compared to negative control), while immobilized EGF surfaces were shown to further increase cell adhesion in an integrin-independent fashion. Of interest, the authors noticed differences in A-431 cell phenotype whether EGF receptors were activated with soluble or tethered EGFs. Cells adhering to tethered EGF were characterized by filipodia structures, whereas cells exposed to soluble EGF displayed lamellipodia structures, hence suggesting that the signal transduction pathways activated in both cases were slightly different.

Cell exposure to immobilized EGF has been reported to sustain EGF-induced autophosphorylation of cell surface EGFR when compared to soluble EGF (*13, 33*). This effect has been attributed to ligand internalization impediment and/or to limited degradation of the EGF-EGFR complexes. Our results support these conclusions and further illustrate the advantage of oriented EGF capture. Indeed, a more intense EGFR autophosphorylation is observed with coiled-coil-captured EGF (oriented approach, 115 pmol/cm^2) when compared to that corresponding to EGF that has been covalently immobilized in a random fashion (330 pmol/cm^2) (Figure 6).

Altogether, our results demonstrate that our coiled-coil based capture approach offers several advantages when compared to previously reported systems for oriented protein immobilization, in terms of protein bioactivity, surface density, and grafting process. First, coil tags do not affect EGF bioactivity, since soluble N- or C-terminally coil-tagged EGF were shown to be behave as EGF in various in vitro cell assays (*17, 23*). This sharply contrasts with the negative effect of an Fc tag that totally abrogated EGF bioactivity when positioned at the N-terminus of EGF (*20*). Second, we observed a maximal EGF surface density for tethered Ecoil-EGF of 115 pmol/cm^2 (Figure 5); this is at least two times higher than previously reported values for tagged EGF grafting, i.e., 16 pmol/cm^2 for immobilization via the Fc portion of immunoglobulin G and 52 pmol/cm^2 for immobilization via polyhistidine tags (*11, 19*). Oriented protein layers may thus be generated over a wider range of surface density with our coiled-coil-based strategy. Furthermore, the length of the coiled-coil motif, in combination with that of LC-

SPDP, provides coiled-coil tethered EGF with enough mobility, a critical factor for optimal EGF signaling (*7, 20*). This is likely dictated by the 2:2 overall stoichiometry of the signaling-competent ligand/receptor complex (*15, 17*).

At last, our coiled-coil-based approach is sequential and versatile: stable Kcoil layers can be produced several days before grafting with any Ecoil-tagged protein. As opposed to protein A or G, Kcoil-derivatized surfaces can be treated with strong acidic, basic, or chaotropic solutions, as Kcoil on its own is unstructured and can thus withstand these treatments (*22*). Moreover, our proposed strategy is simple in its implementation and allows for the oriented immobilization of every coil-tagged protein on any aminated surface.

CONCLUSION

We report a new approach for oriented immobilization of growth factors on aminated surfaces based on a coiled-coil interaction. This method relies on a sequential grafting process based on the covalent grafting of a homogeneous Kcoil peptide layer and on the subsequent capture of Ecoil-tagged proteins. The first step can be realized in dry and nonsterile environment several days before protein immobilization, whereas the second step allows for a specific and stable immobilization of the Ecoil-tagged protein over a wide range of grafting density. Consequently, this easy and versatile approach could be applied to specifically tailor any type of biomaterial.

"Four-Potential" Ferrocene Labeling of PNA Oligomers via Click Chemistry

Nina Hüsken, Gilles Gasser, S. David Köster, and Nils Metzler-Nolte*

Lehrstuhl für Anorganische Chemie I - Bioanorganische Chemie, Fakultät für Chemie und Biochemie, Ruhr-Universität Bochum, Universitätsstrasse 150, D-44801 Bochum, Germany. Received March 20, 2009; Revised Manuscript Received June 4, 2009

The scope of the Cu(I)-catalyzed [2 + 3] azide/alkyne cycloaddition (CuAAC, click chemistry) as a key reaction for the conjugation of ferrocene derivatives to N-terminal functionalized PNA oligomers is explored herein (PNA: peptide nucleic acid). The facile solid-phase synthesis of N-terminal azide or alkyne-functionalized PNA oligomer precursors and their cycloaddition with azidoferrocene, ethynylferrocene, and *N*-(3-ethylpent-1-yn-3-yl)ferrocenecarboxamide (DEPA−ferrocene) on the solid phase are presented. While the click reaction with azidomethylferrocene worked equally well, the ferrocenylmethyl group is lost from the conjugate upon acid cleavage. However, the desired product was obtained via a post-SPPS conversion of the alkyne−PNA oligomer with azidomethylferrocene in solution. The synthesis of all ferrocene−PNA conjugates (trimer t_3-PNA, **3**, **4**, **5**, **6**; 12mer PNA, **10** - t c t a c a a g a c t c, **11** - t c t a c c g t a c t c) succeeded with excellent yields and purities, as determined by mass spectrometry and HPLC. Electrochemical studies of the trimer Fc−PNA conjugates **3**, **4**, **5**, and **6** with four different ferrocene moieties revealed quasi-reversible redox processes of the ferrocenyl redox couple $Fc^{0/+}$ and electrochemical half-wave potentials in a range of $E_{1/2} = -20$ mV to +270 mV vs $FcH^{0/+}$ (Fc: ferrocenyl, $C_{10}H_9Fe$). The observed potential differences $\Delta E_{1/2}{}^{min}$ are always greater than 60 mV for any given pair of Fc−PNA conjugates, thus allowing a reliable differentiation with sensitive electrochemical methods like e.g. square wave voltammetry (SWV). This is the electrochemical equivalent of "four-color" detection and is hence denoted "four-potential" labeling. Preparation and electrochemical investigation of the set of four structurally different and electrochemically distinguishable ferrocenyl groups conjugated to PNA oligomers, as exemplified by the conjugates **3**, **4**, **5**, and **6**, demonstrates the scope of the azide/alkyne cycloaddition for the labeling of PNA with electrochemically active ferrocenyl groups. Furthermore, it provides a PNA-based system for the electrochemical detection of single-nucleotide polymorphism (SNP) in DNA/RNA.

INTRODUCTION

Peptide nucleic acid (PNA) are nucleic acids analogues. In PNA, the negatively charged deoxyribose phosphodiester backbone of DNA and RNA is replaced by a neutral, pseudopeptide backbone of repeating *N*-(2-aminoethyl)glycine units (*1*−*9*). PNA have outstanding properties including faster hybridization with RNA, DNA, and PNA as well as higher binding affinity, mismatch sensitivity, and greater chemical and biological stability compared to natural nucleic acid oligomers (*10, 11*). These exceptional characteristics make PNA attractive for medicinal, biological, and analytical applications such as antigene/antisense therapy (*12, 13*), drug discovery (*14*), or molecular recognition of nucleic acids (*15*).

Promising and relatively new is the application of PNA as electrochemical biosensors for DNA or RNA (*16, 17*). A major advantage of using PNA for this purpose is their ability to reliably discriminate and therefore detect single-base mismatches in oligonucleotide sequences (*18*). Monolayers of PNA-modified transducer surfaces serve as the recognition device, while a reversible redox-active metal complex bound to the PNA sequence serves as the electrochemical probe. This type of biosensor offers the opportunity to monitor and detect the event of hybridization with various electroanalytical methods (*19*). A remaining challenge in the synthesis of an electrochemical PNA biosensor is the linkage of the electroactive metal complex to the PNA strand. In the past years, various examples of label-free electrochemical DNA detection with PNA were reported (*20*−*26*). In these studies, a charged metal complex or charged polymer interacts ionically with the negatively charged DNA backbone of the resulting PNA/DNA duplex. However, this method is limited by the lack of a defined bonding situation, which is crucial for the significance of the obtained electrochemical signal. In this perspective, a facile method to covalently conjugate a metal complex to a PNA strand is needed. Our group already presented the coupling of ferrocene carboxylic acid to the N-terminus of PNA oligomers on the solid phase (*27, 28*). Although this coupling method is efficient, it is limited to carboxylic acid functionalized metal complexes. An enhanced flexibility in the choice of organometallic starting materials would be very attractive, since not every metal complex can be

functionalized with a carboxylic acid, hence limiting the number of organometallic/metal complex PNA bioconjugates.

In order to provide new metal−PNA conjugates with different electrochemical potentials, we searched for an alternative method for the labeling of PNA with various ferrocene derivatives on the solid phase. We rapidly turned our attention to the so-called click chemistry methodology. "Click chemistry" describes a group of reactions that proceed with high yield and chemical specificity (*29*−*33*). The prototype "click reaction" is a Huisgen [2 + 3] dipolar azide/alkyne cycloaddition, and its Cu-catalyzed variant is valued as a key reaction for bioconjugation, since it is chemoselective, reliable, and takes places under mild conditions (*34*−*40*). For metal bioconjugates, this method enlarges the spectrum of metal complex starting materials to be possibly used, as the reagents may be azide- and alkyne-functionalized derivatives. We recently reported the use of click chemistry to generate peptide-functionalized self-assembled monolayers on Au surfaces, which are highly proteophobic (*41*). Furthermore, the first example of (multi)insertion by click chemistry of azidoferrocene into a PNA oligomer containing a new alkyne functionalized PNA monomer synthon was also presented recently (*42*).

In this paper, we report the facile N-terminal functionalization of PNA with azide or alkyne functionalities on the solid phase, and their subsequent conversion by click chemistry with a range of different alkynyl and azido ferrocene derivatives to give a small library of ferrocene−PNA bioconjugates. The metal complexes were chosen such that four readily discernible potentials result, and we therefore speak of "four-potential" labeling. In effect, this will provide the electrochemical equivalent of "four-color" detection, which is evidently important for sequencing applications and single nucleotide polymorphism (SNP) analysis. Hence, this study is of fundamental relevance for the development of new electrochemical DNA biosensors.

EXPERIMENTAL PROCEDURES

General Experimental Conditions. All reagents and HPLC-grade solvents were purchased from Acros (Geel, Belgium), Aldrich/Sigma/Fluka (Deisenhofen, Germany), E. Merck (Darmstadt, Germany), Novabiochem (Laufelfingen, Switzerland), and IRIS Biotech (Marktredwitz, Germany) and were used without further purification. The preloaded polystyrene resins were purchased from Rapp Polymers (Tübingen, Germany). Only L-amino acids were used throughout. PNA monomers were purchased from Link Technologies (Edinburgh, Scotland) and ASM (Hannover, Germany). All solutions were freshly prepared before use. HPLC[1] fractions of all products were frozen in liquid nitrogen and lyophilized using an Edwards Modulyo freeze−dryer. The preparation and handling of azide materials was performed at all stages on the smallest possible amounts and with routine precautions in order to minimize the risk of possible decomposition and explosions. Higher temperatures were avoided generally, and light was excluded during all stages of the handling of azidoferrocene.

General Analytical Procedures. MALDI-TOF mass spectra were measured on a Bruker Daltonics Autoflex in linear mode with positive polarity using sinapic acid as the matrix. ESI mass spectra were recorded on a Bruker Esquire 6000.

HPLC Analysis and Purification. HPLC analysis and purification was performed on a customized Varian ProStar 210 System, equipped with a PDA detector and auto sampler, using Varian DynaStar C-18 reverse-phase columns for analytical (250 × 4 mm, 8 μm) and preparative (250 × 21 mm, 8 μm) runs. Analytical (flow rate: 1.0 mL min^{-1}) and semipreparative (flow rate: 4.7 mL min^{-1}) runs were performed with a linear gradient of A (Millipore water containing 0.1% v/v TFA) and B (acetonitrile (Baker HPLC-grade), containing 0.1% v/v TFA. Analytical runs: t = 0 min 5% B, t = 20 min 80% B, t = 25 min 5% B. Preparative runs: t = 0 min 5% B, t = 12 min 15% B, t = 32 min 40% B, t = 50 min 80% B, t = 60 min 5% B. All samples were filtered before injection using a 0.22 μm syringe filter. Spectra were recorded at 254 nm and 25 °C; retention times (t_R [min]) were noted in each case.

Electrochemical Studies. Cyclic voltammetry and differential pulse voltammetry were performed on a Princeton Applied Research BES potentiostat operated by Princeton Applied Research MS DOS software M270. The measurements were perfomed with a home-made three-electrode microvolume electrochemical cell (*43*), placed in a Faraday cage consisting of copper hole sheet metal. For the measurements, a glassy carbon electrode with a geometric diameter of 2 mm was used as the stationary working electrode, a platinum wire was used as the counter electrode, and Ag/AgCl in 3 M KCl was used as the reference electrode. The Ag/AgCl reference electrode was permanently stored in aq KCl solution (3 M) if not in use. Measurements were carried out in a 1:1 (v/v) mixture of acetonitrile and MOPS buffer (0.15 M) at pH 7.4. Sodium perchlorate (0.2 M) was used as the supporting electrolyte. Solutions were degassed and filtered before use. The working electrode was polished with moistened carpet material before each measurement until DPV[1] of the pure electrolyte solution revealed a clean electrode surface. Ferrocene with the reversible redox couple $FcH^{0/+}$ was used as internal (**4**, **6**) or external (**3**, **5**) reference. To this end, ferrocene was measured three times before and after the respective measurement. Half-wave potentials $E_{1/2}$ and peak separation values ΔE_p were determined as described in Table 2. Return-to-forward peak current ratios I_{pc}/I_{pa} were determined according to the Nicholson procedure (*44*) on individual cyclic voltammograms by applying the following equation:

$$I_{pc}/I_{pa} = (I_{pc})_0/I_{pa} + 0.485(I_{pc})_0/I_{pa} + 0.086$$

Solid-Phase PNA Synthesis. SPPS was performed manually in 5 mL polypropylene one-way syringes as reaction vessels, which were equipped with a frit at the bottom. They were filled with 50 mg of polystyrene resin beads TentaGel R PHB Cys(Trt)Fmoc (0.18 mmol/g) or TentaGel S RAM Lys(Boc)-Fmoc (0.20 mmol/g). The resin was swollen in DMF before use for 1 h. All reactions were performed on a mechanical shaker with 400 rpm, soaking approximately 3−4 mL of freshly prepared solutions into the syringe. Fmoc/Bhoc protected PNA monomers (5 equiv) were preactivated in Eppendorf tubes before every coupling step for 2 min with HATU (4.5 equiv) in DMF, adding DIPEA and 2,6-lutidine (10 equiv each) (A(bhoc)-PNA-monomer, 5 min; C(bhoc)-PNA-monomer, 7 min). The amino acids Fmoc-Ahx and Fmoc-Lys(Boc)-OH were preactivated in an analogous manner with TBTU and HOBt·H_2O (4.5 equiv each). For each coupling step, the resin beads were treated with the activated acid under agitation (50 °C, 20 min) and subsequently washed with DMF. The coupling step was monitored with the Kaiser test. Double Fmoc deprotection was performed with piperidine (20%, v/v) in DMF (2 min + 10 min). The resin beads were then washed successively with DMF, DCM, and DMF. The whole procedure (deprotection, coupling, monitoring) was repeated for every PNA monomer until the PNA sequence was completed. The resin was washed and shrunk with methanol (30 min) and dried under vacuum. Final cleavage of the PNA oligomer from the resin and the deprotection of all Bhoc, Boc and Trt side chain protecting groups were simultaneously performed in TFA/TIS/phenol (85/5/10, v/v/v) (2 h + 1 h). Following the removal of TFA under reduced pressure, the crude product was precipitated with ice-cold diethyl ether, washed twice with ice-cold diethyl ether,

and each time centrifuged (10 min, 8000 rpm). The thus-produced crude oligomer was lyophilized in acetonitrile/water and analyzed by analytical HPLC, showing good purities already (90−98%) for all oligomers. For characterization with analytical HPLC and ESI or MALDI-TOF mass spectrometry, small oligomer quantities were purified by preparative HPLC. All yields given in the following are crude yields, with products likely containing at least traces of excess solvents, TFA, and salts.

Azide/Alkyne-Functionalized Carboxylic Acids and Ferrocene Derivatives. Propynoic acid as well as the ferrocene derivatives ethynylferrocene, ferrocene carboxylic acid, and ferrocenylmethanol were purchased from Acros (Geel, Belgium). All other ferrocene derivatives, namely azidoferrocene, DEPA−ferrocene, azidomethylferrocene, and 2-azidoacetic acid, were synthesized according to known and published synthetic routes. Analytical data of all compounds matched the previously reported data.

Preparation of Azide/Alkyne-Functionalized PNA Oligomers. N-Terminal azide and alkyne functionalizations of PNA oligomers were performed on polystyrene resins, which were preloaded with the respective PNA sequence, synthesized according to the general SPPS procedure. The solid-phase coupling of 2-azidoacetic acid and propynoic acid to the N-terminus of a PNA oligomer followed the Fmoc deprotection of the last PNA monomer of the respective PNA sequence.

Preparation of Propynoic Acid Functionalized PNA Oligomers 1 and 8. 50 mg (**1**, 10 μmol; **8**, 9 μmol) of a polystyrene resin, which was preloaded with the respective PNA sequence (**1**, H-t t t $LysNH_2$; **8**, H-t c t a c a a g a c t c Lys Ahx $CysNH_2$), was successively treated with a solution of DIPEA and 2,6-lutidine (each 10 equiv) in DMF (2 min) and then with a solution of propynoic acid (5 equiv) and HATU (4.5 equiv) in DMF at ambient temperature under agitation for 15 min. The resin was washed after each step with DMF, and the whole process was repeated eight times. When coupling was completed (monitoring with Kaiser test), the resin was washed successively with DMF, DCM, and DMF. The propynoic acid functionalized PNA oligomers were cleaved from the resin following the general procedure.

*Oligomer **1***. TentaGel S RAM Lys(Boc)Fmoc (0.20 mmol/g) was used. **1** was obtained as a white solid. Yield: 86% (8.6 mg, 8.6 μmol). HPLC: t_R = 4.8 min. ESI-MS: *m*/*z* = 996.3 $[M+H]^+$ (100), 498.7 $[M+2H]^{2+}$ (71).

Oligomer **8.** TentaGel R RAM Cys(Trt)Fmoc (0.18 mmol/g) was used. **8** was obtained as a white solid. Yield: 79% (25.6 mg, 7.1 μmol). MALDI-TOF MS: *m*/*z* (%) = 3613.5 $[M+H]^+$ (100).

Preparation of 2-Azidoacetic Acid Functionalized PNA Oligomers 2 and 9. 2-Azidoacetic acid (5 equiv) was preactivated for 3 min in an Eppendorf tube with TBTU and HOBt·H_2O (4.5 equiv each) in DMF, with DIPEA and 2,6-lutidine (10 equiv each). 50 mg (**2**, 10 μmol; **9**, 9 μmol) of a polystyrene resin, which was preloaded with the respective PNA sequence (**2**, H-t t t $LysNH_2$; **9**, H-t c t a c c g t a c t c Lys Ahx $CysNH_2$), was treated with the activated acid under agitation at ambient temperature for 1 h. The resin was then successively washed with DMF, DCM, and DMF. The azide-functionalized PNA oligomer was cleaved from the resin following the general procedure.

*Oligomer **2***. TentaGel S RAM Lys(Boc)Fmoc (0.20 mmol/g) was used. **2** was obtained as a white solid. Yield: 83% (8.6 mg, 8.3 μmol). ESI-MS: *m*/*z* (%) = 1027.3 $[M+H]^+$ (100), 514.2 $[M+2H]^{2+}$ (91).

*Oligomer **9***. TentaGel R RAM Cys(Trt)Fmoc (0.18 mmol/g) was used. **9** was obtained as a white solid. Yield: 80% (26.0 mg, 7.2 μmol). MALDI-TOF MS: *m*/*z* (%) = 3609.6 $[M+H]^+$ (100).

Preparation of Fc-PNA Conjugate 7. The conjugation of ferrocene via peptide coupling was performed on 50 mg (10 μmol) of the resin TentaGel R PHB, which was preloaded with the 12-mer PNA sequence H-t c t a c g a g a c t c Lys Ahx $CysNH_2$, and follows the Fmoc deprotection of the last PNA monomer of this sequence. Ferrocenecarboxylic acid (5 equiv) was preactivated for 3 min in an Eppendorf tube adding HATU and HOBt·H_2O (4.5 equiv each) in DMF, with DIPEA and 2,6-lutidine (10 equiv each). The resin was treated with the activated ferrocenecarboxylic acid under agitation (20 min, 50 °C). The resin was then successively washed with DMF, DCM, and DMF. Cleavage from the resin following the general procedure yielded Fc-PNA conjugate **7** as a yellowish solid. Yield: 83% (31.3 mg, 8.3 μmol). HPLC: t_R = 12.5 min, 100%. MALDI-TOF MS: *m*/*z* (%) = 3785.5 $[M+H]^+$ (100).

Preparation of Fc-PNA-Conjugate 3. 2.00 mg (2.0 μmol) of PNA oligomer **1** was dissolved in an Eppendorf tube in 150 μL of a 1:1 (v/v) mixture of acetonitrile/water containing 10 equiv of DIPEA and 10 equiv of 2,6-lutidine. Successively, the following 1% solutions were added under nitrogen flow: 0.73 mg (3.0 μmol) of azidomethylferrocene in a 1:1 (v/v) mixture of acetonitrile/water, 1.2 mg (6.1 μmol) of sodium L-ascorbate in water, and 0.29 mg (2.0 μmol) of copper(I) bromide in acetonitrile. The reaction mixture was shaken for 2 days. Subsequently, acetonitrile was removed under reduced pressure. The remaining residue was treated with ice-cold diethyl ether, and the supernatant was removed from the resulting precipitate. After washing three times with diethyl ether and air-drying, **3** was obtained as a yellowish solid. Yield: 73% (1.8 mg, 1.5 μmol). MALDI-TOF MS: *m*/*z* (%) = 1279.0 $[M+H+CH_3CN]^+$ (100).

Preparation of Fc-PNA Conjugates 4, 5, 6, 10, 11. Conjugation of ferrocene via [2 + 3]-azide/alkyne cycloaddition was performed on polystyrene resins, which were preloaded with an alkyne or azide functionalized PNA oligomer under inert conditions. All solvents were taken out of crown cap bottles and Eppendorf tubes were flushed with nitrogen before use. Following the synthesis of the azide/alkyne-functionalized PNA oligomers, the resin beads were washed and shrunk with methanol (30 min) and completely dried under reduced pressure. The syringe was then flushed with nitrogen, and the resin was washed and swollen for 1 h with dry DMF. The following solutions were prepared: DIPEA and 2,6-lutidine (each 10 equiv) in DMF, 1% of an azide or alkyne functionalized ferrocene derivative (5 equiv) in DMF, and 1% copper(I) bromide (1 equiv) in acetonitrile. These solutions were successively introduced into the syringe containing the preloaded resin. This reaction mixture was shaken for the given reaction time at ambient temperature. Subsequently, the resin was successively washed with DMF, CH_2Cl_2, CH_3CN, CH_2Cl_2, and DMF. All ferrocene-labeled PNA oligomers were cleaved from the resin following the general procedure.

Preparation of Fc-PNA Conjugate 4. 50 mg (10 μmol) of the resin TentaGel S RAM (0.20 mmol/g), which was preloaded with the propynoic acid functionalized PNA oligomer **1**, was converted according to the general procedure with 11.4 mg (50 μmol, 5 equiv) of azidoferrocene in 2 days. Cleavage from the resin yielded **4** as a yellowish solid. Yield: 78% (8.6 mg, 7.0 μmol). HPLC: t_R = 13.7 min. ESI-MS: *m*/*z* (%) = 1223.2 $[M+H]^+$ (41), 612.2 $[M+2H]^{2+}$ (100).

Preparation of Fc-PNA Conjugate 5. 50 mg (10 μmol) of the resin TentaGel S RAM (0.20 mmol/g), which was preloaded with the azide-functionalized PNA oligomer **2**, was converted

according to the general procedure with 10.5 mg (50 μmol, 5 equiv) of ethynylferrocene in two days. Cleavage from the resin yielded **5** as a yellowish solid. Yield: 88% (10.9 mg, 8.8 μmol). HPLC: t_R = 13.2 min. ESI-MS: *m*/*z* (%) = 1237.2 $[M+H]^+$ (25), 619.2 $[M+2H]^{2+}$ (100).

Preparation of Fc-PNA Conjugate 6. 50 mg (10 μmol) of the resin TentaGel S RAM (0.20 mmol/g), which was preloaded with the azide-functionalized PNA oligomer **2**, was converted according to the general procedure with 16.2 mg (50 μmol, 5 equiv) of DEPA−ferrocene in two days. Cleavage from the resin following the general procedure yielded **6** as a yellowish solid. Yield: 91% (12.3 mg, 9.1 μmol). HPLC: t_R = 13.1 min, 100%. ESI-MS: *m*/*z* (%) = 1350.3 $[M+H]^+$ (22), 675.7 $[M+2H]^{2+}$ (100).

Preparation of Fc-PNA Conjugate 10. 50 mg (9 μmol) of the resin TentaGel R PHB Cys(Trt)Fmoc (0.18 mmol/g), which was preloaded with the propynoic acid functionalized PNA oligomer **8**, was converted according to the general procedure with 10.2 mg (45 μmol, 5 equiv) of azidoferrocene in 2 days. Cleavage from the resin following the general procedure yielded **10** as a yellowish/greenish solid. Yield: 74% (25.7 mg, 6.7 μmol). HPLC: t_R = 14.8 min, 100%. MALDI-TOF MS: *m*/*z* = 3841.1 $[M+H]^+$ (100).

Preparation of Fc-PNA Conjugate 11. 50 mg (9 μmol) of the resin TentaGel R PHB Cys(Trt)Fmoc (0.18 mmol/g), which was preloaded with the azide-functionalized PNA oligomer **9**, was converted according to the general procedure with 9.45 mg (45 μmol, 5 equiv) of ethynylferrocene in 2 days. Cleavage from the resin following the general procedure yielded **11** as a yellowish/greenish solid. Yield: 76% (26.1 mg, 6.8 μmol). HPLC: t_R = 13.7 min, 100%. MALDI-TOF MS: *m*/*z* (%) = 3819.8 $[M+H]^+$ (100).

RESULTS AND DISCUSSION

As a proof of principle, all synthetic reactions and electrochemical studies were first undertaken on a trimer PNA model sequence H-t-t-t-Lys-NH_2. Selected reactions were subsequently carried out on 12mer bacterial PNA sequences to verify the compatibility of the key reactions with mixed-sequence PNA oligomers and various protecting groups.

Synthesis of Azide- or Alkyne-Functionalized PNA Oligomers 1, 2, 8, 9. All PNA oligomers were synthesized by manual standard solid-phase synthesis using Fmoc-protected PNA monomers (see Table 1 for a summary of the sequences synthesized in this work and Schemes 1 and 2 for synthesis details). Oligomers with the trimer model sequence H-t-t-t-Lys-NH_2 were synthesized on Fmoc-Lys(Boc) preloaded TentaGel S RAM resin, while 12mer oligomers were synthesized on Fmoc-Cys(Trt) preloaded TentalGel R PHB resin. Additionally, the Fmoc-protected amino acids lysine (with Boc-side chain protection) and aminohexanoic acid were introduced to increase the solubility of PNAs and as a spacer molecule, respectively. For the synthesis of **2** and **9**, an azide function was introduced by coupling 2-azidoacetic acid (*45*) to the Fmoc-deprotected N-terminus of the PNA oligomer. Correspondingly, for the synthesis of **1** and **8**, an alkyne function was introduced by peptide coupling of propynoic acid to the *N*-terminus. The coupling of 2-azidoacetic acid proceeded under conditions analogous to those for the coupling of α-amino acids and therefore offers the possibility of automation. On the contrary, the coupling of propynoic acid under standard conditions had to be repeated several times until complete conversion was achieved as shown by a negative Kaiser test (*46*). Cleavage from the resin with TFA/TIS/phenol 85:5:10 (v/v/v), precipitation with diethyl ether followed by centrifugation gave products **1**, **2**, **8**, and **9** in good yield and purity. The ESI mass spectra of compounds **1** and **2** show both the $[M+H]^+$ and $[M+2H]^{2+}$ peaks, while the MALDI spectra of **8** and **9** show only the monocationic $[M+H]^+$ peak. Mass spectrometry of the crude products only revealed product mass peaks and no peaks corresponding to truncated sequence fragments. This, in combination with clean HPL chromatograms, proves that all reactions including the coupling of the alkynyl and azido carboxylic acids occurred with nearly complete conversion. However, comparison of mass spectra and analytical HPL chromatograms show that the azide-functionalized PNA oligomers **2** and **9** are not completely stable toward our routine HPL chromatography conditions.

Table 1. Sequences and MS Data of PNA Oligomers 1−11

PNA	Sequence	M_{calc}	M_{found}
1		995.4	996.3[a]
2		1026.4	1027.3[a]
3		1237.1	1279.0[b]
4		1222.4	1223.2[a]
5		1236.5	1237.2[a]
6		1349.5	1350.3[a]
7		3785.6	3785.5[b]
8		3609.6	3613.5[b]
9		3607.6	3609.6[b]
10		3836.6	3841.2[b]
11		3817.6	3819.8[b]

[a] Determined by ESI MS. M_{calc} corresponds the calculated monoisotopic mass. [b] Determined by MALDI-TOF MS. M_{calc} corresponds to the calculated average mass.

Synthesis of Fc-PNA Conjugates 3−7, 10, 11. The conversion of the azide or alkyne functionalized PNA oligomers **1**, **2**, **8**, and **9** in a [2 + 3] azide/alkyne cycloaddition was performed with different alkyne or azide functionalized ferrocene derivatives, namely, the commercially available ferrocene derivative ethynylferrocene and the synthesized derivatives azidoferrocene (*47*), azidomethylferrocene (*48*), and the diethylpropargylamine ferrocene derivative *N*-(3-ethylpent-1-yn-3-yl)ferrocene-carboxamide (DEPA−ferrocene) (*49*). The cycloaddition reactions with ethynylferrocene, azidoferrocene, and DEPA−ferrocene were performed on the solid support, starting from the synthesized azide or alkyne functionalized PNA oligomers **1**, **2**, **8**, or **9** (Schemes 1 and 2). The reactions were carried out in syringes with a frit at the bottom under argon in thoroughly dried solvents using similar reaction conditions to those recently reported by our group for the synthesis of mono- and multiferrocene-

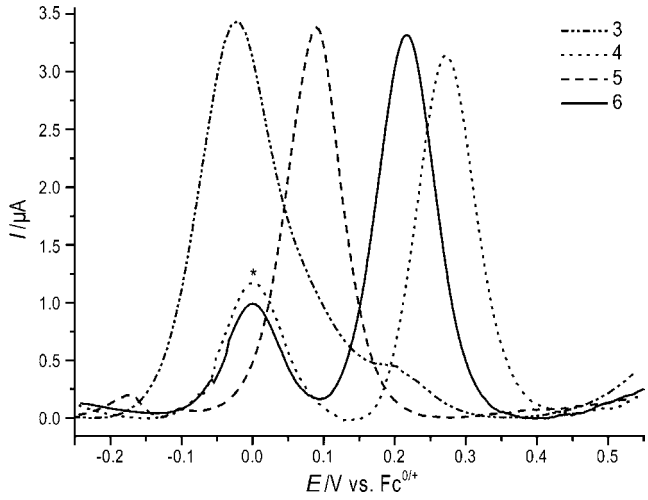

Figure 1. Overlay of differential pulse voltammograms (anodic scan; background subtracted) of Fc conjugates of PNA trimers **3**, **4**, **5**, and **6** at a glassy carbon electrode in 1:1 (v/v) mixture of CH_3CN and MOPS-buffer (0.15 M, pH 7.4) containing $NaClO_4$ as the supporting electrolyte (0.2 M). The experiments were undertaken at a scan rate of 4 mV/s with ferrocene as internal reference for **4** and **6** (smaller signals around 0 V, marked by an asterisk) and as external reference for **3** and **5**.

containing peptides (*50*) and PNA oligomers (*42*). Hence, the preloaded resins were treated with a reagent mixture containing copper(I) bromide as the catalyst and the respective ferrocene derivative. The reactions were carried out in DMF with small amounts of acetonitrile as cosolvent to achieve complete solubility of copper(I) bromide. After cleavage of the oligomer from the resin with TFA/TIS/phenol 85:5:10 (v/v/v), precipitation with ice-cold diethyl ether and lyophilization of the acetonitrile/water solutions, the crude products of **4**, **5**, **6**, **10**, and **11** were obtained as slightly orange powders.

The ESI mass spectra of products **4**, **5**, and **6** show the molecular peak $[M+H]^+$ with low intensity and the calculated peak $[M+2H]^{2+}$ as the base peak. ESI-MS of the crude products only revealed product peaks and not even trace signals of the azide or alkyne functionalized PNA precursors. This, again in combination with HPL chromatography of the crude products, proves that all cycloadditions occurred with practically complete conversion. Furthermore, it indicates that all synthesized Fc-PNA bioconjugates **4**, **5**, and **6** are completely stable to the fairly harsh (for organometallic compounds) cleavage conditions. MALDI-TOF spectra of 12mer Fc-PNA conjugates **10** and **11** reveal as well only peaks $[M+H]^+$ of the clicked products, as found during our previous investigations (*42*). No peaks originating from the azide and alkyne precursors could be detected. HPLC purification was performed to reduce the salt content of the crude products. An overall comparison of the trimer models **4**, **5**, and **6** with analytical data for the 12mer PNA conjugates **10** and **11** did not show any general difference in conversion, purity, or yield. This underscores that the solid-phase conversion of azide- or alkyne-functionalized PNA oligomers in a [2 + 3] cycloaddition with the chosen alkyne or azide ferrocene derivatives, respectively, is compatible with all four PNA monomers and qualified for the ferrocene labeling of even longer mixed-sequence PNA oligomers.

The synthesis of Fc-PNA conjugate **7** succeeded according to the literature procedure (*51*). Comparison of MALDI-TOF spectra and HPL chromatograms of the crude product **7** with those of the crude products **10** and **11** shows that the conjugation of a ferrocene moiety by click chemistry (**10**, **11**) yields comparable conversion and purity like the known conjugation of ferrocene carboxylic acid by peptide coupling (**7**). Click

Table 2. Half-Wave Potentials ($E_{1/2}$), Peak Separation Values (ΔE_p), and Peak Current Ratios (I_{pc}/I_{pa}) of Fc-PNA Trimer Conjugates 3, 4, 5, and 6 as Determined by Cyclic Voltammetry[a]

no.	scan rate/ mVs^{-1}	$E_{1/2}$ vs $FcH^{0/+}$/ mV	ΔE_p/ mV	I_{pa}/ μA	I_{pc}/ μA	I_{sp}/ μA	I_{pc}/I_{pa}
3	250	−14	+114	−9.45	+5.83	−9.14	1.17

5	250	+97	+79	−5.41	+2.88	−3.39	0.92
6	250	+208	+80	−2.66	+1.40	−1.88	0.96
FcH	250	0	+72	−10.67	+7.17	−4.98	0.99

[a] Data for ferrocene (FcH) measured under identical conditions are included for comparison. E_{pa} = anodic peak potential; E_{pc} = cathodic peak potential; half-wave potential $E_{1/2} = (E_{pa} + E_{pc})/2$; I_{pa} = anodic peak current; I_{pc} = cathodic peak current; peak separation value $\Delta E_p = E_{pa} - E_{pc}$; I_{sp} = current at switching potential; peak current ratios I_{pc}/I_{pa} determined as described in experimental section.

Table 3. Peak Potentials (E_p), Peak Currents (I_p), and Peak Widths ($w_{1/2}$) of Fc-PNA Trimer Conjugates 3, 4, 5, and 6 as Determined by Differential Pulse Voltammetry[a]

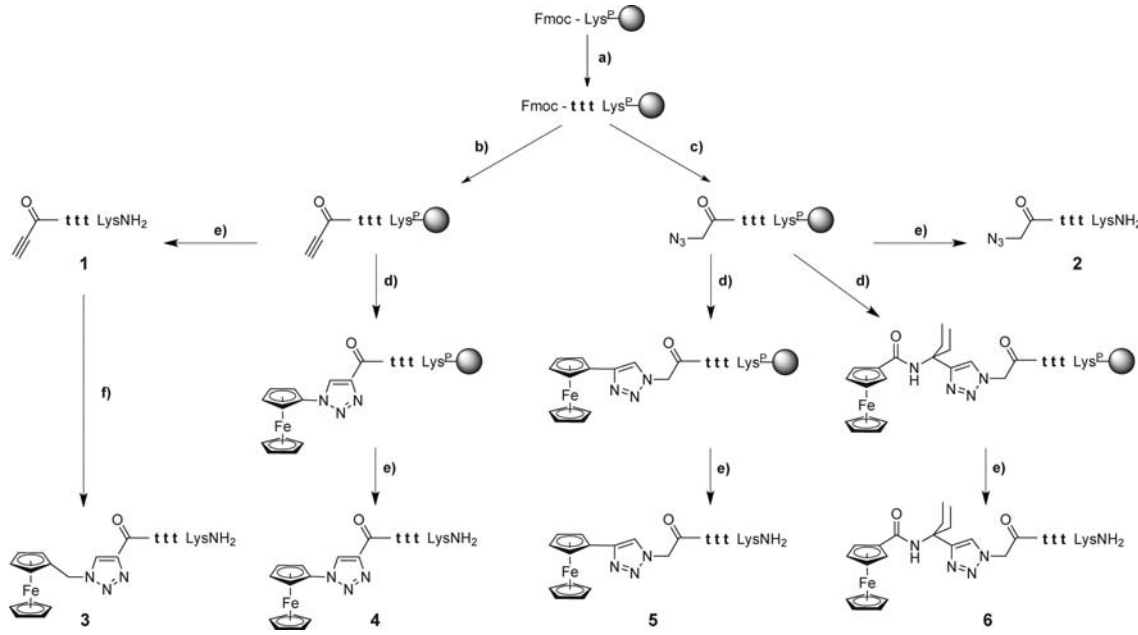
no	ΔE_p vs $FcH^{0/+}$ /mV	I_p /μA	$w_{1/2}$ /mV
3	−20	−3.92	131
4	+272	−3.14	103
5	+89	−8.46	90
6	+212	−3.32	100

[a] Scan rate 4 mVs^{-1}; voltage range 0−800 mV; modulation amplitude 10 mV; pulse width = 50 ms.

chemistry is even superior to the more traditional peptide coupling procedure in that it allows conjugation of a larger range of chemically diverse, commercially available, or easy-to-synthesize ferrocene derivatives. Furthermore, identical procedures and reagent concentrations for the click chemistry labeling with ethynylferrocene, azidoferrocene, and DEPA−ferrocene offer the possibility for automation. This flexibility is crucial for the preparation of PNA biosensors, since it allows the synthesis of metal−PNA conjugates with different electrochemical potentials.

Besides the successful introduction of azidoferrocene, ethynylferrocene, and DEPA−ferrocene, also an N-terminal labeling by click chemistry with azidomethyl ferrocene was attempted on a resin which was preloaded with the alkynyl functionalized PNA oligomer **1**. After cleavage and precipitation with cold ether, the product was characterized by ESI-MS. A major peak at m/z = 1039.3 corresponds to the PNA t_3-trimer, carrying a triazole ring at the N-terminus but *without* an attached ferrocene moiety. We thus conclude that the click reaction had taken place but yielded a product that is not stable to the relatively harsh PNA cleavage conditions as recently reported by Spiccia et al. in their endeavor to synthesize a ferrocenyl PNA monomer (see above and Experimental Procedures) (*52, 53*). We assume that the acidic cleavage conditions first cause a protonation of triazole N-3. In the presence of nucleophiles, the N−C bond is then cleaved with formation of the relatively stable ferrocenyl methyl cation, which finally forms ferrocenylmethanol. Following this line of argument, it is only the strongly acidic cleavage conditions that cause decomposition of the desired oligomer **3**. To exclude the possibility of inherent instability of **3**, the click reaction of azidomethyl ferrocene with the PNA trimer **1** was performed in solution as a postsynthetic labeling strategy. This finally succeeded and gave Fc-PNA conjugate **3** in good yield and purity. The MALDI-TOF mass spectrum of **3** after precipitation and washing revealed just one major peak corresponding to the $[M+H+CH_3CN]^+$ molecular ion. This synthetic work thus reveals the scope of click chemistry for the labeling of PNA oligomers with organometallic complexes. Since an instability toward harsh reaction conditions, e.g., the strong acidic PNA cleavage conditions, is a characteristic of many classes of metal complexes, click chemistry as a key reaction

Scheme 1. Synthesis of Fc-PNA Trimer Conjugates 3, 4, 5, and 6 and Corresponding Azide- and Alkyne-Functionalized PNA Precursors 1 and 2[a]



[a] (a) Standard Fmoc solid-phase PNA synthesis. (b) Coupling of propynoic acid, HATU, DIPEA, 2,6-lutidine in DMF. (c) Coupling of 2-azidoacetic acid, TBTU, HOBt·H_2O, DIPEA, 2,6-lutidine in DMF. (d) Click reaction on solid support: Ferrocene derivative (**4**, azidoferrocene; **5**, ethynylferrocene; **6**, DEPA−ferrocene), DIPEA, 2,6-lutidine in DMF; CuBr in CH_3CN. (e) Cleavage: TFA/TIS/Phenol. (f) Click reaction in solution: Azidomethylferrocene, DIPEA, 2,6-lutidine, CuBr in H_2O/CH_3CN. See experimental section for details, "Lys^P" denotes N-Boc protected lysine.

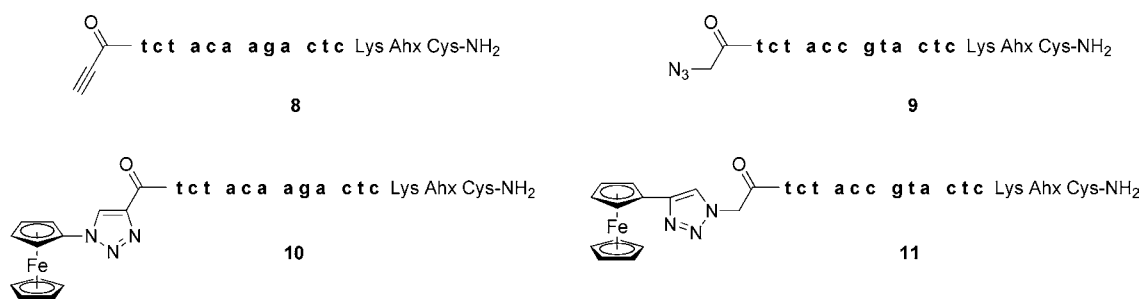
in the synthesis of metal-PNA conjugates is not just applicable as part of the solid-phase synthesis scheme but furthermore offers a reliable alternative as a postsynthetic labeling strategy, effectively yielding the same products.

Electrochemical Studies. The electrochemical behavior of the Fc-PNA conjugates **3**, **4**, **5**, and **6** with the trimer model sequence H-t-t-t-Lys-NH_2 was examined by cyclic voltammetry (CV) and differential pulse voltammetry (DPV). Each of these four compounds contains a ferrocene moiety that was attached to the N-terminus of the t_3-PNA sequence via one of the four specific click reactions described above. Fc-PNA trimer conjugates **3**, **4**, **5**, and **6** present structurally comparable compounds that only show differences in the chemical environment of the ferrocene moiety. An electrochemical microvolume cell with a stationary glassy carbon working electrode, Ag/AgCl in aq KCl (3 M) as reference electrode, and a platinum wire as counter electrode was used. All electrochemical measurements were undertaken with 80 μL of 0.8 mM solutions of the respective Fc-PNA bioconjugate in a 1:1 (v/v) mixture of acetonitrile and MOPS buffer (0.15 M, pH = 7.4) with $NaClO_4$ (0.2 M) as the supporting electrolyte. CV and DPV of ferrocene were performed in the same electrolyte solution, and the electrochemical half-wave potential $E_{1/2}$ of the redox couple ferrocene/ferrocenium $FcH^{0/+}$ vs Ag/AgCl ($E_{1/2}$ = 270 mV) was set to 0 mV as the reference potential for all measurements. Ferrocene was used as an internal reference for the DPV measurements of **4** and **6**. For the DPV measurements of **3** and **5** and for all CV measurements, ferrocene was used as an external reference to avoid an overlap of the corresponding redox processes (Figure 1).

Cyclic voltammograms of all Fc-PNA conjugates revealed one-electron waves with quasi-reversible Nernst behavior. Peak separations ΔE_p between +80 mV and +114 mV were observed, which are 8 to 42 mV higher than the ΔE_p value obtained with the same electrochemical setup for the fully reversible redox couple $FcH^{0/+}$(ΔE_p = +72 mV). Fc-PNA conjugates **5** and **6** yield current ratios I_p^{ox}/I_p^{red} close to unity, while conjugate **3** shows a higher value of 1.17 and conjugate **4** shows a lower value of 0.81, both still being sufficiently close to unity for practical biosensor applications.

The electrochemical half-wave potentials $E_{1/2}$ (vs $FcH^{0/+}$) are determined by CV and spread over 280 mV, ranging from $E_{1/2}$ = −14 mV for compound **3** to $E_{1/2}$ = +269 mV for compound **4**. These electrochemical potentials could be confirmed with DPV. Oligomer **6** revealed a half-wave potential of $E_{1/2}$ = +208 mV vs. $FcH^{0/+}$. This value corresponds well to the literature

Scheme 2. Azide- and Alkyne-Functionalized PNA Oligomers 8 and 9 and Fc-PNA Conjugates 10 and 11 with Bacterial 12mer PNA Sequences[a]



[a] See experimental section for details of the syntheses.

values for PNA with a peptidic bound ferrocene moiety (*51*), which was expected, since oligomer **6** is derived from a propargylamido ferrocene derivative and therefore contains a Cp-bound carboxamido function. Compound **4** reveals a potential of $E_{1/2} = +269$ mV vs $FcH^{0/+}$, showing a shift to positive potentials of 61 mV compared to **6**. In contrast, a potential of $E_{1/2} = +97$ mV vs $FcH^{0/+}$ was determined for oligomer **5**, a shift of 111 mV to negative potentials compared to **6**. Both conjugates **4** and **5** contain ferrocene moieties carrying the triazole structure in α-position to the Cp ring. The ferrocene moiety of **4** is bound to a nitrogen atom (N-1), whereas the ferrocene moiety of **5** is bound to a C_{sp2} atom (C-4) of the respective triazole ring. Independent of any effects of a possible Cp/triazole-conjugation, it can be assumed that differences in the electronegativity of the respective Cp-bound triazole ring atoms have a strong influence on the determined differences in the half-wave potentials of **4** and **5** (*54*). In contrast, the ferrocene moiety of oligomer **3** is disconnected from the triazole ring via a methylene bridge. The determined half-wave potential of **3** just exhibits a small shift to negative potentials compared to ferrocene/ferrocenium ($E_{1/2} = -14$ mV vs $FcH^{0/+}$), which is comparable to literature values for methyl or methylene substituted ferrocene derivatives (*55*).

The minimum differences in the electrochemical half-wave potentials $\Delta E_{1/2}^{min}$ of all Fc-PNA trimer conjugates **3**, **4**, **5**, and **6** were determined from Table 2. Conjugates **4** and **6** show a minimum value of $\Delta E_{1/2}^{min}$ (4, 6) = 61 mV, whereas conjugates **6** and **5** as well as **5** and **3** reveal values of $\Delta E_{1/2}^{min}$ (5, 6) = 111 mV (= $\Delta E_{1/2}^{min}$ (3, 5)). An overlay of differential pulse voltammograms of the four Fc-PNA trimer conjugates **3**, **4**, **5**, and **6** nicely demonstrates the differences in the electrochemical potentials (Figure 1). Generally, potential differences in this range are significant for a reliable resolution with sensitive electrochemical methods like differential pulse voltammetry (DPV) or square wave voltammetry (SWV). Figure 1 reveals that, even with consideration of the respective peak width $w_{1/2}$, ranging from 90 mV for **5** to 131 mV for **3** (see Table 3), a good resolution of the electrochemical potentials is possible, and therefore, a reliable distinction of the Fc-PNA conjugates **3**, **4**, **5**, and **6** with DPV is ensured.

CONCLUSIONS

In summary, the facile, reliable, and high-yielding preparation of new Fc-containing PNA oligomers was accomplished in this work using the click chemistry methodology. In contrast to all earlier work which had used ferrocene carboxylic acid as an electroactive label for PNA oligomers (*56*−*59*), the synthetic method used here allows the formation of a small library of new ferrocenyl PNA bioconjugates through the use of different ferrocenyl starting materials, but employing the same "click" chemistry. Accordingly, different electrochemical potentials could be encoded into PNA oligomer sequences by using one and the same type of reaction. Using the same conditions for the introduction of different labels is a bonus for automation, e.g., for an on-chip or parallel library synthesis. A similar approach was utilized by Seela et al. for the labeling of all four nucleobases with coumarin dyes by click chemistry (*60*). Our electrochemical analysis shows that the four ferrocenyl−triazole PNA oligomers described exhibit electrochemical potentials with potential differences bigger than 60 mV, which can be reliably distinguished by electrochemical methods like DPV. This is unprecedented and of significant interest for a potential application of PNA as electrochemical nucleic acid biosensors. In principle at least, the use of four different potentials in electrochemical labels (called "four-potential" labeling) corresponds to the "four-color" detection with four different dyes in classical DNA analysis. Kuhr and co-workers were the first to show a related electrochemical "four-potential" detection scheme with ferrocene-labeled DNA (*61*, *62*). Apart from the fact that different chemistry had to be used in Kuhr's work for the introduction of all four ferrocene labels into the DNA oligomers, PNA clearly has advantages for DNA biosensors because of its higher affinity and superior mismatch discrimination. Investigations of the electrochemical responses of these oligomers with (non)cDNA/RNA sequences is currently underway in our laboratories and will be published in due course.

ACKNOWLEDGMENT

N.H. is the recipient of a Ruhr-University Research School fellowship for doctoral students. G.G. thanks the Alexander von Humboldt Foundation for a research fellowship. The authors thank Prof. Mallayan Palaniandavar for helpful discussions on the electrochemical measurements and Prof. Wolfgang Schuhmann and his co-workers for experimental help and assistance in the preparation of the glassy carbon electrodes and the microvolume electrochemical cell.

Ag/AgCl in KCl (3M) served as reference electrode and a platinum wire as counter electrode.

Eradication of CD19$^+$ Leukemia by Targeted Calicheamicin θ

Kathrin M. Bernt,[‡] Aram Prokop,[§] Nicole Huebener,[‡] Gerhard Gaedicke,[†,‡] Wolfgang Wrasidlo,[†,||] and Holger N. Lode*[,‡]

Charité Universitätsmedizin Berlin, Department of Pediatrics, Experimental Oncology, Berlin, Germany, Department of Pediatric Hematology/Oncology, Berlin, Germany, and Moore's Cancer Center, University of California, San Diego, California. Received March 24, 2009; Revised Manuscript Received May 18, 2009

Children with relapsed and refractory acute lymphoblastic leukemia (ALL) still face a critical prognosis. We tested the hypothesis that targeted calicheamicin theta (θ) using an anti-CD19-immunoconjugate may provide an effective treatment strategy for CD19$^+$ ALL. Calicheamicin θ is a rationally designed prodrug of the natural enediyene calicheamicin γ, obtained by total synthesis. It offers the advantage of increased in vivo stability and 1000-fold higher antitumor potency over calicheamicin γ. First, we demonstrate efficacy of calicheamicin θ against primary pre-B leukemic cells and multidrug-resistant leukemia cell lines ($IC_{50} = 10^{-9}$ to 10^{-12} M). Second, conjugation of calicheamicin θ to an internalizing murine anti-CD19 monoclonal antibody was demonstrated to affect neither calicheamicin θ mediated cytotoxicity nor binding of the antibody to the target molecule. Third, anti-CD19-calicheamicin θ immunoconjugate revealed a maximum tolerated dose of 10 μg/kg and CD19-specific and long-lasting eradication of established leukemia was demonstrated in a xenograft model. Finally, we show that the antileukemic effect of anti-CD19-calicheamicin θ is mediated by induction of apoptosis proceeding through the caspase-mediated mitochondrial pathway. On the basis of these results, we conclude that anti-CD19-calicheamicin θ immunoconjugates may offer a novel and effective approach for the treatment of relapsed CD19$^+$ ALL.

INTRODUCTION

The treatment success of pediatric patients with newly diagnosed acute lymphoblastic leukemia (ALL) has dramatically inproved over the last decades and overall cure rates are above 70% (*1*, *2*). However, one of the limitations remains a relapse rate of nearly 30% (*3*) as described in stratified and randomized multicenter trials such as ALL-REZ BFM 85 (*4*). Although the overall second complete remission (CR) rate was 92%, the probability of event-free survival (EFS) at 6 years was only 0.31 ± 0.04. Thus, the proposed treatment regimen can induce long-lasting second remissions in about one-third of patients even after intensive front-line treatment. However, the majority of patients still face a critical prognosis particularly subsequent to early relapse.

Alternative treatment approaches to B-cell malignancies were established by using a monoclonal antibody directed against the common B-cell differentiation antigen CD20. Efficacy of adjuvant immunotherapy using anti-CD20 in low-grade B-cell lymphoma has been clearly demonstrated (*5*, *6*) suggesting that anti-CD20 therapy is also effective in more aggressive, high-grade B-cell malignancies such as Burkitts and diffuse large-cell lymphoma (*7*−*10*). The mechanism of action mediated by anti-CD20 is a combination of humoral and cellular immune responses (*11*) and the induction of apoptosis in cells targeted by the antibody (*12*), which can be further improved by labeling the antibody with radioisotopes (*13*). However, the use of this anti-CD20 antibodies in pediatric leukemias is limited by the fact that pre-B cell leukemias do not express CD20. This is in contrast to CD19, an earlier differentiation marker in B-cell differentiation. CD19 expression is induced at the point of B lineage commitment during the differentiation of the hematopoietic stem cell, and its expression continues through preB and mature B cell differentiation until it is finally down-regulated during terminal differentiation into plasma cells. CD19 expression is maintained in B-lineage cells that have undergone neoplastic transformation, and therefore, CD19 is a useful target in leukemia and lymphoma thearpy using monoclonal antibodies (*14*, *15*). CD19 is highly expressed by the majority of relapsed ALL leukemic cells and immunotoxins targeted to CD19 were shown to mediate apoptosis also in rituximab-resistant hematologic malignancies (*16*).

Since induction of apoptosis is one important mechanism of action mediated by anti-CD19 antibodies (*14*), we intended to amplify the mode of action by fusing an anti-CD19 antibody to the enediyene calicheamicin θ. Enediyenes are a group of cytotoxic compounds identified from a broth extract of a soil microorganism, *Micromonospora echinospora calichensis*, which were termed calicheamicins. These compounds were later identified as members of a class of antibiotics incorporating the enediyne moiety which include the esperamicins, dynemicins, and neocarzinostatin (*17*) which were found to exert impressive potencies in a screen for DNA damaging agents (*18*) that exceeded the cytotoxic potency of substances such as CN-MRA (*19*) and ricin (*20*), which have been claimed as some of the most toxic substances known at the time. Within this group of enediyene antibiotics, calicheamicin γ was the most potent compound, which was found to bind in the minor groove of DNA, and the resulting sequence-specific DNA-cleavage has been described (*21*). A novel biologically active and selective enediyene molecule calicheamicin θ was rationally designed on the basis of the mechanism of action of the naturally occurring calicheamicin γ. Unlike its natural counterpart, calicheamicin θ contains structural variations that facilitate molecular triggering to form the active compound under mild

Table 1. Effect of Calicheamicin θ against Primary Patients ALL and Leukemia Cell Lines[a]

cell line[b]	cell type	calicheamicin θ IC_{50} [M][c]
Molt-3	T-cell	2.0×10^{-12}
Molt-4	T-cell	1.5×10^{-13}
MOVP-3	T-cell	4.5×10^{-11}
TCAF	T-cell	1.1×10^{-11}
HL60	Promyelocytic	3.6×10^{-11}
L1210	Lymphocytic Leukemia[d]	1.8×10^{-10}
P-388	Lymphocytic Leukemia[d]	4.5×10^{-9}
Nalm-6	pre B-cell	9.0×10^{-13}
Reh	pre B-cell	1.5×10^{-12}
Patient I	ALL	4.8×10^{-12}
Patient II	ALL	1.9×10^{-10}
Patient III	ALL	5.2×10^{-10}

[a] The IC_{50} concentration of calicheamicin θ was determined against ALL blasts and leukemia cell lines using the XTT assay. [b] Cells used for calicheamicin θ drug sensitivity testing were human and murine cell lines. [c] Values represent the means of experiments in triplicate. Standard deviations were below 10%. [d] Cells of murine origin.

Table 2. Cytotoxicity of Chemotherapeutic Agents on NALM-6 Cells

drug[a]	target	IC_{50} [M][b]
Calicheamicin θ	DNA minor groove (TCCT)	5×10^{-13}
Doxorubicin	topoisomerase II	3×10^{-10}
Camptothecan	topoisomerase I	4×10^{-9}
Paclitaxel	tubulin, microtubles	1×10^{-10}
Etoposide	topoisomerase II	1×10^{-8}
Melphalan	alkylation of DNA	4×10^{-8}
Methotrexate	dihydrofolate reductase	6×10^{-8}
Vinblastine	microtuble depolymerization	2×10^{-6}
Genistein	Src kinase family blocker	6×10^{-6}
Calicheamicin θ -anti CD19	CD19	2×10^{-13}
Doxo-anti-CD19	CD19	1×10^{-9}
Doxo-anti-CD20	CD20	3×10^{-9}
Doxo-anti-CD22	CD22	8×10^{-10}
AntiCD19, 20, 22	CD19, CD20, CD22	$>1 \times 10^{-4}$
Calicheamicin θ -anti CD19[c]	$CD19^+$ (NALM-6)	5×10^{-11}
Calicheamicin θ -anti CD19[c]	$CD19^-$ (Molt-3)	6×10^{-8}

[a] The IC_{50} concentration of indicated chemotherapeutic agents was determined against NALM-6 B-cell lymphoblastic leukemia using the XTT assay. [b] Values represent the means of experiments in triplicate. Standard deviations were below 10%. [c] The IC_{50} concentration of Calicheamicin θ -anti CD19 immunotoxin was determined in CD19 positive and negative cells using a short exposure experiments as described in Materials and Methods.

basic conditions (*22*, *23*). This modification led to a further increase in cytotoxicity over the natural compound when tested against a large number of different human cancer cell lines as determined by the decrease in the concentration at which 50% of cell viability was observed (*22*, *23*). The small size of calicheamicins with molecular weights of approximately 1500 Da combined with their unique mode of action and the extreme potency of calicheamicin θ suggest that this compound might be a good candidate for targeted chemotherapy. In fact, we demonstrated the use of calicheamicin θ for targeted therapy of neuroblastoma using antiganglioside GD2 antibodies (*24*). Here, we expand these findings and establish for the first time efficacy and mechanism of an antibody drug conjugate between a murine monoclonal anti-CD19 mAb and calicheamicin θ that suppresses growth and dissemination of leukemic cells in a Nalm-6 pre B-cell leukemia model.

MATERIALS AND METHODS

Cell Lines and Patient Cells. NALM-6, Reh, Molt-3, Molt-4, TCAF, TCAF-Dox, HL60, L1210, and P-388 cell lines were purchased from ATCC. Cells were maintained in RPMI with 10% fetal bovine serum. Control vector and FADD-dn-transfected BJAB cells expressing a dominant negative FADD mutant lacking the N-terminal death receptor domain have been described earlier (*25*). Leukemic cells from patients were isolated from bone marrow samples at initial diagnosis. Mononuclear cells were prepared by Ficoll centrifugation and characterized by flow cytometry. Patient cells were maintained in RPMI with 20% fetal bovine serum and gentamicin (50 μg/mL).

Mice. Female FOX CHASE C.B-17/lcrCrl-scid BR mice were obtained at 8 weeks of age from Charles River Laboratories, Sulzfeld, Germany. They were housed in the pathogen-free mouse colony at our institution in groups of 8 mice. Mice were fed ad libitum on standard mouse laboratory chow. Animal experiments were performed according to the German guide for the care and use of laboratory animals, i.e., "Tierschutzgesetz".

Cytostatic Agents, Antibodies, and Reagents. Anti-CD19 (mouse IgG2a) was obtained from CellGenics (Freiburg, Germany) and anti-CD19 (mouse IgG2b, clone HID-9703) and anti-CD20 (mouse IgG1, clone L-27) from Baxter (Unterschleissheim, Germany). Human-mouse chimeric antiganglioside GD2 antibody ch14.18 (*26*) was used as a negative control. Conjugation of mAbs with fluorescein isothiocyanate (FITC) was accomplished at pH 9.0 using 20 μL FITC solution (5 mg/mL in DMSO) per mg mAb (1 mg/mL). After 2 h, the pH was lowered to pH 7.4 and FITC-labeled antibody was purified over PD-10 columns (Amersham-Pharmacia, Freiburg, Germany).

Calicheamicin θ (MW 1464 g/mol) was obtained by total synthesis as previously described (*23*). Succinimidyl 6-(3-[2-pyridyldithio]-propionamido)hexanoate (LC-SPDP) and iminothiolane were obtained from PIERCE (Rockford, IL). Doxorubicin, camptothecan, paclitaxel, etoposide, melphalan, methotrexate, vinblastine, genistein, 2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-[(phenylamino)carbonyl]-2*H*-tetrazolium hydroxide (XTT), organic solvents, and phenazine methosulfate (PMS) were obtained from Sigma-Aldrich (Deisenhofen, Germany). All cytotoxic agents were dissolved in DMSO or DMF, and 10 mM stock solutions were stored at −20 °C until use. Cell culture reagents, restriction enzymes, and other molecular biology reagents were from Life Technologies (Karlsruhe, Germany).

Conjugation of Calicheamicin θ. The conjugation of calicheamicin θ to anti-CD19, anti-CD20, and anti-GD2 mAb involved the activation of the sugar amino groups with LC-SPDP, using 4-dimethylaminopyridine (DMAP, Aldrich, Munich, Germany) as a catalyst, followed by disulfide exchange with iminothiolane-modified anti-CD19 and anti-GD2 mAb. For activation, 1 mg calicheamicin θ (1 mg/mL in DMF) was reacted with a 2-fold molar excess of LC-SPDP (succinimidyl 6-(3-[2-pyridyldithio]-propionamido)hexanoate) (37 μL of 20 mM LC-SPDP in DMSO) at 4 °C for 6 h and stored in small aliquots at −80 °C until further use. Sulfhydryl groups were introduced in mAbs (2 mg in 2 mL PBS, pH 8.3) by adding 10 μL iminothiolane (4.4 mg dissolved in 1 mL DMF) for 1 h under nitrogen. The iminothiolane-modified antibody was purified by size exclusion chromatography using a NAP-5 column (Amersham-Pharmacia, Freiburg, Germany) preequilibrated with PBS. The conjugation of activated drugs with thiolated mAb was done at RT for 1 h under nitrogen, using a 5:1 molar ratio followed by size exclusion chromatography. Finally, solutions were filter sterilized. The purity was checked by HPLC analysis (G200 size exclusion column, PBS elution buffer, 0.5 mL/min flow). The number of drug molecules per mAb was on the average two, calculated from the absorption ratios at A333/A280 for calicheamicin in the HPLC spectrum. Free calicheamicin was not detectable in these preparations. The dosage of the conjugate for cytotoxicity experiments was calculated on the basis of the molar concentration of drug on the antibody.

CD19 Expression Analysis. For the analysis of CD19 expression on Nalm-6, Reh and Molt-3 (negative control) anti-CD19-FITC was used. Cells were blocked with PBS (0.1% BSA in PBS, pH 7.4) and incubated with anti-CD19-FITC (1 μg/10^6 cells) or a mouse IgG2a isotype control (PharMingen, La Jolla,

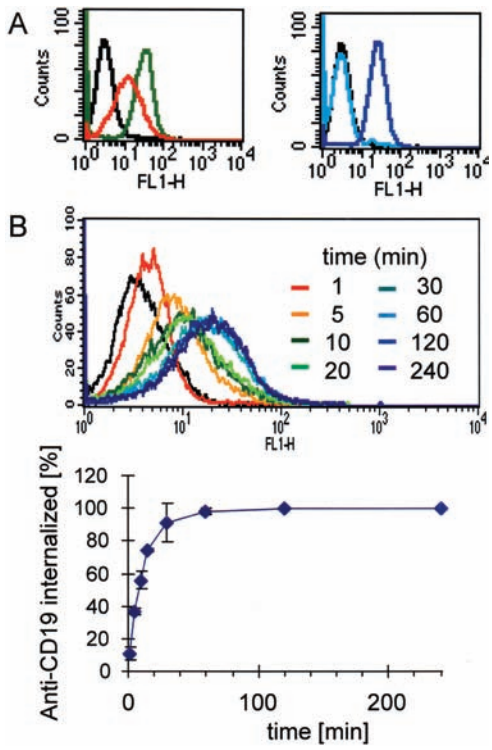

Figure 1. Internalization kinetics of anti-CD19 mAb. (A) Investigation of antibody internalization comparing two different anti-CD19 antibodies. Internalization of anti-CD19 (clone HID-9703) into Nalm-6 leukemia cells was demonstrated as indicated by an increase in fluorescence over background (red signal, left panel). Internalization was absent for anti-CD19 (IgG2a, Cell Genix) (light blue signal, right panel). Two control samples were incubated at 0 °C in the presence of 0.01% NaN_3 in order to block internalization. The first control sample (0 °C; 0.01% NaN_3) was stripped of bound antibody (black signals, left and right panels) and served as a negative control. The second control sample (0 °C; 0.01% NaN_3) was not stripped (green and dark blue signals, left and right panels) and was used as a positive control. All experiments were done in triplicate. (B) Internalization kinetics of anti-CD19 (clone HID-9703) into Nalm-6 leukemia cells over time. Mean fluoresence signals obtained from histograms (top) were used to calculate the percentage of internalized antibody (bottom). 100% equals the signal obtained with Nalm-6 cells incubated with anti-CD19-FITC antibody under non-internalizing conditions (0 °C in the presence of 0.01% NaN_3). Internalization (37 °C) was investigated over time by analysis of fluorescence signals resulting from internalization after stripping cells from non-internalized membrane-bound anti-CD19 antibody as described in Materials and Methods. Data represent mean ± sd ($n = 3$).

CA) for 20 min on ice, washed twice, and analyzed by FACSscan (Becton Dickinson, Franklin Lakes NJ).

Internalization Assay of anti-CD-19-FITC. Cells were washed twice and blocked with PBS + 0.1% BSA on ice. Anti-CD19-FITC (1 μg/10^6 cells) was added on ice. Aliquots were subsequently transferred to 37 °C to allow for internalization. Negative control samples were incubated at 0 °C in the presence of 0.01% NaN_3, conditions which block internalization. An aliquot of each condition was retained at different time points to determine the total amount of bound and internalized antibody. At each time point, a second aliquot was stripped of noninternalized antibody with RPMI titered to pH 2.0 with HCl and adjusted to high salt (1 M NaCl, 2×, 15 min), and washed briefly in PBS (0.1% BSA, pH 7.4) before analysis. The quality of the stripping was assured by the total removal of all antibodies from control cells incubated under non-internalizing conditions. For the integration time course, experimental samples were incubated at 37 °C for the indicated time spans. The amount of integrated antibody in percent total integration was calculated as follows: MFI (time point)/MFI (4 h) × 100. The binding of calicheamicin conjugates was determined by indirect staining using a FITC-conjugated goat-anti mouse IgG secondary antibody (ParMingen), and secondary antibody only as control.

Cytotoxicity Assay. Cytotoxicity was determined by the XTT tetrazolium/formazan assay as previously described (*27*). Briefly, cells were seeded in 96 flat-bottomed well plates at a density of 10^4/well in 100 μL media, incubated overnight, and exposed to drug concentrations ranging from 10^{-6} to 10^{-16} M for calicheamicin θ or calicheamicin θ immunoconjugates and from 10^{-4} to 10^{-14} for all other drugs. In short exposure experiments, plates were washed (×2) by centrifugation after 1 h exposure to calicheamicin θ anti-CD19 immunoconjugates. Cell viability was assessed after 72 h by adding 50 μL XTT-reagent (1 mg/mL in RPMI) activated with 0.2% v/v PMS (1.53 mg/mL in PBS) incubated at 37 °C for 4 h. Plates were analyzed in a Thermomax (Molecular Devices) microplate reader at 450 nm. OD values were plotted as a function of drug concentration and the curves were integrated using the softmax software to obtain the IC_{50} concentration values. In experiments with BJAB cells, the cytotoxicity of calicheamicin θ immnunoconjugate was determined by the release of lactate dehydrogenase (LDH) using a detection kit from Boehringer-Mannheim (Mannheim, Germany).

Nalm-6 Xenograft Model. The Nalm-6 xenograft model was used as previously described (*28*). Briefly, leukemia was induced by injection of 1×10^6 Nalm-6 cells in 100 μL PBS (pH 7.4) into the tail vein of each SCID mouse. Mice ($n = 6$) were treated by intraperitoneal injection of PBS (pH 7.4), anti-CD19-calicheamicin θ and anti-GD2-calicheamicin θ immunoconjugates (1.0, 3.0, and 10.0 μg/kg linked calicheamicin θ; MW 1464 g/mol; 2 molecules per antibody) and anti-CD19 antibody (50, 150, and 500 μg/kg) (MW 150 000 g/mol) in a total volume of 200 μL. Each mouse received a total of 2 injections on days 5 and 7. Event-free survival of mice was followed over time. An event was defined by the development of central nervous system leukemia as indicated by presence paraplegia in individual mice.

Processing of Caspase 3, DNA Fragmentation, and Mitochondrial Permeability Transition. Processing of caspase 3, DNA fragmentation, and mitochondrial permeability transition was determined as previously described (*29*). Processing of caspase 3 was determined by Western blot using 30 μg of cytosolic protein probed with polyclonal rabbit antihuman caspase 3 antibody (1:2000). DNA fragmentation was investigated by flow cytometry of fixed cells after incubation with 50 μg/mL propidium iodide in PBS (pH 7.4), and data are expressed as percent of hypoploidy (subG1), reflecting the percentage of apoptotic cells. Mitochondrial permeability transition was analyzed by staining the cells with JC1 (Molecular Probes, Leiden, Netherlands). Determination of cells with decreased fluorescence signals consistent with mitochondria displaying a lower membrane potential was accomplished by flow cytometry. Data are expressed in percent of cells with low $\Delta\Psi_m$, which reflects the number of cells undergoing mitochondrial apoptosis.

Statistics. The statistical significance of differential findings between experimental groups of animals and control groups and between experimental and control samples was determined by two-tailed Student's *t* test. Findings were regarded as significant if two-tailed *p* values were <0.01.

RESULTS

Determination of the Efficacy of Calicheamicin θ against ALL Cells. The efficacy of calicheamicin θ against ALL cells was determined using a panel of cell lines and primary blasts from bone marrow of ALL patients (Table 1). The IC_{50} concentration for calicheamicin θ was in the picomolar range ($IC_{50} < 10^{-9}$ M) for the majority of ALL cells tested, including T-ALL and multidrug-resistant ALL, as well as the patients cells,

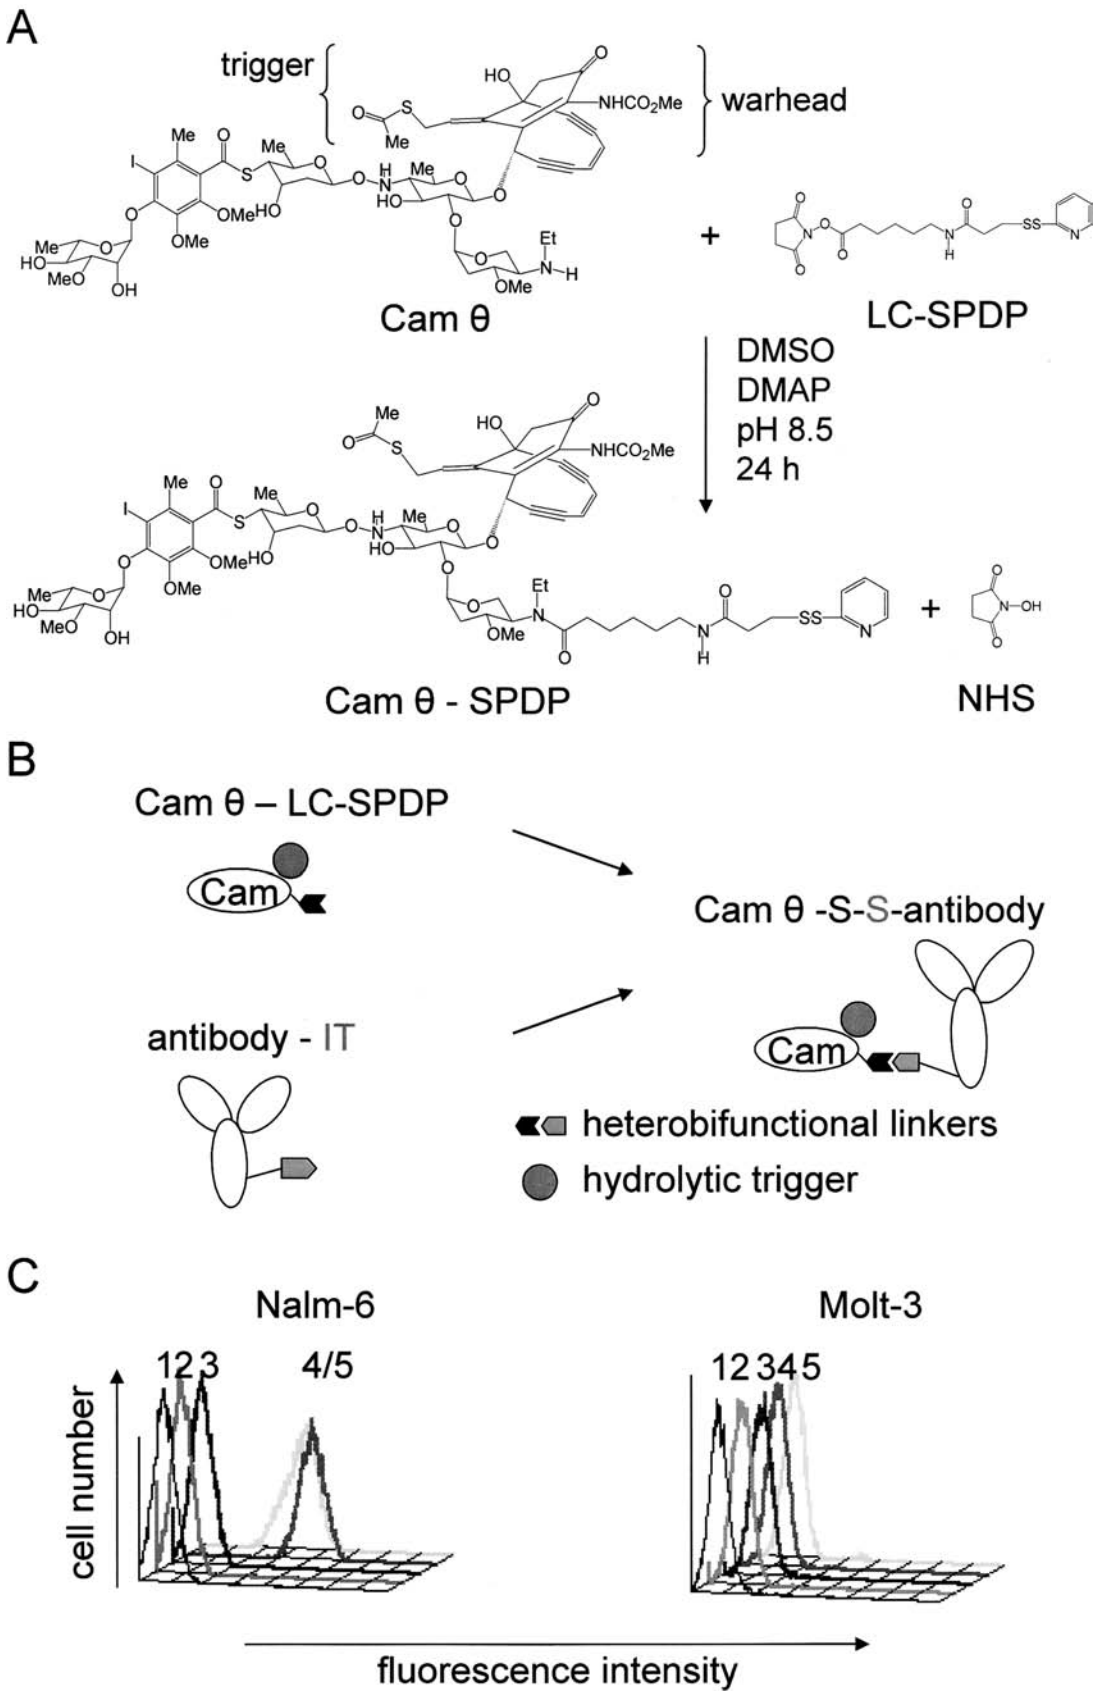

Figure 2. Synthesis and binding of anti-CD19 calicheamicin θ immunoconjugate. (A) Structures and reaction conditions of calicheamicin θ with the LC-SPDP linker to form calicheamicin θ-LC-SPDP. (B) Conjugation of calicheamicin θ-LC-SPDP with iminothiolane (IT) activated anti-CD19 (clone HID-9703) to form anti-CD19 calicheamicin θ immunotoxin. (C) Binding of anti-CD19 calicheamicin θ immunotoxin to CD19 positive Nalm-6 cells (left panel) in contrast to CD19-negative Molt-3 controls (right panel). 1, no antibody; 2, secondary antibody only; 3, anti-CD20; 4, anti-CD19; 5, anti-CD19 calicheamicin θ immunotoxin. All experiments were done in triplicate.

except for P-388 mouse lymphoblastic leukemia. In some cell lines (Molt-4, Nalm-6), the efficacy was even in the femtomolar range ($IC_{50} < 10^{-12}$ M). In order to further evaluate these results, we compared the efficacy of calicheamicin θ with other

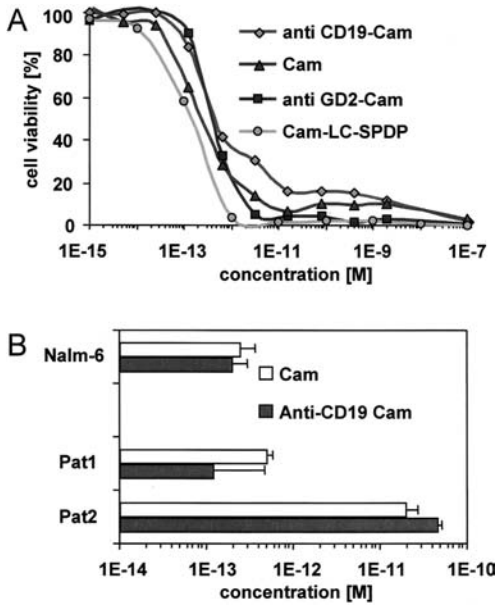

Figure 3. Cytotoxic effect of anti-CD19 calicheamicin θ immunoconjugate in vitro. A) The concentration dependent cytotoxic effects of calicheamicin θ, calicheamicin θ - LC-SPDP, anti-CD19 calicheamicin θ immunoconjugate and anti-GD2 calicheamicin θ immunoconjugate were determined on Nalm-6 cells. Data represent mean values of triplicate experiments. B) Cytotoxic effects of calicheamicin θ and anti-CD19 calicheamicin θ immunoconjugate against blasts obtained from relapsed ALL patients compared to Nalm-6 cells. Data represent IC50 concentrations (mean ± sd, $n = 3$).

established chemotherapeutic compounds used for ALL therapy on Nalm-6 cells (Table 2). Results revealed the lowest IC_{50} concentration for calicheamicin θ ($IC_{50} = 5 \times 10^{-13}$ M) in contrast to all other drugs tested, which were at best 1000-fold less active (i.e., doxorubicin $= 3 \times 10^{-10}$ M). These findings clearly demonstrate the excellent cytotoxic potential of calicheamicin θ for the generation of an immunotoxin for targeted therapy.

Generation and Characterization of an Anti-CD19 Calicheamicin θ Immunotoxin. The selection of the CD19 specific monoclonal antibody for the generation of a calicheamicin θ immunotoxin was based on antibody internalization experiments (Figure 1). Results indicate that the anti-CD19 antibody (Baxter) showed rapid internalization that was nearly complete after 60 min.

Therefore, this anti-CD19 antibody was selected for the conjugation to calicheamicin θ using the heterobifunctional linker LC-SPDP (Figure 2). The conjugation of the linker to calicheamicin θ is complicated by the highly unstable "trigger" and "warhead" portions of calicheamicin θ (Figure 2A). However, the conjugation of the activated NHS ester end of the LC-SPDP linker to the secondary amine of calicheamicin θ to form calicheamicin θ-LC-SPDP was accomplished in organic solvent at pH 8.5, without affecting the cytotoxic potential of calicheamicin θ (Figure 3). The 2-pyridylthiol group at the other end of the LC-SPDP linker was reacted with sulfhydryl residues in the anti-CD19 antibody to form a disulfide linkage (Figure 2B). Binding of the purified immunotoxin to CD19-positive Nalm-6 cells was demonstrated in contrast to CD19-negative Molt-3 cells used as negative controls (Figure 2C). The cytotoxic effect of anti-CD19-calicheamicin θ-immunotoxin was compared to that of free calicheamicin θ, calicheamicin θ-LC-SPDP and anti-GD2 calicheamicin θ (Figure 3A). Results indicate that the level of calicheamicin θ mediated cytotoxicity remained unchanged after conjugation to LC-SPDP and to a monoclonal antibody as determined in one ALL cell line and ALL blasts

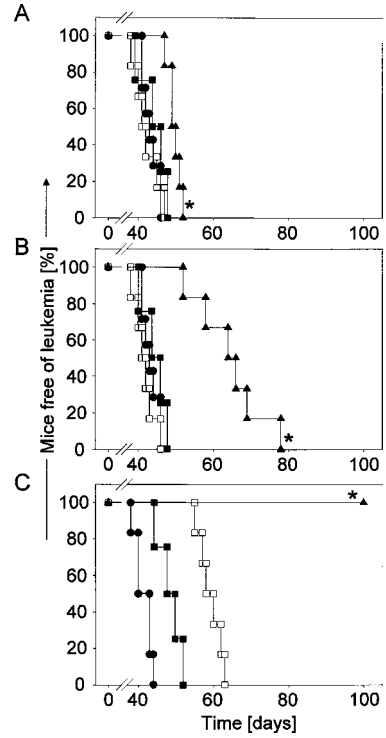

Figure 4. Effect of CD19 targeted calicheamicin θ in vivo. The effect of anti-CD19 calicheamicin θ immunotoxin against CD19-positive leukemia was determined in a xenograft model. Mice ($n = 6$ per group) were injected i.v. with 1×10^6 Nalm-6 cells. Treatment was initiated by two intraperitoneal injections on days 5 and 7 of 1.0 (A), 3.0 (B), and 10.0 μg/kg (C) with anti-CD19 calicheamicin θ immunotoxin (dose indicates linked calicheamicin θ) (closed triangle) and anti-GD2 calicheamicin θ immunotoxin control (open square). Controls received an equivalent amount of unconjugated anti-CD19 abtibody (500, 150, and 50 μg/kg) (closed square). Untreated control groups of animals received PBS injections (closed circles). Data represent the percentage of mice free of leukemia. The difference between groups of mice treated with anti-CD19 calicheamicin θ immunotoxin and all control groups was statistically significant (* $p < 0.01$).

from bone marrow aspirates of two ALL patients (Figure 3B). We could also demonsrate an antigen-specific cytotoxic effect mediated by the anti-CD19-calicheamicin θ-immunotoxin in vitro since the IC_{50} on $CD19^-$ Molt 3 cells is 1000× higher than on $CD19^+$ Nalm-6 cells (Table 2). In summary, we could demonstrate that the conjugation affected neither antigen binding of the anti-CD19 portion of the immunotoxin nor the cytotoxicity of calicheamicin θ, resulting in an immunotoxin with antigen-specific cytotoxic potential similar to free calicheamicin θ.

Effect of Anti-CD19 Calicheamicin θ Immunotoxin in a Leukemia Xenograft Model. The efficacy of CD19-targeted calicheamicin θ therapy was evaluated in a leukemia xenograft model. For this purpose, CD19-positive Nalm-6 B-cell leukemia was established in SCID mice by intravenous injection (1×10^6 Nalm-6 cells). Treatment was initiated 5 days after tumor cell inoculation by two intraperitoneal injections of anti-CD19 calicheamicin θ immunotoxin per mouse (10, 3, and 1 μg/kg; dose indicates linked calicheamicin θ) on days 5 and 7. Controls received an equivalent amount of nonspecific anti-GD2 calicheamicin θ immunotoxin, unconjugated anti-CD19 antibody (500, 150, and 50 μg/kg), and PBS. A control group with free calicheamicin θ was not included, based on previous reports demonstrating high toxicity when used at an equivalent amount to 10 μg/kg calicheamicin θ immunotoxin (all animals died) and lack of activity when used at lower doses (*24*, *30*). We selected the highest dose of 10 μg/kg calicheamicin θ immu-

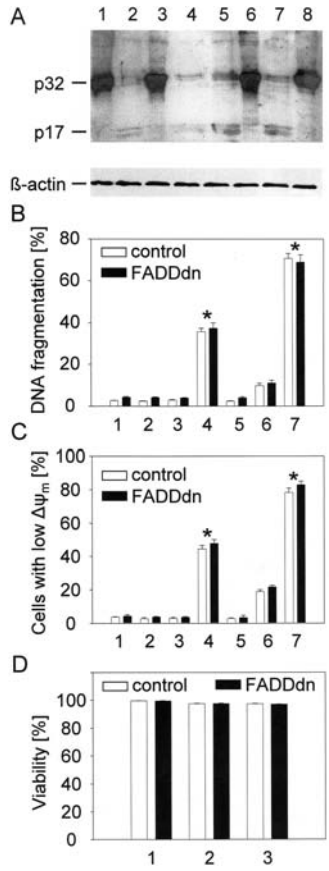

Figure 5. Apoptotic pathway induced by CD19 targeted calicheamicin θ. (A) The effect of anti-CD19 calicheamicin θ immunotoxin on processing of caspase 3 was determined in CD19-positive cALL lymphoblasts of a relapsed patient by Western blot. Procaspase 3 (p32) and activated caspase 3 fragment (p17) are indicated. 1, control (untreated); 2, anti-CD19 calicheamicin θ immunoconjugate (2 pmol/L); 3, anti-CD19 (2 pmol/L); 4, calicheamicin θ (2 pmol); 5, anti-CD19 calicheamicin θ immunoconjugate (20 pmol/L); 6, anti-CD19 (20 pmol/L); 7, calicheamicin θ (20 pmol/L); 8, control (untreated BJAB cells). Induction of DNA fragmentation after treatment for 72 h (B) and loss of mitochondrial membrane potential after treatment for 48 h (C) with anti-CD19 calicheamicin θ immunotoxin was investigated in CD19-positive BJAB cells in the presence (closed bars) and absence (open bars) of dominant negative FADD death receptor expression. 1, control; 2, anti-CD19 (1 pmol/L); 3, calicheamicin θ (1 pmol/L); 4, anti-CD19 calicheamicin θ immunotoxin (1 pmol/L); 5, anti-CD19 (10 pmol/L); 6, calicheamicin θ (10 pmol/L); 7, anti-CD19 calicheamicin θ immunotoxin (10 pmol/L). Data represent mean ± SD ($n = 3$). The difference between anti-CD19 calicheamicin θ immunotoxin and all controls was statistically significant (* $p < 0.01$). (D) Cytotoxic effects of calicheamicin θ immunotoxin were analyzed at concentrations levels with established proapoptotic effect. 1, control; anti-CD19 calicheamicin θ immunotoxin 2, 1 pmol/L; 3, 10 pmol/L. Data represent mean ± SD ($n = 3$).

notoxin based on previous reports demonstrating no toxicity at this level (*24*).

Treatment of mice ($n = 6$/group) with established CD19-positive leukemia using 10 μg/kg anti-CD19 calicheamicin θ immunotoxin (2×, days 5 and 7 after tumor cell inoculation) induced a 3-fold prolongation of the life span with all animals alive at the end of the experiment (Figure 4). Specificity of this therapy was demonstrated, since mice treated with an equivalent amount of anti-GD2 calicheamicin θ immunotoxin used as nonspecific control was far less effective at the 10 μg/kg dose and ineffective at the 3 and 1 μg/kg doses, respectively. Similarly, the use of unconjugated anti-CD19 antibody at dose levels of 3 and 1 μg/kg was ineffective. There was a small effect by unconjugated anti-CD19 antibody at the dose level of 10 μg/kg, related to antibody-mediated immunological effector functions. However, the anti-CD19 calicheamicin θ immunotoxin was far more effective. The treatment was well-tolerated, since none of the mice receiving 10, 3, and 1 μg/kg calicheamicin θ immunotoxin presented with a drop in body weight of >20% as shown by weight loss measurements (data not shown). The antileukemia effect following anti-CD19 calicheamicin θ immunotoxin therapy was dose-dependent and highly significant in all treatment groups ($p < 0.01$).

Mechanism of Antileukemic Effects Mediated by Anti-CD19 Calicheamicin θ Immunotoxin. The mechanism of antileukemic effects mediated by the anti-CD19 calicheamicin θ immunotoxin was determined on CD19-positive primary ALL blasts and CD19-positive BJAB cells in vitro. We could demonstrate that the anti-CD19 calicheamicin θ immunotoxin induced apoptosis in CD19-positive leukemia cells (Figure 5). Induction of apoptosis by anti-CD19 calicheamicin θ immunotoxin involves processing of caspase 3 as indicated by a decrease in procaspase 3 and increase in 17 kDa active caspase subunit (p17) signals. Interestingly, the level of DNA fragmentation and loss of mitochondria membrane potential was more than 5× higher than that observed with an equivalent amount of free calicheamicin θ (Figure 5B,C), consistent with rapid internalization of the anti-CD19 antibody immunotoxin. The induction of apoptosis was demonstrated to be independent from death-receptor/FADD-mediated signals, since the immunotoxin was as effective in induction of apoptosis parameters in BJAB/FADD-dn cells with dominant negative death receptor domains as in BJAB control cells (Figure 5B,C). Results of control experiments with Fas ligand and anti-CD95 mAb for validation of experiments with BJAB/FADD-dn cells shown here were previously reported (*29*). Importantly, these proapoptotic effects were observed under time and concentration conditions with no effect on cell viability (Figure 5D).

DISCUSSION

In order to solve the problem of poor outcome in relapsed pediatric ALL patients, targeting of CD19 constitutes an appealing approach based on the following considerations. The cell surface glycoprotein of the immunoglobulin superfamily CD19 is absent from hematopoietic stem cells, and in healthy individuals, its presence is exclusively restricted to the B-cell lineage and follicular dendritic cells. Furthermore, CD19 is not shed from the cell surface and is rarely lost during neoplastic transformation (*31*). The antigen is expressed on most B-cell malignancies, including cells from patients with acute lymphoblastic leukemia (ALL) (*32*). Importantly, CD19 is consistently expressed on B-precursor and mature B-ALLs, whereas CD20 is frequently absent on B-precursor ALLs. Furthermore, high levels of CD19 expression remains unchanged as shown in diagnostic and relapse flow cytometry phenotypes in childhood ALL (*33*).

The use of CD19-specific antibody conjugates has been evaluated for immunotherapy of B-lineage malignancies with promising results (*34*−*40*). This also applies to anti-CD19 immunotoxins with idarubicin, ricin A, blocked ricin (dose range 20−50 μg/kg) (*34, 35, 41*), deglycosylated ricin A chain (MTD 16 mg/m^2 = 320 μg/kg) (*36*) and genistein (dose range 100−320 μg/kg) (*37*), which showed efficacy in vivo. Here, we report for the first time construction, effect, and mechanism of a novel anti-CD19 immunotoxin using calicheamicin θ (Figures 1−4). The efficacy over the reported immunotoxins was improved, since a dosage of 10 μg/kg was sufficient to eradicate CD19 leukemia in mice (Figure 4). This is mainly a result of the highly potent calicheamicin θ (Tables 1 and 2), a synthetic derivative of calicheamicin γ.

The use of calicheamicin in the treatment of adult and pediatric B-cell malignancies is well-established (*37, 42, 43*). In fact, calicheamicin γ, which is up to 3 logs less potent than calicheamicin θ {Nicolaou, 1994 174 /id}, is currently used as

the cytotoxic component of an immunotoxin targeting CD33 (gemtuzumab ozogamicin, CMA-676, Mylotarg). Efficacy and tolerability of gemtuzumab ozogamicin has been evaluated in children with relapsed or refractory myeloid leukemia, with a promising response rate of 25% (*42*). An important aspect for the efficacy of the gemtuzumab ozogamicin is rapid internalization and subsequent induction of cell death (*44*). We could also demonstrate rapid internalization of the anti-CD19 antibody used for the calicheamicin θ anti-CD19 immunotoxin (Figure 1). This translated into excellent efficacy and specificity in a xenograft model of CD19-positive leukemia in mice (Figure 4). Specifically, mice treated with 10 μg/kg anti-CD19 calicheamicin θ immunotoxin were free of leukemia in contrast to controls treated with an equivalent dose of a nonspecific control immunotoxin (anti-GD2 calicheamicin θ immunotoxin). This control immunotoxin showed a minor nonspecific antileukemic effect at the highest dose level (10 μg/kg) (Figure 4) most likely due to a prolonged half-life of calicheamicin θ as a result of its conjugation to a monoclonal antibody. Importantly, induction of death receptor independent apoptosis proceeding through the mitochondrial pathway in a caspase 3 dependent mechanism was demonstrated for the anti-CD19 calicheamicin θ immunotoxin (Figure 5). The apoptotic pathways observed with anti-CD19 calicheamicin θ immunotoxin were no different from those delineated for unconjugated calicheamicin θ (*29*). Importantly, these effects were observed at picomolar concentrations and were over 5-fold higher than effects observed with free calicheamicin θ (Figure 5), indicating the important role of internalization in this process. These findings establish proof of concept that targeting of CD19 using a calicheamicin θ immunotoxin may be effective against CD19-positive malignancies. Considering established work with calicheamicin γ immunotoxin (gemtuzumab ozogamicin) and in view of the advantages of calicheamicin θ over calicheamicin γ, this study provides an important baseline for the clinical development of an anti-CD19 calicheamicin θ immunotoxin.

ACKNOWLEDGMENT

We would like to thank Anne Strandsby for excellent technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft, Emmy-Noether Program, Lo 635/2-1 (H.N.L) and Kinderkrebs Neuroblastomforschung e.V. Kinderleben e.V. Berlin (A.P.) and AIP fellowships from the Charité (K.B.).

Azide-terminated poly(*tert*-butyl acrylate) was synthesized via atom transfer radical polymerization (ATRP). Subsequent deprotection was performed to yield poly(acrylic acid) (PAA) possessing a reactive chain-end. A one-pot sequential amidation of the PAA with the amine derivatives of a near-infrared fluorescent dye (ADS832WS) and glucose produced NIRF dye-incorporated water-soluble copolymers. End-group modifications were performed to produce alkyne/biotin-terminated copolymers which were further employed to generate dye-incorporated polymer−protein hybrids via the biotin−avidin interaction with avidin or "click" bioconjugation with azide-modified BSA. We have overcome two fundamental limitations in the synthesis of bioconjugates: (a) the basic restriction in the diversity of copolymers which can be synthesized for producing bioconjugates, (b) the limitation in the number of dyes/drug molecules that can be attached per protein molecule. The copolymers possessed enhanced optical properties compared to the dye due to increased solubility in water. Potential utility of these copolymers and conjugates in multiwell plate based assays, cell surface imaging and in vivo animal imaging were explored.

INTRODUCTION

Polymer−protein hybrids are a newly emerging class of bioconjugates with several applications in biotechnology, biopharmaceutical chemistry, and other life science areas (*1*−*4*). There are, however, some fundamental limitations in the current methodologies available for the synthesis of these hybrids: (a) Using current technologies, the number of copies of cytotoxic drugs/dyes that can be chemically conjugated to a protein (antibody, avidin/streptavidin, etc.) is limited. (b) There is a basic limitation in the diversity of copolymers that can be synthesized for bioconjugation. The former limitation arises from the fact that extensive modification of proteins with several copies of a drug/dye would cause deactivation of the active sites and because of the limited numbers of functional groups available per protein molecule for bioconjugation. The latter limitation (in the diversity of copolymers synthesized for bioconjugation) arises from (a) widely different reactivity between monomers and (b) the lack of reactivity of many biologically relevant acrylates (e.g., an acrylate derivative of the anticancer drug candidate curcumin can be synthesized but will not polymerize since the molecule is a radical quencher) (*5*). Biological properties (e.g., bioactivity and self-assembly) of polymer−protein hybrids demands the synthesis of well-defined polymers for bioconjugation (*6*−*8*). In the early embodiments, the polymer component of the conjugates was synthesized via uncontrolled free radical polymerization (*9*).

The synthesis of well-defined polymer−protein hybrids in which the polymers are synthesized via controlled radical polymerization methods (such as atom transfer radical polymerization [ATRP] or reversible addition−fragmentation polymerization [RAFT] is a rich newly emerging field of research (*10*−*19*). The synthesis of living polymer−protein hybrid materials has, however, been restricted to a few acrylate/methacrylate monomers such as poly(ethylene glycol) acrylate/methacrylate and poly(*N*-isopropyl) acrylamide; the recently reported streptavidin conjugates with biotinylated polymers serve as examples (*10, 12, 13*).

Herein, we present a general methodology for significantly increasing the number of dye/drug molecules that can be attached per protein molecule. The diversity of copolymers that can be synthesized for bioconjugation to proteins has also been considerably expanded. The synthesis of poly(acrylic acid)-based near infrared fluorescence (NIRF) dye and glucose incorporated novel copolymers that were further employed for bioconjugation to avidin and bovine serum albumen (BSA) demonstrates this breakthrough. It should be noted that near-infrared (NIR)-absorbing dyes have opened new avenues in optical imaging with direct applications in pharmacology, cellular biology, and diagnostics as living subjects can be monitored with safe, noninvasive optical imaging/contrasting techniques (*20*−*23*). In vitro and in vivo imaging with cyanine-based NIRF dyes are advantageous due to significant reduction of background absorption, enhanced fluorescence, the availability of low-cost sources of irradiation, the versatility of different reporter probes, large molar extinction coefficients, and moderate-to-high fluorescence quantum yields (*24*−*26*).

MATERIALS AND METHODS

Synthesis. Detailed information on the materials used, synthetic procedures, and compound characterization data are provided in the Supporting Information. A few representative experiments are presented here.

Synthesis of Azide-Terminated Poly(*tert*-butyl acrylate) (2). A 100 mL flask fitted with a stopcock was flame-dried under vacuum and allowed to cool at ambient temperature under argon. The flask was charged with CuBr (115 mg, 0.8 mmol). Under positive pressure of argon, a solution of 2-bromo-2-methylpropionic acid 2-[2-(2-azidoethoxy)ethoxy] ethyl ester (118 mg, 0.36 mmol) dissolved in *tert*-butyl acrylate (4 mL, 27.55 mmol) was added via syringe, followed by the addition of 1,1,4,7,7-pentamethyldiethylenetriamine (PMDETA) (0.17 mL, 0.8 mmol). Following three freeze−pump−thaw degassing cycles, the reaction was allowed to stir for 2 h 10 min at 60 °C. The polymerization was quenched by submerging the flask in liquid nitrogen; the mixture was allowed to warm to ambient temperature and diluted with tetrahydrofuran. CupriSorb was added and stirred ca. 30 min to remove copper complex. After filtration, the mixture was poured into a 15% methanol, deionized water solution, and a white solid product was precipitated. The polymer was further purified via reprecipitation and dried under vacuum; isolated yield was 2.18 g (47%). DPn = 64, M_n = 8586 g/mol, M_w/M_n = 1.21. ^{1}H NMR (600 MHz, $CDCl_3$): δ (ppm) 4.19 (s, 2H), 3.55−3.75 (m, 6H), 3.39 (t, 2H), 2.18−2.30 (bm), 1.85 (s), 1.28−1.62 (bm), 1.15 (s, 6H), 0.89 (m). FTIR (film, cm^{-1}): 3433, 2977, 2289, 2113 (azide), 1727, 1619, 1450, 1367, 1255, 1153, 845, 752.

Synthesis of Biotin-Terminated Poly(glucosamine)-Poly-(NIRF dye) Copolymer (6). The biotinylated poly(acrylic acid) polymer (**5**) (76 mg, 1.055 mmol of COOH), Near-infrared absorption dye (ADS832WS) (200 mg, 0.213 mmol), EDC·HCl (213 mg, 1.11 mmol), and HOBt (153 mg, 1.148 mmol) were dissolved in DMF (1.5 mL) in a r.b. followed by the addition of triethylamine (0.15 mL, 1.08 mmol). After stirring for 2 days at room temperature, D-(+)-glucosamine (230 mg, 1.067 mmol) (in water (2 mL) and DMF (1 mL) mixture solution) was added. EDC·HCl (200 mg, 1.043 mmol) was also added, and the mixture was stirred for another 3 days at room temperature. After stopping the reaction, the solution was transferred into a dialysis bag (MWCO 3.5 KDa), and the solution was dialyzed against a continuous flow of deionized water for 24 h. The dialyzed reaction mixture was filtered and lyophilized to yield greenish-brown crude product. The crude product was further purified with Sephadex LH-20 size-exclusion column with deionized water as eluent and lyophilized. Isolated yield: 249 mg. GPC (H_2O): M_n = 23 259 g/mol, M_w/M_n = 1.48. ^{1}H NMR (600 MHz, CD_3OD) δ (ppm) 8.98 (d), 7.18−8.34 (bm), 6.68 (m), 6.37 (m), 5.27 (d), 4.63 (s), 4.30 (s), 3.31−3.96 (m), 3.19 (m), 3.12 (m), 2.99−3.02 (m), 2.86−2.91 (m), 2.79 (s), 1.35−2.22 (m), 1.61 (d), 1.19−1.32 (m), 1.08 (m).

Synthesis of Alkyne-Terminated Poly(glucosamine)-Poly-(NIRF dye) Copolymer (10). Poly(glucosamine)-poly(NIRF dye) copolymer (60 mg, 3 μmol) was dissolved in 3 mL of *t*-BuOH/THF/H_2O (1:1:1) and stirred with propargyl ether (9.14 mg, 10 μL, 31.5 equiv), $CuSO_4 \cdot 5H_2O$ (5 mg, 0.02 mmol), Sodium ascorbate (4 mg, 0.02 mmol) in a r.b. flask under N_2 atmosphere at room temperature for 24 h. The reaction was stopped, and the reaction mixture was dialyzed extensively in deionized water using 10 kD MWCO membrane. The dialyzed mixture was further purified via Sephadex-LH 20 size exclusion chromatography and lyophilized. Yield: 42 mg (70%). GPC (H_2O): M_n = 19 988, M_w/M_n = 1.40. ^{1}H NMR (600 MHz, D_2O) δ (ppm): 1.03 (bs), 1.52−1.75 (bd), 2.01 (bs), 2.58 (s), 2.81 (s), 2.94 (s), 3.36 (s), 3.66−3.73 (bd), 5.06−5.23 (bm), 7.15−8.33 (m). FT-IR (cm^{-1}): 3299, 2928, (No N_3 peak ~2100), 1648, 1536, 1429, 1389, 1351, 1232, 1155, 1113.

Conjugation of Biotin-Terminated Copolymer 6 and Avidin. Avidin (1 mg) was dissolved in 0.25 mL of PBS buffer, pH 7.4. Polymer **6** (5.5 mg) was dissolved in 0.65 mL PBS buffer and slowly added. After 1.5 h at room temperature, the solution was extensively dialyzed using a 50 KDa MWCO membrane in deionized water, and the modified protein was analyzed by fast protein liquid chromatography (FPLC) and SDS-PAGE.

Synthesis of Protein−Polymer Conjugate; BSA-"Clicked"-Poly(glucosamine)-Poly(NIRF dye) Copolymer (14). BSA-azide (5 mg, approximately 1.5 μmol in azide) was incubated with alkyne-poly(glucosamine)-poly(NIRF dye) polymer (20 mg, 1 μmol) in Tris buffer (1800 μL, 0.1 M, pH 8) in the presence of TCEP (4 mM), "click" ligand (4 mM, dissolved in 200 μL of DMF) and copper sulfate (2 mM) for 16 h at 4 °C. The ligand was added before the addition of copper sulfate. The reaction mixture was then dialyzed using Spectra Por 6 dialysis membrane (MWCO 50 KDa) in PBS pH 7.4 for 48 h to remove excess of copper and ligand. The conjugate was further characterized via SDS-PAGE and Fast Protein Liquid Chromatographic system (Akta Purifier, Amarsham Bio-Science's) using HiPrep 26/10 Sephacryl S-200HR (GE Healthcare) size-exclusion column in PBS pH 7.4 as eluent buffer.

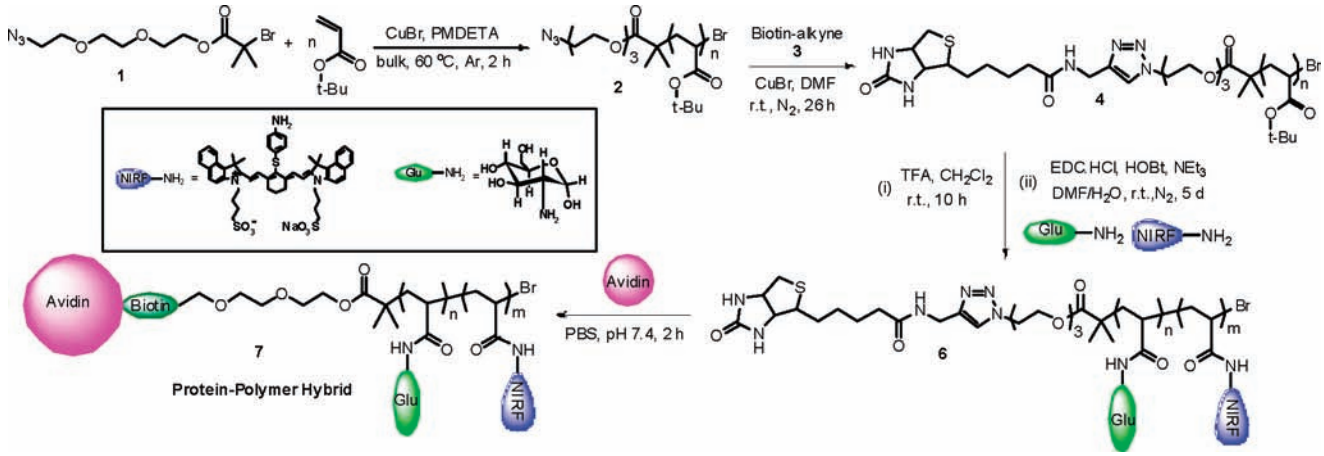
UV−vis−NIR and Fluorescence Spectroscopy of NIRF Dye and Polymer 9. NIRF dye (ADS832WS) (2.8 mg) was dissolved in 10 mL of deionized water to prepare a stock solution of 3 μM. Azide-terminated poly(glucosamine)-poly(NIRF dye) polymer **9** (11.7 mg; 5 dye molecule per polymer chain) was dissolved in 10 mL of deionized water to prepare a solution of 0.3 mM of effective dye concentration. The stock solution of NIRF dye was further diluted to 0.3 μM. The UV−vis−NIR spectra were obtained on an Agilent Technologies 845× UV−vis System using deionized water as blank. The fluorescence spectra of both the dye and the dye-incorporated polymer **9** were obtained on JobinYvon Horiba FluoroMax-3 instrument using the solutions containing 0.3 μM effective dye concentration.

Detection of Binding Affinity of Biotinylated Copolymers to Streptavidin-Coated Wells. Control poly(glucosamine)-poly(NIRF dye) polymer, biotin-terminated poly(acrylic acid)-poly (NIRF dye) polymer (**6a**), and biotin-terminated poly(glucosamine)-poly(NIRF dye) copolymer (**6**). All samples were prepared at a starting effective molar dye concentration of 0.2 mM in PBS (pH = 7.4); then, each of the three samples was successively diluted 10-fold to final concentrations of 0.02, 2.0 × 10^{-3}, and 2.0 × 10^{-4} mM. 50 μL of each solution was then added to the wells and incubated overnight at 4 °C. Then, the wells were washed four times with PBS containing 0.05% Tween 20. Finally, the wells were then visualized using the Odyssey imaging system (LI-COR, Lincoln, NE) at 800 nm.

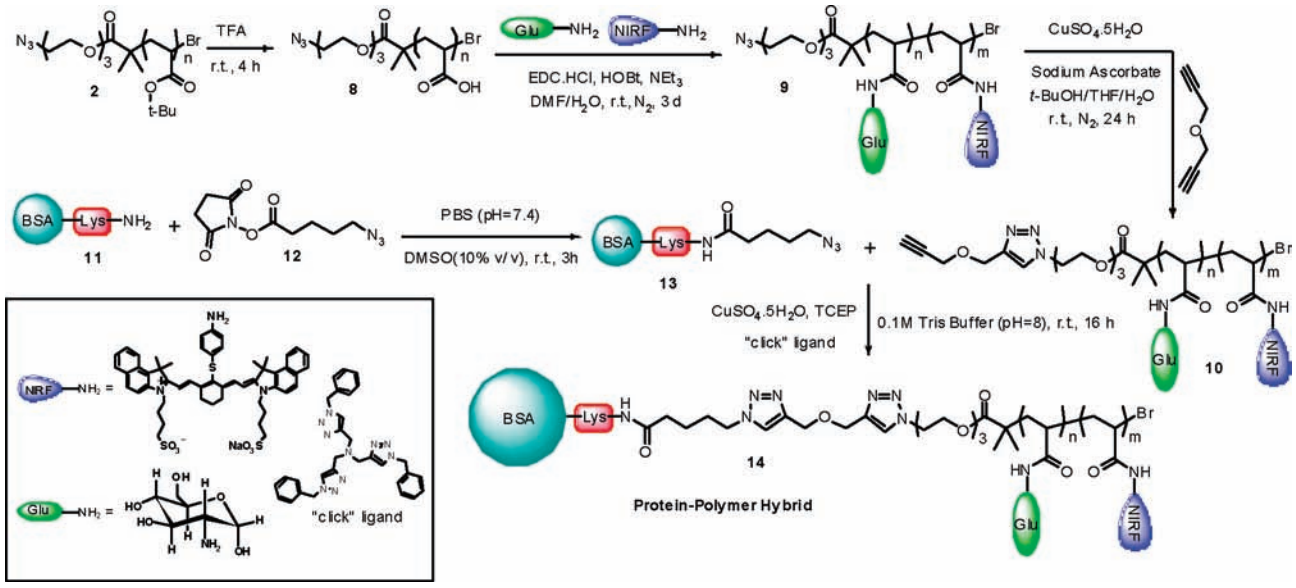
Test of the Utility of NIRF Dye-Incorporated Polymer in Noninvasive Imaging in Mice. Each of two female, six-month-old mice were injected with 200 μL of the NIRF dye, and the biotin-terminated poly(glucosamine)-poly(NIRF dye) polymer **6** (0.2 mM effective dye concentration in both cases) via the tail vein. Each mouse was then anaesthetized using a mixture of 15 μL Xylezene mixed with 54 μL Ketamine to reach a dose of 10 mg/kg body weight of Xylezene and 90 mg/kg bodyweight of Ketamine per mouse, and then scanned using a Odyssey scanner (Near IR) at wavelength 800 nm. To investigate the extent of fluorescence and the extent of catabolism of the polymer, the mice were scanned after 1 and 4 h. Another female six-month-old mouse (control mouse) was anaesthetized with the same mixture and then scanned to eliminate background fluorescence.

In Vitro Imaging Using Retinal Epithelial Cells. Retinal pigment epithelial cells were divided onto four wells and then allowed to grow for three days with regular feeding; the cells were then fixed using 2% PFA, then rinsed three times for five minutes each using PBS (pH = 7.4). The nonspecific binding sites were then blocked using a blocking buffer and incubated overnight. The blocking buffer was then removed, and well (**a**)

Scheme 1. Schematic Synthesis of NIRF Dye Incorporated Synthetic Polymer−Protein Hybrid via Biotin−Avidin Interaction



Scheme 2. Synthetic Representation of Protein−Polymer Hybrid via Bio-Orthogonal "Click" Reaction with NIRF Dye Incorporated Living Copolymer and BSA



only was incubated with the primary antibody and incubated overnight at 4 °C. The primary antibody was then rinsed 3 × 5 min each, and then the biotinylated secondary antibody was added to wells (a,b) and incubated overnight at 4 °C. Rinsing was performed for the excess secondary antibody using the same technique used for the primary antibody; then, 500 μL of Avidin (1 mg/mL) was added to each of wells (a,b,c) and incubated overnight at 4 °C, and excess avidin was washed off with PBS (pH = 7.4) 3 × 5 min each. Finally, 500 μL of poly(glucosamine)-poly(NIRF dye) copolymer **6** (0.1 mg/mL) was added to each of the wells (a,b,c,d) and incubated 2 h at 37 °C in a controlled temperature chamber. Excess polymer was washed off using PBS (pH = 7.4) 3 × 5 min each; fresh PBS was then added to the wells and scanned using Odyssey imaging system (LI-COR, Lincoln, NE) with detection in the NIR region at 800 nm.

RESULTS AND DISCUSSION

Our approach to these polymer−protein conjugates involved three steps: (1) the synthesis of well-defined living polymers containing reactive chain end and functional side chain pendant groups in which the chain end and side chain possesses orthogonal reactivity, (2) the attachment of a number of water-soluble, biocompatible moieties and imaging/therapeutic agents to the functional polymer side chains, and (3) the attachment of the polymers (via the reactive polymer chain end) with proteins to produce the final bioconjugates. Two parallel synthetic designs were employed to establish the feasibility of this concept. In the first design, poly(acrylic acid) with a single reactive biotin chain end was synthesized; straightforward post-polymerization modification of the polymer yielded the final NIRF dye-glucose copolymers for bioconjugation (Scheme 1). The biotinylated copolymers were employed to produce conjugates with avidin via the biotin−avidin interaction ($K_d \sim 10^{15}$) (*27*). In the second embodiment, an alkyne-terminated NIRF dye-glucose copolymer was synthesized and further conjugated to azide linker-modified BSA via the azide−alkyne triazole forming "click" bioconjugation reaction (*28*). The representation of both the copolymer-avidin (Scheme 1) and the copolymer-BSA (Scheme 2) hybrids portray the synthetic breakthrough that has been achieved: a copolymer composed of several copies of an imaging agent/drug displayed in a side chain polymer architecture is attached via a single link to avidin or BSA. Hence, on a per protein molecule basis a larger number of dyes/drugs are being attached using this strategy. In this Article, we also present the potential applications of representative polymers and conjugates in multiwell plate-based bioassays and in in vitro and in vivo imaging. To the best of our knowledge, this is the

first report describing the synthesis of well-defined NIRF dye incorporated living copolymer−protein hybrids.

Polymer−Protein Hybrids via Biotin−Avidin Interaction. The synthesis involved the polymerization of *tert*-butyl acrylate via ATRP (*29*) using an azide-incorporated initiator **1** to produce poly(*tert*-butyl acrylate) **2** (Scheme 1). The intact nature of the azide group in the polymer was confirmed by the presence of the azide peak at 2113 cm^{-1} in the IR spectrum of the polymer (see Supporting Information). The resulting polymer was reacted with an alkyne derivative of biotin **3** under [3 + 2] azide−alkyne triazole forming "click" conditions to produce a polymer with a single biotin chain end **4** (Scheme 1). Peaks arising from the biotin moiety (*14*) at 4.48 ppm and 4.31 ppm were observed in the ^{1}H NMR of **4**; peaks at 7.68 (s) and 7.44 (s) arising from the triazole protons (*30*) were also observed (see Supporting Information). Polymer **4** was treated with trifluoroacetic acid (TFA) to produce poly(acrylic acid) (PAA) with a single biotin chain end **5**. The rationale for synthesizing PAA with a single chain end is based on the facts that (a) PAA is FDA approved and is generally regarded as safe (GRAS); (b) amine derivatives of a broad spectrum of dyes and a wide range of therapeutic agents are readily available commercially and can be employed using amidation chemistry with PAA to produce copolymers; and (c) azidotriethylene glycol and the ATRP initiator with the azide group employed for the polymerizations are safe (many short chain azides are explosive). The amine derivatives, NIRF-NH_2 (ADS832WS) and Glu-NH_2 (D-(+)-glucosamine) were grafted to the PAA polymer **5** using standard amide coupling reagents 1-ethyl-3-(3-dimethyllaminopropyl)carbodiimide hydrochloride (EDC·HCl) and *N*-hydroxybenzotriazole (HOBt) in DMF to produce **6**. The polymers synthesized were characterized via ^{1}H NMR, gel permeation chromatography (GPC), and FT-IR spectroscopy (see Supporting Information).

On the basis of the GPC results, comparing the molecular weights of **4** and **6**, the percentage of the NIRF dye in the polymer **6** was determined to be ~17% per polymer chain (see Supporting Information). Polymers with higher dye loading numbers and a control polymer **6a** (PAA with dye alone) were also synthesized; however, those polymers were not readily soluble in water. Therefore, copolymer **6** was chosen for further studies due to its better solubility in water. It should be noted that, recently, side chain poly(alkyne) polymers were synthesized and various azide molecules were attached to the polymer backbone via "click" chemistry (*31*). The approach is restricted to a few azides because many small azides are potentially explosive (*31*). The copolymer−protein hybrid **7** was synthesized by incubating the copolymer **6** with avidin. The formation of a conjugate was indicated by higher molecular weight bands in SDS PAGE; the conjugate band which glowed when imaged using a NIRF imager was also visible following Coomassie staining indicating the presence of both polymer and protein at the same position (Figure 1B). The formation of the conjugate was further confirmed via size exclusion fast protein liquid chromatography (FPLC) where conjugate **7** eluted earlier (due to its higher molecular weight) in comparison to the synthetic polymer **6** and the control avidin sample (Figure 1A).

Polymer−Protein Hybrids via "Click" Reaction. In the second synthetic methodology (Scheme 2), the azide-terminated polymer **2** was treated with TFA to produce PAA with azide chain end **8**. The pendant carboxylic acid side chains of polymer **8** were grafted with NIRF-NH_2 and Glu-NH_2 via amide-coupling (EDC·HCl and HOBt) in DMF to produce poly(glucosamine)-poly(NIRF dye) copolymer **9**. In a separate reaction, BSA was modified by incubating with NHS-azide or NHS-alkyne heterobifunctional linkers to produce either azide-labeled BSA **13** or alkyne-labeled BSA **13a**, respectively. MALDI-TOF spectroscopy was used to estimate the average number of lysine residue modifications of the BSA (please note that BSA contains 65 lysine groups). Results indicate that on an average BSA was modified with ~35 alkyne or ~45 azide groups (see Supporting Information). Polymer **9** with a reactive azide chain end was incubated with alkyne-modified BSA **13a** under "click" bioconjugation conditions (*11*) but unfortunately without any success (lack of reaction confirmed via SDS-PAGE; data not shown). Earlier reports support the reduced/lack of reactivity of alkyne modified proteins in "click" bioconjugation reactions (*12*). To circumvent the above-mentioned problem, copolymer **9** was reacted with a large excess of dipropargyl ether under "click" condition to convert the azide-terminated copolymer to an alkyne-terminated poly(glucosamine)-poly(NIRF dye) copolymer **10**. The absence of the azide peak (~2100 cm^{-1}) in the FT-IR spectra confirmed the conversion of all the azide end groups to alkyne (see Supporting Information). The incubation of azide-linker modified BSA **13** with alkyne-terminated copolymer **10** finally produced the desired polymer−protein hybrid **14**. The formation of the conjugate was confirmed via FPLC (Figure 2) and SDS-PAGE (Figure 3). The conjugate **14** eluted earlier than both copolymer **10** and modified BSA **13** in the FPLC experiment. The unmodified BSA **11** eluted at the same volume as the modified BSA **13**; hence, it was not shown in the chromatogram (Figure 2). The SDS-PAGE gels were consistent with the FPLC results; the bands which glowed at 800 nm (lanes 4 and 8) also appeared when stained with

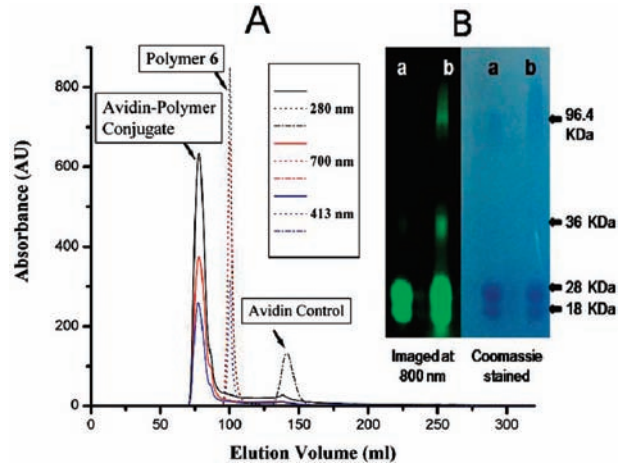


Figure 1. A. Size-exclusion FPLC (Hiprep 26/60 Sephacryl S-200 HR column) of avidin (dashed line), copolymer **6** (dotted line), and conjugate **7** (solid line). B. SDS-PAGE of avidin (lane a) and conjugate **7** (lane b).

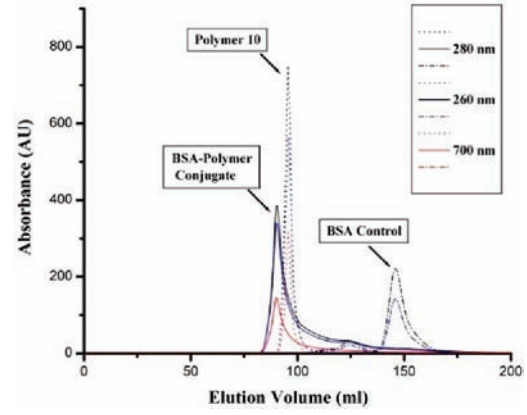

Figure 2. Size-exclusion FPLC (Hiprep 26/60 Sephacryl S-200 HR column) of azide-modified BSA **13** (dashed line), copolymer **10** (dotted line), and conjugate **14** (solid line).

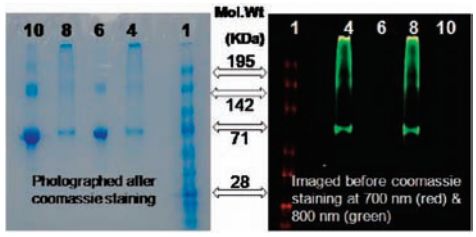

Figure 3. SDS-PAGE of conjugate **14** (lanes 4,8), mixture of azide modified BSA **13** and copolymer **10** without "click" reagents (lane 6), and unmodified BSA (lane 10).

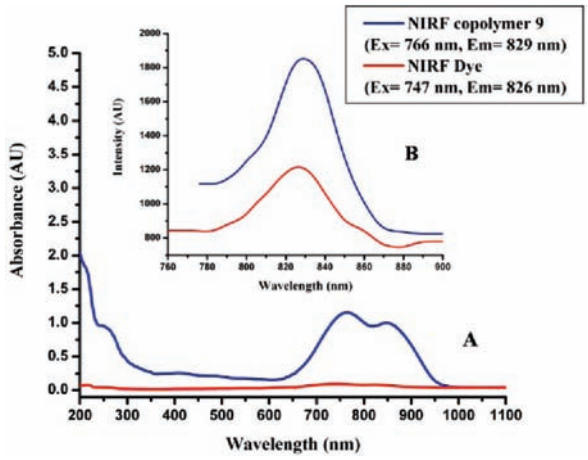

Figure 4. UV/vis/NIR absorption spectra (A) and fluorescence emission spectra (B) of NIRF copolymer **9** (blue line), NIRF dye (red line) in water at 25 °C. The effective dye concentrations in both the cases are identical (0.3 μM).

Coomassie (but the control lanes 6 and 10 did not glow at 800 nm). This confirmed the presence of both protein and polymer at the same ordinate in the conjugate samples. To confirm that copolymer **10** was indeed chemically bonded to the protein, we incubated the mixture of copolymer **10** and modified BSA **13** in the same ratio but without the "click" reagents and dialyzed the mixture with a 50 KDa MWCO membrane; in this case, no higher molecular weight conjugate bands were observed (lane 6).

UV and Fluorescence Study. We have investigated the absorbance and fluorescence emission profiles for the NIRF dye (ADS832WS) and the poly(glucosamine)-poly(NIRF dye) copolymer **9** (Figure 4). Copolymer **9** had superior solubility in water compared to the dye molecule. As a result, higher absorbance values were observed in the case of the polymer sample even though both solutions contained the same effective dye concentration of 0.3 μM (Figure 4A). A red shift of 19 nm (from 747 to 766 nm) in the absorbance maxima (λ_{max}) of the dye was also observed. Although the fluorescence emission intensity of copolymer **9** was higher than that of the dye as expected, the dye displayed larger Stokes shift (79 nm) compared to copolymer **9** (63 nm) (Figure 4B).

Multiwell Plate Binding Assay. Immobilization of the synthesized biotinylated neoglycopolymer was performed on streptavidin-coated multiwell plates where the plates were incubated with a 10-fold serial dilution of (a) nonbiotinylated poly(glucosamine)-poly(NIRF dye) copolymer control (b) polymer **6a** and (c) copolymer **6**. The wells were washed with PBS buffer to avoid nonspecific binding and scanned using an NIRF imaging system; see Figure 5A. The result indicated that the control polymer did not bind to the plates (low fluorescence intensity), whereas the biotin-terminated polymers remained bound to the streptavidin-coated plates, thereby resulting in

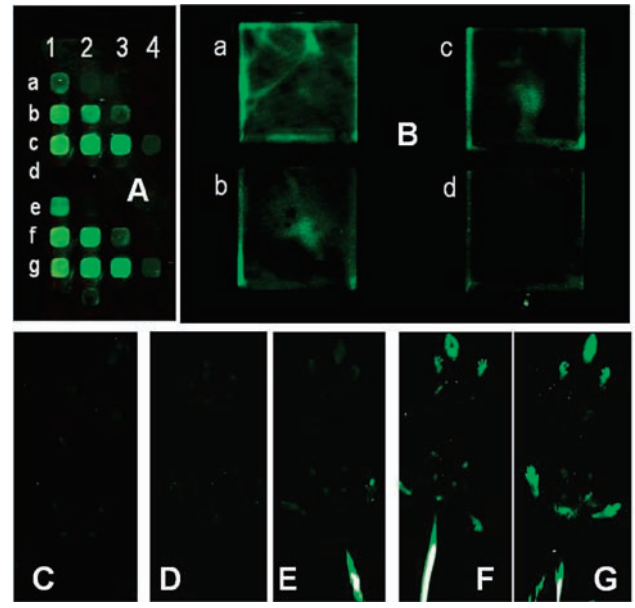

Figure 5. A. Streptavidin-coated multiwell plates treated with nonbiotinylated copolymer control (a,e), polymer **6a** (b,f), and copolymer **6** (c,g). Wells 1−4 correspond to a 10-fold serial dilution of the polymers. B. Fixed retinal pigment epithelial cells (ARPE-19) labeled using copolymer **6**. Slide a was incubated with primary, biotinylated secondary antibody, avidin, and copolymer **6** and imaged. Primary antibody was omitted in slide b; in slide c, the primary and biotinylated secondary antibodies were omitted; in slide d, the primary, biotinylated secondary antibodies and avidin were omitted prior to the copolymer **6** treatment step. C. The control mouse without an imaging agent. D,E. Mouse scanned 1 and 4 h after tail-vein injection with the NIRF dye, respectively. F,G. Mouse scanned 1 and 4 h after tail-vein injection with copolymer **6**, respectively. All the images were scanned using an odyssey NIRF imager at 800 nm.

higher fluorescence intensity. In the case of **6**, the fluorescence intensity was significantly higher than that of **6a** presumably because of the superior water/buffer solubility of **6**. The resulting immobilized neoglycopolymers can interact with complementary cell surface receptors/lectins (*32*). Hence, one can potentially create a convenient platform to study carbohydrate−receptor interactions; by varying the carbohydrates in the polymer and by using dye-modified lectins/cell receptors, which are fluorescence resonance energy transfer (FRET) (*33*) partners for the NIRF dye on the polymers, a range of lectins/cell receptor interactions can be explored.

In Vitro Imaging Study. The utility of copolymer **6** in in vitro imaging cells was also evaluated using retinal pigment epithelial cells. The cells were fixed and treated with primary antibody (2B-α5 rabbit polyclonal IgG), biotinylated secondary antibody, avidin, and poly(glucosamine)-poly(NIRF dye) copolymer **6** (Figure 5B). Slide a was incubated with primary, secondary antibodies, avidin, and copolymer **6**; in slide b, the primary antibody was omitted; in slide c, the primary and secondary antibodies were omitted; in slide d, the primary, secondary antibodies, and avidin were omitted prior to the copolymer **6** treatment step. Slides b, c, and d serve as controls. The results indicate that only slide a showed maximum fluorescence, while control slides show minimal fluorescence.

In Vivo Imaging Study. Polymer **6** also showed considerable promise in noninvasive in vivo imaging of mice: mice injected with the polymer could be imaged more efficiently than mice injected with the small molecule NIRF-NH_2 dye (Figure 5C−G; please note that since the mice were not shaved only the hairless body parts of mice were clearly visible). The polymer is superior for imaging mice compared to the low molecular weight dye probably because of the superior solubility of poly(glucosamine)-

poly(NIRF dye) copolymer **6** in water/blood/serum compared to the dye and because it is not cleared from the blood rapidly via kidney filtration. Employing the copolymer to produce conjugates (with antibodies) for tissue-specific targeted imaging is being currently pursued; this is beyond the scope of the current article.

CONCLUSION

In this study, we have overcome two fundamental limitations in the synthesis of bioconjugates: (a) the basic restriction in the diversity of copolymers which can be synthesized for producing bioconjugates and (b) the limitation that only a small number of dyes/drug molecules can be attached per protein molecule. To demonstrate our synthetic strategy, poly(glucosamine)-poly(NIRF dye) copolymers with reactive chain ends were synthesized via a one-pot amidation of poly(acrylic acid) with NIRF-NH_2 and Glu-NH_2. The copolymers were further employed to produce bioconjugates via (a) biotin−avidin interaction and (b) covalent linkage with BSA (triazole link, "click" bioconjugation reaction) and successfully characterized via NMR, FT-IR, GPC, FPLC, and SDS-PAGE techniques. The synthesized NIRF dye-based copolymers possessed enhanced optical properties compared to their monomeric counterparts. The copolymers were successfully immobilized for potential multiwell plate based assay experiments and utilized for in vitro and in vivo imaging. We are currently exploiting this general synthetic methodology to produce a range of bioactive copolymers and protein/antibody conjugates for applications ranging from tissue-specific imaging to targeted drug delivery.

ACKNOWLEDGMENT

This work was supported by NSF (CHE-0723028) and PSC−CUNY. We sincerely would like to thank Dr. K. B. Sharpless for providing us the "click" ligand and Mrs. Narmandakh Mijid Taylor, Ms. Samar Rizk, and Ms. Francoise Sidime for helping us with experiments.

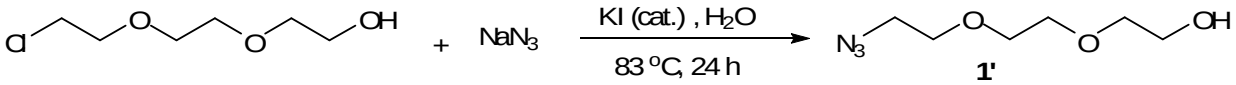
SPECTRAL DATA (^{1}H NMR, ^{13}C NMR, FT-IR) **S28**

GENERAL INFORMATION: Reagent-grade acetone, HPLC grade tetrahydrofuran, methylene chloride, N,N-dimethylformamide, methanol, ethylacetate were used without further purification. Solvents used for reactions were purified using *Puresolv*^{TM} system. 2-(2-(2-chloroethoxy)ethoxy)ethanol, 2-bromoisobutyryl bromide, *tert*-butyl acrylate, 1,1,4,7,7-pentamethyldiethylenetriamine, trifluoroacetic acid, D(+)-glucosamine, N-Hydroxybenzotriazole (HOBt), Copper (II) Sulfate pentahydrate and sodium ascorbate were obtained from Sigma-Aldrich. D(+)-Biotin was obtained from Acros Organics. 1-Ethyl-3-(3-dimethyllaminopropyl)carbodiimide hydrochloride (EDC.HCl) and Avidin were obtained from Pierce Biotechnology. Streptavidin coated 96-Well Plates were obtained from Sigma. NIRF-Dye (ADS832WS) was obtained from American Dye Source, Inc. CupriSorb® was obtained from Seachem Laboratories Inc. Silica gel 60 F 254 plates for thin-layer chromatography (TLC) were purchased from Fisher Scientific. Column chromatographic separations were performed using silica gel (Fisher) with a particle size of 0.040-0.063 mm. Nuclear magnetic resonance (NMR) spectra were recorded on Oxford NMR 600 (600 MHz), Varian Unity (200 MHz) and Varian Unity (300 MHz) spectrometers. Mass spectra (ESI-MS) were recorded using an Agilent LC/MS mass spectrometer. FPLC analysis was performed using an AKTA explorer from GE Biosciences. The Near Infrared images were taken using Odyssey Imaging system (LI-COR, Lincoln, NE). The Mol. Wt. of polymers were determined using Waters HPLC system equipped with either PLgel 5µm Mixed-D or PLaquagel-OH Mixed 8µm columns and Breeze software. Poly(methyl methacrylate) and poly(ethylene glycol) standards were used for organic soluble and water soluble polymers respectively. Agilent Technologies 845x UV-Vis spectrophotometer equipped with ChemStation Rev. A.10.01 software was used to record the UV/Vis/NIR spectra. Fluorescence was recorded on Jobin Yvon Horiba FluoroMax-3 and the data was analyzed with DataMax software. Bruker Daltonics- microflex™ series-MALDI-TOF MS instrument equipped with FlexAnalysis software was used to record the MS of proteins (samples were prepared by mixing the protein with Sinapinic acid (matrix) in apporx. 1:10 molar ratio).

SYNTHETIC PROTOCOLS:

1. SYNTHESIS OF *2-(2-(2-Azidoethoxy)ethoxy)ethanol* (1')

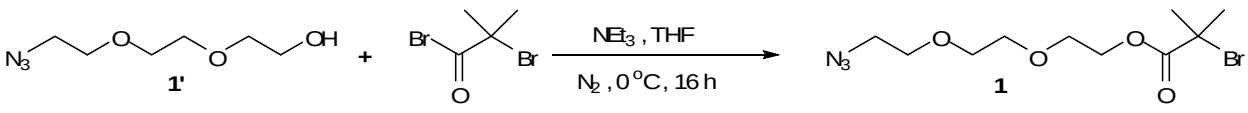
Protocol followed from: Sengupta, S., Raja, K. S., Kaltgrad, E., Strable, E. and Finn, M. G. (2005) Virus-glycopolymer conjugates by copper(I) catalysis of atom transfer radical polymerization and azide-alkyne cycloaddition. *Chem. Comm. 34*, 4315-4317.



A mixture of 2-(2-(2-chloroethoxy)ethoxy)ethanol (7.04 g, 41.72 mmol), sodium azide (13.65 g, 209.94 mmol) and potassium iodide (1.87 g, 11.25 mmol) in water (72 mL) was stirred at 83 ^{0}C for 24 h. The reaction mixture was extracted with ether, and the organic layer was washed with brine and then dried over anhydrous Na_2SO_4. The solvent was evaporated and the product was dried under vacuum to give colourless oil. The product was purified via column chromatography, CH_2Cl_2:MeOH, 95:5 was used as the eluent. Yield: 62%. ^{1}H NMR (600 MHz, $CDCl_3$): δ(ppm) 2.85-2.87 (t, 2H), 3.29-3.31 (t, 2H), 3.50-3.51 (m, 2H), 3.57-3.64 (m, 6H). ^{13}C NMR (150 MHz, $CDCl_3$): δ(ppm) 46.58, 57.58, 65.96, 66.31, 66.57, 68.55. ESI-MS m/z = 198.1 (M+Na); IR (KBr, cm^{-1}) 2104.

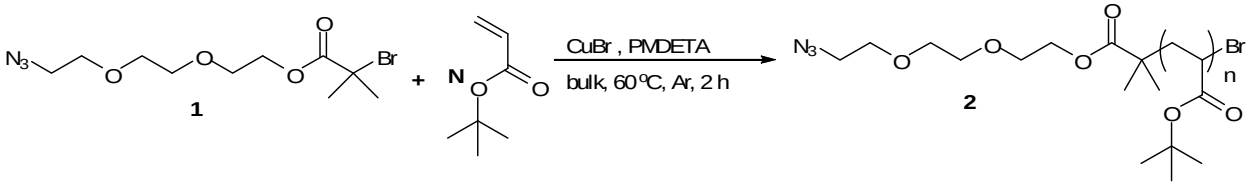
2. SYNTHESIS OF *2-Bromo-2-methylpropionic acid 2-[2-(2-Azidoethoxy)ethoxy] ethyl ester* (1)

Protocol followed from: Sengupta, S., Raja, K. S., Kaltgrad, E., Strable, E. and Finn, M. G. (2005) Virus-glycopolymer conjugates by copper(I) catalysis of atom transfer radical polymerization and azide-alkyne cycloaddition. *Chem. Comm. 34*, 4315-4317.



A solution of 2-bromoisobutyryl bromide (4.58 g, 19.9 mmol) and triethylamine (2.18 g, 21.5 mmol) in THF (5 mL) was cooled to 0 °C in a 2-necked round-bottomed flask. A solution of 2-[2-(2-azidoethoxy)ethoxy]ethanol (3 g, 17.1 mmol) in THF (5 mL) was added dropwise with stirring. The reaction mixture was then stirred under N_2 at room temperature for 16 h, filtered, and the solvent was removed by rotatory evaporator. The crude product was added to a cooled (ice bath) 5% aqueous (Na_2CO_3) solution and the resulting mixture was extracted with ethyl acetate (3 x 50 mL). The combined organic layers were washed with brine, dried over anhydrous (Na_2SO_4), and evaporated to provide **1** as dark-yellow oil. Yield: 5 g (90 %). ^{1}H NMR (600 MHz, $CDCl_3$): δ(ppm) 1.88 (s, 6H), 3.56-3.58 (t, 2H), 3.63 (s, 4H), 3.69-3.70 (t, 4H), 4.26-4.28 (t, 2H). ^{13}C NMR (150 MHz, $CDCl_3$): δ(ppm) 30.53, 42.57, 55.54, 64.89, 68.58, 68.60, 70.43, 70.48, 71.15, 171.37. ESI-MS m/z = 346.10 (M+Na)

3. SYNTHESIS OF *Azide terminated Poly(tert-butyl acrylate)* (2)



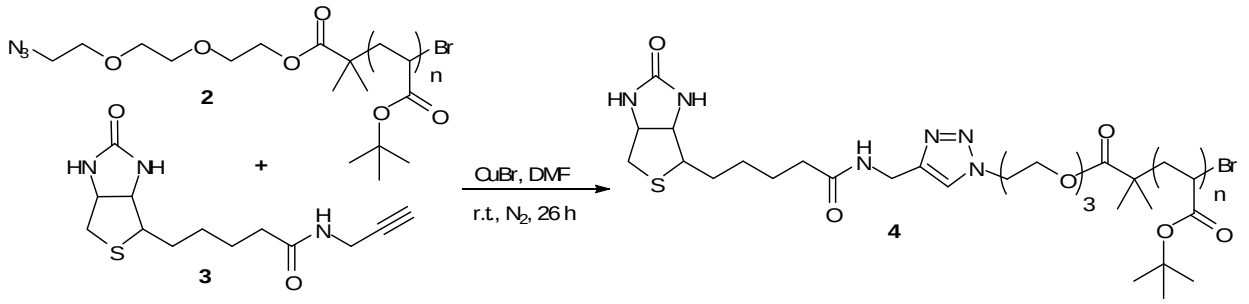
A 100 mL flask fitted with a stopcock was flame-dried under vacuum and allowed to cool at ambient temperature under Argon. The flask was charged with CuBr (115 mg, 0.8 mmol). Under positive pressure of Argon, a solution of 2-Bromo-2-methylpropionic acid 2-[2-(2-Azidoethoxy)ethoxy] ethyl ester (118 mg, 0.36 mmol) dissolved in tert-butyl acrylate (4 mL, 27.55 mmol) was added via syringe, followed by the addition of 1,1,4,7,7-pentamethyldiethylenetriamine (PMDETA) (0.17 mL, 0.8 mmol). Following three freeze-pump-thaw degassing cycles, the reaction was allowed to stir for 2 hour 10 minutes at 60 ^{0}C. The polymerization was quenched by submerging the flask in liquid N_2, the mixture was allowed to warm to ambient temperature, and diluted with tetrahydrofuran. CupriSorb® was added and

stirred ca. 30 minutes for removing copper complex. After filtration, the mixture was poured into a 15% methanol, deionized water solution, white solid product was precipitated. The polymer was further purified via reprecipitation and dried under vacuum; isolated yield was 2.18 g (47%), DPn= 64. M_n=8586 g/mol, M_w/M_n=1.21. (calculated using poly(methyl methacrylate) standards and THF as mobile phase). ^{1}H NMR (600 MHz, $CDCl_3$): δ(ppm) 4.19 (s, 2H), 3.55-3.75 (m, 6H), 3.39 (t, 2H), 2.18-2.30 (bm), 1.85 (s), 1.28-1.62 (bm), 1.15 (s, 6H), 0.89 (m). FTIR (film, cm^{-1}): 3433, 2977, 2289, 2113 (azide), 1727, 1619, 1450, 1367, 1255, 1153, 845, 752.

4. SYNTHESIS OF *5-(2-oxooctahydropyrrolo[3,4-d]imidazol-4-yl)-N-(prop-2-ynyl)pentanamide (Biotin-Alkyne)* (3)

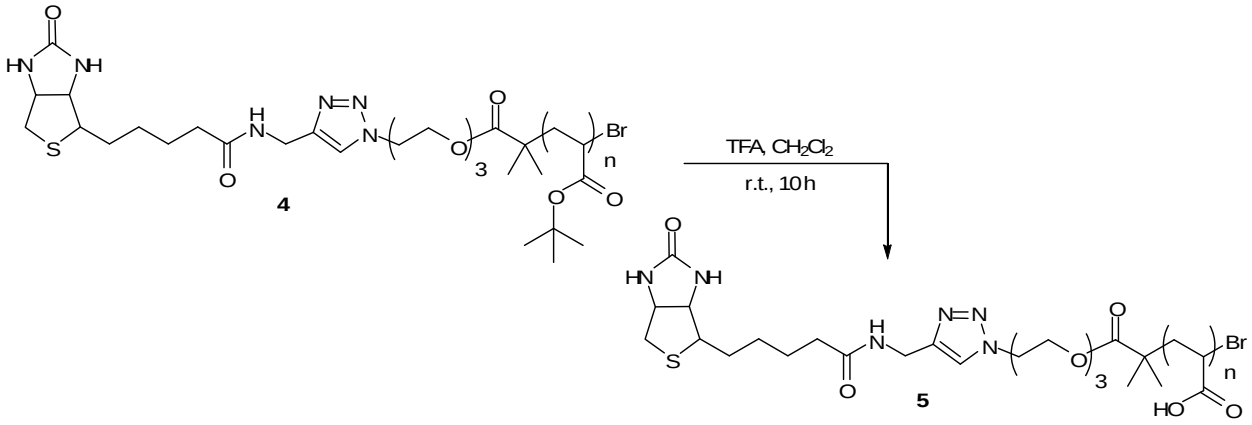
D(+)-biotin (186 mg, 0.76 mmol) was dissolved in 7 mL DMF and a solution of propargylamine (76 mg, 1.37 mmol) in CH_2Cl_2 (7 mL) was added to it followed by EDC.HCl (. After being stirred under N_2 for 24 h at room temperature, the reaction mixture was concentrated in vacuum and diluted by 30 mL of CH_2Cl_2 and the organic layer was washed by water (10 mL×3), dried over Na_2SO_4 and then concentrated in vacuum. The crude product was purified by flash column chromatography (MeOH/CH_2Cl_2=5/95-15/85) to obtain the product 160 mg (75%). ^{1}H NMR (600 MHz, CD_3OD): δ(ppm) 4.48-4.50 (dd, 1H), 4.29-4.31 (dd, 1H), 3.94 (d, 2H), 3.19-3.22 (dt, 1H), 2.91-2.94 (dd, 1H), 2.69-2.41 (d, 2H), 2.58-2.59 (t, 1H), 2.20-2.23 (t, 2H), 1.58-1.74 (m, 4H), 1.42-1.46 (q, 2H); ^{13}C NMR (150 MHz, CD_3OD): δ(ppm) 173.6, 164.1, 78.7, 70.1, 61.3, 59.6, 55.0, 39.1, 34.5, 27.7, 27.4, 24.7. ESI-MS m/z = 282.10 (M+H).

5. SYNTHESIS OF *Biotin Terminated poly(tert-butyl acrylate)* (4)



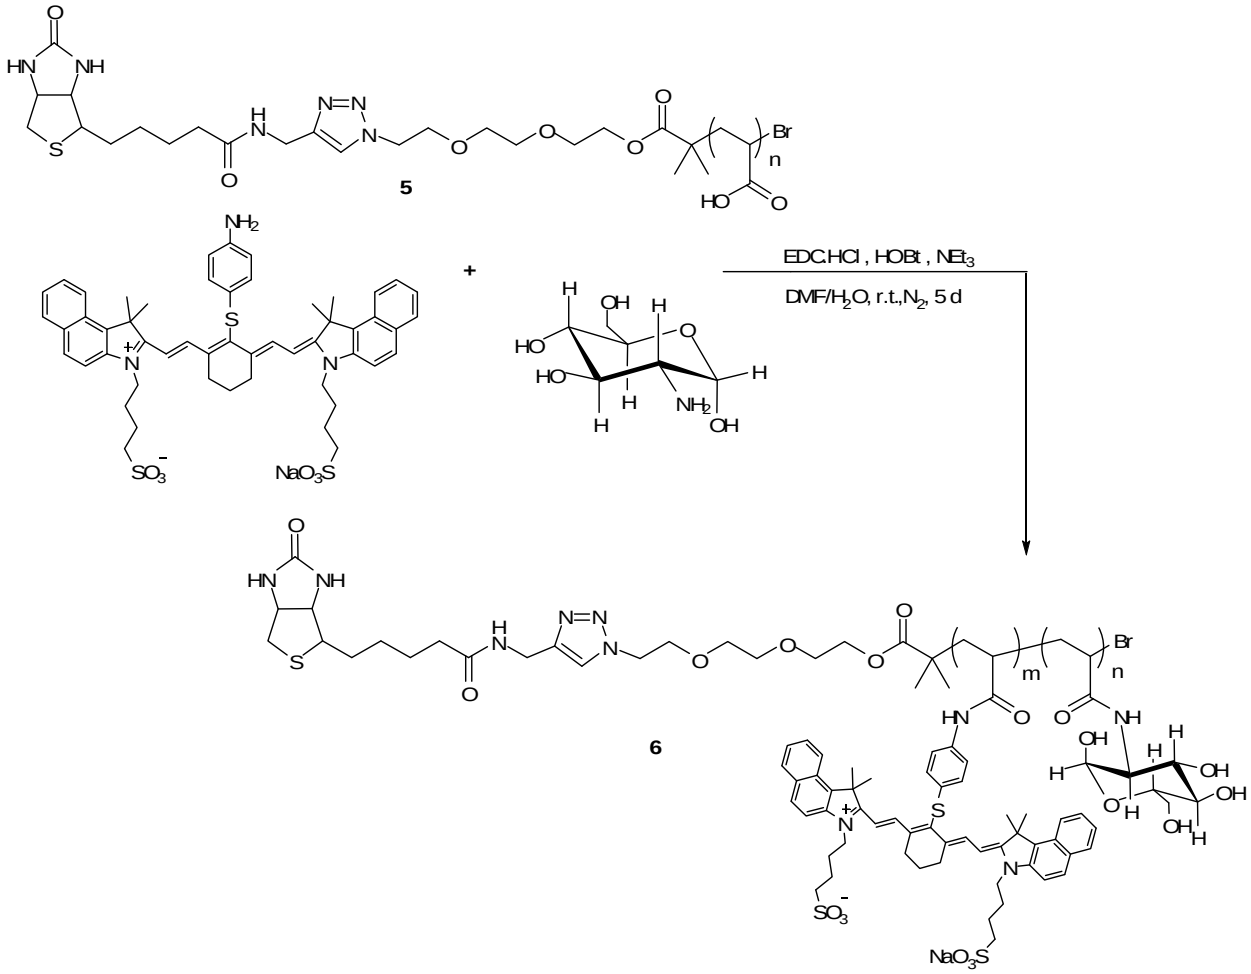
The azide-containing polymer (**2**) (565 mg, 0.073 mmol of azide groups), biotin-alkyne (25 mg, 0.087 mmol), CuBr (35 mg, 0.024 mmol), and 1,1,4,7,7-pentamethyldiethylenetriamine PMDETA (5.2 µL, 0.025 mmol) were placed in a round-bottom flask. The flask was closed with rubber septum and degassed with N_2. Deoxygenated DMF (3 mL) was added with an argon-purged syringe, and the reaction was stirred for 26 h at room temperature. The mixture was diluted with tetrahydrofuran, and CupriSorb® was added stirred ca. 30 minutes to remove copper complex. Solid residue was filtered off and the mixture was poured into a 15% methanol, deionized water solution where white solid product was precipitated. The product was further purified by re precipitation and dried over vacuum. Yield: 537 mg (92%). M_n=8850 g/mol, M_w/M_n=1.30. (calculated using poly(methyl methacrylate) standards and THF as mobile phase). ^{1}H NMR (600 MHz, $CDCl_3$): δ(ppm) 7.68 (s), 7.44 (s), 4.48 (s), 4.31 (s), 4.19 (s), 4.00 (s), 3.3803.64 (m), 3.11 (m), 2.73 (d), 2.18-2.30 (bm), 1.79 (s), 1.28-1.62 (bm), 1.10 (s), 0.89 (m). FTIR (film, cm^{-1}): 3433, 2977, 2932, 2720, 2360, 1991, 1728, 1479, 1449, 1392, 1367, 1256, 1150, 1037, 845, 734.

6. SYNTHESIS OF *Biotin Terminated poly(acrylic acid)* (5)



The polymer (**4**) (489 mg, 0.061 mmol) was dissolved in a solution of trifluoroacetic acid (1.5 mL, 19.5 mmol) in dichloromethane (13 mL). The reaction was allowed to stir at ambient temperature for 10 h. The solvent was removed under vacuum, and the resulting solid was dissolved in deionized water. The solution was transferred to a dialysis bag (MWCO 3.5 KDa), and dialyzed against a continuous flow of deionized water for overnight. The final polymer was isolated by lyophilization: Isolated yield 238 mg, (87%). ^{1}H NMR (600 MHz, $CDCl_3$): δ(ppm) 12.23 (bs), 7.85 (s), 7.78 (s), 4.47 (t), 4.26-4.30 (m), 4.04 (b), 3.38-3.82, (bm), 3.23-3.25 (t), 3.08 (s), 2.87 (d), 2.80-2.83 (t), 2.68-2.74 (m), 2.19 (bs), 2.07 (t), 1.74 (bm), 1.22-1.60 (bm), 1.07 (bm), 0.88 (m).

7. SYNTHESIS OF *Biotin Terminated poly(glucosamine)-poly(NIRF dye) copolymer* (6)



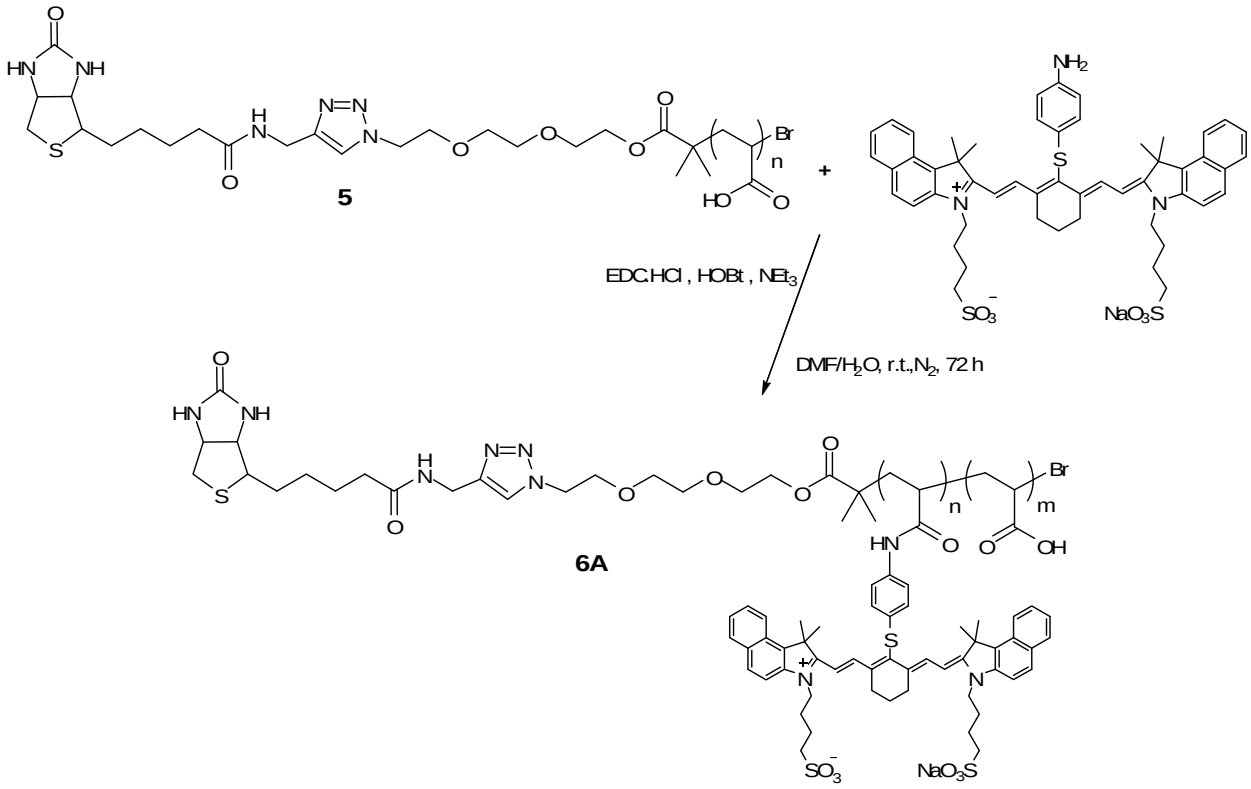
M_n=23259 g/mol, M_w/M_n=1.48. (calculated using poly(ethylene glycol) standards and 0.25 M $NaNO_3$, 0.01 M NaH_2PO_4, pH = 7 buffer as mobile phase). ^{1}H NMR (600 MHz, CD_3OD) δ(ppm) 8.98 (d), 7.18-8.34 (bm), 6.68 (m), 6.37 (m), 5.27 (d), 4.63 (s), 4.30 (s), 3.31-3.96 (m), 3.19 (m), 3.12 (m), 2.99-3.02 (m), 2.86-2.91 (m), 2.79 (s), 1.35-2.22 (m), 1.61 (d), 1.19-1.32 (m), 1.08 (m).

Comparing the *Mn*=8850 of polymer **4** and *Mn*=23259 of polymer **6,** the percent of dyes per polymer chain were calculated: subtracting the mol.wt. of the chain-end groups from *Mn* of polymer **4**, the number of repeat units in polymer **4** was calculated to be 64, this number was used as the total number of repeat units in the copolymer **6**, employing the following equation

the number of dye repeat unit per polymer chain was calculated: $ax + b(64 - x) = (Mn - c)$. Where x = number of dyes per polymer chain, a, b & c are mol.wts. of dye repeat unit, sugar repeat unit and chain-ends respectively, and the number percentage of dyes per polymer chain(please note that there are 64 repeat units per polymer chain) was calculated to be ~17%.

The quantity of different compositions in the copolymer was further quantified by comparing the peaks area of the protons from dye ADS832WS at 7.35-8.40 ppm, glucosamine at 2.89-3.73 ppm, and that of -C*H*$_2$-C*H*- protons from main chain of polymer at 1.82-2.10 ppm. Results showed the loading number of dye ADS832WS and glucosamine were 15.92% and 81.97% respectively.

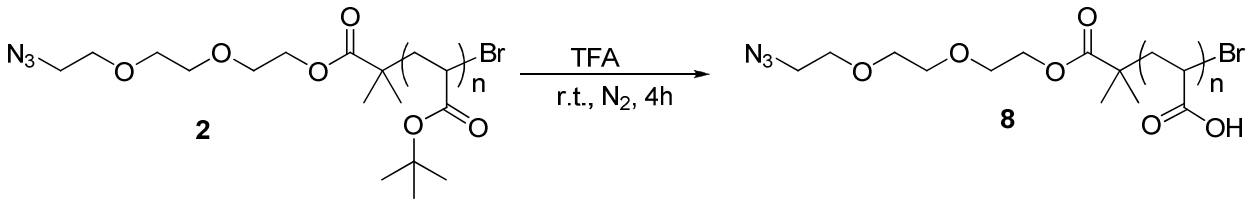
8. SYNTHESIS OF *Biotin Terminated Poly(acrylic acid)-poly(NIRF dye)* (6A)



The polymer (**5**) (76 mg, 1.055 mmol), Near infrared absorption dye (ADS832WS) (498 mg, 0.531 mmol), EDC·HCl (213 mg, 1.11 mmol), and HOBt (153 mg, 1.148 mmol) were

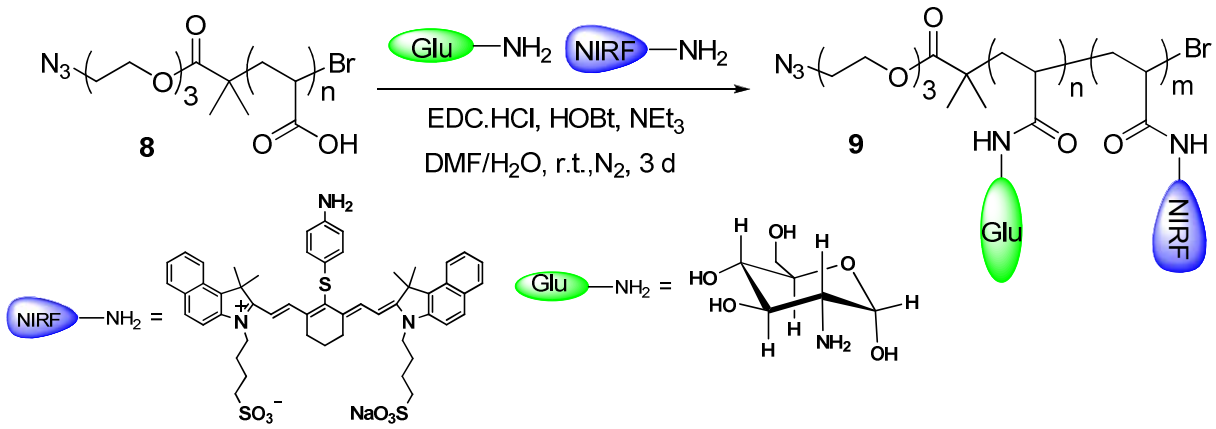
dissolved in DMF (1.5 mL) in a r.b. followed by the addition of Triethylamine (0.03 mL, 0.17 mmol). The mixture was stirred 72 h at room temperature under N_2. After stopping of the reaction, the solution was transferred into a dialysis bag (MWCO 3.5 KDa), and the solution was dialyzed against 10 exchanges of deionized water for 24 h. The dialyzed reaction mixture was filtered and lyophilized to yield dark purple cotton shaped crude product. The crude product was further purified with Sephadex^{TM} LH-20 size-exclusion column with deionized water as eluent. Yield: 40 mg. ^{1}H NMR (600 MHz, CD_3OD): δ(ppm) 8.83 (b), 7.13-8.23 (bm), 6.35 (b), 4.04-4.34 (b), 3.09-3.19 (bm), 2.55-3.07 (bm), 1.02-2.48 (bm).

9. SYNTHESIS OF *Azide Terminated Poly(Acrylic acid)* (8)



Trifluro acetic acid (2 ml, 27 mmol) of was added dropwise to a round bottom flask containing poly(*tert*-Butyl Acrylate) (0.3 g , 0.02 mmol). The reaction was stirred under N_2 for 4 hours. The reaction mixture was dialyzed using 3500 MWCO membrane in distilled water with several exchanges and finally the lyophilization yielded the polymer as white powder. Yield: 97% ^{1}H NMR (600 MHz, D_2O), δ (ppm): 1.14-1.18 (m, 8 H), 1.40 (s, 4 H), 1.61 (s, 46 H), 1.73 (s, 112 H), 1.90 (s, 40 H), 2.36 (s, 104 H), 3.67-4.17 (m, 12 H). FT-IR (cm^{-1}): 3022, 2117 (N_3), 1681, 1454.

10. SYNTHESIS OF *Azide Terminated poly(glucosamine)-poly(NIRF dye) copolymer* (9)



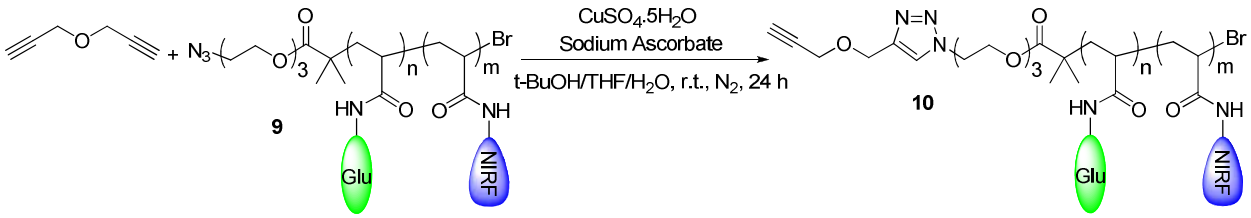
Azide terminated poly(acrylic acid) (72 mg, 0.96 mmol of COOH), NIRF dye (ADS832WS) (100 mg, 0.106 mmol), D(+)-Glucosamine (190 mg, 0.9 mmol), EDC.HCl (575 mg, 3.0 mmol) and HOBt (460 mg, 3.0 mmol) were dissolved in 10 ml of DMF in a round bottom flask and was degassed with N_2 and followed by dropwise addition of Et_3N (0.42 ml, 5 mmol). The reaction mixture was stirred at room temperature for 3 days. The reaction mixture was dialyzed extensively using 10K MWCO membrane and then purified by passing through a Sephadex LH20 column. Finally the product was isolated as dark purple colored fluffy powder after lyophilization. Yield: 76 %. ^{1}H NMR (600 MHz, D_2O), δ (ppm): 1.03 (bs), 1.52-1.66 (bd), 1.76 (s), 2.01(bs), 2.57(s), 2.80 (s), 2.93 (bs), 3.59 (s), 3.65 (s), 3.75 (s), 5.09-5.22 (bm). FT-IR (cm^{-1}): 3431, 2935, 2111 (N_3), 1714, 1538, 1504, 1443, 1393, 1353, 1266, 1233, 1166, 1140, 1115. GPC (H_2O): Mn= 19469, Mw= 25074, PDI= 1.28. (calculated using poly(ethylene glycol) standards and 0.25 M $NaNO_3$, 0.01 M NaH_2PO_4, pH = 7 buffer as mobile phase).

Comparing the *Mn*=8586 of polymer **2** and *Mn*=19469 of polymer **9,** the percent of dyes per polymer chain were calculated: subtracting the mol.wt. of the chain-end groups from *Mn* of polymer **2**, the number of repeat units in polymer **2** was calculated to be 64, this number was used as the total number of repeat units in the copolymer **9**, employing the following equation

the number of dye repeat unit per polymer chain was calculated: $ax + b(64 - x) = (Mn - c)$. Where x = number of dyes per polymer chain, a, b & c are mol.wts. of dye repeat unit, sugar repeat unit and chain-ends respectively, and the number percentage of dyes per polymer chain (please note that there are 64 repeat units per polymer chain) was calculated to be ~8%.

The quantity of different compositions in the copolymer was further quantified by comparing the peak area of the protons from dye ADS832WS at 7.38-8.40 ppm, glucose at 3.36-3.73 ppm to that of -C*H*$_2$-C*H*- protons from main chain of polymer at 1.52-2.09 ppm, and results showed the loading number of dye ADS832WS and glucose was 8.10% and 90.12% respectively.

11. SYNTHESIS OF *Alkyne terminated poly(glucosamine)-poly(NIRF dye) copolymer* (10)

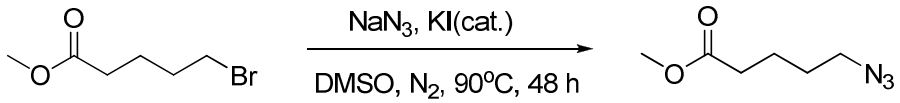


^{1}H NMR (600 MHz, D_2O), δ (ppm): 1.03 (bs), 1.52-1.75 (bd), 2.01(bs), 2.58 (s), 2.81 (s), 2.94 (s), 3.36 (s), 3.66-3.73 (bd), 5.06-5.23 (bm), 7.15-8.33 (m) . GPC: Mn= 19988, Mw= 28168, PDI= 1.40. (calculated using poly(ethylene glycol) standards and 0.25 M $NaNO_3$, 0.01 M NaH_2PO_4, pH = 7 buffer as mobile phase). FT-IR (cm^{-1}): 3299, 2928, (no N_3 peak ~2100), 1648, 1536, 1429, 1389, 1351, 1232, 1155, 1113. The absence of the azide peak (~2100 cm^{-1}) in the FT-IR spectra confirmed that all of the azide-end groups were reacted with dipropargyl ether. The polymer was used for further conjugation as it was.

The calculated dye loading was ~9% by number per polymer chain (please note that there are 64 repeat units per polymer chain) via the subtraction method. The quantity of different compositions in the copolymer was further quantified by comparing the peak area of the protons from dye ADS832WS at 7.38-8.40 ppm, glucose at 3.36-3.73 ppm to that of -CH_2-C*H*- protons from main chain of polymer at 1.52-2.09 ppm, and results showed the loading number of dye ADS832WS and glucose was 8.62% and 89.22% respectively.

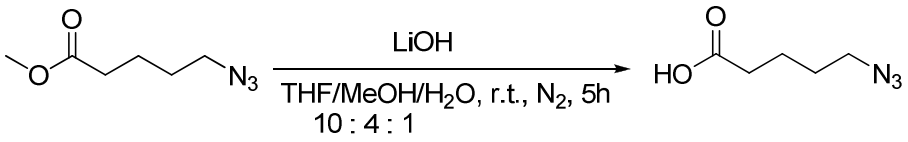
12. ***Synthesis of Methyl-5-azido valerate***

Protocol followed from: Seo, T. S.; Li, Z.; Ruparel, H. an Ju, J. (2003) Click Chemistry to Construct Fluorescent Oligonucleotides for DNA Sequencing. *J. Org. Chem. 68*, 609-612.



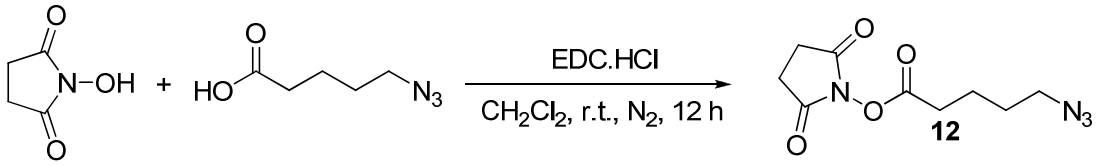
Methyl-5-bromovalerate (2.18 ml, 15.38 mmol) and Sodium azide (10 g, 10 eq) were dissolved in 20 ml DMSO in a round bottom flask and a pinch of KI was added. The mixture was stirred at 90 ^{O}C under N_2 atmosphere for 48 h. The reaction was cooled, diluted with water and extracted with hexanes. Organic layers were combined and dried over anhydrous Na_2SO_4. Solvent was evaporated to yield oily liquid. Yield: 2.2 g (91%); ^{1}H NMR (600 MHz, $CDCl_3$, 25°C): δ = 1.56-1.59 (m, 2H; CH_2), 1.65-1.67 (m, 2H; CH_2), 2.30 (t, *J* =12 Hz, 2H; CH_2), 3.24 (t, *J* =12 Hz, 2H; CH_2), 3.62 (s, 3H; CH_3); ^{13}C NMR (150 MHz, $CDCl_3$, 25°C): δ = 18.0, 24.2, 29.3, 47.0, 47.5, 169.5.

13. SYNTHESIS OF *5-Azido valeric acid*



Methyl-5-azido valerate (2g, 12.73 mmol) was dissolved in 150 ml THF/MeOH/H_2O (10:4:1) mixture and LiOH (3.05 g, 10 eq) was added. The mixture was stirred at room temperature for 5h. The reaction was stopped and acidified to pH =2 with H_2SO_4 and extracted with ethyl acetate. Organic layers were combined, dried over anhydrous Na_2SO_4, and finally the solvent was evaporated to yield oily product. Yield:1.1 g (60%); ^{1}H NMR (600 MHz, $CDCl_3$, 25°C): δ = 1.25 (t, *J* = 12 Hz, 1H), 1.64-1.67 (m, 2H; CH_2), 1.70-1.73 (m, 2H; CH_2), 2.40 (t, *J* =11 Hz, 2H; CH_2), 3.30 (t, *J* =11 Hz, 2H; CH_2); ^{13}C NMR (150 MHz, $CDCl_3$, 25°C): δ = 15.5, 23.2, 29.5, 34.9, 52.4, 180.8.

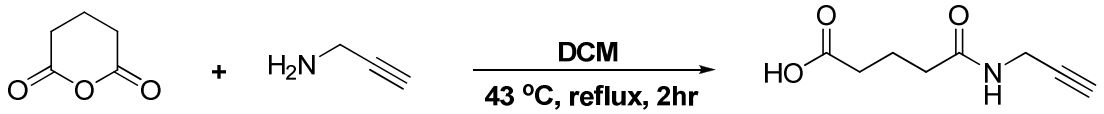
14. SYNTHESIS OF *NHS-Azide* (12)



5-Azidovaleric acid (0.8 g, 5.6 mmol) and EDC.HCl (1.61 g, 1.5 mmol) were dissolved in 10 ml dry DCM and *N*-Hydroxysuccinimide (0.65 g, 1.01 mmol) was added. The reaction was stirred at room temperature under N_2 atmosphere for 12 h. The reaction was stopped, diluted with water and extracted with EtOAc. The organic layers were combined and washed with brine and dried over anhydrous Na_2SO_4. Finally the solvent was evaporated to yield white sticky

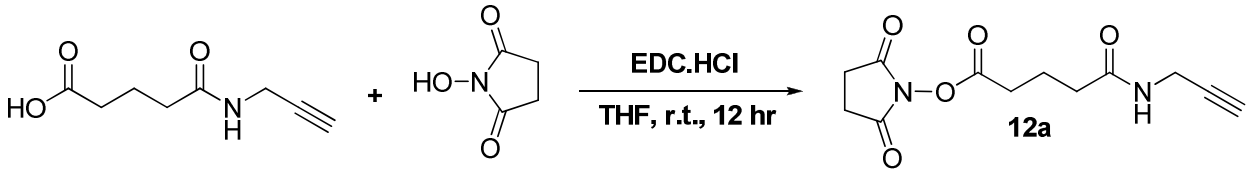
product. Yield: 1.2 g (90%); ^{1}H NMR (600 MHz, $CDCl_3$, 25°C): δ = 1.68-1.71 (m, 2H; CH_2), 1.80-1.84 (m, 2H; CH_2), 2.64 (t, *J* =12 Hz, 2H; CH_2), 2.81 (s, 4H; CH_2), 3.32 (t, *J* =11 Hz, 2H; CH_2); ^{13}C NMR (150 MHz, $CDCl_3$, 25°C): δ = 17.8, 21.6, 23.9, 26.4, 46.8, 164.2, 165.1. ESI-MS m/z = 241.10 (M+H)

15. ***Synthesis of 5-oxo-5-(prop-2-ynylamino)pentanoic acid***



Glutaric anhydride (2.34 g, 0.2 mmol) was dissolved in 100 ml dry DCM in a round bottom flask and degassed with Argon. Propargyl amine (1.4 ml, 20 mmol) was added and the reaction mixture was refluxed at 43 ^{o}C for 2 hours and then stirred at room temperature for 2 hours. The solvent was evaporated and the crude product was purified by column chromatography using 95:5 CH_2Cl_2/ MeOH. Yield: 75%. ^{1}H NMR ($CDCl_3$, 200 MHz) δ (ppm): 1.67-1.76 (m, 2H), 2.09-2.26 (m, 4H), 2.38-2.41 (m, 1H), 3.75-3.76 (d, 2H).

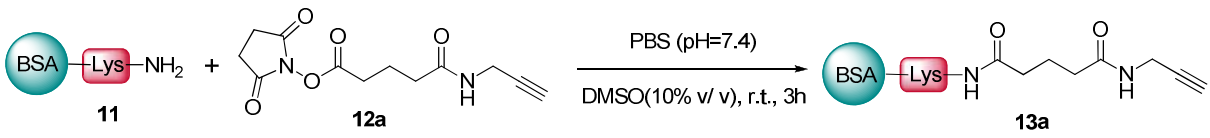
16. ***Synthesis of 2,5-dioxopyrrolidin-1-yl-5-oxo-5-(prop-2-ynylamino)pentanoate (NHS-Alkyne)(12a)***



N-Hydroxy succinimide (0.93 g, 8.05 mmol), 5-oxo-5-(prop-2-ynylamino) pentanoic acid (1.01 g, 6 mmol) and EDC.HCl (1.22 g, 6.4 mmol) were dissolved in 50 ml of THF in a round

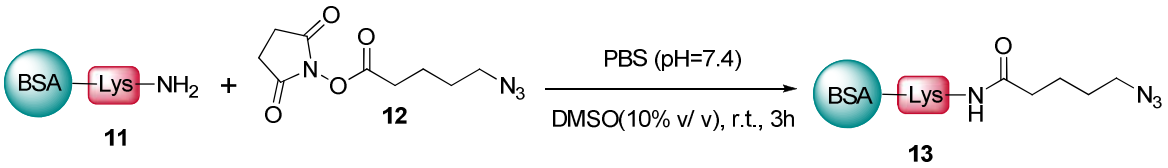
bottom flask and degassed with Ar. The mixture was stirred at room temperature for 12 hrs and then the solvent was evaporated. Further the crude reaction mixture was dissolved in DCM and washed thoroughly with water, saturated $NaHCO_3$, and brine. The organic layer was collected and dried over Na_2SO_4 and finally the solvent was evaporated to produce the product as white powder. Yield: 71 %. ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 2.12-2.19 (m, 2H), 2.23-2.25 (t, 1H), 2.34-2.38 (t, 2H), 2.69-2.75 (m, 2H), 2.89 (s, 4H), 4.06-4.89 (m, 2H), 6.22 (bs, 1H). ESI-MS m/z = 267.10 (M+H), 289.10 (M+Na).

17. *Synthesis of Alkyne modified BSA* (13A)

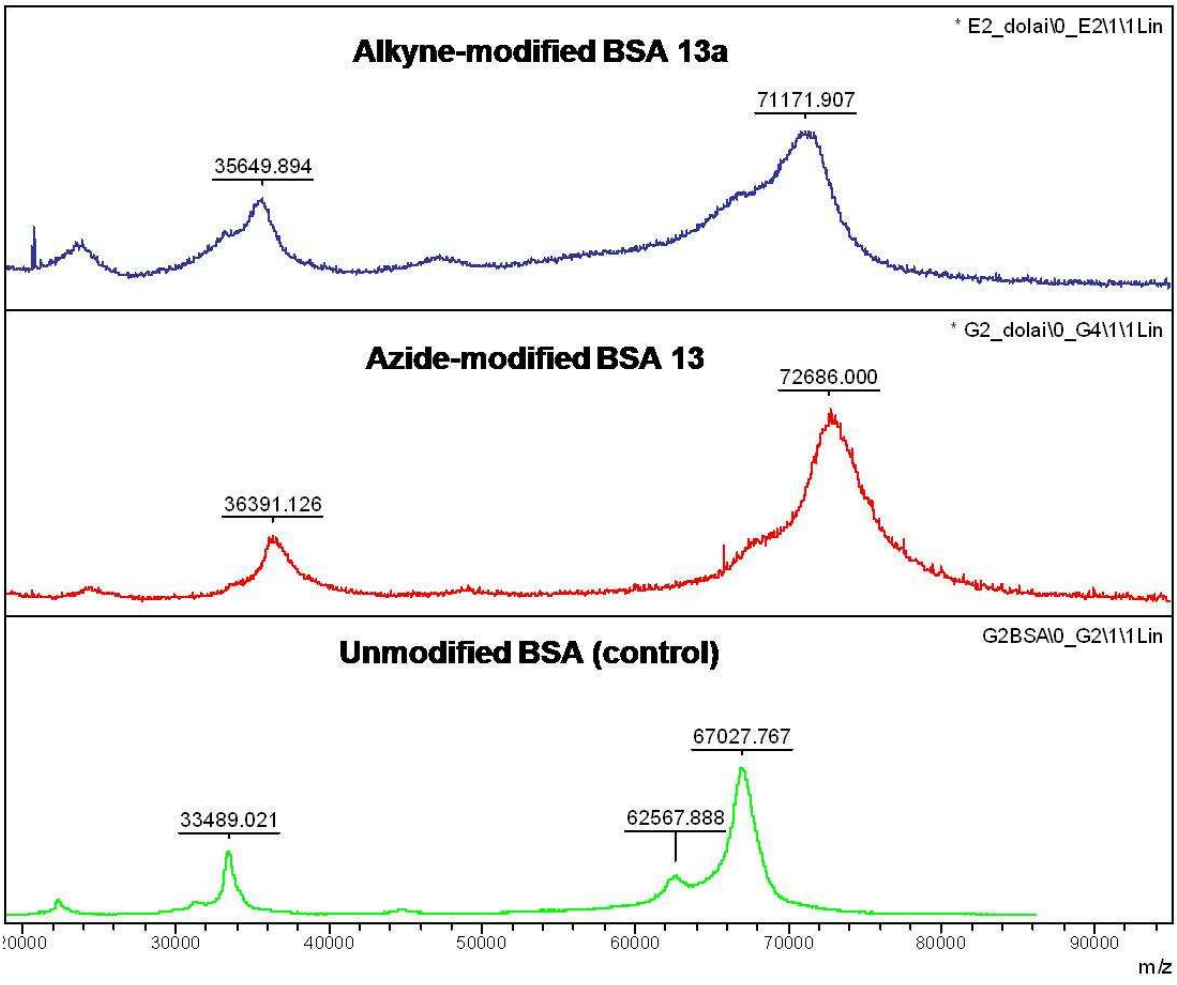


BSA (5mg, 5mg/ml in PBS, pH 7.4) was incubated with NHS-Alkyne **12A** (6 mg in 100 µl DMSO, 10 eq to each modifiable lysine group) at room temperature for 3 h and then dialyzed against 0.1 M Tris buffer, pH 8.0 for 48 h to remove excess of alkyne linker. The dialyzed product was characterized via FPLC, MALDI-TOF and used for further bioconjugation. Comparing the Mol. Wt. of unmodified BSA **11** and alkyne-modified BSA **13A**, it was calculated that about 35 lysine groups were modified by NHS-Alkyne bifunctional linker (see Supplementary Figure S1).

18. *Synthesis of Azide modified BSA* (13)

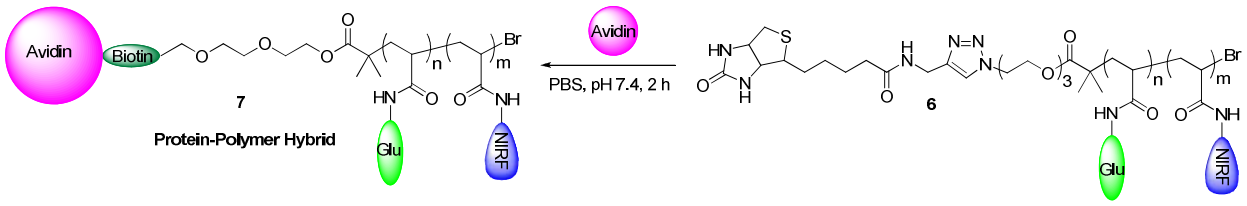


BSA (5mg, 5mg/ml in PBS, pH 7.4) was incubated with NHS-Azide **12** (5mg in 100 µl DMSO, 10 eq to each modifiable lysine group) at room temperature for 3 h and then dialyzed against 0.1 M Tris buffer, pH 8.0 for 48 h to remove excess of azide linker. The dialyzed product was characterized via FPLC, MALDI-TOF and used for further bioconjugation. Comparing the Mol. Wt. of unmodified BSA **11** and azide-modified BSA **13**, it was calculated that about 45 lysine groups were modified by NHS-Azide hetero-bifunctional linker (see Supplementary Figure S1).

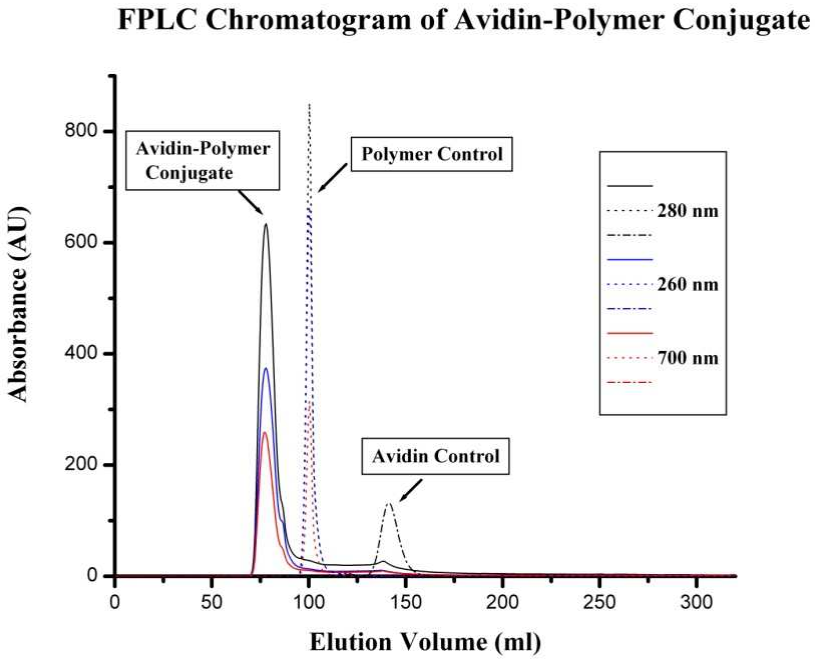


SUPPLEMENTARY FIGURE S1. MALDI-TOF Data comparison of alkyne modified BSA **13A** (red line), azide modified BSA **13** (blue line), unmodified BSA (green line).

19. CONJUGATION OF *Biotin Terminated Polymer (6) and Avidin.*



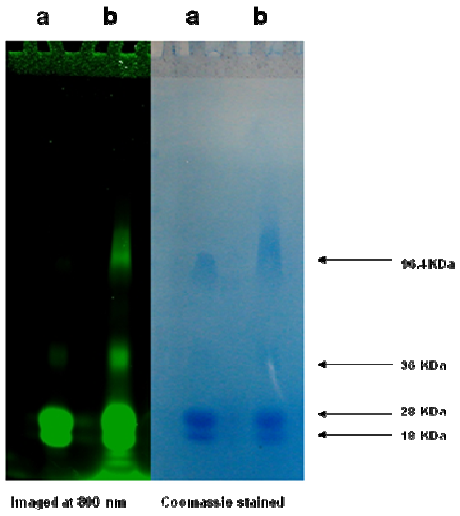
Avidin (1 mg) was dissolved in 0.25 mL of PBS buffer, pH 7.4. Poly(glucosamine)-poly(NIRF dye) copolymer **6** (5.5 mg) was dissolved in 0.65 ml PBS buffer, and slowly added. After 2 h at room temperature, the solution was extensively dialyzed using a 50 KDa MWCO membrane in deionized water, and the modified protein was analyzed by fast protein liquid chromatography (FPLC) and SDS-PAGE.



SUPPLEMENTARY FIGURE S2. Size exclusion FPLC (Hiprep 26/60™ Sephacryl™ S-200 HR column) of Avidin, biotin terminated poly(glucosamine)-poly(NIRF dye) copolymer **6**, and Avidin-polymer (**6**) conjugate .

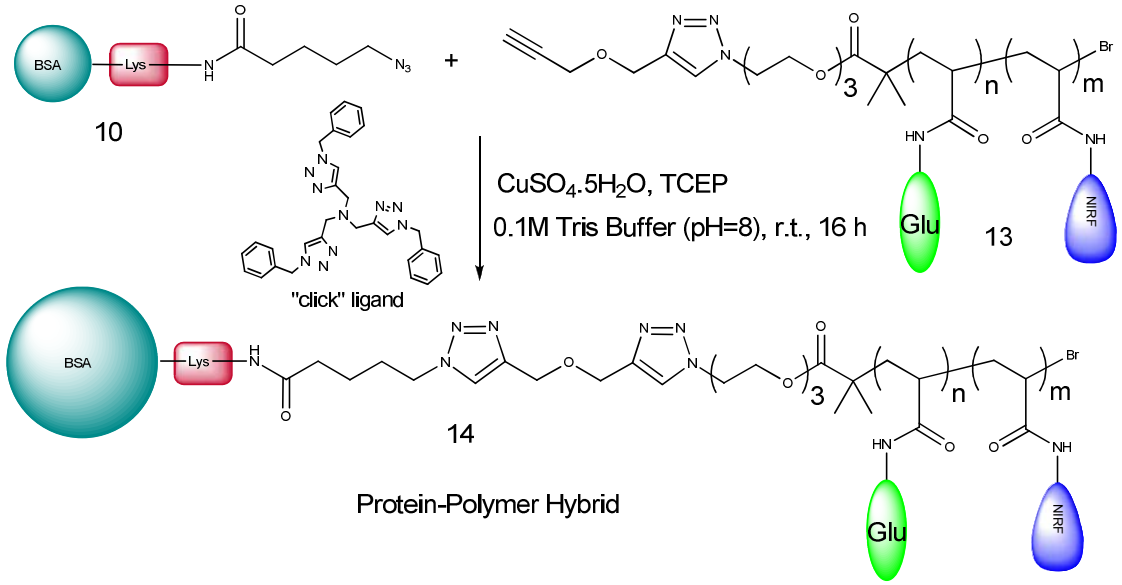
SDS PAGE

Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was performed by forming a complex of avidin with the polymer, and then avidin alone as a control. First a mixture of avidin with the polymer in the ratio of 1:20 was incubated in PBS overnight on a rocking platform at 4 ºC, then the samples were heated and loaded onto 10-20% PAGEgel SDS Cassette Gel 17-Well. The avidin, and the avidin binding complex were visualized using Odyssey imaging system (LI-COR, Lincoln, NE) in the NIR at 800 nm, then detected after protein staining with coomassie.

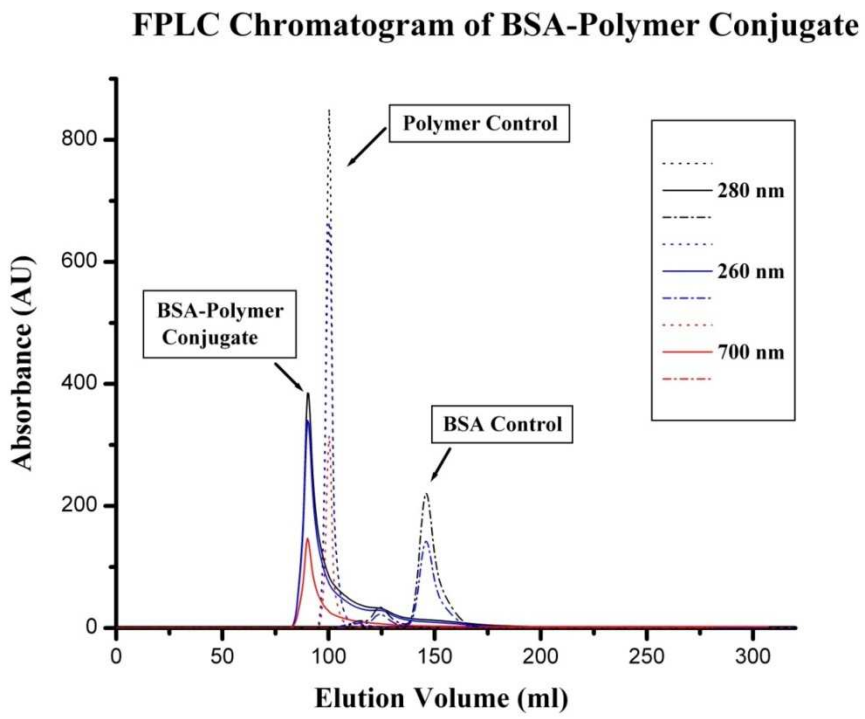


SUPPLEMENTARY FIGURE S13 SDS PAGE of control Avidin and Avidin-polymer **6** conjugate. The conjugate has two higher molecular weight bands imaged using an Odyssey imaging system (LI-COR, Lincoln, NE) with detection in the NIR at 800 nm (left) and after coomassie staining (right).

20. ***Synthesis of Protein-Polymer Conjugate; BSA-"clicked"- poly(glucosamine)-poly(NIRF dye) copolymer*** **(14)**



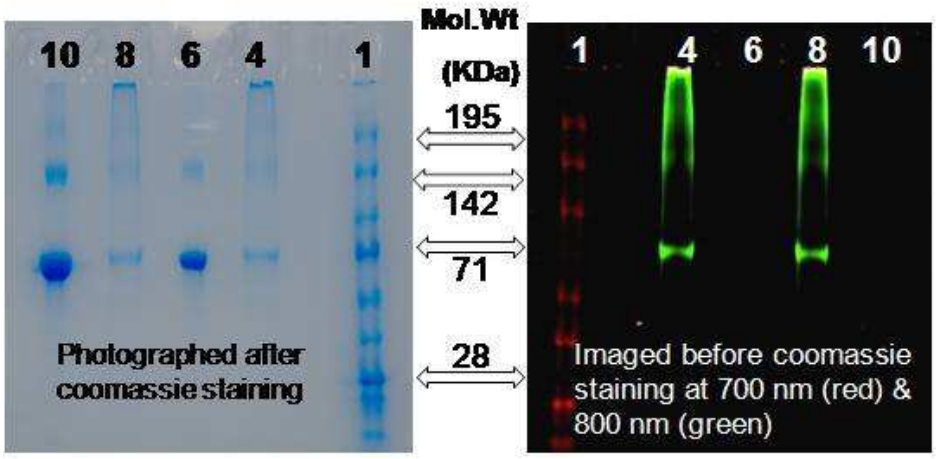
BSA-azide **13** (5 mg, approx. 1.5 µmol in azide) was incubated with alkyne-poly(glucosamine)-poly(NIRF dye) copolymer **10** (20 mg, 1 µmol) in Tris buffer (1800 µL, 0.1 M, pH 8) in the presence of TCEP (4 mM), "click" ligand (TBTA) (4 mM, dissolved in 200 µL of DMF) and copper sulfate (2mM) for 16 h at 4 ^{o}C. The ligand was added before the addition of copper sulfate. The reaction mixture was then dialyzed using Spectra Por 6 dialysis membrane (MWCO 50 KDa) in PBS pH 7.4 for 48 h to remove excess of Copper and ligand. The conjugate was further characterized via Fast Protein Liquid Chromatographic system (Akta Purifier, Amarsham Biosciences) using HiPrep 26/10 Sephacryl S-200HR (GE Healthcare) size-exclusion column in PBS pH 7.4 as eluent buffer. The conjugate was also characterized via SDS PAGE.



SUPPLEMENTARY FIGURES S4. exclusion FPLC (Hiprep 26/60™ Sephacryl™ S-200 HR column) of azide modified BSA **13** (dashed line), copolymer **10** (dotted line), and "clicked" conjugate **14** (solid line).

SDS PAGE

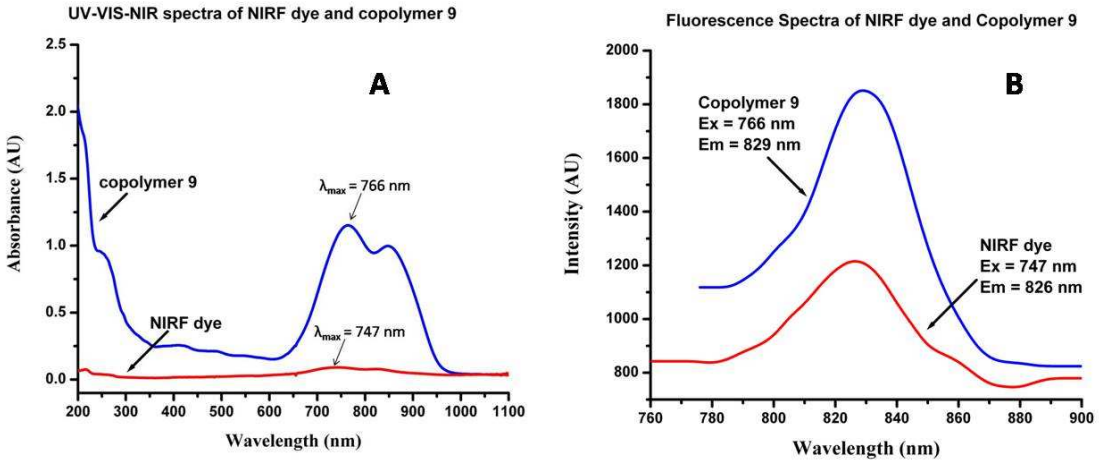
Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was performed with BSA-polymer conjugate **14** and alkyne-terminated poly(glucosamine)-poly(NIRF dye) copolymer **10**, modified BSA **13** as controls using a 10-20% PAGEgel SDS Cassette Gel. To confirm that the copolymer **10** was indeed chemically bonded to the protein, the mixture of copolymer **10** and modified BSA **13** was incubated at 4 ^{o}C for 16h in the same ratio but without the "click" reagents and dialyzed the mixture with a 50 KD MWCO membrane. The gel cassette was visualized using Odyssey imaging system (LI-COR, Lincoln, NE) in the NIR at 800 nm, then detected after protein staining with coomassie.



SUPPLEMENTARY FIGURE S5. SDS-PAGE of conjugate **14** (lane 4&8), mixture of azide modified BSA **13** & copolymer **10** without "click" reagents (lane 6) and unmodified BSA (lane 10).

21. UV-VIS-NIR AND FLUORESCENCE SPECTROSCOPY OF NIRF DYE AND COPOLYMER 9.

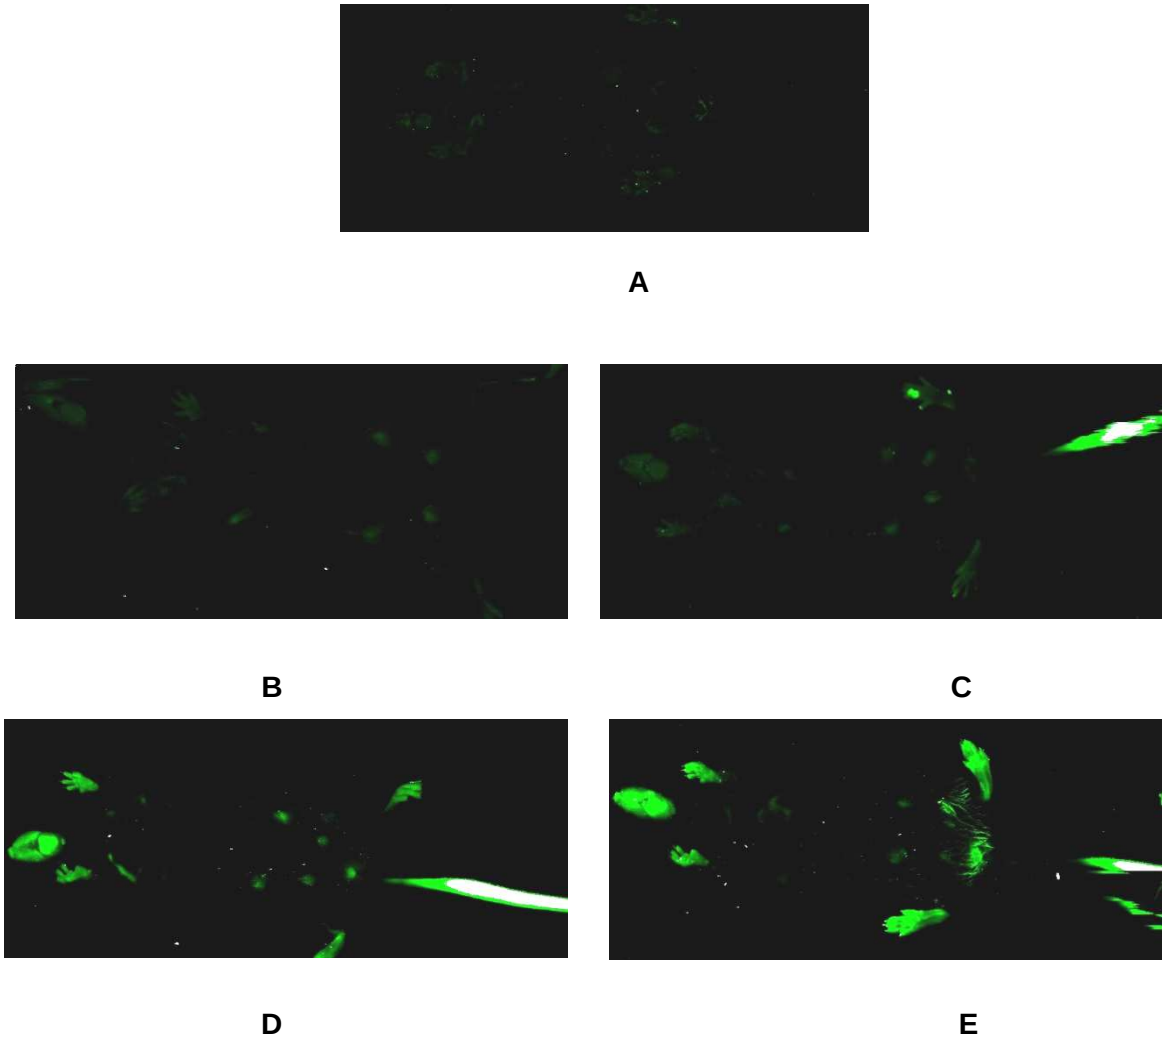
NIRF dye (ADS832WS) (2.8 mg) was dissolved in 10 ml of deionized water to prepare a stock solution of 3 µM. Azide terminated poly(glucosamine)-poly(NIRF dye) copolymer **9** (11.7 mg; 5 dye molecule per polymer chain) was dissolved in 10 ml of deionized water to prepare a solution of 0.3 mM of effective dye concentration. The stock solution of NIRF dye was further diluted to 0.3 µM. The UV-VIS-NIR spectra were obtained on an Agilent Technologies 845x UV-Vis System using deionized water as blank. The fluorescence spectra of both the dye and the dye incorporated copolymer **9** were obtained on JobinYvon Horiba FluoroMax-3 instrument using the solutions containing 0.3 µM effective dye concentration.



SUPPLEMENTARY FIGURE S6. **A.** Visible/NIR absorption spectra, **B.** Fluorescence emission spectra of poly(glucosamine)-poly(NIRF dye) copolymer **9** (blue line) and NIRF dye (red line) in water at 25 ^{o}C. The effective dye concentrations in both the cases are identical (0.3 µM).

22. TEST OF THE UTILITY OF PROTEIN-POLYMER HYBRID IN NON INVASIVE IMAGING IN MICE.

Each of two female, six months old mice were injected with 200 µL of the NIRF dye, and the biotin terminated poly(glucosamine)-poly(NIRF dye) copolymer **6** (0.2 mM effective dye concentration in both cases) via the tail vein. Each mouse was then anaesthetized using mixture of 15 µL Xylezene mixed with 54 µL Ketamine to reach a dose of 10 mg/kg body weight of Xylezene, and 90 mg/kg bodyweight of Ketamine per mouse, and then scanned using a Odyssey scanner (Near IR) at wavelength 800 nm. To investigate the extent of fluorescence, and the extent of catabolism of the polymer the mice were scanned after one hour and four hours. Another female six months old mouse (control mouse) was anaesthetized with the same anesthetic mixture and then scanned to eliminate background fluorescence.

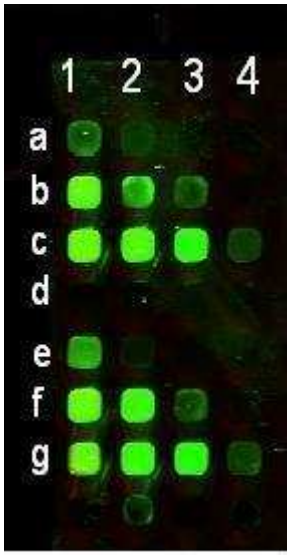


SUPPLEMENTARY FIGURE S7. Picture **A** shows the control mouse without an imaging agent. Pictures **B** & **C** show mouse scanned one, and four hours after injection with the NIRF dye respectively. Pictures **D** & **E** show mouse scanned one, and four hours after injection with the copolymer **6** respectively.

23. DETECTION OF BINDING OF BIOTINYLATED COPOLYMERS TO STREPTAVIDIN COATED WELLS.

Control poly(glucosamine)-poly(NIRF dye) copolymer, biotin terminated poly(acrylic acid)-poly (NIRF Dye) polymer **6A**, and biotin terminated poly(glucosamine)-poly(NIRF dye) copolymer **6**. All samples were prepared at a starting effective molar dye concentration of 0.2

mM in PBS (pH=7.4), then each of the three samples were successively diluted ten-fold to final concentrations of 0.02, 2.0 x 10^{-3}, 2.0 x 10^{-4} mM. 50 µL of each solution was then added to the wells, and incubated overnight at 4 degrees Celsius. Then the wells were washed four times with PBS containing 0.05% Tween-20. Finally, the wells were then visualized using the Odyssey imaging system (LI-COR, Lincoln, NE) at 800 nm.



SUPPLEMENTARY FIGURE 58. Image for Streptavidin coated wells taken by Odyssey imaging system using the 800 nm channel detector where lanes (**A** through **C**) and (**E** through **G**) are the same experiment performed as a duplicate. Lanes **A-C** are samples control poly(glucosamine)-poly(NIRF dye) copolymer, biotin terminated poly(acrylic acid)-poly(NIRF dye) polymer **6A**, and biotin terminated poly(glucosamine)-poly(NIRF dye) copolymer **6** respectively.

24. THE UTILITY OF PROTEIN-POLYMER HYBRID IN IMAGING USING RETINAL EPITHELIAL CELLS.

Retinal pigment epithelial cells were divided onto four wells, and then allowed to grow for three days with regular feeding; the cells were then fixed using 2% PFA, then rinsed three times for five minutes each using PBS (pH=7.4). The nonspecific binding sites were then blocked using a blocking buffer and incubated for overnight. The blocking buffer was then removed, and

well (**A**) only was incubated with the primary antibody, and incubated for overnight at 4 ^{o}C. The primary antibody was then rinsed three times five minutes each, and then the biotinylated secondary antibody was added to wells (**A** & **B**), and incubated for overnight at 4 ^{o}C. Rinsing was performed for the excess secondary antibody using the same technique used for the primary antibody, then 500 µL of Avidin (1 mg/ml) was added to each of wells (**A**,**B** & **C**) and incubate for overnight at 4 ºC, and excess of avidin was washed off with PBS (pH=7.4) three times five minutes each. Finally 500 µL of poly(glucosamine)-poly(NIRF dye) copolymer **6** (0.1 mg/ml) was added to each of the wells (**A**,**B**,**C** & **D**) and incubated for two hours at 37 ºC at a controlled temperature chamber. Excess polymer was washed off using PBS (pH=7.4) three times five minutes each, fresh PBS was then added to the wells and scanned using Odyssey imaging system (LI-COR, Lincoln, NE) with detection in the NIR region at 800 nm.

Blocking solution:

4% Normal goat serum (NGS)

2% BSA

0.05% Tween 20

Antibody dilution buffer:

2% NGS

1% BSA

0.05% Tween 20

50% blocking buffer in PBS was used to prepare the Antibody Dilution Buffer

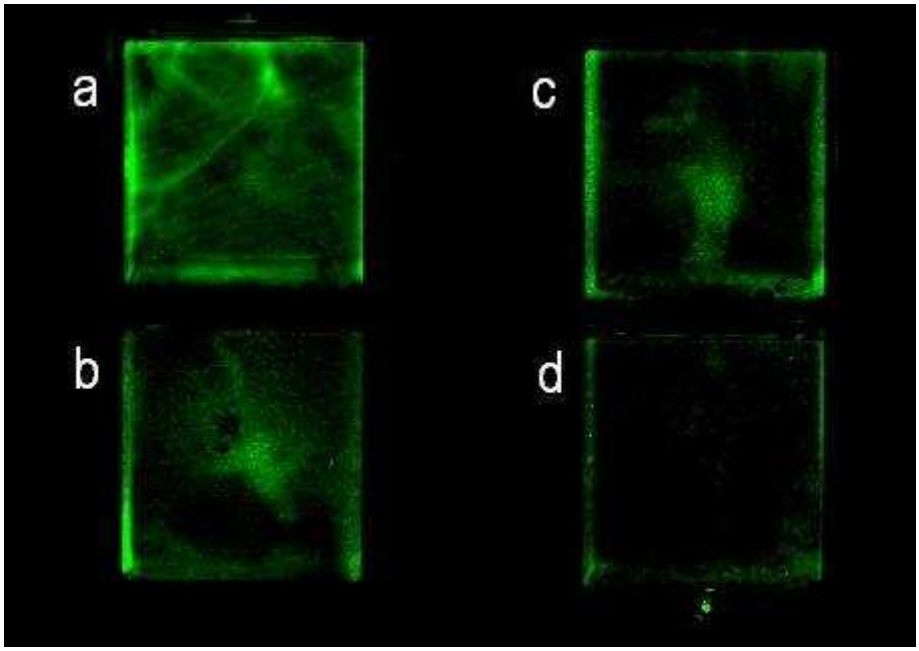
Preparation of Antibodies:

Primary antibody: (2B- α5 Rabbit polyclonal IgG)

1: 200 preparation of the antibody in 2% ADB without Tween (not to permeate the cells).

Secondary antibody: (GtxRb secondary Lot: 0507003644)

1:200 preparartion of the antibody in 2% ADB without Tween (not to permeate the cells).



SUPPLEMENTARY FIGURE 59. Images taken by Odyssey at 800 nm of the pigment epithelial cells. The well which was incubated with primary & biotinylated secondary antibodies, Avidin, and copolymer **6** (well **A**) showed maximum fluorescence, while wells (**B**, **C**, and **D**) showed very little fluorescence relative to (well **A**) and that fluorescence is due to non specific binding to the antigens on the cell surface.
