Ellman's assay A 2 mM solution of MESNA (sodium 2-mercaptoethanesulfonate) in PB (0.1 M, pH 8) was diluted to obtain solutions of the following concentrations: 125 µM, 64 µM, 32 µM, 16 µM, 8 µM, 4 µM, and 2 µM. To 1 mL of each of these solutions, 200 µL of a solution of Ellman′s reagent (5,5′-dithio-bis-(2-nitrobenzoic acid), 4 mg/mL in PB (0.1 M, pH 8)) was added and the absorption of the obtained mixtures was measured at 412 nm in a UV/vis spectrometer to give the calibration curve. The thiol concentrations of the samples were determined analogously by adding 200 µL of the solution of Ellman′s reagent to 1 mL of sample in PB (0.1 M, pH 8) and by measuring the absorption at 412 nm. The number of maleimides per RSA was determined by reacting it with an access of MESNA (5 equiv) and subsequent titration of free thiol with Ellman′s assay.

Polyethylenimine (PEI) is a class of cationic polymers proven to be effective for gene delivery. However, PEI is nondegradable and the molecular weight of PEI affects the cytotoxicity and gene transfer activity. Aiming to prepare a biodegradable gene vector with high transfection efficiency and low cytotoxicity, we conjugated low molecular weight (LMW) PEIs to the biodegradable backbone polyglutamic acids derivative (PEG-*b*-PBLG) by aminolysis to form PEIs combined PEG-*b*-PLG-*g*-PEIs (GGI). Two copolymers, GGI 30 and GGI 40, were synthesized. The chemistry of GGI was characterized using IR, ^{1}H NMR and ^{13}C NMR, GPC, and CD, respectively. The degradation behaviors of copolymer GGI in papain solution were investigated. GGIs showed good DNA condensation ability and high protection of DNA from nuclease degradation. The zeta potential of the GGI/pDNA polyplexes was ~15 mV, and the particle size was in the range 102−138 nm at N/P ratios between 10 and 30. The particle size and the morphology of the polyplex was further confirmed by transmission electron microscope (TEM). In cytotoxicity assay, GGIs were significantly less toxic than PEI 25k. The degradation product of GGI exhibited negligible effects on cells even at high copolymer concentration. The results of GFP flow cytometry and fluorescence imaging showed that the trasnfection efficiencies of GGIs were all markedly higher than PEI 25k in Hela, HepG2, Bel 7402, and 293 cell lines. Importantly, the presence of serum had a lower inhibitive effect on the transfection activity of GGI in comparison to PEI 25k and Lipofectamine 2000. Therefore, PEG-*b*-PLG-*g*-PEI copolymers may be attractive cationic polymers for nonviral gene therapy.

INTRODUCTION

In the past decade, cationic polymers have become the major type of nonviral gene delivery carriers, due to their advantages over viral vectors, including the ability to deliver larger DNA molecules, low immunogenicity, and relative safety (*1*−*4*).

Among the cationic polymers, polyethylenimine (PEI) is regarded to be one of the most successful and widely studied gene delivery polymers. PEI has been proven to be effective in gene delivery due to its condensation of DNA, which facilitates endocytosis, as well as its "proton sponge effect", which can prevent the DNA from endosomal disruption (*5*, *6*).

Many studies have shown that the molecular weight of PEI is the most effective parameter for the gene transfection efficiency and cytotoxicity (*7*−*11*). It was observed that PEI gene transfer activity increased with an increase in molecular weight, whereas the cytotoxicity appears to increase with increasing polymer size. For example, low molecular weight (LMW) PEI (<2 kDa) was proven to be nontoxic but could not effectively condense DNA and displayed very poor transfection activity. In contrast, high molecular weight (HMW) PEI (PEI 25k) showed high transfection efficiency but also significant cytotoxicity. In addition, HMW PEI, which is nonbiodegradable, probably would give rise to the accumulation of cytotoxicity in vivo, so the long-term safety of HMW PEI is further problematic.

To circumvent the problems described above, one rational way was suggested to enhance the gene delivery efficiency of polymer with low cytotoxicity, achieved by combining LMW PEIs together using degradable linkages to form combined PEI with suitable high molecular weights. A series of degradable cross-linked LMW PEIs were investigated, which were synthesized by linking several LMW PEIs to various cross-linking reagents, such as diacrylate (*10*), glutadialdehyde (*12*), oligo(L-lactic acid-*co*-succinic acid) (*13*), dithiobis(succinimidylpropionate), and dimethyl-3,3′-dithiobispropionimidate·2HCl (*14*). The results showed that the transfection efficiency of these cross-linked PEIs was comparable to that of PEI 25k or even higher, while the cytotoxicity was much lower than that of PEI 25k. Another strategy was to employ linear chains to link LMW PEIs together. Wong et al. synthesized PEI-*g*-chitosan by performing cationic polymerization of aziridine in the presence of oligochitosan. The results revealed that PEI-*g*-chitosan showed a higher transfection efficiency than that of PEI 25k both in vitro and in vivo (*15*). Tang et al. employed cyclodextrins to cross-link LMW branched PEI (MW 600) to form HMW cationic polymers (average MW 61 kDa), which displayed high gene transfection and low cytotoxicity in vitro (*16*). Jiang et al. designed the CHI-*g*-PEI copolymer by performing an imine reaction between periodate-oxidized chitosan and LMW PEI (800 Da). The results indicated that CHI-*g*-PEI had a lower cytotoxicity and showed higher transfection efficiency than PEI 25k (*17*).

Polyglutamic acid is a biodegradable polypeptide, which is susceptible to enzymatic digestion in the human body. It is reported that polyglutamic acids are biocompatible, do not elicit an immune response, and have low toxicities in vivo (*18*). Introduction of nonionic hydrophilic PEG to the cationic gene delivery polymer is actively pursued, because PEG facilitates the formation of polyplexes with improved solubility, reduced aggregation, lower cytotoxicity, and possibly decreases opsonization with serum proteins in the bloodstream (*19*, *20*).

Thus, our idea of polymer design was to create biodegradable backbone poly(amino acid) derivates (PEG-*b*-PBLG) first, and

then attach the LMW PEIs (MW 423 Da) to the side chains of poly(amino acid)s by the reaction of aminolysis. It is expected that the novel biodegradable copolymers PEG-*b*-PLG-*g*-PEIs (GGI) show the characteristics of high transfection efficiency, low cytotoxicity, and degradability. In the present study, we reported the synthesis and characterization of GGI. Their degradability, DNA condensation ability, DNA protection ability, and cytotoxicity were checked. The in vitro transfection efficiency was investigated in the absence and presence of serum, compared with PEI 25k and commercially available Lipofectamine 2000.

MATERIALS AND METHODS

Materials. Polyethylenimine with average molecular weight of 423 Da (PEI 423) and 25 kDa (PEI 25k) were purchased from Aldrich. Amine-terminated poly(ethylene glyol) monomethyl ether (mPEG-NH_2) with a molecular weight of 5 kDa was purchased from Kaizheng Biotech Development Co. Ltd., Beijing. 2-Hydroxypyridine (2-HP) was purchased from Fluka. Tetrahydrofuran (THF) was dried and distilled in the presence of sodium immediately before use. *N*,*N*-Dimethylformamide (DMF) was dried over calcium hydride and distilled prior to use. DNase I and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma. Lipofectamine 2000 was obtained from Invitrogen Corporation. The reporter plasmids, pEGFP-C1, was a gift from West China University of Medical Sciences (Chengdu China). The plasmid was propagated in *Escherichia coli* DH5-α and purified by the Qiagen endotoxin-free plasmid purification kit (Qiagen, CA, USA). The DNA concentration was checked by the measurement of UV absorbance at 260 nm using a biophotometer (Eppendorf 5840R, Germany). The other materials and solvents were used as received without further purification.

Synthesis of PEG-*b*-PBLG. First, γ-benzyl glutamate (BLG) was prepared according to the method reported in the literature (*21*). *N*-Carboxyanhydride of γ-benzyl L-glutamate (BLG-NCA) was synthesized by reaction of the ester with triphosgene in THF. Typically, γ-benzyl glutamate (3 g, 0.0127 mol) was suspended in dried THF (30 mL), and triphosgene (1.8 g, 0.0061 mol) was added. The suspension was stirred at 60 °C. After approximately 15 min reaction, the reaction solution turned clear. After reaction for 30 min, the reaction mixture was precipitated with an excess of cold petroleum ether. The mixture then was stored at 4 °C for 24 h to let the crystals grow. The white crystalline product was filtered off and washed with petroleum ether. The precipitate was dried in vacuo at room temperature for 4 h.

Typical synthesis procedure of poly(ethylene glycol)-*block*-poly(γ-benzyl L-glutamate) (PEG-*b*-PBLG) was as follows. BLG-NCA was dissolved in dried $CHCl_3$ (20 mL/1 g). mPEG-NH_2 was added as the macroinitiator at a monomer/initiator ratio of 50:1 for GE 1 and 100:1 for GE 2. The detailed feeding amount of material for PEG-*b*-PBLG synthesis was presented in Table 1. The mixture solution was stirred for 72 h at room temperature. The product mixture was precipitated with an excess of ethanol under vigorous stirring to obtain a white solid, while the unreacted PEG-NH_2 remained dissolved in the mixture solution. After filtration, diblock copolymer PEG-*b*-PBLG was obtained under vacuum at 40 °C for 24 h.

Synthesis of PEG-*b*-PLG-*g*-PEIs (GGI). PEG-*b*-PLG-*g*-PEIs was prepared by aminolysis of PEG-*b*-PBLG using LMW PEI. PEG-*b*-PBLG was dissolved in dried DMF (10 mL/1 g) and put on an oil bath at 40 °*C*. Polyethylenimine (PEI 423) (10× mol ratio to the ester groups of PEG-*b*-PBLG) and 2-hydroxypyridine (2-HP) (5× mol ratio to the ester groups of PEG-*b*-PBLG) were added, and the solution was stirred for 48 h. The detailed feeding amount of material for GGI synthesis was presented in Table 2. The product PEG-*b*-PLG-*g*-PEIs was obtained after precipitation in cold ether, followed by dialysis against water (2 days) using a dialysis bag with 3.5 kDa molecular weight cut off (MWCO), and finally freeze−dried.

Characterization of Polymers. The FTIR spectra of polymers were recorded in pressed KBr pellets on a Fourier transformation infrared spectrometer (Bruker, EQUINOX 55). ^{1}H NMR and ^{13}C NMR spectra in D_2O or $CDCl_3$ were recorded with a superconducing Fourier transform nuclear magnetic resonace spectrometer (Varian INOVA500NB 500 MHZ). Gel permeation chromatography (GPC) was performed using a Waters 515−410 chromatograph to detect the molecular weights and molecular weight distribution of the polymer. Circular dichroism spectra (CD) was recorded on a JASCO J-810 spectrometer on samples with concentrations at 0.5 mg/mL, using a scan rate of 20 nm/min and a cell path length of 1.0 mm.

Polymer Degradation Studies. The degradation profile of LMW PEIs combined copolymer GGI by papain was investigated using capillary viscosity measurements. In a typical experiment, GGI 40 was dissolved in PBS (pH = 7.4) and combined with a papain solution in PBS. The final concentrations of GGI 40 and papain were 2 mg/mL and 1 mg/mL, respectively. The total volume was 12 mL. The mixture was stirred at 37 °C, and 2 mL 20% trichloroacetic acid (TCA) was added as a function of time to prevent further degradation during the measurement of the viscosity. The samples were then freeze−dried for 24 h to get the degradation product. Capillary visosity measurements were carried out to determine the η_{inh} of the degradation product, at 25 °C in PBS. The concentration was 0.5 g/dL. Inherent viscosity (η_{inh}) was calculated by the following equation: $\eta_{inh} = \ln(t/t_0)/c$, where t was the flow time of the polymer solution, t_0 the flow time of the solvent, and c the degradation product concentration. The degree of the degradation was estimated by η_{inh} relative reduction (%). η_{inh} relative reduction (%) = $\eta_{inh\ (t)}/\eta_{inh(t0)}$, where $\eta_{inh(t)}$ was the η_{inh} of polymer solution at the function time of t, $\eta_{inh(t0)}$ was the η_{inh} of the initial polymer solution.

Preparation of Copolymer/pDNA Polyplexes. All polymer/pDNA polyplexes were freshly prepared before use. Polyplexes were prepared by adding polymer solutions to equal volumes of pEGFP-C1 with gentle vortexing and incubated at room temperature for 30 min. The concentration of polymer solution was based on the chosen N/P ratios of polymer/pDNA. The polyplexes were produced in 150 mM NaCl at pH 7.4 [transmission electron microscope (TEM) observation], in 10 mM NaCl at pH 7.4 (particle size and zeta potential measurements), or in PBS at pH 7.4 (other experiments).

Gel Retardation Assay. Agarose gel retardation assay was used to determine the DNA binding ability of copolymer GGI. Polymer/pDNA complexes were prepared at various N/P ratios ranging from 0.5 to 3 in PBS (pH=7.4). The complexes were mixed with appropriate amounts of 6× gel-loading buffer (Sigma), and then electrophoresced on a 0.9% (w/v) agarose gel containing ethidium bromide (0.5 μg/mL of the gel) in 0.5× Tris-boric acid-EDTA (TBE). The location of DNA in the gel was analyzed on a UV illuminator and photographed by a UVIpro gel image sytem (UVItec).

DNase I Protection Assay. Polymer/pDNA complexes were prepared at N/P ratio of 0.5/1 to 10/1 at a final pDNA concentration of 40 μg/mL and 10 μL total volumn. The complex solutions were incubated with 4 μL DNase I (100 μg/mL, in 50 mmol/L Tris-Cl, 10 mmol/L $MgCl_2$, pH = 7.4) at 37 °C for 30 min. The DNase I was inactivated by adding 4 μL of 25 mM ethylenediaminetetraacetic acid (EDTA), followed by incubating at room temperature for 10 min. The pDNA was then released from the polyplexes by adding 1% sodium dodecyl sulfate (SDS), and analyzed by 0.9% agarose gel electrophoresis.

Particle Size and Zeta Potential Measurements. Particle size and zeta potentials of the polymer/pDNA complexes were measured with Malvern Zetasizer Nano ZS90 (Malvern, UK) in a 10 mM NaCl aqueous solution. The morphologies of the complexes of polymer/pDNA were examined with a JEM-2010 HR transmission electron microsope (TEM). Polyplexes were prepared as described above in the preparation of copolymer/pDNA polyplexes procedure. To prepare the samples, a small drop of dilute particle dispersion was spread onto a carbon-coated grid. The dried specimens were then negatively stained with a drop of 2% phosphotungstic acid (PTA) for 30 min and dried at room temperature.

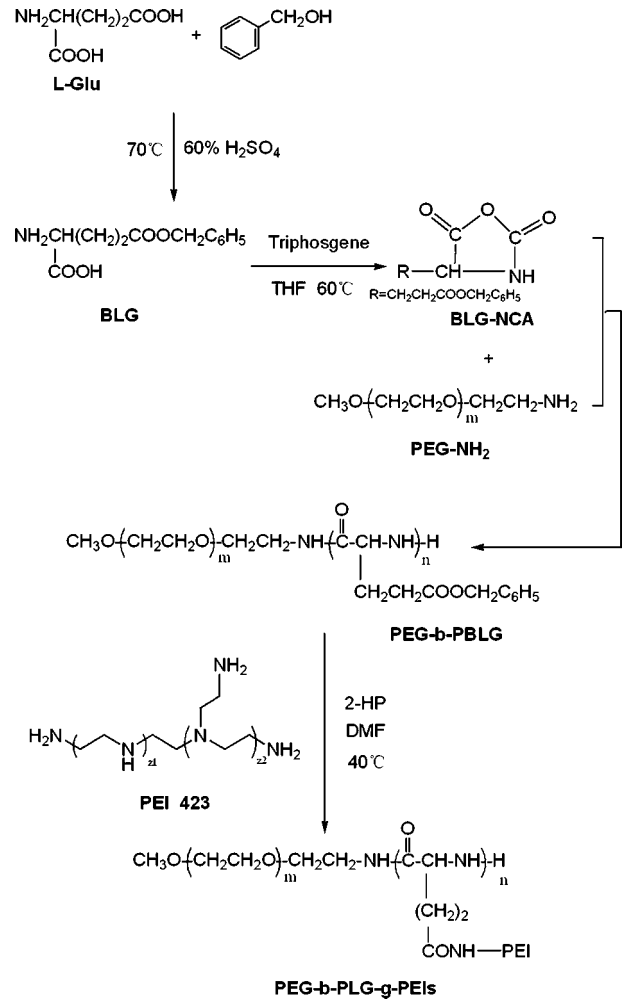
Cell Culture. Human cervix epithelial carcinoma cells (Hela), human hepatoblastoma cells (HepG2), human hepatoblastoma cells (Bel 7402), and human embryonic kidney cells (293) were cultured in Dulbecco's Modified Eagle Medium (DMEM) with 10% (v/v) fetal bovine serum (FBS) and 1% penicillin−streptomycin, at 37 °C under 5% CO_2. The cells were purchased from the Shanghai Cell Bank, Chinese Academy of Medical Sciences.

Cytotoxicity Determination. MTT assay was employed to measure the cytotoxicity of the polymers. Hela cells (1.2×10^4 cells/well) were seeded in 96 well plates in 200 μL DMEM medium containing 10% FBS. When the cells achieved 70−80% confluence (incubation for 20−24 h), the growth media were replaced by fresh serum-free media or media with serum containing various amount of polymers, respectively. The medium in each well was replaced with 200 μL of fresh complete medium 4 h later. After additional incubation for 48 h, 25 μL of stock solution of MTT (5 mg/mL in PBS) was added to each well. After 4 h of incubation, medium was changed with 150 μL DMSO to dissolve the fomazan crystal formed by live cells. Absorbance was measured at 570 nm using an ELISA microplate reader (Bio-Rad). The cell viability was expressed as a percentage of the absorbance to that of the control experiment without polymers.

Transfection Efficiency Measurements. The effectiveness of GGI 30 and GGI 40 as carriers in gene delivery were compared with PEI 25k and Lipofectamine 2000. The transfection efficiency was quantified by the percentage of cells expressing green fluorescent protein (GFP), analyzed by flow cytometry using a FACS Caliber System from Becton-Dickinson (San Joes, CA). The levels of GFP expression were characterized using fluorescence microscopy (Olympus, Japan).

Hela cells (15×10^4 cells/well), HepG2 cells (15×10^4 cells/well), Bel 7402 cells (12×10^4 cells/well), and 293 cells (10×10^4 cells/well) were seeded in 12-well plates, respectively, and incubated at 37 °C under 5% CO_2 for 24 h in 1 mL of DMEM medium containing 10% FBS. GGI/pDNA and PEI 25k/pDNA complexes of various N/P ratios were prepared as described above. At the time of transfection, the media in each well were replaced by 1 mL of DMEM without FBS. 200 μL of polymer/pDNA polyplex suspension, containing 4 μg of pEGFP-C1, was added to each well and incubated with cells for 4 h at 37 °C. After 4 h transfection time, the media were replaced by 1 mL of DMEM containing 10% FBS, and the cells were further incubated for 44−48 h. After being observed using a fluorescence microscope, cells were separately harvested from each well by the trypsin-EDTA treatment, and suspended in 200 μL of PBS (pH 7.4). The cells were transferred to flow cytometry cuvettes for analysis. The nontransfected cells were used as a negative control.

Scheme 1. Synthesis Procedure of GGI



In Vitro Transfection Experiment in Serum. The process of transfection experiments was the same as described above, except that the medium at the time of transfection was replaced with DMEM containing 10% FBS.

Statistical Analysis. Where suggested, all results were summarized as means ± standard deviation, and statistical variations p value between the group means were analyzed by the Student's t-test.

RESULTS AND DISCUSSION

Design and Synthesis of PEG-*b*-PLG-*g*-PEIs (GGI). As described in the Introduction, we aimed to synthesize a low molecular weight (LMW) PEI combined biodegradable polymer GGI. The copolymer GGI was synthesized in two steps as shown in Scheme 1: (1) to prepare the backbone PEG-*b*-PBLG by ring

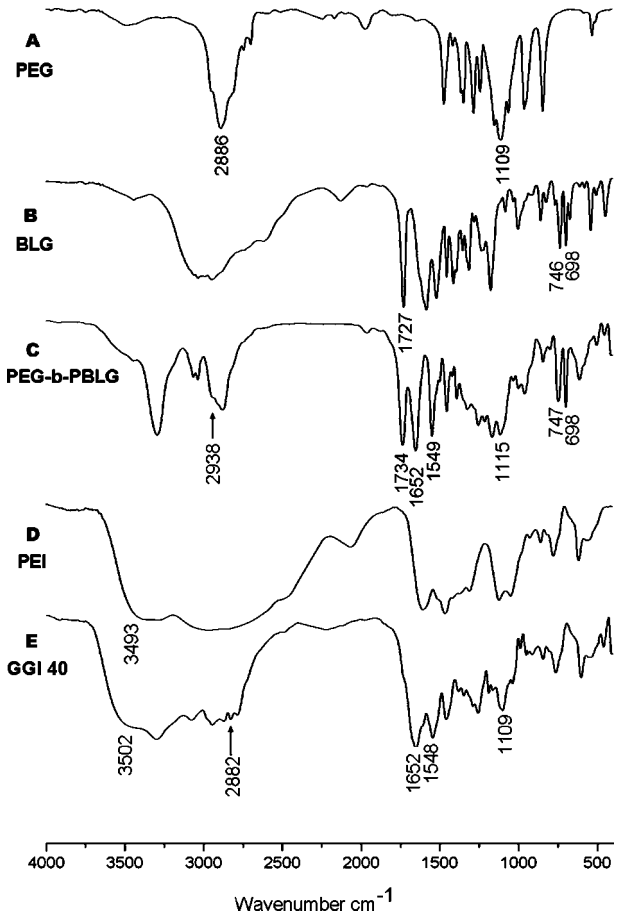


Figure 1. The IR spectra of (A) mPEG, (B) BLG, (C) PEG-*b*-PBLG, (D) PEI 423, and (E) GGI 40.

opening polymerization (ROP) of BLG-NCA in the presence of PEG-NH_2 as macroinitiator. (2) The triblock copolymer GGI was synthesized by aminolysis of PEG-*b*-PBLG using LMW PEI 423.

Aminolysis reaction was employed to form GGI by grafting LMW PEI to the backbone PEG-*b*-PBLG and debenzylation. It was known that chain scission of the backbone (amide linkages of polypeptide) would occur during the process of aminolysis (*22*). Thus, we used 2-hydroxypyridine (2-HP) as a bifunctional catalyst in the reaction to reduce the main chain cleavage according to the literature (*23*). In our pre-experiment, we optimized the reaction conditions for aminolysis to minimize the main chain cleavage, concerning to the reaction temperature, reaction time, and the additional amount of 2-HP. The results of the pre-experiment showed that the aminolysis reaction occurred at 40 °C and lasted for 48 h, with the amount of 2-HP equaling to the ratio of 2-HP to ester 5/1 could minimize the polypeptide degradation.

In addition, since PEI 423 has more than one functional reaction site (primary amine groups) with the ester group of PEG-*b*-PBLG, gelation might occur in the aminolysis reaction theoretically. In our experiment, the reaction mixtures were clear solutions during the whole aminolysis process, and the two products GGI 30 and GGI 40 were water-soluble, indicating that no or negligible gelation product was produced practically.

Characterization of GGI. Figure 1 showed the FTIR spectra of the diblock intermediate and the corresponding graft copolymer. The peak at 2886 cm^{-1} (C−H stretch vibration) and 1109 cm^{-1} (C−O stretch vibration) were characteristics of the PEG block (Figure 1A). Obviously, PEG blocks were present in the intermediate prepolymer PEG-*b*-PBLG (Figure 1C) and the final graft triblock copolymer GGI (Figure 1E). For PEG-*b*-PBLG (Figure 1C), the absorptions at 1652 cm^{-1} (*amide I*) and 1549 cm^{-1} (*amide II*) were attributed to the amide group, suggesting the formation of the polypeptide block. The peaks at 698 cm^{-1} and 747 cm^{-1} from the phenyl group and the peak at 1734 cm^{-1} from the ester carbonyl group were characteristics of PBLG block carrying protection groups. For triblock copolymer GGI (Figure 1E), it similarly owned the characterisitcs absorption at 1652 cm^{-1} (*amide I*) and 1548 cm^{-1} (*amide II*), indicating that the polypetide block PLG block existed. In comparison to diblock copolymer PEG-*b*-PBLG, the absorptions at 698 cm^{-1} and 747 cm^{-1} attributed to the phenyl protection group and the peak at 1734 cm^{-1} disappeared, and a new strong peak at 3502 cm^{-1} assigned to N−H stretch vibration of PEI appeared in the spectrum of GGI, indicating that the aminolysis reaction took place and PEI successfully grafted to the PLG block. These FTIR results were consistent with the expected structures of copolymer GGI.

The structure of the intermediate prepolymer PEG-*b*-PBLG and the graft copolymer GGI were also confirmed by ^{1}H NMR spectra (Figure 2). The peak **a** at 3.65 ppm (-CH_2CH_2-) was attributed to the protons of the PEG block Figure 2A. The characteristic absorption of PEG block was observed also in Figure 2B,D,E, indicating the existence of a PEG block in PEG-*b*-PBLG as well as in the copolymer GGI. For PEG-*b*-PBLG (Figure 2B), the peak **b** at 3.91 ppm (-CH-) and the peaks **c**,**d** at 1.89−2.21 ppm (-CH_2CH_2-) were assigned to the PBLG block. Furthermore, the peak **f** at 7.24 ppm (-C_6H_5) and the peak **e** at 5.02 ppm (-CH_2Ph) were attributed to the phenyl group of the protecting group of PBLG block. The degree of polymerization of PBLG (DP_{PBLG}) in the diblock copolymer PEG-*b*-PBLG was obtained from the integral ratio of -CH_2CH_2- (3.54 ppm, **a**) to -CH_2Ph (5.02 ppm **e**), as shown in the following formula, $DP_{PBLG} = (5000)/(44) \times (2e)/(a)$. Feed composition and molecular characteristics of diblock copolymer PEG-*b*-PBLG were summarized in Table 1. In the case of triblock copolymer GGI 30 (Figure 2D) and GGI 40 (Figure 2E), the peak shifts of them were similar, while the peak areas were inconsistent. The characteristic resonances **g**,**h** (2.12−2.96 ppm, -CH_2CH_2NH-) assigned to the PEI block were observed and the peaks at 7.24 ppm and 5.02 ppm attributed to the phenyl group were absent compared to the ^{1}H NMR spectra of PEG-*b*-PBLG, demonstrating that the protecting groups (phenyl groups) were removed by aminolysis with PEI 423. The results were in line with those described above obtained in the FTIR measurements and suggested the successful synthesis of diblock intermediate copolymer PEG-*b*-PBLG and the triblock graft copolymer GGI.

From the ^{1}H NMR spectra, the PLG length and PEI graft density of the GGI copolymer were calculated from the integral values of the characteristic peaks of PEG (-CH_2CH_2-, **a**, ∼3.65 ppm), PLG (-COCHNH-, **b**, ∼3.91 ppm), and PEI (-CH_2CH_2NH-, **g**−**h**, 2.12−2.96 ppm), using the known molecular weights of PEG and PEI. The detailed compositions and the molecular weights of GGI are summarized in Table 2.

Gel permeation chromatography (GPC) was performed to verify the successful synthesis of graft triblock copolymer GGI. GGI 30 and GGI 40, after purification, both exhibited unimodal molecular weight distributions in the GPC traces, indicating no or negligible homopolymer residue in the graft copolymer product, as illustrated in Figure 3. The molecular weights of GGI 30 and GGI 40 analyzed by GPC (Table 2) were close to those calculated from ^{1}H NMR spectra.

Figure 4 represented the ^{13}C NMR spectra of PEG-*b*-PLG-*g*-PEIs (GGI 40), the corresponding chemical shifts were as follows: the signals of PEG block, 57.4 ppm (CH_3O-, **g**), 68.4 ppm (-OCH_2CH_2O-, **f**); the signals of PLG block, 28.2 ppm (β-C, **a**), 32.3 ppm (γ-C, **b**), 56.5 ppm (α-C, **d**), 175.1 ppm

(-CONH-, **e**). The singals of PEI block were well-separated in the typical area between 35 and 58 ppm (-CH_2CH_2NH-, **c**); the seven signals of the corresponding methylene groups were assigned as indicated in Figure 4.

Since both intermediate copolymer PBLGs and final product GGIs were polypeptide derivatives, circular dichroism (CD) spectroscopy was employed to checked the secondary structure of the PBLG and GGI. First, we took dichloromethane ($CHCl_2$) as the solvent of the copolymers. As shown in Figure 5A, a strong positive $(\pi-\pi^*)_{perpendicular}$ band at ca. 195 nm, a negative $(\pi-\pi^*)_{parallel}$ band at ca. 208 nm, and a negative $n-\pi^*$ band at ca. 222 nm were observed in the spectra of all the four copolymers including PBLGs and GGIs, which suggested the α-helix-like structures of the copolymers. The results indicated that introduction of PEG block and PEI blocks as side chains of the polymer did not affect the α-helix conformation of the polymer. It is reported that the intensity of the peak (polarimetry strength) in the CD spectra is directly proportional to the content of the peptide bond of the polypeptide (*24, 25*), so we judged the content of PLG block of the polymer according to CD spectra. From the CD spectra (Figure 5A), GE 2 showed the highest PLG content, followed by GE 1, GGI 40, and GGI 30, which was in accordance with the results calculated from ^{1}H NMR. In addition, we took 10 mM NaCl (pH 7.4) as the solvent

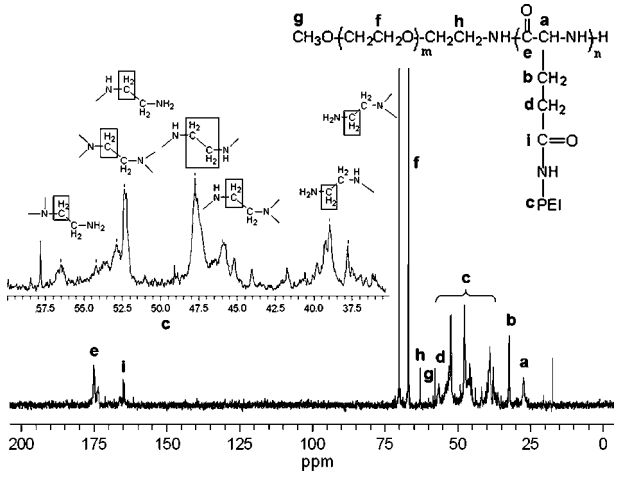

Figure 4. ^{13}C NMR spectrum of GGI 40 dissolved in D_2O.

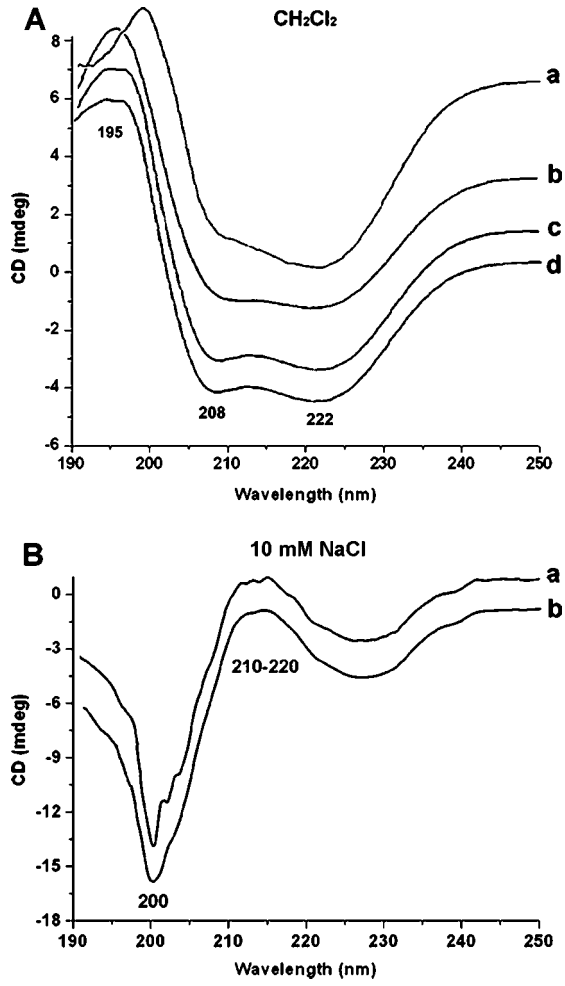

Figure 5. (A) Circular dichroism spectra of copolymers in $CHCl_2$ (a) GGI 30, (b) GGI 40, (c) GE 1, and (d) GE 2. (B) CD spectra of copolymers in 10 mM NaCl (a) GGI 30 and (b) GGI. CD spectra were collected at an ambient temperature.

of the copolymers to check the secondary structure of the copolymer. As PBLG copolymer was water-insoluble, we failed to take the CD spectra of GE 1 and GE 2 for comparison. As shown in Figure 5B, CD spectra of GGI 30 and GGI 40 showed a typical inflected curve with a gradual positive maximum at ca. 210−220 nm and a negative minimum at ca. 200 nm, which was characteristic of a random coil conformation. Due to electrostatic repulsion between the side groups, it is very difficult

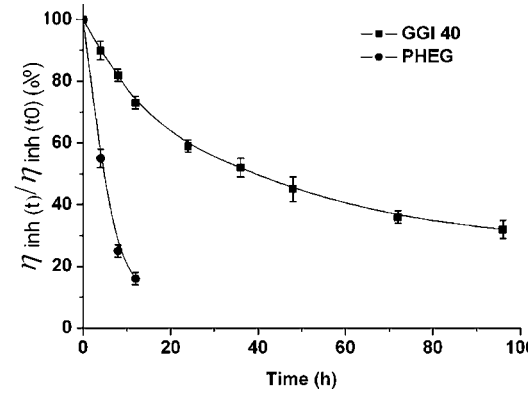

Figure 6. Relative reduction of the η_{inh} of copolymer GGI 40 in function of time after treatment with papain. PHEG was used as control. (n = 3, error bars represented standard deviation.)

to form helical or extended structures in a charged state (*24*). GGI 30 and GGI 40 formed random coil-like structure, not an α-helix conformation, in pH 7.4 solution due to the high charge repulsion between the ionized PEI side chains. From the CD spectra of GGIs, we further confirmed that PEI successfully grafted to the main backbone of PLG as the side chains.

Degradation Profile of GGI. Degradation of the gene carrier is crucial for safe and efficient gene delivery in vivo. The appropriate degradation of the polymer enables reduction of cytotoxicity due to small molecular weights by degradation in vivo and easy elimination by excretion pathway (*10*). The aim of our study is synthesis of biodegradable polymers for gene delivery. Thus, the degradation profile of GGI was investigated in a medium containing papain. Poly(hydroxyethyl L-glutamine) (PHEG) (Mn 52 kDa) was used as the control in the experiment, to study the effection of grafting PEI to the degradation characteristic of polymer. As shown in Figure 6, the result showed that copolymer GGI 40 was biodegradable. There was a rapid initial degradation in the first 24 h, followed by a gradual degradation thereafter. After 96 h, GGI 40 had retained 32% of its original η_{inh}. The control polymer PHEG, degraded much faster, retained only 21% of its initial η_{inh} after 12 h. There seems to be a relationship between the amount of positive charges of the polymer chain and the degradation speed (*23*). The side chains of GGI were PEI 423, which would be protonated in PBS (pH 7.4), while the side chains of PHEG, hydroxyethyl, bore no charges. In addition, the molecular weight and the size of the side chains of GGI were larger than that of PHEG. Probably, the effect of steric hindrance and electrostatic interaction induced by PEI hindered the enzyme papain approach to the degradation reaction site. Thus, grafting PEI to the side chain would lower the speed of degradation comparing to PHEG.

Characterization of GGI/pDNA Complexes. One prerequisite as a polymeric gene carrier is DNA condensation (*20*). Gel retardation assay was performed to investigate whether the synthesized GGIs were able to condense DNA, and the data were compared to that obtained using LMW PEI 423 and HMW PEI 25k. As shown in Figure 7A, PEI 423 used for the preparation of GGI could not retard the migration of pDNA even at an N/P ratio of 100, indicating that pure PEI 423 was incapable of forming complexes with pDNA. These results were consistent with the reported result that only PEI with a molecular weight higher than 2 kDa could form stable complexes with DNA (*12, 26*). In the case of PEI 25k (Figure 7A), an N/P ratio of 2 was sufficient to completely inhibit pDNA mobility. A drop in the total ethidium bromide (EtBr) staining at an N/P ratio of 3 and higher was observed, probably due to exclusion of the dye by plasmid condensation. Figure 7A demonstrated that both

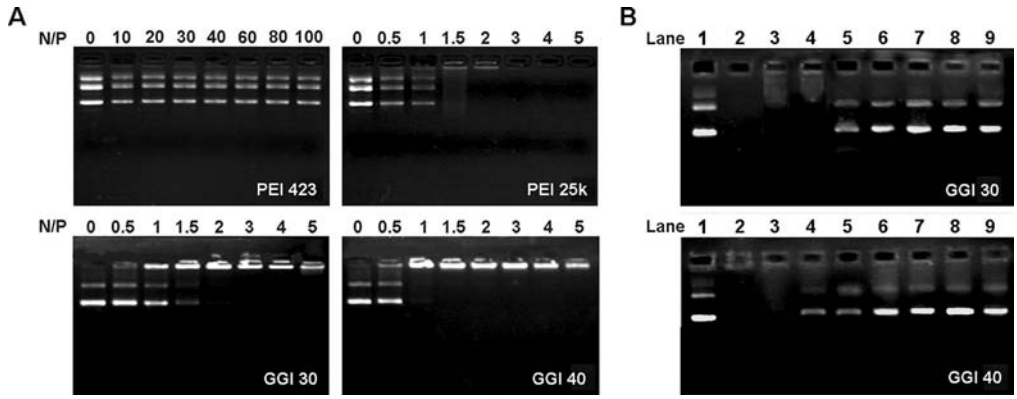

Figure 7. (A) Gel retardation assay. Agarose gel electrophoresis of GGI/DNA (pEGFP-C1) complexes at various N/P ratios. LMW PEI 423 and HMW PEI 25k were used as a control. (B) DNase I protection assay. DNA was released by adding 1% SDS to the GGI/DNA complexes at various N/P ratios after treatment with DNase I. Lane 1: naked plasmid DNA (pEGFP-C1), as negative control. Lane 2: naked DNA treated with DNase I as positive control. Lanes 3−9: GGI/DNA complexes at N/P ratio of 0.1, 1, 1.5, 2, 3, 5, 10.

GGI 30 and GGI 40 had a great capacity to condense DNA effectively where DNA was completely retarded at N/P ratio of 2.0 and 1.0, respectively, showing the similar DNA condensation capability to HMW PEI 25k. However, GGI/pDNA complexes did not lead to EtBr exclusion as PEI 25k did, even at high N/P ratio, suggesting that GGI did not condense DNA as tightly as PEI 25k did. It must be noted that the DNA compaction capabilities of GGIs were significantly enhanced in comparison to PEI 423, indicating that the modification of PEI of grafting LMW PEIs (PEI 423) to the main chain of PEG-PLG to form a LMW PEI combined copolymer GGI with suitable HMW could ameliorate the DNA condensation ability of the polymer. Probably, the extended conformation of GGI and the high molecular weight PEI block of GGI contributed to the good DNA condensation capability. In addition, GGI 40 showed an increasing pDNA condensation capability compared to GGI 30, possibly due to the increasing amino density upon increasing the PLG length as well as the increased PEI molecular weight of the polymer.

For a sufficient gene delivery system, the cationic vectors must be able to protect DNA from degradation by cellular nucleases in serum and extracellular matrix (*27*). In this study, DNase I protection assay was performed to confirm that GGI protected DNA from DNase I degradation. As shown in Figure 7B, after incubation with excess DNase I, both GGI 30 and GGI 40 effectively protected DNA from degradation by DNase I at N/P ratio of 2 and higher, while naked DNA was completely degraded by DNase I. The ability of GGI to protect DNA from enzymatic cleavage was close to that of PEI 25k, which could fully protect DNA from degradation by DNase I at N/P ratio of 1.8 (data not shown). That is to say, the conditions that GGIs bind DNA not as tightly as PEI 25k do not affect its DNA protection ability.

Figure 8A showed the particle sizes of GGI copolymer/DNA complexes prepared in 10 mM NaCl according to various N/P ratios, in comparison with PEI 423/DNA and PEI 25k/DNA complex. As shown in Figure 8A, LMW PEI 423 formed loose polyplexes with a size of approximately 600 nm, from N/P 1:1 to N/P 30:1. The trend of the sizes was in accordance with the results of gel retardation experiments, indicating that PEI 423 could not compact pDNA efficiently. In contrast, two synthesized LMW PEIs combining copolymer GGIs (GGI 30 and GGI 40) could effectively compact pDNA into small nanoparticles. Generally, the particle size decreased with an increase in N/P ratio until the N/P ratio was up to 10. The mean particle size of the complexes was in the range 102−138 nm and remained relatively constant over the range of 10:1 to 30:1 N/P ratios. As presented in Figure 8A, there was no remarkable difference in the diameters between GGI 30/DNA and GGI 40/DNA complexes at high N/P ratios, which were similar to those of complexes prepared with commercially available PEI 25k. However, at N/P ratio between 1 and 5, PEI 25k formed larger complexes with diameters of 320 nm compared with GGIs. This effect can be explained by instabilities of the PEI 25k/pDNA complexes and aggregate formation. In addition, we investigated the stability of the polyplexes in 10 mM NaCl (data shown in Supporting Information, Figure S1). It was found that the size of the GGI/pDNA polyplexes at N/P ratio of 20 remained constant and did not aggregate over a time period of 24 h. On the contrary, the size of PEI 25k/DNA complexes at N/P ratio of 20 changed from ∼200 nm to ∼800 nm, indicating that large aggregates were formed. Obviously, the presence of hydrophilic PEG block for GGI led to a successful colloidal stability of polyplexes even at low polymer concentration or high salt concentration. The great stability of the GGI/pDNA complex may be feasible for in vivo application (*12, 26*).

The formation of GGI/pDNA complexes (in 150 mM NaCl, pH 7.4) was further monitored by observation of the morphology examined with TEM. Both GGI 30 and GGI 40 formed well-defined spherical and compact complexes with plasmid DNA at a representative N/P ratio of 20 (Figure 8B). The micrographs clearly revealed that the sizes of the nanoparticles ranged 140−200 nm, which were suitable applications for endocytic cellular uptake (*28*). The results of the TEM experiments also could be confirmed by DLS measurements of the complexes. The corresponding size distributions of the complexes, measured by dynamic light scattering, were unimodal. The average particle size of GGI 30/pDNA complex was 190 ± 18 nm, and that of GGI 40/pDNA complex was 142 ± 11 nm (Figure 8B).

A positive surface charge of untargeted polyplexes is necessary for the attachment to anionic cell surface and endocytosis (*29*). To estimate the surface charge of the polymer/pDNA complexes, we measured the zeta potentials. The surface charge of copolymer polylexes was measured in 10 mM NaCl solutions, at N/P ratios of 1 to 30. As indicated in Figure 8C, even a large excess of LMW PEI 423 (N/P = 30) did not increase the zeta potential sufficiently, and the zeta potential was still negative. As expected, polyplexes of HMW PEI 25k with pDNA exhibited high zeta potential of 20 mV to 30 mV at the N/P ratio of 10 to 30. In the case of synthesized copolymers GGIs, GGI 30 and GGI 40 showed similar surface charge at various N/P ratios. Generally, at N/P ratio 1, zeta potentials of both GGI 30/pDNA and GGI 40/pDNA were negative, showing incomplete complexation. With increasing N/P ratio, zeta potentials of the GGI/pDNA complexes rapidly increased and reached plateaus about 15 mV at N/P ratios between 10 and 30. It must be noted that GGI/pDNA complexes showed significantly lower zeta potential values compared to PEI 25k/pDNA complexes ($p < 0.01$). This

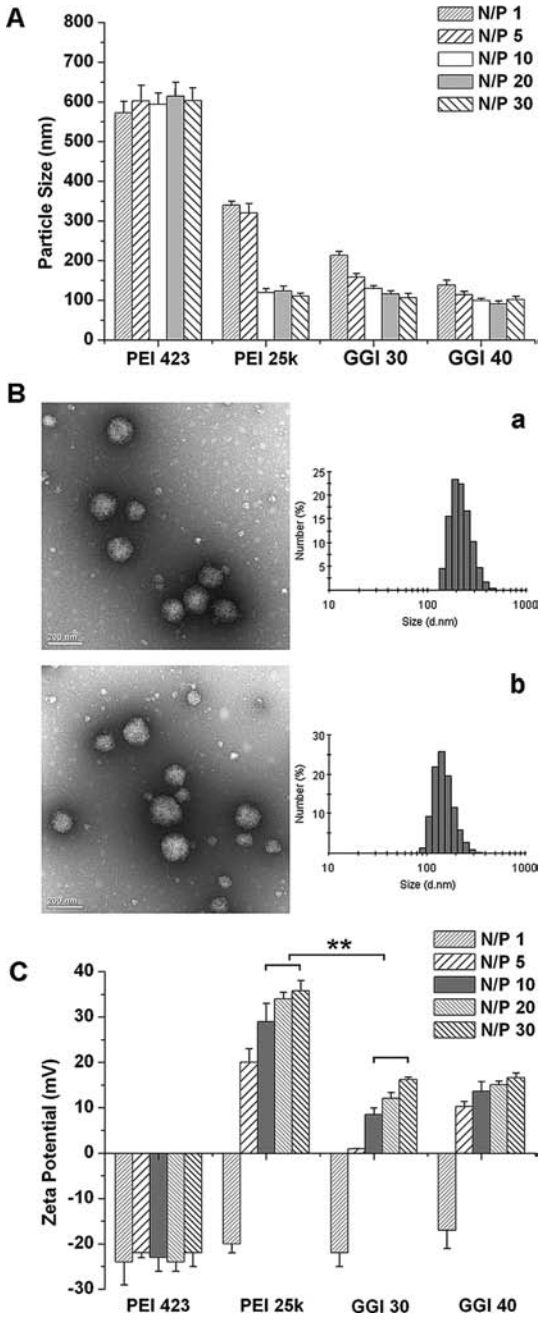

Figure 8. (A) Particle size of complexes formed with GGI copolymers and PEI homopolymers as determined by DLS at various N/P ratios in 10 mM NaCl. (B) TEM images of GGI/DNA complex at N/P ratio of 20 in 150 mM NaCl (scale bar = 200 nm) and the corresponding size distribution of the complexes detected by DLS. (a) GGI 30, (b) GGI 40. (C) Zeta potentials of complexes formed with GGI copolymers and PEI homopolymers as determined by DLS at various N/P ratio in 10 mM NaCl. Significant differences between copolymer and PEI 25k polyplexes are marked with an asterisk, $^{**}p < 0.01$.

could be explained by the structure of copolymer GGI. LMW PEIs combined with GGI did not condense DNA as tightly as PEI 25k did, and the charge shielding effect of PEG possibly led to the lower zeta potential of GGI, in comparison with PEI 25k. Since the positive surface charge of PEI polyplexes is related to cytotoxicity, we assumed that the moderate zeta potentials of GGI polyplexes might be a benefit for obtaining a better balance between cellular uptake and cytotoxicity.

Cytotoxicity of Copolymer GGI. To determine if the LMW PEI combined biodegradable copolymer GGI retained the low cytotoxicity of its starting material PEI 423, we investigated

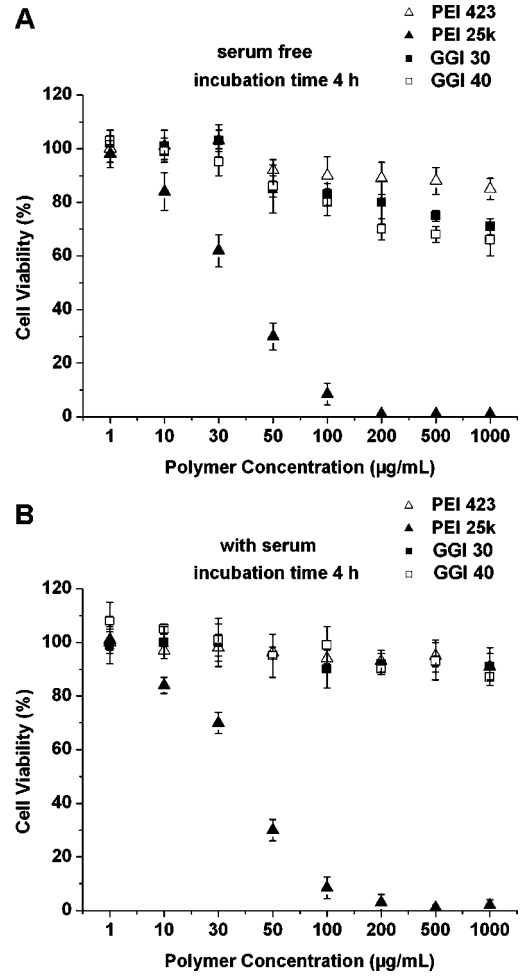

Figure 9. Cell viability of GGI copolymers and PEI homopolymers in the concentration range 1−1000 μg/mL in Hela cell line, determined by the MTT assay. (A) Cells were treated with polymers for 4 h in a serum-free medium. (B) Cells were treated with polymers for 4 h in a serum-containing medium. ($n = 4$, error bars represented standard deviation.)

the cytotoxicity of GGIs using a cell viability assay based on MTT. LMW PEI 423 and HMW PEI 25k were used as reference. Hela cells were exposed to various concentrations of polymers ranging from 1 μg/mL to 1000 μg/mL for 4 h, and cytotoxicity was assayed 48 h later. In agreement with the reported results (*7, 30*), LMW PEI 423 showed very low cytotoxicity. The cell viability was over 90% at the tested concentration (Figure 9A). The results showed that GGIs exhibited good cell viability below the concentration of 100 μg/mL (over 80%) and showed above 70% cell viability at concentration between 100 μg/mL and 1000 μg/mL. Our results also demonstrated that GGI 30 exhibited a slight reduction of cytotoxicity at high concentration compared with GGI 40, probably due to a shorter chain of the PLG block and lower amount of PEI grafted to the PLG block of GGI. On the contrary, the cell viability results showed that HMW PEI 25k, which is commonly used in gene delivery systems, exhibited significantly greater cytotoxicity than both GGI 30 and GGI 40 from the concentration of 10 μg/mL ($p < 0.01$). In addition, a very sharp drop in the number of viable cells was observed for PEI 25k with increasing concentration, while it was much more gradual for GGI. This fact indicated that the therapy window for GGIs was much wider than that of PEI 25k.

It should be noted that, in the presence of 10% serum, both GGI 30 and GGI 40 exhibited similar cell viability as LMW PEI 423, showing above 90% cell viability at the tested

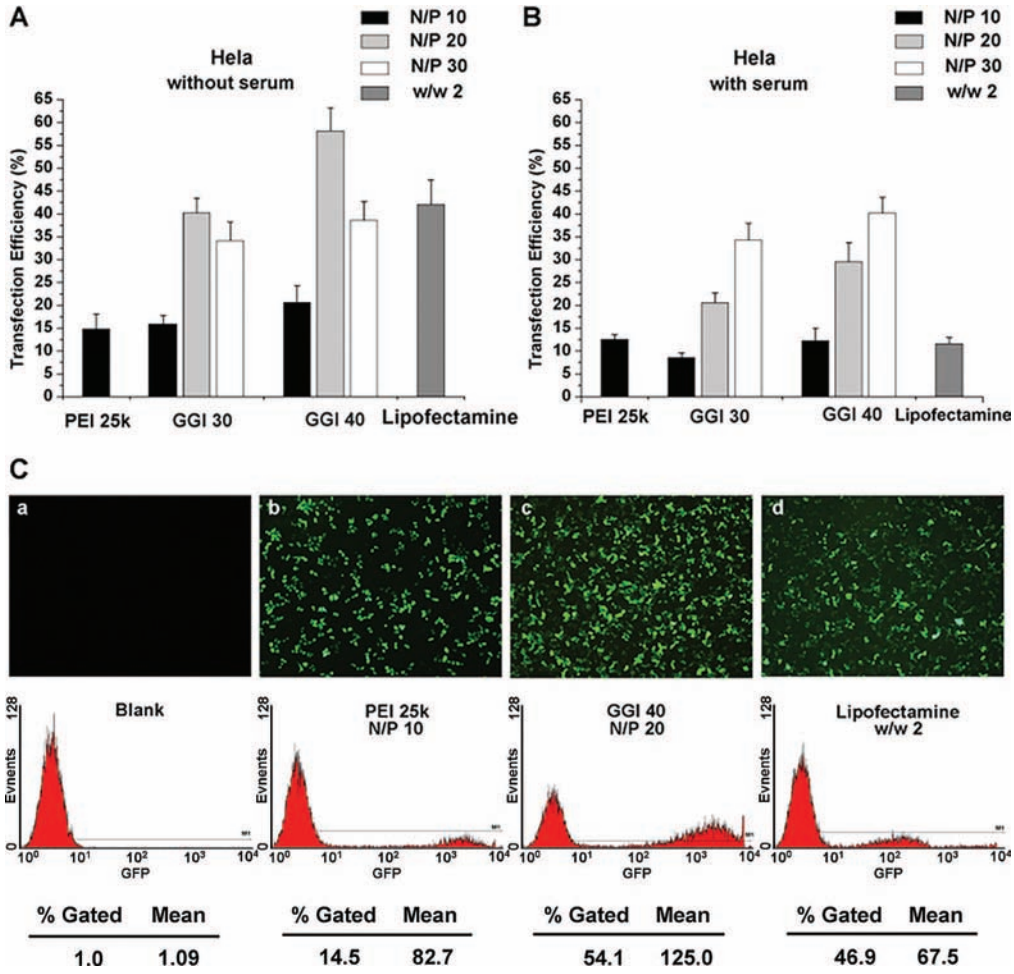

Figure 10. (A) In vitro gene transfection efficiency of the GGI/pEGFP-C1 complexes at various N/P ratios in serum-free medium in Hela cell line, in comparison with that of HMW PEI 25k (at its optimal N/P ratio of 10) and cationic lipid Lipofectamine 2000 (w/w 2). (B) In vitro gene transfection efficiency of the GGI/pEGFP-C1 complexes at various N/P ratios in serum-containing medium in Hela cell line, in comparison with that of PEI 25k and Lipofectamine 2000. ($n = 3$, error bars represented standard deviation.) (C) Fluorescence images (Row 1) and flow cytometry analyzed graphs of cell distribution expressing GFP (Row 2) of Hela cells transfected with (a) PBS (negative control), (b) PEI 25k/pEGFP-C1 (N/P 10), (c) GGI 40/pEGFP-C1 (N/P 20), (d) Lipofectamine 2000 (w/w 2) (magnification 200×).

concentration (Figure 9B). However, HMW PEI 25k still exhibited a remarkably higher cytotoxicity than those of GGI above the concentration of 10 μg/mL, although the serum was presence ($p < 0.01$).

Furthermore, GGIs, which are derived from poly(amino acid)s, are biodegradable copolymers confirmed by previous experiments. The copolymer GGIs may degrade in cells, producing a glutamine acid unit with LMW PEI and PEG. Thus, we investigated the cytotoxicity of the polymer degradation products. Copolymer GGI 30 and GGI 40 were incubated for 24 and 96 h at 37 °C in PBS with papain (the same procedure we used in the degradation assay). MTT was measured after the cell exposure to the lyophilized degraded polymer mixture. The results indicated that, at the observed concentration (1000 μg/mL and 2000 μg/mL), the degradation products exhibited no effect on cell viability (over 90%), suggesting that the degradation products of GGIs were essentially nontoxic (data shown in Supporting Information, Figure S2).

Therefore, the MTT results suggested that GGI retained the characteristics of LMW PEI in cytotoxicity, and the biocompatibility as well as the long-term safety of GGI were significantly improved in comparison to PEI 25k.

Transfection Efficiency in Vitro. The in vitro gene delivery efficiency of the LMW PEI combined copolymer GGI in Hela cells was evaluated using pEGFP-C1 as a marker gene, in the absence and presence of serum. The transfection efficiency of GGI 30 and GGI 40 were compared with HMW PEI 25k and commercially available cationic lipid Lipofectamine 2000.

The transfection efficiency of pEGFP-C1 in Hela was quantified using flow cytometry in terms of cell population expressing GFP. Figure 10A showed the percentage of the Hela cells expressing GFP at different N/P ratios using GGIs in the absence of serum. It revealed that, within the N/P ratios of 10, 20, and 30 we tested, both GGI 30/pEGFP-C1 and GGI 40/pEGFP-C1 polyplexes exhibited their maximum efficiency values at N/P ratio of 20. Up to 58% transfection was achieved by the GGI 40, which was statistically significantly higher than the 14% transfection obtained from the HMW PEI 25k ($p < 0.01$), at its optimal N/P ratio of 10. Also, the transfection efficiency of GGI 40 was very comparable to that of commercially available Lipofectamine (47%). No statistically significant differences existed between the data of GGI 40 at N/P ratio of 20−30 and the data of the Lipofectamine at its opitmal w/w ratio of 2/1.

Furthermore, in order to directly visualize the transfected cells expressing pEGFP, GFP expression in Hela cells was observed by an inverted fluorescent microscope. All the polymers were at their optimal transfection N/P ratio. In the microscopic images (Figure 10C), the cells transfected with GGI 40/pEGFP-C1 showed more bright green fluorescent spots than PEI 25k/pEGFP-C1. It appears that the amount of green cells transfected by GGI 40 and Lipofectamine 2000 were similar, but the

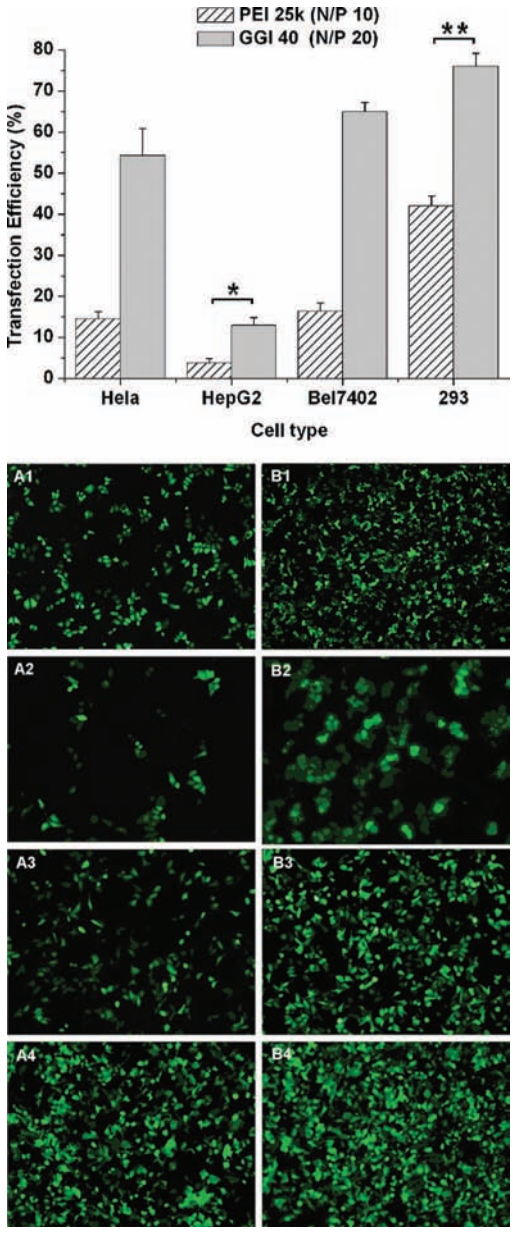

Figure 11. (A) Comparison of the in vitro gene transfection efficiency between GGI 40 and HMW PEI 25k at their optimal N/P ratios in Hela, HepG2, Bel 7402, and 293 cells. Significant differences between GGI and PEI 25k polyplexes are marked with an asterisk: $*p < 0.05$, $**p < 0.01$. ($n = 3$, error bars represented standard deviation.) (B) Comparison of the fluorescence images of (1) Hela, (2) HepG2, (3) Bel 7402, and (4) 293 cells transfected with (A) HMW PEI 25k at its optimal N/P ratio of 10 and (B) GGI 40 at its optimal N/P ratio of 20 (magnification 200×).

fluorescent spots of Lipofectamine 2000 were much dimmer than that of GGI 40, indicating that GGI 40 expressed more fluorescent proteins than those with Lipofectamine. The results were in accordance with the flow cytometry results, suggesting that LMW PEI combined copolymer GGI was more effective as a gene carrier, compared with HMW PEI 25k and Lipofectamine 2000.

In addition, we studied the effect of serum on the transfection efficiency of GGI/pDNA complexes. Since therapeutic gene transfection is in vivo, it is crucial to investigate the influence of serum on the transfection efficiency. As shown in Figure 10B, for GGI 30 and GGI 40 at N/P ratio of 10 and 20, the transfection efficiencies were both slightly decreased in the serum-supplemented medium. At N/P ratio of 30, no significant difference could be observed between the efficiencies in the presence and absence of serum. For PEI 25k and Lipofectamine 2000, however, the transfection efficiencies were decreased drastically with 10% FBS. These results implied that GGI might be more suitable for in vivo gene transfecion.

Since it was reported that the transfection efficiency of polyplexes might be dependent on cell lines (*17*, *31*), we further gave a direct comparison of the transfection efficiency of HMW PEI 25k and LMW PEIs combined copolymer GGI 40 at their optimal N/P ratio, in Hela, HepG2, Bel7402, and 293 cell lines. Both the results of flow cytometry (Figure 11A) and the image of the expression of GFP (Figure 11B) showed that, in four cell lines, the transfection efficiencies of GGI 40 were statistically significantly higher than PEI 25k. It also can be noticed that the transfection efficiencies of GGI 40 and PEI 25k were dependent on cell line. The sequential oreder was 293 > Bel7402 > Hela > HepG2.

CONCLUSION

In this study, we demonstrated that a novel degradable PEG-*b*-PLG-*g*-PEIs copolymer, a kind of combined LMW PEIs, was synthesized and evaluated as a new gene vector. The obtained polymers GGI 30 and GGI 40 showed degradability, a great ability to condense DNA and to protect pDNA against DNase I. The physicochemical properties, particle size, morphology, and zeta potential of GGI/pDNA polyplexes were suitable for gene delivery. The in vitro cell viability as well as gene transfection suggested that GGI had great potential as a gene carrier, especially GGI 40, which had significantly lower cytotoxicity and higher transfection efficiency, as compared to PEI 25k. In particular, the transfection efficiency of GGI was not markedly decreased in the presence of serum in comparison with PEI 25k and Lipofectamine 2000. Therefore, GGI can be a promising new nonviral gene delivery vector for future gene therapy applications, due to its degradability, low cytotoxicity, and high transfection efficiency.

Design and Synthesis of Biomimetic Hydrogel Scaffolds with Controlled Organization of Cyclic RGD Peptides

Junmin Zhu,* Chad Tang, Kandice Kottke-Marchant, and Roger E. Marchant*

Department of Biomedical Engineering, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106, and Department of Clinical Pathology, Cleveland Clinic Foundation, 9500 Euclid Avenue, Cleveland, Ohio 44195. Received October 14, 2008; Revised Manuscript Received December 15, 2008

We report on the rational design and synthesis of a new type of bioactive poly(ethylene glycol) diacrylate (PEGDA) macromers, cyclic Arg-Gly-Asp (cRGD)-PEGDA, to mimic the cell-adhesive properties of extracellular matrix (ECM), aiming to create biomimetic scaffolds with controlled spatial organization of ligands and enhanced cell binding affinity for tissue engineering. To attach the cRGD peptide in the middle of PEGDA chain, a tailed cRGD peptide, c[RGDfE(SSSKK-NH_2)] (**1**), was synthesized with c(RGDfE) linked to a tail of SSSKK. The tail consists of a spacer with three serine residues and a linker with two lysine residues for conjugating with acryloyl-PEG-NHS (**5**) to create cRGD-PEGDA (**6**). cRGD-PEGDA possesses good photopolymerization ability to fabricate hydrogel scaffolds under UV radiation. Surface morphology and composition analysis demonstrates that cRGD-PEGDA hydrogels were well-constructed with porous three-dimensional (3D) structures and uniform distribution of cRGD ligands. Our results show that cRGD-PEGDA hydrogels facilitate endothelial cell (EC) adhesion and spreading on the hydrogel surfaces and exhibit significantly higher EC population in comparison with linear RGD-modified hydrogels at low peptide incorporation. Since ligand presentation in biomimetic scaffolds plays an important role in controlling cell behavior, cRGD-PEGDA has great advantages of controlling hydrogel properties and ligand spatial organization in the resulting scaffolds. Furthermore, cRGD-PEGDA is an attractive candidate for the future development of tissue engineering scaffolds with optimum cell adhesive strength and ligand density.

INTRODUCTION

The shortage of available organ donors has driven the growth and expansion of the field of tissue engineering as a promising alternative to organ transplantation (*1*−*6*). Scaffolds play crucial roles in tissue engineering including providing support and space for cells, encouraging cell adhesion and growth, and guiding cell function (*7*−*15*). Hydrogels are excellent scaffolding materials for repairing and regenerating a variety of tissues, such as cartilage, bone, and vasculature (*16*−*22*). They are attractive because they can provide a highly swollen three-dimensional (3D) environment similar to soft tissues and allow diffusion of nutrients and cellular waste through the elastic network. Synthetic poly(ethylene glycol) (PEG)-based hydrogels have advantages over natural hydrogels, such as the ability of photopolymerization into any shape, injectable capacity for tissue repair, and adjustable mechanical properties to fit various applications (*23*). However, most synthetic hydrogels typically exhibit minimal or no intrinsic biological activity (*16, 17*), and do not provide an ideal environment for culturing anchorage-dependent cells, such as endothelial cells (ECs) and smooth muscle cells (SMCs). To facilitate cell adhesion, small peptides derived from extracellular matrix (ECM) proteins have been important targets for the covalent coupling type of biospecific modification (*24*−*30*). For example, Arg-Gly-Asp (RGD)-modified PEG monoacrylate was copolymerized with PEG diacrylate (PEGDA) to create cell-adhesive PEG hydrogels (*31*−*33*), but the extent of incorporation of RGD-modified PEG monoacrylate into PEGDA hydrogels is limited because increasing incorporation of monoacrylated monomers affects the mechanical properties and the swelling ratio of the resultant hydrogels (*34*−*36*).

To address these limitations, we recently reported on a linear RGD-modified PEGDA macromer, RGD-PEGDA with a GRGD-SP peptide attached in the middle of PEG chain, which stimulates cell adhesion and good control over the hydrogel mechanical properties (*37*). However, a further consideration is that the RGD sequence is exposed at the tip of a loop in the cell-binding domain of fibronectin, which presents the ligand with a spatial constraint that results in increased specificity for cell binding (*38, 39*). It is a challenge to incorporate cyclic RGD (cRGD) peptides into PEGDA hydrogels with controlled spatial organization to mimic the native RGD loop structure. Previous studies have demonstrated that cRGD peptides have the advantage of increasing the specificity to integrin $\alpha_v\beta_3$ and enhance biological activity up to 240 times, in comparison with linear analogues (*40*−*43*). Research in our laboratory has shown that cyclo(Arg-Gly-Asp-D-Phe-Lys) [c(RGDfK)] and cyclo(Arg-Gly-Asp-D-Phe-Glu) [c(RGDfE)] more efficiently compete with fibronectin for specific binding to integrin $\alpha_v\beta_3$ on human pulmonary artery ECs, compared with the linear GRGDSP peptide (*44*). Therefore, we hypothesize that the incorporation of cRGD peptides into the PEGDA hydrogels will better mimic the native fibronectin cell-binding domain and benefit the cell specific adhesion.

Here, we report on the design and synthesis of a new type of bioactive PEGDA macromers, cRGD-PEGDA (**6**), to mimic the cell-adhesive properties of ECM, aiming to create biomimetic scaffolds with controlled spatial organization and enhanced cell binding affinity for tissue engineering. To attach the cRGD peptide in the middle of PEGDA chain, a tailed cRGD peptide, c[RGDfE(SSSKK-NH_2)] (**1**), was synthesized with c(RGDfE) linked to a tail of SSSKK, which consists of a spacer with three serine residues, and a linker with two lysine residues for

conjugating with acryloyl-PEG-NHS (**5**) to create cRGD-PEGDA (**6**). Since ligand presentation in biomimetc scaffolds plays an important role in controlling cell behaviors, cRGD-PEGDA is an attractive candidate for the development of well-defined tissue engineering scaffolds with spatial control of ligand organization and optimization of adhesive strength through controlling ligand density.

EXPERIMENTAL SECTION

Materials. 9-Fluoromethoxycarbonyl (Fmoc)-protected amino acids, *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU), and 1-hydroxybenzotrilazole (HOBt) were purchased from AnaSpec (San Jose, CA). Amino acids had various side chain protect groups, such as *O*-*tert*-butyl (tBu) for Asp and Ser, *O*-*tert*-butoxycarbonyl (Boc) for Lys, and 2,2,4,6,7-pentamethyldihydrobenzofurn-5-sulfonyl (Pbf) for Arg, while allyl (All) was used to protect α-COOH of Glu (Fmoc-Glu-OAll). Fmoc-aminomethyl-3,5-dimethoxyphenoxy-valeric acid (PAL) resin (with a loading of 0.6 mmol/g), tetrakis-(triphenyl phosphine) palladium (0) [$Pd(PPh_3)_4$], piperidine, *N*,*N*-dimethylformamide (DMF), and *N*,*N*-diisopropylethylamine (DIEA) were purchased from Sigma-Aldrich. 1-Hydroxy-1-azabenzotriazoleuronium (HATU) was purchased from GenScript (Piscataway, NJ). PEGDA (Mw 6000) and linear RGD-PEGDA with a sequence of GRGDSP were synthesized according to our previous method (*37*). Acryloyl-PEG-NHS (**5**, Mw 3400) was purchased from Nektar (Huntsville, AL). The cleavage cocktail of Reagent K containing 85% (v/v) TFA was prepared prior to use according to the method described previously (*45*). Irgacure 2959 (I2959, 2-hydroxy-1-[4-(hydroxyethoxy)phenyl]-2-methyl-1-propane) was used as water-soluble photoiniators, which was provided by Ciba (Tarrytown, NY).

Instrumentation. Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry was performed on a Bruker Biflex III MALDI-TOF mass spectrometer by dissolving the sample and the matrix of 2,5-dihydroxybenzoic acid in 1:1 (v/v) ethanol and water, and mass spectra were typically accumulated from 200 laser shots. The surface morphology of freeze−dried hydrogels was examined by scanning electron microscopy (SEM) on a Hitachi S-4500 SEM instrument. Samples were coated with 50 Å of platinum prior to SEM imaging. Attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectra were obtained on a Bio-Rad FTS-575C FTIR spectrometer equipped with a UMA-500 microscope. A germanium crystal was used in the micro-ATR attachment to achieve a sampling depth of 0.1−0.2 μm. X-ray photoelectron spectroscopy (XPS) analysis was carried out on a PHI 5000 VersaProbe X-ray photoelectron spectrometer with the incident radiation consisting of Mg Kα X-ray and the takeoff angle fixed at 45°. Phase contrast photomicrographs of cells were obtained on a Nikon Diaphot 200 inverted phase contrast microscope with a CCD camera using *Metamorph* software package.

Synthesis of Tailed Cyclic RGD Peptide, c[RGDfE(SSSKK-NH_2)] (1). Peptides were synthesized by a three-step synthesis method in a 0.25 mmol scale with PAL resin to produce an amide C-terminus on a 433A Automatic Peptide Synthesizer (Applied Biosystems). In general, couplings were performed with a 4-fold excess of Fmoc-amino acid in the presence of HBTU/DIEA/HOBt (1:1:0.5, v/v/v) for 30 min. Fmoc groups were cleaved with 20% (v/v) piperidine in DMF for 10 min. Briefly, (1) protected linear RGD peptides on resin (**2**) with a sequence of RGDfE(SSSKK) on resin and an α-allyl protective group on Glu were synthesized using standard Fmoc strategy; (2) selectively deprotected peptides on resin (**3**) were obtained by the removal of α-allyl group on Glu manually on peptide synthesizer by 3 equiv of $Pd(PPh_3)_4$, followed by the removal of Fmoc on Arg at the N-terminus by 20% (v/v) piperidine in DMF; (3) protected cyclic RGD peptides on resin (**4**) were formed by cyclization between the amine group (NH_2) on Arg and the α-carboxylic group (COOH) on Glu using HATU. The final cyclized peptides (**1**) were cleaved from the resins using Reagent K and were further purified by reverse-phase HPLC on a Waters 2690 Alliance system (62% yield). MALDI-TOF MS: $m/z = 1121.9$ for $[M + H]^+$ (calculated mass 1122.1); $m/z = 1143.9$ for $[M + Na]^+$ (calculated mass 1144.1).

Synthesis of cRGD-PEGDA (6). c[RGDfE(SSSKK-NH_2)] **1** was dissolved in 50 mM of sodium bicarbonate buffer (pH 8.2). Acryloyl-PEG-NHS (**5**) with 2-fold molar amount as the cRGD peptide was dissolved in 50 mM of sodium bicarbonate buffer (pH 8.2) and added dropwise to the aqueous peptide solution. The mixture was stirred at room temperature for 24 h and then dialyzed against water with membranes of Mw cutoff 5000 for 48 h. The final power product was obtained by lyophilization for 48 h (65% yield). MALDI-TOF MS: a maximum peak at 7658 and a unique distribution with a repeating Mw difference of 44 (corresponding to one PEG repeating unit).

Fabrication of Hydrogels. Hydrogel solution containing 20% (w/v) of cRGD-PEGDA or PEGDA and 0.1% (w/v) of Irgacure 2959 (I2959) photoinitiator in PBS was sterilized by filtering through a 0.2 μm nylon syringe filter and was added to each well of a sterilized 6-well stainless steel mold. The plate was placed under a UV lamp (365 nm, 5−10 mW/cm^2) for 10 min irradiation. Hydrogel disks (8 mm in diameter, 1 mm in thickness) were obtained by lifting the mold plate and transferred to a 24-well culture plate. The swelling ratio (Q) of hydrogels was determined gravimetrically. The resulting hydrogel was placed in a vial containing 4 mL of PBS and incubated under gentle shaking (80 rpm) at 37° for 48 h. Excess fluid was removed to obtain the weight of the wet hydrogel (W_{wet}). The hydrogel was then freeze−dried to obtain the weight of the dried hydrogel (W_{dry}). The swelling ratio (Q) was calculated by using the equation: $Q = W_{wet}/W_{dry}$.

Cell Culturing on Hydrogels. Human pulmonary artery endothelial cells (ECs) (passage 7, Cambrex) were grown to 80−90% confluence using complete growth medium (CGM) in 25 cm^2 tissue culture flasks (Costar) at 37 °C and 5% CO_2. Confluent cells were trypsinized and resuspended in Opti-MEM I (Gibco). EC suspension (1 mL, ∼10^5 cells) was added to each well of the 24-well tissue culture plate containing hydrogel disks. Cells were allowed to attach for 2 h, and then the EC-seeded hydrogel disks were transferred to another 24-well culture plate with CGM and placed in the incubator at 37 °C and 5% CO_2. Culture media were changed every 2 days. Cells were imaged using a Nikon Diaphot 200 inverted phase contrast microscope. EC growth and viability were quantified 96 h after seeding by MTS assays, using CellTiter cell proliferation assay kit (Promega). The absorbance at 490 nm was measured. ANOVA with Tukey's comparison of means ($a = 0.05$, Minitab 15) was used to assess statistic differences.

RESULTS AND DISCUSSION

Rational Design of Well-Defined Hydrogel Scaffolds. The presentation of peptide ligands in scaffolds plays an important role in controlling cell adhesion and motility behaviors, and mechanical properties of tissue engineered constructs. Our design principle of hydrogel scaffolds is that the preconstruction of a bioactive PEGDA macromer with a cRGD peptide attachment in the middle of its chain will lead to controlled ligand spatial organization and ligand distribution in the resulting photopolymerized hydrogel scaffolds, as shown in Figure 1. Since this designed novel macromer has two C═C double bonds on both ends with a similar PEGDA backbone structure, high

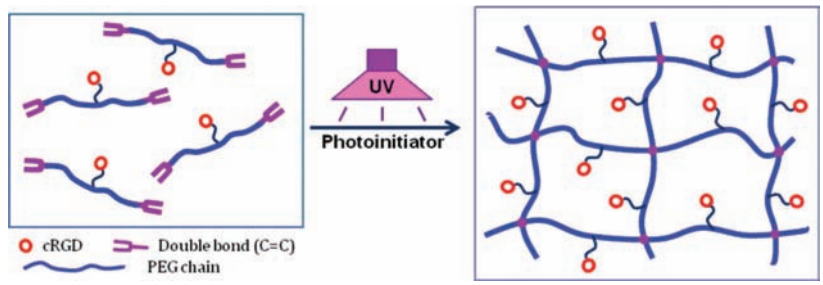

Figure 1. Rational design of cyclic RGD (cRGD)-modified PEGDA macromer for fabrication of biomimetic hydrogel scaffolds with controlled cRGD organization. A novel type of bioactive PEGDA macromers was designed with a cRGD peptide attached in the middle of PEGDA chain, which can be photopolymerized to form 3D hydrogel networks with uniform cRGD distribution.

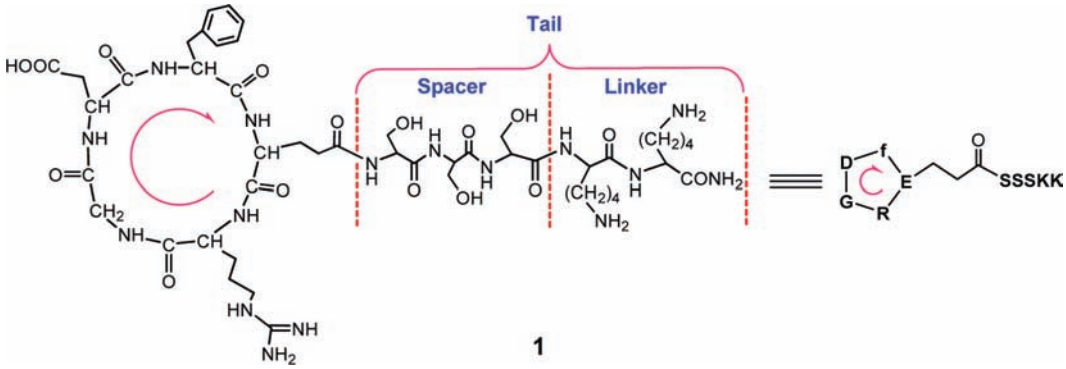

Figure 2. Chemical structure of designed cyclic RGD peptide, c[RGDfE(SSSKK-NH_2)] (**1**) with a tail of SSSKK, which consists of a spacer with three serine residues and a linker with two lysine residues for further conjugation with other molecules. The arrow shows the direction of the amino acid sequence from N-terminus to C-terminus prior to the cyclization of the linear peptide, RGDfE(SSSKK-NH_2).

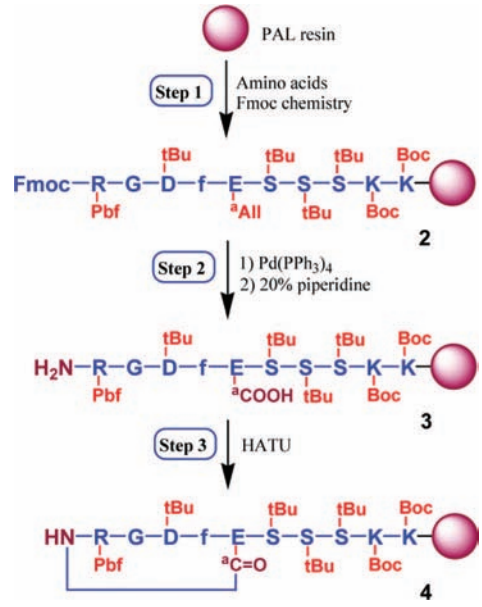
cRGD peptide density can be incorporated into the hydrogels without affecting the hydrogel physical properties. Furthermore, this cRGD-modified macromer can also copolymerize with other monomers to form cell-adhesive hydrogels with less incorporation due to the higher binding ability of cRGD ligands, compared with linear RGD peptides.

Design and Synthesis of Tailed Cyclic RGD Peptide. To attach the cRGD peptide in the middle of PEGDA chain, a tailed cRGD peptide, c[RGDfE(SSSKK-NH_2)] (**1**), was designed with c(RGDfE) linked to a tail of SSSKK through the Glu (E) residue, as shown in Figure 2. The tail consists of a spacer with three serine residues and two lysine residues. The hydrophilic spacer of SSS is used to increase the mobility of the c(RGDfE) ligand, which may lead to enhanced binding ability. Another consideration is that an SSS sequence next to Glu can prevent the unexpected glutarimide formation, which took place with a GGG spacer next to Glu in our previous studies (*45*). The KK acts as a linker with two free amine groups that provide two active sites for conjugating with other molecules. Compared with c(RGDfK) (which has limited spacer length from the side chain of lysine and only one free amino group on Lys for conjugation), the design of tailed cyclic RGD peptide is more flexible (due to the spacer) and affords two or more conjugating sites through the linker, provided that two or more lysine residues are attached.

The tailed cyclic peptide **1** was synthesized by orthogonal solid-phase peptide synthesis (SPPS), as shown in Scheme 1, using Fmoc-protected glutamic acid α-allyl ester (Fmoc-Glu-OAll) on a PAL resin. The allyl group on Glu was used as the orthogonal protecting group for on-resin cyclization with Fmoc strategy. It can be selectively removed to create a free carboxylic group and enable the construction of a lactam bridge between carboxylic and N-terminal amino groups while the peptide is still attached to the resin. This synthesis includes three major steps. First, a protected linear peptide on PAL resin (**2**) was synthesized. Then, allyl and Fmoc groups were removed

Scheme 1. Orthogonal Solid Phase Synthesis of c[RGDfE(SSSKK-NH_2)] 1 by a Three-Step Method



sequentially by $Pd(PPh_3)$ and piperidine to produce a selectively deprotected linear peptide on the resin (**3**). Finally, cyclization of **3** was carried out using HATU to generate the protected cyclic peptide of c[RGDfE(SSSKK-NH_2)] on the resin (**4**). The final deprotected cyclic peptide **1** was obtained by the cleavage of peptides from **4** using Reagent K containing 85% TFA, and purified by reverse-phase HPLC. Its structure was confirmed by MALDI-TOF MS analysis.

Table 1. Properties of Hydrogels from 20% (w/v) Macromers

hydrogel	Mw[a] (g/mol)	*Q*	Mc (g/mol)	ξ (Å)
PEGDA	6303	13.0	1791	64.7
cRGD-PEGDA	7658	17.6	2326	85.4

[a] Initial molecular weight of macromers determined by MALDI MS.

3400), was used to react with the two free amine groups from the linker (KK) of the tailed cyclic peptide **1** to produce cRGD-PEGDA (**6**), as shown in Scheme 2. The formation of the resulting cRGD-PEGDA macromer **6** was verified by MALDI-TOF mass analysis. The maximum peak at 7658 corresponds to the structure of **6**, which resulted from the conjugation of 2 mol **5** (Mw 3400) and 1 mol **1** (Mw 1121.1) with the elimination of 2 mol NHS (Mw 115.1). This novel bioactive PEGDA macromer **6** combines the photopolymerization ability of PEGDA and the bioactivity of cRGD peptides, and possesses the ability to form cell-adhesive hydrogels with uniform distribution of cRGD peptides in the middle of PEG chains through the whole hydrogel.

Hydrogel Fabrication and Characterization. Hydrogels with 20% (w/v) of macromers were fabricated in the form of thin disks (8 mm in diameter, 1 mm in thickness) by photopolymerization. The swelling ratio (*Q*) and mesh size (ξ) results are listed in Table 1. The number-average molecular weights between cross-links (Mc) and average mesh size were calculated according to the Peppas and Merrill model (*46*, *47*). The presence of ionic moieties in hydrogels makes the theoretical treatment of swelling much more complex (*48*). Given that the macromer of cRGD-PEGDA has only two charge groups on each long PEG chain and the resulting hydrogels are not highly charged, we still use the Peppas and Merrill model in order to simply the calculations (*49*). The hydrogel swelling properties and cross-linking density are particularly important from a tissue-engineering perspective, since they impact transport and overall cell viability and influence cell behavior. Under the same processing conditions, hydrogels made from cRGD-PEGDA exhibited a higher swelling ratio with $Q = 17.6$ than the control hydrogels from PEGDA with $Q = 13.0$, as listed in Table 1. As a result, cRGD-PEGDA hydrogels have a lower cross-linking density with a higher Mc (2326 g/mol) and greater mesh size ($\xi = 85.4$ Å) than the PEGDA hydrogels (Mc = 1791 g/mol, $\xi = 64.7$ Å). These results are consistent with the theoretical analysis that cRGD-PEGDA possesses a longer PEG chain (Mw

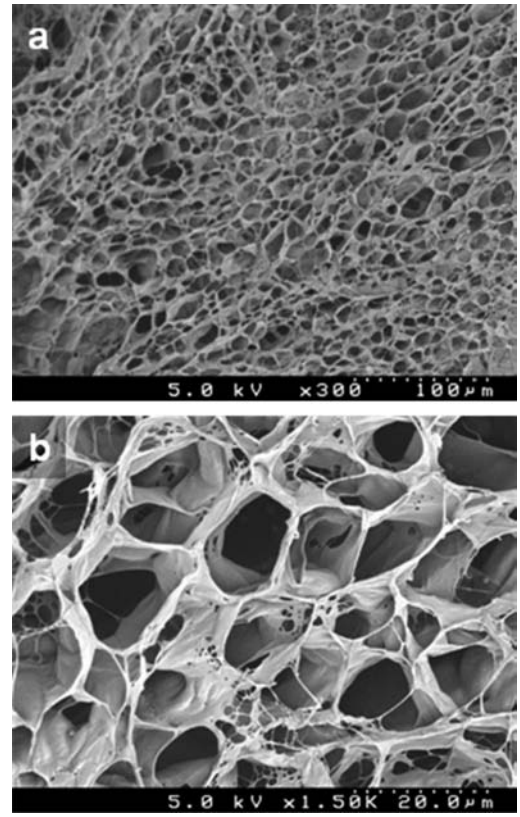

Figure 3. Surface morphology of 20% (w/v) cRGD-PEGDA hydrogel after freeze−drying. (a) SEM photograph with lower magnification (300×); (b) SEM photograph with higher magnification (1500×).

$\sim$ 6800) and much higher molecular weight (7658) after cRGD attachment, compared with PEGDA (Mw = 6303).

Hydrogel Surface Morphology. To obtain insight into the three-dimensional (3D) structure of the cRGD-PEGDA hydrogel, we used SEM to characterize the surface morphology, as shown in Figure 3. The samples were prepared by a freeze−drying method and followed by coating a thin layer of platinum (50 Å) prior to SEM imaging. There are some reports on SEM morphology of dried PEGDA hydrogels showing microporous structures (*50*, *51*), but much care must be taken when making

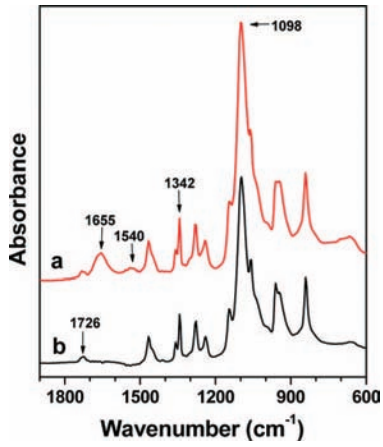

Figure 4. Surface analysis by ATR-FTIR spectroscopy. (a) ATR-FTIR spectrum of cRGD-PEGDA hydrogels after freeze−drying; (b) ATR-FTIR spectrum of PEGDA hydrogels after freeze−drying. cRGD-PEGDA hydrogels show two distinct peaks of amide I and II bands at 1655 and 1540 cm^{-1}, respectively, indicating that cRGD ligands are present on the hydrogel surface.

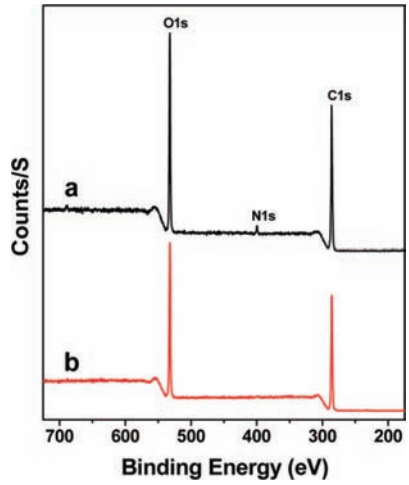

Figure 5. Surface composition analysis by XPS. (a) XPS spectrum of cRGD-PEGDA hydrogels after freeze−drying; (b) XPS spectrum of PEGDA hydrogels after freeze−drying. XPS analysis reveals that cRGD-PEGDA hydrogels have a new peak at binding energy of 398 eV, which is attributed to N_{1s} resulting from cRGD peptides. Quantitative analysis shows that there is 2.9% nitrogen present on the cRGD-PEGDA hydrogel surface.

the dried samples for SEM analysis, since the removal of water held within the porous hydrogel scaffolds may disrupt the structural stability and result in collapse and some artifacts upon drying (*52*). Our results revealed that dried cRGD-PEGDA hydrogels possess a highly porous structure (Figure 3a). The pore sizes range from 10 to 50 μm. More features were observed in the SEM image with higher amplification (Figure 3b). There are some bigger pores containing small pores and some fibrillar networks on the pore walls. In addition, most of the pores are interconnected. It demonstrates that the cRGD-PEGDA hydrogel has the microscopic porous structure with a complex 3D construction in the dried state.

Hydrogel Surface Composition analysis. The peptide ligand presentation in scaffolds plays an important role in controlling cell motility behaviors for tissue engineering (*54*, *55*). To verify the presence and distribution of cRGD peptide ligands on the cRGD-PEGDA hydrogel surface, we used ATR-FTIR (Figure 4) and XPS (Figure 5) to characterize the surface functional groups and surface composition, respectively. ATR-FTIR analysis revealed that PEGDA hydrogels (Figure 4b) show characteristic peaks at 1098, 1342, and 1726 cm^{-1}, which correspond to −C—O− symmetric stretching, −C—H_2 bending, and −C═O stretching from ester bonds, respectively. The ART-FTIR spectrum of cRGD-PEGDA hydrogel (Figure 4a) shows all three of these characteristic peaks, which demonstrates that cRGD-PEGDA hydrogel has a similar backbone structure to PEGDA. However, cRGD-PEGDA hydrogel shows two distinct peaks at 1655 and 1540 cm^{-1}, which correspond to the vibrations of amide (−CO—NH) I and II bands, respectively. These amide groups are from the cRGD peptides, indicating that cRGD ligands are present on the hydrogel surface. XPS analysis reveals that both surfaces of cRGD-PEGDA (Figure 5a) and PEGDA (Figure 5b) hydrogels have similar peaks at binding energies of 531 and 285 eV, which corresponds to O_{1s} and C_{1s}, respectively. However, cRGD-PEGDA hydrogels have a new peak at binding energy of 398 eV, which is attributed to N_{1s} resulting from cRGD peptides. Quantitative analysis shows that there is 2.9% nitrogen present on the cRGD-PEGDA hydrogel surface, which is very close to the theoretical nitrogen content of 2.8%. This indicates that the hydrogel has a well-defined structure with cRGD peptides uniformly presented on the surface and distributed through the material.

Two-Dimensional (2D) EC Seeding and Culturing on Hydrogel Surfaces. Human pulmonary artery ECs were used to test the cell responses to cRGD-PEGDA hydrogels. Cells were seeded on the material surfaces, which were made from 20% (w/v) macromers sterilized with a 0.2 μm syringe filter. Figure 6 shows phase-contrast micrographs of ECs seeded on the hydrogel surfaces at various time points. ECs seeded on the PEGDA hydrogels assumed a rounded morphology with little evidence of spreading 2 h after seeding (Figure 6a) and exhibited an apparent decrease in density 24 h postseeding (Figure 6b), suggesting that ECs have only weak, nonspecific interactions with these materials. ECs seeded on the cRGD-PEGDA hydrogels (cRGD density = 25.3 mM) showed higher initial cell attachment and cell spreading to some extent 2 h after seeding (Figure 6c), and cells were fully spreading 24 h after seeding (Figure 6d). Thus, the enhanced EC attachment and growth on cRGD-PEGDA hydrogels were attributed to the specific binding of cRGD ligands to the integrin receptors on EC surfaces.

Effect of Ligand Binding Affinity on Cell Growth. Quantitative modulation of adhesion strength can be achieved through variation of the affinity and surface density of peptide ligands. To amplify and compare the effects of ligand affinity on EC growth on hydrogels, we incorporated low ligand density into hydrogels to compare cell behaviors responding to cRGD and linear RGD ligands. Hydrogel disks from 5% (w/v) cRGD-PEGDA hydrogels (cRGD density = 6.3 mM) were fabricated by copolymerization with 15% (w/v) PEGDA. MTS cell proliferation assays were performed 96 h postseeding of ECs on the hydrogel surfaces, as shown in Figure 7. Compared with the control PEGDA hydrogel, both 5% cRGD and RGD-modified PEGDA hydrogels exhibit significantly higher ($p < 0.001$) EC population than the control PEGDA hydrogel. This is due to the specific cell adhesion with peptide ligands presented on the hydrogel surfaces. Further analysis shows that 5% cRGD-PEGDA hydrogel shows significantly higher ($p < 0.001$) EC proliferation (cell population increased 44%) than 5% RGD-PEGDA hydrogel. This is attributed to the enhanced cell adhesion resulted from the higher EC binding ability of cRGD peptides.

CONCLUSIONS

In summary, we have synthesized a new type of bioactive PEGDA macromers, cRGD-PEGDA **6**, to mimic the cell-adhesive properties of ECM, aiming to create biomimetic scaffolds with

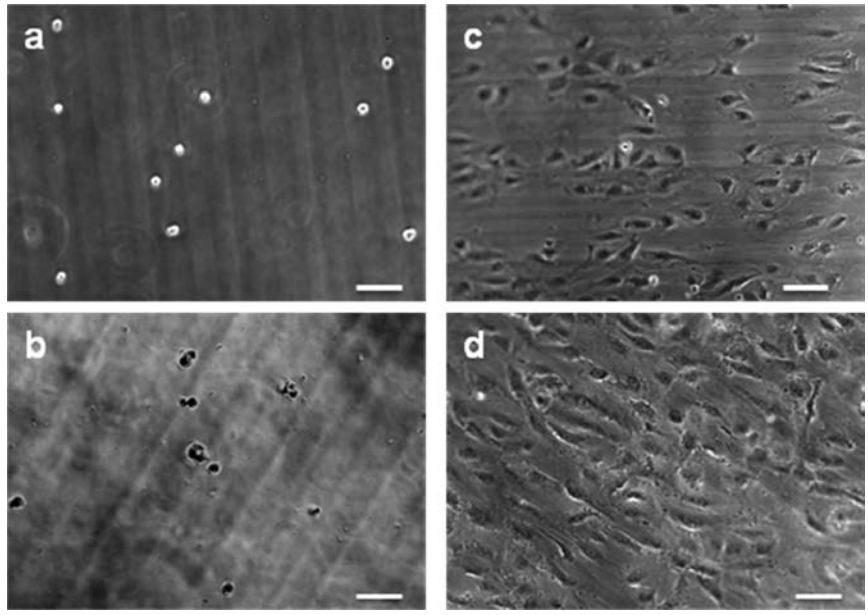

Figure 6. 2D seeding and culturing of endothelial cells (ECs) on hydrogels: (a,b) phase contrast of ECs 2 and 24 h after seeding on PEGDA hydrogel, respectively; (c,d) phase contrast of ECs 2 and 24 h after seeding on cRGD-PEGDA hydrogel, respectively. The images show that ECs seeded on cRGD-PEGDA hydrogels exhibited higher initial cell attachment, greater cell spreading, and higher cell density than on PEGDA hydrogels. (Scale bar = 100 μm).

(a) MTS assays performed at 96 h after EC seeding; (b) phase contrast of ECs 96 h after EC seeding on 5% (w/v) cRGD-PEGDA hydrogel; (c) phase contrast of ECs 96 h after EC seeding on 5% (w/v) RGD-PEGDA hydrogel. 5% cRGD-PEGDA hydrogel shows significantly higher ($p < 0.001$) EC proliferation (cell population increased 44%) than 5% RGD-PEGDA hydrogel. (Scale bar = 100 μm.)

controlled spatial organization and enhanced cell binding affinity for tissue engineering. To attach the cRGD peptide in the middle of PEGDA chain, a tailed cRGD peptide, c[RGDfE(SSSKK-NH_2)] **1** was designed and synthesized with c(RGDfE) linked to a tail of SSSKK, which provides a hydrophilic spacer of SSS and a linker of KK for conjugation. cRGD-PEGDA possesses good photopolymerization ability to fabricate hydrogel scaffolds under UV radiation. The resulting hydrogels were well-constructed with porous 3D structures and uniform distribution of cRGD ligands. Our results show that cRGD-PEGDA hydrogels facilitate EC adhesion and spreading on the hydrogel surfaces, and exhibit significantly higher EC population in comparison with linear RGD-modified hydrogels at low peptide incorporation. Since ligand presentation in biomimetc scaffolds plays an important role in controlling cell behaviors, cRGD-PEGDA has the great advantage of controlling hydrogel properties and ligand spatial organization in the resulting scaffolds. Furthermore, cRGD-PEGDA is an attractive candidate for the future development of tissue engineering scaffolds with optimum cell adhesive strength and ligand density.

Influence of Disulfide Density and Molecular Weight on Disulfide Cross-Linked Polyethylenimine as Gene Vectors

Qi Peng, Chu Hu, Juan Cheng, Zhenlin Zhong,* and Renxi Zhuo

Key Laboratory of Biomedical Polymers of Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received October 20, 2008; Revised Manuscript Received December 30, 2008

Disulfide cross-linked polyethylenimines (PEI_X-SS_Y, where *X* refers to the molecular weight of raw PEI, and *Y* refers to the thiolation degree) were prepared in two steps: First, thiol groups were introduced on a raw polyethylenimine (PEI) by the amine-induced ring-opening reaction of thiirane. Second, thiol groups were oxidized by DMSO to form the disulfide cross-links. The cross-linked PEI_{800}-SS_Y polymers with a moderate thiolation degree (PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, and PEI_{800}-$SS_{4.5}$) could form compact polyplexes with a size of 200−300 nm at an adequate N/P ratio. In contrast, those with a too low or too high thiolation degree (*Y* below 2.6 or above 4.5) formed much looser polyplexes with a size above 600 nm. The polyplexes of PEI_X-$SS_{3.0-4.0}$ series ($X = 800$, 1800, and 25,000) formed small particles with a size below 400 nm at a wide range of N/P ratios. Efficiency of the cross-linked PEIs as gene vectors was evaluated in vitro by transfection of pGL3 to HeLa, COS7, 293T, and CHO cells. The efficiency is disulfide content and molecular weight dependent. The PEI_{800}-SS_Y series with an adequate thiolation degree between 2.6 and 4.5 have relatively lower cytotoxicity and higher gene transfection efficiency than 25 KDa PEI. The polymers with very low or very high thiolation degrees were unable to form compact polyplexes and had very poor transfection efficiency. A suitable molecular weight of raw PEI is also essential to obtain a highly efficient disulfide cross-linked PEI gene vector. Among the three raw PEIs of different molecular weights tested (800 Da, 1800 Da, and 25 KDa), the cross-linked polymer prepared from 800 Da PEI that has the lowest molecular weight gave the best results.

INTRODUCTION

Polymer-mediated gene delivery has recently appeared as a comparable alternative to viral vectors for its lower cost, large nucleic acid loading capacity, and no immunogenesis (*1*−*3*). For example, polyethylenimine (PEI) is one of the most effective nonviral gene delivery carriers. The proton sponge nature of PEI is thought to cause osmotic swelling and physical rupture of the endosome, resulting in the escape of the vector from the degradative lysosomal trafficking pathway (*4, 5*).

High molecular weight is necessary for effective gene transfection with PEI. While high molecular weight PEI possesses high gene transfection efficiency, it has a high cytotoxicity (*6, 7*). Comparatively, low molecular weight PEI showing poor gene transfection efficiency was reported to have much lower cytotoxicity (*8*). Therefore, a reasonable way for resolving the contradiction between efficiency and cytotoxicity was suggested to combine low molecular weight PEIs together with degradable links such as amides, acetals, esters, and disulfides. It was expected to produce a polymer with lower toxicity and relatively high gene transfection efficiency, as well as long-term safety. Recently, many kinds of degradable PEIs showed good transfection efficiency and low cytotoxicity (*9*−*12*).

A disulfide bond can be broken in the presence of glutathione (GSH). The intracellular glutathione concentration is 50−1000 times higher than the extracellular concentration (*13*−*15*). The presence of disulfide in gene vectors could maintain a balance of keeping pDNA polyplexes stable in the extra-cytoplasmic environment and inducing efficient release of the entrapped pDNA from the polyplexes after their movement into the reductive cytoplasmic compartment. It also would limit the toxicity of the polymers. The advantages of disulfide linkages in gene transfection polymers are exemplified in the literature (*11, 16*−*20*). Bioreducible polyamidoamines containing multiple disulfide linkages with low toxicity were able to transfect COS7 cells in vitro with transfection efficiencies significantly higher than those of 25 kDa PEI (*17*). Linear poly(ethylenimine sulfide)s were reported to be safe gene carriers with high transfection efficiencies comparable to 25 kDa PEI (*19*). Branched PEI with an M_w of 800 Da was cross-linked by the reaction with either dithiobis(succinimidylpropionate) (DSP) or dimethyl 3,3′-dithiobispropionimidate dihydrochloride (DTBP), resulting in greatly increased gene transfection efficiency. Also, cytotoxicity was decreased by avoiding long-term polymer accumulation (*21*). Recently, we demonstrated that disulfide cross-linked PEIs synthesized by oxidation of thiolated 800 Da PEI possess simultaneously higher gene transfection efficiency and lower cytotoxicity than 25 KDa PEI (*22*).

It is reasonable to assume that the properties of disulfide cross-linked PEIs as gene vectors would be determined by (i) the type and density of disulfide cross-linkages and (ii) the molecular weights of both raw and cross-linked PEIs. In this paper, the influence of disulfide density and molecular weights of raw PEIs on the molecular weights and transfection efficiency of the cross-linked PEIs is investigated.

MATERIALS AND METHODS

Materials. PEIs with M_w of 800 Da and 25 kDa were purchased from Aldrich, and PEI with a M_w of 1800 Da was from Alfa Aesar. Thiirane was synthesized by literature procedure (*23*). Plasmid pGL3 under the control of SV40 promoter and with enhancer sequences encoding luciferase was obtained from Promega, Madison, WI, USA. Plasmids were propagated in *Escherichia coli* in Luria−Bertani (LB) medium containing 60 μg/mL ampicillin respectively at 37 °C and

[a] Reaction conditions: Step 1 (thiolation): pH 7.2 in CH_3OH, 50 °C for 24 h. Step 2 (oxidation): room temperature in DMSO for 2 days.

purified using E. Z. N. A. Fastfilter Endofree Plasmid Midi kits (Omega) according to the manufacturer's instruction. The purity of DNA was assessed spectrophotometrically by measuring absorbance at wavelengths of 260 and 280 nm (OD_{260}/OD_{280} 1.8 or greater) and confirmed using 0.7% agarose gel electrophoresis containing GelRed. The DNA concentration was determined by measuring the UV absorbance at 260 nm. DNA aliquots of pGL3 were stored at −20 °C prior to use. Dulbecco's modified eagle's medium (DMEM), penicillin−streptomycin, trypsin, Dulbecco's phosphate buffered saline, and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma. Other commercially available reagents were used as received.

Synthesis of Thiolated PEI (PEI_X-SH_Y). In a 25 mL flask, 1.00 g of PEI (800 Da, 1800 Da, or 25 kDa) was dissolved in 5 mL of deionized water. Hydrochloric acid (0.1 N) was added dropwise to the PEI solution while stirring until pH was regulated to 7.2. After removal of water by evaporation under reduced pressure, the yellow solid thus obtained was dissolved in 3 mL of CH_3OH and transferred to an ampule. After the container was purged with argon for 5 min, a calculated amount of thiirane was added. The ampule was sealed and kept in a 50 °C oil bath for 24 h with magnetic stirring. The content of the ampule was transferred to a flask, evaporated to dryness under reduced pressure, and stored under argon. The thiol group content was determined by Ellman's method (*24*, *25*) and listed in Table 1. ^{1}H NMR (300 MHz, D_2O): δ 3.15−2.55 (m, NCH_2CH_2N, NCH_2CH_2S).

Synthesis of Disulfide Cross-Linked PEI (PEI_X-SS_Y). A solution of 1.50 g of PEI_X-SH_Y in 3 mL of methanol and 1.5 mL of dimethyl sulfoxide (DMSO) was stirred for 48 h. The reaction solution was precipitated in diethyl ether three times and dried under high vacuum to give a light yellow viscous glue or solid. ^{1}H NMR (300 MHz, D_2O): δ 3.14−2.66 (m, NCH_2CH_2N, NCH_2CH_2S).

Cytotoxicity Assay of PEI_X-SS_Y. The cytotoxicity assay of PEI_X-SS_Y was performed the same way as described in the previous paper (*17*).

Molecular Weight Determination. Capillary viscosity measurements were carried out to estimate molecular weights (*26*, *27*). The polyamine polymers were neutralized with hydrochloric acid to pH 7.4 and dissolved in 150 mM NaCl at concentration from 20 mg/mL to 5 mg/mL. Viscosity measurements were carried out using a capillary viscometer at 25 °C. The molecular weights of cross-linked polymers were calculated using the Mark−Houwink equation $[\eta] = KM^{\alpha}$, where M is the molecular weight and K and α are Mark−Houwink parameters determined from PEI standards of known molecular weights.

The molecular weights of the polymers were also determined by gel permeation chromatographic (GPC) using a Waters 2690D HPLC equipped with Ultrahydrogel 120 and 250 columns. HAc/NaAc (pH 2.8) buffer solution was used as the eluent at a flow rate of 0.3 mL/min. Poly(ethylene glycol) standards with narrow distribution were used to generate a calibration curve.

Preparation of PEI_X-SS_Y /pDNA Polyplexes and Agarose Gel Retardation. A 0.1 mg/mL aqueous solution of plasmid DNA (pGL3) was diluted to designed concentration (usually 20 μg/mL) using 150 mM NaCl solution under vortexing. Designed amounts of PEI_X-SS_Y aqueous solutions were added slowly to the pDNA solutions. The amount of polymer added was calculated on the basis of chosen N/P ratios of PEI_X-SS_Y/DNA (nitrogen atoms of the polymer over phosphates of pDNA). The mixture was incubated at room temperature for 30 min for the complex formation. A 5 μL sample of the polyplex solution mixed with 1 μL of 6 × A loading buffer was loaded to agarose gel. The polyplexes were electrophoresed on a 0.7% agarose gel containing GelRed with Tris-acetate (TAE) running buffer (pH 8) at 80 V for 80 min. DNA bands were visualized by an UV (254 nm) illuminator and photographed with a Vilber Lourmat imaging system (France).

Particle Sizes and Zeta Potential Measurements. The particle size and zeta potential were measured with a Malvern Nano-ZS ZEN3600 Zeta-Sizer at room temperature. The polyplexes at various N/P ratios were prepared the same way as above. Then, the polyplexes were incubated at room temperature for 30 min. After that, the polyplexes were diluted by 150 or 10 mM NaCl solution to 1 mL volume prior to measure particle sizes or zeta potentials.

Determination of in Vitro Transfection Efficiency. The in vitro transfection efficiency of PEI_X-SS_Y/pGL3 polyplexes was evaluated in HeLa, COS7, 293T, and CHO cells by the procedure as described in the previous paper (*17*).

RESULTS AND DISCUSSION

Preparation of PEI_X-SS_Y. The strategy for preparation of PEI_X-SS_Y is shown in Scheme 1 similar to that in our previous report (*17*) except using thiirane as a thiolation regent instead of methylthiirane. First, a raw PEI is thiolated by a ring-opening reaction with a relevant quantity of thiirane to give the thiolated product PEI_X-SH_Y, where X refers to the molecular weight of the raw PEI and Y stands for the average number of thiol groups on each PEI molecule. Second, PEI_X-SH_Y is cross-linked into a higher molecular weight polymer PEI_X-SS_Y by disulfide-forming oxidation of the thiol groups with DMSO.

Three kinds of PEIs with weight-averaged molecular weights (M_w) of 800 Da, 1800 Da, and 25 kDa, respectively, were thiolated through the ring-opening reaction of thiirane with the primary and secondary amino groups of PEI at pH 7.2 in methanol, affording the thiolated products PEI_X-SH_Y. The thiolation degree Y was determined by Ellman's test (*24*, *25*) and listed in Table 1. As shown in the table, the thiolation degree was correlated to the feed ratio of thiirane/PEI and could be adjusted over a wide range.

Thiolated PEIs were cross-linked by oxidation with DMSO at room temperature, and the final products PEI_X-SS_Y were subjected to Ellman's test for the estimation of residual thiol groups. After 2 days of oxidative cross-linking reaction in DMSO, the amount of remained thiol groups was found to be less than 10% of the initial value for all samples, indicating that the disulfide-forming oxidation was near completion.

For PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, PEI_{800}-$SS_{4.5}$, and PEI_{1800}-$SS_{3.5}$, the reaction mixtures were clear solutions during the whole oxidation process. For PEI_{800}-$SS_{5.5}$, PEI_{800}-$SS_{7.0}$, and PEI_{25K}-$SS_{4.0}$, however, gelatinous products were obtained. The gels dissolved again to become solutions gradually in one to two days at room temperature. The dissolution of the

[a] IC_{50} values measured on HeLa cells at 24 h after the addition of PEI_X-SS_Y series by MTT assay. [b] Average particle sizes of PEI_X-SS_Y/pGL3 measured by DLS at different N/P ratios in 150 mM NaCl. [c] Zeta potentials of PEI_X-SS_Y/pGL3 measured at different N/P ratios in 10 mM NaCl.

gels could be explained by the transform of intermolecular disulfide bonds into intramolecular ones (*17*).

Molecular weights of the PEI_{800}-SS_Y series were estimated by viscosity measurements using a capillary viscometer. In 150 mM NaCl aqueous solution (pH 7.4, 20 °C), the molecular weights of PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, and PEI_{800}-$SS_{4.5}$ were estimated to be 1800, 2900, 4000, 8500, and 8700, respectively. The molecular weight increases with the increase of thiolation degree *Y* when *Y* is below 3.5. The disulfide cross-linked PEIs have very similar molecular weights regardless of their thiolation degree in the range from 3.5 to 4.5. This result suggests that the majority of disulfide cross-links are intramolecular when the thiolation degree is high. Because of the phenomenon of partial gelation, we were unable to estimate the molecular weight of PEI_{800}-$SS_{5.5}$ and PEI_{800}-$SS_{7.0}$.

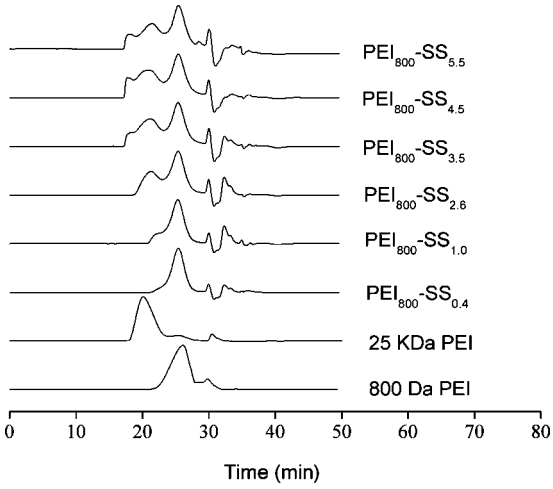

Figure 1. GPC traces of PEI_{800}-SS_Y series, 800 Da and 25 kDa PEI in HAc/NaAc (pH 2.8) buffer solution.

GPC analysis results (Figure 1) revealed that the introduction of disulfides for raw PEIs elevate the average molecular weights of the final products, and with the increase of the content of disulfide in the polymers, the molecular weights of the PEI_{800}-SS_Y ($Y = 0.4$, 1.0, 2.6, and 3.5) correspondingly increased. All PEI_{800}-SS_Ys had a similar peak nearly repeating with 800 Da PEIs. Maybe it can be explained that quite a lot of raw materials interfused the final products without reacting with thiirane. Compared to the raw material 800 Da PEI, PEI_{800}-$SS_{0.4}$ and PEI_{800}-$SS_{1.0}$ showed little improvement in their molecular weights. The peak shape of PEI_{800}-$SS_{0.4}$ seems almost the same as that of its raw materials. From PEI_{800}-$SS_{1.0}$, the cross-linked polymer was formed showing higher molecular weight from

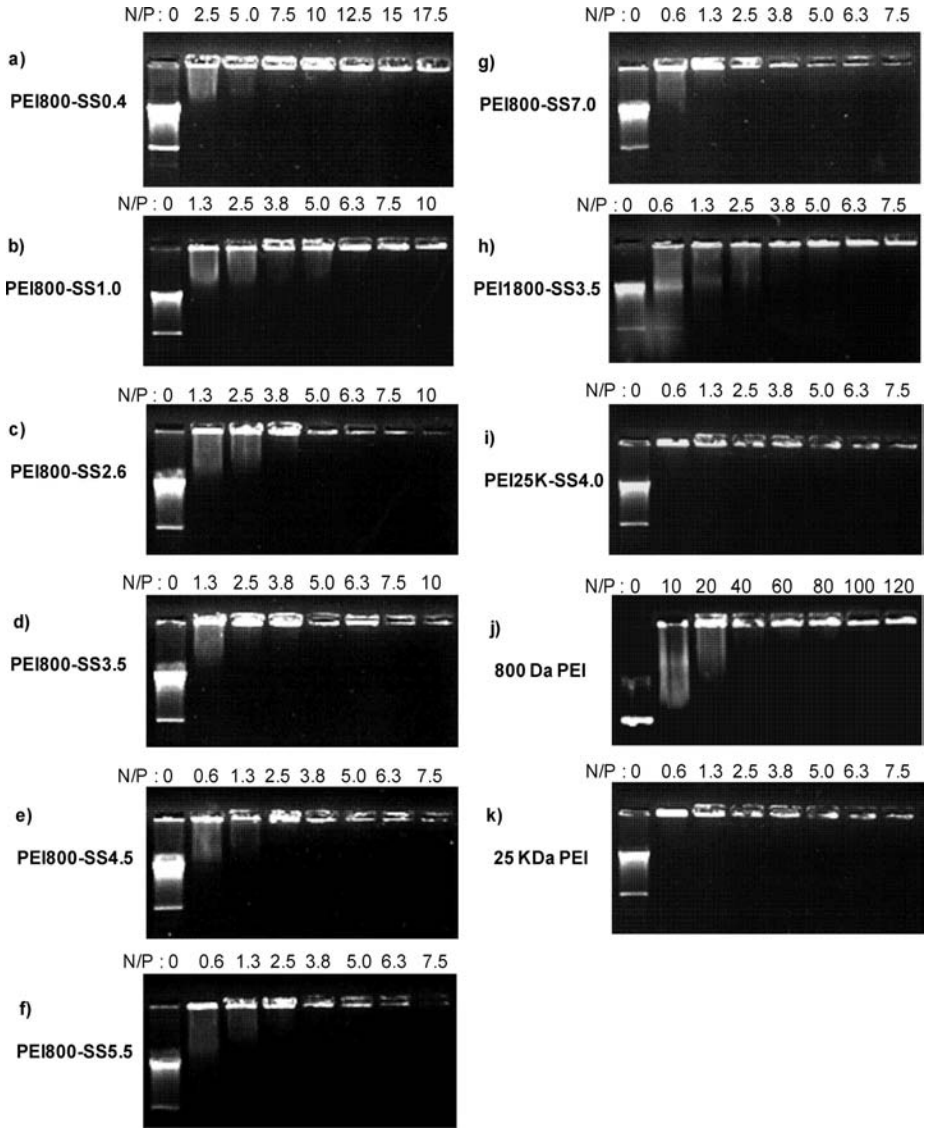

Figure 2. The effect of increasing concentration of PEI_X-SS_Y on the electrophoretic migration of pGL3 through an agarose gel. The polyplex composition (N/P ratio) was expressed as PEI nitrogen atoms per DNA phosphate. Plates a−g: PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, PEI_{800}-$SS_{4.5}$, PEI_{800}-$SS_{5.5}$, and PEI_{800}-$SS_{7.0}$, respectively. Plates h and i: PEI_{1800}-$SS_{3.5}$ and PEI_{25K}-$SS_{4.0}$, respectively. Plate j: 800 Da PEI. Plate k: 25 KDa PEI.

the shorter outflow times of the apexes near the peak. The shapes of apexes of PEI_{800}-$SS_{3.5}$, PEI_{800}-$SS_{4.5}$, and PEI_{800}-$SS_{5.5}$ were nearly the same, and their molecular weights remained constant from the results. In HAc/NaAc buffer solution (pH 2.8, 40 °C), the molecular weights of PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, PEI_{800}-$SS_{4.5}$ were estimated to be 1238, 1365, 1742, 2075, and 2192, respectively. The trend of the results was similar to that obtained from viscosity measurement.

Cytotoxicity of PEI_X-SS_Y. MTT assay was carried out to determine the cytotoxicity of the PEI_X-SS_Y series with the IC_{50} values listed in Table 2. The PEI_{800}-SS_Y series, regardless of the thiol group content, had a lower cytotoxicity compared to 25 kDa PEI in HeLa cells. PEI_{800}-$SS_{0.4}$ and PEI_{800}-$SS_{1.0}$ showed low cytotoxicity similar to 800 Da PEI. With the increasing content of disulfide in the polymers, their toxicity increased and reached a maximum of around 34 μg/mL (IC_{50}) at high thiolation degrees of 5.5 and 7.0. As shown in Table 2, with the similar disulfide content, PEI_X-SS_Y prepared from higher molecular weight raw PEI had higher cytotoxicity than that prepared from lower molecular weight raw PEI. PEI_{25K}-$SS_{4.0}$ showed toxicity similar to that of 25 kDa PEI.

In addition, PEI_X-SS_Y might degrade in vivo into individual low molecular weight PEI molecules with relatively low toxicity, and those low molecular weight fragments of polymers would be cleared more easily from the body.

Formation and Characterization of PEI_X-SS_Y /pDNA Polyplexes. To mediate endocytosis through cell membrane, cationic polymers need to condense DNA into compact particles via electrostatic interactions between the positively charged polymers and the negatively charged phosphates on DNA backbones (*28, 29*). The polyplex of a disulfide cross-linked PEI with a pDNA was prepared by adding PEI_X-SS_Y aqueous solution slowly to the pDNA solution. The amount of polymer added was calculated on the basis of chosen N/P ratios, nitrogen atoms of the polymer over phosphates of pDNA, in PEI_X-SS_Y/pDNA. Formation and characterization of the polyplexes was investigated by agarose gel retardation, particle size, and zeta potential.

Gel retardation assay verified that PEI_X-SS_Y series can condense plasmid DNA at low N/P ratios. As shown in Figure 2, as the concentration of the polymer increased, the capability of integrating with plasmid DNA was enhanced. 800 Da PEI formed stable complexes with DNA only at N/P ratios higher

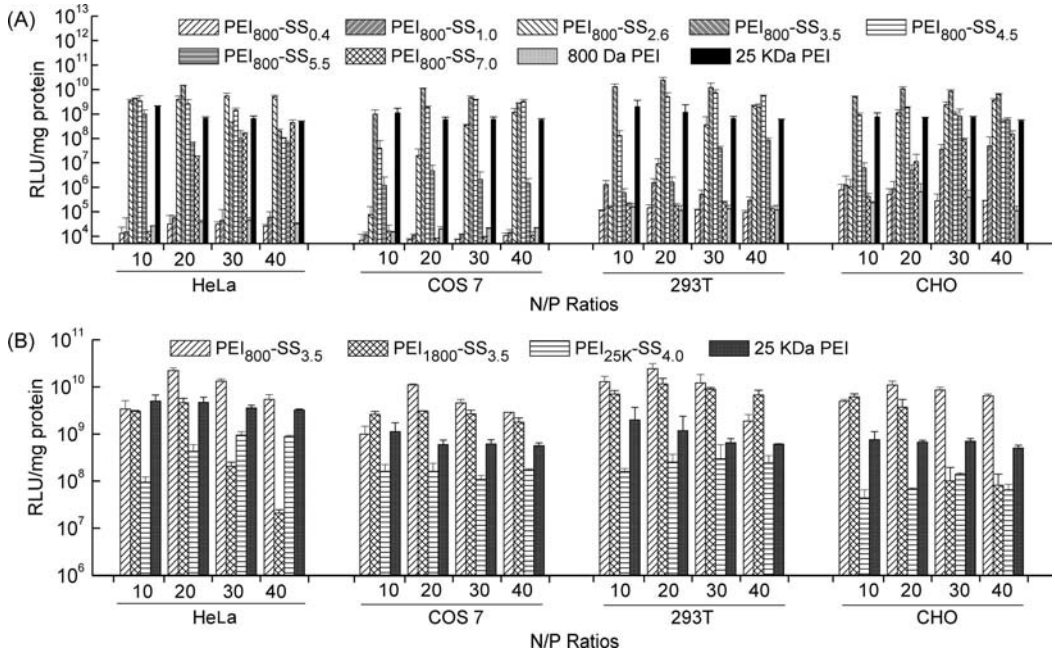

Figure 3. In vitro transfection efficiency of the polyplexes of pGL3 with PEI_{800}-SS_Y (A) and PEI_X-$SS_{3.0-4.0}$ (B) series in HeLa, COS7, 293T, and CHO cells in comparison with 800 Da and 25 kDa PEI.

than 40. In contrast, 25 kDa PEI was the most efficient that it could completely retard DNA migration at a N/P ratio of 0.6. The required N/P ratios were 7.3, 6.3, 3.8, 2.5, 2.5, 2.5, and 2.5 for PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, PEI_{800}-$SS_{4.5}$, PEI_{800}-$SS_{5.0}$, and PEI_{800}-$SS_{7.0}$ to completely retard the pDNA, respectively. The pDNA-binding capacity of PEI_{800}-SS_Y is greatly enhanced by the disulfide cross-linking, but still significantly lower than that of 25 kDa PEI. This could be explained on the basis of GPC analysis results, which showed that there is a big portion of low molecular fraction in the cross-linked products even at high thiolation degree.

The particle sizes of the polyplexes were determined by DLS in 150 mM NaCl solution and shown in Table 2. 25 kDa PEI forms the most compact pDNA polyplexes with a size in the range 150−220 nm, and 800 Da PEI forms the loosest polyplexes with a size of about 1000 nm. The cross-linked PEI_{800}-SS_Y polymers with a moderate thiolation degree (PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, and PEI_{800}-$SS_{4.5}$) could form compact polyplexes with a size of 200−300 nm at an adequate N/P ratio. In contrast, those with a too low or too high thiolation degree (Y below 2.6 or above 4.5) formed much looser polyplexes with a size above 600 nm. The polyplexes of PEI_X-$SS_{3.0-4.0}$ series (X = 800, 1800, and 25 000) form small particles with a size below 400 nm at a wide range of N/P ratios.

Zeta potentials of the polyplexes were measured in 10 mM NaCl solutions and the results are shown in Table 2. The 25 kDa PEI polyplexes have the highest zeta potential above 35 mV, and the 800 Da PEI polyplexes have the lowest zeta potential of around 10 mV. For PEI_{800}-SS_Y series, the zeta potentials are negative, showing an incomplete complexation at N/P ratios below 5 (data not shown). With increasing N/P ratio, zeta potentials of the polyplexes rapidly increase and trends to reach a plateau. For PEI_{800}-$SS_{0.4}$, PEI_{800}-$SS_{1.0}$, and PEI_{800}-$SS_{2.6}$, it reaches plateaus at N/P ratios between 30 and 40. With the increase of disulfide content in the polymers, the plateau is reached earlier at N/P ratio of about 10. For PEI_{800}-SS_Y (Y = 2.6, 3.5, and 4.5), zeta potentials plateau of the polyplexes are all around 25 mV. Surprisingly, PEI_{1800}-$SS_{3.5}$ and PEI_{25K}-$SS_{4.0}$ have lower zeta potentials of about 15 mV.

In Vitro Transfection Efficiency. The gene delivery efficiency of the PEI_X-SS_Y series was evaluated by in vitro transfection experiments of pGL3 into HeLa, COS7, 293T, and CHO cells. Branched 25 kDa PEI, which is one of the most widely used highly efficient polycation gene vectors, was used for comparison.

The transfection results of PEI_{800}-SS_Y/pGL3 polyplexes to cultured HeLa, COS7, 293T, and CHO cell lines were presented in Figure 3A. In the PEI_{800}-SS_Y series, PEI_{800}-$SS_{2.6}$, PEI_{800}-$SS_{3.5}$, and PEI_{800}-$SS_{4.5}$ showed comparable or higher transfection efficiency than 25 kDa PEI at their optimum N/P ratios. Within the range of N/P ratios tested, PEI_{800}-$SS_{3.5}$ showed maximum efficiencies at N/P ratio of 20 in all four cell lines, achieving nearly 10 times higher luciferase expression as compared with the optimal value of 25 kDa PEI. Comparison of the transfection results in Figure 3 with the size of PEI_{800}-SS_Y/pGL3 polyplexes listed in Table 2 reveals that the transfection efficiency is in good accordance with the particle size. The polymers with very low thiolation degrees of 0.4 and 1.0 unable to form compact polyplexes had very poor transfection efficiency. The polymers with moderate thiolation degrees of 2.6, 3.5, and 4.5 forming the most compact polyplexes had highest efficiency within the PEI_{800}-SS_Y series. When the thiolation degree was further increased to a very high level of 5.5 and 7.0, the polyplexes became less compact and the transfection efficiency decreased.

Figure 3B shows the transfection results of PEI_{800}-$SS_{3.5}$, PEI_{1800}-$SS_{3.5}$, and PEI_{25K}-$SS_{4.0}$, which have similar thiolation degrees but different molecular weights of raw PEIs, in HeLa, COS7, 293T, and CHO cells. Among them, PEI_{800}-$SS_{3.5}$ had the highest efficiencies in all four cell lines. PEI_{1800}-$SS_{3.5}$ had comparable efficiency to 25 kDa PEI in Hela and higher efficiency than 25 kDa PEI in COS7, 293T, and CHO cells. Surprisingly, PEI_{25K}-$SS_{4.0}$ had much poorer efficiency. Though PEI_{25K}-$SS_{4.0}$ had similar pDNA retardation capability and cell toxicity compared to 25 kDa PEI, its gene transfection efficiency was much poorer, possibly from the larger sizes and low zeta potentials of its pDNA polyplexes. These results showed that not all raw PEIs with different molecular weights are suitable for cross-linking by disulfide to form degradable polymers possessing an improved capability of gene transfection. Among

the three PEIs of different molecular weights tested (800 Da, 1800 Da, and 25 kDa), the cross-linked polymer prepared from that of the lowest molecular weight (800 Da PEI) gave the best results in all four cell lines tested.

CONCLUSIONS

Various amounts of thiol groups were readily introduced to PEIs with different molecular weights using thiirane as a thiolation agent. The thiolated PEIs were transferred to disulfide cross-linked polyethylenimines (PEI_X-SS_Y) by oxidation of the thiol groups with DMSO.

Transfection efficiency of the cross-linked polymers is dependent on the thiolation/cross-linking degree *Y*, and is in good accordance with the particle size of their pDNA polyplexes. Among the PEI_{800}-SS_Y series with different thiolation degrees prepared from identical raw PEI, the polymers with moderate thiolation degrees of 2.6, 3.5, and 4.5 forming the most compact polyplexes had highest efficiency. The polymers with very low or very high thiolation degrees were unable to form compact polyplexes and had very poor transfection efficiency.

A suitable molecular weight of raw PEI is also essential to obtain a highly efficient disulfide cross-linked PEI gene vector. Among the three raw PEIs of different molecular weights tested (800 Da, 1800 Da, and 25 kDa), the cross-linked polymer prepared from the one with the lowest molecular weight (800 Da PEI) gave the best results. Cross-linking of the high molecular weight PEI (25 kDa) led to decreased transfection efficiency.

Hexadentate Bispidine Derivatives as Versatile Bifunctional Chelate Agents for Copper(II) Radioisotopes▽

Stefanie Juran,† Martin Walther,† Holger Stephan,*,† Ralf Bergmann,† Jörg Steinbach,† Werner Kraus,‡ Franziska Emmerling,‡ and Peter Comba*,§

Forschungszentrum Dresden-Rossendorf, Institute of Radiopharmacy, PF 510119, D-01314 Dresden, Germany, Bundesanstalt für Materialforschung and -prüfung, Richard-Willstätter-Strasse 11, D-12489, Berlin, Germany, and Universität Heidelberg, Anorganisch-Chemisches Institut, Im Neuenheimer Feld 270, D-69120 Heidelberg, Germany. Received October 24, 2008; Revised Manuscript Received December 22, 2008

The preparation and use of bispidine derivatives (3,7-diazabicyclo[3.3.1]nonane) as chelate ligands for radioactive copper isotopes for diagnosis (^{64}Cu) or therapy (^{67}Cu) are reported. Starting from the hexadentate bispidine-based bis(amine)tetrakis(pyridine) ligand **1** with a keto and two ester substituents, the corresponding mono-ol **2** and two dicarboxylic acid derivatives **3** and **5** have been synthesized. A range of techniques, including single-crystal X-ray structure analysis, UV/vis spectroscopy, cyclic voltammetry, thin-layer- (TLC), and high-performance liquid chromatography (HPLC), have been used to characterize the structure and stability of the copper(II)-bispidine complexes. A rapid formation (within 1 min) of stable copper(II)-bispidine complexes under mild conditions (ambient temperature, aqueous solution) has been observed. Challenge experiments of these complexes in the presence of a high excess of competing ligands, such as glutathione, cyclam, or superoxide dismutase (SOD), as well as in rat plasma, gave no evidence of demetalation or transchelation. The bifunctional bispidine derivative **5** can be readily functionalized with biologically active molecules at the pendant carboxylate groups. The coupling of a bombesin analogue βhomo-Glu-βAla-βAla-[Cha^{13},Nle^{14}]BBN(7−14), by condensation of a carboxylate of the bispidine backbone with the N-terminus of the peptide produced the bifunctional ligand **6**. The radiocopper(II) complex of this bombesin−bispidine conjugate has a considerable hydrophilicity (log $D_{o/w} < -2.4$), and this leads to a very fast blood clearance (blood: 0.28 ± 0.02 SUV, 1 h p.i.), low liver tissue accumulation (liver: 1.20 ± 0.27 SUV, 1 h p.i.), and rapid renal-urinary excretion (kidneys: 6.06 ± 2.96 SUV, 1 h p.i.) as shown by biodistribution studies of **^{64}Cu-6** in Wistar rats. Preliminary in vivo studies of **^{64}Cu-6** in NMRI nu/nu mice, bearing the human prostate tumor PC-3 showed an accumulation of the conjugate in the tumor (2.25 ± 0.13 SUV, 12.5 min p.i.; 0.94 ± 0.05 SUV, 55 min p.i.) and allowed a clear visualization of the gastrin-releasing peptide receptor distribution by positron emission tomography (PET).

INTRODUCTION

The extremely rigid diazaadamantane-derived bispidine ligands have first been prepared in an elegant, very versatile, and high-yielding synthesis by Mannich and recently have found extensive applications in various areas of transition metal coordination chemistry (*1*−*7*). Similar to the alkaloid sparteine, from which the bispidines are derived, various derivatives are known for their analgetic and antiarrhythmic activity (*1, 8, 9*), and the stereochemistry of the substituents is of importance for the specific receptor binding (*10*−*13*).

In the correct configuration, bispidines are highly preorganized and exceedingly rigid multidentate ligands leading to a number of very interesting properties of their transition metal coordination complexes (*14*−*18*). The distance of the ring nitrogen atoms N3−N7 of 2.9−3.1 Å allows a very stable chelation of first-row transition metals of medium size in different oxidation states, such as $V^{4+/5+}$, Mn^{2+}, $Fe^{2+/3+}$, $Co^{2+/3+}$, Ni^{2+}, Zn^{2+}, and preferably Cu^{2+}. The number, type, and position of the donor groups, which can be varied during the bispidine synthesis, provides a variety of tailor-made coordination sites for metal ions with differing preferences with respect to size, shape, and electronic properties (*1*). In particular, hexadentate ligands with pyridine units in C2, C4, N3, and N7 positions have been shown to rapidly form stable copper(II) complexes under mild conditions. The stability constants of copper(II)-bispidines are in the same range as those of macrocyclic ligand copper(II) complexes (*1, 19, 20*). As with other open-chained amine-pyridine based ligands (*21*−*23*), the relatively fast complexation kinetics of bispidine ligands in comparison with macrocyclic ligands makes the structurally reinforced bispidine derivatives with pendant pyridine donor groups attractive as chelators for copper(II) radioisotopes. Despite extensive work in this field, a number of challenges such as the specific coupling of ligands with targeting structures and detailed in vivo studies have not been accomplished to date.

^{64}Cu and ^{67}Cu have suitable nuclear decay properties with a half-life of 12.7 and 62 h, respectively, and therefore offer the possibility to be established in tumor targeting for diagnosis and therapy (*24*−*30*). Coupling of the bispidine scaffold to targeting biomolecules is therefore of particular interest. Both the C9 and the C1/5 positions are potential centers to be used for the linkage to biomolecules. The conversion of the keto group to an alcohol at C9 (*31*) and/or hydrolyzation of the C1/5 ester groups (*32*) may provide linker groups for the coupling to vector molecules.

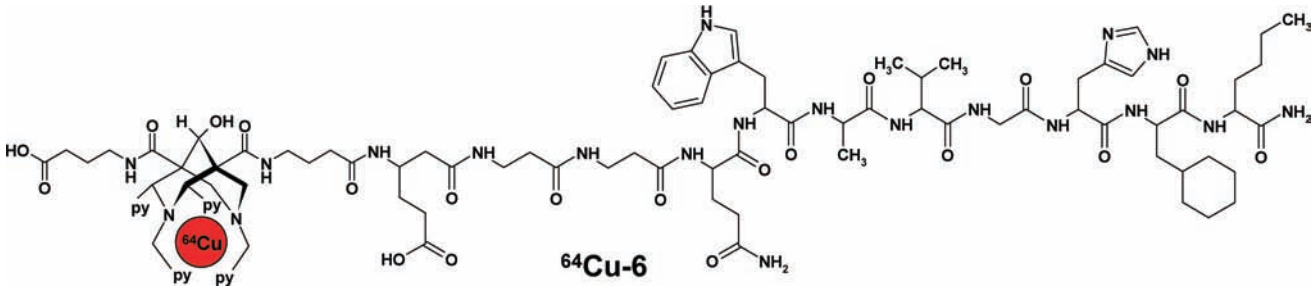
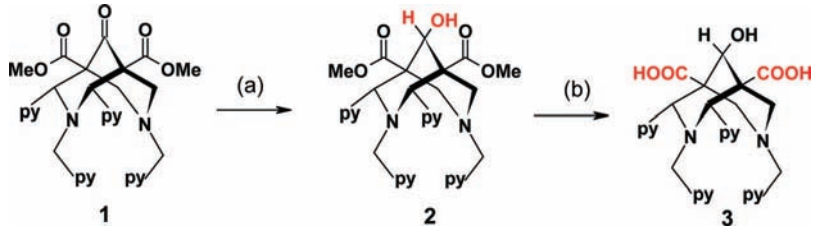
Scheme 1. ^{64}Cu-Labeled Bispidine−Bombesin Conjugate 6 (py = pyridin-2-yl substituent)



Scheme 2. Synthetic Procedure for Preparation of the Reduced Derivative 2 and Ligand 3 with Two Free Carboxylic Groups at C1 and C5 (py = pyridin-2-yl)[a]



[a] (a) (i) $NaBH_4$ in dioxane/water (1/1), r.t., 24 h, (ii) H_2O, HCl, 55%; (b) CsOH, THF, r.t. 24 h, 66%.

Herein, we report the synthesis and copper coordination chemistry of the mono-ol **2** and the dicarboxylic acid derivatives **3** and **5**, starting from the hexadentate bispidine-based bis(amine)tetrakis(pyridine) ligand **1** (Scheme 2). In this first exploratory study, a stabilized bombesin (BBN) derivative βhomoGlu-βAla-βAla-[Cha^{13},Nle^{14}]BBN(7−14) (*33*) was attached as a biomolecule to the bispidine ligand **5**, yielding the bispidine−bombesin conjugate **6** (Scheme 1) as a potential imaging probe for monitoring GRP receptor expression in vivo by means of PET. The radiopharmacological characterization of the ^{64}Cu-labeled bispidine mono-ol ester **^{64}Cu-2**, the dicarboxylic acid derivative **^{64}Cu-3**, and the bispidine-bombesin conjugate **^{64}Cu-6** includes in vitro and in vivo metabolism and biodistribution studies in normal rats, and in small animal PET studies in NMRI nu/nu mice, bearing the human prostate tumor PC-3.

EXPERIMENTAL SECTION

Materials. Chemical reagents and solvents were purchased from commercial sources and used without further purification. The enzyme superoxide dismutase (from bovine liver) was purchased from Sigma. The hexadentate bispidine ligand **1** has been prepared according to a literature procedure (*34*). βhomoGlu-βAla-βAla-[Cha^{13},Nle^{14}]BBN(7−14) was obtained from Biosyntan GmbH, Berlin, Germany. The production of ^{64}Cu was performed at a PET cyclotron, similar to those recently described for the ^{64}Cu−^{61}Co-production process (*35*). For the ^{64}Ni(p,n)^{64}Cu nuclear reaction, 15 MeV protons with a beam current of 10 μA for 2 h were used. The complete separation of ^{64}Cu and ^{61}Co was confirmed by γ-ray spectroscopy. Nickel targets were prepared by electrodeposition of enriched ^{64}Ni (99.6%) on Au disks at amounts of 30−120 mg. The plated diameter was 7 mm, matching more than 80% intensity of the Cyclone 18/9 proton beam, as measured by autoradiography of a ^{nat}Ni disk irradiated with 15 MeV protons to induce the^{nat}Ni(p,x)^{57}Ni reaction. Production runs have yielded 1.5−6.0 GBq Cu-64 (130−331 MBq/μA/h) with specific activities of 30−200 GBq/μmol Cu (*35*−*37*).

Methods and Instrumentation. ^{1}H and ^{13}C NMR spectra were recorded on a 400 MHz Varian Inova spectrometer. The chemical shifts (δ, ppm) are relative to TMS or the solvent. Elemental analyses were performed on a Leco Elemental Analyzer CHNS-932. Electrospray ionization mass spectrometry (ESI-MS) was carried out using a micromass tandem quadropole mass spectrometer (Quattro LC). High-resolution mass spectra were recorded on an Agilent 6210 ESI-TOF instrument, Agilent Technologies, Santa Clara, CA, USA (ESI-TOF = electrospray ionization−time-of-flight); the solvent flow rate was adjusted to 4 μL/min; the spray voltage was set to 4 kV. The drying gas flow rate was set to 1 bar; all other parameters were adjusted to maximize $[M + H]^+$. A Cary 50 Bio UV/vis spectrometer (Varian) was used to record electronic absorption spectra. Thin layer chromatography (TLC) was performed using neutral Al_2O_3 TLC plates (Merck, F_{254}), developed in a 1:1 mixture methanol/ammonium acetate (0.1 M in water). Radioactive detection of ^{64}Cu-labeled compounds was assayed on a radioisotope thin layer analyzer (Rita Star, Raytest Isotopenmessgerät GmbH, Straubenhardt, Germany). Electrochemical measurements were carried out with a BAS100B system with a standard three-electrode cell (glassy carbon electrode, $Ag/AgNO_3$ reference electrode (0.01 M $AgNO_3$), Pt-wire auxiliary electrode) at 25 °C under argon atmosphere. All samples were measured in acetonitrile (0.1 M $(Bu)_4NPF_6$) or water (0.1 M KNO_3) with a scan rate of 100 mV/s. HPLC was performed using either of two eluents (eluent A: acetonitrile, containing 0.1% trifluoroacetic acid; eluent B: water, containing 0.1% trifluoroacetic acid), three instruments, and five methods. HPLC system 1: Knauer Smartline, including a pump 1000, a UV detector 2500, and a manager 5000. Method 1: Jupiter 4 μm C18 90 Å (Phenomenex), 250 mm × 4.6 mm, elution gradient 10% to 70% A in 20 min, 1 mL/min. Method 2: Jupiter 4 μm C18 90 Å (Phenomenex), 250 mm × 4.6 mm, elution gradient 10% to 70% A in 40 min, 1 mL/min. HPLC system 2 for the analysis of the radioactive conjugates: Perkin-Elmer, consisting of a Turbo LC System with a quarternary pump (series 200 LC pump), a programmable absorbance detector model 785A (Perkin-Elmer Instruments, Germany), and a homemade γ-ray detector (well-type, NaI(Tl) crystal). Method 3: Jupiter 4 μm C18 90 Å (Phenomenex), 250 mm × 10 mm, elution 10% to 70% A in 20 min, 2 mL/min. Method 4: Jupiter 4 μm C18 90 Å (Phenomenex), 250 mm × 10 mm, elution gradient 10% to 70% A in 40 min, 3 mL/min. HPLC system 3 for the preparative

sample purification: Knauer Wellchrom instrument, consisting of a pump K-1001, a UV detector U-2501, and a solvent organizer K-1500 for low-pressure gradient operation. Method 5: Zorbax 7 μm 300 SB-C18 Prep (Agilent), 250 mm × 21.2 mm, elution gradient 10% to 70% A in 30 min, 8 mL/min.

Dimethyl-9-hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo[3.3.1]-nonane-1,5-dicarboxylate (2). 1 (500 mg, 0.844 mmol) was dissolved in 8.3 mL dioxane and mixed with 5.8 mL of water. Under ice cooling and stirring, 216 mg (5.71 mmol) sodium borohydride dissolved in 4.5 mL water was dropped into this solution. The reaction mixture was stirred 24 h at room temperature. The pH was set to 1 with dilute hydrochloric acid, the solvent was removed under reduced pressure, and the pH was set to 8 with a 1 M sodium hydroxide solution. The mixture was stirred for 1 h at room temperature and extracted five times with dichloromethane. Crystalline material suitable for X-ray analysis could be obtained from methanol. For further characterization, the crude product was purified by RP-HPLC (method 5) to yield **2** as a white solid after lyophilization. Yield: 276 mg (55%). Mp: 167 °C. Anal. Found (%): C, 64.84; H, 6.03; N, 13.36. Calcd for $C_{33}H_{34}N_6O_5 \cdot 1H_2O$ (%): C, 64.69; H, 5.92; N, 13.72. ESI-MS (*m*/*z*): 595.4 (100%) $[M + H]^+$. HPLC (method 1): $t_R = 9.4$ min.

9-Hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane-1,5-dicarboxylic acid (3). To 200 mg (0.336 mmol) of **2**, dissolved in 6 mL of anhydrous tetrahydrofurane, was added 565 mg (3.36 mmol) cesium hydroxide. Under ice cooling, 34 μL water was added, and after stirring 24 h at room temperature, a milky white emulsion was obtained. After setting the pH to 6 with dilute hydrochloric acid, the solvent was removed in vacuo. The crude product was dissolved in ethanol and purified by preparative RP-HPLC (method 5) to yield **3** as a white solid after lyophilization. Yield: 166 mg (87%). Mp: 174 °C. Anal. Found (%): C, 63.34; H, 5.83; N, 14.32. Calcd for $C_{31}H_{30}N_6O_5 \cdot 1H_2O$ (%): C, 63.69; H, 5.52; N, 14.37. ESI-MS (*m*/*z*): 567.3 (100%) $[M + H]^+$. HPLC (method 1): $t_R = 8.1$ min.

Diethyl 4,4′-{[9-Hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane 1,5-diyl]-bis(carbonylimino)}dibutanoate (4). 50 mg (0.088 mmol) of **3** and 66.9 mg (0.176 mmol) HBTU were dissolved in 500 μL dry dimethylformamide. Subsequently, 76 μL (0.412 mmol) DIPEA and 20 mg (0.154 mmol) ethyl-4-aminobutyrate, dissolved in 1 mL dry dimethylformamide, were added under ice cooling, and the reaction mixture was stirred for 3 h at room temperature. The solvent was removed under reduced pressure, and the crude product was purified by RP-HPLC (method 5) to yield **4** as a white solid after lyophilization. Yield: 14 mg (17%). Anal. Found (%): C, 53.34; H, 5.43; N, 10.62. Calcd for $C_{43}H_{52}N_8O_7 \cdot 2H_2O \cdot (TFA)_2$ (%): C, 53.41; H, 5.53; N, 10.60. ESI-MS (*m*/*z*): 793.6 (100%) $[M + H]^+$. HPLC (method 2): $t_R = 18.5$ min.

4,4′-{[9-Hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane-1,5-diyl]bis(carbonylimino)}dibutanic Acid (5). To 20 mg (0.019 mmol) of **4**, dissolved in 500 μL of anhydrous tetrahydrofurane, was added 32 mg (0.19 mmol) cesium hydroxide. Under ice cooling 5 μL water was added, and after stirring 24 h at room temperature, a milky white emulsion was obtained. After setting the pH to 6 with dilute hydrochloric acid, the solvent was removed in vacuo. The crude product was dissolved in ethanol and purified by preparative RP-HPLC (method 5) to yield **5** as a white solid after lyophilization. Yield: 17 mg (90%). Anal. Found (%): C, 51.64; H, 5.00; N, 11.18. Calcd for $C_{39}H_{44}N_8O_7 \cdot 2H_2O \cdot (TFA)_2$ (%): C, 51.60; H, 5.04; N, 11.20. ESI-MS (*m*/*z*): 737.4 (100%) $[M + H]^+$. HPLC (method 2): $t_R = 13.4$ min.

***N*-{6-[5-(5-Carboxypentanoyl)-9-hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]non-1-yl]-6-oxohexanoyl}-*β*homo-Glu-*β*Ala-*β*Ala-[Cha^{13},Nle^{14}]BBN(7−14) (6).** Five milligrams (6.78 μmol) of **5** and 2.6 mg (6.78 μmol) HATU were dissolved in 400 μL anhydrous dimethylformamide and stirred for 10 min at room temperature. Afterward, 7 equiv of DIPEA (4.1 mg, 0.032 mmol) and 5.5 mg (4.52 μmol) βhomo-Glu-βAla-βAla-[Cha^{13},NIe^{14}]BBN(7−14) in 300 μL anhydrous dimethylformamide were added under ice cooling. The mixture was stirred for 3 h at room temperature, and the solvent was then removed in vacuo. The residue was dissolved in acetonitrile/water (1:1) and purified by RP-HPLC (method 5) to yield **6** as a white solid after lyophilization. Yield: 2.5 mg (19%). ESI-MS (*m*/*z*): 1988.94 (100%) $[M + Na]^+$. High-resolution ESI-TOF-MS (*m*/*z*): Found 983.5108 (45%); calcd 983.5103 for $[M + 2H]^{2+}$. HPLC (method 2): $t_R = 19.9$ min.

Cu-2(NO$_3$)$_2$·H$_2$O. To 100.5 mg (0.169 mmol) of **2**, dissolved in 2 mL methanol, was added a solution of 31.5 mg (0.169 mmol) $Cu(NO_3)_2$ in 1 mL methanol. The mixture was stirred for 30 min (r.t.). The color changed from pale to dark blue. Slow diffusion of diethyl ether into this solution produced crystals that were suitable for X-ray crystallography. Yield: 29.7 mg (22%). Anal. Found (%): C, 49.68; H, 4.61; N, 14.28. Calcd for $C_{33}H_{34}N_8O_{11}Cu \cdot 1H_2O$ (%): C, 49.53; H, 4.53; N, 14.00. ESI-MS (*m*/*z*): 656.4 (100%) $[M + H]^+$. HPLC (method 1): $t_R = 10.2$ min.

Cu-3(NO$_3$)$_2$·2H$_2$O. To 95.7 mg (0.169 mmol) of **3**, dissolved in 2 mL methanol, was added a solution of 31.5 mg (0.169 mmol) $Cu(NO_3)_2$ in 1 mL methanol. The mixture was stirred for 30 min (r.t.), changing the color from pale to dark blue. Slow diffusion of diethyl ether into this solution produced crystals that were suitable for X-ray crystallography. Yield: 34.7 mg (26%). Anal. Found (%): C, 47.31; H, 4.51; N, 14.08. Calcd for $C_{31}H_{30}N_8O_{11}Cu \cdot 2H_2O$ (%): C, 47.12; H, 4.34; N, 14.18. ESI-MS (*m*/*z*): 629.4 (100%) $[M - H]^-$. HPLC (method 1): $t_R = 9.7$ min.

Cu-6(TFA)$_x$. To 10 mg (0.0051 mmol) of **6** dissolved in 1 mL methanol was added a solution of 1 mg (0.0051 mmol) $Cu(NO_3)_2$ in 0.5 mL methanol. The mixture was stirred for 24 h, the solvent was then evaporated, and the resulting oily residue was purified RP-HPLC (method 3) to yield a pale blue solid after lyophilization. Yield: 6.4 mg (58%). ESI-MS (*m*/*z*): 1014.47 (100%) $[M + H]^{2+}$. High-resolution ESI-TOF-MS (*m*/*z*):Found 1013.9698 (35%); calcd 1013.9673 for $[M + Cu]^{2+}$. HPLC (method 3): $t_R = 12.9$ min.

X-ray Data Collection, Processing, and Structural Determination of Cu-1 and Cu-2. The X-ray data were collected at room temperature (293 K) on a SMART-CCD diffractometer (SIEMENS), using graphite monochromatized Mo Kα radiation ($\lambda = 0.710\ 73$ Å). The structures were solved by direct methods with SHELXS-97 (G. M. Sheldrick, Universität Göttingen, 1997). A full matrix least-squares refinement on F^2 was carried out using SHELXL-97. The hydrogen atoms were assigned with common isotropic displacement factors and included in the final refinement by the use of geometrical restrains. Further details of X-ray structure analyses are given in Table 1. Selected bond lengths and angles are listed in Table 2. CCDC 705478 (**2**), CCDC 705479 (**Cu-2**), and CCDC 705480 (**Cu-3**), contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/data_request/cif, by e-mailing data_request@ccdc.cam.ac.uk, or by con-

Preparation of Radioactive Copper Complexes ^{64}Cu-1, ^{64}Cu-2, ^{64}Cu-3, and ^{64}Cu-6[1]. To 200 μL of ligand solution (0.1 mM of **1**−**3** in acetonitrile/0.1 M NH_4OAc = 1/1), an aqueous solution of $^{64}CuCl_2$ (500 kBq, 100 μL, 0.1 M NH_4OAc) was added. The labeling efficiency was investigated as a function of time and ligand concentration. Radiochemical purity was determined by HPLC (method 3) and radio-TLC. For radiolabeling of the bioconjugate **6**, 0.5 mg ligand dissolved in 100 μL acetonitrile/water (1/1) 100 μL $^{64}CuCl_2$ (5−20 MBq, 0.1 M NH_4Oac, pH 6.5) was added. Incubation at 37 °C for 30 min yielded ≥99% radiochemical purity (HPLC, method 3).

Ligand Exchange "Challenge" Studies. UV/vis spectroscopy was used to study the stability of the copper(II) complexes with ligands **1**−**3** in the presence of glutathione. To the copper(II)-bispidine complexes (2 mM in water), 50 equiv glutathione (0.1 M) was added, and the electronic absorption spectra were recorded in the range from 400 to 800 nm as function of time (each 1 h for 24 h). To study the influence of cyclam as competing ligand, radiotracer experiments with ^{64}Cu were used. 250 μL $^{64}CuCl_2$ (500 kBq) in 0.1 M NH_4OAc was added to 500 μg **1**−**3** dissolved in 100 μL acetonitrile/water (1/1). After 15 min, full complexation of the ligand was checked by TLC. Then, 40 mg cyclam (0.2 mmol; more than 1000-fold excess (1000−10 000-fold excess, depending on varying the specific activity of different Cu-64 production runs and time of Cu-64 use after EOB) dissolved in 1 mL acetonitrile/water (1/1) was added to the complex solution, buffered to pH 6 by addition of acetic acid, and stirred for 24 h. The degree of decomposition was determined by radio-TLC and radio-HPLC (method **3**) using aliquots of the mixtures.

[1]Charges and oxidation states are all omitted in this nomenclature; all complexes investigated here are Cu^{II} complexes; ^{64}Cu-1, e.g., is a 2+ charged cation.

SOD "Challenge" Studies. 250 μL $^{64}CuCl_2$ (5 MBq) in 0.1 M NH_4OAc was added to 10 μg of the ligands **1**−**3** dissolved in 100 μL acetonitrile/water (1/1). The complete complexation of the ligand was checked by TLC after 15 min. After removal of the acetonitrile, more than a 1000-fold excess of SOD (5 mg, from bovine liver dissolved in 200 μL of 0.9 M NaCl solution) was added to the complex solution and stirred for 24 h. The degree of decomposition was determined by radio-TLC, using aliquots of the mixture.

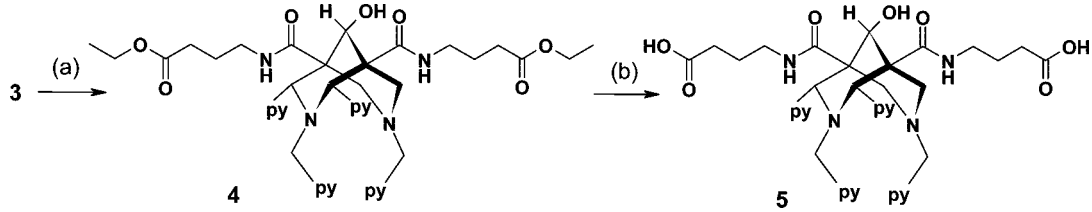
Determination of the Partition Coefficient log $D_{o/w}$. Compounds **2**, **3**, **5**, and **6** were dissolved in 50 μL water (c_0 = 1 mM) and added to a mixture of 390 μL HEPES/NaOH buffer (0.05 M, pH = 7.2, 7.4, 7.8), 10 μL $^{64}CuCl_2$ solution in 0.1 M NH_4OAc and 50 μL 10^{-4} M $Cu(NO_3)_2$ in water. Due to the low water solubility of ligand **1**, the corresponding Cu(II) complex was used. The distribution experiments in 1-octanol/buffer systems were performed at 25 ± 1 °C in microcentrifuge tubes (2 cm^3) by means of mechanical shaking for 30 min. The phase ratio $V_{(1\text{-octanol})}$:$V_{(aq)}$ was 1:1 (0.5 cm^3 each). All samples were centrifuged, the phases separated, and the copper concentration was determined in both phases radiometrically using γ-radiation [^{64}Cu, NaI(Tl) scintillation counter automatic gamma counter 1480, Wizard 3", PerkinElmer].

In Vitro Studies. To 500 μg of the ligands (**1**−**3**, **6**), dissolved in 50 μL water/acetonitrile (1:1), 10 MBq of $^{64}CuCl_2$ was added. After complexation, 250 μL phosphate buffer (0.1 M, pH = 7.4) and 250 μL rat plasma were added, and the solution was incubated at 37 °C for 2 and 24 h, respectively. For precipitation of blood cells and proteins, cold ethanol (500 μL) was added and the supernatant was centrifuged two times. The ethanolic solution was dried under nitrogen, dissolved in 100 μL water/acetonitrile (4/1 + 0.1% TFA), the residue filtered off, and the filtrate checked by HPLC (method 3).

In Vivo Stability. The in vivo stability of **^{64}Cu-6** was analyzed using rat arterial blood samples at various time points after intravenous injection of the radiotracer. For rat arterial blood sampling, a 3.5 Fr umbilical vessel catheter, prefilled with heparinized saline, was inserted into the right carotid arteria, and 100 μL blood samples were taken at 1, 3, 5, 10, 20, 30, and 60 min after intravenous tracer application. The samples were centrifuged to precipitate the blood cells. A solution consisting of 50 μL CH_3CN, 45 μL H_2O, and 5 μL TFA was added to 200 μL of the supernatant, and the mixture was then cooled to −20 °C. After centrifugation, the supernatant was analyzed by radio-HPLC, Zorbax (Agilent) SB-C18, 300 Å, 5 μm, 250 × 9.4 mm; gradient elution using eluents C (acetonitrile containing 0.05% TFA) and D (water containing 0.04% TFA), 10% to 70% eluent C in 20 min, 3 mL/min, 28 °C. The chromatogram of **^{64}Cu-6** (plasma, 0 min) was obtained by addition of **^{64}Cu-6** to rat blood and immediately treating the mixture as described for the in vivo samples. Urine and kidney homogenate (10% in PBS) were treated analogously to the arterial blood samples.

Animals, Feeding, Husbandry, and Biodistribution Studies in Rats. The animal research committee of the Landesdirektion Dresden approved the animal facilities and the experiments according to institutional guidelines and the German animal welfare regulations. The Wistar rats (Harlan Winkelmann GmbH, Borchen, Germany) were housed under standard conditions with free access to standard food and tap water. Animals were between 7 and 9 weeks of age (body weight 227 ± 10 g). The rats were housed in an Animal Biosafety Level 1 (ABSL-1) acclimatized facility with a temperature of 22 ± 2 °C and humidity of 55 ± 5%. Animals were under a 12 h light cycle. The NMRI nu/nu mice were housed under similar conditions except temperature (27 ± 1 °C) in controlled-airflow cabinets. Animals for each time point were intravenously injected into a tail vein with approximately 8 μCi (0.3 MBq) **^{64}Cu-3** or **^{64}Cu-6** conjugate in 0.5 mL electrolyte

Scheme 3. Synthesis of 4 and 5 by Introduction of an Aminobutyric Acid Linkage into 3 to Facilitate the Attachment of Biomolecules into the Bispidine Scaffold (py = pyridin-2-yl)[a]



[a] (a) ethyl-4-aminobutyrate, HBTU, DIPEA, DMF, 0 °C - r.t. 3 h, 17%, (b) CsOH, THF, 0 °C - r.t., 24 h, 90% after recrystallization from ethanol.

solution E-153 (Serumwerk Bernburg, Germany) with 5% Tween 80. Animals were euthanized at 5 and 60 min postinjection. Blood and the major organs were collected, weighed, and counted in a Wallac WIZARD Automatic Gamma Counter (PerkinElmer, Germany). The radioactivity of the tissue samples was decay-corrected and calibrated by comparing the counts in tissue with the counts in aliquots of the injected tracer that had been measured in the gamma counter at the same time. The activity in the selected tissues and organs was expressed as percent injected dose per organ (% ID) or as standardized uptake value (SUV). Values are quoted as means ± standard deviation (mean ± SD) for each group of four animals.

PET Imaging. General anesthesia of rats was induced with inhalation of desflurane 9% (v/v) (Suprane, Baxter, Germany) in 40% oxygen/air (gas flow 1 L/min) and was maintained with desflurane 6% (v/v). General anesthesia of NMRI nu/nu mice was induced with inhalation of desflurane 12% (v/v) (Suprane, Baxter, Germany) in 40% oxygen/air (gas flow 1 L/min) and was maintained with desflurane 8% (v/v). In the PET experiments, approximately 0.5 mCi (18.5 MBq) of the **^{64}Cu-6** conjugate in 0.5 mL was administered intravenously over 1 min into a tail vein. PET imaging of **^{64}Cu-6** in mice was performed over 60 min with a microPET P4 scanner (Siemens CTI Molecular Imaging Inc., Knoxville). Data acquisition was performed in 3D list mode. For estimation of photon attenuation in the subjects, a transmission scan was carried out prior to the injection of **^{64}Cu-6** using a ^{57}Co point source. Emission data were collected continuously for 60 min after injection of **^{64}Cu-6**. The list mode data were sorted into sinograms using a framing scheme of 12° − 10 s, 6° − 30 s, 5° − 300 s, and 5° − 600 s frames. The data were attenuation corrected, and the frames were reconstructed by ordered subset expectation maximization applied to 3D sinograms (OSEM3D) with 14 subsets, 6 OSEM3D iterations, 2 maximum a posteriori (MAP) iterations, and 0.05 β-value for smoothing. The pixel size was 0.8 by 0.8 by 1.2 mm^3, and the resolution in the center of field of view was 1.85 mm. No correction for recovery and partial volume effects was applied. The image files were processed using the *ASIPRO* software (Siemens, CTI Molecular Imaging Inc., Knoxville) and the *ROVER* software (ABX GmbH, Radeberg, Germany). Summed frames from 30 to 90 s postinjection (p.i.) and 30 to 90 min p.i. were used to define the regions of interest (ROI). The data were normalized to the injected radioactivity by using ^{64}Cu standards from the injection solution measured in a μ-well counter (Isomed 2000, Dresden, Germany) cross-calibrated to the PET scanner and expressed in SUV.

Statistical Analysis. The data are expressed as means ± SD. One-way analysis of variance (ANOVA) was used for statistical evaluation. Means were compared using Student's *t* test. A *P* value of <0.05 was considered significant and indicated by an asterisk symbol (*).

RESULTS AND DISCUSSION

Synthetic Approach. The bispidine starting compound **1** was synthesized according to the described procedure in the *endo*−*endo* form with respect to the C2/4 positions (1, 19, 34). The chair−chair conformation of the bicycle combined with the *endo*−*endo* configuration at C2/C4 is well-organized for the complexation of metal ions like copper(II) 19. Subsequent chemical modification (reduction, saponification, peptide coupling) of the products does not alter this conformation. Full coordination of the hexadentate ligand in a distorted octahedral geometry leads to a high degree of shielding of the copper(II) ion from the environment.

The keto group in position 9 was reduced to the corresponding alcohol (ligand **2**) to stabilize the bispidine skeleton (see Scheme 2). This prevents the decarboxylation of the β-keto acid, which would be obtained through the direct ester hydrolysis of **1** *38, 39*. The reduction of the ketone was carried out in the presence of sodium borohydride in a dioxane/water mixture and led stereospecifically to the anti epimer of **2** (*31, 40*). The structure of **2** was confirmed by NMR spectroscopy and X-ray crystallography to show the chair−chair conformation as the preferred conformation in polar solvents (see Supporting Information for details) (*41*).

Experiments to alternative routes for insertion of coupling units such as imines or oximes directly at the keto group 9 fail due to the low reactivity of **1** in common carbonyl reactions (except for the reduction as described above). Therefore, the coupling is based on the ester hydrolysis to the dicarboxlic acid **3**. To increase the distance of the site of coupling to the backbone and hence the accessibility to functionalization with sterically hindered peptides, a 4-aminobutyric acid spacer was introduced (see Scheme 3). The bis ethyl ester derivative **4** was hydrolyzed with cesium hydroxide in tetrahydrofurane to yield the bispidine derivative **5** with two carboxylate functions with reduced steric demand and increased reactivity for subsequent amide coupling reactions with specific biomolecules.

The synthesis of bombesin derivative **6** was carried out in dimethylformamide with HATU, one of the most efficient auxiliary compounds for amide coupling reactions. During the attachment of the βhomo-Glu-βAla-βAla-[Cha^{13}, Nle^{14}]BBN(7−14) derivative to the bispidine **5**, the yield of **6** was limited by formation of a side product without chelate. Intramolecular cyclization of the β-homoglutamic acid residue caused by activation of the peptide leads to this undesired bombesin derivative. The product **6** was separated via HPLC and characterized by HR-MS.

Structure and Stability of Copper(II)-Bispidine Complexes. In-depth information about the complexation behavior and related structural aspects are available from single-crystal X-ray data. In the case of bispidine-type ligands, the problem of isomerism is reflected in the coordination of the copper ion, resulting in different stabilities of the complexes. The synthesis of the complexes **Cu-2** and **Cu-3** was carried out in a methanolic solution, precipitating the desired complexes with diethyl ether. Hexadentate bispidine ligands with two amine and four pyridine coordinating groups preferentially form six-coordinate copper(II) complexes with a distorted octahedral structure (*19, 20, 42, 43*). As expected, the coordination environment is only slightly

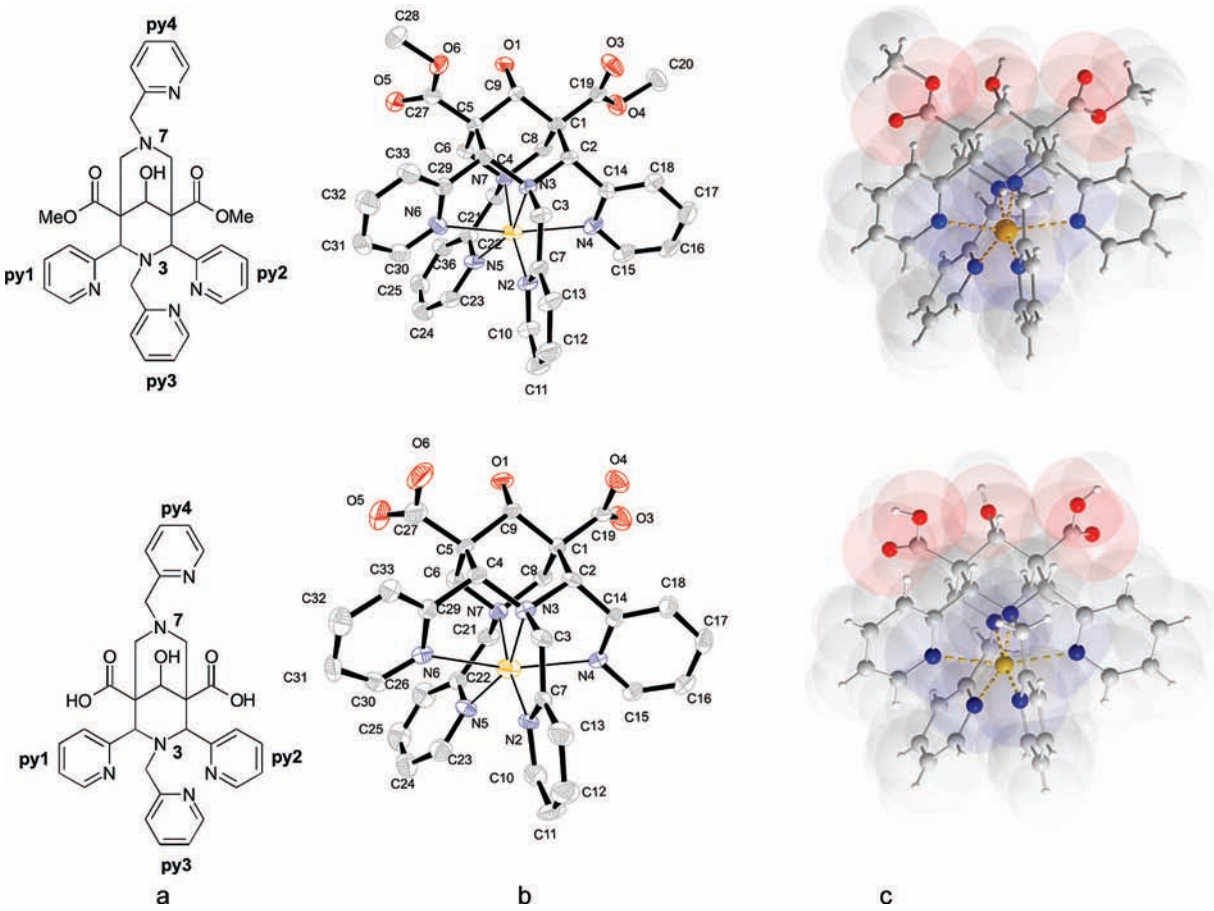


Figure 1. Coordination environment around the Cu^{II} ion in **Cu-2** (upper row) and **Cu-3** (lower row); thermal ellipsoids drawn on a 30% probability level. Gray spheres denote carbon, red spheres oxygen, blue spheres nitrogen, and yellow spheres copper atoms. Note that the crystallographic numbering scheme (b) is different from the IUPAC numbering, given in Chart a. The overlay with the space-filled model shows the efficient encapsulation of the copper ions by ligands **2** and **3** (c).

Table 3. Partition Coefficients (log $D_{o/w}$) of the ^{64}Cu Complexes of 1−3, 5, and 6 at Different pHs

pH	log $D_{o/w}$ ^{64}Cu-1	log $D_{o/w}$ ^{64}Cu-2	log $D_{o/w}$ ^{64}Cu-3	log $D_{o/w}$ ^{64}Cu-5	log $D_{o/w}$ (*64*) ^{64}Cu-6
7.2	−2.73	−2.89	−2.78	−2.14	−2.44
7.4	−2.77	−2.88	−2.76	−2.10	−2.44
7.6	−2.69	−2.85	−2.78	−2.11	−2.46

influenced by the modification of the C1...C5 ligand backbone. The crystal structures of the copper(II) complexes with the bispidol (**Cu-2**) and the corresponding dicarboxylic acid (**Cu-3**) are presented in Figure 1, and structural parameters are assembled in Table 1 (see Supporting Information for crystallographic data of **Cu-2** and **Cu-3**). The molecular structures of complexes **Cu-2** and **Cu-3** illustrate that the *endo*−*endo* geometry leads to an efficient encapsulation of the copper center. This is visualized with the space-filling models in Figure 1c, and this indicates that metal exchange in in vivo applications will be suppressed. In both complexes, the Cu^{II} ions adopts a distorted octahedral geometry which is attributed to the Jahn−Teller-type electronic effects. The Cu...N distances of the amine and pyridine donors involving py(N3) and py(N7) have comparable values in all three complexes (**Cu-1**, **Cu-2**, **Cu-3**).The Cu...N py(C2) distances are more elongated in **Cu-2** and **Cu-3** (d_{Cu-N} = 2.387(6) Å; 2.333(5) Å) than in **Cu-1** (d_{Cu-N} = 2.262 Å), whereas the equivalent distances to py(C4) are slightly shorter in **Cu-2** and **Cu-3** (d_{Cu-N} = 2.538(5) Å; 2.551(5) Å) than in **Cu-1** (d_{Cu-N} = 2.608 Å). The distances between the amine nitrogen atoms (N3...N7) in the bispidine backbone and those between the pyridine donors py(C2) and py(C4) are comparable in the three structures. As in **Cu-1**, the N3−N7-py(N3)-py(N7) plane is distorted, due to repulsion of the *ortho*-hydrogen atoms of the pyridine rings (H10A−H23A: 2.257 Å, **Cu-2**; 2.302 Å, **Cu-3**). The sum of the Cu−N bond distances of **Cu-2** and **Cu-3** is slightly shorter than that of **Cu-1**, consistent with a slightly higher stability of **Cu-2** and **Cu-3**. There are intermolecular hydrogen bonds between hydroxyl and carboxyl groups of the molecular cations and nitrates as well as water molecules in the crystal structures of **Cu-2** and **Cu-3**. In **Cu-3**, the hydrogen bonds about an inversion center lead to the formation of complex dimers (see Supporting Information).

The spectroscopic and electrochemical data of the copper(II) complexes with the bispidine ligands **1**−**3** and cyclam are summarized in Table 2. The absorption spectra of **Cu-1** to **Cu-3** exhibit broad transitions at 615−620 nm, typical for six-coordinate copper(II) complexes with distorted octahedral structure (*19*, *20*). This absorption band may be used to approximately monitor the stability of the copper(II) bispidine complexes. To an aqueous solution of the complexes (2 mM), a large excess of glutathione (100 mM) as competing ligand was added (*44*). The dd transitions remain unaffected in the presence of glutathione for at least 24 h, indicating a high stability of the copper(II) bispidine complexes.

This is further supported by the electrochemical properties of the complexes. Assuming that the copper(I) complexes have similar stability, the potential for the reduction of Cu(II) to Cu(I) can be used for the approximate determination of complex stability of the copper(II) complexes (*20*, *45*). Strongly negative reduction potentials were found as quasi-reversible reactions for the copper(II/I) couples in both acetonitrile and water. By contrast, Cu-cyclam

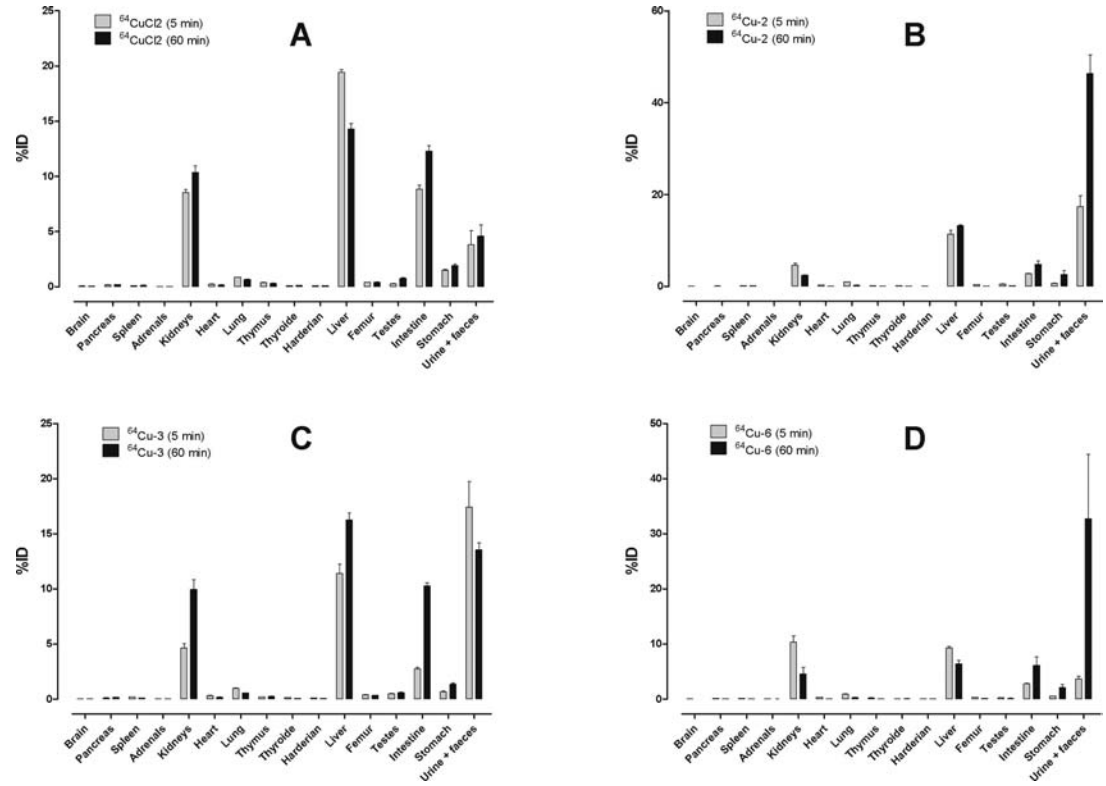

Figure 2. Biodistribution of **^{64}CuCl$_2$** (A), **^{64}Cu-2** (B), **^{64}Cu-3** (C), **^{64}Cu-6** (D) in rats at 5 and 60 min after single intravenous application. The data represent the distribution of the ^{64}Cu activity amount (%ID) in selected organs and excretions (mean ± SD of 4 animals).

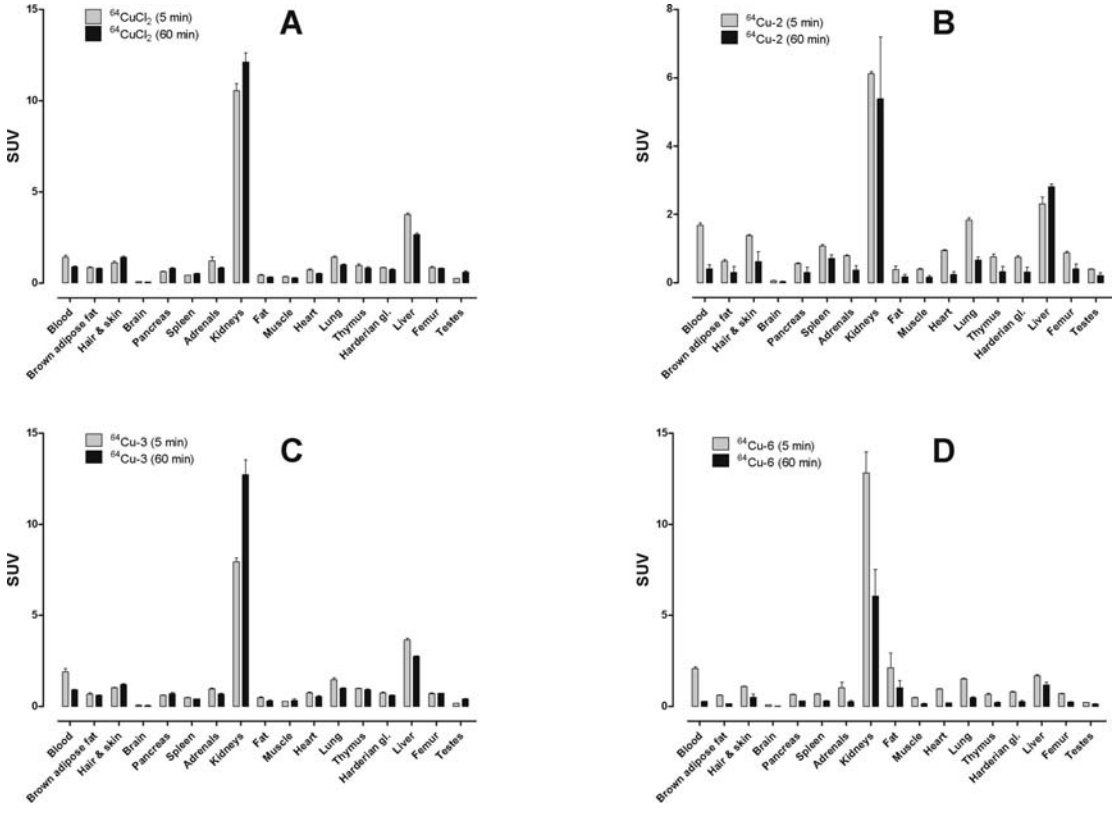

Figure 3. Biodistribution of **^{64}CuCl$_2$** (A), **^{64}Cu-2** (B), **^{64}Cu-3** (C), **^{64}Cu-6** (D) in rats at 5 and 60 min after single intravenous application. The data represent the distribution of the ^{64}Cu activity concentration (SUV) in selected organs and tissues (mean ± SD of 4 animals).

yielded an irreversible reduction in aqueous solution. The reduction potentials in acetonitrile decrease in the order **Cu-1** > **Cu-2** > **Cu-3**, indicating increasing stability from the bispidine complex (**Cu-1**) to the bispidole (**Cu-2**) and the bispidole dicarboxylic acid complex (**Cu-3**) (see above). It is worth mentioning that the reduction potentials of the copper(II) complexes with bispidine ligands are significantly lower than those of the cyclam complex, which forms one of the most stable copper complexes (log K_1 =

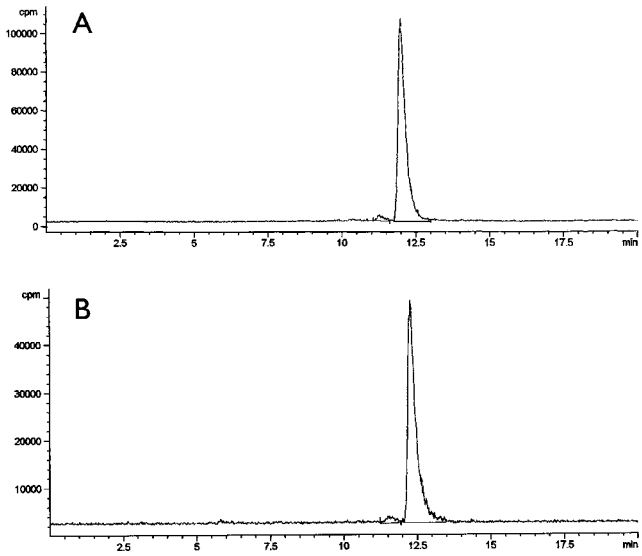

Figure 4. Examples of radio chromatograms of original **^{64}Cu-2** (A) and of rat plasma supernatant 60 min after application of **^{64}Cu-2** (B).

27.2) (*46, 47*). Note that the correlation of Cu(II/I) redox potentials with Cu(II) complex stabilities relies on the assumption of nearly constant Cu(I) stabilities, and this has been shown to be an oversimplification (*20*).

Radiochemistry. Preliminary experiments showed that the rate of copper(II) binding by bispidine ligands is very rapid at pH 6.5 and independent of the buffer system used (there is no difference among acetate, succinate, citrate, and 2-[*N*-morpholino]ethanesulfonic acid (MES) buffer, respectively). That is in contrast to the ^{64}Cu-labeling of tetraaza macrocycles, where relatively slow complexation kinetics have been observed in acetate buffer solution (*48*). ^{64}Cu-labeling of ligands **1**−**3** and **6** has been studied in detail in aqueous ammonium acetate solution. To 200 μL of 0.1 mM ligand dissolved in acetonitrile/NH_4OAc (1/1), an aqueous solution of $^{64}CuCl_2$ (500 kBq, 100 μL, 0.1 M NH_4OAc) was added. The labeling yields were monitored by thin-layer chromatography using neutral alumina plates, which were developed in 0.1 M ammonium acetate/methanol (1/1). The R_f-values of free copper and ^{64}Cu-bispidine complexes are well-separated. $^{64}CuCl_2$ remained at the origin, and the ^{64}Cu-bispidine complexes move further with R_f-values of **^{64}Cu-1**, $R_f = 0.56$; **^{64}Cu-2**, $R_f = 0.52$; **^{64}Cu-3**, $R_f = 0.46$. The bispidine ligands **1**−**3** were quantitatively labeled with ^{64}Cu within 1 min at ambient temperature under these experimental conditions. Further experiments revealed that only 1 μg of ligand is necessary to obtain complete copper complexation (5 MBq ^{64}Cu). ^{64}Cu-labeling of the bispidine bioconjugate **6** is slower than that of the unmodified ligands. Binding of copper(II) in an initial complexation step by peptide donor groups (imidazole) may lead to slower complex formation. Complexation of ^{64}Cu by **6** is complete after approximately 1 h at room temperature and 30 min at 37 °C. Altogether, a very efficient and rapid ^{64}Cu complexation of bispidine derivatives was found under mild conditions.

Challenge experiments in the presence of cyclam and the enzyme superoxide dismutase (SOD) as competing ligands have been performed to obtain further information about the stability of the radio copper bispidine complexes. HPLC (method 3) and TLC studies using neutral alumina plates (see Experimental Section) revealed that the complexes **^{64}Cu-1**, **^{64}Cu-2**, and **^{64}Cu-3** remained completely intact even in a 1000-fold excess of cyclam for at least 24 h. The stability of the radio copper complexes of these ligands was also investigated in the presence of SOD, a homodimeric enzyme which is abundant in liver, kidney, adrenal, and red blood cells. The competition assay using SOD can be used to predict the in vivo stability of radio copper complexes (*49, 50*). The challenge studies have been performed with more than 1000-fold excess of SOD compared to the ^{64}Cu bispidine complexes. The degree of decomposition was checked via TLC (neutral alumina) that allows a clear distinction of the radio copper complexes formed (**^{64}Cu-SOD**, $R_f = 0$; **^{64}Cu-1**, $R_f = 0.56$; **^{64}Cu-2**, $R_f = 0.52$; **^{64}Cu-3**, $R_f = 0.46$). Control experiments using RP-C18 plates (ethanol/MES-NaOH-buffer containing 0.001 M EDTA = 5:1) showed that free copper does not occur in the solution (**^{64}Cu-SOD**, $R_f = 0$; **^{64}Cu-EDTA**, $R_f = 0.69$). The absence of SOD-bound radioactivity indicates no transchelation of copper(II) and emphasizes a very high stability of the copper(II) bispidine complexes.

This is also confirmed by rat plasma stability studies. The plasma stability of ^{64}Cu complexes of ligands **1**−**3** and **6** was evaluated at 2 and 24 h. Radio-HPLC experiments showed that copper(II) is very tightly bound to the bispidine moiety. No demetalation of ^{64}Cu was found in rat plasma up to 24 h. In the case of the dicarboxylate **3**, the radio copper bispidine complex remains completely unchanged after rat plasma incubation. In contrast, for the radio copper complexes of the ester derivatives **1** and **2** two additional peaks appear in the chromatogram, resulting from the corresponding monoester and dicarboxylate caused by cleavage of the ester groups by esterases of the rat plasma (*51*). Furthermore, the in vitro stability studies reveal that peptidases of rat plasma attack the bombesin residue of the bioconjugate **6** (cf. in vivo stability studies).

To facilitate the interpretation of biodistribution data, the partition coefficients of the radio copper complexes have been determined in a 1-octanol/buffer system (Table 3). The copper(II) bispidine complexes are rather hydrophilic. As expected, the introduction of an aminobutyric acid spacer (**^{64}Cu-5**) leads to increased lipophilicity. The radio copper complexes of the bombesin−bispidine conjugate **^{64}Cu-6** and the bombesin−bis(2-pyridylmethyl)-triazacyclononane derivative ($\log D_{o/w} = -2.38$, pH = 7.4) possess almost the same hydrophilicity (*23*). Therefore, comparative biodistribution behavior, such as rapid blood clearance and excretion via the renal pathway, are expected for these ^{64}Cu-labeled pyridine-containing ligands.

In Vivo Studies. Due to the high affinity of the peptide bombesin to gastrin-releasing peptide receptors (GRPr), the design and synthesis of radiolabeled bombesin derivatives has recently attracted much attention (*52*−*55*). GRPs are overexpressed on a variety of human cancer cells, such as lung, breast, pancreatic, and prostate tumors. Therefore, the development of targeting vectors based on radiolabeled bombesin derivatives for imaging (PET, SPECT) and targeted radionuclide therapy is of considerable interest. Most investigations have been performed with ^{99m}Tc-labeled bombesin peptides, and to a lesser extent also with ^{18}F, ^{68}Ga, ^{125}I, ^{111}In, ^{177}Lu, ^{188}Re, ^{86}Y, and ^{90}Y (*33, 52*−*65*). Due to its favorable decay properties, the increasing availability, and the capability of producing high-quality PET images, ^{64}Cu is gaining importance in bombesin labeling (*23, 66*−*74*). In vivo studies performed so far have shown that the pharmacokinetics of the radiolabeled bombesin derivatives are influenced by the radio isotopes chosen, the chelate unit, the spacer elements, the specific modifications made to the peptide sequence and the species selected. Overall, predictions about the biodistribution of appropriate radiotracers are difficult. Therefore, we have investigated in some detail the biodistribution of various ^{64}Cu-labeled bispidine derivatives and the metabolism of the bispidine−bombesin conjugate **6**, and small-animal PET studies have also been performed.

A summary of the biodistribution and elimination data for **$^{64}CuCl_2$** (A), **^{64}Cu-2** (B), **^{64}Cu-3** (C), **^{64}Cu-6** (D) in rats is shown in Figures 2 and 3. The numeric values of %ID (% of total injected dose) and SUV (standardized uptake value) are assembled in the Supporting Information.

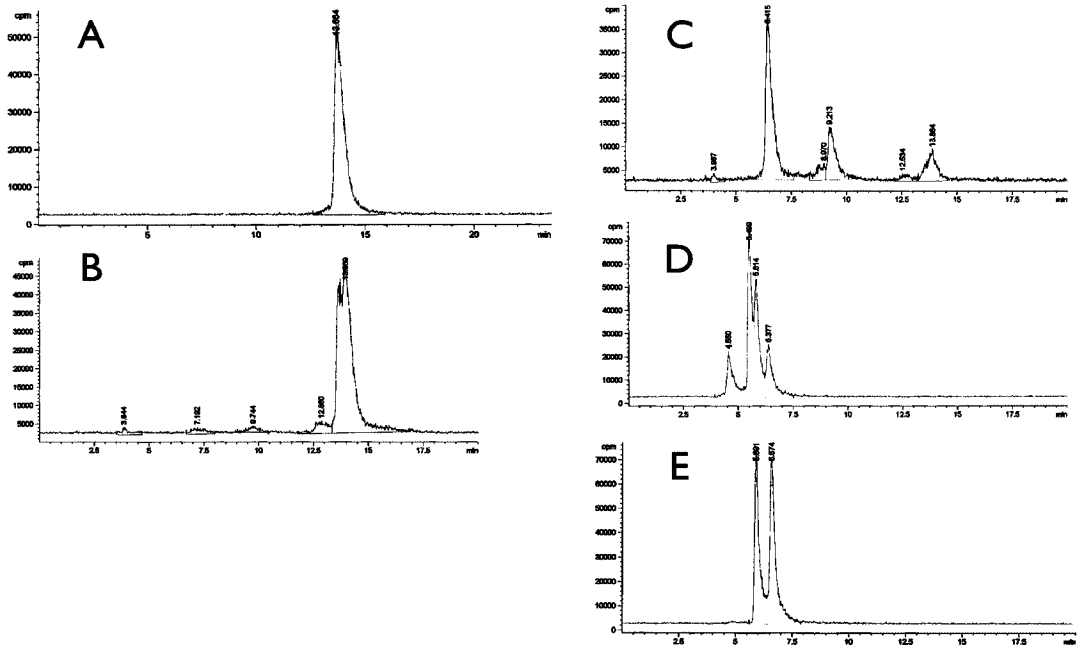

Figure 5. Radio HPLC of **^{64}Cu-6** metabolites in vitro at 1 min (A) and 60 min (B), and 60 min after application in arterial blood plasma (C), kidney homogenates (D), and urine (E).

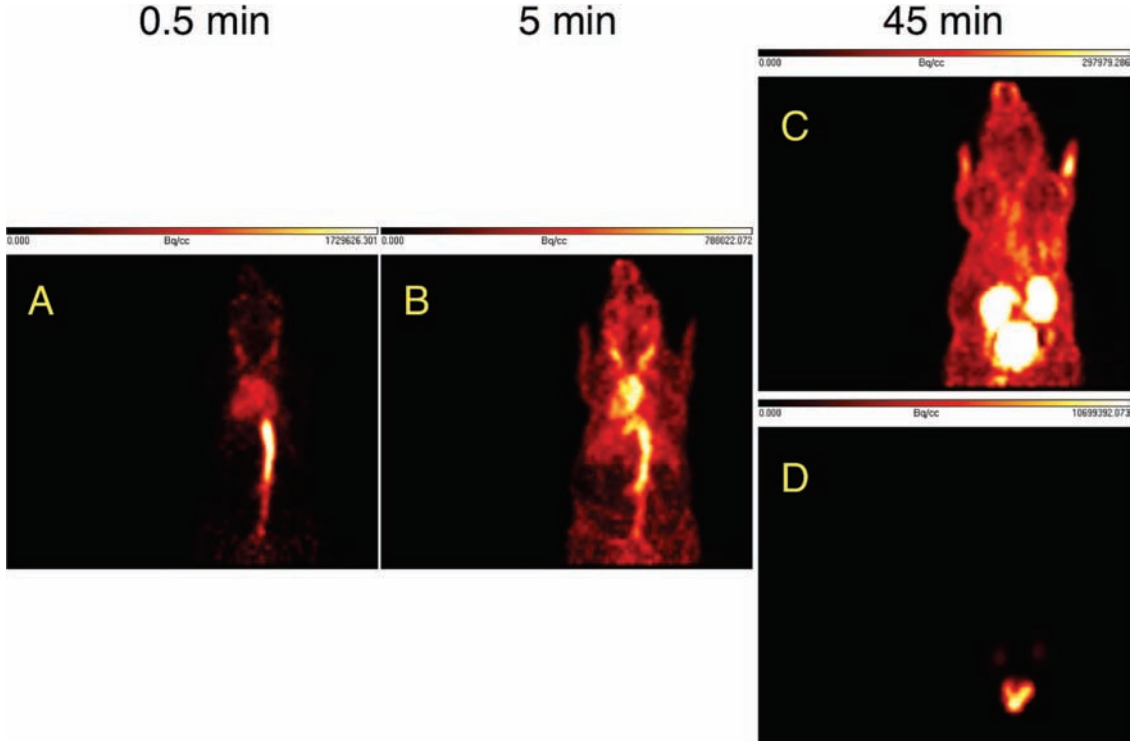

Figure 6. Coronal sections of a small animal PET study of PC-3 tumor-bearing mouse after single intravenous application of **^{64}Cu-6** at 0.5 (A), 5 (B), and 45 min (C, high intensity; D, low intensity).

The application of $^{64}CuCl_2$ resulted mostly in the accumulation of radioactive species in liver and intestine, but also in significant radioactivity retention in the kidneys. The bispidine complexes **^{64}Cu-2** and **^{64}Cu-3** were mainly eliminated into the urine as the original compounds. The metabolic analysis of **^{64}Cu-2** and **^{64}Cu-3** emphasizes the high stability of the complexes in vivo (cf., Figure 4). The initial accumulation of these compounds was similar to $^{64}CuCl_2$ in the liver, but surprisingly, the more hydrophilic acid derivative **^{64}Cu-3** was also hepatobiliary eliminated (the sum of liver and intestine activity was 26.56 ± 1.79% ID, which means more than 50% activity eliminated or on excretion pathway). The highest uptake and the resulting high activity concentration (SUV) was observed in the kidney for all compounds studied. However, the fastest elimination of radioactive species was observed for the bombesin conjugate **^{64}Cu-6**. In rats, low uptake of **^{64}Cu-6** in the pancreas, an accessible GRPr-expressing tissue, was observed. This behavior could have been caused by different effects, such as fast metabolism of the peptide residue and rapid excretion of the radiotracer. Bombesin conjugates bearing ^{99m}Tc(III) '4 + 1' complexes showed similar lack of pancreas accumulation (*64*).

The metabolic stability of **^{64}Cu-2** and **^{64}Cu-6** was determined in arterial blood samples taken at 1, 3, 5, 10, 20, 30, and 60

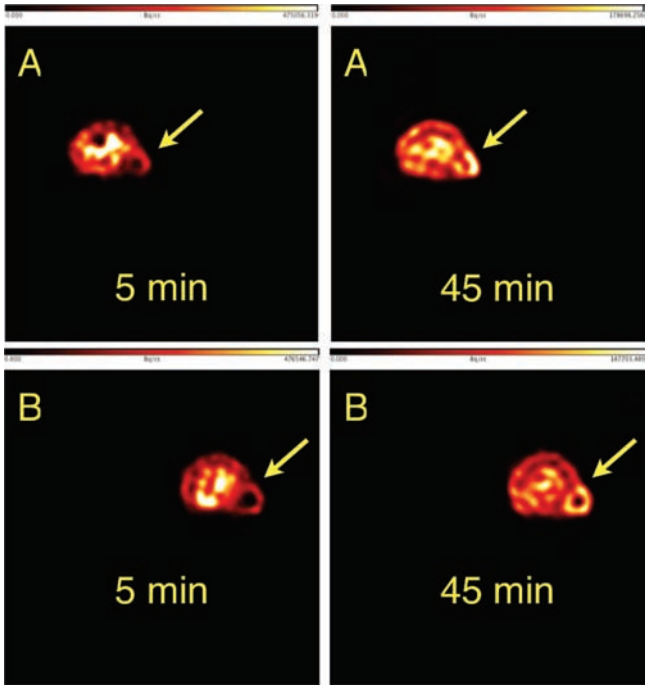

Figure 7. Coronal sections of a small animal PET study of two PC-3 tumor-bearing mice (A,B) after single intravenous application of **^{64}Cu-6** at 5 and 45 min. The arrow shows the tumor.

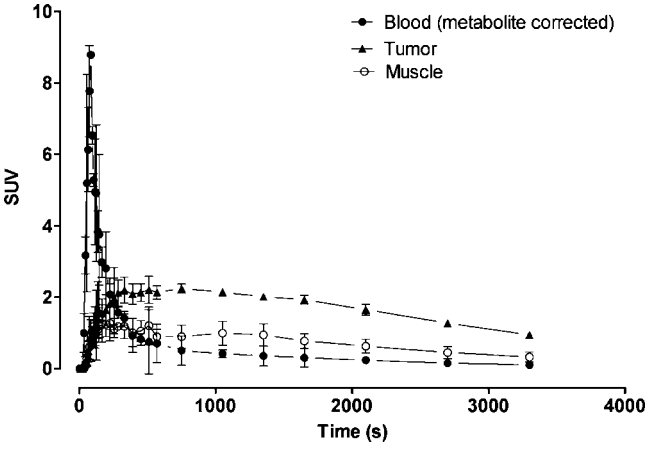

Figure 8. Biokinetics of **^{64}Cu-6** in PC-3 tumor bearing nude mice (mean ± SD of two animals). Time−activity curves were derived from ROIs over the aorta, tumor, and muscle, expressed as SUV_{mean}.

min after a single intravenous application of the radiotracer into a rat. The blood samples were centrifuged to obtain the plasma, which was treated with acetonitrile to precipitate the proteins. The supernatant is referred to as the plasma extract. After **^{64}Cu-2** was applied, the mean relative radioactivity concentration in the plasma was 90 ± 2% of the overall arterial blood activity; the plasma extract samples contained 84 ± 3% of the plasma activity. Furthermore, the plasma extract was analyzed by radio RP-HPLC for radio metabolites. Figure 5 shows the radio chromatograms of the original compound **^{64}Cu-2** and the plasma analysis after 60 min.

The main peak of in vivo samples, assigned to the original **^{64}Cu-2** complex, accounts for 98% and after 60 min for 97% of the activity (see Figure 4). The radiochromatograms of other plasma and also of urine samples are very similar. The mean relative activity of **^{64}Cu-6** in plasma was 88 ± 5% of arterial blood activity; the activity of the plasma extract samples contained 66 ± 12% of the plasma activity. The plasma extract was analyzed by RP-HPLC for radiometabolites (Figure 5).

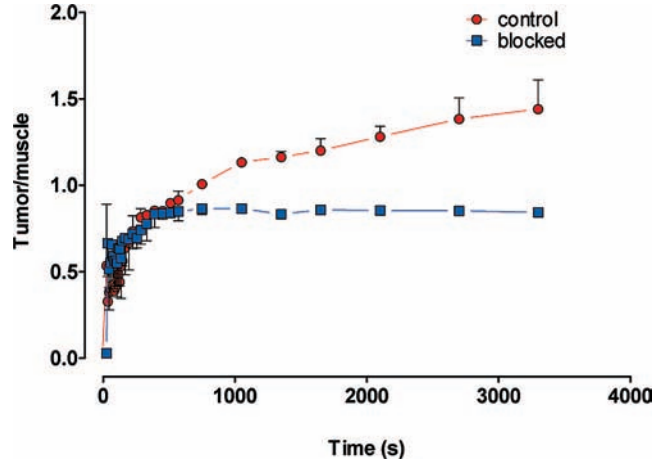

Figure 9. Time course of tumor to muscle relation of **^{64}Cu-6** in PC-3 tumor bearing nude mice (mean ± SD two animals) of control (circles) and blocked (square, 1 mg **^{nat}Cu-6**/kg body weight, simultaneously administered with **^{64}Cu-6**).

The relative amount of the original compound **^{64}Cu-6** (t_R = 13.9 min) decreased from 96% at the time of tracer application (1 min 96%, 3 min 89%, 5 min 80%, 20 min 44%, 30 min 38%) to 3% of the total plasma extract activity after 60 min. **^{64}Cu-6** was converted into three more hydrophilic radiolabeled species. The peak at 3.8 min is not due to free $^{64}Cu^{2+}$ ions, since these are eluted at 3.4 min.

The mixture of residual radioactive species in the analyzed tissues and urine was very complex. Overall, the detected radiometabolites were more hydrophilic than the native compound. The original **^{64}Cu-6** complex could not be detected in kidney extracts or urine. Extensive metabolism of **^{64}Cu-6** has occurred in both species studied (rats and tumor-mice). This is in contrast to the in vitro stability. In vitro incubation of **^{64}Cu-6** in rat blood or blood plasma yielded more than 85% of the original compound after 60 min in the nonprecipitated plasma fraction. However, the decomposition of up to 15% in vitro, which is due to partial hydrolysis, seems to be a sign of a specific effect of the bispidine complex units. A similar bombesin derivative, labeled with ^{64}Cu using 2-[4,7-bis(2-pyridylmethyl)-1,4,7-triazacyclononan-1-yl]acetic acid as bifunctional chelate, showed higher metabolic in vitro stability under analogous conditions (*23*).

Preliminary PET studies in PC-3 tumor-bearing mice have also been performed. The bombesin derivative **^{64}Cu-6** was accumulated in the GRPr-expressing tissue (see Figures 6 and 7) to allow the visualization of the tumor in the right axilla. The highest radiotracer concentration in the unblocked tumors was reached at 12.5 min (2.25 ± 0.13 SUV). However, the activity was very rapidly washed out from the tumor (Figure 8). Therefore, a high intensity is required to distinguish the tumor after 45 min, and this leads to a high background level (Figure 6C). Nonetheless, high-contrast PET images of the tumor could be produced.

The tumor to muscle ratio has been determined as function of time (Figure 9) and shows an increasing value for the unblocked (control) mice (1.78 ± 0.14 at 1 h) in contrast to the blocked animals (0.84 ± 0.01 at 1 h, 1 mg **^{nat}Cu-6**/kg body weight). This finding points to a receptor-mediated tracer uptake into tumor tissue.

CONCLUSION

Five new hexadentate pyridine-containing bispidine derivatives **2**−**6** have been synthesized. X-ray diffraction studies of the copper(II) complexes of **2** and **3** confirmed a distorted octahedral geometry with an efficiently encapsulated and shielded Cu^{2+} center. UV/vis spectra indicate that these cop-

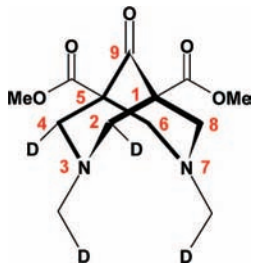
Chart 1



per(II)-bispidine complexes are stable in the presence of a high excess of glutathion and cyclam as competing ligands. Cyclic voltammetry with negative Cu^{II}/Cu^{I} redox potentials is in agreement with a high stability of the copper(II) complexes. The hexadentate bispidine ligands investigated here rapidly form stable radiocopper complexes under mild conditions in almost quantitative yield. Challenge experiments in the presence of superoxide dismutase and in vitro studies in rat plasma gave no evidence of transchelation or demetalation. The bispidine copper complexes **^{64}Cu-2** and **^{64}Cu-3** show in all experiments high stability in vitro and in vivo. The pendant carboxylate groups of the bispidine backbone offer good accessibility toward coupling reactions. With an aminobutyric acid spacer, the bombesin analogue as a vector molecule was conjugated to the bifunctional bispidine ligand **6**. Radiolabeling of bioconjugate **6** with ^{64}Cu was achieved at 37 °C for 30 min, yielding >99% radiochemical purity after HPLC. Comparative biodistribution and metabolic analysis of **^{64}Cu-6** indicated that there was only marginal, if any, in vivo copper demetalation. On the other side, the stabilized bombesin derivative βhomo-Glu-βAla-βAla-[Cha[13],Nle[14]]BBN(7−14) is readily metabolized. The accumulation of the radiolabeled peptide conjugate **^{64}Cu-6** in the GRPr-expressing pancreas is very low. However, PET studies on tumor-bearing PC-3 mice clearly revealed an accumulation of **^{64}Cu-6** in the GRPr-expressing tissue. The blockage study showed that **^{nat}Cu-6** was able to reduce the uptake in the receptor-rich tissue.

Bifunctional hexadentate bispidine ligands represent a versatile platform for the development of new copper radiopharmaceuticals. The two pendant carboxylate groups of the bispidines discussed here hold promising potential to tune the charge of the radiocopper complexes and consequently to influence the biodistribution and pharmacokinetic properties. Moreover, the new bispidine ligands may be readily modified with appropriate vector molecules.

ACKNOWLEDGMENT

The authors would like to thank Romy Schubert, Karin Landrock, Regina Herrlich, and Andrea Suhr for excellent technical assistance. Marion Kerscher and Madlen Matterna are acknowledged for the CV measurements, and Andreas Springer (FU Berlin) for high-resolution ESI-TOF-MS measurements.

Supporting Information Available: NMR data of compounds **2**, **3**, **4**, and **5**. Tables of crystal data, structure refinement, bond lengths and angles for compounds **2**, **Cu-2**, and **Cu-3**, and atomic coordinates and equivalent isotropic displacement parameters for **2** and **Cu-2** are presented. Figures S1 and S2 show the molecular structures of **2**, **Cu-2**, and **Cu-3**. Biodistribution data of **^{64}CuCl$_2$**, **^{64}Cu-2**, **^{64}Cu-3**, and **^{64}Cu-6** in rats are presented as %ID and SUV. This material is available free of charge via the Internet at http://pubs.acs.org.

Table S4. Atomic coordinates (x 10^4) and equivalent isotropic displacement parameters ($Å^2$ x 10^3) for **Cu-3**. U(eq) is defined as one third of the trace of the orthogonalized Uij tensor.

Table S5. Bond lengths [Å] and angles [°] for **2**.

Table S6. Bond lengths [Å] and angles [°] for **Cu-2**.

Table S7. Bond lengths [Å] and angles [°] for **Cu-3**.

Figure S1. a) Molecular structure of **2,** showing the chair-chair arrangement of the bicyclic system; b) two molecules of **2** connected via hydrogen bonds.

Figure S2. Crystal structure of **Cu-2** (left, hydrogen atoms omitted for clarity) and **Cu-3** (right); gray spheres are carbon, red spheres oxygen, blue spheres nitrogen and yellow spheres copper atoms; The green lines indicate hydrogen bonds.

Table S8. Amount of **$^{64}CuCl_2$, ^{64}Cu-2**, **^{64}Cu-3,** and **^{64}Cu-6** in selected organs, tissues, and excretion in rats at 5 and 60 min after single intravenous application. Data expressed as %ID (**mean** [bold] ± SD, n=4).

Table S9. Concentration of **$^{64}CuCl_2$, ^{64}Cu-2**, **^{64}Cu-3,** and **^{64}Cu-6** in selected organs, tissues, and excretion in rats at 5 and 60 min after single intravenous application. Data expressed as SUV (**mean** [bold] ± SD, n=4).

NMR-data of the compounds 2, 3, 4 and 5

Dimethyl-9-hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo[3.3.1]-nonane-1,5-dicarboxylate (2). ^{1}H-NMR (D_2O): 3.48 (d, 2H, ^{2}J = 14.8 Hz, N-CH_2), 3.51 (s, 6H, CH3), 3.67 (s, 2H, N-CH_2-py) 3.71 (d, 2H, ^{2}J = 13.2 Hz, N-CH_2), 4.48 (s, 2H, N-CH_2-py), 4.83 (s, 1H, C*H*-py), 4.92 (s, 1H, C*H*-OH), 6.90 (d, 1H ^{3}J = 8.0 Hz, C*H* pyridyl), 7.05 (m, 2H, C*H* pyridyl), 7.20 (d, 2H, ^{3}J = 7.8 Hz, C*H* pyridyl), 7.54-7.64 (m, 5H, C*H* pyridyl), 7.86-7.95 (m, 4H, C*H* pyridyl), 8.67 (d, 1H, ^{3}J = 5.6 Hz, C*H* pyridyl), 8.90 (d, 1H, ^{3}J = 4.8 Hz, C*H* pyridyl). ^{13}C-NMR (D_2O) 48.8, 53.1, 53.7, 55.9, 62.0, 70.0 (*C*H-OH), 71.2 (*C*H-py), 125.2, 125.3, 125.5, 125.8, 125.9, 127.0, 139.1, 139.3, 140.8, 146.6, 148.5, 149.8, 150.3, 153.1, 153.3, 170.2.

9-Hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane-1,5-dicarboxylic acid (3). ^{1}H-NMR (D_2O): 3.45 (d, 2H, ^{2}J = 13.8 Hz, N-CH_2), 3.66 (d, 2H, ^{2}J = 13.4 Hz, N-CH_2), 3.74 (s, 2H, N-CH_2-py), 4.54 (s, 2H, N-CH_2-py), 4.83 (s, 2H, C*H*-py), 4.88 (s, 1H, C*H*-OH), 6.91 (d, 1H, ^{3}J = 8.0 Hz, C*H* pyridyl), 7.12 (t, 2H, ^{3}J = 6.2 Hz, C*H* pyridyl), 7.35 (m, 2H, C*H* pyridyl), 7.66-7.71 (m, 5H, C*H* pyridyl), 7.91 (m, 2H, C*H* pyridyl), 8.02 (m, 2H, C*H* pyridyl), 8.76 (d, 1H, ^{3}J = 5.6 Hz, C*H* pyridyl), 8.96 (d, 1H, ^{3}J = 4.8 Hz, C*H* pyridyl). ^{13}C-NMR (D_2O): 49.6, 53.3, 56.2, 61.9, 70.8 (*C*H-OH), 71.7 (*C*H-py), 124.6, 124.9, 125.2, 125.6, 125.9, 126.0, 127.1, 129.2, 138.8, 139.3, 140.7, 146.5, 148.7, 149.4, 150.2, 153.9, 172.6.

Diethyl 4,4'-{[9-hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane 1,5-diyl]bis(carbonylimino)}dibutanoate (4). ^{1}H-NMR ($CDCl_3$): 1.21 (t, 6H, ^{3}J = 8.0 Hz, CH_3), 1.77-1.84 (m, 4H, CH_2), 2.32-2.35 (m, 4H, CH_2), 3.06-3.25 (m, 4H, CH_2), 3.59 (d, 2H, ^{2}J = 12.2 Hz, N-CH_2), 3.66 (s, 2H N-CH_2-py), 4.05-4.10 (m, 4H, OCH_2-), 4.14 (d, 2H, ^{2}J = 12.0 Hz, N-CH_2), 4.39 (s, 2H, N-CH_2-py), 5.12 (s, 2H, N-CH_2-py), 5.69 (s, 1H, *C*H-OH), 7.05-7.08 (m, 2H, C*H* pyridyl), 7.19 (m, 2H, C*H* pyridyl), 7.40 (m, 1H, C*H* pyridyl), 7.52-7.57 (m, 4H, C*H* pyridyl), 7.86-7.94 (m, 3H, C*H* pyridyl), 8.04 (m, 2H, C*H* pyridyl), 8.47 (d, 1H, ^{3}J = 5.2 Hz, C*H* pyridyl), 8.85 (broad, 2H, N*H*CO), 8.92 (d, 1H, ^{3}J = 4.4 Hz, C*H* pyridyl).^{13}C-NMR ($CDCl_3$): 14.3, 24.2, 32.2, 39.5, 50.9, 52.4, 60.4, 60.9, 69.2 (*C*H-OH), 70.9 (*C*H-py), 124.4, 125.0, 125.9, 126.2, 137.9, 138.2, 149.5, 150.5, 154.3, 168.3 (NH*C*OOCH_2-), 174.3 (*C*OOCH_2CH_3).

4,4'-{[9-Hydroxy-2,4-dipyridin-2-yl-3,7-bis(pyridin-2-ylmethyl)-3,7-diazabicyclo-[3.3.1]nonane-1,5-diyl]bis(carbonylimino)}dibutanic acid (5).

^{1}H-NMR (D_2O): 1.40-1.72 (m, 4H, CH_2), 1.85-2.02 (m, 4H, CH_2), 2.82-3.02 (m, 4H, CH_2), 3.47 (d, 2H, ^{2}J = 12.0 Hz, N-CH_2), 3.65 (s, 2H N-CH_2-py), 3.90 (d, 2H, ^{2}J = 12.0 Hz, N-CH_2), 4.53 (s, 2H, N-CH_2-py), 4.57 (s, 1H, *C*H-OH), 4.83 (s, 2H, C*H*-py), 6.94 (d, 1H, ^{3}J = 8.0 Hz, C*H* pyridyl), 7.05 (t, 2H, ^{3}J = 6.0 Hz, C*H* pyridyl), 7.20 (d, 2H, ^{3}J = 8.0 Hz, C*H* pyridyl), 7.6 (m, 3H, C*H* pyridyl), 7.85 (m, 2H, C*H* pyridyl), 7.92 (m, 2H, C*H* pyridyl), 8.60 (d, 2H, ^{3}J = 5.6, C*H* pyridyl), 8.88 (d, 1H, ^{3}J = 4.8 Hz, C*H* pyridyl). ^{13}C-NMR (D_2O): 23.3, 30.9, 39.0, 49.0, 52.2, 56.1, 60.3, 69.5 (*C*H-OH), 71.7 (*C*H-py), 124.7, 125.5, 126.4, 126.8, 128.0, 139.9, 140.6, 142.1, 146.4, 146.6, 147.7, 148.9, 152.1, 152.5, 169.0 (NH*C*OOCH$_2$-), 178.1 (*C*OOH).

A Dual-Mode Fluorescence Strategy for Screening HAT Modulators

Nan Xie, Emilia N. Elangwe, Sabrina Asher, and Yujun George Zheng*

Department of Chemistry, Georgia State University, PO Box 4098, Atlanta, Georgia 30302. Received October 27, 2008

Histone acetyltransferases (HATs) are an important class of epigenetic enzymes involved in chromatin restructuring and transcriptional regulation. We describe in this paper a novel approach for the identification and characterization of HAT inhibitors using both fluorescence resonance energy transfer (FRET) and fluorescence polarization. Expressed protein ligation (EPL) was used to label HATs PCAF and p300 with Dabcyl (Dab) as FRET acceptors. Methoxycoumarin (Mca) is conjugated to HAT substrate analogues to function as fluorescent donors, namely, H3CoA20Mca for interacting with PCAF and LysCoAMca for p300. When a ligand−protein interaction occurs, the fluorescent intensity of the donor fluorophore decreases due to FRET quenching by the Dab acceptor. Meanwhile, the formation of ligand−protein complexes causes reduction of the molecular mobility of the donor fluorophore, resulting in increased fluorescence anisotropy. Thus, dual modes of fluorescence measurement, FRET and anisotropy, are integrated in the same assay system. In particular, we demonstrated that both FRET and anisotropy measurements can be used to effectively detect and characterize HAT inhibitors. The developed strategy should be useful in the search of new anticancer drugs that target the substrate interfaces of the HAT targets, as well as find values in mechanistic study of HATs.

INTRODUCTION

The genomes of eukaryotic organisms are tightly packed into chromatin complexes in the nucleus, which not only serve as structural scaffolds of the DNA duplexes, but also function as a dynamic regulator of various DNA-involved nuclear processes such as DNA transcription, replication, recombination, and damage repair (*1*, *2*). The core histones in chromatin are subject to a diverse post-translational modification including acetylation, methylation, and phosphorylation, which has been determined to be an important molecular process that regulates the chromatin structure and gene expression (*3*, *4*). As one of the key types of histone modifications, lysine acetylation is catalyzed by histone acetyltransferases (HATs), which elicit chromatin structural relaxation and gene transcriptional activation either by altering DNA−histone interactions or by attracting downstream effectors (*5*, *6*). HATs are grouped into several distinct families based on sequence and structural homology (*7*−*11*), which include Gcn5/PCAF, p300/CBP, and the MYST family (named after its founding members, MOZ, YBF2/SAS3, SAS2, and Tip60) (*12*). These HAT proteins not only are essential to regulate gene expression in normal cellular processes (e.g., growth, differentiation, apoptosis), but expression and/or activity deregulation of many HATs have also been observed in a range of disease states, especially cancer (*8*, *13*−*17*). It has increasingly become apparent that dysfunctional regulation of histone acetylation constitutes a significant mechanism for malignant diseases (*8*, *14*, *15*). For example, in prostate carcinoma, several HATs including PCAF, p300/CBP, and Tip60 are up-regulated and participate in the acetylation and activation of the androgen receptor and contribute to the pathway of hormone resistance (*18*, *19*). Prostate cancer cells expressing acetylation mimic AR mutants were more resistant to androgen-antagonist flutamide (*20*). Thus, inhibition of deregulated HATs represents a promising approach to new cancer therapy.

Although HDAC inhibitors have been extensively studied and several are in clinical trials (*21*−*23*), progress in developing low-molecular-weight inhibitors of HATs has been relatively slow, partly because of the lack of effective experimental tools for inhibitor screening. Most of the reported small molecule HAT inhibitors to date, such as anacardic acid, garcinol, isothiazolone, curcumin, and cinnamoyl compounds, exhibit nonspecific inhibition and have limited usage in pharmacological settings (*24*). Therefore, new endeavors are needed to develop small molecule inhibitors of HATs.

Currently, only limited approaches exist for HAT inhibitory study in a high-throughput format (*25*−*29*). The classical radioisotope-labeled assay is useful for enzymatic characterization of HATs but is difficult to be implemented to automation and high-throughput screening (HTS) (*30*). Spectrophotometric methods that rely on quantification of the product coenzyme A (CoA) have been reported (*31*−*33*). These coupled reactions contain additional components and are much more complex than a pure HAT assay, which greatly compromises their application. Immunoblotting protocols (e.g., TRF-Cellisas) that rely on antibodies recognizing acetyl-lysines are widely used to study histone acetylation and deacetylation and have also been proposed for inhibitor screening use (*28*, *29*, *34*, *35*). Although the applicability of this type of assay to natural product screening with medium throughput has been demonstrated (*36*, *37*), it suffers from several aspects of shortcomings: antibodies are expensive, the procedure involves extensive washing and is time-consuming, and achieving quantification results is technically problematic. Also, a robust deconvolution scheme is additionally required to validate the action of hits identified in a cell-based screen. Therefore, certain reservation exists concerning their practical utility in a real HTS context (*38*).

We recently developed a simple, single-step assay for direct readout of acetylation products via fluorescent intensity changes (*39*). To gain fluorescence signals adequate for use in inhibitor screening contexts, herein we present a new fluorescence strategy for the study of HAT-ligand interactions. Uniquely, we integrated two principles of photophysical measurement, namely, fluorescence resonance energy transfer (FRET) and fluorescence polarization/anisotropy, within one single system. In this approach, the HAT protein is expressed and chemoselectively labeled with an acceptor chromophore (quencher). On the other hand, a HAT-binding ligand (e.g., a modified substrate analogue)

is chemically synthesized and labeled with a donor fluorophore. When the donor-labeled ligand is mixed with the acceptor-labeled HAT protein to form a complex, a FRET interaction occurs between the donor and the acceptor (e.g., coumarin and dabcyl), and thus, the fluorescence of the donor is quenched (Scheme 1). Along this process, the molecular mobility of the small-molecular-weight donor increases greatly due to complexation with the protein target. This allows for simultaneous fluorescence polarization and anisotropy readout. HAT inhibitors, on the other hand, have the potential to competitively displace the donor molecule from the enzyme, thus inversing the FRET and fluorescence anisotropy responses.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-protected amino acids, Boc-protected amino acids, Rink amide resin, and preloaded Wang resin were purchased from NovaBiochem. All the other chemical reagents were purchased from Sigma-Aldrich or Fisher and used without further purification. *E. coli* strains XL1-Blue, BL-21(DE3), and BL-21(DE3) Codonplus RIPL competent cells were obtained from Stratagene. Chitin beads were purchased from New England Biolab.

Synthesis of Compounds. Solid-phase peptide synthesis (SPPS) was performed on a PS3 peptide synthesizer (Protein Technologies) using the Fmoc (*N*-(9-fluorenyl) methoxycarbonyl) strategy (*40*). All the reactions were performed at room temperature unless indicated otherwise. Removal of Fmoc was performed with 20% v/v piperidine/DMF. For the coupling of each amino acid (AA), 4 equiv of AA/HBTU/HOBt (*N*-hydroxybenzotriazole) were used. *N*-Methylmorpholine (NMM) was used as a base catalyst. The N-terminal amino group was acetylated with acetic anhydride unless indicated otherwise. After solid-phase synthesis, the resins were subsequently washed with DMF and dichloromethane and then dried in vacuum for at least 2 h before cleavage.

Peptides were cleaved from resin by treatment with 95% trifluoroacetic acid (TFA), 2.5% H_2O, and 2.5% triisopropylsilane, or with 94% TFA, 2.5% H_2O, 2.5% ethanedithiol, and 1% triisopropylsilane if the sequences of peptides contain Cysteine(Trt), or with Reagent K (82.5% trifluoroacetic acid, 5% phenol, 5% H_2O, 5% thioanisole, 2.5% ethanedithiol) if the sequences of peptides contain Arginine(Mtr) (handling of TFA must be performed in a secure hood) for 4 h. Cold diethyl ether was used to precipitate the products. Crude products were collected by centrifugation and were washed twice with cold diethyl ether. After lyophilization, the compounds were redissolved in water and purified with reverse-phase (RP) HPLC (C18, Varian) on a Varian Prostar HPLC system using linear gradients of H_2O/0.05% TFA (solvent A) vs acetonitrile/0.05% TFA (solvent B). Analytical HPLC and MALDI-MS were used for characterization.

Cys-Ser-Ser-Lys(Dabcyl)-Gly (1). Fmoc-Lys(Dde)-OH, Fmoc-Ser-OH, Boc-Cys(Trt)-OH, and Fmoc-Gly-Wang resin were used in SPPS. The Dde (dimethyldioxocyclohexylidene) group was removed with a solution of 2% hydrazine in DMF for 2 h (*41*). For fluorescent labeling with the Dabcyl group, the resin was treated with 4 equiv of Dabcyl-OSu and 10 equiv of *N*-methylmorpholine in DMF for 4 h. The final compound was purified with preparative RP-HPLC (gradient 5−50% B over 60 min; flow 10 mL/min; absorption detection at 460 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{32}H_{44}N_9O_9S$ [M + 1] 731.3, found 732.3.

H3(Br)20Mca (2) [Ac−K(Mca)RTKQTARKSTGGK(Br)-APRKQL]. The protected sequence Ac−K(Mca)RTKQTA-RKSTGGK(Dde)APRKQL was synthesized on preloaded Fmoc-Leu-Wang resin using SPPS protocol. After Dde removal, the resin was treated with 10 equiv of bromoacetic acid and 10 equiv diisopropylcarbodiimide (DIC) in a minimal volume of DMF for 4 h. The resins were subsequently washed with DMF and dichloromethane and then dried in vacuum for 2 h before cleavage. The compound was purified with preparative RP-HPLC (gradient 5−35% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{110}H_{185}BrN_{36}O_{33}$ [M + 1] 2620.3, found 2620.5.

H3CoA20Mca (3). A mixture of 5.4 mg of H3(Br)20Mca and 4.7 mg of CoASH was dissolved in 100 μL of sodium phosphate buffer (100 mM, pH 8). The mixture was allowed to stand in the dark for 16 h and then purified with RP-HPLC (gradient 15−20% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{131}H_{217}N_{43}O_{49}P_3S$ [M + Li^+] 3309.5, found 3309.2.

H3(Br)20 (4)[Ac-ARTKQTARKSTGGK(Br)APRKQL]. It was synthesized following the same procedure as for H3(Br)20Mca, but Fmoc-ALa-OH was employed in the place of Fmoc-Lys(Mca)-OH. The compound was purified with preparative RP-HPLC (gradient 5−30% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{95}H_{170}BrN_{35}O_{29}$ [M + 1] 2347.2, found 2347.1.

H3CoA20 (5). 6.8 mg of H3(Br)20 and 6.4 mg of CoASH were dissolved in 100 μL of sodium phosphate buffer (100 mM, pH 8). The mixture was allowed to stand in the dark for 16 h and then purified with RP-HPLC (gradient 10−25% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{116}H_{202}N_{42}O_{45}P_3S$ [M + Li^+] 3036.4, found 3034.4.

CMLVELHTQSQDRFK(Dabcyl)-NH_2 (6). The sequence was synthesized on Rink amide resin using the general SPPS protocol. Following Dde removal, then, the resin was treated with 4 equiv of Dabcyl-OSu and 10 equiv of *N*-methylmorpholine in DMF for 4 h. It should be noted that the N-terminal cysteine needs to be protected with Boc prior to the Dde removal

with 2% hydrazine. The compound was purified with preparative RP-HPLC (gradient 10−60% B over 70 min; flow 10 mL/min; UV−vis detection at 460 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{93}H_{141}N_{27}O_{24}S_2$ [M + 1] 2085.0, found 2085.1.

Ac-Lys(Br)-Ahx-Lys(Mca)-NH_2 (7). Fmoc-Lys(Mca)-OH, Fmoc-Ahx-OH, Fmoc-Lys(Dde)-OH, and acetic anhydride were sequentially coupled to Rink amide resin using the SPPS protocol. Then, the Dde group was removed, followed by bromoacetylation of the ε-amino group of the lysine. The resins were subsequently washed and then subjected to TFA cleavage. The compound was purified with preparative RP-HPLC (gradient 5−30% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using MALDI-MS: calcd. for $C_{34}H_{49}BrN_6O_9$ [M + Na^+] 789.26, found 789.3.

Ac-Lys-CoA-Ahx-Lys(Mca)-NH_2 (LysCoAMca) (8). A mixture of 2 mg of Ac-Lys(Br)-Ahx-Lys(Mca)-NH_2 and 4.1 mg of CoASH was dissolved in 200 μL of sodium phosphate buffer (100 mM, pH 8) and 200 μL of acetonitrile. The mixture was allowed to stand in the dark for 16 h and then purified with RP-HPLC (gradient 15−35% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed by MALDI-MS: calcd. for $C_{55}H_{81}N_{13}O_{25}P_3S$ [M + Li^+] 1455.5, found 1458.3.

Ac-Lys(Br)-NH_2 (9). Fmoc-Lys(Dde)-OH and acetic anhydride were sequentially coupled to Rink amide resin using SPPS protocol. Following Dde removal with 2% hydrazine in DMF, bromoacetylation of the ε-amino group of the lysine was achieved by treating the resin with 10 equiv of bromoacetic acid and 10 equiv diisopropylcarbodiimide (DIC) in a minimal

(b) The titration curve of LysCoAMca (0.2 μM) emission at 396 nm vs the concentrations of p300-Dabcyl. K_d is calculated to be 0.40 ± 0.06 μM. (c) The spectral changes of LysCoAMca (0.2 μM) at increasing concentrations of the p300 inhibitor LysCoA while fixing the concentration of p300Dab at 2.2 μM (λ_{ex} = 326 nm). (d) The fluorescent intensity changes of LysCoAMca (0.2 μM) at 396 nm vs the concentrations of LysCoA (the concentration of p300Dab is 2.2 μM). K_i of LysCoA is calculated to be 0.57 ± 0.07 μM.

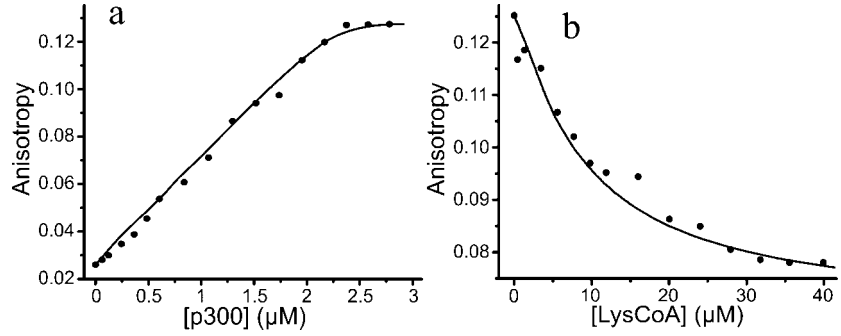

Figure 6. Fluorescence anisotropy changes of LysCoAMca. (a) Titration of LysCoAMca (0.2 μM) with p300-Dab by fluorescence anisotropy (λ_{ex} = 326 nm, λ_{em} = 396 nm). K_d is calculated to be 0.73 ± 0.15 μM. (b) Titration of the binary mixture (0.2 μM of LysCoAMca and 2.2 μM of p300Dab) with HAT inhibitor LysCoA by fluorescence anisotropy (λ_{ex} = 326 nm, λ_{em} = 396 nm). K_i of LysCoA is calculated to be 1.92 ± 0.29 μM.

volume of DMF for 4 h. The resins were subsequently washed with DMF and dichloromethane and then dried in vacuum for 2 h before cleavage. The compound was purified with preparative RP-HPLC (gradient 5−15% B over 60 min; flow 10 mL/min; UV detection at 214 nm). MALDI-MS: calcd. for $C_{10}H_{18}BrN_3O_3$ [M + Na^+] 332.04, found 332.0.

Ac-Lys-CoA-NH_2 (LysCoA) (10). A mixture of 2 mg of Ac-Lys(Br)-NH_2 and 4.1 mg of CoASH was dissolved in 50 μL of

sodium phosphate buffer (100 mM, pH 8) and 50 μL of methanol. The mixture was allowed to stand in the dark for 16 h and then purified with RP-HPLC (gradient 4−5% B over 60 min; flow 10 mL/min; UV detection at 214 nm), and the structure was confirmed using mass spectrometry. MALDI-MS: calcd. for $C_{31}H_{50}N_{10}O_{19}P_3S$ [M + Li^+] 998.2, found 995.3.

Expression of Dabcyl-Labeled PCAF Protein. The DNA construct encoding for the PCAF HAT domain (aa 493−658) in the PTYB2 vector was used for protein expression. In a typical procedure, to 50 μL of BL-21(DE3) competent cells was added 1 μL of the PCAF-pTYB2 plasmid and incubated on ice for 30 min. The tube was then heat shocked at 42 °C for 30 s and put on ice for 2 min. 0.5 mL of NZY solution was added to the cells and allowed to incubate while rotating at 37 °C, 225 rpm, for 1 h. The cells were spread to agar plates and distributed with glass-ball beads. The plates were then incubated overnight at 37 °C. One colony was selected for inoculation of 8 mL of LB media containing ampicillin. The solution was then allowed to incubate at 37 °C overnight with shaking at 225 rpm. The 8 mL cell culture was added to 1 L of LB media and cultured until the OD595 reached 0.6−0.8. Then, the temperature of the incubator was decreased to 16 °C at which point protein expression was induced with 0.3 mM of IPTG. The culture was kept in the incubator for 16−20 h. The cells were harvested by centrifugation at 5000 rpm, 4 °C, for 10 min. The cells were then resuspended in 25 mL of lysis buffer (Hepes 25 mM, pH 8.0, NaCl 500 mM, glycerol 10%, MgSO4 1 mM, PMSF 1 mM). The cells were lysed with a French Press twice, and the lysates immediately were centrifuged at 4 °C, 14,000 rpm for 30 min. The supernatant was collected and loaded to 3.0 mL of chitin beads. The beads were washed with 1× chitin column buffer (25 mM HEPES pH 8.0, 500 mM NaCl, 1 mM EDTA, 0.1% Triton X-100, glycerol 10%, and 1 mM PMSF). After washing, 2 mM of the ligation peptide (CSSK(Dabcyl)G, 1) in 3 mL of ligation buffer (25 mM HEPES pH 8.0, 500 mM NaCl, 1 mM EDTA, glycerol 10%, 1 mM PMSF, and 200 mM MESNA) was added to the beads. The ligation reaction proceeded at room temperature for 40 h. After that, the ligated product was eluted, combined, and dialyzed against a storage buffer (25 mM HEPES pH 7.0, 250 mM NaCl, 1 mM EDTA, glycerol 10%, and 5 mM DTT) and then concentrated in a Millipore centrifuge filter tube. The protein concentration was determined by Bradford assay. The final labeled protein (PCAF-Dab) was aliquoted, flash-frozen with liquid N_2, and stored at −80 °C until use.

Expression of Dabcyl-Labeled p300 Protein. Labeling of p300 protein with Dacyl was achieved using the EPL protocol essentially the same as in the literature (*33*). First, the DNA sequence encoding for the p300 HAT domain (aa 1287−1652) was subcloned into PTYB2 vector (a gift from Prof. Phil Cole). BL-21(DE3) Codonplus RIL competent cells were used for protein expression. The expressed p300-intein-CBP fusion protein was loaded to chitin beads. After extensive washing, 6 mg of the ligation peptide (**2**. CMLVELHTQSQDRFK(Dabcyl)-NH_2) in 3 mL of ligation buffer (25 mM HEPES pH8.0, 250 mM NaCl, 1 mM EDTA, and 200 mM MESNA solution) was added to the beads. The ligation reaction was kept at room temperature for 48 h. The protein product was confirmed with 12% SDS-PAGE. The combined eluents were dialyzed against the storage buffer and then concentrated in a centrifuge filter tube. The concentration of labeled p300 protein (p300Dab) was determined by Bradford assay.

Fluorescence Measurement. The fluorescence experiments were performed on a Fluoromax-4 instrument (Horiba Jobin Yvon, Edison, NJ) at 25 °C using a 0.5 mL cuvette in a buffer solution containing 50 mM Hepes (pH 8.0), 0.1 mM EDTA, 150 mM NaCl, and 1 mM DTT. The dissociation constants (K_d) were determined by measuring the fluorescence signals of Mca-labeled ligands (at fixed concentration) with increasing Dab-labeled protein concentrations.

$$\text{fraction bound} = (F - F_o)/(F_f - F_o) = \{(F_f - F_o)/2[\text{Pr}]_{tot}\}\{b(b^2 - 4[\text{L}]_{tot}[\text{Pr}]_{tot})^{1/2}\} + F_o \quad (1)$$

$$b = K_d + [\text{L}]_{tot} + [\text{PCAF}]_{tot}$$

Where F_0 and F_f are the initial and final fluorescence intensities, respectively, $[\text{Pr}]_{tot}$ is the total protein concentration, and $[\text{L}]_{tot}$ is the total concentration of Mca-labeled ligand.

The inhibition constants (K_i) were determined by measuring the fluorescence signals of the binary mixture containing Mca-labeled ligand and Dab-labeled protein (at fixed concentrations) with increasing concentrations of respective inhibitors. Equation 2 was used for K_i calculation (*42*).

$$K_i = [\text{I}]_{50}/([\text{L}]_{50}/K_d + [\text{Pr}]_o/K_d + 1) \quad (2)$$

where $[\text{I}]_{50}$ denotes the concentration of the free inhibitor at 50% inhibition, $[\text{L}]_{50}$ is the concentration of the free Mca-labeled ligand at 50% inhibition, $[\text{Pr}]_0$ is the concentration of the free protein at 0% inhibition, and K_d is the dissociation constant of the protein−ligand complex.

RESULTS AND DISCUSSION

PCAF Protein Expression and Ligation. To design the donor−acceptor reporter for HATs, it would be ideal if the HAT enzyme can be regioselectively labeled so that its active site will not be affected by the chemical labeling reaction. Mixing a protein sample with common labeling reagents (e.g., fluorescein succinimidyl ester) has a high chance of leading to random placement of introduced tags. To achieve the regioselectivity, we took advantage of expressed protein ligation (EPL), a technique widely used for site-specific protein engineering (*43*, *44*). As a proof of principle, we first conducted fluorescent labeling of the HAT PCAF (Figure 1). The gene sequence encoding for the human PCAF (493−658) was subcloned into a PTYB2 expression vector. From this system, the recombinant protein was expressed in *E. coli* in the fusion form of PCAF-intein-CBD (chitin binding domain). The CBD motif allows for purifying the fusion protein on chitin beads. After washing out impurities, the beads were treated with a ligation buffer containing peptide Cys-Ser-Ser-Lys(Dabcyl)-Gly, abbreviated as CSSK(Dab)G, and 200 mM of 2-mercaptoethanesulfonic acid (MESNA). The thiol treatment produced the PCAF protein with a thioester motif at its carboxyl terminus. In the course, PCAF-thioester reacted with CSSK(Dabcyl)G via native chemical ligation (*45*) and formed the labeled PCAF-CSSK(Dabcyl)G product (PCAFDab).

Design and Synthesis of the Fluorescent Donor Ligand H3CoAMca. PCAF was reported to acetylate the N-terminal tail of histone H3 (*46*). The bisubstrate analogue H3CoA20 in which a CoA motif is linked to the H3 N-terminal sequence at the acetylation lysine site (K14) has been shown as a potent inhibitor of PCAF/GCN5 (*47*). We modified the bisubstrate analogue H3CoA20 with a fluorophore, methoxycoumarin (Mca), to produce a fluorescent donor ligand (Figure 2). The Mca group is attached at the N-terminal end via a lysine residue, distant from the CoA-attaching site to avoid potential interference with the binding ability of the ligand to PCAF.

FRET Response of the PCAF Reporter H3CoAMca. The Mca-labeled H3CoA20 conjugate (H3CoAMca) was characterized for its fluorescence properties. The compound was excited at 326 nm (extinction coefficient ε = 11 820 M^{-1} cm^{-1}) and exhibited a maximum emission at 396 nm (Figure 3). On the other hand, PCAFDab showed a broad absorption across

360−500 nm (not shown). Therefore, excited-state energy of Mca can be effectively transferred to the Dab acceptor when the two chromophores are within the Förster distance. We tested fluorescence emission of H3CoAMca in the presence of PCAFDab. As expected, the fluorescent intensity of H3CoAMca (0.2 μM) gradually decreased as a function of PCAFDab concentration (Figure 3a,b). The maximum quenching was achieved when the concentration of PCAFDab reached 12 μM or higher. From the titration data, the apparent K_d was calculated to be 0.57 ± 0.06 μM.

Next, we evaluated the performance of the donor−acceptor reporter for use in the detection of HAT inhibitors by monitoring FRET-mediated fluorescence intensity changes. A solution of a binary mixture was prepared containing 0.2 μM of H3CoAMca and 12 μM of PCAFDab. Then, an increasing amount of the nonfluorescent HAT inhibitor, H3CoA20, was added to the solution. As shown in Figure 3c,d, the fluorescent intensity increased in response to increasing amounts of H3CoA20. This matches well with our concept that the presence of a HAT inhibitor expels the H3CoAMca donor out of the binding pocket in PCAFDab, which will release the FRET interaction between the donor and the acceptor, thus causing fluorescence enhancement of the H3CoAMca donor. The K_i of H3CoA20 can be conveniently calculated from the competitive binding curve as 0.33 ± 0.03 μM, which is in close range to the value determined from the radioactive assay (0.14 μM) (*48*).

Anisotropy Response of the PCAF Reporter. Compared to its free form, the H3CoAMca ligand in the PCAF complex possesses a larger molecular mass and more restricted molecular mobility, which will correspond to a larger fluorescence polarization and anisotropy. Therefore, the HAT binding assay can also be possibly realized using the mode of fluorescence polarization or anisotropy measurement. As shown in Figure 4a, the fluorescence anisotropy of H3CoAMca gradually increased when increasing amounts of PCAFDab were added to the solution. K_d was calculated to be 1.58 ± 0.22 μM from the titration curve. The value is slightly higher than the value obtained from the FRET measurement, which most likely reflects that not all proteins are labeled by Dab chromophore: FRET measurement is dependent on the Dab labeling, while anisotropy is not. We also tested the use of fluorescence anisotropy in the measurement of inhibitor binding (Figure 4b). A solution of binary mixture containing 0.2 μM of H3CoAMca and 12 μM of PCAF-Dab was prepared. When an increasing amount of the PCAF inhibitor H3CoA20 was added, the fluorescence anisotropy of H3CoAMca at 396 nm decreased concurrently. From the anisotropy assay, K_i of H3CoA20 was determined to be 0.83 ± 0.10 μM. These experiments substantiate that, when H3CoAMca is competitively displaced from binding to the large HAT protein by an inhibitor, its fluorescence anisotropy will decrease due to reduction in molecular mass and rigidity.

Fluorescent Reporter of p300. To demonstrate whether the dual-mode strategy can be applied as a general approach to the study of other HAT proteins, we constructed a similar donor−acceptor assay and evaluated its performance for p300, another important HAT enzyme. Like the site-specific labeling of PCAF, p300 HAT domain (1287−1652) was expressed using a pTYB2 vector and then ligated to a C-terminal peptide CMLVELHTQSQDRFK(Dabcyl) (**6**), thus generating a protein fluorescent acceptor, p300Dab. To make a corresponding fluorescent donor ligand, an Mca-labeled compound, LysCoAMa, was designed on the basis of the reported p300 inhibitor, LysCoA (*47*). As anticipated, upon addition of p300Dab, the fluorescent intensity of LysCoAMca declined in a dose-dependent manner owing to FRET quenching interaction between Dab and Mca (Figure 5a,b). Again, the fluorescence intensity was recovered when the nonfluorescent ligand LysCoA was added to the solution, competitively displacing LysCoAMca out of the binding pocket in p300 (Figure 5c,d). We also performed fluorescence anisotropy measurements of LysCoAMca (Figure 6). In this regard, the performance of LysCoAMca was analogous to that of H3CoA20Mca; the anisotropy value increased upon binding to p300Dab protein, and the change was reversed by increasing concentrations of the competitive inhibitor LysCoA. Therefore, both FRET and anisotropy signals were effective to probe and characterize the p300−inhibitor interactions.

Taken together, we demonstrated a displacement strategy for the study of HAT−inhibitor interactions. The assay is built on the binding between an acceptor-labeled HAT protein and a fluorescent donor-labeled ligand. The HAT protein (PCAF or p300) was chemoselectively labeled using the technique of EPL. FRET and fluorescence anisotropy were utilized as readout to identify and quantify ligand binding. This approach is fast, homogeneous, non-radioactive, and friendly to automation, thus holding promise as a platform for the discovery and characterization of HAT modulators. It should be noted that current screening equipments often harness capabilities to collect data in multiple modes, such as absorption, fluorescence intensity, polarization, FRET, and chemiluminescence, and so forth. Since FRET and polarization measurements are based on two totally different photophysical principles (the measurement of Mca polarization is dispensable to the Dab), availability of dual signals in a primary assay will allow for the generation of two independent data sets from one screening experiment, thus having a high efficacy in substantiating genuine hits and eliminating false positives. Apart from inhibitor discovery, this fluorescence strategy can also be used as a valuable tool to investigate binding kinetics of HAT substrate analogues as well as the enzymatic mechanisms of HAT catalysis.

Received November 4, 2008; Revised Manuscript Received December 12, 2008

A photoaffinity probe, developed for the specific labeling of matrix metalloproteinase (MMP) active sites, was recently shown to covalently modify a single residue in human MMP-12, namely, Lys^{241}, by reacting selectively with the side chain ε-amino group of that residue. The residue in position 241 of MMPs is not conserved; thus, variability in this position may be responsible for the dispersion in cross-linking yield observed between MMPs when labeled by this photoaffinity probe. By studying the pH dependence of the labeling properties of this probe toward different MMPs (MMP-12, MMP-3, MMP-9, and various mutants of human MMP-12) and identifying the site of covalent modification of MMP-3 by this probe, our new data demonstrated that the nucleophilicity of the residue in position 241 plays a key role in determining the cross-linking yield of MMP modification by the probe. However, these studies also reveal that subtle additional structural parameters, including local conformation and flexibility, of the residue in position 241 should also be taken into consideration, a property adding a further degree of complexity in our understanding of the photolabeling probe reactivity and in designing optimal photoaffinity probes for performing functional proteomic studies of zinc proteinases like MMPs.

INTRODUCTION

The development of photoaffinity probes able to covalently label specifically the active site of zinc proteinases (activity-base probe, ABP) may lead to important applications in functional proteomics and diagnosis (*1*−*4*). For serine and cysteine proteinases, successful development of activity-based probes (ABPs) has been achieved by exploiting the presence of highly conserved nucleophiles in the active sites of these enzymes and selecting appropriate reactive groups to perform covalent modification of the targeted enzymes (*5*, *6*). For zinc metalloproteinases, like matrix metalloproteinases (MMPs), the lack of corresponding active site nucleophiles has required the use of a photochemical group that must be incorporated into the structure of synthetic specific MMP inhibitors (*1*, *2*). Following this strategy, we recently developed a selective MMP photoaffinity probe that consists of phosphinic peptide core, able to block potently and selectively a large set of MMPs, to which has been grafted an azido group on the P_1' side chain of the inhibitor (probe **1**, Scheme 1) (*4*). While probe **1** was shown to selectively covalently modify only the active site of MMPs, high variation in the cross-linking yield was observed between different MMPs. In fact, whereas $a \approx 45\%$ of cross-linking yield was determined for the covalent modification of human MMP-12 by probe **1**, for human MMP-8, this yield decreased to few percent (*4*). As the molecular determinants controlling the cross-linking yield of photoaffinity probes to their targets remain poorly understood, we initiated a research project in order to identify in MMPs the site of their covalent modifications by probe **1**. We recently reported results of a first study of human MMP-12 (hMMP-12), showing that probe **1** covalently modifies only a single residue in this MMP, by reacting with the ε NH_3^+ group of Lys^{241} (*7*). This result was unexpected, as Lys^{241} is located on a loop segment of hMMP-12, which, based on both X-ray and NMR studies, displays high flexibility with the lysine side chain exhibiting high mobility (*8*−*10*). Another remarkable feature of this study is the fact that, at pH 7, the conditions of hMMP-12 covalent modification, photoactivated azides are expected to react with good nucleophiles, but less so with the protonated positively charged ε amino group of Lys^{241} (*11*). This remark has led us in the present study to compare the labeling of hMMP-12 by probe **1** at pH 7 and 12. On the basis of the results obtained, human MMP-3 (hMMP-3) was studied in detail, as this MMP possesses in position 241 a histidine residue, whose nucleophilicity is also pH-dependent. Two other MMPs containing an arginine residue in position 241, mouse MMP-12 (mMMP-12) and hMMP-9, were also examined. Finally, to better understand the variability in cross-linking yield observed between MMPs with probe **1**, several mutants of hMMP-12 have been produced and studied. In these mutants, position 241 has been replaced by residues observed in different MMPs in this position.

EXPERIMENTAL METHODS

Commercial reagents were used without additional purification. Buffers and salts were from Sigma. Synthesis and tritium radiolabeling of probe **1** were carried out as previously reported (*4*). Mca-Pro-Leu-Gly-Leu-Dpa-Ala-Arg-NH_2 (Mca-Mat) was from Novabiochem, and TIMP-1 inhibitor was from R&D systems.

Proteins. Synthetic genes encoding the catalytic domain of MMP-12 (Met^{98}-Lys^{266}) and murine MMP-12 (Gln^{109}-Gly^{267}) were from Geneart (Geneart-AG, Germany). Genes were inserted into the pET24a vector, between the NdeI and *Bam*HI sites, for expression under the PT7 promoter. Lys^{241} was substituted by His (primer 5'-ccgtaatgttccccac-ctacCaCtatgttgacatcaacaca-3') or Arg (primer 5'-ccgtaatgttccccacctacCGatatgttgacatcaacaca-3') or Gln (primer 5'-ccgtaatgttccccacctacCaG-

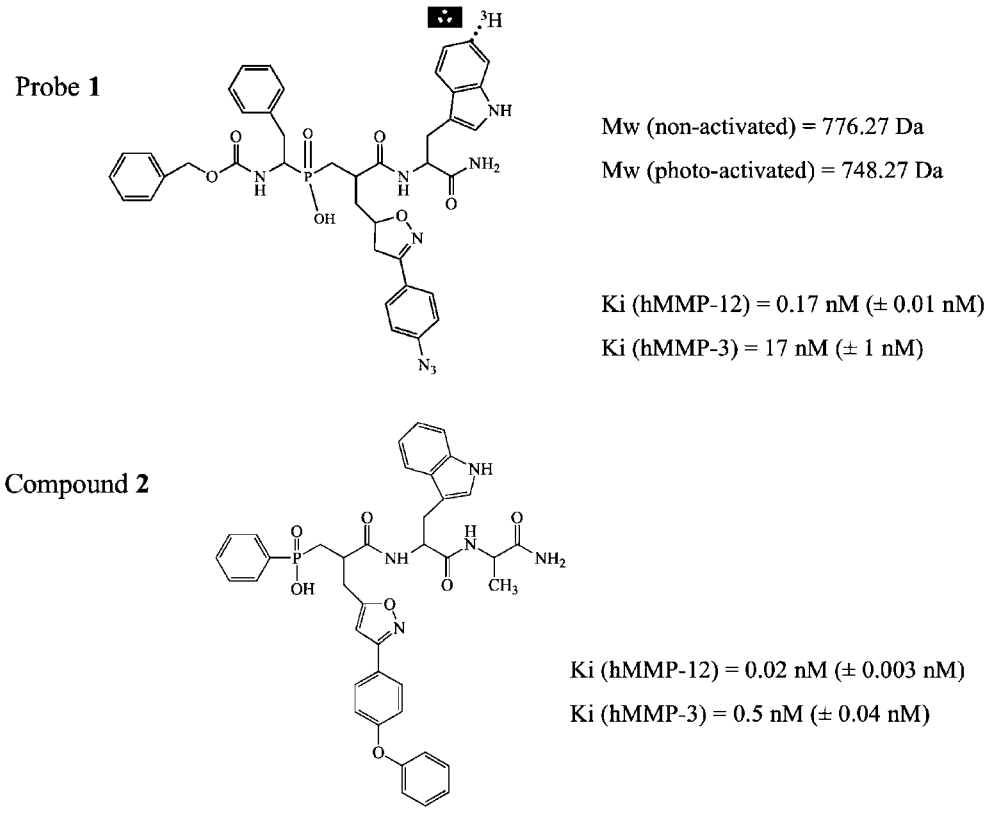
Scheme 1



tatgttgacatcaacaca-3′) or Thr (primer 5′-ccgtaatgttccccacctaca-CGtat-gttga catcaacaca-3′). The corresponding hMMP-12 mutants were produced using the Site-Directed Mutagenesis Kit (Stratagene, Heidelberg, Germany). All plasmids were propagated in the *Escherichia coli* strain XL1-Blue at 37 °C, and all constructions were verified by DNA sequencing using the ABI PRISM 310 Genetic analyzer (Applied Biosystems). Recombinant proteins were expressed in *E. coli* BL21 (DE3 star) cells carrying the MMP-12 catalytic domain-encoding plasmids. Production and purification of MMP-12 mutants were as described in ref *7*. Protein molecular weights were determined by ESI-MS, and the presence of mutations was verified by Malti-TOF, after tryptic digestion. Human catalytic domain of MMP-3 was obtained as previously described (*12*).

Enzyme Assays. Enzyme assays and inhibition and titration experiments were carried out in 50 mM Tris/HCl buffer, pH 7, 10 mM $CaCl_2$, at 25 °C, using the Mca-Pro-Leu-Gly-Leu-Dpa-Ala-Arg-NH_2 (Mca-Mat) substrate, as described in ref *7*. Titration experiments using a calibrated TIMP-1 solution were performed to determine the exact enzyme concentration for each hMMP-12 mutant and wild-type hMMP-12. Values for k_{cat}/K_m were determined from first-order full-time course reaction curves obtained at $[S] \ll K_m$ ($[S] = 0.5$ μM), at 5 nM final enzyme concentration. The K_i of probe **1** was determined using the method proposed by Horovitz and Leviski (*13*).

Mass Spectrometry. nanoESI-MS experiments were performed in an ion trap mass spectrometer (Bruker, Esquire-HCT). Ion trap parameters were set as follows: nanoelectrospray potential, 1000 V; skimmer voltage, 40 V; capillary exit, 226 V; and a source temperature of 150 °C. The MS survey scan was *m*/*z* 400−3000 Da with a target mass fixed at *m*/*z* 1800 Da and a 5 spectrum scan average.

MS/MS Sequencing of Covalently Modified Peptides. Radioactive fractions containing covalent adduct peptides were concentrated using a C_{18} ZipTip. Off-line nanoESI-MS/MS experiments were performed in an ion trap mass spectrometer. Ion trap parameters for MS were set as above. The scan number was increased to 20 spectra over an *m*/*z* of 250−2000 Da, the isolation width was set to 1 Da, and the collision energy was tested using a range of 0.2−0.9 V in the MS/MS mode. MS/MS spectra were recorded for double-charged molecular peptide ions.

***μ*-RP-HPLC.** Peptide separation was carried out in an Agilent 1100 series apparatus using an X-Bridge (Waters) C_{18} 5 μm, 300 Å column (2.1 × 150 mm, 5 μm) at a flow rate of 200 μL/min and with detection at 214 nm. Solvent systems were as follows: (A) 100% water, 0.1% FA, and (B) 100% acetonitrile, 0.09% FA; with the following gradient, $t = 0$ min, 10% B; $t =$ 5 min, 10% B; and $t = 45$ min, 100% B.

Photoaffinity Labeling. MMPs (1 μM) were incubated with 2 μM ^{3}H-probe **1** in 50 mM Tris-HCl, pH 7, 10 mM $CaCl_2$, 0.01% Brij35, for 10 min in the dark at room temperature, as described in ref *7*. For pH dependence studies, prior probe addition, the pH was adjusted by adding ammoniac or chloride acid in order to keep the same buffer composition. After photoactivation, the reaction was quenched by the addition of Laemmli loading buffer followed by boiling (5 min, 95 °C). These samples were immediately processed for subsequent SDS gel analysis.

Electrophoresis. Radiolabeled proteins were diluted in Laemmli loading buffer (final concentration: 0.1% (w/v) bromophenol blue, 2% (w/v) SDS, 10% (v/v) glycerol, 50 mM Tris-HCL pH 6.8, and 100 mM DTT) and were resolved by SDS-PAGE electrophoresis in a 12% 1-mm-thick SDS gel, using a mini-protean III apparatus (BioRad). Silver staining was performed as previously described (*7*).

Blotting. Transfer of proteins onto PVDF (polyvinylidene fluoride) membrane was achieved using a semidry transfer blot apparatus (BioRad). Gels were rinsed in a 50 mM Tris−HCl, pH 8.5, 20% methanol, 40 mM glycine, 0.0375% SDS in distilled water (transfer buffer). The PVDF membrane was activated in a bath of methanol and was then equilibrated in

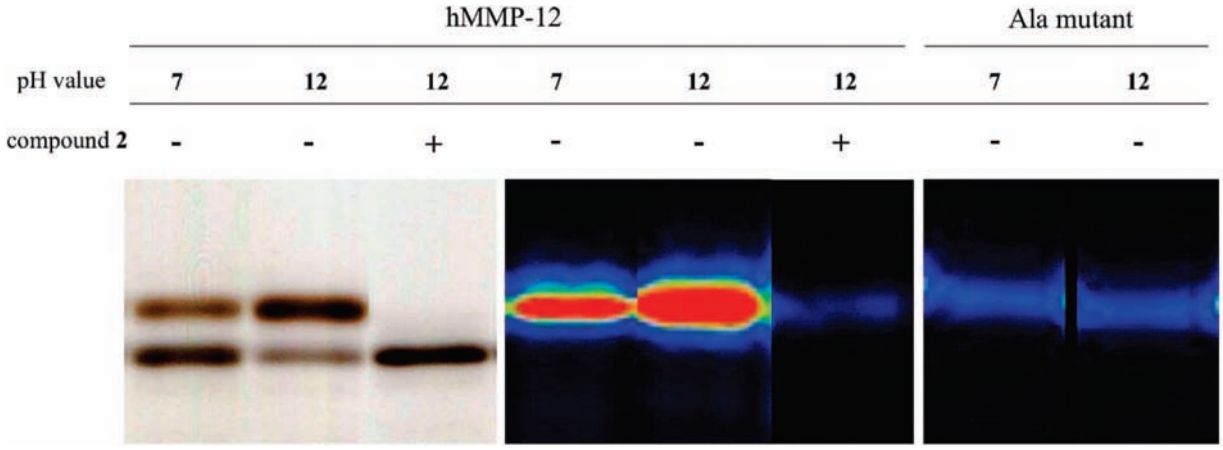


Figure 1. pH dependence for the covalent modification of wild-type h-MMP-12 and Ala-hMMP-12 mutant by probe **1**. hMMP12 or Ala mutant (1 μM) was incubated with probe **1** (2 μM) for 10 min, before UV irradiation (2 min). The corresponding complexes (5 pmol) were resolved by 1D-SDS PAGE electrophoresis and visualized on the gel by silver staining, or the proteins were transferred onto a PVDF membrane that was analyzed with a radioimager.

transfer buffer. We formed a membrane sandwich for protein transfer between the cathode and the anode: this included, from anode to cathode, a sheet of extra-thick blotting paper (BioRad), soaked in transfer buffer, the activated PVDF membrane, gels, and finally 2 sheets of extra-thick blotting paper soaked in transfer buffer. After transfer, membranes were dried before radioactivity analysis or were stained using Coomassie Blue (0.1% R_{250}, 50/49/1 water/ethanol/acetic acid).

Radioimaging. We carried out radioactivity imaging and counting on the PVDF membranes, using the beta-Imager 2000 from Biospace (Paris, France). This apparatus allows absolute counting of the tritium beta particles, with a detection threshold of 0.007 cpm/mm^2 for tritium.

PVDF-Tryptic Digestion. Pieces of PVDF membranes containing labeled or unlabeled h-MMP-12 were excised and destained using a 50/50 water/ethanol solution to remove excess R_{250}. PVDF pieces were incubated in a solution of 50 mM NH_4HCO_3 pH 8/ acetonitrile (50/50) with trypsin (12.5 ng/μL) for 18−20 h at 50 °C. PVDF pieces were then rinsed with a solution of 50% acetonitrile with 0.1% TFA.

Edman Sequencing. N-Terminal amino acid sequence analysis was performed by automated Edman degradation using an ABI model 477A/120A Protein-Peptide Sequencing/ Analysis System and Analysis Software System, model 920A (Applied Biosystems Inc., Foster City, CA). Radioactive fractions eluted from the μ-HPLC column were pooled and loaded onto a TFA-treated cartridge filter, previously conditioned with BioBrene Plus. Prior to each sequence analysis, the filters were calibrated using PTH-amino acids standard solution.

Molecular Modeling. Models of probe **1** interacting with hMMP-12 and hMMP-3 were obtained as previously described. The NMR structures in Figure 8 were selected from an ensemble of 20 NMR structures of the hMMP-12 and hMMP-3 catalytic domain deposited in RCSB PDB under access code 2POJ (*10*) and 2JNP (*14*), respectively.

RESULTS

pH Dependence of hMMP-12 Photolabeling. As shown previously, silver staining of a gel loaded with UV-irradiated hMMP-12 in complex with probe **1** in buffer pH 7 revealed two bands of approximately equal intensity (Figure 1, left panel) (*4*). The lower band was shown to represent the unlabeled form of hMMP-12, while the higher one corresponds to the covalent hMMP-12/probe **1** complex. Relative intensity of these two bands suggested that ∼45% of hMMP-12 has been cross-linked by probe **1**. As expected, a radioactive signal was only observed for the higher band (Figure 1, middle panel; probe **1** incorporates a radioactive tag which allows covalent h-MMP12/probe **1** complexes to be detected by radioimaging; Scheme 1). Under the same experimental conditions, but with photoactivation performed in a buffer pH 12, either silver staining or radioactivity counting indicated a higher cross-linking yield of hMMP-12 by probe **1** (Figure 1, from 45% to 85% based on silver staining). In contrast, when the Ala-MMP-12 mutant (Lys^{241} has been replaced by Ala) is submitted to similar probe **1** labeling, the cross-linking yield remains extremely low, a result similar to that observed at pH 7 (Figure 1, right panel). Thus, this latter observation demonstrated that the pH dependence of the cross-linking reported for the wild-type hMMP-12 relies exclusively on the presence of Lys^{241} in this MMP. When hMMP-12 was first incubated with a potent active site MMP inhibitor (compound **2**; Scheme 1), followed by probe **1** addition and UV irradiation, results reported in Figure 1 (middle panel) indicated that at pH 12 only the active site of hMMP-12 is modified by the probe, as observed previously when these experiments were performed at pH 7 (*4*). In combination with our previous study showing that probe **1** covalently modifies the ε amino group of Lys^{241} (*7*), observations reported in Figure 1 reveal that the Lys^{241} nucleophilicity determines the cross-linking yield of probe **1** toward hMMP-12.

pH Dependence and Site of Covalent Modification of hMMP-3 by Probe 1. hMMP-3 contains in position 241 a histidine residue; thus, the pH dependence of its covalent modification by probe **1** was examined. Incubation of hMMP3 with probe **1** in buffer pH 7, followed by UV irradiation and protein resolution by electrophoresis, led to the observation of two bands in a gel loaded with hMMP-3/probe **1** complex and stained with silver (Figure 2a, left panel, first lane). Radioimaging analysis indicated that only the higher band incorporated radioactivity (Figure 2a, right panel, first lane). Under the same experimental conditions, lowering the pH of the sample from 7 to 5 resulted in a strong decrease of the cross-linking yield (from 65% to less than 1%), as visualized either by silver staining or radioactivity counting (Figure 2a, second and third lanes in left and right panels). It should be mentioned that an optimum pH of 5.5 has been reported for hMMP-3 in cleaving synthetic substrates (*15*), a property explaining the low labeling of hMMP-3 by probe **1** observed previously at pH 5.5 (*4*). When hMMP-3 was first incubated at pH 7 with an excess of compound **2** (Scheme 1), and this was followed by probe **1** addition and UV irradiation, only a single band was observed by silver staining and no radioactivity was detected (Figure 2b,

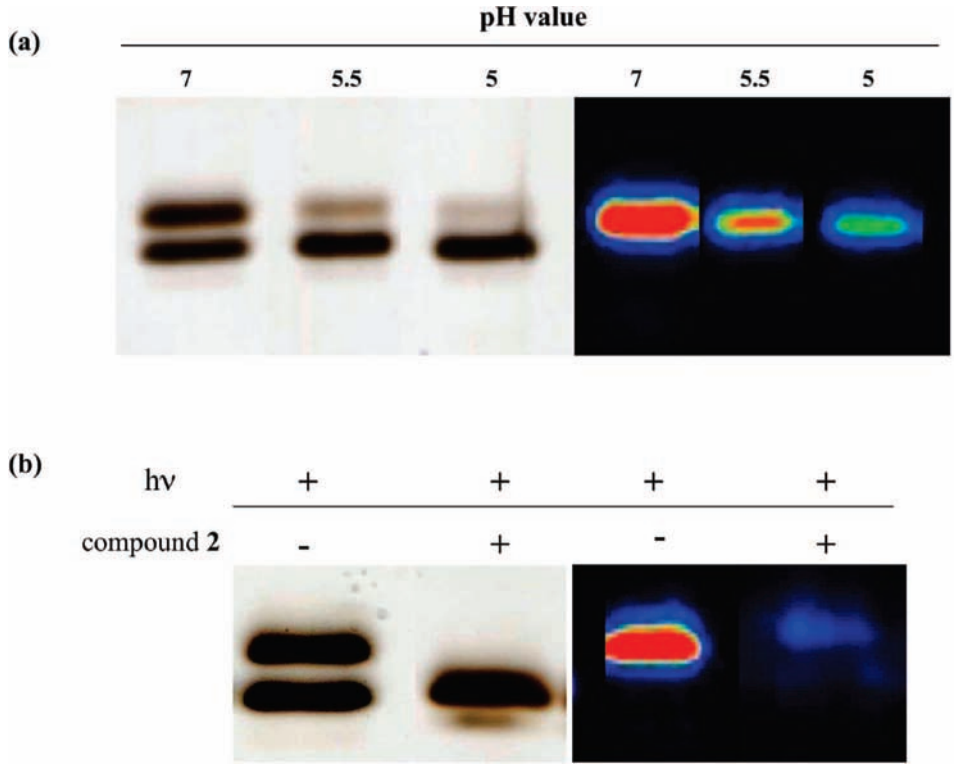

Figure 2. (a) pH dependence for the covalent modification of h-MMP-3 by probe **1**. hMMP-3 (1 μM) was incubated with probe **1** (2 μM) for 10 min, before UV irradiation (2 min). (b) Same experiments, but performed in the presence of compound **2** (10 μM) before the irradiation. The corresponding complexes (5 pmol) were resolved by 1D-SDS PAGE electrophoresis and visualized on the gel by silver staining or the proteins were transferred onto a PVDF membrane that was analyzed with a radioimager.

left and right panels). This result demonstrates that the covalent labeling of hMMP-3 involved exclusively residues of its active site. The marked pH dependence of hMMP-3 labeling by probe **1**, in a range of 5−7 that encompasses the His pK_a value (~6), and the higher labeling observed at pH 7 suggested that probe **1** probably modifies His^{241} in hMMP-3, as His is a better nucleophile at pH 7 than at pH 5.

To confirm the site of hMMP-3 modification, microsequencing and mass spectrometry experiments were carried out. Briefly, the protocol used relied on isolation of covalent hMMP-3/probe **1** complex by 1D-SDS gel, transfer of the corresponding protein species on PVDF membrane, and digestion first by trypsin and then by V-8 proteinase. Unmodified form of hMMP-3 was treated similarly for comparison. The μ-HPLC profiles of the peptide mixtures resulting from the double digestion of unlabeled and labeled hMMP-3 are reported in Figure 3. Comparison of these μ-HPLC profiles indicated that two peaks observed for unmodified hMMP-3 (labeled 1 and 2 in Figure 3, top panel) cannot be detected in the HPLC profile of modified hMMP-3 sample (Figure 3, lower panel). Mass analysis indicated that these two peaks correspond to two S_1' loop fragments of hMMP-3: the first one comprises residues from Ala^{234} to Arg^{248} and the second residues Ala^{234} to Asp^{245}. Lack of these two peaks in the μ-HPLC profile corresponding to modified hMMP-3 suggests that probe **1** probably modifies residues of the S_1' loop, an event affecting their HPLC retention time. Indeed, in the modified sample, radioactivity analysis of the μ-HPLC flowthrough indicated the presence of a radioactive signal in fractions eluting at 25−26 min (Figure 3, lower panel). These radioactive fractions were collected and analyzed by Edman sequencing. N-terminal sequencing started at Ala^{234} and went to Tyr^{240}; next, no amino acid could be assigned (His^{241} position, Figure 4). Afterward, the next sequencing step indicated a Ser^{242}; then, the sequencing identified the expected S_1' loop sequence up to Arg^{248}. Nano-ESI offline mass spectrometry analysis of the above purified radioactive fractions allowed the detection of three peaks (Figure 5), two double-charged ions, $[M_1 + 2H]^{2+} = 1094.6$ and $[M_2 + 2H]^{2+} = 1279.6$ Da, respectively, and one triple-charged ion, $[M_1 + 3H]^{3+} = 853.4$ Da. These ions represent peptide fragments of respective mass: M_w (M_1) = 2187.2 and M_w (M_2) = 2557.2 Da. The mass at 2187.2 Da corresponds to the expected mass of the S_1' loop of hMMP-3 (residues Ala^{234} to Asp^{245}, $M_w(1) = 1422.9$ Da), after trypsin and V8 protease digestion, covalently modified by probe **1** ($M_w = 776.27$ Da, minus 28 Da due to loss of N_2 after irradiation of the azide group). The difference of 16 Da between the expected theoretical mass of the S_1' loop of hMMP-3 covalently modified by probe **1** and the observed mass is explained by Met^{236} oxidation, a residue present in the S_1' loop sequence of hMMP-3. A similar methionine oxidation was also observed in related covalently modified S_1' loop fragments of hMMP-12 (*7*). The second mass at 2557.2 Da is explained by similar arguments, except that the S_1' loop fragment possesses three additional residues (Leu^{246}-Thr^{247}-Arg^{248}. This fragment, which was produced by trypsin cleavage, was not cleaved by the V8 protease. MS/MS experiments were performed on either double-charged or triple-charged ions described above in order to confirm by mass the site of covalent modification in hMMP-3. However, despite several attempts using different values of collision energy for the peptide fragmentation, only peaks of extremely low intensities were observed in the corresponding MS/MS spectra, preventing the sequencing of the covalently modified peptide fragments.

Covalent Labeling of MMP-12 Mutants. Probe **1** was previously shown to modify specifically the lysine residue located in position 241 of hMMP-12 (*7*), a position exhibiting high variability in MMPs ($Ala_{(MMP8)}$, $Gln_{(MMP14)}$, $Thr_{(MMP2,13,11)}$, $Arg_{(MMP9)}$, $His_{(MMP3)}$ (*16*). In order to see how the chemical structure of the side chain in position 241 influences the yield of covalent labeling by probe **1** in hMMP-12, independent of

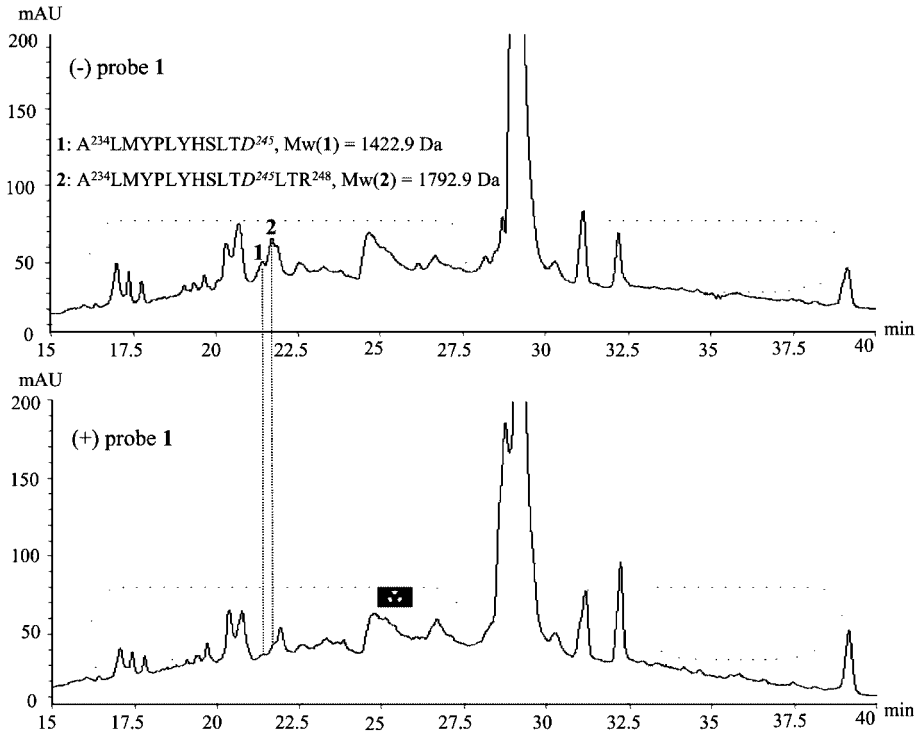

Figure 3. μ-HPLC profile of a peptide mixture obtained by trypsin and V8-protease digestion of unmodified or covalently hMMP-3 by probe **1**. UV trace (214 nm) of a PVDF digest (100 pmol) of unmodified (top panel) and modified h-MMP-3 (lower panel) by probe **1**. Peaks labeled 1 and 2 in top panel correspond to fragments reported in this figure generated by trypsin and V8 protease cleavage of the S_1' loop (2 was not cleaved by the V8 protease). In the lower panel, radioactive fractions corresponding to fragments covalently modified by probe **1** are identified by a radioactive symbol.

the S_1' loop size which varies between MMPs, a series of mutants of hMMP-12 were produced by substituting position 241 in hMMP-12 with residues present in MMPs. Comparison of the catalytic efficiency of these mutants in cleaving a fluorogenic synthetic substrate specific for MMPs, as well as K_i values of probe **1** toward mutants, as compared with wild-type hMMP-12, indicated similar catalytic and recognition properties between mutants and wild-type enzyme (Table 1). Photolabeling of these mutants by probe **1**, analyzed either by silver staining or radioactivity counting, revealed a much lower cross-linking yield of the mutants (~3−6% based on radioactivity), as compared with a cross-linking yield value of ~45% observed in wild-type hMMP-12 (Figure 6). As previously reported, the presence of an alanine in position 241 results in lower cross-linking yield (1%) (*7*).

Covalent Labeling of mMMP-12 and hMMP-9. mMMP-12 and hMMP-9 both contain an arginine residue in position 241. Thus, the labeling of these two MMPs by probe **1** was

Table 1. Characterization of hMMP-12 Mutants (Ala, Arg, Gln, Thr, His)[a]

	hMMP-12	Ala mutant	Arg mutant	Gln mutant	Thr mutant	His mutant
k_{cat}/K_m ($M^{-1}.s^{-1}$)	$1.53 \times 10^4 \pm 0.03 \times 10^4$	$1.32 \times 10^4 \pm 0.05 \times 10^4$	$2.17 \times 10^4 \pm 0.04 \times 10^4$	$1.94 \times 10^4 \pm 0.01 \times 10^4$	$1.44 \times 10^4 \pm 0.02 \times 10^4$	$1.17 \times 10^4 \pm 0.03 \times 10^4$
K_i (nM)	0.17 ± 0.01	0.35 ± 0.04	0.15 ± 0.01	0.27 ± 0.02	0.16 ± 0.01	0.30 ± 0.02

[a] k_{cat}/K_m and K_i were determined in Tris/Hcl buffer 50 mM, pH 6.8, $CaCl_2$ 10 mM.

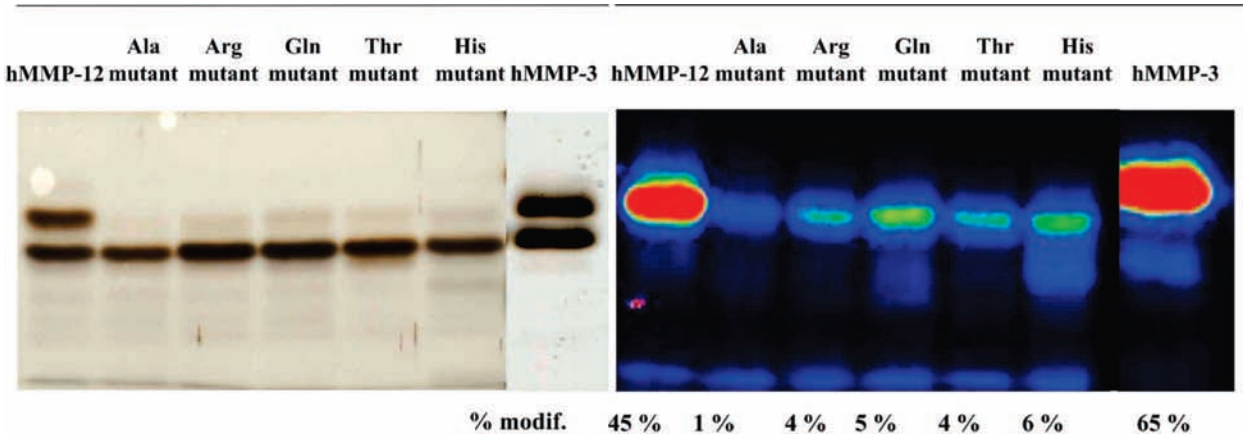

Figure 6. Labeling of hMMP-12 mutants by probe **1**, visualized by silver staining (left panel) or radioimaging (right panel), as compared with hMMP-12 and hMMP-3. Conditions as described in Figure 1.

examined at pH 7 and 13. The pH dependence of probe **1** labeling was also determined toward the Arg-hMMP-12 mutant, for comparison. As shown in Figure 7, for the three proteins stronger labeling was observed by increasing the pH from 7 to 13. Differences in cross-linking yield were observed among the three proteins, at pH 13 (11% for Arg-MMP-12, 16% for mMMP-12, and 19% for hMMP-9). As compared with hMMP-12, the cross-linking yield observed for these MMPs are smaller than that observed for hMMP-12 at pH 12 (85%).

DISCUSSION

Previous studies of the identification of the site of hMMP-12 covalent modification by photoactivated probe **1** have shown that this probe specifically modifies the ε amino group of Lys^{241} in this MMP (*7*). Taking into account the well-known efficiency of the nitrene intermediate in reacting with nucleophiles (*11*, *17*), this result led us to determine the reactivity of probe **1** at pH 12, a pH at which the ε amino group of Lys^{241} should be in its nonprotonated form (NH_2 instead NH_3^+) and thus represents a better nucleophile. The 2-fold increase in cross-linking yield observed for the labeling of hMMP-12 by probe **1** between pH 7 and 12 supports the proposal that the nucleophilicity of Lys^{241} is in fact a key parameter that determines the cross-linking yield of probe **1**. This observation suggests that other MMPs, possessing in position 241 a good nucleophile, like a lysine or any other amino acid bearing on its side chain a nucleophilic moiety, should also be modified by probe **1** with a high cross-linking yield. This led us to examine hMMP-3, the only MMP possessing in position 241 a good nucleophile too, a histidine residue. Indeed, a very high yield of cross-linking (65%) was observed for the covalent modification of this MMP by probe **1** at pH 7. In contrast, at pH 5, a pH at which the nitrogen atoms of the histidine side chain are weaker nucleophiles, a strong decrease of hMMP-3 labeling by probe **1** was observed. Microsequencing and mass spectrometry analyses identified the His^{241} as the unique site of modification of hMMP-3 by probe

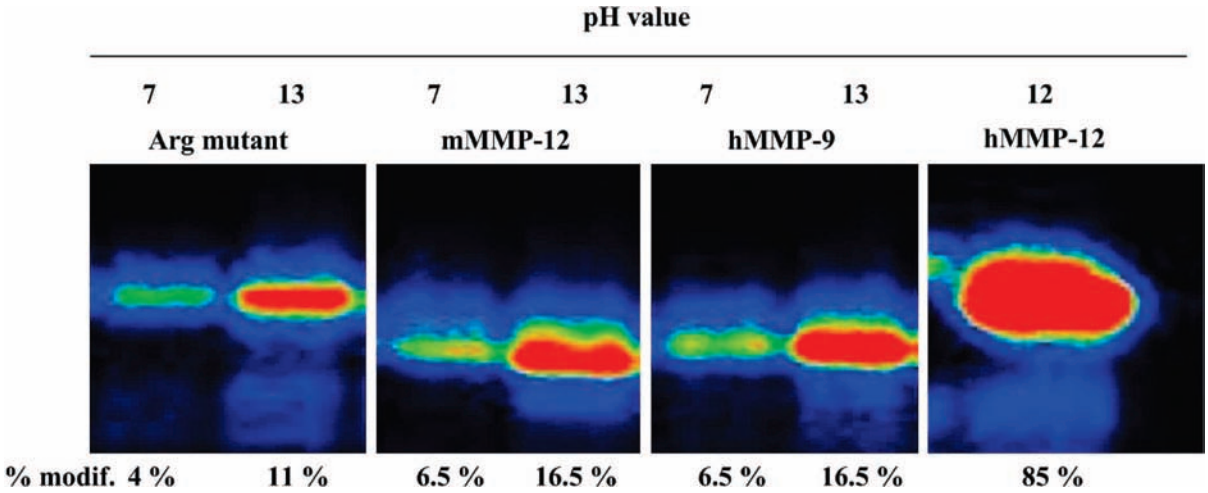

Figure 7. pH dependence for the covalent modification of, from the left to the right, Arg^{241}-hMMP-12 mutant, mMMP-12, and hMMP-9, as analyzed by radioimaging. Conditions as described in Figure 1.

1, a result explaining the observed pH cross-linking dependence. Altogether, these results again highlight the key role played by the nucleophilicity of the residue in position 241 of hMMP-3 and hMMP-12 for high labeling by probe **1**. As mentioned in the results sections, the MS/MS experiments performed to identify the site of covalent modification of hMMP-3 by probe **1** have all failed. These negative results are in contrast with those reported for hMMP-12 (*7*). In this case, it was possible to sequence by MS/MS experiments the whole S_1' loop fragment covalently modified by probe **1** and identify formally the occurrence of the probe modification on the lysine residue. Thus, even with peptides of similar size and sequence, sophisticated techniques like mass spectroscopy may not provide the expected analytical results, rendering classical Edman sequencing a still powerful technique.

According to X-ray and NMR studies, His^{241} in hMMP-3 and Lys^{241} in hMMP-12 are located on a loop segment (*8*−*10*) (*10, 14*), the S_1' loop, which exhibits high flexibility with these two residues displaying high mobility. Thus, the high yield of cross-linking observed for the modification of these two MMPs by probe **1** would be hard to predict taking into consideration this structural and dynamic information. The high cross-linking efficiency reported in this study implies the occurrence in enzyme/probe **1** complexes of conformations in which both Lys^{241} and His^{241} residues point toward the activated form of the probe **1** azide group, as shown in Figure 8. Accordingly, probe **1** can be viewed as a conformational probe providing clues about the structure and dynamics of MMPs (*9*). One important objective indicated by this study would be to determine whether the binding of probe **1**, in its nonactivated or activated form, stabilizes a particular conformation of the hMMP-3 and hMMP-12 S_1' loops; as such, a conformation selection process may have important implications for the design of highly selective inhibitors of MMPs, a challenge only partially achieved today (*18*−*20*).

The pH dependence observed for the efficient labeling of hMMP-3 and hMMP-12 led us to examine the importance of this parameter for the covalent modification of mMMP-12 and hMMP-9, two MMPs harboring an arginine in position 241. Increasing the pH form 7 to 13 resulted in a significant increase of the cross-linking yield (from 6% to 16−19% yield), a result suggesting that, in these two MMPs, like in hMMP-3 and hMMP-12, the amino acid side chain in position 241 is the target of probe **1** covalent modification. It should be noted that Arg^{241} is the only residue in the mMMP-12 and hMMP-9 active sites that can be affected by a pH variation from 7 to 13. The much

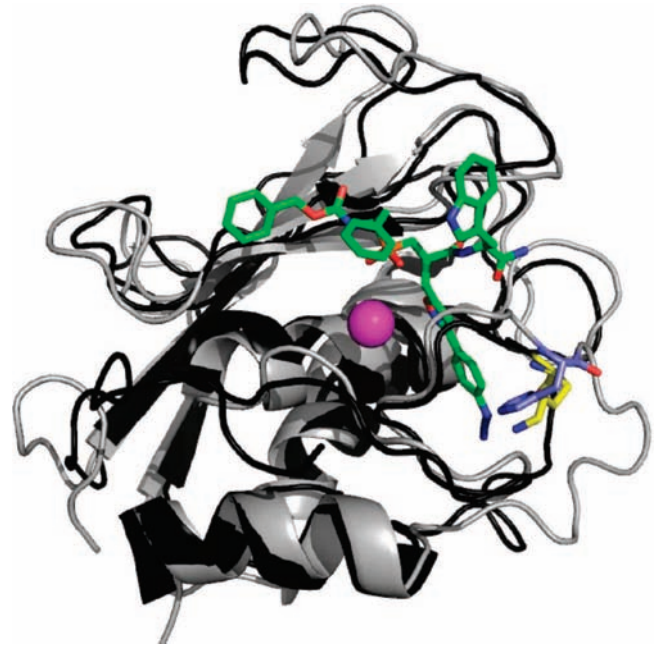

Figure 8. Superimposed model of probe **1** in complex with hMMP-12 and hMMP-3 showing the proximity between the azide group of probe **1** and the Lys^{241} and His^{241}. Ribbon plot representation of the catalytic domain of hMMP-12 (black) and hMMP-3 (gray). Lys^{241} from hMMP-12 is colored in yellow, His^{241} from hMMP-3 is blue, probe **1** in green, and catalytic zinc ion in purple.

lower yield of cross-linking observed for mMMP-12 and hMMP-9 highlights again the importance of the nucleophilicity of the residue in position 241, as the nitrogen atoms borne by the guanidinium moiety of arginine are weaker nucleophiles, as compared with the nitrogen present in the histidine and lysine residues. We previously reported that probe **1** covalently modifies MMPs, but with a very high variation in the cross-linking yield (*4*). The strict identification of the residue targeted by probe **1** in hMMP-3 and hMMP-12, plus the indirect proofs about this residue from the pH dependence observed for m-MMP-12 and hMMP-9, led us to suggest that this cross-linking yield dispersion reflects the variability of position 241 in MMPs (MMP-$8_{(Ala^{241})}$, MMP-2, 11,$13_{(Thr^{241})}$, MMP-$10_{(Asn^{241})}$, MMP-$14_{(Gln^{241})}$). The presence in these MMPs at position 241 of residues harboring weaker nucleophile atoms on their side chain, as compared with hMMP-12 and hMMP-3, explains the

lower cross-linking yield observed for these MMPs. Thus, one possibility to derive a probe displaying similar cross-linking yields toward all MMP members will be to design a new photoaffinity probe able to target conserved residues of the MMP S_1' cavity.

Analysis of hMMP-12 mutants exemplifies that the presence of a nucleophile in the side chain of residue in position 241 is mandatory, as the presence of an alanine instead a of lysine results in less than 1% cross-linking. The site of covalent modification in these mutants has not been determined directly, but the pH dependence observed for the labeling of the Arg mutant is in agreement with the proposal that probe **1** targets the Arg^{241} in this protein. Mutants with a side chain in position 241 containing weaker nucleophiles (Arg, Gln, Thr), as compared with lysine, are labeled with a lower cross-linking yield. In contrast, the observation reported for the His mutant is quiet unexpected. This result illustrates that parameters other than the soil nucleophilicity of the residue in position 241 can determine the cross-linking yield. As discussed above, the conformational properties of the residue in position 241 also play a critical role. The same arguments probably explain the differences in cross-linking yield observed among Arg241-hMMP-12, mMMP-12, and hMMP-9 at pH 13, despite the presence of the same arginine residue in these MMPs. Altogether, these results illustrate the difficulties that must be overcome in developing optimized activity-based probes incorporating photolabile groups, a strict requirement for the covalent labeling of zinc proteinases.

Probe **1** should be useful for the detection of hMMP-12 and hMMP-3 in biological fluids. At neutral pH and in buffer, the detection limit of hMMP-12 and hMMP-3 with this radioactive probe is around 2.5 fmol, a limit that can be improved by a factor two for hMMP-12 by fixing the pH at 12 before the photoactivation step. Operating at basic pH seems to be a requirement for detecting mMMP-12 and hMMP-9. At basic pH, the detection limit with probe **1** should be around 150 fmol for these MMPs, a rather good sensitivity. However, even though the results of gelatin zymography should be interpreted with great caution before drawing conclusions about the presence of active forms of MMP-9 in biological fluids (*21*), it should be kept in mind that this technique is able to detect MMP-9 with a threshold of detection of 100 amol (*22*). Actual failure in detecting active forms of MMPs by using activity-based probes has been explained by arguing that these proteases are mostly expressed as inactive zymogen forms and that most of the activated MMP fractions are blocked by endogenous inhibitors (i.e., the TIMPs) (*3*). Thus, active forms of MMPs may exist at levels that are well below the current limit of activity-based probe detection, even when using the exceptional resolution and sensitivity of multidimensional liquid chromatography coupled with mass spectroscopy. To replace gelatin zymography or to be used in proteomic profiling by mass spectroscopy, activity-based probes for detection of the MMP active form need further improvement. Our results give pointers to the development of a new generation of those probes that should be more efficient for the equivalent detection of all MMPs.

TECHNICAL NOTES

Microplate-Based Analysis of Protein−Membrane Binding Interactions via Immobilization of Whole Liposomes Containing a Biotinylated Anchor

Department of Chemistry, the University of Tennessee, Knoxville, Tennessee 37996. Received September 29, 2008; Revised Manuscript Received November 20, 2008

Cellular membranes play key roles in the regulation of a range of important biological processes. However, the characterization of membrane involvement in these events is difficult to achieve due to the complexity of the membrane bilayer and the challenges associated with handling and analyzing these systems. As such, rapid and reliable approaches for characterizing membrane-based processes are necessary. To address this issue, we have first developed an azide-tagged modular lipid anchor scaffold (**2**) that can be conveniently derivatized via click chemistry to functionalize the membrane surface. This was used to access biotin− and fluorescein−lipid conjugates **1a** and **1b**, respectively. These compounds were then employed to perform and characterize the immobilization of liposomes containing biotin-anchor **1a** onto streptavidin-coated microplates. Results from these studies indicated clean, biotin-dependent surface deposition. This strategy for liposome attachment was then applied to a microplate-based platform to detect the binding of receptor proteins to immobilized liposomes, specifically for the membrane binding of protein kinase Cα (PKCα). The resulting data indicated direct detection of binding to the membrane-functionalized surface. The reported approaches provide efficient methods for the derivatization of the membrane surface, which is applicable to the study of membrane-based processes. Finally, the described microplate-based liposome binding assay allows for high-throughput analysis of important protein-membrane binding events.

INTRODUCTION

Cellular membranes play vital and diverse roles in numerous intra- and extracellular molecular recognition events that correlate to important biological processes. The membrane context provides an environment in which binding interactions occurring between combinations of membrane-associated and solubilized proteins, peptides, lipids, carbohydrates, and other species control a wide range of physiological and pathophysiological events. Membrane-based binding interactions can directly modulate biomolecule function or exert indirect control, such as through the convergence of binding partners on the membrane surface resulting in subsequent pathway activation. In addition, the presentation of ligands on the membrane surface controls receptor binding affinity, as with the affect of ligand density on multivalent binding interactions (*1, 2*). Due to the prominence of membrane recognition in biological processes, it is necessary to characterize the details of these associations at the molecular level in order to fully understand roles in cellular signaling pathways. However, investigation of these interactions is complicated by several issues, including the inherent complexity of membranes due to their heterogeneous nature as well as the diverse mechanisms by which proteins interact with membrane surfaces.

In certain cases, lipids embedded in the bilayer act as site-specific ligands that recruit solubilized receptors to the membrane surface via association. This is the case with signaling lipids including diacylglycerol (DAG) (*3, 4*), phosphatidic acid (PA) (*5, 6*), and the phosphatidylinositol phosphates (PIP_ns) (*7*−*11*), which are present in low percentages in cell membranes and are tightly regulated both spacially and temporally. These ligands become up-regulated during distinct processes, which results in protein recognition that often involves the trafficking of receptors to distinct subcellular locations (*3, 4, 12, 13*). In such cases, receptors often contain a conserved binding module that interacts with the target lipid.

A particularly well studied receptor family is the protein kinase Cs (PKCs), consisting of at least eleven isozymes. PKCs represent multivalent receptors in which the binding domains (one C2 and two C1 modules) exhibit different lipid specificities among the isozymes. PKC isozymes are categorized by lipid-binding properties into conventional (calcium, DAG, and phospholipid dependent), novel (calcium independent, but DAG and phospholipid dependent) and atypical (calcium and DAG independent) subgroups (*3, 4, 14*−*16*). However, complex variations in lipid specificities and affinities are known to exist, even within the same subgroup, and are believed to control subcellular localization. PKCs have been directly implicated in tumorigenesis (*17*−*19*), and compounds that compete for PKC binding, such as the bryostatins (*20*), show promise as cancer therapeutics. However, the exact links between PKC activity and carcinogenesis have not been discerned, which is primarily a result of the difficulty in elucidating the specific activities and localizations of the different isozymes (*18*).

In addition to the actions of lipids as site-specific ligands, numerous other mechanisms exist by which proteins interact with cellular membranes. In many cases, the membrane provides the scaffold for the presentation of cell surface ligands including carbohydrates and peptides, such as with the interaction of GM1 with pentavalent toxins (*21*). Another motif involves the

membrane association of proteins through the insertion of hydrophobic moieties. For example, certain proteins contain post-translationally appended lipid tails that regulate membrane anchoring and subcellular localization. A prominent example involves the Ras GTPases, critical proto-oncogenes for which the cycling between the Golgi apparatus and plasma membrane is directly controlled by the extent of lipidation (*22*−*24*). This acts as a switch that controls Ras trafficking and its critical signaling activities. Receptors also interact with the membrane through the insertion of hydrophobic peptide sequences. For instance, following initial binding of the influenza virus to sialic acid on the cell surface via hemagglutinin (HA), HA then inserts a hydrophobic sequence that results in membrane fusion and viral entry (*25*). Finally, antibacterial peptides such as gramicidin act by inserting into the bacterial cell wall and increasing permeability (*26, 27*).

The challenges associated with the study of protein−membrane binding events have provided a significant barrier to understanding interactions at the molecular level. While assays based on isothermal titration calorimetry (ITC), dye leakage, membrane penetration, and surface plasmon resonance (SPR) have proven effective (*28*), these studies would benefit from an accessible high-throughput method that would allow for efficient analysis on a grand scale. Recently, a solution-phase turbidity assay was reported for detecting associations of lipid-binding domains with liposomes (*29*). While this approach is effective for high-throughput analysis, potential drawbacks include that the receptor being analyzed must be tagged, the assay relies on absorbance measurements, which generally limits sensitivity, and the fact that the receptor is dimerized for detection purposes, which may not accurately mimic the recognition event in the physiological process. For these reasons, we sought to develop a novel assay for high-throughput detection of protein−liposome binding interactions.

Microarray surface analysis offers a beneficial strategy for characterizing receptor−ligand binding interactions that has been exploited for the study of DNA (*30, 31*), protein and peptide (*32*−*34*), carbohydrate (*35*−*43*), and, to a lesser extent, lipid (*44, 45*) binding interactions. Membrane-based microarray analysis has been performed by depositing membrane bilayers onto surfaces, which has primarily been employed to study integral membrane proteins (*46, 47*). Advantages of the microarray approach include that high-throughput analysis can be performed, that miniaturization allows for the use of minute quantities of recognition components and that optical detection yields facile and accessible analysis. Herein, we report the microplate-based detection of protein−membrane binding interactions through whole liposome immobilization toward the development of a high-throughput liposome-based microarray platform.

EXPERIMENTAL PROCEDURES

General. All reagents were purchased from Acros or Aldrich and used as received. Dry solvents were obtained from a Pure Solv solvent delivery system purchased from Innovative Technology, Inc. Column chromatography was performed using 230−400 mesh silica gel purchased from Sorbent Technologies. NMR spectra were obtained using a Bruker AC250 spectrometer updated with a TecMag data collection system, a Varian Mercury 300 spectrometer, or a Bruker Avance 400 spectrometer. Mass spectra were obtained with JEOL DART-AccuTOF and ABI Voyager DE Pro MALDI spectrometers. Optical rotation values were obtained using a Perkin-Elmer 241 polarimeter. HPLC data was obtained using an HP series 1100 HPLC with an Alltech Lichrosphere SI 60 5U column with HPLC-grade solvents purchased from Fisher. L-α-Phosphatidylcholine (PC) and L-α-phosphatidylserine (PS) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Liposome extruder and polycarbonate membranes were obtained from Avestin (Ottawa, Canada). Microplate-based fluorescence measurements were performed using a BioTek Synergy 2 multidetection microplate reader. Clear, white and black reacti-bind streptavidin high binding capacity (HBC) coated 96-well microplates were purchased from Pierce Biotechnology (Rockford, IL). PKCα and rabbit anti-PKCα antibody were purchased from Calbiochem (San Diego, CA). Goat antirabbit igG HRP-conjugate was purchased from Chemicon International (Temecula, CA). Supersignal ELISA femto maximum sensitivity substrate was purchased from Pierce Biotechnology (Rockford, IL). All plots represent the average of at least 3 experiments with error bars included ± the standard error for each set of measurements.

(*R*)-(2,2-Dimethyl-1,3-dioxolan-4-yl)methyl 4-methylbenzenesulfonate (4). (*S*)-(2,2-Dimethyl-1,3-dioxolan-4-yl)methanol (**3**, 1 mL, 8.1 mmol), 4-(*N*,*N*-dimethylamino)pyridine (DMAP, 989 mg, 8.1 mmol), *p*-toluenesulfonyl chloride (2.28 g, 16.2 mmol), and triethylamine (2.25 mL, 16.2 mmol) were suspended in 90 mL of DMF in a round-bottomed flask. The reaction was allowed to stir at room temperature overnight, followed by solvent removal via rotary evaporation. Next, the crude was extracted with methylene chloride (3 × 50 mL) from 50 mL of 1 M HCl. The combined extracts were then dried with magnesium sulfate, filtered, and the solvent was removed under reduced pressure. The product was then purified by column chromatography over silica gel with gradient elution from 10−30% ethyl acetate/hexanes to yield **4** as a yellow oil (2.20 g, 95%). Characterizations matched previous reports (*48*).

(*S*)-4-(Azidomethyl)-2,2-dimethyl-1,3-dioxolane (5). (*R*)-(2,2-Dimethyl-1,3-dioxolan-4-yl)methyl-4-methylbenzenesulfonate (**4**, 2.03 g, 7.1 mmol) and sodium azide (1.27 g, 19.5 mmol) were suspended in a solution of DMF. The reaction was immersed in an oil bath and heated to 80 °C overnight. Next, the reaction was brought to 0 °C with an ice bath and was quenched with saturated sodium bicarbonate solution (50 mL). The mixture was extracted with diethyl ether (2 × 50 mL), and the combined extracts were then washed twice with water (50 mL). Next, the organic layer was dried with magnesium sulfate and filtered. The solvent was then removed by rotovary evaporation without heat to avoid evaporation of the volatile product, which was obtained as a yellow oil (800 mg, 72%). Characterizations matched previous reports (*49*) Note: Care must be taken when working with sodium azide and low molecular weight organic azides such as **5** due to their explosive properties (*50*).

(*S*)-3-Azidopropane-1,2-diol (6). (*S*)-4-(Azidomethyl)-2,2-dimethyl-1,3-dioxolane (**5**, 1.26 g, 8.02 mmol) and *p*-toluenesulfonic acid (76 mg, 4 mmol) were suspended in 90 mL of methanol. The reaction was allowed to stir at room temperature overnight and was then quenched by adding solid sodium bicarbonate, followed by stirring for an additional 20 min. The solvent was removed by rotary evaporation and column chromatography with a solvent gradient of 50−100% ethyl acetate/hexanes, was used to further purify the compound, which was obtained as a yellow oil (744 mg, 79%). Characterizations matched previous reports (*49*).

(*S*)-3-Azidopropane-1,2-diyl distearate (2). (*S*)-3-Azidopropane-1,2-diol (**6**, 340 mg, 2.95 mmol), *N*,*N*′-dicyclohexylcarbodiimide (DCC, 2.15 g, 10.4 mmol), 4-dimethylaminopyridine (1.27 g, 10.4 mmol), and stearic acid (2.97 g, 10.4 mmol) were suspended in 30 mL of methylene chloride in a round-bottomed flask. The reaction was allowed to stir at room temperature overnight and was then filtered through a pad of celite. The product was purified by column chromatography with a solvent gradient of 100% hexanes − 20% ethyl acetate/hexanes to yield **2** as a white solid (1.9 g, 100%).

$[\alpha]_D$ ^{296K} 0.667 (c = 1.5, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$): δ 5.29 (m, 1H), 4.30 (dd, J_1 = 12 Hz, J_2 = 4.5 Hz, 1H), 4.14 (dd, J_1 = 12 Hz, J_2 = 5.4 Hz, 1H), 3.45 (m, 2H), 2.33 (m, 4H), 1.62 (m, 4H), 1.26 (m, 56H), 0.88 (t, J = 6.6 Hz, 6H). ^{13}C NMR (62.9 MHz, $CDCl_3$): δ 173.08, 172.73, 69.97, 62.33, 50.92, 34.20, 34.05, 32.03, 29.82, 29.78, 29.72, 29.66, 29.58, 29.48, 29,37, 29.20, 29.15, 24.93, 24.88, 22.78, 14.16. HRMS $[M + Na]^+$ calcd 672.5650, found 672.5667.

(2*S*)-3-(4-(3,18-Dioxo-22-(2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl)-5,8,11,14-tetraoxa-2,17-diazadocosyl)-1*H*-1,2,3-triazol-1-yl)propane-1,2-diyl distearate (1a). (*S*)-3-Azidopropane-1,2-diyl distearate (**2**, 25 mg, 38.9 μmol) and biotin-TEG-alkyne (**7a**, 20 mg, 38.9 μmol) were suspended in 1 mL of THF. Copper iodide (7.4 mg, 38.9 μmol) and *N*,*N*-diisopropylethylamine (13 μL, 77.8 μmol) were added, and the resulting solution was allowed to stir at room temperature for 18 h. Next, the solvent was removed, and the product was purified by a short column using 12 g silica gel with a solvent gradient of 2−15% methanol/dichloromethane to obtain **1a** as a white solid (20 mg, 44%).

$[\alpha]_D^{296K}$ 12.53 (c = 1.5, $CHCl_3$). ^{1}H NMR (300 MHz, $CD_3OD/CDCl_3$): δ 7.63 (s, 1H), 5.43 (m, 1H), 4.66 (m, 1H), 4.54 (m, 1H), 4.39 (m, 6H), 4.05 (m, 2H), 3.68 (m, 12H), 3.56 (m, 2H), 3.40 (m, 3H), 2.94 (d, J = 4.8 Hz, 1H), 2.78 (m, 1H), 2.29 (m, 6H), 1.64 (m, 8H), 1.27 (m, 58H), 0.88 (m, 6H). MALDI-HRMS $[M + Na]^+$ calcd 1186.8111, found 1186.8082.

(*S*)-5(6)-((1-(2,3-Bis(stearoyloxy)propyl)-1*H*-1,2,3-triazol-4-yl)methylcarbamoyl)-2-(6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoic acid (1b). (*S*)-3-Azidopropane-1,2-diyl distearate (**2**, 58.6 mg, 0.0901 mmol) and 2-oxo-*N*-(prop-2-ynyl)-5(6)-carboxyfluoresceinamide (**7b**, 37.2 mg, 0.0901 mmol) (*51*) were dissolved in 1:1 tetrahydrofuran/water (2 mL). Copper sulfate pentahydrate (28.8 mg, 0.115 mmol) and sodium ascorbate (35.7 mg, 0.180 mmol) were added. The reaction was stirred at room temperature in the dark overnight, at which point the solvent was removed under reduced pressure. Column chromatography with a gradient solvent system of 10−20% methanol/dichloromethane afforded **1b** as a yellow solid (65.3 mg, 68%). Note: since both fluorescein isomers (5 and 6-carboxy) were present in the ^{1}H NMR spectrum for compound **1b**, and the ratio of each isomer is unknown in the commercially available acid, integration values are not reported. ^{13}C NMR data for compound **1b** are not reported due to poor solubility of the compounds and the complex nature of the spectra due to the isomeric mixture.

$[\alpha]_D^{296K}$ 0.8 (c = 1.5, $CHCl_3$). ^{1}H NMR (300 MHz, $CD_3OD/CDCl_3$): δ 8.82 (bs), 8.41−8.29 (m), 7.99−7.87 (m), 7.42−7.26 (m), 7.12 (bs), 6.88−6.55 (m), 5.43 (bs), 4.74−4.58 (m), 4.38−4.30 (m), 4.11−4.08 (m), 3.72−3.67 (m), 2.40−2.27 (m), 1.64−1.59 (m), 1.26 (bs), 0.88 (t, J = 6.5 Hz). MALDI-HRMS $[M + H]^+$ calcd 1063.6730, found 1063.6699.

General Procedure for Liposome Preparation. Solid lipids were dissolved in chloroform to a particular concentration, and a specific amount of each lipid in solution was added to a small glass container. The chloroform was removed under a constant stream of nitrogen, and the resulting lipid film was dried under vacuum overnight. The appropriate volume of buffer (20 mM HEPES, pH 7.4, for studies not involving PKC or 100 mM NaCl, 20 mM HEPES, 1 mM $CaCl_2$, pH 7.4, for studies involving PKC) was added to the dried lipids in order to produce a specific concentration of liposomes after hydration and size reduction. The suspension of lipid and buffer was agitated at 40 °C for 40 min and then subjected to 10 freeze−thaw cycles. Vesicles were prepared by extrusion (19 times) through a 200 nm polycarbonate membrane to control liposome size.

Microplate Liposome Immobilization Experiments. Analysis of liposome microplate immobilization was performed using either clear or black streptavidin-coated microplates. A solution of 20 mM HEPES buffer pH 7.4 was employed as the wash buffer. First, the wells that were to be used for analysis were incubated with 200 μL of wash buffer for 30 min. This was removed, followed by introduction of 100 μL of the various liposome compositions at different concentrations. For the initial fluorescence immobilization study (Figure 1), liposomes containing 98% PC, 1% **1a**, and 1% **1b** were analyzed alongside a control with 99% PC, 0% **1a**, and 1% **1b**. To determine the optimal percentage of biotin for liposome surface attachment (Figure 3), studies utilized different liposome samples containing **1b** fixed at 1%, varying percentages of **1a** (0−2%), and the rest of the liposome was made up of PC (98−100%). After a

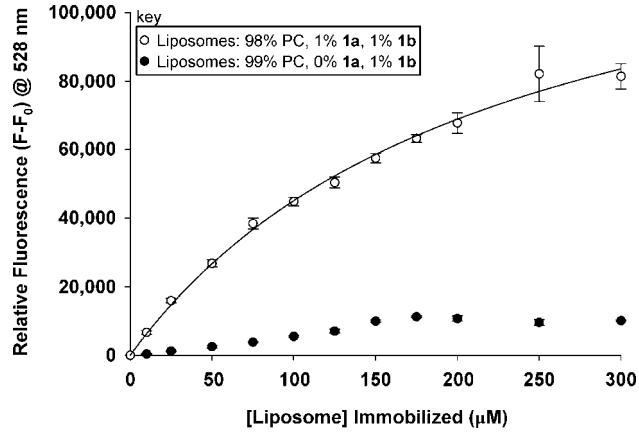

Figure 1. Microplate immobilization studies using functionalized liposomes. Liposomes containing both biotin anchor **1a** and fluorescein anchor **1b** were compared to control liposomes lacking biotin anchor **1a**.

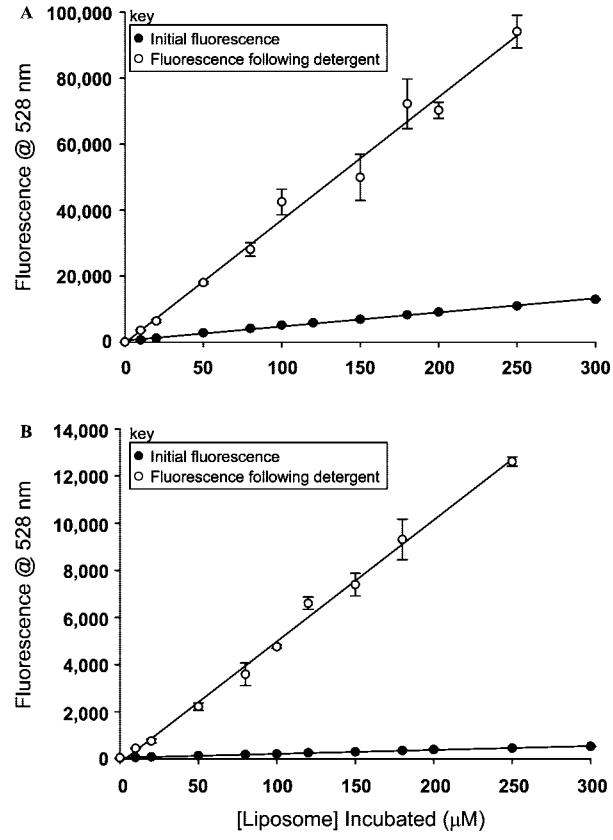

Figure 2. Dye leakage assays performed to rule out vesicle disruption on the microplate surface. Fluorescence before and after treatment of immobilized liposomes with detergent was measured both without (A) and with (B) a prior wash to remove unbound species.

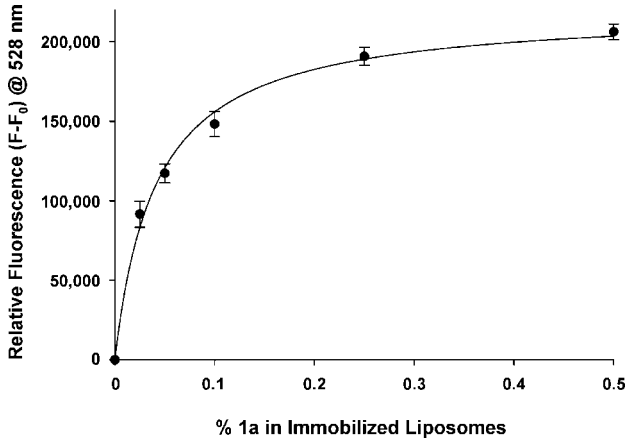

Figure 3. Immobilization of liposomes containing varying percentages of biotin anchor **1a** indicates that a low percentage (~0.25−0.5%) is effective for optimal microplate derivatization with liposomes.

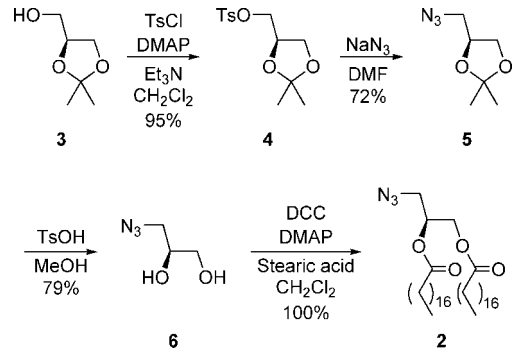
1 h incubation, these solutions were removed and the wells were washed with 3 × 250 μL wash buffer. The microplate was then analyzed for fluorescence using a microplate reader with excitation using a 460 nm (±40 nm) filter and emission detected with a 528 nm (±20 nm) filter.

Procedure for Immobilized Vesicle Leakage Assay. Liposomes encapsulated with 5(6)-carboxyfluorescein (CBF) were prepared following a procedure similar to those previously reported (*52*). A solution of PC (99%) and biotin anchor **1a** (1%) in chloroform was dried under vacuum 4 h. The lipids were rehydrated with CBF buffer (50 mM CBF, 20 mM HEPES, 150 mM NaCl, pH = 7.4) according to the general procedure cited above to give a final concentration of 5 mM liposomes. Vesicles were prepared by extrusion (19 times) through a 200 nm polycarbonate membrane. Unencapsulated dye was removed using a Sephadex G-50 column equilibrated with buffer (20 mM HEPES, 150 mM NaCl, pH = 7.4). Fractions containing liposomes were determined by measuring the fluorescence (excitation λ = 490 nm) followed by the addition of 20 μL of 20% Triton X-100 to release the encapsulated CBF. Analysis of liposome microplate immobilization was performed using black streptavidin-coated microplates. Wells that were to be used for analysis were incubated with 200 μL of wash buffer (20 mM HEPES, 150 mM NaCl, pH = 7.4) for 30 min. This was removed, followed by introduction of 100 μL of liposomes at various concentrations prepared from the combined fractions after SEC chromatography. Incubation was carried out for 1 h. Following incubation, subsequent analysis was performed both with (Figure 2B) and without (Figure 2A) microplate washing (3 × 250 μL buffer) to remove unbound liposomes. In both cases, the microplate was initially analyzed for fluorescence using a microplate reader with excitation using a 460 nm (±40 nm) filter and emission detected with a 528 nm (±20 nm) filter. At this point, 30 μL of a 20% Triton X-100 solution was added to lyse the vesicles, which was followed by a repeat of the previous fluorescence measurement. Subsequent addition of detergent did not lead to a further increase in fluorescence, indicating that all liposomes had been lysed.

Microplate Analysis of Whole Liposome-PKCα Binding. Microplate protein-binding experiments were performed using white streptavidin-coated 96-well microplates. The wash buffer that was used was 20 mM HEPES buffer pH 7.4 with 100 mM sodium chloride and 1 mM calcium chloride for PKC activation. First, the wells that were to be used for analysis were washed with 200 μL of wash buffer for 30 min. This was removed, followed by introduction of different concentrations of liposomes (100 μL of solutions ranging from 0 to 200 μM in wash buffer)

Scheme 1. Synthetic Route to Modular Anchor Scaffold 2



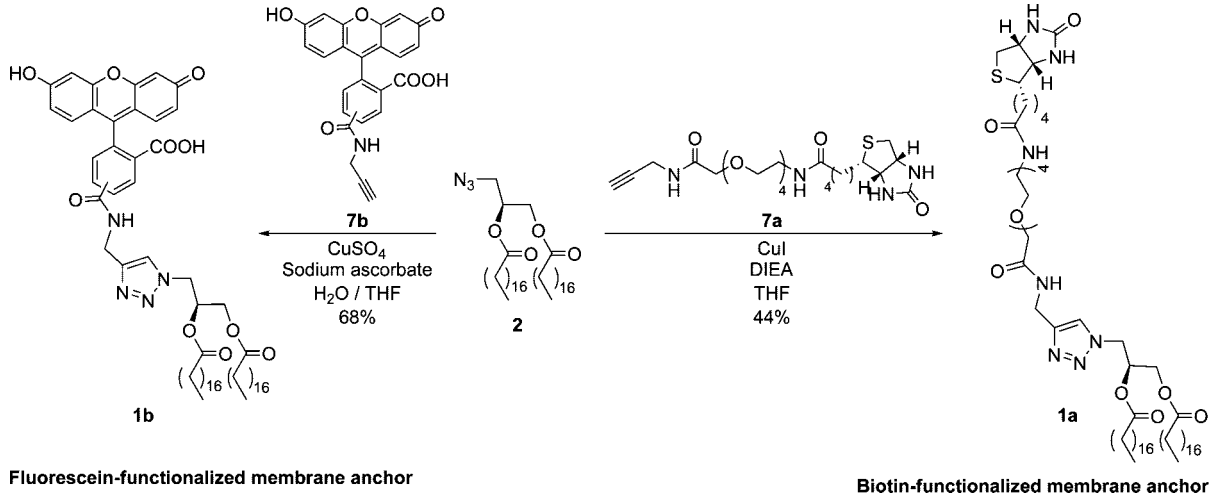
and then incubation for 1 h. Next, these solutions were removed, and the wells were washed with 3 × 250 μL wash buffer. Following this, 200 μL of a 100 ng/mL solution of PKCα in wash buffer was added to each well, followed by a 1 h incubation. At this point, the protein solution was removed, and the wells were washed with 3 × 250 μL wash buffer. Next, 200 μL of a 100 ng/mL solution of rabbit anti-PKCα antibody was added to each well and allowed to incubate for 1 h. This solution was then removed, and the wells were washed with 3 × 250 μL wash buffer. Finally, wells were incubated with goat antirabbit IgG HRP−conjugate for 1 h and then washed with 3 × 250 μL wash buffer and 1 × 100 μL water. Chemiluminescence detection of bound antibody was next performed using supersignal ELISA femto maximum sensitivity substrate. Here, a 1:1 mixture of the substrate and peroxide solutions were mixed, and 100 μL of the resulting solution was added to each well. The microplate was then immediately placed in the microplate reader, and the luminescence at 425 nm was repeatedly measured for ~5 min. Assays were run numerous times, both simultaneously and on separate occasions using newly formed solutions. The chemiluminescence data was then plotted vs the original incubation concentrations using *SigmaPlot* to curve fit the data (nonlinear regression using the Langmuir binding isotherm).

RESULTS AND DISCUSSION

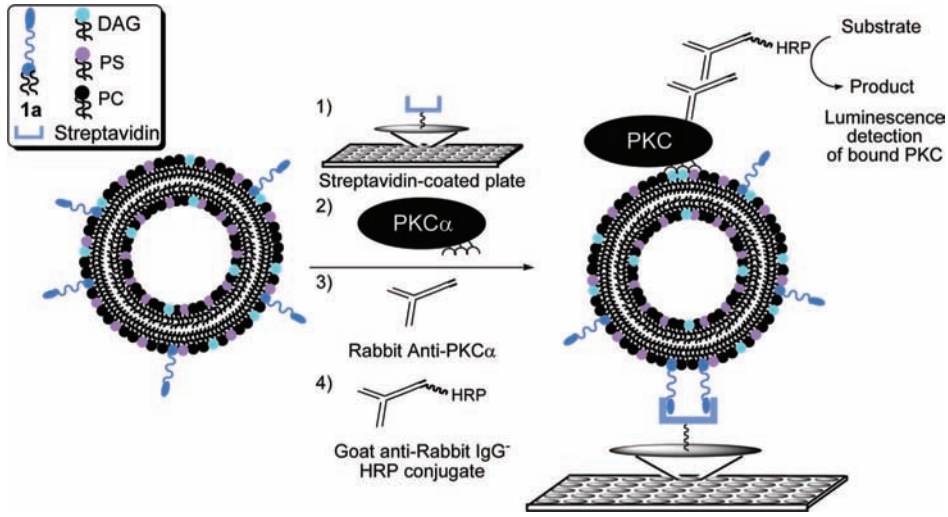
The development of a microplate-based method for detecting protein−membrane binding initially requires successful immobilization of whole liposomes. For this pursuit, one must take into account issues associated with studying unilamelar liposomes, as they are known to degrade within a few days after formation and to fuse and unravel when they come in contact with certain surfaces (*53*). The former problem renders a high-throughput method for analysis particularly beneficial, as this would allow for a large number of binding studies to be performed in a short period of time prior to liposome degradation. The latter situation requires that one take care to ensure that the bilayers are not modified during the course of study. In this regard, literature precedent has shown that the immobilization of whole liposomes onto streptavidin-coated surfaces via the avidin−biotin interaction is particularly effective for avoiding decomposition of the liposomes (*53*−*57*).

The immobilization of whole liposomes has generally been achieved through the inclusion of a biotin-presenting anchor within the membrane bilayer. Previously, with a few exceptions (*58*,*59*), functionalized membrane anchors have generally been accessed through modification of the amino group of phosphatidylethanolamine (PE). However, this is not an economical or facile approach, as it employs a phospholipid as a synthetic precursor. Thus, we initially set out to develop a more cost-effective alternative that would allow for convenient and modular functionalization of a lipid anchor. Toward this end, we designed versatile azido−lipid anchor scaffold **2** (Schemes 1 and 2),

Scheme 2. Convenient Derivatization of Scaffold 2 to Obtain Membrane Anchors of Use for Functionalizing Liposomal Surfaces



Scheme 3. Microplate-Based Assay for Rapid Characterization of Protein−Membrane Binding Interactions



which can be easily functionalized via the azide−alkyne cycloaddition reaction (click chemistry) (*60*−*62*) to produce a range of derivatized membrane anchors in a single synthetic step.

The synthetic route to azide-tagged lipid anchor **2**, illustrated in Scheme 1, commences with commercial (S)-(+)-2,2-dimethyl-dioxolane-4-methanol (**3**). This enantiomerically pure precursor, containing stereochemistry that corresponds to that of a natural phospholipid, was used in case the stereochemistry of the anchor affected presentation in the membrane setting. Precursor **3** was converted to compound **5** via a procedure modified from that described by Martin and co-workers (*49*). First, a toluenesulfonyl (tosyl) leaving group was introduced onto the hydroxyl group of **3** to **4**, followed by substitution with azide to **5**. Care must be taken with the handling of compound **5** due to both its volatile nature as well as the fact that it is a low-molecular-weight azide, and these are known to have explosive properties (*50*). Next, the acetonide group of **5** was removed to provide diol **6**, to which stearyl chains were then appended to access azido-anchor **2**. Modular azido-anchor **2** was then conveniently derivatized to allow for subsequent presentation of desired reporters and tags on the membrane surface (Scheme 2). The first target, biotin-conjugate **1a**, was pursued in order to achieve whole liposome immobilization. Here, a tetraethylene glycol (TEG)-based tether was implemented between the biotin and lipid components to provide effective spacing of the liposomes from the microplate surface following immobilization. Fluorophore-tagged anchor **1b** (fluorescein) was also synthesized to allow for the detection of functionalized liposomes during studies.

Following the development of these compounds for efficient membrane functionalization, we moved on to study the efficacy of whole liposome immobilization using anchor **1a**. Here, unilamellar liposomes were formed using standard conditions, including the control of liposome size (200 nm), which was achieved using extrusion. The resulting samples were analyzed by dynamic light scattering (DLS) to ensure narrow polydispersity. Initial liposomes contained 98% phosphatidylcholine (PC) as the bulk lipid as well as 1% each of biotin-anchor **1a** and fluorescein−lipid conjugate **1b** (sample A). Control solutions with 99% PC and 1% **1b**, but lacking **1a** (sample B), were also implemented. Both sets of liposomes were incubated with streptavidin-coated 96-well microplates, washed thoroughly, and the fluorescence resulting from the presence of the fluorescein tag was detected using a microplate reader. As shown in Figure 1, sample A yielded an increase in fluorescence with liposome concentration. For control sample B, a small amount of nonspecific background was observed for the nonbiotinylated liposomes. Taken together, these studies indicate that biotin-dependent immobilization of whole liposomes was achieved using convenient anchor **1a**.

To provide further evidence that immobilized liposomes remain intact on the microplate surface using this approach, a traditional dye-leakage vesicle cleavage experiment was per-

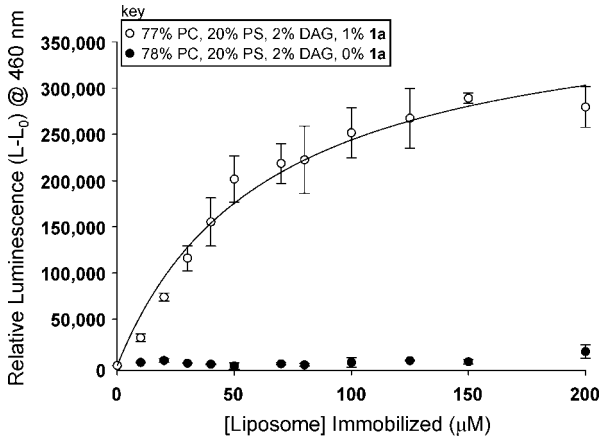


Figure 4. Results from microplate-based analysis of the binding of PKCα to immobilized whole liposomes.

formed (*52*). Here, while fluorescein emission is quenched when the dye is encapsulated within a liposomal interior, fluorescence is activated when the liposome is cleaved and the dye is released into solution. In the current study, PC liposomes containing 1% of biotin anchor **1a** were loaded with fluorescein and incubated at different concentrations for 1 h to immobilize. Initially, the microplate was not washed to remove unbound species. Following an initial fluorescence measurement (Figure 2A), the surface was treated with detergent, which led to a large increase in fluorescein emission, indicating detergent-based cleavage of intact immobilized liposomes. In a complementary experiment, the microplate surface was thoroughly washed after liposome immobilization, emission was detected, and then detergent addition was followed by another fluorescence measurement. In this case, the initial measurement yielded very low background fluorescence (Figure 2B), and the signal was once again greatly enhanced upon treatment with detergent. These studies indicate successful microplate-immobilization of intact liposomes, which were only cleaved upon traditional detergent treatment.

In a subsequent study, we sought to determine the percentage of biotin-anchor **1a** in the liposomes that is required to maximize loading onto the plate. Here, PC-based liposomes containing a variable percentage of **1a** (from 0% to 2%) and a fixed amount of fluorescein-conjugate **1b** (1%) were incubated with the plate, which was then washed and detected. The resulting emission signal was found to increase up to ~0.25−0.5% of anchor **1b**, at which point the signal reached a plateau (Figure 3). These results indicate that relatively small percentages of **1b** are effective for saturating the microplate surface with liposomes.

Following successful characterization of liposome immobilization, we moved on to the detection of protein−membrane binding interactions utilizing the microplate surface. As a proof-of-concept, we pursued the detection of the membrane-binding of PKCα. This PKC isozyme contains two C1 domains that target DAG and a calcium-dependent C1-domain that binds PS. Liposomes similar to those previously reported to be optimal for PKC-binding (*63*−*65*), which included 1% **1a**, 2% DAG, 20% PS, and 77% PC, were employed for studies. The resulting liposome formulations were analyzed via a microplate-based secondary antibody assay as depicted in Scheme 3. Here, liposome solutions of varying concentration were introduced into different wells of 96-well streptavidin-coated microplates for immobilization. This was followed by incubation with PKCα, rabbit anti-PKCα primary antibody, and finally goat antirabbit IgG horseradish peroxidase (HRP)-conjugate as a secondary antibody. Thorough buffer washes were performed after each step to remove unbound species. Finally, the secondary antibody was detected via a chemiluminescence assay catalyzed by the pendant HRP to indicate the amount of bound PKCα in each well. Results, exemplified in Figure 4, showed a typical binding isotherm for the interaction of PKCα with the immobilized liposomes. Figure 4 also indicates results from analysis using control liposomes lacking biotin anchor **1a**, which indicate the low background associated with the assay.

These results indicate the viability of whole liposome immobilization for the direct characterization of protein-membrane binding events. This assay exhibits a number of advantages over previous strategies, including that the target protein does not need to be labeled or modified, effectively mimicking the physiological system, and that chemiluminescence-based signal transduction allows for highly sensitive detection. We are currently working to advance this platform to extend the ability to detect and characterize membrane-based recognition. For instance, the large-scale immobilization of liposomes containing different lipid compositions is being pursued toward the development of a high-throughput microarray assay. In addition, a range of other membrane processes such as membrane fusion (*66*) and disruption (*27*) could also benefit from techniques involving liposome-functionalized surfaces. This approach is also not limited to the study of protein−lipid binding, but could be extended to directly characterize the binding of other ligands, such as peptides and carbohydrates. These ligands could be conveniently lipidated using azido-anchor **2** and incorporated into membrane bilayers, allowing for binding analysis in a fluid multivalent environment that mimics ligand presentation in cellular membranes. In these ways, the described liposomal microplate assay provides an excellent tool for elucidating membrane-based biological processes.

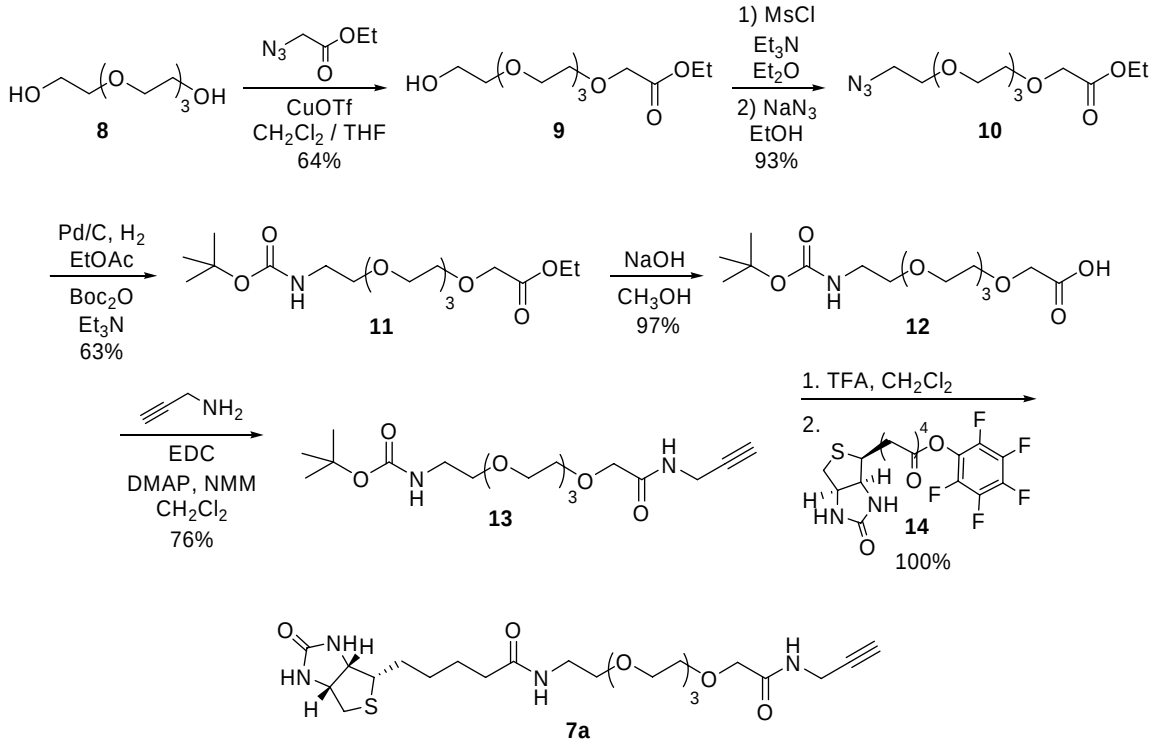
Supporting Information

Synthesis of biotin-TEG-alkyne linker 7a. Biotinylated TEG linker **7a** was synthesized from tetraethyleneglycol (**8**) as shown in Supporting Information Figure 1. First, *N*-Boc and ethyl ester-protected glycol derivative **11** was accessed in four steps using a procedure similar to that described by Lehn and co-workers*(1)*. This compound has also been synthesized with reversed order of addition of the ethyl ester and amino-functionalities*(2)*. Here, an ethylacetyl group is first appended onto **8** to **9**, followed by conversion to azide **10** via mesylation and azide substitution. Next, reduction of the azide group was performed with trapping of the resulting amine with a Boc group to **11**. The ethyl ester of **11** was then deprotected to **12**, followed coupling of the resulting carboxyl group with propargylamine to **13**. Finally, Boc deprotection was followed by direct coupling of the resulting amine with biotin-pentafluorophenyl ester (**14**) to produce biotin-TEG-alkyne conjugate **7a**.



Supporting Information Figure 1. Synthesis of biotin-TEG-alkyne linker **7a**.

Ethyl 14-hydroxy-3,6,9,12-tetraoxatetradecanoate (9). In a 3-neck round bottom flask equipped with a bubbler, tetraethylene glycol (**8**, 43.2 mL, 250 mmol) was dissolved in anhydrous dichloromethane. Copper triflate (904.2 mg, 2.5 mmol) was added along with anhydrous tetrahydrofuran (7 mL). The solution was cooled to 0 °C and placed under a constant stream of nitrogen. Ethyl diazoacetate (5.3 mL, 50 mmol) was dissolved in anhydrous dichloromethane (34 mL) and added dropwise to the stirring solution. The solution was allowed to gradually warm to room temperature and stirring was continued overnight. The reaction was extracted with saturated NaCl and then washed with dichloromethane (100 mL). The combined organic layers were combined and dried with magnesium sulfate and filtered, and the solvent was removed under reduced pressure. Column chromatography with silica gel and a gradient solvent system of 0 - 10 % methanol/ethyl acetate afforded **9** as a yellow oil (8.9 g, 64%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 4.20 (q, *J* = 7.2 Hz, 2H), 4.15 (s, 2H), 3.73-3.54 (m, 16H), 1.27 (t, *J* = 7.2 Hz, 3H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 170.4, 72.6, 70.7, 70.54, 70.52, 70.44, 70.43, 70.2, 68.5, 61.4, 60.6, 14.2; HRMS $[M + H]^+$ cacld: 281.16003, found: 281.15895

Ethyl 14-azido-3,6,9,12-tetraoxatetradecanoate (10). Ethyl 14-hydroxy-3,6,9,12-tetraoxatetradecanoate (**9**, 1.02 g, 3.64 mmol) and triethylamine (1.5 mL, 10.92 mmol) were dissolved in anhydrous diethyl ether (7 mL) at 0 °C under a nitrogen atmosphere. Methanesulfonyl chloride (285 µL, 3.68 mmol) was added dropwise with stirring. Once the addition was complete the solution was allowed to gradually return to room temperature. Stirring was continued for a total of 1 h. At this point solvent was removed under reduced pressure. The residue was dissolved in anhydrous ethanol (10 mL) and sodium azide (239 mg, 3.68 mmol) was added. The reaction was stirred at reflux overnight. The reaction was extracted with dichloromethane (2 x 100 mL) and the organic layer was dried with magnesium sulfate, filtered and the solvent was removed under reduced pressure to yield pure **10** as a yellow oil (1.04 g, 93%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 4.22 (q, *J* = 7.2 Hz, 2H), 4.15 (s, 2H), 3.73-3.67 (m, 14H), 3.40 (t, *J* = 4.8 Hz, 2H), 1.28 (t, *J* = 7.2 Hz, 3H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 170.4, 70.8, 70.65, 70.62, 70.57, 70.0, 68.7, 60.8, 50.6, 14.2; HRMS $[M - N_2 + H]^+$ cacld: 278.16036, found: 278.16152

Ethyl 14-*tert*-butoxycarbonylamino-3,6,9,12-tetraoxatetradecanoate (11). Ethyl 14-azido-3,6,9,12-tetraoxatetradecanoate (**10**, 1.08 g, 3.55mmol) was dissolved in ethyl acetate. Di-tert-butyl dicarbonate (1.55 g, 7.1 mmol), triethyl amine (990 µL, 7.1 mmol) and Palladium on carbon (110 mg) were added with stirring. The flask was evacuated and refilled with hydrogen three times and stirred at room temperature overnight. The reaction mixture was filtered through a pad of celite and the solvent was removed under reduced pressure. Column chromatography with silica gel and and a gradient solvent of 5 : 1 - 2 : 1 chloroform/acetone with 0.1% triethylamine afforded **10** as a yellow oil (853 mg, 63%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 5.10 (bs, 1H), 4.22 (q, *J* = 7.2 Hz, 2H), 4.16 (s, 2H), 3.73-3.53 (m, 14H), 3.34-3.31 (m, 2H), 1.44 (s, 9H), 1.29 (t, *J* = 7.2 Hz, 3H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 170.5, 156.0, 79.1, 70.8, 70.62, 70.57, 70.55, 70.51, 70.21, 68.7, 60.8, 40.3, 28.4, 14.2; HRMS $[M + H]^+$ calcd: 380.22844, found: 380.22788

.

14-*tert*-butoxycarbonylamino-3,6,9,12-tetraoxatetradecanoic acid (12). Ethyl 14-*tert*-butoxycarbonylamino-3,6,9,12-tetraoxatetradecanoate (**11**, 379.4 mg, 1 mmol) was dissolved in methanol (2 mL) and 2M NaOH (2 mL) was added with stirring. The reaction was stirred 30 min. At this point Dowex® 50WX8-200 H^+ ion exchange resin was added until the pH was 4-5. The reaction was filtered and the solvent was removed under reduced pressure to afford **12** as a brown solid (340 mg, 97%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 5.40 (bs, 1H), 4.08 (s, 1H), 3.66-3.54 (m, 14H), 3.34-3.24 (m, 2H) 1.44 (s, 9H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 174.3, 156.3, 79.0, 70.4, 70.1, 70.0, 69.9, 69.4, 69.1, 40.1, 28.4; HRMS $[M + H]^+$ cacld: 352.19714, found: 352.19869.

***N*-(prop-2-ynyl)-14-*tert*-butoxycarbonylamino-3,6,9,12-tetraoxatetradecane carboxamide (13).** 14-*tert*-butoxycarbonylamino-3,6,9,12-tetraoxatetradecanoic acid

(**12**, 340 mg, 0.968 mmol), propargylamine (73 µL, 1.06 mmol), 4-dimethylaminopyridine (DMAP, 118 mg, 0.968 mmol), and *N*-Methylmorpholine (213 µL, 1.94 mmol) were dissolved in anhydrous *N,N*-Dimethylformamide (9mL). The solution was cooled to 0 °C and stirred for 5 min. 1-Ethyl-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC-HCl, 222 mg, 1.16 mmol) was added and the reaction was stirred at room temperature overnight. Next, the solvent was removed under reduced pressure and column chromatography with a gradient solvent system of 5 : 1 - 2 : 1 chloroform/acetone afforded **13** as a yellow oil (285 mg, 76%).

^{1}H NMR (300 MHz, $CDCl_3$) δ 7.44 (bs, 1H), 5.08 (bs, 1H), 4.11-4.09 (m, 2H), 4.03 (s, 2H), 3.70-3.53 (m, 14H), 3.33-3.31 (m, 2H), 2.24 (t, *J* = 2.3 Hz, 1H), 1.45 (s, 9H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 169.9, 156.0, 79.7, 79.2, 77.3, 71.2, 71.1, 70.6, 70.5, 70.3, 70.24, 70.16, 40.3, 28.4, 28.3; HRMS $[M + H]^+$ cacld: 389.22878, found: 389.22797.

13-oxo-3,6,9,12-tetraoxa-14-azaheptadec-16-1-biotinamide(7a). Compound **13** (145 mg, 360 µmol) was dissolved in 20 mL of dry DMF. Triethylamine was added to the solution, which was then stirred for 5 minutes. Biotin-pentafluorophenyl ester (**14**, 148 mg, 360 µmol) was added and the solution was stirred at room temperature overnight. The solvent was then removed by rotary evaporation and the product was purified by column chromatography with a solvent elution of 100% acetone - 40% methanol/dichloromethane. This yielded **7a** as a colorless oil (188 mg, 100%).

$[\alpha]_D^{296K}$ 22.19 (c = 5.25, MeOH/$CHCl_3$); ^{1}H NMR (300 MHz, $CD_3OD/CDCl_3$): δ 4.54 (m, 1H), 4.34 (m, 1H), 4.08 (s, 2H), 4.04 (d, *J* = 2.4Hz, 2H), 3.72 (m, 8H), 3.68 (m, 4H), 3.60 (t, *J* = 4.9Hz, 2H), 3.43 (m, 3H), 3.20 (m, 1H), 2.94 (dd, J_1 = 12.9Hz, J_2 = 4.8Hz, 1H), 2.76 (d, *J* = 12.9Hz, 1H), 2.24 (t, *J* = 7.2Hz, 1H), 1.65 (m, 4H), 1.46 (q, J_1 = 14.4Hz, J_2 = 7.2Hz, 2H); ^{13}C NMR (100.6 MHz, $CD_3OD/CDCl_3$): δ 174.9, 171.0, 164.5, 70.3, 70.2, 70.1, 70.0, 62.2, 60.5, 55.8, 40.3, 39.4, 39.2, 35.8, 28.6, 28.4, 25.7; MALDI-HRMS $[M + H]^+$ calcd: 515.2539, found: 515.2537.

Transglutaminase-Mediated PEGylation of Proteins: Direct Identification of the Sites of Protein Modification by Mass Spectrometry using a Novel Monodisperse PEG

Anna Mero,[†,§] Barbara Spolaore,[†,‡] Francesco M. Veronese,*[,§] and Angelo Fontana*[,‡]

CRIBI Biotechnology Centre, University of Padua, Viale G. Colombo 3, 35121 Padua, Italy, and Department of Pharmaceutical Sciences, University of Padua, Via F. Marzolo 5, 35131 Padua, Italy. Received October 6, 2008; Revised Manuscript Received December 30, 2008

Poly(ethylene glycol) (PEG) has been widely used to prolong the residence time of proteins in blood and to decrease their immunogenicity and antigenicity. A drawback of this polymer lies in its polydispersity that makes difficult the identification of the sites of protein modification. This is a mandatory requirement if a PEGylated protein should be approved as a drug. Here, a fast and reliable method is proposed to characterize proteins conjugated at the level of glutamine (Gln) residues using microbial transglutaminase (TGase). The novelty resides in the use of a monodisperse Boc-PEG-NH_2 for the derivatization that allows the direct identification of the sites of PEGylation by electrospray ionization mass spectrometry (ESI-MS). The procedure has been tested on three model proteins, namely, human granulocyte colony-stimulating factor, human growth hormone, and horse heart apomyoglobin. The Gln residues linked to the polymer chain were easily identified by ESI-MS and tandem MS analyses, demonstrating the advantage of using a monodisperse polymer in combination with mass spectrometry for an easy characterization of conjugated proteins. Interestingly, the PEGylation reaction led to the production only of mono- and bis-derivative products, indicating that the TGase-mediated PEGylation can be extremely selective and thus very useful for the derivatization of protein drugs.

INTRODUCTION

Recombinant proteins are nowadays assuming a relevant role for human therapy in a variety of diseases. However, protein drugs suffer from several limitations, including susceptibility to degradation by proteases, rapid kidney clearance, and propensity to generate immunogenic reactions. To date, the covalent attachment of poly(ethylene glycol) (PEG[1]) on the surface of proteins represents the most promising approach to improve their therapeutic efficacy, thus making them more stable to proteolytic digestion, non-immunogenic, non-aggregating, and with a longer half-life than native proteins (*1*−*3*). The most widely used chemical methods of PEGylation of proteins involve the covalent conjugation of PEG at the level of the ε-amino group of lysine residues by using acylating PEG derivatives. A drawback of these procedures resides in multiple sites of conjugation and thus in the substantial heterogeneity of the PEGylated proteins. In order to obtain site-specific PEGylation, other chemical approaches were developed, such as the selective PEGylation at the level of the thiol group of cysteine residues or at the N-terminal amino group of a polypeptide chain (*2, 4*). More recently, a very promising enzymatic method has been proposed that makes use of transglutaminase (TGase) for the covalent attachment of PEG moieties at the γ-carboxamide group of Gln residues of proteins (*5, 6*). For this purpose, a PEG derivative bearing an amino group is being used (PEG-NH_2).

The development of PEGylated biotech drugs involves the stringent need of a very detailed chemical characterization of the PEGylated proteins, as well as of the raw PEG material used for peptide and protein conjugation. Proper characterization of PEG requires determination of the end group structure, the mass of the repeating unit, and the average molecular weight (MW), as well as the MW distribution. These analyses are made rather difficult because of the polydispersity of the PEG polymer samples. Mass spectrometry (MS) has played an important role in the characterization of polymers and of polypeptide polymer conjugates. In particular, matrix-assisted laser-desorption ionization (MALDI) MS has been often employed, since this MS technique produces ions carrying few charges and thus generates mass spectra of lower complexity (*7*−*9*). Nevertheless, the MALDI technique suffers from poor ionization efficiency when applied to large synthetic polymers or PEGylated proteins. Consequently, accurate average MW can be obtained only for relatively small polymers (*10*). On the other hand, electrospray ionization mass spectrometry (ESI-MS) has a strong tendency to form multiply charged ions of PEGylated proteins, thus hampering the analysis of polymers with molecular masses above a few kilodaltons (*11, 12*).

It should be emphasized that the complete chemical characterization of PEGylated protein drugs also requires the identification of the sites of conjugation. Several analytical methods based on classical protein chemistry methodologies have so far been developed, but they are generally quite time- and protein sample-consuming. Among these methods, the peptide mapping procedure is based on the identification of peptide(s) missing in the digest of the PEGylated protein with respect to that of

the nonmodified protein. Missing peptides are supposed to be those carrying the site of polymer conjugation. Therefore, this method is based on negative information, but it should be noted that a missing peptide may arise also from partial enzymatic hydrolysis of the protein. Moreover, confident identification of the derivatized amino acid residue(s) can be obtained only by the Edman N-terminal sequencing analysis of the purified modified peptide, which is not easy to obtain (*13*). As an alternative, mass spectrometry (MS) appears to be the most suitable technique for the identification of the sites of modification in PEGylated proteins, but until now its use has been limited by the polymer polydispersity (see above). To overcome this problem, our group has previously proposed the derivatization of proteins with a BrCN-cleavable PEG derivative. In this case, the PEGylated protein is reacted with BrCN in order to remove the polymer, while a reporter group of low molecular mass remains linked to the protein chain, thus allowing the identification of the modified amino acid residue(s) by ESI-MS (*14*).

In this paper, a method is described that exploits the sensitivity of MS analyses for the identification of the modified Gln residues in PEGylated proteins prepared using TGase. The novelty resides in the conjugation of proteins with a monodisperse Boc-PEG-NH_2, whose mass can be determined with good accuracy by ESI-MS. With respect to other procedures, in the same MS analysis and with the use of a small amount of digested protein, it is possible to identify the modified peptide and to determine the derivatized amino acid residue by MS/MS analysis. This method has been validated on three model proteins, granulocyte colony stimulating factor (GCSF) and human growth hormone (hGH) (Figure 1A,B), which represent two important pharmaceutical proteins, and apomyoglobin (apoMb), which is a most used model for studies of protein structure, folding, and stability (Figure 1C). The results of this study highlight the advantages of analyzing by MS proteins that are modified with monodisperse polymers. Moreover, it is shown that the use of TGase for the PEGylation of GCSF, hGH, and apoMb yielded only mono- and bis-derivatized products, thus emphasizing the usefulness of the TGase-mediated conjugation for the production of homogeneously modified proteins.

EXPERIMENTAL PROCEDURES

Materials. TGase from *Streptomyces mobaraensis* was purchased from Ajinomoto Co. (Tokyo, Japan), whereas V8-protease from *Staphylococcus aureus* and trypsin were from Sigma Aldrich (St. Louis, MO). GCSF and hGH were supplied by Bioker SpA (Cagliari, Italy). Boc-PEG-NH_2 (556.36 Da) was purchased from LCC Engineering GmbH (Egerkingen, Switzerland) and PEG-NH_2 (5 kDa and 20 kDa) from Shearwater Polymers Inc. (Huntsville, AL). All other chemicals where purchased from Sigma. Apomyoglobin (apoMb) was obtained from horse heart holomyoglobin by removal of heme using the acetone extraction procedure (*15*).

TGase-Mediated PEGylation of Proteins. Boc-PEG-NH_2, previously dissolved in a small amount of acetonitrile, was added at a 10-fold molar excess to solutions containing GCSF or hGH (1.5 mg/mL) in 10 mM phosphate buffer, pH 7.0. TGase was then added at an enzyme to substrate ratio (E/S) of 1:75 (by weight). The reaction mixtures were incubated at room temperature for 4 h and the product(s) purified by RP-HPLC using a Zorbax C18 column (4.6 × 250 mm; Agilent Technologies, Palo Alto, CA) with a linear gradient of 50−70% acetonitrile containing 0.05% TFA over a 25 min period, followed by an isocratic wash at 80% acetonitrile containing 0.05% TFA. The effluent from the column was monitored by measuring the absorbance at 226 nm. The PEGylated proteins of the chromatographic peaks were collected, lyophilized, and used for a peptide fingerprinting analysis by mass spectrometry.

In the case of apoMb, under the experimental conditions given above, a high yield of cross-linked dimer was obtained. Better results were obtained using a protein concentration of 0.7 mg/mL, a large excess of Boc-PEG-NH_2 (100 equiv), and TGase at an E/S ratio of 1:50 (by weight). The reaction was allowed to proceed at room temperature for 3 h and then analyzed by RP-HPLC on a Jupiter C18 column (4.6 × 150 mm; Phenomenex, Torrance, CA), eluted with a gradient of acetonitrile/0.085% TFA versus water/0.1% TFA from 5% to 40% in 5 min and from 40% to 50% in 25 min. The effluent from the column was analyzed as above.

Proteolytic Digestion of PEGylated Proteins. Native and PEGylated proteins (200 μg) were dissolved in 6 M Gdn-HCl, 50 mM Tris-HCl, pH 9.0, to reach a protein concentration of about 1 mg/mL. In order to reduce disulfide bridges, tris(2-carboxyethyl)phosphine was added to the protein solution at a final concentration of 5 mM and the reaction mixture kept for 1 h at 37 °C. The reduced protein was then reacted with 25 mM iodoacetamide, and the S-alkylation was allowed to proceed for 30 min at 37 °C in the dark. Protein samples were purified by RP-HPLC on a Zorbax C18 column as reported above.

The reduced and S-carboxamidomethylated samples of GCSF and PEG-GCSF were dissolved in 8 M urea and diluted in 50 mM phosphate buffer, pH 7.9, to reach a final protein concentration of 0.8 mg/mL and a urea concentration of 0.8 M. An aliquot from a stock solution of V8-protease in 50 mM acetic acid was then added at an E/S ratio of 1:50 (by weight), and the proteolysis was allowed to proceed at 37 °C overnight. The digestion mixtures, desalted by PepClean C-18 spin columns (Pierce, Rockford, IL), were directly analyzed by mass spectrometry. For hGH and its PEGylated samples, the same procedures were employed, but trypsin was used for protein digestion.

In the case of apoMb, the protein and its PEGylated derivative were purified by RP-HPLC, lyophilized, and digested with trypsin overnight at 37 °C in 0.1 M ammonium carbonate buffer, pH 7.8, using an E/S of 1:100 (by weight). Since apoMb does not contain cysteine residues, the steps of reduction and S-alkylation were omitted.

Mass Spectrometry Analyses. MALDI mass spectrometry measurements were performed on a REFLEX time-of-flight instrument (Bruker-Franzen Analytik, Bremen, Germany) equipped with a SCOUT ion source operating in positive linear mode. Ions generated by a pulsed UV laser beam (nitrogen laser, λ 337 nm) were accelerated to 25 kV. A saturated solution of sinapinic acid in acetonitrile/water (1:1, v/v) was used as matrix and mixed with the samples dissolved in 0.1% TFA aqueous solution at a v/v ratio of 1:1.

Electrospray mass spectrometry (ESI-MS) and tandem MS (MS/MS) measurements were performed on a Q-TOF Micro mass spectrometer (Waters, Milford, MA) equipped with a Z-spray nanoflow electrospray ionization interface. Mass spectra of the peptide digests of proteins and PEG derivatives were acquired using the nanoelectrospray source operating at capillary, cone, and extractor voltages of 2000, 30, and 1 V, respectively (positive ion mode). PEGylated derivatives purified by RP-HPLC were lyophilized, redissolved in acetonitrile/water (1:1, v/v) containing 0.1% formic acid, and then analyzed by ESI-MS. MS/MS analyses were performed only for the peptide 124−162 of GCSF and its PEG derivative utilizing the same parameters of the MS instrument as above, using argon as the collision gas and a collision energy setting of 40 V. External calibration was performed using a solution of 0.1% (v/v) phosphoric acid in 50% aqueous acetonitrile. Nanoelectrospray ionization capillaries were prepared in-house. Instrument control, data acquisition, and processing were achieved with the *Masslynx* software (Waters).

RESULTS AND DISCUSSION

TGase-Mediated PEGylation of Proteins. Figure 2 shows the mass spectra of a polydisperse 5 kDa PEG and a monodisperse PEG as Boc-PEG-NH_2. While the polydispersity of the usually employed PEG prevents analysis by ESI mass spectrometry, the recently available monodisperse one (556.36 Da) offers characteristics that make it suitable for analyzing PEGylated proteins by ESI-MS and MS/MS. This possibility was verified using two proteins of pharmaceutical interest, namely, GCSF and hGH, and a model protein as apoMb. As given by their amino acid sequences (see Figure 1), these proteins contain several Gln residues as potential sites of TGase-catalyzed conjugation.

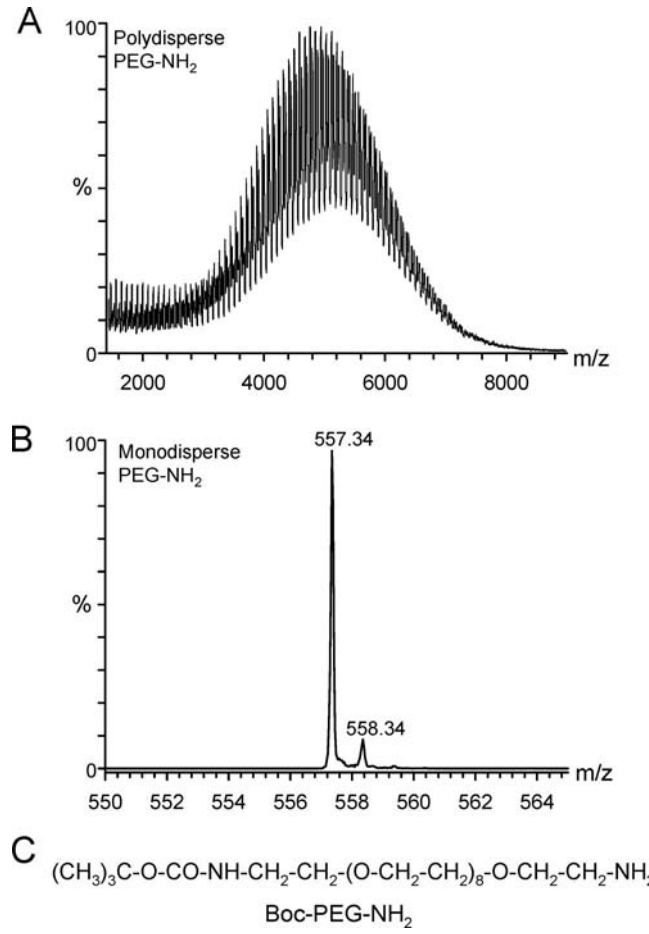

Figure 2. Analysis by mass spectrometry of polydisperse (5 kDa) and monodisperse (556.36 Da) PEG. (A) The MALDI mass spectrum of polydisperse PEG. (B) ESI-TOF mass spectrum of monodisperse PEG. (C) Chemical structure of monodisperse PEG used in this study. The derivative contains the *tert*-butoxycarbonyl (Boc) moiety as N-protecting group.

RP-HPLC analysis of the reaction mixture of GCSF with monodisperse PEG (Figure 3A) shows the complete PEGylation of the protein. The reaction product separated by RP-HPLC was analyzed by ESI-TOF mass spectrometry and a mass of 19207.2 Da was measured, which corresponds to GCSF conjugated to only one chain of PEG (Table 1). On the other hand, the RP-HPLC analysis of the TGase-mediated PEGylation of hGH showed four chromatographic peaks (Figure 3B). When analyzed by ESI-TOF mass spectrometry, these products gave masses corresponding to hGH conjugated to one or two chains of PEG (peaks 1 and 2, respectively), while the protein material of peak 3 corresponded to a mixture of hGH dimer and of hGH covalently bound to mono-PEGylated hGH; the protein material of peak 4 was a dimer of mono-PEGylated hGH (see Table 1 and Figure 3B).

PEGylated apoMb gave a mass of 17491.28 Da corresponding to a mono-PEGylated apoMb (Figure 3C). Of interest, we have observed that, by conducting the TGase-mediated reaction under identical experimental conditions and using a high molecular weight PEG (20 kDa), the same degree of protein modification was achieved with GCSF, hGH, and apoMb (data not shown).

Identification of the Sites of PEGylation by ESI-MS. In order to determine the sites of conjugation by TGase, the cysteine residues of PEG-GCSF and of native GCSF were

reduced and S-carboxamidomethylated, and the two proteins were then digested with V8-protease. This enzyme was used instead of trypsin, since it allowed us to obtain peptide fragments with a lower molecular mass. Indeed, proteolysis with trypsin of GCSF leads to a fragment of 11.3 kDa (residues 41−146), which is not suitable for MS/MS analysis for the identification of the site of modification. Analysis by ESI-MS of the digests of PEG-GCSF and of native GCSF obtained with V8-protease led to a sequence coverage for the protein of 95%, with 10 peptide fragments identified over the 12 expected. The only fragment that was not detected by MS and that contains one Gln residue corresponds to residues 28−33 (sequence GAALQE) (Figure 1). Interestingly, all identified fragments had the same molecular mass in the digests of both PEG-GCSF and native GCSF, except peptide 124−162. Indeed, this peptide fragment deriving from the digest of conjugated GCSF showed an increase in mass corresponding to the addition of one molecule of PEG, thus indicating that PEGylation occurred at the level of this region of the protein chain (Table 2). The derivatization of the peptide 124−162 appears to be quantitative, since in the MS spectrum of the digest of PEG-GCSF, the *m*/*z* signals corresponding to a nonconjugated fragment were not observed. This is evident from an analysis of the region of the spectrum between 1000 and 1200 *m*/*z*, which contains signals of the ion $[M + 4H]^{4+}$ of this peptide (Figure 4A). In the MS spectrum of GCSF, fragment 124−162 shows a signal at 1007.18 *m*/*z* (data not shown). This signal is absent in the spectrum of the digest of PEG-GCSF, where only the signal at 1142.00 *m*/*z* is observed, which corresponds to the ion with four charges of the modified fragment.

Table 2. Molecular Masses of the Fragments Obtained upon Digestion with V8-Protease of GCSF and PEG-GCSF and with Trypsin of hGH and PEG-hGH and of apoMb and PEG-apoMb[a]

[a] Only the molecular masses of the fragments which contain the Gln residues derivatized with PEG are reported. [b] Peptides obtained by proteolysis of GCSF and PEG-GCSF with V8-protease and of hGH and PEG-hGH and apoMb and PEG-apoMb with trypsin. [c] Monoisotopic molecular masses calculated from the amino acid sequence of GCSF, hGH, and apoMb. [d] Experimental molecular masses determined by ESI-MS. [e] These very short and rather hydrophilic peptides were not detected, since likely they were lost in the desalting step of the sample digest (see Experimental Procedures).

Since the GCSF fragment 124−162 contains four Gln residues (see Figure 1), the ion $[M + 4H]^{4+}$ of the derivatized peptide was subjected to MS/MS analysis in order to determine which Gln residue was modified (Figure 4B). For comparison, the nonmodified peptide was also analyzed by MS/MS (data not shown). In the case of both derivatized and non-derivatized peptides, the analysis of the MS/MS spectra indicates that the most intense product ions of the series *b* and *y* are generated from the fourteen N-terminal residues of the fragment, a region that contains two of the four Gln residues. Nevertheless, it was possible to determine the site of specific modification. In the MS/MS spectrum of the PEGylated peptide, fragment ions that contain Gln145 and Gln158 (*y*25−28) and Gln131 (*b*8) have *m*/*z* values expected for the nonmodified peptide, indicating that these Gln residues are not conjugated. On the other hand, all product ions containing Gln134 (*y*35−29) show an increase in mass of 439.28 Da, corresponding to the addition of a Boc-PEG-NH_2 with the N-protecting group (Boc) removed. Indeed, this group is conjugated to PEG via an urethane moiety, which is easily cleaved off under the conditions of the MS/MS analysis. Overall, sequence analysis by MS/MS of the modified GCSF peptide 124−162 clearly demonstrated that the TGase-mediated PEGylation occurs at Gln134.

In the case of hGH, the reduced and S-carboxamidomethylated hGH and mono- and bis-PEGylated hGH conjugates were digested with trypsin. The digested samples were analyzed by ESI-MS, and most of the tryptic fragments were identified, resulting in a sequence coverage of 88%. The only peptide fragments that were not detected in the digests were fragments 17−19, 128−134, and 179−191, with the last fragment having one Gln residue. By comparing the mass spectra of the digests of hGH and of conjugated hGH, it was observed that only the

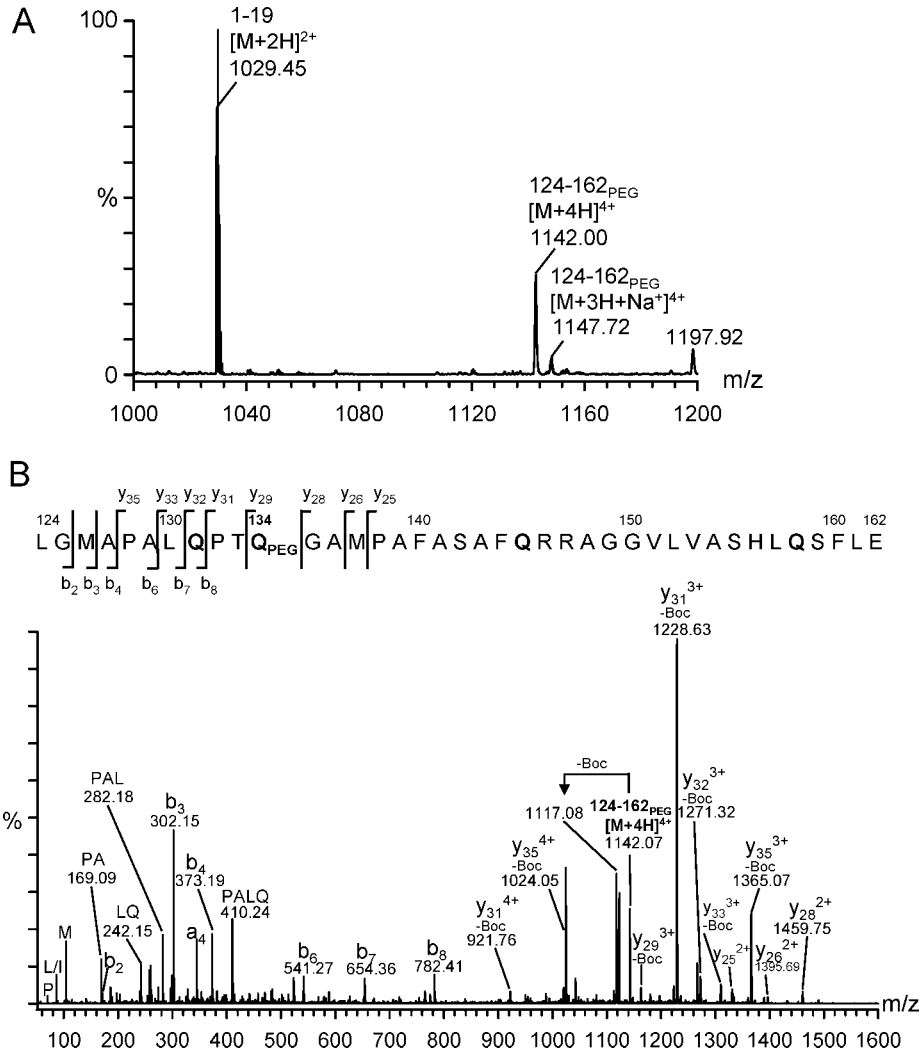

Figure 4. Electrospray mass spectrum of the digest of PEG-GCSF with V8-protease and MS/MS analysis of peptide 124−162. (A) The region of the mass spectrum between 1000 and 1200 *m*/*z* is reported in order to show the derivatization with PEG of peptide 124−162 of GCSF. The signals at 1142.00 *m*/*z* and at 1147.72 *m*/*z* of ions with four charges are indicated. (B) Electrospray MS/MS mass spectrum of the ion at 1142.00 *m*/*z* of peptide 124−162 of GCSF-PEG. (Top) Fragments of the series *b* and *y* that were identified in the MS/MS spectrum are indicated on the sequence of the peptide. Gln residues are shown in bold, and Gln134 is indicated in bold as Q_{PEG}. (Bottom) In the MS/MS spectrum, ions assigned to fragments of the series *y* and *b* are indicated. Some internal fragments and immonium ions are also labeled with their sequence in one-letter amino acid code. Fragments containing Gln134 show a mass increment corresponding to the conjugation with PEG-NH_2 without the Boc moiety, since the N-protecting group dissociates in the MS/MS analysis (-Boc).

spectrum of PEG-hGH displayed a signal at 472.34 *m*/*z*, corresponding to the triply charged ion of fragment 39−41 linked to one chain of PEG, and a signal at 583.41 *m*/*z*, corresponding to the ion with three charges of the mono-PEGylated fragment 141−145 (Figure 5A,B). Of interest, signals of the conjugated peptides without Boc were also detected in the mass spectrum, since the urethane bond, as reported above, is easily fragmented under the conditions of the ESI ionization. The detection by ESI-MS of Boc removal can be used as a further probe of the PEGylation of the peptide. Since fragments 39−41 and 141−145 contain only one Gln residue, it can be concluded that the TGase-mediated PEGylation of hGH took place at Gln40 and Gln141 in the bis-PEGylated form of the hormone, while the mono-PEGylated species was a mixture of the conjugates at Gln40 and Gln141.

In the case of apoMb, samples of native and PEGylated protein were subjected to trypsin digestion. All tryptic fragments were identified for both native apoMb and PEG-apoMb species with a sequence coverage of 98%. However, in the digest of PEG-apoMb, the tryptic fragments 80−96 and 79−96 gave only MS signals corresponding to their PEGylated species. Indeed, in the spectral region between 760−810 *m*/*z*, a signal can be observed at 794.48 *m*/*z*, which corresponds to the ion with three charges of fragment 80−96 modified with a single chain of PEG (Figure 5C). Since fragments 80−96 and 79−96 contain the single Gln91 residue, these data indicate that TGase catalyzes the conjugation of PEG at the level of Gln91 of apoMb.

CONCLUSION

The results here reported demonstrate that the use of a low molecular weight monodisperse PEG (Boc-PEG-NH_2) allows for an accurate identification of the sites of TGase-mediated PEGylation by ESI-MS and MS/MS analyses. The technique requires a small amount of protein and a limited number of analytical steps, at variance from the more laborious analyses so far employed in the characterization of proteins conjugated to high molecular weight polydisperse PEGs. A striking observation of this study is that the use of TGase in the enzymatic PEGylation yields to the specific modification of only few Gln residues, giving rise to mono- or bis-PEG derivatives. Even if GCSF, hGH, and apoMb contain 17, 11, and 6 Gln residues, respectively, just one Gln in GCSF and apoMb and two in hGH were selectively PEGylated. The reason for this selectivity resides in the fact that a flexible polypeptide substrate

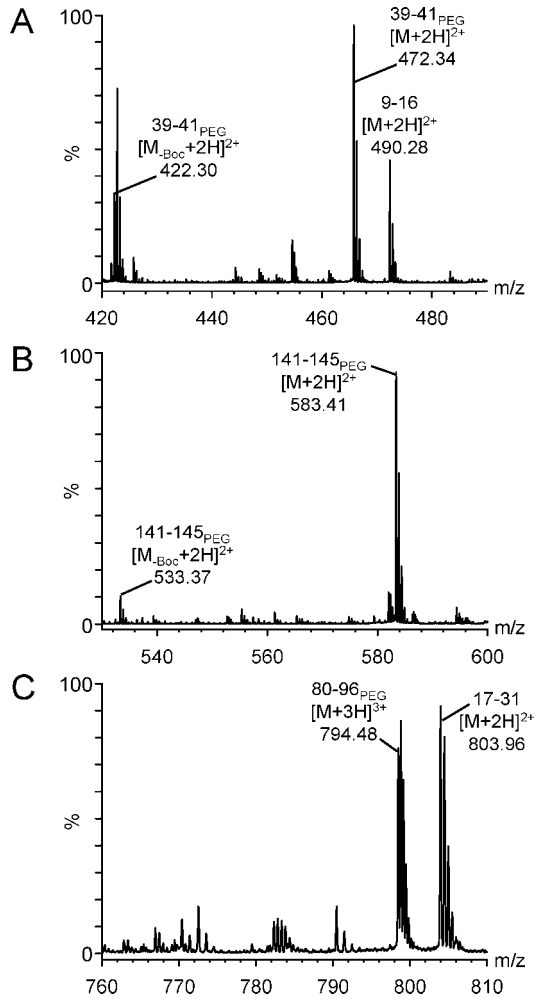

Figure 5. Electrospray mass spectra of the digests of PEG-hGH and PEG-apoMb with trypsin. (A,B) The regions between 420−500 *m*/*z* and 520−600 *m*/*z*, respectively, of the mass spectrum of the digest of PEG-hGH are shown. The signals of the modified peptides 39−41 and 141−145 are indicated. (C) The signals of PEGylated peptide 80−96 and of peptide 17−31 are indicated in the region 760−810 *m*/*z* of the mass spectrum of the digest of PEG-apoMb.

is required for a productive binding and adaptation at the active site of TGase. Indeed, the modified Gln residues of the three proteins herewith investigated are all located in disordered regions of the proteins (*16*). The method described here considers that the modification of proteins mediated by TGase with the low molecular weight PEG occurs at the same Gln residues as those derivatized with the high molecular weight polydisperse polymer. This assumption appears to be valid, since the TGase-modified Gln residues are dictated by the structure and dynamics of the protein substrate and not by features of the primary amines used as acyl acceptors (*16*). Indeed, the results of this study, based on monodisperse PEG, are in agreement with those of recent reports showing that GCSF is selectively PEGylated at the level of Gln134 (*17*) and hGH at Gln40 and Gln141 (*18*) by TGase and high molecular weight PEGs (20 kDa). Therefore, overall our results indicate that Boc-PEG-NH_2 can find a general application for the identification by ESI/MS and MS/MS of the site(s) of protein PEGylation mediated by TGase. Finally, the selectivity of the TGase-mediated reactions suggests a wider application of this enzyme for protein modification, besides PEGylation. While the TGase-mediated products can be homogeneous, a complex mixture of isomers is instead usually obtained by other chemical processes.

ACKNOWLEDGMENT

This research was supported in part by the Italian Ministry of University and Research (PRIN-2006 No. 03035 and FIRB-2003 No. RBNEOPX83). The authors are grateful to BioKer Srl (Pula, Italy) for a generous supply of protein samples of GCSF and hGH. The excellent technical assistance of Marcello Zambonin is also gratefully acknowledged.

Development of Protein-Binding Bifunctional Linkers for a New Generation of Dual-Acting Prodrugs

Khalid Abu Ajaj,[†] Martin L. Biniossek,[‡] and Felix Kratz*,[†]

Tumor Biology Center, Breisacher Strasse 117, 79106 Freiburg, and Institute of Molecular Medicine and Cell Research, Zentrum für Biochemie and Molekulare Zellforschung, Stefan-Meier-Strasse 17, 79104 Freiburg, Germany. Received October 13, 2008; Revised Manuscript Received December 2, 2008

The aim of this work was to develop a new bifunctional maleimide linker for the development of dual-acting prodrugs that incorporate two pharmaceutically different anticancer agents independently bound by enzymatically cleavable substrates. The linker consists of a carboxyl group in one arm and an activated 1,6-self-immolative *para*-aminobenzyloxycarbonyl spacer together with a cathepsin B cleavable dipeptide Phe-Lys in the other. Aided with this linker, we have prepared a thiol-binding prodrug that contains the anticancer drugs doxorubicin and paclitaxel. Bound to the cysteine-34 position of albumin, it was cleaved efficiently by cathepsin B releasing the free drugs.

INTRODUCTION

Macromolecular prodrugs are being intensively studied, preclinically as well as clinically, in order to reduce the toxicity and improve the efficacy of anticancer agents. Modern drug antibody conjugates primarily use highly potent drugs, whereas drug conjugates with synthetic polymers or serum proteins use clinically established agents (*1, 2*). Both forms of drug conjugates couple one type of drug to the carrier (*3*).

For the development of novel prodrugs, it would be desirable to bind two different drugs to the carrier that ideally act additively or synergistically. Thus, we set out to develop such prodrugs, which we nicknamed "dual-acting prodrug" of the general formula shown in Figure 1. The dual-acting prodrug comprises two different pharmaceutically active compounds independently bound by cleavable linkers and a maleimide group as a thiol-binding moiety which is capable of binding to a carrier molecule with HS groups.

In this work, we present the first example of a dual-acting prodrug that incorporates the anticancer agents paclitaxel (*4*) and doxorubicin (*5*) that are useful drugs for treating a broad range of solid tumors. The combination of paclitaxel and doxorubicin is being intensively studied, preclinically as well as clinically. In vitro studies have shown additive (*6*) and synergistic (*7*) effects in human cancer cell lines. Recent clinical studies demonstrated that combination therapy with paclitaxel and doxorubicin was significantly better than single therapy for the treatment of patients with androgen-independent prostate cancer (*8*), advanced breast cancer (*9*−*11*), and endometrial cancer (*12*). Also, their chemical structures allow the design of prodrugs with enzymatically cleavable bonds through the amino group of doxorubicin (*5*) or the 2′-hydroxy group of paclitaxel (*13*). The target molecule with these two drugs is shown in Figure 1.

The prodrug incorporates a 1,6-self-immolative *para*-aminobenzyloxycarbonyl (PABC) spacer (*14*) between the drug and the lysosomally cleavable dipeptide Phe-Lys. This peptide is a substrate for cathepsin B, a cysteine protease that is overexpressed in solid tumors (*15*). The incorporation of a self-immolative spacer between the dipeptide and the drug ensures access to the site of cleavage by lysosomal enzymes such as cathepsin B (*16*). The self-immolative spacer hydrolytically decomposes upon deacylation, spontaneously releasing the free drug. This system has been used by Dubowchik et al. for the synthesis of monoclonal antibody conjugates with doxorubicin (*3, 16*). An additional advantage of the Phe-Lys-PABC spacer is the presence of the basic amino acid lysine that could render water solubility to the dual-acting prodrug.

Following the synthesis of such prodrugs, we wanted to ascertain whether cathepsin B can cleave the dual-acting prodrug once bound to a suitable synthetic polymer or protein carrier.

In our previous work, we have investigated a passive targeting approach in which maleimide-bearing prodrugs bind selectively to the cysteine-34 position of circulating albumin after intravenous administration. This macromolecular prodrug concept is based on two features: (i) rapid and selective binding of a maleimide functionalized prodrug to the cysteine-34 position of endogenous albumin after intravenous administration and (ii) release of the albumin-bound drugs predominantly at the tumor site due to the incorporation of an acid-sensitive or enzymatically cleavable bond between the drug and the carrier (*17*−*19*).

Albumin demonstrates preferential tumor uptake in various tumor animal models (*20*) due to the enhanced permeability and retention of macromolecules for solid tumors (*21*). In situ binding of maleimide-based prodrugs to the cysteine-34 position of circulating albumin is meanwhile a preclinically and clinically validated technology to increase the therapeutic index of anticancer agents. Besides the acid-sensitive prodrug of doxorubicin, the (6-maleimidocaproyl)hydrazone derivative of doxorubicin [INNO-206, previously DOXO-EMCH (EMC = 6-maleimidocaproic acid)] that has been studied clinically (*22*), a series of albumin-binding prodrugs with enzymatically cleavable substrates have been developed in the past five years (*15, 19, 23*−*27*).

In this work, we describe the synthesis of the maleimide bearing prodrug that incorporates both doxorubicin and pacli-

taxel and demonstrates cathepsin B mediated cleavage and release of doxorubicin and paclitaxel in its albumin-bound form.

EXPERIMENTAL PROCEDURES

General. Protected amino acids were purchased from Bachem and Novabiochem. Doxorubicin hydrochloride and paclitaxel were purchased from Yick-Vic Chemicals & Pharmaceuticals (HK) China. Dry solvents were Fluka Sure Seal grade. All other chemicals and solvents were purchased from Sigma-Aldrich, Fluka, Merck, and Roth and were used without further purification. Sodium sulfate was used as the drying agent for extractive workup. Human serum albumin (5% solution) was purchased from Octapharma GmbH (Langenfeld, FRG). The protein contained approximately 60% free thiol groups as assessed with the Ellmann's test. Enzymatically active cathepsin B was purchased from Calbiochem (Bad Soden, FRG). The buffers used were vacuum-filtered through a 0.2 μm membrane (Sartorius, Göttingen, FRG) and thoroughly degassed with ultrasound prior to use. Lyophilization was performed with a lyophilizer Alpha 2−4 (Christ, FRG). Centrifugation was carried out with a Tomy Capsule microcentrifuge model HF-120 (Peninsula Laboratories, Belmont, CA). The solvents were removed under reduced pressure at 30 °C.

Chromatography. Unless otherwise indicated, preparative flash chromatography (FC) was carried out using Merck grade 9385, 230−400 mesh silica gel. Analytical TLC was performed on Merck precoated plates using TLC silica gel 60F_{254} (normal phase), RP-18 F_{254S} (reversed phase), and diol F_{254S} (diol). Visualization of TLC plates was accomplished by one or several suitable detection methods; spots were identified by UV light absorption at λ = 254 and 366 nm, and/or by dipping into a solution of *p*-anisaldehyde (1 mL) and concentrated H_2SO_4 (4 mL) in ethanol (95 mL), and subsequent heating at 140 °C, and/or in a ninhydrin reagent and subsequent heating at 140 °C to color the TLC plates.

Unless otherwise indicated, analytical reversed-phase HPLC of synthetic compounds was carried out on a Kontron System using a solvent delivery system (HPLC Pump 422), a variable wavelength UV−vis detector (HPLC Detector 430) and a 25 cm nucleosil C-18 column (100−5, 250 × 4 mm, Macherey-Nagel). For peak integration, *Geminyx* software (v 1.91 by Goebel Instrumentelle Analytik, FRG) was used. HPLC conditions were as follows: flow rate, 1 mL/min; injection volume, 50 μL; gradient, 0−5 min 100% mobile phase A; 5−30 min increase to 100% mobile phase B; 30−45 min 100% mobile phase B; 45−55 min decrease to 100% mobile phase A; 55−60 min 100% mobile phase A.

System-1. mobile phase A: 80% H_2O, 20% acetonitrile, 0.05% TFA. mobile phase B: 20% H_2O, 80% acetonitrile, 0.05% TFA.

System-2. mobile phase A: 10 mM aqueous Na_2HPO_4 (pH 7)/acetonitrile 80:20. mobile phase B: 10 mM aqueous Na_2HPO_4 (pH 7)/acetonitrile 20:80.

System-3. mobile phase A: 10 mM aqueous Na_2HPO_4 (pH 7)/acetonitrile 80:20. mobile phase B: 10 mM aqueous Na_2HPO_4 (pH 7)/acetonitrile 40:60.

System-4. mobile phase A: 85% H_2O, 15% acetonitrile, 0.1% TFA containing heptane-1-sulfonic acid 2 g/L. mobile phase B: 20% H_2O, 80% acetonitrile, 0.1% TFA containing heptane-1-sulfonic acid 2 g/L.

Preparative reversed-phase HPLC for the separation of the prodrug **16** was performed with a BioLogic Duo-Flow System from Biorad (München, FRG), which was connected with a Lambda 1010 visible monitor from Bischoff (at λ = 495 nm); UV-detection at λ = 254 nm from Biorad; column, 25 cm Nucleosil C-18 column (100−7, 250 × 21 mm) with a precolumn (100−7, 50 × 21 mm) from Macherey-Nagel. Chromatographic conditions: flow rate, 10 mL/minute; injection volume, 5 mL; mobile phase A: 70% H_2O, 30% acetonitrile, 0.1% TFA; mobile phase B: 20% H_2O, 80% acetonitrile, 0.1% TFA.

Analytical reversed-phase HPLC for the synthesis of albumin conjugate **HSA-16** and its cleavage with cathepsin B was carried out on the previously described Kontron System with the following HPLC conditions: column, symmetry 300 (250 × 4.6 mm) from Waters; flow rate, 1 mL/min, λ = 495 and 220 nm; injection volume, 50 μL; gradient, 0−15 min 100% mobile phase A; 15−40 min increase to 100% mobile phase B; 40−45 min 100% mobile phase B; 45−50 min decrease to 100% mobile phase A; 50−60 min 100% mobile phase A; mobile phase A: 70% H_2O, 30% acetonitrile, 0.1% TFA; mobile phase B: 20% H_2O, 80% acetonitrile, 0.1% TFA.

Spectral Analyses. Electron spray ionization mass spectra (ESI-MS) were obtained on a Thermo Electron LCQ Advantage with associated MAT SS 200 data. Mass spectra of compounds **15** and **16** were acquired on a LTQ-FT spectrometer (ThermoFisher Scientific, Bremen, FRG) in the FT mode using electrospray ionization (ESI). Monoisotopic peaks were used for data analysis.

UV/vis-spectrophotometry was carried out with a double-beam spectrophotometer U-2000 from Hitachi. ^{1}H NMR and ^{13}C NMR spectra were run on a Varian Gemini 300 spectrometer at 300 and 75 MHz, respectively. Internal referencing was used, and chemical shifts are reported in parts per million (ppm).

Synthesis of the Bifunctional Maleimide Linker 2.

EMC-Glu(tBu)-OSu 2. A stirred solution of EMC (1 equiv, 121 mmol, 25.56 g) and HOSu (1.05 equiv, 127 mmol, 13.92 g) in dry DMF/THF, 1:6 (400 mL) at 0 °C, was treated with DCC (1.05 equiv, 127 mmol, 26.18 g). After 30 min, the mixture was allowed to warm to room temperature (RT) and was stirred for 20 h (TLC, diol, THF/hexane, 1:1). The solid byproduct was filtered off, washed with dry THF (100 mL), and the filtrate was added at room temperature to a suspension of H-Glu(OtBu)-OH (121 mmol, 24.5 g) and Et_3N (1 equiv, 121 mmol, 17.3 mL) in dry DMF (45 mL). The reaction solution was stirred for 22 h (TLC, $CHCl_3$/MeOH/AcOH, 10:1:0.2). The solvent was removed under reduced pressure, and the residue was purified by FC eluting with $CHCl_3$/MeOH/AcOH, 30:1:0.15. The solvent was removed, and the residue was subjected to another FC (diol, eluting with THF/hexane, 1:1) to remove acetic acid. **1** was obtained as a light yellow oil (29.6 g, 63%). $C_{19}H_{28}N_2O_7$, ESI-MS: calcd $[M + H]^+$ 397.19, found 396.80. HPLC analysis: (system-1; $\lambda = 254$ nm) > 95% of peak area. ^1H NMR ($CDCl_3$): $\delta = 1.30$ (multiplet, 2H), 1.40 (singlet, 9H, 3 × $(CH_3)_3C$), 1.60−1.70 (multiplet, 4H), 1.80−2.40 (multiplet, 6H), 3.50 (triplet, 2H, NCH_2,), 4.55 (triplet, 1H), 6.70 (singlet, 2H, COCHCHCO), 8.0 (singlet, 1H, NH), 9.90 (singlet, 1H, OH). ^{13}C NMR ($CDCl_3$): $\delta = 25.0$, 26.0, 27.0, 29.0, 32.0, 36.0, 39.0 (CH_2), 28.0 (3 × ($\underline{C}H_3)_3C$)), 52.0 ($\underline{C}H_2COOH$), 81.0 $(CH_3)_3\underline{C}$), 134.0 ($\underline{C}H\underline{C}H$), 171.0, 173.0, 174.0, 175.0 (CO). A stirred solution of **1** (12.6 mmol, 5.0 g) and HOSu (1.05 equiv, 13.23 mmol, 1.52 g) in dry THF (60 mL) at 0 °C was treated with DCC (1.05 equiv, 13.23 mmol, 2.73 g). After 20 min, the mixture was allowed to warm to room temperature and was stirred for 16 h (TLC, diol, THF/hexane, 1:1). The solid byproduct was filtered off, washed with dry THF, and the filtrate of **2** was used in the next step. An analytical sample was obtained by purification on FC (diol, eluting with THF/hexane, 1:1). ^1H NMR ($CDCl_3$): $\delta = 1.30$ (multiplet, 2H), 1.40 (singlet, 9H, 3 × $(CH_3)_3C$), 1.60−1.80 (multiplet, 4H), 2.10−2.30 (multiplet, 6H), 2.80 (singlet, 4H, $COCH_2CH_2CO$), 3.50 (triplet, 2H, NCH_2,), 4.90 (triplet, 1H), 6.70 (singlet, 2H, COCHCHCO), 8.0 (singlet, 1H, NH). ^{13}C NMR ($CDCl_3$): $\delta = 24.0$, 25.0, 26.0, 27.0, 29.0, 32.0, 35.0, 37.0 (CH_2), 28.0 (3 × ($\underline{C}H_3)_3C$), 50.0 ($\underline{C}H_2COOH$), 82.0 $(CH_3)_3\underline{C}$), 133.0 ($\underline{C}H\underline{C}H$), 167.0, 168.0, 171.0, 173.0, 174.0 (CO).

Synthesis of the Peptide Substrates.

Fmoc-Phe-Lys(Mtt) 4. A stirred solution of Fmoc-Phe-OH (95.0 mmol, 36.7 g) and HOSu (1.05 equiv, 99.6 mmol, 11.5 g) in dry THF (500 mL) was treated at 0 °C with DCC (1.05 equiv, 99.6 mmol, 20.5 g). After 15 min, the mixture was allowed to warm to room temperature and was stirred for 22 h (TLC-diol, $CHCl_3$/MeOH, 15:1). The solid byproduct was filtered off, washed with dry THF, and the filtrate of **3** was used in the next step without further purification. Fmoc-Lys(Mtt)-OH (80 mmol, 50 g) was dissolved in piperidine in DMF (20%, 100 mL) and stirred for 30 min (TLC, $CHCl_3$/MeOH, 10:1). The solution was added to diethyl ether (2.5 L) to precipitate H-Lys(Mtt)-OH as a white solid that was collected by suction filtration, washed well with ether, and dried in vacuo (31 g, 96%). A stirred suspension of H-Lys(Mtt)-OH (76.76 mmol, 30.9 g) and $NaHCO_3$ (1 equiv, 76.76 mmol, 6.44 g) in water (500 mL) and THF (200 mL) was treated with **3** (76.76 mmol in 500 mL dry THF). The mixture was stirred at room temperature for 22 h (TLC: $CHCl_3$/MeOH, 15:1), and then as much THF as possible was removed in vacuo at 30 °C. The resulting gummy suspension was partitioned between ethyl acetate and pH 5 buffer. The organic phase was washed with water and brine, dried, and concentrated in vacuo at 30 °C to approximately 200 mL, which was added to hexane (1 L). The white precipitate **4** was collected by suction filtration, washed well with ether, and dried in vacuo (55 g, 93%). $C_{50}H_{49}N_3O_5$, ESI-MS: calcd $[M + H]^+$ 772.37, found 772.70. HPLC analysis: (system-2; $\lambda = 254$ nm) > 88% of peak area.

Fmoc-Phe-Lys(Mtt)-PABOH 5. A solution of **4** (23.31 mmol, 18 g) and PABOH (1.2 equiv, 27.96 mmol, 3.45 g) in dry DCM (300 mL) was treated at room temperature with 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ) (1.5 equiv, 34.95 mmol, 8.64 g) and was stirred for 20 h (TLC: $CHCl_3$/MeOH, 10:1). The solvent was then removed in vacuo at 30 °C. The solid residue was triturated with diethyl ether (600 mL), and the resulting suspension was sonicated for 20 min and left to stand at room temperature for 1 h. The resulting white solid **5** was collected by filtration, washed well with ether, and dried in vacuo (17.28 g, 85%). $C_{57}H_{56}N_4O_5$, ESI-MS: calcd $[M + Na]^+$ 899.43, found 899.40. HPLC analysis: (system-2; $\lambda = 254$ nm): > 91% of peak area.

H-Phe-Lys(Mtt)-PABOH 6. A solution of **5** (15.9 mmol, 14 g) in DCM (150 mL) at room temperature was treated with diethylamine (250 mL). The mixture was sonicated briefly and stirred at room temperature for 4 h, after which time no starting material was observed by TLC (DCM /MeOH, 10:1). The solvents were evaporated, and the residue was coevaporated twice with DCM and purified by FC eluting with DCM/MeOH 10:1 to give **6** as a white solid (8 g, 80%). $C_{42}H_{46}N_4O_3$, ESI-MS: calcd $[M + Na]^+$ 677.36, found 677.40. HPLC analysis: (system-2; $\lambda = 254$ nm) > 92%.

Fmoc-Phe-Lys(Mtt)-PABC-PNP 12. *N*,*N*-Diisopropylethylamine (DIPEA) (3 equiv, 3.42 mmol, 580 μL) was added to a solution of **5** (1 equiv, 1.14 mmol, 1.0 g) and bis-PNP carbonate (5 equiv, 5.7 mmol, 1.74 g) in dry DCM (60 mL). The reaction mixture was stirred at room temperature for 3 d (TLC: $CHCl_3$/MeOH, 10:1). The solvent was evaporated at 30 °C, and the residue was dissolved in ethyl acetate (100 mL) and extracted with pH 5 acetate buffer (2 × 20 mL). The organic phase was washed with water, brine, dried, and the solvent was evaporated at 30 °C. The oily residue was purified by FC eluting with $CHCl_3$/MeOH 15:1 to give **12** as a white solid (1.03 g, 87%). $C_{64}H_{59}N_5O_9$, ESI-MS: calcd $[M + H]^+$ 1042.43, found 1042.20; and calcd $[M + Na]^+$ 1064.43, found 1064.50. HPLC analysis: (system-1; $\lambda = 254$ nm) > 97% of peak area.

Synthesis of the Self-Immolative PABC Linker 10.

EMC-Glu-Phe-Lys(Mtt)-PABC-PNP 10. Et_3N (1.1 equiv, 11 mmol, 1.63 mL) was added at room temperature to a solution of **6** (1 equiv, 10 mmol, 7.0 g) and **2** (1 equiv, 10 mmol) in dry THF (60 mL), and the solution was stirred for 18 h (TLC, $CHCl_3$/MeOH, 10:1). The solution was added slowly to water (1 L). The white precipitate was collected by suction filtration, dissolved in DCM (50 mL), and precipitated with ether (300 mL) and dried to give **7** (8.5 g, 77%). $C_{61}H_{72}N_6O_9$, ESI-MS: calcd $[M + H]^+$ 1033.54, found 1033.20. HPLC analysis: (system-2; $\lambda = 254$ nm) > 88% of peak area. Compound **7** (8.2 mmol, 8.4 g) was then dissolved in a mixture of DCM and TFA (1:1; 20 mL) and stirred at room temperature for 2 h (TLC: DCM/MeOH/H_2O/TFA, 85:15: 1:0.2). A yellow solid precipitated upon adding the solution to diethyl ether (2 L). **8** was collected as a TFA-salt by suction filtration, washed with ether, and dried to give 6.6 g (100%). $C_{37}H_{48}N_6O_9$, ESI-MS: calcd $[M + H]^+$ 721.35, found 721.40. A stirred suspension of **8** (4.3 mmol, 3.5 g) in dry DCM (120 mL) under nitrogen at room temperature was treated with trimethylsilyl chloride (3.1 equiv, 13.3 mmol, 1.73 mL) and DIPEA (1.05 equiv, 4.5 mmol, 805 μL). The mixture was heated at reflux for 1 h, during which time it became homogeneous and then cooled to 0 °C. DIPEA (3.1 equiv, 13.3 mmol, 2.4 mL) was added, followed by 4-methyltrityl chloride (1.05 equiv, 4.3 mmol, 1.40 g). The reaction was stirred at room temperature for 16 h (TLC, DCM/MeOH/H_2O/TFA, 85:15:1:0.2). It was stirred with methanol (10

mL) for 5 min. The solvent was evaporated at 30 °C, and the residue was partitioned between DCM and pH 5 acetate buffer. The organic phase was dried, and the solvent was concentrated under vacuo to 50 mL. Precipitation with hexane yielded **9** as a light yellow solid (4 g, 96%). $C_{57}H_{64}N_6O_9$, ESI-MS: calcd $[M + H]^+$ 977.47, found 977.20. A solution of **9** (3.3 mmol 3.8 g) and bis-PNP carbonate (1.2 equiv, 3.9 mmol, 1.18 g) in dry DCM (100 mL) was treated at room temperature with DIPEA (3 equiv, 9.9 mmol, 1.99 mL) and was stirred for 16 h (TLC, DCM/MeOH/H_2O/TFA, 85:15:1: 0.2). The solvent was then removed in vacuo at 30 °C. The solid residue was triturated with diethyl ether (200 mL), and the precipitate was purified by FC eluting with $CHCl_3$/MeOH 10:1 to give **10** as a white solid (2.0 g, 45%). $C_{64}H_{67}N_7O_{13}$, ESI-MS: calcd $[M + H]^+$ 1142.48, found 1141.80. HPLC analysis: (system-3; $\lambda = 254$ nm) > 94% of peak area.

Synthesis of the Building Unit 14.

H-Phe-Lys(Mtt)-PABC-Paclitaxel 14. DMAP (1 equiv, 0.29 mmol, 36.0 mg) was added to a solution of **12** (0.29 mmol, 300 mg) and paclitaxel (1 equiv, 0.29 mmol, 246 mg) in dry DCM (12 mL), and the solution was stirred at room temperature for 18 h (TLC: $CHCl_3$/MeOH 10:1). The solvent was removed under reduced pressure at 30 °C, and the residue was purified by FC eluting with $CHCl_3$/MeOH 20:1 to give **13** as a white solid (388 mg, 77%). $C_{105}H_{105}N_5O_{20}$, ESI-MS: calcd $[M + H]^+$ 1756.74, found 1756.70. DMAP (40 equiv, 6.83 mmol, 834 mg) was added to a solution of **13** (1 equiv, 0.17 mmol, 300 mg) in dry DCM (40 mL), and the solution was stirred at room temperature for 3 days (TLC: $CHCl_3$/MeOH 10:1). The solvent was removed under reduced pressure at 30 °C, and the residue was purified by FC eluting with $CHCl_3$/MeOH 20:1 to give **14** as a white solid (189 mg, 72%). $C_{90}H_{95}N_5O_{18}$, ESI-MS: calcd $[M + H]^+$ 1534.67, found 1534.50. HPLC analysis: (system-2; $\lambda = 254$ nm) > 75% of peak area.

Synthesis of the Prodrug 16. Triethylamine (1 equiv, 1.31 mmol, 182 μL) was added to a solution of **10** (1 equiv, 1.31 mmol, 1.50 g) and doxorubicin hydrochloride (1 equiv, 1.31 mmol, 0.761 g) in dry DMF (20 mL), and the solution was stirred at room temperature for 18 h (TLC: $CHCl_3$/MeOH 7:1). The product was precipitated with ether (1 L) and was purified by FC eluting with $CHCl_3$/MeOH 15:1 to give **11** as a red solid (1.52 g, 75%). $C_{85}H_{91}N_7O_{21}$, ESI-MS: calcd $[M + H]^+$ 1546.63, found 1546.00 $[M + H]^+$. HPLC analysis: (system-3; $\lambda = 220$ nm) > 90% of peak area. A solution of **11** (0.036 mmol, 55 mg), HATU (1.1 equiv, 0.039 mmol, 14.8 mg), HOBt (1 equiv, 0.036 mmol, 4.78 mg), DIPEA (2 equiv, 0.072 mmol, 11 μL), and **14** (1 equiv, 0.036 mmol, 70 mg) in dry DMF (800 μL) was stirred at room temperature for 4 h (TLC, $CHCl_3$/MeOH, 10:1). The product was precipitated with ether (100 mL) and was then purified by FC ($CHCl_3$/MeOH, 15:1) to give after solvent removal in vacuo at 30 °C **15** as a red solid (100 mg, 93%). $C_{175}H_{184}N_{12}O_{38}$, ESI-MS: calcd $[M + 2H]^{2+}$ 1531.65, found 1531.65. HPLC analysis: (system-4; $\lambda = 495$ nm, retention time 42.62 min) > 94% of peak area. A solution of **15** (82 mg) in DCM (5 mL) was treated with a solution of 1% TFA in DCM (5 mL) and was stirred at room temperature for 24 h (HPLC; system-4). The product was precipitated with ether (80 mL), centrifuged, and further washed with ether (40 mL) and centrifuged. The residue was dissolved in MeOH/mobile phase A (1:2, 5 mL) and purified by preparative C_{18}-RP-HPLC. After lyophilization, 30 mg (44%) of **16** was obtained as a red solid. $C_{135}H_{152}N_{12}O_{38}$, ESI-MS: calcd $[M + 2H]^{2+}$ 1275.52, found 1275.52. HPLC analysis: column, symmetry 300 from Waters; ($\lambda = 495$ nm; retention time 29.38 min) > 97% of peak area; ($\lambda = 254$ nm; retention time 29.99 min) > 90% of peak area. Mass spectrum is included as Supporting Information.

Synthesis of the Albumin Conjugate of 16 (HSA-16). A solution of **16** in DMF (500 μL, 6.32 mg/791 μL, 3 mM) was diluted in EtOH (2 mL) and incubated with human serum albumin [(HSA) 5% octalbin] (4.5 mL) under stirring at 37 °C for 1 h, after which no free **16** was detectable by HPLC.

The albumin conjugate was obtained after subsequent size-exclusion chromatography (Sephacryl S-100, 50 mM sodium acetate buffer - pH 5.0). The content of anthracycline in the sample was determined using the ε-value for doxorubicin [ε_{495} (pH 7.4) = 10 650 M^{-1} cm^{-1}]. The concentration of doxorubicin in the conjugate **HSA-16** was adjusted to 290 μM by concentrating the sample with CENTRIPREP-10-concentrators (Amicon, FRG) (4 °C and 4500 rpm) to 800 μL (HPLC analysis: $\lambda = 495$ nm; retention time: 25.16 min >99% of peak area). Samples were kept frozen at −80 °C and thawed prior to use.

Cleavage Studies with Cathepsin B. 300 μL of the **HSA-16** stock solution (100 μM with respect to doxorubicin) was mixed with 10 μL cathepsin B (0.4 μg/mL, 23.8 U/mg) and 30 μL of buffer (50 mM sodium acetate buffer, pH 5.0) containing L-cysteine (8 mM). The mixture was incubated at 37 °C, and aliquots were removed at various time points and analyzed by HPLC.

RESULTS AND DISCUSSION

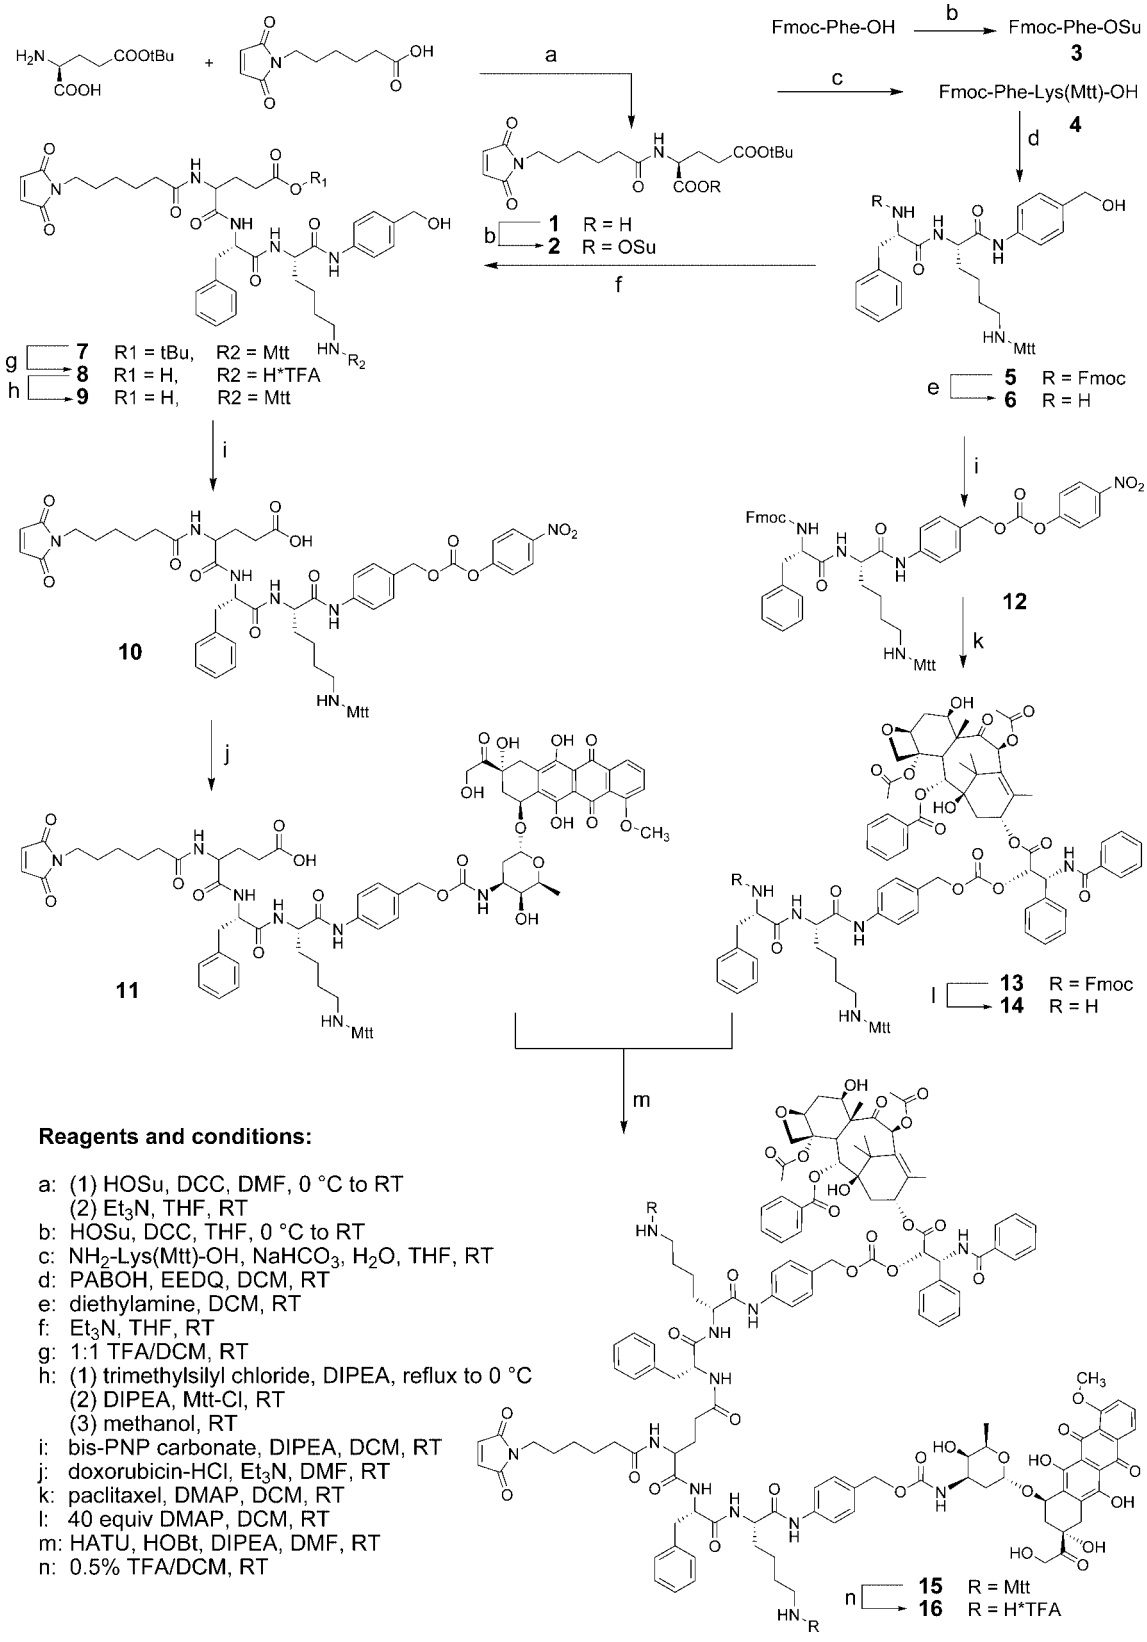
Chemistry. The initial step in the development of our dual-acting prodrugs was the synthesis of a bifunctional maleimide linker **2** that allows the attachment of two enzymatically cleavable substrates for both active compounds. Its synthesis (Scheme 1) is based on the bifunctional compound **1** that incorporates a protein-binding maleimide group and a free as well as a protected carboxylic acid moiety. **1** was obtained from the reaction of *tert*-butyl ester glutamic acid with 6-maleimidocaproic acid in the presence of *N*-hydroxysuccinimide (HOSu) and *N,N′*-dicyclohexylcarbodiimide (DCC). Upon its reaction with HOSu and DCC in THF, **1** was converted into the HOSu-activated ester **2** for subsequent reaction with the free amino groups of a first peptide derivative.

In our route, we wanted to introduce a self-immolative Phe-Lys-PABC-spacer (PABC = *para*-aminobenzyloxycarbonyl) in the two arms of the maleimide derivative **1**. The synthesis of the cathepsin B sensitive peptides **6** was performed according to a modified procedure of the work of Dubowchik et al. (*16*) replacing the methoxytrityl (Mmt) group in the original work with methyltrityl (Mtt) group as the protecting group of the side chain amino group of lysine. Mtt can be removed at the required step in very mild acidic media, such as with 1−2% trifluoroacetic acid (TFA) in dichloromethane (DCM) (*28*) where doxorubicin should be stable.

A triethylamine (Et_3N) catalyzed coupling of the dipeptide moiety **6** to the bifunctional maleimide linker **2** yielded the branched bifunctional peptide **7** that contains a protein-binding maleimide group, a protected carboxylic group, as well as the *para*-aminobenzyl alcohol (PABOH) moiety for conjugating with the first drug (see Scheme 1).

Prior to this, for subsequent binding of the second drug moiety, the *tert*-butyl carboxylic group of **7** needs to be deprotected and the ε-amino group of lysine has to be protected again with the acid-labile Mtt group. Thus, treatment of **7** with 50% TFA in DCM yielded **8** quantitatively. Mtt was further introduced in a one-pot tritylation procedure through activation with trimethylsilyl (TMS) (*29*) of **8** in which both the amino and carboxyl groups are silylated first with TMS-Cl, followed by a base-catalyzed reaction with 4-methyltrityl chloride (Mtt-Cl) to give **9** in high yields. The self-immolative spacer of **9** was subsequently reacted with bis(*para*-nitrophenyl) carbonate (bis-PNP carbonate) to give the activated carbonate **10**.

Scheme 1. Synthesis of Prodrug 16



The bifunctional maleimide linker **10** represents a key building block that can be derivatized with a wide spectrum of anticancer drugs for the development of enzymatically cleavable dual-acting prodrugs. In addition to a protein-binding maleimide group, it incorporates two orthogonal functionalities for the introduction of the drugs: (i) the carbonate group for introducing the first active compound either as a carbonate or as a carbamate through its reaction with the hydroxyl or amino groups of the drug; (ii) a free carboxylic acidic group for binding the second active compound after step (i).

For preparing a doxorubicin−paclitaxel prodrug, we introduced doxorubicin in a first step by reacting the bifunctional linker **10** with doxorubicin in the presence of triethylamine, yielding **11**. To introduce paclitaxel in the prodrug, we

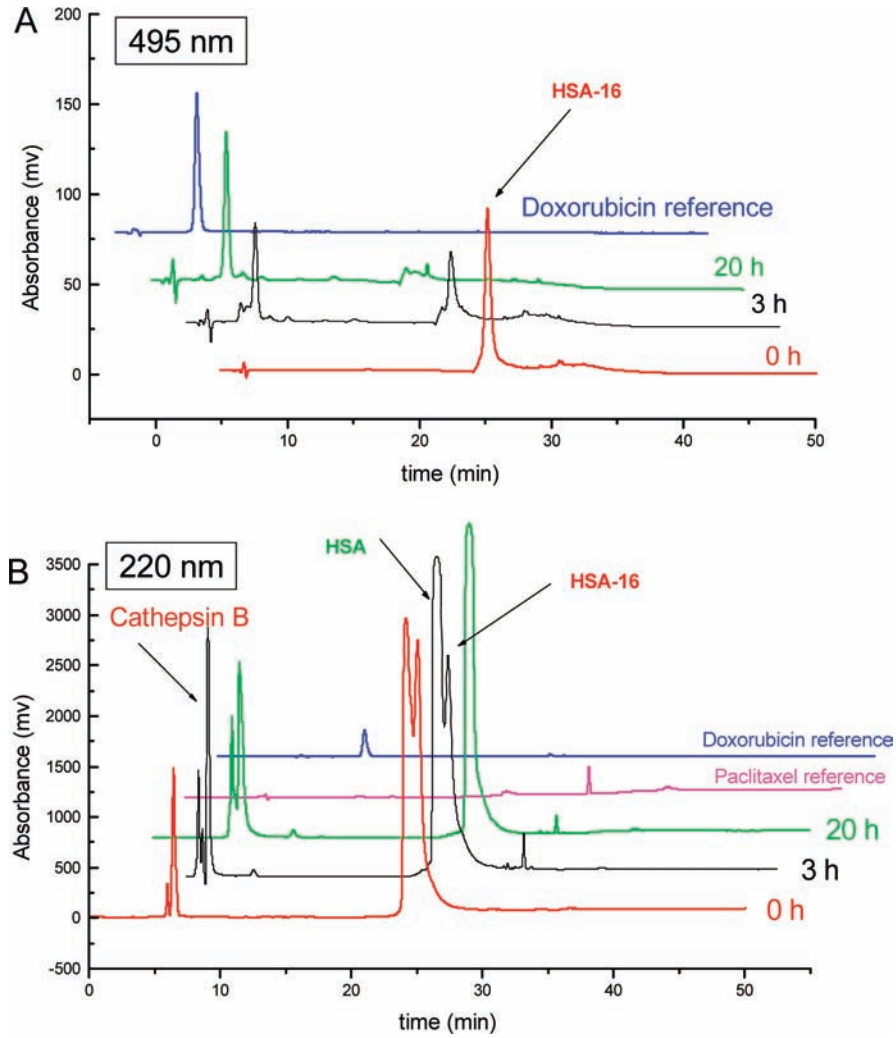


Figure 2. Chromatograms of incubation studies of **HSA-16** (100 μM) with activated cathepsin B (10 μL; 0.095 U) at 37 °C and detected at 495 nm (A) and 220 nm (B). Chromatograms of doxorubicin and paclitaxel (100 μM) are included as references.

synthesized the building block **14** in a 4-(dimethylamino)pyridine (DMAP) catalyzed reaction of paclitaxel and the activated carbonate **12** with subsequent cleavage of the Fmoc group. The desired prodrug in its protected form **15** was obtained from the reaction of **11** with **14** in the presence of *O*-(azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU) and 1-hydroxybenzotriazole (HOBt).

In a final step, we attempted to remove the Mtt groups using the standard cleavage conditions (1% TFA in DCM) of the Mtt-protecting groups in **15**. However, under these conditions, doxorubicin was not stable, producing large amounts of aglycone. To overcome these problems, we optimized the cleavage conditions by dissolving **15** in DCM before it was treated with DCM containing 1% TFA. Cleavage of both groups was successfully performed with a final concentration of 0.5% TFA in DCM. The desired doxorubicin−paclitaxel prodrug **16** was then purified by preparative C_{18}-RP-HPLC chromatography and lyophilized to obtain a red product. The prodrug **16** was characterized by analytical HPLC and ESI-MS (see Supporting Information).

Cleavage Studies with the Albumin-Bound form of 16. Our second aim after the synthesis of the dual-acting prodrug **16** was to ascertain whether cathepsin B can cleave the dual-acting prodrug once bound to a protein carrier. Thus, prodrug **16** was bound through its maleimide moiety to the cysteine-34 group of human serum albumin (HSA) to give the albumin-bound prodrug **HSA-16**. The incubation of **HSA-16** with activated cathepsin B is monitored at two different wavelengths. Doxorubicin and **HSA-16** can be detected at 495 and 220 nm, whereas paclitaxel and cathepsin B can only be observed at 220 nm. The chromatographic profile at 220 nm showed two peaks: the first at 24.2 min corresponding to nonmercaptalbumin, and the second at 25.0 min that we assigned to **HSA-16**, considering that for the synthesis the employed octalbin (5%) contained ~60% free thiol groups (see Figure 2).

The cleavage properties of compound **HSA-16** were evaluated using enzymatically active cathepsin B at pH 5.0. Reverse phase HPLC showed that incubation with cathepsin B resulted in an efficient and almost complete cleavage over a period of 20 h (Figure 2). At 220 nm, the peak at 25.0 min that corresponds to **HSA-16** disappears after incubation with cathepsin B for 20 h. The main cleavage products were identified by HPLC to be the free anticancer agents doxorubicin (eluting at 10.8 min) and paclitaxel (eluting at 30.8 min).

In conclusion, for the development of dual-acting prodrugs we have synthesized for the first time a bifunctional maleimide linker which consists of a maleimide group, a carboxylic acid group, and an activated Phe-Lys(Mtt)-PABC linker **10**. Aided with this linker, we have prepared an albumin-binding prodrug containing the anticancer drugs doxorubicin and paclitaxel **16**. **16** binds rapidly and selectively to the cysteine-34 position of endogenous serum albumin and is cleaved specifically by cathepsin B releasing the free drugs.

We anticipate that such bifunctional linkers will pave the way for the development of a next generation of albumin-binding

prodrugs that contain two anticancer agents. The bifunctional linker **10** has proven to be fruitful in the synthesis of other prodrugs under development in our group (*30*).

^{18}F Labeled Nanoparticles for *in Vivo* PET-CT Imaging

Neal K. Devaraj,† Edmund J. Keliher,† Greg M. Thurber, Matthias Nahrendorf, and Ralph Weissleder*

Center for Systems Biology, Massachusetts General Hospital and Harvard Medical School, Simches Research Building, 185 Cambridge Street, Boston, Massachusetts 02114, and Center for Molecular Imaging Research, Massachusetts General Hospital and Harvard Medical School, Building 149, 13th Street, Charlestown, Massachusetts 02129. Received October 27, 2008; Revised Manuscript Received December 5, 2008

We report the synthesis and in vivo characterization of an ^{18}F modified trimodal nanoparticle (^{18}F-CLIO). This particle consists of cross-linked dextran held together in core−shell formation by a superparamagnetic iron oxide core and functionalized with the radionuclide ^{18}F in high yield via "click" chemistry. The particle can be detected with positron emission tomography, fluorescence molecular tomography, and magnetic resonance imaging. The presence of ^{18}F dramatically lowers the detection threshold of the nanoparticles, while the facile conjugation chemistry provides a simple platform for rapid and efficient nanoparticle labeling.

INTRODUCTION

Polymer-coated metal core nanoparticles have emerged as important platforms for a variety of biological applications such as bioseparation, sensing, molecular imaging, and drug delivery. Examples of such materials include carbohydrate-coated iron oxide nanoparticles (*1*−*3*) for magnetic applications, synthetic polymer coated cores for molecular imaging (*4*, *5*), gold nanoshells for therapy, or biocompatible quantum dots (*6*, *7*). Magnetic nanoparticles, in particular, have received much attention, as they were shown to be biocompatible (*8*) and have low clinical toxicity (*9*), and subsequently were among the first nanomaterials tested in clinical trials (*10*). While native carbohydrate-coated preparations primarily target macrophages, monocytes, and other phagocytic cells in vivo, conjugation of affinity ligands has been used to image other molecular targets in vivo (*11*, *12*). We have recently shown that small molecule modifications (*13*) can yield uniquely targeted nanoparticles with low toxicities (*14*). Despite these advances, the in vivo detection threshold of nanoparticles via magnetic resonance is generally in the micromolar range requiring an estimated ∼200−700 mg (Fe) for a 70 Kg patient.

One avenue to substantially decrease the detection threshold and therefore the clinical dose is to label nanoparticles with positron emitters and detect them by position emission tomography (PET) imaging. Recently, we reported the use of a ^{64}Cu labeled trireporting nanoparticle that could be used at ∼100 times lower doses for PET imaging as compared to MRI and was employed to image macrophages in inflammatory atherosclerotic plaques (*15*). This material was based on aminated cross-linked dextran iron oxide (CLIO) decorated with diethylene triamine pentaacetic acid (DTPA) to transchelate ^{64}Cu. While we showed proof of principle, ^{64}Cu is not widely available, complicating clinical day-to-day on-demand syntheses. On the contrary, ^{18}F is a widely available PET isotope that is produced daily in cyclotrons of most major hospitals and distribution centers. ^{18}F has additional advantages over ^{64}Cu such as higher sensitivity, shorter half-life, and the ability of irreversible covalent bonding. Despite these advantages, the addition of ^{18}F to functionally complex materials is chemically challenging and is a major reason for the absence of reports of ^{18}F iron nanoparticles. Here, we report a facile and straightforward synthesis method for an ^{18}F trimodal nanoparticle (^{18}F-CLIO, Figure 1) and demonstrate its use for in vivo PET imaging. In this work, we have used "click" chemistry (*16*, *17*), the copper-catalyzed azide−alkyne cycloaddition, to introduce ^{18}F onto an azide-modified nanoparticle.

The introduction of ^{18}F to functionally complex molecules has been an outstanding problem in nuclear chemistry. Though there are many reported conjugation methods, most suffer from the requirement of harsh coupling conditions, long reactions times, multistep protocols, or poor overall yields. A number of ^{18}F labeling methods have been described and are conceivable for nanoparticle labeling. One such method, nucleophilic aromatic substitution, used to prepare *N*-succinimidyl 4-[^{18}F]fluorobenzoate and 4-[^{18}F]fluorobenzaldehyde, either requires multiple steps post-labeling to obtain an amine-reactive species for the former or produces a volatile compound difficult to concentrate for subsequent bimolecular reactions in the case of the latter (*18*, *19*). In contrast, "click" chemistry, specifically copper-catalyzed azide−alkyne cycloaddition, has proven to be an extremely robust, mild, conceptually simple, and chemoselective method to conjugate function to complex macromolecules and biomolecules. Recently, there have been a variety of reports demonstrating that the "click" reaction can be used efficiently and mildly to conjugate an ^{18}F label to a variety of peptides and small molecules (*20*, *21*). These reports motivated us to explore the application of "click" chemistry to modify nanoparticles with ^{18}F.

MATERIALS AND METHODS

Materials. All reagents were purchased from from Sigma-Aldrich and used without further purification unless otherwise noted. 1-Amino-11-azido-3,6,9-trioxaundecane was purchased from Toronto Research Chemicals and used as received. Sodium [^{18}F]-fluoride (Na[^{18}F]F) in ^{18}O -enriched water was purchased from PETNET (Woburn, MA). The well-characterized nanoparticle MION (MGH-CMIR, Charlestown, MA) served as starting material (*2*). The dextran coating of the nanoparticle was cross-linked with epichlorin hydrin, aminated, and labeled with near-infrared fluorochrome Vivotag-680 (VT680, VisEn Medical, Woburn, MA) (*22*). The ratio of VT680 per nanopar-

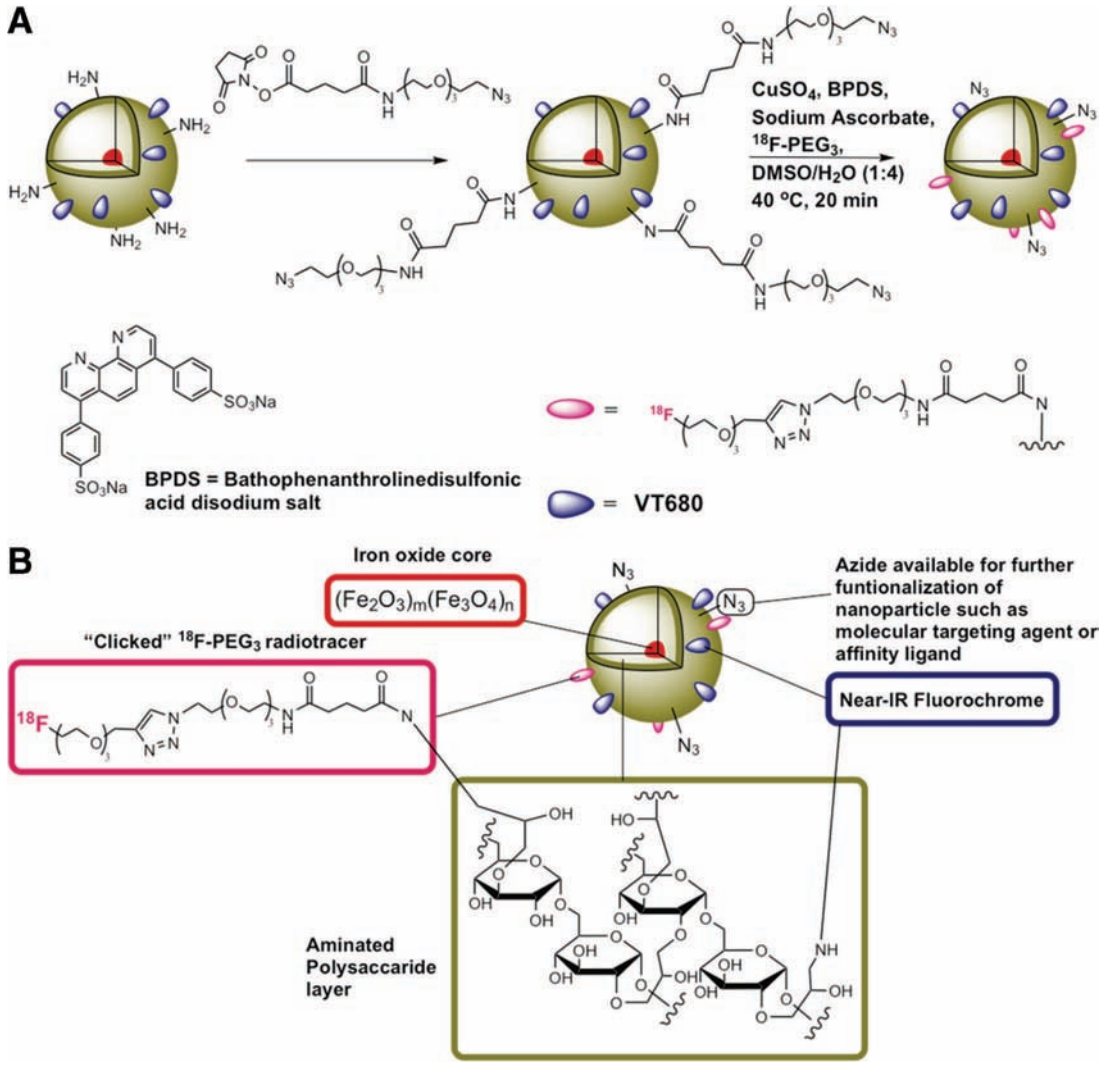

Figure 1. Preparation of ^{18}F-CLIO. (A) Derivatization of primary amines on CLIO-VT680 with the NHS ester of 1-azido-13-oxo-3,6,9-trioxa-12-azaheptadecan-17-oic acid followed by chemoselective "click" of ^{18}F-PEG$_3$ radiotracer. (B) Schematic of ^{18}F-CLIO.

ticle was approximately 5 dye moieties/particle. Preparative-scale high-performance liquid chromatography (HPLC) purification was achieved using a Machery-Nagel Nucleodur C18 Pyramid 250 × 10 mm Vario-Prep column (60:40 0.1% trifluoroacetic acid (v/v) in water−acetonitrile (AcCN) at 5.5 mL.min^{-1}) with a 254 nm UV detector and radiodetector connected in series. Analytical HPLC was performed employing a Grace VYDAC (218TP510) C18 reversed-phase column (eluents 0.1% TFA (v/v) in water and AcCN; gradient: 0−17 min, 5−60% B; 17−21 min, 60−95% B; 21−24 min, 95% B; 24−25 min, 95−5% B; 25−30 min, 5% B; 2 mL.min^{-1}) with a dual-wavelength UV−vis detector and a flow-through gamma detector connected in series. HyperSep C18 cartridges were purchased from Thermo Electron (Bellefonte, PA) and Sep-pak VAC Alumina-N cartridges from Waters (Milford, MA).

Synthesis of ^{18}F-PEG$_3$. The preparation of the 2-(2-(2-(prop-2-ynyloxy)ethoxy)ethoxy)ethyl tosylate (*20*) precursor started from the monopotassium salt of triethylene glycol, which was alkylated with propargyl bromide. This propargyl PEG$_3$ was treated with tosyl chloride in the presence of triethyl amine. 3-(2-(2-(2-[^{18}F]-Fluoroethoxy)-ethoxy)ethoxy)prop-1-yne (^{18}F-PEG$_3$) was prepared using Synthra RN Plus automated synthesizer (Synthra GmbH, Hamburg, Germany) operated by *Explora View* software in an average time of 40 min. The target well was charged with Na[^{18}F]F, n.c.a., (∼1850 MBq, 50 mCi) in $H_2{}^{18}O$ (150 μL), 150 μL of a 74 mM K_2CO_3 solution in water, and 250 μL of 49 mM Kryptofix 2.2.2 in AcCN. The synthesizer reagent vials were filled as follows: A2 with AcCN (350 μL), A3 with tosylate **2** (1.0 mg, 19.2 μmol) in DMSO (400 μL), A5 with DMSO (50 μL), and B2 with H_2O (900 μL). The Na[^{18}F]F/K_2CO_3/K2.2.2 solution was transferred to Reaction Vessel #1 and dried by azeotropic distillation of the acetonitrile/water solution by heating to 60 °C under reduced pressure and a flow of argon to achieve ∼310 mbar for 2 min followed by 98 °C and 270 mbar for 3 min. Reaction Vessel #1 was cooled to 50 °C, tosylate **2** in DMSO (400 μL) added, and the reaction vessel pressurized to 2000 mbar and heated to 110 °C for 15 min. After cooling to 30 °C, the mixture was filtered through an Alumina-N cartridge (100 mg, 1 mL, Waters) into Reaction Vessel #2. The Alumina-N cartridge was washed with DMSO (50 μL), and the combined filtrates were diluted with water (900 μL). This solution was subjected to preparative HPLC purification. ^{18}F-PEG$_3$ was collected (t_R = 4.9 min) in 3−4 mL of solvent and isolated by C18 solid-phase extraction. Elution of the collected material with CH_2Cl_2 (600 μL) to give ^{18}F-PEG$_3$ in 57% average decay-corrected radiochemical yield (RCY). Analytical HPLC demonstrated >99% radiochemical purity of ^{18}F-PEG$_3$, Figure 2.

Preparation of Azido-PEG Modified CLIO. 1-Amino-11-azido-3,6,9-trioxaundecane (218 mg, 1 mmol) and glutaric anhydride (114 mg, 1 mmol) were dissolved in 1 mL methylene chloride and refluxed for 1 h. Evaporation of solvent yielded

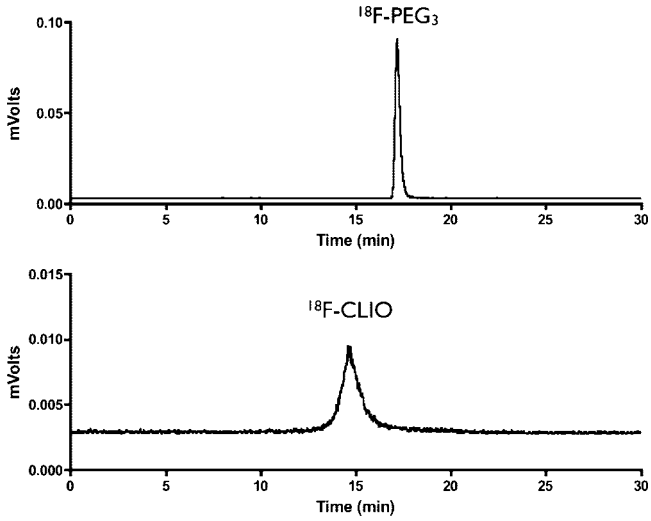

Figure 2. HPLC analysis of purified ^{18}F-PEG$_3$ and ^{18}F-CLIO demonstrating >98% purity.

1-azido-13-oxo-3,6,9-trioxa-12-azaheptadecan-17-oic acid quantitatively, verified by LRMS-ESI $[M + H]^+$ *m*/*z* calc. $[C_{13}H_{25}N_4O_6]^+$ 333.17, found 333.3. The azido−acid (33 mg, 0.1 mmol) was stirred for 3 h in 0.3 mL AcCN with 8 μL of pyridine and 26 mg of disuccinimidylcarbonate. The AcCN was evaporated, and the resulting crude *N*-hydroxysuccinimide ester was used directly with amine-terminated iron oxide nanoparticles. The aminated cross-linked dextran iron oxide (CLIO) nanoparticle was prepared as previously described (*23*). Nanoparticles were approximately 30 nm in diameter and contained on average 40 primary amines. Aminated CLIO was functionalized first with NHS modified VT680 (VisEn Medical, Woburn, MA) such that there were approximately 5 molecules of VT680 per particle. The remaining amines were capped with the NHS ester of 1-azido-13-oxo-3,6,9-trioxa-12-azaheptadecan-17-oic acid to give the CLIO-azide. In a typical coupling procedure, 0.4 mg of amine-terminated CLIO was dissolved in 0.5 mL of 0.1 M sodium bicarbonate buffered to a pH of 8.5. To this solution was added 40 μL of DMSO containing 1 mg of the azido *N*-hydroxysuccinimide ester. The solution was stirred at room temperature for 2 h, purified by centrifuge filtration, and stored in PBS buffered to pH 7.4.

Conjugation. ^{18}F-PEG$_3$ in 50−100 μL water added to the azido-CLIO (50 μL of a 400 μg/100 μL 1×PBS (phosphate buffered solution)) was subjected to water-soluble copper-catalyzed 1,3-dipolar cycloaddition reaction conditions: 40 μL 10 mM $Cu^{(II)}SO_4$/bathophenanthrolinedisulfonic acid disodium salt (BPDS) in distilled water/DMSO (3:1) and 40 uL 100 mM Na-ascorbate in distilled water (*24*). The reaction mixture was incubated for 40 min at 40 °C and filtered to remove the ^{18}F-CLIO from unreacted ^{18}F-PEG$_3$. ^{18}F-CLIO was washed with 1×PBS until no activity was collected in the filtrate (>1 μCi). HPLC analysis demonstrated >99% radiochemical purity of ^{18}F-CLIO (Figure 2). The ^{18}F-labeled nanoparticle was suspended in DPBS (Dulbecco's phosphate buffered solution with Ca^{2+} and Mg^{2+}).

Phantom Experiment. To compare the sensitivity of nanoparticle detection with MRI and PET, ^{18}F-CLIO was diluted in 2% low melting agarose to concentrations ranging from 0.005 to 10 μg Fe /mL and added to wells in a precast gel. PET-CT imaging of 2 gels was followed by MRI using a 7 T Pharmascan magnet (Bruker, Billerica, MA) and employing a T2* weighted gradient echo sequence (TE 140 ms, matrix 128 × 128, FOV 60 × 40 mm^2, slice thickness 0.8 mm).

Mice. Inbred male BALB/c (B/c, H-2d) mice (8−12 weeks old) were obtained from Jackson Laboratory (Bar Harbor, ME). The mice were maintained at the animal facilities of Massachusetts General Hospital, accredited by the American Association of Laboratory Animal Care. All experiments conformed to animal care protocols approved by the institutional review board.

PET Imaging. Mice were imaged with PET-CT one hour after injection of 998 ± 74 μCi of ^{18}F -CLIO (n = 6). This concentration was about 1 order of magnitude lower than previously used for MRI (10−20 mg Fe/kg). PET-CT was performed on an Inveon system (Siemens Preclinical Solutions). PET scans were terminated after 600 million events were recorded, with a typical acquisition time of 45 min. Spatial resolution of PET imaging approximated 1 mm isotropic. Acquisition coincidence data were rebinned using Fourier rebinning in 3D, and the resulting sinogram was reconstructed using an ordered subsets expectation maximization (OSEM) algorithm. For quantification of standard uptake values (SUV), images were reconstructed using 2D filtered back projection (FBP). The CT X-ray source was used with a power of 80 kVp and 500 μA and an exposure time of 370−400 ms. The effective 3D resolution was 90 μm isotropic. Typically, 360 projections were acquired. The reconstruction protocol was set to interpolate bilinearly, used a Shepp-Logan filter, and signal intensity was scaled to Hounsfield units. To achieve appropriate intravascular contrast, iopamidol 61% (Bracco Diagnostics, Princeton, NJ) was continuously infused via tail vein at a rate of 65 μL/min for the time of CT acquisition, which was approximately 7 min. Fused images were converted into DICOM format and analyzed using OsiriX shareware (Geneva, Switzerland, www.osirix-viewer.com) by placing volumes of interest in the various organs for calculation of target-to-background ratios. Standard uptake values (SUV) were calculated as (tissue activity/volume of tissue)/(body activity/body weight).

Pharmacokinetic Analysis. Blood half-life data obtained from the heart (blood pool organ) were fit to a biexponential model, and the half-life is reported as the weighted average of the distribution and clearance phases. For fitting permeability surface area product (PS/V) values, the average concentration of activity (decay corrected) in a region of interest determined by CT was measured for the time series. The interstitial concentration was obtained by subtracting the blood contribution using the plasma fraction for each organ. Assuming an interstitial void fraction of 0.05 for these particles, PS/V was fit using the plasma clearance and specific organ data. Due to the early imaging sequence with ^{18}F, clearance was assumed to be negligible for all organs (uptake only) except the lung. The lung had similar low levels of activity as the kidney but demonstrated decreasing signal at later time points. Here, a value for lymphatic clearance was assumed to obtain a reasonable fit.

RESULTS

3-(2-(2-(2-[^{18}F]-Fluoroethoxy)ethoxy)ethoxy)prop-1-yne (^{18}F-PEG$_3$) was prepared in 57% average decay-corrected radiochemical yield from an alkynyl tosylate (see Supporting Information for full experimental details). ^{18}F-PEG$_3$ is prepared in one step and when compared with 4-[^{18}F]fluorobenzaldehyde is relatively nonvolatile. This quality allows concentration of ^{18}F-PEG$_3$ to almost dryness, thus increasing the yield of the bimolecular second step. "Click" reaction with an azide-terminated CLIO yielded ^{18}F-CLIO with a decay-corrected yield of 58%. Both ^{18}F-PEG$_3$ and ^{18}F-CLIO were analyzed by HPLC to determine radiochemical purity. Following preparative HPLC purification of ^{18}F-PEG$_3$ and microcentrifuge filtration of ^{18}F-CLIO, both were observed to be >98% pure (Figure 2). Average total ^{18}F-CLIO synthesis time was 120 min from the start of radiolabeling of ^{18}F-PEG$_3$. ^{18}F-CLIO had an average specific activity of 1.1 mCi/0.1 mg of nanoparticles. Control experiments

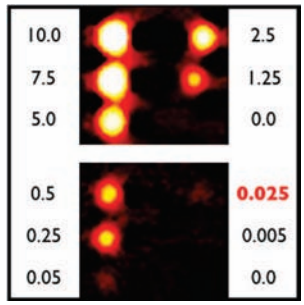

Figure 3. PET imaging of 2 agar phantoms with decreasing concentrations of ^{18}F-CLIO (μg Fe/mL).

using nanoparticles without azides or the absence of the copper catalyst failed in demonstrating the chemoselectivity of the conjugation.

The detection threshold of ^{18}F-CLIO suspended in the agar phantom was 0.025 μg Fe/mL for PET-CT imaging, approximately 200 times lower than by T2*-weighted MR imaging (Figure 3). This is an improvement from ^{64}Cu-labeled nanoparticles of comparable specific activity. The increased sensitivity was expected due to the increased branching ratio for the decay of ^{18}F over ^{64}Cu (*25*). As previously determined, the lowest observed concentration of the nanoparticles by MRI was 5 μg Fe/mL (*15*), demonstrating a PET detection threshold 200 times more sensitive than MRI at current specific activities. It is expected that optimization of reaction yields will further decrease the PET detection threshold.

Purified ^{18}F-CLIO was injected into the tail vein of 3 mice, and dynamic PET imaging was performed to determine organ biodistribution and blood clearance over time. Figure 4 summarizes one imaging series in which data were collected over the course of 16 h after intravenous injection of ^{18}F-CLIO and shows images acquired at 2, 7, and 16 h. Initially, high sustained activity was detected in the blood pool, demonstrated by high PET signal in the cardiac chambers. Over time, this signal declined, while an increase of activity was observed in the liver and spleen. Using compartmental analysis, the uptake rate in the liver was much higher than uptake by the kidney (~4-fold, Table 1), and some of the renal activity may have indeed been due to the close proximity of the region of interest to the liver. The low renal and bladder uptake emphasizes that ^{18}F-CLIO is stable in vivo, and the tracer is not excreted via the kidneys. Taken together, these PET data follow the typical pharmacokinetics of CLIO, showing redistribution of the blood pool signal to the liver and lymphatic organs over the course of several hours (Figure 4D−F).

In vivo dynamic PET imaging showed very high signal-to-noise ratios for injected ^{18}F-CLIO. As summarized in Figures 4 and 5, the nanoparticle has a vascular half-life of 5.8 h in mice and is subsequently internalized into macrophages of liver, spleen, and phagocytic cells of other lymphatic organs. The nanoparticle is biodegradable and had previously been shown to be broken down into elemental components in weeks−months time frames (*8*). There was negligible urine and/or bowel excretion (<2%) over 24 h. The iron is metabolized and is reused in heme synthesis (*8*). The 10 kDa dextran coating is slowly excreted as determined by ^{14}C labeling studies. While long-term toxicity experiments have not been conducted for this agent, an adverse reaction is not expected due to the substantially lower iron doses administered than those of previous studies that demonstrated no adverse acute, subacute, or chronic effects (*8, 15*).

DISCUSSION

A major future application of the above approach is to use nanoparticle platforms for targeted molecular imaging. Nanoparticles allow multivalent attachment of small affinity ligands, vastly increasing avidity. This together with optimized pharmacokinetics of parent materials would allow a modular approach to rapidly building and testing such materials. Our

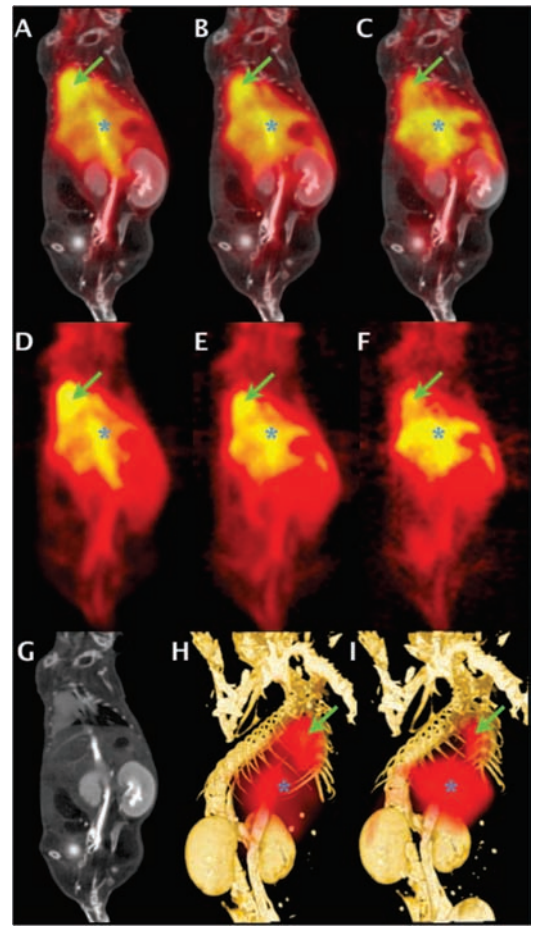

Figure 4. Dynamic PET/CT imaging of BALB/C mouse injected with ^{18}F-CLIO**.** Fused PET/CT coronal images at 2 h (A), 7 h (B), and 16 h (C) postinjection of ^{18}F-CLIO. PET only coronal images at 2 h (D), 7 h (E), and 16 h (F) postinjection of ^{18}F-CLIO. CT only coronal image (G). approach for ^{18}F labeling of such materials is yet another step to rapidly test their efficacy in vivo. The ability to use targeted nanomaterials at 2−4 orders of magnitude lower doses than those required for MR imaging will likely make PET imaging an important platform for clinical molecular imaging.

ACKNOWLEDGMENT

The Center of Cancer Nanotechnology Excellence (U54-CA119349), the Translational Program of Excellence in Nanotechnology (UO1-HL080731), and NIH training grant T32-CA79443 supported this work. The authors would like to thank Jose-Luiz Figureiredo for helpful discussions, Brett Marinelli for conducting the PET-CT imaging, and Nikolay Sergeyev for preparing the CLIO nanoparticles.

MATERIALS AND METHODS

Materials

All reagents were purchased from from Sigma-Aldrich and used without further purification unless otherwise noted. 1-Amino-11-azido-3,6,9-trioxaundecane was purchased from Toronto Research Chemicals and used as received. Sodium [^{18}F]-fluoride (Na[^{18}F]F) in ^{18}O-enriched water was purchased from PETNET (Woburn, MA). The well characterized nanoparticle MION (MGH-CMIR, Charlestown, MA) served as starting material. (1) The dextran coating of the nanoparticle was crosslinked with epichlorin hydrin, aminated and labeled with near infrared fluorochrome Vivotag-680 (VT680, VisEn Medical, Woburn, MA). (2) The ratio of VT680 per nanoparticle was approximately 5 dye moieties/particle. Preparative scale high-performance liquid chromatography (HPLC) purification was achieved using a Machery-Nagel Nucleodur

C18 Pyramid 250 x 10 mm Vario-Prep column (60:40 0.1 % trifluoroacetic acid (v/v) in water-acetonitrile (AcCN) at 5.5 $ml \cdot min^{-1}$) with a 254 nm UV detector and radiodetector connected in series. Analytical HPLC was performed employing a Grace VYDAC (218TP510) C18 reversed-phase column (eluents 0.1% TFA (v/v) in water and AcCN; gradient: 0-17 min, 5-60% B; 17-21 min, 60-95% B; 21-24 min, 95% B; 24-25 min, 95-5% B; 25-30 min, 5% B; 2 $mL \cdot min^{-1}$) with a dual-wavelength UV-Vis detector and a flow-through gamma detector connected in series. HyperSep C18 cartridges were purchased from Thermo Electron (Bellefonte, PA) and Sep-pak VAC Alumina-N cartridges from Waters (Milford, MA).

Synthesis of ^{18}F-PEG$_3$. The preparation of the 2-(2-(2-(prop-2-ynyloxy)ethoxy)ethoxy)ethyl tosylate(3) precursor started from the mono-potassium salt of triethylene glycol which was alkylated with propargyl bromide. This propargyl PEG_3 was treated with tosyl chloride in the presence of triethyl amine. 3-(2-(2-(2-[^{18}F]-Fluoroethoxy)-ethoxy)ethoxy)prop-1-yne (^{18}F-PEG_3) was prepared using Synthra RN Plus automated synthesizer (Synthra GmbH, Hamburg, Germany) operated by Explora View software in an average time of 40 min. The target well was charged with Na[^{18}F]F, n.c.a., (~1850 MBq, 50 mCi) in $H_2{}^{18}O$ (150 μ L), 150 μ L of a 74 mM K_2CO_3 solution in water, and 250 μ L of 49 mM Kryptofix 2.2.2 in AcCN. The synthesizer reagent vials were filled as follows: A2 with AcCN (350 μ L), A3 with tosylate **2** (1.0 mg, 19.2 μ mol) in DMSO (400 μ L), A5 with DMSO (50 μ L), and B2 with H_2O (900 μ L). The Na[^{18}F]F/K_2CO_3/K2.2.2 solution was transferred to Reaction Vessel #1 and dried by azeotropic distillation of the acetonitrile/water solution by

heating to 60 ^{o}C under reduced pressure and a flow of argon to achieve ~310 mbar for 2 min followed by 98 ^{o}C and 270 mbar for 3 min. Reaction Vessel #1 was cooled to 50 ^{o}C, tosylate **2** in DMSO (400 μ L) added, the reaction vessel pressurized to 2000 mbar, and heated to 110 ^{o}C for 15 min. Cooled to 30 ^{o}C, the mixture was filtered through an Alumina-N cartridge (100 mg, 1 mL, Waters) into Reaction Vessel #2. The Alumina-N cartridge was washed with DMSO (50 μ L) and the combined filtrates were diluted with water (900 μ L). This solution was subjected to preparative HPLC purification. ^{18}F-PEG$_3$ was collected (t_R = 4.9 min) in 3-4 mL of solvent and isolated by C18 solid phase extraction. Elution of the collected material with CH_2Cl_2 (600 μ L) to give ^{18}F-PEG$_3$ in 57% average decay-corrected radiochemical yield (RCY). Analytical HPLC demonstrated >99% radiochemical purity of ^{18}F-PEG$_3$, Figure 2.

Preparation of Azido-PEG modified CLIO. 1-Amino-11-azido-3,6,9-trioxaundecane (218 mg, 1 mmol) and glutaric anhydride (114 mg, 1 mmol) were dissolved in 1 mL methylene chloride and refluxed for 1 h. Evaporation of solvent yielded 1-azido-13-oxo-3,6,9-trioxa-12-azaheptadecan-17-oic acid quantitatively, verified by LRMS-ESI $[M+H]^+$ m/z calc. $[C_{13}H_{25}N_4O_6]^+$ 333.17 found 333.3. The azido-acid (33 mg, 0.1 mmol) was stirred for 3 h in 0.3 mL AcCN with 8 μL of pyridine and 26 mg of disuccinimidylcarbonate. The AcCN was evaporated and the resulting crude N-hydroxysuccinimide ester was used directly with amine-terminated iron oxide nanoparticles. The aminated cross-linked dextran iron oxide (CLIO) nanoparticle was prepared as previously described. (4) Nanoparticles were approximately 30 nm in diameter and contained on average 40 primary amines. Aminated CLIO was

functionalized first with NHS modified VT680 (VisEn Medical, Woburn, MA) such that there were approximately 5 molecules of VT680 per particle. The remaining amines were capped with the NHS ester of 1-azido-13-oxo-3,6,9-trioxa-12-azaheptadecan-17-oic acid to give the CLIO-azide. In a typical coupling procedure, 0.4 mg of amine terminated CLIO was dissolved in 0.5 mL of 0.1 M sodium bicarbonate buffered to a pH of 8.5. To this solution was added 40 μL of DMSO containing 1 mg of the azido N-hydroxysuccinimide ester. The solution was stirred at room temperature for 2 h, purified by centrifuge filtration, and stored in PBS buffered to pH 7.4.

Conjugation. **^{18}F-PEG$_3$** in 50-100 μ L water added to the azido-CLIO (50 μ L of a 400 μ g/100 μ L 1xPBS (phosphate buffered solution)) was subjected to water soluble copper catalyzed 1,3-dipolar cycloaddition reaction conditions: 40 μ L 10 mM $Cu^{(II)}SO_4$/bathophenanthrolinedisulfonic acid disodium salt (BPDS) in distilled water/DMSO (3:1) and 40 uL 100 mM Na-ascorbate in distilled water. (5) The reaction mixture was incubated for 40 min at 40 ^{o}C and filtered to remove the ^{18}F-CLIO from unreacted ^{18}F-PEG$_3$. ^{18}F-CLIO was washed with 1xPBS until no activity was collected in the filtrate (>1 μ Ci). HPLC analysis demonstrated >99% radiochemical purity of ^{18}F-CLIO (Figure 2). The ^{18}F-labeled nanoparticle was suspended in DPBS (Dulbecco's phosphate buffered solution with Ca^{+2} and Mg^{+2}).

Phantom experiment

To compare the sensitivity of nanoparticle detection with MRI and PET, ^{18}F-CLIO was diluted in 2 % low melting agarose to concentrations ranging from .005 to 10 μ g Fe /mL

and added to wells in a precast gel. PET-CT imaging of 2 gels was followed by MRI using a 7 Tesla Pharmascan magnet (Bruker, Billerica, MA) and employing a T2* weighted gradient echo sequence (TE 140 ms, matrix 128x128, FOV 60x40 mm, slice thickness 0.8 mm).

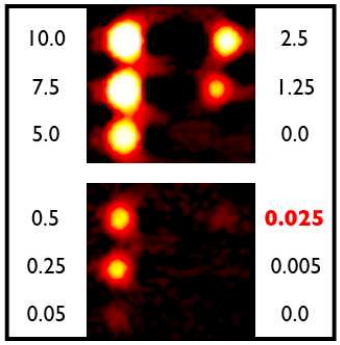

Figure S1. PET imaging of 2 agar phantoms with decreasing concentrations of 18F-CLIO (μg Fe/mL)

Mice

8-12 weeks old inbred male BALB/c (B/c, H-2d) mice were obtained from Jackson Laboratory (Bar Harbor, ME). The mice were maintained at the animal facilities of Massachusetts General Hospital, accredited by the American Association of Laboratory Animal Care. All experiments conformed to animal care protocols approved by the institutional review board.

PET Imaging

Mice were imaged with PET-CT one hour after injection of 998 ± 74 μ Ci of ^{18}F-CLIO

(n=6). This concentration was about one order of magnitude lower than previously used for MRI (10-20 mg Fe/kg). PET-CT was performed on an Inveon system (Siemens Preclinical Solutions). PET scans were terminated after 600 million events were recorded, with a typical acquisition time of 45 minutes. Spatial resolution of PET imaging approximated 1mm isotropic. Acquisition coincidence data were rebinned using Fourier rebinning in 3D, and the resulting sinogram was reconstructed using an Ordered Subsets Expectation Maximization (OSEM) algorithm. For quantification of standard uptake values (SUV), images were reconstructed using 2D Filtered Back Projection (FBP). The CT x-ray source was used with a power of 80 kVp and 500 µA and an exposure time of 370–400 ms. The effective 3D resolution was 90 µm isotropic. Typically, 360 projections were acquired. The reconstruction protocol was set to interpolate bilinearly, used a Shepp-Logan filter, and signal intensity was scaled to Hounsfield units. To achieve appropriate intravascular contrast, iopamidol 61% (Bracco Diagnostics, Princeton, NJ) was continuously infused via tail vein at a rate of 65 μ L/min for the time of CT acquisition, which was approximately 7 minutes. Fused images were converted into DICOM format and analyzed using OsiriX shareware (Geneva, Switzerland, www.osirix-viewer.com) by placing volumes of interest in the various organs for calculation of target to background ratios. Standard uptake values (SUV) were calculated as (tissue activity/volume of tissue)/(body activity/body weight).

PHARMACOKINETIC ANALYSIS

Blood half life data obtained from the heart (blood pool organ) was fit to a biexponential model, and the half life is reported as the weighted average of the distribution and

clearance phases. For fitting permeability surface area product (PS/V) values, the average concentration of activity (decay corrected) in a region of interest determined by CT was measured for the time series. The interstitial concentration was obtained by subtracting the blood contribution using the plasma fraction for each organ. Assuming an interstitial void fraction of 0.05 for these particles, PS/V was fit using the plasma clearance and specific organ data. Due to the early imaging sequence with ^{18}F, clearance was assumed to be negligible for all organs (uptake only) except the lung. The lung had similar low levels of activity as the kidney but demonstrated decreasing signal at later time points. Here a value for lymphatic clearance was assumed to obtain a reasonable fit.

Bioconjugate Chemistry

Editorial: "Conjugates of Oligonucleotides and Modified Oligonucleotides": A Memorable Review by John Goodchild

DNA and RNA oligonucleotides and oligonucleotide conjugates play a critical role in modern day biochemistry and molecular biology research. For example, these agents are used as hybridization probes to detect and characterize DNA; as primers to amplify DNA through polymerase chain reactions (PCR); as primers for DNA sequencing; as substrates for site-directed mutagenesis; as agents for controlling gene expression at both the DNA and RNA level; and as substrates for a variety of biochemical and biophysical studies. In addition, there have been intensive efforts to develop oligonucleotide-based diagnostic and therapeutic agents.

The extensive use of oligonucleotides in these applications has been made possible by the development of automated synthetic procedures. Equally important has been the development of methods to synthesize oligonucleotide conjugates containing various linkers, functional groups, fluorescent tags, and other modifications that impart specific properties, such as nuclease resistance, to the oligonucleotides. The syntheses and properties of oligonucleotide conjugates were extensively reviewed in an article by John Goodchild that appeared in the May/June issue of *Bioconjugate Chemistry* in 1990 *(1)*. This article, which has been cited at least 370 times since its appearance, described methods, both chemical and enzymatic, for preparing backbone modified oligonucleotides and oligonucleotide conjugates, and summarized the general biophysical and biological properties of these molecules. The preparation of modified oligonucleotides and their conjugates continues to be an active and productive area of research as evidenced by the many articles in this area that continue to appear in this journal. Many of the methods described in Goodchild's review are still used today, and reagents for preparing an ever-widening variety of conjugates are commercially available. Because of their central role in molecular biology and their emerging importance as diagnostic/therapeutic tools, it is safe to say that we can look forward to even more novel types and applications of oligonucleotide conjugates in the years to come.

REVIEWS

Bioconjugation with Stable Luminescent Lanthanide(III) Chelates Comprising Pyridine Subunits

Jari Hovinen*,† and Pamela M. Guy‡

PerkinElmer Life and Analytical Sciences, Turku Site, POB 10, FI-20101 Turku, Finland, and PerkinElmer Incorporated, Winter Street, Waltham, Massachusetts 02451. Received August 30, 2008; Revised Manuscript Received October 30, 2008

The use of long-lifetime emitting lanthanide(III) chelate labels or probes together with time-resolved fluorometry in detection provides a method to generate sensitive bioaffinity assays. However, the use of stable chelates demands very complicated optimization of the chelate structure. A great number of chelates have been synthesized, but usually, only the most prominent structures were then converted to corresponding biomolecule labeling reactants. This review covers the syntheses of luminescent lanthanide chelates comprising a pyridine subunit that allow solution and solid-phase bioconjugation.

INTRODUCTION

The idea of using lanthanide chelates as labels in time-resolved fluoroimmunoassays was described almost three decades ago (*1, 2*). The use of long-lifetime emitting lanthanide(III) chelate labels or probes together with time-resolved fluorometry in detection has proven its value in the development of highly sensitive bioaffinity assays (*3*). The heterogeneous DELFIA time-resolved fluorometry assay method uses non-luminescent lanthanide(III) chelates as the labels (*4*−*6*). After immunoreaction, lanthanide(III) ions are dissociated from the non-luminescent chelates by lowering pH, and luminescence is enhanced with a mixture of β-diketone, detergent, and trioctylphosphine oxide (TOPO). The resultant chelates have a very high luminescence, giving excellent detection sensitivity. However, the DELFIA time-resolved fluorometry technology is not useful for applications requiring site-specificity. Furthermore, the use of the additional chelator TOPO is essential for high luminescence. In contrast, the FIAgen time-resolved fluorometry system uses a fluorescent 4,7-bis(chlorosulfophenyl)-1,10-phenanthonine-2,9-dicarboxylate europium(III) as the label, and thus in contrast to the DELFIA system, the signal enhancement step is avoided (*7*−*10*). Due to limited chelate stability, FIAgen assays are performed in the presence of an excess of lanthanide ion. Another assay system, sold under trademark TRACE, was the first real homogeneous time-resolved fluorometry system and is based on an energy transfer between a europium(III) chelate of tris(bipyridine)cryptate and an organic fluorophore (*11*). However, detection sensitivity of the FIAgen and TRACE technologies is considerably lower than in assays based on DELFIA technology. To overcome these limitations, better luminescent lanthanide(III) chelates have to be developed.

For time-resolved fluorometry assay systems, a luminescent lanthanide(III) chelate should fulfill several requirements: (a) the molecule has to be photochemically stable, in both the ground and excited states; (b) the molecule has to be kinetically stable; (c) the molecule has to be chemically stable; (d) the excitation wavelength has to be as high as possible, preferably over 330 nm; (e) the molecule must have a high excitation coefficient in the excitation wavelength; (f) the energy transfer from the ligand to the central ion has to be efficient; (g) the luminescence decay time has to be long; (h) the chelate should be readily soluble in water; and (i) the bioactive molecules have to retain their affinities after the coupling to the lanthanide chelate.

Although organic chelators and their substituents have a significant effect on the photophysical properties of lanthanide(III) chelates, no general rules for the estimation of these effects are available. Thus, finding a highly fluorescent chelate structure to fulfill all the requirements for a label with respect to signal, conjugation, stability, and biocompatibility remains as a challenge. Hundreds of stable fluorescent chelates have been developed at numerous laboratories. A great number of chelates synthesized are basic structures that do not allow biomolecule derivatization; usually, only the most prominent structures have been converted to the corresponding biomolecule labeling reactants. Although there are several excellent review articles on the photophysical properties and bioanalytical applications of lanthanide(III) chelates (*12*−*23*), syntheses of luminescent lanthanide(III) chelates has not been reviewed.

Stable luminescent lanthanide(III) chelates consist of a ligand with a reactive group for covalent conjugation to bioactive molecules, an aromatic structure, which absorbs the excitation energy and transfers it to the lanthanide ion, and additional chelating groups such as carboxylic acid moieties and amines. Unlike organic chromophores, these molecules do not suffer from Raman and Rayleigh scattering or concentration quenching. This allows multilabeling and development of chelates bearing several light-absorbing moieties.

The pyridine moiety is by far the most common chromophoric subunit in luminescent lanthanide chelates. When appropriately

[a] X = Br, I, or Cl; R = an alkyl group.

derivatized, pyridine can serve as the chromophoric moiety alone. Alternatively, it can be present in multimeric forms in open-chain structures and macrocyclic cage-type complexes such as cryptates and cyclic Schiff bases. This review mainly describes synthesis of luminescent lanthanide chelates comprising pyridine subunits that can undergo bioconjugation. Accordingly, luminescent stable chelates with no pyridine subunits, such as those comprising DTPA and DOTA tethered to light-harvesting groups, and chelates based on β-diketones and phenolic compounds, are not discussed here.

THE CHROMOPHORE

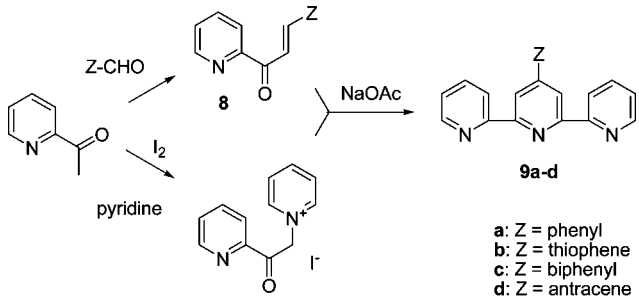
A single unsubstituted pyridine moiety is not efficient enough to serve as a light-absorbing and triplet-sensitizing aromatic group in stable luminescent chelates. Thus, pyridine has often been substituted with various energy-absorbing groups. Pyridine analogues conjugated to five-membered heteroaromatic rings have also been prepared. The chromophores of stable chelates are often composed from one to three conjugated pyridine rings, or the pyridine moieties are connected to each other via N, O, or S-containing hydrocarbon chains. While bipyridine and terpyridine moieties are commercially available, preparation of chromophores based on 4-substituted pyridines and pyridines conjugated to five-membered hetereocyclic rings require numerous synthetic manipulations.

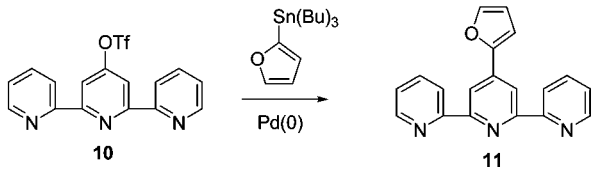
Derivatization of C4 of Pyridine. There are numerous methods for attaching additional light absorbing groups to 4-halopyridines (Scheme 1). Phenylethynyl substitution (**1**) has been performed using the Sonogashira reaction (*24*−*26*). Furyl (**2**) and thienyl (**3**) substituted pyridines have been synthesized using the palladium(0)-catalyzed Stille reaction with the corresponding stannyl derivatives of the additional light-absorbing groups (*28*−*31*). Suzuki coupling of the halopyridine with alkoxyphenylboronates gives rise to the alkoxyphenylpyridine chromophore **4** (*32*). The *trans*-4-styrylpyridine derivative (**5**) has been synthesized by Heck coupling with 4-chloropyridine-2,6-dicarboxylate using the mixture of palladium(II) acetate and triphenyl phosphine (*29*). Aromatic nucleophilic substitution has been exploited in the preparation the 4-(2-napthoxy)pyridine derivative (**6**). The 4-benzoylpyridine-2,6-dicarboxylate **7** was obtained under similar conditions using *O*-(tetrahydropyran-2-yl)mandelonitrile followed by acid-catalyzed cleavage of the THP group (*29*).

Derivatization of Terpyridine. This has most commonly been performed using Claisen-Schmidt condensation of various aromatic aldehydes (*33*−*42*) with 2-acetylpyridine to give the (*E*)-propen-2-enones **8** (Scheme 2). Their reaction with *N*-[2-(pyrid-2-yl)-2-oxoethyl]pyridinium iodide and sodium acetate in methanol yielded the terpyridine derivatives **9a**−**d**. Stille reaction between terpyridine 4-triflate **10** and tributylstannyl furan has been utilized in the preparation of 4-furyl terpyridine **11** (*28*).

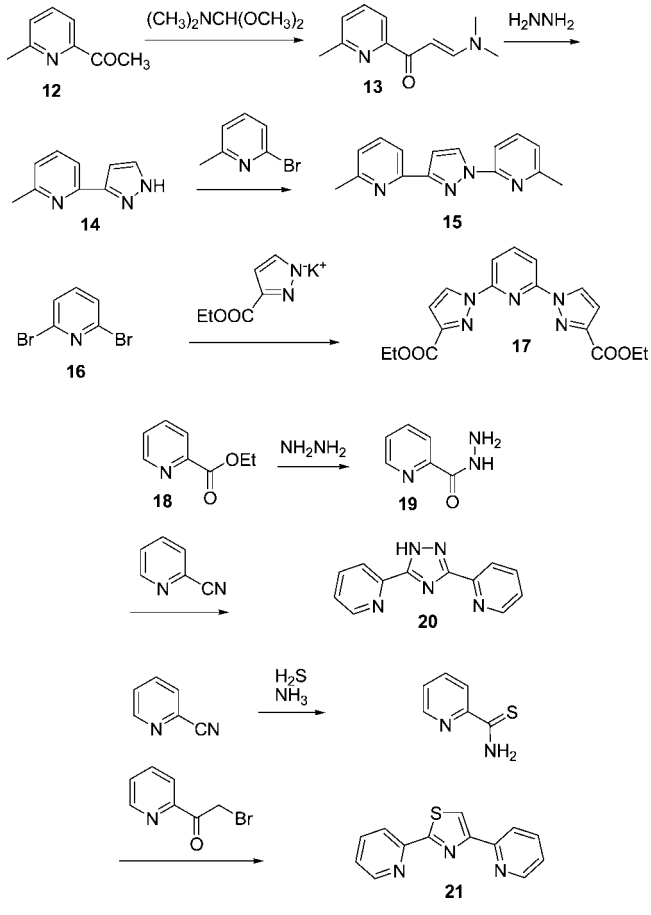
Pyridine Conjugated to Five-Membered Heteroaromatic Rings. A wide range of lanthanide chelates comprising a pyridine subunit conjugated to one or two heteroaromatic rings have been synthesized and claimed (*29*, *43*−*50*). The conjugated chromophore often exhibits a high excitation coefficient, long excitation wavelength, and good energy transfer from the ligand to the lanthanide ion, giving rise to improvements in detection sensitivity. However, only few of these chelates have been converted to the corresponding biomolecule labeling reactants. The key steps of the syntheses of their chromophores are shown in Scheme 3. The preparation of 2,2′-(1*H*-pyrazole-1,3-diyl)-bispyridine chromophore **15** involves treatment of 6-methyl-2-acetylpyridine **12** with *N*,*N*-dimethylformamide dimethyl acetal to give rise to (*E*)-3-(dimethylamino)-1-(6-methylpyridin-2-yl)prop-2-en-1-one **13**, which is cyclized to 2-methyl-6-(1*H*-pyrazol-3-yl)pyridine **14** with hydrazine hydrate followed by

Scheme 2. Derivatization of Terpyridine





Scheme 3. Preparation of Chromophores Comprising Pyridine Conjugated to Five-Membered Heteroaromatic Ring



reaction with 2-bromo-6-methylpyridine (*29*). The key reaction of the most recent synthesis of 2,6-bis(3-methyl-1-pyrazolyl)pyridine **17** starts from nucleophilic substitution of the bromine atoms of 2,6-dibromopyridine **16** with potassium 3-ethoxycarbonylpyrazole in diglyme (*50*). The triazole derivative **20** has been prepared using 2-pyridinecarboxylate **18** as the starting material that was initially treated with hydrazine hydrate to give 2-pyridylhydrazide **19**, the reaction of which with picolinonitrile at 160 °C gave the desired heterocycle (*43*). Synthesis of the thiazole derivative **21** includes treatment of picolinonitrile with

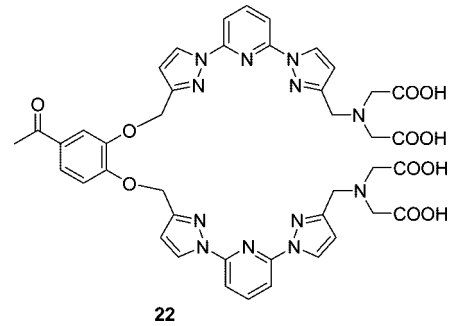


Figure 1. A ligand with two 2,6-bis(*N*-pyrazol-11-yl)pyridine subunits.

hydrogen sulfide in ammonia followed by cyclization with 2-bromoacetylpyridine (*43*).

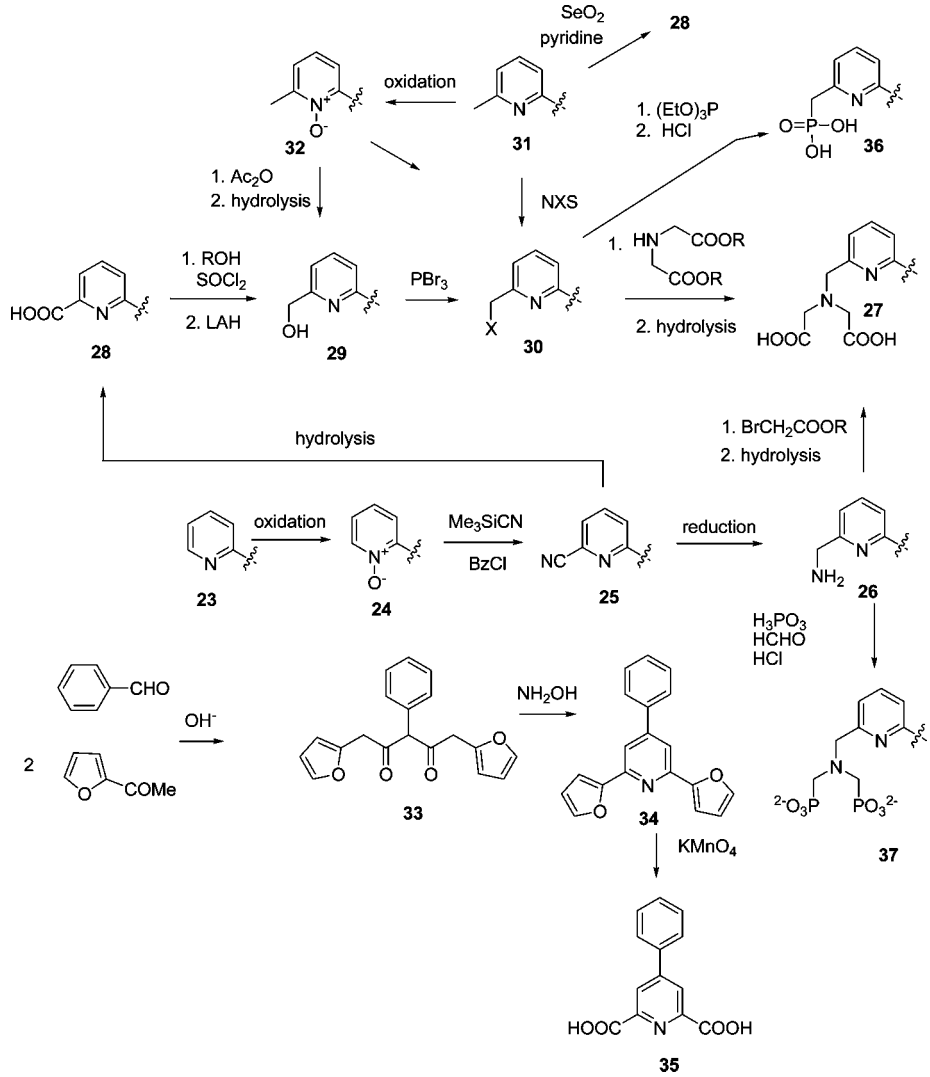
Lanthanide(III) chelates based on 2,6-bis(*N*-pyrazolyl)pyridine **17** and 6,6′-(1*H*-pyrazole-1,3-diyl)bis(pyridine) **15** are among the best and most widely used luminescent terbium(III) chelates synthesized: they have excellent photophysical properties including high luminescent quantum yield and relatively high energy of their lowest triplet state. The chromophore of the lanthanide chelate comprising 1,2,4-triazol-3,5-ylene subunit **20** is negatively charged, a property that stabilizes the chelate. Its suitability in immunoassays has been demonstrated (*43*). No applications for the chelate comprising the chromophore **21** have been published. Also, chelates derived from 2,6-bis(*N*-pyrazol-11-yl)pyridine motif attached to aceto/benzophenone and iminodiatetic subunits **22** (Figure 1) have been synthesized (*51*); however, their quantum yields were significantly lower than those of simpler complexes.

THE CHELATING PART

The lanthanide chelate has to be stable in the presence of external chelators such as EDTA and relatively low pH conditions sometimes used in biochemical assays. Tolerance to high temperatures is required in nucleic acid based assays employing thermal cycling. Because the chromophoric moiety binds weakly to the lanthanide ion, the chelate requires additional metal coordination sites. Enhancement in stability has been obtained by adding chelating groups such as carboxylic acid and phosphonate moieties to the chromophore. Alternatively, incorporating several fluorogenic ligands into one structure (*52*) or encapsulating the metal ion to the chromophoric structure forming polycyclic cage-type compounds such as cryptates and macrocyclic Schiff's bases have been used to enhance stability.

Carboxylic Acid Derivatives. Methods for attaching chelating carboxylic and phosphonic acid moieties to chromophores are shown in Scheme 4. A pyridine ring **23** has been converted to the *N*-oxide **24** using an oxidizer such as *m*-chloroperbenzoic acid or magnesium perphthalate (*29*, *35*, *40*, *53*). There are enormous differences in the reactivities of the pyridine rings: while the terminal pyridine rings of terpyridine are readily oxidized with *m*-chloroperbenzoic acid in dichloromethane in a few hours at ambient temperature, a prolonged reaction time (perphthalate in acetic acid; 8 days at 80 °C) was required for the preparation of the di-*N*-oxide of **15** (*29*). The *N*-oxides have been converted to the corresponding carbonitriles **25** by a modified Reissert-Henze reaction, the reduction of which with borane yields the amines **26** that have been carboxymethylated with alkyl bromoacetate followed by hydrolysis to give the iminoacetic acid derivatives **27**. The nitrile **25** has also been hydrolyzed to carboxylic acid **28**, which was esterified followed by reduction to the alcohol **29** (*29, 53*−*57*). The cyanide **25** has also been obtained by nucleophilic substitution of 2-bro-

Scheme 4[a]



[a] X = Br or Cl; some substituents are omitted for clarity.

mopyridine derivative with cyanide ion (*54*). Treatment of **29** with phosphorus tribromide in DMF or chloroform gives the bromide **30** that has been allowed to react with iminoacetic acid ester followed by hydrolysis to give **27**.

Several alternative approaches have been used when 2-methylpyridine or its derivatives **31** have been used as the key intermediates. One route involves free radical halogenation (*24*, *48*, *53*, *55*) to **30** followed by substitution with iminoacetic acid ester and ester hydrolysis. However, the yield of the free radical reaction may be low due to the formation of unsymmetrical byproduct and the products of different halogenation steps. The yield is highly related to the structure of the alkylpyridine derivative (*57*). Another route comprises oxidation of **31** to the corresponding *N*-oxide **32**. Treatment of this with acetic anhydride followed by base-catalyzed hydrolysis gives the methanol **29** that was converted to the bromide **30** (*29*). The picolinate **31** has also been oxidized to carboxylic acid **28** using selenium(IV) oxide in refluxing pyridine (*53*).

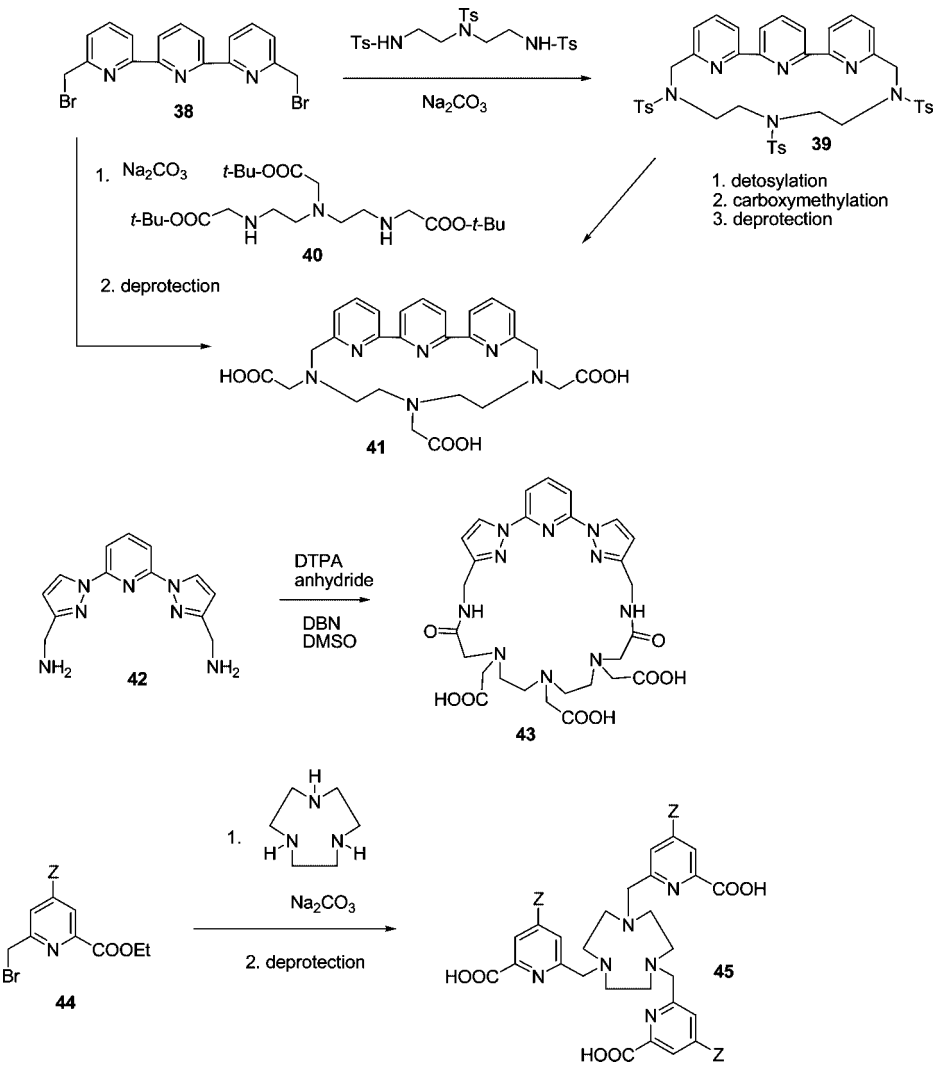
When 2-alkyl picolinates are used as key intermediates, the ester is either hydrolyzed to acid (*23*) or it is reduced to alcohol with $NaBH_4$, followed by bromination with PBr_3, substitution with iminoacetic acid ester, and hydrolysis (*23*).

A method disclosed by Hale and Solas (*52*) includes base-catalyzed condensation of 2-acetylfuran and benzaldehyde to give the pentanedione **33**, which was further converted to the furylpyridine **34** by treatment with hydroxylamine that was finally oxidized to the desired acid **35**.

Phosphonate ligands (**36**, **37**) have been synthesized by an Arbuzov reaction between the bromide **30** and triethyl phosphate followed by ester hydrolysis and by treatment of the amine **26** with H_3PO_3 and formaldehyde in the presence of HCl (*53*). Because there are fewer water molecules coordinated to the lanthanide ion than in the corresponding carboxylate chelate, the phosphonate group has a positive effect on the luminescence. The phosphonate chelates have a high negative charge, and therefore, their coupling to bioactive molecules could change the physical properties of the conjugate. No biomolecule labeling reactants containing phosphonates as chelating units have been synthesized.

Azamacrocycles. Macrocyclic lanthanide chelates comprising an intracyclic chromophoric unit (pyridine, bipyridine, terpyridine, bis(pyrazol-1-yl)pyridine) and pendant carboxylate groups have been shown to exhibit high chelate stability and promising photophysical properties (*23*, *40*, *58*−*63*). Also, macrocycles in which the chromphore comprises two nonconjugated pyridine subunits tethered to each other via a nitrogen-containing hydrocarbon chain has been described and claimed in patents (*28*,*32*). The crucial step in the ligand synthesis is the macrocyclization reaction. Azamacrocyles have been traditionally synthesized via the method of Richman and Atkins (*64*) by condensing disodium

Scheme 5. Preparation of Azamacrocycles[a]



[a] Z = an aromatic group.

salts of pertosylated amines with dihalogeno fragments of the chromophore (Scheme 5). According to the latest modification of this reaction, the synthesis involves a reaction between a bifunctional electrophile (e.g., a dibromide or ditosylate) and a pernosylated amine in dry DMF at an elevated temperature in the presence of cesium or sodium carbonate (*65*−*67*). Finally, the tosyl or nosyl groups are removed with acid or thiol in the presence of base, respectively, giving the desired azamacrocycle. Carboxyalkylation of the secondary amines gives the desired ligands. Also, a cyclization reaction utilizing the Mitsunobu reaction between a dihydroxy fragment of the chromophore and a pernosylated amine has been used (*68*). Galaup et al. have reported an elegant direct method to 18-membered hexaazamacrocyles comprising a functionalized 2,2′:6′,2″-terpyridine moiety **41**, exploiting a metal template ion effect on the macrocylization step (*60*). The acetate pedant arm **40** was synthesized in five steps starting from diethylenetriamine.

Brunet et al. allowed a diamino fragment of the chromophore to react with DTPA anhydride in the presence of base (*63*) to give **43**. The reaction was performed in high dilution, and the yield of the desired ligand was relatively low.

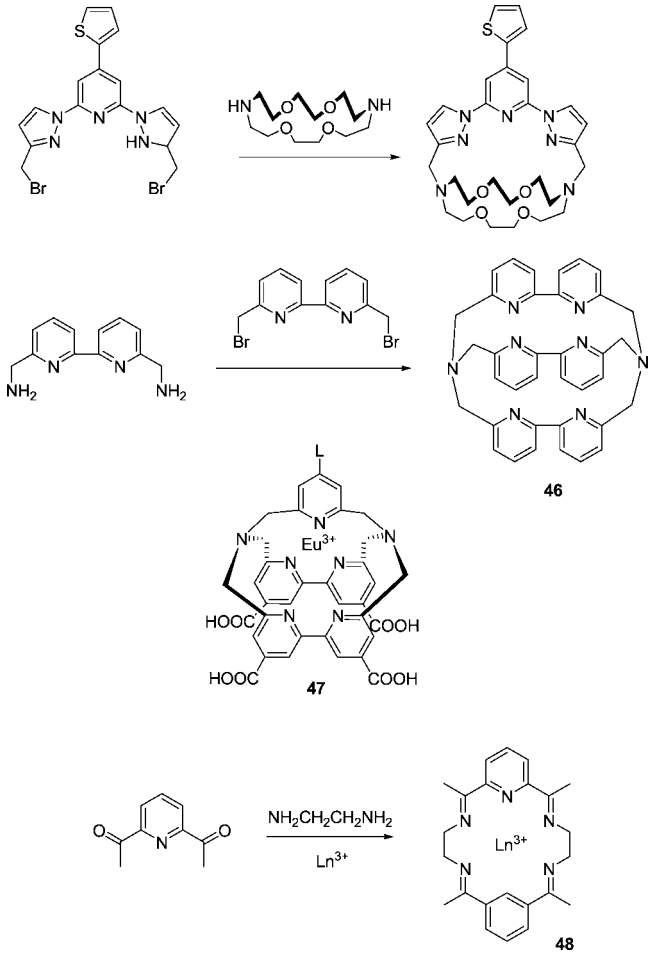
Lanthanide chelates based on 1,4,7-triazacyclononane **45** and 1,4,7-triazacyclodecane also exhibit high kinetic and thermodynamic stabilities (*28*, *32*). Their synthesis is straightforward and involves alkylation of the azacycloalkane with the bromomethyl derivatives of the desired chromophore **44**.

Cryptates. Macropolycyclic inclusion complexes, cryptates, have been designed to provide lanthanide chelates of high kinetic and thermodynamic stability. Practically, all lanthanide chelate cryptates containing bivalent heterocyclic unsaturated five-membered rings and/or one or more pyridine derivatives as a chromophore have been claimed in patents (*42*, *43*, *62*, *69*, *70*). However, only few of these compounds have been synthesized and converted to the corresponding biomolecule labeling reactants. Preparation of cryptates comprising the 4,13-diaza-18-crown 6 ether moiety involves alkylation of the secondary amines with a chromophore having two bromoalkyl groups (Scheme 6). The cryptand formation is assisted by using a metal ion as a directing template. When the metal ion used is a lanthanide (*42*, *71*), the desired lanthanide chelate is formed; otherwise, an additional prolonged metal exchange reaction is needed. The usefulness of cryptates containing a 4,13-diaza-18-crown 6 ether subunit for biomolecule derivatization has not been demonstrated.

The only commercialized lanthanide cryptant is the europium chelate based on three bipyridine moieties **46**. It has been synthesized by treatment of 2,6′-aminomethylbipyridine and 2 equiv of the corresponding dibromide in the presence of base.

Cryptates are kinetically inert and have good stability, because the lanthanide ion is tightly closed inside the molecular cavity. However, the positive net charge may have an adverse effect on antibodies, which are widely used bioactive components in

Scheme 6. Synthesis of Cryptands and Schiff'S Bases[a]



[a] L = a linker.

common assay formats. In addition, water and negatively charged quenchers present in samples must be removed by treatment with fluoride ion. These disadvantages are not present in **47**, since the molecule has a net charge of −1. Also, its quantum yield is relatively high (*70*).

Macrocyclic Schiff Bases. Lanthanide chelates having a macrocyclic Schiff base **48** as a ligand can be prepared from 2,6-diacetylpyridine and diaminoalkane by using a lanthanide ion as a template (Scheme 6). Although Schiff bases are normally labile, the lanthanide ion stabilizes the macrocyclic moiety if the structure formed is an 18-membered macrocycle (*72*). Due to limited chelate stability, assays have been performed in the presence of excess lanthanide ion. Detection sensitivity has been enhanced by using the chelate in association with dissociative enhancement (*73*) or as a mixed ligand chelate with thenoyltrifluoroacetone (*74*).

Figure 2 shows different ligands containing the pyridinyl-4-phenylethynyl chromophore. The corresponding chelates differ from each other with regard to lanthanide/ligand ratio and stability constants of the formed complex. The tridentate pyridine dicarboxylic acid **49** forms 1/1, 1/2, and 1/3 complexes with lanthanide(III) ions, but only the 1/3 complex is highly luminescent. Thus, this ligand is unsuitable for biomolecule derivatization. Ligands with seven or more chelating groups **50**−**56** form luminescent 1/1 chelates with lanthanide(III) ions and thus are suitable for bioconjugation. The stability of the chelate is usually increased as the number of ligating atoms of the chelate are increased. Simultaneously, the number of coordinating water molecules in the first coordinating sphere of the lanthanide ion and the quenching effect of O−H vibrations are decreased, giving rise to enhanced luminescence. Chelate stability has been enhanced by linking several chelates together to give rise to multidentate structures. However, the chelate has to be saturated using an excess of lanthanide ion if the single subunit is tridentate (*75*).

Since lanthanide chelates do not suffer from concentration quenching, development of chelates bearing several light-absorbing moieties is possible. In particular, chelates comprising a triazacyclononane **56** backbone have been shown to be highly luminescent (*28, 30, 32*). The corresponding triazacyclododecane **57** is practically nonluminescent (*30*).

THE LINKER

Although in many applications a reactive group for biomolecule conjugation can be attached directly to the chromophoric group or to the chelating part, it is often desirable, for steric reasons, to have a linker between the reactive group and the chromophoric group or chelating part, respectively. The linker is especially important in case the chelate should be used in solid-phase syntheses of oligopeptides and oligonucleotides, but it is often desirable also when labeling biomolecules in solution.

In one strategy for attaching a linker, an aromatic bromide or iodide was allowed to react with a linker tethered to a terminal alkynyl group using Sonogashira reaction (*28*). Elongation of an amine function was performed using reactions of peptide bond formation. Aromatic amino groups of low reactivity require the use of reactive activators such as HATU (*76*) and 1-(2-mesitylenesulfonyl)-3-nitro-1,2,4-triazole (*24*).

For the preparation of terpyridyl ethers with an ω-substituent, three methods have been reported. The method of Newkome and He (*77*) involves nucleophilic substitution of 4′-chloro-2,2′:6′,2″-terpyridine with various ω-substituted alcohols or thiols in the presence of an excess of KOH in DMSO at elevated temperature (Scheme 7, route A). Although the reactions have to be performed in rather drastic reaction conditions, a wide variety of linkers have been introduced in high yield (*78, 79*). Another tethering strategy, developed by Constable and co-workers (*80*) involves an S_N2 reaction between the nucleophilic 2,6-di(pyridin-2-yl)pyridin-4(1*H*)-one and a tether molecule bearing a good leaving group in its structure (Scheme 7, route B). The third method is based a reaction 2,6-di(pyridin-2-yl)pyridin-4(1*H*)-one and an alcohol under Mitsunobu reaction (Scheme 7, route C). Since the reaction conditions are mild, a wide range of linkers tethered to various substituents can be synthesized (*81*). The reaction has shown to be applicable to pyridine derivatization also.

The addition of a binding arm to energetically isolated positions, such as to the chelating imidoacetate group, allows development of structures without changing the energetic profile of the aromatic part on conjugation. However, synthesis of these structures is more challenging unless the presence of two linker arms for biomolecule derivatization is accepted. Attachment of a single linker arm to the chelating imidoacetate group involves two S_N2 reactions with different amines of similar reactivities reducing the yield of the desired product (*82*). The method also calls for preparation of a modified iminoacetic acid ester (Scheme 8).

When the chromophores are linked to each other via a nitrogen-containing hydrocarbon chain, the linker has been attached to this unit (Scheme 9). Several nine dentate derivatives have been synthesized by a S_N2 reaction of a primary amine in the presence of an excess of a bromide (*28, 32, 83*). The corresponding azamacrocycles have been synthesized using a carbon-substituted cyclic amine (*28, 32, 84*) (Scheme 10). Site-specific derivatization of azacycloalkane bearing a single tether

arm at one of the chromophores was performed using a bis-protected triazacyclononane (*28, 32*).

THE REACTIVE GROUP

In several applications, covalent conjugation of the chelate to bioactive molecules is required. Most commonly, this is performed in solution by allowing a chelate with a reactive group to react with a functional group of a bioactive molecule (*85*). Although derivatization of synthetic biomolecules can be conveniently performed on solid phase using standard oligopeptide and oligonucleotide synthesizers, solution-phase labeling of large biomolecules, such as proteins, is also important. In these cases, the labeling reaction must be as selective and effective as possible. Preparation of the most common activations is depicted in Scheme 11.

Labeling in Solution. Synthesis of the activated chelate often involves reaction of an amino chelate with the desired activator. Treatment of an amine with thiourea gives rise to the corresponding isothiocyanate (*86*). An aromatic isothiocyanate reacts smoothly with primary amino groups forming thiourea bonds (optimal pH of the reaction is 9.0−9.5). Aromatic isothiocyanate is commonly employed for the coupling of lanthanide chelates to proteins, oligopeptides, and oligonucleotides tethered to primary amino groups. Since the aliphatic isothiocyanate is considerably less reactive, this group does not have preparative value.

Amino groups of biomolecules can be selectively labeled also with arenesulfonyl activated chelates (*10*). Due to quite drastic reaction conditions, the activation has to be performed before chelate formation. Although the activated chelate contains two reactive arenesulfonyl groups in its structure, no formation of protein polymers during labeling (protein−protein cross-links)

Scheme 8. Introduction of the Linker Arm to an Energetically Isolated Position of Terpyridine[a]

have been observed. The same has been later observed for an europium chelate tethered to two aromatic isothiocyanate groups (*87*).

When high reactivity is required, the 4,6-dichloro-1,3,5-triazin-3-yl group (DTA) is the activation of choice. The activated chelate has been prepared by treating the amino chelate with cyanuric acid. DTA allows labeling of all functional groups of proteins (*87, 88*). This function has been used even in the labeling of hydroxy groups of sugars. Due to the high reactivity, the selectivity is lost. A study has been conducted to evaluate various less reactive DTA derivatives and their effects on chelate luminescence and antibody functionality by replacing one of the chlorine atoms in the triazine ring with a deactivating substituent (*89*). Histidine and tyrosine residues can be selectively labeled using diazonium coupling. Although no luminescent lanthanide chelates tethered to diazo groups have been synthesized (*90*), they have been claimed in several patents.

Thiols are know to react with haloacetamides, maleimides, disulfides and their analogues, mercurials, vinyl sulfones, aryl halides, aziridines, and oxiranes (*91*). For coupling purposes, the reactions of haloacetamides, maleimides, and disulfides are most commonly employed. From them, the haloacetyl derivatives display a wide range of other reactivities, while disulfides are practically completely specific to thiols. The reactivity of maleimides is intermediate between them. The problem with using disulfides is lability of the bioconjugate in the presence of reducing agents, which are often present in the conjugation reaction. The haloacetamide chelates have been synthesized by allowing the amino chelates or ligands to react with the haloacetic anhydride or halide (*87*). Because of the high reactivity of haloacetamides, the pH of the conjugation reaction has to be carefully controlled. At too low pH, the reaction is slow, while at too high pH, amino functions, often abundantly present in the bioactive molecule to be labeled, compete with the target mercapto function for the label. Accordingly, the haloacetamides are most specific toward thiols at neutral pH. Maleimides have been synthesized by allowing amino chelates or ligands to react with carboxylic acid derivatives bearing an ω-maleimide substituent in the presence of appropriate activating agents (*76*). Disulfides have been prepared by allowing amino chelates to react with the NHS ester of 3-(2-(pyridin-2-yl)-disulfanyl)propanoic acid (*92*). Ge and Selvin allowed a modified DTPA anhydride to react with primary maleimidopropionic acid hydrazide and aminoethylmethanethiosulfonate to give the corresponding mercapto selective labeling reactants (*93*).

Although *N*-hydroxysuccinimidyl (NHS) ester is one of the most common functional groups used in bioanalytical chemistry for covalent coupling of labels to primary amino groups of biomolecules, this activation has not been widely applied to lanthanide chelate conjugation. The coupling reaction with NHS esters is performed under mild alkaline conditions under which the ester reacts specifically with primary amino groups. NHS coupling is not harmful to biologically active compounds, and high reaction yields can be achieved, minimizing protein denaturation. Wieder et al. allowed a chelate comprising an aromatic amino group to react with bis NHS ester of dicarboxylic acid to give rise to the chelate tethered to NHS group (*92*). NHS ester **58** was prepared by allowing the corresponding carboxylic acid to react with *N*-hydroxysuccinimide in the presence of DCC (*46*) (Scheme 12). In this case, the reactive group is attached to the energetically isolated position, but the net charge of the chelate is changed. The NHS ester was not isolated but used in situ for bioconjugation. Weibel et al. (*94*) prepared a europium chelate based on a glutamic acid skeleton bis-functionalized on its nitrogen atoms by 6-methylene-6′-carboxy-2,2′-bipyridine chromophoric units **59**. Since the propionate function on the glutamic residue remained uncoordinated to the central ion, its esterification into an activated *N*-hydroxysuccinimidyl ester could be performed.

Amino groups can be conjugated directly to carboxylic acid groups in the presence of water soluble carbodiimides such as EDAC. This reaction has been utilized especially for antibody and steroid conjugation (*92, 95, 96*).

O-Alkyl hydroxylamines are known to react chemoselectively with ketones and aldehydes under mild conditions, giving stabile oximes in excellent yield. Although aminooxy chelates have been claimed in numerous patents and patent applications, only one stable luminescent europium chelate tethered to a aminooxy group **60** (Figure 3) has been prepared and used for carbonyl group conjugation (*97*). The same chelate structure tethered to a mercapto group **61** has been synthesized and exploited in the detection of phosphopeptides by phosphate elimination and subsequent Michael addition (*98*). Poupart et al. synthesized the aldehyde **62** and used it in oligonucleotide conjugation (*99*). The Schiff base formed was further stabilized by reduction with borohydride to the corresponding amine.

The thioester-mediated ligation of unprotected peptide segments, called natural chemical ligation, has been demonstrated to be extremely effective for the rapid and efficient chemical synthesis of proteins and long oligopeptides (*100*). The method is based on the reaction of a peptide containing a thioester at the α-carboxy group with the *N*-terminal Cys residue of another peptide. The initial thioester ligation product then undergoes rapid intramolecular reaction giving rise to a native peptide bond at the ligation site. In addition to the synthesis of proteins and long oligopeptides, natural chemical ligation has been successfully used in the introduction of affinity groups and organic fluorophores to proteins. A lanthanide chelate tethered to thioester bond **63** has been prepared by allowing a chelate bearing a primary amine to react with pentafluorophenyl *S*-benzyl thiosuccinate (*99*).

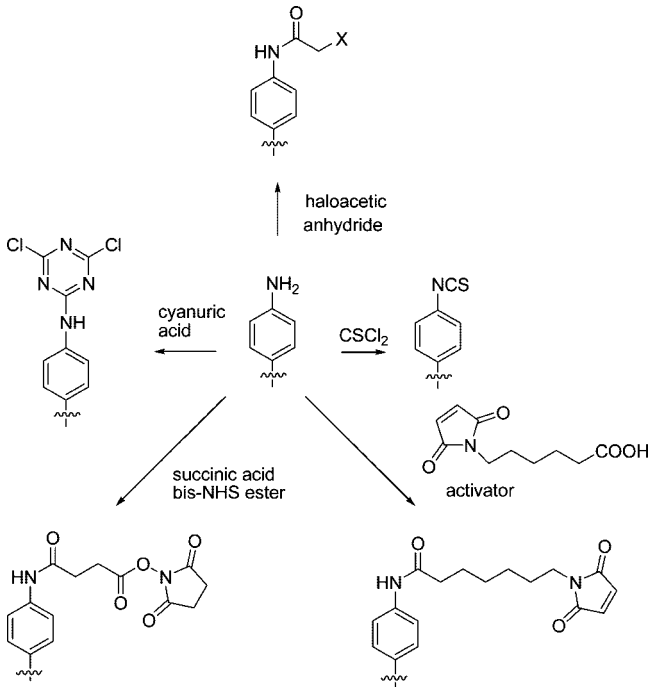
Scheme 11. Activation of an Aromatic Amino Group[a]



[a] X = Br or I.

The copper(I) catalyzed Huisgen's dipolar [2 + 3] cycloaddition of azide and alkynes, called "click chemistry", is a powerful direct method to prepare 1,4-disubstituted 1,2,3-triazoles (*101*). This reaction has been utilized increasingly also in the conjugation of various label molecules to nanomaterials and biomolecules. Recently, this reaction has been utilized with lanthanide chelates (*99*). For example, a protected ligand tethered to an azido group **64** has been reacted with a steroid tethered to an ethynyl group in the presence of copper(I). Removal of the protecting groups followed by treatment with europium ion gave the desired steroid conjugate.

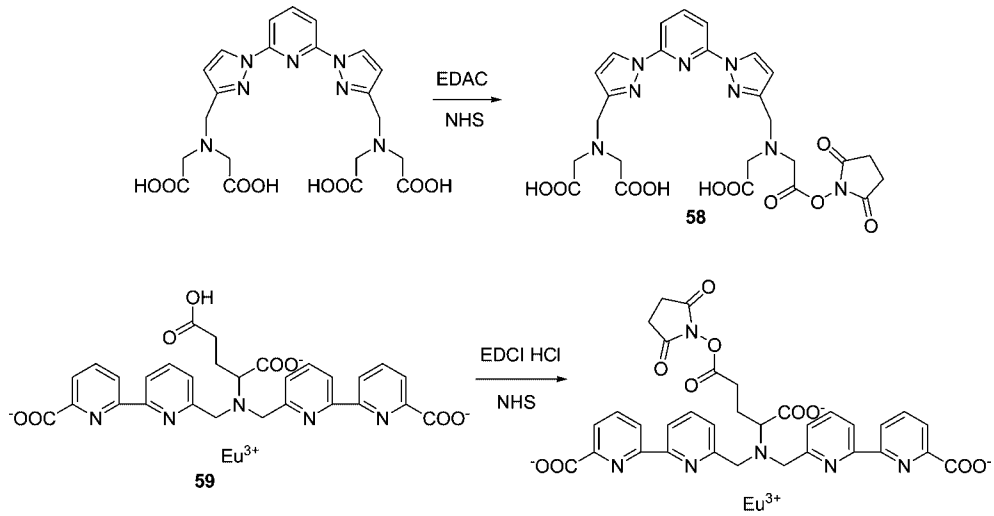
Statistical labeling of oligonucleotides, DNA, RNA and proteins was done using labels tethered to derivatives of *cis*-platinum (*102*). In nucleic acids, the platinum predominantly coordinates to N7 of guanine residues. Although no luminescent lanthanide chelates tethered to platinum have been synthesized, the patent (*102*) has claims directed to platinum tethered to any detectable group. Statistical phosphate labeling using lanthanide titanocene conjugates, such as **65** has also been proposed (*103*).

It has been shown that detection sensitivity can be dramatically enhanced by incorporating lanthanide(III) chelates into particles. Beads containing lanthanide(III) chelates as dye molecules have most commonly been prepared simply by swelling chelates into the bead polymer (*104*). Few of this type of labeled beads are currently commercially available (*23*). If the lanthanide(III) chelates are not covalently bound to the polymer particles, the signal obtained from the particles may decrease as a function of the time because of leaking. This problem has been avoided by linking the chelate covalently to a matrix (*31, 105*−*107*). In case the chelate should be attached to a microparticle or nanoparticle during the manufacturing process of the particles, a lanthanide chelate tethered to a polymerizable group is required. For this purpose, europium(III) chelates based on thienylpyridine subunits tethered to an acrylamide function **66** have been synthesized (*31*).

Labeling on Solid Phase. In almost all biomolecule labelings, the reaction is performed with an excess of an activated label, and accordingly, laborious purification procedures cannot be avoided. In particular, when attachment of several label molecules, or site-specific labeling in the presence of several functional groups of similar reactivity, is desired the isolation and characterization of the resultant biomolecule conjugate is extremely difficult, and often practically impossible. The biomolecule conjugates used in many applications, such as homogeneous quenching assays, must be extremely pure, because even small amounts of fluorescent impurities considerably increase luminescence background and thereby reduce detection sensitivity. Thus, it is highly desirable to perform conjugation of biomolecules on a solid phase, allowing removal of most impurities by washing while the biomolecule is anchored to the solid support. Once the complex is released into the solution, only a single chromatographic or electrophoretic purification is required.

Solid-phase labeling of oligopeptides calls for preparation of the corresponding oligopeptide building blocks (*108*−*110*). Most commonly, the block has an activatable carboxylic acid function and an α-amino group bearing a transient protecting group. The chelating part has to be masked with permanent protecting

Scheme 12. NHS Activation at the Energetically Isolated Position



groups. Building blocks that allow solid-phase introduction of luminescent europium and terbium chelates to olipeptides using standard Fmoc chemistry are shown in Figure 4. The blocks have been coupled either to the amino or carboxyl terminus or to the internal position of the coding sequence using prolonged coupling time but otherwise standard conditions (Scheme 13). The coupling efficiencies of these blocks are comparable to natural amino acid analogues. After completion of the oligopeptide synthesis, the oligopeptides were deprotected and released from the resin using standard procedures. Treatment of the

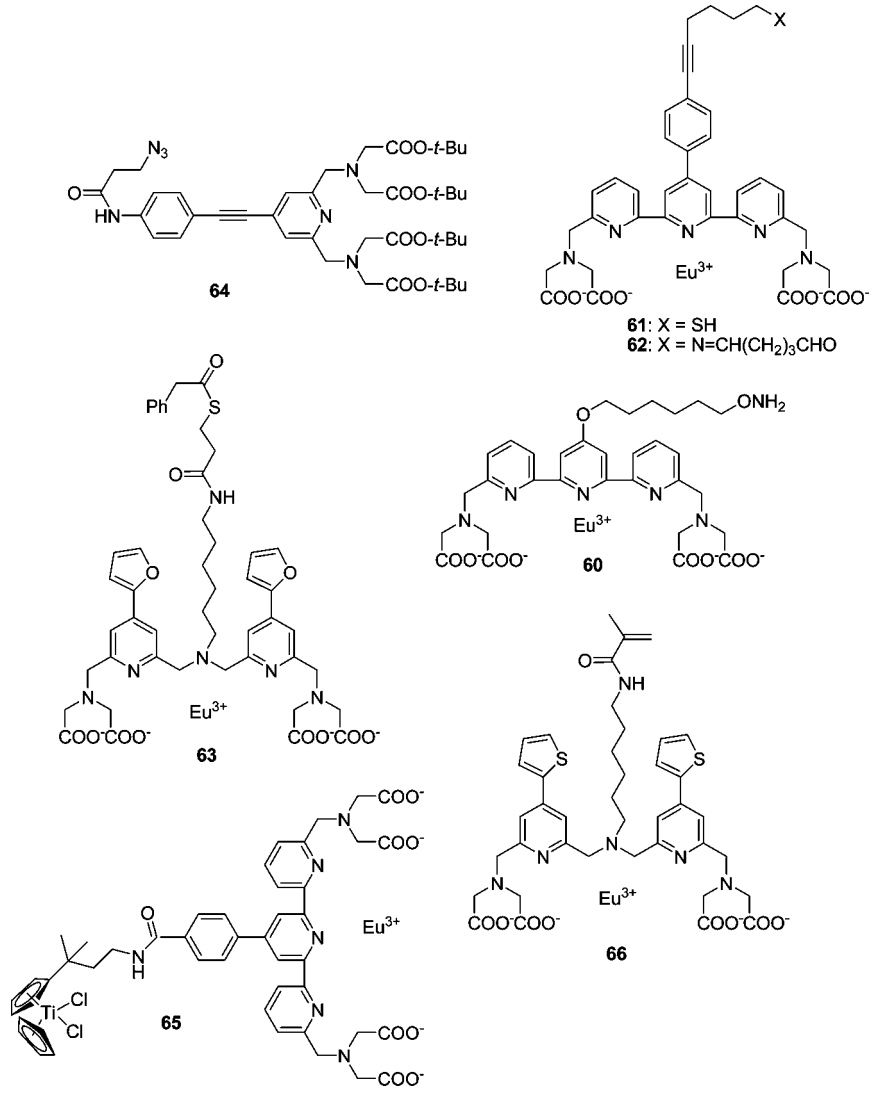


Figure 3. Europium(III) chelates tethered to reactive groups.

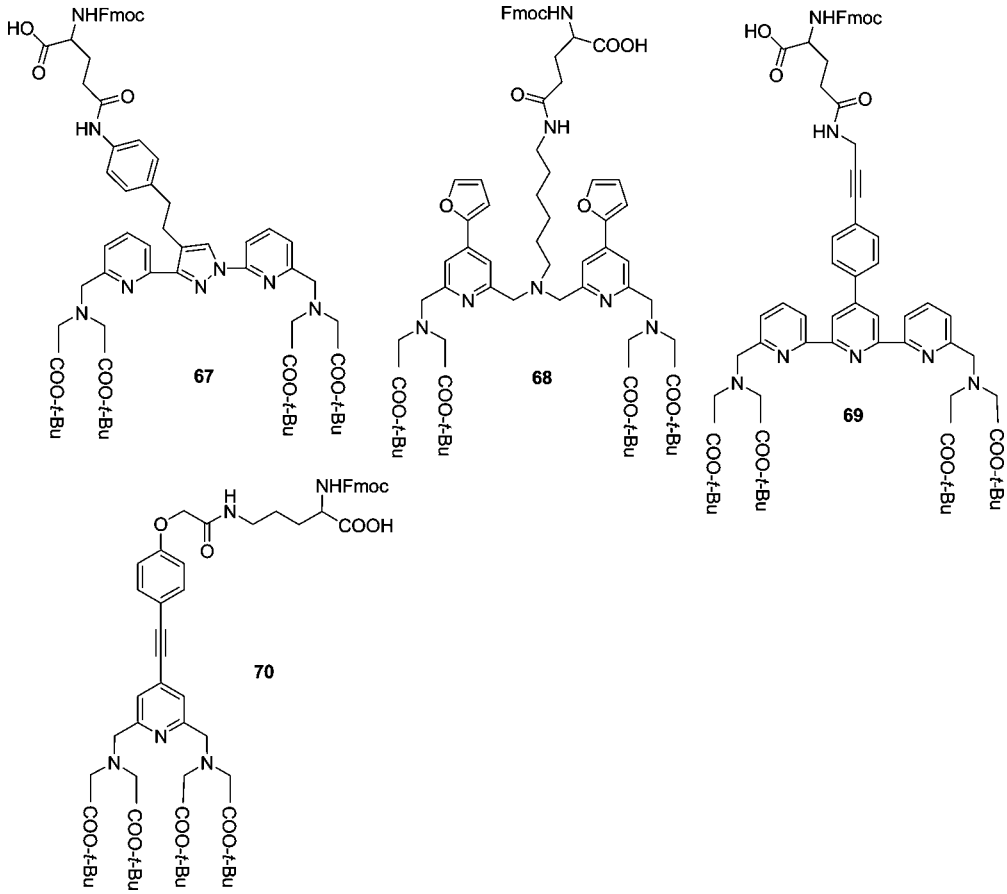

Figure 4. Oligopeptide labeling reactants.

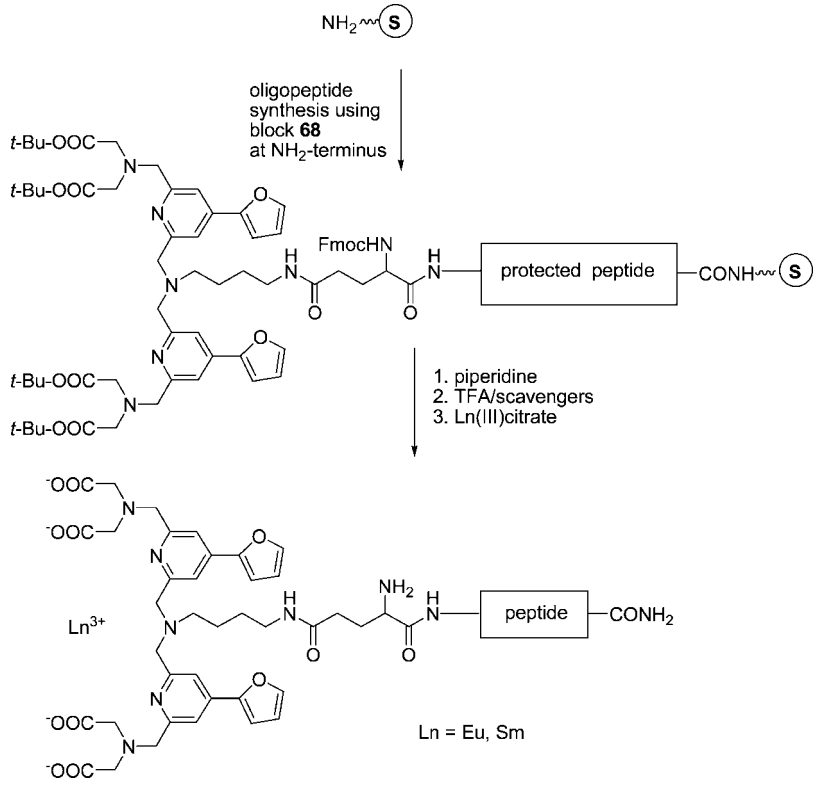
Scheme 13. Labeling of Oligopeptides on Solid Phase



deblocked oligomers with lanthanide(III) salt converts the oligopeptide conjugate to the corresponding lanthanide chelate. These blocks have been shown to be suitable for solid-phase steroid derivatization also (*108*).

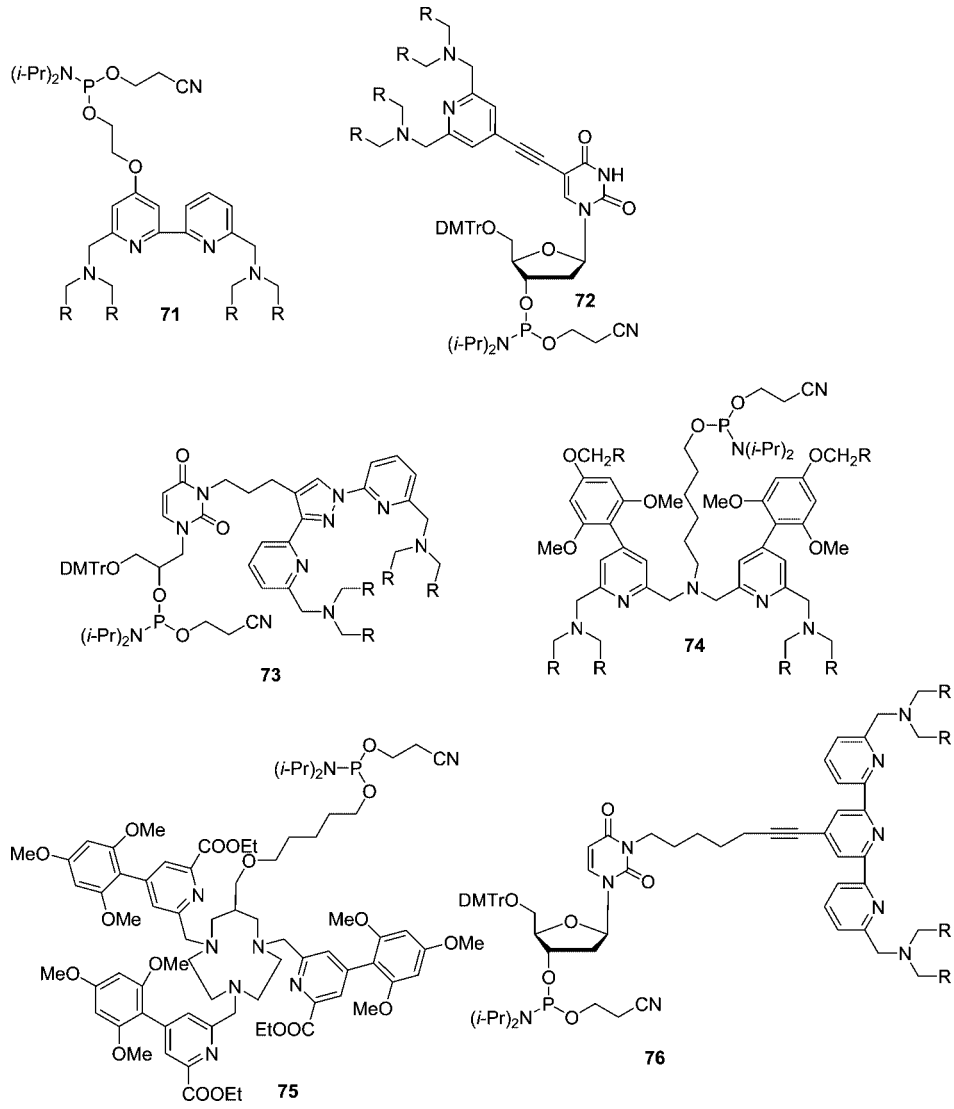


Figure 5. Oligonucleotide labeling reactants. R = COOMe.

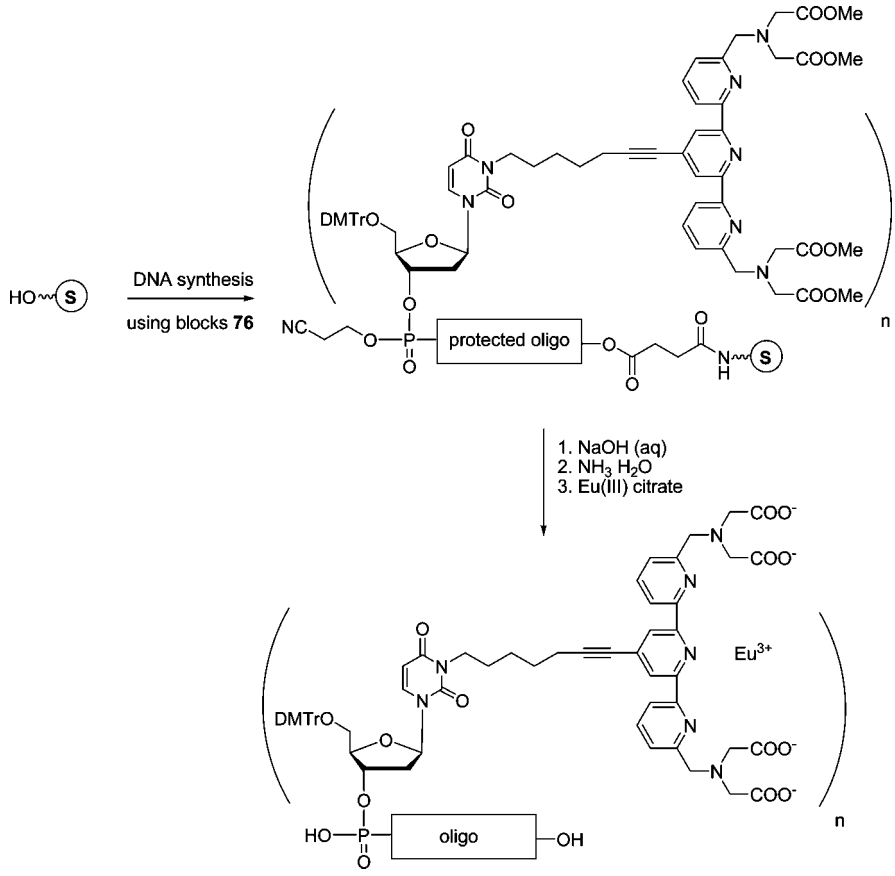
Several nucleosidic and non-nucleosidic building blocks useful for solid-phase oligonucleotide derivatization with lanthanide chelates have been prepared. Illustrative examples are shown in Figure 5. The key step in this labeling reaction is the phosphitylation of the corresponding protected ligand tethered to a hydroxy group. Synthesis of the hydroxy group comprising the precursor has been performed as described above. The chelating carboxylic acid functions were protected with base labile groups compatible with standard oligonucleotide synthesis. Originally, Kwiatkowski et al. synthesized a non-nucleosidic bipyridine derivative **71** that can be coupled to oligonucleotide by phosphoramidite chemistry (*111*). Later, various non-nucleosidic terbium, dysprosium, samarium, and europium blocks in which the linker was attached at the chromophore have been prepared (*28, 112*). The non-nucleosidic blocks are suitable for introduction of a single label molecule to the 5′-terminus of an oligonucleotide. The first nucleosidic blocks including **72** were published by Kwiatkowski et al. (*113*). These blocks comprise a chromophore conjugated to uracil and cytosine base via ethynyl moieties. Accordingly, the nucleobase is a part of the chelate chromophore. They can be introduced also within the coding sequence, since the chelates do not restrict the formation of Watson−Crick base pairs. Later, a more versatile method for the preparation of nucleosidic and acyclo-nucleosidic oligonucleotide building blocks was developed in which the linker is attached at the N3 of uracil and thymine base using a Mitsunobu reaction (*112*−*116*). This approach was applied to multilabeling of oligonucleotides and in the preparation of solid supports that allow 3′-derivatization. Since the labels are attached at sites involved in base pairing, incorporation of these blocks within coding sequences has not been recommended.

The oligonucleotide building blocks described in the literature have been introduced into oligonucleotide structures with high efficiency using a modified deprotection protocol (Scheme 14). Hydrolysis of the protecting groups of the chelating moieties was performed by treatment with aqueous sodium hydroxide prior to ammonialysis to avoid carboxamide formation. The lanthanide ion was introduced as a lanthanide citrate in which the lanthanide is chelated and in solution even under basic conditions.

It is known that trivalent lanthanide ions promote hydrolysis of phosphoesters very effectively (*117*). The catalytic efficiency can be attributed to the formation of a metal hydroxide gel, and the catalysis was suggested to be a complicated heterogenic process (*118*). The lanthanide clusters are formed already in slightly alkaline solutions. Accordingly, it is extremely important that the excess lanthanide ion is not precipitated under the basic conditions needed. It is also known that certain europium chelates based on Schiff bases hydrolyze RNA (*119*). The catalytic activity is considerably reduced with negatively charged

Scheme 14. Labeling of Oligonucleotides on Solid Phase



ligands (*120*). Accordingly, the choice of ligand structure is highly important.

Noncovalent Binding. There exist assay formats in which no covalent binding between biomolecule and label is necessary. The example of preparation of nanobeads by swelling chelates into particles was discussed above. As another example, a cytotoxicity assay in which target cells are labeled with the acetoxymethyl ester of 2,2′:6′,2″-terpyridine-6,6′-dicarboxylic acid has been developed (*121*). The hydrophobic ligand **76** penetrates easily through cellular membranes of viable cells. Upon the action of intracellular esterases, the acetoxymethyl esters are hydrolyzed, generating impermeable hydrophilic ligands within cells. The ligand leakage upon cell disintegration is monitored by enhancing the supernatant with an excess of Eu^{3+}. Another example of an assay application in which no reactive group is needed is the separation of eosinophilic and basophilic cells (*122*). In this application, positively and negatively charged chelates bind with negatively and positively charged cell surfaces, respectively. Reaction of the almost nonluminescent chelate **9d** (Figure 6) with singlet oxygen converts it to the luminescent endoperoxide **77**. This has been utilized in the quantitation of $^1O_2$ generated in various biological systems (*38*).

SOLUBILITY

In general, lanthanide chelates exhibit good water solubility. However, large aromatic chromophores may cause hydrophophic aggregation. The problem has been solved by introduction of hydrophilic substituents to the chelate structure. For example, the aqueous solubility of compound **50** has been enhanced by the addition of COOH (*83*) or carbohydrate (*123*) groups to the chromophore (Figure 7). Also, the nonspecific binding of labeled biomolecules is reduced, whereas the affinity properties of the used biomolecules are almost unchanged. The same strategy has been used also for terbium chelates (*124, 125*).

Very recently, Romieu et al. reported an elegant method for improvement of water solubility of organic dyes (*126*). The method involves the addition of 3-amino-2-sulfopropanoic acid to dyes tethered to active esters of carboxylic acids. The new labeling reactant formed contains a carboxylic acid group for biomolecule conjugation. Although the applicability of 3-amino-2-sulfopropanoic acid to derivatization of lanthanide chelates has not been published, the molecule is worth trying if enhanced water solubility is needed.

Since lanthanide chelates are often extremely hydrophilic, their solubilities in organic solvents are low. This is a serious problem when developing luminescent chelates to be polymerized to produce nanobeads. However, certain europium(III) chelates having thienylpyridine subunits have moderate solubil-

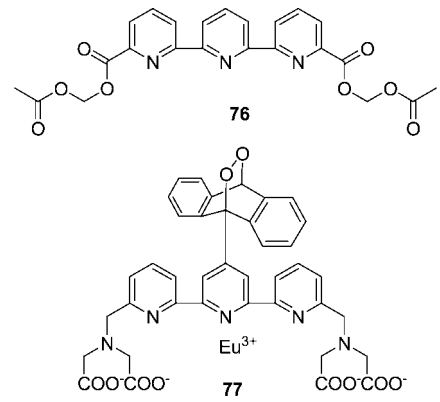


Figure 6. Labels for applications where no covalent binding between biomolecule and label is needed.

ity in organic solvents such as THF that allow the preparation of the beads (*31*).

THE LANTHANIDE(III) ION

Lanthanide(III) chelates are most commonly prepared by the treatment of the free ligand with a slight excess of lanthanide chloride at pH 6−7. When the chelation is completed, the excess of lanthanide is conveniently removed by increasing the pH of the reaction mixture to ca. 11 where the uncomplexed lanthanide ion precipitates as lanthanide hydroxide (*86*). Alternatively, the chelate formation is achieved by passing the ligand through a column of strong cation exchange resin loaded with the appropriate lanthanide ion (*76*).

Eu^{3+}, Tb^{3+}, Sm^{3+}, and Dy^{3+} are the four lanthanide ions that can be used as central ions of luminescent lanthanide chelates. Since there are larger differences in the vibrational levels of the lowest excited state and the highest ground state of Eu^{3+} and Tb^{3+} than of Sm^{3+} and Dy^{3+}, europium and terbium chelates are more efficient light emitters, and thus they are applied more often. The decay times of Sm^{3+} and especially Dy^{3+} chelates are short (*39, 127, 128*). Due to the similarities in the energy levels of Eu^{3+} and Sm^{3+}, ligands highly luminescent with europium are useful with samarium (*129*). This is the case with the terbium and dysprosium pair also. For example, electron releasing substituents in the aromatic moiety of phenyl and naphthyl substituted 2,6-[*N*,*N*-di(carboxyalkyl)aminoalkyl]pyridines have advantageous effects on the photophysical properties on their chelates with terbium and dysprosium, while the corresponding europium and samarium chelates are practically nonluminescent (*131*). However, ligands based on 2,6-bis(*N*-pyrazolyl)pyridine and 6,6′-(1*H*-pyrazole-1,3-diyl)bis(pyridine) have been shown to form luminescent chelates with Eu^{3+}, Sm^{3+}, Tb^{3+}, and Dy^{3+} ions. Accordingly, these ligands are highly useful for multiparametric homogeneous assays simplifying considerably the preparation of chelates needed in these applications. Also, dual-label assays based on luminescent Eu^{3+} and Tb^{3+} chelates of terpyridine have been proposed (*82*).

It has been observed repeatedly that even small modifications in the structure of labeling reagents may cause significant changes in the luminescence properties of the chelate. In this respect, europium is the most robust metal: it is possible to develop assays in which the labeling reagents coupled to a bioactive molecule have luminescence properties almost identical to their parent compounds (*40*). The use of terbium chelates is more complex due to their greater sensitivity to the environment. Li and Selvin have shown that the emission intensity of certain luminescent Tb^{3+} but not the corresponding Eu^{3+} chelates decreases upon conjugation to single-stranded oligonucleotides, and that the signal increases upon hybridization (*132*). The emission intensity is at its highest for unconjugated chelate. This unique property of Tb^{3+} chelates has been exploited in the development of homogeneous DNA hybridization assays (*133*−*137*).

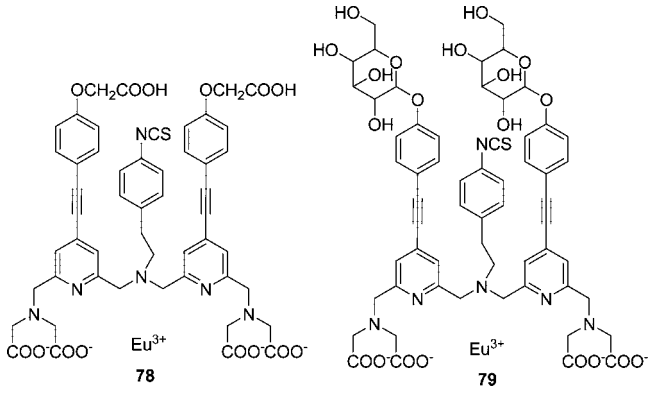

Figure 7. Europium(III) chelates with enhanced water solubility.

Traditionally, the lanthanide-based assay chemistries have allowed only limited multiplexing since the number of usable chelates is limited to four (chelates of Eu^{3+}, Tb^{3+}, Sm^{3+}, and Dy^{3+}) (*138*). However, when luminescent lanthanide chelates are combined with different homogeneous FRET techniques, more multiplexed detections can be performed, since the same donor chelate can be exploited for different analytes in the reaction. With appropriate selection of acceptor labels, one can use either the emission of donor itself (TR-FQA) (*139*) or wavelengths in the Red/NIR region (TR-FRET) (*140*), or wavelengths shorter than the donor emission spectrum (anti Stokes' shift TR-FRET) (*141*) to detect the analyte. In addition, extra signal resolution can be obtained by adjusting the decay time of the acceptor signal (*142*). Accordingly, by using multiple assay chemistries, a single lanthanide chelate can be utilized for measuring at least five analytes simultaneously.

FREEDOM TO OPERATE

Patent literature provides a rich source of information about luminescent lanthanide chelates. Although there are numerous excellent scientific publications, only a small fraction of luminescent lanthanide chelates described in the patent literature have also been described in the non-patent literature. Moreover, many chelates published in the non-patent literature were first described in the patent literature. Thus, a search of chemical literature concerning luminescent lanthanide chelates, as well as many other classes of structures, would be incomplete without a review of published patent applications and patents.

Fortunately, there are many public resources available for patent literature searching, and the patent laws of most countries require publication of a patent application as a condition of granting a patent. Typically, patent applications are published about 18 months from the date of filing in a patent office, for the public benefit of describing the invention in a manner sufficient for others to practice it after the term of protection granted with the patent has expired. Useful patent information is available free of charge, for example, from www.espacenet.com. This worldwide database was designed especially for nonprofessionals and offers efficient contextual help and help files. In addition to providing millions of uploadable patents and patent application publications, this resource provides information about the legal status of specific patents, as well as the countries in which patent applications are pending and patents are granted. More detailed information on patents and pending patent application is available at many governmental patent offices, such as WIPO (www.wipo.int), EPO (www.epoline.org). and USPTO (www.uspto.gov), academic Internet sites, professional societies' sites, and fee-based Internet sources, such as Delphion (www.delphion.com), Micropatent (www.micopat.com), and Nerac, Inc. (www.nerac.com).

Briefly turning to the value of patents to their owners, a patent is a form of intellectual property that grants to the owner the right to exclude others from making, using, importing, and selling the claimed invention. Notably, a patent does not give the owner the right to practice the invention. Patent rights are based on laws of the granting country and most often provide 20 years of protection from the first filing date of the application. In most countries, a patent can protect any subject matter that falls into one of the following categories: a process, machine, article of manufacture, or composition of matter, or any new and useful improvement thereof. From a chemistry perspective, in most countries a patent can protect a new and useful compound, a composition containing the compound, an article

containing or made from the compound, a process for synthesizing the compound, and a method that involves using the compound. Certain subject matter is not patentable in various countries due to specific prohibitions in patent laws or as a result of court decisions ruling on these laws. In particular, laws of nature, physical phenomena, scientific principles, abstract ideas, purely mental processes, and mathematical algorithms are typically nonpatentable subject matter. Given the inherent complexities of patents, from selecting a type of patent application, meeting patentability requirements, and complying with rules in patent offices throughout the world to more commercial aspects such as exercising provisional rights, licensing, and enforcing patent rights, this review article mentions a minute fraction of patent-related issues of interest to chemists. Readers are encouraged to pursue additional information, which fortunately is increasingly available as professional societies and publishers of chemical research literature more frequently provide educational information about patents.

CONCLUSION

Stable luminescent lanthanide chelates have made homogeneous bioaffinity assays possible. However, the use of stable chelates demands very complicated optimization of the chelate structure. The optimal luminescent lanthanide chelate is stable in the presence of additional chelators even at low pH and high temperature. The ideal chelate has an optimal emission profile, high hydrophilicity, small size, good biocompactibility, little effect on biomolecules, and good energy transfer properties. In addition, the chelate should be compatible with different energy acceptors. The synthesis of the molecule should be simple, affordable, and scalable. Naturally, it is advantageous from a commercial perspective that new luminescent lanthanide chelates are protected by patents in relevant international markets.

ACKNOWLEDGMENT

J.H. wish to thank Dr. Ilkka Hemmilä (PerkinElmer Life and Analytical Sciences, Turku Site) for valuable discussions.

Knocking (Anti)-Sense into Cells: The Microsphere Approach to Gene Silencing

Lois M. Alexander, Rosario M. Sánchez-Martín, and Mark Bradley*

School of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, EH9 3JJ United Kingdom. Received December 9, 2008; Revised Manuscript Received February 2, 2009

200 and 500 nm polymeric microspheres have been conjugated to siRNA targeted against EGFP expressed in human cervical cancer (HeLa) cells and shown to efficiently silence protein expression over 72 h, without detrimental cytotoxicity. Furthermore, with use of an independent Cy5 tracking label on the siRNA-laden microsphere, silencing of EGFP could be assessed by selecting only those cells that contained the delivery vehicle (and thus the siRNA) generating a more accurate picture of microsphere-induced gene silencing.

Since it was first described in the 1990s (*1, 2*), interest in the area of RNA interference or the so-called RNAi pathway has grown dramatically. This interest has been heightened by the increased understanding of the role of short interfering RNA (siRNA) (*3*) and the possible therapeutic applications it may have (*4, 5*). However, naked, synthetic siRNA is cell-impermeable and requires a delivery system, which includes, for example, viral methods (*6, 7*) which generate siRNA in vivo, microinjection (*8*), lipofection (*9*), and carbon nanotubes (*10*). Microspheres have been shown to be efficient delivery agents of a range of biological cargos, including sensors, proteins, and reporters (*11*−*14*). As well as having high uptake efficiencies in a wide range of cells, they have additionally been shown to be nontoxic (*14*) and may be readily and easily functionalized. Here, we report the attachment of double-stranded siRNA to 200 and 500 nm polystyrene microspheres via cleavable (disulfide) and noncleavable (amide) linkages and demonstrate the efficient silencing of enhanced green fluorescent protein (EGFP) stably expressed in human cervical cancer (HeLa) cells.

Polystyrene microspheres (200 and 500 nm) with divinylbenzene cross-linking were prepared by dispersion or emulsion polymerization and PEGylated as previously reported (*14*). Initially, in order to quantify the uptake of these microspheres in HeLa cells, fluoresceinamine was coupled to PEGylated microspheres via a noncleavable (amide) linker (Scheme 1, **2a**−**b**) using standard solid-phase techniques (*14*). Analysis of cellular uptake was made by flow cytometry following incubation with the microspheres for 6−72 h and was observed to be over 70% after 24 h and over 80% after 72 h (see Supporting Information, Graph S-1). All flow cytometric analysis was performed in 0.2% trypan blue, which quenches any extracellular fluorescence associated with microspheres on the outside of the cell, ensuring that only fluorescence originating from microspheres inside the cell is measured (*15, 16*). Uptake was additionally confirmed by confocal microscopy, showing fluorescein microspheres localized within the cytoplasmic regions of the cell (see Supporting Information, Figure S-3).

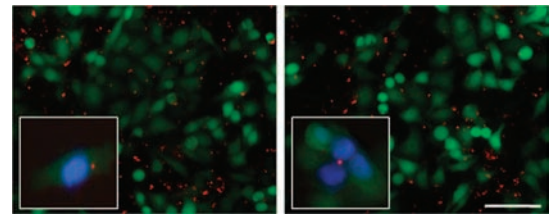

Figure 1. Pseudoconfocal microscopy of HeLa-EGFP cells (green) incubated with (a) 200 nm TAMRA siRNA microspheres (red); (b) 500 nm TAMRA siRNA microspheres (red). Images taken after 24 h (scale bar is 200 μm). Inset images are a 4 × magnification, where nuclei are stained with Hoechst 33342.

In order to achieve an intracellularly cleavable functionality, PEGylated microspheres (**1a**−**b**) were functionalized with a disulfide linker, yielding **3a**−**b**. To evaluate the cleavability of the disulfide linkage, fluoresceinamine was coupled, yielding disulfide-FAM microspheres (Scheme 1, **4a**−**b**) and the constructs were treated with glutathione (10 mM) to facilitate release of thiolated fluoresceinamine, which was assessed by flow cytometry. Reduction of the disulfide linkage was evident after just 1 h and maximal after 24 h (Supporting Information, Graph S-2). **4a** and **4b** were subsequently incubated with HeLa cells and release of the fluorophore into the intracellular environment examined and was found to be prevalent after 12 h when microspheres as fluorescently localized points within cells were no longer extensively visible (see Supporting Information, Figure S-2a,b). In contrast, microspheres exhibiting fluoresceinamine via a noncleavable (amide) linkage retained their fluorescent label regardless of glutathione treatment or the length of incubation time within HeLa cells (see Supporting Information, Graph S-2 and Figure S-3).

Subsequently, the efficiency of siRNA loading onto microspheres was studied using siRNA with a 5′-amino functionality on the sense strand for coupling to the microspheres (Scheme 1) and a 5′ fluorescent label (TAMRA) on the antisense strand allowing quantification of coupling and hybridization by spec-

[a] For siRNA sequences, see Supporting Information.

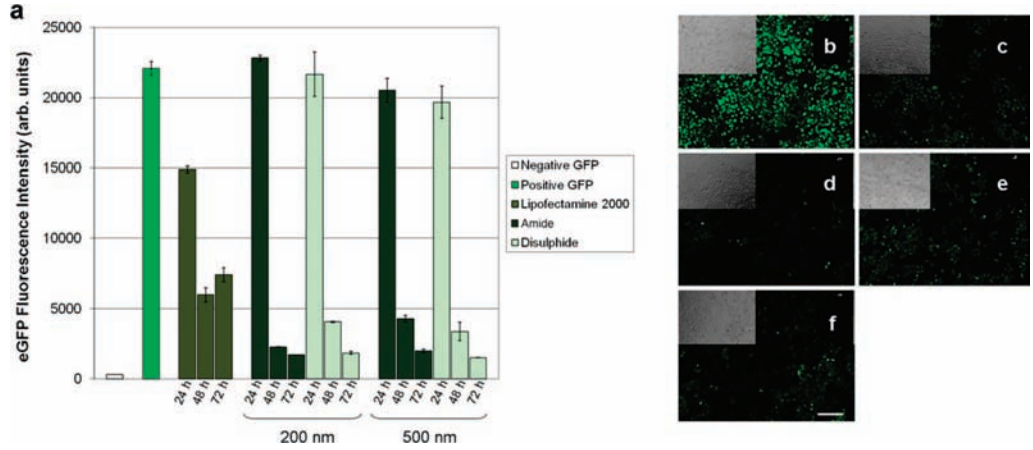

Figure 2. EGFP fluorescence expression in HeLa cells (a) by flow cytometry after 24, 48 and 72 h incubations with siRNA microspheres (200 and 500 nm, amide and disulphide, **5a–d**) and siRNA transfected via Lipofectamine 2000. siRNA concentration = 28 nM in all incubations. Negative GFP = HeLa cells untreated and not transfected with EGFP; Positive GFP = HeLa cells untreated and stably transfected with EGFP. *Right:* by microscopy after 72 h (b) Untreated cells; (c) with 200 nm amide-siRNA microspheres (**5a**); (d) with 200 nm disulphide-siRNA microspheres (**5c**); (e) with 500 nm amide-siRNA microspheres (**5b**); (f) with 500 nm disulphide-siRNA microspheres (**5d**). Scale bar is 350 μm. Inset are phase contrast images, showing approximately 70−80% cell confluency.

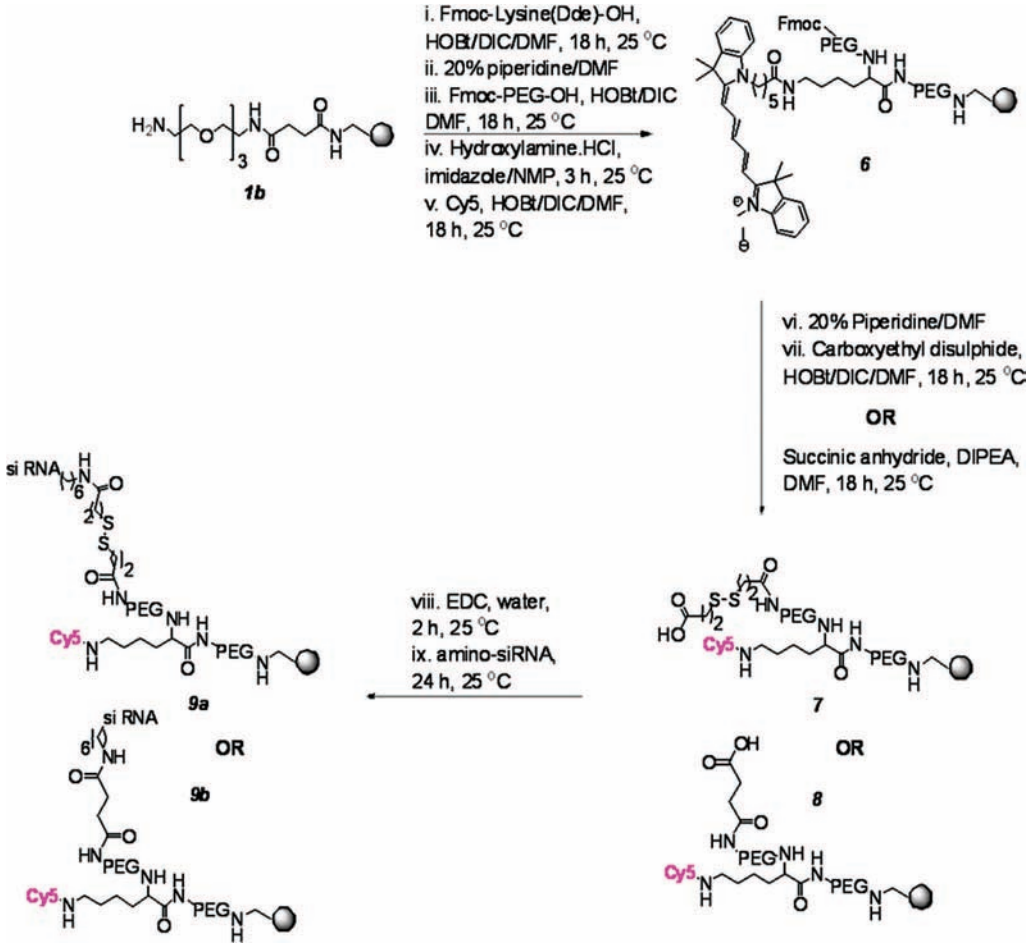
trofluorimetric analysis (see Supporting Information). The quantity of siRNA present on the microspheres was found to be ca. 13 000 molecules (2.2×10^{-20} mol) of siRNA per 500 nm microsphere and ca. 780 chains (1.3×10^{-21} mol) of siRNA

Scheme 2. Preparation of Dual-Labeled 500 nm Cy5-*co*-siRNA Microspheres with Disulfide and Amide Linkages (Fmoc-PEG-OH is Fmoc-NH-CH_2-(CH_2-O-CH_2)$_3$-CH_2-NH-C(O)-CH_2-CH_2-COOH)



per 200 nm microsphere. As such, with a microsphere concentration of 86 μg mL^{-1} (which has been demonstrated to afford excellent and uniform cellular uptake), this equates to a siRNA concentration of 28 nM in cell cultures (assuming all siRNA on the microspheres is cleaved in solution; see Supporting Information, Graphs S4−6). Examining this on a single bead

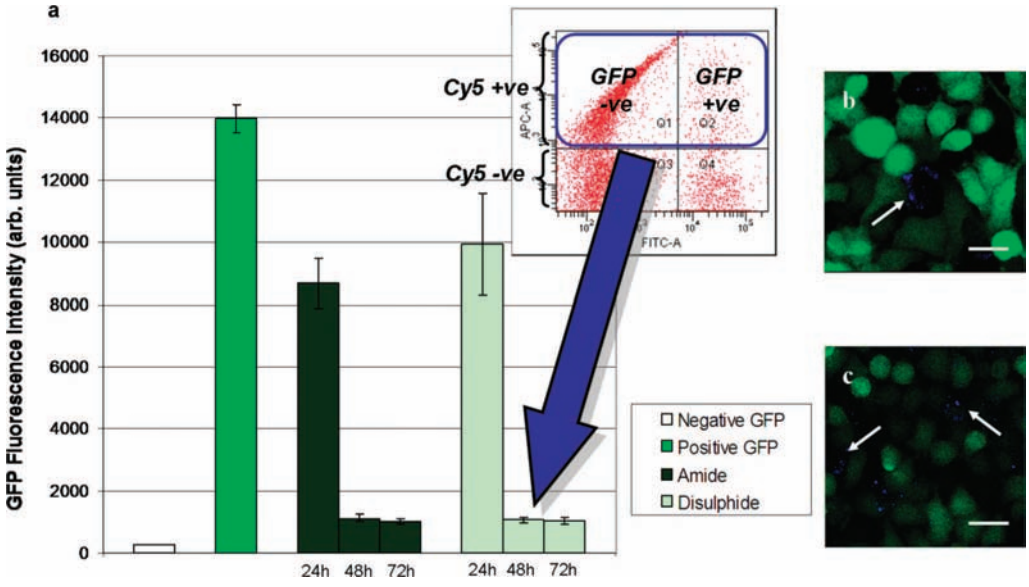


Figure 3. (a) EGFP Intensity in HeLa-EGFP cells after 24, 48, and 72 h incubation with Cy5-*co*-siRNA microspheres (**9a**−**b**). Negative GFP = HeLa cells untreated with beads and not transfected with EGFP; positive GFP = HeLa cells untreated with beads and stably transfected with EGFP. Inset: Dot plot of EGFP (FITC-A) vs Cy5 (APC-A) showing beadfected cells (Q1 and Q2) have a substantial reduction in EGFP intensity. *Right:* Confocal microscopy of HeLa-EGFP cells (green) treated with (b) amide-siRNA 500 nm Cy5 microspheres (**9b**) (scale bar is 70 μm); (c) Disulfide-siRNA 500 nm Cy5 microspheres (**9a**) (scale bar is 100 μm). Microspheres (blue) are indicated with white arrows. Images were collected using a Leica DM IRE2 inverted confocal microscope.

per cell basis, we equate this to an intracellular siRNA concentration of 0.3 nM (200 nm microspheres) to 4 nM (500 nm microspheres), assuming that all siRNA is disengaged from the delivery device and cell volume average of 5000 μ^3 (*17*). However, it must be noted that, in general, cells take up more 200 nm microspheres than 500 nm microspheres. Accordingly, in order to qualify siRNA-laden microsphere uptake, HeLa-EGFP cells were incubated with microspheres loaded with TAMRA labeled siRNA (**5a**−**b**) and assessed for uptake via pseudoconfocal microscopy (Figure 1) (a control was established using TAMRA-siRNA not conjugated to microspheres to measure background staining). Uptake was evident after 24 h, and the siRNA label could be seen localized on the polymer microspheres within cells. Previous studies have indicated that these microspheres enter cells by a mechanism that does not result in their endosomal capture (*11*, *13*), avoiding the need to apply endosomal disrupting agents to achieve cytoplasmic localization.

While siRNA functionalized with a fluorophore can achieve efficient gene knockdown (*18*), labeling of the antisense strand can result in poor silencing (see Supporting Information, Graph S-7) (*19*). As a consequence, **2a**−**b** and **3a**−**b** were conjugated to *unlabeled* siRNA, and HeLa-EGFP cells were subsequently treated with these microspheres (86 μg mL^{-1}, 28 nM siRNA) for 24, 48, and 72 h, before analysis of EGFP expression by microscopy and flow cytometry. After 48 h, excellent reductions in EGFP intensities were observed in cells incubated with all siRNA bead types, which was even more prominent after 72 h (Figure 2), with up to a 90% reduction in EGFP intensity. Positive controls were established using a commercially available transfection agent, Lipofectamine 2000, which achieved a 70% reduction in EGFP after 72 h using the same concentration of siRNA as the microspheres (28 nM, Figure 2). Negative controls included lipofection and beadfection of scrambled siRNA, siRNA without a carrier system, and microspheres without siRNA (Supporting Information, Graph S-8). In addition, the concentration of siRNA-microspheres incubated with HeLa-EGFP cells was varied and the knockdown efficiency was found to be dose- as well as time-dependent (see Supporting Information, Graph S-9). Furthermore, siRNA microspheres were shown to be nontoxic by MTT assay, even after 72 h, at all concentrations analyzed (see Supporting Information, Graph S-3).

Although EGFP silencing was clear, it was considered that a more accurate assessment of the knockdown would be to obtain a system whereby the beadfected cells could be assessed independently from non-beadfected cells. To this affect, a dual-functionalized system was developed. Thus, orthogonally protected lysine (*20*) was employed to allow functionalization of the microspheres with both a fluorophore (Cy5) and siRNA (Scheme 2). As such, HeLa-EGFP cells were incubated with Cy5-*co*-siRNA 500 nm microspheres (**9a**−**b**, 86 μg mL^{-1}, 28 nM siRNA), and EGFP silencing was analyzed after 24, 48, and 72 h by flow cytometry selecting only those cells that were positive for Cy5 (beadfected cells, thus containing siRNA) (Figure 3a). Silencing of EGFP was evident after 24 h and extensive at 48 and 72 h using both cleavable (disulfide) and noncleavable (amide) linkages to the microspheres. Reduction in EGFP expression was confirmed by confocal microscopy (Figure 3b,c), whereby cells containing microspheres (indicated by white arrows) were negative for EGFP expression. Using this method, the gene silencing capabilities of microspheres could be more accurately depicted, since only those cells known to contain the delivery device were considered in analysis of the EGFP expression.

In conclusion, enhanced green fluorescent protein stably expressed in human cervical cancer (HeLa) cells was successfully silenced (by approximately 90%) using siRNA linked to 500 and 200 nm microspheres via cleavable (disulfide) and noncleavable (amide) linkers, exceeding the silencing capabilities of commercially available lipofection products. In addition, a system employing dual-functionalized (Cy5-*co*-siRNA) microspheres allowed independent evaluation of only those cells that had been beadfected with siRNA, yielding gene silencing data based only on those cellular populations that had received the delivery vehicle, generating a more accurate analysis of the gene silencing capabilities of microspheres. This approach additionally allowed HeLa-EGFP cells beadfected with siRNA to be tracked over time, both visually by microscopy and by fluorescence-based flow cytometric methods.

Importantly, the nontoxic nature of the microspheres along with their facile functionalization and controllability over cellular loading makes these constructs particularly suitable to this application in a day and age when efficient, nontoxic, and versatile delivery devices are strongly desired.

ACKNOWLEDGMENT

The authors would like to thank the EPSRC and the BBSRC for funding. R.M. Sánchez-Martín would like to thank the Royal Society for a Dorothy Hogdkin Fellowship. The authors are grateful to M. Lopalco for the Cy5 dye.

Preparation of siRNA Microspheres

200 and 500 nm amino microspheres were firstly functionalised with a modified PEG linker as follows: Microspheres were washed and suspended in DMF (3% solid content, 0.5 mL). Separately, Fmoc-amino carboxy poly(ethylene glycol) (10 equiv.) was dissolved in DMF (0.5 mL) with HOBt and DIC (10 equiv.) and mixed for 10 minutes. After this time, the solution was added to microspheres and mixed for 18 hours at 25 ºC. Subsequently, the microspheres were washed by centrifugation (13,000 rpm, 3 – 10 minutes) with DMF, methanol and water. Fmoc deprotection was subsequently achieved via treatment with 20% piperidine/DMF (3 × 20 minutes) and microspheres (**1a-b**) were sequentially washed as previously.

200 and 500 nm succinic microspheres (**2a-b**) were prepared by the addition of succinic anhydride (10 equiv.) and DIPEA (10 equiv.) in DMF and mixed at 25 ºC for 18 hours. Microspheres were then sequentially washed as described.

200 and 500 nm disulphide microspheres (**3a-b**) were prepared by the addition of carboxyethyl disulphide (10 equiv.), HOBt and DIC (10 equiv.) in DMF and mixed at 25 ºC for 18 hours. Microspheres were then sequentially washed as described.

Microspheres (**2a-b, 3a-b,** 100 µL, 3% solid content) were sterilized by U.V. radiation and with RNase Zap solution (Invitrogen) before pre-activation in MES buffer (pH 5.5) with EDAC.HCl (10 equiv.) for 2 hours at 25 ºC. The microspheres were isolated by centrifugation (as previous) and amino-siRNA (1 nmol) was then added in sterile RNase-Free water (100 µL) and mixed for 24 hours at 25 ºC.

Microspheres were subsequently isolated by centrifugation and stored in sterile RNase-Free water at 4 ºC.

siRNA Sequences: For EGFP silencing: Sense 5'-amino-C6-GCU GAC CCU GAA GUU CAU CUU-3'; Anti-sense 5'-GAU GAA CUU CAG GGU CAG CUU-3' (21).

Scrambled siRNA: Sense 5'-amino-C6-GUG AAA ACC AGG ACA AAA GUU-3'; Anti-sense 5'-CUU UUG UCC UGG UUU UCA CUU-3'.

Preparation of Fluorescein Microspheres

Microspheres (**2a-b, 3a-b**) were pre-activated in MES buffer (pH 5.5) with EDAC.HCl (10 equiv.) for 2 hours at 25 ºC before the addition of fluoresceinamine (10 equiv.) and mixing at 25 ºC for 18 hours. Microspheres were washed sequentially as previous and stored in water at 4 ºC.

Preparation of Dual-Functionalized Microspheres

PEGylated microspheres (**1a-b**), were treated with orthogonally protected Fmoc-Lysine(Dde)-OH (10 equiv.), HOBt and DIC (10 equiv.) in DMF for 18 hours at 25 ºC. Microspheres were subsequently washed as previous and Fmoc deprotected with 20% piperidine/DMF, yielding free amino residues, which were PEGylated as described above. Subsequently, Dde deprotection was afforded by treatment of microspheres with hydroxylamine.HCl (0.4 mmol) and imidazole (0.3 mmol) in NMP (1 mL) for 30 minutes – 1 hour. Microspheres were subsequently labelled with Cy5 by addition of Cy5 (5 equiv.) in the presence of HOBt (5 equiv.) and DIC (5 equiv.) in DMF and mixed for 18 hours at 25 ºC yielding **6**. After washing, microspheres were Fmoc deprotected and then coupled with carboxyethyl disulphide (yielding **7**) or succinic anhydride (yielding **8**) as described above.

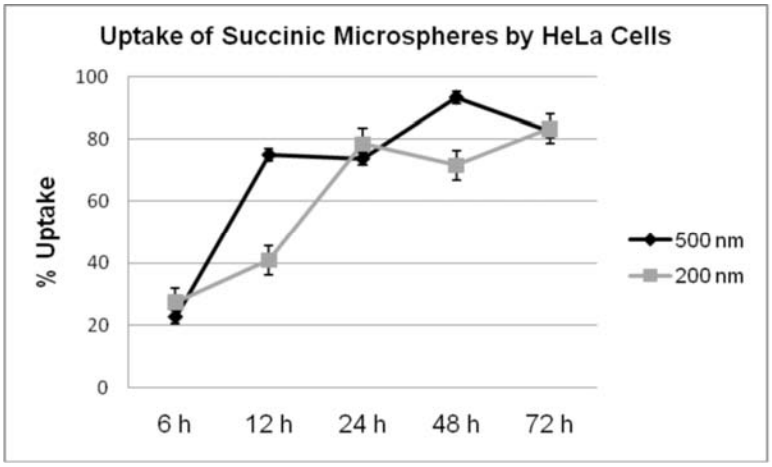
Microspheres were activated and conjugated to siRNA as described above.

Cell Cultures

HeLa and HeLa-EGFP cells were grown in Roswell Park Memorial Institute Medium supplemented with 10% fetal bovine serum, 100 units/mL penicillin/streptomycin and 4 mM L-glutamine to 70 - 80% confluency. The cells were harvested via trypsin/EDTA and collected in growth media. They were seeded at a density of 2×10^4 cell per well in a 24-well plate and incubated at 37 ºC/5% CO_2.

HeLa Cell Uptake of Succinic-Fluorescein Microspheres

HeLa cells were cultured as described above. After 24 hours, 500 nm and 200 nm amide-fluorescein microspheres were added to the cells in fresh growth media at a concentration of 86 μg/mL. After 6, 12, 24, 48 and 72 hours the cells were detached by trypsination, collected in media and pelleted by centrifugation (1200 rpm, 4 minutes). The cell pellet was then resuspended in 0.2% trypan blue in Hank's Balanced Saline Solution (HBSS) for analysis by flow cytometry on a FACS Aria system (BD Biosciences). Excitation was made at 488 nm and emission collected with a 530/30 band pass filter. FACS Diva software was used for analysis. The % uptake is summarized in Graph S-1.



Graph S-1. Uptake of 200 and 500 nm amide-fluorescein microspheres by HeLa cells over 72 hours. % Uptake is calculated as the total % of the cell population that contains a fluorescent microsphere, where 0% uptake is untreated cells.

Disulphide Cleavage with Glutathione

200 and 500 nm disulphide-fluorescein beads (Figure S-1) were treated with 10 mM glutathione in phosphate buffered saline (PBS, pH 7.4) for 1, 6 and 24 hours. Cleavage was assessed on the reduction in fluorescence intensity of the microspheres compared to untreated control beads (Graph S-2).

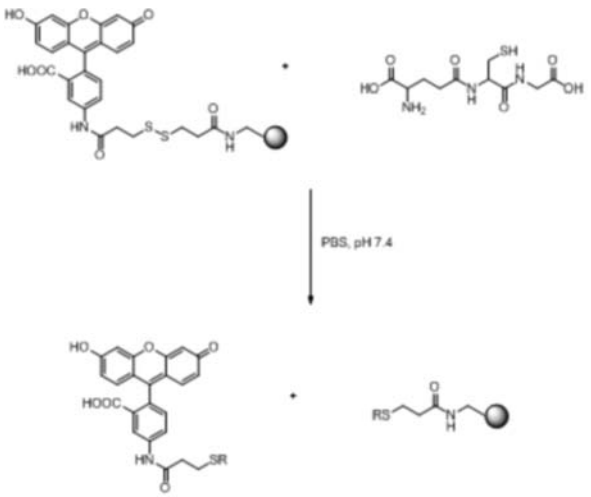


Figure S-1. Cleavage of disulphide-fluorescein beads by treatment with glutathione

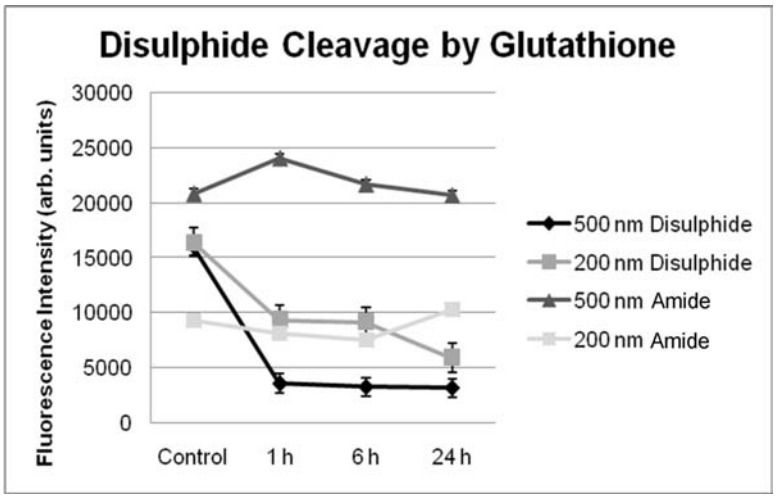

Graph S-2. Cleavage of disulphide-fluorescein beads by treatment with glutathione over 24 hours.

For *in vitro* analysis, HeLa cells (not expressing EGFP) were cultured as described and disulphide-fluorescein microspheres (200 and 500 nm, 86 µg/mL) were added. Microscopy was performed after 6, 12 and 24 hours.

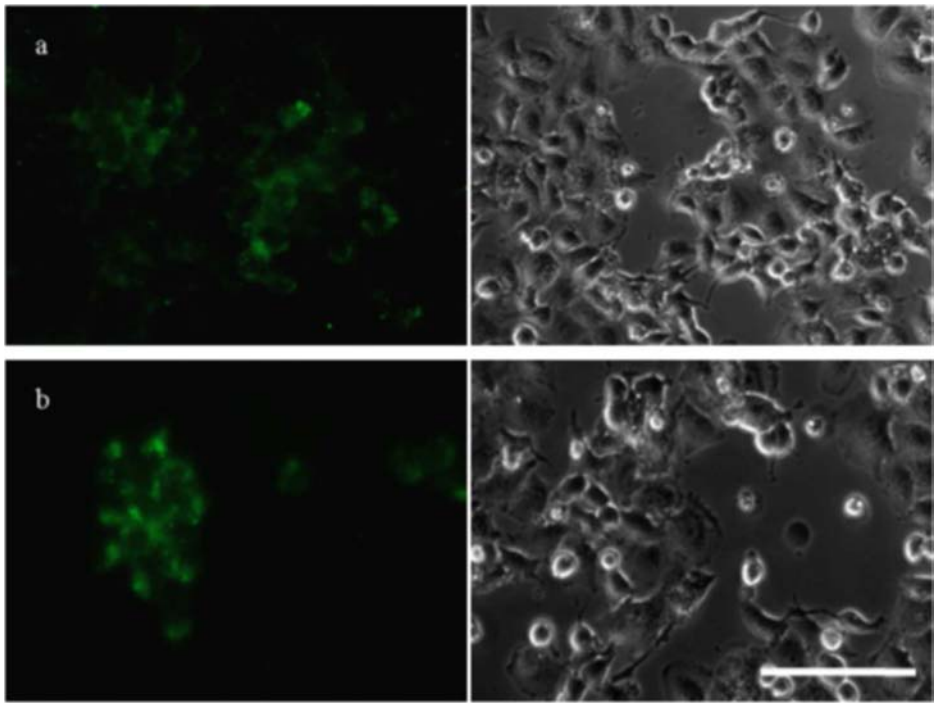

Figure S-2. Microscopy of HeLa cells incubated with **a.** 500 nm disulphide-fluorescein microspheres (**4b**); **b.** 200 nm disulphide-fluorescein microspheres (**4a**). Images taken after 12 hours (scale bar is 100 μm).

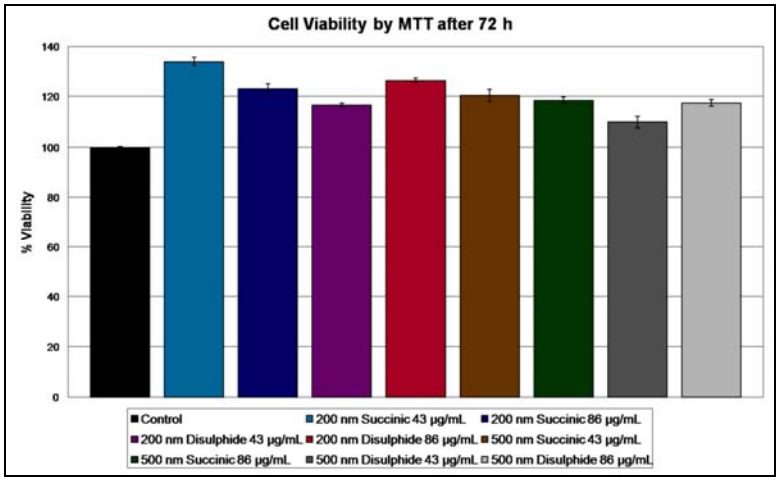
MTT Assays of HeLa-EGFP cells with siRNA Microspheres

HeLa-EGFP cells were cultured as described above. They were seeded into a 96-well plate in growth media. 200 and 500 nm amide and disulphide siRNA microspheres were added to fresh phenol-red free growth media at day 1, day 2 and day 3. After 72 hours after the first microsphere addition, 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide in phenol red-free media (5 mg/mL, 10 μL per well) was added and the cells incubated for a further 5 hours. After this time, MTT solubilization solution was added (10% Triton-X, 0.1 N HCl in isopropanol, 100 μL) and the well plate was gently shaken overnight. Analysis was made at 570 nm. See Graph S-3.



Graph S-3. Toxicity by MTT assay after 72 hours with siRNA microspheres in HeLa-GFP cells

Cell Staining

Staining with Hoechst 33342: Hoechst 33342 (1 µg/mL) was added in PBS (pH 7.4) to cell cultures previously washed with PBS and incubated at 25 ºC for 10 minutes. Cell cultures were washed sequentially with PBS.

Staining with Alexa Fluor® 568-Phalloidin: Cells stained with Hoechst 33342 were fixed in 3% *p*-formaldehyde solution in PBS for 20 minutes. Cultures were then washed with PBS and Alexa Fluor® 568-Phalloidin (1 unit) added in PBS (200 µL) supplemented with 1% Bovine Serum Albumin. Cells were incubated at 25 ºC for 20 minutes before washing with PBS and finally stored in PBS at 4 ºC.

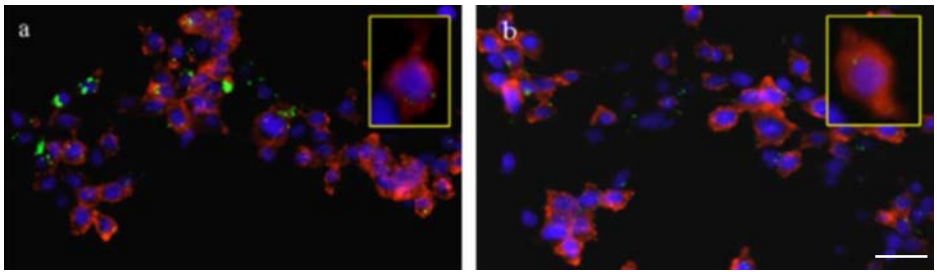


Figure S-3. Uptake of fluorescein labelled succinic **a.** 500 and **b.** 200 nm microspheres by HeLa cells. Actin filaments stained with Alexa Fluor® 568-Phalloidin and nuclei stained with Hoechst 33342. Inset is 2× magnification. Scale bar is 100 µm.

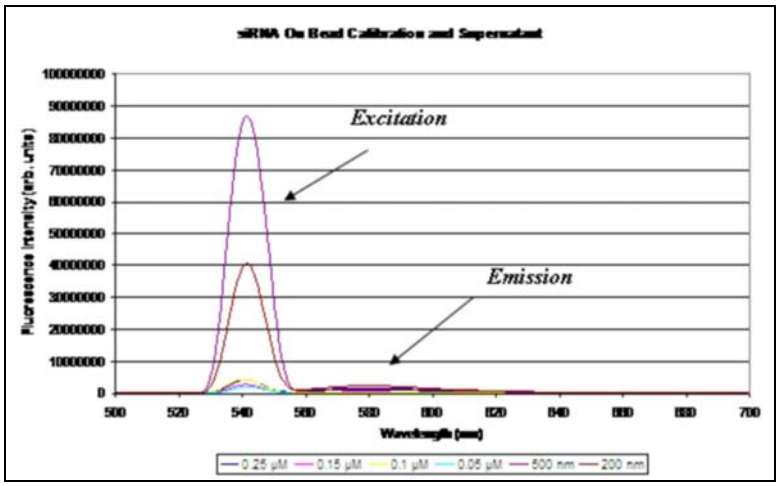
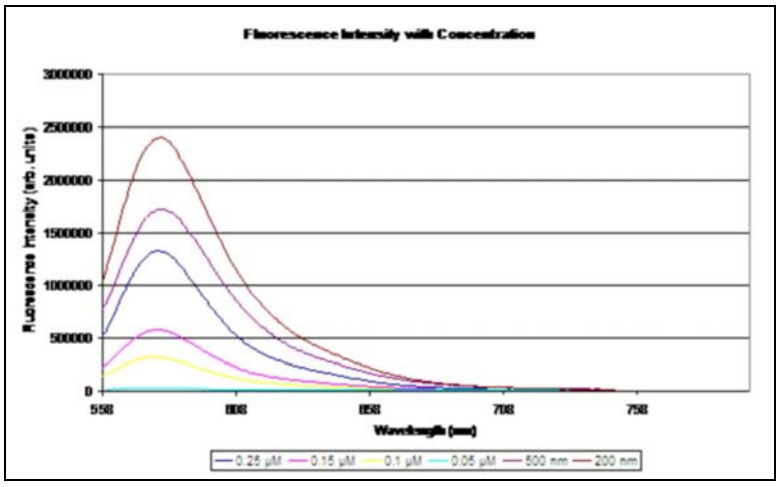
Analysis of siRNA Loading by Spectrofluorometry

The supernatant was collected from the siRNA-bead coupling by centrifugation (13,000 rpm, 2 minutes). Calibration solutions were prepared at concentrations of 0.25, 0.15, 0.1 and 0.05 µM TAMRA labelled siRNA in sterile RNase-free water and analysed on a FluoroMax spectrofluorometer and compared with the supernatant from the coupling reactions exciting at 542 nm and collecting emission from 500 – 750 nm. The emission maximum was found at 578 nm (Graph S-4 and S-5).

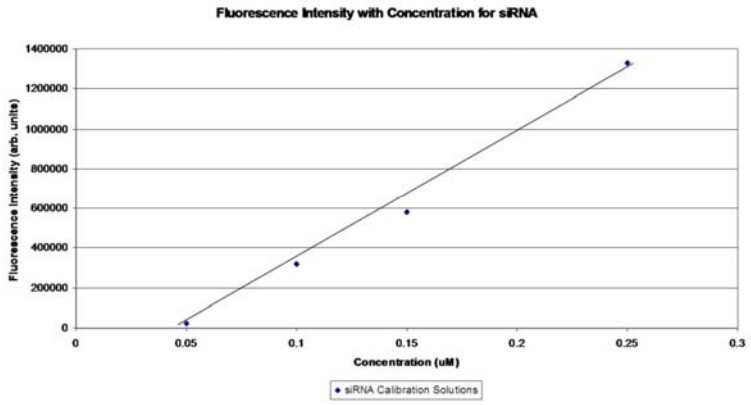


Graph S-4. Fluorescence excitation and emission collected by spectrofluorometry of calibration solutions and coupling supernatant, exciting at 542 nm and collecting emissions over 500 – 750 nm.



Graph S-5. Fluorescence emission only collected by spectrofluorometry of calibration solutions and coupling supernatant, exciting at 542 nm. Emission maximum was at 578 nm.

The calibration solutions were used to correlate TAMRA siRNA concentration to the intensity of fluorescence emission, which was found to be a linear relationship (Graph S-6).



Graph S-6. Fluorescence emission collected by spectrofluorometry of calibration solutions plotted as a function of concentration.

Using the equation of the graph (Equation S-1), the fluorescence emission recorded for the supernatant of the 200 and 500 nm bead-siRNA couplings were used to calculate the concentration of siRNA present in the samples and found to be 0.4 µM for 200 nm bead-siRNA supernatant and 0.3 µM for 500 nm bead-siRNA supernatant.

$$y = 7 \times 10^6 x - 332854 \qquad \textbf{Equation S-1}$$

Therefore: $x = (y + 332854)/7 \times 10^6$

Where x is the concentration (µM) and y is the fluorescence intensity (arb. units).

The 200 nm bead-siRNA supernatant contained 4×10^{-11} moles of siRNA and the 500 nm bead-siRNA supernatant 3×10^{-11} mol of siRNA. A total of 1×10^{-9} moles siRNA was added to the beads originally thus the 200 nm beads must have retained 9.6×10^{-10} moles siRNA (96% of siRNA coupled to microspheres) and the 500 nm beads must have retained 9.7×10^{-10} moles siRNA (97% of siRNA coupled to microspheres).

The number of beads per gram of solid can be calculated by Equation S-2.

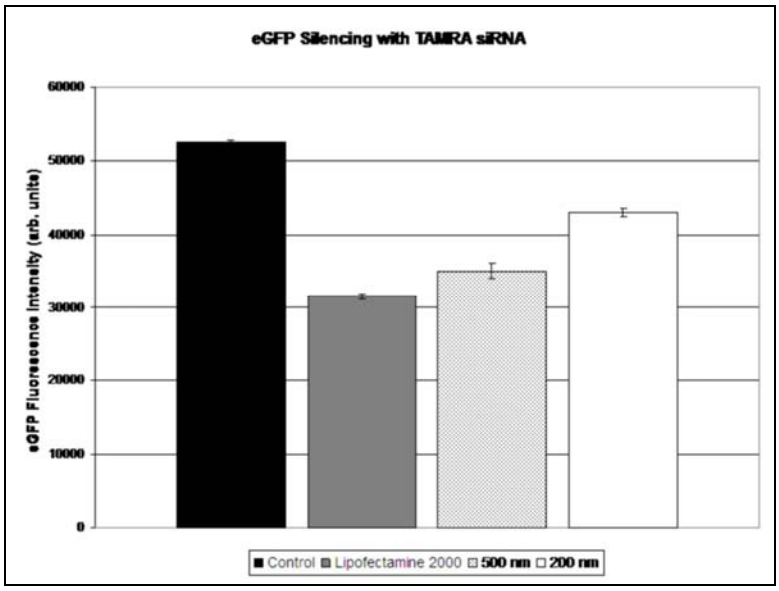
$$Number\ of\ beads/g = 6 \times 10^{12}/(\pi \times \rho \times d^3) \qquad \textbf{Equation S-2}$$

Where ρ is the density of the microspheres (1.0 g/mL for polystyrene microspheres) and d is the diameter of the microspheres. Equation from Bangs Laboratories, Technical Note.

Thus, in the case of 200 nm microspheres, there are 2.4×10^{14} beads/g and in a 100 µL aliquot at a solid content of 3% (as used in the siRNA couplings) there is 3 mg of solid beads. This equates to 7.2×10^{11} beads, therefore each bead holds, on average, 1.3×10^{-21} moles of siRNA, which equates to 783 molecules of siRNA per bead.
In a typical culture where 86 µg/mL microspheres (or 2.1×10^{10} beads/mL) are added to cells, 1.3×10^{-21} moles of siRNA per bead equates to 9.4×10^{-12} siRNA per culture. Given the cell culture volume is 350 µL, this gives a concentration of 2.7×10^{-8} moldm^{-3}.

In the case of 500 nm microspheres, there are 1.5×10^{13} beads/g and in a 100 µL aliquot at a solid content of 3% (as used in the siRNA couplings) there is 3 mg of solid beads. This equates to 4.5×10^{10} beads, therefore each bead holds, on average, 2.2×10^{-20} moles of siRNA, which equates to 13,244 chains of siRNA per bead.
In a typical culture where 86 µg/mL (or 1.3×10^{9} beads/mL) microspheres are added to cells, 2.2×10^{-20} moles of siRNA per bead equates to 1.0×10^{-11} siRNA per culture. Given then cell culture volume is 350 µL, this gives a concentration of 2.8×10^{-8} moldm^{-3}.

Gene Silencing by Beadfection with Fluorescently Labelled and Unlabelled siRNA
HeLa-EGFP cells were cultured in the normal manner (described above) prior to the addition of siRNA conjugated 200 and 500 nm microspheres (86 µg/mL beads or 28 nM siRNA per culture) in serum free media. After 24 hours, the serum-free media was exchanged from complete media and EGFP expression was evaluated by flow cytometry after 24, 48 and 72 hours (results shown after 72 hours) in 2% FBS/PBS. A positive control was established with Lipofectamine 2000 used as according to the manufacturer's instructions using 28 nM siRNA.

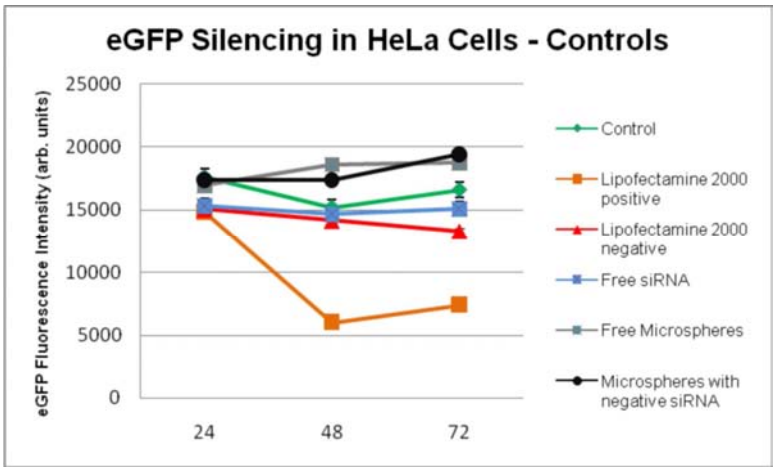


Graph S-7. EGFP silencing in HeLa-EGFP cells after 72 hours by 500 and 200 nm microspheres carrying TAMRA labelled siRNA via an amide linkage (concentration of beads: 86 µg/mL; concentration of siRNA: 28 nM).

Controls for Gene Silencing

HeLa-EGFP cells were incubated with a range of controls and analysed by flow cytometry (2% FBS/PBS) after 24, 48 and 72 hours.

The concentration of siRNA used was 28 nM to reflect that concentration used in beadfections. Lipofectamine 2000 was used as according to the manufacturer's instructions.

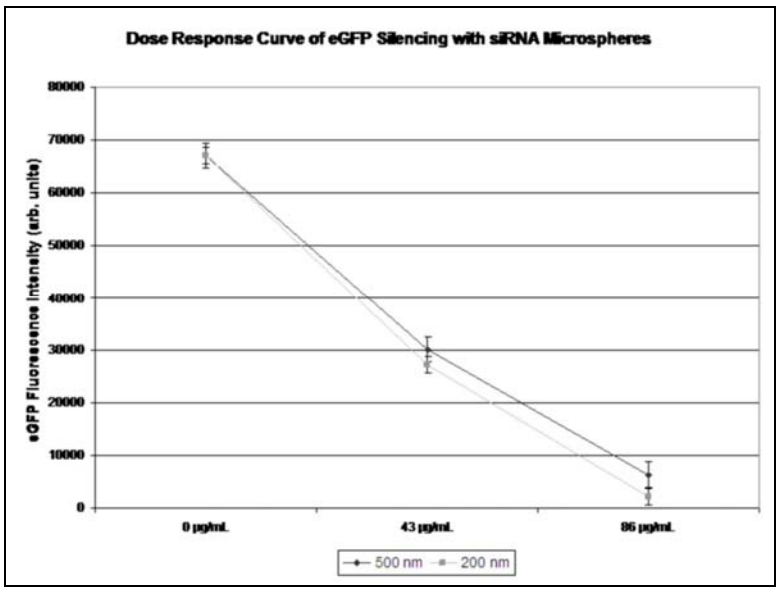


Graph S-8. Controls for gene silencing of EGFP in HeLa cells. (*Control*: untreated cells; Lipofectamine 2000 positive = siRNA transfected with Lipofectamine 2000; *Lipofectamine 2000 negative* = scrambled siRNA transfected with Lipofectamine

2000; *Free siRNA* = siRNA targeted against GFP, without a carrier device; *Free Microspheres* = 500 nm microspheres without siRNA; *Microspheres with negative siRNA* = 500 nm microspheres bound to scrambled siRNA (via an amide linkage).

Dose Response Analysis of Gene Silencing

HeLa-EGFP cells were cultured as stated above and siRNA microspheres (500 and 200 nm, amide linkages) were added to the cultures (86 µg/mL = 28 nM and 43 µg/mL = 14 nM) in serum-free media. After 24 hours, the old media was exchanged from complete media and flow cytometric analysis was carried out as described after 24, 48 and 72 hours (data not shown for 24 and 48 hours) in 2% FBS/PBS.



Graph S-9. Dose response curve following the addition of 500 and 200 nm siRNA microspheres (amide linkage, 86 and 43 µg/mL *or* 28 nM and 14 nM siRNA respectively) to HeLa-EGFP cells. Results shown are after 72 hours.

PEGylated-carbon nanotubes (PNTs) were evaluated as nanocarriers of antisense oligonucleotides into T-cells using protein tyrosine phosphatase N22 (PTPN22) as a model target gene. PTPN22 is an important predisposing gene and drug target in type 1 diabetes and several other human autoimmune diseases. Here, we generated the first anti-PTPN22 20-mer antisense oligonucleotides (ASOs) and tethered them to PNTs through a cleavable disulfide bond. Spectroscopic and atomic force microscopy analyses were used to determine the loading of ASO onto PNTs, whereas the cleavable nature of the disulfide bond connecting the oligonucleotide to the nanocarrier was confirmed by incubation with dithiothreitol followed by agarose gel electrophoresis. PNT-conjugated ASOs achieved efficient (>50%) knockdown of PTPN22 expression in T-lymphocytes in culture at the mRNA and protein level, as measured by quantitative real-time PCR and Western blotting, respectively. Considering the high biocompatibility and low in vivo toxicity of PNTs, we expect that our approach will be easily translated to achieve in vivo knockdown of PTPN22 and other T lymphocyte targets, thus enabling novel ASO-mediated immunotherapies for type 1 diabetes and other autoimmune diseases.

Gene silencing can be achieved using antisense oligomers, ribozymes, DNAzymes, and RNA interference (*1*). Antisense technology permits knockdown in expression of a specific gene for both research and medicinal applications. Typically, a 20-mer antisense oligonucleotide (ASO) is designed to complement the mRNA of a particular target for cleavage by RNaseH endonuclease or by inhibiting translation (*2*). ASOs have been chemically modified to improve their affinity for target mRNA, potency, nuclease resistance, and biostability and to elicit RNaseH-mediated cleavage of target mRNA (*3, 4*). The so-called first generation of ASOs is based on phosphorothioate deoxynucleotides. These sequences have a net negative charge, elicit RNase H-mediated message degradation, and are stable to nuclease degradation (*5*). Systemic injection of ASOs enables the therapeutic knockdown of disease-related genes in important tissues, including liver and bone (*6*). However, their use for immunotherapy has been hampered by inefficient transport across the plasma membranes of immune cells. For example, the negatively charged phosphorothioates have very low bioavailability in B- and T-lymphocytes (*7*).

Chemically engineered nanotechnology-derived carriers (nanocarriers) have recently improved drug delivery into difficult cell targets (*8*). These nanocarriers have been shown to be able to deliver cargo (nucleic acids, peptides, small molecules, etc.) into such specific cell types as B- and T-lymphocytes after injection in mice without causing significant toxicity. Carbon nanotubes (NTs), due to their extremely high aspect ratio (length/diameter), represent a potential scaffold for constructing multivalent delivery systems capable of binding many membrane receptors (*9, 10*). In particular, NTs functionalized with poly(ethylene glycol) (PEG) chains (PEGylated NTs or PNTs) have been reported to deliver small-interfering RNA into cultured cells (including T-lymphocytes) (*11*) and target integrin-positive tumors in mice (*12*). Moreover, PNTs exhibit long circulation times in the blood, low uptake by the reticuloendothelial system (RES) (*13*), and lack of toxicity in vivo (*14*). Both in vitro and in vivo, PNTs were taken into the cytoplasm of T-lymphocytes (*15*). These reports led us to investigate whether PNTs could be used as nanocarriers to deliver ASOs into immune cells.

Here, we used PNT-conjugated ASOs to achieve knockdown of protein tyrosine phosphatase N22 (PTPN22) in T cells. PTPN22 is an important drug target for autoimmune diseases (*16*−*18*). A mutation in its gene is a well-recognized predisposing factor for type 1 diabetes (*19*−*22*), rheumatoid arthritis (*23, 24*), and several other autoimmune diseases (*25*). PTPN22 is found in white blood cells and has a particularly critical function in T-lymphocytes, in which it negatively regulates growth and activation (*26*−*29*). The autoimmune-predisposing C1858T mutation (R620W) (*29, 30*) in the *PTPN22* gene produces a

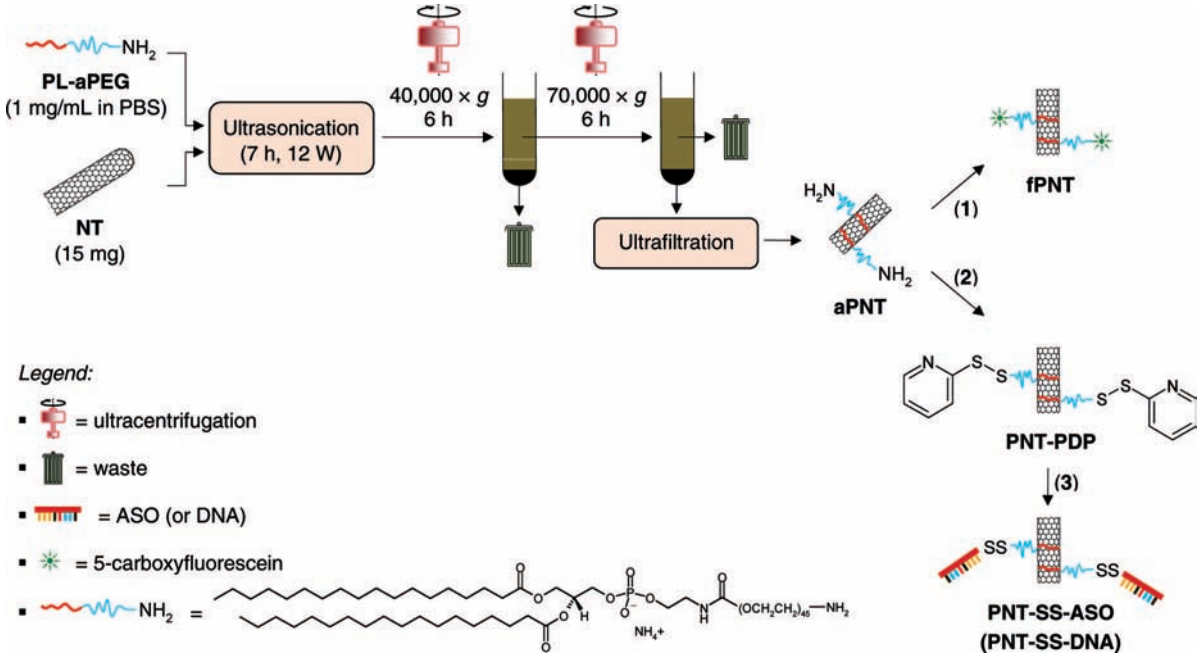
Scheme 1. Fabrication of Antisense Oligonucleotide- And Carboxyfluorescein-Functionalized PEGylated Carbon Nanotubes[a]



[a] Pristine carbon nanotubes (NTs) were sonicated in the presence of 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))$_{2000}$] (PL-aPEG), fractionated by stepwise centrifugation, and purified away from small molecules by ultrafiltration. The amino-functionalized PEGylated NTs (aPNTs) obtained were capped with 5-carboxyfluorescein by reaction with 5-carboxyfluorescein *N*-hydroxysuccinimide ester to give fluorescent PEGylated NTs (fPNTs, **(1)**). Alternatively, aPNTs were capped with ASO8 phosphorothioate by stepwise activation with sulfosuccinimidyl 6-(3′-[2-pyridyldithio]propionamido)hexanoate (sulfo-LC-SPDP) (to give pyridyldithio-functionalized PEGylated NTs, PNT-PDP **(2)**) followed by displacement with 5′-mercapto-terminated ASO8 to give the PTPN22 antisense oligonucleotide tethered to PEGylated NTs through a disulfide bond (PNT-SS-ASO, (**3**)). This procedure was repeated to produce DNA tethered to PNTs through a disulfide bond as a model conjugate (PNT-SS-DNA).

gain-of-function-W620 variant that is a more potent inhibitor of T-lymphocyte activation. Reduced T-lymphocyte growth and activation are important predisposing factors for autoimmune disease (*31*, *32*). Thus, systemic inhibition of *PTPN22* expression is considered to be beneficial for prevention or early treatment of autoimmunity (*18*). Our goal is to develop nucleotide-based *PTPN22* inhibitors and optimize their delivery into T-lymphocytes for treatment of type 1 diabetes and other autoimmune diseases.

PNTs were obtained by hydrophobic adsorption of phospholipids terminated with amino-functionalized PEG chains onto NT sidewalls by using a procedure previously reported by us (*15*) and others (*11*). Pristine (nonfunctionalized) NTs were ultrasonicated with phospholipids terminated with approximately 12-nm-long amino-functionalized PEG chains {1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)$_{2000}$]} (PL-aPEG, Scheme 1), fractionated by stepwise ultracentrifugation to isolate short hydrophilic amino-terminated PEGylated NTs and purified by ultrafiltration to remove free phospholipids (aPNTs). The collected nanocarriers were found to disperse under physiologic conditions and did not display any visible flocculation upon standing for several months at room temperature in PBS pH 7.4. Atomic force microscopy (AFM) images of aPNTs showed the presence of individual particles and small bundles (Figure 1A) having a length of 164 ± 46 nm. We calculated that aPNTs had an approximate molecular weight of 450 kDa and were decorated with 85 ± 14 PEG chains per nanoparticle (see Supporting Information).

The exposed amino groups of the aPNTs were acylated with 5-carboxyfluorescein *N*-hydroxysuccinimide ester to introduce a fluorescent label (Scheme 1). The fluorescent PNTs (fPNTs) were visible by conventional light optical and confocal microscopy (data not shown). The Jurkat human acute lymphoblastoma leukemia T-cell line expressing the SV40 T antigen (TAg) (*33*) was kept at logarithmic growth in RPMI 1640 medium supplemented with 10% FCS, 2 mM L-glutamine, 1 mM sodium pyruvate, 10 mM HEPES pH 7.3, 2.5 mg/mL D-glucose, 100 units/mL of penicillin, and 100 μg/mL streptomycin. The internalization of fPNTs by Jurkat TAg cells was investigated by flow cytometry using a Beckman FC500 instrument. In the presence of fPNTs, 100% cells showed internalization of the nanocarriers already at 30 min and the internal fluorescence of the cells kept increasing during the first 18 h (Figure 1B, cell fluorescence was read in the presence of Trypan blue in order to quench fluorescence of noninternalized fluorescein). Next, we loaded the aPNTs with oligonucleotides using a tether with a cleavable disulfide bond that enables the release of the oligonucleotide cargo once the nanocarrier is transported into intracellular compartments. We acylated the aPNT primary amino groups with sulfosuccinimidyl 6-[3′-(2-pyridyldithio)-propionamido]hexanoate (sulfo-LC-SPDP) to give pyridyldithio-functionalized PNTs (PNT-PDP) and, subsequently, used a SH-terminated 21-mer single-stranded oligonucleotide to displace the pyridyl group and produce the oligonucleotide-tethered PNTs (PNT-SS-DNA) as a model conjugate (Scheme 1). The PNT-SS-DNA were purified by filtration, and the cleavable nature of the disulfide bond connecting the oligonucleotide to the nanocarrier was confirmed by incubation with dithiothreitol (DTT) followed by agarose gel electrophoresis (Figure 1C). The electrophoretic mobility of PNT-SS-DNA (lane 2), which was greater than that of PNT-PDP (lane 1), was decreased after incubation with DTT (lane 3), which cleaved the oligonucleotide off the PNTs by reducing the disulfide bond.

Next, we generated and characterized anti-PTPN22 ASOs. PTPN22 ASO sequences have not been reported. We used the Sfold software (http://sfold.wadsworth.org, Supporting Information) to design a set of 20-mer ASOs against human PTPN22 (Accession: NM_017774; GI: 48928053). After passing a

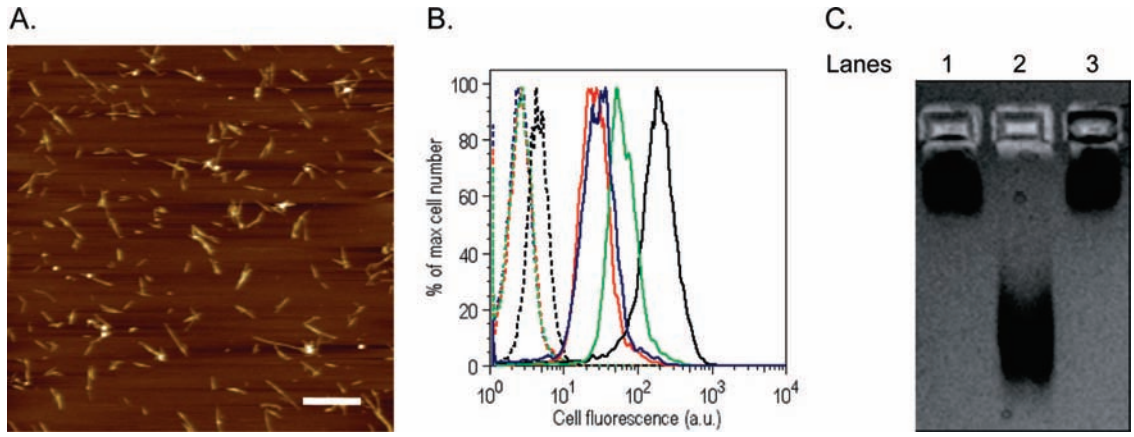


Figure 1. Characterization of PNT-based nanoassemblies. (A) Atomic force microscope (AFM) image of aPNTs (bar length 500 nm). (B) Flow cytometry plot of Jurkat TAg cell fluorescence after incubation with 6 nM fPNT for 30 min (blue line), 1 h (red line), 6 h (green line), or 18 h (black line) compared to nontreated control cells after the same times (dotted lines). Cell fluorescence was measured in the presence of 0.4% (w/v) trypan blue in order to quench fluorescence from noninternalized fluorescein. The histogram shows ungated data from approximately 5000 events; cell fluorescence is reported in arbitrary units (a.u.). (C) Reversible conjugation of a 21-mer single-stranded SH-terminated DNA oligomer to activated aPNTs through a disulfide bond. PNT-PDP (lane 1), PNT-SS-DNA (lane 2), and PNT-SS-DNA incubated with 0.1 M DTT for 30 min (lane 3) were analyzed by 1% agarose gel electrophoresis and visualized under visible light.

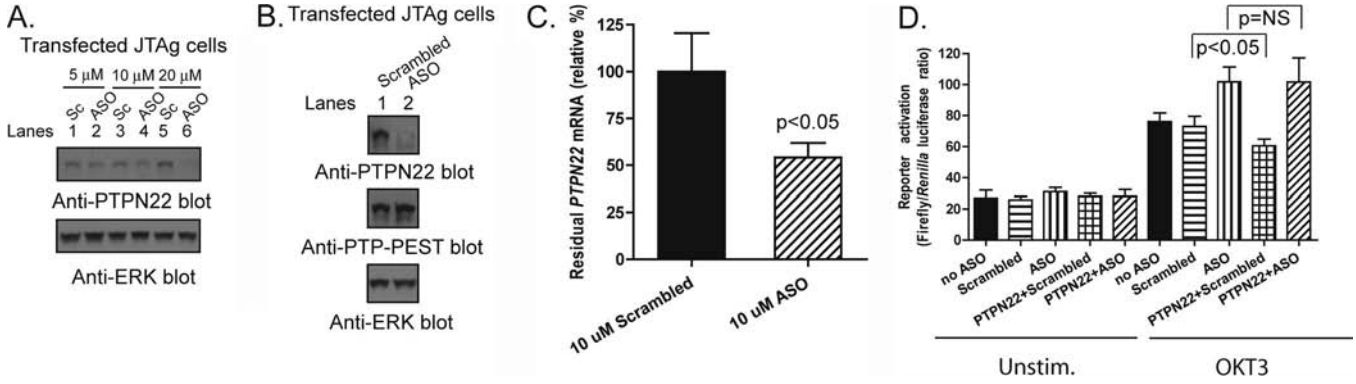

Figure 2. Characterization of a new anti-PTPN22 ASO. (A) Dose-dependent knockdown of PTPN22 using ASO. JTAg cells were electroporated with 5 μM (lanes 1, 2), 10 μM (lanes 3, 4), or 20 μM (lanes 5, 6) scrambled ASO (lanes 1, 3, 5) or ASO8 (lanes 2, 4, 6). Cells were lysed 24 h after transfection. Upper panel shows anti-PTPN22 blot, and lower panel shows control anti-ERK2 blot of total lysates. (B) PTPN22-specific knockdown by ASO8. Jurkat TAg cells were electroporated with a plasmid encoding PTP-PEST and with 10 μM scrambled ASO (lane 1) or ASO8 (lane 2) and lysed 24 h later. Cell lysates were subjected to Western blotting using antibodies to PTPN22, PTP-PEST, and Erk2. (C) ASO8 possesses endonuclease-inducing activity. Jurkat TAg cells were electroporated with 10 μM scrambled ASO or ASO8 and lysed 24 h later for isolation of total RNA. PTPN22 mRNA levels were measured in triplicate by quantitative real-time PCR. The histogram shows residual PTPN22 mRNA (%) in cells treated with ASO8 relative to those treated with scrambled ASO (100%). The statistical significance of differences between the two samples was calculated on the raw data by two-tailed Student's *t* test. (D) ASO8 induces increased T cell receptor (TCR) signaling and rescues the inhibitory effects of PTPN22 overexpression on a TCR reporter activation. Jurkat TAg cells were electroporated with a NFAT/AP1-firefly luciferase reporter plasmid and a pGL3 *Renilla* control plasmid alone (columns 1, 2, 3, 6, 7, 8) or combined with 10 μM scrambled ASO (columns 2, 4, 7, 9) or ASO8 (columns 3, 5, 8, 10) and with a plasmid for hemagglutinin (HA)-tagged PTPN22 (columns 4, 5, 9, 10). Samples represented in columns 1 and 6 represent negative controls and contained no ASO. At 24 h after transfection, half of the samples were stimulated using 1.5 mg/mL of OKT3 for 6 h (columns 6−10) to induce reporter activation, while the remainder (columns 1−5) were not stimulated. The histogram shows reporter activation (firefly/renilla luciferase ratios) as measured by the dual-luciferase assay (see Supporting Information for details). Statistical significance of differences was calculated by one-way ANOVA with Tukey post-test.

counter-screen to disallow nonspecific cross-hybridizers, the three top-scoring antisense sequences (ASO7, ASO8, and ASO9) were synthesized as phosphorothioates. A 20-mer scrambled ASO (*34*) was used as a control in the experiments. Jurkat TAg were transfected with the ASO by electroporation at 240 V with a single 25-ms pulse (*29*), and the expression of PTPN22 protein was assessed by Western blotting (WB) using an anti-PTPN22 antibody (R&D Systems, Minneapolis, MN) compared to that of ERK2, which was detected using anti-ERK2 Ab (Santa Cruz Biotechnology, Santa Cruz, CA) and used as a loading control. Comparison of PTPN22 protein levels in the ASO7, ASO8, ASO9, and scrambled ASO-electroporated Jurkat TAg cells after 24 and 48 h revealed that ASO8 had most effectively knocked down expression by 50% or more (as assessed by densitometric scanning of Western blotting) when compared with the scrambled ASO (Figure S1 in Supporting Information) and showed the highest potency at 24 h. In ASO8-electroporated T-cells PTPN22, knockdown was dose-dependent and became evident at 5 μM concentration (Figure 2A). The specificity of knockdown by ASO8 was next evaluated by controlling for knockdown of the closely related PTP proline, glutamate, serine, and threonine-rich sequence (PTP-PEST) (*35*). Jurkat TAg cells were electroporated with 10 μM of ASO8 or scrambled ASO and with a plasmid encoding PTP-PEST. Western blots of T-cell lysates using an anti-PTPN22 antibody compared to anti-PTP-PEST and anti-ERK2 antibodies showed that ASO8 only caused knockdown of PTPN22 expression without affecting the levels of PTP-PEST (Figure 2B). RT-PCR analysis of T-cells electroporated with 10 μM ASO8 or scrambled ASO showed that PTPN22 mRNA levels were reduced in cells treated with ASO8 compared to cells treated with scrambled ASO, suggesting that ASO8 possesses RNase-activating effects (Figure 2C). We

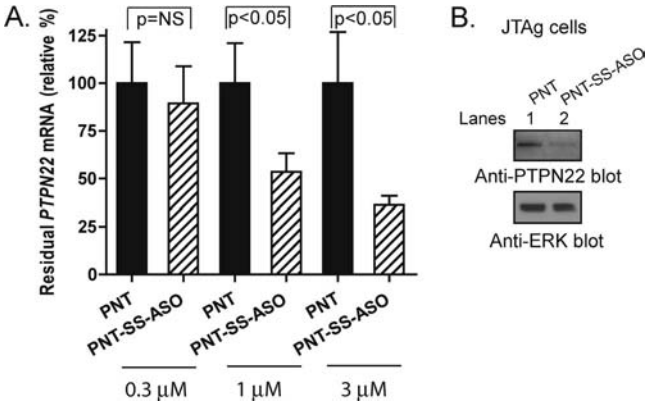

Figure 3. PNT-SS-ASO mediated knock-down of PTPN22 expression in Jurkat TAg cells. (A) Dose-dependent knockdown of PTPN22 mRNA using ASO8-conjugated PEGylated nanotubes (PNT-SS-ASO). Jurkat TAg cells were incubated with approximately 3.5 nM (column 1), 12 nM (column 3), or 35 nM (column 5) aPNT (black column) or approximately 3.5 nM (approximately 0.3 μM ASO8, column 2); 12 nM (approximately 1 μM ASO8, column 4), or 35 nM (approximately 3 μM ASO8, column 6) PNT-SS-ASO (lined columns). Total mRNA was extracted after 24 h. PTPN22 mRNA levels were measured in triplicate by quantitative real time PCR. *Y*-axis shows residual PTPN22 mRNA (%) in cells after treatment with PNT-SS-ASO relative to cells treated with aPNTs (100%). Statistical significance of differences was calculated on the raw data by two-tailed Student's *t* test. (B) Knockdown of PTPN22 protein expression using PNT-SS-ASO. Jurkat TAg cells were incubated with 12 nM aPNT alone (lane 1) or 12 nM PNT-SS-ASO (approximately 1 μM ASO8 or 85 ASO8/PNT, lane 2) and then lysed 24 h later. Anti-PTPN22 antibody staining of total cell lysates is shown in upper panel compared to anti-ERK2 antibody staining in lower panel.

completed the characterization of ASO8 with a functional evaluation of its effect on T cell receptor (TCR) signaling using an NFAT/AP1-luciferase reporter assay in Jurkat TAg cells. This assay monitors the TCR-induced activation of the distal IL-2 promoter following its recruitment of activated NFAT and AP1 transcription factors (see Supporting Information). As shown in Figure 2D, ASO8-mediated knockdown of PTPN22 expression led to increased TCR signaling. ASO8 was also able to rescue the TCR-inhibiting effect of PTPN22 overexpression in Jurkat TAg, as indicated by reduced inhibition of TCR-induced reporter activation in cells overexpressing PTPN22 and treated with ASO8 compared to cells treated with scrambled ASO.

Finally, we conjugated anti-PTPN22 ASO to PNTs and assessed the ability of the PNT-ASO conjugate to enable knockdown of PTPN22 expression in Jurkat TAg cells. Activated PNT-PDP was treated with 5′-SH-terminated-ASO8 (purchased as 5′-C6-S-S(disulfide)-modified ASO from IDT, modification cat. no. 5ThioMC6-D) to produce PNTs conjugated with ASO8 through a cleavable disulfide bond (PNT-SS-ASO). The cleavable nature of the disulfide bond was confirmed by incubation with DTT followed by agarose gel electrophoresis (data not shown). Knockdown of PTPN22 message and protein expression in Jurkat TAg cells incubated for 24 h with PNT-SS-ASO or the same amount of aPNTs was assessed using RT-PCR and Western blotting, respectively. Incubation of cells with PNT-SS-ASO enabled a dose-dependent knockdown of PTPN22 mRNA (Figure 3A) and a significant reduction of PTPN22 protein levels (Figure 3B). Interestingly, a significant reduction of PTPN22 expression was also achieved in these experiments by treating cells with approximately 1 μM PNT-conjugated ASO, which is below the threshold ASO concentration needed to achieve detectable knockdown when ASO8 was introduced by electroporation. The increased potency of the PNT-SS-ASO could be due to the SH termination of the ASO, or it might indicate that silencing of PTPN22 expression through PNT delivery is more efficient than that achieved by the electroporation method.

In conclusion, we generated and characterized the first anti-PTPN22 antisense oligomer and achieved its PNT-mediated delivery into T-cells. Incubation of T cells with PNT-SS-ASO enabled knockdown of PTPN22 expression at the mRNA and protein levels. Considering the high biocompatibility and low in vivo toxicity of PNTs (*14*), we expect that, after appropriate functionalization for targeting of selected immune cell subpopulations, PNT−ASO conjugates could enable ASO-mediated in vivo immunotherapy. Previously, we achieved selective delivery of PNTs to T-cells in vivo by functionalization with anti-CD3 and anti-CD28 antibodies (*15*). Future objectives are to prepare antibody-conjugated PNT−ASOs to achieve specific T-cell specific knockdown of PTPN22 and later translate this approach to in vivo knockdown of PTPN22 for therapy of type 1 diabetes and other autoimmune diseases.

ACKNOWLEDGMENT

This work was supported by a Baxter Foundation Grant (N.B.), PRIN Grant No. 2006069554 from the Italian Ministry of University and Scientific Research (A.M.) and a Master & Back Fellowship from the Sardinian government (L.G.D.). The authors are grateful to Sanjay K. Pandey for the gift of the scrambled ASO and for critically revising the manuscript.

MATERIALS AND METHODS

Antibodies and other reagents. The monoclonal anti-hemagglutinin (HA) antibody (Ab) clone 16B12 was purchased from Covance (Berkeley, CA). The anti-ERK2 (C14) antibody was from Santa Cruz Biotech (Santa Cruz, CA), the anti-PTP-PEST antibody was from Cell Signaling Technology (Danvers, MA), and the anti-PTPN22 goat antibody (raised against the human protein) was from R&D (Minneapolis, MN). OKT3 (*1*) was purified from hybridoma supernatants by ultrafiltration on Falcon Amicon ultra-15 (Millipore cat. n. ufc910024). $F(ab)_2$ antibody and anti-mouse IgG used for cross-linking were purchased from Jackson Immunoresearch (West Grove, PA) and Upstate/Millipore (Billerica, MA), respectively. SDS sample buffer, pre-cast gels, dNTPs, and Taq polymerase were from Invitrogen (Carlsbad, CA). Hybond-ECL nitrocellulose was from GE Healthcare (Piscataway, NJ). Trypan blue was purchased from Sigma (cat.n.T8154). The protein molecular weight standard for polyacrylamide gel electrophoresis was purchased from Fermentas (Glen Burnie, MD). DNA oligonucleotides and all phosphorothioate ASOs against PTPN22 were purchased from IDT (San Diego, CA). The sequence of the anti-PTPN22 ASOs was as follows: ASO7: 5'-CCATTTTTGTCCTTTGTTGG-3', ASO8: 5'-GTTGTGTCAGCATTTTTGTC-3', ASO9: 5'-GCTGTCCACCTCCTTGGTTT-3'. Scrambled ASO was a gift from Dr. Sanjay K. Pandey of Isis Pharmaceuticals (Carlsbad, CA). Unless otherwise specified, other chemicals were from Sigma (St. Louis, MO).

Plasmids, cell culture, transfections, and Western blotting. Full-length human PTPN22 and PTP-PEST were cloned in the *Bam*HI site of the plasmid pEF5 (*2*), which allows the expression of constructs in fusion with an N-terminal HA tag, and under control of the EFalpha promoter. Jurkat cells expressing the SV-40 large T Antigen (Jurkat TAg) (*3*) were were kept at

logarithmic growth in RPMI 1640 medium supplemented with 10% fetal calf serum (FCS, purchased from the USC Norris Cancer Center Cell Culture Core), 2mM L-glutamine, 1 mM sodium pyruvate, 10 mM HEPES pH 7.3, 2.5 mg/mL D-glucose, 100 units/mL of penicillin and 100 μg/mL streptomycin.

Jurkat TAg cell transfections were performed by electroporation at 240 V with a single 25-ms pulse. Cells were lysed in 20 mM Tris/HCl, pH 7.4, containing 150 mM NaCl, 1 mM EDTA, 1% NP40 (TNE buffer), 1 mM PMSF, 10 mg/ml of aprotinin/leupeptin and 10 mg/ml of soybean trypsin inhibitor. Lysates were pre-cleared by centrifugation at 16,000 g for 30 min. For western blotting, proteins were run on denaturing SDS-polyacrylamide gels (Invitrogen, Carlsbad, CA), transferred to nitrocellulose membranes, and identified using appropriate dilutions of unconjugated primary antibodies, followed by HRP-conjugated secondary antibodies (GE Healthcare). Filters were then subjected to a chemiluminescent detection protocol using ECL Plus (GE Healthcare) followed by autoradiography using light or blue film (Kodak, Rochester, NY)**.** Expression of endogenous/transfected PTPN22 and of transfected PTP-PEST proteins (expression levels of endogenous PTP-PEST in Jurkat are extremely low (*4*)) was assessed by Western blotting using an anti-PTPN22 antibody (R&D) or anti-PTP-PEST antibody (Cell Signaling Technology) compared to anti-Erk2 antibody (Santa Cruz Biotech) as a control.

Reporter assays. Luciferase reporter assays were performed as described (*5*). The NFAT/AP-1 reporter plasmid (kindly provided by Dr. Gerald Crabtree, Stanford University, Stanford, CA, USA) carries three tandem copies of the distal NFAT/AP-1 composite element of the human *IL2* promoter (*3*), which are cloned upstream of the minimal *IL2* promoter (from -89 to +51) and the

luciferase reporter gene. The NFAT/AP-1 reporter plasmid and the control pGL3 plasmid, driving constitutive expression of *Renilla* luciferase for use as a transfection control, were cotransfected in Jurkat TAg cells together with and without 10 μM ASO. Cells were subjected to T cell receptor (TCR) stimulation with 1.5 μg/ml of OKT3 (*1*) for 6 h, before luciferase assays were performed in triplicate on cell lysates using the dual luciferase kit from Promega (Madison, WI) according to manufacturer's instructions Luminescence was read on a 1420 Multilabel Counter Victor^3 V plate reader (Perkin-Elmer, Turku, Finland). The difference in the ratio between firefly and *Renilla* luciferase activities in stimulated versus nonstimulated cells was assessed.

Flow cytometry. Flow cytometry was carried out on a Cytomics FC500 cytometer (Beckman Coulter, Fullerton, CA) at the USC Immune Monitoring Core. Cell fluorescence was measured after the cells were washed with a 0.4% (w/v) Trypan Blue solution in order to quench fluorescence from non-internalized fluorescein(*6, 7*). Flow cytometry data analysis and graph preparation were carried out using FlowJo (Tree Star, Inc., Ashland, OR).

mRNA quantification by real-time PCR. Total RNA was extracted from transfected cells using Tryzol (Sigma) to quantify for PTPN22 mRNA expression levels. cDNA was generated by reverse transcription using RETROscript (Ambion, Austin, TX). RT-PCR was performed using Cyber-green (Invitrogen, Carlsbad, CA) and primers 5'- CCAAGAGGATGACAGTGTTCCC -3' (nt 2291-2310 of *PTPN22* coding sequence - NCBI accession#NM_015967, GI#48928053) and 5'- GTGCTTGATTTAGCAGGGTGC -3' (nt 2396-2377 of *PTPN22* coding sequence -

NCBI accession#NM_015967, GI#48928053) on a MJ Research DNA Engine Opticon 2 (Waltham, MA).

Preparation of amino-functionalized PEGylated NTs (aPNTs). Single walled NTs (15 mg) (Carbon Solutions, Riverside, CA) were added to a 1.0 mg/mL solution of 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)$_{2000}$] (PL-aPEG) (Avanti Polar Lipids, Alabaster, AL) in PBS (25 mL) (2.7 mM KCl, 1.5 mM KH_2PO_4, 137 mM NaCl and 8.1 mM Na_2HPO_4, pH 7.4 from Mediatech, Inc., Herndon, VA). The mixture was ultrasonicated (Misonix, Inc., Farmingdale, NY) in an ice-bath for 7 h at a constant power of 15 W and centrifuged (Beckman Optima™ XL-80K Ultracentrifuge, Palo Alto, CA) at 40,000 × *g* for 6 h. Approximately 80% of the supernatant was carefully collected by aspiration and centrifuged at 70,000 × *g* for 6 h. The pellet was dispersed in PBS by brief sonication and filtered six times through a 100-kDa molecular weight cutoff centrifugal filter device (Ultrafree, Millipore Corp., Temecula, CA) to remove free phospholipids from aPNTs.

Preparation of carboxyfluorescein-conjugated PEGylated NTs (fPNTs). aPNTs (50 µg in 1.0 mL of PBS) were incubated with 5-carboxyfluorescein *N*-hydroxysuccinimide ester (25 µg in 25 µL of anhydrous DMF) for 2 h at room temperature in the dark. fPNTs were purified from unlinked 5-carboxyfluorescein molecules by filtration through 10-kDa molecular weight cutoff centrifugal filter devices (Ultrafree).

Preparation of ASO-conjugated PEGylated NTs (PNT-SS-ASO). aPNTs (50 µg in 1.0 mL of PBS) were incubated with sulfosuccinimidyl 6-(3'-[2-pyridyldithio]-propionamido)hexanoate

(sulfo-LC-SPDP, 30 ug in 25 μL of anhydrous DMF) (PNT-PDP) for 2 h at room temperature in the dark and then filtered through a NAP-5 gravity column (GE Healthcare UK Ltd), previously equilibrated with PBS supplemented with 10 mM EDTA. SH-ASO (5'-GTTGTGTCAGCATTTTTGTC-3') or SH-DNA (5'-ATTGATGTAGCTGGAATCCTC-3') in PBS was treated with 100 mM dithiothreitol (DTT) for 30 min and then filtered though a Microspin G-25 column (GE Healthcare UK Ltd) previously equilibrated with PBS supplemented with 10 mM EDTA. PNT-PDP and reduced SH-ASO (or SH-DNA) were mixed in an approximate molar ratio of 1:250 in PBS supplemented with 10 mM EDTA and allowed to react overnight at room temperature. PNT-SS-ASO (or PNT-SS-DNA) were purified from unlinked ASO by several cycles of dilution in PBS followed by ultrafiltration through 100-kDa molecular weight cutoff centrifugal filter devices (Ultrafree).

AFM of PEGylated NTs. A solution of aPNTs in PBS (10 μL) was dropped onto a freshly cleaved mica substrate (Ted Pella, Redding, CA). The droplet was allowed to stand for approximately 10 min at room temperature, and then the mica surface was rinsed with water and dried under a nitrogen stream. Atomic force microscope (5500 AFM, Agilent Technologies, Santa Clara, CA) images were taken using the acoustic alternate current mode (AAC).

Graphs and Statistics. Histograms were prepared using the Prism software package (Graphpad, San Diego, CA). Statistics (ANOVA or Student t-test) were calculated using the Prism or Excel (Microsoft, Redmond, WA) softwares. Standard deviations of differences and ratios were calculated according to error propagation rules described by Taylor (*8*).

Characterization of PEGylated carbon nanotubes. The spectroscopic contribution of 5-carboxyfluorescein grafted onto fPNTs in PBS was calculated by subtracting from the absorbance spectrum of fPNTs that of aPNTs with matching absorption at 830 nm (the spectroscopic contribution of 5-carboxyfluorescein was absent at 830 nm). The calculated absorbance spectrum of 5-carboxyfluorescein grafted onto fPNTs exhibited a 496-nm peak that, under the assumption that all PEG chains were capped with 5-carboxyfluorescein, was used to calculate the concentration (K, [μM]) of PEG chains onto PNTs (aPNTs and fPNTs) having an absorbance value at 830 nm equal to one (A_{830} =1) in PBS.

Next, the concentration (c_{NT}, [mg/L]) of underneath (non-PEGylated)-NTs having A_{830} = 1 in PBS was determined. aPNTs in PBS were dialyzed against water, vacuum dried, carefully weighed, redispersed in PBS by brief sonication and the absorbance at 830 nm recorded. The concentration (c_{aPNT}, [mg/L]) of aPNTs having A_{830} = 1 in PBS was then calculated. Finally, c_{NT} was obtained by subtracting the contribution of PL-aPEGa from c_{aPNT}:

$$c_{NT} = c_{aPNT} - c_{PL\text{-}aPEG} = c_{aPNT} - K \times w_{PL\text{-}aPEG} \quad \textbf{(eq. 1)},$$

where $w_{PL\text{-}aPEG}$ = 2800 Daltons is the molecular weight of PL-aPEG.

AFM images of aPNTs showed individual and small bundles of PNTs having a length of 164 ± 46 nm. We calculated the molecular weight (w_{NT}) of underneath (non-PEGylated) NTs and the concentration (C_{NT}, [μM]) of underneath (non-PEGylated)-NTs having A_{830} = 1 in PBS:

$$w_{NT} = (d_{NT} - 0.34) \times \pi \times \sigma_{graphene} \times L_{NT} \quad \textbf{(eq. 2)},$$

$$C_{NT} = c_{NT} / w_{NT} \quad \textbf{(eq. 3)},$$

where L_{NT} and d_{NT} = 1.4 nm are the length and average outer diameter (the latter from the supplier), respectively, 0.34 nm is the van der Waals diameter of carbon and $\sigma_{graphene}$ = 458.3

[Daltons × nm^{-2}] is the sheet density of graphene. Finally, we calculated the number of PEG chains per aPNT (X) and the molecular weight of aPNT (w_{aPNT}):

$X = K / C_{NT}$ (**eq. 4**),

$w_{aPNT} = w_{NT} + (X \times w_{PL\text{-}aPEG})$ (**eq. 5**).

SUPPLEMENTARY FIGURES

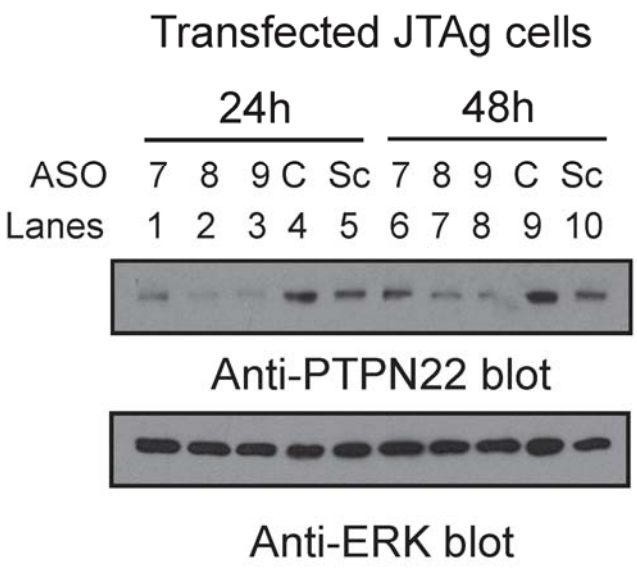

Figure S1. Knock-down of PTPN22 by ASOs. Jurkat TAg cells were electroporated with 20 µM ASO7 (lanes 1 and 6), ASO8 (lanes 2 and 7), ASO9 (lanes 3 and 8) or scrambled ASO (lanes 5 and 10). Cells were lysed 24 h (lanes 1-5) or 48h (lanes 6-10) after electroporation and protein analyzed by Western blotting. Upper panel shows anti-PTPN22 Ab blot, and lower panel shows control anti-ERK2 Ab blot of total lysates. Lanes 4 and 9 show control lysates of non-electroporated cells.

We have used the well-accepted and easily available 2-[^{18}F]fluoro-2-deoxyglucose ([^{18}F]FDG) positron emission tomography (PET) tracer as a prosthetic group for synthesis of ^{18}F-labeled peptides. We herein report the synthesis of [^{18}F]FDG-RGD (^{18}F labeled linear RGD) and [^{18}F]FDG-cyclo(RGD^{D}YK) (^{18}F labeled cyclic RGD) as examples of the use of [^{18}F]FDG. We have successfully prepared [^{18}F]FDG-RGD and [^{18}F]FDG-cyclo(RGD^{D}YK) in 27.5% and 41% radiochemical yields (decay corrected) respectively. The receptor binding affinity study of FDG-cyclo(RGD^{D}YK) for integrin $\alpha_v\beta_3$, using $\alpha_v\beta_3$ positive U87MG cells confirmed a competitive displacement with ^{125}I-echistatin as a radioligand. The IC_{50} value for FDG-cyclo(RGD^{D}YK) was determined to be 0.67 ± 0.19 μM. High-contrast small animal PET images with relatively moderate tumor uptake were observed for [^{18}F]FDG-RGD and [^{18}F]FDG-cyclo(RGD^{D}YK) as PET probes in xenograft models expressing $\alpha_v\beta_3$ integrin. In conclusion, we have successfully used [^{18}F]FDG as a prosthetic group to prepare ^{18}F]FDG-RGD and [^{18}F]FDG-cyclic[RGD^{D}YK] based on a simple one-step radiosynthesis. The one-step radiosynthesis methodology consists of chemoselective oxime formation between an aminooxy-functionalized peptide and [^{18}F]FDG. The results have implications for radiolabeling of other macromolecules and would lead to a very simple strategy for routine preclinical and clinical use.

Currently, time-sensitive methods used for ^{18}F-labeling of peptides for positron emission tomography (PET) imaging involve the development of unique ^{18}F-containing prosthetic groups for attachment to the peptides that will likely require significant effort to pervasively implement for routine preclinical and clinical application. Therefore, the ability to utilize reagents currently well-accepted and easily available in the PET community at the final formulation step will likely be highly beneficial. The use of 2-[^{18}F]fluoro-2-deoxyglucose ([^{18}F]FDG) is well-established in clinical PET centers (*1*), and we show here the potential use of this tracer, without further chemical modifications, to label peptides that can be used to report on one or more biomarkers in vivo.

We herein report the synthesis of a ^{18}F-labeled linear trimeric-peptide, [^{18}F]FDG-RGD, and ^{18}F-labeled cyclic trimeric-peptide, [^{18}F]FDG-cyclo(RGD^{D}YK), by using [^{18}F]FDG without further modification. We chose $\alpha_v\beta_3$ integrin and its peptide ligand because the trimeric peptide sequence argenine-glycine-aspartic acid (RGD) recognizes the $\alpha_v\beta_3$ integrin found on new blood vessels and tumor cells. RGD peptide binds to $\alpha_v\beta_3$ integrin and inhibits angiogenesis (*2*). The $\alpha_v\beta_3$ integrin is highly expressed in activated endothelial and solid tumor cells (*3, 4*). The synthesis of the radiolabeled peptides utilizes the reaction between the aldehyde functionality in the linear, open form of [^{18}F]FDG with an aminooxy functionality in the peptide to form an oxime bond. The resulting ^{18}F-labeled RGD molecules were evaluated in vitro for their binding affinity and ultimately as PET probes in xenograft models expressing $\alpha_v\beta_3$ integrin to demonstrate the integrity of the binders post-labeling.

Chemoselective oxime formation between an aminooxy group and a carbonyl functionality has recently been successfully utilized for [^{18}F]-labeling of peptides (*5, 6*), and we hypothesized that it can be used to directly attach [^{18}F]FDG to biomarker-targeted peptides. The highly specific oxime formation between an aminooxy-functionalized peptide and an 4-[^{18}F]fluorobenzaldehdey ([^{18}F]FBA) has previously offered high-yield, two-step synthesis for ^{18}F-labeled peptides (*6*−*9*). [^{18}F]FBA can be obtained in a nonoptimized radiochemical yield of 50% in 30 min, with reported radiochemical yields of 60−80% for the final ^{18}F-peptides. The hypothesis is further supported by a recent report by Wuest et al., which reported the oxime formation between [^{18}F]FDG and *N*-[6-(aminooxy)hexyl]maleimide to create a thiol-reactive prosthetic group [^{18}F]FDG-maleimide-hexyloxime ([^{18}F]FDG-MHO) in moderately high yield (45−69%) at 100 °C over 15 min (*10*). The basis of this chemistry lies in the fact that, at 100 °C, FDG exists in a dynamic equilibrium between its cyclic form and a linear form, where the latter contains an aldehyde functionality at position 1 that can potentially react with the aminooxy functionality under appropriate conditions. We wanted to understand the feasibility of whether such conditions could be translated directly to a targeting peptide while maintaining the peptide's biological efficacy in cell culture and small living subjects.

[^{18}F]FDG-Peptide Conjugation. The synthesis of FDG-RGD and [^{18}F]FDG-RGD were carried out as outlined in Scheme 1. The linear aminooxy-RGD (RGD-ONH_2, 2 mg) was incubated with 3.7 equiv cold FDG in 16% ethanol in saline (120 μL) in the presence of 0.4% TFA at 100 °C for 40 min to afford FDG-RGD (E- and Z-oximes) in 39.5% yield. The formation of E- and Z-oximes was expected. It has been reported that, in a similar case, the reaction of glucose with *O*-(4-nitrobenzyl)-hydroxylamine afforded E- and Z-oxime isomers (*11*). The mass

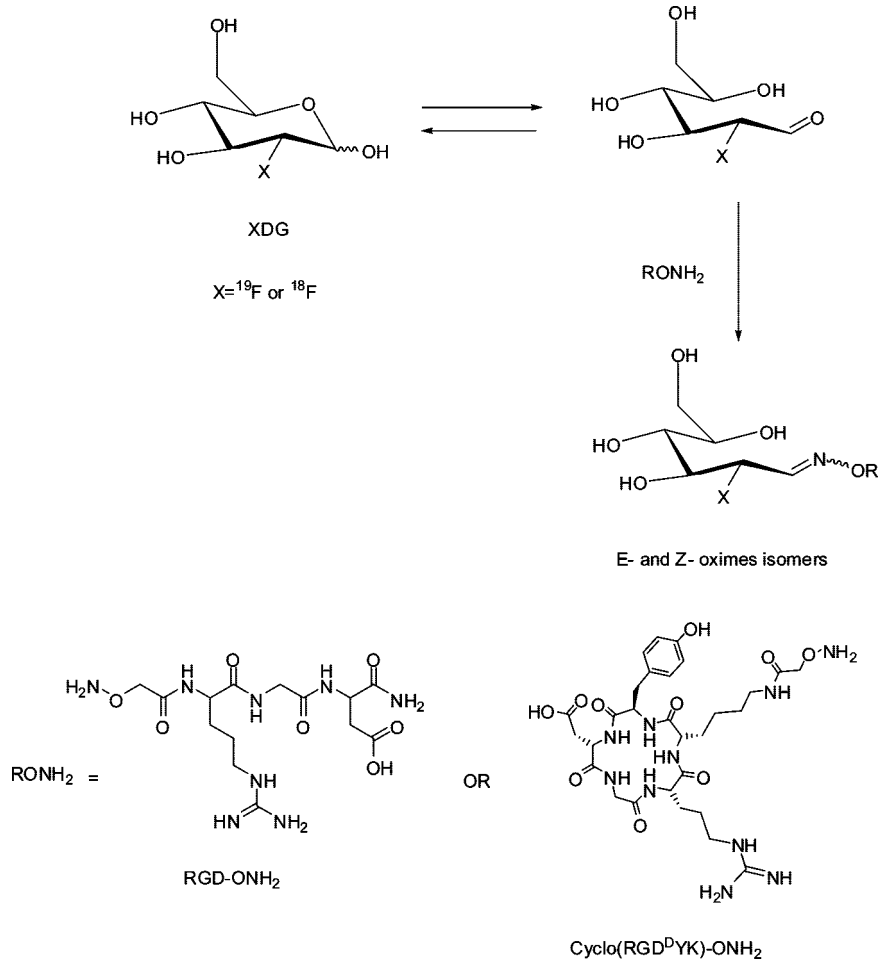
Scheme 1. Schematic Synthesis of FDG-RGD and FDG-cyclo(RGD^{D}YK) (X = ^{19}F) from FDG or [^{18}F]FDG-RGD and [^{18}F]FDG-cyclo(RGD^{D}YK) (X = ^{18}F) from [^{18}F]FGD



spectrometry (ESI-MS) analysis of the isolated product showed two identical mass peaks of 584.2 ([M+H]$^{+}$), which correspond to FDG-RGD (E- and Z-oximes) (calcd [M+H] for RGD-FDG is 584.5). Similarly, aminooxy-RGD (2 mg) was reacted with 4−6 mCi of [^{18}F]FDG in the same condition as above but in 30 min to afford [^{18}F]FDG-RGD (E- and Z-oximes) in 27.5% radiochemical yields based on [^{18}F]FDG (decay-corrected). [^{18}F]RGD-FDG oximes were purified by HPLC and used for biological studies. Similar stereochemistry has been observed in the synthesis of ^{18}F-lableled peptide Gluc-s-Dpr ([^{18}F]BOAT)-TOACF by using an ^{18}F-benzaldehyde (*6*).

Likewise, conjugation of FDG and [^{18}F]FDG to cyclo(RGD-^{D}YK)-ONH$_2$ were achieved according to Scheme 1. Cyclo-(RGD^{D}YK)-ONH$_2$ (2 mg) was incubated with 5.7 equiv of FDG in 16% ethanol in saline (120 μL) and 0.4% TFA at 100 °C for 60 min to give FDG-cyclo(RGD^{D}YK) (E- and Z-oximes) in 41.4% yield. The purified FDG-cyclo(RGD^{D}YK) showed two identical mass peaks of 857.35 ([M+H]$^{+}$) in ESI-MS, which correspond to FDG-cyclo(RGD^{D}YK) (E- and Z-oximes) (calcd M+H for FDG-cyclo(RGD^{D}YK) is 857.47). Conjugation of

[a] Data are expressed as of percentage of injected radioactivity per gram of organ or tissue (% ID/g) after intravenous injection of [^{18}F]FDG-cyclo(RGD^{D}YK) (10−30 μCi) at different times postinjection (n = 3 for each group).

^{18}FDG to cyclo(RGD^{D}YK)-ONH$_2$ (2 mg) afforded [^{18}F]FDG-cyclo(RGD^{D}YK) (E- and Z-oximes) in 41% radiochemical yield based on [^{18}F]FDG (decay-corrected). [^{18}F]FDG-cyclo(RGD-^{D}YK) (E- and Z-) oximes were purified but not separated by HPLC, and the two ^{18}F-labeled products (E- or Z-oximes) were isolated as a mixture and analyzed by analytical HPLC (Figure 1). The exact stereochemistry (E- and Z-) of these two products has not been determined yet. We found that under our experimental conditions maximum radiochemical yields were obtained at pH values of 1.5−2.5. When the reaction was performed at pH 4 in ammonium acetate buffer, no significant products were produced. In our previous report (*9*), we addressed the selectivity of aldehyde toward the aminooxy groups over the amine groups in conjugation of RGD peptides with a simple aldehyde such as 4-flurobenzaldehyde. We found that, when, for example, two RGD aminooxy-functionalized peptides NH$_2$-OCH$_2$CO-Arg-Gly-Asp-NH$_2$ and NH$_2$OCH$_2$CO-Lys-Arg-Gly-Asp-NH$_2$ were reacted at the same condition (8.5−150 equiv, 45−60 min, 70 °C, pH 4) with 4-fluorobenzaldehyde, in each case only one oxime product was formed. It strongly suggests that in conjugation of RGD-ONH$_2$ or cyclo(RGD^{D}YK)-ONH$_2$ with FDG oximes are the major products. Similar selectivity was observed by Poethko et al. (*6*) where they tested the selectivity of 4-[^{18}F]fluorobenzaldehyde for aminooxy groups vs amine groups in amino acids argentine serine, histidine, and lysine in both the presence and the absence of 2-aminooxyacetic acid. The major limitations of our ^{18}F-labeling methodology are the high-temperature (100 °C) and acidic pH conditions. High-temperature and acidic pH are tolerated for the small unprotected peptides but might not be suitable for the large peptides.

Cell Culture Binding Studies. To determine whether FDG-cyclo(RGD^{D}YK) has similar receptor binding affinity for integrin $\alpha_v\beta_3$ as cyclo(RGD^{D}YK), we studied the receptor binding affinity of FDG-cyclo(RGD^{D}YK) for integrin $\alpha_v\beta_3$, using $\alpha_v\beta_3$ positive U87MG cells. The receptor binding affinity study of FDG-cyclo(RGD^{D}YK) for integrin $\alpha_v\beta_3$, using $\alpha_v\beta_3$ positive U87MG cells, confirmed a competitive displacement with ^{125}I-echistatin as a radioligand (Figure 2). The IC$_{50}$ value

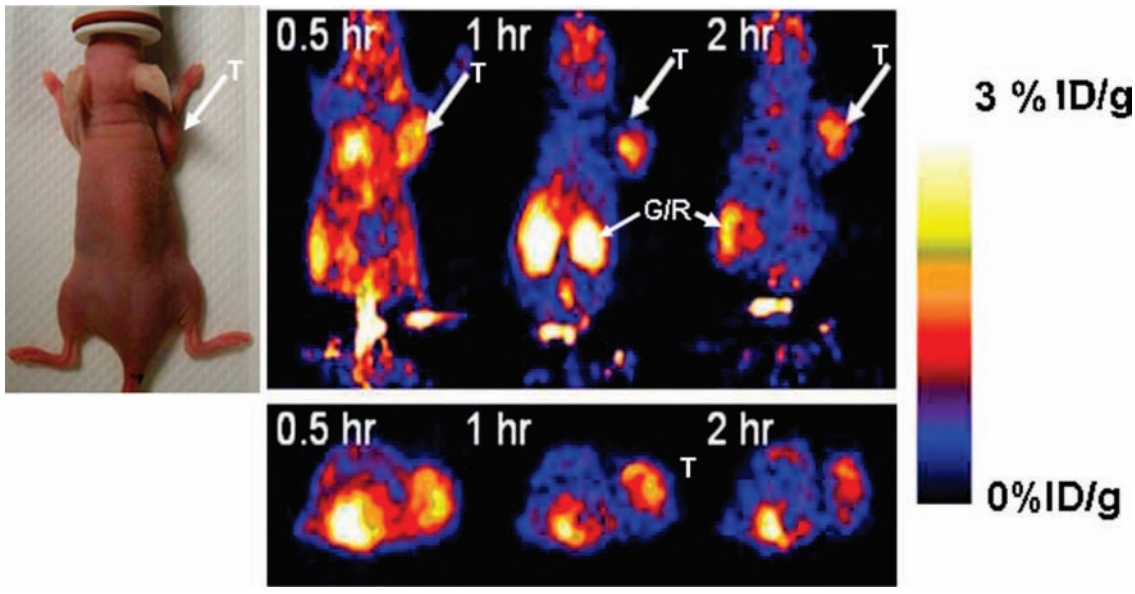

Figure 3. Decay-corrected microPET images (coronal top and trnsaxial bottom) of a nude mouse (photograph shown on left) bearing U87MG xenograft at 0.5, 1, and 2 h after tail injection of 100 μCi of [^{18}F]FDG-RGD. T is for tumor, G/R is gastrointestinal/renal activities, and color bar represents % ID/g.

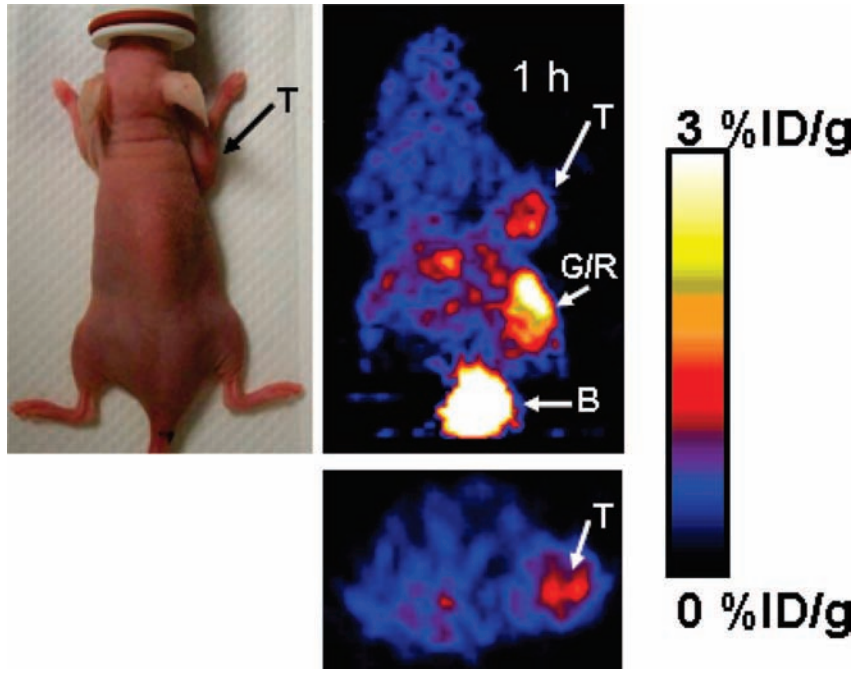

Figure 4. Decay-corrected microPET images (coronal top and trnsaxial bottom) of a nude mouse bearing a U87MG xenograft at 1 h after tail injection of 72 μCi of [^{18}F]FDG-cyclo(RGD^{D}YK). T, tumor; B, bladder; G/R, gastrointestinal/renal activities; and color bar represents % ID/g.

for FDG-cyclo(RGD^{D}YK) was determined to be 0.67 ± 0.19 μM. The corresponding IC_{50} value of cyclo(RGD^{D}YK) is 0.23 μM (*12*).This result suggests that fluorine labeling and the conditions (100 °C and acidic pH) did not have a dramatic affect on its binding affinity.

Biodistribution and Imaging. In order to determine the in vivo imaging performance of [^{18}F]-labeled FDG-RGD over alternatively ^{18}F-labeled RGD analogues, we evaluated [^{18}F]FDG-RGD in U87MG tumor-bearing nude mice that express $\alpha_v\beta_3$ integrin on both tumor vasculature and tumor cells. In vivo biodistribution of [^{18}F]FDG-RGD in U87MG tumor-bearing nude mice ($n = 6$) expressing $\alpha_v\beta_3$ integrin is shown in Table 1. The ratios of tumor to blood, tumor to liver, and tumor to kidney at 2 h postinjection of the probe are comparable to [^{18}F]Galacto-RGD analogue that has been used for biodistribution of [^{18}F]Galacto-RGD in osteosarcoma tumor-bearing nude mice that express $\alpha_v\beta_3$ integrin (*13*). MicroPET images of U87MG tumor-bearing nude mice ($n = 6$) 0.5, 1, and 2 h after tail vein injection of ^{18}F-labeled [^{18}F]FDG-RGD probe were obtained. Figure 3 shows the microPET image of one representative mouse. The subcutaneous U87MG mice tumors could be clearly visualized from surrounding background tissue.

To evaluate in vivo imaging performance of [^{18}F]FDG-cyclo(RGD^{D}YK) in small living subjects, we investigated biodistribution and microPET imaging of U87MG tumor-bearing nude mice expressing $\alpha_v\beta_3$ integrin by using [^{18}F]FDG-cyclo(RGD^{D}YK) as a probe. Biodistribution of [^{18}F]FDG-cyclo(RGD^{D}YK) in U87MG tumor-bearing nude mice ($n = 9$) expressing $\alpha_v\beta_3$ integrin is shown in Table 2. The ratios of tumor to blood, tumor to muscle, and tumor to liver at 2 h postinjection of the probe were 3, 13, and 6, respectively. MicroPET images of U87MG tumor-bearing nude mice ($n = 3$) 60 min after tail vein injection of [^{18}F]FDG]-cyclo(RGD^{D}YK) were also obtained. Figure 4 shows the microPET image of one representative mouse. The subcutaneous U87MG mouse tumor could be clearly visualized from surrounding background tissue. Tracer activity within the tumor was determined to be 1.06 ± 0.20% ID/g, by region of interest (ROI) analysis of the three mice, which matches with the value of 0.95 ± 0.4% ID/g determined by the biodistribution studies (Table 2), and muscle uptake was 0.20 ± 0.12% ID/g. Although the reasons for the relatively fast clearance and moderate tumor uptake after 60 min of injection of [^{18}F]FDG-cyclo(RGD^{D}YK) are not clear, the use of ^{18}F-labeled dimeric or tetrameric ^{18}FDG-labeled RGD should be explored. Recent reports (*14*−*16*) on the radiolabeled DOTA conjugated-cyclic-RGD, monomer, dimer, and tetramer with ^{64}Cu showed that tetrameric cyclic-RGD peptide tracer had about twice as much tumor uptake as the corresponding dimer. Also, the dimer had significantly higher uptake than the monomer counterpart. Likewise, it has been shown that ^{18}F-labeled dimeric RGD peptide, [^{18}F]FB-E[c(RGDYK)]$_2$, has superior imaging characteristics to the corresponding monomer (*17*).

CONCLUSION

We have successfully prepared [^{18}F]FDG-RGD and [^{18}F]FDG-cyclo(RGD^{D}YK) based on a simple one-step radiosynthesis by using [^{18}F]FDG as a prosthetic group. The one-step radiosynthesis methodology consists of chemoselective oxime formation between an easily synthesized aminooxy-functionalized peptide and [^{18}F]FDG. The [^{18}F]FDG labeled RGD peptides can be used to image tumors expressing in living subjects. Imaging of integrin ´$\alpha_v\beta_3$ expression in living subjects would offer a potentially useful approach to diagnose tumors and their metastasis, to help us better understand tumor angiogenesis, and to monitor target-specific antiangiogenesis treatment efficacy. The preliminary mice data support further investigation of the tracers and more comparisons to alternately labeled RGD peptides. The major limitations for generalization of our ^{18}F-labeling methodology are the relatively high temperature (100 °C) and acidic pH conditions required. High temperature and acidic pH are tolerated for the small unprotected peptides but might not be suitable for larger peptides. This approach may also be useful for labeling other biomolecules and would lead to a very simple strategy for routine preclinical and clinical use. The methodology additionally provides benefits such as the use of unprotected aminooxy precursor and the ability to form oximes in aqueous media, providing easy formulation for in vivo use. Indeed, the chemistry has been proven through many biological applications in the synthesis of glycopeptides (*18, 19*), oligonucleotide−peptide conjugates (*20, 21*), complex proteins

(from peptide fragments) (*22*), and conjugation of oligoribonucleotides and proteins with metal chelates (*23*).

Experimental Procedures

General: Cyclic peptide *cyclo*[Arg(Pbf)-Gly-Asp(tBu)-^{D}Tyr(But)-Lys] was purchased from Peptides International (Louisville, KY). All other N-α-Fmoc (Fluorenylmethoxycarbonyl)-protected amino acids, O-benzotriazole-N,N,N',N'-tetramethyluronium hexafluorophosphate (HBTU), O-(7-azabenzotriazol-1-yl)-N,N,N',N'-trimethyluronium hexafluorophosphate (HATU), 1-hydroxy-7-Azabenzotriazole (HOAt), trifluoroacetic acid (TFA), and rink amide resin (100-200 mesh, 1% DVB, 0.5 mmol/g) were purchased from Advanced Chemtech (Louisville, KY). Dimethylformamide (DMF) and methylene chloride were obtained from Fisher Scientific (Fair Lawn, NJ). 20% piperidine in DMF was obtained from Protein Technologies Inc. (Tucson, AZ). Pyridine, acetic anhydride, acetic acid, and anhydrous ether were obtained from J.T.Baker (Phillipsburg, NJ). N-methylmorpholine (NMM), Boc-(aminooxy)acetic acid, N,N-diisopropylethylamine, 1, 2-Ethanedithiol (EDT), and triisopropylsilane (TIPS) were purchased from Aldrich Chemical Company (Milwaukee, WI). HPLC grade acetonitrile (CH_3CN) and Millipore 18 mΩ water were used for peptide purifications. ^{125}I-Echistatin labeled by the lactoperoxidase method with specific activity of 2,000 Ci/mmol was purchased from Amersham Biosciences (Piscataway, NJ). Purification and analysis of the peptides was done on a Dionex Summit HPLC system (Dionex Corporation, Sunnyvale, CA) equipped with a 340 U 4-Channel UV-Vis

absorbance detector and radioactivity detector (Carroll & Ramsey Associates, model 105S, Berkeley, CA). UV detection wavelengths were 218 nm, 254 nm and 280 nm for all the experiments and HPLC reveres phase column (Vydac, Hesperia, CA. 218TP510-C18, 5μ, 10 mm × 250 mm) was used for analysis of labeled peptides. The mobile phase was 0.1% TFA in water , and 0.1% TFA in acetonitrile. Radioactivity measurements were performed by A CRC-15R PETdose calibrator (Capintec Inc., Ramsey, NJ). Electron spray ionization (ESI) mass spectrometry was done by Vincent Coates Foundation Mass Spectrometry Laboratory, Stanford University or an electrospray ionization time of flight mass spectrometer (ESI-TOF-MS, model: JMS-T100LC) (JEOL, Tokyo, Japan) was performed by the Mass Spectrometry Lab at GE Global Research (Niskayuna, NY).

Linear RGD (Arg-Gly-Asp) peptide was synthesized using standard solid phase techniques with N-Fmoc-protected amino acids using substitution 2,4-dimethoxybenzhydrylamine resin (Rink Resin LS, Advanced Chemtech) on a 100 μmol scale. The synthesis was performed in a Rainin/Protein Technology, Inc. Symphony solid phase peptide synthesizer. N-terminal functionalized with aminooxy acetyl group was achieved by using Boc-(aminooxy)acetic acid. Cleavage from the solid support and removal of the acid-labile protecting groups was performed by 95% TFA: 2.5% TIPS (triisopropylsilae): 2.5% water (v/v/v) and purified to afford aminooxy-RGD (RGD-ONH_2) in 72 % yield. Analysis of the peptide by HPLC followed by ESI-MS showed *m/z* = 419.22 for $[M+H]^+$ ($C_{14}H_{27}N_8O_7$, Calculated $[M+H]^+$ = 419.19). For preparation of aminooxyacetyl Cyclo(RGD^{D}YK) [Cyclo(RGD^{D}YK)-ONH_2], initially the protected cyclo[Arg (pbf)-Gly-Asp(tBU)-^{D}Tyr(But)-Lys]-ONH-Boc was prepared by the reaction

of Boc-(aminooxy)acetic acid, O-(7-azabenzotriazol-1-yl)-N,N,N',N'-trimethyluronium hexafluorophosphate (HATU) and Hunig's base with commercially available cyclo[Arg (pbf)-Gly-Asp(tBU)-^{D}Tyr(But)-Lys] in DMF. The protected Cyclo[Arg(pbf)-Gly-Asp(tBU)-^{D}Tyr(But)-Lys]-ONH-Boc was purified by HPLC (white powder,78 % yield). Analysis of peptide by ESI-MS showed *m/z* = 1157.48 for $[M+H]^+$ ($C_{55}H_{85}N_{10}O_{15}S$, calculated $[M+H]^+$ = 1157.58). Removal of the acid-labile protecting groups of cyclo[Arg(pbf)-Gly-Asp(tBU)-^{D}Tyr(But)-Lys]-ONH-Boc was performed as above and purified by HPLC to afford Cyclo(RGD^{D}YK)-ONH_2 in 92 % yield. Analysis of the peptide by ESI-MS showed *m/z* = 693.26 for $[M+H]^+$ ($C_{29}H_{45}N_{10}O_{10}$, calculated $[M+H]^+$ =693.32).

Synthesis of FDG-RGD: The linear aminooxy-RGD (RGD-ONH_2, 2 mg) was incubated with 3.7 equivalents cold FDG in 16 % ethanol in saline (120 μl) in the presence of 0.4 % TFA at 100 °C for 40 min. After cooling to room temperature, the reaction mixture was diluted to 300 μL with water. The resulting solution was injected into a HPLC column (Vydac 218TP54, C18, 5 u, 4.6 X 250 mm, 1mL/min flow rate). The eluent changed from 95% solvent A (0.1 % TFA in H_2O) and 5 % solvent B (0.1% TFA in acetonitrile) (0-3 min) to 35 % solvent A and 65 % solvent B at 33 min. The E and Z oximes were collected (retention time 6.0-7.0 min) and solvents were removed under reduced pressure to yield FDG-RGD (1.1 mg, 39.5 %). The mass spectrometry (ESI-MS) analysis of the isolated product showed two identical mass peaks of 584.2 ($[M+H]^+$) which correspond to FDG-RGD (E- and Z-oximes) (cal. [M+H] for FDG-RGD is 584.5.).

Synthesis of [^{18}F]FDG-RGD: Aminooxy-RGD (RGD-ONH_2, 2 mg) was reacted with 4-6 mCi of [^{18}F]FDG in 100 μl saline in the same condition as above but in 30 minutes.

The poducts (E and Z oximes) were isolated by the above HPLC conditions but with a different gradients. The eluent changed from 97% solvent A (0.1 % TFA in H_2O) and 3 % solvent B (0.1% TFA in acetonitrile) (0-3 min) to 85 % solvent A and 15 % solvent B at 33 min. After products collection, solvents were removed under reduced pressure to afford [^{18}F]FDG-RGD (E and Z) in 27.5 % radiochemical yields based on [^{18}F]FDG (decay corrected).

Synthesis of FDG-Cyclo(RGD^{D}YK): Cyclo(RGD^{D}FK)-ONH_2 (2 mg) was incubated with 5.7 equivalents of FDG in 16 % ethanol in saline (120 μl) and 0.4 % TFA at 100 °C for 60 min. After cooling to room temperature, the reaction mixture was diluted to 300 μL with water. The resulting solution was injected into a HPLC column (above). The eluent changed from 95% solvent A (0.1 % TFA in H_2O) and 5 % solvent B (0.1% TFA in acetonitrile) (0-3 min) to 35 % solvent A and 65 % solvent B at 33 min. The products were collected (retention times 17.5-19 min) and solvents were removed under reduced pressure to yield (E and Z) FDG-cyclo(RGDDYK) (1.03 mg, 41.4 %). The purified FDG-cyclo(RGD^{D}YK) showed two identical mass peaks of 857.35 ([M+H]$^{+}$) in ESI-MS which are corresponding to FDG-cyclo(RGD^{D}YK) (E- and Z-oximes) (cal. M+H for FDG-cyclo(RGD^{D}YK) is 857.47.).

Synthesis of [^{18}F]FDG-Cyclo(RGD^{D}YK): Cyclo(RGD^{D}FK)-ONH_2 (2 mg) was incubated with [^{18}F]FDG (4-6 mCi) in 16 % ethanol in saline (120 μl) and 0.4 % TFA at 100 °C for 45 min. After cooling to room temperature, the products (E and Z oximes) were isolated by the above HPLC conditions which used for the synthesis of FDG-cyclo(RGD^{D}YK)**.** After products collection, solvents were removed under reduced pressure to afford [^{18}F]FDG-cyclo(RGD^{D}YK) (E and Z oximes) in 41 % radiochemical

yields based on [^{18}F]FDG (decay corrected). [^{18}F]FDG-cyclo(RGD^{D}YK) (E- and Z-) oximes were purified but not separated by HPLC and the two ^{18}F-labeled products (E- or Z-oximes) were isolated as a mixture and analyzed by analytical HPLC. The exact stereochemistry (E- and Z-) of these two products has not been determined yet.

U87MG Glioblastoma Xenograft Model

U87MG human glioblastoma cell line was obtained from American Type Culture Collection (Manassas, VA) and was maintained at 37 ºC in a humidified atmosphere containing 5% CO_2 in Iscove's modified Dulbecco's medium and 5% fetal bovine serum (Life Technologies, Inc., Grand island, NY). Animal studies were carried out according to a protocol approved by the Stanford University Administrative Panels on Laboratory Animal Care (A-PLAC). Female athymic nude mice (*nu/nu*), purchased from Charles River Laboratories, Inc. (Cambridge, MA) at 4-6 weeks of age, were inoculated subcutaneously in the flanks with 5×10^6 U87MG glioblastoma cells suspended in 100 μL of phosphate buffered saline (PBS). The tumor bearing mice were subjected to *in vivo biodistribution and* imaging studies when the tumors reached 0.4-0.6 cm in diameter (14-21 d after implant).

Biodistribution

For biodistribution studies, the U87MG tumor-bearing mice (20 g each, n = 3 for each group) were injected with radiolabeled [^{18}F]FDG-RGD or [^{18}F]FDG-cyclo(RGD^{D}YK) (10-30 μCi, 0.37–1.11 MBq) via tail vein and sacrificed and dissected at 30 min to 2 h after injection. Tumor, blood and major tissues of interest were removed

and weighed, and their radioactivity was measured in a gamma-counter. The radioactivity uptake in the tumor and normal tissues was expressed as a percentage of the injected radioactive dose per gram of tissue (% ID/g).

Integrin Binding Characteristics *in vitro*

The receptor binding affinity study of conjugate FDG-cyclo(RGD^{D}YK) for integrin $\alpha_v\beta_3$ was carried out using $\alpha_v\beta_3$ positive U87MG cells. We compared the receptor binding affinity of FDG-cyclo(RGD^{D}YK) by performing competitive displacement studies with ^{125}I-echistatin as radioligand. FDG-cyclo(RGD^{D}YK) inhibited the binding of ^{125}I-echistatin to U87MG cells in a dose dependent manner. The IC_{50} value for FDG-cyclo(RGD^{D}YK) was 0.66 ± 0.22 μM.

MicroPET Imaging

PET scans were performed on a microPET R4 rodent model scanner (Concorde Microsystem Inc.). The mice bearing U87MG were injected with [^{18}F]FDG-RGD or [^{18}F]FDG-cyclo(RGD^{D}YK) via the tail vein and the mice were imaged at 30 min to 2 h after post injection (pi). At different time p.i. (0.5, 1 and 2 h), the mice were anesthetized with 2% isoflurane, and placed in the prone position and near the center of the filed of view of microPET. The 5-min static scans were obtained and the images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. Regions of interest (ROIs) were then drawn over the tumor on decay-corrected whole-body coronal images.

A Modular Monolayer Coating Enables Cell Targeting by Luminescent Yttria Nanoparticles

Christopher A. Traina, T. Joseph Dennes, and Jeffrey Schwartz*

Department of Chemistry, Princeton University, Princeton, New Jersey 08544-1009. Received December 18, 2008; Revised Manuscript Received February 7, 2009

Luminescent Eu^{3+}-doped Y_2O_3 nanoparticles are functionalized for cell targeting using a modular, multisegmented approach based on a phosphonate monolayer platform. The first segment provides hydrolytic stability for the particle−organic interface; the second enables aqueous suspendability; the third is used to bond cell attachment molecules. In vitro imaging experiments showed enhanced cell attachment of activated nanoparticles conjugated with cell attachment peptides compared to control nanoparticles. Peptide-derivatized nanoparticles are not displaced from the cells by their soluble peptide analogue, which suggests strong, polyvalent cell−particle interactions.

Effective biotargeting luminescent nanoparticles must be nontoxic, small relative to the system they are imaging, stable over the course of the experiment, and able to efficiently bond to the desired entity. Rare earth ion-doped yttria (Y_2O_3) nanoparticles are an appealing class of such targeting agents: they are benign in vitro (*1*) and in vivo (*2*) and can be made with diameters of <20 nm (*3*); they can be synthesized to have strong emission in the UV, visible, or IR (*4*) by varying lanthanide dopant ions (so narrow particle size distributions are not necessary as they are for quantum dots (*5*)); and they can be doped for down- (*6*) or up-conversion (*7*) emission. Despite these attractive features, rare earth ion-doped Y_2O_3 nanoparticles have seen only limited use heretofore for targeting biological systems (*2, 8*), which may be due to their limited suspendability in aqueous media and lack of acceptable bioconjugation schemes. We showed that we could control wettability of yttria nanoparticles by bonding monolayers of simple phosphonic acids to them (*9*); these monolayers are stable in organic or aqueous media and are about 1 nm thick. We now report that modular, multifunctional phosphonate monolayers can be synthesized on Y_2O_3 particles to enable their use as cell targeting agents. These tailored monolayers are stable to physiological conditions; they protect the particle−phosphonate interface from hydrolysis, impart particle suspendability in aqueous media, and enable polyvalent bonding of targeting biomolecules to the particles. We also show that luminescent, europium-doped Y_2O_3 nanoparticles that are surface-treated with one such modular monolayer are selective for cell attachment in an in vitro test that can serve as a model for targeting applications.

Monolayers of 11-hydroxyundecylphosphonate attached to micrometer- or nanoscale Y_2O_3 particles (**1**) (*9*) are stable to hydrolysis at pH 7.5 for >12 days; thus, **1** is used as our first module. Treating **1** with *p*-nitrophenyl chloroformate readily gives activated *p*-nitrophenyl carbonate-derivatized **2**, and the second module is introduced by reaction with tri(ethylene glycol) monoamine to give **3**; **3** has good aqueous suspendability and is also stable to hydrolysis at physiological pH. Treating **3** with *p*-nitrophenyl chloroformate gives **4**, which can then bond the desired biotargeting molecule via reaction with a primary amino group (see Scheme 1).

In a typical procedure, Y_2O_3 powder (ca. 1 g; Aldrich) was dispersed by sonication in 60 mL THF. A solution of 11-hydroxyundecylphosphonic acid (*10*) (**5**; 12 mg, 4.76×10^{-5} mol, in 25 mL THF) was added to the suspension, and the reaction mixture was stirred for 3 h at room temperature. The powder was collected by centrifugation, washed to remove excess phosphonic acid, and then dried in vacuo to give **1**, which was then resuspended in 60 mL THF. *p*-Nitrophenyl chloroformate (80 mg) and diisopropylethylamine (0.75 mL) were added, and the mixture was stirred for 15 h. The powder was then recovered by centrifugation and washed to give **2** ($\nu_{C=O} = 1768$ cm^{-1}). It was then treated with tri(ethylene glycol) monoamine (35 mg) and diisopropylethylamine (0.75 mL) in THF with stirring for 20 h. The powder was collected by centrifugation, and excess reagents were removed to give **3**, which was then treated with *p*-nitrophenyl chloroformate (80 mg) as described above. The product was then washed to give **4** ($\nu_{C=O} = 1768$; 1700 cm^{-1}). To determine the surface loading of the two modules on Y_2O_3 particles, a fluorescent dye was coupled to **4**, cleaved, and quantified in solution (*11*); in this way, the surface loading was measured to be 0.25 ± 0.01 mol/cm^2. Full synthesis and characterization details are given as Supporting Information.

As a first step to determining their biocompatibility, cell culture studies using NIH 3T3 fibroblasts were performed to probe cell adhesion on untreated and treated Y_2O_3 particles. Using a standard IR pellet press, aliquots of **4** were pressed into disks ($d = 12$ mm, $h = 1.5$ mm) that were then kept in a solution of Gly-Arg-Gly-Asp-Ser-Pro-Lys (GRGDSPK; 20 mg in 40 mL deionized water adjusted to pH 8−8.5 with aqueous NaOH) for 24 h; peptides containing the RGDS sequence are well-known models for the cell recognition site in fibronectin (*12*). The disks were then removed and rinsed with aqueous NaOH (pH 8.5), deionized water, then methanol to give peptide-terminated **6a** (see Scheme 1). Three surfaces were examined for cell adhesion: unmodified Y_2O_3, **3**, and **6a**. Samples of these particles were pressed into disks and put into cell culture (Supporting Information Figure 2). Quantification of cell adhesion for each surface was assessed by counting the number of cells in randomly generated microscope fields (Figure 1; 10× magnification, minimum of six fields for each type of sample; for cell counting data, see Supporting Information Figure 3). Unmodified Y_2O_3 supported some cell adhesion; importantly, the number of adherent cells was reduced by almost half on **3** and was doubled on **6a**. A two-way analysis of variance (ANOVA) showed a statistically significant difference between

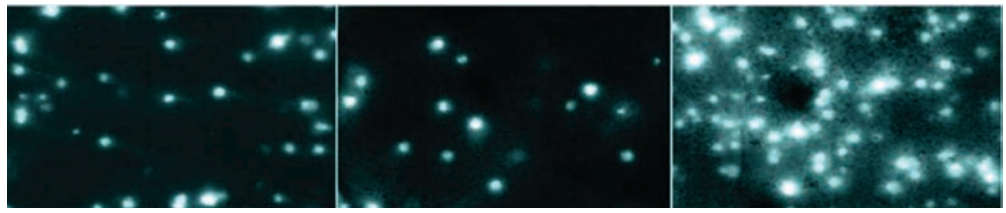

Figure 1. Cell adhesion images for pelletized Y_2O_3: untreated (left), **3** (middle), **6a** (right); cell counting data are given in Supporting Information.

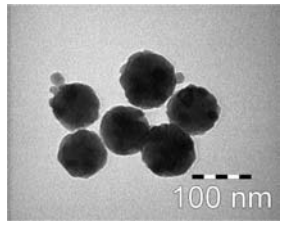

Figure 2. TEM image of Y_2O_3/Eu^{3+}nanoparticles shows diameters of ca. 100 nm.

the mean number of cells attached to RGD-coated and control pellets (for untreated Y_2O_3 vs **3** $p = 0.02$; for untreated Y_2O_3 vs **6a**, $p = 0.001$; for **3** vs **6a**, $p = 0.0001$).

To demonstrate the utility of this modular approach for bioimaging purposes, bioconjugation of luminescent nanoparticles was investigated. Eu^{3+}-doped (5%) Y_2O_3 nanoparticles were synthesized by precipitation of $Y(OH)CO_3$ particles from a refluxing, aqueous solution of Y^{3+} and Eu^{3+} salts and urea (*13*); calcining at 785 °C for 1 h gave cubic Y_2O_3:Eu^{3+} (by powder X-ray diffraction (*13*)). Particles with diameters ranging from ~40 to 180 nm (by TEM) could be obtained by adjustment of reagent concentrations; those with diameters between 80 and 120 nm (Figure 2) were used for subsequent experimentation. A strong band at 612 nm and less intense peaks at 591 and 630 nm were recorded in the particle emission spectrum and are characteristic of Eu^{3+} luminescence (*14*). Importantly, these nanoparticles can be easily visualized using a standard fluorescence microscope under UV (~365 nm) or blue (~488 nm) excitation.

The luminescent yttria nanoparticles were sonicated in THF to break up any agglomeration prior to and during monolayer deposition of **5** to give **1**, which was derivatized with tetra(ethylene glycol) monoamine and then GRGDSPK to give **6a** as described above. Similarly prepared control **6b** used cell adhesion-inactive GRADSPK (*12*) as a control. Suspensions of **6a** and **6b** were introduced into separate fibroblast cell culture dishes (10^5 cells/mL; cells were prestained with cell-tracker dye) which had a confluent cell layer on the plating substrate and the particles were allowed to attach for 3 h; the cells were then washed to remove unbound particles, fixed, and visualized by fluorescence microscopy. There was no change in the emission spectra for **6a**- or **6b**-treated vs untreated nanoparticles; only the doped nanoparticles were visible under UV (365 nm) illumination, but blue (488 nm) irradiation excited both dye-stained cells and nanoparticles. Images of cells treated with control **6b** showed only some large particle aggregates but no specific particle binding to the cells. In contrast, **6a** showed cell attachment with little aggregation (see Supporting Information Figure 8). Since **6a** and **6b** have similar wetting properties and charges, it is unlikely that they would have different aggregative properties in the absence of cell binding opportunities.

Nanoparticle−cell binding was further distinguished from simple precipitation using a nonconfluent cell layer (~50% substrate coverage) that was treated with **6a** or **6b**. Most of the

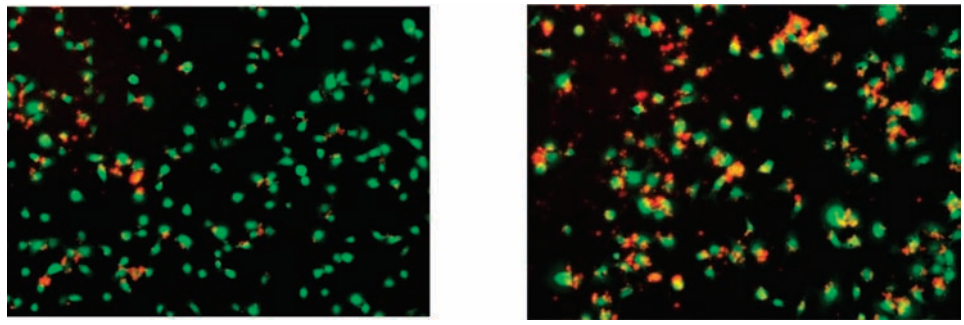

Figure 3. Nonspecific adsorption/aggregation of RAD-modified nanoparticles **6b** (left) versus adherence to cells (green) by RGD-modified nanoparticles **6a** (right) in nonconfluent cell layers. The nanoparticles luminesce red.

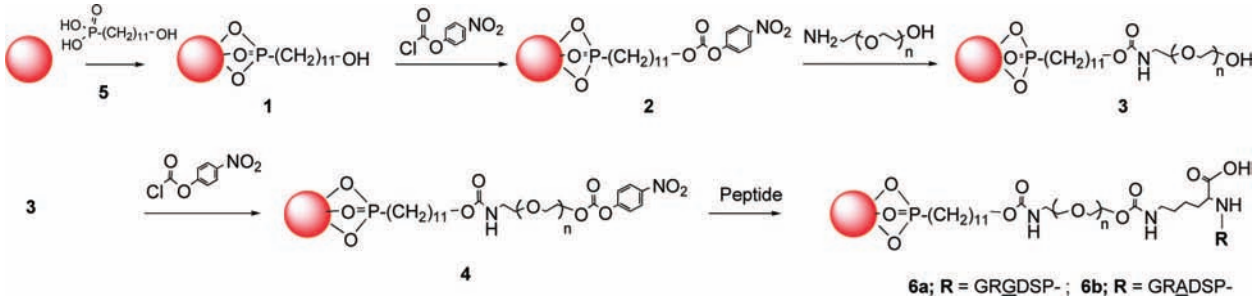
Scheme 1. The Modular Approach to Surface Functionalization of Undoped and Doped Yttria Particles (Red Spheres)



cells treated with **6a** were covered with nanoparticles but very little **6a** deposited on the substrate between the cells; few cells exposed to **6b** were bound to particles (Figure 3). Cell binding by **6a** was not inhibited by soluble GRGDSPK. RGD−integrin binding is reversible (*15*), but due to their size, particles of **6a** cannot be resuspended after cell interaction, which inhibits displacement by the soluble peptide. Importantly for cellular targeting, nanoparticles of **6a** may act as polyvalent binding species (*16*), which would greatly enhance cell binding of the bioconjugated particles vs the soluble peptide: On the basis of calculated surface loadings of the two modules on the Y_2O_3 particles, and assuming an average particle diameter of ∼100 nm, each nanoparticle can have $>10^4$ surface-attached peptide molecules on it, thus making it possible for each particle to bind simultaneously to several receptor sites on the cell surface.

We have shown that the Y_2O_3 surface can be easily and reproducibly functionalized in high yield via a modular scheme based on organophosphonate monolayers that enables control of nanoparticle surface properties. The nanoparticles can be made more cell adhesive or more cell resistant than the native ones by bonding an RGD-containing peptide or an oligo(ethylene glycol) moiety, respectively. This modular scheme was used to derivatize luminescent, Eu^{3+}-doped nanoparticles with an RGD peptide; in vitro experiments showed that increased cell surface−nanoparticle binding interactions could be visualized, and this binding was not suppressed by added soluble peptide. The modular concept may be expanded to examine peptide−receptor specificities; a small library of differently "colored" nanoparticles, each terminated with a different peptide sequence, might in principle be used to identify the presence of peptide-ligand specific cell surface receptor sites.

ACKNOWLEDGMENT

The authors thank the National Science Foundation, CHE-0612572, for support of this research. They also thank Prof. Jean E. Schwarzbauer, Department of Molecular Biology, Princeton University, for critical assistance.

Supporting Information

Full experimental details for synthesis of **1**, **2**, **3**, **4**, and **6**; a calibration curve for measuring surface loading of **4**; calculation of surface loading; cell adhesion cartoon and counting data; IR spectra for **1**, **2**, **3**, and **4**; images of nanoparticles of **6a** and **6b** on a confluent layer of cells.

General. Tetrahydrofuran (ACS grade, EMD) was distilled from Na/benzophenone before use. Acetonitrile (HPLC grade, EMD) was distilled from CaH_2 prior to use. Methanol (EMD), tetra(ethylene glycol), trimethylsilyl bromide (TMS-Br), sodium 5-([2-aminoethyl]amino)naphthalene-1-sulfonate (EDANS), urea, europium(III) chloride hexahydrate, yttrium(III) chloride hexahydrate, *p*-nitrophenyl chloroformate, N,N-diisopropylethylamine, yttrium oxide, sodium hydroxide, tetra(ethylene glycol) monoamine and tri(ethylene glycol) monoamine (Molecular Bioscience) were used as received. Methylene chloride (EMD) was dried over 4Å molecular sieves prior to use. GRGDSPK peptide (99% purity, 80% peptide) and GRADSPK peptide (98% purity, 74% peptide, American Peptide) were used as received. IR spectra were recorded using a Smart Orbit diamond attenuated total reflectance (ATR) attachment on a Nicolet 6700 FT-IR spectrometer (solids) or neat on NaCl plates using a Nicolet 730 FT-IR spectrometer (liquids). Fluorescence measurements were acquired on a Perkin Elmer LS 50 fluorescence spectrometer. Luminescence spectra of nanoparticles were obtained by dispersing particles onto a glass slide fitted with double-sided tape. ^{1}H and ^{31}P NMR spectra were obtained on a Varian Mercury 300 MHz spectrometer. ^{13}C NMR spectra were acquired on a Varian Inova 400 or Inova 500 MHz spectrometer. TEM images were acquired on a Zeiss 910 TEM and powder X-ray diffraction patterns were recorded on a Rigaku MiniFlex X-Ray Diffractometer.

Phosphonate film depositions on Y_2O_3 powder.[1] Yttrium oxide powder (~1 g) was dispersed by sonication in 60 ml THF in a 250 ml round-bottom flask. A solution of 11-hydroxyundecylphosphonic acid (**5**, 12 mg, 4.76×10^{-5} mol, in 25 ml THF) was added to the powder suspension, and the reaction mixture was stirred for 3 hrs at room temperature. The powder was then collected by centrifugation and subsequently washed to remove excess

phosphonic acid. The washing procedure consisted of dispersing the powder in 80 ml methanol containing 0.65 ml 0.05M NaOH/methanol solution and shaking this suspension for 6 min. The particles were then collected by centrifugation and the washing procedure was performed again. The powder was then washed a third time in a similar way but with a solution of 60 ml methanol, 20 ml deionized water, and 0.3 ml 0.05 M aqueous NaOH. The powder was subsequently dried *in vacuo* to give coated particles of **1**.

Reaction of 1 with *p*-nitrophenyl chloroformate. Phosphonate-coated **1** (1 g) was put into a 100 ml round-bottom flask equipped with an argon inlet and stir bar. Dry THF (60 ml) was added, and the suspension was stirred under argon for 5 min. *p*-Nitrophenyl chloroformate (80 mg) and diisopropylethylamine (0.75 ml) were added, and the reaction was stirred for 15 hrs under argon. The powder was then recovered by centrifugation and was subsequently washed twice (sonication for 10 min in 80 ml dry acetonitrile) to give **2**.

Reaction of 2 with tri(ethylene glycol) monoamine. *p*-Nitrophenyl carbonate-derivatized **2** was added to a 100 ml round-bottom flask equipped with an argon inlet and stir bar. Dry THF (60 ml) was added and the suspension was stirred under argon for 5 min. A solution of tri(ethylene glycol) monoamine (35 mg) in dry THF (5 ml) was added along with diisopropylethylamine (0.75 ml), and the reaction was stirred under argon for 20 hrs. The powder was then collected by centrifugation. Excess reagents were removed by dispersing the powder in 80 ml methanol containing 0.65 ml of a 0.05 M NaOH/methanol solution and manually shaking this suspension for 6 min. The powder was recovered by centrifugation. This washing procedure was performed twice to give **3**.

Reaction of 3 with *p*-nitrophenyl chloroformate. The reaction of **3** with *p*-nitrophenyl chloroformate was done as for the preparation of **2**. The product was then washed to give **4**.

Reaction of 4 with GRGDSPK peptide. Powder of **4** was pressed into disks (d = 12 mm, h = 1.5 mm) using a standard IR pellet press. The disks were placed in a solution of GRGDSPK (20 mg in 40 ml deionized water, adjusted to pH 8 – 8.5 with aqueous NaOH) and allowed to react for 24 hrs. The disks were then removed and rinsed by immersion for 12 min in aqueous NaOH (pH 8.5) followed by immersion in deionized water, then methanol, each for 20 sec. Each disk was washed five times using this procedure to give peptide terminated **6a**.

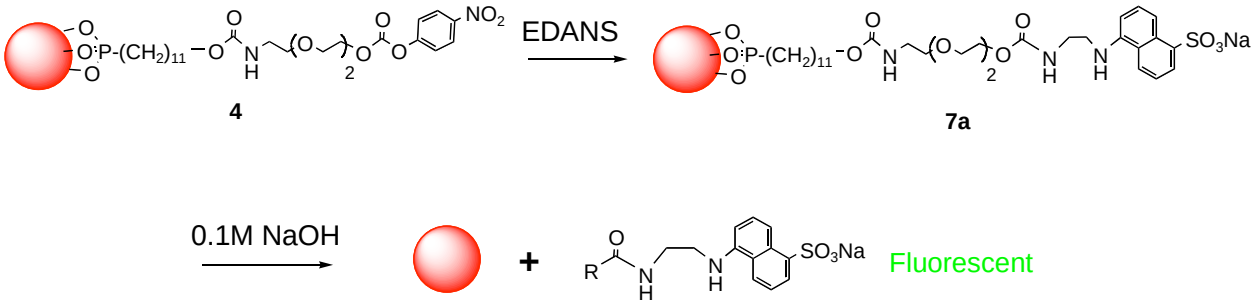
Reaction of 4 with sodium 5-([2-aminoethyl]amino)naphthalene-1-sulfonate (EDANS). To quantify surface bonding to the functionalized nanoparticles, green fluorescent dye sodium 5-([2-aminoethyl]amino)naphthalene-1-sulfonate (EDANS) was attached to **4**, which gives **7a** (Supporting Information Scheme 1); by cleaving the dye from the nanoparticles, surface bonding can be quantified from the amount of dye cleaved from the surface (obtained from fluorescence measurements of the cleaved dye solution), particle mass and surface area[2] (see Supporting Information Figure 1 and Calculation). A solution of EDANS (35 mg in 45 ml deionized water and 3 ml acetonitrile) was adjusted to pH 8.5, and **4** (350 mg) was added. The reaction mixture was stirred at room temperature for 24 hrs and was subsequently centrifuged to collect the powder. The product was washed until no significant fluorescence was visible in the supernatant under UV illumination. The washing procedure consisted of suspending the powder in a solution of 0.15 ml 0.05M NaOH/methanol in 20 ml methanol and manually shaking for 6 min. The powder was recovered by centrifugation to give **7a** (Supporting Information Scheme 1). A

control sample was prepared in a similar way by substituting powder **3** for **4** to give **7b** (not shown).

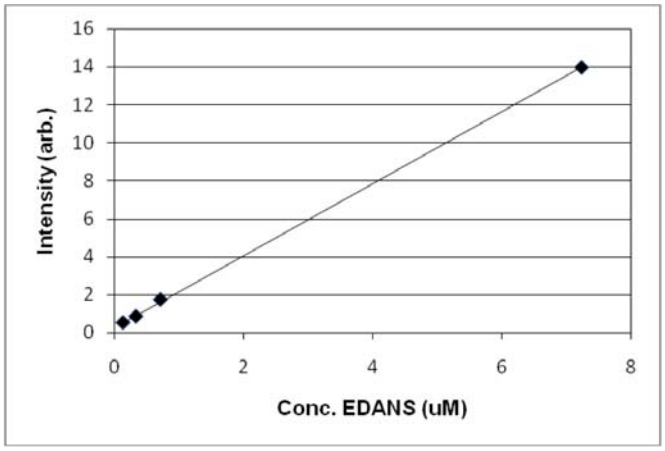
Surface loading of EDANS dye. Product **7a** or control **7b** (20 mg) was put into a 50 ml centrifuge tube. Aqueous NaOH (10.0 ml, pH 7.5) was added, and the samples were placed on a shaker for 24 hrs after which time the samples were centrifuged and fluorescence readings of the supernatant were measured. The supernatant was removed, and fresh pH 7.5 solution was added. Fluorescence measurements and supernatant replacement were repeated every 24 hrs until no significant fluorescence was detected. The supernatant was then removed, and aqueous NaOH (10.0 ml, 0.1 M) was added to cleave the remaining covalently-bound dye from the particles. The samples were shaken for 24 hrs after which time they were centrifuged and the fluorescence intensity of the supernatant was measured. The supernatant was removed, fresh aqueous NaOH (10.0 ml, 0.1 M) was added, and the samples were shaken for an additional 24 hrs. The samples were then centrifuged and fluorescence intensity measurements of the supernatant were taken. To obtain the EDANS concentration in the supernatant, a linear plot of fluorescence intensity versus concentration was constructed from a set of EDANS calibration standards (130 nM – 7 mM in 0.1 M NaOH) (see Supporting Information Figure 1) and the concentration of cleaved EDANS dye was calculated using this linear fit (See Supporting Information Calculation). The concentration of cleaved EDANS along with the volume of supernatant, the amount of powder used for each experiment, and the measured specific surface area of the powder were used to calculate the amount of EDANS dye covalently bound to the yttrium oxide. In this way, the surface loading of dye on **7a** was calculated to be 0.25 ± 0.01 nmol/cm^2, which is similar to

peptide loadings on PUL monolayers on TiO_2/Ti;[2, 3] this loading is assumed to be comparable for attachment of biomolecules of similar "footprint" to that of EDANS.

Supporting Information Scheme 1. Fluorescence-based procedure for determination of surface loading.



Supporting Information Figure 1. EDANS calibration curve used for surface loading calculation of **7a**.



Surface loading calculation

Surface loading = $(nmol_{EDANS,\ total})/(\ SA\ (cm^2)\ )$ (Eq. 1)

$nmol_{EDANS,\ total}$

$intensity_{supernatant} = (m * concentration_{EDANS}) + b$ (Eq. 2)

(from linear fit to calibration curve)

$conc._{sample} = (int_{sample} – b)/m$ (Eq. 3)

$conc._{sample}$ (mM) * $vol._{supernatant}$ (L) = $mmol_{EDANS}$ (Eq. 4)

$mmol_{EDANS,\ day\ 1} + mmol_{EDANS,\ day\ 2} = mmol_{EDANS,\ total}$ (Eq. 5)

(day 1 – first 24 hrs cleavage, day 2 – second 24 hrs cleavage)

$mmol_{EDANS,\ total} * 10^3 = nmol_{EDANS,\ total}$ (Eq. 6)

Surface Area of powder (cm^2)

Surface Area, SA (m^2) = $mass_{sample}$ (g) * 1.2 m^2/g (Eq. 7)

(Surface area per gram measured from Y_2O_3 powder)

SA (cm^2) = SA (m^2) * 10^4 (Eq. 8)

***In vitro* adhesion study (pellet substrate).** NIH 3T3 cells were maintained in Dulbecco's Modified Eagle's Medium (DMEM) with 10% calf serum (Hyclone) and were prepared for cell adhesion experiments as previously described.[4] Cells (10^4 cells/ml in Tris buffer), pre-stained with Cell Tracker Green (30 min at 37 ^oC), were added to tissue culture wells containing peptide-modified pellets pressed from particles of **6a**, tri(ethylene glycol)-modified pellets pressed from particles of **3**, or unmodified Y_2O_3 pellets (See Supporting Information Figure 2). Cells were allowed to attach for 90 min after which time non-adherent cells were removed by several washings with Tris buffer. The cells were then fixed (15 min, 3.7% formaldehyde in PBS) and visualized using a Nikon Optiphot-2 microscope. Images were obtained using a Photometrics

Coolsnap camera, and image analysis was performed using IPLab software. Cell counting data are summarized in Supporting Information Figure 3.

Supporting Information Figure 2. Cartoon illustrating the in vitro pellet experiment.

Synthesis of 5% Europium-Doped Y_2O_3 Nanoparticles (Y_2O_3:Eu^{3+}). A modification of a literature procedure was used.[5] Lanthanide salts $YCl_3 \cdot 6H_2O$ (0.364g, 1.2 mmol) and $EuCl_3 \cdot 6H_2O$ (0.023g, 0.063 mmol) were dissolved in 100 ml deionized (DI) water in a 250 ml round-bottom flask, and urea (1.44g, 24 mmol) was added. The pH was adjusted to between 5.5 and 6, and the solution was heated to 90-100 ^oC. A slight turbidity was visible, and the reaction was allowed to proceed for 90 min. The white suspension that formed was then cooled by immersing the flask in a water bath; ice was added until the flask reached room temperature. The $Y(OH)CO_3$ nanoparticles were then collected by centrifugation (~5000 x g, 40 min) and washed four times with 80 ml DI water followed by centrifugation. The particles were air-dried overnight and then dried for 3 hrs at 110 ^oC under vacuum (~0.5 torr). Annealing at 785 ^oC for 1 hr in air (~2-3 hrs to reach 785 ^oC and <1 hr cool down) converted the nanoparticles from the yttrium hydroxycarbonate precursor to yttrium oxide. X-ray powder diffraction patterns conformed to published data as did low resolution luminescence spectra that were taken to confirm dopant presence;[5] TEM images indicated particle sizes between 80 and 120 nm (Supporting Information Figure 4).[18]

Supporting Information Figure 4. TEM image of Y_2O_3:Eu^{3+}nanoparticle show diameters of ca. 100 nm.

Polyaspartamide-Based Oligo-ethylenimine Brushes with High Buffer Capacity and Low Cytotoxicity for Highly Efficient Gene Delivery

Min Zhang, Min Liu, Ya-Nan Xue, Shi-Wen Huang,* and Ren-Xi Zhuo*

Key Laboratory of Biomedical Polymers, Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received May 23, 2008; Revised Manuscript Received December 11, 2008

Polyaspartamide-based oligo-ethylenimine brushes (PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423) were synthesized from polysuccinimide (PSI) via a ring-opening reaction with N-Boc protected ethylenediamine, tetraethylenepentamine, pentaethylenehexamine, and linear polyethylenimine (Mn 423), respectively. PASP-TEPA, PASP-PEHA, and PASP-PEI 423 possess high buffer capacity between pH 5 and pH 7, which is comparable to that of branched PEI 25000. The cytotoxicity assay indicated that they all are less toxic than PEI 25000. At an *N*/*P* ratio of above 2, all of the four synthetic polycation brushes can condense plasmid DNA to form small sized (160−400nm) polyelectrolyte complexes with positive surface charge. The transfection of HEK 293 cells with oligo-ethylenimine brush/pRE Luc polyplexes indicated that the transfection efficiencies increased with increasing the length of oligo-ethylenimine side chains. The luciferase expression with PASP-PEHA and PASP-PEI 423 were as high as or even a little higher than that of PEI 25000. The results demonstrate that polyaspartamide-based oligo-ethylenimine brushes are a very promising class of novel polycations for highly efficient and less toxic gene delivery.

INTRODUCTION

In the past decade, cationic polymers, as nonviral gene delivery vectors, have received more and more attention and have been widely used to deliver foreign DNA into cells and achieve efficient gene expression in cells (*1*−*3*). A variety of natural and synthetic polycations, such as poly(L-lysine) (PLL) (*4, 5*), poly(ethylenimine) (PEI) (*6*−*8*), polyamidoamine dendrimer (*9*−*13*), cationic polyester (*14*−*18*), cationic polyphosphoester and polyphosphoramidate (*19*−*23*), chitosan (*24*−*26*), etc., have been used as gene carriers. Among the current polymeric gene delivery vectors, PEI is undoubtedly the most successful one and has become the gold standard for designing new polymeric gene carriers. PEI/DNA complexes often show high efficiencies for transfecting a large number of cell lines. It is widely accepted that the good transfection property of PEI is due to its high buffer capacity over a broad pH range, which is called proton sponge theory (*27, 28*). Further protonation of PEI in PEI/DNA complexes localized in the endosomal compartments leads to transfer protons and chloride counterions into the endosomes, which result in destabilization of endosomes and release of PEI/DNA complexes into the cytoplasm. Similarly, the proton sponge mechanism is also applicable for other polycations with a pK_a at or below physiological pH, such as polyamidoamine (*29*,*30*), imidazole-containing polylysine (*31*−*33*), etc.

Both branched PEI and linear PEI have been tested for in vitro and in vivo gene delivery. The transfection efficiencies of branched PEI as gene carriers are dependent on the polymer structures, such as molecular weight and degree of branching (*34*). It was found that high molecular weight branched PEI up to 800 K shows superior ability to form compact and stable PEI/DNA complexes and higher transfection efficiency, compared to lower molecular weight PEI. However, high molecular weight branched PEI is more toxic than lower molecular weight branched PEI. Linear PEI-based gene carriers have also been investigated in recent years. In comparison to branched PEI, linear PEI shows different characteristics, such as DNA compaction, nuclear uptake, transfection efficiency, and toxicity. Linear PEI is often more effective and less toxic than branched PEI. It is more attractive that lower molecular weight linear PEI is almost nontoxic to cells. It is possible to combine the low cytotoxicity of low molecular weight linear PEI and high transfection by grafting low molecular weight linear PEI into a suitable polymer. In the previous work, Zhong et al. reported ABA triblock copolymers PEI-PEG-PEI composed of PEG 3400 and relatively low molecular weight linear PEI (2100 and 4000) as gene carriers (*35*). The optimized transfection efficiency of PEI-PEG-PEI (PEI 4000) is higher than linear PEI 25K. Low molecular weight linear PEI-grafted cyclodextrin, polyaspartamide, chitosan, and dextrane have also been used as highly efficient and less toxic gene carriers (*36*−*43*). However, although many polyaspartamide-derived polycations have been applied to in vitro gene delivery, the transfection efficiencies are often relatively low (*44*−*47*). We here report oligo-ethylenimine brushes, a new kind of polycation, as polymer gene delivery vectors. Oligo-ethylenimine brushes were synthesized from polysuccinimide (PSI) reacting with excess of oligo(ethylenimine). The goal of this work is to develop new types of highly efficient polycation brush gene delivery vectors by the introduction of low toxicity of lower molecular weight PEI side chains into polyaspartamide. The effects of the length of oligo-

ethylenimine side chains on the transfection efficiencies have also been investigated.

EXPERIMENTAL PROCEDURES

Materials and Methods. Tetraethylenepentamine (TEPA), pentaethylenehexamine (PEHA), linear polyethylenimine (Mn 423) (PEI 423), and branched PEI 25000 (M_w = 25000) were purchased from Aldrich-Sigma Chemical Co. MTT (3-{4,5-dimethylthiazol-2-yl}-2,5-diphenyltetrazolium bromide) was purchased from BDH Laboratory Supplies. Dulbecco's modified Eagle's medium (DMEM) and L-glutamine were purchased from Gibco BRL. Giga plasmid purification kit was purchased from Qiagen in China. Fetal bovine serum (FBS) was the product of HyClone. Other reagents and solvents were of analytical grade, obtained from domestic suppliers and used directly. Poly-L-succinimide (PSI) (M_w = 3.41 × 10^4, M_w/M_n = 1.32) was synthesized by thermal polycondensation of L-aspartic acid according to the previously reported method (*48*). *N*-*t*-Butoxycarbonyl-ethylenediamine (N-Boc-EDA) was synthesized according to the literature method (*49*). The luciferase encoding plasmid pRE Luc is an 11.9 kb pcDNA driven by a Rous sarcoma virus promoter inserted into an Invitrogen (Sandiego, CA) pREP7 vector. The plasmid was amplified in *Escherichia coli* and isolated and purified using Qiagen endotoxin free plasmid Gigaprep kits according to the supplier's protocol. The quantity and quality of plasmid DNA was analyzed by spectrophotometric analysis at 260 and 280 nm and by electrophoresis in 0.8% agarose gel. Purified plasmid DNA was diluted in TE buffer and stored at −20 °C.

FTIR spectra were measured on a Perkin-Elmer Spectrum one spectrometer. ^{1}HNMR spectra were recorded on a Mercury VX-300 MHz instrument. Gel permeation chromatography (GPC) measurements were carried out by using a Waters-2690D HPLC equipped with an Ultrahydrogel 120, 250, and 2000 column. Samples were detected with a Wyatt multiangle light-scattering detector and a Waters 2100 differential refractive index detector. PBS (0.1 mol L^{-1}, pH 7.4) was used as the mobile phase at a flow rate of 0.8 mL min^{-1}. The column temperature was 25 °C.

Synthesis of PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423. *PASP-EDA.* A solution of 0.485 g of poly-L-succinimide (PSI) in 10 mL of DMF was added dropwise to a solution of 1.6 g of N-Boc-ethylenediamine (N-Boc-EDA) in 5 mL of DMF at 0 °C. The reaction mixture was stirred for 2 h at 0 °C and stirred for a further 24 h at room temperature, and then poured into 150 mL of ether. The formed precipitate was filtered, dried, and added into 60 mL of 2 mol L^{-1} hydrochloride to remove the protective N-Boc group of polyaspartamide derivative. The suspension mixture was stirred for 4 h at room temperature until the solid gradually dissolved in dilute hydrochloride, and then alkalized with 2 mol L^{-1} sodium hydroxide to pH 12. Next, the solution was dialyzed against distilled water for two days and lyophilized to yield 0.43 g of slightly yellow solid. FT-IR (KBr, cm^{-1}): 3431, 3068, 2923, 2819, 1660, 1533, 1384, 1171 cm^{-1}. ^{1}H NMR (D_2O, ppm) δ: 2.5−2.7 (2H, m, CH_2); 3.0 (2H, m, CH_2); 3.3 (2H, m, CH_2); 4.7 (1H, m, CH). M_w = 1.78 × 10^4. M_w/M_n = 1.40.

PASP-TEPA, PASP-PEHA, and PASP-PEI 423 were synthesized according to the general procedure described below. A solution of 0.097 g of poly-L-succinimide (PSI) in 4 mL of DMF was separately added dropwise to a solution of 10-fold molar excess oligoethylenimine (for TEPA, 1.89 g; PEHA, 2.32 g; and PEI423, 4.23 g) in 5 mL of DMF at 0 °C. The reaction mixture was stirred for 2 h at 0 °C and stirred for a further 24 h at room temperature, then dialyzed against distilled water for two days, and lyophilized to yield PASP-TEPA, PASP-PEHA, and PASP-PEI 423.

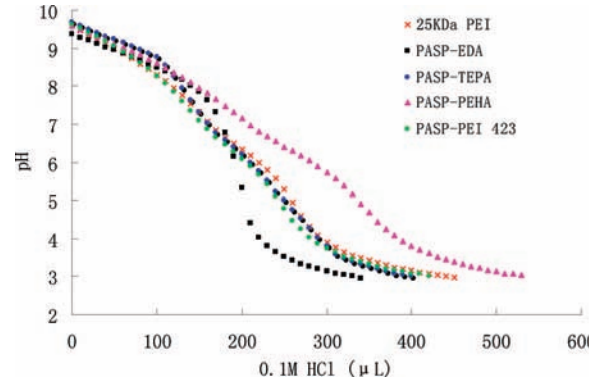

Figure 1. Titration curve of polyaspartamide-based oligo-ethylenimine brushes. A solution of polymer (5 mM total amine) in 0.15 mol L^{-1} NaCl was titrated with 0.1 mol L^{-1} HCl. Branched PEI (M_w 25000) was used as a control.

PASP-TEPA. 68.7 mg. FT-IR (KBr, cm^{-1}): 3436, 2926, 2853, 1643, 1547, 1398, 1128. ^{1}H NMR (D_2O, ppm) δ: 2.4−2.8 (CH_2NH); 2.9 (CH_2CO); 3.2 (CH_2); 4.7 (CH). M_w = 0.98 × 10^4, M_w/M_n = 1.47.

PASP-PEHA. 68.5 mg. FT-IR (KBr, cm^{-1}): 3401, 3081, 2947, 2844, 1649, 1551, 1385, 1123 cm^{-1}. ^{1}H NMR (D_2O, ppm) δ: 2.3−2.8 (CH_2); 2.9 (CH_2); 3.2 (CH_2); 4.7 (CH). M_w = 1.09 × 10^4, M_w/M_n = 1.43.

PASP-PEI 423. 125.9 mg. FT-IR (KBr, cm^{-1}): 3434, 2956, 2851, 1650, 1554, 1384, 1122 cm^{-1}. ^{1}H NMR (D_2O, ppm) δ: 2.3−2.8 (CH_2); 2.9 (CH_2); 3.2 (CH_2); 4.7 (CH). M_w = 1.45 × 10^4, M_w/M_n = 1.22.

Acid−Base Titration. The buffer capacity of synthetic polymers and branched PEI 25000 was determined by acid−base titration. Each polymer was dissolved in 10 mL of 0.15 mol L^{-1} sodium chloride aqueous solution to give a final concentration of total amino groups in the polymer of 5 mmol L^{-1}. Each polymer solution was separately titrated with 0.1 mol L^{-1} HCl at 25 °C. The pH values were recorded with a Microprocessor pH Meter.

In Vitro Cytotoxicity. PASP-EDA, PASP-TEPA, PASP-PEHA, PASP-PEI 423, and branched PEI 25000 were separately dissolved in Dulbecco's modified Eagle's medium (DMEM) supplemented with 4 mmol L^{-1} glutamine, 10% FBS, penicillin, and streptomycin (100U/mL), and sterile-filtered. The solution was diluted with complete DMEM to different concentrations ranging from 3.7 μg mL^{-1} to 4000 μg mL^{-1}. HEK293 cells were seeded into a 96-well plate at a density of 5000 cells/well in 50 μL of complete DMEM. After the cells were cultured at 37 °C for 24 h in an atmosphere containing 5% CO_2, 50 μL of polymer solutions at different concentrations were separately added into the wells. Cells treated with polymers were cultured for a further 24 h at 37 °C, and then MTT solution (5 mg mL^{-1}, 20 μL) in PBS (0.1 mol L^{-1}, pH 7.4) was added into each well except that PBS (20 μL) was added into the background wells, and then incubated at 37 °C for 4 h. After the removal of the medium in each well, 150 μL of DMSO was added to each well to dissolve the formed formazan blue crystal inside the cells. After shaking for 10 min, the absorbance of the solution was measured using a microplate reader (Bio-Rad 550) at 570 nm. The percent relative viability in reference to control wells containing complete DMEM without the added polymer was calculated by the following equation (A = absorbance at 570 nm; A_0 is the absorbance of the solution containing cells and complete DMEM without MTT and polymer): relative cell viability (%) = 100 × $(A_{test} - A_0)/(A_{control} - A_0)$.

Preparation of Polycation/Plasmid DNA Complexes. Polycation/ pRE Luc complexes at various *N*/*P* ratios were separately prepared by rapidly adding 50 μL of polycation solution in 150

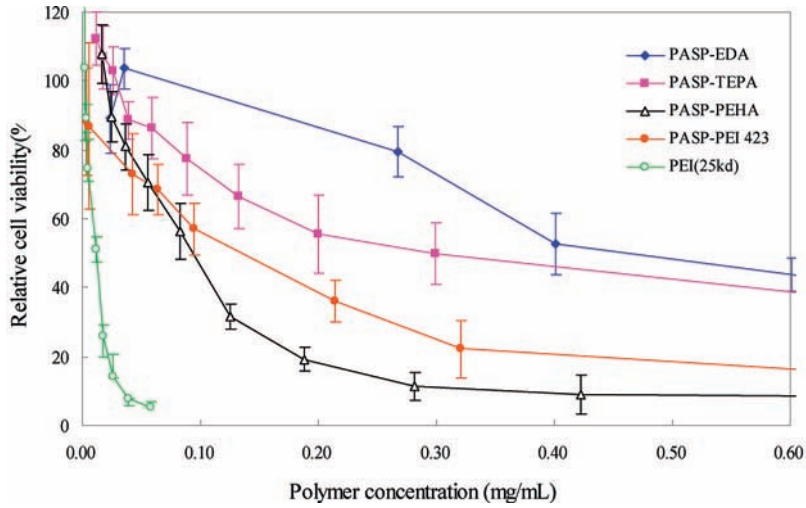

Figure 2. In vitro cytotoxicity of polyaspartamide-based oligo-ethylenimine brushes in HEK 293 cells ($n = 4$).

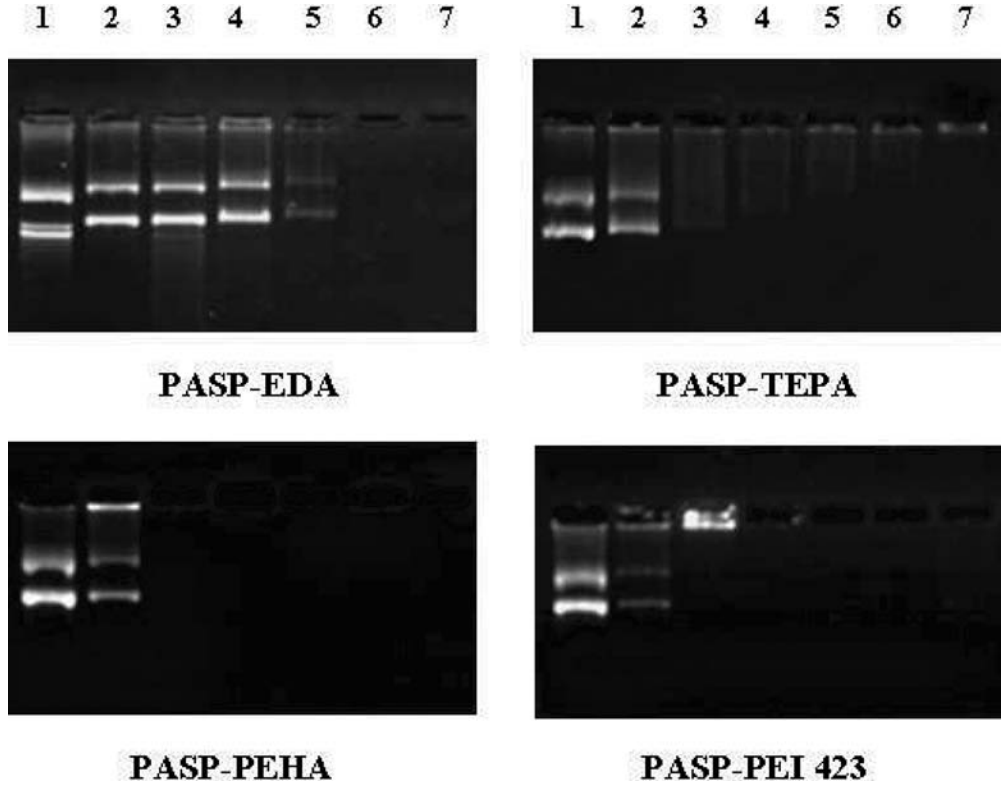

Figure 3. Agarose gel electrophoresis images of complexes formed from polyaspartamide-based oligo-ethylenimine brushes and plasmid DNA. Lane 1, naked DNA; lane 2−7, *N*/*P* ratios of 0.5/1, 1/1, 2/1, 5/1, 10/1, and 20/1, respectively.

mmol L^{-1} sodium chloride at calculated concentration to an equal volume of 150 mmol L^{-1} sodium chloride containing 1 μg of pRE Luc with gentle vortexing and allowed to incubate at room temperature for half an hour.

Agarose Gel Electrophoresis. Polycation/pRE Luc complexes at various *N*/*P* ratios, ranging from 0.5:1 up to 20:1 were separately electrophoresed on 0.8% (W/V) agarose gel containing of 0.1% gel red (V/V) for 80 min at 80 V. Then the gel was illuminated on a UV illuminator to show the mobility of the DNA. Naked DNA was used as reference.

Particle Size and Zeta Potential Measurement. The particle size and zeta potential of the freshly prepared polycation/pRE Luc complexes were measured using a Zetasizer (Nano ZS, Malvern Instruments Ltd., U.K.). The complexes were prepared as described above and directly used without further filtration before measurement.

In Vitro Transfection and Luciferase Assay. HEK 293 cells were seeded into a 24-well plate at a density of 5×10^4 cells/well and incubated in 1 mL of complete DMEM for 24 h prior to transfection. The medium was removed and washed gently with PBS (pH 7.4) when the cells were cultured to 40−50% confluency in the 24-well plate. Serum-free DMEM (1 mL) and 100 μL of 1 μg of DNA-containing polycation/pRE Luc complexes in saline were added into each well. After 4 h of incubation at 37 °C, the serum-free DMEM was replaced by 1 mL of complete DMEM. After 48 h of incubation at 37 °C, the medium was removed and washed with PBS7.4. Then, the cells were treated with 200 μL of reporter lysis buffer (Promega). The lysate was subjected to two cycles of freezing and thawing, and then centrifuged at 10000 rpm for 3 min. Ten microliters of supernatant was mixed with 100 μL of luciferase assay substrate (Promega). The light emission was measured using a

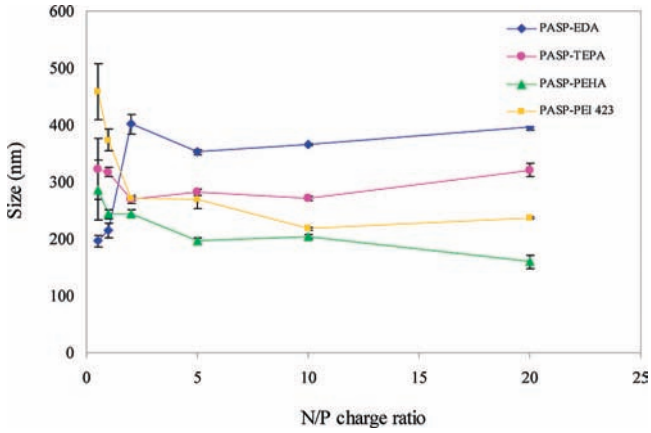

Figure 4. Average sizes of polyaspartamide-based oligo-ethylenimine brushes/DNA complexes prepared at *N*/*P* ratios ranging from 0.5 to 20 in 0.15 M NaCl.

Lumat 9507 luminometer (Berthold, Germany) for 10 s. The relative light units (RLU/mg protein) were normalized against the total protein concentration in the cell extracts, which was determined using a BCA assay kit (Pierce). All of the transfection tests were carried out in duplicate.

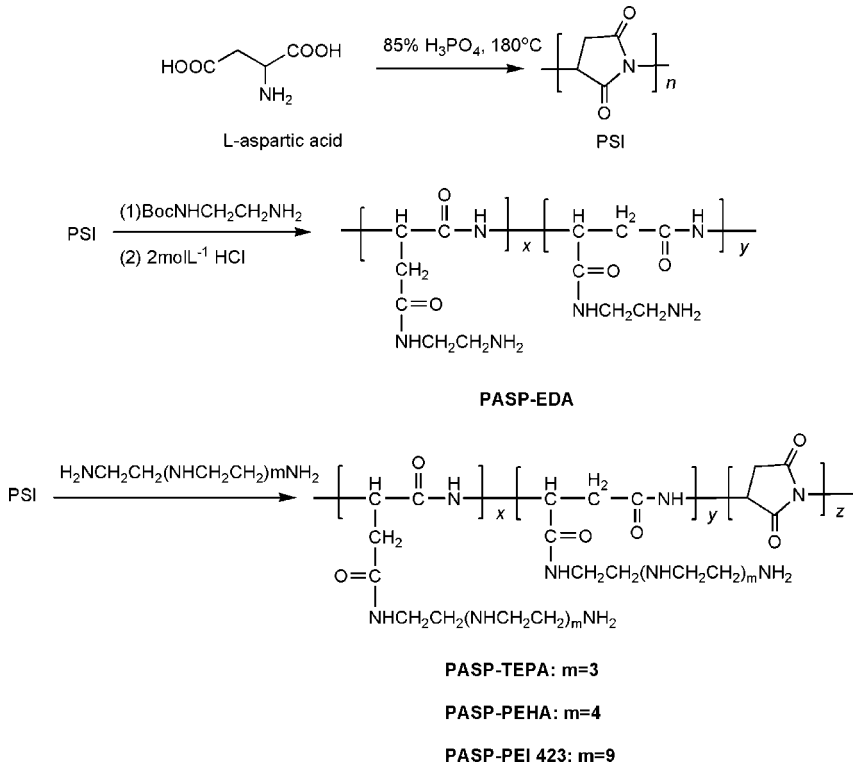
RESULTS AND DISCUSSION

Synthesis and Characterization of Cationic Polymer Brushes. Typically, cationic polyaspartamide derivatives (PASP-TEPA, PASP-PEHA, and PASP-PEI 423) were synthesized from poly-L-succinimide (PSI) by direct ring-opening reaction with oligo-ethlyenimine. However, only a small amount of low-molecular-weight PASP-EDA was obtained by direct ring-opening of PSI with ethlyenediamine. We used a two-step strategy to successfully synthesize PASP-EDA. First, PSI reacted with *N*-*t*-butyloxycarbonyl-ethlyenediamine, and then N-Boc was deprotected in diluted hydrochloride solution. The synthesis of cationic polyaspartamide derivatives is shown in Scheme 1. These cationic polyaspartamide derivatives, we named them oligo-PEI brushes, have polyaspartamide main chains and pendant aminoethyl or oligo-ethylenimine.

The reaction temperature should be strictly controlled at 0 °C for the first 4 h to avoid cross-linking of polyaspartamide. Because there are several amino groups in tetraethylenepentamine, pentaethylenehexamine, and linear PEI 423, the reaction would be very complicated. Either primary amines or secondary amines in polyamine could attract the ring of PSI. The lower temperature was helpful for yielding the polyamide with well-defined structures. The four polyaspartamide deravatives were purified by dialysis against distilled water (molecular weight cut off 3500) and lyophilization. The substituted degrees of PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423, calculated by ^{1}HNMR integral, were 100%, 62%, 56%, and 35%, respectively. The results indicated that the substituted degrees of pendant groups decreased with increasing lengths of oligo-ethylenimine. The partial grafting of polyaspartamide may have resulted from steric hindrance and/or electrostatic repulsion. The four polyaspartamide-based oligo-PEI brushes were characterized with FT-IR and ^{1}HNMR. Polymers were analyzed by size exclusion chromatography combined with multiangle laser light scattering, using PBS (0.1 mol L^{-1}, pH 7.4) as eluent. The weight average molecular weights (M_w) of PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423 were 1.78×10^4, 0.98×10^4, 1.09×10^4, and 1.45×10^4, respectively. We can find that the polymerization degrees of PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423 are lower than that of PSI, which means that the cleavage of the main chain of PSI occurred in the process of ring-opening of PSI with amine. The four polymers are all soluble in water and various buffers at pH 3−10 because of the introduction of hydrophilic amino groups into the polymer side chains.

Buffer Capacity of Cationic Polymers. It has been widely accepted that high buffer capacity of PEI facilitates osmotic swelling and rupture of endosomes by proton sponge effect, which results in the release of polycation/DNA complexes into the cytoplasm and improves the transfection efficiency. We

Scheme 1. Synthesis of Polyaspartamide-Based Oligo-ethylenimine Brushes



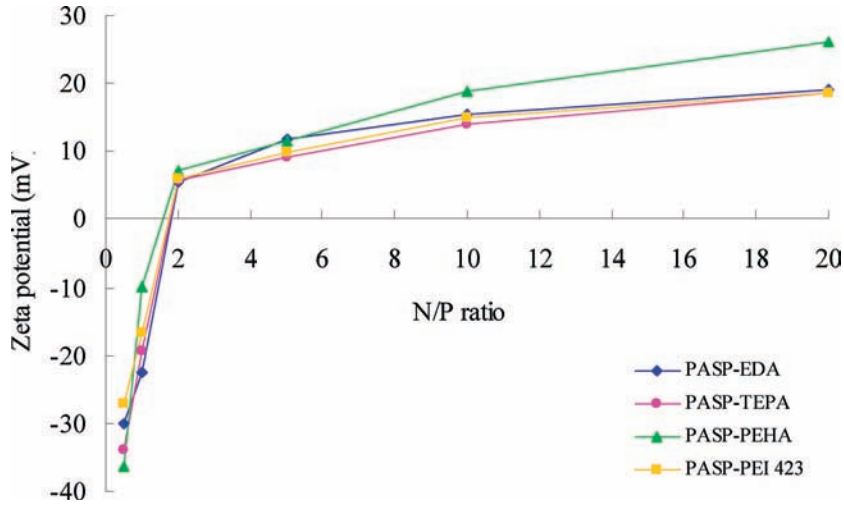


Figure 5. Zeta potential of polyaspartamide-based oligo-ethylenimine brushes/DNA complexes prepared at *N*/*P* ratios ranging from 0.5 to 20 in 0.15 M NaCl.

investigated the buffer capacity of the polycations by acid−base titration of the polymer solution (total amines of 5 mmol L^{-1}) in 0.15 M aqueous sodium chloride with 0.1 mol L^{-1} hydrochloride. Branched PEI (M_w = 25KDa) was also titrated under the same conditions as a control. As shown in Figure 1, the data indicated that there were no significant differences in the acid−base titration curves of the tested 5 polymers at pH ranging from 10 to 7, which means that they all have the same buffer capacity at these pH values. However, we found that the acid−base titration curves of PASP-TEPA and PASP-PEI 423 were still almost the same as that of PEI 25000 at pH from 7 to 5, which implied that the buffer capacities of PASP-TEPA and PASP-PEI 423 were equal to that of PEI 25000 at pH ranging from 7 to5. Meanwhile, PASP-PEHA exhibited relatively higher buffer capacity at pH ranging from 7 to 5 than that of PEI 25000. In contrast, PASP-EDA has very low buffer capacity at pH ranging from 7 to 5 in comparison to that of PASP-TEPA, PASP-PEHA, PASP-PEI 423, and PEI 25000.

Cytotoxicity of Cationic Polymers. The biocompatibility is an important factor for evaluating the application of polycations in nonviral gene delivery. The significant disadvantage of high-molecular-weight PEI as a gene carrier is that PEI shows high cytotoxicity to many types of cells. We used the MTT assay to measure the cytotoxicity of synthesized polycations to HEK 293 cells. Branched PEI (M_w = 25000) was used as a reference. The results, shown in Figure 2, indicated that PEI 25000 had high cytotoxicity to HEK 293 cells (LC50 ~10 μg mL^{-1}), which was in agreement with the results we observed previously (*12, 50*). Although the cell viability also decreased with increasing concentrations of the synthesized polycations in this work, the LC50 of PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423, in the range of 92−452 mg mL^{-1}, are generally 1 order of magnitude higher than that of PEI 25000. The results indicated that PASP-EDA, PASP-TEPA, PASP-PEHA, and PASP-PEI 423 were less toxic than PEI 25000, which confirmed our hypothesis that the graft of oligo-PEI to polyaspartamide partially maintains the low toxicity characteristic of oligo-PEI.

Agarose Gel Electrophoresis. The condensation of DNA into nanosized polyelectrolyte complexes is a prerequisite for polycations as nonviral gene carriers. The binding ability of the polycations to plasmid DNA was investigated by agarose gel electrophoresis. The complexes of polycation and pRE Luc at various amino groups of polycation/phosphate of DNA (*N*/*P* ratio), ranging from 0.5/1, 1/1, 2/1, 5/1, 10/1, and 20/1, were separately electrophoresed in agarose gel. Naked DNA was used as a reference. The migration of naked DNA and polycation/DNA complexes in agarose gel is shown in Figure 3. In the cases of PASP-TEPA, PASP-PEHA, and PASP-PEI 423, a fraction of plasmid DNA was free to migrate in the gel at an *N*/*P* ratio of 0.5:1; however, no migration bands of plasmid DNA were observed at *N*/*P* ratios of 1:1 or above. PASP-EDA could fully retard the migration of DNA in agarose gel at an *N*/*P* ratio higher than 5:1. The results indicated that the DNA binding ability of PASP-TEPA, PASP-PEHA, and PASP-PEI 423 is stronger than that of PASP-EDA.

Particle Size and Zeta Potential of Polycation/DNA Complexes. Small size and positive surface charge of polycation/DNA polyelectrolyte complexes are important for cell uptake and efficient transfection. Dynamic light scattering (DLS) measurement results in Figure 4 showed that small sized polycation/DNA complexes with diameters less than 400 nm were obtained by mixing the polymer solution and DNA solution in 150 mmol L^{-1} of sodium chloride at *N*/*P* ratios above 5:1. The diameters of polycations/DNA complexes are dependent on the structures of polycations. At *N*/*P* ratios of above 5:1, the diameters of PASP-EDA/pRE Luc, PASP-TEPA/pRE Luc, and PASP-PEI 423/pRE Luc were around 400, 300, and 250 nm, respectively. Different from these three polycations, PASP-PEHA condensed pRE Luc to from complexes with diameters less than 200 nm. The diameters of PASP-PEHA/pRE Luc decreased with increasing *N*/*P* ratios from 5:1 to 20:1.

The zeta potential data of polycation/DNA complexes in Figure 5 showed a trend that the zeta potentials of complexes increased with increasing *N*/*P* ratios of polycation amino groups to DNA phosphates. In the case of PASP-EDA, PASP-TEPA, and PASP-PEI 423, the zeta potentials of complexes reached 20 mV when *N*/*P* ratios were 20:1. The zeta potential of PASP-PEHA /pRE Luc was 26 mV when the *N*/*P* ratio was 20:1, which was also different from that of the above three polycations.

In Vitro Transfection of HEK 293 Cells. To evaluate the potential of the synthetic polycations as gene carriers, the tranfection experiments were conducted using polycation/pRE Luc, expressing luciferase, at *N*/*P* ratios of 5:1, 10:1, and 20:1 on the HEK 293 cell line. Naked DNA was used as a negative control and branched PEI 25000 at an optimized *N*/*P* ratio of 10:1 was used as a positive control. The results were shown in Figure 6. We can find that the transfection efficiencies of polycation/DNA complexes in HEK 293 cells are greatly dependent on the structures of polymer side chains. Very low luciferase expression in HEK 293 cells transfected with PASP-EDA/pRE Luc and PASP-TEPA/pRE Luc complexes was observed at various *N*/*P* ratios. The transfection efficiencies of

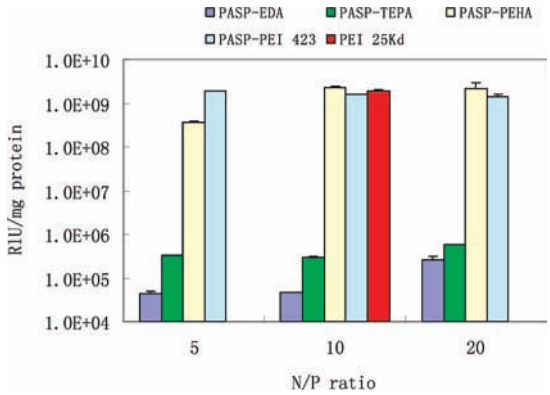

Figure 6. Transfection efficiencies of polyaspartamide-based oligo-ethylenimine brushes/pRE Luc complexes in HEK293 cells. Branched PEI (M_w 25000) was used as a control. Data represent the mean standard deviation ($n = 2$).

PASP-EDA/pRE Luc and PASP-TEPA/pRE Luc complexes in the HEK 293 cell line were almost as low as that of naked DNA. In the case of PASP-PEHA and PASP-PEI 423, the transfection results were interesting and significantly different from that of PASP-EDA and PASP-TEPA. The luciferase expression in HEK 293 cells with PASP-PEHA/pRE Luc and PASP-PEI 423/pRE Luc complexes at various *N*/*P* ratios was as high as that of branched PEI 25000 under optimized conditions (*N*/*P* ratio of 10:1), even a little higher than that of PEI. The high transfection efficiencies of PASP-PEHA/pRE Luc and PASP-PEI 423/pRE Luc in HEK 293 cells ascribe to the combination of high buffer capacity of PASP-PEHA and PASP-PEI 423 and relatively small particle size of PASP-PEHA/pRE Luc and PASP-PEI 423/pRE Luc. The results suggested that the length of oligo-ethylenimine side chains is an important factor for the high transfection efficiencies of polyaspartamide-based oligo-ethylenimine brushes, which provides useful experimental evidence for the design of novel cationic polymer gene carriers.

CONCLUSIONS

We have synthesized polyaspartamide-based oligo-ethylenimine brushes as novel promising nonviral gene delivery vectors. Their in vitro cytotoxicity was significantly lower than that of branched PEI 25000. The four synthetic polycations showed excellent DNA binding ability and condensed DNA to form small sized polyelectrolyte complexes with positive surface charge at higher *N*/*P* ratios. The transfection efficiencies increased with increasing the length of oligo-ethylenimine of polymer side chains. These results will provide some useful evidence for the design of novel highly efficient and less toxic cationic polymer gene delivery vectors.

Received July 15, 2008; Revised Manuscript Received January 12, 2009

Nine complexes of the type $[Ru(N-N)_2(BPG)]Cl_2$ **1**−**4**, $[Ru(N-N)(BPG)_2]Cl_2$ **5**−**8**, and $[Ru(BPG)_3]Cl_2$ **9** where N−N is 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), dipyrido[3,2-*d*:2′,3′-*f*]quinoxaline (dpq), dipyrido[3,2-*a*:2′,3′-*c*]phenazine (dppz), which incorporates bipyridine−glycoluril (BPG-4*b*,5,7,7*a*-tetrahydro-4*b*,7*a*-epiminomethanoimino-6*H*-imidazo[4,5-*f*][1,10]phenanthroline-6,13-dione) as the ancillary ligand, have been synthesized and characterized. These complexes with the peripheral polypyridyl ligands have the ability to form conjugates with DNA. The DNA binding (absorption spectroscopy, steady-state and time-resolved emission measurements, steady-state emission quenching measurements) and cleavage (under dark and irradiated conditions) by these complexes has been studied to investigate the influence of the ancillary ligand. The binding ability of these complexes to DNA is dependent on the planarity of the intercalative polypyridyl ligand, which is further affected by the ancillary bipyridine−glycoluril ligand. The complexes **3**, **4**, **7**, and **8** bind to CT-DNA with binding constants on the order of 10^4 M^{-1}. Time-resolved emission measurements on the DNA-bound complexes **1**, **3**, **5**−**7**, and **9** show monoexponential decay of the excited states, whereas complexes **2**, **4**, and **8** show biexponential decay with short- and long-lived components. Interaction of complexes **2**−**9** with plasmid *pBR322* DNA studied by gel electrophoresis experiments reveals that all complexes cleave DNA efficiently at micromolar concentrations under dark and anaerobic conditions probably by a hydrolytic mechanism. Complexes **3**, **4**, **7**, **8**, and $[Ru(bpy)_2(dppz)]^{2+}$ show extensive DNA cleavage in the presence of light with a shift in mobility of form I of DNA probably due to the high molecular weight of DNA−complex conjugates. However, the extent of the cleavage is augmented on irradiation in the case of complexes **3**, **4**, **7**, and **8**, which include the planar dpq and dppz ligands, suggesting a combination of hydrolytic and oxidative mechanism for the DNA scission. Molecular mechanics calculations of these systems corroborate the DNA binding and cleavage mechanisms.

INTRODUCTION

The interaction of transition metal complexes with DNA is a vibrant area of research (*1*−*4*). An advantage of using these complexes in such studies is that their ligands and metals can be conveniently varied to suit individual applications. Ruthenium(II) complexes with intercalating polypyridyl ligands have been extensively studied in this context, as their luminescence and photochemical reactivity are significantly altered on interaction with DNA (*1*−*11*). Ruthenium polypyridyl complexes are useful probes of DNA structure and DNA oxidation chemistry and in addition are used as sensors (*12*−*49*). Among them, $[Ru(bpy)_2(dppz)]^{2+}$ and $[Ru(phen)_2(dppz)]^{2+}$ are found to be high-affinity intercalators with interesting light switch behavior with potential applications in sensing and signaling, as well as in data storage and communication (*14*, *15*). The versatility of these complexes is modulated by the ligand set, which controls whether a complex is an intercalator, hemi-intercalator, or electrostatic binder (*12*−*49*). In general, ruthenium polypyridyl intercalators like $[Ru(bpy)_2(dppz)]^{2+}$ and $[Ru(phen)_2(dppz)]^{2+}$ have $K = 10^6-10^7$ M^{-1}, whereas electrostatic binders like $[Ru(bpy)_3]^{2+}$ have binding affinities on the order of 10^3 M^{-1}. The affinity of dppz intercalators for DNA can be further enhanced by increasing the surface area of the ancillary ligand (*45*).

Adding groups to the edges of the ruthenium polypyridyl complexes further expands the functionality of these complexes. For example, insertion of two polyamine tridentate arm-like segments in a macrochelating ligand in the complex $[Ru(DIP)_2(macro)]^{n+}$ enables binding of certain divalent metal cations so as to deliver its coordinated nucleophile to the phosphate backbone for hydrolysis of the anionic diester (*50*). In a previous study, we have explored the possibility of modifying reactivity by using the urea-fused bipyridine ligand (BPG) that contains hydrogen bond donor (N−H) and acceptor (C═O) groups. This ligand is capable of forming extensive H-bonding networks resulting in diverse frameworks encapsulating water/solvent molecules depending upon the number of bipyridine−glycoluril ligands (*51*−*53*). We have also demonstrated that the urea groups of the BPG ligand are involved in DNA binding and facilitate hydrolytic cleavage of DNA by the complex $[Ru(bpy)_2(BPG)]^{2+}$ **1** (*54*). Thus, the molecules that can hydrolyze the DNA phosphodiester at specific positions are valuable tools in biotechnology, thus facilitating DNA manipulation in a variety of applications.

To test whether the hydrolytic DNA cleavage mechanism is unique to a ruthenium polypyridyl complex containing a single BPG ligand, we synthesized the series of compounds containing one, two, or three BPG ligands. In complexes with one or two BPG ligands, the remaining ligands were varied to include

ligands that favor a particular binding mode (i.e., intercalation, electrostatic binding, etc.) to assess the influence of the BPG ligands on the binding mode and reactivity. If the reactivity and binding mode of these complexes is dominated by the BPG−DNA interactions, these complexes should cleave DNA via a hydrolytic mechanism, consistent with our previous work on $[Ru(bpy)_2(BPG)]^{2+}$ **1**. Here, we present data on the DNA binding and cleavage ability of these complexes probed by spectroscopic methods, gel electrophoresis, and molecular mechanics calculations.

EXPERIMENTAL SECTION

A. Materials. *1. General Details.* All reagents and solvents were purchased commercially and were used as received. $RuCl_3 \cdot xH_2O$ and $K_4[Fe(CN)_6]$ were obtained from S. D. Fine Chemicals Limited (India). Calf thymus DNA and plasmid *pBR322* DNA were purchased from SRL (India). The enzyme superoxide dismutase (SOD EC1.15.1.1) was purchased from Sigma Chemical Co. USA. Deionized water was used for the preparation of the buffers. Supercoiled *pBR322* DNA (CsCl) purified was obtained from Bangalore Genei (Bangalore, India) and used as received. The concentration of DNA in nucleotide phosphate (NP) was determined by UV absorbance at 260 nm using the molar absorption coefficient as 6600 M^{-1} cm^{-1}. Solutions of calf thymus DNA in phosphate buffer gave a ratio of UV absorbance at 260 and 280 nm, A_{260}/A_{280}, of 1.8−1.9:1, indicating that the DNA was sufficiently free of protein (*55*).

2. Syntheses. The ligands 1,10-phenenthroline-5,6-dione (phendione) (*56*), dipyrido[3,2-*d*:2′,3′-*f*]quinoxaline (dpq) (*57*), and dipyrido[3,2-*a*: 2′,3′-*c*]phenazine (dppz) (*58*) were synthesized according to the literature protocols. BPG [4*b*,5,7,7*a*-tetrahydro-4*b*,7*a*-epiminomethanoimino-6*H*-imidazo[4,5-*f*] [1,10] phenanthroline-6,13-dione] was prepared by modifying the literature method (*59, 60, 51*−*54*). The precursor complexes of the type *cis*-$[Ru(N-N)_2Cl_2]$ (*61, 62*), $[Ru(N-N)Cl_4]$ (*63*) were prepared by using the literature methods, and the synthesis of the complex $[Ru(bpy)_2(BPG)]Cl_2$ **1** (*51, 54*) was reported previously by us.

*3. Series I - Ru/BPG Ratio (1:1). [Ru(phen)$_2$(BPG)]Cl$_2$·4H$_2$O (**2**).* This complex was prepared by the method described for complex **1** (*51, 54*) using *cis*- $[Ru(phen)_2Cl_2] \cdot 2H_2O$ in place of *cis*-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$. The precursor complex *cis*-$[Ru(phen)_2Cl_2] \cdot 2H_2O$ (0.125 g, 0.21 mmol) and BPG (0.0608 g, 0.21 mmol) in a 1:1 molar ratio were dissolved in 50% methanol/50% water (50 mL), and the mixture was heated to reflux for 8 h, whereupon the color of the solution changed from dark purple to red. The red solution was filtered hot and was cooled to room temperature. After evaporation of the solvent, the red solid was collected and washed with small amounts of methanol and diethyl ether and then dried under vacuum. The product was purified by column chromatography on active alumina using acetone and methanol as eluent. The red fraction was collected and concentrated in vacuum, a small amount of diethyl ether was added to the concentrated solution, and a red solid was obtained.

Yield: (67%). Elemental analysis calcd for $RuC_{38}H_{34}N_{10}O_6Cl_2$ (898.35): C 50.76, H 3.81, N 15.59%. Found: C 49.80, H 3.71, N 14.90%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 8.92 (2H), 8.80 (2H), 8.51 (2H), 8.45 (4H), 8.41 (2H), 8.24 (2H), 8.03 (4H), 7.74 (4H), 7.57 (2H) ppm. IR (KBr): $\nu^{\sim}$ = 1708 cm^{-1} (C═O), 3215 cm^{-1} (N−H), 3421 cm^{-1} (O−H), 1647 cm^{-1} (C═N), 1427 cm^{-1} (C═C). UV−visible (H_2O), λ_{max}, nm (log ε): 441 (4.01), 263 (4.77), 223 (4.70). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF$_6$)]): +1.18.

Complexes $[Ru(dpq)_2(BPG)]Cl_2 \cdot 4H_2O$ (**3**) and $[Ru(dppz)_2(BPG)]Cl_2 \cdot 4H_2O$ (**4**) were prepared similarly to the method described for complex **1**, with *cis*-$[Ru(dpq)_2Cl_2] \cdot 2H_2O$ and *cis*-$[Ru(dppz)_2Cl_2] \cdot 2H_2O$ in place of *cis*-$[Ru(bpy)_2Cl_2] \cdot 2H_2O$. However, in the case of **4** the precursor complex *cis*-$[Ru(dppz)_2Cl_2] \cdot 2H_2O$ and BPG in a 1:1 molar ratio was refluxed in ethylene glycol (20 mL) for 12 h whereupon the color of the solution changed to red. The purification was also carried out by column chromatography on an active alumina column.

*[Ru(dpq)$_2$(BPG)]Cl$_2$·4H$_2$O (**3**).* Yield: (60%). Elemental analysis calcd for $RuC_{42}H_{34}N_{14}O_6Cl_2$ (1002.38): C 50.29, H 3.41, N 19.56%. Found: C 50.78, H 3.60, N 19.10%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 9.57 (d, 2H), 9.47 (d, 2H), 9.33 (s, 4H), 8.69 (s, 2H), 8.47 (s, 2H), 8.40 (d, 2H), 8.15 (m, 6H), 7.83 (dd, 2H), 7.75 (d, 2H), 7.49 (dd, 2H) ppm. IR (KBr): $\nu^{\sim}$ = 1703 cm^{-1} (C═O), 3217 cm^{-1} (N−H), 3413 cm^{-1} (O−H), 1645 cm^{-1} (C═N), 1448 cm^{-1} (C═C). UV−visible (H_2O), λ_{max}, nm (log ε): 452 (4.13), 296 (4.60), 256 (4.85), 205 (4.77). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF$_6$)]): +1.16.

*[Ru(dppz)$_2$(BPG)]Cl$_2$·4H$_2$O (**4**).* Yield: (25%). Elemental analysis calcd for $RuC_{50}H_{38}N_{14}O_6Cl_2$ (1102.42): C 56.06, H 3.57, N 18.32%. Found: C 55.99, H 3.87, N 17.98%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 8.85 (m, 8H), 8.45 (s, 4H), 8.12 (m, 5H), 8.02 (d, 4H), 7.82 (m, 9H) ppm. IR (KBr): $\nu^{\sim}$ = 1705 cm^{-1} (C═O), 2923 cm^{-1} (N−H), 3336 cm^{-1} (O−H), 1602 cm^{-1} (C═N), 1407 cm^{-1} (C═C). UV−visible (H_2O), λ_{max}, nm (log ε): 443 (4.05), 371 (4.03), 263 (4.83), 224 (4.68). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF$_6$)]): +1.24.

*4. Series II - Ru/BPG Ratio (1:2). [Ru(bpy)(BPG)$_2$]Cl$_2$·4H$_2$O (**5**).* The precursor complex $[Ru(bpy)Cl_4]$ (0.100 g, 0.190 mmol) and BPG (0.112 g, 0.381 mmol) in a 1:2 molar ratio were refluxed in 50% methanol/50% water (50 mL) for 8 h, whereupon the color of the solution changed from dark green to red. The red solution was filtered hot and was cooled to room temperature. After evaporation of the solvent, the brownish red solid was collected and washed with small amounts of methanol and diethyl ether and then dried under vacuum. The product was purified by column chromatography on active alumina using acetone and methanol as eluent. The red fraction was collected and concentrated in vacuum, a small amount of diethyl ether was added to the concentrated solution and red solid was obtained.

Yield: (65%). Elemental analysis calcd for $RuC_{38}H_{36}N_{14}O_8Cl_2$ (988.38): C 46.13, H 3.67, N 19.84%. Found: C 46.70, H 3.70, N 19.20%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 8.82 (1H), 8.63 (2H), 8.51(3H), 8.38 (2H), 7.79 (12H), 7.60 (8H). IR (KBr, cm^{-1}): $\nu^{\sim}$ = C═O (1709), N−H (3207, 3411), C═N (1616), C═C (1454). UV−visible (H_2O), λ_{max}, nm (log ε): 460 (4.07), 301.5 (4.48), 287.5 (4.53), 255 (4.29), 232.5 (4.47), 204.5 (4.74). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF$_6$)]): + 1.18. Complexes $[Ru(phen)(BPG)_2]Cl_2 \cdot 4.4H_2O$ (**6**), $[Ru(dpq)(BPG)_2]Cl_2 \cdot 3H_2O$ (**7**), and $[Ru(dppz)(BPG)_2]Cl_2 \cdot 2CH_3OH$ (**8**) were prepared similarly to the method described for **5**, with the precursor complexes $[Ru(phen)Cl_4]$, $[Ru(dpq)Cl_4]$, and $[Ru(dppz)Cl_4]$ in place of $[Ru(bpy)Cl_4]$. The purification was also carried out by column chromatography on an active alumina column. Single crystals were grown by slow evaporation of the methanol−water solution.

*[Ru(phen)(BPG)$_2$]Cl$_2$·4.4H$_2$O (**6**).* Yield: (70%). Calcd for $RuC_{40}H_{36.8}N_{14}O_{8.4}Cl_2$ (1019.59): C 47.08, H 3.64, N 19.23%. Found: C 47.63, H 3.83, N 19.63%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 8.57(m, 6H), 8.33(s, 8H), 8.17(s, 2H), 8.05 (d, 2H), 7.97 (d, 3H), 7.70 (m, 3H), 7.54 (d, 2H), 7.27 (d, 2H). IR (KBr, cm^{-1}): $\nu^{\sim}$ = C═O (1703), N−H (3207, 3408), C═N (1616), C═C (1452). UV−visible (H_2O), λ_{max}, nm (log ε): 457 (4.11), 375.5 (3.87), 301 (4.43), 262.5 (4.72), 224 (4.70), 205 (4.84). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF$_6$)]): +1.17.

*[Ru(dpq)(BPG)$_2$]Cl$_2$·3H$_2$O (**7**).* Yield: (63%). Calcd for $RuC_{42}H_{36}N_{16}O_8Cl_2$ (1046.39): C 48.16, H 3.27, N 21.41%. Found: C 47.86, H 3.90, N 21.70%. ^{1}H NMR (300 MHz,

DMSO-d_6, 25 °C): δ = 9.43 (dd, 2H), 9.14 (dd, 2H), 8.85 (s, 6H), 8.34 (m, 3H), 8.22 (m, 6H), 8.19 (dd, 2H), 7.91 (dd, 2H), 7.88 (m, 4H), 7.41 (dd, 1H). IR(KBr, cm^{-1}) $\nu^{\sim}$ = C═O (1699), N−H (3091, 3178), C═N (1614), C═C (1450). *5. Series III - Ru/BPG Ratio (1:3). [Ru(BPG)$_3$]Cl$_2$·4H$_2$O (**9**).* This complex was prepared by the reaction of $RuCl_3 \cdot xH_2O$ (0.100 g, 0.444 mmol) and BPG (0.392 g, 1.331 mmol) in a 1:3 molar ratio in 1:1 methanol/water at reflux for 12 h whereupon the color of the solution changed to red. The resulting red solution was cooled to room temperature and filtered. After evaporation of the solvent, the complex was collected and washed with water and diethyl ether. The product was purified by column chromatography on active alumina using methanol and water as eluent. The red fraction was collected.

Yield: (75%). Elemental analysis calcd. for $RuC_{42}H_{38}N_{18}O_{10}Cl_2$ (1126.43): C 44.71, H 3.39, N 22.36%. Found: C 43.80, H 3.09, N 22.63%. ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): δ = 8.79 (s, 6H), 8.50 (s, 6H), 8.28 (d, 6H), 7.79 (d, 6H), 7.75 (d, 6H) ppm. ^{1}H NMR (300 MHz, D_2O, 25 °C): δ = 8.15 (d, 6H), 7.90 (d, 6H), 7.57 (d, 6H) ppm. UV−visible (H_2O), λ_{max}, nm (log ε): 456 (4.10), 304 (4.48), 262 (4.29), 231 (4.52). $E_{1/2}$ (V vs Ag/AgCl in DMF 25 °C, 0.1 M [([Bu^t]$_4$ NPF_6)]): +1.14.

B. Methods. *1. Spectroscopy.* The microanalyses (C, H, and N) were carried out with a Perkin-Elmer 240 Q elemental analyzer at NCL, Pune. UV−vis spectra were recorded on a Shimadzu UV-1601 spectrophotometer. ^{1}H NMR spectra were measured on a Varian-Mercury 300 MHz spectrometer with (d_6) DMSO as a solvent at room temperature, and all chemical shifts are given relative to TMS. The infrared spectra of solid samples dispersed in KBr were recorded on a Shimadzu FTIR-8400 spectrophotometer. Electrochemical experiments with Ru(II) polypyridyl complexes in DMF solution were performed on a CH-660A (USA) electrochemical instrument in a conventional three-electrode cell assembly with a saturated Ag/AgCl reference electrode, platinum as working electrode for all measurements. Electrochemical measurements were performed using dimethylformamide as solvent and 0.1 M tetrabutylammonium hexafluorophosphate ([Bu^t]$_4$$NPF_6$) as supporting electrolyte. Steady-state emission titrations were carried out on a Shimadzu RF-5301 spectrofluorometer at room temperature. The emission lifetimes were measured with a time-correlated-single-photon-counting spectrometer from IBH, UK, using 455 nm nanosecond light-emitting diode (NanoLed-01) for the excitation of the samples.

2. DNA Binding and Cleavage Studies. a. Absorption Spectral Studies. For electronic absorption titration, a stock 10 μM solution of the complex was made up in a phosphate buffer (pH 7.2); 3000 μL of the solution was loaded into an optical glass cuvette with a path length of 1 cm, and 200 μL was removed with a micropipette and replaced with 200 μL of the complex solution. This cuvette was then loaded into the spectrometer sample block, controlled at 25 °C; 3000 μL of the buffer was loaded to an identical cuvette and placed in the reference cell. Both the cuvettes were mixed 30 times with a micropipette, and all bubbles were removed. After the cuvettes had been allowed to reach equilibrium over the course of 20 min, a spectrum was recorded between 700 and 200 nm. One to 55 mL of CT-DNA was added to both cuvettes and mixed 30 times. The spectrum was recorded after checking for bubbles and showed a drop in absorptivity showing interaction between the DNA and the metal complex. The intrinsic binding constant of the complex with CT-DNA was determined from eq 1 (*64, 65*) where [DNA] is the concentration of DNA in base pairs.

$$[DNA]/[\varepsilon_a - \varepsilon_f] = [DNA]/[\varepsilon_b - \varepsilon_f] + 1/K_b[\varepsilon_b - \varepsilon_f] \quad (1)$$

The apparent absorption coefficients ε_a, ε_f, and ε_b correspond to A_{obsd}/[Ru], the extinction coefficient for the free complex and the extinction coefficient for the complex in the fully bound form, respectively. The slope and the intercept of the linear fit of [DNA]/[ε_a − ε_f] versus [DNA] plot give 1/[ε_a − ε_f] and 1/K_b[ε_b − ε_f], respectively. The intrinsic binding constant K_b can be obtained from the ratio of the slope to the intercept (*64*).

b. Viscosity Measurements. Viscosity experiments were carried out using a semimicro viscometer maintained at 28 °C in a thermostatic water bath. Flow time of solutions in phosphate buffer (pH 7.2) was recorded in triplicate for each sample, and an average flow time was calculated. Data were presented as $(\eta/\eta^0)^{1/3}$ versus binding ratio, where η is the viscosity of DNA in the presence of complex and η^0 is the viscosity of DNA alone (*65*).

c. Thermal Denaturation Study. DNA melting studies were carried out with a JASCO V-630 spectrophotometer equipped with a Peltier temperature-controlling programmer ETC-717 (±0.1 °C) in phosphate buffer. The DNA melting studies were done by controlling the temperature of the sample cell with a water-circulating bath. UV melting profiles were obtained by scanning A_{260} absorbance was monitored at a heating rate of 1 °C/min for solutions of CT-DNA (100 μM) in the absence and presence of ruthenium(II) complexes (20 μM) from 30 to 90 °C. The data were analyzed with the use of separate thermal melting program; the temperature of the cell containing the cuvette was ramped from 50 to 90 °C. The melting temperature T_m which is defined as the temperature where half of the total base pairs are unbound was determined from the midpoint of the melting curves.

d. Steady-State and Time-Resolved Luminescence Spectral Studies. For calculating emission quantum yields, the optical densities of the samples were adjusted to about 0.3 at the excitation wavelength. Emission quantum yields (ϕ) were calculated by integrating the area under the fluorescence curves and by using the formula (*66*)

$$\varphi_{Sample} = \{OD_{Standard}/OD_{Sample}\} \times \{A_{Sample}/A_{Standard}\} \times \varphi_{Standard} \quad (2)$$

where OD is optical density of the compound at the excitation wavelength (450 nm) and A is the area under the emission spectral curve. The standard used for the fluorescence quantum yield measurements was [Ru(bpy)$_3$]Cl$_2$ (*67*). The rate constant, k_0, includes both radiative k_r and nonradiative k_{nr} contributions to the rate of the ^{3}MLCT excited-state decay. Radiative (k_r) and nonradiative (k_{nr}) decay rate constants were determined using the values of τ and ϕ_r (radiative quantum yield) estimated at room temperature (*66*).

The excitation and emission slit widths employed were 5 nm each. Emission titration experiments were performed by using a fixed metal complex concentration to which increments of the stock DNA solutions were added. Typical concentration of metal complex used was 0.025 mM and [DNA]/[Ru] ratio is in the range 0−30. After the addition of DNA to metal complex,

the resulting solution was allowed to equilibrate for 20−30 min at room temperature before being excited in their intense metal to ligand charge-transfer band between 400 and 500 nm.

Steady-state quenching experiments were conducted by adding 75−750 μL aliquots of a 4 mM ferrocyanide stock solution to 3 mL sample solutions containing 0.8 mM nucleic acid concentration and 0.02 mM Ru(II) complex concentration in phosphate buffer. All solutions were allowed to equilibrate thermally for ∼15 min before measurements were made. The Stern-Volmer quenching constant is calculated according to the classical Stern-Volmer equation (*66, 68*)

$$I_0/I = 1 + K_{SV}[Q] \quad (3)$$

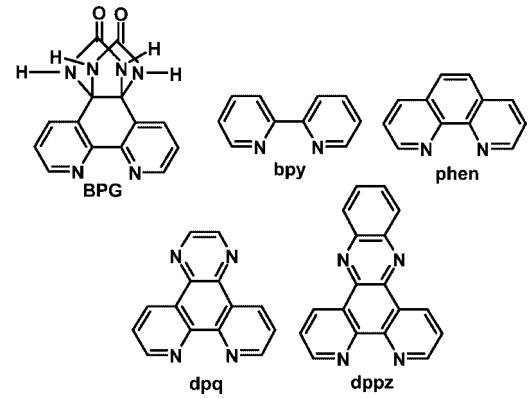
where I_0 and I are the fluorescence intensities of the complex in the absence and presence of $[Fe(CN)_6]^{4-}$, and K_{sv} is the Stern-Volmer quenching constant, which is a measure of the efficiency of fluorescence quenching by $[Fe(CN)_6]^{4-}$.

For time-resolved single photon counting measurements, the samples were excited in their intense metal to ligand charge-transfer band between 400 and 500 nm. Emission was detected in the wavelength range 590−630 nm depending on the sample, using a photomultiplier tube based detection module (model TBX-04 from IBH). The instrument response function for the present setup is ∼1.2 ns (fwhm). The decay curves were analyzed by reconvolution procedure (*69*), using DAS-6 software, obtained from IBH, considering a suitable functional form (mono- or biexponential) of the decays. The quality of the fits were judged by the reduced chi-square (χ^2) values and the distribution of the weighted residuals among the data channels (*69*). For good fits, the χ^2 values were close to unity and the weighted residuals were distributed randomly among the data channels (*69*).

e. DNA Cleavage. The DNA cleavage was carried out by agarose gel electrophoresis as described previously (*54, 70, 71*). A 10 μL total sample volume in 0.5 mL transparent Eppendorf microtubes containing *pBR322* DNA (90 μM in base pairs). For the gel electrophoresis experiments, plasmid *pBR322* DNA was treated with the metal complex (20 μM) and the mixture was incubated in the dark for 2 and 18 h at 37 °C for the dark experiments. The samples were analyzed by 1% agarose gel electrophoresis (Tris-Boric acid-EDTA (TBE) buffer, (pH 8.2) for 2 h at 60 mV. The gel was stained with a 0.5 μg/mL ethidium bromide and visualized by UV light and photographed for analysis. The extent of cleavage of the plasmid *pBR322* DNA was determined by measuring the intensities of the bands using the Alpha Innotech Gel documentation system (AlphaImager 2200). Irradiation experiments were carried out under illuminated conditions using a UV lamp of 365 nm. In irradiation experiments, *pBR322* DNA (90 μM in base pairs) was treated with 20 μM samples of the metal complexes, and the mixtures were incubated for 30 min in the dark followed by 20 min irradiation at 365 nm. For mechanistic investigations, experiments were carried out under irradiated conditions in the presence of radical scavenging agents DMSO, mannitol, DABCO, NaN_3, L-histidine, and SOD, which were added to the plasmid *pBR322* DNA prior to the addition of the complexes.

f. Dialysis Experiments. A typical dialysis experiment was carried out as follows. Three milliliters solution of the ruthenium(II) complexes **1**−**9** ([Ru] = 20 μM) in the presence of CT-DNA ([DNA] = 200 μM) under dark conditions in phosphate buffer (pH 7.2) solution was transferred to the dialysis tubing (molecular weight cutoff 12 000, 14 000) and dialysed with gentle stirring against buffer solution in the dark, with three changes of buffer over a 24 h period. Changes in the absorption spectrum of complexes **1**−**9** in the presence of calf thymus DNA with dialysis (24 h) compared with the dialyzed samples and undialyzed samples were monitored by UV−vis spectroscopy.

Scheme 1. Structure of BPG and Various Polypyridyl Ligands Used in the Present Study



g. Molecular Modeling. Molecular modeling studies were performed on a Silicon Graphics Octane workstation using the software Insight II 2000 (*72*) with the Discover 3 module. Initial models of right-handed B-DNA of sequence $d(C:G)_{12}$ were constructed using the Biopolymer module of Insight II. The coordinates for the metal complex $[Ru(bpy)_2(BPG)]^{2+}$ and derivatives were taken from its crystal structure as a CIF file and were converted to the PDB format using Mercury software (*73*). The all atom extensible systematic force field (ESFF) was used for the entire modeling study. The $[Ru(bpy)_2(BPG)]^{2+}$ and derivative-bound DNA was then soaked in a water box of dimensions 35.0 × 50.0 × 35.0, and periodic boundary conditions were applied. A dielectric constant of 1.0 for electrostatic energy and a cutoff of 9.5 A were used for both the Coulomb as well as van der Waals energies. The nonbonded electrostatic terms were calculated using the Ewald summation method (*74*). The accuracy of convergence for the Ewald Coulomb energy summation was kept to 0.0001 kcal/mol. The system was minimized using the steepest descent gradient algorithm for 1000 steps, followed by the conjugate gradient algorithm for 1000 steps or until the maximum derivative was below 0.1 kcal/mol/A. The Ewald summation method that expands the simple sum of the Coulomb's law terms into several sums including a direct, reciprocal term was used to calculate the long-range electrostatics. As the Ewald sum method is valid for a neutral system, B−DNA−Ru(II) polypyridyl complex, the Ewald summation method calculates charges by homogeneous charge density distribution. The initial 1000 steps of steepest descent minimization were performed to relax the initial strain on the molecule.

RESULTS AND DISCUSSION

A. Syntheses and Properties. The urea fused bipyridine ligand bipyridine−glycoluril (BPG) (Scheme 1) and a series of nine new ruthenium(II) polypyridyl complexes of the type $[Ru(N-N)_2(BPG)]Cl_2$ **1**−**4**, $[Ru(N-N)(BPG)_2]Cl_2$ **5**−**8**, and $[Ru(BPG)_3]Cl_2$ **9** were synthesized and obtained in a racemic form by the reactions of precursor complexes *cis*-$[Ru(N-N)_2Cl_2]$, $[Ru(N-N)Cl_4]$, and $RuCl_3 \cdot xH_2O$ by varying the number of BPG (Scheme 2). Crystal structures of BPG ligand and its complexes **1**, **6**, and **9** have been reported elsewhere (*51, 52*).

The electronic absorption spectra of complexes **1**−**9** are dominated by two sets of transitions (i) low-energy metal-to-ligand charge transfer (MLCT) transitions in the range 440−460 nm and (ii) high-energy ligand-centered $\pi-\pi^*$ transitions (IL) in the range 200−380 nm for all complexes which are similar to the parent $[Ru(bpy)_3]^{2+}$ and other Ru(II) polypyridyl complexes (*75, 76*). The peaks at 371 and 360 nm in compounds **4** and **8** are characteristic of the $\pi-\pi^*$ transition of the dppz

ligand. The synthesized ruthenium(II) complexes **1**−**7** and **9** emit in phosphate buffer at room temperature with maximum between 590 and 640 nm. The emission quantum yields for **1**−**7** and **9** are calculated by using eq 2 and summarized in Table 1. The radiative rate constants for complexes **1**−**7** and **9** are on the order of 10^4-10^5 and nonradiative rate constants are on the order of 10^6 (Table 1) that are in the range expected for Ru(II) polypyridyl emitters (*75, 76*). No detectable luminescence is observed for complex **8** in buffer solution. Single exponential decays are observed for **1**−**7** and **9** in buffer solutions, and the results are tabulated in Table 1.

DNA Binding Studies. *Absorption Spectroscopy Studies.* Absorption spectral titrations are the most common method to investigate the interactions of metal complexes with DNA. Binding of the complexes to DNA through intercalation results in hypochromism and red shift of the bands due to noncovalent stacking of the planar aromatic chromophore between the base pairs of DNA (*77*−*82*). Changes in the electronic absorption spectra of complexes **1**−**9** were measured as a function of DNA concentration, and the titration curves for **3**, **4**, **7**, and **8** are shown in Figure 1. There was insignificant change in the absorption profile of complexes **1**, **5**, **6**, and **9** on sequential addition of DNA, indicating an electrostatic binding similar to that of $[Ru(bpy)_3]^{2+}$ (*3, 78*−*82*), as the nonplanar bpy and urea moiety of BPG precludes intercalation. The binding constants estimated using eq 1 for complexes **2**, **3**, **4**, **7**, and **8** are $(3.86 \pm 0.2) \times 10^3$, $(3.14 \pm 0.1) \times 10^4$, $(6.19 \pm 0.1) \times 10^4$, $(2.87 \pm 0.2) \times 10^4$, and $(9.14 \pm 0.2) \times 10^4$, respectively (Table 2). The absorption spectra of **3** on addition of DNA shows 5.1% hypochromism in the MLCT band at the [DNA]/[Ru] ratio of 8, whereas complex **4** shows 9.6% and 19.5% hypochromicity in both MLCT and IL bands, respectively, at the same [DNA]/[Ru] ratio. The extent of hypochromism and red shift is more in **4** than **3**, indicating strong binding of this complex to CT-DNA. A comparison of the binding constants of **3** and **4** with strong intercalators such as $[Ru(phen)_2dppz]^{2+}$ reveals a weak binding due to hindrance to the intercalation by the second planar dppz and the nonplanar BPG ancillary ligand. For the complex **7**, the hypochromism in the MLCT and IL bands are 3.0% and 5.1% at the same [DNA]/[Ru] ratio. However, for complex **8**, the absorption spectra on addition of DNA shows pronounced hypochromism in both MLCT and IL bands of about 12.3% and 31.0%, respectively, at the ratio of [DNA]/[Ru] of 8. The extent of hypochromism and red shift is particularly pronounced in the interligand absorption band (∼360 nm) for **8** and is typical for stacking interaction of the dppz ligand with the DNA base pairs. These spectral characteristics suggest that complexes **7** and **8** interact with DNA through a mode that involves a stacking interaction of the planar aromatic chromophore and the base pairs of DNA, but with a moderate binding constant as compared to classical intercalators ($[Ru(phen)_2(dppz)]^{2+}$, $K_b = 5.1 \times 10^6$ M^{-1}) probably due to the influence of ancillary BPG ligand. Similar results have been observed for the $[Ru(NH_3)_4(dppz)]^{2+}$, $K_b = 1.8 \times 10^5$ M^{-1} (see Table 2 for comparative data on dppz complexes) for which the NH_3 ligand which has the potential for hydrogen bonding is found to be detrimental for DNA binding (*46*). In the present series, the ancillary ligand bipyridine−glycoluril has the potential for hydrogen bonding interactions with the phosphates or bases of DNA, resulting in lowering the binding constant value as compared to classical intercalators.

Viscosity and Thermal Denaturation Studies. Viscosity measurements, which are sensitive to length change, are regarded as most critical tests for binding mode and were studied in order to assess the binding mode of these complexes with DNA. Changes in relative viscosity provide a reliable method for distinguishing between intercalators and electrostatic binders of DNA. Intercalation of a ligand into DNA is known to cause a significant increase in the viscosity of a DNA solution due to an increase in the separation of the base pairs at the intercalation site and, hence, an increase in the overall DNA molecular length. In contrast, a ligand that binds in the DNA grooves causes a less pronounced change (positive or negative) or no change in the viscosity of a DNA solution. The changes in the relative viscosity of solutions containing DNA upon addition of increasing concentrations of **1**−**9** are shown in Supporting Information Figures S1 and S2. The maximum increase in viscosity of DNA on increasing the [Ru]/[DNA] ratio for complexes **3**, **4**, **7**, and **8** suggest an intercalative binding mode, while a minute/negligible increase in viscosity for the complexes **1** and **2** indicate an electrostatic binding. The incorporation of non-intercalating BPG ligands with bulky peripheral urea groups are expected to influence the efficacy of the intercalative ligand. A similar effect was observed in the case of $[Ru(bpyMe_2)_2(dpq)]^{2+}$ where the orientation of the peripheral $bpyMe_2$ ligands results in partial intercalation of the classical intercalator dpq (*12*). Addition of complexes **5**, **6**, and **9** has no effect on the DNA viscosity, suggesting an electrostatic binding similarly observed previously for $[Ru(bpy)_3]^{2+}$ (*78, 87*). The viscosity data taken together with the hypochromism observed in the absorption data upon addition of DNA are in accord with the fact that the peripheral urea groups influence the ability of the intercalative ligand.

The thermal behavior of the DNA in the presence of complexes would offer some information about the interaction

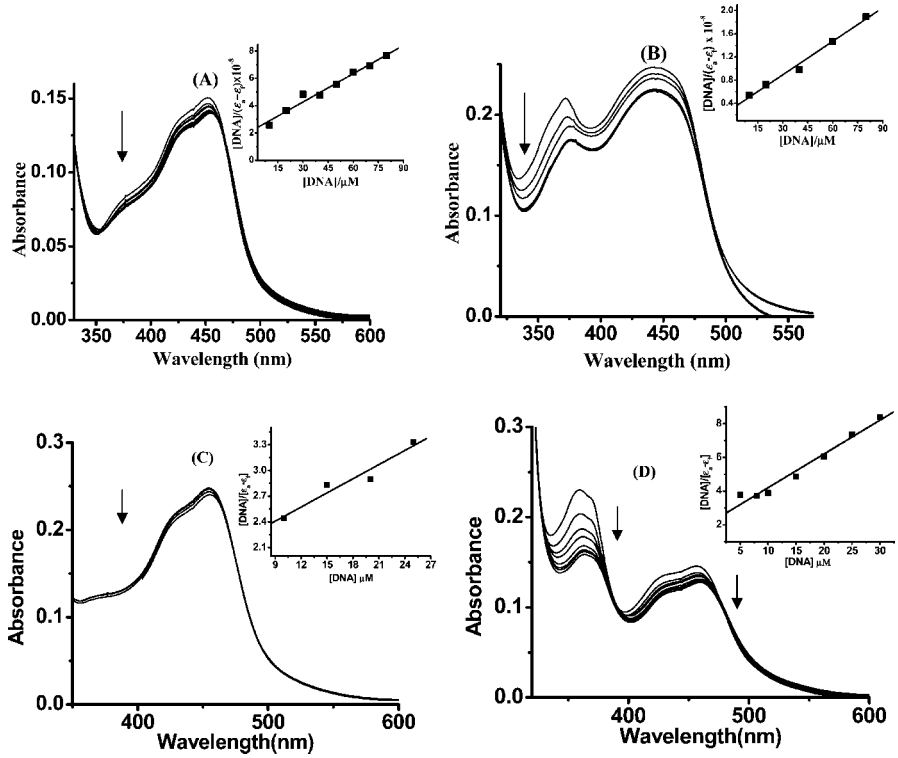

Figure 1. Changes in the electronic absorption spectra of (A) **3** (10 μM), (B) **4** (10 μM), (C)**7** (10 μM), and (D) **8** (10 μM) with increasing the concentrations (0−100 μM) of CT-DNA (phosphate buffer pH 7.2); the inset graph shows a fit of the absorbance data used to obtain the binding constant.

affinities of these complexes with DNA and characterizes the transition from double-stranded to single-stranded DNA. The extinction coefficient of DNA bases at 260 nm in the double helical form is much less than in the single-stranded form; hence, melting of the helix leads to an increase in the absorption at this wavelength. Thus, the melting temperature (T_m) of DNA, which can characterize the transition from double-stranded to single-stranded form of DNA, is usually determined (*43*, *49*). Thermal denaturation Figures S3 and S4 in the Supporting Information and the data for DNA in the presence and absence of ruthenium(II) complexes **1**−**9** investigated in this study are summarized in Table 3. Thermal denaturation experiments carried out on CT-DNA in the absence of added complex revealed that the T_m value for the duplex is 63° ± 1°. It is clear from the data given in the Table 3 that the complexes containing the non-intercalative/partial intercalative ligands shift the T_m values only by up to 2° compared to that of the pure DNA sample. However, the complexes containing the intercalative ligands dpq/dppz shift the T_m values by up to 4° compared to that of the pure DNA sample. This increase in the helix melting temperature indicates the increased stability of the double helix when these compounds **3**, **4**, **7**, and **8** bind to DNA. However, the increase in the melting temperature is relatively lower than the classical intercalators, suggesting that the dpq/dppz complexes bind with DNA through a mode that involves a stacking interaction of the planar aromatic chromophore and the base pairs of DNA, but with a moderate binding, probably due to the influence of ancillary BPG ligand, thus lowering the T_m values for these complexes.

Steady-State Emission Studies. The changes in the emission spectra of Ru(II) polypyridyl complexes in the presence of DNA are a diagnostic means to determine DNA binding (*19, 76*). The emission spectra of complexes **1**−**9** have been measured in the absence and in the presence of CT-DNA (Supporting Information Figures S5 and S6). The dependence of relative emission intensities as a function of DNA concentration in buffered solution at pH 7.2 is shown in Figure 2 (in terms of [DNA]/[Ru]). The spectra profiles and emission maxima for the complexes **1**−**3**, **5**−**7**, and **9** exhibit weak luminescence

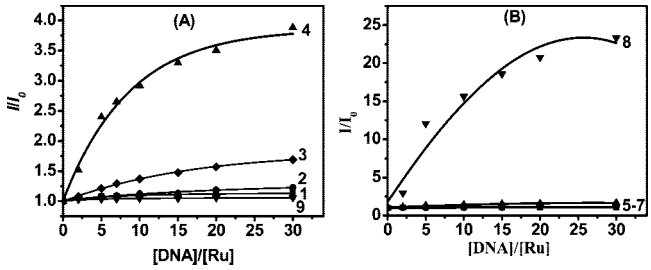

Figure 2. Plots of relative integrated emission intensity versus [DNA]/[Ru] for the complexes: (A) Complexes (■) **1**, (●) **2**, (◆) **3**, (▲) **4**, and (▼) **9** (24 μM). (B) Complexes (●) **5**, (■) **6**, (▲) **7**, (▼) **8** (24 μM) in phosphate buffer, pH 7.2 at 298 K with increasing [DNA]/[Ru] ratio from 0−30.

enhancements in the range 1−1.7 after adding CT-DNA at a ratio of [DNA]/[Ru] = 30 indicating a weak binding of these complexes with CT-DNA by partial intercalation or electrostatic association (Table 3). However, complex **4** exhibits luminescence enhancement of 3.7 indicating strong binding by intercalation of this complex with CT-DNA. On the other hand, complex **8** is nonluminescent in aqueous solution but emits intensely in the presence of CT-DNA. In this case, observed emission enhancement was ascribed to the protection of the phenazine nitrogen atoms of DNA-intercalated excited-state complex from accessibility by water molecules. The fluorescence intensity is observed to vary with the [DNA]/[Ru] ratio. The remarkable sensitivity is observed for complex **8** in the presence of CT-DNA ($R = 0-30$) with the relative emission intensity enhancement of a factor 23.31, much higher than that for the other complexes (Figure S6 in the Supporting Information) that supports the stacking interaction of the planar aromatic dppz ligand into the DNA base pairs, which is consistent with other spectroscopic studies.

Steady-State Emission Quenching Experiment Using $K_4[Fe(CN)_6]$. The fluorescence intensities of the ruthenium polypyridyl complexes, upon visible excitation, are enhanced on binding to DNA (*83*−*85*). Quenching of this luminescent excited state with the use of an anionic quencher such as $[Fe(CN)_6]^{4-}$ has been shown to be able to distinguish bound ruthenium(II) species (*86*). A highly negatively charged quencher is expected to be repelled by the negatively charged phosphate backbone, and therefore, a DNA-bound cationic molecule should be protected from quenching while free complexes should be readily quenched. The results of steady-state emission quenching experiments using $[Fe(CN)_6]^{4-}$ as the quencher are shown in Figures S7 and S8 in the Supporting Information. The results are interpreted in terms of two binding modes: electrostatic, which is easily quenched by ferrocyanide; and intercalative, which is protected from ferrocyanide quenching. Stern-Volmer quenching constants for complexes **1**−**7** and **9** in the absence and presence of DNA are shown in Table 3. In the absence of DNA, complexes **1**−**7** and **9** are efficiently quenched by $[Fe(CN)_6]^{4-}$ with the Stern-Volmer quenching constants on the order of $1.02-3.32 \times 10^3$. The nonlinear nature of the graph for complex **2** indicates that two differential binding modes, viz., partial intercalation and surface binding, may be possible. Barton et al. interpreted the curved Stern-Volmer plots obtained with the anionic quencher $[Fe(CN)_6]^{4-}$ as having two binding modes, one intercalative and one groove-bound, with Δ preferring the former and Λ the latter mode in the case of $[Ru(phen)_3]^{2+}$ (*87*, *88*). However, in the presence of DNA, the maximum decrease in the Stern-Volmer quenching constant is obtained for the complexes **3**, **4**, **7**, and **8**. For these complexes, the Stern-Volmer plot is a straight line, implying that the luminescent complex is homogeneous. The linear nature with negligible difference in the Stern-Volmer quenching constants for complexes **1**, **5**−**6**, and **9** indicates a single component donor−quencher system with electrostatic binding similar to that for $[Ru(bpy)_3]^{2+}$.

Time-Resolved Emission Measurements in the Presence of DNA. The above-mentioned trends in DNA binding are further corroborated by time-correlated single photon counting fluorescence measurements. In the absence of DNA, all the complexes strictly exhibit monoexponential emission decay. Table S1 in the Supporting Information summarizes the luminescence lifetime of the complexes **1**−**9** in the presence of CT-DNA for a ratio [DNA]/[Ru] of 2−30. Complexes **1**, **5**, and **9** show monoexponential decay with negligible change in τ_o value, indicating an electrostatic interaction of these complexes with DNA. Complex **3**, **6**, and **7** also exhibits monoexponential decay; however, the lifetime increases from 330 to 432 ns for **3**, 386 to 404 ns for **6**, and 357 to 426 ns for **7** exhibits monoexponential decay, indicating intercalative/partial intercalative binding mode with DNA. The luminescent characteristics of the complexes **2** and **4** bound to DNA shows biexponential decay in emission indicating the presence of two distinguishable DNA binding modes for the complexes. Two binding modes were proposed for the complex **2**; one may be partial intercalation, while the other is groove-bound interaction or electrostatic interaction in which the excited-state lifetime is comparable to that of the free form. When the binding ratio [DNA]/[Ru] is varied from 2:1 to 30:1 for the complex **4**, the excited-state lifetimes increased from 207 ns to 290 ns for short-lifetime component and from 677 to 1679 ns for long-lifetime component and for the complex **2** from 183 to 334 ns for short-lifetime component and from 329 to 761 ns for long-lifetime component. The steady-state quenching experiments and time-resolved emission measurements on complex **4** suggest that both lifetime components could be assigned to partial intercalative binding depending on the orientations of the two dppz ligands in the complex. The results also are consistent with intercalation and electrostatic binding being the two binding modes. This complex contains the sterically demanding bipyridine glycoluril ancillary ligand, and the other planar dppz ligand, which increases hydrophobicity (*17*). The presence of multiple binding modes for osmium and ruthenium polypyridyl complexes has been suggested recently on the basis of DNA film voltammetry (*21*). The luminescent characteristics of the complex **8** bound to DNA show biexponential decay in emission indicating the presence of two distinguishable DNA binding modes. When the binding ratio [DNA]/[Ru] varied from 2:1 to 30:1 for the complex **8**, the excited-state lifetimes increased up to 125 ns for short-lifetime component and from 346 to 611 ns for long-lifetime component. The lifetimes obtained for long-lived species of complex **8** are higher than the others, confirming its stronger intercalative DNA binding, and does not differ from the excited-state lifetimes in the presence of DNA for $[Ru(phen)_2dppz]^{2+}$ (*10*, *11*, *17*−*21*) indicating that the intercalated dppz ligand is well-protected from solvent.

Preliminary DNA Cleavage Studies under Dark and Light Conditions. Majority of ruthenium−polypyridyl complexes noncovalently bind to DNA by different modes, viz., electrostatic, surface binding, or intercalation, and initiate DNA cleavage reactions on photoirradiation either by electron transfer to base forming covalent photoadducts or by energy transfer to molecular oxygen generating $^1O_2$ or rarely by a hydrolytic mechanism (*50*, *54*, *89*−*95*). We have recently reported the hydrolytic cleavage of plasmid *pBR322* DNA by $[Ru(bpy)_2(BPG)]^{2+}$ **1** in an enzyme-like manner and detailed the kinetic aspects of DNA cleavage by **1** under pseudo and true Michaelis−Menten conditions (*54*). Therefore, in the present study the potential of complexes **2**−**9** to cleave DNA under

dark and light conditions was studied by gel electrophoresis using plasmid *pBR322* DNA.

When incubated for 2 h at 37 °C under dark conditions, it is observed that micromolar concentration of complexes **2**−**4** and **9** shows 22−40% (Figure 3A) and **5**−**8** shows 28−60% (Figure 4A) DNA cleavage as evidenced by the disappearance of form I (supercoiled form) of the plasmid and the appearance of the form II (nicked circular form). A band migration of the supercoiled form of DNA relative to the control lane is observed for complexes **2**−**4** (Figure 3A; lanes 4−6) and for complexes **7** and **8** (Figure 4A; lanes 6 and 7). An increase in DNA cleavage is observed for **2**−**9** after incubation for 2 h in argon atmosphere (Figures S9 and S10A in the Supporting Information) implying an oxygen-independent cleavage mechanism under dark conditions. Extensive DNA cleavage is observed for complexes **2**−**9** in dark conditions when incubated for 18 h at 37 °C (Figures S9B and S10B in the Supporting Information) indicating a hydrolytic mechanism, which suggests that these complexes are oriented in such a way so as to facilitate intramolecular H-bonding with the phosphate group or with the nucleobases. Under similar conditions $[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_2(dppz)]^{2+}$, which binds to DNA by electrostatic binding and intercalation, respectively, and are not capable of H-bonding, cleave DNA to a lesser extent after 2 h incubation as compared to complexes **2**−**9**. Here, we have observed DNA cleavage under dark conditions by ruthenium polypyridyl complexes containing one, two, and three BPG ligands without any bound water molecule, but with the pheripheral urea moiety of the ancillary bipyridyl glycoluril ligand hydrolyzes the phosphodiester bond efficiently.

The rate of RNA hydrolysis is enhanced 3300-fold by monometallic Zn(II) complexes of terpyridine-based ligands with ammonium and guanidinium groups capable of H-bonding to the phosphodiester group compared to the parent complex without the functional H-bonding groups (*96*). A similar effect of enhancing the phosphodiester cleavage was observed by a Zn(II) complex with three aminopyridyl hydrogen bond donors, which orient the complex and the substrate for efficient proximity interactions (*97*−*99*). A series of organometallic ruthenium and *cis*-platin like ethylenediamine based complexes also exploit these H-bonding interactions to direct DNA binding by the NH_2 groups of the metal-bound ethylenediamine ligand favoring H-bonding interactions with nucleobases resulting in site-selectivity (*100*−*102*).

Rhodium(III) intercalators attached to peptide moieties $[Rh(phi)_2(bpy'\text{-peptide})]$ (phi = intercalative ligands), macrocyclic complexes of lanthanides, polyamine derivatives such as cyclen, trpn, and tamen complexes of cobalt(III) can act as catalysts for the hydrolysis of the phosphate esters of DNA and ammonium-functionalized copper(II) complexes and copper(II) complexes of macrocycles, *cis*,*cis*-1,3,5-triaminocyclohexane and neamine have been reported (*103*−*105*). Of those, however, the most highly efficient hydrolytic cleavage agents are mononuclear copper(II) complexes in which a copper-bound hydroxyl group is the active species in the hydrolysis of the nucleic acid phosphate backbone. As far as we are aware, the only other hydrolytic cleavage of DNA by the ruthenium−polypyridyl complex was reported by Barton et al. for the $[Ru(DIP)_2(macro)]^{2+}$, where $Ru(DIP)_2$ binds to DNA via intercalation and macro is a chelating ligand with two polyamine tridentate arm-like segments which bind certain divalent metal cations so as to deliver its coordinated nucleophile to the phosphate backbone for the hydrolysis of the anionic diester (*50*).

Photocleavage of DNA by ruthenium(II) polypyridyl complexes on irradiation is well-documented in the literature (*89*−*95*). Therefore, the photocleavage of plasmid *pBR322* DNA in the presence of complexes **2**−**9** on irradiation at 365 nm was carried out, and the results are shown in Figure 3B and Figure 4B. The complexes **2** and **9** show only 3−12% increase in conversion of form I (SC) of DNA to form II (NC) of DNA, and the complexes **5** and **6** show only 6−7% increase in conversion of form I (SC) of DNA to form II (NC) of DNA as compared to DNA cleavage under dark conditions. The fact that the observed photocleavage for complexes **2**, **5**, **6**, and **9** in air is significantly lower than what is observed for $[Ru(bpy)_3]^{2+}$ possibly indicates lower levels of $^1O_2$ generation. The complexes **3**, **4**, **7**, and **8** and $[Ru(bpy)_2(dppz)]^{2+}$ shows extensive DNA cleavage in the

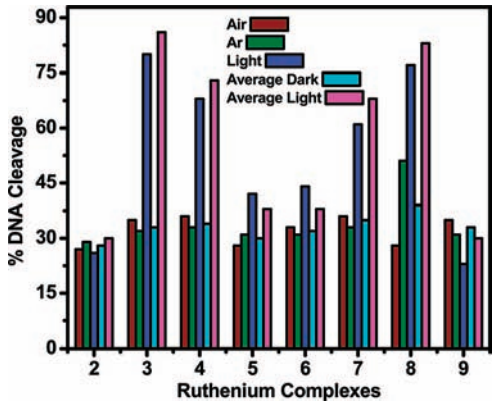

Figure 5. DNA cleavage efficiency of ruthenium(II) complexes containing one, two, and three BPG ligands **2**−**9** in the dark and light conditions.

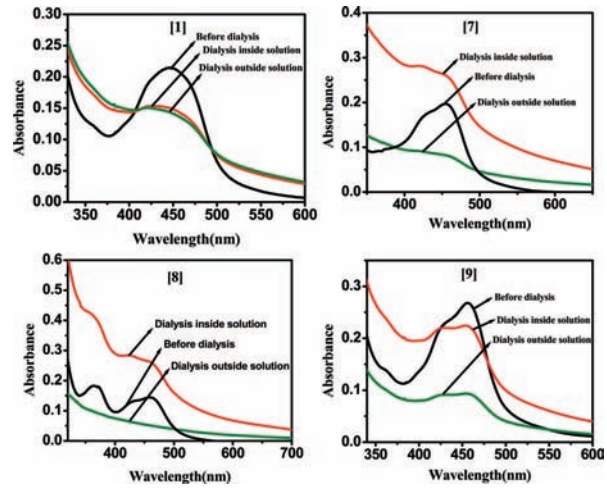

Figure 6. Changes in the absorption spectras of complexes **1** and **7**−**9** in the presence of calf thymus DNA under dark conditions with dialysis (24 h) compared with the dialyzed samples and undialyzed samples in phosphate buffer pH 7.2 solutions. ([Ru] = 20 μM, [DNA] = 200 μM).

presence of light with a shift in mobility of form I of DNA probably due to the high molecular weight of DNA−complex conjugates.

In order to investigate the role of radicals in the DNA damage by these complexes **2**−**9**, reactions were performed under aerobic conditions by incubating the complexes for half an hour and irradiation for 20 min with DNA in the presence of hydroxyl radical scavengers (DMSO and mannitol), singlet oxygen scavengers (NaN_3, histidine, and DABCO) and superoxide scavenger (superoxide dismutase, SOD) (Figures S11−S18, Tables S2−S9 in the Supporting Information). It is observed that the photocleavage by complexes **2** and **9** was not inhibited by reactive oxygen species scavengers indicating hydrolytic pathway for these complexes. However, complexes **5** and **6** show small amounts of inhibition in the presence of reactive oxygen species indicating hydrolytic mechanism. Complexes **3**, **4**, **7**, and **8** containing dpq and dppz intercalating ligands show extensive DNA cleavage in the presence of light, and the photocleavage experiments in the presence of different radical scavengers show inhibition indicating that hydroxyl radicals and singlet oxygen are responsible for DNA cleavage by these complexes upon irradiation. From the above results, it appears that the mechanism of DNA cleavage photoinduced by complexes **3**, **4**, **7**, and **8** involve either singlet oxygen or hydroxyl radicals. However, the photocleavage by these complexes is higher than $[Ru(bpy)_2(dppz)]^{2+}$ complex implying that complexes **3**, **4**, **7**, and **8** with an inherent intercalating ability cleave DNA by a combination of oxidative and hydrolytic cleavage. The cleavage data for all complexes **2**−**9** under dark conditions in the presence and absence of air and under light conditions are tabulated in Table S10 in the Supporting Information and depicted as a histogram in Figure 5.

DNA−Complex Conjugate Investigation by UV−vis Spectroscopy: In order to further investigate the formation of the DNA−complex conjugates, dialysis experiments followed by UV−vis spectroscopy were performed on the ruthenium(II) bipyridine−glycoluril complexes in the presence of CT-DNA under dark conditions in phosphate buffer (pH 7.2). If the complex is covalently bound to the DNA, then this can be verified by dialysis of the samples where the parent metal complex, but not the DNA, would pass through the dialysis membrane (*106, 107*). The formation of the product is monitored by UV−vis spectroscopy, and the results are given in Figure 6 and Figure S19 in the Supporting Information. Figure 6 shows the spectrum of the complexes **1**, **7**, **8**, and **9** kept in the dark for 24 h in the presence of CT-DNA, both before and after dialysis. With complexes **1** and **9**, the large decrease in absorption is observed showing that most of the product is diffused through the dialysis membrane as would be expected for the complexes which are not bound strongly to the CT-DNA. However, the absorption spectrum of the dialyzed samples **2**−**8** in the presence of DNA reveals that the complex remains bound to DNA inside the membrane (Figure 6 and Figure S19 in the Supporting Information). The complexes **2**−**8** after dialysis in the presence of CT-DNA show large increases in absorption in the 345−500 nm region suggesting that these complexes are strongly bound to the CT-DNA and the conjugate formed is retained after dialysis. The UV−vis spectroscopic observations together with the electrophoresis results presented earlier suggests that the DNA−complex conjugates are formed with CT-DNA. A hyperchromic effect and mobility shift in electrophoresis experiments were reported previously for the complexes of the type $[Ru(bpy)_{3-n}(TAP/HAT)_n]^{2+}$ (n = 2, 3), which result in the formation of adducts on irradiation (*106, 107*).

Molecular Modeling. Molecular mechanics calculations have been carried out for complexes **1**−**9** with the models of right-handed B-DNA of sequence $d(C:G)_{12}$. Different modes of binding with different orientations of ruthenium complexes, including groove binding through major/minor groove, and intercalation through major and minor groove, were attempted with the model of right-handed B-DNA of sequence $d(C:G)_{12}$. It was observed that the minimized structure maintains the octahedral form of the complexes and shows the H-bonding to the bases and phosphates of DNA without disrupting the helical structure of B-DNA. The H-bonding distances for **1**−**9** after minimizations are summarized in Table S11 in the Supporting Information. All complexes are stabilized by H-bonding interactions between the DNA and the complexes. It is found that **1** and **2** orients in the minor and major groove, respectively, with hydrogen bonding interactions of the N−H and C−H groups preferably to O1P and O10P phosphate oxygen atoms of DNA for **1** and preferably to O2P phosphate oxygen atom in case of **2** (Figure 7 and Figure S18 in the Supporting Information), while for **9** in the major groove with the H- bonding between the N−H and C═O groups of the bipyridine−glycoluril ligand and the N7 of the guanine. (Figure S24 in the Supporting Information). Such N−H···O H-bonding interactions between one ethylenediamine NH proton and the guanine O6 oxygen have been shown by Sadler and co-workers in the case of organomatallic ruthenium(II) arene complexes of the type $[(\eta^6\text{-arene})Ru^{II}(en)Cl](PF_6)$ (en = ethylenediamine, arene = biphenyl, 5,8,9,10-tetrahydroanthracene, and 9,10-dihydroanthracene) specifically target guanine bases of DNA oligomers (*102*). It is found that

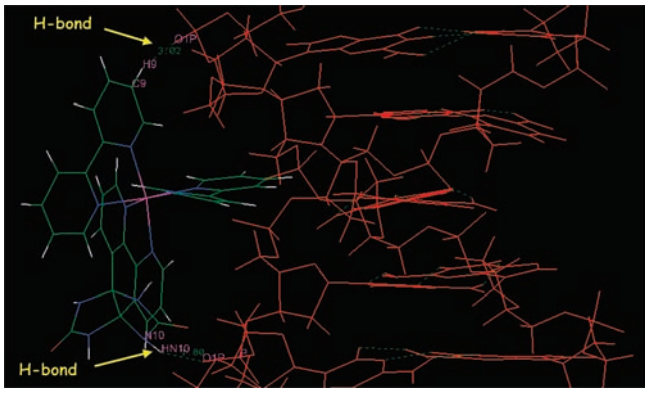

Figure 7. The core view of the bound **1** to DNA with the H-bond patterns observed showing phosphate interactions.

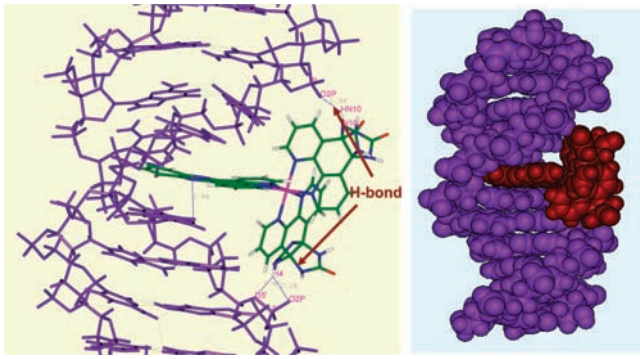

Figure 8. The core view of the bound **8** to DNA showing the intercalation of the dppz ligand between the base pairs of DNA along with the H-bonding interactions of the two BPG ligands with the phosphate groups of DNA.

the binding of **5** and **6** in the major groove with H-bonding interactions of the N−H groups preferably to O2P phosphate oxygen atoms of DNA (Figure S21 and Figure S22 in the Supporting Information). In the complexes **1**, **2**, and **9**, the urea groups exclusively bind with phosphate oxygens of the nucleic acids. Recently, Farrell et al. have reported a phosphate backbone binding mode for a polynuclear platinum(II) complex that has planar arrays of hydrogen bond donors, leading to association with the DNA backbone (*108*). For complexes **3** and **4**, the molecular modeling reveals that the planar dpq and dppz ligands interact with the bases and the other planar ligand with the phosphate oxygens. (Figure S19 and S20 in the Supporting Information). However, the complexes **7** and **8** containing planar aromatic dpq and dppz ligands and with the two ancillary bipyridine−glycoluril ligands show the intercalative binding mode in which the stacking interaction of the planar dpq (Figure S23 in the Supporting Information) and dppz ligand between the base pairs of DNA through major groove side take place along with the phosphate interactions of the N−H groups of the two ancillary bipyridine-glycoluril ligands preferably to O2P oxygen atoms (Figure 8), Such H-bonding suggests that the bipyridine−glycoluril ligand is located in a specific position of the H-bond to the neighboring oxygen atoms of the bases or a phosphate group and thus influences the binding ability of these complexes with DNA.

CONCLUDING REMARKS

In summary, in the present study we have synthesized a series of new Ru(II) polypyridyl complexes containing urea fused bipyridine−glycoluril ligand and characterized by various physical methods. By the incorporation of the simple modification on the ancillary ligand of bipyridine, different DNA binding behaviors for complexes **1**−**9** were observed. The planar aromatic ligands have the potential for intercalation, and the bipyridine−glycoluril ligand with inherent H-bond donor and acceptor groups are accessible for H-bonding with the phosphate groups or with the nucleobases of DNA. The DNA binding and photocleavage measurements revealed that the complexes that favor electrostatic binding mode cleave DNA by hydrolytic mechanism while those that contain intercalating ligands form conjugates with and then cleave DNA by a combination of oxidative and hydrolytic mechanism.

List of Contents:

Figure S1 and S2: Changes in the relative specific viscosity of solutions **1-9** in the presence of CT-DNA.

Figure S3 and S4: Melting curves of CT-DNA in the absence and presence of complexes **1-9.**

Figure S5 and S6: Emission spectra of Ru(II) complexes **1-9** (25 μM) in phosphate buffer with increasing [DNA]/[Ru] ratio from 0-30.

Figure S7 and S8: Emission spectra of Ru(II) complexes **1-9** using anionic quencher $K_4[Fe(CN)_6]$ in the presence and absence of DNA in phosphate buffer.

Table S1: Luminescence decay lifetime of the complexes **1-9** in the presence of CT-DNA.

Figure S9 and S10: DNA cleavage experiment in the presence of 20 μM Ru(II) complexes **2-9**; dark experiments incubation for 2 h in argon atmosphere and dark experiments incubation for 18 h in air.

Figure S11-S18 and Table S2-S9: DNA cleavage experiment in the presence of different radical scavengers for Ru(II) complexes **2-9.**

Table S10: DNA cleavage efficiency of ruthenium(II) complexes containing one, two and three BPG ligands **2-9** in the dark and light conditions.

Figure S19: Changes in the absorption spectra of complexes **2-6** in the presence of DNA before and after dialysis.

Figure S20-S26: The core view of the bound **2-7 and 9** to DNA.

Table S11: Binding energies in Kcal/mol and hydrogen bond information of Ru(II) polypyridyl complexes **1-9** with right handed B-DNA of sequence $d(C:G)_{12}$.

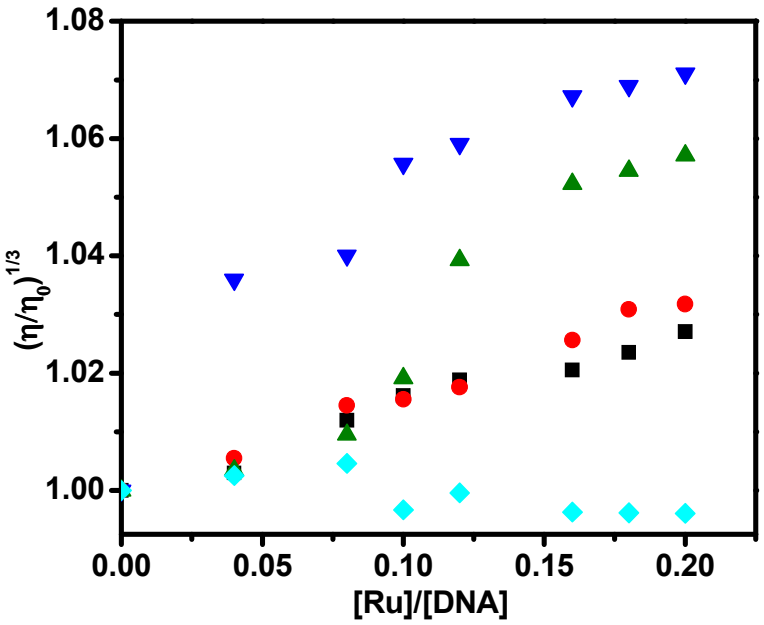

Figure S1. Changes in the relative viscosity of solutions containing 200 μM CT-DNA (Phosphate buffer, pH 7.2) as a function of concentration of (■) **1**, (●) **2**, (▲) **3**, (▼) **4**, (♦) **9;** ([Ru]/[DNA] = 0.02-0.20).

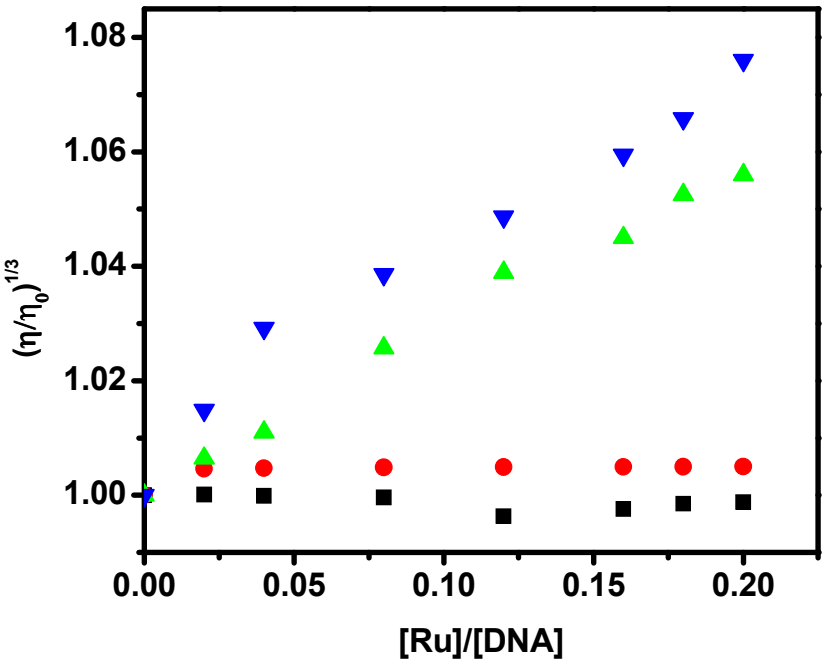

Figure S2. Changes in the relative viscosity of solutions containing 200 μM CT-DNA (Phosphate buffer, pH 7.2) as a function of concentration of (■) **5**, (●) **6**, (▲) **7**, (▼) **8;** ([Ru]/[DNA] = 0.02-0.20).

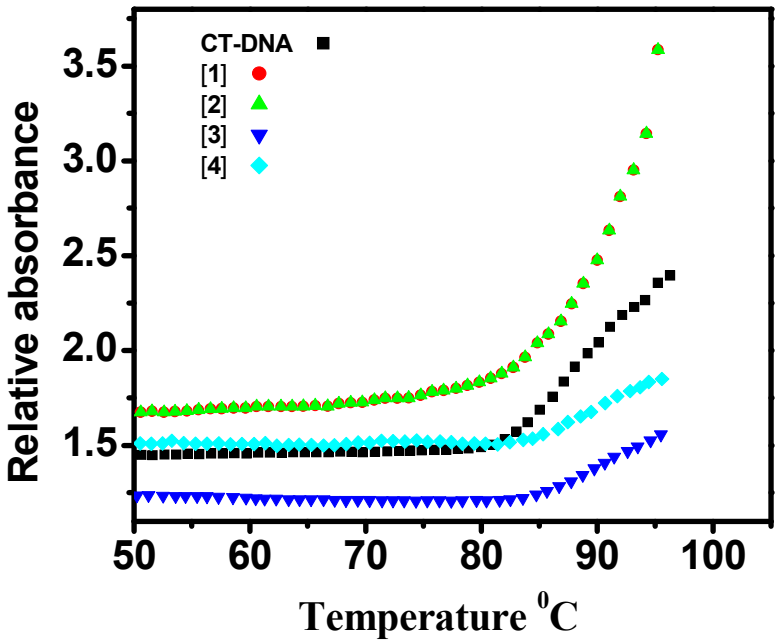

Figure S3. Melting curves of CT-DNA (200 μM) alone (■), DNA + [**1**] (•), DNA + [**2**] (▲), DNA + [**3**] (▼), DNA + [**4**] (♦). ([Ru] = 20 μM, [DNA] = 200 μM).

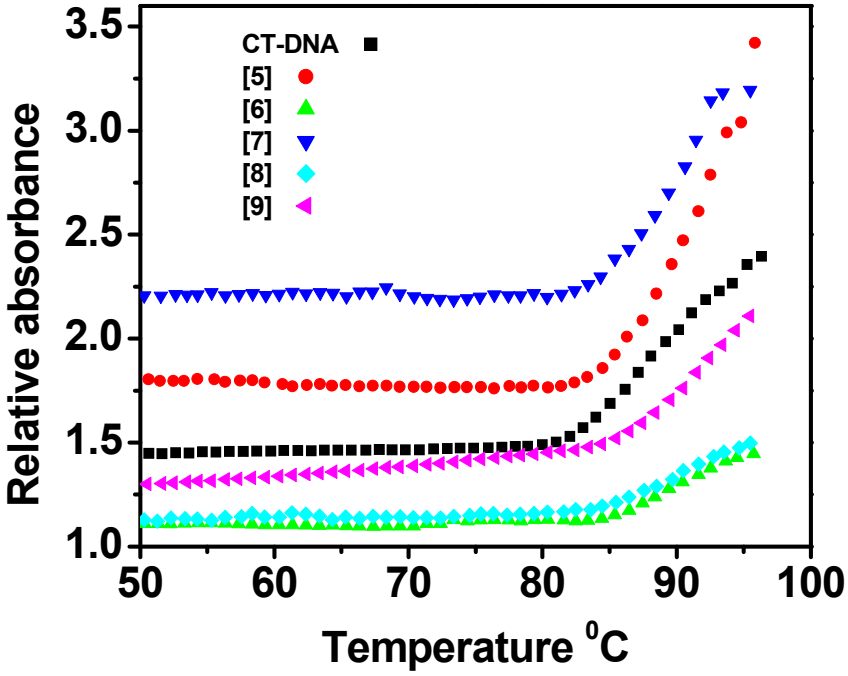

Figure S4. Melting curves of CT-DNA (200 μM) alone (■), DNA + [**5**] (•), DNA + [**6**] (▲), DNA + [**7**] (▼), DNA + [**8**] (♦), DNA + [**9**] (◄). ([Ru] = 20 μM, [DNA] = 200 μM).

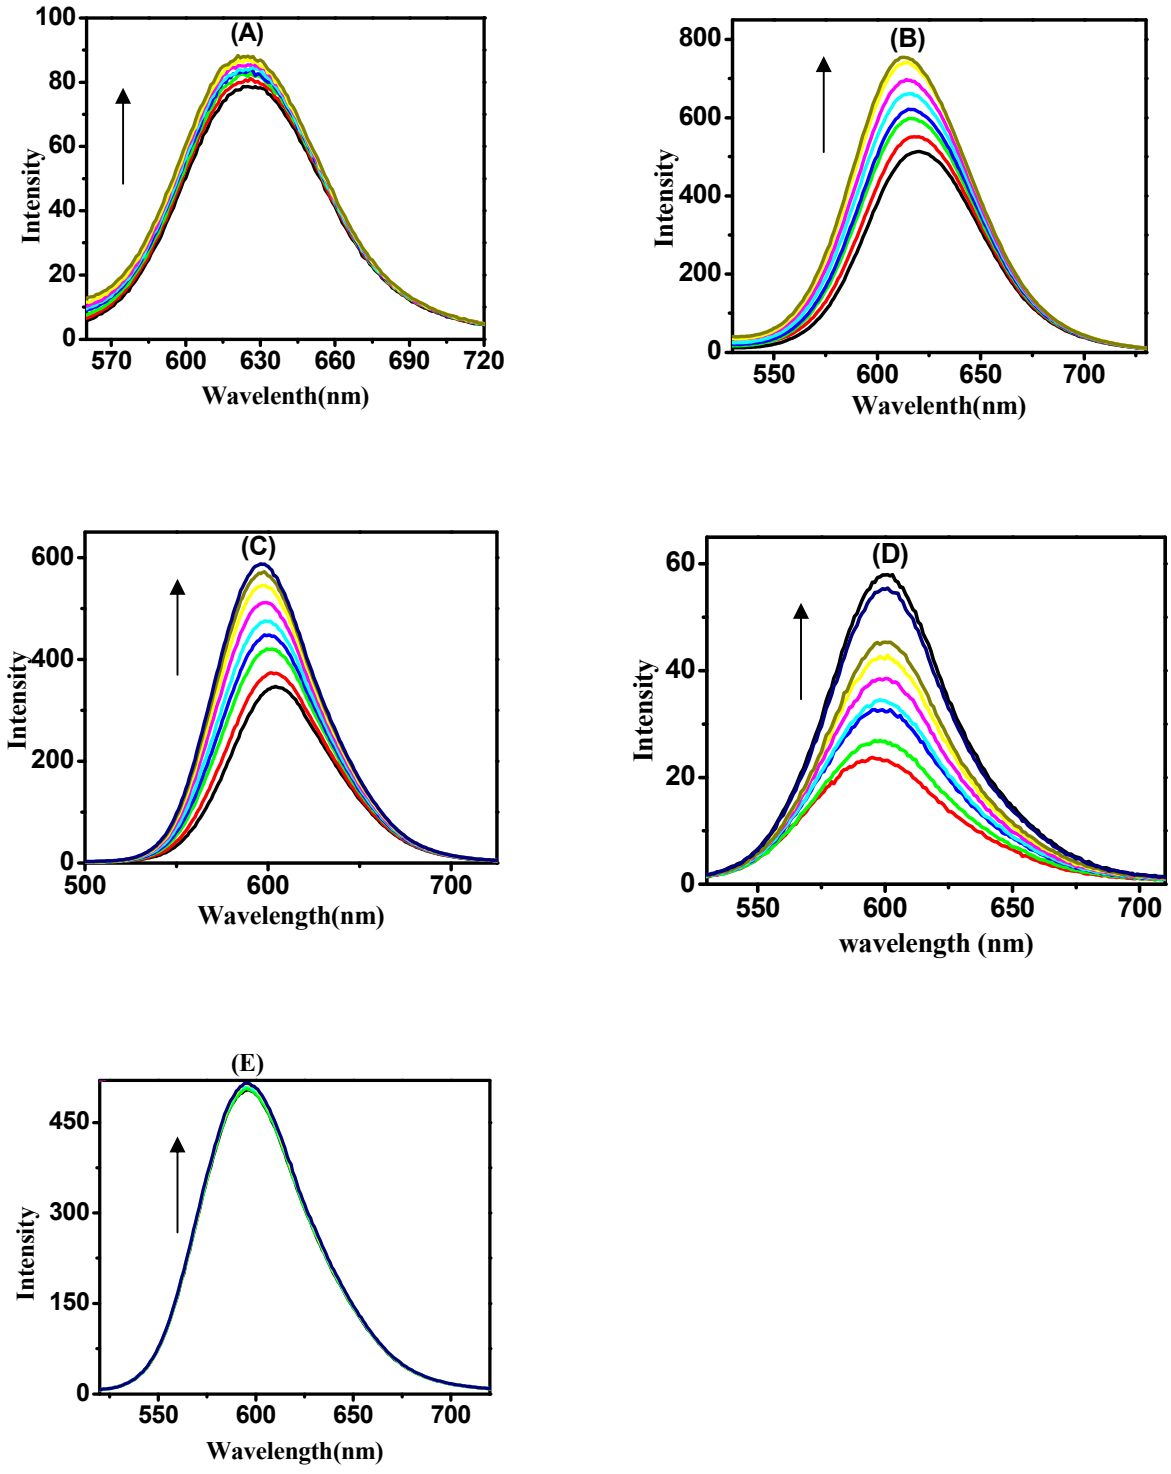

Figure S5. Emission spectra of Ru(II) complexes (A) **1** , (B) **2**, (C) **3**, (D) **4** and (E) **9** (25 μM) in phosphate buffer (pH 7.2) at 298 K with increasing [DNA]/[Ru] ratio from 0-30. Arrow shows the intensity changes upon increasing DNA concentrations.

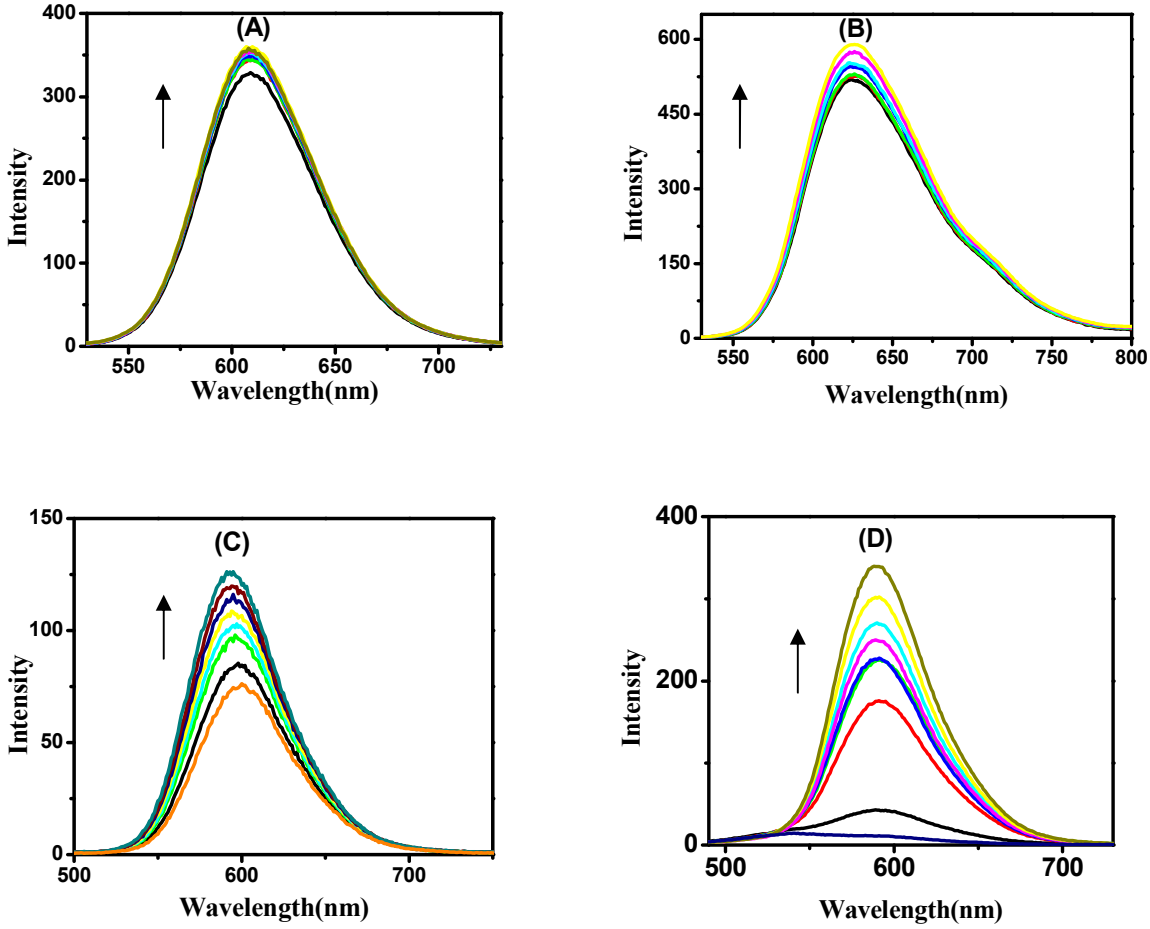

Figure S6. Emission spectra of complexes (A) **5**, (B) **6**, (C) **7, (D) 8** (25 μM) in phosphate buffer (pH 7.2) at 298 K with increasing [DNA]/[Ru] ratio from 0-30. Arrow shows the intensity changes upon increasing DNA concentrations.

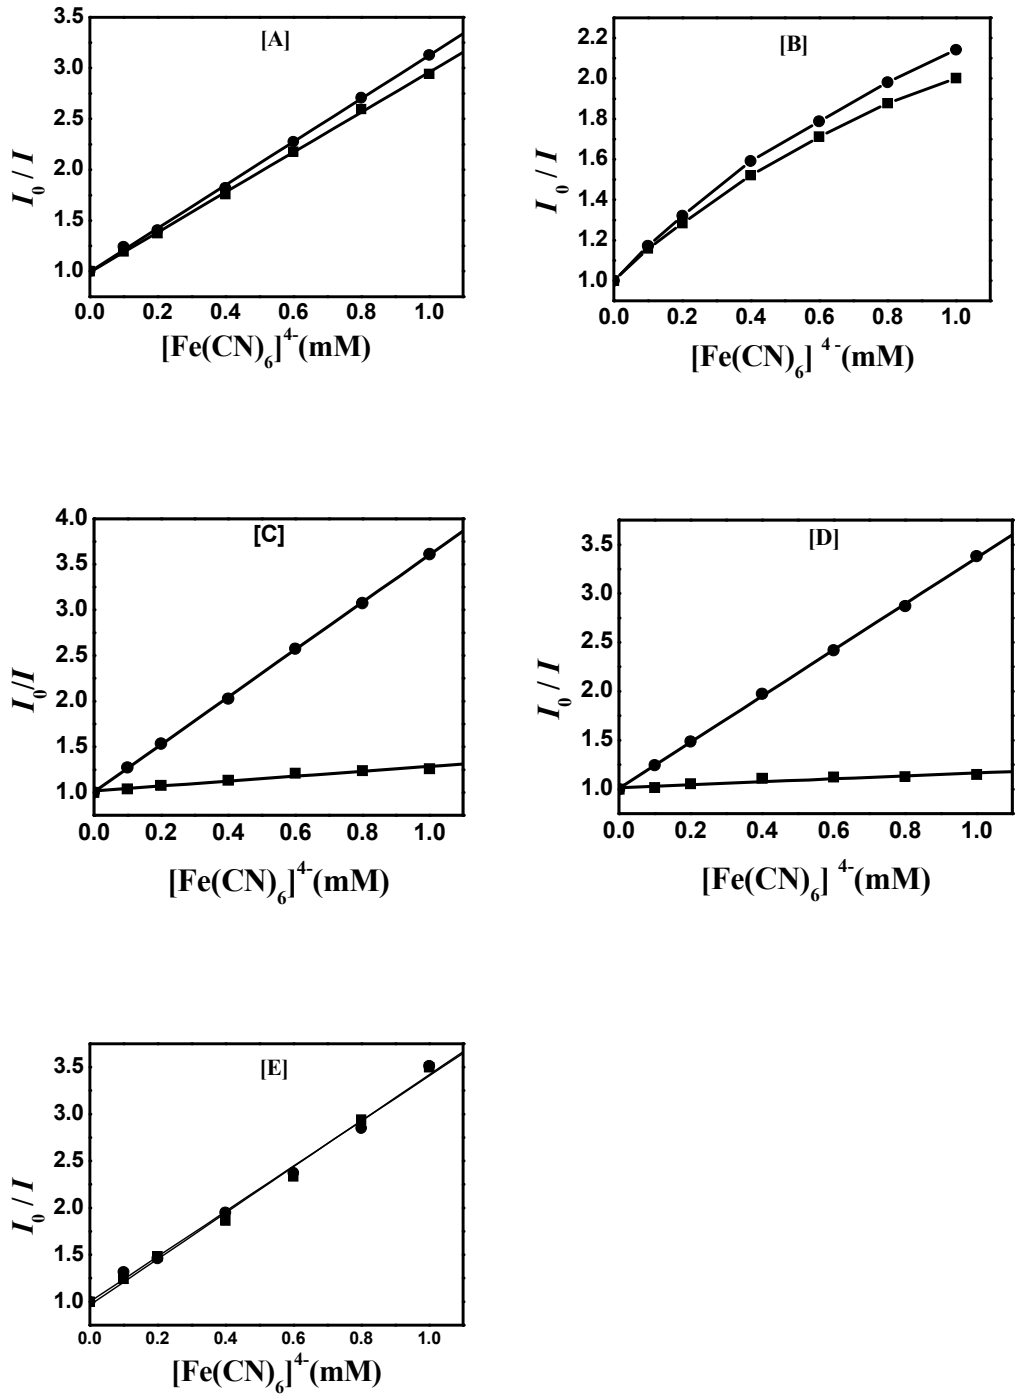

Figure S7. Emission quenching of the ruthenium(II) complexes with increasing concentration of quencher $[Fe(CN)_6]^{4-}$ in the absence (●) and presence (■) of CT-DNA (phosphate buffer pH 7.2); ([Ru] = 20 μM, [DNA]/[Ru] = 40:1), (A) **1**, (B) **2**, (C) **3**, (D) **4**, (E) **9**.

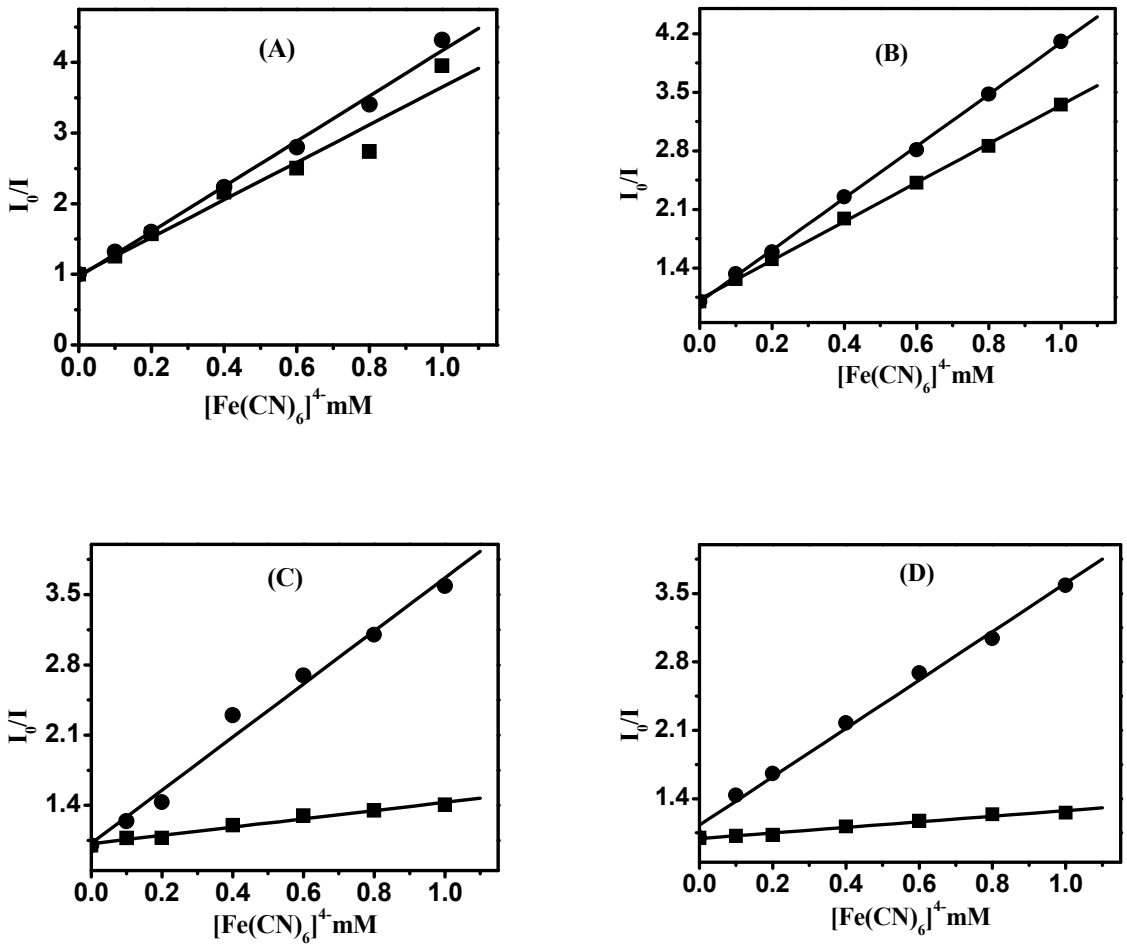

Figure S8. Emission quenching of the Ru(II) complexes with increasing concentration of quencher $[Fe(CN)_6]^{4-}$ in the absence (●) and presence (■) of DNA (phosphate buffer pH 7.2); ([Ru] = 20 μM, [DNA]/[Ru] = 40:1), (A) **5**, (B) **6**, (C) **7**, (D) **8**.

Table S1. Luminescence decay lifetime of the complexes **1-9** in the presence of CT-DNA.

Received July 23, 2008; Revised Manuscript Received January 12, 2009

Nanolipoprotein particles (NLPs) are nanometer-sized, discoidal particles that self-assemble from purified apolipoprotein and phospholipid. Their size and facile functionalization suggest potential application of NLPs as platforms for the presentation and delivery of recombinant proteins. To this end, we investigated incorporation of nickel-chelating lipids into NLPs (NiNLPs) and subsequent sequestration of polyhistidine (His)-tagged proteins. From initial lipid screens for NLP formation, the two phospholipids DMPC and DOPC were identified as suitable bulk lipids for incorporation of the nickel-chelating lipid DOGS-NTA-Ni into NLPs, and NiNLPs were successfully formed with varying amounts of DOGS-NTA-Ni. NiNLPs consisting of 10% DOGS-NTA-Ni with 90% bulk lipid (either DMPC or DOPC) were thoroughly characterized by size exclusion chromatography (SEC), nondenaturing gradient gel electrophoresis (NDGGE), and atomic force microscopy (AFM). Three different His-tagged proteins were sequestered on NiNLPs in a nickel-dependent manner, and the amount of immobilized protein was contingent on the size and composition of the NiNLP.

INTRODUCTION

Nanolipoprotein particles (NLPs) are self-assembled, nanometer-sized discoidal particles comprising lipoproteins and phospholipids (*1, 2*). Recently, NLPs have been used as model membrane mimetics for stabilizing and studying membrane proteins (*3*). While NLP formation requires only purified apolipoprotein and lipid reagents, the diversity in both the protein (*4*−*6*) and the lipid (*4, 7, 8*) components successfully used in NLP assemblies demonstrates the robust nature of the assembly process and hints at facile NLP functionalization by incorporating modified starting materials. Hence, the ability to vary the size and composition of NLPs suggests that they will be versatile platforms for immobilization of biomolecules. Functional NLPs can be used to capture recombinant proteins for a range of applications, such as facilitating the study of receptor−antigen interactions (*9*), providing a versatile platform for in vivo protein delivery (*10, 11*), or functioning as adjuvant-free particulate vaccine carriers for the delivery and presentation of immunogens (*12*−*14*).

With the goal of functionalizing NLPs with recombinant proteins, we have developed nickel-chelating nanolipoprotein particles (NiNLPs) for the targeted immobilization of any polyhistidine-tagged protein (Figure 1). Recombinant engineering of His-tagged proteins is a common intermediary in molecular biology and proteomics and is readily achievable in a variety of expression systems. As such, a substantial library of recombinant His-tagged proteins is available for NiNLP immobilization. Nickel-chelating lipids (*15*−*19*) represent a facile means of imparting NLPs with the ability to bind His-tagged proteins and have been developed for myriad applications, including two-dimensional protein crystallization (*16, 20*), functionalization of supported lipid bilayers or liposomes (*21, 22*), and liposomal or microemulsion antigen delivery (*17, 23*−*25*).

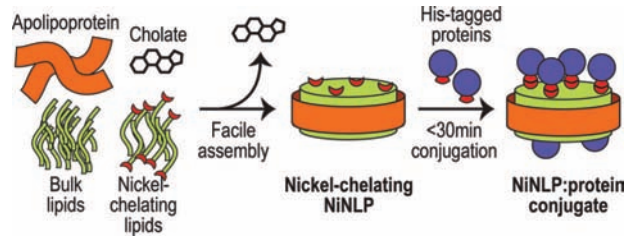

Figure 1. Schematic of NiNLP formation and conjugation of His-tagged proteins. The apolipoprotein E422K is incubated with cholate-solubilized bulk and Ni-chelating lipids. Upon removal of cholate by dialysis, discrete discoidal nanolipoprotein particles form that present nickel-chelating headgroups at the lipid bilayer periphery. The chelated nickel enables binding of polyhistidine-tagged proteins.

Herein, we describe the successful incorporation of nickel-chelating lipids into NLPs. Specifically, varying ratios of a nickel-chelating lipid (1,2-dioleoyl-*sn*-glycero-3-{[*N*-(5-amino-1-carboxypentyl) iminodiacetic acid] succinyl}(nickel salt) (DOGS-NTA-Ni)) were doped into NLP assembly reactions, which consisted of bulk lipids (either 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) or 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC)), the 22 kDa N-terminal truncation of human apolipoprotein E4 (denoted as apoE422K or E422K in the absence or presence of lipid, respectively) (*26*) and sodium cholate. The NLPs assembled with DOGS-NTA-Ni and bulk lipids (subsequently referred to as NiNLPs) were competent in binding various His-tagged recombinant proteins, including the bacteriocin pesticin (Pst) from *Yersinia pestis*, the *Y. pestis* quorum sensing protein lsrG, and the light chain of botulinum neurotoxin A.

EXPERIMENTAL SECTION

Materials. 1,2-Dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1,2-

dioleoyl-*sn*-glycero-3-phosphoserine (DOPS), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), 1,2-dioleoyl-*sn*-glycero-3-ethylphosphocholine (DOEPC), 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP), and the nickel salt of 1,2-dioleoyl-*sn*-glycero-3-{[*N*-(5-amino-1-carboxypentyl)iminodiacetic acid] succinyl} (DOGS-NTA-Ni) were purchased from Avanti Polar Lipids (Alabaster, AL). All other reagents were ordered from Sigma-Aldrich (St. Louis, MO).

Protein Expression and Purification. The expression clone for the 22 kDa N-terminal fragment of apolipoprotein E4 (apoE422K, kindly provided by Dr. Karl Weisgraber) featuring a cleavable His-tag (*26*) was expressed and purified as previously described (*4*). To generate the two *Y. pestis* proteins used in this study, lsrG and Pst, expression clones for each protein were generated by amplification from genomic DNA (*Y. pestis* KIM D27), and the full-length ORFs were directly cloned into a modified pETBlue expression plasmid encoding a C-terminal hexa-His tag. Plasmids were subsequently transformed into BL21(DE3)pLacI competent cells (Novagen, Madison, WI). Cells were grown in LB media with 50 μg/mL ampicillin, pelleted, and lysed using a high-pressure homogenizer (Emulsiflex-C5, Avestin, Ottawa, Canada). Insoluble material was pelleted, and soluble His-tagged protein was purified with Ni-NTA agarose (Qiagen, Valencia, CA). Immobilized protein was eluted with imidazole and further purified by SEC using a HiLoad 26/60 Superdex 75 prep-grade column (GE Healthcare, Piscataway, NJ). His-tagged botulinum neurotoxin type A light chain was expressed and purified according to the published protocol (*27*). Protein concentrations were determined using the Advanced Protein Assay Reagent (Cytoskeleton Inc., Denver, CO).

NLP Assemblies. NLPs were assembled according to a previously reported procedure (*4*) with slight modifications. Briefly, lipids were either prepared or obtained in chloroform and aliquoted into glass vials. Chloroform was then removed using a stream of N_2 under agitation to form a thin lipid film, which was further dried in vacuo for at least 4 h. Lipids were then solubilized in TBS buffer (10 mM Tris, 150 mM NaCl, 0.05% NaN_3, pH 7.4) using sodium cholate. A typical assembly contained 20 mM cholate, although during the initial lipid screen, up to 45 mM cholate was added to ensure lipid solubilization. After addition of E422K apolipoprotein, samples were either incubated at 4 °C for at least 18 h (for those lipids with transition temperatures below 4 °C) or transitioned between 30 and 20 °C three times, followed by an incubation at 23.8 °C for at least 18 h (specifically for DMPC). Assemblies were then dialyzed overnight against TBS to remove cholate and subsequently analyzed and purified by SEC (Superdex 200, 10/300 GL column, GE Healthcare, Piscataway, NJ) in TBS buffer (0.5 mL/min flow rate). NLP fractions were concentrated using a 50 kDa molecular weight cutoff (MWCO) spin concentrators (Agilent Technologies, Santa Clara, CA) and analyzed by NDGGE and/or AFM. Prior to SEC analysis, all samples were filtered using a 0.22 μm spin filter to remove any particulates (Agilent Technologies). A gel filtration calibration kit (GE Healthcare) was used to calibrate the column. The exclusion limit of the column was determined with Blue Dextran 2000. All assemblies were prepared at a 100:1 molar ratio of lipid to E422K, except assemblies with DMPC, which were prepared at a 132:1 molar ratio. Lipid concentrations during assembly typically ranged between 2 and 8 mM (see Supporting Information for details). For nondenaturing gradient gel electrophoresis (NDGGE), 4−20% Tris-glycine polyacrylamide gels were used (Invitrogen, Carlsbad, CA), and subsequently stained with SyproRuby (BioRad, Hercules, CA) and imaged using the Typhoon 9410 Variable Mode Imager (GE Healthcare). Assemblies with various ratios of bulk lipid and DOGS-NTA-Ni were essentially prepared as described above. Higher final concentrations of cholate were required for assemblies incorporating higher fractions of DOGS-NTA-Ni, with up to 35 mM cholate used for 100% DOGS-NTA-Ni assemblies.

NiNLP Component Analysis. To determine the component ratios of assembled NiNLPs, phospholipid, lipoprotein, and nickel content were quantified. Phospholipid content was determined using an enzymatic method to detect choline (Phospholipids C Assay kit, Wako Diagnostics, Richmond, VA). Protein content was assessed using the Advanced Protein Assay Reagent (Cytoskeleton Inc., Denver, CO). Nickel content was quantified by inductively coupled plasma atomic emission spectroscopy (ICP-AES) using a Thermo Elemental inductively coupled plasma - atomic emission spectrometer (Waltham, MA). Briefly, triplicate samples were aspirated using a glass nebulizer into a conical spray chamber. The instrument was calibrated using a five-point calibration curve prepared from NIST traceable certified reference materials. Calibration checks were performed before, during, and after analysis, and were within 5% of the true value of the calibrant (typically <1%). Matrix spikes ensured that the sample matrix did not interfere with the analysis. Samples were acidified (to 2% ultrapure nitric acid) in the dilution process, which was based on mass. Analyses were conducted using three wavelengths: one analytical wavelength (221.647 nm) and two confirmatory wavelengths (231.604 and 341.476 nm). All the wavelengths were in agreement within 1%. The Ni concentration was extrapolated by the instrument from a calibration curve. The correlation coefficients for the calibration curves were 0.99998 (221.647 nm), 0.99999 (231.604 nm), and 0.99952 (341.476 nm).

AFM Analysis of NLPs. Atomic force microscopy was conducted as previously described (*28*). Briefly, samples were incubated for 2 min on an atomically flat muscovite mica surface in imaging buffer (10 mM $MgCl_2$, 10 mM Tris-HCl, 100 mM NaCl, pH 8.0), then lightly rinsed. Height, amplitude, and phase images were collected using a MFP-3D-CFM AFM (Asylum Research, Santa Barbara, CA). NLP diameters were determined by full width half-maximum (fwhm) analysis of particles in the slow scan direction using IgorPro software (WaveMetrics Inc., Portland, OR). To limit instrument broadening during lateral particle sizing, only tips revealing sharp imaging were used for diameter analysis. We have previously determined, based on NLP size and molecular dynamics simulations, that the average tip broadening effect was ∼2−3 nm (*28*). Due to tip architecture, it is assumed that the tip directly contacts the NLP bilayer, rather than the peripheral lipoproteins. Hence, the ∼2−3 nm tip convolution is essentially abrogated as the proteins are estimated to extend ∼2−3 nm from the bilayer (i.e., ∼1.0−1.5 nm on each side of the NLP). To determine the reproducibility of the procedure used for measuring NLP diameters, randomly selected particles were repeatedly imaged to verify consistent diameter measurements. Heights of particles were elucidated from histogram analysis.

Protein−NLP Conjugation. To immobilize His-tagged proteins on NiNLPs, NiNLPs (0.1 μg/μL) were incubated in TBS buffer with various concentrations of His-tagged proteins at room temperature for 45 min in a volume of 100 μL. A portion from each sample (60 μL) was subsequently filtered through a 100 kDa MWCO Microcon spin concentrator (Millipore, Burlington, MA) and washed three times with 200 μL of buffer. For control experiments, NiNLPs were preincubated in TBS buffer supplemented with 4 mM ethylenediaminetetraacetic acid (EDTA) for 45 min at room temperature prior to His-tagged protein addition. For these samples, the wash buffer also contained 4 mM EDTA. Samples were then analyzed by denaturing gel electrophoresis on 16% Tris-tricine polyacrylamide gels (Invitrogen). Gels were stained and imaged as

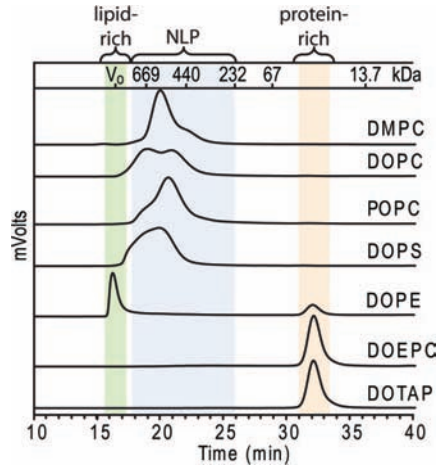

Figure 2. NLP formation with apolipoprotein E422K in the presence of seven bulk lipids (DMPC, DOPC, POPC, DOPS, DOPE, DOEPC, and DOTAP) was screened by SEC. Three important regions of the SEC traces are indicated, corresponding to lipid-rich (~15−17 min), NLP (17−26 min), and protein-rich fractions (31−34 min). Molecular weights of protein standards are indicated, as well as the exclusion limit of the column (V_o).

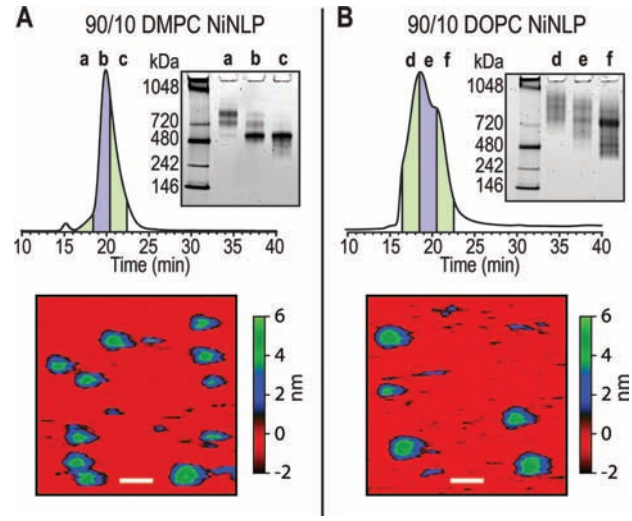

Figure 3. Formation of NiNLPs incorporating nickel-chelating lipids. Characterization of (A) DMPC- and (B) DOPC-based NiNLPs incorporating 10% DOGS-NiNTA using SEC (top), NDGGE of indicated SEC fractions (inset), and AFM (bottom). Scale bar is 50 nm.

indicated above. ImageQuant (GE Healthcare) was used for densitometry measurements. The NiNLPs used for these studies were both composed of pooled SEC fractions. Previously published experimental and modeling data (*28*) were used to extrapolate NiNLP concentration assuming DMPC- and DOPC-based NiNLPs contain five and six E422K lipoproteins per NiNLP, respectively. For AFM analysis of protein binding, samples were prepared as indicated above. In lieu of ultrafiltration, samples were diluted in imaging buffer and pipetted onto the AFM mica surface.

RESULTS

Survey of Lipid Compatibility with NLP Formation. The formation of nickel-presenting lipid bilayers has been extensively demonstrated for a variety of applications and is typically accomplished by mixing low concentrations of a nickel-chelating lipid with a bulk lipid. The first step in developing NiNLPs was to determine the effects of several bulk lipids on NLP assembly. To this end, seven different lipids were tested for NLP formation: DMPC, DOPC, DOPS, POPC, DOPE, DOTAP, and DOEPC. SEC was then used to determine proper assembly of NLPs. As demonstrated in Figure 2, assemblies with DMPC, DOPC, DOPS, and POPC all formed particles with the expected NLP retention times of 18 to 26 min (*4*), indicating NLPs ranging in apparent molecular weight (MW) between 350 and 900 kDa. NDGGE of these samples also indicated particle formation, while AFM confirmed the presence of discoidal particles (data not shown). No NLP formation was observed with DOPE, as the SEC trace depicts two discrete, non-NLP peaks. The first peak at ~17 min is attributed to large lipid-rich aggregates (corresponding to the ~1.5 MDa exclusion limit of the column), while the second peak at ~32 min is characterized as a protein-rich species. The retention time of the protein-rich peak was identical to pure apolipoprotein (data not shown). Assemblies with DOTAP and DOEPC were cloudy after dialysis, and seemingly all precipitated lipids were removed in the prefiltration (0.22 μm) step prior to SEC analysis. No NLP species were observed in the SEC traces, though a peak in the protein-rich region was observed in both samples. These data demonstrate that, by using the assembly conditions and stoichiometry described above, NLPs were successfully formed with DMPC, DOPC, DOPS, and POPC.

NLP Formation with DOGS-NTA-Ni. On the basis of the survey of NLP formation with the bulk lipids, DMPC and DOPC were chosen to evaluate DOGS-NTA-Ni incorporation into NLPs. Initially, NLP assemblies with 1%, 3%, 10%, 30%, and 100% (molar) DOGS-NTA-Ni were tested. All lipid ratios formed NiNLPs (data not shown), so formulations incorporating 10% DOGS-NTA-Ni were deemed acceptable for further study, as 10% ensures the presence of chelated nickel at the NiNLP surface without requiring excessive amounts of costly DOGS-NTA-Ni lipid. These NiNLPs were further analyzed by SEC, NDGGE, and AFM (Figure 3). The NiNLPs consisting of 90% DMPC and 10% DOGS-NTA-Ni (henceforth referred to as 90/10 DMPC NiNLPs) were characterized by a relatively narrow SEC peak with a retention time of ~20 min, indicating an apparent MW of 680 kDa (Figure 3A). NDGGE analysis of the indicated fractions suggested a mixed population of NiNLPs with apparent MW of ca. 800, 710, and 570 kDa (based on a calibration curve using the protein marker standards). The larger NLPs eluted primarily in the first SEC fraction (fraction a), while the main SEC peak (fractions b and c) was dominated by 570 kDa NiNLPs. In contrast, 90/10 DOPC NiNLPs had a larger size distribution (Figure 3B). By SEC, at least two peaks are apparent, corresponding to 950 and 615 kDa (at 18.5 and 20.3 min, respectively). SEC fractions d and e were composed of large particles, whereby three equally intense bands at approximately 950, 890, and 730 kDa could be discerned by NDGGE. The SEC fraction f, on the other hand, was dominated by the 730 kDa NiNLP species.

The NiNLPs prepared with either DMPC or DOPC were further characterized by AFM to elucidate both particle size and morphology. AFM analysis of 90/10 DMPC NiNLP fraction c demonstrated that the majority of NLP species were either 14.5 or 19.0 nm in diameter, with an average of 17.5 ± 3.5 nm. The heights of these particles were measured at 5.24 ± 0.25 nm, illustrating the discoidal morphology of these NiNLPs. AFM indicated that 90/10 DOPC NiNLPs were overall larger in diameter than the 90/10 DMPC NiNLPs, with an average diameter of 21.0 ± 4.2 nm. The heights of these NiNLPs were 5.16 ± 0.18 nm, again demonstrating that these particles are discoidal.

To understand the compositional stoichiometry of the NiNLPs, the protein, phospholipid, and DOGS-NTA-Ni constituents were quantified (see Experimental Section for details). Elemental nickel analysis indicated that both 90/10 DMPC and 90/10 DOPC NiNLPs incorporated similar molar ratios of DOGS-NTA-Ni (11.1 ± 0.1% and 9.3 ± 0.3%, respectively), consistent

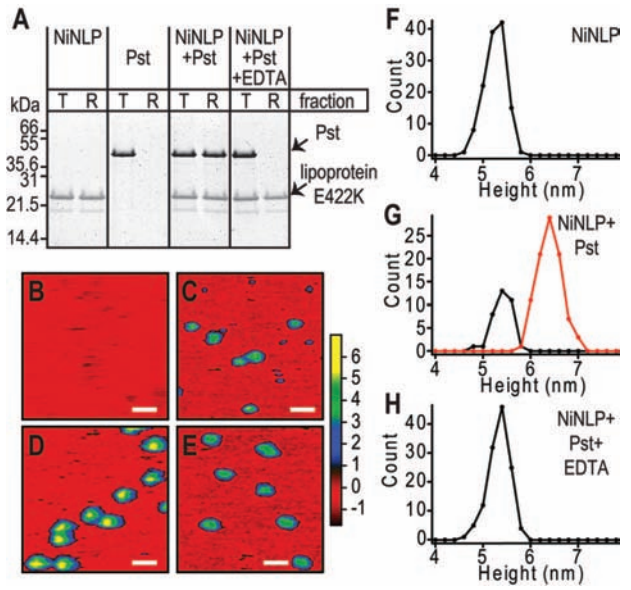

Figure 4. NiNLPs can bind His-tagged proteins. (A) NiNLPs incubated with His-tagged pesticin (Pst) at room temperature for 30 min were analyzed by denaturing SDS-PAGE. Total sample (*T*) was compared to retentate fraction (*R*) after size-exclusion partitioning using a 100 kDa MWCO membrane (see Experimental Section), enabling NiNLPs (>400 kDa) to be separated from unconjugated Pst (40 kDa). Addition of EDTA abrogates any interaction between the protein and the NiNLP. (B−E) Atomic force micrographs of Pst alone (B), NiNLPs alone (C), NiNLPs+Pst (D), and NiNLPs+Pst in the presence of EDTA (E). Scale bar is 50 nm. (F−H) Summary height analyses of NiNLPs (F), NiNLPs with Pst (G), and NiNLPs with Pst in the presence of EDTA (H).

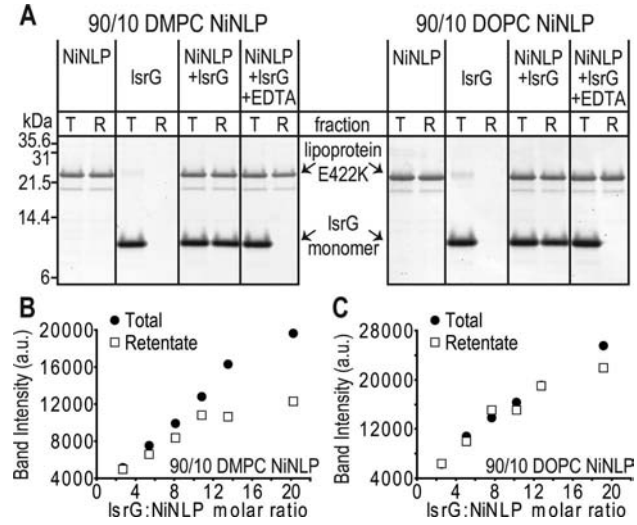

Figure 5. Protein loading of NiNLPs can be controlled by coupling stoichiometry. (A) NiNLPs incubated with His-tagged lsrG at room temperature for 30 min were analyzed by denaturing SDS-PAGE. Total sample (*T*) was compared to retentate fraction (*R*) after size-exclusion partitioning using a 100 kDa MWCO membrane to separate NiNLPs (>400 kDa) from unconjugated lsrG (11.4 kDa). The 90/10 DMPC and 90/10 DOPC NiNLPs are equally competent in protein binding. The faint bands at 24 kDa in the lsrG (*T*) lanes correspond to nondenatured lsrG dimers. (B,C) Incubation of lsrG with NiNLPs at various molar ratios demonstrates conjugation stoichiometry with 90/10 DMPC NiNLPs (B) and the larger 90/10 DOPC NiNLPs (C).

with an initial feed ratio of 10%. When prepared at a 130:1 lipid/E422K molar ratio, the 90/10 DMPC NiNLPs contained a final lipid/E422K ratio of 103.3 ± 6.1. The 100:1 molar ratio used for the DOPC-based NiNLPs resulted in a final lipid/E422K ratio of 86.2 ± 15.0.

Conjugation of His-Tagged Proteins to NiNLPs. To demonstrate functionalization of NiNLPs, the ability to conjugate several His-tagged proteins to NiNLPs was tested. To assess conjugation, samples were partitioned using 100 kDa MWCO spin filters, which retained NiNLPs (and proteins conjugated to the NiNLPs), whereas the unbound His-tagged proteins were passed to the filtrate. Thus, by performing denaturing gel electrophoresis on NiNLP/His-tagged protein mixtures and the 100 kDa MWCO filter retentate, conjugation could be readily assessed. A His-tagged 40 kDa soluble protein from *Y. pestis*, pesticin (Pst), was successfully immobilized on 90/10 DMPC NiNLPs (Figure 4A, lane NiNLP+Pst (R)). To demonstrate that Ni was required for this interaction, NiNLPs were preincubated with EDTA to chelate the Ni from the NiNLP bilayer surface and then mixed with Pst. Under these conditions, no retention of Pst was observed, indicating that specific conjugation to the Ni-chelating lipids had been abrogated. To verify these results, nonpartitioned samples were analyzed by AFM (Figure 4B−H). Upon incubation with Pst, the height profile of the majority of NiNLPs shifted from ∼5.4 nm to ∼6.4 nm. This height shift was absent in the presence of EDTA, demonstrating that the chelated Ni was required for the observed interaction between the His-tagged protein and the NiNLP. Similarly, a partially purified preparation of recombinant His-tagged botulinum neurotoxin A light chain (BoNT/A LC) was successfully immobilized on 90/10 DMPC NiNLPs (see Supporting Information).

To further demonstrate the universal applicability of this approach, conjugation of another His-tagged *Y. pestis* protein, lsrG, was shown with both DMPC and DOPC-based NiNLPs containing 10% DOGS-NTA-Ni (Figure 5A). Various molar ratios of NiNLP to lsrG were tested in the hopes of elucidating conjugation stoichiometry. To simplify analysis, previous modeling data were used to extrapolate the average number of lipoprotein molecules per NiNLP from the NiNLP diameters (*28*). On the basis of these models, the DMPC- and DOPC-based NiNLPs were estimated to have incorporated an average of 5 and 6 lipoprotein molecules, respectively, enabling an approximation of NiNLP molar concentration from measured lipoprotein concentrations. Samples were partitioned and run on denaturing gels, demonstrating that both NiNLPs efficiently bound lsrG (Figure 5B,C). Densitometry of the bands detected in these gels was used to quantify the relative retention of lsrG, and post-partitioned samples were normalized to pre-partitioned samples based on E422K band intensity. This normalization was required to account for the slight loss of material due to filter membrane retention observed at higher concentrations of lsrG, presumably due to an alteration of the NiNLP surface charge and/or polar characteristics by lsrG. On the basis of these data, 90/10 DOPC NiNLPs can accommodate significantly more lsrG molecules prior to saturation than the smaller 90/10 DMPC NiNLPs.

DISCUSSION

We have demonstrated the successful incorporation of nickel-chelating lipids into NLPs that enables direct conjugation of His-tagged proteins to the resultant NiNLP surface. The nickel-chelating lipid DOGS-NTA-Ni has been extensively used for myriad applications (*19, 21, 24, 25*) and always in conjunction with a bulk (non-Ni-chelating) lipid. The use of bulk lipids in these reports permitted control of the number of Ni-chelate groups on the bilayer surface, reduced cost by using an inexpensive bulk lipid, and took advantage of the overall bilayer-formation properties of the bulk lipid. Hence, we screened a variety of bulk lipids that have previously been used in conjunction with DOGS-NTA-Ni for NLP formation using a previously established NLP assembly protocol (*4*). NLP forma-

tion was successful with four of the tested phospholipids: DMPC, DOPC, POPC, and DOPS (Figure 2). NLPs incorporating DMPC have been extensively studied (*4, 5, 28, 29*), in contrast to DOPC-based NLPs. Subsequently, these two lipids were tested for incorporation of DOGS-NTA-Ni. Discoidal NLPs were readily formed with the nickel-chelating lipid and either DMPC or DOPC (Figure 3). At a 10% DOGS-NTA-Ni feed ratio, the DMPC-based NiNLPs had an average diameter of 17.5 ± 2.2 nm as measured by AFM. DOPC-based NiNLPs were more heterogeneous in size, exhibiting a major species ca. 21.0 ± 4.2 nm in size. These results reaffirm published studies indicating that the identity of the bulk lipid as well as the stoichiometry of lipid to apolipoprotein influence the average size of the resultant NiNLPs (*4*). Stoichiometry also plays a role in the heterogeneity of NLPs. Although heterogeneity in this case does not necessarily affect potential applications, certain uses may require particles that are highly monodisperse in size. In these cases, greater homogeneity can be achieved through both optimization of lipid/protein ratios and subsequent SEC fractionation.

It is important to note that the NLP diameters obtained by AFM are not in complete agreement with SEC and NDGGE (which are in greater agreement with each other). Direct comparison of discoidal NLPs to globular protein standards (used for both SEC and NDGGE calibration) proved difficult. To address these discrepancies, we have previously demonstrated a high degree of NLP diameter correlation from three independent single-molecule techniques: AFM, transmission electron microscopy, and ion mobility spectroscopy (*4, 28*). As SEC- and NDGGE-based size determinations are derived from averages of particle ensembles, we have utilized SEC and NDGGE as screening techniques to understand general trends in NLP size, while using AFM for more direct quantification.

Here, we have shown that NiNLPs are functionally active, as they can be readily conjugated with His-tagged proteins. The conjugation of His-tagged proteins to nickel-chelating moieties is an integral process in protein purification and proteomics applications (*30*−*32*). This interaction has also been adapted for functionalization of myriad lipid-based particles and surfaces for biotechnology applications (*15*−*25*). The ease and speed of the conjugation process, coupled with the simplicity of generation of His-tagged proteins, make this a very powerful approach for surface functionalization. We have demonstrated that this process works very well for NiNLPs by demonstrating that all three His-tagged proteins tested were readily immobilized on the NiNLPs. The conjugation was monitored by two independent techniques: denaturing gel electrophoresis of partitioned NiNLPs and AFM. Gel electrophoresis demonstrated that His-tagged proteins were successfully immobilized on NLPs, as partitioning was used to isolate the large NiNLPs from unbound material using a 100 kDa MWCO membrane. The presence of any His-tagged protein in the high molecular weight retentate was possible only through conjugation of the protein to the NiNLP. When the NiNLP was treated with EDTA to remove nickel, no protein was found in the retentate, demonstrating the importance of chelated nickel in the immobilization process. Also, a significant height increase was observed with AFM upon the addition of the His-tagged protein to NiNLPs (Figure 4). Again, this was abrogated if NiNLPs were preincubated with EDTA.

Both size and lipid composition are anticipated to be important determinants in the degree of His-tagged protein loading on the NiNLP. This was demonstrated when overall protein immobilization was compared between the DMPC- and DOPC-based NiNLPs (Figure 5). The larger diameter 90/10 DOPC NiNLPs were able to accommodate more lsrG protein than the smaller 90/10 DMPC NiNLPs. While these data suggest that the diameter of the NiNLPs dictates the amount of immobilized protein, the composition of the lipid can also play a role in bilayer packing and DOGS-NTA-Ni distribution. Performing immobilization assays with a panel of discretely sized NiNLP of uniform composition may provide a means to identify the contribution of both particle size and bilayer composition to protein loading.

In conclusion, we have demonstrated the preparation of NLPs incorporating chelated nickel and that these NiNLPs bind His-tagged proteins. NiNLP technology may be applied to the study of receptor−target interactions at a bilayer surface or to the in vivo delivery or targeting of biological macromolecules. These latter applications suggest that NiNLPs may represent a rapid and versatile means to immobilize a protein or multiple proteins for potential use as vaccines, including multivalent vaccines. The development of a universal particulate platform for the delivery and controlled presentation of recombinant proteins for vaccine applications (*12, 33, 34*) would provide an important step toward greater applicability of recombinant immunogens.

ACKNOWLEDGMENT

The authors thank Dr. Karl Weisgraber for providing reagents and Dr. Roger Martinelli for ICP-AES nickel quantification. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory (LLNL-JRNL-405192) under Contract DE-AC52-07NA27344 with support from Lawrence Livermore National Laboratory (LDRD, 06-SI-003).

We describe microarrays of receptors on gold/glass substrates for the selective capturing of viral particles at high density. Microscale gold squares were surface-modified with alkanethiol derivatives which enabled the immobilization of the His_6-tagged virus-binding domain from the very-low density lipoprotein (VLDL) receptor. The free glass areas surrounding the gold squares were passivated with a dense film of poly(ethylene glycol) (PEG). As assessed by atomic force microscopy, human rhinovirus particles were captured onto the VLDL-receptor patches with a high surface coverage but were effectively repelled by the PEG layer, resulting in a 330 000-fold higher density of the particles on the gold as compared to the glass surfaces. The metal chelate-based coupling strategy was found to be superior to two alternative routes, which used the covalent coupling of viral particles or viral receptors to the substrate surface. The high-density receptor arrays were employed for sensing and characterizing viral particles with so far unprecedented selectivity.

INTRODUCTION

Capturing viral particles from solution onto micropatterned substrates is of relevance for applications in biotechnology, diagnostics, and biomedical research. Similar to the specific binding of DNAs and proteins onto microarrays, selective detection and biophysical characterization of viruses via surface-immobilized receptors is becoming increasingly important (*1*−*5*). Particularly useful in this respect is the combination with high-resolution read-out technologies such as atomic force microscopy (AFM) (*6*−*10*). This technique introduces an additional dimension because the virions are analyzed by AFM with regard to their characteristic morphology and size (*1, 2*).

Microarray patterns of receptor molecules have been generated by microspotting (*11*−*13*), microcontact printing (*14*−*16*), microfluidic networks (*17*), chemical photolithography (*18, 19*), and photochemical patterning (*20, 21*). However, several of these methodologies are either chemically incompatible with the attachment of virus receptors (*18, 19*) or cannot be easily scaled down for the production of small micrometer or submicrometer-sized receptor spots as required in high throughput AFM read-out (*11, 12, 14*−*17*). Recently, an AFM cantilever has been successfully used as a stylus to scratch soft protein layers and thereby generate nanoscale patterns of receptor spots (*1, 22*). However, the procedure is serial and does not benefit from the scalability and ease of parallel processing. Furthermore, virus nanoarrays have been obtained by the AFM-based dip-pen nanolithography approach (*23, 24*) leading to the immobilization of single virions (*2, 6, 7*). The particles were either bound onto chemically activated surfaces (*6, 7*) or captured onto antibody spots (*2*).

By using a human rhinovirus (HRV2) and a recombinant very-low-density lipoprotein receptor (VLDLR) as the model system, we report a new parallel approach toward the specific and high-density immobilization of virions onto solid substrates. HRVs are the main causative agent of the common cold (*25*) and belong to the family of *Picornaviridae*, which comprise small, nonenveloped icosahedral viruses with a single-stranded positive sense RNA genome (*26*). Twelve HRV types (among them HRV2) use very-low density lipoprotein receptor and other members of the low-density lipoprotein receptor family for cell attachment (*27*). These receptors are mosaic proteins with a ligand-binding domain composed of various numbers of similar modules that bind to symmetry-related sites around the icosahedral 5-fold axes of the virion (*28*).

Here, we describe a new strategy that achieves (i) the selective immobilization of VLDL receptors on gold surfaces of microstructured glass substrates and (ii) the high-density capturing of HRV2 particles onto the receptor areas. Using orthogonal chemistries, glass areas were coated with a dense layer of trimethoxy-silane-terminated poly(ethylene glycol) (PEG) to avoid the nonspecific adsorption of protein, while gold surfaces were specifically modified with self-assembled monolayers (SAMs) of alkanethiol derivatives. Two different SAMs were tested for coupling VLDLR and HRV2 to the gold surfaces. The first SAM surface carried terminal bis-nitrilo-triacetic acid (bis-NTA) groups (Figure 1A) to bind His_6-tagged VLDLR via metal−chelate complexes. The second SAM surface featured a layer of carboxyl groups, which were activated with *N*-hydroxysuccinimide (NHS) (Figure 1B) to covalently couple VLDLR or HRV2 via amide bonds. SAM and PEG surfaces were characterized by using water contact angle goniometry and atomic force microscopy (AFM), respectively. The ability of the SAMs to couple protein was assessed using fluorescence microscopy and AFM. Our data show that gold and glass surfaces of the microstructured substrates could be specifically addressed to achieve 330,000-fold higher binding of viral particles to the former as related to the latter surface. By comparing coupling via covalent bonds, metal−chelate bonds, or noncovalent molecular recognition, our article provides

important insight into which factors govern the immobilization and capturing of protein assemblies.

EXPERIMENTAL SECTION

Reagents. All chemicals were of the highest purity available unless stated otherwise. Glass slides ($50 \times 24 \times 0.15$ mm^3), 30% ammonia, 30% hydrogen peroxide, and 37% hydrochloric acid were purchased from Carl Roth GmbH (Karlsruhe, Germany). Glass slides coated with a layer of 10 nm Cr and 100 nm Au were obtained from Epluse (Engerwitzdorf, Austria). Octylmercaptan (1-octanethiol), 16-mercaptohexadecanoid acid, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), and *N*-hydroxysuccinimide (NHS) were from Aldrich (Milwaukee, WI). 12-Mercaptododecanoic acid was synthesized as described (*29*). 2-[Methoxy(polyethyleneoxy)propyl] trimethoxysilane (PEG-silane) was purchased from ABCR GmbH (Karlsruhe, Germany). 16-Mercapto-hexadecanoic acid 2-[2-(2-hydroxy-ethoxy)-ethoxy]-ethyl ester (triethylene glycol matrix thiol) and 16-mercapto-hexadecanoic acid 2-[2-(2-{1,3-bis-[5-(biscarboxymethyl-amino)-5-carboxypentylcarbamoyl]-propylcarbamoyloxy}-ethoxy)-ethoxy]-ethyl ester (bis-NTA thiol) were kindly provided by Robert Tampé (Institute of Biochemistry, Biocenter, Johann Wolfgang Goethe University, Frankfurt, Germany).

MBP-VLDLR-His_6, a recombinant derivative of VLDLR that binds minor group HRVs, such as HRV2, with high affinity, was produced in bacteria as described (*30*). It carries a C-terminal hexahistidine tag and maltose binding protein fused to its N-terminus (*1*). HRV2 was isolated from infected HeLa-H1 suspension cultures and purified by sucrose density gradient centrifugation as described (*1*).

Microfabrication of Substrates. Glass substrates with microscale gold features were fabricated using a photolithographic process. Slides were first spin-coated with a layer of positive photoresist (thickness 500 nm, Photoresist Microposit S1805, Rohm & Haas, PA). An array of squares (50×50 μm, 150 μm center-to-center spacing) was then patterned on the photoresist by placing a mask over the substrate and exposing it to UV light. After developing the resist (Microposit MF319, Rohm & Haas, PA) to remove the exposed photoresist areas, a 5 nm Cr layer and a 50 nm gold film were sequentially deposited onto the substrates by sputtering and thermal evaporation, respectively. The photoresist areas, which had not been exposed to UV light, were then dissolved in acetone, leading to an array of gold-squares.

Targeted Functionalization of Microstructured Substrates using a Multi-Step Procedure. Microstructured substrates were subjected to a selective surface modification procedure in order to coat the glass areas with a dense film of PEG, and to derivatize gold features with a self-assembled monolayer of carboxyl- or bis-NTA-terminated alkanethiol SAMs. The multistep procedure (Scheme 1) followed an adapted version of a published protocol (*31*, *32*) and involved (i) the selective coating of the gold features with a SAM composed of octylmercaptan, (ii) the formation of a PEG layer on the nonblocked glass areas, (iii) the removal of the octylmercaptan SAM by heating the slides to 120 °C, and (iv & vi) the coating of the blank gold surface with a new SAM composed of alkanethiols with terminal carboxyl or bis-NTA groups. The carboxyl SAM was also further derivatized to display NHS-activated esters (v).

Surface Cleaning. Prior to surface functionalization, slides were cleaned in 10:90, 50:50, and 90:10 mixtures of methanol/$CHCl_3$ for 15 min each in an ultrasonic bath, followed by washing in deionized (DI) water, and drying in a stream of nitrogen. The substrates were then incubated twice for 20 min in a mixture of DI water/ammonia/hydrogen peroxide 30% (v/v/v 100/25/20) at 90 °C, rinsed thoroughly with DI water and dried in a stream of nitrogen gas.

Formation of a SAM Composed of Octylmercaptan. An octylmercaptan SAM was formed on the gold regions of the microstructured substrates by immersing the slides in ethanol for 5 min, followed by incubation in a 1 mM ethanolic solution of octylmercaptan for 16−24 h. Subsequently, the modified substrates were sonicated in ethanol for 3 min, rinsed with DI water, and dried with nitrogen gas.

Generation of a PEG Film via Silanization. A PEG-silane layer was formed on the glass areas between the octylmercaptan-coated microstructured gold areas. The slides were immersed in a solution of PEG-silane in anhydrous toluene (10 mg/mL) supplemented with 0.08% HCl. After incubation for 20−24 h, the slides were sonicated in toluene and ethanol for three min each, rinsed with DI water, and dried in a nitrogen stream.

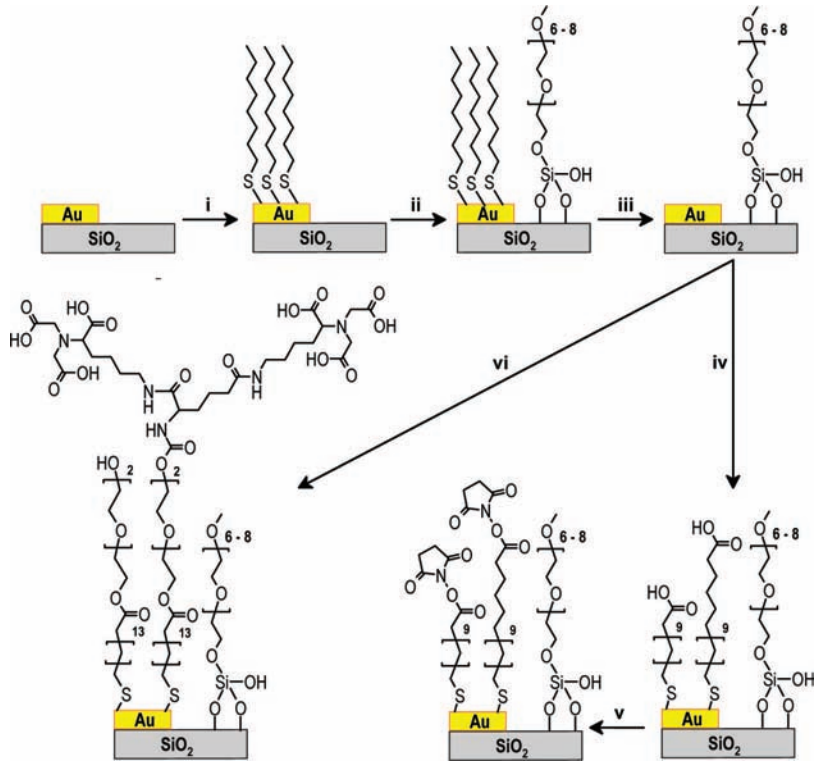
Removal of the Octylmercaptan SAM. After the formation of the PEG layer, the passivating octylmercaptan SAM was removed by baking the substrates in an oven at 120 °C for 1 h, thereby regenerating bare gold surfaces suitable for the functionalization with mercaptoalkane derivatives carrying carboxyl or bis-NTA groups.

Formation of a Carboxyl-Terminated SAM. Bare gold regions were coated with a SAM of carboxyl-terminated alkanethiols by incubating the slides in an ethanolic solution of 1 mM 12-mercaptododecanoic acid and 0.1 mM 16-mercaptohexadecanoic acid following a published procedure (*33*). After 16−24 h of incubation, the slides were sonicated for 5 min in ethanol, rinsed with DI water, and blown dry with nitrogen. The resulting substrates were either used without further modification or surface-treated to activate the COOH groups. NHS-activated carboxyl groups were formed by immersing the slides in an aqueous solution of 200 mM EDC and 50 mM NHS for 15 min, followed by briefly rinsing in deionized water. To avoid hydrolysis, which would decrease the reactivity of the activated ester, NHS-derivatized slides were used for further experiments immediately after their modification with NHS.

Generation of a SAM with Terminal Bis-NTA Groups. Alkanethiols with terminal bis-NTA groups were chemisorbed on bare gold squares by immersing the microstructured substrates in acetonitrile containing 19 μM triethylene glycol-terminated matrix thiol (16-mercapto-hexadecanoic acid 2-[2-(2-hydroxy-ethoxy)-ethoxy]-ethyl ester) and 1 μM bis-NTA thiol (16-mercapto-hexadecanoic acid 2-[2-(2-{1,3-bis-[5-(biscarboxymethyl-amino)-5-carboxypentylcarbamoyl]-propylcarbamoyloxy}-ethoxy)-ethoxy]-ethyl ester) for 24−36 h. The substrates were then sonicated for 5 min in ethanol, rinsed with DI water, and blown dry with nitrogen.

Surface Modification of Gold Substrates for Contact Angle Measurements. Slides with a homogeneous 10 nm Cr and 100 nm Au layer were coated with SAMs for contact angle measurements. Prior to the formation of SAMs, all slides were cleaned as described in Surface Cleaning.

Scheme 1. Multi-Step Functionalization of Gold-on-Glass Substrates to Obtain NHS-Carboxyl and Bis-NTA SAMs on Gold, and a PEG Film on Glass



The octylmercaptan SAM was obtained as detailed in Formation of a SAM Composed of Octylmercaptan and evaporated as described in Removal of the Octylmercaptan SAM without the intermediate PEGylation step. Carboxyl or bis-NTA SAMs were generated by coating gold surfaces (whose octylmercaptan had been removed) with mercaptoalkane derivatives as specified in Formation of a Carboxyl-Terminated SAM and Generation of a SAM with Terminal bis-NTA Groups, respectively. Alternatively, mixed SAMs exhibiting carboxyl or bis-NTA functions were chemisorbed directly onto freshly cleaned gold surfaces without the intermediate steps of formation and removal of an octylmercaptan SAM.

Contact Angle Measurements. Contact angles were determined using a Dataphysics OCA 20 goniometer in combination with the SCA-20 software package (Dataphysics, Filderstadt, Germany). All measurements were performed with DI water under ambient laboratory conditions. Advancing and receding contact angles were measured with a starting volume of 5 μL, an oscillating volume of 8 μL, and a velocity of 0.2 μL/s.

Immobilization of Immunoglobulin-Cy3 and Streptavidin-Cy3 on Microstructured Substrates. The experiments were conducted using structured substrates with gold areas coated with SAMs of NHS-activated alkanethiols, and with glass areas displaying a PEG film. The slides were exposed to 0.1 μM Cy3-labeled immunoglobulin or 0.2 μM Cy3-streptavidin in HEPES buffer (10 mM HEPES, 140 mM NaCl, 5 mM KCl, 1 mM MgCl, pH 7.4) for 1 h. The surfaces were then rinsed in HEPES buffer and DI water, and analyzed using fluorescence microscopy.

Fluorescence Microscopy. Images of patterned surfaces were acquired using a fluorescence scanning device (*34*) based on an inverted epifluorescence microscope (Axiovert 200, Zeiss, Oberkochen, Germany). For all measurements, a 100× objective (Zeiss, α Plan-FLUAR 100×/1.45) was used. After mounting on a scanning stage (Märzhäuser, Wetzlar-Steindorf, Germany), the slides were illuminated with a diode-pumped solid-state laser with an emission line of 532 nm (Millennia Iis, Spectra Physics, Irvine, CA). Images were taken with a Photometrics CoolSnap HQ digital camera (Roper Scientific, Trenton, NJ) (1392 × 1040-element CCD; pixel pitch, 6.45 μm × 6.45 μm; 12-bit; QE, 0.6) using a time delayed integration mode (*34*). Bright fluorescent spots exceeding the maximum detection limit of the CCD camera were visualized by using a filter of optical density 1. V++ (Roper Scientific) was employed for image processing and analysis.

Immobilization of Virus Particles and VLDL-Receptors. To achieve covalent coupling of virus particles, slides with NHS-activated carboxyl SAMs were incubated with 10 μg/mL HRV2 in HEPES buffer followed by rinsing the slides with HEPES buffer. Covalent coupling of the MBP-VLDLR-His_6 was achieved by incubating slides with NHS-activated carboxyl SAMs in 20 μg/mL MBP-VLDLR-His_6 in HEPES buffer. Afterward, the slides were washed and incubated with 10 μg/mL HRV2 in HEPES buffer. Alternatively, MBP-VLDLR-His_6 was bound via metal−chelate complexes to bis-NTA-functionalized gold patterns by covering the slides with a protein solution of 20 μg/mL in Tris-Ni buffer (50 mM Tris, 1 mM $NiCl_2$, pH 7.4) for 2 h followed by rinsing in HEPES buffer. HRV2 was subsequently captured onto the VLDL-receptor surfaces by incubating the slides with the virus at 10 μg/mL (approximately 7.5×10^{11} particles/mL) for 2 h followed by rinsing in Tris-Ni buffer.

Atomic Force Microscopy. *Contact Mode AFM.* For contact-mode imaging, an Agilent 5500 AFM (Agilent Technologies Inc., Chandler, AZ) was used in combination with oxide-sharpened standard silicon nitride cantilevers (Veeco Instruments Inc., NY) with a nominal tip radius of 10 nm and spring constants *k* between 0.3 and 0.01 N/m. The contact mode images were acquired at a scan rate of 1.5 lines/s.

MAC Mode AFM. For acquiring images in MAC Mode, a magnetically driven dynamic force microscope (Agilent Technologies, Chandler, AZ) and magnetically coated MacLevers with a nominal spring constant of 0.1 N/m (Agilent Technologies) were used. During imaging, the vertical position of the cantilever was adjusted by using an electronic feedback loop

Table 1. Water Contact Angles of Carboxyl and Bis-NTA SAMs on Gold

in order to keep the amplitude of the oscillating tip constant. A scanning frequency of 1.5 lines/s was employed for all images. The peak-to-peak oscillation amplitude was set to 5 nm at 7.5 kHz oscillation frequency. Images were acquired in HEPES buffer (for the covalent coupling strategy) or Tris-Ni buffer (for the metal−chelate complex strategy) using a commercial AFM fluid cell.

RESULTS AND DISCUSSION

Targeted Surface Modification of Gold and Glass Areas on Microstructured Substrates. Solid supports composed of glass with 50 × 50 μm gold features were modified by chemically addressing the two different surface types (*32, 35, 36*). Self-assembled monolayers (SAMs) of carboxyl or bis-NTA alkanethiols were formed on gold squares (Figure 1A and B) to facilitate the binding of the viral receptors, while a dense layer of PEG was grafted onto the surrounding glass areas (Figure 1A and B) to render the surface nonadsorptive for the virus. The targeted modification of glass and gold was achieved by using a multistep procedure (Scheme 1). The first step involved the selective coating of the gold squares with a SAM composed of octylmercaptan (Scheme 1, step i), which rendered the surface nonreactive against further chemical modification. In the next step, a PEG layer was formed on the nonblocked glass areas (Scheme 1, step ii) by reacting trimethoxysilane-terminated PEG with the silanol groups of glass. The octylmercaptan SAM was then removed by heating the slides, leaving behind blank gold surfaces (Scheme 1, step iii) (*31*). The gold squares were subsequently coated with a SAM composed of alkanethiols carrying terminal carboxyl groups (Scheme 1, step iv), which were activated with *N*-hydroxysuccinimide (Scheme 1, step v). Alternatively, the bare gold features were functionalized with alkanethiols carrying terminal bis-NTA groups (Scheme 1, step vi).

Analysis of SAMs Using Contact Angle Measurements. The multistep formation of SAMs (Scheme 1, steps i, iii, iv, and vi) was monitored using water contact angle goniometry. Goniometry detects changes in the composition of surfaces with high sensitivity (*37−42*). Our measurements were conducted with slides carrying homogeneous gold films rather than microstructured substrates because the 50 × 50 μm features were much smaller than the water drops. The advancing (θ_a) and receding (θ_r) contact angles of water were measured (Table 1). Treating freshly cleaned gold surfaces (θ_a and θ_r values of 87 ± 3° and 65 ± 2°, respectively) with octylmercaptan increased the contact angles by 15 and 19°, respectively (Table 1), in line with the formation of a hydrophobic SAM. Removal of the octylmercaptan layer by heating lowered the contact angles close to the initial values of cleaned gold (Table 1). The subsequent formation of a carboxyl SAM composed of 12-mercaptododecanoic acid and 16-mercaptohexadecanoic acid was accompanied by a substantial reduction of θ_a and θ_r to 51 ± 2 and 44 ± 3°, respectively (Table 1), in agreement with literature values of related carboxyl SAMs (*43*). Importantly, the hysteresis of the COOH surface with a value of 7 ± 2° was much lower than the hysteresis of the octylmercaptan surface (18 ± 1°) or of thermally treated gold (20 ± 1°) (Table 1). A reduction in hysteresis is typical for hydrophilic surface coatings of high homogeneity (*39*) and therefore indicates the quality of the carboxyl surface. Furthermore, contact angles and hysteresis of the carboxyl SAM are identical, within experimental error, to the corresponding values of surfaces that were obtained by direct modification from bare gold surfaces which had not been subjected to coating and removal of the octylmercaptan SAM (Table 1). The data strongly suggest that the stepwise surface modification procedure was able to reversibly coat gold surface with octylmercaptan as well as to form a SAM carrying terminal carboxyl groups.

By comparison, generating SAMs with bis-NTA groups on thermally treated slides led to advancing and receding contact angles of 33 ± 1 and 28 ± 1°, respectively (Table 1), which is lower than the values of the carboxyl surface (Table 1). The bis-NTA SAM is more hydrophilic than the carboxyl SAM because it contains a 20-fold excess of oligo(ethylene glycol), which is known to result in low contact angles (*44, 45*). Similar to the carboxyl surface, bis-NTA SAMs had a low hysteresis value of 5 ± 1° (Table 1) indicative of a homogeneous surface layer (*44−46*). As a further indication of a dense film, direct bis-NTA modification using bare gold surfaces led to contact angle and hysteresis values, which were identical to those obtained using the octylmercaptan route (Table 1).

AFM Analysis of the PEG Film on Glass. The PEG layer on glass surfaces obtained in step (ii) of Scheme 1 was characterized by AFM in order to determine the film's homogeneity and thickness. AFM is a sensitive tool to probe the quality of PEG films (*38, 46*). Typical topographic images of a bare glass surface before and after PEG coating are shown in Figure 2A and B, respectively. The root-mean-square (rms) noise of the surface roughness for bare glass (Figure 2A) was 1.46 ± 0.23 nm (n = 14), in line with the visible topographic structures, which are partially caused by the cleaning procedure. The rms roughness dropped to 0.22 ± 0.01 nm (n = 14) for PEG-coated glass (Figure 2B), indicative of a compressible polymeric film. In further support of a homogeneous layer, AFM images of the PEGylated glass did not reveal any visible surface defects (Figure 2B). The thickness of the PEG layer was determined by using the AFM cantilever as a stylus to scratch a hole into the film and then measuring the step of the height profile. The observed step size of 2 nm (Figure 2C) compares well with the thickness of PEG films in other studies (*47−49*). On the basis of the known polymer density of PEG and its MW of 500 Da, we calculated (*50*) a high surface density (400 pmol/cm^2) and a corresponding average molecular cross-sectional area of 41 Å^2 per polymer chain. This value indicates a very compact PEG layer because the molecular cross-section of PEG in a crystal of idealized helical form is 21.3 Å^2 (*51*).

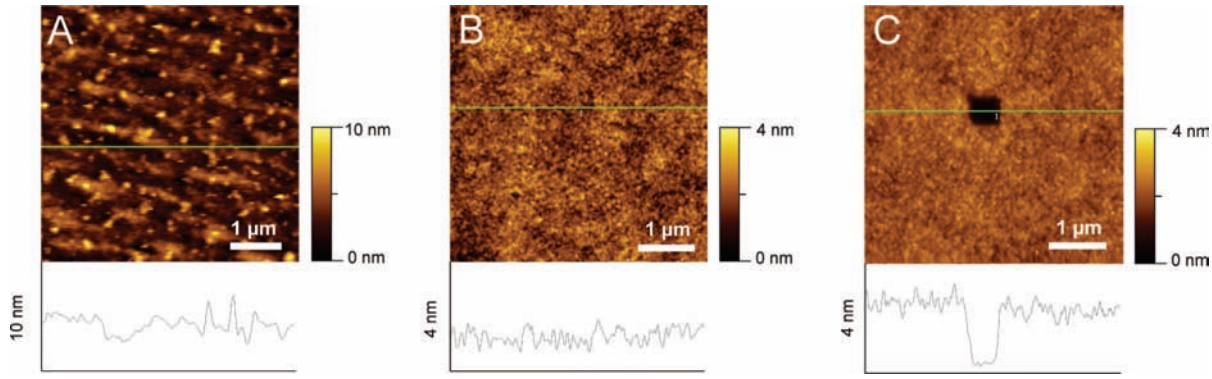

Figure 2. AFM analysis of PEG films on glass areas. (A) Topographic image of a cleaned bare glass surface. (B) Image of a PEG film on a glass surface. (C) A 500 × 500 nm square was scratched into the PEG film. The step size in the height profile is ~2 nm. The scan range is 5 × 5 μm for all images.

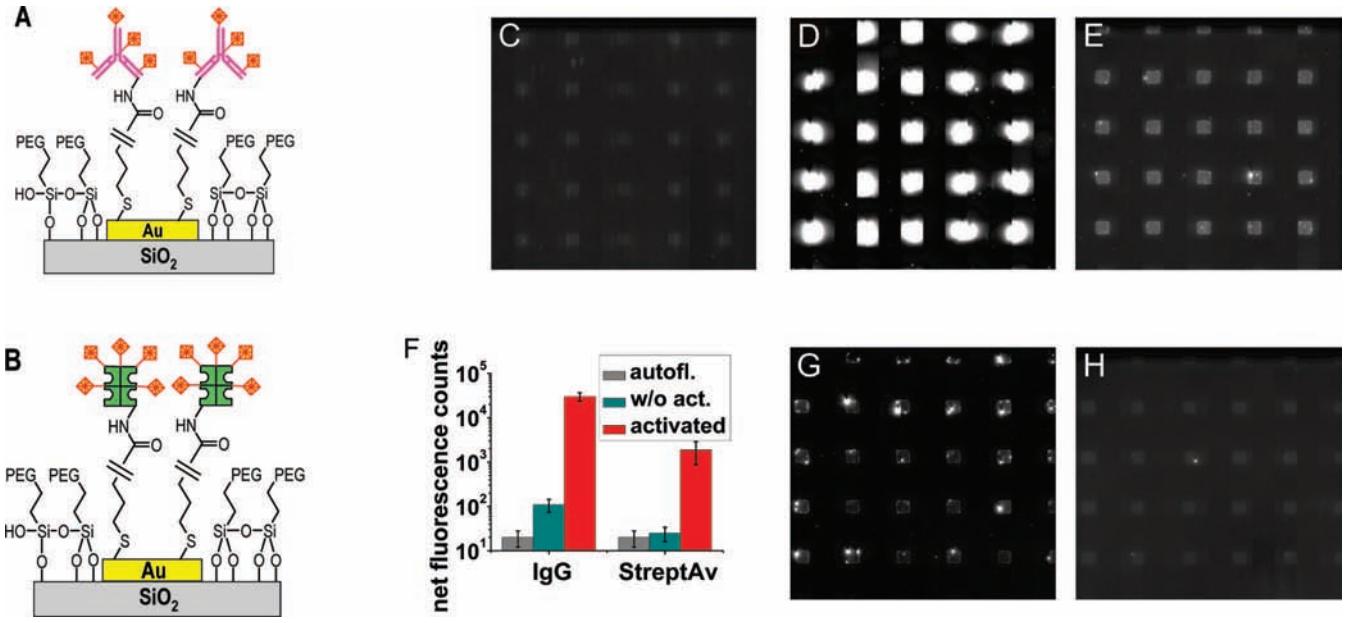

Figure 3. Fluorophore-labeled IgG and streptavidin covalently couple onto NHS-activated carboxyl SAMs on gold squares. (A,B) Schematic illustration of IgG-Cy3 and streptavidin-Cy3 covalently coupled onto NHS-carboxyl SAMs. (C,D) Fluorescence images of bare NHS-carboxyl slides prior to (C) and after (D) exposure to 0.1 μM IgG-Cy3. (E) Image of a nonactivated carboxyl SAM after exposure to IgG-Cy3. (F) Average fluorescence counts on gold squares before and after exposure to fluorescence-labeled protein. The values represent the arithmetic mean ± SD of ten different places on two independently prepared samples. (G,H) Fluorescence images of NHS (G) and carboxyl-coated gold (H) after incubation with 0.2 μM streptavidin-Cy3. Images D and G were obtained using a filter of optical density 1; all other images were acquired without attenuation. The stripes in D are an artifact of the fluorescence scanning procedure but do not interfere with the quantitative analysis of the fluorescence counts. The bright features deviate from the expected square structure as their brightness was within saturation of the fluorescence scanner. The micrographs show an area of 750 × 750 μm^2.

Covalent Coupling of Fluorescence-Labeled Proteins onto NHS-Activated Carboxyl SAMs. Selective covalent attachment of labelled proteins to the NHS-carboxyl gold surfaces was assessed using a fluorescence-based assay. The same assay also probed the absence of nonspecific adsorption of the protein to the PEGylated glass areas. Slides carrying either NHS-activated carboxyl or –for control purposes- non-activated carboxyl groups were incubated with solutions of Cy3 fluorescence-labeled IgG (Figure 3A) and streptavidin (Figure 3B). After removing loosely adsorbed protein in a washing step, the amount of surface-bound protein was quantified by using epifluorescence microscopy. Figure 3C depicts the fluorescence image of an NHS-carboxyl surface, prior to incubation with protein. The regular pattern of gold squares with 150 ± 8 fluorescence counts is discernible from the glass substrate (130 ± 4 cts) because the incident light is weakly reflected from the gold surface. Incubation with 0.1 μM IgG-Cy3 in HEPES buffer (pH 7.2) led to a drastic increase in the fluorescence on the gold squares (Figure 3D, 30130 ± 6390 cts) indicating coupling of the immunoglobulin to the NHS-carboxyl surface. The immobilization was certainly due to the formation of amide bonds between lysine residues of IgG and the carboxyl groups of the SAM because nonactivated carboxyl SAMs without NHS ester functions bound much less protein (Figure 3E, 239 ± 35 cts). The fluorescence counts are also summarized in Figure 3F. A quantitative comparison of these values using the factor ($counts_{NHS,IgG} - counts_{carboxyl,IgG}$)/$counts_{Gold}$ reveals that the NHS-decorated surface leads to a 200-fold higher binding of IgG compared to carboxyl-terminated gold substrates.

The ability of NHS ester surfaces to couple protein was also tested with streptavidin-Cy3. The tetrameric streptavidin possesses a total of 12 surface-exposed lysine residues. This is less than the approximately 30 surface-exposed lysine residues in IgG (PDB ID, 1IGT) (*52*). Given that the covalent coupling to NHS surfaces is mediated by primary amines, it was expected that streptavidin with fewer lysines would be more challenging to immobilize. Moreover, the number of available lysines on the streptavidin-Cy3 surface is further reduced because on

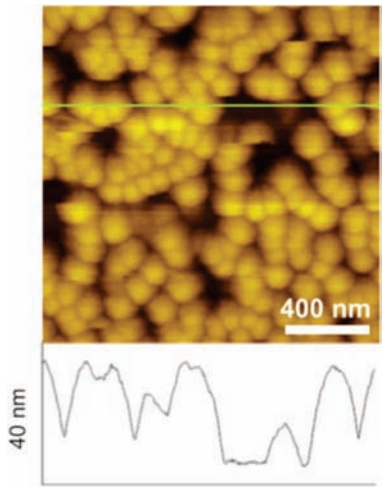

Figure 4. Topographic AFM image of human rhinovirus type 2 adsorbed in Tris-Ni buffer onto mica.

average, six residues are coupled to the Cy3 fluorophores. By comparison, the molar labeling ratio for IgG-Cy3 is four. Images of NHS and carboxyl surfaces incubated with 0.2 μM streptavidin-Cy3 are shown in Figure 3G (2000 $\pm$ 1000 cts) and 3H (155 $\pm$ 9 cts), respectively. The gold areas are less bright than the corresponding surfaces covered with IgG-Cy3 (Figure 3D and 3E). This is in line with the expected lower extent of immobilization for streptavidin. A lower degree of covalent coupling was also apparent from the analysis of fluorescence counts. NHS activation only led to a 12-fold increase in coupled streptavidin when compared to that of carboxyl-terminated gold surfaces (Figure 3F).

All samples displayed low fluorescence counts on the PEG-coated areas, implying that the polymeric layer effectively repelled the labeled protein. For example, the fluorescence counts of PEG areas from NHS-activated slides before incubation with IgG-Cy3 was 132 $\pm$ 3 cts, while incubation with IgG-Cy3 resulted in a very similar fluorescence count of 128 $\pm$ 3. The passivation of the glass surface by a dense layer of PEG is in line with other reports (*33, 35, 38, 53, 54*).

The analysis of fluorescence counts provides insight into the ability of the NHS and PEG surfaces to couple and repel, respectively, proteins. A quantitative comparison between gold and glass surfaces is, however, not possible because of the partial fluorescence quenching by gold (*55, 56*).

Targeted Binding of Viral Receptors and Viral Particles to NHS-Carboxyl and Bis-NTA Surfaces. We compared the ability of NHS-carboxyl and bis-NTA surfaces to bind receptors and viral particles. For the binding assays, MBP-VLDLR-His_6 and HRV2 were used. The appended MPB and His_6 tags in the receptor do not affect its ability to recognize and bind human rhinoviruses (*1*).

HRVs have a diameter of 30 nm as determined by X-ray crystallography (*57*). The same size was also obtained via AFM from the step height in the topographic profile (Figure 4). The AFM image was acquired in the MAC Mode, which uses an external oscillating magnetic field to deflect the cantilever. As the imaging forces are smaller than those in contact mode, the MAC Mode is better suited to image soft biological materials (*58, 59*).

Three different coupling strategies were compared to determine the best one for high-density surface capture of viral particles. In approach A, virions were covalently coupled onto NHS-carboxyl SAMs (Figure 5A). In strategy B, MBP-VLDLR-His_6 was covalently immobilized onto the NHS-carboxyl surface, and viral particles were then captured onto the receptor spots via molecular recognition (Figure 5B). Route C also used the receptor-mediated capture of viral particles, but MBP-VLDLR-His_6 was bound via Ni−chelate bridges to the bis-NTA SAM (Figure 5C). In all three cases, the gold squares were surrounded by PEG-coated glass areas. A secondary aim of the experiments was therefore to probe the ability of the polymer film to prevent the nonspecific adsorption of viral particles onto the glass surfaces.

Binding assay A was conducted by incubating microstructured slides featuring NHS-carboxyl-coated gold squares with a 10 μg/mL suspension of HRV2 in 10 mM HEPES buffer for 2 h. In strategy B, the NHS-carboxyl slides were first treated with a 20 μg/mL solution of MBP-VLDLR-His_6, followed by a washing step and incubation with 10 μg/mL HRV2 in HEPES buffer for 2 h. For strategy C, MBP-VLDLR-His_6 was used in 50 mM Tris buffer supplemented with 1 mM $NiCl_2$ to facilitate metal−chelate-mediated binding onto the bis-NTA-coated gold. HRV2 was captured onto the receptor spots in the same Ni(II)-containing buffer. After each incubation step, the slides were rinsed to remove loosely bound protein or virus particles and imaged using contact mode or MAC Mode AFM, as specified below.

Samples from the direct covalent coupling strategy A (Figure 5A) yielded a typical topographic contact mode image as shown in Figure 6A. The 50 $\times$ 50 μm gold square in the center of the image is clearly visible. The brighter areas on top and at the bottom of the gold square are glass surfaces but their apparent height is skewed by a flattening artifact (*60*). A magnified image of the gold surface (Figure 6B) revealed elevated features with a height of approximately 30 nm, which represent individual or clusters of viral particles. Their surface density had a value of 756 $\pm$ 158 particles per 100 μm^2 (four independent

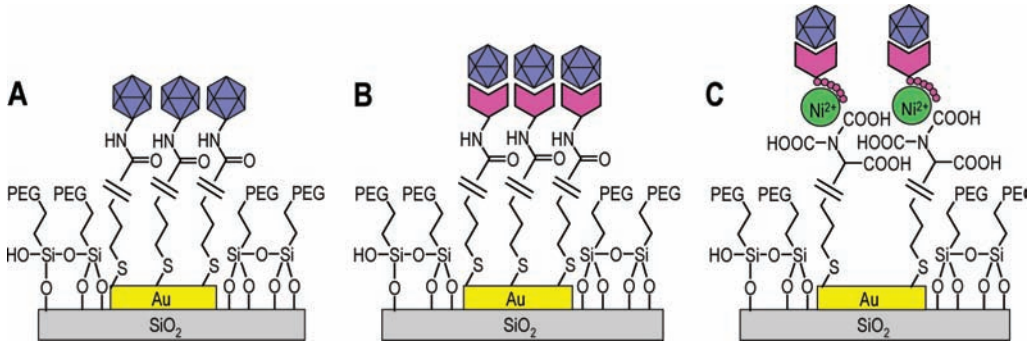

Figure 5. Schematic representation of three coupling strategies used for the immobilization of viral particles onto gold surfaces. (A) Covalent coupling of viral particles onto NHS-carboxyl surfaces. (B) Coupling of viral MBP-VLDLR-His_6 receptors onto NHS SAMs, and the binding of viral receptors via molecular recognition. (C) Immobilization of the His_6-tagged VLDL receptors onto bis-NTA SAMs via Ni(II) chelate complexes, and the molecular recognition of viral particles. For reason of visual clarity, the simplified structures of the SAM components are displayed. See Scheme 1 for the detailed structures.

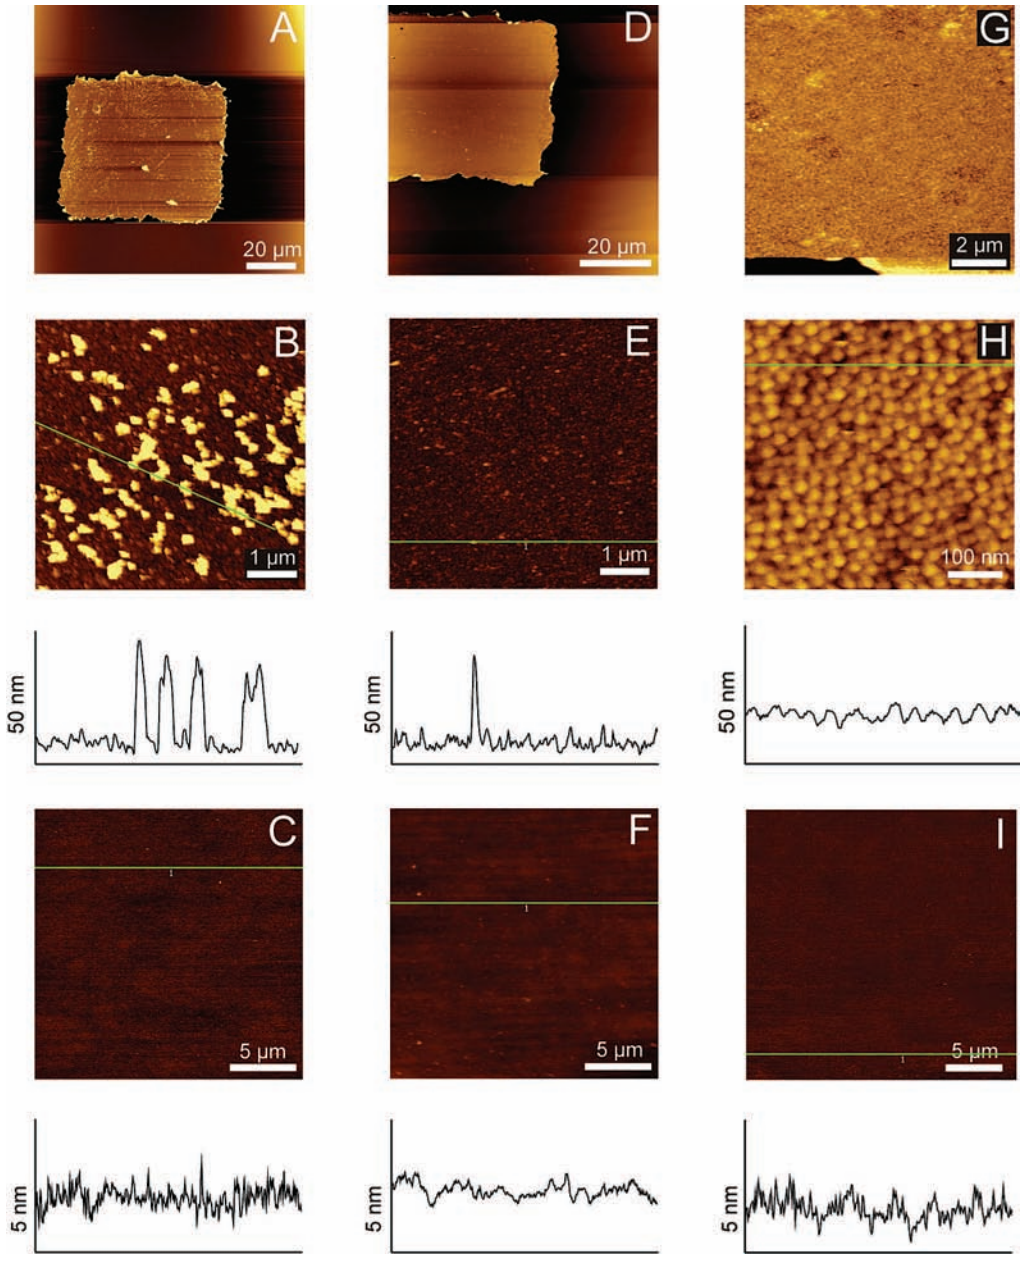

Figure 6. Capturing of viral particles onto receptor-coated gold surfaces via coupling strategies A, B, and C as shown in Figure 5. Topographic AFM images of slides were obtained via strategies A (A−C), B (D−F), and C (G−I). The images display an overview of functionalized gold squares and surrounding glass areas (A, D, and G), a magnified view of the gold surfaces (B, E, and H), and a zoom-in of the PEG-coated glass surfaces (C, F, and I). All images were acquired using the AFM contact mode except for images G, H, and I, which were obtained in MAC Mode. The experiments were repeated twice and gave the same results.

measurements), as determined using an algorithm. The algorithm was based on the detection of topographic peaks above a threshold value of 20 nm, which compares to a diameter of 30 nm for the viral particle. The AFM analysis of the PEG surface showed much fewer peaks (Figure 6C, 1.0 ± 0.8 particles per 100 μm^2), thereby demonstrating that the polymeric layer had effectively prevented the nonspecific adsorption of viral particles, in agreement with the known surface passivating properties of PEG against proteins, cells, or DNA (*33*, *35*, *38*, *53*, *54*).

Strategy B, that is, covalent coupling of MBP-VLDLR-His_6 and the molecular capturing of HRV2 particles (Figure 5B), yielded a contact mode image as shown in Figure 6D. The gold square appeared smoother than the surface from the previous coupling strategy A (Figure 6A). Indeed, a magnified image of the gold area displayed almost no viral particles (Figure 6E). The low density of particles (2.5 ± 1.3 per 100 μm^2) may reflect that very little or no MBP-VLDLR-His_6 had covalently coupled onto the NHS surface. Alternatively, it is also possible that the viral receptor was coupled but lost its binding activity due to steric hindrance or denaturation. Nevertheless, it can be ruled out that MBP-VLDLR-His_6 generally loses its binding activity upon immobilization because the surface-tethered receptor has been used successfully in previous virus-binding studies (*1*).

In contrast, strategy C takes advantage of metal−chelate binding of MBP-VLDLR-His_6 (Figure 5C), and yielded gold surfaces that were densely packed with viral particles (Figure 6G, MAC Mode). A section of the gold square (Figure 6G, top) featured a corrugated surface, while the PEG surface was smooth (Figure 6G, bottom stripe at left). The gold surface was covered with densely spaced clusters of viral particles as displayed in a magnified view (Figure 6H) corresponding to a surface density of 99200 ± 3100 particles per 100 μm^2. In comparison, the very few particles that nonspecifically adsorbed onto PEG areas (Figure 6I) resulted in a low surface density of 0.3 ± 0.2

particles per 100 μm^2. Using the measured surface densities on bis-NTA-derivatized gold and PEG-coated glass, we calculated the very high selectivity factor of over 330 000 for the preferential binding of viral particles onto MBP-VLDLR-His_6 patches.

In this study, we have explored strategies to selectively immobilize viral particles and their cognate receptors onto gold surfaces. Two types of alkanethiol-coated gold surfaces were examined. SAMs were either modified with terminal *N*-hydroxysuccinimide-activated carboxyl or bis-nitrilo-triacetic acid groups. The ability of activated esters to bind protein via covalent amide bonds was confirmed using fluorescence-based assays. The experiments with fluorophore-labeled IgG and streptavidin also highlighted that a higher number of surface-exposed lysine residues increases the extent of immobilization to NHS groups.

The effectiveness of bis-NTA and NHS surfaces was assayed by measuring the density of the captured particles with AFM. Among the three strategies, A, covalent binding of virions, B, covalent binding of viral receptor, and C, binding of the receptor via metal chelate bonds followed by non-covalent binding of virus, route B produced the lowest density of captured particles. It is unlikely that no MBP-VLDLR-His_6 was coupled to the NHS-derivatized SAM because the receptor construct contains 30 surface-exposed lysine residues, which are all located in the N-terminally fused maltose-binding protein. It is therefore most likely that the inability to capture viral particles is accounted for by an unfavorable orientation of the surface-bound receptor, which sterically blocks interaction with the virions. It is possible that the lysine-rich maltose binding protein covalently tethers the N terminus of MBP-VLDLR-His_6 to the surface, while the C-terminal hexahistidine tag electrostatically interacts with the negatively charged, hydrolyzed NHS groups.

Immobilization strategy A, direct covalent binding of virions, yielded higher surface densities. The better performance of approach A as compared to that of route B is somewhat surprising because the molar concentration of virions of 1.3 nM is much lower than the concentration of the VLDL-receptor (280 nM). In addition, the lower diffusion coefficient of the bigger viral particles should slow down the reaction with the NHS surface. Apparently, these factors were outweighed by the high number of surface-exposed lysines (>200) on the viral surface and the concomitant increased extent of reaction with the activated esters.

Approach C resulted in the highest surface densities of viral particles. The excellent performance can be singularly attributed to the use of the bis-NTA surface and the coupling of MBP-VLDLR-His_6 via metal−chelate complexes, because, in comparison to strategy B, all other parameters such as the concentration of viral receptors and particles were the same. It is most probable that bis-NTA is superior to NHS because the chelate-forming group maintains its capacity to bind receptors, while the activated ester suffers hydrolysis and inactivation (*61*). In addition, bis-NTA tethers MBP-VLDLR-His_6 via its C-terminal His_6 tag, which orients the virus-binding moiety of the receptor away from the surface, rendering it highly accessible, while the coupling of protein to the NHS surface can occur for all exposed lysine residues leading to a more randomized orientation of the receptor molecules on the substrate. The advantage of oriented immobilization for protein function has been demonstrated in the context of other studies (*62*−*65*). Here, we have shown a particular realization of this principle, which can be employed in the orthogonal biofunctionalization of micropatterned surfaces.

CONCLUSIONS

In conclusion, this study describes methods with thus far unprecedented selectivity for capturing viral particles on gold-over-glass surfaces. The high-density immobilization of viral receptors is the result of a combination of several advantages such as the conservation of the bis-NTA reactivity and its ability to bind His_6-tagged proteins in an oriented fashion. By comparing the coupling of proteins via covalent bond formation, metal chelation, molecular recognition, or a combination of them, our study provides insight into factors that influence the immobilization of proteins. By providing an experimental strategy for maintaining the biological activity of immobilized receptors (*35*, *65*−*67*) while averting nonspecific binding of ligands using passivating PEG layers, this work is relevant to the wide field of micropatterned biofunctionalization because efficiently addressing glass and gold surfaces for the high-density immobilization of receptors may also be used to selectively capture other protein assemblies, proteins, or cells. We expect that our surface modification approach can be applied to further miniaturize viral arrays to nanoscale dimensions.

Optical Properties and Application of a Reactive and Bioreducible Thiol-Containing Tetramethylrhodamine Dimer

R. James Christie, Constantino J. Tadiello, Lisa M. Chamberlain, and David W. Grainger*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523-1872. Received August 28, 2008; Revised Manuscript Received January 20, 2009

Thiolated dimeric tetramethylrhodamine (TAMRA) was synthesized in a straightforward procedure utilizing commercially available 5(6)-succinimidyl TAMRA and cystamine hydrochloride. The thiol-containing TAMRA dimer displayed distinct spectral properties in reduced and oxidized forms; covalent dimer formation produced greater effects on the spectral properties than previously reported for noncovalent TAMRA dimers or dimers formed with shorter carbon spacers. The resulting TAMRA disulfide dimer exhibited a hypsochromic shift of 34 nm relative to the reduced monomer species and an isosbestic point at 532 nm between reduced monomeric and oxidized dimeric forms. Molar extinction coefficients of the monomer and dimer relative to moles of TAMRA were similar (6.61×10^4 M^{-1} cm^{-1} and 6.42×10^{-4} M^{-1} cm^{-1}, respectively). However, fluorescence emission was altered with >93% of dye fluorescence quenched in phosphate buffered saline upon dimer formation. A 520:554 nm absorbance intensity ratio of 2.64 was observed for the oxidized ssTAMRA dimer, almost twice as high as values reported for noncovalent TAMRA dimers. The resulting disulfide dye was easily reduced using both soluble and agarose gel immobilized tris(2-carboxyethyl) phosphine and fresh cell lysate from cultured RAW 264.7 macrophage cells. Absorbance intensity ratios at 554 and 520 nm were used to determine the oxidation half-life of a 1.2×10^{-5} M solution of reduced TAMRA stored in ambient atmosphere to be ~50 h at 22 °C. The free thiol dye was further reacted with maleimide-derivatized poly(hydroxypropyl methacrylamide) to yield the dye-labeled polymer conjugate. This dye derivative should prove useful as a dithiol reduction-sensitive fluorescent probe in cellular tracking systems, as well as a thiol-based dye-labeling reagent due to its easy preparation from readily available materials, environmental sensitivity, and simple activation to produce distinct spectral states. The enhanced spectral properties of the covalent TAMRA dimer described here could be useful to prepare more advanced reporter molecules and bioconjugates.

INTRODUCTION

Reactive fluorescent dyes have many biological and biomedical applications as assay reporters and tracking molecules both in vitro and in vivo (*1*−*4*). A number of reactive fluorescent dyes are commercially available containing functional groups such as *N*-hydroxy succinimide (NHS) esters, isothiocyanates, maleimides, or iodoacetamides to couple with naturally occurring reactive amine and thiol functional groups on peptides, nucleic acids, saccharides, proteins, and other biomolecules (*5*). Currently, several thiolated fluorescent dyes are commercially available, produced by modification of fluoresceine (Invitrogen and Toronto Research Chemicals Inc.), tetramethylrhodamine (TAMRA), sulforhodamine, dansyl, and Texas Red (Toronto Research Chemicals Inc.). These dyes are available with protective groups (acetyl, methanethiosulfonate) attached to the desired reactive thiol or sold as the free mercaptan form (although a mixture of disulfide and mercaptan dyes is likely). Of the above-mentioned reactive dyes, care must be taken when using fluorescein-based derivatives, as they are known to be pH-sensitive, with quantum yield decreasing by ~70−80% upon acidification and formation of the neutral molecule (*6, 7*). Observing such fluorescein-labeled molecules that are trafficked to lysosomes within cells is difficult due to decreased dye fluorescence signal within these acidic subcellular compartments.

The current popularity of reducible disulfide-containing polymeric cellular delivery systems for therapeutic transgenes, tumor drugs, and imaging agents merits development of new disulfide exchange reagents capable of providing intracellular reporting information on cell-based polymer degradation (*8*−*10*). Investigation of a nonexotic dimeric thiol-containing, pH-insensitive, reactive fluorescent dye reagent was the focus of this work. Tetramethylrhodamine (TAMRA) was chosen for this study because of its excellent photostability, and its quantum yield is unaffected at acidic pH (*11*). In fact, several intracellular pH estimates have been described on basis of the ratio of fluorescence signal from simultaneous observations of fluorescein and TAMRA (*12*−*14*).

In this short work, we reevaluate the optical properties of dimeric TAMRA with the dimer covalently linked via a disulfide bond. This dimer was reversibly converted to monomer by addition of disulfide reducing agent or biological milieu. The observed effect of covalent dimer formation on fluorescence and absorption spectra was significantly higher than previously observed in noncovalent dimer systems.

EXPERIMENTAL PROCEDURES

General. All solvents and reagents were purchased from commercial sources and used as received. NMR spectra were recorded on a Magnex Scientific Inova 400 MHz instrument in DMSO-d_6 containing 5% w/v tetramethylsilane as an internal standard. Absorbance measurements were obtained on a Varian Cary 500 Scan and BioTek Synergy 2 plate reader instruments. All samples were weighed to the nearest 0.01 mg using a Mettler Toledo Pro Balance 220/81 GX 0.1/0.01MG analytical balance.

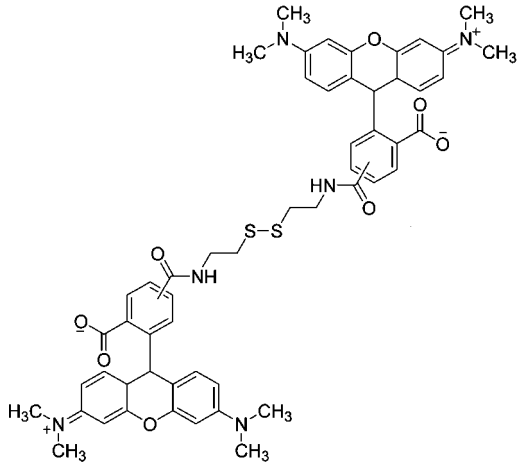

Figure 1. Structure of ssTAMRA dimer.

Size exclusion chromatography was performed using a HP1050 HPLC system equipped with a HP1040A refractive index detector and Biosil 125 column. Sodium phosphate buffer (0.05 M, pH 7.4) mobile phase, 100 μL sample injection, and 0.5 mL/min flow rate was used for each analysis. RAW 264.7 murine monocyte-macrophage cells were obtained from the American Type Culture Collection (Manassas, VA) and cultured in RPMI 1640 (Mediatech) supplemented with 10% fetal bovine serum (FBS, HyClone, Inc.) and 1% penicillin−streptomycin (Life Technologies). Cultures were maintained in T-175 TCPS flasks (Nunc) under standard conditions: incubation at 37 °C, 98% humidity, and 5% CO_2, and dissociated from culture flasks by incubation with Ca^{2+}- and Mg^{2+}-free cell culture grade Hank's balanced salt solution (HBSS, Life Technologies).

Synthesis of Disulfide TAMRA Dimer. TAMRA disulfide dimer (ssTAMRA) was prepared by reacting 5-(6)-carboxytetramethylrhodamine, succinimidyl ester (5(6) TAMRA-NHS, AnaSpec) with cystamine hydrochloride activated using diisopropylethylamine (DIPEA). In a typical experiment, 9.6 mg cystamine hydrochloride (0.085 mmol, 0.9 equiv amines) was activated in 2.5 mL dimethylformamide (DMF) containing 30 μL DIPEA (0.17 mmol, 1.8 equiv). This solution was then added to a solution of 50.0 mg TAMRA-NHS (0.095 mmol, 1.0 equiv) in 1.5 mL DMF and stirred at room temperature for 30 min. Then, 15 μL (0.086 mmol, 1.0 equiv) of DIPEA was added and the reaction was stirred for an additional hour. Product was precipitated by addition of 50 mL cold diethyl ether, washed several times with diethyl ether, and dried under vacuum overnight. Solids were further purified by repeated precipitation from methanol into cold ether. Product yield: 75%. Formation of the desired dimer was confirmed by mass spectrometry, MS-FAB M[H^+] calculated = 977.336, found = 977.334. ^{1}H NMR analysis confirmed formation of the new amide bonds, with four relevant peaks observed in an unambiguous region of the spectrum, corresponding to combinations of 5 and 6 TAMRA isomers (8.58, 8.91, 9.00, 9.07 ppm, triplets, total integration = 2H). The structure of ssTAMRA is shown in Figure 1.

Determination of Molar Extinction Coefficients. ssTAMRA was dried under vacuum overnight, then weighed to the nearest 0.01 mg inside a 200 mL (±0.1 mL) volumetric flask and subsequently dissolved in 200 mL buffer (0.01 M sodium phosphate, 0.15 M NaCl, 10 mM EDTA, pH = 7.2). This solution was then serially diluted using 25 mL (±0.03 mL) volumetric flasks. The absorbance at 520 nM was measured to the nearest 1×10^{-6} absorbance units using a Varian Cary 500 Scan spectrometer. The molar extinction was determined as the slope of the best-fit line of a plot of absorbance vs concentration ($y = 128\,358x$, $R^2 = 0.9999$), and further normalized to moles TAMRA by dividing this value by 2. The molar extinction of reduced sTAMRA was determined in a similar fashion, except that ssTAMRA was dissolved in phosphate buffer supplemented with 10 mM TCEP·HCl and then incubated for 30 min at room temperature before preparing diluted samples. The resulting best-fit line from a plot of absorbance vs concentration was found to be $y = 66\,131x$, $R^2 = 0.9999$. The sample purity was assumed to be 100%, as no starting material was observed in mass spectrometry or NMR measurements.

Oxidation of sTAMRA. Disulfide oxidation was determined following complete reduction of ssTAMRA with agarose gel-immobilized TCEP (Pierce) in buffer (0.01 M sodium phosphate, 0.15 M NaCl, 10 mM EDTA, pH 7.2). Upon removal of reducing agent by filtration, the resulting sTAMRA solution (1.2×10^{-5} M) was capped under ambient atmosphere and maintained in the dark at room temperature (22 °C), and absorbance spectra were recorded at various times. The rate of disulfide formation was determined by plotting the 554/520 nm absorbance ratios.

Reduction of ssTAMRA with Cell Lysate. Reduction of ssTAMRA was monitored in RAW 264.7 murine monocyte−macrophage cell lysate over time. In this experiment, 1 mL of M-PER cell lysate solution (Pierce, Rockford, IL) was added per 1 g of cell pellet, and the resulting solution was processed per manufacturer recommendations and stored at −20 °C prior to use. Cell lysate solution was diluted 1:1 with ssTAMRA solution to yield a final TAMRA concentration of 1.15×10^{-5} M and then incubated at room temperature in a microwell plate. TAMRA absorbance at both 554 and 520 nm was measured at various times using a BioTek Synergy 2 plate reader.

Conjugation of sTAMRA to Poly[*N*-(2-hydroxypropyl)methacrylamide]. Poly *N*-(2-hydroxypropyl)methacrylamide] (HPMA) copolymer containing reactive esters, further converted to hydrazide groups, was prepared as previously described (*15*). Prior to hydrazide modification, a portion of reactive esters were used to conjugate Oregon Green 488 fluorescent dye to the polymer backbone (~0.7 dyes/polymer) by reaction with amine-containing Oregon Green 488 cadaverine in the presence of DIPEA in DMF. Finally, hydrazides were converted to maleimide groups by reaction with the heterobifunctional cross-linker *N*-4-(acetylphenyl) maleimide (APM). Preparation of the reactive HPMA copolymer is outlined in the Supporting Information.

Dimeric ssTAMRA (7.0 mg, 1.6 μmol) was reduced using TCEP reducing gel (2.5 mL slurry/μmol ssTAMRA dimer) for 45 min, followed by removal of the reducing agent by filtration through a 0.2 μm filter. Reduced sTAMRA was then reacted with maleimide-derivatized poly(HPMA) (40.45 mg, 1.60×10^{-6} mol maleimide groups) for 1.5 h in 0.01 M sodium phosphate, 0.15 M NaCl, 10 mM EDTA, pH 7.2; then, remaining maleimide groups were quenched by addition of 2 μL β-mercaptoethanol. The dual dye-labeled poly(HPMA) product was separated from free sTAMRA dye and desalted using size exclusion chromatography (SEC) (Sephadex G-25, 15 × 1 cm, H_2O mobile phase), then isolated using a speed-vac. TAMRA content was determined by absorbance measurements at 554 nm using $\varepsilon = 6.4 \times 10^4$ M^{-1} cm^{-1}. The polymer−TAMRA conjugate was analyzed by SEC; BioSilect 125 column, 0.5 mL/min 0.01 M sodium phosphate buffer containing 0.15 M NaCl and 10 mM EDTA, pH 7.2.

RESULTS AND DISCUSSION

Synthesis of the disulfide-containing ssTAMRA probe was readily achieved by nucleophilic displacement of NHS esters contained on TAMRA by cysteamine's two terminal amines. Cysteamine was selected as the starting material, because it contains an internal disulfide bond; thus, only amide formation between cysteamine and TAMRA facilitates formation of the

disulfide-containing dimer. Preparation of dimeric fluorescent reporter molecules has received much attention due to the different spectral properties of these molecules in monomeric and dimeric forms (*16*−*18*). Spectral properties of the reduced monomeric TAMRA (sTAMRA) and oxidized dimeric thiolated TAMRA (ssTAMRA) are summarized in Table 1. Reduction of the disulfide was readily achieved after incubation in 10 mM tris(2-carboxyethyl) phosphine hydrochloride (TCEP·HCl), with no increase in 554 nm sTAMRA monomer absorbance observed after 30 min, indicating complete reduction. Oxidized ssTAMRA exhibited a hypsochromic shift of 34 nm relative to the reduced sTAMRA absorption maximum, which was close to native TAMRA (Figure 2a, Table 1). This phenomenon has been observed for concentrated aqueous solutions of rhodamine B with the formation of noncovalent dimers (dissociation constant of 6.8×10^{-4} M) observed at mM concentrations (*19, 20*). This hypsochromic shift has also been used to study conformation and subunit exchange of *E. coli* ribosomal protein L7/L12, and conformation of the muscle protein, titin, with cysteine thiol groups labeled with tetramethylrhodamine iodoacetamide (*21, 22*). These studies utilized the ratio of noncovalent dimer absorbance at 518 nm to monomer absorbance at 555 nm to determine proximity of TAMRA labels on the protein, with a 518/554 absorbance ratio of 1−1.3 reported for noncovalent dimeric TAMRA (*21*). Additionally, a 519/550 ratio for an analogous covalent TAMRA dimer linked by thiourea bonds and an ethylene spacer has been reported to be 1.5 (*23*). Results for ssTAMRA in this study show a 520/554 ratio of 2.64 for the covalent disulfide dimer, exceeding all spectral ratios previously described and indicating significantly that the longer disulfide 4-carbon spacer used in this study allows for increased dye interaction and enhanced spectral properties. This ratio might also be further increased by using pure starting material, instead of mixed 5 and 6 TAMRA-NHS isomers as reported here.

Dimer formation had no affect on optical absorption of attached TAMRA, as molar extinction coefficients for reduced and oxidized species were nearly identical. However, fluorescence emission was nearly extinguished upon dimer formation, with fluorescence intensity reduced by >93% in ssTAMRA when excited at the isosbestic point (532 nm). This is likely due to self-quenching from stacked xanthene rings as previously described for analogous rhodamine B, rhodamine 6G, and TAMRA dimers in aqueous solution (*20*, *24*, *25*). Stacking proximity of a folded covalent TAMRA dimer containing an ethylenediamine spacer has been estimated as 0.9 nm (*23*). Fluorescence quenching of rhodamine dimers appears to be solvent-dependent, with no quenching observed in mixed water/organic solvent systems but observed in aqueous buffered systems as also described here (*22*−*25*).

The reversibility of disulfide reduction/oxidation was determined following complete reduction of ssTAMRA and removal of reducing agent. Reduced dye is susceptible to oxidation by divalent metals such as Zn^{2+}, Cu^{2+}, and Mg^{2+}, or oxygen in aqueous media resulting in formation of the dye disulfide dimer. However, in the conditions used in this experiment the major cause of sTAMRA oxidation is likely dissolved oxygen, as deionized water and EDTA were used to reduce ion effects and the solution was not degassed or stored under inert atmosphere. Absorbance spectra at various times are shown in Figure 2a with an isosbestic point apparent at 532 nm. The rate of ssTAMRA disulfide formation was determined by plotting the 554/520 nm absorbance ratios as shown in Figure 2b. The absorbance spectra shown in Figure 2a confirm sTAMRA oxidation and reformation of disulfide bonds by the increasing 520 nm absorbance value over time. In this experiment, the absorbance value for oxidized ssTAMRA never reached the same value as the initial absorbance value shown for reduced sTAMRA, despite very similar extinction coefficients reported in Table 1. This is likely due to the fact that reformation of the ssTAMRA dimer does not proceed to 100% conversion in this time. The reduced dye thiol is relatively stable at μM concentrations in this buffer system for several hours ($t_{1/2} \sim 50$ h), but stability could likely be enhanced by degassing the storage solution and storing it under inert atmosphere. This type of experiment could be useful for preparation of bioconjugates when confirmation of disulfide reduction or sulfhydryl stability information for specific reaction or storage conditions is required.

The utility of ssTAMRA as a disulfide reduction reporter molecule in vitro was demonstrated using fresh lysate from cultured harvested RAW 264.7 macrophage cells. These cells were selected since they are common models for phagocytosis and processing of drugs, toxins, polymers, and particles in the endosomal/lysosomal cell trafficking pathway (*26*). The ssTAMRA dye was effectively reduced in lysed RAW 264.7 cells over time, with ~80% reduction observed after 4 h (Figure 3). Recently, a disulfide-reducible FRET reporter molecule containing folate was used to evaluate disulfide reduction during endocytosis (*27*). In this approach, the FRET pair is prepared by attachment of dyes to the reporter molecule in different synthetic steps; however, reporter systems based on self-quenching of TAMRA molecules covalently bound in close proximity by disulfide groups may reduce synthetic steps and cost by reaction of the reporter molecule with an excess of relatively inexpensive TAMRA derivative.

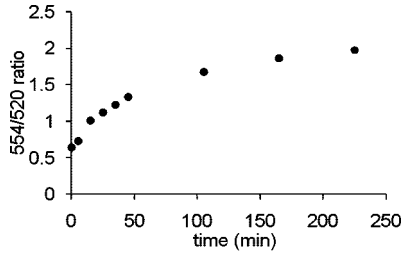

Figure 3. Reduction of ssTAMRA (1.15×10^{-5} M TAMRA) in fresh cell lystae from cultured RAW 264.7 cells at room temperature. Cell lysate background absorbance has been subtracted at both wavelengths for ratios calculated for each data point.

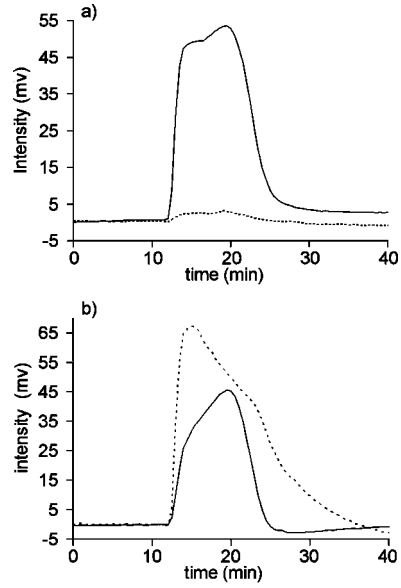

Figure 4. Size exclusion chromatography trace of dual-labeled poly(HPMA) in 0.01 M sodium phosphate buffer containing 0.15 M NaCl and 10 mM EDTA, pH 7.2, before (a) and after (b) sTAMRA conjugation. Detection at 496 nm (solid) corresponds to polymer backbone (Oregon Green), and 554 nm detection (dashed) corresponds to sTAMRA.

Further application of sTAMRA as a traditional reactive probe was realized by covalent reaction with Oregon Green-labeled, maleimide-derivatized, poly[*N*-(2-hydroxypropyl)methacrylamide] (polyHPMA), a polymer often selected as a model for polymer-mediated uptake and processing of drugs and other agents to cells both in vitro and in vivo, and much is known about its endosomal and lysosomal trafficking within cells (*28, 29*). This particular fluorescent-labeled HPMA copolymer was designed for reversible attachment of thiol-containing peptides via hydrazone and maleimide chemistries, and the thiolated ssTAMRA described here served as a model reporter molecule to confirm thiol coupling to the polymer backbone. This dual-labeled water-soluble polymer allowed simultaneous observation of the Oregon Green backbone and reacted sTAMRA using diode array detection at absorption wavelengths for Oregon Green 488 (496 nm) and sTAMRA (554 nm) during SEC analysis. It should be noted that, once conjugated to the polymer backbone in this fashion, the dye loses its environmental sensitivity, so this experiment was performed to confirm the utility of ssTAMRA as a reactive dye probe analogous to other thiolated dyes. Conjugation of reduced sTAMRA to the polymer backbone was confirmed, as TAMRA eluted in the polymer fraction at 12−22 min as shown in Figure 4 (free dye elutes from this column after 30 min under these conditions). The small amount of free dye observed after the polymer peak in Figure 4b is a characteristic of the degradable cross-linker used to incorporate maleimide groups into poly(HPMA), designed for intracellular delivery and release of peptides. The amount of dye conjugated to the polymer backbone was 25.9 μmol/g, corresponding to ~10% conjugation under the conditions described here. This coupling efficiency could likely be increased by longer reaction time and reaction with more stable precursors, as polymer degradation is evidenced as the tailing peak in Figure 4b.

CONCLUSION

In summary, a reactive thiolated dimeric TAMRA-based fluorescent reporter is described that is inexpensive and convenient to produce. The covalent ssTAMRA disulfide dimer exhibits unique spectral properties useful in the study of disulfide exchange or other disulfide redox processes by either absorbance shifts or increases in fluorescence emission after generation of monomeric sTAMRA. Reduction of ssTAMRA dimers is readily achieved using TCEP, with reduced sTAMRA being reactive to maleimide functionality. Conjugation of this reduced sTAMRA to nucleic acids, enzymes, peptides, polymers, proteins, saccharides, or other relevant targets useful for cell trafficking studies is shown to be feasible for application as a reactive fluorescent probe. The sensitivity of ssTAMRA to reduction by biological milieu (i.e., cell lysate) shows its potential as a reporter molecule in cell or organism-based studies where local oxidizing or reducing environmental changes would produce probe spectral shifts in situ.

The enhanced spectral properties of the covalent TAMRA dimer described here could be useful to prepare more advanced reporter molecules and bioconjugates. It would be rather simple to build specialty probes containing dimeric TAMRA that are attached to moieties that affect and track activity in biological systems. For example, many heterobifunctional PEGs and multifunctional cross-linkers are available that could be used to build probes for specific applications. The utility of dimeric TAMRA is not limited to disulfide dimers; TAMRA dimers formed using an acetal as the anchor point would result in a pH-sensitive probe. With TAMRA dimers, environmentally specific information can be obtained using a single fluorophore rather than two as needed in FRET experiments. This would simplify preparation of probes, eliminating the need for extensive purification and complex reaction schemes. Covalent TAMRA dimers could serve as powerful yet simple tools to investigate biological systems.

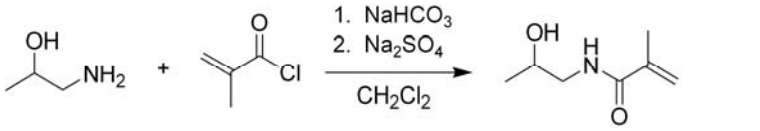
SUPPORTING INFORMATION

1. Poly(HPMA) monomer synthesis

1.1 N-2-hydroxypropyl methacrylamide



N-2-hydroxypropyl methacrylamide
"HPMA"

Scheme S1. Synthesis of N-2-hydroxypropyl methacrylamide monomer.

N-(2-hydroxypropyl)methacrylamide (HPMA) was synthesized by reaction of DL-1-amino-2-propanol with methacryloyl chloride as shown in Scheme S1. 1-amino-2-propanol (24.3 mL, 0.311 mol, 1 eq) and sodium bicarbonate (33.6 g, 0.40 mol, 1.3 eq) was added to CH_2Cl_2 (85 mL) and the suspension was purged with N_2, capped, and placed in an ice bath. A second solution containing methacryloyl chloride (29.5 mL, 0.304 mol, 0.98 eq) in CH_2Cl_2 (40 mL) was prepared and cooled to –20 ^oC. Next, the methacryloyl chloride solution was slowly added to the 1-amino-2-propanol solution under N_2 with vigorous stirring. After complete addition the reaction was stirred for 15 min at 25 ^oC, and anhydrous Na_2SO_4 (10 g) was added. The solution was manually stirred for an additional 10 minutes and the solution was filtered through paper. Solids were washed twice with 20 mL CH_2Cl_2 and the filtrates were combined. The combined filtrates were concentrated under vacuum to ~ 50% of the original volume then placed in a –20 ^oC freezer overnight. HPMA crystals were collected by filtration and washed with cold acetone. Product was purified by repeated crystallization from acetone. Typical yield: ~15.0 g, 30%, semi-transparent white crystals. ^1H NMR, δ ppm: 1.008 (d, 3H), 1.848 (s, 3H), 3.041 (t, 2H), 3.678 (m, 1H), 4.693 (s, 1H), 5.483 (d, 2H), 7.820 (s, 1H). Mp = 72 ^oC (sharp).

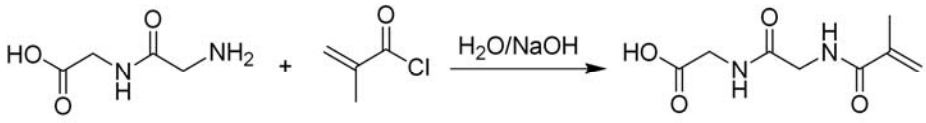
1.2 Methacryloyl glycylglycine



methacryloyl glycylglycine
"MAGG"

Scheme S2. Synthesis of methacryloyl glycylglycine.

N-methacryloyl glycylglycine 4-nitrophenyl ester (MAGGONP) synthesis began with preparation of methacryloyl glycylglycine (MAGG) using the Schotten-Baumann procedure in aqueous alkaline medium as shown in Scheme S2. Glycylglycine (10 g, 76 mmol, 1 eq) was dissolved in 0.5 M NaOH (15.1 mL, 76 mmol, 1 eq) over 30 minutes then cooled to 0 ^oC. Methacryloyl chloride (7.5 mL, 77 mmol, 1eq) and 5.0 M NaOH (15.1 mL, 76 mmol, 1 eq) were added dropwise and simultaneously to the glycylglycine solution while stirring at 0 ^oC. After complete addition, the reaction was stirred for an

additional hour at room temperature, then concentrated HCl was added until a dense white precipitate formed. Solids were collected by filtration and washed with cold water until the filtrate was neutral. Crude solid product was dried under vacuum and further purified by repeat crystallization from 50/50 (v/v) ethanol/water. Typical yield: ~5.0 g, 30%, small white crystals. ^{1}H NMR: (400 MHz, DMSO-d_6) δ ppm: 1.876 (s, 3H), 3.766 (d, 4H), 5.561 (d, 2H), 8.132 (t, 1H), 8.190 (t, 1H), 12.594 (s, 1H). Mp = 175-205 ^{o}C.

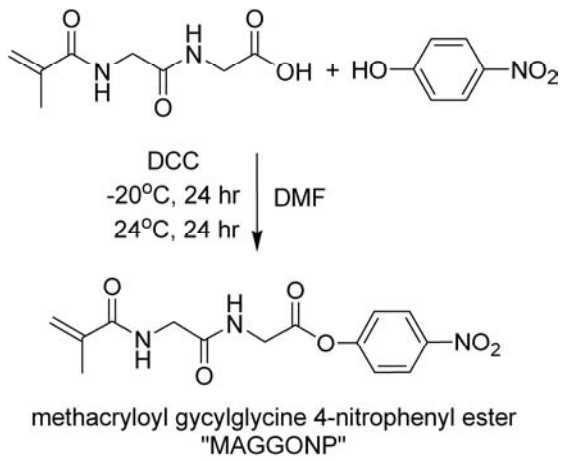
1.3 Methacryloyl glycylglycine 4-nitrophenyl ester



Scheme S3. Synthesis of methacryloyl glycylglycine 4-nitrophenyl ester

Methacryloyl glycylglycine (MAGG) was esterified with 4-nitrophenol using carbodiimide chemistry to yield methacryloyl glycylglycine 4-nitrophenyl ester as shown in Scheme S3. MAGG (5.23 g, 26.1 mmol, 1 eq) was dissolved in dry dimethyl formamide (DMF, 50 mL) and cooled to –15 ^{o}C. 4-nitrophenol (4.0 g, 28.71 mmol, 1.1 eq) and dicyclohexylcarbodiimide (DCC) (5.39 g, 26.1 mmol, 1.0 eq) were each dissolved in DMF (26 mL) in separate flasks and cooled to –15 ^{o}C. After all solutions were cooled, the 4-nitrophenol and DCC solutions were added dropwise to the MAGG solution sequentially while stirring. The reaction was stirred for 4 hr at –15 ^{o}C followed by 24 hr at –20 ^{o}C. Upon complete reaction, dicyclohexyl urea (DCU) byproduct was removed by filtration. The filtrate was collected and allowed to sit at room temperature for 24 hrs under N_2 and then cooled to –20 ^{o}C. The solution was again filtered to remove DCU crystals. The filtrate was retained and 100 mL cold water was added. This mixture was placed on ice for 1 hr. The pale-yellow solids were collected by filtration and dried under vacuum. Hot 50/50 water/ethanol was added to the dried solids until ~ 80% dissolved. The solution was boiled for an additional 10 minutes then filtered. Small, pale-yellow, fish-scale crystals formed slowly in the filtrate over a 3 hr period at room temperature. Solids were collected by filtration and dried under vacuum. Typical yield ~ 2.0 g, 22%, yellow crystals. ^{1}H NMR, δ ppm: 1.884 (s, 3H), 3.809 (d, 2H), 4.176 (d, 2H), 5.577 (d, 2H), 7.435 (m,2H), 8.267 (t, 1H), 8.326 (m, 2H), 8.479 (t, 1H). Mp = 143-160 ^{o}C.

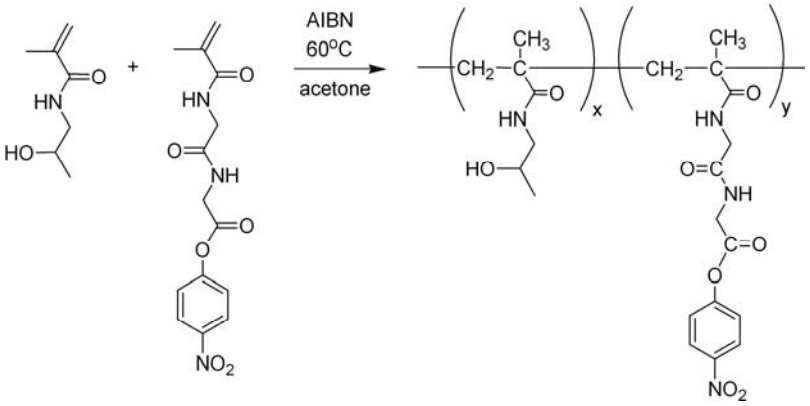
2. HPMA copolymer synthesis

2.1 Free radical initiated polymerization



Scheme S4. Free radical initiated copolymerization of N-2-hydroxypropyl methacrylamide and methacryloyl glycylglycine nitrophenyl ester.

HPMA copolymer was prepared by free radical initiated polymerization as previously described using 12.5% (w/v) monomer and 0.6% initiator (AIBN) in freshly distilled acetone. Reactive side chain content in the polymer product was controlled by feed ratio of MAGGONP. The following is a typical procedure to produce an HPMA copolymer with 95 mole % HPMA units and 5 mole % MAGGONP units. HPMA monomer (3.35 g, 23.4 mmol, 1 eq), MAGGONP (0.40 g, 1.2 mmol, 0.05 eq), and AIBN (0.18 g, 1.1 mmol, 0.05 eq) were added to acetone (26 mL) in a Chemglass 50 mL pressure flask containing a magnetic stirbar. The solution was degassed by sonication under N_2 flow for 5 minutes and then capped. This solution was stirred until all solids dissolved (~ 30 minutes) and placed in a hot water bath and stirred at 60 ^oC for 24 hrs. After complete reaction, solids were collected by filtration, washed with cold acetone, and dried under vacuum. Solids were further purified by repeat precipitation from 90/10 CH_2Cl_2/MeOH (v/v) into a 10-fold excess of cold acetone. Typical yield: ~ 2.2 g, 56%, cream colored powder.

Reference: Kopecek J. (1977) Reactive Copolymers of N-(2-Hydroxypropyl)Methacrylamide with N-Methacryloylated Derivatives of L-Leucine and L-Phenylalanine .1. Preparation, Characterization, and Reactions with Diamines. Makromol. Chem. Macromol. Chem. Phys. *178(8)*, 2169-83.

2.2 Detemination of Active Ester Content in HPMA Copolymers.

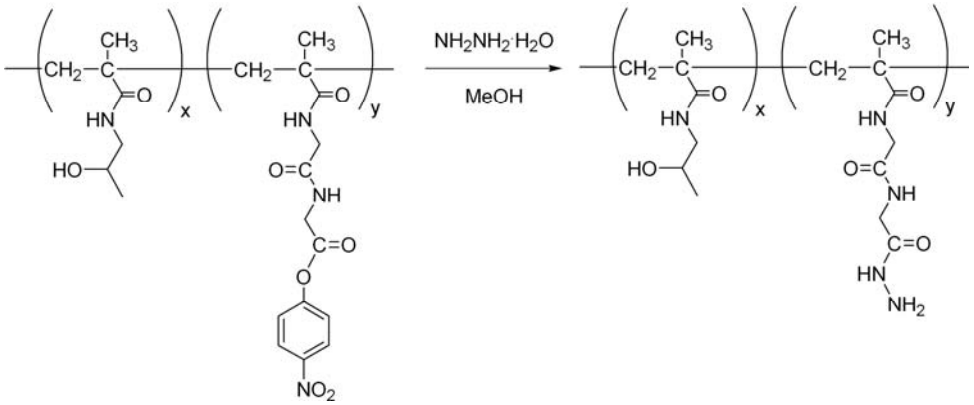
HPMA copolymer product was dissolved in 0.05 M NaOH at concentrations of 0.08-0.1 mg/mL then stirred at 37 ^oC for 3 hrs. The absorbance of the resulting bright-yellow solutions was measured at 400 nm and ester content was estimated using the molar extinction coefficient ($\varepsilon = 1.74 \times 10^4\ M^{-1}cm^{-1}$) of the released p-nitrophenolate anion and the original mass of the polymer sample. The molar extinction coefficient was determined by serial dilution of a p-nitrophenol solution in 0.05 M NaOH. No increase

in absorbance after incubation for 3 hr at 37 ^{o}C was observed, showing complete cleavage p-nitrophenol esters. The reactive ester content was determined to be 4.9% +/- 1.5%.

2.3 Molecular Weight Estimation of HPMA Copolymers

Molecular weight of synthesized poly(HPMA) copolymer was estimated following displacement of reactive ester groups with 1-amino-2-propanol by size exclusion chromatography using an HP1050 HPLC system equipped with an HP1040A refractive index detector and Biosil 125 column. The instrument was calibrated with poly(HPMA) samples of known molecular weight. For each characterization, sodium phosphate buffer (0.05 M, pH 7.4) was used as the mobile phase with a 100 μL sample injection and a 0.5 mL/min flow rate.

2.4 Hydrazide modification



Scheme S5. Conversion of reactive esters to hydrazide groups

Hydrazide groups were generated on HPMA copolymers by reaction of hydrazine with active esters present on MAGGONP side chains as previously described (Scheme S5). A representative procedure follows: HPMA/MAGGONP copolymer (5 mole % MAGGONP, 2.0 g, 0.51 mmol active esters, 1 eq) was dissolved in methanol (25 mL). Hydrazine monohydrate (267 uL, 5.1 mmol, 10 eq) was added to 25 mL methanol in a separate flask. The HPMA copolymer solution was added to the hydrazine monohydrate solution dropwise while stirring over ~ 30 minutes then purged with N_2, capped, and stirred for 3 hr at room temperature. After complete reaction, the mixture was slowly added to 75 mL cold water while stirring, then transferred to dialysis tubing (SpectraPore 7, 6-8 kDa MWCO) and dialyzed against water for 3 days with frequent changing of the dialysis water. Polymer product was isolated by lyophilization. Typical yield: ~ 1.2 g, 60%, white powder.

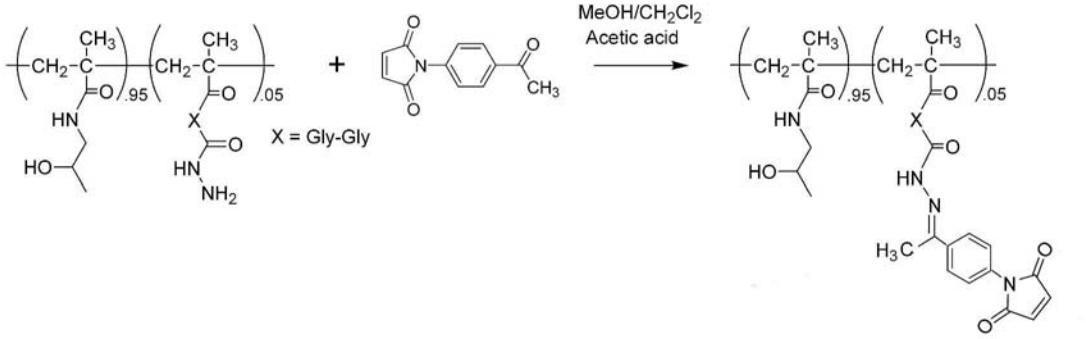
Reference: Etrych, T., Chytil, P., Jelinkova, M., Rihova, B., Ulbrich, K. (2002) Synthesis of HPMA copolymers containing doxorubicin bound via a hydrazone linkage. Effect of spacer on drug release and in vitro cytotoxicity. *Macromol. Biosci. 2*, 43-52.

2.5 Analysis of HPMA Copolymer Hydrazide Content

Hydrazide content in HPMA copolymers was estimated using a modified trinitrobenzene sulfonic acid (TNBSA) assay. TNBSA assay compared ethyl carbazate and methacryloyl glycylglycine hydrazide (MAGGH) as standards. MAGGH was synthesized by reaction of MAGGONP with hydrazine monohydrate. MAGGONP (750 mg, 2.33 mmol, 1 eq) was dissolved in methanol (90 mL) and then slowly added to a solution of hydrazine monohydrate (567 µL, 11.7 mmol, 5 eq) in 10 mL methanol. The reaction was stirred for 5 hr at room temperature under N_2. After complete reaction, solvent was removed under vacuum to yield crude solids. The resulting solids were dissolved in 90/10 CH_2Cl_2/methanol (40 mL), filtered and loaded onto a silica gel column (2.5 x 17.5 cm) equilibrated with 90/10 CH_2Cl_2/MeOH. After the sample was loaded onto the column, the elution solvent was changed to MeOH. MAGGH eluted after the visible yellow 4-nitrophenol band. Yield: 0.156 g, 31%, white powder. ^{1}H NMR, δ ppm: 1.836 (s, 1H), 3.619 (d, 2H), 3.712 (d, 2H), 4.165 (d, 2H), 5.341 (d, 1H), 5.698 (d, 1H), 8.048 (t, 1H), 8.131 (t, 1H), 8.907 (s, 1H). ^{13}C NMR, δ ppm: 18.479, 40.779, 42.402, 119.752, 139.356, 167.597, 168.011, 169.204. MS-FAB m/z = 215.1147 $[M+H]^+$(calculated m/z = 215.1144 $[M+H]^+$)

For each poly(HPMA) hydrazide content analysis, stock solutions of 0.1% w/v TNBSA, ~ 2 x 10^{-4} M MAGGH, and ~ 2 x10^{-4} M ethyl carbazate were prepared in 0.1 M $NaHCO_3$, pH 8.5. MAGGH and ethyl carbazate solutions were further diluted with 0.1 M $NaHCO_3$ to generate standards in the range of ~0.3 - 2 x 10^{-4} M. Next, hydrazide-derivatized HPMA copolymers were dissolved in 0.1 M $NaHCO_3$ at a concentration of 0.2-0.4 mg/mL. Sample or standard solutions (1.0 mL) were combined with 0.5 mL TNBSA stock solution and stirred for 1.5 – 48 hr at 37 °C. After incubation, sample absorbance was measured at 505 nm and hydrazide content was estimated from the equation of the line fit to MAGGH or ethyl carbazate standards plotted as concentration vs. absorbance.

3. Preparation of HPMA-APM conjugate



Scheme S6. Conjugation of *N*-4-(acetylphenyl) maleimide to HPMA copolymer

Hydrazide derivatized poly(HPMA), (0.20 g, 1.0 equiv, 52 µmol hydrazide) was dissolved in 50/50 methylene chloride/methanol (2 mL), and 100 mg Na_2SO_4 was added. *N*-4-(acetylphenyl) maleimide solution (34.0 mg, 3.1 equiv, 160 µmol) was prepared in 50/50 methylene chloride/methanol (2 mL) and then added to the poly(HPMA) solution dropwise. After complete addition, acetic acid (5 µL of 34% v/v solution in methylene chloride, 0.6 equiv, 30 µmol) was added and the reaction was stirred under nitrogen at room temperature for 24 hr. The reaction was terminated by precipitation of poly(HPMA) product into ether. Product was further purified by size exclusion chromatography (Sephadex LH-20, 1 x 15 cm, methanol mobile phase). Typical yield: 126 mg, 63%, white powder. Hydrazide content post-

conjugation was determined using a TNBSA assay, as described above. Crosslinker content was determined by an absorbance measurement at λ_{max} and using the molar extinction coefficients of corresponding ethyl carbazate-crosslinker hydrazone derivative at 288 nm, $\varepsilon = 1.9 \times 10^4\ M^{-1}\ cm^{-1}$. Polymer-crosslinker conjugates were analyzed by ^1H NMR and maleimide functionality was confirmed in the polymer backbone as a sharp singlet at 7.2 ppm.

Targeted Gene Delivery Mediated by Folate-polyethylenimine-block-poly(ethylene glycol) with Receptor Selectivity

Han Cheng, Jing-Ling Zhu, Xuan Zeng, Yue Jing, Xian-Zheng Zhang,* and Ren-Xi Zhuo

Key Laboratory of Biomedical Polymers of the Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received September 22, 2008; Revised Manuscript Received December 30, 2008

The folate receptor (FR) is a tumor marker overexpressed in large numbers of cancer cells. Folic acid has high affinity to the FR and retains its binding affinity upon derivatization via its γ-carboxyl. Therefore, in this article, folate-polyethylenimine-block-poly(ethylene glycol) (FOL-PEI-b-PEG) was designed for specific receptor targeted gene delivery. Physicochemical characterizations of resulting FOL-PEI-b-PEG/DNA complexes in terms of agarose gel electrophoresis, particle size, and zeta potential measurements were investigated. The results indicated that FOL-PEI-b-PEG was able to condense plasmid DNA tightly with a suitable particle size. The cytotoxicity study indicated that the copolymer exhibited less toxicity in comparison with that of 25 kDa PEI. Luciferase assay and green fluorescent protein (GFP) detections were also used to confirm that FOL-PEI-b-PEG could be an effective gene vector. Importantly, transfection efficiency of FOL-PEI-b-PEG with free folic acid was much lower than that of the copolymer without free folic acid on FR-positive HeLa cells, suggesting that FOL-PEI-b-PEG has great potential as a targeting gene vector.

INTRODUCTION

In recent years, gene therapy has attracted much attention for its pharmaceutical application in treating chronic diseases and genetic disorders (*1, 2*). There are two categories of gene delivery vectors: viral and nonviral vectors (*3*−*6*). Nonviral gene vectors are considered to have several advantages over viral gene vectors, such as flexibility in formulation design, ability to be modified with ligands and delivered selectively to a specific tissue/cell, no limitation of carrying capacity in DNA size, and so on (*7*−*10*). Cationic lipids and cationic polymers are the most widely used nonviral vectors that have been extensively studied (*11, 12*). Compared with cationic lipids, cationic polymers are stable, easy to be manipulated, and more economical. Polyethylenimine (PEI), one of the most successful and efficient nonviral vectors, is a cationic polymer and has been broadly utilized for gene delivery both in vitro and in vivo (*13*−*16*). PEI has been shown to form compact interpolyelectrolyte complexes with DNA, and the PEI/DNA polyplexes have been found to be able to mediate efficient transfection of cells in culture.

As we know, transfection efficiency and toxicity of PEI depend on its molecular weight, and it is recognized that high molecular weight PEI shows high transfection activity and cytotoxicity. For example, the well-known commercial branched 25 kDa PEI, as an effective transfection reagent in vitro and in vivo, has high transfection efficiency but has high cytotoxicity too. In order to enhance transfection efficiency and decrease cytotoxicity, synthetic cationic copolymers based on PEI and poly(ethylene glycol) (PEG) were investigated as nonviral gene vectors (*17*−*20*). In recent years, PEG has been widely applied in gene delivery systems. The presence of PEG on the surface of gene vectors can enhance biocompatibility, reduce cytotoxicity, and protect DNA from degradation.

Polycationic gene vector modified with folic acid (FA) was expected to identify specific tissue/cell surface receptors and transfect cells by receptor-mediated endocytosis (*21*−*23*). In this study, folate-polyethylenimine-block-poly(ethylene glycol) (FOL-PEI-b-PEG) was prepared as an effective gene vector. Folic acid was conjugated to PEI to increase the transfection efficiency for targeting purposes, while PEG was used as the biocompatible outer hydrophilic shell to protect the genes and reduce the cytotoxicity of PEI. The in vitro cytotoxicity of the resulting copolymers was examined, while the physiochemical characteristics of the copolymer/DNA complexes were analyzed by agarose gel electrophoresis, particle size, and zeta potential measurements. In addition, the in vitro transfection efficiency of FOL-PEI-b-PEG/DNA complexes in terms of the luciferase assay and green fluorescent protein (GFP) detections were also examined with three cell lines using the branched 25KDa PEI as the control.

EXPERIMENTAL PROCEDURES

Materials. Methoxy polyethylene glycol with a molecular weight of 5000 (PEG 5 kDa) was purchased from Acros and dried by azeotropic distillation with toluene. Polyethylenimine (PEI, 25 kDa, branched) and sodium cyanoborohydride ($NaBH_3CN$) were purchased from Sigma and used as received. Folic acid (FA) and acetic anhydride (Ac_2O) were purchased from Sinopharm Chem. Reagent Co. Ltd., China. The Micro BCA protein assay kit and GelRed were purchased from Pierce and Biotium (CA, USA), respectively. Dulbecco's modified Eagle's medium (DMEM) with a folate concentration of 4 mg/L, fetal bovine serum (FBS), penicillin-streptomycin, trypsin, Dubelcco's phosphate buffered saline (PBS), and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were obtained from Invitrogen Corp. All other reagents and solvents were used as received without further purification.

Two different types of plasmid DNAs, pGL-3 and pEGFP-C1 plasmids, were used in the study. Plasmid pGL3-control with SV40 promoter and enhancer sequences encoding luciferase was obtained from Promega, Madison, WI, USA. Plasmid pEGFP-C1 encoding a red-shifted variant of wild-type green fluorescent protein (GFP) was purchased from Clontech, Mountain View, CA, USA. The former was transformed in *E. coli* JM109, and the latter was transformed in *E. coli* DH5α. Both plasmids were

amplified in LB medium at 37 °C overnight at 250 rpm. Then the plasmids were purified as described by means of EndoFree plasmid purification. The purified plasmid was diluted by TE buffer solution and stored at −20 °C. The integrity of the plasmid was confirmed by agarose gel electrophoresis. The purity and concentration of the plasmid were determined by ultraviolet (UV) absorbance at 260 and 280 nm.

Cell Culture. Human embryonic kidney 293T cells (HEK293T), human cervix carcinoma cells (HeLa), and human hepatocellular carcinoma cells (HepG2) were incubated in DMEM containing 10% FBS and 1% antibiotics (penicillin-streptomycin, 10000 U/mL) at 37 °C in a humidified atmosphere containing 5% CO_2, respectively.

Synthesis of Aldehyde-PEG (PEG-CHO). PEG-CHO was prepared as follows: dried PEG (3 g) was dissolved in 10 mL of dried DMSO and 1 mL of $CHCl_3$, and then Ac_2O (2 mL) was added to the reaction mixture. The reaction was performed at room temperature for 12 h. Then the product was precipitated into diethyl ether. The precipitated product was isolated by filtration and dried under vacuum.

Synthesis of PEI-b-PEG. PEI (2 g) was dissolved in 20 mL of CH_3OH. Then PEG-CHO (2 g) in 20 mL of CH_3OH was added dropwise to the reaction mixture. After 24 h at room temperature under N_2 atmosphere, 0.16 g of $NaBH_3CN$ was added, and the reaction was performed at room temperature for another 48 h. Then the product was dialyzed against distilled water using a dialysis membrane (MWCO 8000-12000) for purification. The aqueous solution in the dialysis bag was freeze-dried to obtain PEI-b-PEG.

Synthesis of FOL-PEI-b-PEG. PEI-b-PEG (480 mg) and FA (15 mg) were dissolved in 10 mL of DMSO, and then DCC (8.5 mg) and DMAP (5 mg) were added to the reaction mixture. The reaction mixture was magnetically stirred for 24 h at 35 °C under N_2 atmosphere to produce FOL-PEI-b-PEG. Thereafter, the mixture was dialyzed against distilled water using a dialysis membrane (MWCO 8000-12000) for further purification. The aqueous solution in the dialysis bag was freeze-dried to obtain the product.

Folic Acid Content of FOL-PEI-b-PEG. The content of folic acid conjugated in FOL-PEI-b-PEG was obtained on the basis of the standard curve by using the UV−vis spectrophotometer. FOL-PEI-b-PEG and folic acid were dissolved in distilled water. FOL-PEI-b-PEG aqueous solution of 290 mg/L, and folic acid aqueous solutions of 13.9−111 mg/L were prepared. Optical absorbance of folic acid aqueous solution at room temperatures was measured from 250 to 400 nm by UV−vis spectrometer and the absorbance at a wavelength of 280 nm was determined. The absorbance values of the peak intensities at 280 nm of the absorbance spectra were analyzed as a function of folic acid concentration. Also, the absorbance value of the peak intensity at 280 nm of FOL-PEI-b-PEG was obtained. The concentration of folic acid in FOL-PEI-b-PEG aqueous solution was calculated according to the calibration curve made from free folic acid, while the content of folic acid was calculated by the concentration ratio of the folic acid and FOL-PEI-b-PEG.

^{1}H NMR Measurements. ^{1}H NMR spectra were recorded on a Varian Unity 300 MHz spectrometer using D_2O as the solvent.

Formation of the Copolymer/DNA Complexes. PEI-b-PEG or FOL-PEI-b-PEG was dissolved in NaCl solution (150 mM pH 7.4) to form a solution of 1 mg/mL. A plasmid DNA stock solution (120 ng/μL) was prepared in Tris-HCl buffer solution (pH 7.4). The volume of the polycation solution and the DNA stock solution was adjusted to 50 μL with 150 mM NaCl solution. Then the polycation solution and DNA stock solution were mixed together to form complexes with different weight ratios of copolymer/DNA. The complexes were incubated at 37 °C for 30 min.

Agarose Gel Retardation Assay. The complexes at different weight ratios were prepared by adding an appropriate volume of PEI-b-PEG or FOL-PEI-b-PEG (in 150 mM NaCl solution) to 96 ng of pEGFP-C1 plasmid DNA (120 ng/μL in 40 mM Tris-HCl buffer solution), the complexes were diluted by 150 mM NaCl solution to 6 μL, and then the complexes were incubated at 37 °C for 30 min. After that the complexes were electrophoresed in the 0.7% (w/v) agarose gel containing GelRed with Tris-acetate (TAE) running buffer at 80 V for 80 min. DNA was visualized with a UV lamp using a Vilber Lourmat imaging system (France).

Particle Size Measurement. The particle size was measured by Nano-ZS ZEN3600 (MALVERN Instr.). PEI-b-PEG/DNA or FOL-PEI-b-PEG/DNA complexes at various weight ratios were prepared by adding an appropriate volume of PEI-b-PEG or FOL-PEI-b-PEG (in 150 mM NaCl solution) to 1 μg of plasmid DNA (in Tris-HCl buffer solution, pH 7.4). The complexes were diluted by 150 mM NaCl solution to 1 mL and incubated at 37 °C for 30 min before the measurement.

Zeta Potential Measurement. The zeta potentials of coplolymer/DNA complexes were measured using Nano-ZS ZEN3600 based on the principle of phase analysis light scattering. The zeta potentials quoted were averages obtained from at least six measurements over duplicate samples.

In Vitro Cytotoxicity Test. For each well in a 96-well plate, 200 μL of cells (HEK293T, HepG2 or HeLa) in DMEM, with a concentration of 2.5×10^4 cells/mL was added. The number of cells in each well was 5000. After incubation for 24 h in an incubator (37 °C, 5% CO_2), the culture medium was changed to 200 μL of DMEM containing polymers with particular concentrations, and the mixture was further incubated for 48 h. Then, DMEM with polymers was replaced by fresh DMEM, and 20 μL of MTT solution (5 mg/mL) was added to the cells. After incubation for 4 h, 150 μL of DMSO was added and shaken at room temperature. The optical density (OD) was measured at 570 nm with a Microplate Reader Model550 (BIO-RAD, USA). The relative cell viability was calculated by the following equation:

$$\text{relative cell viability (\%)} = (\text{OD}_{\text{treated}}/\text{OD}_{\text{control}}) \times 100 \quad (1)$$

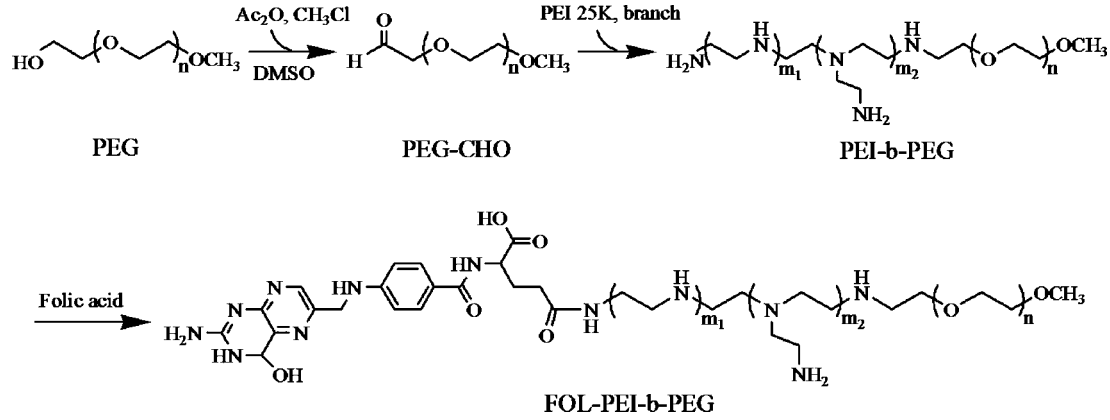
where $\text{OD}_{\text{control}}$ was obtained in the absence of copolymers, and $\text{OD}_{\text{treated}}$ was obtained in the presence of copolymers.

Gene Transfection. For the in vitro transfection study, the HEK293T, HepG2, and HeLa cells were split one day prior to transfection and plated in 24-well plates at a density of 5×10^4 cells/well. Before transfection, the cell culture medium was replaced with serum-free DMEM. The cells were transfected with gene delivery complexes containing 1 μg of plasmid DNA at 37 °C for 4 h. Then the complexes were removed and incubated in fresh DMEM with 10% FBS at 37 °C for another 48 h.

Luciferase Assay. The cells were washed by PBS and lysed with the reporter lysis buffer (Promega, USA). The luciferase activity in cell extracts was measured using a luciferase assay kit (Promega, USA). Each measurement was carried out for 10 s in a single-well luminometer (Berthold Lumat LB 9507, Germany). The relative light units (RLU) were normalized by the total protein concentration of the cell extracts, and the total protein was measured with a BCA protein assay kit (PERBIO, USA). Luciferase activity was expressed as RLU/mg Protein. The statistical significance between two sets of data was calculated using Student's *t*-test. $P < 0.05$ was considered statistically significant.

GFP Detection. The cells expressing green fluorescent proteins were directly observed by an inverted microscope (IX 70, Olympus, Japan).

Scheme 1. Synthesis Route of FOL-PEI-b-PEG



Folic Acid Competition Study. HepG2 cells and HeLa cells were cultured in the same conditions as that of the transfection tests. Cells were seeded into 24-well plates at 5×10^4 cell density per well and incubated for 24 h. The first series of stock solutions containing FOL-PEI-b-PEG/DNA complexes with predetermined weight ratios were prepared. The second series of stock solutions containing the same predetermined weight ratios of FOL-PEI-b-PEG/DNA complexes with free folic acid were prepared by fixing the weight ratio of FOL-PEI-b-PEG/free FA to 32/1 (molar ratio of FOL-PEI-b-PEG/free FA: 43.4/100). The third series of stock solutions containing free folic acid at varied weight ratios of FOL-PEI-b-PEG/free FA ranging from 10/0 to 10/40 were prepared with a fixed FOL-PEI-b-PEG/DNA weight ratio of 10. All of the stock solutions contained 1 μg of plasmid DNA with predetermined weight ratios of FOL-PEI-b-PEG/DNA (the amount of DNA used in each well is 1 μg). Cells were subsequently incubated at 37 °C with one of these solutions for 4 h in the presence of 5% CO_2, respectively. After that, cells were washed once with PBS solution and further incubated with fresh DMEM medium and maintained at 37 °C in 5% CO_2 for another 48 h. The transfection efficiency was then assessed using the same way described in the luciferase assay section.

RESULTS AND DISCUSSION

Synthesis of FOL-PEI-b-PEG. The FOL-PEI-b-PEG copolymer was synthesized through three steps as illustrated in Scheme 1. The first step was to prepare PEG-CHO by the oxidation of the hydroxyl end group of PEG. Then, PEI (25 kDa, branch) was combined with PEG-CHO to form PEI-b-PEG. FOL-PEI-b-PEG was finally synthesized by activating the γ-carboxyl group in folic acid with DCC/DMAP for the conjugating to primary amine groups of PEI-b-PEG.

The ^{1}H NMR analysis was used to determine the molecular weight and composition of the resulting polymers. Figure 1 shows the ^{1}H NMR spectrum of PEI-b-PEG in D_2O. The signal at δ 3.6 ppm related to the PEG, which was marked b. The signals of the NCH_2CH_2N protons of PEI backbone were found in the range of 2.4−3.4 ppm (a). The ratio of integral *a* and integral *b* was 4.63, and the molecular weights (M_n) of the polymers can be calculated from the ratio of these two integrals. The M_n of PEI-b-PEG was calculated to be 3.05×10^4 since that of PEI was 2.5×10^4. The results indicate that about one PEG molecular chain was conjugated to one PEI molecular chain.

As shown in Figure 2, the content of folic acid conjugated in FOL-PEI-b-PEG was 2.48 wt %, i.e., the molar ratio of folate/PEI in the FOL-PEI-b-PEG was around 1.8/1, obtained on the basis of the standard curve by using the UV absorbance at 280 nm as the reference. According to the reference, α- and γ-carboxyl groups on the folic acid have been reported to undergo coupling reactions, but only the γ-conjugate can bind to the folate receptor (FR) (*24*). The DCC-mediated polycondensation reaction involves about 80% γ-linked and 20% α-linked conjugates.

Physicochemical Characterization of Copolymers. The DNA-binding capability of the copolymers is very important for gene vectors (*25*). The condensed form of the copolymer/DNA complexes can protect the plasmid DNA from cell barriers during gene delivery. In order to study complexation and condensation capabilities of copolymers with DNA, agarose gel retardation assays were performed. In this study, the weight ratio instead of the *N*/*P* ratio (*N*/*P* refers to the ratio of moles of the amine groups of copolymer to moles of phosphates of DNA) was used to represent the properties of the copolymer. When the weight ratio of PEI-b-PEG/DNA or FOL-PEI-b-PEG/DNA is 1, the *N*/*P* ratio of corresponding complexes is 6.15 or 5.99, respectively. The agarose gel electrophoresis of copolymer/DNA complexes were examined at varied weight ratios. As shown in Figure 3, the copolymers could efficiently bind DNA at a weight ratio of 3. The complete retardation of DNA was achieved at a copolymer/DNA weight ratio of 5. These results proved that the copolymers might be used to bind DNA as an efficient gene vector.

The particle size of the copolymer/DNA complexes at different weight ratios was shown in Figure 4. All of the sizes of complexes were measured at weight ratios ranging from 2.3 to 11.7. At the lowest weight ratio, the particle size was 325 nm. With the increasing weight ratios of the copolymer/DNA complexes, the particle size increased from 325 to 647 nm. In

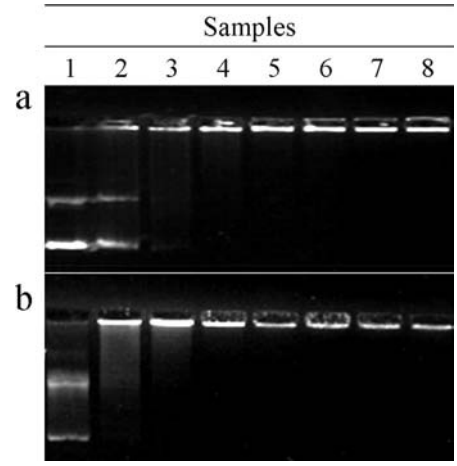

Figure 3. Agarose gel electrophoresis retardation assay of FOL-PEI-b-PEG/DNA (a) and PEI-b-PEG/DNA (b) complexes. Lane 1, naked DNA (plasmid only); lanes 2−8, weight ratios 1 to 13 with increments of 2.

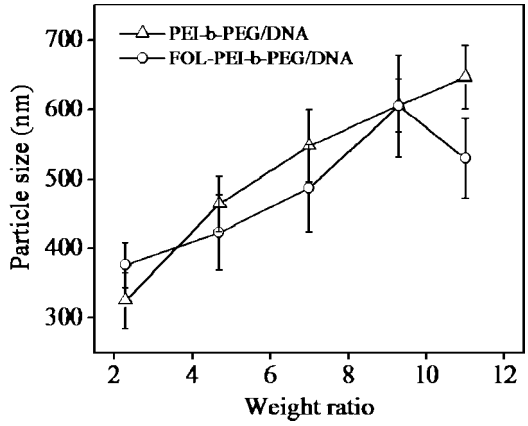

Figure 4. Particle size of FOL-PEI-b-PEG/DNA (a) and PEI-b-PEG/DNA (b) complexes at weight ratios ranging from 2.3 to 11.7.

addition, the two copolymer/DNA complexes, i.e., PEI-b-PEG/DNA and FOL-PEI-b-PEG/DNA had similar particle size at the same weight ratio. Obviously, the complex size of the copolymer/DNA depends on weight ratios.

As shown in Table 1, the zeta potential of the FOL-PEI-b-PEG/DNA complex increased from −6.4 mV to 7.99 mV with increasing weight ratio while that of the PEI-b-PEG/DNA complex increased from 2.11 mV to 13.2 mV correspondingly. At a higher weight ratio, the copolymer/DNA complex possessed a higher zeta potential due to the increasing amount of cationic copolymer. The positive zeta potential of copolymers is necessary to ensure the uptake of complexes by cells due to electrostatic interactions between negatively charged cellular membranes and positively charged complexes (*26, 27*).

Biological Characterization of the Copolymers. The gene vector should not induce cytotoxic effects (*28, 29*). In order to evaluate the cytotoxicity of resulting copolymers, the viability of three different cell lines was tested in the presence of PEI-b-PEG and FOL-PEI-b-PEG at various concentrations. Here, PEI 25 kDa was used as the control. Figure 5 shows that both PEI-b-PEG and FOL-PEI-b-PEG exhibited much lower cytotoxicity compared with that of 25 kDa PEI regardless of cell lines, and the difference of cytotoxicity between FOL-PEI-b-PEG and PEI-b-PEG is not significant. The cytotoxicity of PEI-b-PEG and FOL-PEI-b-PEG increased gradually with increasing concentration. Concurrently, it was found that the cytotoxicity of PEI-b-PEG and FOL-PEI-b-PEG was a little lower in HepG2 cells than that in HEK293T and HeLa cells.

FR is normally elevated in cancer cells. For targeting purposes, the folic acid molecule was conjugated to the PEI-b-PEG copolymer. To investigate the transfection efficiency mediated by PEI-b-PEG and FOL-PEI-b-PEG copolymers, we performed in vitro transfection activity assays using FR-positive (HEK293T and HeLa) and FR-negative (HepG2) cells. The transfection efficiency of copolymer/DNA complexes was visualized by a fluorescence microscope. The images in Figure 6 show that HEK293T, HeLa, and HepG2 cells were transfected with FOL-PEI-b-PEG/pEGFP-C1 or PEI-b-PEG/pEGFP-C1 complexes, respectively. As shown in Figure 6AI and BI, for HEK293T cells no obvious difference of fluorescent density was found because HEK293T cells have been proved to be the kind of cells with high transfection efficiency, and the difference of the transfection efficiency between PEI-b-PEG and FOL-PEI-b-PEG was not significant (*30*). In contrast to HEK293T cells, the fluorescent density showed obvious differences when HeLa cells were transfected with two copolymer/pEGFP-C1 complexes. The fluorescent density of HeLa cells was decreased when we used PEI-b-PEG/pEGFP-C1 complexes instead of FOL-PEI-b-PEG/pEGFP-C1 complexes, while there was not much difference in HepG2 cells. It was also noted that HepG2 cells showed the lowest transfection efficiency among the three cell lines and that the fluorescent spots were markedly reduced. These results indicate that the transfection efficiency, mediated by PEI-b-PEG or FOL-PEI-b-PEG, depended on cell types.

Table 1. Zeta Potential of Copolymer/DNA Complexes with Varied Weight Ratios

weight ratio	2.3	4.7	7	9.3	11.7
FOL-PEI-b-PEG/DNA	−6.4 ± 0.37 mV	5.08 ± 0.36 mV	4.54 ± 0.27 mV	7.57 ± 0.35 mV	7.99 ± 0.65 mV
PEI-b-PEG/DNA	2.11 ± 0.39 mV	6.37 ± 0.26 mV	5.65 ± 0.33 mV	7.19 ± 0.29 mV	13.2 ± 0.41 mV

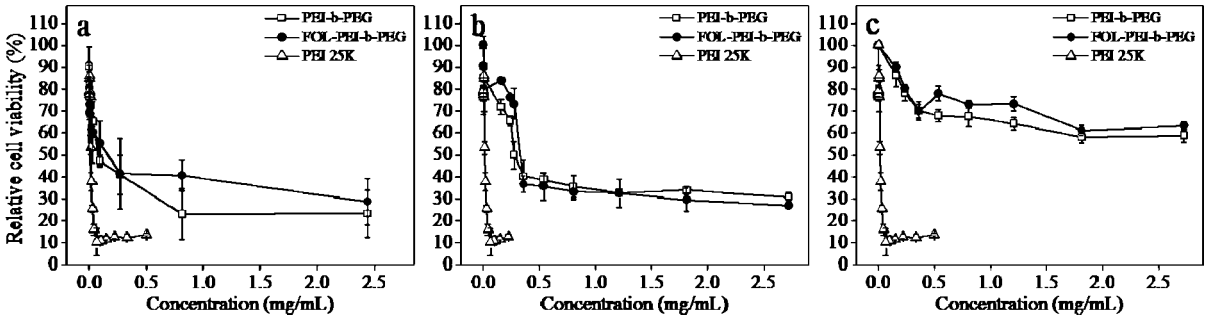

Figure 5. Cytotoxicity of FOL-PEI-b-PEG and PEI-b-PEG copolymers in comparison with 25 kDa PEI in HEK293T cells (a), HeLa cells (b), and HepG2 cells (c).

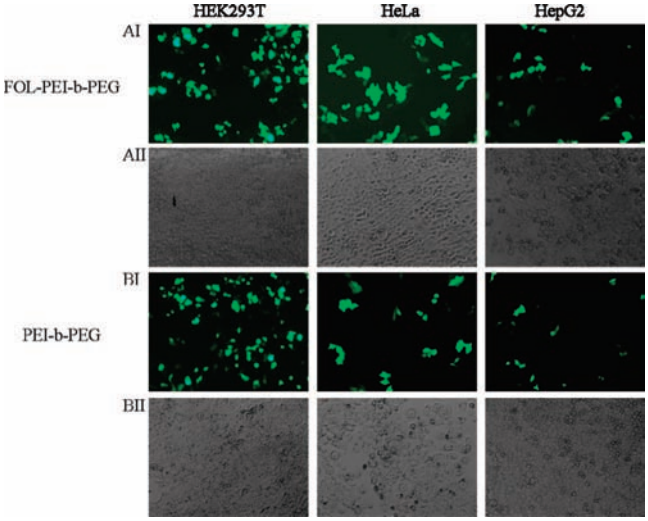

Figure 6. GFP detection of the transfected HEK293T cells, HeLa cells, and HepG2 cells observed by an inverted microscope. Images (AI, BI) are the fluorescent images, and images (AII, BII) are the bright-field images. Images (AI, AII) were observed in HEK293T cells with an FOL-PEI-b-PEG/DNA weight ratio of 14, in HeLa cells with an FOL-PEI-b-PEG/DNA weight ratio of 11, and in HepG2 cells with an FOL-PEI-b-PEG/DNA weight ratio of 14; images (BI, BII) were observed in HEK293T cells with a PEI-b-PEG/DNA weight ratio of 14, in HeLa cells with a PEI-b-PEG/DNA weight ratio of 11, and in HepG2 cells with a PEI-b-PEG/DNA weight ratio of 14. The images were obtained at magnification of 100×.

FOL-PEI-b-PEG/DNA complexes exhibited higher transfection efficiency than that of PEI-b-PEG/DNA complexes in FR-positive HeLa cells, whereas no difference in FR-negative HepG2 cells was found.

To quantify the transfection efficiency, the plasmid pGL-3 was used as the luciferase reporter gene, and the luciferase expression assay induced by the copolymers/pGL-3 complexes was carried out. The luciferase activities of the copolymer/DNA complexes were similar to the results of GFP detection. As shown in Figure 7a, the luciferase activity of PEI/pGL-3 complexes was 3.72×10^8 RLU/mg at an N/P ratio of 10. PEI-b-PEG/pGL-3 complex showed comparable or higher luciferase activities ($1.09 \times 10^8 - 7.82 \times 10^8$ RLU/mg) at certain weight ratios when compared with that of PEI/pGL-3 complexes in HEK293T cell lines, indicating that the conjugation of PEG could reduce the cytotoxicity of copolymers and increase the gene expression to some extent. Compared with the one of FOL-PEI-b-PEG/pGL-3 complexes, the luciferase activity was obviously higher when HEK293T cells were transfected with PEI-b-PEG/pGL-3 complexes at a weight ratio of 4.6, whereas no significant difference (nonsignificant: $P = 0.475$) between PEI-b-PEG/pGL-3 complexes and FOL-PEI-b-PEG/pGL-3 complexes was observed when the weight ratio increased. On the basis of the results, we also found that the PEI-b-PEG/pGL-3 complexes possessed the highest transfection efficiency in HEK293T cells at the weight ratio of 14 (7.82×10^8 RLU/mg).

In HeLa and HepG2 cells, the results became different from those described above. As shown in Figure 7b, the luciferase activities of FOL-PEI-b-PEG/pGL-3 complexes were $0.84 \times 10^8 - 1.97 \times 10^8$ RLU/mg, and the luciferase activities of PEI-b-PEG/pGL-3 complexes were $3.82 \times 10^6 - 5.81 \times 10^7$ RLU/mg at varied weight ratios. These results indicate that luciferase expression was significantly higher ($P < 0.05$) when HeLa cells were transfected with FOL-PEI-b-PEG. By contrast, there was no significant difference (nonsignificant: $P > 0.05$) when HepG2 were transfected with copolymers/DNA complexes of FOL-PEI-b-PEG or PEI-b-PEG. The gene transfection efficiency of the copolymers was initially increased and then decreased with an increasing weight ratio of copolymer/DNA (Figure 7c). Besides, both copolymer/DNA complexes at a weight ratio 14 got the highest transfection efficiency. Obviously, the transfection efficiency of complexes depends on weight ratios, and it seems that there exists a weight ratio equilibrium between the

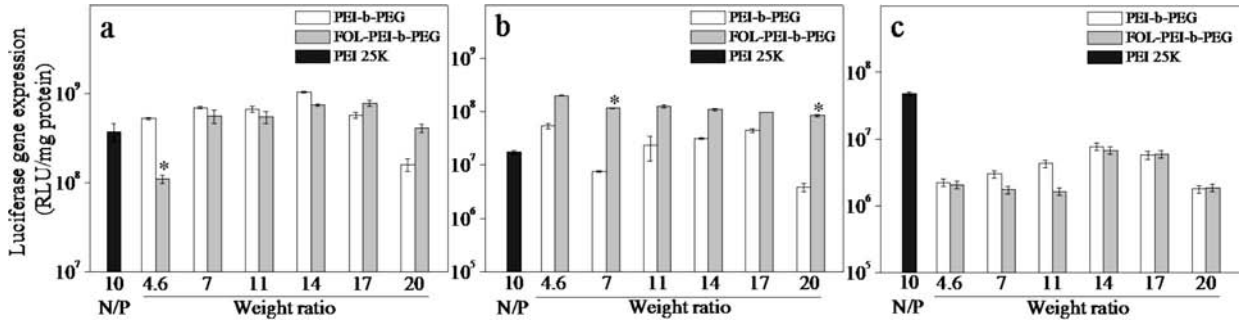

Figure 7. Luciferase expression efficiency in HEK293T cells (a), HeLa cells (b), and HepG2 cells (c). Transfection efficiency of FOL-PEI-b-PEG/DNA and PEI-b-PEG/DNA complexes were evaluated at weight ratios ranging from 4.6/1 to 20/1 with 25 kDa PEI/DNA complexes at the optimal ratio ($N/P = 10$) as the control. Data are shown as the mean ± SD ($n = 3$) (*$P < 0.05$ as compared with the data of PEI-b-PEG).

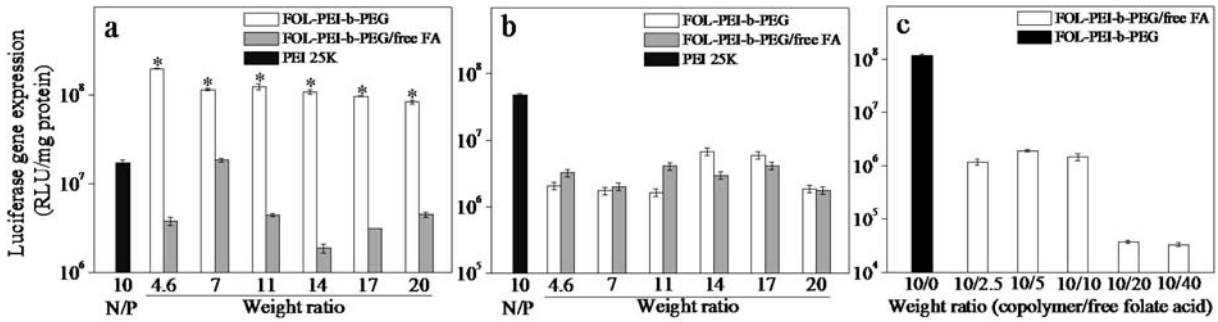

Figure 8. Folic acid competition study. Transfection efficiency of FOL-PEI-b-PEG/DNA complexes, free folic acid with FOL-PEI-b-PEG/DNA complexes, and 25 kDa PEI/DNA complexes in the FR-positive HeLa cells (a) and FR-negative HepG2 cells (b). FOL-PEI-b-PEG/DNA complexes were evaluated at weight ratios ranging from 4.6/1 to 20/1, with fixed FOL-PEI-b-PEG/free FA weight ratio of 32/1, and 25 kDa PEI at the optimal ratio ($N/P = 10$) was taken as control. Transfection efficiency of FOL-PEI-b-PEG/DNA at the fixed weight ratio of FOL-PEI-b-PEG/DNA of 10 with varied weight ratios of FOL-PEI-b-PEG/free FA ranging from 10/0 to 10/40 were evaluated in the FR-positive HeLa cells (c). Data are shown as the mean ± SD ($n = 3$) (*$P < 0.05$ as compared with the data of FOL-PEI-b-PEG/free FA).

copolymer and DNA. Weight ratios of copolymer and DNA that are too high or too low are not favorable to form an effective gene delivery system. These results indicate that gene transfection efficiency could be adjusted by controlling the weight ratio of copolymer/DNA.

The FR-positive HeLa cells and FR-negative HepG2 cells were chosen to further evaluate the targeting effect with free folic acid in the transfection process. First, HeLa cells and HepG2 cells were incubated with the complexes in medium containing varied amounts of free folic acid with a fixed weight ratio of FOL-PEI-b-PEG/free FA. As seen in Figure 8a, luciferase expression was significantly higher ($P < 0.05$) when plasmids were complexed to FOL-PEI-b-PEG to transfection than when the complexes were prepared with FOL-PEI-b-PEG/free FA. The transfection efficiency of HeLa cells was much decreased due to the existence of free FA in culture medium, whereas no significant difference (nonsignificant: $P > 0.05$) was found when HepG2 were transfected in the presence of free folic acid in medium (Figure 8b). Additionally, to further investigate the relationship between the amount of free FA and the transfection efficiency, a series of stock solutions containing free FA at varied weight ratios of FOL-PEI-b-PEG/free FA were added to HeLa cells with a fixed FOL-PEI-b-PEG/DNA weight ratio of 10. As shown in Figure 8c, the transfection efficiency of HeLa cells decreased with increasing amounts of free FA, and when the weight ratio of free FA/FOL-PEI-b-PEG was above 20/10, the transfection efficiency decreased greatly. These findings suggest that free folic acid molecules would prevent the cellular uptake of the complexes by competitive binding to the folate receptors on the cell surface. From another point of view, the conjugation of folic acid indeed improved the transfection efficiency of FOL-PEI-b-PEG for FR-positive cell gene delivery in normal conditions without excess free folic acid.

CONCLUSIONS

In this study, PEG and PEI 25 kDa were combined to prepare PEI-b-PEG; thereafter, FA was further conjugated to prepared FOL-PEI-b-PEG as a cell targeting gene vector. Both PEI-b-PEG and FOL-PEI-b-PEG showed good capability to form complexes with plasmid DNA and exhibited much lower cytotoxicity compared with PEI 25 kDa. PEI-b-PEG/DNA and FOL-PEI-b-PEG/DNA complexes displayed comparable or higher transfection efficiency at certain weight ratios in comparison to that of PEI 25 kDa. Importantly, FOL-PEI-b-PEG/DNA complexes exhibited higher transfection efficiency than that of PEI-b-PEG in FR-positive HeLa cells, whereas no difference in FR-negative HepG2 cells was found. FOL-PEI-b-PEG might be a potential safe and efficient gene vector, particularly for FR-positive cell gene delivery.

Acid-Responsive Linear Polyethylenimine for Efficient, Specific, and Biocompatible siRNA Delivery

Min Suk Shim[†,‡] and Young Jik Kwon*[,‡,§,||]

Department of Macromolecular Science and Engineering, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106, and Department of Chemical Engineering and Materials Science, Department of Pharmaceutical Sciences, and Department of Biomedical Engineering, University of California, Irvine, California 92697. Received October 13, 2008; Revised Manuscript Received December 23, 2008

Efficient intracellular processes including cytosolic release and unpackaging of siRNA from the carrier in the cytoplasm are efficiency-determining steps in achieving successful gene silencing. In this study, acid-degradable ketalized linear polyethylenimine (KL-PEI) was synthesized for efficient, intracellular target-specific, and biocompatible siRNA delivery. The siRNA/KL-PEI polyplexes resulted in much higher RNA interference efficiency than unmodified L-PEI via selective cytoplasmic localization of the polyplexes and efficient disassembly of siRNA from the polyplexes, which were promoted upon acid-hydrolysis of amino ketal linkages. Confocal laser scanning microscopy demonstrated that siRNA was efficiently disassembled from the siRNA/KL-PEI polyplexes that were selectively localized in the cytoplasm. On the contrary, siRNA and unmodified linear PEI were colocalized in both the cytoplasm and the nucleus, and limited unpackaging of siRNA from the polyplexes was observed. In addition, ketalization further reduced the cytotoxicity of linear PEI but did not alter its serum-independent gene delivery efficiency. Therefore, KL-PEI is a promising nonviral vector for efficient and biocompatible siRNA delivery.

INTRODUCTION

Silencing gene expression in a sequence-specific manner by double stranded small interfering RNA (siRNA) has attracted great attention as a potential therapeutic approach for treating diseases arising from genetic defects (*1*−*3*). However, the use of siRNA is restricted by its inherent low stability against degradation and poor cellular uptake into cells in vitro or in vivo (*4, 5*). Therefore, the development of effective carrier systems, which can protect and deliver siRNA to the cytoplasm, where siRNA encounters target mRNA, is a major key to exploit the successful therapeutic and research use of siRNA in mammalian cells (*6, 7*). Among the gene carriers that have been investigated, nonviral vectors have recently attracted more and more attention in comparison to viral vectors, due to their advantages, including the ease of synthesis, delivery of large quantities of genes, and low immune response (*8*). Recently, cationic polymer-based nonviral systems for siRNA delivery have been popularly developed since the cationic polymers form stable polyplexes via electrostatic interaction and protect siRNA from enzymatic digestion (*9*−*13*). Common challenges in using the cationic polymer for siRNA delivery often involve high toxicity and limited siRNA delivery efficiency (*14*).

One of the major bottleneck steps in nonviral gene transfer is the escape of nucleic acid-containing carriers from the endosomal compartment, where acidic pH and nucleases efficiently digest nucleic acids, and the release of nucleic acids in their desired intracellular targets (e.g., cytoplasm for siRNA) (*15*−*18*). Therefore, the facilitated release of siRNA-containing polyplexes from the digestive endosome and efficient polyplex unpackaging in the cytoplasm are indispensible design goals of developing efficient carriers for gene silencing. In recent years, polyethylenimine (PEI)-based carriers have been highlighted as efficient nonviral nucleic acid delivery carriers (*4, 15, 19*−*22*). Among a variety of selections in terms of molecular weights (0.8−800 kDa) and topological isomers (branched or linear structures), linear high molecular weight PEI (L-HMW PEI) (e.g, 22 kDa) and branched high molecular weight PEI (B-HMW PEI) (e.g., 25 kDa) have demonstrated sufficient efficiency. Although both polymers have shown high gene delivery efficiency in vitro (*15, 23*), L-HMW PEI has shown much higher in vivo gene expression with less cytotoxicity in comparison to branched PEI (B-PEI) (*22*−*26*). However, linear PEI shows limited efficiency in siRNA delivery, although the reason for such a discrepancy between DNA and siRNA delivery efficiencies is unclear (*20, 27*). For this reason, finding a strategy to improve siRNA delivery efficiency using linear PEI is of great interest.

In this study, 25 kDa linear PEI was modified to accomplish enhanced siRNA delivery with low cytotoxicity. It was hypothesized that the incorporation of acid-degradable amino ketal branches to secondary amines of linear PEI would facilitate endosomal escape, by broadened buffering capacity of primary, secondary, and tertiary amines, and the subsequent release of siRNA to the cytoplasm, thus resulting in efficient RNA interference. Under the acidic conditions in the endosome, hydrolyzed ketal side branches were expected to induce endosomal destabilization by increased osmotic forces and swollen polyplexes. It was shown that ketalized linear PEI resulted in high RNA interference (RNAi) efficiency, even in the presence of serum, through exclusive cytoplasmic localization of the siRNA-containing polyplexes and efficient unpackaging of

siRNA from the hydrolyzed polyplexes. This study implies that ketalized linear PEI is a promising siRNA delivery carrier offering substantially improved RNAi efficiency and biocompatibility.

MATERIALS AND METHODS

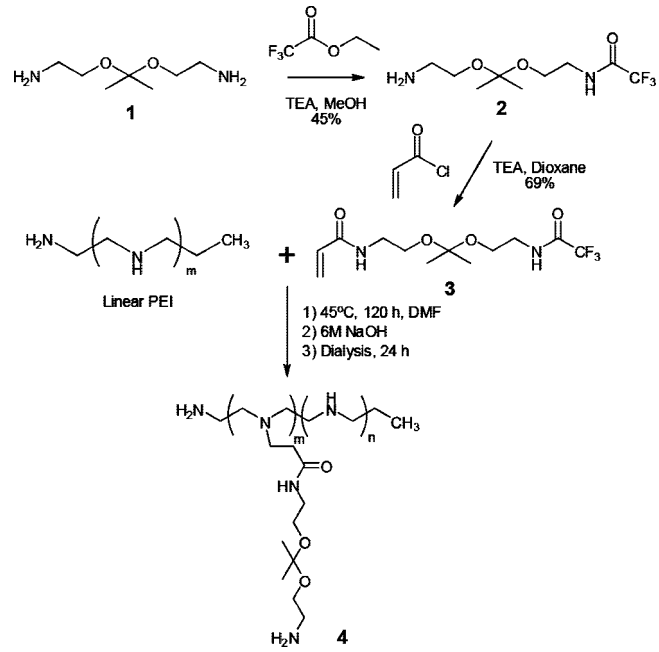
Materials. Linear polyethylenimine (25 kDa, 2.5 kDa) was purchased from Polyscience, Inc. (Warrington, PA). Branched polyethylenimine (25 kDa) and 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazoliumbromide (MTT) were purchased from Sigma Aldrich (Milwaukee, WI). 2-Aminoethanol, pyridinium *p*-toluenesulfonate, ethyl trifluoroacetate, 2-methoxypropene, molecular sieves, and 1,4-diaminobutane dihydrochloride were supplied from Acros (Morris Plains, NJ). Acryloyl chloride was supplied from Alfa Aesar (Ward Hill, MA). Ethidium bromide was purchased from Fisher Scientific (Pittsburgh, PA). Enhanced green fluorescent protein (eGFP)-encoding plasmid DNA was a generous gift from Dr. Pamela Davis (Department of Physiology and Biophysics, Case Western Reserve University, Cleveland, OH). Alexa Fluor 488 carboxylic acid succinimidyl ester dye was purchased from Molecular Probes (Eugene, OR), and DRAQ5 nuclear dye was purchased from BioStatus (Leicestershire, UK). Silencer GFP siRNA and Silencer Cy3-labeled negative control siRNA were purchased from Ambion (Austin, TX). NIH 3T3 cells (ATCC, Rockville, MD) were cultured in Dulbecco's modified Eagle's medium (DMEM) (MediaTech, Herndon, VA) with 10% fetal bovine serum (FBS) (Hyclone, Logan, UT), unless otherwise noted.

Polymer Characterization. Electrospray mass spectra of various monomers were obtained on a Micromass LCT mass spectrometer (Micromass Ltd., Manchester, UK). ^{1}H NMR spectrum of various ketalized linear PEI was obtained by a Bruker Avance 500 MHz NMR spectrometer (Bruker Biospin Corporation, Billerica, MA). Chemical shifts for ^{1}H NMR spectra were reported relative to (2,2-dimethyl-2-silapentane-5-sulfonate sodium salt) (DSS, $\delta = 0.015$ ppm) when D_2O was used as solvent. The molecular weights and molecular weight distributions of various ketalized linear PEI were determined by a gel permeation chromatography (GPC) system equipped with Agilent 1100 series (Agilent Technologies, Santa Clara, CA). The eluent was water, and a flow rate of 1.0 mL/min was used. The sample was diluted to 0.5 mg/mL in DI water and filtered through 0.45 μm PVDF syringe filters, and 100 μL of sample was injected into the GPC system for analysis. The molecular weights were calibrated against poly(ethylene oxide) standards.

Synthesis of Ketalized Linear Polyethylenimine (KL-PEI). Acid-degradable ketalized linear polyethylenimine in which acid-degradable ketal linkages were grafted was synthesized via Michael addition conjugation of acrylated ketal monomers (Scheme 1).

Synthesis of Compound 2 [*N*-(2-(2-(2-Aminoethoxy)propan-2-yloxy)ethyl)-2,2,2-trifluoroacetamide]. [1,1′-(2,2′-(Propane-2,2-diylbis(oxy))bis(ethane-2,1-diyl))diurea] (compound **1**) was prepared as previously reported (*28*). Compound **1** (2.2 g, 13.58 mmol, 1 equiv) was dissolved in 10 mL of methanol with 2.06 g of triethylamine (20.37 mmol, 1.5 equiv). Ethyl trifluoroacetate (1.93 g, 13.58 mmol, 1 equiv) was dissolved in 10 mL of methanol, and the resulting mixture was slowly added dropwise to the solution of compound **1** on ice. The reaction mixture was stirred for 6 h on ice, and then the mixture was extracted with 3 × 30 mL of dichloromethane. The organic layers were combined and evaporated. The product was purified by silica gel chromatography using a gradient from hexane to 60/40 hexane/tetrahydrofuran to obtain the product as a white solid (1.57 g, 6.11 mmol, 45% yield). ESI-MS $[M + H]^+$ calcd 259.1; found, 259.2. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.37 (s, 6H, $CF_3CONHCH_2CH_2OC(C\underline{H_3})_2OCH_2CH_2NH_2$); δ 1.51 (br, 2H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2CH_2N\underline{H_2}$); δ 2.88 (t, 2H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2C\underline{H_2}NH_2$); δ 3.52 − 3.56 (m, 4H, $CF_3CONHC\underline{H_2}C\underline{H_2}OC(CH_3)_2OCH_2CH_2NH_2$); δ 3.70 (t, 2H, $CF_3CONHCH_2CH_2OC(CH_3)_2OC\underline{H_2}CH_2NH_2$); δ 9.50 (br, 1H, $CF_3CON\underline{H}CH_2CH_2OC(CH_3)_2OCH_2CH_2NH_2$).

Scheme 1. Synthesis of Ketalized Linear PEI



Synthesis of Compound 3 [*N*-(2-(2-(2-(2,2,2-Trifluoroacetamido)ethoxy)propan-2-yloxy)ethyl)acrylamide. Compound **2** (1.40 g, 5.42 mmol, 1 equiv) was dissolved in 10 mL of dioxane with 2.19 g of triethylamine (21.68 mmol, 4 equiv), and the mixture solution was kept in an ice bath. Acryloyl chloride solution (0.98 g, 10.84 mmol, 2 equiv) was prepared in 10 mL of dioxane and slowly added to the solution of compound **2**. The reaction mixture was stirred for 10 min, and the product was extracted using 3 × 100 mL of ethyl acetate and then purified by silica gel chromatography using a gradient from hexane to 1/1 hexane/ethyl acetate to obtain the product as a yellow oil (1.17 g, 3.75 mmol, 69% yield). ESI-MS $[M + H]^+$ calcd 313.1; found, 313.2. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.36 (s, 6H, $CF_3CONHCH_2CH_2OC(C\underline{H_3})_2OCH_2CH_2NHCOCHCH_2$); δ 3.48 − 3.53 (m, 8H, $CF_3CONHC\underline{H_2}C\underline{H_2}OC(CH_3)_2OC\underline{H_2}C\underline{H_2}NHCOCHCH_2$); δ 5.67 (dd, 1H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2CH_2NHCOCHCH'\underline{H''}$); δ 6.01 (br, 1H, $CF_3CON\underline{H}CH_2CH_2OC(CH_3)_2OCH_2CH_2NHCOCHCH_2$); δ 6.14 (dd, 1H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2CH_2NHCOC\underline{H}CH_2$); δ 6.33 (dd, 1H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2CH_2NHCOCHC\underline{H'}H''$); δ 7.05 (br, 1H, $CF_3CONHCH_2CH_2OC(CH_3)_2OCH_2CH_2N\underline{H}COCHCH_2$).

Synthesis of Compound 4. Linear low molecular weight PEI (L-LMW PEI, 2.5 kDa) and linear high molecular weight PEI (L-HMW PEI, 25 kDa) (0.1 g, 2.33 mmol of secondary amine groups, 1 equiv) were dissolved in 2 mL of methanol followed by evaporating the methanol under high vacuum for 30 min. The resulting solution was dissolved in 10 mL of dimethylformamide (DMF) with 0.73 g of compound **3** (2.33 mmol, 1 equiv), and 0.23 g of triethylamine (2.33 mmol, 1 equiv), which served as a deprotonating agent as well as a preventer of hydrolysis of ketals, was added. The resulting mixture was stirred for 120 h at 45 °C, and the polymer was precipitated into anhydrous diethyl ether and dried under vacuum. The precipitated polymer was dissolved in 10 mL of 1:9 MeOH/6 M NaOH solution and stirred for 12 h to deprotect trifluoro-

acetate groups. After deprotection, the polymer was dissolved in DI water and purified by dialysis against DI water at 4 °C (Mw cutoff of dialysis membrane = 500 for L-LMW PEI and Mw Cutoff = 6000 for L-HMW PEI). After 24 h of dialysis, each polymer was lyophilized overnight to obtain the product as a powder with a hint of yellow color [60 mg of ketalized linear low molecular weight PEI (KL-LMW PEI) (26% yield) and 72 mg of ketalized linear high molecular weight PEI (KL-HMW PEI) (36% yield)]. ^{1}H NMR (500 MHz, D_2O): δ 1.41 (s, -$NCH_2CH_2CONHCH_2CH_2OC(C\underline{H}_3)_2OCH_2CH_2NH_2$); δ 2.7 − 3.0 (m, -C$\underline{H}_2$-C$\underline{H}_2$-NH-, -NC$\underline{H}_2C\underline{H}_2$$CONHCH_2CH_2OC(CH_3)_2$-$OCH_2CH_2NH_2$, and - $NCH_2CH_2CONHCH_2CH_2OC(CH_3)_2OCH_2$-C$\underline{H}_2NH_2$); δ 3.3 − 3.7 (m, -$NCH_2CH_2CONHC\underline{H}_2CH_2OC(CH_3)_2$-$OCH_2CH_2NH_2$, -$NCH_2CH_2CONHCH_2C\underline{H}_2OC(CH_3)_2OCH_2CH_2$-$NH_2$, and - $NCH_2CH_2CONHCH_2CH_2OC(CH_3)_2OC\underline{H}_2CH_2NH_2$).

Hydrolysis Kinetics of KL-PEI. The hydrolysis rates of KL-PEI at different molecular weights and pH values were investigated by incubating KL-PEI in (10 mg) pH 5.0 acetate, 6.0 acetate, and pH 7.4 Tris-HCl buffers in D_2O at 37 °C (0.6 mL) for various periods of time. Disappearance of the ketal linkage peak (1.41 ppm) was quantified by using ^{1}H NMR spectroscopy in comparison with the constant buffer salt peak. Half-lives of the various PEI at different pH values were obtained by using the Arrhenius equation.

Preparation and Characterization of siRNA/PEI Polyplexes. Two micrograms of siRNA with various amounts of polymers were mixed in 100 μL of DI water at various N/P ratios, followed by incubation for 30 min at room temperature. Then the resulting polyplex solution was diluted with additional 800 μL of DI water. Mean particle diameter (Z-average) and zeta potential of various siRNA/PEI polyplexes were measured at 25 °C by using ZEN3600 Zetasizer (Malvern Instruments, Worcestershire, UK)y. The viscosity (0.887 mPa/s) and the refractive index (1.333) of water at 25 °C were used to analyze the data. The mean values of each sample were yielded from the data obtained from at least 10 measurements. Each sample was analyzed in triplicate.

Ethidium Bromide Exclusion Assay. The ability of KL-PEI to condense siRNA was evaluated by a standard ethidium bromide exclusion assay. After one microgram of ethidium bromide and 1 μg of siRNA in 40 μL of DI water were incubated for 15 min at room temperature, desired amounts of the polymer solution in 60 μL of DI water were added in order to achieve various N/P ratios. After 30 min of incubation, fluorescence intensity was measured using a fluorescence microplate reader (Molecular Devices, Sunnyvale, CA) with an excitation wavelength (λ_{ex}) of 320 nm and an emission wavelength (λ_{em}) of 600 nm. Normalized fluorescence was determined as $(F - F_0)/(F_{siRNA} - F_0)$, where F, F_0, and F_{siRNA} represent the fluorescence of the solution containing ethidium bromide and the polyplexes, the solution of ethidium bromide without siRNA and polymers, and siRNA/ethidium bromide solution, respectively. Reduced fluorescence intensity was used as a quantitative indicator of siRNA condensation in polyplexes.

Agarose Gel Electrophoresis Assay. The binding of siRNA with PEI was determined by 1.2% agarose gel electrophoresis. Desired amounts of ketalized and unketalized L-PEI dissolved in phosphate buffered saline (PBS) were mixed with 1 μg of siRNA in DI water (17 μL in total) to yield various N/P ratios, followed by incubation for 15 min. Three μL of a gel loading dye was added to each polyplex solution, and 20 μL of the resulting polyplex solution was loaded on a gel containing 1 μg/mL of ethidium bromide. To verify the dissociation of the siRNA from the polymers upon hydrolysis, 2 μg of siRNA and desired amounts of polymer were mixed in 8 μL of DI water to obtain various N/P ratios. Then the mixture was incubated for 20 min at R.T. followed by the addition of 26 μL of pH 5.0 acetate buffer. The polyplexes were further incubated for 4 h at 37 °C. A 17 μL aliquot of the sample containing 1 μg of siRNA was mixed with 3 μL of gel loading dye, and 20 μL of the mixture solution was loaded on the agarose gel. The samples were electrophoresed in Tris-acetate-EDTA (TAE) buffer at 60 V for 15 min. The siRNA bands were then visualized under a UV transilluminator at a wavelength of 365 nm.

Transmission Electron Microscopy. Size and morphological changes of various polyplexes upon hydrolysis were analyzed by transmission electron microscopy (TEM). Briefly, siRNA/KL-PEI polyplexes were prepared by mixing 1 μg of siRNA with various PEI in 20 μL of DI water to obtain the N/P ratio of 100. A 2 μL aliquot of the sample solution was dropped on a carbon-coated copper TEM grid (Electron Microscopy Sciences, Hatfield, PA) and air-dried for 10 min at R.T. Grids were then stained with uranyl acetate and dried. To prepare hydrolyzed particles, 20 μL of siRNA/KL-PEI polyplex solution was mixed with 40 μL of pH 5.0 acetate buffer and further incubated for 4 h at 37 °C. Then a 6 μL aliquot of the resulting polyplex solution was deposited on a grid and dried. TEM images were acquired using Philips CM20 (Philips Electronic Instruments, Mahwah, NJ) operated at 200 kV.

Fluorescence Labeling of Polyplexes and Quantification. Desired amounts of various polymers were mixed with 4 μg of siRNA in DI water (400 μL total) to obtain various N/P ratios. The polyplexes were incubated for 30 min at room temperature and then fluorescently labeled with Alexa Fluor 488 dye (Molecular Probes, Inc., Eugene, OR) by following the manufacturer's instructions. Labeled siRNA/L-PEI polyplexes were purified from unreacted dyes by a PD-10 size exclusion column (GE Healthcare, Piscataway, NJ) using DMEM as eluent. To quantify Alexa Fluor 488 conjugation to siRNA/KL-PEI polyplexes, the fluorescence intensity of the Alexa Fluor 488-conjugated polyplexes was compared with the one of Alexa Fluor 488 added for conjugation. Briefly, siRNA/KL-PEI polyplexes were prepared by mixing 71.3 μg of KL-LMW PEI with 4 μg of siRNA in DI water (500 μL total) to achieve the N/P ratio of 100. After 30 min of incubation, KL-LMW PEI (0.11 mmol of primary amines linked to ketal branches, 1 equiv) complexing siRNA reacted with Alexa Fluor 488 carboxylic acid succinimidyl ester dye (1 equiv), and the resulting mixture was incubated for 2 h at R.T. Then unreacted Alexa Fluor 488 dyes were removed using a PD-10 size exclusion column. Fluorescence of the Alexa Fluor 488 labeled-polyplexes was measured using a microplate reader with an excitation wavelength (λ_{ex}) of 488 nm and an emission wavelength (λ_{em}) of 520 nm. In addition, a fluorescence standard curve was constructed using various concentrations of Alexa Fluor 488 dye stock solution in the range of 0.01 mM to 10 mM. In order to quantitatively estimate the amount of free Alexa Fluor 488 released from the ketalized linear PEI upon hydrolysis, Alexa Fluor 488-labeled polyplexes were incubated in pH 5.0 acetate buffer for 4 h at 37 °C. Released free Alexa Fluor 488 dye was removed by eluting the polyplexes through a PD-10 size exclusion column, and the reduced fluorescence intensity of the eluted solution was compared with the one of the unhydrolyzed ploxyplexes-containing solution.

Confocal Laser Scanning Microscopy. Confocal laser scanning microscopy was performed to observe the intracellular localization of various siRNA/PEI polyplexes. NIH 3T3 cells were inoculated at a density of 2.0×10^4 cells/well in a Falcon 8-well cultureslide (BD Biosciences, Franklin Lakes, NJ), 15 h prior to the incubation with the polyplexes. Five hundred twenty microliters of polyplex solution containing 0.6 μg of siRNA in DMEM, prepared as described above, was added to each well. After 6 h of incubation, the cells were washed with PBS four times and fixed with 2% *p*-formaldehyde solution for 30 min

at 4 °C. Then, the nuclei of the cells were counter-stained by treating 1 μM nuclear dye DRAQ5 solution in PBS (BioStatus, Leicestershire) for 20 min, and the cells were washed with PBS. Fluorescence images were acquired using an Olympus IX2 inverted microscope equipped with a Fluoview 1000 confocal scanning microscopy setup (FV10-ASW, Olympus America, Melville, NY) and a 40X/1.3 NA oil immersion planapochromat objective lens. Alexa Fluor 488 was excited with a 488 nm multiple argon laser light, and emission was collected using a SDM 560 dichroic mirror and a 505−605 nm band-pass filter. Images of DRAQ5-stained nuclei were acquired using a 635 nm helium−neon laser excitation light, a 635 nm dichroic mirror, and a 655−755nm band-pass barrier filter. Digital image recording and analysis were carried out using FV10-ASW 1.6 viewer (Olympus America). The cells were scanned in three dimensions as a z-stack of two-dimensional images (1024 × 1024 pixels). An image cutting horizontally through approximately the middle of the cellular height was selected out of a z-stack of images to differentiate the fluorescence from the polyplexes located in the perinuclear and intranuclear areas. To observe siRNA and polymer in NIH 3T3 cells, polyplexes were prepared with Cy3-labeled siRNA, as described earlier. Then linear PEI complexing Cy3-labeled siRNA were labeled with Alexa Fluor 488 dye. Unreacted dyes were removed using PD-10 size exclusion columns. Desired amounts of polyplex solutions containing 0.6 μg of siRNA in DMEM were added to each well containing NIH 3T3 cells inoculated at a density of 2.0×10^4 cells. After 4 h of incubation, the cells were washed several times with PBS and fixed with 2% *p*-formaldehyde solution for 30 min at 4 °C. Then, the fixed cells were counter-stained by DRAQ5 and washed with PBS. Fluorescence images of Alexa Fluor 488 were acquired using a 488 nm excitation light from a multiple argon laser, a SDM560 dichroic mirror, and a 505−540 nm band-pass barrier filter. A 559 nm helium−neon laser, a SMD640 dichroic mirror, and a 575−620 nm band-pass barrier filter were used to obtain the images of Cy3-labeled siRNA. Images of DRAQ5-stained nuclei were acquired using a 635 nm helium−neon laser, a 635 nm dichroic mirror, and a 655−755 nm band-pass barrier filter. Each excitation light was scanned separately for the individual excitation of the dyes to eliminate cross-talk.

RNA Interference. eGFP-expressing NIH 3T3 cells were obtained by retroviral transduction and subsequent G418 selection (*29*). Cells were seeded in a 24-well plate at a density of 2×10^4 cells/well. siRNA-containing polyplexes were prepared by mixing various amounts of polymer stock solutions in PBS with anti-eGFP siRNA or nonspecific control siRNA solutions (75 pmol) in DI water to obtain various N/P ratios in the final volume of 75 μL, followed by 30 min of incubation at R.T. After 24 h, the culture medium in each well was replaced with 300 μL of FBS-free DMEM or 10% FBS-containing DMEM. Then 75 μL of polyplex solutions was added to the cells to obtain a final siRNA concentration of 200 nM. After 4 h of incubation, the medium in the well was replaced with 0.5 mL of fresh DMEM containing 10% FBS, and the cells were further cultured for 72 h. After the cells were harvested by trypsinization and washed with PBS, their eGFP fluorescence was analyzed by using a Guava EasyCyte Plus flow cytometer (Guava Technologies, Hayward, CA). The silencing of eGFP gene expression was quantified by mean fluorescence intensities of the cells incubated with various siRNA-containing polyplexes in comparison with the cells incubated without polyplexes.

Cytotoxicity Assay. eGFP-expressing NIH 3T3 were inoculated at a density of 4×10^3 cells/well in a 96-well plate and incubated for 24 h. The culture medium was replaced with the mixtures of 60 μL of FBS-free DMEM and 15 μL of anti-eGFP siRNA or nonspecific control siRNA (15 pmol) polyplex solutions in a final siRNA concentration of 200 nM in a well. After 4 h of incubation, the medium was replaced with 100 μL of fresh DMEM supplemented 10% FBS. After the cells were further incubated for 24 h at 37 °C, the medium was replaced with the mixture of 10 μL of 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium bromide (MTT) in PBS (10 mg/mL) and 90 μL of growth medium. After 3 h of incubation, the MTT solution was discarded from each well, and the mixtures of 200 μL of DMSO and 20 μL of glycine buffer (0.1 M glycine, 0.1 M NaCl) were added to dissolve the blue formazan crystals formed by live cells. The relative viability of the cells treated with various polyplexes was determined by UV absorbance of formazan products at 561 nm.

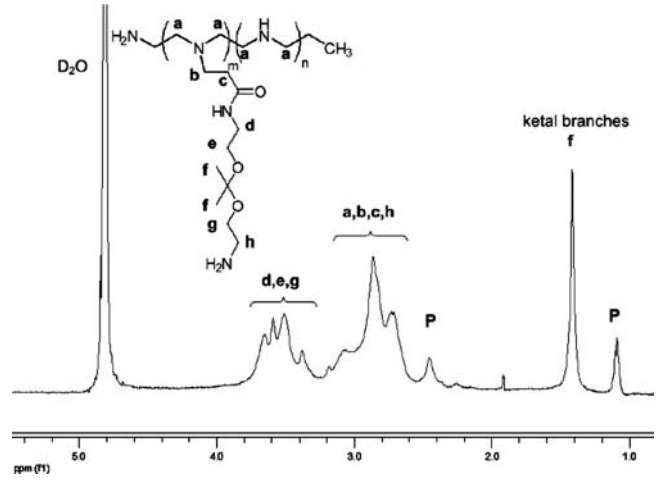


Figure 1. ^{1}H NMR spectrum of ketalized linear low molecular weight PEI (KL-LMW PEI). The peaks appearing at 1.1 ppm and at 2.4 ppm (denoted by P) indicate the -CH_3 and -CH_2- protons of the residual propionyl moiety in commercial linear PEI, respectively.

Statistics. Triplicate data were analyzed using one-way analysis of variance (ANOVA) on the significance level of $p < 0.01$ and presented as mean ± standard deviation.

RESULTS AND DISCUSSION

Design and Synthesis of Ketalized Linear PEI. As intracellular targets for DNA transfection and RNA interference are different (*30, 31*), the design of nonviral carrier for siRNA delivery should be distinguished from the one for DNA delivery in order to obtain desired therapeutic effects. It is hypothesized that efficient cytoplasmic release of free siRNA is required to maximize the therapeutic efficacy and avoid undesirable effects. Therefore, in this study, acid-degradable ketalized linear PEI (KL-PEI) was specifically designed and synthesized to achieve efficient cytoplasmic localization of polyplexes and unpackaging of the polyplexes through hydrolysis of ketal branches grafted to the polymer backbone. Acrylamide groups at the end of amino ketal monomers were conjugated to secondary amines of linear PEI via a Michael addition reaction. A sharp singlet peak at 1.41 ppm (i.e., methyl protons of ketal linkage) in the ^{1}H NMR spectrum of ketalized linear low molecular weight (KL-LMW) PEI indicates successful conjugation of acid-degradable branches (Figure 1). It was found that ketal hydrolyzed at pH 7.4 at 4 °C with a half-life of approximately 200 h. The hydrolysis test using ^{1}H NMR showed that approximately 8.0% of ketal linkages hydrolyzed during the dialysis for the purification of ketalized linear PEI. To quantify the degree of hydrolysis during the dialysis, integral ratios of methyl protons (1.41 pm) of ketal linkage peak to methyl protons (1.1 ppm) of the residual propionyl moiety of linear PEI in ^{1}H NMR spectra were measured before and after dialysis, respectively. Ketalization ratios relative to available secondary amines were calculated

Table 1. Characterization and Hydrolysis Kinetics of Various Ketalized Linear PEI

polymer	degree of ketalization (mol %)	Mn (kDa)	Mw (kDa)	PDI	half-lives (h) pH 5.0	pH 6.0	pH 7.4
L-HMW PEI	0	23.8	45.5	1.91	N/A	N/A	N/A
L-LMW PEI	0	2.2	3.4	1.55	N/A	N/A	N/A
KL-HMW PEI	24	47.2	85.8	1.82	2.3	6.0	21.6
KL-LMW PEI	22	5.0	8.2	1.65	1.9	4.7	20.3

to be approximately 22% for ketalized linear low molecular weight PEI (KL-LMW PEI) and 24% for ketalized linear high molecular weight PEI (KL-HMW PEI), by integral ratios of the peak at 1.41 ppm to the peak at 2.7−3.0 ppm. The polydispersity of the ketalized PEI was not increased during the synthesis (Table 1). It was also found that the buffering capacity of linear PEI was not significantly changed by ketalization (Supporting Information, Figure S1).

Acid-Degradability of KL-PEI. Hydrolysis rates of KL-PEI at endosomal and physiological pH values were investigated by incubating the polymer in acetate and Tris-HCl buffers in D_2O at 37 °C for various periods of time. The disappearance of the ketal linkage peak at 1.41 ppm relative to the constant buffer salt peak at different incubation time points was quantified by ^1H NMR spectroscopy. As shown in Table 1, the half-lives of KL-LMW PEI at pH 5.0, 6.0, and 7.4 were calculated to be 1.9, 4.7, and 20.3 h, respectively, while the half-lives of KL-HMW PEI at each different pH were 2.3, 6.0, and 21.6 h, respectively (Table 1). The results show that the KL-PEI hydrolyzed about 10 times faster at an endosomal pH of 5.0 than at a physiological pH of 7.4, regardless of molecular weights. It is desirable for nucleic acids to be released from the carrier by an intracellular stimulus (e.g., low pH) (*32*), and KL-PEI was found to be capable of intracellular release of siRNA via effective hydrolysis in the acidic endosome, which facilitates endosomal membrane destabilization and unpackaging of siRNA/KL-PEI polyplexes.

Acid hydrolysis of ketal linkages in a test tube depends on the concentration of amines, which can scavenge protons and change pH, but roles of the polymer concentration dependency of ketal hydrolysis in a cell have not been confirmed. In this study, ketal hydrolysis was tested at the concentration of 16.7 mg/mL in a test tube, which was substantially higher than the highest polymer concentration of incubation (i.e., 66 μg/mL at the N/P ratio of 140), although it is very difficult to assess what exactly would be the concentration of the polymer (or amines) in the endosome/lysosome. In addition, the proton concentration in the endosome/lysosome changes by active influx via proton pumps.

Complexation of siRNA with KL-PEI. Condensation of nucleic acids by a gene carrier plays a key role in determining extracellular stability, endocytosis of polyplexes, and eventual gene expression (*33, 34*). The effects of ketalization on siRNA condensation in various PEI polyplexes were confirmed by size reduction. As shown in Figure 2A, the size of siRNA/B-PEI (25 kDa) polyplexes at the N/P ratio of 5 and above was relatively constant in the range of 110 to 160 nm. Unmodified L-LMW and L-HMW PEI formed siRNA-containing polyplexes in similar sizes of 130 to 220 nm in diameter at the N/P ratio of 10 to 120. It was shown that KL-PEI effectively condensed siRNA into nanosized particles at high N/P ratios, allowing them to enter the cell through nonreceptor-mediated endocytosis. The size of siRNA/KL-LMW PEI polyplexes was in the range of 120 to 190 nm at the N/P ratio of 10 to 120, which was close to the size of siRNA/L-LMW PEI and siRNA/L-HMW PEI polyplexes. However, KL-HMW PEI formed polyplexes with diameters of 170 to 400 nm at the observed N/P ratios, indicating lower complexation efficiency of siRNA by KL-HMW PEI than by the other types of PEI.

Ethidium bromide exclusion analysis was also conducted to quantitatively evaluate the abilities of polymers to condense siRNA in the polyplexes. As shown in Figure 2B, siRNA/B-PEI, siRNA/L-LMW PEI, and siRNA/L-HMW PEI showed

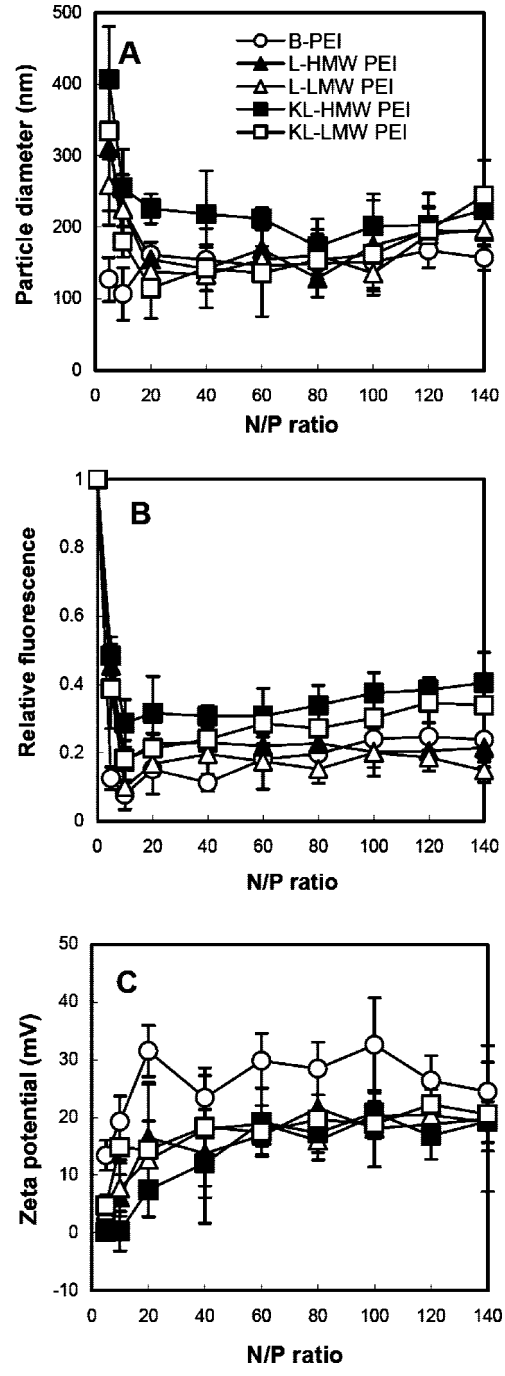

Figure 2. (A) Particle size of various siRNA/PEI polyplexes at various N/P ratios, determined by DLS analysis. (B) siRNA condensation efficiency of various siRNA/KL-PEI polyplexes at various N/P ratios, measured by ethidium bromide exclusion assay. (C) Surface charge density of various siRNA/PEI polyplexes at various N/P ratios.

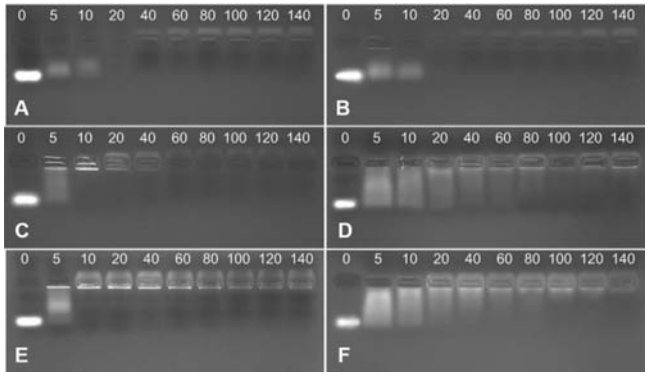

Figure 3. Agarose gel electrophoresis of various siRNA/linear PEI polyplexes at different N/P ratios. (A) siRNA/L-LMW PEI polyplexes, (B) siRNA/L-HMW PEI polyplexes, (C) siRNA/KL-LMW PEI polyplexes before hydrolysis, (D) siRNA/KL-LMW PEI polyplexes after hydrolysis, (E) siRNA/KL-HMW PEI polyplexes before hydrolysis, and (F) siRNA/KL-HMW PEI polyplexes after hydrolysis. Numbers indicate N/P ratios. (0 N/P ratio: naked siRNA only.)

efficient fluorescence quenching, indicating their abilities to efficiently condense siRNA. In contrast, both KL-LMW PEI and KL-HMW PEI showed less efficient siRNA condensation ability compared to unmodified L-PEI. Particularly, siRNA/KL-HMW PEI polyplexes exhibited relatively low condensation efficiency, even at high N/P ratios. The reason for the low condensation efficiency of siRNA by both KL-LMW PEI and KL-HMW PEI can be explained by their spatially hampered interactions with siRNA resulting from bulky ketal arms, especially when they were conjugated to high molecular weight linear PEI (*28*). Generally, it was observed that the siRNA condensation efficiency of various polyplexes determined by the ethidium bromide exclusion assay corresponded to size reduction of the polyplexes (Figure 2A and B).

The measured zeta potentials of various siRNA/PEI polyplexes were shown in Figure 2C. All of the polyplexes had positive surface charges at the observed range of N/P ratios, suggesting that negatively charged siRNA was successfully condensed into the polymers. All KL-PEI and unmodified L-PEI polyplexes prepared at the N/P ratio of 60 and above exhibited relatively constant positive zeta potentials of +16 to +22 mV. The polyplexes formed by both KL-LMW PEI and KL-HMW PEI did not show a noticeable difference in surface charges compared to those of the polyplexes formed by unmodified L-LMW PEI and L-HMW PEI ($p > 0.3$). Polyplexes prepared by siRNA and B-PEI showed the highest cationic surface charge among the various polyplexes, obviously due to the highest cationic density of the B-PEI (*35*).

Efficient Dissociation of siRNA from Hydrolyzed KL-PEI Polyplexes. The formation of various siRNA/PEI polyplexes and the dissociation of the siRNA from the polyplexes upon hydrolysis were demonstrated by agarose gel electrophoresis assay. As shown in Figure 3A and B, siRNA was partially retained by unmodified L-PEI at the N/P ratio up to 20 and completely retarded at the N/P ratios of 40 and above. However, for siRNA/KL-PEI polyplexes, the siRNA was completely retarded even at the N/P ratio of 10, indicating that KL-PEI could efficiently interact with negatively charged siRNA at lower N/P ratios than unmodified L-PEI (Figure 3C and E). This result is expected because of improved interactions of siRNA with amine-bearing branches, which can more closely access to siRNA than the linear cationic backbone of PEI. By the incorporation of ketal branches to linear PEI, secondary amines of linear PEI were altered to tertiary amines, and additional primary amines were generated from the ketal branches. Therefore, the newly added primary amines will make

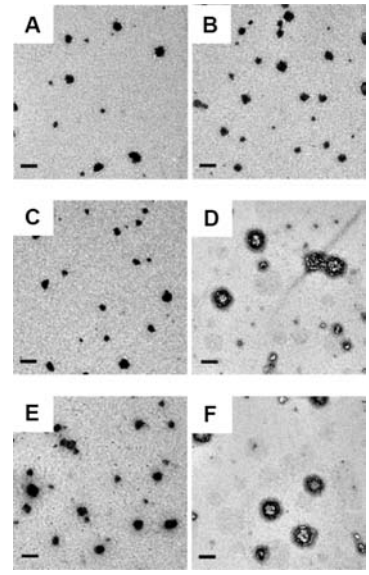

Figure 4. TEM micrographs of (A) siRNA/L-LMW PEI polyplexes (N/P = 40), (B) siRNA/L-HMW PEI PEI polyplexes (N/P = 40), (C) siRNA/KL-LMW PEI polyplexes (N/P = 100) before hydrolysis, (D) siRNA/KL-LMW PEI polyplexes (N/P = 100) after hydrolysis, (E) siRNA/KL-HMW PEI polyplexes (N/P = 100) before hydrolysis, and (F) siRNA/KL-HMW PEI polyplexes (N/P = 100) after hydrolysis. Scale bar = 100 nm.

linear PEI more protonatable and can interact more closely with siRNA than unmodified linear PEI. Various siRNA/KL-PEI polyplexes were treated with pH 5.0 acidic buffer and electrophoresed to demonstrate the disassembly of siRNA from polyplexes upon hydrolysis of ketal branches, which simulates the release of siRNA in the acidic endosome. It was clearly confirmed that the hydrolysis of ketal branches in KL-PEI at mild acidic pH 5.0 facilitated siRNA release from the polyplexes even at high N/P ratios (e.g., 100 and 120) as shown in Figure 3D and F. No detectable degradation of naked siRNA incubated at pH 5.0 for 4 h at 37 °C was observed (data not shown). The results obtained from the gel electrophoresis assay indicate that ketalization of L-PEI did not alter siRNA condensation but facilitated siRNA release from the polyplexes upon hydrolysis in mild acidic environments.

Morphological Changes of siRNA/KL-PEI Polyplexes upon Hydrolysis. Transmission electron microscopy images were acquired to observe the changes of sizes and the morphologies of various siRNA/PEI polyplexes before and after hydrolysis (Figure 4). All of the unmodified L-PEI and KL-PEI formed spherical and compact siRNA-containing polyplexes with a diameter of 40−100 nm (Figure 4A, B, C, and E). In addition, no significant size difference among the polyplexes formed by L-LMW PEI, L-HMW PEI, and KL-LMW PEI was observed ($p > 0.8$). However, the size of siRNA/KL-HMW PEI polyplexes formed at the N/P ratio of 100 was slightly larger that of siRNA/unmodified L-PEI polyplexes (Figure 4E). The larger size of siRNA/KL-HMW PEI polyplexes compared to those of other polyplexes was consistent with the results obtained from DLS analysis (Figure 2A). Again, taken together with the results from ethidium bromide exclusion assay, these results imply that the siRNA complexation ability of KL-HMW PEI was lower than the ones of unmodified L-PEI and KL-LMW PEI, possibly because of steric hindrance from ketal branches. Importantly, the TEM images showed swollen and disrupted siRNA/KL-PEI polyplexes after hydrolysis (Figure 4D and F), indicating that hydrolysis of ketal branches of KL-PEI at the endosomal pH of 5.0 may be able to destabilize the polyplexes and therefore facilitate the disassembly of siRNA from the destabilized polyplexes.

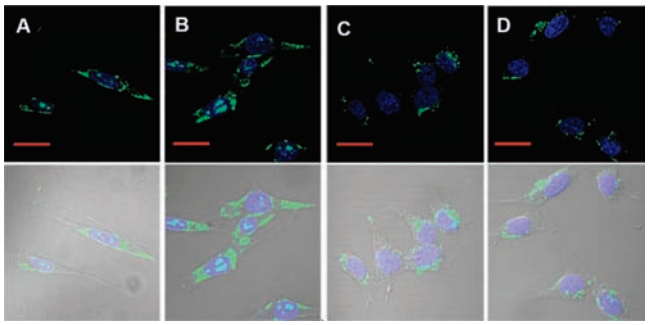

Figure 5. Laser scanning confocal micrographs illustrating the intracellular localization of various siRNA/L-PEI polyplexes in NIH 3T3 cells. (A) siRNA/L-LMW PEI polyplexes (N/P = 30), (B) siRNA/L-HMW PEI polyplexes (N/P = 30), (C) siRNA/KL-LMW PEI polyplexes (N/P = 100), and (D) siRNA/KL-HMW PEI polyplexes (N/P = 100). The upper panel depicts merged images of Alexa Fluor 488-stained polyplexes (green) and DRAQ5-counter-stained nuclei of the cells (blue). The lower panel depicts overlaid images of the upper panel and differential interference contrast (DIC) images of the cells. Images cutting horizontally through approximately the middle of the cell were selected out of a z-stack of images to differentiate the polyplexes in the perinuclear area from ones in the nucleus. Scale bar = 25 μm.

Intracellular Localization of Polyplexes. The intracellular localization of siRNA is an important factor for successful RNA interference. To investigate the intracellular localization of various siRNA/PEI polyplexes after cellular uptake, NIH 3T3 cells were incubated with various siRNA/PEI polyplexes and observed by confocal laser scanning microscopy. Various ketalized and unmodified L-PEI were used to complex unlabeled siRNA or Cy3-labeled siRNA, and the resulting polyplexes were further labeled with Alexa Fluor 488 dye. It was quantified that 42% of primary amines of KL-PEI were conjugated with Alexa Fluor 488. Since 1 equivalent Alexa Fluor 488 was used to react with the 1 equivalent primary amines of the entire KL-PEI complexing siRNA, and Alexa Fluor 488 was conjugated after siRNA complexation, it is presumed that most primary amines on the surface of the polyplexes were conjugated with Alexa Fluor 488 (i.e., actual conjugation ratio of Alex Fluor 488 to primary amines on the surface of the polyplexes was significantly higher than 1). Since Alexa Fluor 488 conjugation to ketalized linear PEI with abundant primary amines and unmodified linear PEI with mainly secondary amines in the backbone is not identical, internalizations of fluorescently labeled and unlabeled polyplexes cannot be directly compared. Therefore, relative numbers of the polyplexes in the cytoplasm to the ones in the nucleus were considered to explore intracellular localizations.

Localization of the various polyplexes was observed in the middle focal plane, which traverses both the cytoplasm and the nucleus of a cell (Figure 5). As shown in Figure 5A and B, a large number of the polyplexes prepared by using unmodified L-PEI were found inside cells regardless of their molecular weights, and these polyplexes were localized not only in the cytoplasm but also in the nucleus. This observation was in agreement with a previous study reporting that L-PEI delivers nucleic acids to the nucleus (*36, 37*). On the contrary, siRNA/KL-LMW PEI and siRNA/KL-HMW PEI polyplexes (and possibly free Alexa Fluor dye released by acid hydrolysis) were exclusively localized in the cytoplasm where siRNA mediates its function (Figure 5C and D), demonstrating that ketalization of L-PEI greatly redirects the intracellular distributions of the polyplexes to the cytoplasm. Hydrolysis of siRNA/KL-PEI polyplexes is hypothesized to make the polyplexes become larger and destabilized as the hydrolyzed KL-PEI has neutrally charged hydroxyl side chains, which hinder tight complexation with the siRNA. Therefore, cytoplasmic localization of the

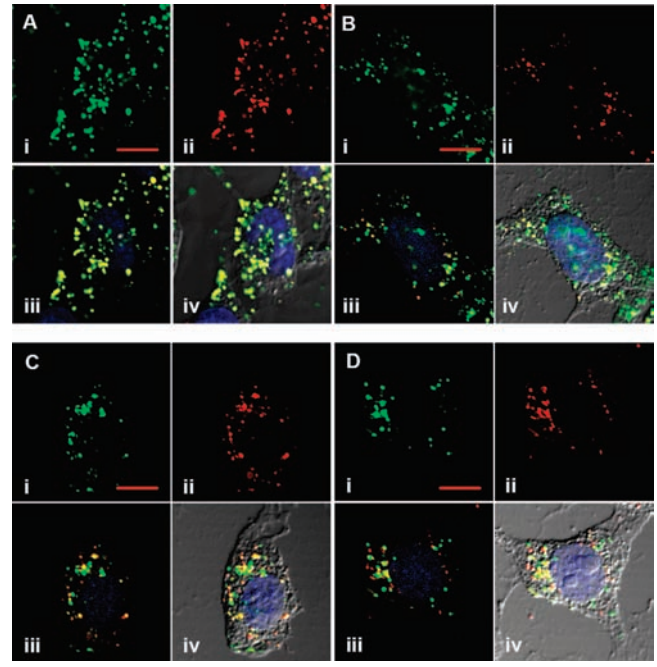

Figure 6. Laser scanning confocal micrographs illustrating the intracellular colocalization of Cy3 labeled-siRNA (red) and Alexa fluor 488 (green)-labeled linear PEI in NIH 3T3 cells. (A) siRNA/L-LMW PEI polyplexes (N/P = 30), (B) siRNA/L-HMW PEI polyplexes (N/P = 30), (C) siRNA/KL-LMW PEI polyplexes (N/P = 100), and (D) siRNA/KL-HMW PEI polyplexes (N/P = 100). The left upper panel depicts images of Alexa Fluor 488-labeled linear PEI (i), and the right upper panel depicts images of Cy3-labeled siRNA (ii). The left lower panel depicts merged images of Alexa Fluor 488-stained polyplexes and Cy3-labeled siRNA with nucleus staining (blue) (iii). The right lower panel depicts overlaid images of image (iii) and DIC image of the cells. Scale bar = 10 μm.

siRNA/KL-PEI polyplexes might be ascribed to their increased size and loose siRNA complexation in the cytoplasm, which prevent transport through nuclear pores.

Localization of Alexa fluor 488-labeled linear PEI (green, i) and Cy3-labeled siRNA (red, ii) was investigated, and the colocalized polymer and siRNA were represented as yellow dots (iii) in Figure 6. When the siRNA/unmodified linear PEI polyplexes were incubated with cells, siRNA and unmodified linear PEI were clearly colocalized both in the cytoplasm and the nucleus as shown in Figure 6A and B. On the contrary, when siRNA/KL-PEI polyplexes were incubated with the cells, both siRNA and the KL-PEI were mainly colocalized in the cytoplasm instead of entering the nucleus as shown in Figure 6C and D. More importantly, there were significantly more red spots, which represent stably labeled siRNA alone, in the cell incubated with siRNA/KL-PEI polyplexes than the ones incubated with siRNA/unmodified L-PEI polyplexes [Figure 6C (iii) and D (iii)] after 4 h of incubation in the cells. In comparison, siRNA/unmodified linear PEI polyplexes resulted in exclusive colocalization of siRNA and unmodified PEI [(Figure 6A (iii) and B (iii)]. Quantitative estimation of the amount of free Alexa Fluor 488 dye released from the ketalized linear PEI upon hydrolysis showed that 70% of the conjugated Alexa Fluor 488 dye was released during hydrolysis. This indicates that some yellow spots in the cells incubated with siRNA/KL-PEI polyplexes probably represent colocalized siRNA and free Alexa Fluor 488. Again, attention should be given to the fact that there were more red spots (i.e., free siRNA alone) in the cells incubated with KL-PEI polyplexes than the ones incubated with unketalized L-PEI polyplexes. This finding clearly demonstrates efficient intracellular disassembly of siRNA from ketalized linear

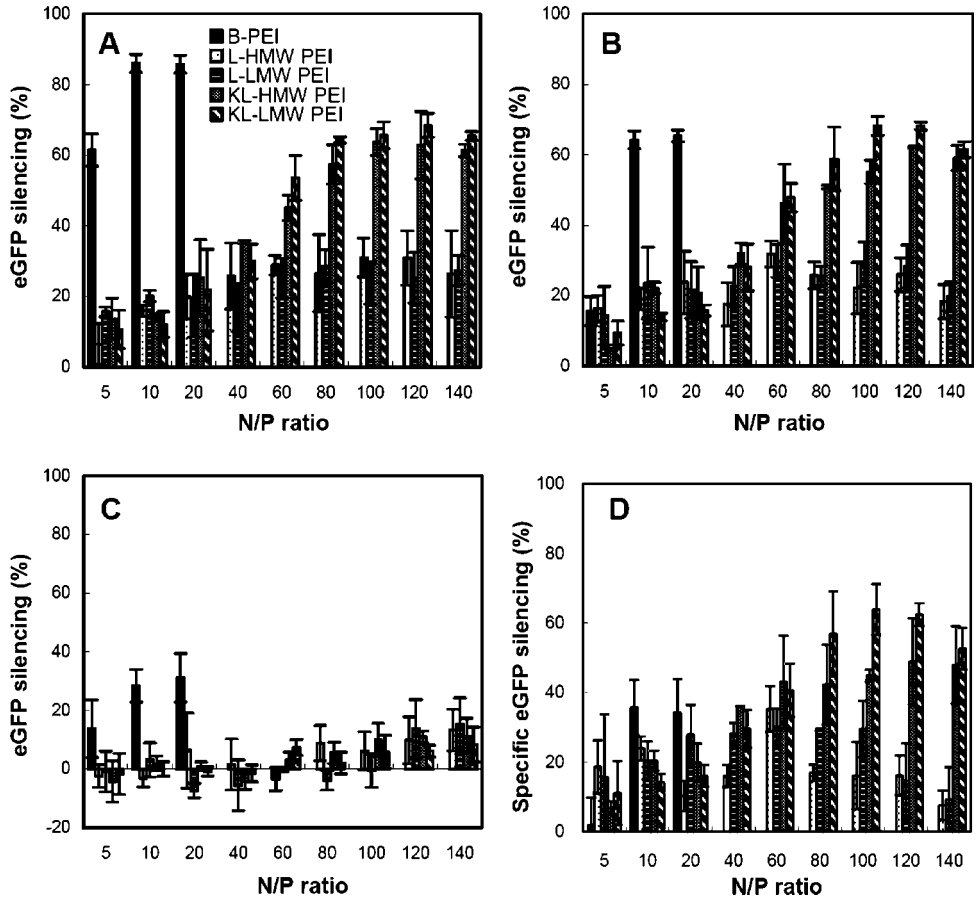

Figure 7. eGFP gene silencing efficiency of various siRNA/PEI polyplexes at various N/P ratios. eGFP knockdown in NIH 3T3 cells by various (A) siRNA/PEI polyplexes in the absence of serum, (B) siRNA/PEI polyplexes in the presence of serum, and (C) siRNA/PEI polyplexes synthesized with control (nonspecific) siRNA in the presence of serum. Specific eGFP silencing efficiency (D) was determined by subtracting nonspecific gene silencing efficiency of siRNA/PEI polyplexes synthesized with control siRNA from the gene silencing efficiency of siRNA/PEI polyplexes synthesized with anti-eGFP siRNA in the presence of serum. Notice that there was an insufficient number of live cells to analyze for gene silencing after being incubated with siRNA/B-PEI at N/P ratio of 40 and above due to severe cytotoxicity.

PEI polyplexes in the cytoplasm and efficient subsequent processes toward RNA interference.

Efficient Gene Silencing with Low Cytotoxicity by siRNA/KL-PEI Polyplexes. RNAi efficiency of various siRNA/PEI polyplexes at various N/P ratios was evaluated by quantifying the reduced expression of eGFP in NIH 3T3 cells. As shown in Figure 7A, to some extent, KL-PEI-mediated RNAi efficiency tended to increase with N/P ratios. This might be due to increased endosomal escape caused by higher numbers of amines (*17*). siRNA/B-PEI polyplexes showed the highest gene silencing efficiency among the various polyplexes in the absence of serum as shown in Figure 7A. Both unmodified L-HMW PEI and L-LMW PEI showed minimal RNAi efficiency at the entire N/P ratios in contrast to their superior DNA transfection efficiency as previously reported (*22*−*26*). In contrast, ketalization of L-PEI remarkably enhanced the RNAi efficiency ($p \ll 0.001$), and the highest gene silencing efficiencies of KL-HMW PEI and KL-LMW PEI were observed at N/P ratios of 100 and 120, respectively. A confocal laser scanning microscopy study showed that siRNA and unmodified L-PEI were exclusively colocalized in both the cytoplasm and the nucleus, although a large number of siRNA/unmodified L-PEI polyplexes were localized in the cytoplasm (Figure 6A and B). This finding indicates limited dissociation of siRNA from the polyplexes in the cytoplasm possibly due to highly stable siRNA complexation by L-PEI, resulting in limited RNAi activity (Figures 2B and 7A). However, acid-degradable KL-PEI was able to facilitate efficient polyplex unpackaging in the cytoplasm and subsequent siRNA release (Figure 6C and D), suggesting that the improvement of RNAi efficiency mediated by KL-PEI compared to that of unmodified L-PEI might be ascribed to more efficient endosomal escape and unpackaging of siRNA/KL-PEI polyplexes in the cytoplasm as well as its targeted cytosolic delivery of siRNA. As shown in Figure 7A, both KL-LMW PEI and KL-HMW PEI resulted in still slightly lower gene silencing efficiencies than B-PEI in the absence of serum. However, the gene silencing efficiency of siRNA/B-PEI polyplexes dramatically decreased in the presence of serum ($p < 0.005$), which might be attributed to an undesirable interaction of the polyplexes with negatively charged serum proteins (*38*). For example, the gene silencing by siRNA/B-PEI polyplexes reduced from 85.7% in the absence of serum to 65.3% in the presence of 10% serum at the N/P ratio of 20. Regardless of molecular weights, unmodified linear PEI did not show significant decrease in RNAi efficiency in the presence of serum ($p > 0.3$), as previously reported (*39*). Similarly, high gene silencing efficiencies of siRNA/KL-HMW PEI and siRNA/KL-LMW PEI polyplexes prepared at the N/P ratio of 80 to 140 remained without significant changes (Figure 7A and B). This result was also clearly presented by confocal laser scanning micrographs (Figure 8) as well as a flow cytometry histogram (Supporting Information, Figure S2). The effects of various serum concentrations on gene silencing efficiency by ketalized PEI were also investigated (Supporting Information, Figure S3). Results showed that KL-PEI, regardless of molecular weights, was able to silence eGFP expression more efficiently than unketalized branched and linear PEI in the presence of up to 50% serum as shown in Figure S3B (Supporting Information)

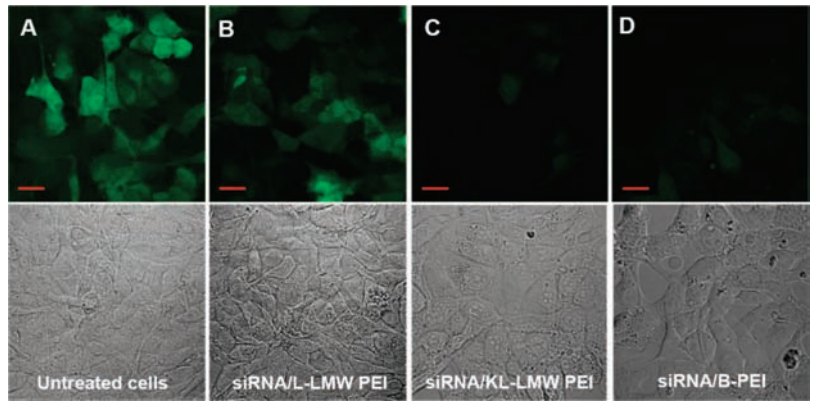

Figure 8. Confocal micrographs of eGFP-expressing NIH 3T3 cells (A) untreated used as a control and incubated with (B) siRNA/L-LMW PEI polyplexes (N/P = 60), (C) siRNA/KL-LMW PEI polyplexes (N/P = 120), and (D) siRNA/B-PEI polyplexes (N/P = 10), in the presence of 10% serum. The upper panel depicts fluorescent images of eGFP-expressing NIH 3T3 cells. The lower panel depicts differential interference contrast (DIC) images of the cells. Scale bar = 20 μm.

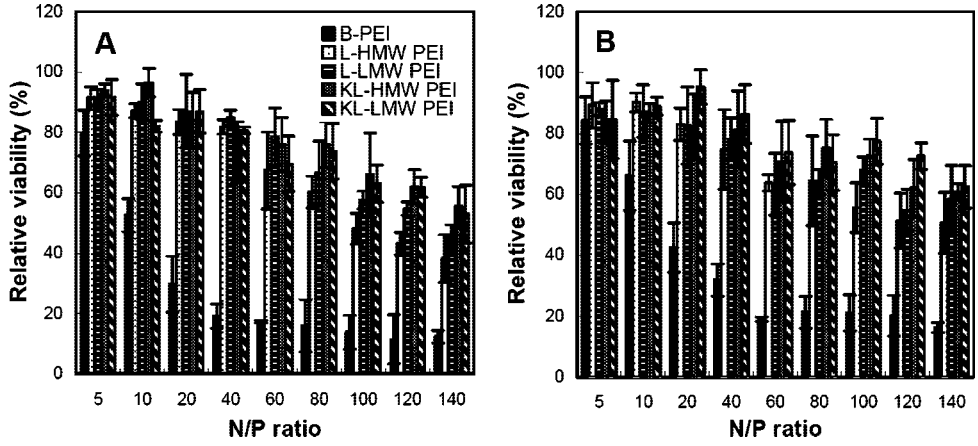

Figure 9. Viability of NIH 3T3 cells incubated with siRNA/PEI polyplexes at different N/P ratios (A) in the absence of serum and (B) in the presence of serum (10%). NIH 3T3 cells were incubated with polyplexes in serum-free or serum-containing medium for 4 h followed by 24 h of incubation with fresh medium supplemented with 10% FBS.

($p < 0.003$), although KL-PEI showed slightly less efficient siRNA condensation capability than unketalized branched and linear PEI (Figure 2B).

In order to exclude nonspecifically reduced gene expression by the polyplexes in gene silencing quantification, the eGFP expressing NIH 3T3 cells were also incubated with the polyplexes prepared by nonsequence-specific (control) siRNA and PEI. For the polyplexes prepared by using unmodified and ketalized linear PEI, nonspecific eGFP knockdown was found to be very minimal (e.g., less than 8% of gene silencing) at low N/P ratios (e.g., N/P $\leq$ 60), although nonspecific effects slightly increased with N/P ratios (Figure 7C). However, siRNA/B-PEI polyplexes showed significant nonspecific gene silencing in a N/P ratio-dependent way ($p \ll 0.001$) (Figure 7C). In other words, specific gene silencing by siRNA/PEI polyplexes must be considered after subtracting nonspecific effects (Figure 7D). Specific eGFP silencing by siRNA/KL-LMW PEI and siRNA/KL-HMW PEI polyplexes in the presence of serum was much higher than that of siRNA/B-PEI polyplexes. The maximum specific eGFP silencing by siRNA/KL-LMW PEI polyplexes at the N/P ratio of 100 was around 63%, which was about 2-fold higher than specific eGFP silencing efficiency by siRNA/B-PEI polyplexes at the N/P ratio of 10.

Cytotoxicity of siRNA/KL-PEI polyplexes was slightly lower than that of siRNA/unketalized L-PEI polyplexes ($p > 0.02$) but significantly lower than that of siRNA/B-PEI polyplexes as shown in Figure 9 ($p \ll 0.001$). Cells incubated with the siRNA/KL-PEI polyplexes remained more than 70% viable at the N/P ratios up to 80 whether they were incubated with serum or not. On the contrary, siRNA/B-PEI polyplexes showed significant cytotoxicity even at the N/P ratio of 20, regardless of the presence of serum ($p \ll 0.001$). This high cytotoxicity seems to contribute to nonspecific gene silencing by siRNA/B-PEI polyplexes (Figure 7C). Unmodified linear PEI showed relatively low cytotoxicity compared to B-PEI as previously reported (*27, 36*). It is well-known that high cytotoxicity of B-PEI is correlated with its high charge density (*40*). Since zeta potentials of siRNA/L-PEI and siRNA/KL-PEI polyplexes were a lot lower than that of B-PEI ($p \ll 0.001$), this low cationic charge density of the polyplexes probably contributed to high cell viability even at high N/P ratios. It seems that low cytotoxicity of KL-PEI is not only a consequence of the inherently low cytotoxicity of L-PEI but also the reduced interactions of hydrolyzed KL-PEI, which has neutral hydroxyl overhangs, with endogenous genes as previously discussed (*28, 41*). The reason for similar characteristics of KL-PEI to ones of unmodified L-PEI with regard to serum-independent gene transfer and low cytotoxicity might be due to a low degree of ketalization (i.e., 22 and 24%). Although linear PEI was transformed to a branched form to a certain extent by ketalization, its advantageous properties (e.g., low cytotoxicity and serum-independence) seem to be preserved. One of the practical challenges for in vivo gene delivery mediated by cationic nonviral vectors is inhibition of gene delivery efficiency by serum and high cytotoxicity (*42*). Although branched PEI, one of the efficient cationic nonviral gene delivery carriers, has been

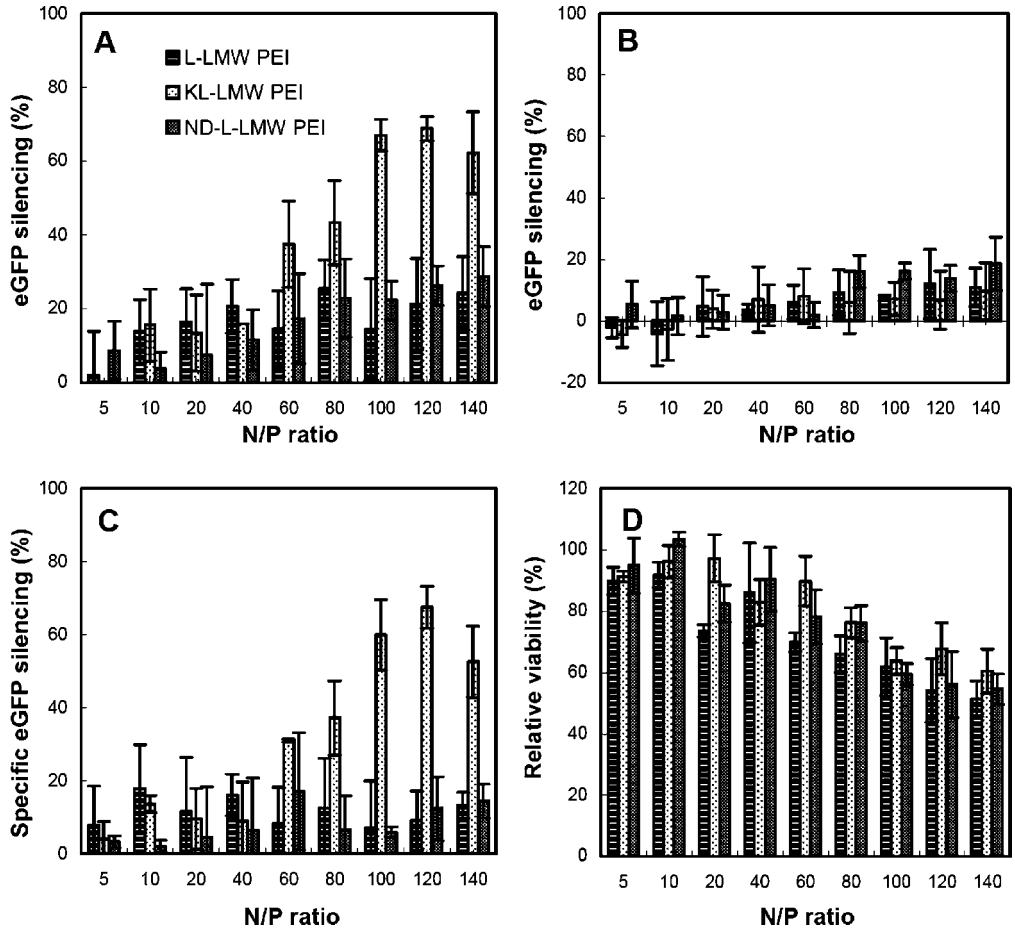

Figure 10. Effects of ketalization of L-PEI on eGFP gene silencing efficiency and cytotoxicity. eGFP knockdown in NIH 3T3 cells mediated by various (A) siRNA/PEI polyplexes in the presence of serum and (B) siRNA/PEI polyplexes synthesized with control (nonspecific) siRNA in the presence of serum, and (C) specific eGFP silencing efficiency of various siRNA/PEI polyplexes in the presence of serum. (D) Cytotoxicity of acid-degradable KL-LMW PEI and nondegradable modified L-LMW PEI (ND-L-LMW PEI) at various N/P ratios. eGFP expressing NIH 3T3 cells were incubated with various siRNA-containing polyplexes in the 10% FBS supplemented medium. After 4 h of incubation, the medium was replaced with fresh DMEM containing 10% FBS, and the cells were further cultured for 72 h.

popularly used for years due to its high transfection efficiency in vitro (*15*), its in vivo application has been limited because of its serum-dependent gene transfection efficiency and high cytotoxicity (*25, 36, 38, 43*). In contrast to branched PEI, KL-PEI showed serum-independent high RNAi efficiency and low cytotoxicity. Moreover, KL-PEI showed higher specific eGFP silencing efficiency than B-PEI (Figure 7D). Our previous study showed that the transfection efficiency of ketalized low molecular weight branched PEI was also influenced by the presence of serum to some extent such as unmodified 25 kDa branched PEI, although ketalized low molecular weight PEI showed enhanced transfection efficiency and significantly reduced cytotoxicity (*28*). Therefore, serum-independent and nontoxic siRNA delivery by KL-PEI in this study implies that the critical drawbacks of PEI-mediated gene delivery for clinical trials can be ameliorated.

Enhanced Gene Silencing by Acid-Degradable Ketal Branches. Contribution of the acid-degradability of KL-PEI to the improved RNA interference was evaluated by comparing RNAi efficiency of modified L-LMW PEI with nondegradable amine-bearing branches. This nondegradable counterpart was prepared by conjugating L-LMW PEI with nondegradable *N*-(4-(2,2,2-trifluoroacetamido)butyl)acrylamide followed by deprotecting the trifluoroacetate group. The synthetic scheme, detailed synthesis procedures, and characterization are described in Supporting Information (Figure S4). As shown in Figure 10A, the eGFP knockdown by siRNA/KL-LMW PEI polyplexes in NIH 3T3 cells was much higher than the one by nondegradable L-LMW PEI (ND-L-LMW PEI) at all observed N/P ratios ($p < 0.004$). Interestingly, siRNA/ND-L-LMW PEI polyplexes showed a similar level of RNAi efficiency in comparison to that of siRNA/unmodified L-LMW PEI polyplexes. This result clearly demonstrates that the acid degradability of KL-LMW PEI remarkably contributed to the efficient RNAi by siRNA/KL-LMW PEI polyplexes. Moreover, siRNA/ND-L-LMW PEI polyplexes showed some nonspecific gene silencing at high N/P ratios (e.g., 80−140) (nonspecific gene silencing degree: ≥ 10%), although it was not significantly different from the one by siRNA/KL-LMW PEI polyplexes (e.g., less than 10% of nonspecific gene silencing) ($p > 0.08$) (Figure 10B). The cytotoxicity result shown in Figure 10D indicates no significant difference in cell viability between degradable and nondegradable polyplexes ($p > 0.34$). These results imply that ketalization of L-PEI indeed increased gene silencing, while keeping the minimal nonspecific RNA interference and cytotoxicity of L-PEI.

CONCLUSIONS

In this study, pH-sensitive ketalized linear PEI was synthesized for siRNA delivery. The conjugation of acid-degradable amino ketal branches resulted in enhanced cytoplasmic release of free siRNA, which could be a crucial part of the reason for the achieved efficient RNA interference. The ketalization preserved the advantages of linear PEI including low cytotoxicity, serum-independent gene delivery, and sequence-specific

gene silencing. It appeared that KL-PEI could be a promising candidate for a nonviral siRNA delivery carrier in vivo.

ACKNOWLEDGMENT

We thank the staff at the Optical Biology Core (OBC) facility in UC Irvine for assistance with the confocal laser scanning microscopy and Ms. Shirley Wong (UC Irvine) for proofreading the manuscript. The authors are also grateful to Dr. Jian-Guo Zheng for his assistance of TEM imaging and analysis at the Materials Characterization Center in UC Irvine.

Supporting Information Available: Buffering capacity of KL-PEI, flow cytometry histogram of eGFP-exprssing cells incubated with various polyplexes, effects of various serum concentrations on RNA interference, and synthesis of nondegradable modified linear polyethylenimine (ND-L-PEI). This material is available free of charge via the Internet at http://pubs.acs.org.

Buffering capacity of KL-PEI. 10 mg of KL-LMW and L-LMW PEI were dissolved in 1.5 mL of DI water and adjusted to pH at approximately 12.5 with 2M NaOH in DI water. The pHs of the polymer solutions at R.T. were measured as aliquots of 1M HCl solution was subsequently added.

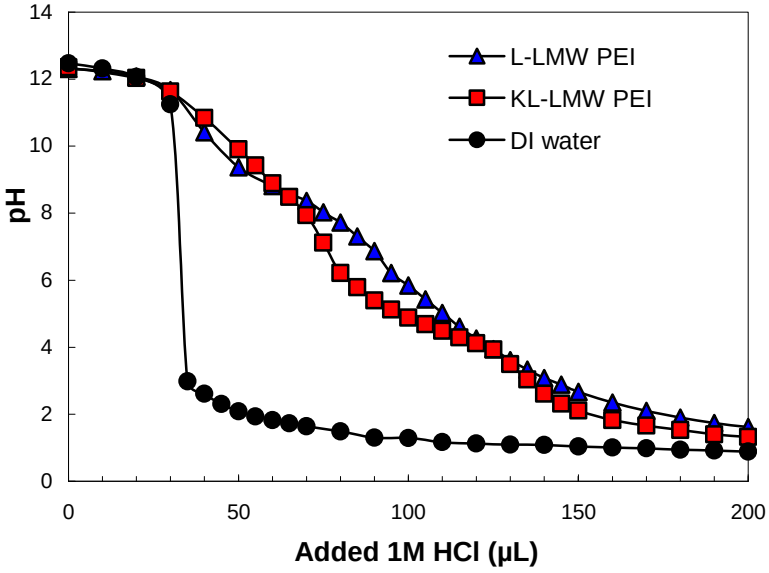

Figure S1. Titration curve of polymer solutions in DI water.

Flow cytometry histogram of eGFP silencing by various polyplexes. eGFP-expressing NIH 3T3 cells were incubated with various siRNA/PEI polyplexes in the presence of 10% FBS. Each polyplex solution was prepared at the optimized N/P ratios for maximum eGFP silencing (e.g., N/P ratio of 60 for siRNA/L-LMW PEI and siRNA/L-HMW PEI, N/P ratio of 120 for siRNA/KL-LMW PEI and siRNA/KL-HMW PEI, and N/P ratio of 10 for siRNA/B-PEI). eGFP silencing was analyzed after 76 h

of incubation. The results demonstrated that both KL-LMW PEI and KL-HMW PEI showed higher gene silencing efficiency than unmodified L-LMW PEI and L-HMW PEI.

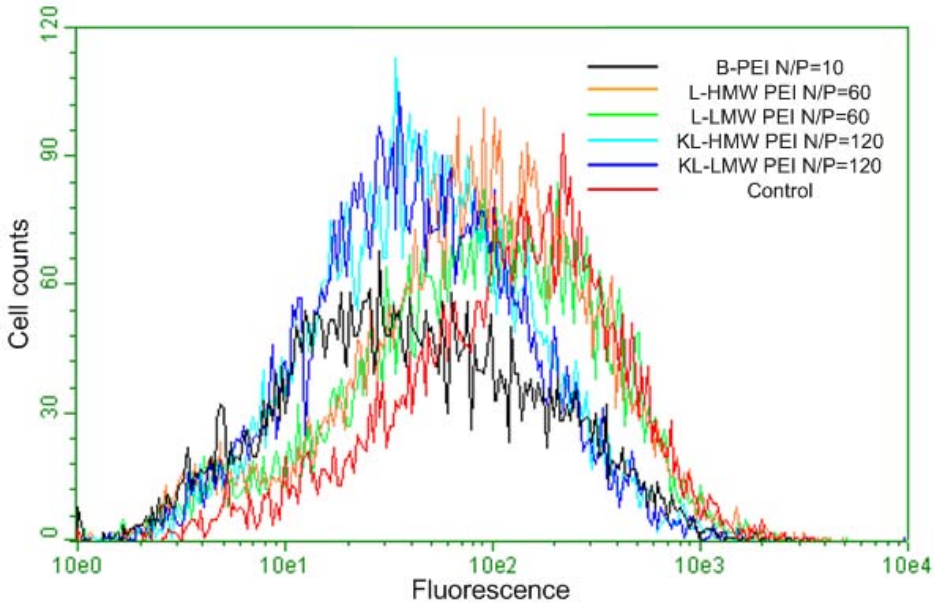

***Figure S2*.** Flow cytometry histogram of eGFP-expressing NIH 3T3 cells incubated with various polyplexes in the presence of 10% serum.

Effects of various serum concentrations on RNA interference. eGFP-expressing NIH 3T3 cells were inoculated in a 24-well plate at a density of 2×10^4 cells/well, 24 h prior to siRNA treatment. siRNA-containing polyplexes were prepared by mixing various amounts of polymer stock solutions in PBS with anti-eGFP siRNA or non-specific control siRNA solutions (75 pmol) in DI water (total in 75 μL). Each polyplex solution was prepared at the optimized N/P ratios for maximum eGFP silencing (e.g., N/P ratio of 60 for siRNA/unmodified linear PEI, N/P ratio of 120 for siRNA/ketalized linear PEI, and N/P ratio of 10 for siRNA/branched PEI). The culture medium in each well was replaced with 300 μL of DMEM containing different concentrations of FBS (e.g., FBS-free, 10% FBS, 20% FBS, 50% FBS, and 100% FBS). After 4 h of incubation, the medium in the well was replaced with 0.5 mL of fresh DMEM containing 10% FBS, and the cells were further cultured for 72 h. After the cells were harvested by trypsinization and washed with PBS, silenced eGFP expression was analyzed by flow cytometry. Specific eGFP silencing efficiency was determined by subtracting non-specific gene silencing by non-specific control siRNA/PEI polyplexes from the gene silencing by anti-eGFP siRNA/PEI polyplexes. RNAi efficiencies of both ketalized linear PEI and unketalized linear PEI decreased as serum concentrations increased. However, ketalized linear PEI, regardless of molecular weights of PEI, was able to induce specific eGFP silencing above the level of 25% at high serum concentrations that were up to 50%, while branched PEI showed almost no specific gene silencing at high serum concentrations (e.g., 50% and 100% FBS). siRNA/unketalized linear PEI polyplexes showed minimal specific eGFP knockdown regardless serum concentrations (e.g., less than 30% of specific gene silencing).

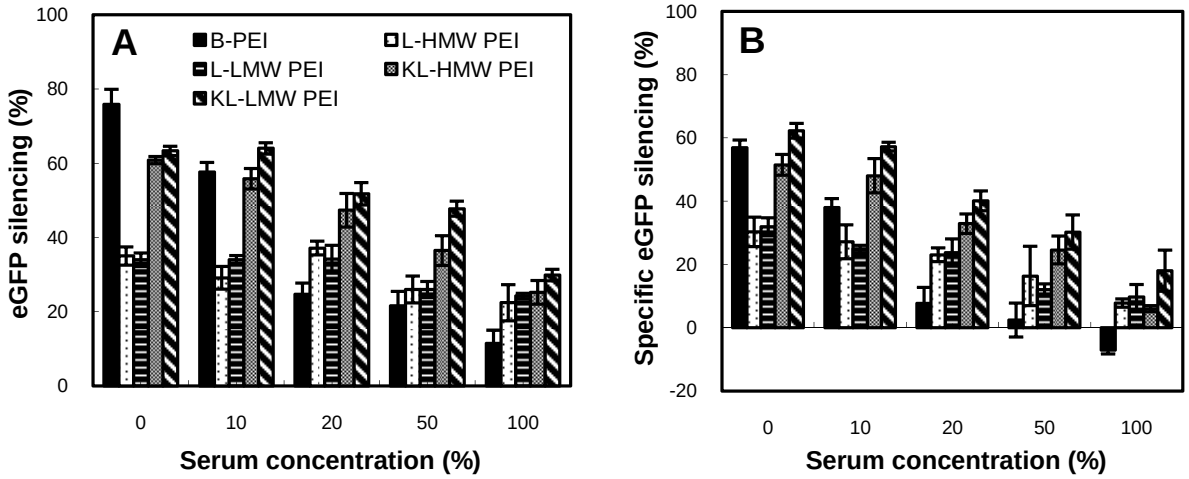

Figure S3. Effects of serum concentrations on eGFP gene silencing by various polyplexes. (A) Overall eGFP silencing by various siRNA/PEI polyplexes in the presence of different serum concentrations. (B) Specific eGFP silencing by various siRNA/PEI polyplexes at different serum concentrations.

Synthesis of non-degradable modified linear polyethylenimine (ND-L-PEI). Non-degradable branch-grafted linear polyethylenimine was synthesized via Michael addition conjugation of (N-(4-(2,2,2-trifluoroacetamido)butyl)acrylamide) as shown in Figure S4.

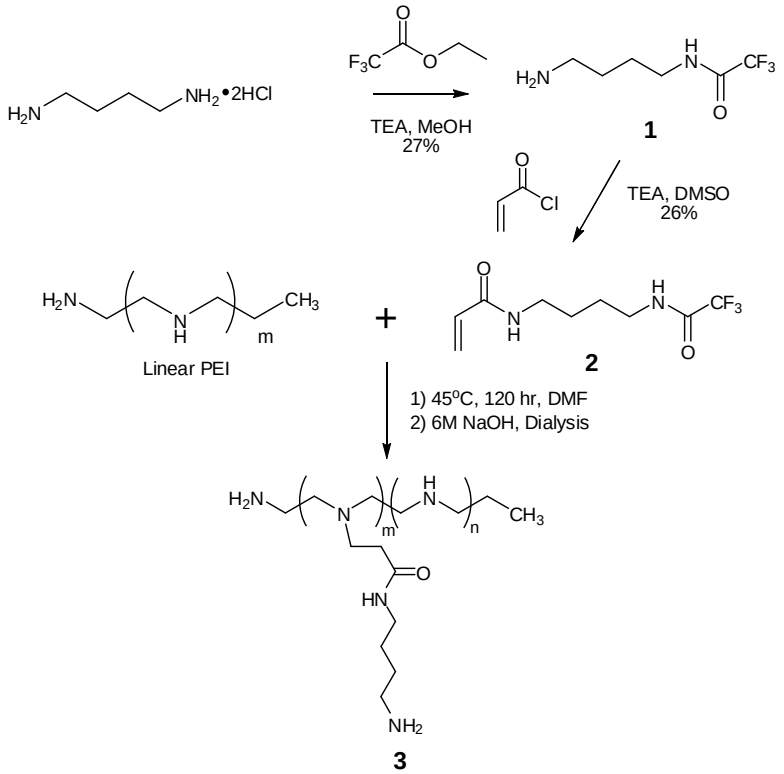

Figure S4. Synthesis of non-degradable modified linear polyethylenimine (ND-L-PEI).

Synthesis of Compound 1 [*N*-(4-aminobutyl)-2,2,2-trifluoroacetamide]. 1,4-diaminobutane dihydrochloride (2.0 g, 12.42 mmol, 1 equiv) was dissolved in 10 mL of methanol with 2.50 g of triethylamine (24.84 mmol, 2 equiv). The solution of ethyl trifluoroacetate (1.76 g, 12.42 mmol, 1 equiv) in 10 mL of methanol was slowly added dropwise to the solution of 1,4-diaminobutane dihydrochloride on ice, and the resulting mixture was stirred for 4 h on ice. After evaporating the solvent, the mixture was extracted with 3 × 50 mL of dichloromethane. The organic layers were collected and evaporated. The product was purified by silica gel chromatography using a gradient from tetrahydrofuran to 80/20 tetrahydrofuran/methanol to obtain the product as a white solid (0.62 g, 3.36 mmol, 27% yield). ^{1}H-NMR (500MHz, DMSO-d6): δ 1.57 (m, 4H, $CF_3CONHCH_2C\underline{H_2}C\underline{H_2}CH_2NH_2$); δ 2.78 (t, 2H, $CF_3CONHCH_2CH_2CH_2C\underline{H_2}NH_2$); δ 3.21 (t, 2H, $CF_3CONHC\underline{H_2}CH_2CH_2CH_2NH_2$); δ 8.08 (br, 2H, $CF_3CONHCH_2CH_2CH_2CH_2N\underline{H_2}$); δ 9.58 (br, 1H, $CF_3CON\underline{H}CH_2CH_2CH_2CH_2NH_2$). ESI-MS $[M + H]^+$ calcd 185.1, found 185.1.

Synthesis of Compound 2 [*N*-(4-(2,2,2-trifluoroacetamido)butyl)acrylamide]. Compound 1 (0.60 g, 3.25 mmol, 1 equiv) was dissolved in 10 mL of DMSO, followed by adding 1.32 g of triethylamine (13.0 mmol, 4 equiv). Acryloyl chloride solution (0.59 g, 6.50 mmol, 2 equiv) prepared in 10 mL of DMSO was slowly added dropwise to the solution of compound 1 on ice. The reaction mixture was stirred for 10 min, and the product was extracted using 3 × 100 mL of ethyl acetate. The product was purified by silica gel chromatography using a gradient from hexane to ethyl acetate to obtain the product as a powder with a hint of yellow color (0.20 g, 0.84 mmol, 26% yield). ^{1}H-NMR (500MHz, $CDCl_3$): δ 1.63 (m, 4H, $CF_3CONHCH_2C\underline{H_2}C\underline{H_2}CH_2NHCOCHCH_2$); δ 3.34 - 3.41 (m, 4H, $CF_3CONHC\underline{H_2}CH_2CH_2C\underline{H_2}NHCOCHCH_2$); δ 5.64 (dd, 1H, $CF_3CONHCH_2CH_2CH_2CH_2NHCOCHCH'\underline{H''}$); δ 6.12 (dd, 1H, $CF_3CONHCH_2CH_2CH_2CH_2NHCOC\underline{H}CH_2$); δ 6.16 (br, 1H, $CF_3CON\underline{H}CH_2CH_2CH_2CH_2NHCOCHCH_2$); δ 6.29 (dd, 1H, $CF_3CONHCH_2CH_2CH_2CH_2NHCOCHC\underline{H'}H''$); δ 7.51 (br, 1H, $CF_3CONHCH_2CH_2CH_2CH_2N\underline{H}COCHCH_2$). ESI-MS $[M + Na]^+$ calcd 261.1, found 261.1.

Synthesis of Compound 3. Linear low molecular weight PEI (L-LMW PEI, 2.5 kDa) (0.03 g, 0.70 mmol of secondary amine groups, 1 equiv) was dissolved in 2 mL of methanol, and the solvent was removed by evaporation under high vacuum for 30 min. The resulting solution was dissolved in 10 mL of dimethylformamide (DMF) containing 0.17 g of compound 2 (0.70 mmol, 1 equiv) and mixed with 0.07 g of triethylamine (0.70 mmol, 1 equiv). The resulting mixture was stirred for 120 h at 45 °C, and the polymer was precipitated into anhydrous diethyl ether and dried under vacuum. The obtained product was dissolved in 5 mL of 1:9 MeOH:6 M NaOH solution and stirred for 12 h to deprotect trifluoroacetate groups. Then the polymer was purified by dialysis against DI water at 4 °C (Mw Cutoff of dialysis membrane = 500) for 24 h, and the resulting polymer was freeze-dried overnight to obtain a white powder (21 mg, 40% yield). The grafting ratio of nondegradable branches relative to available secondary amines was calculated to be approximately 18% by integral ratio of methylene protons (1.59 - 1.67 ppm) of branches to methylene protons (2.7 - 3.1 ppm) of PEI backbone. The molecular weights of the product were determined by GPC using water as eluent, and they were calculated to be M_n = 3810

and M_w = 7164 with polydispersity index (PDI) of 1.88 by using poly(ethylene oxide) standards. ^{1}H-NMR (500MHz, D_2O): δ 1.59 - 1.67 (m, -$NCH_2CH_2CONHCH_2C\underline{H_2}C\underline{H_2}CH_2NH_2$); δ 2.47 (br, -$NCH_2CH_2CONHCH_2CH_2CH_2C\underline{H_2}NH_2$); δ 2.7 - 3.1 (m, -$C\underline{H_2}$-$C\underline{H_2}$-NH- and -$NC\underline{H_2}C\underline{H_2}CONHCH_2CH_2CH_2CH_2NH_2$); δ 3.5 - 3.6 (m, - $NCH_2CH_2CONHC\underline{H_2}CH_2CH_2CH_2NH_2$).

A Novel Antitumor Prodrug Platform Designed to Be Cleaved by the Endoprotease Legumain

Liron Stern,[†,||] Rotem Perry,[‡,||] Paula Ofek,[†] Ariel Many,[§] Doron Shabat,[‡] and Ronit Satchi-Fainaro*[,†]

Department of Physiology and Pharmacology, Sackler School of Medicine, Tel Aviv University, Ramat Aviv, Tel Aviv 69978, Israel, Department of Organic Chemistry, School of Chemistry, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Tel Aviv 69978, Israel, and Lis Maternity Hospital, Sourasky Medical Center, Tel Aviv, Israel. Received October 20, 2008; Revised Manuscript Received December 30, 2008

Chemotherapeutic treatment of neoplastic diseases is often restricted by adverse systemic toxicity, which limits the dose of drug that can be administered, or by the appearance of drug resistance. Therefore, novel targeted therapeutic approaches are being developed to improve current conventional therapy in order to increase specificity and biocompatibility, and decrease toxicity. Legumain represents a recently identified lysosomal protease that has been reported to be overexpressed in the majority of human solid tumors, to promote cell migration and is associated with enhanced tissue invasion and metastases. Therefore, it serves as a promising candidate for prodrug therapy. We synthesized a novel legumain-cleavable prodrug, carbobenzyloxy-alanine-alanine-asparagine-ethylenediamine-etoposide, which releases the chemotherapeutic agent, etoposide, as the active drug. The prodrug was characterized and analyzed by ^{1}H NMR and HPLC. 293 Human embryonic kidney (293 HEK) cells were stably transfected with human legumain, to achieve overexpression in vitro (293 HEK-Leg). 293 HEK-Leg cells expressed both active and inactive legumain and secreted it to the medium. Legumain expression was found to be elevated because of serum starvation in both 293 HEK cells and PC3 human prostate carcinoma cells. The commercial substrate of legumain, carbobenzyloxy-alanine-alanine-asparagine-amino-4-methyl coumarin (CBZ-Ala-Ala-Asn-AMC) and the synthesized prodrug were both cleaved by recombinant human legumain (rhlegumain) and legumain expressed in the 293 HEK-Leg cell lysate. Upon cleavage by rhlegumain, the prodrug showed an inhibitory effect on the proliferation of 293 HEK and 293 HEK-Leg cells. This study suggests a novel platform for prodrug therapy activated by legumain as a promising approach for cancer therapy.

INTRODUCTION

Current conventional chemotherapy, though widely used in cancer treatments, is still far from reaching its optimal potential. Clinically used chemotherapeutic drugs exhibit a short half-life in the bloodstream and a high overall clearance rate. Most chemotherapeutic drugs are considered to be low-molecular-weight compounds, and as such, they diffuse rapidly and are distributed evenly within the body, into tumor tissues as well as healthy ones (*1*). Thus, small amounts of the drug reach the target cancerous site, whereas healthy tissues suffer from many side effects that limit the maximum tolerated dose (MTD[1]) that can be administered (*1*).

The development of cancer prodrug therapies is implemented to solve the limitations of conventional chemotherapy. Prodrugs have been designed for optimal structure, size, and surface characteristics to increase their circulation time in the bloodstream. They are able to carry their loaded active agents to cancer cells by selectively using the unique pathophysiology of tumors, such as the acidic, neoplastic supporting microenvironment. As such, the microenvironment surrounding the tumor has been found to overexpress specific proteases that are active in these acidic conditions (*2*−*4*). It can be utilized for prodrug-targeting by linking a spacer cleavable by hydrolysis at low pH or by lysosomal or tumor-associated overexpressed enzymes resulting in the release of the active drug.

Legumain is a member of the C13 family of peptidases that specifically cleaves asparaginyl bonds. It was first discovered in plants (*5*−*7*) and later in parasites (*8*, *9*) and mammals (*10*, *11*). All legumains are synthesized as a 50−60 kDa pro-enzyme that undergoes activation upon autocleavage at acidic conditions (pH 3.0−6.0). Mature, active mammalian legumain varies in size from 30 kDa to 40 kDa, due to different degrees of glycosylation. Chen et al. detected 3 bands of human legumain in an immunoblot from a cell lysate consisting of a 56 kDa inactive pro-enzyme, a 46 kDa active form, and a 36 kDa mature active

enzyme. Pro-legumain is autocleaved at asparaginyl residues as well as aspartic ones, upon activation at pH 4.5 to produce the 46 kDa active form. Further autocleavage at acidic conditions results in the mature form of the 36 kDa, active human legumain. Once the enzyme is in its active form, raising the pH level up to 7.0 results in enzyme denaturation and therefore inactivation (*12*). The precise physiological role of mammalian legumain in human biology is still poorly understood. It has been found to be involved in the processing of the microbial tetanus toxin (*13*) and to play a role in osteoclast inhibition (*14*). Furthermore, it has been suggested that legumain is responsible for the processing of cathepsins B, H, and L (*15*) and activating progelatinase A to produce mature active gelatinase A (MMP-2) in cultured cells (*16*). A recently published study has also found legumain to regulate the degradation of fibronectin in renal proximal tubular cells. This implicates legumain in the control of extracellular matrix remodeling and turnover, a well-known process in various pathological conditions such as tumor growth, development of metastases and progression of atherosclerosis (*17*). In recent years, legumain has been reported to be overexpressed in tumors (*18*). High levels of legumain were found in tumor cells, as well as in tumor-associated endothelial cells, tumor-associated macrophages, and other stromal cells. Though never explored or examined empirically, legumain has been indicated to be up-regulated in vitro as a result of stress such as serum starvation or in vivo growth (*19*). Legumain is almost undetectable in vitro, suggesting that its expression is highly dependent on the unique microenvironment of the tumor (*19*). Therefore, we generated a cell line stably overexpressing legumain, in order to characterize its activity in vitro. Legumain is not only highly expressed in the lysosomal cell fraction (*10*), but it is also associated with the cell surface and colocalized with integrin β1. In addition, in vitro assays showed that tumor cells overexpressing legumain exhibit increased migration and invasion through the extracellular matrix. Furthermore, legumain was suggested to play a role in promoting tumor progression and correlated with a more aggressive behavior and a poorer prognosis (*20*). Legumain's unique specificity to cleavage of asparaginyl bonds and its connection to cancer progression led to the interesting notion regarding legumain as a target for various prodrug designs in targeted chemotherapeutics (*19*, *21*, *22*).

In this study, we designed and synthesized a legumain-activated prodrug of etoposide. Etoposide, 4′-demethyl-epipodophyllotoxin-9-[4,6-*O*-(*R*)-ethylidene-β-D-glucopyranoside], is a semisynthetic derivative of podophillotoxin, classified as a cell cycle-specific, plant alkaloid antineoplastic chemotherapeutic drug. It was the first topoisomerase II inhibitor to be discovered (*23*). Etoposide does not block the activity of this essential enzyme, but rather increases the steady-state concentration of the covalent DNA cleavage complexes, converting them into physiological toxins. High level of DNA breaks arise in the genome, becoming targets for recombination, sister chromatids exchange, insertions, deletions, chromosomal aberrations, and translocations. These alterations trigger a series of events, resulting in cell death and apoptosis, thus killing the tumor cells (*24*). Etoposide is one of the most highly prescribed anticancer drugs in the world, even though it possesses the same characteristics as most chemotherapeutic drugs do. Being a hydrophobic low-molecular-weight compound (588 g/mol), etoposide diffuses through the bloodstream to healthy tissues and causes many side effects. The primary dose-limiting toxicity of etoposide in clinical use is severe myelosuppression (*25*). Etoposide undergoes hydrolysis and epimerization to generate metabolites that are 100-fold and 500-fold less cytotoxic, or not active at all (*26*). Its low water-solubility forces it to either be solubilized in toxic solvents, such as tween-80 or ethanol, or to be diluted to low concentrations and administered in high volumes of an isotonic solution, causing discomfort either way (*27*). Accumulation of DNA breaks, caused by etoposide, generate potential mutations and chromosomal translocations that may also lead to myeloid/lymphoid or mixed lineage leukemia (*28*). Furthermore, it undergoes nonspecific hydrolysis, and it induces drug resistance in repeated treatment. New drug delivery systems are currently being developed in the hope of evading etoposide's limitations and toxicities while preserving and even elevating its antitumor activity, thus increasing its therapeutic index.

A well-established etoposide−prodrug system will prevail etoposide limitations and improve its efficacy and specificity in various cancer treatments. Here, we show a prodrug of etoposide linked to a tripeptide cleavable by legumain. We hypothesize that this prodrug will be activated by the overexpressed legumain in tumor epithelial and endothelial cells in vivo or by the ectopically or stress-induced overexpressed legumain in model systems in vitro.

EXPERIMENTAL PROCEDURES

Materials. DMEM (Dulbecco's modified Eagle's medium), FBS (fetal bovine serum), androstan, nonessential amino acids, sodium pyruvate, insulin, and penicillin−streptomycin−nystatin were obtained from Biological Industries, Israel; EGM-2 MV medium was obtained from Cambrex; Neomycin (G418) was obtained from Chemicon International; XTT reagent was obtained from biological industries; rhlegumain was obtained from R&D systems, USA; ketamine was obtained from Ketaset, Canada; xylazin was obtained from Medical Market; etoposide, polybrene, *n*-octyl β-D-glucopyranoside, protease inhibitor cocktail (P2714−1BTL), and CHAPS were obtained from Sigma Aldrich, Israel. CBZ-Ala-Ala-Asn-AMC (compound **1**) was obtained from Bachem. CBZ-Ala-Ala-Asn(Trt)-OH (compound **2**) was obtained from Chinese Peptide Company. Bicinchoninic acid (BCA) kit and enhanced chemiluminescence kit (SuperSignal) were obtained from Pierce, USA. Nitrocellulose membrane was obtained from Whatman, Germany. Endothelial mitogen was obtained from Biomedical Technologies, Stoughton, USA. Heparin was obtained from Laboratoire Choay, Paris, France. Monoclonal mouse antiactin was obtained from Sigma (A 1978); goat antimouse immunoglobulin G (IgG) horseradish peroxidase (HRP) was obtained from Jackson Immunoresearch (115-035-166); goat polyclonal antilegumain was obtained from R&D Systems (AF2199); goat polyclonal antilegumain was obtained from Santa Cruz (sc-47105); rabbit antigoat HRP was obtained from Chemicon International (AP106P); rabbit anti-p38 was obtained from Sigma; and goat antirabbit IgG HRP was obtained from Jackson Immunoresearch (11-035-144). The pcDNA3/legumain plasmid was kindly provided by David Roodman and Chang-Sook Hong (University of Texas Health Science Center, San-Antonio, Texas, USA).

Cell Culture. 293 HEK cells were kindly provided by Professor Sara Lavi (Tel Aviv University, Tel Aviv, Israel); U87-human glioblastoma and PC3-human prostate adenocarcinoma cells were obtained from the American Type Culture Collection (ATCC), Manassas, VA; TRAMP C2 cells were kindly provided by Professor Norman Greenberg (Fred Hutchinson Cancer Research Center, Seattle, Washington, USA.); CT26 murine colon carcinoma cells were kindly provided by Professor Eliezer Flescher (Tel Aviv University, Tel Aviv, Israel); human umbilical vein endothelial cells (HUVEC) were isolated in our laboratory as previously described (*29*). Umbilical cords were collected at Lis Maternity Hospital, Sourasky Medical Center, Tel Aviv, Israel. This was approved by the Institutional Review Board (IRB). CT26 colon carcinoma, 293 HEK, PC3-human prostate adenocarcinoma cells were cultured

in DMEM supplemented with 10% FBS, 100 μg/mL penicillin, 100 U/mL streptomycin, 12.5 U/mL nystatin, and 2 mM L-glutamine. TRAMP-C2: cells were cultured in DMEM supplemented with 10% FBS, 100 μg/mL penicillin, 100 U/mL streptomycin, 12.5 U/mL nystatin, 15 un/mL insulin, nonessential amino acids X 1, 10 μM androstan, 1 mM sodium pyruvate, and 2 mM L-glutamine. 293 HEK-Leg and U87 human glioblastoma cells were cultured in DMEM supplemented with 10% FBS, 100 μg/mL penicillin, 100 U/mL streptomycin, 12.5 U/mL nystatin, and 2 mM L-glutamine. For selection purposes, 200 μg/mL of G418 was added. HUVEC: Cells were cultured in M-199 supplemented with with 20% FBS, 100 μg/mL penicillin, 100 U/mL streptomycin, 12.5 U/mL nystatin and 2 mM L-glutamine, 50 μg/mL endothelial mitogen, and 5 U/mL heparin. All cells were grown at 37 °C; 5% CO_2.

Prodrug Synthesis. *Compound* **3.** Compound **2** was dissolved in dry THF (1 g, 1.53 mmol), and the mixture was cooled to −15 °C. *N*-Methyl morpholine (170 μL, 1.53 mmol) was added, and then isobutylchloroformate (239 μL, 1.843 mmol) was added dropwise. The reaction was stirred for 15 min, then, the commercially available *N*-Boc,*N*-methyl ethylenediamine (401.4 mg, 2.30 mmol) was added. The reaction was allowed to warm to room temperature, was stirred for 1 h, and was monitored by TLC (EtOAc/hexane, 85:15). Upon completion of the reaction, the solvent was removed under reduced pressure, and the crude product was purified by using column chromatography on silica gel (EtOAc/hexane, 85:15) to give compound **3** (808 mg, 65%) as a white solid.

^{1}H NMR (400 MHz, MeOD): $\delta = 7.33-7.14$ (20H, m); 5.09 (2H, bs); 4.67 (1H, m); 4.14−4.09 (2H, m); 3.45−3.25 (4H, bs); 3.08 (1H, dd); 2.84 (3H, s); 2.58 (1H, dd); 1.43 (9H, s); 1.34 (6H, s). ^{13}C NMR (100 MHz, MeOD): $\delta = 174.96$, 174.34, 173.74, 172.66, 158.41, 158.11, 146.16, 138.20, 130.43, 81.57, 68.85, 68.85, 52.50, 50.20, 40.39, 39.56, 37.21, 20.20, 19.33, 18.99.

Compound **4.** Compound **3** (100 mg, 0.123 mmol) was dissolved in 1 mL of TFA and stirred for 10 min. The excess of acid was removed under reduced pressure, and the crude amine salt was dissolved in 1 mL of DMF. The activated carbonate of etoposide (*30*) (111 mg, 0.147 mmol) was added, followed by the addition of triethylamine (163 μL, 1.17 mmol). The reaction was stirred for 30 min and was monitored by TLC (EtOAc/MeOH 90:10). Upon completion of the reaction, the solvent was removed under reduced pressure, and the crude product was purified by using column chromatography on silica gel (EtOAc/MeOH 90:10) to give compound **4** (98 mg, 75%) as a white powder.

^{1}H NMR (400 MHz, MeOD): $\delta = 7.33$ (5H, bs); 6.97 (1H, s); 6.49 (1H, s); 6.30 (2H, s); 5.92 (2H, s); 5.06 (2H, m); 4.95 (1H, m); 4.80 (1H, m); 4.66 (2H, m); 4.30 (2H, m); 3.63 (6H, s); 3.50 (7H, m); 2.94 (4H, m); 2.67 (3H, m); 1.32−1.2 (9H, m). ^{13}C NMR (100 MHz, MeOD): $\delta = 177.97$, 176.93, 173.88, 159.09,156.59, 155.58,153.83, 150.53, 148.98, 140.29, 134.28, 130.93,130.01, 129.81, 129.41, 111.72, 111.42, 109.41, 109.28, 103.79, 103.44, 101.25, 82.22, 76.35, 74.98, 74.49, 70.22, 69.61, 68.36, 68.05, 57.10, 52.92, 49.84, 48.88, 48.54, 45.77, 42.69, 39.75, 37.83, 21.12, 18.43, 17.66. HRMS (MALDI-TOF) calculated for $C_{51}H_{62}N_6O_{20}$ 1101.3911 [M + Na^+], found 1101.3899.

Evaluation of the Activity of Rhlegumain and Endogenous Legumain on Its Commercial Substrate CBZ-Ala-Ala-Asn-AMC. Prior to all activity assays, rhlegumain (R&D, Lot MVY01651) was activated by incubation at a concentration of 100 μg/mL in 50 mM NaOAc and 0.1 M NaCl, pH 4.0, for 2 h at 37 °C.

The specific activity of rhlegumain was measured using 100 μM of rhlegumain's commercial substrate CBZ-Ala-Ala-Asn-AMC and 50 ng of active enzyme in 100 μL of 50 mM MES and 0.25 M NaCl at pH 5.0. Cleavage of CBZ-Ala-Ala-Asn-AMC was measured at excitation $\lambda = 380$ nm and emission $\lambda = 460$ nm, in a fluorescence plate reader.

In order to measure the activity of the endogenous cellular legumain, confluent cells were first harvested in PBS and centrifuged at 3,000 rpm for 3 min at 4 °C. The pellet was resuspended in lysis buffer (40 mM citric acid, 121 mM $NaHPO_4$, 1 mM EDTA, and 1% w/v *n*-octyl-β-D-glucopyranoside, pH 5.8) and incubated on ice for 10 min with occasional vortexing. Three cycles of freezing and thawing were performed. Cells were centrifuged at 14,000 rpm for 20 min at 4 °C. The supernatant was collected and tested for its protein concentration using the BCA kit. Then, the enzymatic activity of endogenous legumain was measured using 5−10 μL of cell lysate (depending on total protein concentration), which were placed in a 96-well microtiter plate. The reaction was initiated by the addition of 190 μL of CBZ-Ala-Ala-Asn-AMC solution in assay buffer (40 mM citric acid and 121 mM $NaHPO_4$, pH 5.8, containing 1 mM dithiothreitol, 1 mM EDTA, and 0.1% CHAPS) to give a final concentration of 10 μM substrate. The plates were incubated at 25 °C, and the level of legumain activity was calculated from the obtained cleaved substrate. Fluorescence levels of the released AMC were measured at excitation $\lambda = 360$ nm and emission $\lambda = 460$ nm, in a fluorescence plate reader.

HPLC Analysis. To test etoposide prodrug cleavage by rhlegumain, 100 μL (50 mM MES and 0.25 M NaCl, pH 5.0) of 500 μM prodrug was incubated with 250 ng of activated rhlegumain overnight at 37 °C. A control tube with 100 μL of 500 μM prodrug without rhlegumain was incubated under the same conditions. HPLC analysis was performed using a C-18 RP (reverse phase) analytical column; $\lambda = 290$ nm; flow, 1 mL min^{-1}; eluent, ACN/H_2O; gradient program, $t = 0$ (10% ACN/90% H_2O)−$t = 30$ (100% ACN/0% H_2O).

To test etoposide prodrug cleavage by cell lysates, 293 HEK-Leg, 293 HEK, and CT26 cells were lysed according to cell lysis (endogenous legumain activity assay) described in this section. The etoposide prodrug (250 μM) was incubated with 75 μL of cell lysate (giving total volume of 200 μL) at 37 °C. HPLC analysis was performed using a C-18 RP analytical column; $\lambda = 290$ nm; flow, 1 mL min^{-1}; eluent, ACN/H_2O; gradient program, $t = 0$ (10% ACN/90% H_2O)−$t = 30$ (100% ACN/0% H_2O).

Stable Transfection of Legumain into 293 HEK Cells. 293 HEK cells were plated a day before tranfection to reach 80% confluency during transfection. Cells were stably transfected with pcDNA3/legumain by calcium phosphate/DNA precipitation (*31*). Transfected cells were cultured in medium containing 1.2 mg/mL of G418. Every 3 days, the selection media containing G418 was changed. Following 2 weeks of culture in selection media, cell lysates and conditioned medium were tested for legumain expression by Western blot.

Cell Starvation. CT26 murine colon carcinoma, 293 HEK, TRAMP C2, PC3 human prostate adenocarcinoma, and U87 human glioblastoma cells were plated to reach 90% confluence at starvation. The medium of each cell line was replaced with serum-free medium. An additional plate of each cell line was left with cultured medium as the control. All plates were further incubated at 37 °C and 5% CO_2 for 6 h. Cells were harvested and kept in −80 °C.

Western Blot Analysis. Prior to Western blot analysis, the medium was concentrated and lyophilized O.N. (Benchtop-K, VirTis). The powder was resuspended in 1 mL of DDW.

For cell lysate analysis by Western blot, confluent cells were harvested with PBS and centrifuged at 3,000 rpm for 3 min at 4 °C. The pellet was resuspended in lysis buffer (50 mM Tris-HCl, pH 7.5, 150 mM NaCl, 5 mM EDTA, and 1% triton,

supplemented with 1% protease inhibitor cocktail) and incubated on ice for 20 min with occasional vortex. Cells were centrifuged at 14,000 rpm for 20 min at 4 °C. The supernatant was collected and tested for its protein concentration by the BCA kit.

For tumor and organ analysis by Western blot, murine tumors and organs were weighed. Lysis buffer (50 mM sodium citrate, pH 5.8, 0.1 M NaCl, 1 mM EDTA, and 2 mM β-mercaptoethanol) was added in 8 parts (v/w). Tissues were homogenized using a homogenizer (Politron, Kinematika, Switzerland), and three cycles of freezing and thawing were performed. The homogenates were centrifuged at 14,000 rpm at 4 °C for 20 min. The supernatant was collected and tested for its protein concentration using the BCA kit.

All cell lysates, tissue lysates, and cell medium were boiled in sample buffer × 2 and loaded onto a 12% PAGE gel. Following electrophoresis, the proteins were transferred to nitrocellulose membranes, which were blocked with nonfat milk. For legumain detection, goat antilegumain was incubated with the membrane O.N. (1:1,000 dilution with R&D or 1:200 with Santa Cruz, depending on the samples). The membrane was washed three times with TBST and then incubated with HRP-labeled antigoat IgG (1:5,000) for 1 h. For p38 detection, rabbit anti-p38 was incubated with the membrane for 2 h (1:10,000 dilution). The membrane was washed three times with TBST and incubated with HRP labeled antirabbit IgG (1:10,000) for 1 h. Following incubation with the antibodies, membranes were washed three times with TBST, incubated with Supersignal kit, exposed to film, and developed.

Cell Proliferation Assay. 293 HEK or 293 HEK-Leg cells were plated at 4000 cells/well in a 96-well plate (37 °C; 5% CO_2). For serum-starved cell lines, medium was replaced with serum-free DMEM for 6 h. Cells were then challenged with etoposide, etoposide prodrug, or etoposide prodrug preincubated O.N. with rhlegumain, at serial concentrations. Control cells were grown with DMEM with growth factors and serum. Following 72 h, cell growth was evaluated by an XTT assay (*32*).

For HUVEC proliferation assay, cells were plated at 15,000 cells/well (37 °C; 5% CO_2). Following 24 h, cells were challenged with etoposide, etoposide prodrug, etoposide prodrug preincubated O.N. with rhlegumain, at serial concentrations, Control cells were grown with EGM2-MV. Following 72 h, HUVEC were counted with a Z1-Coulter particle counter (Beckman Coulter).

Animal Studies. All animal procedures were performed in compliance with Tel Aviv University, Sackler School of Medicine guidelines and protocols approved by the Institutional Animal Care and Use Committee. Animal were treated as follows: (a) 7 week old male Balb/c mice were inoculated s.c. with 1×10^6 CT26 cells. Upon exceeding 1000 mm^3 in volume, mice were euthanized by cervical dislocation, and immediately, all tumors and organs were removed and kept at −80 °C. Tumor volume was measured with a caliper and calculated according to the formula width × length^2 × 0.52. (b) 7 weeks old male C57/BL6 mice were inoculated orthotopically into the prostate with 1×10^6 TRAMP C2 cells. Following 2 weeks, mice were euthanized by cervical dislocation, and immediately, all tumors and organs were resected and kept at −80 °C.

Semiquantitative RT-PCR. Total RNA extraction was performed using the EZ-RNA kit (Biological Industries) according to the manufacturer's instructions. The reverse transcriptase reaction was performed with the EZ-first Strand cDNA Synthesis kit (Biological Industries) using oligo(dT) primers. The PCR reactions were carried out using PCR-ReadyTM High Specificity (Syntezza) in an ATC 401 thermocycler (Apollo, CLP). To get semiquantitative results, the number of cycles for each reaction was kept at a minimum.

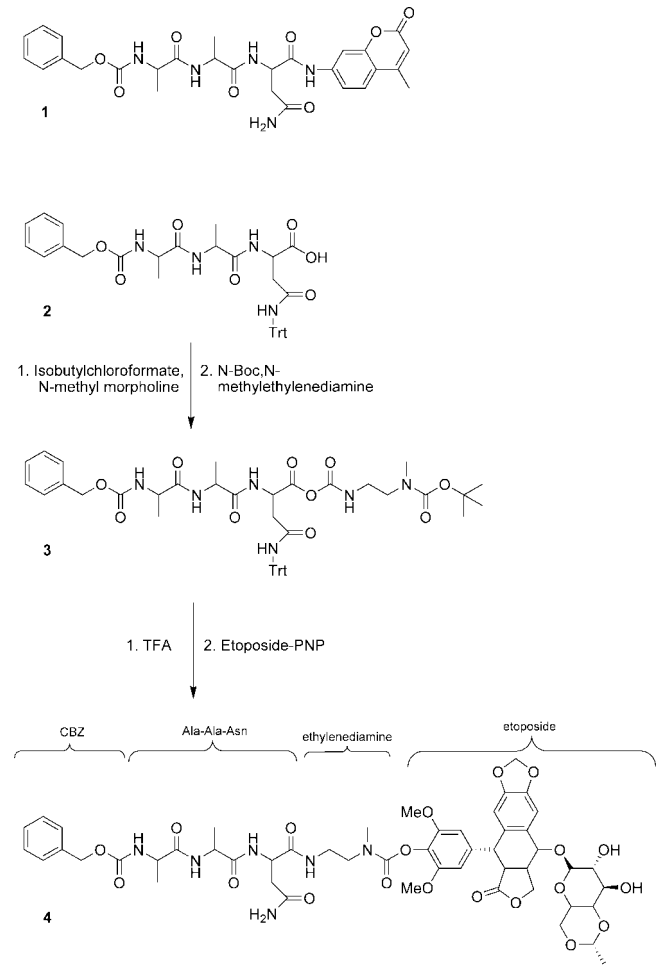

Figure 1. Synthesis of etoposide prodrug (compound **4**). Etoposide was conjugated to the tripeptide (legumain substrate) through an amine spacer (*N*-Boc,*N*-methyl ethylenediamine) to give the final prodrug-compound **4.**

PCR primers: Legumain, 5′-AAGCACTGGGTGGTGATTG-3′ and 5′-TGAGGTCAAGGT GTGTGA-3′; GAPDH, 5′-CCATCACCATCTTCCAGGAGC-3′ and 5′-GGCATGGACT-GTGGTCATGAG-3′.

RESULTS

Etoposide Prodrug Synthesis. On the basis of the standard substrate of legumain, we synthesized a tripeptide substrate, linked to an amine spacer (which is used for etoposide conjugation). The synthesis of the etoposide prodrug is presented in Figure 1. Compound **2**, CBZ-Ala-Ala-Asn(Trt)-OH, was coupled with the commercially available, *N*-Boc,*N*-methylethylenediamine, yielding compound **3**. Compound **3** was dissolved in TFA for deprotection of both the Trityl and the Boc protecting groups. Then, the carbonate derivative of etoposide was reacted with the deprotected substrate, generating the final prodrug **4** (Figure 1).

rhLegumain Cleaved Its Substrate CBZ-Ala-Ala-Asn-AMC More Potently at pH 6.5 than at pH 5.0. Enzymatic activity of legumain was first evaluated by incubating rhlegumain with the commercially available substrate CBZ-Ala-Ala-Asn-AMC. Unexpectedly, the enzymatic activity was greater at a pH value of 6.5 rather than at 5.0. No enzymatic activity was noted at pH 7.0 due to the fact that legumain undergoes denaturation at these basic conditions. The substrate alone showed no spontaneous release of AMC, when incubated without rhlegumain (Figure 2a).

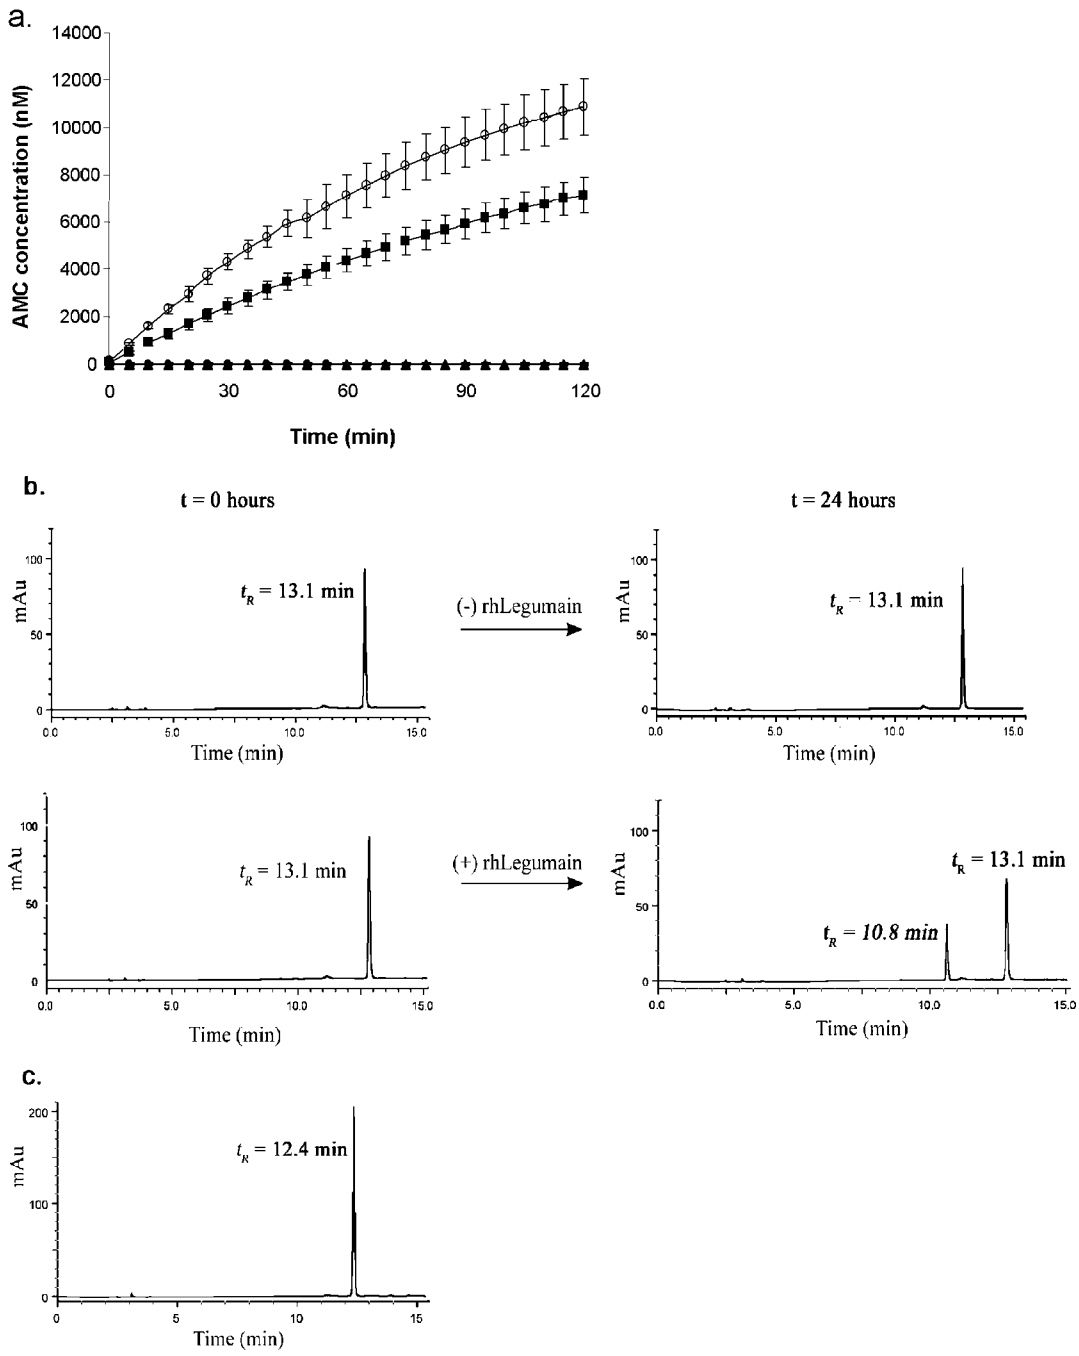

Figure 2. Active rhlegumain potently cleaves its substrate CBZ-Ala-Ala-Asn-AMC and the etoposide prodrug. (a) AMC release at pH 5.0 (■), pH 6.5 (○), pH 7.0 (♦), or in the absence of rhlegumain (▲). Data represent the mean ± SD (b) HPLC analysis of etoposide prodrug in the absence or presence of rhlegumain at $t = 0$ and $t = 24$ h. (c) HPLC analysis of free etoposide.

Characterization of the Etoposide Prodrug. In order to establish its capability to be cleaved by legumain, the etoposide prodrug was incubated with rhlegumain and evaluated using HPLC. The etoposide prodrug eluted as a single peak with an average retention time of $t_R = 13.1$ min and exhibited no self-degradation for 24 h. Incubation of the prodrug with rhlegumain for 24 h resulted in 33% of an inactive etoposide−ethylenediamine (Figure 2b). Further basic conditions were supplied in order for the linker to be released and free active etoposide to be generated, as previously described (*33*). Under the tested conditions, the ethylenediamine failed to undergo cyclization and release free etoposide. Free etoposide eluted as a single peak with $t_R = 12.4$ min (Figure 2c).

293 HEK-Leg Express Legumain. It has been previously reported that legumain expression in vitro is scarce (*19*). Therefore, 293 HEK cells were stably transfected to constitutively overexpress legumain. Legumain expression was evaluated by Western blot analysis. Commercial active (46 kDa) and inactive (56 kDa) rhlegumain were used as size reference controls (Figure 3a). Active legumain was detected in 293 HEK-Leg cells as 46 and 36 kDa bands (mature and nonmature protein) and inactive legumain as a 56 kDa band. 293 HEK-Leg cells also secreted legumain to the conditioned medium. No signal was found in the nontransfected 293 HEK cell lysate and medium. p38 was used as the loading control (Figure 3b).

Expression of Legumain Was Elevated due to Serum Starvation. As previously described, the tumor microenvironment is characterized by a defective supply of blood and nutrients, which exposes the tumor cells to hypoxia and starvation.

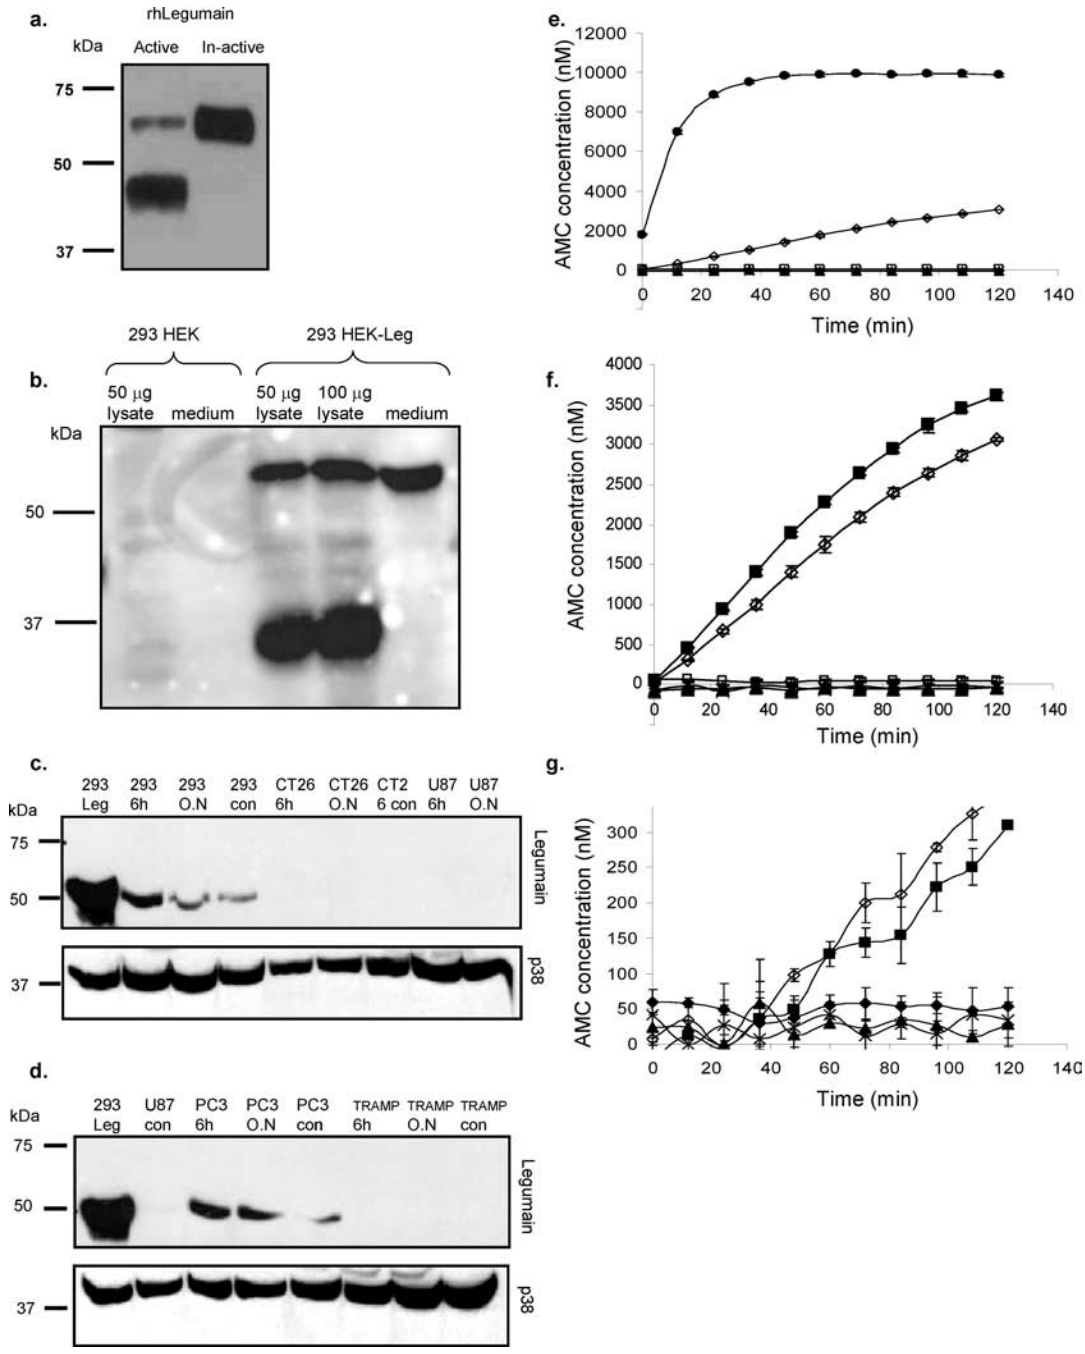

Figure 3. Legumain expression pattern and activity. (a) Western blot analysis of active (46 kDa) and inactive (56 kDa) rhlegumain. (b) Western blot analysis of cell lysate and conditioned medium of 293 HEK and 293 HEK-Leg cells. Active legumain is detected at 46 and 36 kDa (nonmature and mature forms, respectively), and inactive legumain is detected as a band of 56 kDa. p38 antibody was used as loading control. (c,d) 293 HEK, CT26 colon carcinoma, U87-human glioblastoma, PC3-human prostate adenocarcinoma, and TRAMP C2 murine prostate adenocarcinoma cells were serum starved for 6 h, O.N., or not starved at all, respectively. Cells were then harvested, lysed, and analyzed by Western blot. (e) Legumain commercial substrate was incubated with 293 HEK-Leg (●) or 293 HEK cell lysate (◊). Substrate alone (□), 293 HEK cell lysate (▲), and 293 HEKLeg cell lysate (×) were controls. A legumain activity assay was performed as described in Experimental Procedures. (f) Control (◊) or serum-starved (■) 293 HEK cell lysates were incubated with substrate. Substrate alone (□) and 293 HEK cell lysate alone, either serum starved (×) or nonstarved (▲) were controls. A legumain activity assay was performed. Data represent the mean ± SD. (g) Control (◊) or serum-starved (▲) PC3 cell lysate were incubated with the substrate. Substrate alone (♦) and PC3 cell lysate alone, either starved (×) or nonstraved (■) were controls. A legumain activity assay was performed. Data represent the mean ± SD.

Therefore, we wanted to determine whether endogenous legumain elevates as a result of serum starvation. Different cell lines were serum-starved and examined for their legumain expression. Only 293 HEK and PC3 prostate adenocarcinoma cell lines expressed legumain in vitro, and the levels of its inactive form increased following serum starvation. p38 antibody was used as the loading control (Figure 3c,d).

Overexpressed Legumain in 293 HEK-Leg Cells Potently Cleaved CBZ-Ala-Ala-Asn-AMC. 293 HEK-Leg cells were found to overexpress the active form of legumain (Figure 3b). Therefore, we evaluated the enzymatic activity of endogenous and overexpressed legumain. 293 HEK-Leg cell lysates were incubated with legumain's commercial substrate CBZ-Ala-Ala-Asn-AMC and released high levels of AMC. 293

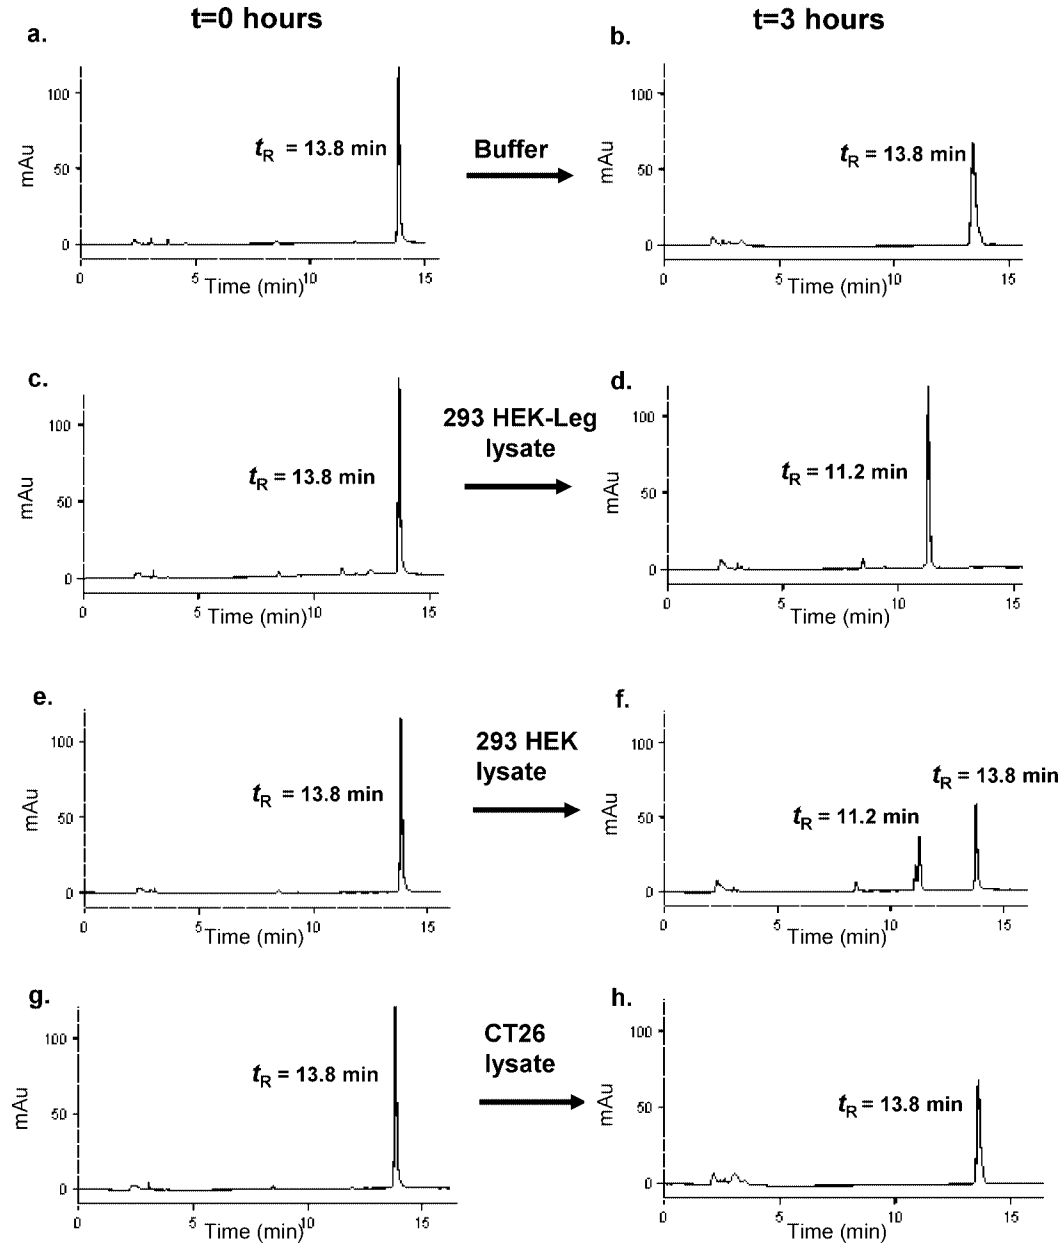

Figure 4. Both endogenous and exogenous legumain effectively and selectively cleave the etoposide prodrug as evaluated by HPLC analysis. (a,b) Etoposide prodrug in buffer at $t = 0$ and 3 h following incubation in buffer. (c,d) Etoposide prodrug with 293 HEK-Leg cell lysate at $t = 0-3$ h. (e,f) Etoposide prodrug with 293 HEK cell lysate at $t = 0-3$ h. (g,h) Etoposide prodrug with CT26 cell lysate at $t = 0-3$ h.

HEK cell lysates showed only a minor enzymatic activity releasing very low levels of AMC (Figure 3e). We further explored whether the elevation in expression of legumain due to serum starvation correlates with an increase in its enzymatic activity. 293 HEK serum-starved cells showed a slight 1.2-fold increase in enzymatic activity toward CBZ-Ala-Ala-Asn-AMC compared to that of nonstarved 293 HEK cells (Figure 3f), while PC3 serum-starved or nonstarved cells showed no significant difference in enzymatic activity (Figure 3g). Substrate alone and cell lysates of starved and nonstarved cells were used as controls.

Overexpressed Legumain Potently and Selectively Cleaved the Etoposide Prodrug. In order to examine whether ectopically expressed legumain specifically cleaves the etoposide prodrug, the prodrug was incubated separately with 293 HEK-Leg, 293 HEK, and CT26 cell lysates. Cleavage was evaluated using HPLC analysis. While the etoposide prodrug alone did not undergo self-hydrolysis within 3 h and elute as a single pick with $t_R = 13.8$ min (Figure 4a,b), incubation of 3 h with 293 HEK-Leg cell lysates resulted in 100% cleavage, generating etoposide−ethylenediamime (etoposide-linker) with $t_R = 11.2$ min (Figure 4c,d). 293 HEK cell lysates, which were previously found to scarcely express legumain, resulted in only 33% cleavage (Figure 4e,f), and CT26 cell lysates left the etoposide prodrug 100% intact following 3 h of incubation (Figure 4g,h).

Etoposide and Etoposide Prodrug Inhibited the Proliferation of 293 HEK and 293 HEK-Leg Cells. To determine the in vitro activity of etoposide and the etoposide prodrug, their inhibitory effect was tested on 293 HEK and 293 HEK-Leg cells. Free etoposide inhibited the proliferation of both cell lines with an IC_{50} of 700 nM. Treatment with the etoposide prodrug alone on both 293 HEK-Leg and 293 HEK cells did not reach the IC_{50} at the concentrations tested ($IC_{50} > 100$ μM). However, when cleaved externally with rhlegumain prior to the proliferation assay, the etoposide prodrug inhibited 293 HEK and 293 HEK-Leg cells with an IC_{50} of 4 μM (Figure 5a).

Serum-Starvation-Induced Inhibition of the Proliferation of 293 HEK Cells by the Legumain-Activated Pro-

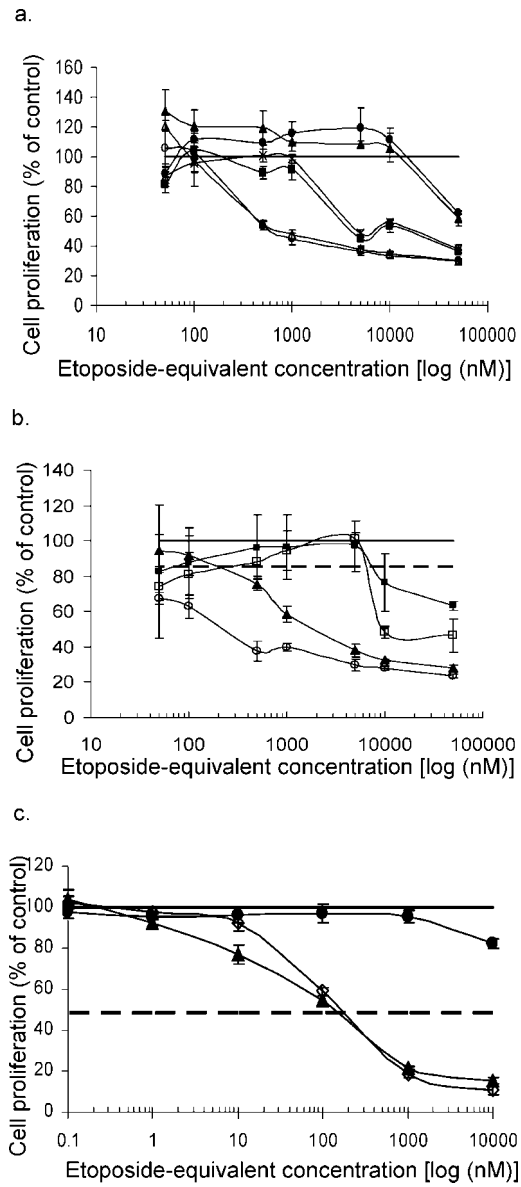

Figure 5. Etoposide and the etoposide prodrug inhibit cell proliferation in vitro. (a) Proliferation assay of 293 HEK-Leg (△,▲) and 293 HEK cells (○,●), following treatment with free etoposide and etoposide prodrug, respectively. 293 HEK cells were also assayed for proliferation following treatment with the externally cleaved etoposide prodrug (■). (b) Proliferation assay of control (black triangles and squares) and serum-starved (white circles and squares) 293 HEK cells, following treatment with free etoposide and etoposide prodrug, respectively. (c) HUVEC proliferation assay following incubation with free etoposide (◊), the etoposide prodrug (●), and the legumain-activated etoposide prodrug (▲). Data represent the mean ± SD.

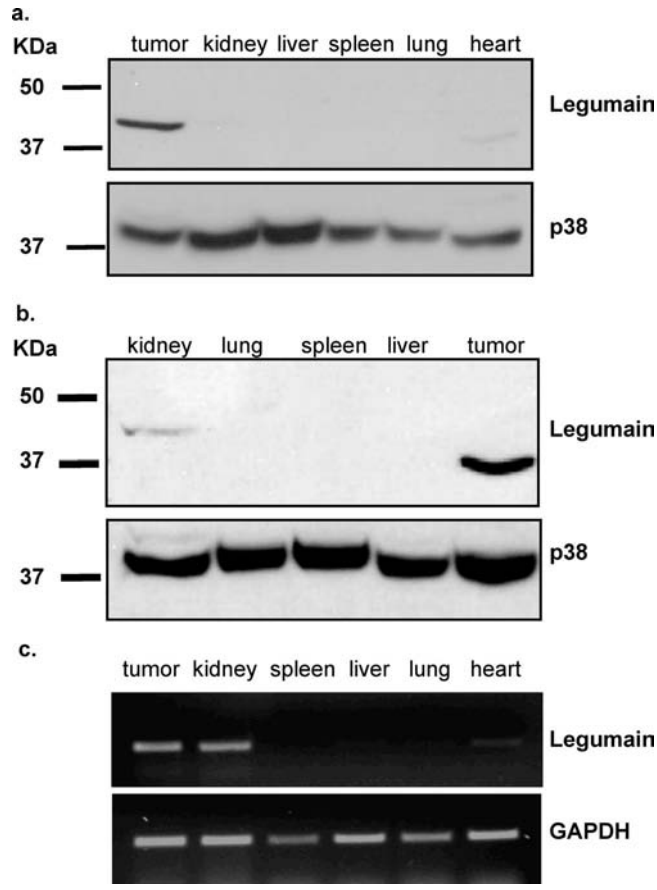

Figure 6. Legumain is overexpressed in murine tumors inoculated in mice compared to normal organs. (a) CT26 tumors inoculated s.c. in Balb/c mice and their normal organs were dissected, homogenized, lysed, and analyzed for legumain expression by Western blot. p38 antibody was used as the loading control. (b) Orthotopic TRAMP-C2 prostate tumors inoculated in C57/BL6 and their normal organs were dissected, homogenized, lysed, and analyzed for legumain expression by Western blot. p38 antibody was used as the loading control. (c) Orthotopic TRAMP-C2 prostate tumors inoculated in C57/BL6 and their normal organs were dissected and homogenized, and RNA was isolated. Legumain mRNA levels were monitored and calibrated to GAPDH mRNA levels (semiquantitive RT-PCR).

drug at High Concentrations. To determine whether the potency of the etoposide prodrug elevates because of the increase in legumain expression, the inhibitory effect of etoposide and the etoposide prodrug was tested on 293 HEK serum-starved or nonstarved cells. Serum starvation of 293 HEK cells was performed in order to elevate legumain expression. Free etoposide inhibited proliferation of both starved and nonstarved cells with IC_{50} values of 200 nM and 2 μM, respectively. The prodrug also had a more toxic effect on serum-starved cells, but only at concentrations higher than 5 μM. At lower concentrations, the prodrug had the same effect on cells grown in the presence or absence of serum (Figure 5b).

Etoposide and the Etoposide Prodrug Inhibited HUVEC Proliferation. It has been recently shown that legumain is also overexpressed in tumor endothelial cells in vivo (*18*). Hence, having shown the inhibitory effect of etoposide on 293 HEK cells, its ability to inhibit HUVEC proliferation was evaluated. Free etoposide and the legumain-activated etoposide prodrug (cleaved externally with rhlegumain prior to the proliferation assay) inhibited HUVEC proliferation with an IC_{50} of 150 nM (Figure 5c). The prodrug alone did not have any inhibitory effect on HUVEC proliferation.

Legumain Is Overexpressed in Murine Tumors Inoculated in Mice Compared to Healthy Organs. In order to demonstrate the potential of an etoposide prodrug activated by legumain in vivo, we examined the expression of legumain in murine tumors inoculated in mice and their healthy organs. CT26 derived tumors and organs of Balb/c mice (Figure 6a) and TRAMP-C2 murine prostate adenocarcinoma and organs of C57/BL6 mice (Figure 6b,c) were lysed and evaluated for legumain expression by Western blot and semiquantitive RT-PCR. Legumain is highly expressed in tumor tissues as opposed to other healthy organs. CT26 cells, subcutaneously inoculated in a Balb/c mouse, showed high expression of murine legumain, while only low levels of legumain were detected in the heart, and no legumain at all in the kidney, liver, spleen, or lung lysates (Figure 6a). TRAMP-C2 prostate tumors, orthotopically inoculated in C57/BL6 mice, expressed high levels of legumain, while

the kidney tissue lysate expressed low levels, and in other organs tested no legumain was detected (Figure 6b). Accordingly, legumain mRNA levels were also higher in the tumor and the kidney in comparison to that in other tissues tested (Figure 6c).

DISCUSSION

The pursuit for effective strategies of targeted chemotherapy treatments for various neoplastic pathologies is still ongoing, as many novel compounds are already in clinical trials. A common method for targeting chemotherapeutic agents specifically to the tumor is the design of a prodrug platform that covalently links the drug to a peptide cleavable by a certain overexpressed protease in the tumor and its microenvironment. Such is legumain, which represents a novel candidate target for chemotherapeutic and antiangiogenic prodrug therapy.

To date, there are only two ongoing prodrug preclinical studies based on legumain, one of which covalently links a peptide cleavable by legumain to doxorubicin. Wu et al. showed that *N*-Suc-Ala-Ala-Asn-Leu-doxorubicin, named LEG-3, was cleavable by legumain and released Leu-doxorubicin at the tumor site (*19*). The second prodrug therapy is a legumain-based DNA vaccine, which leads to suppression of tumor growth and metastasis (*21, 22*).

In this study, we described the synthesis of a prodrug that covalently links the chemotherapeutic agent etoposide to legumain's substrate, CBZ-Ala-Ala-Asn-ethylenediamine-etoposide. The prodrug is designed to be cleaved at acidic conditions by legumain, at the asparagine residue bound to ethylenediamine through a carbamate bond, creating an ethylenediamine−etoposide moiety. According to the chemical synthesis technique established by Perry et al. (*33*), the ethylenediamine linker undergoes cyclization at physiological pH, releasing free etoposide. Thus, the prodrug is designed to be cleaved by legumain in the cell lysosome at acidic pH values and undergo cyclization and etoposide release in the cell cytoplasm.

Enzymatic activity of rhlegumain is known to be optimal at pH 5.0. We evaluated its activity at a pH value of 6.5, an acidic level that better reflects the neoplastic environment, in comparison to the supposedly optimal pH 5 and 7 (Figure 2a). Legumain's enzymatic activity was the highest at pH 6.5, further establishing the concept of it being a suitable target for anticancer prodrug therapy. Evaluation of the enzymatic activity of the commercial legumain led to testing its ability to cleave the prodrug using HPLC analysis (Figure 2b). Our results revealed that the prodrug is in fact cleavable by legumain and generates the ethylenediamine−etoposide moiety at acidic conditions.

We have transfected cells to overexpress legumain in vitro (293 HEK-Leg), which was shown to be highly active against CBZ-Ala-Ala-Asn-AMC (Figure 3b,e). We were also interested in exploring whether stress such as serum starvation would elevate legumain expression in vitro in various cell lines. Our interest was based on the notion that legumain is a stress-responsive gene, as previously suggested by Lui et al. (*18*). This idea was not investigated or tested empirically. Thus, we serum starved various cell lines and examined their endogenous legumain expression (Figure 3d,e). Our findings revealed that legumain expression, though in its inactive form of 56 kDa, is elevated in both 293 HEK and PC3 cell lines following 6 h of serum starvation. Overnight serum starvation did not further elevate legumain expression, probably due to a decrease in cell metabolism, caused by the prolonged stress. The present study is the first to show an increase in legumain expression due to serum starvation in vitro, in any kind of cell line. Although the level of legumain expression was raised, only a slight increase in the enzymatic activity was detected in the serum-starved versus the control 293 HEK cells. There was no difference between the level of legumain enzymatic activity in the control or serum-starved PC3 cells, when tested on the commercial substrate of legumain. This is probably due to the fact that upon serum starvation, only the inactive form of legumain expression level was augmented (Figure 3c,d).

293 HEK-Leg cells cleaved 100% of the prodrug, whereas 293 HEK cells, which express low levels of legumain, cleaved only 33% of it. CT26 cell lysate, in which no legumain expression was found, similarly to our working buffer alone, did not cleave the prodrug at all (Figure 4). This result indicates not only that our transfected 293 HEK-Leg cells successfully cleaved the prodrug but also that the prodrug is specifically and exclusively cleaved by legumain and not by other proteases, as demonstrated by the CT26 cell line, which does not express legumain. Furthermore, the prodrug remains stable and does not undergo nonspecific self-hydrolysis within 72 h.

Establishment of the specificity of the prodrug to be cleaved by legumain enabled us to test its cytotoxic potential. We evaluated the inhibitory effect of the prodrug on the proliferation of 293 HEK and 293 HEK-Leg cells (Figure 5a). As expected, the prodrug did not inhibit the proliferation of 293 HEK cells, and free etoposide inhibited the proliferation of both 293 HEK and 293 HEK-Leg in the same manner, achieving similar IC_{50} values. In contrast to our expectation, the prodrug failed to inhibit the proliferation of 293 HEK-Leg cells. This disappointing result might be due to the fact that upon cleavage by legumain at acidic conditions, the ethylenediamine−etoposide either failed to exit the lysosome and reach the cytoplasm or that cyclization did not occur. Another possibility that can explain the failure of the prodrug to inhibit the proliferation of 293 HEK-Leg cells concerned its uptake by the cells. Even though the prodrug is relatively small in its molecular size and is compact in structure, it is possible that the prodrug failed to enter the cells and therefore did not inhibit cell proliferation. Furthermore, it is plausible that the prodrug did internalize into the cell but did not succeed in entering the lysosome in order to be cleaved. A suitable uptake assay on an adequate prodrug pathway examination is necessary and would reveal whether the prodrug internalizes the cell through passive endocytosis, as expected, or whether it is adsorbed around the cell membrane. A future confocal microscopy analysis of a fluorescently labeled prodrug would disclose its subcellular trafficking and localization. Since etoposide is not fluorescent by itself (unlike doxorubicin), it will be necessary to link a suitable fluorescent molecule for detection purposes that does not interfere with the prodrug's cleavage site.

We have demonstrated that expression levels of endogenous legumain elevate in 293 HEK cells following stress. We hypothesized that cells expressing high levels of endogenous legumain may better cleave and activate the prodrug than 293 HEK-Leg cells, which overexpress ectopic legumain. The inhibitory effect of the prodrug on the proliferation of serum-starved 293 HEK cells revealed that serum starvation turned the cells more susceptible to etoposide (Figure 5b). However, serum starvation in itself had no significant inhibitory effect on the proliferation of 293 HEK cells treated with low concentrations of the etoposide prodrug. The influence of serum starvation was noted at concentrations higher than 5 μM etoposide prodrug. The IC_{50} of the etoposide prodrug on serum-starved 293 HEK cells was lower than the IC_{50} of the etoposide prodrug on nonstarved 293 HEK cells. Thus, at relatively high concentrations of the etoposide prodrug, serum starvation increased the prodrug's potency on the inhibition of proliferation of 293 HEK cells by increasing legumain's expression and augmenting the sensitivity of the cells to the treatment.

Legumain has also been reported to be overexpressed in tumor endothelial cells. Therefore, we evaluated the effect of the etoposide prodrug on tumor angiogenesis by examining the

inhibitory potential of etoposide on proliferating endothelial cells (Figure 5c). Our results indicate that etoposide inhibits HUVEC proliferation at concentrations 1 log-lower than tumor cells; hence, tumor endothelial cells would be sensitive to lower doses of etoposide released from the prodrug.

We inoculated two different cell lines in two different strains of mice (CT26 in Balb/c mice and TRAMP C2 in C57BL/6 mice) in order to show that overexpression of legumain is not cell line-dependent or strain-dependent. Western blot and RT-PCR analysis revealed that legumain is in fact overexpressed in tumor tissues rather than in normal tissues, in both cell lines in both strains (Figure 6). Interestingly, although there was no substantial difference between the mRNA levels of legumain in the tumor and kidney tissues from C57/BL6 mice, the legumain protein levels were substantially higher in tumor tissues. This finding suggests that the expression level of legumain is not governed by enhanced transcription and points to the involvement of post-translational events. Further studies should clarify this issue.

In summary, this study describes the synthesis and characterization of an etoposide prodrug designed to be cleaved by the endoprotease legumain. The prodrug was found to be potently and selectively cleaved by all three forms of legumain: the commercial, overexpressed, and endogenous legumain. Therefore, the prodrug should specifically be cleaved at the tumor site, which will warrant this approach as a novel anticancer targeted therapy.

Received October 20, 2008; Revised Manuscript Received January 6, 2009

Water-soluble triblock copolymers consisting of hydrophobic−hydrophilic−dye segments were synthesized by ring-opening metathesis polymerization (ROMP) of norbornadiene monomers, copper-catalyzed click reaction, osmium-catalyzed dihydroxylation, and the following transformations. These polymers in aqueous conditions could form spherical assemblies, whose diameters were 50−60 nm by TEM measurement. From in vivo optical imaging experiments, the spherical assemblies of these copolymers could be efficiently accumulated in tumor cells. In addition, the spherical assemblies of water-soluble polymers accumulated in a tumor cell over two weeks.

INTRODUCTION

Molecular imaging is an important topic that has gained significant attention in the fields of chemical biology and noninvasive diagnosis of diseases (*1*, *2*). Optical imaging strategies using dyes (*3*−*8*) and quantum dots (QDs) (*9*−*13*) emitting near-infrared fluorescence (NIRF) have been widely investigated in the past decades. The NIRF imaging technique has many benefits such as the high permeability of biological tissue to the fluorescence and resultant noninvasive imaging for patients. In order to carry probes and drugs efficiently to the targets, spherical amphiphilic molecular assemblies, such as liposomes and related self-assemblies (*7*, *14*−*16*) and micelles or vesicles of polymer conjugates (*17*−*29*), have been developed. Recently, to improve the specificity of probe and drug delivery and to prolong their retention time in the target tumor tissues, much attention has been paid to cross-conjugation between polymer conjugate units using further functionalization and polymerization (*30*, *31*). Although triblock copolymers consisting of hydrophobic, hydrophilic, and dye segments have been widely accepted as appropriate components of spherical self-assemblies for optical tumor imaging utilizing the enhanced permeability and retention effect (*32*, *33*), there still exists a problem with selective accumulation of the imaging probe in the target tissue.

Ring-opening metathesis polymerization (ROMP) of strained alkenes, such as bicyclo[2.2.1]hept-2-ene (norbornene) and bicyclo[2.2.1]hept-2,5-diene (norbornadiene), gives multiblock copolymers in high yields with a small polydispersity index (PDI) (*34*, *35*). Since a wide range of functional groups can be introduced in a monomer skeleton, metathesis-based syntheses of amphiphilic block copolymers to construct micellar or vesicular nanoparticles have been well investigated (*36*, *37*). Although amphiphilic polymers synthesized by the ROMP method are known to form stable nanoparticles having low critical micelle concentration (cmc) values in water (0.5−1.0 g/L) (*38*, *39*), the further modification of polymer conjugates is still necessary to use them as imaging probes in vivo. More recently, Grubbs and a co-worker demonstrated the powerful ROMP method followed by cross-linking for the size-tunable synthesis of micellar nanoparticles aimed at a PET imaging probe (*30*). However, Kane and co-workers reported the synthesis of block copolymers from two types of norbornenes using ROMP followed by dihydroxylation of olefin moieties in the polymer to gain solubility in water (*40*). The high water-solubility of polymer conjugates, in the latter case, would be caused by the formation of stable micellar nanoparticles assembled with flexible polymer conjugates having many hydroxyl groups. This successful synthesis of highly water-soluble polymer conjugates prompted us to investigate the ROMP of norbornadienes instead of norbornenes followed by dihydroxylation, which can lead to further enhancement of water-solubility and stability of nanoparticles. Here, we wish to report the synthesis of water-soluble polymer conjugates using ROMP of three types of norbornadiene monomers and osmium-catalyzed dihydroxylation, and their application as an efficient optical tumor imaging probe.

EXPERIMENTAL PROCEDURES

Materials. Grubbs' third catalyst was prepared from Grubbs' second catalyst according to the reported procedure (*35*). Grubbs' second catalyst and potassium osmate dihydrate were purchased from Sigma-Aldrich (St. Louis, MO). Ethyl vinyl ether, sodium azide, L(+)-ascorbic acid sodium salt, copper (II) sulfate pentahydrate, thiophenol, potassium carbonate, chloroform ($CHCl_3$), *N*,*N*-dimethylformamide (DMF), methanol (MeOH), acetone, and dichloromethane (CH_2Cl_2) were purchased from Nacalai Tesque (Japan). 4-Methylmorpholine *N*-oxide and tetrahydrofuran (THF) were purchased from Wako Pure Chemicals Inc. (Japan). Spectra/Por 6 (MW:1000) was purchased from Spectrum Laboratories Inc. (Rancho Dominguez, CA). All monomers containing the norbornadiene (bicyclo-

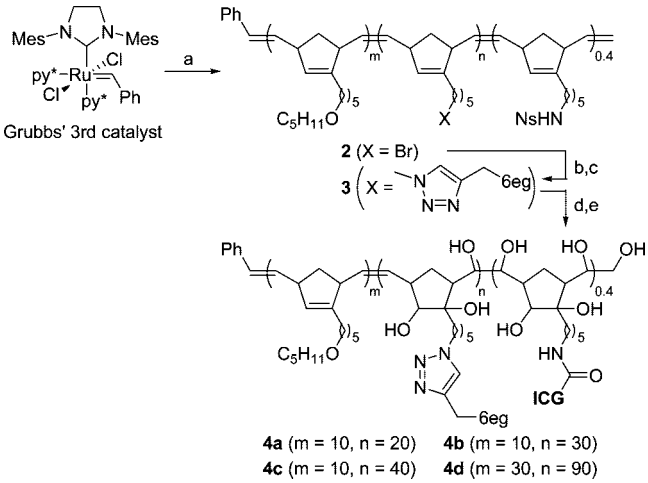
Scheme 1. Synthesis of ICG-Containing Block Copolymers 4[a]



[a] Reaction conditions: (a) **1a** (m equiv), **1b** (n equiv), **1c** (0.4 equiv), CH_2Cl_2, rt, then ethyl vinyl ether; (b) NaN_3, DMF, 50 °C, 15 h; (c) HC≡CCH_2-6eg (**5**), $CuSO_4 \cdot 5H_2O$, sodium ascorbate, THF/H_2O, rt, 48 h; (d) K_2OsO_4, 4-methylmorpholine-*N*-oxide, acetone/MeOH/H_2O, rt, 12 h, then dialysis; (e) PhSH, K_2CO_3, DMF, rt, overnight, then (**6**), rt, 24 h, then dialysis. Mes = 2,4,6-trimethylphenyl, py* = 3-bromopyridine, and 6eg = -$(OCH_2CH_2)_6OCH_3$.

[2.2.1]hepta-2,5-diene) moieties used are shown in Figure 1, and the preparation of monomers from norbornadiene is summarized in Supporting Information. All monomers were purified by gel permeation chromatography (GPC, recycling preparative HPLC LC-908, Japan Analytical Industry Co., Ltd., Japan) with $CHCl_3$ as an eluent and stocked as a dried and degassed CH_2Cl_2 solution in the dark.

Synthesis of Triblock Copolymers 4. We synthesized triblock copolymer **4** by using norbornadiene monomers, 2-(5-pentyloxypentyl)bicyclo[2.2.1]hepta-2,5-diene (**1a**), 2-(5-bromopentyl)bicyclo[2.2.1]hepta-2,5-diene (**1b**), and *N*-(5-bicyclo-[2.2.1]hepta-2,5-dien-2-yl)pentyl-2-nitrobenzensulfonamide (**1c**) (Scheme 1). When the ROMP of **1a**−**c** with a catalytic amount of Grubbs' third catalyst was consequently carried out at room temperature, triblock copolymer **2** was obtained in a nearly quantitative yield. After the nucleophilic substitution of bromide with azide, the Cu-catalyzed [2 + 3] dipolar cyclization reaction (click reaction) (*41*−*44*) of the resulting alkyl azide with propargyl ether **5** gave triblock copolymer **3**. The double bonds in polymer **3** surrounded by hexaethylene glycol moieties were selectively oxidized to vicinal diols using standard Os-catalyzed dihydroxylation under aqueous conditions (*45, 46*). The transamidation with ICG derivative **6** (*47*) gave the ICG-containing water-soluble triblock copolymer **4** after careful dialysis to remove unreacted **6** and lyophilization.

Synthesis of Triblock Copolymer 2. A catalytic amount of Grubbs' third catalyst (4.4 mg, 0.005 mmol) was placed in a flame-dried Schlenk flask and dissolved in CH_2Cl_2 (0.5 mL) under N_2. A 0.10 M solution of **1a** in dried and degassed CH_2Cl_2 (0.50 mL, 0.050 mmol, 10 equiv) was added to the flask at room temperature. After stirring for 20 min at room temperature, to the brown solution was added a 0.075 M solution of **1b** in dried and degassed CH_2Cl_2 (2.0 mL, 0.15 mmol, 30 equiv) at room temperature. After stirring for 20 min, to the brown solution was added a 0.10 M solution of **1c** in dried and degassed CH_2Cl_2 (20 μL, 0.0020 mmol, 0.40 equiv) at room temperature. The resulting pale brown reaction mixture was stirred for 20 min at room temperature and then quenched by ethyl vinyl ether (0.1 mL). After stirring for an additional 30 min, the organic solvent and excess amounts of ethyl vinyl ether were removed under reduced pressure. The crude triblock copolymer **2** (49 mg, >99%, theoretical molecular weight (MW) = 1.00×10^4) was obtained quantitatively and used for the next oxidation reaction without further purification. Triblock copolymer **2** was purified and collected by precipitation in CH_2Cl_2/hexane for spectral measurements (47 mg, 96%).

2: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.87−0.91 (m, 26H), 1.21−1.65 (m, 291H), 1.71−2.14 (m, 142H), 2.30−2.36 (m, 34H), 3.01−3.30 (m, 32H), 3.30−3.70 (m, 147H), 5.00−5.45 (m, 120H), 7.72−7.75 (m, 1.0H), 7.80−7.85 (m, 0.6H), 8.10−8.15 (m, 0.5H).

Synthesis of Triblock Copolymer 3. To a crude triblock copolymer **2** (49 mg) in DMF (3.0 mL) was added sodium azide (53 mg, 0.82 mmol) at room temperature. The reaction mixture was stirred at room temperature for 24 h. The organic solvent was reduced to ca. 0.5 mL under reduced pressure. To the solution was added H_2O (3.0 mL), and the precipitate was collected by filteration and dried under reduced pressure to afford a brown solid (44 mg, >99%, MW = 0.88×10^4).

To a solution of the obtained solid in THF (1.0 mL) were sequentially added a solution of propargyl ether **5** (0.25 g, 0.73 mmol) in THF (1.0 mL), a solution of $CuSO_4 \cdot 5H_2O$ (8.8 mg, 0.035 mmol) in H_2O (1.0 mL), and a solution of sodium ascorbate (13.9 mg, 0.070 mmol) in H_2O (1.0 mL) at room temperature. After stirring the reaction mixture overnight at room temperature, the organic solvent was removed under reduced pressure, and the residue was dialyzed by using Spectra/Por 6 (MW:1000) against H_2O for 1 day. Triblock copolymer **3** (95 mg, >99%, MW = 1.89×10^4) was obtained after lyophilization.

3: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.87−0.91 (m, 34H), 1.19−1.65 (m, 321H), 1.78−2.20 (m, 263H), 2.42−2.47 (m, 25H), 3.38 (br s, 151H), 3.53−3.88 (m, 1014H), 4.34 (br s, 61H), 4.67 (br s, 61H), 4.98−5.50 (m, 120H). The peaks of aromatic protons could not be detected because of high intensity of protons on ethylene glycol moieties. The peaks of unreacted propargyl ether **5** were included at δ 3.38 and δ 3.53−3.88.

Synthesis of Triblock Copolymer 4. To a solution of crude copolymer **3** suspended in acetone (1.0 mL) and MeOH (1.0 mL) was added an aqueous solution of 4-methylmorpholine *N*-oxide (NMO, 71 mg, 0.61 mmol) and K_2OsO_4 (1.0 mg) in H_2O (2.0 mL) at room temperature. The reaction mixture was stirred for 12 h at room temperature, and the organic solvents were removed under reduced pressure. The residue was dialyzed to remove excess amounts of NMO and osmium compound by using Spectra/Por 6 (MWCO:1000) against H_2O.

To a solution of the resulting amphiphilic copolymer in DMF (2.0 mL) were added potassium carbonate (7.5 mg, 0.050 mmol) and thiophenol (10 μL, 0.10 mmol) at room temperature. After stirring overnight at room temperature, a solution of ICG derivative **6** (8.0 mg, 0.01 mmol) in DMF (1.0 mL) was added at room temperature. After stirring overnight at room temper-

ature, the solvent was removed under reduced pressure. The resulting mixture was diluted with H_2O (2.0 mL), and this aqueous solution was washed at least 10 times with Et_2O until the green color of the etheral solution disappeared. (ICG derivative **6** does not show water-solubility. On the basis of this, we believe that the ICG moiety is attached covalently with the polymer side chain. However, we do not exclude the fact that a small amount of **6** is contained inside the polymer assemblies.) The volume of solvent was reduced by using lyophilization, and the resulting aqueous solution was dialyzed by using Spectra/Por 6 (MWCO:1000) against H_2O. ICG-containing amphiphilic triblock copolymer **4** (84% from **3b** ($m = 10$, $n = 30$); MW $= 2.16 \times 10^4$; 68−80% of double bonds were oxidized) was obtained after lyophilization for 48 h. In this case, MW (theoretical molecular weight) means the polymer molecular weight by assuming quantitative conversion of double bonds to vicinal diols and quantitative transformation of all free NH_2 groups from the Ns-protected amino groups with **6**. **4b**: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.70-0.96$ (m, 17H), 0.96−1.50 (m, 171H), 1.50−1.70 (m, 67H), 1.70−2.15 (m, 147H), 2.20−2.42 (m, 35H), 3.20−3.45 (m, 158H), 3.45−4.05 (m, 910H), 4.10−4.52 (m, 71H), 4.52−4.84 (m, 60H), 4.95−5.80 (m, 27H), 7.50−8.00 (m, 43H).

4a (97% from **3a** ($m = 10$, $n = 20$); MW $=1.57 \times 10^4$; 65−75% of double bonds were oxidized): ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.70-0.96$ (m, 10H), 0.96−1.50 (m, 71H), 1.50−1.70 (m, 35H), 1.70−2.15 (m, 35H), 2.20−2.42 (m, 65H), 3.20−3.45 (m, 113H), 3.45−4.05 (m, 967H), 4.10−4.52 (m, 69H), 4.52−4.84 (m, 40H), 4.95−5.80 (m, 22H), 7.50−8.00 (m, 18H).

4c (92% from **3c** ($m = 10$, $n = 40$); MW $=2.77 \times 10^4$; 70−87% of double bonds were oxidized): ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.70-0.96$ (m, 12H), 0.96−1.50 (m, 136H), 1.50−1.70 (m, 69H), 1.70−2.15 (m, 163H), 2.20−2.42 (m, 65H), 3.20−3.45 (m, 195H), 3.45−4.05 (m, 991H), 4.10−4.52 (m, 144H), 4.52−4.84 (m, 80H), 4.95−5.80 (m, 20H), 7.50−8.00 (m, 39H).

4d (59% from **3d** ($m = 30$, $n = 90$); MW $=6.43 \times 10^4$; 65−75% of double bonds were oxidized): ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.70-0.96$ (m, 101H), 0.96−1.50 (m, 569H), 1.50−1.70 (m, 230H), 1.70−2.15 (m, 402H), 2.20−2.42 (m, 100H), 3.20−3.45 (m, 474H), 3.45−4.05 (m, 2328H), 4.10−4.52 (m, 216H), 4.52−4.84 (m, 180H), 4.95−5.80 (m, 98H), 7.50−8.00 (m, 89H).

Transmission Electron Microscopy (TEM) Image Analysis. Transmission electron microscopy (TEM, Model H-9000NAR, Power Supply 200 V, 60 Hz, 15 kVA, Single phase, Hitachi, Ltd., Tokyo, Japan) was used to visualize the morphology of nanoparticles. Samples were dropped onto a TEM copper grid covered with a carbon film (200 mesh, Nisshin EM, Japan) and air-dried for 3 h.

Size Distribution Using Dynamic Light Scattering (DLS) Measurement. The hydrodynamic diameters of spherical assemblies were determined by dynamic light scattering (DLS, FPAR-1000, Otsuka Electronics Co, Ltd., Japan) at 20 °C. The sample solutions were diluted in H_2O and filtered prior to analysis (syringe filter, 0.45 μm pore size, PVDF filter membrane, Whatman, Florham Park, NJ). The light source was a semiconductor laser ($\lambda_0 = 658$ nm), and the correlation function for each solution was obtained at 90°. The measurements of all samples were conducted at least three times. Apparent hydrodynamic diameters of polymer assemblies were obtained using the method of Marquadt. The copolymer concentrations of the analyzed sample solutions were 0.05 mg/mL, in which concentration polymer assemblies were formed according to the results of cmc measurements.

Measurement of Critical Micelle Concentration (cmc). The cmc values of the dye-containing triblock copolymers were determined using static light scattering (SLS, SLS-6000, Otsuka Electronics Co Ltd., Japan) measurements. Several concentrations of the copolymer solution were filtered prior to analysis (syringe filter, 0.45 μm pore size, PVDF filter membrane, Whatman, Florham Park, NJ). The measurements were done with He−Ne laser ($\lambda_0 = 633$ nm) in the angular range of 90−95°. The measurement of samples in each concentration was conducted at least two times, and the intensity of the scattering light (I_s) is an average of all measured values in each concentration. The intensities of the scattering light over the incident light (I_s/I_0) was plotted against log *C* (C = concentration (g/L)), and the ranges of cmc values were determined at the area where I_s/I_0 changed from a constant (near zero) to a larger value (see Supporting Information).

Imaging Experiments. *Cell Culture and Tumor-Bearing Mice.* The human cervical epithelial adenocarcinoma cell line (HeLa) was purchased from American type Culture Collection.

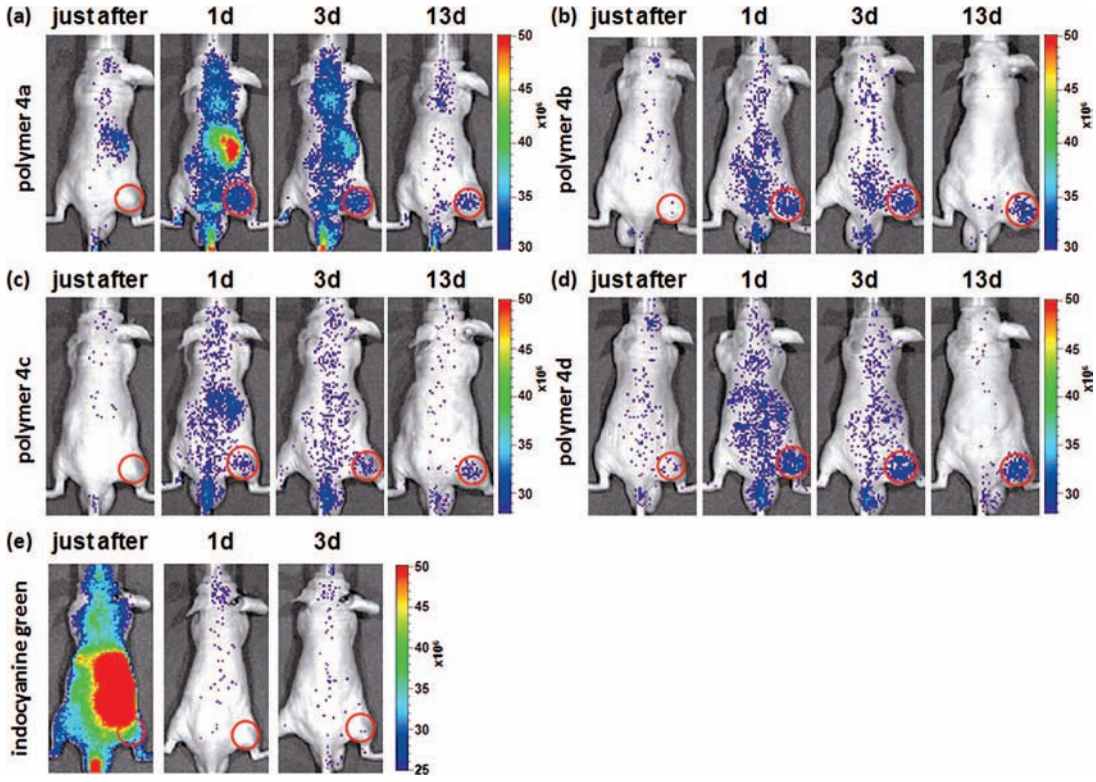

Figure 4. NIRF tomographic images of tumor-bearing mice after injection (just after, 1 day, 3 days, and 13 days) of 100 μL of ICG-containing imaging probes (a) **4a**, (b) **4b**, (c) **4c**, (d) **4d**, and (e) indocyanine green (1.0 mg/mL). Purple, low intensity; red, high intensity; and red circle, tumor site. In order to clarify the data, the fluorescence intensities lower than 3.0×10^7 (polymers **4a** and **4b**), 2.8×10^7 (polymers **4c** and **4d**), or 2.5×10^7 (indocyanine green), and higher than 5.0×10^7 were omitted.

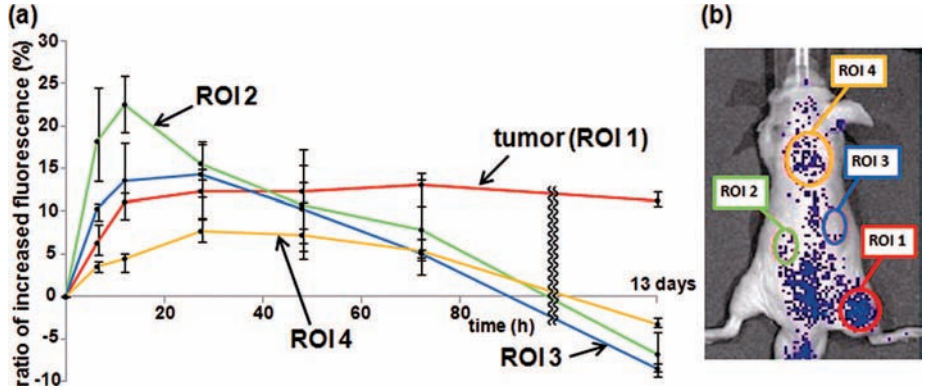

Figure 5. (a) Ratio of increased fluorescence intensity (%) of **4b**. (b) ROI (region of interest). The ratios of increased fluorescence intensity were calculated from the equation: $\{(I_t/I_0) - 1\} \times 100$ (I_t = average fluorescence intensity in each ROI at each time; I_0 = average fluorescence intensity in each ROI just after injection). ROI 1 was located at a tumor, and ROIs 2−4 were located around a lung and a kidney. The photon in each ROI was counted at least three times, and the ranges of these values are shown as error bars.

Cells were maintained in 10% FBS-Dulbecco's modified Eagle's medium and cultured in a well-humidified incubator with 5% CO_2 and 95% air at 37 °C. The suspension of HeLa cells (2×10^6) was subcutaneously inoculated into the right hind leg or left shoulder of 6-week-old nude mice (BALB/c nu/nu mice, SHIMIZU Laboratory Supplies Co. Ltd., Kyoto, Japan).

Fluorescent Imaging in Vivo. Polymers **4a**−**d** in pure water (1 mg/mL) as fluorescence probes were prepared and kept in the dark at room temperature for at least 24 h before injection. One hundred microliters of fluorescence probes were intravenously injected for each experiment. Optical imaging experiments to detect the distribution of the fluorescent probes in tumor-bearing mice were carried out with an IVIS-200 in vivo imaging device (Xenogen, Alameda, CA). During imaging, mice were anesthetized with 2.5% isoflurane gas in the oxygen flow (1.5 L/min). Images were analyzed using Living Image 2.50-Igor Pro 4.09 software (Xenogen), according to the manufacturer's instructions. In all imaging experiments, the fluorescence probe in the same batch was injected to at least two mice, and one set of experiments was repeated at least twice to confirm reproducibility, and representative images are shown. Fluorescence imaging in vitro was carried out with the same device described above.

Ethics of Animal Experiments. All of our animal experiments were approved by the Animal Research Committee of Kyoto University and carried out in accordance with its guidelines.

RESULTS AND DISCUSSION

Synthesis of ICG-Containing Amphiphilic Triblock Copolymers. Water-soluble triblock copolymer **4** was synthesized from norbornadiene monomers **1a**−**c**. At first, triblock copoly-

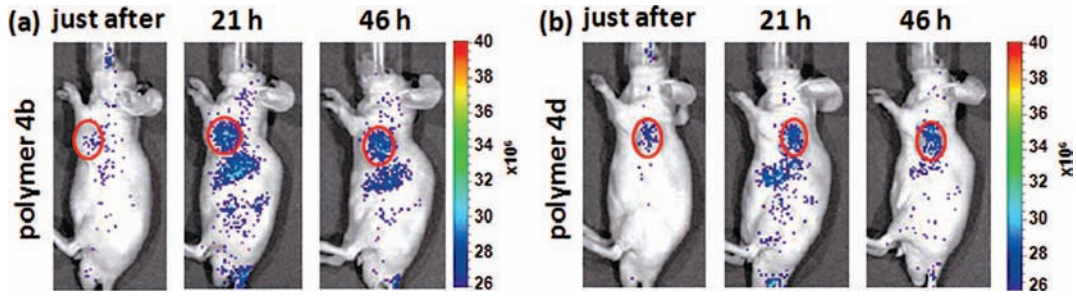

Figure 6. NIRF tomographic images of tumor-bearing mice after injection (just after, 21 h, and 46 h) of 100 μL of ICG-containing imaging probes (a) **4b** and (b) **4d** (1.0 mg/mL). Red circle at a left shoulder indicates the tumor site. In order to clarify the data, the fluorescence intensities lower than 2.6×10^7 and higher than 4.0×10^7 were omitted.

mers **2a**−**d** with different molar ratios of monomers **1a**−**c** to a Grubbs' third catalyst were synthesized by using ROMP in nearly quantitative yields. The number-average molecular weight (M_n) and polydispersity index (PDI) are summarized in Table 1. Although all M_ns were estimated as a little lower value by GPC compared with the theoretical molecular weight (MW) by assuming quantitative conversion of monomers, PDIs indicated that the polymer had a precisely controlled length. The complete consumption of norbornadiene monomers was checked by ^{1}H NMR spectra; three vinyl protons of all mono alkyl-substituted norbornadiene skeletons observed at δ 6.1 (1H) and 6.7 (2H) disappeared, and both a vinyl proton of cyclopentene and two vinyl protons of 1,2-disubstituted ethene newly appeared around δ 5.2. Azide formation followed by Cu-catalyzed [2 + 3] cyclization with propargyl ether HC≡CCH$_2$-6eg (**5**) gave triblock copolymer **3** with >95% introduction efficiency of hexaethylene glycol moiety. The efficiency of the click reaction was estimated by ^{1}H NMR measurement; the integration values of newly appeared methylene protons at α-position of a triazole ring observed around δ 4.3 and 4.7 were compared with that of vinyl protons observed at δ 5.2 before and after the click reaction (see Supporting Information). The obtained copolymer **3** was unfortunately difficult to dissolve in water. To improve the water-solubility of polymer **3**, the double bonds in the polymer backbone surrounded by hexaethylene glycol moieties were selectively oxidized to vicinal diols by using Os-catalyzed dihydroxylation with 4-methylmorpholine *N*-oxide in aqueous conditions. The proportions of vicinal diols were estimated to be 65−75% by ^{1}H NMR spectra; the integration value of vinyl protons observed around δ 5.2 was compared with that of methylene protons next to a triazole ring observed at δ 4.7 before and after the Os-catalyzed dihydroxylation (see Supporting Information). The transamidation of 1,3-thiazolidine-2-thione **6** gave the ICG-containing water-soluble triblock copolymers **4**, which were purified by dialysis and lyophilization.

Size Distribution and cmc. Average diameters of nanometer-size spherical self-assemblies formed by the ICG-containing triblock copolymers **4** in H_2O were measured by TEM and DLS (Table 1). The diameters of nanoparticles were estimated at 50−60 nm by TEM (Figure 3). When the images were measured without osmium tetroxide exposure, 10% of nanoparticles were observed as a black spot. This indicates that a part of the spherical assemblies would contain transition metal species in their supermolecular structure. The self-assembly of the longest polymer **4d** was slightly larger than **4a**−**c**, whose sizes were almost same. The reason why the sizes of nanoparticles were not significantly affected by polymer length might come from large PDI values. The theoretical molecular length of **4a**−**c** as the extended form is estimated to be 25−35 nm, and the diameters of nanoparticles measured by TEM are reasonable as polymer self-assemblies. Although the diameter of **4d** is estimated at ca. 60 nm in the extended form, the nanoparticle size of **4d** was a little smaller than the expected one. However, the diameters of nanoparticles in water measured by DLS were much larger than even twice the extended length of polymers. This might indicate that the polymer assemblies formed larger assemblies such as vesicles in water media. The diameters of self-assemblies of **2a** and **2c** were not determined with certainty by DLS because of large residual values ($>1.0 \times 10^{-2}$).

The cmc values of **4** were determined by static light scattering (SLS) (see Supporting Information). These values are much lower than those of the other polymers synthesized by ROMP without dihydroxylation (*39*, *40*). Low cmc values of self-assemblies of **4** indicate that these polymers form stable assemblies in aqueous media and are good candidates for tumor imaging in vivo.

In Vivo Tumor Imaging. To examine the characteristics of the polymer conjugates as tumor-specific fluorescent probes in vivo, we performed a series of optical imaging experiments. We intravenously injected the polymer conjugates **4a**−**d** and indocyanine green into tumor-bearing nude mice and monitored their distribution using an optical in vivo imaging device (Figure 4). To emphasize the areas where imaging probes specifically accumulated, lower and higher fluorescence intensities were omitted. In the case of imaging data just after, the probes were diffused in a whole body, and the fluorescence intensities could not reach to the lower limit. All nanoparticles could accumulate in the tumor xenograft on the right leg as well as in other organs such as the liver and kidney within one day. Despite the low selectivity, all nanoparticles could stay for at least two weeks in the tumor. The self-assembly of **4a** showed slightly higher fluorescence intensity than those of **4b** and **4c** because **4a** contained larger amounts of the fluorescence probe (Figures 4a-c). In Figure 5, the ratios of increased fluorescence intensities in each region of interest (ROI) for polymer **4b** were calculated and summarized. Interestingly, the accumulation of nanoparticles in all ROIs reached a peak 12−24 h after the injection and decreased gradually in all regions thereafter except ROI 1. When the sizes of ROIs were changed, the fluorescence intensities were also changed, but the tendencies of the increase or decrease in ratios were quite similar to the graphs shown in Figure 5 (see Supporting Information). This phenomenon was also observed using polymers **4c** and **4d**, while the intensities were decreased gradually in all regions in the case of polymer **4a**. The long time retention in the tumor xenograft might be caused by the stability of polymer assemblies predicted from cmc values. A tumor transplanted to another part, such as a left shoulder, could also be visualized (Figure 6).

In conclusion, we have synthesized amphiphilic block copolymers containing the indocyanine green moiety, of the form hydrophobic−hydrophilic−dye segments, using a combination of ROMP, Cu-catalyzed [2 + 3]-dipolar click reaction, and Os-catalyzed dihydroxylation. The amphiphilic polymers modified by dihydroxylation on a polymer backbone exhibit much lower cmc values and form 50−60 nm size nanoparticles in water. Although further modification such as PEGylation (*48*, *49*)

using click chemistry to conjugate a much longer polyethylene glycol chain for a hydrophilic segment is necessary to restrain accumulation in other normal organs, it appears that the prolonged retention of nanoparticles of **4** in solid tumors will be useful for medical treatment using sterically rigid hydrophobic antitumor drugs, such as Taxol, and for cancer diagnosis using conjugating quantum dots (QDs), positron emission tomography, or magnetic resonance imaging probes.

ACKNOWLEDGMENT

This research was supported in part by the Global COE Program "International Center for Integrated Research and Advanced Education in Materials Science" (No. B-09) of the Ministry of Education, Culture, Sports, Science and Technology of Japan. We acknowledge Professor Yoshiki Chujo and Dr. Yasuhiro Morisaki, Kyoto University for DLS measurement, Professor Hideki Matsuoka and Dr. Rati Ranjan Nayak, Kyoto University for SLS measurement, and Ms. Akiyo Morinibu and Ms. Kazumi Shinomiya, Kyoto University for technical assistance in in vivo imaging experiments. We appreciate Nano-Medicine Merger Education Unit, Kyoto University for giving us this opportunity to collaborate.

Supporting Information Available: Preparation of monomers, efficiencies of transformation of polymer side chain, SLS measurements, and the graphs of ratio of increased fluorescence intensity in in vivo tumor imaging. This material is available free of charge via the Internet at http://pubs.acs.org.

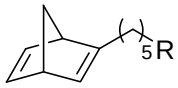
1. Experimental Section

Materials. Bicycle[2.2.1]hepta-2,5-diene (norbornadiene), triethylene glycol monomethyl ether, were purchased from Sigma-Aldrich (St. Louis, MO). 1-Pentanol, potassium carbonate, (DMF), chloroform and dichloromethane were purchased from nacalai tesque (Japan). 2-Nitrobenzenesulfonamide was purchased from Tokyo Chemical Industry Co., Ltd. (Japan). Sodium hydride (60 wt% in oil), propargyl bromide, and tetrahydrofuran (THF) were purchased from Wako Pure Chemicals Inc. (Japan). Silica gel (230-400 mesh) for column chromatography was purchased from Silicycle (Canada). All monomers containing norbornadiene (bicycle[2.2.1]hepta-2,5-diene) moieties used are shown in Figure S1 and the preparation of monomers from norbornadiene is summarized in Supporting Information. All monomers were purified by gel permeation chromatography (GPC, recycling preparative HPLC LC-908, Japan Analytical Industry Co., Ltd., Japan) with $CHCl_3$ as an eluent and stocked as a dried and degassed CH_2Cl_2 solution.

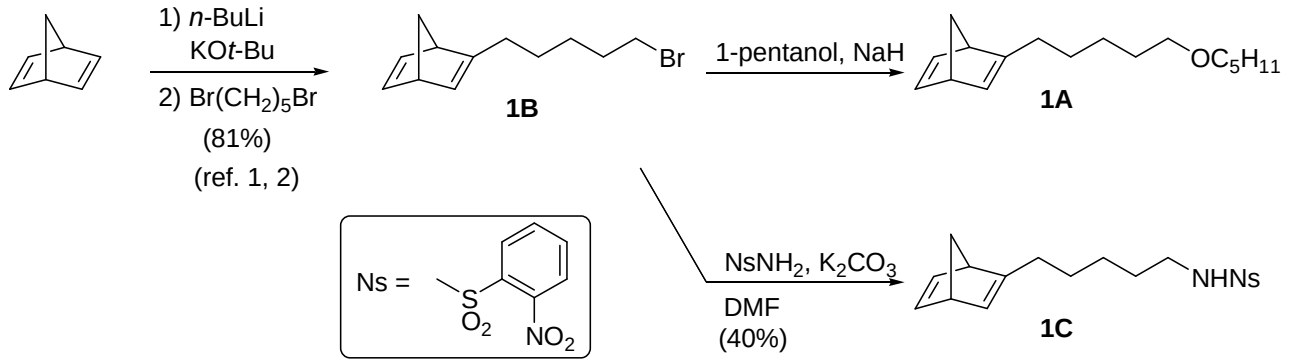


1A: R = OC_5H_{11} **1B**: R = NHNs **1C**: R = Br

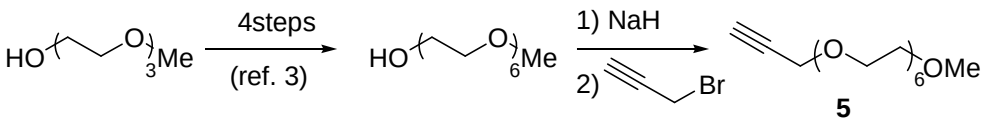
Figure S1. Norbornadiene monomers. Ns = 2-nitrobenzenedulfonyl.

1.1. Preparation of Monomers. The synthetic scheme for norbornadiene monomers from bicycle[2.2.1]hepta-2,5-diene (norbornadiene) is shown in Scheme S1. HC≡C-CH_2-6eg (**5**, 6eg = –$(OCH_2CH_2)_6OCH_3$) was prepared from hexaethylene glycol monomethyl ether (Scheme S2).

SCHEME S1.



SCHEME S2.



*Synthesis of 2-(5-pentyloxypentyl)bicyclo[2.2.1]hepta-2,5-diene (**1a**).* To a solution of 1-pentanol (2.1 g, 24 mmol) in THF (20 mL) was slowly added sodium hydride (60 wt% in oil, 1.2 g, 30 mmol) at 0 °C. After stirring for 1 h at room temperature, to this solution was added a solution of **1b** (*1*,*2*) (3.9 g, 16 mmol) in THF (20 mL) at 0 °C. The reaction mixture was stirred overnight at 60 °C. The reaction mixture was cooled down to room temperature and washed with brine (15 mL x 3). The aqueous layer was extracted with AcOEt (20 mL x 3) and the combined organic solution was dried over $MgSO_4$. The solvents were removed under reduced pressure and the

crude product was subjected to column chromatography on SiO_2 with hexane as an eluent to afford **1a** (1.5 g, 6.1 mmol, 38%) as a colorless oil. IR (neat) 694, 879, 1116, 1302, 1376, 1464, 2859, 2932, 3056cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.90 (t, J = 6.0 Hz, 3H), 1.24-1.47 (m, 8H), 1.53-1.60 (m, 4H), 1.95 (dd, J = 5.4, 15.0 Hz, 2H), 2.12-2.25 (m, 2H), 3.27 (s, 1H), 3.38 (t, J = 6.6 Hz, 2H), 3.48 (s, 1H), 6.12 (d, J = 8.8 Hz, 1H), 6.75 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 14.1, 22.6, 26.0, 27.1, 28.4, 29.5, 29.7, 31.5, 50.0, 53.5, 70.8, 70.9, 73.4, 133.1, 142.3, 143.7, 158.7. HRMS calcd for $C_{17}H_{29}O$ ($M+H^+$) 249.2218, found 249.2212. Anal calcd for $C_{17}H_{28}O$: C, 82.20; H, 11.36. Found: C, 81.99; H, 11.40.

*Synthesis of Amino Moiety-Containing Norbornadiene Monomer **1c***. To a solution of **1b** (*1*,*2*) (2.2 g, 9.0 mmol) in DMF (8.5 mL) was added 2-nitrobenzenesulfonamide (0.97 g, 4.8 mmol) and K_2CO_3 (1.3 g, 9.6 mmol) at 0 °C. The reaction mixture was stirred overnight at 60 °C. The reaction mixture was poured into ice water (50 mL) and the aqueous layer was extracted with AcOEt (20 mL x 3). The organic layer was washed with brine (20 mL) and dried over $MgSO_4$. The solvents were removed under reduced pressure and the crude product was subjected to column chromatography on SiO_2 with ethyl acetate/hexane (v/v = 1/7) as an eluent to afford **1c** (0.70 g, 1.9 mmol, 40%) as a colorless oil. IR (neat) 592, 732, 912, 1170, 1362, 1415, 1541, 2932, 3350 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.25-1.58 (m, 6H), 1.92 (dd, J = 5.6, 11.6 Hz, 2H), 2.03-2.21 (m, 2H), 3.08 (dd, J = 6.8, 13.2 Hz, 2H), 3.22 (s, 1H), 3.46 (s, 1H), 5.35 (t, J = 6.3 Hz, 1H), 6.07 (s, 1H), 6.71-6.72 (m, 2H), 7.74-7.76 (m, 2H), 7.83-7.85 (m, 1H), 8.10-8.12 (m, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 25.9, 26.3, 29.1, 31.0, 43.6, 49.8, 53.2, 73.2, 125.0, 130.6, 132.5, 133.2, 133.4, 133.4, 141.9, 143.4, 147.6, 157.9. HRMS calcd for $C_{18}H_{22}N_2O_4S$ ($M+H^+$): 363.1379. Found: 363.1381. Anal calcd for $C_{18}H_{22}N_2O_4S$: C, 59.65; H, 6.12. Found: C, 59.43; H, 5.96.

*Synthesis of Propargyl Ether **5***. Propargyl ether **5** was synthesized according to the similar reported procedure (*4*). Ether **5** was purified by GPC with $CHCl_3$ as an eluent before use. IR (neat) 733, 849, 921, 1034, 1104, 1200, 1249, 1300, 1351, 1456, 1645, 1739, 2113, 2871, 3245, 3543 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$): δ 2.44 (t, J = 2.0 Hz, 1H), 3.38 (s, 3H), 3.53-3.80 (m, 24H), 4.20 (d, J = 2.0 Hz, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 58.3, 59.0, 69.1, 70.4, 70.5, 70.5, 70.6, 71.9, 74.5, 79.6. Anal calcd for $C_{16}H_{30}O_7$: C, 57.47; H, 9.04. Found: C, 57.24; H, 8.74.

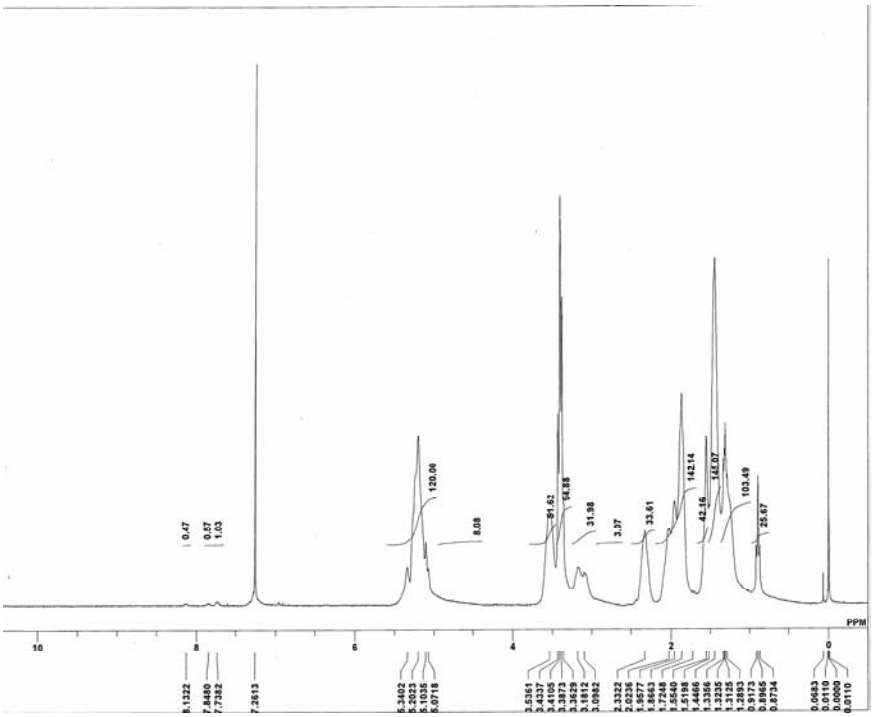
1.2. Efficiencies of Transformation of Polymer Side Chain (Estimated from ^{1}H NMR Spectra)

The click reaction of azide, and the Os-catalyzed dihydroxylation were estimated from ^{1}H NMR spectra. The NMR charts of the nucleophilic substitution of bromide with azide were also summarized below.

1.2.1. Nucleophilic Substitution of Bromide with Azide.

^{1}H NMR spectra before and after the nucleophilic substitution of **2b** were shown below (Figures S2). The conversion were difficult to be estimated, however these might be estimated indirectly around >95% because the efficiency of the click reaction after azide formation was estimated at >95% (see the next page). A vibration peak of -N=N=N: was newly appeared at 2096 cm^{-1} in IR spectra.

(a) Before the substitution reaction of 2b



(b) After the substitution reaction of 2b

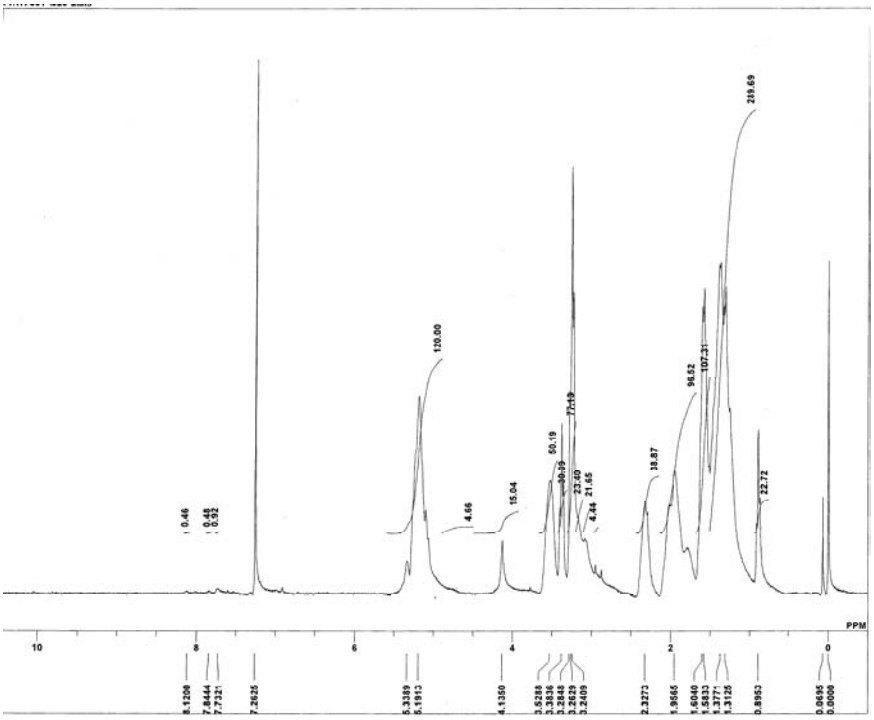


Figure S2. ^{1}H NMR spectra (300 MHz) before (a) and after (b) the substitution of **2b** with azide.

1.2.2. Click Reaction of Azide and Os-Catalyzed Reaction of the Resulting 3b.

The efficiencies of the click reactions were estimated at >95% (Figure S3). Two proton pairs at α-position of triazole ring were assigned at δ 4.3 and 4.7 (The peak at δ 4.2 was assigned as HC≡CCH_2–6eg (**5**)). The integrated values of these peaks were theoretically 60 compared with vinyl protons at δ 5.2 (121.2H), respectively. Based on these values, the efficiencies of conversion on the click reactions were estimated over 95% from the results of several runs. A vibration peak of an azide at 2096 cm^{-1} on IR spectra was disappeared and the broad peak around 1102-1105 cm^{-1} was newly appeared. This might be assigned as a vibration peak of C-O-C bonds in ethylene glycol moieties. Since the integration values at δ 4.7 and 5.2 were theoretically 60 and 121.2, the efficiency of conversion of double bonds was estimated at 68-80% from the results of several runs (Figure S3).

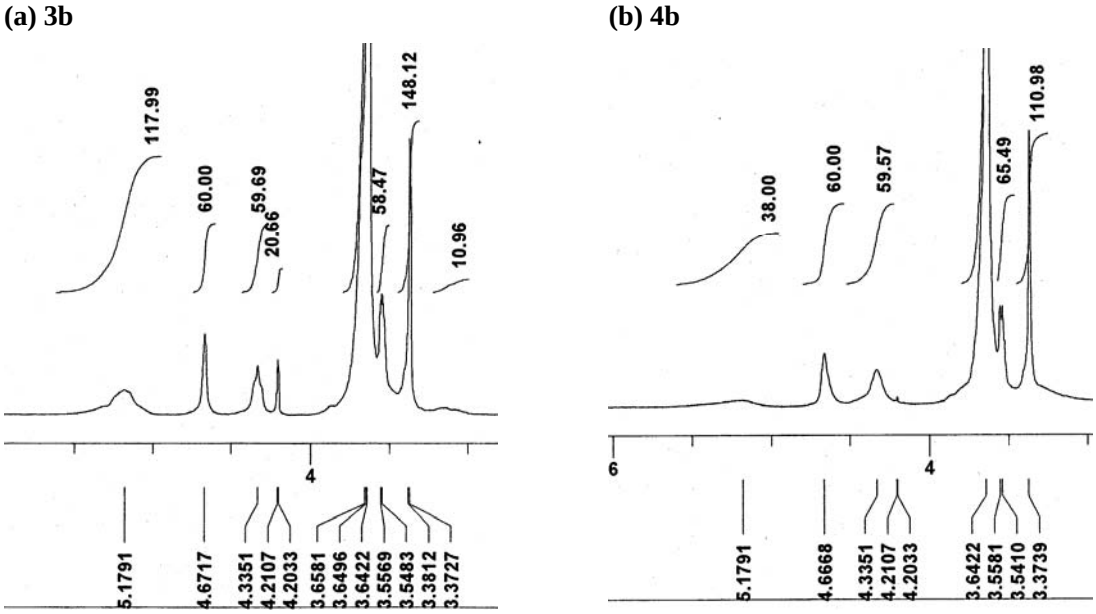

Figure S3. ^{1}H NMR spectra (300 MHz) of **3b** (a) and **4b** (b).

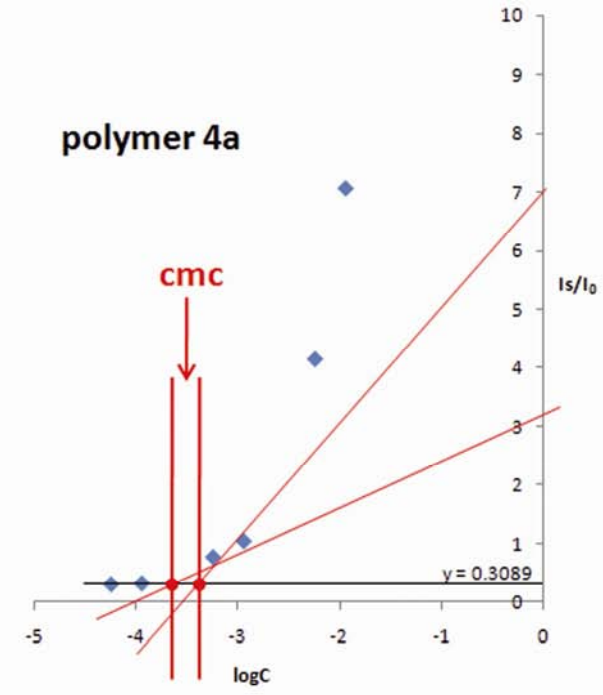
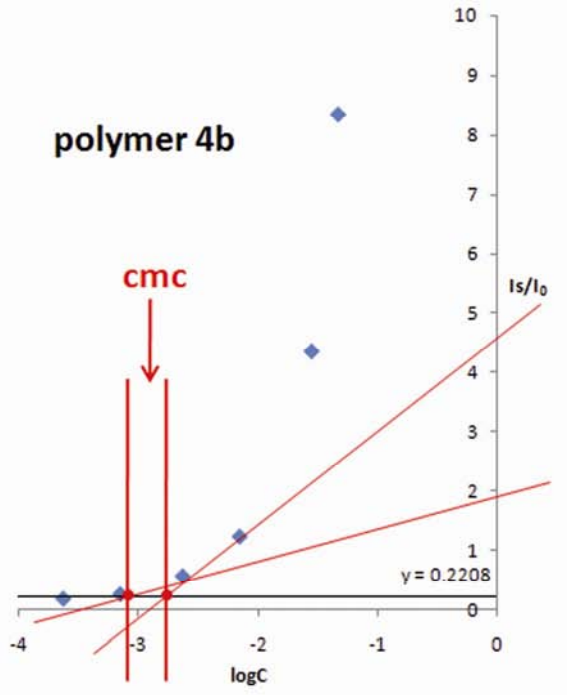
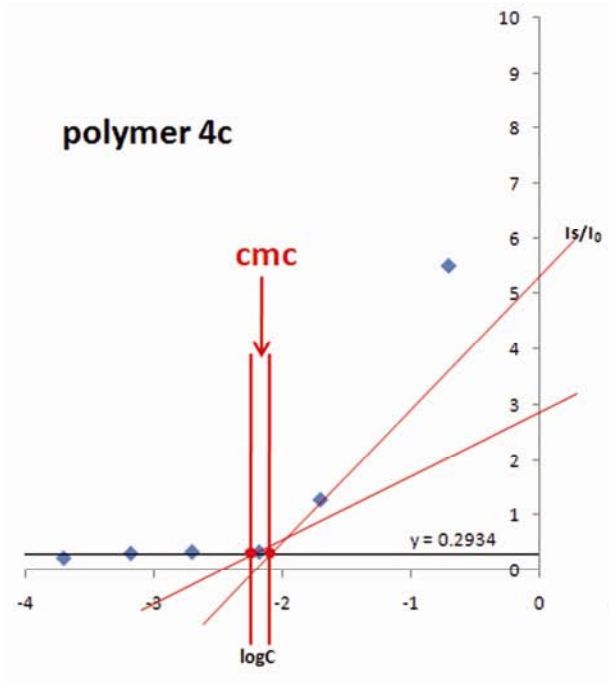
1.3. SLS Measurements

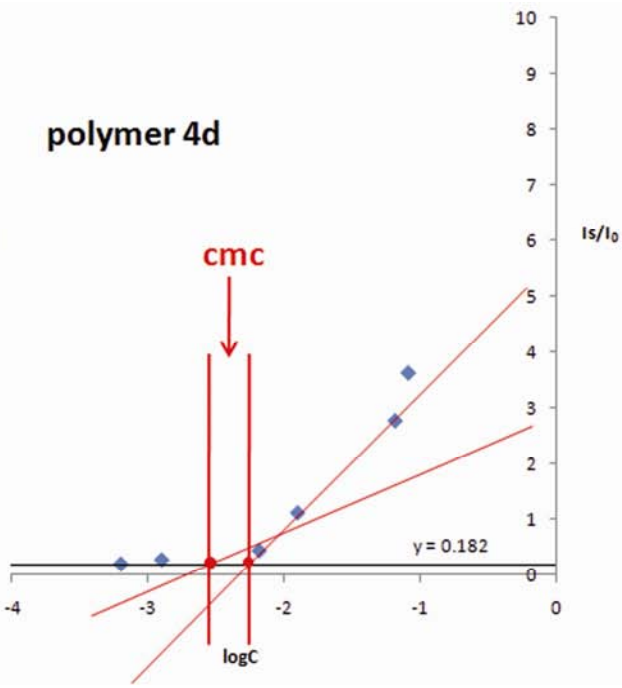
The obtained values of I_s/I_0 from SLS measurement were plotted against log C (see below). I_s : the intensity of the scattering light, I_0 : the intensity of the incident light, C: polymer concentration (g/L).

Since the scattering light could not find in lower concentration and the values (I_s/I_0) converged within 0.2-0.3 in all cases, the ranges of cmc value were determined between two intersections of "y (I_s/I_0) = k (k: the lowest value of I_s/I_0 or average of two or three low I_s/I_0 values)" and two tangent lines of an approximate curve contacted at "y = 1.1 x constant" and "y = 1.0". Each approximate curve was determined by fitting with exponential or polynomial approximation.









1.4. Ratio of increased fluorescence intensity.

The ratio of increased fluorescence intensity in in vivo tumor imaging by using polymer conjugates **4a-d** are summarized in Figure S4 . The sums of fluorescence intensities in all ROI, which was obtained as an average of fluorescence intensity in a ROI measured at least four times, were summarized in Table S1-S4. The accumulation of nanoparticles in all ROIs reached a peak 12–24 hours after the injection and decreased gradually in all regions thereafter except ROI 1, in all cases.

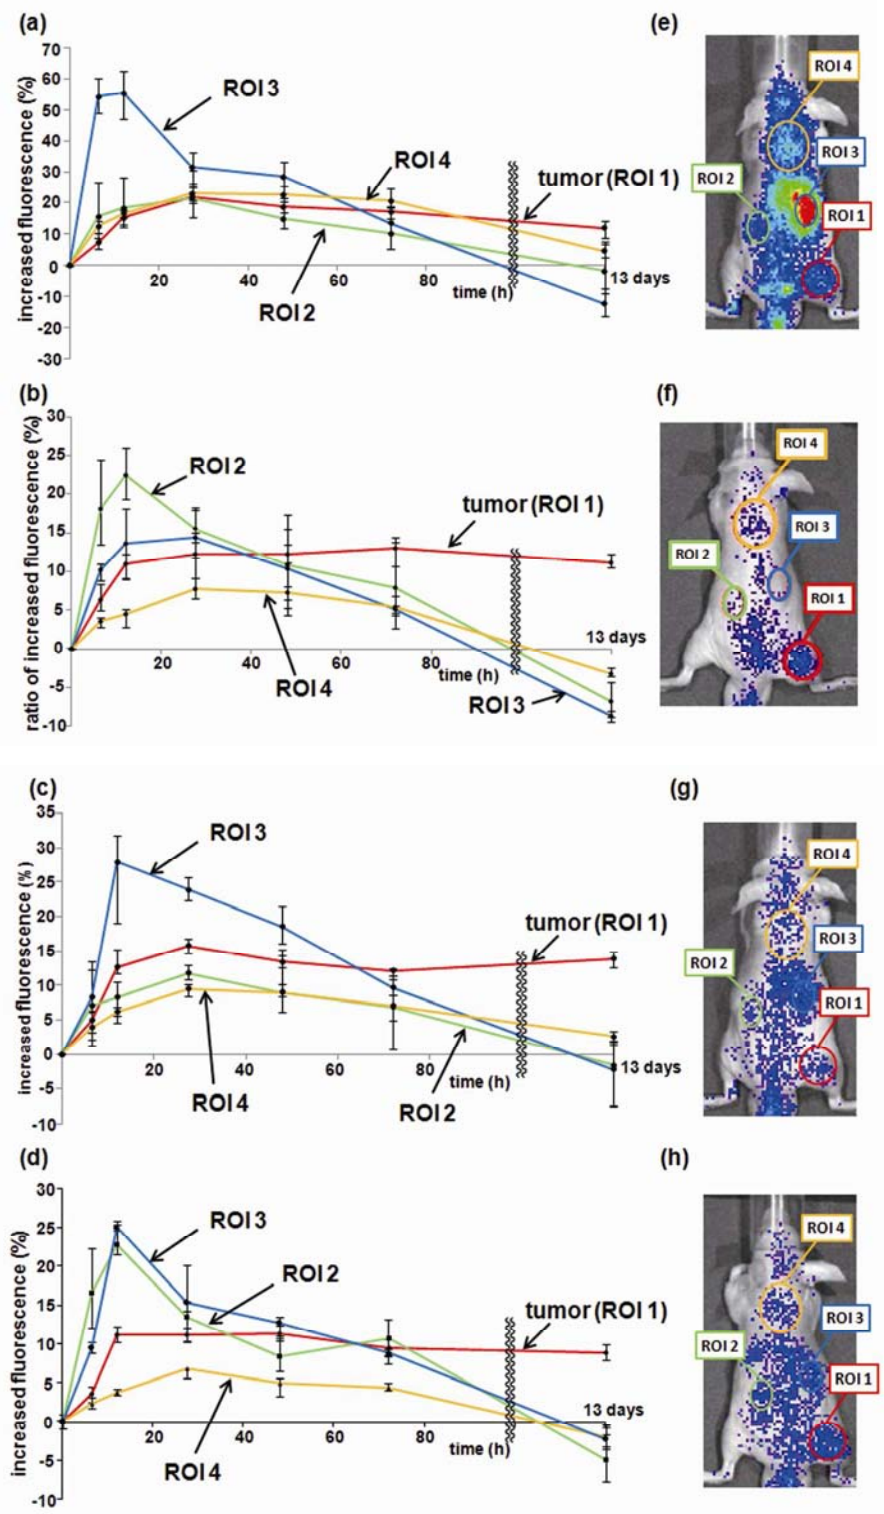


Figure S4. (a) Ratio of increased fluorescence intensity (%) of **4a**, (b) **4b**, (c) **4c** and (d) **4d**. (e) Region of interest (ROI) of **4a**, (f) **4b**, (g) **4c**, and (h) **4d**. The ratios of increased fluorescence intensity were calculated from the equation: $\{(I_t/I_0)-1\}x100$ (I_t: average fluorescence intensity in each ROI at each time, I_0: average fluorescence intensity in each ROI just after injection). ROI 1 was located at a tumor, and ROIs 2-4 were located around a lung and a kidney. The photon in each ROI was counted at least three times and the ranges of these values are shown as error bars.

Table S1. The Sum of Fluorescence Intensities and Ratio of Increased Fluorescence Intensities in All ROI Using Polymer **4a**.

time	sums of fluorescence intensity in ROI				ratio of increased fluorescence intensity (%)			
	ROI 1	ROI 2	ROI 3	ROI 4	ROI 1	ROI 2	ROI 3	ROI 4

Received October 20, 2008

Recent research in the field of nonviral gene delivery vectors has focused on preparing nanoparticles that are stabilized by the incorporation of a PEG coating and where one of the vector components is also cleavable. Here,we describe the synthesis, formulation, transfection properties, and biophysical studies of a PEG-stabilized ternary lipopolyplex vector in which, for the first time, both the lipid and peptide components are designed to be cleaved once the vector has been internalized. A series of cationic lipids, bearing short tri- or hexaethylene glycol groups, attached to the headgroup via an ester linkage, has been prepared. Trifunctional peptides have also been prepared, consisting of a Lys_{16} sequence at the N-terminus (to bind and condense plasmid DNA); a spacer group (containing a sequence recognized and cleaved by endosomal enzymes) and an optional PEG4 amino acid; and an integrin-targeting cyclic peptide sequence (allowing the resulting nanoparticle to be internalized via receptor-mediated endocytosis). Differing combinations of these lipids and peptides have been formulated with DOPE and with plasmid DNA, and complex stability, transfection, and cleavage studies carried out. It was shown that optimal transfection activities in a range of cell types and complex stabilities were achieved with lipids bearing short cleavable triethylene glycol moieties, whereas the incorporation of PEG4 amino acids into the cleavable peptides had little effect. We have synthesized appropriate fluorescently labeled components and have studied the uptake of the vector, endosomal escape, peptide cleavage, and plasmid transport to the nucleus in breast cancer cells using confocal microscopy. We have also studied the morphology of these compact, stabilized vectors using cryo-EM.

INTRODUCTION

Nonviral vectors are now regarded as a clinically important approach for the therapeutic delivery of DNA into cells. They have several advantages over viral vectors; their unlimited packaging capacity, ease of structural modification, and potential for large-scale production are all important for the manufacturing of gene delivery agents. Most importantly, their low immunogenicity means that they have few of the toxicity and safety issues associated with viral gene delivery vectors (*1*, *2*). In early studies, packaging was achieved by the condensation of DNA with polycationic polymers such as polyethylenimine (PEI), peptides, and dendrimers, giving polyplexes (*3*), or with cationic lipids, giving lipoplexes (*4*−*6*). However, these gene delivery complexes initially lacked any mechanisms to overcome the multiple barriers to successful gene transfer (*7*), and frequently, only low transfection efficiencies and poor in vivo stabilities were achieved. As a consequence, very few nonviral vectors have so far reached clinical trials (*8*).

A recent important advance in the design of high-efficiency nonviral gene delivery vectors was the recognition that incorporating targeting moieties on the surface of the complex would lead to vector internalization by receptor-mediated endocytosis, and hence higher transfection efficiencies (*9*). Multicomponent nonviral vectors, incorporating more than one type of carrier molecule, and more closely imitating viruses in their assembly and cell targeting properties, have recently been investigated and have been shown to have enhanced transfection properties (*10*−*12*). Several groups have reported the use of ternary lipid−peptide−DNA lipopolyplex vectors, combining the advantages of polyplexes and lipoplexes and incorporating receptor-targeting moieties (*13*, *14*). Hart et al. (*13*) described the use of the LPD vector, which consists of a self-assembling combination of lipids (L), polycationic peptide (P), and plasmid DNA (D). The dual functional peptide (**1**) comprises both a K_{16} DNA-binding and compaction domain and a cyclic peptide (CRRETAWAC) domain targeted to the $\alpha_5\beta_1$ integrin; the lipids DOTMA (**2**) and DOPE (**3**) are used as a 1:1 mixture (Lipofectin) (Figure 1). The LPD system

was shown to display high transfection efficiencies and, in particular, to efficiently transfect nondividing cells. Moreover, these complexes exhibited low toxicity in vitro and in vivo, with low immunogenicity in vivo (*13, 15*−*17*). We have recently established the stoichiometry of these particles using fluorescence correlation spectroscopy (FCS) and, using freeze-fracture electron microscopy and fluorescence quenching, have demonstrated that the LPD vectors have a tightly compacted DNA−peptide inner core surrounded by a disordered lipid layer, from which the integrin-targeting peptide partially protrudes (*18*). We have also established that this system can be used with a wide variety of targeting peptides, enabling delivery to specific cell types (*19*−*22*).

An additional problem with many nonviral vectors is that cationic polyplexes, lipoplexes, and lipopolyplexes are bound by plasma proteins and are quickly cleared by the reticuloendothelial system (RES). In addition, these formulations are unstable in buffers and plasma and tend to aggregate (*23, 24*). In order for nonviral vectors to be therapeutically useful, these problems must be overcome. It has been shown that coating the surface of these complexes with polymeric poly(ethylene glycol) (PEG) units prevents aggregation, lowers residual toxicity, and prolongs the circulation time (*25*−*29*). However, although the stabilities of such sterically shielded complexes are greatly enhanced, in many cases greatly reduced cell transfection activities are also observed. This has been attributed to a number of factors including particle charge masking (*30*), steric hindrance of targeting ligands (*31*), interference with the ability of the liposome to undergo membrane fusion and destabilization once internalized in the endosome (*32*−*34*), and blocking of intracellular trafficking of the plasmid DNA (*35*). Even when the surface of the stabilized particles was coated with receptor-targeting ligands, in many cases the transfection efficiencies did not improve (*36*). Recent advances in the synthesis of chemically dynamic gene delivery complexes containing components that can be triggered to disassemble or degrade within the liposome (*37, 38*) have been applied to the preparation of PEG-stabilized gene delivery vectors, and more effective transfections have been reported (*39*−*42*). However, all of these studies have been carried out with large polymeric PEG moieties attached, and until very recently, there have been no reports of stabilized gene delivery vectors formulated with components containing shorter ethylene glycol oligomer units of defined length (*43, 44*).

The aim of this work was to design and synthesize gene delivery vectors that would be stable in the circulation and would not be cleared rapidly by the RES, but would retain their capacity to target specific cells and to transfect them efficiently. We report herein the synthesis of lipids and peptides containing short ethylene glycol oligomer units of defined lengths, and our studies of the stability, transfection, structural, and biophysical properties of LPD complexes formulated using these components. These lipids and peptides have, additionally, been designed to incorporate features that can be cleaved by enzymes found in endosomes, ensuring that these components can degrade within the endosome and thus trigger endocytotic release and partial complex disassembly. We have also carried out a detailed study of the uptake and disassembly of these complexes using confocal microscopy.

EXPERIMENTAL PROCEDURES

General Synthetic Methods and Materials for Cell Biology are given in the Supporting Information.

Peptide Synthesis. Protected amino acids, coupling reagents, and solid supports were purchased from Novobiochem (U.K.) or AGTC Bioproducts (U.K.).

Lipids. DOTMA was purchased from Invitrogen Life Technologies, U.K., and TCI Europe N. V. Belgium, respectively. 2-(4,4-Difluoro-5-methyl-4-bora-3*a*,4*a*-diaza-*s*-indacene-3-dodecanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (*β*-BODIPY 500/510 C_{12}−HPC) (**21**) was purchased from Invitrogen Molecular Probes, U.K. DOPE (dioleoylphosphatidylethanolamine) was supplied from Avanti Polar Lipids, USA. 2,3-Di-((9*Z*)-octadecenyloxy)propyl-*N*,*N*-dimethylamine **13** was prepared as previously described (*45*).

Cell Lines. The human bronchial epithelial (16HBE14o-) cell line was kindly given by D. C. Gruenert (University of Vermont, Burlington, VT, USA) (*46*). Mouse neuroblastoma (Neuro 2A) and endothelial (bEND.3) cell lines were obtained from ATCC (Manassas, VA, USA). Primary porcine vascular smooth muscle cells (PVSMCs) were prepared using the explant method described previously (*47*). AJ3.1 is a mouse embryonic fibroblast line derived from A/J embryos. MDA-MB-231 breast cancer cells were a gift from the Randall Division of Cell and Molecular Biophysics, King's College London.

Lipid Synthesis. *5-Bromopentanoic Acid 8-Hydroxy-3,6-dioxooctyl Ester (***15***).* To a stirred solution of triethylene glycol (7.50 mL, 50 mmol, 10 equiv) in dry dichloromethane (20 mL) was added, dropwise, 5-bromopentanoyl chloride (0.670 mL, 5.0 mmol), and the reaction was stirred for 18 h. The mixture was then concentrated in vacuo and the crude oil purified by flash column chromatography (0−4% methanol in dichloromethane), yielding the desired product **15** as a golden yellow oil (1.47 g, 95%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.68 (2H, m), 1.80 (2H, m), 2.28 (2H, t, $J = 7.2$ Hz), 3.31 (2H, t, $J = 6.5$ Hz), 3.47−3.62 (10H, m), 4.14 (2H, t, $J = 4.7$ Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 23.4, 31.9, 33.0, 33.1, 61.5, 63.3, 69.0, 70.2, 70.4, 72.5, 173.1. HRMS *m*/*z* (ES+) calcd 335.04707, found 335.04651 ($[M + Na]^+$).

*5-Bromopentanoic Acid 3,6,9-Trioxodecyl Ester (***16***).* A solution of triethylene glycol monomethylether (0.880 g, 5.5 mmol, 1.1 equiv) in dry dichloromethane (10 mL) was stirred for 10 min at room temperature. 5-Bromopentanoyl chloride (0.670 mL, 5.0 mmol) was then added dropwise, and the reaction was stirred for a further 18 h. The mixture was concentrated in vacuo, and the crude material was purified by flash column chromatography (2−7% methanol in dichloromethane) to yield the title compound as a yellow oil (0.805 g, 51%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.70 (2H, m), 1.81 (2H, m), 2.30 (2H, t, $J = 7.2$ Hz), 3.30 (3H, s), 3.33 (2H, t, $J = 6.5$ Hz), 3.45−3.64 (10H, m), 4.15 (2H, m). ^{13}C NMR (75 MHz, $CDCl_3$): δ 23.4, 31.9, 33.0, 33.1, 59.0, 63.5, 69.1, 70.49 (signals overlap), 70.54, 71.9, 173.0. HRMS *m*/*z* (ES+) calcd 349.06272, found 349.06202 ($[M + Na]^+$).

*5-Bromopentanoic Acid 17-Hydroxy-3,6,9,12,15-pentaoxoheptadecyl Ester (***17***).* A solution of hexaethylene glycol (3.75 mL, 15 mmol, 3 equiv) was stirred in dry dichloromethane (10 mL) for 10 min at room temperature. 5-Bromopentanoyl chloride (0.670 mL, 5.0 mmol) was then added dropwise, and the reaction was stirred for a further 18 h. The mixture was concentrated in vacuo, and the crude material was purified by flash column chromatography (5−10% methanol in dichloromethane) to yield

the title product as a yellow oil (1.43 g, 64%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.64 (2H, m), 1.75 (2H, m), 2.24 (2H, t, J = 7.2 Hz), 3.31 (2H, t, J = 6.5 Hz), 3.42−3.58 (22H, m), 4.08 (2H, t, J = 4.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ 23.2, 31.6, 32.8, 33.0, 61.1, 63.2, 68.8, 70.0−70.3 (signal overlap), 72.4, 172.6. HRMS *m/z* (ES+) calcd 467.12571, found 467.12615 ($[M + Na]^+$).

(2,3-Bis-octadec-9-enyloxypropyl)-(8-hydroxy-3,6-dioxooctyloxycarbonylbutyl)dimethylammonium Bromide (4). A mixture of **13** (0.515 g, 0.83 mmol) and **15** (0.312 g, 1.0 mmol, 1.2 equiv) was stirred in a sealed tube at 100 °C for 96 h. Upon cooling, the crude mixture was purified by flash column chromatography (0−20% ethanol in dichloromethane) to give the title compound as a pale yellow oil (0.427 g, 60%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (6H, t, J = 6.7 Hz), 1.25 (44H, m), 1.53 (4H, m), 1.72 (2H, m), 1.85 (2H, m), 1.99 (8H, m), 2.45 (2H, t, J = 6.8 Hz), 3.36−3.43 (10H, m), 3.54−3.72 (16H, m), 3.88 (1H, d, J = 13.2), 4.06 (1H, m), 4.23 (2H, t, J = 4.6 Hz), 5.32 (4H, m). ^{13}C NMR (75 MHz, $CDCl_3$): δ 14.1 (signal overlap), 21.5, 22.1, 22.7, 26.0, 26.2, 27.2, 29.1−30.2 (signal overlap), 32.6, 33.2, 52.3 (signal overlap), 61.4, 63.4, 65.1, 65.7, 68.4, 69.0, 69.3, 70.2, 70.5, 72.0, 72.5, 73.3, 129.7 (signal overlap), 130.0 (signal overlap), 172.7. HRMS *m/z* (ES+) calcd 852.76558, found 852.76483 (M^+).

(2,3-Bis-octadec-9-enyloxypropyl)-(3,6,9-trioxodecyloxycarbonylbutyl)dimethylammonium Bromide (5). A mixture of **13** (0.430 g, 0.69 mmol) and **16** (0.252 g, 0.80 mmol) in acetone (5 mL) was stirred in a sealed tube at room temperature for 24 h, followed by another 24 h at 80 °C. Upon cooling, the solvent was evaporated in vacuo, and the crude material was purified by flash column chromatography (10% methanol in dichloromethane) to give the title compound as an orange oil (0.264 g, 44%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.85 (6H, t, J = 6.7 Hz), 1.24 (44H, m), 1.53 (4H, m), 1.69 (2H, m), 1.84 (2H, m), 1.99 (8H, m), 2.44 (2H, t, J = 6.8 Hz), 3.34−3.45 (14H, m), 3.54−3.72 (16H, m), 3.88 (1H, m), 4.05 (1H, m), 4.21 (2H, t, J = 4.7 Hz), 5.32 (4H, m). ^{13}C NMR (75 MHz, $CDCl_3$): δ 14.1 (signal overlap), 21.5, 22.1, 22.6, 26.0, 26.2, 27.2, 29.1−30.0 (signal overlap), 31.8, 32.6, 33.1, 52.2, 52.3, 59.0, 63.6, 65.0, 65.6, 68.4, 69.0, 69.2, 70.5 (signal overlap), 70.5, 71.86, 71.92, 73.3, 129.7 (signal overlap), 129.9 (signal overlap), 172.6. HRMS *m/z* (ES+) calcd 866.78123, found 866.78074 (M^+).

(2,3-Bis-octadec-9-enyloxypropyl)-(17-hydroxy-3,6,9,12,15-pentaoxoheptadecyloxycarbonylbutyl)dimethylammonium bromide (6). A mixture of **13** (0.395 g, 0.64 mmol) and **17** (0.330 g, 0.74 mmol) in acetone (5 mL) was stirred in a sealed tube at room temperature for 24 h followed by another 24 h at 80 °C. Upon cooling, the solvent was removed in vacuo and the crude material was purified by flash column chromatography (5−10% methanol in dichloromethane) to yield the title compound as an orange oil (0.300 g, 47%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.85 (6H, t, J = 6.7 Hz), 1.24 (44H, m), 1.52 (4H, m), 1.69 (2H, m), 1.84 (2H, m), 1.98 (8H, m), 2.44 (2H, t, J = 6.9 Hz), 3.37−3.43 (14H, m), 3.54−3.70 (28H, m), 3.92 (1H, m), 4.06 (1H, m), 4.22 (2H, t, J = 4.7 Hz), 5.31 (4H, m). ^{13}C NMR (75 MHz, $CDCl_3$): δ 14.1 (signal overlap), 21.5, 22.1, 22.6, 26.0, 26.2, 27.1, 29.1−29.7 (signal overlap), 30.0, 31.8, 32.5, 33.2, 52.2 (signal overlap), 61.1, 63.5, 65.0, 65.6, 68.5, 69.1, 69.2, 69.9, 70.2−70.3 (signal overlap), 71.9, 72.3, 73.3, 129.7 (signal overlap), 129.9 (signal overlap), 172.8. HRMS *m/z* (ES+) calcd 984.84421, found 984.84335 (M^+).

Peptide Synthesis. All peptides were synthesized on a MultiSynTech Syro peptide synthesizer. Preloaded solid support (Fmoc-Gly-NovaSyn TGT (0.20 mmol/g loading, 0.180 g, 36 μmol)) was used and was preswelled in DMF for at least 30 min before the start of synthesis. All reagents were dissolved in HPLC-grade DMF, with the exception of DIPEA where it was dissolved in NMP. Automated protocols were employed as follows:

Fmoc Deprotection. To a sintered reaction vessel containing the solid support was added the piperidine solution (40% v/v, 0.90 mL, excess), and the resulting mixture was agitated by vortex for 20 s with a 1 min break for a total of 3 min. The excess reagents were removed by filtering under vacuum. A second deprotection step was carried out with a 20% piperidine/DMF (v/v) solution by adding the piperidine solution (40% v/v, 0.45 mL, excess) followed by DMF (0.45 mL), and the resulting mixture was agitated by vortex for 20 s with a 1 min break for a total of 10 min. The excess reagents were removed by filtering under vacuum, and the resin was washed with DMF (6 × 1 mL).

Amino Acid Coupling. To a sintered reaction vessel containing the solid support was added the Fmoc-protected amino acid solution (0.360 mL, 0.40 M, 4 equiv), followed by HBTU (0.360 mL, 0.40 M, 4 equiv) and DIPEA (0.180 mL, 1.6 M, 8 equiv). The resulting mixture was agitated by vortex for 20 s with a 2 min break for a total of 40 min. The excess reagents were removed by filtering under vacuum, and the resin was washed with DMF (4 × 1 mL).

Disulfide Bond Formation. To a sintered reaction vessel containing the solid support with the completed peptide sequence was manually added a solution of iodine (0.100 g) in DMF (1 mL), and the resulting mixture was agitated by vortex for 20 s with a 4 min break for a total of 4 h.

Peptide Cleavage from Resin. Upon completion of the synthesis, the peptidyl resin was washed thoroughly with DCM to remove traces of DMF, and to the sintered vessel was added a cocktail solution of either TFA/TIS/water (95:2.5:2.5, 2 mL, for peptides with disulfide bonds already formed) or TFA/EDT/waterTIS (94:2.5:2.5:1, 2 mL, for peptides containing Cys), and the reaction was left to stand for at least 3 h. The resulting solution was removed from the vessel and the resin was washed with neat TFA (2 × 1 mL). The combined TFA solution was concentrated in vacuo followed by addition of ice−cold ether to precipitate the peptide. This was left in the freezer for a further 2 h, and the mixture was centrifuged. The liquid was decanted, and fresh ether was added. The centrifugation/decanting procedure was repeated twice more. The isolated pellet was dissolved in water or ^{t}BuOH/water and freeze−dried.

Labeled Peptides. Assembly of the linear sequences were carried out as described above (with the use of Fmoc-Lys(ivDde)-OH (0.360 mL, 0.40 M, 4 equiv) on the labeling site and Boc-Lys(Boc)-OH (0.360 mL, 0.40 M, 4 equiv) on the *N*-terminus). This was followed by removal of the ivDde group by treatment with a hydrazine monohydrate solution in DMF (2% v/v, 5 × 1 mL, agitated by vortex for 20 s with a 1 min break for a total of 3 min each) and on resin coupling with either tetramethylrhodamine (0.150 mL, 0.20 M, 2 equiv with HBTU (0.150 mL, 0.40 M, 2 equiv) and DIPEA (0.038 mL, 1.60 M, 4 equiv)) (peptide **19**) or Pacific Blue (succinimidyl ester, 0.150 mL, 0.20 M, 2 equiv, with DIPEA (0.038 mL, 1.60 M, 4 equiv)) (peptide **20**), all with agitation by vortex for 20 s with a 4 min break for a total of 18 h. The peptidyl resin was then washed with DMF (6 × 1 mL), followed by DCM (6 × 1 mL) for cleavage preparation. Labeled peptides were first cleaved from the solid support and worked up as described previously, and the lyophilized solid was dissolved in doubly distilled water (≤0.25 mg/mL) and stirred for 10 days.

Peptide Purification by HPLC. Each peptide was purified by preparative reverse-phase HPLC with aqueous TFA (0.1% v/v) and acetonitrile (with 0.1% TFA, v/v) using a Supelco column (25 cm × 21.2 mm). Each purified peptide was then analyzed by analytical reverse-phase chromatography using a Supelco

column (25 cm × 4.6 mm) with either a 10−100% MeCN or a 10−50% MeCN gradient run over 25 min (Gradient P and Gradient Q, respectively).

Peptide **9.** Purification was carried out as described above (10% to 20% MeCN over 30 min), Gradient Q R_T 7.7 min, *m*/*z* (ES+) 1157.0 ($[M + 3H]^{3+}$), 867.9 ($[M + 4H]^{4+}$), 694.6 ($[M + 5H]^{5+}$), 579.1 ($[M + 6H]^{6+}$), 496.7 ($[M + 7H]^{7+}$).

Peptide **10.** Purification was carried out as described above (10% to 25% MeCN over 30 min), Gradient P R_T 5.2 min, *m*/*z* (ES+) 1829.6 ($[M + 2H]^{2+}$), 1220.4 ($[M + 3H]^{3+}$), 915.6 ($[M + 4H]^{4+}$), 732.7 ($[M + 5H]^{5+}$), 610.5 ($[M + 6H]^{6+}$).

Peptide **11.** Purification was carried out as described above (10% to 25% MeCN over 30 min), Gradient P R_T 5.4 min, *m*/*z* (ES+) 1829.8 ($[M + 2H]^{2+}$), 1220.34 ($[M + 3H]^{3+}$), 915.4 ($[M + 4H]^{4+}$), 733.0 ($[M + 5H]^{5+}$), 610.4 ($[M + 6H]^{6+}$).

Peptide **12.** Purification was carried out as described above (10% to 20% MeCN over 30 min), Gradient P R_T 4.8 min, *m*/*z* (ES+) 1129.3 ($[M + 3H]^{3+}$), 847.1 ($[M + 4H]^{4+}$), 678.1 ($[M + 5H]^{5+}$), 565.3 ($[M + 6H]^{6+}$).

Peptide **19.** Purification was carried out as described above (10% to 25% MeCN over 30 min), Gradient Q R_T 10.5 and 11.4 min (corresponding to the two isomers of tetramethylrhodamine). *m*/*z* (ES+) 1003.2 ($[M + 4H]^{4+}$), 802.8 ($[M + 5H]^{5+}$), 669.3 ($[M + 6H]^{6+}$), 573.7 ($[M + 7H]^{7+}$).

Peptide **20.** Purification was carried out as described above (10% to 25% MeCN over 30 min), Gradient Q R_T 10.8 min, *m*/*z* (ES+) 970.3 ($[M + 4H]^{4+}$), 776.4 ($[M + 5H]^{5+}$), 647.3 ($[M + 6H]^{6+}$), 554.9 ($[M + 7H]^{7+}$).

Plasmid DNA. The plasmid pCI-Luc (5.7 kb) consists of pCI (Promega, Southampton, U.K.) containing the luciferase gene driven by the cytomegalovirus (CMV) immediate/early promoter−enhancer. It was grown in *Escherichia coli* DH5α and purified, after bacterial alkaline lysis, on resin columns (Qiagen Ltd., Crawley, UK). Isopropanol-precipitated DNA pellets were washed with 70% ethanol, then dissolved in water at 1 mg/mL.

Preparation of Lipoplexes and Lipopolyplexes. Small unilamellar vesicles were prepared using the cationic lipid mixed with DOPE (**3**) at 1:1 weight ratio. One milligram of DOPE and 1 mg of cationic lipid were weighed out into a 25 mL round-bottom flask and dissolved in chloroform. The solvent was rotary-evaporated to produce a thin film of lipid, and then evaporated under high vacuum for 24 h. The film was then rehydrated with an appropriate volume of water at 4 °C for 24 h and then sonicated on ice for 2 min using a Lucas Dawes probe sonicator to produce vesicles.

LPD lipopolyplexes were prepared essentially as described previously (*13*). Briefly, the LPD components were mixed in the following order: 50 μL of lipid (L) at 400 μg/mL in PBS, prepared as described above, 70 μL of peptide (P) at 550 μg/mL in PBS, and 50 μL of plasmid pCI-Luc (D) at 200 μg/mL in PBS (10 μg of pCI-Luc plasmid), and diluted in PBS to a final volume of 1 mL. The weight ratio used was 2:4:1 for L:P:D, respectively, which was shown to be the best ratio for gene transfer, corresponding to a charge ratio of +7 (ratio of positive equivalents of the cationic groups to negative charge equivalents of the nucleic acid).

Complex Stability/Particle Size. Complex size was determined in three independent experiments by dynamic light scattering using a Zetasizer 3000 (Malvern Instruments, Worcestershire, U.K.) with the following specifications: automatic sampling time, 10 measurements per sample, refractive index medium of 1.33, and temperature of 25 °C.

Cell Culture. Human bronchial epithelial (16HBE14o-) cell line was maintained in Eagle's minimum essential medium (MEM) HEPES modification supplemented with 10% fetal bovine serum (FBS), 2 mM L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. Mouse neuroblastoma (Neuro 2A) and endothelial (bEND.3) cell lines were maintained in Dulbecco's modified Eagle's medium (DMEM) with Glutamax-1 supplemented with 10% FBS, 1% NEAA solution, 1% sodium pyruvate, 100 U/mL penicillin, and 100 μg/mL streptomycin. AJ3.1 is a mouse embryonic fibroblast line derived from A/J embryos 13.5 days postcoitum as follows: the crania and red organs were removed and the remaining tissue minced using scalpels, digested with trypsin, then passed through a cell strainer. The resulting suspension was plated in DMEM with Glutamax-1 containing 10% FCS and 100 U/mL penicillin and 100 μg/mL streptomycin, with each embryo maintained as a separate culture. Cells were passaged every few days to maintain sparse colonies until the cultures reached senescence, and after 7−10 days, growing colonies of cells were observed. One culture was selected for all further work and is hereafter referred to as AJ3.1. PVSMCs were maintained in DMEM with Glutamax-1 supplemented with 20% FBS and 100 U/mL penicillin and 100 μg/mL streptomycin and used in transfections between passages 3−8. All cells were adherent and grew in Falcon 75 cm^2 plastic tissue culture flasks and were maintained in a humidified atmosphere of 95% air and 5% CO_2 at 37 °C.

MDA-MB-231 cells were cultured in tissue flasks in DMEM cell culture media supplemented with 10% FBS, 1% NEAA solution, 1% L-glutamine, and 1% penicillin−streptomycin solution, at 37 °C, 5% CO_2, and 90% relative humidity. The cells were fed every other day and passaged every three to four days at around 70−80% confluency, using 0.25% trypsin−EDTA solution.

In Vitro Transfections. Cells were seeded into 96 well plates at 2.5 × 10^3 cells per well for bEND.3 cells and at 2 × 10^4 cells per well for all the other cells, then incubated overnight at 37 °C in complete growth medium. The following day, lipopolyplex (LPD) formulations were prepared by mixing the components in the following order: 50 μL of lipid (L) at 80 μg/mL in OptiMEM, 70 μL of peptide (P) at 110 μg/mL in OptiMEM, and 50 μL of plasmid pCI-Luc (D) at 40 μg/mL in OptiMEM corresponding to a weight ratio of 2:4:1, respectively. All the complexes were mixed by pipetting briefly, kept for 1 h at room temperature, and then diluted in OptiMEM to a final volume of 1.57 mL. Two hundred microliters of complexes corresponding at 0.25 μg of plasmid DNA were added to each culture well after removal of the complete growth medium. All the transfections were carried out in 6 wells each. A centrifugation (1500 rpm, during 5 min) was performed to promote the complexe sedimentation and cell contact. The cells were incubated with the complexes for 4 h at 37 °C before replacing with fresh media for 24 h, after which reporter gene expression was analyzed by luciferase assay. For bEND.3 cells, 5 mM sodium butyrate was added to the transfection medium and to the fresh media to achieve optimal expression levels.

MDA-MB-231 cells were seeded on 24 well plates at 1.2 × 10^5 cells per well and incubated at 37 °C for 24 h. On the day of the experiment, the growth media was removed, and the cells were washed twice with PBS buffer and replaced with 200 μL of serum free DMEM. 200 μL of the complexes at 1:4:1 weight ratio were then added to each well, as above, at a final concentration of 1 μg of plasmid per well. The plates were incubated at 37 °C for 4 h after which the cells were washed once with PBS buffer and replaced with FBS containing culture medium. The cells were incubated for a further 48 h, to allow for luciferase expression, which was then measured as below.

Luciferase and Protein Assays. Cells were washed once with PBS before the addition of 20 μL (or 100 μL into a 24 well plate) of 1× Reporter Lysis Buffer to the cells for 20 min at 4 °C before freezing at −80 °C for at least 30 min, followed by thawing at room temperature. Then, the luciferase activity was measured during 10 s using the Luciferase Assay System and

a FLUOstar Optima (BMG Labtech, U.K.). The amount of protein present in each transfection lysate was determined with the Bio-Rad (Hercules, CA, USA) protein assay reagent by the manufacturer's instructions, adding 20 μL from the luciferase test to 180 μL of the reagent diluted 1 in 5 and incubating at room temperature for 10 min before comparing the OD590 to a range of BSA standards. Luciferase activity was expressed as relative light units (RLU) per milligram of protein (RLU/mg).

Cell Viability Assays. Cell viability of MDA-MB-231 cells was tested in the presence of free **4** without DNA or in the presence of **4**/calf thymus DNA complexes using the MTT assay. The cells were seeded at 1.5×10^5 cells per well in 24 well plates and left incubated at 37 °C for 48 h prior to use. On the day of the experiment, the cells were washed once with PBS and replaced with 200 μL of serum-free DMEM media before introducing 200 μL of various concentrations of lipids or lipid/DNA complexes and incubating for 4 h at 37 °C. The controls wells were treated with DMEM media with the same amount of water as the test wells but without the lipids. After incubation, the test solutions were removed and the cells washed once with PBS buffer. One milliliter of 0.8 mg/mL MTT solution in PBS was then introduced to all wells and left incubated for 3 h at 37 °C. 200 μL of neat isopropanol was then applied to solubilize the formazan crystals and the plates stored at 4 °C for 1 h. The contents of the wells were transferred to a clear 96-well plate and the absorbance measured at 550 nm using a Spectromax 190 Microplate Spectrophotometer (Molecular Devices, USA).

In Vitro Cleavage Experiments. *Esterase Cleavage of* **4.** A phosphate buffer stock solution (0.1 M, pH 7.5) was prepared by mixing an aqueous solution of potassium dihydrogen phosphate (0.1 M, 50 mL) with an aqueous solution of sodium hydroxide (0.1 M, 41 mL), all using Baxter water. A stock solution of **4** was prepared (2 mg/mL) according to the method described above, omitting the colipid DOPE. A solution of the pig liver esterase (28 mg, 672 units, capable of hydrolyzing 28 μmol of ethyl butyrate) was prepared by dissolving it in the phosphate buffer (875 μL). To the liposome (125 μL, 250 μg, 0.294 μmol) was added the buffered enzyme solution (875 μL), and the resulting mixture was incubated at 37 °C for 24 h. Aliquots (200 μL) were taken at $T = 1$, 2, 4, 6, and 24 h and immediately freeze−dried. The lyophilized material was dissolved in dichloromethane (50 μL) and analyzed by thin layer chromatography (15% methanol in dichloromethane + acetic acid) with phosphomolybdic acid staining. A sample of the hydrolyzed lipid **18** was previously run under the same conditions and the R_f value determined as a standard. R_f values: **4**, 0.35; **18**, 0.22 (15% methanol, 84% dichloromethane, 1% acetic acid).

Esterase Cleavage of ***4*** *in LPD Complex.* Stock solutions for peptide **9** and pCI-Luciferase were prepared (50 mg/mL and 5 mg/mL, respectively) using Baxter water. Formulation of the stock **4**/DOPE solution (2 mg/mL) was prepared according to the description above. Secondary solutions of the liposome (125 μL), peptide **9** (10 μL), and pCI-Luciferase (12.5 μL) in the phosphate buffer (125 μL, 250 and 250 μL, respectively) were then prepared. The resulting peptide solution was added to the buffered liposome. To the resulting mixture was added the pCI-Luciferase solution, and the mixture was left to equilibrate at RT for 1 h. A solution of the pig liver esterase (28 mg, 672 units, capable of hydrolyzing 28 μmol of ethyl butyrate) in phosphate buffer (223 μL) was then added to the LPD mixture followed by incubation at 37 °C for 24 h. Aliquots (200 μL) were taken at $T = 1$, 2, 4, 6, and 24 h and immediately freeze−dried. The lyophilized material was dissolved in dichloromethane (50 μL) and analyzed by thin layer chromatography (15% methanol in dichloromethane + acetic acid) with phosphomolybdic acid staining. Samples of the hydrolyzed lipid **18** and of DOPE were previously run under the same conditions and the R_f values determined. R_f values: **4**, 0.35; **18**, 0.22; DOPE, 0.07 (15% methanol, 84% dichloromethane, 1% acetic acid).

Furin Cleavage of **9.** A buffer solution was prepared by mixing HEPES (2.38 g, 100 mM), $CaCl_2$ (11 mg, 1 mM), mercaptoethanol (7 μL, 1 mM), Triton X100 (0.5 mL, 0.5%) in Millipore water (100 mL) and adjusted to pH 7.5 with sodium hydroxide (2 M). To the furin (2 units) was added the peptide solution (14 mM, 5 μL) and the buffer (494 μL), and the mixture was incubated at 30 °C. Aliquots (100 μL) were taken at $T =$ 0, 1, 2, and 4 h and transferred to a vial containing acetic acid (5 M, 100 μL) to inactivate the enzyme. The mixture was then freeze−dried, redissolved in water, and analyzed by analytical reverse-phase HPLC (10−50% MeCN in 25 min).

Furin Cleavage of **12.** To the furin (2 units) was added the peptide solution (2.9 mM, 25 μL) and the buffer (473 μL), and the mixture was incubated at 30 °C. Aliquots (100 μL) were taken at $T = 0$, 1, 2, and 4 h and transferred to a vial containing acetic acid (5 M, 100 μL) to inactivate the enzyme. The mixture was then freeze−dried, redissolved in water, and analyzed by analytical reverse-phase HPLC (10−50% MeCN in 25 min).

Cathepsin B Cleavage of **12.** Lyophilized cathepsin B was divided into aliquots, each containing approximately 2 units of cathepsin B, immediately after delivery and stored at −20 °C. An acetate buffer solution (Buffer A) was prepared by mixing sodium acetate (0.164 g, 20 mM) and EDTA (0.0372 g, 1 mM) in Millipore water (100 mL) and adjusted to pH 5.0 with acetic acid. A similar acetate buffer solution (Buffer B) was prepared with the addition of cysteine (0.1202 g, 5 mM). To the cathepsin B (2 units) was added Buffer A (10 μL). To this buffered enzyme solution was added the peptide solution (2.9 mM, 25 μL) and Buffer B (464 μL), and the mixture was incubated at 37 °C. Aliquots (100 μL) were taken at $T = 0$, 1, 2, 4, and 24 h and transferred to a vial containing acetic acid (5 M, 100 μL) to inactivate the enzyme. The mixture was then freeze−dried, redissolved in water, and analyzed by analytical reverse-phase HPLC (10−50% MeCN in 25 min).

Cathepsin B Cleavage of **9.** Lyophilized cathepsin B was divided into aliquots, each containing approximately 2 units of cathepsin B, immediately after delivery and stored at −20 °C. An acetate buffer solution (Buffer A) was prepared by mixing sodium acetate (0.164 g, 20 mM) and EDTA (0.0372 g, 1 mM) in Millipore water (100 mL) and adjusted to pH 5.0 with acetic acid. A similar acetate buffer solution (Buffer B) was prepared with the addition of cysteine (0.1202 g, 5 mM). To the cathepsin B (2 units) was added Buffer A (10 μL). To this buffered enzyme solution was added the peptide solution (13.5 mM, 5 μL) and Buffer B (485 μL) and the mixture was incubated at 37 °C. Aliquots (100 μL) were taken at $T = 0$, 1, 2, 3, and 4 h and transferred to a vial containing acetic acid (5 M, 20 μL) to inactivate the enzyme. The mixture was then freeze−dried, redissolved in water, and analyzed by analytical reverse-phase HPLC (10−50% MeCN in 25 min).

Cathepsin B Cleavage on Peptide **9** *in LPD Complex.* Lipid **4** was formulated with DOPE as described above (2 mg/mL). To this solution (62.5 μL) was added Buffer B (120 μL). To the peptide solution (13.5 mM, 5 μL) was added Buffer B (120 μL). The buffered lipid and peptide mixtures were then mixed together, followed by the addition of a buffered pCI-Luciferase solution (pCI-Luciferase solution at 5 mg/mL (12.5 μL) in Buffer B (160 μL). The resulting LPD complex mixture was left to equilibrate at rt for 1 h. To the cathepsin B (2 units) was added Buffer A (10 μL). To this buffered enzyme solution was added the LPD solution, and the mixture was incubated at 37 °C. Aliquots (100 μL) were taken at $T = 0$, 1, 2, 3, and 4 h and transferred to a vial containing acetic acid (5 M, 20 μL) to

inactivate the enzyme. The mixture was then freeze−dried, redissolved in water, and analyzed by analytical reverse-phase HPLC (10−50% MeCN in 25 min).

Acid Hydrolysis of Lipid **4.** Three buffered solutions were prepared: pH 5.5 (Buffer A from the cathepsin B experiments), pH 3 of citric acid solution (adjusted with sodium hydroxide (2 M)) and pH 1 of 0.1 M HCl solution. Lipid **4** was formulated as described above (2 mg/mL) and diluted 1:10 (v/v) with the buffered solutions and incubated at 37 °C. Aliquots were taken at $T = 1$ and 5 h and spotted onto a thin layer chromatography plate (10% methanol in dichloromethane) and stained with phosphomolybdic acid.

Confocal Fluorescence Microscopy. The pGL-3 plasmid luciferase reporter vector was purified from a transformed *E. coli* JM109 strain using a QIAGEN EndoFree plasmid Giga kit, according to manufacturer's instructions. The purified plasmid was then characterized and tested for yield and purity using UV spectroscopy and gel electrophoresis. The pGL-3 plasmid was then labeled with FluoroRed (rhodamine-4-dUTP) using a Nick translation kit. The manufacturer's protocol was modified in order to increase the yield of the labeled DNA. In an Eppendorf tube containing 30 μg of plasmid in 22 μL of water, 6 μL of 10 mM of each dCTP, dGTP, and dATP and 2.5 μL of 25 nmol tetramethyl-rhodamine-5-dUTP were added, together with 5 μL of polymerase/DNase mix (supplied in the kit) and 2 μL of DNA polymerase I. To all the above, 5.5 μL of NT buffer (10× strength, supplied in the kit) with 1 mM DTT was added. The mixture was gently vortexed and incubated at 15 °C for 4 h, after which the enzyme activity was stopped by the addition of 5 μL of 0.5 M EDTA (pH 8.0) while being placed on ice. The labeled DNA was then purified using a Biospin 6 column (from Bio-Rad, UK) by centrifuging the mixture twice for 5 min at 1000 × *g*. The concentration and purity of the labeled DNA was assessed using UV spectroscopy.

Confocal fluorescence images were acquired on a confocal fluorescence laser-scanning microscope (model LSM 510; Carl Zeiss Inc.) equipped with both 40×/1.3Plan-Neofluar and 63×/1.4Plan-APOCHROMAT oil immersion objectives. MDA-MB-231 cells were transfected with the complexes in 24 well plates fitted with 13 mm circular coverslips as described above using various combinations of labeled (β-BODIPY 500/510 C_{12}−HPC **21**) and unlabeled (DOPE, **3**) lipids with **4**; various combinations of labeled (**19** or **20**) and unlabeled (**9**) peptide; and either labeled or unlabeled plasmid DNA. For experiments where labeled lipid was used, labeled liposomes were initially formulated as described earlier, using a 10:9:1 weight ratio of **4**/DOPE/**21** and used in the preparation of the LPD lipopolyplexes. For experiments where labeled peptide was used, LPD complexes were formulated using 100% of either peptide **19** or peptide **20**. For experiments where the plasmid was being tracked, labeled DNA was either prepared by mixing 25% of the rhodamine-labeled plasmid with 75% of unlabeled plasmid or used at 100%.

After a 4 h incubation period, the LPD complexes were removed and the cells washed once with PBS before changing to serum-containing media. The cells were then fixed with 4% paraformaldehyde at time intervals of 0, 4, 24, and 48 h after the 4 h incubation time. The cells were permeabilized with a 0.2% Triton X-100 solution and DAPI stained by adding a 1 μg/mL solution of DAPI in PBS for 2 min. Washed coverslips were mounted with Mowiol 4−88 mounting media containing 2.5% DABCO as an antifade agent.

Electron Microscopy. Samples were negatively stained with 1% uranyl acetate in water and examined in either a Philips Tecnai T12 or an FEI Tecnai T20 transmission electron microscope. For cryo transmission electron microscopy, approximately 5 μL of the sample was placed on a holey carbon film on a 300 mesh gold grid and blotted to leave a thin film of sample across the holes. It was then rapidly frozen in "slushed" nitrogen and examined by low dose imaging at −170 °C in an FEI Tecnai T20 transmission electron microscope fitted with a Gatan 626DH cryotransfer system.

Statistical Analysis. All experiments were carried out more than three times, and the results are shown as means ± standard deviation. The statistical significance of results was assessed using the Student *t*-test, and results were taken to be significant when $p < 0.05$.

RESULTS

Design of the Lipid and Peptide Components. The lipid components were based on the structure of DOTMA, with short ethylene glycol oligomer units, appended to the headgroup, designed to detach in the endosomal environment. Various studies of vesicles with PEG attached have shown that the PEG molecular weight and loading, and whether the PEG is capped or uncapped, both have a significant influence on the vesicle aggregation process and on prolonging circulation times (*25, 48*). For the LPD system, it was necessary for the ethylene glycol oligomer layer to be relatively shallow, in order to allow the integrin-binding portion of the peptide to be exposed. Although few studies have been reported on the stabilization of lipid structures by short PEG layers, Tirrell et al. have investigated PEG-lipids with different lengths of oligoethylene glycol units, incorporated into a membrane containing a peptide−amphiphile (at a 1:1 ratio of PEG−lipid to peptide−amphiphile) and have determined that shorter PEG chains were required to ensure accessibility of the peptide ligand to cell surface receptors (*49*). Other studies have demonstrated that the use of surfactants conjugated to shorter PEG headgroups (4 to 30 units, MW approximately 180 to 1320), even at 1% PEG-modified surfactant or above, still results in significantly less aggregation compared to controls lacking the PEG units (*50*). All of these factors indicated that PEG headgroups bearing three or six units, capped and uncapped, should be investigated. Indeed, we have previously synthesized DOTMA analogues bearing PEG chains directly attached to the quaternary ammonium headgroup (*43*) and have showed that lipopolyplexes formulated with these lipids have increased serum stability and transfection efficiencies compared to lipopolyplexes formulated with DOTMA. This effect was particularly pronounced with tetraethylene glycol-bearing lipids.

The lipids were designed with an ester as a cleavable linkage between the PEG chain and the quaternary ammonium moiety of the lipid. Ester linkages have been extensively used in drug delivery applications, as they generally remain stable at pH 7 in plasma and in the early endosome, but hydrolyze when the pH changes to 5.5 in the late endosome (*51, 52*). Although aliphatic esters are not generally readily hydrolyzed in vivo (*53*), several studies have indicated that amino esters (*54*−*56*) and mercapto esters (*52, 57, 58*) can be hydrolyzed either within the circulation or within endosomes. It has been shown that in some cases the rate of hydrolysis depends upon the linker length (*58*) and that esterase hydrolysis within the endosome may represent an alternative pathway for degradation (*55*). Taking all of these factors into consideration, lipids **4**, **5**, and **6** were selected for synthesis (Figure 2) and compared with the noncleavable tetraethylene glycol lipid **7** (*43*) that we had prepared previously.

The peptides were designed to incorporate the following: a targeting element; short, ethylene glycol oligomeric chains of defined lengths; and peptide sequences that could be cleaved within the endosome. The end goals of this project are to produce gene delivery vectors that are sufficiently stable in vivo to be administered intravenously, and also to produce vectors

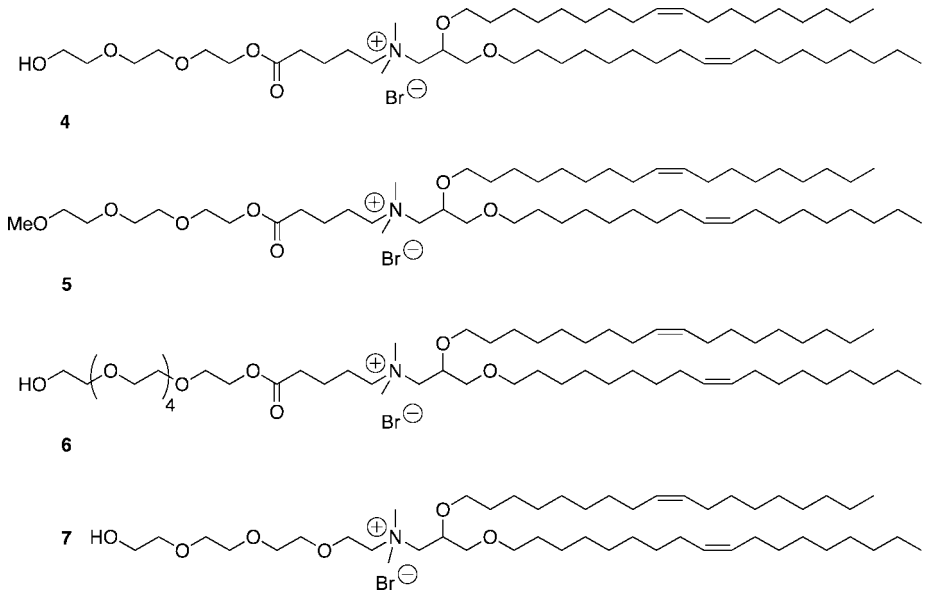

Figure 2. Structures of lipids investigated in this study.

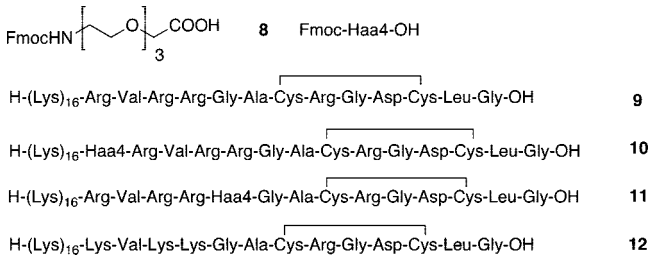

Figure 3. Sequences of peptides investigated in this study.

that will target and deliver genes to tumors that are currently hard to treat, such as neuroblastoma, or that have metastatized. Accordingly, a cyclic peptide sequence, CRDGCLG (*59*), was selected as the targeting element. This sequence is known to bind to the α_v integrin receptors expressed on neuroblastoma (*60*) endothelial (*61*) and breast cancer (*62, 63*) cell lines, as models for the tumor types that would eventually be studied in vivo. We have previously synthesized a range of Fmoc-protected PEG-amino acids and used these to incorporate ethylene glycol oligomer spacers into peptides based on the sequence of **1** using standard solid-phase methods. These peptides, with the short ethylene glycol oligomeric chains, were then used to formulate LPD particles (*64*). In this work, the optimum ethylene glycol oligomer chain length was found to vary with the cell type; however, the amino acid Fmoc-Haa4 **8** (Figure 3) had shown promising transfection properties in some cell lines, and this was therefore selected as a spacer for some peptide sequences.

There are several enzymes that are known to operate efficiently within the acidic environment of the endosome and have been implicated in the processing of endocytosed proteins: in particular, the enzyme furin (*65*) is known to be active within the endosome. Similarly, there are a range of enzymes active within the lysosome, such as cathepsin B (*66*). Peptides containing consensus sequences for cathepsin B (*67*−*69*) have previously been successfully used as cleavable linkers in drug delivery applications. The sequence RVRR was therefore chosen, as this is a consensus sequence for furin cleavage (*65*) and RR a consensus sequence for cathepsin B cleavage (*66*).

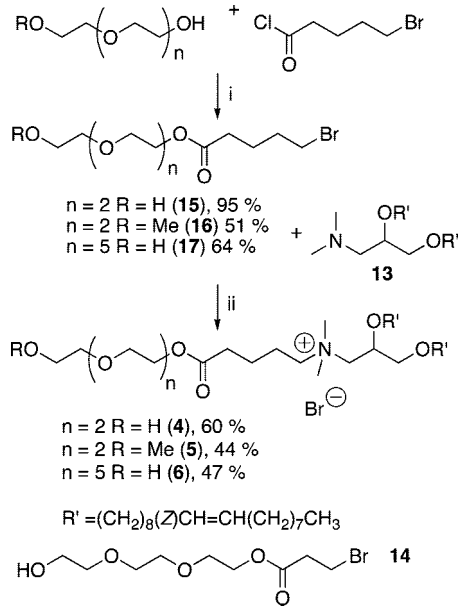
The peptides shown in Figure 3 were designed and synthesized, taking all of these factors into consideration. Peptide **9** has the integrin-targeting sequence CRDGCLG attached via the enzymatically cleavable RVRR linker sequence to the K_{16} DNA binding sequence used in our previous work. Peptides **10** and **11** also have this sequence, but with the tetraethylene glycol spacer, Haa4, on either the K_{16} (peptide **10**) or CRDGCLG (peptide **11**) side of the cleavable linker. Finally, peptide **12**, which lacks both the tetraethylene glycol spacer and a sequence which can be cleaved by processing enzymes, but which retains the overall charge of peptides **9**, **10**, and **11**, was prepared as a control.

Synthesis of Endosomally Cleavable PEG-Containing Lipids. DOTMA analogues can be conveniently prepared via 1,2-dialkyloxy-3-aminopropane or 3-dimethylamino-1,2-propandiol intermediates (*45, 70*), and this approach has been used to synthesize DOTMA analogues bearing ethylene glycol oligomer chains directly attached to the quaternary ammonium headgroup (*43*). The synthesis of 2,3-di-((9*Z*)-octadecenyloxy)propyl-*N*,*N*-dimethylamine **13** was carried out as previously described (*45*). The noncleavable tetraethylene glycol-bearing lipid **7** was also synthesized as a control, as it had previously shown promising transfection and stability properties when formulated with DOPE, peptide **1**, and plasmid DNA (*43*). The approach was then adapted to synthesize the cleavable lipids **4**, **5**, and **6** (Scheme 1). Quaternization of **13** with esters such as **14** to afford cleavable lipids bearing ethylene glycol oligomer chains, linked via a shorter β-amino acid linker, was initially investigated. However, competing elimination reactions resulted in consistently low yields and impure products. Instead, 5-bromopentanoyl chloride was reacted with commercially available triethylene glycol, triethylene glycol monomethyl ester, or hexaethylene glycol, to yield bromoalkyl-oligo(ethylene glycol) esters **15**, **16**, and **17**, respectively. These were then heated in a sealed tube with **13**, to afford the target lipids **4**, **5**, and **6**, respectively, in 47−60% yield.

Synthesis of Endosomally Cleavable PEG-Containing Peptides. For the synthesis of the endosomally cleavable peptides **10** and **11**, containing tetraethylene glycol spacers, Fmoc-Haa4-OH **8** was prepared as previously reported (*64*). Peptides **9**, **10**, **11**, and **12** were then prepared by standard Fmoc-based solid-phase peptide synthesis (SPPS) using HBTU/DIPEA coupling protocol. Prior to peptide cleavage from the solid support, the disulfide linkages were formed by treatment of the Cys(Trt) residues with a solution of iodine in DMF to simultaneously cleave the Trt group and form the disulfide linkage (*71*).

Formulation of LPD Complexes and Measurement of Complex Stability. With a range of cleavable lipids and peptides, with and without ethylene glycol oligomers, in hand,

Scheme 1. Synthesis of Cleavable PEG-Containing Lipids 4, 5, and 6[a]



[a] Reagents: i, CH_2Cl_2; ii, sealed tube, with or without acetone, RT to 100 °C.

LPD formulations using different combinations of peptides and lipids were investigated. It was anticipated that the use of a high density (50% or 100%) of lipid and/or peptide components bearing the short ethylene glycol oligomeric units would result in complexes with a uniform hydrophilic surface that would confer stability on the lipopolyplex, and it was desirable to ascertain which features of each component were important to achieve gene delivery vectors that would be stable in the circulation but would disassemble in the endosome. Initially, the size and stability of the integrin-targeting ternary LPD lipopolyplexes was studied in saline buffer (as a model for physiological conditions), since incorporating lipids or peptides bearing ethylene glycol oligomeric units could have an effect on both the size and the stability of complexes. Four complexes were therefore formulated: one with no ethylene glycol oligomer containing components (Complex **A**); one where only the peptide component had an ethylene glycol oligomer unit (Complex **B**); one where only the lipid component had an ethylene glycol oligomer unit (Complex **C**); and one where both lipid and peptide components had ethylene glycol oligomer units (Complex **D**) (Table 1). The sizes of these complexes were measured by laser-light scattering (Figure 4). Preliminary measurements in water (Table 1) showed the four complexes to be of approximately similar sizes, with complex **A** the largest. Sizing measurements in saline solution were then carried out over a period of 1 h, to ascertain whether the complexes would aggregate in a physiologically relevant buffer. Initially, the size difference between the four complexes was again very small, although complexes **C** and **D**, with lipids containing ethylene glycol oligomers, were slightly smaller, and in the saline solution the complexes were overall larger than in water (in line with previous literature observations (*72*)). However, after 1 h, the size of complexes **A** and **B** had increased dramatically, whereas complexes **C** and **D**, containing lipid **4** with a triethylene glycol unit, had remained at a constant size, indicating the greater stability of these complexes.

In Vitro Transfections. Preliminary transfection experiments, to investigate the effect of the ethylene glycol oligomeric layer on the transfection efficiency of LPD complexes formulated from lipids **4**, **5**, **6**, and **7**, were first carried out. The cleavable hexaethylene glycol lipid **6** was compared with lipopolyplexes formulated with the cleavable triethylene glycol lipid **4** and the noncleavable tetraethylene glycol lipid **7** (and with peptide **9** and plasmid DNA). Complexes formulated with **6** had significantly poorer transfection efficiencies (Supporting Information). This was consistent with our previous studies with noncleavable hexaethylene glycol lipids (*43*) and **6** was therefore not investigated further.

Since the size of the lipopolyplexes could have an effect on transfection efficiencies, in vitro transfections of the integrin-targeting ternary LPD complexes using lipids **4**, **5**, and **7** were then studied following an additional centrifugation (1500 rpm, during 5 min), which was performed to help with sedimentation of the smaller LPD complexes with lipids containing ethylene glycol oligomers, on to the cells.

Transfection Efficiencies of Endosomally Cleavable PEG-Containing Peptides. Transfection efficiencies of endosomally cleavable peptide **9**, and endosomally cleavable peptides **10** and **11** bearing tetraethylene glycol units, complexed with Lipofectin and a plasmid encoding the luciferase gene (pCI-Luc), were studied in Neuro 2A, bEND.3, AJ3.1, 16HBE14o- cell lines and PVSMC primary cells. These complexes were compared with those formulated using the noncleavable control peptide **12** (Figure 5a). In all cells studied, peptide **9** was significantly the best endosomally cleavable peptide, and the transfection efficiencies were not improved with complexes formulated with peptides containing the Haa4 amino acid ($p < 0.05$). Peptide **9** was also significantly more efficient than the noncleavable control peptide **12** in all cells ($p < 0.05$) with the exception of Neuro 2A, where it was as efficient as **12**.

Transfection Efficiencies of Endosomally Cleavable PEG-Containing Lipids. Transfection efficiencies of endosomally cleavable, triethylene glycol-containing lipids **4** and **5** complexed with cleavable peptide **9** and pCI-Luc were then studied in Neuro 2A, bEND.3, AJ3.1, 16HBE14o- cell lines and PVSMCs primary cells. These were compared with complexes formulated using the noncleavable tetraethylene glycol lipid **7**, identified in our earlier work, as a control (Figure 5b). Preliminary studies showed that lipoplex formulations (lacking the peptide) were ineffective transfection agents, and also that the inclusion of the colipid DOPE was necessary (data not shown). Lipid **4**/DOPE was significantly more efficient compared to lipid **5**/DOPE in Neuro 2A, AJ3.1, 16HBE14o-, and PVSMCs cells ($p < 0.05$), and as efficient as in the bEND.3 cells. Therefore, the best-performing lipid was the cleavable, triethylene glycol lipid **4**/DOPE, which was shown to be as efficient as the noncleavable tetraethylene glycol control lipid (lipid **7**/DOPE) in Neuro 2A, AJ3.1, and16HBE14o- cells, and more efficient than the same control lipid in bEND.3 and PVSMCs cells ($p < 0.05$). Similar results were shown when lipids were complexed to a noncleavable peptide (data not shown).

The optimal combination of lipid and peptide for a range of cells was thus identified to be complex **C** (lipid **4**/DOPE/peptide **9**/DNA). This complex was also tested in MDA-MB-231 breast cancer cells and showed it to have greater transfection efficiency than the commercially available transfection agent Lipofectamine (Supporting Information). The viability of cells when treated with the tetraethylene glycol-bearing lipid **4**, alone or formulated as lipoplexes with DNA (Supporting Information), was then investigated. In this cell line, very little toxicity was observed (in line with the low reported toxicities (*73*) of triethylene glycol and tetraethylene glycol) except at much higher lipid/DNA ratios than those used in the present study, where significant amounts of uncomplexed lipid **4** would be expected.

In Vitro Cleavage Studies. As these LPD complexes were designed to cleave and to disassemble during the transfection process, it was necessary to demonstrate that the component

Table 1. Comparison of the Sizes and Stabilities of Different Lipopolyplex Formulations in Water and in Saline Buffer

	composition of complex	size (nm) in water	size (nm) after 5 min in buffer	size (nm) after 1 h in buffer
Complex **A** (no ethylene glycol oligomer)	lipofectin/peptide **9**/pCI-Luc	131 ± 1.0	457 ± 46	1388 ± 198
Complex **B** (tetraethylene glycol on peptide)	lipofectin/peptide **11**/pCI-Luc	n/d	456 ± 46	1417 ± 146
Complex **C** (tetraethylene glycol on lipid)	**4**/DOPE/peptide **9**/pCI-Luc	119 ± 1.3	335 ± 11	394 ± 14
Complex **D** (tetraethylene glycol on peptide and lipid)	**4**/DOPE/peptide **11**/pCI-Luc	n/d	346 ± 15	417 ± 10

peptides and lipids could be degraded under conditions likely to be encountered within the endosome. Model cleavage studies on lipid **4** and peptide **9**, both individually and within LPD complexes, were therefore carried out.

Cleavage Studies on Lipid 4, Alone and in LPD Complex. The expected cleavage product from lipid **4**, lipid **18**, was prepared by hydrolysis of **4** (Scheme 2) in order to serve as a control for the lipid cleavage studies. The conditions required for acid-catalyzed cleavage of **4** were first investigated. Formulated lipid **4** was treated with solutions of sodium acetate, citric acid, and aqueous HCl buffers at pH 5.5, 3, and 1, respectively. The reaction was monitored by taking aliquots at $T = 1$ and 5 h and analysis by thin layer chromatography. The results indicated that hydrolysis of the ester bond occurred only at very low levels (data not shown).

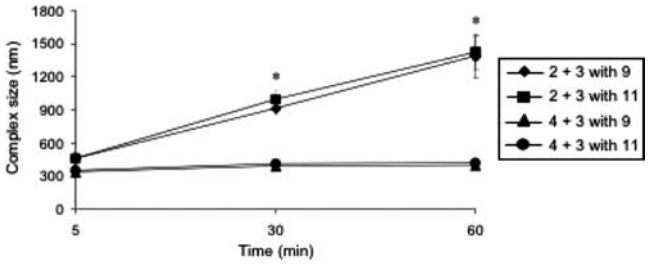


Figure 4. Effect of PEG group on particle stability, illustrated in dynamic light scattering measurements of complex particle size. Lipid/peptide/plasmid complexes containing the PEGylated lipid **4** were stable in physiological saline buffers: non-PEGylated lipids (Lipofectin) rapidly aggregated. (* $p < 0.05$ when complex size was compared between vectors).

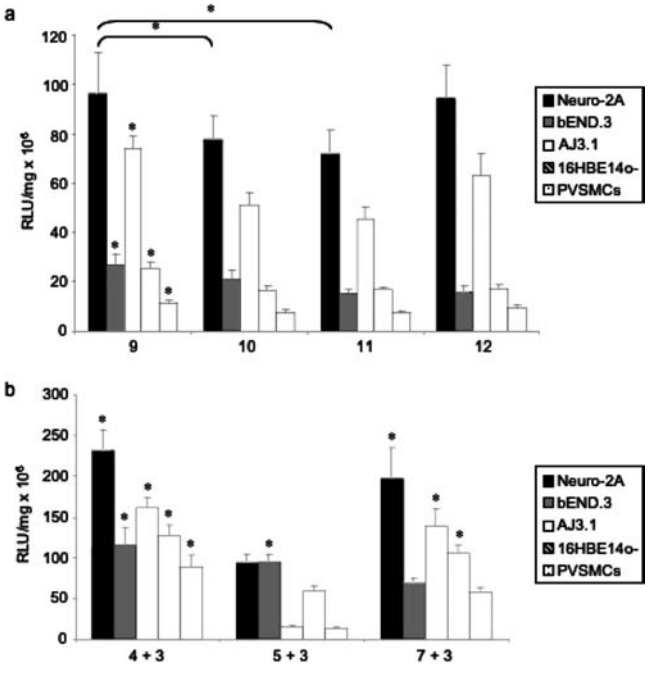

Figure 5. Transfection efficiencies of (a) endosomally cleavable PEG-containing peptides complexed with Lipofectin lipid and pCI-Luc plasmid and of (b) endosomally cleavable PEG-containing lipids complexed with peptide **9** and pCI-Luc plasmid, performed in mouse neuroblastoma (Neuro 2A) cells, mouse endothelial (bEND.3) cells, mouse embryonic fibroblast (AJ3.1) cells, human bronchial epithelial (16HBE14o-) cells, and primary porcine vascular smooth muscle (PVSMCs) cells. Complexes were prepared with a weight ratio of 2:4:1. Transfection incubation was performed for 4 h and luciferase activity was measured 24 h later. The relative light units (RLU) measured for 10 s are expressed as means ± sem per mg of protein. (*$p < 0.05$ when peptide **9** and lipid **4**/DOPE were compared with other peptides and lipids, respectively).

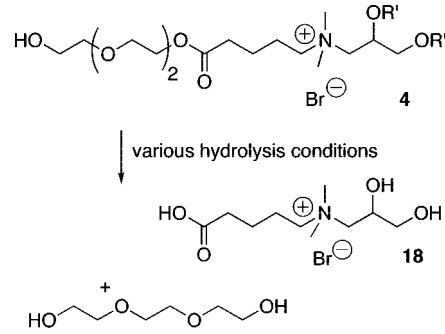
Scheme 2. Hydrolysis of lipid 4[a]



[a] Hydrolysis conditions: NaOH (1 M), H_2O, 2 h; or sodium acetate buffer (pH 5.5); or citric acid (pH 3); or HCl (pH 1); or pig liver esterase (pH 7.5).

As a model (*55*) for the effects of endosomal esterases, **4** was then treated with pig liver esterase buffered at pH 7.5, and the reaction again monitored by thin layer chromatography. Within 1 h, a spot had appeared corresponding to compound **18** (which also has a similar R_f value to that of the other half of the cleaved material, triethylene glycol). The intensity of this spot steadily increased as the reaction proceeded over 24 h. LPD complex **C**, containing **4**/DOPE, peptide **9**, and plasmid pCI-Luc, was then formulated. This was again treated with pig liver esterase buffered at pH 7.5, and a similar pattern of lipid cleavage was observed, indicating that the ester linkage of **4** is still accessible to esterase enzymes even when the lipid forms part of the LPD complex (Supporting Information).

Cleavage Studies on Peptide 9, Alone and in LPD Complex. The cleavage of peptide **9** by two enzymes known to be active within the endosome or the lysosome was then investigated. Peptide **9** was initially treated with the endosomal enzyme furin, with the reaction monitored by HPLC, and after 4 h complete cleavage of **9** was observed (Supporting Information). In contrast, when peptide **12**, which lacks the RVRR consensus cleavage sequence, was treated with furin under the same conditions, significant cleavage was only observed after 24 h. Unfortunately, the buffer required for optimum stability of the enzyme disrupted the LPD complex, and conversely, the furin was inactive in buffer solutions suitable for the LPD complex. Hence, further studies with furin could not be carried out on the complex itself. To investigate whether the peptide consensus cleavage sequence is accessible to proteolytic enzymes when the peptide is within the LPD complex, further studies were carried out with the lysosomal enzyme cathepsin B. Uncomplexed peptide **9** was first treated with cathepsin B, buffered at pH 5.5, with the reaction again monitored by HPLC. Immediate cleavage was observed, evidenced by the appearance of a new signal on the analytical HPLC chromatogram with a retention time (R_T) of 8.5 min compared to **9**, which appeared

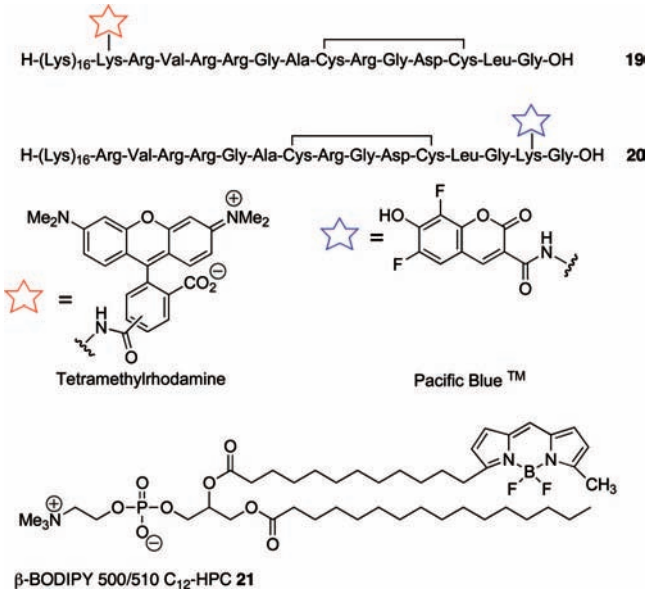


Figure 6. Fluorophore-Labeled Peptides and Lipid for Confocal Microscopy.

at R_T 7.8 min. The intensity of the peak at 8.5 min steadily increased as the reaction proceeded over 4 h, while the intensity of the peak for peptide **9** decreased. (Immediate cleavage, complete within 1 h, was also observed with the control peptide **12**; however, cathepsin B has relatively low sequence specificity, and VKK is also known to be a cleavage sequence for this enzyme (*66*).) Complex **C** was then prepared and treated with cathepsin B, and a very similar cleavage pattern was observed by HPLC (Supporting Information), indicating that the peptide is accessible to proteolytic enzymes within the complex.

Confocal Fluorescence Microscopy. In order to verify the location of the various components of the LPD vector during the transfection process, and also to further investigate the hypothesis that environmentally responsive vector components could be designed to disassemble in the endosome, the transfection process was then studied by confocal microscopy. Fluorescently labeled lipid, peptide, and plasmid DNA components were therefore needed. For the peptide component, selective labeling of residues on either the N-terminal or C-terminal side of the RVRR linker sequence would allow visualization of when the peptide was cleaved during transfection and would allow the movement of the peptide within the cell to be followed. Peptide **19**, where a tetramethylrhodamine label is appended on the N-terminal side of the RVRR sequence, and peptide **20**, where a Pacific Blue label is attached on the C-terminal side (Figure 6), were therefore required. These particular fluorophores were selected to give good contrast in the confocal experiments. In addition, in order to ensure regioselective labeling of the desired residues, it was expedient to prepare the labeled peptides by solid-phase peptide synthesis, using orthogonal protecting group chemistry to reveal only one lysine side chain for labeling, and there was precedent to suggest that both Pacific Blue and tetramethylrhodamine would be robust to treatment with TFA during the peptide cleavage and side chain deprotection steps. Fluorescently labeled peptides **19** and **20** were prepared by initially assembling the desired linear sequences, incorporating Lys(ivDde) at the point where the fluorophore was to be attached (Scheme 3). This was then followed by selective removal of the ivDde group with hydrazine hydrate, on-resin coupling with either tetramethylrhodamine or Pacific Blue, cleavage of the peptide from solid support, and aerial oxidation to form the disulfide bridge, as shown in Scheme 3 for peptide **20**.

For the lipid component, the large size of most fluorescent probes relative to the size of the lipid component meant that attempting to synthesize analogues of lipid **4** with fluorophores either side of the ester linkage was likely to peturb the system to an unacceptable extent. The commercially available fluorescent lipid β-BODIPY 500/510 C_{12}-HPC (**21**, an analogue of DOPE) was therefore used as a general probe to track the movement of lipids within the cell. Finally, rhodamine-labeled plasmid DNA was prepared by standard techniques.

With these materials in hand, transfection of MDA-MB-231 breast cancer cells with labeled LPD complexes was investigated. LPD complexes incorporating lipid **4**, the fluorescent lipid **21** (green), and the fluorescent peptide **19** (red), with unlabeled plasmid DNA, were used to transfect MDA-MB-231 breast cancer cells (Figure 7). The cell nucleus is stained with DAPI (blue). Directly after the initial 4 h incubation period (Figure 7a), both the lipid and the peptide are largely colocated in the cytoplasm of the cell (giving rise to a yellow color), and both components were able to enter the nucleus at that early stage. A similar image was obtained 4 h later, with the cross section images clearly showing the incorporation of both the lipid and the peptide within the center of the nucleus, which is highlighted in blue (Figure 7b). The peptide, unlike the lipid, was still detectable in the nucleus 24 h after incubation (Figure 7c).

In a second set of experiments (Figure 8), LPD complexes were prepared, again incorporating lipid **4** and the fluorescent lipid **21** (green), labeled pGL3 plasmid (red), and the fluorescent peptide **20** (blue). Peptide **20** was selected in order to assess whether the headgroup of the peptide was cleaved from the Lys_{16} DNA-binding moiety after endocytosis. The cell nucleus was not stained. If cleavage of the RVRR sequence takes place in the endosome, then it would be expected that the blue dye (attached to the integrin-binding headgroup) would remain in the endosome or the cytoplasm, whereas the labeled plasmid would be trafficked to the nucleus. Indeed (Figure 8a,b), it can be seen that, at 0 and 4 h after the initial 4 h incubation, there is no obvious internalization of the peptide into the nucleus, although some free DNA has been internalized at 4 h. However, at 24 h (Figure 8c), blue fluorescence is detected in the nuclear region of the cell, suggesting either that the cleaved peptide eventually enters the nucleus or that the peptide is further degraded over 24 h, releasing free dye that then enters the nucleus.

Cryo-Electron Microscopy of LPD Complexes. We had previously studied the morphology of the first generation of LPD complexes using freeze−fracture electron microscopy (*18*). To compare the first-generation LPD complexes with the complexes discussed in this paper, the more sensitive technique of cryo-electron microscopy was used. Cryo-EM images of lipoplexes formulated using Lipofectin and plasmid DNA (Figure 9a) were similar to those formulated from lipid **4**, DOPE, and plasmid DNA (Figure 9b) and showed the spherical shape and absence of internal structure previously observed for similar lipoplexes (*33*). LPD complexes formulated from Lipofectin, peptide **1**, and plasmid DNA produced particles with condensed cores and irregular outer layers, as expected from the freeze−fracture electron microscopy studies (Figure 9c). In contrast to cryo-EM studies of other LPD complexes (*74*), no lamellar structures were seen in the outer layers of the particles. The images (Figure 9d) of the new LPD complex, Complex **C**, formulated from **4**/DOPE, peptide **9**, and plasmid DNA, however, showed marked differences. First, there was a small but significant reduction in the size of the particles when lipid **4** was used, consistent with the smaller particle size observed by laser light scattering (Figure 4). Second, for many of the particles there was a change in the morphology of the internal core, with subdivisions clearly visible. Similar morphologies have been

Scheme 3. Synthesis of Fluorophore-Labeled Peptide 20[a]

previously observed for some lipoplex systems (*75*) and attributed to a phase change in the lipid/DNA complexes, but it is currently unclear what these represent in this system.

DISCUSSION

On the basis of our previous work (*43, 64*), it was postulated that incorporating short ethylene glycol oligomeric moieties of defined length into both lipid and peptide components of the LPD vector would result in increased vector stability. However, whereas complexes formulated with ethylene glycol oligomer-bearing lipid components resulted in minimal aggregation and higher stability of the complexes, compared to complexes formulated with unmodified lipids, peptides incorporating the amino acid Haa4 did not further contribute to the size and stability of the resulting lipopolyplexes (Figure 4). Furthermore, LPD vectors formulated with the triethylene glycol lipid **4** gave particles with discernibly smaller size and altered morphology (Figure 9) compared with the first-generation LPD vectors lacking the ethylene glycol oligomers.

Previous work on sterically stabilized liposomes for drug and gene delivery applications indicated that large polymeric PEG molecules are necessary to inhibit binding to proteins and to prevent aggregation. PEG2000 to PEG5000 molecules are typically used, with larger polymers significantly inhibiting liposome uptake (*25*−*27*). However, these liposomes typically have a low surface density (5−15 mol %) of the surface-anchored PEG; at greater concentrations, the lipid bilayer becomes unstable due to the lateral pressure between the polymer chains (*25*). In these liposomes, therefore, the PEG takes up a "mushroom" configuration: the longer the PEG chain, the larger the mushroom and the more effective the shielding. With lipopolyplexes formulated with lipids such as **4**, in which 50% of the lipid content carries the short ethylene glycol oligomers, complete coverage of the surface can be achieved even with these short oligomers at a high density. Similar observations have been made by Whitesides (*76*) in which it was demonstrated that monolayers formed from monoethylene glycol-conjugated alkanethiols (100%) effectively prevented protein adhesion to the monolayers.

Attachment of ethylene glycol oligomers to the lipid component also appears to improve the transfection efficiencies of the complexes. LPD lipopolyplex (**4**/DOPE/**9**) was 2, 7, 3, 7,

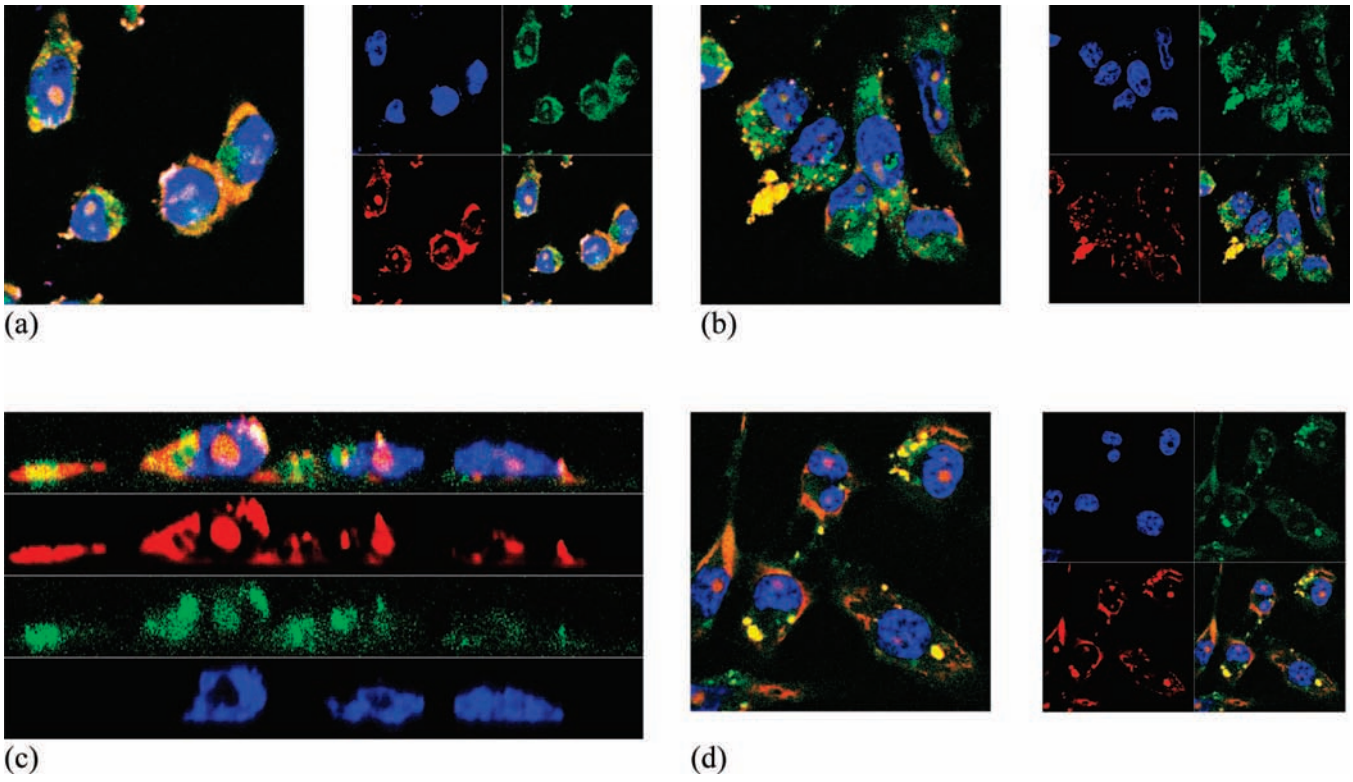

Figure 7. Confocal fluorescence microscopy studies. MDA-MB-231 breast cancer cells were transfected with LPD complexes incorporating the fluorescent lipid **21** (green) at a ratio of lipid **4**:DOPE:**21** of 10:9:1; and the fluorescent peptide **19** (red). The pGL3 plasmid is unlabelled and the cell nucleus is stained with DAPI (blue). Cells were fixed at (a) 0 h (b) 4 h and (d) 24 h after the initial 4 h incubation period. In Figure 7(c), a cross-sectional XZ plane image was taken at 4 h to show the position of the peptide and lipid in relation to the nucleus.

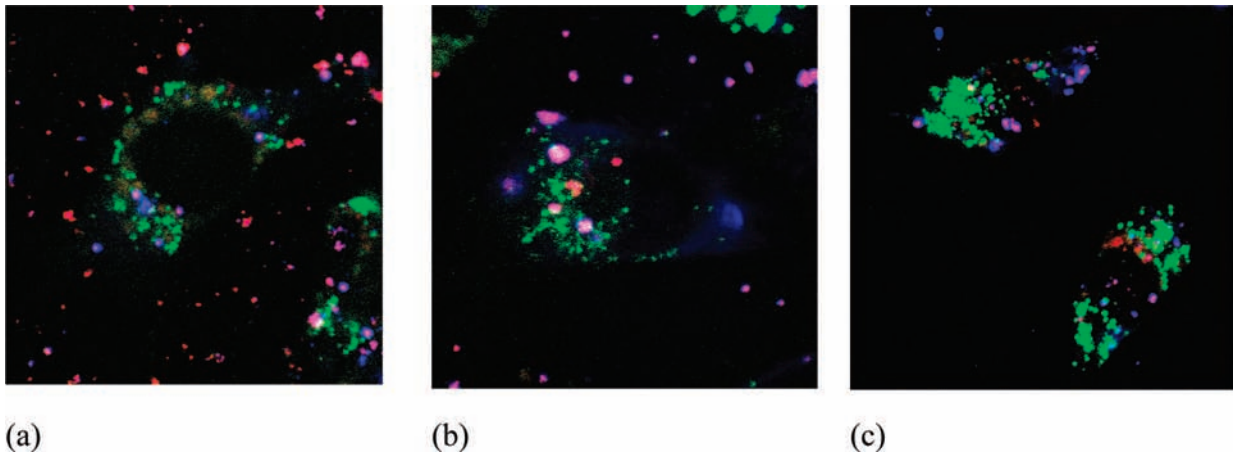

Figure 8. Confocal fluorescence microscopy studies. MDA-MB-231 breast cancer cells were transfected with LPD complexes incorporating the fluorescent lipid **21** (green) at a ratio of lipid **4**/DOPE/**21** of 10:9:1; the fluorescent peptide **20** (blue); and the labeled pGL3 plasmid (red) mixed with unlabeled pGL3 at a 1:3 ratio. The cell nucleus is not stained. Cells were fixed at (a) 0 h, (b) 4 h, and (c) 24 h after the initial 4 h incubation period.

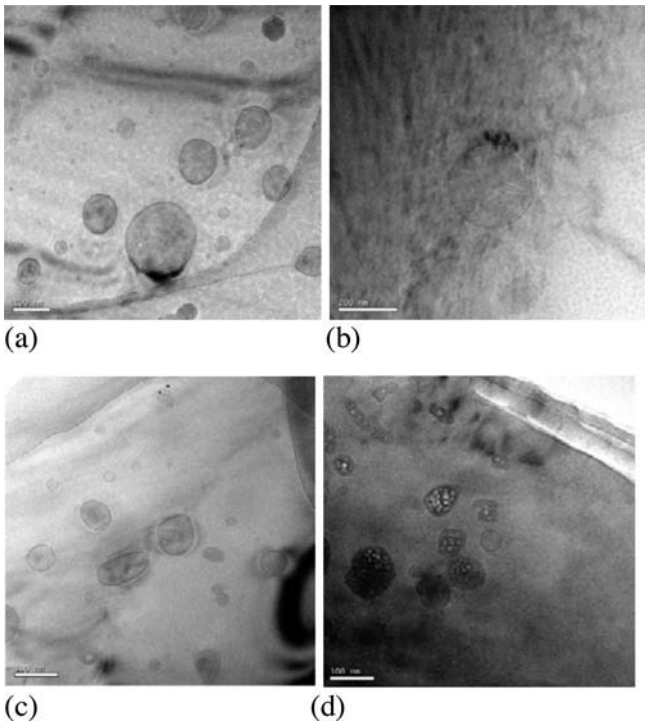

Figure 9. Cryo-EM images of lipoplexes and lipopolyplexes. (a) Lipoplex formed from plasmid DNA and Lipofectin (DOTMA/DOPE). (b) Lipoplex formed from plasmid DNA and **4**/DOPE. (c) LPD complexes formed from plasmid DNA, peptide **1**, and Lipofectin. (d) LPD complexes formed from plasmid DNA, peptide **9**, and **4**/DOPE. All complexes were formulated at 1 mg/mL.

and 9 more efficient for gene transfer than the first generation of noncleavable LPD lipopolyplexes (Lipofectin/**1**), in Neuro 2A, bEND.3, AJ3.1, 16HBE14o-, and PVSMCs cells, respectively ($p < 0.05$). The length and structure of the ethylene glycol oligomeric moieties attached to the lipid also have an important effect on the transfection properties of the resulting complexes. Lipids "capped" with an −OMe group (**5**) performed significantly less well in the majority of cell lines than the "uncapped" lipid **4** when formulated (Figure 5b). Complexes formed with the hexaethylene glycol-bearing lipid **6** had very poor transfection efficiencies, which may be attributable to a reduction in the accessibility of the peptide targeting sequence to the integrin receptors (*49*) or may simply be due to a less compact particle being formed. By contrast (Figure 5a), the inclusion of the amino acid, Haa4, in the peptide sequence had very little effect, marginally reducing the transfection efficiencies of the resulting complexes.

Incorporating lipids and peptides that have the potential to be cleaved within the endosome also results in vectors with enhanced transfection properties. Introduction of the enzyme-cleavable RVRR sequence in the peptide in between the Lys_{16} DNA-binding moiety and the integrin-binding C-terminal amino acids, giving peptide **9**, significantly increases lipopolyplex transfection efficiency (Figure 5a). Similarly, the triethylene glycol-bearing lipid **4**, with an ester linkage which can be cleaved in the endosome, gave LPD complexes with similar, or enhanced, transfection properties compared with the non-cleavable analogue **7** (Figure 5b).

The proposed mechanism for transfection by these stabilized, environmentally responsive lipopolyplexes is as follows. Initial binding of the vector to the α_v integrin receptors expressed on the surface, via the CRGDCLG sequence, which partially protrudes from the complex (*18*), is followed by receptor-mediated endocytosis. Once the particle is encapsulated within the endosome, both the lipid and the peptide undergo cleavage. Removal of the triethylene glycol unit from the cationic lipid reduces steric hindrance and allows the cationic lipids to merge effectively with the endosomal membrane, destabilizing it and allowing the gene delivery particle to escape (*77*). This results in the dispersal of the lipids within the cytoplasm, as demonstrated by confocal microscopy (Figures 7 and 8). In addition, cleavage of the peptide at the RVRR sequence will detach the CRGDCLG sequence, which may still be bound to the α_v integrin, from the DNA/K_{16} complex. The DNA/K_{16} complex will thus be released from both the receptor and the disintegrating endosome and will be able to travel to the nucleus at a very early stage (within 4 h). This is demonstrated by the confocal images of the complex containing peptide **19**, an analogue of **9** bearing the TMR fluorophore on the K_{16} side of the RVRR sequence (Figure 7): the TMR label is rapidly trafficked to the nucleus, presumably complexed to the plasmid DNA. It is additionally possible that the K_{16}-RVRR sequence, being composed of basic, charged amino acids, may function as a nuclear localization sequence (*78, 79*) although it does not correspond to any nuclear localization sequence so far reported (*80*).

We have demonstrated that both the RVRR-linked peptide **9** and the ester-linked lipid **4** can be cleaved in vitro under conditions approximating those found in the endosome. It is noteworthy that, although these LPD complexes are highly

compact, and are clearly stabilized by the incorporation of ethylene glycol oligomer-bearing lipids, both the lipid and the peptide components of the complex are accessible to cathepsin B and to PLE, suggesting that enzyme-mediated cleavage of these components, within the complex and within the endosome, is a viable proposition. Furthermore, we have demonstrated in vitro that the RVRR sequence can be cleaved by furin within 4 h, consistent with the confocal data (Figure 7), which would suggest that endosomal release, complex disassembly, and nuclear trafficking have taken place within this period. In contrast, when peptide **20** (an analogue of **9** with a Pacific Blue label between the RVRR sequence and the integrin-binding CRGDCLG sequence) was used in the LPD complex, the label initially remained in the cytoplasm (Figure 8) and is only visible in the nucleus after 24 h. This may indicate that the Pacific Blue label initially remains, after enzymatic cleavage, associated with the α_v integrin: from there it may be recycled to the outer membrane, or further degradation of the peptide may release free dye, which is later trafficked to the nucleus.

It is also notable that the triethylene glycol lipid **4** was able to enhance the transfection efficiencies of these LPD complexes. Literature precedent strongly suggests that the five-carbon linker used in **4** would be suboptimal for acid-catalyzed cleavage within the endosome (*58*), and, indeed, we saw only very low levels of ester cleavage under acidic conditions.

CONCLUSIONS

We have designed and developed a new class of ternary lipopolyplex gene delivery vectors, with lipids incorporating short ethylene glycol oligomer units of defined length and with both lipid and peptide components designed to degrade within the endosome after internalization of the vector, leading to disassembly of the complexes and release from the endosome. These gene delivery vectors are very compact and show very promising stabilities under physiologically relevant conditions, while maintaining excellent transfection activities. These desirable properties bring us one step closer to developing vectors that can be administered systemically, will be stable enough to persist in circulation and not be cleared by the RES, and yet will be able to find, target, and transfect specific cell types (in this case, specific tumor types) within living organisms. The development of targeted, environmentally responsive vector systems that are able to deliver therapeutic genes efficiently and specifically to the target cells after application into the systemic blood circulation will be vital in treating a range of cancers, particularly metastatic tumors. Detailed studies of the effects of centrifugation of these smaller LPD particles on the efficiency of in vitro transfection and of the in vivo stability and tumor-specific targeting of the complexes are ongoing, and will be published in due course.

ACKNOWLEDGMENT

The BBSRC are thanked for grants to M. F. M. M., S. M. G., and M. E. (BBS/B/03645) and E.-A. R. (BB/D005469/1). The EPSRC is thanked for a DTA studentship (to J. B. W.) and Kings College London for the award of a Maplethorpe Fellowship (to L. K.). We thank Dieter Gruenert, California Pacific Medical Centre Research Institute, San Francisco, CA, USA, for kindly providing the 16HBE14o-cell line.

General Synthetic Methods

All reagents used for synthesis were purchased from commercial suppliers. Cathepsin B and furin were purchased from Sigma. Dichloromethane was dried over anhydrous alumina columns (*1*) moisture levels were usually <15 ppm by Karl Fischer titration. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX300 spectrometer; chemical shifts (δ) are reported in parts per million (ppm) using residual isotopic solvent as an internal reference. Coupling constants (*J*) are reported in Hertz (Hz). Electrospray mass spectra were recorded on Micromass Quattro LC, Thermo Finnegan MAT 900XP or VG ZAB 2SE instruments, and fast atom bombardment mass spectra on Thermo Finnegan MAT 900XP or VG ZAB 2SE instruments.

Materials for Cell Biology

Dulbecco's Modified Eagle's medium (DMEM), foetal bovine serum (FBS), penicillin/streptomycin solution, trypan blue solution 0.4 % w/v, 0.25% Trypsin-EDTA, thiazolyl blue reagent (MTT), 4',6-Diamidino-2-phenylindole dihydrochloride (DAPI) and SYBR-green 10,000x solution were all supplied from Sigma Ltd, UK. Luciferase assay system with reporter lysis buffer was obtained from Promega, UK. RC DC protein assay was purchased from Bio-Rad laboratories. Paraformaldehyde (PFA), Triton-X and sodium borohydride were supplied from Sigma-Aldrich. 100 U/mL penicillin, Glutamax-1, sodium pyruvate, PBS and streptomycin were supplied by InVitrogen (Paisley, UK). MEM-non-essential amino acids (NEAA) and L-glutamine were supplied by either InVitrogen or Sigma. 1X Reporter Lysis Buffer was supplied by Promega (Madison, WI, USA). Mowiol solution was supplied by the Randall division of cell and molecular biophysics department, King's College London.

The pGL-3 plasmid was initially purchased from Promega, UK and grown in a transformed *E. coli* JM109 strain then purified using a QIAGEN® EndoFree plasmid Giga kit (from QIAGEN, UK). A nick translation kit for plasmid fluorescence labelling together with 10mM of dCTP, dGTP and dATP were all purchased form Amersham Bioscience, UK. Tetramethyl-rhodamine-5-dUTP 25nmol/25μL was obtained from Roche, UK, DNA polymerase I and 10mg/ml bovine serum albumin (BSA) were

purchased from New England Biolabs and 0.5M EDTA, 1M Tris HCl and dithiothreitol (DTT) were from Promega, UK.

(2,3-Bis-octadec-9-enyloxypropy)-(carboxybutyl)-dimethylammonium bromide (18) Lipid (**11**) (0.177 g, 0.18 mmol) was dissolved in NaOH (1M, 2 mL) and stirred at room temperature for 2 h. Dichloromethane was then added, and the mixture was washed with saturated $NaHCO_3$ and brine. The separated organic layer was dried over $MgSO_4$ and the solvent was removed *in vacuo*. Purification by flash column chromatography (10% methanol in dichloromethane changing to pure methanol) gave the titled compound (0.017 g, 13%) as a pale yellow oil. ^{1}H (300 MHz, $CDCl_3$): δ 0.87 (6H, t, J = 6.6 Hz) 1.24 (44H, m), 1.53 (4H, m), 1.67 (2H, m), 1.86 (2H, m), 1.99 (8H, m), 2.31 (2H, m), 3.28-3.45 (10 H, m), 3.52-3.68 (7H, m), 3.98 (1H, m), 5.32 (4H, m). ^{13}C (75 MHz, $CDCl_3$): δ 14.05, 22.08, 22.58, 25.94, 26.11, 27.12, 29.10–29.67 (signals overlap), 29.94, 31.80, 32.52, 51.74, 52.30 (signals overlap), 65.26, 65.85, 68.75, 69.32, 71.89, 73.21, 129.67 (signals overlap), 129.85 (2 signals overlap) HRMS *m/z* (ES+) calcd 720.68699, found 720.68512 (M^+).

Fast and sensitive detection of epidemic virus is of the utmost importance for human being in nowadays. Various biosensors have been designed for this goal based on conjugation event between host cell glycolipids and invading virus. However, multihead glycolipids analogous to native receptors on cell surface are known to be very difficult to mimic because of the complexity of chemical synthesis. Here, we developed a new approach where two types of monohead glycolipids, active sialic acid-β-glucoside (G1) and inactive lactose-β-glucoside (G2), are embedded onto the surface of a polydiacetylene (PDA) vesicle to mimic native glycolipids on the cell surface. Vesicles prepared in this manner show good selectivity with a 10 ng/mL detection limit and 5 min response time to Hemagglutinin (HA1), which is more sensitive than any HA1 biosensors ever known. Moreover, in the formation of color-changeable vesicles, a very strong synergistic effect between G1 and G2 has been found, offering a novel strategy to construct effective biosensor receptors, as well as a new way to study the surface combination effect that is potentially important to the immunology study of epidemic disease.

INTRODUCTION

Fast and sensitive detection of epidemic viruses is of the utmost importance for human beings nowadays. A commonly used approach is to mimic biological interfaces upon which specific molecular events could occur (*1*). Such interfacial biological processes have been found to be detectable with the help of a polydiacetylene (PDA) vesicle (*2*−*4*).

Many efforts have been devoted to developing PDA-based vesicles for detection of various biologically important analytes, such as lipophilic enzymes (*5*) (*6*), antibacterial peptides (*7*), mammalian peptides (*8*), ions (*9*), antibodies (*10*−*12*), proteins (*13*), and pharmacologically active compounds (*14*). It is generally believed that the PDA vesicle is a good model system to mimic the cell surface in the study of the surface conjugation events. To the best of our knowledge, however, there are only a few studies on the detection of the key polysaccharide or carbohydrate−protein interaction (*15*−*17*), although it is one of the most widely existing and important types of conjugation in cell membranes. Furthermore, almost all the epidemic virus invading processes involve polysaccharides on cell surfaces. One major limitation to the PDA-based approach is the difficulty of synthesizing complicated probes that contain more than one saccharide group in a molecule as effective binding sites. If these obstacles could be overcome by self-assembly technology, for example, by inserting receptors and various saccharide groups into the same vesicle to make it analogous to natural complex polysaccharide receptors on the cell, a much easier approach for biosensor design and construction would be developed, which may lead to a wide range of applications.

Herein, we report an approach based on the strategy mentioned above. The recognition element assembled in the colorimetric mixed PCDA sensor consists of sialic acid-β-glucoside (G1) and lactose-β-glucoside (G2) receptors, both having a tetraethylene glycol spacer and C12 hydrocarbon. The fragment of influenza virus H5N1 protein of Hemagglutinin (HA1) on the cell surface is used to act as the target for detection.

EXPERIMENTAL PROCEDURES

Materials. 10,12-pentacosadiynoic acid (PDA) was purchased from Lancaster Co. in 98% purity, which was further purified by dissolving in chloroform and then filtered to remove polymerized monomers before use. Dimyristoylphosphatidycholine (DMPC) was purchased from Sigma, and bovine serum albumin (BSA) was purchased from Beijing Reagent Co. *E.coli DH5*α was provided by Institute of Zoology of the Chinese Academy of Sciences. Sialic acid-acid-β-glucoside (G1) and lactose-β-glucoside (G2) receptors were synthesized according to previously reported procedures (*18*−*24*). The fragments of the influenza virus protein of Hemagglutinin on the cell surface (HA1) were obtained as reported (*25*−*29*), with details of abstraction and synthesis procedures given in the Supporting Information (SI).

Preparation of PDA Mixed Vesicles. The PDA vesicles were prepared according to literature procedures (*12, 17*). The typical procedure for the mixed vesicles preparation is as follows. The mixed components (PDA, DMPC, G1, G2) with various molecular fractions were dissolved in $CHCl_3$ followed by solvent evaporation. After adding 0.01 mol/L phosphate buffer (pH 6.9), the suspension (1 mmol L^{-1} of the mixed component) was probe sonicated for 5−6 min at approximately 80 °C. After the sonication, the solution was cooled to room temperature and then stored overnight at 4 °C to induce crystallization of lipid membranes. Polymerization was carried out under irradiation at 254 nm wavelength for 10 s. All vesicles used in our experiment have the same DMPC to PDA ratio of 4:6. The ratios of G1 and G2 in the vesicles were 1:0, 9:1, 7:3,

5:5, 3:7, 1:9, and 0:1, respectively, and the total molar ratio of (G1+G2) to PDA to DMPC is 0.2:6:4.

UV−vis Spectroscopy. Measurement of UV−vis spectra for the mixed lipid vesicles in water were carried out using a two-beam Hitachi U2800 UV−vis spectrometer. The pH of the vesicle solutions was maintained at 6.9 with phosphate buffer. During the measurement, a certain amount of aqueous analyte solution was injected stepwise into the vesicle solution with a syringe. All measurements were carried out at 35 °C.

Colorimetric transition from blue to red was monitored quantitatively by the colorimetric response (CR), which is defined as (*2, 11, 17*)

$$CR = [(PB_0 - PB_f)/PB_0] \times 100\% \quad (1)$$

where $PB = A_{blue}/(A_{blue} + A_{red})$, and A_{blue} and A_{red} are the absorbances of the blue component ($\lambda_{max} \approx 650$ nm) and the red component ($\lambda_{max} \approx 540$ nm) in the UV−vis spectrum; PB_0 and PB_f are the initial and final percentages of the blue component in the vesicle solution before and after adding the analyte, respectively.

RESULTS AND DISCUSSION

The design of a new system for rapid detection of interfacial biomolecular interactions in general, and receptor−ligand recognition in particular, has to fulfill two main objectives. First, the system structure should allow the interaction event to take place readily. Second, the specific interactions between the receptor and the ligand should be easily transformed into a quantified chemical or physical signal, such as transferring the conjugation event into a color change. The Vesicle-(G1+G2) we have designed, shown schematically in Figure 1, satisfies the above two requirements.

We synthesized glycolipids with sialic acid (G1) and lactose (G2), respectively, and designed the headgroups pointing outward from the PDA vesicle surface in order to assemble them to form an analogue to the complicated influenza virus H5N1 receptors where sialic acid linked to galactose by α-2,3 linkage [α-Neu5Ac(2−3)-β-Gal] and α-2,6 linkage [α-Neu5Ac(2−6)-β-Gal], the minimal recognition site for the HA1 (*25*). In our experiment, galactose is replaced by lactose, because the lactose is composed of two galactoses so that a "trap" with sialic acid to HA1 can be formed. In order to make the glycolipids extend in water, a tetraethylene glycol spacer was chosen as linker; G1 and G2 both ended with a C_{12} hydrocarbon chain for the immobilization to the vesicles.

It has been found that local dimyristoylphosphatidylcholine (DMPC) domains incorporated into PDA vesicles not only increase the detection sensitivity, but also open a new avenue for lipophilic biological molecules physically inserting the mixed vesicles. DMPC was used as a component of vesicles. The molar ratio of glycolipid/DA/DMPC equals 0.2:6:4, where the glycolipids can be G1, G1+G2, or G2. A series of vesicles were prepared to study how the combined glycolipids affect the conjugation. In these vesicles, the ratio of G1 to G2 in the vesicles changes in the following way: 1:0, 9:1, 7:3, 5:5, 3:7, 1:9, and 0:1. After photopolymerization, the PDA mixed vesicles appeared to be clear blue to the naked eye and exhibited a maximal absorption at 640 nm, which is due to their backbone alternating ene−yne conjugated structure.

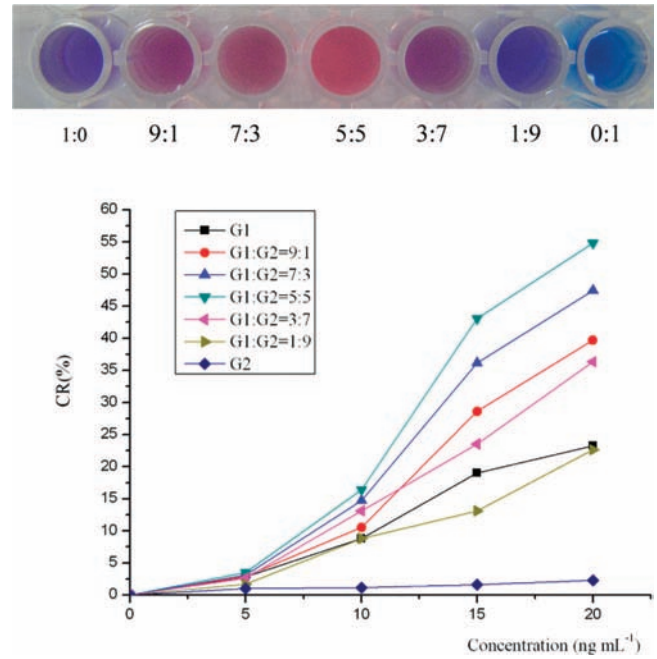

Figure 2. The color of the seven different vesicles with 20 ng mL^{-1} HA1, from left to right, with the ratio of G1 to G2 indicated (up), and the CR% of seven mixed vesicles with addition of different amount of HA1(down).

According to our experiment, the larger the concentration of DMPC in the vesicle, the more sensitive the PDA vesicle will be. However, if the amount of receptor G1+G2 or DMPC exceeds a certain threshold value, the blue-colored PDA vesicle could not be observed, which is believed to be due to the destruction of the effective conjugation length of the PDA backbone.

In Figure 2, the color of PDA vesicles functionalized with G1, G2, or G1+G2 shaded from blue into purple, amaranth,

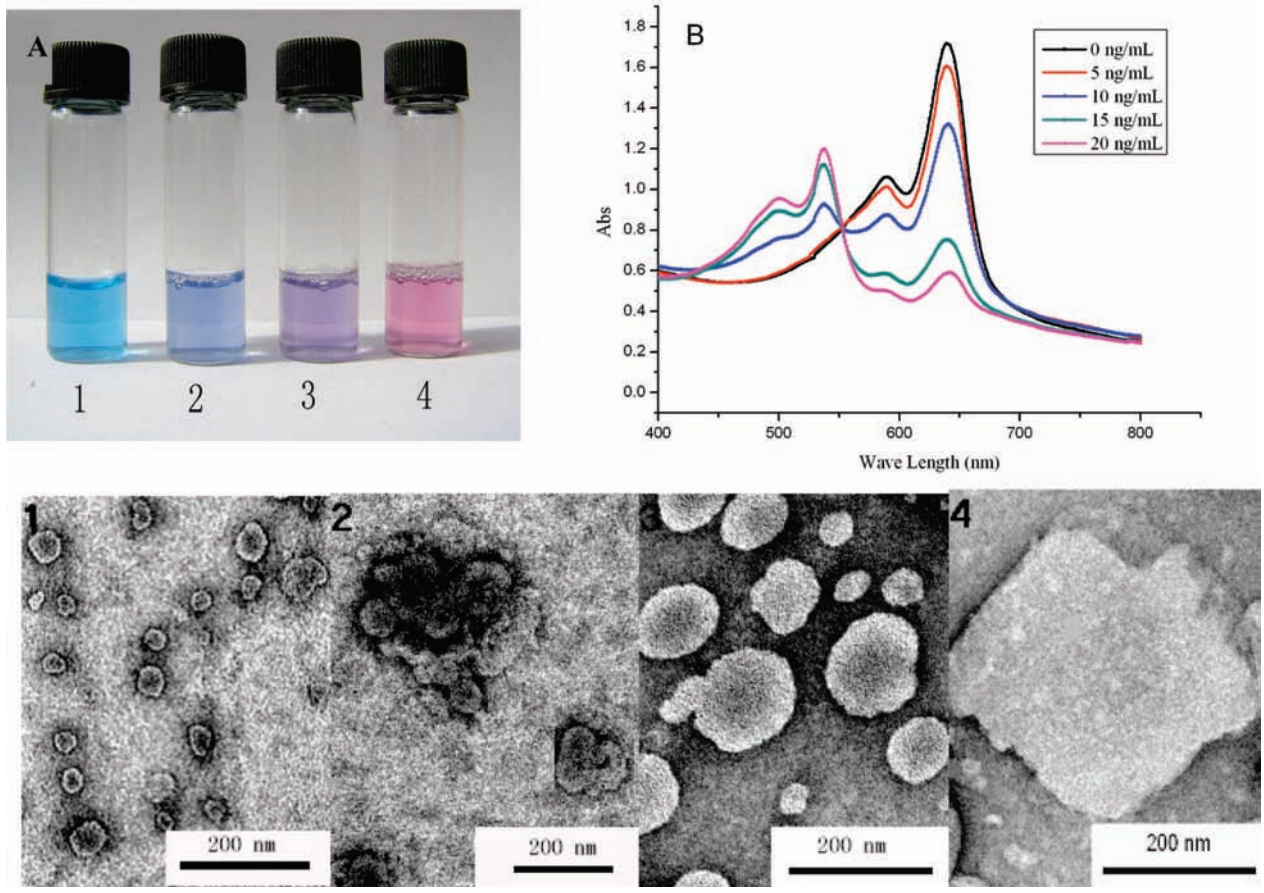

Figure 3. Interaction of vesicle-(G1+G2 = 5:5) with different amounts of HA1 in solution. (A) Photographs. (1) Control without HA1. (2) 5 ng mL^{-1}. (3) 10 ng mL^{-1}. (4) 20 ng mL^{-1}. (B) Visible adsorption spectra of vesicle-(G1+G2 = 5:5) solution mixed with HA1. (C)TEM images of vesicle-(G1+G2 = 5:5) solution tested with different concentration of HA1: (1) control. (2) 5 ng mL^{-1}. (3) 15 ng mL^{-1}. (4) 20 ng mL^{-1}.

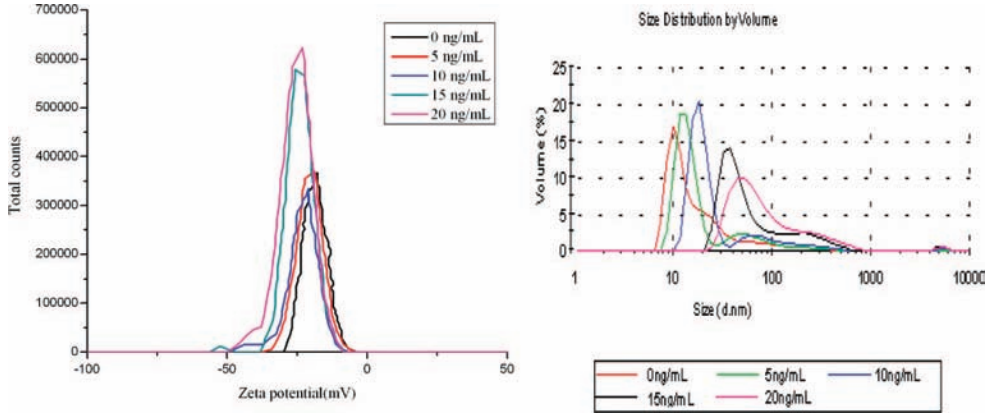

Figure 4. ζ potential and volume distribution of vesicles measured by using a Zetasizer, Nano ZS Malvern Instruments Ltd.

magenta, and red when the surface-assembled receptor was bound to different amounts of HA1. It is intriguing that the degree of the color change of the polymerized vesicles functionalized with G1 or G2 alone was much less than those functionalized with (G1+G2) when HA1 was added; vesicle-G1 underwent a color change from blue to purple as the HA1 concentration reached 20 ng mL^{-1}, whereas the color of vesicle-G2 still remained blue, meaning no conjugation occurred at all. On the other hand, vesicle-(G1+G2), especially G1/G2 = 5:5, causes a remarkabe color change even at a very low concentration of HA1 (ca. 10 ng mL^{-1}), showing a very strong synergistic effect for the recognition of virus HA1. This behavior can also be found in the change of CR% of seven mixed vesicle, as shown in Figure 3, where the value of CR is ordered as follows: vesicle-(G1/G2 = 5:5) > vesicle-(G1/G2 = 7:3) > vesicle-(G1/G2 = 3:7) > vesicle-(G1/G2 = 9:1) > vesicle-G ≈ vesicle-(G1/G2 = 1:9) > vesicle-G2 when 10 ng mL^{-1} HA1 was added. However, the value of CR of the vesicle-(G1/G2 = 9:1) is higher than that of the vesicle-(G1/G2 = 3:7) when HA1 was added from 15 ng mL^{-1} to 20 ng mL^{-1}. These results show that there is some synergistic effect between G1 and G2. It was reported previously (*2*) that lactose (receptor G2) is not a ligand for the hemagglutinin lectin, whereas sialoside (receptor G1) is the selective and sensitive one. To the best of our knowledge, this kind of synergistic effect and high sensitivity have not yet been reported previously.

Figure 3A,B shows the relationship between the color change and the visible absorption spectra of the vesicle-(G1/G2 = 5:5)

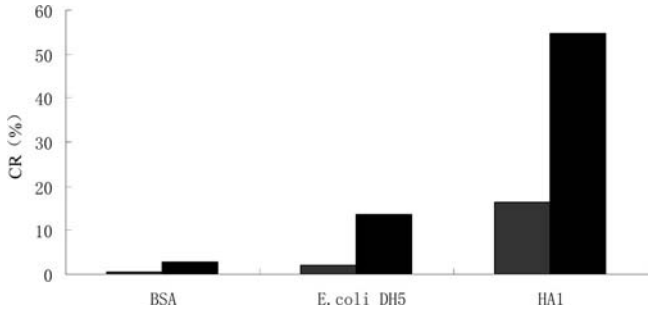

Figure 5. Absorbance difference at 640 nm of vesicle-(G1+G2) changed with different species of biomolecules: (1) BSA. Left: 10 ng mL^{-1}. Right: 25 ng mL^{-1}. (2) *E.coli DH5*. Left: 10 ng mL^{-1}. Right: 25 ng mL^{-1}. (3) HA1. Left: 10 ng mL^{-1}. Right: 20 ng mL^{-1} within 5 min.

as it encountered HA1. When the color changed, the absorption maximum at 640 nm decreased with a concurrent absorption increase in the maximum at 540 nm in visible absorption spectra. It is commonly accepted that the blue−red chromatic transitions observed in PDA can be attributed to the disturbance of the conjugation length of the polydiacetylene backbone. Our experiment showed that binding of the viral hemoglotinen to the glycolipids affects the vesicle conformation to a great extent, which was clearly demonstrated in the TEM picture (Figure 3C). TEM images demonstrated that the vesicle packing shape after recognition with HA1 is much different from that of its original form. As more HA1 adsorbed on the vesicle surface, the size of vesicles-(G1+ G2) grows bigger, accompanied by the shape change due to fusion from spherical to flat rectangular. This occurs presumably because of the interaction between the HA1 proteins on the vesicle surfaces.

Two interesting results were found in these experiments: (1) It is possible to form a highly sensitive biosensing element in the vesicle surface simply by inserting G1 and G2 into the PDA vesicle, thus providing an easy way to mimic the receptors containing multiple saccharide complex on the cell surface. (2) A very strong synergistic effect between sensitive receptor (G1) and nonsensitive receptor (G2) was observed, indicating the importance of the receptor combination effect for the ligand conjugation on the vesicle surface that was less known previously, thus providing us an open area for further investigation.

To gain a deeper insight into the property of the vesicle surface, electrophoresis experimentation for the ζ potential measurement was carried out. It was found that, after adding more HA1, the ζ potential of the vesicles-(G1+G2) gradually changed to a more negative and constant value as shown in Figure 4. In combination with the volume changing in TEM pictures showed in Figure 3, it is reasonable to assume that after conjugating with HA1, the receptor surface was gradually covered by HA1 and reached a constant ζ value mainly due to HA1 no matter how large the vesicle was. TEM and CR measurements show that the agglomeration of particles still continued by the increase of HA1 concentration caused by the interaction between proteins on the vesicle surfaces or protein fragments in the bulk, which further made the aggregate volume and morphology change, and caused CR% to increase, respectively.

In order to further assess the color response due to nonspecific adhesion of the vesicles, some large biomolecules such as *E.coli DH5*α and bovine serum albumin were tested as controls. It appears that these molecules do not cause any vesicle color change even for a long time (at least 5 min) as shown in Figure 5. This is completely different from the case of vesicle-(G1+G2), whose color change from deep blue to amaranth or red may occur within less than 5 min when treated with HA1 10 ng mL^{-1} or 20 ng mL^{-1}. Together, our results show that vesicles-(G1+G2) prepared in this manner are promising candidates for biosensors. It shows very good specificity, high sensitivity, and short respondent time, thus being of great significance in its application in influenza virus H5N1 diagnosis.

CONCLUSIONS

This study describes an approach to the preparation of an effective biosensor for HA1 recognition on a chromatic vesicle surface based on a molecular assembly technique. It overcomes the limitation of current synthesis methods, which were known to be both complicated and difficult. The colorimetric assay is robust and easy to carry out, yielding results that are much faster and more sensitive than commonly used traditional biochemical techniques. Although the exact mechanism of the synergistic effect is not clear yet, the phenomenon itself has already shown great significance in application. Further study of the mechanism of this finding and its applicability by assembling glycolipids to improve the sensitivity in bioconjugate events shall be an attractive area in the future. Our results also show that, in combination with the self-assembly technology, the chromatic vesicle protocol could be utilized as a platform for various biochemical applications, such as for new drug metabolism and for pharmacokinetics of the H5N1 virus, including the establishment of a receptor library for disease diagnostics.

Synthesis of sialic acid- β -glucoside (G1):

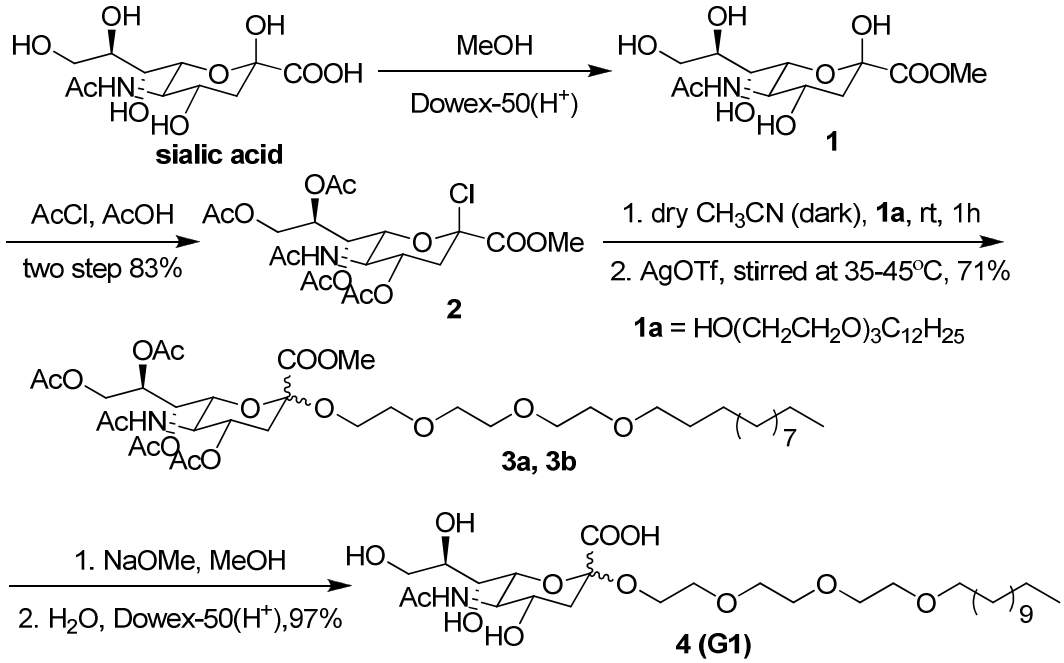

Figure S1. Schematic diagram for the synthesis of glycolipid **G1**

Preparation of Methyl 5-acetamido-3,5-dideoxy-D-glycero-D-galacto-2-nonulopyranosonate **1**:

N-acetylneuraminate (5.0g) was dissolved in MeOH (50 ml). The H^+ ion exchange resin (10.0g) was added at room temperature. After 40 h, the solution was filtrated and the resin was washed by MeOH, the organic layer was concentrated to afford the desired product **1** white solid (4.35g, 83% yield).

R_f=0.60 (EA:MeOH=1:1)

Preparation of

5-Acetamido-4,7,8,9-tetra-O-acetyl-2-chloro-2,3,5-trideoxy-D-glycero-β-

D-galacto-2-nonulosonic acid methyl ester **2**:

A mixture of acetyl chloride (70 ml) and acetic acid (35 ml) was cooled to 0 ℃. **1** (3.55 g) was added. The reaction was stirring at room temperature for 48 h. The reaction solution was concentrated to yield compound **2** as a white solid (3.70 g, 83% yield).

R_f=0.50(EA)，melting point: 65 ℃–67 ℃. ^{1}HNMR ($CDCl_3$, 300MHz) δ 5.90 (d, *J*=10.2,1H), 5.41-5.52 (m, 4H), 5.18 (br, 1H), 4.36-4.43 (m, 2H), 4.20-4.24 (m, 2H), 4.09 (m, 1H), 3.90 (s, 3H), 3.80-3.82 (m, 2H), 2.79 (dd, *J*=4.8, 13.8, 1H), 1.92-2.23 (m, 18H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 175.45, 171.00, 170.78, 170.68, 169.98, 169.84, 165.59, 96.62, 73.86, 70.14, 68.80, 65.95, 62.12, 48.62, 40.59, 22.99, 20.88, 20.80, 20.73, 20.68, 20.65 ppm.

Preparation of 5-Acetamido-4,7,8,9-tetra-O-acetyl-2-(diethylene glycol mono-dodecyl ethyl) -3,5-dideoxy-D-glycero-D-galacto-2-nonulosonic acid methyl ester **3a-3b**:

Compound **2** (0.50 g), 4Å molecular sieve (1.0 g) and triethylene glycol mono-dodecyl ether (0.62 g) was mixed in dry CH_3CN (20 ml), and stirred for 1h at room temperature. The TfOAg (0.50 g) was added in the dark at 35-40 ℃. After 72h, the reaction was stopped and the insoluble solids in reaction mixture were removed by filtration. The organic layer

was washed by saturated $NaHCO_3$ aq, saturated $Na_2S_2O_3$ aq and saturated brine, dried by anhydrous sodium sulfate. The resulting crude mixture of products were separated and purified by column chromatography to afford two pure isomers (**3α:**21% yield, **3β**:21% yield).

α-Isomer **3a**

R_f=0.31(PE:acetone=2:1). ^{1}HNMR ($CDCl_3$, 300MHz): δ 5.36-5.41 (m, 1H), 5.30-5.33 (m, 1H), 5.24-5.27 (m, 1H), 4.81-4.920 (m, 1H), 4.31 (dd, *J*=2.4, 12.4, 1H), 4.00-4.12 (m, 2H), 3.87-3.93 (m, 1H), 3.80 (s, 3H), 3.56-3.65 (m, 9H), 3.42-3.50 (m, 3H), 2.62 (dd, *J*=4.5, 12.9, 1H), 1.81-2.14 (m, 16H), 1.53-1.60(m, 2H), 1.26(br, 18H), 0.86-0.90 (m, 3H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 170.98, 170.60, 170.19, 170.12, 170.00, 168.29, 98.82, 72.48, 71.55, 70.61, 70.56, 70.54, 70.10, 70.05, 69.11, 67.35, 64.50, 62.37, 52.71, 49.45, 31.89, 29.61, 29.59, 29.48, 29.32, 26.08, 23.16, 22.66, 21.07, 20.81, 20.73, 14.08 ppm. MALDITOF-MS: *m/z* 792.4376 $[M + H]^+$ Calcd for $C_{38}H_{66}O_{16}N$: 792.4382.

β-Isomer **3b**

R_f= 0.24 (PE:acetone=2:1). ^{1}HNMR ($CDCl_3$, 300MHz): δ 6.40 (d, *J*=10.2, 1H), 5.31-5.33 (m, 1H), 5.23-5.27 (m, 1H), 5.11-5.22 (m, 1H), 4.82 (dd, *J*=2.4, 12.4, 1H), 4.55 (dd, *J*=2.1, 10.8), 4.01-4.08 (m, 2H), 3.46-3.80 (m,

15H), 3.36 (t, J=6.9, 2H), 2.37 (dd, *J*=5.1, 12.9, 1H), 2.07(s, 3H), 1.93-1.99 (m, 9H), 1.75-1.83 (m, 4H), 1.46-1.51(m, 2H), 1.19 (br, 18H), 0.76-0.83(m, 3H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 170.46, 170.42, 170.37, 170.08, 167.47, 97.72, 72.09, 71.33, 70.63, 70.19, 69.85, 69.77, 69.45, 68.57, 62.75, 62.65, 52.48, 37.12, 31.80, 29.54, 29.51, 29.44, 29.38, 29.23, 25.98, 22.81, 22.57, 20.86, 20.70, 13.99 ppm. MALDITOF-MS: *m/z* 815.4216 $[M + Na]^+$ Calcd for $C_{38}H_{66}O_{16}NNa$: 815.4279.

Preparation of

(2-(triethylene glycol mono-dodecyl ethyl) -3,5-dideoxy-D-glycero-β-D-galacto- 2-nonulosonic acid **4** (**G1**): 80mg of **3β** was dissolved in dry MeOH (2mL), and NaOMe (1M in MeOH, 20μL) was added. After 5 h, water (2 mL) and NaOMe (1M in MeOH, 50μL) was added. After 4h, the H^+ ion exchange resin (1.0g) was added, stirring for 10min. The reaction mixture was filtrated and the filtrate was concentrated to give the desired product **4** (**G1**) as colorless oil (50mg, 97% yield).

^{1}HNMR ($CDCl_3$, 300MHz): δ 3.34-3.84 (m, 23H), 3.20-3.22 (m, 1H), 2.60 (dd, *J*=3.9, 12.3, 1H), 1.90 (s, 3H), 1.42-1.49 (m, 2H), 1.19 (br, 18H), 0.78-0.82(m,3H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 175.20, 170.90, 100.22, 72.47, 72.42, 71.63, 71.58, 71.56, 71.24, 71.19, 64.76, 64.71,

53.82, 53.48, 33.11, 30.82, 30.78, 30.63, 30.50, 27.24, 23.77, 22.77, 14.52 ppm. MALDITOF-MS: *m/z* 610.3799[M + H]$^+$ Calcd for $C_{29}H_{56}O_{12}N$: 610.3803.

Preparation of lactose- β -glucoside(G2)

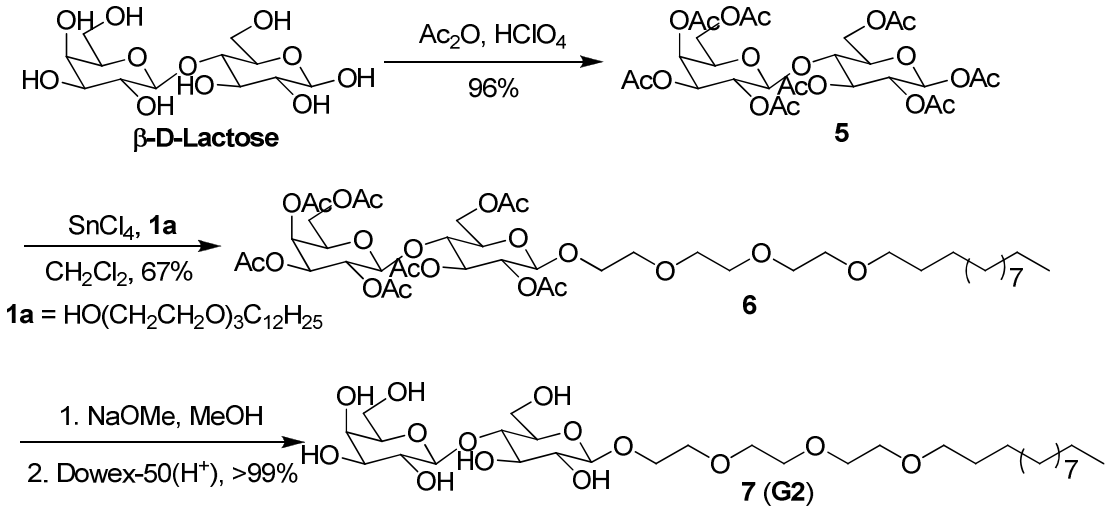

Figure S2. Schematic diagram for the synthesis of glycolipid **G2**

Preparation of β-D-Lactose octylacetate **5**:

$HClO_4$ (3 drops, 70% aq.) was added dropwise to acetic anhydride (20 ml) at 0℃, and β-D-Lactose (5.0g) was the added to the solution under stirring. After stirring at room temperature for 3h, the solution was diluted with CH_2Cl_2 (20 mL), and then poured into ice water (40 mL). The organic layer was washed by $NaHCO_3$ and brine, dried by anhydrous sodium sulfate. The resulting crude product was purified by column

chromatography (96% yield). R_f=0.33 (PE:EA=1:1)

Preparation of triethylene glycol mono-dodecyl ethyl heptacetyl β-D-Lactoside **6** :

The molecular sieve (1.0 g) was added to the solution of triethylene glycol mono-dodecyl ether (0.45 g) and **5** (0.50 g) in CH_2Cl_2 under argon. After 20min, $SnCl_4$ (0.17mL) was added at 35 ℃. After 2 days, the reaction was stopped and the reaction mixture was filtered. The filtrate was washed by saturated NH_4Cl aq, saturated $NaHCO_3$ aq and saturated brine, dried by anhydrous sodium sulfate. The crude product was purified by column chromatography (67% yield).

R_f=0.14(PE:acetone=3:1). ^{1}HNMR ($CDCl_3$, 300MHz): δ 5.34 (d, J=1.8, 1H), 5.07-5.22 (m, 2H), 4.86-4.98 (m, 2H), 5.56 (d, J=11.1, 1H), 4.46-4.50 (m, 2H), 4.07-4.13 (m, 3H), 3.56-5.93 (m, 15H), 3.42-3.46 (m, 2H), 2.17 (s, 3H), 2.15(s, 3H), 2.04-2.06 (m, 12H), 1.96 (s, 3H), 1.56-1.59 (m, 2H), 1.26 (br, 18H), 0.86-0.90 (m, 3H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 170.27, 170.05, 169.95, 169.66, 169.57, 168.98, 101.03, 100.62, 72.84, 71.49, 70.97, 70.68, 70.61, 70.57, 70.22, 70.02, 69.04, 60.80, 31.86, 29.60, 29.55, 29.43, 29.28, 26.05, 22.62, 20.78, 20.74, 20.62, 30.54, 20.42, 14.04 ppm. MALDITOF-MS: *m/z* 959.4458 $[M + H]^+$ Calcd for $C_{44}H_{72}O_{21}Na$: 959.4464.

Preparation of triethylene glycol mono-dodecyl ethyl β-D-Lactoside **7** (**G2**):

6 (340mg) was dissolved in MeOH (10ml), and then NaOMe (1M in MeOH, 100μL) was added to the solution. After the reaction solution had been stirred for 24 h, H^+ ion exchange resin (1.0g) was added to the solution, stirring for another 20min. The reaction mixture was then filtered and the filtrate was concentrated to yield the desired product **7** (**G2**) as white solid (99% yield).

R_f=0.5(EA:MeOH=3:1)，熔点 160 ℃ --161 ℃

^{1}HNMR($CDCl_3$, 300MHz): δ 4.37 (t, J=6.9, 2H), 3.26-4.07 (m, 26H), 3.31-3.33 (m, 3H), 1.56-1.60 (m, 2H), 1.31 (br, 18H), 0.89-0.94 (m, 3H) ppm. ^{13}C NMR (300MHz, $CDCl_3$): δ 105.14, 104.35, 80.74, 77.10, 76.52, 76.33, 74.88, 72.58, 72.42, 71.54, 71.50, 71.17, 70.33, 69.78, 62.50, 33.08, 30.75, 30.60, 30.47, 27.23, 23.74, 14.46 ppm. MALDITOF-MS: *m/z* 643.3899 $[M + H]^+$ Calcd for $C_{30}H_{59}O_{14}$: 643.3905.

Express and purification of HA1

Construction of the expression plasmid. The HA1 gene (Figure S3) was cloned from HA full-length gene with PCR method and then was inserted separately into pET21b vector with T4 DNA ligase. Proper

construction of the final vector pET21b-HA1 was verified by restriction analysis and DNA sequencing. Transformation of BL21 was achieved by $CaCl_2$ with pET21b-HA1 and pET21b (negative control). The recombinant BL21 with pET21b-HA1 was inducted with 0.1mmol L^{-1} IPTG in 37ºC for 2.5 hours. After that, the culture supernatant and cells were separated by centrifugation at 12000 rpm for 5 min and frozen in -20 ºC. Ni-ATA column was used for purification of culture supernatant and cells. The supernatant of E.coli BL21 was analyzed with 12% SDS–PAGE according to an established protocol. Then total proteins were resolved on a 12% SDS-polyacrylamide gel and transferred onto a nylon membrane and incubated with avian influenza positive antigens, followed by incubation with rabbit conjugated anti-chicken IgG secondary antibody (Sigma). The DNA sequence of HA1 is shown in Figure S3.

Received October 23, 2008; Revised Manuscript Received December 31, 2008

We designed a series of γ-polyglutamic acid (γ-PGA)-based glycopolypeptides carrying long/short α2,3/6 sialylated glycans to act inhibitors of the influenza virus. As an alternative design, sialoglycopolypeptides carrying long-spacer linked glycans were engineered by replacement of the *N*-acetyllactosamine (LN) unit by an alkyl chain. The structure−activity relationship of the resulting sialoglycopolypeptides with different glycans in the array has been investigated by in vitro and in vivo infection experiments. The avian viruses specifically bound to glycopolypeptides carrying a short sialoglycan with higher affinity than to a long glycan. In contrast, human viruses, preferentially bound not only to long α2,3/6 sialylated glycan with LN repeats in the receptors, but also to more spacer-linked glycan in which the inner sugar has been replaced by a nonsugar structural unit such as a pentylamido group. Taken together, our results indicate that a spaced tandem/triplet pentylamido repeat is a good mimetic of a tandem/triplet LN repeat. Our strategy provides a facile way to design strong polymeric inhibitors of infection by avian and human influenza viruses.

INTRODUCTION

Influenza viruses infect host cells through the binding of viral hemagglutinins (HAs) to sialoglycoproteins or sialoglycopeptides of the receptors on the host cell surfaces (*1*−*3*). Because the molecular recognition process leads to the adhesion of host cell and virus, molecules having a high affinity for the viral HA act as potent inhibitors of infection by influenza viruses (*4*−*6*). Host cell specificity of the virus is dependent not only on linkage of sialic acids (SAs) to the penultimate galactose, but also on the number of SA residues and the precise nature of the core structure (*7*−*10*). The recognition ability of glycol signals is also known to be greatly enhanced by clustering the sialooligosaccharides on macromolecular scaffolds such as the synthetic glycopolymers (*6, 11*−*16*). The multivalent interactions have been amplified by the so-called glycoside cluster effects (*17*). Various factors are known to influence the affinity and specificity of multivalent binding events including the structure of the individual saccharide residues (*8*−*10*). In this respect, a variety of synthetic glycopolymers carrying multivalent sialooligosaccharides that target HAs have been produced for the influenza virus inhibitors using polyacrylamide (*11, 17*−*22*), poly(acrylacid) (*14, 23*), polystyrene (*12*), and dendrimers (*24*) as polymer backbone. However, synthetic glycopolymers potentially pose several problems for in vivo use, such as low solubility, significant cytotoxicity, and immunogenicity. We have already reported that sialoglycopolypeptides with α- or γ-PGA backbones can be used as a scaffold in the synthesis of multivalent inhibitors of the influenza viruses (*6, 9, 16*). Glycopolypeptides possessing either multivalent SAα2,3Gal or SAα2,6Gal have aided our understanding of human adaptation of the H5N1 influenza virus (*9*). The length of the asialo portion in glycopolypeptides also increased binding affinity to the viral HA in a glycan length-dependent manner (*8*). Recent studies using cocrystal structures with glycan microarrays also showed that human viral HAs specifically bound to long α2,6 sialylated glycans with a length beyond trisaccharide, whereas avian viral HAs bound to short α2,3 sialylated glycans (*25*). These findings indicate that glycan length of the receptors is another determinant of human viral HAs binding to the terminal α2,6 linked sialoside in the core glycan structures.

Thus far in these macromolecular approaches, the use of ligands has been limited to small carbohydrate units containing sialodi- or sialotrisaccharide. Spatial arrangement of the side chains is not usually considered during the design of the ligand. Our strategy of molecular design is to construct an amphiphilic structure, taking into account the contribution of the asialo portion of the glycan chain, by arranging multivalent short or long glycans attached to a polypeptide backbone. We therefore planned to chemoenzymatically synthesize a series of γ-PGA-based sialoglycopolymers carrying glycans or spacers of different lengths in the array, in order to identify the specific SA motifs recognized by the influenza virus. Using these glycopolymers, the structure−activity relationship was elucidated by measurement of the inhibition of infection by avian and human influenza viruses.

EXPERIMENTAL SECTION

Materials. γ-PGA-Na (MW 990 000) from *Bacillus subtilis* was a kind gift from Meiji Food Materia Co. UDP-GlcNAc, UDP-Gal, and CMP-Neu5Ac were gifts from Yamasa Corporation (Chiba, Japan). Bovine milk β1,4-galactosyltransferase (β4GalT), α2,3-(*N*)-sialyltransferase (α2,3SiaT, rat recombinant, *Spodoptera frugiperda*), and α2,6-(*N*)-sialyltransferase (α2,6SiaT, rat recombinant, *S. frugiperda*) were purchased from Calbiochem-Novabiochem (San Diego, CA). β1,3-*N*-Acetylglucosami-

[e] Degree of substitution of sugar derivatives based on DP of g-PGA as 100%. Calculated from ^{1}H NMR data at 25 °C.

nyltransferase (β3GnT) was prepared by our previously described methods (*26*). 5-Trifluoroacetamidopentyl β-lactoside (5-TFAP-β-Lac), 5-TFAP-β-LN, and 5-aminopentyl β-LacNAc (5-AP-β-LN) were synthesized by our previously described methods (*6*). The human and avian influenza virus strains used in this study were propagated and purified as described previously (*2, 27*). Viral hemagglutination units (HAUs) of purified viruses were determined as described previously (*28*). All other reagents were of the highest quality commercially available and were used without further purification.

Enzyme Assay. β3GnT activity was assayed as follows. UDP-GlcNAc (40 mM), LNβ-*p*NP (20 mM), and $MnCl_2$ (16 mM) were dissolved in 150 mM Tris-HCl (pH 6.8) followed by 100 μL of enzyme solution (total vol 200 μL). The reaction was started by addition of β3GnT. At each sample time, 10 μL of the reaction mixture was added to 190 μL of distilled water, followed by immediate boiling for 5 min. After filtration through a 0.45 μm nitrocellulose filter (Millipore, Bedford, MA), the filtrates were analyzed by HPLC using a TSK-gel ODS 80TsQA (4.6 × 250 mm, TOSOH Co.) column. Reaction products were eluted with 10% MeOH containing 0.1% TFA and detected at the absorbance of 300 nm. HPLC was done at 40 °C with a flow rate 1.0 mL/min. One unit of enzyme activity is defined as the amount of enzyme capable of catalyzing the transfer of 1 μmol of GlcNAc per minute.

β4GalT activity was assayed as follows. UDP-Gal (40 mM), GlcNAcβ1,3LNβ-*p*NP (20 mM), and $MnCl_2$ (16 mM) were dissolved in 150 mM Tris-HCl (pH 6.8) followed by 100 μL of enzyme solution (total vol 200 μL). The reaction was initiated by addition of β4GalT. At each sample time, 10 μL of the reaction mixture was added to 190 μL of distilled water, followed by immediate boiling for 5 min. After filtration through a 0.45 μm nitrocellulose filter (Millipore, Bedford, MA), the filtrates were analyzed by HPLC using a TSK-gel ODS 80TsQA (4.6 × 250 mm, TOSOH Co.) column. Reaction products were eluted with 10% MeOH containing 0.1% TFA and detected at the absorbance of 300 nm. HPLC was done at 40 °C with a flow rate 1.0 mL/min. One unit of enzyme activity is defined as the amount of enzyme capable of catalyzing the transfer of 1 μmol of Gal per minute.

HPLC Determination of Neutral Sugar Units in Asialoglycopolypeptides. The artificial asialoglycopolypeptides (0.02 μM, 250 μL) were hydrolyzed with 4 M trifluoroacetic acid (250 μL) at 100 °C for 4 h to release sugar units and the hydrolysates were then freeze-dried. In brief, to dry samples were added water (10 μL) and ethyl 4-aminobenzoate (ABEE) solution (40 μL). Derivatization was carried out at 80 °C for 1 h. The reaction mixture of ABEE derivatization in 10 μL portions was directly injected into a Honenpak C18 column (4.6 × 75 mm) and eluted using 10% CH_3CN containing 0.02% TFA. A JASCO LC-2000 plus HPLC system equipped with an UV-2070 plus UV detector (305 nm), operating isocratically at 1.0 mL/min at a column temperature of 45 °C, was used (Table 2) (*29*).

HPLC Determination of Sialic Acids in Sialoglycopolypeptides. The artificial sialoglycopolypeptides (0.1 μM, 5 μL) were hydrolyzed with 0.05 M HCl (45 μL) at 80 °C for 1 h to release sialic acid units. Next, the samples were added to a 1,2-diamino-4,5-methylenedioxybenzene (DMB) solution (200 μL). Derivatization was carried out at 50 °C for 2.5 h in the dark. All labeled compounds were kept at 4 °C in the dark to prevent degradation. The reaction mixture of DMB derivatization in 10 μL portions was directly injected into a Shodex ODP2 HP-4E column (4.6 × 250 mm, Shodex) and eluted with water/methanol/acetonitrile (84:7:9, v/v/v). A JASCO LC-2000 plus HPLC system equipped with an FP-2020 plus fluorescence detector (excitation, 373 nm; emission, 448 nm), operating isocratically at 0.5 mL/min at a column temperature of 40 °C, was used (Table 2) (*30*).

Analytical Methods. HPLC analysis was carried out using an Asahipak NH2-P50 4-E column (4.6 × 250 mm, Shodex) with a JASCO Intelligent system liquid chromatograph and detection at 210 nm. The bound material was eluted with 80% CH_3CN at a flow rate of 1.0 mL/min at 40 °C. FAB-mass analysis was carried out in positive ion mode using a JEOL JMS DX-303HF mass spectrometer coupled to a JEOL DA-800 mass data system. An accelerating voltage of 10 kV and a mass resolution of 1000 were employed. A sample in distilled water (1 μL) was loaded onto a probe tip and mixed with glycerol (1 μL) as a matrix. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-LA 500 spectrometer at 25 °C. Chemical shifts are expressed in δ relative to sodium 3-(trimethylsilyl) propionate as an external standard. The amount of protein was determined using a Bio-Rad protein assay kit.

Synthesis of LN-Repeating Tetra- And Hexasaccharide Glycosides. 5-Trifluoroacetamidopentyl β-lacto-*N*-neotetraoside (5-TFAP-β-LNnT, **3**) was synthesized by the alternative addition of β1−3 linked GlcNAc and β1−4 linked Gal to 5-TFAP-β-Lac (**1**), using two kinds of glycosyltransferase. Compound **1** (300 mg, 0.56 mmol) and UDP-GlcNAc (725 mg, 1.11 mmol) were dissolved in 150 mM Tris-HCl buffer pH 6.8 (50.3 mL) containing $MnCl_2$ (88.2 mg) and 1% (w/v) NaN_3 (0.56 mL), followed by addition of 540 mU (4.8 mL) of partially purified β3GnT preparation from the cell culture supernatant. The mixture was incubated for 168 h at 37 °C, and the reaction was terminated by boiling for 5 min. UDP-Gal (679 mg, 1.11 mmol) was dissolved the mixture, followed by addition of 4 U (0.2 mL) of β4GalT from bovine milk. The mixture was incubated for 124 h at 37 °C, and the reaction was terminated by boiling for 5 min. The precipitate was removed by centrifugation (8000 *g*, 20 min) and the supernatant was loaded onto a ODS column (3.5 × 60 cm) equilibrated with 10% MeOH at flow rate of 2.0 mL/min. After washing the column with 1500 mL of 10% MeOH, absorbed portion was eluted with 20% MeOH and a fraction size of 25 mL/tube. The eluate was monitored by measuring the absorbance at 210 nm using a spectrometer. An aliquot from fractions 14−28 was then concentrated and lyophilized: compound **3** was obtained in a total yield of 90% (451 mg) based on the acceptor substrate **1**. $[\alpha]_D^{30}$ + 7.0° (*c*

Synthesis of More Spaced Disaccharide Glycosides. Compound **9** (180 mg, 0.39 mmol), HOBT (208 mg, 1.54 mmol) and 6-trifluoroacetamidohexanoic acid (350 mg, 1.54 mmol) were dissolved in DMF (7.0 mL). Then, DIPCD (240 μL, 1.54 mmol) was added to the solution with continuous stirring for 24 h at room temperature. After the reaction mixture was concentrated to a solid, it was dissolved in 5 mL of $CHCl_3$/CH_3OH/H_2O = 7.5/2.5/0.35 and then loaded onto a silica gel 60N column (2.0 × 30 cm). The column was developed with the same solvent at a flow rate of 10 mL/min and a fraction size of 20 mL/tube. Fractions 26−66 were pooled and concentrated: 5-[5′-(trifluoroacetamido) pentanecarboxamido]pentyl β-LN (**7**) was obtained in a total yield of 59% (154 mg). $[\alpha]_D^{30}$−2.9° (*c* 0.1, water). FAB-mass: *m/z* 678 $[M + H]^+$ (matrix: glycerol). ^{1}H NMR (D_2O, 500 MHz): δ 4.52 (d, 1H, $J_{1,2}$ 7.0 Hz, H-1), 4.47 (d, 1H, $J_{1′2′}$ 8.0 Hz, H-1′), 3.98 (dd, 1H, $J_{5,6b}$ 1.2, $J_{6a,6b}$ 12.2 Hz, H-6b), 3.93 (1H, H-4′), 3.90 (m, 1H, H-αb), 3.83 (dd, 1H, $J_{5,6a}$ 4.6, $J_{6a,6b}$ 12.2 Hz, H-6a), 3.78−3.75 (2H, H-6′a, H-6′b), 3.73−3.70 (4H, H-5′, H-4, H-3, H-2), 3.67 (dd, 1H, $J_{2′,3′}$ 10, $J_{3′,4′}$ 4.9 Hz, H-3′), 3.61 (m, 1H, H-αa), 3.60 (1H, H-5), 3.54 (dd, 1H, $J_{1′,2′}$ 8.0, $J_{2′,3′}$ 10 Hz, H-2′), 3.32 (t, 2H, H-ε′), 3.17 (t, 2H, H-ε), 2.24 (t, 2H, H-α′), 2.03 (s, 3H, $C\underline{H}_3CONH—$), 1.64−1.54 (6H, H-β′, H-β, H-ω′), 1.51 (m, 2H, H-ω), 1.32 (4H, H-γ′, H-γ). ^{13}C NMR (D_2O, 500 MHz): δ 179.5 (-$\underline{C}ONH—$), 177.2 ($CH_3\underline{C}ONH—$), 161.8 ($CF_3\underline{C}ONH—$), 117.6 ($\underline{C}F_3CONH—$), 105.7 (C-1′), 103.8 (C-1), 81.3 (C-4), 78.2 (C-5′), 77.6 (C-5), 75.32 (C-3′), 75.28 (C-3), 73.8 (C-2′), 73.1 (C-α), 71.4 (C-4′), 63.8 (C-6′), 62.9 (C-6), 57.9 (C-2), 42.4 (C-ε′), 42.0 (C-ε), 38.4 (C-α′), 31.0 (C-β), 30.7 (C-ω), 30.2 (C-ω′), 28.1 (C-γ′), 27.8 (C-β′), 25.3 (C-γ), 25.0 ($\underline{C}H_3CONH—$). 5-{5′-[5″-(Trifluoroacetamido) pentanecarboxamido]pentanecarboxamido}pentyl β-LN (**8**) was synthesized by the addition of spacer parts to **7** in a similar manner. Compound **8** was obtained in a total yield of 64% (260 mg). $[\alpha]_D^{30}$+8.3° (*c* 0.1, water). FAB-mass: *m/z* 791 $[M + H]^+$ (matrix: glycerol). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 4.40 (d, 1H, $J_{1,2}$ 7.9 Hz, H-1), 4.38 (d, 1H, $J_{1′2′}$ 7.3 Hz, H-1′), 3.87 (dd, 1H, $J_{5,6b}$ 2.5, $J_{6a,6b}$ 12.5 Hz, H-6b), 3.84−3.81 (3H, H-αb, H-4′, H-6a), 3.74 (dd, 1H, $J_{5′,6′b}$ 7.7, $J_{6′a,6′b}$ 11.7 Hz, H-6′b), 3.67 (dd, 1H, $J_{5′,6′a}$ 4.3, $J_{6′a,6′b}$ 11.7 Hz, H-6′a), 3.64−3.59 (4H, H-5′, H-4, H-3, H-2), 3.54−3.48 (2H, H-3′, H-2′), 3.46 (m, 1H, H-αa), 3.41 (m, 1H, H-5), 3.26 (t, 2H, H-ε″), 3.16−3.08 (4H, H-ε′, H-ε), 2.16 (4H, H-α″, H-α′), 1.96 (s, 3H, $C\underline{H}_3CONH—$), 1.63−1.52 (8H, H-β″, H-β′, H-β, H-ω″), 1.46 (4H, H-ω′, H-ω), 1.31 (6H, H-γ″, H-γ′, H-γ). ^{13}C NMR ($CDCl_3$, 500 MHz): δ 175.7 (-$\underline{C}ONH′$-), 175.6 (-$\underline{C}ONH—$), 173.5 ($CH_3\underline{C}ONH—$), 158.8 ($CF_3\underline{C}ONH—$), 115.6 ($\underline{C}F_3CONH—$), 104.1 (C-1′), 102.0 (C-1), 79.9 (C-4), 76.3 (C-5′), 75.6 (C-5), 73.8 (C-3′), 73.3 (C-3), 71.9 (C-2′), 70.4 (C-α), 69.5 (C-4′), 61.9 (C-6′), 61.2 (C-6), 56.0 (C-2), 40.2 (C-ε″), 39.9 (C-ε), 39.8 (C-ε′), 36.63 (C-α′), 36.55 (C-α″), 29.5 (C-β), 29.4 (C-ω, C-ω′), 28.8 (C-ω″), 26.9 (C-γ″), 26.7 (C-β″), 26.1 (C-γ′), 25.9 (C-β′), 23.8 (C-γ), 23.0 ($\underline{C}H_3CONH—$).

Synthesis of Various Aminoalkyl Di-, Tetra- And Hexasaccharide Glycosides. 5-AP-β-LN **9**, 5-AP-β-LNnT **10**, 5-AP-β-$(LN)_2$ **11**, 5-AP-β-(LNβ1,3LNnT) **12**, 5-AP-β-$(LN)_3$ **13**, 5-(5′-aminopentanecarboxamido)pentyl β-LN **14**, and 5-[5′-(5″-aminopentanecarboxamido)pentanecarboxamido]pentyl β-LN **15** were synthesized from **2**−**8** by alkaline hydrolysis according to our previously reported method (*6*).

Synthesis of Asialoglycopolypeptides with γ-PGA Backbones. The amino functions of oligosaccharide glycosides (**9**−**15**) were coupled with the carboxyl group of γ-PGA by a condensation reaction. DSs of the substituted residues in glycopolypeptide were adjusted to 31−49% (Table 1). Poly[LNβ-$O(CH_2)_5NH—$/γ-PGA] **16**, poly[LNnTβ-$O(CH_2)_5NH—$/γ-PGA] **17**, poly[$(LN)_2$β-$O(CH_2)_5NH—$/γ-PGA] **18**, poly[LNβ1,3LNnTβ-$O(CH_2)_5NH—$/γ-PGA] **19**, poly[$(LN)_3$β-$O(CH_2)_5NH—$/γ-PGA] **20**, poly[LNβ-$O(CH_2)_5NHCO(CH_2)_5NH—$/γ-PGA] **21**, and poly{LNβ-$O[(CH_2)_5NHCO]_2(CH_2)_5NH—$/γ-PGA} **22** were prepared from **9**−**15**, respectively, according to our previously reported method (*6*).

Synthesis of Sialoglycopolypeptides with γ-PGA Backbones. α2,3-Sialoglycopolymers **23**−**29** were synthesized from **16**−**22**, respectively, using rat recombinant α2,3-(*N*)-sialyltransferase. In addition, α2,6-sialoglycopolymers **30**−**36** were also synthesized from **16**−**22**, respectively, using rat recombinant α2,6-(*N*)-sialyltransferase according to our previously reported method (*6*).

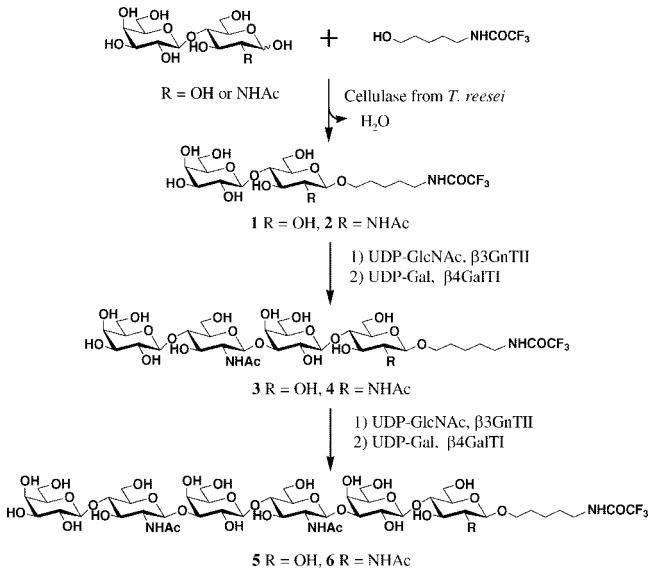
Focus-Forming Assay. Virus titers were determined by focus-forming assay using Madine-Darby canine kidney (MDCK) cells. MDCK cells were seeded at 1.5 × 10^4 cell/well in 96-well plates and cultured in MEM supplemented with 10% fetal bovine serum at 37 °C. After removal of medium, virus solutions were serially diluted with serum-free DMEM and inoculated onto the plates. The cells were then incubated for 30 min at 34.5 °C. After removing the virus solution, overlay medium (DMEM containing 0.5% (w/v) tragacanth gum (Wako, Osaka) and 0.2% (w/v) bovine serum albumin) was added, and the plates were incubated at 34.5 °C for 20−24 h. The cells were then fixed with methanol. Infectious foci were detected with mouse antinucleoprotein (NP) monoclonal antibody (clone H16L-10−4R55, ATCC) as the primary antibody and HRP-conjugated goat antimouse immunoglobulin as the secondary antibody. Detected foci were counted under a light microscope. Virus infectivity was determined as focus-forming units (FFU).

Inhibition of Influenza Virus Infection by Glycopolypeptides. Influenza viruses were mixed on ice with or without glycopolypeptides at the indicated concentrations. The virus-glycopolypeptide mixtures (50 μL) were then inoculated for 30 min at 34.5 °C onto MDCK cells grown in 96-well plates. After washing three times with serum-free DMEM, overlay medium was added and plates were incubated at 34.5 °C for 20−24 h. Virus infectivity was then determined by focus-forming assay as described above. The optimal titer of inoculated virus was predetermined such that more than 80−100 foci appeared per well. Each experiment was performed in triplicate wells. Significant analysis of means of focus numbers between control and treatment was performed by *t* test.

Solid-Phase Binding Assay. The assay measuring direct binding activity of influenza virus to glycopolymers was performed by our method (*9, 31*). Glycopolymers were briefly immobilized on polystyrene Universal-Bind microplates (Corning) under an ultraviolet irradiation method. After blocking with PBS containing 2% bovine serum albumin, the plates were incubated in solutions containing influenza virus in PBS (2^7 HAU of A/WSN/33) at 4 °C overnight. After five washes with ice-cold PBS, the plates were incubated in a substrate solution containing 40 μM of 2′-(4-methylumbelliferyl)-α-D-*N*-acetylneuraminic acid in PBS at 37 °C for 1 h. The reactions were terminated by the addition of a 500 mM carbonate buffer (pH 10.2). Fluorescence was measured at 355 nm (excitation) and 460 nm (emission). The direct virus-binding activity was determined by the quantity of 4-methylumbelliferon released by viral neuraminidases.

Influenza Virus Infection in Mice. Influenza A/WSN/33 virus was used in this study to evaluate antiviral effects of

Scheme 1. Enzymatic Synthesis of LN-Repeating Tetra- And Hexasaccharide Glycosides



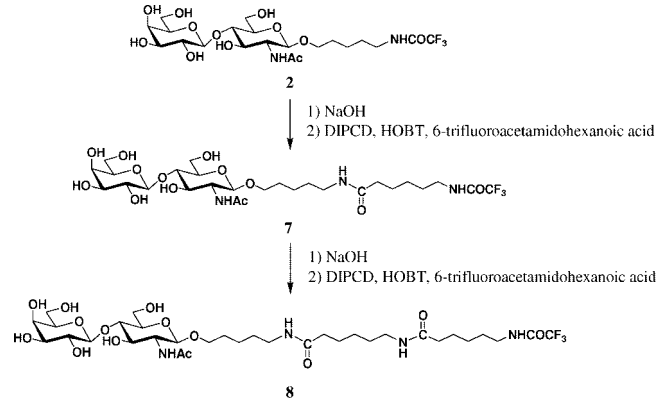
synthetic glycopolymers as described previously (*31*). Briefly, groups of six female BALB/c mice (five weeks old, 14−18 g) were inoculated intranasally with 25 μL of premixes containing viral suspension (2.0×10^4 pfu/mL) and glycopolymers at the indicated concentrations. Control was treated with 25 μL of viral suspension and asialo-glycopolymers. Mice were observed for 13 days after infection. Anti-influenza efficacy was determined by prevention of loss of body weight and protection against lethality caused by influenza virus infection. The significance of differences in the ratios of survival mice between groups treated with asialo- and α2,3-sialoglycopolymers was analyzed by Log-rank test (*32*) on Kaplan−Meier survival curves (*33*). Animal care and experiments were performed in accordance with the guidelines for the care and use of laboratory animals of the Shizuoka University.

Hemagglutination Inhibition Assay. The hemagglutination inhibition (HI) assay was carried out using 96-well microtiter plates as described previously (*22*). Phosphate-buffered saline (PBS, pH 6.5) was used as a dilution buffer. Virus suspension (2^2 HA units in 0.025 mL of PBS) was added to each well containing the synthetic glycopolypeptides (200 to 0.024 nM) in a 2-fold serial dilution in dilution buffer. After incubation for 1 h at 4 °C, 0.05 mL of 0.6% (v/v) guinea pig suspension erythrocytes was added to the plates, and allowed to settle for 2 h at 4 °C. The maximum dilution of the samples showing complete inhibition of hemagglutination was defined as the HI titer.

RESULTS

Convenient Synthetic Route to a New Type of Artificial Glycopolymer. *Synthesis of Oligosaccharide Glycosides Carrying LN Repeats.* We have recently reported that a condensation reaction between lactose (Lac) or LN and 5-trifluoroacetamido-1-pentanol can be catalyzed by cellulase from *Trichoderma reesei* to obtain 5-TFAP-β-Lac (**1**) and 5-TFAP-β-LN (**2**), respectively (**6**). O-Linked oligosaccharide glycosides carrying LN repeats were then derived from the resulting products (Scheme 1). Thus, consecutive additions of β1,3 linked GlcNAc and β1,4 linked Gal to respective **1** and **2** acceptors led to the synthesis of tetrasaccharide glycosides **3** and **4** carrying LNnT and tandem LN repeats, respectively, by using either β3GnT or β4GalTI. GlcNAc and Gal residues can then be added to the resulting glycosides **3** and **4** in a similar way to form hexasaccharide glycosides **5** and **6** carrying LN repeats. The target products **3**−**6** were obtained in high yields of 90−75%, based on the acceptors.

Scheme 2. Synthesis of More Spaced Disaccharide Glycosides

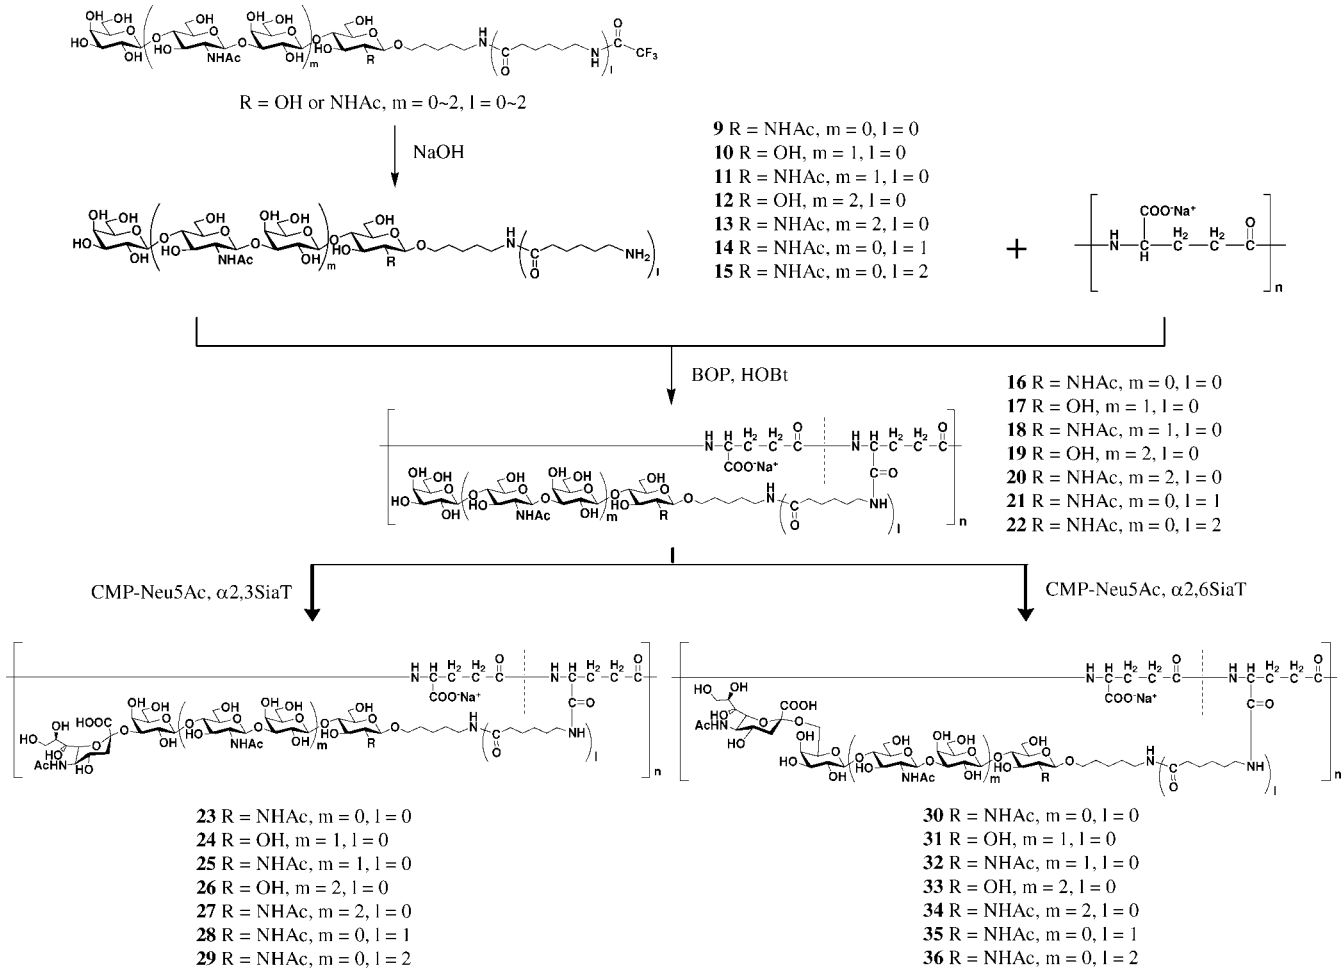


Synthesis of More Spaced Disaccharide Glycosides. The aglycon trifluoroacetamido group of **2** was deacylated to 5-aminopentyl β-LN (5-AP-β-LN) **9** by hydrolysis in an alkaline solution as shown in Scheme 2. The resulting amino function was coupled to 6-trifluoroacetamidohexanoic acid with DIPCD and HOBt in DMF to produce **7** with tandem alkylamido repeats in the aglycon moiety. The resulting glycoside **7** was then subjected to the condensation reaction to produce **8** with triplet alkylamido repeats. The longer spaced disaccharide glycosides **7** and **8** were easily purified with a silica gel column, in yields of 59% and 64% based on the corresponding glycosides, respectively.

Synthesis of Asialoglycopolypeptides. The resulting oligosaccharide glycosides with different glycans in the array were similarly deacylated to the corresponding amino group by alkali treatment as mentioned above (Scheme 3). The amino function of the resulting oligosaccharide glycosides **9**−**15** was reacted with the carboxyl groups of γ-PGA in the presence of the condensation reagents BOP and HOBt, as described earlier. In the synthesis, γ-PGA of 990 kDa was used as the polypeptide base of the glycopolymers. The reaction solution was applied to a column of Sephadex G-25 M PD-10 to separate the glycosylated γ-PGA from the low molecular weight reactants. The degree of substitution (DS) in mole fraction of the substituted residues in the asialoglycopolypeptides **16**−**22** was calculated by two methods: ^{1}H NMR and chemical analyses. The ^{1}H NMR results were based on the relative intensities of signals due to peptide methylene protons and those due to spacer-linked methylene protons in the aglycon. The chemical analysis procedure used the method of Yasuno et al. (*29*). The DS in those asialoglycopolypeptides was limited to the extent of 30−50% by controlling the coupling conditions of the aminated spacer-linked glycosides with γ-PGAs (Tables 1 and 2).

Synthesis of Sialoglycopolypeptides. A series of asialoglycopolypeptides with different glycans in the array were sialylated to **23**−**29** carrying SAα2,3Gal and **30**−**36** carrying SAα2,6Gal by α2,3- and α2,6-SiaTs, respectively (Scheme 3). After separation through a column of Sephadex G-25 M PD-10, the target glycopolypeptides were obtained. The structures of the synthesized glycopolymers were confirmed by ^{1}H and ^{13}C NMR analyses with reference to our previous report (*6*). The DS of sialyl sugar derivatives in the sialoglycopolypeptides was determined by ^{1}H NMR and chemical analyses, such as those of asialoglycopolypeptides mentioned above. The structures of sialoglycopolypeptides **27** and **34** as representative examples were analyzed from the corresponding ^{1}H NMR spectrum. In the ^{1}H NMR spectrum of **27**, characteristic signals at δ 2.76 (dd, 1H, $J_{3''''',\,3''''_{ax}}$, $_{3''''_{eq}}$ 11.6,

Scheme 3[a]



[a] (1) Chemoenzymatic synthesis of LN-repeating and long-spacer linked aminoalkyl oligosaccharide glycosides, (2) coupling of the resulting glycoside with γ-PGA, and (3) sialylation to highly water-soluble glycopolypeptides carrying clustered identical sialooligosaccharide segments.

$J_{3''''eq,\ 4''''}$ 3.7 Hz, H-3′′′′′eq) and δ 1.81 (t, 1H, $J_{3''''ax,\ 3''''eq}$ 11.6, $J_{3''''ax,\ 4''''}$ 11.6 Hz, H-3′′′′′ax) were assigned to the H-3′′′′′ proton. In **34**, δ 2.67 (dd, 1H, $J_{3''''ax,\ 3''''eq}$ 12.2, $J_{3''''eq,\ 4''''}$ 4.3 Hz, H-3′′′′′eq) and δ 1.73 (t, 1H, $J_{3''''ax,\ 3''''eq}$ 12.2, $J_{3''''ax,\ 4''''}$ 12.2 Hz, H-3′′′′′ax) were assigned to the H-3′′′′′ proton. It was possible to evaluate the extent of sialylation from the integration data of the resulting proton signals (Table 2). The properties of the synthesized glycopolypeptides are summarized in Table 2. The chemical analysis was performed using the method of Sato et al. (*30*). The degree of substitution of neutral sugar derivatives (NS) and sialyl sugar derivatives (Sia) was based on the DP of γ-PGA, which was arbitrarily given a value of 100% (Table 2). In the ^{13}C NMR spectra of **27** and **34**, the respective C-3′′′′ and C-6′′′′ signals were distinguished by a downfield position with chemical shifts at δ 78.0 and δ 66.2. These data indicate that the terminal Gal residues of the sugar chains are regiospecifically sialylated in the α2−3 and α2−6 linkages.

Interaction of Synthetic Glycopolypeptides with Influenza Viruses. *Inhibition of Influenza Virus Infection by Glycopolypeptides.* To investigate the inhibitory effects of glycopolypeptides carrying different length glycans in the array on infection of MDCK cells by influenza virus, virus and test agents were inoculated concurrently. The inhibitory activity was determined by focus-forming assay. This experiment was performed to determine whether glycopolymers act directly on viruses in the early stages of viral infection, particularly adsorption. The results are summarized in Table 3. Infection of the avian strains, A/Duck/HongKong/313/4/78 (H5N3), A/Duck/HongKong/47/5/76 (H3N2), and A/Duck/HongKong/47/5/76 (H7N2) were inhibited by sialoglycopolymers carrying the α2,3 sialylated glycan, but not by those carrying the α2,6 sialylated glycan. Inhibition by **23**, **25**, and **27** decreased in a glycan length-dependent manner. Compound **23**, carrying a short glycan of trisaccharide, was shown to be the most effective inhibitor among the glycopolymers tested. The polymer showed 4−10-fold higher inhibitory activity than **27** carrying triplet LN repeats. The virus appears to recognize a short α2,3 sialylated glycan in preference to the long glycan.

In contrast, the human virus, A/WSN/33 (H1N1) was inhibited by glycopolymers carrying long α2,3/6 sialylated glycan with LN repeats. The inhibition clearly occurred in a glycan length-dependent manner. Viral infection was strongly inhibited by **27** and **34** carrying long glycans at a very low concentration (IC_{50} 0.06 pM). Inhibition by **27** displayed 13×10^6-fold higher activity compared to that of **23**, which carries a short glycan. In this case, the sugar elongation of the inner glycan for **27** resulted in a remarkable increase of inhibition activity to enhance the virus binding. IC_{50} of **27** and **34** in the present study is 7.5×10^5-fold stronger than α-PGA-based glycopolypeptide carrying the same LN repeat (*31*). The human virus, A/Aichi/2/68 (H3N2), which has high susceptibility to compounds **32** and **34** (IC_{50} 0.1−0.2 pM), also showed a similar pattern of inhibitory effect. Taken together, our results indicate that the length of the sialylated glycan critically influences binding to the human virus, which is favored by long glycan

units such as LN repeats. As controls, asialoglycopolymers did not affect the virus binding.

Direct Binding Activity of Influenza Virus to Glycopolypeptides. For further investigation, we directly determined the binding activity of glycopolymers to human virus by a solid-phase virus binding assay. We have recently established a direct binding assay with artificial glycopolymers for human and avian influenza viruses (*9*, *31*). In this study, we applied the assay for determination of direct binding dynamics of artificial glycopolymers carrying long glycan units such as LN repeats to human virus, A/WSN/33.

The binding signals were detected when α2,3/6-sialoglycopolymers, but not asialoglycopolymers (data not shown), were used as ligands. As the concentration of sialoglycopolymers with LN repeats increased, the signals from human virus bound to glycopolymers increase in a dose-dependent manner regardless of the core carbohydrate structure. The inhibition by α2,3-sialopolymers **23**, **25**, and **27** carrying single, tandem, and triplet LN repeats increased in a glycan length-dependent manner (Figure 1A). Also, the α2,6-sialopolymers **30**, **32**, and **34** with different LN repeats showed a similar pattern of inhibitory effect as those of the α2,3-sialopolymers (Figure 1B). These results were comparable with those obtained by in vitro infection experiments. Taken together, the human viruses bind exclusively to sialoglycopolymers carrying elongated core carbohydrates with higher affinity.

Protection of Mice by Intranasal Administration of Glycopolypeptides from Death Induced by A/WSN/33 Infection. We examined the protective effects of sialoglycopolymers (**23** and **27**) with single and triplet LN repeats in a murine model of respiratory tract viral infection with A/WSN/33 strain. Asialoglycopolymer (**20**) was used as control to examine influenza infection. Groups of mice were administered glycopolymers at five weeks old. Compound **27** with triplet LN repeats, administered at a dose of 3 nmol/kg corresponding to approximately 15.6 mg/kg, reduced mortality below 0% on day 13 postinfection (Figure 2A). In contrast, compound **23** with a single LN, administered at 3 nmol/kg did not significantly affect lethality in mice induced by infection with A/WSN/33 as compared to administration of asialoglycopolymer **20** (Figure 2A). In mice treated with compound **27** with triplet LN repeat, but neither compound **23** with a single LN or asialoglycopolymer **20** at a dose of 3 nmol/kg, we also observed improvement in the weight gain of mice surviving to day 13 postinfection (Figure 2B). Thus, sialoglycopolymers with an elongated LN chain as core structure showed a significant protective effect in this murine model of influenza virus infection. The protective effect of this glycopolymer is comparable to that observed in vitro (Table 3). Glycopolymer-related toxicity was not observed in any of the groups examined.

Hemagglutinin Inhibition Assay of the Glycopolypeptides Carrying Spacer-Linked Alkylamido Repeats as Sugar Mimetics. Various substances carrying sialooligosaccharide glycosides are known to inhibit hemagglutination by binding to viral HA (*6*). We tested the inhibitory effect of the glycopolypeptides with different glycans and spacers in the array on hemagglutination using human and avian influenza viruses. The hemagglutination inhibition activity toward glycopolypeptides showed a distinct difference between the avian and human strains as in Table 4. The avian viruses reacted with **23**, **25**, and **27** carrying α2,3 sialylated glycans (Table 4A and Figure 3A). Inhibition by the sialopolymers tended to decrease in a glycan length-dependent manner. Furthermore, we prepared different length spacer linked polymers **28**, **29**, **35**, and **36** carrying a trisaccharide α2,3/6 motif (SAα2,3/6LN) in order to elucidate whether the inner sugar should be replaced by a nonsugar structural unit, such as an alkylamido group. The avian virus A/Duck/HongKong/313/4/78 was not greatly affected to inhibition by replacement of alkylamido group (**28** and **29**) by sugar unit (the corresponding **25** and **27**). Thus, the α2,3-sialoglycopolypeptides carrying tandem and triplet alkylamido repeats showed a similar pattern of inhibitory effect to those of the α2,3-

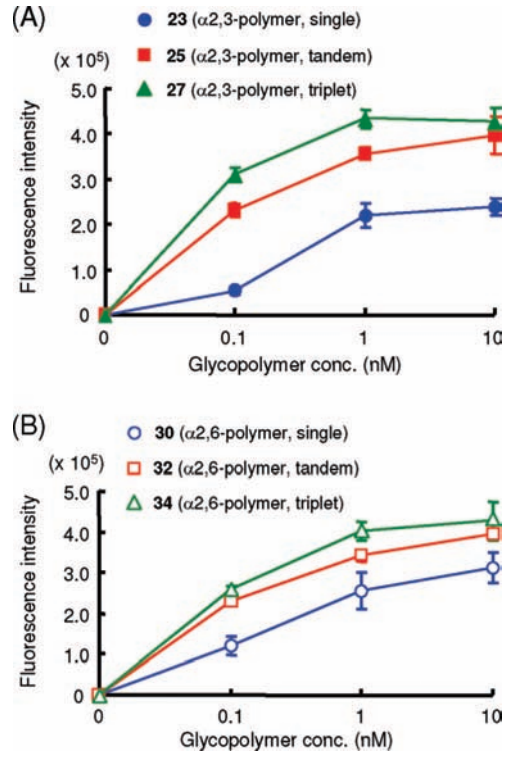

Figure 1. The direct binding activity of human influenza virus, A/WSN/33 (H1N1), to glycopolypeptides carrying a single, tandem, or triplet LN-repeating glycoside was determined by our method (*9*, *31*). (A) SAα2,3-glycopolymers, (B) SAα2,6-glycopolymers.

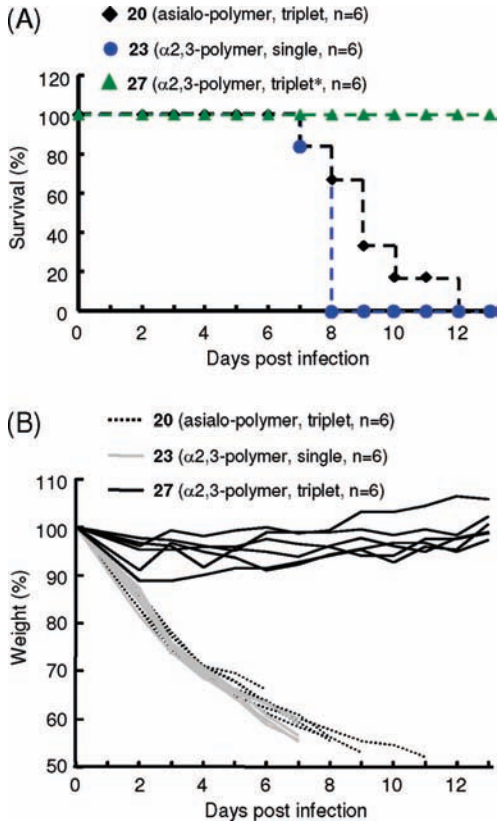

Figure 2. Effect of glycopolymer influenza virus (AWSN/33) infection in mice was performed as described in the Experimental Section. Graph (A) indicates Kaplan−Meier survival curves (*P < 0.01, Log-rank test). Mice were intranasally inoculated with viral suspension and asialo- (**20**, triplet) or SAα2,3- (**23**, single; and **27**, triplet) glycopolymers at a dose of 3 nmol/kg. Graph (B) shows body weight dynamics of mice.

sialoglycopolypeptides carrying tandem and triplet LN repeats (Table 4B and Figure 3A).

In contrast, the human viruses preferentially bound not only to long α2,3/6 sialylated glycan **27** (**26**) and **34** (**33**) with LN repeats in the receptors, but also to more spacer-linked glycan (Table 4A). For the human virus, A/Aichi/2/68, inhibition by α2,6-sialopolymers **30**, **31**, and **33** carrying a single LN, LNnT, and LN-LNnT unit increased in a glycan length-dependent manner (Figure 3B). This result was consistent with in vitro and in vivo infection experiments, suggesting that enhancement of the binding affinity of glycopolymers with viral HA is accompanied with the extension of LN repeats as the core structure. Furthermore, inhibition by the human virus, A/Aichi/2/68, was also strongly inhibited by α2,6-sialopolymers **35** (IC_{50} 0.73 μM) and **36** (IC_{50} 1.5 μM) carrying tandem and triplet alkylamido repeats with 4−8-fold higher affinity compared to **30** carrying a single alkylamido spacer (Table 4B). The inhibitory activity of **35** and **36** gave somewhat similar values to that of **31** and **33** carrying tandem and triplet LN repeats (Figure 3B). It indicates that a spaced tandem/triplet alkylamido repeat is a good mimetic of a tandem/triplet LN repeat. Indeed, **35** and **36** displayed 21−43-fold higher affinities for the viral hemagglutinins relative to the control fetuin (IC_{50} 31.5 μM), which binds both avian and human types of influenza virus due to the presence of two different SA linkages, α2,3 and α2,6. As controls, asialoglycopolymers did not affect influenza virus-mediated hemagglutination (data not shown).

DISCUSSION

The binding specificity of influenza viral HA involves both recognition of the SA linkages as well as the core glycan sequence (*8, 9, 25, 34, 35*). We therefore designed a series of sialoglycopolypeptides to act as potential polymeric inhibitors of infection by avian and human influenza viruses in order to analyze the structure−activity relationship on the viral HA. Each of these compounds comprised three parts: glycan, spaced-linker, and polypeptide backbone. Here, we propose a convenient synthesis of asialo-type polymers with LN repeats starting LN or Lac. Schemes 1−3 represent the pathway via the following three steps: (1) enzymatic and chemical glycosylations of the respective spaced-disaccharide (LN/Lac) glycosides; (2) enzymatic sugar elongation of the LN unit to the resulting disaccharide glycosides by consecutive use of β3GnT and β4GalT to produce tetra- and hexasaccharide glycosides with tandem and triplet LN repeats; (3) coupling of the resulting glycoside to γ-PGA. High molecular-weight γ-PGA was used as a backbone for each glycopolymer. As an alternative design, the resulting disaccharide glycosides were converted to long spacer-linked disaccharide glycosides with tandem and triplet alkylamido repeats by consecutive coupling reactions. These units were then coupled to γ-PGA. The DS (%) of asialoglycan in the resulting glycopolypeptides was adjusted to a proportion of around 40% by controlling the coupling reaction (Table 1). Finally, a series of asialoglycopolypeptides were sialylated to obtain glycopolypeptides carrying α2,3/6 sialylated glycans in the array by the use of α2,3- and α2,6-SiaTs. We have already reported that γ-PGA-based glycopolypeptide carrying a single LN unit can be used as an acceptor of a CMP-Neu5Ac donor by utilizing rat recombinant α2,3/6-SiaTs (*6*). This method was applicable to the sialylation of the present asialoglycopolypeptides. The rat recombinant α2,3/6-SiaTs regiospecifically catalyzed sialylation to the terminal Gal residue in the short asialoglycan as well as the Gal in the long asialoglycan, such as LN repeats (*36*). As a result, sialylation of the asialo-portion of the glycopolymers was almost quantitative at around 40%, whose proportion is based on the optimum result on inhibition of viral infection (Table 2).

To date, infections by influenza viruses have been successively inhibited by sialoglycopolymers carrying short glycans, such as sialyllactose and sialyl LN, no matter how short the glycan chain (*12*). However, recent studies have demonstrated that the length of the glycan beyond a trisaccharide critically influences viral HA binding contacts (*9, 25, 34*). In the present study, the contribution of the asialo portion in the sugar chains was examined by in vitro or in vivo infection experiments, solid-phase binding assay, and hemagglutination inhibition assay using glycopolypeptides carrying different lengths of glycan or spacer-linked glycan in the array. Five strains of avian and human influenza viruses were used as models for studies aimed at identifying the HA glycan binding specificity. First, the in vitro infection experiments (focus-forming assay) examined that artificial glycopolypeptide effectively inhibited cellular infection by avian and human strains (Table 3). The avian viruses specifically recognized a short α2,3 sialylated glycan to an LN/Lac motif in a trisaccharide. In addition, the virus did not bind to the terminal SA-linked α2,6 of the LN/Lac motif. In contrast to this result, human viruses preferentially bound to a long α2,3/6 sialylated glycan with LN repeats that are at least pentasaccharide in length. These results were further supported by solid-phase binding assays that elongation of core carbohydrate portion markedly enhances binding affinity of α2,3/6-sialopolymers with the human viral HA (Figure 1). A possible explanation could lie with the difference in the conformation of the terminal trisaccharides resulting from sialic acid linkage in the cocrystal structures (*25, 34*). Chandrasekaran et al. have proposed that the cone-like and umbrella-like topologies are governed by conformation of

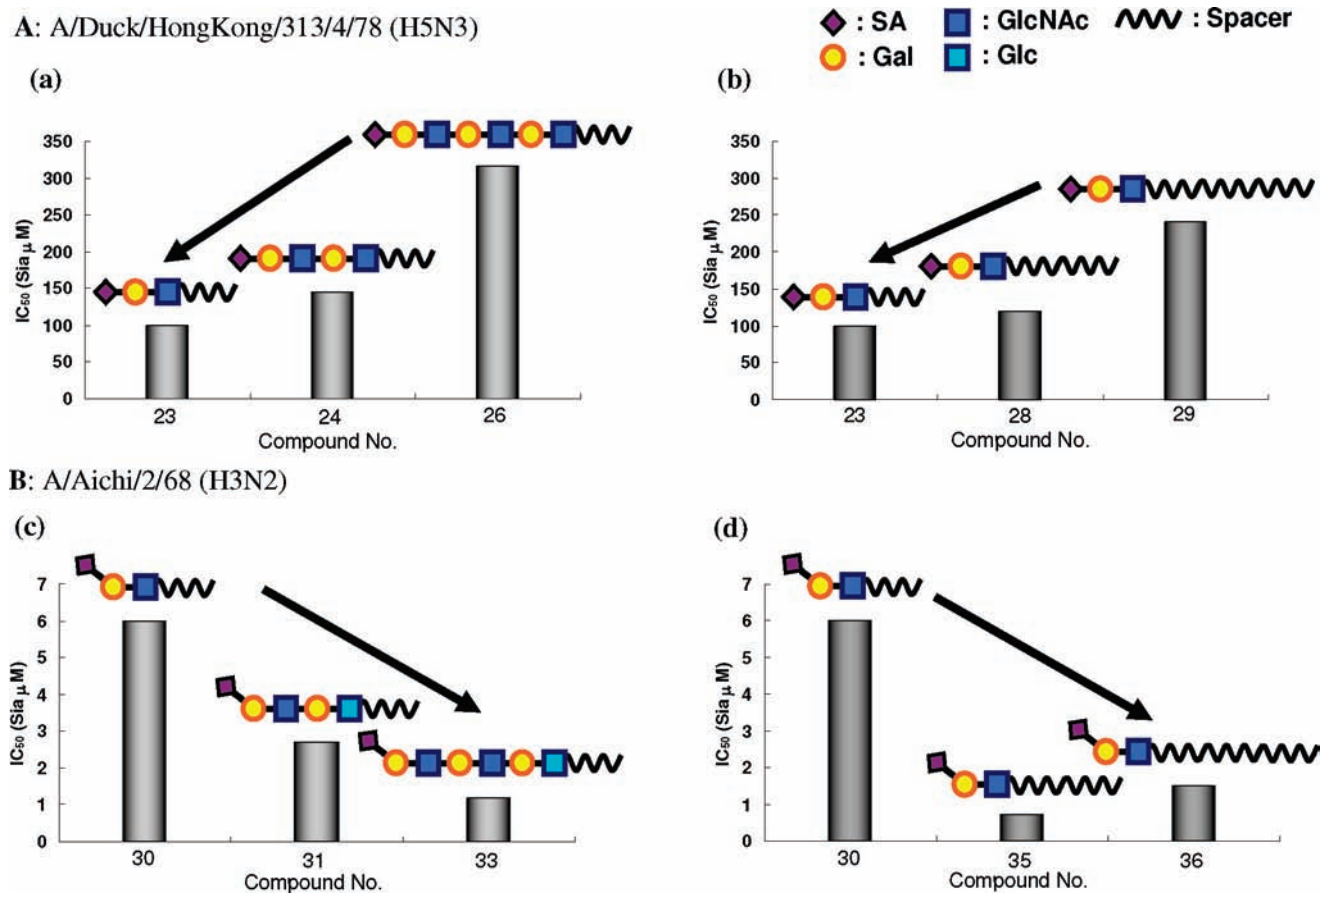

Figure 3. Inhibitory effects of glycopolypeptides with different glycans (**a** and **c**) and spacers (**b** and **d**) on hemagglutination using two strains of influenza viruses: (**A**) Avian strain A/Duck/HongKong/313/4/78 (H5N3) and (**B**) human strain A/Aichi/2/68 (H3N2). (**A**) **a** and **b**: SAα2,3-polymer **23** carrying a short glycan and spacer, was shown to be the most effective inhibitor. (**B**) **c**: Inhibition by SAα2,6-polymers **30**, **31**, and **33** carrying single LN, LNnT, and LN-LNnT units increased in a glycan length-dependent manner. **d**: Inhibition by SAα2,6-polymers **30**, **35**, and **36** carrying single, tandem, and triplet alkylamido repeats increased in a spacer length-dependent manner.

the α2,3 and α2,6 sialylated trisaccharides, respectively (*25*). In the umbrella-like topology, longer α2,6 oligosaccharides (at least pentasaccharide residues) favor this conformation (*25*). Thus, in the umbrella-like topology, which is unique

to α2,6, the specificity for a kink motif of a least five sugar residues long could indicate that a kinked sugar chain of comparable residues is able to reach into the binding locus on the HA surface. This concept was also the case for the present viral HA binding. Therefore, whereas the avian viral HA interactions with the glycans is characteristic of short α2,3 glycans, such as single LN/Lac, human viral HA interactions involve α2,6 and is typically adopted by long glycans with multiple repeating LN units.

To examine the inhibitory activity of sialoglycopolymers carrying multiple LN repeats, we administered glycopolymers to mice as an infection model. After inoculation with A/WSN/33, virus invades and propagates in various tissues, particularly in the lung and brain. As a result, mice develop mortality and typical morbidity, such as loss of movement and food consumption, resulting in loss of weight. Compound **27** carrying sialylated triplet LN repeats, but not with compound **23** carrying sialylated single LN, effectively protected mice from lethal challenge of A/WSN/33. At 13 days postinfection, only mice administered 3 nmol/kg of compound **27** all survived. No toxic effect was observed in mice inoculated with the same concentration of glycopolymer alone. This observation was consistent with the results of in vitro infection experiments. In vitro and in vivo infection experiments clearly showed that the extended structure of the glycan enhanced the inhibitory activity.

Furthermore, we tested the inhibitory effect of glycopolypeptides designed by replacement of nonsugar glycomimetics in the asialo portion of the molecule in order to identify the specific SA motifs recognized by influenza virus. The mimetics under discussion here, such as the spaced sugars, were anticipated to act as functional sugar mimetics, which typically display the activity of a carbohydrate. However, the relationship between the viral binding activity and the core determinant of the glycan is still unclear. Acyclic spacers were used to replace sugar units in a rather flexible way. Long spacer-linked polymers carrying alkylamido repeats linked to a terminal trisaccharide motif (SAα2,3/6LN) were prepared, based on the assumption that the seven-atom spacer of pentylamido group would be a mimetic for two glycosyl units. Interestingly, the mimetics turned out to be strong viral inhibitors against the human strain A/Aichi/2/68 by hemagglutinin inhibition assay. Thus, in the human virus, **35**/**36** carrying a tandem/triplet alkylamido repeat showed 2−4-fold higher inhibitory potency over **31**/**33** carrying a α2,6 sialylated long glycans. The length of the alkylamido chain linked to the terminal SAα2,3/6LN appeared to be critical for recognition by the human viral HA. A tandem alkylamido repeat constituted the minimum length of the bound spacer-linked glycan. Whitesides and colleagues reported that the crucial factors for influenza virus inhibition by conventional SA-conjugated glycopolymers are the cluster of SA units, the molecular weight, electrostatic considerations, presence of bulky/hydrophobic groups, and steric stabilization of the glycopolymer (*17*). Numerous types of synthetic multivalent glycoconjugates have been synthesized with regard to the multivalency principle occurring in the viral HA interactions with glycans. However, contribution of the asialo portion of the glycopolymer on inhibitory activity has not been extensively examined, because the length of glycan was limited to mono-, di-, and trisaccharides. Our study indicates that replacement of a part of the glycan by a nonsugar structural unit, such as pentylamido group, results in good inhibitory activity. This type of structure is suited to build up glycopolypeptides carrying more spacer-linked glycans by replacement of a long glycan. Conventional procedures for obtaining extended glycans, such as LN repeats, are cumbersome and involve several steps. However, nonsugar glycomimetics in the asialo portion of the molecule simplifies the large-scale preparation of the glycopolypeptides. Furthermore, γ-PGA is an obvious starting point to prepare polymeric inhibitors, because it is a readily available and inexpensive polymer. Indeed, the γ-PGA backbone from *B. subtilis* is commercially available in large quantities. The physiological merits of α- and γ-PGAs as the backbone to a glycopolymer in terms of cytotoxicity and immunogenicity have already been investigated. We have demonstrated that sialoglycopolymers with a α-PGA backbone have relatively low immunogenicity (*16*). Generally, conventional glycopolymers with a backbone such as PA can be toxic (*17*, *20*). In our previous study, acrylamide monomer, which is known to be a potent neurotoxin, and PAA-Na were found to be cytotoxic to MDCK cells under the conditions used for the tests (*16*). It has also been shown that sugar-bovine serum albumin (BSA) and PA conjugates act as antigens or immunogens (*16*).

CONCLUSION

Artificial sialoglycopolymers with a γ-PGA backbone that possess a single type of SA linkage (either α2,3 or α2,6) were chemoenzymatically synthesized. These compounds were then used as a tool to study the molecular interactions between receptors and viruses. Replacement by nonsugar glycomimetics in the asialo portion of the molecule made it possible to generate strongly active glycopolypeptides carrying more spacer-linked short glycans that were suitable for large-scale synthesis. It should be emphasized that our PGA-based polymers have an extremely high solubility in water (>10% w/v), as compared with PA-based polymers (1<%), and that they are remarkably heat-stable with no aggregation, even in boiling water. Therefore, PGA-based glycopolymers have ideal characteristics as potential in vivo polymeric inhibitors. Furthermore, precise analysis of the asialo moiety in the array of glycopolypeptides provides a facile way to explore the role of the glycan sequence in the binding of glycopolymers to the viruses, as well as increasing our understanding of the molecular basis to infection by influenza virus.

ACKNOWLEDGMENT

We are grateful to the Yamasa Corporation for the generous gift of the CMP-Neu5Ac, UDP-GlcNAc, and UDP-Gal. This work was supported by a grant-in-aid for Scientific Research (Nos. 19310141, 16380077) and Scientific Research on Priority Areas (18570135 to K.I.H.) from the Ministry of Education, Science, Sports, and Culture of Japan, and a research grant from Cooperation of Innovative Technology and Advanced Research in Evolutional Area (CITY AREA) in the Central Shizuoka Area-, Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan.

In Situ Ligation between Peptides and Silica Nanoparticles for Making Peptide Microarrays on Polycarbonate

Vianney Souplet, Rémi Desmet, and Oleg Melnyk*

Institut de Biologie de Lille, UMR CNRS 8161, Universités de Lille 1 et 2, Institut Pasteur de Lille, IFR 142, 1 rue du Professeur Calmette, 59021 Lille Cedex, France. Received October 31, 2008; Revised Manuscript Received January 14, 2009

Bisphenol A polycarbonate (PC) is emerging as an interesting alternative to silicon oxide substrates for making microarrays. We show that the printing of peptide/nanoparticle mixtures allows the creation of complex peptide microarrays. Semicarbazone ligation was used for linking the peptides to the nanoparticles. The reaction occurred probably after printing due to solvent evaporation and to the in situ concentration of the reagents. Peptide microarrays were used successfully for the specific capture of purified antibodies or of antibodies from serum.

INTRODUCTION

The detection of antibodies in biological samples using polypeptide probes has a wide range of potential applications. Enzyme-linked immunosorbent assays (ELISA) are often used in this field. However, the need for studying large collections of antigens and biological samples has stimulated the development of high-throughput systems. In particular, peptide or protein microarrays (*1*−*3*) are now increasingly used for the study of autoimmune (*4*) or infectious diseases (*5*−*8*) to cite only few applications. Besides the parallelization of the assay, the great advantage of miniaturization is that microspot assay sensitivities can be higher than those obtainable by conventional methods (*9*−*11*). Various methods are used to detect the antibodies captured by the immobilized antigens. Among them, fluorescence is probably the most frequently used detection technique (*12, 13*).

The physicochemical properties of the substrate and the bond formed between the peptide probes and the surface play a crucial role in the performance of the microarray (*14*). A microscope glass slide is a standard substrate for making microarrays. This substrate is cheap, has a low intrinsic fluorescence, and can be easily functionalized with silanes. The attachment of polypeptides to silicon oxide substrates was achieved using different methods (*15*). Chemoselective methods include native (*15*−*17*), oxime (*18*), semicarbazone (*6, 19, 20*), or Staudinger (*21*) ligations as well as various thiol chemistries (*18*). Other methods include random attachment of the polypeptide chain to the surface using amide chemistry (*22*), Ni(II) coordination chemistry (*23*), or the biotin/avidin interaction (*17, 24, 25*). Immobilization of polypeptides can also be achieved by physisorption (*5*−*7*).

The widespread use of microarrays for diagnostic applications requires the development of safe systems. Because glass can break and cut, the analysis of potentially contaminating samples with glass-based devices must be avoided. Bisphenol A polycarbonate is emerging as an interesting material in this field: it is shock-resistant, and it can be easily molded and eliminated by incineration. This polymer is also used for compact disc manufacturing, and the use of this substrate as a platform for high-throughput binding assays has attracted much attention recently (*26*−*29*). Unfortunately, only few chemical methods are available for linking molecules to PC. In the work of La Clair et al., terminal OH residues of PC were first converted to surface-bound chlorophosphate groups, which were subsequently reacted with alcohol-functionalized probes to yield a phosphodiester bond (*30*). In the work of Soper et al., UV-ozone treatment of PC led to the formation of surface-exposed carboxylic acid residues which, upon activation, permitted the immobilization of amine-modified oligonucleotides through an amide bond (*31*). Bańuls et al. derivatized PC compact discs by spin-coating the support with a hydroxy-modified PMMA polymer, followed by treatment with (3-isocyanatopropyl)triethoxysilane (*32*). The same group described recently the preparation of amine- or thiol-derivatized PC discs (*33*). The surfaces were used for immobilizing aminated oligonucleotides (*32*). Bora et al. described the photochemical activation of PC (96-well plates) using 1-fluoro-2-nitro-4-azidobenzene and UV irradiation. Proteins were immobilized randomly by nucleophilic aromatic substitution of fluorine atoms by amine groups. Finally, we have recently shown that silica nanoparticles can be adsorbed on PC to form micropatterns (*34*). These micropatterns were subsequently reacted chemoselectively using semicarbazone ligation with peptides by covering the whole PC substrate with the peptide solution. Consequently, the same peptide was attached to all the micropatterns. Clearly, the methods described cannot be used for the chemoselective attachment of peptides to PC or for the creation of complex peptide microarrays.

We have examined here the possibility of creating different peptide micropatterns on PC by printing mixtures of peptides and nanoparticles and by allowing the ligation to proceed in situ. The influence of different parameters such as the buffer used for printing and the peptide concentration on peptide micropattern formation was examined. The microarrays were used for detecting antibodies using fluorescence detection. The method was first optimized using HA and FLAG tag peptides and their corresponding murine antibodies. Subsequently, a collection of overlapping peptides derived from amyloid beta Aβ 1−42 peptide was synthesized and used to probe an anti-Aβ monoclonal antibody using either the microarray or the ELISA methods. Finally, the specific detection of antibodies in serum was examined to test the usefulness of the microarray method in real detection experiments.

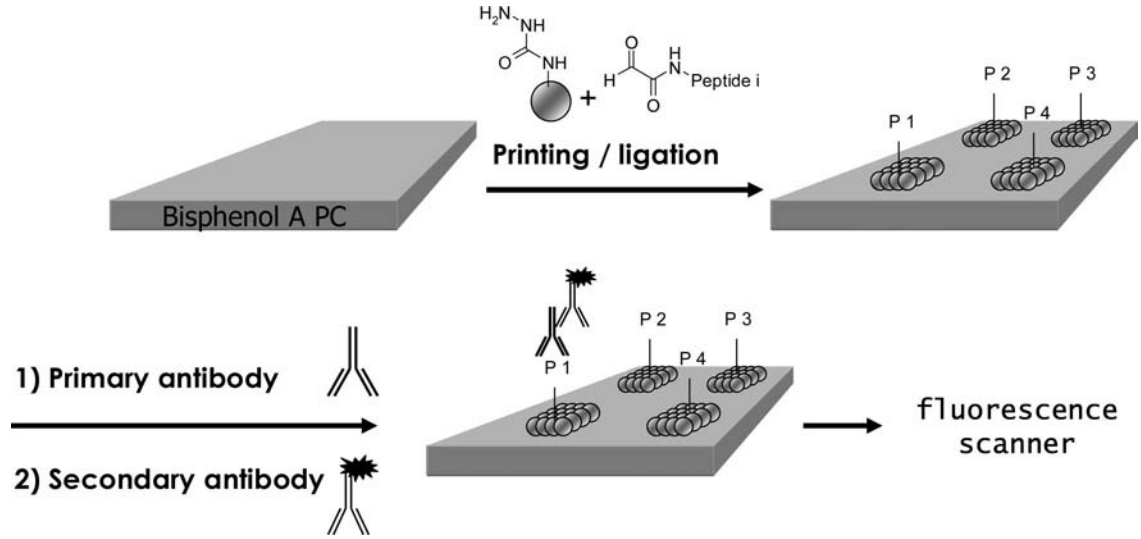

Figure 1. Preparation of peptide microarrays on PC slides by printing mixtures of SSN and COCHO−peptides as microspots. Microarrays were used to detect antibodies using a tetramethylrhodamine-labeled secondary antibody and fluorescence detection at 532 nm.

CHO−DYKDHDGDYKDHDIDYKDDDDKGGS-NH_2) (*36*) peptides was performed by treating the Ser-HA or Ser-FLAG precursors with sodium periodate (*37*). The detailed procedures and characterization data are presented elsewhere (*34*).

APP-COCHO **1**−**12.** APP-COCHO peptides were synthesized on the solid phase using standard Fmoc/*tert*-butyl chemistry and Pioneer synthesizer (Applied Biosystems, CA, USA) (*38*). The peptides were assembled on a tartaramide-NovaSyn TG resin (0.1 mmol, Novabiochem, France) using 1,3-diaminopropane as linker (*39*−*41*). For peptides APP-COCHO **1**−**7** and **9**−**12**, the N-terminal Fmoc group was removed using DMF/piperidine: 4/1 by vol on the synthesizer. The resin was washed with DMF and MeOH and dried. For peptide APP-COCHO 8, the N-terminal Fmoc group was left on the resin to avoid oxidation of N-terminal Ser residue. All the peptidyl resins were deprotected using TFA/water/triisopropylsilane: 95/2.5/2.5 by vol (10 mL) at rt during 1 h 30, washed, and dried.

The resins were resuspended in 20% aqueous AcOH (5 mL). Oxidative cleavage was then performed by adding $NaIO_4$ (0.60 mmol, 128 mg dissolved in 2 mL of 10% aqueous AcOH) in one portion to the peptidyl resins. The resins were agitated 2 min 30 s. Ethanolamine (2.4 mmol, 144 μL) was added to stop the reaction. The resins were filtered and washed with water (2 × 5 mL). The combined filtrates were immediately purified by RP-HPLC on a 120 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05%TFA by vol (6 mL/min, detection 225 nm). The fractions were collected and lyophilized to give APP-COCHO **1**−**7**, **9**−**12** (56−72 mg), and Fmoc-APP-COCHO **8** (70 mg).

Fmoc-APP-COCHO **8** (9.6 μmol, 19.0 mg) was dissolved in DMF (500 μL). DBU (95.7 μmol, 14.3 μL) was added in one portion. After 10 min at rt, the reaction was stopped by adding 10% aqueous TFA (191 μmol, 145.4 μL). The crude peptide was precipitated in Et_2O (30 mL), centrifugated, and purified by RP-HPLC as above to give 9.8 mg of APP-COCHO **8**.

Analytical RP-HPLCs and MALDI-TOF for all peptides are presented in Supporting Information.

Rho-KR-NH(CH_2)$_3$NH-COCHO and Rho-KR-NH_2 Peptides. Peptide Rho-KR-NH(CH_2)$_3$NH-COCHO was prepared on the solid phase using the tartaramide linker as described for APP-COCHO peptides. Rho-KR-NH_2 was prepared on the solid phase using standard Fmoc/*tert*-butyl chemistry. Detailed protocols are available elsewhere (*19, 42*).

Typical Printing Procedure. Commercially available polycarbonate sheets 300 × 300 × 1 mm (Goodfellow, Huntingdon, UK) were cut by high-pressure water jet at the size of microscope glass slides 75 × 25 × 1 mm^3 (Economos, Dunkerque, France). Polycarbonate slides were washed twice with deionized water and absolute ethanol (ACROS Organics, Geel, Belgium), respectively, before use.

The preparation of semicarbazide silica nanoparticles (SSN) was described in detail elsewhere (*34*). These particles are typically prepared as a 10 mg/mL suspension in DMF. This suspension is stable for months when stored at 4 °C. Before printing, the suspension is centrifuged at 21 000 × *g* for 30 min at 10 °C and resuspended under sonication in DMF to obtain a 20 mg/mL suspension.

The peptide/SSN mixtures were prepared in V-bottomed 96-well microtiter plates (ABgene, Surrey, UK, AB-1058, 40 μL/per well) by mixing SSN suspension with peptides dissolved at 20 μM in 5 mM sodium acetate buffer (pH 5.5). The final peptide concentration is 10 μM.

Each peptide/SSN mixture was printed in triplicate on each microarray. The mixtures (3 drops, 300 pL each, 3 replicates per peptide) were printed on PC slides using either a BCA1 Microarrayer (Perkin-Elmer, MA, USA used with long piezoarray tips ref 7601831) or a Qarray2 contact microarrayer (1 hit per dot, Genetix, New Milton, UK, used with tungsten pins ref PTS200, European Biotech Nnetwork, Belgium). The piezoarray tips were washed under sonication with DMF/water: 1/1 by vol buffered at pH 5.5 with 5 mM sodium acetate and water after each sample. The tips used with the Qarray2 microarrayer were washed three times with water and then with ethanol.

Up to 24 patterns can be printed per PC slide. The position of these patterns must be carefully controlled to allow the correct positioning of the patterns in the 96 well microplate microarray hardware used for the subsequent incubations and washing steps (TeleChem International, Inc. CA, USA, ref MMH4 × 24, ref GMMH4 × 24). The printed slides were incubated overnight in an oven at 37 °C and 60% relative humidity to favor ligation of the peptides to the nanoparticles. The slides were stored under nitrogen atmosphere at rt until use.

Typical Incubation Procedure for Microarrays. *PBS-A: 2% w/v BSA in PBS. PBS-B: 0.05% v/v Tween20 in PBS.* Each experiment was performed in triplicate (3 wells or microarrays per incubation). Incubations were performed in an incubator (Biosan, MI, USA, ref PST-60HL-4). The plate was warmed at 37 °C during 15 min and then saturated with PBS-A for 5 min at 37 °C (150 μL per well). The wells were washed twice with PBS-B and then incubated with the primary antibody diluted

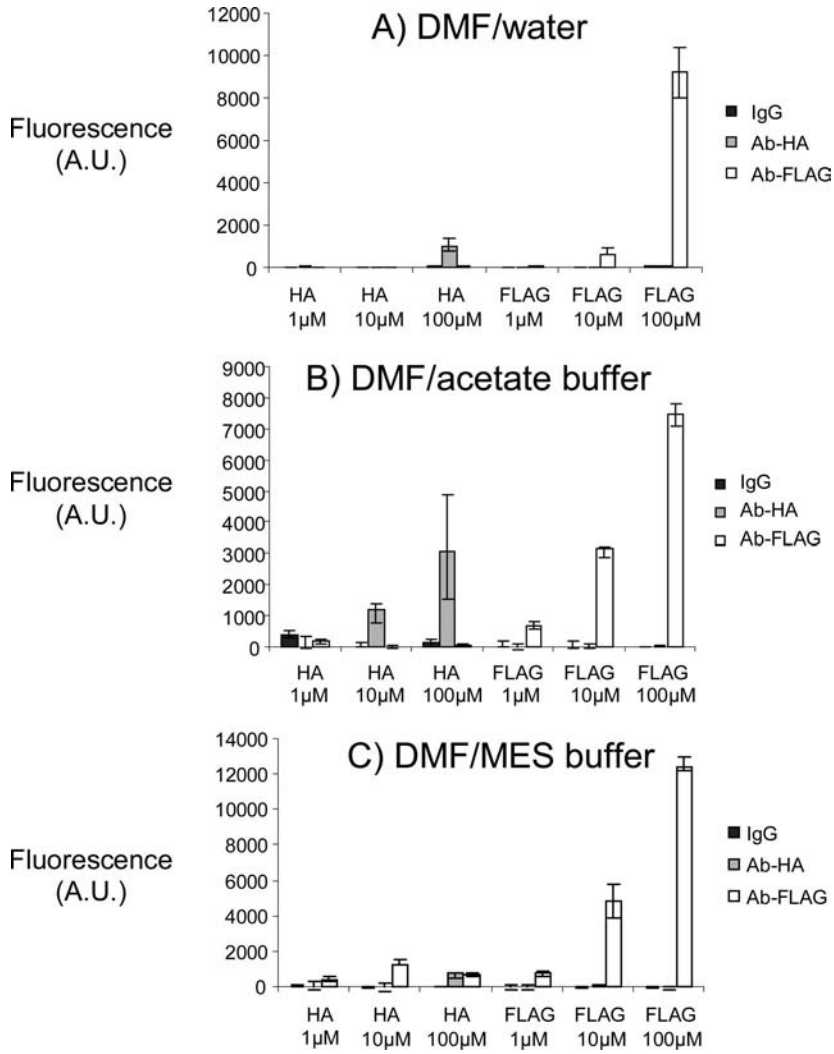

Figure 2. Effect of the buffer on the in situ ligation of COCHO−peptides to semicarbazide nanoparticles. Peptides were printed at 1, 10, or 100 μM in DMF/buffer: 1/1 v/v mixture (final nanoparticle concentration 1% w/v, BCA1 piezoelectric arrayer, 3 drops/spot, 1 nL overall, 5 replicates). (A) DMF/water, (B) DMF/pH 5.5 5 mM sodium acetate, (C) DMF/pH 5.5 5 mM MES. The microarrays were incubated in triplicate with Ab-HA, AbFLAG, or murine IgGs (10 μg/mL) 1 h at 37 °C and then with tetramethylrhodamine-labeled antimurine antibodies. Detection was performed at 532 nm using a standard fluorescence microarray scanner. The data represent the median and interquartile range for 3 microarrays.

in PBS-A for 1 h at 37 °C (120 μL per well). The wells were washed 3 times with PBS-B and incubated immediately with secondary antibody (120 μL per well, 1 h at 37 °C, typically at 10 μg/mL in PBS-A). The wells were washed 3 times with PBS-B and water. The slides were then removed from the microplate hardware, washed with EtOH, dried under N_2, and analyzed at 532 nm with a standard microarray scanner (Innoscan 700, Innopsys, France). 16-bit images were analyzed using Mapix software (Innopsys, France). Fluorescence intensities are expressed in arbitrary units (A.U.). The data presented correspond to the median of the pixel intensities for the analyzed spots.

ELISA. *PBS-C: 3% w/v BSA in PBS.* Peptides were solubilized in pH 9.6 sodium carbonate/sodium bicarbonate buffer at 0.57 μM. The wells (Nunc Immuno Maxisorp 96-well plates, VWR) were coated overnight at 4 °C with the peptide solutions diluted 1/100 (100 μL per well, 2 wells per peptide), washed 3 times with PBS, and saturated 1 h at 37 °C with PBS-C (200 μL per well). The wells were washed 3 times with PBS-B and then incubated 2 h at rt with 6E10 antibody diluted 1/10 000 in PBS-C (100 μL per well, Eurogentec, Belgium). The wells were washed 3 times with PBS-B and then incubated 1 h at 37 °C with horseradish peroxidase (HRP)-labeled goat antimurine antibodies diluted 1/10 000 in PBS-C (100 μL per well, SouthernBiotech, AL, USA). The wells were washed 6 times with PBS-B. TMB solution (100 μL per well, Interchim, France) was added to the wells at rt. After 30 min in the dark, the reaction was stopped with 2 N H_2SO_4 (50 μL per well) and the absorbance at 450 nm was measured immediately.

RESULTS AND DISCUSSION

The derivatization of PC by chemical groups allowing the site-specific immobilization of peptides is difficult to achieve. In this context, the use of silica nanoparticles for functionalizing PC is an attractive strategy because the introduction of various functional group on silica nanoparticles can be performed easily by silanization. In this work, peptides were immobilized within silica micropatterns formed on PC. Besides the use of small amounts of reagents, the advantage of creating micropatterns is that the PC substrate between the microspots and thus its interesting physicochemical properties remain unchanged.

We have recently described a method for micropatterning PC using semicarbazide silica nanoparticles. A suspension of SSN in DMF/water was printed on PC using a piezoelectric non-contact microarrayer. The evaporation of the solvent resulted in an SSN layer on PC. The micropatterns were subsequently reacted chemoselectively with a COCHO−peptide by covering

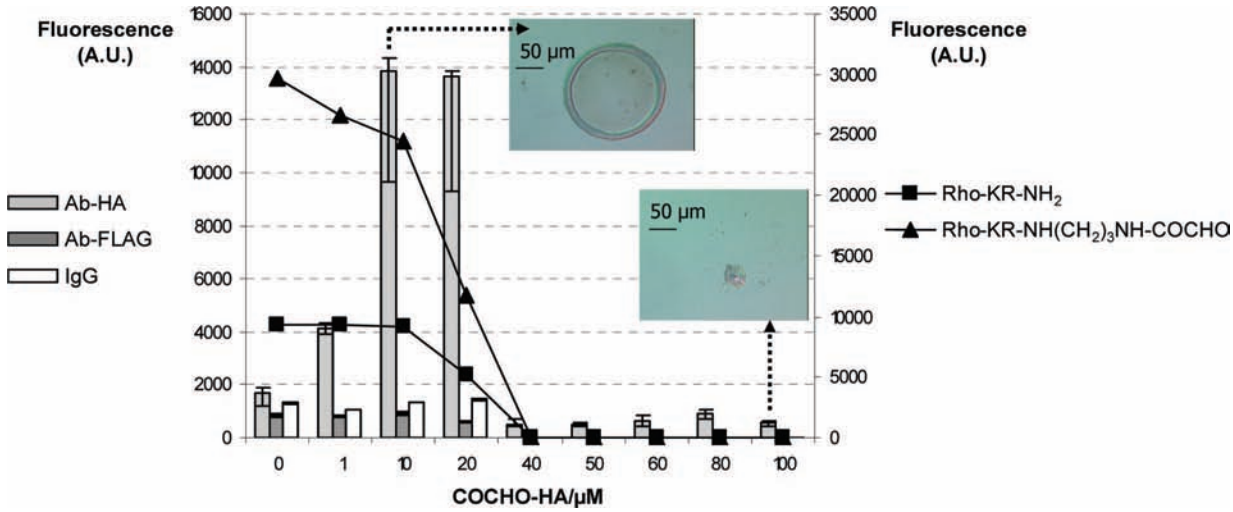

Figure 3. Effect of COCHO−peptide concentration. Peptides were printed at 0−100 μM in DMF/pH 5.5 5 mM sodium acetate buffer: 1/1 v/v mixture containing 1% w/v of SSN (BCA1 piezoelectric arrayer, 3 drops/spot, 1 nL overall, 5 replicates). The microarrays were incubated in triplicate with Ab-HA, Ab-FLAG, or murine IgG (10 μg/mL) 1 h at 37 °C and then with tetramethylrhodamine-labeled antimurine antibodies (left scale) or with peptide Rho-KR-NH$(CH_2)_3$NH-COCHO or Rho-KR-NH_2 (10^{-4} M, 0.1 M pH 5.5 sodium acetate buffer). Detection was performed at 532 nm using a standard fluorescence microarray scanner. The data represent the median and interquartile range. Images correspond to COCHO−HA/SSN microspots at 10 or 100 μM imaged using a microscope operating in the DIC mode.

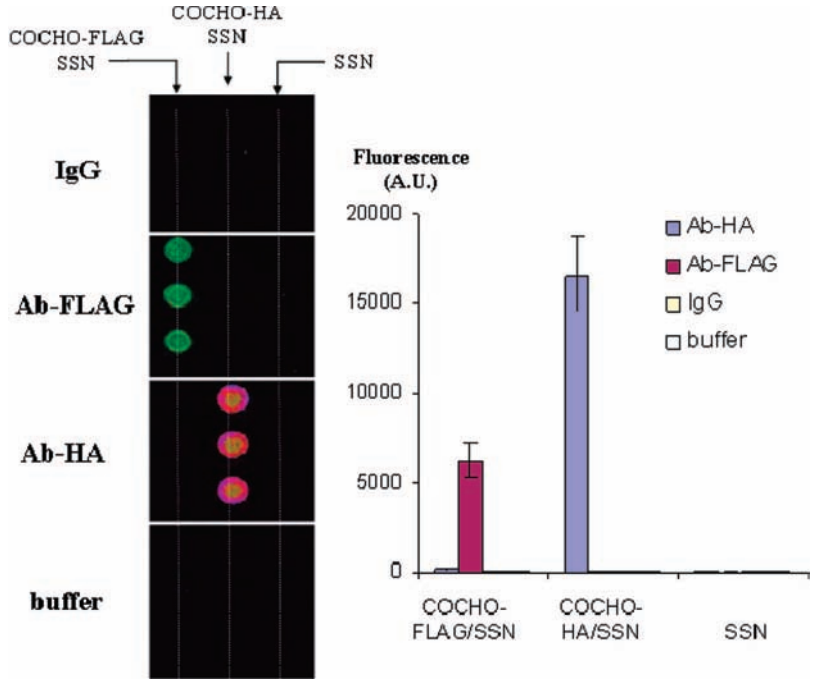

Figure 4. Peptides were printed at 10 μM in DMF/pH 5.5 5 mM sodium acetate buffer: 1/1 v/v mixture (final nanoparticle concentration 1% w/v, Qarray2 microarrayer (Genetix), 3 replicates) on PC slides (75 × 25 × 1 mm^3). The PC slides were inserted in a 96 well microplate microarray hardware (Telechem, Inc., CA, USA) equipped with a silicone gasket. The microarrays were incubated in triplicate with Ab-HA, Ab-FLAG, or murine IgG (10 μg/mL) or the buffer during 1 h at 37 °C and then with tetramethylrhodamine-labeled antimurine antibodies. Incubations and washings were performed using standard 96 well plates incubation and washing stations. Detection was performed at 532 nm using a standard fluorescence microarray scanner. The data represent the median and the interquartile range.

the whole substrate with the aqueous peptide solution. The method is of great interest for immobilizing peptides or proteins which require an aqueous environment to be soluble or to retain their active conformation. However, the method limits the number of probes which can be immobilized within PC-based miniaturized devices.

The preparation of complex peptide microarrays on PC required addressing a collection of peptides on different silica micropatterns in a simple way. SSN are stable for months in DMF/water but aggregate immediately in water. Hopefully, most peptides are soluble in DMF/water mixtures, thus opening the possibility to mix SSN and COCHO−peptides prior to the printing step for addressing a collection of peptides on PC (Figure 1). Ligation between the COCHO−peptide and SSN was expected to occur in solution and/or after printing due the concentration of the reagents on the microspot.

Optimization of the Printing Buffer. The buffer used for printing the mixtures of SSN and COCHO−peptides was expected to play a crucial role, since Schiff base formation between hydrazine derivatives and aldehydes is known to be pH-dependent. The best kinetics for hydrazone or semicarbazone bond formation are generally observed around pH 5.

This parameter was examined using COCHO−HA and COCHO−FLAG peptides derived from well-known tag se-

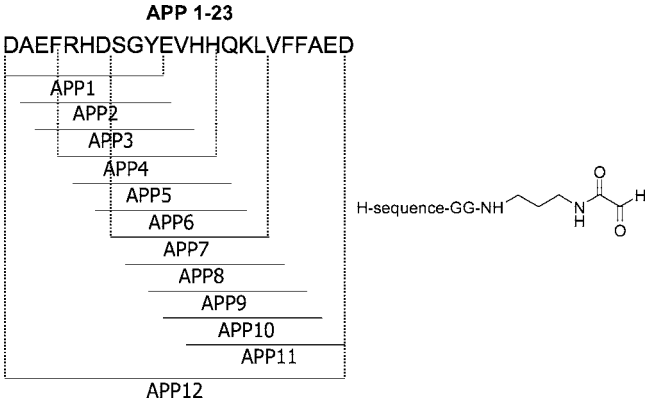

Figure 5. β-amyloid peptides APP **1**−**12** synthesized in this study. The peptides are derived from the N-terminal sequence **1**−**23** of amyloid precursor protein (APP). The peptides were modified by a COCHO group at the C-terminus, separated from the backbone by a 1,3-diaminopropyl spacer and two glycines.

quences. The peptides were printed from 1 to 100 μM in DMF/water, DMF/pH 5.5 acetate buffer, or DMF/pH 5.5 MES buffer. The final SSN concentration was 1% w/v. The substrates were incubated with anti-HA, anti-FLAG, or murine IgG antibodies used as negative control and then tetramethylrhodamine-labeled secondary antibodies (Figure 1). Fluorescence was detected at 532 nm.

The data are presented in Figure 2. At low peptide concentration (1 or 10 μM), the use of buffered mixtures (B and C) gave better results in terms of signal strength than DMF/water mixture (Figure 2A). Examination of the data obtained for COCHO−HA peptide shows that, between the two buffers tested, sodium acetate was by far superior to MES buffer in terms of both signal strength and specificity. Thus, the DMF/sodium acetate buffer was used in the rest of the study.

Effect of COCHO−Peptide Concentration. In the preceding experiment, the highest COCHO−peptide concentration used was 100 μM. Subsequently, the quality of the microarrays prepared using these experimental conditions appeared to be highly variable. Thus, the influence of COCHO−peptide concentration on the formation of the micropatterns was studied in detail using COCHO−HA peptide. After printing, a series of microarrays were incubated with Ab-HA to probe the presence of HA peptide on the micropattern (Figure 3, left-hand-side scale). Another series was incubated with peptide Rho-KR-NH$(CH_2)_3$-COCHO, as a probe for the presence of unreacted semicarbazide groups on the micropattern. Peptide Rho-KR-NH_2 was used as a control to estimate the level of physisorption (Figure 3, right-hand-side scale).

The signal strength of COCHO−HA/SSN microspots after incubating with HA-Ab increased significantly for concentrations up to 20 μM, whereas the signal strength after incubating with peptide Rho-KR-NH$(CH_2)_3$-COCHO decreased significantly in the same concentration range. The same trend was observed with COCHO−FLAG/SSN microspots (data not shown). The concomitant increase of COCHO−HA peptides and decrease of semicarbazide groups on silica nanoparticles is expected if immobilization occurs through site-specific semicarbazone ligation. However, concentrations above 40 μM led to very low signal strengths for both experiments, suggesting that aggregation of the COCHO−HA/SSN mixture occurred before printing. Observation of the PC substrates with an optical microscope operating in the differential interference contrast (DIC) mode showed the presence of a SSN layer at 10 μM but not at 100 μM, thus confirming the probable aggregation of the COCHO−HA/SSN mixture above 40 μM.

Aggregation of COCHO−peptide/SSN mixtures occurred frequently above 40 μM COCHO−peptide concentration. The aggregation kinetics also probably depends on how the COCHO−peptides and the SSN are mixed together, a parameter which cannot be easily controlled due to the small volumes manipulated. Interestingly, COCHO−peptide/SSN mixtures were always found to be stable at 10 μM. Consequently, these experimental conditions were used in the rest of this study.

The reaction between a semicarbazide and an aldehyde group is chemoselective, and the equilibrium usually favors the formation of the semicarbazone in aqueous solution. However, the equilibration kinetics can be slow, especially if concentrations lower than millimolar are used. Because ligation of the COCHO−peptide to the surface of the SSN is not favored at 10 μM, the surface of the SSN is probably unchanged in the COCHO−peptide/SSN mixture, thus explaining the stability of the suspension. We hypothesize that ligation between SSN and COCHO−peptides occurs predominantly on the microspot after printing due to the evaporation of the solvents (in a few seconds) which leads to a concentration of the ligation partners on the PC substrate.

COCHO−peptide/SSN mixtures can be printed using a piezoelectric noncontact microarrayer as above or using a standard contact microarrayer (Figure 4). In this experiment, COCHO−HA or COCHO−FLAG/SSN mixtures were printed on PC slides using tungsten pins. The slides were then inserted in a 96 well device for the incubations and washings using standard ELISA incubation or washing stations. The data illustrate the good specificity of the interaction taking place on the COCHO−peptide/SSN microspots and the absence of carryover between the different COCHO−peptide/SSN mixtures.

Preparation of APP Microarray. The principal aim of the following experiment was to show the interest of the method for preparing microarrays of higher complexity. We have also compared PC microarray data with those obtained using a standard ELISA assay. For this purpose, a series of COCHO-peptides derived from APP protein and monoclonal antibody 6E10 raised against amino acids 4−9 of APP (FRHDSG) were selected (Figure 5) (*43*). APP-COCHO **1**−**11** are overlapped by nine amino acids, whereas APP-COCHO **12** span the whole **1**−**23** sequence of APP. Alzheimer disease (AD) is the major cause of senile dementia. Degradation of APP by several enzymes leads to the formation of β-amyloid (Aβ) peptides which aggregate extracellularly into senile plaques (*44*). Neurodegeneration in AD is due in part to the accumulation of these senile plaques. A huge effort is currently dedicated to the design of vaccines against amyloid deposits since the discovery of Schenk et al. that immunization of APP transgenic mice with Aβ reduces senile plaques and prevents new deposits of β-amyloid (*45*−*47*). The fine control of the specificity of the antibodies produced by immunization is of prime importance to avoid side effects. Thus, besides this model experiment, a peptide microarray presenting different Aβ peptides should be useful for determining the specificity of anti-Aβ antibodies and the relationships between specificity and vaccine efficacy.

APP-COCHO peptides were synthesized on the solid phase using Fmoc/*tert*-butyl chemistry (*38*). For peptides APP-COCHO **1**−**7** and **9**−**12**, the COCHO group was introduced at the C-terminus of the peptides using a tartaramide linker and a solid-phase oxidative cleavage of the tartaramide with sodium periodate (Scheme 1) (*39*−*41*). APP-COCHO **8** features a N-terminal Ser residue and could not be synthesized using the procedure used for the other APP-COCHO peptides, because in this position, Ser residue is also oxidatively cleaved by periodate (*37*). Thus, the N-terminal Fmoc protecting group was left on the peptidyl resin to protect the β-amino alcohol moiety of Ser. Deprotection of the side chains in TFA and periodate cleavage of the tartaramide moiety provided Fmoc-APP-

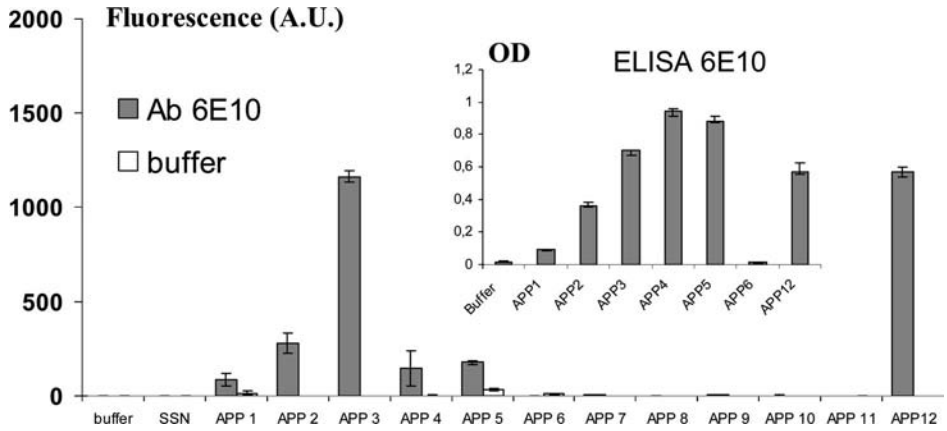

Figure 6. The binding of APP-COCHO **1**−**12** peptides to 6E10 antibody was examined using microarrays prepared on PC slides or the ELISA technique on standard polystyrene 96 well plates. The microarrays were incubated with 6E10 antibody diluted 1/10 000 in PBS and secondary antimurine antibodies labeled with tetramethylrhodamine detected at 532 nm. ELISA assay was performed using an antimurine antibody-HRP conjugate diluted 1/10 000. The absorbance was measured at 450 nm.

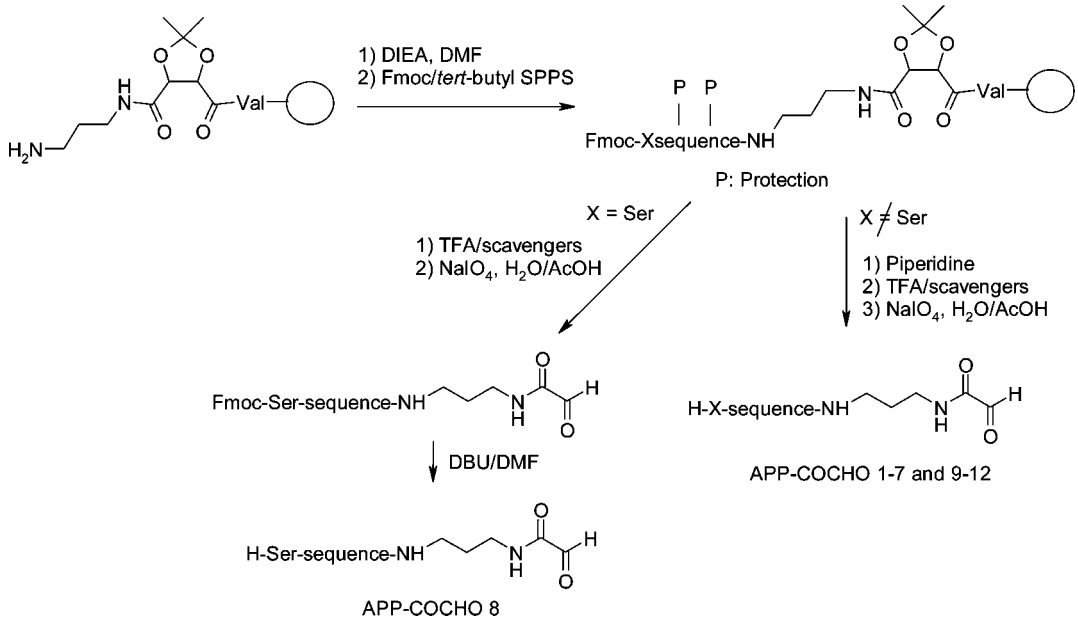
Scheme 1. Synthesis of APP-COCHO Peptides



COCHO **8**, which was subsequently deprotected in the presence of DBU to give APP-COCHO **8**.

The APP-COCHO/SSN mixtures were printed using the contact microarrayer and tungsten pins as above. The concentration of each APP-COCHO peptide solution was verified by RP-HPLC as described elsewhere (*48*). No aggregation was observed before or during printing. The microarrays were incubated with murine 6E10 antibody and tetramethylrhodamine-labeled antimurine antibodies for fluorescence detection at 532 nm. APP-COCHO peptides were also coated on standard polystyrene 96 well plates for ELISA. The data are presented in Figure 6.

Examination of Figure 6 reveals that both assays displayed similar results: (i) peptides APP-COCHO **1**−**5** and **12** bind to 6E10 monoclonal antibody, (ii) APP-COCHO **6** did not react with the antibody, highlighting the critical role of R5 for binding to the 6E10 antibody. APP-COCHO **3** gave the best signal using the microarray method, whereas the highest signal was observed for APP-COCHO **4** using the ELISA. The use of microarrays prepared by printing the APP-COCHO **1**−**12** peptides on semicarbazide-functionalized glass slides led to results very similar to polycarbonate microarrays: APP-COCHO **3** was the best binder, and the signal displayed by APP-COCHO **6** was not significantly different from the background (data not shown). These results suggest that the differences observed between the two detection techniques are probably due to the difference in the mode of binding of the peptides to the substrates rather than to other parameters such as substrate chemical composition or roughness. In the microarray experiment, the peptides were attached site-specifically to the substrate through their C-terminus, whereas in the ELISA assay, the peptides were randomly physisorbed on the polystyrene substrate.

Detection of Antibodies in Biological Samples. The utility of the in situ ligation technique for detecting antibodies in serum was documented using peptide COCHO−HA and Ab-HA antibodies diluted in murine serum. SSN or COCHO−FLAG/SSN microspots were used as controls. The data presented in Figure 7 show the good specificity of the detection since the SSN or COCHO−FLAG microspots were nearly indistinguishable from the background in the entire Ab-HA concentration range. Figure 5B details the data obtained for the lowest Ab-HA concentrations. Ab-HA could be still detected at 10 ng/mL. In this experiment, the same scanning parameters were used for the entire Ab-HA concentration range. The sensitivity of the detection can probably be improved by adjusting the scanning parameters in the low Ab concentration range. Overall,

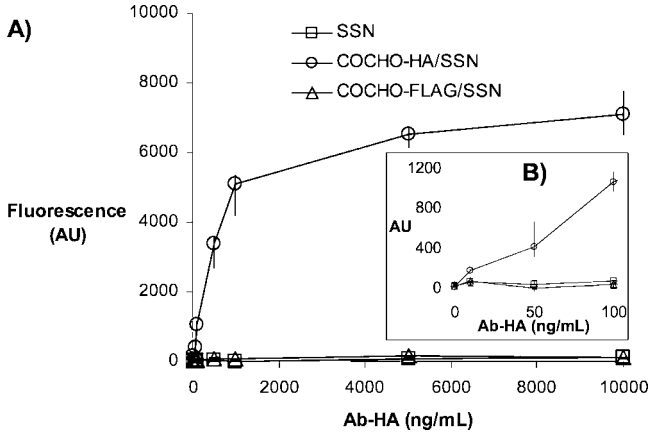


Figure 7. Peptides were printed at 10 μM in DMF/pH 5.5 5 mM sodium acetate buffer: 1/1 v/v mixture (final nanoparticle concentration 1% w/v, Qarray2 microarrayer (Genetix), 3 replicates) on PC slides (75 × 25 × 1 mm^3). The PC slides were inserted in a 96 well microplate microarray hardware (Telechem, Inc., CA, USA) equipped with a silicone gasket. The microarrays were incubated in triplicate during 1 h at 37 °C with Ab-HA diluted from 0 to 10 μg/mL in murine serum (final dilution of serum: 1/50) and then with tetramethylrhodamine-labeled antimurine antibodies. Incubations and washings were performed using standard 96 well plates incubation and washing stations. Detection was performed at 532 nm using a standard fluorescence microarray scanner. The data represent the median and interquartile range for SSN (open squares), COCHO−HA (open circles), or COCHO−FLAG/SSN (open triangles) microspots. Insert (B) shows the data for the lowest concentrations of Ab-HA (0, 10, 50 ng/mL).

these results show the utility of the in situ ligation of COCHO−peptides on SSN for detecting antibodies in complex samples such as serum.

CONCLUSION

We have shown that in situ site-specific ligation of COCHO−peptides on semicarbazide silica nanoparticles allows the preparation of peptide microarrays on polycarbonate. The concentration of the peptide solution used for printing must be in the 10 μM range to avoid the aggregation of the silica nanoparticles. These experimental conditions permitted the preparation of an APP peptide microarray, which was incubated with monoclonal 6E10 antibody. Microarray data were in accordance with ELISA data. Moreover, the microarrays were used successfully for the detection of antibodies in serum.

ACKNOWLEDGMENT

We thank the financial support from the French Ministry of Research, grants from the EEC, from the Région Nord Pas-de-Calais and from Cancéropôle Nord-Ouest. The work was performed in Chemistry Systems Biology platform facility of the Institute of Biology (Lille, France, http://csb.ibl.fr).

Comparison of a Nucleosidic vs Non-Nucleosidic Postsynthetic "Click" Modification of DNA with Base-Labile Fluorescent Probes

Sina Berndl,[†] Nadine Herzig,[†] Péter Kele,[‡] Daniel Lachmann,[†] Xiaohua Li,[‡] Otto S. Wolfbeis,[‡] and Hans-Achim Wagenknecht*,[†]

Institute of Organic Chemistry, University of Regensburg, D-93040 Regensburg, Germany and Institute of Analytical Chemistry, Chemo- and Biosensors, University of Regensburg, D-93040 Regensburg, Germany. Received November 7, 2008; Revised Manuscript Received January 8, 2009

The azides **1** and **2** bearing a phenoxazinium and a coumarin fluorophore, respectively, were applied in postsynthetic "click"-type bioconjugation and coupled to oligonucleotides modified with alkyne groups using two alternative approaches: (i) as a nucleotide modification at the 2′-position of uridine and (ii) as a nucleotide substitution using (*S*)-(−)-3-amino-1,2-propanediol as an acyclic linker between the phosphodiester bridges. The corresponding alkynylated phosporamidites **3** and **6** were used as DNA building blocks for the preparation of alkyne-bearing DNA duplexes. The base pairs adjacent to the site of modification and the base opposite to it were varied in the DNA sequences. The modified duplexes were investigated by UV/vis absorption spectroscopy (including melting temperatures) and fluorescence spectroscopy in order to study the different optical properties of the two chromophores and to evaluate their potential for bioanalytical applications. The sequence-selective fluorescence quenching of phenoxazinium **1** differs only slightly and does not depend on the type of modification, meaning whether it has been attached to the 2′-position of uridine or as DNA base surrogate using the acyclic glycol linker. The 2′-chromophore-modified uridine still recognizes adenine as the counterbase, and the duplexes exhibit a sufficient thermal stability that is comparable to that of unmodified duplexes. Thus, the application of the 2′-modification site of uridine is preferred in comparison to glycol-assisted DNA base surrogates. Accordingly, the coumarin dye azide **2** was attached only to the 2′-position of uridine. The significant Stokes shift of ∼100 nm and the good quantum yields make the coumarin chromophore a powerful fluorescent label for nucleic acids.

INTRODUCTION

Bioanalytical methods based on nucleic acids often require the use of bright DNA labels for fluorescence readout (*1*−*12*). The standard phosphoramidite DNA building block strategy enables a large variety of organic fluorophores to be routinely incorporated at specific positions within the oligonucleotide. Alternatively, postsynthetic labeling with fluorophores can be performed via amide bond formation to internal, 3′- and 5′-terminal modifiers that are commercially or synthetically available as phosphoramidites (*13*). In recent years, the "click" ligation strategy has become an important alternative. Huisgen originally described the [2 + 3]-cycloaddition between alkynes and azides yielding 1,2,3-triazoles (*14*). The utility of this reaction as a bioligation method has grown incredibly after Sharpless had reported that the addition of Cu(I) led to a significant increase in the reaction rate and in regioselectivity (*15*). This type of "click" chemistry has been widely used as a bioconjugation method (*16*−*27*) due to the mild reaction conditions and the bioorthogonal functional groups meaning that both alkynes and azides typically are not present in biopolymers (*28*−*31*). Using the "click" chemistry, up to six modifications have been incoporated simultaneously (*32*) and up to three modifications consecutively into oligonucleotides (*33*). Highly modified DNA can be prepared by a combination of PCR with triphosphates bearing alkynes (*34*).

It became clear that "click" chemistry is predestined for the application as a postsynthetic ligation for nucleic acids in order to avoid the time-consuming synthesis of phosphoramidites as DNA building blocks (*20, 21*). This is especially important for a number of remarkable and brightly emitting fluorophores that are not compatible with the acidic, oxidative, or basic conditions of automated DNA phosphoramidite chemistry and DNA workup. For instance, phenoxazinium and coumarin dyes represent brightly emitting organic fluorophores that are not stable under the typically strong basic conditions during DNA cleavage and deprotection. Hence, these labels cannot be incorporated into oligonucleotides using the conventional phosphoramidite chemistry.

Herein, we present the application of "click" chemistry for postsynthetic attachment of the fluorescent azides *N*-(5-(3-azidopropylamino)-9*H*-benzo[*a*]phenoxazin-9-ylidene)-*N*-methylmethanaminium (**1**) (*35*) and (*E*)-1-(3-azidopropyl)-4-(2-(7-(diethylamino)-2-oxo-2*H*-chromen-3-yl)vinyl)pyridinium (**2**) (*35,36*) (Scheme 1) as representatives of a phenoxazinium and a coumarin dye, respectively. They were coupled to oligonucleotides that are modified with alkyne groups using two alternative structural approaches: (i) as a nucleotide modification at the 2′-position of uridine and (ii) as a nucleotide substitution using (*S*)-(−)-3-amino-1,2-propanediol as an acyclic linker between the phosphodiester bridges. The resulting duplexes were investigated by optical spectroscopy in order to study the different stacking situations of the chromophores and to evaluate their potential in oligonucleotide-based assays.

EXPERIMENTAL PROCEDURES

Materials and Methods. Chemicals were purchased from Aldrich, Alfa Aesar, and Merck. Unmodified oligonucleotides

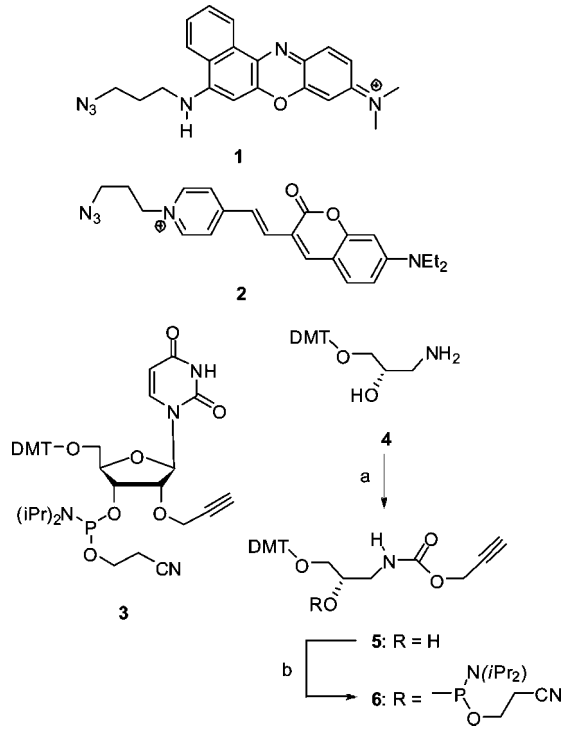
Scheme 1. Building Blocks for the Postsynthetic "Click" Chemistry with Oligonucleotides[a]



[a] Azides **1**, **2** and alkyne phosphoramidites **3**, **4**: (a) 2-propyn-1-ol, 1,1′-carbonyldiimidazole, DMF, r.t., 27 h; 76%; (b) 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite, $EtN(iPr)_2$, CH_2Cl_2, r.t., 3 h.

were purchased from Metabion. TLC was performed on Fluka silica gel 60 F_{254} coated aluminum foil. Flash chromatography was carried out with silica gel 60 from Aldrich (60−43 μm). Spectroscopic measurements were recorded in sodium phosphate buffer solution (10 mM) using quartz glass cuvettes (10 mm). ESI mass spectra were acquired in the central analytical facility of the faculty on a ThermoQuest Finnigan TSQ 7000 in negative and positive ionization mode. NMR spectra were recorded on a Bruker Avance 300 spectrometer in deuterated solvents that had been dried over basic alumina. Chemical shifts are given in ppm relative to TMS. Absorption spectra and the melting temperatures (2.5 μM DNA, 250 mM NaCl, 10−90 °C, 0.7 °C/min, step width 0.5 °C) were recorded on a Varian Cary 100 spectrometer equipped with a 6 × 6 cell changer unit. Fluorescence spectra were acquired on a Jobin-Yvon Fluoromax 3 fluorimeter in spectral steps of 1 nm and an integration time of 0.2 s. All spectra were recorded with an excitation and emission bandpass of 2 nm and are corrected for Raman emission from the buffer solution.

Synthesis of 5. 2-Propyn-1-ol (40 μL, 700 μmol) was dissolved in DMF (5 mL). 1,1′-carbonyldiimidazole (114 mg, 700 μmol) was added and the solution was stirred at room temperature for 3 h. (3-(4,4′-Dimethoxytrityl)-2-hydroxy-propylamine (**4**) (268 mg, 700 μmol) was added and the solution was stirred for another 24 h at room temperature and then evaporated to dryness. The crude product was purified by flash chromatography (CH_2Cl_2, 0.1% NEt_3) yielding a yellow solid (76%). TLC (CH_2Cl_2/MeOH 100:2) R_f = 0.3. ^{1}H NMR (300 MHz, [d_6]-acetone): δ = 7.51−7.48 ppm (m, 2H, arom. DMT), 7.37−7.28 (m, 7H, arom. DMT), 6.89−6.86 (m, 4H, arom. DMT), 6.26 (m, 1H, NH), 4.64 (d, J = 2.47, 2H, C$\underline{H_2}$CCH), 4.17 (d, J = 5.21, 1H, OH), 3.92−3.86 (m, 1H, CH_2CHCH_2), 3.79 (s, 6H, OMe), 3.45−3.37 (m, 1H, CH_2CHCH_2), 3.22−3.15 (m, 1H, CH_2CHCH_2), 3.13−3.05 (m, 2H, CH_2CHCH_2), 2.98 (t, J = 2.47, 1H, CCH). MS (FAB): m/z (%) 303.1 (100) [DMT]$^+$, 475.5 [MH$^+$]. HRMS (FAB): M$^+$ calcd for $C_{28}H_{30}NO_6$ [MH$^+$]: 476.2073. Found: 476.2085.

Synthesis of 6. Compound **5** (350 mg, 0.74 mmol) was dissolved under nitrogen in dry CH_2Cl_2 (5 mL). Dry ethyldiisopropylamine (380 μL, 2.21 mmol) and 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite (181 μL, 0.81 mmol) were added, and the solution was stirred for 3 h at r.t. The mixture was washed with freshly prepared sat. aqueous $NaHCO_3$, dried over Na_2SO_4, and evaporated to dryness. The crude product was purified by flash chromatography (CH_2Cl_2/MeOH 100:2, 0.1% $(^iPr)_2NEt$). The resulting yellow foam (80%) was dissolved in dry MeCN (6.1 mL) and applied directly for automated DNA synthesis. TLC (CH_2Cl_2/MeOH 100:2): R_f = 0.6. ^{1}H NMR (300 MHz, [d_6]-C_3D_6O): δ = 1.06−1.19 (m, 12H, 4 × Me (^{i}Prop)), 2.58 (t, J_z = 6.04, 1H, ≡H), 2.76 (m, 2H), 2.95 (m, 1H), 3.07 (m, 1H), 3.22 (m, 1H), 3.36 (m, 1H), 3.54 (m, 1H), 3.61 (m, 2H), 3.85 (m, 1H), 3.75 (s, 6H, 2 × OMe), 4.10 (m, 1H), 4.60 (dd, J_z = 2.47, CH_2≡), 6.20 (m, 1H, NH), 6.83−6.88 (m, 4H, arom.), 7.25−7.35 (m, 7H, arom.), 7.46−7.49 (m, 2H, arom.). ^{31}P NMR (121 MHz, [d_6]-acetone): = 150.6.

Preparation of Modified Oligonucleotides. Oligonucleotides were prepared on an Expedite 8909 Synthesizer from Applied Biosystems (ABI) using standard phosphoramidite chemistry. Reagents and controlled pore glass (CPG) (1 μmol) were purchased from ABI and Glen Research. The synthesis of DNA oligonucleotides modified with the acyclic linked acetylene was performed using a modified protocol. Activator solution (0.45 M tetrazole in acetonitrile) was pumped together with the building block (0.15 M in acetonitrile) through the CPG vial. The coupling time was extended to 61 min with an intervening step after 30.8 min for washing and refreshing the activator/phosphoramidite solution in the CPG vial. The CPG vial was flushed with dry acetonitrile after coupling. Acetylene-modified uridine was introduced into DNA by using standard coupling conditions. The concentration of the building block was increased to 0.1 M. After preparation, the trityl-off oligonucleotides were cleaved from the resin and deprotected by treatment with conc. NH_4OH at room temperature for 24 h.

"Click" Ligation. The azides **1** (blue) and **2** (red) were synthesized according to the literature (*35*, *36*). The azide **1** or **2** (114 μL, 10 mM), Cu(I) (17 μL, 100 mM), TBTA (34 μL, 100 mM), each in DMSO/^{t}BuOH = 3:1, and sodium ascorbate (25 μL, 400 mM) in H_2O was added to the oligonucleotide (1 μmol). The reaction mixture was vortexed, shaken overnight at room temperature, and then evaporated to dryness using a speedvac. Sodium acetate (100 μL, 0.15 mmol) was added and the mixture stored for 1 h at room temperature. Ethanol (1 mL) was added and the mixture vortexed and frozen (−20 °C) overnight. The suspension was centrifuged (13 000 rpm, 15 min) and the supernatant removed. The pellet was washed twice with ethanol (500 μL) and then dissolved in water (500 μL). Prior to purification by HPLC, the DNA was desalted by NAP-5 column (GE Healthcare).

DNA Purification. The modified oligonucleotides were purified by HPLC on a semipreparative RP-C18 column (300 Å, Supelco) using the following conditions: A = NH_4OAc buffer (50 mM), pH = 6.5; B = acetonitrile; gradient 0−30% B over 50 min, flow rate 2.5 mL/min, UV/vis detection at 260 and 641 nm. The oligonucleotides were lyophilized and quantified by their absorbance in 10 mM sodium phosphate buffer at 260 nm on a Varian Cary 100 spectrometer. Duplexes were formed by heating to 90 °C (15 min) followed by slow cooling. MS (ESI): **DNA1** calc. 5453, found m/z = 1092.1 [M/5]$^{5+}$, 1364.8 [M/4]$^{4+}$, 1819.5 [M/3]$^{3+}$; ε (260 nm) = 159 090 [mol L^{-1} cm^{-1}]. **DNA2** calc. 5562, found m/z = 1390.0 [M/4]$^{4-}$, 1853.8 [M/3]$^{3-}$; ε (260 nm) = 181 650 [mol L^{-1} cm^{-1}]; **DNA3** calc. 5594, found m/z = 1397.9 [M/4]$^{4-}$, 1864.4 [M/3]$^{3-}$; ε (260 nm) = 166 270 [mol

L^{-1} cm^{-1}]; **DNA5** calc. 5503, found m/z = 1833.9 [M/3] $^{3-}$; ε (260 nm) = 164 290 [mol L^{-1} cm^{-1}]; **DNA6** calc. 5612, found m/z = 1402.3 [M/4] $^{4-}$, 1869.9 [M/3] $^{3-}$; ε (260 nm) = 186 850 [mol L^{-1} cm^{-1}]; **DNA7** calc. 5644, found m/z = 1410.3 [M/4]$^{4-}$, 1881.3 [M/3]$^{3-}$; ε (260 nm) = 171 470 [mol L^{-1} cm^{-1}].

RESULTS

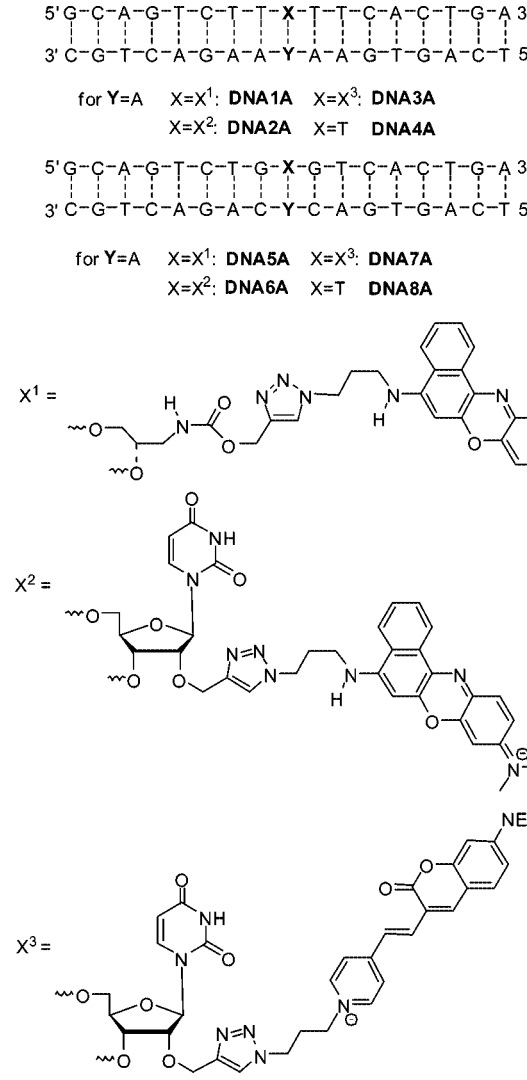
"Click" Bioconjugations. The fluorophore azides **1** (blue) and **2** (red) were incorporated oligonucleotides bearing the alkyne group either as a nucleotide modification at the 2′-position of uridine or as a nucleotide substitution using (*S*)-(−)-3-amino-1,2-propanediol as an acyclic linker between the phosphodiester bridges. The first DNA building block, 5′-*O*-dimethoxytrityl-N^3-pivaloyloxymethyl-2′-*O*-propargyluridine-3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite (**3**), can be synthesized according to the literature procedure (*37*). In the second DNA building block, ethynyl (2*S*)-3-(bis(4-methoxyphenyl)(phenyl)methoxy)-2-((2-cyanoethoxy)(diisopropylamino)phosphinooxy)propylcarbamate (**6**), the 2′-deoxyribofuranoside moiety was replaced by an acyclic linker. Similar glycol linkers have been used by others in order to prepare glycol nucleic acid (GNA) (*38*, *39*), twisted intercalating nucleic acids (TINA) (*25*, *40*), and alkyne-modified oligonucleotides for the "click" cycloaddition as a postsynthetic modification (*33*). We had previously used this structural approach for the incorporation of ethidium (*41*, *42*), indole (*43*), perylene bismimide (*44*, *45*), phenothiazine (*46*), and thiazole orange (*47*) into oligonucleotides via the corresponding phosphoramidites as DNA building blocks. In contrast to the latter examples, we have connected the glycol linker not directly to the propargyl group but via a carbamate function. This facilitates the synthesis of the corresponding DNA building block **6**, since the protection of the N−H group of the linker part is not necessary. The DMT-protected (*S*)-3-amino-1,2-propanediol **4** as the precursor was synthesized according to the literature (*41*). The hydroxy function of commercially available 2-propyn-1-ol was converted into an activated ester by 1,1′-carbonyldiimidazole, and the subsequent nucleophilic acyl substitution with **4** gave the conjugate **5** in 76% yield. The synthesis of the phosphoramidite **6** was accomplished by standard procedures.

The detritylated oligonucleotides were automatically synthesized at the 1 μmol scale using the synthetic phosphoramidites **3** or **6** and coupled to the azides **1** or **2**, respectively, in the presence of an excess of Cu(I), TBTA, and sodium ascorbate in a DMSO/^{t}BuOH (3:1) solvent mixture at room temperature overnight. After lyophilization and ethanol precipitation, the modified single strands **DNA1**-**DNA3** and **DNA5**-**DNA7** were purified by semipreparative HPLC and finally desalted. All modified oligonucleotides were studied by UV/vis absorption and fluorescence spectroscopy (including quantum yields); the corresponding duplexes **DNA1Y**-**DNA3Y** and **DNA5Y**-**DNA7Y** additionally by measurement of the melting temperature (T_m). The unmodified duplexes **DNA4Y** and **DNA8Y** were used as references (Scheme 2).

Phenoxazinium-Modified DNA. The sequences of **DNA1Y**, **DNA2Y**, **DNA5Y**, and **DNA6Y** bear the blue phenoxazinium chromophore in three different structural variations (Scheme 2): (I) The chromophore was either connected to the 2′-position of uridine (**DNA2Y** and **DNA6Y**) or as a non-nucleosidic DNA base replacement (**DNA1Y** and **DNA5Y**). (II) The base pairs directly adjacent to the phenoxazinium modification site were varied (A-T in **DNA1Y**/**DNA2Y** or G-C in **DNA5Y**/**DNA6Y**). (III) The base opposite to the modification site was varied (Y = A, T, C, or G).

First, we measured the melting temperatures (T_m) of the phenoxazinium-modified duplexes at 260 nm (Tables 1 and 2) in order to study the influence of the phenoxazinium moiety on the duplex stability. The following major effects have been observed: (i) The phenoxazinium chromophore as a non-nucleosidic base surrogate in **DNA1Y** and **DNA5Y** does not exhibit any preferential base pairing with the counterstrand. (ii) In contrast, the phenoxazinium-modified uridine in **DNA2Y** and **DNA6Y** clearly prefers the adenine opposite to the modification site. (iii) Regardless of the type of modification and the sequential context, the "mismatched" modified duplexes **DNA1Y**, **DNA2Y**, **DNA5Y**, and **DNA6Y** (Y = T, C, G) are

Scheme 2. Sequences and Numbering of the Modified Duplexes DNA1Y-DNA8Y[a]



[a] Representatively shown for **Y** = A. For **Y** = T, C, G, structures are numbered accordingly (see Table 1 and Table 2).

more stable compared to the corresponding unmodified mismatched duplexes **DNA4Y** and **DNA8Y**, respectively. This result indicates a stabilization of base mismatches by the stacking interactions with the phenoxazinium chromophore. The following additional effects can be drawn if the unmodified and matched **DNA4A** and **DNA8A** are regarded as the references (Figure 1): (iv) The replacement of the 2′-deoxyribofuranoside by the acyclic glycol linker results in a decrease of thermal stability by 5.9 °C in **DNA1A** and 4.0 °C in **DNA5A**. (v) In contrast, the incorporation of the phenoxazinium chromophore as a nucleosidic 2′-modification yields duplexes of equal (**DNA2A**) or even by 2 °C higher thermal stability (**DNA6A**).

The UV/vis spectra of all modified single strands and all duplexes show the typical absorption of the blue chromophore with maxima in the small range between 652 and 661 nm (Supporting Information Figures S1, S2, S4, S5). The absorption properties do not reflect a systematic change of properties as a result of any of the three different structural variations **I**−**III**. In contrast, the fluorescence of the duplexes show the influence of the sequential neighborhood (Figure 2). The quantum yield of the fluorescence of the phenoxazinium duplexes ranges from 12% to 22% provided guanines are not placed in the vicinity of the phenoxazinium dye (Figure 3). The fluorescence is quenched significantly if a guanine is present as the counterbase or as part of the adjacent base pairs, or both. It is important to point out that this profile of emission properties is observed regardless of whether the chromophore has been attached to the 2′-position of uridine or as a non-nucleosidic DNA base surrogate using the acyclic glycol linker. In fact, the quantum yields of the corresponding duplex pairs are similar, e.g., **DNA1A** vs **DNA2A**.

Coumarin-Modified DNA. Due to this similarity that has been observed between the nucleosidic and non-nucleosidic approaches for phenoxazinium-modified DNA duplexes, we decided to incorporate the red coumarin label (azide **2**) only to the 2′-position of uridine. Those modified duplexes would show

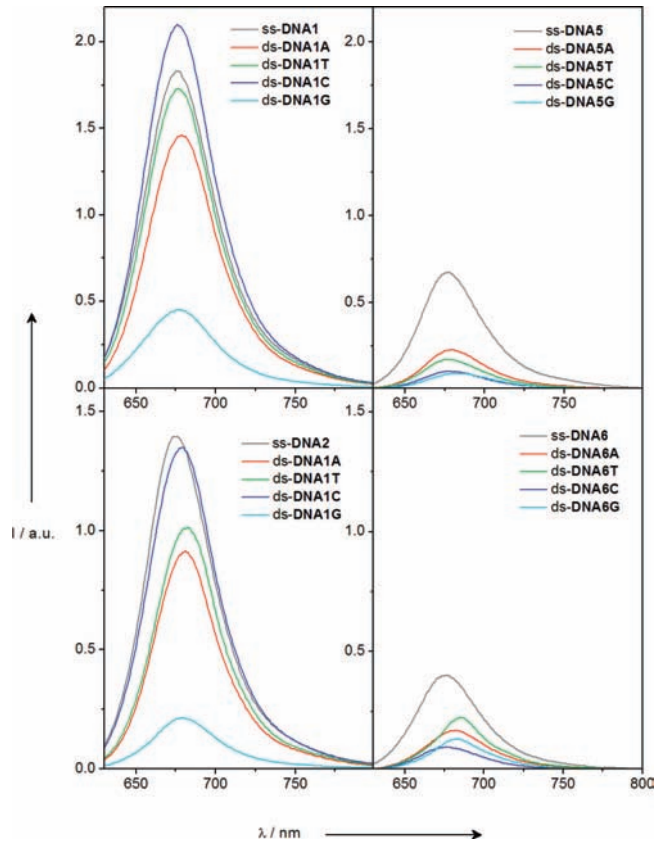

Figure 2. Fluorescence spectra of single-stranded **DNA1**, **DNA2**, **DNA5**, and **DNA6** and the corresponding duplexes (2.5 μM) in sodium phosphate buffer (10 mM) of pH 7.0, NaCl (250 mM), λ_{exc} = 610 nm.

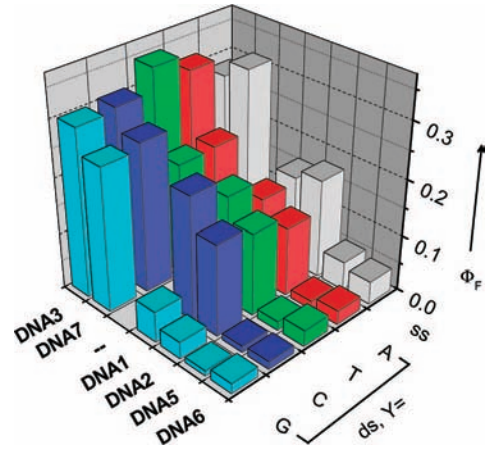

Figure 3. Graphical display of the quantum yields (Θ_F) of the coumarin-modified **DNA3** and **DNA7** and the phenoxazinium-modified **DNA1**, **DNA2**, **DNA5**, and **DNA6**.

defined Watson−Crick base pairing and exhibit a similar thermal stability to that of the unmodified matched duplexes (**DNA4A** and **DNA8A**). Accordingly, we have prepared **DNA3Y** and **DNA7Y** that bear variations of the adjacent base pairs and the counterbase. The melting temperatures show two major trends that are similar to the phenoxazinium-modified **DNA2Y** and **DNA6Y**. (i) As expected, the coumarin-modified uridine clearly prefers the adenine opposite to the modification site. (ii) Compared to the corresponding matched and unmodified duplexes **DNA4A** and **DNA8A**, respectively, the thermal stabilities of the matched but modified duplexes are only slightly lower (−0.5 °C for **DNA7A**) or even higher (+1.0 °C for

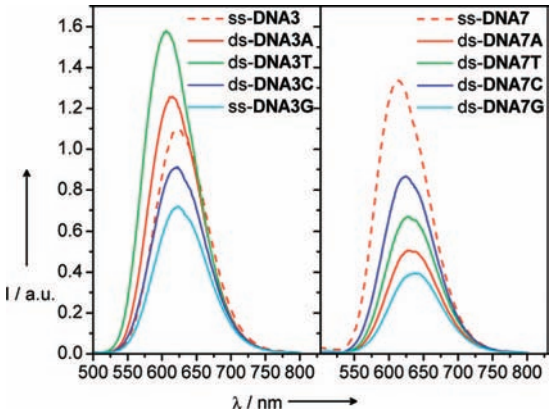

Figure 4. Fluorescence spectra of single-stranded **DNA3** and **DNA7** and the corresponding duplexes (2.5 μM) in sodium phosphate buffer (10 mM) of pH 7.0, NaCl (250 mM), $\lambda_{exc} = 500$ nm.

DNA3A). (iii) The coumarin dye stabilizes mismatches in **DNA3Y** and **DNA7Y** (Y = T, C, G), but not to such an extent as that observed in the case of the corresponding phenoxazinium-modified duplexes.

The UV/vis spectra of the modified single strands and duplexes show an absorption maximum in the range between 515 and 534 nm (Supporting Information Figures S3, S6). It is interesting to note that the duplexes bearing guanine as the counterbase (**DNA3G**) or as the base adjacent to the coumarin modification site (**DNA7Y**) show the most red-shifted absorption, particularly significant in **DNA7G** (534 nm). The steady-state fluorescence spectra of the coumarin-modified duplexes display maxima in the range 606−637 nm (Figure 4). It is important to point out that all modified duplexes exhibit a significant Stokes' shift of approximately 100 nm. The duplexes **DNA3Y** show quantum yields in the range between 30% and 35%. Compared to other coumarins, this is a very large Stokes' shift that is of particular interest with respect to potential fluorescence resonance energy transfer (FRET) studies. In fact, labels **1** and **2** form a well-matched FRET pair excitable with the argon ion laser. The quantum yields of the duplexes with adjacent G-C base pairs (**DNA7Y**) are lower (20−27%); however, a nearly complete fluorescence quenching as in the case of the corresponding phenoxazinium-modified duplexes is not observed.

DISCUSSION

Both the blue phenoxazinium fluorophore of **1** and the red coumarin of **2** are unstable under the basic conditions typically applied for DNA workup. Using the appropriate phosphoramidites as DNA building blocks is therefore a difficult task for the incorporation of these dyes into oligonucleotides. Postsynthetic "click" chemistry, however, allowed the modification of presynthesized alkynylated oligonucleotides with the fluorescent azides **1** and **2** to prepare the corresponding modified duplexes **DNA1Y-DNA3Y** and **DNA5Y-DNA7Y**.

The most critical issue with respect to fluorescent labeling of nucleic acids is fluorescence quenching caused by charge transfer and oxidation of guanines (*48*). Accordingly, there is a major difference between the two fluorophores of **1** and **2** based on photophysical and electrochemical data in the literature. The oxidation potential of guanine is ∼1.3−1.4 V vs normal hydrogen electrode (NHE) (*49*). According to the Rehm−Weller equation, the energy of the singlet−singlet transition E_{00} has to be added to the reduction potential E_{red} in order to calculate the excited-state potential and the driving force of a potential charge transfer reaction. In the case of fluorophore **1**, the excited-state potential is estimated to be $E^*_{red} = 2.2$ eV (vs NHE) using $E_{red} = -0.26$ V (vs decamethylferrocen), $E_{00} = 1.88$ eV, and a correction value of +0.54 V (from decamethylferrocen to NHE reference) (*50*). The excited-state potential of fluorophore **2** is significantly lower and estimated to be $E^*_{red} = 1.5$ eV using $E_{red} = -1.27$ V (vs Ferrocen), $E_{00} = 2.16$ eV and a correction value of +0.63 V (from ferrocen to NHE reference) (*50*). Conclusively, these values indicate that the phenoxazinium label **1** is capable of oxidizing guanines in the sequential neighborhood, whereas the coumarin label **2** represents a borderline case. Hence, we expected sequence-dependent fluorescence quenching of the phenoxazinium dye of azide **1**, and it is important to point out that we decided to use this property as a sensitive tool to compare the electronic interactions of the phenoxazinium chromophore with the DNA base stack in order to evaluate the role of the modification type (nucleosidic vs non-nucleosidic).

Accordingly, azide **1** was incorporated into oligonucleotides either as a nucleotide modification at the 2′-position of uridine (**DNA2Y** and **DNA6Y**) or as a non-nucleosidic base substitution (**DNA1Y** and **DNA5Y**). As expected based on the photophysical data given above, the emission is quenched significantly if a guanine is present as the counterbase, as part of the adjacent base pair, or both. In fact, the fluorescence of the phenoxazinium-modified single strands and duplexes has a quantum yield of >6% only if guanines are not located in direct vicinity of the chromophore. Most importantly, the quantum yield profiles (Figure 3) of the two duplex sets with the nucleoside modification (**DNA2Y** and **DNA6Y**) are very similar in comparison to the duplexes with the non-nucleosidic modification (**DNA1Y** and **DNA5Y**). This is a remarkable result that shows that the optical properties of fluorescent DNA do not depend on whether the dye has been incorporated as a DNA base substitution or as a 2′-nucleoside modification. In both cases, the interactions of the phenoxazinium dye with the counterbase and the adjacent DNA base pairs seem to be electronically similar.

In contrast to the similarity of the fluorescence properties, the phenoxazinium-modified duplexes show different thermal stabilities with respect to the type of modification. Compared to the unmodified and matched duplexes **DNA4A** and **DNA8A**, the replacement of the 2′-deoxyribofuranoside by the non-nucleosidic glycol linker (**DNA1A** and **DNA5A**) result not only in the loss of a preferred base pairing but also in a decrease of thermal stability. Both effects have been expected on basis of the design of the two types of modification (nucleosidic vs non-nucleosidic). However, the second effect is not very pronounced and thus surprising. Typical for single glycol linker substitutions in DNA is a thermal destabilization of more than 10 °C (*43*, *46*, *51*). For the phenoxazinium-modified **DNA1Y** and **DNA5Y**, the values are significantly lower. Obviously, some of the lost thermal stability can be regained by the hydrophobic stacking interactions of the phenoxazinium chromophore, presumably intercalated. The stabilizing effects are highest especially in the presence of adjacent G-C base pairs (**DNA5Y**).

This interpretation is supported by the observation that the mismatched modified duplexes are more stable against thermal dehybridization compared to the corresponding mismatched but unmodified duplexes. This represents another remarkable result, since it indicates that the phenoxazinium dye, presumably intercalated, stabilizes single-base mismatches by its hydrophobic interactions. It is important to point out that, for this effect, similar to the fluorescence quenching, it does not matter whether the phenoxazinium dye has been incorporated as a non-nucleosidic DNA base substitute or as a 2′-nucleoside modification.

Taking together with the results of the phenoxazinium-modified duplexes, it becomes clear that the application of the 2′-modification site of uridine is preferred in comparison to the non-nucleosidic, glycol-assisted DNA base substitution. Hence,

the red coumarin label **2** was attached only to the 2′-position of uridine. The steady-state fluorescence spectra of all coumarin-modified duplexes show a significant Stokes' shift of approximately 100 nm and quantum yields in the ranges 30−35% (**DNA3Y**) and 20−27% (**DNA7Y**). In contrast to the phenoxazinium-modified duplexes, nearly quantitative fluorescence quenching by charge transfer to guanines is not observed here. The lower quantum yields in **DNA7Y** are accompanied by a red-shifted absorption of the coumarin label. Obviously, guanine strongly interacts with the coumarin in the ground state, which also affects the exciplex-type fluorescence originating from the excited state, most significantly observed in the case of **DNA7G**. Nevertheless, the coumarin represents a powerful label for fluorescent nucleic acids based on the Stokes' shift and the quantum yields.

CONCLUSIONS

The blue phenoxazinium azide **1** and the red coumarin azide **2** represent examples of two structurally different but novel types of fluorophores (*35*). A common feature of both dyes is the instability under strongly basic conditions that are typically used for DNA workup. Hence, both chromophores cannot be easily incorporated into DNA using the standard phosphoramidite building block chemistry. However, "click" chemistry allows the postsynthetic modification of oligonucleotides that were presynthesized and modified with an alkyne group. A range of DNA duplexes was modified with the blue phenoxazinium azide **1**; one set of duplexes carried the chromophore attached at the 2′-position of uridine, and a second set contained the chromophore as a non-nucleosidic DNA base surrogate that has been inserted using an acyclic glycol linker. These phenoxazinium-modified duplexes were characterized by optical spectroscopy. A sequence-dependent fluorescence quenching of the phenoxazinium **1** was applied as a sensitive tool to compare the stacking interactions with respect to the structural variations (nucleosidic vs non-nucleosidic). Remarkably, the fluorescence properties do not depend on the modification site. It does not matter whether the chromophore has been attached to the 2′-position of uridine or as DNA base surrogate using the acyclic glycol linker. Thus, the application of the 2′-modification site of uridine is preferred in comparison to glycol-assisted DNA base surrogates. The 2′-chromophore-modified uridine still recognizes adenine as the counterbase and the duplexes do not exhibit a reduced thermal stability in comparison to the unmodified duplexes. Accordingly, the coumarin dye azide **2** was attached only using the nucleosidic approach that means by modification of the 2′-position of uridine. The significant Stokes' shift of ∼100 nm and the good quantum yields make the coumarin chromophore a powerful fluorescent label for nucleic acids in assays or cell biology. The postsynthetic "click" chemistry makes this dye now accessible to fluorescent labeling of nucleic acids.

(*S*)-5-(*p*-Nitrobenzyl)-PCTA, a Promising Bifunctional Ligand with Advantageous Metal Ion Complexation Kinetics

Gyula Tircsó,[†,||] Enikő Tircsóné Benyó,[†,||] Eul Hyun Suh,[‡] Paul Jurek,[§] Garry E. Kiefer,[†,§] A. Dean Sherry,[†,‡] and Zoltán Kovács*[,‡]

Department of Chemistry, University of Texas at Dallas, P.O. Box 830660, Richardson, Texas 75080, Advanced Imaging Research Center, University of Texas Southwestern Medical Center, 5323 Harry Hines Boulevard, Dallas, Texas 75390, and Macrocyclics, 2110 Research Row, Suite 425, Dallas, Texas 75235. Received November 12, 2008; Revised Manuscript Received December 24, 2008

A bifunctional version of PCTA (3,6,9,15-tetraazabicyclo[9.3.1]pentadeca-1(15),11,13-triene-3,6,9,-triacetic acid) that exhibits fast complexation kinetics with the trivalent lanthanide(III) ions was synthesized in reasonable yields starting from *N*,*N*′,*N*″-tristosyl-(*S*)-2-(*p*-nitrobenzyl)-diethylenetriamine. pH-potentiometric studies showed that the basicities of *p*-nitrobenzyl-PCTA and the parent ligand PCTA were similar. The stability of M(NO_2-Bn-PCTA) (M = Mg^{2+}, Ca^{2+}, Cu^{2+}, Zn^{2+}) complexes was similar to that of the corresponding PCTA complexes, while the stability of Ln^{3+} complexes of the bifunctional ligand is somewhat lower than that of PCTA chelates. The rate of complex formation of Ln(NO_2-Bn-PCTA) complexes was found to be quite similar to that of PCTA, a ligand known to exhibit the fastest formation rates among all lanthanide macrocyclic ligand complexes studied to date. The acid-catalyzed decomplexation kinetic studies of the selected Ln(NO_2-Bn-PCTA) complexes showed that the kinetic inertness of the complexes was comparable to that of Ln(DOTA) chelates making the bifunctional ligand NO_2-Bn-PCTA suitable for labeling biological vectors with radioisotopes for nuclear medicine applications.

INTRODUCTION

The choice of chelating system for biomedical imaging and therapeutic applications is largely determined by the nature of the metal ion required for the given application. Several rare earth metal ions (lanthanides and yttrium) and main group III elements are frequently selected for diagnostic (^{111}In, ^{67}Ga, ^{68}Ga, ^{86}Y, ^{177}Lu) and/or therapeutic (^{90}Y, ^{177}Lu, ^{166}Ho,^{149}Pm, ^{153}Sm) nuclear medicine applications (*1, 2*). A common characteristic feature of these metals is their tendency to exist as trivalent cations that form stable complexes in aqueous media with polyamino polycarboxylate type ligands such as the acyclic H_5DTPA (diethylenetriamine-*N*,*N*,*N*′,*N*′*N*″-pentaacetic acid) and the macrocyclic H_4DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-teraacetic acid) systems (Figure 1). Bifunctional derivatives of DOTA are increasingly used to radiolabel peptides, proteins, and other biomolecules (*3*). The success of DOTA-bifunctionals is largely due to their ability to form complexes with these metal ions with high thermodynamic stability and extraordinary kinetic inertness. However, slow complex formation kinetics with DOTA under mild conditions can be a disadvantage, especially when sensitive biological vectors are labeled or when short half-lived isotopes are used (*4, 5*). Therefore, macrocyclic ligands that are complex radioisotopes faster than DOTA and still retain reasonably high kinetic inertness are very desirable. The acyclic octadentate DTPA and its bifunctional versions form complexes much faster than DOTA derivatives, but these complexes have significantly lower kinetic inertness than the corresponding DOTA derivatives despite recent improvements achieved by substituting one of the flexible ethane-1,2-diamine units of DTPA by the more rigid propane-1,2-diamine (MX-DTPA) or cyclohexane-1,2-diamine bridge (CHX-DTPA) (Figure 1) (*6*).

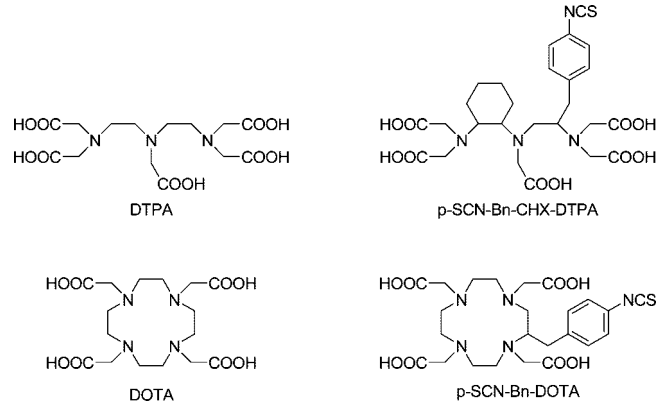

Figure 1. DTPA, DOTA, and two bifunctional derivatives commonly used in nuclear medicine.

Recently, a few attempts have been reported to overcome the problem of slow complex formation involving DOTA-based ligands (Figure 2). Brechbiel and co-workers have synthesized a new class of ligands that integrate a macrocyclic triazacyclononane-diacetic acid and acyclic iminodiacetic acid moiety (bimodal or hybrid ligands). When the two units are linked together through an ethylene bridge, the resulting ligand (NETA) was shown to have improved complexation kinetics (fast complexation with Y^{3+}, excellent serum stability, and rapid clearance of the radiolanthanide chelates) (*7*). A bifunctional version of NETA has also been reported recently (*4, 8*).

Aime and colleagues synthesized an interesting cyclic heptadentate ligand, AAZTA (*9*). Although detailed formation

kinetic data have not been reported for this system, the reaction of AAZTA with lanthanide ions appears to be almost instantaneous (*9*).

Our approach to a bifunctional macrocyclic chelator with improved metal ion complexation kinetics is based on the ligand H_3PCTA (3,6,9,15-tetraazabicyclo[9.3.1]pentadeca-1(15),11,13-triene-3,6,9-triacetic acid, Figure 2). We recently reported that PCTA forms complexes with lanthanide ions about an order of magnitude faster than DOTA (*10*). Furthermore, the acid-catalyzed dissociation rates of the Ln(PCTA) complexes were found to be satisfactorily slow despite their somewhat low thermodynamic stabilities (*10*). Here, we report the synthesis of a bifunctional version of PCTA, (NO_2-Bn-PCTA), the protonation constants of the ligand, the stability constants of the ligand with various metal ions, and the formation and dissociation rates of some Ln(NO_2-Bn-PCTA) complexes.

EXPERIMENTAL SECTION

Synthesis. The detailed synthetic procedures for the bifunctional ligand (*S*)-5-(*p*-nitrobenzyl)-PCTA (NO_2-Bn-PCTA) is reported in the Supporting Information. Analytically pure samples of the ligand used in the equilibrium and kinetics studies were obtained by preparative HPLC purification on a Phenomenex Luna 5u C18(2) column [elution with H_2O (0.038% HCl)/MeCN (gradient elution from 0% MeCN to 50% MeCN in 30 min)].

Equilibrium Studies. pH-potentiometric titrations were carried out with a Thermo Orion EA940 expandable ion analyzer using a Thermo Orion semimicro combination electrode 8103BN in a thermostatted (at 25.0 °C) vessel. A Metrohm DOSIMATE 665 autoburette (5 mL capacity) was used for base additions, and 1.0 M KCl was used to maintain the ionic strength. All equilibrium measurements (direct titrations) were carried out in 10.00 mL sample volumes with magnetic stirring. During the titrations, argon gas was passed over the sample surface to maintain a CO_2-free environment. Standard buffers (borax, 0.01 M, pH 9.180; and KH-phthalate 0.05 M, pH 4.005) were used to calibrate the electrode. The titrant, a carbonate-free KOH solution, was standardized against 0.05 M KH-phthalate solution by pH-potentiometry. The H^+ ion concentrations corresponding to the measured pH values were calculated by the method proposed by Irving et al. (*11*) The ion-product of water was established in a separate acid−base titration experiment ($pK_w = 13.747$) and used in our calculations.

Stock solutions of $MgCl_2$, $CaCl_2$, $ZnCl_2$, $CuCl_2$, YCl_3, $InCl_3$, and $LnCl_3$ were prepared from analytical grade salts (Aldrich and Sigma, 99.9%). The concentration of the stock solutions were determined by complexometric titration using standardized Na_2H_2EDTA solution in the presence of an appropriate end-point indicator (eriochromeblack-T for $MgCl_2$, and $ZnCl_2$, calconcarboxylic acid for $CaCl_2$, murexide for $CuCl_2$, and xylenol orange for YCl_3, $InCl_3$, and $LnCl_3$ stock solutions) (*12*). The concentration of the ligand stock solution was determined by pH-potentiometry from the titration data obtained in the absence and in the presence of about 50-fold excess $CaCl_2$.

The protonation constants of the ligand were calculated from the data obtained by titrating 2.5 mM and 4.4 mM ligand solutions (total 506 data pairs) with standardized KOH solution (0.1713 M) in the pH range of 1.8−11.9. The protonation constants of the ligand (log K_i^H) are defined as follows:

$$K_i^H = \frac{[H_iL]}{[H_{i-1}L][H^+]} \quad (1)$$

where $i = 1, 2,..., 5$ and $[H_{i-1}L]$ and $[H^+]$ are the equilibrium concentrations of the ligand ($i = 1$) and protonated forms of the ligand ($i = 2,.. 5$) and hydrogen ions, respectively.

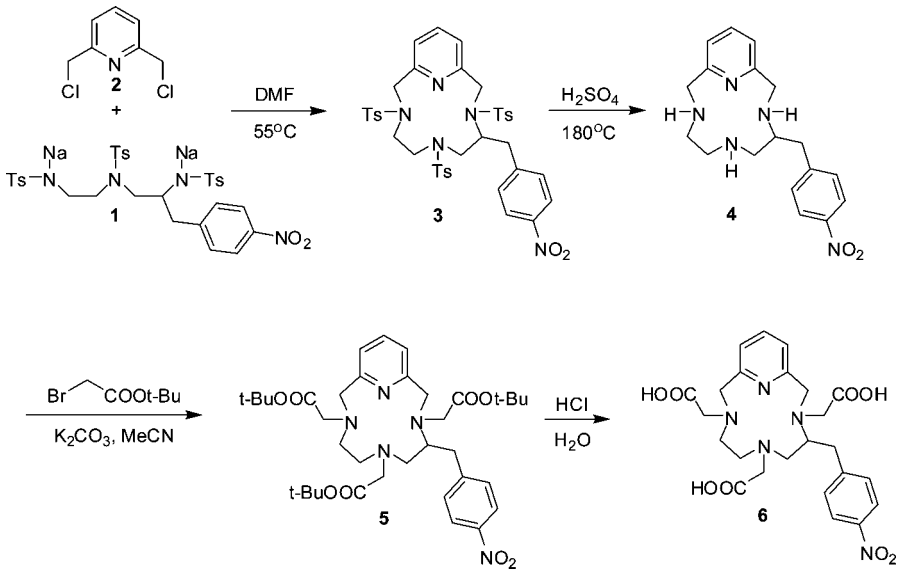
In the systems containing Mg^{2+}, Ca^{2+}, Zn^{2+}, or Cu^{2+}, equilibrium in acidic media was reached rapidly enough to use a direct titration data for stability constant determinations. The titrations were carried out at 1:1 and 2:1 metal to ligand concentration ratio ($C_{Lig} = 2.5$ mM). The data obtained at different concentration ratios were combined and fitted simultaneously. Even though the rate of complex formation of the Ln(NO_2-Bn-PCTA) complexes is faster than that of the Ln-(DOTA) complexes, they are not fast enough to determine the stability of the complexes by direct titration. Because of the slow formation reactions of Y(NO_2-Bn-PCTA) In(NO_2-Bn-PCTA) and the Ln(NO_2-Bn-PCTA) complexes, the out-of-cell technique was applied for the stability constant determinations. The same method was used earlier to determine the stability constants of some Ln(PCTA) complexes, and further details may be found elsewhere (*10*, *13*).

The program PSEQUAD was used to process the titration data (calculation of the protonation and stability constants) (*14*). The reliability of the protonation and stability constants are characterized by the calculated standard deviation values shown in parenthesis and the fitting parameter values (ΔV is the difference between the experimental and the calculated titration curves expressed in mL of the titrant) given in the footnotes of the tables.

Formation Kinetics. The rates of complex formation of Ce(NO_2-Bn-PCTA), Eu(NO_2-Bn-PCTA), and Yb(NO_2-Bn-PCTA) were studied at 25 °C and 1.0 M KCl ionic strength using an Applied Photophysics RX.2000 rapid mixing accessory attached to a Cary 300 Bio UV−vis spectrophotometer. The formation reactions at low pH were sufficiently slow and were followed by conventional UV−vis spectroscopy. The formation rate of Yb(PCTA) was also reexamined in the current study. A typical concentration of PCTA was 0.2 mM, while the concentration of NO_2-Bn-PCTA was approximately 0.075 mM. The concentration of the metal ions was varied in the range 4−40 mM (20 × to 200 × metal excess) when the saturation curves were studied while it was set to 200-fold metal excess for the pH dependent measurements. Yb(PCTA) complex formation was studied in the pH range 3.59−5.16, while in the studies involving the NO_2-Bn-PCTA ligand, the following pH ranges were used: pH 3.93−5.69 for Ce^{3+} and Eu^{3+}, and pH 3.93−5.45 for Yb^{3+}.

Both PCTA and NO_2-Bn-PCTA contain a convenient built-in chromophore (pyridine unit), and both the formation and

Scheme 1. Synthesis of the Bifunctional Ligand, NO_2-Bn-PCTA



dissociation kinetics studies were performed by following the changes in the $\pi \rightarrow \pi^*$ transition at 278 nm. At this wavelength, the absorbance of the metal ions is either weak (Ce^{3+} and Eu^{3+}) or zero (Y^{3+} and Yb^{3+}). During the formation kinetic studies, the noncoordinating buffers *N*-methylpiperazine (NMP, log $K_2^H = 4.83$) and dimethylpiperazine (DMP, log $K_2^H = 4.18$) were used to maintain the pH constant at a concentration of 0.05 M (*14*).

Equation 2 was used to calculate the first order rate constants (k_{obs} for formation and k_p for dissociation), where A_0, A_e, and A_t are the absorbance values measured at the start of the reaction ($t = 0$), at equilibrium, and at time t, respectively. The data were fitted to eq 2 with the Scientist (Micromath) software using a standard least-squares procedure.

$$A_t = A_e + (A_0 - A_e) \cdot e^{(-k_{obs} \cdot t)} \quad (2)$$

The relative error for fitting of the absorbance versus time data was less than 1%, while the calculated first order rate constants, k_{obs} and k_p, were reproduced to within ±3% as determined in 12−15 identical experiments (each point on the curves reflects an average of 12−15 identical kinetic runs) for formation and 3 experiments for the dissociation reactions.

Kinetics of Dissociation. The acid-catalyzed dissociation kinetics of Ce(NO_2-Bn-PCTA), Eu(NO_2-Bn-PCTA), and Yb(NO_2-Bn-PCTA) complexes were measured under pseudofirst-order conditions by mixing the appropriate complexes with a large excess hydrochloric acid (0.25−2.0 M) while keeping the ionic strength constant at 3.0 M with added KCl [$(H^+ + K^+)Cl^-$]. A total of eight reactions was followed by direct spectrophotometry at 25 °C until the conversion reached 80−100% in 0.075 mM complex solutions. Under these conditions, changes of ∼0.2 abs. units were detected throughout the dissociation reaction. In addition, the absorbance data, recorded as a function of time at 278 nm, showed no evidence of significant amplitude loss during the mixing of the components (usually 6−8 s) and were fitted to eq 2 as a single-exponential decay with excellent confidence.

RESULTS AND DISCUSSION

Ligand Design and Synthesis. The aromatic isothiocyanato group is one of the most commonly used reactive functionalities for bioconjugation. It readily reacts with primary amino groups of peptides or proteins to form a stable thiourea linkage under mild conditions. The isothiocyanato functionality can easily be synthesized by reducing the corresponding nitro derivative and reacting the resulting aniline with thiophosgene. Both the aromatic isothiocyanato and amino compounds are sensitive to hydrolysis and oxidation, respectively, and have limited shelf-lives; therefore, they are not suitable for extended equilibrium and kinetic measurements lasting several days (such as the out-of-cell technique). The nitro derivative, however, is stable at room temperature in aqueous solutions and can conveniently be used in these studies. Considering the parent ligand PCTA, the aromatic isothiocyanato function can be attached to three chemically distinct positions: one of the pyridine carbons, one of the acetate sidearms, or one of the carbon atoms of the ethylene bridges in the pyclen backbone. Each of these options has advantages and disadvantages. For example, functionalization of the pyridine moiety would be expected to have the least effect on the chelation properties of the ligand (the *p*-NO_2-benzyl substituent does not have a strong inductive or mesomeric effect, and therefore, it is not expected to significantly alter the electron density on the pyridine N-atom), while sidearm functionalization may have an adverse effect on the metal binding ability of the acetate pendant arms. We have chosen the ethylene bridge for functionalization because our assumption was that this would eliminate any unwanted interference with metal binding, and the rigidifying effect of macrocyclic backbone substitution may actually add to the kinetic inertness of the resulting complexes. In addition, the backbone functionalized PCTA would structurally be analogous to the nitro precursor of the most frequently used bifunctional ligand, *p*-isothiocyanatobenzyl-DOTA, and therefore, comparison of the equilibrium and kinetic properties of these two ligands could provide further insight into the design of new bifunctional chelators. The synthesis of the new bifunctional ligand, (*S*)-5-(*p*-nitrobenzyl)-PCTA (NO_2-Bn-PCTA, **6**) is outlined in Scheme 1. *N*,*N*′,*N*″-tritosyl (*S*)-2-(*p*-nitrobenzyl)-diethylenetriamine was prepared starting from L-nitrophenyl alanine following published procedures (*16*). The key step of the synthesis is the Richman−Atkins-type cyclization of the disodium salt of *N*,*N*′,*N*″-tritosyl-(*S*)-2-(*p*-nitrobenzyl)-diethylenetriamine (tosyl = *p*-toluenesulfonyl) **1** with 2,6-bis(chloromethyl)pyridine **2** in DMF giving about 55% yield of the tritosyl-nitrobenzyl-pyclen (*17*). It is worth noting that the analogous cyclization reaction between the disodium salt of ditosyl-nitrobenzyl ethylenediamine and the tetratosyl derivative of *N*,*N*′-bis(2-hydroxyethyl)-ethylenediamine failed to give the expected tetratosyl nitrobenzyl-cyclen due to side reactions

involving the nitro group (*18*). Interestingly, in this case, the aromatic nitro group did not affect the cyclization reaction, probably because the benzyl-halide type bis(chloromethyl)pyridine is a more reactive alkylating agent than the O-tosyl derivative of *N*,*N*′-bis(2-hydroxyethyl)-ethylenediamine or diethanolamine. The tosyl groups of **3** were removed in concentrated sulfuric acid at 180 °C to afford (*S*)-5-(*p*-nitrobenzyl)-pyclen **4** in good yield. The ^{1}H NMR spectrum of this cyclic tetramine is quite complicated as all the protons are magnetically nonequivalent, and correct assignement could only be achieved with the help of ^{1}H−^{1}H COSY, ^{13}C APT, and ^{13}C−^{1}H HMQC NMR experiments (Supporting Information, Figures S1−S3). Nitrobenzyl pyclen **4** was alkylated with *tert*-butyl bromoacetate in the presence of anhydrous potassium carbonate in acetonitrile to yield the *tert*-butyl ester **5**. The *tert*-butyl ester groups were subsequently cleaved in aqueous hydrochloric acid to afford ligand **6** as the HCl salt in about 35% overall yield.

Protonation and Stability Constant Determinations. The bifunctional ligand (*S*)-5-(*p*-nitrobenzyl)-PCTA has seven protonation sites, and five protonation steps of these were detected in the pH range 1.8−11.8 when the ligand was titrated with strong base (KOH). The protonation constants obtained by pH-potentiometric measurements are presented in Table 1 along with the previously reported values for PCTA, DOTA, and the bifunctional NO_2-Bn-DOTA.

The first and the second protonation constants can be assigned to nitrogen atoms of the macrocyclic ring, while the next 3 protonation steps occur most likely at the acetate pendant arms. The first protonation constant of PCTA and NO_2-Bn-PCTA are nearly identical, but there is a noticeable difference in the second protonation constant (about 0.5 log K units). This was not unexpected as a similar trend has been observed for the protonation constants of DOTA and *p*-NO_2-Bn-DOTA. The somewhat smaller log K_2 values found for the bifunctional versions are likely due to the conformational changes in the ethylene bridge of the macrocyclic ring induced by the *p*-nitrobenzyl substituent (*13*). Interestingly, in the case of NO_2-Bn-DOTA, both the first and the second protonation constants were affected, while for NO_2-Bn-PCTA, only the second protonation constant is affected. This may be explained by the considerably lower conformational flexibility of PCTA derivatives as compared to the DOTA-based ligands due to the rigidifying effect of the pyridine ring. Consequently, the extra strain introduced by the *p*-nitrobenzyl substituent will have a smaller effect on the pyclen macrocycle. Differences in the protonation sequence of NO_2-Bn-PCTA and NO_2-Bn-DOTA may also play a role. According to ^{1}H NMR studies, the most basic site in PCTA is the nitrogen atom opposite the pyridine ring (*25*). Addition of a second proton results in a rearrangement of the protonation sites to the two tertiary nitrogen atoms positioned *trans* to each other and *cis* to the pyridine nitrogen (*25*). In NO_2-Bn-PCTA, the *p*-nitrobenzyl substituent is attached next to a tertiary nitrogen atom positioned *cis* to the pyridine nitrogen, and the extra strain induced at this nitrogen atom reduces its basicity. The total basicity (Σ log K_i^H) of PCTA and NO_2-Bn-PCTA is similar, around 25.8−25.9. Although this value is reasonably favorable, it is about 3 log K units lower than that of the DO3A and 6 to 7 log K units lower than that of DOTA and NO_2-Bn-DOTA. As a consequence, the thermodynamic stability constants for the complexes of PCTA-based ligands are expected to be somewhat lower than the corresponding DOTA complexes.

The stability constants of the complexes of Mg^{2+}, Ca^{2+}, Zn^{2+}, and Cu^{2+} ions with NO_2-Bn-PCTA were determined by pH-potentiometry in the presence of 1.0 M KCl as the ionic background. The stability constants of these complexes along with the constants characterizing the stability of the M(DO3A), M(PCTA) and M(DOTA) complexes are listed in Table 2 (the stability constants of Mg^{2+}, Ca^{2+}, Zn^{2+}, and Cu^{2+} complexes of NO_2-Bn-DOTA have not been reported yet). The pH-potentiomeric titration data for both the 1:1 and 1:2 metal to ligand concentration ratios could be fitted well by assuming the formation of ML and MHL species only. The stability and protonation constants characterizing the formation of the Mg^{2+} and Ca(NO_2-Bn-PCTA) complexes are in excellent agreement with data obtained for the Mg^{2+} and Ca(PCTA) complexes. Unlike the Cu^{2+} and Zn(PCTA) systems, no evidence of formation of ternary hydroxo complexes, MLH_{-1}, was found in titrations with these same metal ions and NO_2-Bn-PCTA, likely due to the higher stability of the latter complexes.

The data in Table 2 show that, unlike DOTA-based ligands, both PCTA and NO_2-Bn-PCTA form more stable complexes with Zn^{2+} than with Cu^{2+}. This observation is in accordance with the results reported earlier by Delgado et al. on the

[i] I = 0.1 M KCl from ref *36*. [j] Ref *19*. [k] Ref *13*. The fitting parameters for trivalent metal ions ranged from 1.1810^{-3} cm^3 (Nd^{3+}) to 7.7410^{-3} cm^3 (Ce^{3+})

selectivity of some pyridine-containing macrocyclic ligands for Zn^{2+} over Cu^{2+} (*26*). Interestingly, the selectivity was observed exclusively for the 12-membered PCTA ligand (*26*). This unexpected selectivity is likely due to the rigid nature of the pyclen backbone and the slightly different type of interaction required (angle) between the pyridine nitrogen atom and Zn^{2+} and Cu^{2+} ions. This explanation is supported by the crystal structure of the [Cu(pyclen)Br]ClO_4, which shows that the pyridine nitrogen−Cu^{2+} bond length is shorter than the secondary amine−Cu^{2+} bonds, while in the ([Zn(pyclen)Cl])$_2ZnCl_4$ complex, the length of the pyridine−N−Zn^{2+} bond is comparable to that of the secondary amine−Zn^{2+} bonds (*26, 30*).

The stability constants (log K_{ML}) of the complexes formed with some Ln^{3+}, Y^{3+}, and In^{3+} ions with NO_2-Bn-PCTA were determined by the out-of-cell potentiometric titration technique because of their slow formation rates. There was evidence for the formation of MHL species only for the larger metal ions (Ce^{3+} and Nd^{3+}, log $K_{CeL}{}^{H}$ = 2.17 and log $K_{NdL}{}^{H}$ = 1.93, respectively), while ternary hydroxo complex formation was not considered. The stability constants of NO_2-Bn-PCTA complexes with these trivalent ions are listed in Table 3 along with previously reported values for structurally related ligands.

As expected, the stability of the Ln(NO_2-Bn-PCTA) complexes increases substantially from Ce^{3+} to Eu^{3+}, then increases only gradually with decreasing ion size, maximizing at Lu^{3+}. This trend is similar to that seen previously for complexes of macrocyclic ligands with a similar size and number of donor atoms (Ln(PCTA), Ln(DO3A), and Ln(DOTA)) (*10, 31, 32, 35, 36*). Despite the similar basicities of PCTA and NO_2-Bn-PCTA, the stability of the Ln(III) complexes formed with the bifunctional ligand are about 0.5−1 log K units lower than those of the parent ligand, PCTA. Since the basicities of these ligands are similar, this difference is likely due to the steric effect of the *p*-nitrobenzyl substituent. Although the thermodynamic stabilities of lanthanide complexes of NO_2-Bn-PCTA are somewhat lower than the stability of the corresponding DOTA complexes, they remain reasonably favorable for potential in vivo applications (*37*).

It is of interest to note that In^{3+} forms quite stable complexes with both PCTA and NO_2-Bn-PCTA (the log K_{ML} value is comparable to the value published for In(DOTA)). However, for a more meaningful comparison, the available literature data on In^{3+}-ligand stability constants should be analyzed carefully because these are often measured in the presence of Cl^- containing electrolytes (e.g., KCl, NaCl, and Me_4NCl) used to maintain the constant ionic strength during titrations. However, Cl^- ions can form relatively stable complexes with the In^{3+} ion with log β_1, log β_2, and log β_3 values of 2.58, 3.84, and 4.20, respectively (25 °C, I = 3.0 M $NaClO_4$) (*38*). If the formation of $InCl_x^{(3-x)+}$ species is not taken into account, then the resulting stability constants only represent the lower limits of stability, and the actual stability constants are somewhat higher (with about 4 log K units). This appears to be the case for In(DOTA), as its stability was measured in the presence of 0.1 M KCl, and the formation of $InCl_x^{(3-x)+}$ species was ignored by Clarke et al. (*36*), whereas it was accounted for in the calculated stabilities of In(PCTA) and In(NO_2-Bn-PCTA) here. In the pH range 1.5−2.5, the conditional stabilities of the In(PCTA) and In(NO_2-Bn-PCTA) complexes are relatively low, and the Cl^- ions can compete well with these ligands. Under the conditions employed in our study (I = 1.0 M KCl), only the complexes $InCl_2^-$, $InCl_3$, and In(PCTA) are present in equilibrium (there is no free In^{3+}), and the stability of the In complexes listed in Table 3 were calculated with the use of the known log β_X values. It is worth noting that the stability of In(PCTA) published by Delgado et al. is 3.3 log K units lower than that measured here (Table 3) (*26*). The competitive Cl^- complex formation cannot explain the discrepancy in this case since Delgado et al. used MeN_4NO_3 to set the ionic strength of the samples (*26*). It is more likely that these differences originate from differences in the protonation constants of the ligand due to the different methods used to evaluate these constants.

Kinetics of Complex Formation. The formation kinetics of the complexes involving macrocyclic ligands are usually considerably slower than the corresponding complexes formed with multidentate, open-chain ligands (*39*). Unlike the polycarboxylate ligands derived from linear polyamines, the corresponding polycarboxylate macrocyclic ligands tend to form relatively stable protonated out-of-cage complexes as intermediates, which then rearrange slowly to the thermodynamically stable complex in a general base-catalyzed step (*40*−*42*). Mono-, di-, and occasionally triprotonated intermediates have been demonstrated by different spectroscopic techniques (UV−vis, luminescence, NMR, EXAFS, etc.) (*43*−*53*). The formation kinetics of Ln(III) complexes are most easily studied by UV−vis spectroscopy (Ce^{3+} and Eu^{3+}) or relaxivity measurements (Gd^{3+}) (*43, 46*−*49*). Complexation of the smaller ionic radii Ln(III) ions that have no absorption in the UV−vis (Yb^{3+} or Lu^{3+}) can be followed indirectly by UV−vis spectroscopy using an appropriate acid−base indicator to register slight pH changes during the course of the reaction (*43, 46, 54*). Fortunately, PCTA and NO_2-Bn-PCTA have a convenient built-in chromophore arising from the $\pi \rightarrow \pi^*$ transition of the pyridine moiety (ε_{max} = 1.25 × 10^4 dm^3 mol^{-1} cm^{-1}, λ_{max} = 269 nm, and pH 3.97, for NO_2-Bn-PCTA) that undergoes a bathochromic shift upon metal ion encapsulation (λ_{max} = 278 nm) (Figure 3). As the bathochromic shift and the molar extinction coefficient are almost independent of which metal ion is encapsulated, this transition can be used to monitor complex formation for a large variety of metal ions. Here, formation kinetics were examined for three lanthanide ions, one of larger ionic radius (Ce^{3+} 103 pm), one of medium ionic radius (Eu^{3+} 95 pm) and one of smaller ionic radius (Yb^{3+} 86 pm) to compare the effect of metal ion size on the rates of complex formation.

The formation kinetics of Ln(NO_2-Bn-PCTA) (Ln = Ce^{3+}, Eu^{3+}, and Yb^{3+}) were studied at different pH and metal ion concentrations (20 to 200-fold metal excess) under pseudofirst-order conditions. In the presence of excess Ln^{3+}, the rate of complex formation may be described as follows:

$$\frac{d[LnL]_t}{dt} = k_{obs}[L]_t \quad (3)$$

where $[L]_t$ is the total concentration of the NO_2-Bn-PCTA (complexed and uncomplexed forms), and k_{obs} is a pseudofirst-order rate constant. Plots of k_{obs} versus Ln^{3+} ion concentraton showed saturation kinetics at high Ln^{3+} concentration. The shape of these plots is characteristic of the rapid formation of an intermediate that rearranges slowly to the final product in a slow, rate-determining step. A similar mechanism has been reported for other Ln(III) complexes formed with macrocyclic polyaminopolycarboxylic acid ligands including Ln(NOTA), Ln(DOTA)$^-$, Ln(TRITA)$^-$, and Ln(PCTA) (*10, 43, 46, 49*). The intermediate formed along the pathway to stable Ln(DOTA) and Ln(PCTA) complexes has been shown to be a diprotonated species, while the intermediate formed in the Ln(NOTA) and Ln(DETA) complexes is monoprotonated (*46, 55*). In each case, the number of protons in the intermediate reflects the basicity of the macrocyclic nitrogen donor atoms in these systems. Tetraazamacrocycles generally have two very basic nitrogen atoms, while triaza macrocycles typically have one basic and one moderately basic nitrogen (*56*); the difference between the first and second protonation constants ($\log K_1^H - \log K_2^H$) is generally larger for triaza macrocycles (4.74 − 6.31 for NOTA) than for tetraaza-macrocyclic ligands ($\log K_1^H - \log K_2^H = 2.33 - 2.90$ for DOTA (the range of the protonation constant differences reflect the literature data reported for the given ligand). The difference between the first and second protonation constants of NO_2-Bn-PCTA (4.59) is somewhat greater than the same difference in PCTA (3.99) and lies between the corresponding differences for DOTA, NO_2-Bn-DOTA, and NOTA. This comparison suggests that the Ln(NO_2-Bn-PCTA) intermediates will likely also be diprotonated. This was verified experimentally for the Yb^{3+} complex in weakly buffered solutions by a UV−vis spectroscopic method described earlier (*43, 46, 54*). Changes in the absorbance of a sample containing an acid−base indicator (methyl orange) in weakly buffered solutions (0.01 M DMP) were calibrated by the addition of a known amount of strong acid stock solution. Using this calibration curve, the concentration (number of moles) of protons released immediately after the mixing of the two components (ligand and metal-ion solution) and at the end of the complexation reaction was determined and compared. The components (ligand and metal ion solutions) were mixed at pH 3.95; a slight pH change was registered upon mixing followed by a more pronounced change in pH during the approach to equilibrium (∼6 h). From the volume of acid needed to return the pH to its original value, it was estimated that about 4 times more protons were released in the slow process than in the fast one. Since the ligand exists as $H_{2.5}L$ at pH ∼4, the release of 0.5 equiv of H^+ upon mixing followed by the liberation of 2 equiv of H^+ after reaching equilibrium is consistent with the formation of a diprotonated intermediate.

Since no major differences in the mechanism of complex formation of Ln(NO_2-Bn-PCTA) and Ln(PCTA) complexes could be detected, the raw data measured for the formation of Ln(NO_2-Bn-PCTA) complexes were treated the same way as the Ln(PCTA) complexes, the details of which will not be repeated here (*10*). Briefly, the pseudofirst-order rate constants obtained at various pH and metal concentrations were fitted to eq 4 (additional information can be found in Supporting Information), and the k_r rate constants and the stability constants of the intermediates $K_{Ln(H_2L)^*}$ were calculated as described for the Ln(PCTA) complexes.

$$k_{obs} = \frac{k_r \frac{K_{Ln(H_2L)^*}}{\alpha_{H_2L}}[Ln^{3+}]}{1 + \frac{K_{Ln(H_2L)^*}}{\alpha_{H_2L}}[Ln^{3+}]} \quad (4)$$

The stability constants of the Ce^{3+} and Eu(H_2NO_2-Bn-PCTA) intermediates determined from the kinetics data were 2.83 ± 0.16 and 2.90 ± 0.11, respectively. The stability of the Yb(H_2PCTA) was also redetermined in the present study and found to be in excellent agreement with our previously published value (2.70 ± 0.08). The stability constants of the intermediates calculated from the kinetic data are lower than those obtained from pH-potentiometric titration for the Ce^{3+}, Eu^{3+}, and Yb(H_2DOTA)$^+$ complexes ($\log K = 4.5$, 4.3, and 4.2, respectively), consistent with differences in the acid-base properties of the ligands as well as differences in the structures expected for these intermediates. The nature of this intermediate has been thoroughly investigated for DOTA. Recent pH-potentiometry, luminescence, and extended X-ray absorption fine structure (EXASF) spectroscopy studies have indicated that the formation of Ln(DOTA) chelates actually involves two diprotonated intermediates (*51, 52*), the first of which is formed instantaneously where the central Ln^{3+} ion is coordinated to oxygens of each of the four carboxylate groups and five water molecules ($q = 5$). This intermediate rapidly converts into the more stable diprotonated species in which the metal ion is coordinated to four oxygens of the acetate side arms, two N-atoms of the macrocyclic ring, and three water molecules ($q = 3$). The stability of the more stable ($q = 3$) intermediate has been determined by both pH-potentiometry and spectrophotometry ($\log K = 4.5$, 4.3, and 4.2 for Ce^{3+}, Eu^{3+}, and Yb^{3+}, respectively, by pH-potentiometry) (*43*). For ligands with three acetate side arms (PCTA, DO3A), the stability of the intermediate is expected to be lower (*57*). There are no stability data available for the intermediates in Ln(DO3A) systems, but q was found to be 4.6 for the Eu(DO3A) complex (*52*). Data published for [10-[2,3-dihydroxy-1-(hydroxymethyl)propyl]-DO3A (DO3A-butriol) ($\log K = 2.4$, 2.5, and 2.43 for the Ce^{3+}, Eu^{3+}, and Yb^{3+} intermediates, respectively) suggest that only the acetate oxygens coordinate (*57*). Considering the Eu^{3+} aqua ion as nine-coordinate, one can assume that the PCTA and NO_2-Bn-PCTA ligands also coordinate to the metal by the three acetate oxygen donor atoms. This assumption is supported by the fact that the stability of the intermediates are higher than the stability of the monoacetate complexes and are very similar to the stability of Ln-dicarboxylic acid complexes (*15*).

It is now generally accepted that the mechanism of complex formation for DOTA and DOTA-like ligands involves the rearrangement of the diprotonated intermediates through rapid deprotonation of the intermediate to a monoprotonated species in a fast equilibrium step. This is followed by the release of the second proton in a slow, rate-determining step and the rapid structural rearrangement of the fully nonprotonated complex to the final product. In accordance with this mechanism, the validity of general base catalysis has been confirmed in some cases (*10, 24, 57*).

Equation 4 can further be simplified if the experimental conditions are chosen so that the conditional stability constant of the intermediate will be high ($K^C_{Ln(H_2L)^*} = K_{Ln(H_2L)^*}/\alpha_{H_2L}$), and the reaction will be pseudofirst-order ($C_{Ln} \geq 10C_L$). Under these conditions, $K^C_{Ln(H_2L)^*} \times [Ln]_{tot} \gg 1$, and thus 1 can be neglected in the denominator of eq 4. This simplifies eq 4 to $k_{obs} \approx k_r$, (k_r is the saturation value of the rate constant k_{obs} when the formation of the intermediate is complete). In other words, the k_r values can be approximated with k_{obs} if a large excess of

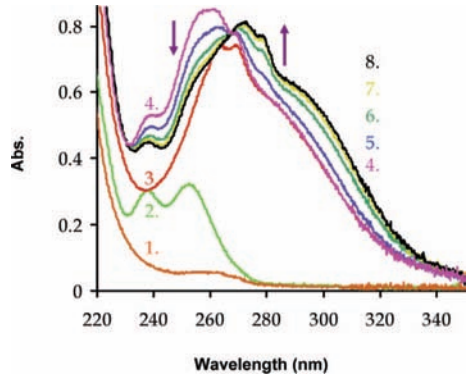

Figure 3. Absorbance changes in the UV region during the formation of Ce(NO_2-Bn-PCTA) after mixing Ce^{3+} and the ligand at 10:1 metal to ligand concentration ratio at pH 4.20 (in 0.04 M DMP, $I = 1.0$ M KCl, and $C_{Lig} = 6 \times 10^{-5}$ M). The curves represent the UV-spectrum of (1) 40 mM buffer, (2) 6×10^{-4} M $CeCl_3$ in DMP buffer, (3) 6×10^{-5} M ligand in DMP buffer, (4) immediately after mixing the Ce^{3+} with the ligand (0 min), (5) after 2 min, (6) after 7 min, (7) after 12 min, and (8) after 70 min (equilibrium).

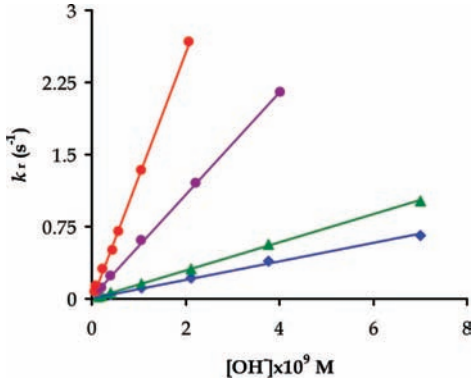

Figure 4. Formation rates of Ce(NO_2-Bn-PCTA) (blue diamonds), Eu(NO_2-Bn-PCTA) (green triangles), Yb(NO_2-Bn-PCTA) (purple circles), and Yb(PCTA) (red circles) vs OH^- ion concentration ($I =$ 1.0 M KCl; 25 °C).

Ln^{3+} is used over the ligand. The necessary excess of the Ln^{3+} to reach the $k_{obs} \approx k_r$ condition can be determined from the expression of the stability constant of the accumulated intermediate (eq 5):

$$K_{Ln(H_2L)^*}[Ln^{3+}] = \frac{[Ln(H_2L)^*]}{[H_2L]} \quad (5)$$

To ensure quantitative formation of the intermediate, the ratio $[Ln(H_2L)^*]/[H_2L]$ ([bound]/[unbound]) in eq 5 should be $\gg 1$. The ratio [bound]/[unbound] will be equal to 1 when the ratio $[Ln^{3+}]/[H_2L] = 19$ (as calculated from the stability constant of the intermediate); therefore, for a more detailed pH dependence study, the ratio $[Ln^{3+}]/[H_2L]$ was set to 200.

The rate constants k_r obtained under these conditions were found to be inversely proportional to the H^+ ion concentration (eq 6) for all of the metal ions and ligands studied in the present work (Figure 4). The k_{OH} values were obtained from the fitting of k_r values gained at different pH values to eq 6 (Table 4).

$$k_r = \frac{k_H}{[H^+]} = k_{OH}[OH^-] \quad (6)$$

The rate of complex formation (rearrangement of the intermediates) increases with decreasing lanthanide-ion size. This decreasing tendency of the k_{OH} values along the lanthanide series is not surprising since it has been reported for numerous cyclen derivatives with acetate pendant arms

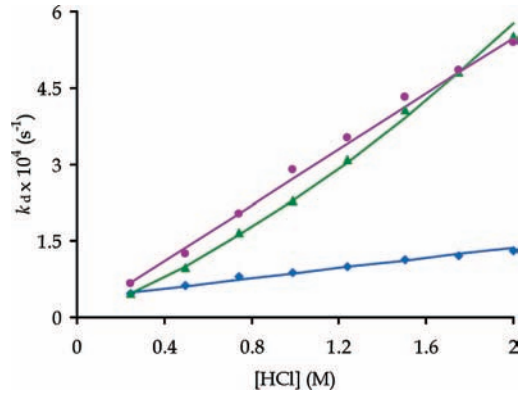

Figure 5. Dependence of the dissociation rate constants (k_d) on the H^+ ion concentration in the dissociation of Ce(NO_2-Bn-PCTA) (blue diamonds), Eu(NO_2-Bn-PCTA) (green triangles), and Yb(NO_2-Bn-PCTA) (purple circles) complexes at 25 °C.

and can be explained by the higher charge density of the heavier lanthanides (the OH^- ion catalyzed deprotonation is faster for the metal ions with greater positive charge density) (*42*). The Ln(NOTA) complexes do not follow this trend, and for some DOTA-tetra(amides), the opposite order of formation constants was recently reported (*46*, *61*, *62*). For the latter complexes, the extremely slow water exchange that is typical of DOTA-tetraamide systems seems to be responsible for this unusual behavior across the lanthanide series (*61*, *62*).

Kinetics of Dissociation. The kinetic inertness of a complex will largely determine its fate in vivo (*63*). Even if the thermodynamic stability of the complex is not very high, it is possible that it can safely be used for biomedical applications if the complex does not dissociate in vivo. The usefulness of acid-catalyzed dissociation rates in predicting the fate of a complex in vivo was first noted by Wedeking when it was found that the extent of long-term Gd-deposition in the whole body, liver, and femur of mice correlated well with the ex vivo acid-catalyzed dissociation rates of various open chain and macrocyclic ^{153}Gd-labeled complexes (*64*). The deposition of Gd was the lowest for Gd(DOTA), and this is in good agreement with its extremely slow proton assisted dissociation rate (*64*). Generally, the dissociation of Ln(III) complexes of DOTA-like ligands are very slow under physiological conditions (*63*), probably because of their tightly packed and highly rigid structure (*45*). Later it was realized that the in vivo dissociation mechanism of acyclic and macrocyclic lanthanide complexes is quite different. The dominant pathway for in vivo dissociation of Ln-chelates of DOTA-like ligands involves the acid-catalyzed dissociation and the acid-independent spontaneous dissociation. However, Ln-complexes of open chain ligands (EDTA and DTPA) dissociate in vivo through a metal ion [Zn(II) and Cu(II)] catalyzed pathway, which is acid-independent above pH 4.5 (*63*). Therefore, the in vitro dissociation kinetic studies of macrocyclic chelates are focused on the acid-catalyzed dissociation, and from the kinetic data, the k_1 and k_2 rate constants corresponding to acid-assisted dissociation of the mono and diprotonated complexes as well as the k_0 rate constant that describes the acid-independent spontaneous dissociation can be estimated (*43*, *45*). Since at pH >2, Ln(NO_2-Bn-PCTA) complexes dissociate too slowly to collect kinetic data over a reasonable period of time, the acid-catalyzed dissociation of Ln(NO_2-Bn-PCTA) complexes was examined at pH $\ll$2, where the complexes are thermodynamically unstable. Under these experimental conditions, proton-assisted dissociation follows first-order kinetics with respect to the complex ($[H^+] \gg$ [Ln(NO_2-Bn-PCTA)]), and

[a] Data for some other complexes formed with macrocyclic ligands are also listed for comparison. [b] Calculated from saturation kinetics from ref *32*. [c] Ref *66*. [d] Data corresponds to the YL complex. [e] Ref *10*. [f] Data corresponds to the EuL complex. [g] Calculated from saturation kinetics obtained in a wide concentration range. [h] Second-order dependence on H^+ ion concentration with third-order rate constant $(5.7 \pm 0.4) \times 10^{-5}$ M^{-2} s^{-1} was also observed. [i] Ref *47*. [j] Second-order dependence on H^+ ion concentration with third-order rate constant 2.0×10^{-3} M^{-2} s^{-1} was also observed (*47*). [k] t = 37 °C; ref *43*. [l] Ref *45*. [m] Data corresponds to EuL (*43*).

the rate of the dissociation is directly proportional to the total concentration of the complex:

$$-\frac{d[LnL]_t}{dt} = k_d[LnL]_t \quad (7)$$

where k_d is a pseudofirst-order rate constant. Under the conditions employed in the current work (0.25 M HCl < C < 2.00 M HCl), complex dissociation proceeds via some combination of acid-assisted and spontaneous dissociation, and consequently, the total concentration of the complex will be a sum of equilibrium concentrations of the complex ([LnL]) and its different protonated forms ([LnH_xL] where x = 1, 2,...).

The dependence of the pseudofirst-order dissociation rate constants (k_d) on the H^+ ion-concentration was measured for Ce^{3+}, Eu^{3+}, and Yb(NO_2-Bn-PCTA) (Figure 5, each point on this figure is an average of two identical kinetic runs). These data demonstrate that the rate of dissociation of the complexes is either proportional to the acid concentration (Ce and Yb) or shows a second-order dependence and can be described by eqs 8 and 9, respectively

$$k_d = k_0 + k_1[H^+] \quad (8)$$

$$k_d = k_0 + k_1[H^+] + k_2[H^+]^2 \quad (9)$$

where k_0 is a constant that describes the acid-independent dissociation (spontaneous dissociation), while k_1 and k_2 correspond to acid-assisted dissociation of the protonated complexes. Ln^{3+} complexes of the parent PCTA behaved slightly differently since Eu(PCTA) and Yb(PCTA) exhibited linear dependence at low acid concentrations, while saturation type dependence was observed for Ce(PCTA), Y(PCTA), and Yb(PCTA) at higher acid concentration. This is likely a consequence of the lower thermodynamic stability of Ln(NO_2-Bn-PCTA) complexes. As a result, the mono and diprotonated intermediates are also expected to have lower stability, and the dissociation curves reach saturation at higher acidity beyond the range of acid concentration used in the study.

The acid-catalyzed dissociation of NO_2-Bn-PCTA complexes very likely follows the same mechanism that accounts for the dissociation of DOTA complexes, with protonation of a carboxylate oxygen as the initial step. The protonated species then undergoes rearrangement, while the proton is transferred from the acetate arm to a ring nitrogen atom. Electrostatic repulsion between the protonated nitrogen and the central metal ion in the macrocyclic cavity of the ligand causes the formation of an out-of-basket complex, which may then dissociate directly or can simultaneously follow a pathway that involves an attack by a second proton. Proton transfer and rearrangement of the complex occurs concurrently, and either of these processes can be the rate-limiting step. The rigidity of the macrocyclic ligand is responsible for the high kinetic inertness of these complexes.

In the physiologically relevant pH range, the contribution of the spontaneous dissociation of the complex, characterized by the k_0 rate constant, may be significant. The value of k_0 can be estimated from the kinetic data (eq 8), but normally its value is zero within the experimental error because under the experimental conditions (pH ≪2), the contribution of the spontaneous dissociation to the dissociation process is very small. In our studies, fitting of dissociation kinetics data for the Eu^{3+} and Yb^{3+} complexes returned a small and negative value for k_0. Similar conclusions were reached by other researchers who determined the rate constant characterizing the spontaneous dissociation of Gd(DOTA) from the kinetic data, and the contribution of the acid-independent dissociation was neglected (*43, 45*). We have found a positive $k_0 = (4.0 \pm 0.3) \times 10^{-5}$ s^{-1} with acceptable uncertainty for Ce(NO_2-Bn-PCTA). However, this value appears to be too high for the spontaneous dissociation of this type of complexes. As reported earlier (*10*), the rate of spontaneous dissociation can be predicted from acid-catalyzed dissociation rate data. By comparing data obtained for complexes of macrocyclic ligands of similar ring size, number, and quality of donor atoms, it was found that the rate of spontaneous dissociation is usually 4−6 orders of magnitude lower than the acid-catalyzed dissociation rate constant, k_1 (*10*). This approximation gives about 10^{-8} to 10^{-9} s^{-1} as the lower limit of the rate constant characterizing spontaneous dissociation of the Ln(NO_2-Bn-PCTA) complexes. In order to determine the k_0 value more precisely, the measurements must be performed at a pH range closer to 7. Preliminary data collected for Gd(PCTA) and Gd(NO_2-Bn-PCTA) in the pH range of 3.0−6.0 and in the presence of Zn^{2+} as scavenger metal ion indicate that an estimate for k_0 is about 10^{-8} to 10^{-9} s^{-1}. Moreover, a recent study on the transmetalation of Gd(PCTA) and its rigidified derivative, Gd(CHX-PCTA) as well as other cyclen based macrocyclic Gd(III) complexes in the presence of Zn^{2+} ions and at physiological pH showed no measureable dissociation of the complexes over the time period of 9000 min (*37, 65*).

The acid-catalyzed dissociation rate constants for some Ln(NO_2-Bn-PCTA) complexes are listed and compared to those of other macrocyclic complexes in Table 5. Interestingly, when compared to the parent ligand, PCTA, the introduction of the *p*-nitrobenzyl substituent did not adversely affect the kinetic inertness of the Ln(NO_2-Bn-PCTA) complexes. Even though the thermodynamic stability of Ln(NO_2-Bn-PCTA) is slightly lower than the corresponding PCTA complexes, their kinetic inertness toward acid-catalyzed dissociation is somewhat higher. This is likely due to the rigidifying effect of the *p*-nitrobenzyl subtituent attached to the pyclen backbone. A similar trend was observed for open-chain and macrocylic ligands when their structures were rigidified. For example, the half-life of Gd(cyclohexyl DOTA) in 1 M HCl is 50 h compared to 23 h of Gd(DOTA) (*67*). The improvement in kinetic inertness is the most pronounced for the Ce^{3+} complex where the rate constant k_1 was found to be at least an order of magnitude lower than it is for the Ce(PCTA). Furthermore, Ce(NO_2-Bn-PCTA) was found to be even more inert toward acid-assisted dissociation than Ce(DOTA).

CONCLUSIONS

The novel bifunctional ligand *p*-nitrobenzyl-PCTA was synthesized in reasonable yields. The total basicity of *p*-nitrobenzyl-PCTA was very similar to that of PCTA and about 6 orders of magnitude less than the basicity of DOTA. As expected, the stability of the complexes of M(NO_2-Bn-PCTA) (M = Mg^{2+}, Ca^{2+}, Cu^{2+}, and Zn^{2+}) is very similar to that of the corresponding PCTA complexes. The stability of the Ln complexes of this new bifunctional ligand is slightly lower ($\Delta\log K = 0.5 - 1.0$) than that of the parent ligand, but the trend of the stability constants across the Ln^{3+} series remains unaffected. The stabilities of In(PCTA) and In(NO_2-Bn-PCTA) were found to be quite high ($\log K \sim 24$), about 3.3 $\log K$ units higher than that previously reported for In(PCTA). This difference is a consequence of competitive complex formation between the Cl^- and In^{3+}. As expected, the formation of Ln(NO_2-Bn-PCTA) complexes proceeds through a diprotonated intermediate, and the rate constant characterizing the OH^- ion catalyzed deprotonation and rearrangement of the intermediate was found to be comparable to that of PCTA complexes. The kinetic inertness of selected Ln(NO_2-Bn-PCTA) (Ln = Ce, Eu, and Yb) complexes was studied by measuring the rate constant characterizing the acid-catalyzed dissociation and was found to be higher than the corresponding PCTA chelates probably due to the rigidifying effect of the *p*-nitrobenzyl substituent. In summary, structural modification of the pyclen backbone with a *p*-nitrobenzyl substiuent does not have an unfavorable influence on either the thermodynamic or kinetic properties of PCTA. The bifunctional ligand forms complexes about an order of magnitude faster than DOTA, while the kinetic inertness of the Ln(NO_2-Bn-PCTA) complexes are comparable to that of DOTA chelates. The rapid complex formation kinetics combined with satisfactory thermodynamic stability and excellent kinetic inertness of the complexes renders this bifunctional ligand particularly suitable for nuclear medicine applications when rapid complex formation is required under mild conditions. In addition, the pyridine moiety is a good sensitizer for luminescent lanthanides such as Eu(III) and Tb(III), and using time gating imaging techniques, the lanthanide emission can be easily separated from the background tissue fluorescence because of the much longer luminescent lifetime (ms) of these ions (*68*). Thus, *p*-nitrobenzyl-PCTA could also be used in the design and construction of in vivo bimodal (nuclear/optical or MRI/optical) imaging probes (*69, 70*).

ACKNOWLEDGMENT

This article is dedicated to Dr Róbert Király (University of Debrecen, Hungary) on the occasion of his retirement. We are grateful to Professor Lynn A. Melton (University of Texas at Dallas) for the access to the RX.2000 Rapid Mixing Accessory. This work was supported in part by grants from the National Institutes of Health (CA-115531, RR-02584 & EB-004582), the Robert A. Welch Foundation (AT-584), the EMIL Project funded by the EC FP6 Framework Program (LSCH-2004-503569), and the Hungarian Science Foundation (OTKA K-69098).

Supporting Information Available: Detailed synthesis of the ligand, $^1H-^1H$ COSY, ^{13}C APT and $^{13}C-^1H$ HMQC NMR spectra of nitrobenzyl pyclen, evaluation of kinetic data, the rate constants characterizing the rearrangement of the intermediates to the final products in formation reactions of Ce(NO_2-Bn-PCTA), Eu(NO_2-Bn-PCTA) and Yb(NO_2-Bn-PCTA) complexes, the k_p values for dissociation of Ce(NO_2-Bn-PCTA), Eu(NO_2-Bn-PCTA), and Yb(NO_2-Bn-PCTA) complexes. Synthesis

General. Reagents were purchased from Sigma-Aldrich (St. Louis, MO) and solvents were obtained from Fisher Scientrific, (Houston, TX) unless otherwise stated. ^{1}H and ^{13}C NMR data were recorded o a Varian Inova 400MHz or a JEOL Eclipse 200MHz FT NMR spectrometer. Chemical shifts are reported as δ in ppm relative to TMS. MALDI-TOF MS spectra were recorded on a Voyager-DE^{TM} PRO (Applied Biosystems) for MALDI-TOF using an α-cyano-4-hydroxycinnamic acid matrix. Electrospray (ESI) mass spectra were obtained from HT Laboratories, San Diego, CA. Elemental analyses were performed by Galbraith Laboratories, Knoxville, TN.

N, N,' N''-Tritosyl-(S)-2-(p-nitrobenzyl)-diethylenetriamine was prepared from L-nitrophenyl alanine following literature procedures.*(1, 3, 4*).

N, N', N"–Tritosyl-2-(p-nitrobenzyl)-diethylenetriamine disodium salt (1). The disodium salt of N, N,' N''-tristosyl-(S)-2-(p-nitrobenzyl)-diethylenetriamine was prepared by the adaptation of the literature procedure for the disodium salt of N,N',N"-tritosyldiethylenetriamine (*2, 5*) N, N', N"–tritosyl-2-(p-nitrobenzyl)-diethylenetriamine (23.00 g) was suspended in absolute ethanol (250 mL) and the mixture was heated to reflux. Sodium ethoxide (freshly prepared by dissolving 1.85 g of sodium metal in 50 mL of absolute ethanol) was added to the hot, stirred reaction mixture in one portion resulting in a clear yellow solution. The mixture was heated at reflux for an additional 5 min. while a fine precipitate formed. The mixture was allowed to cool to room temperature and then it was placed into the refrigerator overnight.

The product was filtered on a fritted glass filter and was washed with ethanol (2x50 mL) and ether (2x50 mL) and dried in high vacuum to give 23.18 g of a pale yellow solid. This product was used without further purification and characterization.

N, N', N"–Tritosyl-5-(p-nitrobenzyl)-pyclen (3). N, N', N"–Tritosyl-2-(p-nitrobenzyl)-diethylenetriamine disodium salt (**1**) (16.00 g) was suspended in DMF (500 mL) and bis(chloromethyl) pyridine (**2**) (4.00 g) was added. The mixture was stirred at 55 °C for 3 days. The solvent was removed by rotary evaporation and the residue was taken up in water (200 mL). The yellow solid was filtered on a Buchner funnel, washed with water (4x200 mL) and dried with air suction. The yield for the crude product was 16.08 g. The crude product was dissolved in hot ethyl acetate (40 mL) and hot absolute ethanol (80 mL) was added. The mixture was boiled until all of the solid dissolved. Upon cooling to room temperature, a large amount solid started to crystallize. It was placed into the refrigerator overnight. The product was filtered on a fritted glass filter, washed with ethanol (2x10 mL) and with ether (2x10 mL) and dried by air suction to give 9.71 g of a yellow solid (56.16%). An analytical sample was obtained by another recrystallization from MeCN. ^{1}H NMR (400MHz, CDCl3) δ: 8.05 (2H, s br, Ar) 7.68 (5H, s br, Ar), 7.34-7.26 (12H, m, Ar), 4.87-3.08 (12H, m br, O$\underline{CH_2}$Ar, N$\underline{CH_2}$ ring) 2.44 (3H, s, CH_3Ar), 2.40 (3H, s, CH_3Ar), 2.36 (3H, CH_3Ar). ^{13}C NMR (100MHz, CDCl3) δ: 153.87, 144.79, 142.00, 141.87, 136.79, 133.80, 128.07, 127.84, 125.41, 125.19, 121.67, 59.90, 53.38, 46.36, 35.18, 19.69, 19.66, 19.55. MS (MALDI-TOF): *m/z* calcd. for $[M + H]^+$: 804.22; found: 804.59. Anal. Calcd for $C_{39}H_{41}N_5O_8S_3$: C, 58.26, H, 5.14, N.8.71. Found: C, 58.15, H, 5.09, N, 9.05.

5-(p-Nitrobenzyl)-pyclen (4). N, N', N"–Tritosyl-5-(p-nitrobenzyl)-pyclen (**3**) (9.00 g) was dissolved in sulfuric acid (40 mL) and the solution was heated at 180 °C for 10 min. The mixture was allowed to cool to room temperature and then placed into an ice bath and ether (500mL) was carefully added in small portions. *Caution! Addition of ether to sulfuric acid generates heat!* A large amount of grey precipitate formed. The ether was decanted and the grey residue was washed and decanted with ether (2x500 mL). The residue was dissolved in water (50 mL) and NaOH solution (15g NaOH in 20 mL of water) was added. A dark oil separated, which was extracted into chloroform (3x150 mL) and the combined chloroform extracts were dried over sodium sulfate, clarified with activated carbon, filtered and evaporated by rotary evaporation to give a yellow oil that crystallized in high vacuum. Yield :3.00 g (78.53%). ^{1}H NMR (400MHz, $CDCl_3$) δ: 8.05 (2H, dd, Ar, *J* = 8.8Hz), 7.45 (1H, t, Ar), 7.25 (2H, dd, Ar, *J* = 8.8Hz), 6.93 (1H, d, Ar, *J* = 7.6Hz), 6.86 (1H, d, Ar, *J* = 7.6Hz), 4.12 (1H, d, N$\underline{CH_2}$ ring, *J* = 16.0Hz), 4.03 (1H, d, N$\underline{CH_2}$ ring, *J* = 16.0Hz), 3.64 (1H, d, N$\underline{CH_2}$ ring, *J* = 16.0Hz), 3.57 (1H, d, N$\underline{CH_2}$ ring *J* = 16.0Hz), 2.89-2.75 (2H, m, NCH$\underline{CH_2}$Ar, N$\underline{CH_2}$ ring), 2.65-2.60 (2H, m, NCH$\underline{CH_2}$Ar, N$\underline{CH}CH_2$Ar), 2.51-2.46 (1H, m, N$\underline{CH_2}$ ring), 2.32 (1H, dd, N$\underline{CH_2}$ ring, *J* = 12.0Hz), 2.25-2.21 (1H, m, N$\underline{CH_2}$ ring), 2.03 (1H, dd, N$\underline{CH_2}$ ring, *J* = 12.0Hz), 1.76-1.70 (1H, m, N$\underline{CH_2}$ ring). ^{13}C NMR (100MHz, $CDCl_3$) δ: 160.43, 159.40, 148.22, 146.65, 136.67, 130.22, 123.66, 120.42, 119.97, 57.00, 54.55, 53.85, 51.84, 50.33, 49.54, 40.36. MS (MALDI-TOF): *m/z* calcd. for $[M + H]^+$: 342.20; found: 342.44 (overlaps with peaks from the matrix). MS (ESI) *m/z* calcd. for $[M + H]^+$: 342.20; found: 342. Anal. Calcd for $C_{18}H_{23}N_5O_2$: C, 63.32, H, 6.79, N, 20.51. Found: C, 62.86, H, 6.82, N, 20.41.

5-(p-Nitrobenzyl)-PCTA (6). 5-(p-Nitrobenzyl)-pyclen (**4**) (2.85 g) was dissolved in acetonitrile (200 mL) and potassium carbonate (9.0 g, anhydrous, -325 mesh) was added. Tert-butyl bromoacetate (5.33 g) was dissolved in acetonitrile (10 mL) and the solution was added to the reaction mixture in small portions over a period of 30 min. The mixture was stirred at 50 °C for five days. The inorganic salts were filtered off and the filtrate was evaporated by rotary evaporation. The residue was dissolved in ether (100 mL) and the solution was washed with water (3x50 mL), dried over sodium sulfate, filtered and evaporated by rotary evaporation to give 5-(p-nitrobenzyl)-PCTA tris(tert-butyl ester) (**5**) as a yellow oil. ^{13}C NMR, 50MHz, $CDCl_3$) δ: 170.99, 170.92, 170.42, 157.30, 156.38, 149.71, 145.90, 136,74, 130.13, 122.71, 122.30, 122.06, 80.93, 80.78, 80.57, 60.26, 59.59, 59.09, 58.47, 58.32, 54.21, 50.14, 49.93, 47.61, 37.58, 28.00, 27.98. MS (ESI) *m/z* calcd. for $[M + H]^+$: 684.39; found: 685. This product was used in the next step without further purification. 5-(p-Nitrobenzyl)-PCTA tris(tert-butyl ester) (**5**) (5.83 g) was dissolved in hydrochloric acid (20%, 100 mL) and the solution was stirred at room temperature for two days. The mixture was treated with activated carbon (0.5 g), filtered and evaporated by rotary evaporation. The residue was redissolved in water and freeze dried to give 4.35 g of a yellow solid (83% from 6). The crude product was purified on a Waters DeltaPrep preparative chromatography system and a Phenomenex Luna C18(2) (250x50 mm, 10 μm) column. Mobile phase was 15/85 CH_3CN/H_2O 0.01 M HCl total. Four injections of 0.5 g in 10 mL of mobile phase were performed. Using a flow rate of 100 mL/min and monitoring the output at 210 nm, a single fraction was collected each run with a retention time of ~9.8 – 13.0 min. All four fractions were placed on the freeze-dryer to remove the solvent. Final solid samples were homogenized by shaking.

The yield was 1.30 g (65%). The chromatographic purity of the final product was 99.1%. ^{1}H NMR (400MHz, D_2O, ND_4OD) δ: 7.87 (2H, s br, Ar) 7.52 (1H, dd, Ar, *J* = 8.0Hz), 7.22 (2H, s, br, Ar), 6.96 (2H, d Ar, *J* = 8.0Hz), 3.83-2.86 (18H, d, m,O$\underline{CH_2}$Ar, N$\underline{CH_2}$ ring, N$\underline{CH_2}$COOH). ^{13}C NMR (100MHz, D_2O, ND_4OD) δ: 178.97, 178.44, 171.29, 159.26, 147.14, 146.35, 138.70, 130.32, 124.08, 121.08, 61.38, 60.49, 58.10, 54.28, 52.43, 51.85, 50.57, 48.22, 33.34. MS (MALDI-TOF): *m/z* calcd. for $[M + H]^+$: 516.21; found: 516.49. Anal. Calcd for $C_{24}H_{29}N_5O_8 \cdot 3HCl \cdot 2H_2O$: C, 43.61, H, 5.49, N.10.60. Found: C, 43.34, H, 5.77, N, 10.59.

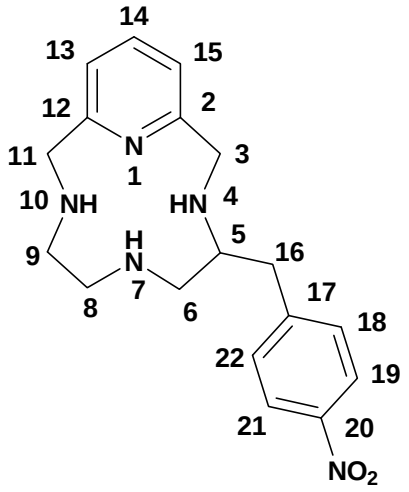
^{1}H-^{1}H COSY, APT ^{13}C and ^{13}C-^{1}H HMQC NMR experiments with nitrobenzyl cyclen

Due to the presence of the nitrobenzyl group, all the protons of nitrobenzyl pyclen are magnetically nonequivalent. The correct assignment of the ^{1}H and ^{13}C NMR spectra were accomplished with the help of APT (attached proton test), ^{1}H-^{1}H COSY (correlated spectroscopy) and HMQC (heteronuclear multiple quantum coherence) experiments. The ^{1}H-^{1}H-COSY spectrum (Figure S1) confirmed the connection of C-5 to C-6 and C-16, C-8 to C-9, C-14 to C-13 and C-15, C-18 to C-19, and C21 to C-22.



The numbering of the nitrobenzyl pyclen skeleton as used here to identify the protons and carbons in the NMR spectra

The APT experiment detected the multiplicity (number of protons attached) of the carbons (Figure S2) while the HMQC experiment established the correlations between the protons and the ^{13}C nuclei by showing the directly coupled C-H peaks (Figure S3). The COSY, APT and HMQC experiments were performed on a Varian Inova 400MHz NMR spectrometer.

Equations used for the formation kinetics data fitting.

The relation of conditional equilibrium constant ($K_{cond}^{Ln(H_2L)}$) and $K_{therm}^{Ln(H_2L)}$ can be obtained from the following equations (where H_2L is the diprotonated form of the ligand NO_2-Bn-PCTA):

$$K_{therm}^{Ln(H_2L)} = \frac{[Ln(H_2L)^{2+}]}{[Ln^{3+}][H_2L^-]} \qquad \text{(S1)}$$

Since we assumed that the rate determining step is the deprotonation and rearrangement of the diprotonated intermediate, the rate of this first-order process can be expressed as in eqn. (S2):

$$\frac{d[LnL]_t}{dt} = k_{obs}[L]_0 = k_r[Ln(H_2L)^-] \qquad \text{(S2)}$$

The total concentration of the ligand can be obtained by summarizing the concentration of the complexed and uncomplexed forms of ligand:

$$[L]_0 = [Ln(H_2L)^-] + [L^{3-}]_{free} \qquad \text{(S3)}$$

The concentration of uncomplexed ligand can be derived by summarizing the concentrations of all ligand species:

$$[L^{3-}]_{free} = [H_5L^{2+}] + [H_4L^-] + [H_3L] + [H_2L^-] + [HL^{2-}] + [L^{3-}] \qquad \text{(S4)}$$

Eqn. S4 can be rewritten using the protonation constants of the ligand:

$$[L^{3-}]_{free} = [H_2L^-](K_1^H K_2^H [H^+]^2 + K_2^H [H^+] + 1 + \frac{1}{K_3^H [H^+]} + \frac{1}{K_3^H K_4^H [H^+]^2} + \frac{1}{K_3^H K_4^H K_5^H [H^+]^3}) \quad \text{(S5)}$$

The term in parenthesis is the α_{H_2L} according to eqn. S6:

$$\alpha_{H_2L} = \frac{K_1^H K_2^H [H^+]^2}{1 + K_1^H [H^+] + K_1^H K_2^H [H^+]^2 + K_1^H K_2^H K_3^H [H^+]^3 + K_1^H K_2^H K_3^H K_4^H [H^+]^4 + K_1^H K_2^H K_3^H K_4^H K_5^H [H^+]^5} \quad \text{(S6)}$$

Thus, $[L^{3-}]_{free}$ can be expressed with α_{H2L} as:

$$[L^{3-}]_{free} = [H_2L^-]\alpha_{H_2L} \quad \text{(S7)}$$

The conditional stability constant ($K_{cond}^{Ln(H_2L)^{2+}}$) of the intermediates are related to the thermodynamics stability constant ($K_{therm}^{Ln(H_2L)^{2+}}$) of the intermediate by the following equation:

$$K_{therm}^{Ln(H_2L)^{2+}} = K_{cond}^{Ln(H_2L)^{2+}} \alpha_{H_2L} \quad \text{(S8)}$$

Finally, from equations S1, S2, S7 and. S8, the final equation used for fittings (eqn. 4) can be derived.

Formation rate constants

Influence of Streptavidin on the Absorption and Fluorescence Properties of Cyanine Dyes

Franziska Luschtinetz, Carsten Dosche,* and Michael U. Kumke

Institute of Chemistry, University of Potsdam, Karl-Liebknecht-Str. 24−25, 14476 Potsdam-Golm, Germany. Received November 17, 2008; Revised Manuscript Received January 22, 2009

Cyanine dyes have become widely used fluorescence labels in clinical and biological chemistry. In particular, cyanine dyes with excitation wavelengths $\lambda_{ex} > 600$ nm are often used in biological applications. However, aggregation behavior and matrix effects on cyanine fluorescence are not fully understood yet and interfere with the data interpretation. In this study, we analyzed the spectroscopic characteristics of a model system consisting of the biotinylated cyanine dyes DY-635 and DY-647 and their streptavidin conjugates. On the basis of the spectroscopic data, the interaction processes between cyanine dye molecules and proteins are discussed. Binding to streptavidin had a significant influence on both fluorescence and anisotropy decays of the cyanine dyes investigated. In particular, the fluorescence anisotropy was significantly altered, making it a promising detection parameter for bioanalytical applications in connection with the cyanine dyes used in the present study. In order to evaluate the time-resolved anisotropy, the introduction of a sophisticated kinetic model was required to describe the contributions from different fluorescing species properly. The rotational motion of streptavidin-bound dyes was analyzed using the associated anisotropy model, which allowed discrimination between contributions from different microenvironments. The anisotropy decay times increased by a factor of up to 20 due to protein binding.

INTRODUCTION

In life sciences, medicine, and clinical diagnostics, fluorescence-based analytical techniques, such as fluorescence immuno analysis (FIA) or fluorescence lifetime imaging microscopy (FLIM), have proven to be most versatile for qualitative and quantitative analysis as well as for basic research. For using fluorescent labels in biological samples, several drawbacks have to be overcome, e.g., (i) the autofluorescence of the sample, (ii) cell damage due to irradiation (by laser light), (iii) the often limited penetration depth of excitation light, and (iv) problems arising from the fluorescence probes such as quenching phenomena or low solubility. Additional important properties needed especially for single molecule detection applications are very high photostability and high fluorescence quantum yield.

By using red- and NIR-absorbing dyes, the autofluorescence of the sample and problems arising from scattered light can be greatly reduced. Because of excitation wavelength $\lambda_{ex} > 600$ nm, the risk of cell damage is reduced and indicates such dyes to be especially suited as fluorescence probes in biological systems. Due to the high fluorescence efficiency, the good photostability, and the high potential to design tailor-made fluorescence probes covering a wide spectral range in absorption and fluorescence, cyanine dyes are highly attractive as fluorescence probes for bioanalytical applications such as cytometry or heterogeneous and homogeneous FIA. However, problem arising from low solubility, self-quenching, and self-aggregation have to be overcome.

Generally, cyanine dyes are based on two heteroarenes coupled by a polymethine chain which determines the spectral properties of the particular cyanine dye. Problems due to low solubility, self-quenching, and self-aggregation can be reduced by the introduction of functional groups like sulfonic acid groups or by applying only very low concentrations (*1*−*4*). Also, the addition of detergents such as Tween20 has been reported to increase the solubility of the cyanine dyes in aqueous solution (*5*). However, the effect of detergents on the fluorescence properties of probes such as cyanine dyes has to be evaluated from case to case.

By implementing reactive groups, the cyanine dyes can be covalently labeled, e.g., to biotin. Particularly, biotinylation of fluorescence probes is an often used approach for detecting and analyzing interaction processes of biomolecules. The biotin−streptavidin binding is widely used for biological sensors since the biotin−streptavidin system is a well-characterized model system for biological binding. Streptavidin is a 52.8 kDa tetrameric protein and binds four biotins per molecule with high affinity ($K_D = 10^{-13}$ M). The neutral isoelectric point of the non-glycosylated streptavidin leads to a high specificity of this binding (*6*). However, binding of biotinylated fluorescence markers to proteins like streptavidin might alter the fluorescence properties of the probe. The frequently used fluorescence probe ATTO 655 was reported to be quenched by the aromatic amino acids tryptophan and tyrosine (*7*). Furthermore, the interaction with neighboring binding sites of proteins can block them from binding another biotinylated probe molecule (*4*). In addition, dye−dye interactions can occur after binding to biological samples. In DNA-bound cyanine dyes, the formation of dimers and H-aggregates was described (*8*). It is also known that the presence of liposomes can lead to dimerization of fluorophores such as cyanine dyes (*9*). Depending on the layout of the bioanalytical application, such alterations in the fluorescence properties of the probe represent a large benefit or drawback (e.g., in a homogeneous FIA, the binding is monitored due to the change of the fluorescence; on the other side in a heterogeneous FIA such change might render the fluorescence probe useless for the application). Therefore, for using fluorescence probes such as cyanine dyes in tailor-made biological applications and for further improved fluorescence probe design, a sound understanding of fundamental molecular interactions among probe molecules, possible matrix components, and proteins (e.g., aggregation effects) is essential.

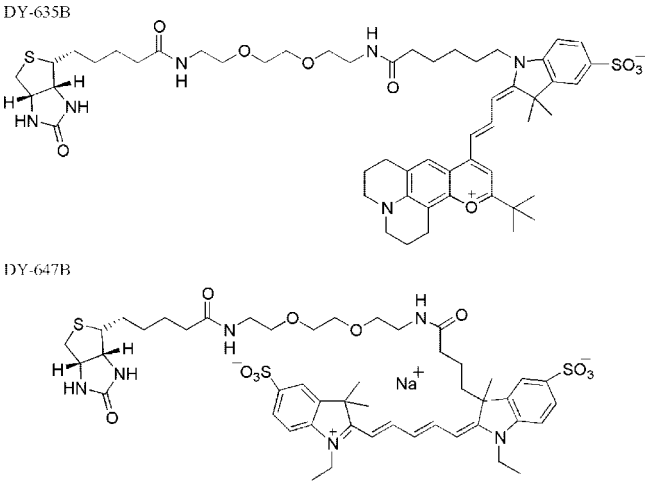

Figure 1. Molecular structures of biotinylated cyanine dyes (DY-635B, DY-647B) used in this study.

In the present study, two fluorescence probes of the cyanine dye class were investigated. DY-635 and DY-647, their biotinylated analogues (DY-635B, DY-647B) (see Figure 1), and complexes with streptavidin were characterized in steady-state and time-resolved fluorescence experiments. In particular, the binding of the biotinylated compounds (DY-635B, DY-647B) to streptavidin was analyzed in detail using steady-state and time-resolved anisotropy. To describe the rotational dynamics of the biotinylated dyes and their corresponding complexes with streptavidin, a global analysis of the time-dependent anisotropy was performed and the rotational correlation times ϕ_i were determined.

EXPERIMENTAL PROCEDURES

Materials. The dyes DY-635, DY-647 (as carboxylic acid), and the corresponding biotin conjugates (DY-635B, DY-647B) (Figure 1) were obtained from Dyomics (Jena, Germany) (CAS Registry Numbers: 375396-02-4 (DY-635), 709668-85-9 (DY-647)). For biotin−streptavidin studies, purified streptavidin was purchased from Promega (Madison, WI).

Stationary Fluorescence and Extinction Measurements. Absorption and fluorescence studies were carried out in a 0.1 M PBS buffer solution (pH 7.4 and $T = 298$ K). To avoid inner filter effects, the maximum absorbance was kept below 0.1 for fluorescence measurements. For low-temperature measurements, a nitrogen-cooled cryostat equipped with an external temperature control (Optistat DN1704, ITC4; both Oxford Instruments, Wiesbaden, Germany) was used. Absorption spectra were recorded in the range 400 nm $< \lambda_{abs} <$ 800 nm using a Cary 500 UV−vis−NIR spectrometer (Varian, Darmstadt, Germany). The extinction coefficients for the unconjugated dyes (DY-635, DY-647) were provided by the product data sheet of the manufacturer.

A Fluoromax-3 spectrofluorometer (Horiba Jobin Yvon, Munich) was used to measure the steady-state fluorescence and anisotropy spectra. For steady-state fluorescence measurements, a spectral bandwidth of $\Delta\lambda = 1.5$ nm in the excitation and emission channel was set, and for fluorescence anisotropy measurements, $\Delta\lambda = 4$ nm was applied. All emission spectra were background-corrected. In the anisotropy measurements, the sample was excited with vertically (I_v) and horizontally (I_h) polarized light. The steady-state anisotropy r was determined according to

$$r = \frac{I_{vv} - I_{vh}G}{I_{vv} + 2I_{vh}G} \tag{1}$$

G is the instrumental correction factor

$$G = \frac{I_{hv}}{I_{hh}} \tag{2}$$

The subscripts v and h refer to the vertical and horizontal orientations of the polarizers in the excitation and emission beam.

Fluorescence Quantum Efficiency. The fluorescence quantum efficiencies were determined using an integrating sphere setup (PL Quantum Yield Measurement System C9920−02, Hamamatsu). Samples with concentrations of 5×10^{-7} M were excited at $\lambda_{ex} = 610$ nm.

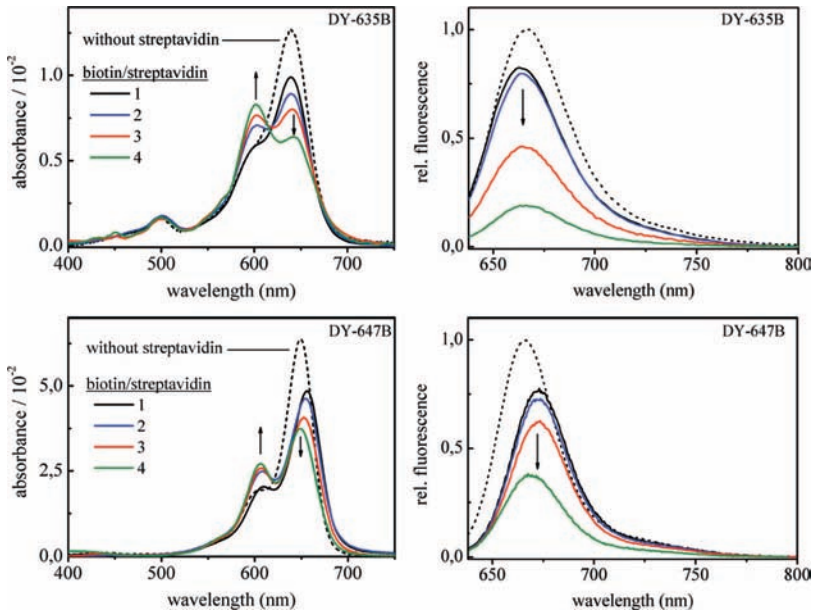

Figure 2. Normalized absorption and fluorescence spectra ($\lambda_{ex} = 620$ nm) of DY-635B ($c = 9 \times 10^{-8}$ M, top) and DY-647B ($c = 2.9 \times 10^{-7}$ M, bottom). Free dyes in absence of streptavidin (dashed lines) and streptavidin-bound biotinylated dyes (solid lines) at different biotin/streptavidin ratios (black, 1:1; blue, 2:1; red, 3:1; green, 4:1) in PBS buffer (pH 7.4).

Fluorescence Decay Measurements. For the measurements of the fluorescence decays, a FL920 fluorescence lifetime spectrophotometer (Edinburgh Instruments, Edinburgh, UK) operated in the time-correlated single photon counting (TCSPC) mode was used. To avoid polarization effects, fluorescence decays were recorded under magic angle conditions (54.8°). With respect to the fluorescence anisotropy decay measurements, the instrument was set up in an L-geometry configuration (*10*). A pulsed laser diode (Picoquant, Berlin, Germany) ($\lambda_{ex} = 635$ nm, rep. rate 2.5 MHz, pulse width (FWHM) 90 ps) was attached as the excitation source. In all time-resolved emission measurements, the excitation beam was vertically polarized. A multichannel plate (Europhoton GmbH, Berlin, Germany) with a Glenn-Thomson polarizer in front of the emission monochromator was used for signal collection.

The experimental data were analyzed using least-squares deconvolution, and the goodness of the fit was judged on the reduced χ_R^2-values. The fluorescence decays were fitted according to a single- or double-exponential decay model

$$I(t) = \sum_{i=1}^{n} \alpha_i \exp\left(-\frac{t}{\tau_i}\right) + B \quad \text{with } i = 1...2 \tag{3}$$

The α_i is the amplitude of the component i with the corresponding fluorescence decay times τ_i. The parameter B accounts for the background. The fractional amounts A_i of the fluorescence decay times are calculated according to

$$A_i = \frac{\alpha_i \tau_i}{\sum_{j=1}^{2} \alpha_j \tau_j} \quad \text{with } i, j = 1...2 \tag{4}$$

Anisotropy Decay Measurements r(t). To obtain anisotropy decays, the values $r(t)$ were determined by measuring the fluorescence decay with the emission polarizer set in a vertical ($I_{vv}(t)$) and horizontal ($I_{vh}(t)$) position, respectively. From the experimental data, $r(t)$ was calculated according to eq 1. The G-factor was obtained by fitting the synthesized fluorescence decay curve $I_{vv}(t) + 2GI_{vh}(t)$ and is described in detail elsewhere (*11*).

The fit for the anisotropy $r(t)$ was weighted according eq 5

$$w_i = \frac{3[I_{vv}(t_i) + 2I_{vh}(t_i)]}{2 + r(t_i) + 5[r(t_i)]^2 - 2[r(t_i)]^3} \quad \text{with } i = 1...2 \tag{5}$$

The rotational diffusion of molecules in a homogeneous environment can be described by the model of general ellipsoids (*8*). In that case, an exponential decay of the anisotropy $r(t)$ can be assumed. As the fundamental anisotropy r_0 at the time $t = 0$ is known from low-temperature steady-state fluorescence anisotropy measurements, the anisotropy decay $r(t)$ can be analyzed using eq 6

$$r(t) = r_0 \sum_j \exp\left(-\frac{t}{\varphi_j}\right) \quad \text{with } j \leq 5 \tag{6}$$

ϕ_j are the rotational correlation times for rotations around the different rotational axes of the molecule. In this simple case, the fluorescence decay time τ_i does not influence the anisotropy decay.

In contrast to a homogeneous distribution of fluorophores, often the anisotropy decay of a heterogeneous environment cannot be described by a simple exponential approach (*12*).

Due to the binding of the fluorescent probes to a protein like streptavidin, a second microenvironment for the fluorophore can subsequently lead to a change in the fluorescence decay time τ_i as well as in the rotational correlation time ϕ_j. For a mixture of free and streptavidin-bound fluorescent probes, a more complex model to account for the observed anisotropy decay has to be used. In particular, the fluorescent decay time τ_i has to be properly considered in the data analysis. The concept of an "associated" anisotropy can be applied in order to account for the correlation of anisotropy and fluorescence decay (*12*−*16*). Assuming that each fluorescence decay time τ_i is directly associated with one rotational correlation time ϕ_j, the observed anisotropy decay $r(t)$ in the case of two microenvironments results in a complex decay and can be described by eq 7

$$r(t) = \frac{\sum_{i=1}^{2} \alpha_i \beta_i \left[-t\left\{\frac{1}{\tau_i} + \frac{1}{\varphi_i}\right\}\right]}{\sum_{i=1}^{2} \alpha_i \exp\left(-\frac{t}{\tau_i}\right)} \quad \text{with } i = 1...2 \tag{7}$$

Here, β_i are the pre-exponential factors of the anisotropy decay. It has to be stressed that in this model the anisotropy decay $r(t)$ is influenced by the fluorescence decay time τ_i of the fluorophores in each environment. In case τ_i is altered due to conjugation and it is correlated to one rotational correlation time, the anisotropy decay curve is found to be nonexponential. Only the special case of an identical fluorescent decay time in both microenvironments results in a biexponential decay of the anisotropy, and $r(t)$ would be independent of the fluorescence decay time τ_i.

The fluorescence and anisotropy decay data were evaluated in a global fitting approach with at least nine different biotin/streptavidin ratios. The values β_i were set as global parameters and kept constant, because no alteration in the fundamental anisotropy r_0 of the dyes due to the binding to streptavidin is expected.

In order to get a rough first approximation for the rotational correlation times, a spherical protein geometry was assumed and the Stokes−Einstein relation was used to estimate the rotation correlation time ϕ_i by means of the molar mass M and the hydration properties (ν, h) of the protein (*10*, *17*):

$$\varphi_i = \frac{\eta M}{RT}(\nu + h) \tag{8}$$

In eq 8, η represents the dynamic viscosity of the solvent and T the absolute temperature. For streptavidin assuming a molar mass of $M = 52.800$ g/mol (provided by the manufacturer), the expected rotational correlation time is around 18 ns (viscosity of water at 298 K: $\eta = 0.89$ cp, hydrodynamic properties (specific protein volume: $\nu = 0.23$ mL/g, hydration $h = 0.73$ mL/g) were taken from the literature (*10*)).

From the rotational correlation time of the free diffusing fluorophores, the theoretical stationary anisotropy r_{calc} was determined according to the Perrin relation (*10*, *18*):

$$r_{calc} = r_0\left(\frac{1}{1 + \tau/\varphi}\right) \tag{9}$$

RESULTS AND DISCUSSION

Steady-State Absorbance and Fluorescence Measurements. The comparison of the parent and biotinylated cyanine dyes showed that the photophysical properties of the dyes were not altered due to biotinylation. However, binding to streptavidin resulted in significant changes in the steady-state photophysical characteristics of DY-635B and DY-647B (see Figure 2). The biotin/streptavidin ratio has a strong effect on the absorption and fluorescence intensity as well as the spectral position of the corresponding maxima. Compared to the absorbance of the free biotinylated dyes, the complex formation of 1:1 complexes

results in a decrease of 20%. The absorption and fluorescence maxima of DY-647B are red-shifted by 6 nm upon binding to streptavidin (Figure 2 - bottom, Table 1). For DY-635B, the fluorescence maximum was blue-shifted (5 nm), while no influence of streptavidin on the absorption maximum was observed in 1:1 complexes (see Figure 2 - top, Table 1).

At higher ratios, these trends became more pronounced (see Figure 2). Moreover, at higher biotin/streptavidin ratios an enhancement of the absorption band at $\lambda \sim 600$ nm was found, which was accompanied by a decrease of the main absorption band of the dyes (see Figure 2). Such spectral change was observed for other cyanine dyes conjugated to biomolecules before and has been attributed to dye−dye interactions (e.g., dimerization) (*15, 19*−*24*).

In order to minimize dye−dye interactions, such as association in following time-resolved experiments, an excess of streptavidin to the solution of the biotinylated dyes was added. Under such conditions, it can be assumed that predominantly 1:1 biotin−streptavidin complexes are formed (*5, 19*). Consequently, it is tempting to attribute the observed enhancement of the absorption band at $\lambda \sim 600$ nm in 1:1 complexes to an (electronic) interaction of the dyes and streptavidin.

Fluorescence Decay Times. In the absence of streptavidin, DY-635B and DY-647B exhibit monoexponential fluorescence decays (in PBS buffer, pH 7.4). The fluorescence of both dyes decays more slowly after binding to streptavidin (Figure 3, Table 1), and for the analysis, a second decay component has to be

introduced in order to properly fit the experimental data. The appearance of a second fluorescence decay time for DY-647B and DY-635B in the presence of streptavidin is attributed to the localization of these dyes in two different microenvironments. The longer fluorescence decay time τ_2 points to a more rigid conformation of the dyes due to binding to streptavidin, e.g., the formation of hydrogen bonds between the dyes and streptavidin (see also the changes in the absorption spectrum of the dyes); e.g., due to the reduced flexibility of the dye, the internal conversion rate is decreased (*21*).

The allocation between the two microenvironments is displayed by the fractional amount A_i of the corresponding

fluorescence decay times τ_i (Figure 4). For both DY-635B and DY-647B, at low concentrations of streptavidin the fractional amount A_2 remains low due to the large amount of unbound dye molecules in solution. Starting at a ratio of about 0.1, a steady increase of the fraction A_2 was found. At a streptavidin/biotin ratio of 0.25, an inflection point can be seen. Above this ratio, all biotinylated dyes are bound to streptavidin resulting in constant values of A_2 of 89% for DY-635B and of 76% for DY-647B, respectively. The remaining amount 11% (24%) of the fluorescence decay time τ_1 can be attributed to a small amount of non-biotinylated dyes in solution or to the presence of different (micro)environments of the biotinylated dyes when bound to streptavidin: (i) closely bound (e.g., via H-bonds, etc.) to the streptavidin, which would also be supported by the changes in the absorption spectra and (ii) a relatively uninfluenced situation, e.g., in which the dye is free to rotate around its linker in solution. From literature (*23*), it is known that the structural similar cyanine dye Cy5 shows two different fluorescent decay times after binding to streptavidin. The referred fluorescent states are converted by light.

Stationary and Time-Resolved Fluorescence Anisotropy Measurements. In order to further characterize the binding of the biotinylated dyes by streptavidin, the rotational correlation times ϕ_i in the absence and presence of streptavidin were determined. Excitation anisotropy measurements of DY-635B and DY-647B in glycerol at 223 K were used to determine the fundamental anisotropy r_0, since the rotation of the dyes is prevented at this temperature (*10*). From the anisotropy spectra (Figure 5), it becomes obvious that only one electronic transition is observed in the spectral range 520 nm $< \lambda_{ex} <$ 650 nm, which can be attributed to the S_0-S_1 transition. In the spectral region of the S_0-S_1 transition, the anisotropy value was determined close to the theoretical limit of 0.4 indicating that the absorption and emission dipole moments are nearly parallel (see also Table 2). In the shorter wavelength region, high electronic transitions (S_0-S_n transitions) are observed as well. In buffer solution at room temperature, anisotropy values of 0.18 (0.19) were found for DY-647B (DY-635B) in the spectral range of the S_0-S_1 transition. The anisotropy data of DY-647B and DY-635B are consistent with data reported for other cyanine dyes (*25*−*28*)

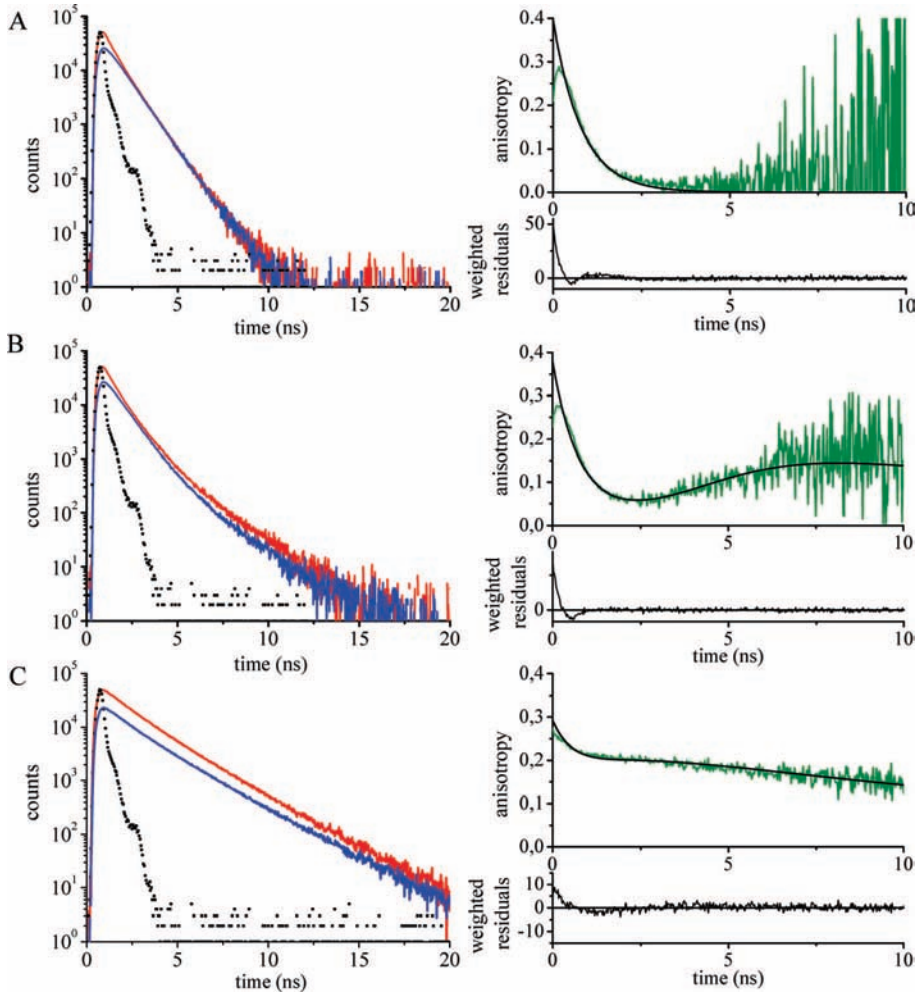

Figure 6. Time-resolved anisotropy measurements for DY-635B at different streptavidin/biotin ratios in PBS buffer pH 7.4 (c(DY-635) = 1.3 × 10^{-7} M). (A) DY-635B in the absence of streptavidin. (B) Streptavidin/biotin: 0.1. (C) Streptavidin/biotin: 1. Left side: polarized fluorescence decay curves (*G*-factor corrected): $I_{vv}(t)$ (red line) and ($I_{vh}(t)$ (blue line). Emission at $\lambda_{em} = 670$ nm, excitation at $\lambda_{ex} = 635$ nm. Instrument response functions are shown (dotted line). Right side: anisotropy decay data (green lines) and the corresponding global fit curve (black line).

For DY-635B the polarized fluorescence decay curves $I_{vv}(t)$ and $I_{vh}(t)$ and the corresponding anisotropy decay data $r(t)$ at different streptavidin/biotin ratios are shown in Figure 6.

In the absence of streptavidin (Figure 6A), the anisotropy of DY-635B decays monoexponentially with a rotational correlation time ϕ of 0.8 ns. By means of the fluorescence decay time τ (0.9 ns) and the fundamental anisotropy r_0, a theoretical value of the steady-state anisotropy r_{calc} at 298 K of 0.18 was obtained with the Perrin equation (eq 9). That value is in good agreement with the stationary fluorescence anisotropy value of 0.19. Similar results were obtained for DY-647B (Table 2).

After addition of a small amount of streptavidin to a solution of DY-635B (10 times excess of biotinylated dye), the anisotropy decay curves show a significant change (Figure 6B, right side). At low streptavidin concentrations (streptavidin/biotin <0.4; see also Figure 4A,B), not all biotinylated dyes are tightly bound to streptavidin (e.g., via H-bonds), and subsequently, the fluorophores are located in two different environments, each with a characteristic fluorescence decay time and rotational correlation time.

At short times, the anisotropy $r(t)$ initially decays with rotational correlation time ϕ_1 very similar to that of biotinylated dyes in streptavidin-free solutions. This could be either due to the presence of nonbound biotinylated dye molecules or to the fact that a fraction of the dye molecules are free to rotate around the linker chain, which would make them appear as "free" molecules. However, at times above 2 ns (after the excitation pulse, see Figure 6B) an increase in anisotropy is found. This rise of the anisotropy at longer times can be associated to streptavidin-bound dyes, which are expected to show a much longer rotational correlation time ϕ_2 due to the increased overall rotational volume (e.g., see also eq 8). To analyze the nonexponential anisotropy decay, the use of an associated model was applied (*11*). Using a global fitting approach, the anisotropy as well as the fluorescence decay curves were fitted simultaneously with the fluorescence decay times τ_1 and τ_2, as well as the rotation correlation times ϕ_1 and ϕ_2 set as global parameters for all streptavidin/biotin ratios. The corresponding global fit curves for the anisotropy decay at streptavidin/biotin ratios of 0, 0.1, and 1 are displayed in Figure 6 (right side). Figure 6C presents the polarized fluorescence and anisotropy decay curves for a streptavidin/biotin ratio of 1. In that case, it is expected that all biotinylated dyes are bound to streptavidin, and consequently, the anisotropy decays monoexponentially with a long rotational correlation time ϕ_2 of about 17 ns. In the anisotropy curve shown in Figure 6C, the remaining fast decay at short times can be attributed to remaining unbound dyes in solution.

CONCLUSION

In our study, two biotinylated fluorophores of the cyanine family and their binding to streptavidin were characterized by time-resolved emission spectroscopy.

Due the sulfonation of the indolene rings of indocarbocyanine dyes, the hydrophilicity of the dyes was increased, and subsequently, it was expected that dimerization in aqueous solution should be greatly reduced. It could be shown that in the case of the biotinylated dyes upon binding to streptavidin spectral changes are induced, which are attributed to dye−protein interactions. Depending on the molecular topography of the dye molecules, the interactions can be strong, which is found as a significant change in the absorptivity of the samples and in an overall alteration of the absorption and/or emission bands. Moreover, for the investigated polymethine dyes both the fluorescence decay times and the anisotropy decays are strongly affected by the complexation to streptavidin. On the basis of the molecular structures (Figure 1), it can be hypothesized that dye DY-635B (compared to DY-647B) is more rigid and hydrophobically judged. Therefore, a strong interaction, e.g., via H-bonding, with the protein can be assumed. This is reflected in the longer fluorescence decay time τ_2 and the corresponding amplitude A_2. However, for dye DY-647B a significant change of the absorption band intensities was observed, which points to a stronger electronic coupling to the protein.

Both the stationary and time-resolved measurements show that four molecules of biotinylated dyes are bound to one streptavidin tetramer. For both biotinylated dyes, the binding to streptavidin greatly changed the rotational motion of the dye molecules. Using an associated anisotropy decay model and global fitting in combination with the fluorescence decay time parameters, it is possible to attribute the upward curvature of time-dependent anisotropy curves in solutions to different microenvironments of the dye molecules. Upon binding, the rotational correlation times increased by a factor of about 20. Consequently, for the investigated dyes anisotropy-based detection schemes can be envisaged for future analytical applications, such as in homogeneous FIA or in fundamental research on the interaction processes between antigens and antibodies in single molecule detection studies. For the latter, but also for the design of improved tailor-made fluorescence probes, in particular, time-resolved fluorescence measurements in combination with anisotropy are valuable tools for an in-depth understanding of the underlying fundamental processes in dye−protein as well as protein−protein interactions.

ACKNOWLEDGMENT

This work was supported by the German Federal Department for Science and Education BMBF (IP 03/517). The authors wish to Dr. Frank Lehmann (Dyomics, Germany) for providing the dyes.

Design, Synthesis, and Preliminary in Vitro and in Vivo Evaluation of *N*-(2-diethylaminoethyl)-4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA): A Novel Potential PET Probe to Image Melanoma Tumors

Sudha Garg, Kanchan Kothari, Shankar R. Thopate, Aniruddha K. Doke, and Pradeep K. Garg*

PET Center, Department of Radiological Sciences, Wake Forest University Medical Center, Winston Salem, North Carolina 27157. Received November 26, 2008; Revised Manuscript Received January 9, 2009

In order to develop a PET radiopharmaceutical to image malignant melanoma, we synthesized *N*-(2-diethylaminoethyl)-4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA). In vitro studies show a high uptake of [^{18}F]-DAFBA by the B16F1 melanoma cells. No significant binding was seen for DAFBA to the sigma-1 and sigma-2 receptors in vitro. The in vivo biodistribution studies performed in normal ICR mice showed a low uptake in the normal tissues followed by further elimination of radioactivity from these tissues with time. The biodistribution studies performed in C57 mice bearing the melanoma tumor xenograft showed a rapid uptake of radioactivity in the tumor that reached a plateau within 30 min postinjection. The F-18 uptake in the tumor was 7.00 ± 2.76, 6.57 ± 1.66, and 5.80 ± 0.98%ID/g at 60, 120, and 180 min, respectively. A steady uptake of radioactivity in the tumor and low uptake in normal tissues resulted in high tumor to normal tissue ratios. For example, at 180 min postinjection, the tumor to tissue ratios were 14.90 ± 6.47, 21.90 ± 4.68, 32.91 ± 6.11, 39.73 ± 11.78, and 6.33 ± 1.9, for the spleen, lungs, muscle, blood, and liver, respectively. The radioactivity rapidly cleared from the blood pool, and it decreased from 0.68 ± 0.21%ID/g at 60 min to 0.13 ± 0.03%ID/g at 180 min. The F-18 uptake in the bones at 60, 120, and 180 min was 0.91 ± 0.27, 0.57 ± 0.32, and 0.17 ± 0.05%ID/g, respectively. This low uptake in the bones reflects its in vivo resistance toward defluorination. A low residual activity in normal tissues and a high tumor uptake signifies the superior imaging potential of this compound. Because of these positive traits, [^{18}F]-DAFBA could help delineate the tumor and its metastases when used for imaging applications. Further in vivo studies are underway to assess the potential of [^{18}F]-DAFBA as a promising PET imaging probe.

INTRODUCTION

Skin cancer is one of the most common cancers in the USA, and one in five people will develop it over the course of their lives. While melanoma accounts for only 3% of all skin cancer cases, 75% of deaths in this group are associated with melanoma. Unfortunately, the incidence of melanoma is increasing more rapidly than any other cancer. The prognosis and the patient's survival heavily depend on the clinical stage of the disease at the time of diagnosis. For example, a 10 year survival rate for stage 1 melanoma patients is 90−97% and only 3% for stage IV melanoma patients. Therefore, an early diagnosis of this disease and accurate assessment of its metastases remain the keys for improved outcome and disease free survival. Several scintigraphic probes such as monoclonal antibodies to melanoma associated antigens (*1, 2*), peptides (*3, 4*), iodoquinolines (*5, 6*), iodoamphetamine (*7, 8*), and guanidines (*9*) have been developed over the years to detect melanoma and localize metastatic lesions. While some of these compounds showed their potential in preliminary evaluations, none of these agents could achieve clinical significance. Therefore, the goal of many research groups including ours has been to develop diagnostic imaging agents with higher specificity and sensitivity to melanoma. More recently, a series of iodinated benzamides were synthesized as potential melanoma imaging agents. Because of the high affinity of iodobenzamides toward melanocytes and favorable tissue distribution characteristics, some of these radioiodinated benzamides were further pursued in humans to image melanoma tumors. This concerted effort yielded several clinically useful scintigraphic probes with good imaging characteristics (*10*−*13*). For an effective treatment outcome, it is important to accurately localize the tumor and its micrometastatic lesions. While positron emission tomography (PET) has recently emerged as an effective and noninvasive three-dimensional (3-D) tomographic imaging modality to provide absolute quantitative data on tracer uptake in the tissues, efforts to develop a PET probe to image melanoma have been rather sparse. The advantages of PET imaging include its ability to provide absolute quantitative data, ease in background subtraction, and tomographic imaging. At present, F-18 FDG PET imaging remains the only available imaging probe to localize melanoma cancer, despite its inherent drawbacks. For example, it is difficult to detect smaller tumor volumes using FDG (*14*). In addition, the sensitivity of these scans depends largely on the stage of the disease. FDG PET sensitivity to detect stage 1 melanoma is 0% but improves to 81% for stage III (*15*), thus ruling out its utility in the early detection of melanoma. In previous studies, FDG failed to detect metastatic disease in all patients with positive sentinel node biopsy (*16*). The presence of infection, inflammation, or recent surgery further increases the rate of false positive results, thus diminishing its efficacy as a reliable diagnostic tool (*17*). F-18 FDG lacking specificity toward melanoma underscores the need to search for more effective probes for early detection of melanoma cancer.

Since *N*-diethylaminoethyl-4-[*I]iodobenzamide (4-[*I]BZA) and *N*-diethylaminoethyl-2-[*I]iodobenzamide (2-[*I]IBZA) show clinical potential and are currently used in the clinics to image melanoma (*10, 18*−*21*), it was imperative that we focus

our initial efforts to develop a PET analogue using the same structural motif. Toward that goal, we replaced the 4-iodo group of 4-[*I]IBZA with a 4-fluoro group while keeping the remainder of the molecule unchanged. If successfully synthesized and promising biological characteristics are observed, this new PET probe could be a useful technique for the early detection of melanoma, especially when lesions are small in size and difficult to detect. In order to develop this PET probe, we initially synthesized the nonradioactive compound *N*-(2-diethylaminoethyl)-4-fluorobenzamide (DAFBA, **1**). This compound was synthesized using a one step synthesis procedure. The radiochemistry to incorporated F-18, a PET radioisotope to prepare *N*-(2-diethylaminoethyl) 4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA) was accomplished using a three step synthesis. Herein, we describe the synthesis of [^{18}F]-DAFBA, the in vitro uptake to melanoma cells, and its in vivo distribution characteristics in normal mice and in mice with a melanoma tumor xenograft.

EXPERIMENTAL PROCEDURES

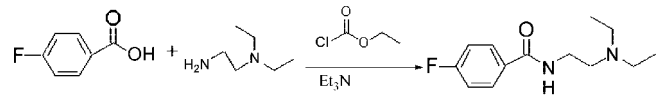
All reactions were carried out under an inert argon atmosphere using dry solvents under anhydrous conditions, unless otherwise stated. Reagents and solvents were purchased from commercial suppliers and were used without further purification. The C-18 plus Sep-Pack and the QMA cartridges were obtained from Waters Corporation, USA. Melting points were determined on an Electrothermal MEL-TEMP melting point apparatus and are uncorrected. Flash column chromatography was carried out over silica gel (60 Å, Mallinckrodt, Baker). ^{1}H NMR data was acquired on a Bruker Advance 300 DPX spectrometer. All chemical shift values are reported in ppm (δ).

High performance liquid chromatography (HPLC) was performed in isocratic mode using a Varian 9010 LC pump, a variable wavelength 9050UV VIS detector (Varian Corp, Palo Alto, CA, USA) set at 254 λ, and a radioisotope detector (Bioscan Inc., Washington, DC. USA) attached to Varian's chromatography software package. The radiochemical yields reported are decay corrected and are calculated to the end of bombardment (EOB) time. The HPLC system used for the purification of [^{18}F]-DAFBA was a C-18 reverse-phase, 7.5 × 250 mm 5 μm column (Phenomenex, Torrence, CA) eluted with MeOH/0.1 M ammonium formate (30:70) using a flow rate of 3 mL/min. Quality control of the purified product was carried out on C-18 QC column (4.6 mm × 250 mm, 5 μm) eluted with the methanol/0.1 M ammonium acetate (50:50) containing 40 μL of triethyl amine/100 mL of solvent with a flow rate of 1 mL/min. The kryptofix solution was prepared by dissolving 120 mg of K222 and 72 mg of K_2CO_3 in 720 μL water followed by the addition of 12 mL of acetonitrile. The C-18 Sep-Pak cartridge was activated by passing 5 mL of ethanol followed by 5 mL of sterile water. The QMA cartridge was activated by washing with 5 mL of 1 N sodium bicarbonate solution followed by flushing with 10 mL of water, and then drying the cartridge by passing air for ~30 s.

The melanoma cells (B16F1) were purchased from American Type Culture Collection (ATCC, Rockville, MD) and were grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum at 37 °C in an incubator maintaining a 5% CO_2 environment. The ICR and the C57 mice (6−8 weeks old) were purchased from Charles River Laboratories. Animal studies were performed under the guidelines established by the Wake Forest University Institutional Animal Care and Use Committee. The radioactivity levels in tissues were assessed with a Packard Cobra γ-counter.

Chemistry. *Preparation of N-(2-Diethylaminoethyl)-4-fluorobenzamide (DAFBA,* **1***).* This compound was synthesized as shown in Scheme 1. A solution of 4-fluorobenzoic acid (1.42 g, 10.3 mmol) in 50 mL of dichloromethane was cooled to 0 °C using an ice bath. To this ice cooled solution, triethylamine (1.3 g, 12.9 mmol) and ethyl chloroformate (1.2 g, 11.1 mmol) were added, and the reaction mixture was stirred for 1 h at 0 °C. A solution of *N*,*N*-diethylethylenediamine (1.0 g, 8.6 mmol) in dichloromethane (10 mL) was added slowly to this reaction mixture. After the addition was completed, the flask was removed from the ice bath, and the reaction mixture was stirred for 2 h at room temperature. Subsequently, the reaction mixture was cooled in the ice bath, and the reaction was quenched with 10 mL of 3 N NaOH. The product was extracted from the crude reaction mixture using dichloromethane (2 × 30 mL). The combined organic layer was dried over sodium sulfate. After evaporating the solvent, a light-yellow colored oil was obtained that was further purified using flash column chromatography (acetone). The desired product **1** was collected as a colorless viscous oil (1.96 g, 96% yield). ^{1}H NMR ($CDCl_3$, δ): 1.04 (t, 6H, J = 7.2 Hz, 2× -CH_2−C**H**$_3$), 2.56 (q, 4H, J = 7.2 Hz, 2× -C**H**$_2$−CH_3), 2.64 (t, 2H, J = 6.3 Hz, -C**H**$_2$−N-(CH_2−CH_3)$_2$), 3.44 − 3.49 (m, 2H, -CONH-C**H**$_2$-), 6.87 (br S, 1H, -N**H**), 7.07 − 7.14 (m, 2H, Ar−H @ C3 and C5), 7.75 − 7.81 (m, 2H, Ar−H @ C2 and C6).

Scheme 1. Reaction Scheme for the Synthesis of *N*-(2-Diethylamino ethyl) 4-fluorobenzamide (DAFBA; 1)



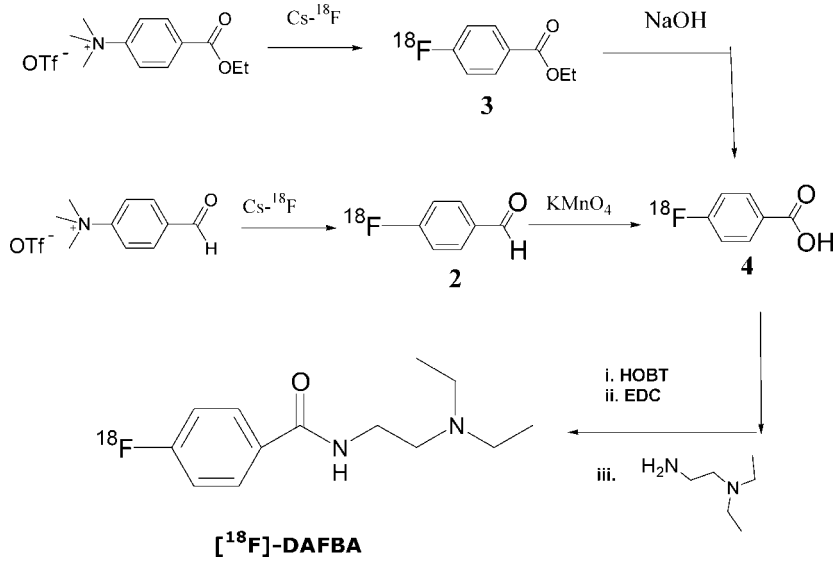
1

Ethyl-4-(N,N,N-trimethylammonium trifluoromethanesulfonyl)-benzoate. This compound was prepared as a precursor for the radiofluorination reaction by using a method analogous to that reported earlier with minor modifications (*22*−*24*). Briefly, ethyl 4-(dimethylamino) benzoate (0.5 g) was dissolved in dichloromethane (20 mL), and the solution was cooled in an ice bath. To this ice cold solution, methyl trifluoromethanesulfonate (0.5 mL) was slowly added while stirring. After the addition was completed, the reaction mixture was stirred for an additional 30 min and filtered, and a colorless to whitish crystalline product was collected as the target compound (0.84 g) mp 110−112 °C (Lit mp 112−114 °C (*24*)). ^{1}H NMR ($CDCl_3$, δ): 1.37 (t, 3H, J = 7.2 Hz, -OCH_2C**H**$_3$), 3.66 (s, 9H, -N(C**H**$_3$)$_3$, 4.40 (q, 2H, J = 7.2 Hz, -OC**H**$_2$$CH_3$), 7.94 (d, 2H, J = 9.3 Hz, Ar−H close to N(Me_3)$_3$), 8.21 (d, 2H, J = 9.3 Hz, Ar−H close to -COOEt).

Radiochemical Synthesis of N-[2-(diethylamino)ethyl]-4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA). The radiochemical synthesis of [^{18}F]-DAFBA was accomplished by first synthesizing 4-[^{18}F]fluorobenzoic acid followed by its coupling to *N*,*N*-diethylethylenediamine, using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) as the coupling agent. The radiochemical synthesis of this compound is shown in Scheme 2.

Synthesis of 4-[^{18}F]Fluorobenzoic Acid (4). Aqueous [^{18}F]fluoride was produced by using an ^{18}O(p, n)^{18}F reaction on 95% enriched [^{18}O]-H_2O in a high volume, high pressure [^{18}F]fluoride target irradiated with a 45 μA beam current. After the irradiation, the ^{18}O−H_2O bolus containing 450−800 mCi of [^{18}F]-fluoride was transferred from the cyclotron onto an AG1 × 8 (Bio-Rad) anion exchange resin cartridge in the hot-cell, and the [^{18}O]-H_2O was recovered. The trapped [^{18}F]fluoride was eluted from the cartridge with aqueous Cs_2CO_3 (0.3 mL, 1 mM) into a reaction vessel. The remainder of water from this mixture was removed azeotropically using acetonitrile. The dried [^{18}F]fluoride was resolubilized in 10 μL of aqueous Cs_2CO_3 solution (1 mM) and reacted with 4-formyl *N*,*N*,*N*-trimethylbenzeneaminium trifluoromethane sulfonate dissolved in 120 μL of DMSO, following the procedure described earlier (*24*). The 4-[^{18}F]fluo-

Scheme 2. Reaction for the Preparation of Radiolabeled Compound *N*-(2-Diethylaminoethyl) 4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA) Using 4-[^{18}F]Fluorobenzoic acid (4) as the Intermediate[a]



[a] Compound **4** was prepared utilizing either 4-[^{18}F]fluorobenzaldehyde (**2**) or ethyl 4-[^{18}F]fluorobenzoate (**3**). Subsequent coupling of **4** with *N*-*N*-diethylethylenediamine in the presence of 1-hydroxybenzotriazole hydrate (HOBT) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) provided the desired compound.

robenzaldehyde (**2**) thus obtained was oxidized by reacting with a 5% solution of $KMnO_4$ in 1 N NaOH (300 μL) at 120 °C for 10 min. Subsequently, sodium bisulphate solution (150 μg in 300 μL water) and 5 N HCl (0.5 mL) were added. The contents were diluted with 6 mL of water, passed through a C-18 Sep-Pak cartridge, and rinsed with 10 mL of water, and the 4-[^{18}F] fluorobenzoic acid (**4**) was eluted from the cartridge in 72 ± 11% (n = 12) radiochemical yield with 3 mL of acetonitrile.

Alternate Synthesis of 4-[^{18}F]Fluorobenzoic Acid via Ethyl-4-[^{18}F]fluorobenzoate as an Intermediate. After the irradiation, the $^{18}O-H_2O$ bolus containing 450−800 mCi of [^{18}F]-fluoride was transferred from the cyclotron onto a preactivated QMA cartridge in the hot-cell, and [^{18}O]-H_2O was recovered. The trapped [^{18}F]fluoride was eluted from the cartridge with 1.5 mL of K2.2.2. solution prepared as described above. The remainder of water from this mixture was removed azeotropically using acetonitrile. The dried [^{18}F]fluoride was reacted with a freshly prepared solution of 5 mg of ethyl-4-(trimethylammonium triflate)benzoate in 120 μL of anhydrous DMSO at 106 °C for 10 min as described earlier (*25*). Subsequently, the reaction vessel was cooled to room temperature, 500 μL of 1 N NaOH was added, and the reaction mixture was heated for 5 min at 100 °C to hydrolyze the ester group without isolating intermediate **3**. After cooling the reaction mixture to room temperature, the contents were acidified using 1 N HCl (∼600 μL) and loaded onto a C-18 Sep-Pak cartridge for purification. The Sep-Pak was washed with 10 mL of water, and 4-[^{18}F]fluorobenzoic acid (**4**) was eluted from the cartridge using 3.5 mL of acetonitrile.

Coupling of 4-[^{18}F]Fluorobenzoic acid with *N*-*N*-diethylethylenediamine to Prepare [^{18}F]-DAFBA. The solvent from the 4-[^{18}F]fluorobenzoic acid solution (**4**) obtained using either of the above two methods was reduced to ∼300 μL. (Note: evaporating to lesser volume resulted in the loss of radioactivity). A solution of 1-hydroxybenzotriazole hydrate (HOBT, 3 mg) in 100 μL of DMF, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC, 3.5 mg), and *N*-*N*-diethylethylenediamine (1 mg) in DMF (100 μL) were added sequentially to the reaction vessel containing 4-[^{18}F]fluorobenzoic acid, and the reaction mixture was stirred for 30 min at room temperature. The solvent was evaporated to ∼150 μL using a gentle stream of nitrogen, diluted with 1 mL of HPLC mobile phase, and the contents were loaded onto the HPLC column. The desired product was collected from HPLC and the solvent evaporated using a rotary evaporator. The residue was redissolved in 0.5 mL ethanol, and 9.5 mL of water was added. The product solution was then filtered through a 0.22 μm filtering cartridge and collected in a 20 mL sterile product vial.

Stability Measurement. A solution of [^{18}F]-DAFBA (5 mCi) in 2 mL of saline was assayed for its room temperature shelf life stability assay using the HPLC method. An aliquot (100 μL) of the above solution was injected into HPLC at 10, 60, 180, 240, and 360 min postsynthesis and analyzed for change in radiochemical purity over time by using the QC HPLC procedure.

Lipophilicity Measurement. Lipophilicity of [^{18}F]-DAFBA was determined via the shake flask method using a 1-octanol and phosphate-buffered saline (pH 7.4) system as described by Wilson et al. (*26*). Briefly, ∼500 Kcpm of [^{18}F]-DAFBA was added to test tubes containing a 1-octanol (1 mL) and PBS (1 mL) mixture (in triplicate), and the test-tubes were vortexed for 3 min. Subsequently, the two layers were allowed to separate, aliquots (100 μL) of the organic and the aqueous layers were withdrawn from each tube, measured for radioactivity, and the log *P* value calculated (*26, 27*).

In Vitro Uptake Assay. The cells were grown to 80−90% confluence in flasks before trypsinizing and then were resuspended in PBS at pH 7.4. After assessing the cell counts, 1×10^5, 5×10^5, 8×10^5, and 1×10^6 cells were aliquoted in triplicate in Eppendorf tubes. To each tube, ∼200 Kcpm of [^{18}F]-DAFBA was added, and the tubes were incubated at 22 °C (ambient temperature) for 1 h. After incubation, the tubes were centrifuged, the media was removed, the pellet was washed with PBS, and the combined wash and the pellets were counted for radioactivity using a gamma counter. The percent uptake (% uptake) was calculated as the percent of the total added radioactivity found in the pellet.

Sigma Receptor Binding Assay. The IC_{50} values for the binding of DAFBA to sigma receptors were performed by using a competitive binding assay. For sigma-1 receptor binding, the assay was performed using the guinea pig brain membrane and the ligand ^{3}H-PENT as described earlier (*28*). For sigma-2 receptor binding, the assay was performed using rat liver

membrane prepared from Sprague−Dawley rats and the ligand ^{3}H-DTG in the presence of 1 μM dextrallorphane to mask sigma-1 receptors, as described earlier (*29*). The competition binding assays for both of the receptors was performed using 7 concentrations of DAFBA ranging from 10^{-6} to 10^{-9} M. The IC_{50} and K_i values were calculated using Prism Software (GraphPad Software Inc., La Jolla, CA).

Tissue Distribution Studies in Normal ICR Mice. The biodistribution studies were performed using ICR mice. The mice were injected with ~15 μCi of [^{18}F]-DAFBA in 100 μL of saline via the tail vein. At 30, 60, 120, and 180 min postinjection, the animals were euthanized, tissues of interest removed, washed with PBS, weighed, and counted for radioactivity using a gamma-counter. The accumulation of radioactivity in various tissues is expressed as percent-injected dose per gram of tissue (%ID/g) by counting the injected dose standard of appropriate count rate along with the tissues. The statistical significance of differences was determined by an unpaired Student's *t*-test using the Microsoft Excel program. Differences were considered significant when $P < 0.05$ was obtained.

Tissue Distribution Studies Using C57 Mice Bearing the B16F1 Tumor Xenograft. Mouse melanoma cells B16F1 were grown in DMEM media as described above. When the flasks were 80−90% confluent, the cells were trypsinized, removed from flask, centrifuged, and resuspended in a 50:50 mixture of Matrigel (Becton Dickinson, San Jose, CA) and PBS (pH 7.4) for inoculation in the animals. The mice were inoculated with 0.1 mL of cell suspension in PBS-containing ~5×10^6 cells in the right flank with a 23-gauge needle. Tumor growth was monitored periodically. The biodistribution studies were performed when the tumor volume reached >200 mm^3. The tumor bearing mice were injected with of ~15 μCi of [^{18}F]-DAFBA in 100 μL of saline via the tail vein. F-18 uptake in the tumor and other tissues was assessed at 30, 60, 120, and 180 min postinjection. At preset time points, the animals were euthanized, tissues of interest removed, washed with PBS, weighed and counted for radioactivity using a gamma-counter.

RESULTS AND DISCUSSION

Synthesis of DAFBA, the nonradioactive compound, is shown in Scheme 1. The desired product was obtained in 84% yield and in 98% chemical purity after flash column chromatography. DAFBA was eluted at 22 ± 1 min using a semipreparatory HPLC column. On the QC column, this product was eluted at 11.1 ± 0.4 min. This nonradiolabeled DAFBA was prepared as an HPLC reference standard for the production of radioactive compound [^{18}F]-DAFBA. The radiochemical synthesis of [^{18}F]-DAFBA was accomplished using two separate routes and is shown in Scheme 2. For the first method, initially 4-[^{18}F]fluorobenzaldehyde was prepared followed by oxidation of the aldehyde group to the carboxylic acid group. Using this route, 4-[^{18}F]Fluorobenzoic acid was synthesized in 72 ± 11% (n = 12) radiochemical yield. Alternatively, 4-[^{18}F]fluorobenzoic acid **4** was prepared in 82 ± 8% (n = 11) radiochemical yield in two steps, first by preparing ethyl [^{18}F]fluorobenzoate followed by hydrolyzing the ester group to yield 4-[^{18}F]fluorobenzoic acid **4** without isolating the intermediate ethyl ester. The coupling of *N*-*N*-diethylethylenediamine to 4-[^{18}F]fluorobenzoic acid **4** was accomplished using EDC as the coupling agent. After the reaction, the mixture was loaded on a semiprep HPLC column, and the desired product was eluted from the column (retention time 22.2 min) in 54 ± 18% radiochemical yield (n = 17) and 97 ± 2% radiochemical purity. The purity and the specific activity of this product were determined using the QC HPLC system. The retention time of [^{18}F]-DAFBA on the QC-HPLC column was 11.3 min, and the specific activity remained >1000 mCi/μmol for all preparations. The overall synthesis time for

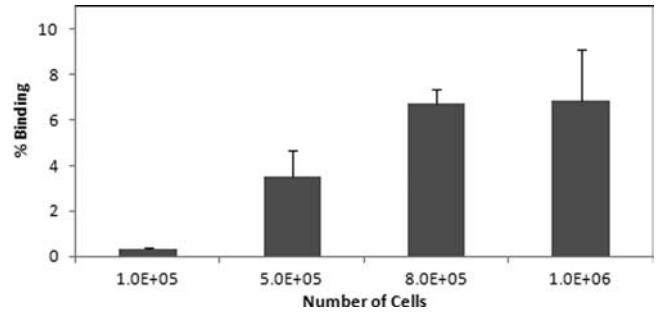


Figure 1. In vitro binding of [^{18}F]-DAFBA to B16F1 melanoma cells. Various concentrations of cells were incubated with [^{18}F]-DAFBA for 60 min at room temperature. The results are presented as a percent of total added radioactivity that was taken up by the cells (mean ± standard deviation; n = 3 tubes for each concentration).

[^{18}F]-DAFBA including the HPLC purification and the final formulation was 175 ± 15 min (n = 17). To assess the stability of [^{18}F]-DAFBA over an extended period of time, an aliquot of the product was injected on a QC-HPLC column at various time points for up to 6 h postpreparation of the product. The shelf life stability studies showed that the radiochemical purity of [^{18}F]-DAFBA remained >95% at all time points, demonstrating the stability of the radiotracer over the 6 h storage period. While these studies were performed to assess the expiration time for this radioactive compound, this data does not reflect in vivo stability of the molecule. While the assessment of biostability and metabolic fate of this compound in vivo remains outside the scope of this study, these important parameters are part of an extensive characterization of [^{18}F]-DAFBA as an imaging probe.

Cell uptake studies were performed using the B16F1 mouse melanoma cells.Triplicate sets of Eppendorf tubes containing various concentrations of cells were incubated with [^{18}F]-DAFBA at room temperature for 60 min. The cells were separated, washed, and counted for radioactivity to determine the percentage of added radioactivity taken up by the cells. The cell uptake data is shown in Figure 1. As see in Figure 1, the uptake of [^{18}F]-DAFBA increased with increasing number of cells with an uptake of 5.60 ± 2.67% when 1×10^6 cells/tube were incubated with [^{18}F]-DAFBA.

Role of Sigma Receptors. The role of sigma receptors on tumor cells has been implicated in the uptake of radioiodinated benzamides in certain tumors. Although it is not known whether B16F1 cells used in our study express sigma receptors, various other tumor cell lines such as PC12, A375 amelanotic melanoma, T47D breast ductal carcimona, SK-N-SH neuroblastoma, and C6 glioma cells highly express sigma receptors. Since these tumor cell lines also show high binding to iodobenzamides, several investigators hypothesized that the binding ability of iodobenzamides to sigma receptors could be exploited to image melanoma and other tumors (*30*−*33*). For that reason, John et al. synthesized a series of iodobenzamides that showed high sigma receptor binding and displayed varying efficacy to image various tumors (*34*, *35*). Therefore, we evaluated sigma receptor binding of DAFBA in vitro. Surprisingly, the in vitro binding assay showed lack of any appreciable binding of DAFBA to sigma-1 and sigma-2 receptors, and the IC_{50} for DAFBA was >1000 nM for both of these receptors. Despite the lack of affinity toward sigma receptors, we observed encouraging [^{18}F]-DAFBA uptake results using the B16F1 melanoma cells. A more expanded in vivo structure−activity-relationship study performed by Eisenhut et al. revealed that the binding of iodinated benzamide to the melanoma tumor does not correlate with sigma receptor binding and concluded that sigma receptors are not important for the uptake of iodobenzamides by the melanoma

Table 1. Biodistribution of *N*-(2-Diethylaminoethyl) 4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA) in Normal Balb/c ICR Mice at Various Time Points after Injection (Mean ± SEM; $n = 5$)

	percent injected dose per gram tissue (%ID/g)			
organ	30 min	60 min	120 min	180 min
liver	3.12 ± 0.62	3.61 ± 0.48	1.14 ± 0.41	1.12 ± 0.20
spleen	2.35 ± 0.07	1.87 ± 0.46	0.43 ± 0.25	0.53 ± 0.08
lung	1.75 ± 0.43	1.84 ± 0.41	0.42 ± 0.14	0.49 ± 0.07
heart	1.10 ± 0.14	0.92 ± 0.10	0.28 ± 0.05	0.23 ± 0.03
kidneys	4.13 ± 0.68	4.20 ± 0.41	1.58 ± 0.51	1.34 ± 0.36
intestine	0.91 ± 0.32	1.39 ± 0.54	0.26 ± 0.26	0.40 ± 0.11
muscle	0.88 ± 0.13	0.65 ± 0.11	0.18 ± 0.10	0.16 ± 0.03
bone	0.81 ± 0.19	0.69 ± 0.08	0.20 ± 0.06	0.24 ± 0.10
blood	0.78 ± 0.07	0.67 ± 0.05	0.20 ± 0.04	0.21 ± 0.03
brain	2.16 ± 0.32	1.54 ± 0.24	0.52 ± 0.07	0.46 ± 0.07

tumors and cells (*36*). Interestingly, an attempt to block sigma receptors in vivo by injecting DuP 734 prior to iodobenzamide administration resulted in a 2-fold increased uptake in the tumor, while it significantly reduced its uptake in the brain and the lungs. These findings further demonstrate that uptake in melanoma tumors is independent of sigma receptors (*33*). The low in vitro binding affinity toward sigma-1 and sigma-2 receptors along with a modest in vitro cell uptake to B16F1 cells seen in our study using [^{18}F]-DAFBA further support those findings.

To explore in vivo tissue distribution characteristics of [^{18}F]-DAFBA, the biodistribution studies were performed using ICR normal mice. The F-18 uptake in various tissues from that study is summarized in Table 1. In general, a low F-18 uptake was observed in most normal tissues. As expected, at earlier time points (30 min), the uptake in the liver and kidneys was somewhat higher than that in other normal tissues (liver 3.12 ± 0.62%ID/g; kidneys 4.13 ± 0.68%ID/g). Nonetheless, the radioactivity from the liver rapidly washed out with time, approaching the levels seen in other normal tissues (liver 1.12 ± 0.20 at 180 min). Similarly, the radioactivity in blood was quite low at all time point studies with radioactivity levels of 0.20 ± 0.04%ID/g at 120 min postinjection.

Since only a few studies have reported the biodistribution characteristics of iodinated benzamides in normal mice, we could only compare our results to biodistribution results reported for the [*I]*N*-(2-diethylaminoethyl)-3-iodo 4-methoxybenzamide ([*I]IMBA), a closely matched structural analogue, that used the C57 normal mice (*37*). The radioiodine uptake levels in most tissues reported for [*I]IMBA were similar to F-18 uptake observed in the current study. For example, in the current study at 60 min postinjection, the F-18 in the liver, lungs, and blood was 3.12 ± 0.62, 1.75 ± 0.43, and 0.78 ± 0.07%ID/g, respectively, as compared to 3.09 ± 0.45, 1.06 ± 0.23, and 0.84 ± 0.08%ID/g, respectively, reported for the [*I]IMBA (*37*). The uptake differences in various tissues between the two studies were small and statistically insignificant ($p > 0.01$). Although the thyroid uptake data was not reported for the [*I]IMBA, a high uptake in the stomach (9.72 ± 1.51%ID/g) and in intestine (7.70 ± 4.70%ID/g) indicated extensive in vivo dehalogenation. In contrast, the [^{18}F]-DAFBA was found to be quite stable in vivo as evident from its low F-18 uptake in the bones (60 min: 0.69 ± 0.08%ID/g) that continued to decrease further with time. Despite disparate specific activities of the tracers used in these two studies (IMBA 0.1−1.0 mCi/μmol; [^{18}F]DAFBA >1000 mCi/μmol) and varied lipophilicities, the tissue distribution results for the two molecules were fairly similar.

To further characterize [^{18}F]-DAFBA for its tumor uptake properties, the biodistribution studies were performed using C57 mice bearing B16F1 melanoma tumor xenografts. The F-18 uptake in various tissues is shown in Table 2. The F-18 accumulation for the tumor bearing mice was quite similar to

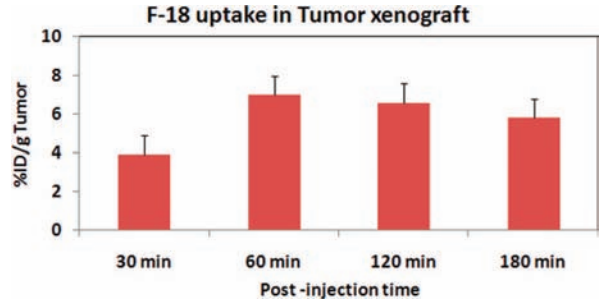

Figure 2. F-18 uptake in the tumor at 30, 60, 120, and 180 min postinjection of [^{18}F]-DAFBA using C57 mice bearing the B16F1 melanoma tumor. The data is expressed as percent injected dose per gram of tumor (%ID/g average ± standard deviation; $n = 5$).

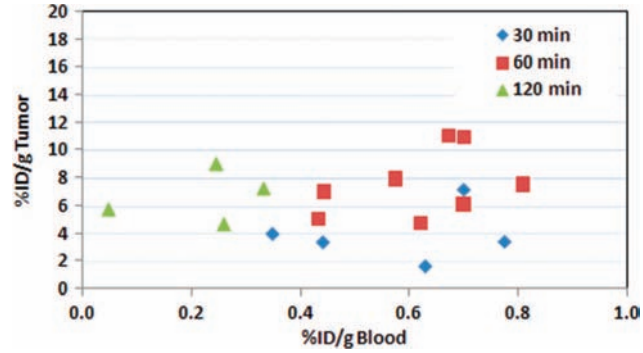

Figure 3. Correlation plot for [^{18}F]-DAFBA uptake in the melanoma tumor versus the radioactivity present in the blood at 30, 60, and 120 min. Each data point represents data from a single mouse. The plot shows that the radioactivity levels in the blood pool is independent of radioactivity in the tumor and that the two variables exhibit a poor Pearson correlation ($r = 0.398$).

that observed using the ICR normal mice. Most normal tissues from tumor bearing mice showed a low accumulation at all time points studied. The radioactivity continued to clear out from normal tissues with time. For example, F-18 uptake in the muscles was 1.1 ± 0.14%ID/g at 30 min, which was further reduced to 0.17 ± 0.03%ID/g at 180 min postinjection, exhibiting a 6-fold reduction. Similarly, the F-18 level in the blood was 0.58 ± 0.18%ID/g and 0.13 ± 0.03%ID/g at 30 and 180 min, respectively. A rapid in vivo clearance of radioactivity and low levels of circulating radioactivity in the blood pool reflected a low affinity of this compound toward erythrocytes and serum proteins. One of the advantages of this low circulating radioactivity in blood would be clear visualization of tumor and metastases in vivo using this probe. The metabolic tissues such as the liver and spleen also showed low uptake of radioactivity that continued to clear out further with time. The bone uptake in normal mice and tumor bearing mice remained significantly low, thereby underscoring the stability of [^{18}F]-DAFBA toward in vivo dehalogenation.

In this study, [^{18}F]-DAFBA displayed a rapid and high uptake in the tumor. The [^{18}F]-DAFBA uptake in the B16F1melanoma tumor xenograft is shown in Figure 2. The tumor uptake reached 7.00 ± 2.76%ID/g by 60 min. While the tumor accumulation decreased slightly by 180 min (5.80 ± 0.98%ID/g), the tumor uptake differences between 60 and 180 min time points were small and statistically insignificant ($p > 0.2$).

Earlier, Pham et al. suggested that iodobenzamides with higher lipophilicity would show better tumor uptake properties. They further hypothesized that a log $P_{7.4}$ of greater than 1.4 is necessary for the enhanced tumor uptake characteristics (*38*). Using the Chem-Draw Ultra software (Cambridge Sof.Com, Cambridge, MA), the calculated log *P* values for the [*I]IBZA

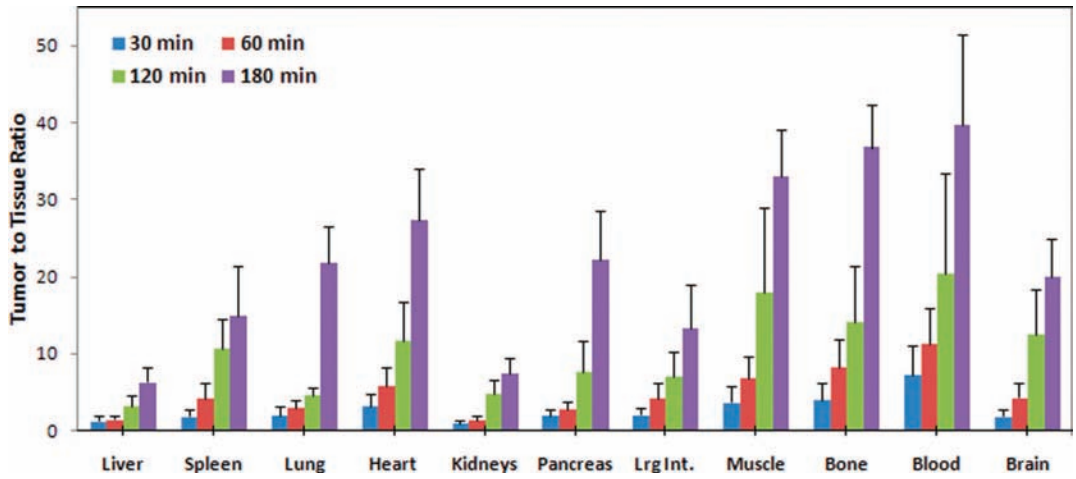

Figure 4. Tumor to normal tissue ratios of [^{18}F]-DAFBA using C57 mice bearing the B16F1 melanoma tumor at 30, 60, 120, and 180 min postinjection. While modest tumor to normal tissue ratios were observed at 30 min, these ratios continued to improve significantly with time.

Table 2. Biodistribution of *N*-(2-Diethylaminoethyl) 4-[^{18}F]fluorobenzamide ([^{18}F]-DAFBA) in C57 Mice Bearing the B16F1 Melanoma Tumor Xenograft at Various Time Points after Injection (Mean ± SEM; $n = 5$)

	percent injected dose per gram tissue (%ID/g)			
organ	30 min	60 min	120 min	180 min
liver	3.27 ± 0.90	5.01 ± 2.06	2.35 ± 1.20	0.80 ± 0.35
spleen	2.14 ± 0.41	1.83 ± 0.54	0.71 ± 0.37	0.44 ± 0.25
lung	2.46 ± 1.27	2.48 ± 1.27	1.47 ± 0.47	0.27 ± 0.07
heart	1.25 ± 0.28	1.27 ± 0.50	0.61 ± 0.20	0.21 ± 0.04
kidneys	4.50 ± 1.33	5.38 ± 1.86	1.41 ± 0.11	0.83 ± 0.23
intestine	1.94 ± 0.51	1.98 ± 0.88	1.02 ± 0.33	0.46 ± 0.22
muscle	1.09 ± 0.18	1.10 ± 0.38	0.57 ± 0.54	0.17 ± 0.03
bone	1.00 ± 0.14	0.90 ± 0.27	0.57 ± 0.32	0.17 ± 0.05
blood	0.58 ± 0.18	0.68 ± 0.21	0.43 ± 0.47	0.13 ± 0.03
brain	2.02 ± 0.35	1.68 ± 0.43	0.64 ± 0.40	0.29 ± 0.05

and [^{18}F]-DAFBA were 3.21 and 2.01, respectively. Both of these compounds showed higher than the minimal suggested log *P* value of 1.4, indicating that they should be useful melanoma imaging agents (*38*). Since Pham et al. suggested the lipophilicity of benzamides as one of the important determinants for their biological efficacy, we experimentally measured the partition coefficient of [^{18}F]-DAFBA using the 1-octanol/PBS method described earlier (*26*). The measured partition coefficient for [^{18}F]-DAFBA was 1.7, a value similar to its calculated log *P* value as stated above. It is possible that iodine for fluoride substitution may have resulted in significantly decreased lipophilicity of [^{18}F]-DAFBA. While the lipophilicity remains an important feature for improved tissue membrane penetration, multiple factors play a critical role to achieve favorable tracer uptake and kinetics (*27, 39*). A higher lipophilicity (higher log *P*) may enhance tissue penetration to improve tumor uptake; it simultaneously would increase the nontarget tissue uptake and lead to higher nonspecific uptake in target and in nontarget tissues. Therefore, it is important to carefully balance physicochemical parameters when designing new probes. In essence, several investigations explicate that the lipophilicity measure of melanoma-specific compounds remains a less reliable predictor of their in vivo behavior (*27, 40*). Physiological parameters such as specific activity of radioactive probe, metabolism, clearance, and excretion are some of the other factors that play vital role in defining the merits of a potentially useful imaging probe.

In order to assess the correlation between the radioactivity levels in blood and its uptake in the tumor, the blood uptake values (%ID/g) from individual mice were plotted against the respective tumor uptake values (%ID/g). The data presented in Figure 3 suggest that the tumor uptake is not dependent on the amount of radioactivity present in the blood pool. While the radioactivity levels in the blood decreased significantly by 120 min, the radioactivity levels in the tumor remained unchanged. No correlation was noted between blood and tumor uptake values. The Pearson coefficient of correlation for these two variables was 0.32.

A high F-18 uptake in the tumor and low accumulation of radioactivity in normal tissues resulted in a favorable tumor to tissue ratio for [^{18}F]-DAFBA. The tumor to normal tissue ratios for various tissues is presented in Figure 4. The tumor to blood ratio increased from 8.3 ± 3 at 60 min to 39 ± 12 by 180 min, a 5-fold increase. Similarly, tumor to lung and tumor to muscle ratios for [^{18}F]-DAFBA were >20 at 180 min. Except for the kidneys, the tumor to tissue ratio for most tissues remained high at 180 min. These results were quite similar to that reported by Moins et al. using the [*I]IBZA (*27*). A rapid and high tumor uptake along with a high tumor to normal tissue ratios seen herein are exceedingly significant because it underscores the potential of this compound for aiding in clear visualization of tumors and its metastases noninvasively and within a time frame compatible with the PET isotope half-life.

The brain is one of the common sites that develop melanoma metastases. Therefore, we were interested in exploring whether [^{18}F]-DAFBA crosses the blood−brain barrier to enter the brain. The tissue distribution studies performed in normal and tumor-bearing mice showed that [^{18}F]-DAFBA enters in the brain within 30 min. At early time points, the radioactivity levels were 2-fold higher in the brain than that in other normal organs. After initial high uptake, the radioactivity cleared from the brain with time. For example, the F-18 uptake in the brain was 2.02 ± 0.35%ID/g at 30 min and reduced to one-seventh of this value by 180 min. While initial accumulation in the brain showed its ability to enter the brain, a rapid washout displayed a low affinity of [^{18}F]-DAFBA toward nontumoral tissues, a positive attribute for a potentially useful imaging agent. [^{18}F]-DAFBA also showed encouraging uptake characteristics in the lungs and the liver, two other tissues known to anchor melanoma metastases. As evident from data presented in Table 2, the uptake and clearance of [^{18}F]-DAFBA in the lungs is similar to that seen for the brain. At 30 min, the F-18 uptake in the lungs was slightly higher than that in the brain, and it decreased exponentially with time and reached radioactivity levels similar to that in the blood by 180 min. The initial modest uptake following a rapid elimination of radioactivity from the organs of metastatic potential would constitute a positive trait of this

probe. If developed further, this probe may have significant potential in delineating brain and lung metastases from normal tissues.

Two of the major traits for a successful imaging agent are high uptake of radioactivity in the tumor and low retention of radioactivity in normal tissues. In the current study, [^{18}F]-DAFBA exhibits both of these properties. A high uptake and retention of radioactivity in tumor along with low retention of radioactivity in normal tissues suggests that if developed further, [^{18}F]-DAFBA could be a potentially useful PET imaging probe to image melanoma.

In summary, we successfully synthesized a melanoma-seeking PET imaging agent [^{18}F]-DAFBA. The radiochemical synthesis was achieved in high radiochemical yields and in a synthesis time compatible with F-18 half-life. The in vitro studies showed that [^{18}F]-DAFBA binds to the melanoma cells. Biodistribution studies in mice showed a rapid and high uptake in the tumor and a low accumulation of F-18 in normal tissues pointing to its potential to provide a high signal-to-noise ratio and to its ability to clearly visualize tumors with low background signals. Besides, a low bone uptake signifies the stability of this ligand toward in vivo dehalogenation. On the basis of these promising in vitro and in vivo results, it is tempting to envision the potential of [^{18}F]-DAFBA as a useful melanoma imaging agent using PET. Additional studies are necessary to fully explore the potential of [^{18}F]-DAFBA as a melanoma imaging agent using PET.

ACKNOWLEDGMENT

We thank Kimberly Black, Holly Smith, and Li Wu for their excellent technical help with the cell uptake assay and tissue distribution studies. We also thank the cyclotron staff for their help with radioisotope production. The partial financial support for this study from the NIH (CA 105383 to PKG) is greatly appreciated.

Reagents for Astatination of Biomolecules. 3. Comparison of *closo*-Decaborate(2-) and *closo*-Dodecaborate(2-) Moieties as Reactive Groups for Labeling with Astatine-211

D. Scott Wilbur,* Ming-Kuan Chyan, Donald K. Hamlin, and Matthew A. Perry

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195. Received December 3, 2008; Revised Manuscript Received January 22, 2009

In vivo deastatination has been a major problem in the development of reagents for therapeutic applications of the α-particle emitting radionuclide ^{211}At. Our prior studies demonstrated that the use of a *closo*-decaborate(2-) ([*closo*-$B_{10}H_9R]^{2-}$) moiety for ^{211}At labeling of biomolecules provides conjugates that are stable to *in vivo* deastatination. In this investigation, the *closo*-decaborate(2-) moiety was compared with the structurally similar *closo*-dodecaborate(2-) ([*closo*-$B_{12}H_{11}R]^{2-}$) to determine if one has more favorable properties than the other for use in pendant groups as ^{211}At labeling molecules. To determine the differences, two sets of structurally identical molecules, with the exception that they contained either a *closo*-decaborate(2-) or a *closo*-dodecaborate(2-) moiety, were compared with regard to their synthesis, radiohalogenation, stability to in vivo deastatination and tissue distribution. Quite different rates of reaction were noted in the synthetic steps for the two *closo*-borate(2-) moieties, but ultimately the yields were similar, making these differences of little importance. Differences in radiohalogenation rates were also noted between the two *closo*-borate(2-) moieties, with the more electrophilic *closo*-decaborate(2-) reacting more rapidly. This resulted in somewhat higher yields of astatinated *closo*-decaborate(2-) derivatives (84% vs 53%), but both cage moieties gave good radioiodination yields (e.g., 79−96%). Importantly, both *closo*-borate(2-) cage moieties were shown to have high stability to in vivo deastatination. The largest differences between pairs of compounds containing the structurally similar boron cage moieties were in their in vivo tissue distributions. For example, $[Et_3NH]_2B_{12}H_{10}I$−CONHpropyl, [^{125}I]**2b** had high concentrations in kidney (1 h, 19.8%ID/g; 4 h, 26.5%ID/g), whereas $[Et_3NH]_2B_{10}H_8I$−CONHpropyl, [^{125}I]**1e** had much lower concentrations in kidney (1 h, 6.6%ID/g; 4 h, 0.27%ID/g). Interestingly, when another salt of the *closo*-decaborate(2-), $[nBu_4N]_2B_{10}H_8I$−CONHpropyl, [^{125}I]**1b**, was evaluated, the route of excretion appeared to be hepatobiliary rather than renal. Identical biotin derivatives containing the two *closo*-borate(2-) cage moieties had similar tissue distributions, except the *closo*-decaborate(2-) derivative had lower concentrations in kidney (1 h, 19.9%ID/g; 4 h, 24.4%ID/g vs 1 h, 38.9%ID/g; 4 h, 40.6%ID/g). In summary, the higher reactivity, faster tissue clearance, and lower kidney concentrations make the *closo*-decaborate(2-) more favorable for further studies using them in reactive groups for ^{211}At labeling of biomolecules.

INTRODUCTION

The radionuclide, ^{211}At ($t_{1/2}$ = 7.21 h) is one of only a few α-emitting radionuclides considered useful for targeted radionuclide therapy of cancer (*1*−*4*). Although ^{211}At has a relatively short half-life ($t_{1/2}$ = 7.21 h), 100% of its decays (in a branched chain) emit an α-particle and the decay process does not result in production of α-particle emitting daughters (*5*). The short pathlengths of α-particle emissions (e.g., 50−80 μm) and the high linear energy deposition (>100 keV/μm) of those emissions make α-particles very effective in cell killing. Most importantly, the cell-killing properties of α-emissions make them potentially useful for killing micrometastatic disease, which is a major impediment to successful therapy of cancer (*6*).

Coupling ^{211}At with biomolecules that target cancer cells is very important for its application to therapy of cancer. Unfortunately, in vivo deastatination of biomolecules labeled with ^{211}At has been problematic in the development of therapeutic radiopharmaceuticals (*7*). In fact, the deastatination of labeled compounds has severely limited the in vivo application of ^{211}At. To circumvent this shortcoming, several research groups have evaluated the use of aryl pendant groups to stabilize the ^{211}At-labeled biomolecules in vivo (*8*−*11*). However, in many examples astatinated aryl groups are not stable to deastatination when the carrier biomolecule is rapidly metabolized. More recently, our research group has focused on using anionic boron cage pendant groups for labeling with ^{211}At. While the in vivo stability was found to be low for ^{211}At-bonded *nido*-carborane[1] pendant groups (*12*), we have found that the pendant groups containing *closo*-decaborate(2-) moieties, $[B_{10}H_9R]^{2-}$, can be used to provide high ^{211}At labeling yields and result in high stability in vivo (*13*).

Other investigators have reported the use of a similar boron cage moiety, *closo*-dodecaborate(2-), [*closo*-$B_{12}H_{11}R]^{2-}$ for radioiodine (*14, 15*) and ^{211}At labeling (*16*). Our interest in using *closo*-borate(2-) cage derivatives as pendant groups in ^{211}At

* Corresponding author. D. Scott Wilbur, Department of Radiation Oncology, University of Washington, Box 355016, 616 N.E. Northlake Place, Seattle, WA 98105. Phone: 206-616-9246, 206-616-8798. dswilbur@u.washington.edu.

[1]Nomenclature of compounds: (a) The designations "*nido*-" refers to a polyhedral structure that is open or "nest-like", and "*closo*-" refers to a polyhedral "cage" (from Greek "*clovo*" (*45*)) structure that is closed such as an icosahedran; (b) the naming of *closo*-borate(2-) compounds is simplified herein for brevity. For example, tetrabutylammonium 2-(*n*-propylamido)-nonahydro-*closo*-decaborate(2-), **1a**, is designated as $[nBu_4N]_2$[*closo*-$B_{10}H_9$-CONHpropyl], and triethylammonium 2-(*n*-propylamido)-undecahydro-*closo*-dodecaborate(2-), **2a**, is designated as $[Et_3NH]_2$[*closo*-$B_{12}H_{11}$-CONHpropyl].

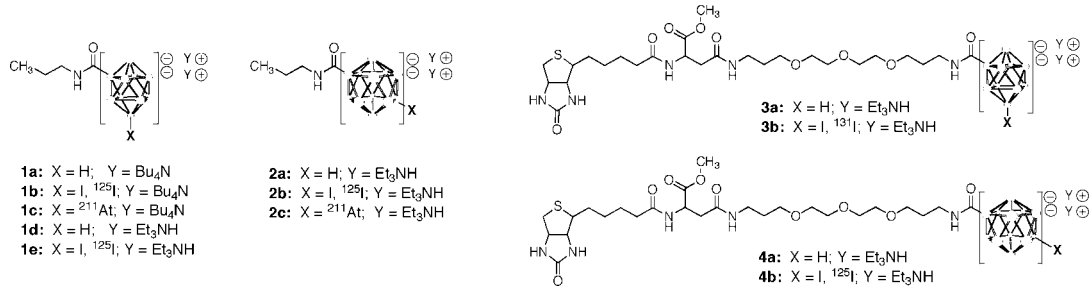

Figure 1. *closo*-Decaborate(2-) derivatives (**1a**−**1e**, **3a**, **3b**) and *closo*-dodecaborate(2-) derivatives (**2a**−**2c**, **4a**, **4b**) were prepared and evaluated. For simplicity in the *closo*-borate(2-) cage depictions, the open circles represent B (where substituted) or BH atoms.

labeling led to an investigation to determine which of the two *closo*-borate(2-) cage moieties has the most favorable properties for in vivo applications. In the investigation, we compared the chemical syntheses, radiolabeling efficiency, and in vivo stability of two pairs of identical compounds containing *closo*-decaborate(2-) and *closo*-dodecaborate(2-) moieties as depicted in Figure 1 (i.e., **1** vs **2** and **3** vs **4**). Use of pairs of compounds having the same structure except for the *closo*-borate(2-) cage permits evaluation of the effect of those moieties on chemical and in vivo properties of the compounds studied. Although the test compounds were identical except for the *closo*-borate(2-) moiety, it was anticipated that differences would be observed, as it is known that the chemistry and properties of *closo*-decaborate (2-) and *closo*-dodecaborate(2-) derivatives can be quite different (*17*−*19*).

In the first part of the investigation, carbonyl derivatives of the two boron cage moieties were modified by *n*-propylamine to provide simple *closo*-borate(2-) derivatives, **1a** and **2a**, which have a (small) lipophilic propylamide moiety attached. In an initial study, the nBu$_4$N salt of *closo*-decaborate(2-), **1a**, was prepared to facilitate its isolation and characterization. The Et$_3$NH salt was used with the *closo*-dodecaborate(2-), **2a**. The propionamide derivatives **1a** and **2a** were radioiodinated and astatinated, and then each radiolabeled *closo*-borate(2-) pair (i.e., [^{125}I]**1b**/[^{211}At]**1c** and [^{125}I]**2b**/[^{211}At]**2c**) was mixed and coinjected into mice to determine their biodistributions and the relative in vivo stability of the ^{211}At attachment. Due to unexpected in vivo distributions of the [^{125}I]**1b**/[^{211}At]**1c** pair of radiolabeled compounds, another biodistribution study was carried out with [^{125}I]**1e**, in which the counterions were changed from nBu$_4$N to Et$_3$NH. As another part of the investigation, biotin derivatives **3a** and **4a** were prepared, again incorporating the two *closo*-borate(2-) cage moieties into otherwise identical chemical structures. To evaluate the differences in their in vivo distributions, the biotin derivatives were radioiodinated to yield [^{131}I]**3b** and [^{125}I]**4b**, and that pair of radiolabeled compounds was coinjected into mice. The results of our investigation to compare chemistry and properties of structurally similar compounds containing the *closo*-decaborate(2-) and *closo*-dodecaborate(2-) moieties are reported herein.

MATERIALS AND METHODS

Materials. All chemicals obtained from commercial sources were analytical grade or better and were used without further purification. 4,7,10-Trioxa-1,13-tridecanediamine, solvents, and most other chemicals were obtained from Aldrich (Sigma-Aldrich, Milwaukee, WI). L-Aspartate-α-methyl ester (H-Asp-OMe) was obtained from Bachem (Bachem California, Inc., Torrance, CA). Biotin *N*-hydroxysuccinimide ester, **9**, was obtained from Quanta BioDesign, Ltd. (Powell, OH). Trifluoroacetyl tetrafluorophenol (TFA-O-TFP) was prepared as previously described (*20*). Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich). Decaborane was obtained from Alfa (Alfa Aesar, Ward Hill, MA).

Radioactivity. All radioactive materials were handled according to approved protocols at the University of Washington. Na[^{125}I]I and Na[^{131}I]I were purchased from Perkin-Elmer Life and Analytical Sciences, Inc. (Waltham, MA) as a high concentration solution in 0.1 N NaOH. ^{211}At was produced by irradiation of a thin layer of bismuth metal (99.999%, Aldrich) with a 28 MeV α-particle beam on a Scandatronix MC-50 cyclotron (University of Washington). Isolation of Na[^{211}At]At was conducted in a charcoal-filtered glovebox (Innovative Technologies, Inc., radioisotope glovebox) by distillation from the irradiated target using the conditions previously described (*13*, *21*). Radiohalogenations were conducted within a charcoal-filtered Plexiglas enclosure (Biodex Medical Systems Inc., Shirley, NY) housed in a radiochemical fume hood. Radiohalogenation reactions were carried out in vials capped with Teflon-coated septa vented through a 10 mL charcoal-filled syringe.

Measurement of ^{125}I, ^{131}I, and ^{211}At was accomplished on the Capintec CRC-15R Radioisotope Calibrator using the manufacturer's settings for those radionuclides. In the experiment evaluating an admixture of ^{131}I with ^{125}I, the ^{125}I counts were compensated for spillover from the ^{131}I window (32%). Tissue samples were counted in a Wallac 1480 gamma counter with the following window settings: channels 35−102 and 165−185 for ^{125}I and ^{131}I were counted together, and channels 20−2000 (open window) when ^{211}At and ^{125}I were counted together. In experiments containing an admixture of ^{211}At/^{125}I counting was conducted twice, soon after animal sacrifice to obtain total counts and again after samples had decayed for 3−5 days to obtain the ^{125}I counts. ^{211}At counts were obtained by subtracting ^{125}I counts from the total counts. All ^{211}At counts were corrected for decay during the counting process.

Spectral Analyses. ^{1}H/^{11}B NMR and mass spectral analyses were obtained on new compounds. The data obtained are provided with the experimental procedures. Spectral data for compounds previously reported are not listed, but were consistent with the reported data. ^{1}H and ^{11}B NMR spectra were obtained on a Bruker AV-300 (300 MHz for ^{1}H; 96.3 MHz for ^{11}B); or a Bruker AV-500 (500 MHz ^{1}H and 160.4 MHz for ^{11}B). ^{1}H NMR data are referenced to tetramethylsilane as an internal standard (δ = 0.0 ppm), and ^{11}B NMR data are referenced to $BF_3 \cdot OEt_2$ as an external standard. Infrared spectra were obtained on a Bruker Vector 33 Fourier transform infrared spectrophotometer. Mass spectral data (both low and high resolution) were obtained on a VG Analytical (Manchester, England) VG-70 SEQ mass spectrometer with associated 11250J Data System. Although several attempts were made, we were unsuccessful in obtaining mass spectral data for two of the *closo*-dodecaborate(2-) derivatives, **2b** and **4b**.

Analytical Chromatography. HPLC separations of the nonradioactive compounds were obtained using a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and an ELSD 2000 evaporative light-scattering detector (Alltech, Deerfield, IL). Analysis of the HPLC data was conducted on Hewlett-

Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (eluant A) and 0.05 M, pH 5.5, aqueous triethylammonium acetate (eluant B). The gradient started with 20% MeOH and 80% eluant B for 2 min; then, the % MeOH was increased linearly to 100% over a 13 min period; following this, the elution continued with 100% MeOH for an additional 5 min. The retention time (t_R) of each iodinated compound is provided with the experimental procedure.

Preparative Chromatography. Products were purified from crude reaction mixtures using a Biotage SP Flash Purification System (Charlottesville, VA) on a reversed-phase C18 FLASH 25+M column. The purification used a gradient mixture composed of MeOH and 0.05 M Et_3NHOAc (TEAA). The gradient started with 80% 0.05 M TEAA, and MeOH was increased linearly to 100% over the next 20 min. Fractions were collected on the basis of UV detection at 215 or 254 nm. Fractions containing pure products were determined by analytical HPLC and were combined, solvent evaporated, and isolated to provide the yields listed.

Radio-HPLC. The product mixtures from radioiodination and astatination reactions were analyzed by HPLC using a C-18 column (Altima C-18, 5 μm, 250 × 4.5 mm; Alltech, Deerfield, IL) eluting at a flow rate of 1 mL/min with a gradient beginning with 20% MeOH/80% of an aqueous Et_3NHOAc solution. The HPLC equipment used in the analyses consisted of a Hewlett-Packard quaternary 1050 gradient pump, Waters 601 UV detector, and a Beckman model 170 radioisotope detector. Analysis of the HPLC data was conducted on Hewlett-Packard HPLC ChemStation software. Isolation of radiolabeled compounds was accomplished by collection of part of (when broad) or the entire radioactive peak. The retention times (t_R) of the radioiodinated and astatinated compounds are provided with the analytical data for individual compounds.

$[Et_3NH]_2$[*closo*-$B_{10}H_{10}$], 5a. This compound was prepared by a modification of the procedure described by Hawthorne and Pilling (*22*). A 25 g quantity (0.21 mol) of decaborane ($B_{10}H_{14}$) was dissolved in 400 mL xylene in a three-necked flask. The flask was flushed with Ar, and then 75 mL (0.54 mol) of Et_3N was added dropwise over 30 min. Following the addition, the reaction mixture was heated to 105 °C for 3 h, then refluxed (140 °C) for another 5 h. The reaction mixture was allowed to cool to room temperature, transferred to a round-bottom flask, and the xylene was removed with heating on a rotary evaporator. Addition of 250 mL of MeOH to the residue gave a colorless precipitate. The precipitate was filtered and set aside. The remaining solution was triturated with EtOAc (750 mL), filtered, and washed with EtOAc (1 L). The combined precipitate was placed under high vacuum to yield 62.3 g (94%) of **5a**. Spectral properties of this compound were as previously reported (*22*).

$[n-Bu_4N]_2$[*closo*-$B_{10}H_{10}$], 5b. A 2.0 g (6.20 mmol) quantity of $[Et_3NH]_2[B_{10}H_{10}]$ was dissolved in water (100 mL), then a solution containing *n*-Bu_4NBr (6.0 g, 18.61 mmol) in water (20 mL) was added slowly with stirring at room temperature. The precipitate was filtered, washed with water (1 L), dried under vacuum for overnight to afford the product as a colorless solid. 3.2 g (86%).

Na_2[*closo*-$B_{10}H_{10}$], 5c. A 25 × 1.5 cm column was filled with Amberlite IR120 resin (Sigma-Aldrich, St. Louis, MO) in deionized H_2O. Then, a 200 mL quantity of 3 M HCl was run across the column, followed by 750 mL of deionized H_2O. After acid conditioning, 250 mL of a NaCl solution (1 M) was passed over the column, followed by 750 mL of deionized H_2O. After conversion to the Na form, 100 mg sample of **5a** (0.31 mmol) was dissolved in 2 mL of a 1:1 mixture of CH_3CN/H_2O and was loaded on the column. The column was eluted with deionized H_2O (100 mL). The eluted aqueous solution was evaporated to a solid residue on a rotoevaporator, then placed under high vacuum overnight to give 51 mg (0.31 mmol, 100%) of **5c**.

$[Et_3NH]_2$[*closo*-$B_{12}H_{12}$], 6. This compound was prepared by a modification of a procedure described by Miller and Muetterties (*23*). A 240 mL quantity of undecane was placed in a 1 L three-necked flask equipped with a thermometer on one neck and a condenser with an addition funnel on top on the middle neck and a septum on the third neck. The addition funnel was capped with a septum for Ar introduction (with bubbler) and hydrogen release. The system was placed under argon and heated to 190−197 °C. In a separate flask, 32.0 g decaborane (262 mmol) was placed in a flask under argon and 84 mL of borane−triethylamine complex (65.3 g, 567 mmol) was added. When the decaborane was dissolved, it was filtered through glass wool into the addition funnel. The mixture was then slowly dripped into the hot undecane, keeping the temperature above 190 °C. Large amounts of hydrogen evolved. After addition of the decaborane solution, the mixture was heated for an additional 30 min. The mixture became thick with white/yellow solid and was difficult to stir. After cooling, the precipitate was filtered by gravity and the solid was washed with 200 mL ether to remove residual undecane. The solid was air-dried, then was dissolved in 1.5 L boiling water and heated for 30 min. A thick gummy material collected, floating on top of the solution. This was then filtered hot, and the resultant solution was allowed to cooled to room temperature, then placed in a refrigerator at 4 °C. After 3 h at 4 °C, the colorless solid was collected by vacuum filtration and dried under high vacuum to yield 34.6 g. The filtrate was concentrated to 200 mL, yielding another 15.9 g. A total yield 50.5 g (53.7%) of **6** was obtained. Spectral properties of isolated **6** were as previously reported (*23*).

$[n-Bu_4N]$[*closo*-$B_{10}H_9$-CO], 7a. This compound was prepared using a procedure similar from that previously reported (*24*). A 0.5 mL quantity (5.26 mmol) of oxalyl chloride was added slowly over 5 min to a solution of $[n-Bu_4N]_2[B_{10}H_{10}]$ (1 g, 1.66 mmol) in anhydrous CH_2Cl_2 (15 mL) at 0 °C. The mixture was stirred at 0 °C for 30 min, then allowed to warm to room temperature while stirring for additional 30 min. The reaction solution was evaporated to dryness on a rotary evaporator under vacuum. The residue was recrystallized from CH_2Cl_2/Et_2O to yield 0.74 g (71%) of brown tacky solid. IR (cm^{-1}, KBr disk): 2389 (s), 2340 (s), 2308 (s). ^{11}B NMR (DMSO-d_6, 160.43 MHz): δ 5.71 (1B), −4.52 (4B), −15.70 (2B), −21.64 (2B), −25.80 (1B).

$[Et_3NH]$[*closo*-$B_{10}H_9$-CO], 7b ((*24*)). A 1.08 mL (12.4 mmol) quantity of oxalyl chloride was added slowly over 5 min to a solution of $[Et_3NH]_2[B_{10}H_{10}]$ (2 g, 6.2 mmol) in anhydrous CH_3CN (30 mL) at 0 °C. The mixture was stirred at 0 °C for 30 min, then allowed to warm to room temperature while stirring for an additional 30 min. The reaction solution was evaporated to dryness on a rotary evaporator under vacuum. The residue was recrystallized from CH_3CN/Et_2O to yield 1.8 g (83%) of a brown tacky solid.

$[Et_3NH]$[*closo*-$B_{12}H_{11}$-CO], 8. A 1 mL (11.46 mmol) quantity of oxalyl chloride was added to a solution of $[Et_3NH]_2[B_{12}H_{12}]$ (1 g, 2.89 mmol) in anhydrous CH_3CN (20 mL) at room temperature, and then the mixture was stirred and heated to reflux for 3 h. The solution was allowed to cool to room temperature, then was evaporated to dryness on a rotary evaporator under vacuum. The residue was recrystallized from CH_3CN/Et_2O to yield 0.84 g (78%) of a brown tacky solid. IR (cm^{-1}, KBr disk): 2392 (s), 2336 (s), 2284 (s). ^{11}B NMR (DMSO-d_6, 160.43 MHz): δ −10.96 (1B), −11.98 (1B), −13.11 (1B), −14.20 (2B), −15.16 (3B), −15.82 (4B).

[*n*Bu$_4$N]$_2$[*closo*-B$_{10}$H$_9$-CONHpropyl], 1a. A solution of [*n*Bu$_4$N][*closo*-B$_{10}$H$_9$-CO], **7a** (400 mg, 1.032 mmol), *n*-propylamine (0.75 mL, 9.12 mmol), Et$_3$N (0.72 mL, 5.16 mmol) in anhydrous CH$_3$CN (10 mL) was stirred at room temperature for 16 h. EtOAc (15 mL) was added and the resultant solution was stirred at room temperature for 20 min. The solvents were decanted, and the crude residue was redissolved in 4 mL of MeOH/CH$_3$CN (1/1) and purified via preparative reversed-phase chromatography. Purification yielded 410 mg (83%) of **1a**. ^{1}H NMR (CD$_3$OD, 500 MHz): δ −0.25−0.75 (m, 9H), 0.86(t, J = 7.4 Hz, 3H), 1.02 (t, J = 7.2 Hz, 24 H), 1.36−1.48 (m, 16 H), 1.65−1.75 (m, 18 H), 2.98 (t, J = 6.8 Hz, 2 H), 3.26−3.29 (m, 16H). ^{11}B NMR (CD$_3$OD, 160.43 MHz): δ −0.62 (1B), −1.39 (1B), −23.90 (1B), −28.26 (7B). LRMS (ES$^-$) calcd for C$_4$H$_{17}$B$_{10}$NO (M)$^-$: 205.2. Found: 205.1. HPLC: t_R = 11.6 min.

[Et$_3$NH]$_2$B$_{10}$H$_8$I-CONH-propyl, 1b. A 746 μL aliquot of a 10 mg/mL solution of chloramine-T (32.7 μmol) in H$_2$O was added to a solution containing 20 mg (65.5 μmol) [Et$_3$NH]$_2$B$_{10}$H$_9$-CONH-Pr, **1a**, and 4.9 mg NaI (49 μL of 100 mg/mL in H$_2$O, 32.7 μmol) in 1 mL MeOH/H$_2$O with 5% HOAc (1:1). The reaction mixture was stirred at room temperature for 30 s, and then Na$_2$S$_2$O$_5$ (622 μL, 32.7 μmol, 10 mg/mL in H$_2$O) was added. The product was identified as a new, more lipophilic, species by reversed-phase HPLC (**1b** had approximately the same peak area as **1a** by ELSD detection). LRMS (ES$^-$) calcd for C$_4$H$_{16}$B$_{10}$INO (M)$^-$: 331.1. Found: 331.1. HPLC: t_R = 4.0 min.

[*n*Bu$_4$N]$_2$B$_{10}$H$_8$I-CONHpropyl, [^{125}I]1b. To 100 μL of 1 mg/mL **1a** in 50/50 water/MeOH with 5% HOAc was added 3 μL of Na[^{125}I]I (980 μCi in 0.1 N NaOH) followed by 10 μL of 1 mg/mL chloramine-T in H$_2$O. After 2 min at room temperature, 10 μL of 1 mg/mL Na$_2$S$_2$O$_5$ was added to quench the reaction. Analytical radioHPLC indicated that an 86% labeling efficiency was obtained. The remainder of the radiolabeled material was injected on the HPLC in two fractions and collected in a peak at 4.2 min to give 250 μCi of isolated product (26% isolated from leading portion of product peak). This was concentrated on a rotary evaporator, diluted with PBS, and neutralized with NaOH for the animal study.

[*n*Bu$_4$N]$_2$B$_{10}$H$_8$At-CONHpropyl, [^{211}At]1c. To 100 μL of 1 mg/mL **1a** in 50/50 water/MeOH with 5% HOAc was added 100 μL of Na[^{211}At]At (500 μCi in 0.05 N NaOH) followed by 10 μL of 1 mg/mL chloramine-T in H$_2$O. After 5 min at room temperature, 10 μL of 1 mg/mL Na$_2$S$_2$O$_5$ in H$_2$O was added to quench the reaction. Analytical radioHPLC indicated that an 84% labeling efficiency was obtained. The remainder of the radiolabeled material was injected on the HPLC, and the leading portion of the peak at 4.8 min to give 180 μCi was isolated (36%). This was concentrated on a rotary evaporator, diluted with PBS, and neutralized with NaOH for an animal study.

[Et$_3$NH]$_2$[*closo*-B$_{10}$H$_9$-CONHpropyl], 1d. This compound was prepared in 79% yield using the same reaction conditions as used to prepare **1a**. HPLC: t_R = 3.8 min.

[Et$_3$NH]$_2$B$_{10}$H$_8$I-CONHpropyl, [^{125}I]1e. To 100 μL of 1 mg/mL **1d** in 50/50 MeOH/5% HOAc was added 4 μL of Na[^{125}I]I (1.4 mCi) in 0.1 N NaOH followed by 20 μL of 1 mg/mL chloramine-T in water. After 1 min at rt, the reaction was quenched with 20 μL of 1 mg/mL Na$_2$S$_2$O$_5$ in H$_2$O. The reaction mixture was injected on the HPLC, and the peak at 12 min was collected for an isolated yield of 81% (HPLC indicated 82% reaction efficiency).

[Et$_3$NH]$_2$[*closo*-B$_{12}$H$_{11}$-CONHpropyl], 2a. A 500 mg (1.84 mmol) quantity of [Et$_3$NH][B$_{12}$H$_{11}$-CO], **8** was dissolved in 10 mL *n*-propylamine and was stirred at room temperature for 16 h. Excess *n*-propylamine was removed under vacuum. The crude residue was dissolved in 6 mL of MeOH/DMF/H$_2$O (1/1/1) and was purified via preparative reversed-phase chromatography. Isolation of the product yielded 510 mg (84%) of **8**. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 0.39−1.30 (m, 11H), 0.87 (t, J = 7.4 Hz, 3H), 1.16 (t, J = 7.2 Hz, 18H), 1.50−1.58 (m, 2H), 2.73 (t, J = 7.4 Hz, 2H), 3.01 (q, J = 7.3 Hz, 12H), 3.15 (s, 1H). ^{11}B NMR (CD$_3$OD, 160.43 MHz): δ −0.43 (1B), −14.92 (5B), −15.54 (6B). LRMS (ES$^-$) calcd for C$_4$H$_{19}$B$_{12}$NO (M)$^-$: 229.2. Found: 229.1. HPLC: t_R = 3.7 min.

[Et$_3$NH]$_2$B$_{12}$H$_{10}$I-CONH-propyl, 2b. A 692 μL (30.4 μmol) aliquot of a 10 mg/mL solution of chloramine-T in H$_2$O was added to a solution containing 20 mg (60.8 μmol) [Et$_3$NH]$_2$-B$_{12}$H$_{11}$−CONH-Pr, **2a**, and 4.56 mg NaI (30.4 μmol; 45.6 μL of a 100 mg/mL solution in H$_2$O) in 1 mL of MeOH/H$_2$O with 5% HOAc (1:1). The solution was stirred at room temperature for 30 s, and then Na$_2$S$_2$O$_5$ (578 μL, 30.4 μmol, 10 mg/mL in H$_2$O) was added. The product was identified as a new, more lipophilic species by reversed-phase HPLC (**2b** had approximately the same peak area as **2a** by ELSD detection). HPLC: t_R = 4.0 min.

[Et$_3$NH]$_2$B$_{12}$H$_{10}$I-CONHpropyl, [^{125}I]2b. To 120 μL of 1 mg/mL **1a** in 50/50 water/MeOH with 1% HOAc was added 1 μL of Na[^{125}I]I (566 μCi in 0.1 N NaOH) followed by 20 μL of 1 mg/mL chloramine-T in H$_2$O. After 2 min at room temperature, 20 μL of 1 mg/mL Na$_2$S$_2$O$_5$ in H$_2$O was added to quench the reaction. Analytical radioHPLC indicated that a 79% labeling efficiency was obtained. The remainder of the radiolabeled material was injected on the HPLC in two fractions and collected in a broad peak at 10 min to give 306 μCi (68%) of isolated product. This was concentrated on a rotary evaporator, diluted with PBS, and neutralized with NaOH for use in the animal study.

[Et$_3$NH]$_2$B$_{12}$H$_{10}$At-CONHpropyl, [^{211}At]2c. To 120 μL of 1 mg/mL **1a** in 50/50 water/MeOH with 1% HOAc was added 100 μL of Na[^{211}At]At (633 μCi in 0.05 N NaOH) followed by 20 μL of 1 mg/mL chloramine-T in H$_2$O. After 10 min at room temperature, 20 μL of 1 mg/mL Na$_2$S$_2$O$_5$ in H$_2$O was added to quench the reaction. Analytical radioHPLC indicated that a 53% labeling efficiency was obtained. A portion of the reaction mixture (250 μCi) was injected on the HPLC and a broad peak at 9 min was collected to give 126 μCi of isolated product (45%). This was concentrated on a rotary evaporator, diluted with PBS, and neutralized with NaOH for the animal study.

Biotin-Asp-α-OMe, 11. H-Asp-OMe, **10** (516 mg, 3.51 mmol), was dissolved in a solution of H$_2$O (15 mL) and NaHCO$_3$ (738 mg, 8.78 mmol), and then biotin *N*-hydroxysuccinimide ester, **9** (1.0 g, 2.93 mmol), and acetone (15 mL) were added, respectively. The resulting solution was stirred at room temperature for 16 h, and then the solution was evaporated to dryness on a rotary evaporator under vacuum. The residue was dissolved in water (50 mL), and the aqueous solution was acidified to pH 2.0 by 1 N HCl. After storage at 5 °C overnight, the white precipitate was filtered, washed with water (500 mL), and dried under vacuum to yield 791 mg (73%) of **11** as a colorless solid. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 1.24−1.36 (m, 3H), 1.41−1.53 (m, 4H), 1.57−1.64 (m, 1H), 2.08−2.12 (m, 2H), 2.56−2.61 (m, 2H), 2.70 (dd, J = 5.9, 16.2 Hz, 1H), 2.82 (dd, J = 5.3, 12.3 Hz, 1H), 3.07−3.11 (m, 1H), 3.61 (s, 3H), 4.11−4.14 (m, 1H), 4.30 (dd, J = 5.4, 7.6 Hz, 1H), 4.57 (dd, J = 7.5, 13.4 Hz, 1H), 6.37 (s, 1H), 6.41 (s, 1H), 8.28 (d, J = 7.5 Hz, 1H), 12.44 (br s, 1H). HRMS (ES$^+$) calcd for C$_{15}$H$_{23}$N$_3$NaO$_6$S (M + Na)$^+$: 396.1205. Found: 396.1202. HPLC: t_R = 4.9 min.

Biotin-Asp-α-OMe Tetrafluorophenyl Ester, 12. TFA-O-TFP (182 mg, 0.70 mmol) was added slowly to a solution of biotin-Asp-OMe, **11** (200 mg, 0.54 mmol), Et$_3$N (0.112 mL, 0.80 mmol), and anhydrous DMF (8 mL) at 0 °C. After stirring at 0 °C for 30 min, the solution was evaporated on a rotary

evaporator under vacuum. The crude product was then purified by silica gel column (1.5 cm × 25 cm) eluting with a gradient solution from 50% EtOAc/hexanes to 100% EtOAc. Purification yielded 235 mg (84%) of **12** as a colorless solid. mp 127−128 °C. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 1.25−1.38 (m, 3H), 1.42−1.55 (m, 4H), 1.58−1.65 (m, 1H), 2.09−2.15 (m, 2H), 2.57 (d, J = 12.6 Hz, 1H), 2.81 (dd, J = 5.9, 16.4 Hz, 1H), 3.06−3.10 (m, 1H), 3.16 (dd, J = 7.1, 16.5 Hz, 1H), 3.29 (dd, J = 6.2, 16.8 Hz, 1H), 3.66 (s, 3H), 4.11−4.14 (m, 1H), 4.30 (dd, J = 5.0, 7.8 Hz, 1H), 4.76 (dd, J = 7.3, 14.5 Hz, 1H), 6.36 (s, 1H), 6.42 (s, 1H), 7.92−7.99 (m, 1H), 8.52 (d, J = 7.7 Hz, 1H). HRMS (ES$^+$) calcd for $C_{21}H_{23}F_4N_3NaO_6S$ (M + Na)$^+$: 544.1141. Found: 544.1126. HPLC: t_R = 11.6 min.

[Et$_3$NH]B$_{10}$H$_9$-CONH-trioxatridecane-NH$_2$, 13. This compound was prepared in 68% yield by reaction of **7b** with 4,7,10-trioxa-1,13-tridecanediamine at room temperature for 3 days as previously reported (*13*).

[Et$_3$NH]B$_{12}$H$_{11}$-CONH-trioxatridecane-NH$_2$, 14. A solution of [Et$_3$NH][B$_{12}$H$_{11}$-CO], **8** (0.30 g, 1.11 mmol), and 4,7,10-trioxa-1,13-tridecanediamine (6.0 mL) was stirred at room temperature for 16 h. EtOAc (10 mL) was added, and the resulting solution was stirred at room temperature for 20 min. The solution was decanted, and the residue was washed with EtOAc (3 × 15 mL). The crude product was dissolved in 4 mL of MeOH/DMF/water (1/1/1) and purified via preparative reversed-phase chromatography. Purification yielded 407 mg (75%) of **14**. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 0.21−1.50 (m, 11H), 1.12 (t, J = 7.2 Hz, 9H), 1.66−1.76 (m, 4H), 1.78 (s, 1H), 2.68−2.75 (m, 4H), 2.94−2.97 (m, 8H), 3.38−3.52 (m, 12H). ^{11}B NMR (DMSO-d_6, 160.43 MHz): δ −6.20 (1B), −15.54 (5B), −16.15 (6B). LRMS (ES-) calc for $C_{11}H_{33}B_{12}N_2O_4LiNa$ (M + Li + Na) 419.4, found 419.4. HPLC: t_R = 3.8 min.

[Et$_3$NH]$_2$B$_{10}$H$_9$-CONH-trioxatridecane-NHCO-Asp-α-OMe-Biotin, 3a. [Et$_3$NH]B$_{10}$H$_9$-trioxatridecane-NH$_2$, **13** (116 mg, 0.249 mmol), was added to a solution of biotin-Asp-OMe TFP ester, **12** (100 mg, 0.192 mmol), Et$_3$N (0.08 mL, 0.575 mmol), and anhydrous DMF (10 mL). The resulting solution was stirred at room temperature for 1 h, and then the volatile materials were removed on a rotary evaporator under vacuum. The residue was dissolved in 5 mL of MeOH/CH$_3$CN (1/1) and purified via preparative reversed-phase chromatography. Purification yielded 108 mg (69%) of **3a**. ^{1}H NMR (CD$_3$OD, 500 MHz): δ −0.18−0.79 (m, 9H), 1.22 (t, J = 7.3 Hz, 18H), 1.38−1.44 (m, 2H), 1.52−1.73 (m, 6H), 2.19−2.27 (m, 2H), 2.66−2.69 (m, 3H), 2.91 (dd, J = 5.0, 12.8 Hz, 1H), 3.06 (q, J = 7.2 Hz, 12H), 3.17−3.23 (m, 4H), 3.48 (t, J = 6.4 Hz, 3H), 3.53−3.56 (m, 2H), 3.58−3.61 (m, 3H), 3.62−3.67 (m, 16H), 3.69 (s, 3H), 4.29 (dd, J = 4.4, 7.8 Hz, 1H), 4.46 (dd, J = 5.0, 8.0 Hz, 1H), 4.69 (t, J = 6.0 Hz, 1H). ^{11}B NMR (CD$_3$OD, 160.43 MHz): δ −0.91 (2B), −23.79 (2B), −27.99 (6B). LRMS (ES$^-$) calcd for $C_{26}H_{53}B_{10}N_5O_9S$ (M)$^-$: 721.5, Found: 721.5. HPLC: t_R = 12.1 min.

[Et$_3$NH]$_2$B$_{10}$H$_8$I-CONH-trioxatridecane-NHCO-Asp-α-OMe-Biotin, 3b. A 246 μL aliquot of chloramine-T solution (11 μmol, 10 mg/mL in H$_2$O) was added to a solution of **3a** (20 mg, 22 μmol), NaI (16 μL, 11 μmol, 100 mg/mL in water), and 5% HOAc of MeOH/water (50/50, 1 mL). The solution was allowed to stir at room temperature for 1 min, then 205 μL of Na$_2$S$_2$O$_5$ (11 μmol, 10 mg/mL in H$_2$O) was added. The product was identified as a new, more lipophilic species by reversed-phase HPLC (**3b** had approximately the same peak area as **3a** by ELSD detection). LRMS (ES$^-$) calcd for $C_{26}H_{53}B_{10}IN_5O_9S$ (M + H + Na): 871.3, Found: 871.3. HPLC: t_R = 4.3 min.

[Et$_3$NH]$_2$B$_{10}$H$_8$[^{131}I]I-CONH-trioxatridecane-NHCO-Asp-OMe-Biotin, [^{131}I]3b. A 20 μL aliquot of a 1 mg/mL solution of chloramine-T was added to a solution containing **3a** (100 μg, 0.11 μmol), Na[^{131}I]I (3 μL, 780 μCi, 0.1 N NaOH solution), and 100 μL of 5% HOAc in 1:1 H$_2$O/MeOH. The reaction was quenched with Na$_2$S$_2$O$_5$ (20 μL of 1 mg/mL solution in H$_2$O) after 1 min at room temperature. Analytical radioHPLC indicated that a 96% labeling efficiency was obtained. A portion of the eluted [^{131}I]**3b** was isolated for the animal study (44%).

[Et$_3$NH]B$_{12}$H$_{11}$-CONH-trioxatridecane-NHCO-Asp-OMe-Biotin, 4a. [Et$_3$NH]B$_{12}$H$_{11}$-CONH-trioxatridecane-NH$_2$, **14** (122 mg, 0.249 mmol) was added to a solution of biotin-Asp-OMe TFP ester, **12** (100 mg, 0.192 mmol), Et$_3$N (0.08 mL, 0.575 mmol), and anhydrous DMF (10 mL). The resulting solution was stirred at room temperature for 1 h, and then the volatile materials were removed on a rotary evaporator under vacuum. The residue was dissolved in 5 mL of MeOH/CH$_3$CN (1/1) and purified via preparative reversed-phase chromatography. Purification yielded 86 mg (53%) of **4a**. ^{1}H NMR (DMSO-d_6, 500 MHz): δ 0.22−1.44 (m, 13H), 1.22 (t, J = 7.3 Hz, 9H), 1.52−1.73 (m, 6H), 2.19−2.27 (m, 2H), 2.66−2.69 (m, 3H), 2.91 (dd, J = 5.0, 12.8 Hz, 1H), 3.06 (q, J = 7.2 Hz, 6H), 3.17−3.23 (m, 4H), 3.48 (t, J = 6.4 Hz, 3H), 3.53−3.56 (m, 2H), 3.58−3.61 (m, 3H), 3.62−3.67 (m, 16H), 3.59 (s, 3H), 4.13 (dd, J = 4.7, 7.8 Hz, 1H), 4.31 (dd, J = 4.8, 7.7 Hz, 1H), 4.55 (dd, J = 6.9, 13.8 Hz, 1H), 6.35 (s, 1H), 6.40 (s, 1H), 7.89 (t, J = 5.3 Hz, 1H), 8.16 (d, J = 7.9 Hz, 1H). ^{11}B NMR (DMSO-d_6, 160.43 MHz) δ −4.55 (1B), −15.88 (5B), −16.55 (6B). LRMS (ES$^-$) calcd for $C_{26}H_{55}B_{12}N_5O_9SNa$ (M + Na): 768.5, Found: 768.5. HPLC: t_R = 3.7 min.

[Et$_3$NH]$_2$B$_{12}$H$_{10}$I-CONH-trioxatridecane-NHCO-Asp-α-OMe-Biotin, 4b. A 240 μL aliquot of a chloramine-T solution (11 mmol, 10 mg/mL in water) was added to a solution of [Et$_3$NH]B$_{12}$H$_{11}$-trioxa-Asp-OMe-biotin (20 mg, 21 μmol), NaI (16 μL, 11 mmol, 100 mg/mL in water), and 5% HOAc of MeOH/water (50/50, 1 mL). After the solution was stirred at room temperature for 1 min, 200 μL of Na$_2$S$_2$O$_5$ (11 mmol, 10 mg/mL in water) was added. The product was identified as a new, more lipophilic species by reversed-phase HPLC (**4b** had approximately the same peak area as **4a** by ELSD detection). HPLC: t_R = 4.5 min.

[Et$_3$NH]$_2$B$_{12}$H$_{11}$[^{125}I]I-CONH-trioxatridecane-NHCO-Asp-OMe-Biotin, [^{125}I]4b. A 20 μL aliquot of a 1 mg/mL solution of chloramine-T was added to a solution containing **4a** (100 μg, 0.11 μmol), Na[^{125}I]I (2 μL, 1 mCi, 0.1 N NaOH solution), and 100 μL of 5% HOAc in 1:1 H$_2$O/MeOH. The reaction was quenched with Na$_2$S$_2$O$_5$ (20 μL of 1 mg/mL solution in H$_2$O) after 10 min at room temperature. Analytical radioHPLC indicated that a 86% labeling efficiency was obtained. A portion of the eluted [^{125}I]**4b** was isolated for the animal study (33%).

Biodistribution Studies. The biodistribution studies were conducted under a protocol approved by the Institutional Animal Care and Use Committee (IACUC) at the University of Washington. Procedures were conducted in compliance with U.S. laws relating to the conduct of animal experimentation. Male athymic mice (*nu*/*nu*), obtained from Simonson Laboratories (Gilroy, CA), were housed for 1 week in the isolator facility prior to beginning the study. In each experiment, the peaks corresponding to the desired products were isolated from the HPLC and were mixed in appropriate quantities to prepare an admixture containing predetermined quantities of each astatinated and/or radioiodinated compound. The admixture was diluted with phosphate buffered saline (PBS) to prepare injection quantities of ∼100 μL. This quantity was injected into each of 10 athymic mice via the lateral tail vein. The actual amount of injectate each animal received was determined by weighing the administering syringe before and after injection. Groups of 5

mice were sacrificed by cervical dislocation at 1 and 4 h post-injection. The tissues were excised, blotted free of blood, weighed, and counted. Blood weight was estimated to be 6% of the total body weight (*25*). Calculation of the percent injected dose per gram (%ID/g) in the tissues was accomplished using internal standards for the ^{211}At and ^{125}I or ^{131}I counts. The quantities injected and data obtained in the biodistribution studies are provided in Tables S1−S4 (Supporting Information).

RESULTS

Preparation of *closo*-Borate(2-) Derivatives. The *closo*-borate(2-) derivatives, **1a**−**1e** and **2a**−**2c**, were prepared by the reaction sequences shown in Scheme 1. $[Et_3NH]_2$[*closo*-$B_{10}H_{10}$], **5a**, was prepared in 94% yield by reaction of decaborane ($B_{10}H_{14}$) with Et_3N in xylene at 105−140 °C (*22*). $[n\text{Bu}_4\text{N}]_2$[*closo*-$B_{10}H_{10}$], **5b**. was prepared in 86% yield from **5a** by counterion exchange in H_2O after mixing with $n\text{Bu}_4\text{NBr}$. The Na salt Na_2[*closo*-$B_{10}H_{10}$], **5c**, was prepared from **5a** by elution over an Amberlite IR120 ion-exchange resin (Na form). $[Et_3NH]_2$[*closo*-$B_{12}H_{12}$], **6**, was prepared in 54% yield by reaction of decaborane with a triethylamine borane complex ($Et_3N\cdot BH_3$) at 190 °C in undecane (*23*). $[n\text{Bu}_4\text{N}]_2$[*closo*-$B_{10}H_{10}$], **5b**, was substituted with carbon monoxide by reaction of oxalyl chloride in anhydrous acetonitrile, initially in an ice bath for 30 min, then at room temperature for 30 min, to provide [$n\text{Bu}_4$N][*closo*-$B_{10}H_9$-CO], **7a**, in 71% yield. [Et_3NH][*closo*-$B_{10}H_9$-CO], **7b**, was prepared in 83% yield using the same reaction conditions. Similarly, $[Et_3NH]_2[B_{12}H_{12}]$, **6**, was substituted with carbon monoxide using the same reaction at reflux for 3 h to provide [Et_3NH][$B_{12}H_{11}$-CO], **10**, in 78% yield. Reaction of **7a** with *n*-propylamine and triethylamine in anhydrous acetonitrile at room temperature for 16 h provided the adduct $[n\text{Bu}_4\text{N}]_2[B_{10}H_9]$-CONHpropyl, **1a**, in 83% yield. Reaction of **8** with *n*-propylamine was slower, requiring it to be used as a solvent. However, the reaction was complete when run at room temperature for 16 h, yielding the adduct, $[Et_3NH]_2[B_{12}H_{11}]$-CONHpropyl, **2a**, in 84%.

The biotin derivatives **3a** and **4a** were prepared in multistep syntheses as depicted in Scheme 2. The reaction sequence began with preparation of a biotinidase-stabilized biotin derivative, the aspartate methyl ester adduct of biotin, **11** (*26*). Reaction of biotin *N*-hydroxylsuccinimide ester **9** with the α-methyl ester of aspartic acid, **10**, in aqueous sodium bicarbonate provided **11** in 73% yield. Activation of the free carboxylate of **11** was accomplished by reaction with trifluoroacetyl tetrafluorophenol (TFA-O-TFP) with Et_3N in DMF at 0 °C for 30 min to give an 84% yield of the tetrafluorophenyl ester, **12**. Reaction of **7b** with 4,7,10-trioxa-1,13-tridecanediamine for 3 days at room temperature gave a 68% yield of the adduct, **13**. Similarly, reaction of **8** with 4,7,10-trioxa-1,13-tridecanediamine for 16 h at room temperature gave a 75% yield of **14**. Reaction of biotin derivative **12** with **13** for 1 h at room temperature in anhydrous DMF containing Et_3N gave the targeted biotin derivative **3a** in 69% yield. Reaction of **12** with **14** under the same reaction conditions gave **4a** in 53% yield.

Iodination reactions were performed on **1a**, **2a**, **3a**, and **4a** to provide HPLC reference standards (**1b**, **2b**, **3b**, and **4b**) for use in the radiohalogenation studies. In the iodination reactions, 0.5 equiv of both NaI and chloramine-T were reacted with each *closo*-borate(2-) derivative in H_2O. This stoichiometry was used to ensure that the reaction did not substitute chlorine or multiple iodine atoms on the *closo*-borate(2-) moiety, and to distinguish the product from starting material (which had 50% remaining) by HPLC. Both of the *closo*-borate(2-) moieties are known to add multiple halogen atoms to the same molecule (*27*) and are reactive with all of the electrophilic halogen species (*28, 29*). Yields of the iodinated products were measured by HPLC (ELSD detection), and in each case were approximately 50% due to limited quantities of iodination reagent used. (Reactions containing 1 equiv each of NaI and chloramine-T have provided isolated iodinated products in >80% after separation of the other halogenated products by Biotage Flash Chromatograpy. In these studies, adequate quantities of products for MS analyses and HPLC standards was obtained by using only 0.5 equiv of reagents.) Iodinated products were isolated from HPLC to obtain a pure sample for use as a HPLC standard. Although attempts were made to obtain mass spectra data for identification of the iodinated standards, this was unsuccessful for some derivatives even though several attempts were made using negative ion electrospray mass spectrometry.

HPLC of *closo*-Decaborate(2-) Salts. The Na, Et_3N, and $n\text{Bu}_4\text{N}$ salts of *closo*-decaborate(2-) (**5c**, **5a**, **5b**, respectively) were prepared and analyzed by reversed-phase HPLC using two different solvent mixtures under the same gradient conditions. One solvent mixture was composed of [solvent A] MeOH and [solvent B] H_2O containing 0.1% HOAc (v/v). The second solvent mixture also employed MeOH as solvent A, but solvent B was 50 mM aqueous Et_3NHOAc. The Et_3NHOAc modifier was used to determine if the Et_3NH ion would displace the counterions on the isolated *closo*-decaborate(2-) under the elution conditions. Detection of the eluted non-chromophoric ions and salts was accomplished by an evaporative light scattering detector (ELSD). Using the ELSD, Na ions are detected, but organic ammonium salts were not (due to volatility). Therefore, the peaks observed are those of nonvolatile Na ions and/or the *closo*-decaborate(2-) derivative salts. Chromatograms showing the peak

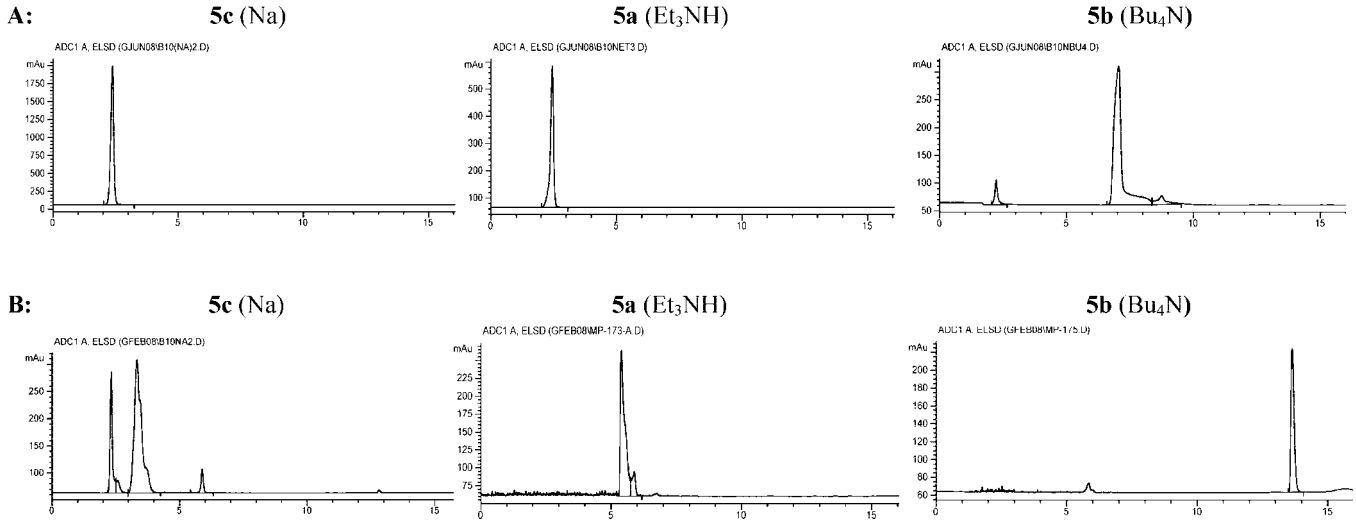

Figure 2. HPLC chromatograms of *closo*-decaborate(2-) having Na (**5c**), Et_3NH (**5a**), or Bu_4N (**5b**) counterions. Identities of the compound and its counterion (in parentheses) are shown above each chromatogram. Panel A chromatograms (3 across) were obtained using MeOH/0.1% aqueous HOAc (v/v) as eluant. Panel B chromatograms (3 across) were obtained using MeOH/50 mM aqueous Et_3NHOAc as the eluant. An evaporative light scattering detector (ELSD) was used for detection. (Note that the small peak at t_R = ~6 min in chromatograms in panel B is likely to be an impurity.)

retention times (t_R) after injecting the same quantity of each salt are shown in Figure 2, panels A and B. The left and middle chromatograms in panel A (3 chromatograms across) show that the Na and Et_3NH salts of *closo*-decaborate(2-) are highly ionic, eluting with the solvent front. In contrast, it appears from the right chromatogram in panel A that at least one of the nBu_4N ions remains with the *closo*-decaborate(2-) under the same conditions, as it elutes with a t_R of ~7 min. Chromatograms in panel B are also informative. As expected, the left chromatogram shows that the Na ions in **5c** are readily displaced by at least one Et_3NH ion. In the case where the isolated compound has two Et_3NH counterions (i.e., **5a**), as in the middle chromatogram of panel B, both Et_3NH counterions appear to elute with the *closo*-decaborate(2-) ion. Interestingly, it appears from the right chromatogram in panel B that both of the nBu_4N ions also elute with the *closo*-decaborate(2-) derivative **5b** when Et_3NHOAc is in the eluting solvent.

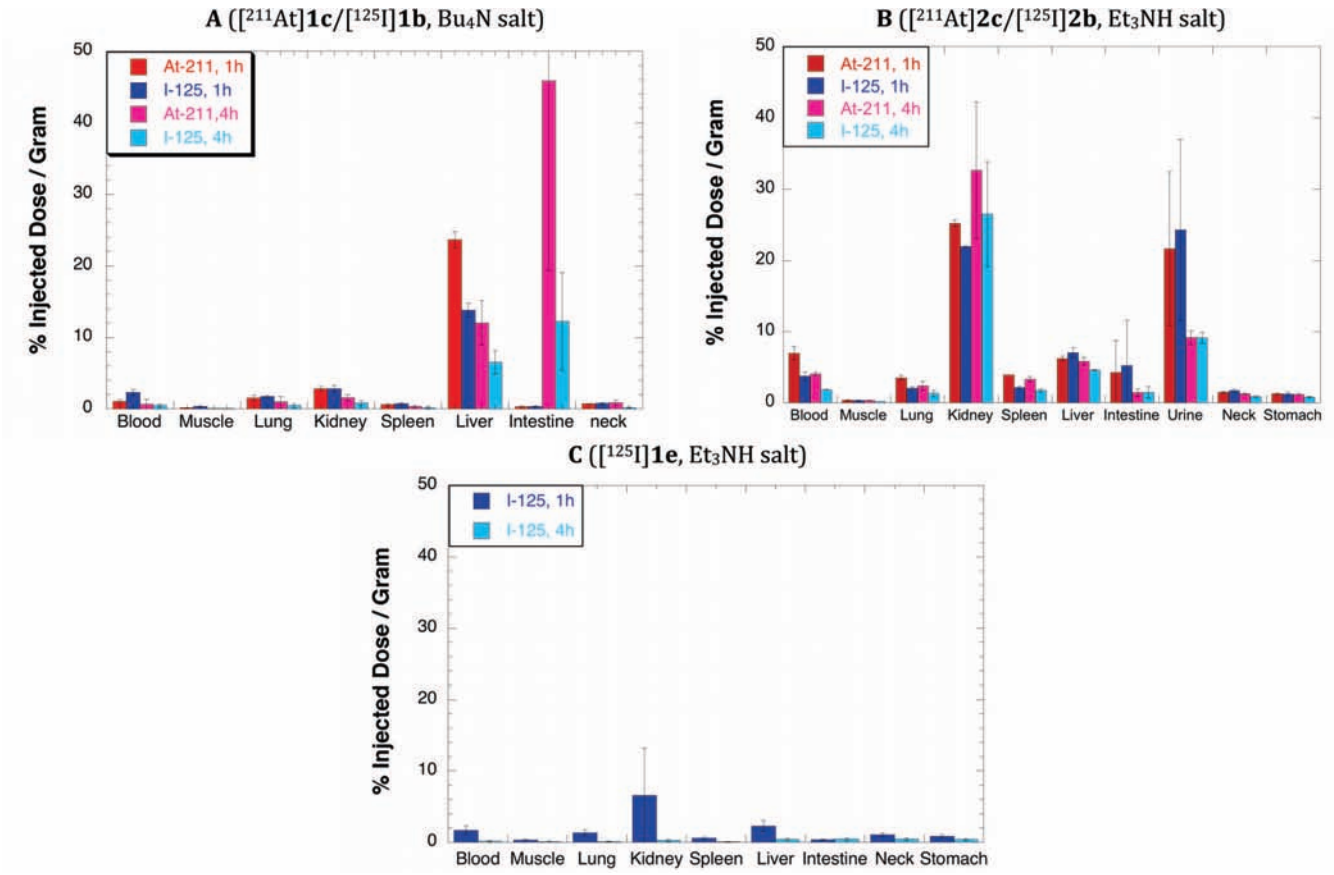

Figure 3. Graphed data from tissue biodistributions in mice at 1 and 4 h after injection of (panel A) *n*Bu4 *closo*-decaborate(2-) labeled with ^{211}At ([^{211}At]**1c**)/^{125}I ([^{125}I]**1b**); (panel B) Et_3NH salt of 2 propylamido closo dodecaborate labeled with ^{211}At ([^{211}At]**2c**]/^{131}I ([^{125}I]**2b**); and (panel C) Et_3NH salt of 2 propylamido-*closo*-decaborate(2-) labeled with ^{125}I ([^{125}I]**1e**). Red bars represent concentration of ^{211}At at 1 h post injection (pi), pink bars represent concentration of ^{211}At at 4 h pi, dark blue bars represent ^{125}I at 1 h pi, and light blue bars represent ^{125}I at 4 h pi. Data have been plotted on the same scale for all three graphs for comparison purposes.

Radiohalogenation Reactions. Radioiodinations (*nca*) were conducted using Na*I/chloramine T in a mixture of 5% HOAc/MeOH/H_2O at room temperature for 1−10 min. Radioiodinations of both *closo*-decaborate(2-) and *closo*-dodecaborate(2-) derivatives were facile, giving labeled compounds in 68−96% yields by HPLC analyses, but the *closo*-dodecaborate(2-) derivatives were slower, requiring up to 10 min to complete. Astatination yields were also high for the *closo*-decaborate(2-) derivative **1c**, providing 84% radiochemical yield after a 5 min reaction time. However, the slower reaction of the *closo*-dodecaborate derivative **2c** gave only 53% yield after 10 min reaction time. No studies were conducted to optimize the reaction conditions, including reaction times. However, radiohalogenations of the *closo*-decaborate(2-) derivatives appeared to be complete within 1 min. and no improvements in labeling yields were observed after 10 min reaction time for the *closo*-dodecaborate. Previous studies by Orlova et al. (*15*) indicated that the astatinataion reaction of *closo*-dodecaborate(2-) was "essentially complete" within 5 min under the conditions they studied. In some examples, isolated radiochemical yields were considerably lower than what the HPLC indicated, as only portions of the prepared radiolabeled compounds were collected from the HPLC effluent. The quantities of radioactivity collected were not optimized, as only small quantities of activity were required for the animal studies.

Biodistribution Studies. Four biodistribution studies were conducted with radiolabeled *closo*-borate(2-) derivatives in this investigation. In the first biodistribution study, radiolabeled *closo*-decaborates [^{211}At]**1c** and [^{125}I]**1b** were mixed and coinjected into athymic mice. At 1 and 4 h post-injection (pi), concentrations of radionuclides were evaluated in blood, urine, and selected tissues. Tissue concentrations (%ID/g) for selected tissues are plotted in Figure 3, panel A, and all data obtained are provided in Table S1 (Supporting Information). Surprisingly, the highest concentrations of both ^{211}At and ^{125}I were found in the liver and intestines. While most tissues had concentrations of ^{211}At and ^{125}I that are not significantly different (paired Student's *t*-test; $P < 0.05$), the concentrations of the two radionuclides in blood, urine, liver, and stomach were significantly different. Interestingly, the concentration of ^{125}I in urine at 1 h pi (174.43 ± 90.33%ID/g) was much higher than that of the ^{211}At (33.11 ± 14.06%ID/g), suggesting that there is a difference in the route of excretion of the otherwise identical radiolabeled *closo*-decaborate(2-) derivatives. In fact, the higher concentration of ^{211}At than ^{125}I observed in liver also supports having different excretion routes. Although ^{211}At concentrations were found to be higher than ^{125}I concentrations in stomach, the fact that there are no significant differences in the concentrations of radionuclides in lung and spleen suggests that only very small amounts, if any, of the free [^{211}At]astatide were present (*7*).

In the second biodistribution study, coadministered radiolabeled *closo*-dodecaborates, [^{211}At]**2c** and [^{125}I]**2b**, were evaluated at the 1 and 4 h pi time points. Selected tissue concentrations (%ID/g) are plotted in Figure 3, panel B, and all data obtained are provided in Table S2 (Supporting Information). The highest tissue concentrations of ^{211}At and ^{125}I were found in kidney, indicating that the kidney was likely to be the route of excretion for this pair of radiolabeled *closo*-dodecaborate(2-) compounds. Unlike the radiolabeled *closo*-decaborate(2-) derivatives [^{211}At]**1c** and [^{125}I]**1b**, there was no significant difference in the concentration of ^{211}At and ^{125}I in urine (at sacrifice). There were

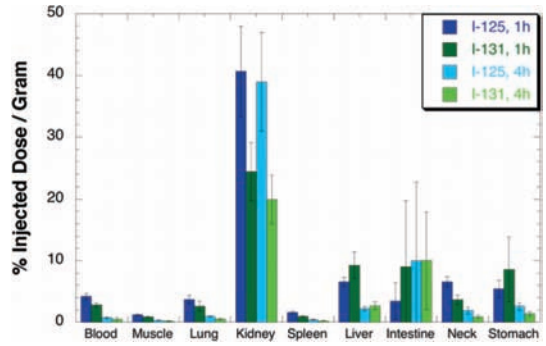

Figure 4. Biodistribution of radioiodinated biotin derivatives in mice at 1 and 4 h postinjection. Dark blue bars show concentrations of biotin derivative containing the *closo*-decaborate(2-) moiety ([^{131}I]**3b**) at 1 h pi and light blue bars show concentrations of that compound at 4 h pi. Dark green bars show concentrations of biotin derivative containing *closo*-dodecaborate ([^{125}I]**4b**) at 1 h pi and light green bars show concentrations of that compound at 4 h pi.

signficant differences (paired Student's *t*-test; $P < 0.05$) between the concentrations of ^{211}At and ^{125}I in lung, spleen, neck, and stomach suggesting that some free ^{211}At was present. However, the %ID/g concentrations of ^{211}At in those tissues indicates that the amount of deastatination was small.

The surprising differences in routes of excretion for the radiolabeled *closo*-decaborate(2-) and *closo*-dodecaborate(2-) led to a third biodistribution study where the tissue distribution of the Et_3NH salt of *closo*-decaborate(2-), [^{125}I]**1e**, was evaluated at 1 and 4 h pi. Selected tissue concentrations (%ID/g) are plotted in Figure 3, panel C, and all data obtained are provided in Table S3 (Supporting Information). The tissue concentration data from the Et_3NH salt, [^{125}I]**1e**, are strikingly different from that obtained with the nBu$_4$N salt, [^{125}I]**1b**, of the same compound. The highest concentration of ^{125}I is in kidney after injection of [^{125}I]**1e**, suggesting that renal clearance is the primary route of excretion. The high concentration in urine at 1 h (320 ± 135%ID/g) also supports renal clearance. Importantly, all tissue concentrations for the Et_3NH salt of [^{125}I]**1e**-labeled *closo*-decaborate(2-) (panel B, blue bars) were much lower than those observed for the nBu$_4$N salt.

In the fourth biodistribution, the biotin derivatives containing the *closo*-decaborate(2-) moiety, [^{131}I]**3b**, and the *closo*-dodecaborate(2-) moiety, [^{125}I]**4b**, were coinjected into athymic mice and evaluated at 1 and 4 h pi. Concentrations (%ID/g) of radionuclides in selected tissues are plotted in Figure 4, and all data obtained are provided in Table S4 (Supporting Information). The highest concentrations were found in the kidney for both radiolabeled compounds, but the biotin derivative containing the *closo*-dodecaborate(2-) moiety, [^{125}I]**4b**, had considerably higher concentrations than the *closo*-decaborate(2-) derivative, [^{131}I]**3b**. The high kidney concentrations may be due, at least in part, to the higher lipophilicity of the methyl esters, as other similar biotin derivatives did not show as high kidney concentrations. For example, the biotin derivative having the same structure as [*I]**3b** without the methyl ester had kidney concentrations of 12.27 ± 1.30 at 1 h pi and 16.24 ± 2.71 at 4 h pi (unpublished data), and in a series of biotin derivatives containing *nido*-carborane moieties, the highest kidney concentrations were <8% ID/g at 1 h pi and <4%ID/g at 4 h pi (*30*).

Significant differences (paired Student's *t*-test; $P < 0.05$) were seen between the two radiolabeled biotin derivatives in blood, lung, kidney, spleen, liver, and neck at 1 h pi, and in lung, kidney, spleen, neck, and stomach at 4 h pi. However, the differences, while significant, were small in most tissues, making the kidney localization/retention the most important factor in deciding between the two *closo*-borate(2-) moieties.

DISCUSSION

Our previous studies demonstrated that biomolecule-conjugated pendant groups having ^{211}At bonded to an aryl carbon can be quite unstable in vivo, releasing [^{211}At]astatide to localize to lung, spleen, stomach, and thyroid (*7, 31*). Since there are no stable nuclides of At found in nature, it is unlikely that there are specific enzymes to cleave the C−At bond. One possible explanation for the in vivo deastatination is that the low bond energy of the C−At bond (*32, 33*) makes it possible for nonspecific processes to release ^{211}At from metabolized biomolecules. We reasoned that the in vivo stability of ^{211}At-labeled compounds might be increased if the At was coupled to the carrier molecule through a stronger bond. This led us to consider boron−halogen bonds, which are considerably stronger than the corresponding carbon−halogen bonds (*34*). We further reasoned that ^{211}At bonded to a boron atom on an aromatic boron cage moiety would likely provide the highest bond energy, as is the case with aromatic C−At bonding (*33*). Thus, we became interested in boron cage moieties as components of pendant (conjugation) groups for ^{211}At labeling.

Our boron-^{211}At labeling studies began with the *nido*-carborane moiety (*12*). While that moiety was relatively easy to modify and incorporate into biomolecules, its conjugation appeared to increase the half-life of the biomolecule in blood compared with the same biomolecule astatinated with an astatobenzoate pendant group (*12, 30*). Importantly, when ^{211}At-labeled molecules containing conjugated *nido*-carborane groups were metabolized, the ^{211}At was released. Following those studies, we evaluated the reactivity of monocarbon carboranes and found that the cage system has a low reactivity for radioiodinations, so astatinations were not conducted (*35*). Subsequently, we evaluated bis-*nido*-carboranes (also called venus flytrap cluster (*36*)) and found that they provided high astatine stability in vivo, but dramatically affected the nature of the biomolecule to which they were attached (*13*). In the later studies, we also found that another boron cage moiety, *closo*-decaborate(2-), **5**, provided high in vivo stability with minimal effect on the biomolecules investigated (*13*).

Orlova et al. reported that a similar boron cage moiety, the *closo*-dodecaborate(2-) cage, could be astatinated in high yield (*16*). The same research group described several modified *closo*-dodecaborate(2-) derivatives that can be used for conjugation to biomolecules (*14, 37*−*39*). The reported *closo*-dodecaborate(2-) derivatives all had hetero atoms (N, O, S) attached to the *closo*-borate(2-) cage. We prepared two of the reported derivatives and found that the rate of halogenation was very slow under the conditions studied (unreported results). It was postulated that the heteroatom attached to the boron cage moiety was protonated under the reaction conditions, resulting in an adjacent positive charge that deactivated the cage to halogenation. To circumvent that situation, we sought derivatives of dianionic *closo*-borate(2-) cage moieties that would not have a protonated heteroatom adjacent to the boron cage. We found that derivatives of *closo*-borate(2-) moieties, which were conjugated to another moiety through an amide bond, retained their high reactivity with halogens. Therefore, our recent studies have focused on derivatives containing amido-bonded *closo*-borate(2-) moieties for ^{211}At labeling.

This investigation was conducted to assess the differences in chemistry and in vivo properties associated with using *closo*-decaborate(2-) or *closo*-dodecaborate(2-) moieties as the labeling components of pendant groups for astatination of biomolecules. To illustrate the differences, 2-*n*-propylamido derivatives of two *closo*-borate(2-) moieties were prepared and evaluated in vivo.

As expected based on prior literature reports, the synthetic chemistry and radiolabeling chemistry differed significantly between the two cage systems. First, while the yields of amine reactions with the two *closo*-borate(2-) carbon monoxide adducts, [*closo*-$B_{10}H_9$−CO]$^{1-}$, **7**, and [*closo*-$B_{12}H_{11}$−CO]$^{1-}$, **8**, were similar (i.e., 78% and 83%), the reaction times for coupling amines with **7** were considerably longer than with **8** (3 days vs 16 h). The low reactivity of **7** with amines most likely reflects the higher electron density of the *closo*-decaborate(2-) cage, which makes the carbon on the carbon monoxide moiety less electrophilic. Importantly, the higher electron density of the *closo*-decaborate(2-) cage makes it more reactive in the no-carrier-added radiohalogenations. Although the radioiodination yields were similar (**1b**, **1f**, **3b** 82−96% vs **2b**, **4b** 79−86%) the astatination yields (**1c**, 84% vs **2c**, 53%) yields favor the use of the *closo*-decaborate(2-) moiety.

An important finding of the investigation was that biodistributions of radiolabeled molecules differing only in the type of *closo*-borate(2-) cage incorporated were significantly different. Indeed, tissue distributions of the radiolabeled *n*-propylamido derivatives of *closo*-decaborate(2-), **1b**/**1c** (Figure 3A), and *closo*-dodecaborate(2-), **2b**/**2c** (Figure 3B), were surprisingly different. Biodistribution data from the Et_3NH salt of radiolabeled *closo*-dodecaborate(2-) derivatives **2b**/**2c** indicated that it was excreted primarily by the kidney. This was not surprising, as renal clearance is the route of excretion that was anticipated for both *closo*-borate(2-) derivatives. However, the biodistribution data from the *n*Bu_4N salt of *closo*-decaborate(2-) indicated that it is primarily excreted by the hepatobiliary system. This surprising result made us consider the other difference in the molecules, the nature of the ammonium counterion used. In our initial study of the in vivo distributions of the *n*Bu_4N salt of *closo*-decaborate(2-) derivatives, [^{211}At]**1c** and [^{125}I]**1b** were investigated. The Bu_4NH salt was employed with the *closo*-decaborate(2-) derivatives to aid purification of the radiolabeled compounds by HPLC. Under the elution conditions employed, the Et_3NH salt eluted at the solvent front whereas the *n*Bu_4N salt eluted at a later time allowing collection of the purified material from the HPLC eluant. The *n*Bu_4N salt was also used in the preparation of *closo*-decaborate(2-) derivatives to assist in isolation and purification of products, as the salts have very low solubility in H_2O. The Et_3NH salts of *closo*-decaborate(2-) derivatives are fairly water soluble (*17*). The *n*Bu_4N salts were not used with the *closo*-dodecaborate(2-) derivatives, as their Et_3NH salts are fairly insoluble in water, making isolation and purification readily achieved.

We surmised that the observed differences in tissue concentrations between the radiolabeled 2-propylamido derivatives of *closo*-decaborate(2-) [^{125}I]**1b** and *closo*-dodecaborate(2-) [^{125}I]**2b** could be due the differences in counterion used. We reasoned that, if the *n*Bu_4N counterion was not readily exchanged by other counterions in the blood, the radiolabeled *closo*-decaborate(2-) derivative would remain highly lipophilic, causing it to bind with proteins in blood, ultimately leading to excretion by the hepatobiliary system. As a cursory assessment of the extent of counterion association with the *closo*-decaborate(2-) derivatives, a simple reversed-phase HPLC comparison was carried out. For the HPLC comparison, the Na, Et_3N, and nBu_4N salts of unsubstituted *closo*-decaborate(2-) (i.e., **5a**, **5b**, **5c**) were prepared and analyzed by reversed-phase HPLC. To create different challenges to the *closo*-decaborate(2-) counterions, two solvent mixtures were used for elution. In one solvent mixture, the counterions were challenged by hydronium ion (H_3O^+), and in the other solvent mixture, the counterions were challenged with ammonium ions (Et_3NH^+). The chromatograms obtained are shown in Figure 2, panels A and B. It appears from the HPLC analyses that the *n*Bu_4N counterions of the *closo*-decaborate(2-) are not readily displaced, even under conditions that would seem to favor their displacement (i.e., high concentrations of H_3O^+ or Et_3NH^+). In contrast, both the Na and Et_3NH salts appear to be highly ionic as they elute at the solvent front when there are no ammonium ions in the eluant. As expected, the Na and Et_3NH ions appear to exchange rapidly with Et_3NH when it is present in the eluant.

The HPLC elution data did not prove that the *n*Bu_4N counterions remain with the radiolabeled *closo*-decaborate(2-) derivative in vivo. Thus, the ultimate test was to evaluate the Et_3NH salt in vivo and compare the biodistributions of the two identical compounds that only differ in the nature of their counterions. The tissue distributions for the *n*Bu_4N salt, [^{125}I]**1b**, and the Et_3NH salt, [^{125}I]**1e**, at 1 and 4 h pi are very different (Figure 3, panels A and C). While the *n*Bu_4N salt had high concentrations in the liver, the Et_3NH salt had its highest tissue concentration in the kidney. This finding suggests that the highly lipophilic *n*Bu_4N counterion remains associated with the *closo*-decaborate(2-) derivative in vivo. Importantly, all of the tissue concentrations were substantially lower when the Et_3NH salt was used, making this counterion preferred for use when the compounds have in vivo applications. Although the Na salts of *closo*-decaborate(2-) can be prepared and used in vivo, it does not seem to be a requirement. This is fortunate, as we now routinely use Et_3NHOAc as a modifier in the HPLC eluant to move the radiolabeled *closo*-decaborate(2-) derivative away from the solvent front, resulting in isolation of the Et_3NH salt.

The fourth biodistribution evaluated the differences in tissue distributions between the *closo*-decaborate(2-) and *closo*-dodecaborate(2-) moieties (both as Et_3NH salts) in a more complex biomolecule, a biotinidase-stabilized biotin derivative. For in vivo evaluation, stabilization of the biotinamide bond to cleavage from the serum enzyme biotinidase (*40*−*42*) is required so that the radiolabel remains with the biotin moiety. Our previous studies have demonstrated that a number of functional groups can be built into the carbon α to the biotinamide bond to block enzymatic cleavage of that bond (*26*, *43*, *44*). In this study, a carboxylate methyl ester was used in the biotin derivatives. The carboxylate methyl ester is not generally used for biotinidase blocking due to its high lipophilicity. However, for this comparison, optimization of the biotin derivative was not required, so the methyl ester was used in the study because it can be readily prepared. The radioiodinated derivatives [^{131}I]**3b** and [^{125}I]**4b** were evaluated in mice at 1 and 4 h pi. The biodistribution data (Figure 4) show that the only substantive difference between the two radioiodinated biotin derivatives is in the kidney concentrations. As might be expected based on the prior studies with simple *n*-propylamide-substituted *closo*-borate(2-) moieties, the *closo*-dodecaborate(2-) derivative, [^{125}I]**4b**, had significantly higher kidney concentrations than the corresponding *closo*-decaborate(2-) derivative, [^{131}I]**3b**.

SUMMARY

The goal of this investigation was to compare the synthetic chemistry, radioiodine and ^{211}At labeling efficiencies, and in vivo tissue distributions between compounds that were identical except that they contained either a *closo*-decaborate(2-) or a *closo*-dodecaborate(2-) moiety. Synthesis of *closo*-borate(2-) derivatives **1a**, **2a**, **3a**, and **4a** pointed out differences in reaction rates between the two *closo*-borate(2-) moieties. However, the differences are not considered important in choosing one *closo*-borate(2-) moiety over the other, as both could be substituted with carbon monoxide and subsequently coupled with amine-containing molecules. While only one comparison was done, it appears that ^{211}At-labeling efficiency is higher in compounds containing the more electron-rich *closo*-decaborate(2-). The tissue distribution data indicated that the ^{211}At-labeled derivatives

with both *closo*-borate(2-) moieties have high stability toward in vivo deastatination, making this parameter unimportant in the decision between the use of two *closo*-borate(2-) moieties. However, the tissue distribution indicated that the *closo*-dodecaborate(2-) is highly sequestered and retained in the kidney, whereas the *closo*-decaborate(2-) is not. An interesting finding was the fact that the counterion can have a large influence on the tissue distribution, with the highly lipophilic nBu$_4$N salt causing the compound to be excreted by the hepatobiliary system, whereas the Et$_3$NH salt appears to have much less influence on the distribution. In the final analysis, the low kidney sequestration and rapid tissue clearance of the *closo*-decaborate(2-) make it the better candidate for use as a pendant group in ^{211}At-labeling (or radioiodination) of biomolecules for in vivo therapy applications.

ACKNOWLEDGMENT

We thank Holly Nguyen and Dr. Robert Vessella for assistance with the animal studies conducted in this investigation. Funding for this research was provided by NCI, NIH (CA11343).

Osmium Complexation of Mismatched DNA: Effect of the Bases Adjacent to Mismatched 5-Methylcytosine

Akiko Nomura, Kazuki Tainaka, and Akimitsu Okamoto*

Advanced Science Institute, RIKEN (The Institute of Physical and Chemical Research), Wako, Saitama 351-1098, Japan.
Received December 10, 2008; Revised Manuscript Received January 12, 2009

The efficiency of osmium complex formation at 5-methylcytosine in mismatched DNA duplexes is a key point for the design of sequence-specific detection of DNA methylation. Osmium complexation was not observed in fully matched duplexes, whereas the complexation site and efficiency in mismatched duplexes changed depending on the type of 5′-neighboring base of the 5-methylcytosine forming a mismatched base pair. In particular, when the base adjacent to the 5′ side of the mismatched base pair was thymine, a unique "side reaction" was observed. However, the nature of the mismatched base pairs in the reaction site did not influence the selectivity of osmium complex formation with methylated DNA.

INTRODUCTION

A number of reactions for pyrimidine bases have been reported, such as photodimerization (*1, 2*), Michael addition (*3*−*5*), and oxidation (*6*−*9*). Osmium oxidation is one of the known pyrimidine-targeting sequencing methods, and in this case, the C5−C6 double bonds of thymine and 5-methylcytosine are oxidized (*10*−*15*). A highly stable pyrimidine glycol−osmate−bipyridine triad is formed on reaction with osmium tetroxide (*10, 11*) or potassium osmate activated by potassium hexacyanoferrate(III) in the presence of bipyridine as a ligand (Figure 1a) (*12*−*15*). On the other hand, the oxidation of cytosine is much slower than that of 5-methylcytosine (*10, 12*).

Cytosine methylation, in which the C5 position of the cytosine base is methylated enzymatically, is an epigenetic modification that can play an important role in the control of gene expression in mammalian cells, and about 70% to 80% of cytosines are methylated in the CpG sequence. The sequence-selective distinction between methylated and unmethylated cytosines is very important for studies of gene deactivation (*16, 17*). In addition, erroneous DNA methylation may contribute to the etiopathogenesis of tumorigenesis (*18*−*20*). Cytosine methylation is one of the most important epigenetic events in cells, and its detection is very significant. The oxidation of pyrimidine bases may be useful for the detection of the presence/absence of a methyl group at cytosine C5.

A 5-methylcytosine-adenine mismatched base pair made possible the sequence-selective formation of an osmium complex at 5-methylcytosine (*21*). This is different from the negligible reactivity of the fully matched duplex, because the formation of a cytosine-adenine mismatched pair causes partial disruption of π-stacking of the DNA duplex and facilitates oxidation at the C5−C6 double bond of the cytosine forced out of the DNA major groove. This system was applied to a new DNA probe for methylation detection, the so-called ICON probe (Figure 1b). The formation of a mismatched base pair by hybridization with the ICON probe and the location of bipyridine attached to the probe DNA results in complexation at a specific 5-methylcytosine. Toward development of more effective, sequence-selective 5-methylcytosine detection based on the formation of mismatched base pairs, a more detailed investigation of the osmium complexation efficiency and selectivity depending on the nature of the mismatched base pairs and neighboring sequences is required. This knowledge facilitates prior estimation of the reaction abilities of probes and helps in the design of highly methylation sensitive probes.

In this paper, we describe the osmium oxidation efficiency at methylated CpG (MpG) in a series of duplexes with a single base mismatch. The oxidation efficiency was investigated through alkaline strand cleavage for a variety of duplexes with different complementary bases of 5-methylcytosine and different 5′-flanking base pairs of MpG. Sequence-selective osmium complexation at the target 5-methylcytosine was detected for mismatched duplexes, and the unique reactivity of 5′-neighboring thymine was also observed.

EXPERIMENTAL PROCEDURES

General. The reagents for 5-methylcytosine oxidation were purchased from Wako, and the reagents for the DNA synthe-

sizer, such as A, G, C, T, and M-β-cyanoethyl phosphoramidite, were purchased from Glen Research. Oligodeoxynucleotides (ODNs) were purchased from Gene Design. HPLC was performed on a Cosmosil 5C-18AR or Chemcobond 5-ODS-H column (10 × 150 mm) with a Gilson Chromatography model 305 using a UV detector model 118 at 254 nm. Micro Bio-Spin chromatography columns used for desalting were purchased from Bio-Rad. ICON probes were prepared as in our previous report (*21*).

Preparation of ^{32}P-5′-End-Labeled DNA. The ODNs (400 pmol-strand) were 5′-end-labeled by phosphorylation with 4 μL of [γ-^{32}P]ATP (GE Healthcare) and T4 polynucleotide kinase using a standard procedure. The 5′-end-labeled ODN was recovered by ethanol precipitation and further purified by 15% denaturing polyacrylamide gel electrophoresis (PAGE).

Osmium Oxidation of ^{32}P-5′-End-Labeled DNA. The 5′-end-labeled ODN (10 pmol-strand) to be examined was incubated in a solution of 1 μM mismatch-forming ODN or ICON probe, 5 mM potassium osmate, 100 mM potassium hexacyanoferrate(III), 100 mM bipyridine, and 1 mM EDTA in 100 mM Tris-HCl buffer (pH 7.7) and 10% acetonitrile at 0 °C for 5 min. The reaction mixture was ethanol precipitated with the addition of 15 μL of 3 M sodium acetate (pH 5.0), 10 μL of salmon sperm DNA (1 mg/mL), and 1 mL of cold ethanol. The precipitate was washed with 150 μL of 80% cold ethanol and dried in vacuo. The residue was redissolved in 50 μL of 10% piperidine (v/v), heated at 90 °C for 20 min, and then evaporated to dryness by vacuum rotary evaporation. The dried reaction sample was resuspended in 5−20 μL of 80% formamide loading buffer (a solution of 80% formamide (v/v), 1 mM EDTA, 0.1% xylenecyanol, and 0.1% bromophenol blue). The samples (1 μL, 3−10 kcpm) were loaded onto 15% denaturing 19:1 acrylamide−bisacrylamide gel containing 7 M urea, electrophoresed at 1900 V for approximately 1 h, transferred to a cassette, and stored at −80 °C with X-ray film.

Melting Temperature (T_m) Measurement. All T_m values of the ODN duplexes (2.5 μM, duplex concentration) were taken in a buffer containing 1 mM EDTA, 100 mM Tris-HCl buffer, and 100 mM sodium chloride, pH 7.7. Absorbance vs temperature profiles were measured at 260 nm using a Shimadzu UV-2550 UV/vis spectrometer connected to a Shimadzu TMSPC-8 temperature controller. The absorbance of the samples was monitored at 260 nm from 5 to 90 °C at a heating rate of 1 °C/min. From these profiles, first derivatives were calculated to determine T_m values.

RESULTS AND DISCUSSION

Osmium Oxidation at Mismatched 5-Methylcytosine. We prepared ^{32}P-labeled DNA containing an MpG or CpG dinucleotide with different 5′-flanking bases, or ODN(XNG), 5′-^{32}P-d(AAAAGAXNGAGAAAA)-3′ (N = M or C; X = C, G, A, or T), which were hybridized with ODN′(CN′X′) 5′-d(TTTTCTCN′X′TCTTTT)-3′ (N′ = G, A, C, or T; X′ = G, C, T, or A), to examine the reactivity on osmium oxidation (Figure 2a and Supporting Information Figure S1). The duplex was incubated in a solution of 5 mM potassium osmate, 100 mM potassium hexacyanoferrate(III), 100 mM bipyridine, 1 mM EDTA in 100 mM Tris-HCl (pH = 7.7) and 10% acetonitrile at 0 °C for 5 min. The oxidized strand was cleaved at the damaged pyrimidine base with hot piperidine (90 °C, 20 min), and the products were analyzed as bands representing the shortened strands using PAGE. Typical results of PAGE are shown in Figure 2b. No cleavage band was observed for the fully Watson−Crick base-paired duplex (N′ = G). The strong suppression of oxidation of bases was due to the protection of the C5−C6 double bond by the stacking of the flanking base pairs. On the other hand, the osmium oxidation specifically

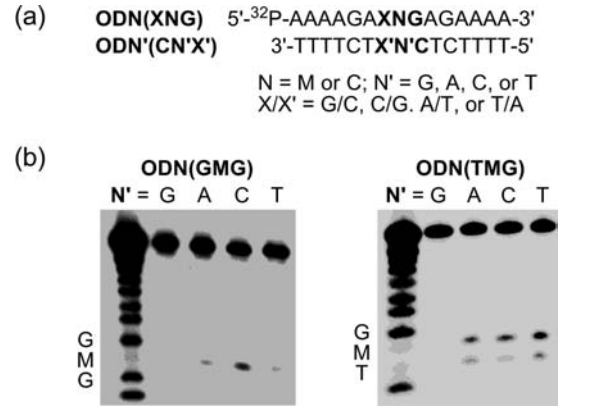

Figure 2. Osmium oxidation of mismatched duplexes. (a) The sequence of the duplex ^{32}P-ODN(XNG)/ODN′(CN′X′). (b) Two typical examples of gel images after PAGE of the oxidation products. The duplexes were incubated in a solution of 5 mM potassium osmate, 100 mM potassium hexacyanoferrate(III), 1 mM EDTA, and 100 mM bipyridine in 100 mM Tris-HCl (pH = 7.7), and 10% acetonitrile at 0 °C for 5 min. Recovered DNA was treated with piperidine (10% v/v, 90 °C, 20 min) to cleave the oxidized strand. (Left) Oxidation of ^{32}P-ODN(GMG)/ODN′(CN′C). (Right) Oxidation of ^{32}P-ODN(TMG)/ODN′(CN′A).

proceeded at the mismatched 5-methylcytosine of ODN(GMG), ODN(AMG), and ODN(CMG), although some difference in strand cleavage efficiency between the types of bases opposite 5-methylcytosine appeared (Figure 3). The small difference in the reactivity can be explained by duplex stability or T_m values. Higher duplex stability resulted in the appearance of the weaker strand cleavage band at 5-methylcytosine (Figure 4). For example, the T_m value of ODN(CMG)/ODN′(CAG) was slightly higher (34 °C) among those of the mismatched duplexes. This mismatched duplex showed relatively low strand cleavage intensity (the relative band intensity was 9%). It is more difficult for oxidants to access the 5-methylcytosine of stable mismatched duplexes compared with 5-methylcytosines in less stable mismatched duplexes, as well as strong suppression of oxidation because of low accessibility in the fully matched duplex. Cleavage of unmethylated ODNs, namely, ODN(GCG), ODN(ACG), and ODN(CCG), was negligible regardless of the nature of the base opposite cytosine.

Unique Reaction Site Selectivity in TMG Sequence. The site selectivity of the strand cleavage observed for ODN(TMG) was quite different from that of the sequences described above (Figures 2 and 3). The ODN(TMG) strand was oxidized at 5-methylcytosine regardless of the nature of the base opposite 5-methylcytosine. In addition, the 5′-neighboring thymine also reacted in spite of the formation of a Watson−Crick base pair with the complementary adenine base. This may be because the accessibility of oxidants to the C5−C6 double bond of the thymine base adjacent to the mismatched base pair is higher compared with a thymine base in a fully matched duplex. ODN(TCG) also showed oxidation of the mismatch-neighboring thymine base, but the efficiency was lower. Oxidation at cytosine was negligible, as well as of other unmethylated cytosine sequences. To learn more about the reactivity of mismatch-neighboring thymine, we prepared an artificial methylation sequence GMT, where a thymine base was located at the 3′ side of 5-methylcytosine, and the oxidation site was examined (Supporting Information Figure S2). In the GMT sequence, 5-methylcytosine was predominantly oxidized. Oxidation at the 3′-neighboring thymine was much lower. The site selectivity of oxidation for the GMT sequence is quite different from oxidation at the 5′-neighboring thymine, but this is an expected result because the thymine forms a stable base pair with the complementary adenine. Compared with the oxidation of the

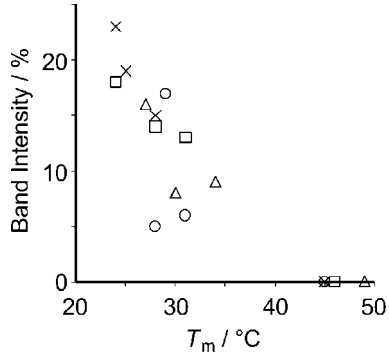

Figure 4. Relationship between the value of T_m and osmium complexation at 5-methylcytosine. Circles, ODN(GMG) hybridized with ODN′(CN′C); squares, ODN(AMG) hybridized with ODN′(CN′T); triangles, ODN(CMG) hybridized with ODN′(CN′G); crosses, ODN(TMG) hybridized with ODN′(CN′A).

thymine located at the 3′ side of the mismatched 5-methylcytosine, the reactivity of the 5′-neighboring thymine is higher and unique.

We have reported that osmium complexation proceeds rapidly at thymines and 5-methylcytosines in a single-stranded DNA, and also that methylated and unmethylated cytosines are clearly distinguished by the oxidation rate (*12*). In addition, we have shown that enhancement of osmium oxidation is observed for

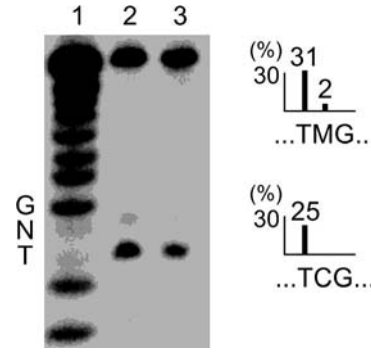

Figure 5. Osmium complexation of single-stranded ODN(TNG). Reaction time was 15 s. Lane 1, G + A sequencing lane; lane 2, N = M; lane 3, N = C.

5′ thymine of TT and TM sequences, whereas it is low at the thymine of the TC sequence (*22*). In brief, the reactivity at thymine greatly depended on the pyrimidine bases located at the 3′ side. This phenomenon seems to indicate that a methyl group at C5 of the 3′-neighboring pyrimidine base enhanced the reactivity of thymine. The result of osmium oxidation of single-stranded ODN(TNG) is shown in Figure 5. This figure exhibits not only the high reactivity of thymine bases, but also the enhancement of reaction at thymine by a methylated cytosine located at the 3′ side of thymine. The unique reactivity of mismatched ODN(TNG) described above can be explained by these phenomena. Mismatched ODN(TMG) reacted at 5-methylcytosine, but the 5′-neighboring thymine base was also oxidized in spite of the Watson−Crick base pair formation of thymine. The high accessibility of oxidants to thymine is supported by the predominant formation of a (5*R*,6*S*)-thymine glycol complex (*23*) showing that the oxidant approached the target thymine from the 3′ mismatched base pair side. In addition, the fact that a methyl group of 5-methylcytosine enhanced the reactivity of 5′-neighboring thymine would also support the reaction at thymine of mismatched ODN(TMG). On the other hand, the reaction efficiency of ODN(TCG) was lower at thymine and negligible at cytosine. The thymine can be oxidized because of high accessibility from the 3′ mismatched base pair side, but the oxidation efficiency decreased because of lack of enhancement of oxidation ability by the "methyl group effect". The reason the modification of cytosine with a methyl group enhanced the reactivity of 5′-neighboring thymine is unclear, but the methyl group of a 3′-neighboring 5-methylcytosine base may play an important role in electronic or hydrophobic promotion of oxidant approach or might have worked as a bridgehead for the approach of oxidants to 5′-neighboring thymine (*22*). The low reactivity of thymine of the GMT sequence can also be explained by the difficulty of approach of oxidants from the 3′ side and loss of the "methyl group effect" by the 3′-neighboring base.

ICON Probe. The ICON probe is a conceptually new DNA for sequence-specific short-term methylation analysis supported by a chemical basis (*21*). The formation of a methylated/unmethylated cytosine-adenine mismatched base pair in hybridization of the probe and the target DNA is applied for sequence-selective methylation detection because this mismatched base pair is well-known to adopt a wobble-type structure with the cytosine displaced laterally into the major groove and the adenine into the minor groove by hydrogen bonding between the 6-amino group of adenine and the N3 of cytosine (*24, 25*). Osmium complexation using the probe may also result in oxidation of the thymine base in the TNG sequence. We examined the oxidation site of TNG sequences using ICON probes under the same reaction conditions as described above except for the absence of bipyridine, which

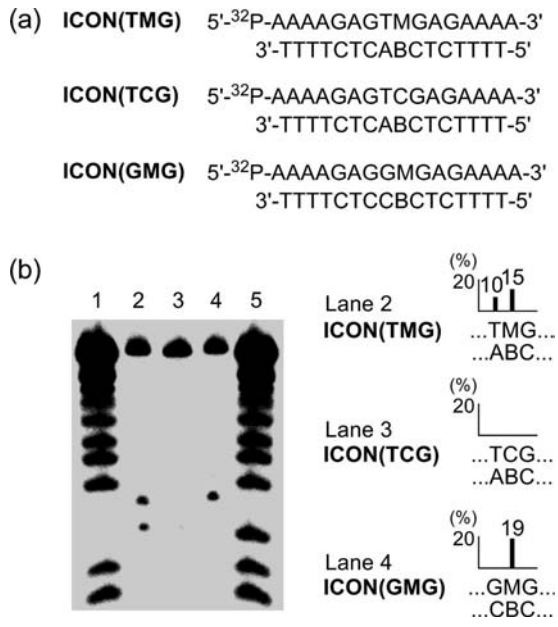

Figure 6. Osmium oxidation using the ICON probe. (a) The sequence of the duplexes formed by hybridization of ^{32}P-labeled target DNA and ICON probes. (b) The reactivity at each base. Lane 1, G + A sequencing lane for ICON(TMG) and ICON(TCG); lane 2, ICON-(TMG); lane 3, ICON(TCG); lane 4, ICON(GMG); lane 5, G + A sequencing lane for ICON(GMG).

was replaced by the ICON probe (Figure 6). For a TMG sequence, oxidation was observed at both thymine and 5-methylcytosine. In contrast, for a TCG sequence, oxidation was negligible at both thymine and cytosine. Because the bipyridine ligand of the ICON probe is fixed near the target 5-methylcytosine base because of the linker length, the reaction efficiency at the thymine neighboring the target is significantly decreased. The reaction at thymine was suppressed in the TCG sequence. However, even though the bipyridine was fixed, oxidation of thymine was still observed for the TMG sequence. Oxidation suppression at the neighboring thymine is due to the combination of three effects: Watson−Crick base pair formation at thymine, small enhancement of thymine reactivity by 3′-neighboring cytosine, and limitation of the reaction site by the bipyridine-connecting linker. As a result, the function of the ICON probes, which discriminate methylated cytosine from unmethylated cytosine using osmium complexation efficiency, is completely maintained, although complexation at the thymine of TMG occurs. There is no problem in quantification of 5-methylcytosine through interstrand cross-linking between the target methylated DNA and the ICON probe.

In conclusion, the efficiency of osmium complex formation at 5-methylcytosine in mismatched DNA duplexes is a key point for the design of sequence-specific detection of DNA methylation. We have described the osmium oxidation efficiency at 5-methylcytosines in a series of duplexes with a single base mismatch. The complexation site and efficiency in mismatched duplexes changed depending on the type of 5′-neighboring base of the 5-methylcytosine forming a mismatched base pair. In particular, when the base neighboring the 5′ side of the mismatched base pair was thymine, oxidation at thymine was also observed. The nature of the mismatched base pairs and their neighboring bases influences the reaction site and efficiency. However, the variation of the reaction site does not degrade the characteristic function of ICON probes, in that it captures only methylated DNA although 5′-neighboring thymine may react. The osmium complexation efficiency and selectivity depending on the nature of mismatched base pairs and neighboring sequences is demonstrated. This knowledge facilitates prior estimation of the reaction abilities of probes and helps in the design of highly methylation sensitive probes.

Studies on wild-type and mutant glycosyltransferases have shown that they can transfer modified sugars with a versatile chemical handle, such as keto or azido group, that can be used for conjugation chemistry and detection of glycan residues on glycoconjugates. To detect the most prevalent glycan epitope, *N*-acetyllactosamine (LacNAc (Galβ1−4GalNAcβ)), we have mutated a bovine α1,3-galactosyltransferse (α3Gal-T) enzyme which normally transfers Gal from UDP-Gal to the LacNAc acceptor, to transfer GalNAc or C2-modified galactose from their UDP derivatives. The α3Gal-T enzyme belongs to the α3Gal/GalNAc-T family that includes human blood group A and B glycosyltransferases, which transfer GalNAc and Gal, respectively, to the Gal moiety of the trisaccharide Fucα1−2Galβ1−4GlcNAc. On the basis of the sequence and structure comparison of these enzymes, we have carried out rational mutation studies on the sugar donor-binding residues in bovine α3Gal-T at positions 280 to 282. A mutation of His280 to Leu/Thr/Ser/Ala or Gly and Ala281 and Ala282 to Gly resulted in the GalNAc transferase activity by the mutant α3Gal-T enzymes to 5−19% of their original Gal-T activity. We show that the mutants ^{280}SGG^{282} and ^{280}AGG^{282} with the highest GalNAc-T activity can also transfer modified sugars such as 2-keto-galactose or GalNAz from their respective UDP-sugar derivatives to LacNAc moiety present at the nonreducing end of glycans of asialofetuin, thus enabling the detection of LacNAc moiety of glycoproteins and glycolipids by a chemiluminescence method.

INTRODUCTION

Glycan moieties of glycoproteins and glycolipids, by mediating protein−carbohydrate (*1*−*4*) and carbohydrate−carbohydrate interactions (*5*−*7*), play an important role in several cellular processes and are implicated in human diseases and cancer. The terminal sugar residues of the glycans are often important for their specific protein−carbohydrate interactions; for example, only the sialyated glycans have high affinity for CD22, a regulatory molecule that prevents the overactivation of the immune system and the development to autoimmune diseases (*4*). Similarly, desialyated glycans with terminal galactose bind mostly to galectin molecules. The pathophysiological role of glycans, as seen in the presence of the unusually short glycans, such as Tn carbohydrate in Core 1 glycan or elongated glycans, such as the polylactosamine moiety in N-glycans, have been associated with cancer (*8*−*10*). Therefore, the ability to detect different terminal sugar moieties is vital for determining the association of these moieties with different cellular states. The detection of these sugar moieties have been achieved mostly through lectin- or antibody-binding studies. These methods, however, lack high specificity and sensitivity. In limited situations, modified sugars with a unique chemical handle have been used for in vivo incorporation in the metabolic pathway to enable the detection of sugar residues on the glycoconjugates of a cell (*11*−*14*). Consequently, a highly specific and sensitive chemoenzymatic method to detect β-GlcNAc[1] residue at the nonreducing end of glycans using the mutant enzyme of β1,4-galactosyltransferase, Y289L β4Gal-T1, has been recently developed (*15*−*18*).

A mutation of the residueTyr289 to Leu289 in bovine β4Gal-T1 broadens the sugar donor specificity of the enzyme in such a way that the mutant enzyme, Y289L β4Gal-T1, transfers GalNAc from UDP-GalNAc to a sugar acceptor with the same efficiency as Gal from UDP-Gal (*15*). The mutant enzyme also transfers galactose analogues that have a chemical handle at the C2 position of the galactose and are similar in size and shape to the N-acetyl group, such as 2-keto-galactose (*16*) or GalNAz (Gal-2-NH-CO-CH_2-N_3) from their respective UDP-sugar substrates (*17*). The transfer of these galactose analogues with a unique chemical handle at the C2 position, such as a keto or azido group, by the mutant enzyme enables one to detect GlcNAc residue using a sensitive chemiluminescence method or to conjugate a variety of molecules in a site-specific manner via GlcNAc residue (*17*, *18*). Similarly, the polypeptide-α-

GalNAc-T2, which transfers GalNAc from UDP-GalNAc to the side chain hydroxyl group of a Thr/Ser residue of a specific peptide sequence, has been shown to transfer the modified galactose with a chemical handle, either 2-keto-galactose or GalNAz, from its respective UDP-sugar (*19*).

It has been shown that only a few residues in the sugar donor-binding pocket of glycosyltransferases determine the sugar donor specificity of these enzymes and that mutation of these residues can alter their sugar donor specificity (*15, 20*−*22*). Consequently, novel glycosyltransferases with broader donor specificities can be designed to transfer a sugar residue with a chemically reactive functional group to specific terminal moieties of glycoconjugates. To detect the terminal *N*-acetyllactosamine (LacNAc (Galβ1−4GlcNAc)) moiety that is the most prevalent sugar moiety found on cells, we engineered the bovine α3Gal-T enzyme, which has high acceptor specificity toward LacNAc, to transfer GalNAc or C2-modified galactose which can be used to detect LacNAc. Because of its high acceptor specificity, α3Gal-T enzyme has been previously used to transfer Gal from UDP-Gal to asialo-glycoprotein with the free LacNAc moiety at its N-linked glycans (*23*).

The α3Gal-T enzyme transfers only galactose from UDP-Gal to the terminal galactose sugar of the LacNAc or lactose moiety forming the product with Galα1−3-linkage. It belongs to a family of α3Gal/GalNAc glycosyltransferases to which human blood group transferases A and B also belong. The blood group transferases A (α1,3-GalNAc-T-A) and B (α1,3-Gal-T-B) transfer GalNAc and Gal, respectively, to galactose moiety of the fucosylated LacNAc acceptor, Fucα1−2Galβ1−4GlcNAc. The amino acid sequences of transferase A and transferase B are identical (*24, 25*) except for four amino acids. Two of the four residues at positions 266 and 268, Leu266 and Gly268 in blood group A transferase, and Met266 and Ala268 in blood group B transferase, determine their respective sugar donor specificities. In fact, in blood group A and B enzymes a mutation of the residue at position 266 is sufficient to alter the donor specificity of these enzymes (*20, 21*). Since α3Gal-T exhibits high sequence similarity and nearly identical crystal structure with the blood group A and B enzymes, a mutation of the corresponding sugar donor-binding residue in α3Gal-T, specifically, His280, is expected to alter the sugar donor specificity of the α3Gal-T enzyme (*26*). Indeed, recently the mutations of the residues in the sugar donor-binding site of bovine α3Gal-T have been shown to enhance the GalNAc transfer from UDP-GalNAc (*27, 28*). In the present study, we have rationally mutated not only His280 residue, but also its neighboring residues to alter its sugar donor specificity from Gal to GalNAc. We show that the mutants also selectively transfer the modified sugar 2-keto-Gal from its UDP derivative to LacNAc. This handle is used in biotinylation and subsequent detection of terminal LacNAc moiety in glycoproteins by chemiluminescence.

MATERIALS AND METHODS

The pET23a vector, His-Bind resin, His-Bind kit buffers, and BL21 (DE3) LysS cells were purchased from Novagen. XL2 blue ultracompetent cells were purchased from Stratagene. The Taq DNA polymerase, PCR nucleotide mix, and rapid DNA ligation kit were purchased from Roche Pharmaceuticals. DNA miniprep spin, PCR purification, and low-melting agarose extraction kits were from Qiagen. Restriction enzymes and PNGase F were purchased from New England Biolabs Inc. DNA primers were synthesized by Integrated Technologies Inc. Ampicillin, UDP-Gal, UDP-GalNAc, lactose, and asialofetuin was obtained from Sigma-Aldrich. UDP-[6-^{3}H] galactose was purchased from Amersham Biosciences, and UDP-[6-^{3}H]-N-acetylgalactosamine was from American Radiolabeled Chemicals. AG 1-X8 chloride resin, form 200−400 mesh, was from Bio-Rad. The micro spin column with active charcoal was from Harvard Apparatus. UDP-GalNAz was purchased from Invitrogen Inc., and UDP-2-keto-Gal was synthesized using the method described (*16*). The *N*-aminooxymethylcarbonylhydrazino-D-biotin (AOB), an aldehyde reacting probe (ARP), was purchased from Dojindo Laboratories.

Site-Directed Mutagenesis and Protein Expression. Site-directed mutagenesis was performed using PCR. Construction of the mutants was carried out using the plasmid pET23a-αGal-T-d79, described previously (*29*), that contains a *Bam*HI/*EcoRI* DNA fragment that codes for residues 80−368 of bovine α3Gal-T. The mutation primers corresponding to the upper and lower DNA strands, respectively, for each mutant were

Mutation codons are shown in bold letters The restriction sites, which are part of the mutation codons, are shown in italics and are underlined. Typically, the entire α3Gal-T cDNA was PCR amplified as two fragments. For the amplification of fragment 1, the primers used were the lower-strand mutation primer and the terminal cloning primer, 5′-CGC*GGATCC*CACCACCACCACCACGAAAGCAAG*C*TTAAGCTA-3′, that introduced *BamH I* restriction site. For the amplification of fragment 2, the primers used were the upper-strand mutation primer and the terminal cloning primer, 5′-CCG*GAATTC*TCAGACATTATTTCTAACCACATTATACTCTTT-3′, that introduced the *EcoRI* restriction site. The fragments were then cut with the restriction enzymes *BspE I, NgoM IV, Eag I, NgoM IV, SspI*, and *Age I* for mutants ^{280}SGG^{282}, ^{280}AGG^{282}, ^{280}AAA^{282}, ^{280}GAG^{282}, ^{280}VGG^{282}, and ^{280}TGG^{282}, respectively, and ligated. The full α3Gal-T cDNA with the mutation was PCR amplified using the terminal cloning primers and then inserted at the *BamHI*/*EcoRI* restriction site into the pET23a vector and transfected in ultracompetent XL2-blue cells. Clones were selected for the unique restriction site introduced with the mutagenesis primer. Each mutation was confirmed by sequence analysis of the insert in the plasmid DNA. Clones that were positive for the desired mutation were transformed into BL21(DE3)LysS cells. The proteins were expressed and purified according to the published method (*29*). The protein concentrations were measured using the Bio-Rad Protein Assay kit, based on the Bradford method, and further confirmed by SDS-the PAGE electrophoresis using ovalbumin as the standard protein marker.

Enzymatic Assay for Wild-Type and Mutant α1,3Gal-T. For specific activity measurements, reactions were carried out at 37 °C for 15 min in a 100 μL volume containing 5 mmol $MnCl_2$, 25 mmol Tris/HCl (pH 7.0), 500 μmol UDP-Gal, or UDP-GalNAc, 0.5 μCi of ^{3}H-labeled sugar nucleotide and 20

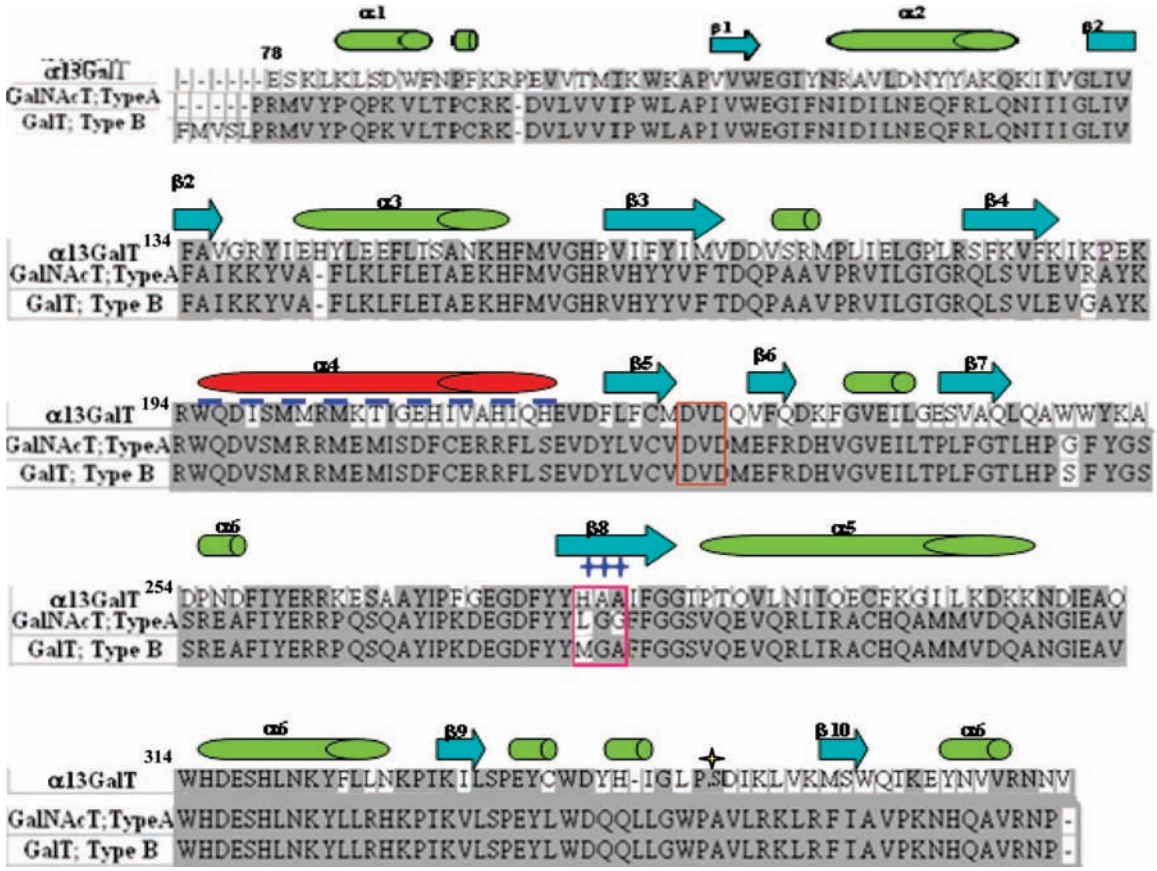

Figure 1. Sequence comparison of the catalytic domain of α3Gal-T with the blood group A and B transferases. The DVD motif (red box) and the sugar donor binding site residues (pink box) are labeled. Secondary structural motifs of these proteins are shown above the sequence; green and red tubes indicate α helix; blue arrows indicate *β* strands; dashed navy line indicates missed internal loop in blood group A and B transferase structure. Sites of mutation of α3Gal-T are indicated by navy stars at positions 280−282.

mmol lactose for wild-type and 200 mmol lactose for mutants with 1 μg of enzyme. The reactions were terminated by the addition of 200 μL ice-cold water to the incubation mixture and analyzed as described (*29*).

Kinetic Analysis for Wild-Type and Mutant α1,3GalT. Different concentrations of the sugar donor, UDP-Gal in the range 10−500 μmol, and UDP-GalNAc in the range 100−1000 μmol, and six different concentrations of the lactose were used in a range that allowed for an accurate Michaelis−Menten plot to be derived. Data were analyzed for a two-substrate system using the following equation:

$$v = \frac{v[\mathrm{A}][\mathrm{B}]}{K_{ia}K_{\mathrm{B}} + K_{\mathrm{B}}[\mathrm{A}] + K_{\mathrm{A}}[\mathrm{B}] + [\mathrm{A}][\mathrm{B}]}$$

The EnzFitter Program, a nonlinear curve-fitting program for Windows from Biosoft, was used to obtain the kinetic parameters K_a, K_b, K_{ia}, and V_{max} from the fitted curves using the rate equation above.

MALDI Mass Spectroscopic Analysis of Oligosaccharides. MALDI mass spectrometry was performed using a 4700 Proteomics Analyzer (Applied Biosystems, Framingham, MA). Two microliters of sample was mixed with 2 μL of DHB/DMA matrix on a stainless steel plate and air-dried or dried under a light vacuum at room temperature as described (*30*). MS spectra were obtained using a laser intensity between 4500 and 6000 kW, with 2000 shots per sample.

Transfer of Modified Sugars from Their UDP Derivatives to the LacNAc Residue on Galactosylated Chitotetrose and on a Glycoprotein, Asialofetuin. Reactions were carried out at 37 °C overnight in a 25 μL volume containing 5 mmol $MnCl_2$, 25 mmol Tris/ HCl (pH 7.0), 500 μmol UDP-Gal-2-keto or UDP-GalNAz, and 0.1 mmol sugar acceptor galactosylated chitotetrose (Galβ1−4GlNAc(β1−4GlcNAc)$_3$) and 2 μg of mutant enzymes SGG, AGG, or TGG. The samples were analyzed by MALDI-MS as described above. The *N*-acetyllactosaminyl-chitoriose (galacto-chitotetrose) used as an acceptor

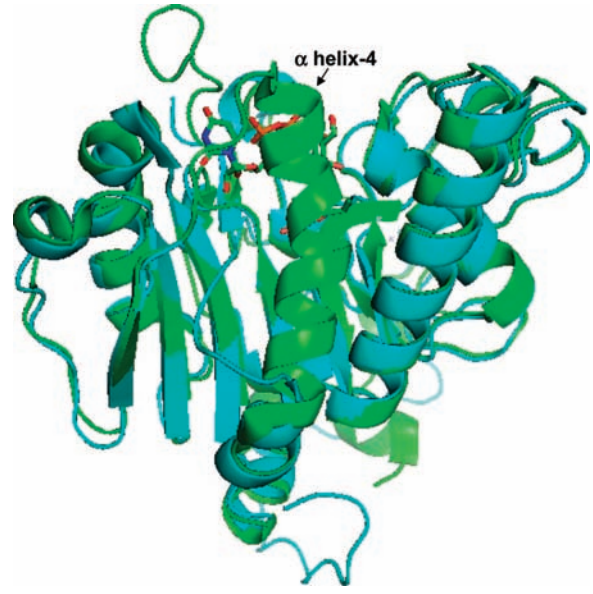

Figure 2. Superposition of the structure of α3Gal-T with UDP-Gal complex (green) with blood group A transferase (cyan). The structural similarity of the two enzymes is very high. The α helix-4 is visible in α3Gal-T and is disordered in the blood group A and B transferase structures.

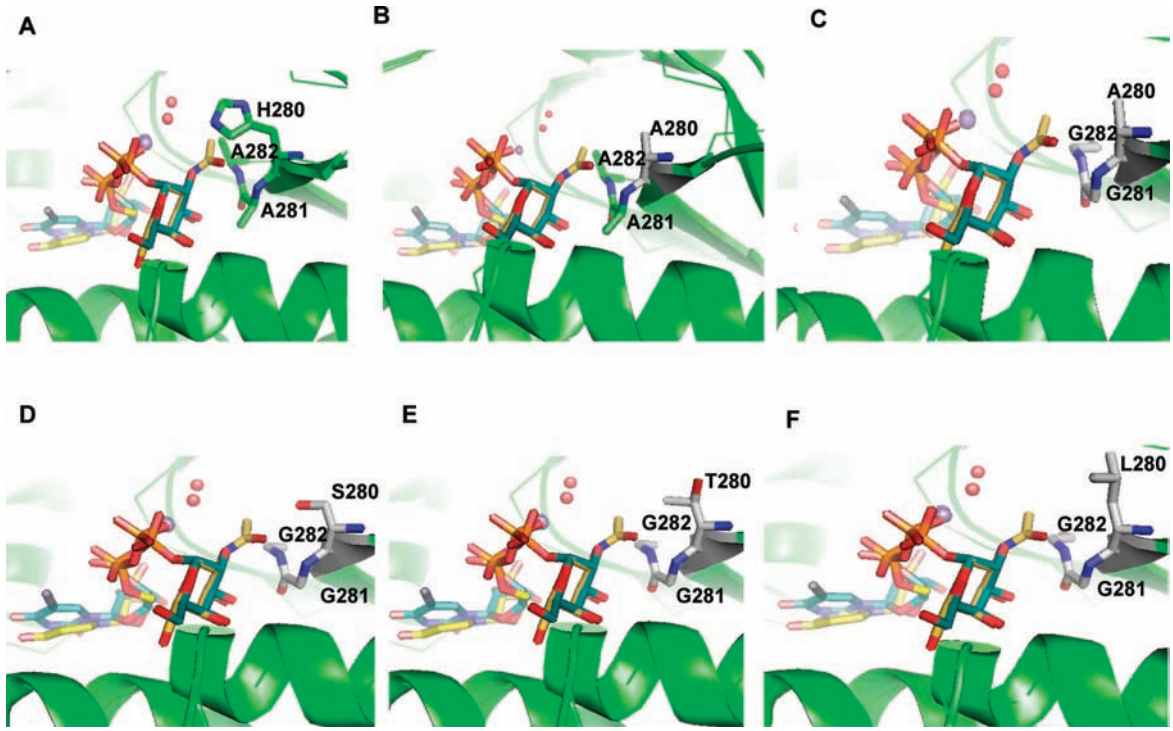

Figure 3. Comparison of sugar donor binding site residues of wild-type α3Gal-T with the bound UDP-Gal (green) (A) (PDB 1fg5) with the modeled structures of the mutants AAA (B), LGG (C), TGG (D), AGG (E), and SGG (F). The UDP-GalNAc structure (yellow) (from PDB 1oqm) is superimposed in these structures. H280 residue causes steric hindrance with the *N*-acetyl moiety of GalNAc. A mutation of H280 to S280 or A280 and a mutation of residues A281 and A282 to G281 and G282, respectively, accommodate the N-acetyl group from UDP-GalNAc in the sugar donor binding site.

substrate in the transfer reactions was synthesized by galactosylation of chitotetrose (GlcNAcβ1−4-GlcNAcβ1−4 GlcNAcβ1−4GlcNAcβ) with wild-type β-1,4-galactosyltransferase. Full conversion of chitotetrose to galacto-chitotetrose (Galβ1−4GlcNAcβ1−4-(GlcNAcβ1−4)$_3$) was achieved by incubating 100 μL of the mixture containing 1 mmol chitotetrose, 3 μg of recombinant bovine C342T-Gal-T1 (15), 500 μM UDP-Gal, 5 mmol $MnCl_2$, and 25 mmol Tris-HCl (pH 8.0), overnight at 37 °C.

Asialofetuin (200 μg) was incubated with 1 mmol UDP-2-keto-Gal and 4 μg of the α3Gal-T1 SGG and AGG mutants in a 10 μL final incubation mixture containing 5 mmol $MnCl_2$ and 25 mmol Tris-HCl (pH 7.0). Reactions were incubated overnight at 37 °C. The samples were placed on a Microcon YM-10 filter, washed with 1 mL of water, and samples were eluted into 20 μL of water. A portion of the sample was analyzed by conjugation with AOB and detected by the chemiluminescence method as described previously (*17*) (see below). Meanwhile, a portion of the sample that contained 10 μg of 2-keto-galctosylated asialofetuin was digested with 2500 units of PNGase F in 20 μL of 50 mmol sodium phosphate buffer for18 h at 37 °C. The oligosaccharides released from the PNGase F-treated samples were purified on a micro SpinColumn with active charcoal prior to MALDI-MS analysis.

Biotinylation and Western Blotting of 2-Keto-Galactosylated Asialofetuin. The 2-keto-galactosylated asialofetuin samples (100 μg) were diluted to 30 μL in a mixture containing 50 mmol NaOAc (pH 3.9) and 3 mmol AOB. The AOB reaction mixtures were incubated with gentle shaking for 12 h at 25 °C, and the reaction was stopped by boiling in Tris-glycine-SDS sample buffer containing β-mercaptoethanol. The biotinylated protein, 25 and 50 ng, was analyzed by Western blotting and detected by chemiluminescence using streptavidin conjugated with HRP as described previously (*16*, *17*).

RESULTS AND DISCUSSION

Comparison of Sequence and Structure of α3Gal-T with the Human Blood Group A and B Glycosyltransferases. The protein sequence of the catalytic domain of bovine α3Gal-T used in our present and past studies (*29*) is identical to the sequence reported by Zhang et al. (*26*) except at position 347, where there is Ser instead of Ala (Figure 1). Comparison of the α3Gal-T sequences from different species in the sequence database show that mouse, rat, and capuchin also have Ser at the corresponding position. We have mutated the Ser347 in our clone of bovine α3Gal-T to Ala347 and found that the two enzymes have comparable enzymatic and kinetic parameters (see Supporting Information). All our mutational studies reported here have been carried out with Ser at position 347 and are considered, in this paper, as the wild-type α3Gal-T.

A comparison of the protein sequences of the catalytic domain of bovine α3Gal-T with the human blood group A (α3GalNAc-

T-A) and B (α3Gal-T-B) shows a 46% similarity (Figure 1). On the contrary, the blood group A and B transferases differ by only four amino acids: Gly176, Ser235, Leu266, and Ala268 for transferase A; and Arg176, Gly235, Met266, and Gly268 for transferase B. Among these four amino acids, the residue at position 266, Met (for B) and Leu (for A), largely determines the sugar

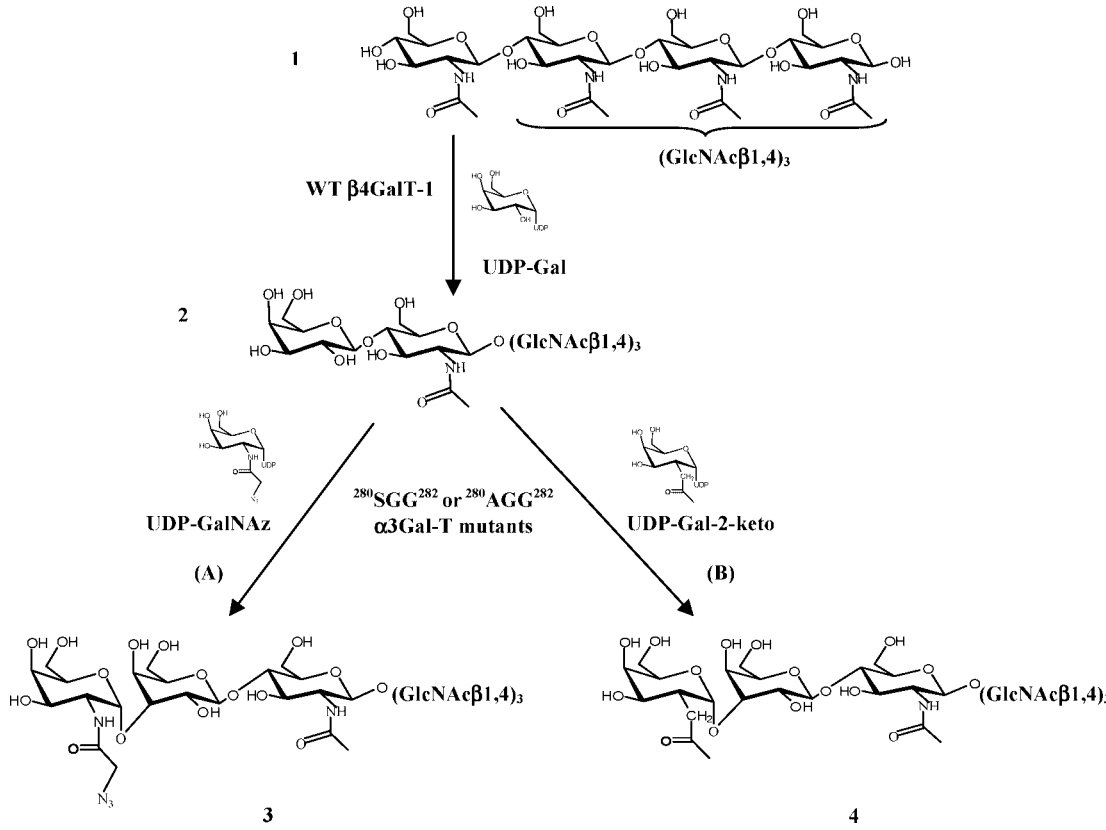

Figure 5. Scheme of the chemoenzymatic synthesis of galacto-chitotetrose, Galβ1,4-GlcNAcβ1,4-(GlcNAcβ1,4)$_3$) (**2**) and the transfer of modified sugars by the α3Gal-T mutants, SGG or AGG. Galactose was transferred to chitotetrose (**1**) by the wild-type (WT) β1,4Gal-T1 to give galacto-chitotetrose (**2**) that has a terminal LacNAc disaccharide moiety. Modified sugars, GalNAz (A) or 2-keto-Gal (B), were transferred from their UDP derivatives to galacto-chitotetrose, synthesizing the products **3** or **4**, respectively, by the mutants SGG or AGG.

donor specificity for Gal or GalNAc, respectively (*24, 25*). At the corresponding position in α3Gal-T is the residue His280. Several other differences are found between α3Gal-T and the blood group A and B transferases, such as residues in the sugar acceptor-binding site.

A number of crystal structures of both bovine α3Gal-T (*26, 31*−*33*) and human blood group A and B enzymes (*34*−*36*), with and without substrates, are available, and they show that the crystal structure of the bovine α3Gal-T is quite similar to that of the human blood group A and B enzyme, with an rms deviation of Cα atoms of only 0.8 Å (Figure 2). These crystal structure studies have shown that, in these enzymes, two similar, flexible regions undergo conformational changes upon Mn^{2+} and UDP-Gal/GalNAc binding. In α3Gal-T, the first flexible region is found between residues 190 and 199, and the second region is its C-terminal 11 amino acids (*26, 31*−*33*); in the blood group A and B transferases, the first flexible region is between residues 177 and 195, and the second is its C-terminal 10 amino acids (*34, 35*). Although these two flexible regions belong to the same part of their three-dimensional structure, the nature of the conformational change in the first region between the two proteins is quite different, while the conformational change in the C-terminal region is the same. During the conformational changes in α3Gal-T, the first flexible region positions the side chain of Trp195 residue (corresponding residue Trp181 in blood group A and B) to form hydrophobic interactions with the bound donor sugar substrate. The second flexible region, the C-terminal end, in addition to burying the bound donor substrate, positions the side chain of Arg359 residue (Arg352 in blood group A and B) in such a way that it forms a stacking interaction with the side chain of Trp195 residue from the first flexible loop (*32*).

Although the crystal structures of the donor substrate, UDP-Gal, bound to α3Gal-T and blood group B enzymes are available, the crystal structure of UDP-GalNAc bound to blood group A enzyme is not yet known. While the conformation of the bound UDP-Gal is the same in these crystal structures, its molecular interactions with the protein molecules show few differences. In the UDP-Gal-bound α3Gal-T crystal structure (*32*), the side chain NH atom of His280 forms a strong hydrogen bond with the O2 hydroxyl group of the galactose sugar; in the blood group B structure, however, the corresponding residue, Met266, forms only hydrophobic interactions with the O2 hydroxyl group (*36*).

A simple modeling of an N-acetyl moiety at the C2 of galactose that converts the donor residue to GalNAc in the crystal structure of UDP-Gal-bound bovine α3Gal-T indicates that the side chains of His280 and Ala282 residues cause steric hindrance with the N-acetyl moiety of GalNAc (Figure 3A). Interestingly, the corresponding residues in the blood group A and B transferases are the ones that determine the sugar donor specificity of these enzymes, indicating that His280 and Ala282 may determine the sugar donor specificity of α3Gal-T toward galactose. In addition, the sequence comparison reveals that the Ala281 residue, the backbone of which forms a hydrogen bond with O3′ of galactose in α3Gal-T (*32*), is also naturally present as a Gly residue in both human blood group A and B transferases. Thus, to accommodate a substitution at the C-2 position of galactose in the sugar donor-binding site of bovine α3Gal-T enzyme, the three contiguous residues, His280-Ala281-Ala282, were considered potential target residues for mutagenesis. A previous study on bovine α3Gal-T (which has Ala at position 347) has shown that, when the His280 residue was mutated to the Ala residue, the mutant enzyme exhibited weak

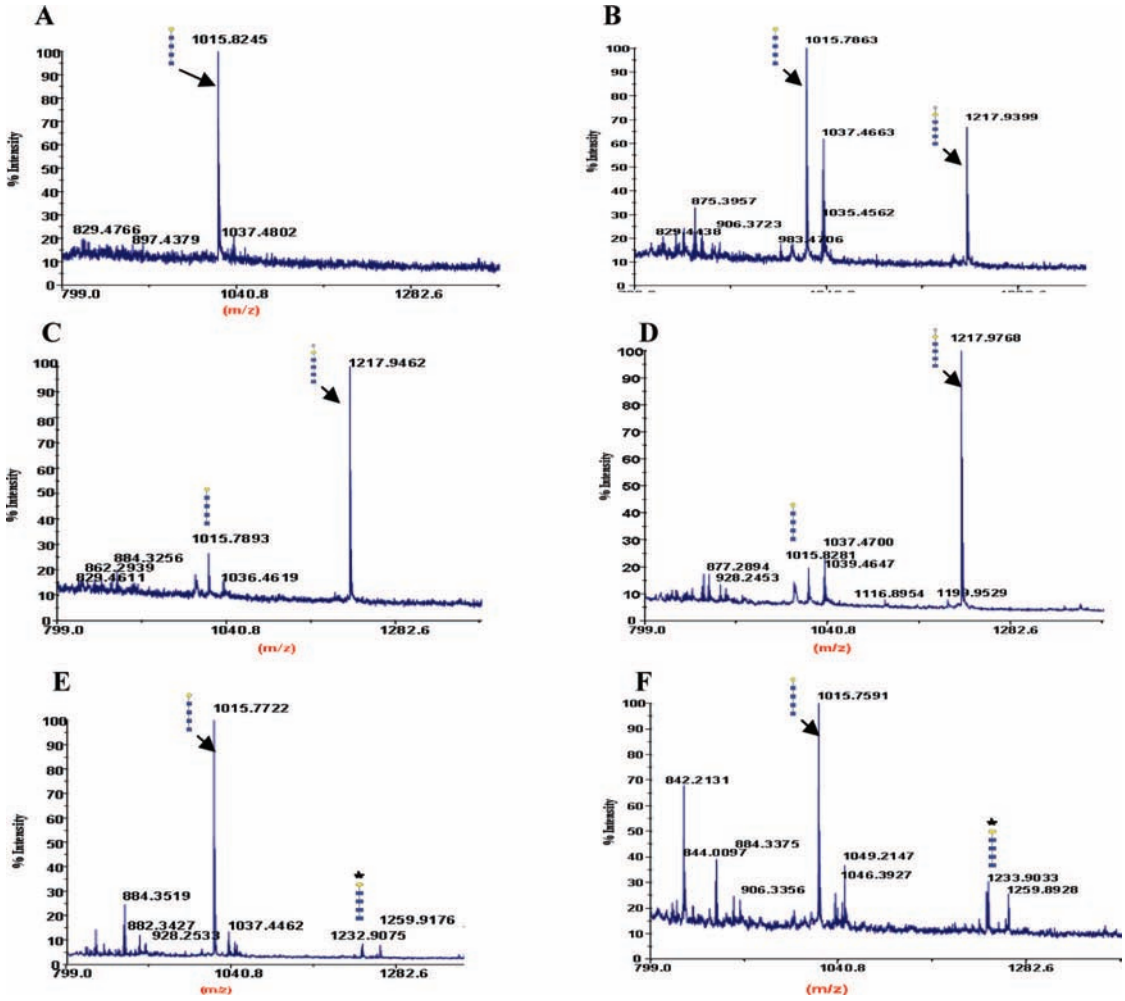

Figure 6. MALDI mass spectra of the acceptor galacto-chitotetrose, Galβ1,4-GlcNAcβ1,4-(GlcNAcβ1,4)$_3$) (A) and after the transfer of 2-keto-Gal (B,C,D) and GalNAz (E,F) to the sugar acceptor. Major peaks are annotated with the carbohydrate structure shown in the symbols for monosaccharides, according to the nomenclature adopted by the consortium for functional glycomics, http://www.functionalglycomics.org/static/consortium/. (GlcNAc [blue square], Gal [yellow circle], 2-keto-Gal [yellow stars], and GalNAz [blue stars]). The symbols were drawn using the *GlycoWorkbench* program found in the eurocarb database http://www.eurocarbdb.org/. The transferred 2-keto-Gal moiety by the mutants TGG (B), SGG (C), and AGG (D), and the transferred GalNAz by the mutants SGG (E) and AGG (F) are shown. (A) Peak at 1015 *m*/*z* corresponds to the linear glycan structure, galacto-chitotetrose. (B−D) Shift in the molecular mass after addition of 2-keto-Gal moiety to galacto-chitotetrose, from the starting ion at 1015 *m*/*z* to a peak of 1218 *m*/*z* (Material and Methods section). (E,F) Shift in the molecular mass after addition of a GalNAz moiety to galacto-chitotetrose, from the starting ion at 1015 *m*/*z* to a peak of 1232 *m*/*z*.

GalNAc-T activity at 20 mmol lactose concentration and was very unstable (*26*). To convert α3Gal-T (which has Ser at position 347) into an efficient α3GalNAc-T, based on the structural details of the two enzymes, we have considered (1) substituting the His280 residue to Ala, Gly, Ser, Thr, Leu, and Val, and (2) substituting the next two residues, Ala281 and Ala282, to Gly281 and Gly282, which are the residues at the corresponding positions in the blood group A and B transferases. A mutation of His280 to Gly (GAA) did not produce stable protein and thus could not be analyzed. Thus, in this study we have characterized the following α3Gal-T mutants: Ala280-Ala281-Ala282 (AAA); Gly280-Ala281-Gly282 (GAG); Ala280-Gly281-Gly282 (AGG); Ser280-Gly281-Gly282 (SGG); Thr280-Gly281-Gly-282 (TGG); Leu280-Gly281-Gly282 (LGG); and Val280-Gly281-Gly282 (VGG) (Table 1). The final yield of the purified mutant proteins ranged from 2 to 6 mg per liter of bacterial culture, and they were stable at a concentration of 2 to 4 mg/mL.

Mutation of His280 Residue Affects the Acceptor Affinity of the Enzyme. In the Gal-T activity, the K_m value of the acceptor substrate lactose is only 4.5 mmol, which is 4-fold lower than the value (20 mmol) found by Zhang et al. (*26*). At the saturation concentration of UDP-Gal, the wild-type enzyme reached its maximum catalytic activity at less than 20 mmol lactose concentration and only very little inhibition even at 200 mmol lactose concentration (Figure 4A and insert; Table 1). A mutation of His280 residue to Ala, mutant AAA, reduces Gal-T activity to 14% at 20 mmol lactose, while at 200 mmol lactose, the reduction is 41%, indicating that the mutant has also lost the affinity for the acceptor substrate (Table 1). The AAA mutant, and including other mutants, shows linear catalytic activity from 20 to 200 mmol lactose concentration for nearly 4 h (Figure 4B and insert). In the crystal structure of bovine α3Gal-T, the side chain of the acceptor substrate-binding residue Gln247 stacks on the side chain imidazole ring of the His280 residue. Therefore, a mutation of His residue to a smaller side chain residue is expected to affect the side chain conformation of Gln247, which may cause a loss of acceptor substrate affinity. This hypothesis is confirmed by the K_m values found for the acceptor substrate in the enzyme kinetic data of both the Gal-T and GalNAc-T mutants (Table 2).

Mutation of His280 to Gly280, the mutant GAA, produces unstable protein that precipitated during purification and thus could not be analyzed further. In contrast, mutation of His280 to Ala280, the mutant AAA, produced stable and active protein. This mutant was analyzed for GalNAc-T activity. In contrast

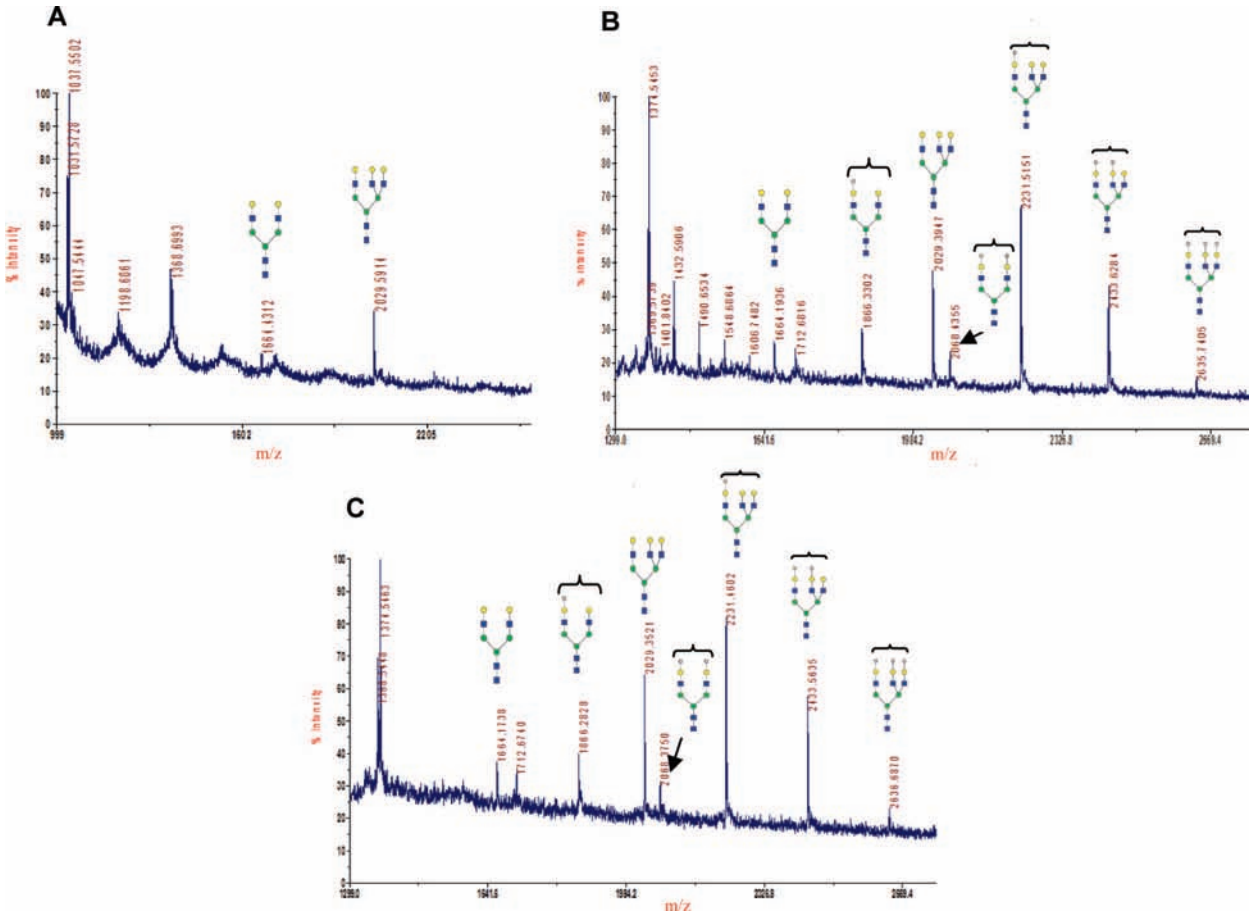

Figure 7. MALDI mass spectra of the glycans released from asialofetuin. After PNGase F treatment of asialofetuin, the released oligosaccharides were passed through SpinColumn with active charcoal and analyzed by MALDI mass spectrometry. Only the peaks of interest are annotated, showing their molecular mass and possible structures. All carbohydrate structures are shown in symbol form, as described in the Figure 6 legend, and Man is drawn as a green circle. Glycans released from the commercial sample (Sigma) of asialofetuin before 2-keto-Gal transfer (A). Ions at 1664 *m*/*z* (biantennary galactosylated N-glycans) and 2029 *m*/*z* (triantennary galactosylated N-glycans) are assigned to N-glycan structures reported for asialofetuin (*37*). Glycan structures released from asialofetuin after the transfer of 2-ket-Gal from UDP-2-keto-Gal with the mutant enzymes α3Gal-T1-SGG (B) and AGG (C). Ions at 1866 and 2068 *m*/*z* indicate mass of biantennary N-glycans with transferred 2-keto-Gal on one and two arms, respectively. Ions at 2231, 2433, and 2635 *m*/*z* indicate mass of triantennary N-glycans with one, two, and three transferred 2-keto-Gal residues to the three arms, respectively.

to wild-type enzyme HAA, the mutant enzyme AAA has 4% and 6% GalNAc-T activity at 20 and 200 mmol lactose concentration, respectively. Thus, the substitution of His280 by Ala280 seems to have reduced the steric hindrance and created a space to accommodate the N-acetyl group of the sugar donor GalNAc (Figure 3B). A mutation of His280 to Gly280, together with the mutation of Ala282 to Gly282 (GAG mutant), shows reduced activity at 200 mmol lactose with both UDP-Gal (27%) and UDP-GalNAc (2%) as donor substrates, compared with the AAA mutant (Table 1).

With sugar donor substrate UDP-Gal, the mutants AGG, SGG, TGG, VGG, and LGG with a Gly residue at both positions 281 and 282 (which is similar to the blood group A and B transferases) exhibit only 0.4%, 5%, 3%, 4%, and 2% Gal-T activity, respectively, at 20 mmol lactose concentrations, and 1%, 5%, 15%, 16%, and 1% Gal-T activity, respectively, at 200 mmol lactose. When UDP-GalNAc was used as the donor substrate, the wild-type α3Gal-T enzyme exhibited no GalNAc-T activity; however, the mutant enzymes at 20 mmol lactose concentration exhibited GalNAc-T activity that corresponds to 3%, 2%, 1%, 0.5%, and 3%, respectively, of the Gal-T activity of the wild-type α3Gal-T at 20 mM lactose (Table 1). Nevertheless, at 200 mmol lactose, the mutants showed higher GalNAc-T activity, with the AGG and SGG mutants showing 19% and 11% activity, respectively (Table 1). Recently, Tumbale et al. (*28*) have generated bovine α3Gal-T mutants with altered donor specificity from the wild-type α3Gal-T that has Ala at position 347 (α3Gal-T-Ala347). The donor substrate mutants of α3Gal-T-Ala347 where ^{280}HisAlaAla^{282} is mutated to ^{280}AlaGlyGly^{282} require mutation of Ile283 to Leu283 to make the mutant proteins stable (*28*). As stated above the mutations in the donor substrate site affects the acceptor binding (Table 1), increasing the lactose concentration from 20 to 200 mM increases the specific activity toward UDP-GalNAc (Figure 4), the observation also made by Tumbale et al. (*28*). However, in their studies this observation was not exploited for screening the mutants from the library at higher acceptor concentrations of lactose.

In the present studies, the mutants AGG and SGG with highest activity toward UDP-GalNAc were selected for kinetic studies.

Kinetic Parameters of SGG and AGG Mutants. The results of the kinetic analysis with UDP-Gal and UDP-GalNAc for the wild-type α3Gal-T (HAA) and the mutants AGG and SGG are presented in Table 2. The k_{cat} values for the UDP-Gal of the mutants AGG and SGG were 170- and 34-fold lower, respectively, than that of the wild-type. The K_m values for the UDP-Gal (K_a) and K_{ia} decreased by about 20- and 10-fold for AGG and SGG, respectively, while the K_m for the acceptor lactose (K_b) of the two mutants increased 60- and 40-fold, respectively. Thus, a mutation of HAA to either AGG or SGG results in increased binding and decreased dissociation of UDP-Gal and

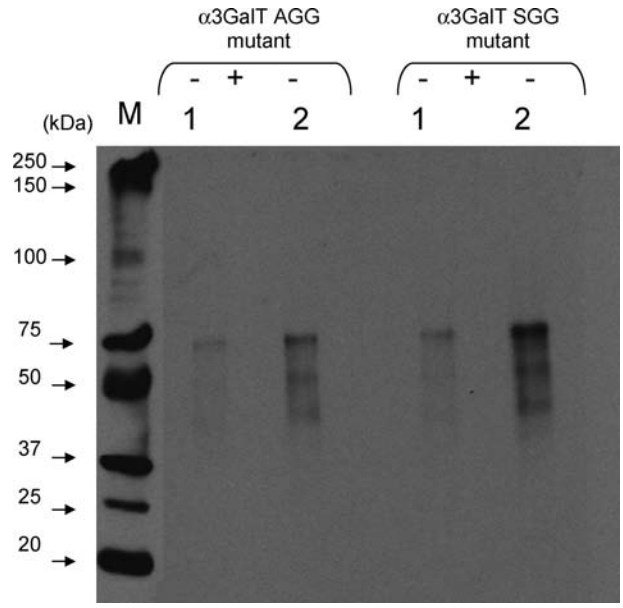

Figure 8. Chemoenzymatic detection of the transferred 2-keto-Gal on asialofetuin. The transfer of 2-keto-galctose to LacNAc residues on the N-glycans chains of asialofetuin by the α3Gal-T mutant enzyme SGG and AGG was monitored by linking with the AOB, followed by Western blotting and chemiluminescence detection. The chemiluminescence was detected only in the samples that contained UDP-2-keto-Gal and mutant enzyme and 25 ng (1) and 50 ng (2) of asialofetuin. After the transfer of 2-keto-Gal, asialofetuin samples were treated with PNGase F (see Materials and Methods section), which removes the N-glycan chains from the protein (+). In contrast to the untreated samples (−), the PNGase F-treated samples (+) exhibited no chemiluminescence indicating that the transfer of 2-keto-Gal is selective for the glycan portion of asialofetuin.

lower affinity for the acceptor lactose. However, in contrast to the wild-type enzyme, the mutants have GalNAc-T activity and the k_{cat} for UDP-GalNAc about 0.3−0.4 s^{-1}, which is one-tenth the wild-type k_{cat} for UDP-Gal. In these mutants, the K_m and K_{ia} for the UDP-GalNAc are similar to the K_m and K_{ia} for the UDP-Gal of the wild-type enzyme, while the K_m for the acceptor lactose (K_b) is nearly 60-fold higher.

In the modeled structures, the "HAA residue" in the sugar nucleotide-binding pocket of the wild-type enzyme was mutated to AAA, AGG, SGG, TGG, or LGG. Moreover, the UDP-GalNAc structure was superimposed on the bound UDP-Gal structure in these models (Figure 3B−F). The N-acetyl group of GalNAc moiety in the AGG mutant has no steric hindrance and is well-accommodated in the substrate-binding pocket (Figure 3C). In contrast, in the SGG mutant, the side chain of the Ser residue seems to have some steric hindrance to the N-acetyl group (Figure 3D). For this mutant, the K_m for UDP-GalNAc is also one-and-a-half-times higher than that for the AGG mutant. The mutants TGG (Figure 3E), LGG (Figure 3F), and VGG (not shown), which have a residue with a more extended side chain than that of Ser, exhibit much lower GalNAc-T activity (Table 1).

Transfer of Modified Sugars UDP-Gal-2-keto and UDP-GalNAz by α3Gal-T SGG and AGG Mutants to LacNAc Acceptor. In our previous studies with the Y289L-β1,4-galactosyltransferase mutant (*15*−*18*) and the polypeptide *N*-acetylgalactosaminyltransferase (*19*), we have shown that the enzymes that accommodate the N-acetyl group of the sugar donor GalNAc in the binding pocket also accommodate C2-modified galactose, which has a chemical handle, such as a 2-keto- or N-2-azido group. In this study, we show that the α3Gal-T mutants SGG and AGG, which transfer GalNAc from UDP-GalNAc, also transfer the modified sugars 2-keto-galactose or GalNAz from their respective UDP derivatives to the LacNAc residues linked to chitotriose (galacto-chitotetrose, *N*-acetyl-lactosaminyl-chitotrios) (Figures 5 and 6) or the LacNAc on the glycoprotein, asialofetuin (Figure 7).

Transfer of 2-Keto-Galactose or 2-Azido-Galactose to LacNAc Moiety in *N*-Acetyl-Lactosaminyl-Chitotriose (Galacto-Chitotetrose). The transfer of C2 modified galactose, 2-keto-galactose, and GalNAz by the mutant enzymes was followed by MALDI mass profiling, and the results are shown in Figure 6E, F. The galacto-chitotetrose (Galβ1−4-GlcNAcβ1−4-(GlcNAcβ1−4-)$_3$) used as an acceptor substrate in the transfer reactions was prepared by galactosylation of chitotetrose (GlcNAcβ1−4-(GlcNAcβ1−4-)$_3$) with β-1,4-galactosyltransferase (Figure 5(2)). The MS analysis of the starting material used as an acceptor substrate for the transfer of 2-keto-galactose or GalNAz from their UDP derivatives by the α3Gal-T mutants showed one peak at 1015 *m*/*z* corresponding to the mass of galacto-chitotetrose (Figure 6A). The mutant enzymes SGG (Figure 6C) and AGG (Figure 6D), in contrast to TGG (Figure 6B), transferred 2-keto-galactose efficiently, converting the acceptor substrate galacto-chitotetrose (1015 *m*/*z* in Figure 6A) completely into 2-keto-galactosylated galacto-chitotetrose, which has a mass of 1218 *m*/*z* (Figure 6C,D). The mutant enzymes SGG and AGG transferred the GalNAz very poorly in contrast to the transfer of 2-keto-galactose (Figure 6E, F).

Transfer of 2-Keto-Galactose to LacNAc Moiety on Asialofetuin. The transfer of 2-keto-Gal to the LacNAc moiety of glycoprotein asialofetuin, known to have N-linked glycans with terminal LacNAc residues, by the mutant enzymes SGG and AGG, is shown in Figure 7B,C. The MALDI analysis of the N-glycans released after the PNGase F treatment of asialofetuin show biantennary (1664 *m*/*z*) and triantennary (2029 *m*/*z*) structures (Figure 7A) as reported (*37*). Both mutants, SGG (Figure 7B) and AGG (Figure 7C), transfer 2-ket-Gal to one (1886 *m*/*z*) or both (2086 *m*/*z*) arms of the biantennary glycan, and to one (2231 *m*/*z*), two (2433 *m*/*z*), or all three (2636 *m*/*z*) arms of the triantennary structure. The MS analyses indicate that the preferred transfer of 2-keto-Gal is to one arm of the biantennary and triantennary structures.

After the 2-keto-galactose was transferred to LacNAc residues on the N-glycans of asialofetuin by SGG and AGG mutants, the ketone moiety at the C-2 position of galactose was coupled with AOB (Figure 8). The biotinylated product was analyzed on Western blots and detected by chemiluminescence with streptavidin conjugated to HRP (Figure 8, (−) samples). Chemiluminescence was detected only when samples were not treated with PNGase F before Western blot analysis (Figure 8, (−) samples), in contrast to samples treated with PNGase F (Figure 8, (+) samples), indicating that the transfer of 2-keto-galactose occurred only to the N-linked carbohydrate moiety. These results show that the transfer of 2-keto-galactose to the LacNAc moieties of glycoproteins can be used for detection of LacNAc moieties of glycoproteins with very high sensitivity and to conjugate glycoproteins via glycan chains. The transfer of modified galactose with a chemical handle at the C-2 position to the LacNAc residues of a glycoprotein using the AGG and SGG mutants makes it possible to (1) detect a LacNAc disaccharide unit in a glycoprotein with high sensitivity and (2) site-specifically conjugate a glycoprotein via its glycan chain.

CONCLUSION

Lactosamine (LacNAc) moiety on glycoconjugates is the most prevalent sugar found on cells. α3Gal-T transfers Gal moiety to LacNAc (Galβ1−4GlcNAc), forming a Galα1−3Galβ-linkage. On the basis of the structural information of wild-type α3Gal-T and human blood group A and B glycosyltransferases, we have engineered bovine α3Gal-T enzyme in such a way that

it can transfer a galactose residue with a chemical handle at the C2 position, such as a keto group to lactosamine that can be used for conjugation chemistry and detection of LacNAc residues on glycoconjugates. In the blood group A glycosyltransferase sugar donor binding site, three residues (Leu266, Gly267, and Gly268) allow transfer of 2-N-acetylated galactose (GalNAc) to fucosylated LacNAc. At the corresponding positions in the α3Gal-T, three residues (His280, Ala281, and Ala282) determine the sugar−donor specificity toward Gal. We have mutated these three residues to Ala280, Gly281, and Gly282 (AGG mutant) and to Ser280, Gly281, and Gly282 (SGG mutant). These mutants lost Gal-T activity by 95% but gained the GalNAc transferase activity, which is 10−20% of the Gal-T activity at 200 mmol lactose concentration. The mutation results show that creation of a cavity in the sugar-donor binding site allows the transfer of galactose with a C2 substitution of a bulky group. The transfer of modified sugar that has a chemical handle at the C2 position of galactose, e.g., 2-keto-Gal to the LacNAc moiety of a pentasaccharide, galactochitotetrose, and of a glycoprotein, asialofetuin, was demonstrated by MS analysis of the product and by bioconjugation of the transferred 2-keto-Gal to the aminooxy-biotinylated derivative, which was detected by the chemiluminescence method.

ACKNOWLEDGMENT

We thank Dr. Linda Hsieh-Wilson, CalTech, for helping Dr. Maria Manzoni during the synthesis of UDP-2-keto galactose and Dr. Natalia Mercer for the critical reading of the manuscript. This project has been funded in whole or in part with federal funds from the National Cancer Institute, National Institutes of Health, under contract N01-CO-12400. The content of this publication does not necessarily reflect the views or policies of the Department of Health and Human Services, nor does mention of trade names, commercial products or organizations imply endorsement by the U.S. Government. SM-Figure 1. MALDI mass spectra of glycans after the transfer of 2-keto-Gal by the mutant enzyme SGG to a sugar acceptor galacto-chitotetrose Galβ1,4-GlcNAcβ1,4-(GlcNAcβ1,4-)$_3$. Incubation mixtures of 25 µl, containing 0.5 µg of the enzyme, 0.1 mM acceptor, 500 µM UDP-2-keto-Gal, 5 mM $MnCl_2$ and 25 mM Tris/HCl (pH 7.0), were incubated at 37^0 C for 1 h, 2 h, 6 h and overnight and analyzed by MS (A–D). The major peaks are annotated with the carbohydrate structure shown in the symbols for monosaccharides, according to the nomenclature adopted by the consortium for functional glycomics, http://www.functionalglycomics.org/static/consortium/. GlcNAc (blue squares), and 2-keto-Gal (yellow stars). MS analysis shows a shift in the molecular mass from the starting ion at 1015 *m/z* to a peak of 1217 *m/z* after the addition of 2-keto-Gal moiety (see Material and Methods section), for 1 h (A), 2 h (B), 6 h (C) and overnight incubation (D). A peak after the transfer of 2-keto-Gal moiety (1217 *m/z*) increases with time compared to the starting ion 1015 *m/z,* showing that the enzyme is stable and transfers modified sugar donor during the entire incubation time.

TECHNICAL NOTES

A Multidentate Peptide for Stabilization and Facile Bioconjugation of Gold Nanoparticles

Željka Krpetić,[†] Paola Nativo,[‡] Francesca Porta,[†] and Mathias Brust*,[‡]

Dipartimento di Chimica Inorganica Metallorganica Analitica "Lamberto Malatesta", University of Milan, Via Venezian 21, Milan 20133, Italy, and Centre for Nanoscale Science, Department of Chemistry, University of Liverpool, Liverpool L697ZD, United Kingdom. Received July 16, 2008; Revised Manuscript Received January 22, 2009

Gold nanoparticles of two different sizes stabilized by a 15-*mer* peptide ligand specifically designed for this purpose have been prepared in aqueous solution and characterized by UV−vis spectroscopy and TEM. The presence of the ligand and its binding mode to the particles via its four cystein thiols is evidenced by FTIR and NMR spectroscopy. Biotinylation of the particles via binding to a freely accessible lysine residue is demonstrated.

INTRODUCTION

There is increasing interest in the preparation of nanoparticles that are stable in aqueous media and can be readily functionalized with biomolecules by established bioconjugation procedures. Such materials have many applications including biolabeling for a range of optical and electron microscopic techniques, biosensing, and as potential carriers for drug and gene delivery (*1*−*4*). Gold nanoparticles have been investigated extensively in this context owing to their unique optical properties, excellent stability, and relative ease of preparation (*5, 6*). Several efficient stabilization methods based on capping the particles with protective thiol-based ligands have been reported, including the use of mercaptodextranes (*7*), thiolated PEG derivatives (*8*−*14*), and peptides (*15*−*25*). A number of different approaches to conjugating such particles to biomolecules have also been reported. These include click chemistry (*26*), biotin−avidin coupling (*27*−*29*), ligand exchange (*30, 31*), and a range of standard bioconjugation procedures (*32, 33*). Recently, peptides containing several regularly spaced amine (lysine) or thiol (cysteine) functions have been introduced as very strongly binding "multidentate" ligands to stabilize gold nanoparticles (*34*). A special feature of these peptides is that unlike most compounds that contain more than one thiol group they do not generally lead to particle aggregation by cross-linking. This frequently observed adverse side effect is avoided if a sufficient amount of peptide is used and the pH of the solution is controlled so that the acid group of the peptide is present in anionic form. Under such conditions, the peptide molecule readily replaces citrate and binds to the gold particle with all its thiol moieties comparable to the behavior of the well-established hand-in-glove effect observed when multiply thiolated dextranes are used as ligands (*7*). Here, we report the use of a new peptide of this family, specifically designed for the stabilization and subsequent bioconjugation of gold nanoparticles. This ligand can bind to the nanoparticle via the thiol groups of four cysteine moieties and contains a central lysine that provides an amine function to which biomolecular functionality can be readily attached. This protection method is very robust and can be used either for the one-step synthesis of relatively small (2−4 nm) particles or for the stabilization of preprepared, larger (10−20 nm) colloids. The materials have been characterized by TEM, UV−vis, ATR-FTIR, and ^{1}H NMR spectroscopy. As an example of facile bioconjugation, a biotin moiety has been introduced via a standard coupling procedure, and binding of the biotinylated particles to streptavidin-modified surfaces has been demonstrated.

EXPERIMENTAL PROCEDURES

Chemicals. All the chemicals were of the highest grade available and purchased from Aldrich. As a biotin labeling agent *N*-hydroxy sulfosuccinimidobiotin (Sulfo-NHS-Biotin) was used. Water-soluble 15-*mer* peptide with amino acidic sequence H_2N-G**C**GG**C**GG**K**GG**C**GG**C**G-COOH (Figure 1), named GCK15, was purchased from Aldrich (purity >95%). GCK15 aqueous stock solution and Au@Citrate colloidal solution were filtered through 0.45 m Millipore syringe filters prior to use.

Spectroscopy and Microscopy. UV−vis spectra were recorded on a Thermo Spectronic spectrometer, Genesys 20-S. Transmission electron microscopy (TEM) micrographs of the colloidal dispersions were obtained using a FEI Tecnai Spirit instrument operated at an accelerating voltage of 120 kV. Carbon-supported copper grids were used to support the colloidal dispersions. Specimens for imaging by TEM were prepared by evaporating a droplet of gold nanoparticle solutions onto carbon-coated copper grids. A histogram of the particle size distribution and the average particle diameter were obtained by measuring about 200 particles.

ATR FTIR analysis was performed on a JASCO FT/IR-4100 spectrometer. For the ATR FTIR analysis, the samples of gold colloids were freeze−dried, and the analysis of the free peptide and GCK15 stabilized gold particles was performed in the solid state.

^{1}H and COSY ^{1}H NMR spectra were recorded on a Bruker AVANCE 400 MHz spectrometer. For analysis, purified samples

were redispersed in a H_2O/D_2O (9:1) mixture. Chemical shifts (δ ppm) were referenced to 3-(trimethylsilyl) propionic-2,2,3,3-d_4 acid sodium salt (δ Me = 0).

HR-MAS (high-resolution magic angle spinning) ^{1}H NMR spectra were recorded on a Bruker AVANCE 500 MHz spectrometer, spinning at 3 KHz and operating at T = 302 K. For analysis, the sample was prepared by centrifugation of gold nanoparticles (13000 rpm, 15 min), subsequent redispersion in 50 μL of D_2O, and placing of the sample into a 12 mm high precision ceramic rotor (sample tube).

Preparation of Au-GCK15 (2.4 nm). To a 13 mL of mQ water, an aqueous solution of $NaAuCl_4$ (0.162 mL; 6.16×10^{-2} M) was added. Under vigorous stirring, an aqueous solution of GCK15 peptide (1.51 mL, 1.98×10^{-2} M) was added, in order to set up the molar ratio between Au and the peptide 1:0.3. After 5 min, an aqueous solution of $NaBH_4$ was added (0.3 mL, 0.1 M) and a brown sol was immediately formed. It was left under stirring for further 60 min. The particles were purified by dialysis for 48 h (Sigma-Aldrich dry dialysis tubing).

Preparation of Au-GCK15 (15 nm). 15 nm citrate-capped gold nanoparticles were prepared by the Turkevich/Frens method, showing a typical UV−vis plasmon peak at 520 nm. To 20 mL of citrate-capped gold nanoparticles ($C_{NPs} = 1.9 \times 10^{-9}$ M), 9.5 μL of GCK15 aqueous solution (1.98×10^{-3} M) was added, and the mixture was left overnight to allow the complete ligand exchange between citrate ligand and the peptide molecule. The amount of peptide was calculated in order to have 500 molecules of the GCK15 15-*mer* peptide on the surface of each gold particle. Prior to peptide addition, the pH of the gold sol was adjusted to 8 by adding dilute NaOH. The particles

were centrifuged (13 000 rpm, 15 min) and purified by 3 cycles of repetitive centrifugation and redispersion in fresh mQ water.

Characterization of Au-GCK15 (2.4 nm). GCK15 coated gold nanoparticles were characterized using UV−vis (Figure 2a), ATR-FTIR (Figure 4), and NMR spectroscopy (Figure 5), while the morphology and size distribution of these particles were investigated by TEM (Figure 3a).

Characterization of Au-GCK15 (15 nm). GCK15 coated gold nanoparticles obtained by ligand exchange reaction were characterized using UV−vis (Figure 2b) and HR-MAS ^{1}H NMR spectroscopy (Figure 8), while the morphology and size distribution of these particles were investigated by TEM (Figure 3b). UV−visible spectra of Au-Citrate-GCK15 particles before and after biotinylation redispersed in PBS showed no significant changes in the plasmon peak absorption (520 nm) and particle size distribution (Figure A, Supporting Information).

Biotinylation Procedure for 15 nm Au-GCK15 Nanoparticles. *N*-Hydroxy sulfosuccinimidobiotin (Sulfo-NHS-Biotin) was used as the biotin-labeling agent. By mixing 300 μL of GCK15 coated gold nanoparticles redispersed in PBS (pH 7.4) and 20 μL of Sulfo-NHS-Biotin (50 mM) in dimethylsulfoxide. The excess of the biotin label was set up to be at least 1000 times more than lysine molecules present in the peptide. The excess of biotin ligand was removed by centrifugation and subsequent redispersion in PBS.

Biotin Detection Methods. *Streptavidin Beads Assay.* Biotin labeled nanoparticles were added to the suspension of streptavidin beads (commercially available suspension in 0.01 M sodium phosphate, pH 7.2, 0.15 M NaCl, 0.02% NaN_3) and stirred for 10 min. After centrifugation (2 min, 2000 rpm), the color change of the beads was observed passing from colorless to red, as a demonstration of biotin molecule specifically bounded to the GCK15 peptide.

Dot Blot Specific Biodetection of Biotin. Samples of capped gold nanoparticles were deposited onto a PVDF membrane (previously prepared by soaking in 70% EtOH/H_2O for 5 min and then two times for 2 min in H_2O). The membrane was blocked 40 min with phosphate buffer containing 5 mg/mL bovine serum albumin (BSA) and then incubated with streptavidin-horseradish peroxidase (HRP). After the rinsing with H_2O, a luminol reagent (ECL reagents) was pippeted for 5 min continually. The membrane was then placed between a cling film and the X-ray image was recorded. In the case of a positive outcome, for biotinylated Au NPs, the dark spot appeared on the place where biotinylated Au NPs were placed.

RESULTS AND DISCUSSION

Gold nanoparticles of 2.4 nm diameter were prepared in a one-step reaction by borohydride reduction of tetrachloroaurate in the presence of the stabilizing peptide H_2N-G**C**GG**C**GG**K**G-G**C**GG**C**G-COOH (Figure 1). The four cysteine (C) residues binding to the particle surface and the lysine (K) available for subsequent bioconjugation are represented in bold. The particles were purified by dialysis. A clear brown solution was obtained indicating the formation of gold particles in the size range below 3 nm. This conclusion was confirmed by the absence of a plasmon absorption band in the UV−vis spectrum (Figure 2a) and by the observation of very small (2 to 5 nm) particles by TEM (Figure 3a). These results are typical for preparations of monolayer protected clusters (MPCs), although usually much simpler thiol ligands are employed, which generally do not lend themselves to facile bioconjugation (*35*). Structural investigations of the ligand shell of MPCs always represent a formidable challenge, even in the case of alkane thiol ligands (*36*−*38*). Only recently, the complete molecular structure of an MPC, $Au_{102}MBA_{44}$ (MBA: *p*-mercaptobenzoic acid), has been determined by X-ray crystallography (*39*). Usually, IR and NMR signatures of the MPCs are compared to those of the free ligands in solution, and the formation of the ligand shell is inferred from the similarity of the spectra. In some cases, it is possible to assign conformational features that are specific to the molecules in the ligand shell, based on subtle spectroscopic differences between bound and free ligands (*40, 41*). Usually, the ligand shell contributes to the broadening and blurring of spectral features, particularly in NMR experiments (*42*−*45*). We have used both FTIR and NMR spectroscopy to demonstrate that our peptide indeed constitutes the ligand shell of the particles. A comparison between the FTIR spectrum of the free peptide and that of the peptide-protected particles is shown in Figure 4. As found previously for peptide ligands of this family, it can be inferred from the spectra that the amide functions participate in the bonding of the ligand to the surface (*34*). This is concluded from the shift of the amide A band from 3291 cm^{-1} in the free peptide to 3197 cm^{-1} in the particles suggestive of unusually strong hydrogen bonding. Otherwise, both spectra are very similar and thus indicate that the intact peptide indeed acts as a surface bound stabilizing agent. Hydrogen bonding is supported also by NMR results, as shown in Figure 5a, where peaks in the NH region (6.8−8.8 ppm) had significantly changed their position and shape upon binding to gold particles, suggesting possible interaction between vicinal peptides on the gold surface, besides coordination to gold.

Unfortunately, the S−H vibration of the cysteine thiols is not visible in the IR spectrum of the free peptide, and hence, its absence in the spectrum of the particles is not diagnostic for

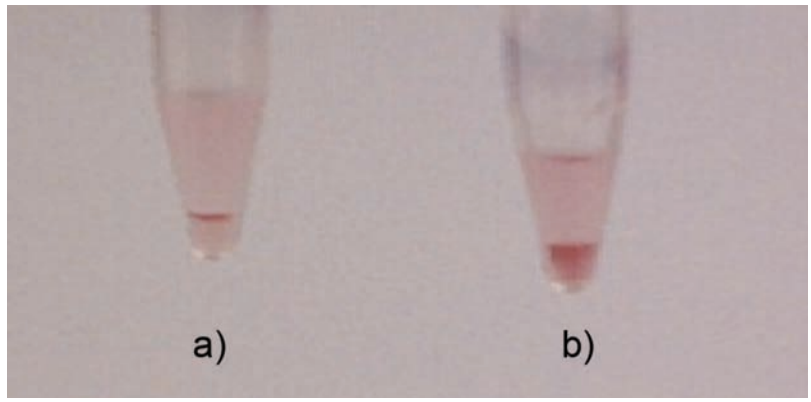

Figure 7. Specific binding of the biotinylated particles to streptavidin-modified agarose beads. (a) 15 nm Au@GCK15 nanoparticles and (b) biotinylated 15 nm Au@GCK15 nanoparticles attached onto streptavidin-modified agarose beads.

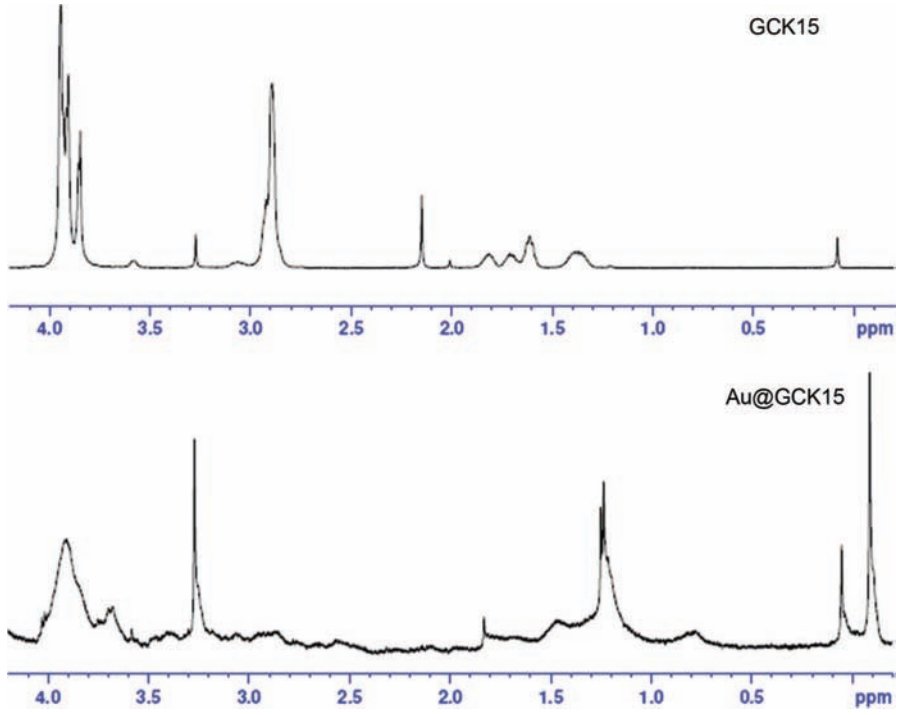

Figure 8. HR-MAS ^{1}H NMR of GCK15 peptide and 15 nm Au@GCK15 nanoparticles.

binding to the gold surface via the thiols. This, however, can be demonstrated by ^{1}H NMR spectroscopy. The NMR spectra of the free peptide and of the particles in 9:1 H_2O/D_2O mixtures are shown in Figure 5. In the spectrum of the free peptide, the 8 cysteine β-methylene groups vicinal to the thiol groups appear, as expected, as a sharp doublet centered at 2.90 ppm. Upon binding to the particles, this feature disappears. This is commonly observed for signals that are due to hydrogen atoms very close to the gold surface (*46*, *47*). What remains is a weak triplet centered at 3.01 ppm that we attribute to the ε-methylene group of the central lysine side chain, which is occulted in the spectrum of the free peptide by the strong β-methylene doublet (Figure 5b). From these observations, we conclude that the ligand binds to the surface of the particles via all its thiol functions leaving the lysine amine group freely accessible, as intended.

Gold nanoparticles of 15 nm diameter were obtained via the classic Turkevich/Frens method (*48*, *49*), subsequently protected by addition of our peptide and purified by repeated centrifugation and redispersion. The particles are extremely stable and can be centrifuged and redispersed in pure water many times without detectable loss of material, whereas the as-prepared citrate-stabilized particles cannot be redispersed in pure water after the first centrifugation. The UV−vis spectrum in Figure 2b shows a plasmon absorption band at 520 nm typical for gold particles of this size range. The TEM image of the peptide-coated gold particles in Figure 2b indicates a narrow size distribution centered at 14 nm. The type of aggregation of particles on the sample grid observed here is fairly common for charged particles derived from hydrosols and does not suggest that particles are aggregated in solution. In addition, the UV−vis spectrum and the ruby red color of the hydrosol rule out the presence of a significant number of aggregates.

There are many reports in the literature on the passivation of gold nanoparticles with polythiolated ligands. While such ligands often cause irreversible aggregation of particles by cross-linking (*50*−*56*), there are also several reports in which their use results in the formation of stable colloids (*7*, *57*). In our case, we have in fact also observed aggregation but only when the peptide ligand was added at a pH value of 6 or below. On the other hand, at pH 8 no aggregation occurs, presumably because the acid group of the peptide is deprotonated, which facilitates the rapid and efficient replacement of citrate.

The analysis of the ligand shell in the case of these larger particles is more difficult due to the very small proportion

of peptide present in the total amount of material, which is predominantly gold. However, using high-resolution magic angle spinning (HR-MAS) well-resolved ^{1}H NMR spectra of 15 nm Au@GCK15 nanoparticles were obtained (Figure 8). The absence of citrate peaks (quartet centered at 2.5−2.7 ppm) suggests complete ligand exchange by exposure to the peptide. The sharp doublet centered at 2.90 ppm in the spectrum of the free peptide ligand is due to the 8 cysteine β-methylene groups vicinal to the thiol groups and disappears completely upon binding to the particles. This indicates that all cysteine thiol groups are involved in the surface binding process.

Biotinylation of peptide-stabilized gold nanoparticles was achieved using the standard sulfo-NHS-biotin labeling agent. This is illustrated in Figure 6. Binding of the particles to streptavidin-modified substrates was demonstrated as evidence for successful biotinylation. Specific binding of the biotinylated particles to streptavidin-modified agarose beads leading to an intense coloration of the beads is shown in Figure 7. Particles that have not been biotinylated do not attach to the beads. Dot blot experiments (not shown) also clearly indicate efficient biotinylation of the particles.

CONCLUSIONS

A simple and versatile new route to stable biofunctional gold nanoparticles in aqueous media has been described. Stabilization is robust owing to the presence of four thiol groups per ligand molecule, which are all capable of binding to the surface of the particles. This binding configuration has been confirmed by NMR spectroscopy. Subsequent attachment of biomolecular functionality of choice, e.g., biotin, is possible by standard procedures due to the presence of a central lysine residue that is not involved in the binding of the ligand to the surface of the particles. The same capping ligand can be used to cover a range of particle size from ca. 1 to 20 nm. Preliminary results indicate that larger particles (up to 50 nm) can also be stabilized by this ligand. Custom-made variations of the ligand are readily available from commercial peptide suppliers. To date, it has been difficult to determine the exact number of ligands per particle, which will strongly depend on particle size. Once this figure is known, the stabilizing approach shown here will allow controlling the precise number of biomolecules attached to each particle, by ligand design.
