
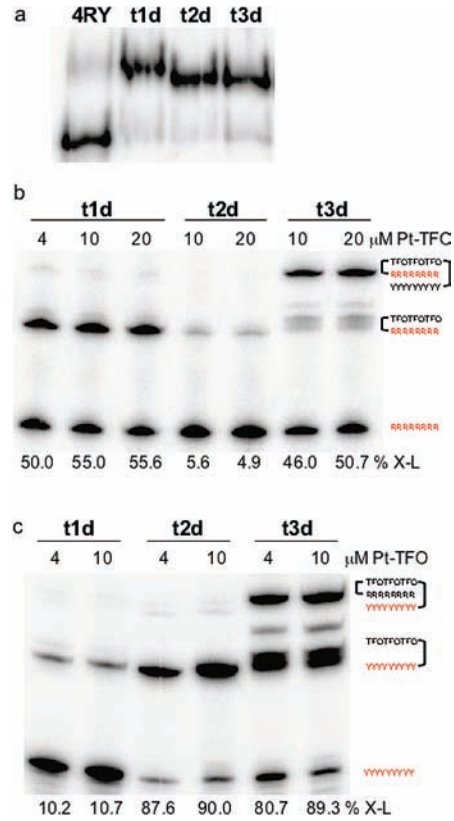

Figure 1. Interactions of platinated TFOs with DNA duplex **4RY**. (a) Solutions containing 10 μM platinated TFO and 1 μM duplex **4RY**, whose purine strand was labeled with ^{32}P-phosphate, were incubated at 4 °C in triplex buffer that contained 100 mM MOPS, pH 6.5, 100 mM sodium acetate, and 2.5 mM magnesium acetate, and were then subjected to electrophoresis on a 20% native polyacrylamide run at 4 °C and 100 V. (b) Solutions containing platinated TFO and 1 μM duplex **4RY**, whose purine strand was labeled with ^{32}P-phosphate (shown in red), were incubated at 37 °C for 48 h in triplex buffer and were then subjected to electrophoresis on a 20% denaturing polyacrylamide gel. Percent adduct formation is shown below the corresponding lane (% X-L). (c) Solutions containing platinated TFO and 1 μM duplex **4RY**, whose pyrimidine strand was labeled with ^{32}P-phosphate (shown in red), were incubated at 37 °C for 48 h in triplex buffer and were then subjected to electrophoresis on a 20% denaturing polyacrylamide gel. Percent adduct formation is shown below the corresponding lane (% X-L).

5% adduct formation was observed with TFO-Pt **t2d**. Approximately 50% adduct formation was observed when Pt-TFO-Pt **t3d** was incubated with purine strand-labeled **4RY**. In this case, however, the electrophoretic mobility of the adduct was significantly slower than that observed for the adducts formed by either **t1d** or **t2d**. This slower mobility suggested that **t3d** had formed adducts with both strands of the duplex. Reaction of Pt-TFO **t1d** with pyrimidine-labeled **4RY** resulted in approximately 10% adduct formation, as shown in Figure 1c, whereas approximately 90% adduct formation was observed with TFO-Pt **t2d**. A similar level of adduct formation was also observed with Pt-TFO-Pt **t3d**. As seen in Figure 1c, **t3d** formed two types of adducts, one whose mobility was similar to that of adducts formed by **t1d** and **t2d**, and a slower mobility adduct. This latter adduct, which represents approximately 35−40% of the total adduct formation, is most likely the TFO cross-linked to both strands of the duplex. It migrates more slowly on the denaturing gel because the three strands are linked together as indicated schematically in Figure 1c. These results show that adduct formation can occur when the *trans*Pt-dG is placed at either end of the TFO and that either strand of the duplex can be targeted. These results also suggest that cross-linking is strand

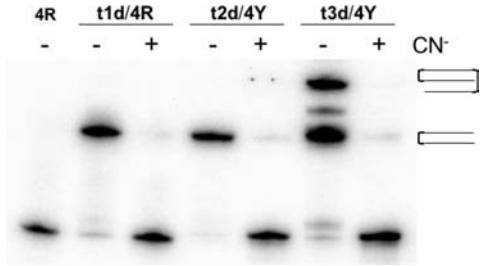

Figure 2. Reversal of platinated TFO adducts by treatment with cyanide. Adducts formed by reaction of the platinated TFOs with duplex **4RY** were isolated and treated with either water or 200 mM sodium cyanide. The reaction mixtures were then subjected to electrophoresis on a 20% denaturing polyacrylamide gel. The labeled strand of duplex **4RY** is indicated at the top of the gel.

specific and possibly sequence specific depending on the location, 5′ or 3′, of the platinated-G in the TFO.

It seemed likely that the *trans*Pt-dG group of the TFO platinates the guanine residues of **4RY** adjacent to the TFO binding site. It has been shown that cyanide is an extremely strong ligand for platinum and that adding cyanide to a Pt-G adduct will displace the platinum from guanine (*46*−*50*). The **t1d-4R**, **t2d-4Y**, and **t3d-4Y** adducts were isolated from the gel and were treated with 200 mM sodium cyanide. The products of these reactions were then analyzed on a denaturing gel. As shown in Figure 2, the mobilities of the treated adducts reverted to those of the labeled strand alone. This result is consistent with the formation of a platinum adduct between the platinated TFO and the labeled target strand.

In order to better understand the base preference of adduct formation, a series of duplexes were synthesized in which a set of two identical base pairs, which could serve as sites for platination, were placed at each end of the duplex. The sequences of the four duplexes containing the four possible combinations of the base pairs are shown in Figure 3a. The purine- or pyrimidine-rich strand of each duplex was labeled with ^{32}P, and the labeled duplexes were reacted with the platinated TFOs at 37 °C and the products analyzed by denaturing polyacrylamide gel electrophoresis (PAGE). The results are summarized in Figure 3b. As expected, significant adduct formation was observed with duplexes whose labeled strand contained guanine (**GY** or **GR**) or adenine (**AY** or **AR**) residues at the ends of the duplex. It is likely that adduct formation occurred as a result of platination of the N-7 of these bases. Very little adduct formation was observed when either cytosines or thymines were placed at the ends of the labeled strands, a result consistent with the known reactivity of these bases with platinum. We were surprised to find that adduct formation occurred equally well on either the pyrimidine or purine strand of the duplex when guanines or adenines were the target of platination. In a previous study of a 5′-*trans*Pt-dG modified TFO, no adduct formation with the pyrimidine strand was observed (*36*). However, in this case the pyrimidine strand of the target duplex contained only pyrimidines at the platination site.

The duplexes shown in Figure 3a contain two potential sites for platination: one base from the end of the triplex binding site (n-1) and two bases from the end of the triplex binding site (n-2). In order to better characterize the precise site of platination for each of the platinated TFOs, we employed another set of duplexes (shown in Figure 4a) that have a single G residue at either the n-1 or the n-2 position. The purine or pyrimidine strand of each duplex was 5′-end labeled with a ^{32}P phosphate group, and reactions were carried out with each of the platinated TFOs as described above. As shown in Figure 4b, a clear pattern of adduct formation emerged for each of the platinated TFOs.

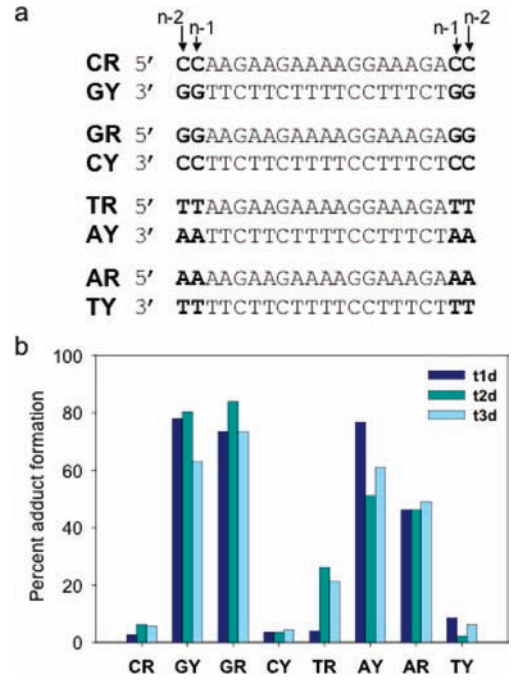

Figure 3. Adduct formation between platinated TFOs and DNA duplexes. (a) Sequences of the DNA duplexes. Bases shown in bold lie outside the TFO binding site. (b) Percent adduct formation between platinated TFOs **t1d** (dark blue), **t2d** (medium blue), or **t3d** (light blue) and the purine or pyrimidine strands of each of the DNA duplexes. Solutions containing 1 μM ^{32}P-labeled duplex and 2 μM platinated TFO were incubated in triplex buffer at 37 °C for 48 h and then analyzed by PAGE on a 20% denaturing gel. The amount of adduct formed was quantitated by phosphorimaging the gel.

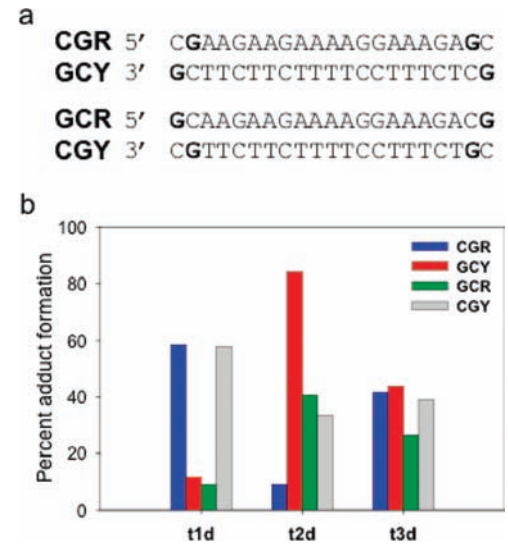

Figure 4. Adduct formation between platinated TFOs and DNA duplexes. (a) Sequences of DNA duplexes. Potential sites of platination are shown in bold. (b) Percent adduct formation between platinated TFOs **t1d**, **t2d**, or **t3d** and the purine or pyrimidine strands of the DNA duplexes. Solutions containing 1 μM ^{32}P-labeled duplex and 2 μM platinated TFO were incubated in triplex buffer at 37 °C for 48 h and then analyzed by PAGE on a 20% denaturing gel. The amount of cross-linking was quantitated by phosphorimaging the gel.

Preferential adduct formation by the Pt-TFO, **t1d**, was observed with duplexes that contained guanine at the n-1 position in either the purine or pyrimidine strand of the duplex. In contrast, adduct formation by the TFO-Pt, **t2d**, occurred to the greatest extent with the duplex whose pyrimidine strand contained a guanine at position n-2, and to lesser extents with the duplexes that

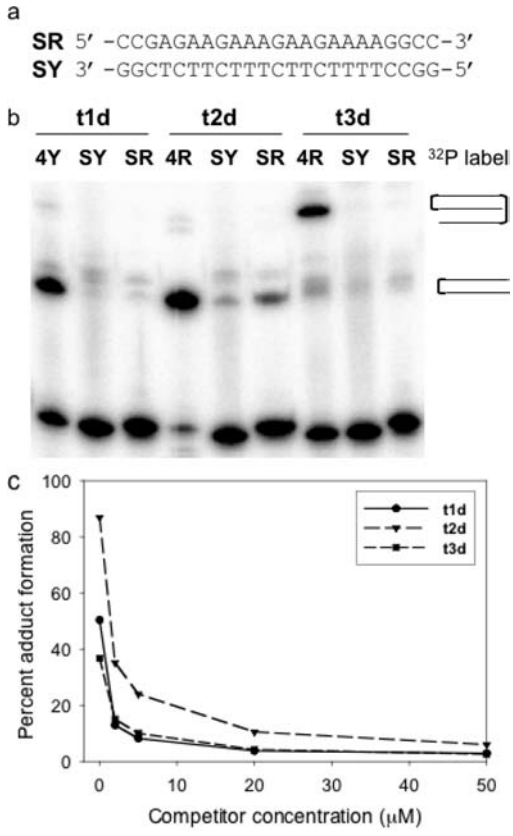

Figure 5. Sequence dependent interactions between platinated TFOs and DNA duplexes. (a) Sequence of the scrambled duplex, **SRY**. (b) Solutions containing 1 μM ^{32}P-labeled duplex **SRY** or 1 μM ^{32}P-labeled duplex **4RY** and 2 μM platinated TFO were incubated in triplex buffer at 37 °C for 48 h and then analyzed by PAGE on a 20% denaturing gel. (c) Solutions containing 1 μM ^{32}P-labeled duplex **4RY**, 2 μM platinated TFO, and increasing concentrations of competitor nonplatinated TFO were incubated in triplex buffer at 37 °C for 48 h and then analyzed by PAGE on a 20% denaturing gel. The percentage of adduct formed by each platinated TFO versus competitor concentration was determined.

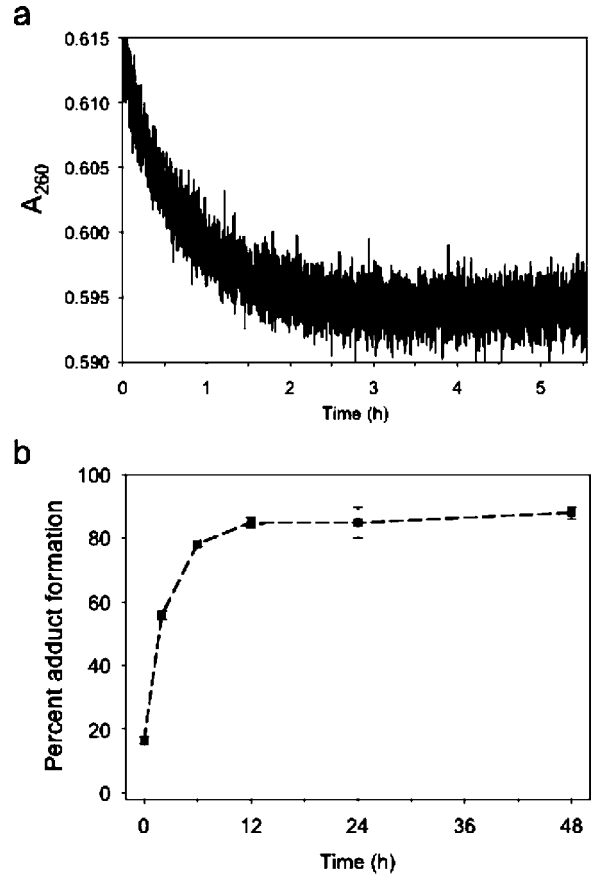

Figure 6. Kinetics of triplex adduct formation. (a) Equal volumes of solutions containing 1 μM TFO **1d** and DNA duplex **4RY** in triplex buffer were mixed, and the absorbance at 260 nm was recorded as a function of time at 37 °C. (b) Solutions containing 1 μM ^{32}P-labeled duplex **4RY** and 2 μM **t2d** were incubated in triplex buffer at 37 °C for various lengths of time and analyzed by PAGE on a 20% denaturing gel. The percent adduct formation was determined as a function of time.

contained an n-2 guanine in the purine strand or an n-1 guanine in the pyrimidine strand. As expected, the bis-platinated Pt-TFO-Pt, **t3d**, formed adducts equally well with the pyrimidine and purine strands of both duplexes.

The experiments described above show that platinated TFOs can form adducts with DNA duplexes that contain guanines or adenines adjacent to the TFO binding site in either strand of the duplex. These platinated TFOs retained approximately 60−90% of their initial activity after storage for 1.5 months in aqueous 50% acetonitrile at 4 °C. These results suggest that it should be possible to design stable platinated TFOs that can target a rather broad range of sequences in DNA.

Specificity of Adduct Formation. Experiments were carried out using a scrambled DNA duplex to ensure that adduct formation by the platinated TFOs was dependent upon the ability of the TFO to bind to its target. The sequence of this scrambled duplex, **SRY**, is shown in Figure 5a. It contains the same number of CG and TA base pairs as DNA duplex **4RY** (see Table 1) and has the same terminal sequences adjacent to the TFO binding site. Each of the platinated TFOs was incubated at 37 °C with duplex **SRY**, whose purine or pyrimidine strand was labeled with a 5′-^{32}P-phosphate group, and the products of the reaction were analyzed by denaturing PAGE. Control reactions were run using ^{32}P-labeled **4RY** as a target duplex. As shown in Figure 5b, the platinated TFOs formed adducts with either the purine or the pyrimidine strand of the **4RY**. In contrast, very little adduct formation with either the **SR** or the **SY** strand of the scrambled duplex was observed. In a second experiment, increasing concentrations of nonplatinated TFO were added to reaction mixtures containing the platinated TFOs and DNA duplex **4RY**. The amount of adduct formation was determined by denaturing PAGE. The results are summarized in Figure 5c. A significant decrease in adduct formation by each of the platinated TFOs was observed in the presence of an equimolar amount of competitor nonplatinated TFO (2 μM), and adduct formation was completely inhibited at higher competitor concentrations.

Taken together, the results described above demonstrate that adduct formation between the platinated TFOs and DNA duplex **4RY** is driven by the ability of the TFO to bind specifically to this target and not by nonsequence-specific platination of the DNA duplex. This behavior suggests that it should be possible to design platinated TFOs that can react with their designated DNA targets in a specific manner with little or no off-target effects.

Kinetics of TFO Binding and Adduct Formation. The kinetics of triplex formation were determined by observing the decrease in absorbance upon mixing TFO **1d** with DNA duplex **4RY** at 37 °C as shown in Figure 6a. The average rate constant, k_{on}, for the association of the TFO with the duplex is 654.51 s^{-1} M^{-1} as determined from four separate experiments. This translates to a half-life of triplex formation of 25.5 min. This value can be compared with those of Xodo, who found a k_{on} of 2557 M^{-1} s^{-1} for a 18-mer deoxy TFO that was assayed at 26.1

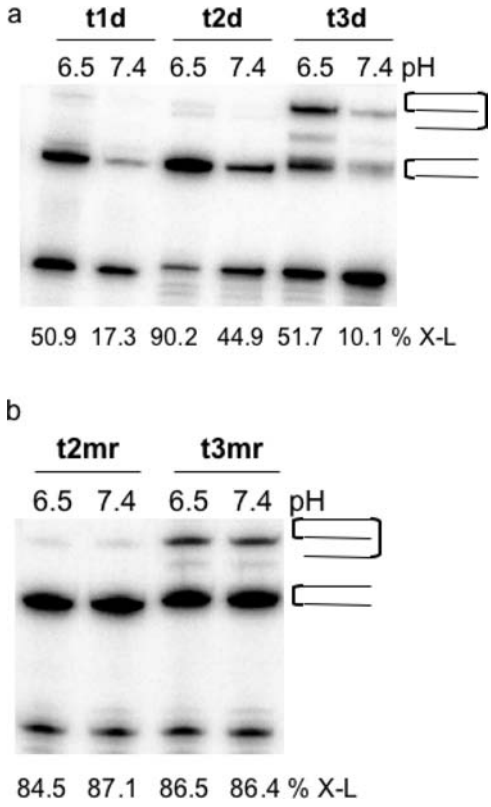

Figure 7. Effect of pH on adduct formation by platinated deoxyribo- and 2′-*O*-methylribo-TFOs. (a) Solutions containing 1 μM duplex **4RY** and 2 μM platinated deoxyribo-TFOs **t1d**, **t2d**, or **t3d** in pH 6.5 or pH 7.4 triplex buffer were incubated at 37 °C for 48 h and then subjected to 20% denaturing PAGE. (b) Solutions containing 1 μM duplex **4RY** and 2 μM platinated 2′-*O*-methylribo-TFOs **t2mr** or **t3mr** in pH 6.5 or 7.4 triplex buffer were incubated at 37 °C for 48 h and then subjected to 20% denaturing PAGE. The percent adduct formation as determined by phosphorimaging is shown below each lane. The purine strand of duplex **4RY** is labeled in each case.

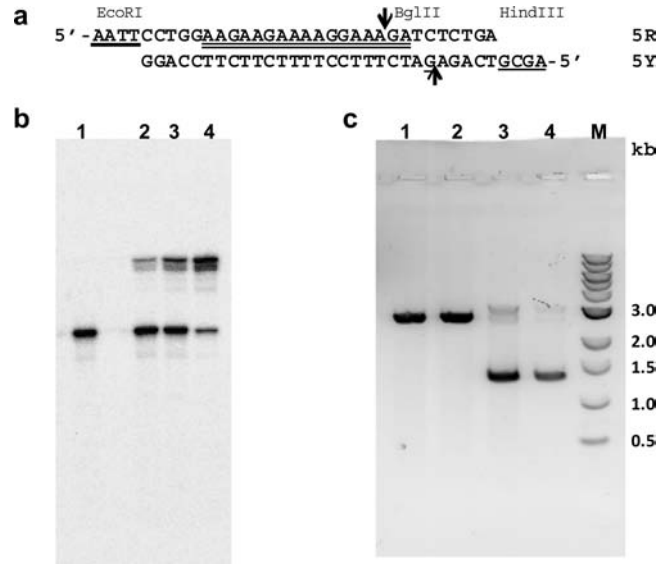

Figure 8. Interaction of platinated TFO with plasmid DNA. (a) Sequence of duplex insert **5RY**. The TFO binding site is indicated by the double underline; the guanine target for reaction with platinated TFO **t2mr** is underlined; *Eco*RI and *Hin*dIII complementary overhangs are indicated by heavy underlines; and the *Bgl*II restriction site is indicated by the arrows. (b) Reaction of 1 μM **5RY** with 0 μM (lane 1), 2 μM (lane 2), 4 μM (lane 3), or 10 μM **t2mr** in buffer containing 50 mM HEPES, 100 mM sodium chloride, and 5 mM magnesium chloride, pH 7.5, incubated at 37 °C for 24 h. The **5Y** strand was labeled with ^{32}P and the products of the reaction were analyzed on a 15% denaturing polyacrylamide gel. (c) Reaction of 500 ng of p-GEM-TFO with 0 μM TFO (lane 1), 10 μM **2mr** (lane 2), 10 μM **t2mr** (lane 3), or 0 μM TFO (lane 4) in buffer containing 50 mM HEPES, 100 mM sodium chloride, and 5 mM magnesium chloride, pH 7.5, incubated at 37 °C for 72 h. Following the reaction, the plasmids were digested with 10 units (lanes 1−3) or 0 units (lane 4) of *Bgl*II, and the digests were analyzed by electrophoresis on a 0.8% agarose gel. Lane M is a 1 kb DNA ladder.

°C (*39*), and Puri et al., observed a k_{on} value of approximately 600 M^{-1} s^{-1} for a 17-mer 2′-*O*-methylribo TFO at 25 °C (*40*).

The kinetics of adduct formation between the platinated TFO **t2d** and DNA duplex **4RY** were determined. In these experiments, 1 μM **4RY** was incubated with 2 μM platinated TFO, **t2d**, at 37 °C, and the extent of adduct formation at various times was assayed by denaturing PAGE. Figure 6b shows the averaged results from three independent experiments. The platinated TFO achieves maximal adduct formation after 10−12 h, and the $t_{1/2}$ of adduct formation is approximately 3 h. This result suggests that adduct formation occurs at a rate significantly slower than that at which the TFO binds to its target. It appears then that platination is the rate limiting step in adduct formation. These observations are consistent with the specificity of adduct formation described above and further support the idea that TFO binding precedes platination of the DNA target.

Effect of pH on Adduct Formation. The experiments described above were carried out at pH 6.5, a pH that favors protonation of the 5-methylcytosines in the TFO and thus enhances the stability of the triplex. A 2−5-fold decrease in adduct formation was observed when the reactions were carried out at pH 7.4 (see Figure 7a). As demonstrated in Table 1, triplex stability can be increased significantly by replacing deoxyribonucleotides in the TFO with 2′-*O*-methylribonucleotides. This change significantly increases the amount of adduct formation as shown in Figure 7b. The 3′-platinated mr-TFO, **t2mr**, and 3′,5′-bis-platinated mr-TFO, **t3mr**, both give extensive adduct formation with duplex **4RY** at both pH 6.5 and pH 7.4. These results suggest that platinated 2′-*O*-methyribo-TFOs could be designed that would function effectively under physiological conditions.

Interactions with Plasmid DNA. The interaction of 3′-platinated mr-TFO **t2mr** with a purine tract in the supercoiled form of plasmid p-GEM-TFO was studied. This plasmid was constructed by inserting duplex **5RY**, whose sequence is shown in Figure 8a, into the *Eco*RI and *Hin*dIII restriction sites of the polylinker region of p-GEM-3Z. Duplex **5RY**, whose purine tract is identical in sequence to that of duplex **4RY**, contains a unique *Bgl*II restriction site that is not otherwise found in p-GEM-3Z. The underlined guanine located 10 nucleotides from the 5′-end of **5Y** serves as a target site for platination by TFO **t2mr**.

Binding experiments were carried out at pH 7.5 and 37 °C to measure the extent of adduct formation between **t2mr** and duplex **5RY**, whose pyrimidine-rich strand was labeled with ^{32}P. As shown in Figure 8b, addition of increasing concentrations of **t2mr** resulted in the formation of a new product whose mobility on a denaturing polyacrylamide gel was consistent with formation of an adduct between **t2mr** and strand **5Y** of the duplex. Quantification of the phosphorimage of the gel showed that 79% of the duplex was converted to adduct after incubation with 10 μM **t2mr** for 24 h. The cross-linked duplex was not hydrolyzed when treated with *Bgl*II (data not shown). This result demonstrates that triplex and adduct formation by **t2mr** obstructs the recognition site of the restriction enzyme.

Plasmid p-GEM-TFO was incubated with 10 μM **t2mr** or 10 μM nonplatinated TFO **2mr** at 37 °C. The plasmid DNA was then treated with *Bgl*II, and the resulting digests were

analyzed by agarose gel electrophoresis. As shown in Figure 8c, supercoiled plasmid alone (lane 1) or supercoiled plasmid that had been incubated with **2mr** (lane 2) was completely converted by *Bgl*II to linear DNA. In contrast, 84% of the plasmid that had been incubated with **t2mr** was resistant to digestion by *Bgl*II and remained in the supercoiled form (lane 3). These results show that platinated TFO **t2mr** can bind to and react with the **5RY** insert in the supercoiled plasmid under essentially physiological conditions.

The site on the plasmid into which duplex **5RY** was inserted is flanked by promoter sequences for T-7 and Sp6 RNA polymerases. The insert is oriented such that the strand containing the **5Y** sequence would be used as a template for transcription by T-7 RNA polymerase. Run-off transcription experiments were carried out to determine if transcription is inhibited when **t2mr** is bound to the plasmid. Plasmid that had been incubated with **t2mr** as described above was linearized by digestion with *Bgl*II. The linearized plasmid was then transcribed using T-7 RNA polymerase, and the amount of runoff transcript, which is 42 nucleotides in length, was compared to that obtained from untreated p-GEM-TFO or plasmid treated with **2mr**. The nonplatinated TFO, **2mr**, inhibited transcription approximately 25%, whereas transcription was inhibited approximately 95% by the platinated TFO, **t2mr**.

In addition to inhibiting transcription, the platinated TFO would also be expected to interfere with plasmid replication. To test this, **2mr**- or **t2mr**-treated p-GEM-TFO, which contains an ampicilin resistance gene, was electroporated into wild type DH5α *E. coli* cells, and the electroporated cells were spread on LB agar plates that contained ampicilin. The number of colonies formed by cells electroporated with **2mr** was reduced 67% relative to cells electroporated with untreated pGEM-TFO. An even greater amount of inhibition of colony formation, 84%, was observed for the cells electroporated with **t2mr**-treated p-GEM-TFO.

Taken together, the experiments described above suggest that the platinated 2′-*O*-methylribo-TFO can bind effectively to supercoiled DNA and that such binding is able to interfere with transcription and replication of plasmid DNA. Experiments are currently in progress to determine if platinated TFOs of this type can be used to inhibit gene expression in mammalian cells.

ACKNOWLEDGMENT

This research was supported by a grant from the National Institutes of Health, GM 057140 (to P.S.M.). We thank Ms. Lynn Periera for carrying out the transcription experiments; the laboratory of Dr. Michael Matunis for providing electrocompetent DH5α cells; and Ms. Erica Hlavin for advice on transforming *E. coli* cells.

Figure S3 - Melting curves of triplexes formed by deoxyribo- and 2'-O-methylribo-TFOs

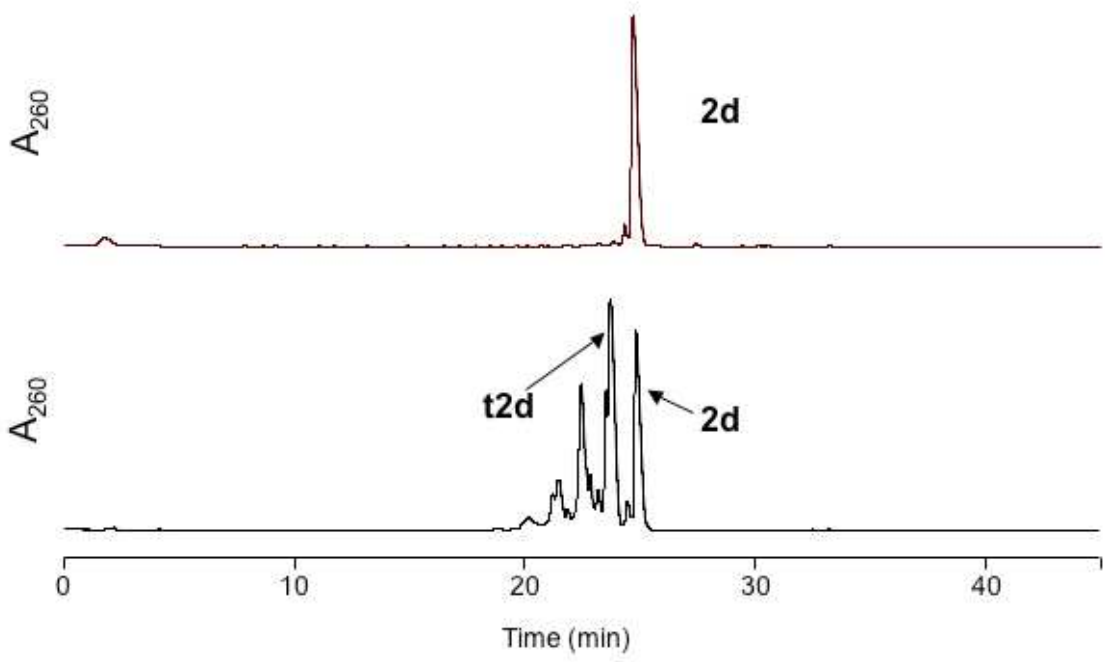

Figure S1 *Purification of **t2d** by SAX HPLC.* TFO **2d** was incubated with 72 μM *trans*-diamminediaquaplatinum(II) dinitrate for 3h at 37°C. The upper chromatogram shows **2d** before platination and the lower chromatogram shows platination reaction mixture. The peak labeled **t2d** was isolated, desalted, and analyzed by MALDI-TOF mass spectrometry. The SAX HPLC column was eluted with a 30 min linear gradient of 0 to 0.5 M NaCl in solution containing 0.1 M Tris, pH 7.8 and 10% acetonitrile at a flow rate of 1.0 mL/min.

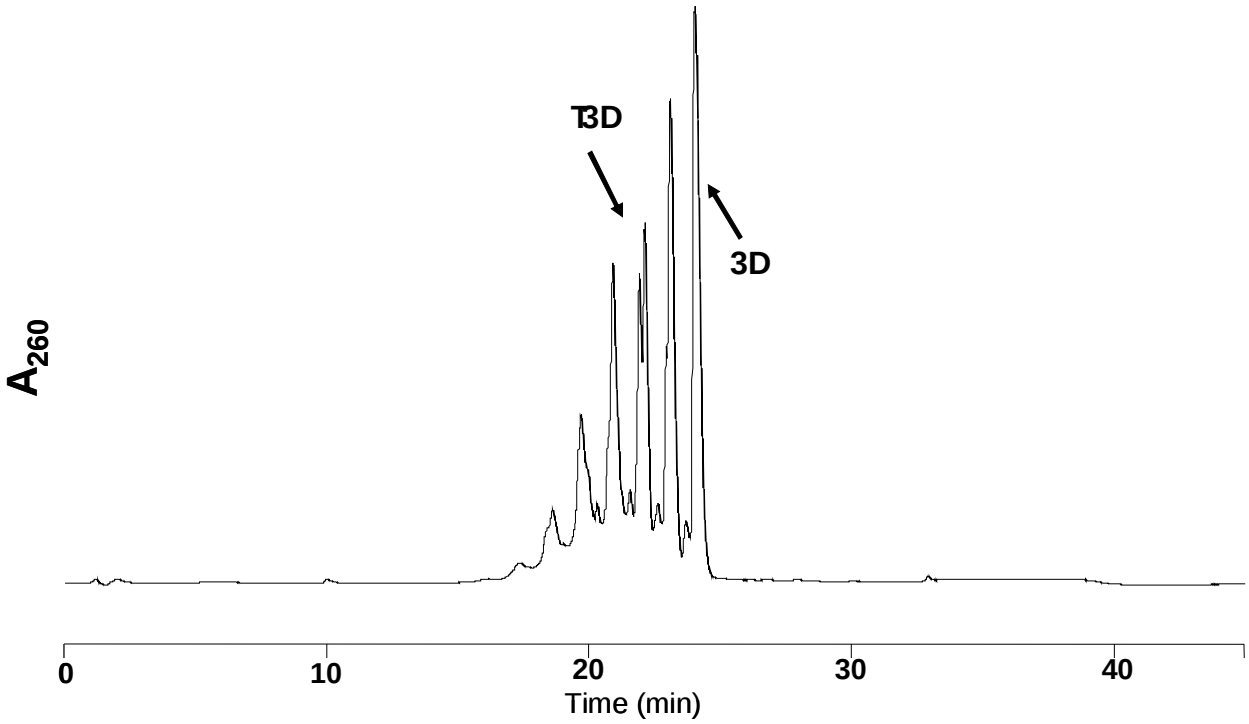

Figure S2 *Purification of **t3d** by SAX HPLC.* TFO **3d** was incubated with 144 μM *trans*-diamminediaquaplatinum(II) dinitrate for 2h at 37°C. The peak labeled **t3d** was isolated, desalted, and analyzed by MALDI-TOF mass spectrometry. The SAX HPLC column was eluted with a 30 min linear gradient of 0 to 0.5 M NaCl in solution containing 0.1 M Tris, pH 7.8 and 10% acetonitrile at a flow rate of 1.0 mL/min

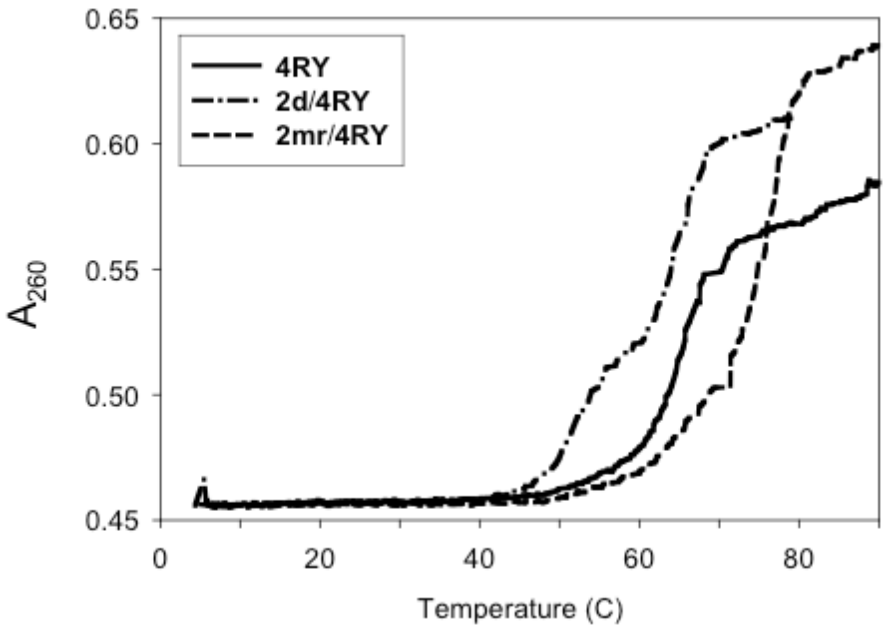

Figure S3 *Melting curves of triplexes formed by deoxyribo- and 2'-O-methylribo-TFOs.* Absorbance versus temperature profiles were recorded for solutions containing 1 μM deoxyribo-TFO **2d** and 1 μM **4RY**, 1 μM 2'-*O*-methylribo-TFO **2mr** and 1 μM **4RY**, or 1 μM **4RY** alone in pH6.5 triplex buffer. In the case of the **2d**/**4RY** triplex, the first transition corresponds to dissociation of the TFO from the triplex and the second transition corresponds to dissociation of duplex **4RY**. The single transition observed for triplex **2mr**/**4RY** indicates that all three strands dissociate simultaneously at a temperature above the melting temperature of the duplex **4RY**.

Efficient Gene Delivery with Osmotically Active and Hyperbranched Poly(ester amine)s

Received April 22, 2009; Revised Manuscript Received October 22, 2009

Degradable and hyperbranched poly (ester amine)s (PEAs) were successfully synthesized by Michael addition reaction between hydrophilic glycerol triacrylate (GTA) and low-molecular-weight polyethylenimine (LMW-PEI) and evaluated as nonviral gene carriers. PEAs effectively condensed DNA with particle sizes below 200 nm and suitable surface charges (15−45 mV), suitable for intracellular delivery. PEAs degraded in a controlled fashion showing half-lives of more than 12 days and were essentially nontoxic in three different cell lines. Elevated transfection levels by luciferase assay revealed the superiority of PEAs over PEI 25K and Lipofectamine. PEAs synthesized using 1:4 mol ratio of GTA to PEI [GTA/PEI-1.2(1:4)] showed highest transfection efficiency in HepG2 cells. PEAs showed significant gene expression *in vitro* as well as *in vivo* through aerosol administration. Reduction in packed cell volume (PCV) of cells when treated with polyplexes supported the hyperosmotic effect of PEAs. Effect of bafilomycin A1 on transfection efficiency of PEAs on 293T cells indicated its endosomal buffering capacity. High transfection efficiency was attributed to the synergism from hyperosmotic glycerol backbone in the PEAs and endosomal buffering capacity of PEI amine groups. Therefore, this convergence of osmotically active biodegradable PEAs suggests their potential as a safe and efficient gene delivery vector.

INTRODUCTION

The human genome project has substantially increased our knowledge about molecular mechanisms of cancer during the past decade, thus opening up new possibilities for cancer gene therapy. Gene therapy is one of the most challenging and promising therapies of inherited and acquired diseases. However, the lack of safety and efficient gene carriers limits the success of gene therapy. Viral vectors are more potent gene delivery vehicles because of their specific machinery to enter the cell and to deliver the nucleic acid into the cell and into the nucleus (*1, 2*). However, severe immune responses, limited insert size, and insertional mutagenesis risk limits their use as a successful gene delivery vehicle. Polymeric vectors have remarkable advantages as gene delivery vectors which make them a promising alternative to most efficient recombinant viruses (*3*−*6*). Polyethylenimine (PEI) is one of the successful and widely used gene delivery polymers which have become the gold standard of nonviral gene delivery because of its proton sponge effect (*7, 8*). However, several groups have reported that PEI is cytotoxic in many cell lines. Moreover, higher molecular weight reveals higher toxicity and high transfection efficiency compared with low-molecular-weight PEI (LMW-PEI) (*9, 10*).

Several natural and synthetic biodegradable polymers such as polyesters (*11, 12*), linear poly(ester amine)s (*13, 14*), polypeptides (*15*), PEA networks (*16*), and cyclodextrins (*17*) are among the most preferable materials for the preparation of nonviral vectors in terms of their long-term safety and biocompatibility. Our group developed various biodegradable polymeric gene carriers using LMW-PEI and various cross-linkers such as poly(ethylene glycol) diacrylate (PEGDA) (*18*), polycaprolactone diacrylate (PCLDA) (*19*), poloxamer diacrylate (GDM) (*20*), and glycerol dimethacylate (*21*) to reduce cytotoxicity and increase transfection efficiency. Various strategies to enhance transfection efficiencies and reduce cytotoxicity and polyplex stability are being explored. One approach is the generation of biodegradable polymers by cross-linking LMW-PEI having low cytotoxicity with various cross-linkers so as to produce high-molecular-weight polycations with high transfection efficiency and reduced cytotoxicity.

It is noteworthy that successful carriers possess sufficient DNA binding ability, effective polyplex uptake by cells, subsequent release into cytoplasm, trafficking of polyplex to nucleus, and immediate dissociation of the polyplex. On the basis of the reports by Zauner et al., polyplex uptake and its subsequent release from endosomal environment to the cytoplasm have been considered as one of the rate-limiting steps for successful delivery of gene (*22*). In correlation with the above assumptions, our approaches to enhance transfection efficiency, reduce cytotoxicity, and increase cellular uptake are designed on the synthesis of biodegradable poly(ester amine) (PEA) containing LMW-PEI and hydrophilic glycerol triacrylate (GTA) as a cross-linker. PEAs based on GTA and LMW-PEI will facilitate cellular uptake by exerting a hyperosmotic effect owing to the presence of a glycerol backbone while PEI residues will enhance the endosomal release by the "proton sponge effect".

MATERIALS AND METHODS

Materials. Branched PEI (1.2 and 25 kDa), glycerol triacrylate (GTA) (MW: 254 Da), and anhydrous methanol were purchased from Sigma (St. Louis, MO, USA) and were used as received. Cell Titer 96 AQueous One Solution Reagent for cell viability, luciferase reporter 1000 assay system for *in vitro*

transfection and pGL3-control vector with SV-40 promoter, and enhancer encoding firefly (*Photonus pyralis*) luciferase were obtained from Promega (Medison, WI, USA). Plasmid pEGFP-N_2, which has the early promoter of CMV and enhanced green fluorescence protein (EGFP) gene, was obtained from Clontech (Palo Alto, CA, USA). The plasmid was amplified with a competent *E. coli* strain JM109.

Synthesis of PEAs. PEAs were successfully synthesized following modified Michael addition reaction as reported previously (*19*). Briefly, GTA and LMW-PEI (M_n: 1.2 kDa) were separately dissolved in anhydrous methanol, and GTA solution was slowly added to PEI solution at three different GTA/PEI stoichiometric ratios (Table 1). The reaction mixtures were heated at 60 °C with constant stirring for 24 h. Subsequently, the reaction mixtures were dialyzed at 4 °C for 24 h using Spectra/Por membrane (molecular mass cutoff 3.5 kDa; Spectrum Medical Industries, Inc., California) against distilled water. Finally, the polymers were lyophilized and stored at 0 °C.

Characterizations of PEAs. ^{1}H NMR samples were prepared by dissolving polymers in $CDCl_3$ at a concentration of 10 mg/mL. NMR spectra were recorded using Avance 500 spectrometer (Bruker, Germany). Absolute molecular weights of the polymers were measured by gel permeation chromatography coupled with multiangle laser light scattering (GPC-MALLS) using Sodex OHpack SB-803 HQ (Phenomenox, USA) column (column temperature at 25 °C; flow rate 0.5 mL/min). Ammonium acetate (0.5M, pH 5.5) was used as a mobile phase (*19*).

Degradation of PEAs. The extent of polymer degradation was estimated by measuring the reduction in molecular weight of PEAs. Polymers dissolved in PBS (0.1 g/mL) were incubated in a shaking incubator (37 °C; 100 rpm) and sampled at various time intervals. Subsequently, the lyophilized samples were subjected to GPC for molecular weight determination.

Complexation Study. Polymer/pDNA complexation was carried out in sterilized distilled water by gently mixing DNA (pGL3 control; 0.1 μg) with polymer solutions (10 μL) at various N/P ratios to mitigate the possibilities of mechanical damage of DNA. The complexes were incubated at room temperature for 30 min, and a 12 μL volume including loading dye mixture was loaded on 0.8% agarose gel containing ethidium bromide (0.1 μg/mL). The gel was run with tris-acetate buffer at 100 V for 40 min. The gel image was captured under UV illumination.

Protection and Release Assay of DNA. Protection and release of DNA in complexes were measured using electrophoresis, according to the method in our previous reports (*19*).

Particle Size and Zeta Potential Measurement. Particle sizes and zeta potentials of polymer/DNA complexes (prepared in water at various N/P ratios) were measured using dynamic light scattering spectrophotometer (DLS) (ELS8000, Otsuka Electronics, Osaka, Japan), with 90 and 20° scattering angles, respectively. Polymer/DNA complexes were prepared in water from N/P ratios 1 to 30.

Transmission Electron Microscopy (TEM). The morphology of PEA/DNA complexes was observed using energy filtered TEM (EF-TEM) (JEM 1010, JEOL, Japan).TEM specimens were prepared by placing a drop of PEA/DNA complexes on a copper grid and stained with 1% uranyl acetate solution for 5 s. The specimens were allowed to dry further for 10 min and were then examined under the microscope.

Cell Lines and Cell Culture. Human cervix epithelial carcinoma cells (HeLa), human hepatoblastoma cells (HepG2), and human kidney transformed cells (293T) were maintained in a DMEM culture medium supplemented with 10% heat-inactivated FBS, penicillin/streptomycin. Cells were grown under standard conditions, in a 37 °C humidified incubator containing 5% CO_2.

Cell Viability Assay *in Vitro*. Cell viability of PEAs was investigated by Cell Titer 96 Aqueous One Solution Cell Proliferation Kit (Promega). Cells seeded in 96 well plate at an initial density of 1×10^4 (HeLa and 293T) or 2×10^4 (HepG2) cells/well in 0.2 mL growth medium were incubated for 18−20 h to reach 80% confluency prior to the addition of PEAs. Growth medium was replaced by fresh serum-free media containing PEA solutions at various concentrations (5, 10, 20, and 40 μg/mL), and the cell viability study was carried out by the method reported in our previous reports (*19*).

***In Vitro* Cell Transfection.** All assays were conducted in 24 well plates. One milliliter of HeLa, 293T and HepG2 cell cultures (for HeLa and 293T, 1×10^5 cells/mL; and for HepG2, 2×10^5) was grown to ∼70−80% confluency under standard incubation conditions. The media in the wells were replaced with either serum-free media or 10% serum-containing media supplemented with 1 μg of polymer/pGL3 complexes of various N/P ratios, and incubated at 37 °C for 6 h. Subsequently, serum-free media were replaced with fresh media containing serum and incubated for additional 24 h under standard incubation conditions. The luciferase assay was carried out per manufacturer's protocol (Promega). Relative light units (RLU) were measured with chemiluminometer (Autolumat, LB953, EG&G Berthold, Germany). The obtained RLUs were normalized with respect to protein concentration in the cell extract determined using BCA protein assay kit.

Flow Cytometry and Confocal Microscopy Study. The transfection efficiency was also verified by flow cytometric measurement using EGFP reporter gene. 293T cells after being transfected with PEA/pEGFP-N_2 were washed with PBS and trypsinized. Transfection efficiency was evaluated by scoring the percentage of cells expressing green fluorescence protein using a FACS Calibur System from Becton-Dickinson (San Joes, CA). The experiments were performed in triplicate and 20 000 cells were counted in each experiment (*21*).

293T cells were plated on collagen-coated glass coverslips in 24 well plates (5×10^4 cells/well) and were grown to ∼60−70% confluency. The media were then replaced with serum-free media containing PEA/pEGFP-N_2 (1 μg) complexes (N/P ratio 30). After 6 h of incubation, serum-free media were changed with fresh media containing serum and incubated for additional 18 h. Cells were washed twice with PBS and immobilized by adding 200 μL of 2% glutaraldehyde solution. The coverslips were washed with PBS and enclosed in glycerol, and finally, the cells were visualized by confocal laser scanning microscopy (CLSM) (Micro Systems LSM 410, Carl Zeiss, Germany) equipped with a 488 nm argon/krypton laser. Fluorescence emission was collected using a 515 nm/30 nm

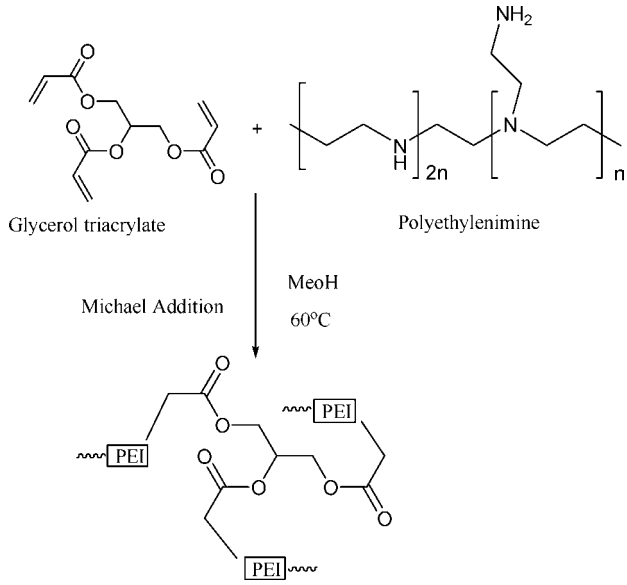

Figure 1. Synthesis scheme of PEAs. GTA linker reacts with primary and secondary amines of PEI resulting in formation of ester bonds.

bandpass filter. Cells treated with only PBS or polymers were taken as controls.

Packed Cell Volume Measurement. Trypsinized 293T cells were centrifuged and resuspended in DMEM supplemented with 10% FBS. To monitor the effect of glycerol content (wt %) in PEAs on packed cell volume (PCV), different concentrations of PEAs and/or PEA/DNA complexes were then added to the cell suspensions. For each set, 1 mL of cell suspension was transferred to a mini-PCV tube (TPP, Trasadingen, Switzerland) and centrifuged for 1 min at 5000 rpm. The volume of the packed cells in the graduated capillary was reported as the % PCV and compared with the experiments done under the identical conditions using different concentrations of glycerol instead of PEA/DNA complexes as control.

Effect of Bafilomycin A_1. 293 T cells seeded in 12 well plates (2×10^5 cells/well) were incubated for 18 to 20 h to reach 80% confluency. The cells were incubated for 10 min before transfection, with endosome proton pump inhibitor, bafilomycin A1 (a specific inhibitor of vacuolar type H^+-ATPase). The cells were then subjected to *in vitro* luciferase assay as described above. The cells without treatment with bafilomycin A1 were taken as control.

***In Vivo* Transfection.** Aerosol administration in mice was carried out to determine the *in vivo* transfection ability of PEAs. Thirteen-week-old female BALB/c mice, maintained at 23 ± 2 °C and relative humidity of 50 ± 20%, were placed in nose-only exposure chamber (NOEC; Dusturbo, Seoul, Korea) and exposed to aerosol administration. Aerosol was prepared using 1 mg of pEGFP-N_2 plasmid DNA, and transfection ability of PEAs was evaluated according to a method previously reported (*19*).

RESULTS AND DISCUSSION

Synthesis and Characterization of PEAs. In general, PEAs are formed from nucleophilic addition of amines to acrylates under normal conditions. The main objective of this study is to rationally design, characterize, and evaluate a novel class of potentially safe, biodegradable, and hyperbranched polymers with poly(ester amine) backbone based on hydrophilic glycerol triacrylate and LMW-PEI. Hyperbranched PEAs were obtained using LMW-PEI (M_n: 1200 Da) as amine nucleophile and glycerol triacrylate (GTA) as a cross-linker at different stoichiometric ratios in anhydrous methanol through Michael addition reaction (Figure 1). The absence of water during synthesis should prevent hydrolysis of sensitive ester linkages. Triacrylate linker reacts with PEI by Michael addition reaction to either primary or secondary amines, generating ester-based

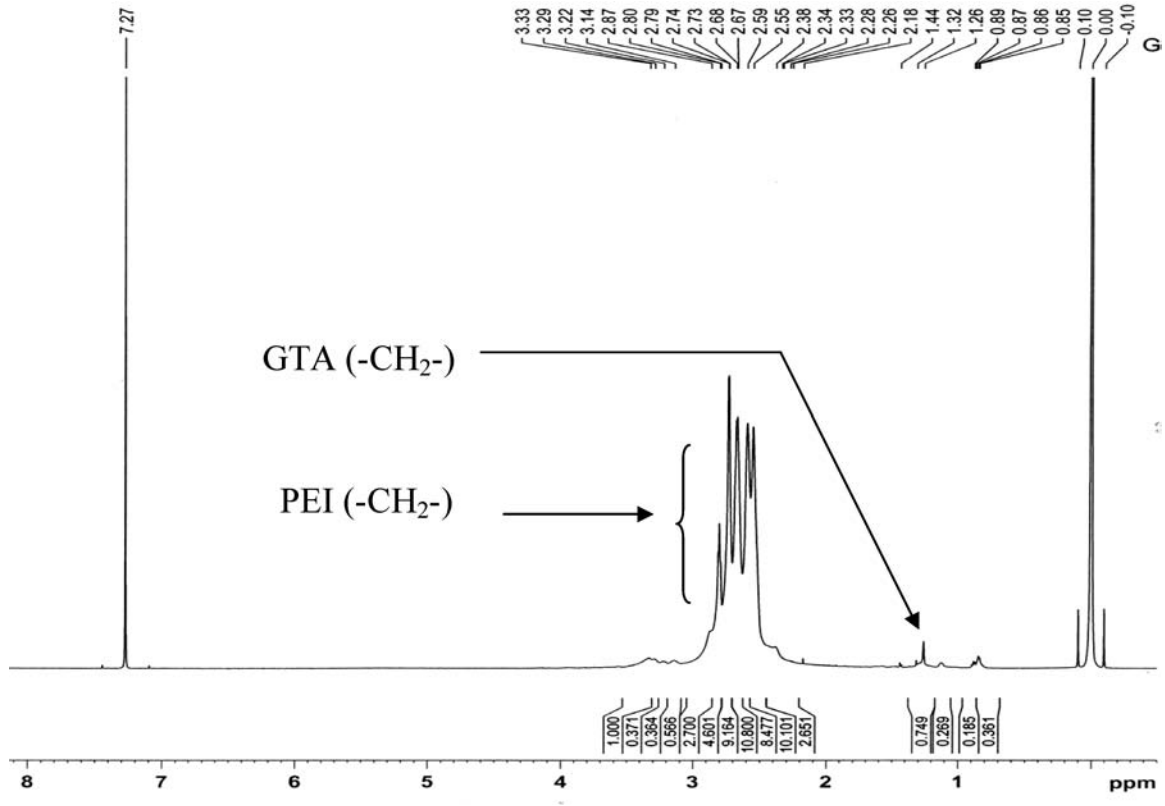

Figure 2. Representative ^{1}H NMR spectrum of PEA [GTA/PEI-1.2(1:4)] in $CDCl_3$.

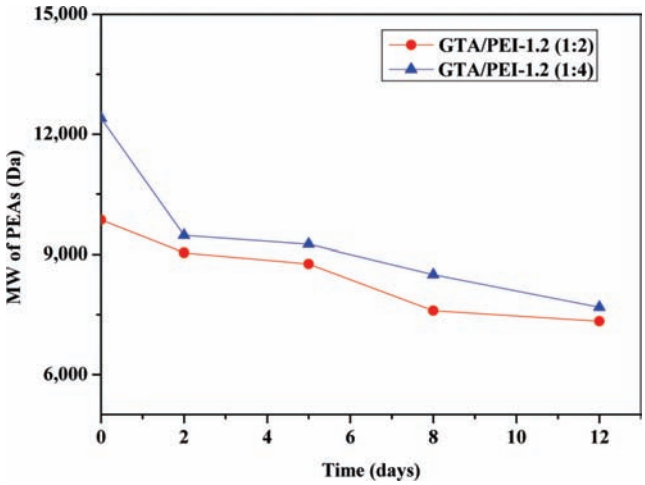

Figure 3. Degradation pattern of PEAs.

polymers. An excess of cross-linker resulted in gelation and originated highly cross-linked polymers insoluble in aqueous media. Unlike the reaction condition mentioned in our earlier previous work, the reaction was carried out at slightly elevated temperature (60 °C) to increase the cross-linking and thereby the molecular weight of final polymer (*19*, *21*). The characteristics of synthesized PEAs at different GTA/PEI stoichiometric ratios are summarized in Table 1. Unlike the reports by Langer group, no significant difference in the MW of PEAs was observed through variation in stoichiometric ratio of GTA to LMW PEI (*13*). The compositions of synthesized PEAs were confirmed through ^{1}H NMR spectroscopy (Figure 2). The signals at δ 1.3 ppm are related to GTA protons, which are highlighted by arrows. The signals of PEI protons were found in the range δ 2.2−3.0 ppm. The ratios of integrals of GTA protons to PEI protons and molecular weight are shown in Table 1.

Unlike our previous reports, the composition of PEAs was found to match those of the stoichiometric feed ratios of the reactants (*21*). Cross-linking of these small polycations using potentially degradable linkages was conceived as a way of increasing molecular weight and thus enhanced DNA binding capacity and polyplex stability while maintaining their nontoxic nature and high transfection efficiency. One feature that has to be fulfilled by the compacting domains is high DNA binding affinity and, moreover, the ability to form stable DNA complexes. As DNA binding activity of polyplexes is strongly influenced by charge density and molecular weight (*23*), the biophysical characterization provided preliminary information about the original structures. It has been shown from the reports of Lynn et al. that DNA condensation, transfection efficiency, and cytotoxicity are significantly affected by the molecular weight of the carrier. In addition, monomer structure, choice of solvent, and reaction temperature affects the average molecular weight of polymer which lies in the range 2000−50 000 Da (*8*, *24*). GPC-MALLS measurements were performed to characterize PEAs, and it was found that maximum molecular weights were observed at equivalent stoichiometric ratios as reported by Langer group and our previous reports (*14*, *19*). The average molecular weights of synthesized PEAs were found not to vary widely (4190 to 5480 Da), with polydispersity indices close to 2 indicating the difficulty in controlling cross-linking by simple change in reactant feed ratio (Table 1). To determine the degradability, PEAs were subjected to aqueous degradation environment incubated at 37 °C and aliquots were removed at appropriate time points. The degradation was calculated by measuring the reduction in the molecular weight. Figure 3 shows the degradation profile of PEAs as a function of time. The results showed that PEAs degraded slowly and

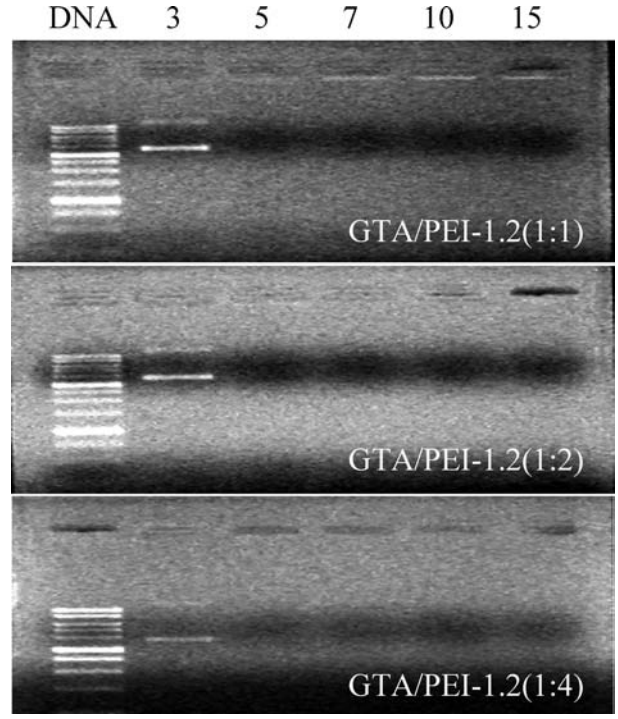

Figure 4. Agarose gel electrophoresis of PEA/DNA (pGL3-control) complexes at various N/P ratios: (a) GTA/PEI-1.2 (1:1), (b) GTA/PEI-1.2 (1:2), and (c) GTA/PEI-1.2 (1:4). 0.1 μg pDNA was used to prepare complexes with PEAs.

the half-life of degradation was approximately more than 12 days. Absence of cytotoxicity is one of the significant features for *in vivo* application of any polymeric gene carriers. Generally, cytotoxicity arises from accumulation of nondegraded and nondischarged polymers in the cell (*16*). The ester bonds in PEAs are susceptible to hydrolysis at physiological conditions to form the respective diol linker and amino acid, thereby generating low-molecular-weight nontoxic byproduct.

PEA/DNA Polyplex Characteristics. One feature that has to be fulfilled by the compacting domains is high DNA binding affinity and, moreover, the ability to form stable DNA complexes. The ability of polymers to complex with plasmid DNA (pGL3) was demonstrated using agarose gel electrophoresis. The band of pGL3-control was retarded as the amount of PEAs increased. As shown in Figure 4, all PEAs have a great capacity to condense DNA effectively where pGL3-control was completely retarded at N/P ratio 5. In contrast, the pDNA band was completely moved. N/P ratio 5 at which all PEAs showed complete DNA binding was considered in future characterization.

Effective DNA condensation by polycation and polyplex stability are important requirements for DNA stability against degradation by nucleases (*25*). PEA efficacy to protect DNA from attack of DNase-I was confirmed by agarose gel electrophoresis. PEAs were able to guard DNA as compared with naked DNA, which was completely degraded by DNase-I (data not shown).

Successful transfection efficiency of gene carrier depends on its ability to condense negatively charged DNA into nanosized particles with positive charges so as to enter into the cell. The size and surface charge of PEA/DNA complexes were measured using dynamic light scattering as shown in Figure 5. It was found that all three PEAs effectively condensed DNA into nanosized, positively charged polymer/DNA complexes. Lower amounts of polymer tended to give larger nanoparticles owing to the aggregation. An increase in PEA/DNA charge ratio produced smaller-sized nanoparticles. All three PEAs showed

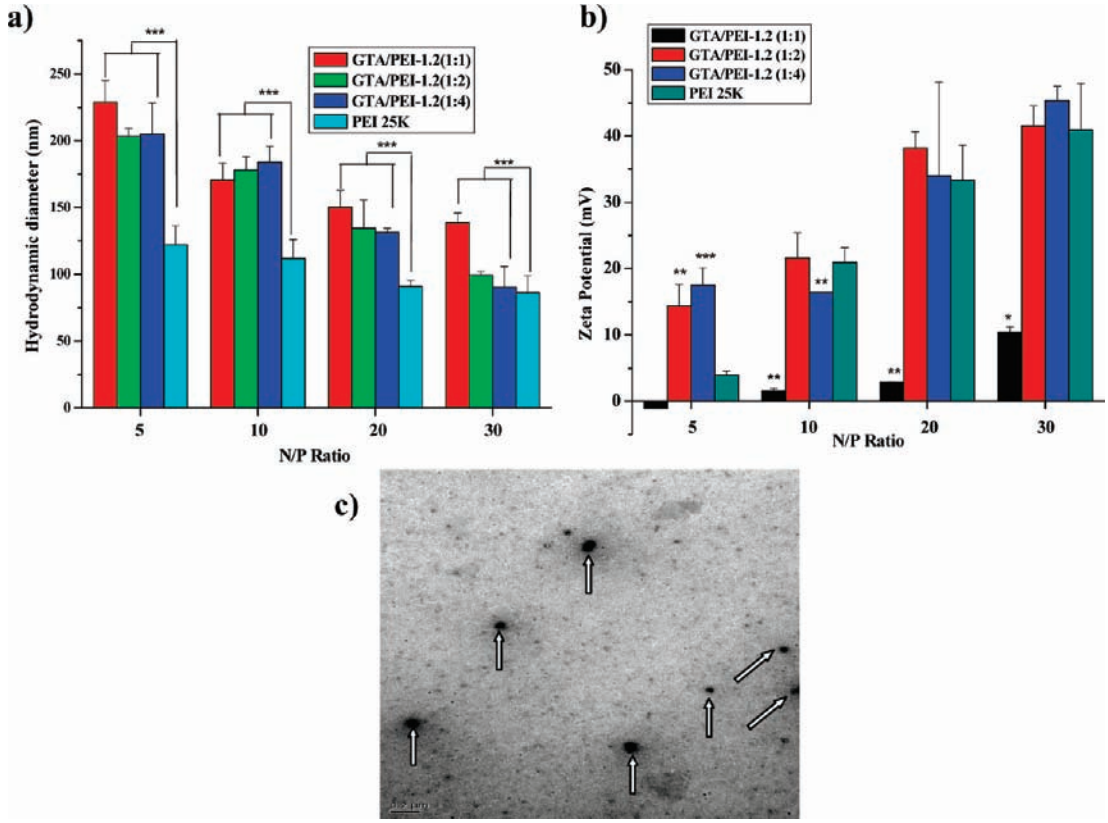

Figure 5. Biophysical properties of PEA/DNA complexes at various N/P ratios: (a) particle size measurement of PEA/DNA complexes, (b) zeta potential measurement of PEA/DNA complexes, and (c) EF-TEM images of GTA/PEI-1.2(1:4)/DNA complexes at N/P ratio 30 ($n = 3$). (*$p < 0.1$; **$p < 0.05$; ***$p < 0.01$, two-tailed Student's *t*-test).

polyplex sizes below 200 nm which are suitable for intracellular delivery. In all three PEA cases, the polyplexes had positive surface charges in the range 15−45 mV. An increase in the charge ratio from 5 to 30 increased the surface charge of the polyplexes from 15 to 45 mV as shown in Figure 5b. In correlation with our previous findings, the particle size and zeta potential results of PEA/DNA polyplexes typically match the DNA condensation pattern where DNA was initially condensed into larger particles upon addition of cationic PEAs through a charge neutralization mechanism (*19, 21*). The particle sizes and zeta potential measurements indicated that polymer/DNA complexes were cationic with effective diameter below 200 nm and surface charges cationic enough for attachment to anionic cell surfaces. These features suggest that PEA/DNA particles are cationic enough for association with negatively charged cell membranes and subsequent endocytosis.

For efficient endocytosis and transfection, the polyplexes must be small, compact, and spherical. The morphology of PEA/DNA polyplexes was observed by EF-TEM. Figure 5c shows morphology of GTA/PEI-1.2(1:4) at N/P ratio 30. The GTA/PEI-1.2(1:4)/pDNA polyplexes reveal the formation of spherical nanoparticles with an average diameter smaller than that obtained in particle size measurement.

Cell Cytotoxicity. Cell compatibility studies were performed by incubating PEA solutions in different concentrations on cells and assessing the metabolic activity by MTS-based cell viability method after 24 h. PEAs prepared from hydrophilic glycerol triacrylate and LMW-PEI have remarkably low cytotoxicity in all three cell lines compared with highly cytotoxic PEI 25K. As depicted in Figure 6, all PEAs showed reduced cytotoxicity with concentrations as high as 60 μg/mL. In contrast, PEI 25K showed significant cytotoxicity reflected by the fact that less than 40% of the cells were viable when the concentration of PEI 25K was higher than 20 μg/mL. Among the many attempts to reduce the cytotoxicity of the gene carrier, the introduction of biodegradable linkage, i.e., ester linkage, has been the prominent method until today (*11*−*14*, *18*−*21*). Reduced cytotoxicity of PEAs is undoubtedly a significant advantage of the degradable ester linkage over nondegradable PEI 25K. It also appears that the reduced cytotoxicity may be correlated with PEA degradation. The increased cell viability is undoubtedly due to the nontoxic building blocks and biodegradation products appearing from the ester backbone of PEAs. It is noteworthy that cytotoxicity of PEAs is cell-line dependent and free polymers are usually more toxic to cells and tissues, while the cytotoxicity is reduced when polymers are complexed with DNA (*10, 26*). As shown in Figure 6, interestingly all PEAs revealed at least 70% cell viability in all three cell lines at concentration as high as 60 μg/mL. In contrast, in case of nondegradable PEI, it aggregates on cell surface, thereby impairing important membrane functions (*10*), and reduces cell viability. MTS assay results clearly indicated the significant cell viability of PEAs, and thereby, it is potential as a safe gene carrier.

***In Vitro* Transfection by Luciferase Assay.** The ability of PEAs based on GTA and LMW-PEI to deliver DNA into cells was determined by performing luciferase reporter gene transfections. Figure 7 shows the transfection efficiency of PEAs in HeLa, HepG2, and 293T cells. *In vitro* luciferase activity of PEAs was assessed in triplicate using 1 μg of pGL3 complexed with PEAs at various N/P ratios from 5 to 30. After 48 h gene expression time, lysates of transfected cells were assessed for luciferase activity by measuring the relative light units (RLUs) normalized by total protein content. All PEAs showed increase in reporter gene expression owing to effective DNA binding ability thereby forming nanosized polyplexes. Interestingly, all PEAs were able to mediate higher levels of gene expression despite lower levels of molecular weight. Consistent with our

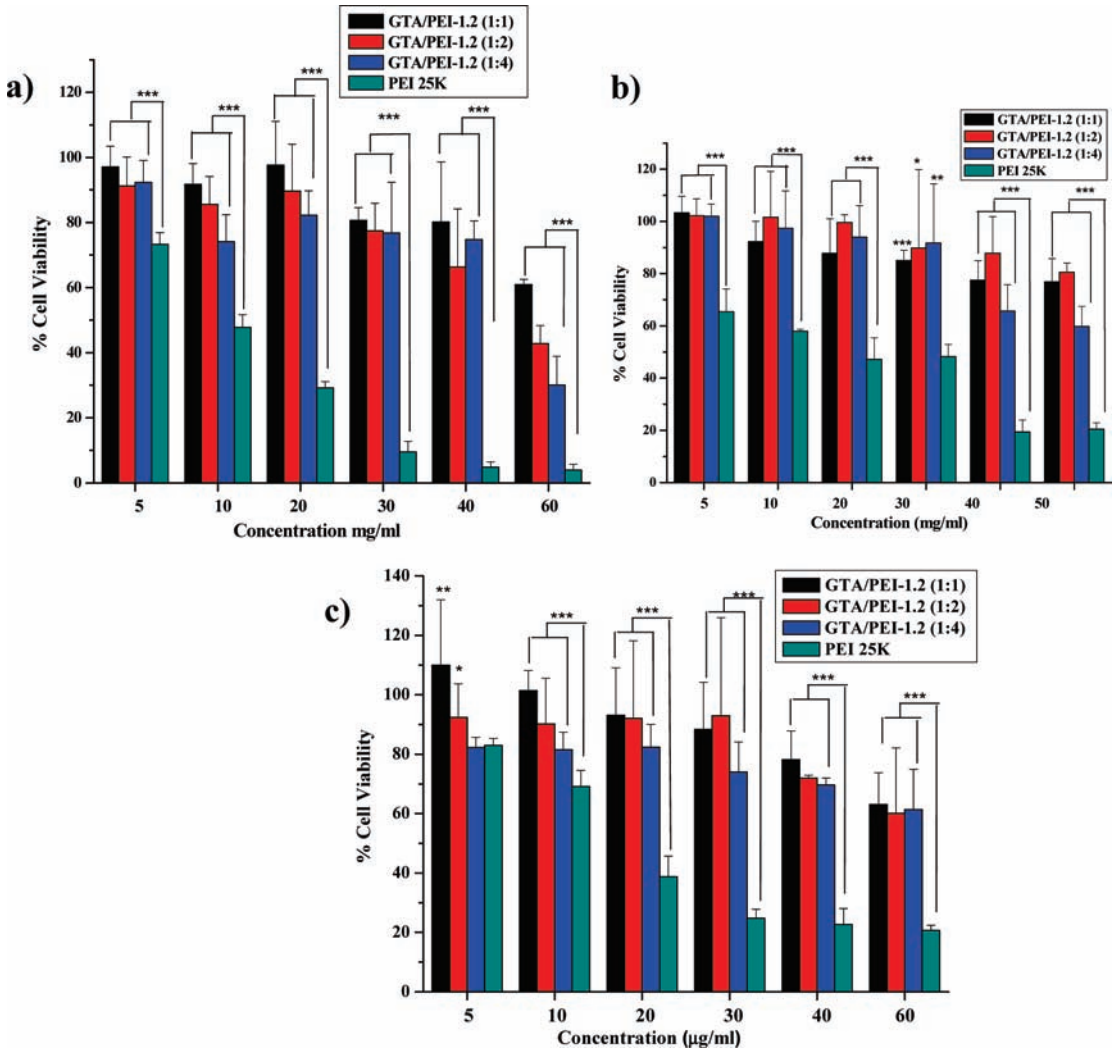

Figure 6. Cytotoxicity of PEAs at various concentrations in different cell lines: (a) HeLa, (b) HepG2, and (c) 293T cells (*$p < 0.1$; ** $p < 0.05$; ***$p < 0.001$, two-tailed Student's *t*-test) ($n = 3$, error bar represents standard deviation).

previous work (*21*), PEAs composed of GTA and LMW-PEI also revealed higher gene expression levels owing to the presence of biodegradable ester linkage, thereby reducing the cytotoxicity. It was noteworthy that GTA/PEI-1.2(1:4) showed 30−35-fold higher transfection levels compared with "golden standard" PEI 25K at N/P ratio of 30 in all three cell lines. Reporter gene expressions in HeLa and 293T cells remained at rather similar levels in the case of all three PEAs probably due to a smaller difference in the molecular weights, as transfection efficiency of PEAs was shown to be dependent on molecular weight, in correlation with the reports by our group and Mikos group (*9, 19, 21*). As expected from our previous results, transfection results of GTA/PEI-1.2 copolymers followed a somewhat similar pattern where the introduction of an ester bond with hydrophobic/hydrophilic balance boosted the gene-carrying activity on one hand and reduced cytotoxicity on other hand, which is also in agreement with reports by Anderson et al. (*19, 27*). Unlike our previous reports, the extent of hydrophobicity in GTA/PEI-1.2 copolymers is higher than GDM/PEI-1.2 owing to the absence of a free hydroxyl group (*21*). Even though PEI 25K is a highly transfection efficient polymer used in gene delivery, its transfection was decreased with increasing charge ratio owing to its cytotoxicity. As depicted in Figure 7, it was found that the transfection efficiency of PEAs in HepG2 cells was in the order GTA/PEI-1.2(1:1) < GTA/PEI-1.2(1:2) < GTA/PEI-1.2(1:4).

Figure 7d shows the transfection efficiency of PEA/pDNA complexes with and without serum in HeLa cells at N/P ratio of 30. A normal difference was found between the transfection abilities of PEAs in the absence and presence of serum. Polyplexes prepared from PEAs and pDNA were stable and showed a quite similar transfection profile in the presence and absence of 10% serum owing to the hydrophilic property of glycerol moieties in PEA backbone, which correlates with our previous reports (*21*). This also matches the hypothesis reported by Kabanov et al. where complexes formed by P123-*g*-PEI (2K) and DNA in the presence of free polaxamer reveals stability in a variety of conditions especially in the presence of serum (*28*). All three PEAs showed a little decrease in the gene expression level when tested in the presence of serum compared with serum-free transfection. On the other hand, PEI 25K showed a significant reduction in the transfection level when tested in the presence of serum.

Confocal Microscopy and Flow Cytometry. The transfection ability of PEAs was also checked using GFP gene by CLSM and flow cytometry. Figure 8a shows the GFP reporter gene expression shown by PEAs using confocal microscopy in A549 cells. Optimized charge ratios (N/P ratio 30) of PEA/pDNA complexes (checked by Luciferase assay) were used for confocal experiments. Polyplexes containing PEA/pEGFP-N_2 transfection complexes transfected into A549 cells and revealed interesting

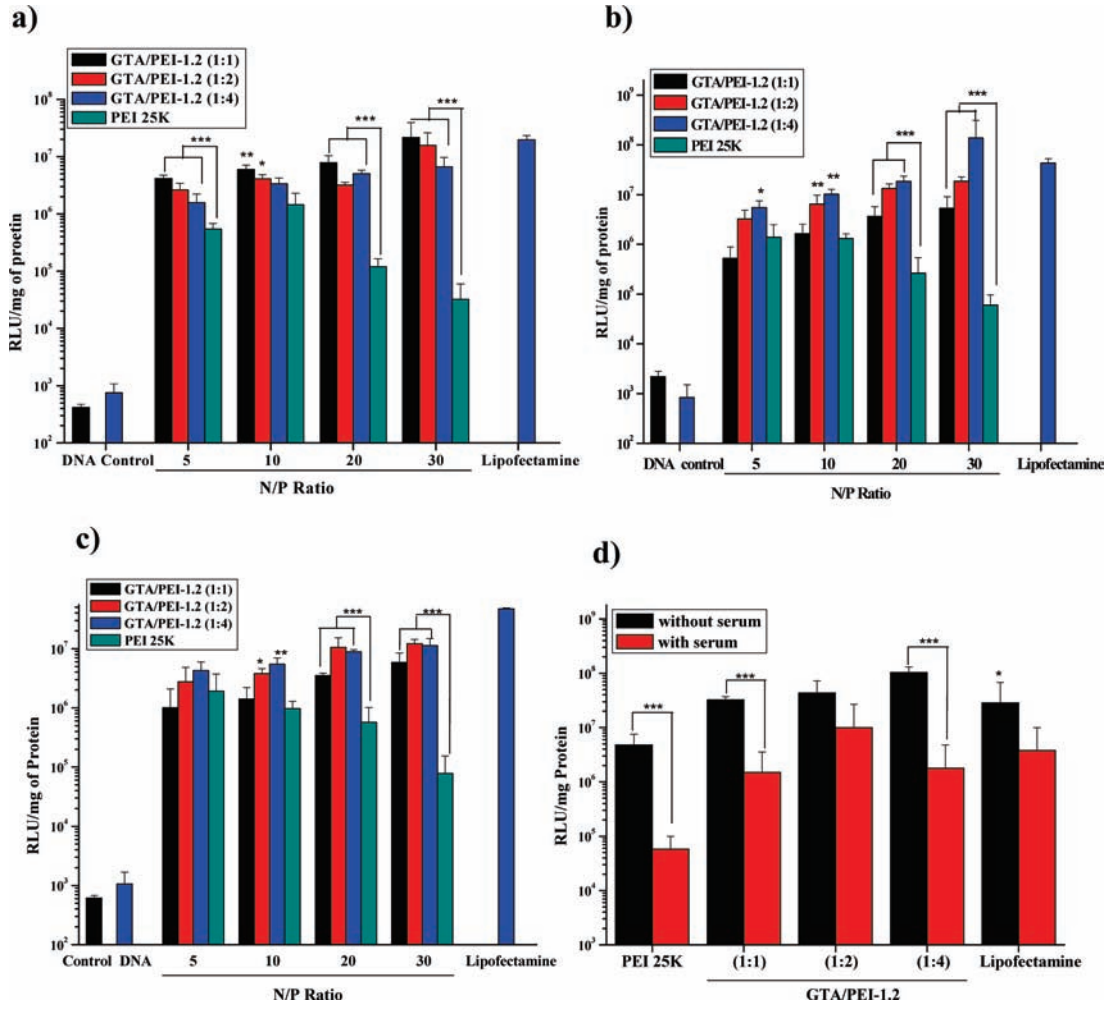

Figure 7. Luciferase activity of PEA/pGL3-control at various N/P ratios in three different cell lines: (a) HeLa, (b) HepG2, (c) 293T, and (d) with and without serum on HeLa cells (*$p < 0.1$; **$p < 0.05$; ***$p < 0.01$, two-tailed Student's *t*-test) ($n = 3$, error bar represents standard deviation).

fluorescence compared with PEI 25K in correlation with luciferase assay results.

The transfection efficiency of PEAs using pEGFP-N_2 was also monitored by flow cytometry. Flow cytometry studies in 293T cells revealed a significantly high level of transfection as shown in Figure 8b. With increasing N/P ratio, the maximum in transfection efficiency shifted to polyplexes made with GTA/PEI-1.2(1:4) at N/P ratio of 30. The mean fluorescence intensity of pEGFP-N_2 positive cells can serve as the average expression of GFP per cell. In contrast, PEI 25K showed optimum transfection at N/P ratio of 10 and further decreased up to 30 owing to its cytotoxicity. This significant increase in transfection efficiency of PEAs is undoubtedly the advantage of ester linkage which on one hand increases the momentum of transfection efficiency and on the other hand reduces the cell cytotoxicity. The above results of transfection level as a measure of luciferase and GFP expression clearly indicate the excellence of PEAs over PEI 25K as a potential gene carrier.

Effect of Bafilomycin A1. To elucidate the mechanism of transfection efficiency of PEAs, we analyzed the effect of bafilomycin A1, an endosome proton pump inhibitor (*29*) on the transfection efficiency of PEA in 293T cells. Reporter gene expression shown by PEAs was reduced by more than 20−25-fold when transfected in the presence of 200 nM bafilomycin A1, compared to the experiments without inhibition of endosomal acidification as shown in Figure 9a. The decrease in reporter gene expression levels shown by PEAs in the presence of bafilomycin A1 is undoubtedly the advantage of the presence of PEI moieties in the PEA backbone which acidifies these endosomal vesicles, thereby allowing the influx of water and swelling and bursting the endosome. Thus, PEAs with significant bursting capacity in the lysosomal pH range show a much higher transfection capability. The evidence of the reduction in transfection efficiency of PEAs in the presence of bafilomycin A1 strongly suggests the involvement of the proton sponge effect in PEI-mediated transfection.

Estimation of Hyperosmolarity of PEAs. Nevertheless, it has not been shown yet whether the presence of glycerol moiety in the PEA backbone has any effect on increased cell cellular uptake and thereby increased transfection efficiency. To elucidate the mechanism of increased transfection efficiency of PEA through increased cellular uptake, we analyzed the reduction in packed cell volume in 293T cells when treated with PEA/pDNA polyplexes. To determine the impact of the osmotic effect of polyplexes containing PEAs, 293T cells were suspended in DMEM with 10% FBS and GTA/PEI-1.2(1:4)/pGL3 complexes with varying glycerol content (3, 4, and 5 wt %) in the polymer backbone and the same protocol followed as reported by us previously (*21*). As shown in Figure 9b, GTA/PEI-1.2(1:4)/pGL3 complexes with increasing glycerol content (viz. 3, 4, and 5 wt %) reduced PCV by 18%, 17%, and 27%, respectively. The differences in the osmolarity of different glycerol solutions and polymer/DNA polyplexes are also shown in Table 2. Pure glycerol was used as a control in the same amounts of

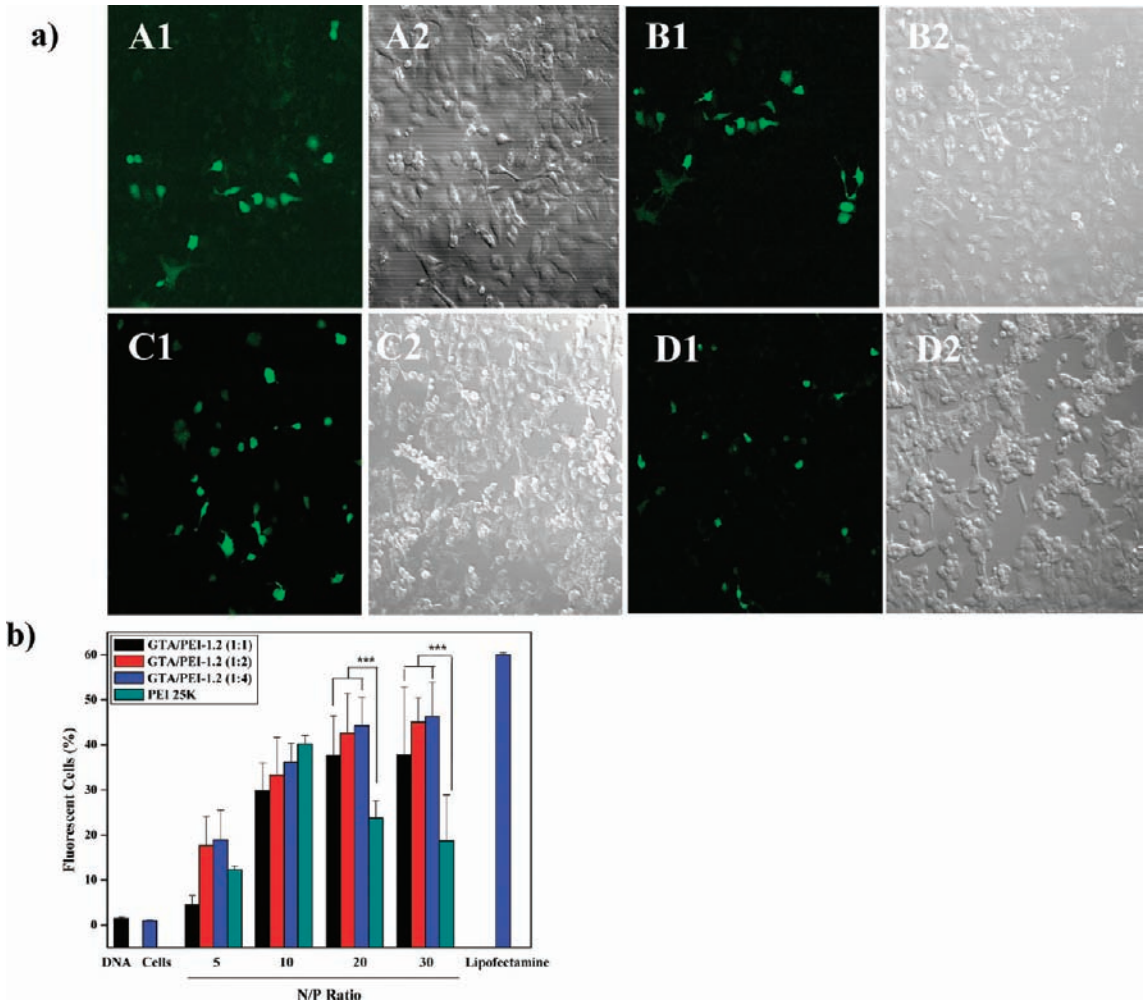

Figure 8. (a) GFP expressed in the A549 cell line transfected with PEA/pEGFP-N_2 complexes at N/P ratio of 30. A1, B1, C1, and D1 represent the fluorescent images of the pEGFP-N_2 reporter gene complexed with GTA/PEI-1.2(1:1), GTA/PEI-1.2(1:2), GTA/PEI-1.2(1:4), and PEI 25K, respectively. Phase contrast images are also shown along with fluorescent images, respectively (A2 to D2). (b) pEGFP-N_2 expressed in 293T cells transfected with PEA/DNA (pEGFP-N_2) complexes at various N/P ratios and analyzed by flow cytometry (*$p < 0.1$; **$p < 0.05$; ***$p < 0.01$, two-tailed Student's *t*-test) ($n = 3$, error bar represents standard deviation).

concentration (3, 4, and 5 wt %) and revealed 20%, 20%, and 38% reduction in PCV, respectively, whereas almost a 50% decrease in cell volume was observed as a result of exposure to 10 wt % glycerol in DMEM.

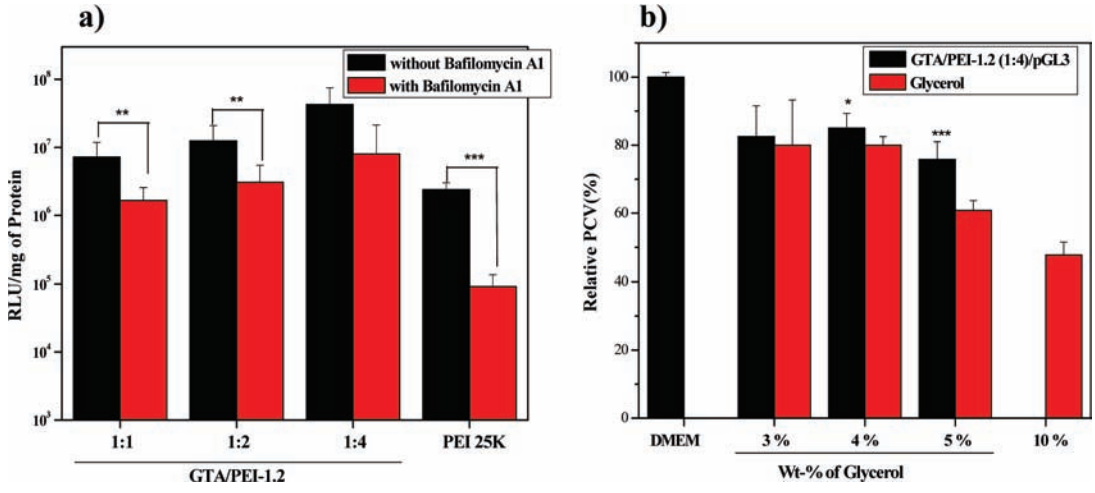

Figure 9. (a) Effect of bafilomycin A1, an inhibitor of vacuolar type H^+-ATPase, on pGL_3 expression with PEAs at N/P ratio of 30 in serum-free transfection medium determined by luciferase assay. (b) Effect of high osmolarity of GTA/PEI-1.2(1:4)/pGL3 complexes and glycerol concentration on cell volume. The approximate volume of 293T cells was determined using mini-PCV tubes following exposure to the conditions indicated for 5 min. As a control, the cells were suspended for 5 min in DMEM prior to the PCV determination. Each bar represents the average of three independent experiments (*$p < 0.1$; **$p < 0.05$; ***$p < 0.01$, two-tailed Student's *t*-test) ($n = 3$, error bar represents standard deviation).

Table 2. Osmolarity Measurement of Various Solutions and Complexes

		osmolarity [mOsm]
DMEM + 10% FBS		354 ± 3
Glycerol	3%	751 ± 4
	4%	914 ± 3
	5%	1102 ± 3
GTA/PEI-1.2(1:4)/DNA complexes	3% glycerol (wt %)	601 ± 2
	4% glycerol (wt %)	649 ± 2
	5% glycerol (wt %)	759 ± 7

Grosjean et al. reported the significant decrease in cellular volume and thereby an increase in transient reporter gene expression in nonsynchronized CHO cells after post-transfection shocks (*30*). In addition, the synergistic effect of glycerol and poly(L-lysine) (PLL) was able to lyse human erythrocytes as well as internal vesicles (microsomes) of H225 cells more efficiently than either glycerol and PLL alone as per the reports of Zauner et al. It was found that vesicular membranes became susceptible to PLL-mediated disruption owing to glycerol labilization, thereby releasing the vesicular content into the cytoplasm. However, unlike calcium phosphate mediated transfection, post-transfection osmotic shocks with glycerol barely increased gene transfer activity in transferrin-PLL mediated gene delivery stating the need for synergism between glycerol and polyplexes during transfection (*22*). Hyperosmotic glycerol generally causes shrinkage of cells and thus increases cellular uptake; however, a reduction in transfection efficiency was observed owing to increased cytotoxicity by using glycerol concentration higher than 15% according to the reports of Wilson et al. (*31*). In the case of polyplexes formed from PEA, the reduction in PCV can be explained by the evidence that the glycerol backbone in PEAs exerted osmotic pressure on the cell membrane, which in turn labilizes the vesicular membrane and facilitates cellular uptake by improving membrane permeability.

pEGFP-N_2 Expression after Aerosol Administration. Encouraging *in vitro* results of PEA-mediated gene delivery, especially reduced cytotoxicity, increased cellular uptake, and significant transfection efficiency, prompted us to investigate its *in vivo* gene delivery potential by aerosol administration. One would expect that the presence of glycerol backbone and PEI moieties in PEAs boosts the delivery of nucleic acid *in vivo* after aerosol administration. PEA [GTA/PEI-1.2(1:4)] showing optimum transfection efficiency *in vitro* was selected for aerosol administration in mice. pEGFP-N_2 expression in the lungs after aerosol administration is shown in Figure 10. Although some groups (*32*, *33*) reported the superior efficacy of simple positively charged polyplexes with linear PEI 22 K by aerosol administration, the application of such polyplexes remains restricted because of severe toxicity in the pulmonary region (*34*). In addition, according to the reports of Koshkina

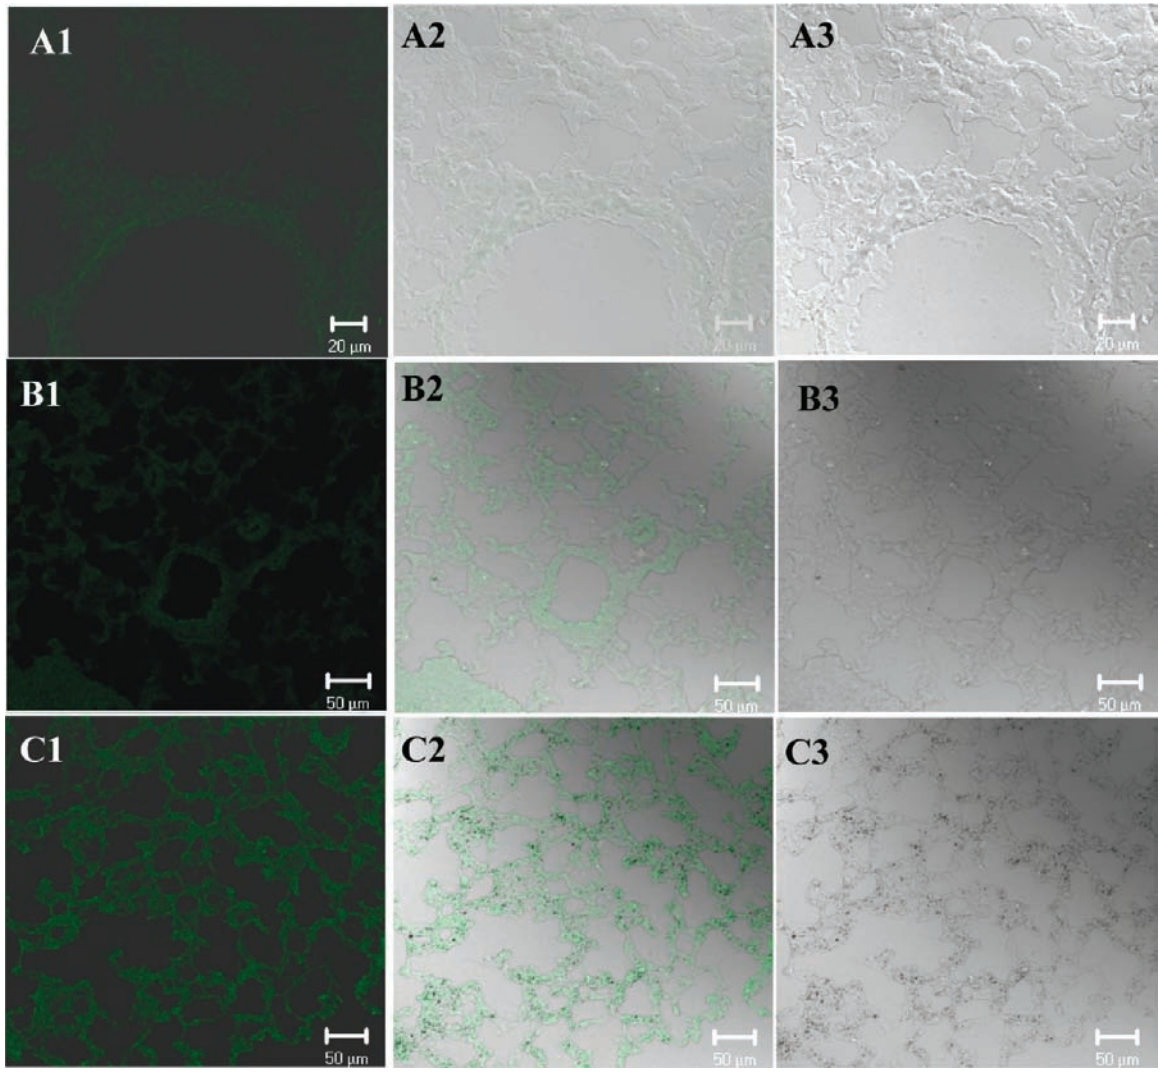

Figure 10. *In vivo* pEGFP-N_2 expression analysis after aerosol administration to lungs. A1, B1, and C1 are the fluorescent images of control, PEI 25K, and GTA/PEI-1.2(1:4), respectively. A2, B2, and C2 are the merged images of control, PEI 25K, and GTA/PEI-1.2(1:4), respectively. A3, B3, and C3 are phase contrast images of control, PEI 25K, and GTA/PEI-1.2(1:4), respectively ($n = 3$, error bar represents standard deviation).

et al., even though both aerosol and intravenous (i.v.) routes deliver gene to lung, aerosol administration is more promising and advantageous, because it results in substantial deposition of DNA and its extended retention in the pulmonary region (*35*). GTA/PEI-1.2(1:4)/pEGFP-N_2 showed promising GFP fluorescence compared to PEI 25K after aerosol administration as shown in Figure 10. This increased GFP expression level shown by GTA/PEI undoubtedly evidences its ability as a potential gene carrier *in vitro* and *in vivo*. Because of the large surface area of the pulmonary region, alveolar cells are much more eligible to internalize PEA/pEGFP-N_2 polyplexes, resulting in elevated levels of transfection efficiency. On the contrary, smaller levels of gene expression shown by PEI 25K may be supported by its low uptake into the lung and its non-biodegradability, which leads to cytotoxicity.

Despite development of various successful cationic polymers by our group which showed remarkable transfection efficiency both *in vitro* and *in vivo*, the superior efficacy of the present polymeric system and an earlier one (GDM/PEI-1.2 copolymers) over others is the hyperosmotic effect that it exerts because of the presence of glycerol moieties in the PEA backbone. This present polymer system exhibits a higher gene expression level presumably due to the synergistic effect of endosomal buffering capacity (resulting from PEI amine groups) and the hyperosmotic effect (resulting from glycerol backbone).

CONCLUSIONS

The approach described in this paper represents an easy and efficient method to obtain a fairly stable vector system with hyperbranched, degradable, and osmotically active PEAs. These PEAs were successfully synthesized by the Michael addition reaction between GTA and LMW-PEI and exhibited remarkable biophysical properties such as polyplex size below 200 nm and surface charge in the range 15−45 mV suitable for intracellular gene delivery carrier. The presence of ester linkage indicated the controlled hydrolytic degradation of PEAs with a half-life of more than 12 days and was essentially nontoxic in all three cell lines (HeLa, HepG2, and 293T cells) at higher doses as compared with PEI 25K. Furthermore, PEAs exhibited higher levels of transfection efficiencies *in vitro* and *in vivo* compared with the "gold standard" PEI 25 K and Lipofectamine as a commercial control. The higher transfection levels of PEAs over PEI could be attributed to the synergism arising from the hyperosmotic effect from glycerol backbone and the "proton sponge effect" from PEI residues. Currently, we are conducting more comprehensive studies such as structure−activity relationships of this vector system with regard to the cellular uptake, reduction in cytotoxicity, and increased transfection efficiency.

Bioactive small molecules such as metabolites and drugs play important roles in regulating biological functions. A technique for visualizing such small molecules is very useful to understand their molecular mechanisms. In this study, an RNA−protein conjugate, which consists of an RRE-RNA sensor protein (EYFP-Rev-ECFP) and an altered RRE-RNA, was constructed to detect bioactive small molecules by fluorescent resonance energy transfer (FRET). We designed a theophylline-aptamer-inserted RRE-RNA (Theo-RRE) to detect theophylline as a model target molecule. Theo-RRE formed an RNA−protein conjugate with EYFP-Rev-ECFP in the presence of theophylline. As a result, theophylline was specifically detected down to 10 μM by the FRET increase in distinction from theophylline analogue, caffeine, in cell lysates.

INTRODUCTION

There are a wide variety of functional small metabolites inside cells. They modulate biological functions by working as extracellular and intracellular messengers for signal transduction through complex metabolism networks (*1, 2*). In addition, small analogous molecules of such metabolites can be molecular-targeted drugs, agonists or antagonists, for regulating cellular functions or treating metabolic disorders (*3*). To investigate intracellular functions of those bioactive small molecules, metabolites, and drugs, it is important to directly detect them inside cells.

In previous works, many molecular probes have been constructed to visualize intracellular signal transductions and their messenger molecules by using GFP-based fluorescent proteins (*4*−*6*). They are promising tools for understanding biomolecular events in living cells. However, it is difficult to accommodate functionally unidentified molecules because proteins or domains that are functionally related to the target molecules have been utilized as sensor moieties in their systems. Therefore, it is desirable to construct a biosensor system, which is flexibly applicable to many types of biomolecules.

Some specific RNA sequences and structures have the ability to recognize biomolecules, such as proteins and peptides, with strong affinity. Many kinds of RNA−protein and RNA−peptide interactions have been discovered from natural RNA sequences (*7*−*11*). In addition, systematic evolution of ligands by exponential enrichment (SELEX) technology has been applied to *in vitro* selection of artificial combinative RNA sequences, known as RNA-aptamers, from random sequence libraries (*12, 13*). RNA-aptamers targeting not only natural proteins and peptides but also organic small molecules and nonnatural drugs have been discovered by the SELEX technology (*13*−*15*). Since many of the RNA-aptamers induce conformational changes in response to target binding, they can be utilized as biosensor moieties, if the conformational changes will be detected by an obvious output signal (*16*−*20*).

Previously, we constructed a protein probe containing a Rev-peptide inserted between EYFP and ECFP (EYFP-Rev-ECFP; YRG0C-11ad) (*21*) for detecting a rev response element RNA (RRE-RNA) by the increase of a FRET signal. The interaction between the RRE-RNA and the Rev-peptide is one of the most well characterized interactions between natural RNA and peptides, originating from the HIV-1 virus (*7*). The YRG0C-11ad indicated a conformational change in response to RRE-RNA binding and increased its FRET signal both *in vitro* and *in vivo* (*21, 22*). In this study, YRG0C-11ad and RRE-RNA were utilized as basal units to form an RNA−protein conjugate for visualizing target small molecules. Theophylline-aptamer is an *in vitro* selected aptamer that binds to a small bronchodilator theophylline (*23, 24*) and is widely utilized to construct theophylline-triggered RNA switches (*18, 25*−*30*). Here, the theophylline-aptamer was inserted into the RRE-RNA (Theo-RRE). Theo-RRE specifically binds theophylline and induces a conformational change, which results in the reconstruction of the RRE-RNA structure. Then, the YRG0C-11ad binds to the reconstructed Theo-RRE to form the RNA−protein conjugate and increases its FRET signal as an output signal (Figure 1). The detection system schemed in Figure 1 was confirmed in a HeLa cell lysate expressing YRG0C-11ad.

MATERIALS AND METHODS

Preparation of RNAs. RNAs used in this study (Table 1) were transcribed by T7 RNA polymerase from DNA templates, which were prepared by primer extension (*31*). The crude transcripts were purified in a 12% denaturing polyacrylamide gel. The sense primer containing the T7 promoter was 5′-GGCTAATACGACTCACTATAGG-3′. Antisense primers annealed with the sense primer were as follows: RRE-RNA, 5′-GGGCCTGTACCGTCAGCTTGCGCTGCGC-CCAGACCCTATAGTGAGTCGTATTAGCC-3′; Theo-RRE, 5′-CTGCGCCCAGCTGCCAAGGGCCTTTCGGCTGGTATCTG-TACCGTCAGATCCTATAGTGAGTCGTATTAGCC-3′; Theo-

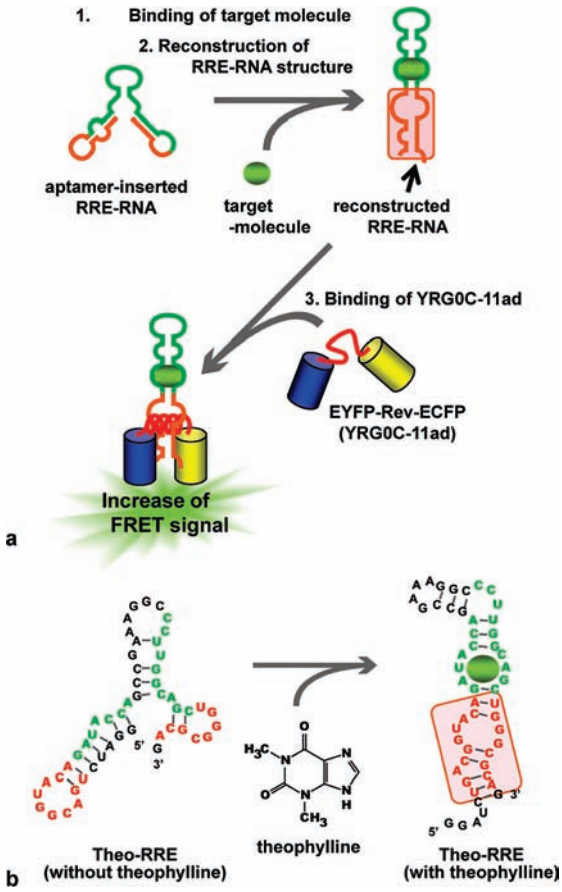

Figure 1. (a) Principle of detection system for small molecules by RNA−protein conjugates. Aptamer-inserted RRE-RNA captures a target small molecule (*1*). The RRE-RNA structure is reconstructed by the RNA conformational change (*2*). Protein probe, YRG0C-11ad, binds to the reconstructed RRE-RNA and increases the FRET signal (*3*). (b) Sequence and expected conformational change of Theo-RRE before (left) and after (right) theophylline binding. RNA structure without theophylline was estimated by GENETYX (Genetyx Corporation). RNA sequences essential for the binding of theophylline (green) or YRG0C-11ad (orange) are indicated as bold characters.

RRE(ex), 5′-TTGGCTGCGCCCAGCTGCCAAGGGCCTTT-CGGCTGGTATCTGTACCGTCAGATCCTATAGTGAGT-CGTATTAGCC-3′; and Theo-RRE(mut), 5′-CTGCGCCCAGC-TGCCAAGGGCCTTTCGGCTGGTATCTGTAACGTCAGA-TCCTATAGTGAGTCGTATTAGCC-3′.

Preparation of Cell Lysate. HeLa cells stably expressing the YRG0C-11ad fluorescent protein were cultured as described (*21*). Cells were trypsinized and suspended in buffer (10 mM HEPES, 100 mM KCl, 1 mM $MgCl_2$, 0.5 mM EDTA, and 10% glycerol, pH 7.5). They were lysed by sonication for 7 min and filtered through a 0.45 μm Ultrafree-MC filter (Amicon) following centrifugation at 3,500*g* for 3 min. The amount of total protein in the lysate was measured by Bio-Rad Protein Assay (Bio-Rad).

Gel Mobility Shift Assay. Interaction between RNA and the YRG0C-11ad was evaluated by nondenaturing polyacrylamide gel electrophoresis as described before (*21*). Briefly, the cell lysate (total protein amount of 0.7 μg) was mixed with RNA, RRE-RNA, or Theo-RRE, and the ligand, theophylline or caffeine, in 16 μL of reaction buffer (50 mM Tris-HCl and 1 mM $MgCl_2$, pH 7.5). After 30 min of incubation at 37 °C followed by 30 min of incubation at 25 °C, the mixture was resolved on a 12% nondenaturing polyacrylamide gel. The YRG0C-11ad mobility shift patterns were imaged by a fluorescence image scanner (FMBIO III; Hitachi) using a 488 nm excitation laser and a 555 nm emission filter.

FRET Measurement. Varied concentrations of the RNA and the ligand were mixed with the cell lysate (total protein amount of 4.4 μg for the fluorescence spectrum and 3.5 μg for the multiwell assay) in 100 μL of reaction buffer. The fluorescence spectrum of the mixture was recorded on a fluorescence spectrometer (FluoroMax-2; ISA). For the multiwell assay, samples were mixed in a 96-well black plate (Sumilon), and FRET signals were evaluated by a fluorescence microplate reader (FLUOstar OPTIMA; BMG). The fluorescence signal was obtained using a 427 ± 5 nm filter for excitation, 480 ± 5 nm for ECFP emission, and 530 ± 5 nm for EYFP emission. For both assays, FRET signals of the mixtures were measured after 30 min of incubation at 37 °C followed by 30 min of incubation at 25 °C.

Evaluation of the Dissociation Constant. The increases of FRET signals under different RNA concentrations were evaluated from the ratios of fluorescence intensities (530 nm/480 nm), with respect to the ratio in the absence of the RNA. Concentration of the YRG0C-11ad in the cell lysate or values of the dissociation constant were calculated from the FRET increase by using Origin8 software (Origin Lab). The theoretical formula fitted to the FRET increase is expressed as follows (*32*):

$$\text{FRET increase} = 1 + \Delta(\text{FRET increase}) \times \frac{\text{Kd} + [\text{protein}] + [\text{RNA}] - \sqrt{(\text{Kd} + [\text{protein}] + [\text{RNA}])^2 - 4[\text{protein}][\text{RNA}]}}{2[\text{protein}]}$$

RESULTS AND DISCUSSION

Formation of RNA−Protein Conjugates and FRET Increase in the Presence of Theophylline. Figure 2a shows a fluorescence image of a nondenaturing polyacrylamide gel which visualizes mobility shift patterns of YRG0C-11ad. In the lanes in which the lysate was mixed with the ligands without RNA, YRG0C-11ad did not migrate into the gel and stayed on thresholds (lanes 1−3). In contrast, strong bands were observed at lower shift positions, when the lysate was mixed with wild type RRE-RNA, regardless of ligand addition (lanes 4−6). These results agreed with our previous result (*21*) and indicate that the ligands did not affect YRG0C-11ad mobility. In the case of Theo-RRE, although a small amount of shifted band was observed without the ligand (lane 7), the band intensity increased by the addition of theophylline even at 250 μM (lanes 8−10). The addition of caffeine by 1 mM did not affect the band intensity even if a slight increase was observed at 2 mM (lanes 11−13). These results indicate that the formation of the RNA−protein (Theo-RRE/YRG0C-11ad) conjugate was enhanced specifically in the presence of theophylline.

Then, fluorescence spectra were measured to confirm whether the FRET signal was increased by the addition of theophylline through the formation of the Theo-RRE/YRG0C-11ad conjugate (Figure 2b). The addition of Theo-RRE at 20 nM without the ligand decreased ECFP intensity and increased EYFP intensity compared to the lysate only. In addition, however, the additional theophylline at 2 mM induced further ECFP decrease and EYFP increase, while caffeine did not affect the spectrum. Fluorescence intensity ratios (523 nm/473 nm) calculated from the spectra (Figure 2c) indicated that either without Theo-RRE or with RRE-RNA, the addition of the ligands did not affect the FRET signal as well as the gel mobility shift assay. From the results, it was revealed that the FRET increase was caused by the formation of the Theo-RRE/YRG0C-11ad conjugate and specifically enhanced by the addition of theophylline.

Characterization of Theo-RRE Variants. Since the FRET signal was moderately increased by an addition of Theo-RRE without ligand, sequence variants of Theo-RRE (Table 1 and Figure 3a) were designed to prevent a self-interaction between

Table 1. RNA Variants, Sequences, and Dissociation Constants Calculated from FRET Increase

RNA	sequence	dissociation constant (nM)	
		without theophylline	with 4 mM theophylline
RRE-RNA (36-mer)	5′-GGGUCUGGGCGCAGCGCAAGCUGACG GUACAGGCCC-3′	0.19 ± 0.07	
Theo-RRE (51-mer)	5′-GGAUCUGACGGUACAGAUACCAGCCG AAAGGCCCUUGGCAGCUGGGCGCAG-3′	36.04 ± 5.22	2.53 ± 0.34
Theo-RRE(ex) (55-mer)	5′-GGAUCUGACGGUACAGAUACCAGCCG AAAGGCCCUUGGCAGCUGGGCGCAGCCAA-3′	18.63 ± 2.67	0.14 ± 0.20
Theo-RRE(mut) (51-mer)	5′-GGAUCUGACGUUACAGAUACCAGCCG AAAGGCCCUUGGCAGCUGGGCGCAG-3′	N.D.	140.0 ± 44.0

Theo-RRE and the YRG0C-11ad in the absence of theophylline. Theo-RRE(ex) was designed to form 4 additional basepairs at the 3′-end, not to easily open the stem. Theo-RRE(mut) was designed to depresses an interaction between the RRE-RNA and the Rev-peptide by a G11U mutation at the bulge region, which is important for the interaction (*33*).

First, the wild type RRE-RNA was added to the lysate, and the FRET increase was evaluated by a fluorescence microplate reader. From the FRET increase under different RRE-RNA concentrations, the concentration of the YRG0C-11ad at the experimental conditions (3.5 μg of total lysate protein in 100 μL of reaction buffer) was estimated at 5.96 nM (see Supporting Information, Figure 1). Then, the value of the concentration of YRG0C-11ad was fixed to the calculated result, 5.96 nM, and dissociation constants between Theo-RRE variants and YRG0C-11ad in the presence (4 mM) or absence of theophylline were calculated from the FRET increase under different Theo-RRE concentrations (Table 1 and Figure 3b). In the presence of 4 mM theophylline, the variants were supposed to completely bind to theophylline and reconstruct the RRE-RNA structure. As a result, in the presence of 4 mM theophylline, all of the Theo-RRE variants indicated smaller dissociation constants than those in the absence of 4 mM theophylline. In the case of Theo-RRE(mut), the self-interaction between YRG0C-11ad and RNA was successfully repressed, and the dissociation constant could not be calculated in the absence of theophylline. However, Theo-RRE(ex) had no effect on repressing the self-interaction, rather it indicated a smaller dissociation constant than Theo-RRE. Longer basepairs were possibly required to repress the self-interaction because Theo-RRE(ex) already contained a stem loop of similar length at the 5′-end, which might be as effective as the 3′-end stem loop.

Homogeneous Detection of Theophylline in Cell Lysate. Theo-RRE(mut) (150 nM) was mixed with the cell lysate, and relative FRET increases were evaluated under different concentrations of theophylline or caffeine (Figure 4). The FRET increase was dependent on theophylline concentration and was not affected by caffeine. The result indicates that theophylline could be specifically detected down to 10 μM by the Theo-RRE/YRG0C-11ad conjugate. Although a more sensitive theophylline biosensor has performed using other detection systems (*18*, *26*), our system worked in a composite and homogeneous solution of the cell lysate without any modification of RNA or protein. When Theo-RRE was mixed with the cell

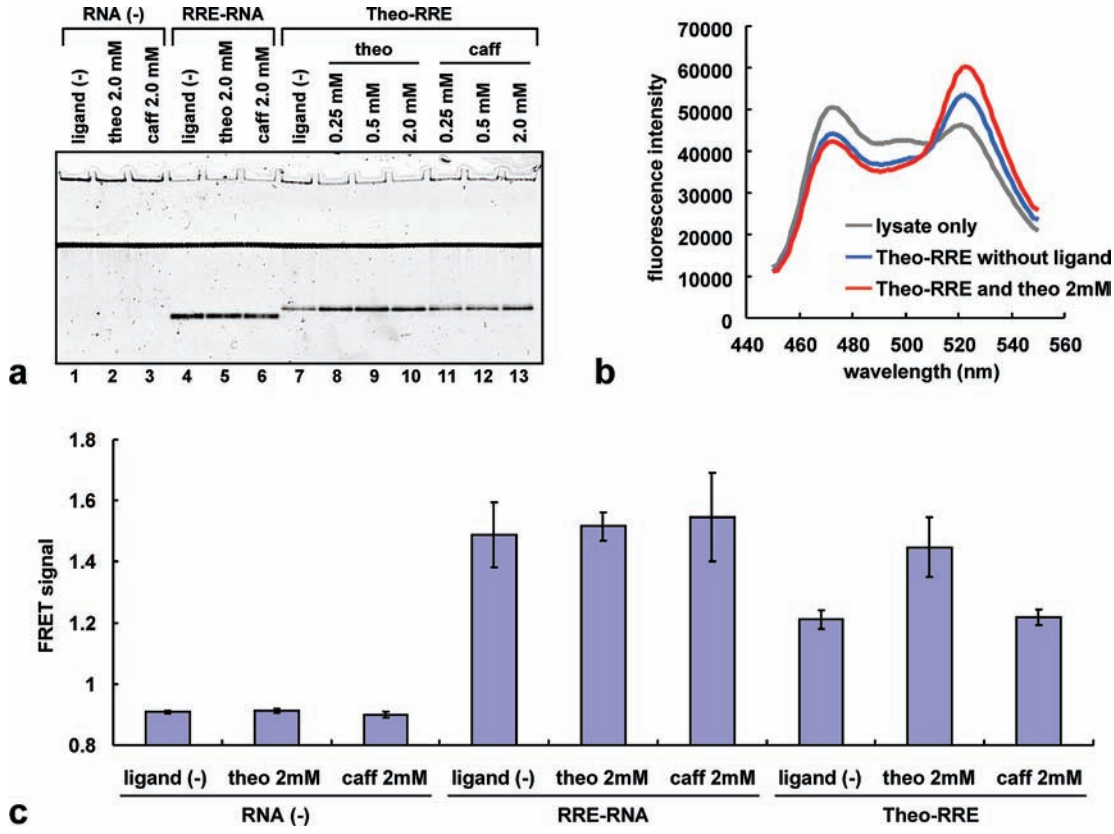

Figure 2. (a) Gel mobility shift assay. Wild type RRE-RNA or Theo-RRE was added to the cell lysate at 20 nM. Additional theophylline (theo) or caffeine (caff) was added at different concentrations (0.25, 0.5, or 2.0 mM). (b) Fluorescence spectra of the cell lysate. The mixture was excited at 425 nm, and spectra were measured from 450 to 550 nm. (c) FRET signals calculated from fluorescence spectra (523 nm/473 nm). Values are average with standard deviation ($n = 3$).

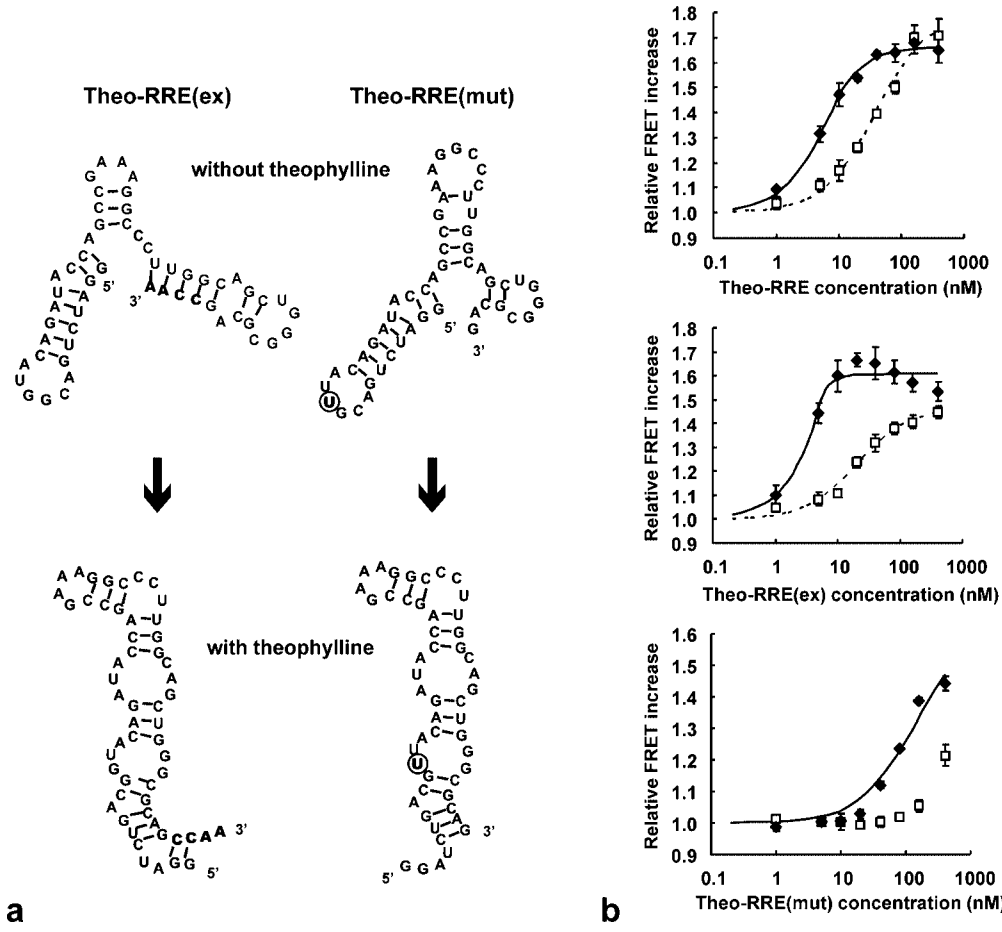

Figure 3. (a) Sequences and expected conformational changes of Theo-RRE variants. RNA structure without theophylline was estimated by GENETYX. Extended bases were indicated as bold characters in Theo-RRE(ex), and the mutated base in Theo-RRE(mut) was indicated as an encircled bold character. (b) FRET increase under different concentrations of Theo-RRE variants in the presence (♦) or absence (□) of theophylline (4 mM). The dashed line and solid line represent fitting curves calculated by Origin 8. Values are average with standard deviation ($n = 3$).

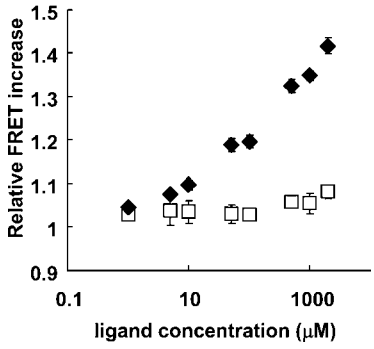

Figure 4. Homogeneous detection of theophylline by FRET increase caused by the formation of the Theo-RRE(mut)/YRG0C-11ad conjugate. Varied concentrations of theophylline (♦) or caffeine (□) were mixed with the cell lysate (3.5 μg of total protein) and Theo-RRE(mut) (150 nM). Values are average with standard deviation ($n = 3$).

lysate at 20 nM, FRET increase was also observed down to 10 μM, even though the error bars were larger than that of Theo-RRE(mut) (see Supporting Information, Figure 2).

CONCLUSIONS

The RNA−protein conjugate sensor consists of a pair of unmodified RNA (Theo-RRE) and fluorescent protein (YRG0C-11ad) and specifically detected a small bioactive molecule, theophylline, by FRET increase. They worked in a composite and homogeneous solution of the cell lysate and enabled theophylline detection down to 10 μM. It would be one of the useful bioimaging techniques because Theo-RRE and the YRG0C-11ad can be stably and continuously produced in living cells by transfecting DNA vectors (*22*). In addition, since the Rev-peptide inserted in YRG0C-11ad functions as a cell penetrating peptide (*34, 35*), it might be practical if the purified YRG0C-11ad could be introduced into significant cells, such as neuronal and embryonic cells.

High throughput metabolome analyses or drug screenings are expected to identify valuable molecules that contribute to interesting bioactivities, such as embryogenesis and particular diseases (*36, 37*), and an intracellular detection system of such molecules would be desirable. The RNA−protein conjugate demonstrated in this study has a unique property, compared with those of other GFP-based FRET sensors, in that the RNA functions as a recognition unit for target molecules, while the fluorescent protein functions as a signaling unit. Artificially selected RNAs, aptamers, have an ability to recognize many types of biomolecules, and its selection method has been well established. Therefore, the RNA−protein conjugate sensor would be flexibly applicable for other small molecules by using other aptamers or selecting RNAs, which specifically interact with YRG0C-11ad in the presence of target molecules (*38, 39*).

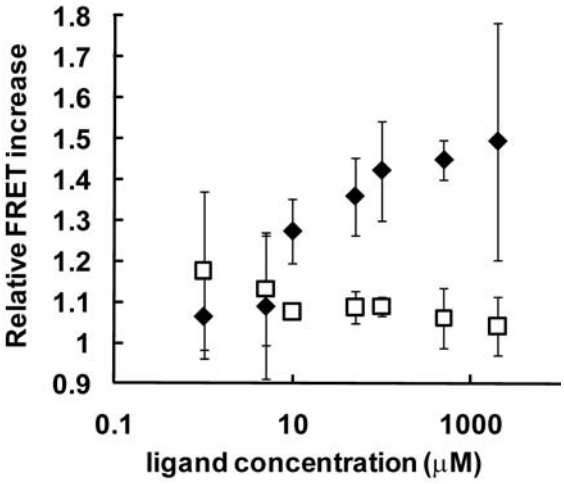
Supplementary Figure 1

Varied concentrations of the wild type RRE-RNA were mixed with the cell lysate (3.5 μg total proteins in 100 μL reaction buffer), and FRET signals were evaluated by using fluorescence microplate reader. The concentration of the YRG0C-11ad ([A]) in the cell lysate was calculated by fitting the above formula to the relative FRET increase under the different concentrations of the RRE-RNA. Values were average with standard deviation (n = 3).



Supplementary Figure 2

Homogeneous detection of theophylline by FRET increase caused by the formation of theo-RRE/YRG0C-11ad conjugate. Varied concentrations of theophylline (filled diamond) or caffeine (open square) was mixed with the cell lysate (3.5 μg total proteins) and Theo-RRE (20 nM). Values were average with standard deviation (n =3).

Tamoxifen−Poly(ethylene glycol)−Thiol Gold Nanoparticle Conjugates: Enhanced Potency and Selective Delivery for Breast Cancer Treatment

Erik C. Dreaden,[†] Sandra C. Mwakwari,[‡] Quaovi H. Sodji,[‡] Adegboyega K. Oyelere,*[,‡] and Mostafa A. El-Sayed*[,†]

The breast cancer treatment drug tamoxifen has been widely administered for more than three decades. This small molecule competes with 17β-estradiol for binding to estrogen receptor, a hormone receptor upregulated in a majority of breast cancers, subsequently initiating programmed cell death. We have synthesized a thiol-PEGylated tamoxifen derivative that can be used to selectively target and deliver plasmonic gold nanoparticles to estrogen receptor positive breast cancer cells with up to 2.7-fold enhanced drug potency in vitro. Optical microscopy/spectroscopy, time-dependent dose−response data, and estrogen competition studies indicate that augmented activity is due to increased rates of intracellular tamoxifen transport by nanoparticle endocytosis, rather than by passive diffusion of the free drug. Both ligand- and receptor-dependent intracellular delivery of gold nanoparticles suggest that plasma membrane localized estrogen receptor alpha may facilitate selective uptake and retention of this and other therapeutic nanoparticle conjugates. Combined targeting selectivity and enhanced potency provides opportunities for both multimodal endocrine treatment strategies and adjunctive laser photothermal therapy.

INTRODUCTION

Binding of the steroidal hormone 17β-estradiol (E_2) to estrogen receptor (ER)[1] is a process essential to normal cell proliferation and differentiation in women. E_2 binding induces a conformational change in ER, which allows it to recruit cofactors necessary for the transcription of various genes commonly upregulated in malignant cells (*1*) (e.g., transforming growth factor alpha (*2*), *c-myc* (*3*), and cathepsin D (*4*)). Accordingly, hormone receptors such as ER or progesterone receptor are overexpressed in 75−80% of all breast cancers (*5*). Antiestrogen compounds, such as the small molecule breast cancer treatment drug tamoxifen (TAM) compete with E_2 for binding to ER, conformationally preventing adoption of associated transcription cofactors and subsequently initiating programmed cell death (*6*−*9*).

Diagnostic and therapeutic applications of functionalized nanoparticles are highly attractive due to the inherently multivalent nature of their surfaces (*10*−*14*). Like divalent antibodies, the binding affinity of a nanoparticle conjugate is enhanced proportional to the density of its binding sites. Receptor-mediated therapeutic response (i.e., potency) is similarly increased as a function of local ligand concentration and in cases where intracellular drug transport relies on passive diffusion, uptake of nanoparticle conjugates can greatly increase delivery rates (*15, 16*). Enhanced permeability and retention (EPR) of nanosized drug conjugates can also lead to augmented and preferential accumulation at tumor sites in vivo (*17, 18*). Due to their biocompatibility (*19, 20*), stability (*21*), and potential use in photothermal laser treatments (*18, 22*−*26*), gold nanoparticles are excellent candidates for such ligand−receptor targeting strategies of cancer treatment.

Selective targeting and delivery of gold nanoparticles functionalized with ligands of cell surface receptors overexpressed by malignant cells has been well documented. Huang et al. have shown that oral cancer cells upregulating human epidermal growth factor receptor (EGFR, HER1, ErbB1) can be selectively labeled and photothermally destroyed by gold nanospheres and nanorods targeted with IgG antibodies (*24, 27*). ScFv fragments of anti-EGFR have also been used to selectively target and accumulate gold nanoparticles at tumor sites in vivo (*28*). Folate receptor has been employed to selectively deliver gold nanospheres to malignant cells in vitro (*29*), while Wei and co-workers have similarly demonstrated selective uptake and photothermal therapy of cancer cells using gold nanorods functionalized with a thiol−poly(ethylene glycol) (PEG−SH) folate derivative (*25, 30*).

Like several members of the hormone receptor family, ER isoforms are located both intracellularly and on the cell membrane (*31*−*33*). Gold nanoparticle analogs of the commercial pharmaceutical tamoxifen could therefore act not only as selective targeting agents but also as increasingly potent endocrine treatments for malignancies that overexpress ER (e.g., breast cancer). To this aim, a PEG−SH−tamoxifen derivative was synthesized for subsequent gold nanoparticle (AuNP) conjugation (Scheme 1). A biocompatible (*18, 34*) PEG−SH linker was employed (i) to enable covalent attachment to the AuNP surface (Au−S 126 kJ·mol^{-1}) (*35, 36*), (ii) to minimize opsonin binding and reticulo-endothelial system uptake (*37*), (iii) to suppress nonspecific cell binding/uptake (*38*) and protein adsorption (*18, 21*), and (iv) to afford stability (*21*) over a wide range of temperature, ionic strength, and pH.

Our results have shown enhanced potency and selective intracellular delivery of tamoxifen-targeted gold nanoparticles to ER(+) breast cancer cells in vitro. Particle uptake was observed in both a receptor- and ligand-dependent fashion with up to 2.7-fold enhanced drug potency versus the free drug. Both

delivery and therapeutic response were shown to be suppressed by estrogen competition. Optical microscopy/spectroscopy and cell viability indicate that augmented growth inhibition versus the free drug can be attributed to increased rates of intracellular TAM transport by cellular uptake of the nanoparticle conjugate. Receptor- and ligand-dependent nanoparticle delivery suggests that the plasma membrane localized estrogen receptor alpha may facilitate selective particle uptake and presents future opportunities for coadministration of laser photothermal therapy (*18*, *22*−*26*).

EXPERIMENTAL PROCEDURES

Synthesis of Thiol−PEGylated Tamoxifen (TAM−PEG−SH). Octa(ethylene glycol) (OEG), tamoxifen, and all chemicals used in the synthesis were purchased from Sigma Aldrich. Anhydrous solvents and other reagents were purchased and used without further purification. Analtech silica gel plates (60 F_{254}) were used for analytical TLC, and Analtech preparative TLC plates (UV 254, 2000 μm) were used for purification. UV light was used to examine the spots. Silica gel (200−400 mesh) was used in column chromatography. NMR spectra were recorded on a Varian-Gemini 400 magnetic resonance spectrometer. ^{1}H and ^{13}C NMR spectra (Figures S1−8, Supporting Information) were recorded in parts per million (ppm) relative to the peaks of $CDCl_3$ (7.24 and 77.0 ppm, respectively). Mass spectra were recorded at the Georgia Institute of Technology mass spectrometry facility in Atlanta, GA.

*Synthesis of N-Desmethyl Tamoxifen (**1**).* The synthetic procedure was adapted from Olofson et al. (*39*). Briefly, tamoxifen (0.53 g, 1.43 mmol) was dissolved in anhydrous CH_2Cl_2 (15 mL) at 0 °C followed by addition of α-chloroethyl chloroformate (0.17 mL, 1.49 mmol). After 15 min at 0 °C, the reaction was refluxed for 24 h. The solvent was evaporated off to obtain a yellowish oil, to which methanol (10 mL) was added, and the mixture was refluxed for approximately 3 h. The solvent was evaporated off, and purification was performed by gel filtration using CH_2Cl_2, then 10:1 CH_2Cl_2/CH_3OH to obtain 0.52 g (91%) of *N*-desmethyl tamoxifen, **1**. ^{1}H NMR (DMSO, 400 MHz) δ 0.89 (3H, t, J = 7.2 Hz), 2.43 (2H, q, J = 14.8, 7.6 Hz), 2.56 (3H, s), 3.12 (2H, t, J = 4.0 Hz), 4.08 (2H, t, J = 4.8 Hz), 6.57 (2H, d, J = 8.8 Hz), 6.76 (2H, d, J = 8.8 Hz), 7.03−7.31 (10H, m), 9.56 (1H, br); HRMS [FAB, mnba] $(C_{25}H_{27}NO)^+$ calcd, 358.2171; found, 358.2198.

*Synthesis of Tosyl Octa(ethylene glycol) (**2**).* The synthetic procedure was adapted from Bouzide and Sauvé (*40*). Briefly, octa(ethylene glycol) (0.50 g, 1.35 mmol) was dissolved in anhydrous CH_2Cl_2 (7 mL) at 0 °C, followed by addition of freshly prepared Ag_2O (0.47 g, 2.02 mmol), KI (0.09 g, 0.50 mmol), and then TsCl (0.26 g, 1.35 mmol). The reaction mixture was left to stir at 0 °C under argon for 30 min, after which TLC deemed the reaction complete. Ag_2O was filtered off over a pad of Celite cake, washing with 12:1 CH_2Cl_2/CH_3OH. The filtrate was concentrated and purified on a silica column using 3:2 then gradually 1:4 CH_2Cl_2/acetone to yield the title compound as a colorless oil (0.55 g, 78%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 2.44 (3H, s), 2.81 (1H, br), 3.58−3.70 (30H, m), 4.15 (2H, t, J = 4.8 Hz), 7.35 (2H, d, J = 8.4 Hz), 7.80 (2H, d, J = 8.4 Hz); HRMS [ESI] $(C_{23}H_{40}O_{11}S + H)^+$ calcd, 525.2364; found, 525.2377.

*Synthesis of Tamoxifen−OEG−OH (**3**).* *N*-Desmethyl tamoxifen (**1**) (0.27 g, 0.68 mmol) and tosyl octa(ethylene glycol) (**2**) (0.54 g, 1.05 mmol) were dissolved in anhydrous DMF (10 mL), followed by addition of K_2CO_3 (0.95 g, 6.85 mmol), and stirred under argon at ∼85 °C for 24 h. DMF was evaporated off. Ethyl acetate was added to the residue, and the resulting suspension was filtered to remove excess K_2CO_3. Solvent was evaporated from the filtrate, and the crude was purified by preparatory TLC using 12:1:0.1 CH_2Cl_2/CH_3OH/NH_4OH to obtain 0.342 g (70%) of compound **3** as an oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 0.90 (3H, t, J = 7.2 Hz), 1.85 (1H, br), 2.31 (3H, s), 2.44 (2H, q, J = 14.0, 7.2 Hz), 2.64 (2H, t, J = 6.0 Hz), 2.76 (2H, t, J = 6.0

Hz), 3.53−3.72 (30H, m), 3.91 (2H, t, $J = 6.4$ Hz), 6.54 (2H, m), 6.76 (2H, m), 7.10−7.40 (10H, m); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 13.8, 29.2, 43.3, 50.7, 56.6, 57.2, 61.7, 65.6, 69.1, 70.3, 70.5, 70.6, 70.7, 70.8, 73.0, 113.6, 126.2, 126.7, 128.0, 128.3, 129.7, 129.9, 132.1, 135.8, 138.4, 141.5, 142.6, 144.0, 156.8; HRMS [ESI] $(C_{41}H_{59}NO_9 + H)^+$ calcd, 710.4262; found, 710.4253.

Synthesis of Tamoxifen−OEG−Tosylate (4). Tamoxifen−OEG−OH (**3**) (0.33 g, 0.46 mmol) was dissolved in anhydrous CH_2Cl_2 (10 mL) at 0 °C, followed by addition of Ag_2O (0.16 g, 0.69 mmol), KI (0.03 g, 0.18 mmol), and then TsCl (0.096 g, 0.5 mmol). Stirring was continued for 2 h at 0 °C, then at room temperature overnight. Ag_2O was filtered off through a pad of Celite cake, washing with ethyl acetate. Purification was performed on a silica column, eluting with 12:1 CH_2Cl_2/CH_3OH yielding the title compound as oil (0.24 g, 60%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 0.91 (3H, t, $J = 7.2$ Hz), 2.31−2.46 (8H, m), 2.71 (2H, br), 2.83 (2H, br), 3.57−3.70 (28H, m), 3.95 (2H, br), 4.15 (2H, t, $J = 4.4$ Hz), 6.53 (2H, d, $J = 8.4$ Hz), 6.76 (2H, d, $J = 8.8$ Hz), 7.10−7.34 (12H, m), 7.80 (2H, d, $J = 8.4$ Hz); LRMS [ESI] $(C_{48}H_{65}NO_{11}S + H)^+$ calcd, 864.1; found, 864.5.

Synthesis of Tamoxifen−OEG−SAc (5). KSAc (0.079 g, 0.69 mmol) was added to tamoxifen−OEG−tosylate (**4**) (0.12 g, 0.14 mmol) dissolved in anhydrous THF and refluxed under argon at ∼75 °C for 16 h. TLC analysis indicated a substantial consumption of the starting material. THF was evaporated off, and the crude product was dissolved in ethyl acetate. Decolorizing carbon was added and then filtered. Solvent was evaporated from the filtrate and the crude was purified by preparatory TLC using 12:1 CH_2Cl_2/CH_3OH to obtain 50 mg (48%) of **5** as reddish oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.03 (3H, t, $J = 7.2$ Hz), 2.45 (3H, s), 2.47 (3H, s), 2.56 (2H, q, $J = 15.2$, 7.6 Hz), 2.80 (2H, t, $J = 6.0$ Hz), 2.91 (2H, t, $J = 5.6$ Hz), 3.21 (2H, t, $J = 6.0$ Hz), 3.70−3.80 (28H, m), 4.05 (2H, t, $J = 6.0$ Hz), 6.66 (2H, d, $J = 8.0$ Hz), 6.88 (2H, d, $J = 8.0$ Hz), 7.22−7.46 (10H, m); HRMS [ESI] $(C_{43}H_{61}NO_9S + H)^+$ calcd, 768.4139; found, 768.4118.

Synthesis of Thiol−PEGylated Tamoxifen (6). Tamoxifen−OEG−SAc (**5**) (0.05 g, 0.065 mmol) was dissolved in acetone (1.5 mL) at 0 °C, followed by addition of 1 M NaOH (1.5 mL), and stirring continued at 0 °C for 7 h. The reaction mixture was quenched with water (20 mL) and then extracted with 20% CH_3OH in CH_2Cl_2 (4 × 15 mL). The organic layers were combined, dried under sodium sulfate, evaporated, and purified on preparatory TLC using 11:1 CH_2Cl_2/CH_3OH to give 10 mg (21%) of the title compound as reddish semisolid. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 0.90 (3H, t, $J = 7.2$ Hz), 2.32 (3H, s), 2.44 (2H, q, $J = 8.0$,7.6 Hz), 2.65 (2H, t, $J = 6.0$ Hz), 2.76 (2H, t, $J = 6.4$ Hz), 2.85 (2H, t, $J = 6.8$ Hz), 3.53−3.72 (28H, m), 3.91 (2H, t, $J = 6.0$ Hz), 6.52 (2H, d, $J = 8.8$ Hz), 6.74 (2H, d, $J = 8.8$ Hz), 7.08−7.32 (10H, m);^{13}C NMR ($CDCl_3$, 100 MHz) δ 13.5, 28.9, 29.6, 38.3, 43.3, 56.4, 57.0, 65.6, 69.2, 69.6, 70.3, 70.4, 70.5, 70.6, 113.3, 125.9, 126.4, 127.8, 128.0, 129.4, 129.6, 131.8, 135.4, 138.1, 141.2, 142.3, 143.7, 156.6; HRMS [ESI] $(C_{41}H_{59}NO_8S]^+$ calcd, 725.3961; found, 725.4011.

Gold Nanoparticle Synthesis and TAM−PEG−SH Conjugation. Gold nanoparticles (25 nm dia) were synthesized by Turkevich reduction of chloroauric acid (*41*). Briefly, 20 mL of 3.5 mg/mL aqueous sodium citrate was added to 200 mL of 1.0 mM aqueous $HAuCl_4$ under reflux, with stirring. The solution was refluxed for 15 min, then removed from the heat and stirred for an additional 30 min. Excess sodium citrate was removed from the crude AuNP solution by centrifugation (13 000 × *g*).

TAM−PEG−SH (5 mg) was solubilized in 100 μL of ethanol and diluted to 0.5 mM in deionized water. PEG−SH (0.5 mM, 5 kDa, Lysan Bio) was solubilized in deioninized water, and PEG−SH or a 1:1 ratio TAM−PEG−SH and PEG−SH were added at a (1.4×10^4)-fold molar excess to a concentrated solution of citrate-capped AuNPs followed by overnight sonication. Particle concentration was estimated using the molar extinction coefficient for 23 nm citrate-capped gold nanospheres determined by Orendorff and Murphy (*42*) (1.3×10^9 M^{-1} cm^{-1}). TAM−PEG−SH−AuNP conjugates were dispersed in DMEM growth media without L-glutamine and phenol red supplemented with 10% v/v heat-inactivated fetal bovine serum, penicillin (100 U/mL), streptomycin (100 μg/mL), 4.5 g/L glucose, and 4.5 g/L sodium pyruvate to final *ligand* concentrations of 0.1, 0.5, 1, 2, 5, 10, and 20 μM and used immediately.

Gold Nanoparticle and Bioconjugate Characterization. Gold nanoparticles were analyzed by diffraction-contrast transmission electron microscopy (TEM, JEOL 100CX II) and UV−vis absorption spectroscopy (Ocean Optics, HR4000CG-UV-NIR). Absorption of TAM−PEG−SH at 280 nm was used to quantify the number of bound TAM−PEG−SH ligands per nanoparticle. An aqueous solution of gold nanospheres was incubated with a (1.4×10^4)-fold molar excess of both TAM−PEG−SH and PEG−SH overnight with sonication. Nanoparticle conjugates were removed from solution by centrifugation (45 min, 13 000 × *g*), and the observed change in UV absorption (280 nm) before and after nanoparticle conjugation was used to approximate the number of bound ligands. No contribution to absorption by PEG−SH was observed at these wavelengths, and it was assumed to occupy the majority of the remaining surface sites.

Zeta potential of the gold nanoparticles and conjugates was measured using a NanoZS Zetasizer particle analyzer (Malvern) equipped with a 633 nm laser.

Cell Culture and Nanoparticle Incubation. ERα(−) MDA-MB-231 and ERα(+) MCF-7 breast cancer cells (human adenocarcinoma, ATCC) or ERα(+) human squamous cell carcinoma (*43*−*45*) (HSC-3) cells were cultured to 10^5 cells/cm^2 in DMEM growth media without L-glutamine and phenol red supplemented with 10% v/v heat-inactivated fetal bovine serum, penicillin (100 U/mL), streptomycin (100 μg/mL), 4.5 g/L glucose, and 4.5 g/L sodium pyruvate at 37 °C in a 5% CO_2 humidified atmosphere. Growth media was removed from the cell cultures and replaced with identical media containing gold nanoparticle conjugates heated to 37 °C at time = 0 h.

Cell Viability Assay. Following incubation, growth media containing gold nanoparticle conjugates was removed, and cells were rinsed twice in sterile Dulbecco's phosphate-buffered saline (DPBS). Mitochondrial dehydrogenase activity was assessed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) or 2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carboxanilide (XTT) spectrophotometric assay (Sigma TOX1, TOX2) following the manufacturer's instructions. The assay was performed using a SpectraMax Plus 384 microplate reader and statistical analysis was performed by *t* test.

Selected-Area Absorption Microspectrometry and Dark-Field Scattering Microscopy. Collagen-coated growth substrates were prepared by immersion of 18 mm diameter glass coverslips in ethanol, followed by 30 min UV sterilization. Coverslips were immersed in a 0.22 μm filtered 0.04 mg/mL collagen (Roche) solution, prepared by solubilization in 5 mL of 1% v/v aqueous acetic acid and dilution in 250 mL of sterile DPBS, for 6 h at 37 °C in a 5% CO_2 humidified atmosphere. The coated substrates were rinsed in sterile DPBS and placed in 12-well plates immediately prior to cell passage. Following incubation with gold nanoparticle conjugates, substrates were twice rinsed in sterile DPBS buffer, and cells were fixed in cold 4% wt/wt paraformaldehyde in DPBS buffer for 15 min.

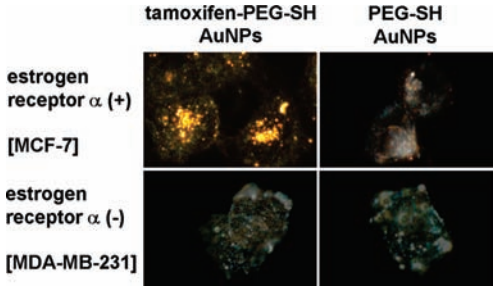

Figure 1. Dark-field scattering microscopy showing ligand- and receptor-dependent intracellular targeting of breast cancer cells by gold nanoparticle conjugates. Representative dark-field scattering images of ERα(+) [MCF-7, top] and ERα(−) [MDA-MB-231, bottom] human adenocarcinoma cells incubated for 24 h with 1 μM TAM−PEG−SH−AuNP (left) and PEG−SH−AuNP (right) conjugates (ca. 1.2 × 10^4 TAM−PEG−SH per AuNP).

Coverslips were coated in glycerol, then mounted and sealed onto glass slides.

Dark-field microscopy was performed using an inverted objective Olympus IX70 microscope fitted with a dark-field condenser (U-DCW), 100×/1.35 oil iris objective (UPLANAPO), tungsten lamp, and Nikon D200 digital SLR camera. Optical extinction spectra were obtained in a transmission configuration using a SEE110 absorption microspectrometer fitted with a pinhole aperture, fiber optic-coupled CCD array detector, 50× objective, and tungsten lamp. Periodic oscillations observed in some spectra are the result of interference between adjacent surfaces of the glass slides.

RESULTS AND DISCUSSION

The crude AuNP colloid (ca. 3 nM) was found by TEM to be predominantly comprised of 25 nm gold spheres exhibiting an extinction maximum at 530 nm (Figure S9, Supporting Information). Based on the change in UV absorption (280 nm) of TAM solutions following nanoparticle conjugation and removal, we estimate 12 000 TAM−PEG−SH ligands per particle, 41% of the maximum theoretical surface coverage for a 25 nm diameter Au(111) surface. A change in zeta potential from −38.4 to −5.79 mV was also observed following TAM−PEG−SH functionalization. To preserve aqueous stability, TAM−PEG−SH−AuNPs were not centrifuged prior to in vitro experiments, leaving 13% of free drug in solution. For comparison with the free drug, concentrations for the nanoparticle conjugate are reported as total effective ligand concentration (i.e., TAM−PEG−SH) throughout.

Dark-field scattering microscopy was performed to assess intracellular nanoparticle uptake. Figure 1 illustrates representative images of ERα(+) [MCF-7, top] and ERα(−) [MDA-MB-231, bottom] breast cancer cells incubated for 24 h with 1 μM TAM−PEG−SH−AuNPs and PEG−SH−AuNPs. ERα(+) breast cancer cells displayed a high degree of intracellular and perinuclear localization of TAM−PEG−SH−AuNPs, while ER(−) breast cancer cells showed no such labeling. These findings are consistent with both reported expression levels and cellular localization (*46*) of ERα in MCF-7 (*47*−*49*) and MDA-MB-231 (*48*, *50*) cell lines. As anticipated (*38*), AuNPs labeled only with PEG−SH exhibited no apparent cellular labeling or uptake for either ERα(+) or ERα(−) breast cancer cells. Uptake of TAM−PEG−SH−AuNPs by ERα(+) breast cells was observed to be time-dependent, with marginal cell surface labeling at 2−6 h and a high degree of perinuclear and cytoplasmic localization at 24 h (Figure S10, Supporting Information). To further demonstrate ER expression-dependent targeting, ERα(+) human squamous [HSC-3] oral cancer cells were incubated for 24 h in the presence of 1 μM TAM−PEG−SH−AuNPs and PEG−SH−AuNPs. Dark-field scattering images from HSC-3 cells show selective uptake of the TAM−PEG−SH−AuNPs in a manner similar to that obtained from MCF-7 breast cancer cells (Figure S11, Supporting Information). Selected-area optical extinction spectra obtained from the ERα(+) and ERα(−) breast cells exhibited AuNP surface plasmon extinction exclusively from perinuclear regions of ERα(+) cells incubated with TAM−PEG−SH−AuNPs (s/n ≈ 10) (Figure S12, Supporting Information). Extinction from PEG−SH−AuNPs was not observed from either cell line.

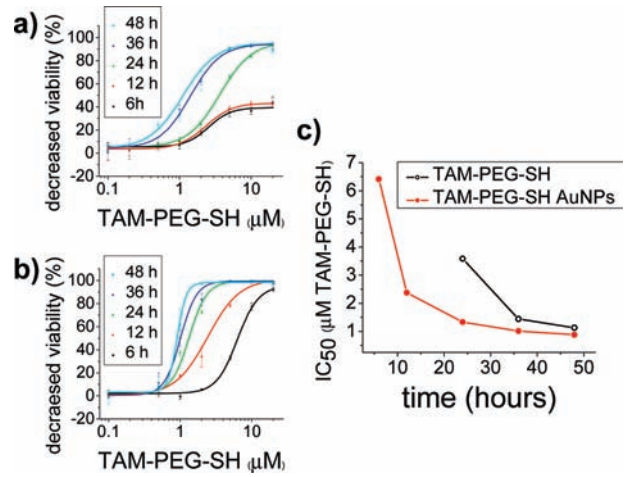

Figure 2. Time-dependent dose−response curves for cell viability of estrogen receptor alpha positive [MCF-7] breast cancer cells incubated with equivalent concentrations of TAM−PEG−SH as a free drug (a) and as a gold nanoparticle conjugate (b). Time-dependent IC_{50} (50% inhibitory concentration) values (c) show 1.3−2.7-times enhanced potency from the nanoparticle conjugate versus the free drug. Error bars represent standard deviation: 3.6, 1.4, 1.1 μM TAM−PEG−SH IC_{50} (24, 36, 48 h, respectively) versus 6.4, 2.4, 1.3, 1.0, 0.88 μM TAM−PEG−SH−AuNP IC_{50} (6, 12, 24, 36, 48 h, respectively).

Figures 2a,b illustrates time-dependent dose−response curves for cell viability of ERα(+) MCF-7 breast cancer cells incubated with equivalent concentrations of TAM−PEG−SH as the free drug and the nanoparticle conjugate, respectively. A comparison of the time-dependent IC_{50} (50% inhibitory concentration) values obtained for the free drug and its AuNP conjugate indicate 1.3−2.7-fold enhanced potency (Figure 2c) for TAM−PEG−SH−AuNPs. While IC_{50} values for TAM−PEG−SH alone are comparable to or better than those previously reported for MCF-7 breast cancer cells treated with both tamoxifen (*43*) and its active metabolite (*51*), a much more dramatic improvement is observed upon nanoparticle ligation, in contrast to the free drug, with significant growth inhibition observed for TAM−PEG−SH−AuNPs at both 6 and 12 h incubation (6.4 and 2.4 μM IC_{50}, respectively). In accordance with previous studies (*19*), no cytotoxic effects were observed in MCF-7 cells treated with PEG−SH−AuNPs at the highest concentrations and incubation times used in the present study ($P > 0.75$). Moreover, cytotoxic effects were not observed in ERα(−) MDA-MB-231 breast cancer cells incubated with TAM−PEG−SH alone, PEG−SH−AuNPs, or TAM−PEG−SH−AuNPs at the highest concentrations and incubation times used in the present study ($P > 0.28$, 0.33, and 0.11, respectively). Although differences in sensitivity to and rates of particle or drug uptake and metabolism for ERα(+) and ERα(−) cell lines may contribute to variation in apparent cytotoxicity, the observed ligand dependency correlates well with levels of cellular ER expression, particularly under the conditions of extended incubation time and excess concentration used. In addition, cell viability following incubation with TAM−PEG−SH−AuNPs in the absence of free drug was found to be statistically indistinguishable in difference from that

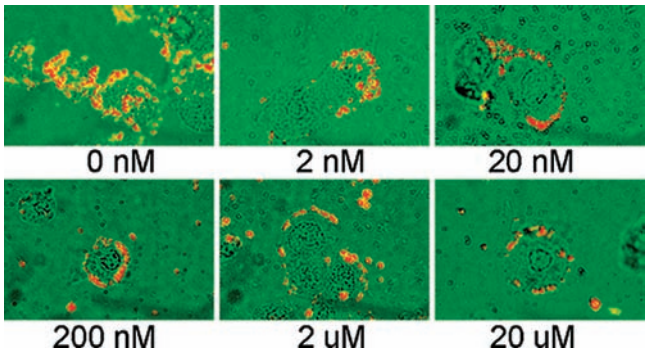

Figure 3. Representative dark-field scattering (red) and bright-field transmission (green) image overlays of TAM−PEG−SH−AuNP competitive binding following 24 h incubation with 17β-estradiol. ERα(+) breast cancer cells [MCF-7] were incubated overnight with increasing concentrations of estrogen, followed by 24 h incubation with 10 μM tamoxifen−gold nanoparticle conjugates.

observed in its presence. Here, AuNPs functionalized with TAM−PEG−SH equivalent to that present at the 24 h IC_{50} of the conjugate in the presence of free drug subsequently exhibited 57% ± 14% cell viability ($P > 0.6$). The lack of significant growth inhibition by the free drug at short incubation times, together with an observed decrease in the disparity between IC_{50} values of the free drug and the AuNP conjugate over time, and the apparent ligand-dependent response indicate increased rates of TAM−PEG−SH transport by the AuNP conjugate.

Although our results with the HSC-3 cell line, an ERα(+) oral cancer cell line, further attested to the role of ERα in nanoparticle uptake, it is however conceivable that particle lipophilicity could also contribute to differences in cellular uptake and cytotoxicity. In light of this possibility, blocking experiments were performed using ERα's endogenous ligand 17β-estradiol (estrogen) to further confirm receptor-dependent targeting and therapeutic response. ERα(+) MCF-7 breast cells were incubated overnight with increasing concentrations of estrogen, followed by 24 h incubation with 10 μM TAM−PEG−SH−AuNPs. Image overlays from bright-field transmission and dark-field scattering microscopy of these cells (Figure 3) indicate near complete suppression of TAM−PEG−SH−AuNP intracellular localization at estrogen concentrations as low as 20 nM. Decreased cell surface labeling was also observed with increasing estrogen concentration. Such competitive effects are in agreement with previous reports indicating 1−2 orders of magnitude greater ERα binding affinity for 17β-estradiol versus TAM (*52*). Cell viability experiments with ERα(+) breast cells incubated for 24 h with 10 μM TAM−PEG−SH−AuNPs and previously blocked overnight with equimolar concentrations of estrogen were also performed (Figure 4). As in previous studies with the free drug (*8*), the cytotoxic activity of TAM-labeled AuNPs was near completely suppressed following pre-exposure of the cells to estrogen ($P > 0.87$), while they retained optimal potency in the absence of estrogen ($P < 0.0001$). These findings correlate ERα binding with both TAM−PEG−SH−AuNP intracellular localization and subsequent cell death.

The ERα expression-dependent uptake observed here also suggests that the cell membrane-associated receptor may facilitate intracellular nanoparticle transport. Indeed, plasma membrane localized ERα is well documented, as is its recognition of both antibody epitopes for the nuclear receptor and 17β-estradiol in mammalian cells (*31, 33*). The functions of membrane ERα beyond classical gene transcription and more recently membrane-initiated signaling are however less understood (*53*). Comprehensive studies by Levin and co-workers indicate intracellular transport and caveolar localization of ERα in the plasma membrane of MCF-7 cells in vitro (via caveolin-1

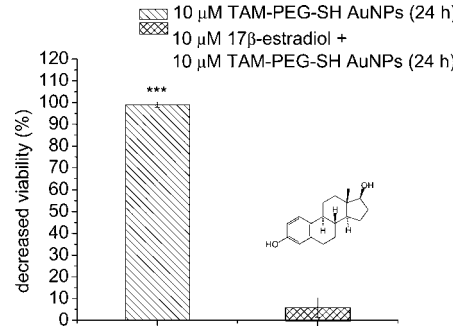

Figure 4. Suppression of TAM−PEG−SH−AuNP activity by estrogen competition in ERα(+) breast cancer cells. Growth inhibition of MCF-7 cells incubated for 24 h with 10 μM TAM−PEG−SH−AuNPs when previously untreated (left) and treated overnight with 10 μM 17β-estradiol (right).

and -2 association) (*49*). In order to determine whether plasma membrane localized ERα could contribute to receptor-mediated endocytosis of TAM−PEG−SH−AuNP conjugates, cytotoxicity was examined under conditions of negligible endocytotic activity. MCF-7 cell viability was shown to increase by 87% ± 2% following incubation with 20 μM TAM−PEG−SH−AuNPs for 6 h at 4 °C versus 37 °C ($P < 0.04$), indicating that endocytosis, in addition to ERα binding and intracellular particle delivery, is required for therapeutic response from tamoxifen-labeled AuNP conjugates.

CONCLUSIONS

In summary, tamoxifen−gold nanoparticle conjugates were shown to selectively target estrogen receptor alpha in human breast cancer cells with up to 2.7-times enhanced potency in vitro. Optical microscopy and spectroscopy indicate a high degree of perinuclear and cytoplasmic localization of the targeted particles, while neither localization nor cytotoxic effects were observed from the untargeted nanoparticles. Time-dependent dose−response studies show that augmented potency results from increased rates of drug transport by nanoparticle uptake versus passive diffusion of the free drug. Receptor-selective and estrogen-competitive cytotoxicity and uptake of the nanoparticle conjugates indicates no additive effects associated with the gold particles themselves and suggests that plasma membrane-localized ERα may facilitate selective endocytotic transport of these and other therapeutic nanoparticle conjugates. Increased potency and selective intracellular delivery of tamoxifen−gold nanoparticle conjugates provides opportunities for further enhancement by cofunctionalization or adjunctive laser photothermal therapy.

ACKNOWLEDGMENT

Center for Radiopharmaceutical Science of ETH, PSI and USZ, Department of Chemistry and Applied Biosciences, ETH Zurich, CH-8093 Zurich, Switzerland, Bayer Schering Pharma AG, Global Drug Discovery, D-13342 Berlin, Germany, Department of Chemistry and Biochemistry - Organic Chemistry, FU Berlin, Takustraβe 3, D-14195 Berlin, Germany. Received June 3, 2009; Revised Manuscript Received October 30, 2009

Methods for the radiolabeling molecules of interest with [^{18}F]-fluoride need to be rapid, convenient, and efficient. Numerous [^{18}F]-labeled prosthetic groups, e.g., *N*-succinimidyl 4 [^{18}F]-fluorobenzoate ([^{18}F]-SFB), 4-azidophenacyl-[^{18}F]-fluoride ([^{18}F]-APF), and 1-(3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl)pyrrole-2,5-dione ([^{18}F]-FpyMe), for conjugating to biomolecules have been developed. As the synthesis of these prosthetic groups usually requires multistep procedures, there is still a need for direct methods for the nucleophilic [^{18}F]-fluorination of biomolecules. We report here on the development of a procedure based on the trimethylammonium (TMA) leaving group attached to an aromatic ring and activated with different electron-withdrawing groups (EWGs). A series of model compounds containing different electron-withdrawing substituents, a trimethylammonium leaving group, and carboxylic functionality for subsequent coupling to peptides were designed and synthesized. The optimal model compound, 2-cyano-4-(methoxycarbonyl)-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate, was converted to carboxylic acid and coupled to peptides. The results of the one-step [^{18}F]-fluorination of tetrapeptides and bombesin peptides show that the direct ^{18}F-labeling of peptides is feasible under mild conditions and in good radiochemical yields.

INTRODUCTION

Positron emission tomography (PET) is of particular interest in diagnostic nuclear medicine as it can track positron emitting probes in a repetitive and noninvasive manner (*1, 2*). ^{18}F is considered an ideal PET isotope because it has the best imaging characteristics due to the low positron energy (0.64 MeV). In addition, the 110 min half-life of ^{18}F is sufficiently long to permit complex or multistep organic syntheses, commercial distribution to other imaging centers, and extended *in vivo* investigations.

In general, large biomolecules such as peptides or oligonucleotides are not readily amenable to direct fluorination with no-carrier-added (nca) ^{18}F-fluoride. As a result, ^{18}F has been incorporated into many biologically active molecules such as peptides (*3*−*6*), proteins (*7, 8*), and oligonucleotides (*9, 10*) via indirect methods using as building blocks so-called prosthetic groups. These prosthetic groups serve to enhance the efficiency and site-specificity of labeling. The first report on protein labeling with ^{18}F-fluoride was published by Mueller-Platz et al. (*11*) who tagged urokinase with ^{18}F-acetate. Herman et al. (*12*) successfully labeled human serum albumin (HSA) protein using two pentafluorophenyl derivatives as prosthetic groups. The well-known ^{18}F-SFB (*13, 14*) has been employed by several research groups to label bioactive molecules. Besides the aforementioned ^{18}F labeling synthons, a large number of other ^{18}F-labeled prosthetic groups have been investigated (*12, 15, 16*) and prominent routes for their conjugation to macromolecules have been mainly via ^{18}F-fluoroalkylation (*16, 17*), ^{18}F-fluoroacylation (*18, 19*), ^{18}F-fluoroamidation (*20, 21*), thiol-coupling (*22, 23*), or photochemical conjugation (*8, 24*). Among the above-mentioned methods, nucleophilic aromatic fluorination with nca ^{18}F-fluoride has been well-established. The ^{18}F-for-$^{+}$N(CH$_3$)$_3$ substitution was first reported more than two decades ago, and a large variety of ^{18}F-labeled aromatic radiopharmaceuticals have been reported (*25*). A disadvantage, however, of the established methods is the fact that the synthetic methods entail multistep syntheses and the ^{18}F label is incorporated very early in the synthesis sequence. In order to circumvent this shortcoming, research groups are focusing on new synthetic strategies that avoid the use of prosthetic groups. Recent studies have demonstrated the feasibility of labeling organoboron and organosilicon bioconjugates with ^{18}F in a single step (*26*−*28*). The one-step process can easily be automated for routine production. The aim of this work was to develop a direct one-step method for the nca fluorine-18 labeling of peptides.

EXPERIMENTAL PROCEDURES

General. All chemicals unless otherwise stated were purchased from Sigma-Aldrich or Merck and used without further purification. Fmoc-amino acids were purchased from IRIS Biotech except Fmoc-statine and FA01010, which were purchased from NeoMPS (now Polypeptide). The solvents were of HPLC quality. Peptide syntheses were carried out using Rink amide resin (0.68 mmol/g) following the standard Fmoc strategy (*29*). All amino acid residues were, if not further specified, L-amino acid residues. FA01010 denotes (4*R*,5*S*)-4-amino-5-methylheptanoic acid, statine (Sta) (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid, and Ava 5-aminopentanoic acid. High-

performance liquid chromatography (HPLC) analyses were performed using either a Altech Econsphere C18 RP column (53 × 7 mm, 3 μm) or an ACE C18 column (50 × 4.6 mm, 3 μm) under the indicated conditions. Analytical HPLC chromatograms were obtained using an Agilent 1100 system with *Gina* software, equipped with UV multiwavelength and Raytest Gabi Star detectors. Semipreparative HPLC purifications were carried out using a semipreparative ACE C18 column (250 × 10 mm, 5 μm) under the indicated conditions. Semipreparative HPLC system used was a Merck-Hitachi L6200A system equipped with Knauer variable wavelength detector and Eberline radiation detector.

TMA-Based Peptides Syntheses. *Peptide Synthesis (General Procedure).* The resin-bound Fmoc peptide was treated with 20% piperidine in DMF (v/v) for 5 min. This step was repeated with a reaction time of 20 min, and thereafter, the resin was washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×). A solution of Fmoc-Xaa-OH (Xaa = amino acid, 4 equiv), HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, 4 equiv), HOBT (1-hydroxybenzotriazole, 4 equiv), DIPEA (*N*,*N*′-di-iso-propylethylamine, 8 equiv) in DMF was added to the resin-bound free amine peptide and shaken for 90 min at room temperature. This step was repeated with a reaction time of 60 min, and the resin was washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×). The two steps of Fmoc-deprotection and amino acid addition were then repeated until the final elongation of the desired peptide was achieved. The peptides were typically prepared starting with 147 mg (0.1 mmol) of the resin. The amounts of reagents and building blocks in all subsequent reactions were calculated on the basis of this amount.

*Procedure for the Synthesis of (4-Trimethylammonium-3-cyanobenzoyl)-Functionalized Peptides Trifluoroacetate Salts (Precursor Compounds **6a**−**11a**).* Representative procedure: *N*-methylmorpholine (NMM, 22 μL, 0.2 mmol) was added to a solution of 2-cyano-4-carboxylphenyl)trimethylammonium triflate salt (71 mg, 0.2 mmol) and 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methylmorpholinium tetrafluoroborate (66 mg, 0.2 mmol) in DMF (2 mL). The mixture was added to the resin-bound, side-chain-protected, Fmoc-deprotected peptide (0.1 mmol, based on the initial resin loading), which was prepared by following the general procedures described above. The reaction mixture was shaken intensively for 4 h. The resin was then filtered and washed with DMF (3 × 4 mL) and CH_2Cl_2 (3 × 4 mL). The coupling step was repeated. Thereafter, the resin was treated with a mixture of trifluoroacetic acid, distilled water, phenol, and triisopropylsilane (85/5/5/5, 1.5 mL) for 3 h. The mixture was added to ice-cold methyl *tert*-butyl ether, and the precipitate was separated by centrifugation. Water was added to the pellet, and the supernatant was lyophilized. The residue was purified by preparative RP-18 HPLC-MS with a gradient of 5−30% acetonitrile in 20 min and 0.1% trifluoroacetic acid as cosolvent. The desired fraction was collected and lypophilized, and the product was analyzed by HPLC-MS.

3-Cyano-4-trimethylammonium-benzoyl-Val-βAla-Arg-Gly-NH_2-trifluoroacetate salt (tetrapeptide **6a**, 17 mg, 24%): *m*/*z* M^+ calcd 587.3; found 587.4.

3-Cyano-4-trimethylammonium-benzoyl-Val-βAla-Phe-Gly-NH_2-trifluoroacetate salt (tetrapeptide **7a**, 25 mg, 36%): *m*/*z* M^+ calcd 578.3; found 578.6.

3-Cyano-4-trimethylammonium-benzoyl-Val-βAla-Lys-Gly-NH_2-trifluoroacetate salt (tetrapeptide **8a**, 19.5 mg, 29%): *m*/*z* M^+ calcd 559.3; found 559.1.

3-Cyano-4-trimethylammonium-benzoyl-Val-βAla-Met-Gly-NH_2-trifluoroacetate salt (tetrapeptide **9a**, 19 mg, 28%): *m*/*z* M^+ calcd 562.3; found 562.5.

3-Cyano-4-trimethylammonium-benzoyl-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH_2-trifluoroacetate salt (**10a**, 0.03 mmol scale, 15 mg, 37%): *m*/*z* M^+ calcd 1235.7; found 1235.8.

3-Cyano-4-trimethylammonium-benzoyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2-trifluoroacetate salt (**11a**, 10 mg, 7%): *m*/*z* $[M+H]^{2+}/2$ calcd 711.4; found 711.9.

*Syntheses of Fluorinated TMA-Based Peptides (Reference Compounds **6b**−**11b**).* Representative procedure: A solution of 3-cyano-4-fluorobenzoic acid (66 mg, 4 equiv), HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, 151 mg, 4 equiv), HOBT (1-hydroxybenzotriazole, 61 mg, 4 equiv), and DIPEA (*N*,*N*′-di-iso-propylethylamine, 70 μL, 4 equiv) in DMF (2 mL) was added to the resin-bound, side-chain-protected peptide (0.1 mmol, based on the initial resin loading), which was prepared by following the general procedures described above. The reaction mixture was shaken intensively for 4 h. The resin was then filtered and washed with DMF (3 × 4 mL) and CH_2Cl_2 (3 × 4 mL). Thereafter, the resin was treated with a mixture of trifluoroacetic acid, distilled water, phenol, and triisopropylsilane (85/5/5/5, 1.5 mL) for 3 h. The mixture was added to ice-cold methyl *tert*-butyl ether, and the precipitate was separated by centrifugation. Water was added to the pellet, and the supernatant was lyophilized. The residue was purified by preparative RP-18 HPLC-MS with a gradient of 5−50% acetonitrile in 20 min and 0.1% trifluoroacetic acid as cosolvent. The desired fraction was collected and lypophilized, and the product was analyzed by HPLC-MS.

3-Cyano-4-fluorobenzoyl-Val-βAla-Arg-Gly-NH_2 (tetrapeptide **6b**, 32 mg, 58%): *m*/*z* $[M+H]^+$ calcd 548.3; found 548.0.

3-Cyano-4-fluorobenzoyl-Val-βAla-Phe-Gly-NH_2 (tetrapeptide **7b**, 18 mg, 33%): *m*/*z* $[M+H]^+$ calcd 539.2; found 539.1.

3-Cyano-4-fluorobenzoyl-Val-βAla-Lys-Gly-NH_2 (tetrapeptide **8b**, 16.5 mg, 32%): *m*/*z* $[M+H]^+$ calcd 520.3; found 520.1.

3-Cyano-4-fluorobenzoyl-Val-βAla-Met-Gly-NH_2 (tetrapeptide **9b**, 17 mg, 33%): *m*/*z* $[M+H]^+$ calcd 523.2; found 523.0.

3-Cyano-4-fluorobenzoyl-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH_2 (**10b**, 0.03 mmol scale, 9 mg, 25%): *m*/*z* $[M+H]^+$ calcd 1196.6; found 1196.7.

3-Cyano-4-fluorobenzoyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**11b**, 0.03 mmol scale, 6.5 mg, 16%): *m*/*z* $[M+2H]^{2+}/2$ calcd 692.9; found 692.4.

^{18}F-Radiolabeling of TMA-Based Model Compounds and Peptides. *General.* No-carrier-added [^{18}F] fluoride was produced via the ^{18}O (p,n) ^{18}F nuclear reaction by irradiation of enriched [^{18}O] water. ^{18}F-fluoride was trapped on an anion-exchange resin cartridge (Sep-Pak QMA light, Waters). The cartridge was eluted with a solution of Kryptofix (5 mg), potassium carbonate (1 mg), or Cs_2CO_3 (2.4 mg) in water (500 μL) and MeCN (1 mL). The solvent was removed by azeotropic drying at 110 °C under vacuum for 10 min with a stream of nitrogen. Anhydrous MeCN (1 mL) was added and evaporated. This step of adding acetonitrile (1 mL) was repeated two more times. The tested precursor was dissolved in DMSO and added to the dry K[^{18}F]F/$K_{2.2.2.}$ or Cs[^{18}F]F/$K_{2.2.2}$ complex. The reaction mixture was then heated at 50−70 °C for 5−15 min. An aliquot was taken from the reaction mixture and analyzed by analytical HPLC. The ^{18}F-labeled product was confirmed by coinjection with the nonradioactive reference compound on the same analytical HPLC using either ACE C18 column (50 × 4.6 mm, 3 μm) or Altech Econsphere C18 RP column (53 × 7 mm, 3 μm). Elute conditions with ACE C18 column: 10 mM K_2HPO_4 in water (solvent A), 10 mM K_2HPO_4 in water/acetonitrile 3/7 (solvent B); 0 min, 5% B; 0−7.00 min, 5→95% B; 7.00−7.10 min, 95→100% B; 7.10−8.80 min, 100% B; 8.80−9.00 min, 100→5% B. The flow rate was 2 mL/min. Elute conditions with Altech Econsphere C18 RP column: 0.1% aq TFA (solvent A), 0.1% TFA in acetonitrile/water 9/1 (solvent B); 0 min, 5% B;

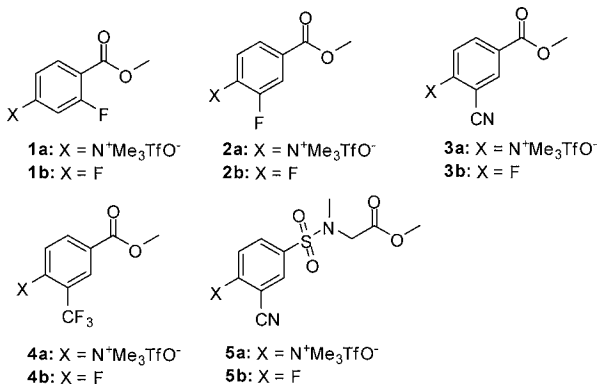

Figure 1. Structures of synthesized TMA-based model precursor compounds **1a**−**5a** and their corresponding fluorinated compounds **1b**−**5b.**

0−7 min, 5→95% B; 7.00−7.10 min, 95→100% B; 7.10−8.80 min, 100% B; 8.80−9.00 min, 100→5% B; flow rate: 2 mL/min.

^{18}F-Radiolabeling of TMA-Based Model Compounds. TMA-based bifunctional model precursor compounds (**1a**−**5a**, Figure 1) were synthesized and characterized (see Supporting Information). Their corresponding reference compounds (**1b**−**5b**) are, in most cases, commercially available. Typical experimental conditions for the ^{18}F-radiolabeling of precursor compounds **3a** and **5a** are described below.

Methyl-3-cyano-4-[^{18}F]fluorobenzoate (**[^{18}F]3b**). Compound **3a** (4.2 mg) in anhydrous DMSO (300 μL) was added to a reaction vial containing dry K[^{18}F]F/$K_{2.2.2}$ complex (6.57 GBq). After heating at 50 °C for 15 min, an aliquot was taken for HPLC analysis (ACE C18 column), and more than 90% ^{18}F-incorporation was obtained. The reaction mixture was diluted with water (1.5 mL), and this solution (3.86 GBq) was injected onto an ACE semipreparative HPLC column (0.1% TFA in water (solvent A), 0.1% TFA in acetonitrile/water 9/1 (solvent B), isocratic 30% B, flow rate: 4 mL/min). The decay-corrected radiochemical yield of the isolated product (2.89 GBq) was around 77% and radiochemical purity was greater than 99%. Specific activity was 95 GBq/μmol at the end of the synthesis.

Methyl 2-(3-cyano-4-[^{18}F]fluoro-*N*-methyl-phenyl-sulfonamido)acetate (**[^{18}F]5b**). A solution of compound **5a** (1 mg) in anhydrous DMSO (100 μL) was added to a reaction vial containing dry K[^{18}F]F/$K_{2.2.2}$ complex. After heating at 70 °C for 5 min, an aliquot of the reaction mixture was taken for HPLC analysis (ACE C18 column). The ^{18}F-incorporation was 80%.

^{18}F-Radiolabeling of TMA-Based Peptides. ^{18}F-labeling of the TMA-based peptides (Figure 2) was performed under similar reaction conditions as described above.

3-Cyano-4-[^{18}F]fluorobenzoyl-Val-βAla-Arg-Gly-NH_2 (**[^{18}F]6b**). A solution of compound **6a** (2 mg) in anhydrous DMSO (300 μL) was added to a reaction vial containing dry K[^{18}F]F/$K_{2.2.2}$ complex. After heating the reaction mixture at 50 °C for 15 min, the crude reaction mixture was analyzed using an Altech Econsphere C18 RP column (53 × 7 mm, 3 μm) with the following elute: 0.1% aq TFA (solvent A), 0.1% TFA in acetonitrile/water 9/1 (solvent B); 0 min, 5% B; 0−7 min, 5→95% B; 7.00−7.10 min, 95→100% B; 7.10−8.80 min, 100% B; 8.80−9.00 min, 100→5% B; flow rate: 3 mL/min.). The ^{18}F-incorporation determined by HPLC was 92%.

The similar procedure described for **[^{18}F]6b** was used for the preparation of 3-cyano-4-[^{18}F]fluorobenzoyl-Val-βAla-Phe-Gly-NH_2 (**[^{18}F]7b**) and 3-cyano-4-[^{18}F]fluorobenzoyl-Val-βAla-Lys-Gly-NH_2 (**[^{18}F]8b**), and resulted in 80% and 25% ^{18}F-incorporation, respectively.

3-Cyano-4-[^{18}F]fluorobenzoyl-Val-βAla-Met-Gly-NH_2 (**[^{18}F]9b**). A solution of compound **9a** (2 mg) in anhydrous DMSO (300 μL) was added to a reaction vial containing dry K[^{18}F]F/$K_{2.2.2}$ complex. After heating at 90 °C for 15 min, the crude reaction mixture was analyzed under the same analytical HPLC conditions as described for **[^{18}F]6b**. The ^{18}F-incorporation determined by HPLC was 89%. The reaction mixture was diluted with water and injected onto an ACE semipreparative HPLC column (0.1% TFA in water (solvent A), B: 0.1% TFA in acetonitrile/water 9/1 (solvent B), isocratic, 35% B, flow rate: 4 mL/min) and the product was collected. The decay-corrected radiochemical yield of the isolated product was around 57% and radiochemical purity was greater than 99%. Specific activity was 74 GBq/μmol at the end of the synthesis.

3-Cyano-4-[^{18}F]fluorobenzoyl-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH_2 (**[^{18}F]10b**). A solution of compound **10a** (2 mg) in DMSO (150 μL) was added to a reaction vial containing dry Cs[^{18}F]F/$K_{2.2.2}$ complex. The reaction vessel was sealed and heated at 70 °C for 15 min. Analysis of an aliquot of the crude reaction mixture afforded an ^{18}F-incorporation of 77% with ACE C18 column. Thereafter, the reaction mixture was transferred to a vial containing water (4 mL) and then injected onto a semipreparative ACE column (0.1% aq TFA (solvent A); 0.1% TFA in acetonitrile/water 9/1 (solvent B), gradient 0−5 min, 30% B, flow rate 2 mL/min; 5−15 min, 30→70% B, flow rate: 3 mL/min). The desired ^{18}F-labeled product was collected (253 MBq, 20% d.c.), and the specific activity was around 75 GBq/μmol at the end of the synthesis.

3-Cyano-4-[^{18}F]fluorobenzoyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**[^{18}F]11b**). A solution of compound **11a** (2 mg) in DMSO (150 μL) was added to a reaction vial containing dry C_S[^{18}F]F/$K_{2.2.2}$ complex. The reaction vessel was sealed and heated at 70 °C for 15 min. An aliquot was taken from the crude reaction mixture and analyzed by HPLC (ACE C18 column); the ^{18}F-incorporation was 74%. The reaction mixture was then transferred to a vial containing water (4 mL). This product was purified using a semipreparative HPLC column (ACE C18, 0.1% aq TFA (solvent A); 0.1% TFA in acetonitrile/water 9/1 (solvent B), 0−5 min, 29% B; 5−25 min, 29→34% B, flow rate: 3 mL/min). The desired ^{18}F-labeled product was collected (150 MBq, 21% d.c.), and the specific activity obtained was 73 GBq/μmol at the end of the synthesis.

***In Vitro* Binding Affinity Assay.** The receptor affinities of two bombesin (BBN) analogues **10b** and **11b** were determined in quadruplicate in a scintillation proximity assay (SPA) using cellular membranes transfected with human bombesin 2 receptors (gastrin-releasing peptide receptors) from PerkinElmer (RBHBS2M). The membranes and agglutinin-coupled SPA beads type A (PVT PEI Treated Wheatgerm, Amersham Bioscience) were mixed in assay buffer (50 mM Tris/HCl pH 7.2; 5 mM $MgCl_2$; 1 mM EGTA, protease inhibitor (Roche Diagnostics GmbH; 1 tablet/50 mL) and 0.3% polyethylenemine) to give final concentrations of approximately 20 μg/mL protein and 8 mg/mL PVT-SPA beads. The ligand [^{125}I]-Tyr^4-bombesin (PerkinElmer; specific activity: 81.4 TBq/mmol) was diluted to 0.2 nM in assay buffer. The test compounds were dissolved in DMSO to give 1 mM stock solutions. They were further diluted in assay buffer to 2 pM to 300 nM. Unspecific binding was determined by an excess of 10 000 nM Tyr^4-bombesin (Sigma).

The assay was then performed as follows: First, 10 μL of compound solution to be tested for binding was placed in white 384 well plates (Lumitrac 200, Greiner). Next, 20 μL GRPR/PVT-SPA bead mixture and 20 μL of the ligand solution were added. After 120 min incubation at room temperature, another 50 μL of assay buffer was added; the plate was sealed and centrifuged for 10 min at 520 × *g* at room temperature. Signals were measured in a TopCount (Perkin-Elmer) for 1 min integration time per well. Unspecific binding determined by an

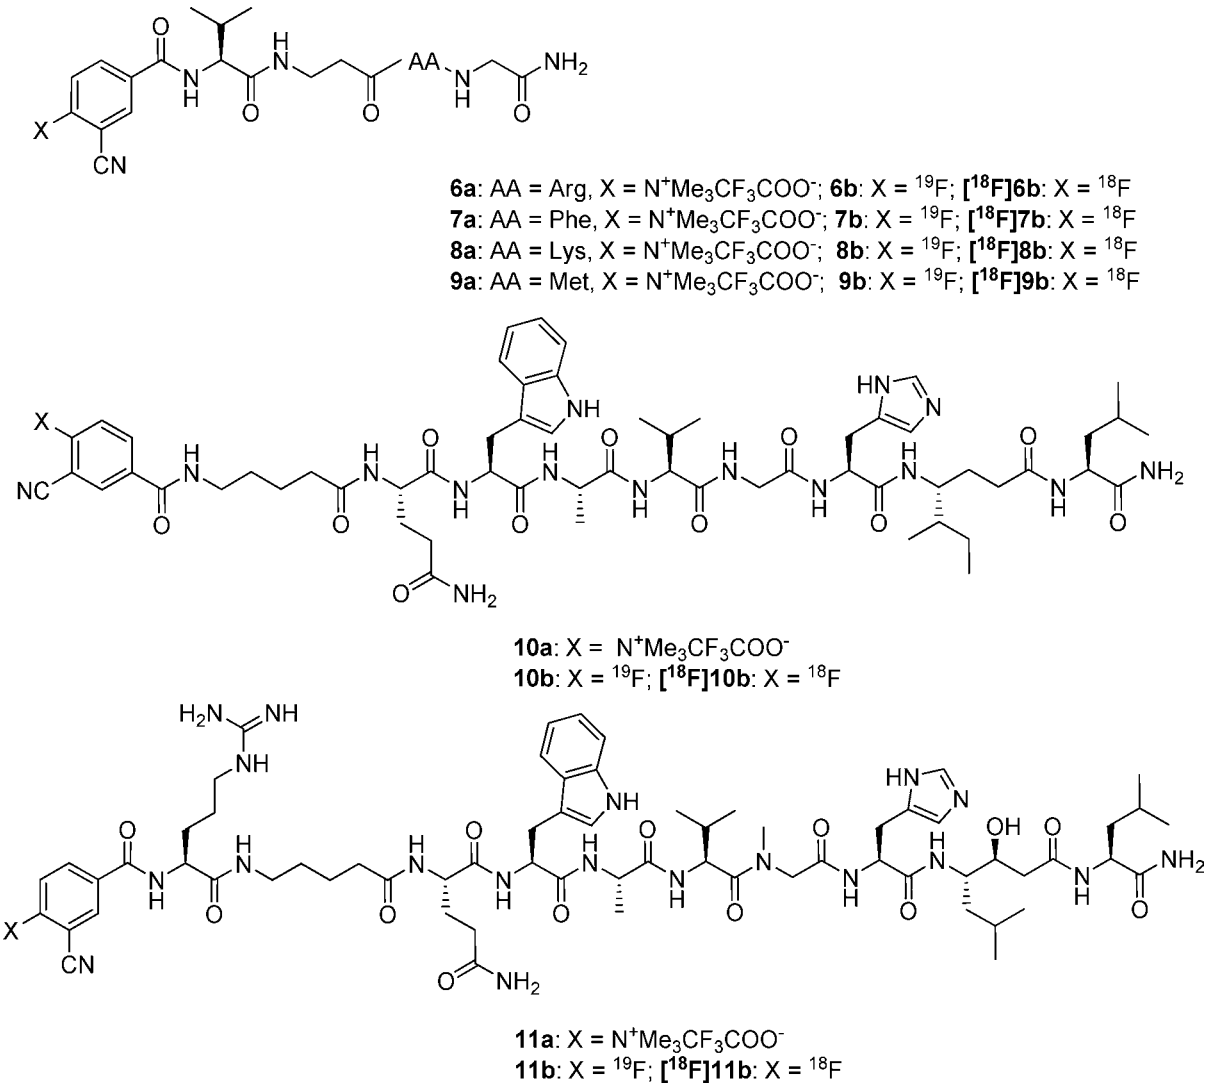

Figure 2. Structures of TMA-based peptides.

excess of Tyr^4-bombesin was subtracted from total binding to yield the specific binding at each concentration. The IC_{50} and K_i values were calculated by nonlinear regression using *GraFit 5* data analysis software (Erithacus Software Ltd.).

Plasma Stability Studies. The stability of the radiolabeled compound **[^{18}F]10b** and **[^{18}F]11b** was investigated in mouse plasma at different time points (from 0 to 90 min) at 37 °C. Phosphate-buffered saline (PBS) was used as a control. After incubation, plasma proteins were precipitated with acetonitrile followed by centrifugation (10 min, 13 000 rpm) at 4 °C. The PBS controls were diluted with the same volume of acetonitrile. The supernatants and PBS controls were analyzed by HPLC (Column Ecosphere C18, 53 × 7 mm, 3 mm, flow rate: 1.8 mL/min). The percentage of intact compound was determined at different incubation times.

RESULTS AND DISCUSSION

Syntheses and ^{18}F-Labeling of TMA-Based Model Compounds. Precursor compounds **1a**−**5a** were obtained in two steps with moderate to good yields (Supporting Information). In most cases, the displacement of fluoride with dimethylamine was carried out via nucleophilic aromatic substitution under basic conditions. The quarternization of dimethylamine intermediate with methyl triflate was performed under normal or increased pressure (1−10 bar). The crude products were purified by reversed-phase column chromatography. All the corresponding reference compounds **1b**−**5b** are commercially available except **3b**. Compound **3b** was obtained in two steps starting from commercially available 2-fluoro-5-formylbenzonitrile, which was converted to the corresponding acid by classical oxidation method followed by acid esterification.

Since nucleophilic aromatic substitutions of ^{18}F-for-$^{+}$N(CH$_3$)$_3$ typically require high temperatures (>100 °C) which are not suitable for radiolabeling of peptides, electron withdrawing groups such as −CF$_3$, −CN, and −F and a carbonyl functionality have been introduced to the aromatic ring in order to increase the reactivity of the trimethylammonium leaving group. To demonstrate the feasibility of direct ^{18}F-labeling of peptides, a series of trimethylammonium-based model compounds **1a**−**5a** (Figure 1) bearing electron-withdrawing groups (−CN, −CF$_3$, −F) were tested. The carbonyl functionality has the added attraction that, via conversion to the corresponding acid, these trimethylammonium building blocks can be coupled to peptides. There are only a few publications on nucleophilic aromatic substitution of a TMA group by ^{18}F-fluoride ion in aromatic compounds containing two or more substitutents besides the trimethylammonium moiety (*30*, *31*). The radiosynthetic route is depicted in Scheme 1, and the radiolabeling results are shown in Table 1.

From the results shown in Table 1, high ^{18}F-incorporation was obtained with all the model compounds under mild radiolabeling conditions. The radiolabeling efficiency was not

Table 1. ^{18}F-Radiolabeling of TMA-Based Model Compounds[a]

entry	compd.	precursor amount	temp (°C)	reaction time	conversion(%)
1	**1a**	1 mg	70	15 min	79 ± 7 (n = 3)
2	**2a**	1 mg	50	15 min	82 ± 4 (n = 3)
3	**3a**	4 mg	50	15 min	89 ± 4 (n = 3)
4	**3a**	2 mg	50	15 min	83 ± 15 (n = 2)
5	**3a**	1 mg	50	15 min	80 ± 2 (n = 2)
6	**4a**	2 mg	50	15 min	79 ± 10 (n = 2)
7	**5a**	1 mg	50	5 min	65 ± 4 (n = 3)
8	**5a**	1 mg	70	5 min	80 ± 4 (n = 2)

[a] ^{18}F-labeling was carried out in DMSO with K_2CO_3 as the base. Conversion was determined from radio-HPLC chromatogram representing the percentage of radioactivity area of product related to the total radioactivity area.

dramatically influenced by the amount of precursor (Table 1, entries 3−5). However, by increasing the reaction temperature from 50 to 70 °C, the ^{18}F-incorporation of compound **[^{18}F]5b** increased from 65% to 80% (Table 1, entries 7 and 8). Although no detailed study on the influence of reaction time was performed, it seems that 5 min reaction time is sufficient for a good conversion. The combined effect of the electron-withdrawing group and the carbonyl/sulfonyl on the phenyl ring facilitated an easy ^{18}F-for-$^{+}N(CH_3)_3$ substitution. This would explain why no decomposition of the ammonium precursors and the formation of volatile methyl [^{18}F]fluoride were observed with precursor compounds **1a**−**5a** under the indicated radiolabeling conditions (Table 1) compared to published results (*32*). Furthermore, no ^{18}F−^{19}F isotopic exchange was observed for compounds **[^{18}F]1b** and **[^{18}F]2b** under the mild radiolabeling conditions (50 and 70 °C). The large polarity difference between the TMA-precursor and fluorinated product allowed an easy semi-HPLC separation of the ^{18}F-labeled products from their corresponding precursors. For example, the radiochemical purity of compound **[^{18}F]3b** was greater than 99% after semi-HPLC purification, and the specific activity obtained was around 95 GBq/μmol at the end of the synthesis. Among the model compounds studied, compound **[^{18}F]3b** with the cyano-activating group gave the best radiochemical yield of 77%.

Syntheses and ^{18}F-Labeling of TMA-Based Peptides. On the basis of the radiolabeling results of model compounds **1a**−**5a**, compound **3a** was converted to its corresponding acid 4-carboxy-2-cyano-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate (Supporting Information) for coupling to target peptides using standard solid-phase peptide synthesis protocols (*29*). For TMA-based tetrapeptides, amino acids such as Arg, Phe, Lys, and Met were introduced in order to study their influence on ^{18}F-labeling efficiency. Two bombesin analogues were synthesized with modifications of the amino acid sequence of BBN(7−14)-NH_2. Non-natural amino acid such as FA01010 or Sta were incorporated into the bombesin peptide sequence for increasing its metabolic stability; Ava or Arg-βAla was used as a linker for attaching the aryltrimethylammonium building block and the N-terminal bombesin peptide. The corresponding standard references were synthesized by the conjugation of 3-cyano-4-fluorobenzoic acid with the same peptides applying similar protocols used for the syntheses of the precursors.

Table 2. ^{18}F-Radiolabeling of TMA-Based Peptides[a]

entry	compd.	temp (°C)	base	reaction time	conversion (%)

2	**7a**	50	K_2CO_3	15 min	80 (n = 1)
3	**8a**	90	K_2CO_3	15 min	0 (n = 2)
4	**8a**	90	Cs_2CO_3	15 min	24 ± 8 (n = 3)
5	**9a**	50	K_2CO_3	15 min	19 ± 4 (n = 3)
6	**9a**	90	K_2CO_3	15 min	89 ± 3 (n = 3)
7	**10a**	70	Cs_2CO_3	15 min	70 ± 7 (n = 3)
8	**11a**	70	Cs_2CO_3	15 min	51 ± 5 (n = 2)

[a] ^{18}F-labeling was carried out in DMSO (200−300 μL) with 2 mg of precursor. Conversion was determined from radio-HPLC chromatogram representing the percentage of radioactivity area of product related to the total radioactivity area.

The direct one-step ^{18}F-labeling was applied to four tetrapeptides (Table 2, entries 1−6) differing only in one amino acid in the peptide sequence. Using similar radiolabeling conditions as applied to the model compounds, tetrapeptides **6a** and **7a** gave ^{18}F-incorporation of 92% and 80%, respectively. In the case of the lysine-containing tetrapeptide **8a** (entry 3), there was no product formation when potassium carbonate was used as the base; however, a moderate ^{18}F-incorporation (24%) was achieved with cesium carbonate as the base at 90 °C. The low ^{18}F-incorporation might be due to the presence of free amino functionality. Nevertheless, the improvement is remarkable. With the methionine-containing tetrapeptide **9a**, the temperature effect for the ^{18}F-incorporation is worth mentioning. The ^{18}F-incorporation was only 19% after 15 min at 50 °C; however, by increasing the temperature to 90 °C, a dramatic increase of ^{18}F-incorporation (89%) was achieved (Table 2, entries 5 and 6). Because these results were encouraging, this one-step ^{18}F-labeling approach was applied to two bombesin peptides **10a** and **11a**. As shown in Table 2, more than 70% ^{18}F-incorporation was found for **[^{18}F]10b** when an aliquot was directly removed from the reaction mixture and analyzed by HPLC. A typical radio-HPLC profile of compound **[^{18}F]10b** is shown in Figure 3. Only two radioactive peaks were observed from the analytical HPLC chromatogram of the reaction mixture. Apart from free ^{18}F-fluoride and the desired ^{18}F-labeled compound (retention time = 7.2 min), no other radioactive compound was observed. After adding HPLC eluent to the reaction vial and purifying the mixture by semi-HPLC, around 20% (decay-corrected) radiochemical yield of the final product was obtained. The relatively large difference between isolated radiochemical yield and ^{18}F-incorporation of compound **[^{18}F]10b** (20% vs 70%) is due to the fact that Cs[^{18}F]F/$K_{2.2.2}$ complex can be absorbed on the surface of the reaction vial (*33*). This absorbed ^{18}F-fluoride activity is, however, not taken into account when an aliquot of the reaction mixture is taken for analysis. The radiochemical purity was 99% and specific activity was around 79 GBq/μmol at the end of synthesis.

With respect to the stereochemistry of the peptides, similar peptides have been labeled under basic conditions (pH 8−10) and even at higher or elevated temperatures (75−100 °C), and no racemization of the peptides was observed (*34*−*36*). Because our radiolabeling conditions (pH < 8, temp 50−70 °C) are even milder than those previously reported, we do not expect that racemization will occur with any of the peptides reported in this manuscript.

***In Vitro* Binding Affinity Assay.** The *in vitro* binding affinity of the fluorinated bombesin peptides **10b** and **11b** to the gastrin-releasing peptide receptor were assessed via a competitive displacement assay using [^{125}I]-Tyr^4-bombesin as the radioligand. Both peptides demonstrated high binding affinity to the gastrin-releasing peptide receptor with IC_{50} values of 9.20 nM and 2.71 nM (Figure 4). The K_D value of the radioligand I-125-Tyr^4-bombesin was determined in former assays to be ap-

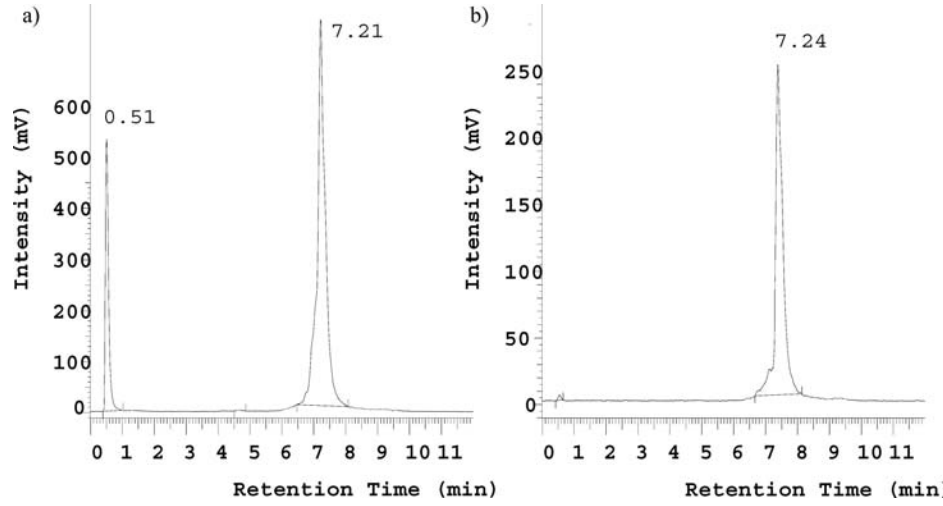

Figure 3. Radio-HPLC profiles of 3-cyano-4-[^{18}F]fluorobenzoyl-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH_2 (**[^{18}F]10b**): (a) reaction mixture; (b) purified compound.

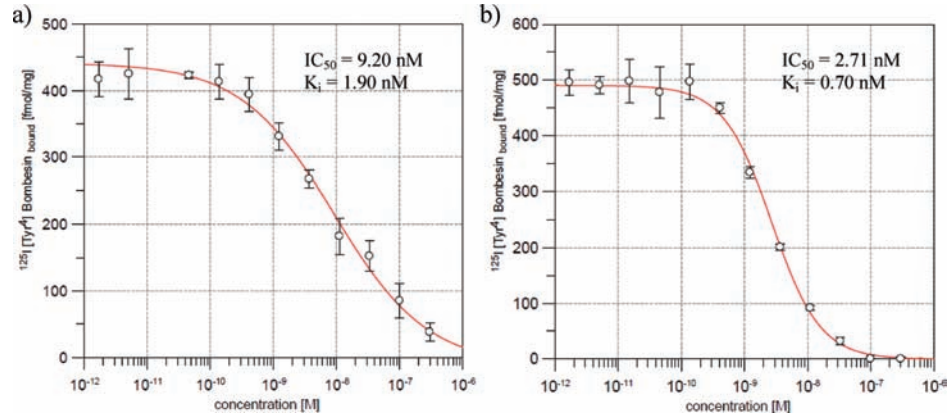

Figure 4. Competitive binding of (a) 3-cyano-4-fluorobenzoyl-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH_2 (**10b**) and (b) 3-cyano-4-fluorobenzoyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2 (**11b**) versus [^{125}I]-Tyr^4-bombesin on human bombesin 2 receptor membranes in a scintillation proximity assay.

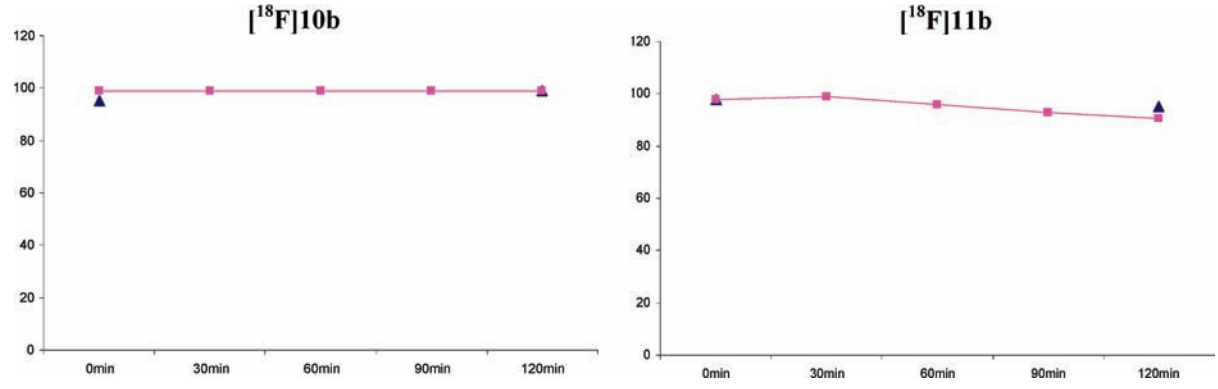

Figure 5. Radiochemical stability studies of **[^{18}F]10b** and **[^{18}F]11b** at 37 °C. ▲, with PBS; ■, with mouse plasma.

proximately 0.06 nM. Therefore, the normalized binding affinities represented excellent K_i values of 1.90 nM and 0.70 nM for **10b** and **11b**, respectively (Figure 4). For comparison, human GRP serving as a positive control showed a K_i of 5−10 nM, whereas Neuromedin B serving as a negative control had a K_i of >500 nM (see Supporting Information).

Plasma Stability Studies. Plasma stability was evaluated for both bombesin peptides **[^{18}F]10b** and **[^{18}F]11b** in mouse plasma at time points of 0, 30, 60, 90, and 120 min at 37 °C, with PBS as control. As indicated in Figure 5, **[^{18}F]10b** showed excellent plasma stability over the tested time period. **[^{18}F]11b**, however, was slightly degraded to ^{18}F-fluoride, but is stable enough to allow for *in vivo* studies. There are no significant differences between plasma results and PBS findings of compounds **[^{18}F]10b** and **[^{18}F]11b.**

CONCLUSION

In conclusion, a series of trimethylammonium-based model compounds containing different electron-withdrawing substituents, a trimethylammonium (TMA) leaving group, and a linker

for coupling to peptides were designed and synthesized. The appropriate model compounds were converted to their corresponding carboxylic acids and coupled to model tetrapeptides containing different amino acids and bombesin peptides. High ^{18}F-incorporation was obtained with all the model compounds under mild radiolabeling conditions. The results of the one-step [^{18}F]-fluorination of the tetrapeptides and bombesin peptides show that the direct ^{18}F-labeling of peptides is feasible under mild conditions and in good radiochemical yields. This method might not be applicable in all cases. However, in our hands, we were able to achieve a 24% radiochemical yield of one of the peptides bearing a free amino group in lysine. Peptides containing histidine, tryptophan, and arginine amino acids are also amenable to fluorine-18 labeling using this direct approach. Under normal circumstances, these amino acids would require protection with appropriate protecting groups. We are currently working on more peptides which contain cysteine and tyrosine amino acids. In conclusion, this work demonstrates that a rational approach to peptide design can be useful for the direct ^{18}F labeling of peptides and other large biomolecules.

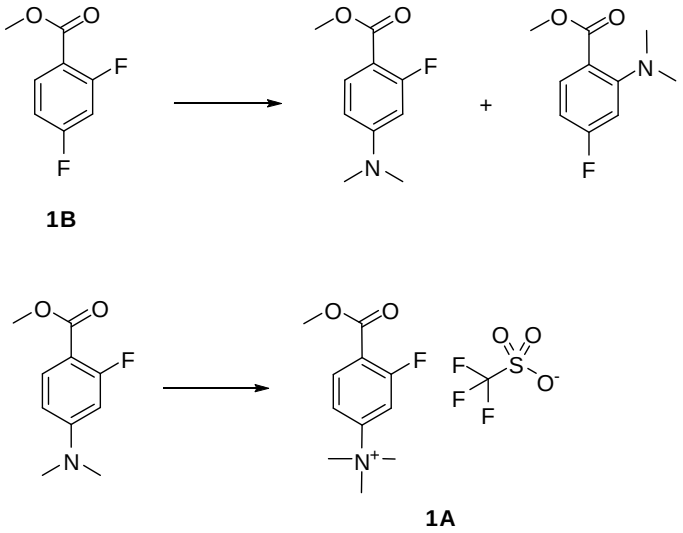
Supporting Information

General. All chemicals unless otherwise stated were purchased from Sigma-Aldrich or Merck and used without further purification. Analytical thin–layer chromatography (TLC) was performed on silica gel, NH_2 or RP-18 (60 F_{254}) plates (0.25 mm) precoated with a fluorescent indicator. Preparative thin-layer chromatography (preparative TLC) was performed on silica gel (60 F_{254}) plates (0.5 mm with concentrating zone) precoated

with a fluorescent indicator. Bruker Avance 300 and 400 were used for NMR measurements. ^{1}H-NMR, ^{13}C-NMR spectra were recorded as δ values relative to the solvent signal. Coupling constants are reported in Hertz. The multiplicity is defined by s (singlet), d (doublet), t (triplet), sept (septet), br (broad), m (multiplet).

Preparation of TMA-based model compounds

3-Fluoro-4-(methoxycarbonyl)-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate (1a)



Scheme 1: Synthetic route for compound **1a**

To an autoclaved vessel was added methyl 2,4-difluorobenzoate (40 g, 225 mmol) in DMSO (600 ml) followed by dimethylamine hydrochloride (22.3 g, 270 mmol) and potassium carbonate (65.4 g, 473 mmol). The suspension was stirred for 5 hours at 55°C under a pressure of 0.5 bar. The reaction mixture was concentrated and the residue was

dissolved in dichloromethane and washed with water, brine, dried over Na_2SO_4 and concentrated *in vacuo*. The crude residue was subjected to silica chromatography (Hexane:EtOAc, 20:1 to 8:1) to give the methyl 4-(dimethylamino)-2-fluorobenzoate (25.2 g, 57%) and a by-product identified to be methyl 2-(dimethylamino)-4-fluorobenzoate (13.9 g, 31%).

Methyl 4-(dimethylamino)-2-fluorobenzoate

^{1}H NMR (400 MHz, $CDCl_3$) δ ppm 3.01 (s, 6 H), 3.86 (s, 3 H), 6.29 (dd, *J*=14.9, 2.5 Hz, 1 H, H-3), 6.41 (dd, *J*=8.9, 2.5 Hz, 1 H, H-5), 7.80 (t, *J*=8.9 Hz, 1 H, H-6)

^{13}C NMR (75 MHz, $CDCl_3$) δ ppm 40.1, 51.7, 98.8, 105.1, 107.1, 133.4, 154.8, 163.9 (d, *J* = 256.7 Hz), 165.3

ESI-MS: m/z 198 $[M+H]^+$

Methyl 2-(dimethylamino)-4-fluorobenzoate

^{1}H NMR (400 MHz, $CDCl_3$) δ ppm 2.87 (s, 6 H, NCH_3), 3.89 (s, 3 H, OCH_3), 6.52 (ddd, *J*=8.6, 7.6, 2.3 Hz, 1 H, H-5), 6.62 (dd, *J*=12.0, 2.3 Hz, 1 H, H-3), 7.70 (dd, *J*=8.6, 6.9 Hz, 1 H, H-6)

^{13}C NMR (75 MHz, $CDCl_3$) δ ppm 43.5, 52.1, 103.5, 105.5, 116.2, 134.1, 154.4, 165.4 (d, *J* = 250.7 Hz) 167.9

ESI-MS: m/z 198 $[M+H]^+$

To a solution of methyl 4-(dimethylamino)-2-fluorobenzoate (2.5 g, 13 mmol) in anhydrous dichloromethane (50 ml) was added methyl trifluoromethanesulfonate (20.5 g, 125 mmol) dropwise under a nitrogen atmosphere. The reaction mixture was refluxed for 2 days. The reaction mixture was concentrated and diethylether was added slowly. The product precipitates and the solvent was decanted. The solid was washed with

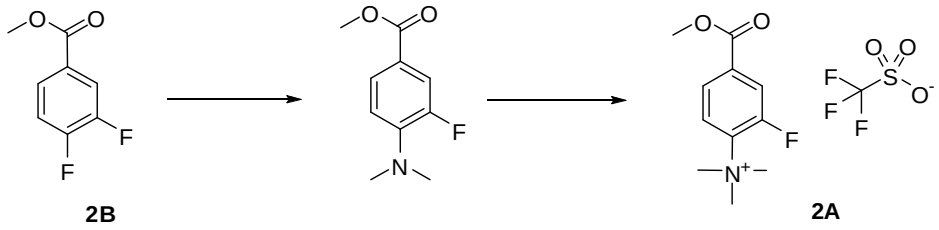
diethylether and purified by (C-18) RP-column chromatography (acetonitrile/water-gradient 1:99 to 80:20). The desired product **1a** was obtained in 78% yield (3.5 g).

^{1}H NMR (300 MHz, D_2O) δ ppm 3.59 (s, 9 H), 3.87 (s, 3 H), 7.69 (dd, *J*=8.7, 2.6 Hz, 1 H, H-5), 7.78 (dd, *J*=11.8, 2.6 Hz, 1 H, H-3), 8.10 (dd, *J*=8.7, 8.1 Hz, 1 H, H-6)

^{13}C NMR (75 MHz, D_2O) δ ppm 53.1, 57.0, 110.4, 116.2, 120.1, 133.9, 150.6, 161.6 (d, *J* = 261.5 Hz), 164.9

ESI-MS: m/z 212 $[M]^+$

2-Fluoro-4-(methoxycarbonyl)-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethane-sulfonate (2a)



Scheme 2: Synthetic route for compound **2a**

To an autoclaved vessel was added methyl 3,4-difluorobenzoate (4 g, 23 mmol) in DMSO (60 ml) followed by dimethylamine hydrochloride (2.2 g, 27 mmol) and potassium carbonate (6.5 g, 47 mmol). The suspension was stirred for 5 h at 55°C under a pressure of 0.5 bar. The reaction mixture was concentrated and the residue was dissolved in dichloromethane (100 ml) and washed with water (2 x 50 ml), brine, dried over Na_2SO_4 and concentrated *in vacuo* to give methyl 4-(dimethylamino)-3-fluorobenzoate (3.9 g, 88%) which was used without further purification.

^{1}H NMR (600 MHz, $CDCl_3$) δ ppm 2.98 (d, *J*=1.5 Hz, 6 H), 3.87 (s, 3 H), 6.78 (t, *J*=8.6 Hz, 1 H), 7.64 (dd, *J*=14.7, 2.0 Hz, 1 H), 7.71 (dd, *J*=8.6, 2.0 Hz, 1 H)

ESI-MS: m/z 197 $[M]^+$

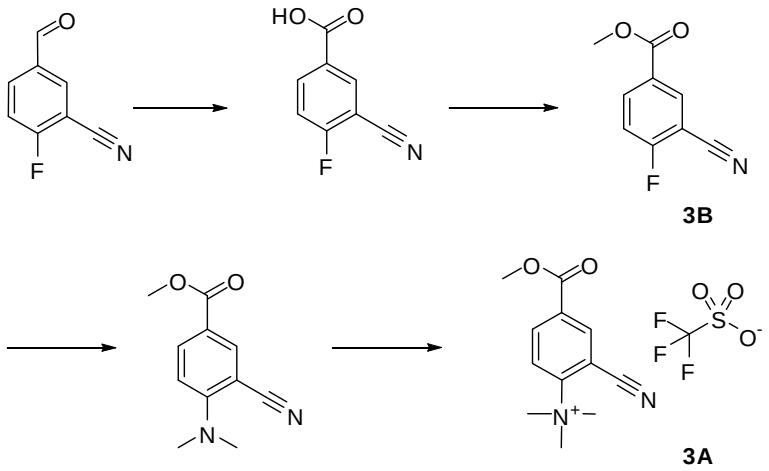
To a stirred solution of methyl 4-(dimethylamino)-3-fluorobenzoate (3.9 g, 20 mmol) in anhydrous dichloromethane (70 ml) was added methyl trifluoromethanesulfonate (32.8 g, 603 mmol) dropwise under nitrogen atmosphere. The reaction mixture was stirred for 2.5 days at RT and diethylether was added slowly. The product precipitates and the solvent was decanted. The solid was washed with diethylether and purified by (C-18) RP-column chromatography (acetonitrile/water-gradient 1:99 to 80:20). The desired product **2a** was obtained in 71% yield (5.1 g).

^{1}H NMR (300 MHz, D_2O) δ ppm 3.73 (s, 9 H), 3.93 (s, 3 H), 7.80 - 8.13 (m, 3 H)

^{13}C NMR (75 MHz, D_2O) δ ppm 53.2, 56.5, 120.0, 122.3, 126.6, 134.3, 136.1, 154.6 (d, *J* = 253.1 Hz), 166.2

ESI-MS: m/z 212 $[M]^+$

2-cyano-4-(methoxycarbonyl)-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate (3a)



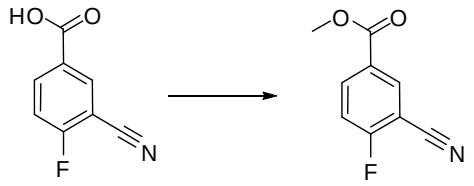
Scheme 3: Synthetic route for compound **3a** and **3b**

To an ice-cooled solution of 2-fluoro-5-formylbenzonitrile (20 g, 130 mmol) in tert-butanol (840 ml) and deionized water (200 ml) was added 2-methyl-2-butene (73 ml, 680 mmol), NaCl (54.4 g, 480 mmol) and Na_2HPO_4 (47.9 g, 307 mmol). The reaction mixture was stirred for 16 h at RT. The suspension was diluted with water and acidified to pH 3.5 with 1 M HCl. The solution was extracted twice with a mixture of dichloromethane and isopropanol (10:1). The combined organic phases were dried over sodium sulphate and concentrated. The solid residue was dissolved in sodium hydrogen carbonate solution and washed three times with diethylether. The aqueous phase was acidified to pH 3.5 with HCl (1 M) and the resulting precipitate was collected by filtration. The solid was dissolved in methanol, dried over Na_2SO_4, filtered and concentrated *in vacuo*. The resulting solid was washed with hexane and dried *in vacuo* at 35°C to give the 3-cyano-4-fluorobenzoic acid (20.2 g, 94%) which was used without further purification.

^{1}H NMR (300 MHz, MeOD) δ ppm 7.19 - 7.57 (m, 1 H), 8.23 - 8.44 (m, 2 H)

ESI-MS: m/z 164 $[M-H]^+$

Synthesis of methyl 3-cyano-4-fluorobenzoate (**3b**)



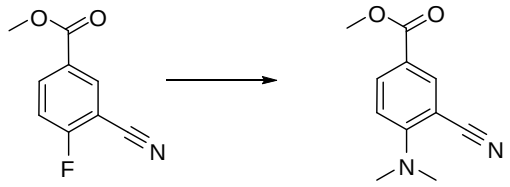
3B

To an ice-cooled suspension of 3-cyano-4-fluorobenzoic acid (24.6 g, 145 mmol) in methanol (250 ml) was added acetyl chloride (64 ml, 894 mmol) dropwise. The reaction mixture was stirred for 15 h. The reaction mixture was filtered and concentrated. The residue was dissolved in dichloromethane (300 ml) and washed with saturated $NaHCO_3$ solution (2 x 300 ml). The organic phase was dried over Na_2SO_4, filtered and concentrated to give the methyl 3-cyano-4-fluorobenzoate (24,6g, 92%) which was used without further purification.

^{1}H NMR (300 MHz, $CDCl_3$) δ = 3.96 (s, 3 H), 7.31 (t, *J*=8.6 Hz, 1 H), 8.19 - 8.40 (m, 2 H) ppm.

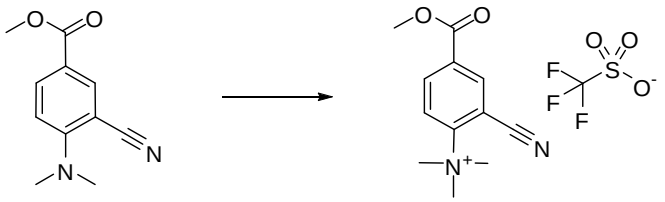
^{13}C NMR (63 MHz, $CDCl_3$) δ ppm 52.9, 112.2, 116.8, 117.1, 135.6, 136.5, 136.6, 164.3, 165.6 (d, *J*=218.3)

ESI-MS: m/z 180 $[M+H]^+$



To a stirred solution of methyl 3-cyano-4-fluorobenzoate (19.5 g, 109 mmol) in DMSO (195 ml) was added dimethylamine hydrochloride (10.8 g, 131 mmol) followed by

potassium carbonate (31.6 g, 229 mmol). The reaction mixture was stirred at room temperature overnight and concentrated. The residue was dissolved in dichloromethane (200 ml) and washed with water (2 x 100 ml), brine, dried over Na_2SO_4 and concentrated *in vacuo* to give the methyl 3-cyano-4-(dimethylamino)benzoate in quantitative yield and was used without further purification in the next step.



3A

To a stirred solution of methyl 3-cyano-4-(dimethylamino)benzoate (23.5 g, 115 mmol) in anhydrous dichloromethane (120 ml) was added methyl trifluoromethanesulfonate (100 g, 603 mmol) dropwise. The reaction was stirred at RT for 16 h and tert-butylmethylether (120 ml) was added slowly. The suspension was filtered and the collected solid was washed with tert-butylmethylether. The crude product was purified by (C-18) RP-column chromatography (acetonitrile/water-gradient 1:99 to 80:20) to afford product **3a** (14.8 g) in 63% yield.

^{1}H NMR (400 MHz, D_2O) δ ppm 3.87 (s, 9 H), 3.93 (s, 3 H), 8.15 (d, *J*=9.1 Hz, 1 H), 8.44 (dd, *J*=9.1, 2.1 Hz, 1 H), 8.67 (d, *J*=2.1 Hz, 1 H)

^{13}C NMR (101MHz, D_2O): δ ppm 53.6, 57.3, 105.9, 116.0, 122.9, 132.8, 136.4, 139.1, 148.7, 165.4

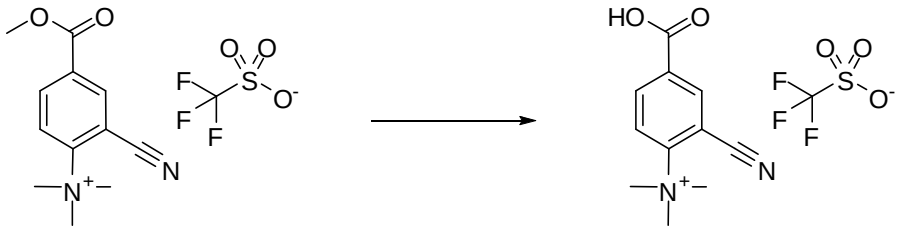
4-carboxy-2-cyano-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate



A solution of **3a** (5.4 g, 15 mmol) in water (127 ml) and TFA (127 ml) was heated at 120°C for 48 h. The reaction mixture was concentrated *in vacuo*, the light green oil was treated with diethylether to result a suspension. This solid was collected by filtration, washed with diethylether and dried *in vacuo* to give 4-carboxy-2-cyano-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate (4.6 g, 89%)

^{1}H NMR (300 MHz, DMSO) δ ppm 3.85 (s, 9 H), 8.23 - 8.35 (m, 1 H), 8.39 - 8.49 (m, 1 H), 8.58 (d, *J*=2.07 Hz, 1 H)

^{13}C-NMR (101 MHz, D_2O) δ ppm 57.3, 105.7, 116.1, 122.7, 133.8, 136.5, 139.2, 148.5, 166.8

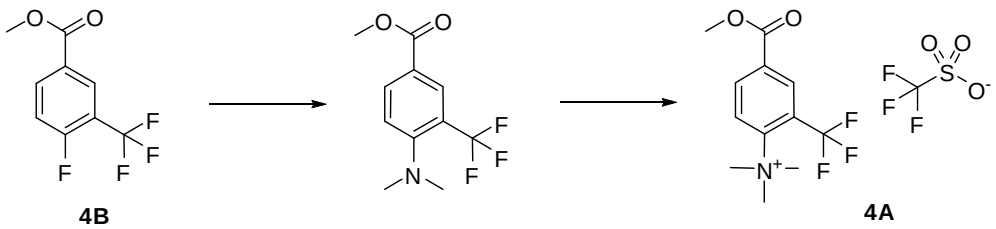
4-(methoxycarbonyl)-*N*,*N*,*N*-trimethyl-2-(trifluoromethyl)benzenaminium trifluoro-methanesulfonate (4a)



Scheme 4: Synthetic route for compound **4a**

To a solution of methyl 4-fluoro-3-(trifluoromethyl)benzoate (45.5 g, 200 mmol) in DMSO (500 ml) under nitrogen atmosphere was added dimethylamine hydrochloride (20.0 g, 250 mmol) followed by potassium carbonate (59.5 g, 430 mmol). The reaction mixture was stirred at 60°C for 8 h in an autoclave and then concentrated with high vacuum rotation evaporator at 65°C. The residue was dissolved in dichloromethane (200 ml) and washed with water (2 x 100 ml), brine, dried over Na_2SO_4 and concentrated. The oily crude product was purified by column chromatography (Hexane: EtOAc; 9:1) to give methyl 4-(dimethylamino)-3-(trifluoromethyl)benzoate (12.3 g, 45%).

^{1}H NMR (300 MHz, $CDCl_3$) δ ppm 2.94 (s, 6 H, NCH_3), 3.94 (s, 3 H, OCH_3), 7.15 (d, *J*=8.8 Hz, 1 H, H-6), 8.07 (dd, *J*=8.8, 2.1 Hz, 1 H, H-5), 8.31 (d, *J*=2.1 Hz, 1 H, H-3)

^{13}C-NMR (125 MHz, $CDCl_3$) δ ppm 44.4, 52.2, 110.5, 119.9, 124.3 (q, *J*=272 Hz), 130.6, 133.6, 135.0, 156.0, 166.2

ESI-MS: m/z 248 $[M+H]^+$

To a stirred solution of methyl 4-(dimethylamino)-3-(trifluoromethyl)benzoate (22.4 g, 91 mmol) in anhydrous dichloromethane (400 ml) under a nitrogen atmosphere was added dropwise methyl trifluoromethanesulfonate (150.2 g, 603 mmol). The reaction was stirred at RT for 60 h. To the reaction mixture was added diethylether slowly which led to the precipitate. After filtration, the residue was purified by using a LiChroPrep RP18 column (H2O 100% to H2O:acetonitrile 3:1). Starting material (8.8 g, 39%) and 4-

(methoxycarbonyl)-*N*,*N*,*N*-trimethyl-2-(trifluoromethyl) benzenaminium trifluoro-methanesulfonate (11.8 g, 32%) was isolated.

^{1}H NMR (400 MHz, D_2O) δ ppm 3.86 (s, 9 H, NCH_3), 3.97 (s, 3 H, OCH_3), 8.28 (d, *J*=9.0 Hz, 1 H, H-6), 8.44 (dd, *J*=9.0, 2.1 Hz, 1 H, H-5), 8.65 (d, *J*=2.1 Hz, 1 H, H-3)

^{13}C NMR (100 MHz, D_2O) δ ppm 55.9, 61.6, 120.6, 123.7, 125.7 (d, *J*=232 Hz), 126.7, 135.0, 137.9, 149.5, 168.4

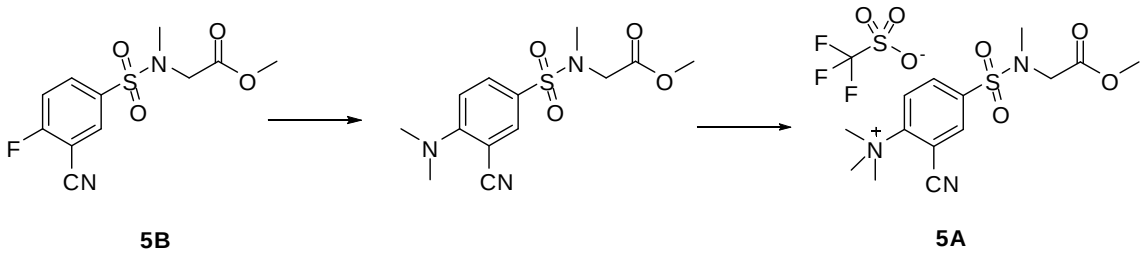
2-cyano-4-(*N*-(2-methoxy-2-oxoethyl)-*N*-methylsulfamoyl)-*N*,*N*,*N*-trimethylbenzenaminium trifluoromethanesulfonate (5a)



Scheme 5: Synthetic route for compound **5a**

To a stirred solution of methyl 2-(3-cyano-4-fluoro-*N*-methylphenyl-sulfonamido)acetate (5.7 g, 20 mmol) in DMSO (60 ml) were added dimethylamine hydrochloride (2.0 g, 24.7 mmol) and potassium carbonate (6.0 g, 43 mmol). The reaction mixture was stirred over night and then concentrated under high vacuum at 60°C. The residue was diluted with dichloromethane and washed twice with water. The combined aqueous phases were extracted with dichloromethane. The combined dichloromethane phases were washed with diluted sodium hydrogen carbonate solution, dried over sodium sulphate and

concentrated. The oily crude product methyl 2-(3-cyano-4-(dimethylamino)-*N*-methylphenylsulfonamido) acetate was obtained in 95% yield (5.9 g, 20 mmol) and was used directly in the next step without further purification.

To a stirred solution of methyl 2-(3-cyano-4-(dimethylamino)-*N*-methylphenylsulfonamido)acetate (3.9 g, 13 mmol) in dichloromethane (50 ml) was added methyl trifluoromethanesulfonate (20.5 g, 125 mmol) dropwise. The reaction mixture was refluxed for 2 days then cooled to room temperature. Diethylether was added. The desired compound precipitated and the solvent was decanted off. The crude product was purified by (C-18) RP-column chromatography (acetonitrile/water - gradient 1:99 to 80:20). The desired compound **5a** was obtained in 43 % yield (2.6 g, 5 mmol).

^{1}H NMR (400 MHz, D_2O) δ ppm 3.03 (s, 3 H), 3.75 (s, 3 H), 4.00(S, 9H), 4.29 (S, 2H), 8.37 (d, *J*=9.1 Hz, 1 H), 8.44 (dd, *J*=9.1, 2.2 Hz, 1 H), 8.73 (d, *J*=2.2 Hz, 1 H)

^{13}C NMR (100 MHz, D_2O) δ ppm 35.5, 50.9, 52.9, 57.3, 106.8, 115.3, 123.7, 134.3, 136.8, 140.6, 148.7, 171.1

ESI-MS: 326 (M^+ , 100).

^{18}F-labeling of TMA-based model compounds

Methyl-2-fluoro-4-[^{18}F]fluorobenzoate (**[^{18}F]1b**). ^{18}F-fluoride (839 MBq) was azeotropically dried in the presence of Kryptofix $K_{2.2.2}$ (5 mg in 1 ml MeCN) and potassium carbonate (1.0 mg in 0.5 ml water) by heating under nitrogen at 105°C for 30 min. During this time 2 × 1 ml MeCN were added and evaporated. After drying, a solution of compound **1a (**1 mg) in DMSO (100 μl) was added. The reaction vessel was

sealed and heated at 70°C for 15 min to effect labeling. The crude reaction mixture was analyzed using an analytical HPLC (ACE C18 column (50 × 4.6 mm, 3 μm)), the incorporation yield was 79%. The ^{18}F labeled product was confirmed by co-injection with the ^{19}F cold standard on the same column.

Methyl-3-fluoro-4-[^{18}F]fluorobenzoate (**[^{18}F]2b**). ^{18}F-fluoride (751 MBq) was azeotropically dried in the presence of Kryptofix $K_{2.2.2}$ (5 mg in 1 ml acetonitrile) and potassium carbonate (1 mg in 0.5 ml water) by heating under nitrogen at 105°C for 30 min. During this time 2 × 1 ml MeCN were added and evaporated. After drying, a solution of compound **2a** (1 mg) in DMSO (100 μL) was added. The reaction vessel was sealed and heated at 50°C for 15 min to effect labeling. The crude reaction mixture was analyzed using an analytical HPLC (ACE C18 column (50 × 4.6 mm, 3 μm)), the incorporation yield was 82%.

Methyl-3-trifluoromethyl-4-[^{18}F]flurobenzoate (**[^{18}F]4b**). ^{18}F-fluoride (73 MBq) was azeotropically dried in the presence of Kryptofix $K_{2.2.2}$ (5 mg in 1.5 ml MeCN) and potassium carbonate (1 mg in 0.5 ml water) by heating under nitrogen at 105°C for 30 min. During this time 2 × 1 ml MeCN were added and evaporated. After drying, a solution of methyl 3-trifluoromethyl-4-trimethylammoniumbenzoate triflate salt (2 mg) in DMSO (300 μL) was added. The reaction vessel was sealed and heated at 50°C for 15 min to effect labeling. The crude reaction mixture was analyzed using an analytical HPLC (ACE C18 column), the incorporation yield was 79%. The ^{18}F labeled product was confirmed by co-injection with the ^{19}F cold standard on the same HPLC column.

Snail1 Down-Regulation using Small Interfering RNA Complexes Delivered through Collagen Scaffolds

Rosa Viñas-Castells,[†,‡] Carolyn Holladay,[†] Andrea di Luca,[†] Victor Manuel Díaz,[‡,§] and Abhay Pandit*[,†]

Network of Excellence for Functional Biomaterials, National University of Ireland, Galway, Ireland, Programa de Recerca en Cancer, IMIM-Hospital del Mar, Barcelona, Spain, and Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain. Received June 10, 2009; Revised Manuscript Received October 16, 2009

Control of gene expression via small interfering RNA has enormous potential for the treatment of a variety of diseases, including cancer and Huntington's disease. However, before any therapies can be developed, effective techniques for controlled delivery of these molecules must be devised. In this proof-of-concept study, small interfering RNA was complexed with a polymer and loaded into a biomaterial scaffold. The scaffold was introduced primarily to control the release of the complexes, and the polymer was introduced to improve the transfection efficiency. An optimal dose and complexation ratio were selected, at which more than 50% down-regulation of the target gene Snail1 was observed in two-dimensional culture. Delayed release of the complexes was observed, and significant sustained down-regulation of Snail1 was seen in a three-dimensional scaffold system after 7 days. Thus, the use of the scaffold altered the transfection profile significantly, demonstrating the feasibility of a collagen scaffold as a controlled release system for delivery of small interfering RNA−dendrimer complexes.

INTRODUCTION

Cancer manifests through six basic alterations in cell behavior that lead to malignant growth: self-sufficient growth signaling, insensitivity to growth-inhibitory signals, evasion of apoptosis, unlimited reproduction, sustained angiogenesis, and metastasis (*1*). In epithelial tumor progression, metastasis can occur when loosely attached cancerous cells detach and migrate via the bloodstream to other tissues and organs.

E-cadherin (EC), which is localized in the adherens junctions between epithelial cells, has been found to be down-regulated in epithelial tumors that undergo a process termed "epithelial to mesenchymal transition" (EMT). Decreasing EC levels damage the adherens junctions, and therefore low EC is hypothesized to be among the factors promoting metastasis. The transcription factor Snail1 represses EC production (*2, 3*). Therefore, elevated levels of Snail1 decrease the strength of adherens junctions and thus increase tumor metastasis (*4*). Down-regulation of Snail1 is thus hypothesized to decrease metastasis of epithelial tumors.

RNA interference is a technique used in gene therapy to down-regulate expression of targeted genes. Short (21−23 nucleotides), double-stranded RNA sequences are incorporated into a RNA-induced silencing complex (RISC) and then can bind complementary mRNA strands. The bound mRNA is degraded, thus preventing translation of the gene in question (*5, 6*). However, to be effective, the small interfering RNA (siRNA) must reach the RISC and selectively bind the targeted sequence. Thus, the siRNA must be internalized by the targeted cell type, escape the endosome or lysosome, avoid incorrect intracellular routing, and still be bioactive when it reaches the RISC (*7*). Many of the challenges cited here are similar to those encountered for plasmid gene delivery (*8*).

siRNA is not biologically stable, and even *in vitro*, chemical modification of the sequence or complexation with a carrier system is required to prevent rapid degradation. While chemical modifications can increase the half-life of the siRNA, they do not significantly increase internalization. Thus, carrier systems are an appealing alternative. Both *in vitro* and *in vivo* delivery of siRNA using cationic liposomes and polymers has been described (*7*). Many of these systems are theoretically suitable for conjugation to targeting molecules that can guide them to the targeted tissues or cell types. These carriers may also have the potential to improve endosomal escape and intracellular routing (*9*).

Early transfection studies using the polyamidoamine (PAMAM) dendrimeric system indicated that PAMAM could be effectively complexed with a variety of forms of nucleic acids, and that increased complexation could be achieved by modifying the chemistry of the interaction (*10*). However, later studies focused on modified PAMAM dendrimers (*11−13*). In many of these studies, a partially degraded version, SuperFect (dPAMAM), has been shown to be among the most effective transfection reagents on the market (*10−20*). These compounds have been used both *in vitro* and *in vivo* with significant success (*10, 11, 18, 21, 22*).

Biomaterials have also been described as gene transfer agents, both for plasmids and for siRNA. Atelocollagen, in particular, has been found to be an effective complexing agent for siRNA (*23*). Atelocollagen−siRNA complexes were found to be efficiently internalized and resistant to nucleases that would ordinarily destroy exogenous nucleic acids (*24*). Furthermore, treatment with these atelocollagen−siRNA complexes resulted in effective down-regulation of targeted genes both *in vitro* and *in vivo* (*24, 25*).

The relative success of dendrimer−siRNA complexes in protecting siRNA, increasing its level of internalization, and assisting its endosomal escape make these agents promising vectors. However, it is well-known that the time scale of siRNA transfection can be problematic; for greater than 90% inhibition of a target gene, biologically active siRNA must be able to act for longer than three times the half-life of the protein in question

	5′-PCUAUAGUUGGGCUUCCGGCUU (antisense)

(*7*). Thus, a combination of dendrimer−siRNA complexes with an atelocollagen scaffold is proposed. It is hypothesized that combining the high transfection efficiency of the dendrimer and the slow release mechanism from the collagen will allow efficient, longer-term gene down-regulation.

Optimization of dendrimer−siRNA complexation was required prior to any transfection experiments. Characterization of the chemical interactions between the two components, followed by basic internalization experiments was used to choose the formulations tested for transfection ability. Basic transfection experiments were then used to determine the optimal complex formulation for use in the final set of experiments. The final experiments test the hypothesis that the combination of dendrimer−siRNA complexes with an atelocollagen scaffold can be used to control the release rate of the complexes and the time course of siRNA-mediated protein down-regulation.

EXPERIMENTAL PROCEDURES

Anti-Snail1 siRNA. Anti-Snail1 siRNA was purchased from Dharmacon (Chicago, IL). The siRNA was specific to the Snail1 homologue 1 (*Drosophila*), ID20613 for mouse (SNAI1) ON-TARGET*plus* SMART*pool*. It was supplied as a pool of four sequences (Table 1). The dPAMAM (SuperFect) used to complex siRNA for delivery was purchased from Qiagen (Germany).

Preparation of Complexes. Control siRNA (siGLO anti-cyclophilin B siRNA ON-TARGET*plus* control siRNA, Dharmacon, Chicago, IL) was combined with dPAMAM at a variety of amine to phosphate (N/P) ratios. The dPAMAM concentration was approximately 2.8 mM amine groups (2.8 nmol/μL). Thus, 1 μg of siRNA combined with 1 μL of dPAMAM yielded complexes at an N/P ratio of 1:1. The siRNAs were supplied lyophilized and were resuspended in an RNase-free buffer (20 mM KCl, 6 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) at pH 7.5 and 0.2 mM $MgCl_2$) at a concentration of 20 μM. Appropriate volumes of dPAMAM solution were combined with the siRNA solution in sterile TE buffer. The siRNA-containing solutions were kept on ice to minimize siRNA degradation.

Confirmation of Complexation. Complexation was confirmed using two methods. For dye exclusion studies, complexes prepared at N/P ratios of 1−10 were loaded into a polyacrylamide gel. The gel was run at 150 V for approximately 1 h, then removed from the electrophoresis apparatus and stained with SYBRGold nucleic acid gel stain (Invitrogen, Paisley, U.K.) for 45 min. The gel was imaged at 254 nm in a transilluminator (Universal Hood II, Bio-Rad, Hercules, CA). For the TEM studies, complexes were prepared at varying N/P ratios then imaged with a Hitachi H-7500 transmission electron microscope (Tokyo, Japan).

Cell Culture. NIH3T3 fibroblast cells were used for all cell culture experiments since they are well-characterized and readily available. Furthermore, they constitutively express high levels of Snail1, which is a good model to use to revert or reduce EMT. Twenty-four hours before siRNA was delivered, 2×10^5 NIH3T3 cells were plated in 6 well plates. After 24 h incubation, which was necessary to allow cells to attach and start proliferating, the cells were washed with phosphate-buffered saline (PBS) and fluorescently tagged control siRNA complexes were delivered at N/P ratios of 1−10 and at doses of 50, 75, 100, and 200 nM. The transfected plates were then returned to the incubator and left for 24 h.

Internalization Studies. The internalization studies included fluorescent microscopy and fluorescence-activated cell sorting (FACS) analysis. In the samples intended for microscopy, the transfected cells were washed, fixed, and stained with 4′,6-diamidino-2-phenylindole (DAPI). Images were taken with DAPI and rhodamine filter sets and superimposed over phase contrast images.

For FACS analysis, cells were washed twice with PBS, trypsinized, centrifuged, washed again, and resuspended in media. The resuspended cells were analyzed with a FACScalibur (Becton Dickinson, Franklin Lakes, NJ) equipped with CellQuest software, V3.3. The threshold was selected based on unmodified NIH3T3 cells (control).

Cytotoxicity Studies. The cytotoxicity of the complexes was evaluated by measuring the metabolic activity of transfected wells. The metabolic activity was assessed with the AlamarBlue (AB) assay (Invitrogen, U.K.). Briefly, 24 h after transfection, cells were washed with PBS, a dilution of 1:10 of AB in PBS was added to the wells, and the plate was returned to the 37 °C incubator for 3 h. The AB solution was then transferred into a 96 well plate, and the fluorescence was read at 590 nm.

Semiquantitative Reverse Transcription Polymerase Chain Reaction (RT-PCR). Initial transfection experiments indicated that a single delivery of siRNA complexes, while allowing high levels of internalization, did not measurably decrease protein expression levels. Thus double delivery of the complexes was used in the transfection experiments. The transfection protocol used was similar to that described earlier, except that 24 h after the first transfection, the same dose and N/P ratio of siRNA complexes was added and the cells were left a further 24 h. In this case, the control condition was control siRNA complexed at an N/P of 8. It was also delivered twice.

Analysis of mRNA levels was carried out by RT-PCR using 0.25 μg of total RNA per sample. RNA was extracted using PureLink Micro-to-Midi total RNA purification system (Invitrogen, Carlsbad, CA) and quantified using a Nanodrop system (ND-1000 spectrophotometer with the analysis software V3.3.0).

PCR analysis was performed using SuperScript OneStep RT-PCR kit with Platinum Taq (Invitrogen, Carlsbad, CA) and using oligonucleotides corresponding to the sequence +104/+125 and +290/+31 in order to analyze the RNA levels of Snail1 in the cells. The following oligonucleotides were used for the analysis of Snail1: 5′-GGCGGATCCACCATGCCGCGCTCCTTCCTG-3′ for forward transcription and 5′-CAAGATATCCGCCTC-CGGAGCA-3′ for reverse transcription. The endogenous housekeeping gene HPRT (hypoxanthine-guanine phosphoribosyl transferase) was used to normalize the RNA quantifications, using the oligonucleotides 5′-GGCCAGACTTTGTTGGATTTG-3′ for forward transcription and 5′-TGCGCTCATCTTAG-GCTTTGT-3′ for reverse transcription. All primers were obtained from Invitrogen (UK) and the thermocycler was from Biometra (T-Gradient Thermoblock, Göttingen, Germany).

Western Blotting. Analysis of protein expression levels was conducted using Western blotting. Twenty-four hours after the second delivery of siRNA, the cells were washed with PBS and lysed using 150 μL of total lysis buffer (20 mM HEPES, pH 7.8, 25% glycerol, 420 mM NaCl, 1% Triton X-100, 1.5 mM $MgCl_2$, 0.2 mM EDTA, and protease inhibitors). The lysate was scraped from the plate, placed in a centrifuge tube and agitated at 4 °C for 10 min. The tubes were centrifuged to precipitate insoluble particles. Total protein quantity was estimated using a standard kit (Bio-Rad Laboratories, Hercules, CA). Bovine serum albumin was used as a standard. Snail1 protein levels were measured via Western blotting. Annexin II was used as

loading control. Anti-Snail1 antibody was monoclonal (*26*), and antiannexin II was rabbit polyclonal (*27*).

Scaffold Preparation. One milligram cross-linked atelocollagen scaffolds were prepared as described by Holladay et al. (*28*). Briefly, 333 μL of 3 mg/mL atelocollagen solution was lyophilized, then cross-linked with 1-ethyl-3-(3-dimethylaminopropyl) (EDC) and *N*-hydroxylsuccinimide (NHS) at an EDC−NHS−collagen carboxyl group ratio of 5:5:1. The scaffolds were then washed thoroughly and freeze-dried again. siRNA−dPAMAM complexes (200 nM) in a total volume of 30 μL were loaded into the dry 1 mg scaffolds.

Elution Studies. Release of the siRNA−dPAMAM complexes was evaluated using the fluorescence from the control siRNA, which is labeled with rhodamine. Briefly, complexes were prepared at N/P = 8 then loaded onto the cross-linked scaffolds in a black 96 well plate. The loaded scaffolds were incubated for 2 h at room temperature to allow the complexes to associate with the scaffold. After this time, cell culture media containing 10% FBS was added to each scaffold. The scaffolds were removed from the media and placed in fresh media. At each time point, this process was repeated. At the end of the experiment, the siRNA content of the solutions was quantified by measuring the fluorescence with a Varioskan Flash spectral scanning multimode reader (Thermo Scientific, Vantaa, Finland) and the cumulative release of siRNA−dPAMAM complexes from the scaffold was calculated.

Scaffold-Based Transfection. siRNA−dPAMAM complexes (200 nM) in a total volume of 30 μL were loaded into dry 1 mg scaffolds. The loaded scaffolds were incubated at room temperature for 2 h to allow the complexes to associate with the collagen. NIH3T3 cells (7×10^4) were added to the scaffolds after this incubation. After 24 h, the scaffolds were transferred to a new plate to ensure that all of the cells were attached to the scaffold and not to the plate. New media was added to the scaffolds in the new plate, and the media was changed every 2 days until the end of the experiment.

At given time points (24 h, 48 h, and 7 days), the scaffolds were removed from the wells, placed in centrifuge tubes, and centrifuged for 5 min at 3000 rpm, and the supernatant was discarded. The scaffolds were stored at −20 °C. When the samples from all of the experiments were ready, the tubes were thawed, and 25 μL of 2× Laemmli sample buffer was added to each sample. The samples were vortexed for 5 min, then boiled for 5 min at 100 °C. Western blotting, as previously described, was then carried out. Quantification was performed with densitometry using annexin II levels as a normalizing control.

Statistics. Graphical results are expressed as mean ± standard deviation. Where applicable, statistical significance was assessed using the analysis of variance (ANOVA). *P* values of <0.05 were considered significant. The minimum sample size (*n*) was 3.

RESULTS

Basic confirmation of siRNA−dPAMAM complexation was performed by dye exclusion of SYBRGold nucleic acid stain. Figure 1 shows an acrylamide gel with a variety of N/P ratios, and uncomplexed siRNA as a control. With increasing N/P ratio, the degree of complexation increases as evidenced by the decreasing intensity of the bands. Complexation was further confirmed with TEM, as shown in Figure 2. The particles formed at N/P = 4 had an average diameter of approximately 100 ± 25 nm, while the particles prepared at N/P = 8 were much smaller, with an average diameter of 25 ± 12 nm.

Having observed complex formation, it was necessary to determine that the complexes were internalized. Thus, control siRNA with a fluorescent tag was complexed at a variety of N/P ratios and added to cell culture media. The cells were

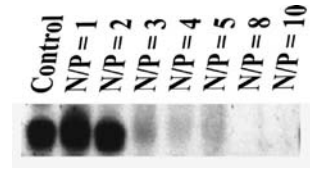

Figure 1. siRNA complexation as a function of N/P ratio. As the degree of complexation increases, the binding of SYBRGold stain to the siRNA becomes more inhibited. Thus, the SYBRGold is able to bind completely in the control band, and it is only at a N/P ratio of 3 that visually clear inhibition of binding occurs.

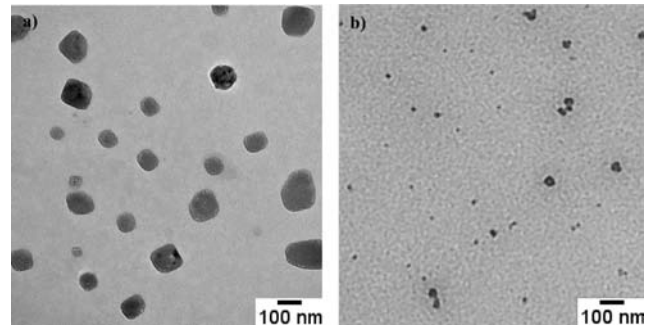

Figure 2. Representative transmission electron micrographs (TEM) of siRNA−dendrimer complexes. Complexes prepared at (a) N/P = 4 and (b) N/P = 8 demonstrate the effect of N/P ratio on the size of the complexes. At N/P = 4, the size of the complexes were significantly larger than at N/P = 8. The average particle diameters were, respectively, 100 ± 25 nm and 25 ± 12 nm.

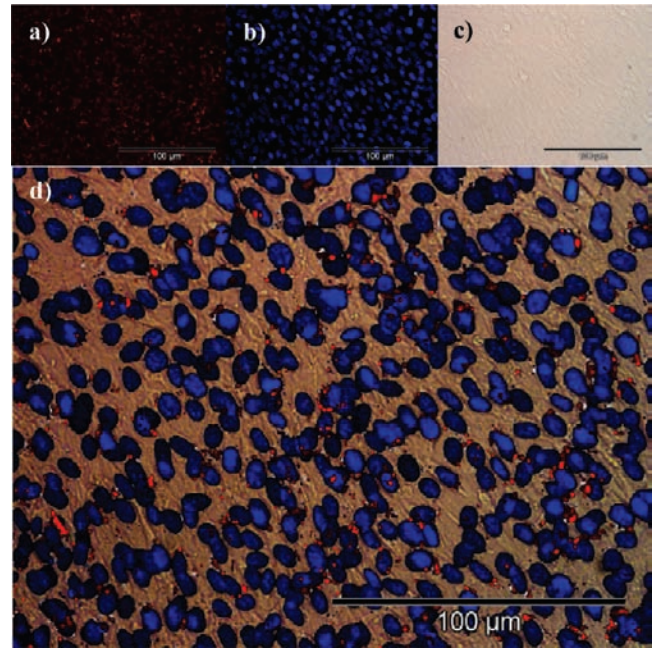

Figure 3. Micrograph showing uptake of DY-547 tagged siRNA by NIH3T3 cells. The siRNA dose used in this experiment was 200 nM at an N/P of 8. The control siRNA used in this experiment (siGLO cyclophilin B control siRNA, Dharmacon) fluoresces in the Cy3/rhodamine range. The siRNA appears to mostly localize to the nuclei (stained blue with DAPI). The two fluorescence images are superimposed over a phase-contrast image of the same area.

washed to remove unbound complexes, and analyzed by fluorescence microscopy 48 h after exposure to complexes. Figure 3 shows red complexes inside the vast majority of cell, indicating relatively high internalization levels. Figure 4 consists of FACS output graphs showing fluorescence vs side scatter from control cells and cells transfected with 100 and 200 nM

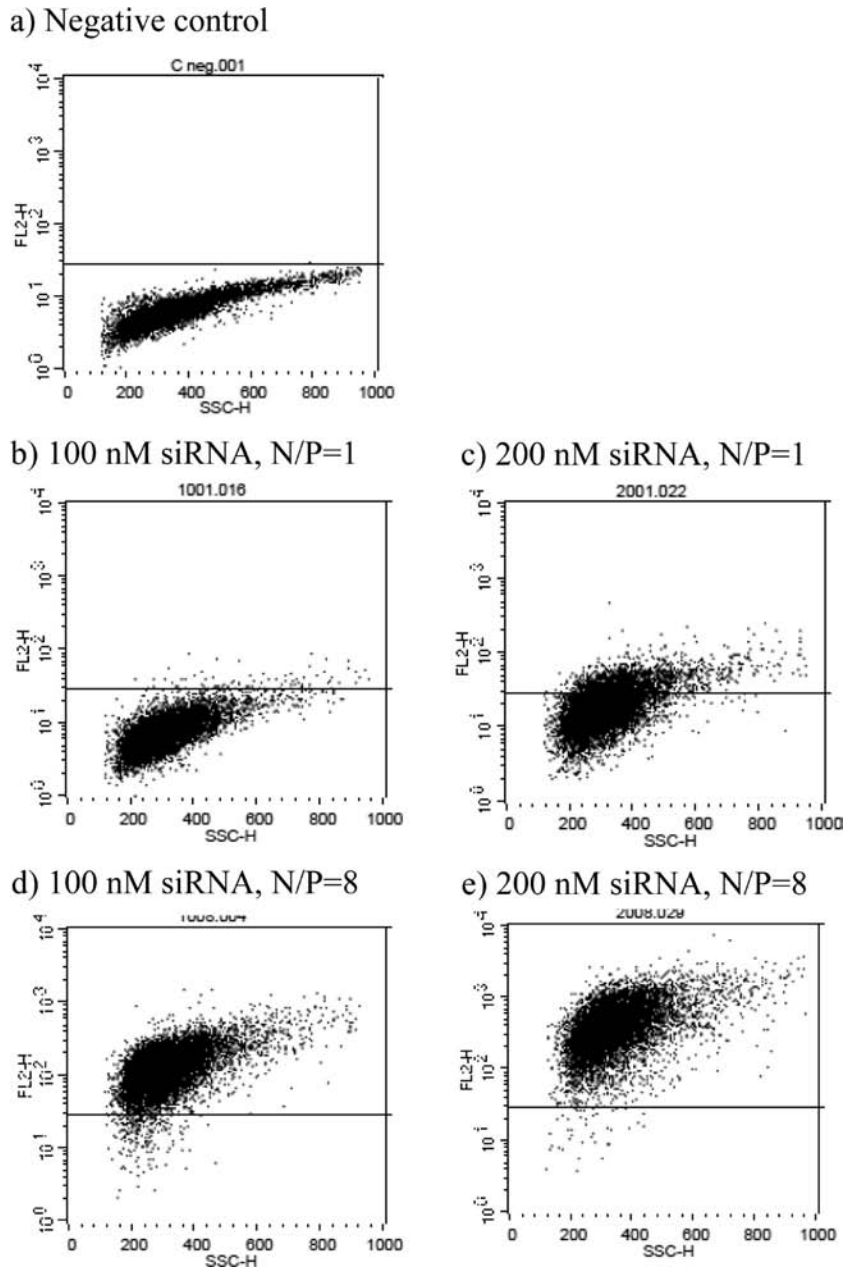

Figure 4. FACS output after transfection of siGLO control siRNA into NIH3T3 cells. The control sample had no fluorescent signal above the line, whereas with increasing N/P ratio and dose, the fluorescent signal of the cells was significantly increased implying internalization of labeled siRNA.

siRNA doses at two different N/P ratios. The distribution of fluorescence with respect to side scatter shifts slightly upward after exposure to siRNA at N/P = 1. Exposure of cells to siRNA complexed at N/P = 8 shifted the distribution almost entirely outside of the range of the control cells. The 200 nM dose had a more significant effect than the 100 nM dose at both N/P = 1 and N/P = 8. Because the lower N/P ratios were found to be less effectively internalized, only N/P ratios of 4−8 were tested in subsequent studies.

Cytotoxicity was evaluated by comparing the metabolic activity of NIH3T3 cells after exposure to 100 and 200 nM doses at N/P = 4−8 as shown in Figure 5. No significant differences were observed between the two doses, nor was any dependency on N/P ratio observed. In fact, no difference between any group and the control samples was found to be statistically significant. Because no effect on cell viability could be observed, it was concluded that the complexes demonstrated negligible cytotoxicity.

The effects of Snail1 transfection were evaluated at the mRNA level, as well as the protein expression level. Figure 6 shows representative semiquantitative RT-PCR bands of cells transfected with 200 nM anti-Snail1 siRNA and N/P ratios of 6−8. These bands are compared with cells transfected with control siRNA (200 nM, N/P = 8). The only band that qualitatively showed a major change in Snail1 level was a dose of 200 nM at N/P = 8. Figure 7 shows representative protein expression levels (Western blot) at 100 and 200 nM doses and an N/P ratio of 4−8. No significant differences were observed after densitometry analysis of the bands treated with 100 nM of anti-Snail1 siRNA, but the 200 nM dose was found to significantly decrease Snail1 production at N/P = 5−8.

The optimal formulation for anti-Snail1 siRNA−dPAMAM complexes was thus selected as a dose of 200 nM and N/P = 8 for NIH3T3 cells. Significant down-regulation was observed at both the mRNA and protein level with this formulation. The

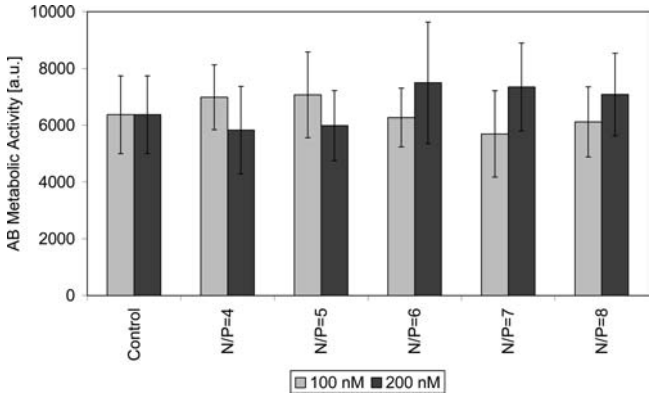

Figure 5. Metabolic activity as a function of siRNA dose and N/P ratio. No significant differences were observed between the control (no siRNA added) and 100 and 200 nM doses nor varying charge ratios, indicating negligible cytotoxicity (ANOVA, $p < 0.05$, $n = 5$).

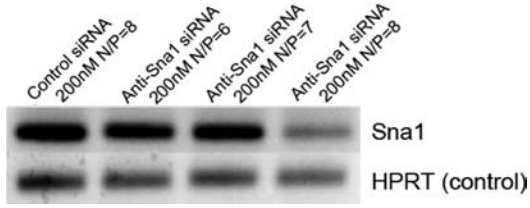

Figure 6. Down-regulation of Snail1 mRNA levels as a function of dose and N/P ratio. Twenty-four hours in advance, 2×10^5 NIH3T3 cells were seeded in a 6 well plate. siRNA complexed with dPAMAM was delivered twice (24 and 48 h after seeding), at a variety of charge ratios, and mRNA levels were evaluated with RT-PCR 72 h after seeding. HPRT was used to normalize the data. Three N/P ratios were compared with control (anticyclophilin B) siRNA.

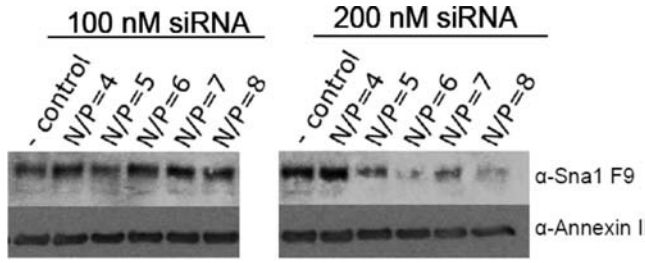

Figure 7. Protein expression as a function of siRNA dose and N/P ratio. Twenty-four hours in advance, 2×10^5 NIH3T3 cells were seeded in a 6 well plate. siRNA complexed with dPAMAM was delivered twice (24 and 48 h after seeding), at a variety of charge ratios, and protein levels were evaluated by Western blot 72 h after seeding. α-Annexin II was used to normalize the data, and the control condition was cells transfected with anti-cyclophilin B siRNA. No significant differences were observed at a dose of 100 nM, but at 200 nM, above a N/P of 5, significant down-regulation was observed (ANOVA, $p < 0.05$, $n = 3$).

final section of this study was thus performed using the optimized complexes.

The controlled release of siRNA−dPAMAM complexes from a collagen matrix is shown in Figure 8. The encapsulation of the siRNA was observed to be relatively high at time 0 (98%) but a significant amount of complex was released in the following 3 h. After 2 days, the release of complexes slowed significantly to a rate of approximately 10 ng siRNA/day.

The ability of a complex-loaded scaffold to control protein expression in a time-dependent manner was evaluated by measuring Snail1 levels from NIH3T3 cells seeded on collagen scaffolds loaded with anti-Snail1 siRNA−dPAMAM complexes. Figure 9a shows representative Western Blot

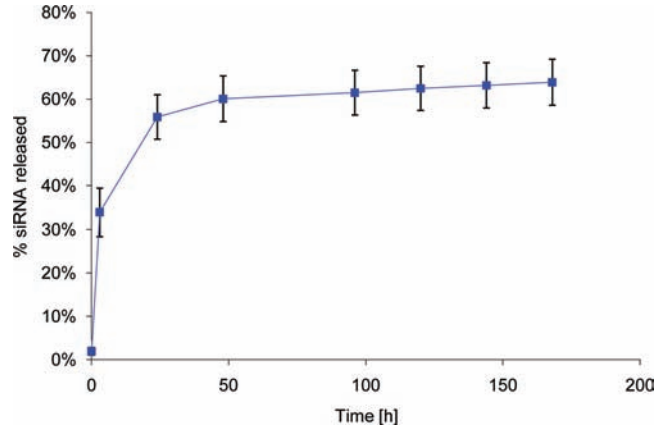

Figure 8. Cumulative percent release of siRNA−dPAMAM complexes from cross-linked collagen scaffolds over time. While only approximately 2% of the complexes were removed at time 0, indicating a 98% encapsulation efficiency, almost 35% were released within the first 3 h. After 7 days, approximately 35% of the siRNA complexes originally loaded into the scaffold were still retained with the matrix. Slow release of the complexes was still observed at this point, but only approximately 10 ng of siRNA was eluted per day, translating to a dose of approximately 50 nM.

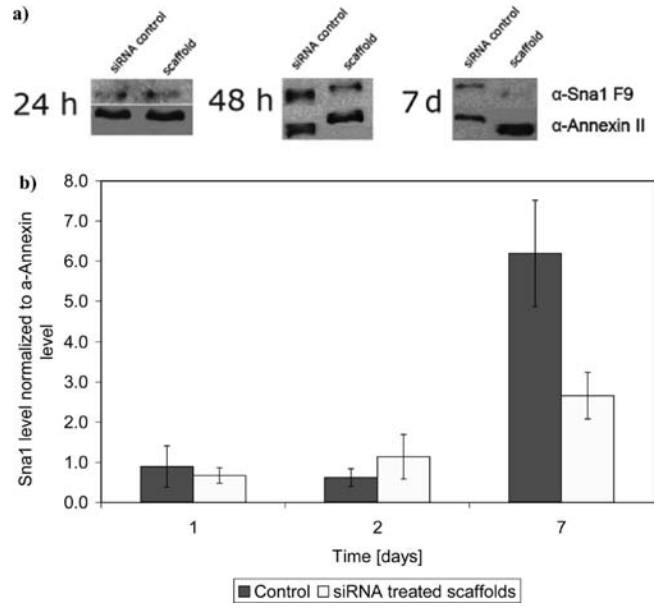

Figure 9. Protein expression from fibroblasts grown on anti-Snail1 siRNA loaded scaffolds as a function of time. Anti-Snail1 siRNA was loaded onto collagen scaffolds at a dose of 200 nM and an N/P of 8. Western blotting was used to evaluate the protein levels. Panel a shows a representative sample of the Western blot. α-Annexin II was used to normalize the results. Densitometry quantification (panel b) reveals significant down-regulation only after 7 days. (ANOVA, $p < 0.01$, $n = 3$). Thus while adherent cells showed significant down-regulation of Snail1 after 2 days, the scaffold reservoir system delays the effect of the siRNA until 7 days after cells were seeded onto the scaffold.

bands for cells grown on scaffolds containing the siRNA control (anti-cyclophilin B) compared with cells grown on scaffolds loaded with anti-Snail1 siRNA (both at concentration of 200 nM, N/P = 8). Figure 9b shows the densitometry quantification of all samples and controls, normalized to annexin II levels. Thus significant down-regulation of Snail1 levels was not observed until 7 days after cells were seeded onto the siRNA complex loaded scaffolds. This is in marked contrast to the earlier studies on siRNA transfected into

adherent cells where significant effects were observed only 48 h after transfection.

DISCUSSION

While it has been established that complexation of dendrimers to siRNA is possible (*7*), the optimal ratios and doses remain undefined. For plasmids, it has been observed that different cell types have different optimal N/P ratios and doses. Thus, characterization and optimization of complexes are necessary initial steps. Dye exclusion is an effective technique for estimating the quality of complexation, as most nuclear stains cannot access tightly bound nucleic acids (*29*). The bands shown in Figure 1 give a qualitative measure of complexation, which is confirmed by the TEM micrographs in Figure 2. The average diameter of the complexes was observed to vary inversely with N/P ratio, implying higher levels of interaction at higher N/P ratios. This correlates with observations in plasmid−dPAMAM interactions (*10, 14, 28*).

The cell membrane provides a major barrier for nonviral transfection, whether with siRNA or plasmids. Thus, complexes that are capable of crossing that barrier are much more likely to be able to affect gene expression. Figure 4 shows the increase in fluorescence of cells as an indirect measure of the amount of internalized fluorescent siRNA, while Figure 3 is an image of siRNA control complexes inside a select group of cells. The micrograph in Figure 3 was taken 48 h after transfection, the same point at which significant levels of Snail1 down-regulation were observed in Figures 6 and 7. Thus it would appear that the siRNA complexes internalized within 48 h were biologically active.

The efficiency of dPAMAM-mediated plasmid DNA transfection has been measured in other studies as approximately 17% in HeLa cells (*30*), 15% in CHO cells, and 18% in HEK 293 cells (*31*). No measurements of siRNA transfection efficiency are available. This may be because silencing is not necessarily complete, and therefore quantification of the number of siRNA transfected cells is very difficult. Comparison of relative protein levels is the most practical method of quantifying transfection; however this method does not provide insight into the mechanics of siRNA transfection. While almost 100% of the cells in Figure 4e have greatly increased fluorescence indicating internalization of fluorescent complexes, it is not valid to assume that internalized siRNA affects gene expression in all of these cells. The first barrier to transfection is the cell membrane, but it is not the only barrier. Depending on the internalization mechanism, lysosomal escape and cytoplasmic transport can pose major problems as well. Detailed analysis of internalization pathways involved in nonviral gene delivery has been conducted (*8, 9, 32−34*), but without similar analysis with siRNA complexes, it is difficult to be sure that the same barriers exist. However, the siRNA complexes measured in this study were observed to be approximately the same size as the plasmid complexes measured by Holladay et al., and thus it seems likely that the internalization mechanisms and pathways are similar.

Cytotoxicity is often cited as a downfall of cationic DNA complexation agents (i.e., polyethylene imine (PEI), poly(L-lysine) (PLL), (diethylamino)ethyl (DEAE)-dextran) (*35*). Dendrimers are considered less cytotoxic than some alternatives, (*10,12,13*) but this may be a function of the cell types and transfection protocols used (*36*). This study found no significant differences between control samples and test samples, indicating negligible cytotoxicity. This may be because the dose was not high enough to cause significant damage, but no "cytotoxic" control was used to compare. Regardless, the lack of change in metabolic activity indicates that changes in gene expression are more likely to be as a result of siRNA transfection than cytotoxicity from complexes. Furthermore, while the control condition in the cytotoxicity study had no siRNA added, the controls used in subsequent experiments were cells transfected with control siRNA, namely, anti-cyclophilin B siRNA, which should not have affected Snail1 gene expression but would control for any effects of the transfection procedure including cytotoxicity.

The down-regulation of Snail1 expression, as quantified at the mRNA and protein level in Figures 6 and 7 respectively, demonstrate the effects of anti-Snail1 siRNA transfection. Forty-eight hours after the initial transfection is evidently a sufficient interval over which to evaluate the siRNA transfection of adherent cells because significant down-regulation in mRNA and protein expression was observed. The discrepancy between the mRNA and Western blot results highlights the importance of measuring protein levels and not solely mRNA. While mRNA levels may correlate in some cases to protein expression levels, protein expression is dependent on a number of other factors, including post-transcriptional modifications to the mRNA and degradation rates of the proteins (*37−39*).

Combining siRNA−dPAMAM complexes with a collagen scaffold was hypothesized to extend the duration of action of the siRNA. It has been previously demonstrated that plasmid−dPAMAM complexes can be encapsulated in collagen scaffolds to change the release and transfection profiles (*28*). In that study, the peak transfection level from the scaffolds was (in some cases) decreased as compared with the transfected adherent cells, but the period of transfection was extended for up to three weeks. While the current study looked at a more limited time period, similar observations were made. The release profile (Figure 8) showed that the scaffold was capable of acting as a reservoir. The transfection profile was also affected because the two-dimensional transfection study (Figure 7) showed significant down-regulation after 48 h, but in the scaffold study, significant down-regulation was not observed until after 7 days (Figure 9).

Atelocollagen has been investigated in conjunction with siRNA delivery in a number of studies, both *in vitro* and *in vivo* (*23−25, 40*). However, while atelocollagen is generally described as a complexing agent, Minakuchi et al. observed that a solution of atelocollagen−siRNA complexes solidified when injected *in vivo* (*24*). Thus, an atelocollagen−siRNA complex system may be considered relatively similar to the system described in this paper. In studies with a luciferase reporter gene, approximately 60% inhibition (compared with a nonsense siRNA control) was observed *in vitro* (*23, 24*).

In this study, greater than 55% inhibition of Snail1 level was observed at day 2 when siRNA−dPAMAM complexes were delivered directly to a monolayer of cells. A similar level of inhibition was observed at day 7 when the complexes were delivered through scaffolds. Without an *in vivo* study, it is unclear whether the level of inhibition is therapeutically significant, but the *in vitro* results are comparable to the studies using atelocollagen as a complexing agent.

The delay in Snail1 down-regulation may be partly due to changes in the protocol and not solely the siRNA transfection. In the two-dimensional transfection study, cells were seeded and allowed to adhere for 24 h before siRNA complexes were introduced. In the scaffold study, the siRNA complexes were allowed to bind to the scaffold, then cells were added directly to the loaded scaffold. Thus the cells were not allowed to adhere prior to transfection. A similar protocol was used in the plasmid−dPAMAM complex study by Holladay et al., but transfection was observed in that study after 48 h, (*28*) whereas no effects on gene expression were observed until 7 days in this study.

Snail1 is involved in the initial stages of detachment and migration of tumor cells into other tissues (*4*). As shown in

Figure 9, the levels of Snail1 expressed in the control cells at 24 and 48 h after seeding were relatively low, but this level greatly increased at the 7 day time point. This might be partly due to the increase in the total cell number and partly due to up-regulation of genes that promote migration of the fibroblasts throughout the scaffold. The scaffold in this case is a collagen matrix, which may actually stimulate migration of fibroblasts. To have significant down-regulation, high expression levels might be required. Alternatively, the siRNA may be bound more tightly to the collagen matrix than the plasmid−dPAMAM complexes were, and thus longer incubation times were required for internalization.

Because the only Snail1 down-regulation in the scaffold study was observed after 7 days, measurement of Snail1 levels over longer growth periods needs to be investigated. If the scaffold is capable of suppressing Snail1 expression for 3 weeks (as in the plasmid scaffold transfection study by Holladay et al.) but has no effects for the first 7 days, the system may not be ideal for epithelial cancer treatment. While long-term delivery of siRNA would possibly allow long-term down-regulation of the Snail1, thereby decreasing the level of metastasis, there would be no major therapeutic benefit to delaying siRNA delivery. However, *in vivo* studies with the system are required to determine the *in vivo* transfection profile and efficacy before any hypothesis can be put forward regarding the overall therapeutic potential of this system.

Thus, complexation between siRNA and dPAMAM was confirmed with SYBRGold dye exclusion and TEM. Confocal microscopy and FACS demonstrated that NIH3T3 cells readily internalized fluorescently tagged siRNA complexed with dPAMAM. Negligible cytotoxicity was observed with 100 or 200 nM siRNA complex doses and with varying N/P ratios. Snail1 gene expression was down-regulated at mRNA level and protein expression level when anti-Snail1 siRNA was complexed with dPAMAM and transfected into adherent NIH3T3 cells. Finally, it was observed that siRNA complexes were slowly released from a collagen scaffold and down-regulation of protein expression was delayed by up to 7 days.

ACKNOWLEDGMENT

This project was supported by the Irish Research Council for Science Engineering and Technology (IRCSET) funded by the National Development Plan and a grant awarded by the Ministerio de Ciencia y Tecnología (SAF2006-00339) to Antonio García de Herreros. Partial support from Instituto Carlos III (RD06/0020/0040) and from the Generalitat de Catalunya (2005SGR00970) is also appreciated. V.M.D. was a recipient of a Juan de la Cierva contract. Thanks to Dr. Antonio García de Herreros for his input in this project. Additional acknowledgement is due to Dr. Oliver Carroll for editorial assistance.

Received June 16, 2009; Revised Manuscript Received September 29, 2009

Two bisphosphonate adaptors were designed to immobilize histidine-tagged proteins onto glass substrates coated with a zirconium phosphonate monolayer, allowing efficient and oriented immobilization of capture proteins, affitins directed to lysozyme, on a microarray format. These bifunctional adaptors contain two phosphonic acid anchors at one extremity and either one nitrilotriacetic acid (NTA) or two NTA groups at the other. The phosphonate groups provide a stable bond to the zirconium interface by multipoint attachment and allow high density of surface coverage of the linkers as revealed by X-ray photoelectron spectroscopy (XPS). Reversible high-density capture of histidine-tagged proteins is shown by real-time surface plasmon resonance enhanced ellipsometry and in a microarray format using fluorescence detection of AlexaFluor 647-labeled target protein. The detection sensitivity of the microarray for the target protein was below 1 nM, despite the monolayer arrangement of the probes, due to very low background staining, which allows high fluorescent signal-to-noise ratio. The performance of these Ni-NTA-modified zirconium phosphonate coated slides compared favorably to other types of microarray substrates, including slides with a nitrocellulose-based matrix, epoxide slides, and epoxide slides functionalized with Ni-NTA groups. This immobilization strategy has a large potential to fix any histidine-tagged proteins on zirconium or titanium ion surfaces.

INTRODUCTION

Proteins play a key role in cellular mechanisms, but most of their functions remain unknown (*1*). Proteomics, which is the study of protein function, expression, and localization on a cellular-wide scale, needs more high-throughput analysis tools to achieve this goal. By analogy to work in genomics with DNA microarrays (*2, 3*), protein capture microarrays have been used successfully to identify differentially expressed biomarker proteins (*4*−*8*). However, it is still an emerging technology, which needs selective methods for surface immobilization (*1, 9*) and alternative strategies to antibodies for use as capture agents in protein microarrays (*10, 11*).

A significant challenge for protein microarrays is attachment on the chip surface. Immobilization of the protein by nonspecific adsorption is often associated with problems such as a high background signal and significant loss of the protein probes during stringent washes (*12*). Furthermore, random orientations of the immobilized proteins affect their activities, which decrease the sensivity of detection (*13, 14*). Therefore, specific protein attachment through covalent coupling (*15*−*22*) or affinity interaction (*23*−*27*) is considered to be a better strategy (*13*). In the present work and in other studies (*28*−*31*), specific orientation of capture proteins is achieved by affinity interaction between a histidine-tag protein and a transition metal chelated to a nitrilotriacetic acid (NTA) moiety. Ni-NTA resins (*32*−*34*) are routinely used for the purification of oligo-histidine-tagged proteins, which can be easily prepared by genetic fusion of an oligohistidine tag to the C- or N-terminus. Despite the moderate affinity ($K_d \approx 1-10\ \mu M$) (*35*−*37*) and stability of individual Ni-NTA/oligohistidine complexes, this strategy has been successfully used in a microarray format for the immobilization of about 6000 histidine-tag-labeled yeast proteins, of which more than 80% were shown to retain their biological activity after immobilization (*38*). However, most NTA surfaces used for the design of protein microarrays are obtained by spreading a functionalized polymer matrix on a glass surface, leading to inhomogeneous surface coatings without rigorous control of the NTA density.

In previous work on DNA microarrays, our laboratories described a new ultraflat support with which the biological probes are bound to a monolayer-coated surface through an "inorganic" linkage, in contrast to existing systems based on the covalent attachment of the DNA probes via covalent organic bonds. We demonstrated the spontaneous linkage of oligonucleotide probes, phosphorylated at their 5′ end, onto a zirconium phosphonate modified surface (*39*). More recently, we demonstrated that the phosphate/zirconium bond is strong enough for dsDNA attachment and for studying DNA/protein interactions (*40*). The zirconium−phosphonate linkage has been shown to be very robust between pH 1 and pH 10 and stable to displacement by competing bases (*39*). On the other hand, unmodified proteins are poorly adsorbed on such zirconium phosphonate surfaces and oligo-histidine-tagged proteins do not provide specific binding on these surfaces.

In order to provide specific anchoring of oligo-histidine-tagged proteins to the zirconium phosphonate surface, we

designed a bifunctional adaptor containing a multivalent phosphonic acid anchor at one extremity and a NTA group at the other. The phosphonate groups provide a stable bond to the zirconium interface by multipoint attachment. This affinity tag strategy provides a uniform orientation of proteins on the surface and high-density coverage without the need to perform complicated chemistry on the protein targets or on the solid support. Stable binding of the bifunctional adaptor is demonstrated, allowing reversible capture of histidine-tagged proteins. This technology is applied to a new class of small and stable capture proteins, the affitins (*41, 42*), which are shown to keep their binding properties when immobilized on the zirconium phosphonate surface and to exhibit a high signal-to-noise ratio relative to arrays prepared from other NTA-functionalized supports.

EXPERIMENTAL PROCEDURES

Materials. Glass slides were purchased from Gold Seal Products (cat no. 3013, 3×1 in.^{2}, thickness 0.93−1.05 mm). Reagents were of analytical grade and used as received from commercial sources, unless indicated otherwise. Hydrophobic glass slides were made using octadecyltrichlorosilane (OTS) following a method by Sagiv (*43*). The zirconium octadecylphosphonate Langmuir−Blodgett monolayers were prepared on the hydrophobic slides as described previously (*44, 45*). Nexterion Slides E were obtained from Schott. FASTslide coated with nitrocellulose were obtained from Whatman/Schleicher & Schuell. *N*α,*N*α-bis(carboxymethyl)-L-lysine hydrate and lyzozyme were purchased from Sigma Aldrich.

Synthesis of the Mono-NTA and Bis-NTA Bisphosphonate Adaptors. The synthesis of the monovalent and multivalent linkers is outlined in Scheme 1; the details are given in Supporting Information.

Protein Expression and Purification. H4 and B3 are recombinant proteins derived from Sac7d from *Sulfolobus acidocaldarius* and evolved by ribosome display to bind lysozyme (*41, 42*). H4 was overexpressed in a recombinant *Escherichia coli* BL21 strain carrying the corresponding plasmid. The culture was grown in Luria−Bertoni medium containing ampicillin (50 μg/mL) at 37 °C until an OD600 of 0.8−1. Induction using isopropyl-1-β-D-thio-1-galactopyranoside (IPTG) (0.5 mM) was continued overnight. The protein was purified on nickel−nitrilotriacetic acid (Ni-NTA) columns according to the manufacturer's recommendations (Qiagen, Courtaboeuf, France), eluting with a TBS 250 buffer (20 mM TrisHCl, pH 7.4, 150 mM NaCl, 250 mM imidazole). The protein concentration was measured using a Nanodrop 1000 spectrophotometer (Thermoscientific). The same procedure was applied to B3.

Microoarray Spotting and Incubation Conditions. To prepare the LB Ni-NTA substrate, the zirconium phosphonate modified slides were incubated overnight with a 1 mM mono-NTA (**13**) or bis-NTA (**18**) adaptor aqueous solution. For the Nexterion Slide E Ni-NTA substrate, Nexterion Slides E were incubated overnight with a 3 mM solution of *N*α,*N*α-bis(carboxymethyl)-L-lysine hydrate in PBS (12 mM phosphate, pH 8.3, 150 mM NaCl). Slides were washed 3 times with ultrapure water and then incubated for 1 h with a 100 mmol L^{-1} $NiCl_2$ aqueous solution. The slides were washed again 3 times with ultrapure water and dried by centrifugation (1500 rpm, 1 min).

The slides were then spotted with a microcaster TM 8-pin system (Whatman/Schleicher & Schuell). The spotted slides were placed overnight in an incubation chamber at 4 °C and 75% humidity. To passivate the unspotted areas, slides were treated after spotting with a solution of 0.3% α-casein (Sigma) in a TBS (Tris-buffered saline) solution of TrisHCl (20 mM) and NaCl (150 mM) at pH 7.4. Incubation was performed by applying an Alexa 647-labeled lysozyme solution (1 μM in TBS−0.3% α-casein) to the substrate for 1 h at room temperature. Microarrays were washed 3 times with TBS−0.05% Tween 20 for 5 min, then once with TBS and ultrapure water. Finally, the slides were spun dry centrifuging at 1500 rpm for 1 min. All washes and incubations were performed in small staining jars at room temperature on an oscillating shaker.

Microarray Analysis. All microarrays were scanned on a Scanarray Gx apparatus (Perkin-Elmer) with a laser power and gain value of 60. Suitable excitation wavelength and emission filter were used to detect Alexa 647: 650 nm (excitation), 665 nm (emission). The location of each analyte spot on the array was outlined using the mapping software Genepix (Axon laboratories, Palo Alto, CA).

X-ray Photoelectron Spectroscopy (XPS). XPS was performed using a UHV XPS/ESCA PHI 5100 system. Survey scans and multiplex scans (Zr 3d, P 2p, N 1s, Ni 2p3) were taken with an Al Kα X-ray source (using a power setting of 300 W and a takeoff angle of 45° with respect to the surface). Survey scans were taken for all samples with a pass energy of 89.4 eV and multiplex scans were taken with a pass energy of 22.36 eV. The peak areas were determined using commercial XPS analysis software with Shirley background subtraction. Elemental ratios reported in the text are averages of at least three experiments.

Slides for XPS analysis containing the NTA linkers were prepared using a Whatman Fast-Frame slide plate and a two-pad incubation chamber. One pad of the zirconium phosphonate modified slide was immersed in 1 mL of 1 mM biphosphonate adapter, while the other pad was immersed in 1 mL of nanopure water as an experimental control. The slide was kept at 4 °C overnight, rinsed with water, and then deposited in a solution of 100 mM $NiCl_2$ for 1 h. Finally, the slide was then rinsed with nanopure water and spin-dried in air for analysis.

Surface Plasmon Resonance (SPR) Spectroscopy. Surface plasmon resonance enhanced ellipsometry measurements were performed on a commercial EP^3−SW imaging system (Nanofilm Surface Analysis, Germany). The ellipsometer employed a frequency-doubled Nd:YAG laser (adjustable power up to 20 mW) at 532 nm. Linearly p-polarized light was directed through a 60° equilateral SF10 prism coupled to a gold-coated SF10 slide via diiodomethane index matching oil in the Kretschmann configuration. The angle of incidence was kept at 64° for all kinetics experiments because this condition provided the highest sensitivity. Curve fitting of the kinetics data used the AnalysR software from Nanofilm, using a 1:1 Langmuir binding model.

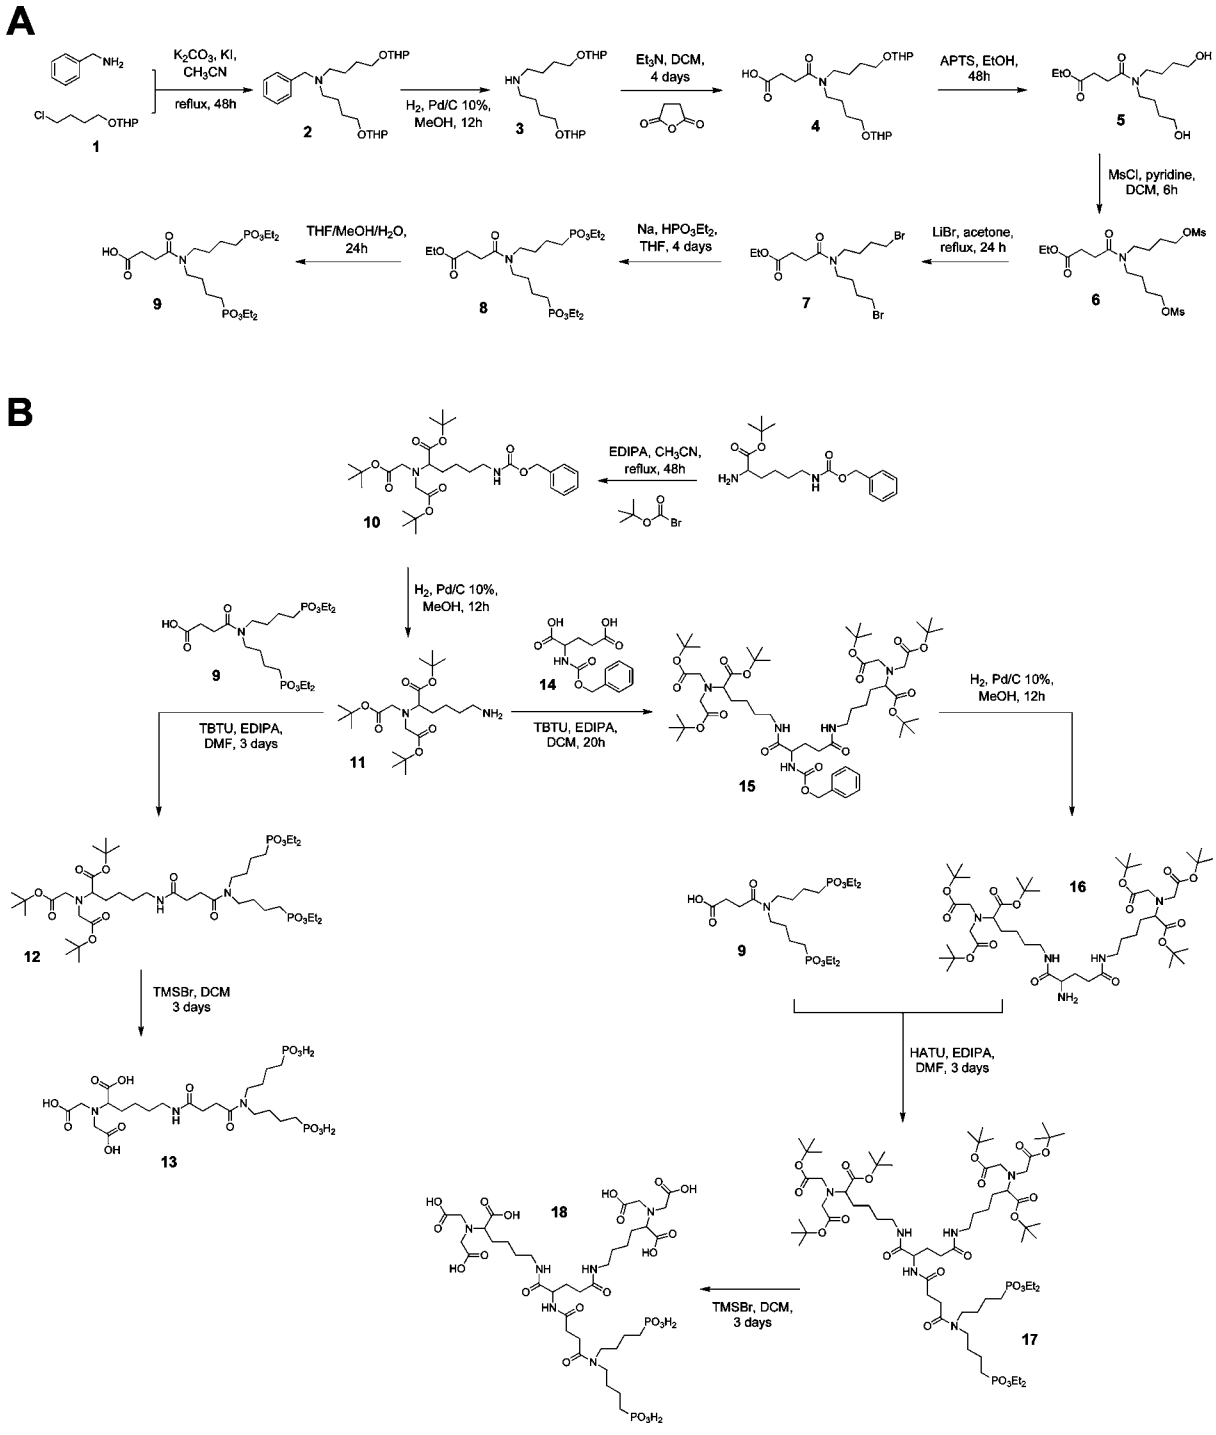
SPR slides were prepared by rendering the gold-coated slides hydrophobic with octadecylmercaptan before transferring the zirconium phosphonate layer. The slides were then immersed overnight in 1 mM aqueous solutions of either the mono-NTA linker or the bis-NTA linker, followed by rinsing with ultrapure water and drying under a stream of nitrogen. The NTA-modified slides were placed in the SPR flow cell and treated with a 100 mM solution of nickel chloride. Protein binding onto the Ni-NTA surface was carried out by injecting 5 μM protein solutions in TBS. The surface was regenerated using 250 mM imidazole in TBS buffer.

RESULTS AND DISCUSSION

Design of the Anchoring Linker. In previous studies, we showed that oligonucleotides and dsDNA can be immobilized on zirconium phosphonate surfaces and that phosphate-terminated oligonucleotides are selectively adsorbed over those without terminal phosphates (*39, 40*). It was also shown that dsDNA phosphorylated at both ends binds better to the zirconium surface than monophosphorylated DNA.

Based on these results, in order to make the zirconated phosphonate film suitable for oligohistidine-tagged protein

Scheme 1. Synthesis of the Mono-NTA and Bis-NTA Bisphosphonate Adaptors



immobilization, surface modification with either mono-NTA or bis-NTA end groups was performed using adaptors **13** and **18**, respectively, which contained a similar scaffold bearing two phosphonic acid functions for binding to the zirconated surface (Scheme 1A,B). These two adaptors were synthesized in around 15 steps in good yield. First benzylamine was alkylated twice using compound **1** synthesized by reacting 4-chloro-1-butanol with 3,4-dihydro-2*H*-pyran to yield compound **2**. After hydrogenolysis, compound **3** was reacted with succinimide to produce the acid compound **4**. Reaction with *p*-toluene sulfonic acid in ethanol resulted in the esterification of the carboxylic acid function and removal of the THP protective groups. The two alcohol groups were then activated (mesylate) and substituted by bromine atoms, which were subsequently replaced by diethyl phosphonate groups using sodium salt of diethylphosphite to yield compound **8**. Finally, saponification of the ester function led to compound **9,** which was then coupled to the mono-NTA or bis-NTA precursors **11** and **16**, respectively, as described in Scheme 1B, to obtain the two expected bisphosphonate mono- and bis-NTA adaptors **13** and **18**. Compounds **11** and **16** were derived from L-lysine, as previously reported by Lata et al. (*46*).

Similar adaptors with only one phosphonic acid moiety were found to bind poorly to the zirconated surface and were inadequate for the present application.

Zr/phosphonate Surfaces and Linker Anchoring. Zirconium phosphonate modified surfaces are generated by adsorbing Zr^{4+} ions to surface phosphonate or phosphate groups. An active metal layer results when the phosphorylated groups are closely organized into a monolayer so that the Zr^{4+} ions bind to the surface groups to form a layer while retaining some coordination

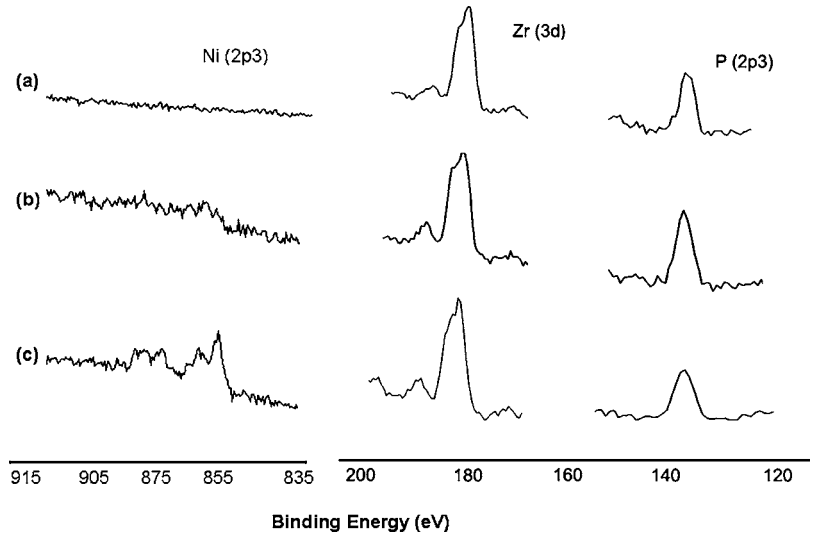


Figure 1. Peaks of Ni(2p3), Zr(3d), and P(2p3) obtained from XPS analysis for (a) zirconium phosphonate monolayer surface, (b) mono-NTA modified surface, and (c) bis-NTA modified surface. No Ni(2p3) is seen on the bare zirconium phosphonate surface.

sites that are free of the surface phosphate or phosphonate ligands. The starting phosphorylated surfaces can be prepared in different ways, including covalent attachment of the phosphorylated groups to silica (*47*−*54*) or gold (*49, 50, 53, 55, 56*) and by Langmuir−Blodgett deposition of an organophosphonic acid (*44, 45, 57*−*60*). We have long utilized LB methods to prepare the zirconium phosphonate monolayers because the surface films formed in this way are of high quality, stable, and highly reproducible, and the surface chemistry can be applied to nearly any substrate material, permitting application of a wide range of surface analytical techniques on the same surface (*61*) Modification of the zirconium phosphonate surface was thus investigated by incubating the substrate in a 1 mM aqueous solution of the desired bisphosphonate adaptor (**13** or **18**), the binding of which was then monitored by XPS. XPS is a powerful surface analytical technique, which provides qualitative and quantitative information about the elements on a surface, and was recently shown to be an efficient, label-free method for studying DNA surface coverage on zirconium phosphonate surfaces (*62, 63*). The P/Zr ratio of 1.1 for the naked zirconated phosphonate monolayer indicates that it is almost fully reticulated by the zirconium ions (*44*). Upon reaction with adaptor **13**, a significant increase of this ratio was observed (P/Zr = 1.4), which confirms binding of the bisphosphonate on the surface (Figure 1). Knowing the surface density of the zirconium ions within the monolayer, 4.2×10^{14} atoms/cm^2 (*44*), the mono-NTA adaptor coverage can be estimated at 6.3×10^{13} molecules/cm^2, which corresponds to one NTA moiety every 1.58 nm^2. With the bis-NTA adaptor (**18**), a P/Zr ratio of 1.18 was determined, which indicates half the surface coverage observed for the mono-NTA molecule. However, because this adaptor presents two NTAs per molecule, the NTA density on the surface is roughly similar to that obtained with the mono-NTA adaptor.

Nickel complexation to the NTA end groups was then performed to make them capable of covalent binding to histidine-tagged proteins. In Figure 1, XPS spectra of mono-NTA and bis-NTA coated slides are compared with the bare zirconium phosphonate surface, after exposure to Ni^{2+}. Binding to the NTA-coated slides is evident, with more Ni^{2+} complexed to the bis-NTA coated slide.

Protein Immobilization. The octadecylphosphonic acid (OPDA)-Zr surfaces modified with mono-NTA and bis-NTA end groups were used to study the specificity and reversibility of their interaction with histidine-tagged proteins as well as the proteins' activity when immobilized. For this purpose, monomeric proteins (affitins) with a single N-terminal oligohistidine tag were used. These affitins were derived from the Sac7d scaffold and selected by ribosome display to selectively recognize lysozyme (*41, 42*). Binding of the H4 affitin on the zirconium phosphonate monolayer functionalized with nickel-loaded NTA groups was first studied using SPR (Figure 2). As a control experiment, low and totally reversible binding of the protein was observed in the absence of nickel complexation to the NTA group (Figure 2a). In the case of both adaptors **13** and **18**, the surface exhibits a high and specific binding of the histidine-tagged-affitin (Figure 2b,c). A higher phase shift amplitude was observed for the binding of the affitin to the mono-NTA adaptor ($\Delta\Delta\psi \approx 0.22°$) than for the bis-NTA ($\Delta\Delta\psi \approx 0.17°$), reflecting a higher amount of bound protein using the mono-NTA adaptor. This result can be correlated to the higher surface coverage with this adaptor. However, a significant dissociation of the affitin was observed with the mono-NTA linker upon prolonged washing (~1 h) (Figure 2b), while washing out of the protein was reduced in the case of the bis-NTA linker (Figure 2c). This observation reflects the intrinsically low affinity of mono-NTA toward a polyhistidine sequence ($K_d \approx 10^{-5}$ to 10^{-6} M), which can be improved when bis-NTA functional groups are used (*29*). After washing, the amount of the proteins retained on the surface was similar for both adaptors. The specificity of the interaction is confirmed by the full reversibility of binding upon injection of a high concentration of imidazole (Figure 3). The protein loading followed by imidazole washing cycle can be repeated without a decrease in binding amplitude, as shown in Figure 3 for two cycles.

Microarray Experiments. Having shown that both linkers **13** and **18** can be efficiently immobilized on the zirconium phosphonate surface, making it suitable for histidine-tagged protein immobilization, the next step was to verify that the immobilized proteins are still functional and capable of binding lysozyme. Affitin immobilization on a microarray format was carried out according to Scheme 2. The nickel-loaded NTA functionalized slides were spotted with affitin at fixed concentrations prior to a blocking step with α-casein, which due to its high phosphate content provides efficient saturation of the nonspotted areas, hindering nonspecific protein binding (*40*). The activity of the immobilized affitin was investigated upon incubation of the surface with AlexaFluor 647 labeled lysozyme overnight. To verify that immobilization of the affitin proceeds via the expected Ni-NTA/histidine-tag interaction, the same

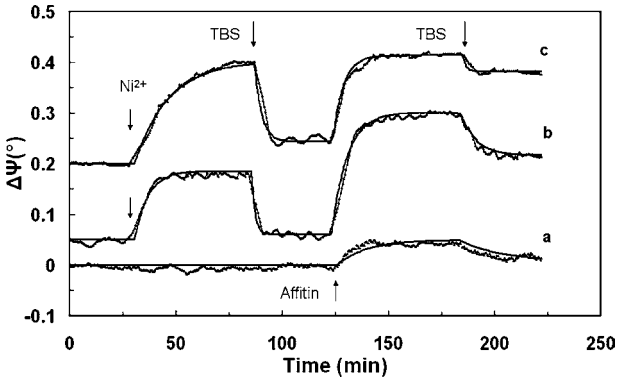

Figure 2. Affitin immobilization on the zirconium phosphonate surface functionalized with mono- and bis-NTA, probed in real time by surface plasmon resonance enhanced ellipsometry (SPREE). Kinetic adsorption curves of affitin on (a) mono-NTA without nickel, (b) mono-NTA with nickel, or (c) bis-NTA with nickel. Experimental data (dotted line) were fitted (solid line) using a 1:1 Langmuir binding model for each step. Curves b and c were shifted by 0.05° and 0.2°, respectively.

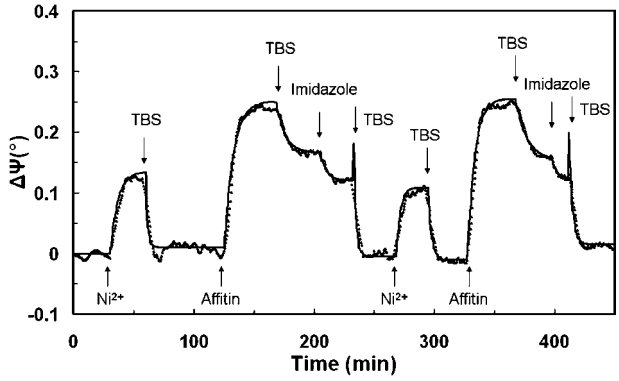

Figure 3. Sensorgram for the interaction of affitin with a mono-NTA functionalized surface that shows binding of Ni^{2+}, adsorption and desorption of affitin, and regeneration of the surface by 250 mM imidazole. This procedure was then repeated to show the reproducibility of the surface. Experimental data (dotted line) were fitted (solid line) using a 1:1 Langmuir binding model for each step.

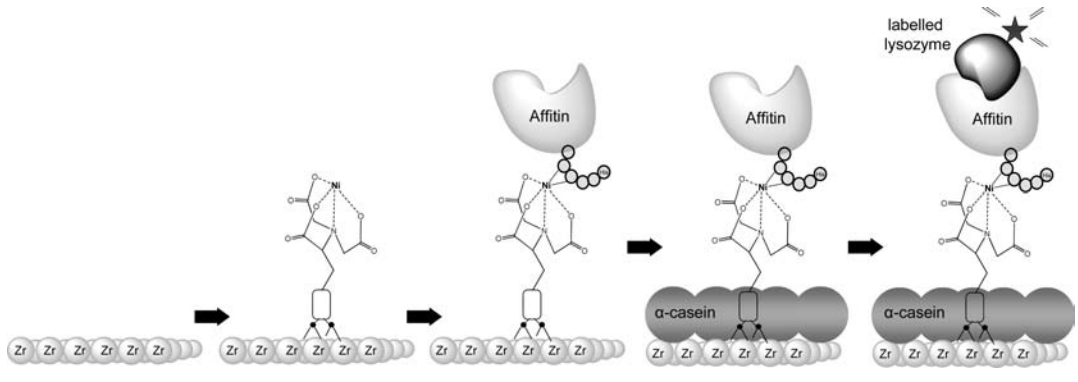
experiment was performed on the naked zirconium octadecylphosphonate surface. To avoid interslide variation, each slide had only half of its surface functionalized with Ni-NTA groups, and incubation chambers with two compartments were used. As an additional control, the affitins were spotted under two different conditions, one in a 25 mM imidazole-containing buffer to reduce nonspecific bonding to the Ni-NTA surface and the second in a 250 mM imidazole containing buffer to prevent histidine-tagged protein binding by competition (Figure 4). A negative control experiment was also performed with an affitin that does not bind lysozyme. At low imidazole concentration, only spots present on the surface functionalized with the Ni-NTA groups gave high signal intensities, which indicated that affitins were still functional after immobilization. As expected, a high concentration of imidazole (250 mM) prevented affitin binding on the Ni-NTA surface and subsequent lysozyme capture. Interestingly, a very low background value was observed in the absence of affitin, confirming the low nonspecific interaction of lysozyme with the surface when saturated with α-casein. However, nonspecific binding of the affitin on the naked zirconated surface was not completely avoided by α-casein saturation since a low intensity signal was detected in that control.

Different spotting concentrations of the affitins were explored, incubating at a fixed concentration of the lysozyme target. An increase in signal intensity was detected, with no saturation of the lysozyme capture, using affitin concentrations of 1.25−10 μM (Figure 5), confirming the high density of Ni-NTA groups available on the surface of the slides. Both bisphosphonates **13** and **18** led to similar fluorescence intensities at a given affitin concentration, in agreement with SPR data, which had shown that the amount of bound protein after washing is similar with the two linkers. However, the spot shape remains better defined on the bis-NTA modified surface. On the mono-NTA functionalized surface, the spot shape was irregular if affitin was spotted at high concentration, likely as a result of significant dissociation occurring during the washing steps. In the case of the bis-NTA functionalized surface, stronger binding of the histidine tag by a bivalent interaction strongly reduces this effect (Figure 5).

The sensitivity of the microarrays was explored by spotting with a constant affitin concentration and incubating with decreasing concentrations of AlexaFluor 647-labeled lysozyme, using the same slide divided into several independent incubation areas. For this experiment, two affitins differing in their affinity for lysozyme were chosen (H4, $K_d = 5 \times 10^{-9}$ M, and B3, $K_d = 2.9 \times 10^{-7}$ M) (see Supporting Information). For the H4 affitin, the observed limit of detection was below 1 nM (Figure 6). As expected, the slide spotted with B3 affitin, which has a lower affinity for lysozyme, exhibited a detection limit around 0.1 μM, with low sensitivity even at high lysozyme concentration, likely because the weakly associating B3 lysozyme is lost during the washing process.

Comparison with Other Microarray Surfaces. The performance of our Ni-NTA-modified zirconium phosphonate surface was evaluated relative to other types of microarray substrates, including slides coated with a nitrocellulose-based matrix (FAST slides, Schleicher & Schuell), epoxide slides (Nexterion, Schott), and epoxide slides functionalized with Ni-NTA groups using *N*α,*N*α-bis(carboxymethyl)-L-lysine hydrate. All slides were spotted with the same affitin concentrations and incubated with a fixed concentration of the labeled lysozyme. The resulting fluorescence intensities are reported in Figure 7.

Scheme 2. Description of the Different Steps Employed To Test Affitin Activity on a Microarray Platform



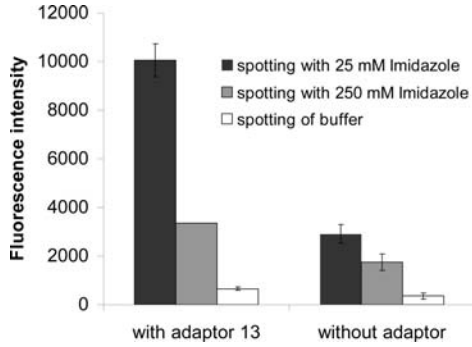


Figure 4. Detection of lysozyme captured by affitin spotted at 1 μM on a Ni-NTA-modified zirconium phosphonate microarray: white bar, buffer spotted only; light gray bar, affitin spotted with 250 mM imidazole; dark gray bar, affitin spotted with 25 mM imidazole. Fluorescence intensities were measured at 90% laser power and 50% photomultiplier gain.

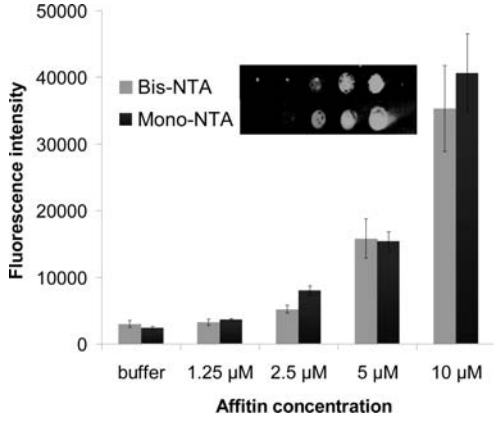

Figure 5. Fluorescence intensity versus concentration of spotted affitin on zirconium phosphonate slides functionalized with mono-Ni-NTA (dark gray) and bis-Ni-NTA (light gray) groups. Fluorescence data values correspond to the mean and the ecart type range for three replicates within one slide (inset) image obtained at 60% laser power and 60% photomultiplier gain.

Slides coated with nitrocellulose membrane gave the highest fluorescence signal, making it necessary to use a lower laser power in this case to avoid excessive background. However, even at lower laser power, the background signal is still high, resulting in a low signal-to-noise ratio (S/N = 1.5). It is known that this polymeric material with defined microporosity binds large amounts of protein in a noncovalent and nonspecific way (*13*). The poor signal-to-noise ratio could be related to the nature of the affitin, which is very small, and possibly easily washed out during the incubation process.

Slides modified with a chemical reactive group, such as an epoxide, provide a covalent yet random immobilization of the proteins via reaction with amino groups present on the protein surface. At the highest concentration of spotted protein (10 μM), the fluorescence intensity using the epoxide E slide is about 50% lower than that obtained using the zirconium phosphonate slides functionalized with Ni-NTA. Somewhat surprisingly, when the epoxide E slides were functionalized with Ni-NTA groups using *N*α,*N*α-bis(carboxymethyl)-L-lysine hydrate, the observed fluorescence intensities were comparable to those obtained for the unmodified E slides. Although modifying the epoxide slides with Ni-NTA groups should provide an oriented immobilization of the affitins, similar to the Ni-NTA-functionalized zirconium phosphonate surface, the observed fluorescence intensity was lower throughout the 1.25−10 μM spotting concentration range. A possible reason might be that the

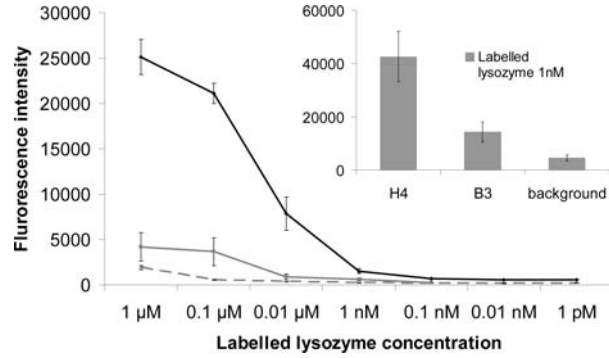

Figure 6. Fluorescence intensity versus concentration of AlexaFluor 647-labeled lysozyme in the incubation solution. Affitins H4 (black line) and B3 (gray line) were spotted (5 μM) on a mono-Ni-NTA-functionalized ODPA/Zr surface. The gray dotted line corresponds to spotting of buffer.

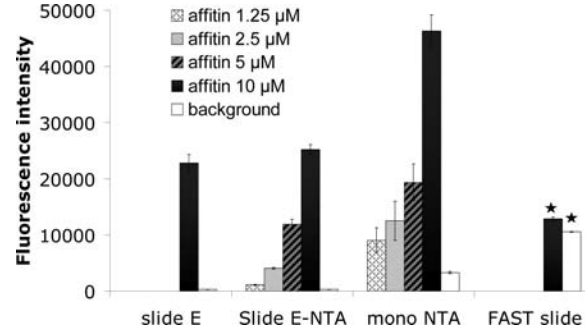

Figure 7. Compared performances for lysozyme capture of H4 affitin immobilized on different substrates: slide E, epoxide surface from Nexterion; slide E-NTA, Ni-NTA functionalized epoxide surface; mono-NTA, mono Ni-NTA functionalized ODPA/Zr surface; FAST slide. The ∗ indicates the fluorescence intensities were measured at lower laser power (30) and gain value (40) with the FAST slide.

zirconium phosphonate surface provides a higher density of NTA groups compared with the epoxide surface. Alternatively, the long spacer separating the NTA group from the phosphonic acid groups attached to the zirconium phosphonate surface may provide better accessibility to the proteins.

CONCLUSION

In this paper, we demonstrate that a zirconium phosphonate modified surface can be efficiently functionalized with metal NTA groups in order to specifically bind histidine-tagged proteins in an oriented way. The NTA linkers bind the zirconated surface via a bis-phosphonic acid functional group with high avidity for the surface. These results further extend to the protein microarray field the applications of mixed organic/inorganic zirconium phosphonate surfaces, on which simple and irreversible modifications can be introduced without the need for chemical activation steps. By use of these bifunctional adaptors, a high density of accessible NTA groups was obtained, allowing high efficiency of protein binding. Proteins immobilized in this way retain their ability to capture protein target with high sensitivity, and the modified zirconium phosphonate surfaces were shown to compete favorably with commercially available substrates designed for protein microarrays. Finally, we also show that the affitin scaffold (*41, 42*) can be used as a capture agent on different types of microarray slides. The small size of this scaffold (66 aa), which has been evaluated as an alternative to antibodies, allows a high density of spotting and consequently a high level of specific activity of the surfaces.

Phosphonated Adaptors for Specific Protein Anchoring on Zirconium Phosphonate-based Microarrays

Contents

1) Synthesis of the phosphorylated mono-NTA (13) and bis-NTA linker (18)
Experimental procedure for the synthesis of coumponds **1** to **18**.
^{1}H, ^{13}C NMR spectra for **1** to **18**

GENERAL:

All experiments were done under argon atmosphere. THF was distilled from sodium/benzophenone and dichloromethane from CaH_2. DMF was purchased from Aldrich as extra dry grade. Other solvents and reagents were purchased from Aldrich and used without further purification. All NMR spectra were recorded on a AC-300 or AC-400 Bruker spectrometer. Chemical shifts were reported in ppm using the residual solvent signal of $CDCl_3$ (^{1}H spectra: 7.28 ppm: ^{13}C spectra: 77.23 ppm) or D_2O (^{1}H spectra: 4.78 ppm). In reporting spectral data, the following abbreviations were used: s = singlet, d = doublet, t = triplet, q = quadruplet, m = multiplet, dd = doublet of doublet, dt = doublet of triplet. Constants (*J*) are given in Hertz (Hz). Low resolution (MS) mass spectra were taken under ESI mode on a LCQAdvantage (Thermo) micromass instrument or under CI mode on a DSQ-II (Thermo) micromass instrument with ammonia as reagent gas. All mass data and are reported in *m/z* units. Flash chromatographies were performed using Kieselgel-60 silica gel (230-400 mesh, Merck). Thin layer (TLC) analyses were done with Merck silica gel F-254 aluminum-backed plates.

Compound 1

To a stirred solution of 4-chlorobutanol (21.6 g, 198 mmol) and 3, 4-dihydro-2H-pyran (16.7 g, 198 mmol) in CH_2Cl_2 (900 mL), PTSA (catalytic) was added at room temperature. The mixture was stirred during 20 h, then washed with a saturated $NaHCO_3$ solution, dried over $MgSO_4$, filtered and evaporated under reduced pressure. The residue was purified by flash chromatography (EP/AcOEt, 95/5) to give **1** (29.36 g, 152.4 mmol, 77%). **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.46-1.60 (m, 4H); 1.62-1.80 (m, 4H); 1.81-1.94 (m, 2H, -

$C\underline{H}_2CH_2Cl$); 3.40 (dt, *J* = 9.7, 6 Hz, 1H, -$C\underline{H}_2O$-); 3.44-3.52 (m, 1H, -$C\underline{H}_2O$-); 3.56 (t, *J* = 6.5 Hz, 2H, -$C\underline{H}_2Cl$); 3.75 (dt, *J* = 9.7, 6 Hz, 1H, -$C\underline{H}_2O$-); 3.79-3.87 (m, 1H, -$C\underline{H}_2O$-); 4.46 (t, *J* = 2.2, 1H, -OC<u>H</u>O-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 19.56 (-$CHCH_2\underline{C}H_2$-); 25.40 (-$CH(CH_2)_2\underline{C}H_2$-); 27.07 ($Cl(CH_2)_2\underline{C}H_2$-); 29.60 ($ClCH_2\underline{C}H_2$-); 30.70 (-$CH\underline{C}H_2$-); 44.92 (-$\underline{C}H_2Cl$); 62.30 (-$\underline{C}H_2O$-, THP); 66.55 (-$\underline{C}H_2O$-); 98.80 (-O<u>C</u>HO-).

Compound 2

To a stirred solution of benzylamine (6.22 g, 58.12 mmol) and O-tetrahydropyranyl-4-chlorobutanol (**1**) (28 g, 145.31 mmol) in CH_3CN (150 mL), K_2CO_3 (20 g, 145.31 mmol) and KI (1.7 g, 11.62 mmol) were added at room temperature. The reaction mixture was refluxed for 48 h under argon atmosphere. The reaction mixture was cooled to room temperature, and the insoluble material was filtered off and the filtrate was concentrated under reduced pressure. The residue was purified by flash chromatography (EP/AcOEt, 100/0 to 30/70) to give **2** (15.1g, 36 mmol, 62%) as a colourless oil. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.54-1.90 (m, 20H); 2.43 (dd, *J* = 6.6 and 7.3Hz, 4H, -$NC\underline{H}_2$-); 3.35 (m, 2H, -$OC\underline{H}_2$-); 3.47 (m, 2H, -$OC\underline{H}_2$-, THP); 3.54 (s, 2H, $PhC\underline{H}_2$-); 3.70 (m, 2H, -$OC\underline{H}_2$-); 3.84 (m, 2H, -$OC\underline{H}_2$-, THP); 4.54 (dd, J = 2.7 and 4.4Hz, 2H, -OC<u>H</u>O-); 7.15-7.35 (m, 5H, aromatic). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 19.6 (-$CHCH_2\underline{C}H_2$-); 23.8 (-$NCH_2\underline{C}H_2$-); 25.5 (-$CH(CH_2)_2\underline{C}H_2$-); 27.6 ($NH(CH_2)_2\underline{C}H_2$-); 30.7 (-$CH\underline{C}H_2$-); 53.5 (-$N\underline{C}H_2$-); 58.6 (-$\underline{C}H_2O$-, THP); 62.3 ($Ph\underline{C}H_2$-); 67.5 (-$\underline{C}H_2O$-); 98.8 (-O<u>C</u>HO-); 126.6 (CAr); 128.1 (CAr); 128.8 (CAr); 140.2 (CAr).

Compound 3

To a stirred solution of **2** (12 g, 28.59 mmol) in methanol (60 mL), 10% Pd/C (1.2 g) was added and argon was bubbled in the resulting mixture. The flask was then evacuated and flushed with hydrogen. The reaction mixture was vigorously stirred under hydrogen overnight, and then filtered through a celite pad. The celite was washed with methanol and the solvent was concentrated *in vacuo* to yield **3** quantitatively. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.39-1.89 (20H); 2.65 (m, 4H, -$NC\underline{H}_2$-); 2.77 (s, 1H, -N<u>H</u>-); 3.38 (m, 2H, -$OC\underline{H}_2$-); 3.48 (m, 2H, -$OC\underline{H}_2$-, THP); 3.73 (m, 2H, -$OC\underline{H}_2$-), 3.83 (m, 2H, -$OC\underline{H}_2$-, THP); 4.55 (m, 2H, -OC<u>H</u>O-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 19.61 (-$CHCH_2\underline{C}H_2$-); 25.42 (-$CH(CH_2)_2\underline{C}H_2$-); 26.47 ($NHCH_2\underline{C}H_2$-); 27.49 ($NH(CH_2)_2\underline{C}H_2$-); 30.71 (-$CH\underline{C}H_2$-); 49.44 (-$N\underline{C}H_2$-); 62.32 (-$\underline{C}H_2O$-, THP); 67.32 (-$\underline{C}H_2O$-); 98.84 (-O<u>C</u>HO-). **MS** (CI, $C_{18}H_{35}NO_4$): 330.2 $[MH]^+$.

Compound 4

To a stirred solution of **3** (9.92 g, 30.13 mmol) in CH_2Cl_2 (50 mL), Et_3N (7.62 g, 75.33 mmol, 10.5 mL) and succinimide (4.52 g, 45.20 mmol) were added sequentially at room temperature. The reaction mixture was stirred for 4 days and then poured into water. The organic layer was washed with water (4 times). The aqueous layers were separated, acidified at pH = 2 with HCl and washed with CH_2Cl_2. Then, the organic layers were collected, dried over $MgSO_4$, filtered and evaporated under reduced pressure. Product **4** was obtained (11.87 g, 27.64 mmol, 92%) and used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.39-1.78 (20H); 2.61 (s, 4H, -CO($C\underline{H}_2$)$_2$CO-); 3.21-3.47 (m, 8H, -OC$\underline{H}_2$- and –NC$\underline{H}_2$-); 3.63-3.82 (m, 4H, -OC$\underline{H}_2$-); 4.49 (m, 2H, -OC$\underline{H}$O-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 19.75 (-CHCH$_2\underline{C}$H$_2$-); 24.53 (-CH(CH$_2$)$_2\underline{C}$H2-); 25.42, 25.82; 26.90; 27.12; 27.98; 30.12 (-$\underline{C}$H$_2$CO-); 30.73 (-CH$\underline{C}$H$_2$-); 46.20 (-$\underline{C}$H$_2$N-); 47.96 (-$\underline{C}$H$_2$N-); 62.42 (-$\underline{C}$H$_2$O-, THP); 62.61 (-$\underline{C}$H$_2$O-, THP); 66.87 (-$\underline{C}$H$_2$O-); 67.17 (-$\underline{C}$H$_2$O-); 98.94 (-O$\underline{C}$HO-); 99.10 (-O$\underline{C}$HO-); 171.97 (-N$\underline{C}$O-); 175.69 (-$\underline{C}$O$_2$H). **MS** (MALDI, ESI, $C_{22}H_{39}NO_7$): 429.9 $[MH]^+$, 452.2 $[MNa]^+$.

Compound 5

To a stirred solution of **4** (5 g, 11.63 mmol) in EtOH (250 mL) PTSA (5.5 g, 29 mmol) was added at room temperature. The reaction mixture was stirred for 48 h and then partially concentrated under reduced pressure. The reaction mixture was poured into CH_2Cl_2 and washed with a saturated $NaHCO_3$ aqueous solution. The aqueous layer was extracted with CH_2Cl_2 (3 times). The organic layers were collected, dried over $MgSO_4$, filtered and concentrated *in vacuo*. Product **5** was obtained (2.56 g, 8.85 mmol, 75%) and used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.25 (t, *J* = 7.1Hz, 3H); 1.48-1.75 (m, 8H, -CH$_2$($C\underline{H}_2$)$_2$CH$_2$-); 2.58-2.68 (m, 4H, -COC$\underline{H}_2$C$\underline{H}_2$CO-); 3.33 (m, 4H, -C$\underline{H}_2$N-); 3.66 (m, 4H, -C$\underline{H}_2$OH); 4.12 (q, *J* = 7.15 Hz, 2H, CH$_3$C$\underline{H}_2$O-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 14.04 ($\underline{C}$H$_3$CH$_2$O-); 24.03; 25.30; 27.78; 29.37; 29.47; 29.54; 45.71 (-$\underline{C}$H$_2$N-); 47.71 (-$\underline{C}$H$_2$N-); 60.52 (CH$_3\underline{C}$H$_2$O-); 61.77 (-CH$_2\underline{C}$H$_2$O-); 61.82 (-CH$_2\underline{C}$H$_2$O-); 171.08 (-$\underline{C}$ON-); 173.27 (-$\underline{C}$O$_2$Et). **MS** (CI, $C_{14}H_{27}NO_5$): 290.2 $[MH]^+$.

Compound 6

Under argon atmosphere, pyridine (1.18 g, 15 mmol, 1.21 mL) was added to a stirred solution of **5** (0.88 g, 3 mmol) in dry CH_2Cl_2 (20 mL). The reaction mixture was cooled with an ice bath and methanesulfonyl chloride (2.16 g, 15 mmol, 1.46 mL) was added. The reaction was stirred at room temperature for 6 h. The reaction mixture was then diluted with ether, washed with cold 10% aqueous HCl, cold 10% aqueous NaOH, water and brine. The

organic layer was dried over $MgSO_4$, filtered and evaporated *in vacuo*. Product **6** was obtained (1.34 g, 3 mmol, 100%) and used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.25 (t, 3H, *J* = 7.14Hz, $C\underline{H}_3CH_2O$-); 1.49-1.85 (m, 8H, $-NCH_2(C\underline{H}_2)_2CH_2$-); 2.56-2.68 (m, 4H, $-CO(C\underline{H}_2)_2CO$-); 3.00 (s, 3H, $C\underline{H}_3S$-); 3.02 (s, 3H, $C\underline{H}_3S$-); 3.26-3.41 (m, 4H, $-NC\underline{H}_2$-); 4.12 (q, 2H, *J* = 7.14Hz, $CH_3C\underline{H}_2O$-); 4.21-4.29 (m, 4H, $-CH_2C\underline{H}_2S$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 14.17 ($\underline{C}H_3CH_2O$-); 23.85; 25.17; 26.62; 27.98 ($-OCOCH_2\underline{C}H_2CO$-); 29.52 ($-OCO\underline{C}H_2CH_2CO$-); 37.49 ($\underline{C}H_3S$-); 45.19 ($-\underline{C}H_2N$-); 47.20 ($-\underline{C}H_2N$-); 60.48 ($CH_3\underline{C}H_2O$-); 68.99 ($-\underline{C}H_2OS$-); 69.64 ($-\underline{C}H_2OS$-); 171.11 ($-\underline{C}ON$-); 173.00 ($-\underline{C}O_2Et$). **MS** (MALDI, ESI, $C_{16}H_{31}NO_9S_2$): 446 $[MH]^+$**,** 468 $[MNa]^+$.

Compound 7

To a stirred solution of **6** (1.34 g, 3 mmol) in acetone (60 mL), LiBr (2.6 g, 30 mmol) was added at room temperature. The reaction mixture was refluxed for 24 h under argon atmosphere. The solvent was removed under reduced pressure and the reaction mixture was diluted with CH_2Cl_2. The organic layer was washed with water (3 times), dried over $MgSO_4$, filtered and concentrated under reduced pressure. Product **7** was obtained (1.08 g, 2.6 mmol, 87%) and used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.25 (t, 3H, *J* = 7.14Hz, $C\underline{H}_3CH_2O$-); 1.50-1.96 (m, 8H, $-NCH_2(C\underline{H}_2)_2CH_2$-); 2.56-2.71 (m, 4H, $-CO(C\underline{H}_2)_2CO$-); 3.33 (m, 4H, $-NC\underline{H}_2$-); 3.43 (m, 4H, $-C\underline{H}_2Br$); 4.13 (q, 2H, *J* = 7.14Hz, $CH_3C\underline{H}_2O$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 14.11 ($\underline{C}H_3CH_2O$-); 26.22; 27.33; 27.81 ($-COCH_2\underline{C}H_2CON$-); 29.34 ($-CO\underline{C}H_2CH_2CON$-); 29.67; 29.85; 32.75 ($-\underline{C}H_2Br$); 33.39 ($-\underline{C}H_2Br$); 44.79 ($-N\underline{C}H_2$-); 46.75 ($-N\underline{C}H_2$-); 60.47 ($CH_3\underline{C}H_2O$-); 170.87 ($-\underline{C}ON$-); 173.03 ($-\underline{C}O_2Et$). **MS** (MALDI, ESI, $C_{14}H_{25}Br_2NO_3$): 416 $[MH]^+$, 438 $[MNa]^+$.

Compound 8

Under argon atmosphere, diethylphosphite (1.11 g, 8.1 mmol, 0.8 mL) was added to a stirred suspension of metallic sodium (0.19 g, 8.1 mmol) in dry THF (30 mL). The reaction mixture was stirred at room temperature until all sodium had reacted. Then, a solution of **7** (1.08 g, 2.6 mmol) in dry THF was added via a canula and salt formation occurred rapidly in the reaction mixture. The reaction mixture was stirred for 4 days and then poured into ethyl acetate. The organic layer was washed with a NH_4Cl saturated solution and then brine. The aqueous layer was extracted 3 times with CH_2Cl_2. The organic layers were combined, dried over $MgSO_4$, filtered, and concentrated *in vacuo*. The residue was separated by flash chromatography (EP/AcOEt, 100/0 to 0/100 and next AcOEt/MeOH, 90/10 to 70/30) to give

8 (1.16 g, 2.19 mmol, 81%) as a colourless oil. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.25 (t, 3H, *J* = 7.14, $C\underline{H}_3CH_2OCO$-); 1.31 (t, 6H, *J* = 7.05, $C\underline{H}_3CH_2OPO$-); 1.32 (t, 6H, *J* = 7.05, $C\underline{H}_3CH_2OPO$-); 1.82-2.24 (m, 12H, -$PO(C\underline{H}_2)_3CH_2$-); 2.53-2.69 (m, 4H, -$CO(C\underline{H}_2)_2CO$-); 3.21-3.35 (m, 4H, -$CONC\underline{H}_2$-); 4.01-4.17 (m, 10H, $CH_3C\underline{H}_2OCO$- and $CH_3C\underline{H}_2OPO$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 14.09 ($\underline{C}H_3CH_2OCO$-); 16.35 ($\underline{C}H_3CH_2OP$-); 16.41 ($\underline{C}H_3CH_2OP$-); 19.92 (-$\underline{C}H_2CH_2P$-); 24.29; 24.41; 26.16; 26.29; 27.78 (-$OCOCH_2\underline{C}H_2CON$-); 28.35; 28.56; 29.32 (-$OCOCH_2\underline{C}H_2CON$-); 29.55; 29.75; 45.47 (-$\underline{C}H_2N$-); 47.36 (-$\underline{C}H_2N$-); 60.44 ($CH_3\underline{C}H_2OCO$-); 61.46 ($CH_3\underline{C}H_2OP$-); 170.70 (-$OCOCH_2CH_2\underline{C}ON$-); 173.07 (-$O\underline{C}OCH_2CH_2CON$-). **MS** (MALDI, ESI, $C_{20}H_{41}NO_9P_2$): 502.1 $[MH]^+$, 524.1 $[MNa]^+$.

Compound 9

To a stirred solution of **8** (1.16 g, 2.19 mmol) in a THF/MeOH/H_2O (3/1/1) mixture, LiOH (0.13 g, 5.47 mmol) was added. The reaction mixture was stirred for 24 h and then acidified with a 0.2 M HCl aqueous solution. The aqueous layer was extracted 4 times with CH_2Cl_2. The organic layers were combined, dried over $MgSO_4$, filtered and concentrated *in vacuo*. Product **9** was obtained (1.11 g, 2.21 mmol, 100%) and used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.32 (m, 12H, $C\underline{H}_3CH_2OP$-); 1.47-1.83 (m, 12H, -$NCH_2(C\underline{H}_2)_3P$-); 2.58-2.72 (m, 4H, -$CO(C\underline{H}_2)_2CO$-); 3.27 (m, 2H, -$NC\underline{H}_2$-); 3.38 (m, 2H, -$NC\underline{H}_2$-); 4.01-4.18 (m, 8H, $CH_3C\underline{H}_2OP$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 16.33 ($\underline{C}H_3CH_2OP$-); 16.39 ($\underline{C}H_3CH_2OP$-); 19.70 (-$\underline{C}H_2CH_2P$-); 19.98 (-$\underline{C}H_2CH_2P$-); 24.45; 26.30; 28.18; 28.30; 28.52; 29.58; 29.77; 29.98; 45.30 (-$\underline{C}H_2N$-); 47.53 (-$\underline{C}H_2N$-); 61.34 ($CH_3\underline{C}H_2OP$-); 61.69 ($CH_3\underline{C}H_2OP$-); 171.76 (-$OCOCH_2CH_2\underline{C}ON$-); 174.33 (-$O\underline{C}OCH_2CH_2CON$-). **MS** (MALDI, ESI, $C_{20}H_{41}NO_9P_2$): 502 $[MH]^+$, 524.1 $[MNa]^+$.

Compound 10

tert-Butyl bromoacetate (12.52 g, 64.20 mmol, 9.47 mL) and EDIAP (6.63 g, 51.36 mmol, 8.48 mL) were added to a solution of N^{ε}-benzyloxycarbonyl-L-Lysine *tert*-butyl ester (4.32 g, 12.84 mmol) in CH_3CN (40 mL). The reaction mixture was purged with argon and then refluxed for 48 h. The volatiles were evaporated *in vacuo*. The residue was purified by flash chromatography (EP/AcOEt, 100/0 to 80/20) to give **10** as a colourless oil (6.24 g, 11.05 mmol, 86%). **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.44 (s, 18H, $((C\underline{H}_3)_3COCOCH_2)_2N$-); 1.47 (s, 9H, $(C\underline{H}_3)_3COCOCH$-); 1.49 (m, 4H, -$NHCH_2(C\underline{H}_2)_2$-); 1.59 (m, 2H, -$NH(CH_2)_3C\underline{H}_2$-); 3.20 (m, 2H, -$NHC\underline{H}_2$-); 3.31 (t, 1H, *J* = 7.1 Hz, -$NC\underline{H}$-); 3.46 (dd, 4H, *J* = 4.9 Hz and *J* = 17.2 Hz,

(($CH_3)_3COCOC\underline{H}_2)_2N$-); 5.07 (s, 2H, ($C_6H_5)C\underline{H}_2O$-); 7.33 (m, 5H, aromatic). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 23.02 (-$\underline{C}H_2(CH_2)_2NH$-); 28.11 ($\underline{C}H_3$-); 29.24 (-$\underline{C}H_2(CH_2)_3NH$-); 30.13 (-$\underline{C}H_2CH_2NH$-); 40.83 (-$\underline{C}H_2NH$-); 53.92 (($CH_3)_3COCO\underline{C}H_2)_2N$-); 65.10 (-N(CH2)$_4\underline{C}H$-); 66.45 (Ar$\underline{C}H_2CO$-); 80.71 (($CH_3)_3\underline{C}OCOCH_2)_2N$-); 81.11 (($CH_3)_3\underline{C}OCOCH$-); 127.94 (Ar); 128.43 (Ar); 136.79 (Ar); 156.48 (Ar$CH_2\underline{C}O$-)); 170.74 (($CH_3)_3CO\underline{C}OCH_2)_2N$-); 172.32 (($CH_3)_3CO\underline{C}OCH$-). **MS** (MALDI, ESI, $C_{30}H_{48}N_2O_8$): 565 $[MH]^+$.

Compound 11

After dissolution of **10** (11 g, 19.47 mmol) in methanol (50 mL), 10% Pd/C (300 mg) was added and the resulting mixture was purged with argon. The flask was evacuated and flushed with hydrogen. The reaction mixture was vigorously stirred under hydrogen overnight, and then filtered through a celite pad. The celite was washed with methanol and the solvent was concentrated *in vacuo*. The residue was purified by flash chromatography (EP/AcOEt, 80/20 to 50/50 and next CH_2Cl_2/MeOH, 90/10) to give **11** as a colourless oil (5.78 g, 13.43 mmol, 70%). **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.44 (s, 18H, (($C\underline{H}_3)_3COCOCH_2)_2N$-); 1.47 (s, 9H, ($C\underline{H}_3)_3COCOCH$-); 1.51 (m, 4H, $NH_2CH_2(C\underline{H}_2)_2$-); 1.62 (m, 2H, $NH_2(CH_2)_3C\underline{H}_2$-); 2.69 (t, 2H, J = 7.1 Hz, $NH_2C\underline{H}_2$-); 3.31 (t, 1H, -NC$\underline{H}$-); 3.47 (dd, 4H, J = 5.1 Hz and J = 17.2 Hz, (($CH_3)_3COCOC\underline{H}_2)_2N$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 23.16 ($NH_2(CH_2)_2\underline{C}H_2$-); 28.17 (($\underline{C}H_3)_3COCOCH_2)_2N$-); 28.25 (($\underline{C}H_3)_3COCOCH$-); 30.40 (-$\underline{C}H_2(CH_2)_3NH_2$); 32.48 (-$\underline{C}H_2CH_2NH_2$); 41.74 (-$\underline{C}H_2NH_2$) 54.03 (($CH_3)_3COCO\underline{C}H_2)_2N$-); 77.19 (($CH_3)_3COCO\underline{C}H$-); 80.68 (($CH_3)_3\underline{C}OCOCH_2)_2N$-); 80.99 (($CH_3)_3\underline{C}OCOCH$-); 170.74 (($CH_3)_3CO\underline{C}OCH_2)_2N$-); 172.32 (($CH_3)_3CO\underline{C}OCH$-). **MS** (MALDI, ESI, $C_{22}H_{42}N_2O_6$): 431 $[MH]^+$.

Compound 12

To a stirred solution of **9** (0.45 g, 1.16 mmol) in extra dry DMF (5 mL), TBTU (0.55 g, 1.73 mmol) and EDIAP (0.31 g, 2.43 mmol, 0.4 mL) were added. The reaction mixture was purged with argon and stirred for 30 min. Then, a solution of **11** (0.6 g, 1.39 mmol) in DMF (10 mL) was added via a canula. The reaction mixture was stirred under argon atmosphere for 48 h. DMF was evaporated under reduced pressure and the reaction mixture was diluted in CH_2Cl_2. The organic layer was washed with water (3 times), dried over $MgSO_4$, filtered and evaporated under reduced pressure. The residue was purified by flash chromatography (CH_2Cl_2/MeOH, 100/0 to 90/10) to give **12** (0.42 g, 0.46 mmol, 40%). **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.28-1.34 (m, 12H, $C\underline{H}_3CH_2OP$-); 1.43 (s, 18H, (($C\underline{H}_3)_3COCOCH_2)_2N$-)); 1.45 (s,

9H, ($C\underline{H}_3$)$_3$COCOCH-); 1.49-1.82 (m, 18H); 2.46-2.66 (m, 4H, -CO($C\underline{H}_2$)$_2$CO-); 3.14-3.33 (m, 7H, -$C\underline{H}_2$N-, (CH_3)$_3$COCO$C\underline{H}$- and –$C\underline{H}_2$NHCO-); 3.44 (dd, 4H, *J* = 5.4 and 17.1 Hz, ((CH_3)$_3$COCO$C\underline{H}_2$)$_2$N-)); 3.98-4.17 (m, 8H, $CH_3C\underline{H}_2$OP-); 6.25 (t, 1H, *J* = 4.8 Hz, -N$\underline{H}$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 16.46; 16.54; 20.02; 23.15; 24.46; 26.28; 26.34; 28.13; 28.21; 28.45; 28.64; 28.80; 29.64; 29.84; 30.07; 31.48; 39.34; 45.56; 47.50; 53.82; 61.42; 61.52; 61.62; 65.03; 80.72; 170.72; 171.46; 172.31; 172.39. **MS** (MALDI, ESI, $C_{42}H_{81}N_3O_{14}P_2$): 914.4 $[MH]^+$.

Compound (13)

To a stirred solution of **12** (0.42 g, 0.46 mmol) in dry CH_2Cl_2 (5 mL), bromotrimethylsilane (0.85 g, 5.56 mmol, 0.73 mL) was added. The reaction mixture was stirred at room temperature for 4 days and volatiles were evaporated *in vacuo*. The reaction mixture was diluted with water and washed with CH_2Cl_2 (3 times). The aqueous layer was evaporated under reduced pressure to give **13** (quantitative) as a hygroscopic white solid. **^{1}H NMR (400 MHz, D_2O) δ:** 1.45-2.09 (m, 18H); 2.54 (t, 2H, *J* = 6.7 Hz, -CO($C\underline{H}_2$)$_2$CO-); 2.74 (t, 2H, *J* = 6.7 Hz, -CO($C\underline{H}_2$)$_2$CO-); 3.22 (m, 2H, –$C\underline{H}_2$NHCO-); 3.37(m, 3H, -$C\underline{H}_2$N- and (CH_3)$_3$COCO$C\underline{H}$-); 3.43 (t, 2H, *J* = 7.4 Hz, -$C\underline{H}_2$N-); 4.16 (s, 4H, ((CH_3)$_3$COCO$C\underline{H}_2$)$_2$N-)). **MS** (MALDI, ESI, $C_{22}H_{41}N_3O_{14}P_2$): 633.2 [M].

Compound (15)

To a stirred solution of **11** (1 g, 2.32 mmol) in dry CH_2Cl_2 (50 mL), was added **14** (0.28 g, 1 mmol), TBTU (0.93 g, 2.9 mmol) and EDIAP (0.4 g, 3.5 mmol, 0.57 mL). The slurry solution obtained was purged with argon and stirred for 20 h at room temperature. The reaction mixture was washed with water (3 times), 0.5 M HCl (1 time) and 0.5 M NaOH (1 time). The organic layer was dried over $MgSO_4$, filtered, and evaporated *in vacuo*. The residue was separated by flash chromatography (EP/AcOEt, 80/20 to 30/70) to give **15** (1.06 g, 0.96 mmol, 96%). **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.43 (s, 36H, (($C\underline{H}_3$)$_3$COCOCH_2-); 1.45 (s, 18H, ($C\underline{H}_3$)$_3$COCOCH-); 1.47-1.65 (m, 12H, -NCH($C\underline{H}_2$)$_3$-); 1.96-2.04 (m, 2H, -NHCH$CH_2C\underline{H}_2$-); 2.22-2.30 (m, 2H, -NHCH$C\underline{H}_2$-); 3.14-3.30 (m, 6H, -N$C\underline{H}$(CH_2)$_3C\underline{H}_2$NH-); 3.46 (m, 8H, ((CH_3)$_3$COCO$C\underline{H}_2$)$_2$N-); 4.17 (m, 1H, -NHC$\underline{H}$-); 5.03 (s, 2H, (C_6H_5)$C\underline{H}_2$-); 6.40 (m, 1H, (C_6H_5)CH_2OCON$\underline{H}$-); 6.53 (m, 1H, (-OCONHCHCON$\underline{H}$-); 6.90 (m, 1H, -NHCH(CH_2)$_2$CON$\underline{H}$-); 7.28 (m, 5H, aromatic). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 22.81 (-CONH(CH_2)$_2\underline{C}H_2$-); 23.07 (-CONH(CH_2)$_2\underline{C}H_2$-); 28.12 (($\underline{C}H_3$)$_3$COCOCH_2)$_2$N-); 28.21 (($\underline{C}H_3$)$_3$COCOCH-); 28.78; 29.25; 29.67; 30.03; 32.43 (-NHCO$\underline{C}$HC$H_2\underline{C}H_2$CO-); 38.61 (-

Compound (16)

Upon dissolving **15** (1.06 g, 0.96 mmol) in methanol (20 mL), 10% Pd/C (70 mg) was added and the resulting mixture was purged with argon. The flask was evacuated and flushed with hydrogen. The reaction mixture was vigorously stirred under hydrogen overnight, and then filtered through a pad of celite. The celite was washed with methanol and the solvent was concentrated *in vacuo*. The product **16** obtained (0.92 g, 0.95 mmol, 100%) was used without further purification. **^{1}H NMR (300 MHz, $CDCl_3$) δ:** 1.43 (s, 36H, (($C\underline{H}_3)_3COCOCH_2$-); 1.45 (s, 18H, ($C\underline{H}_3)_3COCOCH$-); 1.47-1.65 (m, 12H, -NCH($C\underline{H}_2)_3$-); 2.00-2.10 (m, 2H, -NHCHC$\underline{H}_2$-); 2.37-2.44 (m, 2H, -NHCHC$H_2C\underline{H}_2$-); 3.20-3.30 (m, 6H, -NC$\underline{H}(CH_2)_3C\underline{H}_2NH$-); 3.36-3.50 (m, 8H, (($CH_3)_3COCOC\underline{H}_2)_2N$-); 3.56 (m, 1H, -NHC$\underline{H}$-); 6.88 (m, 1H, $NH_2CH(CH_2)_2CON\underline{H}$-); 7.68 (m, 1H, $NH_2CHCON\underline{H}$-). **^{13}C NMR (100.6 MHz, $CDCl_3$) δ:** 23.02 (-CONH$(CH_2)_2\underline{C}H_2$-); 23.30 (-CONH$(CH_2)_2\underline{C}H_2$-); 28.12 (($\underline{C}H_3)_3COCOCH_2)_2N$-); 28.20 (($\underline{C}H_3)_3COCOCH$-); 28.56; 29.11; 29.91; 30.25; 31.28; 33.02; 38.94 (-$\underline{C}H_2NH$-); 39.27 (-$\underline{C}H_2NH$-); 53.74 (($CH_3)_3COCO\underline{C}H_2)_2N$-); 53.88 (($CH_3)_3COCO\underline{C}H_2)_2N$-); 54.41 (-NHCO$\underline{C}H(CH_2)_2CO$-); 64.93 (-N(CH2)$_4\underline{C}H$-); 65.07 (-N(CH2)$_4\underline{C}H$-); 80.69 (($CH_3)_3\underline{C}OCOCH$-); 80.78 (($CH_3)_3\underline{C}OCOCH$-); 81.11 (($CH_3)_3\underline{C}OCOCH$-); 170.68; 170.78; 172.34; 172.97; 174.76. **MS** (MALDI, ESI, $C_{49}H_{89}N_5O_{14}$): 973 $[MH]^+$

Compound (17)

To a stirred solution of **9** (0.12 g, 0.30 mmol) in extradry DMF (5 mL) was added HATU (0.175 g, 0.46 mmol) and EDIAP (0.083 g, 0.64 mmol, 0.107 mL). The reaction mixture was purged with argon and stirred at room temperature for 30 min. Then, a solution of **16** (0.3 g, 0.3 mmol) in DMF (10 mL) was added by canulation. The reaction mixture was stirred under argon atmosphere for 48 h. DMF was evaporated under reduce pressure and the reaction mixture was diluted in CH_2Cl_2. The organic layer was washed with water and the aqueous layer was extracted 3 times with CH_2Cl_2. The organic layers were combined, dried over $MgSO_4$, filtered and evaporated under reduce pressure. The residue was separated by flash chromatography (CH_2Cl_2/MeOH, 99/1 to 95/5) to give **17** (0.38 g, 0.26 mmol, 85%). **^{1}H**

NMR (300 MHz, $CDCl_3$) δ: 1.25 (dt, 12H, *J* = 3.9 and 7.2 Hz, -$POCH_2C\underline{H}_3$); 1.37 (s, 36H, $(C\underline{H}_3)_3COCOCH_2$-); 1.38 (s, 18H, $(C\underline{H}_3)_3COCOCH$-); 1.42-1.82 (m, 22H); 1.87-2.75 (m, 10H); 3.01-3.28 (m, 10H); 3.30-3.45 (m, 8H, $(CH_3)_3COCOC\underline{H}_2$-); 3.92-4.11 (m, 8H, -$POC\underline{H}_2CH_3$); 4.29 (m, 1H, -NHC<u>H</u>-); 6.72 (t, 1H, *J* = 5.1 Hz, -N<u>H</u>-); 7.33 (t, 1H, *J* = 5.1Hz, -N<u>H</u>-); 7.54 (d, 1H, *J* = 7.5 Hz; -N<u>H</u>CH-).

Compound (18)

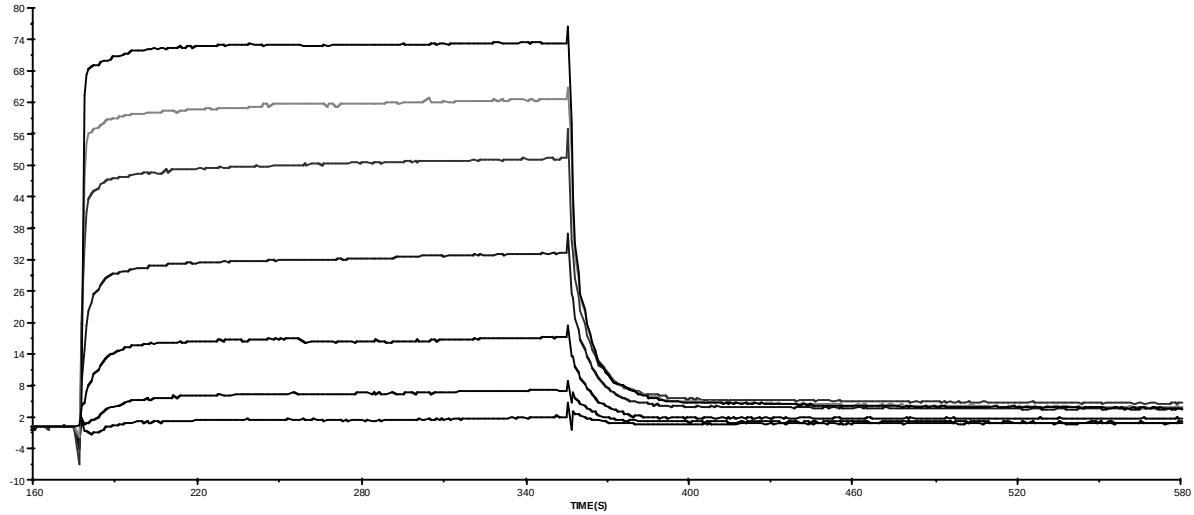
To a stirred solution of **17** (0.15 g, 0.10 mmol) in dry CH_2Cl_2 (15 mL) was added bromotrimethylsilane (0.315 g, 2.06 mmol, 0.27 mL). The reaction mixture was stirred at room temperature for 4 days and MeOH was added. The solution was stirred for 30 min and volatiles were evaporated *in vacuo*. The reaction mixture was diluted with water and washed with CH_2Cl_2 (3 times). The aqueous layer was evaporated under reduce pressure to give **18** quantitatively. **^{1}H NMR (300 MHz, D_2O) δ:** 1.30-2.03(m, 24H, -CH_2-) ; 2.29 (m, 2H); 2.53 (m, 2H); 2.72 (m,2H); 3.17 (m, 4H); 3.27-3.40 (m, 5H); 4.00-4.27 (m, 10H). **MS** (MALDI, ESI, $C_{37}H_{64}N_6O_{22}P_2$): 1005.2 $[MH]^-$

2) Lysozyme affinity determination of affitins H4 and B3

Surface plasmon resonance (SPR) was measured using a BIAcore 3000 instrument (BIAcore, Uppsala Sweden). All measurements were performed at a flow rate of 60 μL/min. A solution of lysozyme at 4 μg/mL in sodium acetate buffer (10 mM, pH= 5.5) was used for the target immobilization on CM5 chip and lysozyme was immobilized at 250 RU. Kinetics was realized for B3 (A) with concentrations of 2000, 1000, 500, 166, 55, 18, 6, 2, 0.69 nM. For H4 (B), concentrations used were 500, 166, 55, 18, 6, 2, 0.69, 0.23 and 0 nM. Association and dissociation times were 3 and 10 min respectively. The kinetic data of the interaction were evaluated with a global fit using Langmuir model (Bioevaluation software 4.1). For each affitin a representative set of fitted curves are shown below.

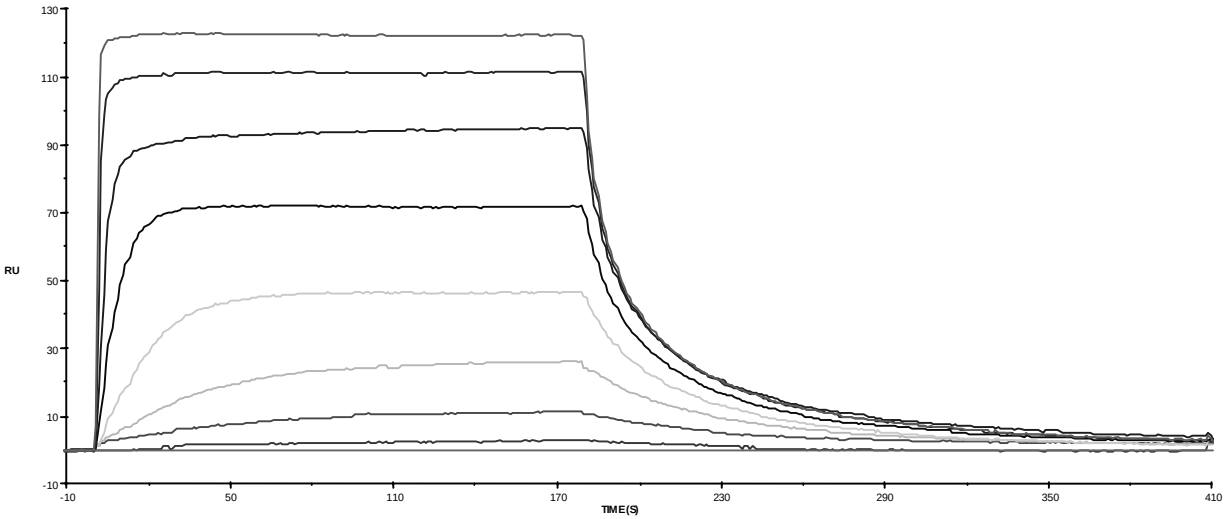
$$\frac{dR}{dt} = ka \,.\, C \,.\, (Rmax - R) - kd \,.\, R$$

A) B3



K_D = 286 nM; k_{on} = 4.38 x 10^5 $M^{-1}s^{-1}$; k_{off} = 0.125 s^{-1}

B) H4



K_D = 4.6 nM; k_{on} = 2.53 x 10^6 $M^{-1}s^{-1}$; k_{off} = 0.029 s^{-1}

Alignment of Gold Clusters on DNA via a DNA-Recognizing Zinc Finger-Metallothionein Fusion Protein

Shinya Ariyasu,[†] Akira Onoda,[‡] Ryota Sakamoto,[†] and Takeshi Yamamura*[,†]

Department of Chemistry, Faculty of Science, Tokyo University of Science, Kagurazaka 1-3, Shinjuku-ku, Tokyo, 162-8601, Japan, and Department of Applied Graduate School of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka. Received June 20, 2009; Revised Manuscript Received September 18, 2009

The complementary recognition of base pairs (bp) is the major strategy in the "DNA lithography" of gold (Au) clusters or nanoparticles, where single-stranded DNAs sulfurized at their termini are generally used to bind Au clusters or nanoparticles. In this report, we discuss a new material that can be used to locate Au clusters on the desired positions of DNA. For this purpose, we combined a two-domain zinc finger (ZF) and the analogue of α domain of rat's liver metallothionein (MT) to utilize the DNA-recognizing ability of ZF motifs and the heavy-metal binding ability of MTs, and prepared an artificial fusion protein, ZFZF-MTα (**1**). Titration experiments monitored by absorption and circular dichroism spectroscopies, as well as an electrophoretic mobility shift assay and quantification using 5,5′-dithiobis(2-nitrobenzoic acid), clarified that (1) the ZF domain traps two divalent metal ions to fold in a ZF structure with $M(Cys)_2(His)_2$ (M = Co, Zn, and Cd) coordination units, (2) the MT domain traps metal ions to form clusters (Cd^{2+} particularly forms a $Cd_4(Cys)_9$ cluster) without interfering with the folding of the ZF domain, and (3) **1** recognizes the 5′-GGGGGG-3′ (G_6) bp sequence in the presence of Zn^{2+} based on the amino acid sequence encoded in the ZF domain. The titration of $Au_{11}(PPh_3)_8Cl_3$ (Au11) into the solution of **1** in the presence of Zn^{2+} revealed that the MT domain strongly binds the Au11 cluster with a 1:1 ratio, and a Au_{11}-containing conjugate, ZF(Zn)ZF(Zn)-MTα(Au_{11}) was obtained. Transmission electron microscopy (TEM), energy-dispersive X-ray spectroscopy, and X-ray photoelectron spectroscopy showed that this conjugate maintains an Au_{11} core in the form of $Au_{11}(PPh_3)_4(S\text{-}Cys)_6$ without disturbing the folding nature of the ZF domain. ZF(Zn)ZF(Zn)-MTα(Au_{11}) recognizes the bp sequence G_6 with $K_{d1} = 450$ nM, while simultaneously forming a dimer on the DNA with $K_{d2} = 200$ nM. TEM experiments showed that the conjugates form parallelograms or triangles (defective parallelograms) on a double crossover (dx) DNA, according to the positions of G_6 encoded in the dx DNA.

INTRODUCTION

The alignment of inorganic large clusters and nanoparticles (nps) on the "desired points" of double-stranded (ds) DNA[1]is one of the gateways for "DNA lithography" (*1*), which has the potential to provide new electronic and optical devices based on the nanoscale patterning of mesoscale compounds. In order to approach this problem, complementary interaction between two single-stranded (ss) DNAs is generally used, where the terminus of an ssDNA is thiolated to SH to bind Au clusters (*2*).

In this study, we developed a new method for positioning Au clusters at will on DNA; that is, we coupled the DNA-recognizing ability of a zinc finger (ZF) (*3, 4*) motif with the heavy-metal binding ability of a metallothionein (MT) (*5*). We prepared a new artificial fusion protein ZFMT (comprising ZF and MT domains) as the linker that mediates the positioning of Au clusters at the desired points of DNA.

ZFs are DNA-binding motifs that rank with the leucine-zipper (*6*) and helix−loop−helix motifs (*7*) in DNA recognition ability. ZFs are classified into $[Zn(Cys)_4]^{2-}$ (*8*), $[Zn_2(Cys)_6]^{2-}$ (*9*), and $Zn(Cys)_2(His)_2$ (*10*) from the viewpoint of Zn coordination geometry. Among these ZFs, we focused our attention on the $Zn(Cys)_2(His)_2$ type, because this ZF is the smallest of the ZFs (its consensus sequence is written as [Tyr/Phe]-X-Cys-$X_{2\text{-}4}$-Cys-X_3-Phe-X_5-Leu-X_2-His-$X_{2\text{-}4}$-His, comprising only 25−30 amino acid residues) and folds into a compact $\beta\beta\alpha$ structure in the presence of Zn^{2+}. $Zn(Cys)_2(His)_2$-type ZFs strongly and accurately recognize the specific positions of dsDNA when they are connected in tandem repeat structures (*11*); therefore, this type is more versatile (*12*) than the other types of ZFs and DNA-binding motifs. However, the most important point is that the $Zn(Cys)_2(His)_2$-type ZF is easy to handle. It is easily prepared by solid-phase synthesis and elongated by the native chemical

Figure 1. Positioning of an Au cluster on dsDNA using ZF(Zn)ZF(Zn)-MTα(Au_{11}).

ligation (NCL) method. Furthermore, the amino acid sequence is easily designed for the recognition of DNA based on the code tables reported by Pabo (*10*), Choo (*13*), and Sera (*14*).

On the other hand, MTs are ubiquitous, small, and Cys-rich proteins that strongly bind heavy metal ions such as zinc (Zn^{2+}), copper (Cu^{2+}), cadmium (Cd^{2+}), and silver (Ag^{+}) ions (*15, 16*) to reduce the ionic concentrations to physiological or nontoxic levels (*17*). MTs not only trap these metal ions as $M_x(Cys)_y$ clusters (*18*), but also react with Au^{+} to form nanoparticles (*19*). Recently (*20*), we succeeded in demonstrating that $Au_{11}(PPh_3)_8Cl_3$ cluster (Au11), a small cluster with discrete electronic states (*21*), reacts with a MT-like peptide MTα (**2**),[2]composed of N-terminus α domain of rat's liver MTII and Cys-Gly to form 1:1 conjugate, where Cys-Gly is a junction assumed for introducing new peptide moieties by NCL (*22*).

In this study, we synthesized a novel fusion protein ZFZF-MTα (**1**) (Figures 1 and 2) composed of a two-domain $Zn(Cys)_2(His)_2$-type ZF, ZFZF (**3**), and **2** by applying the NCL method. In our previous study, we also constructed a fusion protein comprising a two-domain ZF and **2**. Unfortunately, the ZF domain did not bind to the specific positions of DNA; therefore, we designed and synthesized a new protein in this study. **1** showed binding affinities to heavy metal ions, such as Co^{2+}, Zn^{2+}, and Cd^{2+}, as well as Au11. Titration experiments monitored by UV−vis and CD spectroscopies showed that each domain of **1** independently coordinated to Zn^{2+} and Au11 without losing the original folding structures of the ZF and MTα. The fusion protein **1** containing two Zn^{2+} ions in the ZF domain and a Au11 cluster in the MTα domain, ZF(Zn)ZF(Zn)-MTα(Au_{11}) (**9**), realized the alignment of Au clusters on ds and double crossover (dx)DNAs based on the information encoded in the DNA sequences.

RESULTS

Sequence Design and Synthesis. 3 was designed to recognize 5′-GGGGGG-3′ (G_6) and its complementary bp (Figure 2) based on the amino acid sequence of zif268 (*23*); therefore, each ZF of **1** has a set of four key amino acid residues—Arg, Asp, His, and Arg—at the −1, 2, 3, and 6 positions, respectively, counting from the starting point of the α-helix. The two ZFs are connected to each other via the canonical linker Thr-Gly-Glu-Lys-Pro. The C-terminus of **3** contains the N-terminal part of the canonical linker Thr-Gly-Gly to stabilize the C-terminus of the finger part. It is assumed that the extra Gly gives sufficient flexibility to this part in cooperation with the adjacent amino acid residue, Gly; thus, steric hindrance between **2** and **3** is avoided.

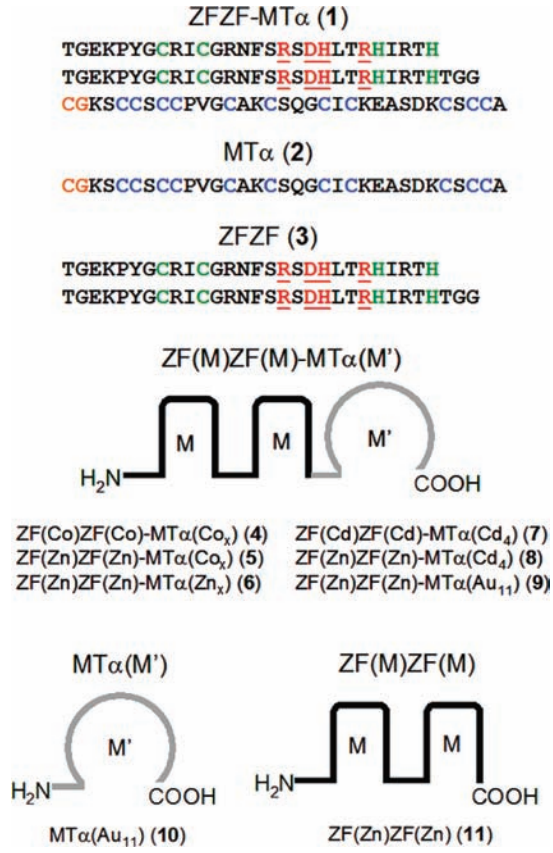

Figure 2. Schematic drawings of the peptides **1**, **2**, and **3** and the inorganic bioconjugates investigated in this study **4**, **5**, **6**, **7**, **8**, **9**, **10**, and **11**. The amino acid sequences are written according to the IUPAC-IUB JCBN nomenclature. The DNA-recognizing and metal-binding residues of the ZF domain are shown by the underlined red and green characters, respectively, whereas the metal-binding residues of the MT domain are shown by the blue characters. The orange characters denote the residues for NCL.

The syntheses of **2** and **3** were carried out by a standard solid-phase method with Fmoc/*t*-Bu chemistry, and the C-terminus of **3** was thioesterificated using 25 equiv of PyBOP and HOBt (*24*) to obtain **3-COSR**. This reaction was completed within 24 h in spite of the length of ca. 60 residues. The synthesis of **1** by the NCL method from **3-COSR** and **2** was completed within 24 h.

Metal Coordination and Folding of ZFZF-MTα. The complexation of artificial or consensus ZF proteins was confirmed by Co^{2+} titration monitored by UV−vis spectrometry (*25*). In order to discuss whether or not the ZF and MTα domains of **1** independently folded into the ZF and MTα structures without interfering, titration experiments on **1** were carried out in the presence of Co^{2+}. The results are shown in Figure 3. In the first stage of the Co^{2+} titration (0−1 equiv) into **1**, we observed a rapid increase in the basal absorption for the whole wavelength region of 600−750 nm; the intensities of the three peaks at 525, 655, and 725 nm prominently increased with the amount of Co^{2+}. In the second stage of the titration (Co^{2+} 1−2 equiv), the intensities of the peaks at 525 and 725 nm decreased with an increase in the amount of Co^{2+},

[2]Numbering and abbreviations of the compounds (collected in Figure 2). Two types of abbreviations are adopted: first, the apo-proteins and their metallo compounds are numbered with bold Arabic numerals **1**, **2**, ---, and **11**; second, supplementary abbreviations are also introduced to help chemical understanding for the compounds. For example, ZFZF-MTα (**1**) denotes the apo-fusion protein composed of ZFZF and MTα, where ZFZF denotes the two-domain ZF. **2** and **3** denote apo-MTα and apo ZFZF, respectively. The metal ions coordination to ZF and MTα domains is shown in the parentheses adjacent to domains. The abbreviations and numberings are as follows: ZF(Co)ZF(Co)-MTα(Co_x) (**4**), ZF(Zn)ZF(Zn)-MTα(Co_x) (**5**), ZF(Zn)ZF(Zn)-MTα(Zn_x) (**6**), ZF(Cd)ZF(Cd)-MTα(Cd_4) (**7**), ZF(Zn)ZF(Zn)-MTα(Cd_4) (**8**), and ZF(Zn)ZF(Zn)-MTα(Au_{11}) (**9**), MTα(Au_{11}) (**10**), and ZF(Zn)ZF(Zn) (**11**). The dsDNAs having one, two, and zero ZF-recognizing regions are abbreviated as **ds1**, **ds2**, and **ds3**, respectively (see Figure 5 for the base sequences). The dxDNA having four ZF-recognizing regions is abbreviated **dx1** (see Figure 13 for the base sequences).

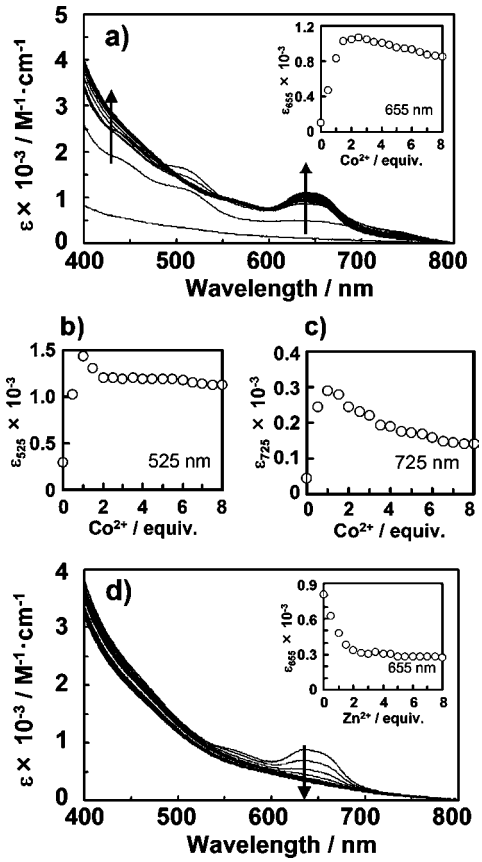

Figure 3. The results of Co^{2+} (2 mM) titration to a solution (10 mM Tris−HCl) containing **1** (50 μM) monitored by UV−vis spectroscopy (a). The titration curves monitored at 655, 525, and 725 nm are shown in the insets of (a), (b), and (c), respectively. The result of Zn^{2+} (2 mM) titration to a solution (10 mM Tris−HCl) containing **4** (50 μM) (d). The inset shows the titration curve monitored at 655 nm.

whereas the intensity of the peak at 655 nm gradually increased. Finally, in the third stage (Co^{2+} > 2 equiv), the intensity of the peak at 655 nm decreased; however, the degree of decrease in the 725 nm peak was larger than that in the 655 nm peak. Among the three absorption peaks, the peak at 725 nm was assigned to the d−d transition arising from $[Co(Cys)_4]^{2-}$ coordination, according to Michael (*25*); on the other hand, the peak at 655 nm was assigned to the d−d transition arising from $Co(Cys)_2(His)_2$ coordination. The feature of the increase in the basal absorption observed at 400−800 nm was similar to that observed in the titration process of Co^{2+} to **2**, which forms a Co_xCys_y cluster (Supporting Information). This means that Co^{2+} is incompletely distributed in either the MTα or ZF domains of **1** at the initial stage of Co^{2+} titration; however, as titration proceeds, it begins to form the cobalt finger with the ZF domain, as well as a $Co_x(Cys)_y$ cluster with the MTα domain (Figure 3a) to form ZF(Co)ZF(Co)-MTα(Co_x) (**4**).

The reverse titration of Zn^{2+} with the solution of **4** was then carried out in the presence of a sufficient amount of Co^{2+} in order to verify the superiority of Zn^{2+} in ZF domain. As expected, the intensity of the peak at 645 nm decreased with an increase in the amount of Zn^{2+}, which means that the Co^{2+} ions trapped in the ZF domain of **4** were substituted with Zn^{2+} as titration proceeded (Figure 3d). The titration curve (inset of Figure 3d) shows that each of the ZFs of **4** bind 1 equiv of Zn^{2+}, which is similar to a wild-type ZF, whereas the Co^{2+} ions trapped in the MTα domain of **4** are not substituted with Zn^{2+}. Consequently, the reverse titration generates ZF(Zn)ZF(Zn)-MTα(Co_x) (**5**) at the final stage.

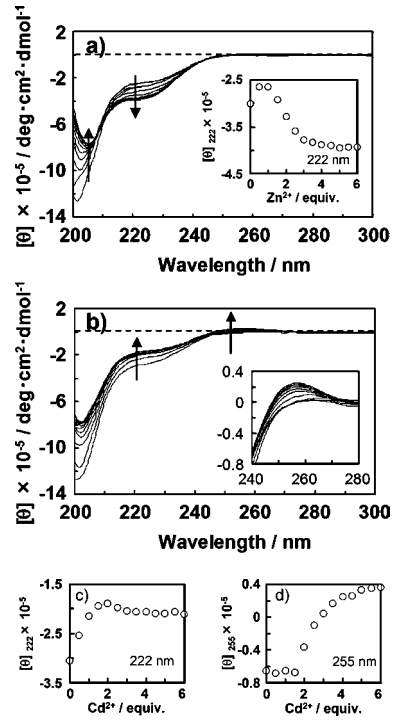

Figure 4. Results of Zn^{2+} and Cd^{2+} titrations for **1** monitored by CD spectroscopy: (a) **1** + Zn^{2+}, the inset shows the titration curve observed at 222 nm; (b) **1** + Cd^{2+}; (c) the titration curve observed at 220 nm; and (d) 255 nm. 500 μM aqueous solutions of Zn^{2+} or Cd^{2+} was added dropwise to 10 mM of Tris-HCl solution containing 12.5 μM of **1**.

The folding nature of **1** was investigated in the presence of Zn^{2+} and Cd^{2+} using CD spectroscopy. As shown in Figure 4, the intensity of the negative CD peak at 205 nm decreased with an increase in the amount of Zn^{2+} added to **1** (Figure 4a), whereas that of the peak at 222 nm increased. The addition of Zn^{2+} caused almost no change at the ligand−metal charge transfer (LMCT) region (~255 nm) of the MTα domain. The spectral change, particularly at 222 nm, was similar to that shown by wild-type ZF upon addition of Zn^{2+} (*26*). In conjunction with the above-mentioned results of reverse titration with Zn^{2+}, this result means that Zn^{2+} preferentially reacts with the ZF domain of **1** so as to fold into $\beta\beta\alpha$ structures; however, Zn^{2+} does not clearly affect the folding of the MTα domain; therefore, ZF(Zn)ZF(Zn)-MTα(Zn_x) (**6**) is finally formed. On the other hand, the addition of Cd^{2+} to **1** weakens the intensities of the negative CD peaks at 210 and 222 nm, whereas it slightly strengthens the intensity of the positive peak at 255 nm (Figure 4b). The feature of the spectral change at 255 nm is similar to that shown by a wild-type MTα upon addition of Cd^{2+} (*27*); however, the peak intensity is about 1/7 of the Cd_4Cys_{11} cluster of the α domain of wild-type MTα. The titration curves observed at 222 and 255 nm indicated that 2 equiv of Cd^{2+} coordinated to the ZF domain at the first stage. Then, it began to coordinate to the MTα domain. From the amount of Cd^{2+} used for the completion of the reaction, the species formed at the final stage was estimated to be ZF(Cd)ZF(Cd)-MTα(Cd_4) (**7**) that contains two Cd^{2+} in the ZF domain and a Cd_4Cys_y cluster in the MTα domain. The reverse titration with Zn^{2+} indicated that two Cd^{2+} ions in the ZF domain of **7** were substituted with Zn^{2+} ions at the final stage to form ZF(Zn)-ZF(Zn)-MTα(Cd_4) (**8**). On the other hand, Cd^{2+} titration into **6** indicated the formation of **8** (Supporting Information). A quantification experiment using 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) revealed that about three of the twelve Cys residues remained free from the coordination to Zn^{2+} and Cd^{2+}. Considering the results, the species obtained in the final stage

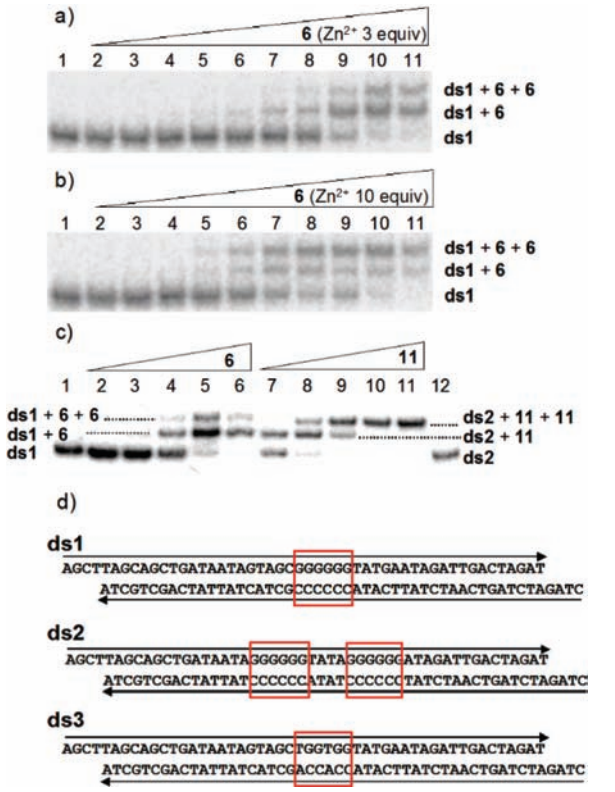

Figure 5. EMSA for **6** (^{32}P labeled DNA was used). (a) **6** (3 equiv of Zn^{2+}) + **ds1**. (b) **6** (10 equiv of Zn^{2+}) + **ds1**. The concentration of **6** increases from left to right in lanes 1−11 (0, 2.9, 5.9, 11.7, 23.4, 46.4, 93.8, 187.5, 375, 750, and 1500 nM). (c) Lanes 2−6, **6** (10 equiv of Zn^{2+}) + **ds1**; lanes 7−11, **11** (10 equiv of Zn^{2+})+ **ds2**. The concentration of **6** or **11** increases from left to right in the lanes. Each loading mixture contained 10 mM Tris-HCl (pH 8), 33.3 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM dithiothreitol, poly-(dI-dC) (10 ng/μL), and ^{32}P-end-labeled DNA fragments (ca. 500 cpm). (d) The base sequences of the DNAs, **ds1**, **ds2**, and **ds3**, used in this study (lower). The ZF-recognizing bp are surrounded by red squares.

comprised a Cd_4Cys_9 cluster in the MTα domain. This is an interesting observation, considering that the α domain of rat's liver MTII and a natural-occurring MT-ZF fusion protein SmtA (*28*) form Cd_4Cys_{11} and $Cd_4Cys_9(His)_2$ clusters, respectively.

Consequently, it can be said that both the ZF and MTα domains of **1** conserve their original metal-coordination and folding natures. The ZF domain favors Zn^{2+}, whereas the MTα domain favors Cd^{2+}; however, they are not independent of each other in the initial stage of the metal ion insertion in spite of their independence in coordination and folding. It was impossible to separate the two species in which either the ZF or MTα domain is metal-free. The nucleophilicities of these two parts for Zn^{2+} and Cd^{2+}seem to be close to each other in the initial stage of metal insertion.

DNA Binding Ability of ZF(Zn)ZF(Zn)-MTα(Zn_x). The DNA binding ability of **6** was determined by an electrophoretic mobility shift assay (EMSA) in the presence of different amounts of Zn^{2+} using **ds1** (Figure 5), which had the ZF-recognizing region G_6. The EMSA results observed in the presence of 3 and 10 equiv of Zn^{2+} are shown in Figure 5a,b, respectively; the figures clearly show the binding of **6** to **ds1**. A control experiment using a DNA, **ds3**, with noncognate 5′-TGGTGG-3′ instead of G_6, clarified that **6** does not bind **ds3**. These figures demonstrate that **ds1** yields two shift bands suggestive of the binding of two proteins of **6**. The intensity ratio of these two shift bands changed with the amount of Zn^{2+}, with an increase in the amount of Zn^{2+} leading to an increase in the relative amount of the higher molecular band. As **ds1** yielded only one shift band for simple Zn-bound **3**, ZF(Zn)-ZF(Zn) (**11**), the appearance of the second band was induced by the formation of Zn_xCys_y cluster in the MTα domain of **6** (see Supporting Information). Considering that the mobility of the second band observed in **6** + **ds1** (Figure 5c, lanes 2−6) almost agreed with that of the second band in **11** + **ds2** (Figure 5c, lanes 7−11), where **ds2** (Figure 2) was a new dsDNA having two G_6 sequences 5′-GGGGGGTATAGGGGGG-3′, the species of the second band in Figure 5a,b was estimated to be a dimer of **6**.

Figure 6. Schematic drawing of the formation of a **6** dimer on **ds1**.

$$2(\text{monomer}) \rightleftarrows \underset{1-\gamma}{\text{dimer}}_{0.5\gamma} \qquad [\text{monomer}] = (1-\gamma)[\text{monomer}]_{tot}, \quad [\text{dimer}] = 0.5\gamma[\text{monomer}]_{tot}$$

$$\text{monomer} + \textbf{ds1} \overset{K_{d1}}{\rightleftarrows} \text{monomer-}\textbf{ds1}$$

$$\text{dimer} + \textbf{ds1} \overset{K_{d2}}{\rightleftarrows} \text{dimer-}\textbf{ds1}$$

$$K_{d1} = \frac{[\text{monomer}][\textbf{ds1}]}{[\text{monomer-}\textbf{ds1}]} \qquad [\text{monomer-}\textbf{ds1}] = \frac{(1-\gamma)[\textbf{ds1}][\text{monomer}]_{tot}}{K_{d1}}$$

$$K_{d2} = \frac{[\text{dimer}][\textbf{ds1}]}{[\text{dimer-}\textbf{ds1}]} \qquad [\text{dimer-}\textbf{ds1}] = \frac{\gamma[\textbf{ds1}][\text{monomer}]_{tot}}{2K_{d2}}$$

Figure 7. Equations for the dimerization of **6**. K_{d1} and K_{d2} denote the dissociation constants of the monomeric and dimeric **6**, respectively, from **ds1**. γ denotes the degree of the association of **6** to a dimeric **6**.

On the other hand, gel permeation chromatography (GPC) and SDS-PAGE experiments carried out under anaerobic conditions (details in Supporting Information) showed that simple **2** increases in size upon the addition of Zn^{2+} or Cd^{2+}. Consequently, dimerization of **6** will be mediated by Zn^{2+} (Figure 6).

Assuming the formation of the **6** dimer mediated by Zn^{2+}, the dissociation constants of the monomer and the dimer, K_{d1} and K_{d2}, respectively, from **ds1** were determined by simulating the results of the EMSA experiments based on the formula shown in Figure 7.

The system gives $K_{d1} = 150$ nM and $K_{d2} = 150$ nM in the presence of 3 equiv of Zn^{2+}, whereas it gives $K_{d1} = 100$ nM and $K_{d2} = 60$ nM in the presence of 10 equiv of Zn^{2+}. These values are larger than that observed for **11** ($K_d = 7.5$ nM). This can be attributed to the steric hindrance between the large-sized MTα domain containing the Zn_xCys_y cluster and dsDNA. On the other hand, the decrease in the second dissociation constant, K_{d2}, in the presence of higher amounts of Zn^{2+} indicates that the second recognition process, which is promoted by Zn^{2+} via dimer formation, may contain nonspecific recognition of the second ZF by dsDNA.

Complexation of ZF(Zn)ZF(Zn)-MTα(Zn_x) with Au11. Next, the complexation of **6** with Au11 was investigated. Experiments were carried out in the presence of 3 equiv of Zn^{2+} to conserve the folding of the ZF domain of **6** referring to the results mentioned above. Figure 8 shows the results of the titration of Au11 into **6** (monitored by CD spectroscopy). The negative peak enhancement observed at 222 nm upon

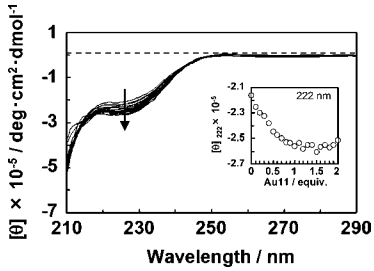

Figure 8. CD spectral change observed for Au11 titration into **6**. The titration curve observed at 222 nm is shown in the inset. A 50 μM MeOH solution of Au11 was added dropwise to 10 mM of Tris-HCl solution containing 12.5 μM of **6** (3 equiv of Zn^{2+}).

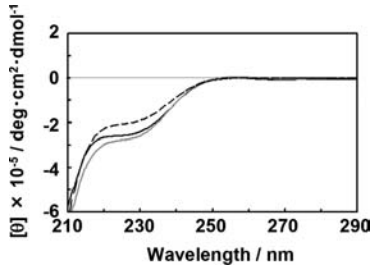

Figure 9. Additivity observed in the CD spectra of **9** systems: the CD spectra of **6** (black dashed line) and **9** (black solid line), and the sum of **6** + Au11 calculated by adding the CD spectra of **10** and **11** (gray solid line).

addition of Au11 is similar to that of our previous results for the complexation between **2** and Au11, MTα(Au_{11}) (**10**) (*20*). The titration curve at 222 nm shows that **6** reacts with an equimolar amount of Au11, which indicates that **6** forms a 1:1 complex with Au11, ZF(Zn)ZF(Zn)-MTα(Au_{11}) (**9**). As will be mentioned later, **9** conserves the number of Au atoms in the process of the reaction with Au11. The CD spectrum of **9** (the black solid line in Figure 9) almost overlaps the sum of the CD spectra of **11** and **10** (the gray solid line in Figure 9). These results indicate that **9** conserves the $\beta\beta\alpha$ folding of the ZF domains of **9** after being coupled with Au11.

Au Core of ZF(Zn)ZF(Zn)-MTα(Au_{11}). We used transmission electron microscopy (TEM) to estimate the number of Au atoms in the Au cluster of **9**. The TEM image is shown in Figure 10a. From the cluster size distribution shown in Figure 10b, we can obtain 0.9 $\pm$ 0.2 nm as the average particle size, which is close to that reported for Au11 (average 0.8 $\pm$ 0.2 nm) (*29*). Furthermore, energy-dispersive X-ray spectroscopy (EDS) measurements on the black regions of this image showed that the regions contained Au, P, S, and Zn (Figure 10c). Therefore, the TEM results strongly indicated that the number of Au atoms in the Au cluster was conserved at 11 under the complexation conditions adopted here. The Au-binding state of **9** was analyzed by X-ray photoelectron spectroscopy (XPS) (Figure 11), which gave peaks attributable to Au 4f at 87.8 ($4f_{5/2}$) and 84.0 ($4f_{7/2}$) eV. These values agreed well with those we previously observed for **10** (87.7 and 84.1 eV) (*20*). In our previous paper, we simulated the XPS spectrum by $Au_{11}(PPh_3)_4(S\text{-}Cys)_6$, based on the quantification results for the amounts of S and P. According to our previous assignment, the results obtained here indicate that **9** contains the Au cluster as $Au_{11}(PPh_3)_4(S\text{-}Cys)_6$ and that six CysSH are free from coordination.

DNA-Binding Ability of ZF(Zn)ZF(Zn)-MTα(Au_{11}). In order to clarify whether or not the ZF domains of **9** had an affinity for **ds1**, EMSA experiments on **9** were carried out in the presence of 3 equiv of Zn^{2+}. As is shown in Figure 12, **9** yielded two shift bands. Considering the molecular weight of the two shift bands, which correspond to those observed for **6**

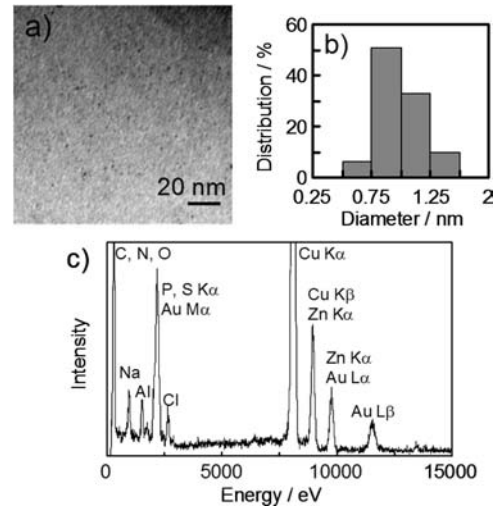

Figure 10. Results of TEM-EDS analyses for **9** (accelerating voltage, 200 kV; bright-field mode; resolution of scale bar, 20 nm). (a) TEM image of **9**. (b) Core size distribution of the Au clusters in **9**. (c) EDS analyses for **9** (the EDS peaks of Cu and Al originate from the Cu grid and sample holder, respectively).

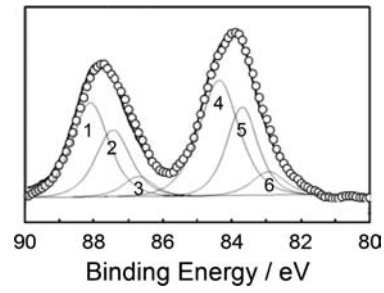

Figure 11. XPS spectrum of **9** observed at the Au 4f region (Mg Kα, $h\nu$ = 1253.6 eV). The observed spectrum is shown by the black circles. The deconvolution results are shown by the gray lines. The resolved spectra are shown by the black lines. The peak numbers 1−6 indicate Au−S $4f_{5/2}$, Au−P $4f_{5/2}$, internal Au $4f_{5/2}$, Au−S $4f_{7/2}$, Au−P $4f_{7/2}$, and internal Au $4f_{7/2}$, respectively.

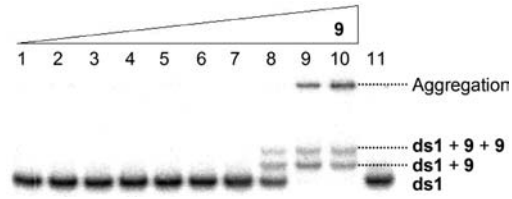

Figure 12. EMSA of **9** + **ds1** (^{32}P labeled DNAs were used). The concentration of **9** was increased from left to right in lanes 1−11 (0, 3.9, 7.8, 15.6, 31.3, 62.5, 125, 250, 500, 1000, and 2000 nM). Each loading mixture contained 10 mM Tris-HCl (pH 8), 33.3 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM dithiothreitol, poly-(dI-dC) (10 ng/μL), and ^{32}P-end-labeled DNA fragments (ca. 500 cpm).

(Figure 5c), as well as the results of the Au11 titration experiment monitored by CD spectroscopy, which showed 1:1 complexation between **6** and Au11, the lower molecular weight band of Figure 12 is assigned to **ds1** + **9**, whereas the higher molecular weight band is assigned to **ds1** + **9** + **9**. The dissociation constants (K_{d1} = 450 nM, K_{d2} = 200 nM) were estimated by simulating the intensity of each band according to the formula in Figure 7. These dissociation constants were 2−3 times higher than those of the cases observed for **9** probably because of an increase in molecular size and rigidity due to the existence of **10**. **9** also specifically recognized the sextet G_6 site

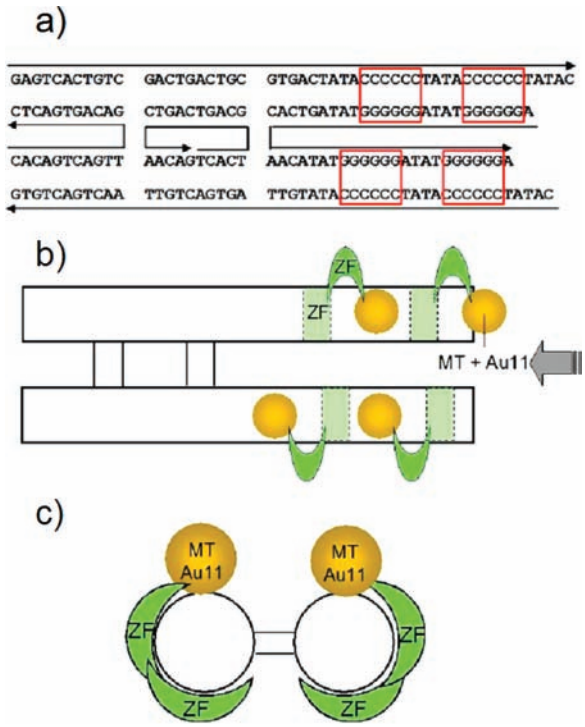

Figure 13. DNA or nucleotide sequence and design of **dx1**. DNA or nucleotide sequence of **dx1** (a). Schematic images of the position of **9** on **dx1** from the (b) top view and (c) side view.

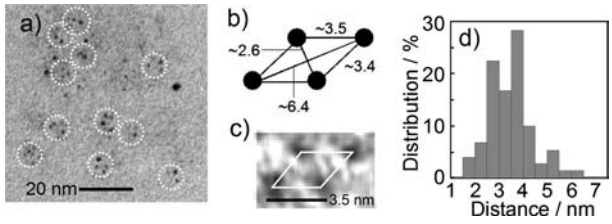

Figure 14. TEM observation of the Au cluster alignment used by **9** + **dx1** (accelerating voltage, 200 kV; bright-field mode; resolution of scale bar, 20 nm). (a) TEM observation of the mixture of **9** and **dx1**. (b) Expected interparticle distances of Au clusters on **dx1**. (c) Expanded TEM image of the typical parallelogram comprising four Au_{11}. (d) The interparticle distance distribution in **9** + **dx1**.

in dsDNA, because it did not bind to **ds3** without this sextet (Supporting Information).

Alignment of Multiple Au_{11} Clusters on dxDNA via ZF(Zn)ZF(Zn)-MTα(Au_{11}). A double-crossover dxDNA, **dx1**, with four G_6 sequences as the ZF-recognizing units, was designed and synthesized according to the dxDNA by Seeman et al. (*30*) and the idealized alignment of **9** on the dxDNA template was estimated using the reported X-ray structure (or cystral structure) of ZF-dsDNA (*31*) (see Figure 13). dxDNA is composed of five ssDNAs, in which two dsDNAs are doubly cross-linked. Because of these cross-linkings, dxDNAs are thought to be more rigid than simple dsDNAs. The four G_6 sequences were aligned to form a parallelogram that crossed over the gap between the two dsDNA of **dx1**. The two recognition sequences in each arm are located ~3.5 nm, namely, 10 bps = one turn, apart from each other, directed virtually toward the plane made of the two dsDNA. At the same time, the sequences on different arms form shorter (~2.6 nm) and longer (~6.4 nm) diagonals (Figure 14b). A TEM image of the mixture of **9** and **dx1** is shown in Figure 14a, in which we observe a 14% four-particle alignment, 35% three-particle alignment, and 51% two-particle alignment. The distances between the nearest-neighbor spots seen in this figure are shown in Figure 14d as a frequency map, which demonstrates the existence of two maxima at ~2.7 and ~3.7 nm. These values agree with those of the designed distances for the recognition sequences mentioned above. A typical parallelogram observed in the expanded TEM image is shown in Figure 14c with the theoretical one. These results show that the fusion protein can align an Au_{11} cluster on **dx1**, as expected.

DISCUSSION

Au clusters show attractive electronic properties, such as Coulomb blockade, which are applicable for nanodevices such as a single electron transistor (*32*, *33*), and quantum cell automata, which originate from the quantum size effect. Au clusters synthesized by chemical processes based on a bottom-up strategy are suitable for large-scale preparation; however, it is difficult to construct Au clusters in the complex patterns desired for nano electronics. Many groups have used DNA as programmable templates for the patterning of Au clusters, in which the complementary recognition of bps is the main strategy for "DNA lithography". They generally sulfurize the termini of ssDNAs to bind Au clusters and introduce the ssDNA conjugates to the other complementary ssDNAs to form dsDNAs. This method may be limited to simple DNAs because ssDNAs cannot hold rigid structures as templates; therefore, it is impossible to design complex DNA architectures. On the other hand, the insertion of an Au-attached ssDNA to a dsDNA, which yields a triplex DNA (*34*), distorts the duplex structures of the target dsDNA and changes the helical phase.

This report proposed a new method that utilizes the sequence information of bps via the interaction between a dsDNA and a DNA-recognizing motif, ZF, to align Au clusters on the desired points of the dsDNA. The ZF method, in principle, can escape the limit of the complementary ssDNA method mentioned above. However, it also has a limit. The DNA recognition depends on the binding constants. The ZF domain adopted in this study is short and requires only a sextet of bps to fix an Au cluster on dsDNA; therefore, the binding constant is small. In practice, the observed ratio of the desired alignment of four Au_{11} particles on the dxDNA (**dx1**) is not high (only 15%). This result may be attributed to three points: (i) the existence of Au_{11}-bound MTα domain increases ~10^2 times the dissociation constants K_ds (from ~nM to ~10^2 nM) as we showed in control experiments using **11**. (ii) In this study, we could not mix an excess amount of **9** with **dx1** to avoid the disappearance of the parallelogram alignment of Au_{11} into the crowd of free **9**. (iii) The four ZF-binding regions in **dx1** may be too close to each other to maintain the stable formation of dsDNA. It should be noted that ZF slightly bends dsDNA (*31*), which weakens the subsequent binding of the second, third, and fourth ZFs. These problems may be solved by optimizing the interaction between DNA and ZF, as well as ZF and MTα.

EXPERIMENTAL PROCEDURES

Materials. Reagents for peptide syntheses, such as Fmoc-protected amino acids, Fmoc-Ala Wang resin, H-Gly-2Cl-Trt resin, dicyclohexylcarbodiimide (DCC), benzotriazole-1-yl-oxy-tris-pyrolidino-phosphonium hexafluorophosphate (PyBOP), hydroxybenzotriazole (HOBt), piperidine, trifluoroacetic acid (TFA), 1,2-ethanedithiol (EDT), triisopropylsilane (TIS), acetic acid (AcOH), trifluoroethanol (TFE), ethyl 3-mercaptopropionate (MPAEt), diisopropylethylamine (DIEA), guanidine hydrochloride, benzyl mercaptan, and thiophenol were purchased from Peptide Institute, Inc., Tokyo Chemical Industry, and Novabiochem. Metal source reagents, such as zinc sulfate heptahydrate, cobalt(II) sulfate heptahydrate, copper(I) iodide, and cadmium chloride were purchased from Kanto Kagaku Reagent Division. Solvents for peptide syntheses and HPLC, such as dichlo-

romethane (DCM), methanol (MeOH), *N*-methyl-2-pyrolidinone (NMP), *N*,*N*-dimethylformamide (DMF), diethyl ether, distilled water, and acetnitrile (MeCN) were purchased from Kanto Kagaku Reagent Division. 5,5′-Dithiobis(2-nitrobenzoic acid) (DTNB) for the quantification of SH groups was purchased from Nacalai tesque. The matrix reagents for matrix-assisted laser desorption ionization−time-of-flight (MALDI-TOF) mass spectrometry measurements, such as α-cyano-4-hydroxy-cinnamic acid (CHCA), were purchased from Aldrich.

Synthesis. 2 (*20*) and **3** were synthesized by the standard solid-phase method. The Fmoc/*t*-Bu chemistry in NMP was adopted using DCC and HOBt as the coupling reagents. H-Gly-2Cl-Trt resin and Fmoc-Ala Wang resin were used for the syntheses of **2** and **3**, respectively. The coupling reactions were carried out with a peptide synthesizer (Applied Biosystems model 433A). DCM and MeOH were used for washing the resins. **3-COSR** was synthesized by the modified method of Futaki et al. (*24*) Namely, ZF(side chain protected)-2Cl-Trt resin was treated with 2% $(Boc)_2O$/NMP for 1 h at room temperature to protect the NH_2 group of the N-terminus; then, it was treated with DCM/AcOH/TFE = 8:1:1 for 2 h at room temperature to remove the Boc-ZF(side chain protected)−OH. The obtained peptide solution was concentrated and reacted with a solution containing 25 equiv of PyBOP, HOBt, and DIEA, as well as 50 equiv of MPAEt, for 24 h at room temperature in an Ar atmosphere to obtain Boc-ZF(side chain protected)-MPAEt (**Boc-3-COSR**). The solution was dried in vacuo, redissolved into DCM, washed with water five times, and dried in vacuo. Finally, the deprotection of **Boc-3-COSR** was carried out with TFA/EDT/H_2O/TIS = 95:5:2.5:2.5 for 4 h at room temperature. The solution was concentrated in vacuo, diluted with diethyl ether, and centrifuged to obtain crude solids. Mass analysis: Calcd for $[\mathbf{2}]^+$, m/z = 3268.2; observed, m/z = 3268.4. Calcd for $[\mathbf{3}]^+$, m/z = 6790.3; observed, m/z = 6790.0. Calcd for $[\mathbf{3\text{-}COSR}]^+$, m/z = 6910.8; observed, m/z = 6910.9.

The fusion peptide **1** was synthesized by the NCL method. This reaction was carried out by mixing **3-COSR** and **2** with a 1:1 molar ratio in a 0.1 M sodium phosphate buffer (pH 8.0) solution containing 6 M guanidine hydrochloride, 4% (v/v) thiophenol, and 4% (v/v) benzyl mercaptan for 24 h at room temperature in Ar atmosphere. After reaction completion, the solution was washed five times with diethyl ether, deionized using a Sep-Pak 3 cm^3 + C18 column, and purified on a reverse-phase HPLC column. The solutions were lyophilized to white powders. Mass analysis: Calcd for $[\mathbf{1}]^+$, m/z = 10046.6; observed, m/z = 10046.6.

Au11 was prepared according to the method by Bartlett et al. (*21*, *35*), and characterized by UV−vis spectroscopy (λ_{max}: 420 nm) and TEM (core size distributions: 0.8 ± 0.2 nm).

dx1 and **dx2** were constructed according to the method of Fu et al. (*30*) from the component ssDNAs (the DNA sequences are shown in the Supporting Information) purchased from Nihon Gene Research Laboratories and used without further purification. Ten micromolar ssDNA solutions, each containing 40 mM of Tris buffer, 20 mM of acetic acid, 2 mM of ethylenediaminetetraacetic acid (EDTA), and 12.5 mM of magnesium acetate, were mixed and set at 95 °C, then annealed to room temperature for over 12 h. The obtained dxDNA solutions were dialyzed by distilled water to remove EDTA, which forms a chelate complex with Zn^{2+}, prior to use for EMSA and TEM measurements.

Analysis and Physicochemical Measurements. A process analysis was carried out with a Shimadzu LC-6AD HPLC system and a Shiseido CAPCELLPAK C18 UG120 (4.6 × 250 mm). Crude peptides were purified on a reverse-phase HPLC column (Senshu Docosil-B C22 column 30 × 50 mm) with MeCN and water as an eluent (gradient containing 0.1% TFA). A Shimadzu LC-10 HPLC system and a Shodex Asahipak GF-310HQ (7.6 × 300 mm) were used for gel permeation chromatography (GPC). UV−vis measurements were performed with a Shimadzu UV-2450 spectrophotometer. Circular dichroism (CD) spectra were recorded on a Jasco J-725 spectrophotometer. The MALDI-TOF mass spectra were recorded on a PerSpective Biosystems Voyager Liner RD VDA-500 system with CHCA as the matrix. All of the samples used in the Ellman test, **1**, **2**, and **3**, were prepared in an N_2 atmosphere in a glovebox (P_{O2} < 0.1 ppm; dew point < −87 °C).

Electrophoretic Mobility Shift Assay. Before EMSA experiments, the unincorporated ^{32}P label and EDTA were carefully removed by gel filtration equilibrated in deionized water, followed by dialysis against water. Each reaction mixture contained 10 mM Tris-HCl (pH 8), 50 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM dithiothreitol, ^{32}P-end-labeled substrate DNA fragments (ca. 500 cpm), and a selected concentration of zinc finger peptides. The experiments were performed in the presence of a competitor DNA, poly(dI-dC) (10 ng/μL). The binding of the ZF and DNAs was completed by incubating at 25 °C for 3 h. Gels were pre-electrophoresed for at least 30 min at a constant voltage. The DNA-bound proteins and free probe were electrophoretically separated on a 15% polyacrylamide gel with 0.5× Tris-Borate running buffer at 230 V. The gels were vacuum-dried and visualized by autoradiography using an FLA-2000 (FUJI FILM). The bands were quantified with the MacBAS (FUJI FILM) software.

Fluorescent-labeled (IRD700) oligo nucleotides were purchased from LI-COR, and used for fluorescent EMSA, which was performed according to the procedures used in ^{32}P-labeled experiments. The gels were visualized by an ODYSSEY infrared imaging system (LI-COR).

ACKNOWLEDGMENT

We gratefully acknowledge Fumiaki Uchiumi and Hidetaka Torigoe for access to ^{32}P-EMSA and IRD EMSA experiments, respectively. This work was supported by Grants-in Aid for Scientific Research 16651051 and 18350034 from the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of the Japanese Government.

1. Co^{2+} titration on MTα monitored by UV-vis spectroscopy.

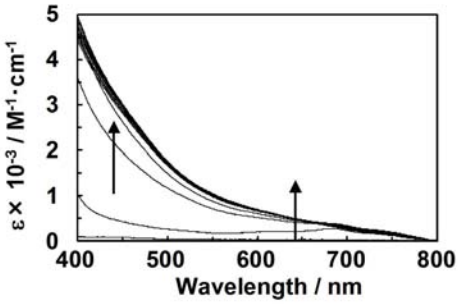

Fig. S1. Results of Co^{2+} titration on **2** monitored by UV-vis spectroscopy. A 2 mM aqueous solution of Co^{2+} was added dropwise to a 10 mM of Tris-HCl solution containing 50 μM of **2**.

As shown here, the spectral change of MTα (**2)** upon Co^{2+} titration is similar to that of ZFZF-MTα (**1)** (manuscript). In the first stage of Co^{2+} titration (0~1 equiv) to **2**, we observe a rapid increase of the absorption in all wavelength regions, suggesting that this absorption originates from the formation of a Co cluster Co_xCys_y in **2**. This result suggests that the increase of the basal absorption observed in the Co^{2+} titration into **1** (manuscript) originates

from the formation of Co_xCys_y at MT domain.

2. Zn^{2+} and Cd^{2+} titrations into holo-ZFZF-MTα monitored by CD spectroscopy

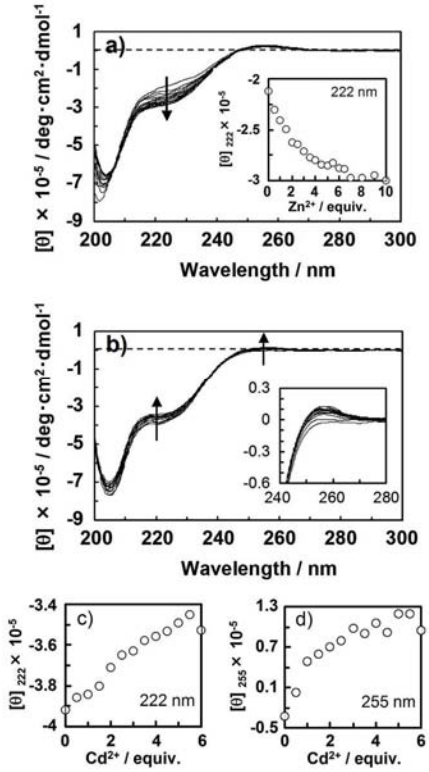

Fig. S2. Results of Zn^{2+} and Cd^{2+} titrations into holo-**1** monitored by CD spectroscopy: (a) **7** + Zn^{2+}, the inset shows the titration curve observed at 222 nm, (b) **6** + Cd^{2+}, (c) and (d) the titration curves observed at 220 nm and (d) 255 nm, respectively. Aqueous solutions containing 500 μM of Zn^{2+} or Cd^{2+} were added dropwise to 10 mM of Tris-HCl solution containing 12.5 μM of holo-**1**.

The negative peak observed at 222 nm in Zn^{2+} titration into ZF(Cd)ZF(Cd)-MTα(Cd_4) (**7**) (Fig. S2a) originates from the ββα folding of the ZF domain. This spectral change is similar to that of Zn^{2+} titration for **1**; however, the titration requires more of Zn^{2+} than the case of simple Zn^{2+} titration into apo protein to finish the spectral change. This is probably because the Cd^{2+} ion already added to the solution prior to Zn^{2+} titration interrupts the insertion of Zn^{2+} to the ZF domain. The positive peak at 255 nm, which is conserved through Zn^{2+} titration, originates from Cd_4Cys_y at the MT domain.

On the other hand, in the case of Cd^{2+} titration into ZF(Zn)ZF(Zn)-MTα(Zn_x) (**7**) (Fig. S2b), the negative peak observed at 222 nm decreases, whereas the positive peak at 255 nm increases.

This spectral change is similar to that of the formation of Cd_xCys_4 at the MT domain of **1** (manuscript). The spectral change is moderate in comparison with that of the apo protein. This difference was also speculated that excess Zn^{2+} already contained before Cd^{2+} titration interrupted the exchange to Cd^{2+} at the MT domain.

3. EMSA of ZF(Zn)ZF(Zn) + ds1

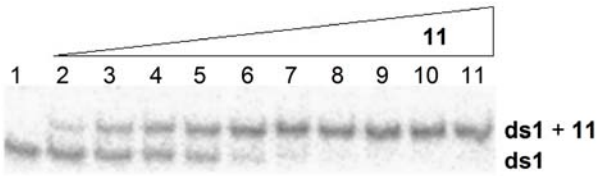

Fig. S3. EMSA of **11** + **ds1** (^{32}P labeled DNA were used). Concentration of **11** increases from left to right (lane 1~11; 0, 1.5, 2.9, 5.9, 11.7, 23.4, 46.4, 93.8, 187.5, 375, 750 nM). Each mixture loaded contains 10 mM Tris-HCl (pH 8), 33.3 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM DTT, poly-(dI-dC) (10 ng/μl), and ^{32}P-end labeled DNA fragment (ca 500 cpm).

As shown here, ZF(Zn)ZF(Zn) (**11**) affords only one shift band originating from DNA-ZF differently from the case of ZF(Zn)ZF(Zn)-MTα(Zn_x) (**6**), which shows the existence of two DNA-ZF spices. Furthermore, the dissociation constant K_d calculated from radioactive intensities of Fig. S3 is estimated to be 7.5 nM, which is 1/10 of the case for **6**.

4. EMSA of ZF(Zn)ZF(Zn)-MTα(Zn_x) + ds3

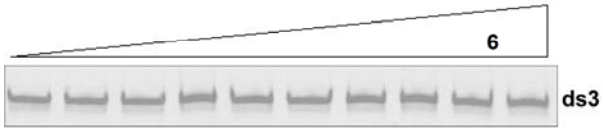

Fig. S4. EMSA of **6** + **ds3** (IRD700 labeled DNA were used). Concentration of **6** increases from left to right (lane 1~11; 0, 2.9, 5.9, 11.7, 23.4, 46.4, 93.8, 187.5, 375, 750, 1500 nM). Each mixture loaded contains 10 mM Tris-HCl (pH 8), 33.3 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM DTT, poly-(dI-dC) (10 ng/μl), and IRD700-end labeled DNA fragment (ca 0.1 μM).

ds3 has 5'-GGGGGG-3' instead of 5'-TGGTGG-3'. As is shown here, **6** do not show affinity to **ds3**. This result shows that **6** does not undergo non-specific binding to DNA.

5. GPC trace and nonreduced SDS-PAGE for MTα.

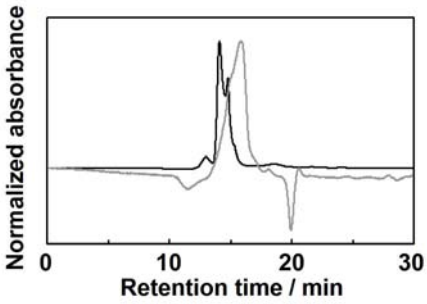

Fig. S5. GPC trace for **2** + Cd^{2+}. 10 μl injections of 100 μM **2**/0.1% TFA/H_2O solution and 100 μM **2** + Cd^{2+}/H_2O solution are shown by gray and black lines, respectively. 50 % MeOH/H_2O was used as the eluent. Flow rate was controlled at 0.5 ml/min. The negative peak at 20 min originates from the solvent at sample injection.

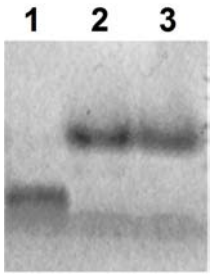

Fig. S6. Nonreduced SDS-PAGE experiments for **2** + Zn^{2+} or Cd^{2+}. Lanes 1, 2, and 3 show the bands for **2**, **2** + Zn^{2+}, and **2** + Cd^{2+}, respectively. Each concentration of **2** was controlled at 80 μM.

This GPC result indicates that the addition of Cd^{2+} to MTα (**2**) induces the increase of molecular size. This is supported by the result of nonreduced SDS-PAGE of **2** (Fig. S6). The addition of Zn^{2+} or Cd^{2+} to **2** causes the band of **2** shift to a higher side. This result suggests that the size of **2** increases with the addition of metal ions. Considering the results of Figs. S5

and 6, those observed in the Fig. 5C of the manuscript suggest that the dimerization of **6** originates from the MT domains through binding of Zn^{2+}.

6. Alignment of multiple Au_{11} clusters on dxDNA via ZF(Zn)ZF(Zn)-MTα(Au_{11}).

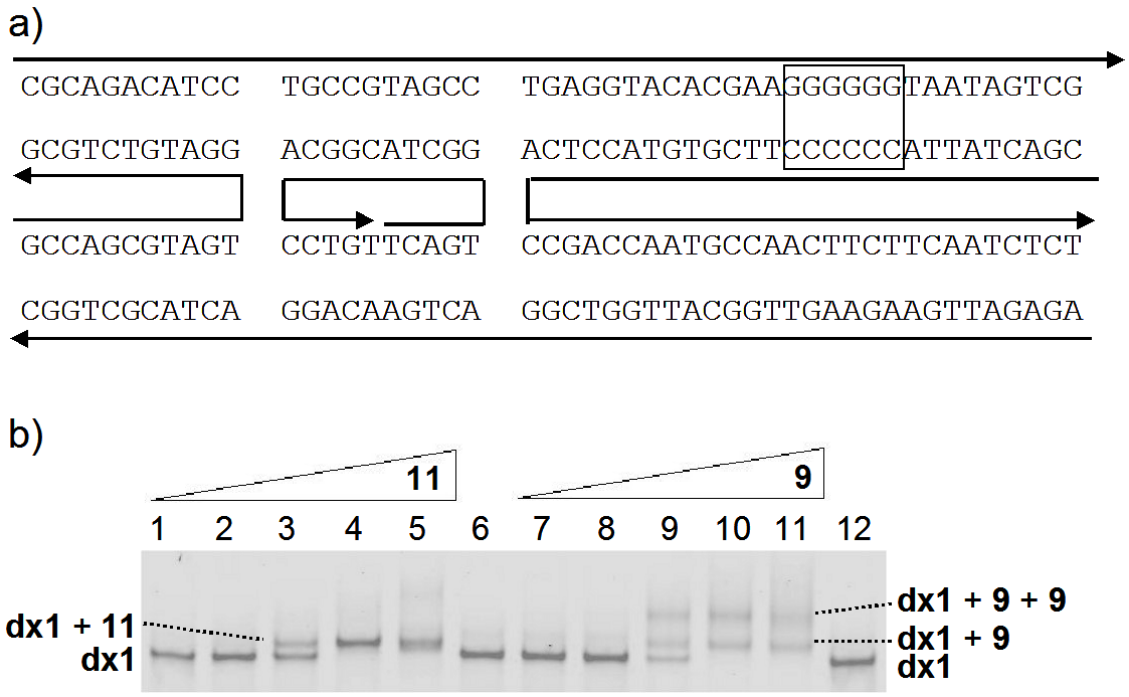

Fig. S7. a) Nucleic-acid base sequences of **dx2**. ZF-recognizing sequence is shown with black square. b) EMSA of **6** + **dx2** (IRD700 labeled DNA were used). lanes 1~5: **11** + **dx2**、lanes 7~11: **9** + **dx2**. Concentrations of **11** and **9** increase from left to right in the lanes. Each loading mixture contains 10 mM Tris-HCl (pH 8), 33.3 mM NaCl, 5% glycerol, 0.005% NP-40, 1 mM DTT, poly-(dI-dC) (10 ng/μl), and ^{32}P-end labeled substrate DNA fragment (ca 500 cpm). IRD700-end labeled substrate DNA fragment (ca 0.1 μM).

As is shown here, both peptides have affinity to dxDNA, although dxDNA is sterically crowded more than dsDNA.

New Strategy for the Extension of the Serum Half-Life of Antibody Fragments

Sabrina Trüssel,[†] Christoph Dumelin,[‡] Katharina Frey,[†] Alessandra Villa,[‡] Fabian Buller,[†] and Dario Neri*[,†]

Department of Chemistry and Applied Biosciences, Institute of Pharmaceutical Sciences, and Philochem AG, ETH Zurich, Wolfgang-Pauli-Str. 10, CH-8093 Zurich, Switzerland. Received June 26, 2009; Revised Manuscript Received September 9, 2009

Antibody fragments can recognize their cognate antigen with high affinity and can be produced at high yields, but generally display rapid blood clearance profiles. For pharmaceutical applications, the serum half-life of antibody fragments is often extended by chemical modification with polymers or by genetic fusion to albumin or albumin-binding polypeptides. Here, we report that the site-specific chemical modification of a C-terminal cysteine residue in scFv antibody fragments with a small organic molecule capable of high-affinity binding to serum albumin substantially extends serum half-life in rodents. The strategy was implemented using the antibody fragment F8, specific to the alternatively spliced EDA domain of fibronectin, a tumor-associated antigen. The unmodified and chemically modified scFv-F8 antibody fragments were studied by biodistribution analysis in tumor-bearing mice, exhibiting a dramatic increase in tumor uptake for the albumin-binding antibody derivative. The data presented in this paper indicate that the chemical modification of the antibody fragment with the 2-(3-maleimidopropanamido)-6-(4-(4-iodophenyl)butanamido)hexanoate albumin-binding moiety may represent a general strategy for the extension of the serum half-life of antibody fragments and for the improvement of their *in vivo* targeting performance.

INTRODUCTION

Monoclonal antibodies represent the fastest growing class of pharmaceutical biotechnology (*1*). While intact IgG immunoglobulins often represent the format of choice for pharmaceutical applications, antibody derivatives (*2, 3*), antibody fragments (*4*), and globular protein mutants capable of specific binding to cognate antigens (*5*−*7*) are increasingly being considered for the implementation of diagnostic and therapeutic biomedical strategies, in view of their potency and of considerations related to the manufacturing process.

Antibody fragments and small globular proteins are typically cleared very rapidly from circulation via the renal route shortly after intravenous administration (*8*−*12*). While short serum half-life values may be desirable for certain pharmaceutical applications (e.g., radionuclide-based imaging, clearance of toxic drugs, transient interference with the function of a target protein *in vivo*), in many cases a long circulation time in the blood is desirable in order to ensure antibody function *in vivo* over an extended period of time and reduce the number of administrations. For this reason, a number of strategies for the extension of serum half-lives of antibody fragments have been considered and implemented at the clinical or preclinical level. They include antibody modification with polymers (such as PEG[1] or polysialic acid) (*13*−*16*), as well as fusion of the antibody molecule with albumin (*17, 18*) or with albumin-binding polypeptides (*19*−*21*). Interestingly, a recent comparative analysis of the tumor targeting properties of the monoclonal antibody Herceptin has revealed that a variant of the antibody Fab fragment format fused to an albumin-binding peptide yielded a more homogeneous *in vivo* targeting of tumor cells, compared to the unmodified Fab or IgG format (*22*).

We have recently described a novel, general approach for the extension of serum half-lives of small organic molecules, based on their chemical modification with a portable 6-(4-(4-iodophenyl)butanamido)hexanoate moiety, which mediates a stable noncovalent interaction with serum albumin in mouse, monkey, and man. The K_d values for the interaction between Albu-fluorescein and human serum albumin were 108 nM range at 25 °C and 330 nM range at 37 °C, respectively (*23*). In that study, we could show that the serum half-life of two commonly used contrast agents for biomedical imaging (fluorescein and gadolinium-DTPA) could be dramatically extended by chemical modification with the portable albumin-binding moiety. In principle, a similar strategy could be considered for the improvement of pharmacokinetic properties of globular proteins, including recombinant antibody fragments.

In this paper, we describe the experimental implementation of a site-specific modification of recombinant antibodies with 2-(3-maleimidopropanamido)-6-(4-(4-iodophenyl)butanamido) hexanoate ("Albu" tag), with the aim of prolonging circulatory half-lives and improving pharmaceutical properties. We used for these studies the F8 antibody, which binds with high affinity and specificity to the alternatively spliced EDA domain of fibronectin, a marker of tumor angiogenesis (*3, 24*−*27*). The F8 antibody was originally isolated from a human antibody library and was shown to efficiently localize to the tumor neovasculature *in vivo* following intravenous administration. At the beginning of this study, F8 was available in recombinant scFv (*28*), SIP (*27, 29, 30*), and IgG format and had been shown to stain a variety of different tumors in mouse, while being negative in most mouse and rodent tissues, with an exception

made for the endometrium in the proliferative phase and some vessels in the ovaries (*26, 27*).

ScFv-F8 was cloned and expressed in mammalian cells in scFv format with a C-terminal cysteine residue and with either a 14-aa linker between VH and VL (leading to the formation of both monomer and noncovalent homodimer) or with a 5-aa linker (driving the preferential formation of a diabody structure) (*27, 31, 32*). ScFv-F8-Cys with the 5-aa linker and carrying a site-specific chemical modification with the Albu tag exhibited the best *in vivo* tumor targeting profiles, with percent injected doses per gram of tissue (%ID/g) in the tumor of >20% at 24 h, which persisted for several days. The data presented in this paper indicate that the chemical modification of the antibody fragments with albumin-binding moieties may represent a general strategy for the extension of the serum half-life of antibody fragments and for the improvement of their *in vivo* targeting performance.

EXPERIMENTAL PROCEDURES

All chemicals were purchased from Sigma-Aldrich unless specified.

Synthesis of the Albu Tag. To a solution of 10 μmol of 4-(-*p*-iodophenyl)butanoic acid in 50 μL of dimethyl sulfoxide (DMSO), 8 μmol of *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC-HCl) and 10 μmol of *N*-hydroxysuccinimide (NHS) were added and the reaction mixture was stirred for 3 h at 30 °C. After addition of 20 μmol of Fmoc-Lys−OH-HCl (Bachem) and 43 μmol of triethylamine (TEA) in 100 μL of DMSO, the reaction was stirred overnight at 30 °C. Removal of the Fmoc-protection group was performed by addition of 30 μL of 5 M KOH and stirring for 2 h at 30 °C. The reaction was purified by HPLC (Waters 2795 Alliance HT with 2487 dual-wavelength absorbance detector, Waters XTerra Prep RP_{18} column (5 μM, 10 × 150 mm), buffers 0.1% trifluoroacetic acid and acetonitrile), the desired fractions with the obtained intermediate 6-(4-(4-iodophenyl)butanamido)hexanoate were collected and solvents and buffer were removed under vacuum. The synthesis of the maleimide derivative was performed as follows: 27 μmol of maleimidopropionic acid, 30 μmol of EDC-HCl, and 30 μmol of NHS in 600 μL of dry DMF were stirred for 3 h at 30 °C. The reaction mixture was added to 32 μmol of the previously obtained 6-(4-(4-iodophenyl)butanamido)hexanoate dissolved in 650 μL of 200 mM phosphate buffer, pH 7. After stirring for 2 h at room temperature and quenching of excess reagents by addition of HCl, HPLC purification was performed. The resulting product 2-(3-maleimidopropanamido)-6-(4-(4-iodophenyl)butanamido)hexanoate ("Albu" tag) was collected and dried under vacuum.

6-(4-(4-Iodophenyl)butanamido)hexanoate. ESI-MS (*m*/*z*): 418.9 [M + H^+], calcd.: 418.1. ^{1}H NMR (D_2O, TFA): 7.31 (d, 8.1 Hz, 2H), 6.66 (d, 8.3 Hz, 2H), 3.88 (t, 6.4 Hz, 1H), 2.93 (t, 6.5 Hz, 2H), 2.27 (t, 7.6 Hz, 2H), 1.97 (t, 7.4 Hz, 2H), 1.86−1.68 (m, 2H), 1.65−1.54 (m, 2H), 1.36−1.18 (m, 4H). 2-(3-maleimidopropanamido)-6-(4-(4-iodophenyl)butanamido) hexanoate. ESI-MS (*m*/*z*): 569.8 [M + H^+], calcd.: 569.1.

Affinity Resins of HSA and 11A12. Human serum albumin (HSA) and the antigen 11A12, a recombinant preparation of an EDA-containing human fibronectin fragment (*27*), were conjugated to sepharose beads as follows: 300 mg of CNBr-sepharose (GE-Healthcare) beads were resuspended in cold 1 mM HCl resulting in 1 mL resin after swelling. The resin was washed several times with cold 1 mM HCl (200 mL/g resin) and 100 mM $NaHCO_3$, 500 mM NaCl, pH 8.2 (coupling buffer, 20 mL/g resin), followed by addition of HSA (5−10 mg/mL resin) or 11A12 (5 mg/mL resin), respectively, dissolved in coupling buffer. After incubation overnight at 4 °C, the resin was washed again several times with coupling buffer (5 column volumes) and excessive reactive groups on the beads were quenched by addition of 100 mM Tris/HCl, pH 8.9. After blocking for 2 h at room temperature, the beads were washed repeatedly with alternating buffers (100 mM HOAc/NaAc, 500 mM NaCl, pH 4, and 100 mM Tris/HCl, 500 mM NaCl, pH 8). The resin was washed with PBS, redissolved in PBS containing 0.1% sodium azide, and stored at 4 °C.

Cloning, Expression, and Purification of scFv-F8 with a C-Terminal Cysteine Residue. ScFv-F8(14aa) as well as scFv-F8(5aa) were amplified and the residues Gly-Gly-Cys introduced at the C-terminal using the primers (5′-CCAAGCTTGTCGAC-CATGGGCTGGAGC-3′ and 5′-GGCCAAGGGACCAAGGTG-G A A A T C A A A G G C G G A T G T T A A T G A G C G G C-CGCAAAAGGAAAA-3′). After digestion with the restriction enzymes *Hind*III and *Not*I and Ligation into a *Hind*III/*Not*I double-digested vector pcDNA3.1, the ligation product was electroporated into electrocompetent *E. coli* TG1, sequenced, and used for transfection of CHO-S cells (Gibco/Invitrogen, Basel, Switzerland) with Amaxa Nucleofactor (Lonza, Vervier, Belgium) following the manufacturer's protocol. The transfected cells were grown in RPMI media supplemented with 10% FBS (fetal bovine serum) and selected using 500 μg/mL of Geneticin (G418, Calbiochem, San Diego, CA, USA). After cell-sorting by FACS (BD FACSAria, Becton Dickinson, Basel, Switzerland; equipped with FACSDiva Software) (*33*), monoclonals were grown in RPMI supplemented with 10% FBS. The best expressing monoclonal culture was determined by ELISA, brought into suspension, and cultured in PowerCHO-2 CD (Lonza, Vervier, Belgium) supplemented with 8 mM glutamine and HT supplement (Gibco/Invitrogen, Basel, Switzerland). The recombinant scFv were purified from supernatant using 11A12-affinity resin. After elution with 100 mM glycine, pH 3, the purified scFv were dialyzed against PBS overnight at 4 °C and characterized by SDS-PAGE, size-exclusion chromatography using a Superdex 75 HR 10/30 column (GE Healthcare), surface plasmon resonance (BIAcore 3000 system, GE Healthcare) studies, and LC-ESI-MS measurements. LC-ESI-MS: scFv-F8(5aa)-Cys (deconvoluted) m 25006, calcd. 25004; scFv-F8(14aa)-Cys (deconvoluted) m 25549, calcd. 25548 (Supporting Information Figure 1).

Conjugation of the Albu Tag to the scFv. The conjugation was performed by reducing 500 μL of 18 μM of scFv-F8-Cys with 1 mM final concentration of Tris(2-carboxyethyl)phosphine hydrochloride (TCEP-HCl, Thermo Scientific) for 20 min at room temperature followed by addition of 100-fold molar excess of the Albu tag. The reaction was stirred overnight at 4 °C, and the turnover of the conjugation was confirmed by LC-ESI-MS. The purification was performed as follows: the reaction mixture was loaded on an 11A12-affinity resin and incubated for 30 min at room temperature. The resin was then washed with PBS (10× the column volume), the bound antibody conjugate eluted with 100 mM glycine, pH 3, and dialyzed twice 2 h against PBS at 4 °C. In order to completely remove eventually nonconjugated antibody and confirm the ability of the antibody conjugate to bind to HSA, the purification was repeated on an HSA-affinity resin. Each step of the purifications was monitored by SDS-PAGE, and the final antibody conjugate was characterized by LC-ESI-MS, SDS-PAGE, and size exclusion chromatography using a Superdex 75 HR 10/30 column (Amersham Biosciences). The binding of the antibody−conjugate to the antigen 11A12 was confirmed by ELISA and surface plasmon resonance (BIAcore 3000 system, GE Healthcare) studies using a low-density coated chip. LC-ESI-MS scFv-F8(5aa)-Albu (deconvoluted) m 25574.0, calcd. 25574.2; scFv-F8(14aa)-Albu (deconvoluted) m 26122.0, calcd. 26117.7.

Analysis by Mass Spectrometry. Low molecular weight compounds: all molecules synthesized were characterized by

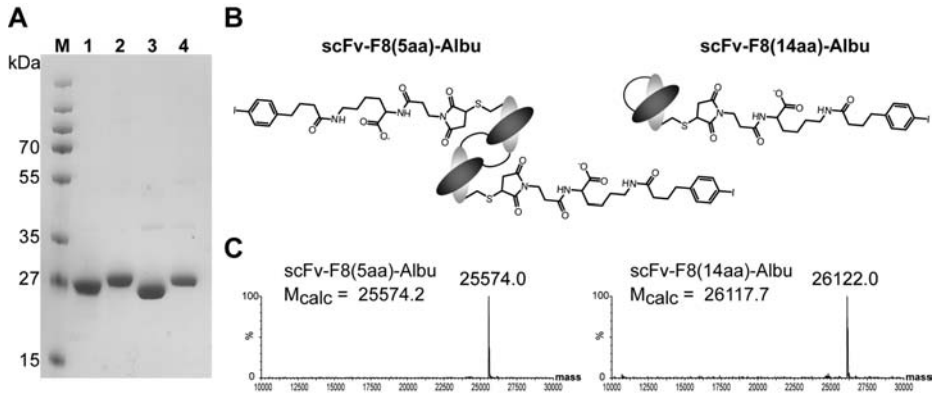

Figure 1. (A) Nonreducing SDS-PAGE analysis documenting the conjugation of the antibodies to the Albu tag. M: molecular weight marker. Lane 1, reduced scFv-F8(5aa)-Cys; lane 2, reduced scFv-F8(14aa)-Cys; lane 3, purified scFv-F8(5aa)-Albu; lane 4, purified scFv-F8(14aa)-Albu (B) schematic representation of the antibody formats scFv-F8(5aa)-Albu and scFv-F8(14aa)-Albu (C) LC-ESI-MS characterization of the antibody conjugates scFv-F8(5aa)-Albu and scFv-F8(14aa)-Albu after deconvolution of the spectra.

mass spectrometry on a Micromass Quattro API instrument. The antibodies and antibody conjugates were analyzed by LC-ESI-MS on a Micromass Quattro API instrument using a XBridge BEH300 C_4 column (3.5 μM, 2.1× 50 mm) running a gradient from 20% to 80% acetronitrile in 0.1% formic acid.

The digestion and MALDI-TOF/TOF analysis were performed as follows: both scFv-F8-Albu conjugates as well as the nonmodified scFv-F8-Cys were diluted to a concentration of ~140 nM in 500 μL of digestion buffer (50 mM Tris/HCl, 1 mM $CaCl_2$, pH 8), followed by addition of 8 nmol of sequencing grade modified trypsin (Promega, Madison, WI, USA). After digestion overnight at 37 °C in a thermomixer (Eppendorf, Hamburg, Germany) at 1000 rpm, purification and concentration of the tryptic peptides were performed using C_{18} microcolumns (Omix Pipette Tips C18, Varian, Lake Forest, CA, USA) according to the manufacturer's protocol with elution in 90% acetonitrile, 0.1% TFA. MALDI-TOF-TOF mass spectrometric analyses were carried out with a 4800 Proteomics Analyzer (Applied Biosystems, Foster City, CA, USA). Spectra were processed and analyzed by the Global Protein Server Workstation (Applied Biosystems).

Cell Line and Tumor Mouse Model. The tumor cell line used was F9 murine teratocarcinoma (CRL-1720, ATCC). The cell line was maintained in DMEM, supplemented with 10% fetal bovine serum (FBS) and antibiotic−antimycotic solution in flasks coated with 0.1% gelatin. F9 tumor-bearing mice were obtained by s.c. injection of 3×10^7 million F9 murine teratocarcinoma cells into the left flank of 10- to 12-week-old female 129SvPas mice (Charles Rivers Laboratories, Sulzfeld, Germany). For biodistribution, F9-tumors were allowed to grow for 8−10 days to a size of typically 100−200 mm^3.

Biodistribution Experiments. The *in vivo* targeting performances of scFv-F8-Cys and the corresponding conjugates scFv-F8-Albu were evaluated by quantitative biodistribution analysis as previously described (*34*). Briefly, purified antibody and antibody conjugate preparation were radiolabeled using ^{125}I and Chloramine T solution (0.25 μg Chloramine T per 1 μg protein) followed by purification on a PD-10 column (GE Healthcare) and injected into the tail vein of immunocompetent 129SvPas mice bearing s.c. implanted F9 murine teratocarcinoma (~30 μg per mouse). Mice were sacrificed 3, 24, 48, and 72 h after injection (4−5 mice per group). Organs were weighed and radioactivity was counted with a PackardCobra γ counter. Radioactivity content of representative organs was expressed as the percentage of the injected dose per gram of tissue (%ID/g). The immunoreactivity of the radiolabeled antibodies and antibody conjugates was confirmed by radioimmunoassay (*34*), using 11A12 as antigen and measuring the bound radioactivity. Further the binding capacity of the radiolabeled antibody conjugates toward HSA was also confirmed on a HSA-affinity resin. Prior to the radiolabeling, the monomeric fraction of scFv-F8(14aa)-Cys as well as scFv-F8(14aa)-Albu was separated and collected using size-exclusion chromatography (Superdex 75 HR 10/30 column, GE Healthcare).

Microautoradiography. Mice were sacrificed 24 h after the i.v. injection of radiolabeled scFv-F8(5aa)-Albu and tumors and organs were embedded and frozen in OCT medium (MICROM). Sections of 10 μm were cut, fixed with 4% *p*-formaldehyde in PBS, followed by washing with PBS and deionized water, and dried. The sections were then coated with NBT KODAK autoradiography emulsion, dried, and stored at 4 °C in the dark for ~9 weeks. The autoradiography emulsions were developed (Kodak Developer D-19) for 4 min and fixed (Kodak Eastman Fixer) for 5 min. Finally, slides were rinsed with deionized water and counterstained with hematoxylin (Sigma).

BIAcore Studies. BIAcore sensograms were recorded on a BIAcore 3000 instrument (GE Healthcare) using CM5 microsensor chips coated with recombinant 11A12 fibronectin fragment, as previously described (*27*).

RESULTS

Design, Production, and Characterization of Albumin-Binding Antibody Derivatives. ScFv-F8-Cys was cloned and expressed in CHO cells, appending the Gly-Gly-Cys tag (GGC) at the C-terminus of the molecule (*35*) and omitting any peptidic tag for immunodetection (see also Experimental Procedures). Two different variants of the scFv-F8-Cys antibody were used: one with a 14-aa linker (GGGGSGGGGSGGGG) and one with a 5-aa linker (GSGGS) between VH and VL domains. Both antibody fragments could be produced with high yields (25−30 mg/L in roller bottles) in nonoptimized conditions and purified to homogeneity by affinity chromatography (Figure 1A). As expected, the antibody with the 5aa linker yielded a stable noncovalent homodimer when analyzed by gel filtration (data not shown) corresponding to a diabody structure (Figure 1B) (*27*, *31*, *32*). By contrast, the antibody fragment with the 14aa linker yielded a mixture of monomer and noncovalent homodimer, from which the monomeric fraction could be quantitatively recovered by preparative gel filtration (Figure 1B). Both antibody preparations could be chemically modified with the Albu tag, yielding the corresponding albumin-binding antibody derivatives (scFv-F8(5aa)-Albu and scFv-F8(14aa)-Albu; Figure 1B), which displayed the expected theoretical mass in LC-ESI-MS analysis (Figure 1C). Maldi-TOF/TOF analysis after tryptic digestion confirmed the site-specific chemical

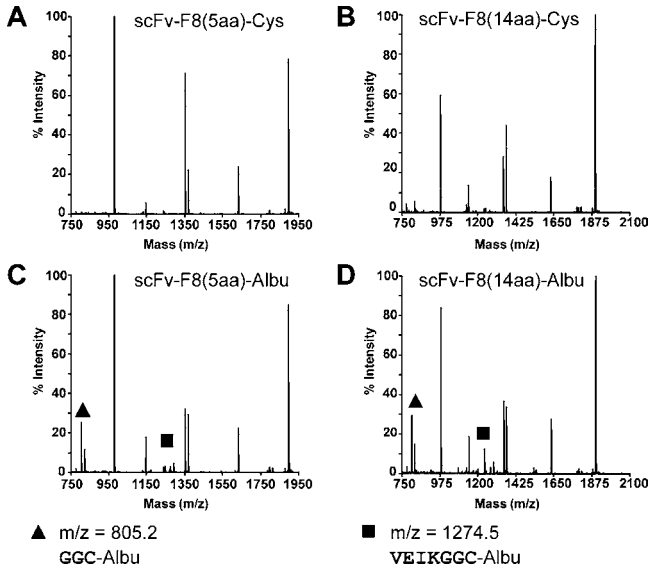

Figure 2. Mass spectra of tryptic peptides of (A,B) scFv-F8-Cys and (C,D) modified scFv-F8-Albu. (C,D) The spectra of the modified scFv-F8-Albu show two peaks not present in the nonmodified scFv-F8-Cys with the *m*/*z* of 805.2 (▲) corresponding to the modified peptide GGC-Albu and with the *m*/*z* of 1274.5 (■) corresponding to the larger modified peptide VEIKGGC-Albu of the C-terminus.

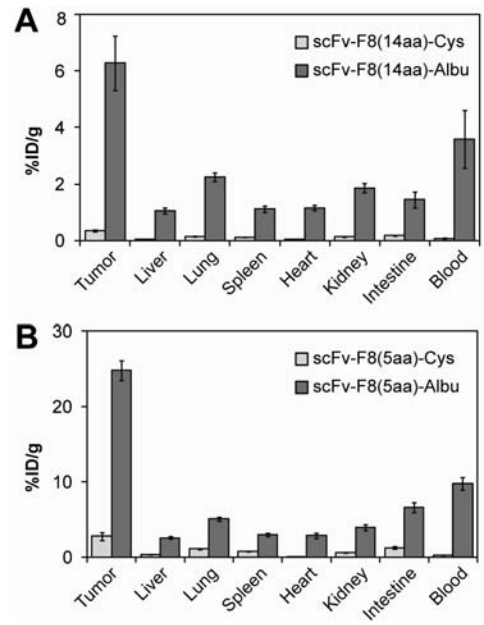

Figure 3. Biodistribution studies of radioiodinated scFv-F8-Cys antibodies and scFv-F8-Albu antibody derivatives 24 h after i.v. injection into F9 tumor bearing 129SvPas mice. Mean targeting results are expressed as %ID/g ± standard error (A) scFv-F8(14aa)-Cys and scFv-F8(14aa)-Albu (B) scFv-F8(5aa)-Cys and scFv-F8(5aa)-Albu.

modification of the antibody derivatives (Figure 2). In the spectra of the chemically modified albumin-binding antibody derivatives (scFv-F8(5aa)-Albu and scFv-F8(14aa)-Albu), two newly emerging peaks were identified, which corresponded to the C-terminal peptides modified with the Albu tag (Figure 2C,D). As expected, scFv-F8-Cys preparations displayed identical performance in BIAcore analysis in the presence or in the absence of chemical modification with the Albu tag (Supporting Information Figure 2).

Tumor Targeting Properties of Albumin-Binding Antibody Derivatives. The tumor targeting properties of scFv-F8(5aa)-Albu and scFv-F8(14aa)-Albu were investigated by quantitative biodistribution analysis in mice bearing F9 tumors, following antibody radioiodination, using conventional organ counting (*9, 27, 30, 34*). After radioiodination, full retention of immunoreactivity and of albumin-binding activity for the conjugates was confirmed by affinity chromatography (see Experimental Procedures). In a first *in vivo* experiment, biodistribution results (expressed as percent injected dose per gram of tissue; %ID/g) for scFv-F8(14aa) and scFv-F8(5aa) were studied 24 h post injection, in the presence or the absence of the Albu tag (Figure 3). In line with previous reports for scFv fragments devoid of a C-terminal cysteine residue, the homodimeric scFv-F8(5aa)-Cys antibody displayed a greater tumor uptake (2.8%ID/g) compared to the monomeric scFv-F8(14aa)-Cys antibody (0.4%ID/g). In both cases, the antibody exhibited a preferential accumulation at the tumor site (Figure 3). As expected, the chemical modification of the recombinant antibodies with the albumin-binding moiety resulted in a dramatic increase of antibody uptake at the tumor site (6.3% ID/g for scFv-F8(14aa)-Albu, and 24.8%ID/g for scFv-F8(5aa)-Albu), as a result of a slower blood clearance profile (3.6% ID/g for scFv-F8(14aa)-Albu, and 9.8%ID/g for scFv-F8(5aa)-Albu).

In order to study in more detail the pharmacokinetic properties of the antibody derivative which displayed the highest tumor uptake (scFv-F8(5aa)-Albu), we performed a new series of biodistribution studies in F9 tumor bearing mice, sacrificing the animals at 3, 24, 48, and 72 h. Figure 4 presents the biodistribution results, expressed as %ID/g and as tumor/organ ratios. In Figure 4A,B, the uncorrected data are presented, while in Figure 4C,D, a correction for the increase of tumor mass during the experimental protocol was applied. Indeed, F9 tumors have a doubling time of approximately 1−2 days (*34*), with the result that the antibody dose in the tumor mass gets "diluted" while the neoplastic mass increases in size. The maximal antibody uptake in the tumor was observed at 48 h (25%ID/g and 64%ID/g in the absence or presence of the correction for tumor growth, respectively; Figure 4A,C), but in general, we observed an excellent antibody retention at the tumor site, in line with previous preclinical and clinical studies obtained with antibodies specific to the extradomain B (EDB) of fibronectin (*30, 36−39*). From the data of Figure 4A, blood clearance can be fitted with a single exponential, corresponding to a half-life of 1000 min. By contrast, unmodified scFv fragments typically exhibit a monoexponential clearance profile, with half-lives of approximately 20−30 min (*30, 34*). As a consequence of antibody clearance from blood and tissues, tumor/organ ratios were found to continuously increase through the whole duration of the biodistribution experiment (Figure 4B,D). As expected, the radiolabeled antibody was found to preferentially localize at tumor neovascular sites (*27*), as evidenced by *ex vivo* microautoradiographic analysis (Figure 5).

DISCUSSION

In this article, we have shown that the site-specific modification of the tumor-targeting recombinant antibody F8 with a small organic chemical moiety, conferring high-affinity binding to albumin, resulted in an ∼10-fold increase in antibody tumor uptake and in an ∼35-fold reduction of blood clearance rate. When correcting for tumor growth during the biodistribution studies, tumor uptake values >60% ID/g could be observed at optimal time points (48 h), with excellent tumor/organ ratios (Figure 3).

The observation that antibody uptake in the tumor grows as a consequence of a corresponding increase of serum half-life is in line with the results of previous biodistribution studies, in which the targeting properties of antibodies in different formats (e.g., scFv, mini-antibody, IgG) were compared (*30, 37, 38, 40, 41*). Similarly, chemical modification of antibody fragments with PEG or polysialic acid polymers has previously been shown to

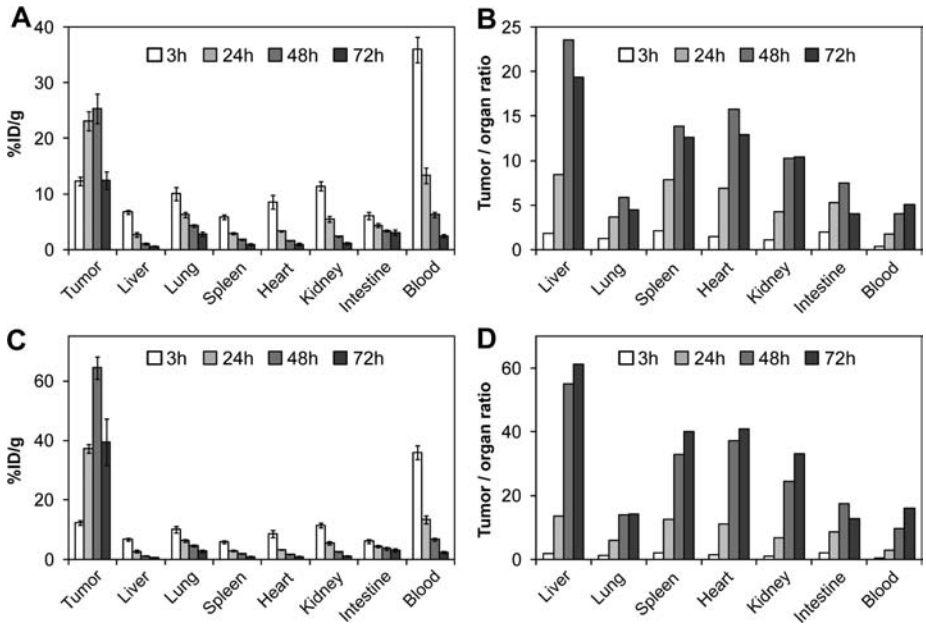

Figure 4. Biodistribution studies of radioiodinated scFv-F8(5aa)-Albu 3, 24, 48, and 72 h after i.v. injection into F9 tumor bearing 129SvPas mice. Results are depicted as follows: (A) %ID/g of all four time points and (B) the tumor to organ ratio. In addition, panels (C) and (D) present biodistribution data results corrected for the tumor volume increase, during the time period between injection and sacrifice of the mice.

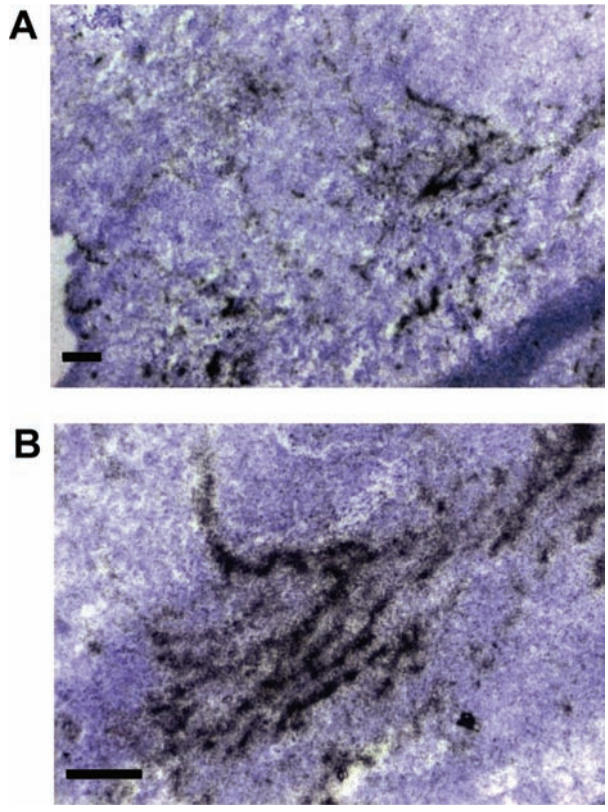

Figure 5. Microautoradiography of a 10-μm-thick F9 tumor section, obtained 24 h after i.v. injection of ^{125}I-scFv-F8(5aa)-Albu. (A,B) Scale bar = 100 μm.

considerably extend serum half-lives and tumor uptake values (*13*−*15*). However, Albu-tagging technology as described in this article may have the potential advantage of yielding a single molecular species in mass spectrometric analysis (Figure 1), thus facilitating batch-to-batch comparison, while polymer-based modification strategies typically exhibit a distribution of molecular weights.

In the past, we had performed C-terminal tagging of scFv fragments with cysteine residues, using *E. coli* and *P. pastoris* expression systems (*35, 42*). In our hands, the CHO-cell based expression strategy described in this article appears to be particularly suited for pharmaceutical development programs, in view of the good expression yields, excellent product homogeneity, and absence of proteolytic degradation of the C-terminal tail. Monomeric and noncovalent homodimeric preparations of scFv-F8 can be quantitatively separated and recovered (*31, 43, 44*) by gel filtration or by ion exchange chromatography, with no detectable subsequent interconversion, if the antibodies are stored at micromolar concentrations (or higher) in physiological solution at neutral pH and room temperature, over a period of several weeks. The site-specific and stoichiometric modification of recombinant antibody fragments described in this article for Albu tags may be adapted in order to accommodate other conjugation strategies (e.g., drugs with cleavable linkers, photosensitizers) (*45*−*48*).

ACKNOWLEDGMENT

Financial support from the ETH Zürich (ETHIRA Grant), the Swiss National Science Foundation (grant # 3100A0-105919/1), the Swiss Cancer League (Robert-Wenner-Award), the SWISSBRIDGE-Stammbach Foundation and European Union Projects IMMUNO-PDT (grant # LSHC-CT-2006-037489), DIANA (grant # LSHB-CT-2006-037681), and ADAMANT (HEALT-F2-2008-201342) is gratefully acknowledged. Furthermore, we would like to thank Dr. Christoph Schliemann and Dr. Christoph Rösli for their technical help.

Impact of Molecular Weight in Four-Branched Star Vectors with Narrow Molecular Weight Distribution on Gene Delivery Efficiency

Yasushi Nemoto,[†,‡,§] Alexey Borovkov,[†,‡] Yue-Min Zhou,[†,||] Yoshiaki Takewa,[||] Eisuke Tatsumi,[||] and Yasuhide Nakayama*[,†,‡]

Received June 29, 2009; Revised Manuscript Received September 20, 2009

A series of star-shaped cationic polymers, termed star vectors (SVs), has been developed as effective nonviral gene delivery carriers. In this study, we separated SVs into several fractions having different molecular weights with very narrow molecular weight distributions in order to examine in detail the influence of the molecular weight of the SVs on the gene transfection efficiency. As a model compound for several types of SVs, 4-branched poly(*N*,*N*-dimethylaminopropyl acrylamide) having a molecular weight (M_n) of approximately 35 kDa and polydispersity of 1.6 was prepared by iniferter-based radical polymerization. The SVs were separated using size-exclusion chromatography to obtain seven fractions having M_n ranging from 27 kDa to 73 kDa with polydispersity ranging from 1.1 to 1.2. All the fractionated SVs have similar pH of 10.2−10.4 and were able to interact with and condense luciferase-encoding plasmid deoxyribonucleic acid (DNA) to yield SV/DNA polyplexes. A water-soluble tetrazolium-1 (WST) assay showed that all SVs had minimal cellular cytotoxicity under an N/P charge ratio of 10. The critical micellar concentration decreased with an increase in the M_n of the fractionated SVs; however, the particle size of the polyplexes, exclusion activity of ethidium bromide, and ζ-potential of the polyplexes increased. An in vitro evaluation using COS-1 cells at an N/P ratio of 10 showed that transfection activity increased almost linearly with M_n. The highest transfection activity was obtained for SVs with the highest M_n (73 kDa), which was over 7 times that for the SVs with the lowest M_n (27 kDa), the nonfractionated original SV, or PEI standard. The transfection efficiency was more correlated with the amphiphilicity or hydrophobicity of the SVs and the surface potential and condensate density of the polyplexes than with the particle size.

INTRODUCTION

Almost all synthetic cationic polymers can spontaneously condense polyanionic deoxyribonucleic acid (DNA) to form electrostatic complexes, termed polyplexes, which is a requirement for gene transfer in most cell lines (*1*−*4*). The gene transfection efficiency of these cationic polymers strongly depends on their structural, chemical, and physical properties. Molecular weight is one of the greatest influences on gene transfection efficiency. This influence has been evaluated by many researchers; it was found that the gene transfection efficiency, in general, was high for cationic polymers having high molecular weight (*5*−*12*). Godbey et al. reported that linear polyethylenimine (PEI) having a molecular weight of 1.8 kDa or less showed no gene transfection activity; however, PEI having a molecular weight higher than 1.8 kDa showed gene transfection activity, which peaked at a molecular weight of 70 kDa (*13*). On the other hand, Park et al. reported that there was no difference between the gene transfection efficiencies of linear PEI having molecular weights of 50 kDa and 200 kDa (*14*). Hennink et al. reported that poly(*N*,*N*-dimethylaminoethyl methacrylate) (PDMAEMA) having a molecular weight of 60 kDa or less did not exhibit gene transfection activity; however, PDMAEMA having a molecular weight of 309 kDa and more exhibited gene transfection activity (*15*). A similar molecular weight dependency was observed in a higher molecular weight region. Recently, the influence of molecular weight on PDMAEMA-mediated DNA delivery was investigated by Long et al. (*16*). Extremely high molecular weight PDMAEMA showed high transfection activity among five molecular weights ranging from 43 to 915 kDa. However, the polymers examined, unfortunately, had very wide molecular weight distribution. In our previous study, 4-branched poly(*N*,*N*-dimethylaminopropyl acrylamide) (PDMAPAAm) had molecular weights of approximately 10, 20, and 50 kDa and polydispersity of approximately 1.4, which were prepared by living radical polymerization (*17*). Although detailed examination was not performed, the luciferase expression increased with the molecular weight.

The objective of our study was to elucidate structure−transfection relationships in polycation-mediated plasmid DNA delivery. To improve the efficiency of gene transfection, several types of star-shaped polymers were attempted (*17*−*21*). We recently designed a novel nonviral vector, i.e., a star vector (SV), which is a star-shaped and cation-based polymer (*22*) or its cross-linked complex (*23*). The SVs have been shown to be effective in inducing gene expression from plasmid DNA (pDNA) and gene silencing from siRNA or shRNA in vitro and in vivo (*24*). In addition, in combination with ligands such as C45D18 peptide (*25*), which promotes nuclear trafficking, or an integrin-binding

RGD peptide (*26*), DNA can be selectively delivered to macrophages or endothelial cells.

In this study, we investigated the influence of molecular weight with narrow molecular weight distribution in polycation on the transfection activity. In general, synthetic polymers have a range of molecular weights, even if they are synthesized by living radical polymerization. In other words, these polymers are a mixture of molecules having different molecular weights. Therefore, molecular weight distribution is an important factor for characterizing polymers. Unfortunately, the distribution, including polydispersity, has not been described in most reports in the field of gene delivery. In the evaluation of transfection activity, use of uniform polymers is considered ideal. Therefore, we attempted to separate the SV into seven fractions having different molecular weights with narrow molecular weight distributions in order to examine the effect of molecular weight of the SV in terms of gene transfection efficiency. Previously, we designed a series of branched cationic polymers, linear and 3-, 4-, or 6-branched SVs, prepared to have the same molecular weights of about 18 kDa. The relative gene expression efficiency increased in the degree of branching that may affect the cationic charge density. On the other hand, iniferters for preparation of 6-branched SVs were very hard to treat because of their lower solubility in polymerization solvents. Therefore, as a model compound, in this study, we selected 4-branched SV. Physicochemical properties including pH and the critical micellar concentration of the fractionated SVs, particle size, exclusion efficiency of ethidium bromide, and ζ-potential of SV/DNA polyplexes were measured to determine the reason for the molecular-weight-dependent gene-transfection efficiency change.

EXPERIMENTAL SECTION

Materials. 1,2,4,5-Tetrakis(*N,N*-diethyldithiocarbamylmethyl)benzene (iniferter) was synthesized according to our previously reported method (*17*). DMAPAAm purchased from Tokyo Kasei Co. (Tokyo, Japan) was used after distillation. Other solvents and chemical reagents, all of which were of special reagent grade, were purchased from Kanto Chemical Co. (Tokyo, Japan) or Aldrich (Milwaukee, WI) and were used without further purification. pGL3 control vector (5266 bp, Promega Inc., Tokyo, Japan) encoding luciferase was used as luciferase reporter plasmid DNA; it was amplified in competent *Escherichia coli* (Promega Inc.) cells and purified using Maxiprep according to a protocol of QIAGEN (Tokyo, Japan). ExGen 500 (linear 22 kDa PEI) was obtained from Cosmo Bio Co., Ltd. (Tokyo, Japan).

Synthesis and Fractionation Separation of SV. Iniferter (45.6 mg, 63 mmol) was dissolved in approximately 20 mL of toluene. DMAPAAm (7.88 g, 50.5 mmol) was added to the solution. The total volume of the mixture was increased to 50 mL with toluene. The final concentrations of the iniferter and monomer were 5.0 mM and 1.0 M, respectively. The mixture was poured into a hard-glass cubic cell (40 mm $\times$ 40 mm; glass thickness of 3 mm) and bubbled with N_2 gas (G1 grade, 99.9999% purity or more, Japan Fine Products Co., Kanagawa, Japan) at a flow rate of 2 L/min for 10 min. The solution was irradiated for 30 min with ultraviolet (UV) light (light intensity of 2.5 mW/cm^2) using a 300 W xenon lamp (MAX-301, Asahi Spectra Co., Ltd., Tokyo, Japan). The light intensity was adjusted to 2.5 mW/cm^2 using a photometer (UIT-150 with UVD-405 detector, Ushio, Tokyo). The reaction mixture was concentrated to approximately 10 mL using a rotary evaporator and poured into 1 L of diethyl ether to obtain a polymeric precipitate. The diethyl ether solution supernatant was removed by decantation. Reprecipitation was carried out six times in a chloroform/diethyl ether system. The final precipitate was dried under vacuum and dissolved in an adequate quantity of H_2O. The resultant aqueous solution was filtered with a disposable syringe filter unit having a pore size of 0.22 μm (Mixed Cellulose Ester, Toyo Roshi Ltd., Tokyo, Japan) and freeze−dried for 72 h using a vacuum pump (GCD136X, ULVAC, Tokyo) and freeze−dryer (FUD 2200, EYELA, Tokyo) to yield the SV. The molecular weight of the SV was determined by gel permeation chromatography (GPC) analysis as 35 kDa (polydispersity; 1.6). ^{1}H NMR measurements (300 MHz, in chloroform-d_1) were δ 1.5−1.7, 1.8−2.0, 2.1−2.2, 2.2−2.4, 3.0−3.2, and 7.4−7.8.

The fractionation separation of SVs was performed by GPC (LC-9101, Japan Analytical Industry Co., Ltd. Tokyo, Japan) with a styrene−divinylbenzene gel column (JAIGEL-2H-40, JAIGEL-3H-40, 40 mm $\times$ 600 mm) and chloroform mobile phase with 50 mM triethylamine. The flow rate of the mobile phase was adjusted to 10 mL/min.

General Procedures. UV/visible (VIS) absorption spectra were recorded using a spectrophotometer (U-1800, Hitachi, Tokyo). GPC of *N,N*-dimethylformamide with 30 mM lithium bromide for molecular weight measurements was carried out with a high-performance liquid chromatography system (LC-10Avp, Shimadzu, Kyoto, Japan) and columns (Asahipack GF-710HQ and Asahipack GF-510HQ, Shodex, Tokyo, Japan) that were calibrated for molecular weight with narrow weight distribution poly(ethylene glycol) standards. The mean diameter was determined by static light scattering (SLS) on a Zeta Sizer Nano-ZS system (Sysmex, Kobe, Japan).

Critical Micellar Concentration. The critical micellar concentration of the SV was determined by dye (1,6-diphenyl-1,3,5-hexatriene) solubilization into a water assay. SVs were dissolved into deionized water and adjusted to aqueous solutions having concentrations of 0.08, 0.10, 1.25, 2.50, 5.00, 10.0, 25.0, 50.0, and 100 mg/mL. Ten microliters of the 1,6-diphenyl-1,3,5-hexatriene solution, prepared by dissolving 2.2 mg of 1,6-diphenyl-1,3,5-hexatriene into 25 mL of methanol with sonication in the dark for 10 min, was added to 1 mL of the SV solutions and incubated at room temperature in a dark condition for 6 h. A reference solution mixture was prepared by adding 10 μL of the 1,6-diphenyl-1,3,5-hexatriene solution to 1 mL of deionized water. UV absorption spectra of these solution mixtures were measured at 365 nm using a UV/vis spectrophotometer. The absorption at 365 nm was plotted against the concentration of the SV, and the crossing point of extrapolated straight lines for the low-concentration region and high-concentration region was defined as a critical micellar concentration of the SV.

Preparation of Polyplexes. SVs were dissolved in a saline solution at a concentration of 0.24 μg/μL. 60 μL aliquots of the SV solution were mixed with 90 μL of Tris-HCl buffered saline solution (pH 7.4) containing plasmid DNA (pGL3-control) at a concentration of 3.33×10^{-2} μg/μL at room temperature. The solutions (total volume of 150 μL, plasmid concentration of 20 μg/mL) were mixed using a pipet to obtain polyplexes at a charge (N/P) ratio of 10.

Mean diameters of the polyplexes in a saline solution were obtained by dynamic light scattering (DLS) using an ELS-8000 system (Otsuka Co., Osaka, Japan) equipped with a 10 mW He−Ne laser by cumurant analysis in multimodal. Since data of the diameters were reproducible ($n = 4$, SD < 10%), only the average values have been described.

The ζ-potentials of the polyplexes in water solution were measured by employing a ζ-potential meter in the Zeta Sizer Nano-ZS system (Sysmex) at 25 °C. The concentration was set at 1/10 of the transfection concentration at an N/P ratio of 10.

Ethidium Bromide Exclusion Assay. DNA condensation was evaluated by the fluorescence of the polyplex solution upon addition of ethidium bromide solution. 90 μL of DNA (con-

centration of 33.3 μg/mL in 10 mM Tris-HCL buffer with 1 mM EDTA) was placed into each well of a 96-well microplate after 60 μL of 0.26, 0.51, 1.02, 1.28, or 2.56 μg/μL of aqueous SV solutions was placed so that the N/P ratio was from 0.25 to 10.0. A 37.5 μL quantity of aqueous ethidium bromide solution (20 μg/mL) was added to each well. After 10 min incubation, the fluorescence strength was measured by a Luminous CT-9000D fluorescence microplate reader (Dia-Iatron, Tokyo, Japan) with an excitation wavelength at 560 nm and emission wavelength at 620 nm. Results are given as relative fluorescence where 1.0 is fluorescence of the DNA solution without the SV and 0.0 is the remaining fluorescence of the non-intercalating ethidium bromide.

Cell Lines. COS-1 African green monkey kidney cells were purchased from Riken Cell Bank (Tsukuba, Japan). COS-1 cells were maintained in Dulbecco's modified Eagle's medium (DMEM; Gibco, Invitrogen Corp., Carlsbad, CA) with 10% fetal calf serum (FCS; Hyclone Laboratories Inc., Logan, UT), 200 units/mL penicillin (ICN Biomedicals Inc., Aurora, OH), and 200 mg/mL streptomycin (ICN Biomedicals Inc.) in a 5% CO_2 atmosphere at 37 °C.

In Vitro Transfection Assays. COS-1 cells were seeded at a density of 6×10^4 cells/well in a 24-well plate in medium containing 10% FCS and grown to reach 70−80% confluence prior to transfection for 24 h. Transfections were performed with 0.5 μg of plasmid DNA (pGL3-control) and 2.4 μg of SVs in 24-well dishes containing 0.2 mL of OPTI-MEM I (Gibco) for COS-1. After 3 h incubation, the cells were washed once with phosphate-buffered saline (PBS) (−) and cultured in 1 mL of appropriate medium for an additional 48 h. The medium was removed, and the cells were washed twice with PBS (−), lysed with 0.2 mL of cell lysis buffer (Promega, Madison, WI), and mixed by vortexing. The lysate was centrifuged at 15 000 rpm for 1 min at 4 °C, and 5 μL of the supernatant was analyzed for luciferase activity using a Luminous CT-9000D (Dia-Iatron, Tokyo, Japan) luminometer. The relative light unit (RLU)/s values were converted into the amount of luciferase (pg) using a standard luciferase curve, which was obtained by diluting recombinant luciferase (Promega) in lysis buffer. The protein concentrations of the cell lysates were measured by performing a Bio-Rad protein assay (Bio-Rad, Hercules, CA) with bovine serum albumin as a standard. The final amount of luciferase was determined as the amount of expressed luciferase (mole quantity) standardized to the total protein content of the cell lysate. Data are given as mean ± standard deviation (SD) of the mean ($n = 5$).

Cell Viability Assays. Cytotoxicity was assessed by performing a cell viability assay using the water-soluble tetrazolium (WST)-8 method (Dojindo, Kumamoto, Japan). The COS-1 cells were seeded 24 h prior to treatment in 96-well plates at 5000 cells/well. The cells were treated under the same conditions as those used for the luciferase assay; 6.2 μL of the transfection mixture, containing 0.124 μg of pDNA and 0.6 μg of the SV, was added to each well. The cells were treated under the appropriate conditions for 3 h, washed once with PBS, and cultured in 50 μL of DMEM (Gibco) containing 10% fetal calf serum for an additional 24 h. To each well, 10 μL of WST-8 reagent (5 mmol/L) was added. After 2 h incubation at 37 °C, the absorbance at 450 nm was determined using a Bio-Rad microplate reader (model 680). Data are given as mean ± SD ($n = 5$).

RESULTS

Fractionation Separation and Characterization of the SV. An SV having a molecular weight of 35 kDa and relatively wide polydispersity of 1.6 was prepared by the iniferter-based radical polymerization of a cationic monomer, DMAPAAm, from a 4-functional iniferter, 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamylmethyl)benzene (*17*). The chemical structure of the SV is shown in Figure 1. The SV was loaded with size exclusion chromatography to separate seven elution fractions with different molecular weights. GPC of each fraction showed that SVs having molecular weights of approximately 27, 32, 37, 42, 48, 56, and 73 kDa with narrow polydispersity of less than 1.2 were obtained (Table 1). Overlaid gel permeation chromatograms for all SV samples are shown in Figure 2. The molecular weight determined by GPC correlated well with the molecular weight calculated from the molecular diameter determined by SLS analysis (Table 1).

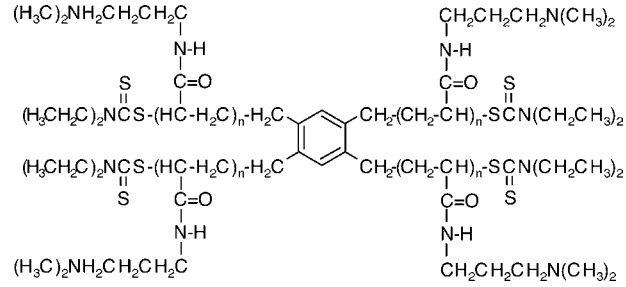

Figure 1. Chemical structure of 4-branched cationic star vector (SV).

Table 1. Molecular Weights of the Fractionated SVs

sample	M_n (kDa)[a]	M_w/M_n[a]	molecular diameter (nm)[b]	pH
crude	35	1.6	-	10.2
fraction 1	73	1.2	6.4	10.4
fraction 2	56	1.2	5.5	10.4
fraction 3	48	1.1	5.1	10.3
fraction 4	42	1.1	4.6	10.4
fraction 5	37	1.1	4.0	10.2
fraction 6	32	1.2	3.7	-
fraction 7	27	1.2	3.3	-

[a] Determined by GPC (PEO standard). [b] Determined by SLS.

SVs composed only of DMAPAAm units are strong cationic polymers originating from *N*,*N*-dimethylaminopropyl functional groups at the terminal of the polymer side chains, which are considered to be hydrophilic chemical compounds. All the SVs before and after fractionation had similar pH of 10.2−10.4. On the other hand, polymer main chains are considered to be hydrophobic; therefore, SVs having high molecular weights are considered to be amphiphilic compounds. Therefore, with an increasing concentration of the SVs, it is considered that the

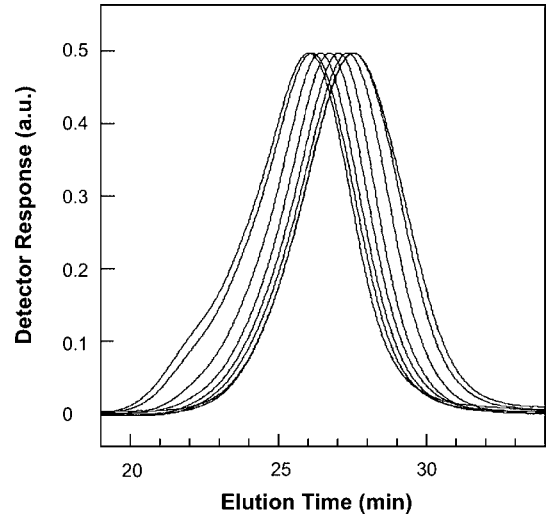

Figure 2. Overlaid GPC chromatograms of the fractionated SVs.

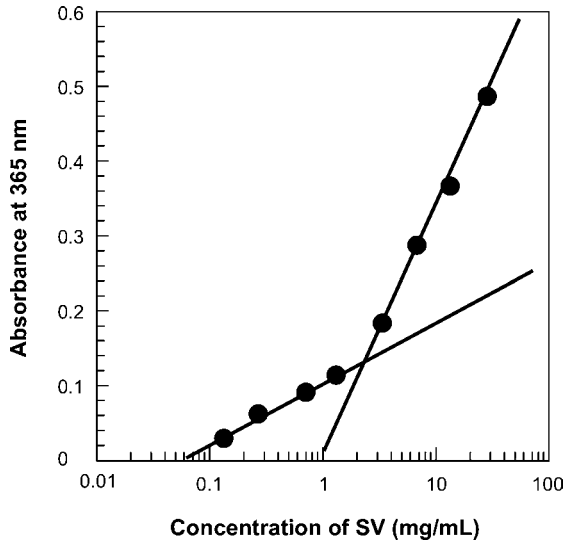

Figure 3. Behavior of the relationship between a concentration of the fractionated SV having molecular weight of 42 kDa and polydispersity of 1.1 and absorbance of an aqueous solution of the SV and 1,6-diphenyl-1,3,5-hexatriene. The critical micellar concentration of the SV having molecular weight of 42 kDa was determined to be 2.2 mg/mL, which was the cross point of two extrapolated straight lines in the low concentration region and high concentration region.

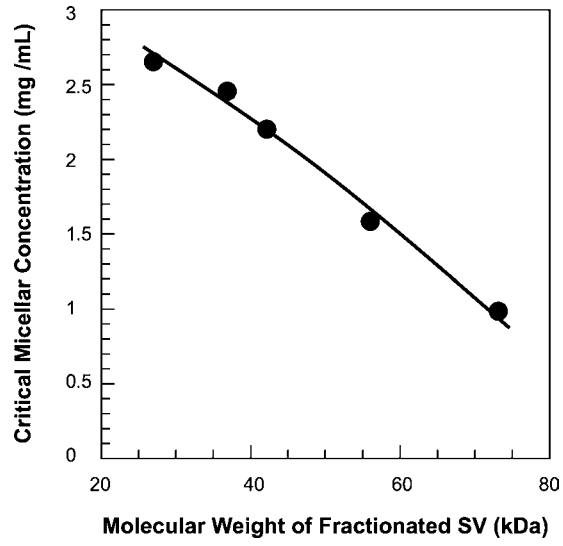

Figure 4. The relationship between the critical micellar concentration and molecular weight of the fractionated SVs.

SVs can usually form multimolecular micelles or micellar aggregates. 1,6-Diphenyl-1,3,5-hexatriene having λ_{max} of 365 nm is a hydrophobic compound, of which the water solution has no UV absorption at 365 nm. Figure 3 shows the typical relationship between the concentration of an SV having a molecular weight of 42 kDa and absorbance of the aqueous mixture of the SV and 1,6-diphenyl-1,3,5-hexatriene. As expected, with the formation of micelles with SVs, 1,6-diphenyl-1,3,5-hexatriene was partitioned into the micelles as hydrophobic cores and this resulted in the increase in the absorbance of an aqueous solution of SVs at 365 nm. The critical micellar concentration of the SV was determined to be 2.2 mg/mL, which was the crossing point of extrapolated straight lines for the low-concentration region and high-concentration region. The critical micellar concentrations of other SVs were determined using the same procedure. Figure 4 shows the relationship between the critical micellar concentration and molecular weight of the SVs.

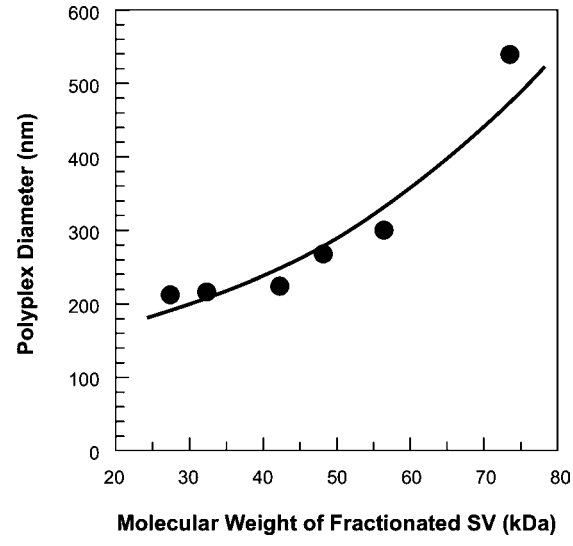

Figure 5. Mean diameters of the polyplexes prepared from the fractionated SVs and pDNA after 10 min.

The hydrophobicity increased with an increase in the molecular weight of the SVs.

Characterization of Polyplexes. Approximately 10 min after mixing a Tris-HCl-buffered solution of pDNA (pGL3-control) and a saline solution of the fractionated SVs at a charge (N/P) ratio of 10, an increase in the scattering intensity in the DLS measurements was clearly observed, indicating the formation of DNA polyplexes as observed previously in the original SVs. The mean diameters of the polyplexes after 10 min are shown in Figure 5. An SV with lower molecular weight produced a polyplex with smaller diameter, whereas the particle size was the largest for the polyplexes formed from the SV having the highest molecular weight (73 kDa).

ζ-Potentials of the polyplexes were measured after dilution of the polyplex solutions, prepared at an N/P ratio of 10, with saline solution to 1/10 of the cell transfection concentration. Moderate positive ζ-potentials over 20 mV were observed for all polyplexes irrespective of the molecular weight of the SVs (Figure 6). The ζ-potential increased with the molecular weight of the SVs. The polyplexes for the SV with the highest molecular weight had the highest surface positive charge.

The pDNA condensation potential of the polyplexes was evaluated using an ethidium bromide exclusion assay. Ethidium bromide produces strong fluorescence when intercalating with pDNA but very weak fluorescence in its free form. If pDNA is condensed by SVs and stabilized polyplex particles formed, then ethidium bromide molecules cannot intercalate with DNA. As shown in Figure 7, a significant exclusion of ethidium bromide was observed at an N/P ratio of more than 4 for polyplexes prepared from three SVs with different molecular weights. The polyplexes formed from SVs with higher molecular weight had higher exclusion activity, indicating higher condensate density of the polyplexes.

In Vitro Transfection Efficiency and Cell Cytotoxicity. The transfection efficiencies of SVs before and after fractionation were evaluated in COS-1 cells at an N/P ratio of 10. The highest transfection activity was obtained for SVs with the highest molecular weight (73 kDa), which was more than 7 times that for SVs with the lowest molecular weight (27 kDa), the nonfractionated original SV, or PEI (ExGen 500), which is one of the major commercially available typical polymeric vectors used as a positive control (Figure 8).

The in vitro cytotoxicity of polyplexes was studied as a function of the molecular weight of SVs using the WST assay. All the polyplexes prepared from SVs with different molecular

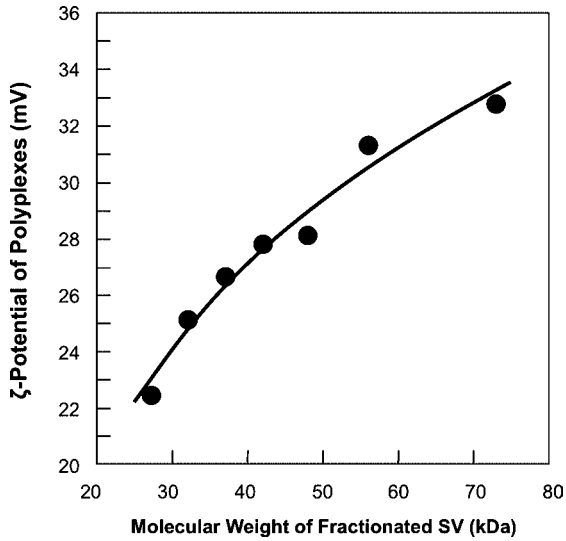

Figure 6. Relationship between ζ-potentials of the polyplexes and molecular weight of the fractionated SVs in the polyplexes. The polyplexes were prepared in N/P ratio of 10. The ζ-potentials were measured after dilution of the polyplex solutions with saline solution to 1/10. The resultant diluted solution corresponded to the cell transfection concentration.

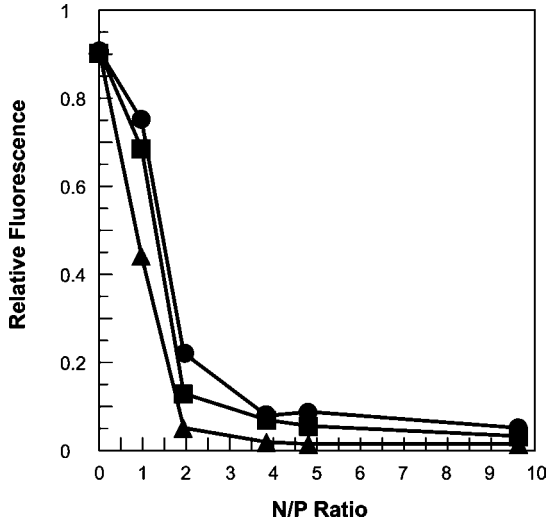

Figure 7. Condensation potential of the fractionated SVs as determined by ethidium bromide exclusion assay. Molecular weights are 37 kDa (•), 56 kDa (□), and 73 kDa (▲).

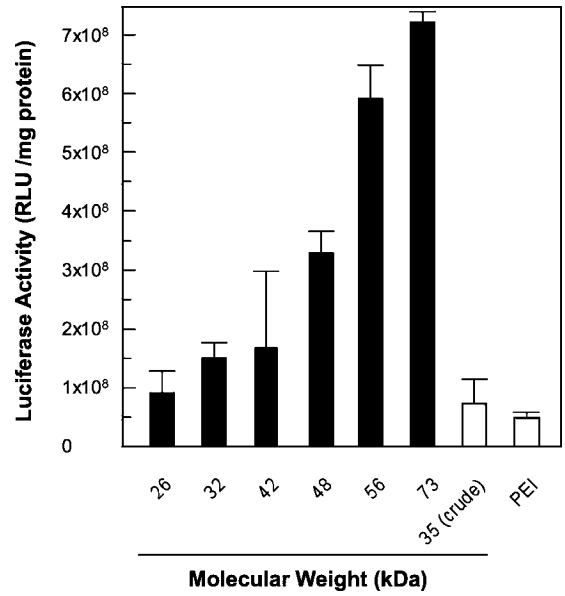

Figure 8. The transfection efficiency of polyplexes prepared by mixing DNA (pGL3-control) and the fractionated SVs at N/P ratio of 10 or linear PEI (ExGen 500) at the charge ratio of 5 in the COS-1 cell line.

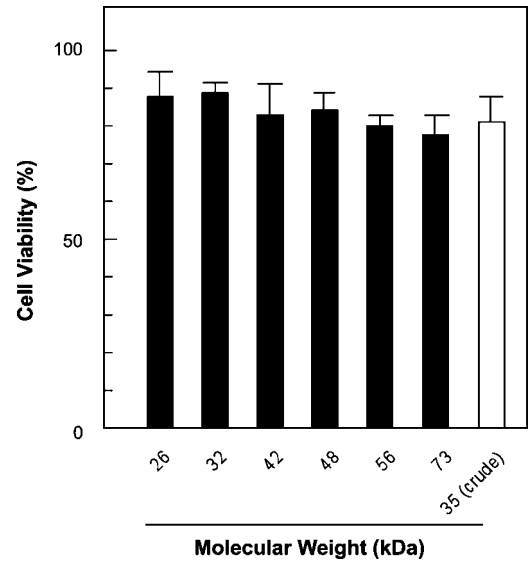

Figure 9. Cytotoxicity of polyplexes prepared by mixing DNA (pGL3-control) and the fractionated SVs at N/P ratio of 10 in COS-1 cell line. Cell viability was determined by the WST assay.

weights had permissible cell viability (Figure 9). Although the molecular weight of the cationic polymers was confirmed as the main parameter affecting their interaction with the cell membrane and consequently cell damage, SVs with molecular weights of less than 73 kDa are considered to have no significant cytotoxicity.

DISCUSSION

This study demonstrated that the molecular weight with narrow molecular weight distribution in SVs was found to have a dramatic influence on transfection activity, and luciferase reporter gene expression increased with the molecular weight. In our previous report, the molecular weight dependent transfection activity change in SVs having molecular weights ranging from approximately 10 kDa to 50 kDa with wider polydispersity of approximately 1.4 than this study was also observed at different N/P ratio of 5, which is half of this study (*17*). It was said that in 4-branched SVs the higher molecular weight resulted in the higher transfection activity in the molecular weights ranging from approximately 10 kDa to 73 kDa. On the other hand, interestingly, it was clearly indicated that narrowing of the molecular weight distribution induced high transfection activity. In the similar molecular weight of approximately 30−35 kDa, the transfection activity of the fractionated SV was two times larger than that of the crude one. The mixture of the different molecular weights may avoid uniform formation of polyplexes, which may induce less transfection activity. The narrow molecular weight distribution may be important in achieving a high efficiency as well as a high molecular weight. We are planning the investigation of effect of the molecular weight distribution, where the effect of combination of different molecular weight fractions will be also evaluated. These results will be reported in the near future.

The physicochemical properties of SVs or polyplexes are factors that control the polyplex-mediated DNA delivery (*27, 28*).

In this study, with an increase in the molecular weight of SVs, the amphiphilicity or hydrophobicity of SVs, determined by critical micellar concentration measurements, decreased (Figure 4); however, the particle size of polyplexes, determined by DLS measurements (Figure 5), surface potential of polyplexes, determined by ζ-potential measurements (Figure 6), and condensate density of polyplexes, determined by an ethidium bromide exclusion assay (Figure 7), increased. On the other hand, it is considered that DNA expression due to the polyplex was observed owing to five sequential steps: (1) attachment of the polyplex onto the cell surface, (2) internalization of the polyplexes into the cell, (3) endosomal escape of the polyplex, (4) DNA release from the polyplex, and (5) internalization of DNA into the nucleus. However, despite our better understanding of nonviral gene delivery, there are many unanswered questions relating to its fundamental mechanisms. Since the cell surface has a negative charge owing to the existence of glycoproteins on the cellular membrane, positively charged polyplexes can easily attach onto the cell surface by electrostatic interaction, similar to the case of polyplex formation from negatively charged DNA and a positively charged SV. Therefore, for more positively charged polyplexes, which form from SVs having higher molecular weights (Figure 6), attachment of polyplexes onto the cell surface is enhanced, which might be advantageous for the aforementioned first step.

On the other hand, polyplexes formed from SVs having lower molecular weight had smaller particle size (Figure 5). In general, it was found that transfection efficiency was low for large particles owing to the difficulty internalizing the polyplexes into cells (*29, 30*). Hennink et al. reported that PDMAEMA-induced polyplexes with large particle size (0.5−1.0 μm) have a lower transfection efficiency than those with small particle size (0.15−0.20 μm) (*30*). Therefore, the polyplexes formed from SVs with a higher molecular weight might be at a disadvantage in penetrating the cell membrane owing to their steric factor, which may be correlated by the aforementioned second step. However, the higher molecular weight of an SV induces higher transfection efficiency. This suggests that the polyplex size is less important to the overall transfection efficiency in this system. This was also observed in PDMAEMA-mediated DNA delivery (*16*).

SVs with higher molecular weight had higher amphiphilic ability on the basis of increasing hydrophobicity (Figure 4). Therefore, polyplexes formed from SVs having high molecular weights had high amphiphilic ability, i.e., they could fuse to the cell membrane or endosome membrane (*31, 32*), which may correlate with the aforementioned second and third steps. On the contrary, the hydrophobic character of SVs might induce rigidity of the polyplexes. Indeed, it was seen from the condensate density measurements that the polyplexes formed from SVs having higher molecular weights were more rigid (Figure 7). These are advantages for the prevention of DNase degradation but disadvantages for the intracellular DNA decondensation correlating with the aforementioned fourth step, which may induce low transfection efficiency owing to the difficulty of the DNA releasing from the polyplexes.

In summary, we used 4-branched SV consisting of *N*,*N*-dimethylaminopropyl acrylamide monomer units as a model polymer. The highest transfection activity was obtained for the SV with the highest molecular weight (73 kDa) and was more than 7 times that for the SV with the lowest molecular weight (27 kDa) or the nonfractionated original SV. The transfection efficiency correlated more with the amphiphilicity or hydrophobicity of the SV and the surface potential and condensate density of the polyplexes than with particle size. It was very difficult to clearly explain the relationship between the transfection activity and the physicochemical properties of SVs or the polyplexes. However, SV with the highest molecular weight could be easily extracted by separation using size-exclusion chromatography. In the comparison with the fractionated SVs with narrow molecular weight distribution, a small difference of molecular weight induced great difference of the physicochemical properties and the transfection efficiency. It is considered that the optimal molecular weight is different for each polymeric vector species because the vectors show different physicochemical properties. Therefore, precise and reliable evaluation of the transfection activity needs to be performed using polymeric vectors with narrow molecular weight distribution. The fractionation will be useful for enhancement of the efficiency of gene transfection induced also by other cationic polymers.

ACKNOWLEDGMENT

We would like to express our thanks to Ayaka Ishikawa for technical assistance.

Received July 8, 2009; Revised Manuscript Received August 24, 2009

Genetic engineering of phage provides novel opportunities to build various nanomaterials by displaying functional peptide motifs on its surface coat protein. However, any genetic modifications of phage coat proteins must be able to accommodate their many biological roles in the phage replication process. To express functional but inherently unfavorable peptide motifs on major coat protein pVIII, we devised a novel genetic conjugation method to circumvent bacterial biological censorship. Constraining the designed peptides among the degenerate flanking residues, we obtained a pVIII library of phage that retained the desired sequences yet could navigate through the phage replication process due to the naturally selected flanking residues. Further, we systematically analyzed the biochemical and size-related compensation mechanisms of the pVIII expressed peptides by constructing four chemically diverse (His, Trp, Glu, Lys) partial library series. Described genetic conjugation methodology can serve to improve the design of engineered phage and allow further exploitation of these particles as functional nanobiomaterials for various applications.

INTRODUCTION

Monodisperse nanofibers with a uniform programmable surface that are able to store information and be reproduced in mass quantities can serve a multitude of biological and material needs. Filamentous bacteriophage (phage) are bacterial viruses 880 nm long and 6.6 nm in diameter (*1, 2*). Through genetic engineering, phage have been shown to be extremely versatile in peptide presentation on both their major coat protein, pVIII, and minor coat proteins, pIII and pIX (*1*−*7*). Additionally, the monodispersity of their shape and chemical character, derived from clonal replication, allows them to self-assemble into directionally organized liquid crystalline structures. Previously, these phage have demonstrated an ability to be formed into one-dimensional ordered fibers, two-dimensional films, and three-dimensional materials (*4, 6, 8*−*10*).

The potential to control both structural organization and chemical function of materials at the nanoscale level makes genetically engineered phage very appealing candidates for use as material building blocks. The surface of the filamentous phage is represented by 2700 copies of its major coat protein, pVIII, which packs around the phage DNA to make a tight and cylindrical shell (*11*). The acidic N-termini of pVIII form a dense periodic display spaced at 2.7 nm (*1, 12*). The final five residues of pVIII have been determined to be structurally unconstrained and exposed to the solvent (*11*), therefore presenting an optimal target for engineering, manipulation, and substrate interaction.

A tremendous amount of research has gone into studying the structural characteristics and biological interactions of pVIII through the phage and *Escherichia coli* (*E. coli*) life cycle (*13*−*23*). Numerous peptide libraries have been developed for use as information mining tools in a high-throughput evolutionary screening method called phage display (*1, 2*). Additionally, research efforts have gone into finding out how to improve the diversity of the amino acid libraries presented by the phage, thereby potentially improving the quality of binding information between the peptide and its target (*24*−*26*). More recently, functionalized bacteriophage and virus capsids have become an attractive tool for material synthesis (*27, 28*). The "landscape" peptide presentation on the major coat protein of the filamentous phage has been utilized to template inorganic crystals for energy and memory storage devices (*4, 6, 9, 10*) and make stimulus-responsive materials (*29*). The phage has also been exploited for medical applications, such as targeted drug (*30*), gene (*31*), and imaging agent (*32*) delivery, as well as a tissue engineering material (*33*).

To further exploit and push the limits of the phage particle versatility, it is important to understand the intricate biological processes that occur before pVIII proteins can be successfully packaged into a viable phage. If a very low copy number vector such as fd-tet is utilized (*24*), the stress on the replication process is reduced, and an engineered octapeptide pVIII library has a capability of forming 10^9 various phage particles (*1*). The utilization of a phagemid cloning system also allows a much greater versatility of expressed proteins in terms of both size and chemical characteristic, albeit on a much lower percentage of phage proteins (*2*). Even though the phagemid system offers greater flexibility, limitations still exist. A recent study showed that both the charge of the expressed peptide as well as its size influence the number of fused peptides that could be displayed on the phage particle (*34*). The potential complexity of the libraries drops when using a higher copy vector or when expressing the desired peptide on every protein of the phage (*25*). However, as the yield of propagated phage and the density of expressed peptides become much more important for material synthesis applications these attributes should play an important role in choosing both the phage type and the expression system.

Whether the certain insert sequence will be expressed or not depends strongly on its fitness for the processes encountered

by pVIII during its lifecycle, including (1) transcription, (2) translation, (3) membrane insertion, (4) signal peptide cleavage, (5) assembly and extrusion, and finally (6) infection and intrusion (*23*, *35*); see Figure 1. If the interactions of the engineered pVIII are favorable within this context, its genetic sequence will be more stable, and more phage will be produced during amplification. If the insert sequence makes pVIII interactions less biologically favorable, it will be more likely to mutate and/or produce fewer phage particles. Here, we describe a novel partially constrained library method to add peptide motifs to every copy of pVIII protein. We show how this approach was used to display an Arg-Gly-Asp (RGD) integrin-binding peptide on every copy of pVIII protein to promote cell interaction, which we developed for phage-based novel tissue engineering materials. Additionally, we show how this method can be useful for presenting other functionally designed groups on the major coat protein of the phage. Finally, we quantitatively analyze how the characteristics of the inserts and their constrained sequences affect their expression on a phage particle.

EXPERIMENTAL PROCEDURES

Reagents. Phusion high-fidelity DNA polymerase was purchased from Finnzymes (Espoo, Finland). *Pst*I, *Bam*HI, and *Dpn*I restriction endonucleases, T4 DNA ligase, and dNTP 10 mM solution mix were from New England Biolabs (Ipswich, MA). QuikChange Site-Directed Mutagenesis Kit was from Stratagene (La Jolla, CA). DNA purification was performed with the help of QIAquick PCR Purification and Gel Extraction Kits, and QIAprep Spin Miniprep Kit all from QIAGEN, Inc. (Valencia, CA).

Bacterial and Phage Strains. M13KE single-stranded phage that was used as a base for the library and insert construction was purchased from New England Biolabs. XL10-Gold Ultracompetent Cells (F′ *lacI*^{q}*Z*Δ*M15*) from Stratagene were used to transform the ligated DNA products. XL1-Blue Competent Cells (F′ *lacI*^{q}*Z*Δ*M15*) from Stratagene were used for phage amplification.

Inverse PCR Method for M13 Phage Cloning. To present peptide motifs on every copy of M13 major coat protein, an inverse polymerase chain reaction (PCR) cloning method was adapted (*36*). The insert was positioned between the first and fifth amino acids of the wild-type pVIII, replacing wild-type M13KE residues 2−4 (Ala-**Glu-Gly-Asp**-Asp to Ala-(**Insert**)-Asp). All primers were ordered from IDT DNA technologies (Coralville, IA). To allow for recircularization of the vector following the PCR, a *Pst*I restriction site was created upstream of the insert location using a QuikChange Site-Directed Mutagenesis Kit by changing position 1372 of M13KE vector from T to A (CTGCAG), as previously described (*1*). The resulting DNA was verified by picking blue plaques resulting from phage transformation, isolating the DNA using common biological methods (*37*), and sequencing at the University of California, Berkeley DNA sequencing facility (Berkeley, CA).

For the inverse PCR reaction, the forward primer was designed to include a *Pst*I restriction site followed by an insert sequence and a segment complementary to the gVIII 3′−5′ strand. The reverse primer, designed to make the M13 plasmid linear, also included the *Pst*I restriction site and was fully complementary to the gVIII 5′−3′ region. To incorporate the gene sequences, PCR was performed using Phusion high-fidelity DNA polymerase, the two primers, and an M13 vector with an engineered *Pst*I restriction site as the template. The obtained product was purified on an agarose gel, eluted with spin column purification, digested with *Pst*I enzyme, and recircularized with an overnight ligation at 16 °C with T4 DNA ligase (*37*). The ligated DNA vector was transformed into XL10-Gold Ultracompetent bacteria cells, and the resulting phage verified via DNA sequencing.

Partial Library Cloning Method. All the libraries were cloned into the M13 vector by following the above scheme. For the partial libraries, the primers were designed to constrain a region of interest (i.e., RGD) and to allow degeneracy within the flanking codons (i.e., XXXRGDXX). As in previous phage libraries, a 32 codon degeneracy was used (X = NNK, N = A/T/C/G, K = G/T) to reduce the bias among presented amino acids (AAs) and eliminate two of the three potential stop codons (*1*, *2*). For a fully unconstrained library, degeneracy was allowed at all of the 8 positions. See Table 1 for primer and corresponding library sequences. To reduce the advantage of

[a] X's refer to degenerate residues, **Bold** to constrained, and *Italics* to the insert portion. [b] Full primer sequence shown only for the first listed; for the rest, only the *Pst*I restriction site and the insert portion are included. [c] X^c refers to residues coded for by a GNK codon (i.e., A,D,E,G,V). [d] Glu libraries shown as representative; same pattern applied for Lys library (AAA AAG codons); for His (CAT) and W (TGG) libraries, only one type of codon was used.

wild-type or fast-amplifying phage, the cells were allowed to recover for only 30 min after transformation (*38*). To analyze the library sequence space, the cells were plated in agarose top, and phage-formed plaques after an overnight incubation at 37 °C were picked and their DNA sequenced.

Library Quantification and Analysis. *Number of Transformants.* Using 2 μL of each ligation reaction, 50 μL of XL-10 Gold Ultracompetent cells were transformed via heat shock following the manufacturer's recommendations. The cells were recovered in 1 mL LB at 37 °C incubator with shaking for 30 min. Aliquots of 150 and 450 μL of cells were then plated in agarose top on LB plates with IPTG/Xgal (*37*). The number of transformants was quantified for each of the engineered libraries by calculating an average quantity of plaque forming units.

Amino Acid Diversity. Ten sequences were obtained for each library producing plaques (*37*), except for the 3H library where only seven plaques could be obtained with retained 3H sequence. The frequency and number distributions were determined on the basis of the amino acid (AA) side-chain characteristic (i.e., aromatic, negative, and positive), both in the degenerate positions and in the insert as a whole. Observed frequency of occurrence (*F*) was calculated via the following formula: $F =$ (# of type of AA)/(total # AAs in sequences evaluated) $\times$ 100%, with type of AA = Aromatic (Trp, Tyr, Phe), Negative (Asp, Glu), or Positive (Arg, Lys). Expected frequency (E.F.) was calculated on basis of the number of codons corresponding to each AA residue as used in a 32 codon library, and grouped by the type of AA.

RESULTS

Fabrication of Partially Constrained pVIII Library with Desired Peptides. We fabricated a partially constrained pVIII library with desired peptides for construction of engineering materials. The initial purpose for engineering the pVIII protein of M13 phage was to decorate it with cell signaling motifs, so it could serve as a novel material for tissue regeneration scaffolds (*33*). As the target cell type was of neural origin, the signaling motifs chosen were IKVAV and RGD, which are peptide groups taken from laminin and fibronectin and previously shown to have a positive effect on neural progenitor cell attachment and differentiation (*39, 40*). Initial cloning attempts were to display an AS**IKVAV** and a GG**RGD**-SP peptide immediately at the N-terminus of pVIII, thereby maintaining the signaling motifs within their naturally occurring flanking sequences (*41, 42*). After the original attempt failed, the insert sequences were modified to shift the ASIKVAV to start at position three of the mature pVIII (i.e., AE-*AS***IKVAV**DP), and GRGDS was shortened and moved to start after the first Ala residue (i.e., A*G**RGD**S*DP). Both were redesigned to contain a positive and a negative residue, making the overall charge of pVIII N-terminus -1. The described measures should have theoretically allowed for the expression of the insert (*3*). However, both of the constructed bacteriophage showed a strong tendency for deletions and single nucleotide mutations, which resulted in amino acid substitutions. In nine out of ten sequences obtained, the ASIKVAV insert had a K6N mutation (AE*ASINVAV*), and only one preserved the desired IKVAV sequence with an A3D mutation (AE*DS**IKVAV***).

A GRGDS peptide addition on pVIII resulted in a phage that made very small plaques, initially indicating a greatly reduced fitness of the phage (*3, 15, 16, 24*). Furthermore, when the phage was amplified and titrated following standard microbiological procedures (*37*), the resulting phage all had G2D, R3X (i.e., A*D***RGD***S*DP or A*GXGDS*DP, with X = residue from a single base mutation, i.e., Pro, Leu, Gly, His) or deletion mutations. Even when a DRGDS phage was amplified, the resulting population again showed consistent instability at the Arg position, often mutating it to a neutral residue. From these initial cloning attempts, it was seen that the preference for the phage expression was not to have a positive residue in the N-terminus insert location, unless stabilized by at least two negative charges. However, even with two negative residues the shorter DRGDS peptide continued to remain unstable.

A partial 8mer library was utilized to display the unfavorable RGD peptide, which allowed the unconstrained library residues to be controlled and chosen by the *E. coli* host (see Figure 1). In this manner, only the favorable full inserts would be displayed and contain both the designed constrained motif as well as a flanking amino acid library chosen by the natural selection pressures of the *E. coli* cellular mechanisms. Cloning the RGD sequence with the partial library method as described above resulted in formation of phage particles that upon sequencing were found to retain the RGD sequence (see Table 2). From the resulting RGD library, the most physiologically relevant flanking amino acids GRGDT (for a full sequence of A*DS*-**GRGDT***E*DP) were chosen to resemble a fibronectin integrin binding domain GRGDS (*43*). The stability of both the IKVAV- and RGD-modified phages was verified by mass amplification (*33*). Furthermore, they were found to have specific interaction with cells and were used to build tissue engineering scaffolds that could control cell behavior in two and three dimensions (*33*).

To further verify the utility of the partial library method to express unfavorable short peptide groups on every copy of the major coat protein, we attempted to express a WHWQ sequence found previously in our lab as a trinitrotoluene (TNT) binding peptide (*44*). A fully defined WHWQ insert and four different WHWQ libraries were attempted (see Table 1). The fully constrained WHWQ insert (A*G****WHWQ****GGG*DP) resulted in no plaque forming phage. The transformation of a library with two unconstrained positions (A*XX****WHWQ****XGG*DP) resulted in several plaques, but all were either wild-type mutants or original template phage. Finally, libraries constructed with degeneracy at three (A*XXX****WHWQ****XG*DP) and four positions (A*XXX****WHWQ****XXX*DP or A*XX****WHWQ****XX*DP) resulted in phages that were able to retain the desired WHWQ sequences (see Table 3). Within the resulting sequences, there was a very strong tendency of the unconstrained residues to be negative. From 20 of the phage that were sequenced and found to display the WHWQ motif, 18 had 3 negative residues in the unconstrained space and 2 had 2 negative residues. These 2 phage were from the A*XX****WHWQ****XX*DP library, and both had the negative charges preceding the constrained WHWQ motif.

Limitation and Compensation Trends in Partially Constrained pVIII Libraries. To explore whether there was any compensation between the constrained and unconstrained sequence space of the insert and elucidate any potential trends, several partially constrained library series were designed. One to six amino acids of the 8mer inserts were defined in the middle of the pVIII libraries as His, Lys, Trp, or Glu, leaving the rest as degenerate (see Table 1). The purpose was to systematically test the constraints of insert expression for amino acids with side groups of diverse chemical characteristics and potential functionalities. Histidine, a very functionally interesting residue, has a nearly physiological pK_a of 6.0, and is therefore very sensitive to its surroundings. However, in a more basic *E. coli* environment (*45*) it is most often found in a neutral confirmation. Lysine (pK_a = 10.53) is consistently positive in *E. coli* and has a modifiable amine group, whereas glutamic acid is negative (pK_a = 4.25) and similarly has a chemically modifiable carboxyl group. Tryptophan is uncharged, but it is the largest (mol wt = 186.21 g/mol) hydrophobic amino acid that is both aromatic and polar by nature, lending itself to a variety of binding interactions.

Effect of pVIII Constrained Sequence on Library Size. The size of the libraries, as measured by the quantity of plaque-forming phage after library transformation, was seen to strongly depend on the sequences constrained within the 8mer library inserts (Figure 2). The most apparent trend was that for all libraries the number of plaque forming phage produced within the library declined as the number of repeating residues increased. For the H-libraries, 1H and 2H constraints produced

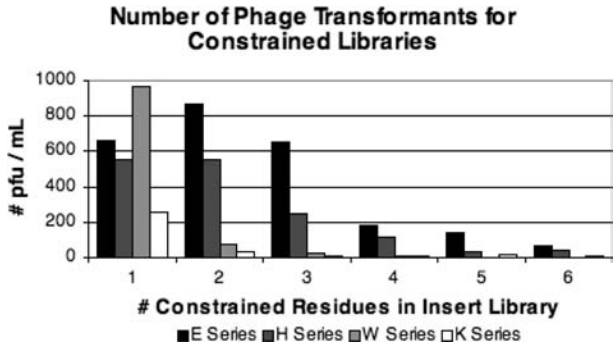

Figure 2. Partial library size dependence on the constrained peptide. Average number of plaque forming units (pfu) is shown in relation to the number of constrained residues in each of the constructed libraries.

an equal population of transformants at 550 pfu/mL and the 3H library population was reduced by half to 240 pfu/mL. The 4H library produced 120 pfu/mL, but did not result in any phage containing four His residues. Instead, the phage sequence always either had a deletion, wild-type revertant mutations, or original template background. Even though the 5H and 6H libraries produced some plaques, they were similar in quality to the 4H library. The W-libraries had the most dramatic change where the 1W seemed a very favorable constraint producing 970 pfu/mL, but the drop to the 2W library population was more than 10 times to 70 pfu/mL, and 3W was again reduced by another half to 30 pfu/mL. The 4W libraries produced less than 10 pfu/mL and had no 4W sequences. The 5W and 6W libraries produced no plaques at all. Within the K-series, only 1K (at ~260 pfu/mL) contained the constrained Lys residue. The 2K−6K libraries produced a population of plaques, but each was either a deletion or wild-type mutant, or original template DNA background. The E-constrained phage showed high numbers of pfu/mL in the 1−3E libraries (650−870 pfu/mL), with the 2E library being the best producer. The 4E library showed a marked decline (180 pfu/mL), and even though it did contain some deletion and revertant mutants, there was still a population of phage expressing the constrained 4E sequences. The 5E (140 pfu/mL) and 6E (70 pfu/mL) libraries produced a fairly large population of plaque-forming phage compared to other high repeating libraries. However, among the obtained sequences, there were no phage that expressed five or six Glu repeats. Instead, these libraries had a high number of deletion mutants, often displaying one to four Glu residues.

Dependence of Partial Library Diversity on the Constrained Sequence. In the constructed partial libraries, the unconstrained library amino acids were seen to partially compensate for the constrained amino acids in both chemical character and size, in order to preserve the overall favorability of insert display. The residues were grouped and characterized by their side-chain functionality rather than by individual presence. The positive groups, Lys and Arg, as well as the hydrophobic groups Trp, Tyr, and Phe, were previously described to aide in anchoring the pVIII protein in the cell membrane (*46, 47*). The negative residues (Asp and Glu) are thought to assist in the electrophoretic dependent insertion of pVIII across the *E. coli* membrane and serve as its hydrophilic anchors (*22, 47*). This diversity analysis was done on the whole 8mer inserts including the constrained sequences, as well as on only the degenerate parts of the inserts, that exclude the constrained sequences (see Figure 3). These distributions were compared to an 8mer pVIII library population constructed in a similar fashion, as well as expected frequencies of these amino acids as based on the 32 codon representation (NNK codon library). As observed in previously constructed libraries, the frequency of expression of negative Asp and Glu residues were greatly overrepresented in the fully unconstrained library, whereas both the aromatic and the positive residues were underrepresented in relation to the theoretically expected frequencies (*3, 25*). However, as more constraints were imposed on the insert space some trends were seen to emerge. The most pronounced effect was the direct relationship between the number of charged residues and the aromatic residues. The constriction of aromatic amino acids showed a dramatic influence on the increase of negatively charged residues within the library portions of these phage pVIII proteins (10% increase for 1W, 41% increase for 2W, and 62% increase for 3W libraries in relation to fully unconstrained). Inversely, while the expressed frequency of aromatic residues did not increase for 1E and 2E libraries, it more than tripled, in relation to the library expression, to 14% for 3E and 15% for 4E library. It is also noteworthy that, whereas the number of aromatic residues is underrepresented in the fully unconstrained and most of the constrained libraries, it exceeds the expected rate of representation (9%) by 50−60% in the 3E and 4E libraries. Additionally, the 1K library had the third largest expression rate of aromatic residues, exactly matching the expected frequency at 9%.

Since the more constrained libraries have a lower quantity of unconstrained residues, a similar number of residues of a certain type will inherently result in a higher frequency of expression. Therefore, to better interpret the behavior of the full pVIII protein, it is useful to also evaluate the average number of residues seen in the whole 8mer insert (see Figure 4) compared to both the fully unconstrained library and the wildtype residues replaced by library insertion (A**EGD**DP). With this approach, even though less dramatic, the same trends as seen with the frequency of expression can be observed. While the number of negative residues is ~1.7 per insert for the fully unconstrained library, there is a significant increase in negative residues for the 2W and 3W as related to the library (2.5 and 3.1, respectively). Due to the overall low rate of expression of aromatic residues within unconstrained library portions of the phage, there was a large variance within each population. Therefore, besides the constrained aromatic libraries there were no statistically significant changes in the expression of aromatic residues as compared to the library. However, there was an upward trend of aromatic residue expression in the negatively constrained 3E and 4E libraries (0.6 residue/insert) in relation to the library.

When analyzing the expression of positive residues, it was seen that a maximum of one positive residue was expressed in any of the insert libraries, whether it was a constrained Lys residue or positive residues appearing in the unconstrained sections of other libraries. The constrained library had significantly higher expression of positive residues than any other library. Even though all of the negatively constrained libraries had an increased expression of positive residues, the only one that was significantly higher than the fully unconstrained library was the 2E constrained phage library. In fact, the 2E phage library expressed a significantly higher number of positive residues than all the other phage libraries with the exception of the other Glu libraries. Furthermore, in all of the inserts displaying a positive group, at least two negative residues were present.

A direct compensation mechanism seemed to occur for the constrained 1K library. It expressed an average charge of −1.5 (2.5 negative residues and 1 positive residues per insert), the same as the unconstrained library with an average charge of −1.54 (1.74 negative residues and 0.2 positive residues per insert) (Figure 3). The aromatic Trp constrained libraries expressed positive residues but at a lower rate than the unconstrained library. On the other hand, as mentioned above the Lys constrained library showed a relatively high rate of

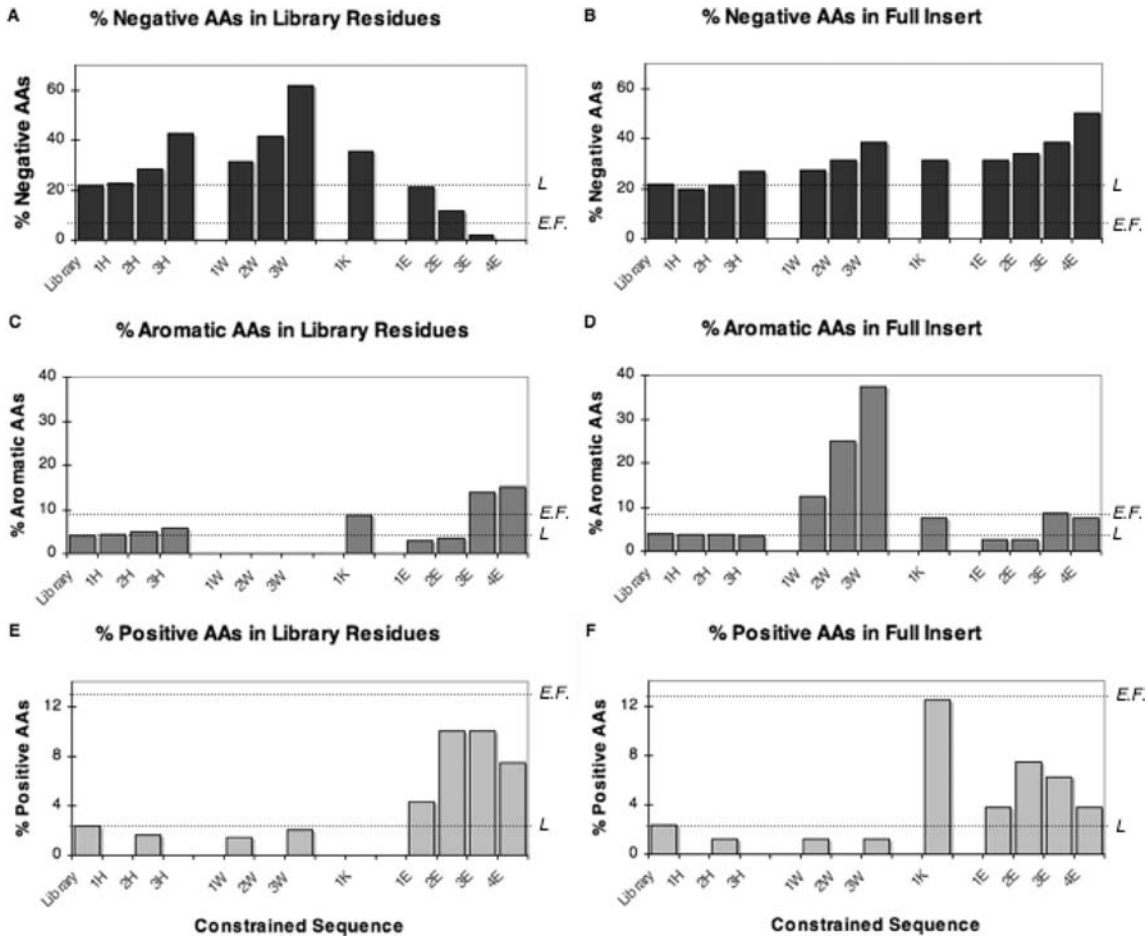

Figure 3. Frequency distribution of functional groups in expressed partial library inserts. The observed frequency of AAs with (A,B) negative, (C,D) aromatic, and (E,F) positive side chain groups is shown for both (A,C,E) the unconstrained library populations only, as well as for (B,D,F) the full 8mer insert containing both the unconstrained and the constrained sequences. Comparison lines are indicated at frequency of differently functional AAs seen in the fully unconstrained 8mer library (marked by L), and the expected frequency (marked by E.F.) as based on number of AA codons in a 32 codon library.

aromatic residue expression. When the whole insert was analyzed, the library had 0.6 aromatic residues/insert, which is similar to 3E and 4E constrained libraries.

Furthermore, with the exception of 1E, 2E, and 3E none of the constrained libraries showed any of the residues of same functionality within their unconstrained regions (i.e., Trp libraries expressed no additional aromatic residues). For the Glu libraries, the unconstrained space for 1E had the same frequency of expression for negative residues as the fully unconstrained library. The 2E library had 50% of that rate, 3E only 10%, whereas the 4E library expressed no extra negative residues within its unconstrained sequences (see Figures 3 and 4).

The His constrained libraries showed no significant variation of the aromatic residues from the fully unconstrained libraries or among each other. There was a slightly lower representation of positive residues in the His libraries, which could be attributed to the His pK_a of 6.0 having the potential to act as a slightly positive residue depending on its surroundings. The number of negative residues in the full 8mer insert did not differ significantly from the library, or each other, matching the fully unconstrained library for 1H and 2H library and then rising slightly by ~25% for the 3H library (Figure 4).

Correlation between Charge and Size on the pVIII Inserts. The size of the pVIII inserts, quantified by their molecular weights, was found to have a significant inverse relationship with their charges, indicating that larger inserts tended to be more negatively charged. The size−charge correlation was assessed independently for each of the library series and is depicted here by a linear regression and characterized by the correlation coefficient r, population size n, and the significance value p for a two-tailed t-value, with $t = r\sqrt{[(n-2)/(1-r^2)]}$. The correlation strength varied among different libraries. It was moderately weak for the fully unconstrained library ($r = -0.43$, $n = 53$, $p < 0.01$) and the E-series ($r = -0.40$, $n = 40$, $p < 0.02$), moderately strong for both H-series ($r = -0.59$, $n = 27$, $p < 0.01$) and W-series ($r = -0.60$, $n = 30$, $p < 0.001$), and very strong for the K-series ($r = -0.86$, $n = 10$, $p < 0.01$) (see Figure 5C). Regardless of the linear strength of this relationship, it was found to be statistically significant for all libraries considered. Additionally, all of the 8mer libraries expressed on pVIII seemed to have a preferred size and charge range (Figure 5A,B). The majority of inserts expressed and subsequently sequenced from all the libraries had a molecular weight between 700 and 1000, and had a net charge of −1 to −3 charges. Within that space, there was a visible shift toward both greater size and greater charge preference from unconstrained (average: −1.5, 810 Da) to constrained libraries (average: −2.3, 890 Da).

DISCUSSION

M13 bacteriophage can serve as a versatile and multifunctional material building block due to the ease of its genetic manipulation and its monodisperse filamentous shape. The coat proteins of this phage may be modified with rationally designed

Figure 4. Average number of functional groups in expressed partial library inserts. Average number of AAs with (A) negative, (B) aromatic, and (C) positive side chain groups is shown for the constructed libraries. A contribution to the total number of groups is shown from both the unconstrained and constrained residues within the insert. Comparison lines are indicated for fully unconstrained library (marked L) and for the replaced wild-type pVIII residues at positions 2−4 (A**EGD**DP) (marked pVIII). Significant differences in expression (indicated by yellow shading) among the libraries are indicated in (D−F), with *p*-values shown as obtained from a Student's *t* test.

short peptides, or endowed with peptide libraries to find specific binding information via a phage display directed evolution screening method (*2, 48, 49*). We have previously demonstrated the use of such genetically engineered phage for a tissue engineering scaffold application (*33*). As specific phage interaction with the cells was the main goal, a rational design approach was chosen to display well-known RGD and IKVAV cell signaling motifs (*39*−*41*). Additionally, a peptide expression on every copy of pVIII was preferred over a more sparse phagemid system display (*2, 34*), in order to obtain a high density of the signaling motifs ($\sim 1.5 \times 10^{13}$ epitopes/cm^2) (*33*). Surfaces displaying such a high density of peptide motifs have been shown to promote a stronger cellular response ranging from attachment to differentiation (*39, 40*).

Whereas the sequence of the wild-type pVIII protein has naturally evolved to be a good fit for all of the biological interactions and processes involved in phage replication, any engineered protein additions or modifications have to pass through this imposed censorship prior to expression (see Figure 1). PVIII is a product of M13 phage gene gVIII and begins its existence through transcription and translation by the *E. coli* cell machinery. PVIII is a very high copy number protein, with 0.5 to 5 million units being transcribed and translated every cell division cycle, and 2700 units are needed to package every virus before it is able to leave the cell (*19, 50*). The full protein, called procoat, is 73 amino acids in length, and contains a signal and mature peptide regions (Figure 1C). Positive Lys charges at both its amino and carboxy ends target the procoat molecule to the phospholipid membrane by electrostatic attraction (*51*) (Figure 1D). Once at the membrane, the hydrophobic segments located in the signal and mature portions of the procoat protein partition into the lipid bilayer. YidC transporter protein and electrophoretic potential are responsible for inserting the connecting loop into the periplasm (*22, 23, 52, 53*). Leader peptidase is a protein that is responsible for releasing the signal peptide sequences from many bacterial transmembrane proteins. The cleavage site utilized by the peptidase is dictated by the sequence of the substrate protein, its position in relation to the membrane interface, and the quality of fit to the peptidase (*54*−*56*). The pVIII procoat is one of the proteins cleaved by the leader peptidase, releasing the N-terminus of the mature peptide (*16, 17, 54*). After a sufficient concentration of the pVIII protein has been processed and collected in the *E. coli* inner membrane, the pVIII units pack around the extruding phage DNA strand (*23*). The phage extrusion process is orchestrated by pI and pXI phage proteins and an *E. coli* protein threoxin.

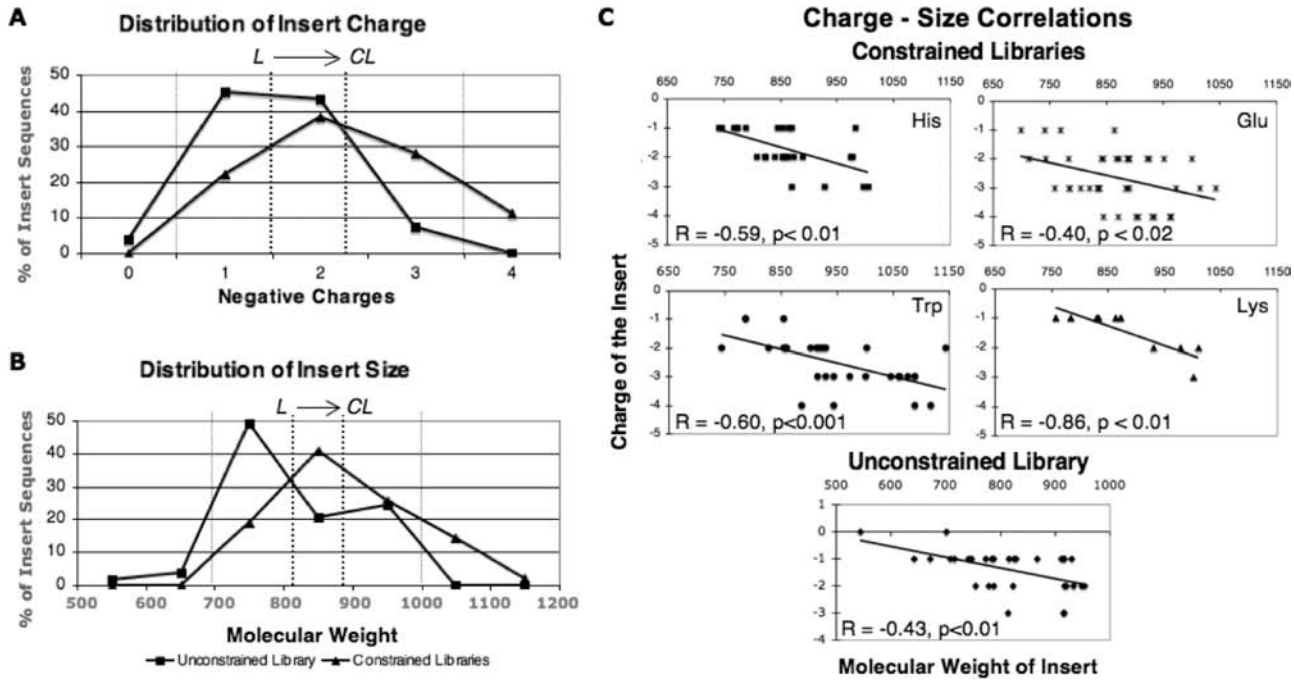

Figure 5. The charge and size of the expressed pVIII library inserts. (A) Charge and (B) molecular weight distributions of the pVIII unconstrained library (■) were compared to the partially constrained insert libraries (▲). The light dashed lines indicate the preferred size and charge for both libraries, whereas the dark dashed lines show a shift of average charge and average size from the unconstrained library (marked by *L*) to the partially constrained libraries (marked by *CL*). (C) An inverse relationship of insert charge to insert size is represented by a linear regression for all of the constructed libraries. The correlation coefficient *R*, and the statistical significance value *p*, is indicated for each of the libraries.

As the phage leaves the cell, it moves through a complex formed by the three above-mentioned proteins from the inner membrane, as well as through a multimeric pore formed by the pIV phage proteins in the outer membrane (*14*). The extrusion is propelled by the packing of the pVIII molecules around the phage DNA (*57*) and by the energy derived from the ATP hydrolysis and proton motive force (*58*). The phage reenters the cell via infection, which depends on the binding event between the pIII minor phage coat protein to the F-pili of the cell and pVIII interaction with both the TolQRA and pIII proteins (*13*). If the infection is successful, the phage DNA is unpackaged and injected into the cell, restarting the process over again.

To find the full insert sequence that would be expressed on pVIII protein, yet contain the desired RGD motif, we used a partially constrained library approach described above (see Figure 1). Although similarly constrained libraries are often used in phage display approaches to improve the binding of the identified short motif sequences (*59, 60*), in our application it was utilized as a means to display the initially unfavorable RGD peptide by allowing the unconstrained library residues to be controlled and chosen by the *E. coli* host. In this manner, the full inserts that were expressed contained both the designed constrained motif and a library chosen through evolutionary selection processes by the *E. coli* cellular mechanisms. This biologically chosen favorability of the insert would then allow for resulting phage particles to preserve their sequence during large-scale amplifications, which could then be used to build structured phage materials.

As seen in previous studies investigating pVIII peptide libraries, when attempting to express IKVAV and RGD cell signaling peptides, or later, Lys constrained libraries on M13 pVIII protein, we succeeded only when the overall charge of the insert was lower than or equal to −1 (*3*). Whereas Lys residues are expressed easily by the bacteria at the signal peptide end as well as the C-terminus of pVIII (Figure 1), their apparent lack in the periplasmic loop, which later becomes the N-terminus of the mature pVIII is well-documented (*22, 25, 34*). This distribution of positive charges on pVIII can be explained by their function within the phage replication process. As explained above, the presence of positive residues on either end of the procoat protein is needed for the electrostatic binding and anchoring of the protein to the phospohlipid membrane interface of bacteria, and then later to the phage DNA. Their lack in the periplasmic loop can be attributed to the electrophoretic gradient across the bacterial cell membrane that drives the negatively charged portions of the protein across and keeps the positively charged portions in the cytoplasm (*22, 45, 47, 61*).

Further application of the partial library method allowed us to express a TNT binding peptide WHWQ on pVIII (*44*). With expression on all 2700 copies, the WHWQ M13 phage has a very high avidity, likely improving its utilization as a sensor material (*44*). The bulky aromatic peptide motif could only be displayed when surrounded by two to three negative residues, corresponding to an observed increased display of negative residues in the aromatic Trp constrained libraries. The under-representation of aromatic residues at the N-terminus portion of M13 pVIII and other mature peptides of bacterial proteins has previously been observed (*25, 55, 56*). Potentially, this trend can be attributed to the "anti-snorkeling" properties of the aromatic residues located just outside of the membrane interface. Anti-snorkeling refers to the tendency of the aromatic residues to bury their side groups in the membrane interface region, facing the aromatic portion toward the hydrophobic lipid chains and the polar groups toward the negative phospholipid layer (*46, 47, 61*−*63*).

In the wild-type pVIII, the leader peptidase cleavage site is framed by a transmembrane segment of the signal peptide and the acidic periplasmic loop. A hydrophobic Phe residue at position −2 is likely buried in the membrane, while three negatively charged hydrophilic residues at positions +2, +4, and +5 serve as a hydrophilic anchor of the periplasmic loop, propelling it out of the membrane and away from the negatively charged membrane phospholipid groups (Figure 1C). These

opposing forces expose the leader peptidase cleavage site in the periplasm, allowing the leader peptidase to cleave the signal peptide and release the mature pVIII protein. The increase of negatively charged residues observed in the unconstrained spaces of the library inserts carrying large aromatic segments (WHWQ, 2W, and 3W) could be necessary to counteract the affinity of such constrained sequences toward the interface region. Thus, it is possible that only the proteins where the cleavage site was sufficiently exposed in the periplasm were cleaved and could be further processed into viable phage. The reverse trend was seen for the very negatively constrained libraries (3E and 4E) where the frequency of aromatic residues was 50−60% higher than expected. This could explain the opposite side of this phenomenon, where the aromatic residues served to counteract the tendency of very hydrophilic Glu amino acids to pull the signal peptide out of the membrane, therefore shifting the position of the cleavage site and making it less accessible for processing (*54*).

Protein translation was another process that was seen to impose strong limitations on the allowed insert sequences. In our library engineering efforts, none of the four designed series were able to display five or six long amino acid repeats, and only the 4E library was successful in producing phage with four repeating consecutive residues. This observation can be attributed to a previously shown dependence of protein translation accuracy and library residue expression on tRNA isoacceptor population in the *E. coli* host (*50, 64*). The repetitive use of amino acids combined with the high copy number of the pVIII protein resulted in draining the pool of the available corresponding tRNA isoacceptors. The necessary recharging of the isoacceptors could have slowed the translation process to a rate that was too slow to keep up with the demand of pVIII proteins necessary to package and extrude the accumulated single-stranded phage DNA, thus causing the host cell death (*50, 64*−*66*). The more repetitive pVIII phage inserts that were incorporated, translated, and packaged had mutations containing a large number of deletions (data not shown), which is common in long stretches of repeating residues (*67*). Even though the 4E phage still occasionally showed deletions and mutations, it was the only kind that could sustain a four amino acid repeat. This was likely due to the large number of Glu isoacceptors in *E. coli* cells (*50*) and to the favorable negative charge at pVIII N-terminus location.

The inverse charge−size relationship seen within the libraries might be attributed to the increased number of negatively charged groups expressed in the large aromatic group containing inserts. However, this relationship is seen even when the inserts are not aromatic and is most pronounced when the constrained insert is carrying a positively charged residue. The size of the insert presented at the N-terminus of pVIII protein is thought to be partially limited by both the size and the properties of the phage extrusion channel formed by pIV proteins (*12, 35*), measuring 6-9 nm in diameter (*18*). The exact structure of pIV protein has not yet been solved, and the exact mechanism of phage extrusion is unknown. However, a strong homology has been identified between the phage extrusion mechanism and type II secretion proteins, which control macromolecule export from bacterial outer membranes (*19, 68*). Many of the type II secretion proteins, including phage pIV protein, have highly conserved C-terminal domains, composed of strongly amphipathic β-sheet structures. These structures anchor the pore in the membrane with the hydrophobic residues and face the charged residues toward the center of the pore to make a large aqueous channel (*20, 69*). Additionally, it has been shown that transport through these channels depends on both ATP hydrolysis and the proton motive force (*58*). Thus, in our system, the greater hydrophilicity of the phage surface is favorable to reduce the hydration necessary for hydrophobic molecules when traveling through a hydrophilic pore (*70*), and the negative charge is favorable to help the phage molecule move down the proton motive force gradient.

In summary, we have described a novel partially constrained library cloning method that allows for the expression of short functional peptide motifs on all of the phage major coat proteins. Our cloning method works through adaptation of the flanking library residues by host induced natural selection, to make the full protein favorable for phage replication. Furthermore, we analyzed the ability of such 8mer insert partial library systems to display positive, negative, and hydrophobic groups, as well as the relationship between the insert charge and its size. Such host−pathogen interaction analysis could be combined with a recently developed virus protein association assay to further our knowledge of general phage biology, and potentially identify novel targets for antibacterial drug development (*71*).

The utilization of such a library engineering approach would be useful in any application where a short functional peptide motif is known, and the current phage display methodology might not provide superior information (*72, 73*). This approach allows not only to express a desired functional group on every copy of the major coat protein of the phage, but also to identify the phage particles that can preserve their sequence during large-scale amplification. Thus, it would be beneficial in a variety of materials applications where density and uniformity of peptide display are favored, including crystal templation (*10, 27, 28*), cell differentiation (*39, 40*), and sensor platforms (*44*). Overall, the utilization of the novel partial library method to express desired peptide groups on all of the major coat proteins of the M13 bacteriophage can serve to further exploit it as a functional nanobiomaterial.

ACKNOWLEDGMENT

Molecular umbrella provided a promising avenue for the design of the intracellular delivery of hydrophilic therapeutic agents. However, the limited understanding of its cellular uptake would be a roadblock to its effective application. Herein, we investigate the ability and mechanism of cellular entry of a fluorescently labeled diwalled molecular umbrella, which was synthesized from cholic acid, spermine, and 5-carboxyfluorescein, into Hela cells, with the extent of uptake analyzed by confocal fluorescence microscopy and flow cytometry. It is found that the as-synthesized diwalled molecular umbrella can greatly facilitate cellular uptake of hydrophilic agent, 5-carboxyfluorescein. *In vitro* experiments with diffuse marker, endocytic marker, and inhibitors suggested that several distinct uptake pathways (e.g., passive diffuse, clathrin-mediated endocytosis, and caveolae/lipid-raft-dependent endocytosis) are involved in the internalization of diwalled molecular umbrella. These results, together with its low toxicity and good biocompatibility, thus demonstrate the suitability of molecular umbrella for application as vectors in drug delivery systems.

INTRODUCTION

Cellular internalization of hydrophilic therapeutic agents such as anticancer drugs, proteins, and nucleic acids is still a challenge because the strongly hydrophobic interior of the plasma membrane inhibits the entry of these molecules (*1, 2*). Therefore, intracellular delivery of these pharmaceuticals relies on delivery systems that allow improved transport across the cell membrane.

A novel drug delivery vector, molecular umbrella, devised by Regen's group (*3*) in 1996, has been extensively studied for its potential to transport across the cell membrane. The classical molecular umbrella was composed of two facially amphiphilic units (i.e., rigid units having a hydrophobic and a hydrophilic face) and a central scaffold bearing a bioactive agent (*3, 4*). When the hydrophilic agent that attached to a molecular umbrella is immersed in an aqueous environment, an exposed conformation is favored such that intramolecular hydrophobic interactions are maximized and the external face of each wall is hydrated. In contrast, in a hydrophobic environment such as a lipid bilayer, the umbrella is closed on the compound in a shielded conformation so that the hydrophilic faces of the sterols now interact with the compound while the hydrophobic faces interact with the lipid tails (*3*−*5*). So far, many biologically active agents, such as glutathione (*6*), antisense oligonucleotides (*7*), and ATP (*8*), have been reported to be bound to the molecular umbrellas, and these agents were transported across the synthetic phospholipid bilayers by passive diffusion under the assistance of molecular umbrella. Recently, an important question for molecular umbrellas as drug carriers, i.e., whether molecular umbrellas are capable of crossing the plasma membrane of living cells, was sought by Mehiri et al. (*9*). Using confocal microscopy, they found that fluorescently labeled molecular umbrellas could enter live Hela cells and the distributions of molecular umbrellas were throughout the cytoplasm and the nucleus. This finding raises the possibility that molecular umbrellas could be used as drug vectors of intracellular delivery.

In order to design a new drug delivery system of a molecular umbrella for intracellular delivery more rationally, it is important to understand its cellular uptake mechanism. In general, the main routes into a cell are endocytosis, active transport, facilitated diffusion, and passive diffusion (*10*). Since molecular umbrella has the ability to cross liposomal membranes by passive diffusion and the cell membrane consists of phosolipid bilayer and proteins, Mehiri et al. suggested that passive diffusion should be a pathway in cellular uptake of molecular umbrella (*9*). However, whether there are other mechanisms that are contributing to the cellular entry of molecular umbrella is still unknown. This limited understanding of cellular uptake of the molecular umbrella has been a roadblock to its effective application.

In this paper, we synthesized a fluorescently labeled diwall molecular umbrella, and evaluated the ability and mechanism of molecular umbrellas across the cell membrane. We chose cholic acid as the amphiphilic wall and spermidine as the central scaffold. The diwall molecular umbrella (N_1,N_3-dicholeamidospermidine) was prepared by coupling two cholic acid molecules on the spermidine. Followed by conjunction of N_1,N_3-dicholeamidospermidine and 5-carboxyfluorescein (5-cf), 5-cf labeled molecular umbrella (5-cf-mu) was obtained. The cytotoxicity of 5-cf-mu toward Hela cells was described by MTT assays. The internalization of 5-cf-mu was tracked by confocal fluorescence microscopy (CLSM) and flow cytometry analysis (FACS). *In vitro* colocation and endocytosis inhibition experiments were further used to evaluate the cellular uptake of 5-cf-mu in Hela cells.

EXPERIMENTAL DETAILS

Materials and Methods. Cholic acid, spermidine, and diisopropylethylamine were purchased from Acros Organic

(USA). *N*,*N*-Dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), sodium azide (NaN_3), 5-carboxyfluorescein (5-cf), 2′-(4-hydroxyphenyl)-5-(4-methyl-1-piperazinyl)-2,5′-bi-1*H*-benzimidazole (Hoechst 33258), 3-hydroxy-1,2,3-benzotriazin-4(3*H*)-one (HOObt), Nocodazole (Noc), and chlorpromazine hydrochloride (CpZ) were obtained from Sigma-Aldrich (USA). Carboxyfluorescein diacetate succinimidyl ester (CFSE), Alexa Fluor 546-transferrin, Alexa Fluor 594-Ctx B reagent, and LysoTracker Red were purchased from Molecular Probe (USA). Trypsin and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were obtained from Amresco Inc. (America). Penicillin and streptomycin were purchased from Bio Basic Inc. (Canada). Fetal bovine serum (FBS) was purchased from Sangon (China). 2-deoxy-D-glucose (2-DG) and β-cyclodextrin (β-CD) were obtained from ABCR GmbH & Co. KG (Germany) and Tokyo Kasei Kogyo Co. (Japan), respectively. Hela cells were obtained from Committee on Type Culture Collection of Chinese Academy of Sciences (CTCCCAS, China). Dulbecco's Modified Eagle's Medium (DMEM) was purchased from Invitrogen Corporation (USA). All materials used were of analytical grade and used without further purification. The glassware was thoroughly cleaned and rinsed with deionized water.

HSGF 254 silica gel (150−200 μm thickness; Yantai Jiangyou Silica Gel Development Co., Shandong, China) was used for the preparative thin-layer chromatography (TLC); column chromatography employed 200−300 mesh silica gels (Sinopharm Chemical Reagent Co., Shanghai, China). Detection on TLC was made by a combination of sulfuric acid 10% in water, I_2, and UV (254 and 365 nm). Melt points were recorded on an X-4 Microscopic Melting Point Apparatus (Beijing Tech Instrument Co., China). Infrared spectrum was recorded on an Avatar 360 Fourier transform infrared spectrometer (Nicolet, USA). ^{1}H NMR was recorded on a Bruker AV-400 NMR spectrometer (Bruker, German); chemical shifts were reported in parts per million (ppm, δ). The electron spray ionization mass spectrometry (ESI-MS) was carried out on a 3200 Q TRAP instrument (Applied Biosystems, USA).

Synthesis of 5-cf Labeled Molecular Umbrella. *NHS Ester of Cholic Acid.* To a solution of cholic acid (409 mg, 1 mmol) in dry tetrahydrofuran (8 mL) and dry acetonitrile (2 mL), NHS (127 mg, 1.1 mmol) was added. To the resulting homogeneous solution, DCC (206 mg, 1 mmol) in dry tetrahydrofuran (2 mL) was added dropwise at 10−15 °C. The mixture was stirred at 25 °C for 12 h and the precipitated *N*,*N*′-dicyclohexylurea was removed by filtration. The solvent was removed under reduced pressure, and the residue was extracted with ethyl acetate (3 × 20 mL). The extract was washed successively with aqueous $NaHCO_3$ and water. The extract was then dried over Na_2SO_4, and ethyl acetate was removed under reduced pressure to get crude solid. The dried white solid was purified by column chromatography [silica, ethyl acetate/methanol (50/1, v/v)] to give the NHS ester of cholic acid as a white powder (283 mg, 60%) having R_f 0.26 [silica, ethyl acetate/methanol (50/1, v/v)] and mp 118−119 °C (lit. (*11*) mp 119−120 °C); IR ν_{max} (KBr)/cm^{-1} 3420, 1816, 1785, 1738; ^{1}H NMR ($CDCl_3$) δ 0.64 (s, 3 H, 18-H), 0.83 (s, 3 H, 19-H), 0.96 (d, 3 H, 21-H), 1.00−2.00 (m, 22 H, steroidal H), 2.20 (m, 2 H, 23-H), 2.78 (s, 4 H), 3.40 (m, 1 H, 3-H), 3.79 (m, 1 H, 7-H), 3.92 (m, 1 H, 12-H); ESI-MS for $[C_{28}H_{43}NO_7+Na]^+$ calcd 528.6, found 528.5 (100%).

N_1,N_3-Dicholeamidospermidine. The NHS ester of cholic acid (202 mg, 0.4 mmol) was dissolved in 5 mL anhydrous *N*,*N*′-dimethlformamide (DMF), and the resulting solution was added dropwise at room temperature to 1 mL of anhydrous DMF, which contained 29 mg (0.2 mmol) of spermidine and 100 μL (0.6 mmol) diisopropylethylamine. The resulting homogeneous solution was stirred for 4 h at room temperature, and the reaction mixture was poured into 50 mL of saturated aqueous solution of $NaHCO_3$. The precipitate was collected through centrifugation and purified by column chromatography [silica, $CHCl_3$/CH_3OH/NH_4OH, 65/25/4, v/v/v] to afford 113 mg (60%) of N_1,N_3-dicholeamidospermidine having R_f 0.63 [silica, $CHCl_3$/CH_3OH/NH_4OH, 65/25/4, v/v/v] and mp 163−165 °C; ^{1}H NMR (CD_3OD) δ 0.67 (s, 6 H), 0.88 (s, 6 H), 0.99 (d, 6 H), 1.1−2.0 (m, 50 H), 2.23 (m, 4 H), 2.98 (m, 4H), 3.17 (m, 2 H), 3.25 (m, 4 H), 3.76 (br s, 2 H), 3.92 (br s, 2 H); ESI-MS for $[C_{55}H_{95}O_8N_3+H]^+$ calcd 926.7, found 926.3 (100%).

5-cf Labeled Molecular Umbrella. To a solution of 5-cf (94 mg, 0.25 mmol) and HOObt (41 mg, 0.25 mmol) in 5 mL of anhydrous DMF, 52 mg (0.25 mmol) of DCC was added. The homogeneous solution was stirred at room temperature for 24 h in dark. The precipitated dicyclohexylurea was removed by filtration, and the filtrate was concentrated under reduced pressure. The resulting yellow solid was dried under reduced pressure to give the triazinyl ester (166 mg).

To a stirred solution of N_1,N_3-dicholeamidospermidine (102 mg, 0.11 mmol) and the triazinyl ester (55 mg, 0.11 mmol) in 1.0 mL of anhydrous DMF, 62 μL (0.44 mmol) of triethylamine was added. The mixture was then stirred at room temperature for 48 h in dark. The solvent was removed under reduced pressure at 45 °C. The crude product was washed with water, then dissolved in little methanol and purified by preparative TLC [silica, $CHCl_3$/CH_3OH/NH_4OH, 20/10/3 (v/v/v)] to give 35 mg (25%) of 5-cf labeled molecular umbrella (5-cf-mu) having R_f 0.36 [silica, $CHCl_3$/CH_3OH/NH_4OH, 20/10/3 (v/v/v)] and ^{1}H NMR (CD_3OD) δ 8.03 (m, 1 H), 7.83 (m, 1 H), 7.34 (d, 1 H), 6.73 (s, 2 H), 6.65 (s, 2 H), 6.59 (m, 2 H), 3.98 (m, 2 H), 3.82 (s, 2 H), 3.4−3.7 (m, 8 H), 3.17 (m, 2 H), 2.2 (m, 4 H), 1.1−2.0 (m, 62 H), 0.74 (s, 6 H). ESI-MS for $[C_{76}H_{105}N_3O_{14}+Na]^+$ calcd 1306.7, found 1306.6 (100%).

Cells and Cell Cultures. Hela cells were cultured as exponentially growing subconfluent monolayers on 100 mm plates in DMEM supplemented with 10% (v/v) FBS, penicillin (100 units/mL), and streptomycin (100 μg/mL) in a humidified incubator containing 5% CO_2 atmosphere.

MTT Cell Viability Assays. The MTT assay was used to determine the toxicity of 5-cf-mu toward Hela cells. Hela cells were seeded in 96-well plate at a density of 1×10^4 cells/well and cultured in DMEM supplemented with 10% FBS and 1% penicillin−streptomycin at 37 °C. The cells were allowed to adhere to the well bottom upon overnight incubation. After that, the medium was removed and the cells were incubated with the 5-cf-mu at concentration of 25, 50, 100, and 200 μM, respectively. At the designated time (24 h), the supernatant of each well was removed and the cells were washed twice by PBS. Twenty microliters of MTT solution (5 mg/mL in PBS) and 100 μL medium were then introduced. After 4 h incubation, the formed precipitates were solubilized by 100 μL dimethyl sulfoxide (DMSO). Absorbance intensity was then measured by the microplate reader (model 680, Bio-RAD, USA) at 490 nm with a reference wavelength of 620 nm. Cell viability was expressed by the following equation:

$$\text{cell availability (\%)} = \frac{\text{Abs}_{\text{sample}}}{\text{Abs}_{\text{control}}} \times 100\% \qquad (1)$$

The results are given as relative value to the negative control in percent, whereas the negative control is set to be 100% viable.

Flow Cytometry. To analyze the internalization of fluorochrome-labeled molecular umbrellas by FACS, exponentially growing Hela cells were dissociated with 0.25% trypsin. 6×10^5 cells were plated and cultured overnight on 60 mm dishes. The culture medium was discarded, and the cells were washed with PBS (pH 7.2). Then, PBS was discarded, and the cell

monolayers were incubated with different concentrations of 5-cf-mu for 1 h at 37 °C to analyze dose−response of 5-cf-mu uptake. To examine the effects of time, the cells were incubated with 10 μM of 5-cf-mu at different incubation times.

To investigate the cellular uptake mechanism of 5-cf-mu, the incubations of Hela cells were carried out as follows: (1) Cells were kept at 4 °C for 1 h, instead of the regular 37 °C condition. (2) For the ATP-depletion studies, the cells were preincubated in PBS supplemented with NaN_3 (50 mM) and 2-DG (0.5%) for 1 h at 37 °C. (3) For cholesterol depletion assay, the cells were pretreated with β-CD (10 μM) in PBS for 1 h at 37 °C. (4) The inhibition of clathrin- and caveolae/lipid raft-mediated endocytosis were carried out by preincubating cells with CpZ (30 μM) and Noc (10 μM) in PBS for 1 h at 37 °C. Once treatments were complete, 5-cf-mu (10 μM) was added and cells were incubated for another 1 h. The cells were then resuspended in ice-cold PBS buffer solution, and the fluorescent cells with 5-cf-mu were then measured from 2×10^4 cells by using an EPICS XL flow cytometer (Beckman Coulter, USA) in the FL1 channel. Data analysis was performed with EPICS XL flow cytometer software, and the cellular uptake of 5-cf-mu was expressed by the following equation:

$$\text{cellular uptake (\%)} = \frac{\text{CFD}_i}{\text{CFD}_{37}} \times 100\% \qquad (2)$$

where, CFD_i and CFD_{37} represent the mean value of cell fluorescence distribution for each incubation condition and the normal condition (37 °C), respectively.

Confocal Laser Scanning Microscope. To investigate the colocalization of 5-cf-mu and LysoTracker Red, 5-cf-mu (10 μM) was added and incubated with Hela cells (5×10^5) in a 30 mm cell culture coverslip for 1 h. After washing away the extracellular 5-cf-mu with PBS, cells were then treated with LysoTracker Red for 15 min for lysosome staining. For investigation of endocytosis, Hela cells (5×10^5/30 mm cell culture coverslip) were incubated with 5-cf-mu (10 μM) in a serum-free medium, together with CFSE (10 μM), Alexa Fluor 546-transferrin (50 μg/mL), and Alexa Fluor 594-Ctx B (10 μg/mL) for 5 h at 37 °C, respectively. Extracellularly bound 5-cf-mu was removed by washing three times with PBS.

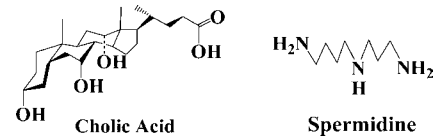
After fixing with paraformaldehyde (4% in PBS) for 30 min and subsequently washing twice with PBS, the stained cells were finally observed with CLSM (Fluoview FV1000, Olympus, Japan) equipped with a Plan-Apochromat 60 × 0.7 NA lens (λ_{ex}, 488 nm, and λ_{em}, 520 nm, for 5-cf-mu; λ_{ex}, 577 nm, and λ_{em}, 590 nm, for LysoTracker Red; λ_{ex}, 488 nm, and λ_{em}, 530 nm, for CFSE; λ_{ex}, 556 nm, and λ_{em}, 573 nm, for Alexa Fluor 546; λ_{ex}, 590 nm, and λ_{em}, 617 nm, for Alexa Fluor 594). Images were captured by multitracking to avoid bleedthrough between the fluorophores and further processed and analyzed with Olympus CLSM software.

RESULTS AND DISCUSSION

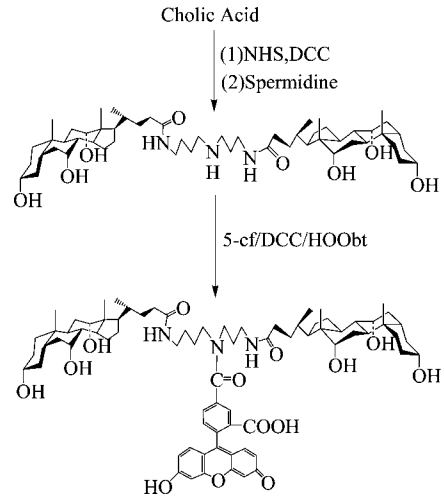
Design and Synthesis of 5-cf Labeled Molecular Umbrella. Molecular umbrellas are synthesized from materials that are potentially biocompatible. Generally, cholic acid and spermidine are selected as amphiphilic wall and central scaffold, respectively (*12, 13*). Cholic acid, a major component of bile acids, has a sterol nucleus that presents a hydroxylated, hydrophilic face and also a face that is all-hydrocarbon and lipophilic. Spermidine, which is also found in mammalian cells, has terminal amino groups that can be used for wall attachment, and a secondary amino group can serve as a handle to bind a cargo. Their structures were shown in Scheme 1.

Here, we focus on the diwalled molecular umbrella, which has amphiphilic walls for effective shielding. Cholic acid was

Scheme 1. Structures of Cholic Acid and Spermidine



Scheme 2. Synthetic Route to 5-cf Labeled Molecular Umbrella



first activated with NHS to afford the corresponding NHS ester of cholic acid and then coupled to both terminal amino groups of spermidine to give the diwalled molecular umbrella. 5-cf with high hydrophilicity was selected as a fluorescent label because it was difficult to transport across the biological membrane and because its green fluorescence could be easily detected (*14*). The carboxyl group of 5-cf was preactivated with DCC/HOObt and then coupled to the secondary amino group of spermidine on the molecular umbrella. The synthetic route of 5-cf labeled molecular umbrella was shown in Scheme 2.

Cytotoxicity of 5-cf-mu. To verify that molecular umbrellas could be used for drug delivery vectors, it is important to gain information about its toxicity toward the cells. Here, the cytotoxicity of 5-cf-mu was evaluated in Hela cells by the MTT assay.

The viability of Hela cells after 24 and 48 h treatment with 5-cf-mu at concentrations ranging from 50 to 200 μM was illustrated in Figure 1. 5-cf-mu exhibited low toxicity to Hela cells at concentrations as high as 200 μM following 24 h incubation. Although the concentration of 5-cf-mu from 50 to 200 μM exhibited some inhibition to cells after 48 h incubation, 5-cf-mu showed no toxicity to Hela cells at 25 μM even after 48 h. The MTT assay results thus indicated that the molecular umbrella was a good biocompatible vector.

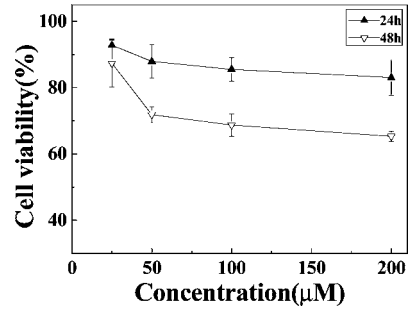


Figure 1. Cytotoxicity of 5-cf-mu toward Hela cells. The cell viability following 24 and 48 h exposure of Hela cells to 5-cf-mu was quantified by the colorimetric MTT assay. All samples were tested in triplicate, and results are given as the average values ± standard.

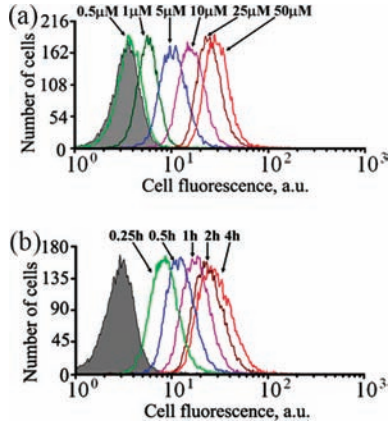

Figure 3. (a) Concentration dependence by FACS analysis. Cells were exposed to 5-cf-mu at the corresponding concentration for 60 min. (b) Incubation dependence by FACS analysis. Cells were exposed to 5-cf-mu (10 μM) for corresponding hours.

Cellular Uptake of 5-cf-mu. Molecular umbrellas may function as novel carriers for hydrophilic therapeutic agents which need transportation into living cells. Previously, many studies demonstrated that molecular umbrellas could transport these molecules across lipid bilayers (*3*−*8, 15, 16*). Herein, we investigated the membrane-penetrating ability of diwalled molecular umbrella into living cells. 5-cf was set as the fluorescently label molecule facilitating the detection of molecular umbrella entering into cells. As shown in Figure 2a, 5-cf-mu (green) was demonstrated to enter into Hela cells by tomography of CLSM as lots of green dots distributed in the cytoplasm district. Note that 5-cf only entered into cells slightly. For quantitative analysis of internalization of 5-cf-mu and 5-cf, cells within the visual field were selected randomly and presented as the ellipse. The average cell fluorescence intensity of 5-cf-mu was about 4.8-fold higher than that of 5-cf (Figure 2b), indicating that molecular umbrellas can greatly facilitate cellular uptake of 5-cf. Moreover, the fluorescence information within cells with different depths indicated that most 5-cf-mu was distributed in the middle of Hela cells (data not shown).

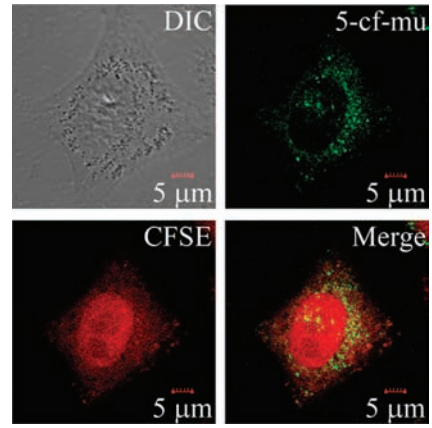

Figure 4. Colocalization (yellow dots) with carboxyfluorescein diacetate succinimidyl esters (CFSE, red) with 5-cf-mu (green) in Hela cells.

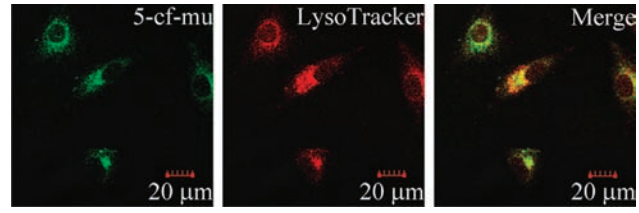

Figure 5. Colocalization of 5-cf-mu (green) and lysosome tracker (red) in Hela cells. Overlay of the two fluorescent layers results in yellow fluorescent emission wherever overlap is complete.

The entrance of 5-cf-mu into cells was further confirmed by FACS. As shown in Figure 3, the cell fluorescence increased gradually along with the concentration and incubation time, respectively. It is thus suggested that the cellular uptake of 5-cf-mu has the characteristics of both concentration- and incubation time-dependence.

Internalization Pathways of 5-cf-mu. Different entry mechanisms may be preferred depending on the application, as the mode of entry affects cell-type specificity, the rate of internalization, and the fate of the compound once inside the cell. In order to design molecular umbrella-based drug delivery systems more rationally, it is important to understand the physiological processing of molecular umbrellas.

Despite molecular umbrellas having been used as carriers of peptides, nucleotides, and oligonucleotides (*7, 15, 16*), the mechanism of transduction responsible for the entry of molecular umbrellas into cells is still poorly understood. In a pioneering work, Mehiri et al. (*9*) ascribed the cellular uptake of exogenously added molecular umbrellas to a diffusion pathway. One of the limitations of this hypothesis is based on the fact that the treatment of NaN_3 and 2-deoxyglucose (to deplete ATP production) causes no significant reduction of molecular umbrella cellular uptake. However, some studies indicated that ATP depletion might specifically impair macropinocytosis process (*17*−*19*), but not the whole endocytic pathway, which is indeed subdivided into four categories: (1) clathrin-mediated endocytosis, (2) caveolae/lipid raft-mediated endocytosis, (3) macropinocytosis, and (4) phagocytosis (*20*). Interestingly, Mehiri et al. (*9*) also found no cellular uptake of molecular umbrellas at 4 °C, which is consistent with the endocytic pathway. Hence, one question might arise regarding whether the transport of molecular umbrellas across cell membranes could be due to the combination of diffusion and endocytosis. In the work reported herein, we sought to answer this question.

To obtain direct visual evidence of the internalization diffusion pathway described by Mehiri et al. (*9*), we first cocultured 5-cf-mu with CFSE, which is a well-known marker

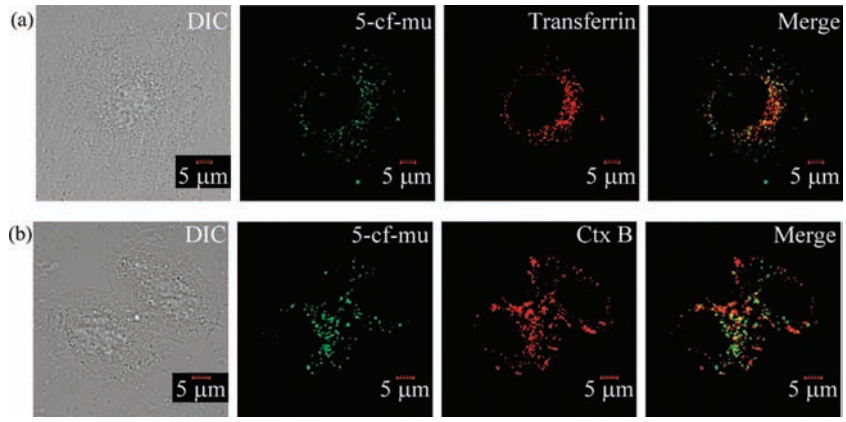

Figure 6. Colocalization of 5-cf-mu with Alexa Fluor 546-labeled transferrin (a) and Alexa Fluor 546-labeled Ctx B (b) in Hela cells, respectively. The emissions for 5-cf and Alexa Fluor 546 are green and red, respectively. Overlay of the two fluorescent layers results in yellow fluorescent emission wherever overlap is complete.

for diffusion (*21, 22*). It is indicated from Figure 4 that 5-cf-mu (green) was partly colocalized with CFSE (red) presenting as yellow dots. Note that CFSE is distributed as a dispersion within both cytoplasm and nucleus, while the distribution of 5-cf-mu was an association between diffuse and puncta. The former is generally considered to be an indication of cellular entry via passive diffusion, while the latter implies that 5-cf-mu might enter Hela cells by a fundamentally different pathway, most probably via endocytosis. It is noteworthy that the distribution of 5-cf-mu is not all the same as that of persulfated molecular umbrellas synthesized by Mehiri et al. (*9*), indicating that the framework of molecular umbrellas might affect their internalization pathway. The above finding inspires us to further investigate the internalization pathways of 5-cf-mu.

Taking into account the fact that the cell membrane comprises not only lipid bilayers but also a lot of specific districts and proteins which might offer the cell membrane the active transport ability via endocytosis for carrying materials into cells, it is reasonable to suppose that molecular umbrellas could undergo endocytosis. To test this hypothesis, we determined whether 5-cf-mu internalized by the cells is indeed in endosomal compartments. LysoTracker Red was used to track endosomes in the cells because it has been extensively shown to partition to acidic compartments within a cell, e.g., lysosomes and endosomes (*23*). The CLSM analysis indicated part of 5-cf-mu (green) in the endosome (red), presented as dots (Figure 5). The FACS analysis further demonstrated that the uptake of 5-cf-mu was considerably inhibited at 4 °C compared to 37 °C (Supporting Information). On this basis, we posit that endocytosis is one of internalization pathways for cellular uptake of 5-cf-mu.

To further explore subcategories of endocytosis, we respectively performed colocalization experiments by using Alexa Fluor 594-labeled transferrin (a positive marker of clathrin-mediated endocytosis) and Alexa Fluor 594-labeled Ctx B (a marker for caveolae/lipid-raft-mediated endocytosis) on Hela cells. It is observed from CLSM images (Figure 6a) that a part of 5-cf-mu (green) colocalized with Alexa Fluor 594-labeled transferrin (red) presented as yellow dots. On the other hand, 5-cf-mu (green) had much colocalization with Alexa Fluor 594-labeled Ctx B (red), presented as yellow dots (Figure 6b).

We also examined the effects of the endocytosis inhibitors on the uptake of 5-cf-mu into the cells by using four different types of chemical inhibitors: (1) NaN_3/2-DG, which is a ATP-depleting agent, for macropinocytosis (*17*−*19*), (2) β-CD, which is a cholesterol-depleting agent, for caveolae/lipid raft-mediated endocytosis pathway (*17, 20, 24*), (3) Noc, which can disrupt the intracellular vesicles transport along microtubule, for caveolae/lipid raft-mediated endocytosis pathway (*25*), (4) CpZ, which can interact with clathrin, for clathrin-mediated endocytosis pathway (*20, 26*). It is demonstrated from Figure 7 that the cellular uptake of 5-cf-mu was not inhibited by pretreating cells with NaN_3/2-DG. This is consistent with Mehiri's result (*9*). In contrast, it is observed that the cellular uptake level of 5-cf-mu from CpZ, β-CD, and Noc pretreated cells dramatically plunged to 72.11%, 26.59%, and 50.29%, respectively. With these results taken together, our experimental data thus suggested that the following uptake pathways are involved in the cell uptake of 5-cf-mu: (1) passive diffuse; (2) clathrin-mediated endocytosis; (3) caveolae/lipid-raft-dependent endocytosis.

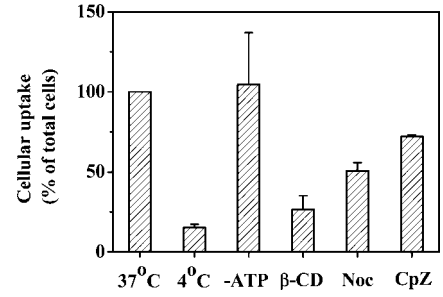

Figure 7. Cellular uptake mechanism of 5-cf-mu as measured by FACS. The inhibitory effect of 4 °C, NaN_3/2-DG, β-CD, or CpZ on the cellular uptake of 5-cf-mu, compared to normal cellular uptake efficiency (37 °C). Means ± SD are indicated ($n = 3$).

CONCLUSIONS

A diwalled molecular umbrella bearing 5-cf as a fluorescent label was synthesized. The molecular umbrella was prepared through coupling of cholic acid to both terminal amino groups of spermidine with the DCC and NHS. Further attachment of 5-cf to the remaining secondary amine on the molecular umbrella was performed with DCC and HOObt to obtain 5-cf-mu. Little toxicity was detected even after 24 h incubation at a high concentration of 5-cf-mu by MTT assay. Confocal microscopy showed that molecular umbrellas were able to transport high hydrophilic agent 5-cf across biological membrane of Hela cells. FACS results indicated that the uptake of 5-cf-mu depends on incubated time and concentration. By analyzing the mechanism of transmembrane movement, we reason that 5-cf-mu transported across the cell membrane in an association pathway between diffusion and endocytosis. All of these results indicate that the molecular umbrella is highly feasible as a smart intracellular delivery carrier for hydrophilic molecules, molecular probes, and therapeutic drugs.

Poly(β-aminoester)s with Pendant Primary Amines for Efficient Gene Delivery

Min Liu, Jun Chen, Ya-Nan Xue, Wen-Ming Liu, Ren-Xi Zhuo, and Shi-Wen Huang*

Key Laboratory of Biomedical Polymers of Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received July 16, 2009; Revised Manuscript Received November 2, 2009

Three hydrolytically degradable poly(β-aminoester)s containing ester bonds in the main chain and primary amines in the side chain, synthesized by Michael polyaddition, were applied to deliver foreign DNA into cells *in vitro*. These linear polycations can condense DNA into small-sized particles with positive surface charge at high N/P ratios. Their high buffer capacity at pH 5−7 facilitated the escape of DNA from the endosome and resulted in efficient gene expression. Under the optimal conditions, poly(β-aminoester)s with a pendant aminoethyl group (**1a**) showed higher transfection efficiencies than branched poly(ethylenimine) (PEI) 25KDa in 293T cells. The effect of side chain structure of the poly(β-aminoester) on transfection efficiency has been investigated, which indicated that the poly(β-aminoester) containing the pendant aminoethyl group was the most efficient carrier for both of 293T cells and COS-7 cells. The combination of hydrolytical degradation, high buffer capacity, relatively low cytotoxicity, and high transfection efficiency suggested that this kind of poly(β-aminoester)s are novel promising nonviral gene carriers.

INTRODUCTION

The safe and efficient delivery of DNA remains a great challenge in the application of gene delivery (*1*−*3*). Nonviral vectors are less efficient than viral vectors; however, nonviral vectors have certain advantages, including ease of production, safety of use, large DNA binding capacity, and low immunogenicity and toxicity (*4, 5*). A wide variety of cationic polymers have been developed for gene delivery, such as poly(L-lysine) (PLL) (*6, 7*), poly(ethylenimine) (PEI) (*8*−*11*), poly(amidoamine) dendrimer (*12*−*14*), etc. These cationic polymers can condense DNA into nanosized particles with positive surface charge; as a result, the polymers can facilitate cellular uptake and protect DNA from nuclease degradation to improve transfection efficiencies (*15*).

Cationic polymers have been widely applied in both *in vitro* and *in vivo* gene delivery (*16*). However, many of the current polymeric gene delivery vectors are nondegradable under physiological conditions. Recent efforts in designing new nonviral gene carriers have partly focused on the introduction of hydrolyzable linkage into the polymer main chains in order to improve biodegradability and decrease toxicity (*17*−*20*). Typically, these polymers contain both an amino group, interacting with polyanionic DNA via electrostatic interaction, and a degradable region, such as a hydrolyzable linkage. The important examples include poly(4-hydroxy-L-proline ester) (*21,22*), cationic polyphosphoester (*23, 24*), poly(β-aminoester)s (*25*−*27*), etc. These hydrolytically degradable polycations are significantly less toxic than branched PEI 25KDa and possess high transfecion efficiencies.

Poly(β-aminoester)s are promising and efficient gene delivery vectors (*25*−*27*), which were first synthesized by Langer et al. They reported a library of more than 2000 poly(β-aminoester)s with a variety of pendant groups including hydroxyl, tertiary amine, etc. About 2% of these polycations showed equal or higher transfection efficiencies than PEI in COS-7 cells. Among the current poly(β-aminoester)s as gene carriers, we have not found poly(β-aminoester)s with pendant primary amines applied in gene delivery. It was expected that the introduction of primary amine into the side chain of poly(β-aminoester)s would enhance the ability to condense DNA and improve biodegradabilty. We have previously described the synthesis and hydrolytical degradation of poly(β-aminoester)s with a tertiary amine in the main chain and a primary amine in the side chain via Michael polyaddition of N-Boc protected diamine to butanediol diacrylate, followed by removing Boc-protective groups under anhydrous acidic conditions (*28*). We report here the ability of poly(β-aminoester)s with pendant primary amines to condense DNA and efficiently deliver foreign DNA into cells.

EXPERIMENTAL PROCEDURES

Materials. Poly(β-aminoester)s (polymers **1a**−**1c**) were synthesized as previously described (*28*), branched PEI 25KDa and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazoplium bromide (MTT) were obtained from Sigma-Aldrich and used directly. Dulbecco's modified Eagle's medium (DMEM), L-glutamine, streptomycin, and penicillin were purchased from Gibco BRL (Grand Island, NY), and fetal bovine serum was purchased from domestic suppliers and used directly. Other reagents and solvents were of analytical grade obtained from domestic suppliers and used directly. 293T and COS-7 cells were purchased from China Center for Type Culture Collection (CCTCC) (Wuhan University) and cultured in DMEM supplemented with 4 mmol L^{-1} L-glutamine, 10% fetal bovine serum (FBS), and antibiotics (100 U/mL penicillin and 100 μg/mL streptomycin) at 37 °C in a humidified air atmosphere containing 5% CO_2.

Plasmid DNA. pGL-3 was used as the luciferase reporter gene and transformed in *E. coli* JM109. pEGFP-C1 was used as the green fluorescent protein gene and transformed in *E. coli* DH5α. Both plasmids were amplified in Luria-Bertani (LB) medium at 37 °C for 12−16 h at 250 rpm. They were purified by a QIAfilter plasmid Giga kit according to the manufacturer's protocol. The quantity and quality of plasmid DNA were analyzed by spectrophotometric analysis at 260 and 280 nm and by electrophoresis in

Published on Web 11/25/2009

0.7% (w/v) agarose gel. The purified plasmid was dissolved in Tris-EDTA (TE) buffer and stored at −20 °C.

Buffer Capacity. The buffer capacity of polymers **1a**−**1c** was determined by acid−base titration as described previously (*28*,*29*). Briefly, polymers **1a**−**1c** were separately dissolved in 10 mL of 150 mmol L^{-1} sodium chloride aqueous solution. The concentration of primary amine in each sample solution was 5 mmol L^{-1}. After the solution was titrated to pH 10 with 0.1 mol L^{-1} sodium hydroxide solution, the solution was titrated to pH 2 with 0.1 mol L^{-1} hydrochloride solution. The pH values were recorded with a Microprocessor pH meter.

***In Vitro* Cytotoxicity Assay.** MTT assay was used to measure the cytotoxicity of polycations against 293T and COS-7 cells. 293T and COS-7 cells were separately seeded into 96-well plates at a density of 6000 cells/well in 100 μL of complete DMEM. When cells achieved 50−60% confluence after 24 h of incubation, 100 μL of polymer solution in DMEM at different concentrations was added to each well and incubated for further 24 h. Then, 20 μL of MTT solution (5 mg/mL in PBS) was added to each well except for the background wells and incubated for further 4 h. The medium was removed, and 150 μL of DMSO was added. The absorbance was measured at 570 nm using a microplate reader (BIO-RAD, Model 550, USA). The percent relative viability in reference to control wells containing complete DMEM without the added polymer was calculated by the following equation (A is absorbance at 570 nm; A_0 is the absorbance of the solution containing cells and complete DMEM without MTT and polymer): relative cell viability (%) = $100 \times (A_{test} - A_0)/(A_{control} - A_0)$.

Formation of Polymer/DNA Complexes. All of the polymer/DNA complexes were prepared fresh before use. Appropriate amounts of polymer solution (in 150 mmol L^{-1} NaCl) were added to the DNA solution in equal volume to achieve desired N/P ratios, then complexes were mixed by vortexing for 5 s and incubated for 30 min at room temperature.

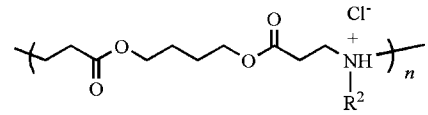
Agarose Gel Retardation Assay. Complexes for this assay were prepared at N/P ratios of 0.5:1, 1:1, 2:1, 5:1, 10:1, 15:1, and 20:1. Various amounts of polymer solution in 150 mmol L^{-1} NaCl were rapidly mixed with 100 ng of pEGFP-C1 in equal volume of 150 mmol L^{-1} NaCl solution, then vortexed for 5 s, and incubated at room temperature for 30 min. Gel electrophoresis was carried out in TAE buffer in 0.7% (w/v) agarose gel containing GelRed at 80 V for 80 min. The gel was visualized by a Vilber Lourmat imaging system (France).

Particle Size and Zeta Potential Measurements. The particle size and zeta potential of polymer/DNA complexes were measured by Nano-ZS (MALVERN Instr.) at 25 °C. The polymer/DNA complexes at various N/P ratios were prepared by adding appropriate volumes of polymer solution (in 150 mmol L^{-1} NaCl) to 1 μg of pEGFP-Cl in equal volume, followed by vortexing for 5 s and incubating at room temperature for 30 min, and then the solution was diluted to 1 mL with 150 mmol L^{-1} NaCl for particle size measurement or pure water for zeta potential measurement.

SEM Imaging of Complexes. Freshly prepared aqueous solutions of polymer/DNA complexes were examined by scanning electron microscopy (SEM, FEI Quanta 200). The complexes at an N/P ratio of 30 were prepared by adding appropriate volumes of polymer solution to 1 μg of pEGFP-C1 in equal volume, followed by vortexing for 5 s and incubating for 30 min at room temperature. Afterward, a drop of solution was dropped onto a glass slide and stored in a desiccator overnight.

***In Vitro* Transfection.** Transfection experiments were carried out in 293T and COS-7 cells. 293T cells were seeded into 24-well plate at a density of 8×10^4/well with 1 mL of complete DMEM containing 10% FBS under 5% CO_2 at 37 °C. The cells were incubated for 24 h to 60% confluence prior to transfection. For the transfection experiment, the media were replaced with fresh DMEM without serum, and then, 100 μL of polycation/pGL-3 or polycation/pEGFP-C1 complexes containing 1 μg of DNA at various N/P ratios prepared as described above were added to each well. Afterward, the cells were incubated for 4 h, followed by replacement of the media with complete DMEM, and the cells were incubated for further 48 h.

Scheme 1. Chemical Structures of Poly(β-aminoester)s with Pendant Primary Amines (1a−1c)



1a R^2=$CH_2CH_2NH_3^+Cl^-$

1b R^2=$CH_2CH_2CH_2CH_2NH_3^+Cl^-$

1c R^2=$CH_2CH_2CH_2CH_2CH_2CH_2NH_3^+Cl^-$

For luciferase expression, after 48 h of transfection with polymer/pGL-3 complexes, DMEM was replaced with 200 μL of cell lysis buffer and freezed−thawed twice. The lysate was centrifuged at 12000 rpm for 3 min, 20 μL of supernatant was mixed with 100 μL of the luciferase assay substrate (Promega), and light emission was measured with a Lumat 9507 luminometer (Berthold, Germany) for 10 s. The relative light units (RLU/mg protein) were normalized against the total protein concentration in the cell extracts, which was determined using a BCA assay kit (Pierce).

For green fluorescent protein (GFP) expression, after 48 h of transfection with polymer/pEGFP-C1 complexes at an N/P of 30, the cells expressing GFP were observed by a reverse fluorescent microscope (IX 70, Olympus, Japan).

To evaluate the effect of serum on gene delivery, we used DMEM containing 10% FBS for transfection of cells with polymer/pGL-3 or polymer/pEGFP-C1 complexes. For transfection in the presence of serum, when the cells achieved 60% confluence, the media were replaced with fresh DMEM containing 10% FBS, and then, complexes at various N/P ratios were added to each well. The other procedure was the same as that described above.

In the case of the transfection of COS 7 cells, cells were seeded into 24-well plates at a density of 5×10^4/well. The other procedure was similar to that of 293T cells.

RESULTS AND DISCUSSION

Characterization of Poly(β-aminoester)s with Pendant Primary Amines (1a−1c). The preparation and characterization of poly(β-aminoester)s (**1a**−**1c**) were reported in our previous work (*28*). The chemical structures of **1a**−**1c** are shown in Scheme 1. The molecular weight and polydispersity of polymers **1a**−**1c** were determined by size exclusion chromatography combined with multiangle laser light scattering. The weight average molecular weights (M_w) of **1a**−**1c** were 1.01×10^4, 8.34×10^3, and 6.68×10^3 with the polydispersity index ranging from 1.20−1.40, respectively.

The degradation kinetics of ester bonds in the main chains of **1a**−**1c**, measured with ^{1}H NMR, demonstrated that the degradation rate of **1b** is the fastest among **1a**, **1b**, and **1c**. The half-lives for ester degradation in **1a**−**1c** in phosphate buffer at pH 7.4 were approximately 144, 48, and 72 h, respectively (*28*). The degradation rate differences among **1a**−**1c** should be attributed to the length of side chains because the main chains of polymers **1a**−**1c** are same.

Buffer Capacity of the Polymer. According to the "proton sponge hypothesis" proposed by Behr et al. (*29*), the buffer

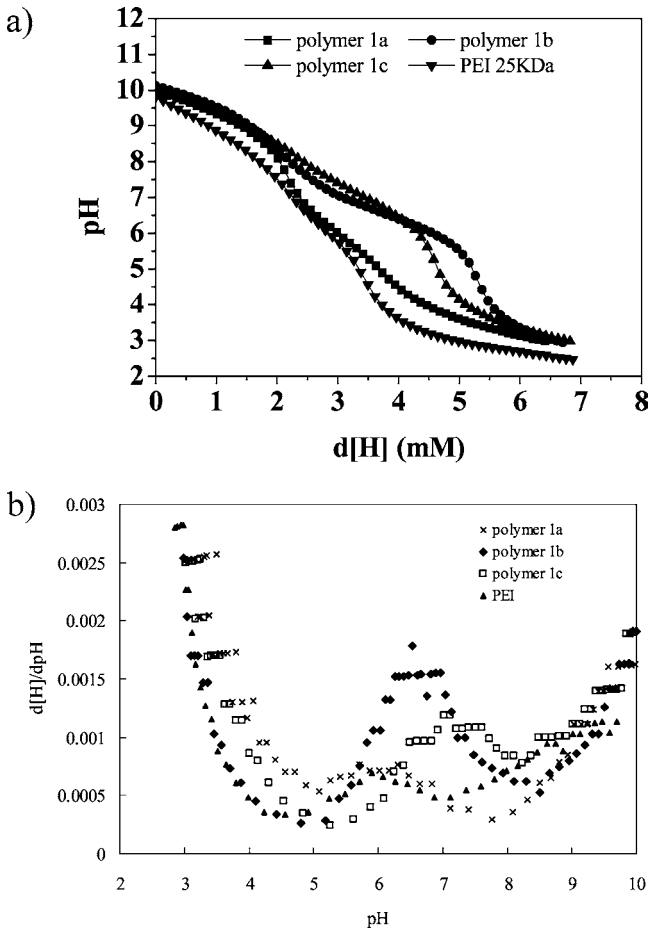


Figure 1. (a) Acid−base titration of polymers **1a**−**1c** in 150 mmol L^{-1} NaCl aqueous solution. Titration curves were obtained by titrating solutions of polymers **1a**−**1c** in 10 mL of 150 mmol L^{-1} NaCl aqueous solution from pH 10 to 3. Branched PEI 25KDa was used as a control. (b) Buffer capacities (d[H]/dpH) of polymers **1a**−**1c** and PEI 25 KDa in solution as a function of pH. Buffer capacities were calculated from potentiometric titration curves according to ref *30*.

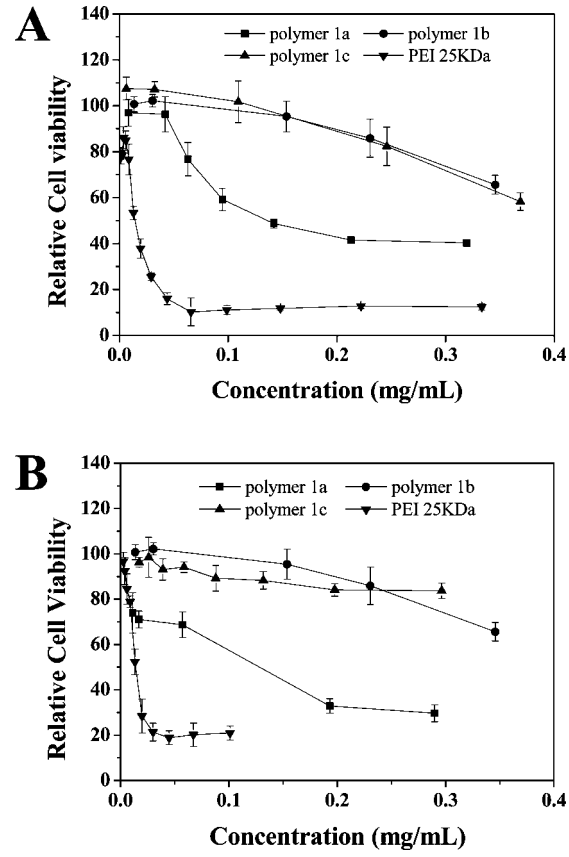

Figure 2. *In vitro* cytotoxicity of polymers **1a**−**1c** against 293T (A) and COS-7 (B) cells. Branched PEI 25KDa was used as a control.

capacity of the polycation at low pH values of 5−7 may play an important role in nonviral gene delivery, which can facilitate the escape of polycation/DNA complexes from endosomes. The buffer capacity of PEI and **1a**−**1c** was determined by acid−base titration. The titration curves are shown in Figure 1a. Buffer capacity (p[H]/dpH) was calculated from acid−base titration data according to ref *30*, which are shown in Figure 1b. We found that the buffer capacity of polymer **1a**−**1c** and PEI 25 KDa changes as a function of the pH values. At pH from 8 to 10, all of polymers **1a**−**1c** and PEI possess high buffer capacity, and there are no significant differences among polymers **1a**−**1c** and PEI. At pH values from 5 to 6, significant differences can be found. The buffer capacity of polymer **1a** was comparable to that of PEI, which was relatively lower than that of polymer **1b**. In contrast, the buffer capacity of polymer **1c** was significantly lower than those of polymers **1a**−**b** and PEI. The high buffer capacity of polycations at pH 5−7 will be beneficial in facilitating endosomal escape of polycation/DNA complexes and improving transfection efficiencies.

Cytotoxicity Assay. *In vitro* cytotoxicity is an important parameter for polycations in gene delivery. The efficacy of a gene carrier is influenced by its toxicity. In this study, the MTT assay, a colorimetric test based on the ability of mitochondrial reductase enzymes in viable cells to reduce MTT to a purple formazan, was carried out to evaluate the cytotoxicity of polymers **1a**−**1c** against 293T and COS-7 cells. Branched PEI 25KDa was used as a control. The results are shown in Figure 2. The cytotoxicity of all polymers was found to be concentration dependent, namely, the cell viability decreased with increasing polymer concentration. Branched PEI 25KDa showed high cytotoxicity against both 293T and COS-7 cells, which was in accordance with the results we observed previously (*12*). Figure 2A shows the cytotoxicity of polymers **1a**−**1c** against 293T cells. The cytotoxicity of polymers **1a**−**1c** was much lower than that of branched PEI 25KDa. In addition, the cytotoxicity of polymers **1b** and **1c** was almost same. The viability of 293T cells incubated with the solution of polymers **1b** and **1c** was about 60% at a concentration of 0.4 mg/mL, while the viability of 293T cells with polymer **1a** was about 50% at 0.4 mg/mL, which was a little lower than that of polymers **1b** and **1c**. Figure 2B shows the cytotoxicity of polymers **1a**−**1c** against COS-7 cells. The viability of COS-7 cells incubated in the solution of polymers **1a**−**1c** at a concentration of 0.4 mg/mL was about 30%, 70%, 90%, respectively. For COS-7 cells, polymers **1b** and **1c** were also less toxic than polymer **1a**, whose toxicity was similar to that in the case of 293T cells.

The cytotoxicity of cationic polymers is possibly caused by the aggregation of polymers on the cell surface via the electrostatic interaction between positively charged polymers and negatively charged sites on the cell, which induces cell membrane damage and leads to cell death (*31*, *32*). Many factors, including molecular weight, charge density (the ratio of amine numbers to polymer molecular weight), type of amines, chemical structures, biodegradation etc., affect the cytotoxicity of polycations. Generally, polycations with high molecular weight and high density of primary/or secondary amine show high cytotoxicity. In addition, the introduction of a biodegradable unit into the polycations reduces their cytotoxicity. In our previous work, we have demonstrated that the degradation rates of **1b** and **1c** are much faster than that of **1a** (*28*). We can conclude that the combination of relatively high molecular

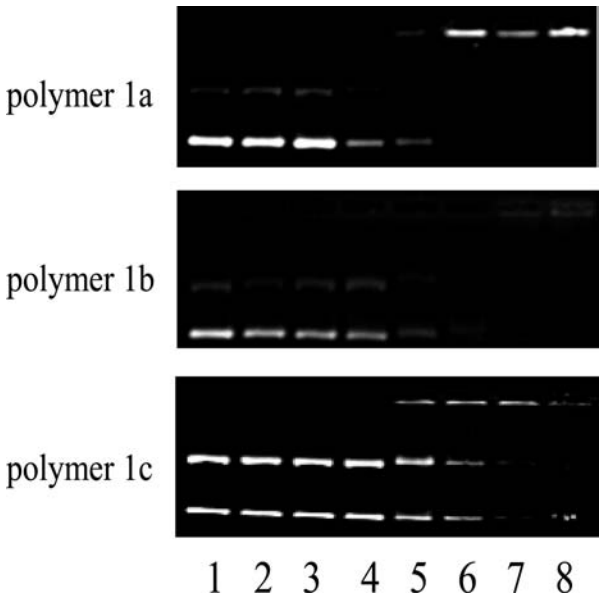

Figure 3. Agarose gel electrophoresis retardation assay of polymer/DNA complexes at various N/P ratios. Lane 1, naked DNA; lane 2−8, N/P ratios of 0.5/1, 1/1, 2/1, 5/1, 10/1, 15/1, 20/1, respectively.

weight, charge density, and slower degradation of **1a** results in the highest cytotoxicity among **1a**, **1b**, and **1c**.

DNA Condensation and Characterization. The ability of polycations to condense DNA into nanoparticles is important for gene delivery. To facilitate efficient gene expression, cationic polymers should strongly condense DNA to protect the DNA against digestion by enzymes, which can improve the transfection efficiency. The interaction of polymers **1a**−**1c** with the pEGFP-C1 plasmid was characterized by the gel retardation assay, particle size and zeta potential measurement, and SEM observation.

Agarose gel retardation assays were performed to study the condensation ability of polymers **1a**−**1c**. As shown in Figure 3, in the case of **1a**, DNA was entirely retained in the wells at the N/P ratio above 5. In contrast, **1b** and **1c** completely retarded the migration of DNA in the gel at N/P ratios above 10 and 20, respectively. The ability to bind and condense DNA followed the order of **1a** > **1b** > **1c**. Polycations with high molecular weight and high charge density often show strong DNA binding ability at low N/P ratios. In this work, the order of DNA binding ability is consistent with that of the molecular weight and charge density of **1a**−**1c**.

The complexation of positively charged polycation and negatively charged plasmid DNA via electrostatic interaction between amino groups and phosphate groups usually results in the formation of small-sized particles. The physical properties of the formed complexes particles, such as sizes and zeta potentials, have great impact on transfection efficiency. Complexes with positive charge and small size are beneficial for cellular uptake and intracellular trafficking. The average sizes of **1a**−**1c**/pEGFP-C1 complex particles at various N/P ratios were measured using dynamic light scattering. As shown in Figure 4, the average diameters of polymer/DNA complexes are dependent on both the chemical structure of polycations and N/P ratios. The average diameters of **1b** and **1c**/DNA complexes at N/P ratios ranging from 10 to 60 are between 400 and 500 nm. N/P ratios had no significant effects on the sizes of **1b** and **1c**/DNA complexes. In the case of **1a**, the average diameters varied between 120 and 480 nm, which decreased with the increase of N/P ratios. In comparison to **1b** and **1c**, the relatively high molecular weight and charge density of **1a** resulted in the formation of polycation/DNA complexes with smaller sizes,

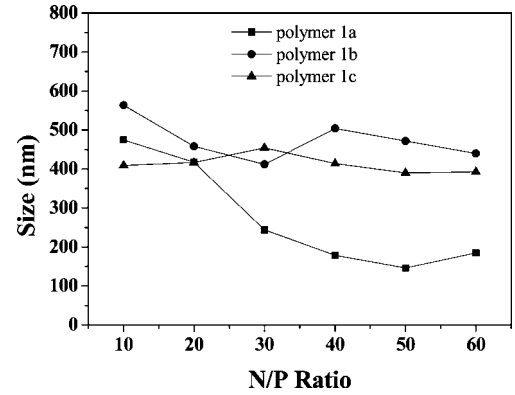

Figure 4. Particle sizes of polymer/DNA complexes at N/P ratios ranging from 10 to 60 in 150 mmol L^{-1} NaCl aqueous solution.

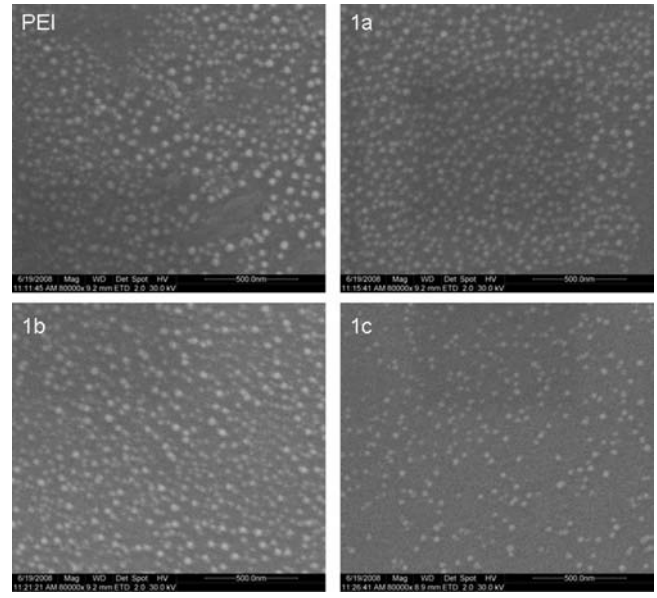

Figure 5. Scanning electron microscopy (SEM, FEI Quanta 200) of polymers **1a**−**1c**/pEGFP-C1 complexes at an N/P of 30, while the branched PEI 25KDa/pEGFP-C1 complex was at an optimal N/P of 10.

which is consistent with the DNA binding ability measured by the agarose gel assay.

The size and shape of **1a**−**1c**/pEGFP-C1 complexes at an N/P ratio of 30 were observed by SEM. PEI/pEGFP-C1 complexes at an N/P of 10, which is optimal for *in vitro* transfection, were measured as a reference. The results are shown in Figure 5. In the cases of all polycations we used in this work including PEI and **1a**−**1c**, the complexes of polycation/DNA were observed to be nanosized and uniform spherical particles. The diameters of PEI/DNA complexes at an N/P ratio of 10 ranged from 30 to 50 nm, whereas those of **1a**−**1c**/DNA complexes at an N/P ratio of 30 ranged from 20 to 40 nm. There was no significant difference in **1a**−**1c**/DNA complexes, which was greatly different from that measured by dynamic light scattering in solution. Similar results have been observed in our previous work (*10*) in the cases of PEI/DNA and cross-linked PEI 800/DNA complexes measured with TEM. The results demonstrated that the weak ability of **1b** and **1c** to bind DNA induced the formation of loose polycation/DNA complexes in solution with relatively large sizes and that the strong ability of **1a** and PEI to bind DNA resulted in the formation of compact complexes with small sizes. In comparison to compact complexes of PEI and **1a**/DNA, the loose complexes of **1b** and **1c**/DNA were easier to collapse to be small-sized particles under

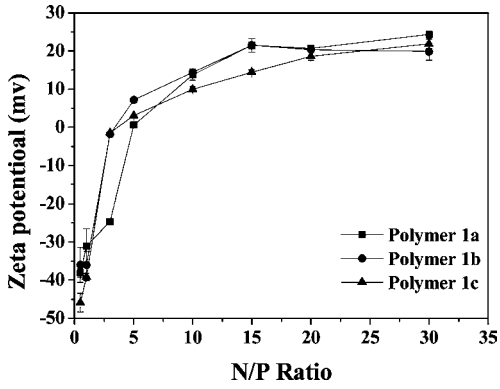

Figure 6. Zeta potentials of polymer/DNA complexes at N/P ratios ranging from 0.5 to 30 in 150 mmol L^{-1} NaCl aqueous solution.

vacuum conditions for SEM measurements. As a result, no obvious difference in the morphologies and diameters of **1a**−**1c** and PEI/DNA complexes was observed by SEM.

Positive surface charge of polycation/DNA complexes can facilitate the nonspecific attachment of complex nanoparticles to the negatively charged cellular membranes and the uptake of polycation/DNA complexes by cells. The zeta potentials of polycation/DNA complexes were measured to assess their surface charge. As shown in Figure 6, at the same N/P ratios, **1a**−**1c**/DNA complexes possessed similar surface charge. At N/P ratios below 5, the zeta potentials of all the complexes are negative, indicating incomplete complexation. With the increase of the N/P ratio, the zeta potential rapidly increased and reached a plateau of about 22 mV, which is a little lower than that of PEI/DNA complexes. The N/P ratios for the plateau zeta potentials of **1a**−**1c** were 15, 15, and 20, respectively. The N/P ratio for the plateau zeta potentials of **1c** is higher than those of **1a** and **1b**, also indicating the weak ability of **1c** to condense DNA. In comparison to PEI/DNA complexes, the moderate surface charges of **1a**−**1c**/DNA complexes are expected to be suitable for reaching a better balance between cellular uptake and cytotoxicity.

***In Vitro* Transfection.** *In vitro* transfection was conducted on 293T and COS-7 cells to evaluate the ability of the polycations **1a**−**1c** to deliver foreign DNA into cells. Branched PEI 25KDa at the optimal N/P ratio of 10 was used as a positive control, and pGL-3 plasmid, expressing luciferase, was used as the report gene.

As shown in Figure 7A, the transfection results revealed that polymer **1a** showed excellent transfection efficiency in 293T cells at the tested N/P ratios from 10 to 60, which was comparable or higher than that of branched PEI 25KDa at the optimal N/P ratio of 10. Luciferase expression (RLU/mg protein) was related to the N/P ratio. Optimized luciferase expression (RLU/mg protein) in 293T cells with **1a**/pGL-3 complexes was 2.27×10^9, which was a little higher than that with PEI/pGL-3 complexes (2.09×10^9). In contrast, **1b** and **1c** showed very low luciferase expression in 293T cells at N/P ratios of 10 and 20, respectively. Although the transfection efficiencies gradually increased with the increase of N/P ratios, they were still lower than that of PEI. The low transfection efficiencies of **1b** and **1c** should be related to the combinational factors including the low DNA binding ability of **1b** and **1c**, the relatively large sizes (about 400−500 nm) of **1b** and **1c**/pGL-3 complexes at the tested N/P from 10 to 60, and rapid hydrolytical degradation of **1b** and **1c** under physiological conditions as described in our previous work (*28*). The degradation of **1b** and **1c** at pH 7.4 is much faster than that of **1a**, especially at the early stage within 24 h. The rapid degradation of **1b** and **1c** is considered to be unsuitable to prevent the incorporated DNA from degradation before entering the cell nucleus.

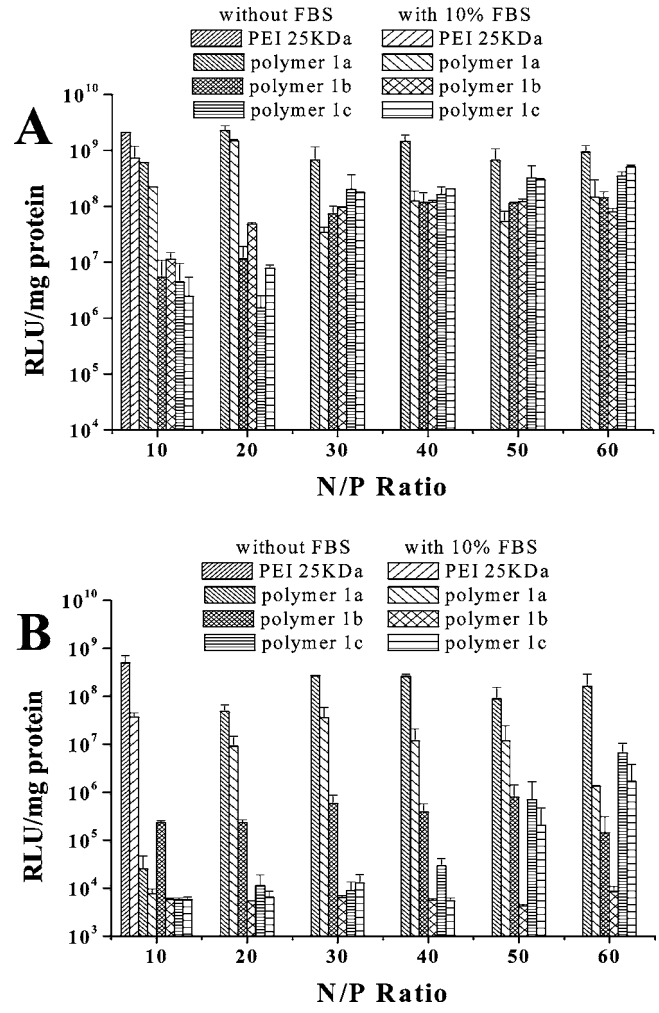

Figure 7. Transfection efficiencies of polymers **1a**−**1c**/pGL-3 complexes in 293T (A) and COS-7 cells (B). Branched PEI 25KDa was used as a positive control.

Similarly, COS-7 cells were transfected with **1a**−**1c** and PEI/pGL-3 complexes. The results shown in Figure 7B indicated that **1a** was the most efficient carrier among **1a**, **1b**, and **1c**. The highest luciferase expression in COS-7 cells with **1a**/pGL-3 complexes at optimized N/P ratios of 30 and 40 was comparable to that of PEI/pGL-3 complexes at an N/P of 10. The effects of N/P ratios on the luciferase expression level in COS-7 cells are similar to that in 293T cells.

Serum protein can hinder cellular uptake and promote aggregation, which often reduces the transfection efficiency (*33*). Transfection experiments were then performed with 293T and COS-7 cells in the presence of 10% FBS. As shown in Figure 7A and B, 10% of serum inhibited luciferase expression in 293T and COS-7 cells with each polycation tested in this work including PEI and **1a**−**1c**. The results illustrated that luciferase expression in 293T cells only slightly decreased, while serum significantly decreased luciferase expression in COS-7 cells at various N/P ratios. However, we also found that luciferase expression with polymer **1a** only slightly decreased both in 293T and COS-7 cells at various N/P ratios, which indicated that **1a**/DNA complexes are less serum-sensitive for *in vitro* transfection.

pGFP Transfection. *In vitro* transfection with **1a**/pEGFP-C1 complexes at an N/P of 30 was then conducted on 293T and COS-7 cells to directly visualize the transfected cells expressing green fluorescent protein (GFP). Branched PEI 25KDa was used as a control. The transfected cells which express GFP were observed by a reverse fluorescent microscope.

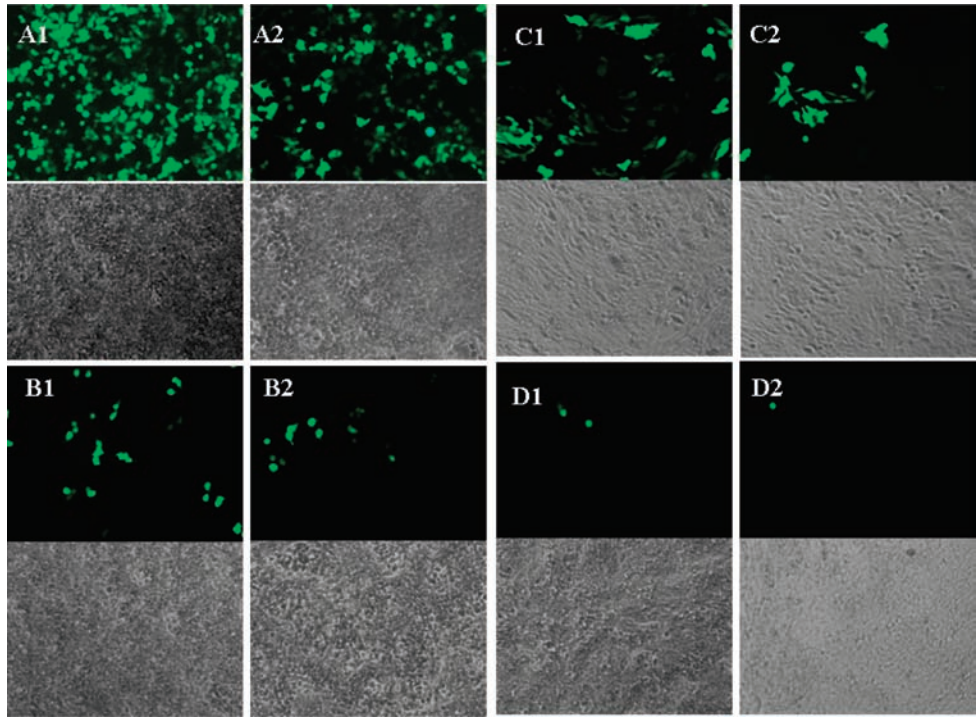

Figure 8. Fluorescent microscope images of 293T cells (A,B) and COS-7 cells (C,D) transfected with **1a**/pEGFP-C1 complexes at an N/P of 30 and branched PEI 25KDa/pEGFP-C1 complexes at an optimal N/P ratio of 10. A1 (PEI), A2 (**1a**), C1 (PEI), and C2 (**1a**) show the transfection without serum, while B1 (PEI), B2 (**1a**), D1 (PEI), and D2 (**1a**) show the transfection in the presence of 10% FBS. Transfected cells were observed by a reverse fluorescent microscope (IX 70, Olympus, Japan; 400×).

The results shown in Figure 8A1 and A2 indicates that the percentage of GFP-expressed 293T cells transfected with **1a**/pEGFP-C1 complexes at an N/P ratio of 30 is only slightly lower than that with PEI/pEGFP-C1 complexes.

Figure 8B1 and B2 shows that the percentage of GFP-expressed 293T cells transfected with PEI and **1a**/pEGFP-C1 complexes in the presence of 10% FBS obviously decreased, which indicated that the serum greatly inhibited the transfection efficiency of PEI and **1a**. In Figure 8C and D, we found a similar trend in the effect of serum on the transfection of COS-7 cells with PEI and **1a**/pEGFP-C1 complexes. In addition, GFP expression in COS-7 transfected with PEI and **1a**/pEGFP-C1 complexes is lower than that in 293T cells, which implied that both PEI and **1a** were cell-dependent for *in vitro* transfection.

CONCLUSIONS

In summary, novel hydrolytically degradable poly(β-aminoester)s with pendant primary amine were evaluated for gene delivery including buffer capacity, cytotoxicity, DNA binding ability, charaterization of polyplexes, and *in vitro* transfection. We have demonstrated that poly(β-aminoester)s with a pendant aminoethyl group (**1a**) show slightly higher gene delivery efficiencies than PEI 25 KDa under optimal conditions, while the IC_{50} of **1a** is 1 order of magnitude higher than that of PEI 25 KDa. The results revealed the potentials of novel hydrolytically degradable polycations in gene delivery and will provide valuable insight into the design of highly efficient and less toxic polycationic gene carriers.

Received July 28, 2009; Revised Manuscript Received October 25, 2009

This study demonstrates a unique, nontranscriptional assay system based on molecular tension of a luciferase artificially appended by protein−protein binding. We hypothesized that an artificially appended molecular tension to a full-length luciferase may diversify the enzymatic activity through a modification of the active site. For the basic probe design, a full-length luciferase was sandwiched between two component proteins of interest. The length of flexible linkers between the components was minimized to exert an efficient molecular tension to the sandwiched luciferase. When N- and C-terminal ends of *Renilla* luciferase 8 were flanked by the ligand-binding domain of human estrogen receptor α (ER LBD) and SH2 domain of Src, named ERS, this simple probe was surprisingly sensitive to estrogens. The luminescence spectra by ERS were largely enhanced by an addition of 4-hydroxytamoxifen (OHT), 17β-estradiol, and genistein. The detection limit of ERS reached 1 nM OHT. Quantum yield (QY) and Michaelis−Menten constant of ERS were found to be 6.3% and 94.3 μM, respectively. The enzymatic activities of ERS are also governed by different types of coelenterazine (CTZ) variants. The two hydroxy groups in CTZ are critical for the enzymatic activities of ERS. This study is the first example that an artificially appended molecular tension to a full-length luciferase can be taken as an optical signature upon molecular imaging. This study also provides new insight into the construction of a new lineage of bioluminescent probes for estimating protein−protein interactions.

INTRODUCTION

Recent revolutionary advances in enzyme manipulation technologies now allow researchers to carry out quantitative examination of molecular dynamics and cell signaling in living subjects (*1*).

Luciferases are nearly ideal reporters for bioanalysis and molecular imaging: (i) The assays are potentially very simple, sensitive, and do not require an external light source or cofactors. (ii) The assay time is usually less than one min, which enables a high throughput analysis. (iii) The assay is cheap, nonhazardous, and broadly applicable to living organisms.

To date, various luciferases have been engineered for determining protein−protein interactions: (i) Bioluminescence resonance energy transfer (BRET) is a potential technique for determining protein−protein interactions on the basis of energy transfer between bioluminescent donor and acceptor proteins (*2*) (*3*) (*4*). (ii) Two-hybrid assay allows a simple determination of protein−protein interactions in living mammalian cells and animals (*5*). (ii) Protein-fragment complementation assay (PCA) is another strategy for determining protein−protein interactions in cell lines, where monomeric luciferases are split into two fragments with resulting temporally inactive portions (*6*) (*7*) (*8*) (*9*) (*10*). The luciferase activity is reconstituted only upon protein−protein interactions. (iii) Recently, a circular permutation (CP) of a dissected luciferase was utilized to determine protein−protein interactions. Original N- and C-terminals of a luciferase are directly linked with a flexible linker, whereas new N- and C-terminals are created in the middle of the luciferase sequence, and modified with proteins of interest (*11*) (*12*). This manipulation exerts a conditional reconstitution of the luciferase activity in response to ligand-activated protein−protein interactions.

Many of the previous studies dissect the luciferases into two fragments for a temporal loss and conditional recovery of luciferase activities. However, this methodology inevitably invades the intrinsic enzymatic property of the luciferase and recovers merely 0.5−5% of the original luciferase activity (*13*) (*14*). The poor absolute luminescence intensities are especially problematic upon application to living animals. Furthermore, the luciferase-dissection strategy requires a sophisticated probe design and a tedious optimization step for deciding a suitable splitting site for the luciferase. These procedures consequently consume time and resources. In our review examinations, many of the previous dissection sites in luciferases are frequently inadequate in other protein−protein interaction cases (*15*).

To address such drawbacks of the conventional methods, we have investigated a simple but efficient bioluminescent probe for determining protein−protein interactions. We initially hypothesized that a luciferase activity may vary according to the molecular tension artificially appended to the full-length luciferase. *Renilla* luciferase 8 (RLuc8) was selected to examine the probability. N- and C-terminal ends of full-length RLuc8 were fused with the ligand-binding domain of the human estrogen receptor (ER LBD)[1] and the Src homology domain 2 of *v*-Src (SH2), respectively. Upon ligand activation, Tyr537 in ER LBD is phosphorylated, and consequently recognized by the adjacent SH2 domain. The ligand-activated ER LBD–SH2 binding appends a molecular tension to the sandwiched full-length RLuc8. The consequent variation in the luciferase activity was surprisingly large enough to be indexed as an optical signature. This probe was named ERS from the consecutive component initials, that is, ER LBD-RLuc8-SH2.

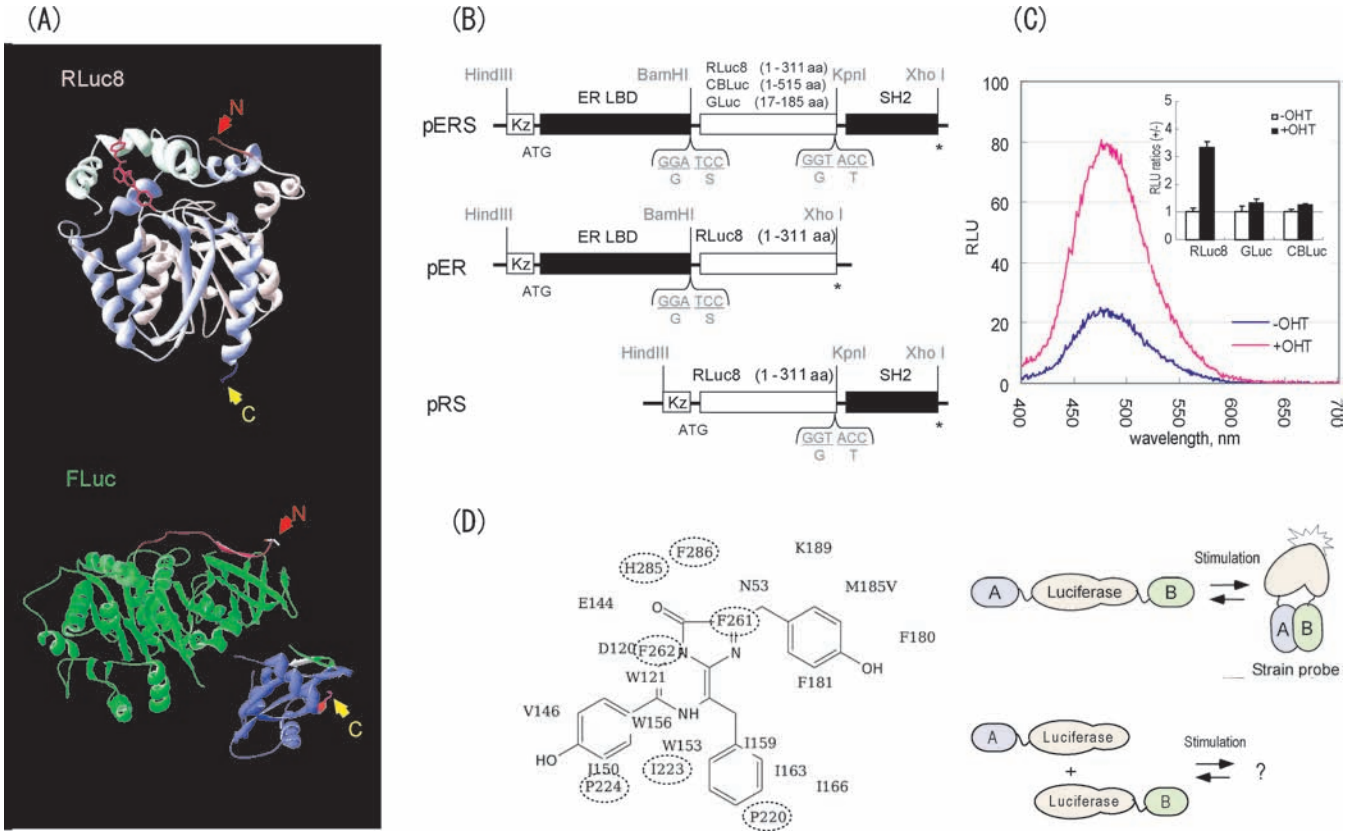

Figure 1. (A) Crystal structure of *Renilla* luciferase 8 (RLuc8; pdb 2PSJ) and firefly luciferase (FLuc). Red and yellow arrows indicate N- and C-terminal ends, respectively. The red chemical in RLuc8 shows coelenterazine (CTZ). The rectangular active site embraces CTZ. An external molecular tension may distort this rectangular frame. (B) Schematic structures of cDNA constructs. Abbrevations: ER LBD, ligand binding domain of human estrogen receptor; RLuc8, *Renilla* luciferase 8; CBLuc, click beetle luciferase red; GLuc, *Gaussia* luciferase; SH2, SH2 domain of Src; Kz, kozak sequence. (C) Variance in the bioluminescence emission spectra before and after addition of 1 μM 4-hydroxytamoxifen (OHT), obtained by a spectrophotometer (F-7000, Hitachi). Inset shows the relative luminescence intensities before and after addition of 1 μM OHT, obtained by a luminometer (Berthold). ER LBD-RLuc8-SH2 (ERS) showed a considerable enhancement in the bioluminescence in response to OHT, whereas ER LBD-GLuc-SH2 (EGS) and ER LBD-CBLuc-SH2 (ECS) did not enhance the luminescence intensities. (D) The chemical structure shows coelenterazine (CTZ) interacting with the active site of RLuc8 (left: a modification of a reference (*18*)). Dotted circles highlight amino acids close to the C-terminal end of RLuc8. An illustration of the working mechanism of ERS in response to a ligand (right). A ligand activates an interaction between proteins A and B, which consequently transforms the sandwiched luciferase. This transformation is not valid in *ER+RS* combination.

The sensitivity and selectivity of ERS to various ligands are initially demonstrated with respect to the sensorial properties. The spectral properties of ERS according to various coelenterazine (CTZ) derivatives are also discussed. Quantum yields (QYs), turnover rates, and Michaelis−Menten constants (K_M) of ERS are reported. Finally, we propose the molecular mechanism of ERS upon sensing estrogens based on a series of control studies.

[1]Abbreviations: ER LBD, the ligand-binding domain of the human estrogen receptor (305−550 AA); SH2, the Src homology domain 2 of a proto-oncogene tyrosine-protein kinase, *v*-Src; ERS, a bioluminescent probe custom-made and named from the consecutive component initials, that is, ER LBD-RLuc8-SH2; *p*Cold I vector, A Coldshock expression vector (Takara) for *E. coli*; *p*Ers, a custom-made plasmid encoding ERS (ER LBD-RLuc8-SH2); *p*Ecs, a custom-made plasmid encoding ECS (ER LBD-CBLuc-SH2); *p*Egs, a custom-made plasmid encoding EGS (ER LBD-GLuc-SH2); *p*Er, a custom-made plasmid encoding *ER* (ER LBD-RLuc8); *p*Rs, a custom-made plasmid encoding *RS* (RLuc8-SH2); COS-7, a mammalian culture cell line derived from African green monkey kidney fibroblast; OHT, a known antagonist of estrogen receptors called 4-hydroxytamoxifen; CTZ, a native luciferin for various luciferases derived from marine animals called coelenterazine; CTZ *hcp*, a synthetic derivative of coelenterazine carrying hydrogen (*h*) at C2 and cyclopentyl (*cp*) group at C8 position; CTZ *cp*, a synthetic derivative of coelenterazine carrying a cyclopentyl (*cp*) group at C8 position; CTZ *fcp*, a synthetic derivative of coelenterazine carrying fluorine (*f*) at C2 and cyclopentyl (*cp*) group at C8 position; CTZ *ip*, a synthetic derivative of coelenterazine carrying iodine (*i*) at C2 and 2-propionyl (*p*) group at C8 position; E_2, an agonist of estrogen receptors called 17β-estradiol; CTZ *400A*, a synthetic derivative of coelenterazine carrying no side chains at C2, C6, and C8 positions, also called DeepBlueC.

EXPERIMENTAL PROCEDURES

Construction of Plasmids. As a template for polymerase chain reaction (PCR), cDNAs encoding the following luciferases were obtained from the corresponding providers: *Renilla* luciferase 8 (RLuc8) was kindly presented by Professor Gambhir (Stanford University); click beetle luciferase red (CBLuc) was purchased from Promega; and *Gaussia* luciferase (GLuc) from Nanolight. cDNAs encoding the human estrogen receptor (hER) and full-length *v*-Src were presented by Professor Umezawa (Tokyo University).

The cDNAs encoding ER LBD and SH2 domain of *v*-Src were generated by PCR using corresponding primers to introduce unique restriction sites, *Hind*III/ *BamH*I and *Kpn*I/ *Xho*I, respectively. Both ends of cDNAs encoding RLuc8, CBLuc, and GLuc were also modified by PCR to introduce specific restriction sites, *BamH*I and *Kpn*I. The cDNA blocks were ligated to make a series of chimera constructs as shown in Figure 1 and subcloned into a mammalian expression vector *p*cDNA 3.1(+) vector (Invitrogen).

A plasmid for *Escherichia coli* expression was constructed as follows: The cDNA encoding ERS was modified by PCR to

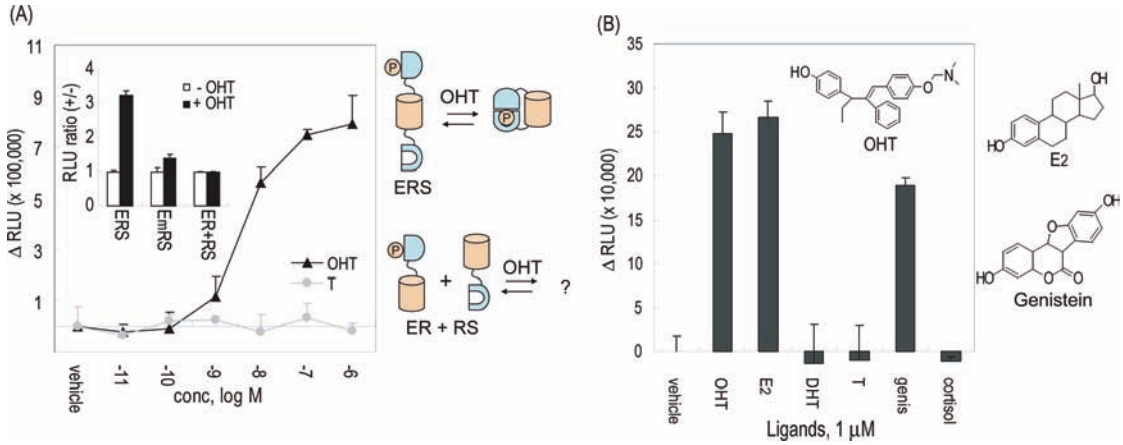

Figure 2. (A) Dose−response curves of ER LBD-RLuc8-SH2 (ERS) in response to steroid hormones. The luminescence intensity reflects the enzymatic activity of transformed RLuc8 in ERS in response to varying concentrations of OHT. Inset shows ligand sensitivity of a series of control probes. E_mRS shows a point-mutated form of ERS at Tyr537, while *ER+RS* means coexistence of the two truncated forms of ERS, that is, *ER* and *RS*. Values were measured in triplicate. The working mechanism of ERS and *ER+RS* was illustrated in the middle column. (B) Ligand selectivity of ERS. The luminescence intensities were compared after activation of ERS with various ligands. Abbrevations: 4-hydroxytamoxifen (OHT), 17β-estradiol (E_2), 5α-dihydrotestosterone (DHT), testosterone (T), genistein (genis).

introduce unique restriction sites, *Sac*I/ *Xho*I, at the 5′- and 3′-ends. The chimera DNA restricted by *Sac*I and *Xho*I was subcloned into the *E. coli* Coldshock expression vector *p*Cold I vector (Takara).

The sequences of the cDNAs were confirmed with a BigDye Terminators v1.1 cycle sequencing kit and a genetic sequencer (ABI PRISM 310 Genetic Analyzer, Applied Biosystems). The consequent plasmids were named *p*Ers, *p*Ecs, *p*Egs, *p*Er, and *p*Rs according to the consecutive component initials. The corresponding probes after expression were named ERS, ECS, EGS, *ER*, and *RS*. The *p*Cold I vector for expressing ERS was named *p*Cold-Ers.

Bioluminescence Spectra of COS-7 Cells Carrying *p*Ers. Variance in the bioluminescence spectra from mammalian COS-7 cells carrying *p*Ers was examined in the presence or absence of 4-hydroxytamoxifen (OHT) (Figure 1C).

For the present experiment, COS-7 cells were cultured in a Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS; Gibco) and 1% penicillin/streptomycin (P/S; Gibco) at 37 °C in 5% CO_2. The cells were seeded in 12-well culture plates, transiently transfected with 2 μg of *p*Ers per well using a transfection reagent, TransIT-LT1 (Mirus), and incubated for 16 h at 37 °C in 5% CO_2 before experiments.

The cells on the 12-well plates were stimulated for 20 min with vehicle (0.1% DMSO) or 1 μM 4-hydroxytamoxifen (OHT). The cells were washed once with phosphate buffered saline (PBS; pH 7.4, 0.01 M), and lysed with a lysis buffer (Promega). The lysates were transferred into a quartz cuvette for monitoring the spectral variance with a spectrophotometer (F-7000, Hitachi) in the presence of coelenterazine native (CTZ).

Ligand Sensitivity of COS-7 Cells Carrying *p*Ers, *p*Ecs, or *p*Egs. Relative ligand sensitivities among ERS, ECS, and EGS were examined in the presence or absence of OHT (Figure 1C Inset).

COS-7 cells carrying *p*Ers, *p*Ecs, or *p*Egs were stimulated with vehicle (0.1% dimethyl sulfoxide (DMSO)) or OHT for 20 min, washed once with PBS, and finally lysed with a lysis buffer for 15 min. The cell lysates were transferred to test tubes, and the subsequent bioluminescence intensities were determined with a luminometer (MiniLumat LB9506; Berthold) in the presence of coelenterazine (CTZ).

The brief procedure for the normalization of bioluminescence was as follows: The RLuc luminescence intensities were expressed as a ratio of relative luminescence unit (RLU), that is, RLU (+)/RLU (−), where RLU (+) and RLU (−) are the luminescence intensities with 1 μg of cell lysate after the cells were incubated with and without a ligand, respectively; the RLU is an amplified value of photon counts generated from the luminometer (arbitrary unit).

Sensorial Properties of ERS to Varying Concentrations of Ligands. Sensorial properties of ERS to ligands were estimated with different concentrations of ligands (Figure 2A). COS-7 cells were transfected with *p*Ers as described in Figure 1C.

The cells cultured on 24-well plates were stimulated with vehicle (0.1% DMSO) or varying concentrations of OHT or testosterone (T) for 20 min. The cells were washed once with PBS and lysed. Ligand-activated ER LBD–SH2 interactions were estimated on the basis of the bioluminescence variance using a spectrophotometer (F-7000, Hitachi). The ΔRLU was calculated as shown in a previous study (*16*): the bioluminescence intensities developed by varying concentrations of a ligand were subtracted by the bioluminescence intensities developed by vehicle (0.1% DMSO). Values were measured in triplicate.

A series of control studies was parallely conducted with COS-7 cells carrying *p*Ers, *p*E_mRS, or both *p*Er and *p*Rs (Figure 2A Inset). The cells were stimulated with vehicle (0.1% DMSO) or 1 μM OHT for 20 min. The subsequent luminescence variances were determined with a luminometer (MiniLumat LB9506; Berthold).

Substrate Dependence of OHT-Activated ERS. Contribution of coelenterazine derivatives to the enzymatic activities of ERS was examined on the basis of the bioluminescence spectra (Figure 3A). COS-7 cells transfected with *p*Ers were cultured on 24-well plates. The cells were stimulated with 1 μM OHT for 20 min, washed once with PBS, and lysed. The lysates were transferred into a quartz cuvette for monitoring the spectral variance with a spectrophotometer (F-7000, Hitachi) in the presence of coelenterazine native (CTZ), coelenterazine *hcp* (CTZ *hcp*), coelenterazine *cp* (CTZ *cp*), coelenterazine *fcp* (CTZ *fcp*), or coelenterazine *ip* (CTZ *ip*). Values were measured in duplicate.

Enzymatic Properties of ERS in the Presence or Absence of OHT. ERS was affinity-column purified for determining quantum yields (QYs) and turnover rates according to ligand stimulations and variation of CTZ derivatives (Table 1).

*p*Cold-Ers was transformed into BL21 (DE3) *p*LysS competent cells (Novagen). The seed culture of the bacterial strain carrying *p*Cold-Ers was initially grown in 10 mL of Luria−Bertani

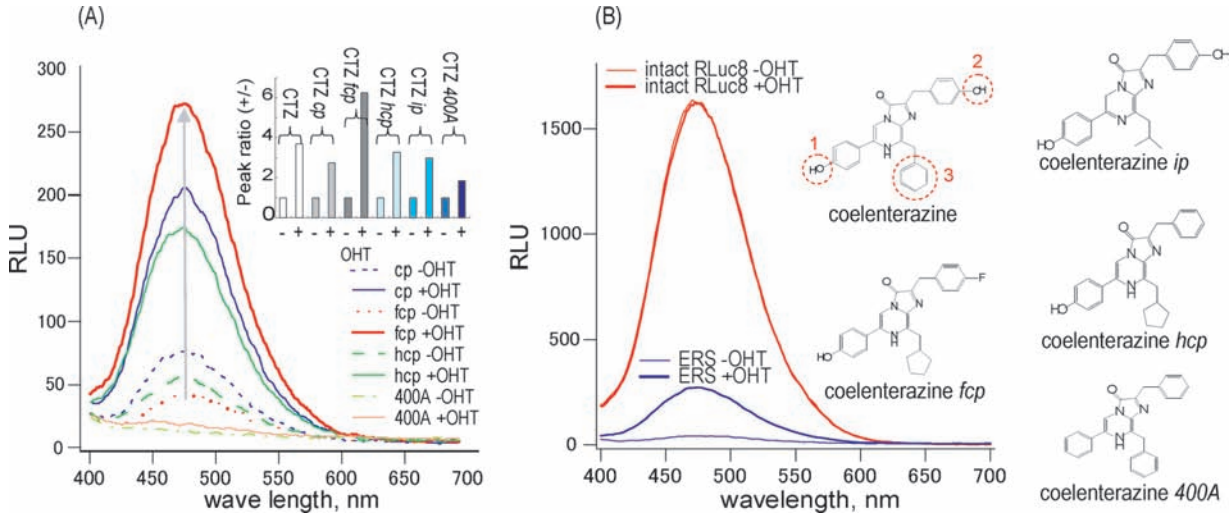

Figure 3. (A) Bioluminescence emission spectra before and after stimulation of 1 μM 4-hydroxytamoxifein (OHT). The spectra generated by ER LBD-RLuc8-SH2 (ERS) were recorded using a spectrophotometer (F-7000, Hitachi). The gray arrow shows the spectrum variance before and after supplementation of 1 μM OHT. Inset shows the peak heights of the spectra before and after addition of 1 μM OHT. Maximal bioluminescence intensities were obtained in the presence of native coelenterazine (CTZ), while coelenterazine fcp (CTZ *fcp*) exhibited the largest signal-to-background ratios. Values were averaged after duplicate determination. The marks "+" and "−" show the presence or absence of 1 μM OHT. (B) Comparison of the bioluminescence emission spectra of ERS and net *Renilla* luciferase 8 (RLuc8) alone before and after stimulation of 1 μM OHT. All of the luminescence spectra were recorded in the presence of CTZ *fcp*. Intact RLuc8 alone was insensitive to OHT, that is, the spectra are almost superimposed (red lines), whereas ERS varied with the luminescence spectra in response to OHT (black lines). The dotted circles show critical side chains of CTZ for interacting with ERS. Dotted circles *1*, *2*, and *3* highlight (i) the *p*-OH of the phenol attached at C6 of native CTZ, (ii) the *p*-OH group on the benzyl substituent at C2 of native CTZ, and (iii) the benzyl group attached at C8 of native CTZ, respectively.

[a] Values were measured in quadruplicate, and standard errors of the mean are given. As the internal standards, quantum yields (QYs) of RLuc and RLuc8 were parallelly estimated with our instrument (Mithras LB940; Berthold). [b] CTZ indicates coelenterazine dissolved in a phosphate buffered saline (PBS; 0.01 M, pH 7.4). [c] K_M means Michaelis−Menten constant. [d] Vehicle represents 0.1% dimethyl sulfoxide (DMSO). [e] OHT and E_2 were dissolved in 0.1% DMSO to make 1 μM (final concentration). [f] Values are from the literature (*21*).

(LB) broth supplemented with ampicillin (0.14 mM) at 37 °C for 16 h. The seed culture was transferred into 400 mL of LB broth in a flask, extensively incubated in a cooled incubator (Taitac) at 15 °C for 24 h after addition of isopropyl β-D-1-thiogalactopyranoside (IPTG; a final concentration of 1 mM). The cells harvested by centrifugation at 5000 *g* were dissolved in 10 mL of Tris-HCl (20 mM, pH 7.6) and crushed with a tip sonicator for cell homogenation. His-tag-fused ERS in the homogenate was purified with a TALON metal affinity resin (Clontech). The eluted ERS solution was dialyzed overnight at 4 °C against phosphate buffered saline (PBS; 0.01 M, pH 7.4). Concentration of the purified ERS was determined using a Bradford reagent (Bio-Rad).

In the presence of an excess level of enzymes, quantum yields (QYs) are defined by N_{tot}/S_{tot}, where N_{tot} and S_{tot} mean the total amounts of emitted photons and consumed substrate, respectively (*17*). If a luciferase level is excess compared to luciferins ($E \gg S$), all of the luciferins should be consumed. In this case, the initial level of luciferin is equivalent to the total consumed luciferin.

For measurements of quantum yields (QYs), ERS was first mock-stimulated or stimulated with vehicle (0.1% DMSO), 1 μM OHT (final concentration), or 1 μM 17β-estradiol (E_2; final concentration). A quantity of 60 μL of ERS (24 pmol) was set on each well of a 96-well plate, which was then loaded in a microplate reader (Mithras LB940; Berthold). At the same time, the injector of the microplate reader was filled with CTZ solution dissolved in 0.01 M PBS (pH 7.4). Immediately after automatic injection of 10 μL of CTZ (0.59 pmol) into each well, the total light emission was integrated until the reaction approached completion (ca. 10 min) at room temperature (22.5 °C).

QYs according to CTZ variants were estimated as follows: 10 μL of CTZ or its derivatives (0.59 pmol per well) was set in each well of the 96-well plate, while the ERS solution was loaded in the injector. After automatic injection of 30 μL of the ERS solution (12 pmol per well) to each well, the total light emission was integrated until the reaction approached completion (ca. 10 min). As internal standards, QYs of RLuc and RLuc8 were estimated in the same instrumental setup for fidelity.

Turnover rate is defined by v_{max}/E_{tot}, where v_{max} and E_{tot} are the maximal reaction rate and the total enzyme amount applied. For the measurement, 40 μL of native CTZ (ranging from 1.2 to 0.075 nmol) was set in each well of a 96-well plate, while PBS-buffered ERS solution was loaded in the injector before

the experiments. After automatic injection of 10 μL of ERS (1 pmol) to each well, the kinetics were immediately recorded every 0.05 s. The initial rates were plotted against the CTZ concentrations applied. The kinetic data were processed using a kinetic curve fitting software GraFit6 (Erithacus Software).

RESULTS

Correlation between Molecular Tension and Bioluminescence Intensity of RLuc8. For an initial evaluation of molecular tension−bioluminescence correlation, a series of luciferases were sandwiched between ER LBD and Src SH2 domain (Figure 1). The examined luciferases include a full-length *Renilla* luciferase 8 (RLuc8; 36 kDa), *Gaussia* luciferase (GLuc; 20 kDa), and click beetle luciferase red (CBLuc; 60 kDa).

Bioluminescence spectra of ERS largely varied before and after supplementation of 4-hydroxytamoxifen (OHT). The peak height (λ_{max}: 486 nm) was surprisingly 3.5 times enhanced by a stimulation of 1 μM OHT. In contrast, both EGS and ECS did not exhibit a considerable variance in the luminescence intensities in the same experimental setup.

The results are interpreted as follows: (i) According to the crystal structural analysis on RLuc8, the active site of RLuc8 consists of amino acids ranging from Asn53 to Phe286 (*18*). A ligand-activated ER LBD−SH2 binding should append a tension to the active site of the sandwiched RLuc8 (Figure 1D). (ii) Molecular structural comparison of ERS with EGS and ECS reveals that globular RLuc8 is appropriate to receive molecular tension, and thus advantageous for determining protein−protein interactions compared to other luciferases.

Verification of Phosphorylation of ER LBD and the Subsequent ER LBD−SH2 Binding. It was previously demonstrated with a Western blot analysis that Tyr537 of ER LBD is phosphorylated by an addition of E_2 and recognized by the SH2 domain of *v*-Src (*9*) (*19*) (*20*). Additionally, we verified the ligand-activated ER LBD−SH2 binding with a point mutant of ERS at Tyr537 to phenylalanine (Y537F), named E_mRS (Figure 2A Inset). E_mRS exhibited a largely diminished signal-to-background (*S*/*B*) ratio (ca. 1.7 times) compared to intact ERS.

As another control study, ERS was split into *ER* and *RS* for exerting a tension-free experimental setup, where *ER* and *RS* mean ER LBD-linked RLuc8 and RLuc8-linked SH2 (Figure 2A Inset), respectively. COS-7 cells carrying both *ER* and *RS* exhibited no variance in the luminescence intensities in response to 1 μM OHT, whereas ERS efficiently enhanced the bioluminescence intensities in response to the same stimulation.

These results in Figure 2A Inset demonstrate that (i) a ER LBD−SH2 binding appends a molecular tension to the sandwiched RLuc8, resulting in an enhancement of the enzymatic activity; (ii) the ER LBD−SH2 binding occurs through a ligand-activated conformation change and phosphorylation of Tyr537 of ER LBD; and (iii) the luminescence intensities enhanced by ER LBD−SH2 binding can be taken as a measure of the estrogenicity of ligands.

Ligand Sensitivity and Selectivity of ERS. Ligand sensitivity and selectivity of ERS were estimated in varying concentrations and types of ligands (Figure 2A,B).

First, COS-7 cells carrying ERS were stimulated with varying concentrations of OHT or testosterone (T) for 20 min, and the consequent elevation of bioluminescence intensities was determined with a luminometer (Minilumat LB9507; Berthold). The luminescence intensities were quickly enhanced from 1 nM OHT and reached a plateau at 1 μM OHT. Fifty percent effective concentration (EC_{50}) appeared at 6 nM OHT.

In addition, we estimated the ligand selectivity of ERS in the presence of various steroids and chemicals. COS-7 cells carrying ERS were stimulated for 20 min with vehicle (0.1% DMSO) or 1 μM of E_2, OHT, 5α-dihydrotestosterone (DHT), testosterone (T), genistein, or cortisol. The consequent bioluminescence intensites by ligands were subtracted by those from COS-7 cells stimulated with vehicle (0.1% DMSO).

The results show that E_2 elevates the bioluminescence intensities, which are almost equivalent with OHT, while genistein called a phytoestrogen also exhibited significant luminescence intensities under the same conditions. On the other hand, the other steroids such as DHT, T, and cortisol did not exhibit any considerable activity for ER LBD−SH2 binding.

Genistein is one of several known isoflavones to interact with animal and human ER, that is, phytoestrogen or dietary estrogens. E_2 is a natural, steroidal agonist of ER, whereas OHT is known as the synthetic antagonist. The luminescence intensities by ligands decreased in the following order: $E_2 \geq$ OHT > genistein $\gg$ DHT = T = cortisol.

The results represent that (i) the estrogenicities of E_2, OHT, and genistein are efficiently converted by ERS to bioluminescence intensities through an intramolecular ER LBD−SH2 binding and (ii) ERS exerts ligand selectivity.

Substrate Specificity of ERS. We fabricated a bioluminescent probe, where an intramolecular ER LBD−SH2 binding appends a molecular tension to the active site of RLuc8. Thus, we speculated that this transformation of the active site may influence substrate specificity. On the basis of this consideration, we examined the substrate specificity of ERS in the presence or absence of OHT (Figure 3). According to the results, the native coelenterazine, CTZ, was superior to other derivatives in the absolute bioluminescence intensities, whereas CTZ *fcp* was beneficial in the *S*/*B* ratio. The absolute luminescence intensities in the presence of native CTZ were ca. four times stronger than those in the presence of the other CTZ derivatives. The peak ratio before and after supplementation of OHT was as large as six in the presence of CTZ *fcp* (Figure 3A Inset). The distinctive luminescence intensities of native CTZ compared to other derivatives corresponded to the results in Table 1.

Enzymatic Properties of ERS. To examine the enzymatic properties of ERS, the quantum yields (QYs), Michaelis−Menten constant (K_M), and turnover rates were estimated by altering the ligands and CTZ variants (Table 1). The measurements were conducted using a luminescence microplate reader (Mithras LB940; Berthold) equipped with an automatic injector.

QY, K_M, and turnover rate of column-purified ERS were 6.3 $\pm$ 1.1%, 94.3 $\pm$ 37.1 μM, and 6.05 $\pm$ 0.51 $\times$ 10^{19} photons/s/mol, respectively. This QY of ERS is approximately equivalent to a previous calculation, that is, 6.9 $\pm$ 0.1%, with intact RLuc8 (*21*). On the other hand, the present K_M value of ERS is 58 times higher than a reference evaluation, that is, 1.6 $\pm$ 0.2 μM with native RLuc8. The turnover rate of ERS is 705 times slower than a previous calculation with intact RLuc8 (Table 1) (*22*). These comparisons demonstrate that enzymatic properties of RLuc8 except the QY are largely impaired by modification with ER LBD (28 kDa) and SH2 (12 kDa).

QYs were similarly estimated after stimulation of vehicle-, OHT-, or E_2-stimulated ERS (Table 1). QYs were found to be invariant by stimulation of the ligands. It is because E_2 or OHT may alter the conformation of ER LBD in the purified ERS. However, ER LBD in purified ERS is not phosporylated because of the deficiency of endogenous protein kinases. This is additional evidence of phosphorylation-mediated ER LBD−SH2 binding.

In addition, QYs of ERS were determined in the presence of a different kind of coelenterazine (CTZ) variant (Table 1). The results exhibited that ERS with native CTZ exhibited approximately four times higher QYs than the other CTZ derivatives, implicating substrate selectivity of ERS to native CTZ. This substrate preference was not significant in a previous study with intact RLuc8 (*21*).

Considering that the chemical backbone of CTZ is similar to that of the variants, the side chains of CTZ should play a critical role in the substrate selectivity of ERS. The basic structure of CTZ is called imidazo[1,2-*a*]pyrazin-3(7*H*)-one. CTZ *400A* is deficient in both (i) the *p*-OH group of the phenol attached at C6 of native CTZ and (ii) the *p*-OH group on the benzyl substituent at C2 of native CTZ. The importance of these functional groups in CTZ was proven with the poorest luminescence intensity and *S*/*B* ratio in the presence of CTZ *400A* as shown in Figure 3A. CTZ *cp* lacks the benzyl group attached at C8 of native CTZ. In practice, CTZ *cp* showed a diminished luminescence intensity and *S*/*B* ratio compared to native CTZ.

Taken together, the present structural comparison between native CTZ and its variants revealed that three side chains are critical for the substrate activity: (i) the *p*-OH of the phenol attached at C6 of CTZ, (ii) the benzyl group attached at C8 of CTZ, and (iii) the *p*-OH group on the benzyl substituent at C2 of CTZ. Their contributions to enzymatic reactions of ERS were significant in this decreasing order: (i) > (ii) > (iii).

DISCUSSION

Molecular Mechanism of the Present Molecular Distortion-Indexed Probe. The phosphorylation of estrogen receptor (ER) at Tyr537 is recognized by the Src homology domain 2 of υ-Src (SH2), known as a nongenomic pathway of ER (*19*) (*20*). We previously demonstrated that both 17β-estradiol (E_2) and 4-hydroxytamoxifen (OHT) phosphorylate Tyr537 of ER LBD using both our custom-made probes and Western blot analysis (*9*). In the present study, when RLuc8 is sandwiched between ER LBD and SH2 with a tight, minimal linker, the enzymatic activity surprisingly depended on the estrogenicity of the stimulators (Figures 1 and 2). Our control studies using both E_mRS and *ER+RS* revealed that this activity variance is mediated by ligand-activated ER LBD−SH2 binding and the subsequent molecular distortion of the active site of RLuc8.

Thus, the molecular mechanism may be explained as follows: (i) A specific ligand phosphorylates ER LBD at Tyr537; (ii) the phosphorylation is recognized by SH2, initiating ER LBD−SH2 binding; (iii) this binding should append a molecular tension to the sandwiched, globular RLuc8. In practice, Asn53, His285, and Phe286 in the active site of RLuc8 are in proximity of N- or C-terminal end of RLuc8 (1−311 AA) (*18*); and consequently, (iv) the molecular tension artificially appended by ER LBD–SH2 binding should vary the enzymatic activities.

In contrast to RLuc8, beetle luciferases such as FLuc consist of two main domains linked with a long flexible hinge (*23*) (Figure 1A). The flexible hinge should relieve the molecular tension appended by ER LBD–SH2 binding. This relaxation of molecular tensions in CBLuc results in poor variance in the bioluminescence intensities of ECS by ligand activations. EGS carrying a full-length GLuc also enhanced little bioluminescence in response to OHT (Figure 1C). The sandwiched GLuc in EGS is the smallest luciferase among those discovered, which may sterically relieve the molecular tension to GLuc.

Interpretation of Enzymatic Properties of ERS. According to a previous measurement, quantum yield (QY) and turnover rate of native *Renilla* luciferase 8 (RLuc8) are ca. 6.9 ± 0.1% and (4.4 ± 0.2) × 10^{22} photons/s/mol enzyme (*21*). This QY approximately corresponds with our calculation with ERS, whereas the literature turnover rate of intact RLuc8 is 7.1 × 10^2 times higher than that of ERS. A fundamental difference between native RLuc8 and ERS is the modification of RLuc8 with ER LBD (28 kDa) and SH2 (12 kDa). Considering that some amino acid membering the active sites are close to the N- and C-terminals of RLuc8 (*18*), the modification of RLuc8 with ER LBD and SH2 is considered to influence the turnover rate rather than QY. In addition, both ER LBD and SH2 inside ERS were prepared by genetic truncation from a full-length ER and Src. The hydrophobic cross sections may have been exposed to the cytosol and would have been easy to impair, aggregate, or decompose.

QYs before and after stimulation of purified ERS with 1 μM OHT or E_2 were almost invariant (Table 1). These results are interpreted as follows: It is known that both OHT- and E_2-bound ER LBDs expose the hydrophobic site to the cytosol and recruit phosphorylation (*24*) (*25*). However, the present *in vitro* system with purified ERS lacks tyrosine kinases. Ligand-activated ER LBD cannot be phosphorylated and thus are not recognized by SH2. This is indirect evidence that ER LBD−SH2 binding occurs via phosphorylation of ER LBD. The other control studies in Figure 2A using E_mRS ("m" abbreviates the mutation in Tyr537) and *ER+RS* and literature comprising a Western blot analysis (*9*) (*19*) (*20*) also support this view.

Determination of Protein Phosphorylation with ERS. Phosphorylation-mediated protein−protein interactions prevail among intracellular signal transduction pathways in mammalian cells (*26*) (*27*). The phosphorylation of Tyr537 is a prerequisite for pivotal actions of ER including (i) estrogen-dependent hyperphosphorylation of the serine residues, (ii) dimerization, (iii) nuclear retention, and (iv) DNA binding (*20*). In particular, a number of effects of estrogens such as kinase activation in the cytosol are so rapid that they cannot be related to direct gene expression. These actions are known as nongenomic actions and mediated through phosphorylation of membrane-associated ERs (*28*). The phosphorylation is conducted by cytoplasmic Src (*19*) (*20*) and thus can be an index of nongenomic actions of ER mediated by Src. On the basis of this knowledge, ERS was designed as a molecular distortion-indexed bioluminescent probe, in which ER LBD−SH2 binding was fabricated to evoke a molecular tension to the sandwiched RLuc8.

Conventional approaches to determine protein phosphorylation heavily depend on the Western blot analysis. However, by using such a conventional method, it is impossible to trace the ligand-activated, rapid dynamics of intracellular protein−protein interactions. The present study represents a competent methodology for tracing ligand-activated protein−protein interactions via molecular distortion.

Sensorial Properties of ERS. Cell-based assays may be categorized into (i) genetic, transcriptional, and (ii) nontranscriptional assays. A genetic, transcriptional assay such as a reporter gene assay requires a long ligand stimulation time until the reporter protein is sufficiently accumulated. In contrast, the present method is characterized as a nontranscriptional assay using an intramolecular transformation of a luciferase. ERS is expressed earlier and localized in adequate intracellular compartments of interest. The luminescence intensity is ready to be developed once the cell is stimulated by a signal. The present data acquisition time, 20 min, is largely shortened in comparison with those of the reporter gene and protein-splicing schemes, which require from 2 to 24 h (*29*). Thus, the present method is applicable to a high-throughput analysis of the activities of bioactive small molecules, which activate temporal, short-term molecular events.

The detection limits of precedent nontranscriptional assays such as FRET-based and single-chain probes to E_2 ranged from 0.1 nM to 10 nM (*9*) (*30*) (*31*). Considering that the detection limit of ERS to OHT is close to 0.1 nM, the present scheme is competent for a sensitive determination of estrogen activities.

Taken together, we have demonstrated a unique, nontranscriptional assay system based on the molecular tension of a luciferase appended by ER LBD−SH2 binding. Full-length RLuc8 was sandwiched between ER LBD and Src SH2 for constructing an integrated molecule-format probe. The working mechanism is supposed as follows: (i) estrogens first activate a phosphorylation of Tyr537 of ER LBD and subsequent intramolecular interaction between ER LBD and Src SH2. (ii) This

binding triggers a distortion of the active site of full-length RLuc8. (iii) This molecular tension results in an enhancement of the luciferase activity. Modification of RLuc8 with ER LBD and Src SH2 interestingly decrease the turnover rate rather than the QY. ERS exhibited substrate selectivity to native CTZ, and was as sensitive as 1 nM OHT. The present strategy for determining phosphorylation and the consequent molecular distortion may be utilized in evaluating a broad range of ligand-mediated protein−protein interactions. Future studies should be directed for investigating an optimal combination of luciferases and a pair of interacting proteins, where distortion of the active site of luciferases may exert significant color changes and sensitive intensity variances.

Polymeric Phosphorylcholine−Camptothecin Conjugates Prepared by Controlled Free Radical Polymerization and Click Chemistry

Xiangji Chen, Samantha McRae, Sangram Parelkar, and Todd Emrick*

Polymer Science & Engineering Department, 120 Governors Drive, University of Massachusetts, Amherst, Massachusetts 01003.
Received July 31, 2009; Revised Manuscript Received October 9, 2009

Novel polymer−drug conjugates, consisting of zwitterionic poly(methacryloyloxyethyl phosphorylcholine) (polyMPC) as the polymer component, and camptothecin (CPT) as the drug, were prepared by two methods. In one case, CPT was transformed by acylation into a functional initiator for copper catalyzed atom transfer radical polymerization (ATRP), and polyMPC was grown from this therapeutic initiator. In the other case, a one-pot ATRP-"click" conjugation strategy was employed to synthesize novel polyMPC structures containing multiple copies of the drug pendant to the zwitterionic polymer chain. The latter method allows polyMPC-*graft*-CPT conjugates to be prepared with a high weight percent drug loading (up to 14% CPT) with excellent solubility in pure water (>250 mg/mL). The linkage chemistry chosen between the polyMPC backbone and the pendant drugs proved critically important for assuring drug release within a time frame reasonable to consider these structures as a platform for injectable cancer therapeutics. Liberation of the drug from the polymer backbone was monitored by high-performance liquid chromatography, using size-exclusion and reverse-phase columns, and the toxicity of the polymer−drug conjugates was examined in cell culture against breast (MCF7), ovarian (OVCAR-3), and colorectal (COLO 205) cancer cell lines.

INTRODUCTION

Small molecule antitumor agents used clinically often display poor pharmacokinetics, undesired toxicity and side effects, and poor water solubility that presents delivery difficulties. Numerous chemotherapeutic drugs used today have a relatively low therapeutic index, or therapeutic ratio, described as the lethal dose divided by the therapeutic dose (LD_{50}/ED_{50}). In essence, therapeutic benefits are offset by detrimental side effects. Conjugation of chemotherapeutics to water-soluble polymers can greatly enhance their aqueous solubility and ease of administration, and further reduce side effects toward improving therapeutic efficacy by altering pharmacokinetics. The underlying *in vivo* characteristics of polymer drugs that lead to their beneficial effects are described by the enhanced permeation and retention (EPR) effect (*1*), which provides for a passive and selective uptake of the polymer-bound drugs into tumor tissue, and retention in that tissue due to a characteristic poor lymphatic drainage.

Effective polymer therapeutics requires the use of biocompatible polymers with high water solubility and biocompatibility. Poly(ethylene glycol) (PEG) has been conjugated to numerous therapeutic protein and peptide drugs to enhance their therapeutic efficacy, such as erythropoeiten (EPO) and granulocyte-colony stimulating factor (G-CSF), and interferon (IFN). PEGylation increases the apparent size of the proteins and peptides (thereby reducing the rate of renal clearance), shields them from proteolytic enzymes, and improves their pharmacokinetic profile (*2*). Advantages stemming from PEGylation have led to the development of new and improved medicines, such as the PEGylated proteins PEG-Intron (PEGylated Interferon α-2b) and Pegasys (PEGylated Interferon α-2a) for the treatment of Hepatitis C (*3*). PEGylation also offers opportunities to improve small molecule drug delivery, needed for example in chemotherapy. Prominent among PEGylated cancer drug candidates is camptothecin, for which PEGylated versions show modestly enhanced circulation time and reduced side effects (*4*). PEGylated camptothecin, described by Enzon, Inc., as Prothecan, consists of a 40 000 g/mol PEG chain with camptothecin at each chain end, connected by ester linkages at the C-20-OH position of the drug (*5*). The chemotherapeutic agent doxorubicin (DOX) has also been improved by PEGylation, including, for example, by linear PEG conjugation (*6*), as well as through elegant architectures such as "bow-tie" dendrimers (*7*), with the resulting DOX-polymer therapeutic displaying increased water solubility, decreased toxicity, and enhanced specificity due to the action of the EPR effect.

Phosphorylcholine-containing polymers, such as poly(methacryloyloxyethyl phosphorylcholine) (polyMPC), are among the most biocompatible polymers known. PolyMPC has been used extensively in bulk materials and as coatings, for contact lenses and blood-contacting devices, for which a high level of biocompatibility and resistance to protein adsorption is required (*8*−*14*). As polyMPC has a decidedly lower commercial availability than functional PEG-based derivatives (even the MPC monomer is not readily available), its use in conjugation chemistry toward polymer therapeutics has been limited to only a few recent examples. However, polyMPC shows excellent promise in injectable therapeutics, having been conjugated recently to therapeutic proteins, such as EPO and G-CSF, using end-functional derivatives prepared by atom transfer radical polymerization (ATRP) (*15*). Such structures were shown to possess in vivo pharmacokinetic profiles superior to PEGylated proteins (*16*).

Living free radical polymerization techniques, such as ATRP (*17*−*20*) and reversible addition−fragmentation chain transfer (RAFT) (*21, 22*), enable the preparation of well-defined polyMPC−drug conjugates with diverse architectures that cannot be achieved by conventional PEGylation. In particular, through covalent grafting to polyMPC copolymers, a very high drug loading can be envisaged, whereas PEGylation chemistry restricts covalent drug attachment to the polymer chain end(s). It should be noted that physical encapsulation of drugs using

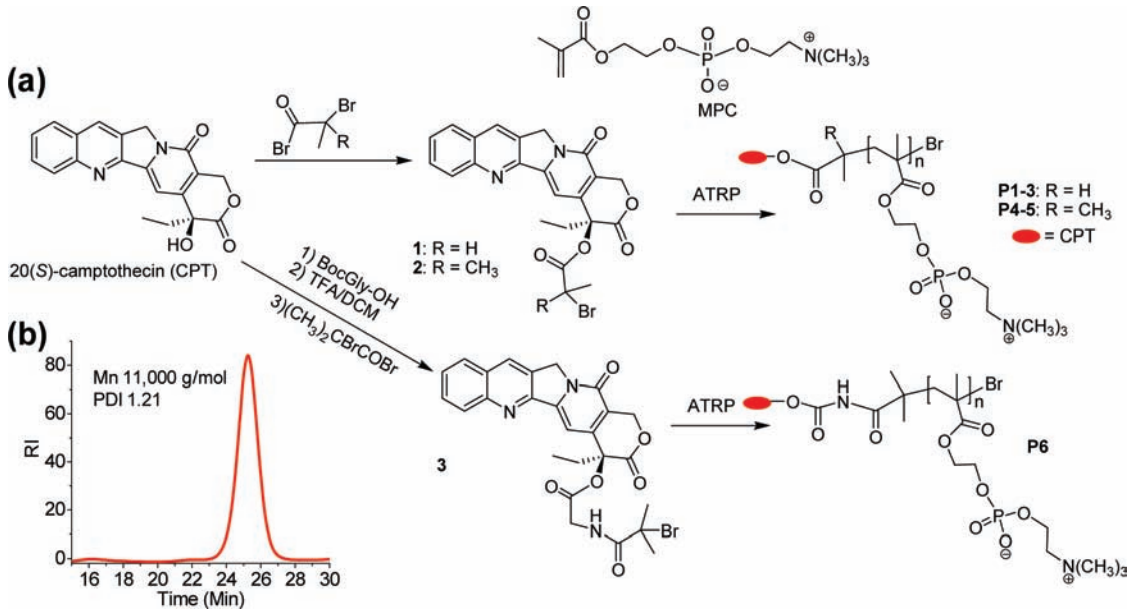

Figure 1. (a) Synthesis of ATRP initiators **1**, **2**, and **3**, and CPT-terminated polyMPC structures; (b) aqueous GPC trace of CPT terminated polyMPC P2.

polyMPC-based micelles has been reported, in which self-assembly of polyMPC copolymers gives micelles that sequester drugs in the hydrophobic core (*20, 21, 23*−*25*). For example, cholesterol-polyMPC amphiphiles were synthesized and tested as a novel drug delivery system, incorporating adriamycin (ADR) in the micelle core (*26*). These micelles released ADR in a manner that was controlled by polyMPC molecular weight and drug concentration.

Here, we describe the preparation of polyMPC copolymers tailored for Cu(I)-catalyzed Huisgen 1,3-cycloaddition of azides and alkynes, a type of "click" chemistry that has recently permeated small molecule (*27*−*29*), dendrimer (*30*), and polymer synthesis (*31, 32*). The efficiency and regioselectivity of the azide−alkyne click reaction, combined with its tolerance toward a diverse range of functionality, has enabled the preparation of novel, complex materials (*33, 34*). Well-defined functional materials have also been synthesized by combining Cu(I)-catalyzed ATRP with click chemistry, such as star-shaped polystyrene (*35*) and glycopolymers (*36*). Here, we exploit the advantages of click chemistry for bioconjugation and polymer therapeutics, providing a robust triazole cycloadduct, good tolerance to aqueous conditions and functionality present on CPT, and the high yields that enable the generation of such materials in appreciable quantities.

The natural alkaloid 20(*S*)-camptothecin (CPT) was first isolated from the Chinese tree *Camptotheca acuminate* in the 1960s (*37*). CPT shows potent anticancer activity over a broad range of cancer cells (*38, 39*), but has poor water solubility (2.5 μg/mL) and high toxicity that has limited its clinical use. The more water-soluble CPT derivatives, Topotecan and Irinotecan, were approved in 1997 by the U.S. Food and Drug Administration (FDA) to treat some forms of ovarian and colon cancers. However, like CPT, the efficacy of these derivatives is compromised by opening of the E-ring lactone, giving the corresponding carboxylate at physiological pH (*40, 41*). Binding of the carboxylate to serum albumin contributes to the observed toxic side effects. In order to help solubilize CPT, its conjugation to water-soluble polymers has been explored, especially by acylation at the 20-OH position; this carries an added benefit of stabilizing the ring-closed (lactone) form of the drug (*42*). Water-soluble polymers such as poly(ethylene glycol) (PEG) (*5, 43*), poly-*N*-(2-hydroxypropyl)methacrylamide (HPMA) (*44, 45*), poly(L-glutamic acid) (PG) (*46*−*48*), cyclodextrin-based polymers (*49, 50*), and PEG-grafted polyesters (*32*) have been used to conjugate CPT; these polymer−CPT conjugates show increased in vivo efficacy, over CPT itself, to varying degrees.

Our aim is to apply click chemistry methodology to CPT conjugation on the polyMPC backbone, using an acylated and azide-modified form of CPT that gives polyMPC−CPT conjugates with high drug loading and potential for future integration into CPT-based injectable cancer therapeutics. To first demonstrate the compatibility of CPT with ATRP conditions, we functionalized CPT with propionyl bromide and isobutyryl bromide, giving CPT-ATRP initiators for polymerization of MPC (Figure 1). This approach gives CPT−polyMPC conjugates (i.e., having one drug per chain). With that demonstration in hand, we sought to prepare polyMPC copolymers in which CPT is integrated into the structure as pendant groups (Figure 2). The latter strategy permits control over drug loading, by altering the average number of CPTs on the polymer backbone through variation of the feed ratio of the protected alkyne monomer. Different drug release rates were achieved by incorporating different linkers between CPT and the polyMPC backbone. Finally, cell culture experiments were performed to test the activity of the conjugates in vitro with a variety of cancer cell lines.

RESULTS AND DISCUSSION

Synthesis of CPT-Terminated polyMPC. CPT-ATRP initiators **1** and **2** were synthesized as shown in Figure 1. The 20-OH group of CPT was acylated with 2-bromopropionyl bromide and 2-bromoisobutyryl bromide in the presence of *N*,*N*′-diisopropylethylamine (DIPEA) and 4-*N*,*N*-(dimethylamino)pyridine (DMAP) in CH_2Cl_2. A typical reaction mixture was stirred at 0 °C for 1 h, then at room temperature for 1 h, to give compounds **1** or **2** in ∼75−85% yield, respectively. In addition to CPT initiators **1** and **2**, glycine-linked initiator **3** was prepared by reacting BocGly-OH with CPT in the presence of *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC). Boc-removal with trifluoroacetic acid (TFA), and reaction of the liberated amine with 2-bromoisobutyryl bromide, generated **3** in 62% yield.

[a] N_{MPC}, targeted number of MPC monomer units per polymer chain; diameter, solution size as determined by dynamic light scattering (DLS).

Polymerizations of MPC using these CPT-ATRP initiators were performed with a Cu(I)Br/bipyridine catalyst/ligand system in DMSO−MeOH mixtures at room temperature. Monomer conversion was monitored by ^{1}H NMR spectroscopy, integrating the vinyl protons of MPC against the methyl and methylene protons of the polymer backbone, using signals at 5.6 ppm (monomer CH_2═C), 6.1 ppm (monomer CH_2═C), 1.4−2.1 ppm (polymer CH_2), and 0.5−1.2 ppm (polymer CH_3). The CPT−polyMPC conjugates were isolated by precipitation in tetrahydrofuran (THF), and purified over a short column of silica gel to remove residual copper. The DMSO−MeOH mixture was chosen to provide solution homogeneity throughout the course of the reaction (the initiators are soluble in DMSO and the polymer in MeOH). Good initiator solubility is critically important for enabling clean polymerization kinetics to give polymer products with low PDI values. Characteristic of a controlled polymerization, the CPT-terminated polyMPC structures obtained displayed narrow PDI values (∼1.2, as seen in Figure 1) over a range of molecular weights from 6 to 17 kDa (Table 1), and number-average molecular weights (M_n) in agreement with monomer-to-initiator ratios (as judged by aqueous gel permeation chromatography (GPC) against PEO calibration standards). Initiators **1** and **2** gave higher initiation efficiency than **3**, which required longer reaction times (48 h) and gave higher-than-targeted molecular weights and PDI (>1.3). This observation is consistent with literature reports on ester vs amide-containing ATRP initiators (*51, 52*).

CPT-terminated polyMPC structures are highly water soluble, as the hydrophilic polymeric zwitterionic structure easily solubilizes the hydrophobic CPT end-group. Preliminary dynamic light scattering (DLS) results suggest that dilute solutions of CPT-terminated polyMPC do not exhibit significant aggregation (i.e., are essentially molecularly dissolved), with estimated solution diameters of 8 nm or less (Table 1). ^{1}H NMR analysis of CPT-polyMPC in CD_3OD showed broad and weak aromatic CPT signals, in the range 7−9 ppm (Supporting Information-Figure S1). Poor local solvation of the hydrophobic CPT component of the conjugate is likely responsible for this broadening, which precludes a reliable molecular weight estimation by NMR spectroscopic end-group analysis. TEM experiments were also performed on the CPT-polyMPC polymers, providing visualization of small discrete structures of ∼13 nm diameter.

PolyMPC-*graft*-CPT Copolymer Synthesis. With confirmation that CPT can be used effectively in conjunction with ATRP conditions, and considering our prior work that demonstrated the amenability of CPT to click chemistry (*32*), we prepared polyMPC-*graft*-CPT conjugates by combining these synthetic methodologies. For this, we chose copolymerization of MPC with trimethylsilyl (TMS)-protected propargyl methacrylate (TMS-PgMA), prepared from 3-TMS-propargyl alcohol and methacryloyl chloride (*36*). However, this method proved unsatisfactory, as the ethyl 2-bromoisobutyrate initiated ATRP copolymerization of MPC and TMS-PgMA gave copolymers with high PDI (nearly 2), and often multimodal elution peaks by GPC. Moreover, ^{1}H NMR spectroscopy of these copolymers indicated a loss of the TMS protecting groups, likely the result of copper(I) acetylide formation during polymerization. Similar TMS deprotection and copper(I) acetylide formation has been observed by others in polar organic solvents as well (*53*). This undesired side reaction promotes interchain coupling or even light cross-linking, and control experiments showed that the TMS protecting group was lost completely when TMS-PgMA was stirred in solution under typical ATRP conditions.

Considering the role of copper(I) acetylide as an intermediate in the Cu(I)-catalyzed Huisgen azide−alkyne click cycloaddition, we attempted to perform the ATRP and click reactions

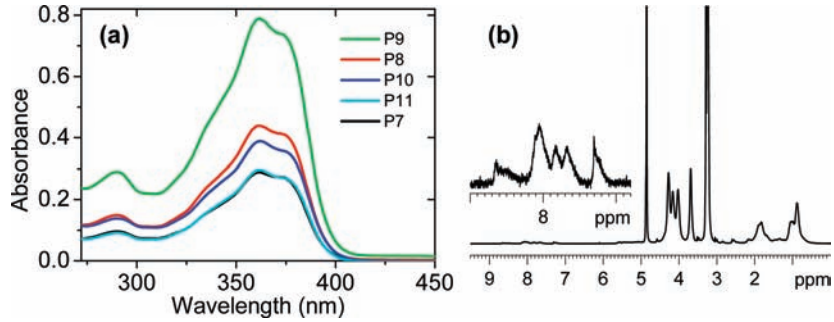

Figure 3. (a) UV/vis absorbance of the polyMPC-*graft*-CPT copolymers at 1 mg/mL in 1:1 DMSO/MeOH solution; (b) ^{1}H NMR spectrum of P7 in CD_3OD.

Table 2. PolyMPC-*graft*-CPT Copolymers Prepared by One-Pot Procedure[a]

polymer	N_{CPT}	CPT-*Z*-N_3	target CPT wt %	monomer conversion	M_n (kDa)	PDI	diamter (nm)	UV Cal. CPT wt %	M_n' (kDa)	PDI′
P7	1.4	**6**	5%	94%	5.2	1.27	5.3	5.1%	6.8	1.17
P8	3	**6**	10%	96%	5.5	1.25	5.5	7.7%	7.5	1.16
P9	5	**6**	15%	>98%	5.1	1.36	5.7	13.8%	7.5	1.17
P10	3	**7**	8.5%	>98%	13	1.31	9.3	7.0%	15	1.18
P11	3	**8**	8.5%	>98%	7.0	1.26	6.8	5.1%	9.0	1.16

[a] N_{CPT}, number of CPT groups per polymer chain; CPT-*Z*-N_3, CPT azide compounds varying linker, *Z*; Conversion, average conversion of both monomers; M_n' = number-average molecular weight of polymer after CPT cleavage from the polymer; PDI′ = PDI of polymer after CPT is cleaved from polymer by hydrolysis.

simultaneously, by introduction of CPT-azide at the outset of the polymerization. This one-pot ATRP/click reaction, shown in Figure 2a, used reaction conditions similar to those we employed to prepare the CPT-terminated polyMPC conjugates. Monomer conversion was monitored by ^{1}H NMR spectroscopy, and cycloaddition was followed by disappearance of the CPT-azide N═N═N stretching signal at ~2100 cm^{-1} in the FTIR spectrum. The polyMPC-*graft*-CPT conjugates prepared in this fashion were purified by precipitation into THF, followed by passage over a short plug of silica gel in mixed solvents.

The polyMPC-*graft*-CPT copolymers were characterized by aqueous GPC as shown in Figure 2 and NMR spectroscopy as shown in Figure 3. The PDI values of the copolymers obtained by this one-pot procedure were slightly higher than the CPT-terminated polyMPC conjugates, in the range 1.25−1.36. A homogeneous distribution of CPT functionality throughout the polymer molecular weight distribution was confirmed by overlaying the UV and RI traces obtained from GPC characterization (Supporting Information Figure S3). Aqueous solution sizes of these structures were also characterized using dynamic light scattering (DLS), showing the copolymers as largely nonaggregated, in which the hydrophilic polymers can be expected to form a corona around a collapsed core of hydrophobic CPT groups. Up to 20 mg/mL, the highest concentration tested, the graft copolymers showed a narrow diameter distribution of less than 10 nm, as shown in Figure 2c.

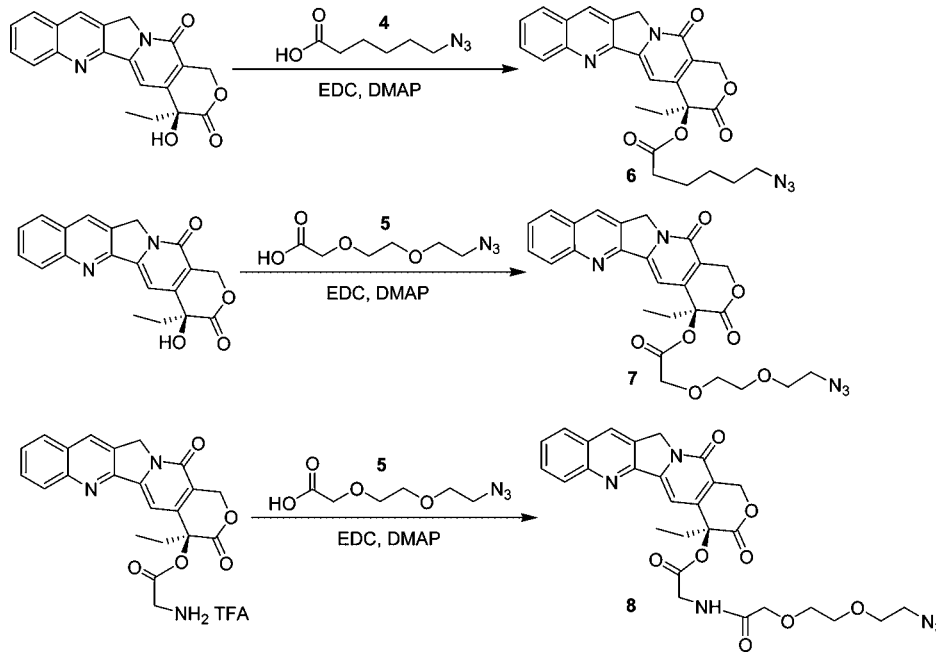
We found that CPT loading levels on the polyMPC backbone could be varied easily by adjusting the MPC/TMS-PgMA/CPT ratio, as exemplified by the samples listed in Table 2, containing different levels of CPT loading. Importantly, PDI control was achieved at CPT loadings up to 14 wt % (compare this to SN-38-PEG 4-arm stars containing 3.7 wt % CPT (*54*)), and the aqueous solubility of this highly drug-loaded polyMPC structure was excellent (>250 mg/mL, or >35 mg/mL of CPT). The lactone form of CPT alone has a solubility of 2.5 μg/mL; thus, the polyMPC framework provides orders-of-magnitude greater solubility. Aqueous solutions of these conjugates exhibit viscosities that qualitatively resemble pure water, a notable difference from PEGylated drugs that often exhibit an undesirably high solution viscosity. The strongly hydrated zwitterionic moiety affects a wide variety of properties, from solubility to sliding friction (*55*), making these structures appealing for many biological applications including cancer drug delivery.

The GPC-estimated molecular weight values of these polyMPC-*graft*-CPT copolymers (calibrated against linear PEO standards) were lower than expected theoretically, suggesting a possible effect of intramolecular collapse of the hydrophobic pendant CPT groups in aqueous solution, perturbing solution size relative to PEO standards. Interestingly, when the grafted CPT groups were cleaved from the polyMPC-*graft*-CPT copolymers, using 1 N NaOH solution, the GPC-estimated molecular weights were actually seen to increase (Table 2). This observation can be rationalized by the homogeneous hydrophilicity of the CPT-liberated polyMPC product relative to the grafted structure containing CPT-hydrophobes.

^{1}H NMR spectroscopic analysis of the polyMPC-*graft*-CPT copolymers in CD_3OD again presented difficulties in quantifying CPT incorporation, showing only weak aromatic CPT signals in the 7−9 ppm range (Figure 3). This chemical shift region overlaps with the expected proton resonance from the triazole generated by click cycloaddition. Light scattering performed on the polyMPC−CPT copolymers indicated the presence of structures with diameters less than 10 nm (Table 2). As seen in CPT-terminated structures, the characteristic CPT protons in the graft copolymer conjugates broaden significantly in the ^{1}H NMR spectra. However, the intensity of the CPT resonances was seen to change as a function of NMR solvent; signals for CPT and MPC protons were best visualized in a 1:1 DMSO-d_6/CD_3OD mixture. Moreover, UV−vis spectroscopy proved useful for estimating CPT loading. Recording the UV absorbance of the CPT-loaded polymer at 370 nm (Figure 3a) allowed for a calculation of weight percent CPT in the polymer, using known concentrations of the CPT-azide compounds and their molar extinction coefficients. The CPT loading for each sample is given in Table 2 as CPT weight percent. As expected, the relative absorbance at 370 nm from CPT increased with increasing amount of CPT incorporated, with experimental values corresponding reasonably well with that expected for the number of CPT grafts per chain.

The polyMPC-*graft*-CPT copolymers with different linkers between CPT and the polymer backbone, as depicted in Scheme 1, were synthesized to investigate drug release associated with

Scheme 1



ester linkages of variable hydrophilicity. For example, to contrast the case of the hydrophobic 6-azidohexanoic acid linker (*32*), 2-[2-(2-azidoethoxy)ethoxy]acetic acid was synthesized. This was done by oxidation of 2-[2-(2-chloroethoxy)ethoxy]ethanol to the corresponding carboxylic acid using Jones reagent at room temperature, followed by displacement of the chloride with NaN_3 at 80 °C, to give azide **5** in 53% overall yield. The presence of the azide group was confirmed by its characteristic infrared spectral signal at ∼2100 cm^{-1}, and the α-azido methylene ($\underline{C}H_2N_3$) resonance at 50.6 ppm in the ^{13}C NMR spectrum. CPT azide compounds were obtained by acylation of CPT with linkers **4** and **5** in the presence of EDC and DMAP. Fortunately, we found the linkers to have little-to-no effect on the polymerization and cycloaddition reactions, as indicated by the relatively low PDI values, and theoretical-to-experimental agreement in the drug loadings. Thus, this one-pot click/ATRP procedure provides an easy one-step process to introduce the very hydrophobic camptothecin into hydrophilic, biocompatible MPC polymers with good control over drug loading. We expect that various synthetic camptothecin derivatives will also be amenable to such grafting chemistry.

While a one-pot simultaneous Cu(I)-catalyzed ATRP and "click" was reported for propargyl methacrylate and different organic azide compounds, including 1-octyl azide, methoxytriethylene glycol azide, and 2′-azidoethyl-α-mannopyranoside (*56*), the TMS-protected alkyne has not, to our knowledge, been used in such click cycloadditions without prior deprotection. The facile deprotection, and rapid ensuing click reaction, allows the polymerization and click-conjugation to proceed cleanly in one pot, without complications associated with conventional free radical polymerization in the presence of an alkyne.

Drug Release from polyMPC−CPT Conjugates. In vitro drug release studies were performed on polyMPC−CPT conjugates to gauge their relative release rates and potential utility in delivery applications. To begin, CPT-terminated polyMPC materials were incubated in PBS at various buffered pH values (5.5, 7.4, and 9.1) to measure the CPT hydrolysis half-lives from the polymer backbone. Polymers prepared from CPT initiator **1** (containing one methyl group) showed very slow CPT release (at $t = 30$ days, no drug release was seen at pH 5.5, and only 5% at pH 7.4). However, in human plasma, which contains enzymes that can accelerate ester cleavage, 50% of the drug was released in 10 days. Interestingly, no CPT release was detected from the polymer prepared from CPT initiator **2** (containing two methyl groups), pointing to the importance of the local steric environment around the ester linkage. Placing a glycine linkage between the polymer and CPT did little to accelerate ester bond cleavage and drug release.

For the polyMPC-*graft*-CPT copolymer conjugates, the choice of backbone-to-drug linkage led to significant changes in ester cleavage and drug release. The 6-azidohexanoic acid linker was first chosen for CPT conjugation, giving copolymers **P7**−**9**. These structures exhibited very little hydrolysis over four days incubation under several different aqueous conditions, suggesting that this hydrophobic linker forms conjugates that are possibly too stable for effective in vivo use. To expedite ester hydrolysis, the more hydrophilic linker 2-[2-(2-azidoethoxy)-ethoxy]acetic acid was used to prepare copolymers **P10** and **P11**. Results obtained from hydrolysis studies in different media are given in Figure 5 and Table 3. For example, SEC-HPLC traces of **P10** incubated in cell culture medium are shown in Figure 4a, where the polymer−drug conjugate elutes at 9.4 min and the free CPT elutes at 16.9 min. Over the course of 96 h, the conjugate peak intensity diminishes, while the CPT peak intensity increases, as expected when CPT is released from the polymer backbone. Reverse-phase HPLC analysis of the copolymers after incubation is shown in Figure 4b, confirming CPT release. Copolymers **P10** and **P11**, despite their rather long half-lives of 210−220 h in PBS (pH 7.4), showed much faster release profiles than the CPT-terminated polyMPC structures and polyMPC-*graft*-CPT copolymers containing the 6-azidohexanoic acid linker. Copolymers **P10** and **P11** showed progressively shorter half-lives in mouse serum (∼80 h), cell culture medium (∼40 h), and human plasma (8−9 h). The combined hydrophilicity and substituent effects of the linker accelerate ester cleavage and thus drug release.

Cell Culture Assays Using polyMPC−CPT Conjugates. HPLC characterization of CPT liberation from polyMPC-*graft*-CPT conjugates confirmed the importance of tailored linker chemistry and was informative for in vitro cell culture evaluation of conjugate toxicity against various cell lines. Taking **P10** and **P11** as examples, both containing **5** as linkers, one as an ester (*7*) and the other as a glycine form (*8*), a much faster CPT release profile was seen in human plasma relative to PBS.

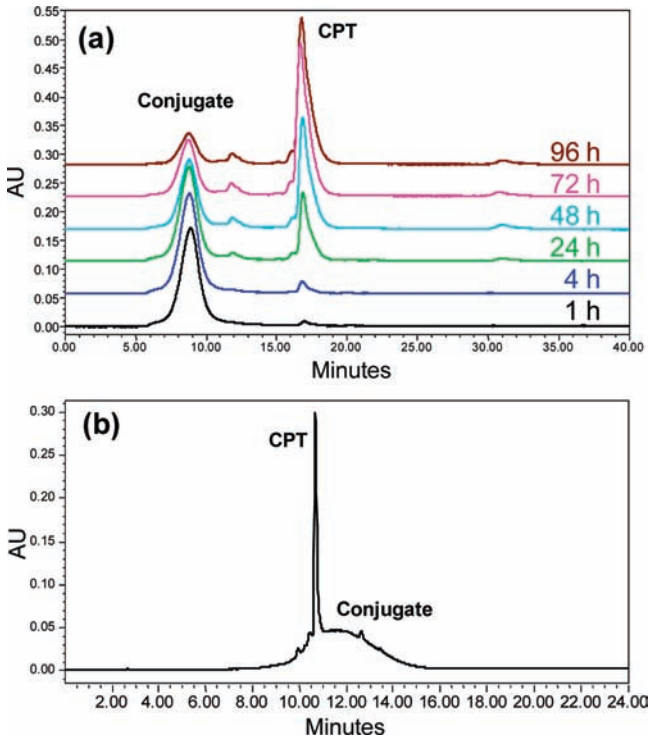


Figure 4. (a) SEC-HPLC traces of **P10** incubated with cell culture medium at 37 °C for different times; (b) reverse-phase HPLC trace of **P10** incubated with PBS at pH 7.4 for 72 h, with a sharp peak for free CPT, and a broad conjugate peak.

However, these CPT hydrolysis half-lives are slower than those reported for PEGylated-SN38 conjugates (*54*), suggesting an expected longer in vivo circulation time.

The anticancer activity of these polyMPC-*graft*-CPT structures (**P10** and **P11**) was tested against different cancer cell lines, including human breast (MCF7), ovarian (OVCAR-3), and colon (COLO 205) adenocarcinoma cells. This was done by incubating CPT-equivalent concentrations of **P10** and **P11** with these cell lines for 72 h, followed by cell viability measurements using a luminescence plate reader (see Experimental Section). Control experiments included a DMSO solution of CPT and polyMPC itself in sterile distilled water. Dose−response curves showed that both **P10** and **P11** were potent against the cancer cell lines tested, and importantly, the cytotoxicity was through the CPT only, since polyMPC by itself was, as expected, nontoxic (Figure 6). Table 4 shows that both **P10** and **P11** induced cytotoxicity at IC_{50} values higher than native CPT, an expected result of the gradual liberation of CPT from the polymer chain over time. From Table 4, it can also be seen that the colon cancer cells were the most sensitive to these novel CPT-polyMPC conjugates of the three cell lines tested (IC_{50} **P10** 3.9 and **P11** 2.3 μM). The comparable IC_{50} values for conjugates **P10** and **P11** originate from their similar hydrolysis rates. The tunable hydrolysis rate, using these and other linkers, will be of benefit for controlling drug release in vivo, and the very high solubility and drug weight percent loading possible in these polyMPC conjugate systems will allow for future in vivo evaluation of very high drug loadings, at any of a range of polyMPC molecular weights, with an objective of maximizing drug efficacy and minimizing toxicity.

EXPERIMENTAL SECTION

Materials. Sodium azide, 4-*N*,*N*-(dimethylamino)pyridine (DMAP), *N*,*N*′-diisopropylethylamine (DIPEA), triethylamine (TEA), *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC), 2-bromopropionyl bromide, 2-bromoisobutyryl bromide, copper(I) bromide, 2,2′-bipyridine (bpy), 6-bromohexanoic acid, 2-[2-(2-chloroethoxy)ethoxy]ethanol, ethyl 2-bromoisobutyrate, 3-(trimethylsilyl)propargyl alcohol, methacryloyl chloride, mouse serum, and human plasma were purchased from Aldrich. 20(*S*)-Camptothecin (CPT) was purchased from Acros. Chromium trioxide was purchased from Alfa Aesar. TFA was purchased from Fisher Scientific. Boc-Gly-OH was purchased from Advanced ChemTech. MPC monomer was synthesized on the basis of literature methods (*57*). Dichloromethane (DCM) was distilled over CaH_2. All other materials were used without additional purification. The human colon (COLO 205), ovarian (OVCAR-3), and breast (MCF7) adenocarcinoma cells were purchased from American Type Culture Collection (ATCC), and RPMI 1640 and MEM cell culture media were purchased from Invitrogen and Mediatech, respectively. Fetal bovine serum (FBS) was purchased from Atlanta Biologicals and bovine insulin from Aldrich. Cell viability was measured using CellTiter-Glo luminescent cell viability assays (Promega).

Instrumentation. NMR spectra were recorded on Bruker DPX300 spectrometer ($\omega_{13C} = 0.25\ \omega_{1H}$). High-resolution mass spectral (HRMS) data were obtained on a JEOL JMS700 MStation. UV/vis absorbance measurements were taken on a Perkin-Elmer Lambda 25 UV/vis spectrometer. IR data were recorded on a Perkin-Elmer Spectrum One FT-IR spectrometer equipped with a universal ATR sampling accessory. Dynamic light scattering was performed on the Malvern Zetasizer Nano-ZS, and transmission electron microscopy (TEM) was performed on JEOL 2000 FX MARK II 200 keV transmission electron microscope. Molecular weights and polydispersity indices (PDIs) were estimated by gel permeation chromatography (GPC) in sodium nitrate (0.1 M with 0.02 wt % of NaN_3) aqueous solution, calibrated against poly(ethylene oxide) standards, operating at 1.0 mL/min with an HP Series 1050 Pump, HP 1047A refractive index detector, and three Waters Ultrahydrogel linear columns (300 × 7.8 mm). The HPLC consisted of the Waters Alliance system with a 2996 photodiode array detector. A size-exclusion Shodex KW-803 column was used, eluting with 10% ethanol in PBS buffer (pH 7.4) at a flow rate of 1 mL/min, on a reverse-phase C18 column (250 × 4.6 mm) with a gradient of 5−95% of acetonitrile in 0.05% TFA.

Synthesis of CPT-polyMPC Homopolymer. *Synthesis of Initiator **1**.* CPT (600 mg, 1.72 mmol) and DIPEA (445 mg, 3.45 mmol) were suspended in 30 mL of dry DCM. After adding DMAP (440 mg, 3.45 mmol), the suspension was cooled to 0 °C. 2-Bromopropionyl bromide (745 mg, 3.45 mmol) in 20 mL of dry DCM was added to the suspension dropwise. The reaction mixture was stirred at 0 °C for 1 h, then at room temperature for 1 h. After washing with 1 N HCl (50 mL × 3), 1% $NaHCO_3$ (50 mL × 3), and brine (50 mL × 1), the organic phase was dried over $MgSO_4$, filtered, and concentrated by rotary evaporation, giving the crude product. This was crystallized in MeOH/CH_2Cl_2 (95:5) to give compound **1** (650 mg, 78% yield) as a light yellow solid. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.44 (s 1H), 8.29 (d, J = 8.7 Hz, 1H), 7.97 (d, J = 8.1 Hz, 1H), 7.86 (t, J = 7.5 Hz, 1H), 7.70 (t, J = 7.2 Hz, 1H), 7.52 (s 1H), 5.73 (d, J = 17.4 Hz, 1H), 5.43 (d, J = 17.4 Hz, 1H). 5.32 (s 2H), 4.62 (q, J = 6.9 Hz, 1H), 2.16−2.41 (m, 2H), 1.86 (d, J = 6.9 Hz, 3H), 1.03 (t, J = 7.5 Hz, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 169.0, 167.1, 157.3, 152.2, 148.8, 146.4, 145.0, 131.2, 130.7, 129.8, 128.4, 128.1(2C), 120.2, 96.2, 76.9, 67.2, 50.0, 38.7, 31.8, 21.1, 7.6. HRMS-FAB (m/z): $[M+H]^+$ calculated for $C_{23}H_{20}BrN_2O_5$: 483.0556, found: 483.0587.

*Synthesis of Initiator **2**.* CPT (300 mg, 0.86 mmol) and DIPEA (222 mg, 1.72 mmol) and DMAP (210 mg, 1.72 mmol) were stirred in 20 mL of dry DCM at 0 °C. 2-Bromoisobutyryl bromide (594 mg, 2.58 mmol) in 10 mL of dry DCM was added

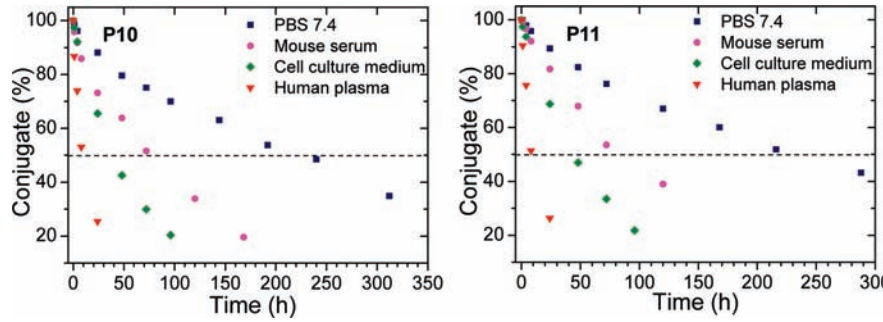

Figure 5. PolyMPC−CPT conjugate (**P10** and **P11**) degradation data over time in different media at 37 °C.

Table 3. Half-Lives ($T_{1/2}$) of polyMPC-*graft*-CPT Copolymers with Hydrophilic Linkers in Different Media

medium		PBS 7.4	mouse serum	cell culture medium	human plasma
$T_{1/2}$	**P10**	212 h	80 h	43 h	8.4 h
	P11	220 h	76 h	37 h	9.0 h

to the suspension dropwise. The reaction mixture was stirred at 0 °C for 1 h, then room temperature for 1 h. After washing with 1 N HCl (40 mL × 3), 1% $NaHCO_3$ (40 mL × 3), and brine (40 mL × 1), the organic phase was dried over $MgSO_4$. The solvent was removed under reduced pressure to give a crude product, which was crystallized from MeOH/CH_2Cl_2 (95:5) to give compound **2** (300 mg, 89% yield) as a light yellow solid. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.40 (s, 1H), 8.24 (d, J = 8.3 Hz, 1H), 7.95 (d, J = 7.9 Hz, 1H), 7.84 (t, J = 7.1 Hz, 1H), 7.67 (t, J = 7.5 Hz, 1H), 7.45 (s, 1H), 5.74 (d, J = 17.0 Hz, 1H), 5.44 (d, J = 17.0 Hz, 1H), 5.30 (s, 2H), 2.15−2.41 (m, 2H), 2.12 (s, 3H), 1.95 (s, 3H), 1.65 (t, J = 7.5 Hz, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 170.3, 167.0, 157.4, 152.4, 149.0, 146.5, 145.5, 131.0, 130.5, 130.0, 128.4, 128.2, 128.1, 128.0, 120.0, 96.0, 76.8, 67.1, 54.7, 50.0, 31.7, 30.5, 30.4, 7.7. HRMS-FAB (m/z): $[M+H]^+$ calculated for $C_{24}H_{22}O_5N_2Br$: 497.0712, found: 497.0669.

Synthesis of Initiator ***3.*** CPT (1.0 g, 2.87 mmol) and Boc-protected glycine (1.0 g, 5.7 mmol) were added into 50 mL of dry DCM. After the suspension was cooled to 0 °C, DMAP (0.70 g, 5.74 mmol) and EDC·HCl (1.1 g, 5.7 mmol) were added to the suspension. The reaction mixture was stirred at 0 °C for 20 min, then at room temperature for 1 h. After washing with 1 N HCl (100 mL × 3), 1% $NaHCO_3$ (100 mL × 3), and brine (100 mL × 1), the organic phase was dried over $MgSO_4$, filtered, and concentrated by rotary evaporation to give CPT-Gly-Boc (1.23 g, 86% yield), which was used in the next step without further purification. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.42 (s, 1H), 8.26 (d, J = 7.6 Hz, 1H), 7.96 (d, J = 7.5 Hz, 1H), 7.86 (t, J = 7.5 Hz, 1H), 7.69 (t, J = 7.5 Hz, 1H), 7.30 (s, 1H), 5.71 (d, J = 17.5 Hz, 1H), 5.42 (d, J = 17.5 Hz, 1H), 5.31 (s, 2H), 4.99 (b, 1H), 4.14 (m, 2H), 2.13−2.38 (m, 2H), 1.42 (s, 9H), 1.00 (t, J = 6.9 Hz, 3H). To a solution of compound CPT-Gly-Boc (1.3 g, 2.57 mmol) in 30 mL of DCM was added 4 mL of TFA. The reaction mixture was stirred at room temperature for 1 h, and the solvent was removed under vacuum. The product was precipitated in ethyl ether, filtered, and dried under vacuum to give compound CPT-Gly (1.2 g, 90% yield). ^{1}H NMR (DMSO, 300 MHz): δ 8.74 (s, 1H), 8.37 (b, 3H), 8.16 (d, J = 8.2 Hz, 2H), 7.89 (t, J = 7.6 Hz, 1H), 7.74 (t, J = 7.6 Hz, 1H), 7.30 (s, 1H), 5.56 (s, 2H), 5.34 (s, 2H), 4.36 (d, J = 18.0 Hz, 1H), 4.11 (d, J = 18.0 Hz, 1H), 2.19 (m, 2H), 0.96 (t, J = 7.4 Hz, 3H). ^{13}C NMR (DMSO, 75 MHz): δ 167.4, 167.3, 156.9, 152.8, 148.3, 146.5, 145.1, 132.2, 131.0, 130.3, 129.2, 129.1 128.5 128.3, 119.35, 96.0, 77.9, 66.8, 50.7, 40.2, 30.6, 8.0. HRMS-FAB (m/z): $[M+H]^+$ calculated for $C_{22}H_{20}O_5N_3$: 406.1403, found: 406.1401.

To a solution of compound CPT-Gly (280 mg, 0,69 mmol) and DIPEA (267 mg, 2.07 mmol) in 10 mL DCM was added dropwise 2-bromoisobutyryl bromide (318 mg, 1.38 mmol) in 5 mL of DCM at −20 °C. The reaction mixture was stirred at −20 °C for 20 min and then room temperature for 2 h. After washing with 1 N HCl (30 mL × 3), 1% $NaHCO_3$ (30 mL × 3), and brine (30 mL × 1), the organic phase was dried over $MgSO_4$. After removing the $MgSO_4$ by filtration, evaporation of the solvent under reduced pressure gave the crude product as a yellow solid, which was crystallized from MeOH/CH_2Cl_2 (95:5) to give initiator **3** (135 mg, 35% yield) as light yellow solid. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.42 (s, 1H), 8.25 (d, J = 8.6 Hz, 1H), 7.90 (d, J = 8.1 Hz, 1H), 7.86 (t, J = 7.5 Hz, 1H), 7.69 (t, J = 7.5 Hz, 1H), 7.15 (s, 1H), 5.72 (d, J = 17.3 Hz, 1H), 5.42 (d, J = 17.3 Hz, 1H), 5.30 (s, 2H), 4.20−4.40 (m, 2H), 2.13−2.39 (m, 2H), 1.97 (s, 3H), 1.92 (s, 3H), 1.01 (t, J = 7.4 Hz, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 172.2, 168.7, 167.1, 157.3, 152.2, 148.9, 146.6, 145.2, 131.2, 130.8, 129.7, 128.4, 128.2, 128.1, 120.1, 96.0, 87.2, 77.2, 67.2, 61.6, 50.0, 42.1, 32.4, 32.3, 31.9, 7.6. HRMS-FAB (m/z): $[M+H]^+$ calculated for $C_{26}H_{24}O_6N_3Br$: 554.0927, found: 554.0927.

General Procedure for ATRP of MPC from CPT-Initiators. CPT-initiator (29.0 mg, 0.06 mmol) was charged into a 10 mL two-neck round-bottom flask and three cycles of vacuum−nitrogen were employed. Nitrogen gas bubbled DMSO (1.5 mL) was injected with a syringe. After the initiator was dissolved completely, CuBr (8.6 mg, 0.06 mmol) and bipyridine (18.7 mg, 0.12 mmol) were added quickly under nitrogen atmosphere. Different amount of MPC dissolved in MeOH (0.5 mL) was then added to the mixture. The reaction mixture was subjected to four freeze−pump−thaw cycles, then stirred at room temperature, and the polymerization conversion was monitored by NMR. The polymerization was stopped by precipitating the reaction mixture into THF (100 mL), and the crude product was isolated by filtration. The polymer was purified by column chromatography on silica gel, eluting with MeOH−DCM mixtures. The polymers were characterized using ^{1}H NMR and aqueous GPC.

Synthesis of polyMPC-*graft*-CPT Copolymers. *Synthesis of Compound* ***5.*** Chromium trioxide (25.0 g, 164 mmol) was dissolved in 300 mL of 1.5 M H_2SO_4, and the solution was cooled to 0 °C. 2-[2-(2-Chloroethoxy)ethoxy]ethanol (8.3 g, 49 mmol) in 150 mL acetone was added dropwise, and the reaction mixture was stirred at room temperature for 6 h. Acetone was removed by evaporation under vacuum, and the aqueous phase was extracted with DCM (3 × 100 mL). After the combined organic phase was dried over $MgSO_4$, the 2-[2-(2-chloroethoxy)-ethoxy]acetic acid (6.3 g, 70% yield) was obtained by removing the solvent by rotary evaporation. IR: (cm^{-1}) 1734 (C═O). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 10.49 (b, 1H), 4.23 (s, 2H), 3.80 (t, J = 5.8 Hz, 4H), 3.74 (t, J = 5.7 Hz, 2H), 3.66 (t, J = 5.8 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 174.4, 71.4, 71.1, 70.4, 68.5, 42.6.

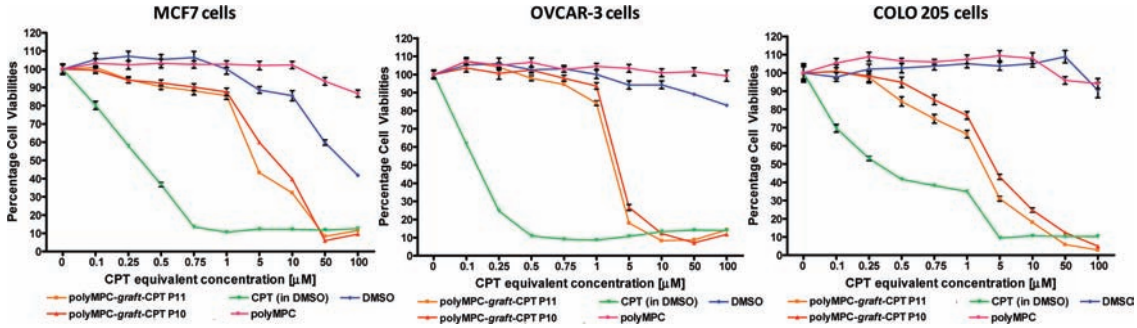

Figure 6. In vitro cytotoxicity of polyMPC-*graft*-CPT conjugates in cell culture of human breast (MCF7), ovarian (OVCAR-3), and colon (COLO 205) adenocarcinoma cells.

Table 4. IC_{50} Values (μM) of polyMPC-*graft*-CPT Copolymers Across Various Cancer Cell Lines

cell type	**P10**	**P11**	CPT
MCF7	6.7	4.6	0.29
OVCAR-3	3.3	2.5	0.13
COLO 205	3.9	2.3	0.32

2-[2-(2-Chloroethoxy)ethoxy]acetic acid (6.3 g, 34 mmol) and NaN_3 (9.00 g, 138 mmol) were dissolved in 20 mL of water. The reaction mixture was stirred with heating at 80 °C for 48 h. After cooling to room temperature, the reaction mixture was acidified with HCl solution and extracted with DCM (4 × 50 mL). The combined organic phase was dried over $MgSO_4$. Filtration and extraction by rotary evaporation gave compound **5** as a clear oil (5.0 g, 77% yield). IR: (cm^{-1}) 2097 (N═N═N). ^1H NMR ($CDCl_3$, 300 MHz): δ 10.80 (b, 1H), 4.22 (s, 2H), 3.79 (t, J = 5.7 Hz, 2H), 3.69−3.74 (m, 4H), 3.43 (t, J = 5.3 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 174.7, 71.2, 70.5, 70.1, 68.4, 50.6. HRMS-FAB (*m*/*z*): $[M+H]^+$ calculated for $C_6H_{12}O_4N_3$: 190.0828, found: 190.0816.

Synthesis of Compound ***6.*** Compound **4** was synthesized according to a literature procedure (*32*). 6-Bromohexanoic acid (5 g, 25.6 mmol) was stirred with sodium azide (8.40 g, 129 mmol) in 50 mL of DMSO at room temperature to afford compound **4**, 6-azidohexanoic acid. Esterification of compound **4** with CPT using EDC/DMAP catalysis in DCM gave compound **6**. IR: (cm^{-1}) 2094 (N_3). ^1H NMR ($CDCl_3$, 300 MHz): δ 8.43 (s, 1H), 8.24 (d, J = 8.3 Hz, 1H), 7.97 (d, J = 8.0 Hz, 1H), 7.87 (t, J = 7.0 Hz, 1H), 7.70 (t, J = 7.1 Hz, 1H), 7.23 (s, 1H), 5.71 (d, J = 17.6 Hz, 1H), 5.43 (d, J = 17.6 Hz, 1H), 5.31 (s, 2H), 3.25 (t, J = 6.8 Hz, 2H), 2.45−2.63 (m, 2H), 2.11−2.37 (m, 2H), 1.71 (qp, J = 7.6 Hz, 2H), 1.63 (m, 2H), 1.42 (m, 2H), 1.00 (t, J = 7.3 Hz, 3H).

Synthesis of Compound ***7.*** A solution of compound **5** (327 mg, 1.72 mmol) and EDC hydrochloride (330 mg, 1.72 mmol) in 20 mL DCM was stirred at 0 °C. CPT (300 mg, 0.86 mmol) and DMAP (210 mg, 1.72 mmol) were added. The reaction was stirred at room temperature until the suspension became visibly homogeneous. After washing with 1 N HCl (50 mL × 3), 1% $NaHCO_3$ (50 mL × 3), and brine (50 mL × 1), the organic phase was dried over $MgSO_4$. Filtration and concentration by rotary evaporation gave a yellow solid, which was recrystallized from MeOH/CH_2Cl_2 (95:5) to give pure compound **7** (389 mg, 87% yield) as a light yellow solid. IR: (cm^{-1}) 2104 (N═N═N). ^1H NMR ($CDCl_3$, 300 MHz): δ 8.43 (s, 1H), 8.24 (d, J = 8.0 Hz, 1H), 7.97 (d, J = 8.0 Hz, 1H), 7.87 (t, J = 7.5 Hz, 1H), 7.70 (t, J = 7.5 Hz, 1H), 7.23 (s, 1H), 5.73 (d, J = 17.4 Hz, 1H), 5.44 (d, J = 17.4 Hz, 1H), 5.31 (s, 2H), 4.39 (d, J = 5.0 Hz, 2H), 3.77 (t, J = 5.5 Hz, 2H), 3.66−3.70 (m, 4H), 3.40 (t, J = 5.1 Hz, 2H), 2.13−2.39 (m, 2H), 1.00 (t, J = 7.4 Hz, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 169.7, 167.3, 157.3, 152.2, 148.9, 146.4, 145.4, 131.2, 130.7, 129.6, 128.4, 128.2, 128.2, 128.1, 120.3, 95.9, 76.4, 71.1, 70.6, 70.0, 68.2, 67.2, 50.6, 50.0, 31.8, 7.6. HRMS-FAB (*m*/*z*): $[M+H]^+$ calculated for $C_{26}H_{26}O_7N_5$: 520.1832, found: 520.1821.

Synthesis of Compound ***8.*** A solution of compound **5** (304 mg, 1.60 mmol) and EDC hydrochloride (461 mg, 2.40 mmol) in 20 mL DCM was stirred at 0 °C. CPT-Gly TFA salt (415 mg, 0.80 mmol) and DMAP (293 mg, 2.40 mmol) were added. The mixture was stirred at room temperature for 5 h, then washed with 1 N HCl (30 mL × 3), 1% $NaHCO_3$ (30 mL × 3), and brine (30 mL × 1). The organic phase was dried over $MgSO_4$, filtered, and concentrated by rotary evaporation to give the crude product, which was recrystallized from MeOH to give pure compound **8** (374 mg, 81% yield). IR: (cm^{-1}) 2113 (N═N═N). ^1H NMR ($CDCl_3$, 300 MHz): δ 8.41 (s, 1H), 8.26 (d, J = 8.5 Hz, 1H), 7.95 (d, J = 7.7 Hz, 1H), 7.85 (t, J = 7.0 Hz, 1H), 7.68 (t, J = 7.7 Hz, 1H), 7.37 (t, J = 5.3 Hz, 1H), 7.27 (s, 1H), 5.71 (d, J = 17.2 Hz, 1H), 5.43 (d, J = 17.2 Hz, 1H), 5.29 (s, 2H), 4.46−4.54 (dd, J_1 = 18.6 Hz, J_2 = 6.5 Hz, 1H), 4.18−4.26 (dd, J_1 = 18.6 Hz, J_2 = 4.7 Hz, 1H), 4.02 (q, J = 8.2 Hz, 1H), 3.66−3.70 (m, 2H), 3.62 (t, J = 5.0 Hz, 4H), 3.34 (t, J = 4.9 Hz, 2H), 2.14−2.40 (m, 2H), 1.00 (t, J = 7.5 Hz, 3H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 170.3, 169.0, 167.1, 157.3, 152.2, 148.9, 146.6, 145.3, 131.2, 130.7, 129.8, 128.4, 128.2 (2C overlap), 182.1, 120.2, 96.0, 76.9, 71.1, 70.3, 70.2, 70.0, 67.2, 50.6, 50.0, 40.4, 31.9, 7.6. HRMS-FAB (*m*/*z*): $[M+H]^+$ calculated for $C_{28}H_{29}N_6O_8$: 577.2047, found: 577.2021.

Synthesis of TMS-PgMA. The TMS-protected alkyne monomer was synthesized according to a literature method (*36*). 3-(Trimethylsilyl)propargyl alcohol (2.00 g, 15.6 mmol) and triethylamine (2 g, 20.3 mmol) in 20 mL of dry ethyl ether was cooled to −20 °C. A solution of methacryloyl chloride (2 g, 18.7 mmol) in 10 mL of dry ethyl ether was added dropwise over 30 min. The reaction mixture was stirred for 30 min at −20 °C, then overnight at room temperature. The precipitate was removed by filtration, and the solvent was removed by rotary evaporation. The crude product was further purified on silica column chromatography eluting with hexane−ethyl ether (100:1) to give the pure TMS-PgMA monomer as colorless oil (4.0 g, 58% yield). IR: (cm^{-1}) 2961 (C−H), 1723 (C═O), 1638 (C═C). ^1H NMR ($CDCl_3$, 300 MHz): δ 6.16 (m, 1H), 5.61 (m, 1H), 4.75 (s, 2H), 1.95 (m, 3H), 0.18 (s, 9H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 166.6, 135.7, 126.4, 99.1, 91.9, 53.0, 18.3, 0.3. HRMS-FAB (*m*/*z*): $[M]^+$ calculated for $C_{10}H_{16}O_2Si$: 196.0920, found: 196.0891.

General Procedure for One-Pot ATRP and Click Cycloaddition. CPT azide was charged into a 10 mL two-neck round-bottom flask and three cycles of vacuum-nitrogen were employed. Degassed DMSO (2 mL) was injected with a syringe. After the CPT azide was dissolved completely, a solution of ethyl 2-bromoisobutyrate (11.7 mg. 0.06 mmol), MPC and alkyne monomer in 0.7 mL MeOH was injected. CuBr (17 mg, 0.12 mmol) and bipyridine (37.4 mg, 0.24 mmol) were added quickly under nitrogen atmosphere. The reaction mixture was then subjected to four freeze−pump−thaw cycles. The reaction

mixture was stirred at room temperature for 20 h, and monomer conversion was monitored by ^{1}H NMR spectroscopy. The polymerization was stopped by precipitating the reaction mixture into THF (100 mL), and the crude product was isolated by filtration. The crude product was further purified by column chromatography on silica gel, eluting with MeOH−DCM mixtures, to give the polyMPC-*graft*-CPT copolymers as light yellow solid. The polymers were characterized by NMR spectroscopy and aqueous GPC.

TEM. TEM images were obtained using a JEOL 2000FX transmission electron microscope operating at an acceleration voltage of 200 kV. The samples were prepared by dropping 2 μL of polymer solution onto the carbon-coated copper grid. After the samples were dried, 1 wt % phosphotungstenic acid solution (PTA) was used for staining.

DLS Measurements. DLS was performed on a Malvern Zetasizer Nano-ZS (4 mW He−Ne laser, 633 nm) with a detector set to collect backscattered light at a 173° angle. The light scattering intensity was recorded with fixed measurement position and attenuator for different concentrations. The size measurements were performed at polymer concentration of 1 mg/mL, and optimum position and automatic attenuation were selected to generate the optimum correlation curve. Samples was dissolved in water and filtered through a 0.45 μm filter membrane before the measurement. Each measurement was performed at 25 °C by equilibrating the samples for 10 min.

Calibration of CPT Loading in Polymer. Compounds **6**, **7**, and **8** were dissolved in DMSO−MeOH (1:1) at a concentration of 0.01 mg/mL, and copolymers (**P7**−**P11**) were also dissolved in DMSO−MeOH (1:1) at a concentration of 0.1 mg/mL. The CPT loading in each polymer was calculated on the basis of UV absorbance values at 370 nm and known concentration of its corresponding CPT azide compound.

CPT Release Measurements. The CPT containing polymers were dissolved in different media at a concentration of 3 mg/mL. The mixtures were incubated at 37 °C, and aliquots (100 μL) were taken at different time points. Twenty microliter aliquots of the sample from PBS and cell culture media were analyzed by SEC-HPLC. The samples taken from mouse serum and human plasma were mixed with 200 uL of PBS and filtered through a 0.45 μm filter membrane; 60 μL of the filtrate was analyzed on SEC-HPLC. The stability profile was generated by plotting the percentage of remaining CPT on the polymer over a time course. The percentage was calculated on the basis of peak area of UV absorbance at 370 nm. The sample was also analyzed by RP-HPLC, and the integrity of the released CPT (i.e., ring-opened or ring-closed form) was based on the retention times.

Cell Culture. The OVCAR-3 and COLO 205 cancer cells were cultured in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS) or 20% FBS and 0.01 mg/mL bovine insulin, while MCF7 cells were cultured in MEM medium supplemented with 10% FBS and 0.01 mg/mL bovine insulin. All cells were grown in 5% CO_2 incubators at 37 °C. For in vitro cytotoxicity assays, cells were seeded into 96 well plates, and after reaching about 40% cell density were incubated for 72−96 h with varying camptothecin equivalent concentrations of polymer drug conjugates, as well as polymer control samples (i.e., no attached drug). Cell viability post-treatment was measured using CellTiter-Glo luminescent cell viability assays (Promega) as per manufacturer's instructions on a FLUOstar OPTIMA plate reader (BMG LABTECH). The percentage camptothecin mediated toxicity was calculated with respect to untreated cells and graphed to give dose−response curves. IC_{50} values for each treatment were then calculated using the GraphPad *Prism4* statistical analysis software.

Knottins are small constrained polypeptides that share a common disulfide-bonded framework and a triple-stranded β-sheet fold. Previously, directed evolution of the *Ecballium elaterium* trypsin inhibitor (EETI-II) knottin led to the identification of a mutant that bound to tumor-specific $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors with low nanomolar affinity. The objective of this study was to prepare and evaluate a radiofluorinated version of this knottin (termed 2.5D) for microPET imaging of integrin positive tumors in living subjects. Knottin peptide 2.5D was prepared by solid-phase synthesis and folded *in vitro*, and its free N-terminal amine was reacted with *N*-succinimidyl-4-$^{18/19}$F-fluorobenzoate ($^{18/19}$F-SFB) to produce the fluorinated peptide $^{18/19}$F-FB-2.5D. The binding affinities of unlabeled knottin peptide 2.5D and ^{19}F-FB-2.5D to U87MG glioblastoma cells were measured by competition binding assay using ^{125}I-labeled echistatin. It was found that unlabeled 2.5D and ^{19}F-FB-2.5D competed with ^{125}I-echistatin for binding to cell surface integrins with IC_{50} values of 20.3 ± 7.3 and 13.2 ± 5.4 nM, respectively. Radiosynthesis of ^{18}F-FB-2.5D resulted in a product with high specific activity (ca. 100 GBq/μmol). Next, biodistribution and positron emission tomography (PET) imaging studies were performed to evaluate the *in vivo* behavior of ^{18}F-FB-2.5D. Approximately 3.7 MBq ^{18}F-FB-2.5D was injected into U87MG tumor-bearing mice via the tail vein. Biodistribution studies demonstrated that ^{18}F-FB-2.5D had moderate tumor uptake at 0.5 h post injection, and coinjection of a large excess of the unlabeled peptidomimetic c(RGDyK) as a blocking agent significantly reduced tumor uptake (1.90 ± 1.15 vs 0.57 ± 0.14%ID/g, 70% inhibition, $P < 0.05$). *In vivo* microPET imaging showed that ^{18}F-FB-2.5D rapidly accumulated in the tumor and quickly cleared from the blood through the kidneys, allowing excellent tumor-to-normal tissue contrast to be obtained. Collectively, ^{18}F-FB-2.5D allows integrin-specific PET imaging of U87MG tumors with good contrast and further demonstrates that knottins are excellent peptide scaffolds for development of PET probes with potential for clinical translation.

INTRODUCTION

Recent advancement in *in vitro* display technologies (phage, bacterial, yeast, ribosome, and mRNA) and rational protein engineering has resulted in many novel peptide scaffolds that bind to a variety of molecular targets (*1*−*5*). Following the discovery of these new affinity ligands came their adaptation for use in cancer imaging applications (*6*, *7*). These small polypeptides can easily be produced by chemical approaches such as solid-phase peptide synthesis or generated recombinantly using the tools of molecular biology. Moreover, the small size of these polypeptides generally leads to fast tumor targeting and relatively short *in vivo* half-life compared with monoclonal antibodies. Collectively, these properties bode well for nuclear imaging applications with potential for clinical translation.

Cystine knot proteins (also known as knottins) are small constrained polypeptides that share a common disulfide-bonded framework and a triple-stranded β-sheet fold (Figure 1A) (*8*). Indeed, the scaffold's core structure is very rigid. In general, this class of polypeptides is relatively stable in various physical, chemical, and biological environments. Individual family members share little sequence homology except the core cysteine residues. Knottin family members possess one or more surface-exposed loops that tolerate much sequence diversity. These looped regions are responsible for a range of biological activities (*9*, *10*). However, in most cases, their natural functions remain unknown.

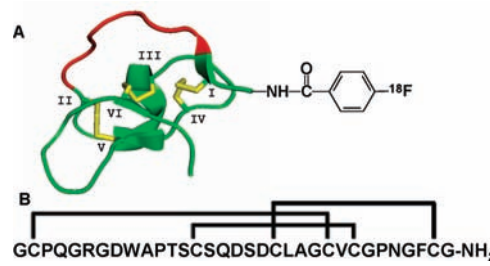

Figure 1. Schematic and sequence of engineered knottin peptides. (A) Cartoon representation of knottin peptide scaffold. The imaging label ^{18}F-FB was site-specifically conjugated to the N terminal amino group. (B) Amino acid sequence integrin-binding knottin peptide 2.5D with disulfide bonds between Cys1-Cys4, Cys2-Cy5, and Cys3-Cys6.

Previously, the *Ecballium elaterium* trypsin inhibitor II (EETI-II), a knottin from the squash family of protease inhibitors, was used as a scaffold for directed evolution studies (*11*). An Arg-Gly-Asp (RGD) integrin binding motif was grafted into a surface-exposed loop, where yeast surface display combined FACS led to the identification of peptides including 2.5D that bound integrin receptors ($\alpha_v\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$) with low

nanomolar affinities (Figure 1). Near infrared-dye Cy5.5- and ^{64}Cu-DOTA-conjugated knottin peptides were then synthesized and evaluated in mouse xenograft models (*12*). Biodistribution and micropositron emission tomography (microPET) imaging studies revealed that these engineered knottin peptides performed well *in vivo* and show promise as a new class imaging agent. These peptides demonstrated rapid and high tumor accumulation, fast clearance from blood and normal organs, and low uptake in the kidney and liver (*12*).

^{18}F is the most commonly used PET[a] radionuclide and has almost ideal physical properties ($t_{1/2}$: 110 min, emits $\beta+$ particles at E_{max} = 635 keV and E_{ave} = 250 keV, 97% abundant) for PET imaging. In this study, to further evaluate the clinical translation ability of engineered knottins, peptide 2.5D was site-specifically labeled with ^{18}F by conjugation with the radiofluorination synthon, *N*-succinimidyl-4-^{18}F-fluorobenzoate (^{18}F-SFB), through the peptide N-terminus amine (Figure 1). ^{18}F-FB-2.5D was then evaluated in nude mice bearing subcutaneous U87MG xenografts characterized by high levels of integrin expression (*13*).

EXPERIMENTAL PROCEDURES

General. SFB was obtained from ABX GmbH (Radeberg, Germany). All 9-fluorenylmethyloxycarbonyl (Fmoc) protected amino acids were purchased from Novabiochem/EMD Chemicals Inc. (La Jolla, CA) or CS Bio (Menlo Park, CA). ^{125}I-labeled echistatin and c(RGDyK) were purchased from GE Healthcare Life Sciences (Piscataway, NJ), and Peptides International (Louisville, KY), respectively. Phosphate buffered saline (PBS) was from Gibco/Invitrogen (Carlsbad, CA). Echistatin and *N*,*N*′-diisopropylethylamine (DIPEA) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). All other chemicals were purchased from Thermo Fisher Scientific (Fair Lawn, NJ) unless otherwise specified. The U87MG human glioblastoma cell line was obtained from American Type Culture Collection (Manassas, VA). Nude mice (nu/nu, female 5−6 weeks old) were purchased from Charles River Laboratory (Wilmington, MA). A CRC-15R PET dose calibrator (Capintec Inc., Ramsey, NJ) was used for all radioactivity measurements. Reverse-phase high-performance liquid chromatography (RP-HPLC) was performed on a Dionex Summit HPLC system (Dionex Corporation, Sunnyvale, CA) equipped with a 170U 4-Channel UV−vis absorbance detector and radioactivity detector (Carroll & Ramsey Associates, model 105S, Berkeley, CA). UV detection wavelengths were 218, 254, and 280 nm for all the experiments. Both semipreparative (Vydac, Hesperia, CA. 218TP510-C18, 10 mm × 250 mm) and analytical (Dionex, Sunnyvale, CA. Acclaim120 C18, 4.6 mm × 250 mm) RP-HPLC columns were used. The mobile phase was solvent A, 0.1% trifluoroacetic acid (TFA)/H_2O, and solvent B, 0.1%TFA/acetonitrile. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) were performed on a Perseptive Voyager-DE RP Biospectrometry instrument (Framingham, MA) by the Stanford Protein and Nucleic Acid Biotechnology Facility (Stanford, CA).

Chemistry and Radiochemistry. Peptide 2.5D was synthesized on a CS Bio CS336 instrument (Menlo Park, CA) using Fmoc-based solid-phase peptide synthesis method. Briefly, Rink amide resin was swollen in *N*,*N*-dimethylformamide (DMF) for 30 min. Fmoc groups were removed with 20% piperidine in DMF. Aliquots of amino acids (1 mmol) were activated in a solution containing 1 mmol of hydroxybenzotriazole (HOBt) and 0.5 M diisopropylcarbodiimide (DIC) in DMF. Following synthesis, side-chain deprotection and resin cleavage was achieved by addition of a 94:2.5:2.5:1 (v/v) mixture of trifluoroacetic acid (TFA)/trimethylsilane/ethanedithiol/water for 2 h at room temperature. The crude product was precipitated with cold anhydrous diethyl ether and purified by a preparative or semipreparative RP-HPLC using a Varian Prostar instrument and Vydac C_{18} columns. Peptide purity was analyzed by analytical-scale RP-HPLC using a Vydac C_{18} column.

Folding reactions were performed by incubating the linear peptide with 2.5 mM reduced glutathione and 20% dimethyl sulfoxide (DMSO) in 0.1 M ammonium bicarbonate, pH 9, with gentle rocking. The final oxidized product was purified by RP-HPLC as described above; the folded knottin peptide exhibited a distinct chromatographic profile that allowed it to be separated from unfolded and misfolded isomers (*11*). Following purification, folded peptide 2.5D was lyophilized and stored at room temperature until use. Purified peptide was dissolved in water, and concentration was determined by amino acid analysis (Molecular Structure Facility, Davis, CA). Peptide purity and molecular mass were determined by analytical-scale RP-HPLC and MALDI-TOF-MS or ESI-MS.

Nonradioactive ^{19}F-FB-2.5D, a reference standard, was prepared by reaction of knottin peptide 2.5D with SFB. Briefly, 0.15 μmol of knottin peptide 2.5D (0.5 mg in 400 μL of DMSO) was mixed with 1.5 μmol of SFB (0.36 mg in 100 μL of DMSO) and 30 μL of DIPEA and reacted for 1 h at 60 °C. The resulting conjugate ^{19}F-FB-2.5D was then purified by RP-HPLC on a semipreparative C_{18} column using a gradient system of 0.1% trifluoroacetic acid in acetonitrile (solvent B) and 0.1% trifluoroacetic acid in water (solvent A). The flow rate was 3 mL/min, with the mobile phase starting from 90% solvent A and 10% solvent B (0−3 min) to 35% solvent A and 65% solvent B at 33 min. Fractions containing the product were collected and lyophilized. The identity of ^{19}F-FB-2.5D was confirmed by MALDI-TOF-MS.

^{18}F-SFB was prepared on the basis of a previously reported procedure (*14*). The specific activity of ^{18}F-SFB was 200−250 GBq/μmol at the end of synthesis (EOS), as estimated by radio-HPLC. Radiolabeling agent ^{18}F-SFB in 100 μL of DMSO was added to knottin peptide 2.5D (100 μg, in 100 μL of DMSO) and 10 μL of DIPEA and reacted for 1 h at 60 °C. After adding 50 μL of TFA to quench the reaction, the mixture was purified with semipreparative HPLC, using the same elution gradient as for the cold ^{19}F-FB-2.5D purification. The eluted fractions containing the ^{18}F-FB-2.5D were then collected, combined, and dried using a rotary evaporator. The radiolabeled peptide was reconstituted in PBS (0.01 M, pH 7.4) and passed through a 0.22 μm Millipore filter into a sterile vial for cell culture and animal experiments.

Octanol/Water Partition Coefficient. To determine the hydrophilicity of ^{18}F-FB-2.5D, approximately 370 kBq of the probe in 500 μL of PBS (0.01 M, pH 7.4) was added to 500 μL of octanol in a microcentrifuge tube. The resulting biphasic system was mixed vigorously for 0.5 h and left at room temperature for another 0.5 h. The two phases were then separated by centrifugation at 3000 *g* for 5 min (model 5415R Eppendorf microcentrifuge; Brinkman, Westbury, NY). An aliquot of 100 μL was removed from each layer and analyzed in a γ-counter (model 1470; PerkinElmer). The partition coefficient (log *P*) was then calculated as a ratio of counts in the octanol fraction to the counts in the water fraction. The experiment was repeated three times.

Cell Culture. U87MG cells were cultured in DMEM containing high glucose (Gibco, Carlsbad, CA), which was supplemented with 10% fetal bovine serum (FBS) and 1% penicillin−streptomycin. The cells were expanded in tissue culture dishes and kept in a humidified atmosphere of 5% CO_2 at 37 °C. The media was changed every other day. A confluent

[a]Abbreviations: PET, positron emission tomography; HPLC, high-performance liquid chromatography; pi, postinjection.

monolayer was detached with 0.5% Trypsin−EDTA and 0.01 M PBS (pH 7.4) and dissociated into a single-cell suspension for further cell culture and assays.

U87MG Cell Binding Assay. This assay was performed as previously described (*11, 12*). Briefly, 2×10^5 U87MG cells were incubated with 0.06 nM ^{125}I-labeled echistatin and varying concentrations of compounds (echistatin, knottin 2.5D, ^{19}F-FB-2.5D) in integrin binding buffer [IBB, 25 mM Tris pH 7.4, 150 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$, and 0.1% bovine serum albumin (BSA)] at room temperature for 3 h. The cell-bound radioactivity remaining after washing was determined by gamma-counting. IC_{50} values, the concentration of competitor required to inhibit 50% of the radioligand binding, were determined by nonlinear regression analysis using Kaleidagraph (Synergy Software, Reading, PA), and are presented as the average of three experiments performed.

Animal Biodistribution Studies. All animal studies were carried out in compliance with federal and local institutional rules for the conduct of animal experimentation. Approximately 10×10^6 cultured U87MG cells were suspended in PBS and subcutaneously implanted in the left shoulders of nude mice. Tumors were allowed to grow to a size of 0.5 cm (2−3 weeks) before imaging experiments. For biodistribution studies, mice bearing U87MG xenografts ($n = 3$ for each group) were injected with approximately 740 KBq (20 μCi) of ^{18}F-FB-2.5D with or without 330 μg of unlabeled c(RGDyK) via the tail vein and sacrificed at 0.5 h post injection (p.i.). Tumor and normal tissues of interest were removed and weighed, and their radioactivity was measured in a gamma counter. The radioactivity uptake in the tumor and normal tissues was expressed as a percentage of the injected radioactive dose per gram of tissue (% ID/g).

MicroPET Imaging. Mice bearing U87MG xenografts were injected with approximately 4.44 MBq (120 μCi) of ^{18}F-FB-2.5D with or without 330 μg of c(RGDyK) via the tail vein and PET imaging was performed using a microPET R4 rodent model scanner (Siemens Medical Solutions USA, Inc., Knoxville, TN). At 0.5 and 1 h p.i., mice were anesthetized with isoflurane (5% for induction and 2% for maintenance in 100% O_2). With the help of a laser beam attached to the scanner, mice were placed in the prone position and near the center of the field of view of the scanner, and 3 min static scans were obtained. For dynamic scanning, approximately 3.7MBq (100 μCi) of ^{18}F-FB-2.5D was injected into U87MG tumor-bearing mice via the tail vein, and a 35 min duration dynamic scan (10×1 min, 10×2 min, 1×5 min; total of 21 frames) was started approximately 2.5 min after injection of the probe. Images were reconstructed by a two-dimensional ordered subsets expectation maximization (OSEM) algorithm. No background correction was performed. Region of interests (ROIs; 5 pixels for coronal and transaxial slices) were drawn over the tumor on decay-corrected whole-body coronal images. The maximum counts per pixel per minute were obtained from the ROIs and were converted to counts per milliliter per minute using a calibration constant. ROIs were then converted to counts per gram per minute based on the assumption of a tissue density of 1 g/mL, and image ROI-derived %ID/g values were determined by dividing counts per gram per minute by injected dose. No attenuation correction was performed.

Statistical Method. Statistical analysis was performed using the Student's *t*-test for unpaired data. A 95% confidence level was chosen to determine the significance between groups, with $P < 0.05$ being designated as significantly different.

RESULTS

Chemistry and Radiochemistry. Knottin peptide 2.5D was synthesized in two steps. First, the linear peptide was prepared by conventional solid-phase peptide synthesis and purified by RP-HPLC. Next, the peptide was oxidatively folded using a mixture of glutathione and DMSO, and the final oxidized product was purified by semipreparative reversed-phase HPLC (*11*).The folded peptide was obtained in ~10% yield with >95% purity. Reaction of SFB with the N-terminal amine of knottin peptide 2.5D generated ^{19}F-FB-2.5D, a nonradioactive species, as a reference compound for cell binding affinity studies. For all knottin peptides prepared above, the measured molecular weights were consistent with the expected masses: 2.5D linear peptide, $m/z = 3249.6$ Da for $[M+H]^+$ (calculated $[M+H]^+ = 3249.6$ Da); 2.5D folded peptide, $m/z = 3243.8$ Da for $[M+H]^+$ (calculated $[M+H]^+ = 3243.6$ Da); ^{19}F-FB-2.5D, $m/z = 3365.7$ Da for $[M+H]^+$ (calculated $[M+H]^+ = 3365.7$ Da).

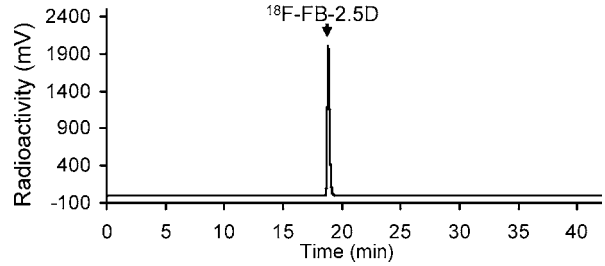

Figure 2. HPLC radiochromatogram of purified ^{18}F-FB-2.5D.

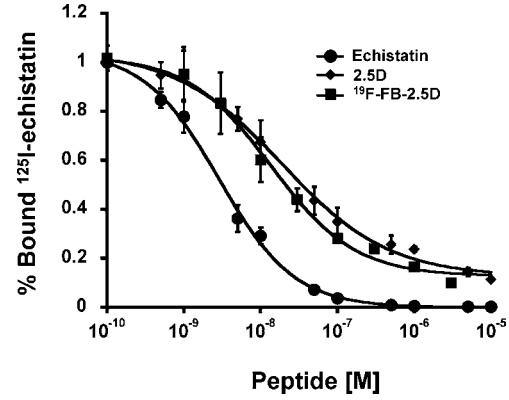

Figure 3. Inhibition of ^{125}I-echistatin binding to integrin receptors on U87MG cells by 2.5D, ^{19}F-FB-2.5D, and echistatin [$IC_{50} = 20.3 \pm 7.3$ (♦), 13.2 ± 5.4 (■) and 3.7 ± 1.1 (•) nM, respectively). Results are expressed as the percentage of ^{125}I-echistatin binding and are the mean of triplicate measurements ± SD.

Similarly, ^{18}F-FB-2.5D was synthesized by coupling knottin peptide 2.5D with radiosynton ^{18}F-SFB. Radiolabeled ^{18}F-FB-2.5D, which had a retention time of 20.2 min, was easy to differentiate by RP-HPLC compared to unlabeled knottin peptide 2.5D, which had a retention time of 16.9 min. Radiosynthesis and purification of ^{18}F-FB-2.5D was completed in approximately 3 h, which is important for experimental use due to the short half-life of ^{18}F. The maximum overall radiochemical yield with decay correction was 28.3% at EOS. The radiochemical purity of the labeled peptide was over 95% as verified by analytic HPLC analysis (Figure 2). An octanol/water distribution study performed on ^{18}F-FB-2.5D showed good hydrophilicity with a partition coefficient number (log *P*) of −1.68.

U87MG Cell Binding Assay. The relative binding affinities of 2.5D and ^{19}F-FB-2.5D to cell surface integrin receptors were determined through a competition binding assay with ^{125}I-echistatin. Echistatin, a snake venom protein that binds to $\alpha_v\beta_3$ integrin with $K_D \sim 0.3$ nM, was also used as the positive control (*15*). Both knottin peptides inhibited the binding of ^{125}I-echistatin to integrin-expressing U87MG cells in a concentration-dependent manner (Figure 3). The mean ± standard deviation IC_{50} values of 2.5D, ^{19}F-FB-2.5D, and echistatin were 20.3 ± 7.3

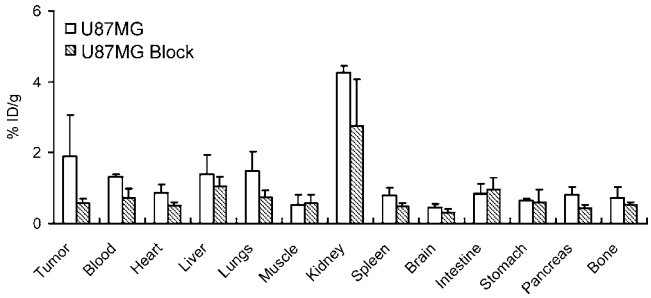

Figure 4. Biodistribution data for ^{18}F-FB-2.5D in nude mice bearing subcutaneous U87MG human tumor xenografts. Data are expressed as the percentage administered activity (injected dose) per gram of tissue (%ID/g) after intravenous injection of 370 kBq (10 μCi) ^{18}F-FB-2.5D at 0.5 h p.i. with or without coinjection of 330 μg of c(RGDyK) (n = 3 for each group). Significant inhibition of U87MG tumor uptake (P < 0.05) was observed upon co-injection of this blocking agent.

nM, 13.2 ± 5.4 nM, and 3.7 ± 1.1 nM, respectively. These studies indicate that conjugation of fluorobenzoic acid moiety to the N-terminus of knottin peptide 2.5D does not reduce its integrin binding affinity.

Biodistribution Studies. The *in vivo* biodistribution of ^{18}F-FB-2.5D was next performed in mice bearing U87MG human glioblastoma xenografts 0.5 h p.i. (Figure 4). Radiolabeled ^{18}F-FB-2.5D displayed moderate accumulation in U87MG tumors (1.90 ± 1.15%ID/g at 0.5 h p.i.). Kidney and liver uptake were 4.24 ± 0.19 and 1.38 ± 0.55%ID/g, respectively. Lower levels of radioactivity were observed in blood (1.32 ± 0.07%ID/g) and the most other organs. To measure integrin specificity, ^{18}F-FB-2.5D was coinjected with an excess (330 μg) of the unlabeled c(RGDyK) to block integrin binding sites. Co-injection of c(RGDyK) specifically reduced the tumor uptake of ^{18}F-FB-2.5D to 0.57 ± 0.14%ID/g (70% inhibition, P < 0.05), without changing the distribution of the probe in most normal tissues studied.

MicroPET Imaging. The *in vivo* tumor targeting profile of ^{18}F-FB-2.5D was further investigated in U87MG tumor-bearing nude mice by dynamic microPET scanning over a 35 min time period. As shown in Figure 5A, ^{18}F-FB-2.5D rapidly accumulated in the tumor and reached a maximum of 3.5%ID/g at 5 min p.i. and gradually decreased to 1.73%ID/g over the duration of the 35 min scan. The scan revealed relatively low radioactivity in the muscle. Lung uptake was high at early time points and rapidly washed out to 1.09%ID/g at 35 min p.i. Rapid blood clearance of the probe was determined by ROI analysis of the heart. At 35 min p.i., radioactivity in the blood was approximately 9.2% of the amount observed at 3 min p.i. (Figure 5B). High kidney uptake was observed at early time points (for example, 51.8%ID/g at 4 min p.i.), but this activity rapidly cleared out and dropped to 6.2%ID/g at 35 min p.i. ^{18}F-FB-2.5D displayed relatively low liver uptake, in agreement with previous data on knottin peptides (*12*). Collectively, these data indicate that ^{18}F-FB-2.5D was mainly cleared through the renal system.

Representative decay-corrected coronal (top) and transaxial (bottom) microPET images of nude mice bearing U87MG tumors on their left shoulder at 0.5 and 1 h after tail vein injection of 4.44 MBq (120 μCi) of ^{18}F-FB-2.5D are shown in Figure 6. The U87MG tumor was clearly delineated with good tumor to contralateral background contrast at 0.5 and 1 h p.i. (left and right images in Figure 6). Moreover, coinjection of an excess of c(RGDyK) peptide reduced the tumor uptake of ^{18}F-FB-2.5D, resulting in lower tumor to background contrast at 0.5 h (middle images in Figure 6). Finally, relatively high activities were observed in the bladder and gallbladder. Quantitative analyses were performed on microPET images (Figure 7). Tumor uptake values were determined to be 2.60 ± 0.72%ID/g at 0.5 h p.i., and decreased to 1.46 ± 0.35%ID/g at 1 h p.i. Co-injection of c(RGDyK) significantly blocked uptake of the radiotracer in the tumor to 0.61 ± 0.14%ID/g (P < 0.05) at 0.5 h p.i., which agreed well with biodistribution results.

DISCUSSION

Novel nonimmunogenic scaffold-based polypeptides have drawn a lot of attention for the development of molecular imaging probes because of easy synthesis, site-specific labeling, stable structure, and high versatility targeting various cancer biomarkers. In our recent work, an antihuman epidermal growth factor receptor type 2 (HER2) Affibody molecule, engineered from one IgG binding domain of protein A and ~1/20 size of an antibody, was site-specifically labeled with ^{18}F. The resulting probe demonstrated great potential for PET imaging of the expression of HER2 in the clinic (*16*). HER2 Affibody molecules have also been labeled with many other radioisotopes and organic dyes for preclinical and clinical imaging (*17*−*19*). These progressions in scaffold protein based molecular probe development have motivated us to explore other scaffold protein as molecular platforms targeting different biomarkers.

The cystine knot miniprotein family represents a unique peptide scaffold of ~3 kDa with three interwoven disulfide bridges. Engineered knottin peptides, such as the integrin-binding peptide 2.5D, have been identified, and their potential for *in vivo* integrin molecular imaging has recently been evaluated as a ^{64}Cu-labeled PET tracer (*12*). Preliminary evaluation of ^{64}Cu-labeled knottin peptides showed excellent tumor imaging properties in living mice. To facilitate the translation of knottin peptides as clinical imaging agents, we next tested an ^{18}F-labeled version of knottin peptide 2.5D in tumor-bearing mouse models in this research. With these studies, we wanted to determine whether there are any advantages and disadvantages of using knottin scaffolds as imaging agents, as well as to further enrich our understanding of the *in vivo* behavior of knottin peptides when they are coupled with different radionuclides.

In this research, ^{18}F-SFB was used as a prosthetic group for site-specifically labeling knottin 2.5D (Figure 1). Methods to couple ^{18}F-SFB have been well-established in our program (*14*). The nonradioactive version, ^{19}F-FB-2.5D, competes with ^{125}I-echistatin for binding cell surface integrins with an IC_{50} of 13.2 ± 5.4 nM, which is similar to that of the unmodified knottin peptide 2.5D (20.3 ± 7.3 nM). These data suggest that the N-terminal amine of the knottin peptide tolerates modification, and further *in vivo* evaluation of its radioactive counterpart confirmed this finding. Radiofluorination of 2.5D was efficiently achieved through site-specific conjugation of the radiosynthon, ^{18}F-SFB, with the N-terminal amino group under mild conditions (60 °C, 1 h). ^{18}F-FB-2.5D was prepared in a reasonable yield (final yield, 28.3%) and high specific activity (~100 GBq/μmol) at EOS, which boded well for clinical applications.

Considering the short physical half-life of ^{18}F as well as short biological blood half-life of the knottin peptide, our biodistribution and imaging data of ^{18}F-FB-2.5D were acquired in a relatively short time frame (up to 1 h p.i.). Consistent with our expectation, we observed good tumor uptake resulting in good image quality. These data are attributable to the peptide's tumor targeting ability and rapid clearance from normal tissues (Figure 4). As early as 0.5 h p.i., probe uptake in the tumor was 1.90 ± 1.15%ID/g. Liver uptake remained low at around 1.4 ± 0.5%ID/g at 0.5 h, which was similar compared with its ^{64}Cu labeled knottin counterpart (2.3 ± 0.8%ID/g) (*12*). Overall, microPET imaging data correlated well with the data derived from biodistribution studies. The U87MG tumor is clearly delineated from normal tissue at both 0.5 and 1 h p.i..

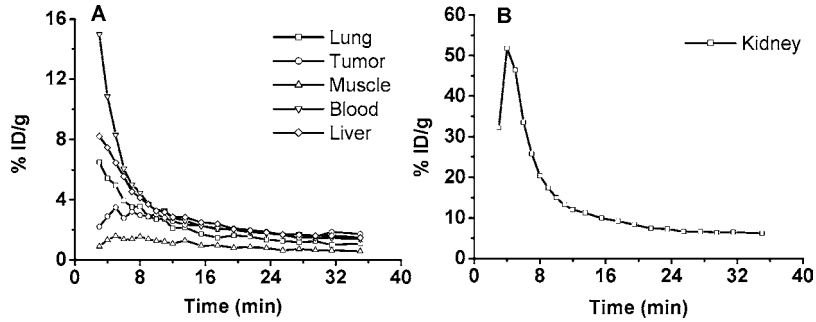

Figure 5. Time activity curves of major organs derived from a microPET dynamic scan of a mouse bearing U87MG tumors, after intravenous injection of ~3.7MBq (~100 μCi) ^{18}F-FB-2.5D.

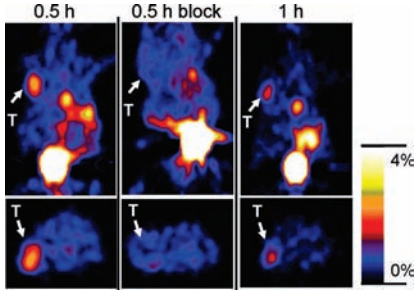

Figure 6. Decay corrected coronal (top) and transaxial (bottom) microPET images of nude mice bearing U87MG tumors (unit: %ID/g). Images were acquired 0.5 and 1 h after tail vein injection of 4.44 MBq (120 μCi) of ^{18}F-FB-2.5D with or without coinjection of 330 μg of c(RGDyK) ($n = 3$ for each group). Arrows indicate the location of tumors (T). Gallbladder and bladder can also be clearly seen.

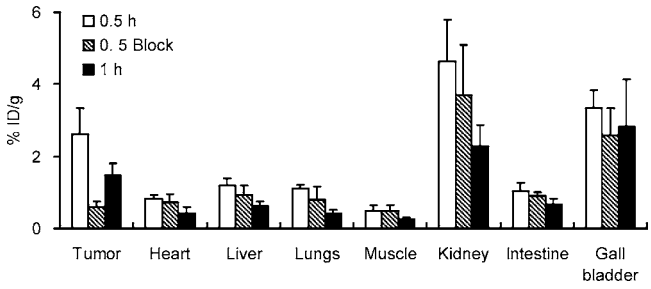

Figure 7. PET imaging quantification of intravenously injected ^{18}F-FB-2.5D measured by using ROI analysis of static small-animal PET data sets in nude mice bearing U87MG tumors ($n = 3$).

Quantification of microPET images showed that 56% of the activity remained in the tumor 1 h p.i., compared to the 0.5 h time point. Dynamic PET scans showed that the majority of ^{18}F-FB-2.5D was quickly cleared through renal system, and the blood radioactivity concentration dropped dramatically in the first 35 min p.i. These pharmacokinetic properties suggest translational potential.

Integrin $\alpha_v\beta_3$ expression *in vivo* has extensively been imaged by small, backbone cyclized peptidomimetics [c(RGDyK), c(RGDfK), etc.] (*20*−*24*). ^{18}F-FB labeled c(RGDyK) [abbreviated as FB-RGD] was reported to moderately target U87MG tumors *in vivo* (ca. 3 and 2.5%ID/g uptake at 0.5 and 1 h, respectively) (*21*). ^{18}F-FB-2.5D demonstrated lower liver uptake (1.5%ID/g at 0.5 h p.i.) compared to ^{18}F-FB-RGD (ca. 2.5 and 1%ID/g at 0.5). However, ^{18}F-FB-2.5D has lower tumor uptake (ca. 2% ID/g at 0.5 h p.i.), and the kidney uptake is slightly higher than ^{18}F-FB-RGD (4.5 vs 3.5%ID/g at 0.5 h p.i.). The findings presented here are different from our previous experience. In our recent report, ^{64}Cu labeled DOTA-2.5D did show significant advantages over ^{64}Cu-DOTA-c(RGDyK) (*12*). This difference indicates that various labeling methods impact *in vivo* performance of knottins. Moreover, it suggests that further optimization of ^{18}F-FB-2.5D may lead to a radiofluorinated knottin probe with improved properties. It was reported that PEGylation enhanced the tumor uptake and prolonged the retention of ^{18}F labeled c(RGDyK) (ca. 5%ID/g at 0.5 h and 2.5%ID/g at 2 h p.i.), while the liver uptake remained the same (ca. 2.6%ID/g at 0.5 h) (*24*). Similar strategies could be adapted to improve the tumor uptake and retention of ^{18}F-labeled knottins and increase the tumor-to-liver ratios.

As an important target for cancer therapy, $\alpha_v\beta_3$ integrin is highly overexpressed on tumor cells and the tumor neovasculature of many cancer including melanoma and glioblastoma (*13, 25, 26*). An optimized ^{18}F labeled 2.5D probe could be used for diagnosis of $\alpha_v\beta_3$-positive tumors, at both primary and metastatic sites. ^{18}F-labeled 2.5D could also be used for stratification of patients, detection of cancer recurrence, and monitoring therapeutic efficacy of integrin-targeted drugs. In conclusion, radiolabeled knottin peptide ^{18}F-FB-2.5D allows integrin-specific PET imaging of U87MG tumors with good contrast and is mainly cleared from the body through the renal system. Knottins are excellent peptide scaffolds for the development of PET probes for clinical translation.

ACKNOWLEDGMENT

This work was supported, in part, by Department of Radiology, Stanford University (ZC), National Cancer Institute (NCI) In Vivo Cellular Molecular Imaging Center (ICMIC) grant P50 CA114747 (SSG), NCI Small Animal Imaging Resource Program (SAIRP) grant R24 CA93862, NCI 5R01 CA119053 (ZC), NCI 5K01 CA104706 (JRC), and the Edward Mallinckrodt Jr. Foundation (JRC). The Stanford University cyclotron team, particularly Fred Chin, is acknowledged for radionuclide production.

Targeting Glioma Cells in Vitro with Ascorbate-Conjugated Pharmaceutical Nanocarriers

Stefano Salmaso,*[,†,‡] Juan S. Pappalardo,[†] Rupa R. Sawant,[†] Tiziana Musacchio,[†] Karen Rockwell,[†] Paolo Caliceti,[‡] and Vladimir P. Torchilin[†]

Department of Pharmaceutical Sciences and Center for Pharmaceutical Biotechnology and Nanomedicine, Northeastern University, Boston, Massachusetts 02115, and Department of Pharmaceutical Sciences, University of Padova, via F. Marzolo 5, 35131 Padova, Italy. Received August 19, 2009; Revised Manuscript Received October 16, 2009

6-Ascorbate-PEG-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine (6-ascorbate-PEG-PE) was synthesized according to a two-step procedure: (1) activation of ascorbic acid with bromine, and (2) synthesis of 6-ascorbate-PEG-PE by reacting 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino (poly(ethylene glycol))-2000] with an excess of 6-Br-ascorbic acid. The 6-ascorbate-PEG-PE was recovered by precipitation in diethyl ether and purified by gel permeation chromatography. The analysis of the product by ^{1}H NMR and UV−vis spectroscopy confirmed the identity of the conjugate. Liposomes and PEG-PE-based lipid-core micelles were prepared by thin film hydration technique incorporating 6-ascorbate-PEG-PE as targeting moiety. The targeting properties of the ascorbate-decorated nanosystems were tested by fluorescence-activated cell sorting (FACS) analysis and fluorescent microscopy on a panel of tumor cell lines preliminary selected for their ability to express the SVCT2 ascorbate transporter. Cell lines had been selected on the basis of the immunological properties assessed by FACS, which showed that two glioma cell lines, C6 and F98, and fibroblasts NIH/3T3 express plasma membrane-associated SVCT2 transporter for reduced ascorbic acid. Ascorbate-decorated pharmaceutical nanocarriers were endowed with selective targeting properties toward the SVCT2 transporter expressed in glioma cell models. This study shows that SVCT2 transporter for ascorbic acid expressed both in peculiar epithelial cells of the choroid plexus responsible for the filtering of vitamin C into the central nervous system (CNS) and, in some brain tumor cell lines, can be conceivably exploited as a potential target for delivery of drug-loaded pharmaceutical nanocarriers to the brain.

INTRODUCTION

In the past decades, a great deal of research has focused on targeting the central nervous system for therapeutic and diagnostic purposes. The goal appeared to be extremely challenging due to the physiological architecture of the biological barriers, namely, the blood−brain barrier (BBB) and the blood−cerebrospinal fluid (CSF) barrier, which have poor permeability and allow for only restricted access to selected molecules. Such barriers limit the permeation to the brain compartment, protecting the nervous systems from toxic compounds, metabolites, viruses, and bacteria. By virtue of these physiologic barriers, most of the targeting strategies for drug delivery to the brain have shown limited efficiency.

Central nervous system penetration is favored for molecules having low molecular weight and adequate hydrophilic/hydrophobic balance (*1*). Besides unspecific permeation, endothelial cells of the brain capillaries, which constitute the BBB, are provided with selective transport systems for specific nutrients and endogenous biomolecules. Thus, they are responsible for the transport of glucose; neutral, acidic, and basic amino acids; alanine and taurine; some monocarboxylic acids; amines; neuromediators, such as choline; some vitamins; nucleosides; and the peptide transport system for small neurotropic peptides (*2, 3*).

A limited district of the BBB, namely, the epithelium of the choroid plexus (CP), is considered to be responsible for the maintenance of central nervous system (CNS) homeostasis of few micronutrients, namely, vitamin C and riboflavin (*4*). It has been found that, in some neurons, ascorbic acid concentration can reach up to 200-fold higher than that measured in the bloodstream (*5*). Specific physiological mechanisms are operating in order to transfer ascorbic acid from the blood, where its concentration is ∼50 μM, into the cerebrospinal fluid where the concentration is maintained at 200 μM (*6*). Within the CNS, ascorbic acid plays a pivotal role as a cofactor in a number of different enzymatic activities relating to the neurotransmitters processing and as an antioxidant allowing for neuroprotection.

According to H. Tsukaguchi, the reduced form of ascorbic acid is taken up by a mechanism that involves the sodium-dependent-vitamin C transporters SVCT2, whose RNA was detected in the choroid plexus epithelium (*7*). SVCT2 transporter was found to be expressed by neuroepithelial cells of the choroid plexus and the retinal pigmented epithelium mostly. Despite other mechanisms having been proposed raising options for ascorbic acid penetration mechanism into the brain as the oxidized form, the SVCT2-mediated pathway seems the most likely one, since the oxidized form of vitamin C is undetectable in the blood at physiological conditions and unstable in water (*8*). Besides, the evidence that ascorbic acid reaches the cerebrospinal fluid through the route of CP and then slowly penetrates the brain substance from the CSF was demonstrated by the intravenous injection of [^{14}C] ascorbic acid (*9*). How specifically ascorbic acid exits CSF to permeate the brain is still to be investigated, and no extensive data are available in literature so far.

Few in vitro cell models are available for evaluating the mechanism of ascorbic acid uptake mediated by the SVCT2 translocator. SVCT2 transporter expression and function in primary cell culture of astrocytes (*10, 11*) and in monolayers obtained from the porcine choroid epithelial cells have been investigated (*12*−*14*). Many studies concerning SVCT function and targeting for drug delivery have been carried out by using cloned *Xenopus* oocytes, which were induced to express the desired plasma membrane associated vitamin C translocator (*7, 15, 16*).

Only a limited number of studies are available in the literature on the exploitation of ascorbic acid SVCT transporter as a biological target mediating the brain delivery of therapeutic or diagnostic molecules. Small molecular weight prodrugs were synthesized according to adequate chemical strategies combining ascorbic acid with CNS active molecules and underwent investigation for brain therapeutic activity. It was shown that ascorbic acid endowed such prodrugs with efficient binding features to epithelial-associated SVCT2 translocator (*17*). Despite the fact that such prodrugs were not found to cross the BBB, they were effective in releasing the drug in the vicinity of the site of action and promote the diffusion through the brain barrier. These results outline the potential of ascorbic acid transporter as a new mediator for drug delivery by using drug-loaded systems, which bind the CP epithelium and possibly either translocate through it or release the drug payload that, by virtue of its hydrophilic/hydrophobic balance, can permeate into the brain.

So far, the literature is lacking in macromolecular systems aimed at brain targeting, which take advantage of the SVCT2 transporter features, namely, molecular selectivity and physiological disposition. In order to set up a new in vitro cellular model to exploit for brain delivery studies, immunological characterization of a panel of immortalized cell lines was carried out to assess which of them express the SVCT2 transporter. The potential of pharmaceutical nanocarriers, namely, liposomes and lipid-core polymeric micelles, to target such cells via the SVCT transporter was investigated after the nanocarriers were decorated with ascorbate by modifying the 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-PEG_{2kDa}-NH_2 with ascorbic acid.

MATERIALS AND METHODS

Cell lines, mouse fibroblast NIH/3T3 and melanoma B16−F10, human glioblastoma LN-18 and neuroblastoma SK-N-AS, rat glioma C6 and F98, were purchased from the American Type Culture Collection (Manassas, VA). All cell culture media, RPMI, heat-inactivated fetal bovine serum (FBS), and penicillin/streptomycin stock solutions were purchased from Cellgro (Herndon, VA).

LAB-TEK 4-well cell culture chambers were purchased from Nunc (Rochester, NY). Goat polyclonal antibody anti-SVCT2 transporter (G-19) and donkey antigoat IgG-FITC were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz Biotechnology, CA). Goat antimouse IgG antibody was from ICN Biomedical (Aurora, OH).

Egg phosphatidylcholine (PC), cholesterol, 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy (poly(ethylene glycol))-2000] ($mPEG_{2kDa}$-PE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-N-[amino(poly(ethylene glycol))2000] (PE-PEG_{2kDa}-amine) and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (Rh-PE) were obtained from Avanti Polar Lipids, Inc. (Alabaster, AL). Bovine serum albumin and all other chemicals and buffer solution components were from Sigma (St. Louis, MO) and were of analytical grade. Sephadex G25 superfine medium was from GE Healthcare Bio-Sciences Corp. (Piscataway, NJ, USA).

Synthesis of 6-Bromodeoxy-ascorbic Acid. The preparation of the 6-bromo derivative of ascorbic acid was performed according to the published procedure (*18*) with some modifications. Two grams of ascorbic acid (11.35 mmol) was added to 2.7 mL of 33% w/v hydrobromic acid in glacial acetic acid (17.18 mmol). The suspension was stirred overnight at room temperature. Afterward, hydrobromic and acetic acid were removed by nitrogen flux and rotary evaporation. Five milliliters of deionized water was added to the syrup, and the mixture was stirred at 60 °C for 30 min. After reduction of the volume by rotary evaporation, the residue was extracted 6 times with 5 mL of ethylacetate, and traces of water were removed by sodium sulfate treatment. The organic solvent was removed under reduced pressure, and the resulting solid product was dissolved in 3 mL of acetonitrile warmed to 70 °C. The solution was cooled to 4 °C to allow crystallization. The white crystals were redissolved and recrystallized according to the same procedure. The final product was recovered by filtration and dried under the vacuum overnight.

6-Bromodeoxy-ascorbic acid dissolved in DMSO-d_6 was analyzed by ^{1}H NMR and ^{13}C NMR using a Varian 500 MHz spectrometer. ^{1}H NMR: δ 3.36 (dd, 1H, J = 10.06, δ 7.14 Hz, BrCC*H*H), δ 3.60 (dd, 1H, J = 10.06, 6.56 Hz, BrCCH*H*), δ 3.96 (t, 1H, J = 6.67 Hz, BrCH2C*H*OH), δ 4.83 (broad s, 1H, OCH), δ 5.63 (broad s, 5.63, 1H, BrCH2CHO*H*), δ 8.42 (s, 1H, OCOCOHCO*H*), δ 11.66 (s, 1H, OCOCO*H*COH). ^{13}C NMR: δ 34.6 (BrC), 68.2 (BrC*C*), 75.2 (OCH), 152.3 (OC-*C*OH), 118.1 (OCCOH═*C*OH), 170.3 (OC═O). Mass spectroscopy analysis was carried out by MALDI-TOF using 2,5-dihydroxybenzoic acid as a matrix. The negative ion was found to have 237.05 *m*/*z*.

Synthesis of 6-Ascorbate-PEG-PE. Into a 25 mL round-bottomed flask, 2.8 mL of a 25 mg/mL solution of PE-PEG_{2kDa}-amine in chloroform was added (25 μmol, 70 mg). The solvent was removed by rotary evaporation, and the solid residue was dissolved in 2 mL of DMF. Then, 60 mg of 6-bromodeoxy-ascorbic acid (250 μmol) and 35 μL of triethylamine (250 μmol) were added. The solution was stirred overnight under argon in the dark. The mixture was precipitated by dropwise addition to cold diethyl ether under stirring. The crude precipitate was washed several times with diethyl ether, and the solid was dried under vacuum. The dry powder was dissolved in 2 mL of deionized water, and the derivative was purified by size exclusion chromatography using a column prepacked with Sephadex G25 superfine medium eluted with milli-Q water. Fractions positive both to UV analysis and iodine test were pooled together and lyophilized. Yield was 40 mg (57%).

In order to assess the PEG/ascorbate molar ratio in the conjugate, iodine test for PEG (*19*), UV spectroscopic analysis for ascorbate (*20*), and Snyder colorimetric test for the residual PEG unconjugated amino groups (*21*) were carried out on a weighed amount of the purified derivative. 6-Ascorbate-PEG-PE dissolved in $CDCl_3$ underwent ^{1}H NMR spectroscopic analysis. ^{1}H NMR: δ 3.73 (d, 1H, OC*H*CHOHCH$_2$ of ascorbate), δ 3.642 (s, ∼180 H, −[OCH$_2$CH$_2$]$_n$− of PEG), δ 2.308 (m, 4H, OCOC*H*$_2$ of phospholipid stearate), 1.249 (m, 56 H, −[CH$_2$]$_n$− of phospholipid stearate).

Preparation and Characterization of Liposomes and Micelles. Rhodamine-labeled targeted liposomes were prepared by thin film hydration technique. A lipid film was obtained by removing organic solvent from the chloroform solution of 6-ascorbic acid-PEG-PE, egg PC, cholesterol, and Rh-PE in 3/60/30/0.25 molar ratio. The lipid film was suspended in RPMI, pH 7.4, containing 300 μM Tris(2-carboxyethyl)phosphine (TCEP) at a total lipid concentration of 0.435 mg/mL and sonicated in a bath sonicator for 10 min, followed by 11 passages through a mini-extruder equipped with 200 nm pore size polycarbonate filter (Avanti Polar Lipids). Untargeted

liposomes were prepared according to the same procedure using $mPEG_{2kDa}$-PE instead of 6-ascorbic acid-PEG-PE.

Rhodamine-labeled targeted micelles were prepared by dissolving 6-ascorbic acid-PEG-PE in chloroform. To that solution, 1 mol % of Rh-PE was added. The organic solvent was then removed by rotary evaporation, and the film was rehydrated at a final concentration of 1 mg/mL in RPMI containing TCEP 300 μM. Untargeted micelles were prepared using $mPEG_{2kDa}$-PE according to the same procedure.

The micelle and liposome sizes and size distributions were measured by dynamic light scattering (DLS) using a Zeta Plus instrument (Brookhaven Instrument Corporation, Holtsville, NY). The sample suspensions were analyzed after the appropriate dilution required for DLS. For each sample, size distribution measurements were performed six cycles per run.

The zeta-potential of liposome and micelle formulations was measured by a Zeta phase Analysis Light scattering (PALS) with an ultrasensitive Zeta Potential Analyzer instrument (Brookhaven Instruments, Holtsville, NY). The micelle and liposome suspensions were diluted properly with a 1 M KCl solution. All zeta-potential measurements were performed in triplicate.

Assessment of SVCT2-Expressing Cell Lines by Flow Cytometry. In order to select immortalized cell lines, which express SVCT2 transporter on plasma membrane, cells (NIH/3T3, B16−F10, LN-18, SK-N-AS, C6, and F98) were grown in RPMI with 10% FBS in 10 cm tissue culture plates for 72 h. Medium was removed; cells were washed with RPMI and detached by prechilling incubation for 15 min and pipetting. Cells were recovered by centrifugation at 1500 rpm, and 1 million cells were resuspended in 50 μL of PBS containing 3% FBS. Three microliters of a 200 μg/mL goat polyclonal anti SVCT2 transporter (G-19) or goat antimouse IgG antibody was added to each sample and incubated in the dark in an ice-cold bath for 30 min. Cells were then washed once with 1 mL of PBS containing 3% FBS, recovered by centrifugation, resuspended in 50 μL of the same medium, and treated with 3 μL of 200 μg/mL donkey antigoat IgG-FITC for 30 min in the dark in the ice bath. After washing with PBS containing 3% FBS, samples were fixed with 2% paraformaldehyde in PBS and analyzed by FACS (10 000 cells in average count) using BD FACSCalibur flow cytometer and BD CellQuest Pro software (Beckton Dickinson Biosciences, San Jose, CA). Cells were live-gated upon acquisition using forward versus side scatter to exclude debris and dead cells.

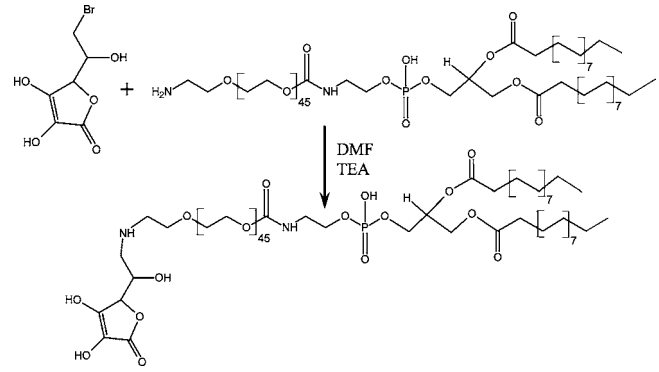
Ascorbate-Mediated Targeting of Pharmaceutical Nanocariers. *FACS Analysis.* In order to assess the cell-targeting capacity of ascorbate-conjugated nanocarriers, SVCT2-expressing cells incubated with liposomal or micellar formulations were subjected to the FACS analysis. SVCT2-expressing cells (C6, F98) were grown in 10 cm cell culture plates for 48 h.

Cells were washed with serum-free medium, detached by prechilling incubation and repetitive pipetting, recovered by centrifugation, and 1 million cells were resuspended in serum-free medium containing fluorescently labeled either targeted or untargeted nanocarriers prepared as described. Samples were incubated at 37 °C in the dark with gentle shaking for 90 min. Afterward, the cell samples were recovered by centrifugation, washed twice with PBS, and gated using forward versus side scatter to exclude debris and dead cells and analyzed (10 000 cells in average count) using BD FACSCalibur flow cytometer and BD CellQuest Pro software.

Epi-Fluorescence Microscopy. C6 and F98 cells were investigated using the fluorescence microscopy after incubation with fluorescently labeled targeted liposomes and micelles or untargeted nanocarriers as a reference. After the initial passage in tissue culture flasks, cells were grown in four-well tissue culture detachable LAB-TEK chambers, at a concentration of 5×10^5 cells per well in RPMI with 10% FBS. After 24 h, the chambers were washed twice with RPMI and then incubated at 37 °C with 0.5 mL of liposome or micelle formulations prepared as described in RPMI. After 1 h incubation, the medium was removed, and the plates were washed with medium three times. Samples were further incubated for 10 min at 37 °C with complete medium containing 0.5 μg/mL of Hoechst 33342 and washed twice with complete medium. Individual slides were covered with coverslips. Cells were observed immediately on a Nikon Eclipse E400 fluorescence microscope equipped with appropriate filters for bright light, Rhodamine and Hoechst detection, and a Nikon N60 camera.

For competition studies with ascorbic acid, cells grown on LAB-TEK chambers were washed twice with RPMI and incubated at 37 °C with 0.5 mL of 200 μM ascorbic acid in RPMI for 30 min followed by incubation for an additional 1 h with 6-ascorbate-PEG-PE-containing liposomes (0.464 mg/mL of total lipids). Samples were then washed three times with PBS and mounted with the fluormount medium. Cells were observed immediately by fluorescence microscopy as described, and the fluorescence intensity associated with the cells was quantified by image analysis software (*ImageJ*).

Scheme 1



RESULTS

Synthesis and Characterization of 6-Ascorbate-PEG-PE and Ascorbate-Conjugated Nanocarriers. The preparation of the 6-ascorbate-PEG-PE was carried out by a two-step procedure: (1) activation of ascorbic acid with bromine; (2) synthesis of 6-ascorbate-PEG-PE by PE-PEG_{2kDa}-amine reaction with excess of 6-Br-ascorbic acid. The procedure adopted to synthesize the 6-bromodeoxy ascorbic acid allowed, after the crystallization, a 40.5% yield. The ^{1}H NMR spectroscopic analysis showed that hydroxyl groups of ascorbate in positions 2, 3, and 5 are unmodified as confirmed by the corresponding signals at δ 8.42, 11.66, and 5.63, respectively. Mass spectrometry analysis of 6-bromo-ascorbic acid showed a signal at 237.05 *m*/*z*, which has been attributed to the monodeprotonated ion $[6\text{-bromoscorbate-H}^+]^{-1}$.

The reaction of the commercially available PE-PEG_{2kDa}-amine with a 20-fold molar excess of 6-bromo-ascorbate (Scheme 1) allowed for obtaining 6-ascorbate-PEG-PE in 12 h as determined by the disappearance of the primary PEG amino group by ninhydrin assay. The conjugation was carried out in anhydrous conditions in order to avoid water deactivation of the 6-bromo-ascorbate.

The crude product was precipitated in ether and dissolved in water to allow the formation of the micelles. The conjugate was purified by size exclusion chromatography from the unreacted 6-bromo-ascorbate yielding 70% product recovery. UV−vis, iodine, and Snyder colorimetric tests were carried out on a 1

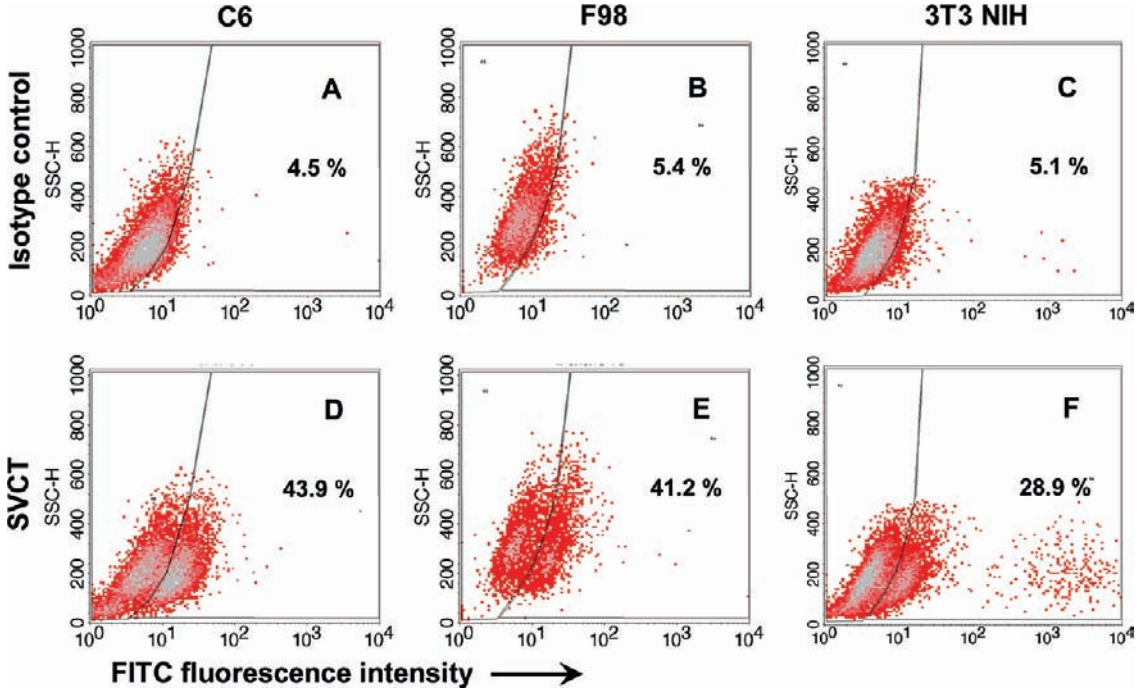


Figure 1. Characterization of SVCT2 expression in different cells. Cells were treated and analyzed by flow cytometry to evaluate expression of SVCT2 transporter. (A,D) C6 cells; (B,E) F98 cells; (C,F) NIH/3T3 cells. Above: cells treated with isotype control. Below: cells treated with goat polyclonal antibody anti SVCT2 transporter.

mg/mL water solution of 6-ascorbate-PEG-PE in order to assess ascorbate, PEG, and free amino groups, respectively. According to the tests, the conjugation yield was 98.9%, i.e., practically complete conjugation of the amino-terminating PEG-phospholipid to ascorbate was achieved by the procedure reported. The chemical identity of the conjugate was confirmed by ^{1}H NMR spectroscopy that showed typical signals of phospholipids at δ 2.308 and 1.249, PEG at δ 3.642, and ascorbate at δ 3.73.

The newly synthesized ascorbate-conjugated moiety was incorporated into liposomes or lipid-core PEG-PE micelles. As shown by the dynamic light scattering analysis, the lipid film rehydration techniques and extrusion yielded liposomal formulations of a similar size: 175.1 ± 21.2 nm and 181.9 ± 24.9 nm for untargeted and targeted liposomes, respectively. Micelle size was found to be 13.65 ± 5.1 nm and 21.3 ± 2.4 nm for $mPEG_{2kDa}$-PE and 6-ascorbate-PEG_{2kDa}-PE micelles, respectively. A slight increase in the micelle size can be ascribed to the additional presence of ascorbate moieties in the outer surface of the micelles.

Zeta-potential analysis of the lipid-based nanosystems showed that the presence of the ascorbate on their surface enhances their negative character due to the dissociation of the acid. PEGylated liposomes and PEG-PE-based micelles had zeta-potential of −12.8 ± 3.2 mV and −13.2 ± 2.3 mV, respectively, while ascorbate-conjugated liposomes and micelles showed a slight increase in the negative surface charge with zeta-potentials of −16.4 ± 4.2 mV and −19.2 ± 7.3 mV, respectively. Liposome and micelle sizes and zeta-potentials were unaffected by the presence of the reducing agent TCEP.

Selection of SVCT2-Expressing Cell Lines. In order to select a proper cell model suitable for further targeting studies, a panel of immortalized cell lines was tested to identify those expressing SVCT2 translocator on the plasma membrane by using saturating amounts of specific antibodies against the extracellular domain of SVCT2 protein. SK-N-AS (human neuroblastoma), LN18 (human glioblastoma), C6 and F18 (rat gliomas), NIH 3T3 (mouse fibroblasts), and B16−F10 (mouse melanoma) cells were investigated.

Cell lines were grown in an appropriate medium and detached by prechilling incubation and pipeting to prevent surface proteins from being proteolitically degraded by trypsin treatment, which is commonly used to recover cells from culture plastic surfaces. Detached cells were first incubated with goat polyclonal IgG anti SVCT2 transporter, which has selectivity for the detection of SVCT2 of mouse, rat, and human origin as stated by the provider. After washing, cells were incubated with donkey FITC-labeled antigoat antibody as a secondary antibody, and the degree of binding was determined by FACS analysis. Isotype control was performed by incubating cells with goat antimouse IgG in order to detect nonspecific antibody binding on the cell membrane.

As shown in Figure 1, 43.9%, 41.1%, and 28.9% of C6, F98, and NIH/3T3 cells stained positive for the SVCT2 expression, respectively (panels D, E and F), while nonspecific immunostaining with the isotype control was about 5% only (panels A, B, and C, respectively).

When the FACS analysis was carried out with murine LN18, SK-N-AS, and B16F10 cell lines treated with the monoclonal anti SVCT2 transporter, only a nonspecific weak immunoreactivity was detected, and the cell-associated fluorescence increase accounted for about 5% regardless of cell incubation with goat polyclonal IgG anti SVCT2 transporter or goat antimouse IgG antibody. The FACS experiments demonstrated that such cell lines do not express constitutionally the plasma membrane SVCT2 transporter.

Nanocarrier Targeting Studies. *FACS Analysis.* The ability of ascorbate-conjugated nanocarriers to selectively target SVCT2 transporter-expressing cells was evaluated using FACS analysis after an hour and a half incubation with liposomes or micelles. Ascorbate-free PEGylated liposomes or $mPEG_{2kDa}$-PE micelles were used as control. Two different cell lines of rat origin, C6 and F98 glioma cell lines, both expressing SVCT2 transporter, were incubated with liposomes containing 3% of 6-ascorbate-PEG-PE or with 6-ascorbate-PEG-PE micelles fluorescently labeled with Rh-PE.

As depicted in Figure 2, FACS analysis showed that ascorbate conjugation increases C6 cells targeting by 23.2% and 10.1%

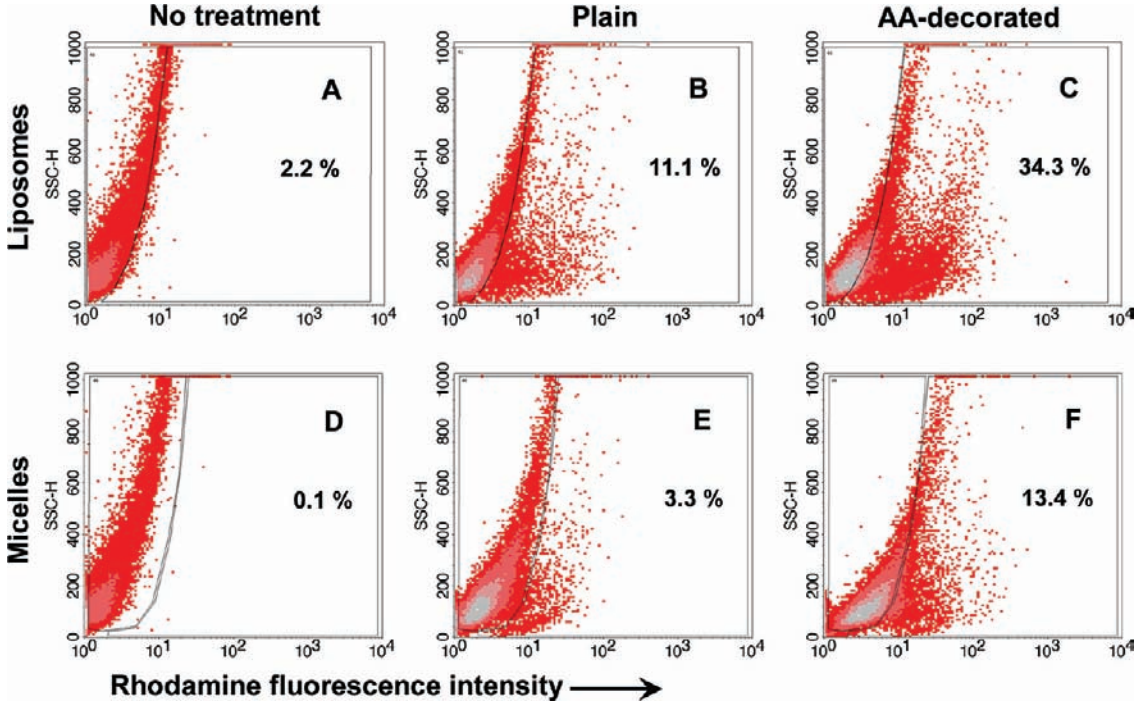

Figure 2. FACS analysis of rat C6 cells untreated (A,D), and after 1.5 h treatment with rhodamine-labeled PEG-liposomes (B), ascorbate-PEG-liposomes (C), $mPEG_{2kDa}$-PE micelles (E), and ascorbate-PEG-PE micelles (F).

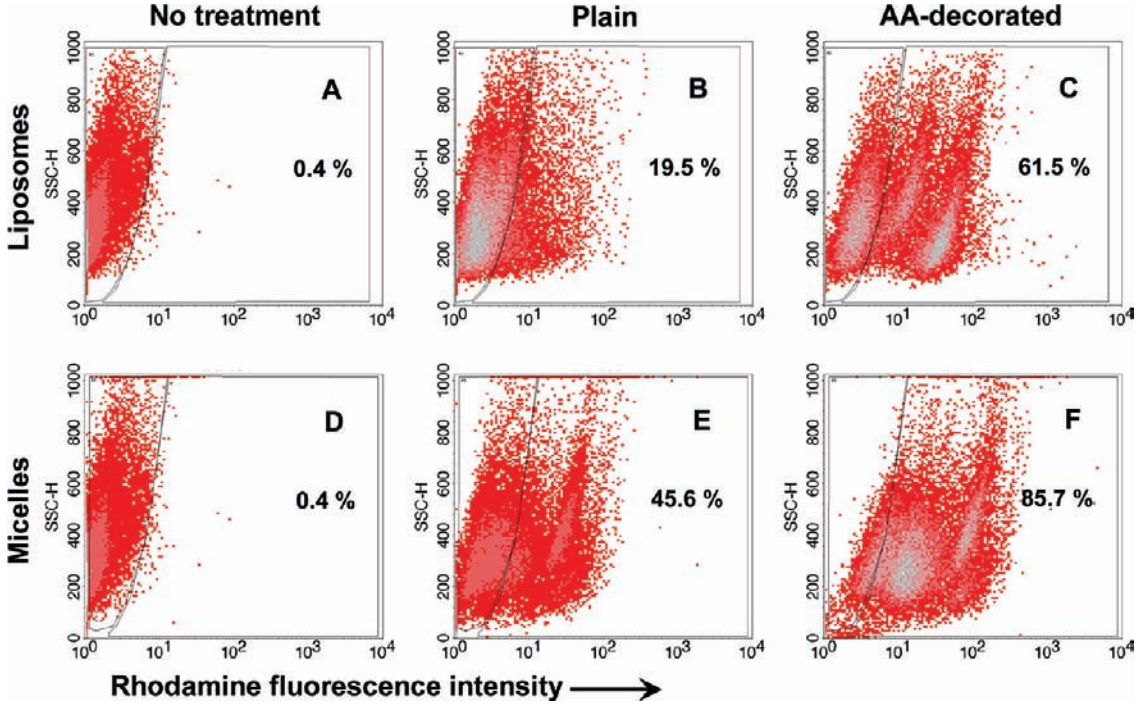

Figure 3. FACS analysis of rat F98 cells untreated (A,D), and after 1.5 h treatment with rhodamine-labeled PEG-liposomes (B), ascorbate-PEG-liposomes (C), $mPEG_{2kDa}$-PE micelles (E), and ascorbate-PEG-PE micelles (F).

when targeted liposomes and micelles were employed, respectively (pannels C and F), compared to ascorbate-free PEG-liposomes and $mPEG_{2kDa}$-PE micelles controls. Nonspecific cell targeting was shown to account for about 9% and 3% fluorescence increase for PEGylated liposomes and $mPEG_{2kDa}$-PE micelles (panels B and E, respectively) with respect to untreated cell samples (panels A and D, respectively). Cells were analyzed as a whole without gating (data not shown).

Figure 3 reports the results obtained by FACS analysis to evaluate the targeting efficiency of ascorbate-conjugated nanocarriers toward F98 glioma cell line. F98 cells fluorescence increase was remarkably higher compared to C6 cells when cell samples were treated with ascorbate-decorated liposomes (C) and micelles (F), 42% and 40.1%, respectively. A stronger nonspecific cell-associated fluorescence was also found on the F98 cell line for nontargeted liposome and micelles, 19.1% and 45.2%, respectively (B and E), compared to the C6 cell line, which could be explained by the higher nonspecific uptake activity of these cells.

Epifluorescence Microscopy. To additionally evaluate whether the ascorbate can be employed as a targeting moiety to deliver pharmaceutical nanocarriers to SVCT transporter-expressing

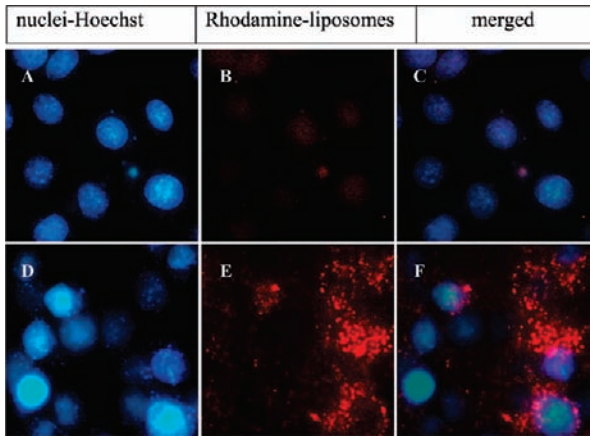

Figure 4. Epifluorescent microscopic examination of C6 cell line treated with fluorescently labeled PEG-liposomes (A,B,C) and ascorbate-PEG-liposomes (D,E,F). Cell images were acquired in a blue channel for nuclei detection after staining with Hoechst 33342 (panels A and D) and red channel for Rh-PE-labeled liposome detection (panels B and E). Panels C and F are the superimpositions of the two channels. Images were taken at 100× magnification.

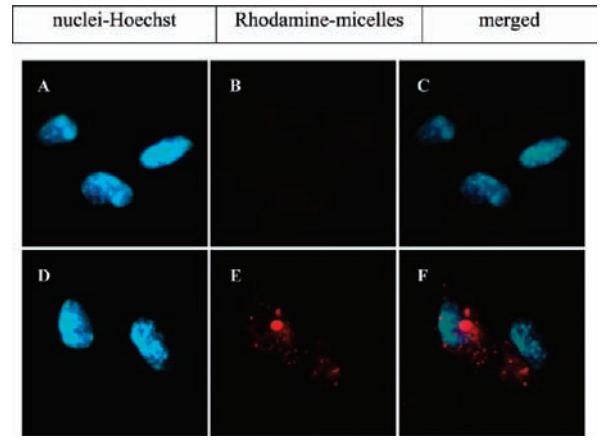

Figure 5. Epifluorescent microscopic examination of C6 cell line treated with fluorescently labeled PEG-PE micelles (A,B,C) and ascorbate-PEG-PE micelles (D,E,F). Cell images were acquired in a blue channel for nuclei detection after labeling with Hoechst 33342 (panels A and E) and red channel for rhodamine-labeled micelles detection (panels B and E). Panels C and F are the superimpositions of the two channels. Images were taken at 100× magnification.

cells, C6 cells were also investigated using fluorescence microscopy after the incubation with fluorescently labeled liposomes and micelles. Nuclei were stained by Hoechst 33342 treatment (Figure 4, blue fluorescence on panels A and D). The epifluorescence micrographs obtained clearly support ascorbate-PEG-liposome targeting to the investigated glioma cells. In fact, strongly fluorescent red spots associated with the cells were clearly visible (panel E in Figure 4 shows the red fluorescence of targeted liposomes; panel F shows superimposition of blue and red fluorescence). On the contrary, the treatment with nontargeted PEGylated liposomes did not result in any defined fluorescent spots associated to the glioma cells, indicating the lack of targeting toward this cell line (panel B in Figure 4 shows undetectable red fluorescence of PEG-liposomes; panel C shows superimposition of blue and red fluorescence). It is important to note here that PEGylated liposomes are commonly recognized for their stealth properties, which reduce the interaction with biological surfaces.

The ascorbate-mediated targeting was investigated also after the treatment of C6 cells with rhodamine-labeled micelles as shown in Figure 5. Panels A and D report nuclei staining by the Hoechst treatment. Panels B and E report red fluorescence of cells treated with untargeted micelles and ascorbate-PEG-PE micelles, respectively, while panels C and F are the superimpositions of the two channels. Cells treated with ascorbate-conjugated micelles showed small punctuate red fluorescent spots (panels E and F), which might be due to aggregation of micelles and uptake of the aggregates by C6 glioma cells.

Competition studies were performed with epifluorescence microscopy by C6 cells preincubation with free ascorbic acid followed by the treatment with rhodamine-labeled ascorbate-PEG-liposomes. The presence of ascorbic acid in the medium dramatically reduced the cell-associated fluorescence as depicted in Figure 6 (panel B) compared to cell samples treated with targeted liposomes only (Figure 6, panel A). The preincubation of cell samples with ascorbic acid followed by the treatment with ascorbate-PEG-liposomes reduced the cell-associated fluorescence induced by targeted nanosystems by 7-fold as determined by the image analysis (Figure 7).

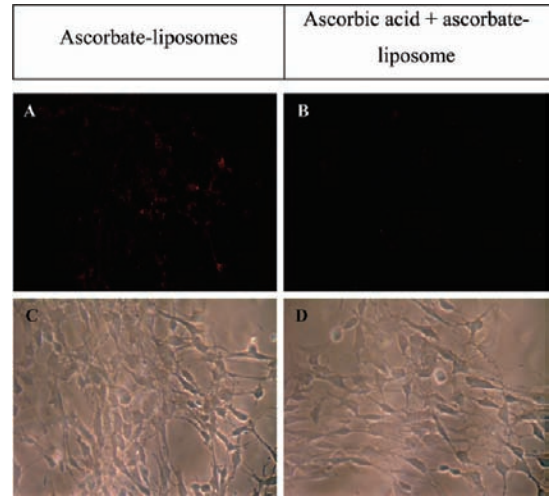

Figure 6. Epifluorescent microscopic examination of C6 cells treated with fluorescently labeled ascorbate-PEG-liposomes without (A) and with (B) ascorbic acid preincubation. Images were acquired in a red channel for rhodamine detection. Panels C and D show the bright light acquisition of the same samples. Images were taken at 40× magnification.

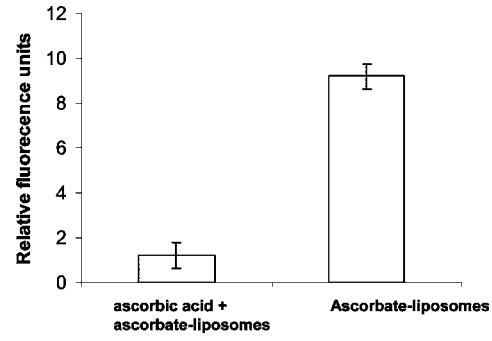

Figure 7. Relative fluorescence intensity associated with C6 cells after treatment with rhodamine-labeled ascorbate-PEG-liposomes with or without preincubation with free ascorbic acid.

DISCUSSION

In the present study, we have investigated the targeting capacity of ascorbic acid moiety to confer selectivity to pharmaceutical nanocarriers. A new in vitro cellular model was set up to evaluate the targeting activity of ascorbate-conjugated nanocarriers.

Ascorbic acid was activated as a bromo derivative, and the chemical identity of the intermediate was confirmed by ^{1}H NMR

and mass spectroscopy. Activation at the carbon in position 6 of ascorbic acid was chosen according to reported data which showed the biological activity and the selective binding capacity of the 6-deoxy-ascorbic acid derivatives toward the SVCT2 transporter (*22*). Activated 6-bromodeoxy-ascorbic acid was reacted in anhydrous condition with the primary amino group of commercially available PE-PEG_{2kDa}-amine by using excess of the 6-bromo-ascorbic acid. At the end, the excess of reactive ascorbic acid was removed by precipitation of the reaction mixture in diethyl ether and size exclusion chromatography that allowed for obtaining a product with high purity. The identity of the conjugated product was investigated by ^{1}H NMR and UV spectroscopy and colorimetric tests for assessing ascorbate and PEG in the conjugate. The tests confirmed high conjugation yield and 1/1 ascorbic acid/PEG-PE molar ratio. In order to maintain the conjugated ascorbic acid in the reduced form, which binds selectively SVCT transporter, buffered solutions were kept in the dark and in the presence of TCEP as reducing agent, which allowed the regeneration of traces of oxidized ascorbate eventually formed during the conjugation and purification processes (*20*).

The targeting moiety was incorporated into pharmaceutical nanocarriers, such as liposomes and polymeric lipid-core micelles, by the thin film rehydration method that allowed for obtaining liposomes and micelles with defined dimensions and surface properties. As assessed by photocorrelation spectroscopy, targeted and untargeted liposomes had diameters of about 180 nm and negative zeta potential, which was expectedly increased by the presence of ascorbic acid. Micelle dimensions were found to be in a close range (15−20 nm) regardless of the presence of ascorbate on the surface. Slight increase of the negative zeta-potential was found for ascorbate micelles similar to liposomes.

In order to set up a cell model to evaluate the targeting performance of ascorbate-decorated nanocarriers, a panel of diverse immortalized cell lines underwent investigation for the expression of SVCT2 transporter by immunostaining and flow cytometry analysis. Keeping in mind the future use of this approach for brain-targeted delivery, we have chosen for investigation a panel of cell lines related to the brain glia (LN-18, SK-N-AS, C6, and F98) as well as cells with potential involvement in processing of ascorbic acid (NIH/3T3 and B16−F10) (*23, 24*). Cells were treated with a goat polyclonal anti SVCT2 trasporter antibody recognizing an extracellular epitope of the protein. Among the cells scanned, two rat glioma cells, C6 and F98, were shown to express plasma membrane-associated SVCT2 transporter. NIH/3T3 cells also gave positive test results. This cell-line phenotypic characterization technique is new with respect to many SVCT transporter expression studies reported in the literature, which were aimed at assessing solely the presence of RNA encoding for such protein, rather than its disposition on the cell surface (*25*).

The partial positivity of the cellular population to the immunological characterization, which results in only partial shift of the cells in Figure 1, can be explained by variation of the ascorbate transporter expression throughout the cell cycle. In light of such immunologic results, it is conceivable that C6 and F98 glioma cells represent a good cancer cell model to analyze a possible use of the SVCT2 transporter for specific targeting of pharmaceutical nanocarriers. Such a model can be complementary to reported primary cell culture (*13, 26*) and SVCT2-transfected *Xenopus* oocytes models (*22*) for investigation of drug delivery systems intended to target SVCT2-expressing cells. Besides, such a study introduces the perspective that the SVCT2 transporter can be a good ligand to target the brain through the choroid plexus, where it is selectively expressed, and allow drug delivery systems to reach SVCT2-expressing tumor cells.

On the basis of the results originating from the immunological characterization, we have studied the targeting capacity of ascorbate-conjugated liposomes and micelles toward C6 and F98 glioma cells. Flow cytometry analysis of C6 and F98 cells treated with targeted liposomes and micelles labeled with Rh-PE showed that both nanosystems bind with the target cells much better than nontargeted ascorbate-free nanocarriers used as controls. FACS analysis displayed that untargeted liposomes and micelles associate to a different extent with C6 and F98 cell lines. Nonspecific cell uptake of untargeted liposomes was lower with both cell lines, C6 and F98 (panels B in Figure 2 and 3, respectively), testifying to better "stealth" properties of PEGylated liposomes compared to micelles. Instead, nonspecific cell uptake of $mPEG_{2kDa}$-PE based micelles is detectable with C6 cells (Figure 2, panel E) but more remarkable in the case of F98 cells (Figure 3, panel E). The different behavior may be ascribed to the diverse physical stability of the two nanosystems. This can allow for membrane fusion of micelles rather than liposomes within the same cell line. On the other hand, the different surface properties of the two cell lines investigated may affect the biological behavior of a given nanosystem. However, the unspecific uptake does not prevail over the effect of ascorbate-mediated cell targeting for both nanosystems.

The capacity of ascorbate-conjugated liposomes and micelles to selectively interact with SVCT2-expressing cells was also investigated with glioma C6 cells by fluorescence microscopy. It was found that the cell-associated liposomes (the quantity of cell-associated rhodamine fluorescence) were clearly visible already after 1 h contact with targeted liposomes (Figure 4). Well-defined red spots were found to be coupled to the cells; they may be deposited either on the outer side of the plasma membrane or inside the cytosol undergoing intracellular trafficking. The increase in cell-associated fluorescence observed for ascorbate liposomes compared to nontargeted liposomes may be explained by the ascorbate-mediated cellular uptake. Samples treated with nontargeted liposomes do not show red fluorescence (Figure 4, panels B and C). Similar patterns were observed when C6 cells were imaged by fluorescence microscopy after the treatment with ascorbate-targeted and nontargeted PEG-PE micelles (Figure 5). These results clearly demonstrate targeting selectivity of the ascorbate-conjugated nanocarriers toward these cells.

In order to confirm the specific addressing of SVCT transporter by ascorbate-conjugated nanocarriers, we have performed the competition study in the presence of an excess of free ascorbic acid. Preincubation of tumor cells with free ascorbic acid strongly reduced the ascorbate−liposome cellular association confirming that the nanosystems selectively target the ascorbate cell membrane transporter.

Nanosystems that target solely the ascorbic acid transporter can potentially reach and accumulate in the brain due to local expression of SVCT2, which is limited to choroid plexus epithelial cells, some neurons, tanycytes, astrocites, and the arachnoid membrane (*7*). The conjugation of the ascorbate moiety to nanocarriers via the carbon in position 6 was shown to preserve its binding recognition for SVCT2 transporter and avoid binding to the glucose (GLUT) transporters, which are targeted by the oxidized ascorbic acid. Furthermore, the eventually oxidized form of conjugated 6-deoxyascorbate cannot bind the GLUT transporters, which are spread over the whole body (*22*). The targeting of the glucose transporter by ascorbate-conjugated pharmaceutical nanocarriers was unlikely, since the cells were treated with the medium containing 2 g/L of glucose that competes with the oxidized ascorbate if any of its trace is present. According to these considerations, ascorbate moiety can be considered as a potential site-selective targeting agent for brain delivery.

As reported in the literature, great efforts have focused on targeting the brain with nanosystems having adequate dimension,

morphology, and surface properties. Systemically administered polymeric nanoparticles were shown to be filtered through fenestrated capillaries of the CP and were rapidly transported into the CSF by absorptive transcytosis (*27*). Reported nanosystems showed promising performance, which could be ascribed to the tiny dimensions and decoration with a proper BBB transporting vector. Some peculiar features make such colloidal systems potential tools for brain drug delivery and support new perspectives that the CP can be exploited as a physiologic gateway to reach the brain. With this in mind, adequate nanosystems can be designed, which filter off the capillaries and bind to SVCT2 transporters of the choroid ependymal cells (*12*). At this site, they can either release their payload, which can diffuse into the brain, or undergo transcytosis allowing for further delivery toward the brain.

This study has also highlighted that ascorbic acid can be employed as a targeting agent to promote the disposition of drug-loaded nanosystems to neoplastic tissues (namely, the gliomas). Our data may facilitate the potential therapeutic use of ascorbate-conjugated nanosystems for the treatment of some brain-associated diseases.

ACKNOWLEDGMENT

This research was based in part on a concept suggested by Anthony Manganaro.

Gallium-67-Labeled Lactam Bridge-Cyclized α-Melanocyte Stimulating Hormone Peptide for Primary and Metastatic Melanoma Imaging

Haixun Guo,[†] Jianquan Yang,[†] Nalini Shenoy,[†] and Yubin Miao*[,†,‡,§]

College of Pharmacy, Cancer Research Treatment Center, and Department of Dermatology, University of New Mexico, Albuquerque, New Mexico 87131. Received September 28, 2009; Revised Manuscript Received October 19, 2009

The purpose of this study was to examine the melanoma imaging properties of a novel ^{67}Ga-labeled lactam bridge-cyclized α-melanocyte stimulating hormone (α-MSH) peptide. A lactam bridge-cyclized α-MSH peptide, DOTA-GlyGlu-CycMSH {DOTA-Gly-Glu-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp]}, was synthesized and radiolabeled with ^{67}Ga. The melanoma targeting and pharmacokinetic properties of ^{67}Ga-DOTA-GlyGlu-CycMSH were determined in B16/F1 flank primary melanoma-bearing and B16/F10 pulmonary metastatic melanoma-bearing C57 mice. Flank primary melanoma and pulmonary metastatic melanoma imaging were performed by small animal single photon emission computed tomography (SPECT)/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe. ^{67}Ga-DOTA-GlyGlu-CycMSH was readily prepared with greater than 95% radiolabeling yield. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited substantial tumor uptake (12.93 ± 1.63%ID/g at 2 h postinjection) and prolonged tumor retention (5.02 ± 1.35%ID/g at 24 h postinjection) in B16/F1 melanoma-bearing C57 mice. The uptake values for nontarget organs were generally low (<0.30%ID/g) except for the kidneys at 2, 4, and 24 h postinjection. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited significantly ($p < 0.05$) higher uptakes (1.44 ± 0.75%ID/g at 2 h postinjection and 1.49 ± 0.69%ID/g at 4 h postinjection) in metastatic melanoma-bearing lung than those in normal lung (0.15 ± 0.10%ID/g and 0.17 ± 0.11%ID/g at 2 and 4 h postinjection, respectively). Both flank primary B16/F1 melanoma and B16/F10 pulmonary melanoma metastases were clearly visualized by SPECT/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe 2 h postinjection. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited favorable melanoma targeting and imaging properties, highlighting its potential as an effective imaging probe for early detection of primary and metastatic melanoma.

INTRODUCTION

G protein-coupled melanocortin-1 (MC1) receptors are distinct molecular targets for developing melanoma-specific peptide radiopharmaceuticals due to their overexpression on human and mouse melanoma cells (*1*−*5*). α-Melanocyte stimulating hormone (α-MSH) peptides can specifically target the MC1 receptors with diagnostic and therapeutic radionuclides through specific peptide−receptor interaction for melanoma imaging and therapy (*6*−*18*). Recently, we have reported a novel class of ^{111}In-labeled lactam bridge-cyclized α-MSH peptides as effective imaging probes for melanoma detection (*19, 20*). Unique lactam bridge cyclization made the radiolabeled peptides stable both *in vitro* and *in vivo*. Both primary melanoma and pulmonary melanoma metastases were clearly visualized by small animal SPECT/CT using ^{111}In-DOTA-GlyGlu-CycMSH {^{111}In-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid-c[Lys-Nle-Glu-His-DPhe-Arg-Trp-Gly-Arg-Pro-Val-Asp]} as an imaging agent (*19, 20*), highlighting the potential applications of radiolabeled lactam bridge-cyclized α-MSH peptides as effective diagnostic and therapeutic agents for melanoma.

Gallium-67 and Gallium-68 are suitable SPECT and positron emission tomography (PET) radiometals with desirable radiophysical properties (*21, 22*). Gallium-67 has a half-life of 78.3 h and decays with three γ-emissions at 93 keV (38% abundance), 185 keV (24% abundance), and 300 keV (16% abundance) that are suitable for SPECT imaging (*23, 24*). Moreover, ^{67}Ga is also a potential therapeutic radiometal due to its emissions of Auger and conversion electrons (*25*). Gallium-67 is a cyclotron-produced radionuclide (^{68}Zn(p, 2n)^{67}Ga) and is commercially available. The relatively long half-life of ^{67}Ga (78.3 h) makes it feasible to ship to the hospital or research institution after the production at the cyclotron site. Gallium-68 is an attractive radionuclide for PET imaging due to its 89% positron emission (maximum energy of 1.92 MeV). Gallium-68 has a half-life of 68 min and can be easily obtained via an in-house commercial ^{68}Ge−^{68}Ga generator, making the production of ^{68}Ga independent of an onsite dedicated cyclotron (*26*). The 68-min half-life of ^{68}Ga allows the generator elution every 3−4 h, which is ideal for several clinical studies in patients in one day. The half-life of the parent ^{68}Ge is 260.8 days, which makes the shelf life of a ^{68}Ge/^{68}Ga generator greater than one year. Importantly, ^{67}Ga and ^{68}Ga can be easily conjugated by the DOTA-peptides, which makes the kit formulation possible and facilitates the clinical use of gallium radiopharmaceuticals for SPECT and PET imaging.

Our laboratory has been interested in developing radiometal-labeled lactam bridge-cyclized α-MSH peptides for melanoma SPECT imaging. Hence, we prepared ^{67}Ga-DOTA-GlyGlu-CycMSH and examined its melanoma imaging properties in primary and pulmonary metastatic melanoma models to determine whether it could be used as an effective SPECT agent for both primary and metastatic melanoma detection in this study. The biodistribution and melanoma imaging properties of ^{67}Ga-DOTA-GlyGlu-CycMSH were determined in B16/F1 flank primary melanoma-bearing C57 mice and B16/F10 pulmonary metastatic melanoma-bearing C57 mice. The effect of L-lysine

coinjection in reducing the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was examined in B16/F1 melanoma-bearing C57 mice.

MATERIALS AND METHODS

Chemicals and Reagents. Amino acids and resin were purchased from Advanced ChemTech Inc. (Louisville, KY) and Novabiochem (San Diego, CA). DOTA-tri-*t*-butyl ester was purchased from Macrocyclics Inc. (Richardson, TX). $^{67}GaCl_3$ was purchased from MDS Nordion, Inc. (Vancouver, Canada). All other chemicals used in this study were purchased from Thermo Fischer Scientific (Waltham, MA) and used without further purification. B16/F1 and B16/F10 murine melanoma cells were obtained from American Type Culture Collection (Manassas, VA).

Complexation of the Peptide with ^{67}Ga. DOTA-GlyGlu-CycMSH was synthesized as described previously (*19*) and identified by mass spectrometry. DOTA-GlyGlu-CycMSH was radiolabeled with ^{67}Ga using a 0.5 M NH_4OAc-buffered solution at pH 3.5. Briefly, 10 μL of $^{67}GaCl_3$ (18.5−37.0 MBq in 0.05 M HCl), 10 μL of 1 mg/mL DOTA-GlyGlu-CycMSH aqueous solution and 100 μL of 0.5 M NH_4OAc (pH 3.5) were added into a reaction vial and incubated at 90 °C for 20 min. After the incubation, 10 μL of 0.5% EDTA aqueous solution was added into the reaction vial to quench the reaction. The radiolabeled peptide was purified to single species by Waters RP-HPLC (Milford, MA) on a Grace Vadyc C-18 reverse-phase analytical column (Deerfield, IL) using the following gradient at a flow rate of 1 mL/min. The mobile phase consisted of solvent A (20 mM HCl aqueous solution) and solvent B (100% CH_3CN). The gradient was initiated and kept at 84:16 A/B for 3 min followed by a linear gradient of 84:16 A/B to 74:26 A/B over 20 min. Then, the gradient was changed from 74:26 A/B to 10:90 A/B over 3 min followed by an additional 5 min at 10:90 A/B. Thereafter, the gradient was changed from 10:90 A/B to 84:16 A/B over 3 min. The purified ^{67}Ga-peptide sample was purged with N_2 gas for 20 min to remove the acetonitrile. The pH of final solution was adjusted to 7.4 with 0.1 N NaOH and normal saline for cell work and animal studies. Serum stability of ^{67}Ga-DOTA-GlyGlu-CycMSH was determined by incubation in mouse serum at 37 °C according to the published procedure (*19*) for 24 h, and monitored for degradation by RP-HPLC.

Cellular Internalization and Efflux of ^{67}Ga-DOTA-GlyGlu-CycMSH. Cellular internalization and efflux of ^{67}Ga-DOTA-GlyGlu-CycMSH were evaluated in B16/F1 melanoma cells. After being washed once with binding medium, B16/F1 cells in cell culture plates were incubated at 25 °C for 20, 40, 60, 90, and 120 min ($n = 3$) in the presence of approximately 200 000 counts per minute (cpm) of HPLC-purified ^{67}Ga-DOTA-GlyGlu-CycMSH. After incubation, the reaction medium was aspirated and the cells were rinsed with 2 × 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS. Cellular internalization of ^{67}Ga-DOTA-GlyGlu-CycMSH was assessed by washing the cells with acidic buffer [40 mM sodium acetate (pH 4.5) containing 0.9% NaCl and 0.2% BSA] to remove the membrane-bound radioactivity. The remaining internalized radioactivity was obtained by lysing the cells with 0.5 mL of 1 N NaOH for 5 min. Membrane-bound and internalized ^{67}Ga activities were counted in a γ-counter. Cellular efflux of ^{67}Ga-DOTA-GlyGlu-CycMSH was determined by incubating B16/F1 cells with ^{67}Ga-DOTA-GlyGlu-CycMSH for 2 h at 25 °C, removing nonspecific-bound activity with 2 × 0.5 mL of ice-cold pH 7.4, 0.2% BSA/0.01 M PBS rinse, and monitoring radioactivity released into cell culture medium. At time points of 20, 40, 60, 90, and 120 min, the radioactivities on the cell surface and in the cells were separately collected and counted in a Wallac 1480 automated γ-counter (PerkinElmer, NJ).

B16/F1 Flank Primary and B16/F10 Pulmonary Metastatic Melanoma Models. B16/F1 flank primary melanoma and B16/F10 pulmonary metastatic melanoma models were generated to evaluate the biodistribution properties of ^{67}Ga-DOTA-GlyGlu-CycMSH. B16/F1 or B16/F10 melanoma cells were cultured in RPMI 1640 medium (Invitrogen Corporation, Grand Island, NY) containing $NaHCO_3$ (2 g/L), which was supplemented with 10% heat-inactivated fetal calf serum, 2 mmol/L L-glutamine, and 48 mg of gentamicin. B16/F1 flank primary melanoma tumors were generated by subcutaneously inoculating 1×10^6 B16/F1 cells/mouse in the right flank of the C57 mice (Harlan, Indianapolis, IN). The tumors reached approximately 0.2 g 10−12 days after the cell implantation. Pulmonary metastatic melanoma tumors were generated via injecting 2×10^5 B16/F10 cells/mouse into the C57 mice through the tail vein. The metastatic melanoma-bearing mice were used for biodistribution studies 16 days after cell injection.

Biodistribution Studies. All the animal studies were conducted in compliance with Institutional Animal Care and Use Committee approval. The biodistribution properties of ^{67}Ga-DOTA-GlyGlu-CycMSH were determined in B16/F1 flank melanoma-bearing C57 mice. Each mouse was injected with 0.037 MBq of ^{67}Ga-DOTA-GlyGlu-CycMSH through the tail vein. Groups of 5 mice were sacrificed at 0.5, 2, 4, and 24 h postinjection; and tumors and organs of interest were harvested, weighed, and counted. Blood values were taken as 6.5% of the whole-body weight. The results were expressed as percent injected dose/gram (%ID/g) and as percent injected dose (%ID). The specificity of the tumor uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was determined by blocking the tumor uptake with the coinjection of 10 μg of non-radiolabeled DOTA-GlyGlu-CycMSH. The biodistribution of ^{67}Ga-DOTA-GlyGlu-CycMSH in B16/F10 pulmonary metastatic melanoma-bearing C57 mice was determined and compared with that in normal C57 mice at 2 and 4 h postinjection.

Effect of L-Lysine Co-Injection on the Renal Uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH. L-Lysine coinjection is effective in decreasing the renal uptakes of radiolabeled α-MSH peptides. Hence, the effect of L-lysine coinjection on the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was examined in B16/F1 melanoma-bearing C57 mice. A group of 5 mice were injected with a mixture of 0.037 MBq of ^{67}Ga-DOTA-GlyGlu-CycMSH and 15 mg of L-lysine. The mice were sacrificed at 2 h postinjection, and tumors and kidneys were harvested, weighed, and counted in a γ-counter.

Imaging Melanoma with ^{67}Ga-DOTA-GlyGlu-CycMSH. The melanoma imaging properties of ^{67}Ga-DOTA-GlyGlu-CycMSH were examined in B16/F1 primary melanoma-bearing and B16/F10 pulmonary metastatic melanoma-bearing C57 mice. Two B16/F1 flank melanoma-bearing C57 mice were injected with 7.1 MBq of ^{67}Ga-DOTA-GlyGlu-CycMSH with or without 30 μg of non-radiolabeled DOTA-GlyGlu-CycMSH via the tail vein to demonstrate the specificity of the melanoma uptake. The mice were anesthetized with 1.5% isoflurane for small animal SPECT/CT (Nano-SPECT/CT, Bioscan) imaging 2 h postinjection. The 9 min CT imaging was immediately followed by the SPECT imaging of whole body. The SPECT scans of 24 projections were acquired, and total acquisition time was 60 min. Reconstructed data from SPECT and CT were visualized and coregistered using InVivoScope (Bioscan, Washington, DC).

A B16/F10 pulmonary metastatic melanoma-bearing mouse was used for ^{67}Ga-DOTA-GlyGlu-CycMSH SPECT/CT imaging to determine whether the melanoma metastases developed in the early stage (13 days after the cell injection) could be detected. The mouse was injected with 4.6 MBq of ^{67}Ga-DOTA-GlyGlu-CycMSH via the tail vein. The mouse was anesthetized

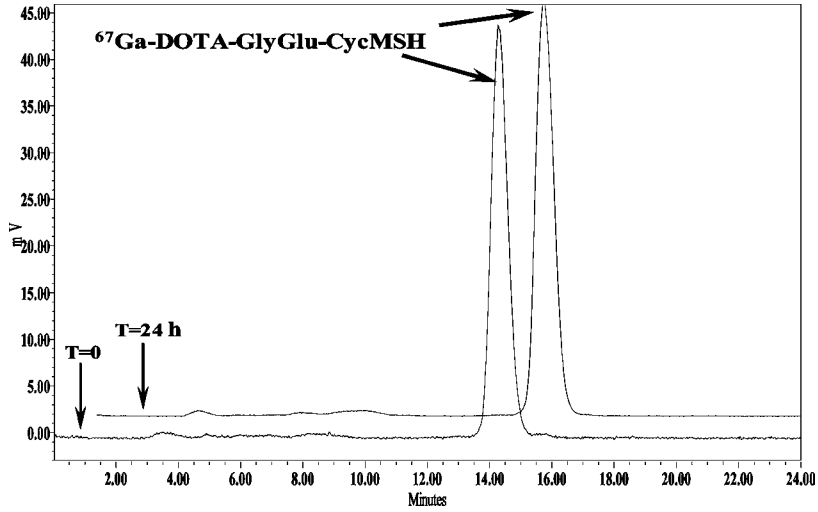

Figure 2. HPLC profile of radioactive ^{67}Ga-DOTA-GlyGlu-CycMSH ($T = 0$) and mouse serum stability of ^{67}Ga-DOTA-GlyGlu-CycMSH ($T =$ 24 h) after 24 h incubation at 37 °C. The retention time of ^{67}Ga-DOTA-GlyGlu-CycMSH was 14.4 min.

with 1.5% isoflurane for small animal SPECT/CT (NanoSPECT/CT, Bioscan) imaging 2 h postinjection. The 9 min CT imaging was immediately followed by the SPECT imaging of whole body. Reconstructed data from SPECT and CT were visualized and coregistered using InVivoScope (Bioscan, Washington, DC).

Statistical Methods. Statistical analysis was performed using the Student's *t* test for unpaired data to determine the significant differences between ^{67}Ga-DOTA-GlyGlu-CycMSH with or without non-radiolabeled DOTA-GlyGlu-CycMSH coinjection, between the bodistribution of ^{67}Ga-DOTA-GlyGlu-CycMSH in pulmonary metastatic melanoma-bearing mice and normal mice, and between ^{67}Ga-DOTA-GlyGlu-CycMSH with or without L-lysine coinjection. Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

DOTA-GlyGlu-CycMSH was synthesized, purified by RP-HPLC, and characterized by electrospray ionization mass spectrometry. DOTA-GlyGlu-CycMSH displayed greater than 95% purity with 30% overall synthetic yield. The peptide was labeled with ^{67}Ga using a 0.5 M NH_4OAc-buffered solution at pH 3.5. The radiolabeling yield was greater than 95%. Figure 1 illustrates the schematic structure of ^{67}Ga-DOTA-GlyGlu-CycMSH. ^{67}Ga-DOTA-GlyGlu-CycMSH was completely separated from its excess nonlabeled peptide by RP-HPLC. The retention times of ^{67}Ga-DOTA-GlyGlu-CycMSH and its nonlabeled peptide were 14.4 and 15.9 min, respectively. ^{67}Ga-DOTA-GlyGlu-CycMSH was stable in mouse serum at 37 °C. Only ^{67}Ga-DOTA-GlyGlu-CycMSH was detected by RP-HPLC after 24 h of incubation (Figure 2).

Cellular internalization and efflux of ^{67}Ga-DOTA-GlyGlu-CycMSH were evaluated in B16/F1 cells. Figure 3 illustrates cellular internalization and efflux of ^{67}Ga-DOTA-GlyGlu-CycMSH. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited rapid cellular internalization and extended cellular retention. There was 53.82 ± 3.96% of the cellular uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH activity internalized in the B16/F1 cells 20 min post incubation. There was 69.91 ± 3.33% of the cellular uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH activity internalized in the cells after 90 min incubation. Cellular efflux results demonstrated that 79.77 ± 9.49% of the internalized ^{67}Ga-DOTA-GlyGlu-CycMSH activity remained inside the cells 2 h after incubating cells in culture medium.

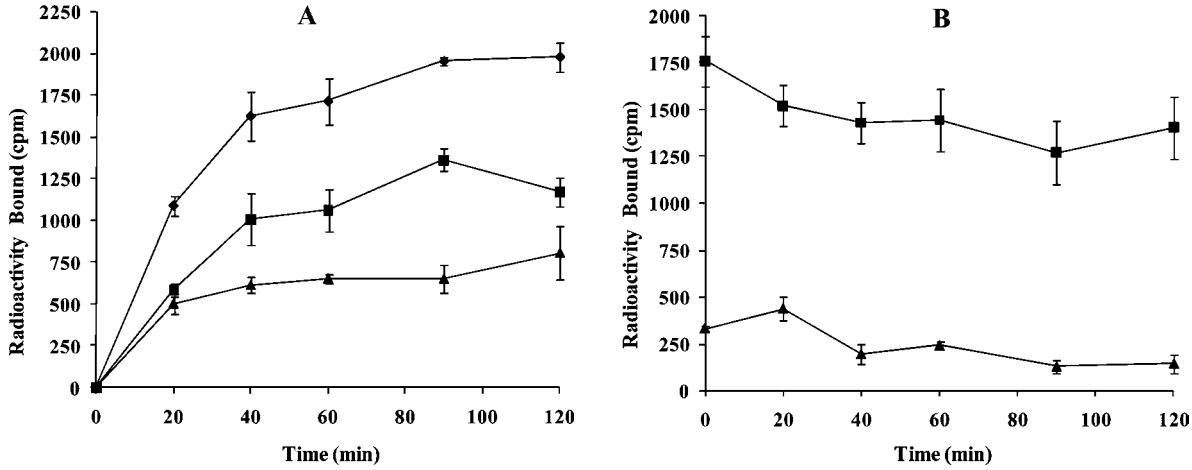

Figure 3. Cellular internalization (A) and efflux (B) of ^{67}Ga-DOTA-GlyGlu-CycMSH in B16/F1 melanoma cells at 25 °C. Total bound radioactivity (◆), internalized activity (■), and cell membrane activity (▲) were presented as counts per minute (cpm).

[a] The data were presented as percent injected dose/gram or as percent injected dose (mean ± SD, $n = 5$). [b] $p < 0.05$, significance comparison between ^{67}Ga-DOTA-GlyGlu-CycMSH with or without peptide blockade at 2 h postinjection.

The pharmacokinetics and tumor targeting properties of ^{67}Ga-DOTA-GlyGlu-CycMSH were determined in B16/F1 flank primary melanoma-bearing and B16/F10 pulmonary metastatic melanoma-bearing C57 mice. The biodistribution results of ^{67}Ga-DOTA-GlyGlu-CycMSH are shown in Tables 1 and 2. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited rapid and substantial tumor uptake. The tumor uptake value of ^{67}Ga-DOTA-GlyGlu-CycMSH was 8.59 ± 1.37%ID/g at 0.5 h postinjection. ^{67}Ga-DOTA-GlyGlu-CycMSH reached its peak tumor uptake value of 12.93 ± 1.63%ID/g at 2 h postinjection. There was 8.12 ± 0.60%ID/g of the ^{67}Ga-DOTA-GlyGlu-CycMSH activity remaining in the tumors at 4 h postinjection. The tumor uptake value of ^{67}Ga-DOTA-GlyGlu-CycMSH decreased to 5.02 ± 1.35%ID/g at 24 h postinjection. In the blocking study, the tumor uptake value of ^{67}Ga-DOTA-GlyGlu-CycMSH with 10 μg of non-radiolabeled DOTA-GlyGlu-CycMSH coinjection were only 2.9% of the tumor uptake value without non-radiolabeled DOTA-GlyGlu-CycMSH co-injection at 2 h postinjection ($p < 0.05$), demonstrating that the tumor uptake was specific and receptor-mediated. Whole-body clearance of ^{67}Ga-DOTA-GlyGlu-CycMSH was rapid, with approximately 82% of the injected radioactivity cleared through the urinary system by 2 h postinjection (Table 1). Normal organ uptakes of ^{67}Ga-DOTA-GlyGlu-CycMSH were generally very low (<0.30%ID/g) except for the kidneys at 2, 4, and 24 h postinjection. The renal uptake values of ^{67}Ga-DOTA-GlyGlu-CycMSH were 23.94 ± 7.15, 27.55 ± 7.87, 22.60 ± 4.03 and 20.92 ± 5.77%ID/g at 0.5, 2, 4, and 24 h postinjection. High tumor/blood and tumor/normal organ uptake ratios were demonstrated as early as 0.5 h postinjection except for the tumor/kidney ratio (Table 1). Co-injection of 15 mg of L-lysine reduced the kidney uptake value of ^{67}Ga-DOTA-GlyGlu-CycMSH to 8.32 ± 5.18%ID/g (69.8% reduction) without affecting the tumor uptake at 2 h postinjection (Figure 4).

The biodistribution results of ^{67}Ga-DOTA-GlyGlu-CycMSH in B16/F10 pulmonary metastatic melanoma-bearing C57 mice

[a] The data were presented as percent injected dose/gram or as percent injected dose (mean ± SD, $n = 5$). [b] $p < 0.05$, significance comparison between ^{67}Ga-DOTA-GlyGlu-CycMSH in pulmonary metastatic melanoma-bearing and normal C57 mice.

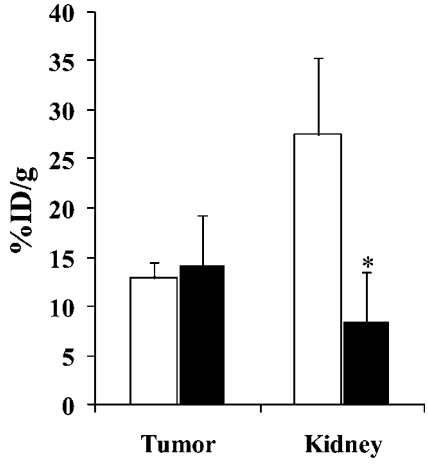

Figure 4. Effect of L-lysine co-injection on the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH at 2 h postinjection. Black and white columns represented the tumor and kidney uptakes of ^{67}Ga-DOTA-GlyGlu-CycMSH with or without L-lysine coinjection, respectively. L-Lysine coinjection significantly (*$p < 0.05$) reduced the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH by 69.8% at 2 h postinjection without affecting the tumor uptake.

at 2 and 4 h postinjection are presented in Table 2 and compared with those in normal C57 mice. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited significantly ($p < 0.05$) higher uptake value in metastatic melanoma-bearing lung than that in normal lung. The uptake values of ^{67}Ga-DOTA-GlyGlu-CycMSH radioactivity in the metastatic melanoma-bearing and normal lungs were 1.44 ± 0.75 and 0.15 ± 0.10%ID/g, 1.49 ± 0.69 and 0.17 ± 0.11%ID/g at 2 and 4 h postinjection, respectively. The ^{67}Ga-DOTA-GlyGlu-CycMSH displayed higher lung/normal organ uptake ratios in pulmonary metastatic melanoma-bearing mice than those in normal mice (Table 2). Similar rapid whole-body clearance of ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited in both B16/F10 pulmonary metastatic melanoma-bearing C57 mice and normal C57 mice (Table 2).

Two B16/F1 flank primary melanoma-bearing C57 mice were injected with ^{67}Ga-DOTA-GlyGlu-CycMSH with or without nonradioactive DOTA-GlyGlu-CycMSH to visualize the tumors and determine the specificity of the tumor uptake

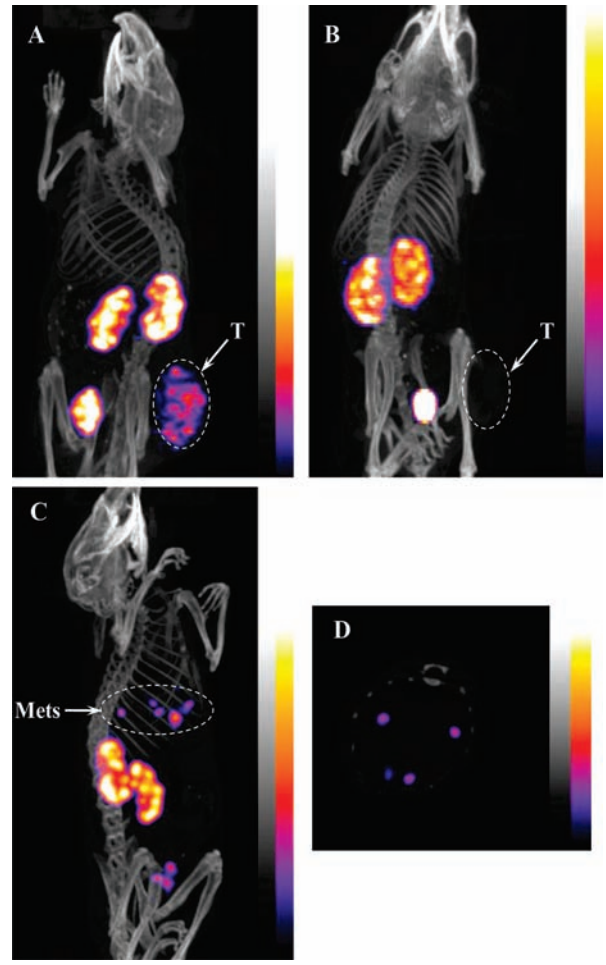

Figure 5. Whole-body images of ^{67}Ga-DOTA-GlyGlu-CycMSH in B16/F1 flank melanoma-bearing C57 mice with or without peptide blockade (A and B) at 2 h postinjection; whole-body (C) and transversal (D) images of ^{67}Ga-DOTA-GlyGlu-CycMSH in a B16/F10 pulmonary metastatic melanoma-bearing C57 mouse at 2 h postinjection. Flank melanoma (T) and pulmonary melanoma metastases (Mets) were highlighted with arrows on the images.

at 2 h after dose administration. The whole-body SPECT/CT images of the mice are presented in Figure 5A and B. The flank melanoma tumors were clearly visualized by SPECT/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe. ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited high tumor to normal organ uptake ratios except for the kidney, which were coincident with the biodistribution results. Accumulation of the ^{67}Ga-DOTA-GlyGlu-CycMSH activity in the bladder demonstrated the major urinary clearance. Co-injection of nonradioactive DOTA-GlyGlu-CycMSH blocked the melanoma uptake (Figure 5B), demonstrating that the melanoma uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was specific and MC1 receptor-mediated. A B16/F10 pulmonary melanoma-bearing C57 mouse was injected with ^{67}Ga-DOTA-GlyGlu-CycMSH via the tail vein to image melanoma metastases early developed in the lung (13 days after the cell injection). The whole-body and transverse images are presented in Figure 5C and D. The pulmonary metastatic melanoma foci were clearly visualized in both whole-body and transversal images by SPECT/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe.

DISCUSSION

Gallium-67 and gallium-68 are attractive radiometals in nuclear medicine due to their suitable imaging properties for

SPECT and PET. Compared to ^{68}Ga, ^{67}Ga has longer half-life and is thus a better radionuclide to use for examining the melanoma targeting property of the radioactive gallium-labeled lactam bridge-cyclized α-MSH peptide *in vivo*. In this study, we selected ^{67}Ga to radiolabel the novel lactam bridge-cyclized DOTA-GlyGlu-CycMSH peptide to evaluate its potential for primary and metastatic melanoma detection. DOTA-GlyGlu-CycMSH was readily labeled with ^{67}Ga in greater than 95% radiolabeling yield. The metal chelator DOTA formed a stable complex with ^{67}Ga. ^{67}Ga-DOTA-GlyGlu-CycMSH was stable in serum at 37 °C for 24 h (Figure 2). ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited substantial melanoma uptake and prolonged melanoma retention in B16/F1 melanoma-bearing C57 mice (Table 1). ^{67}Ga-DOTA-GlyGlu-CycMSH showed higher melanoma uptake values than those of ^{111}In-DOTA-GlyGlu-CycMSH (*19*). The tumor uptake values of ^{67}Ga-DOTA-GlyGlu-CycMSH were 1.24, 1.10, and 2.12 times the tumor uptake values of ^{111}In-DOTA-GlyGlu-CycMSH at 2, 4, and 24 h postinjection. In 2004, Froidevaux et al. (*13*) reported a ^{67}Ga-labeled linear α-MSH peptide (^{67}Ga-DOTA-NAPamide) for melanoma targeting. The tumor uptake values of ^{67}Ga-DOTA-NAPamide were 9.43 ± 1.06 and 3.10 ± 0.36%ID/g at 4 and 24 h postinjection in the B16/F1 flank melanoma-bearing C57 mice (*13*). ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited a 14% lower tumor uptake value than ^{67}Ga-DOTA-NAPamide at 4 h postinjection. However, the tumor uptake value of ^{67}Ga-DOTA-GlyGlu-CycMSH was 1.62 times the tumor uptake value of ^{67}Ga-DOTA-NAPamide at 24 h postinjection. The renal uptake values of ^{67}Ga-DOTA-GlyGlu-CycMSH were 5.68 and 10.25 times the renal uptake values of ^{67}Ga-DOTA-NAPamide at 4 and 24 h postinjection. Recently, it has been reported that different pathways may play roles in the mechanism of the renal uptakes of radiolabeled peptides besides the electrostatic interaction between the peptides and tubule cells (*27, 28*). For instance, the use of colchicines (preventing endocytosis in tubular cells) decreased the renal uptake up to 25% in a rat model (*28*). The transmembrane glycoprotein megalin is involved in the renal uptakes of radiolabeled somatostatin analogues (*29*). Since the extracellular domains of megalin can accommodate a variety of ligands, megalin may be involved in the renal uptakes of other radiolabeled peptides. L-Lysine coinjection decreased the renal uptake value by 69.8% at 2 h postinjection (Figure 4), demonstrating that the electrostatic interaction between the peptide and tubular cells was a key factor for the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH. Reduction of the nonspecific renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH by L-lysine coinjection in this study was consistent with the published results on radiolabeled metal-cyclized α-MSH peptides (*4*). Although more studies need to be conducted in the future, it is likely that other mechanisms besides the electrostatic interaction are involved in the renal uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH as well.

Despite the clinical use of [^{18}F]FDG in melanoma staging and melanoma metastases identification, [^{18}F]FDG is not a melanoma-specific imaging agent and is also not effective in imaging small melanoma metastases (<5 mm) and melanomas that have primary energy sources other than glucose (*30*−*32*). Radiolabeled lactam bridge-cyclized α-MSH peptides are melanoma-specific and can be employed to noninvasively confirm the identity of a tumor as melanoma. As shown in Figure 5, the flank primary melanoma lesions were clearly visualized by SPECT/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe. Importantly, the melanoma uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was blocked by 30 μg of nonradioactive DOTA-GlyGlu-CycMSH, demonstrating the melanoma uptake of ^{67}Ga-DOTA-GlyGlu-CycMSH was specific and MC1 receptor-mediated. ^{67}Ga-DOTA-GlyGlu-CycMSH may have its greatest utilization when combined with a therapeutic radiometal-labeled DOTA-GlyGlu-CycMSH. Since the DOTA can form stable complexes with a variety of therapeutic radiometals (i.e., ^{177}Lu, ^{90}Y, and ^{212}Pb), the same DOTA-conjugated lactam bridge-cyclized α-MSH peptide can be radiolabeled with diagnostic and therapeutic radionuclides to yield matched-pair diagnostic and therapeutic peptides. The radiolabeled diagnostic peptide can be used to not only detect melanoma lesions, but also identify the expression levels of the MC1 receptors in different melanoma lesions. The important information on the expression of the MC1 receptors will provide the physicians critical guidance for selecting the right melanoma patients for MC1 receptor-targeted radionuclide therapy. The patient-specific dosimetry determined by the diagnostic peptide will guide the physicians to select safe and effective doses of the therapeutic peptide for the melanoma patients. Moreover, the follow-up imaging using the radiolabeled diagnostic peptide can monitor the response of melanoma to the treatment and provide the physicians the evidence for choosing more efficacious and safer therapeutic peptide doses to the melanoma patients for further treatment.

High mortality of malignant melanoma is tightly associated with the occurrence of metastatic melanoma due to its aggressiveness and resistance to current chemotherapy and immunotherapy regimens. Over the past several years, both radiolabeled linear and cyclic α-MSH peptides have been investigated to target the MC1 receptors for the detection of melanoma metastases (*7, 12, 13, 20*) by tissue autoradiograph and small animal SPECT/CT. Initially, linear ^{111}In-DOTA-MSH$_{oct}$ and ^{67}Ga-DOTA-NAPamide were reported to be able to identify both melanotic and amelanotic melanoma metastases in lung by tissue autoradiograph (*12, 13*). In 2007,^{99m}Tc- and ^{111}In-labeled metal-cyclized DOTA-Re(Arg^{11})CCMSH were reported to be successful in visualizing well-developed B16/F10 pulmonary melanoma metastases (24 days after the cell injection) in euthanized melanoma-bearing mice by small animal SPECT/CT (*7*), demonstrating the potential of using radiolabeled α-MSH peptides for noninvasive melanoma metastases imaging. Recently, we reported the successful utilization of ^{111}In-labeled lactam bridge-cyclized DOTA-GlyGlu-CycMSH in detecting B16/F10 relatively early developed pulmonary metastases (17 and 20 days after the cell injection) in live melanoma-bearing mice by Nano-SPECT/CT (*20*). Both individual metastatic melanoma foci (17 days after the cell injection) and bigger lesions (20 days after the cell injection) developed in the lung were clearly visualized with ^{111}In-DOTA-GlyGlu-CycMSH (*20*), demonstrating the feasibility of using ^{111}In-DOTA-GlyGlu-CycMSH as an imaging probe to monitor tumor response to therapy. Despite the fact that ^{111}In-DOTA-GlyGlu-CycMSH was superior to [^{18}F]FDG in detecting pulmonary melanoma metastases reported in our previous publication (*20*), it was not determined whether the metastatic melanoma foci in the even earlier stage of development (<17 days) could be detected by Nano-SPECT/CT using radiolabeled DOTA-GlyGlu-CycMSH as an imaging probe. It seemed to us that it would be possible to detect the metastatic melanoma foci in the even earlier stage of development (<17 days) based on the fact that the spatial resolution of Nano-SPECT with multiple-pinhole collimator was approximately 0.8 mm for a Jaszczak phantom filled with ^{111}In aqueous solution. It was reported that pulmonary metastatic melanoma deposits were initially detectable by small animal CT approximately 15−18 days post tail vein injection of 0.2 million of B16/F10 melanoma cells (*33*). Hence, we selected 13 days after the cell injection (0.2 million B16/F10 cells) as an early development time point of

pulmonary melanoma metastases to evaluate the imaging property of ^{67}Ga-DOTA-GlyGlu-CycMSH in this study. As shown in Figure 5C and D, individual pulmonary metastatic melanoma foci were clearly visualized by SPECT/CT using ^{67}Ga-DOTA-GlyGlu-CycMSH as an imaging probe 2 h postinjection. Compared to the metastatic melanoma images we reported previously (*20*), the images of melanoma metastases reported in this study were even more striking since the pulmonary melanoma metastases were developed only 13 days after the cell injection. The remarkable images of melanoma metastases presented in this study demonstrated the feasibility of using ^{67}Ga-DOTA-GlyGlu-CycMSH as an effective imaging probe for early detection of metastatic melanoma.

In conclusion, ^{67}Ga-DOTA-GlyGlu-CycMSH exhibited favorable primary and metastatic melanoma targeting and imaging properties, highlighting its potential as an effective imaging probe for early detection of primary and metastatic melanoma.

ACKNOWLEDGMENT

We appreciate Dr. Fabio Gallazzi and Mr. Benjamin M. Gershman for their technical assistance. This work was supported in part by the Southwest Melanoma SPORE Developmental Research Program, the Oxnard Foundation, the DOD grant W81XWH-09-1-0105 and the NIH grant NM-INBRE P20RR016480. The image in this article was generated by the Keck-UNM Small Animal Imaging Resource established with funding from the W.M. Keck Foundation and the University of New Mexico Cancer Research and Treatment Center (NIH P30 CA118100).

Photo-Click Immobilization of Carbohydrates on Polymeric Surfaces—A Quick Method to Functionalize Surfaces for Biomolecular Recognition Studies

Oscar Norberg,[†] Lingquan Deng,[†] Mingdi Yan,*[,‡] and Olof Ramström*[,†,‡]

Department of Chemistry, KTH - Royal Institute of Technology, Teknikringen 30, S-10044, Stockholm, Sweden, and Department of Chemistry, Portland State University, P.O. Box 751, Portland, Oregon 97207-0751. Received August 10, 2009; Revised Manuscript Received October 10, 2009

Methods to rapidly functionalize specific polymeric surfaces with alkynes, which can subsequently be linked to azide-containing carbohydrates, are presented. The methods comprise two main concepts: azide photoligation and Cu-catalyzed azide−alkyne cycloaddition. 2-Azidoethyl-functionalized α-D-mannopyranoside was synthesized and covalently attached to alkyne-functionalized polymeric surfaces using the techniques. The protein recognition properties of the carbohydrate-presenting surfaces were evaluated using quartz crystal microbalance biosensor instrumentation.

INTRODUCTION

Carbohydrates play highly diverse roles in biology. In polymeric form, they act as an energy source as well as a cell form stabilizer. In mono- and oligomeric forms, they build up DNA/RNA and function in the glycosylation process to increase protein diversity and stability. Carbohydrates also exist in high concentrations in the cell membrane where they have key functions as recognition markers, e.g., in cell−cell communication, cell adhesion and development, fertilization, immune response, signal transduction, and viral/bacterial infections (*1*−*4*). Considering the vast amount of data obtained from DNA and protein microarrays to date, it is desirable to apply the same methods to carbohydrates. Unfortunately, the analyses of these interactions are associated with several difficulties, which have made glycobiology a demanding area of research. The most important difference between carbohydrates and other biomolecules, like DNA and proteins, is that the biosynthesis of carbohydrates is not performed by replication of a template, but rather by a complex pathway of glycosyltransferases and glycosidases in several compartments of the cell, which severely complicates the *in vivo* amplification and purification of complex oligosaccharides. Further, the complex structure and reactivity aggravates the *in vitro* synthesis and quantification, creating a bottleneck that has delayed the development of high-throughput analysis methods, like microarrays, in glycobiology. Finally, since glycans in biology are presented in a specific direction, attached at the reducing end, the manufacturing of glycan arrays requires highly selective methods of immobilization (*1, 5, 6*). Despite, or perhaps due to, the difficulties in glycobiology, several promising examples of glycoarrays have appeared to date (*7*−*11*).

Herein, we present a 1-/2-step method to quickly functionalize specific polymeric surfaces with alkynes using a photoligation technique based on perfluorophenylazide (PFPA). The alkyne surfaces can subsequently be linked to azide-containing biomolecules like carbohydrates using Cu-catalyzed azide−alkyne cycloaddition (CuAAC, click chemistry) (*12, 13*). Both azides and alkynes are rare in biological systems and have been shown to be highly inert under biological conditions (*14*). CuAAC has received a lot of attention since its discovery, especially within glycobiology where several examples of carbohydrate arrays utilizing CuAAC have been published (*15*−*21*).

EXPERIMENTAL PROCEDURES

General. All commercially available starting materials were of reagent grade and used as received. Lectins were purchased from Sigma-Aldrich and Vector Laboratories. QCM crystals were purchased from Attana AB. ^{1}H, ^{13}C, and ^{19}F NMR data were recorded on a Bruker Avance 400 instrument at 400 MHz (^{1}H) or a Bruker DMX 500 instrument at 500 MHz (^{1}H), 125 (^{13}C), or 470 MHz (^{19}F). Chemical shifts are reported as δ values (ppm) with $CDCl_3$ (^{1}H: $\delta = 7.26$, ^{13}C = 77.16), DMSO-d_6 (^{1}H: $\delta = 2.50$, ^{13}C = 39.52), or D_2O (^{1}H: $\delta = 4.79$) as internal standard. *J* values are given in Hz. ^{1}H peak assignments were made by first-order analysis of the spectra supported by standard ^{1}H−^{1}H correlation spectroscopy (COSY). Thin layer chromatography (TLC) was performed on precoated Cromatofolios AL Silica gel 60 F_{254} plates (Merck). Flash column chromatography was performed on silica gel 60, 0.040−0.063 mm (SDS). All experiments containing penta-/tetrafluorophenylazide groups were conducted in the absence of light with all reaction flasks covered with aluminum foil to prevent decomposition.

2-(2-(2-(Prop-2-ynyloxy)ethoxy)ethoxy)ethanol (2). Triethylene glycol (22.3 mL, 167 mmol) was added to a flask containing ground potassium hydroxide (3.7 g, 61.7 mmol). The mixture was stirred at 40 °C for 30 min after which propargyl bromide (6 mL, 55.7 mmol) was added. The mixture was then stirred at 60 °C for 3 h. The mixture was then diluted with water (50 mL) and acidified to pH 1 with 1 M hydrochloric acid (∼80 mL). The resulting mixture was extracted with EtOAc (3 × 100 mL) and the extract was washed with brine (2 × 100 mL). The organic phase was dried (Na_2SO_4) and the solvent evaporated under reduced pressure giving a yellow oil (6.3 g). The crude product was purified by flash column chromatography using solvent system hexanes/EtOAc (1:1 v/v) giving **2** as a colorless oil (3.76 g, 36%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 4.21 (d, 2 H, $J = 2.2$ Hz, CHCC*H*$_2$O), 3.74−3.66 (m, 11 H, OC*H*$_2$ and O*H*) 3.61 (t, 2 H,

J = 4.6 Hz, CH_2OH), 2.43 (t, 1 H, J = 2.4 Hz, C*H*CCH$_2$). ^{13}C NMR (125 MHz, $CDCl_3$): δ 79.68, 74.72, 72.60, 70.76, 70.51, 70.47, 69.20, 61.89, 58.54.

2-(2-(2-(Prop-2-ynyloxy)ethoxy)ethoxy)ethyl 4-methylbenzenesulfonate (3). 2-(2-(2-(Prop-2-ynyloxy)ethoxy)ethoxy)ethanol (**2**) (1.639 g, 8.7 mmol) was dissolved in DCM (10 mL). Tosyl chloride (1.826 g, 9.6 mmol) was added, and the mixture was cooled to 0 °C on an ice bath. KOH (1.95 g, 34.8 mmol) was added slowly, and the mixture was stirred vigorously for 2 h. The mixture was then poured on ice water and extracted with DCM (3 × 50 mL). The combined organic phase was washed with brine, dried over $MgSO_4$, and evaporated under reduced pressure to give **3** as white crystals in quantitative yield (2.977 g).

^{1}H NMR (500 MHz, $CDCl_3$): δ 7.80 (d, 2 H, J = 8.2 Hz, ArH), 7.34 (d, 2 H, J = 8.2 Hz, ArH), 4.19 (d, 2 H, 2.2 Hz, CHCCH_2O), 4.16 (t, 2 H, J = 4.7 Hz, CH_2OTs), 3.70−3.67 (m, 4 H, OCH_2), 3.65−3.63 (m, 2 H, OCH_2), 3.59 (s, 4 H, OCH_2), 2.45 (s, 3 H, ArCH_3), 2.43 (t, 1 H, J = 2.3 Hz, C*H*CCH$_2$). ^{13}C NMR (125 MHz, $CDCl_3$): δ 144.93, 133.18, 129.97, 128.14, 79.77, 74.68, 70.90, 70.72, 70.59, 69.37, 69.24, 68.85, 58.55, 21.79.

3-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)prop-1-yne (4). 2-(2-(2-(Prop-2-ynyloxy)ethoxy)ethoxy)ethyl 4-methylbenzenesulfonate (**3**) (2.515 g, 7.34 mmol) was dissolved in DMF (20 mL). Then, NaN_3 (525 mg, 8.08 mmol) and tetrabutyl ammonium iodide (TBAI) (271 mg, 0.734 mmol) was added, and the mixture was stirred vigorously at 45 °C overnight. The resulting mixture was diluted with EtOAc and washed with saturated $NaHCO_3$ (aq). The water phase was extracted twice with EtOAc, and the combined organic phase was washed with water and brine and dried over $MgSO_4$. Evaporation under reduced pressure yielded 1.705 g of crude product, which was purified by flash column chromatography using solvent system hexanes/EtOAc (1:1, v/v) yielding **4** (1.055 g, 67%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 4.21 (d, 2 H, J = 2.4 Hz, CHCCH_2O), 3.72−3.67 (m, 10 H, OCH_2), 3.39 (t, 2 H, J = 5.1 Hz, CH_2N$_3$), 2.43 (t, 1 H, J = 2.4 Hz, C*H*CCH$_2$). ^{13}C NMR (125 MHz, $CDCl_3$): δ 79.65, 74.51, 70.71, 70.69, 70.52, 70.07, 69.13, 58.42, 50.71.

2-(2-(2-(Prop-2-ynyloxy)ethoxy)ethoxy)ethanamine (5). 3-(2-(2-(2-Azidoethoxy)ethoxy)ethoxy)prop-1-yne (**4**) (1.055 g, 4.95 mmol) was dissolved in dry THF (25 mL). PPh_3 (1.427 g, 5.44 mmol) was added, and the mixture was stirred at r.t. for 2.5 h. The temperature was then raised to 30 °C, and the mixture was stirred overnight. Water (0.2 mL) was added, and the mixture was stirred at 30 °C for 25 h, after which the solvent was evaporated under reduced pressure. The crude product was dissolved in EtOAc and extracted four times with 1 M HCl (aq). The combined water phase was then basified with ground NaOH to basic pH and extracted four times with EtOAc. The combined organic phase was dried over $MgSO_4$ and evaporated under reduced pressure to give the crude product, which was purified by flash column chromatography using solvent system hexanes/EtOAc (1:1, v/v) yielding **5** (648 mg, 70%).

^{1}H NMR (500 MHz, D_2O): δ 4.26 (s, 2 H, OCH_2CCH), 3.77−3.76 (m, 2 H, OCH_2), 3.73−3.68 (m, 6 H, OCH_2), 3.58 (t, 2 H, J = 5.4 Hz, CH_2NH$_2$). ^{13}C NMR (125 MHz, D_2O): δ 78.86 (t, J = 7.4 Hz, OCH$_2$*C*CH), 75.72 (t, J = 38 Hz, OCH$_2$C*C*H), 71.99, 69.60, 69.41, 69.31, 68.67, 57.87, 39.80.

Methyl 4-Azido-2,3,5,6-tetrafluorobenzoate (7). Methyl pentafluorobenzoate (2 mL, 13.55 mmol) was dissolved in a 2:1 (v/v) mixture of acetone and water (30 mL). Sodium azide (1.15 g, 17.6 mmol) was added to the flask and the mixture was refluxed at 90 °C for 2 h. The mixture was subsequently cooled to r.t., diluted with water (60 mL), and extracted with diethyl ether (3 × 60 mL). The extract was dried (Na_2SO_4) and the solvent evaporated under reduced pressure, yielding **7** as white crystals (3.4 g, quant.).

^{1}H NMR (400 MHz, $CDCl_3$): δ 3.97 (s, 3 H, COCH_3). ^{19}F NMR (470 MHz, $CDCl_3$): δ −138.6 (m, 2 F), −150.9 (m, 2 F).^{13}C NMR (125 MHz, $CDCl_3$): δ 159.98, 146.59−144.35 (m, J_{C-F} = 260 Hz), 141.69−139.50 (m, J_{C-F} = 250 Hz), 123.53, 107.77, 53.42.

4-Azido-2,3,5,6-tetrafluorobenzoic Acid (8). Methyl 4-azido-2,3,5,6-tetrafluorobenzoate (**7**) (3.86 g, 15.49 mmol) was dissolved in MeOH (14.6 mL), aqueous sodium hydroxide solution (20%, w/w; 1.5 mL) and water (3.1 mL). The mixture was then stirred at r.t. for 2.5 h, acidified with 1 M aqueous hydrochloric acid and extracted with DCM (3 × 60 mL). The solvent was evaporated under reduced pressure, yielding **8** (3.4 g, 84.4%).

^{13}C NMR (125 MHz, DMSO-d_6): δ 160.09 (s), 145.40−143.06 (m, J_{C-F} = 250 Hz), 141.32−139.02 (m, J_{C-F} = 250 Hz), 122.70 (m), 108.41 (m).

2,5-Dioxopyrrolidin-1-yl 4-azido-2,3,5,6-tetrafluorobenzoate (9). 4-Azido-2,3,5,6-tetrafluorobenzoic acid (**8**) (933 mg, 3.97 mmol), *N*-hydroxysuccinimide (502 mg, 4.36 mmol), and EDAC (836 mg, 4.36 mmol) were dissolved in DCM (15 mL) and stirred at 35 °C for 22 h. Additional EDAC (433 mg, 2.26 mmol) was then added, and the mixture was stirred at 35 °C for another 3 h. The resulting mixture was diluted with water and extracted twice with DCM. The combined organic phase was washed with water, dried over $MgSO_4$, and evaporated under reduced pressure to give **9** as white crystals (1.244 g, 94%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 2.91 (s, 4 H, COCH_2CH_2). ^{13}C NMR (125 MHz, $CDCl_3$): δ 168.47, 155.31, 147.72−145.30 (m, J_{C-F} = 260 Hz), 141.82−139.52 (m, J_{C-F} = 250 Hz), 126.49, 102.13, 25.75.

4-Azido-2,3,5,6-tetrafluoro-*N*-(2-(2-(2-(prop-2-ynyl-oxy)-ethoxy)ethoxy)ethyl)benzamide (10). 2-(2-(2-(Prop-2-ynyl-oxy)ethoxy)ethoxy)ethanamine (**5**) (402 mg, 2.15 mmol) and 2,5-dioxopyrrolidin-1-yl 4-azido-2,3,5,6-tetrafluorobenzoate (**9**) (713 mg, 2.15 mmol) were dissolved in MeCN (6 mL) and stirred at r.t. overnight. A white precipitate was formed, and the mixture was filtered through a glass filter and washed with MeCN. The filtrate was evaporated under reduced pressure and the crude product purified by flash column chromatography using solvent system hexanes/EtOAc (1:1, v/v) yielding product **10** (605 mg, 70%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 6.90 (s, 1 H, NH), 4.11 (d, 2 H, J = 2.4 Hz, CHCCH_2O), 3.69−3.64 (m, 12 H, OCH_2CH_2), 2.41 (t, 1 H, J = 2.4 Hz, C*H*CCH$_2$). ^{13}C NMR (125 MHz, $CDCl_3$): δ 157.92, 145.32−143.11 (m, J_{C-F} = 250 Hz), 141.67−139.48 (m, J_{C-F} = 250 Hz), 121.79, 111.98, 79.44, 74.74, 70.64, 70.40, 70.35, 69.54, 69.16, 58.45, 40.20. Anal. $C_{16}H_{16}F_4N_4O_4$ calcd. C 47.53, H 3.99, N 13.86; found C 47.60, H 4.10, N 13.79.

1-(2-Azidoethyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (12). A solution of 2-azidoethanol (424 mg, 4.88 mmol) in DCM (20 mL) was added to α-D-mannose pentaacetate (1.586 g, 4.06 mmol). The mixture was stirred at 0 °C and $BF_3 \cdot Et_2O$ (2.04 mL, 16.25 mmol) was added slowly. After 1 h, the mixture was allowed to reach r.t., and after 18 h added to ice water (20 mL). The resulting mixture was extracted with DCM (2 × 20 mL), and the combined organic phase was washed with ice water, saturated $NaHCO_3$ (aq), and ice water. The organic phase was dried over Na_2SO_4 and the solvent evaporated under reduced pressure, yielding product **12** (1.411 g, 83%).

^{1}H NMR (500 MHz, $CDCl_3$): δ 5.34 (dd, 1 H, J = 3.5 and 9.8 Hz, H-3), 5.28 (d, 1 H, J = 10.1 Hz, H-4), 5.25 (dd, 1 H, J = 1.9 and 3.5 Hz, H-2), 4.85 (d, 1 H, J = 1.9 Hz, H-1), 4.26 (dd, 1 H, J = 5.4 and 12.3 Hz, H-6), 4.10 (dd, 1 H, J = 2.2 and

12.3 Hz, H-6′), 4.02 (ddd, 1 H, J = 2.5, 5.4, and 9.8 Hz, H-5), 3.85 (ddd, 1 H, J = 3.8, 6.9, and 10.7 Hz, CH_2CH$_2$N$_3$), 3.65 (ddd, 1 H, J = 3.9, 6.2, and 10.3 Hz, CH_2CH$_2$N$_3$), 3.47 (ddd, 1 H, J = 3.5, 6.9, and 13.2 Hz, CH_2N$_3$), 3.42 (ddd, 1 H, J = 3.8, 6.0, and 13.2 Hz, CH_2N$_3$), 2.14 (s, 3 H, Ac), 2.08 (s, 3 H, Ac), 2.03 (s, 3 H, Ac), 1.97 (s, 3 H, Ac). ^{13}C NMR (125 MHz, CDCl$_3$): δ 170.74, 170.13, 169.93, 169.88, 97.88, 69.53, 69.00, 68.98, 67.18, 66.14, 62.59, 50.49, 21.00, 20.87, 20.83, 20.78.

Compound 13. 1-(2-Azidoethyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (**12**) (203 mg, 0.486 mmol), 2-(2-(2-(prop-2-ynyloxy)ethoxy)ethoxy)ethyl 4-methyl-benzenesulfonate (**3**) (200 mg, 0.5837 mmol), CuI (4.6 mg, 0.024 mmol), and DIPEA (8.5 μL, 0.049 mmol) were dissolved in MeCN (15 mL) and stirred at r.t. for 28 h. Additional CuI (5 mg) was subsequently added, and the mixture was stirred at r.t. for 20 h. The resulting mixture was evaporated under reduced pressure, and the crude product was purified by flash column chromatography using solvent system DCM/MeCN (1:1, v/v) yielding product **13** (279 mg, 76%).

^{1}H NMR (500 MHz, DMSO-d_6): δ 8.09 (s, 1 H, triazol-H), 7.78 (d, 2 H, J = 8.3 Hz, Ar−H), 7.47 (d, 2 H, J = 8.3 Hz, Ar−H), 5.08−5.04 (m, 2 H, H-2 and H-4), 5.01 (dd, 1 H, J = 3.4 and 10.2, H-3), 4.90 (s, 1 H, H-1), 4.67−4.58 (m, 2 H, OCH_2CH$_2$N-triazol), 4.52 (s, 2 H, OCH_2C-triazol), 4.11 (t, 2 H, J = 4.4 Hz, OCH_2), 4.07 (dd, 1 H, J = 5.0 and 12.3 Hz, H-6), 4.02−3.89 (m, 3 H, H-7 and OCH$_2$CH_2N-triazol), 3.57 (t, 2 H, J = 4.4 Hz, OCH_2), 3.54−3.51 (m, 3 H, H-5 and OCH_2), 3.50−3.48 (m, 2 H, OCH_2), 3.44 (s, 4 H, OCH_2), 2.41 (s, 3 H, Ar−CH_3), 2.09 (s, 3 H, Ac), 2.01 (s, 3 H, Ac), 2.00 (s, 3 H, Ac), 1.92 (s, 3 H, Ac). ^{13}C NMR (125 MHz, DMSO-d_6): δ 169.99, 169.55, 169.54, 169.40, 144.89, 143.98, 132.41, 130.12, 127.61, 124.29, 96.33, 69.97, 69.68, 69.67, 69.65, 68.87, 68.57, 68.48, 67.92, 67.88, 65.71, 65.09, 63.46, 61.65, 48.94, 21.07, 20.55, 20.48, 20.39, 20.37. $[\alpha]^{20}_D$ +27.0 (*c* 0.673).

Compound 14. Compound **13** (279 mg, 0.368 mmol) and NaN_3 (29 mg, 0.441 mmol) were dissolved in DMF (25 mL) and stirred at 65 °C for 20 h. The solvent was then evaporated under reduced pressure yielding a crude product, which was dissolved in a small amount of DCM/MeCN (1:1, v/v) and passed through a short silica column yielding product **14** (221 mg, 95%).

^{1}H NMR (500 MHz, DMSO-d_6): δ 8.09 (s, 1 H, triazol-H), 5.08−5.04 (m, 2 H, H-2 and H-4), 5.00 (dd, 1 H, J = 3.3 and 10.2 Hz, H-3), 4.90 (d, 1 H, J = 1.3 Hz, H-1), 4.67−4.58 (m, 2 H, OCH_2CH$_2$N-triazol), 4.53 (s, 2 H, OCH_2C-triazol), 4.06 (dd, 1 H, J = 5.0 and 12.3 Hz, H-6), 4.01−3.89 (m, 3 H, H-7 and OCH$_2$CH_2N-triazol), 3.59 (t, 2 H, J = 4.9 Hz, OCH_2), 3.56−3.51 (m, 9 H, H-5 and OCH_2), 3.38 (t, 2 H, J = 4.9 Hz, OCH_2), 2.09 (s, 3 H, Ac), 2.02 (s, 3 H, Ac), 2.00 (s, 3 H, Ac), 1.92 (s, 3 H, Ac). ^{13}C NMR (125 MHz, DMSO-d_6): δ 170.00, 169.56, 169.53, 169.41, 144.00, 124.28, 96.33, 69.80, 69.73, 69.67, 69.23, 68.91, 68.57, 68.48, 67.91, 65.72, 65.09, 63.47, 61.64, 49.98, 48.94, 20.55, 20.49, 20.39, 20.38. MS (ESI$^+$): [M+Na]$^+$ *m/z* calcd for $C_{25}H_{38}N_6O_{13}$, 653.24; found 653.27. $[\alpha]^{20}_D$ +30.6 (*c* 0.727).

Compound 15. Compound **14** (399 mg, 0.632 mmol) was dissolved in MeOH (15 mL) under nitrogen atmosphere. NaOMe (17 mg, 0.316 mmol) in MeOH (1 mL) was added, and the mixture was stirred at r.t. for 2 h. The resulting mixture was neutralized with Amberlyst 15 and filtered. Pd/C (10%, 67 mg, 0.0632 mmol) was added, and the reaction vessel was subjected to H_2-atmosphere (1 atm) for 5 h at r.t. The mixture was subsequently filtered through Celite, and the filtrate evaporated under reduced pressure to yield compound **15** (204 mg, 74%).

^{1}H NMR (500 MHz, D$_2$O): δ 8.13 (s, 1 H, triazol-H), 4.82 (d, 1 H, J = 1.4 Hz, H-1), 4.73−4.70 (m, 4 H, CH_2N-triazol + CH_2C-triazol), 4.14 (ddd, 1 H, J = 11.0, 7.0, 4.1 Hz, CH_2CH$_2$N-triazol), 3.96 (dt, 1 H, J = 9.1, 4.3 Hz, CH_2CH$_2$NNC), 3.88 (dd, 1 H, J = 3.2, 1.7 Hz, H-2), 3.77−3.59 (m, 15 H), 3.07 (ddd, 1 H, J = 9.4, 5.8, 2.2 Hz), 2.94 (t, 1 H, J = 5.3 Hz, CH_2NH$_2$). ^{13}C NMR (125 MHz, D$_2$O) δ 143.91, 125.59, 99.56, 72.79, 70.39, 70.22, 69.85, 69.58, 69.48, 69.35, 68.89, 66.35, 65.48, 62.97, 60.64, 50.08, 39.57. MS (ESI$^+$): [M+H]$^+$ *m/z* calc for $C_{17}H_{32}N_4O_9$, 437.23; found 437.27.

Compound 16. 2,5-Dioxopyrrolidin-1-yl 4-azido-2,3,5,6-tetra-fluorobenzoate (**9**) (178 mg, 0.537 mmol) and compound **15** (195 mg, 0.448 mmol) were dissolved in 10 mL of DMF and stirred at r.t. for 22 h. The solvent was then evaporated under reduced pressure to give 289 mg of crude product which was purified by flash column chromatography with solvent system DCM/MeOH (6:1, v/v) yielding product **16** (201 mg, 69%).

^{1}H NMR (500 MHz, D$_2$O): δ 8.10 (s, 1 H, triazol-H), 4.80 (d, 1 H, J = 1.6 Hz, H-1), 4.71−4.67 (m, 4 H, CH_2NNC + CH_2CNC), 4.12 (ddd, 1 H J = 11.0, 7.0, and 4.0 Hz, CH_2CH$_2$NNC), 3.97−3.91 (m, 1H, CH_2CH$_2$NNC), 3.87 (dd, 1 H J = 3.2 and 1.7 Hz, H-2), 3.76−3.57 (m, 17 H), 3.07 (ddd, 1 H, J = 9.5, 5.7, and 2.2 Hz). ^{13}C NMR (125 MHz, D$_2$O): δ 160.66, 144.60−142.39 (dm, J = 250 Hz), 143.97, 141.44−139.30 (dm, J = 252 Hz), 125.46, 122.51−122.26 (m), 110.12 (t, J = 19.1 Hz), 99.57, 72.79, 70.40, 69.86, 69.65, 69.55, 69.49, 68.96, 68.46, 66.36, 65.47, 63.01, 60.64, 50.06, 39.72. MS (ESI$^+$): [M+Na]$^+$ *m/z* calcd for $C_{24}H_{31}F_4N_7O_{10}$, 653.21; found 653.27. Anal. $C_{24}H_{31}F_4N_7O_{10}$ calcd. C 44.11, H 4.78, N 15.00; found C 44.07, H 4.77, N 14.92. $[\alpha]^{20}_D$ +21.4 (*c* 0.58).

1-(2-Azidoethyl)-α-D-mannopyranoside (17). 1-(2-Azidoethyl)-2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (**12**) (66 mg, 0.158 mmol) was dissolved in 30 mL of MeOH. Then sodium methoxide (25.5 mg, 0.474 mmol) was added and the reaction mixture was stirred at r.t. until TLC indicated full conversion. Then, Amberlyst 15 was added until pH reached ∼7. The Amberlyst was then filtered off and the solvent was evaporated under reduced pressure, giving the pure product **17** (37 mg, 95%).

^{1}H NMR (500 MHz, D$_2$O): δ 4.93 (d, 1 H J = 1.6 Hz, H-1), 3.99 (dd, 1 H, J = 1.6 and 3.5 Hz, H-2), 3.93 (ddd, 1 H, J = 3.4, 7.0, and 10.8 Hz, CH_2CH$_2$N$_3$), 3.91 (dd, 1 H, J = 1.3 and 12.3 Hz, H-6), 3.85 (dd, 1 H, J = 3.5 and 9.1 Hz, H-3), 3.77 (dd, 1 H, J = 5.7 and 12.0 Hz, H-6′), 3.73 (ddd, 1 H, J = 3.2, 6.3, and 11.0 Hz, CH_2CH$_2$N$_3$), 3.70−3.65 (m, 2 H, H-4 and H-5), 3.56 (ddd, 1 H, J = 3.1, 6.9, and 13.6, CH_2N$_3$), 3.50 (ddd, 1 H, J = 3.2, 6.4 and 13.6, CH_2N$_3$).^{13}C NMR (125 MHz, D$_2$O): δ 99.80, 72.88, 70.37, 69.92, 66.67, 66.29, 60.90, 50.19.

General Surface Modification (cf. Figure 1). All QCM experiments were performed on gold-plated 10 MHz quartz crystals (Attana), either coated with poly(ethylene glycol) by a previously reported method (*22*) or purchased precoated with polystyrene. The photoreaction step was performed at 240−400 nm at a measured intensity of 13.3−13.5 mW/cm^2 with a LC8 equipped Hg−Xe UV-lamp from Hamamatsu Photonics. The fabricated crystals were mounted in a flowthrough QCM system (Attana 100).

Method A - 1-Step Functionalization. The precoated QCM crystal was immersed in a methanol solution of **16** (2.0 mM) for 5 min, after which it was dried under a stream of N_2 for 5 min, and irradiated for 5 min with UV light. The crystal was then rinsed with methanol in a supersonic bath for 5 min, dried under N_2, and placed in the QCM flowthrough system.

Method B - 2-Step Functionalization. The precoated QCM crystal was immersed in a methanol solution of **10** (2.0 mM) for 5 min, after which it was dried under a stream of N_2 for 5 min, and irradiated for 5 min with UV light. The crystal was then rinsed with methanol in a supersonic bath for 5 min and dried under N_2. The crystal was then immersed in a solution of

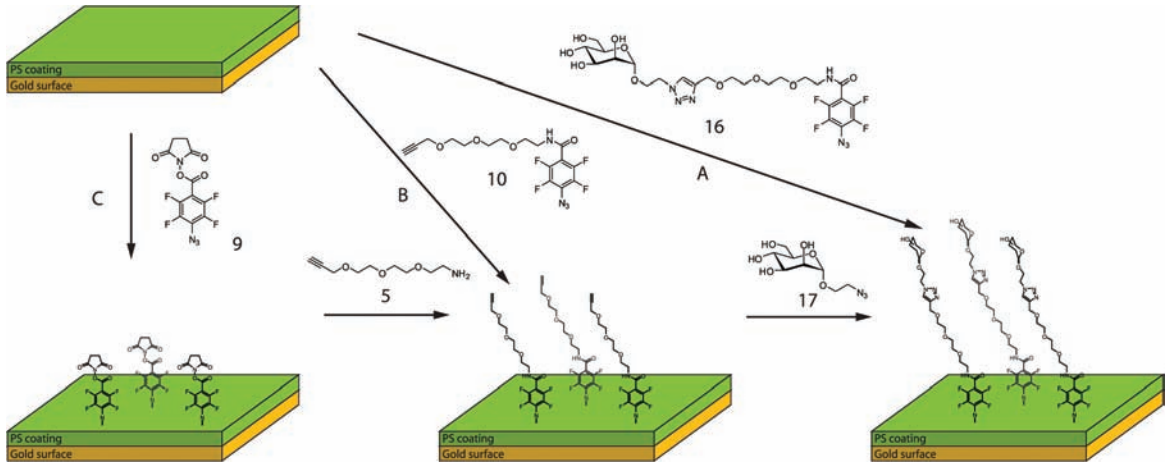

Figure 1. Developed methods for carbohydrate functionalization on polystyrene (PS) surfaces. Method A consists of one step in which a carbohydrate-functionalized PFPA is covalently bound to the polystyrene surface using UV-irradiation. In method B, the surface is primarily functionalized with alkynes and subsequently connected to carbohydrate-azides via Click chemistry. Method C consists of three steps in which a NHS-activated PFPA-ester is immobilized using UV irradiation. Then, compound **5** is attached to the surface, by the formation of a stable amide bond, creating an alkyne-functionalized surface (equivalent to method B), which is subsequently bound to carbohydrate-azides using Click chemistry.

water:acetonitrile (1:1, v/v) containing **17** (19.2 mM), CuI (0.96 mM), and DIPEA (9.7 mM) for 10 h. The crystal was then rinsed, first with acetonitrile/methanol, and then with acetonitrile/water (1:1, v/v) in a supersonic bath for 5 min. The crystal was then dried under N_2 and placed in the QCM flowthrough system.

Method C - 3-Step Functionalization. The precoated QCM crystal was immersed in an ethanol solution of **9** (5.0 mM) for 5 min after which it was dried under a stream of N_2 for 5 min and irradiated for 5 min with UV light. The crystal was then immersed in an acetonitrile solution of **5** (50 mM) for 8 h after which it was rinsed with methanol in a supersonic bath for 5 min. The crystal was then dried under N_2 for 5 min and subsequently immersed in a solution of water/acetonitrile (1:1, v/v) containing **17** (19.2 mM), CuI (0.96 mM), and DIPEA (9.7 mM) for 10 h. The crystal was then rinsed, first with acetonitrile/methanol, and then with acetonitrile/water (1:1, v/v) in a supersonic bath for 5 min. The crystal was then dried under N_2 and placed in the QCM flowthrough system.

General Surface Analysis. A continuous flow of running buffer (PBS 10 mM, pH 7.4, 25−50 μL/min) was used throughout the experiments, and samples of Concanavalin A (Con A) and peanut agglutinin (PNA) were prepared in the same buffer (sample injection volume: 50 μL). The crystals were washed/equilibrated with buffer solution prior to manipulations/measurements. After the crystal was equilibrated in the flowthrough system, it was subjected to several injections of BSA (1 mg/mL), low pH buffer (pH 1.5), and BSA (1 mg/mL) to fully block any nonfunctionalized surface. Binding to the surface was monitored by frequency logging with Attester 1.1 (Attana) and adsorption/desorption to the surface recorded as the resulting frequency shifts. Solutions (0.2 mg/mL) of Con A (1.92 μM) or PNA (1.82 μM) were then injected on the system, where the resulting shift in frequency corresponds to the binding to the surface. Bound lectin was released from the surface between measurements by several successive injections of low pH buffer (PBS 10 mM, pH 1.5). The procedure was then repeated several times for each lectin to determine the surface stability over time.

RESULTS AND DISCUSSION

Perfluorophenylazides (PFPAs) have been shown to be efficient reagents in photolabeling using UV light. Unlike other aryl azides, which quickly decompose upon radiation, PFPA forms a less reactive nitrene intermediate, which inserts into C−H bonds with moderate to high efficiency (*23*−*25*). We have previously reported the use of PFPA in the immobilization of carbohydrates to poly(ethylene glycol) surfaces for quartz crystal microbalance (QCM) and microarray studies (*22*, *26*). In the present approach, the versatility of the system is further improved by introducing the Cu-catalyzed azide−alkyne cycloaddition (click chemistry) step. This enables the use of more readily available carbohydrate-azides in the manufacturing of the surfaces.

To demonstrate the concept of the method, three experimental procedures of immobilizing the carbohydrates were designed, all of which resulted in very similar final surfaces (Figure 1). This experimental design also enabled the evaluation and analysis of the efficiency of the different steps, i.e., the photoligation and the CuAAC reaction. The simplest method (A) consists of a single photoligation step in which a carbohydrate-derivatized photoprobe (α-D-mannopyranose derivative **16** in the example) is immobilized on the surface by UV irradiation. In method B, an alkyne-functionalized PFPA (**10**) is primarily coupled to the surface by UV irradiation. The alkyne surface is then coupled to a 2-azidoethyl functionalized carbohydrate species (**17**) using CuAAC. In method C, the alkyne surface is produced in two steps. First, the polymeric surface is functionalized with an NHS-activated PFPA-ester (**9**) (*24*, *25*), and the resulting surface is subsequently submerged in an acetonitrile solution of an alkyne-functionalized amine linker (**5**), forming a stable amide bond with the surface. The alkyne surface is then subjected to the same procedure as the last step in method B.

All three methods result in carbohydrate-functionalized surfaces of the same type. Methods B and C, however, generate stable alkyne-functionalized intermediate surfaces, which in a one-step highly chemoselective reaction can be linked to azide-containing molecules, in this case, carbohydrates. The photoligation step, in the presence of surface C−H bonds, results in stable amine bonds, which makes hydrocarbon-based polymers a suitable substrate. This expands the end use of this method to a large extent, considering the extensive use of polymeric analysis equipment in life sciences. In this study, we have evaluated the methods on poly(ethylene glycol) (PEG) and polystyrene (PS) surfaces with successful results in both cases.

All compounds used were synthesized according to Schemes 1 and 2. The NHS-activation of compound **8** was essential for the synthesis of compounds **10** and **16**. The reaction between compound **10** and compounds **12** and **17**, to form structure **16**,

Scheme 1[a]

resulted in complex mixtures due to the higher reactivity of the aryl azide group compared to the carbohydrate azide moiety. This reactivity difference necessitated the chosen route to compound **16**. Compound **10** was also found to undergo self-cycloaddition in concentrated form, but proved stable in dilute solution at low temperature.

During initial studies, different catalytic systems for the cycloaddition reaction were examined, including $CuSO_4 \cdot 5H_2O$ + sodium ascorbate in water and water/*t*-butanol (1:1, v/v), $Cu(OAc)_2$ in water, and CuI + DIPEA in water/acetonitrile (1:1, v/v). The CuI system was, however, found to be the most appropriate for the surfaces used. Experiments were also performed for method B without the copper catalyst, in which the concentration of compound **17** was increased from 19.2 mM to 300 mM. Preliminary results indicated similar efficiencies of the thermal cycloaddition reaction but required longer reaction times (>19 h) and heating to 40 °C. This could, however, be a useful approach if copper needs to be avoided during immobilization.

The biorecognition properties of the surfaces were subsequently analyzed by injections of the lectins Con A (primarily specific for α-D-mannopyranose units) and PNA (primarily specific for β-D-galactopyranose units) in the flowthrough QCM system. The QCM technique allows for real-time monitoring of the association and dissociation of the lectins and provides an easy way to assess the stability of the immobilization over several injections.

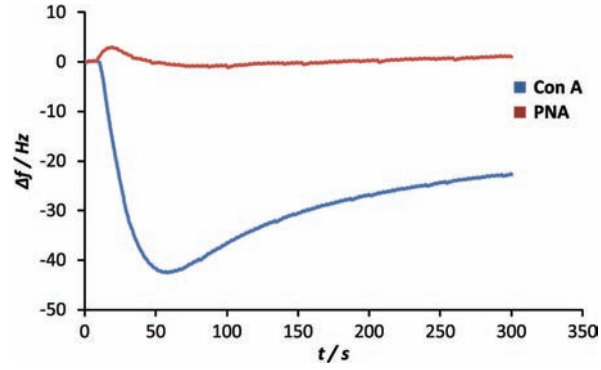

Figure 2. General binding curve of Con A and PNA to mannose-functionalized surface.

The binding study was performed by measuring the decrease in frequency upon lectin injection. Typical binding curves for the two lectins are presented in Figure 2. As can be seen for the α-D-mannopyranose-specific lectin Con A, the frequency drops immediately upon injection as a consequence of the association of the lectin to the surface. As the injection plug comes to an end, dissociation takes place where the lectin is washed away from the surface. In comparison, PNA shows no binding in agreement with the specificities for this protein.

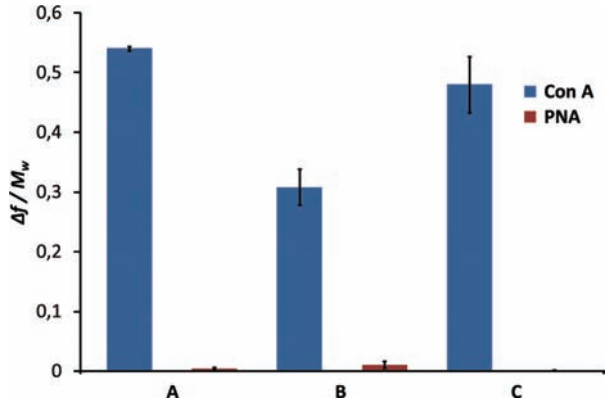

Figure 3. Binding results for the three different methods (normalized for the molecular weight of the lectins).

The resulting binding analyses for all three methods are presented in Figure 3, where the maximum decrease in frequency corresponds to the binding of the lectins at the conditions used. As can be seen, method A produces the highest and most consistent binding of Con A, with negligible nonspecific binding of PNA to the surfaces. This observation is reasonable, since method A is the simplest approach with only one photoligation step and is also most likely to produce the most carbohydrate-dense surface. On the other hand, both methods B and C show high specific binding of Con A with good consistency, although the capacity differs slightly between the methods. These results confirm the generality of the different methods to produce surfaces of similar quality. Method C requires roughly 8 h longer preparation time than method B, but in return produces surfaces which stabilize faster in the QCM system than surfaces produced by method B (cf. Figure 4). This indicates that surfaces produced by method C have lower thickness and are more uniform, which is most likely due to the increased potential cross-linking of compound **10** compared to compound **9** in the photoligation step. This also explains the slightly lower capacity of method B, where more alkyne moieties are likely buried, resulting in lower surface density of alkynes in method B than in method C. Method B further deviates from method A and C in the regeneration step, where it results in considerably larger responses to the change in pH, similar to the 3D pH-responsive dynamic polymer surfaces previously reported (*27*). The response times for all methods are, however, generally good, although surfaces produced by method A or C respond much faster than surfaces produced by method B, a desirable feature in real-time monitoring instrumentations. This supports the theory that methods A and C produce more ordered surfaces than method B.

CONCLUSIONS

Fast and straightforward methods to regio- and chemoselective functionalization of polymeric surfaces with carbohydrate structures have been developed and evaluated. The methods make use of the highly efficient PFPA-photoligation technique, combined with the CuAAC chemistry. The surfaces were evaluated using a QCM instrumentation, allowing for real-time analysis of the association/dissociation effects of unlabeled proteins. High specificities and capacities were recorded for all surfaces. All methods can be used for a variety of polymeric substrates, and methods B and C can furthermore be easily expanded with more azide-functionalized carbohydrates, as well as other structures. These features make the developed technology highly versatile, and show the potential for other applications.

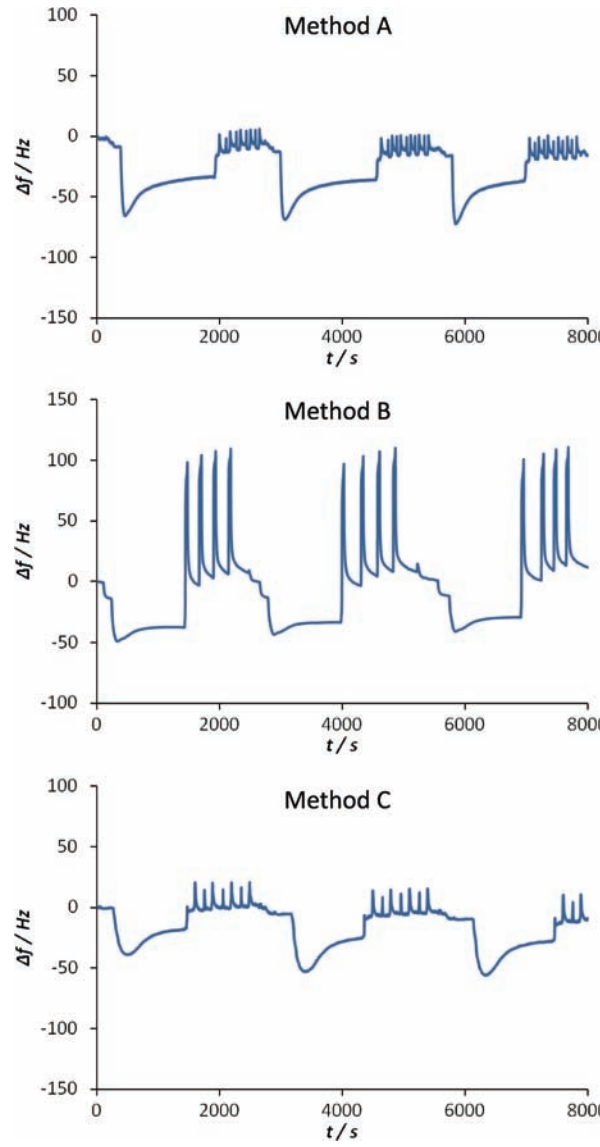

Figure 4. General frequency response curves for the three different methods. Con A was injected at 400 s, 3000 s, and 5900 s. The positive frequency peaks between lectin injections correspond to regeneration by release buffer solution. The average Con A binding values are presented in Figure 3.

Polyfluorophore Excimers and Exciplexes as FRET Donors in DNA

Yin Nah Teo and Eric T. Kool*

Department of Chemistry, Stanford University, Stanford, California 94305. Received September 5, 2009; Revised Manuscript Received October 15, 2009

We describe studies aimed at testing whether oligomeric exciplex and excimer fluorophores conjugated to DNA have the potential to act as donors for energy transfer by the Förster mechanism. Oligodeoxyfluorosides (ODFs) are composed of stacked, electronically interacting fluorophores replacing the bases on a DNA scaffold. The monomer chromophores in the twenty tetramer-length ODFs studied here include pyrene (Y), benzopyrene (B), perylene (E), dimethylaminostilbene (D), and a nonfluorescent spacer (S); these are conjugated in varied combinations at the 3′ end of a 14mer DNA probe sequence. In the absence of an acceptor chromophore, many of the ODF-DNAs show broad, unstructured long-wavelength emission peaks characteristic of excimer and exciplex excited states, similar to what has been observed for unconjugated ODFs. Although such delocalized excited states have been widely studied, we know of no prior report of their use in FRET. We tested the ability of the twenty ODFs to donate energy to Cy5 and TAMRA dyes conjugated to a complementary strand of DNA, with these acceptors oriented either at the near or far end of the ODF-conjugated probes. Results showed that a number of the ODF fluorophores exhibited relatively efficient energy transfer characteristic of the Förster mechanism, as judged by drops in donor emission quantum yield and fluorescence lifetime, accompanied by increases in intensity of acceptor emission bands. Excimer/exciplex bands in the donors were selectively quenched while shorter-wavelength monomer emission stayed relatively constant, consistent with the notion that the delocalized excited states, rather than individual fluorophores, are the donors. Interestingly, only specific sequences of ODFs were able to act as donors, while others did not, even though their emission wavelengths were similar. The new FRET donors possess large Stokes shifts, which can be beneficial for multiple applications. In addition, all ODFs can be excited at a single wavelength; thus, ODFs may be candidates as "universal FRET donors", thus allowing multicolor FRET of multiple species to be carried out with one excitation.

INTRODUCTION

Multichromophoric systems have displayed tremendous utility in numerous applications, giving some useful advantages over their monomeric counterparts. Applications in light harvesting, material science, electronic, photonic, and sensor devices have inspired the design of systems like conjugated polymers (*1*−*3*), dendrimers (*4*, *5*), photonic wires (*6*, *7*), and functionalized polypeptides (*8*). In recent years, the deoxyribose backbone of DNA has also been harnessed as a scaffold for the design of new multichromophoric systems. Oligodeoxyfluorosides (ODFs), an example of the latter, are a novel system of fluorophores built on the deoxyribose backbone. Aromatic fluorophores such as pyrene, perylene, and benzopyrene are attached to consecutive anomeric positions of the deoxyribose backbone (*9*, *10*). This backbone provides a rigid structure that brings the aromatic fluorophores into close proximity, allowing π-stacking interactions and various forms of photophysical interactions to occur (*11*, *12*).

Other systems of functionalizing the DNA scaffold with multiple chromophores have been developed recently. Häner and co-workers assembled a series of phenanthrenes and pyrenes as non-nucleosidic base surrogates (*13*, *14*). These aromatic compounds interact favorably through stacking interactions. In work by Wagenknecht, clusters of aromatic chromophores covalently attached to uridine were also shown to form a helical π-array along the major groove of the DNA duplex (*15*, *16*). Strongly enhanced emission from clusters of stacked pyrene-labeled uridines was observed. Nonfluorescent methyl red and napthyl red dyes had been incorporated as base substitutes and assembled as clusters into duplex DNA (*17*, *18*). Bipyridyl and biphenyl moieties were employed by Leumann as base substitutes for C-nucleosides to synthesize a zipper-like interstrand stacking motif of DNA (*19*). Excimer formation has also been observed by Inouye in alkynyl C-nucleosides with pyrene, perylene, and anthracene as base substitutes (*20*). Besides DNA, multilabeling of other nucleic acids architectures, RNA (*21*, *22*) and LNA (*23*), was also carried out. Noncovalent assembly of chromophores on the DNA structure had been explored with cyanine dyes in the minor groove (*24*, *25*).

A number of laboratories have also explored multichromophore FRET (Förster resonance energy transfer) interactions in DNA using traditional monomeric fluorescent dyes (*26*, *27*). In addition, multifluorophore systems based on conjugated polymers have also been employed as FRET donors (*28*, *29*). FRET is widely employed in biological and biophysical studies because of the well-known distance dependence of the nonradiative energy transfer (*30*, *31*). This allows quantitative information about the association of biomolecules and their relative distance and orientation on length scales beyond what other methods can provide. Because of this broad utility, the addition of new classes of chromophores that can undergo FRET can positively affect the types of experiments that can be carried out.

Here, we report studies in employing the multichromophore excimer and exciplex interactions of the stacked chromophores of ODFs to test a set of possible FRET donors that can be excited at a single wavelength. To the best of our knowledge, the use of excimers and exciplexes as FRET donors has not been explored. In this report, twenty different ODFs were

attached to DNA sequences as potential donors, and common acceptor dyes TAMRA and Cy5 were placed on complementary DNA strands at either proximal or distal ends. Upon hybridization, Förster energy transfer was observed between several ODF donors and Cy5 or TAMRA acceptors. Since multiple ODFs can be excited at a single wavelength, this might ultimately lead to their use as "universal" FRET donors.

EXPERIMENTAL SECTION

Fluoroside Phosphoramidites Syntheses E, Y, D, S, B. Syntheses of the monomer 1′-α-2′-deoxyriboside 5′-dimethoxytrityl-3′-phosphoramidite derivatives of pyrene (Y), perylene (E), benzopyrene (B), and dimethylaminostilbene (D) were carried out as previously described (*9*, *10*, *32*). The abasic tetrahydrofuran spacer S was obtained commercially (dSpacer CE phosphoramidite from Glen Research Corporation).

Synthesis of ODF-Labeled Oligodeoxynucleotides. Oligodeoxynucleotides were synthesized on an Applied Biosystems 394 DNA/RNA synthesizer on a 1 μmol scale and possessed a 3′-phosphate group. Coupling employed standard β-cyanoethyl phosphoramidite chemistry, but with extended coupling time (900 s) for fluoroside phosphoramidites. ODFs were synthesized directly on the CPG beads, and the DNA sequence was then built on its 5′ end. All oligomers were deprotected using the Ultramild deprotection method with potassium carbonate solution (25 °C, 8 h), then purified by reverse-phase HPLC. The recovered material was quantified by absorbance at 260 nm with molar extinction coefficients determined by the nearest-neighbor method. Molar extinction coefficients for ODFs were estimated by adding the measured value of the molar extinction coefficient of the fluoroside (at 260 nm) to the calculated value for the natural DNA fragments. ODF-labeled oligomers were characterized by MALDI-TOF mass spectrometry (data are given in the Supporting Information, Table S1). TAMRA-CPG, TAMRA-dT, and Cy5 phosphoramidites were purchased from Glen Research Corporation. Phosphoramidites were attached to either the 3′- or 5′-end of the complementary DNA sequence using manufacturer's methods. Purification was achieved using reverse-phase HPLC.

Optical Methods. Steady-state absorption measurements were carried out on a Varian Cary 100 UV−visible spectrophotometer. Steady-state fluorescence measurements were carried out at 2 μM concentration (each strand) on a on a HORIBA Jobin Yvon Fluorolog-3 fluorescence spectrometer (2 nm slit width) equipped with Lauda Brinkmann RM6 temperature controller at 25 °C. Samples were buffered at pH 7.0 with 100 mM NaCl, 10 mM $MgCl_2$, and 10 mM Na·PIPES. Buffers were not deoxygenated. The excitation wavelength for ODF-labeled strands was 330 nm. To prevent aggregation and reabsorption of light during quantum yield measurements, samples were diluted to solutions with absorption of less than 0.1 at wavelengths longer than λ_{ex}. 9,10-Diphenylanthracene (Φ = 0.90) (*33*) in cyclohexane was used as the reference for quantum yield calculations. Quantum yields were calculated using the following equation (*34*)

$$\frac{\Phi}{\Phi_R} = \frac{n^2}{n_R^2} \times \frac{A_R}{A} \times \frac{\int F}{\int F_R}$$

where Φ and Φ_R are the quantum yields of the unknown and reference compounds respectively. n and n_R are the refractive indices of water and cyclohexane, respectively. A and A_R denote the absorbances at 330 nm for the unknown and reference samples and $\int F$ and $\int F_R$ are the integrals of fluorescence emission intensities of the unknown and the reference samples, respectively.

Fluorescence lifetime measurements were carried out on a PTI EasyLife instrument using 325 nm LED for excitation of all ODFs. A bandpass filter with transmittance from 400−510 nm was used to ensure that only emission from the donor ODF was monitored. Fitting and analysis was performed using *Felix32* software. The goodness of fit was evaluated based on χ^2 values and the randomness of the residuals. The instrument response function (IRF) was measured using a 2% Ludox scattering solution (Sigma Aldrich, MO). To prevent aggregation and reabsorption of light, samples were diluted to absorption at λ_{max} of less than 0.05.

T3′	3′- TAM - AGG TGT CTT TGT AT -5′

[a] XXXX denotes the sequence of ODF (listed in Table 2).

Analysis of Energy Transfer. The efficiency of FRET, E_{FRET}, was calculated from the sensitized emission of the acceptors using eq 1 (*35*, *36*)

$$E_{FRET} = \left(\frac{I_{AD}}{I_A} - 1\right)\frac{\varepsilon_A}{\varepsilon_D} \quad (1)$$

where I_{AD} and I_A are the fluorescence emission intensities of the acceptor in the presence and absence of donor, respectively. ε_A and ε_D are the molar extinction coefficients of the acceptor and donor, respectively, at the excitation wavelength. The excitation wavelength was 330 nm for all experiments. TAMRA emission was monitored at its emission maxima at 580 nm, while Cy5 emission was monitored at its emission maxima at 662 nm. Where only a diminished donor emission signal was observed, and the acceptor emission remained the same or decreased, quenching was likely due to contact quenching. This quenching efficiency was calculated using eq 2

$$Q_{eff} = 1 - \frac{I_{DA}}{I_D} \quad (2)$$

where I_{DA} and I_D are the integrated emission intensities of the donor in the presence and absence of the acceptor, TAMRA, respectively. The efficiency of FRET computed from lifetime measurements, EL_{FRET}, was determined using eq 3 (*35*).

$$EL_{FRET} = 1 - \frac{\langle\tau_D\rangle}{\langle\tau_D^0\rangle} \quad (3)$$

where $\langle\tau\rangle = (\sum_i \alpha_i\tau_i)/(\sum_i \alpha_i)$ and $\langle\tau_D\rangle$ and $\langle\tau_D^0\rangle$ are the amplitude-averaged donor lifetimes in the presence and absence of the acceptor, respectively.

RESULTS

A representative set of 20 tetrameric sequences of ODFs was chosen from a larger random library for this study; for hybridization experiments, they were appended to the 3′-terminus of a 14-mer probe DNA sequence (Table 1). The ODF labels were synthesized from five monomeric 2′-deoxyfluorosides where the base-replacement fluorophore was a benzopyrene (B), pyrene (Y), perylene (E), or dimethylaminostilbene (D), or an abasic spacer-tetrahydrofuran moiety (S) (see Figure 1A). The α-glycosidic anomers, which like β-anomers can stack with one another in a DNA context (*11*), were used for synthetic convenience in this study. ODFs were assembled using automated DNA synthesis chemistry from phosphoramidite derivatives of the monomeric fluorosides. Note that sequences of ODFs are listed in 5′ to 3′ order in analogy to DNA.

Fluorescence Properties of ODFs. Absorption and emission spectra of the twenty ODF labels conjugated to single-stranded

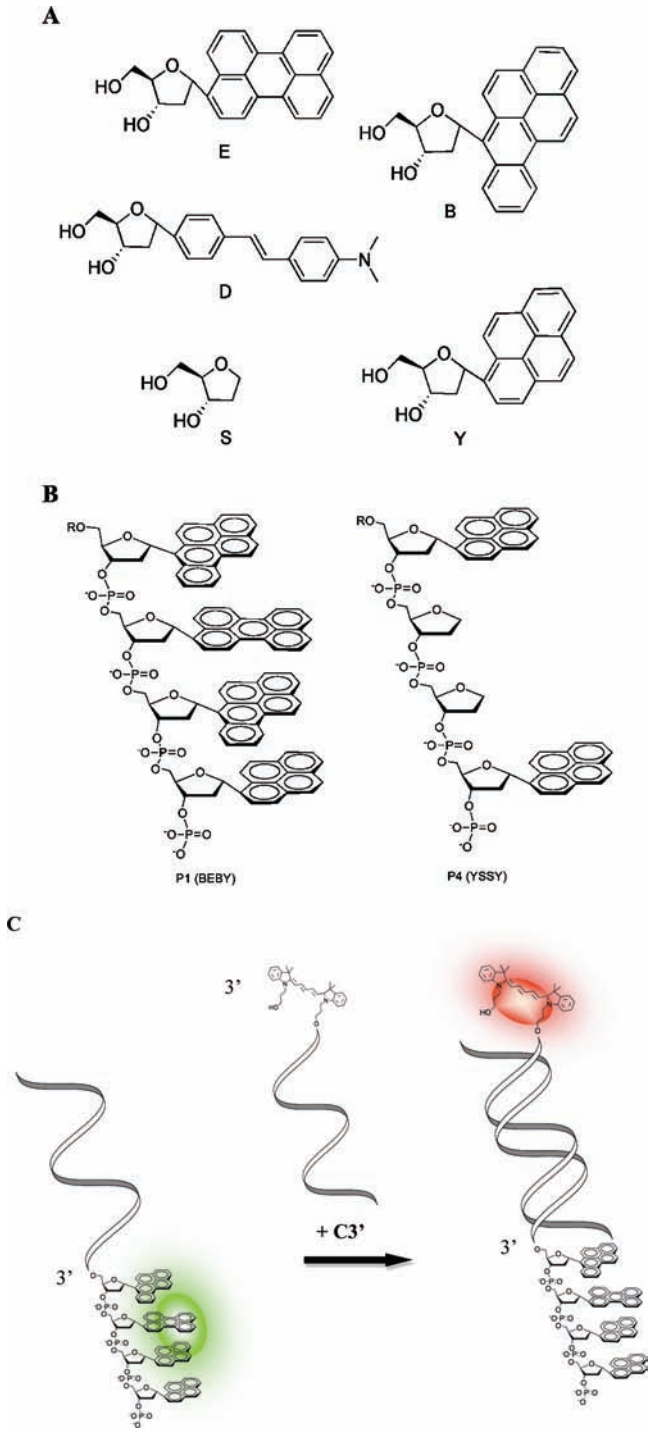

Figure 1. Structures in this study. (A) Monomeric 2′-deoxyfluorosides B, E, Y, D, and S. (B) Structures of two representative ODFs (BEBY and YSSY) that were studied as DNA conjugates. These were attached to the 3′ end of a DNA probe sequence (R). (C) An example of a hybridization experiment: hybridization of BEYY-labeled probe (P2) with an acceptor-labeled complement (C3′).

DNA were measured in pH 7.0 hybridization buffer containing 100 mM Na^+ and 10 mM Mg^{2+} (see Experimental Procedures). The primary absorption and emission bands are given in Table 2, and emission spectra are shown in Supporting Information. Quantum yields for fluorescence were measured in the same buffer (Table 2). Emission spectra of the ODF labels were in nearly all cases quite different from the combined monomer emissions, which were reported previously (*37*). Most cases showed broad bands between 450 and 600 nm, consistent with excited-state dimer (exciplex and excimer) states. The maxima of these bands varied from 460 to 530 nm, and some cases showed multiple maxima (as many as three) in this range. In general, the twenty DNA-conjugated ODFs were efficient fluorophores, with quantum yields for emission as high as 42% (Table 2). The quantum yields varied with chromophore composition and sequence; for an example of the latter, SSYY (Φ_{FL} = 19%) and YSSY (Φ_{FL} = 2.5%) have the same composition but substantially different fluorescence quantum yields.

ODFs as Donors in Förster Energy Transfer. To test the possibility of Förster energy transfer between ODFs and common acceptor dyes, we hybridized the 3′-ODF-conjugated probes with their DNA complements carrying Cy5 or TAMRA dye (Figure 1). To test the effect of distance between the putative donors and acceptors, we prepared dye-conjugates in which Cy5 or TAMRA was located at either the 5′ end of the ODF complement (proximal to the ODF) or at the 3′ end (distal to the ODF). Since the probes were 14 nt in length, the difference in distance at proximal and distal locations was approximately 56 Å based on a 3.4 Å rise per base pair of B-DNA. This distance was calculated from the middle of each ODF donor dye to either Cy5 or TAMRA. Hybridization and fluorescence experiments were performed using DNA strand concentrations of 2 μM each, and 10 mM PIPES buffer with 100 mM NaCl, 10 mM $MgCl_2$, at a temperature of 25 °C. An example is shown in Figure 1C.

The sequences of the ODFs in this initial, labeled DNA probe set were chosen essentially at random from an earlier study of quenching behavior (*38*) (see sequences in Table 2) with some additional cases included on the basis of early observations in this study. To initially screen the photophysical interactions of each ODF with the Cy5 and TAMRA acceptors, we measured the emission spectra of the duplexes containing both ODF putative donors and the acceptor dyes. In addition, we measured the emission spectra of the acceptor dyes (conjugated to their DNAs) alone and the ODF donor strands alone, again using this same excitation wavelength (330 nm; chosen for efficient excitation of the aromatic monomers in the ODFs). At this wavelength, the absorbances of TAMRA or Cy5-conjugated strands are minimal.

As a control for the effects of the acceptor dyes on ODF quenching, we also measured the effects of hybridizing the ODF DNAs to unlabeled DNA complement, D1 (see Supporting Information). The effects of hybridization to D1 varied from a small enhancement of fluorescence to a small degree of quenching, and several of the ODFs displayed no change. Thus, in the majority of cases, the quenching effects observed in the hybridization experiments came entirely (or nearly so) from the presence of the acceptor fluorophore on the complement DNA strand.

Exciplexes as FRET Donors. Emission data from selected experiments are shown in Figures 2 (TAMRA) and 3 (Cy5); see Supporting Information for spectra from all cases. Upon hybridization, the long-wavelength emission band between 460 and 510 nm of the donor ODF was diminished in all cases, compared to the emission before hybridization. In addition, a significant enhancement of fluorescence intensity at 590 nm was observed when the ODF strands were hybridized to T3′. This corresponded to the sensitized emission of TAMRA upon hybridization. Since TAMRA cannot be significantly excited at 330 nm, the enhanced emission was likely due to energy transfer from the ODF donor, upon its excitation. Since there is significant overlap of the emission spectra of ODFs and the absorbance spectra of TAMRA, and both ODF and TAMRA are about 14 DNA bases apart (~56 Å), the energy transfer was tentatively characterized as a long-range weak dipole−dipole interaction, or Förster resonance energy transfer (FRET).

[a] T3′ is 3′-conjugated TAMRA on the complementary strand; T5′ is 5′-conjugated TAMRA. C3′ is 3′-conjugated Cy5; C5′ is 5′-conjugated Cy5. B is benzopyrene deoxyriboside; D is dimethylaminostilbene deoxyriboside; E is perylene deoxyriboside; Y is pyrene deoxyriboside, and S is an abasic spacer. [b] E_{FRET} values were calculated using eq 1. n.a. indicates no FRET observed. Q_{eff} is quenching efficiency, given for T5′, where no significant FRET was observed.

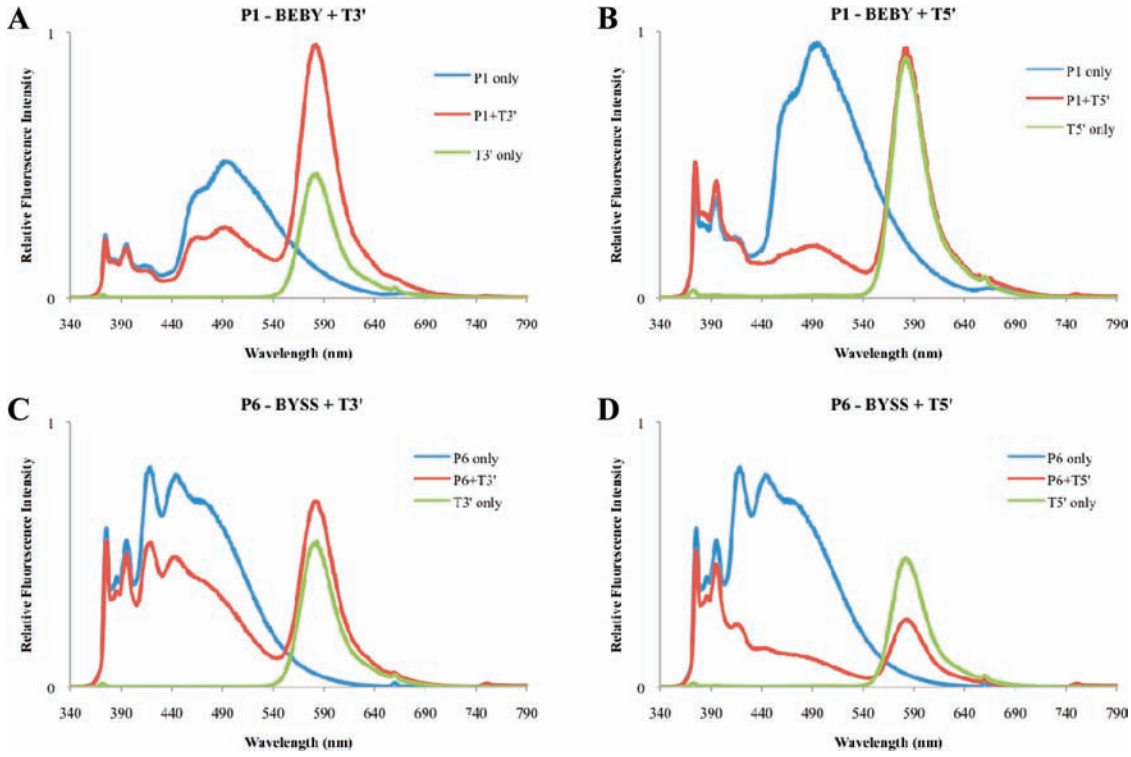

Figure 2. Representative evidence for FRET between ODF fluorophores and TAMRA in a DNA duplex (see full data in Supporting Information). Fluorescence emission spectra (excitation 330 nm) are shown for hybridization of P1 and P6 with T3′ and T5′ (red lines) and individual emission spectra of P1, P6 (blue), T3′, and T5′ (green). Note spectral changes characteristic of FRET for the distal-substituted TAMRA (A,C).

The sensitized enhancement of the acceptor emission can be used to determine the efficiency of FRET (E_{FRET}, see Experimental Procedures). As shown in Table 2, the ODF sequence EYSS displayed the highest apparent efficiency of FRET to T3′ at 0.752, followed by BEBY (0.244) and ESBS (0.159). The other ODF sequences had relatively low E_{FRET}, showing weak or borderline FRET behavior, possibly due to low quantum yields, weak dipoles, or unfavorable dipolar orientation.

Contact Quenching in Proximally Labeled ODF Strands. When the 3′ ODF-labeled strands were hybridized to 5′ TAMRA-labeled complement or 5′ Cy5-labeled complement, the ODF dyes were at a proximal distance to the acceptor fluorophores. Contact quenching can come into play when the two fluorophores are within close distance of each other (*39*). As observed from our experimental data, quenching of more than 30% was observed in 19 out of 20 ODF-labeled strands when hybridized to T5′. Only one strand, P20 (EEDE), experienced little (4%) quenching upon hybridization (see Supporting Information for complete emission spectra). Quenching efficiency, Q_{eff}, for each pair was determined (see Experimental Procedures) and is shown in Table 2. Q_{eff} values ranged from 0.038 to 0.739. The TAMRA emission band was also

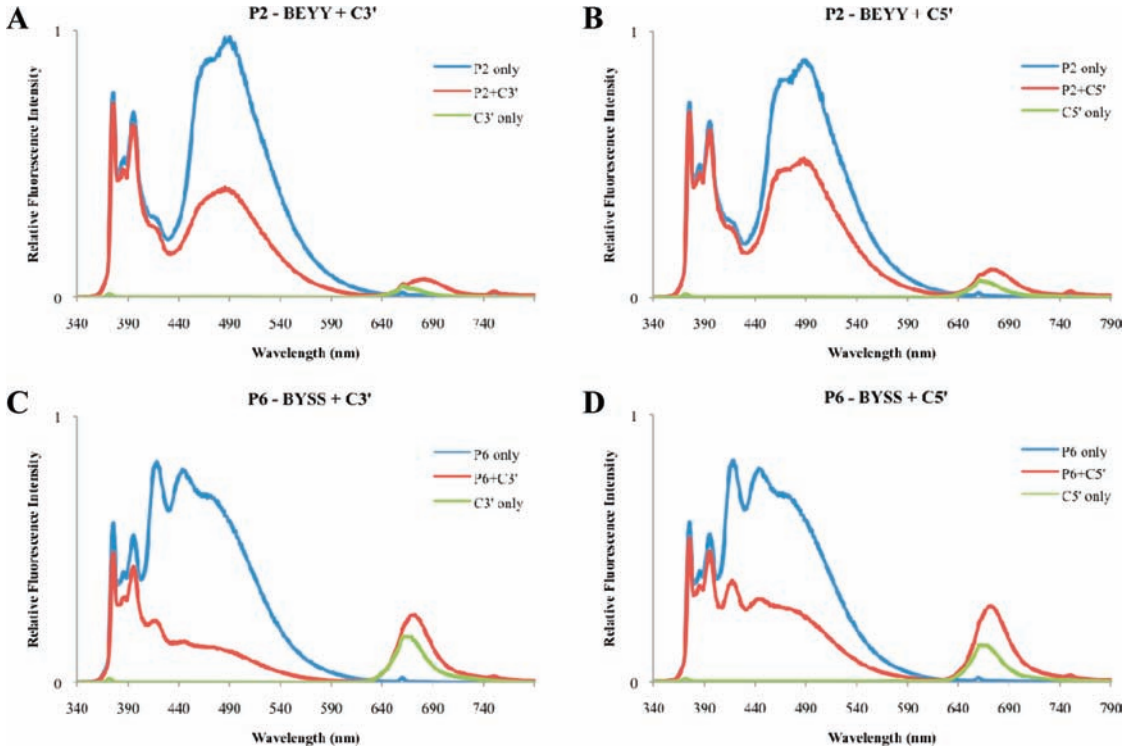

Figure 3. Evidence for FRET between ODF donors and a Cy5 acceptor in duplex DNA. Fluorescence emission spectra are shown for hybridization of ODF conjugates P2 and P6 with C3′ and C5′ (red lines) (λ_{ex} = 330 nm) and individual emission spectra of P2, P6, C3′, and C5′ (λ_{ex} = 330 nm) (blue and green lines). Note quenching of excimer and exciplex bands (440−560 nm) concomitant with enhancement of Cy5 emission at ∼670 nm.

quenched in most cases, or experienced no change in emission intensity. Because quenching in these cases was not coupled to an associated increase in TAMRA emission, we assigned these cases to simple contact quenching and not to FRET. Additional evidence for contact quenching was obtained for one case (sequence P6; BYSS) by measurement of the lifetime of the acceptor (data not shown). Results showed a decrease in lifetime of the TAMRA acceptor fluorophore upon hybridization with donor ODF-labeled strand at the direct excitation wavelength of TAMRA.

Hybridization with Cy5-Labeled Complements. Hybridization between ODF-labeled strands and their Cy5-labeled complements, C3′ and C5′, also resulted in the sensitized emission of the acceptor Cy5 coupled with a decrease in donor emission in some of the strands. Selected examples are given in Figure 3. The emission intensity of the hybrid at 660 nm was enhanced compared to the emission profile of the acceptor dye strand alone in 7 out of the 20 strands tested with distal cyanine dye (C3′), consistent with FRET behavior. Interestingly, hybridization of ODF-labeled strands with proximal C5′ also resulted in the enhancement of acceptor emission in 9 cases, which was distinct from the results with TAMRA, where quenching dominated. The remaining cases with Cy5 exhibited quenching of both the donor emission and acceptor emission upon hybridization, most probably due to the phenomenon of contact quenching.

Excimers as FRET Donors. The above examples document FRET behavior in exciplexes, which have inherent dipoles. To test if similar effects were observed in excimers (which in some cases do not have dipoles in the excited state; see Discussion), the pyrene excimer was used and three different ODF variants were synthesized. Two pyrene nucleosides were placed adjacent to each other in SSYY (P3), producing the highest efficiency of excimer formation. The efficiency of excimer formation was tested by placing spacer groups (S) between the pyrenes in YSSY (P4) or two dihydrothymidine nucleosides (H) between the pyrenes in YHHY (P5). Dihydrothymidine was shown in a previous study to possess excited-state "insulating" effects in oligodeoxyfluorosides (*40*).

The data for hybridization with TAMRA-containing strands are shown in Figure 4; results showed little if any evidence for FRET, displaying only a decrease in donor emission intensity, typical of contact quenching. In marked contrast, hybridization of the pyrene excimer-emitting ODFs to DNAs containing Cy5 (either proximal or distal, Figure 5) yielded significant decreases in donor emission intensity and strong increases in the acceptor emission intensity, providing evidence for efficient FRET. Detailed emission spectra are shown in the Supporting Information. The most efficient FRET occurred in the case of adjacent pyrenes or pyrenes with dihydrothymidine monomers in between, while the addition of spacers lowered the efficiency substantially.

Time-Resolved Measurements. To seek additional evidence for a putative FRET energy transfer mechanism from donor ODF fluorophores to acceptor TAMRA or Cy5, we measured donor emission lifetimes in the absence and presence of the acceptor dye. For the Förster mechanism, one expects a decrease in lifetime of the ODF donor in the presence of the acceptor. If this occurred, this would provide further evidence for FRET with these unusual donors, in addition to the above steady-state spectral observations. Time-resolved fluorescence decay profiles were measured for selected ODF dyes upon hybridization with TAMRA- and Cy5-labeled complement strands. Emission filter sets were selected to ensure that only the lifetime of the donor ODF was measured. Lifetime measurements were determined before and after the addition of the complement and results are shown in Table S2 (Supporting Information).

The results showed that ODF labels (P1−P8) that experienced sensitized acceptor emission and decreased donor emission as described above also experienced shortened donor emission lifetimes. Hybridization with the acceptor-containing strands lowered excited-state lifetimes by 8−27%, with one exception (P5 + C5′). Combined with data from the steady-state studies, this provides further evidence for the occurrence of FRET

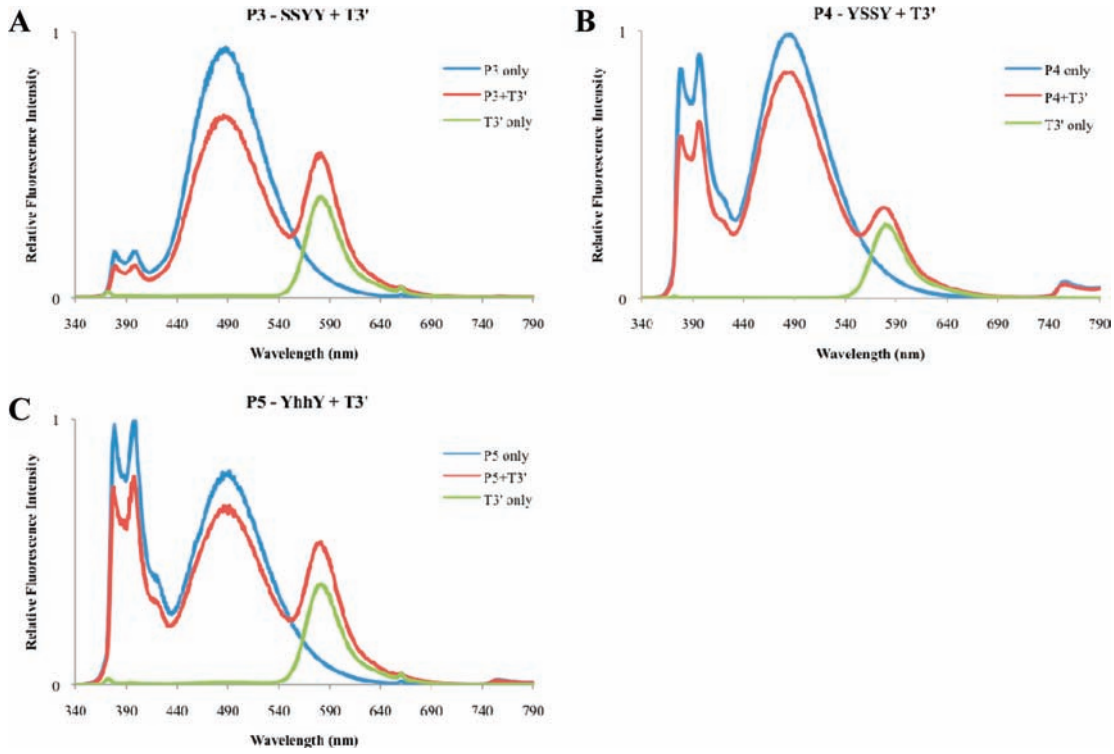

Figure 4. Testing possible FRET donation from pyrene excimers to TAMRA. Fluorescence emission spectra upon hybridization of (A) P3; (B) P4; and (C) P5 with T3′, respectively (red lines) (λ_{ex} = 330 nm) and individual emission spectra of P3, P4, P5, and T3′ (λ_{ex} = 330 nm).

between ODFs and acceptor TAMRA and Cy5 dyes. It is worth noting that the E_{FRET} and EL_{FRET} values calculated from the two methods were not especially well correlated; the most extreme examples are the P5 cases, where two dihydrothymine bases are placed between excimer-forming pyrenes in the ODF donor. We hypothesize that poor correlations for this ODF are due to a delay in formation of the excimer state by the intervening bases (see below). In addition, differences between efficiency values measured from different FRET methods can result from the presence of more than one species in the excited state, which results in lifetimes that vary from single exponential decay, and also by factors such as cross-talk in emission detection and bleedthrough in excitation (*41*).

Determination of Förster Distance, R_0. To further characterize ODFs as FRET donors we measured the Förster distance, R_0, with TAMRA and Cy5. Förster distance, R_0, determined using eq 4, is the distance between the donor and acceptor when the FRET efficiency is 50%. The orientation factor, κ^2, in the determination R_0 can be approximated to 2/3 if both donors and acceptors sample random orientations during the excited state lifetime, and an estimation of $\kappa^2 = 1/3$ is used for cases when either the FRET donor or acceptor experiences static orientation (*36, 42*). Although the orientations of ODFs are not known to certainty, evidence suggests they are stacked with the adjacent DNA, which suggests the use of $\kappa^2 = 1/3$. Nevertheless, we calculated R_0 between each ODF-labeled strand and its complement T3′ strand, using either $\kappa^2 = 1/3$ or $\kappa^2 = 2/3$; these are shown in Table 3 for comparison. R_0 values ranged from 25.3 Å (P4, YSSY) to 42.6 Å (P7, EYSS), and varying the value of κ^2 led to a ~10% difference in the value of R_0. The R_0 values calculated for P1−P20 and T3′ are typical of values of commonly used FRET dye pairs such as dansyl and FITC (33−41 Å) or pyrene and perylene (36 Å) (*43*).

$$R_0(\text{cm}) = [(8.79 \times 10^{-25})\kappa^2\eta^{-4}Q_D J(\lambda)]^{1/6} \quad (4)$$

where κ^2 is the orientation factor, η is the refractive index of water (1.33), Q_D is the quantum yield of the donor, and $J(\lambda)$ is the spectral overlap integral between the emission spectrum of the donor and absorption spectrum of the acceptor. The spectral overlap $J(\lambda)$ is calculated with eq 5

$$J_{DA} = \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 \, d\lambda \quad (5)$$

where F_D is the normalized donor emission and ε_A is the molar extinction coefficient of the acceptor.

Upon the determination of R_0, the actual distance between the donor (ODF) and acceptor (TAMRA) of FRET, R_{DA}, can be determined by eq 6. Using both E_{FRET} and EL_{FRET}, R_{DA} was calculated and shown in Table 3. The ODF fluorophore in P1−P20 and TAMRA in T3′ were 14 base pairs apart. On the basis of canonical B-DNA structure, the distance between them approximated from the center of a tetrameric ODF to the TAMRA dye stacked on the end of the double strand was approximately 56.1 Å. As shown in Table 3, the calculated values of R when using $\kappa^2 = 2/3$ and E_{FRET} were within 25% of this approximated distance, except for three cases (P7, P10, and P16), where the calculated distance was considerably longer, reflecting very poor FRET efficiency. Interestingly, calculations of R_{DA} using $\kappa^2 = 1/3$ provided closer approximations to the theoretical distance of 56.1 Å, giving smaller average deviation per strand. This is, however, an approximation and deviations can occur due to the flexible tether of TAMRA on T3′ and the varied distance of the excited donor of each ODF.

$$E = \frac{R_0^6}{R_0^6 + R_{DA}^6} \quad (6)$$

where E is the energy transfer efficiency, using either E_{FRET} or EL_{FRET}.

DISCUSSION

Taking both the steady-state and time-resolved spectroscopy data together, our results establish that both exciplex and excimer ODFs can act as FRET donors to the common acceptor

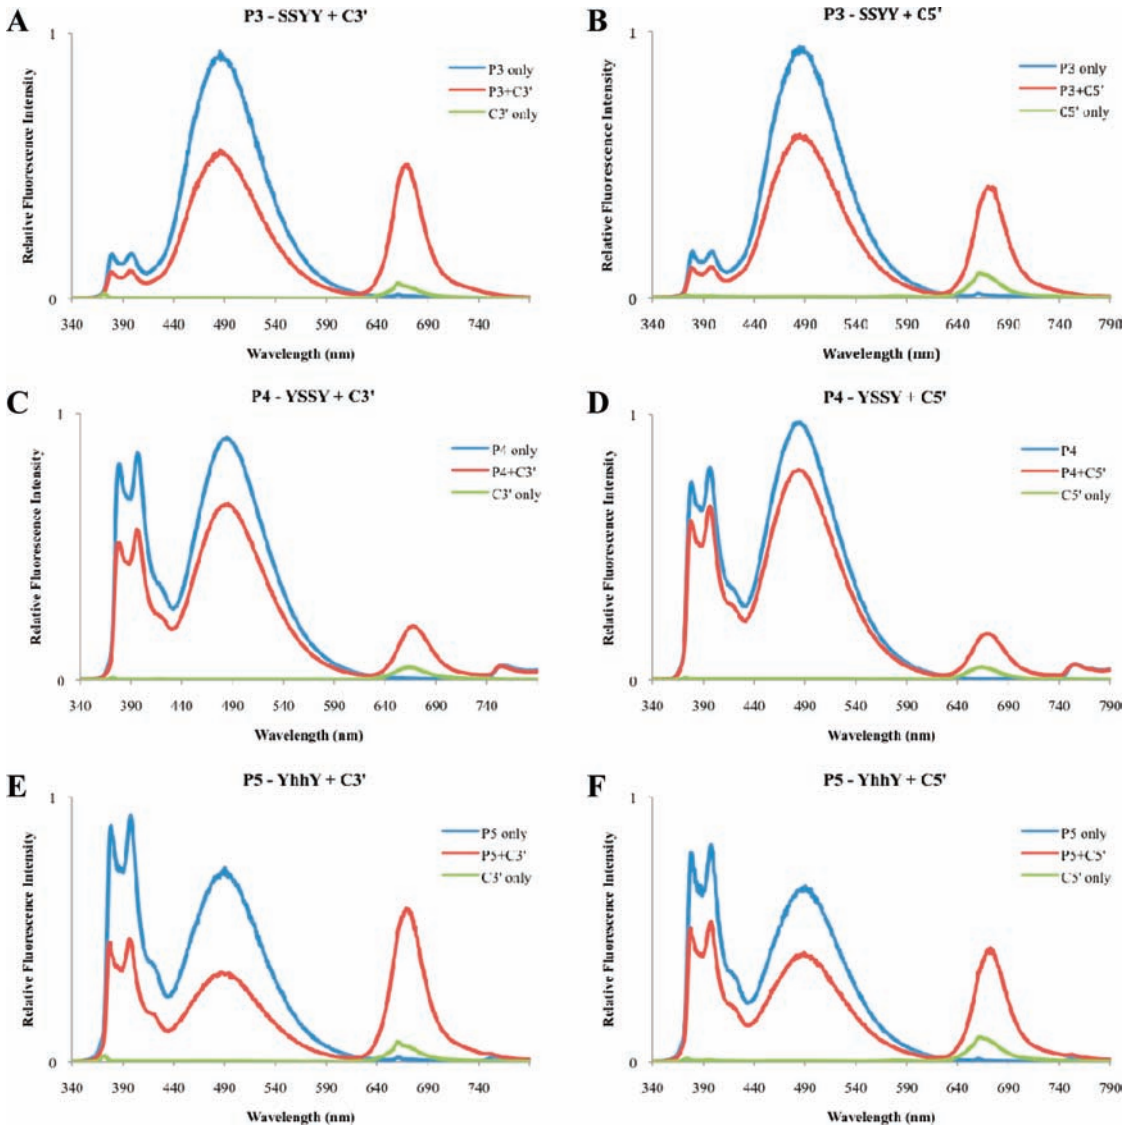

Figure 5. Evidence for strong FRET donation from pyrene excimers to Cy5 acceptor in DNA. Fluorescence emission spectra upon hybridization of P3, P4, and P5 with C3′ and C5′, respectively (red lines) (λ_{ex} = 330 nm) and individual emission spectra of P3, P4, P5, C3′, and C5′ (blue and green lines) (λ_{ex} = 330 nm).

[a] Note that only a subset of cases exhibit efficient FRET (Table 2). n.d. = not determined. R_0 = R value calculated from drop in donor emission; R_{0A} = value calculated from changes in both donor and acceptor.

fluorophores TAMRA and Cy5. To the best of our knowledge, neither of these delocalized excited-state species has been reported as a FRET donor before. Excimers and exciplexes are unusual as fluorophores in the sense that the excited state is delocalized over two adjacent chromophores. For exciplexes, where the two chromophores are different, this has the important consequence of creating an excited-state dipole that is expected to have a strong component perpendicular to the plane of the stacked chromophores. If (as expected) (*11*) they are stacked with the neighboring DNA, the dipole then has a strong directional component parallel to the helix axis. This is quite different from other DNA-stacked dyes (such as 2-aminopurine), where the chief dipole lies in the plane of the chromophore. Excimers are yet more unusual because the two chromophores are identical. In the absence of DNA, a pyrene excimer has no net excited-state dipole due to symmetry (*44*). As a result, it should not be able to participate in Förster energy transfer. However, by placing pyrenes in DNA the symmetry is broken, and our data establish that a net dipole clearly exists in the present structural context, since FRET from pyrene excimer donors appears to be among the most efficient cases observed here.

All of the ODF fluorophores studied here have emission bands between 440 and 540 nm. Most of them likely have substantial or dominant components of excimer and exciplex that account for this long-wavelength emission, since the monomers B, D, Y, and S do not emit above 430 nm. However, perylene (E) monomer emits at 440−470 nm, and a few of the perylene-containing ODF donors here are likely to emit as a mixture of perylene monomer and excimer or exciplex states. In those cases, we cannot rule out FRET from the perylene monomer state rather than (or in addition to) the delocalized states. However, some of the strongest FRET donors here are unambiguous. For example, P6 (BYSS) emits strongly at 450−550 nm, far red-shifted from the monomer emissions of B or Y and strongly indicative of an exciplex. In the presence of a Cy5 acceptor, this emission drops by 60−80% in intensity, while the Cy5 acceptor emission increases by 25% to >100% (depending on acceptor distance). Likewise, the sequence P3 (SSYY) is an excimer donor, emitting strongly at 440−560 nm. In the presence of Cy5, the donor band is quenched by 25−30%, and the acceptor increases its emission intensity by strong factors of 5−10-fold. Exciplex and excimer FRET cases are also supported by the time-resolved data (Supporting Information Table S2). Interestingly, monomer emission bands of pyrene are also quenched in these excimer donor cases. Since the pyrene monomer emission does not overlap with the absorbance of Cy5 (with a nearly 100 nm gap separating them), it is unlikely that pyrene monomers contribute directly to the FRET donor properties of these cases. It seems possible that this quenching instead reflects the dynamic equilibrium between excimer and monomer excited states.

Of the two acceptor dyes examined here, a distal TAMRA (T3′) was able to act as a more universal acceptor dye for FRET, which may be due to its greater spectral overlap of ODF donor emissions with TAMRA absorption. Thus, weak to moderate FRET occurred from all 20 of the ODF labels to the distal T3′ label. The most efficient donors for TAMRA were the exciplex ODF sequences BEBY and EYSS, which showed relatively large spectral changes in donor and acceptor emission (Figure 2 and Supporting Information). At too close proximity, when P1−20 were hybridized near TAMRA (T5′), this resulted in mutual quenching of the ODF emission and its own emission.

Cy5 was also shown here to be an acceptor dye for FRET with ODF donors, and indeed showed highest efficiency with some examples. FRET was observed in 7 and 9 cases of hybridization of P1−20 with C3′ and C5′, respectively. It is interesting to note that, in these cases, the hybridization of ODF to a proximal Cy5 acceptor did not result in mutual quenching. The most efficient donors for the Cy5 acceptor were found to be the pyrene excimer cases SSYY and YHHY, which showed strong spectral changes due to FRET (Figure 5). This occurred despite the non-optimal spectral overlap of the donor excimer emission (440−590 nm) with the Cy5 absorption band (band 548−689 nm; maximum at 646 nm). The results are consistent with a strong dipole in the ODF excimer and efficient dipolar interaction with Cy5.

Interestingly, although the emission bands of the present donor ODFs were mostly around the same range of wavelengths, FRET efficiencies varied considerably. One possible reason is that quantum yields vary to a substantial extent among ODF donors. Quantum yields of the donors affect the Förster distance, R_0, directly, and thus plays a role in E_{FRET}. The varying excited-state lifetimes of the donors could also affect the ability of the ODFs to sample favorable orientations and allow efficient FRET to occur. Thus, ODF donors with longer lifetimes typically displayed higher FRET efficiencies. In addition, the dipole strength and orientation of the excimers and exciplexes in the various ODFs may vary significantly, resulting in different degrees of FRET efficiency.

As mentioned above, the lifetimes measurements for these unusual multichromophore FRET donors can be complicated by two factors that may not be seen in some common single-chromophore donors: namely, the presence of multiple excited-state species, and the competing kinetics of delayed formation of an excited state. The former can complicate evaluation of decay kinetics by presenting more than one overlapping decay curve. The latter can result when excimer- or exciplex-forming species are separated physically. For example, the P5 + C5′ case, where two H residues separate two pyrenes, shows clear steady-state evidence of FRET (Figure 5F) but no shortening of lifetime (Supporting Information Table S2). We suggest that in this case the kinetics most likely reflect the added time required for structural reorganization of the chromophores during the long pyrene monomer excited state, until the favored conformation for excimer interaction can be reached. As a result of such effects, we consider the steady-state spectral changes (see Figures 2−5, Table 2) to be the most convincing measurement of FRET behavior for multichromophore ODF donors, and interpret the decrease in lifetimes as being consistent with, but not necessarily diagnostic of, FRET. More detailed time-resolved studies would be useful in investigating these phenomena.

The uncertainty of the orientation dipole factor (κ^2) in R_0 calculations is a known problem in the literature (*45*, *46*). In our study, we used two estimations of κ^2: a value of 1/3 (typically used when one member of the FRET pair is in a static orientation), and the value 2/3, assuming both donor and acceptor sample random orientations during the excited state. In our experiments, the former assumption yielded a better approximation to the theoretical distance between donor ODF and acceptor TAMRA. This would be consistent with the notion that either ODF donor chromophores or TAMRA and Cy5 acceptor dyes were stacked at the end of the DNA with relatively fixed orientation. Previous studies have shown that aromatic hydrocarbons such as those in these ODFs stack with DNA with high affinity (*11*) and absorption spectra support the notion that the neighboring aromatic chromophores are stacked with one another in the ground state as well (*37*). NMR studies showed that a significant population of Cy5 dyes can stack onto the end of a DNA duplex (*47*) while some remain freely mobile as shown in single molecule experiments and simulations (*48*).

Not only is the observance of FRET from excimer and exciplex dyes of theoretical interest, but the ODFs also offer some potential advantages in practical use. Relative to common donors used with

TAMRA and Cy5, the ODFs offer high quantum yields and a fixed orientation in the DNA. In addition, ODFs are directly incorporated into DNA using automated solid-phase synthesis, unlike some common dyes that require postsynthetic labeling. The ODFs are composed of combinations of a small set of monomers; for example, optimal donor ODFs for TAMRA and Cy5 are composed of only two fluorescent monomers (Y and E) along with a commercially available spacer (S).

In addition to the above, perhaps the most distinctive aspect of the current multichromophoric dyes as FRET donors is their unusual spectral characteristics. Since all the ODFs studied can be excited simultaneously at one wavelength (330 nm was used here), the ODFs can function as FRET donors potentially to a wide variety of acceptors using a simple filter set. Further experiments will be needed to confirm this. In addition, the ODFs have unusually large Stokes shifts (144−149 nm in the present cases), thus providing a large spectral separation between exciting light and emission. These properties can simplify experimental setups involving simultaneous analysis of multiple species. Thus, these multichromophore labels present substantial potential for development and application in biomolecular analysis and imaging.

ACKNOWLEDGMENT

We thank the U.S. National Institutes of Health (Grant GM067201) for support. Y.N.T. acknowledges an A*STAR NSS scholarship.

Supporting Information Available: Mass spectrometric data for ODF-containing oligonucleotides; fluorescence lifetimes measurements; emission spectra from hybridization experiments of all ODF-DNA duplexes with 5′-TAMRA, 5′-Cy5, 3′-TAMRA, and 3′-Cy5-labeled complementary strands; as well as the natural complementary strand. P8	1.03	0.71	6.25 (±0.39)	0.07	23.92 (±4.74)	7.83	
P8+T3'	0.92	0.52	4.61 (±0.003)	0.20	11.50 (±0.01)	6.50	0.170

[a] A single exponential was used to fit the fluorescence decay profile in these cases.

Figure S1. Fluorescence emission spectra for hybridization of P1-P20 with T3', T5', C3' or C5'. Conditions: 10 mM Na·PIPES, 100 mM NaCl, 10 mM $MgCl_2$, pH 7.0, 25°C, 2 μM of P1-P20 with 1.0 molar equivalents of T3', T5', C3' or C5'.

Figure S2. Fluorescence emission spectra for hybridization of P2, P3, P5, P8, P13 and P19 with unlabeled DNA complementary strand, D1 (5'- TAT GTT TCT GTG GA – 3'). Conditions: 10 mM Na·PIPES, 100 mM NaCl, 10 mM $MgCl_2$, pH 7.0, 25°C, 2 μM of P1-P20 with 2.0 molar equivalents of D1. Please refer to attached in press paper (Teo, Wilson, Kool Chem. Eur. J. 2009, in press) for hybridization data of other strands with D1.

Received August 3, 2009; Revised Manuscript Received October 23, 2009

A robust method to immobilize a maltose biosensor is described using an engineered maltose periplasmic binding protein (PBP) covalently coupled to NBDamide, an environmentally sensitive fluorophore. A mesoporous silica sol−gel derived from diglycerylsilane (DGS) was constructed to embed the maltose biosensor, and the ligand reporting fluorescence properties were measured. When sequestered in the DGS-derived silica matrix, the biosensor retained maltose-dependent fluorescence sensing capability with micromolar affinity, which is consistent with the protein free in solution. The MBP-NBD conjugate was further modified by covalent conjugation with poly(ethylene glycol)-5000 (PEG) to promote the retention of water molecules around the protein and to reduce possible steric effects between the silica matrix and protein. Bioconjugation with PEG molecules does not significantly affect the signaling response of the protein in solution. When immobilized in the DGS polymer, a consistent increase in fluorescence intensity was observed as compared to the protein not functionalized with PEG. To our knowledge, this report presents the first successful method to embed a PBP biosensor in a polymerized matrix and retain signaling response using an environmentally sensitive probe. The immobilization method presented here should be easily adaptable to all conformation-dependent biosensors.

INTRODUCTION

The construction of protein biosensors for the detection of analytical targets requires high ligand specificity and selectivity, combined with a robust delivery strategy (e.g., *refs* 1, 2). The first two criteria are determined by the polypeptide utilized in the biosensing scheme, whereas a reliable way to mobilize the sensor out of the lab requires a deliberate, empirical approach that ideally leads to operational and storage stability (*3*). One protein superfamily studied for the design of fluorescent protein biosensors is the periplasmic binding proteins [1](PBPs), which facilitate the collection of nutrients from the surrounding environment for use in bacterial metabolism (*4*). A diverse set of PBPs has been characterized with binding capabilities to a variety of ligands including metals, sugars, amino acids, and anions (*5*−*7*). PBPs share a conserved structural organization whereby a single polypeptide chain folds into two easily identifiable domains separated by a hinge region where binding to cognate ligand may occur (*8*). Upon ligand binding, the protein domains undergo large bending or rotational motions around the hinge region. As a result of these well-documented conformational changes, many spectroscopic and electrochemical techniques provide a measurable signal output to report on ligand binding.

Two factors have inhibited the advancement of promoting the design of PBP biosensors. First, because large conformational changes are required for signal transduction, it has been difficult to construct a system using these potential biosensors embedded in a polymeric matrix which typically prevents conformational flexibility. Second, the majority of PBP biosensors are designed using environmentally sensitive probes covalently attached to single cysteine residues (*5*). Because all measurements and associated calculations are optimized in an aqueous solution, transfer of the system to an altered environment (e.g., different polarity medium) may have a significant impact on signal output, response, and stability. In this report, we tested a silica gel polymer derived from diglycerylsilane (DGS) as a carrier for a maltose biosensor. Sugar alcohol- and polyol-modified silanes, such as DGS, have been extensively used for the gentle encapsulation of biomolecules because these materials condense at neutral pH while releasing benign glycerol molecules (*9*−*11*). We also examined the effect of covalent attachment of poly(ethylene glycol) (PEG) on maltose-dependent fluorescence intensity changes upon encapsulation in the sol−gel; this polymer conjugation is intended to increase the hydration of the protein, as well as prevent interactions between the protein and silica matrix walls. To our knowledge, this report presents the first successful method to embed a PBP biosensor in a polymerized matrix and retain signaling response using an

environmentally sensitive probe. The immobilization method presented here is general and should be easily adaptable to other conformation-dependent biosensors.

EXPERIMENTAL SECTION

Construction of the Maltose Biosensor. Purification of *E. coli* MBP D95C was performed as previously described using Ni-NTA affinity chromatography (*12*). Covalent attachment of a thiol-reactive NBDamide (Anaspec, Inc., San Jose, CA) was performed either at room temperature for 4 h or overnight at 4 °C in the dark with a 3-fold molar excess of dye. Unbound probe was removed using PD-10 gel filtration chromatography followed by dialysis against 5 mM phosphate buffer, pH 7.0. Typically, PEGylation was then performed by combining an 8-fold molar excess of NHS-PEG-5000 (Nanocs, Inc.) to MBP D95C for 12 h at room temperature. The mixture was then filtered through a 10 kDa microcentrifuge column (Microcon) to remove unreacted PEG; no further attempt was made to separate PEGylated protein from the unmodified protein. Dynamic light scattering (Zetasizer Nano, Malvern Instruments) was used to measure the hydrodynamic radii of the protein before and after PEGylation. Mass spectrometry was performed on a 4800 Plus (ABI, Framingham, MA) MALDI-TOF mass spectrometer.

DGS was synthesized following previously reported procedures (*13, 14*). In a typical silica gel preparation, ~150 mg of DGS was partially dissolved in deionized water (>18.0 MΩ cm) and sonicated for 30 min at 10−15 °C. The resulting solution was filtered through a 0.45 μm polycarbonate filter to remove any undissolved particulates of DGS and then mixed in a 96 well plate with an equal volume of labeled protein in 5 mM phosphate buffer (pH 7). The resulting monoliths measure 7 mm × 6 mm (height × width). The plate was covered with parafilm, and samples were allowed to gel at 4 °C for at least 5 days before performing maltose binding assays. Sensors were stable and operationally viable for at least 2 months stored at 4 °C.

Steady-State Fluorescence. Fluorescence measurements were performed at room temperature using a Varian Cary Eclipse spectrofluorometer equipped with a plate reader and thin film polarizers set to the magic angle (0° excitation and 54.7° emission). Protein conjugate samples were excited at 480 nm and were titrated with increasing amounts of maltose to achieve signal saturation. Fluorescence intensity at the emission maximum was plotted against maltose concentration to determine the apparent binding constant of the protein conjugate as previously described (*15*). Data analysis was performed using the nonlinear curve fitting procedures in the *Origin 7.0* software.

RESULTS AND DISCUSSION

The maltose-dependent fluorescence response of a MBP-D95C mutant labeled with IANBDamide (NBD) has been characterized previously (*12*). This bioconjugate sensing system is one of the few PBP biosensors where the mechanism of ligand-dependent fluorescence change is understood to result from a specific hydrogen bond interaction between the NBD and the hydroxyl group on Tyr171. Upon binding maltose, the hinge-bending motion of MBP removes this contact resulting in an increase in NBD emission. For device applications, immobilization of these types of proteins in a solid matrix is preferred. However, many encapsulating systems, like silica, dehydrate over time causing proteins to denature. Functionalization of MBP with a poly(ethylene glycol) (PEG) polymer may improve the protein's ability to maintain proper conformation in a solid matrix, as PEG is known to be heavily hydrated by water (*16*). In addition, the steric bulk of the PEG moieties should reduce protein−matrix sidewall interactions, which can disrupt protein function (*17*).

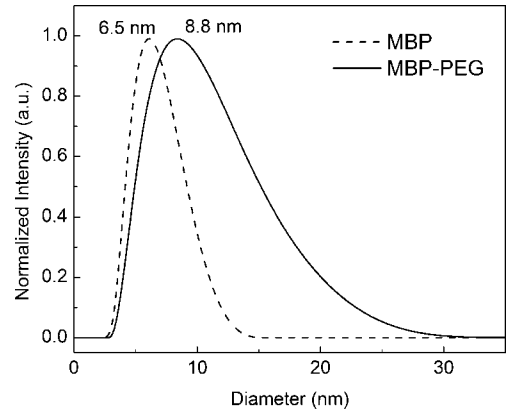

Figure 1. Representative dynamic light scattering data for MBP D95C before (6.5 nm) and after (8.8 nm) the reaction with an 8-fold molar excess of amine-reactive PEG-5000.

Prior to encapsulation, we investigated the addition of an amine-reactive PEG-5000 moiety to lysine residues of the maltose biosensor. Because PEG is spectroscopically inactive, we used dynamic light scattering to measure the increase in molecular volume upon reaction with PEG and MALDI-TOF MS to further characterize the PEGylated biomolecules. Before the PEGylation reaction, the ensemble of proteins in the MBP solution showed a narrow light scattering curve with an average diameter of 6.5 nm, as seen in Figure 1, which is consistent with previous determinations of the hydrodynamic radius for similar MBP monomeric proteins in solution (*18*). Following the labeling of amino groups with 8 mol equiv of PEG, the mean distribution broadened significantly and shifted to an average diameter near 8.8 nm (Figure 1). While there is a clear increase in the hydrodynamic diameter for the PEGylated-MBP which represents a correlation to the increase in size of the protein−PEG conjugate, it is difficult to quantitatively determine the average number of PEG molecules attached to each protein (*19*). A distribution of the number of PEG units covalently attached to the protein is observed, and additional experimentation with changes to the PEG and protein concentration had little effect on the resulting scattering data providing consistent evidence for the addition of PEG molecules to the protein. To further investigate what PEGylated species were present following conjugation, MALDI-TOF MS was used. Prior to PEGylation, a singly charged MBP parent ion was observed around 42 kDa. After PEGylation, three new peaks were observed at ~46 kDa, 52 kDa, and 56 kDa as expected for MBP plus one, two, or three PEG molecules, respectively (see Supporting Information), along with the parent MBP ion at ~42 kDa. While MALDI of intact proteins is not accurately quantitative, these spectra provide a reasonable estimate of the level of PEGylation in our samples. Taken together, the DLS and MALDI-TOF data demonstrate that MBP was labeled with a distribution of PEG groups.

Following PEGylation, we tested the protein samples for any quantitative differences in maltose sensing ability in solution compared to the non-PEGylated protein sensor. The fluorescence response of NBD-labeled MBP with and without PEG showed no significant differences in phosphate buffered solution with respect to reporting on maltose concentration (Figure 2). A 4.5-fold increase in fluorescence was measured for both systems, and the dissociation constant for maltose of the PEGylated protein conjugate was determined to be 5 μM (Figure 2, inset). PEGylation of the protein does not produce a noticeable lag in response time in solution, where signal equilibrium is reached within the mixing time. Also, the dissociation constant measured

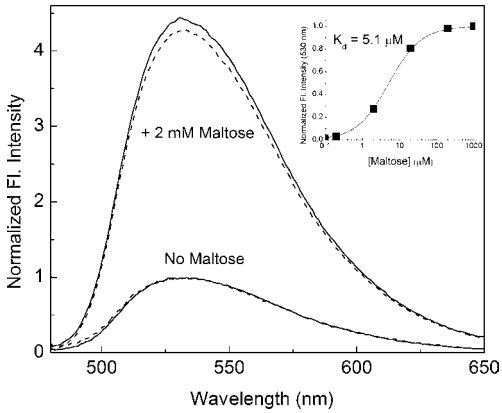

Figure 2. Fluorescence emission spectra of MBP D95C-NBD with (solid lines) and without (dashed lines) the attachment of PEG in the presence and absence of maltose. (inset) Titration of PEGylated protein with maltose in solution yields a dissociation constant of 5 μM.

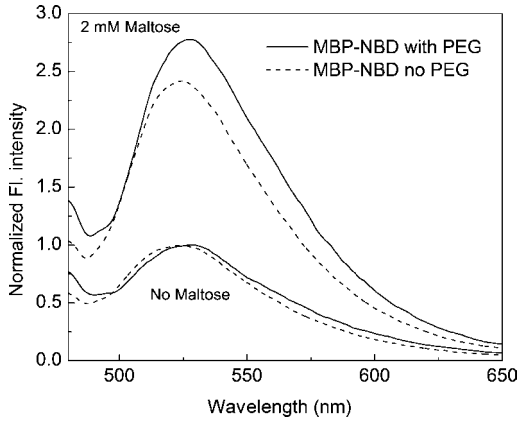

Figure 3. Fluorescense spectra of a maltose biosensor embedded in DGS before (dashed) and after (solid) conjugation with PEG. Spectra were normalized to the signal measured for the unbound protein immobilized in DGS. Samples were prehydrated with phosphate buffer, pD 7.0, and measurement was performed in a 96 well plate.

for the PEGylated protein is consistent with the value found previously for the maltose sensor in the absence of PEG, providing further support that the PEG molecules conjugated to the MBP sensor do not produce a significant effect on the binding characteristics of the protein (*12*).

The fluorescently tagged MBP with and without PEG conjugation was encapsulated into DGS-derived sol−gel slabs or cast as thin films in 96 well plates. Several spectral differences were observed between unmodified and PEGylated protein upon encapsulation into the DGS polymer and titration with maltose. The fluorescence intensity of the starting material was checked prior to addition of ligand to ensure consistency of the experimental data collected. Following immobilization in the DGS-derived sol−gels, the PEGylated sensor demonstrated a 2.8-fold increase in fluorescence intensity upon saturation with maltose, while the protein without PEG showed a smaller 2.4-fold change in emission intensity (Figure 3). In general, we observed a ∼10% increase in fluorescence from PEG-functionalized MBP compared to unfunctionalized MBP upon encapsulation and exposure to maltose. Additionally, we observed a 5 nm red shift of the NBD emission maximum in the PEGylated MBP, which suggests that the probe molecule may be experiencing an increased level of polarity in its microenvironment compared to the protein free in solution (*20*). While a difference in signal intensity is observed between the two protein conjugates trapped in DGS-derived sol−gel films, titration with

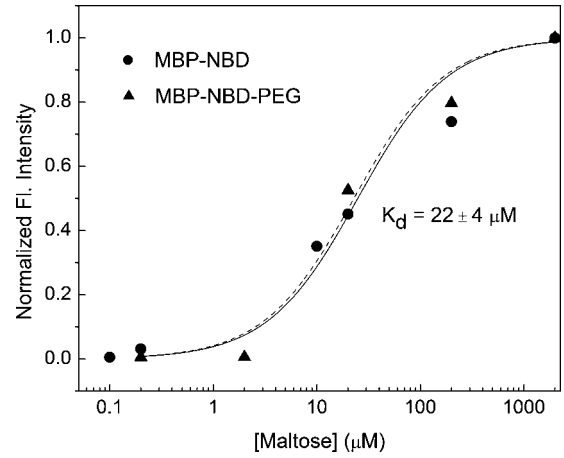

Figure 4. Representative maltose titration data for the constructed biosensor in DGS with (triangle) and without (circle) the covalent attachment of PRG-5000. The data were fit to a single binding isotherm and the K_d was calculated to be approximately 22 μM for maltose for both sensors.

increasing concentrations of maltose (0 to 2 mM) yielded similar dissociation constants (∼22 μM) as shown in Figure 4.

There have been few reports in the literature describing the successful interface of PBP-based fluorescent biosensors on surfaces for the construction of immobilized biosensors. Cass and colleagues reported the first successful surface immobilization of a PBP biosensor using a glutamine binding protein translational fusion with a C-terminal hydrophobic polypeptide (*21*). Using thermophilic PBPs, deLormier et al. were able to covalently attach glucose and ribose sensing proteins to the bottom of well plates via masked cysteine residues (*22*). However, both of these methods required further engineering of the protein biosensor, and because emission is provided from a single layer of protein molecules, there is a reduced level of signal intensity which may lower the sensitivity of the sensor. There are examples in the literature of protein immobilization entrapment in silica-based polymers with retention of ligand binding and fluorescence signaling (*20, 23*); however, these systems typically do not require the magnitude of the conformational flexibility needed for ligand binding in PBPs.

We tested the ability of an MBP sensor to respond to maltose when encapsulated in a DGS-derived silica matrix. The ideal matrix needs to allow easy diffusion of ligand to the protein, as well as allowing for the conformational transition between open and closed states of MBP, which is required for proper signal transduction of the binding event. Typical matrices used to embed proteins include polyvinyl alcohol, carboxydextran, and polyethylenimine. All of these polymers have been tried and found to greatly reduce or eliminate the ligand-dependent fluorescence response of PBP-based biosensors (unpublished observations). DGS, however, forms a silica gel that has not previously been used with PBP sensing systems and has several benefits including condensation at neutral pH and optical transparency. The DGS matrix was shown to be effective at allowing an observable signaling response to maltose. Although there was a considerable lag in response time compared to solution (∼20 min for 50% signal intensity), there is no difference in time response between PEGylated and non-PEG protein in DGS, suggesting that the time required for signaling is most likely due to diffusion of maltose into the DGS matrix. Retention of protein flexibility upon entrapment is clearly adequate for maintenance of equilibrium binding affinity, despite the slowed dynamics upon entrapment within the biogels. This trend is consistent with earlier observations showing arrested nanosecond rotational reorientation dynamics for intact poly-

clonal antidansyl antibodies sequestered within sol−gel-derived biogels accompanied by minimal losses in the equilibrium binding constant describing antibody association with its target hapten (*24*). Covalent conjugation with PEG may have increased the stability of MBP by keeping it better hydrated even after immobilization within the silica gel, as well as minimizing denaturing steric effects. We believe that the beneficial effects of PEGylation will be even more significant for PBP biosensors where the signaling response is not as well-characterized as the MBP system studied here. In summary, the covalent attachment of PEG chains to residues on protein surfaces, followed by mild immobilization procedures based upon bioconjugate entrapment within sol−gels formed from biofriendly precursors such as DGS, may prove to be a generic approach to designing robust, portable fluorescent protein biosensor platforms and forms the subject of future research in our group.
