
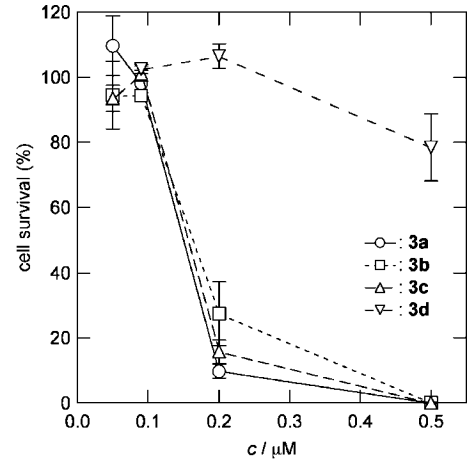

Figure 5. Plot of cell survival (%) as a function of the concentration (*c*) of S-glucosylated photosensitizers **3a**, **3b**, **3c**, and **3d**. The light dose applied was 16 J·cm^{-2}. Values are the mean ± standard deviation of six replicate experiments.

Photophysical and Photochemical Properties of S-Glucosylated Photosensitizers. Figure 1 shows UV−vis spectra of the S-glucosylated photosensitizers **2a**, **2b**, **2c**, **2d**, **3a**, **3b**, **3c**, and **3d** in DMSO at 25 °C and Table 1 lists the spectral data. There were no significant differences between photosensitizer **2** and the corresponding **3**. Free-base porphyrins **2a** and **3a** showed typical UV−vis spectra with one intense peak (Soret band) at ca. 415 nm and four vibronic peaks (Q bands) at ca. 507, 539, 580, and 635 nm. Zn(II) complexes **2b** and **3b** showed significantly red-shifted UV−vis spectra compared with those of **2a** and **3a**, while the UV−vis spectra of Pd(II) and Pt(II) complexes **2c**, **2d**, **3c**, and **3d** showed blue-shifted spectra. The disappearance of Q(0,0) of **2b** and **3b** is caused by axial ligation of DMSO to the Zn(II) ion; the intensity ratio of Q(0,0) to Q(1,0) of **1b** is known to be very sensitive to the axial ligand (*27*). Table 1 also lists the oscillator strength in the wavelength region over 500 nm ($f_{>500\text{nm}}$), which is a photophysical parameter used in our photocytotoxicity test (vide infra). The $f_{>500\text{nm}}$ values of S-glucosylated photosensitizers were substantially constant at around 0.09−0.14, despite the remarkable shift in maximum absorption wavelength upon complexation. Figure 2 shows steady-state luminescence spectra of the S-glucosylated photosensitizers **2a**, **2b**, **2c**, **2d**, **3a**, **3b**, **3c**, and **3d** in DMSO at 25 °C and Table 2 lists spectral data. While free-base porphyrins and Zn(II) complexes **2a**, **2b**, **3a**, and **3b** emitted light upon photoirradiation, Pd(II) and Pt(II) complexes **2c**, **2d**, **3c**, and **3d** were nonluminescent in DMSO.

The singlet oxygen ($^1O_2$)-producing ability of S-glucosylated photosensitizers **2a**, **2b**, **2c**, **2d**, **3a**, **3b**, **3c**, and **3d** was evaluated by measuring the degradation rate of 1,3-diphenylbenzofuran (DPBF) by $^1O_2$ generated upon photoirradiation using 100 W halogen lamp equipped with a Y-50 cutoff filter ($\lambda > 500$ nm) at 37 °C. The degradation of DPBF followed pseudo-first-order kinetics with an apparent rate constant k' s^{-1}, and we normalized the value to the k' value for TPPS under the same condition to give a relative scale of the rate constant *k* (Table 3). The *k* value for S-glucosylated porphyrin **2a** (1.14) is significantly lower than that for porphyrin **1a** (1.67). Hence, S-glucosylation of **1a** leads to a significant reduction of the $^1O_2$-producing efficiency. The introduction of Zn(II) and Pd(II) ions improves the $^1O_2$-producing efficiency of S-glucosylated porphyrin **2a**, presumably

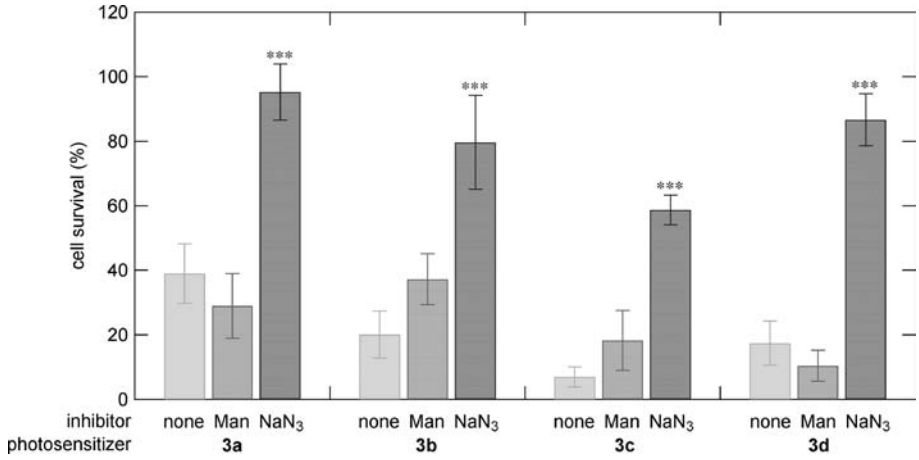

Figure 6. Cell survival (%) of HeLa cells treated with S-glucosylated photosensitizers **3a**, **3b**, **3c**, and **3d** in the absence of ROS quenchers and in the presence of 40 mM D-mannitol (Man, OH-scavenger), and 5 mM sodium azide (NaN_3, $^1O_2$-quencher). The light dose applied was 16 J·cm^{-2}. The concentrations of photosensitizers were 0.1 μM for **3a**, **3b**, and **3c** and 2 μM for **3d**. Values are the mean ± standard deviation of six replicate experiments. ***Significant difference, $p < 0.001$ vs none (without inhibitor).

due to heavy atom effect, while Pt(II) complexes **2d** and **3d** have essentially no photosensitizing ability. The exceptionally low efficiency in $^1O_2$ production of Pt(II) complexes was also found in the case of TPPS, which is a sulfur-containing porphyrin, as reported by Mosinger et al. (*28*). They reported that the $^1O_2$ quantum yield of TPPS and its Pt(II) complex in D_2O were determined to be 0.62 and 0.06, respectively. Although the photophysical mechanism is not fully understood, the introduction of Pt(II) ion into sulfur-containing porphyrins appears to reduce the $^1O_2$-producing efficiency.

In Vitro Photocytotoxicity in HeLa Cells. First, we examined the time course of the cellular uptake of **3a** in HeLa cells by using fluorometry, in order to determine an appropriate incubation time. Figure 3 shows the cellular uptake (percentage of the total amount of photosensitizer) of **3a** as a function of incubation time. The amount of cellular uptake reached a plateau level after 6 h. This result is similar to that reported for 5,10,15,20-tetrakis(3-hydroxyphenyl)chlorin (Foscan) by Leung et al. (*29*). In order to eliminate the influence of incubation time, we incubated HeLa cells in the presence of S-glucosylated photosensitizers for 24 h in the photocytotoxicity test (vide infra).

The cytotoxicity of eight S-glucosylated photosensitizers **2a**, **2b**, **2c**, **2d**, **3a**, **3b**, **3c**, **3d**, and TPPS was evaluated at the concentration of 0.5 μM without photoirradiation and under photoirradiation (16 J·cm^{-2}) in HeLa cells. The percent cell survival was determined after incubation for 24 h following photoirradiation (Figure 4). None of the S-glucosylated photosensitizers showed cytotoxicity without photoirradiation. S-Glucosylated photosensitizers **3a**, **3b**, and **3c** showed potent photocytotoxicity, and completely killed the HeLa cells, while the protected compounds **2a**, **2b**, **2c**, and **2d** and TPPS showed no photocytotoxicity. These results clearly demonstrate the importance of the sugar moieties, presumably for increasing cellular uptake. Despite the potent photocytotoxicity of the S-glucosylated photosensitizers **3a**, **3b**, and **3c**, as expected, the Pt(II) complex **3d** showed hardly any photocytotoxic effect. In order to explore the photocytotoxicity in more detail, the S-glucosylated photosensitizers **3a**, **3b**, **3c**, and **3d** were further examined in the concentration range from 0.5 μM to 0.09 μM (Figure 5). All of them showed similar plots, and the drug concentration inducing 90% cell death (EC_{90}) was estimated to be ca. 0.2 μM in each case. This EC_{90} value is much lower than that of the corresponding O-glucosylated tetraphenylporphyrin derivatives ($EC_{90} > 5$ μM) (Chart 1), which we have reported previously (*12*).

Upon photoirradiation in the presence of an S-glucosylated photosensitizer, two types of photochemical reactions, namely electron and/or proton transfer (type I reaction) and energy transfer (type II reaction), could be initiated. Type I reaction generates hydroxyl radical (·OH), superoxide anion (O^{2-}), and so on. On the other hand, type II reaction mainly forms $^1O_2$ which is thought to be a key species in the photodynamic effect because of its relatively long lifetime (ca. 2 μs in water) (*6*). In order to explore the origin of the photocytotoxicity, the photocytotoxicity of S-glucosylated photosensitizers **3a**, **3b**, **3c**, and **3d** was measured after a short (2 h) incubation of the cells with sodium azide (NaN_3) as a $^1O_2$-inhibitor or D-mannitol (Man) as a ·OH-scavenger prior to photoirradiation. Figure 6 shows the cell survival rate in the presence of **3a**, **3b**, **3c**, and **3d** in the absence and the presence of reactive oxygen species (ROS) inhibitors. Sodium azide dramatically reduced the photocytotoxicity of **3a**, **3b**, **3c**, and **3d**, while only a small increase of cell survival rate was found in the presence of Man. These results suggest that $^1O_2$ is a dominant species for the cytotoxic effect in **3a**, **3b**, **3c**, and **3d**. However, the photocytotoxicity of **3a**, **3b**, and **3c** in HeLa cells seemed to be insensitive to the $^1O_2$-producing ability in DMSO (the order was **3a** < **3b** < **3c**). This suggested that the $^1O_2$-producing ability of photosensitizers is not the limiting factor for in vitro photocytotoxicity, in which oxygen may be more abundant than in vivo. These findings support the idea that the Zn(II) and Pd(II) complexes of S-glucosylated porphyrin **3b** and **3c** act as efficient $^1O_2$-generators with enhanced cellular uptake owing to the sugar moieties.

In conclusion, S-glucosylated porphyrin and its metal complexes were prepared by means of a complexation-first approach. The $^1O_2$-producing ability increased in the order of free-base porphyrins < Zn(II) complexes < Pd(II) complexes, which is consistent with the well-known heavy-atom effect, but Pt(II) complexes showed unexpectedly low quantum yields for $^1O_2$ formation. Zn(II) and Pd(II) complexes of S-glucosylated porphyrin are promising photosensitizers having enhanced cellular uptake due to their glucosylation and high $^1O_2$-generating ability due to the heavy-atom effect.

Cytosolic Targeting of Macromolecules Using a pH-Dependent Fusogenic Peptide in Combination with Cationic Liposomes

Received December 10, 2008; Revised Manuscript Received March 18, 2009

pH-Sensitive peptides and polymers have been employed as additives to enhance the cytosolic delivery of drugs and genes by facilitating their endosomal escape. However, little attention has been paid to the intracellular fate of these peptides and polymers. In this study, we explored the possibility of utilizing GALA, a pH-sensitive fusogenic peptide, as a cytosol-targeting vehicle. In combination with cationic liposomes, Lipofectamine 2000 (LF2000), the feasibility of this approach for the cytosolic targeting of proteins and nanoparticles was exemplified through the delivery of avidin (68 kDa) and streptavidin-coated quantum dots (15−20 nm) in serum-containing medium. The use of cationic liposomes is critical to enhance the cell-surface adhesion of the GALA conjugates and eventual endosomal uptake. Circular dichroism studies suggest that the GALA can be liberated from cationic liposomes at a reducing pH to form a helical structure and this may eventually lead to disruption of the endosomal membrane to achieve an efficient leakage of the GALA conjugates into the cytosol.

INTRODUCTION

Plasma membranes isolate the inside of cells from the outside and maintain cellular functions and homeostasis. These membranes also work as barriers to protect the cells against attack from outside the cells. Therefore, it is necessary to find a means to efficiently cross the membranes to allow cell entry of bioactive molecules with low membrane permeability. Certain classes of viruses have achieved this by using fusogenic peptides that often act at the level of the endosome once the virus is internalized. For example, influenza viruses adsorb on the cell surface by interaction with sialic acids expressed on the plasma membrane and gain access through endocytosis. The pH decrease in endosomes induces conformational changes in a viral coat protein hemagglutinin 2 (HA2), which leads to the fusion of endosomal membranes with viral membranes to allow leakage of the viral genes into the cytosol.

Studies have been reported describing efforts to mimic methods employed by viruses for intracellular delivery of membrane-impermeable macromolecules (*1, 2*). GALA is such a peptide that was developed by Szoka and co-workers (WEAALAEALAEALAEHLAEALAEALEALAA). This peptide is composed of repeating sequences of Glu-Ala-Leu-Ala and has an amphiphilic structure (*3*). A decrease in the endosomal pH leads to a decrease in negative charges of Glu residues and conversion of the structure from random to helical (*2*−*7*). This promotes its interaction with endosomal membranes, leading to their disruption. Therefore, GALA has been employed to facilitate endosomal escape of liposomes and polymers complexed with plasmid DNAs as a method to improve transfection efficiency (*1, 2, 8*−*14*).

In the course of our study assessing the capacity of GALA to enhance transfection, we observed that a FITC-labeled GALA peptide effectively diffused into the cytosol when administrated to cells as a plasmid DNA complex with cationic liposomes. By use of FITC as a model marker for cytosolic delivery, these results strongly support the potentyial of GALA as a vehicle to enhance the delivery of attached cargo to the cytosol (*11*).

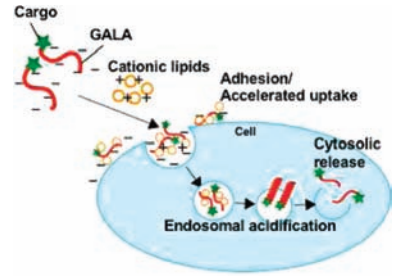

Figure 1. Concept of cytosolic targeting using GALA as an addressing vehicle in combination with cationic liposomes.

In this report, we explore the possibility of GALA as a cytosol-addressing vehicle with pH-sensitive fusogenic activity (Figure 1). Here, a high efficiency of cytosolic targeting using the GALA-based systems is not achieved without entrapment of GALA and the cytosol-targeting molecules in endosomes at a high concentration. Cationic liposomes are known to effectively adsorb onto cell surfaces and be endocytosed, and since GALA has negative charges, cationic liposomes can also form complexes with it. Conjugation or complex formation of cargo molecules with GALA was critical for it to be localized to endosomes where cytosolic escape would take place. The use of cationic liposomes further enhanced the cellular uptake of GALA/cargo molecules and increases the amount localized to endosomes (Figure 1).

phase peptide synthesis as previously reported (*15*). Actual sequences of the synthesized peptides are as follows: GALA, WEAALAEALAEALAEHLAEALAEALEALAA-amide; scrambled GALA (sGALA), AAALHAALAAEAELLEEWLAAEEAELLAAA-amide; FITC-labeled GALA (FITC-GALA), FITC-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-amide; FITC-labeled scrambled GALA (FITC-sGALA), FITC-NH-$(CH_2)_3$-CO-AAALHAALAAEAELLEEWLAAEEAELLAAA-amide; biotinamidocaproyl-GALA peptide (biotin-GALA), biotin-amidocaproyl-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-amide; biotinamidocaproyl-GALA bearing SV40-derived nuclear localization signal (biotin-GALA-NLS), biotinamidocaproyl-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-GG-PKKKRKV-amide; biotinamidocaproyl-scrambled GALA peptide (biotin-sGALA), biotinamidocaproyl-NH-$(CH_2)_3$-CO-AAALHAALAAEAELLEEWLAAEEAELLAAA-amide; CG-GALA, CG-WEAALAEALAEALAEHLAEALAEALEALAA-amide. Details of the preparations of these peptides are described in the Supporting Information.

EGFP−GALA Fusion Protein. The enhanced green fluorescent protein (EGFP) fused with GALA at its C-terminus was prepared by expressed protein ligation (EPL) essentially as previously reported (*16*). Briefly, EGFP was bacterially expressed as a fusion protein with the C-terminal intein bearing the chitin-binding domain (CBD) tag in *E. coli*. Affinity purification was performed on chitin beads (IMPACT system, New England Biolabs) followed by subsequent intein cleavage by the addition of 100 mM 2-mercaptoethanesulfonic acid (MESNA), leading to thioester formation. Ligation of EGFP thioester with CG-GALA was conducted in 0.1 M Tris-HCl (pH 8.5) containing 500 mM NaCl at 4 °C for 24 h in the presence of 10 mM MESNA to yield the EGFP−GALA fusion protein.

Cell Culture. Human cervical-cancer-derived HeLa cells were cultured as exponentially growing subconfluent monolayers on 60 mm dishes in α-minimum essential medium (α-MEM) supplemented with 10% (v/v) heat-inactivated bovine serum (BS) (Invitrogen). Chinese hamster ovary (CHO) K1 cells were cultured in F-12 nutrient mixture (Ham's F-12) supplemented with 10% (v/v) heat-inactivated BS. Mouse fibroblast-derived NIH3T3 cells and human epidermoid carcinoma-derived A431 cells were cultured in Dulbecco's modified Eagle medium (D-MEM) supplemented with 10% (v/v) heat-inactivated BS. The respective cells were maintained at 37 °C in a humidified 5% CO_2 incubator, and a subculture was performed every 3−4 days.

Cellular Uptake Experiments and Microscopic Observation. The 1.5×10^5 HeLa cells were plated into 35 mm glass base dishes (Iwaki) and cultured for 24 h. Lipofectamine 2000 (LF2000, Invitrogen) (2 μL) diluted with serum-free α-minimum essential medium [α-MEM(−)] (18 μL) was added to a solution of the FITC-labeled GALA peptide (10 μM) in α-MEM(−) (20 μL), and the mixture was incubated for 15 min at room temperature. Heat-inactivated BS (13 % (v/v)) in α-MEM (160 μL) was then added to yield a solution of the GALA peptide (1 μM) containing LF2000 (2 μL) in α-MEM containing 10% (v/v) BS [α-MEM(+)] (200 μL). After the HeLa calls were incubated with this mixture at 37 °C under 5% CO_2 for 4 h, the cells were washed twice with PBS and fresh α-MEM(+) (1 mL) was added to the cells. Internalization of the peptides was analyzed in live cells using an FV300 Olympus confocal laser scanning microscope (CLSM) equipped with a 40× objective.

For the treatment of EGFP−GALA/LF2000 complex, EGFP−GALA (20 μM) in α-MEM(−) (20 μL) was mixed with LF2000 (8 μL) in α-MEM(−) (20 μL) and incubated for 15 min at room temperature. α-MEM (160 μL) containing 13% BS was then added to yield a solution of the EGFP−GALA (2 μM) in α-MEM(+) containing LF2000 (8 μL). HeLa cells were incubated with this mixture at 37 °C under 5% CO_2 for 8 h. The cells were then washed twice with PBS containing heparin sodium salt (0.5 mg/mL) (Sigma). Internalization of the EGFP was analyzed in a fresh medium using CLSM.

For assessment of the internalization of FITC-avidin/biotin-GALA complexes, biotinylated-GALA (10 μM) in α-MEM(−) (20 μL) was mixed with LF2000 (2 μL) in α-MEM(−) (20 μL) and incubated for 15 min at room temperature prior to adjustment of the total volume of the mixture to 200 μL with a solution of FITC-avidin (Sigma) in 13% BS-containing α-MEM to yield a solution of the FITC-avidin/biotin-GALA complex (FITC-avidin 0.25 μM; biotin-GALA 1 μM) in α-MEM(+) containing 2 μL of LF2000. HeLa cells were incubated with this mixture at 37 °C under 5% CO_2 for 6 h. The cells were then washed twice with PBS, and fresh medium (1 mL) was added prior to analysis of the internalization of the FITC-avidin by CLSM.

For the treatment of the streptavidin-coated quantum dot (QD-SA)/biotin-GALA complex, a solution of QD-SA (80 nM) (Invitrogen) in PBS (5 μL) was mixed with biotin-GALA (10 μM) in PBS (20 μL) and incubated for 20 min at room temperature. LF2000 (2 μL) diluted with PBS (18 μL) was then added to the mixture and incubated for 20 min at room temperature. The total volume of the mixture was then adjusted to 200 μL with 13% BS-containing α-MEM. HeLa cells were treated with this mixture for 24 h and washed twice with PBS. Internalization of the QD-SA was analyzed in a fresh medium using CLSM.

For FAST DiI staining, FAST DiI (1,1′-dihexadecyl-3,3,3′,3′-tetramethylindocarbocyamineperchlorate) (Invitrogen) was added to the described mixture of QD-SA/biotin-GALA/LF2000 in 200 μL of α-MEM(+) (final concentration of FAST DiI, 20 μM) prior to the addition to HeLa cells. Lysotracker staining was conducted after incubation of HeLa cells with the mixture of QD-SA/biotin-GALA/LF2000 followed by two PBS washings. The cells were incubated in α-MEM(+) (200 μL) containing Lysotracker (50 nM) (Invitrogen) for 1 min and washed twice with PBS prior to observation by CLSM.

Flow Cytometry. HeLa cells (5×10^4) were plated into 24-well microplates (Iwaki) and cultured for 48 h. The cells were incubated with the FITC-GALA/LF2000 complex (1 μM, 2 μL) in α-MEM(+) (200 μL), similarly prepared as for CLSM observation, for 4 h. The cells were then washed twice with PBS and treated with 0.01% trypsin for 10 min at 37 °C. The cells were harvested and centrifuged at 700*g* for 5 min. The cell pellets were suspended, washed twice with PBS, and finally resuspended in PBS (400 μL) for fluorescence analysis with a FACS Calibur flow cytometer (BD Biosciences) using 488 nm laser excitation and a 515−545 nm emission filter. Each sample was analyzed for 10 000 events.

Circular Dichroism. The circular dichroism (CD) spectra of the peptides were scanned by a JASCO J-820 spectrometer using a quartz optical cell with a 1 mm path length at 23 °C. All the spectra were obtained in the presence of egg yolk phosphatidylcholine (EPC) liposomes. The EPC liposomes were prepared similarly to that reported by Szoka and co-workers (*3*). Briefly, the dried film lipid of EPC (11 mg) was hydrated in 5 mM sodium acetate buffer (pH 5.0) containing 100 mM KCl [or in 5 mM sodium phosphate buffer (pH 7.5) containing 100 mM KCl] (2.5 mL) with gentle vortex mixing at room temperature. This emulsion was intermittently sonicated to obtain a clear solution in an ice bath for 40 min and diluted to 5.25 and 2.68 mL with the same buffer to yield 2.5 and 4.9 mM EPC liposome solutions for the CD measurements in the absence and the presence of LF2000, respectively. For the former measurement, 25 μM GALA in 50 mM sodium acetate buffer (pH 5.0) [or 50 mM sodium phosphate buffer (pH 7.5)] (200 μL) was added to the above 2.5 mM solution (100 μL) to

yield 17 μM GALA in the EPC liposomes (lipid concentration, 0.83 mM; lipid/peptide molar ratio, 50/1) in 35 mM sodium acetate buffer (pH 5.0) [or in 35 mM sodium phosphate buffer (pH 7.5)] containing 33 mM KCl. For the latter study, LF2000 (50 μL) was added to 25 μM GALA in 50 mM sodium acetate (pH 5.0) [or 50 mM sodium phosphate (pH 7.5)] (200 μL) and incubated for 15 min at room temperature prior to the addition of 4.9 mM EPC liposome (50 μL). The ratio peptide/LF2000 was the same as that in the cellular uptake experiments. To correct the base lines, spectra of the EPC liposomes in the absence and presence of LF2000 at the same concentrations in the respective buffers were subtracted from those with GALA.

Size Distribution and ζ-Potential Analysis. FITC-GALA (10 μM) in PBS (80 μL) was mixed with LF2000 (8 μL) in PBS (80 μL). The mixture was then diluted with PBS (640 μL) and subjected to size distribution and ζ-potential analysis using a Malvern Zetasizer Nano ZS. For the measurement of LF2000, a solution of PBS (800 μL) containing LF2000 (8 μL) was employed.

RESULTS AND DISCUSSION

Enhanced Cytosolic Diffusion of GALA Peptide by Coadministration with Cationic Liposomes. To assess the ability of GALA as a vehicle to target membrane impermeable bioactive molecules into the cytosol, the FITC-labeled GALA peptide (FITC-GALA) was synthesized and administered to cells. The FITC moiety can be regarded as a model of small molecular weight compounds impermeable to biological membranes, and the intracellular fate can be traced by microscopic observation. GALA has seven Glu residues in its sequence and is negatively charged at neutral pH. The administration of GALA to cells in the presence of cationic liposomes may enhance its adhesion on cell surfaces by increasing interactions with cell surface molecules and thus promoting its cellular uptake. We thus examined the internalization and localization of the GALA peptide in the presence of cationic liposomes. Commercially available Lipofectamine 2000 (LF2000), allowing its use in the presence of serum, was employed as a model of cationic liposomes.

To establish the optimum condition of this system, HeLa cells were treated with FITC-GALA (0.5, 1, 5, and 10 μM) and LF2000 [0.5, 1, and 2% (v/v)] in α-minimal essential medium containing 10% (v/v) BS [α-MEM(+)] at 37 °C for 4 h, as detailed in our previous study (*11*) (Figure 2A). As a result, 1 or 5 μM FITC-GALA in the presence of 1% (v/v) LF2000, and 5 μM FITC-GALA in the presence of 2% (v/v) LF2000 yielded more diffuse cytosolic labeling compared with other conditions. It seems likely that there may be optimum ranges in GALA/LF2000 ratios for efficient cellular uptake diffuse labeling of the cytosol. Excess amount of GALA and LF2000 did not necessarily yield higher cytosolic localization as witnessed by FITC signals. Dynamic light scattering and ζ potential analysis suggested that there was an increase in the averaged particle size of LF2000 and a positive-to-negative alternation in total charge by complex formation with the GALA peptide, respectively (Table 1). Therefore, excess amount of GALA peptide may increase the sizes and negative charges of the complexes to reduce the efficiency of cellular uptake of the complexes. A similar tendency was observed in other cell lines, including Chinese hamster ovary (CHO)-K1, mouse fibroblast-derived NIH3T3, and human epidermoid carcinoma-derived A431 cells (Supporting Information Figure S1), and another commercially available cationic liposome, Lipofectin (Supporting Information Figure S2). From the data it appears that a combination of 1−5 μM GALA with 1% (v/v) liposomes yielded effective cytosolic diffusion of GALA. To avoid possible cytotoxicity caused by the use of increasing amounts of cationic liposomes and GALA peptide, we predominantly employed a combination of 1 μM FITC-GALA and 1% (v/v) LF2000 for further studies.

Table 1. Physicochemical Properties of the GALA/LF2000 Complex[a]

	average particle size, nm (PdI)	ζ potential value, mV
1% (v/v) LF2000	518 ± 51 (0.22 ± 0.04)	15.1 ± 2.9
1% (v/v) LF2000 + 1 μM FITC-GALA	745 ± 112 (0.48 ± 0.08)	−18.4 ± 1.5

[a] The particle size, ζ potential, and the polydispersion index (PdI) were determined using a Zetasizer Nano ZS instrument.

A time course study using 1 μM FITC-GALA and 1% (v/v) LF2000 demonstrated that diffuse FITC-GALA in the cytosol was observed within 2 h after the administration of FITC-GALA/LF2000 to the cells (Figure 2B). The signals then became more diffuse and intense in a time dependent fashion. The diffuse signal of FITC-GALA was observed in the cytosol of almost all cells after 6 h. These results suggested that the endosomal acidification stimulated disruption of the endosomal membranes by GALA even in the presence of cationic liposomes and that this led to efficient leakage of FITC-GALA into the cytosol. Additionally, no significant disruption of the plasma membrane or cytotoxicity was observed during these incubations and this was confirmed by propidium iodide costaining (*17*) and MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] assays (*18*), respectively (data not shown).

Covalent cross-linking between the GALA peptide and molecules targeted into the cytosol as well as co-incubation with cationic liposomes was necessary to achieve efficient cytosolic targeting (Figure 3A). No significant cytosolic spread of FITC was observed following FITC-GALA incubations in the absence of LF2000 or with a mixture of fluorescein and GALA (without covalent bonding) in the presence of LF2000 (Figure 3A). FACS analysis showed that the cellular uptake of FITC-GALA in the presence of LF2000 was about 30 times higher than that in the

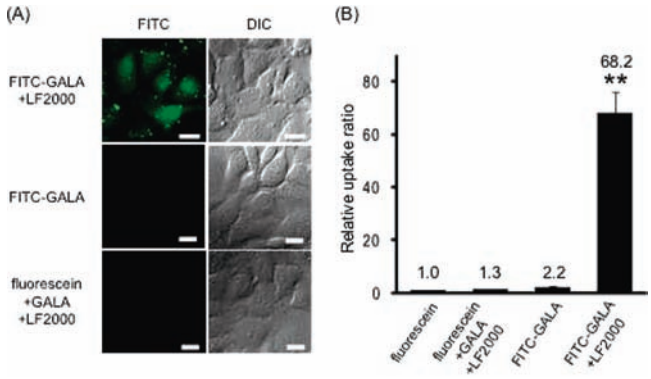

Figure 3. Necessities of conjugation with GALA and coadministration with LF2000 to attain effective cytosolic targeting. (A) HeLa cells were treated with (i) 1 μM FITC-GALA in the presence of 1% (v/v) LF2000 (top), (ii) 1 μM FITC-GALA in the absence of LF2000 (middle), and (iii) a mixture of 1 μM fluorescein and 1 μM GALA (without conjugation) in the presence of 1% (v/v) LF2000 (bottom) in α-MEM(+) for 4 h and analyzed by confocal microscopy. Scale bars, 20 μm. (B) FACS analysis of the FITC (fluorescein) uptake. HeLa cells were treated with (from the left) 1 μM fluorescein, 1 μM fluorescein/1 μM GALA (without conjugation)/1% (v/v) LF2000, 1 μM FITC-GALA, 1 μM FITC-GALA/1% (v/v) LF2000 for 4 h, respectively. The results were normalized by the fluorescein uptake (left). Error bars represent the mean ± standard deviation ($n = 3$). The statistical analysis was done using the Student t test. The symbol ** indicates statistical significance ($p < 0.01$).

absence of LF2000 (Figure 3B) and about 60 times higher than that of fluorescein in the presence or absence of LF2000. Therefore, the electrostatic interaction of the negatively charged GALA with cationic liposomes recruits the GALA-modified molecules onto the cell surface that leads to the efficient endocytic uptake and eventual leakage into the cytosol. The involvement of endocytosis was confirmed by inhibition of the cellular uptake at 4 °C where energy-driven processes including endocytosis are suppressed (Supporting Information Figure S3A). The importance of endosomal acidification in this targeting system was further ascertained by inhibition of the cellular uptake in the presence of nocodazole, a microtubule-disrupting agent that reversibly blocks the transport of endosomes to the lysosomes (*19*), and NH_4Cl, known to prevent endosomal acidification (*20*) (Supporting Information Figure S3B).

Dynamic pH-Dependent Structural Alteration of the GALA Peptide in the Presence of Cationic Liposomes. The results strongly suggest that GALA retains its ability to disrupt endosomal membranes at a reducing pH even when coadministered with cationic liposomes. The induction of the helical structure of the GALA peptide to increase membrane interaction is regarded as the key step that leads to the endosomal disruption by this peptide, and this was analyzed by the circular dichroism (CD) spectra of the GALA peptide in the presence of liposomes (Figure 4B). As reported by Szoka and co-workers (*3*), the GALA peptide (17 μM) took a modest helical structure at pH 7.5 in the presence of liposomes prepared from egg yolk phosphatidylcholine (EPC) (0.83 mM), and the helical content was about 60% [deduced on the basis of $[\theta]_{222}$ (*21*)]. The helical content increased to approximately 90% at pH 5.0 presumably because of the decrease in the electrostatic repulsion between the glutamic acid residues to yield a stronger membrane interaction. However, the GALA showed no typical secondary structure at pH 7.5 in the presence of EPC together with 1% (v/v) LF2000, suggesting a strong interaction between GALA and LF2000 (Figure 4B, right). Interestingly, GALA yielded a CD spectrum of a typical helical peptide at pH 5.0 even in the presence of 1% (v/v) LF2000 (Figure 4B, right), and the spectrum was very similar to that in the absence of LF2000

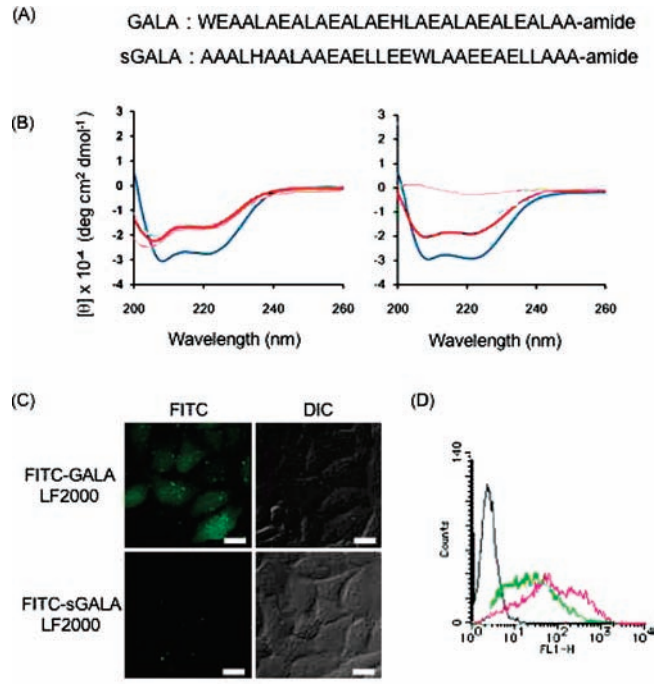

Figure 4. Importance of the GALA structure on cytosolic targeting. (A) Amino acid sequences of GALA peptide and scrambled GALA (sGALA) peptide. (B) The circular dichroism spectra of the peptides (17 μM) in the presence of egg yolk phosphatidylcholine vesicles (0.83 mM) and in the absence (left) and the presence (right) of 1% (v/v) LF2000: GALA at pH 7.5 (light blue) and pH 5.0 (dark blue); sGALA at pH 7.5 (light red) and pH 5.0 (dark red). (C) HeLa cells were incubated with these peptides and LF2000 in α-MEM(+) for 4 h and analyzed by confocal microscopy. Scale bars, 20 μm. (D) FACS analysis of the FITC uptake by the cells after treatment with 1 μM GALA peptides or fluorescein in the presence of 1% (v/v) LF2000 for 4 h: nontreated cells (control) (black); cells treated with FITC-sGALA/LF2000 (green) and FITC-GALA/LF2000 (magenta).

(Figure 4B, left). The decrease in the negative charges of GALA at the reducing pH may diminish its interaction with cationic liposomes, allowing it to form a helical structure that then interacts with the EPC membranes. The possible destabilization of LF2000 at the reducing pH (*22*) may also assist the liberation of GALA from the cationic liposomes.

To further confirm the importance of the induction of the helical structure at the reducing pH for endosomal membrane disruption, we designed an alterative peptide with a scrambled GALA sequence (designated as sGALA) (Figure 4A). Analysis by CD revealed that sGALA has the same degree of helical content as GALA at pH 7.5 in EPC liposomes. However, in marked contrast to GALA, sGALA yields no significant increase in helicity at the reducing pH (Figure 4B, left). In the presence of 1% (v/v) LF2000, no typical secondary structure was predicted for sGALA from its CD spectrum in EPC liposomes at pH 7.5 as in the case for GALA (Figure 4B, right). At pH 5.0, sGALA yielded a helical structure, but the helical content was about two-thirds of that of GALA under the same conditions. Additionally, the helical content of sGALA was similar in the presence (Figure 4B, right) and absence (Figure 4B, left) of LF2000 at pH 5.0. This suggests that this peptide, like GALA, is liberated from the cationic liposomes at pH 5.0.

A significant difference in fluorescence was observed between the cells treated with FITC-GALA and FITC-sGALA (Figure 4C). In contrast to the diffuse signals observed in FITC-GALA treated cells, FITC-sGALA gave predominantly punctate signals without showing any cytosolic diffusion, suggesting that the majority of the peptide was trapped in the endosomes, even when co-incubated with LF2000. The amount of cellular uptake

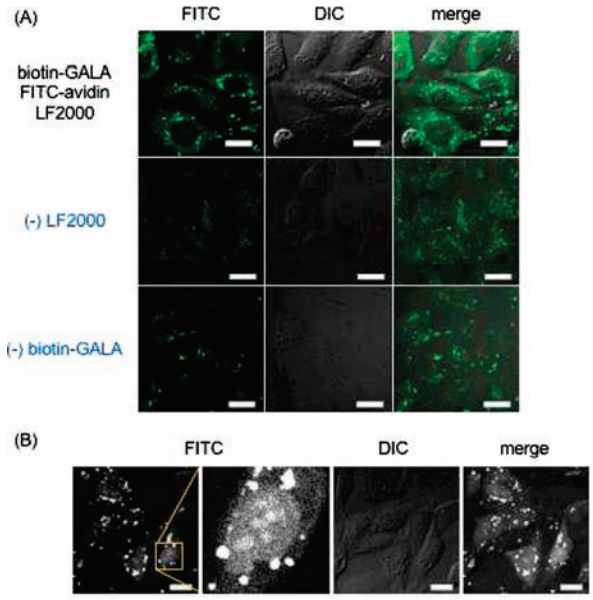

Figure 5. Application of GALA/LF2000 system to cytosolic targeting of avidin. (A) Confocal microscopic observation of HeLa cells treated with a mixture of 1 μM biotin-GALA, 0.25 μM FITC-avidin, and 1% (v/v) LF2000 for 6 h. Absence of LF2000 or biotin-GALA hampered the efficient cytosolic diffusion of FITC-avidin. (B) HeLa cells were incubated with a mixture of biotin-GALA-NLS (1 μM), FITC-avidin (0.25 μM), and 1% (v/v) LF2000 for 6 h. The nuclear translocation of FITC-avidin suggested that the complex structure with biotin-GALA-NLS was retained after its cytosolic release.

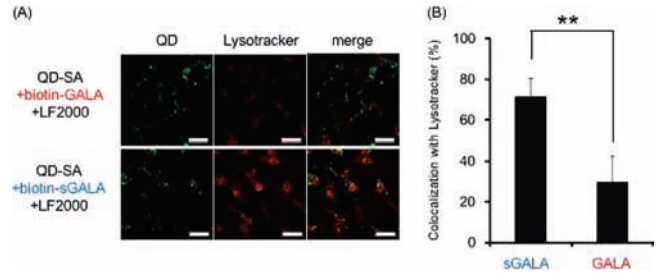

Figure 6. Application of GALA/LF2000 system to cytosolic targeting of QDs. (A) Confocal microscopic observation of HeLa cells treated with a complex of 2 nM streptavidin-conjugated QDs (QD-SA), 1% (v/v) LF2000 and biotin-GALA or biotin-sGALA (1 μM each) for 24 h in the presence of Lysotracker. Scale bars, 10 μm. (B) Statistical analysis of colocalization of the QD-SA signals with those of Lysotracker. HeLa cells were treated with biotin-sGALA/QD-SA/LF2000 (left column) or biotin-GALA/QD-SA/LF2000 (right column) for 24 h and then stained with Lysotracker after two washings with PBS. Total number of dots of QD-SA signal in the cells (775 and 1003 dots for the cells treated with biotin-GALA and biotin-sGALA containing QD-SA/LF2000 mixture, respectively), and the merged dots with the signal from Lysotracker were counted. Error bars represent the mean $\pm$ standard deviation. Statistical analysis was done using the Student *t* test. The symbol ** indicates statistical significance ($p < 0.01$).

of sGALA in the presence of LF2000 was 30% of that of GALA (Figure 4D). Considering the difference in the CD spectrum of sGALA from that of GALA, the conformational change in endosome-trapped sGALA may not be sufficient to induce its effective leakage into the cytosol. The negative charges of the GALA contribute to its endosomal packaging, but the induction of a highly helical structure at the reducing pH should also be an important criteria for efficient cytosolic targeting.

Cytosolic Targeting of Proteins Using the GALA in the Presence of Cationic Liposomes. The results shown indicated that this approach may be utilized for cytosolic targeting of bioactive molecules of relatively small molecular weights (<2000). Applicability of this approach to the cytosolic delivery of whole proteins was then assessed using avidin (68 kDa). Avidin is known to form a 1:4 complex with biotin with an apparent dissociation constant of 10^{-15} M (*23*, *24*). HeLa cells were treated with a mixture of FITC-avidin (0.25 μM), the N-terminal biotinylated GALA (biotin-GALA) (1 μM), and LF2000 [1% (v/v)] in α-MEM(+) for 6 h (Figure 5A). Although the large punctate signals of FITC-avidin were observed in the perinuclear area, significant diffuse signals were observed in the cytosol of most cells, suggesting that an acceleration of cytosolic targeting occurs for much larger molecules. In contrast, only punctate signals of lower intensities were observed in cells treated in the absence of LF2000 or biotin-GALA (Figure 5A). This also indicates the effectiveness of the GALA/LF2000 system to recruit exogenous molecules into endocytic pathways that then lead to endosomal escape.

Nuclear pores serve as gates on nuclear membranes to selectively separate the inside of the nucleus from the cytosol (*25*). Relatively small proteins (<30−40 kDa) can penetrate these pores by passive diffusion, whereas larger proteins cannot permeate unless they utilize the nuclear pore machinery whose function it is to allow access of selective macromolecules. Cellular traffic systems using importins achieve this by recognizing one of a number of different nuclear localization sequence (NLS). Addition of the NLS sequence (PKKKRKV) derived from the simian virus 40 (SV40) (*26*) to the GALA segments (biotin-GALA-NLS) significantly improved the nuclear localization of the FITC-avidin (Figure 5B). This suggests that certain portions of FITC-avidin/biotin-GALA-NLS retained its complex structure even after endosomal escape into the cytosol. Cytosolic and nuclear delivery using this system may therefore allow retention of complex structures comprising multiple components, thus offering a further advantage of this approach.

Applicability of this approach to intracellular delivery of proteins was also assessed using EGFP (27 kDa) as an alternative model. Presumably because of the increase in hydrophobicity and negative charges of EGFP when fused with the GALA segment, we noticed considerable amount of aggregation when it was added to LF2000, leading to a decrease in the cellular uptake of the protein. Although endosome-like, punctate signals of EGFP were observed in most of the cells; only 20−40% of the cells yielded diffuse signals of EGFP after an 8 h treatment with HeLa and CHO-K1 cells (Supporting Information Figure S4). Aggregate formation may be a drawback of this approach, and the physicochemical properties of cargo may affect this. However, since no significant signal was observed when cells were treated with EGFP−GALA in the absence of LF2000, the combination of GALA and cationic liposomes was still effective in promoting cytosolic delivery of the protein.

Application to the Cytosolic Targeting of Quantum Dots. Applicability of the GALA/LF2000 system for cytosolic targeting of nanoparticles was next evaluated using semiconductor quantum dots (QDs). QDs are a novel class of fluorescent probes with unique features that include tunable fluorescence emission, exceptional brightness, and photostability when compared to conventional organic dyes and fluorescent proteins (*27*). The efficient cytosolic delivery of QDs would open new avenues to cellular imaging and even some clinical applications for which the QDs hold the most promise (*28*−*30*). Streptavidin-conjugated QDs (QD-SA) (diameter, 15−20 nm; an average of 10 molecules of streptavidin are doped on one QD particle) were employed here to form complexes with biotin-GALA. HeLa cells were treated with a mixture of biotin-GALA (1 μM), QD-SA (2 nM), and 1% (v/v) LF2000 in α-MEM(+) for 24 h.

Unlike the treatment with FITC-avidin/biotin-GALA in the presence of LF2000 (Figure 5A), this treatment with QD-SA yielded only punctate signals in the cells (Figure 6A). However,

the majority of the signals of QD-SA did not show any colocalization with Lysotracker, a representative marker of late endosomes/lysosomes (*31*). A detailed analysis of the 775 spots of QD-SA signals in the former case showed that only about 30% of the fluorescent spots overlapped with those of Lysotracker. On the other hand, when the cells were treated with a mixtures of QD-SA (2 nM), biotinylated scrambled GALA (biotin-sGALA) (1 μM), and 1% (v/v) LF2000, a high degree of colocalization of the QD-SA signals with Lysotracker was observed (Figure 6). In addition, overlap of the signals of QD-SA with FAST DiI, an early/recycling endosome marker (*31, 32*), was about 20% (Supporting Information Figure S5). On the other hand, in the case when scrambled GALA was employed instead of GALA, as many as 70% of 1003 spots merged with those stained with Lysotracker (Figure 6B) and 20% of QD-SA spots showed colocalization with FAST DiI (Supporting Information Figure S5). The above results strongly suggested that the majority of the QD-SA escaped from the endosomes and reached the cytosol with the aid of GALA. Punctate signals from QD-SA may suggest possible aggregate formation in the cells. However, considering that no significant aggregates were extracellularly observed during these incubations and that QDs have a general tendency to aggregate, further studies are necessary to elucidate the structural characteristics that yield these punctate signals.

CONCLUSIONS

In this report, we have demonstrated the applicability of the GALA peptide as a cytosol-addressing vehicle having pH-sensitive fusogenic activity. In this system, the coadministration of cationic liposomes plays a critical role in enhancing the cell-surface adhesion and cellular uptake of molecules conjugated to GALA. The pH decrease in endosomes most probably alters the structure of GALA in the endosomes, and this liberates it from the cationic liposomes to achieve efficient endosomal escape. Cytosolic delivery of proteins (EGFP and avidin) and nanoparticle (QD) were also demonstrated. In this study we (i) employed direct conjugation of GALA with FITC (a model small molecular weight compound), (ii) expressed protein ligation for the preparation of EGFP−GALA fusion protein, and (iii) employed complex formation between QD-SA/biotin-GALA complex. Other methods to form chemical cross-linking and fusion proteins may also be employable for the tethering of the GALA peptide with the cargo of interest. Of special note is that this system can be employed in the presence of serum. A similar strategy may be applicable using other polycations including polyethyleneimine and polyarginine instead of cationic liposomes. There are, however, limitations to this approach including possible aggregation formation or incomplete cytosolic translocation especially in protein/large particle delivery, and these should be addressed in future studies. Despite these limitations, this system may serve as a prototype for a novel cytosol targeting strategy not only for chemical and biological studies of cell functions but also for diagnostic and therapeutic applications including in vivo bioimaging and the ex vivo treatment of cells for regenerative medicine.

ACKNOWLEDGMENT

This work was supported in part by Grant-in-Aid for Scientific Research on Priority Areas “Life Surveyor” from the Ministry of Education, Culture, Sports, Science and Technology of Japan. S.P. is grateful for a FPU fellowship and a temporary stay grant from the Ministerio de Ciencia e Innovación. The authors are grateful to Dr. Y. Higuchi and Prof. M. Hashida, Kyoto University, for their assistance in obtaining the size distribution and ζ-potential of the GALA/LF2000 complex.

Supporting Information Available: Details of peptide synthesis including HPLC retention times and MALDI-TOF MS results of the peptides synthesized in this study; confocal microscopy images. This material is available free of charge via the Internet at http://pubs.acs.org.

Supporting Information

Peptide Synthesis and Fluorescence Labeling.

All the peptides in this report were chemically synthesized by Fmoc (9-fluorenylmethyloxycarbonyl) solid-phase peptide synthesis on Rink amide resin using the standard protocol of a Shimadzu PSSM-8 peptide synthesizer as previously reported (*15*). For the coupling system, a combination of

benzotriazole-1-yloxytrispyrrolidinophos-phonium hexafluorophosphate (PyBOP), 1-hydroxy-benzotriazole (HOBt), and 4-methylmorpholine (NMM) was employed. Treatment of the peptide resin with trifluoroacetic acid (TFA)-ethanedithiol (EDT) (95:5) for the cleavage of the peptide from the resin and deprotection of the peptides at 25 °C for 3 h and high-performance liquid chromatography (HPLC) purification of the deprotected sample gave a pure peptide. The fidelity of the products was confirmed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS). Amino acid sequences and characterization of the synthesized peptides: GALA peptide, WEAALAEALAEALAEHLAEALAEALEALAA-amide, MALDI-TOFMS: 3032.5 [calcd. for $(M+H)^+$: 3032.4]; scrambled GALA (sGALA) peptide, AAALHAALAAEAELLEEWLAAEEAELLAAA-amide, MALDI-TOFMS: 3032.4 [calcd. for $(M+H)^+$: 3032.4]. CG-GALA, CG-WEAALAEALAEALAEHLAEALAEALEALAA-GG-PKKKRKV-amide, MALDI-TOFMS: 3192.4 [calcd. for $(M+H)^+$: 3192.6].

For the preparation of the fluorescently labeled peptides, a γ-aminobutyryl (GABA) residue was attached to the N-terminus of the peptide resin as a spacer for

connecting with a fluorescence label, and then the N-terminus of the resin was treated with fluorescein-5-isothiocyanate (Sigma) and N-ethyldiisopropylamine (DIEA) (3 eq. each to the peptide resin) in N, N-dimethylformamide (DMF) at 25 °C for 3 h. The fluorescein labeled peptide resin was treated with TFA-EDT (95:5), purified, and identified as stated above. Amino acid sequences and characterization of the synthesized peptides: FITC-GALA peptide, FITC-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-amide, MALDI-TOFMS: 3506.9 [calcd. for $(M+H)^+$: 3507.2]; FITC-scrambled GALA (FITC-sGALA) peptide, FITC-NH-$(CH_2)_3$-CO-AAALHAALAAEAELLEEWLAAEEAELLAAA-amide, MALDI-TOFMS: 3506.8 [calcd. for $(M+H)^+$: 3506.8].

For the preparation of biotinylated-GALA peptide (biotin-GALA) and biotinylated-scrambled GALA peptide (biotin-sGALA), the GABA residue was attached to the N-terminus of the peptide resin as a space followed by the treatment with biotinamidocaproate N-hydroxysuccinimide ester (Sigma) in the presence of DIEA (3 eq. each to the peptide resin) in DMF at 25 °C for 20 h. Biotinylated-GALA peptide

having the nuclear localization signal sequence, derived from SV40 T antigen, on its C-terminus (biotin-GALA-NLS) was similarly synthesized as stated; the Gly-Gly segment was inserted here between GALA sequences and NLS sequences as a spacer. The products were purified and analyzed as stated above. Amino acid sequences and characterization of the synthesized peptides: biotinylated-GALA peptide, biotinamidocaproyl-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-amide, MALDI-TOFMS: 3373.9 [Calcd. for $(M+H)^+$: 3373.9]; biotin-GALA-NLS, biotinamidocaproyl-NH-$(CH_2)_3$-CO-WEAALAEALAEALAEHLAEALAEALEALAA-GG-PKKKRKV-amide, MALDI-TOFMS: 4352.8 [calcd. for $(M+H)^+$: 4353.1]; biotinamidocaproyl-scrambled GALA peptide (biotin-sGALA), biotinamidocaproyl-NH-$(CH_2)_3$-CO-AAALHAALAAEAELLEEWLAAEEAELLAAA-amide, MALDI-TOFMS: 3371.9 [calcd. for $(M+H)^+$: 3373.9].

The conditions and the retention time for the synthesized peptides were following: column, Cosmosil Protein R (4.6 × 150 mm); gradient: 45-85% B in A over 40 min (A = H_2O containing 0.1% (v/v) CF_3COOH, B = CH_3CN containing 0.1% (v/v)

CF_3COOH); flow, 1.0 mL/min; detection, 215 nm. GALA, 17.2 min; sGALA, 5.3 min; GC-GALA, 20.1 min; FITC-GALA, 22.8 min; FITC-sGALA, 13.2 min; biotin-GALA, 21.5 min; biotin-GALA-NLS, 13.6 min, biotin-sGALA, 10.9 min.

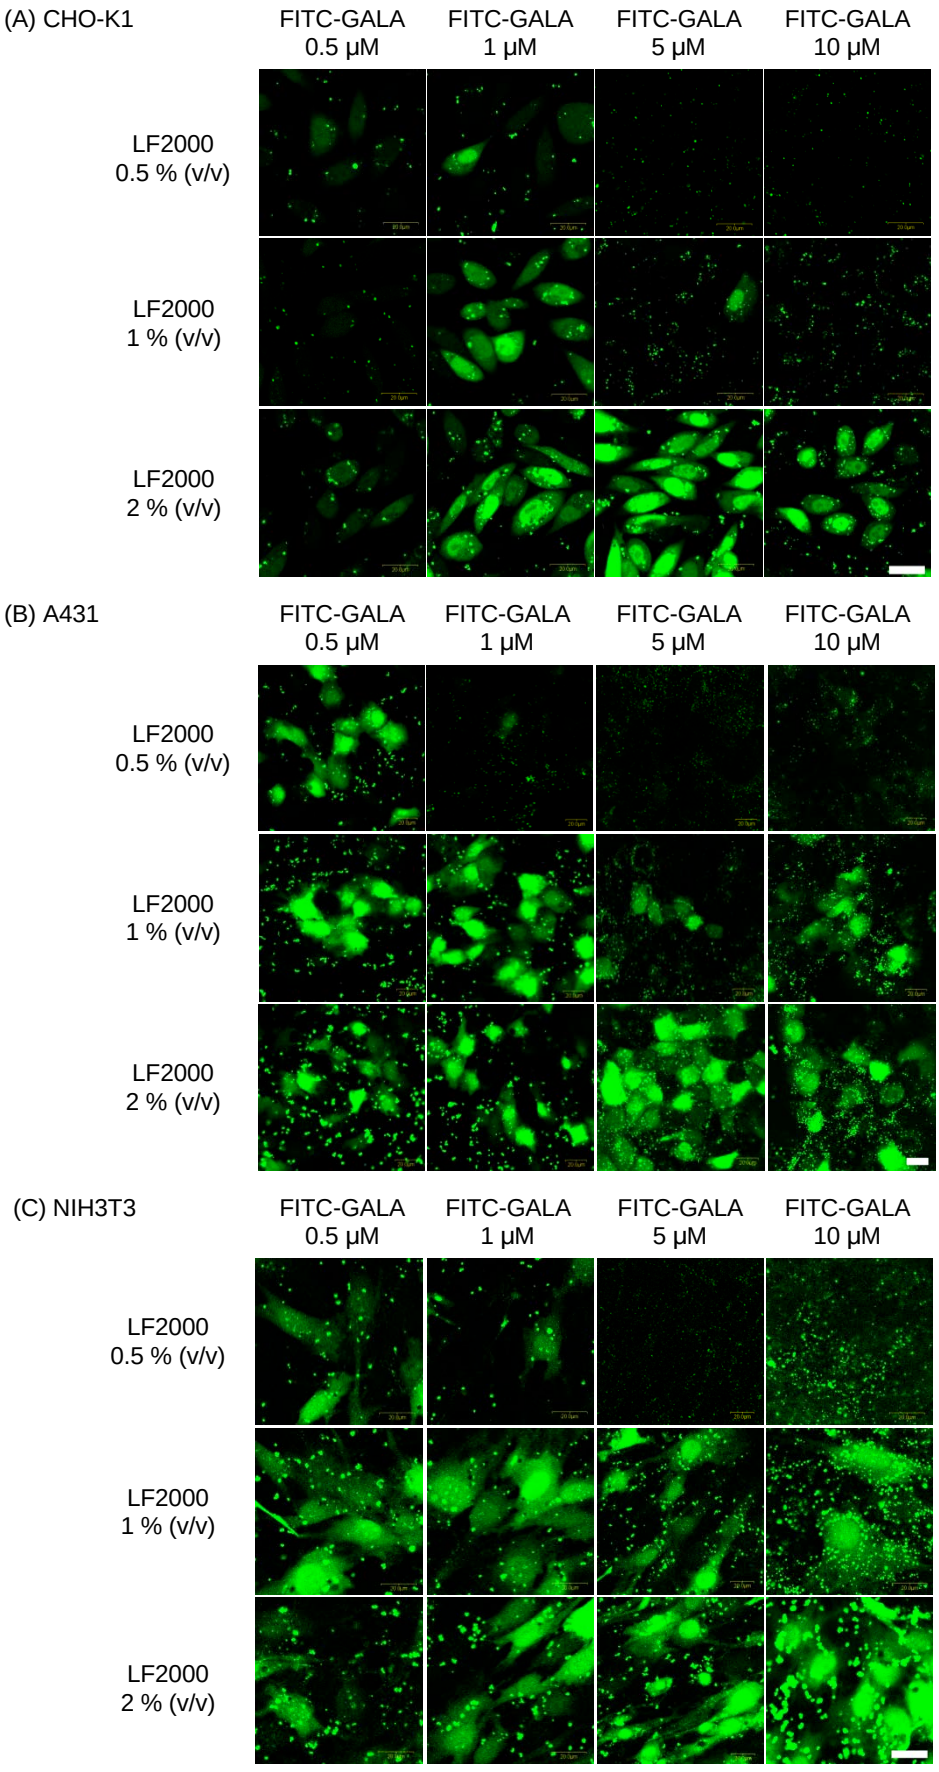

Figure S1. Effect of GALA/LF2000 ratios in cytosolic targeting of FITC as a model of membrane impermeable molecules. Cell, CHO-K1 (A), A431 (B), NIH3T3 (C). Scale bars, 20 μm. Incubation, 4 h.

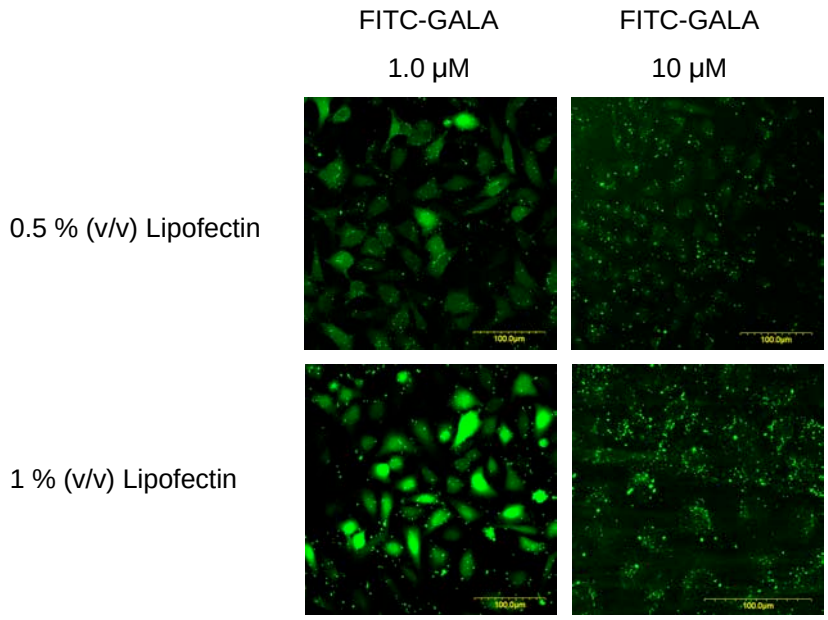

Figure S2. Effect of concentration of GALA and Lipofectin on the cellular distribution of the FITC signals. HeLa cells were treated with FITC-GALA in the presence of Lipofectin in α-MEM without containing serum for 6 h. Scale bars, 100 μm.

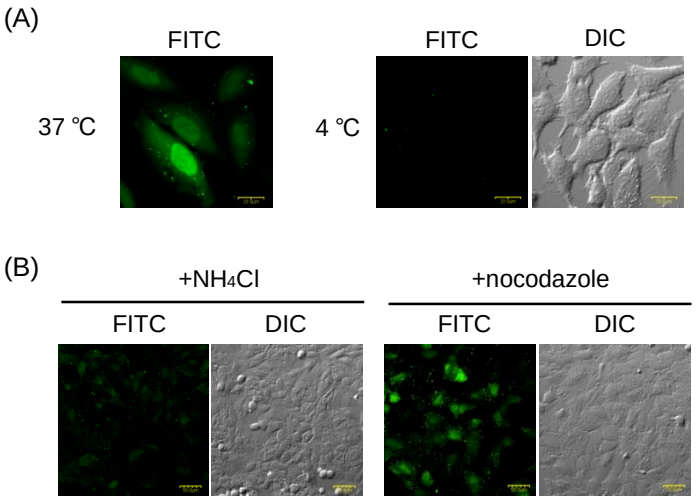

Figure S3. Involvement of endocytosis and importance of endosomal acidification for this cytosol targeting system. (A) HeLa cells were incubated with FITC-GALA (1 μM) in the presence of 1 % (v/v) LF2000 in α-MEM(+) at 37 °C or 4 °C for 2 h, respectively, and analyzed by confocal microscopy after PBS wash. Scale bars, 20 μm. (B) HeLa cells were incubated with 1 μM FITC-GALA/1%(v/v) LF2000 in the presence of NH_4Cl (50 mM) or nocodazole (20 μM) in α-MEM(+) at 37 °C for 2 h. Scale bars, 50 μm.

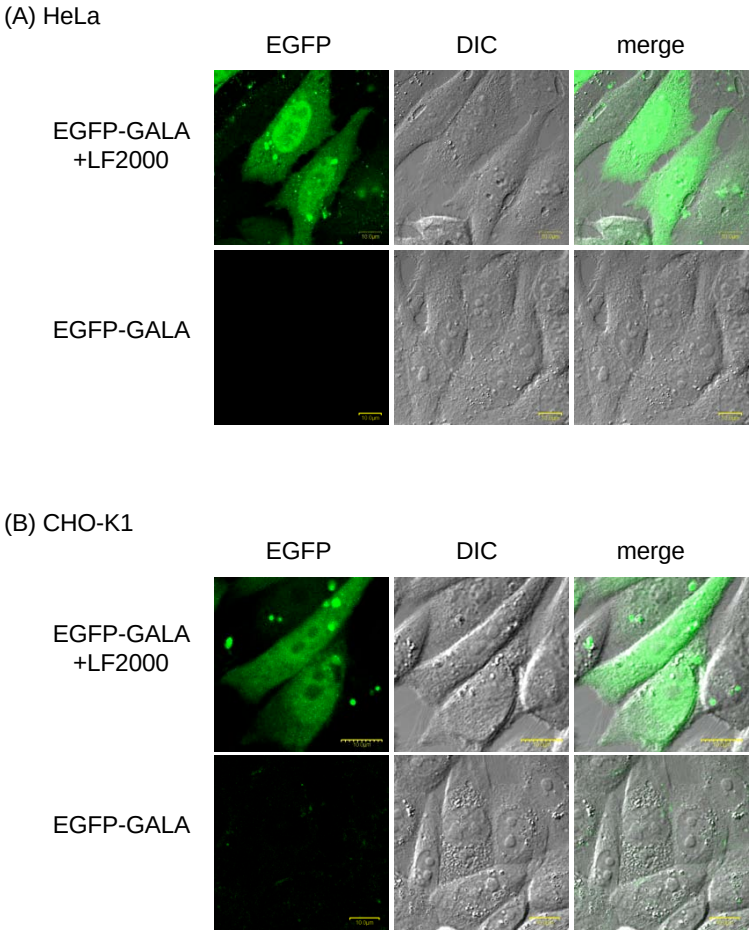

Figure S4. Application of GALA/LF2000 system to cytosolic targeting of EGFP. (A) Confocal microscopic observation of HeLa cells treated with 2 μM EGFP-GALA and 4% (v/v) LF2000 for 8 h. (B) CHO-K1 cells were treated with 0.5 μM EGFP-GALA and 1% (v/v) LF2000 for 8 h. Efficient cytosolic diffusion of EGFP-GALA was not observed in the absence of LF2000.

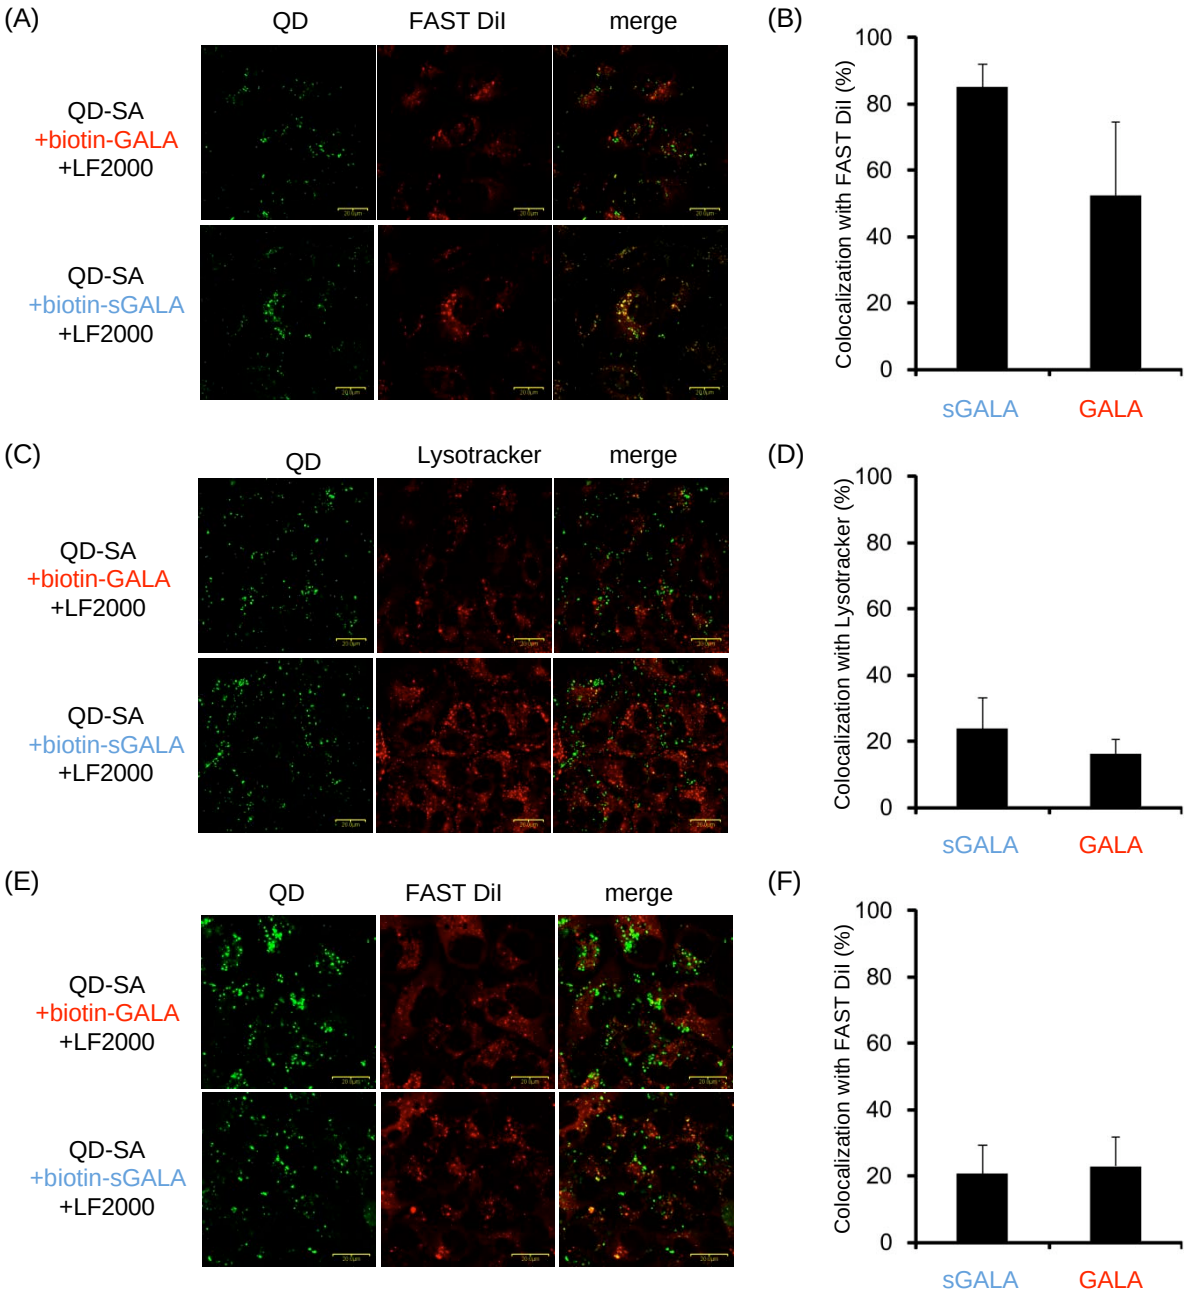

Figure S5. (A, C, E) Confocal microscopic observation of HeLa cells treated with the complex of QD-SA (2 nM), 1% (v/v) LF2000 and biotin-GALA or biotin-sGALA (1 μM each) for 6 h in the presence of FAST DiI (A) and Lysotracker (C), and 24 h in the presence of FAST DiI (E), respectively. FAST DiI was added to the medium 6 h prior to the microscopic observation. (B, D, F) Statistical analysis of colocalization of the QD-SA signal with that of FAST DiI or Lysotracker. HeLa cells were similarly treated with QD-SA/biotin-sGALA/LF2000 (left column) or QD-SA/biotin-GALA/LF2000 (right column) for 6 h (B, D) or 24 h (F). The total number of dots showing the QD-SA signal in the cells and the merged ones with the signals of Lysotraker or FAST DiI were manually counted (931, 1405, and 1210 counts for QD-SA/biotin-sGALA/LF2000-treated cells, and 1180, 632, and 883 counts for QD-SA/biotin-GALA/LF2000-treated cells, respectively). Scale bars, 20 μm. At 6 h, over 50% of QD-SA signals overlapped with those of FAST DiI, suggesting that a considerable portion of QD-SA were trapped in early endosomes (B), whereas only 20% of QD-SA localized in lysosomes (D). At 24 h, those overlapping with FAST DiI became 20%, suggesting the escape of QD-SA to cytosol or the shift to lysosomes.

Peptide-Functionalized Nanogels for Targeted siRNA Delivery

William H. Blackburn,[⊥,†,‡] Erin B. Dickerson,[⊥,‡,§,||] Michael H. Smith,[⊥,†,‡] John F. McDonald,[‡,§,||] and L. Andrew Lyon*[,†,‡]

School of Chemistry and Biochemistry, Petit Institute for Bioengineering and Bioscience, School of Biology, and Ovarian Cancer Institute, Georgia Institute of Technology, Atlanta, Georgia 30332. Received December 16, 2008; Revised Manuscript Received February 25, 2009

A major bottleneck in the development of siRNA therapies is their delivery to the desired cell type or tissue, followed by effective passage across the cell membrane with subsequent silencing of the targeted mRNA. To address this problem, we describe the synthesis of core/shell hydrogel nanoparticles (nanogels) with surface-localized peptides that specifically target ovarian carcinoma cell lines possessing high expression levels of the Eph2A receptor. These nanogels are also demonstrated to be highly effective in the noncovalent encapsulation of siRNA and enable cell-specific delivery of the oligonucleotides in serum-containing medium. Cell toxicity and viability assays reveal that the nanogel construct is nontoxic under the conditions studied, as no toxicity or decrease in cell proliferation is observed following delivery. Importantly, a preliminary investigation of gene silencing illustrates that nanogel-mediated delivery of siRNA targeted to the EGF receptor results in knockdown of that receptor. Excellent protection of siRNA during endosomal uptake and endosomal escape of the nanogels is suggested by these results since siRNA activity in the cytosol is required for gene silencing.

INTRODUCTION

Significant effort has been invested in the design of colloidal drug carriers in order to improve drug localization and bioavailability (*1*−*3*). Ideally, an actively targeted particulate drug carrier will increase the therapeutic efficacy of a drug by delivery to the diseased site, while reducing drug-associated side effects. Attainment of this goal would greatly advance treatment of diseases (e.g., cancer) where the toxic effects of therapeutics administered systemically may outweigh their benefit. To date, many types of delivery vehicles have been explored for in vitro and in vivo drug delivery applications, including inorganic nanoparticles (*4, 5*), polyelectrolyte complexes (*6*), liposomes (*7, 8*), block copolymer micelles (*9*−*11*), and polymeric nanoparticles (*12*−*15*).

A particularly compelling phenomenon from the standpoint of cancer therapy is RNA interference (RNAi). RNAi is a relatively new approach to gene silencing, which has been demonstrated effective both in vitro and in vivo (*16, 17*). This technique employs small 21−25 nucleotide long double stranded small interfering RNAs (or siRNAs) to inhibit gene expression through degradation of a targeted mRNA (*18*). Whereas the potential for therapeutic oncology applications exist where siRNA would be used to specifically shut down genes necessary for tumor growth, the lack of efficient methods for in vivo siRNA delivery prevent widespread therapeutic use (*16, 17*). In addition to the confounding issues associated with systemic, intraveneous delivery of siRNA, its polyanionic nature and high molecular weight (∼13 kDa) prevent transport across the cell membrane (*16, 17*). Thus, effective siRNA carriers must enable efficient transport through the vasculature to the tumor and then must additionally enable intracellular delivery of the cargo. A common method currently used for siRNA delivery in vitro employs cationic lipid-based carriers (*16, 17, 19*) or polyelectrolytes (*6*). These charged moieties form polyplexes with the siRNA, forming aggregates that can be taken up into the cells, thereby delivering the siRNA to the cytosol. However, these carriers can have notable drawbacks with respect to toxicity and difficulties in specific cell targeting (*16, 17, 20*), thereby giving rise to a need for alternative delivery methods. A number of new approaches have been reported that overcome some of the shortcomings of lipid-based approaches. For example, Schiffelers et al. used an RGD (Arg-Gly-Asp peptide ligand)−PEG−PEI complex to target siRNA to tumor neovasculature (*21*). Song et al. presented the use of a protamine−antibody fusion protein using the Fab fragment of HIV-1 envelope antibody for siRNA delivery (*22*). Another targeting motif has been the use of liposomes in the form of an immunoliposome complex reported by Pirollo et al. (*23*). A number of other similar approaches have been taken (*6, 20, 24*−*29*), and these siRNA carriers have enabled certain degrees of success. However, issues of toxicity, leakiness, and payload capacity still persist, especially in the context of in vivo gene silencing (*16, 17*).

Building upon many of the lessons learned from these approaches, we and others have developed drug delivery methods that employ the synthetic hydrogel nanoparticle (nanogel) (*13, 15, 30, 31*). Nanogels possess a high degree of porosity, permitting a high payload capacity, and can also be selectively surface-functionalized to enable tumor-specific targeting. Thus, we have developed straightforward, scalable syntheses of surface-functionalized, ∼100-nm diameter, core/shell nanogels composed of poly(*N*-isopropylmethacrylamide) (pNIPMAm) (*32, 33*), an amphiphilic polymer that is strongly hydrated at physiological temperature and is likely therefore to resist protein adsorption relative to more hydrophobic carriers. This polymer has also garnered interest because of its dramatic thermoresponsivity; it undergoes an entropically driven coil-to-globule (swollen-to-collapsed) transition at ∼43 °C, which may have utility for thermally triggered delivery (*32, 33*). However, in the present demonstration, this thermoresponsivity is only used to enable the synthesis of monodispersed core/

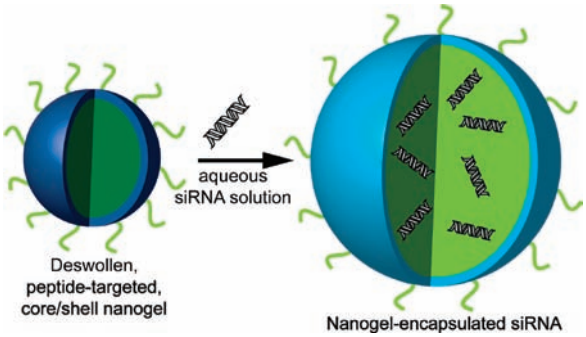
Scheme 1. Noncovalent Encapsulation of siRNA in Peptide-Targeted Core/Shell Nanogels



shell nanogels via precipitation polymerization, as we have discussed previously (*32*, *34*). The core/shell pNIPMAm nanogel construct used to encapsulate and deliver siRNA to ovarian cancer cells is illustrated in Scheme 1. A previously described 12 amino acid peptide (YSAYPDSVPMMS or YSA) (*35*) was coupled to the surface of ~100-nm diameter core/shell nanogels to permit cell-specific targeting and subsequent delivery of high concentrations of siRNA to the target cells. The YSA peptide mimics the ligand ephrin-A1, which binds to the erythropoietin-producing hepatocellular (Eph) A2 receptor. In addition to specific expression in neovasculature (*36*, *37*), EphA2 is highly expressed by a number of tumor cells including those derived from ovarian (*38*, *39*), prostate (*40*, *41*), breast (*42*, *43*), and colon (*44*, *45*) cancers, making it an excellent target for tumor-specific delivery. Thus, we demonstrate herein that pNIPMAm nanogels have a high loading capacity for siRNA, and that these nanogels are delivered to the cytoplasm of ovarian cancer cells via ligand−receptor binding mediated endocytosis. Importantly, overt cytotoxicity was not observed to arise from the nanocarrier, suggesting that this approach could be a highly efficacious one. In addition, delivery of siRNA to cells in culture can be performed in the presence of serum, suggesting that nanogels may be of particular advantage for in vivo delivery.

MATERIALS AND METHODS

All materials were purchased from Sigma-Aldrich (St Louis, MO) and used as received unless otherwise noted.

Nanogel Core Synthesis. Nanogel core particles were synthesized by free-radical precipitation polymerization, as previously reported (*32*). The use of thermally phase separating polymers enables the use of precipitation polymerization for the synthesis of highly monodispersed nanogels (*32*). The molar composition was 98% *N*-isopropylmethacrylamide (NIPMAm), 2% *N*,*N*′-methylenebis(acrylamide) (BIS), with a total monomer concentration of 140 mM. The solution also contained a small amount (~0.1 mM) of acrylamidofluorescein (AFA) to render the nanogels fluorescent for visualization via confocal microscopy (*30*, *32*). In a typical synthesis, 100 mL of a filtered, aqueous solution of NIPMAm, BIS, and sodium dodecyl sulfate (SDS, 8 mM total concentration) was added to the reaction flask, which was then heated to 70 °C. The solution was purged with N_2 gas and stirred vigorously until the temperature remained stable. The AFA was added, and after 10 min the reaction was initiated by the addition of a 1 mL solution of 800 mM ammonium persulfate (APS) to make the final concentration of APS in the reaction ~8 mM. The solution turned turbid, indicating successful initiation. The reaction was allowed to continue for 4 h under an N_2 blanket. After synthesis, the solution was filtered through Whatman filter paper to remove a small amount of coagulum.

Nanogel Shell Synthesis. The core nanogels described above were used as seeds for the addition of a hydrogel shell in a seeded precipitation polymerization scheme. The detailed procedure of the shell synthesis has been reported previously (*32*). Briefly, 10 mL of the core nanogel solution and 0.0577 g of SDS were first added to a three-neck round-bottom flask and heated under N_2 gas to 70 °C. A 50 mM monomer solution with molar ratios of 97.5% NIPMAm, 2% BIS, and 0.5% aminopropyl methacrylate (APMA, Polysciences, Warrington, PA) was prepared in 39.5 mL of dH_2O. The solution was added to the three-neck round-bottom flask, and the temperature was stabilized at 70 °C while continuously stirring. The reaction was initiated by a 0.5 mL aliquot of 0.05 M APS. The reaction proceeded for 4 h under N_2 gas. Following the synthesis, the solution was filtered through Whatman filter paper, and the nanogels were purified by centrifugation followed by resuspension in dH_2O.

Nanogel Characterization. Multiangle laser light scattering (MALLS) (Wyatt Technology Corporation, Santa Barbara, CA) detection following asymmetric field flow fractionation (AFFF) was used to determine the distribution of *z*-average radii (R_z) for all nanogels. For all separations, a cross-flow of 0.30 mL/min was used with a channel flow of 1.0 mL/min. The MALLS detector is equipped with a Peltier device to maintain a flow cell temperature of 25 °C and collects scattered light from 16 different fixed angles to determine the R_z of the nanogels. By measuring R_z as a function of elution time, we constructed a chromatogram that permits the determination of the weight fraction of nanogels as a function of radius, thereby providing a sample polydispersity. ASTRA 5.1.5.0 software was used to determine R_z values using the Debye fit method. The core/shell nanogels synthesized using the methods described above were determined to have R_z values of ~54 nm with size polydispersities of <10%, as described previously (*32*); representative AFFF/MALLS data are shown in Supporting Information.

Characterization of the refractive increment (d*n*/d*c*) of nanogels was performed to determine particle molecular weight by static light scattering. Differential refractive index analysis (dRI, OptiLab rEX, Wyatt Technologies, Inc.) was performed in batch mode. To ensure accurate data, the refractive index was calibrated prior to each measurement using sodium chloride concentrations ranging from 0.1 mg/mL to 15.0 mg/mL. All nanogel dilutions were prepared in dust-free vials, which were rinsed sequentially with deionized water, absolute ethanol, and HPLC-grade acetone. Nanogels were resuspended in distilled, deionized water over a concentration range from 2.5×10^{-6} g/mL to 3.75×10^{-4} g/mL. The use of MALLS in conjunction with the rEX differential refractometer permitted the measurement of the *z*-average molecular mass (M_z) from the determined d*n*/d*c* values and the angle-dependent light scattering data.

YSA Synthesis. The YSA peptide (YSAYPDSVPMMSC) was synthesized using standard Fmoc chemistry as described previously (*46*). Peptide synthesis was carried out by K. D. Clark, University of Georgia. Following synthesis, the peptide was cleaved from the resin and deprotected for 4 h in reagent K after air-drying. The peptide was purified using a series of 5 mL injections onto a preparatory HPLC column (10-m; particle size, 21.2 mm 25 cm, Jupiter C18; Phenomenex Inc., Torrance, CA) using HPLC-grade H_2O and a linear gradient of acetonitrile (0−70 min, 10−80%) at 5 mL per min. Both the acetonitrile and H_2O contained 0.05% trifluoroacetic acid. The desired peak was identified by matrix-assisted laser desorption ionization time-of-flight mass spectrometry, and the peaks from multiple runs were pooled, lyophilized, and stored at 4 °C in solid form. A scrambled form (SCR) of the YSA peptide (DYPSMAMYSPSVC) was also synthesized via this method for use as a control. On other occasions, the YSA and SCR peptides were purchased from GenScript Corp (Piscataway, NJ).

Peptide Conjugation. In this study we produced a maleimide-functionalized nanogel through the EDC coupling of ε-maleimidocaproic acid (EMCA) to the primary amines in the shell of the nanoparticle. As described in the nanogel shell synthesis, primary amines were introduced through the copolymerization of APMA (0.5% molar ratio). Given that APMA is efficiently incorporated at these low molar ratios, we can estimate the amine equivalents available for bioconjugation ($\sim 2.2 \times 10^{-6}$ amines per 88.3 mg of lyophilized particles). From this estimate, peptide coupling was performed by introducing YSA peptide in a 1:1 molar ratio with amine (YSA molecular weight = 1450.66 g/mol). The YSA peptide was then conjugated to the nanogels via maleimide coupling to the cysteine residue on the C-terminal end of the peptides.

First, 88.3 mg of nanogels ($\sim 2.2 \times 10^{-6}$ amine equivalents) was resuspended in 35.0 mL of pH 6.0 MES buffer and allowed to shake for 2 h. A second solution was prepared where 4.4×10^{-6} mol (0.68 mg) of 1-ethyl-3-methyl-(3-dimethylaminopropyl)carbodiimide (EDC, Pierce, Rockford, IL), 4.4×10^{-6} mol (0.96 mg) *N*-hydroxysulfosuccinimide (NHSS), and 2.2×10^{-6} mol (0.46 mg) of EMCA were dissolved in 3.0 mL of pH 6.0 MES buffer. This solution was reacted for 30 min at room temperature to activate the EMCA acid groups, which permits amide coupling to take place between the EMCA acid groups and the amines on the nanogel surface. This activated EMCA solution was then added to the nanogel solution and reacted for 2 h on a shaker table. The nanogels were centrifuged three times to remove any unreacted material, with resuspension in pH 6.0 MES buffer following each centrifugation. Finally, 3.2 mg of the appropriate peptide was added to the activated nanogels and reacted overnight. Peptide-functionalized nanogels were purified by centrifugation and resuspended in distilled, deionized water.

The number of bioconjugated YSA targeting peptides per particle was estimated by considering the number of primary amines available for conjugation and the number density of nanogels used during bioconjugation (as measured by static light scattering). Through differential refractometry, the nanogel refractive increment was determined to be 0.176 ± 0.002 mL/g. Measurement of *z*-average molecular weight through multi-angle static light scattering provided the *z*-average mass of nonconjugated particles, $M_z = 2.19 \times 10^7$ g/mol (1° Debye fitting, 0.1% fit error). Thus, a total mass of 88.3 mg of lyophilized particles used during conjugation is equivalent to 2.43×10^{15} particles. Assuming a 50% peptide conjugation efficiency (*47*) and 2.2×10^{-6} amine equivalents available for bioconjugation, we conservatively estimate a peptide density of ~225 YSA peptides/particle.

In Vitro siRNA Encapsulation and Release. Our group employs a "breathing-in" method for the encapsulation of various macromolecules within nanogels. In a typical method, lyophilized nanogels are resuspended in an aqueous solution containing the macromolecule to be loaded. Importantly, this is done using a loading solution volume that is almost completely imbibed by the swelling nanogels. In this fashion, the hydrogel network imbibes the payload with high efficiency and without relying on simple equilibrium partitioning to determine the maximum loading level. To determine the rate of siRNA release from nanogels loaded in this fashion, a mixture of oligonucleotide was prepared containing 0.250 mL of 20 μM siGLO red transfection indicator and 1.00 mL of 20 μM siGENOME Lamin A/C control siRNA (Dharmacon, Lafayette, CO). Particles were resuspended in this mixture at a concentration of 4 mg per 250 μL siRNA solution. This concentration of particles is near the solubility limit for the nanogels in PBS, ensuring a high degree of solvent and solute uptake into the hydrogel network. The particles were allowed to resuspend for 12 h at room temperature while shaking.

The encapsulation efficiency was determined via ultracentrifugation of the nanogel loading solution and measurement of supernatant siRNA concentration by UV−vis spectroscopy (Shimadzu UV-1601). The moles of siRNA in the loading solution ($m_{\text{siRNA,loading}}$) and in the supernatant ($m_{\text{siRNA,supernatant}}$) were determined via interpolation from a separately constructed standard curve of absorbance vs concentration ($R^2 > 0.99$). The encapsulation efficiency (EE) of the system could then be calculated through analysis of the amount of siRNA in the loading solution and the remaining moles of siRNA in the supernatant after nanogel swelling was complete, as illustrated by eq 1 and in similar encapsulation experiments (*48*).

$$\text{EE} = \frac{m_{\text{siRNA,loading}} - m_{\text{siRNA,supernatant}}}{m_{\text{siRNA,loading}}} \times 100 \qquad (1)$$

The release of solutes from nanogels was performed in 10% serum to simulate physiological conditions. Release experiments were performed by dispersing 200 μL of loaded nanogels in 2.20 mL of 0.01 M phosphate-buffered saline containing 10% fetal bovine serum (equilibrated at 37 °C) in 3.2 mL of polycarbonate centrifuge tubes (Beckman Coulter, Fullerton, CA). The nanogel suspension was allowed to incubate at 37 °C while being shaken. At specific time points, the tubes were centrifuged for 90 min at 687 000*g* (at 37 °C), and an aliquot of supernatant (0.75 mL) was removed for UV−vis analysis. This volume was replaced with fresh buffer. Upon centrifugation, the gel pellet had a homogenously distributed bright pink color, indicating significant retention of siRNA throughout the experiment. The cumulative siRNA released was calculated by calculating the total moles detected in the supernatant as a function of time, as described in eq 2.

$$\text{cumulative siRNA released} = \frac{m_{\text{TOTALsiRNA,supernatant}}}{m_{\text{siRNA,loading}}} \times 100 \qquad (2)$$

All release studies were performed in triplicate for statistical analysis, using identical nanogel loading and release conditions.

Zeta-Potential Determination. Excluding the 0.5 mol% APMA copolymerized into the shell of our nanogel particles, the nanogels are composed of largely nonionic monomers. To confirm their suspected electroneutrality, which should be critical for reducing nonspecific cell and protein interactions, we measured the zeta-potential of both YSA-conjugated and nonconjugated core/shell nanogels (Zeta-Sizer Nano, Malvern, U.K.). All nanoparticles used in this investigation demonstrated zeta-potential values $< +0.300$ mV, suggesting that they are only weakly charged and should therefore not interact strongly with serum proteins or cell surfaces via Coulombic forces.

Cell Culture. Hey cells were provided by Gordon B. Mills, Department of Systems Biology, the University of Texas, M. D. Anderson Cancer Center. Hey cells were cultured in RPMI 1640 (Mediatech, Manassas, VA) supplemented with 10% v/v heat-inactivated fetal calf serum (Invitrogen), 2 mM L-glutamine (Mediatech), 10 mM HEPES buffer (Mediatech), penicillin (100 U/mL), and streptomycin (100 μg/mL). The BG-1 cell line was provided by Julie M. Hall and Kenneth S. Korach, Receptor Biology Section, Laboratory of Reproductive and Developmental Toxicology, National Institute of Environmental Health Sciences, NIH, Division of Intramural Research, Environmental Disease and Medicine Program, Research Triangle Park, NC. BG-1 cells were propagated in DMEM:F12/50:50 (Mediatech) supplemented with 10% v/v heat-inactivated fetal calf serum, penicillin, and streptomycin.

siRNA Encapsulation for Cell Studies. Using the "breathing-in" method for encapsulation (as described above), dried

nanogels were reswollen in the presence of the siRNA, thereby imbibing the solute within the hydrogel network. In a typical procedure for in vitro cell delivery, a 20 μM solution (250 μL) of a fluorescent siRNA transfection indicator, siGLO (Dharmacon), or EGFR siRNA (Dharmacon, Lafayette, CO) was prepared in phosphate-buffered saline (PBS). Lyophilized nanogels were dissolved in the siRNA solution at a concentration of 4 mg in 250 μL and allowed to shake overnight at room temperature. Importantly, this nanogel concentration results in nearly all of the solvent being taken up by the nanogels. This volume-filling approach ensures a maximal uptake of siRNA within the nanogels. After being shaken, the nanogels were centrifuged to remove any free siRNA and resuspended in PBS. A standard curve for increasing concentrations of siRNA was made by measuring the absorbance at 260 nm using a Shimadzu UV 1601 spectrophotometer. After siRNA was encapsulated in the nanogels, they were centrifuged, and the absorbance of the supernatant was measured to determine the amount of incorporated siRNA.

Cell Transfection Using Nanogels. Hey or BG-1 cells were plated onto an eight-well chamber slide (5×10^3 cells/well) and the cells allowed to adhere overnight at 37 °C in a 5% CO_2 atmosphere. After the wells were washed with PBS and the media were replaced, siGLO-loaded/YSA-conjugated nanogels, unloaded YSA-conjugated nanogels, pNIPMAm nanogels, or siGLO only were added to wells. Cells were incubated in each case for 4 h. In experiments where preincubation of ephrin-A1 was used to initiate internalization and degradation of EphA2, ephrin-A1 was added to the media at a final concentration of the ligand of 2 μg/mL. After incubation, the cells were washed with PBS, and the medium replaced. For fixation prior to confocal imaging, the cells were incubated with 2% (v/v) paraformaldehyde for 30 min.

Immunoblotting. Hey cells were plated into six-well plates (5×10^5/well) and allowed to adhere overnight at 37 °C, 5% CO_2. The cells were lysed with 100 μL of lysis buffer (50 mM Tris-HCl, pH 7.5, 150 mM NaCl, 2 mM EDTA (Fisher), 2 mM EGTA (Fisher), 1 mM sodium orthovanadate, 2.5 mM sodium pyrophosphate, 1 mM β-gycerol phosphate, 1 mM phenylmethanesulfonyl fluoride, 10 μg/mL aprotinin, 10 μg/mL leupeptin, 1% Triton X-100, and 5% glycerol), and the cell lysates were sonicated four times for 5 s each. The lysates were cleared by centrifugation at 11 000*g* rcf for 15 min at 4 °C. Cell lysates were prepared for analysis by the addition of an equal volume of Laemmli 2X sample buffer. The samples were heated to 95 °C for 5 min to denature the proteins. The proteins were separated on a 10% SDS-PAGE gel and transferred onto nitrocellulose. The blots were blocked with either 5% nonfat dry milk (NFDM) or 5% bovine serum albumin (BSA) in 10 mM Tris-buffered saline, pH 7.5, plus 1% Tween 20 (TBST, BioRad), for 1 h at room temperature. The blots were probed with anti-EGFR antibody (Cell Signaling, Danvers, MA; cat. no. 4405) or with a β-actin antibody (Millipore, Billerica, MA; Mab1501) diluted in 5% NFDM or 5% BSA overnight, with shaking at 4 °C. For EphA2 detection, the blots were probed with an anti-EphA2 polyclonal antibody (Santa Cruz Biotechnology, Santa Cruz, CA; sc-294). The blots were washed three times with TBST and probed with goat antirabbit IgG (Santa Cruz, sc-2004) or with goat antimouse IgG (Santa Cruz, sc-2005) linked to horseradish peroxidase (HRP). Bands were visualized on film (Pierce) using the ECL reagent, SuperSignal West Pico (Pierce).

Confocal Microscopy. A Zeiss LSM510 confocal microscope was used to take cell images. Cells were incubated with nanogels for 4 h. After 4 h, the cells were washed and then fixed on the slide. An Ar^+ laser was used to excite the AFA-labeled nanogels, whereas a HeNe laser was used to excite the fluorescently labeled siGLO. LSM510 software was used to view the images.

Flow Cytometry. Hey cells were plated at 2.5×10^5 cells/well in a 12-well, cell culture plate. Cells were allowed to adhere overnight in an incubator at 37 °C in a 5% CO_2 atmosphere. Cells were washed, and fresh medium was added containing YSA-pNIPMAm or SCR-pNIPMAm nanogels at a concentration of 0.8 mg/mL and incubated for 4 h. Following incubation, the cells were washed with PBS and removed from the plate by trypsin−EDTA treatment. The cells were washed with PBS and fixed with 2% (v/v) paraformaldehyde. Cells were analyzed using a LSR Flow Cytometer (BD Biosciences). Data analysis was carried out using FlowJo software.

Toxicity Studies. *Trypan Blue Exclusion Assay.* Hey cells were plated onto an eight-well chamber slide (1×10^4 cells/well) and allowed to adhere overnight at 37 °C and 5% CO_2. The medium was removed, the wells were washed with PBS, and the medium was replaced. PNIPMAm nanogels, YSA-conjugated nanogels, and SCR-conjugated nanogels were added to cells and incubated for 72 h. Untreated cells were used as controls. After 72 h, the cells washed with PBS, and a 1:1 solution of trypan blue was added to each well. After 1 min, the trypan blue was removed, the cells were washed with PBS, fixed with 2% (v/v) paraformaldehyde, and air-dried. Each well was then viewed via bright field microscopy to determine the number of stained (dead) versus unstained cells. Five fields were viewed for each treatment. Representative images are shown in Supporting Information.

Tox 8 Assay. Hey cells were plated onto 96-well plates (1×10^4 cells/well) and allowed to adhere overnight at 37 °C and 5% CO_2. The media was removed, and the cells were washed with PBS followed by replacement of the medium. Cells incubated with EGFR siRNA-loaded YSA-labeled nanogels, unloaded YSA-labeled pNIPMAm nanogels, unlabeled pNIPMAm, or YSA peptide alone were tested using this assay. The cells were incubated under all conditions for 4 h. The cells were then washed with PBS, the medium was replaced, and the cells were incubated for an additional 72 h in medium. The Tox 8 reagent (Sigma) was added to the cells according to the manufacturer's instructions. The fluorescence at 590 nm was read after 1 h and the extent of cellular viability/proliferation determined.

RESULTS AND DISCUSSION

The nanogels described in this contribution were developed around two main design criteria, as depicted in Scheme 1. For this application, both peptide-based targeting of ovarian cancer and efficient encapsulation and delivery of RNA inhibitors (RNAi's) are required. The core/shell nanogels synthesized using the methods described above were determined to have R_z values of ~54 nm with size polydispersities of <10%, as described previously (*32*). Representative AFFF/MALLS chromatograms for both the core and core/shell nanogels are shown in Supporting Information. To determine the time scale for retention of siRNA within the pNIPMAm nanogels, we investigated siRNA leakage using simulated physiological conditions. As described above, nanogels were loaded using a model mixture of siRNA, containing both the siGLO red transfection indicator and the siGENOME Lamin control. The nanogel was observed to encapsulate the siRNA with high efficiency (93 ± 1%), which is equivalent to a loading level of 1.6 wt% or 16 μg siRNA/mg of nanogels. As shown in Figure 1, only ~33% of the siRNA is observed to leak from the nanogels within the first 12 h (67% retained). Indeed, this approximate level of retention persists out to 35 h, suggesting very efficient entrapment of the siRNA within the nanogel network. Retention of this magnitude is promising for intravenous oligonucleotide

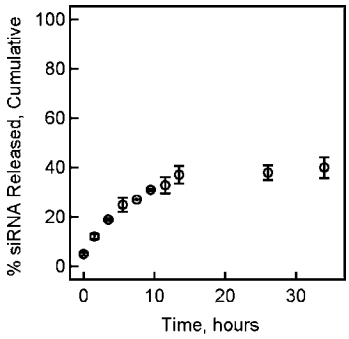


Figure 1. siRNA release profile from nanogels at 37 °C in PBS containing 10% fetal bovine serum. The error bars represent ±1 standard deviation about the mean value ($n = 3$).

delivery given previously determined time scales (~6 h) for extravasation via the enhanced permeability and retention effect (*49*).

To establish the efficacy of targeting in vitro, we determined the uptake of nanogels by two ovarian cancer cell lines, Hey and BG-1. We previously demonstrated high expression of EphA2 by Hey cells and low expression of the receptor by the BG-1 cell line (see Supporting Information) (*50*). Because of these differences in EphA2 expression, we expected to see higher levels of nanogel uptake via receptor-mediated endocytosis with Hey cells as compared to BG-1 cells. Furthermore, we expected that the degree of siRNA delivery to those cells would be dependent on the cell type and the presence of the peptide ligand. To load siRNA into the nanocarrier, lyophilized nanogels were loaded with siGLO (a fluorescently labeled siRNA delivery tracker) by reswelling them in a concentrated solution of the siRNA, as described above. To obtain a relative concentration of the siGLO taken up by the nanogels, absorbance measurements were compared to a standard curve of siGLO in solution ($R^2 > 0.99$). We determined in a series of three trials that 80−95% (by mass) of the siGLO was incorporated into the nanogels by this method, in agreement with the loading levels calculated in the release kinetics experiment described above.

Following loading with siGLO, nanogels were incubated with either Hey (high EphA2 expression) or BG-1 (low EphA2 expression) cells in order to compare the levels of targeted uptake by ovarian cancer cells. Uptake of the nanogels into the cells was followed using a fluorescent tag (AFA) incorporated into the nanogel core as well as by the fluorescence of the siGLO. In previous studies, we determined that high levels of nanogel uptake by cells occurred after 4 h (data not shown). As a result, cells were incubated for 4 h with siGLO-loaded/YSA-conjugated nanogels to monitor specific targeting to EphA2. Unloaded YSA-conjugated nanogels, nontargeted pNIPMAm nanogels, and siGLO only were used as controls, with identical 4-h incubation times. In all experiments described in this manuscript, we maintained a constant nanogel/cell ratio of 1 mg nanogels/5×10^5 cells. For siRNA-loaded nanogels, this corresponds to 16.6 μg siRNA/5×10^5 cells. After incubation, the cells were washed and the slides fixed for confocal microscopy imaging. Figure 2a shows that Hey cells targeted with YSA-conjugated nanogels have high levels of nanogel uptake as indicated by the presence of green fluorescence. At this time point, siGLO was retained at high levels within the internalized nanogels as indicated by the cell-localized red fluorescence. Merging of the two fluorescence channels showed strong overlap, further indicating delivery of the siGLO by the nanogels into the Hey cells. Hey cells incubated with YSA-targeted but unloaded nanogels showed strong green fluorescence, indicating cell uptake. A small amount of nontargeted uptake was observed for nanogels lacking the YSA peptide. Note that it was extremely difficult to find evidence of nonspecific uptake, and the fluorescence shown in the figure represents the appearance of the rare uptake event observed and does not represent the overall fluorescence from the entire population of cells. When Hey cells were incubated with siGLO alone, no cell-localized red fluorescence was detected; this is expected since RNA does not easily permeate the cell membrane in the absence of a carrier vehicle (*16, 17*).

Targeting experiments were also performed using low EphA2 expressing BG-1 cells (Figure 2b). Decreased levels of green fluorescence were observed in BG-1 cells when compared to the fluorescence observed in the Hey cell cultures. The lower amount of nanogel uptake by the BG-1 cells was most likely because of the reduced EphA2 receptor expression; we have demonstrated a ~2.5-fold difference in EphA2 expression levels between these two cell lines (Supporting Information). Control studies using nontargeted pNIPMAm nanogels or siGLO only showed no fluorescence in either the green or red fluorescent channels. These results indicate that the YSA peptide imparts targeting properties to the nanogels in the case of both the high (Hey) and low (BG-1) EphA2 expressing cells, and that the amount of nanogel uptake was dependent upon the level of EphA2 receptor expression. These results also indicate that nonspecific or nontargeted uptake of nanogels by cultured cells is low, and that the siRNA is unable to penetrate the cell membrane in the absence of a carrier vehicle. Together, these initial results illustrate the promise of the targeted nanogel construct for targeted delivery of oligonucleotide cargo.

To further establish the mechanism of nanogel targeting and uptake, we took advantage of the known receptor internalization properties of the EphA2 receptor. Specifically, it has been shown that binding of ephrin-A1, a ligand for EphA2, to EphA2 receptor causes internalization and degradation of the receptor−ligand complex (*51*). Figure 3 shows the results of studies wherein this receptor recycling process was used to establish the nanogel target by preincubating Hey cells with ephrin-A1 before YSA-targeted nanogel incubation. We hypothesized that if uptake of nanogels is EphA2 receptor-mediated, YSA-targeted uptake after cell exposure to ephrin-A1 should be reduced, as the EphA2 receptor will be internalized and less available for binding to the nanogels. Hey cells were incubated overnight in an eight-well chamber slide. Two μg/mL of ephrin-A1 was added, and the cells were incubated for 1 h at 37 °C. After ephrin-A1 incubation, siGLO-loaded/YSA-conjugated nanogels were added to both ephrin-A1 and control (PBS) treated wells. The cells were incubated for 4 h, washed, and processed for imaging. Figure 3 shows the nanogel uptake in Hey cells preincubated with ephrin-A1. Whereas these cells (top three panels) show some uptake of nanogels and encapsulated siGLO, the amount of uptake is greatly diminished compared with untreated cells (lower three panels). These results suggest that YSA-conjugated uptake by Hey cells is conducted to a large extent through EphA2; however, a small amount of uptake may occur through nonspecific mechanisms or via binding of YSA to other Eph receptors (*35*). This is not surprising, given the fact that ephrin and various small molecule ephrin mimics display binding affinities for multiple receptors of the Eph family (*52, 53*). Flow cytometry was also used to establish the EphA2-associated binding of the peptide-targeted nanogels. In this case, a scrambled (SCR) peptide sequence (DYPSMAMYSPSVC) possessing the same amino acid composition of the YSA peptide was tethered to the nanogels. The resultant nanogels should therefore possess the same physicochemical surface properties as the YSA-labeled nanogels but should not specifically bind to the EphA2 receptor. Figure 4 shows the results of these studies, where cells incubated with YSA-labeled

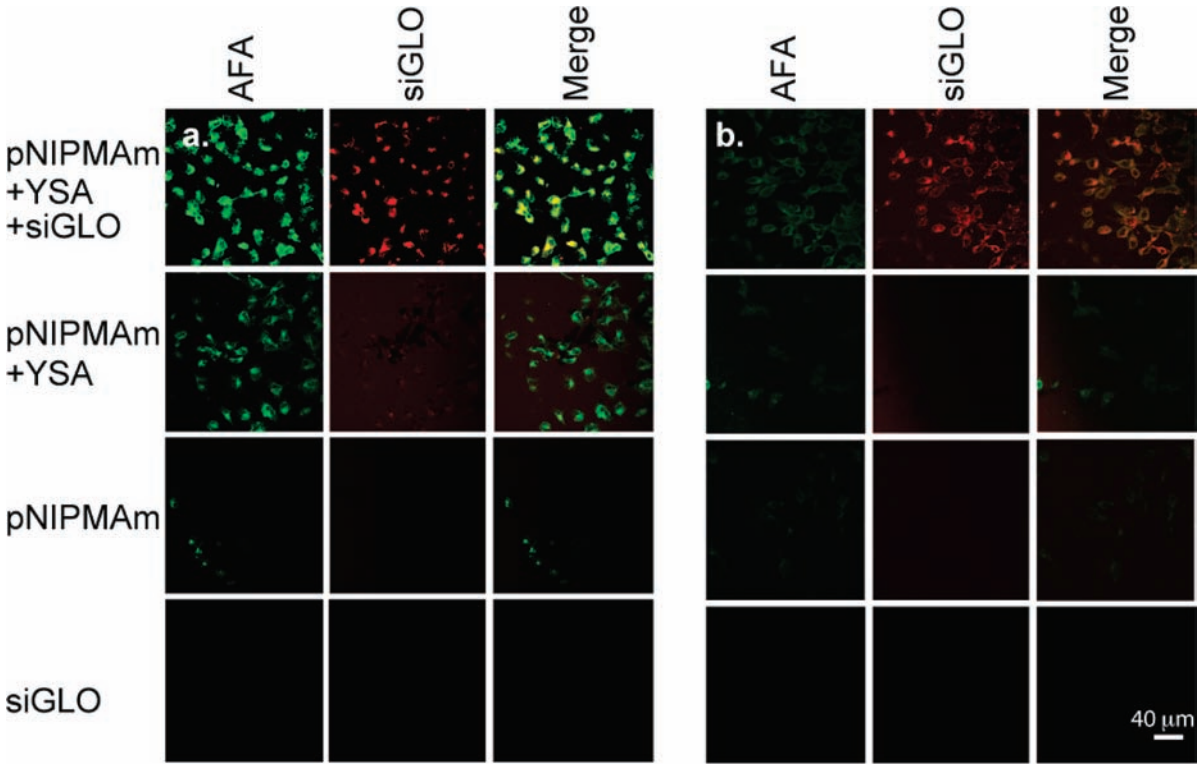

Figure 2. Confocal microscopy images of (a) Hey cells and (b) BG-1 cells following exposure to siGLO-loaded/YSA-conjugated pNIPAMAm nanogels, YSA-nanogels alone, unlabeled nanogels, and siGLO alone. The AFA and siGLO fluorescence channels are shown individually, along with a merge of the two channels. Scale bar = 40 μm.

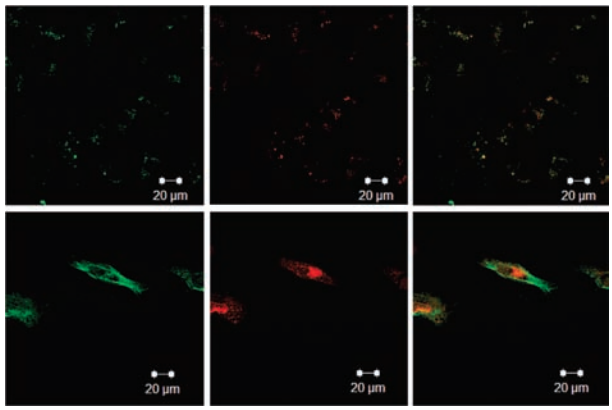

Figure 3. Confocal microscopy images of Hey cells (top) following exposure to siGLO-loaded/YSA-conjugated nanogels after 1 h ephrin-A1 incubation, and (bottom) following exposure to siGLO-loaded/YSA-conjugated nanogels alone. The fluorescence channels shown are as in Figure 2. Scale bar = 20 μm.

nanogels display ~10-fold greater fluorescence relative to those incubated with SCR-labeled nanogels. Furthermore, the fluorescence signal associated with cells incubated with SCR-labeled nanogels is only slightly greater than the cell autofluorescence background signal.

The effect of nanogels on tumor cell toxicity and proliferation was examined using two cell viability assays. For the trypan blue exclusion assay, Hey cells were incubated with pNIPMAm nanogels, YSA-conjugated nanogels, or SCR-conjugated nanogels for 72 h. The cells were then washed with PBS, and trypan blue was added to the cells. Five fields were observed via microscopy for each treatment group. Blue cells, indicating dead cells, were not observed in any of the fields examined for any of the treatment groups. Representative images are shown in the Supporting Information. To more precisely establish any negative effects associated with nanogel-based delivery, we used the Tox 8 viability proliferation assay. Hey cells were incubated in 96-well plates overnight, and nanogels were delivered and removed via the usual method. In the gene silencing data shown below, we chose siRNA targeting epidermal growth factor receptor (EGFR); knockdown of this receptor is nonlethal but has clinical relevance in the treatment of drug resistant ovarian carcinomas (*54*). This siRNA was therefore used in these toxicity studies as well. Again, we maintained a ratio of 1 mg nanogels/5 $\times$ 10^5 cells for all samples. For the EGFR siRNA-loaded nanogels, this corresponds to 16.6 μg siRNA/5 $\times$ 10^5 cells. Wells were washed with PBS, and 100 μL of cell culture medium was added to the wells. After 72 h, Tox 8 was added to the cells according to the manufacturer's instructions, and the cell viability was determined spectrophotometrically. This analysis (Figure 5) revealed no significant difference for any treatment when compared with control (untreated) cells, although exposure to nontargeted nanogels and siRNA-containing nanogels showed slight decreases in viability; the origin of this effect is currently under investigation. These results indicate that treatment of Hey cells with targeted nanogels does not greatly inhibit cell proliferation, indicating limited toxicity of the nanogels under these conditions.

These promising preliminary studies clearly illustrate the efficacy of peptide-targeted delivery of siRNA cargos via nanogel carriers. The lack of toxicity observed is of particular interest, given the high toxicity observed for some cationic lipid-based siRNA targeting methods, which limits the maximum doses that can be delivered, and also compromises the potential for in vivo delivery. In the present studies, a ratio of 16 μg siRNA or 1 mg nanogels/5 $\times$ 10^5 cells was used throughout without significant toxicity being observed. These concentrations are somewhat higher than those suggested for common commercial regents such as RNAiFect (Qiagen) or DharmaFECT

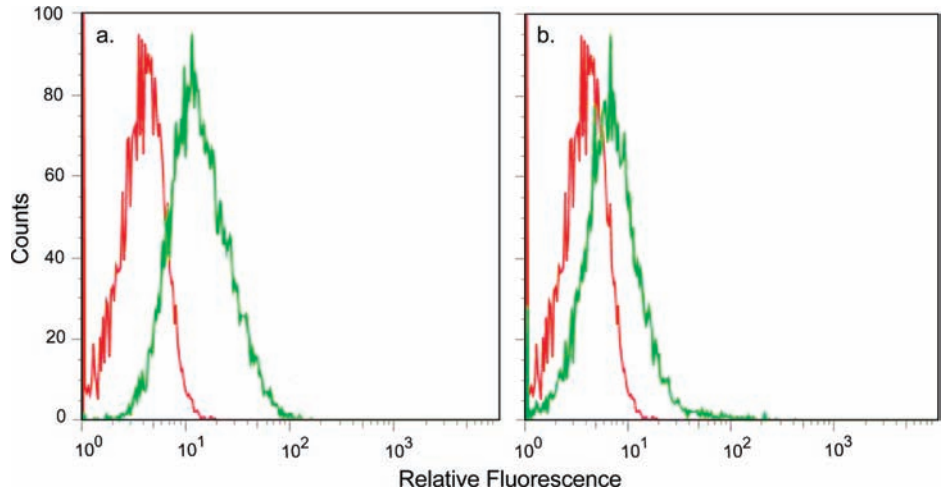

Figure 4. Flow cytometry data comparing (a) cell autofluorescence (red) vs cells incubated with YSA-pNIPMAm nanogels (green) and (b) cell autofluorescence (red) vs cells incubated with SCR-pNIPMAm nanogels (green). The differential uptake between the YSA- and SCR-labeled nanogels indicates the Eph2A receptor-specific binding and uptake pathway.

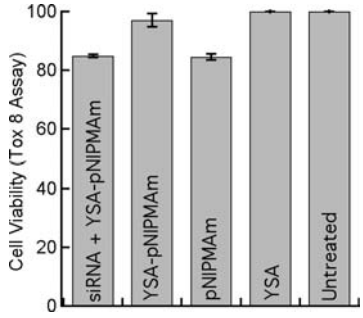

Figure 5. Cell viability as determined with a Tox 8 assay for untreated Hey cells and Hey cells following a 4 h incubation with EGFR siRNA-loaded YSA-labeled nanogels, YSA-labeled pNIPMAm nanogels, unlabeled pNIPMAm, or YSA peptide alone. Error bars represent ±1 standard deviation about the average value ($n = 3$).

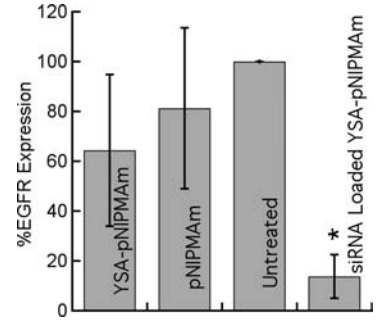

Figure 6. EGFR expression, as determined by immunoblot, in Hey cells following a 4 h incubation with either unloaded YSA-nanogels, unloaded nontargeted nanogels, or siRNA loaded YSA-nanogels. Untreated cells were set at 100% expression. All cells were harvested 48 h after removal of the nanogels. Error bars represent ±1 standard deviation about the average value ($n = 3$, $^*p < 0.01$ relative to untreated sample).

(Dharmacon), suggesting that the nanogel approach is capable of delivering siRNA amounts at or above those achievable by optimized commercial reagents. Another complicating factor in current methodologies is the frequent need for cellular delivery under serum free conditions; serum lipids and proteins compromise the stability of many liposomal formulations, making their efficacy significantly lower. In the studies described herein, we have illustrated that delivery of siGLO is excellent in serum-containing medium, further establishing the promise of this construct. As a final preliminary test of the efficacy of the approach, we performed a limited investigation of siRNA-based silencing. Clearly, any delivery approach must deliver *functional* siRNA to the cell interior in order for it to be truly useful. If the nanogel carrier were unable to protect the cargo against degradation in the endosomal or lysosomal compartments, or if the nanogels were unable to escape from endosomes in order to deliver the siRNA to the cytosol, the amount of RNAi would be very low. Thus, we have undertaken a preliminary study of gene silencing to illustrate a minimal requirement for siRNA delivery: the functional silencing of a target mRNA.

As described above, we chose siRNA targeting EGFR; knockdown of this receptor is nonlethal but has clinical relevance in the treatment of drug resistant ovarian carcinomas (*54*). To determine if we could effectively knockdown EGFR in vitro, EGFR siRNA was encapsulated at a concentration of 16.6 μg of EGFR siRNA/mg of nanogels, using the loading technique described above. Nanogels were then added to Hey cells (1 mg of nanogels or 16.6 μg siRNA/5 $\times$ 10^5 cells) and incubated at 37 °C for 4 h. The unincorporated nanogels were then removed by washing the cells, and the medium was replaced. Controls included cells incubated with unloaded YSA-targeted nanogels, pNIPMAm nanogels, and untreated cells. All cells were harvested at 48 h and assayed for EGFR expression by immunoblotting, as described in the Experimental Section. Figure 6 shows the results of this experiment; a significant reduction in EGFR expression is observed under these conditions relative to all controls ($p < 0.01$ relative to untreated sample by paired t test, $n = 3$). A small, statistically insignificant decrease in EGFR expression was noted in the unloaded, YSA-targeted nanogel control ($p > 0.1$). If this observation is indeed a real one, it may be due to cross talk between the EGFR and the EphA2 receptors, as described by Larsen and colleagues (*55*). In addition, a small decrease in EGFR expression was observed when cells were incubated with pNIPMAm nanogels alone, although the difference is not statistically significant ($p > 0.3$) in light of the large observed variability in expression.

These preliminary results illustrate that the targeted nanogels are capable of functional delivery of siRNA to ovarian carcinomas without overt toxic effects, and that the subsequently internalized siRNA is available for gene silencing. Whereas this preliminary demonstration is relatively focused in scope, it clearly shows the promise of the construct. We are currently exploring the generality of this approach in a detailed study of

silencing timecourse, persistence, cell type dependence, dose response, and applicability to other known silencing targets.

CONCLUSIONS

Peptide-labeled nanogels with a high loading capacity for siRNA have been developed and can be effectively targeted to ovarian carcinomas by receptor−peptide binding. The encapsulated siRNA is transported into the cell interior, where it is available for gene silencing, as illustrated in this case by EGFR knockdown. Since the locus of siRNA-mediated gene silencing is the cytosol, the results are suggestive of the surprising conclusion that endosomal uptake of the nanogels is followed by endosomal escape, resulting in efficient transport/release of the siRNA to the cytosol. Whereas we do not currently know the exact mechanism by which endosomal escape occurs. It is plausible that the nanogels respond to endosomal changes in osmotic pressure and ionic strength by undergoing a volume change. This phenomenon, called osmotic swelling/deswelling (*56*) is fundamental to the phase behavior of gel networks and may serendipitously be responsible for the excellent delivery properties described above. In addition to the gene-silencing efficacy, the nanocarriers are demonstrated to be nontoxic under the conditions investigated and are effective even when delivered in serum-containing medium. As a result of these studies, we are currently investigating the fundamental mechanisms of nanogel endosomal release. Additionally, the gene silencing results are being validated in a broader study of RNAi with plans to extend their use to in vivo delivery and silencing in animal models.

ACKNOWLEDGMENT

The authors acknowledge support from Emory−Georgia Tech Nanotechnology Center for Personalized and Predictive Oncology (5-40256-G11). L.A.L. acknowledges financial support from the DHHS (1 R21 EB006499-01). The ovarian cancer studies (E.B.D. and J.F.M.) were supported by the Georgia Cancer Coalition, The Debora Nash Harris Endowment Fund, and The Ovarian Cancer Institute. Thanks to Roman Mezencev for his help with the flow cytometry studies.

Tuning of Peroxidase Activity by Covalently Tethered DNA Oligonucleotides

Maximilian Glettenberg and Christof M. Niemeyer*

Technische Universität Dortmund, Fakultät Chemie, Biologisch-Chemische Mikrostrukturtechnik, Otto-Hahn Strasse 6, D-44227 Dortmund, Germany. Received December 24, 2008; Revised Manuscript Received February 25, 2009

We report on the modulation of the peroxidase activity of hybrid catalysts, comprising short DNA oligonucleotides and heme enzymes by means of sequence variation of tethered oligonucleotides. In particular, binary mixtures of native heme (protophorphyrin IX) and single-stranded DNA oligonucleotides as well as the analogous covalent heme-oligonucleotide conjugates were compared with DNA−enzyme conjugates, prepared by reconstitution of apo-myoglobin or apo-horseradisch peroxidase, using the aforementioned covalent heme−oligonucleotide conjugates. In all systems, it was clearly evident that the implemented oligonucleotides markedly influence the catalytic activity in a sequence-dependent matter. Greater than 100-fold changes in catalytic constants were observed, depending on which oligonucleotide was incorporated in the hybrid catalyst. We also observed that the tethered oligomers affect the inhibition of HRP-mediated peroxidation by means of small molecule inhibitors. On the basis of the quantitative description of this phenomenon and consideration of the current state of knowledge, we hypothesize that distinct interactions, such as hydrogen bonding or electrostatic contacts, occur between the oligonucleotides and the heme-containing catalyst, which account for the effects observed.

INTRODUCTION

The design of biocatalysts is of major importance for many technical processes and commercial applications (*1*). Mainstream developments in this area focus on either the search for new enzymes in natural habitats or else the *a priori* design or *in vitro* evolutionary optimization of known enzymes. However, novel approaches are currently being explored, in which semiartificial bioinorganic hybrid catalysts are generated by a combination of natural biomacromolecules and synthetic building blocks (*2, 3*). For example, catalytically inactive molecules, such as streptavidin (*4*−*7*), papain (*8*−*10*), serum albumin (*11*), or double-stranded DNA (*12, 13*), have been modified with organometallic moieties to create catalysts for hydrogenation, alkylation, Diels−Alder, or other chemo- and stereoselective transformations. Moreover, naturally occurring enzymes have been modified with synthetic groups to alter existing catalytic reactivities and create novel ones. For instance, hemoenzymes have been modified with synthetic analogues of their native prosthetic group to change catalytic specificity (*14, 15*). Enzymes have also been attached to colloidal semiconductor nanoparticles to generate light-switchable photocalysts (*16*−*18*) or with gold nanoparticles to produce electrically addressable catalysts for biosensing (*19, 20*).

The reconstitution of apoenzymes, which are enzymes whose natural prosthetic group has been removed by chemical treatment, with artificial prosthetic group analogues represents a powerful approach to generate bioinorganic hybrid catalysts (*14, 15, 21*). We have previously applied this method to the synthesis of semisynthetic DNA oligonucleotide conjugates of myoglobin (Mb, in Figure 1) (*22, 23*) or horseraddish peroxidase (HRP) (*23, 24*). It should be noted that Mb, whose main physiological function concerns the reversible storage of oxygen in muscle tissue, under certain conditions can act as peroxidase (*25*−*27*); however, its peroxidase activity is several orders of magnitude lower than that of classical peroxidases, such as HRP. Owing to the highly specific binding capabilities of the DNA oligomers attached to Mb or HRP, these conjugates can be specifically immobilized at solid surfaces by means of DNA hybridization. Thus, they can be considered as programmable catalysts, useful for applications in biocatalysis or sensing (*24, 28*). Interestingly, the attachment of the oligonucleotide to the enzyme's active site leads to significant changes in catalytic activity. While HRP−DNA conjugates revealed a reduced peroxidase activity, the enzymatic activity was largely increased in the case of Mb (*23*). These effects were observed for both conjugates, containing either one or two DNA oligomers (MbD_1 and MbD_2, respectively, in Figure 1), and they may result from steric constraints of the DNA strands leading to an opening of the active site, thereby facilitating an increased accessibility for substrate molecules (*23*). We here report a novel phenomenon, observed in the course of kinetic analyses of the Mb- and HRP−DNA conjugates, that the catalytic activity of the enzyme can be significantly changed by alterations of the nucleotide sequence of the appended DNA moiety.

EXPERIMENTAL PROCEDURES

Syntheses of rMb−DNA (*22*), rHRP−DNA conjugates (*23*), and chemical HRP−DNA conjugates (*24*) were carried out as previously described. Kinetic measurements of the H_2O_2-mediated peroxidation of Amplex Red have also been described elsewhere (*23*). Full details on experimental protocols for conjugate synthesis, Michaelis−Menten kinetic measurements, data analysis, and controls are available in the Supporting Information.

RESULTS

In this work, we studied the influence of DNA oligonucleotide sequences on the enzymatic activity of covalent DNA−enzyme conjugates. As schematically depticted in Figure 1, semisynthetic DNA−heme enzyme conjugates were prepared in a two-step process (*22, 23*). Initially, covalent on-column coupling of aminoalkyl-modified DNA oligonucleotides with heme (protoporphyrin IX) was carried out to synthesize two DNA−heme

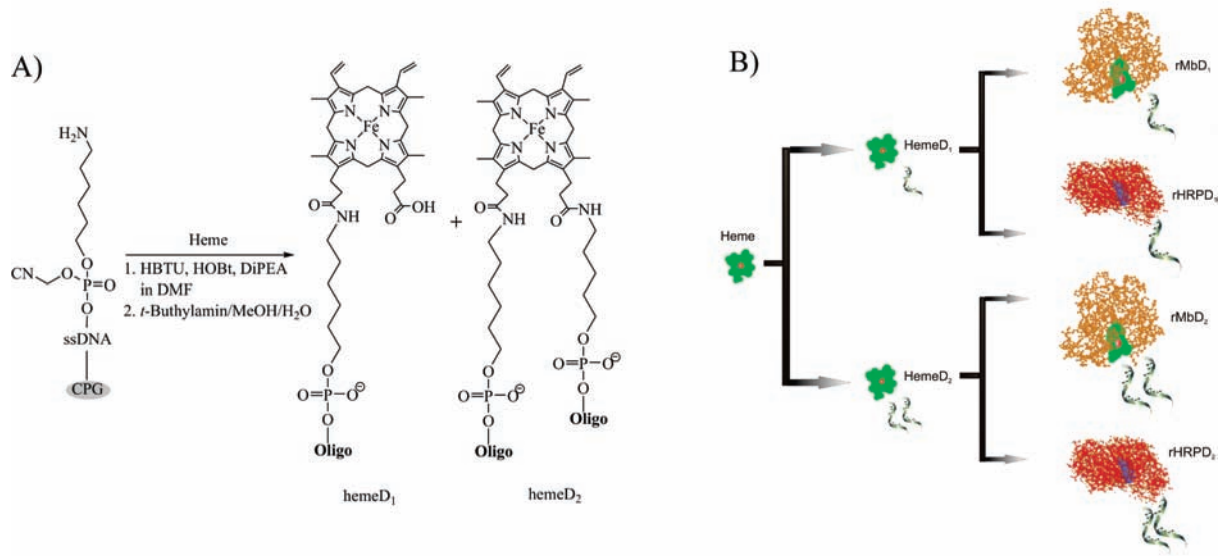

Figure 1. Overview on the preparation of semisynthetic DNA−heme enzyme conjugates. (A) Covalent on-column coupling of aminoalkyl-modified DNA oligonucleotides with heme (protoporphyrin IX) yields two DNA−heme conjugates, containing one (hemeD$_1$) or two (hemeD$_2$) single-stranded oligonucleotides, linked to the propionate chains of heme. (B) The two conjugates are separated by ion-exchange chromatography and used for the reconstitution of apo-myoglobin (Mb, orange) and apo-horseraddish peroxidase (HRP, red), respectively.

conjugates, containing one (hemeD$_1$) or two (hemeD$_2$) single-stranded oligonucleotides, linked to the propionate chains of heme (Figure 1A). The two conjugates were separated by ion-exchange chromatography and then used for the reconstitution of apo-myoglobin and apo-horseraddish peroxidase, respectively, previously prepared by Teale's methylethylketone extraction method (*29*). The reconstitution of the apoenzymes led to the formation of the desired semisynthetic DNA−enzyme conjugates (rMbD$_1$, rMbD$_2$, rHRPD$_1$, and rHRPD$_2$ in Figure 1B), which were purified by FPLC and characterized spectrophotometrically (Figures S1 and S2, in the Supporting Information) (*30*).

In the course of Michaelis−Menten kinetic studies of the peroxidase activity of the DNA−enzyme conjugates in the H_2O_2-mediated conversion of the fluorogenic substrate Amplex Red to form the highly fluorescent product resorufin (*30*), we observed that hybrids, which contained different oligonucleotides, revealed significant differences in their enzymatic activity. For example, we investigated the reconstituion of apoMb with a set of 22-mer oligonucleotides, denominated as F1, F5, F9, and F10 (Table 1), which had previously been designed and selected for orthogonal and highly efficient hybridization characteristics in DNA-directed immobilization of oligonucleotide−protein conjugates (*31*). Typical Michealis−Menten kinetic curves of rMb conjugates, reconstituted with oligomers F1−F10, are shown in Figure 2. The kinetic curves of the conjugates revealed substrate inhibition characteristics, which was accounted for by using the appropriate two-parameter fit for the Michaelis−Menten kinetics fitting method (*30*, *32*). It was clearly evident from naked-eye inspection of the curves, that the activity of D$_1$-conjugates was highest when oligomer F10 was used (Figure 2a). In the case of the D$_2$-conjugates, however, greatest activity was observed when oligomer F5 was used (Figure 2b). More precisely, the order of enzyme activity was F10 > F5 > F9 > F1 in the case of D$_1$-conjugates (Figure 2a), while F5 ≫ F9 > F10 ≈ F1 was observed for D$_2$-conjugates (Figure 2b).

Since these results were rather unexpected, we repeated the kinetic measurements using entirely independent samples, prepared from different batches of oligonucleotides and apoenzymes, at least three times. The Michaelis−Menten parameters (K_M, k_{cat}, and k_{cat}/K_M) obtained from kinetic analyses of various hybrid conjugates were then calculated and listed in Table 2. Because of the large number of independent repetitions (n = 3−7), the data can be considered highly reproducible. To compare the reactivity of two enzymes acting on the same substrate, the so-called catalytic efficiency (k_{cat}/K_M) is frequently used (*33*). This k_{cat}/K_M value, also termed as specificity constant, is a useful index for comparing the relative rates of an enzyme acting on alternative, competing substrates. Since Eisenthal and collegues have recently emphasized that the use of k_{cat}/K_M as a quantitative index of catalytic power is at best misleading and at worst invalid (*33*), we here restrict our discussion on the comparison of k_{cat} values, which are the catalytic constants for the conversion of a substrate (Amplex Red) to a product (resorufin). Inspection of k_{cat} data obtained from the aforementioned eight rMb-oligonucleotide conjugates (entries 11−14, in Table 2) indeed confirmed the obove described order in activity, i.e., that F10- and F5-modification induced highest activity for the D$_1$- and D$_2$-conjugates, respectively. Moreover, comparison with native Mb (entry 10) confirmed our previous observation that the reconstitution of apoMb with oligonucleotide−heme conjugates leads to an increased peroxidase activity, as compared to the native enzyme (*22*, *23*).

Peroxidase Activity of Heme−DNA Conjugates. To systematically investigate the sequence-dependent peroxidase activity of the conjugates, we measured whether the *F*-oligonucleotides do influence the peroxidase activity of heme (entries 1−5, in Table 2) and of the respective heme−DNA conjugates (entries

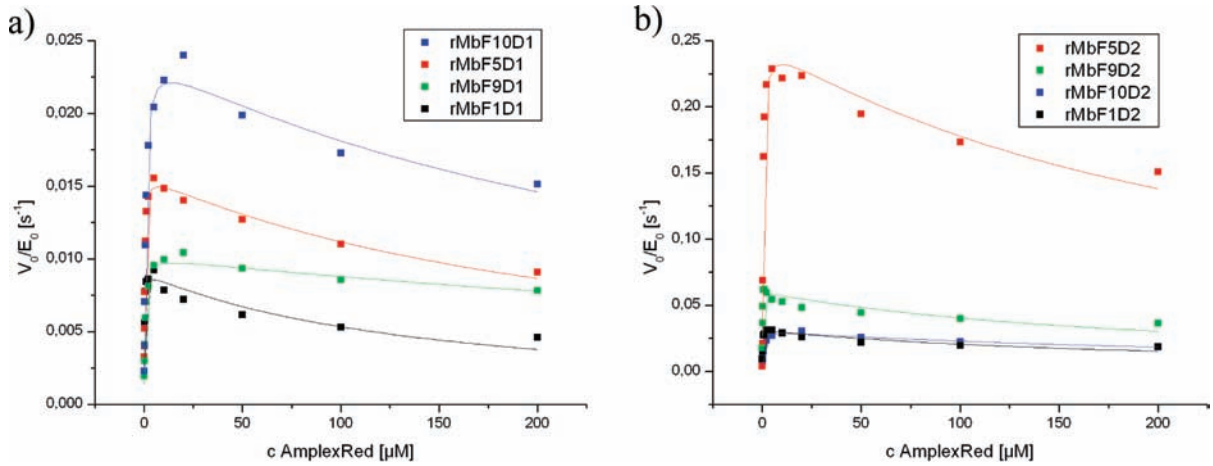

Figure 2. Representative kinetic curves obtained from myoglobin, reconstituted with four different 22-mer oligonucleotide−heme conjugates, synthesized from oligonucleotides F1 (black), F5 (red), F9 (green), and F10 (blue). Shown are the kinetic curves determined for the respective $rMbD_1$ (a) and $rMbD_2$ (b) conjugates.

[a] Conjugates with one or two DNA oligonucleotides are denoted as D_1 or D_2, respectively. [b] Native heme was mixed with 1 or 2 M equivalents of amino-modified DNA *F*-oligonucleotides, as indicated with 1:1 or 1:2, respectively.

6−9). In the case of two component mixtures containing native heme and the amino-modified *F*-oligonucleotides, the addition of F1 and F5 oligonucleotides increased the peroxidase activity of native heme about 2-fold (entries 2, 3, and 1, respectively), while the presence of oligomers F9 and F10 (entries 4, 5) did not reveal significant effects. Interestingly, the addition of two molar equivalents of the *F*-oligonucleotides led to an about 2-fold decrease in heme activity. In the case of covalent *F*-oligonucleotide−heme conjugates (entries 6−9), peroxidase activity of the monoadducts ($hemeD_1$), sequences F1 and F10, affected the activity only slightly (≤2-fold), while oligomers F5 and F9 significantly increased the peroxidase activity ≈7-fold. The bis-adducts ($hemeD_2$) containing oligomers F1 and F10 showed activity similar to that of the monoadducts; however, sequence F9 strongly decreased the activity, while the $hemeD_2$−F5 conjugate revealed a significant (>30-fold, entry 7) increase in activity, as compared to the native heme.

To ease the comparison of the above-described data, Figure 3A−C shows a graphical representation of k_{cat} values. It is evident that the oligonucleotides markedly influence the catalytic constants; however, no distinctive patterns or trends are evident in terms of which sequence increases or decreases the catalytic activity. For a discussion of the observed phenomena, one should initially take into account that it is well known that noncovalent adducts of folded nucleic acid motifs, such as G-quadrupletts or aptamer sequences, and heme can exhibit fairly strong peroxidase activity. For instance, Sen and collegues have previously reported on the selection of a catalytic DNA−heme complex, which reveals peroxidase activity substantially greater than those of heme proteins, such as catalase and Fe(III)-myoglobin (*34*−*37*). On the basis of these achievements, designed aptamer−heme adducts have already been employed in a variety of bioanalytical assays (*38*−*40*). Therefore, the changes in heme catalytic activity induced by covalent coupling (Figure 3A) or simple addition (Figure 3B) of oligonucleotides suggest the formation of folded secondary structures or even oligomeric aggregates, which interact with heme. Although the

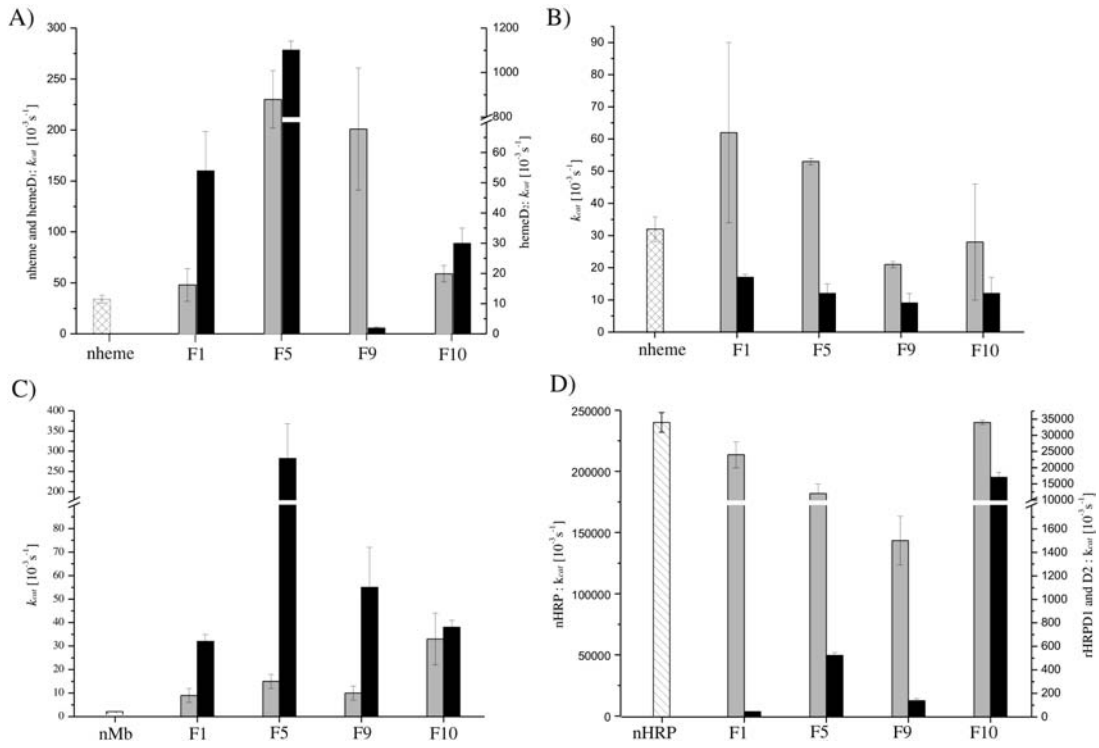

Figure 3. Column diagrams of the experimentally determined k_{cat} value of (A) covalent heme−DNA conjugates and native heme (hatched bar), (B) binary mixtures containing native heme, amino-modified *F*-oligonucleotides, and native heme (hatched bar), (C) reconstituted Mb−DNA conjugates and native Mb (hatched bar), and (D) reconstituted HRP−DNA conjugates and native HRP (hatched bar). The light gray and black bars represent the D_1- and D_2-conjugates, respectively. Note that the heme−D_2 conjugate of F5 in A revealed a strongly increased peroxidase activity, indicated by the differently scaled *y*-axis in A.

F-oligonucleotides had previously been designed by applying the criteria of minimized secondary structure and homodimer formation (*31*), we again analyzed these sequences *in silico*, using the DINAMelt web server (*41*), which also allows one to adjust sodium chloride concentration. Under the given peroxidase assay conditions ($T = 25$ °C, 300 mM NaCl), no appreciable secondary structure formation was detected. The most stable secondary and homodimer structures were detected for oligomers F5 ($\Delta G = -0.9$ or -6.1 kcal/mol, respectively) and F1 ($\Delta G = -0.76$ or -4.3 kcal/mol, respectively, see Figure S3, Supporting Information). Thus, *in silico* analysis did not provide any distinctive trends that helped to explain the observed reactivity patterns (Figure 3A,B).

Peroxidase Activity of Mb−DNA Conjugates. In the comparison of oligonucleotide-induced k_{cat} patterns observed for heme−DNA (Figure 3A) and the respective rMb−DNA conjugates (Figure 3C), it is evident that sequence F5 has the strongest activating effect in the D_2-conjugates; however, this trend is not consistent in the case of the D_1-conjugates. It is well known that native Mb is a relatively weak peroxidase (*14*). This fact is reflected by the data in Table 2, which indicate that the absolute k_{cat} value, and thus peroxidase activity, of native Mb (entry 10) is about 25-fold lower than that of native heme (entry 1). This suggests that the protein shell of native Mb in fact reduces the peroxidase activity of heme. Thus, it is most likely that this general effect also occurs in the reconstituted rMb−DNA conjugates. Monzani et al. have reported that the introduction of hydrogen donor and acceptor peptide groups to the heme influences the hydrogen bond network of the Mb, thereby leading to a slight rigidification of the active site and an increased stability of compound I (*42*). They also showed that the heme-binding pocket is not sufficiently large to entirely accommodate the peptide-modified heme derivatives, and therefore, the peptide-carrying propionate chains extend to the outside of the heme pocket. On the basis of these observations, we have previously hypothesized that the attachement of the bulky negatively charged DNA in close proximity to the enzyme's active site may lead to an opening of the active site, thereby facilitating an increased accessibility for substrate molecules (*23*). Unfortunately, this general steric model is not sufficient to explain the sequence-dependent data reported here.

To further investigate this phenomenon, we analyzed a number of analogous rMb−DNA conjugates containing longer or shorter DNA oligomers, which also included a set of GC-rich oligomers (Table S1, Supporting Information). The latter were chosen to investigate whether guanine or cytosine nucleobases might specifically contribute to the sequence-dependent peroxidase activity of rMb−DNA conjugates. Guanine has a lower redox potential than other nucleobases, and chemical oxidation of this base has been observed experimentally (*43*), while cytosine bases are known be to easily protonated and thus play an important role in RNA-based catalysis (*44*). Although we again observed sequence-dependent peroxidase activity, regrettably no distinct patterns could be deduced from the kinetic data summarized in Table S1 (Supporting Information).

Peroxidase Activity of HRP−DNA Conjugates. We then investigated whether sequence-dependent peroxidase activity can also be observed for other reconstituted heme enzymes. To this end, rHRP−DNA conjugates were prepared by using the *F*-oligomers. The resulting kinetic data are summarized in Table 3 and graphically depicted in Figure 3D. As expected from previous results (*23*), the peroxidase activity was significantly higher than that of the rMb−DNA conjugates. Specifically, native HRP showed an about 170.000-fold higher k_{cat} value than native Mb, while the rHRP−DNA conjugates revealed on average about a 500-fold increase, as compared to the rMb−DNA conjugates. Thus, the rHRP−DNA conjugates were significantly less active than native HRP. This was also observed for chemically linked conjugates (entries 6−9, in Tab. 3), which

4	rHRP-F9	17.1 ± 7.1	10.4 ± 1.3
5	rHRP-F10	26.9 ± 7.7	26.8 ± 2.9

were synthesized by coupling 5′-alkylthiol-modified *F*-oligonucleotides to accessible lysin residues of the HRP's surface, using the heterobifunctional cross-linker sSMCC (*24*). Interestingly, the chemical conjugates revealed an almost identical k_{cat} value of about 17000 × 10^{-3} s^{-1}, regardless of the oligomer attached to the HRP. Since the chemical coupling occurs statistically at one of the 4 lysine residues of HRP, one can assume that mere synthetic manipulations decrease the activity of native HRP about 14-fold. In contrast, reconstitution of apoHRP with the various heme−DNA conjugates led to large variations in peroxidase activity (entries 6−9, in Table 3). In particular, k_{cat} values ranged from 1500 (F9) to 24.000 10^{-3} s^{-1} (F1) and 44 (F1) to 17.000 10^{-3} s^{-1} (F10) for the D_1- and D_2-conjugates, respectively. The observed activity pattern (Figure 3D) differed significantly from that observed for heme−DNA (Figure 3A) or heme−rMb conjugates (Figure 3C). Moreover, yet another pattern of DNA-dependent peroxidase activity was observed when the heme−rHRP-D_1 conjugates were allowed to hybridize with one molar equivalent of the complementary oligomer (cF1, cF5, cF9, or cF10; see Table S2, Supporting Information).

Small Molecule HRP Inhibitors. We also investigated whether the action of small-molecule inhibitors is affected by the tethered F-oligonucleotides attached to HRP's active site. In the course of another project, we had accidentally observed that fluoranthene and 9-methylanthracene act as strong inhibitors of native HRP in the peroxidation of Amplex Red (Rabe, K. S., and Niemeyer, C. M., unpublished results). We here followed up on this qualitative observation and determined the inhibitory concentrations (IC_{50}) of fluoranthene and 9-methylanthracene for native HRP and the respective rHRP-D_1 conjugates (Table 4). The IC_{50} values of both inhibitors were significantly decreased for the rHRP-D_1 conjugates, as compared to native HRP. This means that, for example, the IC_{50} value of 9-methylanthracene was almost 20-fold reduced when oligomer F5 was present in the rHRP-D_1 conjugate. Interestingly, the analogous chemical conjugates revealed no such strong dependence on the oligomer sequence attached (Table S3, Supporting Information). Since we determined that both fluoranthene and 9-methylanthracene act as competitive inhibitors (Figure S4, Supporting Information), the decrease in IC_{50} indicates that the sequence of the tethered DNA moiety increases the affinity of the inhibitor for the enzyme's active site to a different extent. The data thus provide a hint toward a changed geometry and/or conformational flexibility of the active site. However, no distinct correlation could be deduced between the inhibitor enhancement (Table 4) and peroxidase activity modulation (Table 3) by the various *F*-oligomers under investigation.

DISCUSSION

In conclusion, we here reported on the modulation of the activity of biomolecular peroxidation catalysts by means of sequence variation of tethered oligonucleotides. Five independent systems, i.e., binary heme/oligonucleotide mixtures, covalent heme−oligonucleotide conjugates, and rMb−DNA and rHRP−DNA conjugates as well as the inhibition of peroxidase activity of rHRP−DNA conjugates, were investigated. In all systems, it was clearly evident that the oligonucleotides involved in the system markedly influence the catalytic activity in a sequence-dependent matter. Regrettably, however, no distict patterns or trends were evident in terms of which sequences induce an increase or decrease in the catalytic activity. Thus, the present work is restricted to the phenomenological description of these effects and possible explanations are hypothetical. On the basis of (i) the *in silico* analysis of oligonucleotide sequences and (ii) the variability of reactivity patterns observed for the various systems, it seems safe to assume that the formation of stable oligonucleotide secondary structures or homodimers is not the predominant mode of action. In addition, since we used only one substrate (Amplex Red) throughout the entire study, the reactivity patterns observed cannot originate from interactions between the substrates and/or inhibitors with the nucleic acid or protein because this should bias all catalyst systems in a similar way. More likely, therefore, distinct interactions, such as hydrogen bonding or electrostatic contacts, between the oligonucleotides and the heme-containing catalyst may account for the effects observed. As discussed above, this hypothesis is supported by numerous previous studies of artificial heme enzymes, reconstituted with non-natural heme derivatives. It is clearly evident from these studies that the introduction of hydrogen donor and acceptor groups to the heme do influence the hydrogen bond network of the Mb. This can signficantly change the catalytic activity of the enzyme and also affect its secondary and tertiary structures (*42*, *45*). Similar effects have also been observed for other heme enzymes, such as hemoglobin (*46*). Therefore, we speculate that sequence-dependent, distinct contacts between the nucleic acid and the protein are responsible for the observed phenomenon. The detailed analysis of structural origins on the molecular level might be unraveled by NMR or X-ray crystallography, and efforts toward this challenging goal are currently underway.

Even without knowing the detailed mechanism of action, the present work has implications on the design and development of semiartificial biomolecular hybrid catalysts. On the one hand, catalysts containing only nucleic acids as the biomolecular component should be carefully analyzed for similar sequence-dependent secondary effects (*12*, *13*). On the other hand, hybrid catalysts comprising proteins as the biomolecular component (*4*−*11*) might be revisited to explore whether the synthetic appendix induces conformational changes in addition to providing the primary catalytic effect. Moreover, our study demonstrates that hybrid catalysts containing both nucleic acid and protein components have an intrinsic potential for tuning the catalytic activity by simply changing the base composition. As

demonstrated here, a weak catalyst, such as myoglobin, can be improved either 30-fold or even 280-fold by simply changing the oligonucleotide sequence. We therefore anticipate that current developments of nucleic acid−based hybrid catalysts will benefit from focusing on designed oligomer sequences, selected by either rational or evolutive methods, to facilitate the generation of novel powerful catalysts.

ACKNOWLEDGMENT

This work was supported through funding from Zentrum für Angewandte Chemische Genomik (ZACG), a joint research initiative funded by the European Union and the Ministry of Innovation and Research of the state Northrhine Westfalia. We thank Jens Reiber for experimental support and Dr. Ljiljana Fruk, Dr. Udo Feldkamp, and Kersten Rabe for valuable discussions.

1. Experimental

Chemicals and Materials. Horseradish peroxidase (HRP; purity number of 3), horse heart myoglobin (Mb), Hemin (Protoporphyrin IX), Fluoranthene, 2-Butanone, Dithiothreitol (DTT) and all used oligonucleotides with modifications or left on solid support (see Table 1) were purchased from Sigma-Aldrich. O-(benzotriazol-1-yl)-N,N,N',N'-tetramethyluronium hexafluorophosphate (HBTU), hydrogen peroxide (30%) and 3% dichloroacetic acid in dichloromethane were from Fluka. N,N-dimethylformide (DMF), *tert*-butylamine, N,N-Diisopropylethylamine (DIPEA) and 9-Methylanthracene was obtained from Acros. Acetonitrile (ACN) and Methanol (MeOH) were purchased from Roth. N-Hydroxybenzotriazole (HOBt) and AmplexRed were from Nova Biochem and Invitrogen, respectively. Bifunctional crosslinker Sulfosuccinimidyl 4-[N-maleimidomethyl]cyclohexane-1-carboxylate (sSMCC) was obtained from Pierce. VIVA-Spin columns (MWCO 10kDa) were purchased from VivaScience, untreated F96 microtiterplates and F16-maxisorp modules from NUNC and Sephadex NAP-5 and Sephadex NAP-10 size exclusion columns from Amersham Bioscience.

Buffers. Phosphate buffer (mix of 0.1 M KH_2PO_4 and K_2HPO_4 to obtain a pH of 7.4), PBS buffer (phosphate buffer + 300 mM NaCl), TE (10 mM Tris-Cl, 1 mM EDTA, pH 7.4), TRIS A (20 mM Tris-Cl, pH 8.3), TRIS B (20 mM Tris-Cl, 1.5 M NaCl, pH 8.3)

DNA-heme conjugates. Synthesis of the DNA-heme conjugates was carried out as reported before (*1, 2*). In brief, Hemin (Protoporphyrin IX) was activated in solution by using O-(benzotriazol-1-yl)-N,N,N',N'-tetramethyluronium hexafluorophosphate (HBTU), N-

Hydroxybenzotriazole (HOBt) and N,N-Diisopropylethylamine (DIPEA) in DMF and coupled to the 5'-alkylamino-modified oligonucleotides. The oligonucleotides were still attached the the controlled porous glass (CPG) solid support, while the trityl amino protecting group was removed by use of 3% dichloroacetic acid in methylcyanide (ACN) as deprotection solution. Coupling at room temperature (1.5 hours) yielded, after thorough washing with DMF, ACN and drying under Argon, heme-DNA conjugates with 1 ($hemeD_1$) or 2 ($hemeD_2$) DNA-oligonucleotides attached to the carboxylic groups of the heme. Subsequent to incubation of the CPG coupled products in a solution of *tert*-butylamine, MeOH, H_2O (1:2:1 v/v/v) and 65°C to cleave them from the solid support, the heme-DNA conjugates were purified with reversed-phase HPLC (A:Ammoniumacetate, B:Acetonitrile, linear gradient). For examplary chromatogram, see Figure S1A). Buffer exchange using NAP-5 and NAP-10 columns with water as solvent yielded the desired $hemeD_1$ and $hemeD_2$ which were subsequently analyzed by MALDI (see Figure S2A and B).

Apoenzyme reconstitution to generate DNA-enzyme conjugates. The apoenzymes apoMb and apoHRP, lacking their heme cofactor, were prepared by Teale's 2-butanone method (*3*). Briefly, 200 μL of a 50 μM aqueous solution of the enzyme was acidified to pH 2.3 (Mb) or 2.5 (HRP) using 0.1 M HCl and the heme was extracted by addition of ice cold 2-butanone. The colorless apoenzyme solution was then passed through a NAP-5 size exclusion column to remove the excess of 2-butanone. These freshly prepared apoenzymes were then reconstituted with DNA-heme conjugates (in phosphate buffer) at 4°C and incubated 24 to 48 hours, since the reconstitution of apoHRP with DNA-heme conjugates takes more time, as described before (*1*). The semisynthetic DNA-enzyme conjugates (rMbD1, rMbD2 and rHRPD1, rHRPD2, see Figure 1) were analyzed and purified by FPLC by using a linear gradient of 1.5 M NaCl in Tris buffer, pH 8.3 (TRIS B) over 25 min (for example, see Figure S1B) that followed centrifugation with VIVA-Spin columns (MWCO 10kDa) and rebuffering to PBS buffer. Concentrations were determined spectrophotometrically.

Chemical DNA-HRP conjugates. For the activation of the 5'-thiolated oligonucleotide (SHF1, SHF5, SHF9 or SHF10; oligonucleotide sequences are identical to those given for oligomers F1, F5, F9, and F10 in Table 1) in TE buffer, 60 μL of a 1 M dithiothreitol (DTT) solution in H_20 was added, briefly mixed and incubated overnight at 37°C. In the meantime, 2 mg of the bifunctional crosslinker sulfosuccinimidyl 4-[N-maleimidomethyl]cyclohexane-1-carboxylate (sSMCC) were dissolved in 60 μL of DMF. The sSMCC-solution was then combined with 200 μL of a 100 μM solution of HRP in phosphate buffer (0.1M, pH 7.4). This mixture was protected from light and incubated for 1 hour at room temperature. Prior to

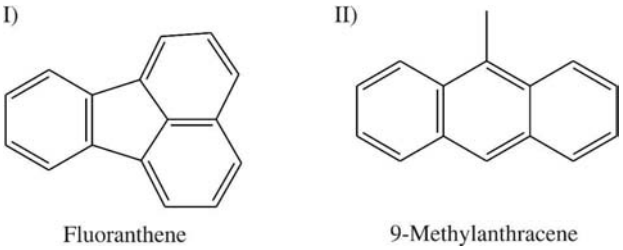
combining the thiolated DNA and the HRP-crosslinker solutions, both solutions were purified by size exclusion chromatography using NAP-5 and NAP-10 columns, using phosphate buffer (0.1M, pH 7.4). The combined solutions were protected from light and incubated at room temperature for 2 hours. Subsequently, the reaction mixture was transferred to a VIVA-Spin column (MWCO 10kDa) for buffer exchange to TRIS A and to remove starting materials. Repeated centrifugation steps at 4500 rpm were used for concentration of the sample until a final volume of 200 – 300 μL was reached. The chemical DNA-HRP conjugates were then further purified via FPLC using MonoQ Anion Exchange Column and linear gradient (TRIS A and TRIS B). The DNA-HRP conjugates, containing only one oligonucleotide per HRP, were collected, concentrated and rebuffered in PBS using VIVA-Spin column. Concentration was determined spectrophotometrically and purity was analyzed by non-denaturing acrylamide gel-electrophoreses.

Peroxidase assays. Michaelis-Menten kinetic analyses of the various enzyme-DNA conjugates were carried out as previously described (*2*). Peroxidase assays were measured with the multiwellplate reader Synergy II from BioTek (Bad Friedrichshall, Germany) and carried out in black 96-well microtiterplates from NUNC. In one row of the plate the reaction mixture consisting of hydrogen peroxide and AmplexRed in phosphate buffer (0.1 M, pH 7.4, 300 mM NaCl) was prepared in sufficient amount to start the reaction in each well simoultaneously with a multichannel pipette. In the next rows of the plate the negative control and the enzyme solutions were present (each 50 μL). Subsequent 50 µL of the reaction mixture were added to each well to start the reaction. The final concentrations were 1 mM hydrogen peroxide, 10 nM rMb and 5 nM rHRP respectively. The AmplexRed concentrations varied from 0.05 to 200 µM. Determination of Michaelis-Menten-constants was carried out similar as described before (*2*). All the kinetic curves of the conjugates revealed substrate inhibition characteristics, which was accounted for by using the appropriate two parameter fit for Michaelis-Menten kinetics (*4*). To obtain Michaelis–Menten parameters Equation (1) was used, which takes into account the effects occurring from substrate inhibition.

$$\frac{v_0}{[\mathrm{E}]_0} = \frac{k_{\mathrm{cat}}[\mathrm{S}]}{K_{\mathrm{M}} + [\mathrm{S}]\left(1 + \frac{[\mathrm{S}]}{K_{\mathrm{S}}}\right)} \qquad (1)$$

Determination of competetive vs non-competetive inhibitor action. To determine the nature of inhibition of HRP by 9-Methylanthracene and Fluoranthene (Scheme S1), kinetic measurements of Amplex Red peroxidation were carried out as described above, however, in

presence of constant inhibitor concentrations. To prepare the Lineweaver-Burk-Plots, the data obtained were normalized and $1/v_0$ was plotted against 1/[S], depicting the reziprokal substrate concentration of Amplex Red (*5*). Exemplary figures are shown in Figure S4.



Scheme S1: Structures of the two inhibitors of HRP used in this study.

Determination of IC50 values. For the determination of the IC50 values the similar pippetting scheme was used, as described for Michaelis-Menten kinetics. However, various concentrations of the inhibitors 9-Methylanhracene and Fluoranthene were present in these measurements while Amplex Red concentration was fixed to 10 μM. The inhibitors were diluted in Acetonitrile and adjusted to a range of concentration (10^{-5} μM to 500 μM). This way the same volume of Acetonitrile was present in all samples. Enzyme concentrations were always 5 nM and the concentration of hydrogen peroxide was 1 mM. Analysis was carried out in 96-well microtiterplates from NUNC using the Synergy II microplate reader for fluorescence measurements. The resulting data are shown in Figures S5-S9.

Enhanced Survival of Neural Cells Embedded in Hydrogels Composed of Collagen and Laminin-Derived Cell Adhesive Peptide

Makiko Hiraoka, Koichi Kato, Tadashi Nakaji-Hirabayashi, and Hiroo Iwata*

Institute for Frontier Medical Sciences, Kyoto University, 53 Kawahara-cho, Shogoin, Sakyo-ku, Kyoto 606-8507, Japan.

To develop biomaterials that serve to improve the survival of neural cells transplanted into central nervous tissues, type I collagen-based hydrogels were prepared as a cell carrier. The hydrogels were modified with a laminin-derived peptide that is known to have an affinity for alpha3beta1 integrin, to transduce antiapoptotic signaling in embedded cells. For the modification of collagen, the peptide was fused to the N- or C-terminus, or both termini of a collagen-binding polypeptide domain by means of recombinant DNA technology. The chimeric proteins were characterized by polyacrylamide gel electrophoresis and circular dichroism spectroscopy, while binding of chimeric proteins to collagen-coated substrates was verified by surface plasmon resonance analysis under physiological conditions. Cell culture assays revealed that the adhesion of neurosphere-forming cells to collagen-coated polystyrene surfaces was significantly promoted by the incorporation of the chimeric proteins in a peptide-density dependent manner. The live/dead assays for cells cultured for 24 or 48 h in the hydrogels revealed that peptide incorporation improved the survival of cells embedded in collagen hydrogels. These results suggest that collagen hydrogel containing the laminin-derived peptide provides microenvironments suitable for the survival of neural cells.

INTRODUCTION

Recently, stem cell transplantation has received much attention as potential treatments for neurodegenerative diseases and traumatic injuries of the central nervous system (*1*). Neural stem/progenitor cells derived from brain tissues or embryonic stem cells have been transplanted after appropriate processing in vitro. Many studies demonstrated the engraftment of neural stem/progenitor cells directly infused into the brain of model animals (*2*). However, the number of cells surviving initial few days in the host tissues is limited, which reduces therapeutic effects of cell transplantation (*3*). One of the most critical causes of this problem may be cellular apoptosis that is triggered by disruption of cell−cell and cell−extracellular matrix interactions upon cell harvesting for transplantation (*4, 5*). In addition, infiltration of inflammatory microglia into transplanted sites is considered as another cause for limited engraftment (*6, 7*).

In an attempt to promote cell survival, we have studied the development of collagen-based hydrogels to be used as a carrier for neural cells (*8, 9*). We expect that the form of hydrogels serves as a temporal barrier against infiltrating microglia, reducing adverse effects due to acute inflammation. To enhance cell survival, attempts were made to incorporate epidermal growth factor to the collagen matrix (*8*). That study led us to suppose as well that, in addition to growth factor stimulation, signaling through cell adhesion molecules would have additional effects for promoting cell survival. In practice, hippocampus neurons were shown to adhere and extend neurites on collagen that incorporated a peptide mimetic of the neural cell adhesion molecule (*9*). In contrast, here we examined the effects of an integrin-binding peptide on the survival of neural cells.

It has been reported that neural stem cells express various integrin complexes (*10*) whose interactions with extracellular matrix play important roles in the development of the central nervous system (*11, 12*). Among integrins expressed on neural stem cells, $\alpha 3\beta 1$ integrin is known to interact with laminin-5 and has been implicated in brain development (*13*) through the modulation of neuronal migration and neuron-glial interactions (*14, 15*). In addition, cell adhesion to laminin-5 via $\alpha 3\beta 1$ integrin was reported to mediate survival signaling in a variety of epithelial cells (*16, 17*). For these reasons, we sought a peptide sequence capable of specific binding to $\alpha 3\beta 1$ integrin and incorporated such a peptide into collagen hydrogels to promote the survival of embedded neural cells on account of integrin signaling.

We employed here a small peptide, PPFLMLLKGSTR, derived from the G3 domain of a laminin $\alpha 3$ chain of laminin-5 (designated this peptide as G3P hereafter). Kim et al. (*18*) demonstrated that this sequence has a strong affinity for $\alpha 3\beta 1$ integrin expressed on epithelial cells. To incorporate the peptide into collagen hydrogels, we adopted a similar strategy as in our previous studies (*8, 9*): Chimeric proteins consisting of G3P and the A3 domain of von Willebrand factor (vWF) that has an affinity for collagen α chains (designated this domain as CBD hereafter) were prepared by recombinant DNA technology. It was shown that (*8*) CBD contained in the chimeric proteins specifically bound to type I collagen under physiological conditions, presenting its fusion partners on collagen.

In the present study, chimeric proteins with different domain structures were prepared. The G3P was fused to the C- or N-terminus, or both termini of CBD, which allows us to study the effects of molecular architecture. Another polypeptide that contained no G3P was prepared and used as a control. These proteins were bound to a collagen-coated polystyrene surface to evaluate the effect of chimeric proteins on the adhesion and neurite extension of the neural stem cell-containing population. Further investigation was conducted to determine the viability of neural cells embedded in collagen hydrogels that incorporated G3P-containing chimeric proteins. In this article, we report that the incorporation of G3P significantly promotes cell survival in collagen hydrogels.

EXPERIMENTAL PROCEDURES

Genetic Engineering. A bacterial expression system was used to synthesize three types of chimeric proteins consisting of G3P

and CBD. The structures of these proteins are shown in Figure 1. Chimeric proteins fused with G3P at the N-, C-, and both termini are designated as nG3P-CBD, cG3P-CBD, and dG3P-CBD, respectively. A control protein lacking G3P is designated as CBD. The complete sequence of chimeric proteins is provided in Supporting Information.

For the preparation of chimeric genes, polymerase chain reaction (PCR) was performed using primers shown in Table 1. A DNA sequence encoding GP3 was incorporated in forward and/or reverse primers depending on the structure of chimeric proteins. Forward primers contained an Nde I restriction site, while reverse primers contained an Xho I site. The chimeric genes for four proteins are separately amplified from the EGF-CBD expression vector (*8*). PCR was performed using a thermal cycler (Gene Amp PCR 9700G, Applied Biosystems) under the following conditions: 35 cycles, denaturation at 94 °C for 30 s, annealing at 62 °C for 30 s, and extension at 72 °C for 30 s. DNA fragments thus obtained were separated by agarose gel electrophoresis and digested with restriction enzymes, Nde I and Xho I. The fragments were inserted into the upstream of 6 × histadine-tag in pET-22b(+) plasmid (Novagen) and transformed to *Escherichia coli* (*E. coli*) DH5α. After overnight culture, colonies were randomly picked up, and the presence of the plasmid was verified by colony PCR using primers specific for T7 promoter and T7 terminator. The correctness of the plasmids was verified by sequencing. Cells harboring the correct plasmid were cultured in LB medium to prepare glycerol stocks.

Protein Expression. *E. coli* strain BL21-CodonPlus (Stratagene) was transformed with the plasmid and cultured in a medium (Overnight Express Autoinduction System, Novagen) at 37 °C for 12 h. Proteins expressed as inclusion bodies were extracted with 20 mM phosphate buffer (pH 7.4) containing 8 M urea and 5 mM 2-mercaptoethanol and purified by Ni-chelate affinity chromatography using a Prime ÄKTA system (GE Healthcare) equipped with a His Trap HP column (GE Healthcare). The purity and the molecular size of the proteins were analyzed by sodium dodecylsulfate−polyacrylamide gel electrophoresis (SDS-PAGE). The proteins were refolded by stepwise dialysis against the series of buffers (see Supporting Information for buffer compositions). Finally, the solutions of refolded proteins in 5 mM 2-amino-2-hydroxymethyl-1,3-propanediol (Tris)-HCl buffer were stored at −80 °C until use.

Circular Dichroism (CD) Spectroscopy. CD spectra were recorded using JASCO J-805 spectropolarimeter. Stock solutions of proteins were diluted with 5 mM Tris-HCl (pH 8.9 for CBD, nG3P-CBD, and cG3P-CBD; pH 9.5 for dG3P-CBD) to the final concentration of 150 μg/mL. Far-UV CD spectra were recorded in a 0.1 cm path length cell at 20 °C, a response time of 0.5 s, a bandwidth of 1 nm, and a scan speed of 100 nm/min with an accumulation of eight scans. Pure Tris-HCl buffer (5 mM, pH 8.9 or 9.5) was used as reference.

Surface Plasmon Resonance (SPR) Analysis. The binding of chimeric proteins to collagen was analyzed by SPR as reported before (*9, 19*). In brief, a glass plate bearing a thin gold layer and a carboxylic acid-terminated self-assembled monolayer was mounted to the hemicylinderical glass prism of an SPR sensor equipped with an He−Ne laser tube. Light reflectance was continuously monitored at a fixed incident angle, while protein or pure buffer solution was sequentially circulated over the surface of the plate in a flow cell at 37 °C and a flow rate of 3 mL/min. After equilibrating with phosphate-buffered saline (PBS), the surface was exposed to 100 μg/mL type I collagen solution (Sigma) in 0.1 M acetic acid buffer (pH 4.9) for 30 min, followed by circulation of PBS for 60 min to wash the surface. Then, chimeric protein solution (diluted with PBS to a final concentration of 50 μg/mL) was circulated for 60 min to bind the protein to preadsorbed collagen, followed by washing with pure PBS for 60 min. The reflectance changes were used to determine a resonance angular shift and then converted to the surface density of protein assuming the unit angular shift of 0.5 μg/cm^2/DA (*20*).

Cell Isolation and Adhesion Assay. Chimeric protein was diluted with PBS to a concentration of 50 μg/mL. The solution was added to a collagen-coated polystyrene dish (Asahi Techno Glass Corp., Tokyo, Japan) and incubated at room temperature for 2 h to bind chimeric protein onto collagen. The plate was washed with PBS to remove unbound protein and immediately used for cell adhesion assays. As reported previously (*21*), the striatum was isolated from rat fetuses (embryonic day 16) and dissociated into single cells, according to the guideline of the institutional Animal Welfare Committee. The cells were cultured in suspension to form neurospheres (*22*) that contained neural stem cells (50−60% of total cells) as well as more differentiated cells (*21*). Neurospheres at passage 2 were dissociated into single cells by trypsin treatment. This cell population is referred to as neurosphere-forming cells in this paper. The cells were suspended in DMEM/F12 (1:1) (Gibco) containing 2% B27 supplements (Gibco), 5 μg/mL heparin, 100 unit/mL penicillin, and 100 μg/mL streptomycin. The cells were seeded to the protein-bound dish at a density of 5.0 × 10^4 cells/cm^2 and incubated at 37 °C under 5% CO_2 atmosphere. In separate experiments, soluble peptide (PPFLMLLKGSTR, Invitrogen) was dissolved in a cell suspension to a concentration of 25 μg/mL, and the cells were incubated at 37 °C for 30 min prior to seeding. The cells were then cultured on the protein-bound dish under the same condition as described above to confirm the specific effect of surface-bound peptide on cell adhesion. After incubation for 6 h, cells were washed gently with the same medium as mentioned above to remove weakly attaching cells and observed with a phase-contrast optical microscope (DP51, Olympus Optical CO., Ltd., Tokyo, Japan). The number of cells that adhered to the dish was determined on the microphotographs acquired at five different sights (area: 0.33 mm^2) on the same sample and averaged. The data are expressed in this paper as mean ± standard deviation for four independent samples.

was mixed on ice with 5-fold concentrated culture medium and reconstitution buffer (50 mM NaOH, 260 mM $NaHCO_3$, 200 mM HEPES) at a volume ratio of 7:2:1. Then, nG3P-CBD solution was added to the mixture to an nG3P-CBD concentration of 300 μg/mg collagen. An aliquot of the mixture (500 μL) was added into each well of a 12-well tissue culture plate and incubated at 37 °C for 90 min to allow formation of hydrogels with a thickness of approximately 1 mm. The neurosphere-forming cells obtained as above were seeded onto the collagen hydrogel at a density of 1.0×10^5 cells/cm^2 and incubated for 4 h at 37 °C under 5% CO_2 and subsequently overlaid with 500 μL of a chimeric protein-containing collagen hydrogel of the same composition as described above to embed the cells in a hydrogel. The embedded cells were additionally cultured for 24 and 48 h in an incubator at 37 °C under 5% CO_2 atmosphere.

Cell Viability. The live/dead assay (*23*) was performed by staining cells with 3′,6′-di(*O*-acetyl)-4′,5′-bis[*N*,*N*-bis(carboxymethyl)aminomethyl]fluorescein, tetraacetoxymethyl ester (calcein-AM), and propidium iodide (PI). Cells cultured in a collagen gel for 24 and 48 h were exposed to PBS containing 1 μg/mL calcein-AM, 1 μg/mL PI, 0.05 mM $MgCl_2$, and 0.9 mM $CaCl_2$ for 30 min and then washed with PBS containing 0.05 mM $MgCl_2$ and 0.9 mM $CaCl_2$. In this procedure, calcein-AM penetrates into the cytosol of living cells and fluorescently stains them in green, while PI fluorescently stains the nucleus of dead cells in red. The microphotographs of cells stained in green and red were recorded using the epifluorescent microscope (DP70, Olympus). For the quantification of living cells, the number of cells stained in red (dead cells) was determined on five different microphotographs (area: 0.54 mm^2) recorded for each sample, while total cell numbers were determined by Hoechst staining. Cell viability was determined as percent living cells to the total cells and presented as mean ± standard deviation for four independent samples.

Statistical Analysis. The results of cell proliferation and viability assays were statistically analyzed using a software (JMP5.0.1a, SAS Institute Inc., Cary, NC). One-way analysis of variance (ANOVA) was performed for assessing significant differences. Tukey's honestly significant difference (HSD) test was performed for multiple comparisons at a significance level set of $p < 0.05$.

RESULTS

Preparation of Chimeric Proteins. Figure 2 shows the result of SDS-PAGE analysis for the chimeric and control proteins. These proteins were separated as single bands. The molecular weight estimated from the mobility of protein bands are as follows: CBD 22 kDa, nG3P-CBD 23 kDa, cG3P-CBD 23 kDa, and dG3P-CBD 24 kDa. These results are consistent with the molecular weights predicted from their amino acid compositions.

As shown in Figure 3, all the proteins gave CD spectra with minima at 208 and 222 nm for the α-helix and at 216 nm for the β-sheet (*24*). Compared with CBD, nG3P-CBD and cG3P-CBD exhibited slightly decreased Cotton effects, indicating lower contents of secondary structure. dG3P-CBD exhibited much more reduction in negative Cotton effects at 208, 216, and 222 nm. The α-helix contents of these proteins were determined from mean residue molar ellipticity at 222 nm (*25*) and compared with those calculated based on crystallographic data (*26*). The results are shown in Table 2. The experimentally determined α-helix contents are in good agreement with predictions for CBD, nG3P-CBD, and cG3P-CBD, suggesting the structural integrity of these proteins. In the case of dG3P-CBD, a relatively large difference was observed between experimental and predicted values. This is probably due to the fact that proper refolding is hindered by hydrophobic amino

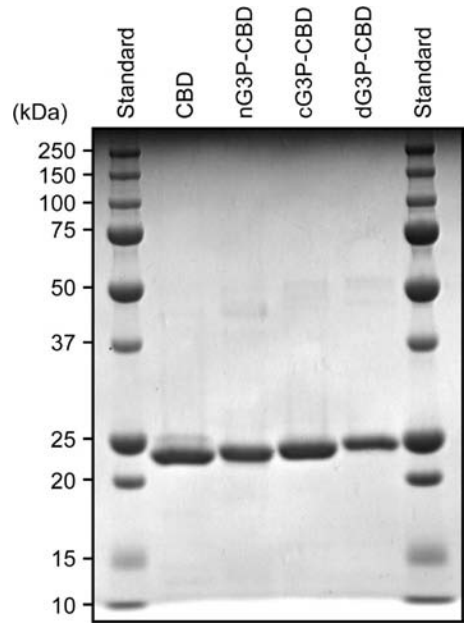

Figure 2. The result of SDS-PAGE analysis. Chimeric proteins were electrophoresed in 12.5% polyacrylamide gel and visualized by coomassie brilliant blue staining. Molecular weight standard was electrophoresed in two lanes at both sides.

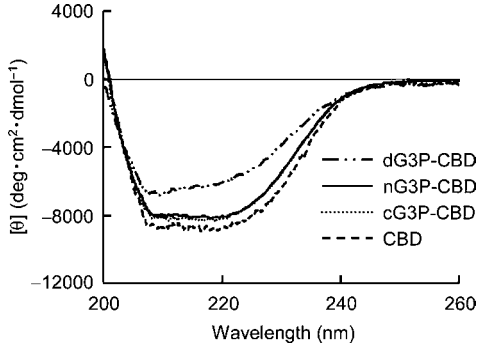

Figure 3. Far UV circular dichroism spectra of chimeric proteins recorded at 20 °C. Mean residue molar ellipticity [θ] is shown as a function of wavelength.

Table 2. α-Helix Content Determined from CD Spectra

protein	α-helix content (%) determined from CD spectra	α-helix content (%) predicted from structural data[a]
CBD	28.4	28.9
nG3P-CBD	26.2	27.3
cG3P-CBD	26.2	27.3
dG3P-CBD	19.5	25.8

[a] Calculated under the assumption that G3P, hexahistidine, and Leu-Glu sequence have no α-helical structure. α-Helix content of the wild-type A3 domain is 30.2% when calculated from structural data (*23*).

acids rich in G3P. In practice, dG3P-CBD had poor solubility in buffer solutions compared with other chimeric proteins. This appeared remarkably when the solutions at relatively high concentration were dialyzed against neutral buffer solutions.

Binding of Chemic Proteins to Collagen. Figure 4 shows SPR sensorgrams recorded for the binding of chimeric proteins to collagen. The amounts of bound proteins determined from these sensorgrams are shown in Table 3. As is seen, CBD, nG3P-CBD, and cG3P-CBD bound to collagen at a similar density to each other. On the other hand, more than 2-fold larger amount of dG3P-CBD bound to the collagen compared with

Table 3. Amount of Chimeric Proteins Bound to the Collagen-Coated Surface Determined by SPR Analysis[a]

chimeric protein	chimeric protein bound (ng/cm^2)[b]	surface density of G3P (10^4 molecules/μm^2)
CBD	47 ± 6	—
nG3P-CBD	57 ± 16	1.5 ± 0.4
cG3P-CBD	61 ± 11	1.6 ± 0.3
dG3P-CBD	131 ± 27	6.6 ± 1.4

[a] The amount of collagen preadsorbed to the substrate: 120 ± 30 ng/cm^2 (mean ± standard deviation for n = 12). [b] Mean ± standard deviation for n = 3.

nG3P-CBD and cG3P-CBD. Accordingly, the surface density of G3P is approximately 4-fold higher with dG3P-CBD than with nG3P-CBD and cG3P-CBD. It seems that the hydrophobic nature of dG3P-CBD has an additional contribution to collagen binding.

Cell Adhesion to Collagen-Coated Surfaces. Reverse transcriptase-PCR (RT-PCR) was performed to analyze the expression of mRNA for α3 and β1 integrins in neurosphere-forming cells. As shown in Supporting Information Figure S1, these cells certainly express both α3 and β1 integrins, although the presence of an α3β1 complex is not identified. These cells were cultured for 6 h on the collagen-coated surfaces bound with chimeric proteins. Figure 5 shows the phase-contrast images of these cells. It is clearly seen that few cells adhered to the collagen-coated dish bearing no chimeric proteins (Figure 5A). Similarly, poor cell adhesion was observed on a collagen-coated surface bound with CBD (Figure 5B). In contrast, a substantial number of cells are seen on surfaces with nG3P-CBD, cG3P-CBD, and dG3P-CBD (Figure 5C−E). These cells extended dendrites, producing cellular networks. The addition of soluble G3P to the medium largely blocked cell adhesion to the collagen-coated surface with chimeric proteins (Figure 5F), suggesting that the observed cell adhesion (Figure 5C−E) is mediated by specific interaction of cells with the surface-bound G3P. The number of adhering cells are shown in Figure 6. The data show that cell adhesion to collagen was significantly promoted by nG3P-CBD and cG3P-CBD, and much more by dG3P-CBD.

It seems that cell differentiation was not effectively induced by the chimeric proteins because of the short period (6 h) after seeding. The formation of dendrites (Figure 5C−E) is not indicative of cell differentiation. In fact, as shown in Supporting Information Figure S2, the fraction of neural stem cells was rather higher in the cells adhering to the G3P-bearing surface (70%) than that in neurosphere-forming cells (50−60%) (*21*), indicating somewhat preferential adhesion of neural stem cells to the G3P-bearing surface.

Cell Survival in Collagen Hydrogels. Figure 7 shows the phase-contrast images of cells cultured in a collagen hydrogel with or without incorporated nG3P-CBD. Although cell adhesion was most effectively promoted by dG3P-CBD on polystyrene-based substrates (Figures 5 and 6), we used nG3P-CBD in this experiment. This is because the handling of nG3P-CBD was much easier because of its moderate hydrophilicity. As shown in Figure 7, observation of cells with an optical microscope was difficult because cells were not distributed in the same plane. However, careful inspection of cells revealed that most of the cells had round shapes in a pure collagen hydrogel. On the other hand, many cells are seen to flatten and extend dendrites in the collagen hydrogel with incorporated nG3P-CBD. Compared to the cells on rigid polystyrene substrates (Figure 5), cell aggregation is noticeable in the hydrogels.

Figure 8 shows the results of live/dead assays performed for cells cultured in collagen hydrogels with or without incorporated nG3P-CBD. In pure collagen hydrogels, the fraction of living cells decreased rapidly likely due to an anoikis effect, and only

Figure 4. All measurements were carried out at 37 °C.

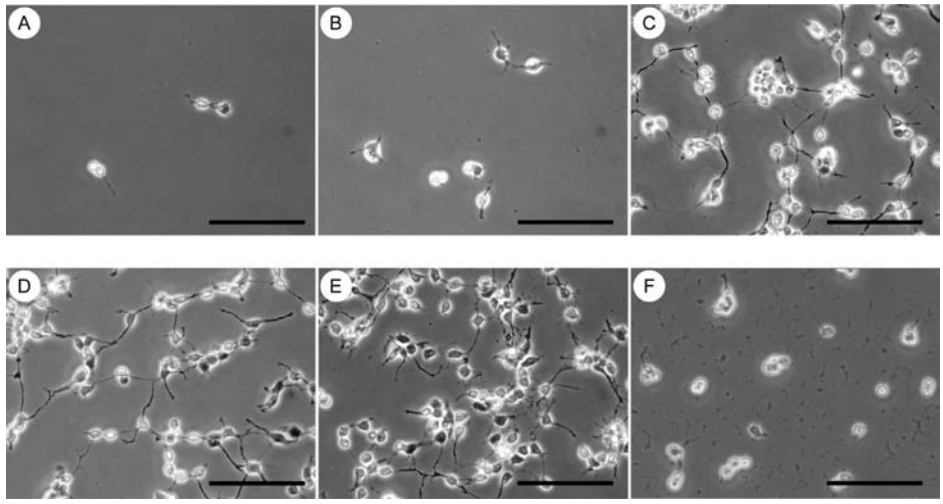

Figure 5. Phase-contrast microphotographs of cells cultured for 6 h on the collagen-coated polystyrene surfaces bound with or without chimeric proteins. (A) No chimeric proteins were bound (collagen-coated surface). (B−E) Collagen-coated surfaces bound with (B) CBD, (C) nG3P-CBD, (D) cG3P-CBD, and (E) dG3P-CBD. (F) Cells were cultured on the collagen-coated surface bound with dG3P-CBD in a medium containing 25 μg/mL soluble G3P. Bars: 100 μm.

21.0 ± 5.6% of cells survived 2 days. On the other hand, a significantly larger number of cells survived 24 h (54.0 ± 4.8%) or 48 h (45.5 ± 3.7%) in collagen hydrogels with incorporated nG3P-CBD. These results indicate that cell death was delayed by incorporating nG3P-CBD.

DISCUSSION

This study demonstrates that the viability of neurosphere-forming cells embedded in a collagen hydrogel is improved by incorporating G3P to the hydrogel (Figures 7 and 8). Because the viability of most cells largely relies on adhesion signaling (*27*), the improved viability is conceivably the consequence of enhanced cell adhesion in the hydrogel networks. In fact, neurosphere-forming cells cultured in the G3P-incorporating collagen hydrogel exhibited more extended forms than in the pure collagen hydrogel. The continued existence of an increased number of living cells for 2 days will be greatly beneficial to cell transplantation therapy in the brain.

In this study, the peptide G3P was attached to collagen networks through specific interactions of the fusion partner CBD with collagen. To date, a variety of conjugation methods have been reported for the modification of collagen with various peptides (*28, 29*) including G3P as well (*30*). These methods often require severe reaction conditions. In addition, it is not always straightforward to modulate the orientation and density of peptides with conventional chemical methods. Our approach using biospecific interactions allows us to densely immobilize a peptide on collagen under physiological conditions. This is exemplified by the data presented in Table 3 as well as our previous studies (*8, 9*). In addition, one can easily design

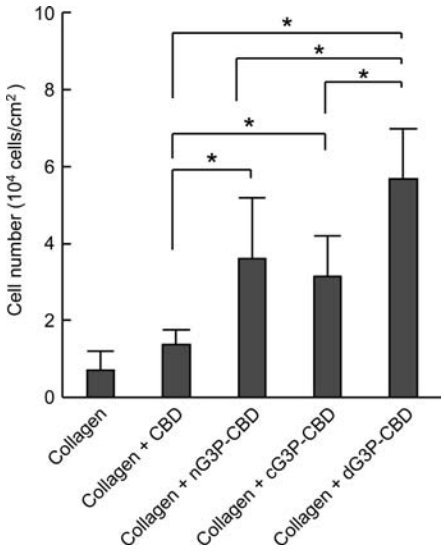

Figure 6. The number of cells adhered to collagen-coated polystyrene surfaces bound with chimeric proteins. Data are expressed as mean ± standard deviation for $n = 4$. *Statistically significant ($p < 0.05$, Tukey's HSD test).

collagen-binding chimeric proteins bearing different peptides using the CBD as a universal coupler.

The laminin-derived cell-adhesive peptide, G3P, was originally identified by Kim et al. as a ligand for $\alpha 3\beta 1$ integrin expressed on epithelial cells (*18*). This peptide is contained in a G3 domain of a laminin α3 chain, a component of a laminin-5 isoform. The interaction between laminin-5 and $\alpha 3\beta 1$ integrin was reported to have an antiapoptotic effect in a variety of epithelial cells (*16*, *17*). Laminin-5 is abundantly found in epithelial basement membranes (*31*) and also expressed in developing brain tissues (*32*). Therefore, the collagen matrix bound with G3P can be regarded as a biomaterial that mimics in part the native basement membrane.

We examined the effects of chimeric proteins with three different structures: G3P was fused at the N- or C-terminus, or both termini of CBD (Figure 1). It was shown that nG3P-CBD and cG3P-CBD had comparable properties with regard to solubility, collagen binding (Table 3), and cell adhesion (Figure 5). This finding suggests the structural and functional similarities between G3Ps in nG3P-CBD and cG3P-CBD. A CBD contains a disulfide bond between two cysteine residues located at the N- and C-terminal regions (*26*), forming a globular domain with both termini close each other. Accordingly, it is expected that G3Ps in nG3P-CBD and cG3P-CBD have minor differences with regard to their arrangements in the proteins, although the peptides are tethered to CBD in an opposite orientation.

Among chimeric proteins studied, dG3P-CBD having G3P at the both ends exhibited the highest binding capacity for collagen (Table 3). As described earlier, dG3P-CBD exhibited low solubility due in part to the high occupancy of amino acids with nonpolar side chains (P, F, M, L, and G). Presumably, two G3Ps raise the hydrophobicity of dG3P-CBD. In addition, the slightly disordered structure of this protein, as demonstrated by CD spectroscopy (Figure 3), suggests the enhanced exposure of hydrophobic amino acids that would be located in the core region in the native state. It is likely that such structural alteration enhances the nonspecific adsorption of dG3P-CBD to collagen and hence gives rise to elevated surface density.

The highest cell density observed for the dG3P-CBD-collagen surface (Figures 5 and 6) may be directly related to exceptionally high surface density of G3P (Table 3). The probability of interaction between G3P and integrin may be enhanced on this surface. The range of the G3P density that has influence on the number of adhering cells (15 000−66 000 molecules/μm^2) is similar to the dynamic range of ligand density reported by Maheshwari et al. (*33*) for the adhesion of fibroblasts via interaction between integrins and surface-immobilized RGD peptide. On the other hand, it may not be the case that two G3Ps in the same molecule simultaneously engage in binding to two proximal integrins, contributing to the clustering of

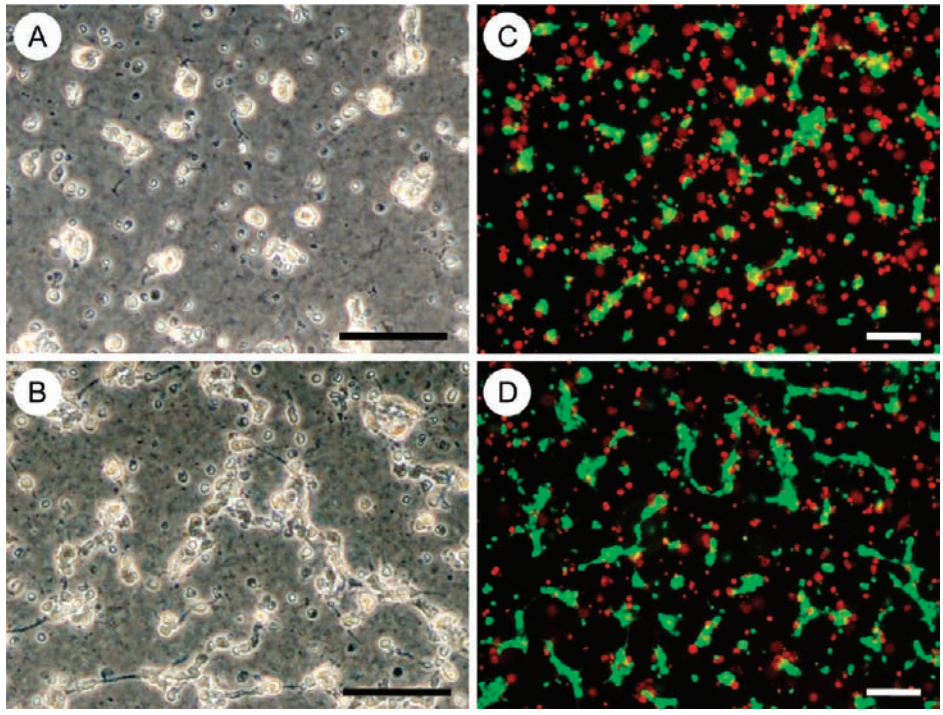

Figure 7. Results of cell culture assays in collagen hydrogels with or without incorporated nG3P-CBD. (C, D) Fluorescent microphotographs of cells cultured for 48 h in (C) a pure collagen hydrogel and (D) a collagen hydrogel containing nG3P-CBD. Cells were stained with calcein-AM (live cells in green) and propidium iodide (dead cells in red). Bars: 100 μm.

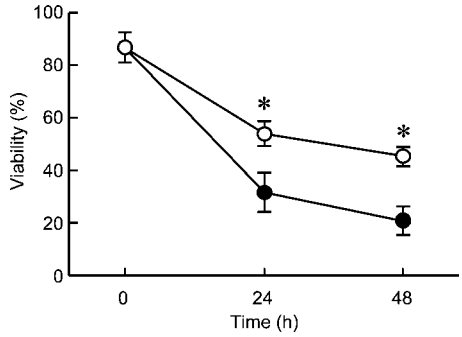

Figure 8. The viability of cells cultured for 24 and 48 h in (○) collagen hydrogels containing nG3P-CBD or (●) pure collagen hydrogels. Data are expressed as mean ± standard deviation for $n = 4$. *Statistically significant ($p < 0.05$, Tukey's HSD test).

integrins and the formation of focal contacts. This is because an $\alpha 3\beta 1$ integrin complex is much larger than the spun of two G3Ps contained in a single dG3P-CBD molecule.

As we observed in the live/dead assays (Figures 7 and 8), a larger number of neurosphere-forming cells survived in collagen hydrogels containing nG3P-CBD than in pure collagen hydrogels. We were unable to distinguish necrotic cells from apoptotic ones by PI staining alone, and possibly both mechanisms were involved in observed cell death. Regarding necrotic conditions, if any, cells were equally effected in both hydrogels, and cell viability may be improved by optimizing culture conditions such as oxygen and nutrient supply. For the observed difference in viability, we assume that this is due to antiapoptotic signaling cascades activated in the cells in consequence of an interaction between G3P and $\alpha 3\beta 1$ integrin. Actually, integrin subunits $\alpha 3$ and $\beta 1$ are both expressed on the neurosphere-forming cells (Supporting Information Figure S1), being in agreement with reports for neural stem cells (*10*), cerebral cortex neurons (*34*), and differentiating neuroblastoma cells (*35*). However, we need further mechanistic study on intracellular signaling to understand more deeply the effect of the incorporated G3P.

CONCLUSION

The chimeric proteins consisting of the laminin-derived G3P and the vWF-derived CBD bind to collagen under physiological conditions, providing collagen-based substrates to which neurosphere-forming cells are able to adhere. When incorporated in collagen hydrogels, the chimeric protein serves to enhance the survival of neurosphere-forming cells in the hydrogels. Although further mechanistic studies are needed, the promoted cell adhesion and survival may be ascribed to signaling mediated by the specific interaction of the G3P with $\alpha 3\beta 1$ integrin. The composite hydrogels reported here have the potential to improve the survival and engraftment of neural cells transplanted into central nervous tissues.

2. Buffer solutions used for refolding of chimeric proteins

Chimeric proteins were sequentially dialyzed against the following buffer solutions:

(1) 50 mM Tris-HCl, 8 M urea, 10 mM NaCl, 0.2 M L-Arg, 0.2 mM DTT

(2) 50 mM Tris-HCl, 8 M urea, 10 mM NaCl, 0.2 M L-Arg

(3) 50 mM Tris-HCl, 2.5 M urea, 10 mM NaCl, 0.2 M L-Arg, 3.75 mM GSH, 0.375 mM GSSG

(4) 50 mM Tris-HCl, 2.5 M urea, 10 mM NaCl, 0.1 M L-Arg, 0.5 mM GSH, 0.3 mM GSSG

(5) 50 mM Tris-HCl, 10 mM NaCl, 0.1 M L-Arg

(6) 20 mM Tris-HCl

(7) 10 mM Tris-HCl

(8) 5 mM Tris-HCl

Abbreviations: Tris; 2-amino-2-hydroxymethyl-1,3-propanediol, L-Arg; L-arginine hydrochloride, DTT; dithiothreitol, GSH; the reduced form of glutathione, and GSSH; the oxidized form of glutathione.

3. Gene expression analysis

Total RNA was isolated from neurosphere-forming cells using SV Total RNA Isolation system (Promega). A hundred nanogram of RNA was used per reverse transcription (RT) reaction using Ready-to-Go You-Prime First-Strand Beads (Amersham) primed by oligo$(dT)_{15}$ (Promega). First-strand cDNA was then amplified by polymerase chain reaction (PCR) using specific primers: integrin α3, (sense) gtggccgtatgaagttacca and (antisense) cacggtctcagacttggctt; integrin β1, (sense) caacctgtgagacctgtcag and (antisense) caatgtccttctccttgcag; glyceraldehyde-3-phosphate dehydrogenase, (sense) tgaacgggaagctcactgg and (antisense) tccaccaccctgttgctgta. Thirty cycles of PCR was performed under the thermal cycling conditions of denaturation at 94 ^{o}C for 30 s, annealing at 55 ^{o}C for 30 s, and elongation at 72 ^{o}C for 30 s. All samples were run triplicate, and the products were analyzed by electrophoresis in 2% agarose gel with ethidium bromide staining. The electrophoresed DNA was imaged using Gel Doc 2000 (BioRad). As shown in Figure S1, neurosphere-forming cells express both α3 and β1 integrins.

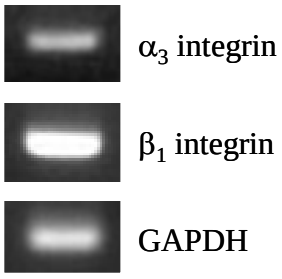

Figure S1. RT-PCR analysis for the expression of α_3 and β_1 integrin mRNA in neurosphere-forming cells. Glyceraldehyde-3-phosphate (GAPDH) was analyzed as an internal standard.

4. Immunocytochemistry

A neural stem cell marker (nestin) and differentiation markers of neuron (β-tubulin III; βIII) and astrocyte (glial fibrillary acidic protein; GFAP) were immunfluorescently stained as reported before (Nakaji-Hirabayashi, T., Kato, K., Arima, Y., and Iwata, H. *Biomaterials* **2007**, *28*, 3517–3529). In brief, after fixation with 4% paraformaldehyde and 0.1% glutaraldehyde, cells were permeabilized by treating with 0.5% TritonX-100 solution and subsequently treated with 2% skim milk solution to block non-specific adsorption of antibodies. Then, the cells were reacted with antibody against nestin (1:200, mouse monoclonal Rat 401, BD Pharmingen), GFAP (mouse monoclonal, MAB3402, Chemicon), or βIII (1:600, rabbit polyclonal, Covance, Princeton, NJ), followed by binding of fluorescently-active secondary antibodies (1:500, Alexa Fluor 594 anti-mouse immunoglobulin G and Alexa Fluor 488 anti-rabbit immunoglobulin G, both from Molecular Probes). Cell nuclei were counterstained with 1 mg/mL Hoechst33258. The localization of secondary antibodies and Hoechst dye was analyzed with an epifluorescent microscope. The results are shown in Figure S2.

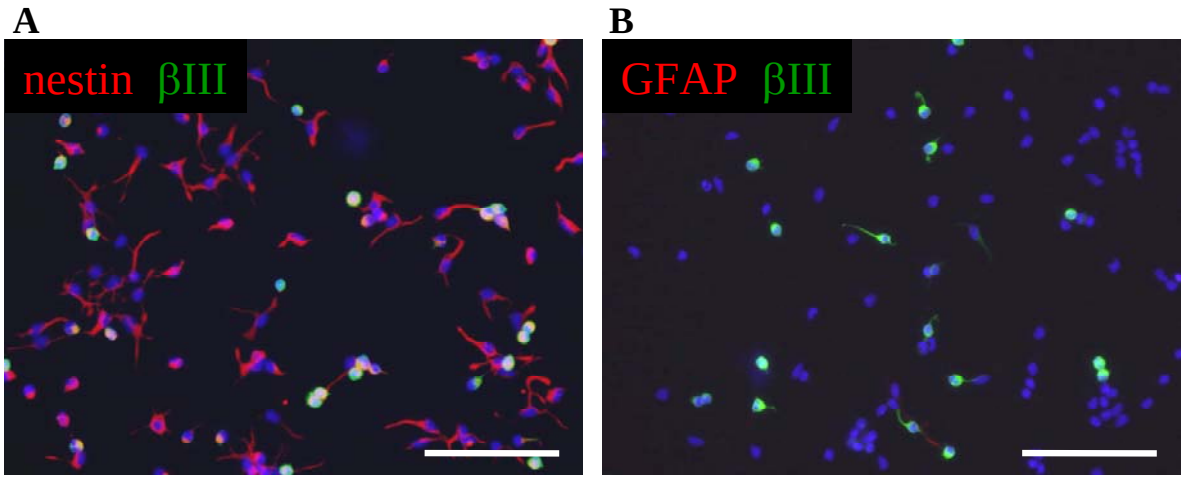

Figure S2. Immunofluorescent staining of neurosphere-forming cells cultured for 6 h on the collagen-coated surface with nG3P-CBD. Primary antibody used: A, nestin (red) and βIII (green); B, GFAP (red) and βIII (green). Nuclei were stained with Hoechst dye. Note that GFAP expression was negligible. The fraction of subpopulations: nestin^{+}βIII^{-}, 70%; nestin^{+}βIII^{+}, 20%; nestin^{-}βIII^{+}, 6%; nestin^{-}βIII^{-}, 4%. Bars: 100 μm.

Glycosylated DOTA−α-Melanocyte-Stimulating Hormone Analogues for Melanoma Targeting: Influence of the Site of Glycosylation on in Vivo Biodistribution

Jean-Philippe Bapst, Martine Calame, Heidi Tanner, and Alex N. Eberle*

Laboratory of Endocrinology, Department of Biomedicine, University Hospital and University Children's Hospital, Basel, Switzerland. Received January 8, 2009; Revised Manuscript Received March 9, 2009

α-Melanocyte-stimulating hormone (α-MSH) is known to bind to the melanocortin receptor 1 (MC1R) which is overexpressed on melanotic and amelanotic melanoma cells. α-MSH analogues are potential candidates for specific targeting of melanoma metastases. Several linear and cyclic radiolabeled MSH peptides have been designed and tested in the past, showing both high affinity for the MC1R in vitro and good incorporation in tumor xenografts in vivo. However, considerable kidney reabsorption of the radiopeptides could not be avoided. With the aim to increase the tumor-to-kidney ratio, we synthesized six glycosylated derivatives of NAPamide, an α-MSH octapeptide analogue with high tumor selectivity and coupled them to the chelator DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid). The peptides were evaluated in vitro for MC1R binding and bioactivity and, after labeling with ^{111}In, for in vitro cellular uptake and in vivo tissue distribution in mice carrying B16F1 melanoma tumors. The glycopeptides showed excellent binding affinities in the low nanomolar to subnanomolar range using both murine and human melanoma cell lines. However, five glycopeptides displayed lower selectivity in vivo than the parent DOTA−NAPamide, because of either a lower tumor uptake or a higher kidney uptake. In particular C-terminal extension of the amide group by a galactosyl moiety increased the kidney retention dramatically. By contrast, an N-terminally positioned galactose residue in DOTA−Gal-NAPamide improved the tumor-to-kidney ratio (4−48 h AUC of 1.34) by a factor of about 1.2 as compared to the parent DOTA−NAPamide (4−48 h AUC of 1.11), thus serving as new lead compound for MC1R-targeting molecules.

INTRODUCTION

The melanocortin type-1 receptor (MC1R), which is overexpressed on the plasma membrane of melanoma cells, is a potential target for the diagnosis or therapy of metastases of malignant melanoma (*1*−*3*). Radiolabeled α-melanocyte-stimulating hormone (α-MSH), the natural ligand of MC1R, and various types of synthetic linear or cyclic analogues have been studied as candidates for MC1R targeting (*4*−*10*). These analogues not only showed excellent binding properties to both murine and human melanoma cells in vitro but also good tumor uptake in vivo (*4*−*10*). However, because of considerable unspecific retention of radioactivity in the kidneys, clinical studies with these compounds remained scarce (*11*).

Generally, renal toxicity of DOTA−containing radiopeptides remains one of the main dose-limiting factors for peptide-targeted radiotherapy (*12*, *13*), as demonstrated for somatostatin analogues (*14*, *15*) which are routinely used in the clinic for the diagnosis and therapy of various tumors expressing somatostatin receptors (*16*, *17*). To improve the in vitro and in vivo characteristics of peptide hormone analogues in general, and of radiolabeled somatostatin or α-MSH derivatives in particular, different types of modification of the chelator−peptide structures have been examined, such as structural stabilization of the peptide (*16*, *18*), reduction of the size of the peptide (*8*), chemical variation of the radiometal chelator (*19*−*21*), the use of different radiometals such as $^{67/68}$Ga, ^{111}In, ^{90}Y, ^{177}Lu, ^{99m}Tc, and ^{188}Re (*6*, *9*, *22*, *23*), the adjustment of the net charge of chelator−peptide complexes (*7*, *24*), the position of the chelator on the peptide (*7*), cyclization of the peptides via a rhenium core (*5*, *9*), and the synthesis of dimerized α-MSH analogues (*25*). Another approach to reduce nonspecific uptake of, for example, somatostatin (*26*) or α-MSH (*6*), by the kidneys is the coinjection of cationic amino acids. All these strategies improved melanoma targeting with radiolabeled α-MSH analogues in experimental models, but none of these lowered kidney uptake sufficiently to allow a broad clinical evaluation of diagnostic or therapeutic MSH radiopharmaceuticals.

Alternative approaches to obtain α-MSH compounds with improved pharmacokinetic properties are needed, yielding molecules with particularly high receptor affinity, low nontarget tissue retention, and an almost exclusively urinary excretion route with minimal kidney reabsorption and retention, in order to further minimize nephrotoxicity. Coupling of carbohydrate moieties to radiopeptides can strongly influence the pharmacokinetics of peptides, owing to the more hydrophilic character of glycosylated molecules (*27*). The excretion of glycosylated radiopeptides into the primary urine may be favored, and reuptake by the tubular system of the kidneys reduced, as shown for glycosylated peptides and proteins (*27*, *28*). It has been shown that carbohydrates, if properly positioned, preserve structure−activity relationships (SAR) of the peptides with their target receptors. For example, glycosylated enkephalin derivatives maintained their binding properties and exhibited prolonged bioavailability (*29*, *30*). The in vivo stability of renin inhibitors could also be improved by glycosylation (*31*), and carbohydrated somatostatin analogues displayed a more favorable pharmacokinetic profile with reduced liver uptake and biliary excretion (*32*−*34*), thus switching the excretion route from hepato-biliary to renal. Sugyama and colleagues (*27*, *28*, *35*) investigated numerous modifications of Arg-vasopressin by coupling a

variety of different sugar moieties to the peptide in order to improve kidney targeting. Their investigations revealed that the affinity of the peptides for kidney tubular cell membranes could be influenced, depending on the type of sugar used (*27*, *28*, *35*).

In this study, we synthesized and evaluated, both in vitro with mouse and human melanoma cells and in vivo with biodistribution experiments using melanoma tumor-bearing mice, several radiolabeled carbohydrated α-MSH analogues whose structure was based on [^{111}In]DOTA−NAPamide previously synthesized in our laboratory and found to be one of the most efficient MSH targeting derivatives (*6*). The novel MSH peptides which contained different carbohydrate moieties inserted into the C-terminus and N-terminus as well as side chains of the NAPamide peptide, included DOTA−NAPamide-Gal, N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, DOTA−[Asp(Gal)^2]-NAPamide, DOTA−Mtr-NAPamide, DOTA−Gluc-NAPamide, DOTA−Gal-NAPamide (Figure 1).

EXPERIMENTAL PROCEDURES

Peptides and Analytical Procedures. α-MSH was a gift from Novartis (Basel, Switzerland), and [Nle^4, D-Phe^7]-α-MSH (NDP-MSH) was purchased from Bachem (Bubendorf, Switzerland). The reference compound DOTA−NAPamide (*6*) and all other peptides were synthesized in our laboratory using a Pioneer peptide synthesizer (PerSeptive Biosystems Inc., Framingham, MA) and the continuous-flow strategy with Fmoc (9-fluorenylmethoxycarbonyl) protection of N$^\alpha$-amino groups (for recent details, see Bapst et al. (*25*)). Fmoc-amino acids were purchased from Novabiochem (Läufelfingen, Switzerland). Fmoc-PAL−PEG−PS polystyrene resin was from Applied Biosystems (Rotkreuz, Switzerland) and TentaGel S TRT-Lys(Boc)-Fmoc acid-labile resin from Fluka (Buchs, Switzerland). Fmoc-Asp(1,2:3,4-diisopropylidene-6-amino-α-D-galactosyl)-OH was a gift from SynphaBase AG (Muttenz, Switzerland). Other carbohydrates and organic reagents were purchased from Fluka or Sigma (Buchs, Switzerland).

NMR spectra were recorded on a Bruker Avance DMX-500 (500 MHz) spectrometer (Bruker, Fällanden, Switzerland). Assignment of ^{1}H and ^{13}C spectra was achieved using 2D methods (COSY, HSQC). Chemical shifts are expressed in ppm using residual $CDCl_3$ and CHD_2OD as references. Mass spectra (MS) were recorded on a Finnigan LCQ Deca (Thermo Fisher Scientific Inc., Waltham, MA) electrospray ion trap small molecules and proteomics MS system. Analytical reversed-phase high-performance liquid chromatography (RP-HPLC) of all peptides was performed on a Jasco PU-980 system (Jasco Inc., Easton, MD) usually with a Waters (Waters, Milford, MA) Symmetry C18 analytical column (5 μm, 3.9 × 150 mm), or a Vydac (Grace, Deerfield, IL) 218TP54 C18 analytical column (5 μm, 4.6 × 250 mm). Preparative RP-HPLC of peptides was performed on the same system but either with a Vydac 218TP510 C18 semipreparative column (5 μm, 10 × 250 mm) or a Waters SymmetryPrep C18 preparative column (7 μm, 19 × 150 mm). Peptides were eluted by applying a gradient of 5−95% solvent B (solvent A: 0.1% trifluoroacetic acid (TFA) in H_2O; solvent B: 0.1% TFA in 70:30 acetonitrile/H_2O; gradient

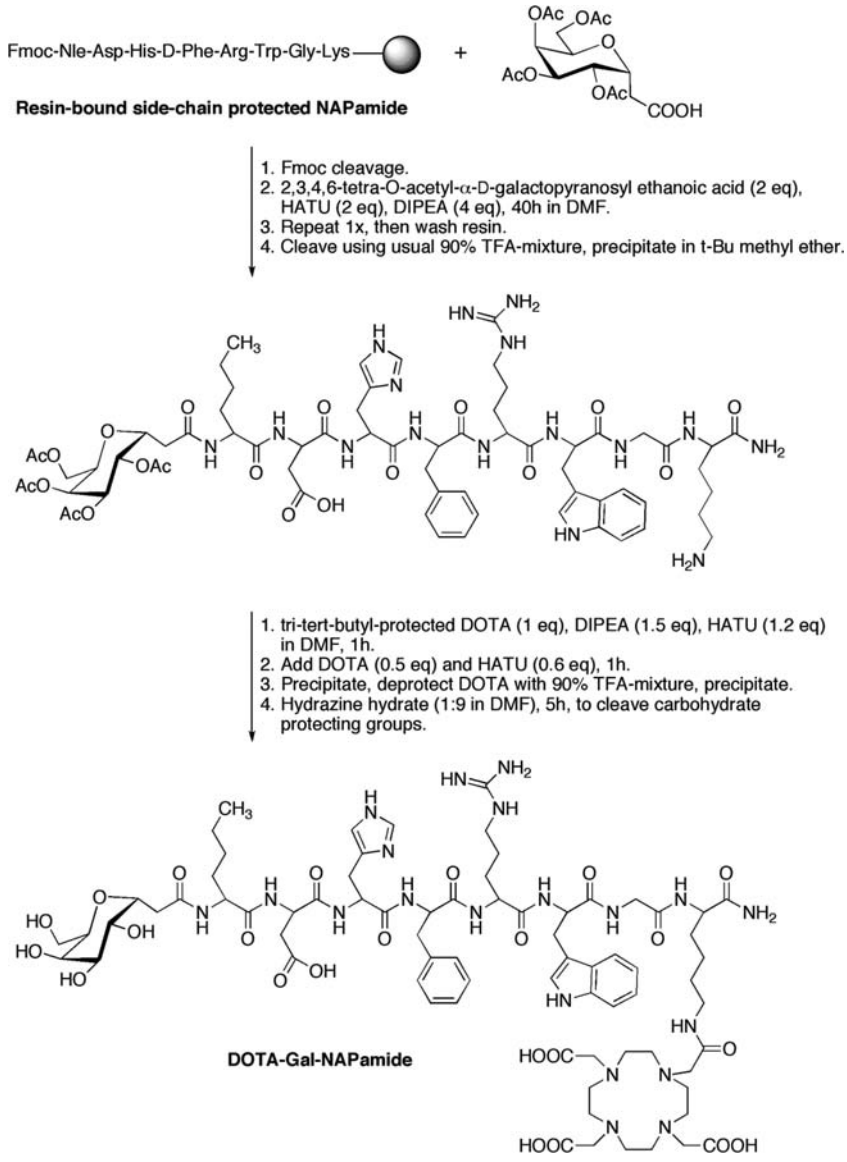

Figure 2. Summary of the synthesis and structures of Gal-NAPamide and DOTA−Gal-NAPamide.

cycle: 0−27 min, 95%−10% A; 27−30 min, 10%−95% A; 30−32 min, 95% A) in 32 min at constant flows of 1 mL/min for the analytical columns, 3 mL/min for the semipreparative column, and 5 mL/min for the preparative column. UV detection was performed at 280 nm on a Jasco UV-1570 UV−vis detector.

Preparation of Glycopeptides. *DOTA−Gal-NAPamide.* The peptide with an N-terminal Gal and DOTA on the Lys side chain (DOTA−Gal-NAPamide) was synthesized by first preparing a Gal-octanoic acid (*36*).

*Allyl-2,3,4,6-tetra-O-acetyl-*α*-D-galactopyranoside.* 1,2,3,4,6-Penta-*O*-acetyl-*β*-D-galactopyranose (10.24 mmol, 1 equiv) was dissolved in anhydrous acetonitrile (40 mL) and cooled to 0 °C. Allyltrimethylsilane (30.76 mmol, 3 equiv) and boron trifluoride diethyl etherate (58.4 mmol, 5.7 equiv) were carefully added under an N_2 atmosphere. The mixture was slowly warmed up to room temperature and stirred overnight under N_2. It was then neutralized by pouring the solution into an Erlenmeyer flask containing $NaHCO_3$ (40 mL). Once the bubbling was over, the reaction mixture was transferred to a separation funnel, extracted with dichloromethane (2 × 40 mL), and dried over Na_2SO_4. The crude product was purified by column chromatography (petroleum ether/ethyl acetate 3:1 to 2:1), resulting in a clear syrup. Yield: 6.96 mmol (68%).

^{1}H NMR ($CDCl_3$, 500.1 MHz) δ: 1.97 (s, 3H, CH_3), 1.98 (s, 3H, CH_3), 2.01 (s, 3H, CH_3), 2.06 (s, 3H, CH_3), 2.21 (m, 1H, CH_2CH=CH_2), 2.40 (m, 1H, CH_2CH=CH_2), 4.00−4.04 (m, 2H, H-5, H-6a), 4.14 (m, $^3J_{5,6b}$ = 9.1 Hz, $^2J_{6a,6b}$ = 12.9 Hz, 1H, H-6b), 4.24 (m, 1H, H-1), 5.03−5.08 (m, 2H, CH_2CH=CH_2), 5.15 (dd, $^3J_{3,4}$ =3.3 Hz, $^3J_{2,3}$ = 9.3 Hz, 1H, H-3), 5.21 (dd, $^3J_{1,2}$ = 5.0 Hz, $^3J_{2,3}$ = 9.3 Hz, 1H, H-2), 5.35 (m, 1H, H-4), 5.69 (m, 1H, CH_2C*H* = CH_2). ^{13}C NMR ($CDCl_3$, 125.8 MHz) δ: 20.67, 20.73, 20.74, 20.79 (4C, 4 CH_3), 30.92 (1C, CH_2CH=CH_2), 61.45 (C-6), 67.58 (C-4), 67.90 (C-3), 68.24 (2C, C-5, C-2), 71.43 (C-1), 117.67 (1C, CH_2CH=CH_2), 133.30 (1C, CH_2C*H*=CH_2), 169.81, 169.94, 170.09, 170.56 (4C=O).

*2,3,4,6-Tetra-O-acetyl-*α*-D-galactopyranosyl Aldehyde.* A solution of allyl-2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside (6.96 mmol) was dissolved in anhydrous CH_2Cl_2 (100 mL) and cooled to −70 °C. Ozone (O_3) was bubbled through the solution for approximately 1 h, until the solution turned blue. The mixture was deozonized by bubbling N_2 through the solution until it was colorless. Acetic acid (10 mL) and zinc dust (7.5 g) were added to the solution, and the suspension was slowly warmed up to room temperature overnight under stirring. The suspension was filtered through Celite, and the filtrate was concentrated to dryness. The crude product was purified by column chroma-

[a] MC1R affinity of α-MSH analogues was assessed by competition binding experiments with B16F1 or HBL cells and ^{125}I-NDP-MSH as radioligand (n = 3−16). [b] Biological activity of α-MSH analogues was determined by melanin assay with B16F1 cells, and results are expressed as relative concentration inducing half-maximal response (rEC_{50}, n = 3−10) normalized on α-MSH = 1. [c] $P < 0.05$ vs DOTA−NAPamide.

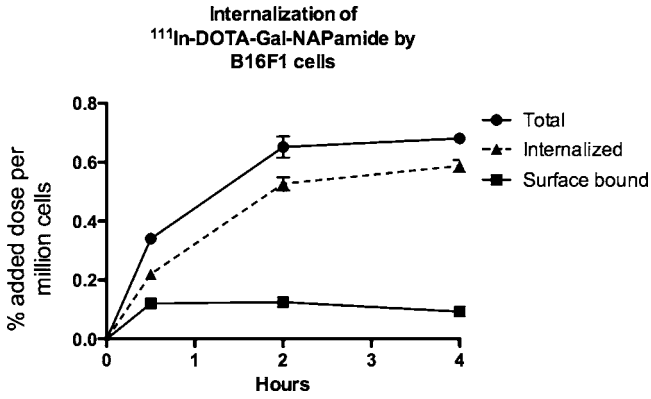

Figure 3. Internalization of ^{111}In-DOTA−Gal-NAPamide into B16-F1 mouse melanoma cells (exemplary experiment showing the means of n = 3 individual determinations).

tography (petroleum ether/ethyl acetate 1.5:1) and dried under high vacuum. Yield: 4.74 mmol (68%).

^{1}H NMR ($CDCl_3$, 500.1 MHz) δ: 2.05 (s, 6H, 2 CH_3), 2.06 (s, 3H, CH_3), 2.11 (s, 3H, CH_3), 2.65−2.76 (m, 2H, CH_2CHO), 4.05−4.11 (m, 2H, H-5, H-6a), 4.32 (m, 1H, H-6b), 4.86 (m, 1H, H-1), 5.17 (dd, $^3J_{3,4}$ = 3.2 Hz, $^3J_{2,3}$ = 8.5 Hz, 1H, H-3), 5.28 (dd, $^3J_{1,2}$ = 4.7 Hz, $^3J_{2,3}$ = 8.4 Hz, 1H, H-2), 5.41 (m, 1H, H-4), 9.72 (m, 1H, CHO). ^{13}C NMR ($CDCl_3$, 125.8 MHz) δ: 20.63, 20.67, 20.70 (4C, 4 CH_3), 41.94 (CH_2CHO), 60.82 (C-6), 66.62 (C-1), 66.88 (C-4), 67.72 (C-3), 67.84 (C-2), 69.67 (C-5), 169.61, 169.72, 169.88, 170.63 (4 C═O), 198.31 (CHO).

2,3,4,6-Tetra-O-acetyl-α-D-galactopyranosylethanoic Acid. A solution of 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl aldehyde (4.74 mmol) in *tert*-butyl alcohol (20 mL) and a solution of KH_2PO_4 (1.25 M, 8 mL) were added to a vigorously stirred solution of $KMnO_4$ (1 M, 9 mL). The mixture was stirred for 20 min. A solution of saturated Na_2SO_3 was added dropwise until $KMnO_4$ was neutralized, yielding a brown precipitate of MnO_2 which was filtered through Celite and washed with ethanol (2 × 25 mL). Ethanol was then removed from the filtrate under reduced pressure, and the remaining solution was acidified to pH 3 using 1 N HCl and then extracted with dichloromethane (4 × 30 mL). The combined extracts were concentrated and dried under high vacuum to yield a white foam (4.31 mmol, 91%).

^{1}H NMR ($CDCl_3$, 500.1 MHz) δ: 2.04 (s, 6H, 2 CH_3), 2.07 (s, 3H, CH_3), 2.12 (s, 3H, CH_3), 2.63 (dd, ^3J = 5.6 Hz, ^2J = 15.7 Hz, 1H, CH_2CO_2H), 2.72 (dd, ^3J = 8.9 Hz, ^2J = 15.6 Hz, 1H, CH_2CO_2H), 4.10−4.17 (m, 2H, H-5, H-6a), 4.24 (dd, $^3J_{5,6b}$ = 6.9 Hz, $^2J_{6a,6b}$ = 10.7 Hz, 1H, H-6b), 4.70 (m, 1H, H-1), 5.17 (dd, $^3J_{3,4}$ = 3.3 Hz, $^3J_{2,3}$ = 8.9 Hz, 1H, H-3), 5.33 (dd, $^3J_{1,2}$ = 5.0 Hz, $^3J_{2,3}$ = 8.9 Hz, 1H, H-2), 5.43 (m, 1H, H-4). ^{13}C NMR ($CDCl_3$, 125.8 MHz) δ: 20.65, 20.65, 20.70 (4C, 4 CH_3), 33.02 (CH_2CO_2H), 61.04 (C-6), 67.04 (C-4), 67.56 (C-2), 67.77 (C-3), 68.73 (C-1), 69.45 (C-5), 169.57, 169.85, 169.98, 170.65 (4 C═O), 174.90 (CO_2H).

The Gal-octanoic acid was attached to the N-terminus of partially protected NAPamide: 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosylethanoic acid (2 equiv) in DMF was preactivated with HATU (2 equiv) for 10 min and added to a suspension of solid-phase-bound, partially protected NAPamide (1 equiv) containing DIPEA (4 equiv). After 40 h at room temperature, the resin was washed (DMF, MeOH, DMF) and the coupling cycle repeated. After the resin was washed, the peptide was cleaved using a 90% TFA-mixture (*25*), precipitated in *t*-butyl methyl ether, and purified by RP-HPLC (t_R = 12.51 min). The DOTA moiety was then coupled to the ε-amino group of Lys^{11} and deprotected in acid-treated (2 N HCl; >1 h) glassware using the standard procedure (*25*). Deprotection of the acetyl groups of the carbohydrate moiety was carried out in liquid phase using hydrazine hydrate (diluted 1:9 in DMF, 1 mL/20 mg peptide) for 5 h and purified by RP-HPLC (Vydac semipreparative column, t_R = 14.8 min). Calculated monoisotopic mass: 1647.79 g mol^{-1}; measured: 1647.5 g mol^{-1}.

DOTA−Gluc-NAPamide. The glucose moiety was coupled to solid-phase bound NAPamide using the Maillard reaction which is a slow nonenzymatic chemical reaction of reducing sugars modifying amino groups of peptides, proteins, lipids, and nucleic acids (*37*), thus leading to the formation of Amadori products (*38*−*40*). The resin containing NAPamide (1 equiv) was stirred in the presence of β-D-glucose (10 equiv) under reflux in a mixture of MeOH/AcOH (95:5) at 60 °C for 72 h. After the mixture was washed with MeOH and 2-propanol, completion of the reaction was checked by the Kaiser test. The peptide was then cleaved from the resin, precipitated with *t*-butyl methyl ether, and purified by RP-HPLC (t_R = 8.94 min). Coupling and deprotection of DOTA followed standard procedures (see above), followed by purification using RP-HPLC (t_R = 9.1 min). Calculated monoisotopic mass: 1605.6 g mol^{-1}; measured: 1605.5 g mol^{-1}.

DOTA−Mtr-NAPamide. The maltotriose moiety was coupled to solid-phase-bound NAPamide using the Maillard reaction, followed by the addition and deprotection of DOTA, as described above for DOTA−Gluc-NAPamide. RP-HPLC yielded the product peak at t_R = 7.8 min. Calculated monoisotopic mass: 1930.03 g mol^{-1}; measured: 1930.1 g mol^{-1}.

DOTA−[Asp(Gal)^2]-NAPamide. To the solid-phase-bound partial NAPamide sequence His-D-Phe-Arg-Trp-Gly-Lys-resin (with side-chain protection), Fmoc-Asp(1,2:3,4-diisopropylidene-6-amino-α-D-galactosyl)-OH and, subsequently, Fmoc-Nle-OH were coupled manually using the HOBt-DIPC method. After cleavage of Fmoc, the N-terminal acetyl group was introduced to the peptide-resin (1 equiv, suspended in a very small amount of DMF) by the addition of *p*-nitrophenyl acetate (2 equiv) activated by HOBt (1 equiv). After 24 h, the resin was filtered and extensively washed with DMF and with 2-propanol. The peptide was cleaved from the resin using a 90% TFA-mixture, precipitated, and purified by RP-HPLC (Vydac analytical column, t_R = 13.71 min). The DOTA moiety was then coupled to the ε-amino group of Lys^{11} and deprotected as

[a] Data for DOTA−NAPamide from Froidevaux et al. (2005) *J. Nucl. Med. 46*, 887−895. [b] Tissue radioactivity is expressed as mean ± SEM (n = 4−12). [c] $P < 0.05$ vs DOTA−NAPamide.

described above. RP-HPLC yielded the product peak at t_R = 10.68 min. Calculated monoisotopic mass: 1646.8 g mol^{-1}; measured: 1646.8 g mol^{-1}.

N$^{\alpha}$-DOTA−[Lys(Gluc)^8]-NAPamide. Solid-phase bound NAPamide was first N-terminally extended by DOTA and cleaved from the resin, and then Gluc was attached to the ε-amino group of Lys^{11}. DOTA was coupled using the standard procedure. The peptide was then cleaved from the resin, and the chelator complex was simultaneously deprotected using the standard 90% TFA-mixture. After precipitation, the peptide was purified by RP-HPLC (t_R = 9.5 min) and lyophilized. The carbohydrate moiety was coupled using a slightly modified Maillard reaction: N$^{\alpha}$-DOTA−NAPamide (1 equiv) and β-D-glucose (10 equiv) were stirred for only 45 h at 60 °C under reflux and an N_2 atmosphere using a mixture of MeOH/AcOH (95:5). After the mixture was washed with MeOH and 2-propanol, the completion of the reaction was checked by the Kaiser test. The peptide was directly purified by RP-HPLC (t_R = 8.59 min) and lyophilized. Calculated monoisotopic mass: 1605.75 g mol^{-1}; measured: 1605.8 g mol^{-1}.

DOTA−NAPamide-Gal. NAP (Nle-Asp-His-D-Phe-Arg-Trp-Gly-Lys) was assembled on TentaGel S TRT-Lys(Boc)-Fmoc resin containing an acid-labile linker producing a free C-terminal acid under very mild acid cleavage conditions, without deprotection of the side chains. The free N$^{\alpha}$ group of Nle was acetylated as described above and the peptide cleaved from the resin using DCM/TFE/AcOH 7:2:1 (1 mL/0.1 g of resin; 1 h). The solvent volume was reduced by careful evaporation, and the peptide was precipitated by the addition of 10 volumes of ice-cold diethyl ether and purified by RP-HPLC (t_R = 21.32 min). Calculated monoisotopic mass: 1851.21 g mol^{-1}; measured: 1850.69 g mol^{-1}. The peptide (1 equiv) was dissolved in DMF and its free C-terminal -COOH group preactivated with HATU (2 equiv) for 10 min. 1-Amino-1-deoxy-β-D-galactose (2 equiv) and DIPEA (4 equiv) were added, and the mixture was agitated for 1 h and then left at room temperature overnight. It was purified by RP-HPLC (t_R = 20.95 min) and lyophilized. Calculated monoisotopic mass: 1770.05 g mol^{-1}; measured: 1770.10 g mol^{-1}. Side-chain protecting groups were then cleaved using a 94% TFA-mixture (2 h) containing only 1% thioanisole, which kept the formation of side products minimal. Solvents were removed by careful evaporation with the help of added diethyl ether as solvent carrier. The peptide was dissolved by consecutive addition of 20% AcOH, H_2O and CH_3CN and purified by RP-HPLC (t_R = 9.9 min). Finally, the DOTA moiety was coupled to the ε-amino group of Lys^{11} and deprotected using standard procedures as described above. Purification was achieved by RP-HPLC (t_R = 10.12 min). Calculated monoisotopic mass: 1647.79 g mol^{-1}; measured: 1648.0 g mol^{-1}.

Radioligands. *^{111}In-Labeled Peptides.* Incorporation of ^{111}In into DOTA−peptides was performed by the addition of 55.5 MBq of ^{111}In-Cl_3 (Mallinckrodt, Petten, The Netherlands; stock concentration: 370 MBq/mL) to the DOTA−peptides (10 nmol) dissolved in 54 μL of acetate buffer (0.4 mol/L, pH 5) containing 2 mg of gentisic acid. After 10 min of incubation at 95 °C, the radiolabeled DOTA−peptides were purified on a small reversed-phase cartridge (Sep-Pak C18, Waters), using sodium acetate buffer (pH 7) for washing out unbound radioisotope, followed by elution of the radiopeptide with ethanol. The purity of the resulting radioligands was assessed by RP-HPLC on a Jasco PU-980 chromatography system, connected to a Radiomatic 500TR LB506C1 γ-detector (Packard) and a Waters Spherisorb ODS2/5-μm column under the following conditions: eluent A = 0.1% TFA in water; eluent B = 0.1% TFA in acetonitrile; gradient = 0−2 min, 96% A; 2−22 min, 96%−45% A; 22−30 min, 45%−25% A; 30−32 min, 25% A; 32−34 min, 25%−96% A; flow rate, 1.0 mL/min. The specific activity of the radioli-

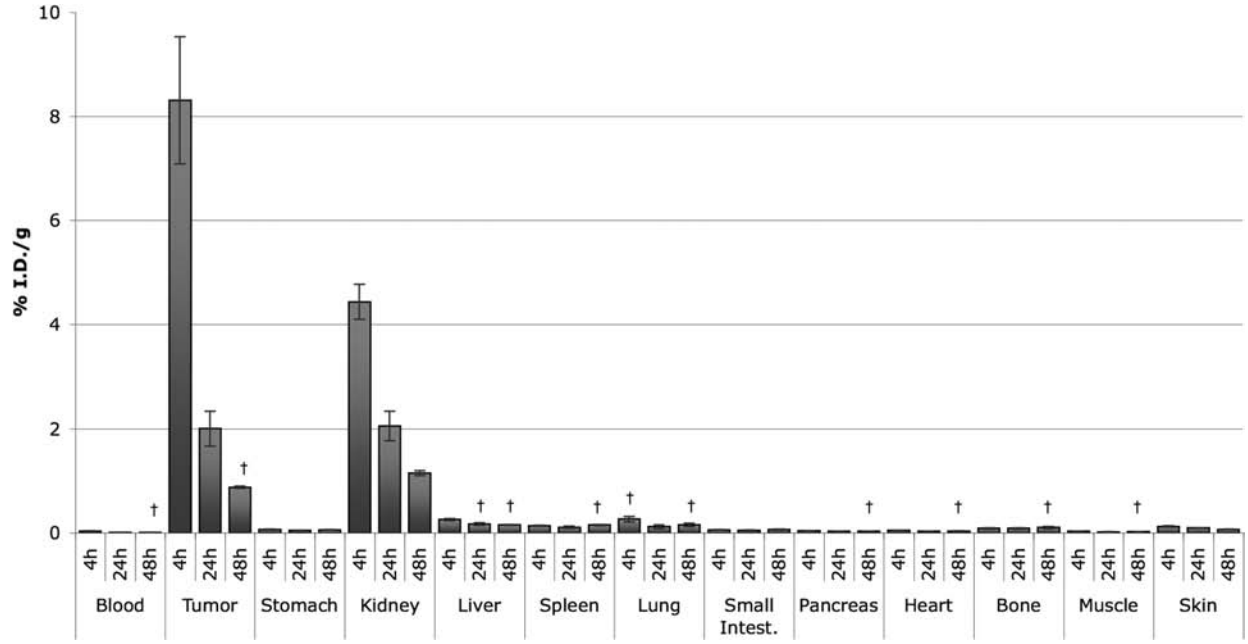

Figure 4. Tissue distribution of [^{111}In]DOTA−Gal-NAPamide at 4, 24, and 48 h postinjection. Results are expressed as % of injected dose per gram of tissue (%ID/g; means ± SEM; $n = 4$). $^{\dagger}P < 0.05$ vs [^{111}In]DOTA−NAPamide.

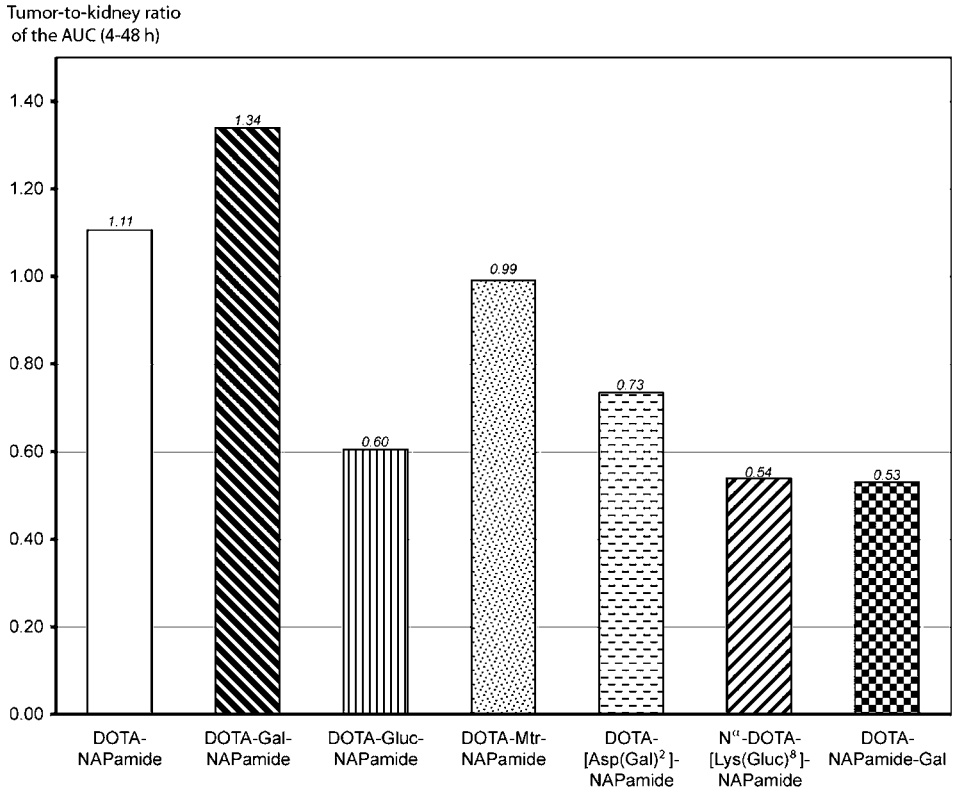

Figure 5. Tumor vs kidney ratio of the area under the curve (4−48 h) of the glycopeptides compared to DOTA−NAPamide in B16F1 melanoma-bearing mice.

gands was estimated by HPLC analysis of radioligand peaks in comparison with HPLC profiles of the parent radioligand DOTA−NAPamide whose specific activity had previously been determined in a competitive binding assay using an antibody which exhibited the same affinity to labeled and unlabeled peptide (for methodological details, see (*41*)). From these profiles, it was estimated that the specific activity of all ^{111}In-labeled peptides was ∼7.4 GBq/μmol.

^{125}I-Labeled Peptide. NDP-MSH was iodinated using the IODO-GEN method. NDP-MSH (12.14 nmol) was mixed with 37 MBq of Na^{125}I (Amersham Bioscience, Otelfingen, Switzerland; stock concentration: 3.7 GBq/mL) in 60 μL of phosphate buffer (0.3 M, pH 7.4) in IODO-GEN-precoated tubes (Pierce, Rockford, IL). After 15 min of incubation at room temperature under shaking, the mixture was loaded on a small reversed-phase cartridge (Sep-Pak C18, Waters) and washed

with water and acetic acid (0.5 M), and finally the peptide was eluted with methanol and collected. The fractions containing ^{125}I-NDP-MSH were supplemented with dithiothreitol (1.5 mg/mL) and stored at −20 °C. Before each binding experiment, an additional purification was performed by RP-HPLC using γ-detection.

Cell Culture. The mouse B16F1 melanoma cell line (*42*) was cultured in modified Eagle's medium (MEM; Biochrom AG, Germany) supplemented with 10% heat-inactivated fetal calf serum, 2 mmol/L L-glutamine, 1% nonessential amino acids, 1% vitamin solution, 50 IU/mL penicillin, and 50 μg/mL streptomycin (all from Gibco/Invitrogen, Carlsbad, CA) at 37 °C in an atmosphere of 95% air/5% CO_2. For expansion or experiments, the cells were detached with 0.02% ethylenediaminetetraacetic acid (EDTA) in PBS (150 mmol/L, pH 7.2−7.4).

The human HBL melanoma cell line was cultured in modified RPMI medium (Biochrom AG) supplemented with 10% heat-inactivated fetal calf serum, 2 mmol/L L-glutamine, 50 IU/mL penicillin, and 50 μg/mL streptomycin in the same culture and expansion conditions as B16F1 cells.

In Vitro Binding Assay with B16F1 or HBL Cells. Competition binding experiments were performed by incubating MC1R-expressing B16F1 or HBL cells in microplates with the radioligand ^{125}I-NDP-MSH and a series of dilutions of competitor peptides (from 1×10^{-6} to 1×10^{-12} mol/L) as described previously (*43*). Triplicates of 100 μL of B16F1 or HBL cell suspensions adjusted to 4×10^6/mL were incubated in 96-well U-bottom microplates (Falcon 3077) for 3 h at 15 °C (B16F1) or for 2 h at 37 °C (HBL) with 50 μL of ^{125}I-NDP-MSH (50 000 cpm). The binding medium consisted of MEM with Earle's salts (Biochrom AG), 0.2% bovine serum albumin, and 1,10-phenanthroline (0.3 mmol/L; Merck). The reaction was stopped by incubation on ice for 10 min, and the cell-bound radioactivity was collected on filters by use of a cell harvester (Packard, Meriden, CT). The radioactivity was counted by use of a TopCount microplate scintillation counter (Packard), and the 50% inhibitory concentration (IC_{50}) was calculated with the Prism 5.0 software (GraphPad Software, Inc.).

In Vitro Melanin Assay. The biological activity of the α-MSH derivatives was assessed with an in situ melanin assay (*44*). B16F1 cells (2500 per well, 100 μL) were distributed in cell culture flat bottom 96-well plates in medium consisting of MEM without phenol red and supplemented with 10% heat-inactivated fetal calf serum, 2 mmol/L L-glutamine, 0.31 mmol/L L-tyrosine, 1% nonessential amino acids, 1% vitamin solution, 50 IU/mL penicillin, and 50 μg/mL streptomycin. After overnight incubation in a cell incubator at 37 °C, serial concentrations of α-MSH derivatives, ranging from 1×10^{-8} to 1×10^{-12} in 100 μL volume, were added and incubation was prolonged for an additional 72 h. Melanin production was then monitored through measurement of the absorbance at 310 nm in a microplate reader (Spectra MAX 190, Molecular Devices, Menlo Park, CA).

In Vitro Internalization Assay. B16F1 cells were seeded in six-well plates and incubated overnight at 37 °C in B16F1 cell culture medium. For the experiments, B16F1 medium was removed and replaced by 1 mL of Mouse Binding Medium (MBM) internalization buffer, consisting of MEM with Earle's salts (Biochrom AG, Germany), 0.2% bovine serum albumin, and 1,10-phenanthroline (0.3 mmol/L; Merck). After 1 h of incubation at 37 °C, 74 kBq of radioligand (^{111}In-labeled peptides) was added, and the plates were incubated for different times. Nonspecific internalization was assessed by addition of 50 μL of a 1 μM nonradioactive α-MSH solution. Samples were taken from the supernatant after 0.5, 2, and 3.5 h to determine the total dose added, immediately followed by extensive washings of the cells (6×) using prewarmed (37 °C) MBM to remove the excess of radioligand. The cells were then incubated in 2 mL of ice-cold acid buffer (acetate-buffered HBSS, pH 5) for 10 min to dissociate surface-bound ligand. After collection of the acidic fraction, cells were rinsed once with MBM and the washing was pooled with the acid buffer fraction. The cells were washed once more with MBM (37 °C), lysed in 1% Triton X-100, and finally transferred to tubes for quantification. The radioactivity of all collected fractions was determined in a Cobra II Auto-Gamma γ-counter (Packard). One counting plate was subjected to the same treatment as the plate incubated for the longest time. Cells from this plate were not lysed but detached (EDTA) and counted. Results of the experiments are expressed as the percentage of added dose per million cells.

Biodistribution in B16F1 Tumor-Bearing Mice and Stability of Radioligands after Kidney Excretion. All animal experiments were performed in compliance with Swiss regulations for animal welfare. Female B6D2F1 mice (C57BL/6 × DBA/2 F1 hybrids; breeding pairs obtained from IFFA-CREDO) were implanted subcutaneously with 0.5 million B16F1 cells in phosphate-buffered saline (PBS) to generate a primary skin melanoma. One week later, 200 μL containing 185 kBq (25 pmol) of radioligand diluted in PBS/BSA (pH 7.4) was injected intravenously in the lateral tail vein of each mouse. To allow determination of nonspecific uptake, 50 μg of α-MSH (30 pmol) was coinjected with the radioligand in some mice. The animals were killed at the indicated time points; organs and tissues of interest were dissected and rinsed of excess blood and weighed, and the radioactivity measured in a γ-counter. The percentage of the injected dose per gram tissue (%ID/g) was calculated for each tissue. The total counts injected per animal were calculated by extrapolation from counts of a standard taken from the injected solution for each animal.

As part of the biodistribution experiments, samples of urine were collected from melanoma-bearing mice 10, 15, 20 min, and 4 h after injection of 185 kBq of ^{111}In-DOTA peptide and kept frozen at −80 °C until use. Urine (1 vol) was mixed with methanol (2 vol) to precipitate the proteins and was analyzed by RP-HPLC/γ-detection under the conditions mentioned above.

Analysis of Data. Unless otherwise stated, results are expressed as mean ± standard error of the mean (SEM). Statistical evaluation of the binding assays was performed by using Student's *t*-test. For the analysis of data collected during biodistribution experiments, the mean value obtained for each organ was compared individually to each DOTA−NAPamide organ values by using Student's *t*-test, and the results were corrected with the Bonferroni correction. A *P*-value of <0.05 was considered statistically significant. The area under the curve (AUC) was calculated for a particular time period (4−48 h) using the GraphPad Prism software; mean tissue uptake values at each time point were used for this calculation.

RESULTS

Synthetic Glycosylated DOTA−NAPamide Analogues. The preparation of glycosylated DOTA−NAPamide analogues followed four different strategies: (1) synthesis of a galactopyranosylethanoic acid for straightforward attachment to the N^{α}-terminal amino group of the peptide, as indicated for DOTA−Gal-NAPamide (Figures 1 and 2), requiring a three-step synthesis of the glyco derivative (allylation of its anomeric center, followed by ozonolysis and oxidation (*36*)); (2) Maillard reaction of β-D-glucose or maltotriose with the N^{α}-terminal or the N^{ε}-side-chain amino group, as exemplified for DOTA−Gluc-NAPamide, DOTA−Mtr-NAPamide, or N^{α}-DOTA−[Lys(Gluc)^8]-NAPamide (Figure 1); (3) use of the Fmoc-Asp(1,2:3,4-diisopropylidene-6-amino-α-D-galactosyl)-OH building block for a direct introduction of the carbohydrate during solid-phase

assembly into the side-chain position of residue 2 of DOTA−[Asp(Gal)^2]-NAPamide; (4) functionalization of the C-terminal amide as glycoamide, by attachment of 1-amino-1-deoxy-β-D-galactose to the free carboxy terminus of a side-chain-protected peptide, followed by deprotection and attachment of the DOTA group at the N$^\varepsilon$-side chain of Lys 8.

The glycopeptides were usually obtained in high purity (>99%) but in low yields. Indeed, if DOTA−Gal-NAPamide was obtained in a total yield of 7.4%, the total yields of other glycopeptides were 3% for DOTA−Gluc-NAPamide, 3.4% for DOTA−Mtr-NAPamide, 2% for DOTA−[Asp(Gal)^2]-NAPamide, 1% for N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, and 3.1% for DOTA−NAPamide-Gal.

The retention times of ^{111}In-labeled peptides on analytical γ-detection RP-HPLC were found to be 18.6 min for DOTA−Gal-NAPamide, 19.2 min for DOTA−Gluc-NAPamide, 18.0 min for DOTA−Mtr-NAPamide, 20.6 min for DOTA−[Asp(Gal)^2]-NAPamide, 19.1 min for N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, and 19.6 min for DOTA−NAPamide-Gal. Their level of radiochemical purity always exceeded 97%, and the specific activity did not appear to differ significantly between the different glycosylated peptides as deduced from HPLC analysis.

Receptor Binding. MC1R affinity of the glycosylated NAPamide analogues was assessed by competition binding assays against ^{125}I-NDP-MSH on both murine B16F1 and human HBL melanoma cell lines, using α-MSH and DOTA−NAPamide as reference compounds. All peptides showed very good binding affinities to mouse and human MC1R with IC_{50}s ranging from 0.45 to 7.61 nmol/L (Table 1). DOTA−[Asp(Gal)^2]-NAPamide displayed the highest affinity for the MC1R on both B16F1 and HBL cells and exceeded that of DOTA−NAPamide by a factor of 3 to 3.5. DOTA−NAPamide-Gal was also slightly more active than DOTA−NAPamide. DOTA−Gal-NAPamide and DOTA−Gluc-NAPamide displayed slightly lower IC_{50}s than DOTA−NAPamide, while the affinity of DOTA−Mtr-NAPamide and N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide was about 2- to 3.5-fold lower than that of DOTA−NAPamide. The glycopeptides without the DOTA chelator all showed markedly higher affinity (data not shown).

Biological Activity. In the melanin assay using B16F1 cells, all DOTA−glycopeptides, except for N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, displayed higher biological (agonist) activity than DOTA−NAPamide, all in the picomolar range. In order to compare the EC_{50} of different experiments, these were normalized against the EC_{50} of the reference compound α-MSH whose rEC_{50} was defined as 1 (Table 1). DOTA−[Asp(Gal)^2]-NAPamide and DOTA−Gluc-NAPamide displayed the lowest rEC_{50}s with 0.26 and 0.34, respectively. The values of the other glycopeptides were comparable to that of DOTA−NAPamide. The induction of melanin synthesis by B16F1 cells started at doses matching their IC_{50}s and lower. Only DOTA−Mtr-NAPamide showed a slightly worse rEC_{50} but still matching that of α-MSH. Again, DOTA−[Asp(Gal)^2]-NAPamide exhibited the best agonist activity in vitro.

Internalization Assay. Internalization assays were carried out to determine if and how fast the glycopeptides were internalized by B16F1 cells. The results were excellent, all glycopeptides being almost totally internalized in 2 h or less. As an example, Figure 3 shows the internalization kinetics of DOTA−Gal-NAPamide, which reached a plateau after 2 h when internalization of the peptide was almost total. These data show that internalization of the peptide by tumor cells cannot be an issue regarding the in vivo tumor uptake.

Biodistribution in Melanoma-Bearing Mice. Table 2 shows the tissue distributions of the different ^{111}In-labeled, glycosylated DOTA−NAPamide peptides in comparison with [^{111}In]-DOTA−NAPamide at 4, 24, and 48 h after injection of the radioligand. Coinjection of an excess of α-MSH to block MC1R reduced the 4-h tumor uptake of DOTA−Gal-NAPamide by >90%, of DOTA−Mtr-NAPamide by 89%, of N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide by 86%, of DOTA−Gluc-NAPamide by 80%, of DOTA−NAPamide-Gal by 77%, and of DOTA−[Asp(Gal)^2]-NAPamide by 75%, indicating that all these derivatives are taken up by melanoma cells through receptor-mediated internalization. DOTA−Gal-NAPamide showed the highest tumor uptake among the glycopeptides, comparable to that of DOTA−NAPamide (Figure 4), followed by DOTA−Mtr-NAPamide, DOTA−NAPamide-Gal, DOTA−[Asp(Gal)^2]-NAPamide, N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, and DOTA−Gluc-NAPamide. The ranking of melanoma uptake of the different glyco-NAPamide peptides did not correspond with the in vitro MC1R binding affinity.

Clearance of ^{111}In from the kidneys was found to be quite a slow process, as also reported for other peptides. Indeed, 46% of the radioactivity measured in the kidneys 4 h after injection of DOTA−Gal-NAPamide was still present after 24 h, and 26% after 48 h. For DOTA−[Asp(Gal)^2]-NAPamide the values were 49% and 33%, for DOTA−Mtr-NAPamide 34% and 27%, for DOTA−Gluc-NAPamide 65% and 43%, and for N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide 66% and 35%. The slowest clearance from the kidneys was observed for DOTA−NAPamide-Gal whose values were 99% and 34% and hence was opposed to the expectation that glycosylation of the C-terminal amide of Lys^8 may increase kidney clearance and reduce reuptake.

Radioactivity release from the tumor was faster than from the kidneys, with 25% of the radioactivity measured after 4 h still present after 24 h and 11% after 48 h for DOTA−Gal-NAPamide, and slightly higher but comparable values for DOTA−[Asp(Gal)^2]-NAPamide, DOTA−Gluc-NAPamide, N$^\alpha$-DOTA−[Lys(Gluc)^8]-NAPamide, and DOTA−NAPamide-Gal, in part due to their lower overall tumor uptake. Indeed, DOTA−Mtr-NAPamide, which displayed an almost similar tumor uptake as that of DOTA−Gal-NAPamide after 4 h, exhibited values of 22% and 8% at 24 and 48 h.

The glycopeptides with the highest in vitro binding affinity displayed a lower in vivo accumulation in melanoma than would have been predicted from their in vitro potency. DOTA−Gal-NAPamide, showing an average receptor binding affinity comparable to DOTA−NAPamide, delivered a more favorable biodistribution profile with higher tumor uptake after 4 h (8.30% ± 1.22%ID/g) and higher tumor-to-kidney ratio after 4 h (1.87 ± 0.15) than that for any other glycopeptide. Indeed, DOTA−Gal-NAPamide exhibited a 4−48 h AUC tumor-to-kidney ratio of 1.34 (Figure 5), which exceeds that of DOTA−NAPamide (1.11) by 17%. It was unfortunately impossible to compare directly the tumor-to-kidney ratio of the AUC of the peptides synthesized in this work with peptides synthesized by others, because of the lack of 48 h data in their work. Nevertheless, their 4 h tumor-to-kidney-ratio could be compared, and it appeared that DOTA−Gal-NAPamide was among the best radiolabeled α-MSH analogues synthesized so far. Indeed, as mentioned above, DOTA−Gal-NAPamide displayed a 4 h tumor-to-kidney ratio of 1.87 while, for instance, ^{111}In-DOTA−ReCCMSH (1.02) (*4*), ^{188}Re-(Arg^{11})CCMSH (0.32) (*10*), ^{111}In-DOTA−NAPamide (1.63) (*7*), [^{111}In-DOTA−Nle^4, Asp^5,D-Phe^7,Ac-Lys^{11}-NH$_2$]-α-MSH$_{4-11}$ (1.06) (*7*), ^{90}Y- or ^{177}Lu-DOTA−Re(Glu^2,Arg^{11})CCMSH (1.30 and 1.57) (*9*), ^{111}In-DOTA−Cyc-MSH (0.35) (*45*), or ^{111}In-DOTA−GlyGlu-Cyc-MSH (0.61) (*45*) exhibited lower tumor-to-kidney ratios after 4 h.

DISCUSSION

This study focused on the influence of introducing a few different types of carbohydrates at the N- or C-terminal end

and at side-chain positions of the α-MSH derivative DOTA−NAPamide. In view of the reports that glycosylation of peptides or proteins would reduce reuptake by the tubular system of the kidneys (*27*, *28*), our first attempt was to study a DOTA−NAPamide derivative whose C-terminal amide was glycosylated. Previous observations in our laboratory (unpublished data) demonstrated that an important metabolite of [^{111}In]DOTA−NAPamide was H-Lys([^{111}In]DOTA)-NH_2 which was regularly observed in the urine collected from mice treated with this peptide. However, DOTA−NAPamide-Gal showed a higher and much longer kidney retention than all other glycopeptides which we investigated. Most likely, the C-terminal carbohydration led to increased reuptake and trapping of the peptide or its metabolites in endosomes in tubular cells of the kidney.

Glycosylation of the amino acid side chains of Asp^2 or Lys^8 does not seem to be a good alternative either. DOTA−[$Asp(Gal)^2$]-NAPamide and N^{α}-DOTA−[$Lys(Gluc)^8$]-NAPamide both displayed slightly lower tumor uptake and higher kidney uptake than the other glycopeptides. Again, the increased kidney uptake may be the result of higher rate of internalization and marked retention by tubular cells. A precise molecular explanation would require a detailed analysis, particularly in view of the very high in vitro potency of DOTA−[$Asp(Gal)^2$]-NAPamide which would rule out steric hindrance by the side-chain galactosyl group for receptor binding.

Finally, three different glycopeptides bearing a glucose, galactose, or maltotriose moiety at their N-terminal end were then examined in order to assess the influence of the type of sugar on the pharmacokinetics. The derivative with a glucose residue showed poor pharmacokinetic properties, displaying an in vivo tumor-to-kidney ratio (4−48 h AUC) of only 0.60 (Figure 5), although it exhibited a similarly low kidney uptake after 4 h (4.48%ID/g) as the structurally similar [^{111}In]DOTA−Gal-NAPamide. The analogue with N-terminal maltotriose showed much better properties with a tumor-to-kidney ratio (4−48 h AUC) of 0.99. The tumor uptake was similar to that of [^{111}In]DOTA−NAPamide, but the higher kidney uptake led to a lower ratio as compared to DOTA−NAPamide. The most encouraging data were obtained with [^{111}In]DOTA−Gal-NAPamide which exhibited the relatively highest melanoma uptake and lowest kidney uptake in vivo, leading to a tumor-to-kidney ratio which exceeded that of [^{111}In]DOTA−NAPamide by a factor of about 1.2. This result is very valuable, as it shows the direction to follow in order to improve tumor-to-nontarget-tissue ratios which are fundamental for future therapeutic applications.

In conclusion, we demonstrated that introduction of different types of sugars at various positions along the sequence of ^{111}In-labeled NAPamide affect the in vitro binding affinity and the in vivo pharmacokinetic behavior. It is noteworthy that carbohydration generally did not reduce the binding affinity when compared to the nonglycosylated reference peptide. Also, the sugar moieties appeared to be without influence on the extent of ^{111}In-labeling of DOTA, owing to a rigidly standardized labeling protocol. Kidney reuptake and retention, however, were increased with side-chain and C-terminal sugar groups but decreased with an N-terminal galactosyl group. This compound, DOTA−Gal-NAPamide, exhibited favorable pharmacokinetic data. Its high melanoma uptake and lower kidney retention, and above all its improved tumor-to-kidney uptake ratio, opens the door to the development of novel glycosylated radiolabeled α-MSH derivatives for melanoma targeting with further reduced nephrotoxicity.

Biotinylated Glyco-Functionalized Quantum Dots: Synthesis, Characterization, and Cytotoxicity Studies

Xiaoze Jiang, Marya Ahmed, Zhicheng Deng, and Ravin Narain*

Department of Chemistry and Biochemistry, Biomolecular Sciences Program, Laurentian University, 935, Ramsey Lake Road, Sudbury, Ontario P3E 2C6, Canada. Received January 13, 2009; Revised Manuscript Received April 14, 2009

Quantum dots (QDs) containing surface carboxylic groups have been successfully modified using biotinylated glycopolymer and carbohydrate/biotin reagents via EDC coupling. The biotinylated glycopolymer was synthesized in controlled dimension via the reversible addition−fragmentation chain transfer (RAFT) polymerization of the three monomers containing biotin, sugar, and amine groups as pendent groups, respectively. The modified QDs were analyzed by dynamic light scattering and fluorescence spectrophotometry, and the data revealed no change in the physical properties of QDs after surface modification. Furthermore, the surface modified QDs showed excellent water solubility and colloidal stability. Subsequently, the availability of the biotin ligand on the surface of functionalized QDs was quantified using 4-hydroxyazobenzene 2-carboxylic acid (HABA)/avidin binding assay. Cell viability studies revealed that the cytotoxicity of QDs after surface functionalization is improved and that the biotinylated glycopolymer modified QDs showed an enhancement in biocompatibility as compared to that of the original QDs. The biotinylated glyco-functionalized quantum dots may act as new suitable fluorescent probes in biomedical applications.

INTRODUCTION

Semiconductor nanocrystals (usually called quantum dots, QDs) have been receiving enormous attention in recent years (*1*−*6*). QDs display unique size dependent optical properties for potential applications from electronic to biomedical fields. In the field of biomedicine, the high luminescence, single excitation narrow emission, and low photobleaching properties of high quality water-soluble QDs with low toxicity are exploited for *in vivo* labeling/imaging of cells (*7*−*11*), and their surfaces have been functionalized with DNA (*12*−*14*), peptides (*15, 16*), proteins (*5, 6, 17, 18*), and other small ligands (*19*−*21*) to realize their applications as a new class of size-tunable optical probes.

Several strategies have previously been reported in the surface functionalization of water-soluble QDs with surface functional groups (*22*−*27*). The promised method generally used for the functionalization of QDs is encapsulating the QDs with water-soluble polymer chains (*26, 27*) or charged proteins (*18*), which improve their solubility, reduce toxicity, and essentially preserve their initial optical properties in physiological conditions. As the main application of functionalized QDs concern the labeling of cells, specific ligands have to be incorporated for site specific binding of the functionalized QDs, and the cytotoxicity of QDs have to be considered as well.

Protein−carbohydrate interactions are involved in a wide variety of cellular recognition processes including cell growth regulation, differentiation, adhesion, cancer cell metastasis, cellular trafficking, inflammation by bacteria and viruses, and immune response (*28, 29*). However, individual carbohydrate−protein interactions are generally weak, and multivalent forms of carbohydrate ligands, such as glycopolymers (*30*−*34*), glycodendrimers (*35*−*37*), or glyconanoparticles (*38, 39*), have been used to enhance them through cooperative multiple interactions. Therefore, the functionalization of QDs with carbohydrates is of interest for the study of carbohydrate−cell interactions. The incorporation of carbohydrates on the surface of the QDs is also expected to improve the solubility and biocompatibility, and reduce the toxicity of fluorescent nanocrystals. Sun and co-workers (*20*) were the first to report glyco-functionalized QDs with biotin end-terminated glycopolymers synthesized via a cyanoxyl-mediated free radical polymerization. However, the glycopolymers with free hydroxyl groups were obtained via polymerization of the protected glycomonomer and deprotection after polymerization. Recently, Babu et al. (*19*) reported the functionalization of QDs with several carbohydrates bearing reactive thiol groups at the end chains in aqueous solution via the ligand exchange method, and the special binding of the fluorescent glyconanoparticles to glycoproteins was studied. However, in both of the reports, the biocompatibility of the carbohydrate functionalized QDs, which is important for potential biomedical applications, is still to be investigated.

Biotinylated QDs have also been synthesized for the study of site-specific biomolecular interactions of biotin and avidin as a ligand−receptor pair, which was widely used in the fields of biology and medicine (*40, 41*). Two new ligands consisting of thiol and biotin terminal groups were synthesized to functionalize the surface of QDs reported by Reiss et al. (*7*) Another new series of ligands comprising a poly(ethylene glycol) chain, a dihydrolipoic acid, and a potential biological functional group such as biotin were designed and prepared by Mattoussi and co-workers (*9*). However, both of the biotinylated QDs were prepared via the ligand exchange method, which usually changes the optical properties of original QDs, and the ligands used generally need complicated synthesis. Therefore, designing well-defined biotinylated glycopolymers bearing biotin and carbohydrates moieties as pendent groups is interesting for the fabrication of high quality water-soluble and bioactive QDs with low toxicity.

In order to maximize the biological functions of the QDs, we herein report two different strategies to prepare stable surface functionalized QDs with both biotin and carbohydrates moieties. Our motivation here is to incorporate carbohydrate and biotin moieties on the surface of QDs for improving biocompatibility

and cell viability of the original QDs. Two strategies are used to functionalize the surface of original carboxyl-capped QDs, and the bioavailability of the biotin ligands on the surface of functionalized QDs is quantified. The cytotoxicity of biotinylated glyco-functionalized QDs is clearly reduced as shown by MTT assay results.

EXPERIMENTAL SECTION

Materials. 2-Aminoethyl methacrylamide hydrochloride (AEMA) (*42, 43*), gluconamidoethyl methacrylamide hydrochloride (GAEMA) (*44*), and *S*,*S*′-bis(α,α′-dimethyl-α″-acetic acid) trithiocarbonate (CTA1) (*45*) were synthesized as previously described. 4,4′-Azobis(4-cyanovaleric acid) (ACVA, 97%) was purchased from Acros Organics and used as received. 1-Ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride (EDC) and *N*-hydroxysuccinimide (NHS) were purchased from Sigma-Aldrich and used as received. The synthesis and characterization of biotinyl-*N*-hydroxysuccinimide ester (biotin-NHS), *N*-(2-aminoethyl) biotinamide (biotin-NH_2), *N*-(2-aminoethyl) gluconamide hydrochloride (sugar-NH_2), and biotinyl-2-aminoethyl methacrylamide hydrochloride (BAEMA) are given in Supporting Information.

Quantum dots (yellow color, carboxy-functionalized CdS-capped CdTe nanoparticle solution, sodium as carboxyl counterion; 20 mg/mL in water, and emission maxima wavelength and full-width at half-maximum (FWHM) are 563 and 90 nm at 350 nm of excitation, respectively) with surface carboxylic groups were obtained from Northern Nanotechnologies Inc., and their detailed information could be checked at https://store.vivenano.com/library/Qdots_specs.pdf. Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum, phosphate buffered solution at pH 7.4 (DPBS), trypsin, and a (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, a tetrazole) assay kit (MTT assay kit) were purchased from Sigma-Aldrich Chemicals.

Preparation of P(GAEMA-*stat*-AEMA-*stat*-BAEMA) Copolymer via RAFT Polymerization. The RAFT polymerization was achieved at 70 °C, employing ACVA as the initiator and CTA1 as the chain transfer agent. A typical protocol was as follows. In a 10 mL flask, GAEMA (0.5 g, 1.46 mmol) and BAEMA (0.21 g, 0.54 mmol) were dissolved in distilled water (3 mL) at 40 °C and then cooled to room temperature. AEMA (0.18 g, 1.09 mmol, dissolved in 1.0 mL water) and the mixture of ACVA (2.0 mg, 0.007 mmol) and CTA1 (10 mg, 0.035 mmol) dissolved into 2 mL of dioxane were added into the above solution. After degassing via three freeze-pump-thaw cycles, the flask was placed in an oil bath preheated at 70 °C to start the polymerization. After 18 h, the flask was placed into liquid nitrogen to quench the polymerization. The mixture was diluted with water and then precipitated into an excess of isopropanol. This purification cycle was repeated twice. The obtained slightly yellow powder (0.60 g, 67% yield) was dried in a vacuum oven overnight at room temperature.

EDC Coupling. Quantum dots solution (1 mL) was added to PBS buffer solution (pH 7.4, 4 mL) of EDC (2.6 mg) and NHS (1.5 mg). The reaction mixture was stirred for 30 min at room temperature. Then the P(GAEMA-*stat*-AEMA-*stat*-BAEMA) copolymer (10.0 mg in 35 mL of PBS buffer solution) or the mixture of sugar-NH_2 (2.6 mg, dissolved in 34 mL of PBS buffer solution) and biotin-NH_2 (1.1 mg in 1 mL of DMF) was added to the above PBS buffer solution. After stirring the reaction mixture overnight at room temperature, the mixture was purified by dialysis against distilled water for 2 days using the dialysis membrane molecular weight cut-off (MWCO) of 12,000−14,000. The desired QDs were freeze-dried under vacuum for 2 days.

Instrumentation. ^{1}H NMR spectra of the monomers and polymers were recorded on a Varian 200 MHz instrument. Aqueous gel permeation chromatography analysis was performed on a Viscotek Instrument using a 0.5 M sodium acetate/acetic acid buffer as eluent, two Waters WAT011545 columns, and a flow rate of 1.0 mL/min. Six near-monodisperse PEO standards (M_p = 1,010−101,200 g mol^{-1}) were used for calibration.

The products were analyzed by an Agilent HPLC 1100 interfaced with an Electro-Spray Ionization Agilent Mass Spectrometer Model 6120 with a Chemstation data system LC-MSD B.03.01.

Dynamic light scattering (DLS) was performed at room temperature using a Viscotek DLS instrument with an He−Ne laser at a wavelength of 632 nm and a Pelletier temperature controller. The surface functionalized quantum dot aqueous solutions (20 nM) were filtered through Millipore membranes (0.45 μm pore size). The data was recorded with OmniSize Software.

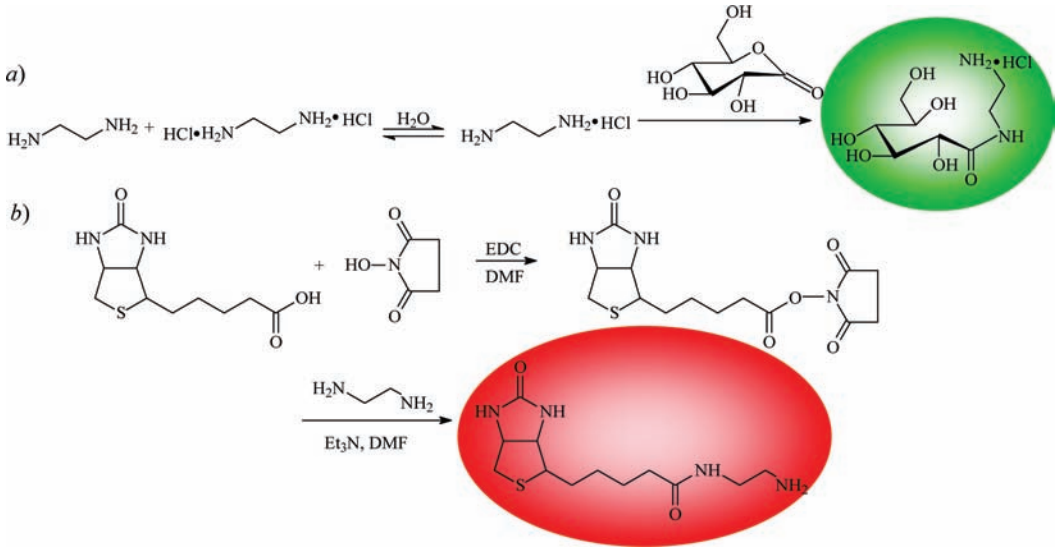
The 4-hydroxyazobenzene 2-carboxylic acid (HABA)/avidin binding assay was performed as described by Green group (*46, 47*). UV−visible absorption spectra were recorded on a Cary UV 100 spectrophotometer from the aqueous solution of surface functionalized quantum dots at room temperature. The absorbance values at 500 nm for the HABA/avidin reagent and for the solution after the addition of surface functionalized quantum dots were monitored. Before the samples were tested, the solutions were filtered through Millipore membranes (0.45 μm pore size) and then concentrated or diluted to the appropriate concentration. The change of absorbance at 500 nm of HABA/avidin and after HABA/avidin added surface functionalized quantum dots should be at 0.1−0.4.

Fluorescence measurements were performed on an OLISRSM-1000 (Desa rapid-scanning monochromator spectrophotometry system). The spectra were recorded in the wavelength range of 500−650 nm upon excitation at 490 nm; a 1.00 cm path length rectangular quartz cell was used for this study. Very dilute solutions of surface functionalized quantum dots (20 nM) were used in the experiment.

Cell viability/cytotoxicity of quantum dots was characterized using an MTT (3-(4,5-bimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, a tetrazole) assay. HeLa cells were plated in a 96-well plate at a density of 15000 cells/well in 100 μL of growth medium consisting of Dulbecco's modified Eagle's medium (DMEM) with 5% fetal bovine serum and antibiotics (100U/mL penicillin and 100 μg/mL streptomycin). Cells were incubated for 24 h at 37 °C and 5% CO_2, after which time the growth medium was replaced with DMEM medium containing different concentrations of quantum dots. The preparation of QD stock solutions was as follows. All aqueous quantum dot solutions were dissolved into Dulbecco's phosphate buffer at a final concentration of 32 nM. The samples were autoclaved, and different volumes of prepared solution were added into different volumes of DMEM medium to obtain final concentrations of 2, 10, and 20 nM of QDs in the medium. The cells were further incubated for 24 h under the same conditions, after which 25 μL of MTT dye was added to each well, and the plate was incubated for 2 h. Next, 100 μL of MTT lysis solution was added to each well, and cells were incubated overnight. Absorbance was measured at 570 nm (Power wave X plate reader). Survival percentage was calculated by comparison to blank cells (100% survival).

Confocal microsocopy was performed to determine the uptake of QDs by HeLa cells. HeLa cells were grown in Dubelcco's modified Eagle's medium, DMEM, containing 10% fetal bovine serum, and 1% penicillin/streptomycin, in a humidified atmosphere with 5% CO_2 at 37 °C. Upon 80% confluency, cells were trypsinized and neutralized with an equal amount of medium. The cells were then reseeded in a 6 well plate, in which each

Scheme 1. Schematic Illustration of the Synthesis of *N*-(2-Aminoethyl)gluconamide Hydrochloride (Sugar-NH_2) and *N*-(2-Aminoethyl)biotinamide (Biotin-NH_2)



well contained sterile glass coverslips. The plate was incubated in a humidified atmosphere at 37 °C, and upon 80% confluency, 75 nM QDs containing medium was introduced in chambered cover glass. The cells were further incubated for 3 h at 37 °C. The growth medium was then removed, and the cells were washed several times with phosphate buffered saline. The cells were fixed with 4% paraformaldehyde solution at room temperature for 5 min, followed by washing with PBS. The cover glass was then mounted on a microscopic glass slide and was studied under a microscope. The fluorescent images were obtained using a Zeiss LSM 510 Meta confocal microscope with a 63× objective. The wavelengths of excitation and emission used were 490 and 510 nm, respectively.

RESULTS AND DISCUSSION

Quantum dots (QDs) have attracted tremendous interest because of their remarkable and unique properties such as photochemical stability, size dependent broad absorption, very high extinction coefficients, and high fluorescence quantum yield (*1, 2, 48, 49*). Such features make the QDs an indispensable tool for use in biomedical research, especially for biological assays and imaging. Recent advances in QD nanoparticles have led to the development of high-quality water-soluble biotin or sugar functionalized QDs to reduce the toxicity of QDs for biomedical applications (*7, 20*). To the best of our knowledge, there is only one report that describes the functionalization of QDs using both biotin and sugar groups (*20*). However, the reported method requires a multiple step synthetic process, and therefore, our goal was to find a simple method to fabricate biotin and sugar functionalized QDs without protecting group chemistry.

The original quantum dots (yellow color) used in this study were donated by Northern Nanotechnologies, which were carboxy-functionalized in CdS-capped CdTe nanoparticle solution, with sodium as carboxy counterion, and stabilized in aqueous solution by the carboxyl terminated polymer chains. The polymers improve their water solubility in basic conditions and provide the surface for further functionalization. In order to obtain the surface biotin and sugar functionalized QDs from the carboxyl-capped QDs, two methods could be used. The first approach is to modify the COOH groups with small biotin and carbohydrate molecules bearing amine groups. Alternatively, the QD surface could be modified with biotinylated glycopolymers bearing biotin, amine, and carbohydrate as pendent moieties.

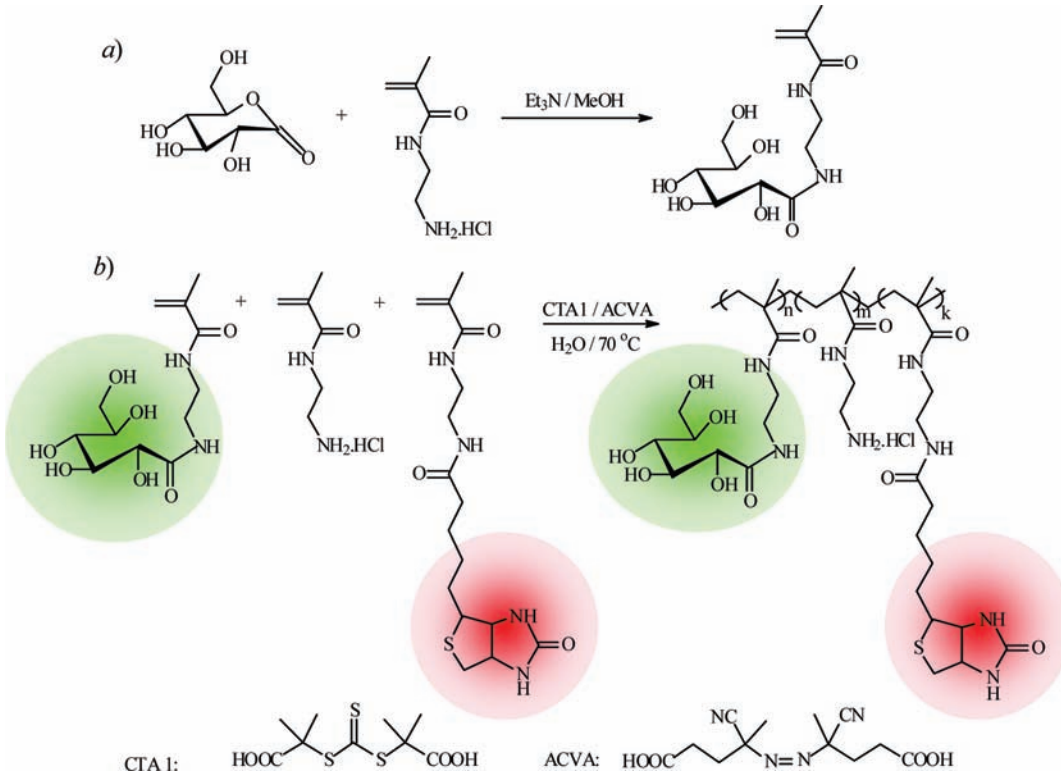
Synthesis of Biotin-NH_2 and Sugar-NH_2. Although, various biotin functionalized QDs have been reported in the literature, very few studies deal with the direct functionalization of the QD surface. The general approach deals with the fabrication of QDs with avidin groups, which are then conjugated with biotin to form the desired QDs. Recently, biotinylated CdSe/ZnSe nanocrystals were directly synthesized by Reiss et al. (*7*) with two new ligands consisting of a thiolated diethylene glycol derivative and an alkylthiol substituted biotin molecule by the ligand exchange method. They further demonstrated that functionalized QDs could be used for special fluorescent labeling. However, the fabrication process of two ligands needs multistep synthetic pathways in their study, and the ligand exchange method usually changes the optical properties of original QDs. Therefore, we have aimed at the synthesis of biotin and sugar reagents via a simple and straightforward method to obtain the biotinylated glyco-functionalized QDs.

Herein, the biotin bearing terminal amino group was fabricated via a two-step synthesis to functionalize the carboxyl-capped QDs from D-biotin. The D-biotin was first activated by the NHS to form biotin-NHS and then reacted with ethylenediamine to obtain biotin-NH_2 as shown in Scheme 1a. In order to minimize side reactions in the fabrication process, the DMF solution of BNHS was added dropwise into the flask containing ethylenediamine to avoid any possible side reactions. The product was characterized by ^{1}H NMR in d_6-DMSO solvent and mass spectrometry to confirm the formation of the desired product (Figures S1 and S2, Supporting Information).

Similarly, the sugar bearing terminal amino group (sugar-NH_2) was synthesized by the reaction of D-(+)-gluconic acid δ-lactone with ethylenediamine as shown in Scheme 1b. A sticky yellow product was obtained in high yield (~90%), and the chemical structure was confirmed by mass spectrometry (as shown in Figure S3 in Supporting Information).

Synthesis of Monomers and RAFT Polymerization. Quantum dots were usually encapsulated with water-soluble polymer chains to improve their water solubility and reduce their toxicity. The polymers bearing the sugar or biotin groups were found to be ideal to enhance biocompatibility and for their potential use in biosensing applications. These new types of nanoparticles linked with bioactive groups will maintain the optical properties of original QDs and offer new opportunities for multicolor imaging of molecular targets in living cells. We have therefore synthesized the monomers bearing sugar or biotin moieties and

Scheme 2. Schematic Illustration of the Synthesis of the 2-Gluconamidoethyl Methacrylamide (GAMEA) Monomer and the P(GAEMA-*stat*-AEMA-*stat*-BAEMA) Copolymers



the monomer containing amino groups for realizing the possibility to link the polymer chain onto the surface of original QDs.

The detailed synthesis process of the amine-based monomer (AEMA) and carbohydrate-containing monomer (GAEMA) has been reported by our group (*42*−*44*). Similarly, a novel biotin-containing monomer, BAEMA, was prepared by the reaction of biotin-NHS with AEMA. The structure has been confirmed via ^{1}H NMR spectroscopy and mass spectrometry (as shown in Figures S1d and S4, Supporting Information).

Reversible addition−fragmentation chain transfer polymerization (RAFT) is a highly versatile method as it works well both in aqueous and organic media for the synthesis of polymers with controlled dimensions (*50*−*54*). The controlled RAFT polymerizations of AEMA and GAEMA monomers in aqueous media have been well documented in our group (*42, 44*). PBAEMA could also be obtained via RAFT polymerization for the characteristic RAFT processes. In preliminary experiments, RAFT polymerization of BAEMA was attempted in 1,4-dioxane and water (v/v = 1:2) at 70 °C using CTA 1 as the chain transfer agent. The PBAEMA homopolymer could be obtained with narrow polydispersity (less than 1.3), but the conversion is very low (about 30% calculated from ^{1}H NMR spectroscopy) even after 18 h. This may be related to the hindrance effect of the biotin group in the RAFT process. In our case, our aim is to obtain the copolymer-bearing biotin groups to functionalize desired QDs. As BAEMA was structurally similar to AEMA and GAEMA, the statistical RAFT copolymerization of AEMA, GAEMA, and BAEMA using CTA 1 as the RAFT agent was quite expected, leading to the formation of the P(GAEMA-*stat*-AEMA-*stat*-BAEMA) copolymer (Scheme 2).

Polymerization was carried out using CTA1 as the chain transfer agent and ACVA as the initiator. The ratio of CTA to initiator was set to 5. The AEMA monomer was used in the protonated form during polymerization to prevent any side reactions of the primary amino group to the chain transfer groups. Furthermore, it has been demonstrated in previous reports that the amine groups of the AEMA monomer in the protonated form have no influence on the RAFT process (*42, 43*). The carbohydrate monomer used, GAEMA, is a kind of acrylamide monomer and is very stable in aqueous solution. After polymerization for 18 h, the final statistical glycopolymer was obtained and denoted P(GAEMA$_{36}$-*stat*-AEMA$_{24}$-*stat*-BAEMA$_{4.4}$) from the ^{1}H NMR and HABA/avidin binding assay results, and the GPC trace in Figure S5b (Supporting Information) shows a monomodal peak with a very low polydispersity index (1.19), which has a M_n about 12,900 g/mol using polyethylene oxide as standards. The details are given in Supporting Information.

Bioconjugated Quantum Dots via Covalent Functionalization. Water-soluble QDs (yellow color) containing surface carboxylic groups were used in this study. The QDs are originally dispersed in basic aqueous solution, but they rapidly lost fluorescence below pH 6−6.5. Some of the carboxylic groups on the surface of the QDs are activated using the NHS/EDC coupling method once the pH of the QDs solution was fixed at 7.4 using PBS and subsequently reacted with the biotinylated glycopolymer or the mixture of biotin-NH_2 and sugar-NH_2 as shown in Figure 1. The primary amino group on the statistical copolymer or biotin and sugar reagents was targeted to react with the activated carboxylic groups on the QDs. Since we are only aiming at modifying the surface carboxyl groups of the QDs, we do not expect a significant change in the quantum yield of the original QDs. Fluorescence spectra were recorded on the original QDs, biotin and sugar functionalized QDs, and biotinylated glycopolymer functionalized QDs. Both surface functionalized QDs still show strong fluorescence indicating that the surface modification did not cause a significant change in the optical properties of the original QDs (Figure 2), which is as expected.

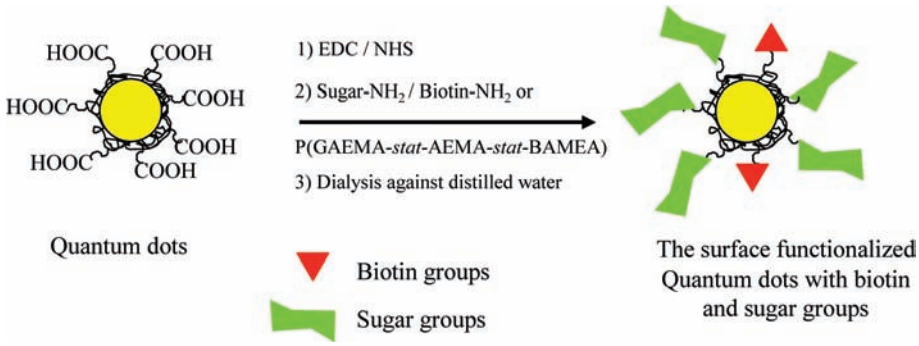


Figure 1. Schematic illustration of the fabrication of biotin and sugar surface functionalized or glycopolymer functionalized QDs.

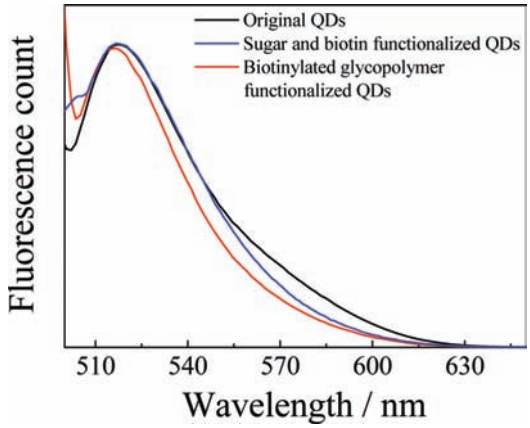

Figure 2. Emission spectra of original QDs, biotin and sugar functionalized QDs, and biotinylated glycopolymer functionalized QDs, where the excitation wavelength is at 490 nm.

After surface functionalization, the QDs were further investigated by dynamic light scattering (DLS). Figure 3 shows the number size distribution of original QDs, biotin and sugar functionalized QDs, and biotinylated glycopolymer functionalized QDs. The size distributions of both surface functionalized QDs are relatively narrow (less than 0.15), and the size of biotin and sugar functionalized QDs is similar to that of original QDs, which further confirms that surface functionalization has no influence on the physical states of original QDs. The glycopolymer functionalized QDs revealed a larger size (10−11 nm), which confirms the successful functionalization of the glycopolymer to the QDs. It should be noted that the covalent attachment of the RAFT copolymer to a carboxylated polymer chain coating already present on the surface of the original QDs causes a significant increase in the size of QDs. The DLS data and fluorescence spectra confirm that surface functionalization of QDs does not alter their optical properties.

The functionalized QDs are stable, and no precipitates were observed even after several weeks when dispersed in aqueous basic solution condition. This is not considered as a significant change in the water solubility of surface functionalized QDs, when compared to that of the original QDs. However, when the solution pH is changed to acidic conditions (pH 5−6) the surface functionalized QDs remain stable and maintain their fluorescence even after two weeks. It clearly shows that the QDs after surface modification have excellent water solubility and colloidal stability compared to those of the original QDs over a broad pH range.

HABA/Avidin Binding Assay. After EDC coupling, the surface of functionalized QDs must contain the biotin groups, but the amount of surface available biotin groups was difficult to calculate directly especially for the surface modification

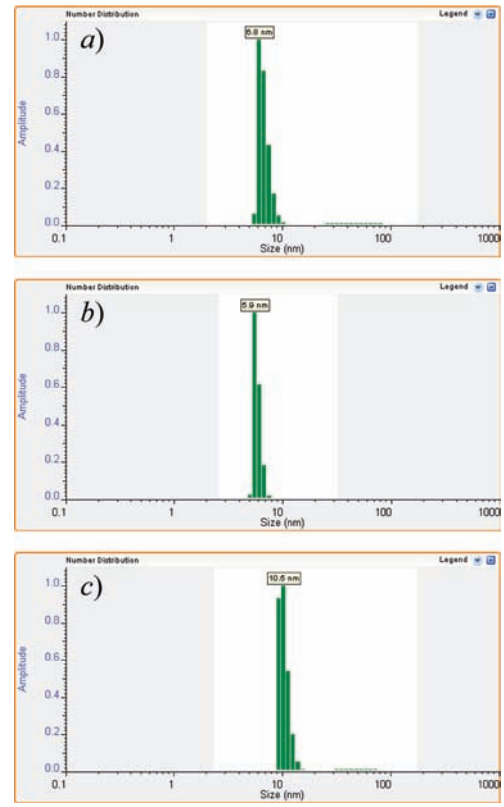

Figure 3. DLS number average distribution of original QDs, biotin and sugar functionalized QDs, and biotinylated glycopolymer functionalized QDs.

of QDs using the synthesized glycopolymer. To prevent possible flocculation of the QDs, the coupling reaction was carried out under high dilution to decrease the possibility of side reactions, and the amount and bioavailability of biotin presented from the functionalized QDs was evaluated and quantified using the HABA/avidin binding assay.

HABA is a dye that binds to avidin, and when HABA is complexed with avidin in water, the aqueous solution has a maximum absorbance at 500 nm. Upon addition of biotin or biotinylated reagents to the HABA/avidin solution, HABA is displaced quantitatively by available biotin, as avidin's affinity for biotin ($K_d = 10^{-15}$ M) is much higher than that of HABA ($K_d = 10^{-6}$ M). This displacement can be quantitatively monitored by the decrease in UV absorbance at a wavelength of 500 nm.

Upon addition of the functionalized QDs, the absorbance value at 500 nm of HABA clearly decreases, suggesting that HABA is displaced from the HABA/avidin complex by available biotin presented on the QD surface. The results of these analyses are shown in the overlaid UV−vis spectra

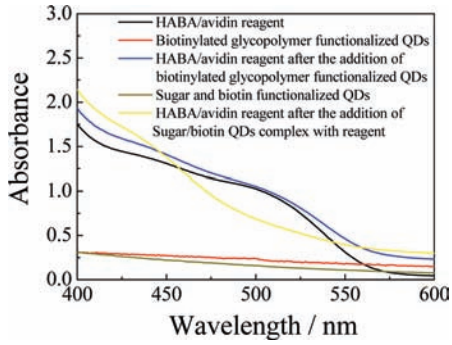

Figure 4. UV−vis spectra of the HABA/avidin reagent before and after the addition of surface functionalized QDs, biotinylated glycopolymer QDs, and sugar and biotin functionalized QDs, where the QDs concentrations were 0.02 μM and 0.1 μM for biotinylated glycopolymer QDs and sugar and biotin functionalized QDs, respectively.

(Figure 4). The amount of biotin in each biotinylated QD solution could be calculated by the following formula:

$$\Delta A_{500} = 0.9\ A_{\text{HABA / avidin}} + A_{\text{QDs}} - A_{\text{HABA / avidin+QDs}}$$

$$\mu\text{mol biotin/mL} = 10(\Delta A_{500}/34)$$

where the dilution factor of HABA/avidin is 0.9, the mM extinction coefficient of biotin at 500 nm is 34, and the dilution factor of QDs is 10.

The aqueous solution of QDs before or after surface functionalization is a colored solution and has an absorbance of about 0.238 at 500 nm after surface functionalization of QDs using polymer chains. So the total decreased absorbance of the HABA/avidin complex after the addition of surface functionalized QDs should be considered the initial absorbance of QDs. Although the absorbance of HABA/avidin complex solution seems to increase after the addition of the glycopolymer functionalized QDs solution as shown in Figure 4, the total absorbance after mixing actually decreases, and this decrease can be calculated by the above formula to be 0.11. The amounts of available biotin per mL of QDs solution were thus calculated to be 1.29 μmol and 0.93 μmol for the glycopolymer functionalized QDs and biotin and sugar functionalized QDs, respectively. According to the concentration of original QDs, which is about 0.8 μM, the quantity of available biotin per QD could be calculated to be ~1600 and ~1100 for biotinylated glycopolymer functionalized QDs and biotin and sugar functionalized QDs, respectively.

Cytotoxicity of the QD Solution. The actual application of QDs in biology needs to address the question about its toxicity. Many methods including polymer or silica encapsulation have been reported to reduce the toxicity of QDs, and it has been shown that the toxicity of QDs can be reduced by modifying the surface area of QDs (*55, 56*). In a recent study, biotin or carbohydrate coated QDs have been synthesized and are shown to be biocompatible. The main idea is to find new strategies that can encapsulate the QDs using biocompatible polymer chains to reduce toxicity. We have addressed this issue by surface functionalization of carboxylic acid coated QDs with polymer chains bearing a variety of biocompatible materials.

The *in vitro* cytotoxicity of the QDs is obtained using the MTT assay on the HeLa cell line. The assay determines the number of viable cells based on the mitochondrial activity of the cells. The MTT dye produces formazan crystals based on the mitochondrial activity of the cells. The MTT lysis buffer dissolves the formazan crystals produced, and their absorbance can be read at 570 nm, giving the approximate number of viable cells in each well. The wells that contained only the media were used as the negative control, and the wells containing untreated cells were used as the positive control. Each experiment was performed in triplicate and, % cell viability was obtained by QD treated cells/absorbance of positive control.

Confocal microsocopy was performed to determine the uptake of QDs by HeLa cells. The fluorescent images obtained were overlapped on bright field images to determine the site of localization of QDs in the cells shown in Figure 5. The images show the uptake of QDs by cells, after 3 h of incubation with cells. The images obtained confirm that MTT data provide the toxicity of QDs after their uptake by the cell line. The QDs are found to be mostly localized in the endosomes of the cells, thus indicating that the possible mechanism of uptake is receptor mediated endocytosis.

The cytotoxicity of QDs has been studied as a function of concentration. The biological and biomedical applications of QDs are highly dependent upon their biocompatibility. We therefore, studied the toxicity of QDs before and after surface functionalization at different concentrations. As shown in Figure 6, QDs were coated with sugar and biotin reagents, and glycopolymer P($GAEMA_{36}$-*stat*-$AEMA_{24}$-*stat*-$BAEMA_{4.4}$) individually, and their cytotoxicity values were compared to those of the original QDs. At very low concentration (2 nM), the cell viability of all QDs are found to be above 75%. Increasing the concentration of QDs up to 20 nM causes a significant increase in the toxicity of the original QDs, and the cell viability is only 59%. However, the cell viability for the glycopolymer functionalized QDs is 89% at this concentration. It is also apparent from the graph that biotin and sugar coated QDs also show

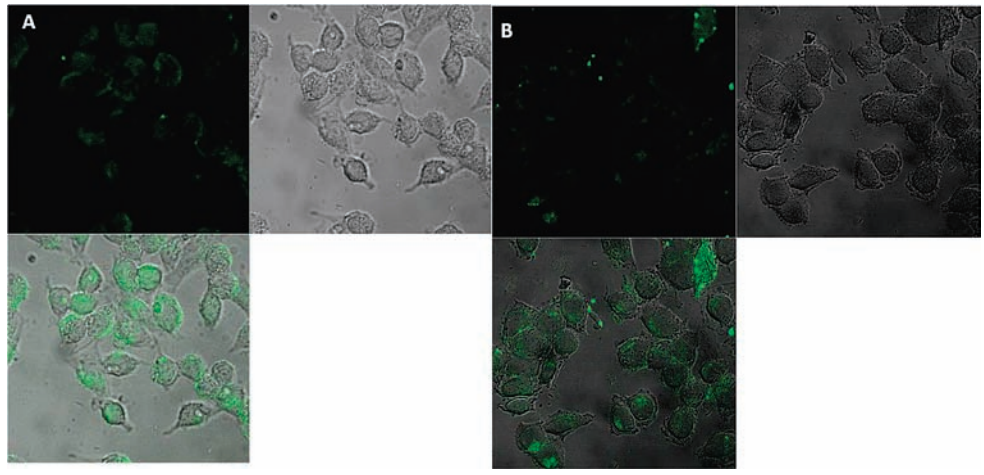

Figure 5. Representative fluorescent and white cell images of HELA cells incubated with (A) sugar and biotin functionalized QDs and (B) biotinylated glycopolymer functionalized QDs.

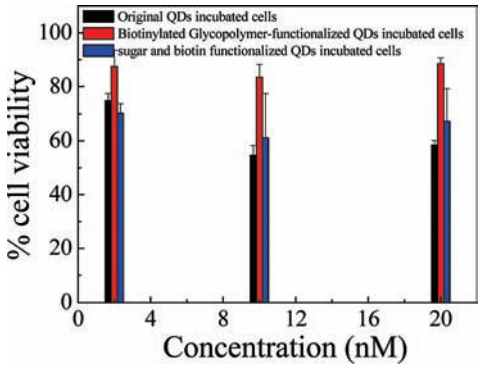

Figure 6. Percent cell viability/cytotoxicity as a function of different QD concentrations before and after surface functionalization.

concentration dependent cytotoxicity, which is comparable to that of the original QDs, whereas the cytotoxicity is negligible for glycopolymer stabilized QDs, regardless of concentration. Although, all of the molecules used for the surface functionalization of QDs are biocompatible, the 12.9 kDa glycopolymer seems to mask the surface of QDs more efficiently, thus accounting for the low toxicity, when compared to small molecules such as sugar and biotin coated QDs. The biotinylated glycopolymer functionalized QDs may be suitable for use in some potential biomedical applications.

It should also be noted that the original QDs have been functionalized by water-soluble polymer chains, which also prevent the release of metal and increase the cell viability of QDs.

CONCLUSIONS

We have successfully synthesized biotin and carbohydrate functionalized reagents for the surface functionalization of QDs. The modified QDs have a high affinity biotin ligand as well a high density of surface carbohydrate moieties. The surface modified QDs showed excellent optical properties and colloid stability compared to those of the original QDs at whole pH conditions. The amount of available biotin was quantified via the HABA/avidin binding assay, and surface functionalization using the glycopolymer chains bearing biocompatible biotin and carbohydrate moieties clearly reduces the cytotoxicity of original QDs. Therefore, the designed biotinylated glyco-functionalized QDs have high potential for applications in biodiagnostic devices or *in vivo* cellular imaging. In our current case, the amount of carbohydrate moieties and their interaction with protein have not been studied. We will study the bioavailability of the surface carbohydrate moieties on the QDs for various carbohydrate−protein interactions in our next work, which is of considerable interest in biomedicine.

Biotinylated Glyco-Functionalized Quantum Dots: Synthesis, Characterization, and Cytotoxicity Studies

Xiaoze Jiang, Marya Ahmed, Zhicheng Deng, and Ravin Narain*

Department of Chemistry and Biochemistry, Biomolecular Sciences Program, Laurentian University, 935, Ramsey Lake Rd, Sudbury, ON, P3E 2C6, Canada

Experimental Section

Materials. D-Biotin, D-(+)-gluconic acid δ-lactone, *N*-hydroxysuccinimide (NHS), Ethylenediamine, 1-ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride (EDC), 1,3-Dicyclohexylcarbodiimide (DCC), and ethylenediamine dihydrochloride were purchased from Sigma-Aldrich and used as received. 2-Aminoethyl methacryl-amide hydrochloride (AEMA) was synthesized as previously described (1). 4,4'-Azobis(4-cyanovaleric acid) (ACVA, 97%) was purchased from Acros Organics and used as received. *N*,*N*'-Dimethylformamide (DMF), isopropanol, methanol, hydroquinone, 1,4-dioxane, and other chemical solvents were purchased from Caledon Chemicals and used as received. Doubly distilled de-ionized water was used in all experiments, and PBS buffer solution (pH 7.4) was used.

Synthesis of Biotinyl-*N*-hydroxysuccinimide Ester (Biotin-NHS)

D-Biotin (2.00 g, 8.19 mmol) and *N*-hydroxysuccinimide (0.94 g, 8.19 mmol) were dissolved into hot anhydrous DMF (60 mL, 70 ^{o}C) in a 100 mL round-bottom flask with

stirring. 1,3-Dicyclohexylcarbodiimide (DCC, 2.19 g, 10.65 mmol) was added, and the solution was stirred overnight at room temperature. The formed dicyclohexylurea was filtered off; most of the solvents were evaporated, and the residue precipitated into excess ether. The white precipitate was filtered and washed with isopropanol three times to give a white powder, and this solid was recrystallized in isopropanol. The final yield of the product is 85%. Finally, its structure was confirmed via ^{1}H NMR spectroscopy as shown in Figure S1b. ^{1}H NMR in d_6-DMSO, δ (ppm): 4.1 and 4.3 [m, 2H, (C*H*NH)$_2$CO], 3.1(m, 1H, SC*H*), 2.7-2.9 (d and s, 6H, SCH_2 and CH_2CON), 2.6(t, 2H, CH_2COO), 1.0-1.7(m, 6H, CHCH_2CH_2CH_2).

Synthesis of *N*-(2-Aminoethyl) Biotinamide (Biotin-NH$_2$)

Ethylenediamine (150 *u*L, 2.2 mmol), triethylamine (1.5 mL), and DMF (10 mL) were added into a round-bottom 50 mL flask fitted with a stirrer. A DMF solution (5 mL) of biotin-NHS (0.75 g, 2.2 mmol) was added dropwise at room temperature under nitrogen atmosphere and stirred overnight. The formed precipitate was filtered off, most of the solvents were evaporated, and the residue precipitated into excess hexane. The white precipitate was filtered and washed with isopropanol three times to give a white powder. The final yield of the product is 70%. ^{1}H NMR in d_6-DMSO as shown in Figure S1c, δ (ppm): 4.1 and 4.3 [m, 2H, (C*H*NH)$_2$CO], 2.9-3.2(m, 3H, SC*H* and CONHCH_2), 2.8(d and dd, 2H, SCH_2), 2.6(t, 2H, CH_2NH$_2$), 2.0(t, 2H, CH_2CONH), 1.0-1.7(m, 6H, CHCH_2CH_2CH_2). ESI-MS: calcd. For $(C_{12}H_{22}N_4O_2S + H)^+$: 287.4; found: 287.2.

Synthesis of *N*-(2-Aminoethyl) Gluconamide Hydrochloride (Sugar-NH$_2$)

Ethylenediamine (5.5 mL, 0.08 mol) was added to an ethylenediamine dihydro-

chloride solution (12.76 g, 96 mmol, in 100 mL distilled water) in a round-bottom flask fitted with a stirrer. After 1 h of stirring, aqueous solution (70 mL) of D-(+)-Gluconic acid δ-lactone (14.25 g, 0.08 mol) was added dropwise into the above solution cooled in an ice bath condition. The mixture was stirred at room temperature overnight. Finally, the solvent was removed under vacuum; the crude product was washed with isopropanol twice. The product was dissolved into methanol and precipitated into isopropanol twice; the viscous product was dried under vacuum. The final yield of the product is 90%. ^{1}H NMR in D_2O, δ (ppm): 4.35(d, 1H), 4.1(t, 1H), 3.5-3.85 (m,6H), 3.1-3.2(t, 2H). ESI-MS: calcd. For ($C_8H_{19}N_2O_6Cl$) : 274.7; found: 275.

Synthesis of Biotinyl-2-Aminoethyl Methacrylamide Hydrochloride (BAEMA)

Biotin-NHS (0.85 g, 2.5 mmol), hydroquinone (0.05 g), triethylamine (0.7 mL), and 2-aminoethyl methacrylamide hydrochloride (AEMA, 0.41g, 2.5 mmol) were dissolved in 15 mL anhydrous DMF. This solution was stirred overnight at room temperature, the solid formed was filtered off and DMF was evaporated under reduced pressure. The residue was precipitated into ether and was washed with isopropanol three times. The powder was dried overnight under vacuum. The yield is 70%. ^{1}H NMR in d_6-DMSO as shown in Figure S1d, δ (ppm): 5.3 and 5.6(s, 2H, CH_2CCH_3), 4.1 and 4.3 [m, 2H, (CHNH)$_2$CO], 2.9-3.2(m, 5H, SCH, CONHCH_2, and CH_2CH_2NH), 2.8(d and dd, 2H, SCH_2), , 2.0(t, 2H, CH_2CONH),, 1.7 (s, 3H, CH_2CCH_3), 1.0-1.7(m, 6H, CHCH_2CH_2CH_2). ESI-MS: calcd. For ($C_{16}H_{26}N_3O_4S$ + Na)$^+$: 377.5; found: 377.2.

Synthesis of Gluconamidoethyl Methacrylamide Hydrochloride (GAEMA)

D-(+)-Gluconic acid δ-lactone (1.77 g, 0.08 mol) and hydroquinone (0.05 g) were dissolved in methanol at 50 °C and then cooled to room temperature before the addition of 2-aminoethyl methacrylamide hydrochloride (AEMA) (2.0 g, 0.012 mmol) and triethylamine (10 mL). The mixture was stirred overnight at room temperature, concentrated by rotary evaporation, and precipitated into isopropanol. The white solid formed was filtered, washed with isopropanol three times, and dried under vacuum. The final yield of the product was 95%. ^{1}H NMR (D_2O, ppm): 5.7(s, 1H), 5.4(s, 1H), 4.35(d, 1H), 4.1(t, 1H), 3.6-3.85 (m, 4H), 3.4 (t, 4H).1.85 (s, 3H).

Characterization

1. Characterization of small reagents. The characteristic signals of biotin, biotin-NHS, and biotin-NH_2 were shown in Figure S1, and the characteristic signals of succinimide group at δ 2.8 ppm could be detected in the ^{1}H NMR spectrum of biotin-NHS (shown in Figure S1b), and subsequently disappear after reaction with ethylenediamine (shown in Figure S1c). From the peak integration, the purities of both desired products could be calculated to be above 95%. The purity of biotin-NH_2 was further confirmed by mass spectrum (shown in Figure S2 in supporting information).

Similarly, the sugar bearing terminal amino group (Sugar-NH_2) was synthesized by the reaction of D-(+)-Gluconic acid δ-lactone with ethylenediamine, and the chemical structure was confirmed by mass spectrum (shown in Figure S3).

BAEMA monomer was synthesized by the reaction of biotin-NHS with AEMA, it's structure was confirmed via ^{1}H NMR spectroscopy (shown in Figure S1c). The characteristic signals of double bond at δ 5-5.5 ppm of BAEMA are clearly evident, and the signal of succinimide group for biotin-NHS at δ 2.8 ppm also disappear after being replaced by AEMA. The purity of obtained BAEMA monomer could be calculated to be above 95% based on integration of the peaks at δ 5-5.5 ppm and δ 4.0 ppm, and the purity was further confirmed also by mass spectrum shown in Figure S4.

2. Characterization of biotinylated glycopolymer. The final statistical glycopolymer was obtained and analyzed by ^{1}H NMR in D_2O solvent. The GAEMA monomer conversion is about 80% in this polymerization condition, and the DP_n of GAEMA and AEMA could be calculated to be 36 and 24, respectively, from their characteristic signals at δ 3-4 ppm shown in Figure S5a. However, the signals of BAEMA could not be clearly detected or quantified by ^{1}H NMR as the characteristic peaks of BAEMA were masked. The amount of biotin contents in the glycopolymer was therefore further quantified to 4.4 using HABA/avidin binding assay. By dissolving the glycopolymer into water and adding into the HABA/avidin solution, the change of absorbance of HABA/avidin complex at 500 nm was monitored using UV-vis absorption spectra. The obtained glycopolymer was thus denoted P(GAEMA$_{36}$-*stat*-AEMA$_{24}$-*stat*-BAEMA$_{4.4}$). Aqueous gel permeation chromatography was used also to analyze the polymer, and a mono-modal peak with a very low polydispersity index was obtained as shown in Figure S5b. The M_n and M_w/M_n were determined to be 12,900 and 1.19, respectively. By comparing to the theoretical molecular weight

($M_{n,theo}$ = 18,130) calculated from the conversion using ^{1}H NMR spectroscopy, the experimental M_n is found to be smaller and this is attributed to the fact that a conversion GPC calibration was used using polyethylene oxide as standards.

Design, Synthesis, and Imaging of Small Amphiphilic Rhenium and ^{99m}Technetium Tricarbonyl Complexes

Eszter Boros,[†,§] Urs O. Häfeli,[‡] Brian O. Patrick,[†] Michael J. Adam,*[,§] and Chris Orvig*[,†]

Medicinal Inorganic Chemistry Group, Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, British Columbia V6T 1Z1, Canada, Faculty of Pharmaceutical Sciences, University of British Columbia, 2146, East Mall, Vancouver, British Columbia, V6T 1Z3, Canada, and TRIUMF, 4004 Wesbrook Mall, Vancouver, British Columbia, V6T 2A3, Canada. Received January 20, 2009; Revised Manuscript Received March 9, 2009

The design, synthesis, radiolabeling, evaluation of stability, and in vivo investigation are presented of three variably charged, novel, short C_8 chain derivatized chelators for the $[M(CO)_3]^+$ core (M = ^{99m}Tc or Re). Labeling with $[^{99m}Tc(CO)_3]^+$ showed complex formation in under 1 h reaction time and high stability toward 24 h histidine and cysteine challenges, as well as distinctive log *P* values for each complex. Distinct localization of small amphiphilic molecules in in vivo systems depends on the charge of the polar moiety and was studied via biodistribution (4 h) and imaging (15 min, 1, 2, and 4 h) in female C57Bl/6 mice.

INTRODUCTION

Because of its low cost and availability, ^{99m}Tc has been a radionuclide of interest in radiopharmaceutical chemistry and nuclear medicine for the past four decades (*1*). Resulting from intensive research, the vast majority of nuclear medicine scans utilize this isotope, which displays the ideal physical properties $t_{1/2} = 6$ h and $\gamma = 141$ keV for imaging with single photon emission computed tomography (SPECT) (*2*). While today's imaging facilities still rely on high oxidation state Tc cores (*3*−*5*), much research has turned its focus toward the versatile and highly stable *fac*-$[^{99m}Tc(CO)_3(H_2O)_3]^+$ core developed by Alberto et al. (*6*). The *fac*-$[^{99m}Tc(CO)_3(H_2O)_3]^+$ complex has the metal center in a ^{99m}Tc(I)-d^6 low-spin electron configuration (inert toward a broad range of experimental conditions) and can be prepared in high yields via a commercially available kit (Isolink, Covidien, Mansfield, MA) under aqueous conditions using boranocarbonate anion as the reducing agent and in situ CO source (*6*). Simple exchange of the three water molecules can be achieved with suitable chelates in a *fac* coordination mode (*7*, *8*), shown previously on examples of bioconjugates such as derivatized amino acids, carbohydrates, peptides, and nucleosides (*9*−*11*).

Over the past decade, synthesis of novel imaging agents based on ^{99m}Tc has shifted toward target-specific peptide derivatives with one type of chelating entity for the $[^{99m}Tc(CO)_3]^+$ core, following the so-called "technetium-tagged" approach (*12*), In contrast to this, it was our aim in this work to obtain a simple, small, and nonspecific "technetium-based" complex with potential uptake in a large range of different tissues and also to explore the in vivo properties of novel, amphiphilic metal complexes of the $[Tc(CO)_3]^+$ core. In an attempt to achieve this, the synthesis incorporated a mimic of the charge distribution of molecules highly abundant and essential to cell membranes such as sphingosine (neutral), lysophosphatidic acid (negatively charged headgroup), and sphingomyelin (zwitterionic headgroup), aiming for an in vivo distribution of the resulting complexes comparable to other small amphiphilic molecules such as cocamidopropyl betaine (CAPB, zwitterionic), sodium dodecylsulfate (SDS, anionic), and octanol (neutral). These compounds, also known as surfactants, are known to integrate into the lipid bilayer, before their concentration (much larger than the concentration range imaging agents usually operate at) exceeds the saturation concentration and solubilizes the membrane (*13*). The synthesis was achieved by varying the tridentate chelator but attaching a short, saturated C8-chain in a consistent fashion via a simple ester bond; this differs strongly from the previously used tagged approach with long-chain fatty acids (*14*). The goal was also to investigate and compare the heart-specific uptake of these new compounds with strictly cationic conjugates (*15*, *16*). Therefore, the design of these molecules was such that the size of the polar and lipophilic entities are in the same size range but of strongly differing polarity (Figure 1). Exploring the in vivo behavior of these compounds, following the less investigated approach of nontarget-specific uptake of small amphiphilic molecules, was of major interest.

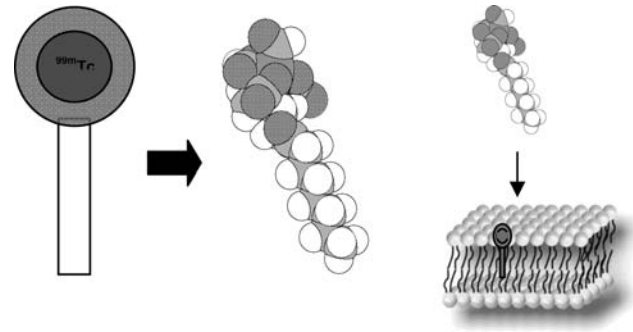

Figure 1. Envisioned biological pathway of the "integrated approach molecules".

EXPERIMENTAL DETAILS

Instruments and Materials. All solvents and reagents were used as received. $Re(CO)_5Br$ is commercially available (Strem). The analytical thin-layer chromatography (TLC) plates were aluminum-backed ultrapure silica gel 60, 250 μm; the flash column silica gel (standard grade, 60 Å, 32−63 mm) was from

Silicycle. ^{1}H and ^{13}C NMR spectra were recorded on Bruker AV300 or AV400 instruments at ambient temperature; the NMR spectra are expressed on the δ scale and referenced to residual solvent peaks or internal tetramethylsilane. Electrospray ionization mass spectrometry (ESI-MS) spectra were recorded on a Micromass LCT instrument at the Department of Chemistry, University of British Columbia. High-performance liquid chromatography (HPLC) analysis of cold compounds was done on a Phenomenex Synergi 4 μm Hydro-RP 80A column (250 $\times$ 4.6 mm) in a Waters WE 600 HPLC system equipped with a 2478 dual-wavelength absorbance UV detector run using the Empower software package. IR spectra were collected neat in the solid or liquid state on a Thermo Nicolet 6700 FT-IR spectrometer. TLC analysis of radiolabeled compounds was performed on a Bioscan-System 200 Imaging scanner, equipped with a Bioscan-Autochanger 100. Radio-TLCs were prepared with acetonitrile as the mobile phase. HPLC analyses of radiolabeled complexes were performed on a Knauer Wellchrom K-1001 HPLC equipped with a K-2501 absorption detector and a Capintec radiometric well counter. A Phenomenex Hydro-Synergi 4 μm C18 RP analytical column with dimensions 250 $\times$ 4.6 mm was used. HPLC solvents consisted of 0.1% trifluoroacetic acid in water (solvent A) and methanol (solvent B). Samples were analyzed and purified with a linear gradient method (100% solvent A to 100% solvent B over 30 min). For biodistributions, organ samples were counted in a Packard Cobra II autogamma counter one to two days after administration. μSPECT and CT images were recorded on an XSPECT instrument from Gamma Medica (Northridge, CA).

Syntheses (Schemes 1 and 2). *N*-Boc-Ethanolamine. Boc_2O (2.18 g, 10 mmol) was added to ethanolamine (610 mg, 10 mmol) at 0 °C and allowed to stir for 1 h. A colorless precipitate formed immediately with the evolution of heat. Column chromatography (hexanes/ethyl acetate, silica, 6:1) with subsequent evaporation of the solvent yields 1.45 g of the desired product as a colorless oil (9.9 mmol, yield 90%, $R_f = 0.1$). ESI-MS (MeOH, 30 V): 184.1 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 3.55 (t, CH_2-OH, 2H), 3.14 (t, CH_2-NH-Boc, 2H), 1.33 (s, (CH_3)$_3$, 9H), ^{13}C NMR ($CDCl_3$, 300 MHz, δ): 155.6 (carbonyl-*C*), 79.34 (*C*-(CH_3)$_3$), 61.6 (*C*H_2-OH), 42.98 (*C*H_2-NH-Boc), 28.17 ((*C*H_3)$_3$). IR (cm^{-1}): 1682 (m), 1517 (m), 1164 (m).

***N*-Boc-2-Aminoethyl Ester Octanoic Acid.** *N*-Boc-Ethanolamine (1.45 g, 9.9 mmol) was dissolved in toluene (50 mL) to afford a clear solution. EDMA (ethyldimethylamine, 20 mL) and octanoyl chloride (1.908 g,11.78 mmol, 1.3 equiv) were added dropwise simultaneously. A cloudy precipitate formed immediately, and the reaction solution was stirred at room

temperature for another 1.5 h, after which time the solvent and a large fraction of the added EDMA were evaporated under reduced pressure. The residue was redissolved in H_2O (30 mL) and extracted into ether (30 mL) twice. The organic phase was collected and the solvent evaporated under reduced pressure to afford the crude product as a yellow oil which was purified by column chromatography (hexanes/ethyl acetate, 1:1, $R_f = 0.6$) to yield *N*-Boc-2-aminoethyl ester octanoic acid (1.505 g, 5.45 mmol, yield 53%) after solvent evaporation. ESI-MS (MeOH, 30 V): 326.2 $[M + K]^+$. ^{1}H NMR ($CDCl_3$, 400 MHz, δ): 4.07 (t, CH_2-OCOR, 2H), 3.33 (t, CH$_2$-N*H*COR, 2H), 2.27 (t, ROCO-CH_2, 2H), 1.57 (m, ROCOCH$_2$-CH_2, 2H), 1.40 (s, (CH_3)$_3$, 9H), 1.24 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.83 (t, CH_3, 3H). ^{13}C NMR ($CDCl_3$, 400 MHz, δ): 173.54 (carbonyl-*C*), 155.69 (carbamate-*C*), 79.55 (*C*-(CH$_3$)$_3$), 63.22 (*C*H$_2$-OCOR), 39.55 (*C*H$_2$-NH-Boc), 33.98, (ROCO-*C*H$_2$), 31.48, (ROCOCH$_2$-*C*H$_2$), 28.75 (ROCO(CH$_2$)$_2$-*C*H$_2$), 28.17 ((*C*H$_3$)$_3$), 24.72 (*C*H$_2$), 22.42 (*C*H$_2$-CH$_3$), 13.86 (*C*H$_3$). IR (cm^{-1}): 1684 (m), 1631 (m), 1482 (w).

2-Aminoethyl Ester Octanoic Acid. *N*-Boc-2-Aminoethyl ester octanoic acid (1.505 g, 5.45 mmol) was dissolved in dichloromethane (4 mL). Trifluoroacetic acid (4 mL) was added, and the reaction solution was stirred for 20 min after which time a slow change of color to light yellow was observed. TFA and DCM were removed in vacuo, and the oily residue was purified by column chromatography (DCM/MeOH, 4:1, R_f = 0.15) yielding 2-aminoethyl ester octanoic acid (444 mg, 2.37 mmol, yield 43%) after rotary evaporation as a colorless oil which solidifies upon standing. ESI-MS (MeOH, 30 V): 188.2 $[M + H]^+$, 210 $[M + Na]^+$. ^{1}H NMR (MeOD, 300 MHz, δ): 4.47 (s, NH_2, 2H), 3.55 (t, CH_2-OCOR, 2H), 3.25 (t, CH_2-NH$_2$, 2H), 2.15 (t, ROCO-CH_2, 2H), 1.57 (m, ROCOCH$_2$-CH_2, 2H), 1.28 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.86 (t, CH_3, 3H). ^{13}C NMR (MeOD, 300 MHz, δ): 173.7 (carbonyl-*C*), 62.27 (*C*H$_2$-OCOR), 43.42(*C*H$_2$-NH$_2$), 37.61−23.95 (six signals, *C*H$_2$), 14.66 (*C*H$_3$). IR (cm^{-1}): 3312 (w), 2954 (s), 2924 (s), 2855 (s), 1637 (s), 1552 (m), 1464 (m).

***N*-Pyridinemethyl-2-aminoethyl Ester Octanoic Acid.** 2-Aminoethyl ester octanoic acid (0.51 g, 2.7 mmol) was dissolved in dry ethanol (15 mL). Na_2CO_3 (~10 equiv, 2.86 g) was added to afford a turbid solution. Pyridine-2-aldehyde (0.27 g, 237 μL, 0.95 equiv) was added, and the reaction mixture was stirred overnight at room temperature. After the formation of the intermediate imine was monitored by TLC, $NaBH_4$ (95 mg, 2.51 mmol, 0.98 equiv) was added and the reaction mixture was subsequently stirred for another 1 h. DCM (20 mL) was then added and extracted twice with a saturated solution of $NaHCO_3$ (20 mL). The organic fractions were collected, and the solvent was evaporated. The crude product was purified by column chromatography (DCM/MeOH, 85:15, R_f = 0.55) yielding *N*-pyridinemethyl-2-aminoethyl ester octanoic acid (361 mg, 1.3 mmol, yield 48%) as a colorless oil with low viscosity, after evaporation of the solvent. ESI-MS (MeOH, 30 V): 279 $[M + H]^+$, 301.2 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 8.48 (d, *o*-pyridine-*H*, 1H), 7.66 (t, *p*-pyridine-*H*, 1H), 7.32 (d, *m*-pyridine-*H*, 1H), 7.17 (t, *m*-pyridine-*H*, 1H), 4.72 (s, N*H*, 1H), 3.91 (s, pyr-CH_2, 2H), 3.63 (t, CH_2-OCOR, 2H), 3.37 (t, CH_2-NH, 2H), 2.14 (t, ROCO-CH_2, 2H), 1.56 (m, ROCOCH$_2$-CH_2, 2H), 1.22 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.82 (t, CH_3, 3H). ^{13}C NMR ($CDCl_3$, 300 MHz, δ): 174.54 (carbonyl-*C*), 149.03 (*o*-pyridine-*C*), 148.27 (*o*-pyridine-*C*), 136.84 (*m*-pyridine-*C*), 122.26 (*m*-pyridine-*C*), 120.71 (*p*-pyridine-*C*), 64.21 (pyr-*C*H$_2$), 61.60 (*C*H$_2$-NH$_2$), 54.06 (*C*H$_2$-OCOR), 42.12−22.46 (six signals, *C*H$_2$), 13.93 (*C*H$_3$). IR (cm^{-1}): 3294 (br), 2925 (s), 2855 (s), 1632 (s), 1595 (s), 1549 (m).

***N*-Bis(*tert*-Butylcarboxyethyl)-2-aminoethyl Ester Octanoic Acid.** 2-Aminoethyl ester octanoic acid (0.1 g, 0.53 mmol) was dissolved in dry DCM (10 mL). Na_2CO_3 (1 g) was added to afford a turbid solution. *tert*-Butyl bromoacetate (209 mg, 179 μL, 1.06 mmol, 2 equiv) was added, and the mixture was stirred for 2 days. After the presence of the product was confirmed by ESI-MS, the solvent was evaporated and the crude mixture was purified by column chromatography (silica, hexanes/ethyl acetate, 1:1, R_f = 0.8) to yield *N*-bis(*tert*-butylcarboxyethyl)-2-aminoethyl ester octanoic acid (60 mg, 0.144 mmol, yield 27%) after rotary evaporation of all solvents. ESI-MS (MeOH, 30 V): 438.3 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 4.13 (t, CH_2-OCOR, 2H), 3.69 (s, ^{t}Bu-carbonyl-C-CH_2-N, 4H), 3.45 (t, CH_2-N, 2H), 2.95 (t, ROCO-CH_2, 2H), 1.55 (m, ROCOCH$_2$-CH_2, 2H),, 1.41 (s, (CH_3)$_3$, 18 H), 1.21 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.84 (t, CH_3, 3H). ^{13}C NMR ($CDCl_3$, 300 MHz, δ): 170.18 (carbonyl-*C*), 166.03 (^{t}Bu-carbonyl-*C*), 62.68 (*C*H$_2$-OCOR), 58.19 (^{t}Bu-carbonyl-*C*-CH$_2$-N), 52.42 (*C*H$_2$-N), 34.06−22.40 (six signals, *C*H$_2$), 27.61 ((*C*H$_3$)$_3$), 13.88 (*C*H$_3$).

***N*-*N*-(*tert*-Butylcarboxyethyl)-pyridinemethyl-2-aminoethyl Ester Octanoic Acid.** *N*-Pyridinemethyl-2-aminoethyl ester octanoic acid (361 mg, 1.3 mmol) was dissolved in dry DCM (20 mL). Na_2CO_3 (~10 equiv, 2.86 g) was added to afford a turbid solution. *tert*-Butyl bromoacetate (1.4 equiv, 354 mg, 1.8 mmol) was added, and the mixture was stirred for 2 days. The solvent was evaporated after confirmation of product presence by ESI-MS, and the crude product was purified by column chromatography (silica, DCM/MeOH, 95:5, R_f = 0.8) yielding *N*-*N*-(*tert*-butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid (109 mg, 0.27 mmol, yield 21%), after rotary evaporation of all solvents, as a light yellow oil. ESI-MS (MeOH, 30 V): 415.3 $[M + Na]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 8.52 (d, *o*-pyridine-*H*, 1H), 7.68 (t, *p*-pyridine-*H*, 1H), 7.56 (d, *m*-pyridine-*H*, 1H), 7.17 (t, *m*-pyridine-*H*, 1H), 4.16 (t, CH_2-OCOR, 2H), 4.03 (s, pyr-CH_2, 2H), 3.40 (s, ^{t}Bu-carbonyl-C-CH_2-N, 2H), 3.00 (t, CH_2-N, 2H), 2.26 (t, ROCO-CH_2, 2H), 1.56 (m, ROCOCH$_2$-CH_2, 2H), 1.46 (s, (CH_3)$_3$, 9 H), 1.26 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.87 (t, CH_3, 3H). ^{13}C NMR ($CDCl_3$, 300 MHz, δ): 184.65 (^{t}Bu-carbonyl-*C*), 173.66 (carbonyl-*C*), 148.64 (*o*-pyridine-*C*), 136.82 (*o*-pyridine-*C*), 122.91 (*m*-pyridine-*C*), 122.11(*m*-pyridine-*C*), 62.52 (pyr-*C*H$_2$), 60.30 (*C*H$_2$-N), 56.21 (^{t}Bu-carbonyl-C-*C*H$_2$-N), 52.53 (*C*H$_2$-OCOR), 34.24−22.54 (six signals, *C*H$_2$) 28.15 ((*C*H$_3$)$_3$), 14.02 (*C*H$_3$).

***N*-*N*-Bis(*tert*-Butylcarboxyethyl)-pyridinemethyl-2-aminoethyl Ester Octanoic Acid.** *N*-*N*-Bis(*tert*-Butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid is afforded as a side product of the synthesis of *N*-*N*-(*tert*-butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid and separated from the main product by column chromatography (silica, DCM/MeOH, 95:5, R_f of product: 0.35) yielding *N*-*N*-bis(*tert*-butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid (37 mg, 0.072 mmol, yield 5.6%) after solvent evaporation as a light orange oil. ESI-MS (MeOH, 30 V): 507.3 $[M]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 9.59 (d, *o*-pyridine-*H*, 1H), 8.48 (t, *p*-pyridine-*H*, 1H), 8.21 (d, *m*-pyridine-*H*, 1H), 8.05 (t, *m*-pyridine-*H*, 1H), 4.38 (t, CH_2-OCOR, 2H), 4.10 (s, pyr-CH_2, 2H), 3.71 (s, ^{t}Bu-carbonyl-C-CH_2-N, 2H), 3.92 (t, CH_2-N, 2H), 2.26 (t, ROCO-CH_2, 2H), 1.56 (m, ROCOCH$_2$-CH_2, 2H), 1.47 (s, (CH_3)$_3$, 18 H), 1.23 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.83 (t, CH_3, 3H). ^{13}C NMR ($CDCl_3$, 300 MHz, δ): 169.48 (*o*-pyridine-*C*), 164.73 (*o*-pyridine-*C*), 155.39 (*m*-pyridine-*C*), 128.75 (*m*-pyridine-*C*), 64.74 (*C*H$_2$-N), 61.74, (pyr-*C*H$_2$) 55.21 (^{t}Bu-carbonyl-C-*C*H$_2$-N), 52.65 (*C*H$_2$-OCOR), 34.04−22.42 (six signals, *C*H$_2$) 27.25 ((*C*H$_3$)$_3$), 13.91 (*C*H$_3$).

***N*-*N*-Carboxyethyl-pyridinemethyl-2-aminoethyl Ester Octanoic Acid (HL1).** *N*-*N*-(*tert*-Butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid (109 mg, 0.27 mmol) was dissolved in dry DCM (1 mL). TFA (1 mL) was added, and the reaction mixture was stirred for 30 min at room temperature. Xylene (1 mL) was added, and all the solvents

were evaporated under reduced pressure to yield the crude product, which was purified by preparative HPLC to afford *N*-*N*-carboxyethyl-pyridinemethyl-2-aminoethyl ester octanoic acid (45 mg, 0.133 mmol, yield 49%) after solvent evaporation. ESI-MS (MeOH, 30 V): 337.2 $[M + H]^+$. ^{1}H NMR (MeOD, 400 MHz, δ): 8.76 (d, *o*-pyridine-*H*, 1H), 8.41 (t, *p*-pyridine-*H*, 1H), 7.93 (d, *m*-pyridine-*H*, 1H), 7.86 (t, *m*-pyridine-*H*, 1H), 4.48 (s, HOOC-CH_2-N, 2H), 4.22 (t, CH_2-OCOR, 2H), 3.78 (s, pyr-CH_2, 2H),, 3.23 (t, CH_2-N, 2H), 2.28 (t, ROCO-CH_2, 2H), 1.56 (m, ROCOCH$_2$-CH_2, 2H), 1.29 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.9 (t, CH$_3$, 3H). ^{13}C NMR (MeOD, 400 MHz, δ): 184.22 (carboxyl-*C*), 171.35 (carbonyl-*C*), 156.08 (*o*-pyridine-*C*), 146.14 (*o*-pyridine-*C*), 144.42 (*m*-pyridine-*C*), 127.00 (*m*-pyridine-*C*), 84.15 (HOOC-*C*H$_2$-N), 63.06 (pyr-*C*H$_2$), 57.75 (*C*H$_2$-N), 55.30 (*C*H$_2$-OCOR), 35.22−23.97 (six signals, *C*H$_2$), 13.93 (*C*H$_3$). IR (cm^{-1}): 2929 (w), 2858 (w), 1727 (m), 1668 (m).

***N*-Bis(carboxyethyl)-2-aminoethyl Ester Octanoic Acid (H_2L2).** The exact same procedure as for H**L1** was followed with *N*-bis(*tert*-butylcarboxyethyl)-2-aminoethyl ester octanoic acid (120 mg, 0.288 mmol) to yield *N*-bis(carboxyethyl)-2-aminoethyl ester octanoic acid (56 mg, 0.184 mmol, yield 64%). ESI-MS (MeOH, 30 V): 304.2 $[M + H]^+$. ^{1}H NMR (MeOD, 400 MHz, δ): 4.60 (s, HOOC-CH_2-N, 4H), 3.86 (t, CH_2-OCOR, 2H), 3.44 (t, CH_2-N, 2H), 2.35 (t, ROCO-CH_2, 2H), 1.61 (m, ROCOCH$_2$-CH_2, 2H), 1.32 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.91 (t, CH_3, 3H). ^{13}C NMR (MeOD, 400 MHz, δ): 183.61 (carboxyl-*C*), 177.18 (carbonyl-*C*), 62.45 (*C*H$_2$-OCOR), 57.55 (carboxyl-C-*C*H$_2$-N), 55.64 (*C*H$_2$-N), 38.33−24.10 (six signals, *C*H$_2$), 16.22 (*C*H$_3$). IR (cm^{-1}): 2928 (w), 2857 (w), 1737(m), 1682 (m).

***N*-*N*-Bis(carboxyethyl)-pyridinemethyl-2-aminoethyl Ester Octanoic Acid (H_2L3).** The exact same procedure as for H**L1** was followed with *N*-*N*-bis(*tert*-butylcarboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid (37 mg, 0.072 mmol) to afford *N*-*N*-bis(carboxyethyl)-pyridinemethyl-2-aminoethyl ester octanoic acid (12 mg, 0.0303 mmol, yield 42%). ESI-MS (MeOH, 30 V): 395.2 $[M]^+$. ^{1}H NMR (MeOD, 400 MHz, δ): 8.95 (d, *o*-pyridine-*H*, 1H), 8.65 (t, *p*-pyridine-*H*, 1H), 8.30 (d, *m*-pyridine-*H*, 1H), 8.11 (t, *m*-pyridine-*H*, 1H), 5.77 (s, HOOC-CH_2-N, 4H), 4.32 (t, CH_2-OCOR, 2H), 4.07 (s, pyr-CH_2, 2H), 3.91 (t, CH_2-N, 2H), 2.19 (t, ROCO-CH_2, 2H), 1.60 (m, ROCOCH$_2$-CH_2, 2H), 1.31 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.90 (t, CH_3, 3H). ^{13}C NMR (MeOD, 400 MHz, δ): 186.22 (carboxyl-*C*), 169.48 (*o*-pyridine-*C*), 163.94 (*p*-pyridine-*C*), 128.20 (*m*-pyridine-*C*), 65.31 (*C*H$_2$-N), 61.79 (pyr-*C*H$_2$) 56.65 (HOOC-*C*H$_2$-N), 52.65 (*C*H$_2$-OCOR), 37.26−23.81 (six signals, *C*H$_2$), 14.54 (*C*H$_3$). IR (cm^{-1}): 2927(w), 2857(w), 1731(m), 1630 (m).

***N*-*N*-Carboxyethyl-pyridinemethyl-2-aminoethyl Ester Octanoic Acid Tricarbonylrhenium(I) [Re(L1)(CO)$_3$].** A solution of $[NEt_4]_2[ReBr_3(CO)_3]$ (0.040 g, 0.052 mmol) and H**L1** (0.017 g, 0.052 mmol) in MeOH (5 mL) was allowed to reflux overnight. The solution flask was placed into the freezer for 2 h to afford the product as a white solid (0.021 g, 0.034 mmol, yield 66%) after filtration. Small, colorless crystals were obtained by slow diffusion of the product dissolved in DCM into diethyl ether. ESI-MS (MeOH, 30 V): 605.1 $[^{185}Re + H]^+$, 607.1 $[^{187}Re + H]^+$. ^{1}H NMR ($CDCl_3$, 300 MHz, δ): 8.84 (d, *o*-pyridine-*H*, 1H), 7.79 (t, *p*-pyridine-*H*, 1H), 7.56 (d, *m*-pyridine-*H*, 1H), 7.46 (t, *m*-pyridine-*H*, 1H), 4.55 (s, HOOC-CH_2-N, 2H), 4.48 (t, CH_2-OCOR, 2H), 3.89 (s, pyr-CH_2, 2H), 3.78 (t, CH_2-N, 2H), 2.40 (t, ROCO-CH_2, 2H), 1.54 (m, ROCOCH$_2$-CH_2, 2H), 1.30 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.89 (t, CH_3, 3H). IR (cm^{-1}): 2020 (m), 1905 (w), 1870 (m) ($\nu_{C=O}$).

Sodium *N*-Bis(carboxyethyl)-2-aminoethyl Ester Octanoic Acid Tricarbonylrhenate Na[Re(L2)(CO)$_3$]. A solution of $[NEt_4]_2[ReBr_3(CO)_3]$ (0.040 g, 0.052 mmol) and **L2** (0.016 g, 0.052 mmol) in MeOH (5 mL) was allowed to reflux overnight.

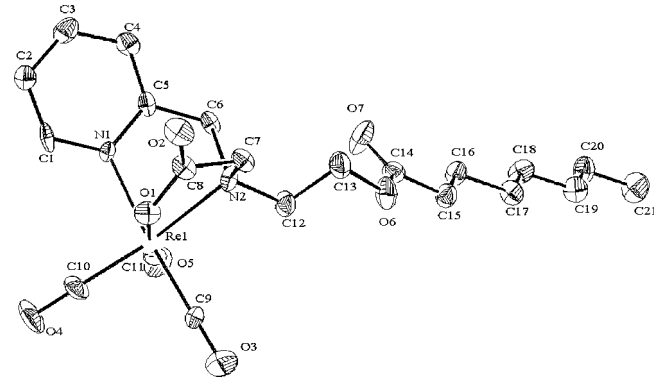

Figure 2. ORTEP view of complex Re(CO)$_3$**L1** (50% thermal probability ellipsoids).

The solvent was evaporated, and the oily residue was purified by preparative HPLC to afford the product as a white solid (0.005 g, 0.0087 mmol, yield 15%) after rotary evaporation of all solvents. ESI-MS (MeOH, 30 V): 570.1 $[^{185}Re]^-$, 572.1 $[^{187}Re]^-$. ^{1}H NMR (MeOD, 300 MHz, δ): 4.80 (s, HOOC-CH_2-N, 4H) 3.97 (t, CH_2-OCOR, 2H), 3.78 (t, CH_2-N, 2H), 2.35 (t, ROCO-CH_2, 2H), 1.62 (m, ROCOCH$_2$-CH_2, 2H), 1.31 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.90 (t, CH_3, 3H). IR (cm^{-1}): 2017 (m), 1881 (m, br) ($\nu_{C=O}$), 1606 (w).

***N*-*N*-Bis(carboxyethyl)-pyridinemethyl-2-aminoethyl Ester Octanoic Acid Tricarbonylrhenium [Re(L3)(CO)$_3$].** A solution of $[NEt_4]_2[ReBr_3(CO)_3]$ (0.040 g, 0.052 mmol) and H_2**L3** (0.016 g, 0.052 mmol) in MeOH (5 mL) was allowed to reflux overnight. The solvent was evaporated, and the oily residue was purified by preparative HPLC to afford the product as a yellow solid (0.003 g, 0.0045 mmol, yield 8%). MALDI-MS: 663.1 $[^{185}Re + H]^+$, 665.1 $[^{187}Re + H]^+$. ^{1}H NMR (MeOD, 400 MHz, δ): 8.96 (d, *o*-pyridine-*H*, 1H), 8.66 (t, *p*-pyridine-*H*, 1H), 8.30 (d, *m*-pyridine-*H*, 1H), 8.08 (t, *m*-pyridine-*H*, 1H), 5.71 (s, HOOC-CH_2-N, 4H), 4.36 (t, CH_2-OCOR, 2H), 4.14 (s, pyr-CH$_2$, 2H),, 3.97 (t, CH_2-N, 2H), 2.32 (t, ROCO-CH_2, 2H), 1.54 (m, ROCOCH$_2$-CH_2, 2H), 1.30 (m, CH$_2$-CH_2-CH$_2$, 8H), 0.90 (t, CH_3, 3H). IR (cm^{-1}): 2018 (s), 1894 (m), 1874 (m) ($\nu_{C=O}$), 1661 (w).

[^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ Labeling Studies. The organometallic precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was prepared from a saline solution of Na[^{99m}TcO$_4$] (1 mL, 200 MBq) using the Isolink kit. A solution of Na[^{99m}TcO$_4$] (1 mL) was added to the Isolink kit, and the vial was heated to reflux for 25 min. Upon cooling, 0.1 M HCl solution (1 mL) was added to adjust the pH to 7−8. Labeling was achieved by mixing an aliquot (0.2 mL) of the $[^{99m}Tc(H_2O)_3(CO)_3]^+$ precursor with a 0.1 mM solution of **L1**−**L3** (with the solution pH previously adjusted to 7−7.5 with an aqueous 0.1 M $NaHCO_3$ solution) at 90 °C for 25 (**L1**), 35 (**L2**), or 45 (**L3**) min. Analysis was performed by HPLC and TLC. HPLC solvents consisted of 0.1% trifluoroacetic acid in water (solvent A) or neat methanol (solvent B). Samples were analyzed with a linear gradient method (100% solvent A to 100% solvent B over 30 min). TLCs were analyzed with acetonitrile as mobile phase.

Cysteine and Histidine Challenge Experiments. To a solution of either cysteine (0.1 M, 0.9 mL) or histidine (0.1 M, 0.9 mL) in PBS (phosphate-buffered saline, 1 mM, pH 7.4) was added a solution of the ^{99m}Tc complex (final ligand concentration 10^{-5} M). The samples were incubated at 37 °C and aliquots analyzed after 24 h by analytical TLC and HPLC.

Octanol−Water-Distribution Coefficients. The log $P_{o/w}$ values of complexes [^{99m}Tc(CO)$_3$**L1**], Na[^{99m}Tc(CO)$_3$**L2**], and [^{99m}Tc(CO)$_3$**L3**] were determined by extraction with equivalent amounts of octanol and aqueous solutions of the ^{99m}Tc complex

Table 1. Experimental Conditions and log $P_{o/w}$ Data for All Complexes

complex	radio-chemical yield (%)	labeling time (min)	T (°C)	ligand concn	t_R (min)	log $P_{o/w}$	R_f
^{99m}Tc(CO)$_3$L1	>95	25	90	3×10^{-4}	20.5 (21.3)[a]	−0.034	0.49
[^{99m}Tc(CO)$_3$L2]$^-$	>95	35	90	3.3×10^{-4}	15.6 (14.01) [a]	−1.014	0.39
^{99m}Tc(CO)$_3$L3	~ 30	45	90	1×10^{-3}	18.1 (18.7) [a]	−0.38	0.46

[a] Retention time for the analogous cold-chemical Re complexes.

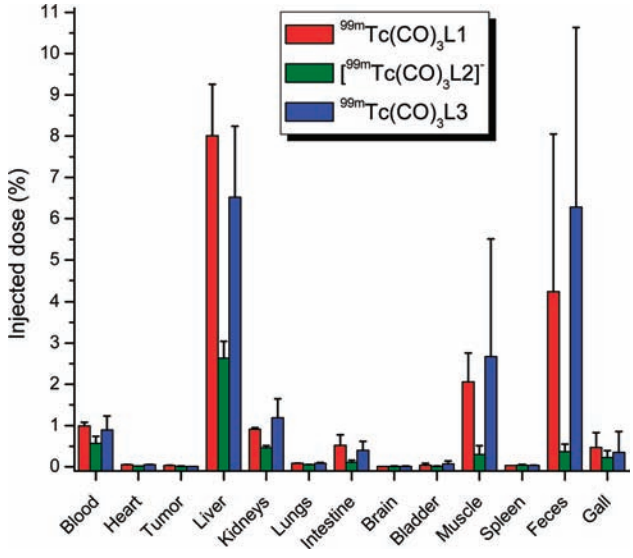

Figure 3. Biodistribution of ^{99m}Tc-labeled ligands at the 4 h time point ($n = 4$).

(*17*). Octanol (1 mL) was mixed with an equivalent amount of the aqueous reaction mixture and stirred for 1 min. Subsequently, the two phases were partitioned, and the activity of both was determined by the measurement of activity of 5 μL droplets of each solution on a radio-TLC-plate.

X-ray Diffraction Analysis of Re(CO)$_3$L1. The sample was mounted on a glass fiber and cooled to 173 K. X-ray data were collected and processed using a Bruker X8 APEX II diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) to a maximum 2θ value of 48.0°. Data were collected and integrated using the Bruker SAINT software package (*18*) and corrected for Lorentz and polarization effects, as well as for absorption effects, using the multiscan technique (SADABS) (*19*). The X-ray structure was solved using direct methods (SIR92) (*20*) and expanded using Fourier techniques (*21*). All calculations were performed using the SHELXTL crystallographic software package (*22*).

Imaging and Biodistribution. Animals were used in accordance with the regulations on the protection of animals in Canada. Female C57Bl/6 mice were obtained from Sarah Reid, McMaster University. Each mouse had a 4 mm tumor in its neck, grown from a primary cell line at passage six derived from mammary tumors of a PyVMT transgenic mouse. ^{99m}Tc complexes were prepared as described above. While complexes [^{99m}Tc(CO)$_3$**L1**] and [^{99m}Tc(CO)$_3$**L2**]$^-$ were injected without any further purification because of their high yield in synthesis, [^{99m}Tc(CO)$_3$**L3**] was purified by preparative HPLC. The solvent was removed from the collected fraction in vacuo, and [^{99m}Tc(CO)$_3$**L3**] was redissolved in 0.9 M saline solution. Aliquots (100 μL) of complex solutions of [^{99m}Tc(CO)$_3$**L1**], [^{99m}Tc(CO)$_3$**L2**]$^-$, and [^{99m}Tc(CO)$_3$**L3**] were injected into groups of four mice via their tail vein. After injection of [^{99m}Tc(CO)$_3$**L1**] and [^{99m}Tc(CO)$_3$**L2**]$^-$, dynamic imaging was carried out during the first 15 min. All animals were imaged under isoflurane anesthesia in the supine position during the first 15 min, and then 1, 2, and 4 h after injection for 15 min each. After the last time point, animals were sacrificed by an overdose of pentobarbital, and samples of blood, liver, kidney, muscle, spleen, heart, brain, lung, gallbladder, intestine, stomach, bladder and tumor were removed, weighed, and counted in a gamma counter. Results are expressed as the percentage of the injected dose per gram of tissue (%ID/g). Tumor-to-organ ratios were calculated from %ID/g of the tumor and relevant organs.

RESULTS AND DISCUSSION

Proligand Synthesis. The tridentate chelator moieties of H**L1** and H$_2$**L2** were selected for this study since they were previously known for forming highly stable complexes with the metals of interest (*8*, *23*). The chelation entity of H$_2$**L3** is of a novel type arising from the synthesis of H**L1** where its *tert*-butyl-protected form appears as a byproduct in the synthesis of *tert*-butyl-protected H**L1**. All three ligand systems were synthesized via the free, C$_8$-chain-derivatized amine, which was subsequently converted by reductive amination and/or alkylation into the corresponding protected ligand system and in a final step was deprotected and purified by preparative HPLC. The identity of all ligands was confirmed by characterization through ^{1}H and ^{13}C NMR spectroscopy, as well as mass spectrometry and IR spectrophotometry. Elemental analysis was uninformative because of the oily consistency of the synthesized compounds.

Re Complexes. Re(CO)$_3$ complexes were synthesized as macroscopic models for the ^{99m}Tc(CO)$_3$ complexes by mixing a methanolic solution of ligand with [Re(CO)$_3$Br$_3$][NEt$_4$]$_2$ previously dissolved in H$_2$O and stirring the mixture at elevated temperatures overnight (*24*). While the neutral complex [Re(CO)$_3$**L1**] precipitates from the reaction solution, the solutions of the complexes Na[Re(CO)$_3$**L2**] or [Re(CO)$_3$**L3**] turn slightly yellow in color without precipitation of the product. Na[Re(CO)$_3$**L2**] and [Re(CO)$_3$**L3**] were isolated and purified via preparative HPLC. All complexes were characterized by ^{1}H and ^{13}C NMR spectroscopy, as well as mass spectrometry and IR spectrophotometry, where intense, diagnostic CO bands between 2020 and 1870 cm^{-1} can be assigned to the *fac*-[Re(CO)$_3$**L**]-products.

Solid-State Structure of [Re(CO)$_3$L1]. Colorless crystals of [Re(CO)$_3$**L1**] were obtained by slow diffusion of the product dissolved in DCM into diethyl ether. An ORTEP diagram is shown in Figure 2. The complex displays a nearly perfect octahedral coordination sphere. The Re−C bond lengths are all close to 1.9 Å and therefore shorter than the Re−O bond length (2.142 Å) and the Re−N bond lengths (2.184 Å, 2.227 Å). The Re−N2 bond proves to be the longest because of the nondirected lone pair on the tertiary amine nature of the nitrogen atom N2.

Synthesis, Stability, and Lipophilicity of ^{99m}Tc Complexes. The complexes [^{99m}Tc(CO)$_3$**L1**] and [^{99m}Tc(CO)$_3$**L2**]$^-$ were prepared in high radiochemical yield through reaction of *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ with the ligands H**L1** and H$_2$**L2**. The ligands were initially deprotonated with NaHCO$_3$ (0.1 M solution, 2 equiv) and added to the technetium tricarbonyl solution with final concentrations of approximately 3×10^{-4} M.

After a reaction time of 25−35 min at 90 °C, the chelation reaction was 95% complete as verified by HPLC and radio-TLC analysis. No major byproducts were detected by HPLC. ^{99m}Tc(CO)$_3$**L3** was produced in only 30% yield after a 45 min reaction time. Several byproducts were visible in the γ-trace of

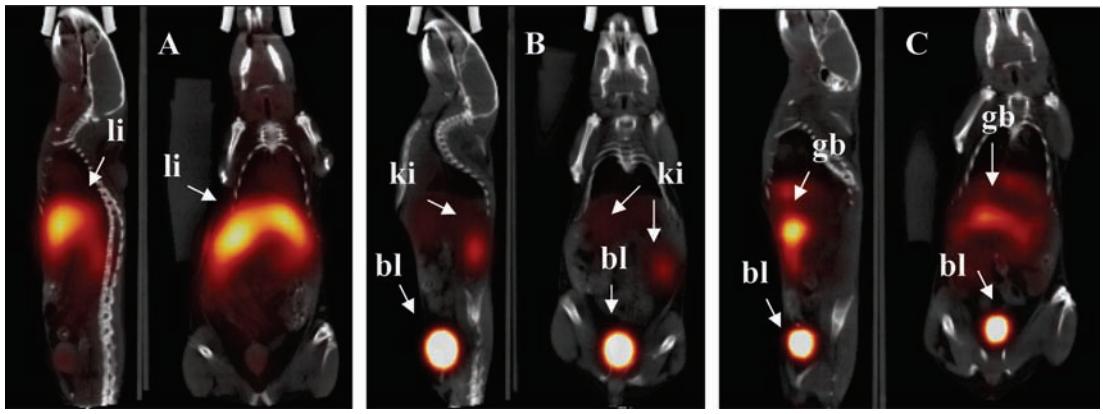

Figure 4. Representative μSPECT/CT pictures taken 15 min after injection of (A) [^{99m}Tc(CO)$_3$**L1**], (B) [^{99m}Tc(CO)$_3$**L2**]$^-$, and (C) [^{99m}Tc(CO)$_3$**L3**]. Abbreviations of organs: li: liver, ki:kidney, bl: bladder, gb: gallbladder.

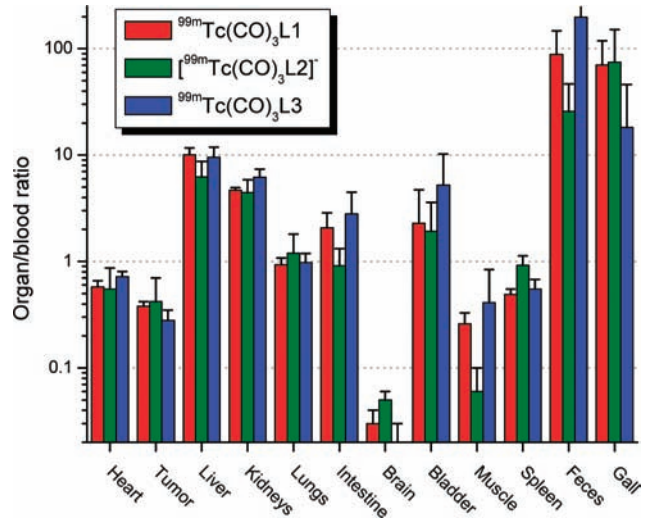

Figure 6. Logarithmic table of organ/blood ratio of ^{99m}Tc-labeled ligands at the 4 h time point ($n = 4$).

the HPLC spectrum, perhaps from coordination with decomposition fragments of **L3**.

The product peak was assigned by comparison of the retention time of the Re complex isolated by preparative HPLC. To investigate the complex stability toward the naturally occurring amino acids cysteine and histidine (both can act as potential tridentate ligands), the ^{99m}Tc-complexes were kept in 10^{-3} M cysteine/histidine solutions in PBS (pH = 7.4, 37 °C) for 24 h. In the subsequent HPLC analysis of the solution, no noticeable decomposition could be detected for any of the three complexes.

The lipophilicity of the complexes was determined by evaluation of water/octanol partition coefficients. [^{99m}Tc(CO)$_3$**L2**]$^-$ should be the most ionic compound by virtue of its full −1 charge, followed by the zwitterionic [^{99m}Tc(CO)$_3$**L3**] and the nonpolar [^{99m}Tc(CO)$_3$**L1**]; this was confirmed by the order of lipophilicity log P values ranging from [^{99m}Tc(CO)$_3$**L1**] > [^{99m}Tc(CO)$_3$**L3**] > [^{99m}Tc(CO)$_3$**L2**] (listed in the order from highest to lowest lipophilicity, Table 1).

Imaging and Biodistribution. Imaging of all three compounds was performed at 15 min, 1 h, 2 h, and 4 h after injection. Biodistribution studies were performed at the 4 h time point after injection (Figure 3). This tumor-bearing model was used to evaluate the imaging potential of [^{99m}Tc(CO)$_3$**L1**], [^{99m}Tc(CO)$_3$**L2**]$^-$, and [^{99m}Tc(CO)$_3$**L3**]. Data from the imaging is displayed in Figures S2, S3, and S4 (Supporting Information). Data from the biodistribution is displayed in Figures 5 and 6 as well as in Tables S3 and S4 (Supporting Information). Imaging screenshots of mice 15 min postinjection are shown in Figure 4.

All compounds show very distinct biodistribution behavior. The in vivo distribution of [^{99m}Tc(CO)$_3$**L1**] could be followed from the onset of injection. Very fast localization of the complex in the liver was observed, with clearance through the intestines, which is confirmed through the biodistribution data, showing large uptake of activity in liver, intestines, and feces. This behavior is not surprising considering that this complex has no overall charge and a very small log P value. [^{99m}Tc(CO)$_3$**L2**]$^-$ was also followed after injection with dynamic imaging. Here, fast processing of the compound through the kidneys, within the first 5−10 min after injection, and consequent localization in the bladder, followed by excretion was observable. The excretion of large portions of the dose is confirmed by the small fraction of the originally injected dose in the biodistribution measurements. The large log P value of this compound, plus its localized negative charge, determines its fate to be excreted through the renal tract. Finally, for [^{99m}Tc(CO)$_3$**L3**] after 1 h after injection, high localization in the gall bladder was observed, paired with slow clearance through the intestines. The biodistribution profile shows some similarity to the profile of [^{99m}Tc(CO)$_3$**L1**], but with faster excretion through the intestines and the renal system (high percentage of dose in the feces, elevated organ/blood ratio in kidneys), which can be a conse-

quence of the increased polarity of the complex (compared to [^{99m}Tc(CO)$_3$**L1**]). No significant heart, brain, or tumor uptake was observed for any of the investigated compounds.

CONCLUSION

For the first time, small amphiphilic ^{99m}Tc(CO)$_3$ complexes of which one bore a localized negative charge, one was a zwitterionic complex, and one was an entirely neutral molecule, have been synthesized, fully characterized, and investigated for their lipophilicity and behavior in vivo. Among the molecules, for the zwitterionic complex, a new type of chelation entity was incorporated, forming eight-membered rings between the metal center and the ligand sphere. This chelator proves to be slower coordinating but still high in stability toward cysteine and histidine challenges. Lower reaction yields arise from instability of the ligand toward prolonged heating at 90 °C. The products afforded by this decomposition are capable of coordinating to the metal center and make an additional purification step inevitable.

Unfortunately, none of the three investigated complexes showed significant brain, tumor, or heart uptake. The last confirms that negatively charged or zwitterionic complexes not do show the same potential for myocardial uptake as do other, cationic complexes for this very purpose. One way to confirm this would be the investigation of the corresponding cationic compound.

Also, for a more efficient mimicking of phospholipid-type molecules, a technetium-tagged approach might be more suitable, such as for example attachment of a small neutral ^{99m}Tc-complex to the aliphatic residue of the corresponding molecule. Changing the charge of a small amphiphilic molecule results in highly contrasting but still defined biodistribution behavior in an in vivo system. This is somewhat surprising and of potential importance for future applications.

ACKNOWLEDGMENT

The authors acknowledge UBC for a University Graduate Fellowship (E.B.), Troy Farncombe, Chantal Saab, and Rod Rhem for excellent imaging support at the McMaster Centre for Preclinical and Translational Imaging (MCPTI) and for use of their SPECT/CT scanner, Drs. Andrea Armstrong and John Valliant for advice and use of the radiochemistry facilities in the McMaster Institute of Applied Radiation Sciences (McIARS), MDS Nordion (Canada) for some financial support of this project, Covidien for the donation of Isolink Kits, Vancouver Coastal Health-UBC Hospital for [^{99m}TcO$_4$]$^-$, and the Natural Sciences and Engineering Research Council of Canada (NSERC) for a Strategic Grant.

Supporting Information Available: Crystal data for [Re(CO)$_3$L1], radio-HPLC traces of reaction mixtures of ^{99m}Tc-compounds, curves of all ^{99m}Tc-compounds' levels in selected organs taken from the SPECT/CT images. This information is available free of charge via the Internet at http://pubs.acs.org.

Recombinant antibodies are promising tools for a wide range of bioanalytical and medical applications. However, the chemical modification of such molecules can be challenging, which limits their broader utilization. Here we describe a universal method for the site-specific labeling of antibody fragments and protein ligands by genetically fusing them to an engineered version of the human DNA-repair enzyme *O*(6)-alkyllguanine DNA alkyltransferase (AGT), known as SNAP-Tag (*1*−*3*). Substrates containing *O*(6)-benzylguanine are covalently bound to the fusion proteins via a stable thioether bond in a rapid and highly specific self-labeling reaction. The coupling is site-directed, allowing the design and synthesis of antibody conjugates with predefined stoichiometry. We cloned a series of ligand SNAP-Tag fusion proteins and expressed them in HEK 293T cells. The antibody/ligand-fusions were characterized by labeling with different fluorophores, labeling with biotin, or by coupling them to fluorescent nanobeads, followed by analysis by flow cytometry and confocal microscopy. All ligands retained their original antigen-binding properties when fused to the SNAP-Tag. The combination of recombinant antibodies or protein ligands with the SNAP-Tag facilitates simple and efficient covalent modification with a broad range of substrates, thus providing a useful and advantageous alternative to existing coupling strategies.

INTRODUCTION

Recombinant antibodies and protein ligands have many applications in nanobiotechnology, analytical assays, diagnosis, and therapy, but there is an increasing demand for efficient strategies to further functionalize these proteins. Available methods often rely on the random modification of sulfhydryl, amine, or carboxyl groups and thus have unpredictable side effects on the stability, solubility, and affinity of the modified proteins. Directed coupling via carbohydrate residues works well for many full-size antibodies, but this approach is not easily transferred to other recombinant proteins, particularly antibody fragments that lack glycan chains. Genetic engineering can be used to introduce or remove additional reactive groups, such as cysteine residues, but this requires laborious screening procedures to identify suitable positions on the antibody for modification, and complex chemistry may be necessary to achieve site-specific coupling (*4*−*7*). An alternative method for the site-specific labeling of proteins is the introduction of short peptide tags that function as label acceptor sites. Here the label is attached either through an intrinsic activity of the tag or the activity of an enzyme supplied in trans. Site-specific biotinylation, as mediated by the biotin holoenzyme synthetase BirA, allows tagged proteins to be combined with a broad range of avidin/streptavidin reagents but does not allow direct labeling (*8*−*10*). Proteins fused to the LUMIO-tag (a hexapeptide containing a tetracysteine motif) can be stained directly with dyes containing two arsenic atoms, but the modification is noncovalent and thus far limited to a small number of fluorescent dyes (*11, 12*). In addition the significant toxicity of arsenic prevents the application of this technology in vivo. When using recombinant antibodies for analytical, diagnostic, or therapeutic applications, it is useful to have a broad range of modification options available, facilitating the adaptation of particular antibodies to suit diverse purposes. The SNAP-Tag technology allows us to equip a given fusion partner with many different dyes, with biotin, or with other effector molecules. It also facilitates coupling to nanoparticles and directed immobilization on chemically modified surfaces. The Tag is derived from the human DNA-repair enzyme *O*(6)-alkylguanine DNA alkyltransferase (AGT) (*1*). It rapidly, specifically, and covalently binds substrates that contain *O*(6)-benzylguanine. The SNAP-Tag reacts with para-substituted *O*(6)-benzylguanine (BG) derivatives by transferring the substituted benzyl group to its active site through a nucleophilic substitution reaction while releasing free guanine. The technology has been applied in a variety of experimental systems, ranging from in-cell labeling of tagged proteins to the immobilization of proteins on chip surfaces (*3, 13*). We cloned and expressed a series of single-chain antibodies (scFv) and natural protein ligands as SNAP-Tag fusions, to develop a platform for the directed modification of these molecules (Figure 1). The fusion proteins were expressed efficiently in 293T and CHO cells and retained the antigen-binding properties of their parent ligands. To demonstrate the versatility of the method, we present fluorescence-activated cell

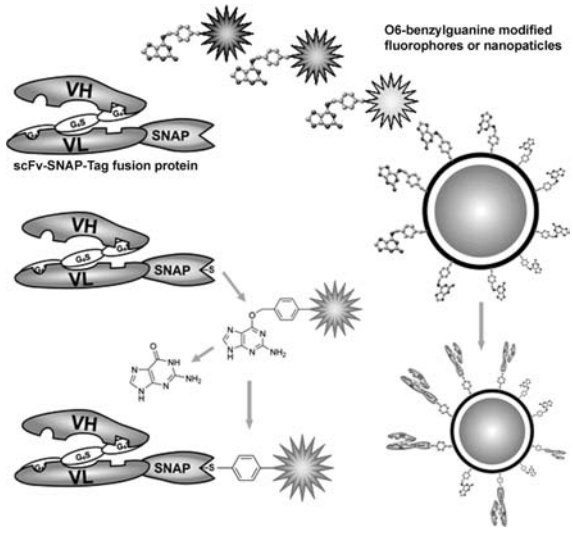

Figure 1. Site-directed modification of recombinant antibody fragments mediated by the SNAP-Tag. Para-substituted *O*(6)-benzylguanine (BG) derivatives are bound by transfer of the substituted benzyl group to the active site of the SNAP-Tag through a nucleophilic substitution reaction while releasing free guanine. Small compounds like fluorophores as well as nanometer- to micrometer-sized particles can be bound without affecting the antibody or protein ligand activity.

sorting (FACS) and confocal microscopy data for an anti-CD30 scFv and its natural ligand CD30L labeled with different dyes, labeled with biotin and coupled to fluorescent silica beads.

EXPERIMENTAL PROCEDURES

Bacterial Strains, Oligonucleotides, and Cloning. All plasmids were prepared using *E. coli* strain XL1-blue (*sup*E44 *hsd*R17 *rec*A1 *end*A1 *gyr*A46 *thi rel*A1 *lac*F0[*pro*AB$^+$ *lac*I^q *lac*ZDM15 Tn*10*(tet^r)]). Molecular cloning steps were performed by standard methods. Synthetic oligonucleotides were supplied by MWG (Martinsried, Germany). The source plasmid containing the SNAP-Tag sequence was provided by Covalys (Witterswil, Switzerland).

Single Chain Antibodies and Ligands. The ligands used to generate the SNAP-Tag fusions have been described (*14*−*18*). The CD30 receptor is highly overexpressed on Hodgkin Reed−Sternberg cells. The human CD30L as well as scFvKi4, a high affinity antibody fragment generated from a monoclonal anti-CD30 antibody, has been shown to target L540 Hodgkin lymphoma cells efficiently (*19*, *20*).

Construction of Mammalian Expression Vectors. We used a modified version of the pSecTac vector (*21*) and introduced the SNAP-Tag sequence to generate both N-terminal and C-terminal fusions. An internal SfiI restriction site was removed by using splice overlap PCR to introduce two silent mutations, allowing scFv fragments and other fusion partners to be introduced by standardized SfiI/NotI restriction.

Culture and Transfection of HEK-293T Cells. HEK-293T cells were transfected with RotiFect (Carl Roth GmbH; Karlsruhe, Germany) using 1 μg of plasmid DNA and 3 μL of RotiFect, according to the manufacturer's instructions. The expression and functionality of each fusion protein was tested 3 days after transfection by FACS analysis of the culture supernatant, using an antipenta-HisAlexa488 antibody (Qiagen). SNAP-Tag activity was tested by staining 10 μL of supernatant with a BG derivative modified with carboxyfluorescein (Vista-Green, Covalys) followed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and visualization of the labeled protein with a UV-transilluminator. Further subcultivation of transfected cells and expression of the recombinant SNAP-Tag fusion proteins were carried out as previously described (*21*). Established transfected cultures were grown in RPMI 1640 medium supplemented with 10% (v/v) heat inactivated fetal calf serum (FCS), 50 μg/mL penicillin, 100 μg/mL streptomycin, 2 mM L-glutamine, and 100 μg/mL Zeocin (all components were obtained from Invitrogen, Carlsbad, CA). For the production of larger amounts of protein, triple flasks were inoculated and 500−1000 mL of supernatant was collected for purification.

Protein Purification. His-tagged proteins were purified from cell-free supernatants by Ni−NTA metal affinity chromatography as described (*21*). Larger volumes were purified on an Äkta FLPC system with a 5 mL Ni-NTA Superflow cartridge (Qiagen) after equilibration with 4× buffer (200 mM NaH_2PO_4, 1.2 M NaCl, 40 mM imidazole, pH 8). After elution, proteins were dialyzed against phosphate-buffered saline (PBS) containing 1 mM dithioerythritol. After concentration to 0.5−1 mg/mL (if necessary) with a 5 kDa MWCO VivaSpin Column (Sigma-Aldrich), ectoine was added as cryopreservative (*22*) to a final concentration of 50 mM and aliquots were stored at −20 °C until further use.

Protein Labeling with BG Derivatives of Organic Fluorophores or Biotin. Purified SNAP-Tag fusion proteins were conjugated with the BG-modified dyes (Covalys AG, Witterswil) by incubation in the dark with 1.5−3-fold molar excess of dye for 2 h at room temperature or overnight at 4 °C. Residual dye was removed by gel filtration chromatography using PD10 columns (GE) or dialysis. Alternatively, the conjugation was performed with the protein still bound to the Ni-NTA resin with one bed volume of a 2 μM dye solution in 1× Ni-NTA wash buffer (300 mM NaCl, 50 mM sodium phosphate, pH 7.5). The labeled protein was eluted with 500 mM imidazole after washing away residual dye.

Coupling efficacy was determined photometrically using the extinction coefficients of the corresponding dyes and the theoretical extinction coefficient of the fusion protein. Stained proteins were visualized after separation by SDS-PAGE with either a UV transilluminator (BioRad Gel Doc XR gel documentation) or with a CRi Maestro imaging system using the blue, red, and near-infrared filter sets. Biotinylation was performed by incubating the fusion proteins with a 2−5 fold molar excess of BG-Biotin using the same procedure described above.

Coupling SNAP-Tag Fusion Proteins to Luminescent Silica Beads. We used spherical silica nanoparticles labeled with carboxyrhodamine to demonstrate coupling of the antibodies. The particles were prepared using a modified Stöber synthesis method (*23*) and had an average diameter of 90 nm. Amine functions were introduced at the bead surface using bifunctional aminosilane (*24*). The average number of amino functionalities on the bead surface was determined with the fluorescamine test and adjusted to ∼320 functions per bead as described (*25*). To facilitate benzylguanine coupling, the beads were dispersed in dimethylformamide (DMF) and incubated with a 60-fold molar excess of BG-NHS (Covalys) over amino groups for 3 h at room temperature. The beads were washed three times with PBS (pH 7.4) and dispersed in the same buffer. For coupling, beads where dispersed in RPMI containing 10% FCS and 0.1% Tween 20 (R10-T) and sonicated to disrupt aggregates. Approximately 0.2 nmol of BG-beads was incubated with 50 μg of Ki4-SNAP (1 nmol) in 100 μL of R10-T for 2 h at room temperature. Coupled beads were washed four times with R10-T and dispersed in 200 μL of RPMI-10% FCS, and 60 μL of the bead preparation was used for analysis by flow cytometry and confocal microscopy. To block SNAP-Tag mediated coupling, Ki4-SNAP was incubated beforehand with a 3-fold molar excess of bromothenylpteridine (BTP, Covalys) for 1 h at room temperature.

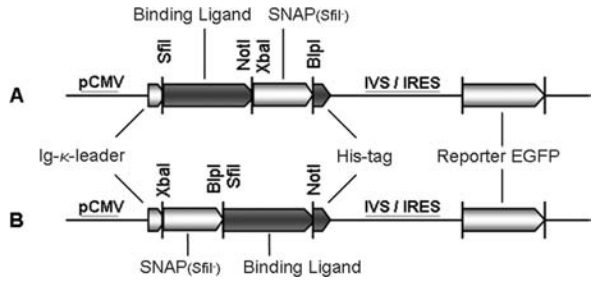

Figure 2. Expression cassettes for C-terminal (A) and N-terminal (B) SNAP-Tag fusions. The coding sequences for the protein ligands are introduced using SfiI/NotI either upstream or downstream of the *SNAP26m* gene, modified to delete an internal SfiI site. The fusion proteins are secreted into the culture supernatant of transfected cells and can be purified via the C-terminal His-tag.

Flow Cytometry. The labeled fusion-proteins were analyzed by flow cytometry with a FACSCalibur (Becton & Dickinson) and CellQuest software. The $CD30^+$ cell line L540 was used as the target for scFv Ki4-SNAP and SNAP-CD30L, whereas the $CD30^-$ histiocytic lymphoma cell line U937 was used as control. Approximately 4×10^5 cells were incubated in 300 μL of PBS containing 1 ng to 1 μg of labeled protein for 20 min on ice. For detection of biotinylated proteins, cells were washed and incubated with 1.5 μg/mL StreptavidinDyLight^{488} for 20 min on ice. The cells were then washed twice with 1.8 mL of PBS in a conventional cell washer.

Confocal Microscopy. All images were taken with a LEICA confocal microscope (TCS SP5). Cells were prepared as described above for flow cytometry. The cells were resuspended in 30 μL of PBS, and 10 μL of the cell suspension was incubated for 5 min with 2 μL of a 1:100 diluted Draq5 solution (Biostatus, Shepshed, UK) to counterstain the nucleus.

RESULTS

Expression of SNAP-Tag Fusion Proteins in HEK 293 Cells. We cloned and expressed several N- and C-terminal SNAP-fusion proteins by transfecting 293T cells and selecting transformants on the basis of Zeocin resistance and reporter GFP fluorescence. To facilitate cloning, the internal SfiI restriction site in the vector was removed by splice overlap PCR, and the modified SNAP-Tag sequence was inserted into different pMS vectors for the generation of C- and N-terminal fusions (Figure 2). A selection of the functionally expressed constructs is shown in Table 1. Ki4-SNAP and SNAP-EGF expression was also assessed in CHO-K1 cells. Active protein could be purified from the culture supernatant, but more intensive selection and screening was required and expression levels as achieved with the 293T cells were not reached. The SNAP-Tag was active irrespective of the position in the fusion protein. The single chain antibodies were usually used in the C-terminal position, in accordance with other fusion proteins based on these ligands. In contrast, the ligands CD30L and EGF were functional only with the SNAP-Tag at the N-terminal position. High expression levels were observed for most of the fusion proteins, e.g., up to

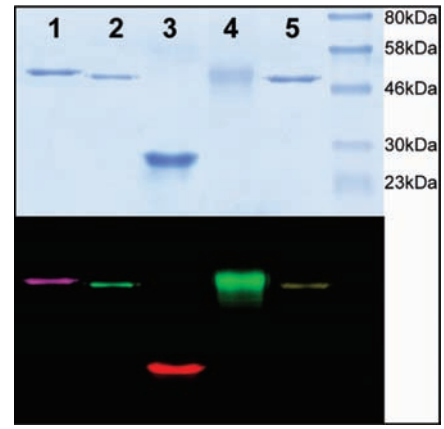

Figure 3. Purified SNAP-Tag fusion proteins labeled with different fluorophores. (1) scFv425-SNAP-782; (2) scFvKi4-SNAP-VistaGreen; (3) SNAP-EGF-Alexa Fluor647; (4) SNAP-CD30L-505 (glycosylation leads to band broadening and an increase in size); (5) scFvH22-SNAP-TMR-star. Approximately 1 μg of labeled protein was separated by SDS-PAGE and visualized with a CRi Maestro Imaging System (lower part) and then stained with coomassie brilliant blue (upper part). Different dye spectra were unmixed using Maestro software.

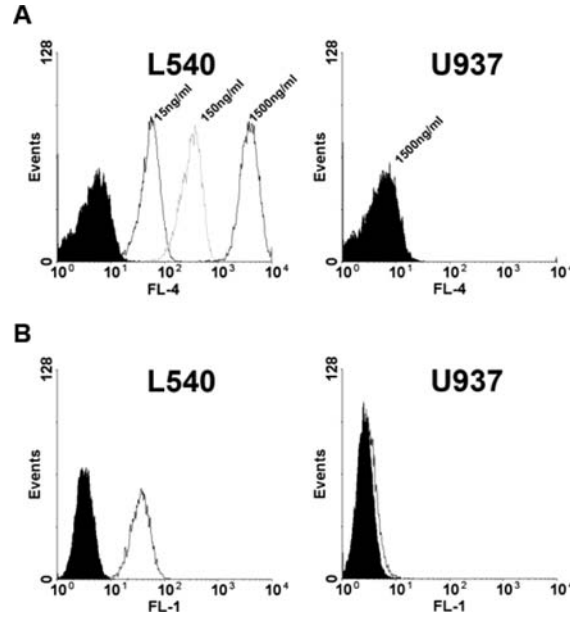

Figure 4. FACS analysis with Ki4-SNAP and SNAP-CD30L. (A) Increasing amounts of Ki4-SNAP labeled with BG-Alexa Fluor647 on L540 ($CD30^+$) and U937 ($CD30^-$) cells. (B) SNAP-CD30L labeled with BG-biotin and detected with StreptavidinDyLight488.

17.5 mg/L culture supernatant for scFv 425-SNAP, and 5−10 mg/L for the others (Table 1). Comparisons of the fusion proteins and their parental counterparts indicated that the SNAP-Tag did not have a negative impact on expression levels. Stability was not tested in detail for every fusion protein, but scFv Ki4-SNAP showed no significant loss of binding activity

Table 1. Selection of Successfully Expressed Ligand−SNAP-Tag Fusion Proteins

fusion protein	target	tag position	expression rate in 293T cells	binding confirmed on
scFv Ki4-SNAP (49 kDa)	CD30	N-term.	>10 mg/L	L540
SNAP-CD30L (41 kDa + glycosylation)	CD30	C-term.	~5 mg/L	L540
scFv 425-SNAP (48 kDa)	EGFR	N-term.	>15 mg/L	A431/L3.6pl
SNAP-EGF (28 kDa)	EGFR	C-term.	>10 mg/L	A431/L3.6pl
SNAP-Myelin Oligodendrocyte Glycoprotein (MOG) (38 kDa)	anti MOG Ig	N-term.	>10 mg/L	8.18-C5 murine hybridoma cells
Annexin V-SNAP (59 kDa)	Phosphatidyl-serine	N-term. or C-term.	nd	apoptotic L3.6pl cells
scFv H22-SNAP (48 kDa)	CD64	N-term.	~ 8 mg/L	U937
scFv RFT5-SNAP (48 kDa)	CD25	N-term.	nd	L540

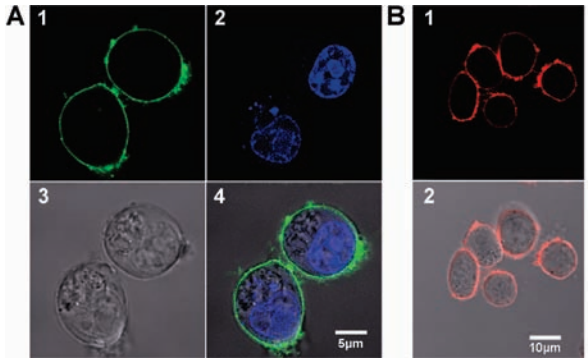

Figure 5. Confocal microscopy of Ki4-SNAP and SNAP-CD30L on $CD30^+$ L540 cells. (A) Ki4-SNAP labeled with BG-505. 1= 505 fluorescence signal, 2 = nucleus stained with Draq5, 3 = transmission light picture, 4 = overlay of 1−3. (B) SNAP-CD30L labeled with BG-Alexa Fluor 647. One = Alexa Fluor 647 fluorescence signal, 2 = overlay of fluorescence and transmission light picture. The high CD30 expression on the L540 cell surface results in a strong membrane staining mediated by the Ki4 single chain antibody, as well as the natural human CD30L, fusion protein.

or SNAP-Tag activity when concentrated at ∼1 mg/mL and stored at 4 °C for 4 weeks. All the constructs we tested were still active after at least 4 months when stored at −20 °C.

Labeling of SNAP-Tag Fusion Proteins with Organic Fluorophores. Figure 3 shows a selection of five fusion proteins labeled with different fluorophores and stained with Coomassie Brilliant Blue after separation by SDS-PAGE. Coupling efficiencies were independent of the SNAP-Tag fusion partner. We achieved rates of 90−100% efficiency after overnight incubation using different constructs and different dyes (BG-Alexa Fluor647, BG-TMR-star, BG-505 and BG-Vista-Green, BG-782), and in most cases 60−70% efficiency after 1 h at room temperature. A 1.5-fold molar excess of dye was sufficient to achieve these labeling efficiencies.

Confocal Microscopy and FACS Analysis. To evaluate the activities of the different fusion proteins, we carried out FACS analyses with proteins purified from the supernatant of transfected 293T cells and stained with various BG-modified fluorescent dyes. All the labeled proteins we tested gave a strong fluorescence signal on the corresponding target cell line but not on control cells. To exemplify these results, FACS and confocal microscopy data are shown for the anti-CD30 scFv Ki4-SNAP and the corresponding human ligand SNAP-CD30L. For Ki4-SNAP labeled with BG-Alexa Fluor647, less than 15 ng/mL was sufficient to detect binding to target cells by flow cytometry (Figure 4A). Confocal microscopy of Ki4-SNAP labeled with BG-505 confirmed homogeneous membrane staining on L540 cells (Figure 5A). A similar staining pattern was observed with the natural ligand of CD30, CD30L, labeled with Alexa Fluor647 (Figure 5B). We also used BG-biotin to label the fusion proteins, and FACS analysis of cells treated with biotinylated CD30L followed by StreptavidinDyLight 488 is shown in Figure 4B.

SNAP-Tag Coupling to Silica Beads. To test the versatility of the coupling procedure, we used carboxyrhodamine-labeled silica beads and modified them with an *N*-hydroxysuccinimide-ester derivativeof BG (BG-GLA-NHS) via surface amino groups. The anti-CD30 scFv Ki4 was coupled to these beads, and the labeling and binding properties were analyzed by FACS (data not shown) and confocal microscopy. The bead conjugates showed specific labeling of $CD30^+$ L540 cells (Figure 6 A) while only minimal background was observed when the SNAP-Tag was blocked with bromothenylpteridine (Figure 6 B). No binding of the beads was observed on $CD30^-$ U937 cells (not shown). The multivalency of the conjugated beads led to the

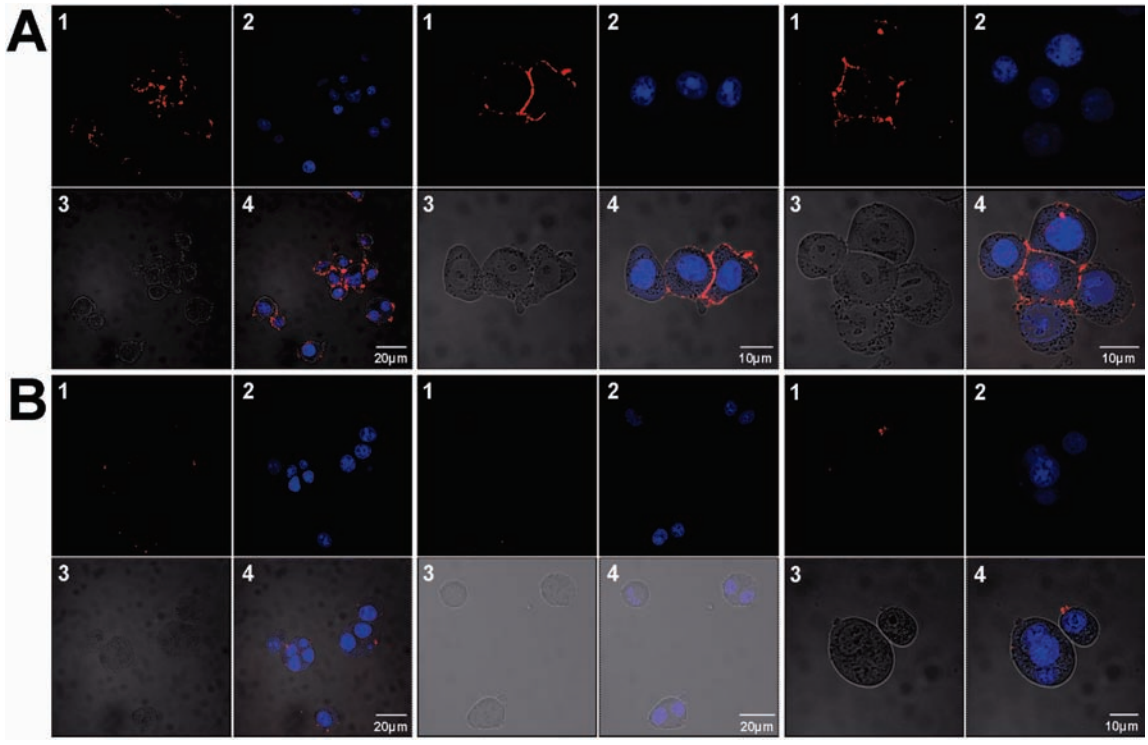

Figure 6. Confocal microscopy with Ki4-SNAP coupled to benzylguanine-modified fluorescent beads on L540 cells. (A) Ki4-SNAP-coupled beads. (B) Beads incubated with Ki4-SNAP with the SNAP-Tag previously blocked with bromothenylpteridine. In each panel, 1 = signal from carboxyrhodamine silica beads, 2 = nucleus stained with Draq5, 3 = transmission light picture, and 4 = overlay of 1−3. The Ki4-SNAP coupled beads bind to and lead to aggregation of the L540 target cells while only minimal attachment of bead aggregates is observed with the blocked Ki4-SNAP-Tag.

formation of cell aggregates, linking several cells via their surface receptors.

DISCUSSION

To demonstrate the feasibility of directed coupling of protein ligands and antibodies using the SNAP-Tag method, we cloned and expressed a series of SNAP-Tag fusion proteins containing either a single chain antibody fragment or a corresponding natural ligand directed against well-characterized tumor markers. All constructs listed in Table 1 retained both the binding activity of the parental molecule and SNAP-Tag activity. The fact that such activity could be demonstrated for a range of different ligand formats, the extracellular domains of membrane glycoproteins (CD30L, MOG), a secreted peptide ligand (EGF), and engineered antibody fragments, provides ample evidence for the broad applicability of this method. SNAP-Tag fusions have previously been expressed in *E. coli*, yeast, and mammalian cells (*13*, *26*) but never with the intention of producing large amounts of a reagent for further applications. Expression in 293T cells provides a convenient system that allows rapid screening of the fusion proteins, since 293T cells are easy to transfect and expression of the target protein can be assessed directly by correlation with eGFP expression levels (*21*). The average yield of purified fusion protein was 10 mg/L supernatant (Table 1), and this was achieved without further enrichment for high-performance clones, indicating that much higher yields should be possible.

Several different approaches have been used to engineer antibody fragments for site-specific coupling/labeling, including the introduction of additional cysteine residues at the C-terminus (*27*) or at the end of each linker connecting the V_H and V_L chains in a scFv diabody (*28*). The site-specific immobilization of a scFv fusion protein by transglutaminase has also been reported (*29*) as well as the directed biotinylation of different antibody fragments by coexpression with the bacterial biotin ligase BirA in HEK293 cells (*30*).

Despite these successes, it would be advantageous to increase the versatility of site-specific labeling systems to allow diverse labels to be used with the same parental protein. Labeling with the SNAP-tag is advantageous because large quantities of very pure ligands can be produced and made directly available for coupling, and the activity of the ligand is not affected by the fusion or by coupling to a substrate. Furthermore, conjugation is covalent, stable, is site-specific, and has a predefined stoichiometry. The approach is not limited to a single class of recombinant proteins but is applicable to a wide range of protein ligands.

The targeted delivery of nanoparticles for imaging and drug delivery has become a very active area of biomedical research. Quantum dots, iron oxide or gold nanoparticles, liposomes and polymers have all been equipped with antibodies for targeted delivery in vivo (*31*−*33*). The coupling strategy described here enables the efficient modification of such particles with recombinant proteins, as demonstrated for BG-functionalized silica nanobeads.

By genetically fusing antibody fragments and other targeting ligands to the SNAP-Tag, we have developed and evaluated a new platform for the directed modification of diverse protein molecules. A series of different ligands has been cloned, expressed, and successfully labeled with several fluorophores, biotin, and silica nanoparticles, showing the versatility of the approach. Experimental data is shown for a single chain antibody fragment directed against CD30 and the natural human ligand CD30L. This new platform could have a significant impact on the labeling of recombinant proteins used as reagents in nanobiotechnology, molecular biology, and cell biology, as well as proteins used in analytical assays, disease diagnosis, and therapy.

ACKNOWLEDGMENT

We would like to thank Dr. Richard Twyman for the critical reading of the manuscript.

^{18}F, ^{64}Cu, and ^{68}Ga Labeled RGD-Bombesin Heterodimeric Peptides for PET Imaging of Breast Cancer

Zhaofei Liu,[†,‡] Yongjun Yan,[†] Shuanglong Liu,[†] Fan Wang,[‡] and Xiaoyuan Chen*[,†]

The Molecular Imaging Program at Stanford (MIPS), Department of Radiology, Biophysics, and Bio-X Program, Stanford University School of Medicine, 1201 Welch Road, Stanford, California 94305-5484, and Medical Isotopes Research Center, Peking University, Beijing, 100191, China. Received January 21, 2009; Revised Manuscript Received March 25, 2009

Radiolabeled RGD (Arg-Gly-Asp) and bombesin (BBN) radiotracers that specifically target integrin $\alpha_v\beta_3$ and gastrin releasing peptide receptor (GRPR) are both promising radiopharmaceuticals for tumor imaging. We recently designed and synthesized a RGD-BBN heterodimeric peptide with both RGD and BBN motifs in one single molecule. The ^{18}F-labeled RGD-BBN heterodimer exhibited dual integrin $\alpha_v\beta_3$ and GRPR targeting in a PC-3 prostate cancer model. In this study we investigated whether radiolabeled RGD-BBN tracers can be used to detect breast cancer by using microPET. Cell binding assay demonstrated that the high GRPR expressing breast cancer cells typically express low to moderate level of integrin $\alpha_v\beta_3$, while high integrin $\alpha_v\beta_3$ expressing breast cancer cells have negligible level of GRPR. We labeled RGD-BBN heterodimer with three positron emitting radionuclides ^{18}F, ^{64}Cu, and ^{68}Ga and investigated the corresponding PET radiotracers in both orthotopic T47D (GRPR$^+$/low integrin $\alpha_v\beta_3$) and MDA-MB-435 (GRPR$^-$/integrin $\alpha_v\beta_3^+$) breast cancer models. The three radiotracers all possessed in vitro dual integrin $\alpha_v\beta_3$ and GRPR binding affinity. The advantages of the RGD-BBN radiotracers over the corresponding BBN analogues are obvious for imaging MDA-MB-435 (GRPR$^-$/integrin $\alpha_v\beta_3^+$) tumor. ^{18}F-FB-PEG$_3$-RGD-BBN showed lower tumor uptake than ^{64}Cu-NOTA-RGD-BBN and ^{68}Ga-NOTA-RGD-BBN but was able to visualize breast cancer tumors with high contrast. Synthesis of ^{64}Cu-NOTA-RGD-BBN and ^{68}Ga-NOTA-RGD-BBN is much faster and easier than ^{18}F-FB-PEG$_3$-RGD-BBN. ^{64}Cu-NOTA-RGD-BBN showed prolonged tumor uptake but also higher liver retention and kidney uptake than ^{68}Ga-NOTA-RGD-BBN and ^{18}F-FB-PEG$_3$-RGD-BBN. ^{68}Ga-NOTA-RGD-BBN possessed high tumor signals but also relatively high background uptake compared with the other two radiotracers. In summary, the prosthetic labeling groups, chelators, and isotopes all have a profound effect on the tumor targeting efficacy and in vivo kinetics of the RGD-BBN tracers for dual integrin and GRPR recognition. Further development of suitably labeled RGD-BBN tracers for PET imaging of cancer is warranted.

INTRODUCTION

Breast cancer is the most frequently diagnosed malignancy among women in the Western world and the second leading cause of cancer-related deaths in women (*1*−*3*). Early detection of the primary breast cancer or its metastases at distant sites remains the best approach for improving the odds of curing or controlling this disease. The receptors overexpressed on the surface of cancer cells or uniquely expressed during the progress of cancer invasion and metastasis represent the promising targets for breast cancer diagnosis or therapy.

Gastrin-releasing peptide receptor (GRPR[1]) is one of the subtypes of the bombesin (BBN) receptors. GRPRs have been found to be massively overexpressed in several types of human cancers, such as lung cancer, colon cancer, gastric cancer, pancreas cancer, breast cancer, and prostate cancer (*4*, *5*). In the past decade, various bombesin and analogues were labeled with different isotopes like ^{99m}Tc, ^{111}In, ^{90}Y, ^{64}Cu, ^{177}Lu, ^{18}F, or ^{68}Ga and investigated for GRPR-positive tumor targeted imaging and therapy in both animal models and human trails (*6*−*18*). Several bombesin related radiotracers were also investigated for breast cancer imaging (*9*, *19*, *20*).

It is well documented that integrin $\alpha_v\beta_3$ plays an important role in the regulation of tumor growth, angiogenesis, local invasiveness, and metastatic potential (*21*−*23*). Integrin $\alpha_v\beta_3$ is up-regulated on the activated tumor endothelial cells and also highly expressed on some tumor cells such as glioblastoma, breast, and prostate tumors, malignant melanomas, and ovarian carcinomas (*24*). Radiolabeled RGD (Arg-Gly-Asp) peptides and analogues that specifically target integrin $\alpha_v\beta_3$ have been wildly tested for tumor imaging in preclinical and clinical studies (*25*−*32*). Most recently, two ^{18}F labeled RGD based tracers studied in breast cancer patients showed promising results (*28*, *33*).

For the one target based breast cancer imaging, the cell-surface receptor must be highly expressed in tumors relative to normal tissues, which may not occur during the whole process of tumor development and in all types of breast cancers. It is thus desirable to develop a new type of radiotracer that can target two types of receptors simultaneously, allowing tumor contrast when either or both receptor types are expressed. We recently designed and synthesized a RGD-BBN heterodimeric peptide that contain both the RGD and BBN motifs in one single molecule (Figure 1) (*34*, *35*). The ^{18}F labeled RGD-BBN heterodimer exhibited excellent in vivo kinetic and dual GRPR and integrin $\alpha_v\beta_3$-receptor targeting properties in a PC-3 prostate cancer xenograft model. Here, we test whether radiolabeled

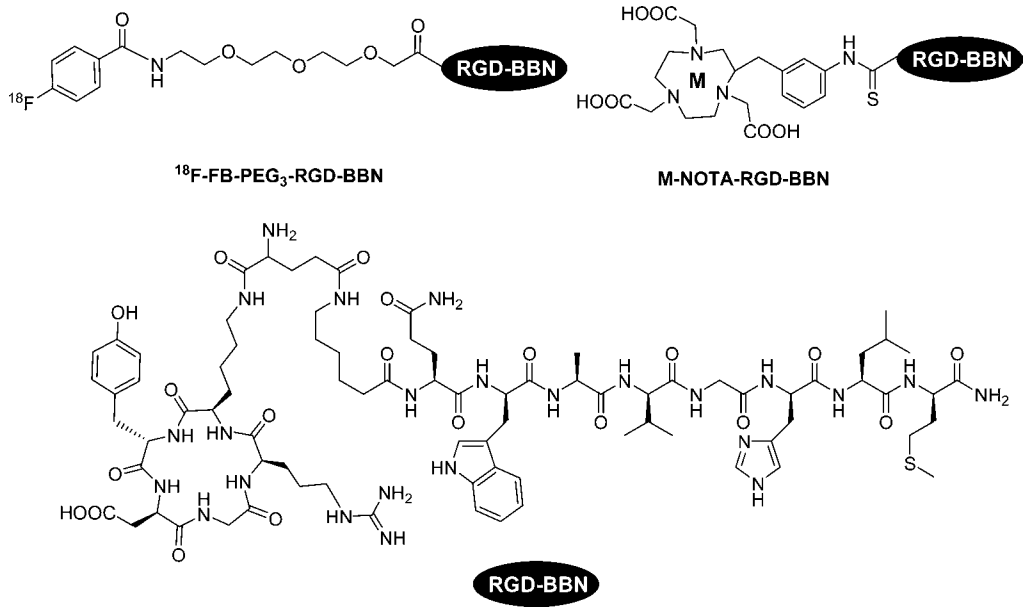

Figure 1. Chemical structures of ^{18}F-FB-PEG$_3$-RGD-BBN and NOTA-RGD-BBN with M corresponding to the chelated ^{64}Cu or ^{68}Ga. RGD-BBN: cyclo(Arg-Gly-Asp-D-Tyr-Lys)-Glu-(Aca-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH$_2$).

RGD-BBN heterodimers can be generally used for the diagnosis of breast cancers as well. In this study, we first screened the GRPR and integrin $\alpha_v\beta_3$ expression in various breast cancer cell lines. We found that among all the tested breast tumor cell lines, almost all the GRPR high expressing tumor cells (e.g., BT474 and T47D) have low to moderate level of integrin $\alpha_v\beta_3$, while the high integrin $\alpha_v\beta_3$ expressing tumor cells (e.g., MDA-MB-435 and MDA-MB-231) have low or undetectable level of GRPR. We thus chose two representative breast cancer models T47D (GRPR$^+$/low integrin $\alpha_v\beta_3$) and MDA-MB-435 (GRPR$^-$/integrin $\alpha_v\beta_3{}^+$) for in vivo test of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN (Figure 1).

EXPERIMENTAL PROCEDURES

All commercially obtained chemicals were of analytical grade and used without further purification. *p*-SCN-Bn-NOTA was purchased from Macrocyclics (Dallas, TX). Chelex 100 resin (50−100 mesh) was purchased from Sigma-Aldrich (St. Louis, MO). Water and all buffers were passed through Chelex 100 column before use in ^{64}Cu and ^{68}Ga labeling procedures to ensure that the aqueous buffer is heavy-metal-free. The syringe filter and polyethersulfone membranes (pore size, 0.22 μm; diameter, 13 mm) were obtained from Nalge Nunc International (Rochester, NY). The peptides Aca-BBN(7−14) and c(RGDyK) were synthesized by Peptides International (Louisville, KY). RGD-BBN heterodimer and PEG$_3$-Glu-RGD-BBN were synthesized from Aca-BBN and c(RGDyK) as we previously described (*35*). Na^{125}I was purchased from Perkin-Elmer (Waltham, MA). ^{125}I-[Tyr^4]BBN (2,000 Ci/mmol) was purchased from GE Healthcare (Piscataway, NJ). ^{64}Cu was obtained from University of Wisconsin (Madison, WI). No-carrier-added ^{18}F−F$^-$ was obtained from an in-house cyclotron (GE Healthcare). ^{68}Ga was obtained from a ^{68}Ge/^{68}Ga generator (Obninsk, Russia) and eluted with 0.1 N HCl. The reversed-phase high-performance liquid chromatography (HPLC) system was the same as previously reported (*27, 36*). For NOTA conjugates and ^{18}F-labeled peptides purification, a Vydac protein and peptide column (218TP510; 5 μm, 250 mm × 10 mm) was used with a flow rate of 5 mL/min. For analytical HPLC and ^{64}Cu or ^{68}Ga labeling purification, a Vydac 218TP54 column (5 μm, 250 mm × 4.6 mm) was used with a flow rate of 1 mL/min. The mobile phase was changed from 95% solvent A (0.1% trifluoroacetic acid [TFA] in water) and 5% solvent B (0.1% TFA in acetonitrile [ACN]) (0−2 min) to 35% solvent A and 65% solvent B at 32 min. The UV absorbance was monitored at 218 nm, and the identification of the peptides was confirmed on the basis of the UV spectrum acquired using a photodiode array (PDA) detector. The radioactivity was detected by model 105S single-channel radiation detector (Carroll and Ramsey Associates).

Synthesis of NOTA Conjugates. NOTA-BBN and NOTA-RGD-BBN conjugates were prepared as we previously described (*37*). In brief, a solution of 2 μmol of peptide (BBN or RGD-BBN) was mixed with 6 μmol of *p*-SCN-Bn-NOTA in 0.1 N $NaHCO_3$ solution (pH 9.0). After the mixture was stirred at room temperature for 5 h, the NOTA conjugates were isolated by semipreparative HPLC. The collected fractions were combined and lyophilized to afford the final product as a white powder. NOTA-bombesin (NOTA-BBN) was obtained in 72% yield with 22.1 min retention time on analytical HPLC. MALDI-TOF-MS was *m*/*z* 1504.0 for $[MH]^+$ ($C_{69}H_{102}N_{18}O_{16}S_2$, calculated molecular weight 1503.8). NOTA-RGD-BBN was obtained in 52% yield with 20.7 min retention time on analytical HPLC. MALDI-TOF-MS was *m*/*z* 2235.3 for $[MH]^+$ ($C_{102}H_{149}N_{27}O_{26}S_2$, calculated molecular weight 2234.6).

^{68}Ga Radiolabeling. The ^{68}Ga labeling procedure was conducted according to the methods we previously described (*37*). Briefly, 5 nmol of NOTA-BBN or NOTA-RGD-BBN peptide was dissolved in 500 μL of 0.1 M sodium acetate buffer and incubated with 4 mCi (148 MBq) of ^{68}Ga for 15 min at 40 °C. ^{68}Ga-NOTA-BBN or ^{68}Ga-NOTA-RGD-BBN product was then purified by analytical HPLC, and the radioactive peak containing the desired product was collected. After removal of the solvent by rotary evaporation, the activity was then reconstituted in PBS and passed through a 0.22 μm Millipore filter into a sterile multidose vial for in vitro and in vivo experiments. The labeling was done with 95% decay-corrected yield for NOTA-BBN (t_R = 21.8 min) and 90% for NOTA-RGD-BBN (t_R = 20.3 min).

^{64}Cu Radiolabeling. The ^{64}Cu labeling was performed as we previously described (*26, 38*). Briefly, 5 nmol of NOTA-BBN or NOTA-RGD-BBN dissolved in NaOAc buffer was labeled with 2 mCi (74 MBq) of ^{64}Cu for 15 min at 40 °C. The labeled

peptides were then purified by analytical HPLC. The radioactive peak containing the desired product was collected and rotary evaporated to remove the solvent. The products were then formulated in phosphate-buffered saline (PBS) and passed through a 0.22-μm Millipore filter into a sterile multidose vial for in vitro and in vivo experiments. The labeling was done with 94% decay-corrected yield for NOTA-BBN ($t_R = 21.4$ min) and 92% for NOTA-RGD-BBN ($t_R = 20.5$ min).

^{18}F-Radiolabeling. The detailed labeling procedure was reported previously (*35*). PEG_3-RGD-BBN or BBN was labeled with ^{18}F using *N*-succinimidyl-4-^{18}F-fluorobenzoate (^{18}F-SFB) as the synthon. The desired fractions containing ^{18}F-FB-PEG_3-RGD-BBN or ^{18}F-FB-BBN were combined and rotary evaporated to dryness, respectively. The products were then passed through a 0.22 μm Millipore filter into a sterile multidose vial for in vitro and in vivo experiments.

Cell Lines and Animal Models. The MDA-MB-231, MDA-MB-468, BT-474, BT-20, T47D, MCF-7, and MDA-MB-435 human breast cancer cell lines, U87MG human glioblastoma cell line, and PC-3 human prostate carcinoma cell line were all obtained from the American Type Culture Collection (ATCC, Manassas, VA) and maintained under standard conditions according to ATCC. Animal procedures were performed according to a protocol approved by the Stanford University Institutional Animal Care and Use Committee. The MDA-MB-435 tumor model was established by orthotopic injections of 5×10^6 cells into the right mammary fat pad of female athymic nude mice. For T47D tumor model establishment, the female nude mice were first subcutaneously implanted with 60-day release 17β-estradiol pellets (Innovative Research of America, Sarasota, FL) in the left neck. One day after the estradiol implantation, 1×10^7 T47D cells were orthotopically injected into the right mammary fat pad of the nude mice. The mice were subjected to microPET studies when the tumor volume reached 100−300 mm^3 (2−3 weeks for MDA-MB-435 and 4−5 weeks for T47D).

Cell Binding Assay. ^{125}I-[Tyr4]BBN and ^{125}I-c(RGDyK) were used as the radioligands to detect the GRPR and integrin $\alpha_v\beta_3$ receptor levels on the various breast cancer cells, respectively. We labeled c(RGDyK) with Na^{125}I and purified it with HPLC according to our previously described method (*39*). The ^{125}I-c(RGDyK) was prepared in high specific activity (~1200 Ci/mmol). Different breast cancer cells were seeded in the 96-well multiscreen DV plates (10^6 cells/well) and then incubated with ~30,000 cpm ^{125}I-[Tyr^4]BBN or ^{125}I-c(RGDyK) for 2 h at room temperature with or without excess doses of cold Acta-BBN(7−14) or c(RGDyK) as blocking agents. After the mixture was washed with PBS, hydrophilic PVDF filters were collected and the radioactivity was determined using a γ counter (Packard, Meriden, CT). Results were expressed as percent added dose per million cells (% AD/10^6 cells). Experiment was repeated twice with five parallel samples.

The integrin $\alpha_v\beta_3$ receptor-binding affinity of NOTA-RGD-BBN and FB-PEG_3-RGD-BBN was determined by competition binding assay using ^{125}I-c(RGDyK) as the radioligand on integrin $\alpha_v\beta_3$ high-expressing U87MG cells as we previously described (*26*). The GRPR receptor-binding affinity of NOTA-RGD-BBN and FB-PEG_3-RGD-BBN was determined by competition binding assay using ^{125}I-[Tyr^4]BBN as the radioligand on GRPR high-expressing PC-3 cells as we previously described (*10*). The best-fit 50% inhibitory concentration (IC_{50}) values were calculated by fitting the data with nonlinear regression using Graph-Pad Prism (GraphPad Software, Inc.). Experiments were performed twice with triplicate samples.

Immunofluorescent Staining. The expression of GRPR, human integrin $\alpha_v\beta_3$, and murine integrin β_3 on T47D and MDA-MB-435 tumor tissues was detected by immunofluorescent staining. Briefly, frozen T47D and MDA-MB-435 tumor slices (5 μm thickness) from the tumor-bearing nude mice were fixed with ice-cold acetone, rinsed with PBS, and blocked with 10% goat serum for 30 min at room temperature. The slices were incubated with goat anti-GRPR antibody (1:100; Santa Cruz Biotechnology, Santa Cruz, CA), humanized antihuman integrin $\alpha_v\beta_3$ antibody Abegrin (MedImmune, Gathersberg, MD, 20 μg/mL) (*40*) with FITC-conjugated donkey antigoat, Cy3-conjugated donkey antihuman, and FITC-conjugated goat antihamster secondary antibodies (1:200; Jackson Immuno-Research Laboratories, West Grove, PA), respectively.

Cell Uptake Studies. The cell uptake studies were performed as we previous described with some modifications (*10, 34, 35*) the day before experiment to allow adherence. Cells were incubated with ^{18}F-FB-PEG_3-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN (~18 kBq/well) at 37 °C for 15, 30, 60, and 120 min. Tumor cells were then washed three times with chilled PBS and harvested by trypsinization with 0.25% trypsin/0.02% EDTA (Invitrogen, Carlsbad, CA). The cells suspensions were collected and measured in a γ counter (Packard, Meriden, CT). The cell uptake was expressed as the percent added dose (% AD) after decay correction. Experiments were performed twice with triplicate wells.

MicroPET Imaging. PET scans and image analysis were performed using a microPET R4 rodent model scanner (Siemens Medical Solutions, Malvern, PA) as previously reported (*26, 27*). The microPET studies were performed by tail-vein injection of 3.7~5.6 MBq (100~150 μCi) ^{18}F-FB-PEG_3-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN into nude mice bearing T47D or MDA-MB-435 tumor xenografts under isoflurane anesthesia. Five-minute static PET images were acquired at 30 min, 1 h, and 2 h time points postinjection (p.i). Ten-minute static PET images were acquired at 4 and 24 h pi for ^{64}Cu-NOTA-RGD-BBN ($n = 4$/group). The images were reconstructed by a two-dimensional ordered-subsets expectation maximum (OSEM) algorithm, and no correction was necessary for attenuation or scatter correction. For control studies, each group of three mice bearing MDA-MB-435 tumors were injected via tail-vein with 3.7 MBq (100 μCi) of ^{18}F-FB-BBN, ^{64}Cu-NOTA-BBN, or ^{68}Ga-NOTA-BBN. Five-minute static PET scans were then acquired at 30 min pi ($n = 3$/group).

Serum Stability and Metabolism. ^{18}F-FB-PEG_3-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN was incubated in fetal bovine serum (FBS) for 2 h at room temperature to test the in vitro serum stability. After passing through a 0.22 μm Millipore filter, the samples were analyzed by radio-HPLC. For metabolism studies, female nude mice ($n = 2$/group) were injected with ^{18}F-FB-PEG_3-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN at a dose of 7.4 MBq (200 μCi) in 0.2 mL PBS via tail vein. At 60 min pi, the urine samples were collected and then centrifuged at 8000 rpm for 5 min. The supernatant was collected, filtered through a 0.22 μm Millipore filter, and then analyzed by radio-HPLC.

Statistical Analysis. Quantitative data were expressed as the mean ± SD. Mean values were compared using one-way analysis of variance (ANOVA) and Student's *t* test. *P* values of <0.05 were considered statistically significant.

RESULTS

Chemistry and Radiochemistry. The NOTA conjugates of BBN and RGD-BBN were analyzed by both HPLC and mass spectrometry to confirm the identity of the products. The characterizations of ^{18}F-FB-PEG_3-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN (Figure 1) are listed in Table 1. The decay-corrected labeling yield of ^{18}F-FB-PEG_3-RGD-BBN was 40−50% based on ^{18}F-SFB. The decay-corrected labeling yields of ^{64}Cu-NOTA-RGD-BBN and ^{68}Ga-

Table 1. Characterizations of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN[a]

	receptor affinity IC_{50} (nM)				
	integrin $\alpha_v\beta_3$	GRPR	labeling yield (%)	radiochemical purity (%)	preparation time (min)
^{18}F-FB-PEG$_3$-RGD-BBN	13.77 ± 1.82	73.28 ± 1.57	40−50	>98	~180
^{64}Cu-NOTA-RGD-BBN	16.15 ± 2.77	92.75 ± 3.53	>90	>98	~40
^{68}Ga-NOTA-RGD-BBN			>90	>98	~45

[a] The IC_{50} was determined by FB-PEG$_3$-RGD-BBN and NOTA-RGD-BBN. Labeling yield of ^{18}F-FB-PEG$_3$-RGD-BBN was based on ^{18}F-SFB. Preparation time of ^{18}F-FB-PEG$_3$-RGD-BBN was determined from ^{18}F−F.

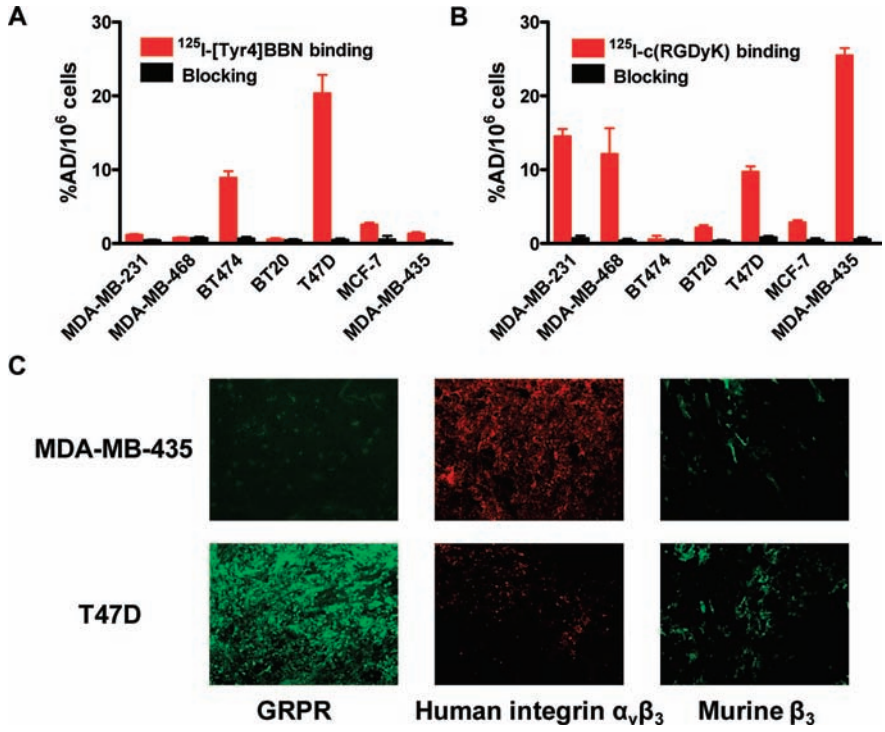

Figure 2. (A, B) GRPR and integrin $\alpha_v\beta_3$ levels in different breast cancer cell lines determined by cell binding assay using ^{125}I-[Tyr^4]BBN (A) or ^{125}I-c(RGDyK) (B) as the radioligand (mean ± SD, $n = 5$). (C) Immunofluorescent staining for GRPR, human integrin $\alpha_v\beta_3$, and murine integrin β_3 in MDA-MB-435 and T47D tumor tissues.

NOTA-RGD-BBN were both higher than 90% under the conditions of reaction at 40 °C for 15 min. After the purification with HPLC, the radiochemical purity of each tracer was higher than 98%. The overall preparation time was ~180 min for ^{18}F-FB-PEG$_3$-RGD-BBN starting from ^{18}F−F, ~40 min for ^{64}Cu-NOTA-RGD-BBN from $^{64}CuCl_2$, and ~45 min for ^{68}Ga-NOTA-RGD-BBN from $^{68}Ga^{3+}$ elution. The specific activity of ^{64}Cu-NOTA-RGD-BBN and ^{68}Ga-NOTA-RGD-BBN used in the in vitro and in vivo experiments was typically 7.4−14.8 MBq/nmol (0.2−0.4 Ci/μmol) at the end of synthesis.

Receptor Binding Affinity. The integrin $\alpha_v\beta_3$ receptor-binding affinities of NOTA-RGD-BBN and FB-PEG$_3$-RGD-BBN were determined by performing competitive binding assay with ^{125}I-c(RGDyK) as the radioligand on U87MG tumor cells. The IC_{50} values for NOTA-RGD-BBN and FB-PEG$_3$-RGD-BBN were 16.15 ± 2.77 and 13.77 ± 1.82 nM, respectively (mean ± SD, $n = 3$, Table 1). The binding affinities of NOTA-RGD-BBN and FB-PEG$_3$-RGD-BBN for GRPR were evaluated using GRPR-positive PC-3 cells with ^{125}I-[Tyr^4]BBN as the radioligand. The IC_{50} values were determined to be 92.75 ± 3.53 nM for NOTA-RGD-BBN and 73.28 ± 1.57 nM for FB-PEG$_3$-RGD-BBN (mean ± SD, $n = 3$, Table 1). The comparable IC_{50} values from these two sets of experiments suggest that NOTA-RGD-BBN and FB-PEG$_3$-RGD-BBN possessed comparable integrin $\alpha_v\beta_3$ binding affinities to c(RGDyK) and GRPR receptor-binding affinities to Aca-BBN(7−14).

GRPR and Integrin $\alpha_v\beta_3$ Expression on Breast Cancer Cells. The expression of GRPR and integrin $\alpha_v\beta_3$ on various breast cancer cells was determined by radioligand receptor-binding assay using ^{125}I-[Tyr^4]BBN and ^{125}I-c(RGDyK) as radioligands, respectively. As shown in Figure 2A, among all the breast cancer cells tested, T47D expressed the highest level of GRPR, as the cell binding percentage of ^{125}I-[Tyr^4]BBN was the highest. The binding specificity of ^{125}I-[Tyr^4]BBN with T47D cells was confirmed by blocking study with cold BBN. The expression of integrin $\alpha_v\beta_3$ on the breast cancer cell lines followed the order MDA-MB-435 > MDA-MB-231 > MDA-MB-468 > T47D > MCF-7 > BT20 > BT474 (Figure 2B). After blocking with cold c(RGDyK), the cell bound ^{125}I-c(RGDyK) all decreased to a background level, indicating the binding of ^{125}I-c(RGDyK) with the tumor cells was integrin $\alpha_v\beta_3$-mediated specific binding.

Immunofluorescent Staining. The expression of GRPR and integrin $\alpha_v\beta_3$ in the T47D and MDA-MB-435 tumor tissues was detected by immunofluorescent staining. As shown in Figure 2C, T47D tumor showed strong GRPR staining while MDA-MB-435 tumor had only weak background staining, which is consistent with the cell-based radioligand study (Figure 2A). The anti-integrin $\alpha_v\beta_3$ antibody Abegrin we used can only recognize the human integrin $\alpha_v\beta_3$, which does not cross-react with murine integrin $\alpha_v\beta_3$ of the tumor cells. MDA-MB-435 tumor tissue showed much higher human integrin $\alpha_v\beta_3$ expression than T47D tumor tissue. Besides human integrin $\alpha_v\beta_3$

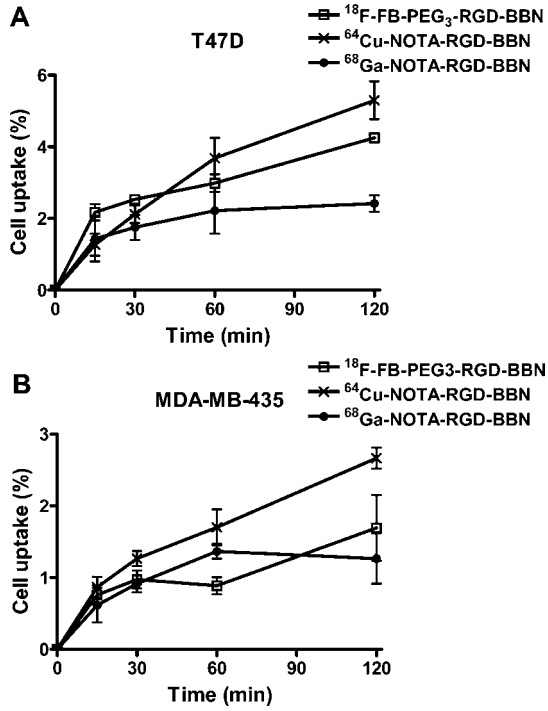

Figure 3. Cell uptake assay of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN on T47D (A) and MDA-MB-435 (B) tumor cells (mean ± SD, $n = 3$).

expressed by the tumor cells, the tumors grown in the nude mice also expressed murine integrin $\alpha_v\beta_3$ on the tumor vasculature. As shown in Figure 2C, both T47D and MDA-MB-435 tumors expressed murine integrin β_3, which can also be recognized by RGD.

Cell Uptake Studies. The cell uptake studies of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN were performed on T47D and MDA-MB-435 tumor cells. As shown in Figure 3, all the radiotracers exhibited an increased uptake with time on both tumor cell lines. Generally speaking, the cell uptake levels of the three tracers on the T47D cells were all higher than those on the MDA-MB-435 tumor cells, which may be due to the higher GRPR expression of the T47D cells, and the GRPR is more easily internalized into the cells than integrin. For both tumor cells, the uptake of ^{64}Cu-NOTA-RGD-BBN was significantly higher than that of ^{18}F-FB-PEG$_3$-RGD-BBN and ^{68}Ga-NOTA-RGD-BBN at late time points ($P < 0.05$). For example, the T47D cell uptake value at 120 min was 4.25 ± 0.13% AD for ^{18}F-FB-PEG$_3$-RGD-BBN, 5.30 ± 0.53% AD for ^{64}Cu-NOTA-RGD-BBN, and 2.42 ± 0.23% AD for ^{68}Ga-NOTA-RGD-BBN, respectively ($n = 3$).

MicroPET Imaging. Representative coronal microPET images of T47D and MDA-MB-435 tumor-bearing mice ($n = 4$/group) at different times after intravenous injection of 3.7−5.6 MBq (100−150 μCi) of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN are shown in Figure 4. The tumors after injection of the radiotracers were all clearly visible with high contrast to contralateral background at all time points measured beginning 30 min. The mice injected with ^{64}Cu-NOTA-RGD-BBN showed higher abdominal activity accumulation than those injected with ^{68}Ga-NOTA-RGD-BBN or ^{18}F-FB-PEG$_3$-RGD-BBN. Prominent uptake of ^{18}F-FB-PEG$_3$-RGD-BBN was observed in the kidneys and urinary bladder at early time points, suggesting that this radiotracer is mainly excreted through the renal route. Quantification of tumor and major organ activity accumulation in the microPET scans was realized by measuring the regions of interest (ROIs) that encompass the entire organ on the coronal images. The tumor and major organ uptake comparison of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN is depicted in Figure 5 and Table 2. The T47D and MDA-MB-435 tumor uptake was expressed as the average of each radiotracer in four mice, while the normal organ uptake was expressed as the average of each tracer in eight mice (four T47D tumor-bearing mice and four MDA-MB-435 tumor-bearing mice per tracer). As shown in Figure 5, for all three radiotracers, the uptake in T47D tumors was higher than that in MDA-MB-435 tumors at any time point examined, which is consistent with the in vitro cell uptake studies. For example, the tumor uptake comparison of ^{18}F-FB-PEG$_3$-RGD-BBN in T47D tumor and MDA-MB-435 was 2.96 ± 0.53 vs 2.72 ± 0.80, 1.81 ± 0.34 vs 1.59 ± 0.65, and 0.91 ± 0.12 vs 0.84 ± 0.22% ID/g at 30, 60, and 120 min pi, respectively (Figure 5A,B). The tumor uptake of ^{68}Ga-NOTA-RGD-BBN was higher than that of the ^{18}F- and ^{64}Cu-labeled RGD-BBN radiotracers from 30 to 120 min pi, and the differences were statistically significant compared with ^{18}F-FB-PEG$_3$-RGD-BBN at any time tested ($n = 4$, $P < 0.05$). ^{18}F-FB-PEG$_3$-RGD-BBN also showed rapid washout in the blood and normal organs. As can be seen from Figure 5, the uptake of the ^{18}F-labeled RGD-BBN decreased rapidly with time in the blood, kidneys, and liver. The uptake values of ^{18}F-FB-PEG$_3$-RGD-BBN in the blood and normal organs were all significantly lower than those of the ^{64}Cu and ^{68}Ga tracers at any time from 30 to

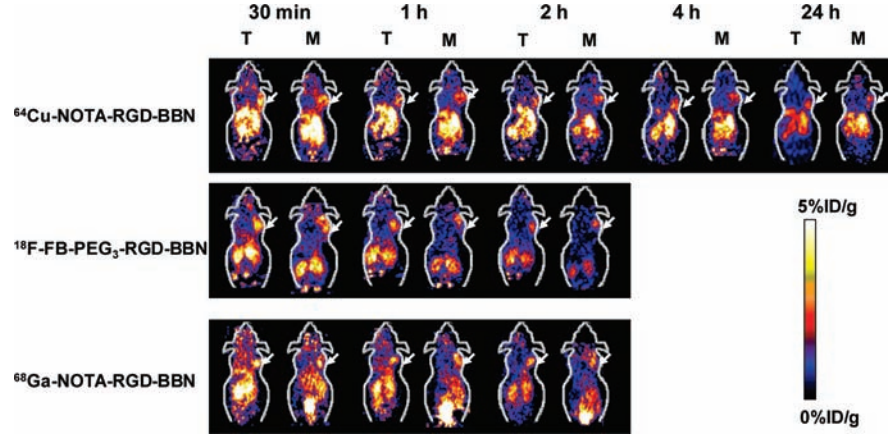

Figure 4. Decay-corrected whole-body coronal microPET images of T47D (T) and MDA-MB-435 (M) tumor-bearing mice at 30 min, 1 h, 2 h, 4 h, and 24 h after injecting 3.7−5.5 MBq (100−150 μCi) of ^{64}Cu-NOTA-RGD-BBN, ^{18}F-FB-PEG$_3$-RGD-BBN, or ^{68}Ga-NOTA-RGD-BBN. Images shown are static scans of a single mouse, which is representative of the four mice tested in each group. Arrows indicate the presence of T47D (T) or MDA-MB-435 (M) tumors.

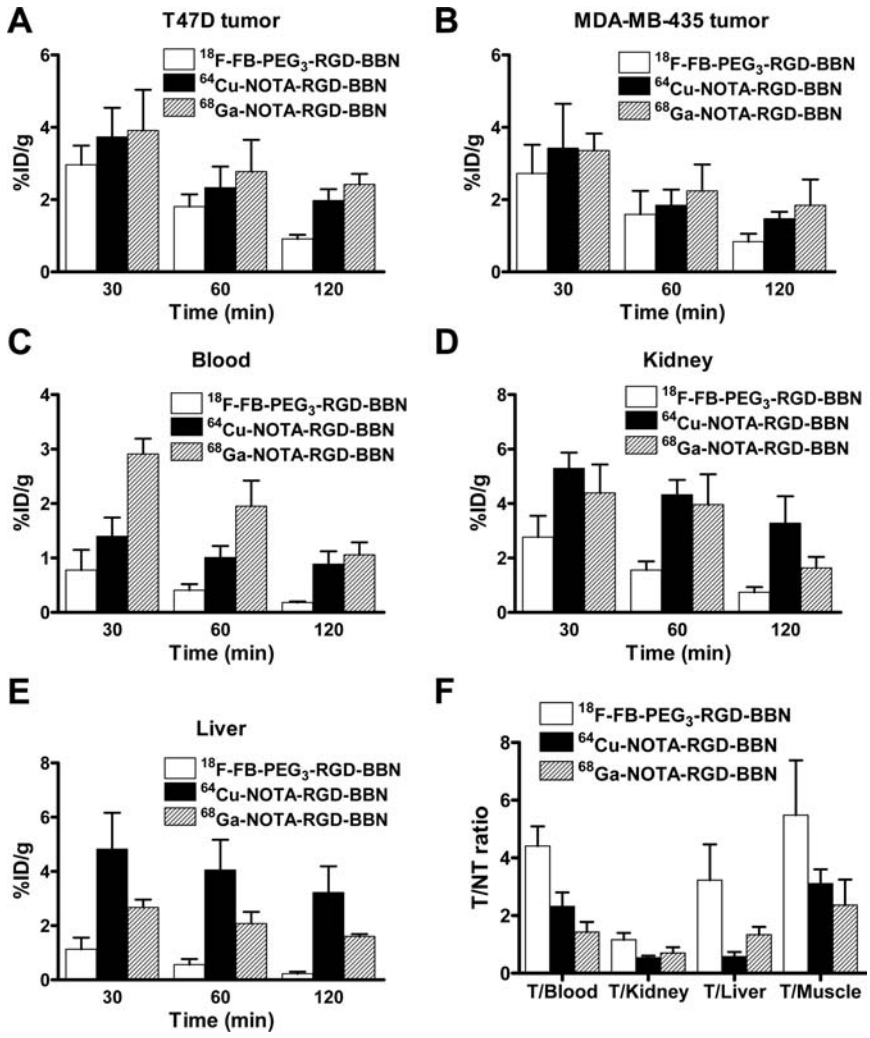

Figure 5. (A−E) Comparison between the uptake of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN in T47D tumor (A), MDA-MB-435 tumor (B), blood (C), kidneys (D), and liver (E) after injection of 3.7−5.5 MBq (100−150 μCi) tracer in T47D or MDA-MB-435 tumor-bearing mice (n = 4−8, mean ± SD). (F) Comparison of tumor (T) with blood, kidney, liver, and muscle ratio of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN at 60 min after injection of 3.7−5.5 MBq (100−150 μCi) tracer in T47D tumor-bearing mice (n = 4/group, mean ± SD).

120 min (n = 8, P < 0.05). ^{68}Ga-NOTA-RGD-BBN also showed higher blood retention compared to the ^{18}F and ^{64}Cu radiotracers (Figure 5C). The kidney uptake of ^{68}Ga-NOTA-RGD-BBN and ^{64}Cu-NOTA-RGD-BBN decreased with time, and ^{68}Ga-NOTA-RGD-BBN seemed to be cleared slightly more rapidly than ^{64}Cu-NOTA-RGD-BBN. At 120 min pi, the kidney uptake was 0.74 ± 0.19% ID/g for ^{18}F-FB-PEG$_3$-RGD-BBN, 1.64 ± 0.40% ID/g for ^{68}Ga-NOTA-RGD-BBN, and 3.28 ± 0.99% ID/g for ^{64}Cu-NOTA-RGD-BBN, respectively (n = 8, Figure 5D). The liver uptake of ^{64}Cu-NOTA-RGD-BBN was significantly higher than those of the ^{18}F- and ^{68}Ga-labeled RGD-BBN radiotracers at any time point examined (n = 8, P < 0.05). At 4 and 24 h pi, the liver uptake of ^{64}Cu-NOTA-RGD-BBN was still higher than that of the tumor uptake (Table 2). The liver uptake of ^{18}F-FB-PEG$_3$-RGD-BBN was very low with the highest uptake being 1.13 ± 0.43% ID/g at 30 min p.i., indicating that the ^{18}F labeled RGD-BBN was excreted predominantly through the renal route (Figure 5E). Although the absolute tumor uptake of ^{18}F-FB-PEG$_3$-RGD-BBN was lower than that of the other two radiotracers, the tumor-to-nontumor (T/NT) ratios of ^{18}F-FB-PEG$_3$-RGD-BBN were all significantly higher than those of ^{64}Cu-NOTA-RGD-BBN and ^{68}Ga-NOTA-RGD-BBN (P < 0.05), because of the rapid washout of the tracer in blood and normal organs (Figure 5F).

MDA-MB-435 tumor is integrin $\alpha_v\beta_3$-positive but GRPR-negative (Figure 2B). As shown in Figure 6A, the BBN radiotracers appeared to be more lipophilic than the corresponding RGD-BBN radiotracers, resulting in significant activity accumulation in the gallbladder and intestines. Because of the absence of GRPR, neither ^{18}F-FB-BBN, ^{64}Cu-NOTA-RGD-BBN, nor ^{68}Ga-NOTA-RGD-BBN was able to visualize the tumors. The MDA-MB-435 tumor uptake at 30 min pi was 0.45 ± 0.11% ID/g for ^{18}F-FB-BBN, 0.63 ± 0.17% ID/g for ^{64}Cu-NOTA-RGD-BBN, and 0.57 ± 0.13% ID/g for ^{68}Ga-NOTA-RGD-BBN, which was significantly lower than the corresponding RGD-BBN radiotracers (P < 0.01, Figure 6B).

Serum Stability and Metabolic Stability. The serum stability of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN was tested by incubating with FBS for 2 h at room temperature. As shown in Figure 7A, all three radiotracers showed good in vitro serum stability, with only minor peaks (t_R around 5 min) for ^{18}F-FB-PEG$_3$-RGD-BBN and ^{64}Cu-NOTA-RGD-BBN as detected by radio-HPLC. We also studied the metabolic stability of the three radiotracers in mice urine at 60 min after injection. As shown in Figure 7B, all three radiotracers showed detectable metabolites in the urine. Although we did not identify the composition of the metabolites, it was found that all metabolites eluted earlier from the HPLC

Table 2. Quantified MicroPET Imaging Data of ^{18}F-FB-PEG$_3$-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, and ^{68}Ga-NOTA-RGD-BBN in T47D and MDA-MB-435 Tumor-Bearing Nude Mice (Mean ± SD, n = 4−8)

Figure 6. (A) Decay-corrected whole-body coronal microPET images of MDA-MB-435 tumor-bearing mice at 30 min after injection of 3.7 MBq (100 μCi) ^{18}F-FB-BBN, ^{64}Cu-NOTA-BBN, or ^{68}Ga-NOTA-BBN. Images shown are static scans of a single mouse, which is representative of the three mice tested in each group. Arrows indicate the presence of MDA-MB-435 tumors. (B) Comparison between the quantified uptake of ^{18}F/^{64}Cu/^{68}Ga labeled RGD-BBN tracers with ^{18}F/^{64}Cu/^{68}Ga labeled BBN tracers in MDA-MB-435 tumors (n = 3−4/group, mean ± SD).

column than the parent compounds. The major metabolite peaks were found at about 17 min for ^{68}Ga-NOTA-RGD-BBN and ^{18}F-FB-PEG$_3$-RGD-BBN and about 20 min for ^{64}Cu-NOTA-RGD-BBN. Because the RGD peptides seemed to be more metabolically stable than BBN peptides in urine (*11, 40*), we speculate that the metabolites of the RGD-BBN radiotracers were more likely to be from the BBN counterparts of the radiolabeled heterodimers.

DISCUSSION

In this study, we investigated whether radiolabeled RGD-BBN heterodimers can be used as probes for breast cancer PET imaging. The RGD-BBN was labeled with the three most commonly used positron emitters (^{18}F, ^{64}Cu, and ^{68}Ga), and the tumor targeting and in vivo kinetics of the corresponding radiotracers were compared in two orthotopic breast cancer models.

Breast cancers can be sorted into two categories, estrogen dependent (ER$^+$) and estrogen-independent (ER$^-$), based on the presence or absence of estrogen receptors (*41*). We screened the GRPR and integrin $\alpha_v\beta_3$ expression in both the ER$^+$ (T47D, BT474, MCF-7) and ER$^-$ (MDA-MB-231, MDA-MB-435, MDA-MB468, BT20) breast cancer cells (*42*−*45*). T47D and BT474 cells had high GRPR but low to moderate integrin $\alpha_v\beta_3$ expression. On the other hand, the estrogen-independent tumor cells such as MDA-MB-435, MDA-MB-231, and MDA-MB-468 had high integrin $\alpha_v\beta_3$ but undetectable GRPR expression (Figure 2A,B). It is of note that MDA-MB-435 cells were reported to express GRPR at the mRNA level (*43*), but our receptor binding assay using ^{125}I-[Tyr^4]BBN indicated low level of GRPR at the protein level. We selected the T47D and MDA-MB-435 tumor cells for further investigation, which represent the two typical types of breast cancers. The tumor tissues were investigated by immunohistochemical staining to confirm the receptor expression. The expression of GRPR and human integrin $\alpha_v\beta_3$ was consistent with the cell binding assay data. Although the tumor cells are of human origin, the tumor endothelial cells are of murine origin. We thus also checked integrin expression on the tumor vasculature murine integrn

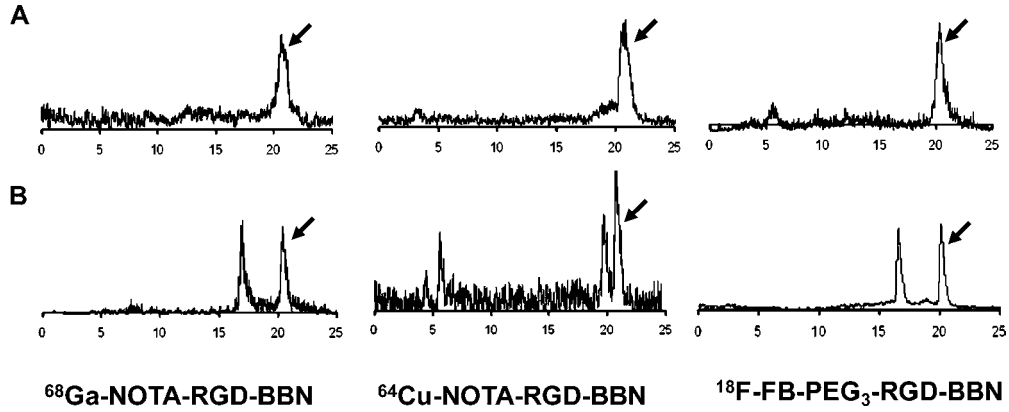

Figure 7. (A) In vitro serum stability of ^{68}Ga-NOTA-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{18}F-FB-PEG$_3$-RGD-BBN after incubating in fetal bovine serum (FBS) for 2 h at room temperature. (B) Metabolic stability of ^{68}Ga-NOTA-RGD-BBN, ^{64}Cu-NOTA-RGD-BBN, or ^{18}F-FB-PEG$_3$-RGD-BBN in mice urine at 1 h after injection ($n = 2$).

β_3 staining and found that both T47D and MDA-MB-435 tumor vasculatures were integrin positive (Figure 2C).

The RGD-BBN peptides were labeled with ^{18}F, ^{64}Cu, and ^{68}Ga, respectively. ^{18}F labeling of peptides typically require lengthy procedures because $^{18}F-F^-$ is cyclotron-dependent and a prosthetic group such as ^{18}F-SFB needs to be synthesized before peptide labeling. In contrast, the metal isotopes such as ^{64}Cu and ^{68}Ga can be easily labeled with the chelated RGD-BBN peptides. In particular, ^{68}Ga can be easily acquired from an in-house ^{68}Ge/^{68}Ga generator (^{68}Ge, $t_{1/2} = 270.8$ days) instead of from a medical cyclotron. All three radiotracers showed similar dual receptor binding affinity as determined by receptor binding assay, indicating that the radiotracers maintained comparable in vitro dual receptor-binding properties. Each radiotracer can be acquired in high radiochemical purity after being purified by HPLC, which is sufficient for both in vitro and in vivo experiments. The in vitro cell uptake studies demonstrated that the cell uptake values of the radiotracers on T47D tumor cells were higher than those on MDA-MB-435 tumor cells, which may be caused by the much higher GRPR expression on the T47D cells, leading to efficient internalization of the radiotracers.

The in vivo behaviors of the three radiotracers were tested by microPET in orthotopic T47D and MDA-MB-435 breast cancer models. The radiolabeled BBN was also tested in the non-GRPR expressing MDA-MB-435 tumor model as a control. The much higher tumor uptake of the ^{18}F, ^{64}Cu, and ^{68}Ga labeled RGD-BBN radiotracers than those of the corresponding BBN radiotracers indicates that the RGD-BBN tracers are more useful for imaging than BBN tracers in GRPR negative tumors. We did not compare the tumor imaging characteristics of RGD-BBN and RGD radiotracers in vivo, as we were unable to identify a breast cancer model that is completely integrin negative because all the integrin negative tumor cell lines when inoculated into mice develop integrin positive tumor vasculature. The metal isotopes labeled radiotracers showed higher background than ^{18}F tracers, and ^{18}F labeled RGD-BBN showed a more rapid washout than the ^{64}Cu- and ^{68}Ga-labeled peptides. The tumor uptake of ^{18}F-FB-PEG$_3$-RGD-BBN was also found to be lower than that of the ^{64}Cu and ^{68}Ga labeled RGD-BBN radiotracers. A similar trend has been previously found in both BBN and RGD peptide cases (*29*).

The selection of chelators for radiometal labeling is important. For ^{68}Ga labeling, NOTA is commonly used because the rapid reaction kinetics of NOTA can meet the short half-life of ^{68}Ga ($t_{1/2} = 68$ min). The NOTA conjugates can reach a higher yield when incubated with ^{68}Ga for 10 min at room temperature (*37*). For ^{64}Cu labeling, DOTA was previously reported as a widely used "universal" chelator, and we have reported a series of ^{64}Cu-DOTA peptide tracers for tumor imaging (*10, 26, 38, 46, 47*). The high and prolonged liver uptake is problematic for ^{64}Cu-DOTA radiotracers, which was suggested to be the slow dissociation of ^{64}Cu from the DOTA chelator (*48*−*51*). The instability of the ^{64}Cu-DOTA conjugates would result in demetalation and subsequent accumulation in nontarget tissues such as the liver (*49*). Recently, Prasanphanich et al. (*49*) reported ^{64}Cu-labeled bombesin analogues using NOTA as a chelator. Their results suggested high in vivo kinetic stability of ^{64}Cu-NOTA-BBN vectors with little or no dissociation of ^{64}Cu from NOTA. From the microPET data, the liver uptake of ^{64}Cu-NOTA-RGD-BBN was relatively lower than other ^{64}Cu-DOTA radiotracers (*18, 26*) but still higher than ^{68}Ga-NOTA-RGD-BBN, which may be caused by the ^{68}Ga chelating ability of NOTA being higher than ^{64}Cu (*52*).

ACKNOWLEDGMENT

This work was supported in part by the National Cancer Institute (NCI Grants R01 120188, R01 CA119053, R21 CA121842, R21 CA102123, P50 CA114747, U54 CA119367, and R24 CA93862). We thank the cyclotron team at Stanford University for $^{18}F-F^-$ production and thank the cyclotron team of University of Wisconsin-Madison for ^{64}Cu production. Z.L. acknowledges the China Scholarship Council (CSC) for partial financial support during his study at Stanford University.

Oligonucleotide-templated reactions are attracting attention as a method for RNA detection in living cells. Previously, a reduction-triggered fluorescence probe has been reported that is based on azide reduction to switch fluorescence on. In this article, we report a more advanced probe, a reduction-triggered fluorescent amplification probe that is capable of amplifying a target signal. Azidomethyl fluorescein was newly synthesized and introduced into a probe. Azido-masked fluorescein on the probe showed a strong turn-on fluorescence signal upon oligonucleotide-templated Staudinger reduction. The catalytic reaction of the probe offered a turnover number of 50 as fluorescence readout within 4 h. Finally, probes were introduced into human leukemia HL-60 cells by use of streptolysin O pore-forming peptide. We successfully detected and quantitated the 28S rRNA and β-Actin mRNA signal above the background by flow cytometry. In addition, the same RNA targets were imaged by fluorescence microscopy. The data suggest that a reduction-triggered amplification probe may be a powerful tool in analyzing the localization, transcription, or processing of RNA species in living eukaryotic cells.

INTRODUCTION

The detection and imaging of RNA species in native human cells have been gaining importance in the biological and biomedical research fields (*1*−*7*). Several approaches for imaging mRNAs in genetically engineered cells have been reported recently (*8*−*10*). Although such a strategy can be a useful tool for biological studies, it is not applicable for imaging native RNAs in unmodified cellular specimens. Our specific goal is the detection of RNA sequences in intact cells at single nucleotide resolution using a fluorescence signal as readout. This requires no extraction of RNA species from the cell; therefore, it should be a very rapid and simple method for disease-related RNAs as a biomedical application. Messenger RNAs are expected to be more difficult to detect than rRNAs because they exist in smaller quantities in living cells (*11*). Moreover, their sequences vary widely, and their structures are generally unknown; it is therefore very difficult to find an optimal target site (*12*−*14*). In addition, there is the issue of breaching the barrier of the cell membrane in live human cells. Finally, live cells also show numerous enzymatic activities that degrade oligonucleotide probes.

No method has yet been successful enough to gain wide application for the imaging and detection of mRNA in living cells. However, a small number of molecular approaches have been reported as potentially practical methods (*15*−*37*). Prominent among these approaches are quenched-probe strategies, including molecular beacon (MB) probes (*16*−*20, 28*) and quenched autoligation (QUAL) probes (*21*−*27*). The most important issue for detection in living cells is to keep a low background signal in the absence of the RNA target. These probes allow target-dependent fluorescence enhancement based on the resonance energy transfer (RET) mechanism, for which a pair of quencher and fluorescence dyes is normally used. Recent reports have shown evidence for detection by fluorescence microscopy of mRNAs by MB probes and QUAL probes in intact human cells (*19, 21*−*23, 35*−*40*). Moreover, QUAL probes have been used for flow cytometric detection of RNA species in native human cells (*23*). However, these approaches still need improvement in signal/background (S/B) ratio to become established methods.

Oligonucleotide-templated reactions (OTRs) have received attention as a potential approach for RNA detection in living cells (*21, 23*). This strategy exploits the target strand as a template between two functionalized DNAs or PNAs. For example, native chemical ligation (*41*−*43*), catalytic hydrolysis (*44*−*46*), the Staudinger reaction (*47*−*50*), transfer of a reporter group (*51*), DNAzyme (*52*), an S_N2 quencher displacement ligation reaction (QUAL probe) (*25*), and organomercury-activated reactions (*53*) have been applied to fluorescence nucleic acid reactions. However, few methods have been applied to RNA detection in living human cells (*23*). We considered two important issues to develop a highly sensitive RNA detection probe based on OTR. These are a new fluorogenic system to offer a higher S/B ratio and turnover of OTR to offer amplification of RNA signal.

The catalytic turnover reaction can provide signal amplification and enable sensitive oligonucleotide detection in living cells. Various chemistries for the catalytic turnover have been reported (*26, 41, 46, 47, 49*−*51, 54*). A few laboratories have reported that self-ligation reactions provide amplified products. However, theoretically, ligation reactions suffer from an increased affinity of the product for the oligonucleotide template (*41,54*). This causes product inhibition and prevents higher catalytic activity of the template. Therefore, to reduce product inhibition, a few other laboratories have recently investigated unligated

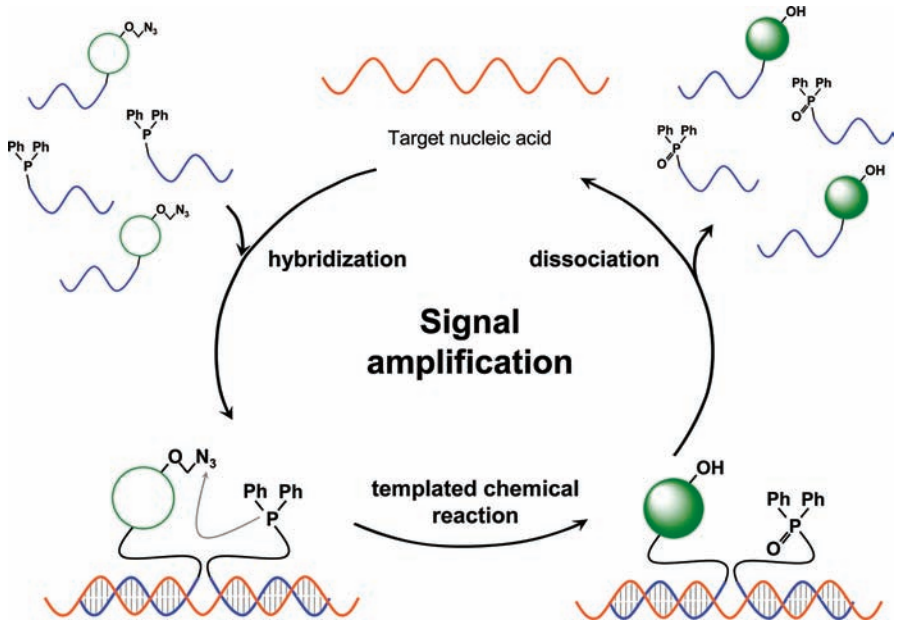

Figure 1. Illustration of the turnover of the azide reduction, which can generate multiple signals per target.

systems by using pairs of modified probes to generate an amplified signal. These approaches are catalytic ester hydrolysis (*46*), the Staudinger reaction (*47*, *49*, *50*), DNAzyme (*52*), and transfer of a reporter group (*51*). Even though they showed significant a turnover number up to 400 times in a test tube, application to living human cells has not been demonstrated. This implies that these methods still need to be improved in background fluorescence or sensitivity.

Recently, various fluorogenic compounds have been developed for the detection of small biological substances (*55*−*59*). Fluorescence modulation of these compounds is caused by photoinduced electron transfer or absorption change triggered by a chemical reaction accompanied with transformation of chemical structure. The S/B ratio for these types of molecules could exceed that of the RET mechanism (*60*). Combined with the catalytic turnover mechanism, this type of fluorogenic system could become a very powerful method for RNA detection in living cells. However, there are only a few reports that describe chemical reaction-triggered fluorogenic molecules for oligonucleotide sensing with amplification of signal in test tubes (*47*,*49*,*50*).

Recently, we reported a reduction-triggered fluorescence (RETF) probe having a rhodamine azide as the fluorogenic molecule that showed a response with a high S/B ratio (*48*). However, this probe did not offer a catalytic turnover because of an unexpected ligated intermediate on OTR. Here, we report another fluorogenic molecule using the azidomethyl protecting group (*61*, *62*) for the fluorescein compound, although Kool and co-workers very recently reported an azidomethyl-protected coumarin dye for OTR that has not been applied to RNA detection in living cells (*50*). The new reduction-triggered fluorescent amplification (RETFA) probe enables catalytic turnover under isothermal conditions without significant product inhibition (Figure 1). The turnover mechanism in the steady state was analyzed by fluorescence spectroscopy, and association and dissociation rate constants for the probe on a template were calculated by BIAcore technology. Finally, by using this RETFA probe design, we show that endogenous mRNA, as well as 28S rRNA in living human HL60 cells, could be imaged by fluorescence microcopy and detected by flow cytometry.

EXPERIMENTAL PROCEDURES

Monoalkyl Fluorescein (1). To a solution of fluorescein (3.00 g, 9.03 mmol) and sodium iodide (271 mg, 1.81 mmol) in DMF (50 mL) chilled via an external ice bath was added a THF (30 mL) solution of potassium *t*-butoxide (3.04 g, 27.1 mmol). After the solution was clear, methyl bromoacetate (944 μL, 9.94 mmol) was slowly added. The reaction was allowed to warm gradually to room temperature. After 2.5 h, the reaction mixture was diluted with AcOEt and washed with H_2O and brine. The combined organic extracts were pooled and dried over Na_2SO_4. Na_2SO_4 was removed by filtration and volatiles removed *in vacuo*. The residue was purified by flash column chromatography (silica, gradient elution 30:1 $CHCl_3$/MeOH to 20:1 $CHCl_3$/MeOH with 0.5% triethylamine) to afford a clear syrup on concentration (820 mg, 23%) (**1**). ^{1}H NMR (400 MHz, CD_3OD) δ7.91 (1H, d, J = 7.32 Hz), 7.62 (2H, dt, J = 16.40, 15.10 Hz), 7.10 (1H, d, J = 7.56 Hz), 6.79 (1H, d, J = 2.20 Hz), 6.67−6.55 (4H, m), 6.44 (1H, dd, J = 2.20, 2.44 Hz), 4.70 (2H, s), 3.69 (3H, s). ^{13}C NMR (100 MHz, CD_3OD) δ 180.6, 172.5, 169.9, 163.5, 159.4, 155.1, 138.8, 137.6, 129.6, 129.1, 124.9, 116.3, 116.0, 114.5, 104.7, 102.3, 66.1, 52.7. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m*/*z* 404.0896 [MH+] $C_{23}H_{16}O_7$: 405.0974; found, 405.0987.

Monoalkyl Thiomethyl Fluorescein (2). Monoalkyl fluorescein (**1**) (720 mg, 1.78 mmol) was dissolved in dry CH_3CN (36 mL) under Ar (g). Silver oxide (620 mg, 2.67 mmol) and chloromethylmethylsulfide (223 μL, 2.67 mmol) were added followed by the addition of one drop of pyridine. After stirring for 15 h at room temperature, the remaining solid residue was removed by filtration. The filtrate was concentrated and subjected to flash column chromatography. Elution with a slow gradient of hexane/AcOEt from 6:1 to 2:1 (v/v) with 0.5% triethylamine gave monoalkyl thiomethyl fluorescein (**2**) as a pale yellow crystalline solid (206 mg, 25%). ^{1}H NMR (400 MHz, $CHCl_3$) δ8.01 (1H, d, J = 7.08 Hz), 7.64 (2H, dt, J = 16.10, 15.10 Hz), 7.15 (1H, d, J = 7.56 Hz), 6.83 (1H, d, J = 2.44 Hz), 6.83−6.62 (5H, m), 5.15 (2H, s), 4.66 (2H, s), 3.80 (3H, s), 2.24 (3H, s). ^{13}C NMR (100 MHz, CDCl3) δ 168.94, 168.43, 159.04, 152.64, 151.86, 134.80, 129.08, 128.87, 126.41, 124.75, 123.78, 112.66, 102.82, 101.65, 82.57, 72.34, 65.12, 52.27, 14.59. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m*/*z* 464.0930 [MH+] $C_{25}H_{20}O_7S$: 465.1008; found, 465.1004.

Monoalkyl Azidomethyl Fluorescein (3). Monoalkyl thiomethyl fluorescein (**2**) (164 mg, 350 μmol) was dissolved in dichloromethane (7 mL). A dichloromethane (1 mL) solution of *N*-chlorosuccinimide (51.8 mg, 390 μmol) and trimethylsilyl

chloride (42.0 mg, 390 μmol) was added. The resulting solution was stirred at ambient for 1 h, and the reaction was quenched with saturated Na_2CO_3 aqueous. The aqueous layer was extracted with $CHCl_3$ ($\times$ 2), and the combined organic layers were concentrated in vacuum to give the crude, which was subjected to the next reaction. Sodium azide (34.4 mg, 530 mmol) was dissolved in H_2O (3.5 mL) and added to a solution of the crude in DMF (7 mL) in room temperature. After stirring for 1 h, the reaction was quenched with saturated aqueous Na_2CO_3. The aqueous layer was extracted with AcOEt ($\times$2), and the combined organic layers was concentrated in vacuum and subjected to flash column chromatography. Elution with a slow gradient of hexane/AcOEt from 5:1 to 3:2 (v/v) with 0.5% triethylamine gave monoalkyl azidomethyl fluorescein (**3**) as a pale yellow crystalline solid (71.3 mg, 44%). ^{1}H NMR (400 MHz, $CHCl_3$) δ8.02 (1H, d, J = 7.80 Hz), 7.65 (2H, dt, J = 15.2, 14.9 Hz), 7.16 (1H, d, J = 7.32 Hz), 6.90 (1H, d, J = 2.20 Hz), 6.76−6.63 (5H, m), 5.18 (2H, s), 4.66 (2H, s), 3.82 (3H, s). ^{13}C NMR (100 MHz, CDCl3) δ 169.02, 168.54, 157.87, 152.64, 152.76, 152.08, 134.95, 129.70, 129.27, 126.46, 124.95, 123.80, 111.79, 103.26, 101.80, 82.46, 79.43, 65.27, 52.42. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): [MH^+] $C_{24}H_{17}N_3O_7$: 460.1145; found, 460.1134.

Azidomethyl Carboxyfluorescein (4). Monoalkyl azidomethyl fluorescein (**3**) (27.8 mg, 60 μmol) was dissolved in methanol (605 μL). An aqueous solution of 1 M NaOH (66.6 μL, 66.6 μmol) was added. The resulting solution was stirred at ambient for 1 h, and the reaction was quenched with 0.1 M HCl. The aqueous layer was extracted with AcOEt ($\times$2), and the combined organic layers were concentrated in vacuum and subjected to flash column chromatography. Elution with a slow gradient of $CHCl_3$/MeOH from 30:1 to 20:1 (v/v) with 0.5% triethylamine gave azidomethyl carboxyfluorescein (**4**) as a pale yellow crystalline solid (28.2 mg, 100%). ^{1}H NMR (400 MHz, $CHCl_3$) δ 8.01 (1H, d, J = 7.32 Hz), 7.64 (2H, dt, J = 14.9, 15.2 Hz), 7.16 (1H, d, J = 7.56 Hz), 6.88 (1H, d, J = 2.20 Hz), 6.82 (1H, d, J = 2.20 Hz), 6.73−6.63 (4H, m), 5.18 (2H, s), 4.51 (2H, s). ^{13}C NMR (100 MHz, CDCl3) δ 173.69, 169.17, 157.76, 152.79, 152.30, 134.83, 129.23, 128.61, 126.62, 124.82, 123.91, 112.30, 103.22, 101.74, 82.50, 79.41, 67.57. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m*/*z* 445.0910 [MH+] $C_{23}H_{15}O_7N_3$: 446.0988; found, 468.0808.

Azidomethyl Fluorescein NHS Ester. Azidomethyl carboxyfluorescein (**4**) (4.60 mg, 10.3 μmol) and *N*-hydroxysuccinimide (1.30 mg, 11.4 μmol) were dissolved in DMF (205 μL). DCC (2.35 mg, 11.4 μmol) was added. After stirring for 2 days at room temperature, the remaining solid residue was removed by filtration. The filtrate was subjected to coupling with 3′-amino DNA without purification.

Synthesis of Unmodified Oligonucleotides. All oligonucleotides were synthesized on a 0.2 μmol scale on a DNA synthesizer (H-8-SE; Gene World) using standard phosphoroamidite coupling chemistry. Deprotection and cleavage from the CPG support was carried out by incubation in concentrated ammonia for 4 h at 55 °C. Following deprotection, the oligonucleotides were purified by reverse-phase column chromatography (MicroPure II column; Biosearch Technologies) and quantitated by UV absorbance using the nearest neighbor approximation to calculate molar absorptivities.

3′-Monoazidomethyl Fluorescein-Conjugated Oligonucleotide. The crude product of azidomethyl fluorescein NHS ester was reacted with 3′-amino-modified oligonucleotide. 3′-PT-amino-modifier C3 CPG (Glen Research) was used to prepare the 3′-amino-modified oligonucleotide. Fifty nanomoles of the 3′-amino-modified oligonucleotide in 50 μL of 80 mM sodium tetraborate (pH 8.5) was shaken for 5 h at room temperature with 0.75 μmol of the compound in 200 μL of dimethylformamide. The reacted products were collected by ethanol precipitation. Next, the collected products were purified by reverse-phase HPLC (0−80% acetonitrile/50 mM triethylammonium acetate gradient). The probe structure was confirmed by ESI-TOF mass spectrometry (Table S1, Supporting Information).

5′-Triphenylphosphine (TPP)-Linked Oligonucleotide. A carboxy-triphenylphosphine (TPP) NHS ester was reacted with a 5′-amino-modified oligonucleotide. 5′-Amino-modifier C6 (Glen Research) was used to prepare the 5′-amino-modified oligonucleotide. Fifty nanomoles of the 5′-amino-modified oligonucleotide in 135 μL of 93 mM sodium tetraborate (pH 8.5) was shaken for 5 h at room temperature with 2 μmol of TPP NHS ester in 115 μL of dimethylformamide. The reacted products were collected by ethanol precipitation. Next, the collected products were purified by reverse-phase HPLC (0−50% acetonitrile/50 mM triethylammonium acetate gradient). The probe structure was confirmed by ESI-TOF mass spectrometry (Table S1, Supporting Information).

3′-Bisazidomethyl Fluorescein-Conjugated Oligonucleotide. The bromoacetyl group of the bisazidomethyl fluorescein was reacted with the phosphorothioate group on the oligonucleotides. For 3′-phosphorothioate sequences, the 3′-phosphate CPG was sulfurized by the sulfrizing reagent (Glen Research) after the first nucleotide was added. Seventy-five nanomoles of the 3′-phosphorothioate oligonucleotide in 50 μL of 400 mM triethylammonium bicarbonate buffer was shaken for 5 h at room temperature with 750 nmol of compound **9** in 200 μL of dimethylformamide. The reacted products were collected by ethanol precipitation. Next, the products were purified by reverse-phase HPLC (0−80% acetonitrile/50 mM triethylammonium acetate gradient). The probe structure was confirmed by ESI-TOF mass spectrometry (Table S1, Supporting Information).

Measurement of Quantum Yield. A 1 mM DMF stock solution of each compound was prepared. Absorption spectra were obtained with a 20 mM tris-HCl buffer (pH 7.2) solution of each compound at the desired concentration, adjusted by appropriate dilution of the 1 mM DMF stock solution. For determination of the quantum efficiency of fluorescence (Φ_{fl}), fluorescein in 0.1 M NaOH was used as a fluorescence standard (Φ = 0.85). The quantum efficiency of fluorescence was obtained with the following equation (F denotes fluorescence intensity at each wavelength, and Σ [F] was calculated by summation of fluorescence intensity).

$$\Phi_{fl}^{sample} = \Phi_{fl}^{standard} Abs^{standard} \Sigma[F^{sample}]/Abs^{sample} \Sigma[F^{standard}]$$

DNA-Templated Reaction. Reactions on the DNA template were performed in 1.2 mL of tris-HCl buffer (20 mM, pH 7.2) containing 100 mM $MgCl_2$ and 0.01 mg/mL BSA with *bcr/abl*-1 or -2, probe 1 (50 nM), and probe 2 (50 nM) at 37 °C. The increase of fluorescence intensity produced by the reduction of probe 1 was continuously monitored at time intervals. Reactions were observed by fluorescence spectrometry (FP-6500; JASCO). For the time course of the azide reduction, the fluorescence intensity was measured for 0.5 s at 1 min intervals: excitation, 490 nm; emission, 520 nm.

Cell Culture and Streptolysin O (SLO) Permeabilization. HL60 cells (RIKEN BRC cell bank) were grown in DMEM without phenol red and containing 10% FCS, 50 units/mL penicillin, and 50 mg/mL streptomycin. They were passaged in 75-cm^2 culture flasks (Falcon). Cells were maintained at 37 °C in an atmosphere of 5% CO_2 at 1 $\times$ 10^5 cells/mL and within 0−20 passages after purchasing from the supplier.

SLO was purchased from BioAcademia (Japan). SLO was activated according to the procedure reported by Abe et al. (*23*). Briefly, SLO (10,000 units/mL) was incubated in Mg^{2+}/Ca^{2+}-

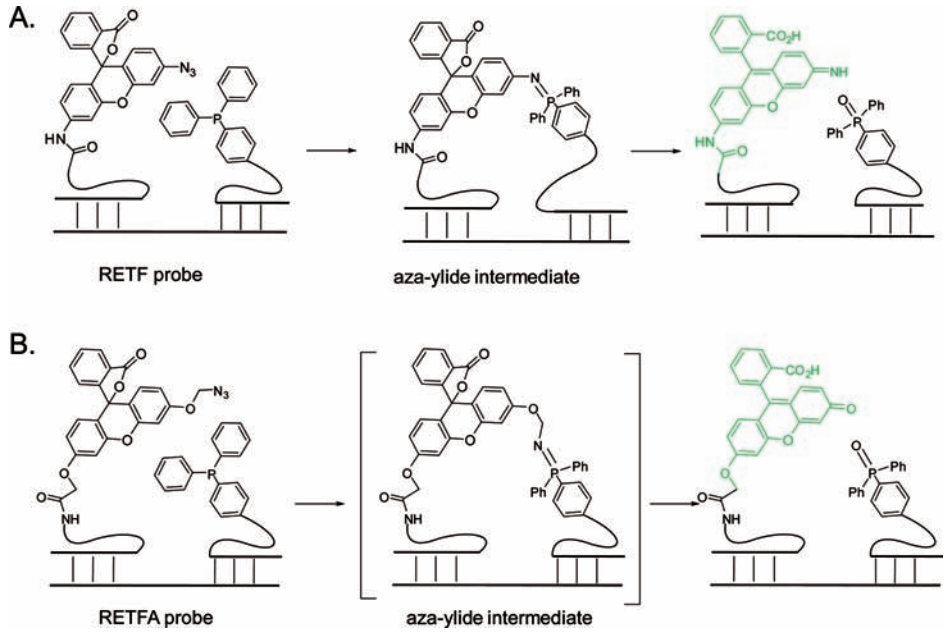

Figure 2. Fluorescence emission of an RETF probe (A) and RETFA probe (B) by triphenylphosphine as reducing reagents.

free PBS buffer solution containing 10 mM DTT and 0.05% BSA at 37 °C for 2 h. Small aliquots of activated SLO were stored at −20 °C. To introduce probes into cells, HL60 cells were washed with Mg^{2+}/Ca^{2+}-free PBS twice and then incubated with 300 mL of Mg^{2+}/Ca^{2+}-free PBS buffer solution containing SLO (50 units/mL), BSA (0.01 mg/mL), and calf thymus DNA (1 mg/mL). After 15 min, the 3′-bisazidomethyl fluorescein-conjugated probe (200 nM) and TPP-conjugated probe (200 nM) were added. After 30 min, cells were resealed by the addition of 1 mL of DMEM containing $CaCl_2$ (0.2 g/L) and incubated for 1 h at 4 °C.

Flow Cytometry. The live cell suspension was directly analyzed without any washing step with a Cytomics FC500 instrument (Beckman Coulter). Fluorescent signals were observed under the following conditions: excitation by argon laser, 488 nm; emission, 515−535 nm. Forward angle light scatter (FSC), side angle light scatter (SSC), and fluorescence data were recorded, and for each measurement, above 1,000 events were stored. Data were analyzed with the CXP analysis software (Beckman Coulter). Fluorescent intensity was determined as the mean of fluorescent value of single cells lying in a gate that were defined in a FSC versus SSC dot plot.

Microscopy and Data Processing. Intracellular distributions of 28S rRNA and β-Actin mRNA were observed using an inverted microscope (IX-81, Olympus). Specimens were illuminated with the 488-nm line of an Ar^+ laser (543-A-A03, Omnichrome) through a 60× oil-immersion objective (PlanApo, Olympus). Fluorescence images were acquired at 500−550 nm through the same objective using an image intensifier (C8600-05; Hamamatsu) and an EB-CCD camera (C7190-20; Hamamatsu) and recorded on a digital videotape. Bright field images of cells in the same field of view were recorded successively to the fluorescence images. Image processing was carried out using MetaMorph software (Molecular Devices). Experiments were performed at 27 °C.

Surface Plasmon Resonance Analysis. Kinetic parameters were assessed using BIAcore equipment with a Series S SensorChip SA (GE Healthcare bioscience). The central part of this equipment is the sensor chip consisting of a gold surface covered with a layer of dextran, which in our case contained streptavidin chemically coupled to dextran. The biotinylated DNA strands (target DNA: *bcr/abl-1*) were immobilized to the streptavidin chip. The association as well as dissociation kinetics of two probes, probe 1 and probe 2, were studied. All kinetics experiments were performed in 20 mM Tris-HCl buffer (pH 7.2) containing 100 mM $MgCl_2$ at 37 °C. To immobilize the biotinylated DNA strand to the streptavidin on the chip surface, 5′-biotin-labeled DNA was dissolved in Tris-HCl buffer at a concentration of 600 nM. The solution (15 μL) was injected with a flow rate of 5 μL/min, and the immobilization was followed in the corresponding sensorgram as a function of time. Probes were dissolved in running buffer at appropriate concentrations (15.6−150 nM). A volume of 75 μL (30 μL/min) was injected to measure the association kinetics, and immediately thereafter, the dissociation was followed by purging running buffer through the system. After an approximately 150 s buffer wash, the immobilized DNA surface was regenerated with 30 μL of 10 mM HCl (30 μL/min). The association and dissociation rate constants for each probe were calculated with BIAcore T100 evaluation software (GE Healthcare bioscience).

RESULTS

Design and Molecular Mechanism of the RETFA Probe. Our chief goal was to develop a new RNA detection probe having a chemical reaction-based fluorogenic compound that was capable of signal amplification under isothermal conditions. As one achievement, we recently reported a RETF system that uses a fluorogenic compound, rhodamine azide derivative, that is activated only by reducing reagents and enhanced 2100 times in fluorescence intensity (Figure 2A) (*48*). Reaction of the RETF probe on an oligonucleotide target proceeded without any enzymes or reagents, and offered high signal and very low background fluorescence under biological conditions. We successfully applied the probe to the detection of oligonucleotides in solution and endogenous RNA in bacterial cells. However, the reaction between the rhodamine azide probe and the TPP probe in the RETF system initially produces a ligated intermediate between the two halves of the probe connected with a stable aza-ylide bond, and then gradually gives half of the fluorescent rhodamine product through hydrolysis of the aza-ylide bond over 24 h (Figure 2A). Formation of a ligated product with an aza-ylide bond between the two probes prevents catalytic turnover because the long product binds the template with higher affinity than the reactant probe did before

reaction. To achieve higher sensitivity for detecting less abundant RNA species such as intracellular mRNA, the RETF system still shows room for improvement to achieve efficient turnover.

To obtain a high turnover in the reaction mechanism of the RETF probe, the aza-ylide bond of the ligated intermediate must be quickly hydrolyzed to reduce product inhibition. We assumed that the aza-ylide bond in the RETF system is stabilized by long π-conjugation between rhodamine and triphenylphosphine (*63*). Therefore, it was suggested that to destabilize the aza-ylide bond, π-conjugation of the intermediate should be minimized. Here, we designed a fluorogenic molecule based on azidomethyl-protected fluorescein that was switched on by reduction (Figure 2B). In the first step of the reaction, the unstable aza-ylide bond is formed and quickly hydrolyzed. Consequently, the azide group is transformed to an amino group, and TPP is transformed to the corresponding phosphorus compound. The resulting amino-hemiacetal group is quickly hydrolyzed to give an unmasked phenol group, and the probe emits a fluorescence signal. A reduction-triggered fluorescence amplification (RETFA) system with azidomethyl-protected fluorescein is expected to offer efficient turnover because of the short life of the ligated intermediate (Figure 2B).

Synthesis of Azidomethyl Fluorescein. We designed two fluorogenic compounds, monoazidomethyl fluorescein (MAF) and bisazidomethyl fluorescein (BAF). MAF offers a quantitative fluorescence signal to give a single product after deprotection of the azidomethyl group. However, BAF offers a more potent fluorescent signal after deprotection of the two azidomethyl groups. The synthesis of MAF (**4**) is shown in Scheme 1. Mono-*O*-carboxymethyl fluorescein **1** was synthesized by treatment with one equivalent of methyl bromoacetate in the presence of potassium *tert*-butoxide and sodium iodide from commercially available fluorescein in 23% yield (*64*). The treatment of compound **1** with chloromethyl methyl sulfide and Ag_2O in pyridine gave methyl thioacetal **2** in 25% yield (*62*). Activation of *O,S*-acetal with *N*-chlorosuccinimide (NCS) in the presence of *tert*-butyldimethylsilyl chloride (TMS-Cl) provides the chloromethyl intermediate. The intermediate was unstable during purification by flash chromatography and was used for the next reaction without further purification. The transformation of the intermediate to azide **3** was carried out by treatment with sodium azide in 44% yield in two steps. Hydrolysis of methyl ester **3** with NaOH provided the desired azidomethyl carboxyfluorescein (**4**). The NHS ester was prepared by dicyclohexylcarbodiimide-mediated coupling of *N*-hydroxysuccinimide with compound **4**. This activated ester cannot be purified by flash chromatography because of hydrolysis; therefore, the crude product of the NHS ester was directly used for coupling with the DNA probe. Synthesis of BAF is shown in Scheme 2. 5-Iodofluorescein was protected with chloromethyl methyl sulfide to give bismethyl thioacetal **6** in 25% yield. Compound **6** was transformed to bisazidomethyl fluorescein **7** by treatment with NCS and NaN_3. Finally, the desired BAF **9** was obtained by Sonogashira coupling between **7** and 2-bromoacetyl propargylamide.

Spectrum Analysis of Azidomethyl Fluorescein. We tested the photochemical properties of azidomethyl fluorescein (Figure 3). MAF **3** showed no absorbance at wavelengths longer than 350 nm in 20 mM Tris-HCl (pH 7.2), whereas the corresponding monoalkyl fluorescein **1** showed absorption bands at 455 and 490 nm. When a high concentration of dithiothreitol (DTT) was added to a solution of MAF **3**, a

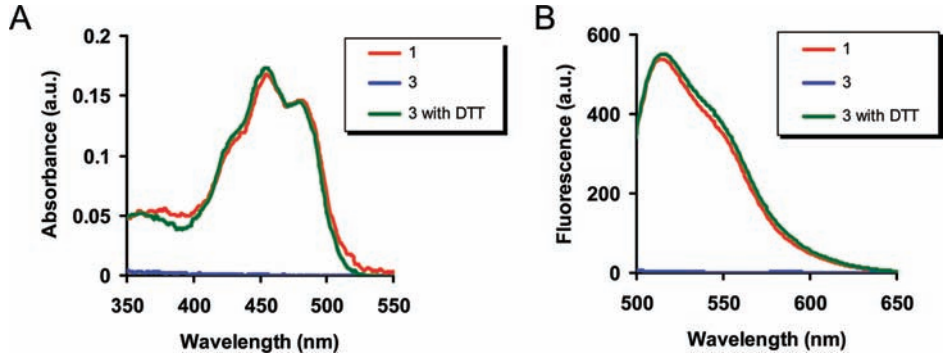

Figure 3. Spectrum analysis. (A) Absorption spectra of 100 μM **1** (red), **3** (blue), or **3** treatment with 100 mM DTT (green) in 20 mM Tris-HCl (pH 7.2) in 50% DMF/H_2O at 25 °C. (B) Fluorescent emission spectra with excitation at 490 nm of 500 nM **1** (red), **3** (blue), or **3** treatment with 100 mM DTT (green) in 20 mM Tris-HCl (pH 7.2) in 5% DMF/ H_2O at 25 °C.

peak having a maximum at 455 nm appeared, resulting from reduction followed by hydrolysis of the azidomethyl group (Figure 3A). The fluorescence properties of azidomethyl fluorescein (MAF) were also examined. No significant fluorescence with excitation at 490 nm was observed for MAF **3**. However, monoalkyl fluorescein **1** showed strong fluorescence emission at around 520 nm. After the addition of DTT to the solution of MAF **3**, a strong emission appeared around 515 nm; the emission was enhanced almost 300-fold (Figure 3B). Monoalkyl fluorescein **1** showed high fluorescence quantum yields (0.20) in contrast with the low yield of MAF **3** (<0.01) (Table 1). We also measured the quantum yields of BAF **7** and its deprotected form **5**. The quantum yields of **5** were 0.68, which is higher than monoalkyl fluorescein **1**, whereas BAF **7** also shows a low quantum yield (<0.01) (Table 1).

Reaction of the RETFA Probe *in Vitro.* We designed two DNA probes to test the utility of the RETFA system for fluorescence-based oligonucleotide detection (Figure 4). The probes and target sequences are shown in Figure 4A. Probe 1 was modified at the 3′-terminal with MAF, where the crude NHS-ester product derived from **4** was reacted with the amino group at the 3′-end of the DNA probe (Figure S1A, Supporting Information). Probe **2** was modified at the 5′-terminal with 2′-carboxytriphenylphosphine (TPP), which was conjugated with the 5′-amino linker of the DNA probe through amide bond formation (Figure S1B, Supporting Information). Two DNA templates originating from the human *bcr/abl* junction site sequence, which is related to chronic myelogenous leukemia, were designed containing *bcr/abl-1* with a full match sequence and also *bcr/abl-2* with a one-base mismatch to evaluate the ability for single-base discrimination that is important for diagnostic applications (*65*).

To prove whether the probes could function by emitting fluorescence, we tested the RETFA probe *in vitro*. The RETFA probe pairs consisted of an 8-mer MAF probe (probe 1) and a 10-mer TPP probe (probe 2). The T_m of two adjacent probes and target DNA was 46.7 °C (Figure S2, Supporting Information). When 50 nM probe 1 and probe 2 were incubated in Tris-HCl buffer (pH 7.2) at 37 °C, the increase in fluorescence at 520 nm was monitored. In the presence of target *bcr/abl-1*, the signal at 520 nm reached saturation within 3 min by deprotection of the azidomethyl group of probe 1 (Figure 4B). The signal

Table 1. Quantum Yields of the Compounds[a]

compound	**1**	**3**	**5**	**7**
Φ_F[b]	0.202	<0.001	0.683	0.002

[a] All measurements were performed in Tris-HCl buffer (20 mM, pH 7.2). Compounds were excited at 490 nm. [b] Quantum yields were determined using fluorescein in 0.1 M NaOH as a standard (Φ_F = 0.85).

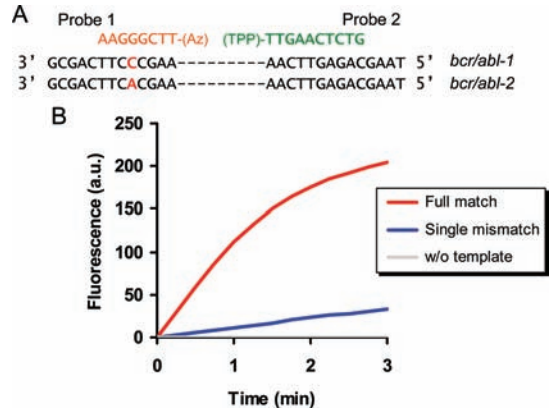

Figure 4. (A) Probe sequences for the *bcr/abl* gene. Designed 8- or 10-mer probes are azidomethyl fluorescein probe or TPP probe, respectively. The DNA targets are 27-mer ODNs with a full matched sequence *bcr/abl-1* and a single mismatched sequence *bcr/abl-2*. (B) Time course of the fluorescence intensity in the reaction between 50 nM probe 1 and 2 with 50 nM matched *bcr/abl-1* or mismatched DNA *bcr/abl-2* in pH 7.2 Tris-HCl buffer containing 100 mM $MgCl_2$ and 10 μg/mL BSA. The reaction was monitored by excitation at 490 nm and emission at 520 nm.

did not increase in the absence of target *bcr/abl-1* for 3 min. HPLC and MALDI-TOF mass analyses showed that 97.7% of probe 1 that reacted with probe 2 on the template after 5 min was converted to the deprotected product (Figure S3, Supporting Information). Next, the reaction of probe 1 and probe 2 in the presence of one-base-mismatched target *bcr/abl*-2 was tested and showed good single-base mismatch discrimination, dropping in initial rate by 9.5-fold, compared with fully matched *bcr/abl-1* (Figure 4B).

Turnover Measurements. The RETFA system was expected to cause multiple reactions with turnover using target oligonucleotide as a catalytic template. Thus, we tested the ability for fluorescent signal amplification. Catalytic turnover, and the associated signal amplification, is useful when target concentrations are low (*49, 51, 54*). Under these conditions, one would typically use a large excess of the probe relative to the number of targets. To measure turnover with the current probes, we compared the number of equivalents of fluorescent signal with moles of target. This required the development of a method for carefully quantitating the signal and confirming that the signal arises from true template-dependent intermolecular reactions rather than from background sources such as intermolecular reactions independent of the template strand or photolysis of the azidomethyl group by the excitation light.

To evaluate this, we performed DNA-templated reactions at various target concentrations and continuously monitored the

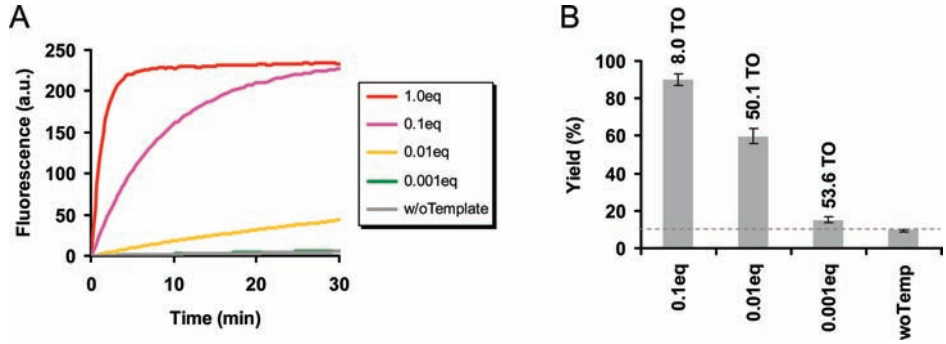

Figure 5. Turnover experiment. (A) Time course of fluorescence intensity in the reaction between 50 nM matched azidomethyl fluorescein and 50 nM matched TPP probe at shown target DNA concentrations in pH 7.2 Tris-HCl buffer containing 100 mM $MgCl_2$ and 10 μg/mL BSA. (B) Reaction yields after 4 h and turnover numbers (TO).

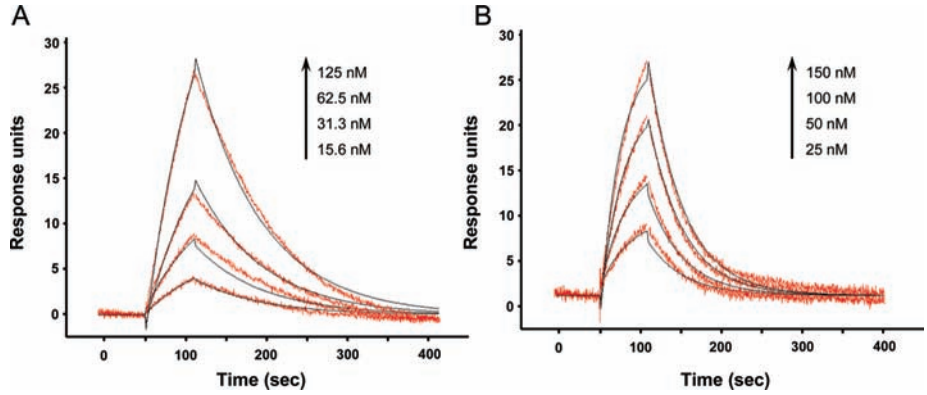

Figure 6. DNA hybridization sensorgrams (fully complementary duplex) analyzed by biacore with varying concentrations of the azidomethyl fluorescein probe (A) or TPP probe (B). The values inside the graphs indicate the probe concentrations.

fluorescent signals as a function of time (Figure 5A). We first prepared a standard dilution curve to make a calibration plot of fluorescent intensity as a function of the amount of the deprotected (= fluorescent) probe 1. This plot showed good linearity and allowed us to take a given signal and, from the plot, extract the number of moles of fluorescent product in solution. Turnover (TO) number was obtained by dividing the number of moles of fluorescent product by that of template DNA (Figure 5B). The turnover of reaction products from the target DNA is expected to increase as the concentration of target decreases. To test this, we varied target concentrations over the range from 50 nM to 50 pM. The probe concentrations were held constant at a considerable excess (50 nM). To ensure that the signal was not the result of template-independent reactions or hydrolysis, we subtracted background signals from identical reactions lacking templates.

The time course of the fluorescent signal at 520 nm showed a rapid signal increase in the presence of 1 equiv of matched DNA *bcr/abl-1* (Figure 5A, red line) within 5 min. Catalytic amounts of *bcr/abl-1* (0.1 equiv, 5 nM) also proved efficient in conferring a rapid signal increase, reaching a plateau within 30 min, which is the same level of fluorescence signal to the stoichiometric amount of *bcr/abl-1* (Figure 5A, pink line), and provided 90% yield of reaction product after 4 h calculated from the fluorescence standard curve (Figure 5B). In the absence of DNA, 50 nM probes 1 and 2 yielded 9.7% background reaction after 4 h (Figure 5A, gray line). When the background signal is subtracted, the RETFA probe achieved 8.0 TO in the case of 0.1 equiv *bcr/abl-1*. With a load of 0.01 equiv (500 pM) *bcr/abl-1*, the reaction showed slower fluorescence increase than in the case of 0.1 equiv *bcr/abl-1* (Figure 5A, yellow line) and furnished 69% of the fluorescent product with 50 TO after 4 h. The highest TO number of 54 was achieved with 0.001 equiv *bcr/abl-1* (50 pM; Figure 5A, green line). The speed of the DNA-catalyzed reaction is reduced at very low DNA/probe ratios to an extent that reaction yields are dominated by the off-template background reaction. However, the 15% reaction product obtained with 0.001 equiv *bcr/abl-1* (50 pM) demonstrates that the DNA-templated reaction (5.4%) proceeds more efficiently than the background reaction (9.7%), even with such a very low concentration of target.

Kinetic Analysis of the DNA-Templated Reaction. The mechanism of a DNA-catalyzed reaction gives important information for optimizing the RETFA probe and designing new probes. However, a study of the mechanism has not been carefully carried out. In particular, the rate-limiting step of the DNA-catalyzed reaction is still unclear. Thus, we evaluated the association and dissociation rate constants for the DNA hybridization between *bcr/abl-1* and the RETFA probe, and the rate constants of the azide reduction on DNA templates to obtain information on the rate-limiting step.

The kinetics of association (k_a) and dissociation (k_d) of probe 1 or probe 2 to the immobilized *bcr/abl-1* were successfully monitored using BIAcore technology (*66*). Figure 6 shows that BIAcore trajectories of *bcr/abl-1*/probe 1 or *bcr/abl-1*/probe 2 hybridization runs at different concentrations of each probe in solution. The k_a and k_d for each probe were calculated with BIAcore T100 evaluation software and are summarized in Table 2. The k_a for probes 1 and 2 are 3.1×10^4 M^{-1} s^{-1} (k_{a1}) and 1.3×10^4 M^{-1} s^{-1} (k_{a2}), respectively. The concentration of the DNA-templated reaction (C_0) was 50 nM. Therefore, the k_a' ($k_a \times C_0$) for probes 1 and 2 are calculated as 1.5×10^{-3} s^{-1} (k_{a1}') and 6.3×10^{-3} s^{-1} (k_{a2}'), respectively. However, the k_d for probes 1 and 2 showed about 10 times higher values, 2.2×10^{-2} s^{-1} (k_{d1}) and 1.2×10^{-2} s^{-1} (k_{d2}), than k_a'.

Next, to determine the rate constant of azide reduction on DNA templates, the plots of $\ln[\text{probe 1}]_t/[\text{probe 1}]_0$ versus time were analyzed by linear regression as simple first-order kinetics

Table 2. Kinetic Parameters for the Hybridization of Each Probe and DNA-Templated Reaction

	k_a ($\times 10^4$ M^{-1} s^{-1})	k_a' ($\times 10^{-3}$ s^{-1})	k_d ($\times 10^{-2}$ s^{-1})	k_{app} ($\times 10^{-3}$ s^{-1})
hybridization (probe 1)[a]	3.06	1.53	1.25

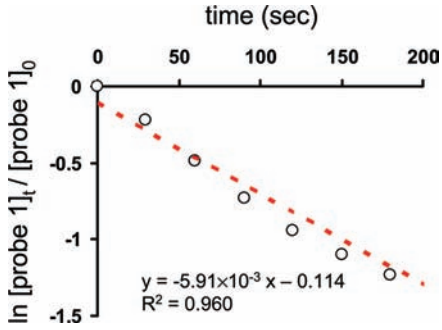

Figure 7. Plots of ln[probe 1]$_t$/[probe 1]$_0$ versus time for 50 nM azidomethyl fluorescein and TPP probe with 50 nM target in 20 mM Tris-HCl (pH 7.2) containing 100 mM $MgCl_2$ and 10 μg/mL BSA.

by Microsoft Excel (Figure 7). [probe 1]$_0$, [probe 1]$_t$, and [reduced probe 1]$_t$ correspond to initial concentration of probe 1, time dependent concentration of probe 1, and concentration of reduced product, respectively. [probe 1]$_t$ was calculated according to [probe 1]$_t$ = [probe 1]$_0$ − [reduced probe 1]$_t$, and [reduced probe 1]$_t$ was calculated from a standard curve. The apparent first-order rate constant, k_{app}, was obtained from the slope of this plot as 5.9×10^{-3} s^{-1}. The value of k_{app} is very close to the association rate constants k_{a1}' and k_{a2}', which is the slower step in the hybridization kinetics. This similarity suggests that the actual reaction rate of an azide reduction on DNA templates (k_{act}) is close to or even faster than the hybridization kinetics. Therefore, we assumed that the association of the probe to the DNA template might be the rate-limiting step for the DNA-catalyzed reaction for the RETFA probe.

Flow Cytometric Analysis of RNAs in HL60 Cells. So far, there has only been one example of quenched probes in living human cells. Flow cytometry (FC) offers the possibility of rapid analysis of a large number of cells and quantitative evaluation of an average over all RNA signals. Thus, we evaluated the feasibility of FC analysis of RNAs by the RETFA probe in HL60 cells. In the in-cell experiment, we used the bisazidomethyl-quenched fluorescein probe because the quantum yield for the deprotected form of **9**, 0.683, is higher than that of monoazide **3**, 0.202. As described above, our probes have a potential for catalytic turnover. Therefore, both azidomethyl groups on **9** should be deprotected. The targets we chose were 28S rRNA, which is abundant in cells, and β-Actin mRNA, which has relatively low copies in cells (~2500 molecules per cell) (*36*). To decide if the RETFA probe offers the desired fluorescent signal from the target and evaluate any undesired background fluorescence signal from the nontemplated reaction or decomposition of the probe, we carried out a series of control experiments by testing the following conditions: the scramble probes, only the profluorescent azide probe, and no probe (the cellular autofluorescence). The sequence of the scramble probe was designed so as not to hybridize next to each other on the target RNA. The probe and target site sequences for 28S rRNA and β-Actin mRNA are described in Figures S4A and S5A (Supporting Information), respectively. Prior to the FC analysis, we determined whether the probes could generate a target-dependent fluorescence signal *in vitro* using a short DNA target. As shown in Figure S4B (Supporting Information), no significant background fluorescence was observed in the absence of the short 28S rRNA target. In the case of targeting β-Actin mRNA, we used three sets of probes for multiple target sites to increase sensitivity (Figure S5A, Supporting Information). The three sets of probes for β-Actin mRNA (33.3 nM each) and DNA targets (33.3 nM each) were mixed to adjust the total concentrations to 100 nM. Reaction of the scramble probe was tested under the same conditions. The reaction with the β-Actin probe shows a strong fluorescence signal with the target and generated a slight background signal without the target, which was comparable with the background level in the case of the scramble probes (Figure S5B, Supporting Information).

The FC data are summarized in Figure 8. To introduce the probes into cells, the cells were permeabilized with streptolysin O (SLO) according to the previously reported method. The cells were incubated with SLO in the presence of the RETFA probe for 30 min, resealed with cell culture medium containing $CaCl_2$, and incubated for 1 h at 37 °C and analyzed by FC. The histogram data indicate cell populations with varied fluorescence intensity, which correspond to 28S rRNA, three sets of β-Actin mRNA, scramble probes, only azide probe, and no probe (Figure

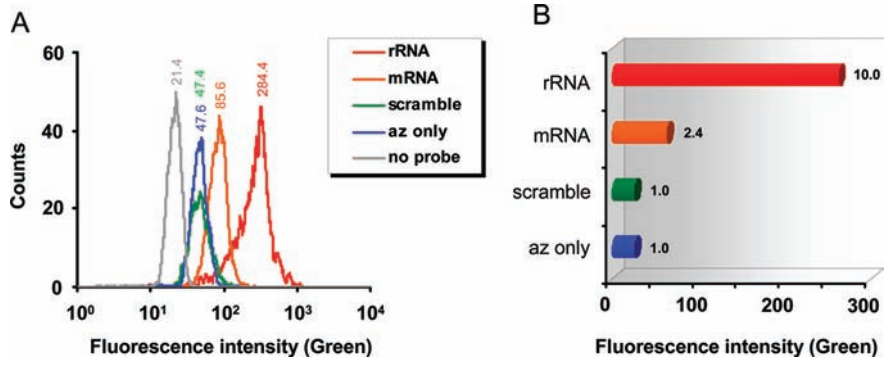

Figure 8. Detection of intracellular RNAs in HL60 cells by flow cytometry. (A) Flow cytometry histogram showing cell-count frequency vs fluorescence intensity for each probe. These histograms correspond to cells that were treated by no probe (negative control, gray); by azidomethyl fluorescein probe only (negative control, blue); by scramble probe (negative control, green); by β-Actin mRNA targeted probes (orange); and by 28S rRNA targeted probes (red). The values on each histogram indicate the mean fluorescent signals. (B) Means of fluorescence intensity and signal to background calculated from the histograms. The bars were corrected by cell autofluorescence background (no probe). The values next to the bars indicate the ratios between each probe and scramble probe as a signal to background.

8A). The median values of fluorescence intensity after subtraction of autofluorescence from cells (no probe) are plotted in Figure 8B. The values on the bars indicate signal to background (S/B) ratio, which is defined as the relative ratios of fluorescence intensity to background signal from the scramble probe. Both 28S rRNA and the three sets of β-Actin mRNA probes offered significantly higher fluorescence signals than did the controls, although each set of β-Actin mRNA probes did not produce a significant signal. The background value from the scramble probes was comparable with that from the azide probe alone, indicating that undesirable intermolecular reactions between the TPP probe and the azidomethyl probe did not occur in living cells. The S/B ratios were 10.0 and 2.4 for 28S rRNA and β-Actin mRNA, respectively. This result clearly showed that cellular endogenous 28S rRNA and β-Actin mRNA can be detected by our RETFA probes and is consistent with the notion that 28S rRNA is more abundant than β-Actin mRNA in the cells.

Fluorescence Microscopic Analysis of RNAs in HL60 Cells. To demonstrate that our approach can give a clear and detailed picture of intracellular localization in living cells, we carried out fluorescence microscopic analysis of RNA species. The imaging technique may reveal important information on mRNA processing, transport, and protein production. Fluorescence images of 28S rRNA and β-Actin mRNA in HL60 cells are shown in Figure 9. First, imaging 28S rRNA was performed using bisazidomethyl fluorescein and TPP probes as for the FC experiment. After the probes were introduced into cells using the SLO method, the cell suspension was directly spotted on glass slides without any washing step and was imaged by a fluorescence microscope. Specimens were illuminated with a 488 nm laser, and the specific fluorescence signal from the probe was directed at fluorescein emission 500−550 nm. Panels C and D in Figure 9 display the fluorescent signal of the scramble probes, showing that little or no signal was observed. However, a strong signal was observed in the nucleolus using target-specific probes (panels A and B), which is in fair agreement with previous results by FISH in fixed specimens (*67*).

Next, to confirm that our system can detect low-expression RNA in cells, β-Actin mRNA probes were delivered into HL60 cells using SLO. Again, the majority of the fluorescent signals was observed around the nucleus only from target-specific probes (panels E and F), whereas the scramble probes gave small signals (panels G and H). We conclude that signals from specific RNAs can be observed using the designed RETFA probe in human cells.

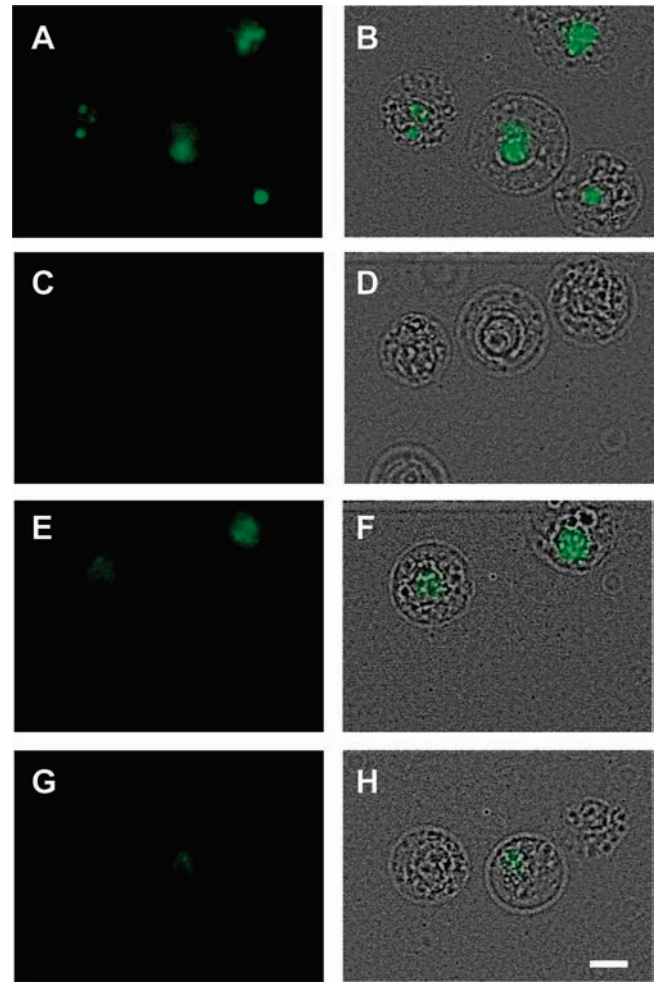

Figure 9. Detection of intracellular human 28S rRNA and β-Actin mRNA by fluorescence microscopy. (A−D) 28S rRNA probe (A and B) and scramble control (C and D). A and C show fluorescent signal only. B and D show its overlay with bright field image. (E−H) β-Actin mRNA probe (E and F) and scramble control (G and H). E and G show the fluorescent signal only. F and H show its overlay with bright field image. Bar: 10 μm.

DISCUSSION

The Staudinger reduction of organic azides by TPP holds promise for OTR because of its exceptional degree of bioorthogonality. Several ideas have been applied to link the Staudinger reaction to the fluorescence turn-on event for OTR. These strategies can be categorized into two types. One strategy involves the reaction step where the azide probe unmasks a 2-(diphenylphosphino)benzoate derivative of fluorescein (*47*). Alternatively, a TPP-probe activates the azide-masked fluorophores, which are 7-azidocoumarin (*49*) and azide-substituted rhodamines (RETF probe) (*48*). In addition, azidomethyl-protected coumarin has very recently been reported as a new fluorogenic molecule (*50*). These probes demonstrate excellent signal amplification with fluorescence readout except for the RETF probe. However, possible drawbacks limit the scope of in-cell applications because of increased undesired background fluorescence. This may be due to the hydrolysis of the phenolic ester or light decomposition of the azide group when azide-protected coumarin is irradiated with excitation light in the ultraviolet region. In general, oxidation of TPP in living cells was also involved. Consequently, these previous approaches have not been applied to imaging or detection of RNA in living cells (*47*−*50*).

In this article, we have demonstrated that the RETFA probe with azidomethyl-protected fluorescein can detect endogenous RNAs in living cells. Azidomethyl-protected fluorescein is quickly uncaged by reduction of the azide group and emits fluorescence at 520 nm with excitation at 490 nm, which is a suitable wavelength for in-cell detection. In addition, the RETFA probe completed the stoichiometric reaction within 3 min and can amplify fluorescence signals based on a catalytic OTR when the target is at a very low concentration compared with that of the probes (*26*, *41*, *46*, *47*, *49*−*51*). The TO number reached up to 50 when 100 times excess of probe was used. This amplification property is one of the great improvements compared with our previous RETF probe (*48*).

Quantitative detection of 28S rRNA and β-Actin mRNA was successfully carried out on the FC instrument. A single probe was sufficient for the detection of 28S rRNA. However, simultaneous introduction of three sets of probes offered significant signal for detection of β-Actin, although each individual probe offered no significant signal. Cellar mRNA is known to form complex secondary or tertiary structures. It is very hard to design an optimum probe with accessibility to target sites. This result indicates that introducing multiple sets of

probes might be one solution to achieve accessibility by opening up the complex mRNA structure. However, accessibility or turnover of RETFA probe is different on each RNA target. Therefore, further study is required to estimate the exact amount of RNA species in living cells.

Finally, development of an efficient catalytic reaction on the oligonucleotide template is still challenging. The RETFA probe is expected to moderate product inhibition on catalytic OTR because the T_m of unreacted probes or products to the target is almost same. Unreacted probes and products become exchangeable on the target to give turnover when the T_m is close to reaction temperature. Therefore, probe length was designed to give a T_m that is close to 37 °C at biological conditions. Next, we carried out a mechanistic study of the catalytic reaction on the RETFA probe to obtain clues for designing efficient turnover probes. Kinetic analysis by BIAcore technology showed that the association step of the probe (k_a') is 10 times slower than the dissociation step (k_d') on probe hybridization. The apparent rate constant of the fluorogenic chemical reaction (k_{app}) has a value similar to that of k_a'. Presumably, association might be the rate-limiting step for the amplification reaction from these results, although this experiment did not reflect an exact phenomenon in solution. We assume that new probe designs should enhance association speed to achieve more efficient turnover.

CONCLUSIONS

We have developed a reduction-triggered fluorescent amplification (RETFA) probe with a new azidomethyl-protected fluorescein. The RETFA probe completes the reaction within 3 min and can amplify the fluorescence signal from the target up to 50 times. The probe was successfully applied to the detection of endogenous RNA in living human cells using flow cytometry and fluorescence microscopy.

Experimental section

Iodo fluorescein (5). (Reference 1) Fluorescein (1.60 g, 4.61 mmol) was dissolved in 12N HCl (16.4 ml) and 8.2 g of ice. An aqueous solution (8.2 ml) of sodium nitrite (397 mg, 5.76 mmol) was added slowly. After stirring for 2.5 hour, an aqueous solution (13.2 ml) of potassium iodide (15.3 g, 92.2 mmol) was added slowly. The reaction was allowed to warm gradually to room temperature. After stirring for 5 hour, the reaction mixture was diluted with $CHCl_3$ and washed with H_2O and brine. The combined organic extracts were pooled and dried over Na_2SO_4. The Na_2SO_4 was removed by filtration and volatiles removed *in vacuo.* The residue was purified by flash column chromatography (silica, gradient elution 10:1 hexane/AcOEt to 3:1 hexane/AcOEt (v/v) with 0.5% triethylamine) to afford a yellow solid (1 g, 47%) (**5**). ^{1}H NMR (400MHz, CD_3OD) δ8.33-8.31(1H, m), 8.08-8.04 (1H, m), 7.00-6.96 (1H, m), 6.67-6.50 (4H, m). ^{13}C NMR (100MHz, CD_3OD) δ 169.5, 161.3, 153.9, 145.1, 134.7, 130.3, 130.0, 127.1, 113.6, 110.7, 103.5, 95.6. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m/z* 457.9651 [MH+] $C_{20}H_{11}IO_5$: 458.9729, found: 458.9721

Bisthiomethyl fluorescein (6). Iodo fluorescein (**5**) (1 g, 2.18 mmol) was dissolved in dry CH_3CN (36 ml) under Ar (g). Silver oxide (1.52 g, 6.55 mmol) and Chloromethylmethylsulfide (550 µl, 6.55 mmol) was added followed by addition of five drop of pyridine. After stirring for 24 hour at 40 °C, the remaining solid residue was removed by filtration. The filtrate was concentrated and subjected to flash column chromatography. Elution with a slow gradient of hexane/AcOEt from 10:1 to 3:1 (v/v) with 0.5% triethylamine gave thiomethyl fluorescein (**6**) as pale yellow crystalline solid (234 mg, 19%). ^{1}H NMR (400MHz, $CDCl_3$) δ 8.35 (1H, s), 7.96 (1H, d, J = 8.1Hz), 6.92 (1H, d, J = 8.3Hz), 6.83 (2H, d, J = 2.2Hz), 6.73-6.65 (4H, m), 5.16 (4H, s), 2.26 (6H, s). ^{13}C NMR (100MHz, $CDCl_3$) δ 167.3, 158.6, 152.2, 152.0, 143.6, 133.9, 128.9, 128.6, 125.6, 112.9, 111.3, 103.0, 94.9, 83.1, 72.5, 14.8. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m/z* 577.9719 [MH+] $C_{24}H_{19}IO_5S_2$: 578.9797, found: 578.9775

Bisazidomethyl fluorescein (7). Thiomethyl fluorescein (**6**) (200 mg, 350 μmol) was dissolved in dichloromethane (7 ml). N-chlorosuccinimide (102 mg, 760 μmol) was added. After stirring for 2 hour at room temperature, trimethylsilyl chloride (97.3 μl, 760 μmol) was added. The resulting solution was stirred at ambient for 6 h and the reaction was quenched with saturated Na_2CO_3 aqueous. The aqueous layer was extracted with $CHCl_3$ (×2) and the combined organic layers was concentrated in vacuum to give the crude which was subjected to the next reaction. Sodium azide (67.5 mg, 1.04 mmol) was dissolved in H_2O (3.5 ml) and added to a solution of the crude in DMF (7 ml) in room temperature. After stirring for 30 hour, the reaction was quenched with saturated Na_2CO_3 aqueous. The aqueous layer was extracted with AcOEt (×2) and the combined organic layers was concentrated in vacuum and subjected to flash column chromatography. Elution with a slow gradient of hexane/AcOEt from 10:1 to 3:1 (v/v) with 0.5% triethylamine gave azidomethyl fluorescein (**7**) as pale yellow crystalline solid (41.0 mg, 21%). ^{1}H NMR (400MHz, $CDCl_3$) δ 8.36 (1H, s), 7.99-7.97 (1H, m), 6.94-6.90 (3H, m), 6.77-6.70 (4H, m), 5.19 (4H, s). ^{13}C NMR (100MHz, $CDCl_3$) δ 167.3, 158.1, 152.1, 152.0, 143.7, 134.0, 129.2, 128.5, 125.5, 112.7, 112.3, 103.4, 95.0, 82.6, 79.4. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m/z* 567.9992 [MH+] $C_{22}H_{13}IN_6O_5$: 569.0070, found: 569.0065

Bromoacetyl acetylene linker (8). (Reference 2) To a solution of propargylamine (116.28 μl, 1.82 mmol) and potassium carbonate (251 mg, 1.82 mmol) in benzene (18.2 ml) chilled via an external ice bath was added bromoacetyl bromide (159μl, 1.82 mmol). After stirring for 20 h, the reaction mixture was diluted with ether and washed with H_2O. The combined organic extracts were pooled and dried over Na_2SO_4. The Na_2SO_4 was removed by filtration and volatiles removed *in vacuo*. The residue (**8**) (118 mg, 37.1%) was subjected to the coupling with azidomethyl fluorescein. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m/z* 174.9633 [MH+] C5H6BrNO: 175.9711, found: 175.9703

Bisazidomethyl bromoacetyl linker fluorescein (9). Azidomethyl fluorescein (**7**) (50 mg, 88 μmol) was dissolved in THF (1.6 ml) under Ar (g). Tetrakis (triphenylphosphine) palladium (10.2

mg, 8.8 μmol), copper iodide (3.35 mg, 1.8 μmol) and triethylamine (61.9 μl, 440 μmol) were added followed by addition of bromoacetyl acetylene linker (**8**) (77.0 mg, 440 μmol). After stirring for 3 hour, the remaining solid residue was removed by filtration. The filtrate was concentrated and subjected to flash column chromatography. Elution with a slow gradient of hexane/AcOEt from 5:1 to 1:1 (v/v) with 0.5% triethylamine gave azidomethyl bromoacetyl linker fluorescein (**9**) as pale yellow crystalline solid (20 mg, 37%). ^{1}H NMR (400MHz, $CDCl_3$) δ 8.06 (1H, s), 7.70 (1H, d, J = 8.04), 7.27 (2H, s), 7.11 (1H, d, J = 8.1), 6.91 (2H, d, J = 2.2), 6.77-6.69 (4H, m), 5.19 (4H, s), 4.36 (2H, d, J = 5.6), 3.94 (1H, s), 3.76 (1H, s). ^{13}C NMR (100MHz, $CDCl_3$) δ 168.1, 166.6, 158.0, 152.3, 152.0, 138.2, 131.8, 129.2, 128.3, 123.9, 113.0, 112.6, 112.5, 103.4, 86.7, 82.5, 81.8, 79.4, 30.9, 28.8. QSTAR (Applied Biosystems/MDS SCIEX) (ESI): *m/z* 615.0502 [MH+] $C_{27}H_{18}BrN_7O_6$: 616.0580, found: 616.0578

Thermally Gated Liposomes: A Closer Look

Ravil R. Petrov, Wen-Hua Chen, and Steven L. Regen*

Department of Chemistry, Lehigh University, Bethlehem, Pennsylvania 18015. Received February 25, 2009; Revised Manuscript Received March 23, 2009

A homologous series of pore-forming amphiphiles (PFAs), derived from cholic acid, lysine, and spermine, have been used as "thermal gates" for releasing sucrose from liposomes made from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) and 1,2-dipalmitoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)] (sodium salt) [DPPG]. Binding measurements have established that these PFAs are fully bound to these liposomes in their gel state and that their transfer to fluid phase membranes is negligible. Release experiments have shown that thermal gating is sensitive to both the size and the concentration of the PFA that are used. Increases in the extent of release of sucrose with increasing temperature that have been found in the gel/fluid coexistence region indicate the existence of heterogeneity among the liposomes.

INTRODUCTION

Finding ways to control the release of encapsulated agents from the aqueous interior of liposomes continues to attract broad interest from an applications standpoint (*1*−*22*). Although most of this interest has centered around drug delivery, a variety of other applications can be considered as well, e.g., the release of catalysts, reagents, cosmetics, flavors, dyes, fragrances, contrast agents, etc.

One well-established approach for controlling the release of liposome-encapsulated agents takes advantage of differences in membrane permeability between the gel (i.e., solid-like) and the liquid−crystalline (i.e., fluid-like) state. In particular, whereas gel-phase bilayers are characterized by tight lipid packing and low permeability, fluid phase analogues are loosely packed and have relatively high permeabilities (*23*−*26*). Thus, by increasing the temperature of liposomes beyond their gel to liquid−crystalline phase transition temperature (T_m), one can observe increased permeation rates (*24*−*26*). In some instances, it has been noted that maximum rates occur at or near the lipid's T_m, where half of the membrane has melted and gel and fluid phases coexist (*27*). Although the reason for this maximum has not been firmly established, it has been suggested that a mismatch in lipid packing between the two phases produces defects through which permeants can pass (*27*).

Previously, we introduced the concept of "thermally gated liposomes", whereby a pore-forming agent (PFA) derived from facially amphiphilic cholic acid is used to enhance thermally induced liposomal release (*28*). Our working hypothesis is that these PFAs assemble into pores either in the fluid phase or at gel/fluid interfaces (Figure 1).

In the work reported herein, we sought to gain insight into the interactions between PFAs and gel phase liposomes and to better characterize the thermally gated release process. Of particular interest was to determine whether PFAs are fully bound to gel phase liposomes, whether they are transferrable to fluid phase analogues, and whether thermally gated release is dependent on the size of the PFA that is used. We also sought to distinguish between thermally gated release occurring in the fluid phase versus gel/fluid interfaces.

In earlier studies, we showed that a nonfacially amphiphilic, ion conductor is "squeezed out" of liposomal membranes and released into the aqueous phase when the bilayer is converted from the fluid phase to the gel state (*29*). If PFAs derived from cholic acid were to behave similarly, this would limit their usefulness in drug delivery, since they would be expected to undergo competitive binding to cell membranes. For this same reason, transfer of a PFA from gel phase liposomes to fluid phase membranes via direct membrane−membrane contact would be a significant limitation. Thus, the inherent stability of thermally gated liposomes in the presence of fluid membranes has practical implications. Equally important from a drug delivery standpoint is the rate at which encapsulated agents are released from liposomes. Since release rates approaching "burst kinetics" are most suitable for drug targeting via localized hyperthermia, knowing whether release is faster in the fluid phase or in the gel/fluid coexistence region has practical relevance. In addition, knowing whether the size of a PFA significantly influences release rates is an important consideration. Although we have shown that the activity of a PFA for Na^+ transport increases exponentially with increasing size, whether the size of a PFA influences the rate of release of molecules from liposomes *under thermally gated conditions* remains to be determined (*28*).

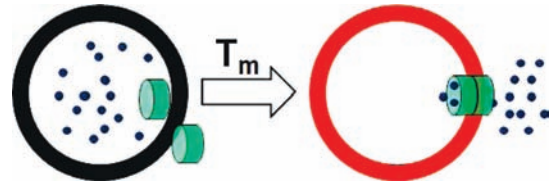

Figure 1. Stylized illustration showing two PFAs forming a pore in a melted bilayer.

RESULTS

Experimental Design. To examine these issues, we employed liposomal carriers (∼200 nm diameter, extrusion) made from 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) and a small amount (5 mol %) of the negatively charged analogue 1,2-dipalmitoyl-*sn*-glycero-*e*-[phospho-*rac*-(1-glycerol)] (sodium salt) [DPPG]. The latter was included in these dispersions to stabilize them by preventing aggregation. Extrusion procedures used in forming thermally gated liposomes (200 nm Nuclepore membranes) are described in the Supporting Information.

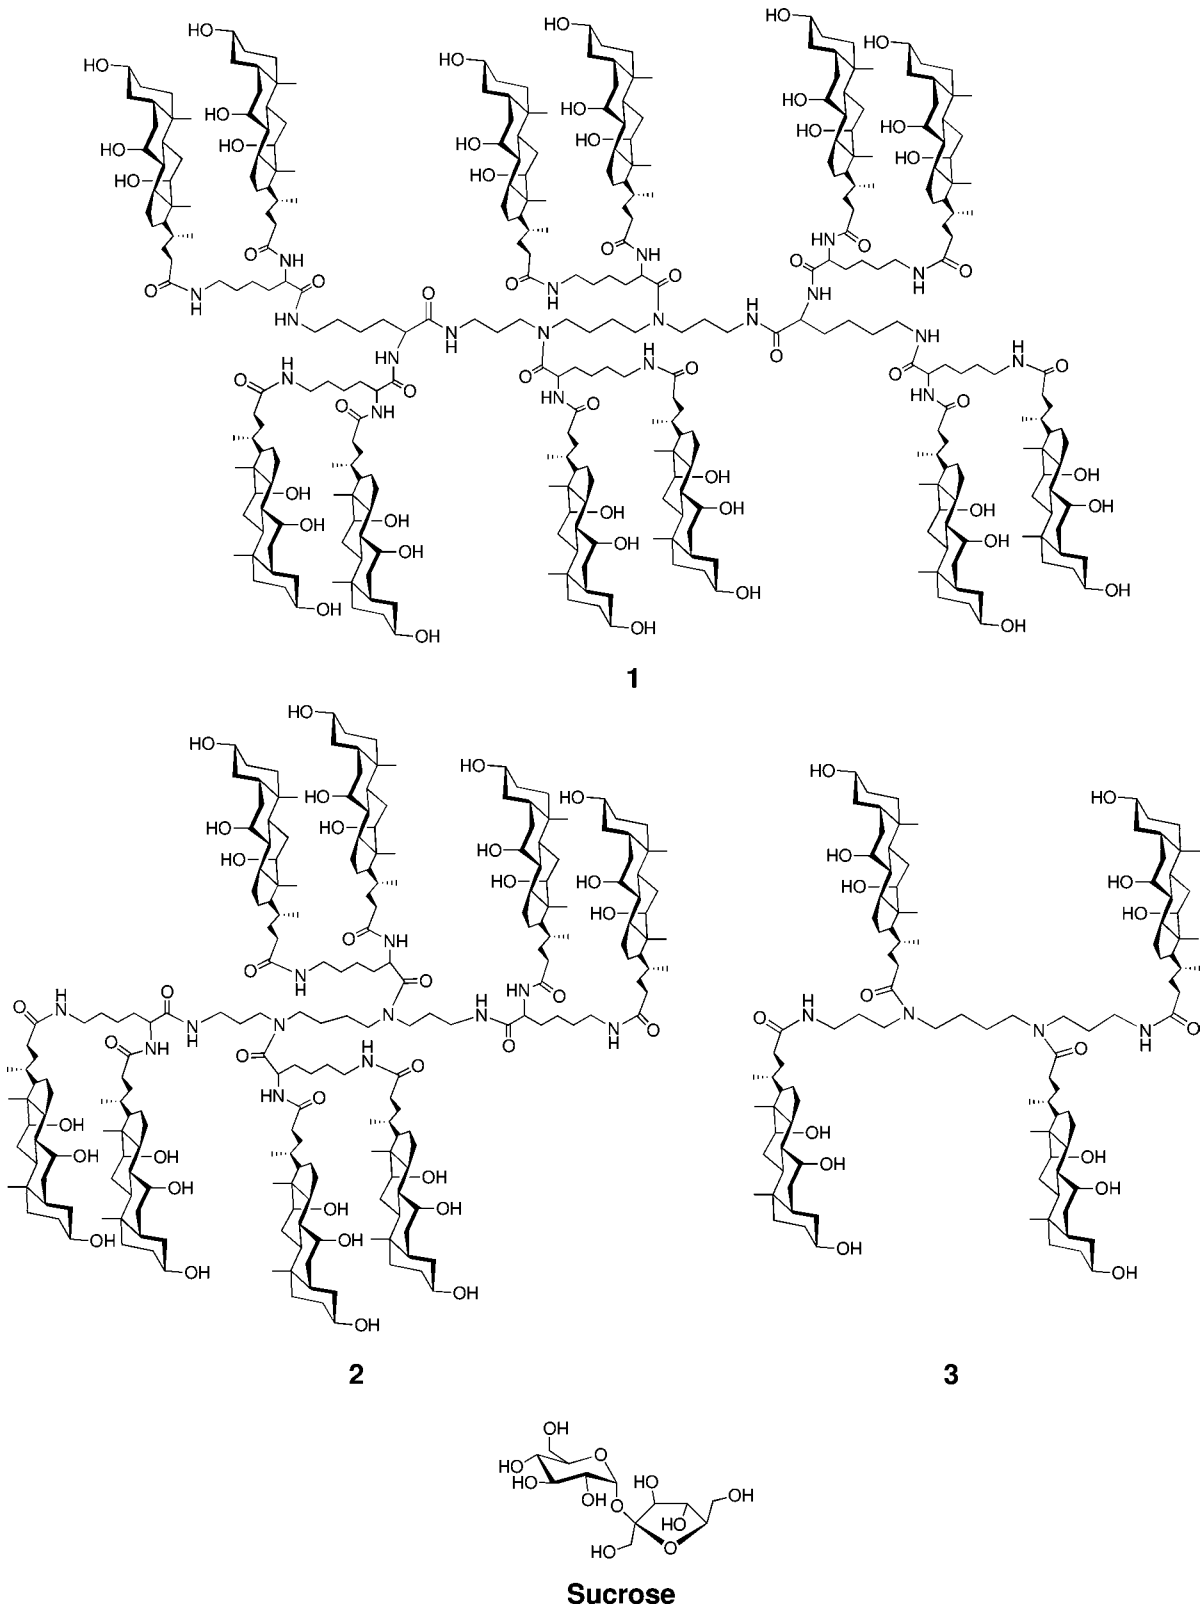

Figure 2. Structures of pore-forming amphiphiles and permeant (sucrose) used in this study.

Because DPPC and DPPG have a T_m of 41 °C, which is slightly above physiological 37 °C, these liposomes could be considered for drug delivery.

Three pore-forming agents that were chosen for this study were derived from cholic acid, lysine, and spermine (Figure 2). The largest one (i.e., **1**) contains 12 choloyl groups coupled to a spermine backbone that has been extended at each end by one lysine group (*30*). An intermediate-sized analogue (i.e., **2**) has a total of eight choloyl groups bound to this same framework (*30*). Finally, a relatively small analogue (i.e., **3**) has only four choloyl groups bound to spermine (*31*). In this work, sucrose was chosen as a model permeant because it is uncharged and highly water-soluble.

Thermotropic Properties. Before carrying out thermally gated release experiments, we first examined the melting properties of our liposomes in the absence and in the presence

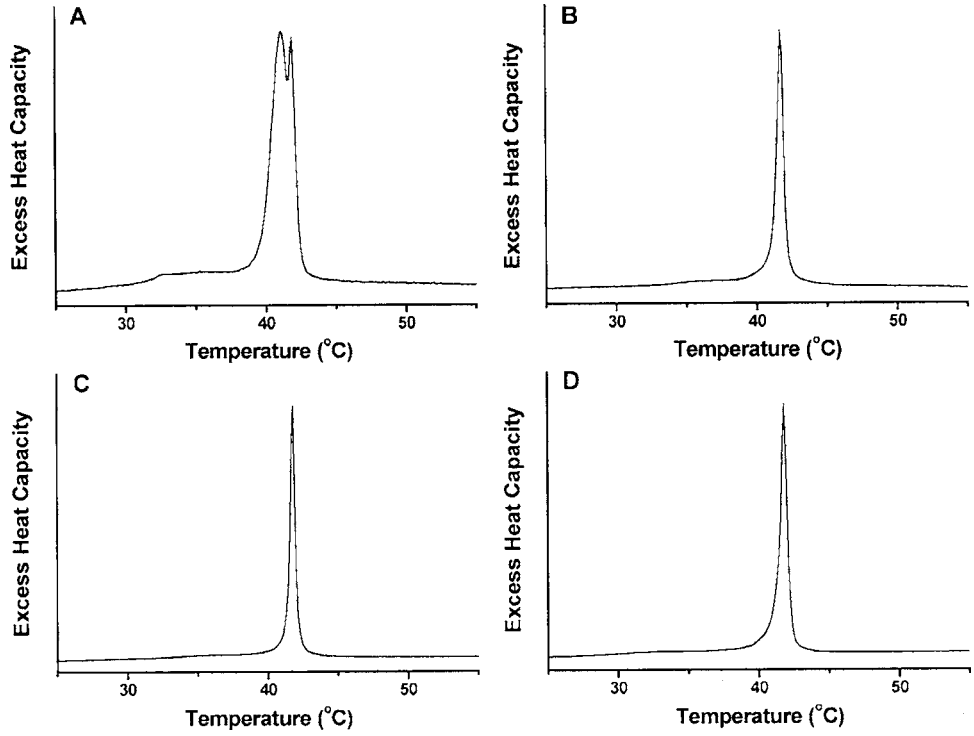

Figure 3. High-sensitivity differential scanning calorimetry data for extruded liposomes made from DPPC/DPPG (95/5, mol/mol) with (A) no PFA added, (B) 0.1 mol % of **1**, (C) 0.15 mol % of **2**, and (D) 0.3 mol % of **3**.

Table 1. Quantification of Liposome-Bound PFAs before and after Gel Filtration[a]

	integrated density of TLC spots					
	before gel filtration			after gel filtration		
PFA	PFA	DPPG	ratio of PFA/DPPG	PFA	DPPG	ratio of PFA/DPPG
1	107 423	401 666	0.27	79 194	315 235	0.25
2	197 958	919 363	0.22	203 264	885 709	0.23
3	125 934	755 700	0.17	75 604	470 334	0.16

[a] Integrated densities measured for PFAs and DPPG are in arbitrary units.

of **1**, **2**, and **3** by high-sensitivity differential scanning calorimetry (hs-DSC). For these measurements and for thermally gated release experiments, a low concentration of PFA was used, that is, 1.2 mol % choloyl groups, corresponding to 0.1, 0.15, and 0.3 mol % of **1**, **2**, and **3**, respectively.

In the absence of PFAs, a broad pretransition was observed at ~35 °C. In addition, the main gel to liquid−crystalline phase transition appeared as a doublet, centering at ~41 °C (Figure 3). It is noted that similar splitting has been reported for other phosphocholine-based liposomes when their diameters are less than ~200 nm (*32*). In the presence of each of these PFAs, the pretransition was essentially eliminated and the main phase transition was converted into a sharp single endotherm.

Binding of PFAs to Gel Phase Liposomes. To judge the extent of binding of each PFA by gel phase liposomes, we determined relative concentrations in dispersions before and after gel filtration by quantitative thin layer chromatography. For these analyses, the DPPG that was present in the liposomes was used as an internal standard. Since the ratio of PFA/DPPG was essentially the same before and after gel filtration in all cases, these results indicate that these PFAs are fully bound (about ±5%) to these gel phase liposomes at 23 °C (Table 1).

Attempted Transfer of a PFA from Gel to Fluid Phase Liposomes. In an attempt to transfer a PFA from gel phase liposomes to fluid analogues, we mixed an extruded dispersion made from DPPC/DPPG (95/5, mol/mol) containing 0.3 mol % of **3** with multilamellar vesicles (MLVs) made from 1-palmitoyl, 2-oleoyl-*sn*-glycero-3-phosphocholine (POPC, $T_m = -2.6$ °C) (*33*, *34*). After an incubation period of 16 h at 37 °C with 10 equiv of POPC, the resulting dispersion was cooled to room temperature and centrifuged to pellet the MLVs. Under these conditions, the extruded liposomes remain dispersed. Analysis of the ratio of **3**/DPPG in the supernatant by quantitative TLC indicated no loss of **3** from the gel phase liposomes.

Thermally Gated Release of Sucrose. To test for thermal gating, sucrose was encapsulated in liposomes containing **1**, **2**, or **3**. After gel filtration to remove external sucrose, the liposomes were then immediately heated to either 37 or 43 °C. Aliquots were withdrawn as a function of time and rapidly gel-filtered a second time to remove the sucrose that had been released. The amount of sucrose that was retained by the liposomes was quantified by spectrophotometry after digestion (see Supporting Information). In Figure 4 are shown the release profiles. In the absence of a PFA, the release of sucrose was negligible at both of these temperatures. When **1** was included in the liposomes, however, the release was rapid and complete at 43 °C. Somewhat unexpectedly, a similar release profile was observed at 37 °C. When **2** was used as the PFA, the extent of release was nearly complete at both temperatures but was apparently slower at 37 °C. In contrast to **1** and **2**, the use of **3** as the PFA resulted in thermal gating; that is, there was negligible release at 37 °C and rapid and substantial release at 43 °C.

The difference in release rates for **2** at 37 °C versus 43 °C suggested that an even greater difference might be observed using a lower concentration of the PFA. Consistent with this

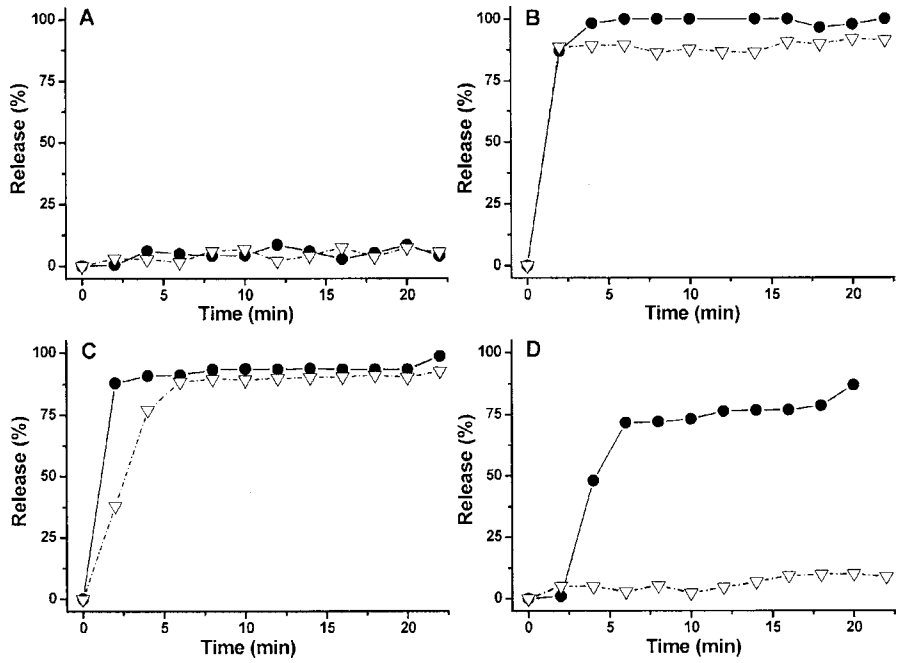

Figure 4. Plot of percent of sucrose released as a function of time from liposomes made from DPPC/DPPG (95/5, mol/mol) with (A) no PFA added, (B) 0.1 mol % of **1**, (C) 0.15 mol % of **2**, and (D) 0.3 mol % of **3** at (▽) 37 °C and (●) at 43 °C.

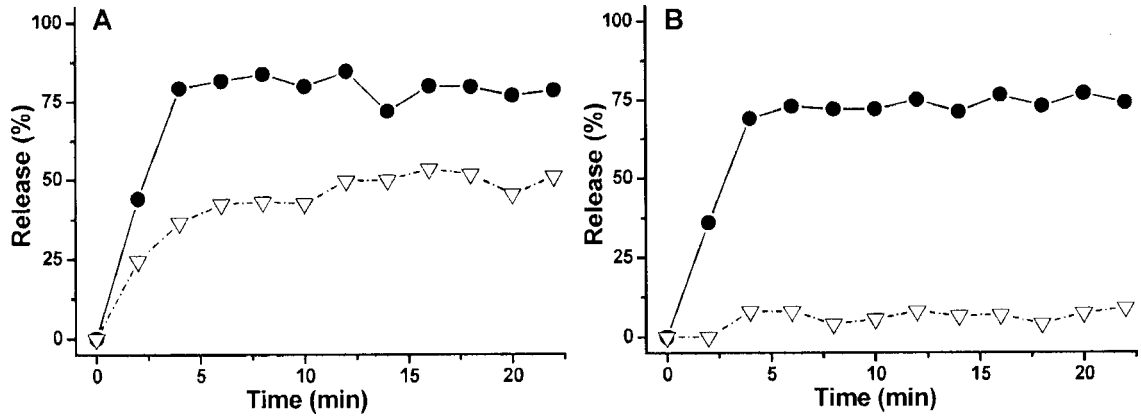

Figure 5. Release of sucrose as a function of time from liposomes made from DPPC/DPPG (95/5, mol/mol) containing (A) 0.010 mol % of **1** and (B) 0.015 mol % of **2** at (▽)37 °C and (●) 43 °C.

thinking, when only 0.015 mol % of **2** was used, the extent of release at 37 °C was negligible; however, at 43 °C, a rapid and significant release was observed (Figures 5). Qualitatively, similar behavior was observed when 0.010 mol % of **1** was used.

Dynamic light scattering measurements that were made for liposomes containing 0.10 mol % of **1**, 0.15 mol % of **2**, and 0.30 mol % of **3** showed diameters before (and after) thermally gated release that were 164 ± 59 nm (164 ± 62 nm), 150 ± 57 nm (150 ± 60 nm), and 148 ± 59 nm (148 ± 56 nm), respectively.

In an effort to determine whether thermally gated release is favored in the fluid phase or the gel/fluid coexistence region, a similar set of experiments was carried out using **3** at 41 °C and at 43 °C; that is, at the T_m of the bilayer and at a temperature in which the bilayer is fully melted. Thus, if release were favored in the gel/fluid coexistence region, the efflux rate should be greater at 41 °C than at 43 °C; if release were favored in the fluid phase, then a greater efflux rate should be observed at 43 °C. Although the release profiles at 41 °C showed a slight time lag for the onset of release, the similarity in the slopes at both temperatures does not allow a clear distinction to be made between preferred release in fluid phase versus the gel/fluid coexistence region (Figure 6). One interesting difference between these release profiles is *the lower extent of release* at the lower temperature. To confirm this behavior, we prepared a similar dispersion and divided it into 10 portions. Each portion was heated for 6 min at temperatures ranging between 36.5 and 43.5 °C, and the extent of release was determined. As shown in Figure 7, a maximum release was found when the membrane was fully melted.

Further evidence for greater release occurring when the liposomes were fully melted was obtained by dividing a dispersion containing 0.3 mol % of **3** into two portions. One portion was rapidly heated to 41.5 °C and held at that temperature for 6 min and cooled to room temperature. This heating/cooling cycle was then repeated five additional times, and the extent of sugar release was analyzed after each cycle. The second portion of liposomes was heated only once to 43 °C and held for 6 min before cooling to room temperature. As shown in Figure 8, only a modest increase in the amount of sucrose that was released was observed with additional heating/

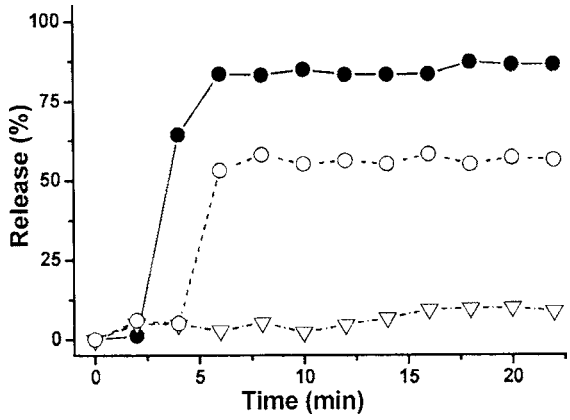

Figure 6. Release of sucrose as a function of time from liposomes made from DPPC/DPPG (95/5, mol/mol) containing 0.3 mol% of **3** at (▽) 37 °C, (○) 41 °C, and (●) 43 °C.

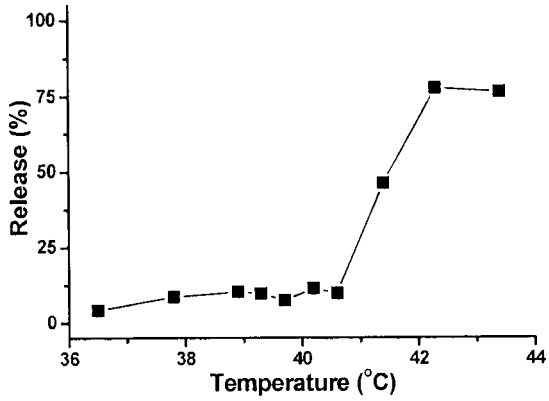

Figure 7. Release of sucrose from liposomes made from DPPC/DPPG (95/5, mol/mol) containing 0.3 mol % of **3** as a function of temperature using a 6 min incubation period.

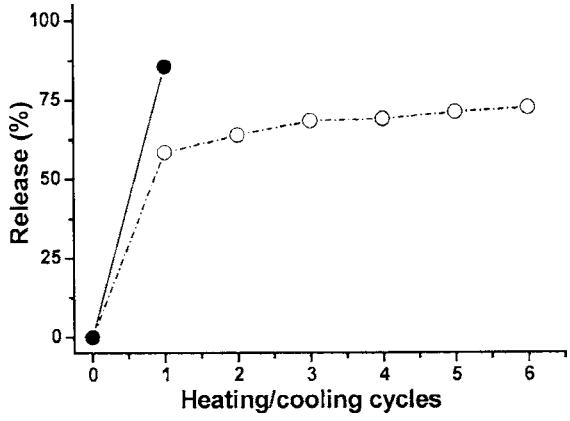

Figure 8. Release of sucrose from liposomes made from DPPC/DPPG (95/5, mol/mol) containing 0.3 mol % of **3** as a function of the number of heating/cooling cycles at 41.5 °C (○) and from one heating period at 43 °C (●). In all cases 6 min incubation periods were used.

cooling cycles at 41.5 °C. In contrast, the extent of release at 43 °C was significantly greater.

DISCUSSION

Analysis of the gel phase liposomes used in this study by hs-DSC, in the absence of PFAs, showed a main phase transition that appeared as a doublet, which is similar to observations that have been made by other researchers for highly curved phosphocholine-based liposomes (*32*). Although the basis for this splitting remains to be established, one possibility is that the inner-concave and outer-convex leaflets have distinct melting characteristics due to differences in packing. Regardless of its origin, the addition of very small amounts of **1**, **2**, and **3** was sufficient to promote greater cooperativity in the melting process and the conversion to a sharp single endotherm. We suspect that this effect may be due to a "filling in" of gaps within each of the leaflets by the PFA.

Binding measurements that were made for **1**, **2**, and **3** have shown that these PFAs are fully bound to gel phase liposomes made from DPPC/DPPG (95/5, mol/mol) and that the transfer of **3** to a fluid phase analogue is negligible. Thus, thermally gated liposomes would appear to be reasonably stable.

The dependency of thermally gated release on the size of the PFA that is used was found to be significant. The fact that **1** and **2** release almost all of the entrapped sucrose at 37 °C (when 0.10 and 0.15 mol % are used, respectively), but release very little when their concentration is reduced by 1 order of magnitude, suggests that aggregates may be responsible for release from gel phase liposomes. A previous study of **1** and **2** as agents for promoting the transport of Na^+ across fluid bilayers has shown that two PFAs combine to form a pore (*28*, *30*). If the release of sucrose is favored in fluid regions of the membrane under thermal-gating conditions, then a similar pore structure may be involved.

The fact that the maximum amount of sucrose, which is released under thermal gating conditions, is dependent on temperature and that repetitive heating/cooling cycles at a fixed temperature in the gel/fluid coexistence region barely increase the extent of this release indicates that there is heterogeneity among the liposomes; that is, some of liposomes release their contents at a given temperature while others do not. The origin of this heterogeneity is not presently clear. One model that can be considered is based on the following assumptions: (i) the PFAs are nonuniformly distributed among the liposomes; (ii) the effective concentration of a PFA within a liposome is determined by its total concentration in the membrane and by the fraction of the membrane that has been converted into the fluid phase; (iii) those PFAs that reside in gel regions of the membrane do not form pores at sufficiently low concentrations; (iv) small aggregates of PFAs are formed in fluid regions, and it is these pores that are responsible for thermally gated release. Thus, at a given temperature in the gel/fluid coexistence region, some of the liposomes have a sufficient concentration of PFA in fluid regions to form pores, which release sucrose. As the temperature is increased and a greater percentage of the membranes are melted, the concentration of PFAs in fluid regions is then increased and the release of sucrose from those liposomes containing lesser amounts of PFA is possible.

The finding that less than 100% of sucrose is released even at 43 °C (under thermal gating conditions) is consistent with a nonuniform distribution of PFAs among the liposomes. The fact that at 43 °C, 100% release was found using 0.1 mol % of **1**, slightly less than 100% release was found using 0.15 mol % of **2**, and significantly less than 100% release was observed using **3** suggests that the larger PFAs are more efficient in releasing sucrose, if one assumes that their distribution among the liposomes is similar. From an operational standpoint, the fact that 0.015 mol % of **2** shows thermal gating behavior that is very similar to that found with 0.3 mol% of **3** indicates that a main virtue of the use of larger PFAs is that much lower concentrations can be employed.

Studies that are currently in progress are aimed at determining (i) the size of the pores that are created under thermal gating conditions by examining the release of entrapped sugars of varying size and (ii) whether aggregates of such amphiphiles

produce pores when these membranes have been converted to the fluid phase by means of kinetic measurements (*30*).

CONCLUSIONS

Experimental evidence has been obtained showing that PFAs **1**, **2**, and **3** are fully bound to gel-phase liposomes made from DPPC/DPPG (95/5, mol/mol), that transfer of a PFA from gel phase liposomes to fluid phase analogues is negligible, and that thermally gated release is sensitive to both the size and the concentration of the PFA that is used. Relatively high concentrations of PFAs favor the release of entrapped sucrose from gel phase liposomes, suggesting that aggregates may be responsible. An increase in the extent of sucrose release with increasing temperatures within the gel/fluid coexistence region has also revealed heterogeneity among the liposomes. The question of whether thermally gated release is favored in the fluid phase or the gel/fluid coexistence region has not been answered unambiguously, although the present findings suggest that the fluid phase may be more likely.

SUPPORTING INFORMATION

Experimental Section

General Methods. Unless noted otherwise, all chemicals and reagents were obtained from Sigma-Aldrich (St. Louis, MO) and used as obtained. 1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine and 1,2-dipalmitoyl-*sn*-glycero-3-[phospho-*rac*-(1-glycerol)]) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL) as dry powders and used directly. Stock solutions of DPPC (10 mg/mL) and DPPG (0.51 mg/mL) were prepared by dissolving DPPC (400 mg, 545 μmol) and DPPG (20.3 mg, 27 μmol) in 40 mL of chloroform/methanol (2:1, v/v). Conjugates **1**, **2** and **3** were synthesized using methods similar to those previously described (*1,2*). House-deionized water was purified using a Millipore Milli-Q filtering system containing one carbon and two ion-exchange stages. The PBS buffer that was used in all experiments (0.1 M NaCl and 0.01 M NaH_2PO_4, pH 7.4) was prepared by dissolving commercially available NaCl (23.4 g, 400 mmol) and NaH_2PO_4 (4.8 g, 40 mmol) in 4 L of deionized water, and adjusting the pH to 7.4 with 0.1 M HCl and 0.1 M NaOH solutions. An Orion Triode™ pH electrode that was purchased from Thermo Fisher Scientific (Beverly, MA) was used for pH adjustments. Thin layer chromatography (TLC) was performed on glass plates coated with 0.25 mm silica gel (60Å pore size, cat. no. 57457-100) obtained from VWR (West Chester, PA) (*3,4*). Osmotic pressures were measured using a Precision Systems Model 2007 Osmometer

from Thomas Scientific (cat. no. # 7180B10). Densitometry analyses were carried out using Scion Image software (*5*). A Digital 2-Block Model 125DQ Dry Bath Incubator (cat. no. 11-715-125DQ) that was used for thermal-gating was purchased from Fisher Scientific (Pittsburgh, PA). Particle sizes were determined by dynamic light scattering measurements using a Nicomp Model 270 Submicron Particle Sizer (Pacific Scientific, Santa Barbara, CA). The temperatures inside the tubes that were used for thermal-gating were monitored using a digital thermometer (VWR, cat. no. 12777-842) with 0.1 ºC readability.

Preparation of Liposomes. Typically, 2 mL of a stock solution of DPPC/DPPG (95:5, mol/mol) was transferred to a 10 mL glass tube, and the following amounts of pore-forming agents were added as methanol solutions: 1 mL of compound **1** (0.16 mg/mL, 0.1 mol%), 388.4 μL of compound **2** (0.404 mg/mL, 0.15 mol%), or 455 μL of compound **3** (0.317 mg/mL, 0.3 mol%). The solvents were then removed under a stream of nitrogen by rotating the test tube, and the resulting thin film of lipid dried for 12 h under reduced pressure (0.1 Torr). For thermally-gated release experiments, a 100 mM sucrose solution in PBS buffer was used to form multilamellar vesicles (MLVs) instead of pure PBS. Typically, 2 mL of PBS buffer was added to a given tube and the lipids dispersed by vortex mixing to give a final concentration of DPPC equalling 10 mg/mL. The MLVs were then frozen in liquid nitrogen and warmed to 65°C. This freeze/thaw cycle was repeated an additional four times. The dispersion was then extruded ten times through 400 nm Nucleopore membranes (Whatman Nuclepore; Clifton, NJ), followed by ten extrusions through 200 nm Nuclepore membrane using a gas pressure assisted extrusion devise with the temperature of the system that was maintained at 65 ºC.

Calorimetric Measurements. High-sensitivity differential scanning calorimetry (*hs*-DSC) measurements were made using a MC-2 calorimeter from MicroCal (Northampton, MA) in the heating scan mode with a 30ºC/h heating rate. This instrument was interfaced to a PC computer via the DA-2 digital system that was supplied by Microcal Inc. The sample cell was filled with ca. 1.3 mL of phospholipid dispersion with a lipid concentration of 1.6 mg/mL; the reference cell was filled with a corresponding buffer solution. Excess heat capacities, ΔC_p, are given with respect to the reference as evaluated by the software package provided by Microcal Inc. Each sample was scanned at least five times. No significant differences were noticed among each of the scans.

Phospholipid Analysis. Phospholipid concentrations were determined using methods similar to those described by Stewart (*6*). In a typical analysis, 50 µL of a given dispersion was added to a 1.5 mL Eppendorf safe-lock micro polypropylene tube followed by 200 µL of an ammonium ferrothiocyanate solution (containing 0.1 M ferric chloride hexahydrate and 0.4 M ammonium thiocyanate). After shaking for 10 min, 200 µl of chloroform was added followed by 20 s of vigorous vortexing. The chloroform layer was then carefully transferred to a glass optical cell and the absorbance measured at 485 nm. Control experiments showed that there was no interference by sucrose.

Analysis of Sucrose. Specific methods that were used for sugar analysis were similar to those described in the literature, using a freshly prepared stock of digestion solution for experiments carried out at 37°C and at 43°C (*7*).

Binding of PFAs to Gel Phase Liposomes. Liposomes that were used in these experiments were prepared as described above. Typtically, a 2 mL dispersion containing

a given PFA was divided into two equal portions. The first portion was frozen in liquid nitrogen and lyophilized to determine PFA/DPPG ratios before gel filtration. The second portion was gel-filtered using a disposable PD-10 column that was filled with 8.5 mL of Sephadex G-25 (VWR, cat. no. 95017-001), which had been equilibrated with PBS buffer. Before use, the PD-10 columns were allowed to drain until the flow was stopped by a polypropylene frit. Then, the second portion of liposomes (1 mL) was loaded onto the column, followed by addition of PBS buffer (9 mL, 3 mL at a time), and 2 mL-fractions were collected. The phospholipid dispersion that was recovered in the void volume was frozen in liquid nitrogen and lyophilized. To the lyophilized residue was added 200 µL of chloroform/methanol (2/2, v/v) and the sample then sonicated (bath-type) for 1 h, followed by centrifugation. The resulting solution was decanted, concentrated with a stream of nitrogen to approximately half of its original volume and centrifuged. Aliquots of the resulting clear solutions were deposited onto TLC plates using a 1 µL disposable Drummond micropipette (VWR; cat. no. 53440-001). The TLC plates were then developed with chloroform/methanol/water (6/4/1, v/v/v). Detection was made using a reagent that was prepared by adding, sequentially, $MnCl_2 \cdot 4H_2O$ (0.2 g) and concentrated H_2SO_4 (2 mL) to a solution made from 30 mL of water and 30 mL of methanol that was cooled by an ice-water bath. The thin layer chromatography plates were developed by immersing them into this solution and removing the excess solution with polyethylene sorbent pads (VWR, cat. no. 56616-380). The plates were then heated to 220°C for 2 min and cooled to room temperature. Analysis of DPPC, DPPG, and PFA was then made by densitometry. Images of the TLC plates were recorded with 300 dpi resolution in the grey scale mode (8 bits) using a digital scanner, and saved in the BMP

(bitmap) file format. The integrated densities of TLC chromatographic spots were analyzed by the Scion Image software by comparing integrated densities of the corresponding areas (5).

Attempted Transfer of 3 from Gel Phase to Fluid Phase Liposomes. A liposomal dispersion that was made from DPPC/DPPG (95/5, mol/mol) and 0.3 mol% **3** was centrifuged two times (10000 rpm, 5 min, rt) prior to use in this experiment. A separate batch of liposomes was prepared from POPC in PBS buffer in MLV form using methods similar to those described above for DPPC/DPPG. After a 1.5 mL portion of these MLVs (20 mg of total lipid/mL) was pelleted by centrifugation (10000 rpm, 5 min, rt), and the supernatant completely removed by careful decantation, 1.5 mL of the extruded liposomes made from DPPC, DPPG, and **3** were added. The mixed liposomal dispersion was stirred, gently, for 16 h at 37°C. After this incubation period, the MLVs were pelleted by centrifugation (10000 rpm, 20 min, rt), and the supernatant frozen in liquid nitrogen and lyophilized. The residue was dissolved in 200 μL of $CHCl_3$/MeOH (2:1, v/v) with bath sonication, centrifuged and decanted. The resulting solution was concentrated with a stream of nitrogen to approximately half of the original volume and centrifuged. The PFA content of the clear solution was then quantified by TLC with respect to the DPPG concentration as described above. Typical R_f values were DPPC (R_f 0.22), DPPG (R_f 0.31), **3** (R_f 0.33) using chloroform/methanol/water (6/4/1, v/v/v) as the eluent.

Thermally-Gated Release of Sucrose. In these experiments, sucrose was entrapped within extruded liposomes by including it in PBS buffer. Removal of non-entrapped sugar was carried out by gel filtration (Sephadex G-25) where the liposomes were

collected in the void volume (determined by the Blue Dexran). Prior to these filtrations, the columns were equilibrated and washed with four void volumes of osmotically-compensated PBS buffer, which took into account the increase in osmolarity due to the presence of sucrose. Specifically, 3.9 g (67 mmol) of NaCl was added per 1 L of PBS buffer. Following the gel-filtration step, the size of liposomes was monitored by dynamic light scattering.

Thermally-gated release experiments were carried out by rapidly heating 1.2 mL of a given dispersion from room temperature to a desired temperature (typically 37°C or 43°C) and withdrawing 90 μL aliquots using a single channel micropipettor at 2 min time intervals. These aliquots were immediately applied to the gel-media (analytical spin-columns; Handee,™ Mini-Spin Columns from Pierce Biotechnology, Rockford, IL), which were equilibrated with osmotically-balanced buffer. The spin-columns were then centrifuged two times (10000 rpm, rt), each with the duration of 1 min. For these gel filtrations, spin-columns columns were filled with Sephadex G-50. An Eppendorf 5415C Micro Centrifuge was used for these gel filtrations. The amount of sucrose that was retained by the liposomes was quantified by spectrophotometry after digestion using procedures described above. The percentage of sugar release was calculated according to the formula: % release = $(I_0\text{-}I_t)/I_0 \times 100$, where I_o is the sugar content of unheated samples that were gel filtered, and I_t is the sugar content of heated samples at the different time intervals. In all cases, the fractions that were collected were monitored for phospholipid recovery using a standard Stewart assay and were typically greater than 95%.[6] Specific values for the phospholipid recovery were used to correct for the extent of carbohydrate release.

Photographs of TLC plates used for densitometry of PFAs (i) before and (ii) after gel filtration for (A) **1**, (B) **2** and (C) **3**, respectively; lane (iii) shows the migration of only the PFAs. The order of elution was PFA> DPPG > DPPC, using $CHCl_3/CH_3OH/H_2O$ (6/4/1) as the eluent.

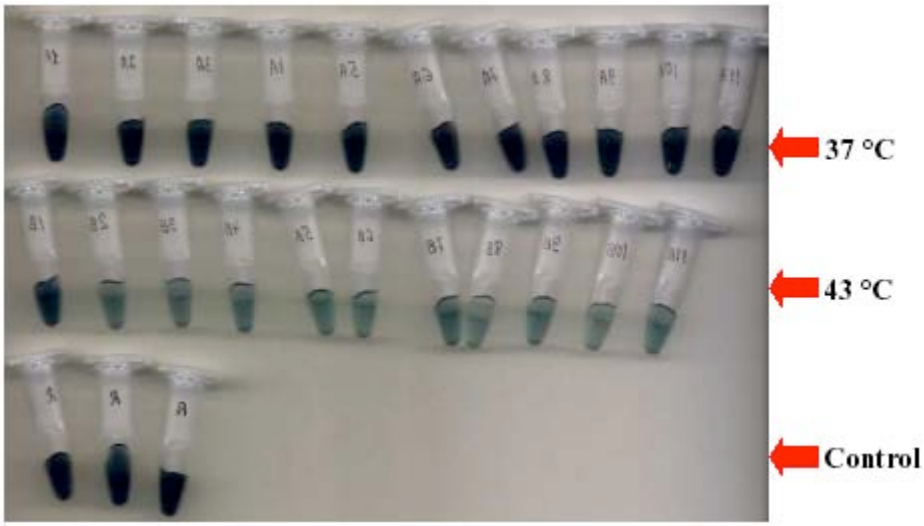

Figure S2. Release of sucrose as a function of time from liposomes made from DPPC/DPPG (95/5, mol/mol) containing 0.015 mol% of **2** at 37°C and at 43°C. Each microtube shows an aliquot of the dispersion that was taken after 2-minute intervals (starting from the left side of each row), gel filtered and digested using an anthrone-sulfuric acid reagent. The microtubes shown in the bottom row were samples that were not heated.

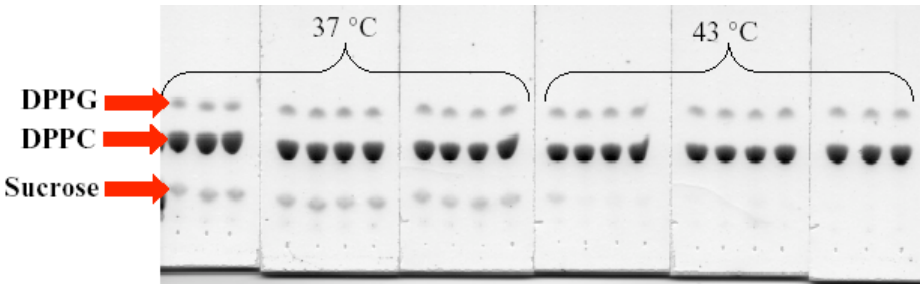

Figure S3. Release of sucrose as a function of time from liposomes made from DPPC/DPPG (95/5, mol/mol) containing 0.015 mol% of **2** at 37°C and at 43°C. Each lane shows an aliquot that was taken after 2-minute intervals (starting from the left side of the photograph), gel filtered, and developed on the TLC plate. The PFA is not readily visible in this photograph due to the very low concentration that was used.

Guanidinylated Polyethyleneimine−Polyoxypropylene−Polyoxyethylene Conjugates as Gene Transfection Agents

Conjugates of linear and branched polyethyleneimine (PEI) and monoamine polyether Jeffamine M-2070 (PO/EO mol ratio 10/31, 2000 Da) were synthesized through polyether activation by cyanuric chloride followed by attachment to PEI and guanidinylation by 1*H*-pyrazole-carboxamidine hydrochloride. The resulting guanidinylated PEI−polyether conjugates (termed gPEI−Jeffamine) efficiently complexed plasmid DNA, and their polyplexes possessed enhanced colloidal stability in the presence of serum proteins. *In vitro* studies with mammalian CHO-1, 3T3, and Cos-7 cell lines demonstrated improved transfection efficiency of the pCMVβ-gal plasmid/gPEI−Jeffamine polyplexes. The guanidinylation of the amino groups of PEI and the conjugation of PEI with the Jeffamine polyether enhanced the conjugates' interaction with genetic material and reduced the cytotoxicity of the polyplexes in experiments with the L929 cell line.

INTRODUCTION

The polyethylenimine (PEI) family of polymers of varying molecular weight and branching has evolved into the polycations most frequently applied in the field of polymer-assisted gene transfer. Because of its high ion-exchange capacity and affinity toward protons, PEI can promote the escape of the genetic material to the cytosol from endosomes via the proton sponge effect, and significant DNA transfer efficiency can be observed *in vitro* and *in vivo* (*1*−*5*). Polyplexes based on high molecular weight PEI are typically much more potent as well as more toxic than those of low molecular weight PEI (*6*). In general, the transfection efficiency of PEI polyplexes remains rather low compared to that of viral vectors. Several recognized traits have been noted that could explain the deficiency of the polymer vectors versus viral ones. Polyplexes of high-molecular weight PEI have low colloidal stability and show considerable *in vivo* toxicity (*7*). Also, such polycations have a relatively weak affinity to DNA, resulting in the formation of polyplexes that are readily dissociated under physiological conditions. The buffer capacity of polycations may be hampered by their facilitated protonation due to the zipper effect of the neighboring group during the complexation process with DNA (*8*). An approach toward improvement of the PEI transfection efficiency and decrease in its cytotoxicity has been actively pursued that involves covalent attachment of hydrophilic and biocompatible polymers such as poly(ethylene glycol) or poly(ethylene oxide) (PEO) onto PEI (*9*−*11*). Polyplexes of PEO-modified high-MW PEI show decreased cytotoxicity and improved colloidal and serum stability. However, the steric repulsion and competition for water between PEO and other hydrophilic surfaces often result in a diminished transfection due to decreased cellular association and internalization (*6*). A variation of the PEI modification by PEO route is a recent trend toward the utilization of polycations modified by conjugation with self-assembling block copolymers of PEO and poly(propylene oxide) (PEO-PPO-PEO, trade name Pluronic) in gene delivery (*12*−*16*). Self-assembling, colloidal properties such as surface activity, micellization, ability to bind biological membranes, and favorable hydrophilic−lipophilic balance of the Pluronic-polycation conjugates enhance the transfection efficiency both *in vitro* and *in vivo* and provide a favorable biodistribution of the transfected DNA. The presence of the hydrophobic PPO block in Pluronics tends to enhance the stability of the complex between the polycation and the DNA. In the present study, we adopted an approach toward PEI modification similar to that with Pluronics, but chose a diblock PEO-PPO copolymer with a rather short PO_6 chain in the hope of stabilizing the polyplex with multiple PPO chains, yet without excessive association capability that could result in the binding of several polyplex particles together into large aggregates that would impede gene transfer. From a synthesis standpoint, the monoamine Jeffamine polyether is preferable over Pluronic, which needs to be additionally modified at its hydroxyl termini if multifunctional conjugates are to be obtained. Furthermore, in the present work the PEI−Jeffamine conjugates were guanidinylated with the goal of lowering conjugate cytotoxicity.

MATERIALS AND METHODS

Materials. Polyethyleneimine, end-capped by ethylenediamine (PEI1, average M_w ~800 by LS; average M_n ~600 by GPC), branched polyethyleneimine (PEI2, nominal M_n ~10 kDa by GPC; M_w ~25 kDa by LS), triethylamine (99.5%), 1-naphthol-4-sulfonic acid (sodium salt), L-arginine (98%), 2′-(4-hydroxyphenyl)-5-(4-methyl-1-piperazinyl)-2,5′-bi-1*H*-benzimidazole hydrate (Hoechst 33258 Dye), trihydrochloride 1*H*-pyrazole-carboxamidine hydrochloride (99%), 2,4,6-trichloro-1,3,5-triazine (99%, cyanuric chloride, or C-Cl), *o*-nitrophenyl-β-D-glucopyranoside (>99%), human male serum, fetal bovine serum

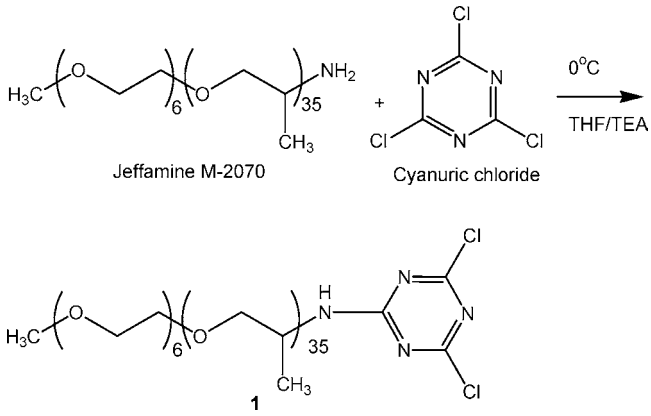
Scheme 1. Activation of the Jeffamine Polyether by Cyanuric Chloride (C-Cl)

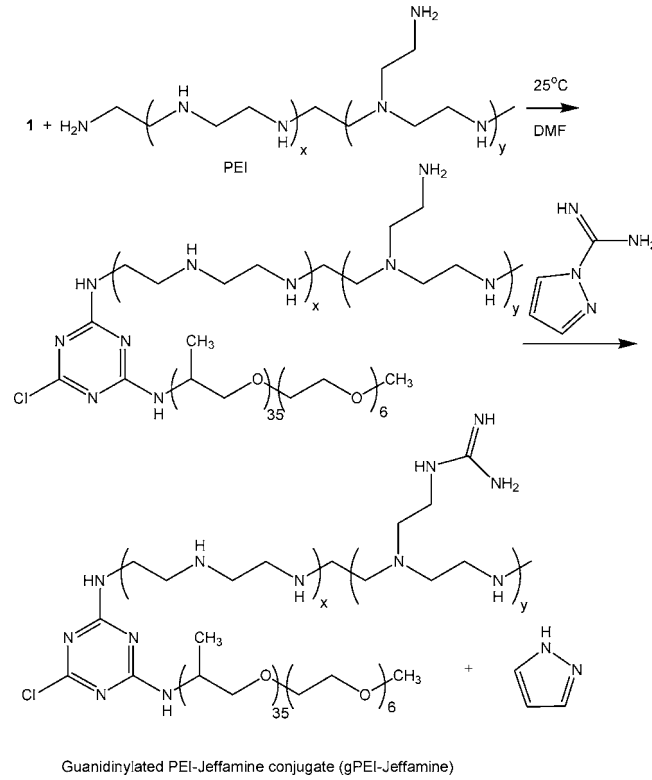


(FBS), 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid, sodium salt (HEPES, 99%) and DNA, sodium salt from salmon testes were purchased from Sigma-Aldrich Co. (St. Louis, MO). PEI2 was dialyzed against DI water (12−14 kDa MW cutoff), and its solution pH was adjusted to 7.5. After dialysis, the solution was lyophilized and dry polymer stored at −20 °C. Polyether monoamine, Jeffamine M-2070 (PO/EO mole ratio 10/31, 2000 Da) was obtained from Huntsman Chemical Corp. (The Woodlands, TX) and used as received. Ethidium bromide (EB) solution (1% in water) was supplied by Fluka (Switzerland). Luminiscent β-galactosidase reporter system 3 and pβgal-control vector were obtained from Clontech Takara Bio, Inc. (Japan). Plasmid DNA encoding β-galactosidase (pCMV-β), double-stranded DNA of pUC18 plasmid (2.7 kb) isolated from *E. coli* strain DH5α, and Lipofectamine 2000 reagent were obtained from Invitrogen Corp. (Carlsbad, CA). SuperFect Transfection reagent was obtained from Qiagen Inc. (Valencia, CA). Deuterated solvents were obtained from Cambridge Isotope Laboratories (Andover, MA), and all other chemicals were received from commercial sources and were of the highest purity available.

Polymer Syntheses. *Jeffamine Activation by Cyanuric Chloride (Scheme 1) (17).* A solution of Jeffamine M2070 (30 g, 15 mmol) in 100 mL of dry tetrahydrofuran was charged to a three-neck, round-bottom flask equipped with a magnetic stirrer, nitrogen inlet−outlet lines, and a thermometer, and the mixture was stirred on ice at 0−4 °C under nitrogen atmosphere. Then a powder of C-Cl (2.77 g, 15 mmol) was added, and the mixture was continuously agitated at 0−4 °C for 5 min followed by the addition of triethylamine (1.5 g, 15 mmol). Cloudiness due to the formation of a quaternary ammonium salt was observed at this point. The reaction was allowed to proceed for 8 h at 0−4 °C while stirring under nitrogen atmosphere. The flask was allowed to equilibrate at ambient temperature, the products were filtered through Whatman #5 filter paper, and the filtrate was concentrated using a rotary evaporator. The product (yield, ∼95 wt %) was stored at −80 °C. For elemental analysis, the product was dialyzed against DI water (MWCO, 500 Da) and lyophilized. ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 1.1$ (3H, methyl, β to -N, β to -C-R), 1.9 (1H, methine), 3.3−3.1 (2H, methylene; 3H, methyl α to -O-C), 3.55 (2H, methylene α,β to −O-C, β to -N-CR). Calcd for $C_{62}H_{120}Cl_2N_4O_{41}$: C, 45.17; H, 7.34; Cl, 4.30; N, 3.40. Found: C, 46.55; H, 8.11; N, 3.22.

Guanidinylation of PEI (18). Guanidinylation of PEI1 and PEI2 was accomplished in 15 wt % aqueous solutions of PEI with a known concentration of primary amino groups, wherein an equimolar amount of 1*H*-pyrazole-carboxamidine hydrochloride was added. The reaction was allowed to proceed at neutral pH for 24 h at room temperature under stirring; the products were exhaustively dialyzed against DI water (MWCO, 1 kDa) and lyophilized. Titration of guanidine groups in the gPEI and gPEI−Jeffamine copolymers was accomplished spectrophotometrically using the Sakaguchi reaction of guanidine with 1-naphthol-2-sulfonic acid and hypobromite (1% Br_2 v/v in 1.25 M NaOH) (*19*). Calibration curves were developed using L-arginine as a standard (*20*). Approximately 5 meq/g of guanidine groups were detected in either gPEI1 or gPEI2.

Scheme 2. PEI−Jeffamine Conjugation and Guanidinylation



PEI−Jeffamine Conjugation and Guanidinylation (Scheme 2). A solution of Jeffamine activated by C-Cl (10 g, 6 mmol) and PEI (9 g) in 50 mL dry *N*,*N*-dimethylformamide was stirred at room temperature for 24 h. The mixture was then dissolved in 50 mL of deionized water, dialyzed against excess water (membrane MWCO, 1 kDa), and lyophilized. For guanidinylation, the PEI−Jeffamine conjugate (4 g) was dissolved in 50 mL of water, 1*H*-pyrazole-carboxamidine hydrochloride (2 g, 13.6 mmol) was added, and the solution was kept at room temperature for 24 h while stirring. The product was exhaustively dialyzed against DI water (MWCO 1 kDa) and lyophilized. Yield, 75%. Calculated, on the basis of a 1:1 mol ratio of gPEI1/Jeffamine ($C_{180}H_{378}Cl_2N_{44}O_{82}$; mol mass 4.53 kDa): C, 47.60; H, 8.39; Cl, 1.56; N, 13.57; O, 28.88. Found, %: C, 48.31; H, 8.72; N, 14.12. ^{1}H NMR (400 MHz, D_2O): $\delta = 1.06$ (3H, methyl), 2.48 (2H, methylene, α to -N(C)C, β to -N-C), 2,55 (2H, methylene, α,β to -N, β to -N(C)C, β to -N-C), 3.4 (2H, methylene, α to -O-C, β to -C). For gPEI2−Jeffamine, the obtained elemental analysis (found, %: C, 50.14; H, 9.15; Cl, 0.94; N, 16.86) indicated a PEI molecule of ∼15 kDa conjugated with 12 residues of activated Jeffamine, with primary amino groups guanidinylated. The total calculated, nominal MW was 34.4 kDa. Calcd ($C_{1412}H_{3076}Cl_{12}N_{432}O_{492}$): C, 49.29; H, 9.01; Cl, 1.24; N, 17.59; O, 22.88. The experimentally measured molecular weights of gPEI1−Jeffamine and gPEI2−Jeffamine were 4.04 (Pd ∼1.67) and 28.1 (Pd ∼1.92) kDa, respectively, which correlated with the elemental analyses. The main properties of the PEI−Jeffamine conjugates are collected in Table 1.

Methods. Proton NMR spectra of polymer solutions in D_2O or $CDCl_3$ were acquired on a Bruker AMX400 spectrometer.

Table 1. Properties of gPEI−Jeffamine Conjugates

species	MW (kDa)	pK_a	Jeffamine content (meq/g)	guanidine group content (meq/g)
gPEI1−Jeffamine	4.04	11.1	0.44	1.3
gPEI2−Jeffamine	28.1	11.6	0.35	1.9

The copolymer MW was measured in DMF using a Hewlett-Packard series 1100 HPLC system as described previously (*21*). Potentiometric titration was performed at 25 ± 1 °C using a 736 GP Titrino potentiometric titration system (Metrohm Ltd., Herisau, Switzerland) as described previously (*22*).

Preparation of DNA−Polymer Complexes. A stock solution of a cationic polymer of known concentration was added dropwise to a stock 10 μg/mL solution of double-stranded plasmid cloning vector pUC18 (2686 bp, 1.74 MDa) in 10 mM HEPES buffer (pH 7.4). Then the mixture was vortexed for 2−3 s and left at room temperature for 0.5 h for equilibration. Throughout this work, we used the total molar concentration ratio of nitrogen atoms in the polycation (N) to the phosphate groups (P) in the DNA as the metric characteristic of the complex formation. An average molecular weight per nucleotide of 324.5 g/mol PO_4^- (*23*) and the percentage in N of the copolymers obtained by elemental analysis were used to calculate the N/P molar ratio. Thus, suspensions of known concentrations and N/P ratios were obtained. To visualize complex formation, a fluorometric dye exclusion assay was performed using Hoechst 33258 dye. Fluorescence emission by DNA and dye solutions was measured using a TimeMaster Fluorescence Spectrometer (Photon Technology International, Inc.) before and after polymer solution addition.

Dynamic Light Scattering (DLS). Dynamic light scattering (DLS) experiments were performed with a Brookhaven BI-200SM light scattering system (Brookhaven Instruments Corp.) at a measurement angle of 90° and 37 °C. Number-average particle size distributions were obtained using the built-in software, and the reported particle mean hydrodynamic diameters are the average of five measurements, each conducted for 1 min. All samples dispersed in aqueous 10 mM HEPES buffer (pH 7.4) were filtered with a 0.45 μm syringe filter followed by equilibration at 37 °C prior to the DLS tests.

ζ-Potential Measurements. All ζ-potential measurements were performed using a Brookhaven ZetaPALS ζ-potential analyzer (Brookhaven Instruments Corp.). The Smoluchowski equation was used to calculate the ζ-potential from the electrophoretic mobility. The reported ζ-potential values are an average of 5 measurements, each of which was obtained over 25 electrode cycles. Measurements were conducted in triplicate at 25 °C in 10 mM HEPES buffer at pH 7.4. Standard deviations are shown.

Titration Microcalorimetry. Calorimetric experiments were performed in duplicate using a Tronac-450 isoperibol microcalorimeter equipped with Tronac FS101 calorimetry software (Tronac Inc., Orem, UT). In each experiment, a copolymer solution (0.16% w/w in pH 7.4 phosphate buffer, 47.5 mL) was placed in a Dewar reaction vessel, and a relatively concentrated salmon DNA solution (0.75% in pH 7.4 phosphate buffer) was loaded into a 2 mL calibrated buret. The entire assembly was then immersed in a water bath equilibrated at 310.0 K. After thermal equilibration, the DNA solution was delivered at a constant rate of 0.33 mL/min into the reaction vessel, wherein a stirrer rapidly mixed the two solutions. This approach leads to a minimum dilution of the copolymer and, thus, to the release of less ionization energy. In the experiments carried out in a reverse way, i.e., by adding a concentrated copolymer solution (4%) into the dewar containing 0.03% DNA, the ionization energy during the addition of the polycations was so high that it completely hindered the quantification of the energy of interaction between the copolymer and DNA. Previous studies of the interaction of branched and linear PEI with DNA using isothermal titration calorimetry (ITC) have reported similar difficulties (*24*). The temperature change in the system was monitored using a thermistor and later reproduced using a heating coil in the reaction vessel. The apparent enthalpy was calculated from the applied current and voltage, and heating time. A buffer solution was used as a blank instead of the DNA dispersion. The system was calibrated by titration of tris(hydroxymethyl)aminomethane with HCl. The integral binding heat for the polymer/DNA interaction (Q_{agg}) process was estimated by subtracting from the measured heat produced by the addition of DNA to the copolymer solution (Q_p) the heat effects due to the dilution/ionization of the copolymer in the buffer solutions used as a blank (Q_d) (*25*):

$$Q_{agg} = Q_p - Q_d$$

The enthalpies of DNA dilution and Jeffamine/DNA interaction were negligible.

Ethidium Bromide Displacement Assay. Aliquots of PEI or gPEI−Jeffamine solutions were added within a given range of N/P ratios to 5 mL of solutions of salmon DNA (0.06%) and EB (0.03%) in phosphate buffer (pH 7.4). The systems were diluted with buffer medium up to 10 mL. The final concentrations of cationic polymer ranged from 0.0024% to 0.010 wt %. The samples were stirred overnight in the dark and stored at 20 °C. The EB emission spectra were recorded with a Fluoro-Max2 spectrofluorometer (HORIBA Jobin Yvon, Irvine, CA). The excitation and emission wavelengths were 545 and 596 nm, respectively. Solutions of DNA (0.03%) and EB (0.015%) containing approximately 2 EB molecules per 5 base pairs were used as a blank (*26*).

Transfection Studies with CHO-K1 Cells. Chinese hamster ovary cells (CHO-K1) obtained from the American type Culture Collection (Manassas, VA) were grown in DMEM Ham's F-12 Nutrient Mixture supplemented by 10% FCS (both from Invitrogen). The cells were seeded in a 24-well plate (Nunc, Denmark) one day prior to the transfection at a density of 1×10^5 cells/cm^2 in 500 μL of the growth medium. The cells were 90−95% confluent at the time of transfection. Stock solutions of PEI2 and gPEI2−Jeffamine were prepared in Dulbecco's modified Eagle's medium (DMEM, D-2902, Sigma-Aldrich). The plasmid/copolymer complexes were prepared by diluting 1.6 μL of pβgal-control vector solution (500 ng/μL) in DMEM to 50 μL followed by dropwise addition of 50 μL of copolymer solution of appropriate concentration to obtain a N/P ratio of 4 or 6. The complexes were incubated at room temperature for 20 min. The cells were then transfected with pβgal-control vector for β-galactosidase expression following the manufacturer's protocol developed for Lipofectamine 2000. Solutions of either Lipofectamine/plasmid or copolymer/plasmid complexes (100 μL) were added to each well, containing cells with 500 μL of fresh growth medium supplemented by 10% FCS. After 5 h in contact with the polyplexes, the medium was replaced by DMEM Ham's F-12 Nutrient Mixture supplemented by 10% FCS and the cells further incubated at 37 °C in a CO_2 incubator (NuAire Inc., Plymouth, MN) for 48 h. Then, the cells were rinsed with PBS and lysed using a detergent solution according to the protocol described by the manufacturer. β-Galactosidase expression was quantified by chemiluminescent assay using a plate luminometer (ULTRA Evolution Multi-Detection Microplate Reader, Canada) recording light signals as 5-s integrals. Cell viability after transfection was confirmed by observation using an inverted microscope. Negative controls were prepared by adding pβgal-basic vector to the cell lysate from untransfected cells. The average value obtained for three negative controls was subtracted from each experimental result. Positive controls were prepared by adding bacterial β-galactosidase to the cell lysate obtained from intact cells.

Transfection Studies with 3T3 Cells. Cytomegalovirus-β-galactosidase plasmid (pCMVâ-gal, 7.2 kbp, Clontech, Mountain View, CA), which contains the human CMV promoter and the *E. coli* β-galactosidase gene, was utilized in the *in vitro* transfection study. *In vitro* transfection studies were conducted with 3T3-Swiss albino mouse embryo fibroblast cells (ATCC CCL-92) grown for 24 h in 24-well plates (2×10^4 cells/well) in DMEM supplemented with 10% fetal bovine serum, 100 mM L-glutamine, and 100 mM antibiotics (penicillin, streptomycine, and amphotericin B) at 37 °C and 5% CO_2. For complex preparation, the amount of DNA was kept constant at 0.6 μg, and the amount of polycation stock solution added was varied at the required N/P ratio. Plasmid DNA/polymer suspensions in the medium containing 10% human serum were added to the cells (100 μL/well). Transfection with polymers of the present study was compared to that using SuperFect cationic polyamidoamine dendrimer solution (*27*). The N/P ratio for SuperFect was calculated according to the manufacturer's protocols. The cells were incubated for 24 h, washed with PBS three times, and lysed by three freezing and thawing cycles. The β-galactosidase Enzyme Assay System kit (Promega, Madison, WI) combined with a BCA Protein Assay Reagent kit (Bio-Rad Laboratories, Inc., Richmond, CA) were used for assaying β-galactosidase activity in lysates prepared from the transfected cells following the assay protocol from the manufacturer. The β-galactosidase activity was determined against *o*-nitrophenyl-β-D-glucopyranoside (ONPG) as a substrate of the enzyme. The ONPG solution was added to the cells and incubated at 37 °C for 2 h; then the reaction was stopped by the addition of 1 M sodium carbonate solution. The enzyme activity was characterized by the appearance of the yellow-colored *o*-nitrophenol product assayed spectrophotometrically ($\lambda_{max} = 420$ nm, $n = 6$) (*21*). Untreated cells that did not undergo transfection were taken as a control.

Transfection Studies with Cos-7 Cells (28). African green monkey kidney fibroblast-like Cos-7 cells, SV40-transformed, ATCC CRL-1651 (Sigma-Aldrich Co.) were cultured in DMEM supplemented with HEPES (20 mM), penicillin (100 μU/mL), streptomycin (100 μg/mL), and FBS (0%). The day before transfection, cells were seeded in 12-well plates (2×10^4 cells/well) in complete culture medium. The cells were incubated with the polyplexes of tested polycations with the plasmid pCMV-LacZ (pCMV-βgal), which contained a CMV promoter to drive β-galactosidase (LacZ) gene expression, in the absence or presence of 10% FBS, at 37 °C and under a humidified 5% CO_2 atmosphere. After 3 h, the excess complexes were removed, and the cells were washed with DMEM and were further cultured for 24 h in culture medium with 5% serum. In order to evaluate β-galactosidase expression, cells were washed twice with PBS and lysed with the Mammalian Protein Extraction Reagent (Thermo Scientific Pierce, Rockford, IL). ONPG, the β-galactosidase substrate (100 μL, 4.4 mM) was mixed with 100 μL of cell lysates and incubated at 37 °C. After 30 min, absorbance (415 nm) was measured. For each sample, protein concentration was determined according to the Bio-Rad Protein Assay protocol using BSA as a standard. Positive control experiments were performed with the same plasmid and cell line using Lipofectamine 2000 according to the Invitrogen protocols. Results are expressed as relative transfection efficiency, i.e., absorbance units observed with a particular polyplex divided by absorbance observed with Lipofectamine (*21*). The results are presented as the mean ± standard deviation of quadruplicate determinations.

Cytotoxicity Assay with the Mammalian Cell Line. Cell line L929 (ATCC CCL-1) derived from normal subcutaneous areolar and adipose tissue of a male C3H/An mouse (Sigma-Aldrich) was used for the evaluation of polymer cytotoxicity. The cells were grown without the addition of antibiotics in Eagle's minimum essential medium supplemented by 10% fetal bovine serum (FBS, Invitrogen Corp). The MTT cytotoxicity assays (Mosmann's test) were performed as follows (*29*). The L929 cells were seeded onto 96-well cell culture plates, 0.1 mL/well, at a density of 10^6 cells/mL to reach >80% confluence. At 24 h after seeding, 0.1 mL of fresh medium and pUC18 plasmid DNA/polymer solutions of known concentrations (DNA content, 10 μg; N/P ratio maintained at 6.0 throughout) pre-equilibrated at 37 °C in the cell medium were added. Six replicate wells per concentration were tested. After 36 h of incubation in a humidified atmosphere of 5% CO_2/95% air at 37 °C, the medium was removed, and the wells were washed twice for 2−3 min with 0.2 mL of the fresh medium. Then, the fresh medium containing 0.5 mg of MTT (0.1 mL) was added at 37 °C and kept in the wells for another 4 h. The yellow tetrazolium salt is reduced in viable cells to a blue formazan product. After incubation, the media were completely removed, the cells were washed carefully with two washes of PBS (0.25 mL) for 3 min, and the solutions were aspirated. Cell-incorporated NR dye was extracted by adding 0.2 mL of 1% (v/v) acetic acid/50% (v/v) ethanol, and the blue formazan product was dissolved in 0.2 mL of 0.04 M HCl in 2-propanol. The plates were agitated on an orbital shaker for at least 1 h in order to ensure quantitative extraction and dissolution of the dyes. The optical density of each well was measured spectrophotometrically at 570 nm using a Bio-Rad Benchmark Plus Microplate Reader (Bio-Rad Laboratories, Hercules, CA), and the data were normalized by subtracting the background absorbance at 655 nm. The results were expressed as a percentage of the viability versus control (L929 cells not exposed to the test solution or dispersion). All experiments were performed three times in the independent measurements. The Student's statistical test (unpaired *t*-test) was used for statistical calculations. Probabilities of correlation using the Pearson coefficient (p) considered p values below 0.05 as a statistically significant threshold.

RESULTS AND DISCUSSION

The present work deals with the polycationic conjugates specifically designed for an effective complexation between polycations and DNA, with the resulting polyplexes, hopefully of reduced toxicity, enabling DNA transfection and enhanced stability in the presence of plasma proteins.

The synthetic route of PEI modification via polyether activation and conjugation to the primary amino groups of PEI followed by guanidinylation is simple and utilizes commercially available polyethers. Conjugation of one amino terminus of Jeffamine to C-Cl in the process of activation is ensured by the proper choice of temperature (0−5 °C) (*17, 30*). The attained yields of the gPEI−Jeffamine conjugates (≥75%) are acceptable, with the losses occurring primarily during purification. Importantly, since the polyether chains were activated and conjugated at one terminus only, it was possible to avoid byproduct conjugates with alternating structures typical of bifunctional polyether segments. Unmodified PEO or PEO-PPO-PEO blocks cannot be attached selectively via a single terminus, unless a monosubstituted diol such as monomethoxy PEG is used. In contrast to the design employed in the present work, the products of bifunctional polyether conjugation need to undergo preparative separation from the bisubstituted products attached at both termini using preparative chromatography and the like, if conjugates of a well-defined composition are desired (*31*).

We assessed mechanisms of the conjugate−DNA interactions using microcalorimetric titrations and ethidium bromide (EB) assays to see whether the polycation−DNA electrostatic interaction is preserved while the polycation structure provides charge shielding with pendant polyether chains.

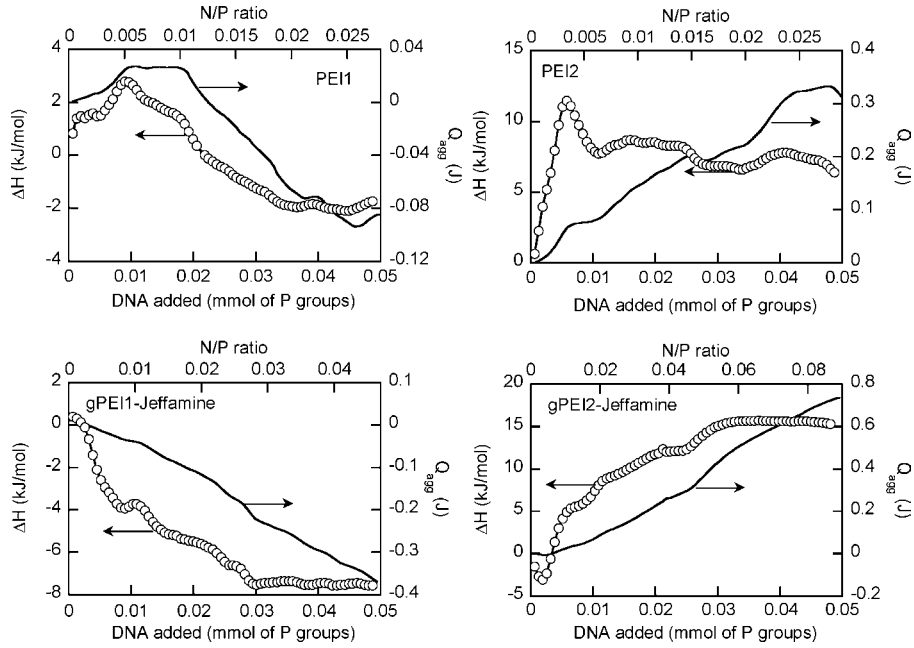


Figure 1. Calorimetric titration of 0.16% polycation solutions with 0.75% salmon DNA solution in 50 mM phosphate buffer at pH 7.4. The solid line and open points show the integral binding heat of the polymer/DNA interaction (Q_{agg}) and the interaction enthalpy of the copolymers, respectively.

Thermodynamics of Polycation−DNA Binding. Isoperibol titration calorimetry and EB fluorescence assay were used to compare the binding between the polycations under study and DNA. The energy plots shown in Figure 1 indicate that the binding of PEI1 to DNA is practically null; the enthalpy changes related to the process (+2.8 J/mmol and −2.0 J/mmol when 0.01 and 0.04 mmol DNA were added) are of the same magnitude as the thermal energy RT (2.6 kJ/mol). PEI1 is apparently too short for a cooperative binding with the DNA molecules. By contrast, guanidinylation and conjugation with Jeffamine rendered the resulting PEI1 conjugate (gPEI1−Jeffamine) capable of interacting exothermically with the DNA, the enthalpy of interaction being −7.6 kJ/mol. Binding of PEI2 and gPEI2−Jeffamine with DNA was an endothermic process accompanied by significant changes in enthalpy, 11.5 and 15.7 kJ/mol, respectively. In general, the energy of gPEI−Jeffamine interaction with DNA was greater, in absolute value, than that of the parent PEI. Condensation and aggregation above 0.04 mmol DNA (expressed via the phosphate group contents) led to a phase separation of the polyplexes from the solution. Both exothermic and endothermic interactions between polymers and DNA have been reported (*32*−*35*). The enthalpy values result from the combination of electrostatic interactions, protonation changes, and hydrogen bonding (*36*). ITC experiments carried out with 750 kDa PEI and plasmid DNA indicated that the binding process was exothermic and entropy-driven with an enthalpy of −2.7 kJ/mol (*37*). We have previously observed greater enthalpy changes with a block copolymer of poly[(2-dimethylaminoethyl)methacrylate] and PEO (−31 kJ/mol) or Pluronic P123 (45 kJ/mol) interacting with salmon DNA (*25*). Related, but neutral amphiphilic polyethers, such as tetrafunctional block copolymers of PEO-PPO bound to ethylenediamine (Tetronic), can also form polyplexes with DNA via hydrogen bonding as well as hydrophobic interactions (*38*). DNA and gPEI−Jeffamine act as hydrogen-bond donor and acceptor, respectively, and bind via hydrophobic, endothermic processes as well as via other (exothermic) events. The predominance of one or the other type of interactions, together with conformational changes that may accompany such interactions, determine whether the process is exo- or endothermic as a whole. The branched PEI2 is known to contain three different types of amino groups: secondary and tertiary amino groups in the main chain, and secondary and primary amino groups in the side chain. The ratio of primary-to-secondary-to-tertiary amino groups is 1:2:1 (*39*, *40*). However, PEI1 contains only secondary amino groups in the main chain, which is less sterically constrained than that of the branched PEI2 and readily undergoes conformational changes. Divergent exo- or endothermic processes have been recorded for branched and linear PEIs interacting with an anionic surfactant sodium dodecylsulfate, depending on the different conformations adopted by the PEI-surfactant mixed micelles (*41*). Analogously, the fact that gPEI1−Jeffamine led to an exothermic binding while gPEI2−Jeffamine led to an endothermic event may be explained, at least partially, to be due to different conformations adopted by the polyplexes. Furthermore, in the case of gPEI−Jeffamine polycations one should take into account the contribution of the guanidinium groups to the interaction with DNA. Titration experiments carried out with Jeffamine alone revealed no detectable binding with DNA. By contrast, it has been shown previously that positively charged guanidinium groups significantly enhance the capability of the imine-containing polymers to bind to the negatively charged DNA (*42*). The effect of guanidinylation is more significant for gPEI1−Jeffamine than for gPEI2−Jeffamine because the long PEI2 chains of the latter already bind DNA significantly even before guanidinylation. However, the unfavorable ΔH of PEI2 and of gPEI2−Jeffamine binding to DNA (endothermic process) is similar to the ΔH of +10 kJ/mol recorded for spermine and, as expected for electrostatic interactions, is compensated for by a favorable entropy change (*43*). It was not possible to achieve valid fits to common binding models for PEI and gPEI−Jeffamine because of the tendency for their complexes to aggregate. Therefore, neither an affinity constant nor the entropy change for the binding of PEI and gPEI−Jeffamine to DNA could be estimated. Analogous problems were reported previously with PEI and other strongly binding gene vectors (*24*, *43*). The enhancement of the binding observed with gPEI−Jeffamine compared to that of its parent PEI resembles the beneficial effect of the conjugation of Pluronic L92 to poly[(2-dimethylaminoethyl)methacrylate] (*21*, *25*). Similar to Pluronic, Jeffamine can facilitate the formation of polyplexes with a core−shell structure, in which

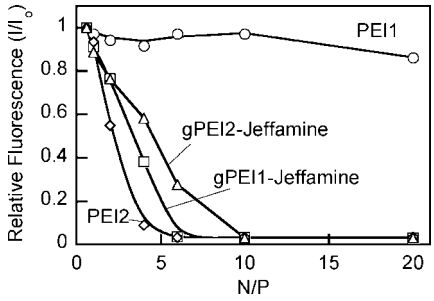

Figure 2. Ethidium bromide exclusion assay of 0.3 mg/mL salmon DNA solution in 50 mM phosphate buffer at pH 7.4.

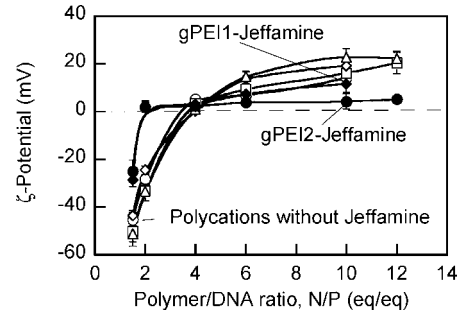

Figure 3. ζ-Potentials of the complexes formed between plasmid cloning vector pUC18 and polycationic copolymers as a function of the polymer/DNA (N/P) ratio at pH 7.4. Data points with PEI1, PEI2, gPEI1, gPEI2, gPEI1−Jeffamine, and gPEI2−Jeffamine are shown by open circles, open squares, open diamonds, open triangles, filled diamonds, and filled circles, respectively.

the shells are composed of PEO chains and ionized amino groups, while the cores comprise PPO blocks and neutralized DNA−PEI complexes (*25*). Such a notion is based on the P/N ratios at which the polyplex phase separation occurs and the Q_{agg} values level off (Figure 1). In the case of PEI2, a plateau was reached at a P/N ratio of 0.025. This ratio corresponds to 40 nitrogen atoms for each nucleotide, which means that most of the amine groups of PEI did not bind to the DNA effectively. In the case of the gPEI1−Jeffamine and gPEI2−Jeffamine copolymers, the plateau was observed at a P/N ratio of 0.03 (N/P = 33) and 0.06 (N/P = 16.7), respectively. These results indicate that the chemical modification of the PEI structure by the Jeffamine polyether facilitates the interaction with DNA, probably because of the enhanced solubility of the polyplexes that makes the amino groups of the copolymer more accessible to the nucleotides. This also explains the higher enthalpy values.

Ethidium Bromide Exclusion Assay. EB is a DNA intercalator that exhibits an increase in fluorescence intensity upon DNA intercalation. This fluorescence is reduced by EB competitors, such as polycations, via EB exclusion from its complex with DNA. Therefore, the ability of the polycation to reduce the EB fluorescence is used as a measure of the DNA−polycation binding strength. The results of the EB exclusion assay with the parent PEI1, PEI2, and their modified conjugates gPEI1−Jeffamine and gPEI2−Jeffamine are shown in Figure 2. The presence of PEI1 did not result in any appreciable change in the EB fluorescence, which is indicative of poor intercalation of the PEI1 and is in accord with the microcalorimetric results. In contrast, gPEI1−Jeffamine derived from the PEI1 polymer was quite effective in EB exclusion. The DNA binding strength, which is reported by the IC_{50} value (the N/P ratio of polymer necessary to inhibit 50% of the relative EB-DNA fluorescence) was estimated to be approximately 2.2, 3.5, and 4.5 for PEI2, gPEI1−Jeffamine, and gPEI2−Jeffamine, respectively. It is interesting to observe that the conjugation with Jeffamine slightly increased the IC_{50} for gPEI2−Jeffamine compared to that of its parent PEI2. Nevertheless, gPEI2−Jeffamine and all other polycations except for PEI1 quenched EB fluorescence completely at N/P = 10, indicating a strong polycation−DNA binding. The results of both the microcalorimetric experiments and EB fluorescence studies indicate that suitable N/P ratios for the polyplex formation with the polycations under study are in the range of 4 to 10 or higher. These ratios are in agreement with those previously found for polyplexes based on linear, 25 kDa PEI as well as branched 2 kDa, 25 kDa, and 750 kDa PEI (*24*).

Polyplex Stability in Water and in the Presence of Blood Components. Microcalorimetric titrations and the EB exclusion assays described above pointed to a strong complexation between the polycations under study (except for PEI1) and salmon DNA. In order to elucidate the effect of the PEI modifications on their ability to bind the plasmid DNA relevant for transfection, we conducted experiments with a double-stranded plasmid cloning vector pUC18 as a model, measuring the electrophoretic mobility and size of the polyplex particles. The effect of the polycation/DNA molar ratio (N/P value) on the polyplex ζ-potential in aqueous buffer (pH 7.4) is shown in Figure 3. At N/P ratios below 2, the polyplexes with polycations that were not modified with the polyether chains were strongly anionic, with ζ-potentials in the −45 to −35 mV range, whereas the presence of Jeffamine in the gPEI−Jeffamine conjugates reduced the charge somewhat (ζ-potential in the range of −30 to −25 mV). Pronounced aggregation and sedimentation of the polyplex particles was observed with PEI2, gPEI1, and gPEI2 in the N/P value range below 4. At N/P ranging from 6 to 12, where the polyplexes were positively charged, the polyplex particles were significantly more stable and possessed a number-average hydrodynamic diameter size in the 65−85 nm range. Modification of PEI with Jeffamine altered the colloidal behavior of the polyplexes. No precipitation of the gPEI−Jeffamine /DNA polyplexes was observed at a N/P ratio of 2, and a slight change of N/P from 1.5 to 2 afforded a dramatic shift from negatively charged (ζ-potential from −30 or −25 mV) to positively charged (ζ-potential approximately +2 mV) polyplex particles. The particles remained only slightly charged throughout the range of N/P ≤ 12, with the ζ-potential not exceeding +12 and +5 mV for gPEI1−Jeffamine and gPEI2−Jeffamine, respectively. This is in contrast to other polycations devoid of Jeffamine, polyplexes of which became significantly more charged at N/P > 6. These observations indicate the charge shielding by the PEO chains of Jeffamine, which probably comprise the hydrophilic, stabilizing shell of the polyplex. The sharp neutralization of the gPEI−Jeffamine chains by DNA (compare with the smooth negative-to-positive charge transition spanning 3.5 N/P units for all polycations devoid of Jeffamine) indicates enhanced cooperativity of the polycation−DNA binding. Overall, these observations are in agreement with the calorimetric results.

It has been demonstrated previously that the coagulation cascade proteins present in human serum can dramatically accelerate the aggregation of polycation−DNA polyplexes (*44*). Such an aggregation is highly undesirable for *in vivo* gene targeting and can be avoided through polycation conjugation with PEO chains of appropriate length and grafting density (*45*). It has been demonstrated that the presence of PEO-PPO-PEO triblock copolymer segments on the polycationic transfection vector provides polyplex stability in serum as well (*21, 46*). Herein, we extended an approach toward stabilization of the polyplexes by PEO-PPO polyethers by the use of Jeffamine, a $EO_{35}PO_6$ diblock. As is seen in Figure 4, the conjugation of gPEI with Jeffamine was effective in preventing polyplex aggregation in the presence of as much as 10% serum. Polyplexes of all polycations devoid of Jeffamine aggregated

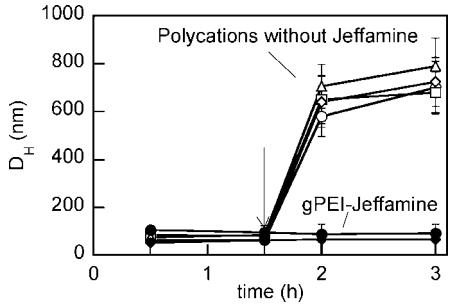

Figure 4. Effect of plasma on aggregation of DNA/polycation complexes at 37 °C. The complexes comprised double-stranded plasmid cloning vector pUC18 and a polycation at a fixed N/P ratio of 10 suspended in 10 mM HEPES buffer (pH 7.4). The number-average hydrodynamic diameter (D_H) was measured by dynamic light scattering following a 0.5-h equilibration at 37 °C. At a time point indicated by an arrow, human serum was added to each sample to result in a 10 vol% serum concentration. The samples were then incubated at 37 °C, and the D_H values were measured 1 and 2 h from the time of serum addition. Data with PEI1, PEI2, gPEI1, gPEI2, gPEI1−Jeffamine, and gPEI2−Jeffamine are shown by open circles, open squares, open diamonds, open triangles, filled diamonds, and filled circles, respectively.

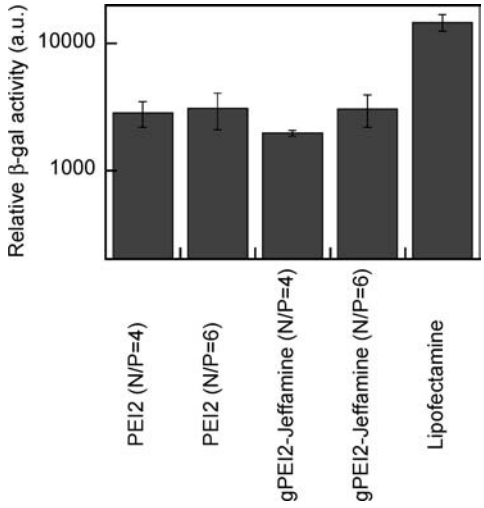

Figure 5. Transfection of Chinese hamster ovary (CHO-K1) cells with pCMVβ-gal plasmid DNA using polyplexes based on PEI2, gPEI2−Jeffamine, and Lipofectamine 2000 in medium supplemented with 10 vol % fetal bovine serum (FBS). Chemiluminiscent β-gal signal in arbitrary units was taken as a measure of β-galactosidase activity as a result of transfection.

when serum was present. These results are indicative of the steric repulsion of the serum proteins by the PEO segments of the Jeffamine in the outer shell of the DNA/gPEI−Jeffamine polyplex particles.

***In Vitro* DNA Transfection.** To test the *in vitro* gene transfer effectiveness of the polylexes, we used β-galactosidase expression in three mammalian cell lines (Figures 5, 6, and 7). gPEI−Jeffamine conjugates maintained the cell transfection efficiency in the CHO-K1 hamster ovary cell line comparable to that of the parent PEI, which was ~5-fold lower with gPEI2−Jeffamine at N/P = 6 than with the Lipofectamine 2000 cationic lipids used as a transfection standard (Figure 5). However, gPEI−Jeffamine enhanced the transfection in 3T3 fibroblast cells 2−3-fold, compared to that of their parent PEI species, throughout the polymer/DNA ratio range studied (Figure 6). Transfection of the pCMV-βgal plasmid with PEI1 polycation was inefficient because of its poor binding with DNA, which correlated well with the microcalorimetric and binding assays (compare with

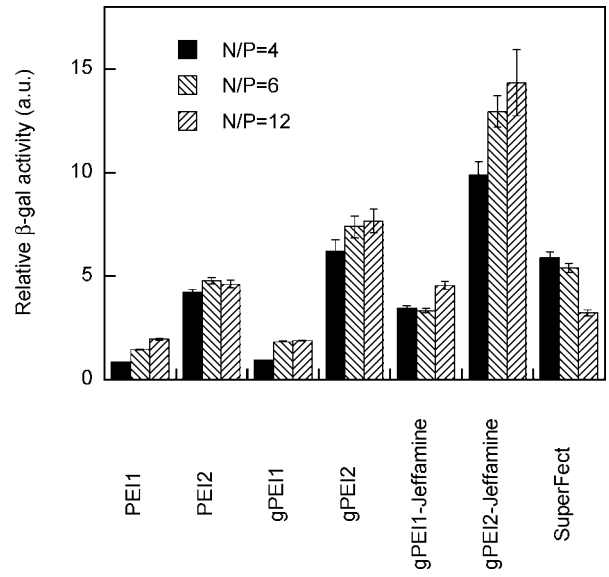

Figure 6. Transfection of 3T3 mouse embryo fibroblast cells with pCMVβ-gal plasmid DNA using the polycations of the present study and SuperFect in medium supplemented with 10% human serum. Relative β-galactosidase activity was expressed as the ratio of the spectrophotometric absorbance reading with a given transfection agent relative to the control readings with untreated cells that did not undergo transfection (see Materials and Methods).

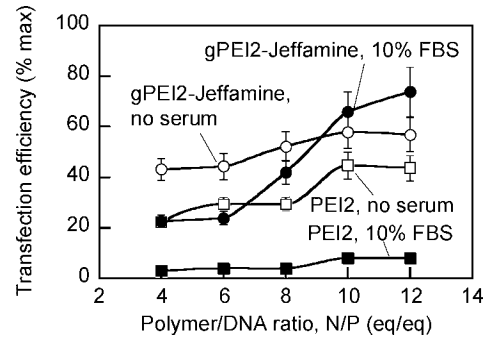

Figure 7. Transfection of Cos-7 green monkey kidney fibroblast cells with pCMVβ-gal plasmid DNA using PEI2 or gPEI2−Jeffamine in the presence of 10% FBS or in the absence of serum as a function of the polymer/DNA (N/P) ratio in the polyplexes. Relative transfection efficiency, was expressed via β-gal signal intensity (absorbance units) observed with a particular polyplex, divided by the absorbance observed with Lipofectamine 2000.

Figures 1 and 2). Interestingly, a notable improvement in the transfection efficiency was observed at higher N/P ratios in the case of gPEI2 and gPEI2−Jeffamine but not with cationic dendrimer formulation, SuperFect (Figure 6). At N/P = 12, polyplexes with the gPEI2−Jeffamine conjugate transfected the plasmid over 4-fold more efficiently than those with SuperFect. At N/P > 10, DNA/PEI or DNA/gPEI−Jeffamine complexes were positively charged, but in the case of gPEI−Jeffamine, the charges were substantially shielded by the polyether chains (compare with Figure 3), which contributed to the transfection efficiency with this polymer at higher N/P values. A more detailed study of the DNA transfection with gPEI2−Jeffamine and parent PEI2 polycations, without and in the presence of 10% serum using the Cos-7 cell line, revealed that without serum, plasmid transfection with gPEI2−Jeffamine was 1.3- to 1.9-fold more efficient than with the parent PEI2 throughout the N/P range of 4 to 12 studied (Figure 7). However, the presence of 10% serum lowered the efficiency of the PEI2 as a transfection agent due to the persistent aggregation but did not signifi-

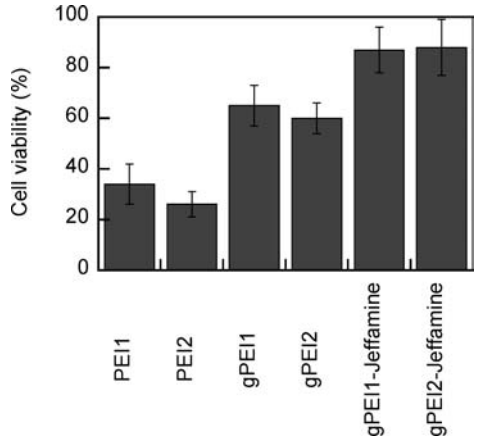

Figure 8. Viability of the L929 mouse fibroblast cells in the presence of plasmid DNA/polymer complexes measured by MTT assay in 10% fetal bovine serum. The N/P ratio of 10 was maintained in all experiments. Only statistically significant data and standard errors are shown.

cantly affect that of the gPEI2−Jeffamine so that the latter was 6- to 10-fold more efficient than the former when the serum was present. This result is in excellent accord with the observation of the gPEI−Jeffamine stability in the presence of serum proteins (see Figure 3). At N/P = 12, the efficiency of the transfection with gPEI2−Jeffamine reached over 70% of that with Lipofectamine 2000. Hence, the results with the 3T3 and Cos-7 cell lines indicate that gPEI2−Jeffamine is a rather effective transfection agent, with DNA transfection efficiency comparable to or exceeding that of the commercially available transfection agents, especially at N/P ratios of 10 or 12.

Cytotoxicity Study. The results of the cytotoxicity studies with the polycations of the present study are shown in Figure 8. The study was designed to compare the cytotoxicity of the polyplexes made with different polycations. A fixed N/P ratio of 10 was set throughout these experiments, as this ratio resulted in a significant binding of polycations (except for PEI1) and plasmid DNA and an efficient DNA transfection with gPEI−Jeffamine conjugates. The low-MW PEI1 (nominal MW 600) was less cytotoxic than PEI2 (MW 10 kDa), in agreement with the literature (*47*). Guanidinylation of either PEI1 or PEI2 lowered the cell morbidity approximately 2-fold. The positive effect of guanidinylation of the primary amino groups on polymer biocompatibility has been noted with branched PEI (*48*) and some poly(propylene imine) dendrimers (*42*). Although it has been suggested that guanidinylation of the primary amino group results in randomization of the cationic charges along the PEI chains (*48*), the mechanism of the lower cytotoxicity of the guanidinylated PEI vs original PEI is not well understood. However, it appeared that guanidinylation and Jeffamine conjugation afforded a synergistic effect of enhanced cell viability, i.e., the gPEI−Jeffamine conjugates were less cytotoxic than PEI or gPEI polycations (Figure 8). The plasmid cloning vector pUC18 DNA/gPEI−Jeffamine complexes were compatible with L929 fibroblast cells (viability, ∼90%) and demonstrated 200% and 25−30% higher cell viability than their parent PEI and gPEI counterparts, respectively. This interesting result indicates the enhancement of cell survival due to the presence of PEO chains of Jeffamine, which partially shield the positive charges of the polyplexes at N/P = 10. This effect is somewhat analogous to the previously reported effect of PEGylation of PEI, with the resulting PEGylated PEI−DNA complexes preventing the aggregation of mouse erythrocytes (*44*).

CONCLUDING REMARKS

The enhancement of polyplex transfection efficiency by polycation conjugation with PEO-PPO-PEO (Pluronic) triblock copolymers has been reported previously (*13*, *46*, *49*) and explained by the decreasing polyplex particle size through hydrophobic binding of poly(propylene oxide) chains of Pluronic with nonpolar sites in the polyplex. In the present work, we employed a monoamine diblock PEO-PPO copolymer (Jeffamine), which afforded a simple synthetic route toward polycation−polyether conjugates. *In vitro* studies demonstrated that guanidinylation of the amino groups of PEI and conjugation of PEI with Jeffamine polyether reduce the cytotoxicity of the polyplexes, enhance the conjugates' interaction with genetic material, protect the polyplexes from aggregation in the presence of serum proteins, and improve the transfection efficiency of the conjugates.

TECHNICAL NOTES

Synthesis and Characterization of Hyperbranched Poly(glycidol) Modified with pH- and Temperature-Sensitive Groups

Chie Kojima,[§,†] Kohei Yoshimura,[†] Atsushi Harada,[†] Yuichi Sakanishi,[‡] and Kenji Kono*[,†]

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, Osaka, Japan, and Daicel Chemical Industries, Ltd., Osaka, Japan. Received January 15, 2009; Revised Manuscript Received March 3, 2009

Hyperbranched poly(glycidol)s with varying degrees of polymerization were modified by reaction with succinic anhydride and isopropylamine to obtain novel pH- and thermosensitive polymers. These polymers exhibited phase transitions in response to decreasing pH and/or increasing temperature, depending on the degree of polymerization and the ratio of succinyl group to *N*-isopropylamide. It was possible to harvest a bioactive molecule, rose bengal, from solution using the phase transition of thermosensitive hyperbranched poly(glycidol).

INTRODUCTION

Dendrimers and hyperbranched polymers have three-dimensional structures and unique properties that are different from those of linear polymers (*1, 2*). For example, various types of dendrimers have been shown to be capable of encapsulating guest molecules, and many researchers have investigated their potential as carriers of bioactive molecules (*3*−*5*). Despite the lower regularity of their branched backbone structures, hyperbranched polymers tend to have spherical structures and exhibit properties in common with dendrimers. In addition, hyperbranched polymers tend to be more easily prepared than dendrimers (*6*−*8*). Thus hyperbranched polymers may be more useful, from a practical viewpoint, than dendrimers. To increase the usefulness of hyperbranched polymers, it is crucial to impart desired functionality to target hyperbranched polymers with appropriate structure and properties. However, there have been only a few reports on the modification of hyperbranched polymers with functional groups (*9, 10*).

Stimuli-sensitive properties are among the most useful functions of polymers for various fields of application. In particular, temperature- and pH-responsiveness are of great importance for biomedical applications. The temperature of target sites, such as tumor tissues, in the body can be changed safely by hyperthermia. Also, it is known that some cellular compartments and tissues have lower pH environments than normal physiological pH. For those reasons many efforts have been made to develop polymers with temperature-sensitive and pH-sensitive properties for biomedical use (*11*−*15*).

To increase the potential usefulness of hyperbranched polymers in the biomedical and related fields, in the present study we have attempted to render biocompatible hyperbranched polymers sensitive to temperature and pH. We propose a novel method for imparting thermosensitivity to temperature-insensitive polymers, by which side-chain units of thermosensitive polymers are introduced to the target polymer as temperature-sensitive moieties. We have previously reported that temperature-insensitive poly(amidoamine) and poly(propyleneimine) dendrimers can exhibit lower critical solution temperatures in aqueous solution after incorporation of isobutylamide or *N*-isopropylamide in their chain terminal groups (*16*−*19*). In the present study, we have applied this method to biocompatible hyperbranched poly(glycidol) (HPG) and examined the effectiveness of the method for the temperature sensitization (*20*). We have also attempted to impart pH sensitivity to HPG by the introduction of carboxyl groups. We have succeeded in making biocompatible hyperbranched polymers that respond to temperature and pH in ranges around normal physiological conditions, by controlling the relative proportions of the temperature-sensitive and pH-sensitive units.

MATERIALS AND METHODS

Materials and General Characterization. HPG with DP 10, 20, and 40 (HPG10, HPG20 and HPG40) were provided by Daicel Chemical Industries, Ltd. (Osaka, Japan). Succinic anhydride and pyridine were purchased from Kishida Chemical (Osaka, Japan). Triethylamine (TEA) was purchased from Sigma-Aldrich Corp. (St. Louis, MO). Isopropylamine (IPA) and rose bengal (RB) were purchased from Wako Pure Chemical Industries Ltd. (Osaka, Japan), 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) was obtained from Watanabe Chemical Industries, Ltd. (Hiroshima, Japan). ^{1}H NMR spectra were recorded using a JEOL JNM-LA400 instrument (JEOL, Japan).

Synthesis of Succinylated Hyperbranched Poly(glycidol)-(Suc-HPG). HPG10 (5.7 g, 7.5 mmol), HPG20 (5.8 g, 3.9 mmol), or HPG40 (5.9 g, 2.0 mmol) was dissolved in pyridine (60 mL). Twenty-five grams (2.6×10^2 mmol) of succinic anhydride was added, and the solution was stirred at 60−65 °C for 7 h under argon in the dark. The reaction mixtures were filtered to remove the solid deposit and concentrated by evaporation. The precipitates produced by addition of diethyl ether were purified on a Sephadex LH-20 column (GE health-

care) by elution with methanol to obtain Suc-HPG10, Suc-HPG20, and Suc-HPG40 with yields 5.2 g (37%), 8.3 g (59%), and 10.3 g (74%), respectively.

δ_H (Suc-HPG, 400 MHz, CD_3OD): 2.6 (br, OCOCH_2CH_2COOH), 3.4−4.1 (br, HPG-scaffold), 4.1−4.5 (br, CH_2OCO), 5.0−5.3 (br, >CHOCO).

Synthesis of *N*-Isopropylamination of Succinylated Hyperbranched Poly(glycidol) (NIPAM-Suc-HPG). Suc-HPG10, Suc-HPG20, and Suc-HPG40 were dispersed in water and evaporated. This treatment was repeated four times, and then the residues were lyophilized to completely remove methanol. The methanol-free Suc-HPG10, Suc-HPG20, and Suc-HPG40 were reacted with isopropylamine at different ratios (see reaction conditions given in Table 1). Because HBTU is an effective condensation reagent that can form ester bonds, it is necessary to take care to avoid contamination and addition of alcohol. In a typical preparation Suc-HPG20 was dissolved in distilled DMF (13 mL), triethylamine and HBTU were added, IPA diluted with distilled DMF (2.32 M) was added, and the mixture was stirred at 28−30 °C for 3 days under argon in the dark. After evaporation of the reaction mixture, the residue was purified by reprecipitation from acetic acid−1 N HCl and washed several times with diethyl ether. The crude product, dispersed in acetic buffer (pH 4−5) to adjust pH, was purified on a Sephadex LH-20 column (GE Healthcare) by elution with methanol. Other polymers were synthesized by varying the amounts of each material according to Table 1. The yields of the synthesized polymers are given in Table 1.

δ_H (400 MHz, CD_3OD): δ 1.1 (d, NHCH(CH_3)$_2$), 2.5 (br, OCOCH$_2$CH_2CONH-), 2.6 (br, OCOCH_2CH_2COOH and OCOCH_2CH$_2$CONH), 3.4−4.1 (br, HPG-scaffold), 3.9 (br, COONHCH(CH_3)$_2$), 4.1−4.5 (br, CH_2OCO), 5.0−5.3 (br, >CHOCO), 7.8 (br, CONH).

Measurement of Phase Transition. The turbidity of solutions of NIPAM-Suc-HPGs in 10 mM phosphate containing 150 mM NaCl buffer, pH 5.0−7.4, was measured at 700 nm using a Jasco Model V-560 spectrophotometer equipped with a Peltier type thermostatic cell holder coupled with an ETC-505T controller. The heating rate of the sample cell was maintained at 1.0 °C min^{-1}. The cloud points were taken as the initial break points in the resulting transmittance versus temperature curves.

Temperature-Dependent Separation of Rose Bengal. A solution of rose bengal (59 μM) containing NIPAM-Suc-HPG40 (5 mg mL^{-1}, 0.59 mM) or unmodified HPG40 (5 mg mL^{-1}, 1.7 mM) in phosphate buffer (10 mM phosphate containing 150 mM NaCl buffer, pH 7.4) was prepared. After 30 min incubation at 4 or 40 °C, the solution was centrifuged at 15 000 rpm for 30 min at 4 or 40 °C. The supernatants of rose bengal solutions without polymer were also prepared. The absorption spectra of the supernatants were obtained using a Jasco Model V-560 spectrophotometer equipped with a thermomodule (ETC-717T, Jasco Inc., Japan).

RESULTS AND DISCUSSION

Synthesis of NIPAM-Suc-HPGs. Stimuli-responsive polymers based on HPG were synthesized according to Scheme 1. HPGs with degree of polymerization (DP) 10, 20, and 40 were reacted with excess succinic anhydride to provide a pH sensitive unit for HPG (Suc-HPG). Suc-HPGs were then reacted with different amounts of isopropylamine. The experimental conditions for the polymers that were synthesized are shown in Table 1. The synthesized compounds were characterized by ^{1}H NMR. The NMR spectra of unmodified HPG20, Suc-HPG20, and NIPAM-Suc-HPG20 (#5) are shown in Figure 1. The spectrum of Suc-HPG20 reveals signals derived from HPG (3.4−4.0 ppm) and the succinyl unit (2.6 ppm). The signals at 5.0−5.3 ppm and 4.1−4.5 ppm were shifted from 3.4−4.0 ppm by making ester bonds in HPG20 (methine and methylene, respectively). The integral ratio of the succinyl unit signal (2.6 ppm) to the HPG20 signals (3.4−4.1, 4.1−4.5, and 5.0−5.3 ppm) indicates that virtually all terminal hydroxyl groups of HPG20 were succinylated. The same results were obtained for HPG10 and HPG40. The spectrum of NIPAM-Suc-HPG20 (#5) is shown in Figure 1C. Signals from the NIPAM unit (1.1 and 3.9 ppm) were observed in addition to the Suc-HPG signals. The signals

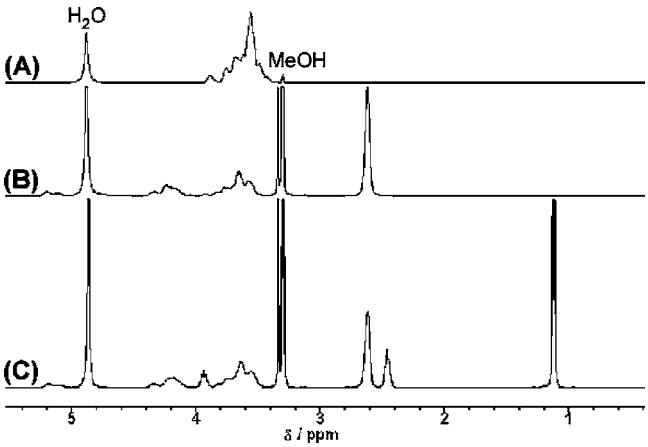

Figure 1. [1]H NMR spectra of HPG20 (A), Suc-HPG20 (B), and NIPAM-Suc-HPG20 (#5) (C) in CD_3OD.

at 2.6 ppm were shifted to 2.5 ppm by making amide bonds in Suc-HPG20. From the integral ratios of the succinyl and NIPAM unit signals to the HPG20 signals, we estimated the proportions of NIPAM and Suc in HPG. The results for all of the polymers that were synthesized are shown in Table 1. We found that the extent of succinylation slightly decreased after amidation with isopropylamine. This might be caused by the hydrolysis of ester bonds in the second reaction step and purification. We synthesized polymers with different DPs and with varying proportions of NIPAM groups and unreacted carboxyl groups.

Phase Transitions of NIPAM-Suc-HPGs. The phase transition of aqueous solutions containing the synthesized polymers was examined. We could not observe a phase transition for unmodified HPGs and Suc-HPGs in 10 mM phosphate buffer containing 150 mM sodium chloride (pH 5.0−7.4). However, NIPAM-Suc-HPGs exhibited thermosensitive behavior depending on the conditions of preparation. We examined first the influence of the DP on the thermosensitivity of the polymers. Figure 2A shows the optical transmittance of aqueous solutions (pH 5.0) of $NIPAM_{0.96}$-Suc-HPG10, $NIPAM_{0.94}$-Suc-HPG20, and $NIPAM_{0.96}$-Suc-HPG40, in which almost all of the hydroxy groups were replaced by NIPAM groups. The transmittance changed drastically at 16, 10, and 7 °C which are called cloud points. The decrease of cloud point with increasing DP of the HPG polymers is consistent with previously reported observations (*9*). It is thought that increase of the terminal group density and van der Waals interaction might result in the lower cloud point of polymer with higher DP. These cloud points are lower than the LCST of polyNIPAM (32 °C). The lower cloud point may be caused by the different structure of the polymer and hydrogen bonds between the main chain and the side chain of the polymer.

We also investigated the influence of the relative proportions of NIPAM groups and unreacted carboxyl groups on the thermosensitivity of the polymers. Figure 2B shows that the optical transmittance of aqueous solutions (pH 5.0) of $NIPAM_{0.94}$-Suc-HPG20, $NIPAM_{0.79}$-Suc-HPG20, and $NIPAM_{0.60}$-Suc-HPG20 drastically changed at 10, 13, and 25 °C, respectively, but that of $NIPAM_{0.33}$-Suc-HPG20 did not. Similar behavior was observed for solutions of a series of HPG40-based polymers (see Supporting Information), indicating that a larger proportion of NIPAM groups induced the phase transition because of the enhanced hydrophobicity.

Because the unreacted carboxyl groups of the NIPAM-Suc-HPG can act as a pH sensor, we investigated the influence of pH on the thermosensitivity of the polymers. The cloud points of $NIPAM_{0.60}$-Suc-HPG20 at pH 5.0, 5.2, and 5.4 were 28, 38, and 56 °C (Figure 2C), respectively, and a cloud point was not

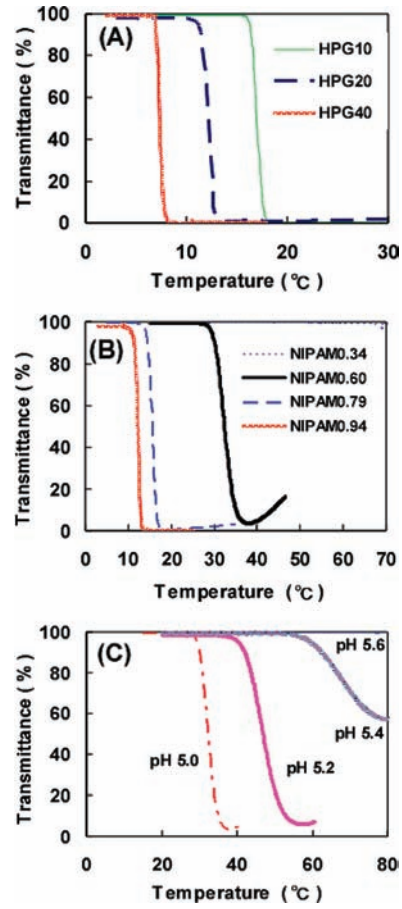

Figure 2. pH- and temperature sensitivity of various NIPAM-Suc-HPGs. (A) The influence of the DP of HPG on the thermosensitivity. Temperature dependence of transmittance for solutions of $NIPAM_{0.96}$-Suc-HPG10, $NIPAM_{0.94}$-Suc-HPG20, and $NIPAM_{0.96}$-Suc-HPG20 at pH 5.0. (B) The influence of the proportion of NIPAM on the thermosensitivity. Temperature dependence of transmittance for solutions of $NIPAM_{0.34}$-Suc-HPG20, $NIPAM_{0.60}$-Suc-HPG20, $NIPAM_{0.79}$-Suc-HPG20, and $NIPAM_{0.94}$-Suc-HPG20 at pH 5.0. (C) pH-sensitivity of $NIPAM_{0.60}$-Suc-HPG20. Temperature dependence of transmittance for solutions of $NIPAM_{0.60}$-Suc-HPG20 at pH 5.0, 5.2, 5.4, and 5.6.

detected at pH 5.6. Similar behavior was observed for solutions of a series of HPG40-based polymers (see Supporting Information). Since $NIPAM_{0.60}$-Suc-HPG20 contained 40% carboxyl group and 60% NIPAM group, this polymer was responsive to both pH and temperature, as we expected. Protonated carboxyl groups at lower pH may increase the hydrophobicity and induce hydrogen bond formation, leading to lower cloud point. The cloud points of $NIPAM_{0.94}$-Suc-HPG20 at pH 5.0 and 7.4 were the same temperature (see Supporting Information). Because this polymer contained few remaining carboxyl groups, it was not sensitive to pH. Consequently, polymers containing an appropriate amount of carboxyl groups can sense both pH and temperature, and it is possible to control pH- and thermosensitivity by tuning the DP, and the relative proportions of NIPAM and carboxyl groups.

Temperature-Dependent Separation of Rose Bengal by Using NIPAM-Suc-HPGs. Thermosensitive dendrimers can act as a nanocapsule for harvesting bioactive molecules (*5*). We investigated the temperature-dependent encapsulation ability of NIPAM-Suc-HPG to rose bengal (RB), which is a type of photosensitizer (*4, 21*). RB aqueous solution with and without NIPAM-Suc-HPG were prepared and heated to 40 °C. After centrifugation, the UV−vis spectra of the solutions were obtained. As shown in Figure 3, the absorption spectrum of RB in the presence of NIPAM-Suc-HPG almost disappeared after

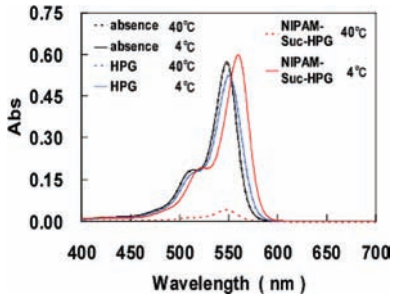

Figure 3. UV−vis spectra of RB in the absence (black) and the presence (red) of $NIPAM_{0.96}$-Suc-HPG40 at 4 °C (solid lines) and 40 °C (dotted lines). The spectrum in the presence of unmodified HPG40 (blue) is also shown.

heating, although the spectrum in the absence of NIPAM-Suc-HPG was unchanged. The spectrum at 40 °C in the presence of HPG, which is not thermosensitive, was the same as at 4 °C. Thus the thermosensitive hyperbranched polymer is a candidate as a temperature-dependent carrier of bioactive molecules. This property is of benefit for accumulation of drug molecules at the site of heated tissue.

In conclusion, we synthesized and characterized NIPAM-Suc-HPG, which contained both carboxyl groups as pH-sensing units and NIPAM groups as thermosensitive units. The pH- and thermosensitivity is dependent on the DP of based polymers and the relative proportions of pH- and thermosensing units. The pH- and thermosensitivity of the polymer can thus be adjusted and controlled by selecting the DP and tuning the reaction conditions. Shen et al. reported very recently a preparation of a type of thermosensitive HPG, by modification of *N*-isopropylacrylamide after the substitution of hydroxyl groups by amino groups. This polymer was sensitive to pH and temperature due to the tertiary amino groups and the NIPAM groups (*9*). However, the pH range of pH sensitivity was above pH 7, which is unlikely to occur in the body. By contrast, our polymers responded in the range from pH 5 to 7, a typical physiological pH range, and a photosensitizer, rose bengal, can be harvested by adding these polymers and heating. Consequently, NIPAM-Suc-HPG is a candidate as a functional material for biomedical applications.

ACKNOWLEDGMENT

We are grateful to Daicel Chemical Industries, Ltd. (Osaka, Japan) for the kind gift of HPGs and for financial support.

Preparation of Mammalian Expression Vectors Incorporating Site-Specifically Platinated-DNA Lesions

Wee Han Ang, William Wesley Brown, and Stephen J. Lippard*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139. Received January 26, 2009; Revised Manuscript Received February 26, 2009

FDA-approved platinum-based anticancer drugs, cisplatin, carboplatin, and oxaliplatin, are some of the most effective chemotherapies in clinical use. The cytotoxic action of these compounds against cancer requires a combination of processes including cell entry, drug activation, DNA binding, and transcription inhibition resulting in apoptotic cell death. The drugs form Pt lesions with nuclear DNA, leading to the arrest of key cellular functions and triggering a variety of cellular responses. DNA probes containing Pt−DNA conjugates are important tools for studying the molecular mechanisms of these processes. In order to facilitate investigation of specific Pt−DNA lesion processing within live cells, we devised a strategy for constructing plasmids containing a single site-specific Pt−DNA adduct. The method involves the use of nicking restriction enzymes to create closely spaced tandem gaps on the plasmid followed by removal of the intervening doubly nicked DNA strand to form a short single-stranded gap. Synthetic platinated oligonucleotides were incorporated into the gapped plasmid construct to generate a covalently closed circular platinated plasmid in good yield. We discuss the application of this methodology to prepare plasmids containing a platinum 1,2-d(G*pG*) or 1,3-d(G*pTpG*) intrastrand cross-link, two notable adducts formed by the three clinically approved drugs.

INTRODUCTION

The simple inorganic compound *cis*-diamminedichloroplatinum(II) or cisplatin confers one of the most remarkable treatments for cancer, particularly testicular germ-cell cancer (*1, 2*). The cytotoxic action of cisplatin occurs by a sequence of steps involving cell entry, drug activation, DNA binding, and transcription inhibition, resulting in apoptotic cell death (*3*). Formation of Pt−DNA adducts is an important determinant of the anticancer activity of platinum-based drugs, leading to the arrest of key cellular functions, including transcription (*4*−*7*), triggering a variety of cellular responses, including nucleotide excision repair (*8*−*11*). Cisplatin reacts with nuclear DNA to form predominantly 1,2-d(G*pG*), 1,2-d(A*pG*) intrastrand, and to a lesser extent, 1,3-d(G*pNpG*) intrastrand and interstrand cross-links, where the asterisks denote the platinated nucleosides (*12, 13*). Understanding how the cell processes these specific lesions is important in elucidating the mechanism of action and in forming a basis for the rational design of improved drugs.

Our group along with others have synthesized and utilized a variety of platinated DNA constructs as probes to investigate the action of platinum-based drugs in vitro and the processing of Pt−DNA adducts by cellular proteins (*14*−*17*). In particular, we are interested in preparing site-specifically platinated plasmids that can be used in live cells for application as in vitro transcription probes. A widely used method involves priming a single-stranded circular DNA template with a platinated oligonucleotide followed by extension around the template with a DNA polymerase (*18*−*20*). However, we require a more efficient means of preparation that can be applied to existing mammalian expression vectors with minimal modification to the construct and which can generate the platinated plasmid in good yield. In related work, plasmids containing site-specific mismatches as substrates for mismatch repair studies were prepared by treatment with nicking endonucleases followed by incorporation of synthetic oligonucleotides into the resulting gap (*21, 22*). This method, together with some special design elements devised during the present study, has the potential to generate plasmids containing specific Pt−DNA lesions for mechanistic work. In the present technical note, we demonstrate the power of this methodology to generate the desired constructs using commercial mammalian expression vectors as the host. Plasmids containing the most mechanistically important Pt−DNA adducts, 1,2-d(G*pG*)-Pt and 1,3-d(G*pTpG*)-Pt, formed by the clinically relevant cisplatin, carboplatin, and oxaliplatin anticancer drugs, were prepared and characterized. The key design features incorporated in our study ensure a high yield of the desired bioconjugates.

EXPERIMENTAL PROCEDURES

Materials. Restriction endonucleases (REases), Nt.BbvCI nicking enzyme, calf intestinal phosphatase (CIP), T4 polynucleotide kinase (T4 PNK), and T4 DNA ligase were obtained from New England Biolabs (NEB), and enzymatic reactions were carried out in the reaction buffers that were provided with the enzyme. Ethidium bromide (EtdBr) and nuclease S1 were purchased from Promega and supercompetent XL1BLUE *E. coli* cells, from Stratagene. K_2PtCl_4 was obtained as a gift from Engelhard Corporation. Cisplatin and [Pt(*R*,*R*-dach)Cl_2] were prepared according to literature procedures (*23, 24*). Desalted oligonucleotides were ordered from Integrated DNA Technologies (IDT, Coralville, Indiana, USA) unless otherwise stated.

Vector Construction and Preparation. A mammalian vector expressing *Gaussia* luciferase, pCMV-GLuc (NEB), was used as the vector construct. pCMV-GLuc (NEB) was treated sequentially with HindIII and BamHI to digest the vector between the *CMV* promoter and *GLuc* reporter genes. A synthetic insert designed for subsequent incorporation of the 1,2-d(G*pG*)-Pt DNA lesion was prepared by annealing 5′-AGCTGCTGAGGACCGGTGCTGAGG with 5′-GATCCCT-CAGCACCGGTCCTCAGC, which left 5′-AGCT/GATC noncohesive overhangs, and ligated to the HindIII/BamHI-digest

of pCMV-GLuc. Similarly, the synthetic insert for the 1,3-d(G*pTpG*)-Pt DNA lesion was prepared from 5′-AGCTGAGGAGGAGCACGTGGAGGGAGAGGCTGAG and 5′-GATCCTCAGCCTCTCCCTCCACGTGCTCCTCCTC. The ligation mixtures were transformed directly into XL1BLUE cells on LB agar plates supplemented with 100 mg/L of ampicillin. Colonies were randomly picked and plasmid extracted (Qiagen miniprep kit). Incorporation of synthetic inserts was confirmed by restriction analysis and sequencing (MWG Operon, Huntsville, Alabama, USA) prior to large scale plasmid preparation. The modified vectors for the 1,2-d(G*pG*)-Pt and 1,3-d(G*pTpG*)-Pt DNA lesions are designated as pGLuc1temGG and pGLuc2temGTG, respectively (Figure 1).

Preparation of 13-mer Insertion Strands Containing 1,2-d(G*pG*)-Pt Lesions. Desalted 5′-TCAGCACCGGTCC oligonucleotide was ordered from IDT (Chart 1). The 13-mer nonplatinated insertion strand (13-is) was obtained by purifying the desalted oligonucleotide using ion-exchange HPLC. To prepare the 13-mer insertion strand with the 1,2-d(G*pG*)-[$Pt(NH_3)_2$] lesion (13-is-Pt), desalted oligonucleotide (800 nmol) was allowed to react with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (1200 nmol) in buffer (1 mL, 10 mM sodium phosphate at pH 6.0) for 2 h at 37 °C (*25*). The platinated oligonucleotide was purified twice by ion-exchange HPLC. The linear gradient was 10−45% B over 13.5 min, where solvent A contained 20 mM Tris·HCl at pH 8.0 and 20% acetonitrile, and solvent B contained solvent A supplemented with 1 M NaCl. The final yield was 120 nmol (15.0%). The 13-mer insertion strand with the 1,2-d(G*pG*)-[Pt(*R*,*R*-dach)] lesion (13-is-oxPt) was purified by the same method except that the conditions were 800 nmol of oligonucleotide and 1200 nmol of $[Pt(R,R\text{-dach})(H_2O)_2]^{2+}$ in buffer (1.5 mL, 10 mM sodium phosphate at pH 6.0) for 4 h at 37 °C. The final yield was 10.5 nmol (1.3%).

Preparation of 27-mer Insertion Strands Containing 1,3-d(G*pTpG*)-Pt Lesions. The 27-mer insertion strand (27-is) 5′-TCAGCCTCTCCCTCCACGTGCTCCTCC was prepared by using an Applied Biosystems 392 DNA/RNA synthesizer on a 1 μmol scale by standard phosphoramidite protocols and purified with PolyPak II reverse-phase cartridges (Glen Research) in accord with the manufacturer's instructions (Chart 1). The 27-mer insertion strand with the 1,3-d(G*pTpG*)-[$Pt(NH_3)_2$] lesion (27-is-Pt) was prepared by ligating a platinated 17-mer strand to a 10-mer in the presence of a 35-mer scaffold. The 10-mer 5′-TCAGCCTCTC and 17-mer 5′-CCTCCACGTGCTCCTCC strands were prepared on the DNA synthesizer and purified as described for 27-is. The 17-mer oligonucleotide (250 nmol) was allowed to react with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ (375 nmol) in buffer (1 mL, 10 mM sodium phosphate at pH 6.0) for 2 h at 37 °C and purified by ion-exchange HPLC (*25*). The linear gradient was 30% B for 3 min, 30−52.5% B over 13.5 min, where solvent A contained 20 mM Tris·HCl at pH 8.0, and 20% acetonitrile, and solvent B contained solvent A supplemented with 1 M NaCl.

The platinated 17-mer (25 nmol) was phosphorylated using T4 PNK (50 U) in buffer (250 μL, 70 mM Tris·HCl at pH 7.6, 10 mM $MgCl_2$, 5 mM DTT, and 1 mM ATP) for 6 h at 37 °C, treated with phenol/chloroform/isoamyl alcohol (25:24:1), and dialyzed against water for 4 h. The phosphorylated 17-mer, 10-mer (30 nmol), and the 35-mer scaffold 5′-TTTTGGAGGAGCACGTGGAGGGAGAGGCTGATTTT (37.5 nmol) were annealed and ligated using T4 DNA ligase (200 U) in buffer (200 μL, 50 mM Tris·HCl at pH 7.6, 10 mM $MgCl_2$, 10 mM DTT, and 1 mM ATP) at 16 °C for 36 h. The product was purified by 14% urea−PAGE, followed by ion-exchange HPLC. The linear gradient used was 60−77.5% B over 13 min, where solvent A contained 10 mM NaOH, and solvent B contained solvent A supplemented with 1 M NaCl. The yield obtained was 0.8 nmol (3.2%). The 27-mer insertion strand containing the 1,3-d(G*pTpG*)-[Pt(*R*,*R*-dach)] lesion (27-is-oxPt) was prepared using the same method, and the final yield was 1.5 nmol (6.0%).

Characterization of Platinated and Nonplatinated Insertion Strands. The insertion strands were characterized by MALDI-TOF MS to determine their molecular mass, which in all cases was within 0.1% of the calculated value. Mass spectra of the synthesized oligonucleotides were recorded on a Bruker OmniFlex instrument. The analyte was mixed with a matrix containing 10 mg/mL 2,4,6-trihydroxyacetophenone with 25 mM ammonium citrate in 50% MeCN solution and applied on the target using the dried droplet method. External calibration was performed using ABI Biosystems Calibration Mixture 2. The insertion strands were analyzed for nucleotide composition by enzymatic digestion. The oligonucleotide (500 pmol) was digested with nuclease S1 (10 U) for 12 h at 37 °C in buffer (100 μL, 50 mM NaOAc, 280 mM NaCl, and 4.5 mM $ZnSO_4$). Next, Tris·HCl buffer (1.5 M at pH 8.8) and calf intestinal phosphatase (10 U) were added, and the reaction was incubated for 4 h at 37 °C. The digests were analyzed by reverse-phase HPLC using a Supelcosil LC-18-S column. The method used was 5−15% B over 30 min, where solvent A contained 10 mM NaOAc, and solvent B contained 100% methanol.

Preparation of the Site-Specifically Gapped Plasmid. The plasmid (200 μg) was incubated with Nt.BbvCI (50 U) at 37 °C for 1.5 h. The enzyme was deactivated by heating the reaction at 80 °C for 20 min and removed by phenol/chloroform/isoamyl alcohol (25:24:1) treatment. The single-stranded gap was formed by trapping the nicked strand with its complement (Chart 2). Briefly, the plasmid solution was supplemented with synthetic cDNA (1:500 molar ratio) in annealing buffer (10 mM Tris·HCl at pH 8.0, 2 mM $MgCl_2$, and 0.4 M NaCl), and heated in a thermocycler (80 °C for 5 min then −10 °C/min to 20 °C for 5 cycles). The gapped plasmid was purified by repeated washing (6−8 times) through a diafiltration centrifugal device (Pall, MWCO 30 KDa or 100 KDa) and dissolved in buffer (10 mM Tris·HCl at pH 8.0).

Incorporation of Platinated/Nonplatinated Insertion Strands into the Gapped Plasmid. The insertion strands were phosphorylated by T4 PNK in buffer (70 mM Tris·HCl at pH 7.6, 10 mM $MgCl_2$, 5 mM DTT, and 1 mM ATP) at 37 °C for 1 h. The phosphorylated insertion strands were treated with phenol/chloroform/isoamyl alcohol (25:24:1), dialyzed against water, and dried in vacuo. The gapped plasmid (40 μg) was added at 1:10 to 1:100 molar ratio (vs the insertion strands), and the mixture was annealed in a thermocycler (80 °C for 10 min, then cooling to 4 °C at −1 °C/min). The reaction was supplemented with T4 DNA ligase (80 U) in buffer (50 mM Tris·HCl at pH

7.6, 10 mM $MgCl_2$, 10 mM DTT, and 1 mM ATP) and incubated at 16 °C for 12 h. The mixture was supplemented with 6× loading buffer (NEB), heated at 75 °C for 15 min, and separated using preparative 0.8% w/v agarose gel electrophoresis containing 0.5 μg/mL EtdBr. The DNA bands were revealed using a hand-held UV lamp and the band with higher electrophoretic mobility, corresponding to the covalently closed circular product, was excised. Gel extraction was carried out using a commercial kit (Promega).

The platinated plasmids were purified further by treatment with AgeI (5 U) or PmlI (40 U) at 37 °C for 30 min. The enzyme was deactivated by heating the reaction at 75 °C for 15 min and separated using preparative 0.8% w/v agarose gel electrophoresis containing 0.5 μg/mL EtdBr. The DNA bands were revealed with a hand-held UV lamp and the band with higher electrophoretic mobility, corresponding to the covalently closed circular product, was excised. Gel extraction was carried out as described above (Qiagen). Quantitation of the platinated and nonplatinated plasmid was carried out using the picogreen assay (Molecular Probes). Overall yields range between 5−25%.

Restriction Analysis on Ligated Platinated/Nonplatinated Plasmids. pGLuc1temGG plasmid (100 ng) was incubated with AgeI (0.5 U) at 37 °C for 15 min, and the enzyme was inactivated by heating at 75 °C for 15 min. The plasmids were analyzed using 0.8% w/v agarose gel electrophoresis containing 0.5 μg/mL EtdBr. Pt−DNA lesions were chemically removed by treating the platinated plasmid (200 ng) with 0.2 M NaCN at 55 °C for 10 h, followed by dialysis against water for 4 h (*14*, *26*), prior to REase treatment. pGLuc2temGTG (100 ng) were treated with PmlI (2 U) in the same manner except that the mixture was incubated at 37 °C for 45 min. Control lanes containing untreated plasmids were also added for comparison. The gels were imaged using BioRad Fluor-S MultiImager.

RESULTS AND DISCUSSION

Vector Design Considerations. The strategy used to prepare platinated plasmids is to create single-stranded gaps within the DNA and to fill them in by using synthetic platinated insertion strands containing the precise complementary sequences (Figure 2). The single-stranded gap is created by removing the DNA strand positioned between two closely spaced nicks in the plasmid. Nicking enzymes were employed to introduce single-stranded scissions site-specifically into the plasmid. These enzymes were developed from REases that recognize asymmetric DNA sequences (Type IIA) but are engineered to cleave only one strand of the sequence (*27*). By designing their recognition sequences in tandem into the vector, we can use the nicking sites to predefine the sequence and position of the gap within the plasmid. In addition, the Pt−DNA lesion is intentionally situated within a REase recognition site on the plasmid. Platination at the recognition site

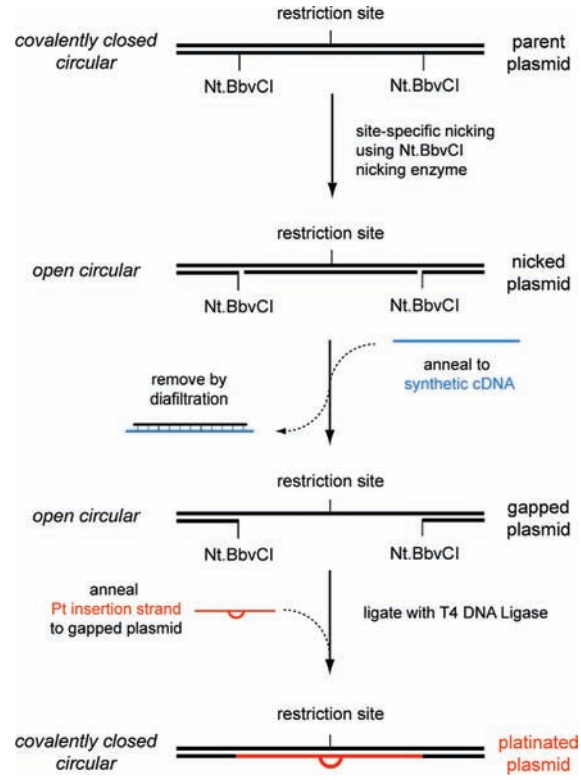

Figure 2. Overall scheme for preparing platinated plasmids.

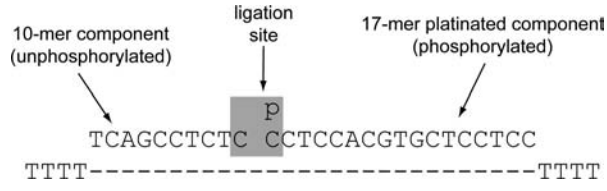

Figure 3. Preparation of platinated 27-mer insertion strands.

blocks REase cleavage and provides a facile method for discriminating between platinated and nonplatinated plasmids. In order to achieve a high level of control and specificity, both the nicking enzyme and the REase for the platination site must be unique and be noncutters of the parent vector. The design of these sequences must be such that they insert with noncohesive overhangs for directional ligation into the vector backbone (Figure 1).

An initial search for appropriate restriction sites was performed on pCMV-Gluc *in silico* to determine that the commercially available REases we selected have no restriction sites on the plasmid (*28*). Nt.BbvCI (CC↓TCAGC) was chosen as the nicking enzyme, and AgeI (A↓CCGGT) and PmlI (CAC↓GTG) as the REases for the platinated inserts for 1,2-d(G*pG*)-Pt and 1,3-d(G*pTpG*)-Pt lesions, respectively (Chart 2). Since platinated oligonucleotides are prepared by treating unplatinated single strands with the diaqua derivatives of cisplatin or oxaliplatin, the insertion strand sequence should ideally contain G bases only at the desired 1,2-d(GpG) or 1,3-d(GpNpG) platination site. In utilizing Nt.BbvCI for tandem nicking, the gap formed necessitates an insertion strand with a 5′-TCAGC starting and a 3′-CC terminal sequence. The presence of 1,2-d(ApG) in the starting sequence, in particular, complicates the preparation of insertion strands containing 1,3-d(G*pTpG*)-Pt lesions. Therefore, additional CT-rich sequences were designed into the insertion strands so that they could be constructed in a modular manner from separate component strands (see below).

Preparation of Platinated Insertion Strands. Platination of the 13-mer synthetic oligonucleotide 5′-TCAGCACCGGTCC was carried out with *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ or $[Pt(R,R\text{-dach})(H_2O)_2]^{2+}$, in accordance with reported procedures (*7, 14, 16, 25*), to prepare oligonucleotides carrying the 1,2-d(G*pG*)-Pt lesions formed by anticancer drugs cisplatin/carboplatin and oxaliplatin (*12, 13*). The 1,2-d(ApG) sequence competed directly with the 1,2-d(GpG) sequence for platination and resulted in an additional peak overlapping with the abundant product peak in the HPLC chromatogram. We were able to separate the major 1,2-d(G*pG*)-Pt product by repeated HPLC runs, however (Figure S1, Supporting Information). The MALDI-TOF MS and enzymatic digestions with nuclease S1 and CIP were consistent with the formation of a single 1,2-d(G*pG*)-Pt lesion on the 13-mer insertion strand (Table S1, Supporting Information).

The 27-mer insertion strands containing 1,3-d(G*pTpG*)-$[Pt(NH_3)_2]$ or 1,3-d(G*pTpG*)-[Pt(*R,R*-dach)] lesions were constructed by ligating the platinated 17-mer fragment to the 10-mer fragment using a DNA scaffold (Figure 3). This strategy was adopted because direct platination of the 27-mer synthetic oligonucleotide 5′-TCAGCCTCTCCCTCCACGTGCTCCTCC might yield the 1,2-d(A*pG*)-Pt adduct as a major product rather than the desired 1,3-d(G*pTpG*)-Pt cross-link. The 17-mer 5′-CCTCCACGTGCTCCTCC synthetic oligonucleotide was therefore platinated with *cis*-$Pt(NH_3)_2(H_2O)_2]^{2+}$ or $[Pt(R,R\text{-dach})(H_2O)_2]^{2+}$. The 17-mers containing the 1,3-d(G*pTpG*)-$[Pt(NH_3)_2]$ or 1,3-d(G*pTpG*)-[Pt(*R,R*-dach)] lesion were readily isolated by ion-exchange HPLC (Figure S2, Supporting Information). Next, the platinated 17-mer was phosphorylated with T4 PNK and ligated, using T4 DNA ligase, to the 10-mer 5′-TCAGCCTCTC fragment using the 35-mer 5′-TTTTGGAGGAGCACGTGGAGGGAGAGGCTGATTTT DNA as a scaffold. Although the product was obtained in modest yield (3−6%), characterization of the ligated material using MALDI-TOF MS and nucleotide composition analysis was consistent with a 27-mer sequence with platination at the desired 1,3-d(G*pTpG*) site (Table S1, Supporting Information).

Preparation of Site-Specifically Platinated Plasmids. A gapped plasmid was prepared by tandem nicking with Nt.BbvCI at the predefined sites and removal of the intervening nicked strand by trapping with synthetic cDNA in large molar excess (Chart 2). The plasmid was purified quantitatively by repeated washings through diafiltration devices, which separate the gapped plasmid from excess cDNA and annealed duplexes.

In order to verify that the single-stranded gap was formed, a set of control ligation experiments were carried out on an analytical scale. The gapped plasmid was mixed with water, as a control, or with the various phosphorylated insertion strands at a 1:100 ratio, annealed, and treated with T4 DNA ligase. In the absence of the insertion strands, ligation of the gapped plasmid could not be achieved; only the open circular (oc) precursor was observed by agarose gel electrophoresis. This result confirmed that the gapping procedure was successful (Figure 4, lanes 1 and 5). In contrast, ligation of the gapped plasmid with both unplatinated and platinated insertion strands yielded significant quantities of covalently closed circular (cc) DNA products (Figure 4, lanes 2−4 and 6−8). Preparation of platinated and nonplatinated plasmids was carried out on a preparative scale. The phosphorylated insertion strands were annealed to the gapped plasmid by using a shallow thermal gradient of −1 °C/min. Ligation with T4 DNA ligase formed the desired covalently closed circular DNA product in good yield. Ligation efficiency was estimated by comparing the fluorescence intensity of the open and covalently closed circular bands on the gel by a BioRad Fluor-S MultiImager, typically ranges lying between 40−60%. The platinated plasmids were purified further by REase treatment, which linearizes nonplatinated plasmid contaminants. Purification of the plasmids was carried out by preparative agarose gel electrophoresis with commercial gel extraction kits at an efficiency of 50−70%. The overall yield from the entire procedure was typically 5−25%. Better yields were obtained on larger, preparative scales (results not shown), but purification of a greater amount of plasmid using agarose gel electrophoresis also becomes more challenging.

The incorporation of the Pt−DNA lesion site-specifically into the plasmid was verified by REase treatment of the synthesized plasmid and analytical agarose gel electrophoresis. In the absence of the Pt−DNA adduct, the plasmid was readily linearized by REase (Figures 5 and 6, lanes 1 and 2). In contrast, plasmids containing the site-specific Pt−DNA lesions were not linearized by the respective REases (Figures 5 and 6, lanes 3 and 4). The reagent NaCN is capable of chemically reversing Pt−DNA cross-links from platinated DNA as $[Pt(CN)_4]^{2-}$ (*14, 26*). Treatment of the platinated plasmids with NaCN at 55 °C for 10 h restored the susceptibility of the plasmids toward REase linearization (Figures 5 and 6, lanes 5 and 6), confirming that the Pt−DNA adducts were site-specifically incorporated into the REase recognition site of the plasmid.

CONCLUSIONS

The method of inserting platinated oligonucleotides into a single stranded gap provides ready access to large platinated DNA constructs, such as plasmids, in a controlled and selective fashion. The key advantage of the method is the high specificity involved in annealing the synthetic oligonucleotide into the gap since only the correct sequence length will result in successful ligation. Only two products are expected from the ligation, the unligated open

circular form and the ligated covalently closed circular product, both of which are easily separated by conventional techniques. Good product yields are thus obtained, which is essential for the large-scale production of platinated plasmid for transfection studies in live cells. By comparison, the method of extending a platinated oligonucleotide primed on a single-stranded circular DNA, using DNA polymerase, can lead to the formation of multiple products due to nonspecific priming or incomplete extension, complicating product purification. In addition, the single-stranded circular DNA production from the plasmid template is accomplished using helper phages, and the strand of plasmid produced is dictated by the orientation of the f1 sequence on the plasmid. Since most expression vector systems contain the f1 sequence oriented to yield the template strand to facilitate DNA sequencing, the platinated oligonucleotide can only be extended on the coding strand.

The main challenge in applying the single-stranded gapping methodology in the production of platinated plasmid is that sequence of the gap is highly dependent on the nicking enzyme

used which, in turn, affects the design of the insertion strand. Ideally, the insertion strand should contain only G bases at the platination site, but due to the gap sequence, it may not be possible to exclude them entirely. Nevertheless, we have shown that it is possible to overcome these limitations through more extensive purification or by applying more innovative methods to produce the platinated oligonucleotides.

In summary, the methodology of incorporating platinated oligonucleotides into synthetically gapped plasmid constructs is a versatile way of accessing site-specifically platinated plasmids with different Pt−DNA lesions. Application of the platinated plasmids as in vitro transcription and other probes in mammalian cells is currently underway.

REVIEWS

Solid-Phase Synthesis of Oligonucleotide Conjugates Useful for Delivery and Targeting of Potential Nucleic Acid Therapeutics

Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received September 23, 2008; Revised Manuscript Received November 13, 2008

Olignucleotide-based drugs show promise as a novel form of chemotherapy. Among the hurdles that have to be overcome on the way of applicable nucleic acid therapeutics, inefficient cellular uptake and subsequent release from endosomes to cytoplasm appear to be the most severe ones. Covalent conjugation of oligonucleotides to molecules that expectedly facilitate the internalization, targets the conjugate to a specific cell-type or improves the parmacokinetics offers a possible way to combat against these shortcomings. Since workable chemistry is a prerequisite for biological studies, development of efficient and reproducible methods for preparation of various types of oligonucleotide conjugates has become a subject of considerable importance. The present review summarizes the advances made in the solid-supported synthesis of oligonucleotide conjugates aimed at facilitating the delivery and targeting of nucleic acid drugs.

INTRODUCTION

Selective inhibition of gene expression by oligonucleotides, including single-stranded antisense oligonucleotides (*1*−*8*), ribozymes (*9*), and double-stranded siRNAs (*10*−*12*), shows promise as a novel form of chemotherapy, which instead of proteins uses nucleic acids as targets. In addition, aptamers (*13*) and immunostimulatory CpG-oligonucleotides (*14*) exhibit potential as therapeutic agents recognizing proteins. While some of these approaches, above all antisense and siRNA technology, are extensively used for target validation of conventional small molecule drugs, the pathway to exploitation of oligonucleotides themselves or their structural analogues as drugs has been long; despite considerable advances, several thresholds still remain to be overcome (*15*−*21*).

Among the existing problems, inefficient cellular uptake and subsequent release from endosomes to cytoplasm appear to be the most severe ones. In addition, cell type or organ specific targeting, proper intracellular distribution, and increased plasma half-lives are subjects that play a central role in development of oligonucleotide-based therapeutics.

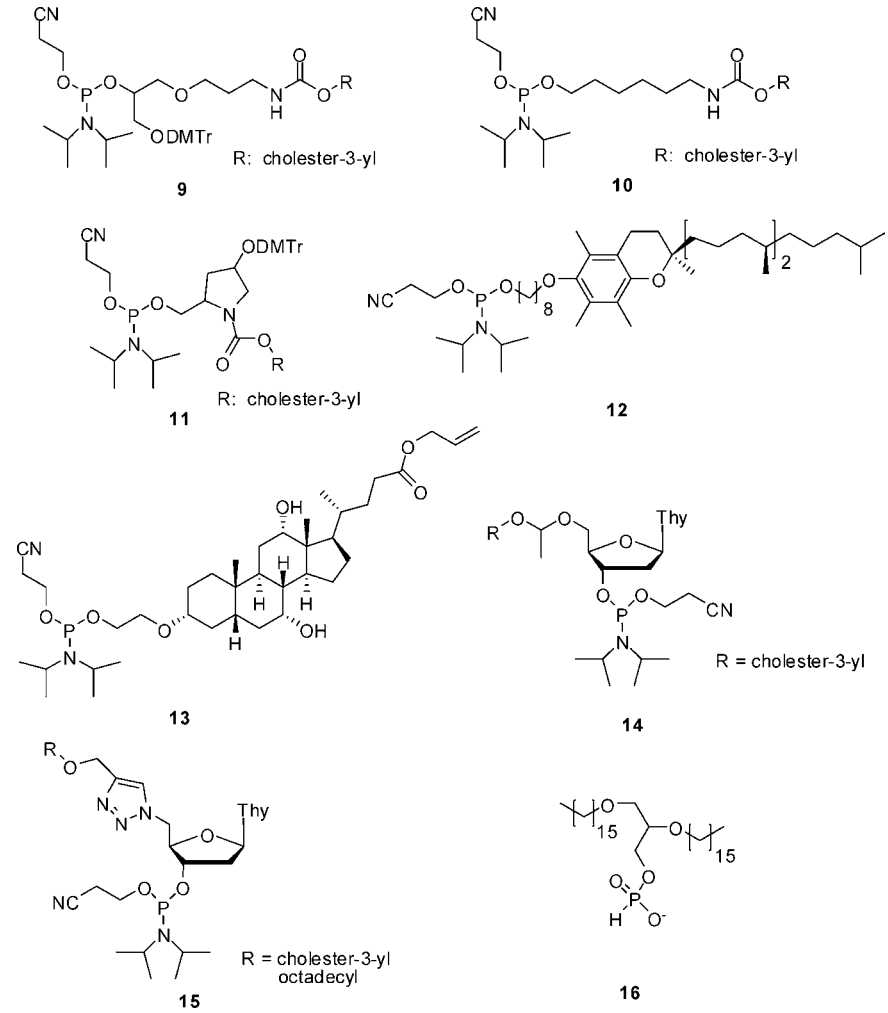
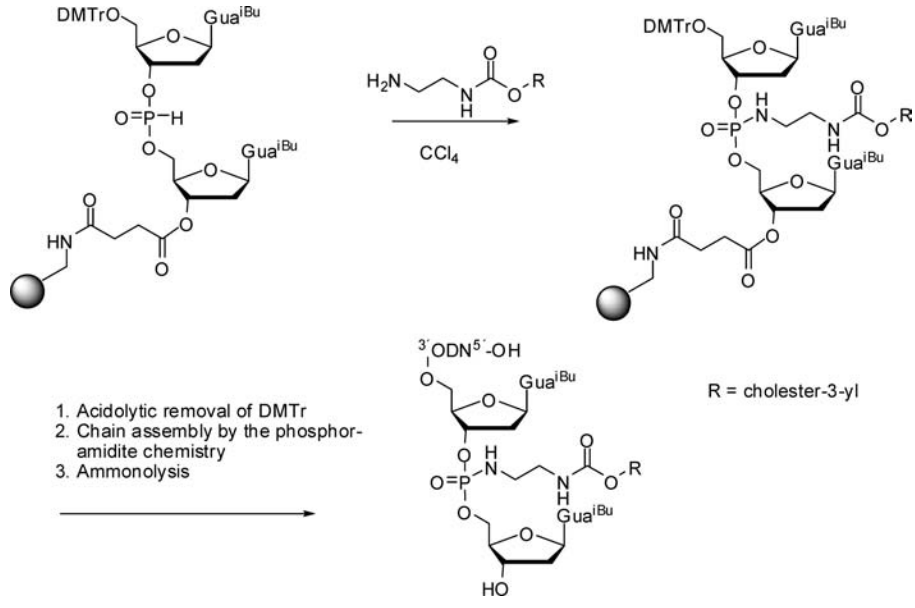
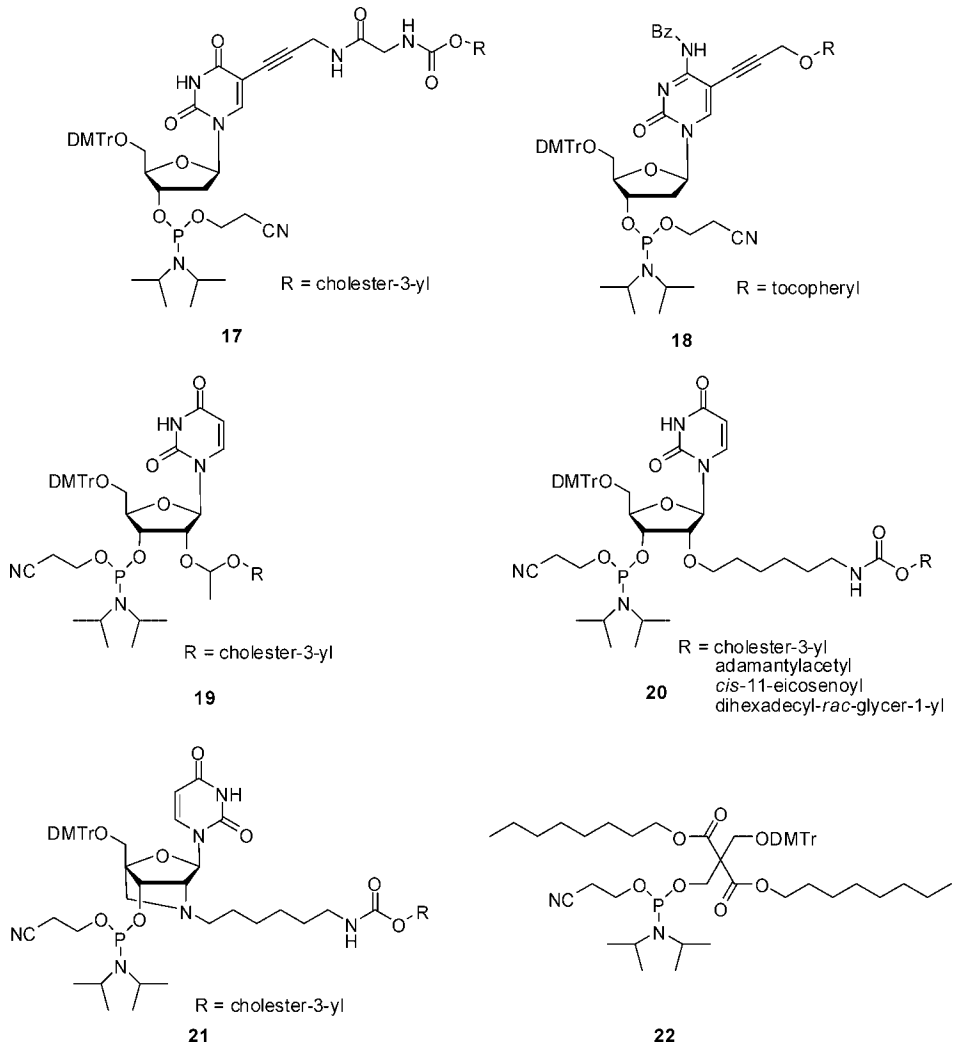


Scheme 2

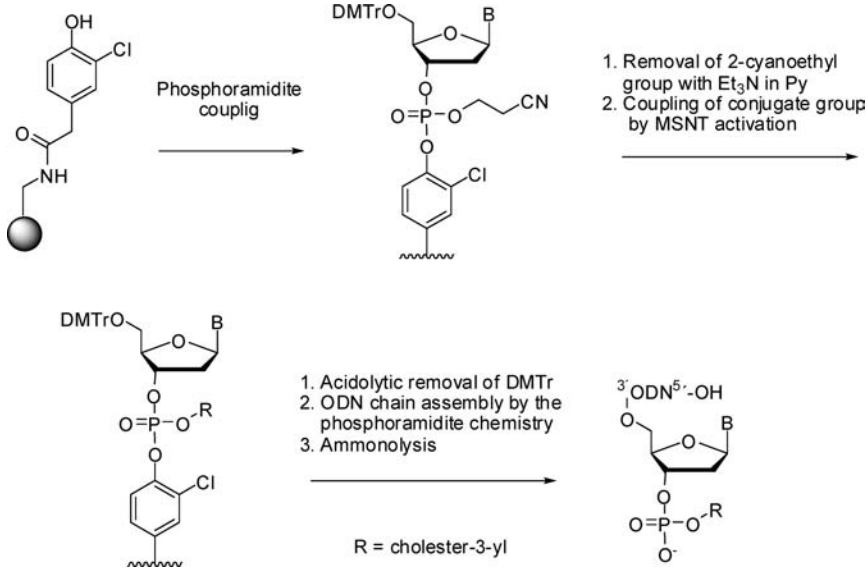


Conjugation of oligonucleotides with molecules that provide the conjugate with a desired novel property offers a feasible way to respond to these requirements. For example, oligonucleotides bearing a conjugate group known to be internalized by receptor-mediated active transport expectedly exhibit enhanced uptake compared to their nonconjugated counterparts (*22*−*24*). Cell-penetrating peptides, glycoclusters, lipids, polyamines, and numerous small molecules have all received interest as possible carriers of oligonucleotides. Although none of these approaches has so far led to a real breakthrough,

Chart 3



Scheme 3



many encouraging observations have been made. Conjugation of neutral peptide nucleic acid (PNA[1]) or phosphoramidate morpholino analogues of oligonucleotides to arginine-rich peptides has been reported to significantly enhance their cellular uptake and strengthen their antisense effect (*25*−*29*). Galactosylated conjugates of oligodeoxyribonucleotide (ODN) phosphorothioates are internalized via the galactose-specific asialoglycoprotein receptor-mediated endycytosis (*30*). Poly(ethylene glycol) (PEG) conjugation has been shown to prolong the half-life in plasma (*31*), and conjugation with

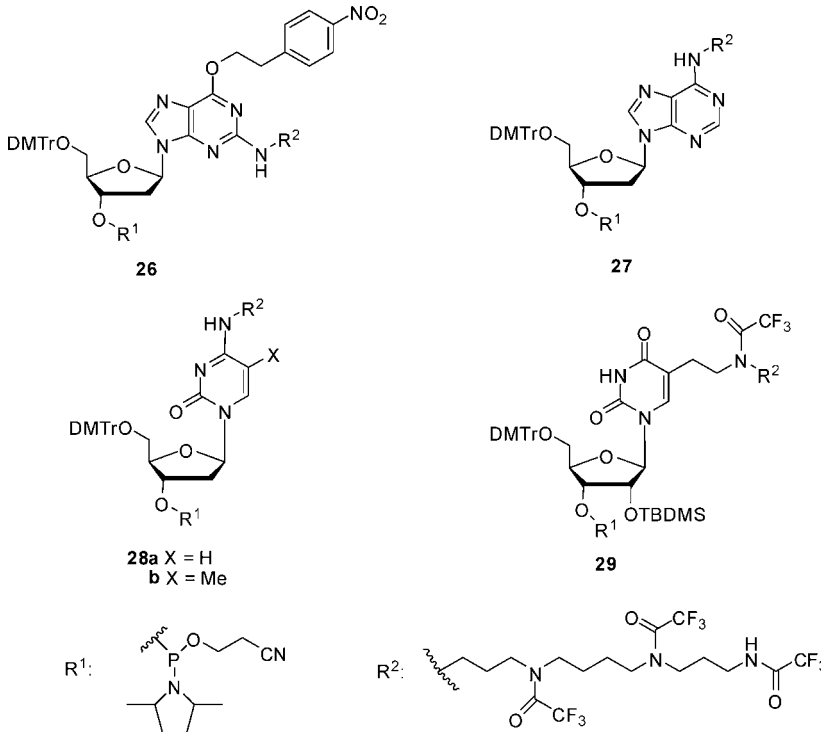
25

lipophilic groups (*32*−*34*) or aptamers (*35*) has increased the efficiency of siRNA-induced gene silencing in vivo. Owing to these and many other promising results, development of efficient and reproducible methods for convenient preparation of various types of oligonucleotide conjugates has become a subject of considerable importance. Workable chemistry is a prerequisite for extensive biological studies.

The methods used for the preparation of oligonucleotide conjugates fall in two major categories: solution- and solid-phase conjugation. On applying the solution-phase approach, the oligonucleotide is at some stage of its solid-phase synthesis equipped with an appropriate functionality, to which the conjugate group is coupled in solution after release and purification of the oligonucleotide. When the solid-phase methodology is used, the entire conjugate is assembled on a single support, either by conjugation of a prefabricated conjugate group or by assembling the conjugate moiety by a stepwise process prior to or after the oligonucleotide synthesis. The advantage of the solid-supported method compared to conjugation in solution is a less laborious

Chart 5



purification. To achieve high coupling efficiency, the conjugate group is usually used in considerable excess, which complicates the purification when the conjugation is carried out in solution. By contrast, on a solid support, the unreacted conjugate group and the possible side products may be removed by simple washing, which markedly facilitates the chromatographic purification after release from the support. The use of a solid support may also help to avoid the problems otherwise arising from limited solubility of one of the reactants.

The present paper reviews the methods described for the solid-supported synthesis of oligonucleotide conjugates useful for delivery and targeting of potential nucleic acid therapeutics. Accordingly, preparation of oligonucleotides conjugated with lipids, polyamines, peptides, carbohydrates, PEG, and some small molecules are discussed. In addition, synthetic procedures for oligonucleotides bearing biodegradable or thermolabile phosphate protecting groups are summarized.

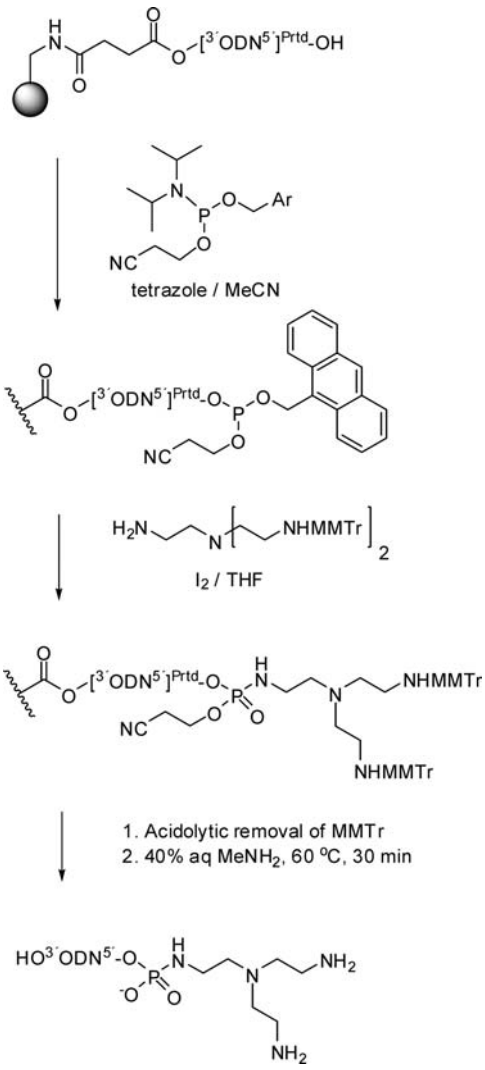
HYDROPHOBIC CONJUGATES

Since the hydrophobic interior of the phospholipid bilayer forms the main obstacle to internalization of polyanionic oligonucleotides, it is quite natural that conversion of oligonucleotides to their lipid conjugates has long received interest as a possible method to enhance their cellular uptake (*36*). Reduction of the hydrophilic nature of the oligonucleotide is not, however, the only reason for lipid conjugation. Some hydrophobic pendants, above all cholesterol, are believed to bind to lipoproteins and particles of low-density lipoproteins (LDL), a cholesterol transporter in blood. Consequently, the cholesterol conjugate becomes recognized by hepatitic cells (*37*−*39*) and, hence, internalized by lipoprotein-mediated endocytosis. As mentioned above, conjugation with cholesterol has been shown to increase the efficacy of siRNA-induced silencing of the apoB mRNA gene in rodents' liver and jejunum (*32*).

The hydrophobic conjugates of oligonucleotides are usually obtained by one of the following solid-phase approaches: (i) 3′-conjugates by chain assembly on a support bearing the desired conjugate group, (ii) 5′-conjugates by introduction of the conjugate group as a phosphoramidite reagent, and (iii) intrachain conjugates by making use of prefabricated nucleosidic building blocks or their congeners incorporating the conjugate group. Scheme 1 shows an illustrative example of the preparation of the 3′-conjugates. A branched alcohol bearing orthogonally protected amino and hydroxyl groups is attached to the support via a succinyl linker. The conjugate group bearing a hydroxyl function is first attached to the deprotected amino group of this handle as a chloroformate ester, and the ODN is then assembled on the deprotected hydroxyl function (*40*). Support **1** (Chart 1) had earlier been used similarly (*41*). While in these cases a stepwise immobilization has been applied to obtain the cholesterol bearing support, related supports have more often been prepared by immobilization of a prefabricated linker−cholesterol conjugate (*34*, *42*−*48*). Among these, support **6** has been used for construction of oligoribonucleotide (ORN) conjugates (*34*) and **2**−**5** for the synthesis of ODN conjugates. Supports **4** derived from *trans*-L-hydroxyprolinol have additionally been used for the preparation of ODN conjugates of many other steroids and diacylated glycerols (*49*). 2′-*O*- (*50*) and 3′-*O*-succinylated uridine (*51*), **7** and **8**, conjugated with cholesterol via the remaining secondary hydroxyl function represent still another type of support utilized for preparation of the 3′-terminal conjugates.

Chart 2 shows the structures of the phosphoramidite (**9**−**15**) and H-phosphonate (**16**) reagents, both non-nucleosidic and nucleosidic ones, used to introduce hydrophobic conjugate groups into the 5′-terminus of ODNs (*46*, *47*, *49*, *51*−*55*). Building block **13** deserves special attention. This phosphoramidite reagent derived from the allyl ester of 3-α-(2-hydroxyethoxy)cholic acid is obtained by selective phosphitylation of the primary hydroxyl group with 1.1 equiv of 2-cyanoethyl-*N*,*N*-diisopropylphosphorochloridite without interference of the secondary hydroxyl functions (*54*). The allyl protection may then be removed on-support with $Pd[PPh_3]_4$. 5′-Palmitoyl ODNs have been obtained by using base-labile *t*-butylphenoxyacetyl protecting groups for base moiety amino functions and oxalyl

Scheme 5

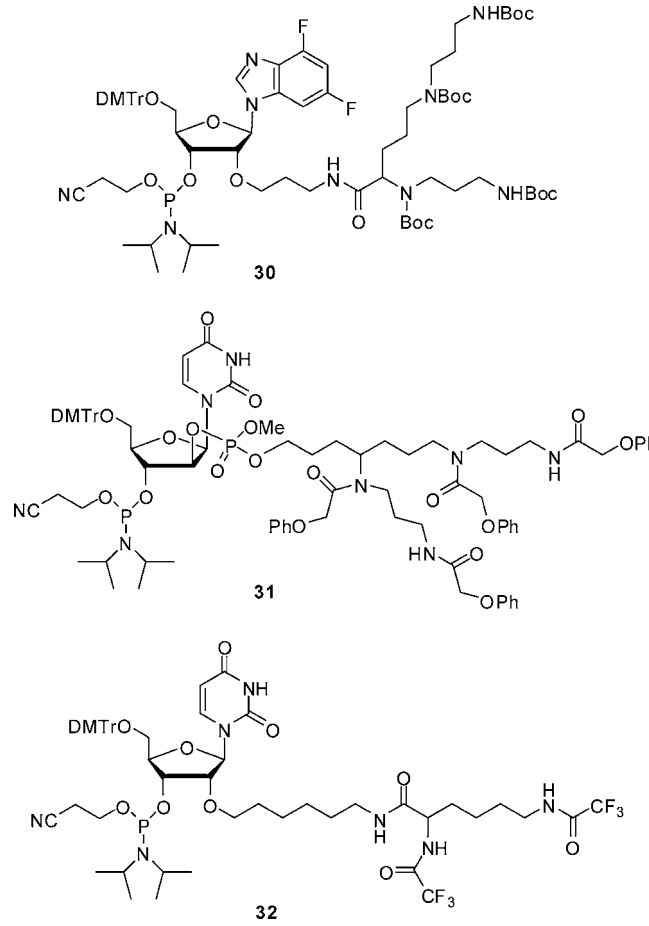


linker. These modifications to the standard phosphoramidite strategy allow mild deprotection with ethanolamine, and hence, the 5′-ester linkage remains intact (*56*).

Incorporation of hydrophobic groups into intrachain positions of the oligonucleotide chain is usually performed with the aid of prefabricated nucleosidic or non-nucleosidic building blocks. The nucleosidic building blocks exploited include the phosphoramidites of C5-derivatized pyrimidine 2′-deoxyribonucleosides (**17**, **18**) (*57, 58*), 2′-*O*-derivatized uridine (**19**, **20**) (*50, 51*), and a thymine amino-LNA monomer (**21**) (*59*). Several hydrophobic conjugate groups including cholesterol (*50, 57, 59*), α-tocopherol (*58*), adamantanylacetic acid (*50*), long chain fatty acids (*50*), and diacylglycerol (*50*) have been introduced in this manner (Chart 3). A prolonged coupling time is required to couple the lipidated block (*57, 58*). Octyl groups have been incorporated into ODNs using a phosphoramidite building block derived from dioctyl 2,2-bis(hydroxymethyl)malonate (*60*). Again, a prolonged coupling time (10 min) is required for high coupling yield (>98%) and the subsequent detritylation has to be carried out with TFA. Interestingly, the ester linkages at internucleosidic positions withstand normal ammonolysis.

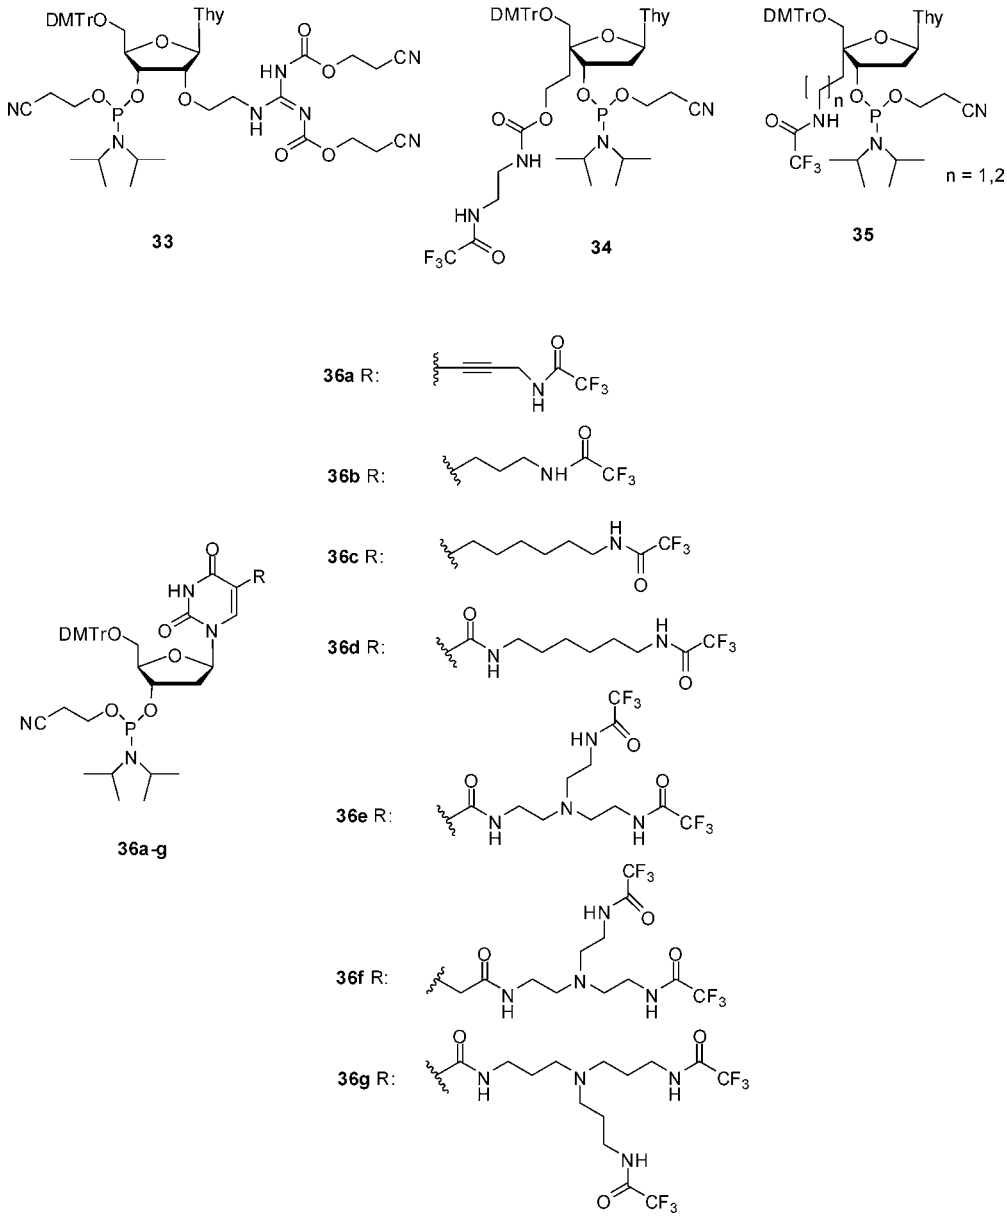
Besides exploitation of prefabricated solid supports and phosphoramidite reagents bearing the conjugate group, several on-support conjugation procedures have been reported. In fact, the first solid-phase synthesis of a cholesterol conjugate is a nice example of such an approach, involving oxidative phosphoramidation of a support bound dinucleoside-3′,5′-(*H*-phosphonate) with CCl_4 in the presence of cholester-3-yloxycarbonylaminoethylamine and subsequent assembly of the ODN chain (Scheme 2) (*61*). Interestingly, one of the very recent approaches follows a related principle. Instead of conventional succinyl linker, an aminoalkyl support is acylated with 3-chloro-4-hydroxyphenylacetic acid, and the 3′-terminal nucleoside is coupled to the hydroxyl function by the normal phosphoramidite chemistry (Scheme 3) (*62*). The 2-cyanoethyl protection is then removed with triethylamine in pyridine (1 h, 50 °C) and the conjugate group, e.g., cholesterol, is coupled to the exposed phosphodiester linkage by the phosphotriester chemistry. On using MSNT as an activator, the coupling yield has been reported to range from 75% to 80%. The ODN chain is then assembled by phosphoramidite chemistry. Upon ammonolysis, only the ODN bearing the conjugate group is released from the support, since the phosphodiester linkage is not cleaved by ammonolysis, not even when aryl pohosphodiesters are concerned. It is also possible to remove the 2-cyanoethyl protection and assemble the ODN chain prior to the introduction of the conjugate group. In case one wishes to conjugate amines instead of alcohols, the phosphodiester linkage is first tosylated, and a nucleophilic displacement with the amine is then carried out.

Chart 6



Thiocholesterol has been conjugated to the 5′-terminus of a support-bound ODN by elongation of the chain with 6-chloroacetamidohexanol phosphoramidite and displacing the chloro substituent with thiocholesterol in dioxane in the presence of DBU. Normal ammonolysis then releases the conjugate (Scheme 4A) (*63*). Long chain aliphatic alkyl groups and small aromatic groups have been introduced similarly. Several lipophilic alcohols, including cholesterol, borneol, menthol, and heptadecanol, have been converted to 2-alkoxy-2-thiono-1,3,2-oxathiaphospholane and reacted in DCM in the presence of DBU with

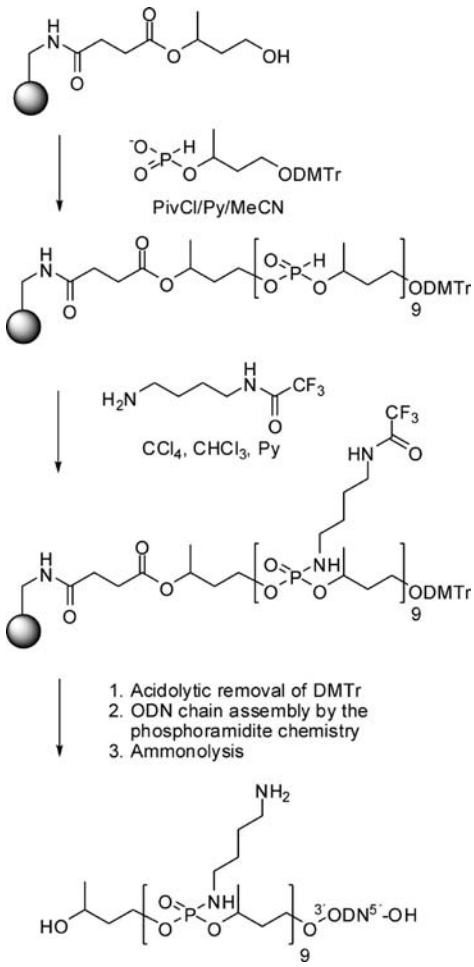
Chart 7



the 5′-hydroxy group of a support-bound ODN (Scheme 4B) (*64*). Again, a normal ammonolysis is finally carried out.

Masking of the internucleosidic phosphodiester bonds of an antisense oligonucleotide with biodegradable or thermolabile protecting groups represent another type of utilization of hydrophobic conjugate groups. The most extensively studied examples are *S*-acyl-2-mercaptoethyl and alkoxymethyl-protected ODNs. The former pro-oligonucleotides have been assembled by the phosphoramidite chemistry using *S-tert*-butyl-2-mercaptoethyl-*N*,*N*-diisopropylphosphoramidites instead of the 2-cyanoethyl protected ones (*65*). Since the phosphotriester linkages do not withstand ammonolysis, the base moiety acyl protecting groups have been replaced with photolabile 6-nitroveratryloxycarbonyl or 2,2′-bis(2-nitrophenyl)ethoxycarbonyl group, and the synthesis has been carried out on a photolabile 1-(2-nitrophenyl)-1,3-propanediol linker. For the *S*-acetyl-2-mercaptoethyl protected oligomers, three alternative strategies have been proposed. First, the chain assembly has been carried out on a photolabile linker, but the base moieties have been protected with a Pd(0)-labile allyloxycarbonyl group and those phosphodiester linkages that do not bear a 2-methylthioethyl group with an allyl group (*66*). Second, fluoride-ion-labile protections, viz., 4-(*tert*-butyldiphenylsilyloxymethyl)benzoyl group for the base moieties and 2-(trimethylsilyl)ethyl group for the phosphate moieties, have been used (*67*). When the oligomer is assembled on a phosphoramidate linker, it is released by the $Et_3N\cdot(HF)_3$ treatment used to remove the base and phosphate protections. The third alternative is chain assembly on a disulfide linker using building blocks that bear 2-(trimethylsilyl)ethoxycarbonyl protections on nucleobases and 2-(trimethylsilyl)ethyl protection on phosphate moieties (*68*). The base moiety and phosphate protections are removed by a single $ZnBr_2$-treatment on the support and the deprotected oligomer is released reductively into the solution. *O*-(4-Acyloxybenzyl)phosphorothioate linkages have also been site-specifically introduced into oligonucleotides by the phosphoramidite strategy using building blocks bearing a 4-acyloxybenzyl group instead of the 2-cyanoethyl group. *N*-Pent-4-enoyl group, cleaved upon release of the oligomer from the support with methanolic K_2CO_3, has been used for the base moiety protection (*69*). 3-Pivaloyloxy-2,2-bis(ethoxycarbonyl)propyl protections have been introduced into ODNs as prefabricated dimeric phosphoramidite reagents (*70*).

Scheme 6



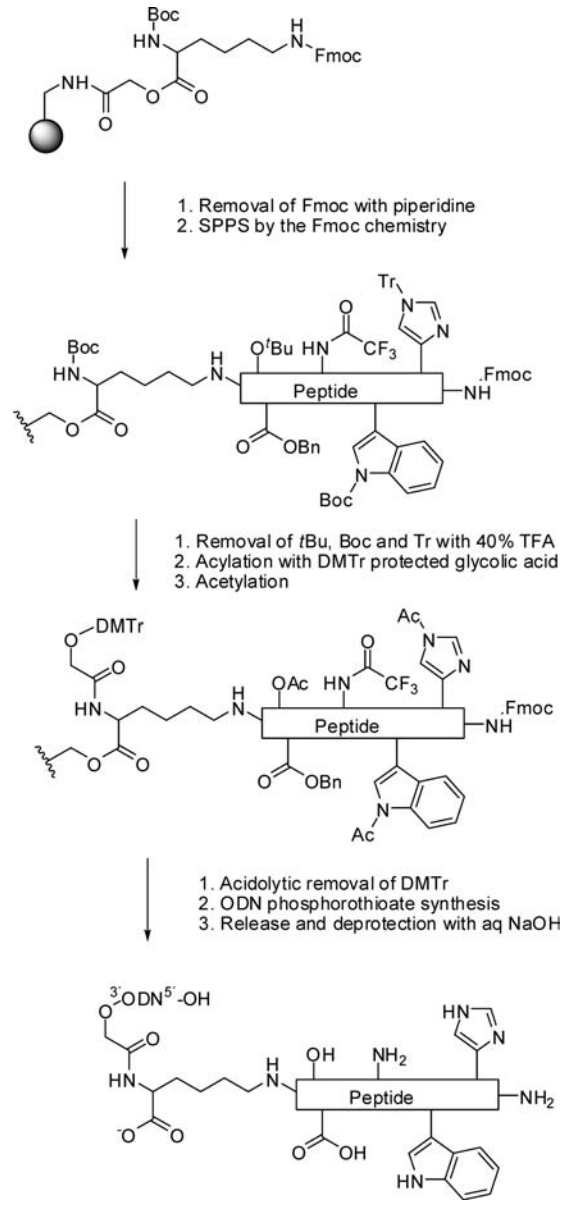
All the pro-oligonucleotides discussed above bear esterase-labile protecting groups. In addition, oligonucleotides bearing spontaneously cleavable phosphate protections have been suggested to be viable antisense prooligonucleotides. For this purpose, ODNs bearing 3-hydroxypropyl (*71*), 4-hydroxybutyl (*71*), or *N*-formyl-*N*-methyl-2-aminoethyl (*72*) protecting groups on selected internucleosidic phosphodiester linkages have been prepared. The departure of all these groups is based on thermolytic cyclization. For the synthesis, conventional phosphoramidite chemistry may be applied when nucleoside 3′-(*N*,*N*-diisopropylphosphoramidites) bearing the desired protecting groups are used and normal ammonolysis is replaced by treatment with pressurized ammonia at 25 °C.

POLYAMINE CONJUGATES

Polyamines, being positively charged at physiological pH, form complexes with negatively charged oligonucleotides. These complexes, known as polyplexes, interact with the negatively charged phospholipids of the cell membrane and, hence, enhance the cellular uptake (*73*). Dendrimeric polyamines, for example, are extensively used as transfection agents for plasmids, but also for siRNA and oligonucleotides. Accordingly, it is no surprise that covalent polyamine−oligonucleotide conjugates have received attention as potential facilitators of the delivery of therapeutic oligonucleotides. In addition, it is worth noting that some oligoamines, such as spermine and spermidine, are naturally occurring metabolites known to complex in cells with RNA (*74*), and they may, hence, affect the biodistribution of their oligonucleotide conjugates.

Oligoamines, either linear or branched, are usually attached to the 5′-terminal hydroxyl function of the chain, to a C5 site

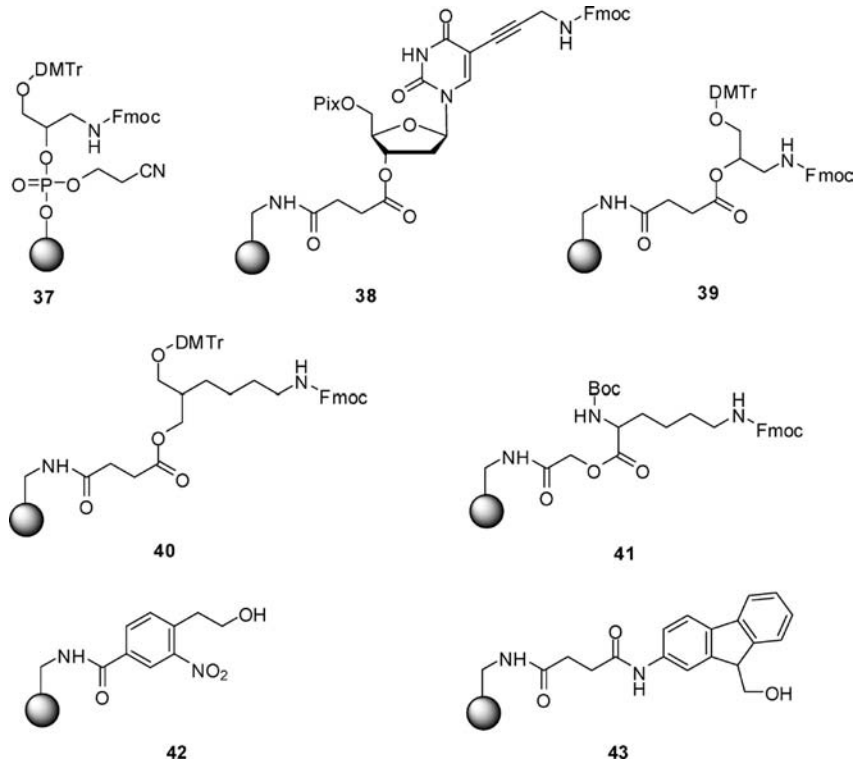
Scheme 7



of a pyrimidine base or to 2′-*O* of a ribonucleoside unit. Up to 6 α,ω-bis(4-hydroxybutyl)spermine molecules have been incorporated as trifluoroacetyl protected phosphoramidite reagents (**23**; Chart 4) into the 5′-terminus of ODNs, giving a long linear spermine−phosphate tail (*75*). The coupling efficiency of these building blocks has been reported to be as high as 90−96%. Standard ammonolysis is adequate to remove all trifluoroacetyl protections. A single C-branched spermine has been incorporated as a phenoxyacetyl protected phosphoramidite reagent (**24**) (*76*, *77*). More complex 5′-terminal polyamine structures have been constructed by coupling a 5′-amino-5′-deoxythymidine phosphoramidite bearing a spruce-like methoxyoxalamido-functionalized polyamine (**25**) as the last building block of the chain assembly. Upon release and deprotection of the conjugate with a primary amine, e.g., spermidine or histidine, each branch becomes further derivatized with this amine by formation of oxalyldiamide linkages (*78*). Tetrazole activation with 15 min reaction time has been used for coupling of this highly branched block.

Several spermine moieties have been incorporated into ODNs with the aid of appropriately protected phosphoramidites of N^2-derivatized 2′-deoxyguanosine (**26**; Chart 5) (*79*, *80*), N^6-

Chart 8



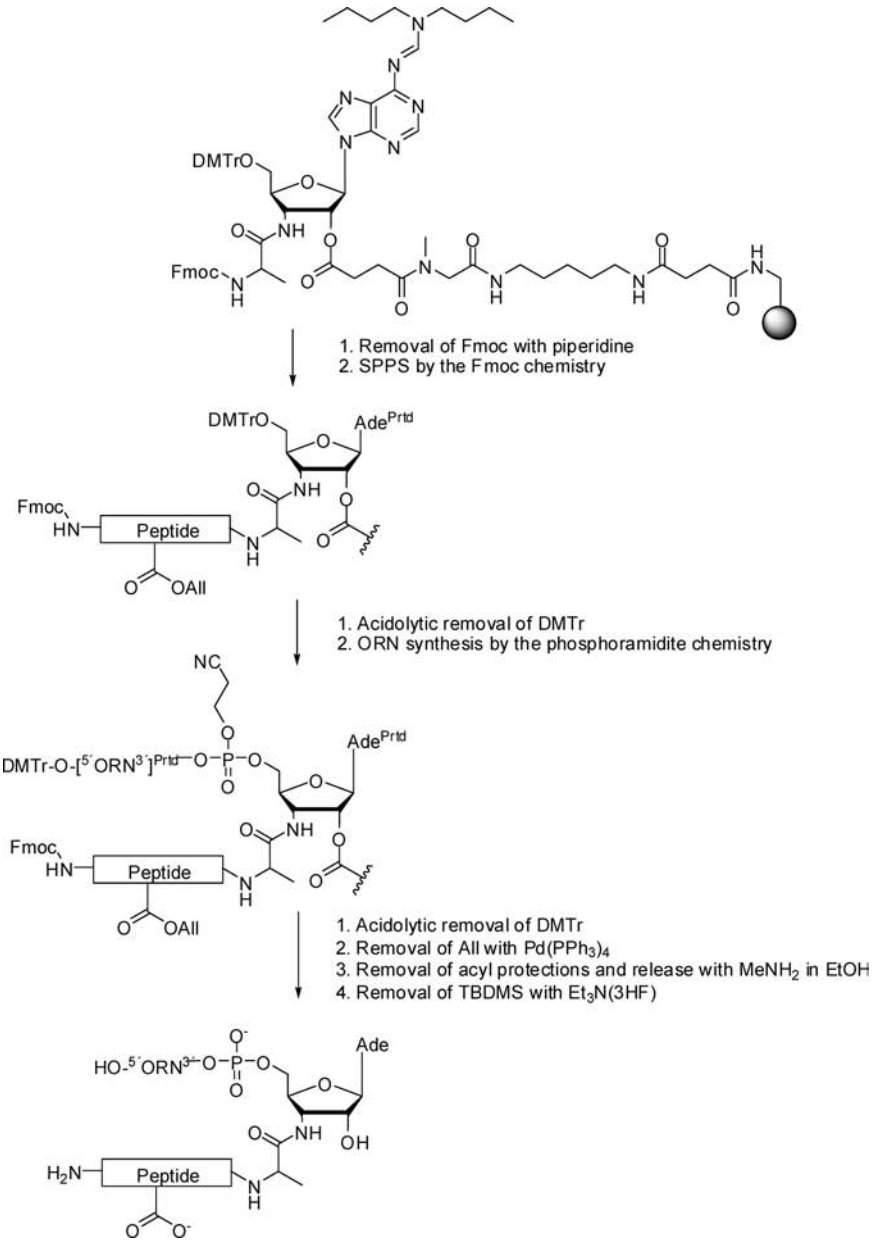
derivatized 2′-deoxyadenosine (**27**) (*80, 81*), and N^4-derivatized 2′-deoxycytidine (**28a**) (*82*) and its 5-methyl analogue (**28b**) (*83*). The cytidine derivative coupled as well as the unmodified 2′-deoxynucleoside building blocks, but for the guanosine derivative, repeated coupling and prolonged coupling time (10 min) had to be applied to obtain a coupling efficiency of 95%. Into ORNs, spermine moieties have been incorporated with a C5-modified 5′-*O*-DMTr-2′-*O*-TBDMS-uridine 3′-phosphoramidite building block (**29**) (*84*). A coupling efficiency of 96% has been achieved by using 5-benzylthiotetrazole as an activator.

Besides the phosphoramidite chemistry, oligoamines have been introduced into oligonucleotides by on-support nucleophilic displacement and oxidative amidation. 5-Methoxycarbonylmethyl-2′-deoxyuridine (*85*) or 2-fluoro-2′-deoxyinosine (*86*) has been incorporated into a desired site of the sequence, and treatment with sperimine has then resulted in conjugation by aminolysis of the methoxycarbonyl group upon release and deprotection of the conjugate. Similarly, treatment of the electrophilic conjugate depicted in Scheme 4A with spermine gives the desired oligoamine conjugate (*63*). Spermine can be used as a cleaving agent in an unprotected form, since the primary amino group is a much more efficient nucleophile than the secondary one. A branched oligoamine, N^1,N^1-bis(2-aminoethyl)ethane-1,2-diamine, has, in turn, been conjugated by oxidative amidation (*87*). For this purpose, the 5′-hydroxy function has been phosphitylated with (anthracen-9-yl)methyl 2-cyanoethyl *N*,*N*-diisopropylphosphoramidite and oxidation with I_2 in THF in the presence of the appropriately protected amine has then been carried out (Scheme 5). 98% of the (anthracen-9-yl)methyl group becomes oxidatively displaced with the amine. A special feature of this kind of conjugation is that the phosphoramidate linkage is acid-labile and may, hence, be cleaved, although expectedly quite slowly, at the relatively low pH of endosomes (pH 5).

Another possible way to introduce several aliphatic amino groups into an oligonucleotide is incorporation of several modified nucleosidic building blocks, each bearing a single amino group, into the chain along its entire length. 2′-*O* has been regarded as an appropriate site for tethering of aminoalkyl groups, since 2′-*O*-alkylated oligonucleotides hybrizide even better than their 2′-deoxy counterparts (*88*). In addition, the catalytic argounaut proteins within the RISC complex appear to tolerate well 2′-*O*-modifications of siRNA (*89*). All canonical ribonucleosides have been prepared as 2′-*O*-(*N*-phthaloyl-3-aminopropyl) derivatives and introduced into oligonucleotides as appropriately protected phosporamidites (*90*). The oligonucleotides prepared contained long, contiguous sequences of the aminoalkylated nucleosides. A coupling efficiency of 98.5% has been achieved by repeated coupling steps. In addition to normal ammonolysis, a treatment with 10% aq methylamine has been applied to remove the phthaloyl protections. Several contiguous 2′-*O*-(3-dimethylaminopropyl)- (*91*) and 2′-*O*-[2-(2-dimethylaminoethoxy)ethyl]-5-methyluridine (*92*) blocks have been introduced without any amino protection, whereas 2′-*O*-(6-aminohexyl)-adenosine and -uridine blocks have been inserted as trifluorocetamides (*93*).

The shortcoming of the attachment of bulky groups to 2′-*O*, however, is reduced coupling efficiency. For example, the phosphoramidite **30** (Chart 6) bearing a bulky Boc-protected carboxyspermine has been reported to couple only in 40% yield (*88*). By contrast, phosphoramidite **31**, having an *ara* configuration and bearing a branched phenoxyacetyl protected spermine attached to the 2′-*O* via a phosphotriester linkage, has been observed to couple without marked difficulty (*76*, *77*). Oligonucleotides bearing up to five contiguous 2′-*O*-(*N*-lysyl-6-aminohexyl)uridines (**32**), introduced in *N*-trifluoroacetylated form, have been successfully assembled on a solid support by using extended coupling times (*94*, *95*). Like amino groups, guanidinium groups remain protonated and, hence, positively charged at physiological pH. ODNs bearing 2′-*O*-[2-(guanidinium)ethyl] groups have been prepared by using phosphoramidite **33** (Chart 7), where the guanidinium moiety is protected with 2-cyanoethoxycarbonyl groups (*96*). *tert*-Butylhydroperoxide or 1-*S*-(+)-(10-camphorsulfonyl)oxaziridine has been used for the oxidation and the 2-cyanoethoxycarbonyl groups have been removed with piperidine before normal ammonolysis to

Scheme 8



prevent cyclization of the guanidinium group to triazine. Aminoalkyl groups have also been tethered to C4′ of thymidine, and several such modified nucleosides (**34**, **35**) have been incorporated into ODNs by the phosphoramidite chemistry (*97, 98*). A 96% coupling efficiency has been achieved on using a prolonged coupling time (6 min) and a high phosphoramidite concentration (1.2 mol L^{-1}).

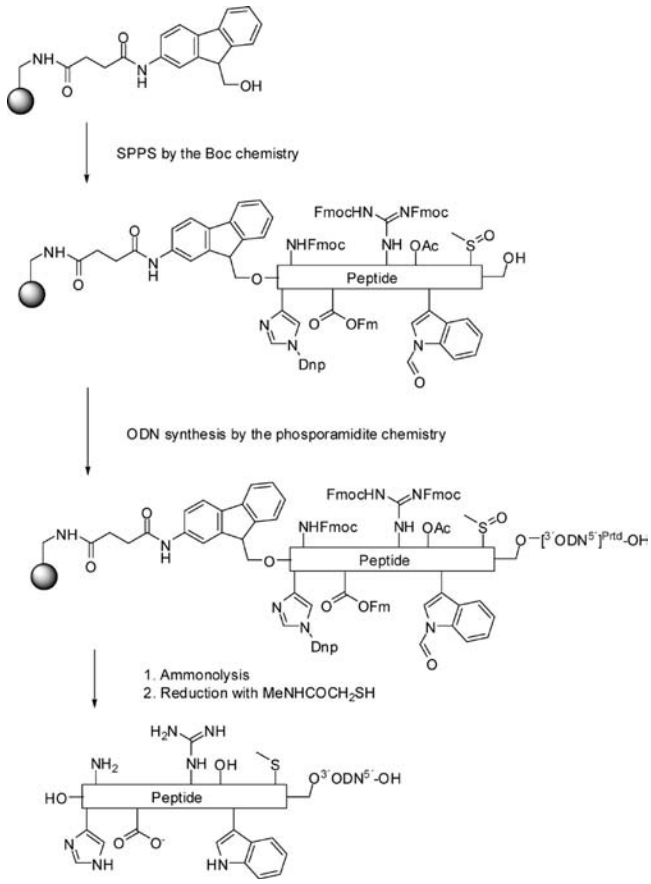
Besides the sugar hydroxyl functions, C5 of pyrimidine nucleosides has been used as a site for the attachment of aminoalkyl groups. Several 2′-deoxyuridines and 2′-deoxycytidines bearing linear (*99*−*102*) or branched (*103, 104*) aminoalkyl side chains at C5 have been incorporated into ODNs by normal phosphoramidite chemistry. Immobilization of the corresponding nucleosides to an aminoalkylated solid support via a succinyl linker has allowed synthesis of conjugates having the 3′-terminal nucleoside modified also (*100, 103, 105*). Additionally, a postsynthetic approach has been applied to obtain aminoalkyl-derivatized oligonucleotides. 5-(Methoxycarbonyl)-2′-deoxyuridine has first been introduced into the ODN chain, and treatment with ethane-1,2-diamine or hexane-1,6-diamine has then resulted in aminolysis of the methoxycarbonyl function to an ω-aminoalkylcarbamoyl function upon the release and deprotection of the conjugate (*106*).

ODNs bearing an aminoalkylated phosphoramidate tail at the 3′-terminus have been prepared by assembling first a non-nucleosidic backbone for the tail from 3-DMTrO-1-methylpropyl H-phosphonates and oxidizing the H-phosphonate diester linkages obtained with CCl_4 in the presence of *N*-trifluoroacetylbutane-1,4-diamine (Scheme 6). The oligonucleotide chain is then assembled by phosphoramidite chemistry (*107*). Similarly, ODNs bearing a 5′-polyimidazole tail have been prepared by consecutive coupling of several 4-DMTrO-butyl H-phosphonates to the 5′-terminus of an otherwise fully protected support-bound ODN and subsequent oxidation with CCl_4 in the presence of histamine (*108*).

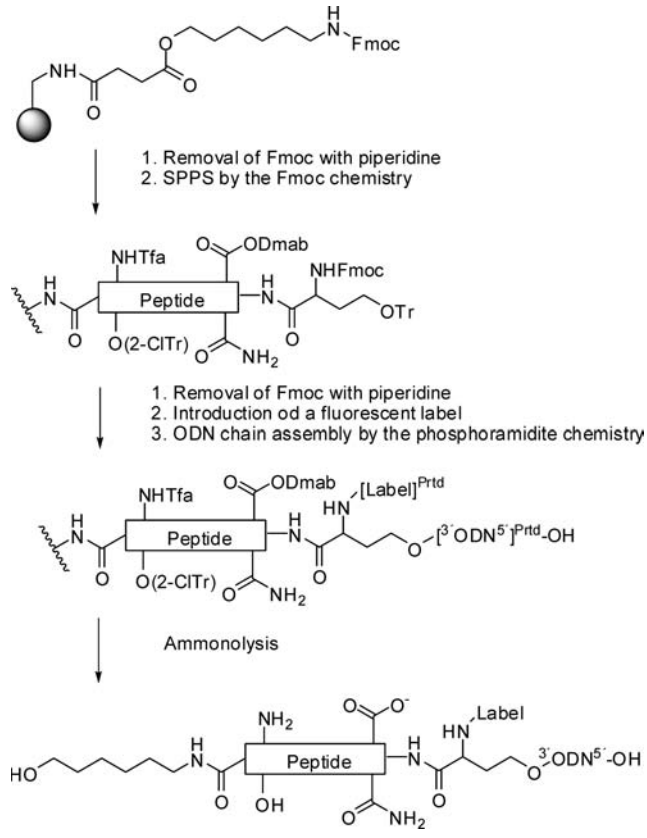
PEPTIDE CONJUGATES

Some rather short peptides have been discovered to translocate across cell membranes, partly by endocytic processes but partly by endocytosis-independent cytoplasmic entry (*109*). Such peptides usually are Arg- or Lys-rich. The two naturally

Scheme 9

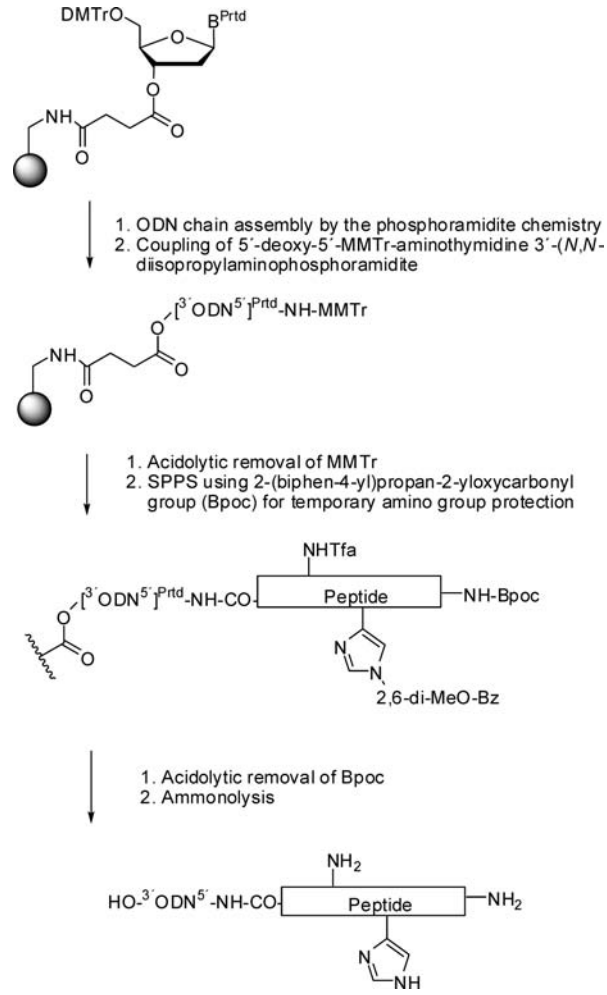


Scheme 10



occurring sequences, Penetratin and Tat peptide, and a synthetic hybrid, Transportan, of two naturally occurring sequences are

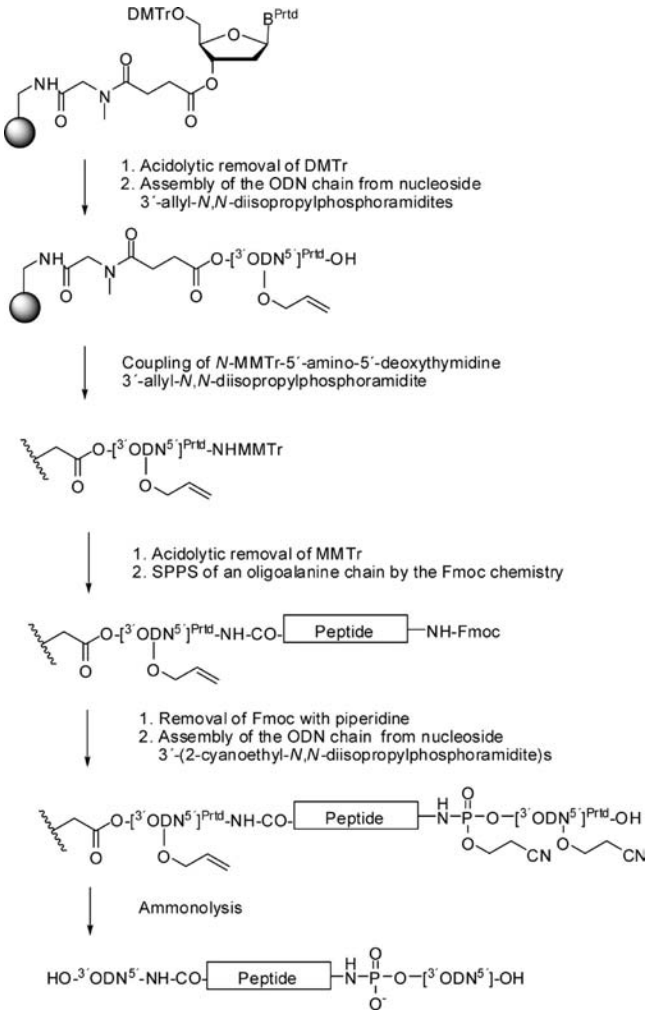
Scheme 11



the best-known examples (*110*). Conjugation of antisense oligonucleotides with these cell-penetrating peptides has received wide interest as a possible way to enhance their delivery into cells (*111*−*113*). In addition, conjugation with nuclear localization signal peptides has been studied as a means to affect the intracellular distribution of oligonucleotides (*114*). It is not, hence, surprising that synthesis of peptide conjugates has been the subject of more intensive studies than any other category of oligonucleotide conjugates. The progress of the field has been reviewed every few years (*115*−*119*). In the present review, attention is only paid to alternative approaches of solid-supported synthesis and, in particular, to novel approaches applicable to preparation of reasonably long peptide conjugates. The solution-phase conjugation of prefabricated peptides and oligonucleotides bearing mutually reactive functionalities is not discussed, although such methods are often highly useful and still more extensively used than solid-phase syntheses (*116*−*118, 120*).

Although the solid-phase synthesis of both oligonucleotides and peptides is well-established, assembly of oligonucleotide−peptide conjugates from monomeric units on a single support still is a considerable challenge. The existing protocols of oligonucleotide synthesis are largely based on acid-labile temporary protection and base-labile global protection, whereas the opposite is true for the peptide synthesis, or alternatively, both the temporary and global protecting groups are acid-labile. Accordingly, at least one of the existing strategies must be considerably modified to enable a stepwise chain assembly. The stepwise strategies suggested so far fall into two major categories: either a branched linker bearing an amino group for peptide synthesis and a hydroxyl function for subsequent

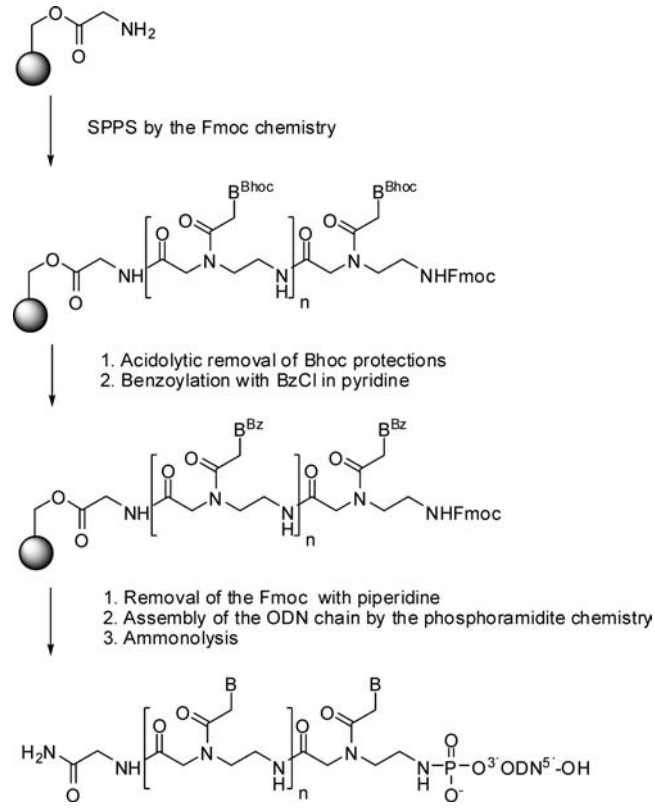
Scheme 12



assembly of the oligonucleotide sequence is utilized, or a linker bearing a hydroxyl function is attached to the amino terminus of the support-bound peptide and used as a starting point for the oligonucleotide chain assembly. Both approaches face the same difficulty, viz., incompatibility of the protecting group strategies usually applied to oligonucleotide and peptide synthesis.

As far as the peptide moiety containing no side-chain fuctionalities, or only those that can be protected with orthogonally removable groups or such base-labile groups that withstand the Fmoc removal with piperidine, the situation is not very problematic. The synthesis may be carried out on a branched linker bearing an Fmoc-protected amino group and a DMTr-protected hydroxy function. The peptide moiety is first assembled on the amino group by the Fmoc chemistry and the ODN moiety then on the hydroxyl function by the phosphoramidite chemistry. The early examples of such an approach are offered by the synthesis of a conjugate of 17-mer ODN and a 3′-terminal tripeptide on linker **37** (Chart 8) (*121*) and a conjugate of a 23-mer ODN and a base moiety bound dipeptide on linker **38** (*122*). Among these, **37** may be cleaved by successive treatments with ethane-1,2-diamine in ethanol and IO_4^- in aqueous acetonitrile and **38** by normal ammonolysis. More recently, a branched linker strategy (**39**) has been applied to preparation of a 14-mer phosphorothioate ODN bearing a 16-mer membrane permeable peptide, viz., the hydrophobic region of the signal peptide sequence of the *Kaposi* fibroblast growth factor (*123*). While this sequence does not contain any trifunctional amino acids, incorporation of some such residues appears feasible. Linker **40** has been successfully used for

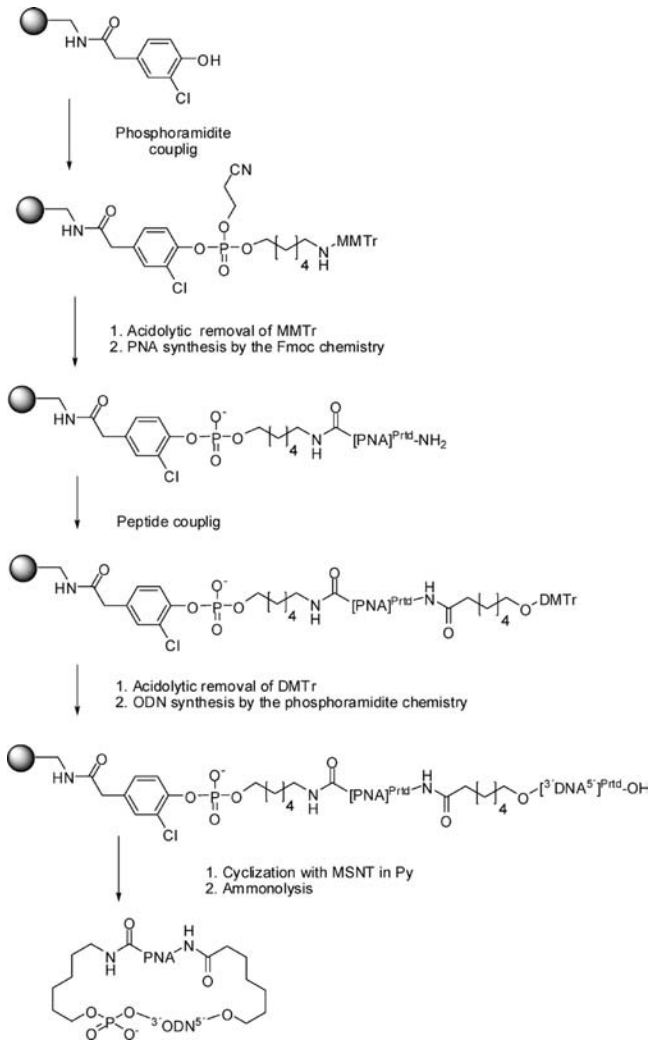
Scheme 13



synthesis of peptide conjugates containing Cys, Lys, and Ser residues (*124*). Their side-chain functionalities have been protected with Tr, Boc, and TBDMS groups, respectively. Although these protecting groups are acid-labile, they have been reported to tolerate the repeated removal of DMTr protections during the assembly of a 15-mer ODN. They have been removed after the ODN assembly, but before the ammonolysis. When an even more generally applicable procedure is required, exchange of the acid-labile side-chain protecting groups of the peptide moiety to base-labile acetyl protections before assembly of the ODN chain appears to be an attractive alternative (*125*). The synthesis is carried out on linker **41**, the essential part of which is N^{α}-Fmoc-N^{ε}-Boc-lysine anchored to the support through an ester linkage (Scheme 7). The peptide moiety is assembled by the normal Fmoc chemistry on the α-amino group of this lysine handle. The acid-labile side-chain protections, including Tr on histidine, Boc on tryptophan, and *t*Bu on serine, are removed, as well as the Boc protection of the lysine handle. The exposed ε-amino group is acylated with DMTr-protected glycolic acid, and the side-chain functionalities of the peptide moiety are acetylated. The oligonucleotide chain is then assembled on the detritylated hydroxy function of the glycolic acid residue by the phosphoramidite strategy. The conjugate obtained is deprotected and cleaved from the support with aqueous sodium hydroxide. Apart from arginine, this protocol allows introduction of all trifunctional amino acids. Arginine residues have to be incorporated in the sequence as ornithines and converted postsynthetically to arginines by treatment with *N*,*N*′-bis-Fmoc-guanidine-*N*″-triflate (*126*).

Peptide conjugates of ORNs have been prepared by using an aminonucleoside as a branched linker (Scheme 8). An appropriately protected 3′-amino-3′-deoxyadenosine bearing a Fmoc protected alanyl group at 3′-*N* is immobilized to an amino-functionalized support via a 2′-*O*-succinyl linker (*127*). A peptide chain, containing only hydrophobic or allyl ester protected amino acids, is assembled on the alanyl residue by the Fmoc chemistry, after which the ORN sequence is assembled

Scheme 14

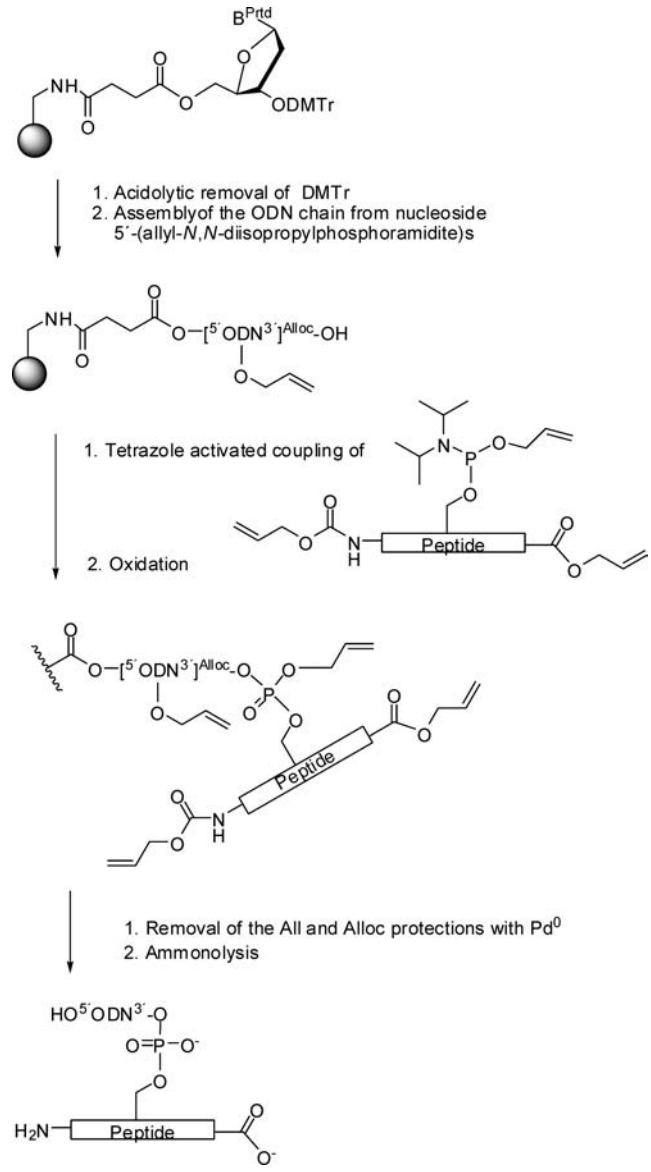


on the 5′-OH by the TBDMS/phosphoramidite chemistry. The allyl protections are removed with $Pd(PPh_3)_4$ on the support and the silyl protections in solution after ammonolysis. Another example of the utilization of an aminonucleoside as a branched linker is synthesis of ODN phosphorothioates bearing a 2′-*O*-trilysylsuccinyl tail on the 3′-terminal nucleoside. 2′-Deoxy-2′-(2-benzyloxy-1,2-dioxoethylamino)uridine has been immobilized to a PEG-grafted support via a 3′-succinyl linker (*128*). After the ODN chain assembly, the benzyl group is reductively removed and N^{ϵ}-trifluoroacetyllysine benzyl ester is coupled to the exposed carboxy function using carbodiimide activation. The procedure is repeated until the desired number of Lys residues have been coupled. Ammonolysis completes the synthesis.

Still, one possible way to use a nucleoside as a branched linker is to immobilize it through the base moiety to the support. 3′-*O*-TBDMS-5′-*O*-DMTr-2′-deoxycytidine has been immobilized through the N^4-atom via a succinyl linker to an aminoalkylated support (*129*). The ODN moiety is then assembled on the detritylated 5′-OH in an inverse direction using appropriately protected nucleoside 5′-phosphoramidites. After desilylation, the 3′-hydroxy group is phosphitylated with *N*-MMTr-6-aminohexylphosphoramidite, and the deprotected amino group is used as a starting point for the synthesis of the peptide moiety by the Fmoc chemistry.

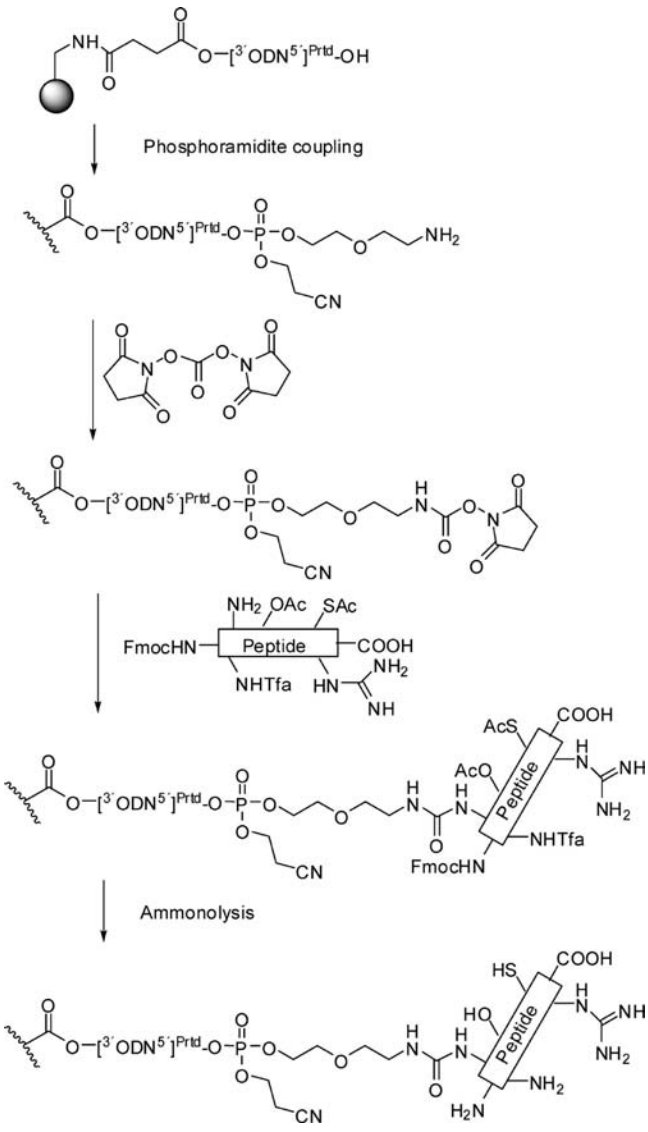
Instead of a branched linker, the hydroxyl function serving as the starting point of the ODN synthesis may be provided by an *N*-terminal *ω*-hydroxyacyl group or by a side-chain hydroxyl function of an *N*-terminal amino acid. The limitations concerning

Scheme 15



the side-chain protections of the peptide moiety are naturally similar to those using a branched linker. On applying this methodology, the peptide synthesis has often been carried out by the Boc chemistry on a base-labile 2-nitrophenylethanol (**42**) or 9-fluorenylmethanol linker (**43**) and the ODN chain is then assembled on a side-chain hydroxyl functionality of the *N*-terminal amino acid, viz., tyrosine, threonine, or serine (Scheme 9) (*130*−*137*). Use of homoserine instead of serine appears, however, preferable, since this increases the stability of the conjugate toward basic conditions (*138*, *139*). When desired, the ODN synthesis may also be initiated from a nonterminal amino acid, usually serine or homoserine (*138*, *140*). The side chains are protected with base-labile groups: Asp with Fm (*132*, *133*), His with Dnp (*138*), Lys with Fmoc or Tfa (*134*), Arg with Fmoc (*134*), Trp with formyl (*134*), and Ser, Thr, and Tyr with Ac (*134*). These groups expectedly withstand repeated acidolytic detritylations during the ODN synthesis and are removed by ammonolysis together with the nucleobase acyl protections. Met-containing conjugates are obtained by introducing methionine as a sulfoxide and reducing it back to methionine postsynthetically (*141*). Examples of the use of a hydroxyl-bearing linker between the ODN and peptide moieties include assembly of the peptide chain by the Boc chemistry on an ester linker and acylation of the *N*-terminus with 4-hydroxybenzoic

Scheme 16



acid (*142*) or 2,2-dimethyl-3-hydroxypropionic acid (*143*), peptide synthesis on an *o*-nitrophenylethanol linker followed by *N*-terminal acylation with *N*-succinyl-6-aminohexanol (*144, 145*), peptide synthesis on a 4-hydroxybutanoyl linker followed by *N*-terminal acylation with 4-[(6-hydroxyhexyl)amino]-4-oxobutanoic acid (*146*), and use of 10-hydroxydecanoyl group both as a support-bound linker and as an intervening spacer (*147, 148*).

Alternatively, Fmoc chemistry may be applied to the initial assembly of the peptide chain. In a rather recent report exploiting this overall strategy, homoserine has been used as a connector between the peptide and ODN moieties (*149*). While the homoserine residue provides the hydroxyl function required as the starting point for the ODN chain assembly, it simultaneously offers an amino function to be used for fluorescent labeling. 6-Aminohexanol esterified to a succinyl linker has been used as a handle for the peptide synthesis, and the side chains have been protected with base-labile protecting groups: Tfa for Lys, Dmab for Asp, and 2-ClTr for Tyr (Scheme 10). N^{α}-Fmoc-asparagines have been coupled as pentafluorophenyl esters without amide protection to avoid the side reactions that the HATU activation induces. Coupling of N^{α}-Fmoc-*O*-Tr-homoserine to the *N*-terminus, fluorescent labeling of the deprotected amino group, and ODN chain assembly on the detritylated hydroxyl group, followed by conventional ammonolysis, complete the synthesis. Earlier, a related strategy involving normal Fmoc peptide synthesis on a hydroxy-functionalized support, followed by coupling of 10-hydroxydecanoyl (*150*), 4-hydroxybutanoyl (*151, 152*), or 4-(6-hydroxyhexylamino)-4-oxobutanoyl (*152*) group as an intervening linker between the peptide and ODN moiety, has been applied. Very recently, a 35-mer peptide containing 25 trifunctional residues has been synthesized on a Rink-MBHA amide resin by the normal Fmoc/*t*Bu chemistry and elongated with 3-trityloxypropionic acid. After acidolytic detritylation, an oligothymidylate sequence has been assembled by phosphoramidite chemistry. Consecutive treatments with piperidine in DMF and 95% TFA have then given the conjugate (*153*). The question that remains to be answered is whether a heterosequence withstands without depurination the acidolytic removal of the *t*Bu-derived side-chain protecting groups.

Although the stepwise synthesis of oligonucleotide−peptide conjugates is usually initiated by assembly of the peptide moiety, the opposite is also possible. The use of conventional Fmoc chemistry for the synthesis of the peptide moiety is, however, hampered by the fact that repeated removals of the Fmoc groups with organic bases also remove the 2-cyanoethyl protections from the internucleosidic phosphodiester linkages. To avoid this, an acid-labile 2-(biphen-4-yl)propan-2-yloxycarbonyl group (Bpoc) has been introduced for the α-amino protection (Scheme 11) (*154*). This group may be removed under the same conditions as used for removal of the 5′-*O*-DMTr groups during the ODN synthesis. MMTr protected 5′-amino-5′-deoxythymidine has been coupled as the last nucleoside to provide the amino group required for the peptide synthesis. Acyl protections can be used for both the amino acid side-chains and the nucleic acid bases, and hence, release from support and global deprotection is achieved by conventional ammonolysis. In spite of instability of the 2-cyanoethyl phosphate protections to Fmoc removal, Fmoc chemistry has been applied to the synthesis of 5′-peptide conjugates of ODNs on a single support (*155*). Up to octapeptide conjugates have been obtained by this approach. The acid-labile side-chain protections, viz., PhiPr for Asp and Glu, MMTr for Lys and Cys, Tr for Gln and His, and ClTrt for Tyr, are removed with TCA in DCM before ammonolysis. Compatibility with incorporation of arginine has not been tested. Previously, an essentially similar protocol has been applied to synthesis of up to tetrapeptide 5′-conjugates (*156*).

Another possible way to avoid the problems arising from incompatibility of the 2-cyanoethyl phosphate and N^{α}-Fmoc protections is the use Pd^0-labile allyl group instead of 2-cyanoethyl group for protection of the phosphodiester linkages. Peptide−ODN hybrids consisting of two terminal ODN sequences and an intervening peptide segment have been prepared by this strategy (*157*). The 3′-ODN segment is first assembled on a sarcosine linker by the phosphoramidite chemistry, using 5′-*N*-MMTr-5′-amino-5′-deoxythymidine 3′-allyl-*N*,*N*-diisopropylphosphoramidite as the last building block (Scheme 12). The peptide sequence is then assembled on the deprotected amino group by the Fmoc chemistry, and the 5′-terminal ODN sequence is assembled on the terminal amino group. The allyl protecting groups and sarcosine linker are compatible with the Fmoc peptide chemistry when DBU is used for the removal of the Fmoc group. It is, however, worth noting that the feasibility of the approach has not been demonstrated with trifunctional amino acids. 3′,5′-Dipeptidyl conjugates of ODNs bearing very short peptide segments have been synthesized similarly (*158, 159*).

Peptide nucleic acids (PNA), isosteric analogues of oligonucleotides where the nucleic acid bases are linked through *N*-(1-oxoethylene) bridges to a peptide-like backbone composed of *N*-(2-aminoethyl)glycine units (*160*), are biologically stable and hybridize more efficiently and selectively than oligonucleotides, and they, hence, show potential as therapeutic oligonucleotide analogues. Unfortunately, they exhibit low cellular uptake and

Scheme 17

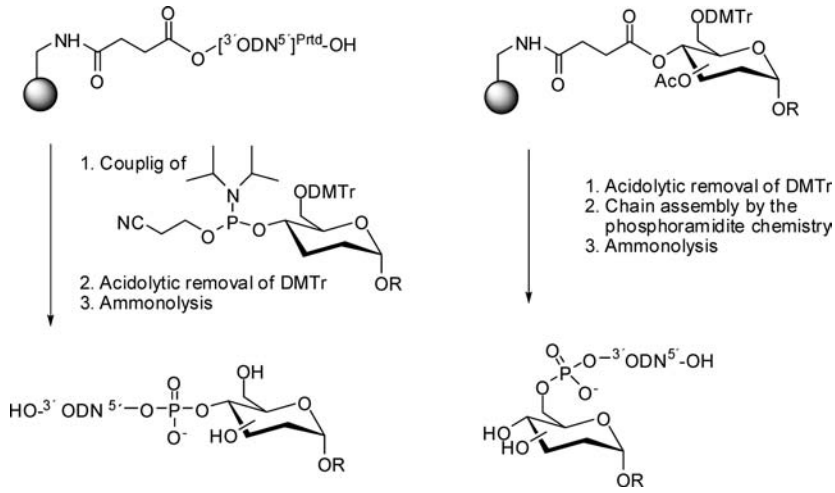


Chart 9

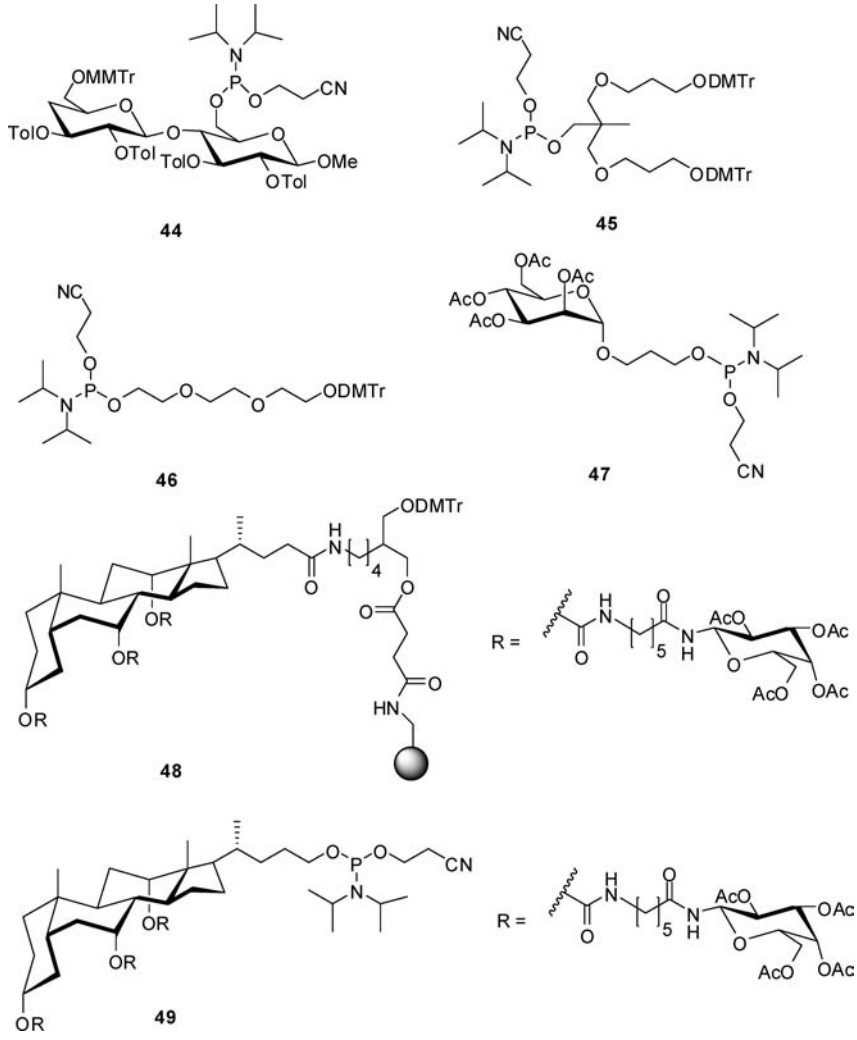
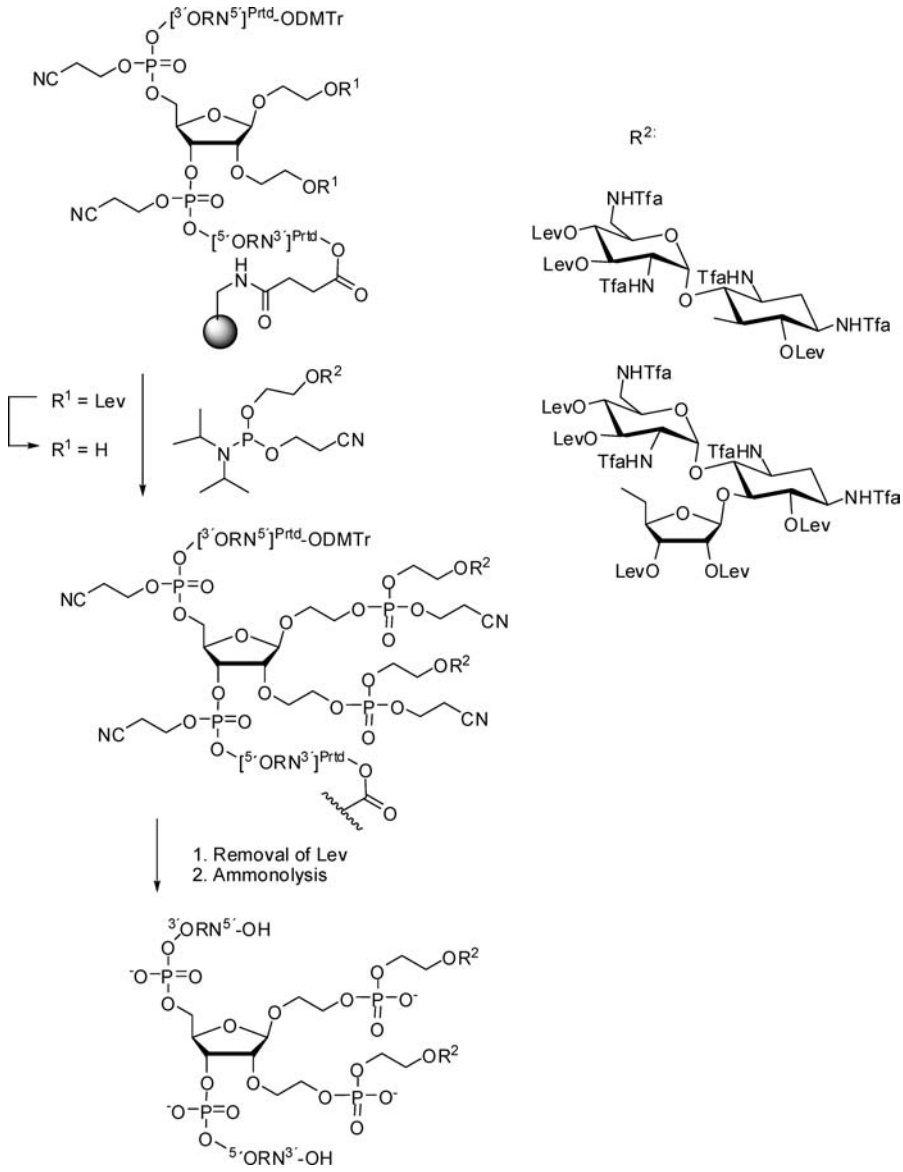


are unable to activate RNaseH, an enzyme that cleaves the RNA component of an mRNA/antisense oligomer duplex, providing the antisense oligomer with turnover (*161*). In addition, PNAs often suffer from solubility problems (*161*). Accordingly, conjugation of PNA with ODNs is not of any help for the targeting and internalization of ODNs. With PNA−ODN conjugates, the ODN moiety may rather be regarded as a conjugate group, which increases the solubility of PNA and provides it with the ability to activate RNaseH. 5′-Terminal PNA−ODN conjugates have been prepared as described above for 5′-peptide conjugates, viz., by introduction of 5′-amino-5′-deoxythymidine at the 5′-terminus of the support-anchored ODN and subsequent elongation of the chain by the PNA chain assembly (*162*). The 3′-conjugates have, in turn, been synthesized by using PNA building blocks bearing benzhydryloxycarbonyl (Bhoc) protection at the amino functions of the nucleic

Scheme 18

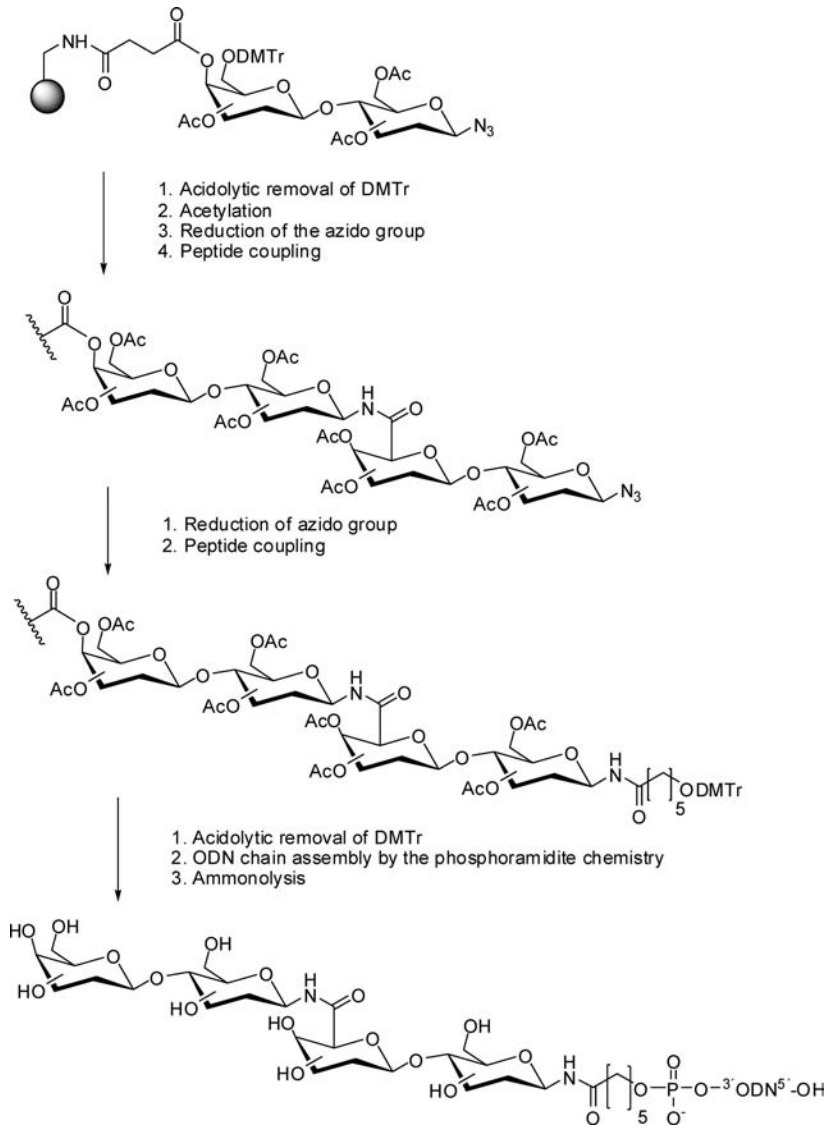


acid bases (*163*). The key point is that, after the assembly of the PNA sequence by the Fmoc chemistry, the Bhoc groups are removed with TFA and replaced with conventional benzoyl protections on the support (Scheme 13). Finally, the terminal Fmoc group is removed, and the ODN chain is assembled on the exposed amino group. Cyclic ODN−PNA chimeras have been synthesized on an *O*-(2-chlorophenyl)-*N*-(6-aminohexyl)-phosphoramidate linker (*164*). PNA is first assembled by Fmoc chemistry on the amino group of the linker and elongated with 6-DMTrO-hexanoic acid (Scheme 14). Owing to repeated removal of the Fmoc group with piperidine, the phosphodiester linkage becomes deprotected. The ODN moiety is then synthesized on the detritylated hydroxyl function, and the PNA−ODN hybrid is cyclized on support by treatment with MSNT in pyridine. Normal ammonolysis releases the cyclic conjugate and removes the base moiety protections.

Fragmental coupling offers an alternative for the stepwise synthesis on a single support: a prefabicated peptide bearing a single unprotected amino group and base-labile side-chain protecting groups is conjugated to a support-bound oligonucleotide. Usually, the oligonucleotide is first assembled on the support and an appropriately activated peptide is linked to the 5′-terminal hydroxyl function. One possible activation method is conversion of the peptide to a phosphoramidite ragent. Normal tetrazole activated coupling and subsequent oxidation to phosphoramidate is then carried out. The C-terminal amido nitrogen (*165*) and the side-chain hydroxyl group of a serine residue (*166*) have been used as a site of the phosphoramidite activation with 2-cyanoethyl-*N*,*N*-diisopropylphosphorochloridite. Both 3′- and 5′-conjugates have been prepared (*166*). 3′-Conjugates have been obtained by assembling the ODN chain in the inverse 5′→3′ direction and coupling the peptide phosphoramidite to the 3′-terminal hydroxy function of the support-bound chain (Scheme 15). On using conjugation through the serine side chain, deprotection under drastically basic conditions may result in elimination of the ODN as a 5′-phosphate or 3′-phosphate by concomitant conversion of the serinyl residue to dehydroalanine. To avoid this, the phosphate linkages and the C-terminal carboxy function of the peptide have been protected with allyl groups and the nucleoside amino groups and the *N*-terminal amino group with Alloc groups.

In an alternative approach, an α,ω-alkanediamine is tethered to the 5′-hydroxy function by 1,1′-carbonyldiimidazole activation and a preprepared protected peptide is coupled to the amino group by PyBOP/HOBt-promoted peptide bond formation (*167*). Up to dodecyl peptides have been successfully coupled. A long C12 spacer between the peptide and ODN and, interestingly, removal of the 2-cyanoethyl protections have improved the

Scheme 19



coupling yield (*168*). More recently, 1,6-diisocyanatohexane has been utilized to tether peptides bearing an *N*-terminal β-alanine to the 5-amino-3-oxapentyl tail of a protected support-bound ODN (*169*). The ε-amino functions of the peptides have to be protected with trifluoroacetyl groups, but no other side chain protections are necessary. On using the peptide in 10-fold excess, coupling yields up to 20% are achieved. Another feasible conjugation method depends on conversion of the 5′-aminoalkyl tail to an active urethane by reaction with bis(*N*-succinimidyl)-carbonate (*170*). Up to 18-mer peptides have been attached in this manner to ODN phosphorothioates (Scheme 16). Instead of a 5′-aminoalkyl tail, the *N*-(3-aminopropanoyl) sidearm of a 2′-amino-2′-deoxy-*arabino* nucleotide within an otherwise protected support-bound oligonucleotide has been used as the site of conjugation (*171*).

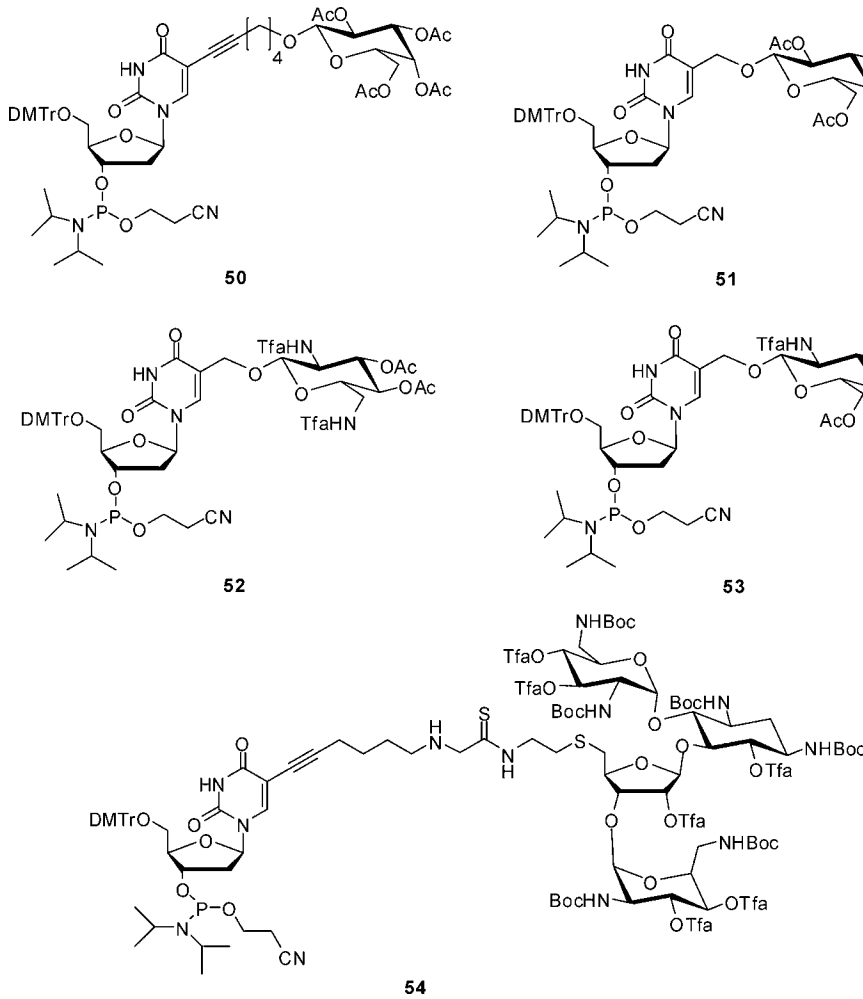
Unprotected peptides up to an heptamer have been conjugated by TBTU/HOBt coupling to solid-supported ODNs incorporating either a 2′-*O*-carboxymethyluridine unit (*172*) or a 5′-carboxyalkyl tail (*173*). 80% yields have been obtained using the peptide in 100-fold excess. The carboxymethylated unit can be introduced as a phosphoramidite having the carboxy group protected as an Pd^0-labile allyl ester and the 5′-carboxy group as a 1-methyl-4-oxo-4-trityloxybutyl phosphoramidite. An *N*-Fmoc-*O*-Tr-homoserinyl linker attached via an amide linkage to an amino-functionalized resin has been exploited in preparation of 3′-oligolysine conjugates by fragment coupling (*40*). The Fmoc group is first removed, and a trifluoroacetyl protected oligolysine is coupled. After that, the trityl protection is removed, and the ODN chain is assembled.

Reaction of an aldehyde with hydrazine or alkoxyamine is one of the conjugation methods most extensively applied in the solution phase (*120*). The same method has also been successfully applied to solid-supported conjugation. Laminin peptide (H-RSGIYGPD-OH) has been conjugated as a C-aminooxy or hydrazine derivative to an aldehyde-functionalized ODN on a solid support (*174*). For this purpose, an appropriately protected 2′-*O*-[2,3-bis(allyloxycarbonyloxy)propyl]cytidine phosphoramidite building block has been introduced into the ODN sequence, the Pd-labile Alloc groups have been removed on-support, and the resulting 2′-*O*-(2,3-dihydroxypropyl) group has been oxidized with periodate ion to a 2′-*O*-(2-oxoethyl) group. Treatment with a 1000-fold excess of the peptide conjugate and subsequent ammonolysis have given the conjugates in high yield.

GLYCOCONJUGATES

Carbohydrate−protein interactions play a central role in cellular recognition. Usually, multiantennary carbohydrates anchored to proteins or lipids of cell membranes recognize

Chart 10

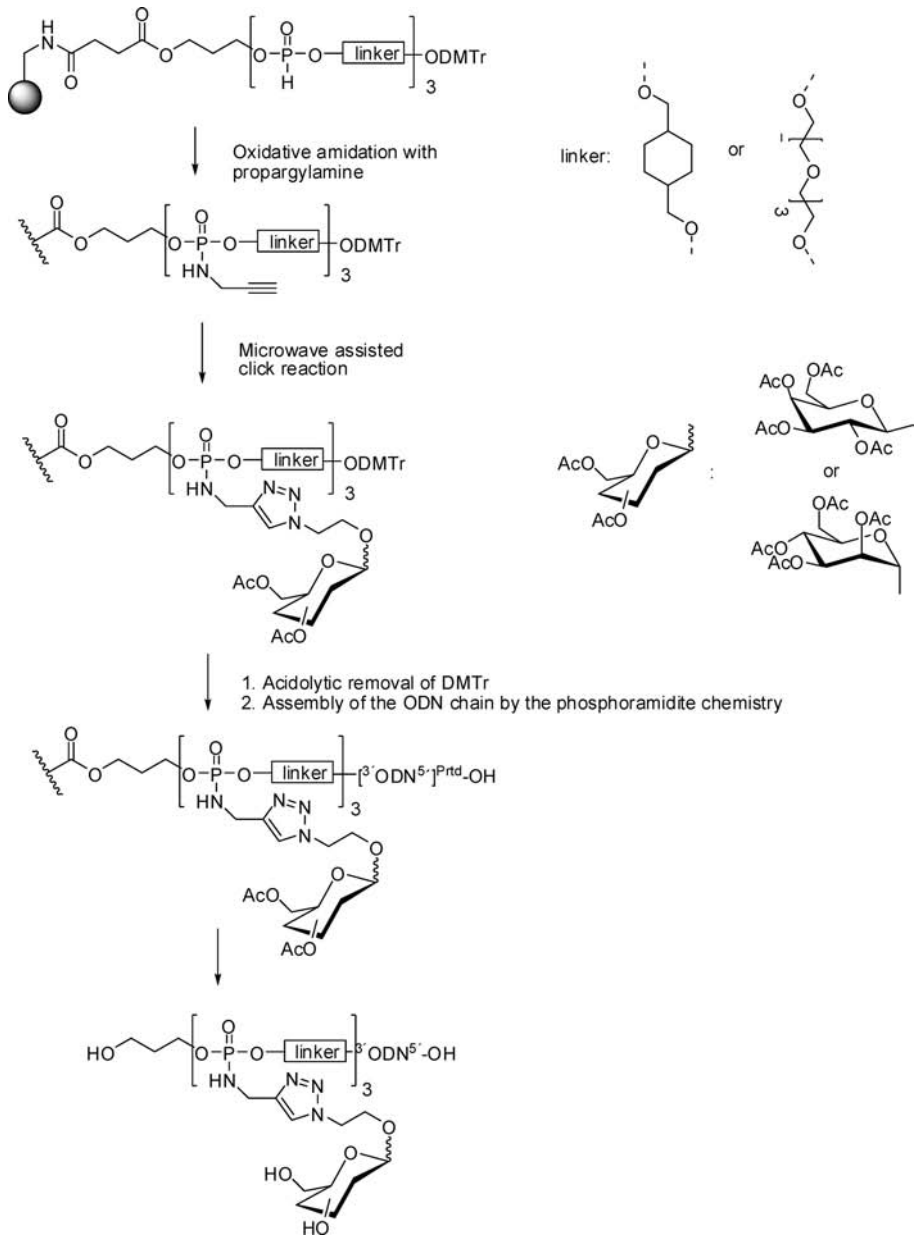


extracellular proteins, but the opposite is also possible (*175*−*177*). For example, hyaluronic acid, a linear polysaccharide composed of a repeating disaccharide unit of D-glucuronic acid and *N*-acetyl-D-glucosamine, [→3)-*β*-D-GlcNAc-(1→4)-*β*-D-GlcUA-(1→]$_n$, is the main ligand for a transmembrane glycoprotein CD44 that is overexpressed in many cancers (*178*), and hyaluronic acid conjugates of cancer drugs have been shown to exhibit increased uptake to cancer cells (*179*). Galactosylated PEG-conjugates of ODN phosphorothioates have, in turn, been reported to show enhanced uptake via the galactose-specific asialoglycoprotein receptor-mediated endycytosis (*30*), and antigenic peptides have been targeted to dendritic cells by an appropriate glycoconjugation (*180*). Additionally, it has been shown that galactosylated dendrimers are able to inhibit at nanomolar concentrations cellular binding of pathogens bearing galactose-binding membrane proteins (*181*). Accordingly, several lines of evidence suggest that glycotargeting may well be a viable method with which to enhance the delivery of therapeutic oligonucleotides (*182*). Preparation of oligonucleotide glycoconjugates has previously been reviewed in 2004 (*183*). In the present survey, attention is paid only to solid-phase methods and mainly to those published since 2004.

The protocols reported so far for the solid-phase synthesis of oligonucleotide glucoconjugates utilize phosphoramidite coupling, Cu(I) promoted 1,3-dipolar cycloaddition ("click reaction"), or oximation. Among these approaches, the phosphoramidite coupling is oldest, but still extensively applied. The simplest example is offered by introduction of a single mono- or disaccharide unit into a terminal position of a support-bound ODN. To obtain 5′-glycosylated conjugates, appropriately protected methyl glycosides have been converted to phosphoramidite reagents and introduced into the ODN by the last coupling cycle (Scheme 17) (*184, 185*). Besides sugar hydroxyl functions, the *ω*-hydroxy group of appropriately protected *ω*-hydroxyalkyl glycosides has been used as the site of phosphitylation (*186, 187*). 3′-Terminal sugar conjugates have, in turn, been prepared by assembling the ODN chain on the primary hydroxyl group of an *O*-acetyled glycoside immobilized to the support via a succinyl linker (*184, 185*). Conjugates bearing a sucrose moiety at both termini have been obtained by using these two approaches in combination (*188*). The 3′-terminal sugar tail has been elongated by coupling one O6-DMTr protected sugar phosphoramidite building block to the support-anchored sugar before the assembly of the ODN chain (*189*). A phosphoramidite building-block derived from methyl 4′-deoxy-*β*-D-lactoside (**44**; Chart 9) has been used to introduce a sugar moiety within the ODN chain (*190*). A spruce-like tetramannosyl conjugate has been prepared by using phosphoramidate **45** for branching, **46** for elongation of the branches, and **47** for the terminal mannosylation (*191*).

In addition to mono- and disaccharides, more complicated carbohydrate structures have been conjugated to oligonucleotides by the phosphoramidite chemistry. Very recently, solid-phase synthesis of aminoglycoside conjugates bearing two neamine or ribostamycin units at an intrachain position has been described (*192*). The procedure is outlined in Scheme 18. The oligonucleotide chain is assembled by conventional phosphoramidite chemistry. At the desired site of aminoglycoside conjugation, an abasic ribofuranose phosphoramidite bearing one or two levulinoyloxyalkyl side arms is introduced. The levulinoyl

Scheme 20



protecting groups are removed with hydrazinium acetate on support and the appropriately protected aminoglycosides are coupled to the exposed hydroxyl functions as phosphoramidite reagents. An important detail of the synthesis is the protection of the aminoglycoside building block. Acyl groups readily migrate from hydroxyl functions to amino groups under basic conditions. That is why removal of the acyl protections from hydroxyl groups, while keeping the amino groups still protected, is highly desirable. Therefore, levulinoyl groups have been used instead of more common acetyl groups for protection of the hydroxyl functions. These groups may be removed under conditions that leave trifluoroacetyl protections on the amino groups intact. The latter protections are then removed upon ammonolysis used for the global deprotection and release of the conjugate from the support.

Other complex structures conjugated to oligonucleotides by the solid-supported phosphoramidite chemistry include a triga-lactosylated tetrahydroxycholane, introduced into the 3′-terminus of oligonucleotides with the aid of a branched linker (**48**) and to the 5′-terminus as a phosphoramidite reagent (**49**) (*193*), and 3′-(*β*-cyclodextrin) conjugates obtained by assembling the ODN chain in the reversed 5′ → 3 ′ and conjugating an amino-functionalized cyclodextrin to the terminal 3′-hydroxy function activated as a 4-nitrophenyl carbonate (*44*). Cyclodextrin conjugates have also been obtained by applying the phospho-triester conjugation method outlined in Scheme 3 in the foregoing (*62*). 3′-Conjugates derived from a tetrasaccharide glycomimetic have been prepared by sequential peptide and phosphoramidite coupling on a single support (*194*). An example is outlined in Scheme 19. An acetylated 1-azido-1-deoxy-6′-*O*-DMTr-*β*-D-lactose is immobilized via a 4′-*O*-succinyl linker to an amino-functionalized support. The DMTr protection is converted to an acetyl protection and the azido group reduced with 1,3-propanedithiol. The resulting amino group is then subjected to peptide coupling with fully acetylated 1-azido-1-deoxy-*β*-D-lacturonic acid using HATU/HOBt/DIPEA activation. The azido function is again reduced to an amino group, and a DMTr protected 6-hydroxyheptanoic linker is coupled. The ODN chain is then assembled on the detritylated hydroxyl function of this linker. Conventional ammonolysis gives the fully deprotected glycoconjugate.

56

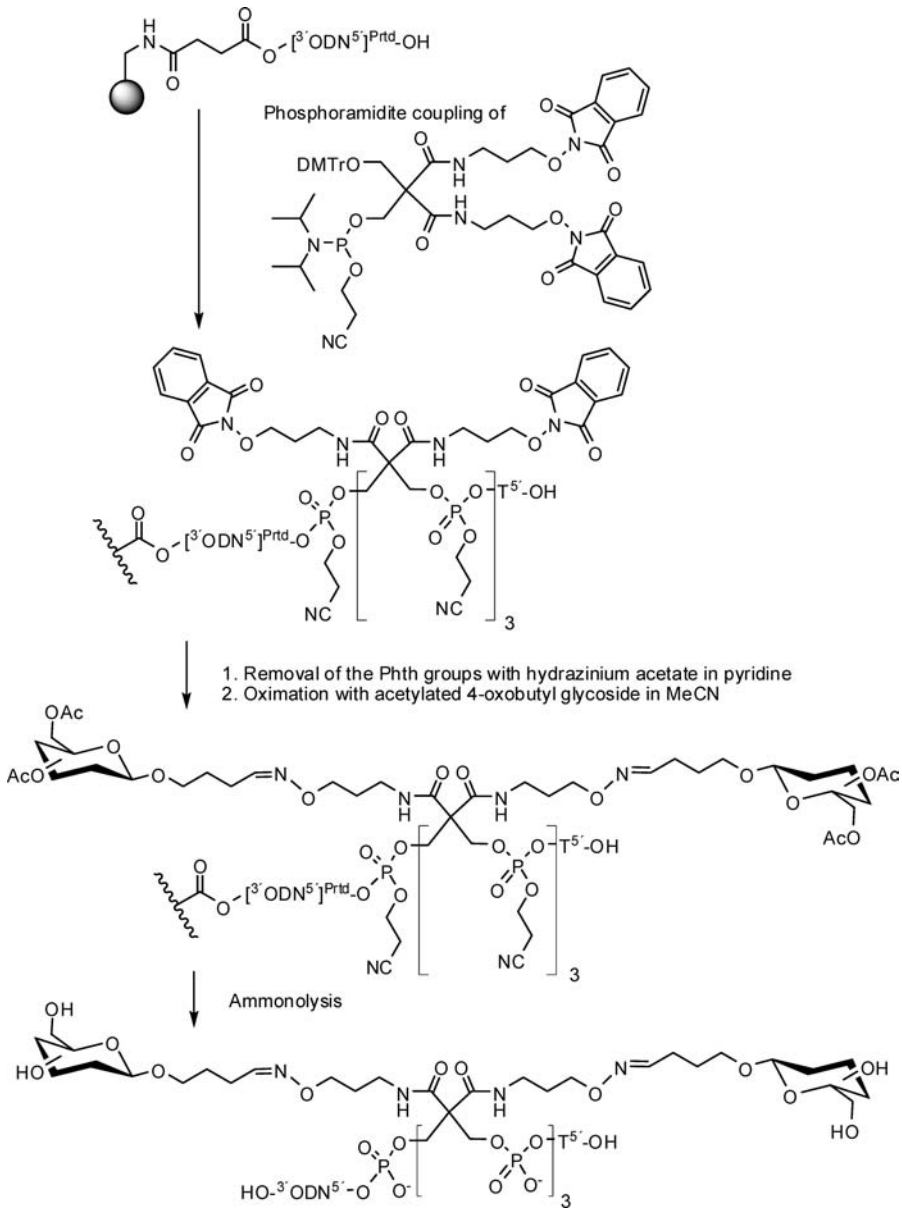
The most frequently used method for incorporation of sugars into intrachain positions of oligonucleotides is the use of phosphoramidites derived from prefabricated nucleoside conjugates. The building blocks successfully incorporated include 5′-*O*-DMTr protected 3′-(2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite)s of 5-[6-(2,3,4,6-tetra-*O*-acetyl-*β*-D-galactopyranosyloxy)-1-hexynyl]-2′-deoxyuridine (**50**; Chart 10) (*195, 196*), 5-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosyloxy)methyl-2′-deoxyuridine (**51**) (*197*), 5-[2,6-bis(trifluoroacetamido)-3,4-di-*O*-acetyl-2,6-dideoxy-*β*-D-glucopyranosyloxy]methyl-2′-deoxyuridine (**52**) (*198*), and 5-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-*β*-D-glucopyranosyloxy)methyl-2′-deoxyuridine (**53**) (*199*). This approach has been applied to introduction of even very complex carbohydrate groups into ODNs. For example, an aminoglycoside antibiotic, neomycin, has been incorporated into oligonucleotides as a C5-tethered 2′-deoxyuridine 3′-phosphoramidite building block (**54**) (*200*). An exceptionally long reaction time (30 min) was, however, required to couple this modified block. The Boc protections were removed after ammonolytic release in solution phase with a mixture of 3% TFA and 1% *m*-cresol in dioxane. It should be noted that the ODN chain contained no purine nucleosides prone to acid-catalyzed cleavage of the *N*-glycosidic bond. Several contiguous *N*-acetyl-D-galactosamine groups have been introduced into ORNs with the aid of a phosphoramidite reagent derived from *N*-[12-(3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-*β*-D-galactopyranosyl)dodecanoyl]threoninol (*201*).

Click chemistry has recently gained popularity in preparation of bioconjugates. Several applications concerning solid-supported synthesis of oligonucleotide glycoconjugates have also been reported. Usually, sugar azides are conjugated to support-anchored alkynylated oligonucleotides. ODNs bearing up to three *β*-D-galactopyranosyl or α-D-mannopyranosyl groups at the 3′-terminus have been obtained by consecutive application of oxidative amidation and microwave-assisted click chemistry (*202, 203*). Scheme 20 outlines the procedure. A non-nucleosidic tail consisting of cyclohexane-1,4-diyldimethanol or tetraethylene glycol units is first assembled by H-phosphonate chemistry, and the H-phosphonate diester linkages obtained are subjected to amination with propargylamine. Fully acetylated 8-azido-3,6-dioxaoctyl glycopyranosides are then attached by Cu(I)-promoted 1,3-dipolar cycloaddition under microwave irradiation. The ODN sequence is assembled by the phosphoramidate chemistry on the hydroxyl function of the last non-nucleosidic unit, and conventional ammonolysis completes the synthesis.

Another indication of the applicability of click chemistry to the solid-supported construction of oligonucleotide glycoconjugates is the synthesis of fucosylated pentaerythrityl phosphodiester oligomers (*204*). Very recently, an example of a reaction of an alkynylated sugar with a support-bound azido-functionalized oligonucleotide has been reported (*205*). A 5′-DMTr protected 3′-H-phosphonate monomer derived from 4′-*C*-azidomethylthymidine has been prepared and inserted into an ODN by the H-phosphonate chemistry (Scheme 21). The corresponding phosphoramidite building block cannot be prepared, owing to an intramolecular Staudinger reaction between the azido and phosphoramidite moieties. The unmodified nucleosides may, however, be coupled as phosphoramidites even though 4′-*C*-azidomethylthymidine blocks would have already been incorporated into the chain. While the click reaction has been observed to be virtually quantitative, removal of the copper complex of tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA) used as a promoter requires special attention, as indicated by capillary electrophoresis of the released product before and after HPLC purification.

Solid-phase oximation has been applied to preparation of ODN 5′-glycoconjugates bearing up to 6 identical monosaccharides (*206*) For this purpose, a non-nucleosidic phosphoramidite building block containing two phthaloyl protected aminooxy functions has been prepared and inserted into an ODN by the phosphoramidite chemistry. These protections may be easily removed on a solid support, and sugars may be introduced by oximation with alkyl glycosides bearing an aldehyde function on the aglycon (Scheme 22).

Scheme 22



The oxime linkages withstand standard ammonolysis, which also quantitatively removes the acetyl protections from the sugar hydroxyl functions.

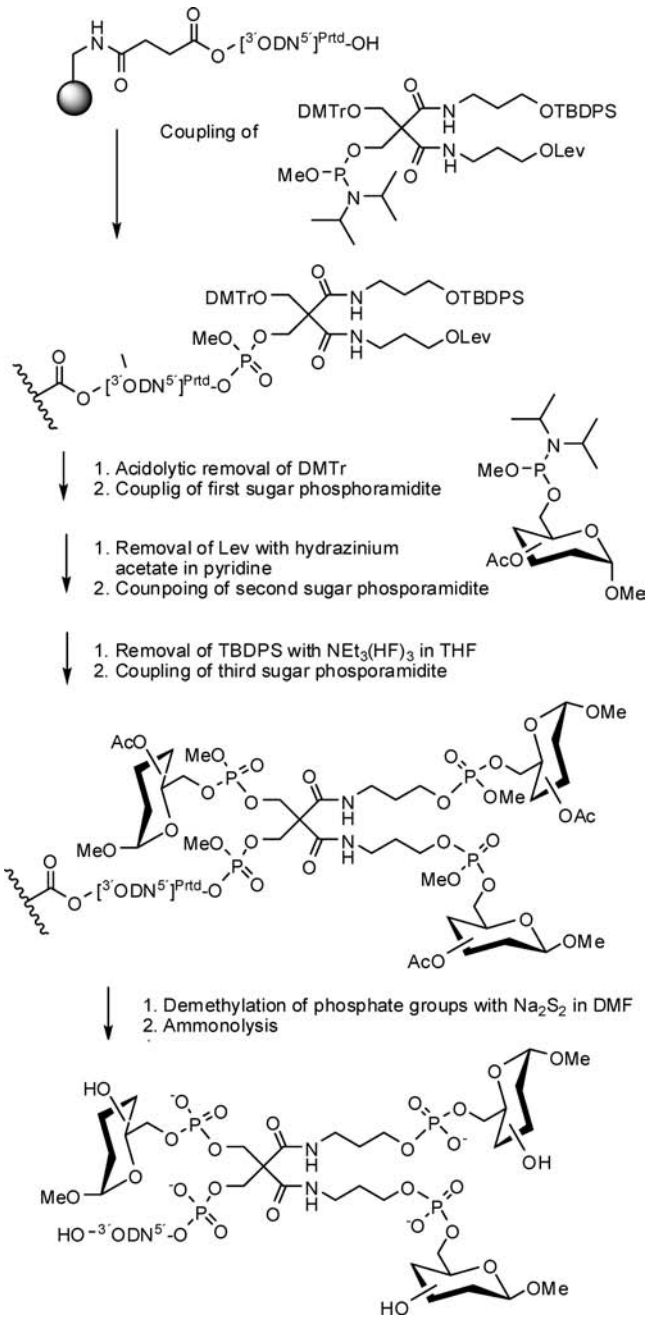
Usually, lectins bind only one type of sugar, and hence, homoclusters are considered to adequately guarantee high affinity binding (*175*, *177*). There are, however, some indications that in special cases heteroclusters containing more than one type of sugars bind more tightly than the corresponding homoclusters (*207*). For example, mixed-type α-Man, *β*-Glc and α-Man, *β*-Lac heteroglycoclusters exhibit 8 times higher affinity to Con A than α-Man homoclusters of identical valency (*208*). Accordingly, synthesis of oligonucleotide glycoconjugates containing more than one type of sugar ligands is of interest. To construct such conjugates on a solid support, a non-nucleosidic bis(hydroxymethyl)-malondiamide-based building block bearing three orthogonally removable hydroxy protections has been prepared and introduced into the 5′-terminus of a solid-supported ODN (*209*). The hydroxyl protections are removed in a stepwise manner, and the sugar units are introduced as phosphoramidite reagents. Methyl-protected phosphoramidites have to be used for the chain assembly, since the 2-cyanoethyl groups do not withstand removal of the fluoride ion labile TBDPS group. For the same reason, a polymer support has to be used instead of CPG. As depicted in Scheme 23, the first sugar unit is attached after detritylation. Then, the levulinoyl protection is removed and the second sugar phosphoramidite is coupled, and removal of TBDPS with triethylamine hydrogen fluoride followed by coupling of the last sugar completes the conjugation process. The phosphodiester likages are demethylated before normal ammonolysis.

Solid-supported glycosidation has very seldom used for the preparation of oligonucleotide glycoconjugates on a single solid support. Glycosidation usually depends on electrophilic activation, and this easily results in depurination of the ODN chain. Very short 5′-glycosylated conjugates of ODNs have, however, been obtained by glycosylating the 5′-terminal hydroxyl function of the support-bound ODN with fully benzoylated glycopyranosyl trichloroacetimidate using trimethylsilyl triflate as an activator (*210, 211*).

MISCELLANEOUS

Conjugation of ODN phosphorothioates with poly(ethylene glycol) polymers ranging from 6 to 20 kDa has been shown

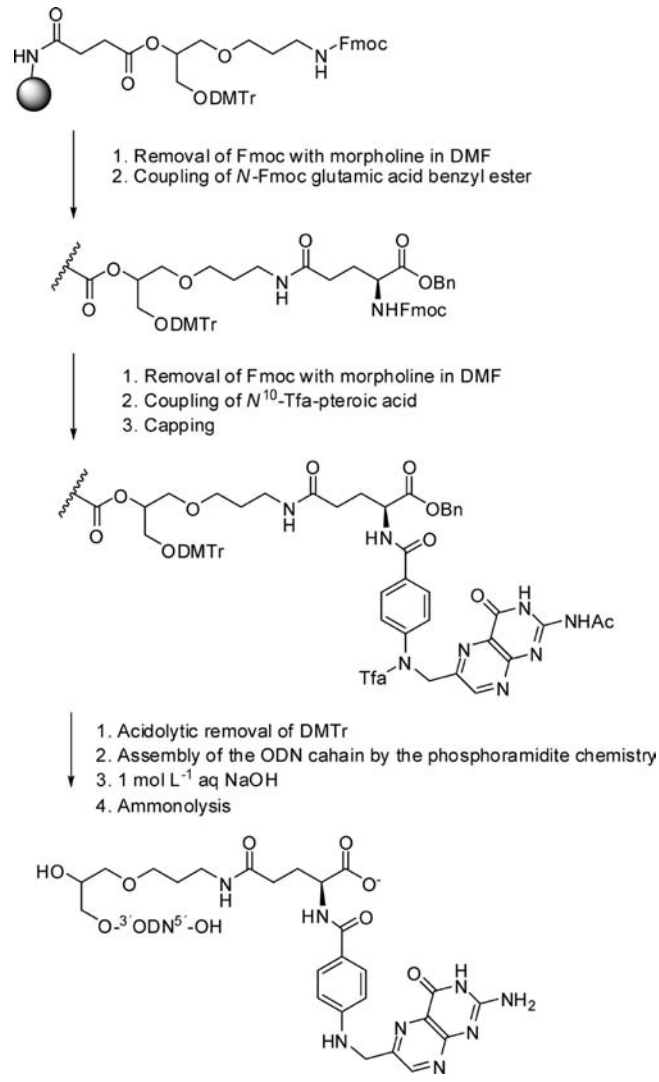
Scheme 23



to increase their half-life in rat plasma, to enhance the stability against nucleases, and to improve the pharmacokinetics (*31*). 3′-Terminal ODN conjugates of poly(ethylene glycol)s with degrees of polymerization up to 150 have been prepared by immobilization of the PEG oligomer to an aminoalkylated support via a succinyl linker and subsequent synthesis of the ODN chain by the phosphoramidite (*212*−*214*) or H-phosphonate chemistry (*215*). *N*-Fmoc protected amino-poly(ethylene glycol)-900 (*216*) and PEG polymers up to the length of 120 units (*213*, *214*) have been conjugated as phosphoramidite reagents to the 5′-terminus of a support-bound oligonucleotide.

Among small molecules known to undergo receptor-mediated cellular uptake, folic acid has received interest as a potential carrier of oligonucleotides into cells. 3′-Terminal folic acid conjugates have been prepared with the aid of a branched linker, as depicted in Scheme 24 (*217*), and intrachain conjugates by insertion of an appropriately protected non-nucleosidic phosphoramidite reagent

Scheme 24



(**55**; Chart 11) into the desired place of the chain (*201*). Puromycin, porphyrins, groove binders, and intercalators have also received considerable interest as conjugate groups. Although these conjugates are not primarily aimed at exhibiting enhanced cellular uptake or cell-type specific targeting, their solid-phase synthesis is briefly discussed here. 3′-Conjugates of puromycin have been obtained by conventional ODN synthesis on puromycin-derived linker **56** (*218*, *219*). Porphyrins have been conjugated as nucleoside derived phosphoramidite (*220*) or hydrogen phosphonate (*221*) building blocks, as non-nucleosidic phosphoramidite (*222*) or hydrogen phosphonate (*223*, *224*) reagents, or as carboxy-functionalized derivatives to the 5′-amino group of a support-bound ODN (*225*). Groove binders have been coupled as pentafluorophenyl esters to a 5′-amino tail of a support-bound ODN (*226*, *227*) or to an amino group of a support-bound linker before the ODN chain assembly (*227*, *228*), or they have been coupled as an alcohol to the 5′-terminal OH activated as 2-cyanoethyl *N*,*N*-diisopropylphosphoramidite (*229*). Intercalators are introduced as non-nucleosidic phosphoramidite reagents (*230*, *231*) or prefabricated nucleoside-derived building blocks (*230*), or they are attached as an active ester to an amino group of a branched linker (*233*, *234*).

Shell-Detachable Micelles Based on Disulfide-Linked Block Copolymer As Potential Carrier for Intracellular Drug Delivery

Ling-Yan Tang,[†] Yu-Cai Wang,*[,‡] Yang Li,[†] Jin-Zhi Du,[‡] and Jun Wang*[,†]

Hefei National Laboratory for Physical Sciences at Microscale and School of Life Science, Hefei, Anhui 230027, People's Republic of China, and Department of Polymer Science and Engineering, University of Science and Technology of China, Hefei, Anhui 230026, People's Republic of China. Received April 2, 2009; Revised Manuscript Received April 28, 2009

Aiming at development of a micellar nanoparticle system for intracellular drug release triggered by glutathione in tumor cells, a disulfide-linked biodegradable diblock copolymer of poly(ε-caprolactone) and poly(ethyl ethylene phosphate) was synthesized. It formed biocompatible micelles loaded with doxorubicin in aqueous solution but detached the shell material under glutathione stimulus, resulting in rapid drug release with destruction of micellar structure. These glutathione-sensitive micelles also rapidly released the drug molecules intracellularly and led to enhanced growth inhibition to A549 tumor cells, suggesting that this nanoparticle system may have potential for improving drug delivery efficacy.

Despite the discovery of many anticancer drugs for cancer therapy, clinical outcomes have been disappointing due to the severe side effects. Various nanovehicles such as polymeric micelles and vesicles (*1*−*3*), liposomes (*4*), and nanogels (*5, 6*) have been developed to overcome the problems. Such nanoparticle-based vehicles can passively accumulated in solid tumor tissues owning to the enhanced permeation and retention effect and improve the therapeutic efficiency (*7*). However, the concentration of active anticancer drug within cancer cells is often insufficient due to the inefficient release of drug from the vehicle into the cytoplasm, resulting in a requirement for higher drug dosage. The promising approach to improving the efficacy is to develop carrier systems that can release the drug triggered by intracellular stimuli, such as pH (*8*−*11*), glutathione (*12*−*15*), and enzyme (*16*). Upon reaching the targeted tumor, such carriers can be rapidly localized intracellularly and subsequently provoked by the stimuli to release the drug, hence inducing aggressive activity within tumor cells and leading to maximal therapeutic efficacy with reduced side effects.

Chemical reaction involving the reductive degradation of disulfide bonds of polymers by intracellular glutathione (GSH) has been widely investigated for responsive drug and gene delivery (*17*−*19*). GSH is a thiol-containing tripeptide and reduces disulfide bonds in the cytoplasm. It has been demonstrated that the intracellular concentration of GSH (ca. 10 mM) is significantly higher than the level in the cell exterior (ca. 2 μM) (*17*). We have previously demonstrated that micellar nanoparticles assembled from diblock copolymer of poly(ε-caprolactone) (PCL) and hydrophilic poly(ethyl ethylene phosphate) (PEEP) is potential as a drug carrier (*20, 21*). In the present work, aiming at development of micellar nanoparticle system for intracellular drug release triggered by GSH in tumor cells, we synthesized a disulfide-linked diblock copolymer of PCL and PEEP (PCL-SS-PEEP), which formed biocompatible micelles in aqueous solution, and detached the shell material under GSH stimulus, resulting in rapid drug release with destruction of micellar structure (Scheme 1).

PCL-SS-PEEP was synthesized by a coupling reaction between the thiol end group functionalized poly(ε-caprolactone) (PCL-SH) with the pyridyldisulfide groups at the end of poly(ethyl ethylene phosphate). PCL-SH was obtained through polymerization of ε-caprolactone initiated by 2-(2,4-dinitrophenylthio)ethanol in the presence of stannous octoate ($Sn(Oct)_2$) to give a precursor polymer PCL-DNP, followed by deprotection of dinitrophylenyl groups with mercaptoethanol. As shown in Figure 1, the ^1H NMR spectrum of PCL-SH indicates that proton signals at δ 7.76, 8.37, and 9.05 from 2-(2,4-dinitrophenylthio) groups of PCL-DNP are no longer present, demonstrating the successful deprotection. The degree of polymerization (DP) of PCL-SH is 32, which is calculated from the integration ratio of resonance at δ 4.02 of PCL-DNP against those at δ 7.76, 8.37, and 9.05. In another aspect, the pyridyldisulfide end group functionalized poly(ethyl ethylene phosphate) (PEEP-Py) was synthesized through ring-opening polymerization of ethyl ethylene phosphate, initiated by 2-(2-pyridyldithio)-ethanol and $Sn(Oct)_2$. The ^1H NMR spectrum of PEEP-Py given in Figure 1 shows resonances at δ 7.13, 7.56, 7.70 and 8.50, assigned to protons of pyridyl end groups. The DP of PEEP is 22, calculated based on the integration ratio of resonances at δ 4.1−4.3 against those at δ 7.13, 7.56, 7.70 and 8.50. The molecular weights determined by gel permeation chromatography (GPC) analyses are summarized in Table 1.

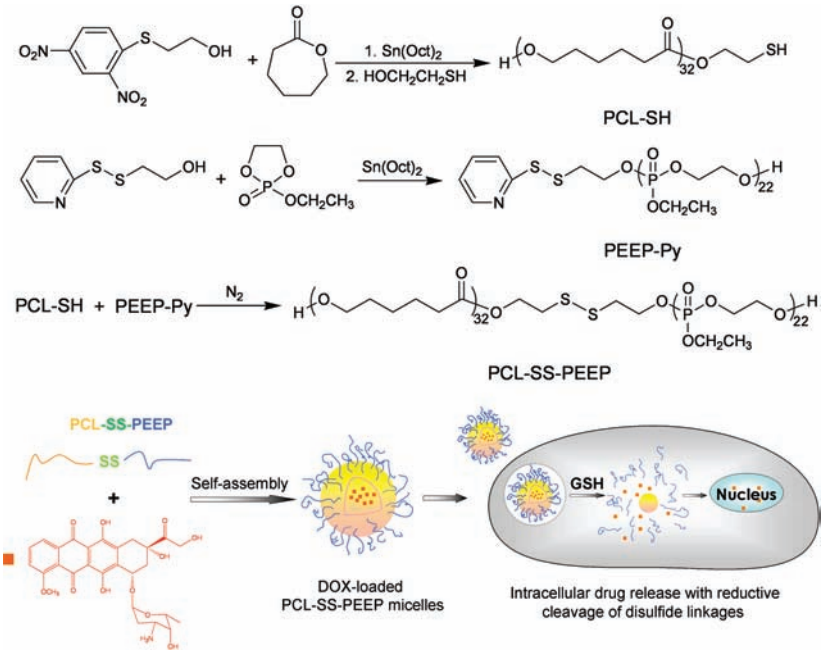
Scheme 1. Synthesis Pathway of the Disulfide-Linked PCL-SS-PEEP and Schematic Illustration of Intracellular Drug Release



The coupling reaction of PCL-SH and PEEP-Py was carried out at room temperature under N_2 atmosphere carefully to minimize the air oxidation and homodimerization. The feed ratio of PEEP-Py to PCL-SH was set at 1.2:1. The excessive PEEP-Py was removed by precipitating the product in methanol, followed by thorough dialysis in water. GPC profile of the disulfide-linked diblock copolymer PCL-SS-PEEP compared with the precursor polymers PCL-SH and PEEP-Py (Supporting

polymer	M_n[a]	M_w[a]	PDI[a]	M_n[b]
PCL-SH	4780	5500	1.15	3650
PEEP-Py	2900	3950	1.36	3480
PCL-SS-PEEP	6420	8670	1.35	6950

[a] Determined from GPC. [b] Determined from ^{1}H NMR.

Information Figure S1) shows a significant shift toward higher molecular weights, suggesting successful coupling. ^{1}H NMR of PCL-SS-PEEP in Figure 1 also shows the complete disappearance of pyridyl group resonances at δ 7.13, 7.56, 7.70 and 8.50, indicating successful conversion of PEEP-Py to the targeted copolymer.

Like previously reported diblock copolymer PCL-b-PEEP (*21*), PCL-SS-PEEP is amphiphilic and self-assembles into micelles in aqueous solution. The critical micellization concentration of PCL-SS-PEEP is 3.1×10^{-3} mg mL^{-1}, which was determined by fluorescent measurements with pyrene as the probe (*20*). Using the dialysis method, anticancer drug doxorubicin (DOX) was encapsulated into the core of the micelles with 2.8% drug loading content. Transmission electron microscopy image shown in Figure 2A exhibits the spherical morphology of DOX-loaded PCL-SS-PEEP micelles, with a diameter around 70 nm, which is consistent with that observed by dynamic light scattering (DLS) measurements.

The disulfide bridge linkage between PCL and PEEP block makes PCL-SS-PEEP micelles reductively breakable with response to GSH. To demonstrate the responsiveness, micelles were treated with 10 mM of GSH, and at different time intervals, the particle sizes were measured by DLS. As shown in Figure 2B, the average diameter of GSH-treated micelles immediately raised, reaching about 1000 nm within 10 min. Further incubation resulted in microsized particles and severe aggregations. However, without GSH treatment, PCL-SS-PEEP micelles showed negligible size variation within the same period of time. The variation of particle size in the presence of GSH was caused by the cleavage of disulfide linkages, which led to detachment of the PEEP shells from the micellar nanoparticles and resulted in enhanced hydrophobic PCL core material interaction.

The effect of PEEP shell detachment to the DOX release from the drug-loaded PCL-SS-PEEP micelles was directly observed by measuring DOX fluorescence of the micelle solution with treatment of 10 mM of DL-dithiothreitol (DTT). The relative fluorescence intensities of treated micelles to the nontreated micelles were plotted in Figure 2C. It has been reported that incorporation of DOX in the hydrophobic core of micelles decreases the fluorescent intensity of DOX when compared with free DOX at the same concentration (*22, 23*). The enhanced DOX fluorescence of DTT-treated DOX-loaded micelles therefore should be due to the rapid release of drug from the micelles. The drug release was also quantitatively studied by incubation of nanoparticles in GSH-containing medium. The DOX release profiles are displayed in Figure 2D. The DOX release from micelles was around 40% in 4 days in the absence of GSH, indicating lack of stability of micelles; however, in the presence of 10 mM of GSH corresponding to an intracellular level, the DOX release from the micelles was much faster, reaching almost complete drug release. These results demonstrate that cleavage of disulfide bridge linkages accelerated the drug release. It can be assumed that, under the stimulus of GSH, the disulfide bridge linkages of PCL-SS-PEEP are reduced and broken, which destabilizes the micellar nanoparticles and results in accelerated DOX release.

The intracellular behavior of DOX-loaded PCL-SS-PEEP micelles was evaluated in A549 cells to assess whether these GSH-responsive micelles function in the intracellular environment. Most tumor cells have an elevated GSH level compared with normal cells (*24*−*26*). As a model system, A549 cells were incubated with glutathione monoester (GSH-OEt) for 2 h to manipulate the intracellular GSH concentration. GSH-OEt can penetrate cellular membranes and rapidly generates high intracellular GSH concentration with ethyl ester hydrolyzation in cytoplasm (*13, 24*). After pretreatment with 10 mM of GSH-OEt, the cells were further incubated with DOX-loaded PCL-SS-PEEP micelles for 2 h. The DOX fluorescence of the cells

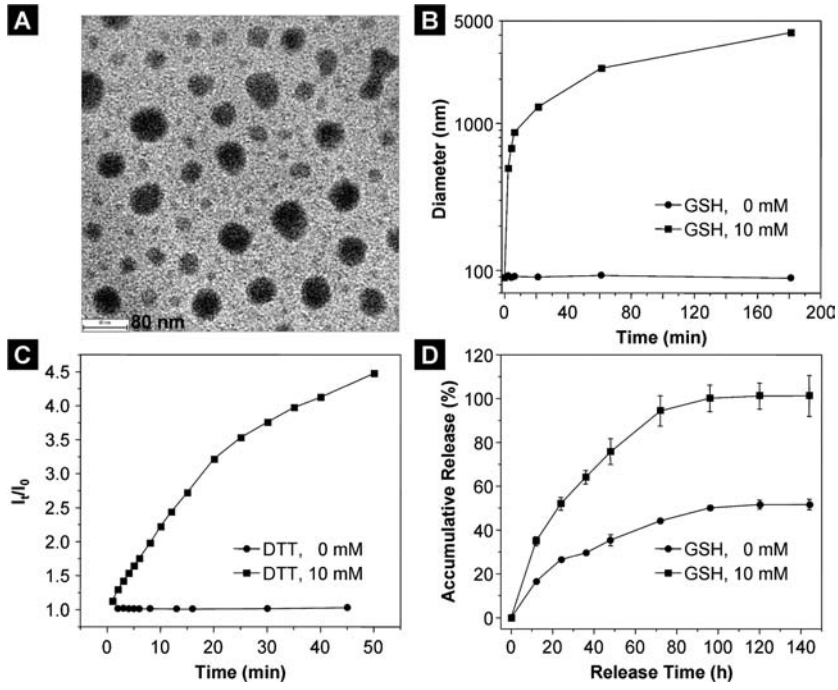

Figure 2. Transmission electron microscopy image of doxorubicin-loaded PCL-SS-PEEP micelles (A); dynamic light scattering measured PCL-SS-PEEP micelle size changes with glutathione (GSH) treatment (B); relative fluorescence intensity of doxorubicin-loaded PCL-SS-PEEP micelles with treatment of DL-dithiothreitol (DTT) (C); *in vitro* release of doxorubicin from PCL-SS-PEEP micelles in PBS (pH 7.4) at 37 °C with or without GSH treatment (D).

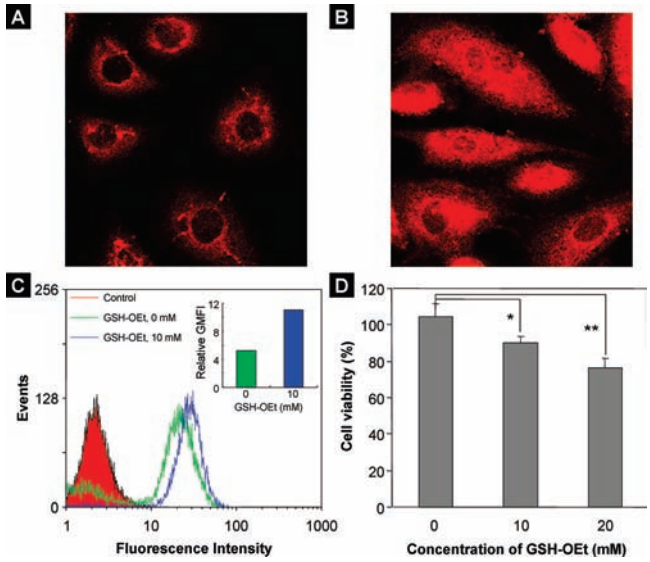

Figure 3. (A,B) Confocal laser scanning microscopy observation of nonpretreated (A) and GSH-OEt pretreated A549 cells (B) after 2 h incubation with DOX-loaded PCL-SS-PEEP micelles. (C) Flow cytometric analyses of nonpretreated and GSH-OEt pretreated A549 cells incubated with DOX-loaded PCL-SS-PEEP micelles for 2 h. Nonpretreated A549 cells without DOX-loaded micelle treatment was used as the control. The relative geometrical mean fluorescence intensities (GMFI) of cells are shown as an inset. (D) Viability of non-pretreated and pretreated A549 cells with either 10 or 20 mM of GSH-OEt incubated with DOX-loaded PCL-SS-PEEP micelles for 24 h. * $p < 0.05$, ** $p < 0.01$ by Student's *t*-test.

was observed under confocal laser scanning microscopy and analyzed by flow cytometric analyses. The results were compared with the A549 cells not pretreated with GSH-OEt but incubated for 2 h with the same dose of DOX-loaded PCL-SS-PEEP micelles. As shown in Figure 3A,B, stronger DOX fluorescence was observed in the cytoplasm of GSH-OEt pretreated cells. Flow cytometric analyses shown in Figure 3C also exhibit similar results, and relative geometrical mean fluorescence intensities (GMFI) of GSH-OEt pretreated cells are about 2-fold of nonpretreated cells. It is noteworthy that incubating DOX-loaded PCL-*b*-PEEP micelles without reducible disulfide bridges did not result in significant DOX fluorescence difference between non-pretreated and pretreated A549 cells, indicating that GSH-OEt pretreatment did not affect the endocytosis ability of A549 cells. On the other hand, broken disulfide linkages of PCL-SS-PEEP micelles enhanced the DOX fluorescence (Figure 2C). Therefore, the enhanced intracellular DOX fluorescence in GSH-OEt pretreated cells is due to the rapid intracellular DOX release from the DOX-loaded PCL-SS-PEEP micelles. Pretreatment of A549 cells with GSH-OEt up-regulated the intracellular GSH concentration, which subsequently accelerated the DOX release from the micelles owning to GSH-responsive disulfide bridge linkage degradation.

Such an enhanced intracellular release of DOX from PCL-SS-PEEP micelles led to improved cytotoxicity. DOX-loaded PCL-SS-PEEP micelles at the same dose were incubated with A549 cells, which were either non-pretreated or pretreated with GSH-OEt at 10 or 20 mM for 2 h. Cell viability measured by MTT assay shows significant differences between GSH-OEt pretreated and nonpretreated cells, as shown in Figure 3D. Incubation of DOX-loaded PCL-SS-PEEP micelles at a DOX dose of 3.4 μg mL^{-1} with non-pretreated A549 cells for 24 h did not exhibit significant inhibition to the cell proliferation, while the viability of GSH-OEt pretreated cells significantly decreased with increased GSH-OEt concentration for the pretreatments. However, proliferation of A549 cells incubated with free DOX was not affected by the treatment of GSH-OEt (Supporting Information Figure S2). On the other hand, treatments of both GSH-OEt and DOX free PCL-SS-PEEP micelles did not result in significant cytotoxicity to A549 cells under the same conditions (Supporting Information Figure S3). These results demonstrated that the destabilization of PCL-SS-PEEP micelles by intracellular GSH accelerated DOX release, and the cell proliferation inhibition was thus enhanced due to the faster intracellular DOX release. To further confirm such a response to intracellular GSH concentration, viability of incubation of A549 cells with DOX-loaded PCL-SS-PEEP micelles was examined after buthionine sulfoximine (BSO) pretreatments. BSO is an inhibitor of intracellular GSH synthesis (*27*) and does not affect the proliferation of A549 cells at the tested concentrations up to 0.5 mM (Supporting Information Figure S4). With the pretreatment of BSO at higher concentration, DOX-loaded PCL-SS-PEEP micelles exhibited lower cytotoxicity (Supporting Information Figure S4). This is due to that incubation of A549 cells with BSO lowered down the intracellular GSH concentration; therefore, destabilization of DOX-loaded PCL-SS-PEEP micelles was suppressed, resulting in less DOX release from the micelles.

In conclusion, micelle nanoparticles self-assembled from a disulfide-linked diblock copolymer PCL-SS-PEEP have been prepared for enhanced intracellular drug delivery. The micelles exhibit GSH-responsive structure change, and the intracellular DOX release is accelerated at higher GSH concentration. The enhanced intracellular DOX release leads to more significant growth inhibition to A549 cells. This GSH-triggered drug release system has the potential to maximize the delivery efficiency for cancer chemotherapy.

Experimental

Materials: Ethyl ethylene phosphate (EEP) was synthesized and purified as previously reported [1]. ε-Caprolactone was dried over CaH_2, distilled twice under reduced pressure and stored under a nitrogen atmosphere. 2-(2,4-Dinitrophenylthio)-ethanol and 2-(2-pyridyldithio)-ethanol were synthesized following previously reported procedures [2,3]. Stannous octoate was purified according to a method described in literature [1]. Tetrahydrofuran (THF) was refluxed over potassium–sodium alloy under N_2 atmosphere. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), glutathione (GSH), glutathione monoester (GSH-OEt) and buthionine sulfoximine (BSO) were purchased from Sigma-Aldrich Co. Doxorubicin (DOX) hydrochloride was purchased from Zhejiang Hisun Pharmaceutical Co. Ltd. Mercaptoethanol, Triethylamine and other solvents were analytical grade and used as received.

Characterization and Measurements: NMR spectra were recorded on a Bruker AV300 NMR spectrometer. Gel permeation chromatography (GPC) measurements were performed on a Waters 1515 HPLC system, equipped with a Waters 2414 refractive index detector. Chloroform was used as the eluent and delivered at 40 °C at a flow rate of 1.0 mL min^{-1}. Monodispersed polystyrene standards from Waters Co. were used to generate the calibration curve. Transmission electron microscopy observation was performed on a JEOL–2010 transmission electron microscopy with an accelerating voltage of 200 kV. The samples were prepared by pipetting a drop of the micelle solution (about 1 g L^{-1}) onto a 230 mesh copper grids coated with carbon

and allowing the sample to dry in air before measurements. Particle sizes were characterized on a Malvern Zetasizer Nano ZS90 with a He-Ne laser (633 nm) and 90° collecting optics. Fluorescence spectra were recorded on a Shimadzu RF-5301PC spectrofluorophotometer.

Synthesis of thiol-terminated Poly(ε-caprolactone) (PCL-SH): ε-Caprolactone (8.06 g, 70.7 mmol), 2-(2,4-dinitrophenylthio)-ethanol (0.493 g, 2.02 mmol), and $Sn(Oct)_2$ (0.036 g, 0.088 mmol) were added into a round flask stirred at 120 °C for 12 h in a glove box with water content less than 0.01 ppm. The resulted solution was dissolved in CH_2Cl_2 then precipitated into cold diethyl ether twice. The precipitate was collected after filtration and dried under vacuum to a constant weight. The obtained polymer was further dissolved in mercaptoethanol (100 equiv) with triethylamine at pH 8. After 15 h stirring the mixture was precipitated into cold methanol twice to give the thiol-terminated PCL (PCL-SH) with an overall yield of 82%. The Mw is 5500 with a polydispersity of 1.15 as determined by GPC analysis.

Synthesis of 2-pyridyldithio-termianted poly(ethyl ethylene phosphate) (PEEP-Py): In a nitrogen filled glove box with water content less than 0.01 ppm, to a solution of EEP (5.12 g, 33.6 mmol) and 2-(2-pyridyldithio)-ethanol (0.210 g, 1.12 mmol) in THF at 30 °C was added $Sn(Oct)_2$ (0.241 g, 0.60 mmol). After 3 h reaction, the mixture was concentrated and precipitated in cold diethyl ether twice. The polymer was collected and dried under vacuum to give PEEP-Py with a yield of 71%. The Mw is 3950 with a polydispersity of 1.36 as determined by GPC analysis.

Synthesis of disulfide-linked block copolymer PCL-SS-PEEP: PEEP-Py (1.1 g) was dissolved in THF, and the solution was freeze-thawn for three times. PCL-SH (0.97 g) was then added to this solution in a glove box filled with nitrogen. The mixture was allowed to react for 24 h, concentrated, and precipitated into diethyl ether/methanol (10:1 v/v) for three times. The precipitate was dried in vacuum and dialyzed against water at 4 °C for 3 days and freeze dried to obtain the product with a yield of 65%. The Mw is 8670 with a polydispersity of 1.35 as determined by GPC analysis.

Determination of critical micellization concentration (CMC) of PCL-SS-PEEP: A predetermined amount of pyrene in acetone was added into a series of ampoules, and the acetone was then removed by gently flowing N_2 and then by vacuum. Predetermined volume of PCL-SS-PEEP solutions and ultrapurified water (Millipore, 18.2 MΩ) were added into the ampoules consecutively to get solutions of different concentrations ranging from 1.0×10^{-4} to 0.1 g L^{-1} while the concentration of pyrene in each flask was fixed at 6.0×10^{-7} mol L^{-1}, slightly lower than the saturation solubility of pyrene in water. Fluorescence spectra were recorded at 373 nm excitation wavelength and 5 nm slit width. The intensity ratio of the bands at 338.0 and 335 nm (I_{338}/I_{335}) as a function of the logarithm of the concentration of PCL-SS-PEEP was plotted and the CMC value was taken as the intersection of the tangents to the horizontal line of intensity ratio with relatively constant values and the diagonal line with rapid increased intensity ratio.

Preparation of DOX-loaded PCL-SS-PEEP micelles: One milligram of DOX hydrochloride and 15 mg of PCL-SS-PEEP were dissolved in 1 mL of DMSO, and

then 1 μL of triethylamine was added. The mixture was stirred for 2 h at room temperature. Thereafter, the solution was added dropwise to 5 mL of ultrapurified water and transferred into a dialysis membrane tubing (MWCO=2000 Da, Spectrum®). It was dialyzed against water for 24 h to completely remove DMSO. After centrifugation at 3000 g for 3 min to remove possible free DOX, the DOX-loaded micelles were obtained. The DOX concentration and drug loading content were determined according to our previous method using HPLC analyses [4].

Destabilization of PCL-SS-PEEP micelles: GSH was added to the micelle solution (0.5 mg mL^{-1}) in N_2 bubbled ultrapurified water to achieve a final concentration at 10 mM. Immediately, the micelle solution was subjected to particle size measurements at 25 °C using Malvern Zetasizer Nano ZS90 with a He-Ne laser (633 nm) and 90° collecting optics. On the other hand, DOX-loaded PCL-SS-PEEP micelles with similar treatment of DL-dithiothreitol was immediately followed by fluorescence measurements with excitation wavelength at 479 nm and the emission spectra were recorded at different time intervals using a Shimadzu RF-5301PC spectrofluorophotometer.

Glutathione-mediated drug release: DOX-loaded PCL-SS-PEEP micelles prepared above was diluted to 1 mg mL^{-1} and transferred to a 1-mL dialysis membrane tubing (MWCO=14,000, Spectrum®). It was immersed in a tube containing 8 mL of phosphate buffered saline (PBS, 0.01 M, pH 7.4) or PBS with 10 mM GSH in a shaking water bath at 37 °C. At predetermined time intervals, 4 mL of the external buffer was withdrawn and it was replaced with 4 mL of fresh PBS or PBS with 10

mM GSH. The release medium was freeze-dried, dissolved in acetonitrile-water (50:50, v/v), and the concentration of DOX was analyzed by HPLC analysis.

Confocal laser scanning microscopy observation and flow cytometric analysis (FACS) of DOX-loaded PCL-SS-PEEP micelle treated A549 cells: A549 human lung carcinoma cells were seeded on coverslips in a 24-well plate at a density of 50,000 cells/well with complete Dulbecco's modified Eagle's medium (DMEM, Gibco) supplemented with 10% Hyclone fetal bovine serum (FBS) and 4 mM L-glutamine. The cells were incubated for 24 h in a humidified atmosphere with 5 % CO_2 at 37 °C, and then treated with GSH-OEt for 2 h. Cells were washed by PBS and incubated at 37 °C for additional 2 h with DOX-loaded PCL-SS-PEEP micelles at a final DOX concentration of 3.4 μg mL^{-1} in complete DMEM. Cells without GSH-OEt treatment was used as the control. The cells were washed with PBS twice and fixed with 4% formaldehyde. The slides were mounted and observed with a Zeiss LSM510 Laser Confocal Scanning Microscope imaging system (Germany) with an upright confocal microscope and a 40× objective. For FACS analyses, A549 cells were seeded onto 24-well tissue-culture plate at 150,000 cells/well and incubated for 24 h. Cells were either treated with GSH-OEt for 2 h or not, and washed with PBS. Cells were then incubated at 37 °C for additional 2 h with DOX-loaded PCL-SS-PEEP micelles in complete DMEM. Cells were washed with PBS twice and harvested, then suspended in 200 μL of PBS for FACS analyses using FACSCalibur flow cytometer (BD Biosciences, USA).

Cell growth inhibition measurements: A549 cells were seeded in 96-well plate at a density of 5000 cells/well and further incubated for 24 h. The cells were then treated with GSH-OEt for 2 h or BSO for 24 h. After washing off the GSH-OEt or BSO with PBS, DOX-loaded PCL-SS-PEEP micelles diluted in complete DMEM (100 μL) was added to cells to reach a final DOX concentration at 3.4 μg mL^{-1} and the cells were further incubated for 24 h or 48 h. The cytotoxicity was evaluated by a MTT assay as described previously [4].

Lamellarin D Bioconjugates I: Synthesis and Cellular Internalization of PEG-Derivatives

Daniel Pla,[†,‡] Andrés Francesch,[§] Pilar Calvo,[§] Carmen Cuevas,[§] Rosa Aligué,[||] Fernando Albericio,*[,⊥,†,‡] and Mercedes Álvarez*[,#,†,‡]

Institute for Research in Biomedicine, Barcelona Science Park-University of Barcelona, and CIBER-BBN Networking Centre on Bioengineering, Biomaterials, and Nanomedicine, Baldiri Reixac 10, E-08028 Barcelona, Spain, Pharma Mar S. A., Avda de los Reyes 1, E-28770 Colmenar Viejo, Madrid, Spain, and Department of Cell Biology, Faculty of Medicine, University of Barcelona, Casanova 143, E-08036 Barcelona, Spain. Received November 24, 2008; Revised Manuscript Received March 24, 2009

Herein is reported the design and synthesis of poly(ethylene glycol) derivatives of Lamellarin D with the aim of modulating their physicochemical properties and improving the biological activity. Mono-, di-, and tri-PEG conjugates with improved solubility were obtained in 18−57% overall yields from the corresponding partially protected phenolic derivatives of Lamellarin D. Conjugates **1**−**9** were tested in a panel of three human tumor cell lines (MDA-MB-231 breast, A-549 lung, and HT-29 colon) to evaluate their cytotoxicity. Several compounds exhibited enhanced cellular internalization, and more than 85% of the derivatives showed a lower GI_{50} than Lam-D. Furthermore, cell cycle arrest at G2 phase and apoptotic cell-death pathways were determined for Lamellarin D and these derivatives.

INTRODUCTION

Compounds with a good therapeutic profile often do not reach the drug market because they show poor pharmacokinetics, mainly due to poor solubility. Attachment of well-defined, water-soluble, biocompatible, nontoxic, and non-immunogenic polymeric systems to drug candidates can overcome this limitation. Furthermore, these chemical modifications can significantly improve tumor targeting, in addition to therapeutic efficacy, by EPR[1] effect of the drug in tumor tissue. Advances in this field require robust and reliable chemical strategies for the preparation of such derivatives of key pharmacological lead compounds, because very often the polymeric backbone should be incorporated in the chemical structure in the middle of the synthetic strategy.

Lam-D (*1*−*6*) (**1**) is a marine alkaloid with a wide range of biological activities, such as antiproliferative activity against various tumor cell lines in the low nanomolar concentration. Lam-D inhibits the Topo I (*3*), thereby disrupting the potential of mitochondrial transmembrane (*4*), which promotes apoptosis (*7*). The conjugation of water-soluble biocompatible polymers to low molecular weight anticancer drugs has been reported to enhance the solubility of the drugs, enhance their accumulation in tumors, and prolong their retention in the circulatory system, thereby improving the drugs' pharmacodynamics and pharmacokinetics (*8*, *9*). Notwithstanding, further controlled drug delivery by means of a readily hydrolyzable conjugation bond is required for the appropriate release of the bioactive drug (*10*). Therefore, modulation of biopolymers that bind drugs is of paramount importance for preclinical research and developments with new lead compounds (*11*). Recently, PEGylated compounds used in cancer therapy have been shown to promote the EPR effect (*12*, *13*), raising the local concentration of drug accumulated in targeted solid tumors. It has been proposed that this effect is caused by vascular leakage in the tumor and a reduction in the tumor's lymphatic drainage (*14*).

Our group sought to modulate the physicochemical properties of Lam-D by creating a series of mono-, di-, and tri-PEG ester conjugates of this drug. Herein are described the syntheses using

modified synthetic strategies of these conjugates, as well as their biological activity.

EXPERIMENTAL PROCEDURES

General Procedures and Product Characterization. *A. General Procedures for Cross-Coupling Reactions.* A solution of bromide derivative **14** (1.0 mmol) in DMF (20 mL) was purged with Ar for 10 min, and boronate **12** (1.0 mmol), $Pd(PPh_3)_4$ (10%) and 2 M K_3PO_4 (3.0 mmol) were then added. The reaction mixture was stirred at 115 °C, and then another portion of boronate **12** (2.0 mmol) was added dropwise using a syringe pump during the first hour of reaction. The solvent was removed, and the residue was dissolved in EtOAc. The organic solution was washed with water and brine, dried, and concentrated to give a crude material, which was later purified by column chromatography on silica gel. Elution with hexane/EtOAc (75:25 to 60:40) gave **15a**−**c** (69−77% yield).

B. General Procedure for Oxidation. Synthesis of Compounds **16.** A mixture of **15** (1.0 mmol) and DDQ (1.0 mmol) in dry $CHCl_3$ (15 mL) was purged with Ar in a sealed vessel and heated in a microwave at 120 °C for 10 min. The organic solution was washed with water and brine and then dried ($MgSO_4$), filtered, and evaporated in a vacuum. The crude material was purified by column chromatography on silica gel. Elution with hexane/EtOAc (85:15 to 60:40) gave **16a**−**c** (65−93% yield).

C. General Method for Benzyloxy Removal. Pd/C (10%) was added to a solution of **16** (1.0 mmol) in MeOH (50 mL). The suspension was purged with H_2 and stirred for 16 h. The reaction mixture was filtered through a Celite pad, which was washed with CH_2Cl_2. The solvent was removed under vacuum to provide the compounds **17a**−**c** (yield 70−95%).

D. General Method for Lactonization. NaH (60% dispersion, 1.1 equiv) was washed twice with dry THF and a solution of **17** (1 mmol) was added in THF (60 mL). The mixture was stirred for 3 h at r.t. The solvent was then removed under reduced pressure, and EtOAc was added to the residue. The organic solution was washed with saturated aq. NH_4Cl, water, and brine, then dried and concentrated to provide the compounds **18a**−**c** (86% quant. yield).

E. General Method for Esterification. EDC·HCl (4 mmol × free OH) was added in one solid portion to a solution of DMAP (0.6 equiv in SM) PEG-COOH (4 mmol × free OH), and either Lam-D (*15*) or **18** (1 mmol) in dry CH_2Cl_2 (45 mL). The resulting solution was stirred at r.t. for 3 h. The reaction mixture was diluted with CH_2Cl_2 and washed with sat. aq. $NaHCO_3$ and brine. The organic phase was dried over anhydrous $MgSO_4$, and the solvent was removed under vacuum. The residue was directly purified on silica gel to provide compounds **8**, **9**, **19a**−**f** (40% quant. yield).

F. General Method for Isopropoxy Deprotection. Anhydrous $AlCl_3$ (1.3 equiv) was added to a solution of compound **19** (1 mmol) in dry CH_2Cl_2 (1 mL). The mixture was sonicated for 10 min, quenched with sat. NH_4Cl, and then washed with water and brine. Compounds **19b** and **19d** were treated only with brine, and the aqueous solution was extracted with EtOAc. The organic extracts were dried and evaporated. The crude product was purified by flash chromatography to give compounds **2**−**7** (yield 19−59%).

Methyl 1-(4-Benzyloxy-3-methoxyphenyl)-8-isopropoxy-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (13a). A solution of methyl 1-bromo-8-isopropoxy-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (543 mg, 1.4 mmol) in DMF (40 mL) was purged with Ar, and 2-(4-benzyloxy-3-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (**11a**) (703 mg, 2.1 mmol), $Pd(PPh_3)_4$ (159 mg, 0.1 mmol), and 2 M K_2CO_3 (2.8 mL, 5.5 mmol) were added. The reaction mixture was stirred at 125 °C for 16 h. The solvent was removed after cooling to r.t., and the residue was dissolved in EtOAc. The organic solution was washed with water and brine, dried ($MgSO_4$), and concentrated to give a crude material, which was later purified by column chromatography on silica gel. Elution with hexane/EtOAc (90:10 to 75:25) gave **13a** (543 mg, 1.38 mmol) as a yellow oil (727 mg, quant.). IR (film) ν 1670, 1464, 1440, 1242. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.37 (d, J = 6.0 Hz, 6H); 2.98 (t, J = 6.4 Hz, 2H); 3.31 (s, 3H, OMe); 3.84 (s, 3H, OMe); 3.85 (s, 3H, OMe); 4.52 (h, J = 6.0 Hz, 1H, OCH); 4.60 (t, J = 6.4 Hz, 2H); 5.19 (s, 2H); 6.73 (s, 1H); 6.86 (s, 1H); 6.89 (s, 1H); 6.93 (dd, J = 8.0, 1.8 Hz, 1H); 6.96−7.00 (m, 2H); 7.31 (d, J = 7.2 Hz, 1H); 7.35 (dd, J = 7.2, 7.2 Hz, 2H); 7.44 (d, J = 7.2 Hz, 2H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 22.2 (2q); 29.0 (t); 42.6 (t); 51.1 (q); 55.4 (q); 56.1 (q); 71.0 (t); 71.4 (d); 109.1 (d); 113.1 (d); 114.1 (d); 114.7 (d); 119.2 (d); 121.1 (s); 121.47 (s); 121.54 (s); 125.6 (d); 127.1 (2d); 127.8 (d); 128.5 (2d); 129.8 (s); 137.2 (s); 146.5 (s); 146.8 (s); 148.5 (s); 149.5 (s); 161.7 (s). MS (ESI) 528 (M+1, 100); 529 (M+2, 37). HRMS *m*/*z* calcd for $C_{32}H_{34}NO_6$ 528.2381, found 528.2373.

Methyl 1-(4-Benzyloxy-3-methoxyphenyl)-2-bromo-8-isopropoxy-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (14a). NBS (82 mg, 0.46 mmol) was added in one portion to a solution of **13a** (245 mg, 0.46 mmol) in THF (10 mL). The mixture was stirred at 70 °C under Ar for 90 min. The solvent was removed under reduced pressure. The residue was dissolved in CH_2Cl_2 and filtered through a pad of neutral alumina. **14a** was obtained as a yellow oil (278 mg, 99%). IR (film) ν 1693, 1462, 1112 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.35 (d, J = 6.0 Hz, 6H); 2.98 (t, J = 6.4 Hz, 2H); 3.20 (s, 3H, OMe); 3.86 (s, 3H, OMe); 3.90 (s, 3H, OMe); 4.51 (h, J = 6.0 Hz, 1H, OCH); 4.59 (t, J = 6.4 Hz, 2H); 5.20 (br, 2H); 6.54 (s, 1H); 6.70 (s, 1H); 6.85−7.00 (m, 3H); 7.28−7.47 (m, 5H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 22.0 (2q); 28.6 (t); 43.4 (t); 51.1 (q); 55.0 (q); 56.0 (q); 70.7 (t); 71.2 (d); 107.6 (s); 108.9 (d); 113.0 (s); 113.7 (d); 113.9 (s); 114.3 (d); 114.5 (d); 119.1 (s); 122.2 (s); 123.2 (d); 125.3 (s); 126.9 (2d); 127.6 (d); 128.4 (2d); 131.8 (s); 137.0 (s); 146.6 (s); 147.3 (s); 148.3 (s); 149.4 (s); 161.1 (s). MS (ESI) 606 (MBr^{79}+1, 100); 607 (MBr^{79}+2, 23); 608 (MBr^{81} + 1, 95). HRMS *m*/*z* calcd. for $C_{32}H_{33}NO_6Br$ 606.1486, found 606.1485.

Methyl 2-(2,4-Dibenzyloxy-5-methoxyphenyl)-8-isopropoxy-1-(4-isopropoxy-3-methoxyphenyl)-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (15a). Following the general procedure **A** and starting from **14b** (*16*) (674 mg, 1.21 mmol) and 2-(2,4-dibenzyloxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (**12b**), a yellow oil (719 mg, 75%) was obtained. IR (film) ν 1691, 1254, 1212. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.31 (d, J = 6.2 Hz, 6H); 1.35 (d, J = 6.0 Hz, 6H); 3.03 (t, J = 6.4 Hz, 2H); 3.32 (s, 3H, OMe); 3.47 (s, 3H, OMe); 3.53 (s, 3H, OMe); 3.59 (s, 3H, OMe); 4.35−4.65 (m, 4H, 2OCH); 4.74 (s, 2H); 5.01 (s, 2H); 6.46 (s, 1H); 6.55 (s, 1H); 6.61 (br, 1H); 6.69−6.79 (m, 4H); 7.08−7.13 (m, 2H); 7.17−7.26 (m, 4H); 7.27−7.35 (m, 4H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 21.8 (2q); 22.0 (2q); 28.9 (t); 42.8 (t); 50.7 (q); 54.9 (q); 55.5 (q); 56.2 (q); 71.0 (t); 71.2 (d, t); 71.5 (d); 102.8 (d); 109.1 (d); 114.6 (2d); 115.8 (d); 115.9 (d); 118.2 (s); 118.7 (s); 121.1 (s); 121.5 (s); 122.9 (d); 125.4 (s); 126.5 (2d); 127.1 (2d); 127.5 (2d); 128.0 (2d); 128.2 (2d); 128.6 (s); 130.8 (s); 136.8 (s); 137.6 (s); 143.3 (s); 145.4 (s); 146.0 (s); 146.8 (s); 148.2 (s); 149.8 (s); 150.3 (s); 162.2 (s). MS (MALDI-TOF) 797 (M, 100), 798 (M+1, 54).

Methyl 2-(2-Benzyloxy-4-isopropoxy-5-methoxyphenyl)-1-(4-benzyloxy-3-methoxyphenyl)-8-isopropoxy-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (15b). Following the general procedure **A** and starting from **14a** (277 mg, 0.46

mmol) and 2-(2-benzyloxy-4-isopropoxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (**12a**), a yellow oil (282 mg, 77%) was obtained. IR (film) ν 1692, 1254, 1212. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.26 (d, J = 6.0 Hz, 6H); 1.36 (d, J = 6.0 Hz, 6H); 3.03 (t, J = 6.0 Hz, 2H); 3.21 (s, 3H, OMe); 3.55 (s, 3H, OMe); 3.57 (s, 6H, 2OMe); 4.37 (h, J = 6.0 Hz, 1H, OCH); 4.52 (h, J = 6.0 Hz, 1H, OCH); 4.63 (br, 2H); 4.82 (s, 2H); 5.12 (s, 2H); 6.46 (s, 1H); 6.55 (s, 1H); 6.66 (s, 1H); 6.72 (br, 4H); 7.16−7.41 (m, 10H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 21.9 (2q); 22.0 (2q); 28.0 and 28.9 (t); 42.2 and 42.8 (t); 50.7 (q); 55.0 (q); 55.5 (q); 56.2 (q); 70.5 (t); 71.1 (d); 71.3 (d); 71.5 (t); 104.5 (d); 109.0 (d); 113.3 (d); 114.3 (d); 114.4 (d); 116.1 (d); 118.2 (s); 118.7 (s); 121.0 (s); 121.4 (s); 122.9 (d); 125.4 (s); 126.5 (2d); 126.8 (2d); 127.1 (d); 127.5 (d); 127.7 (s); 128.0 (2d); 128.2 (2d); 130.8 (s); 137.0 (s); 137.7 (s); 144.0 (s); 145.9 (s); 146.0 (s); 146.1 (s); 148.1 (s); 148.8 (s); 150.2 (s); 162.2 (s). MS (ESI-TOF) 798 (M+1, 100), 799 (M+2, 39), 800 (M+3, 7). HRMS *m/z* calcd. for $C_{49}H_{51}NO_9$ 798.3636, found 798.3621.

Methyl 2-(2,4-Dibenzyloxy-5-methoxyphenyl)-1-(4-benzyloxy-3-methoxyphenyl)-8-isopropoxy-9-methoxy-5,6-dihydropyrrolo[2,1-*a*]isoquinoline-3-carboxylate (15c). Following the general procedure **A** and starting from **14a** (255 mg, 0.42 mmol) and 2-(2,4-dibenzyloxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (**12b**), a reddish oil (246 mg, 69%) was obtained. IR (film) ν 1692, 1438, 1252, 1212. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.38 (d, J = 6.0 Hz, 6H); 3.04 (t, J = 6.0 Hz, 2H); 3.24 (s, 3H, OMe); 3.54 (s, 3H, OMe); 3.56 (s, 3H, OMe); 3.63 (s, 3H, OMe); 4.54 (h, J = 6.0 Hz, 1H, OCH); 4.64 (br, 2H); 4.77 (s, 2H); 5.05 (s, 2H); 5.14 (s, 2H); 6.50 (s, 1H); 6.59 (s, 1H); 6.67 (s, 1H); 6.71−6.77 (m, 4H); 7.11−7.14 (m, 2H); 7.21−7.42 (m, 13H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 22.0 (2q); 28.8 (t); 42.8 (t); 50.6 (q); 55.0 (q); 55.6 (q); 56.3 (q); 70.5 (t); 71.0 (t); 71.2 (d); 71.5 (t); 102.9 (d); 109.1 (d); 113.5 (d); 114.46 (d); 114.54 (d); 116.0 (d); 118.3 (s); 118.8 (s); 121.0 (s); 121.5 (s); 122.9 (d); 125.4 (s); 126.6 (2d); 126.8 (2d); 127.19 (d); 127.21 (2d); 127.6 (2d); 127.9 (s); 128.0 (2d); 128.3 (2d); 128.3 (2d); 128.6 (s); 130.8 (s); 136.9 (s); 137.1 (s); 137.7 (s); 143.4 (s); 146.1 (s); 146.3 (s); 146.9 (s); 148.3 (s); 149.0 (s); 150.4 (s); 162.2 (s). MS (ESI-TOF) 846 (M+1, 100), 847 (M+2, 49), 848 (M+3, 12). HRMS *m/z* calcd. for $C_{53}H_{52}NO_9$ 846.3636, found 846.3621.

Methyl 2-(2,4-Dibenzyloxy-5-methoxyphenyl)-8-isopropoxy-1-(4-isopropoxy-3-methoxyphenyl)-9-methoxypyrrolo[2,1-*a*]isoquinoline-3-carboxylate (16a). Following the general procedure **B** and starting from **15a** (686 mg, 0.86 mmol), a yellow oil (637 mg, 93%) was obtained. IR (film) ν 1682, 1380, 1121 cm^{-1}. ^{1}H NMR ($CDCl_3$, 100 MHz) δ 1.32 (d, J = 6.0 Hz, 6H); 1.37 (d, J = 6.0 Hz, 6H); 3.42 (s, 6H, 2OMe); 3.59 (s, 3H, OMe); 3.63 (s, 3H, OMe); 4.49 (h, J = 6.0 Hz, 1H, OCH); 4.64 (h, J = 6.0 Hz, 1H, OCH); 4.78 (br, 2H); 5.03 (s, 2H); 6.48 (s, 1H); 6.54−6.73 (m, 2H); 6.79−6.94 (m, 3H); 7.03−7.11 (m, 3H); 7.15−7.20 (m, 3H); 7.23−7.34 (m, 6H); 9.31 (d, J = 7.6 Hz, 1H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 21.7 (2q); 22.0 (2q); 50.6 (q); 54.9 (q); 55.5 (q); 56.3 (q); 70.9 (d); 71.1 (t); 71.2 (d); 71.3 (t); 102.5 (d); 105.4 (d); 110.3 (d); 111.7 (d); 112.7 (s); 115.2 (d); 115.6 (d); 115.7 (s); 115.9 (d); 118.0 (s); 118.4 (s); 119.5 (s); 123.2 (d); 123.6 (d); 126.4 (d); 127.1 (d); 127.2 (2d); 127.5 (2d); 128.0 (2d); 128.2 (2d); 129.0 (s); 130.0 (s); 131.6 (s); 136.8 (s); 137.5 (s); 143.1 (s); 145.7 (s); 147.0 (s); 147.2 (s); 149.6 (s); 149.9 (s); 150.3 (s); 162.3 (s). MS (MALDI-TOF) 795 (M, 100), 796 (M+1, 73).

Methyl 2-(2-Benzyloxy-4-isopropoxy-5-methoxyphenyl)-1-(4-benzyloxy-3-methoxyphenyl)-8-isopropoxy-9-methoxypyrrolo[2,1-*a*]isoquinoline-3-carboxylate (16b). Following the general procedure **B** and starting from **15b** (1.06 g, 1.32 mmol), a yellow oil (685 mg, 65%) was obtained. IR (film) ν 1704, 1377, 1214 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.41 (2d, J = 6.0 Hz, 12H); 3.28 (s, 3H, OMe); 3.57 (br, 3H, OMe); 3.62 (s, 3H, OMe); 3.65 (br, 3H, OMe); 4.39 (h, J = 6.0 Hz, 1H, OCH); 4.65 (h, J = 6.0 Hz, 1H, OCH); 4.86 (br, 2H); 5.14−5.18 (m, 2H); 6.47 (br, 1H); 6.76−6.88 (m, 2H); 6.91 (d, J = 7.6 Hz, 1H); 7.03 (s, 1H); 7.14−7.21 (m, 3H); 7.27−7.49 (m, 10H); 9.31 (d, J = 7.6 Hz, 1H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 21.9 (2q); 22.0 (2q); 50.7 (q); 55.2 (q); 55.6 (q); 56.4 (q); 70.6 (t); 70.8 (t); 71.0 (d); 71.5 (d); 104.3 (d); 105.5 (d); 110.3 (d); 111.8 (d); 112.8 (s); 113.3 and 113.6 (d); 115.2 (d); 116.2 (d); 118.5 (s); 119.6 (s); 123.4 (d); 123.7 (d); 127.0 (2d); 127.4 (s); 127.75 (2d); 128.2 (2d); 128.5 (2d); 128.6 (d); 128.7 (s); 128.8 (d); 129.2 (s); 130.2 (s); 131.9 (s); 137.2 (s); 137.7 (s); 144.1 (s); 146.6 (s); 147.4 (s); 149.7 (s); 150.4 (s); 162.6 (s). MS (ESI-TOF) 796 (M+1, 100), 797 (M+2, 54). HRMS *m/z* calcd. for $C_{49}H_{50}NO_9$ 796.3480, found 796.3480.

Methyl 2-(2,4-Dibenzyloxy-5-methoxyphenyl)-1-(4-benzyloxy-3-methoxyphenyl)-8-isopropoxy-9-methoxypyrrolo[2,1-*a*]isoquinoline-3-carboxylate (16c). Following the general procedure **B** and starting from **15c** (244 mg, 0.29 mmol), a yellow oil (181 mg, 74%) was obtained. IR (film) ν 1681, 1374, 1212 cm^{-1}. ^{1}H NMR ($CDCl_3$, 100 MHz) δ 1.43 (d, J = 6.0 Hz, 6H); 3.30 (s, 3H, OMe); 3.52−3.65 (m, 9H, 3 OMe); 4.60−4.90 (m, 3H); 5.07 (s, 2H); 5.18−5.21 (m, 2H); 6.50 (s, 1H); 6.59 (br, 1H); 6.74 (br, 1H); 6.82−6.89 (m, 2H); 6.94 (d, J = 7.6 Hz, 1H); 7.06 (s, 1H); 7.09−7.15 (m, 2H); 7.20−7.23 (m, 4H); 7.30−7.46 (m, 10H); 9.33 (d, J = 7.6 Hz, 1H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 21.9 (2q); 50.7 (q); 55.1 (q); 55.7 (q); 56.4 (q); 70.6 (t); 70.9 (d); 71.2 (t); 71.4 (t); 102.5 (d); 105.4 (d); 110.2 (d); 111.8 (d); 112.8 (s); 113.3 (d); 115.1 (d); 116.0 (d); 118.1 (s); 118.4 (s); 119.5 (s); 123.3 (d); 123.6 (d); 126.5 (d); 126.9 (2d); 127.2 (2d); 127.3 (2d); 127.7 (2d); 128.1 (2d); 128.3 (2d); 128.4 (2d); 129.0 (s); 130.1 (s); 131.7 (s); 136.9 (s); 137.1 (s); 137.5 (s); 143.2 (s); 146.5 (s); 147.1 (s); 147.3 (s); 149.0 (s); 149.6 (s); 150.4 (s); 162.4 (s). MS (ESI-TOF) 820 (M+1, 100), 821 (M+2, 39); 822 (M+2, 14). HRMS *m*/*z* calcd. for $C_{42}H_{46}NO_{16}$ 820.2811, found 820.2797.

Cell Lines and Culture. Established human-derived cell lines used in this study were purchased from ATCC (American type Culture Collection): A-549, human lung carcinoma; BJ, Skin Fibroblast; HT-29, human colorectal adenocarcinoma; and MDA-MB-231, human breast adenocarcinoma. All cell lines were maintained in DMEM supplemented with 10% FBS and 100 units/mL penicillin and streptomycin at 37 °C and 5% CO_2.

GI_{50} Analysis. Triplicate cultures were incubated for 72 h in the presence or absence of test compounds **1**−**9** (at ten concentrations, typically ranging from 0.0026 to 10 μg/mL).

A colorimetric assay using SRB was adapted for a quantitative measurement of cell growth and viability, following a previously described method (*16*). Cells were plated in 96-well microtiter plates at a density of 5×10^3/well and incubated for 24 h. One plate from each different cell line was fixed, stained, and used for Tz reference (see next paragraph). The cells were then treated with vehicle alone (control) or the test compounds at the concentrations indicated. The treated cells were incubated for additional 72 h, and then assayed for cytotoxicity via colorimetric analysis.

The cells were washed twice with PBS, fixed for 15 min in 1% glutaraldehyde solution, rinsed twice in PBS, and stained in 0.4% SRB solution for 30 min at room temperature. The cells were then rinsed several times in 1% acetic acid solution and air-dried. SRB was then extracted in 10 mM trizma base solution, and the absorbance at 490 nm was then measured. Cell survival is expressed as a percentage of control cell growth.

Dose−response curves were obtained by using the NCI algorithm (*17*): Tz = number of control cells at time t_0, C = number of control cells at time t, and T = number of treated cells at time t.

If Tz < T < C (growth inhibition), then the result is 100 × ([T − Tz]/[C − Tz]).

If T < Tz (net cell death), then the result is 100 × ([T − Tz]/Tz).

After dose−curve generation, the results were expressed as GI_{50}.

General Treatments for Imaging. A-549, MDA-MB-231, and HT-29 cells were seeded onto MatTek (Ashland, USA) glass-bottomed microwell dishes at 30×10^3 cells/cm^2. After 24 h, the culture medium was discarded and then replaced by fresh DMEM medium containing compound **9** at 25 nM. A negative control (no compound) was also used. The cells were then incubated for 48 h at 37 °C.

The following dyes were used for colocalization experiments: WGA-FITC (Sigma, USA) and Mitotracker Red (Molecular Probes). Standard staining protocols were employed for live-cell imaging. Images were then subsequently acquired within the following 30 min.

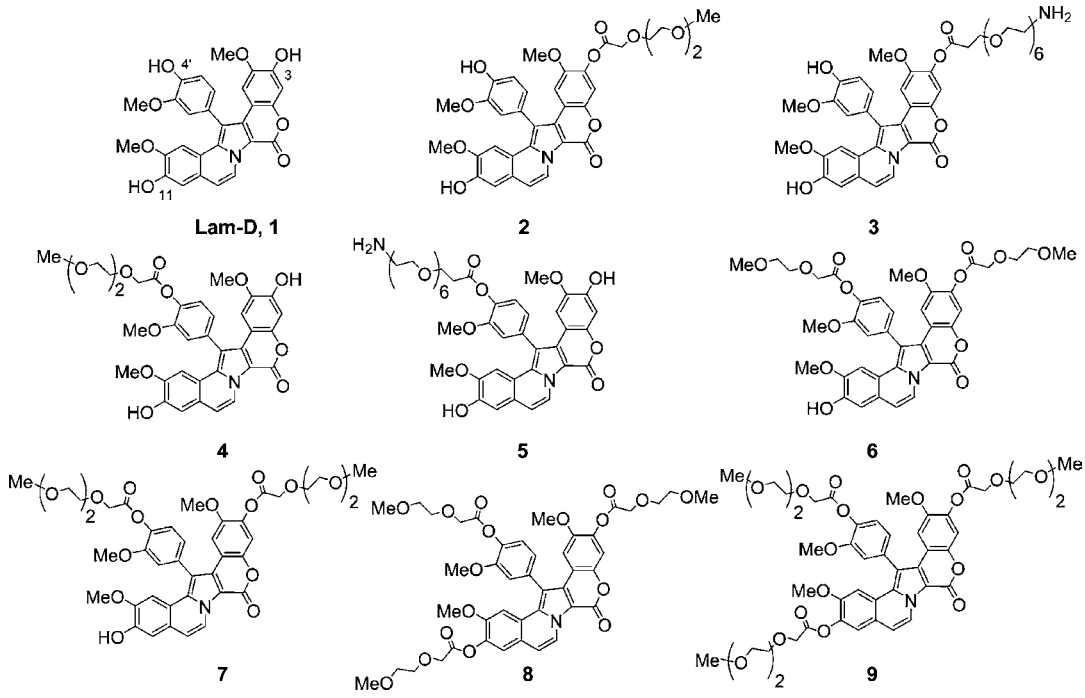

Figure 1. Structures of Lam-D 1 and PEG derivatives **2**−**9**.

Confocal Laser Scanning Microscopy. Confocal laser scanning microscopy was performed with a Leica TCS SPII spectral confocal laser scanning microscope (Leica Microsystems Heidelberg GmbH, Mannheim, Germany), using a 63× objective. FITC fluorescence was excited with an Ar laser at 488 nm. Lam-D and its derivatives were excited at 351 nm. Mitotracker was excited at 543 nm. The same microscope settings were maintained for each conjugate and concentration. To avoid crosstalk, two-fluorescence scanning was performed in a sequential mode.

Apoptosis Assay. The methodology used is based on fluorochrome inhibitors of caspases (FLICA; CaspaTag in situ caspase detection kits, Chemicon International, U.S. and Canada). The inhibitors are cell-permeable and non-cytotoxic. Once inside the cell, the inhibitor covalently binds to the active caspase. This kit uses a carboxyfluorescein-labeled fluoromethyl ketone peptide inhibitor of caspase-3 (FAM-DEVD-FMK), which fluoresces green. When added to a group of cells, the FAM-DEVD-FMK probe enters each cell and covalently binds to a reactive cysteine residue in the large subunit of the active caspase heterodimer, thereby inhibiting further enzymatic activity (*18*).

Cell cultures previously incubated with Lam-D for 48 h at a concentration of 25 nM were tested for apoptosis determination. After the latter drug treatments, 30 × FLICA reagent was added at 1:15 dilution in culture medium and then incubated for 1 h at 37 °C. The cells were then washed with PBS and subsequently analyzed by confocal scanning microscopy. The green fluorescence signal was a direct measure of the amount of active caspase-3/7 present in the cell at the time the reagent was added.

Uptake Measurements by FACS Flow Cytometry. 1×10^6 A-549, BJ, MDA-MB-231, and HT-29 cells were seeded onto 25 cm^2 cell culture flasks (Nalgene Nunc International, Naperville, USA) with 10 mL of DMEM. After 12 h, the culture medium was discarded and replaced by fresh DMEM medium containing compounds **1**−**9** at a concentration of 1 μM. A negative control (no compound) was also used. Cells were then incubated for 12 h at 37 °C. After incubation, cells were washed with 3 × PBS, detached with trypsin−EDTA 0.25%, and centrifuged at 1000× rpm. Finally, the medium was decanted, and the cellular pellet was resuspended in PBS and kept at 0 °C until measurements were performed. Fluorescence analysis was performed with a MoFlo cytometer (DakoCytomation, Colorado, USA), using the 351 nm excitation line of Ar laser (25 mW) and emission detection at 450 nm (tolerance range ±65 nm). CIQ is expressed as a percentage value in reference to Lam-D. It was calculated as a division of the fluorescence value obtained by the Lam-D fluorescence control under the same experimental conditions.

Cell Cycle Analysis. Cell cycle analysis were performed by DRAQ5 (Biostatus) staining to determine DNA content. DRAQ5 was added to the previous PBS cell culture suspensions (1 μL/4 × 10^5 cells), incubated for 15 min at 37 °C, and the cells were directly analyzed without any further treatment. Fluorescence analysis was performed with a MoFlo cytometer (DakoCytomation, Colorado, USA), using the 488 nm excitation line of an Ar laser (150 mW) and emission detection at 670 nm (tolerance range ±30 nm). Cell cycle profile was analyzed using *Cell Quest* software.

RESULTS

Lam-D contains three phenolic sites susceptible to modification. Despite previous SAR studies that highlighted the relevance of the phenolic residues at the C-3 and C-11 positions of Lam-D (*3*, *19*), and their essential role for cytotoxicity and topoisomerase I inhibition (*3*), in this study, the free OH groups were chosen for attachment the PEG moiety. As esters readily hydrolyze under physiological conditions, our group envisioned that these derivatives would enable gradual release of the drug. Use of Lam-D derivatives having differently protected phenols allowed selective deprotection and further conjugation with PEG-carboxylic acids to enable synthesis of mono-PEG (**2**−**5**), di-PEG (**6**, **7**), and tri-PEG (**8**, **9**) conjugates (Figure 1).

The derivatives prepared contain monodisperse PEG backbones with OMe (**2**, **4**, **6**, **7**, **8**, and **9**) and NH_2 (**3**, **5**) terminal moieties and vary in their chain length. The PEGs used for derivatization contain one, two, or six sequentially linked units of ethylene glycol. Another source of diversity introduced in the PEG carriers was a spacer; acetyl (**2**, **4**, **6**, **7**, **8**, and **9**) or propanoyl (**3**, **5**) moieties were used.

9	4.08×10^{-6}	4.69×10^{-8}	8.57×10^{-8}	2.67×10^{-8}

The methodology developed in our group for the total synthesis of Lam-D (*15*) was used for the preparation of conjugates **2**−**9**. The key steps of the synthesis comprise two successive processes of regioselective bromination and Pd(0)-catalyzed cross-coupling reactions starting from the scaffold **10**.

As shown in **Scheme 1**, several dialkoxy and trialkoxyphenylboronates **11a**,**b** and **12a**,**b** were required. These compounds were obtained with good yields by borylation of the corresponding aryl bromides with pinacolborane using $Pd(OAc)_2$ and DPE-Phos as catalysts (for details, see Supporting Information). The protected alkoxy-aryl bromides required were obtained by protection of commercially available phenols followed by mild bromination via NBS in THF at −78 °C (*20*).

Regioselective bromination of **10** (*21*) at position 1 using one equivalent of NBS in THF followed by Pd(0)-catalyzed cross-coupling reaction with the boronic ester **11a** or **11b** afforded the monoaryl scaffolds **13a** and **13b** (*15*), respectively, which were converted into the bromides **14a** and **14b** (*15*) by regioselective bromination at position 2. A second cross-

[a] The CIQ has been calculated in reference to the cellular uptake of Lam-D.

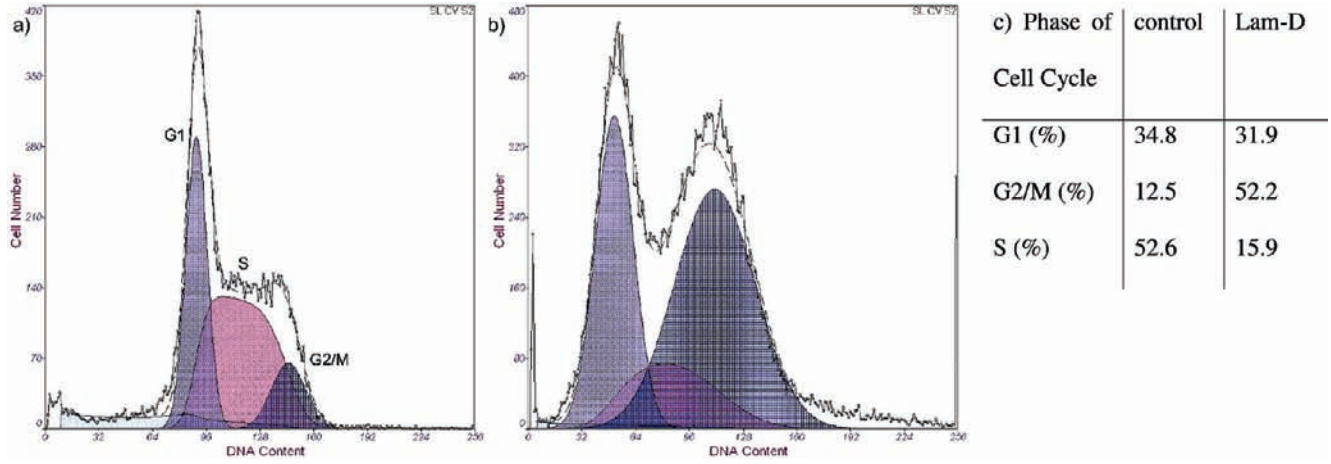

Figure 3. Cell cycle progression of Lam-D in HT-29 cancer cell line. (a) HT-29 asynchronous colon cell line; (b) HT-29 with 1 μM Lam-D for 12 h.

coupling reaction, using the trialkoxyphenylboronates **12a** or **12b**, gave the diaryl derivatives **15a**−**c** (with the desired orthogonal protected phenol groups as *i*Pr/Bn ethers) in 45−64% yields from the scaffold **10**.

Tight control of the oxidation of **15** using 1 equiv of DDQ and MW irradiation at 120 °C for 10 min gave **16a**−**c** (65−93% yield), avoiding the complex mixtures obtained by simultaneous *O*-Bn cleavage using other conditions (*22*).

The *O*Bn protecting group was successfully removed to give **17a**−**c** in 70−95% yields by hydrogenolysis over Pd−C in methanolic solution. Lactonization in excellent yields (86% to quant.) was achieved by direct treatment of the methyl esters **17a**−**c** with sodium hydride in THF. Lactonization was needed before PEGylation to protect the phenol required in the lactone formation and to prevent undesired PEG removal caused by the instability of the ester bond under the basic reaction conditions.[2] Compounds **18a** and **18b**, having only one free phenol group (each of which at a distinct position), and **18c**, with two free phenol groups, were then further conjugated. The PEG-groups were successfully introduced by esterification of the free phenols of **18a**−**c** to give compounds **19a**−**f** using EDC·HCl with a catalytic amount of DMAP in CH_2Cl_2 (*23*). The same reaction conditions were used for the conjugation of Lam-D, obtained by deprotection of two isopropyl groups of **18c** with $AlCl_3$, to give the triester derivatives **8** and **9**. The isopropyl-protecting groups of **19a**−**f** were eliminated using $AlCl_3$ in CH_2Cl_2 with moderate to good yields, with concomitant removal of the *N*-Boc-protecting groups of **19b** and **19d**.

High-polarity solvents such as DMSO and PEG-400 were required to dissolve Lam-D (**1**), which is insoluble in most common solvents. The solubility of monoPEG compounds **2**−**5**, with a single conjugation of one phenolic residue, is much better to that of Lam-D.[3] Conjugate **3**, bearing six units of ethylene glycol and a NH_2 termination, showed 80-fold greater solubility in water than Lam-D. The solubility of conjugates **3**, **7**, and **9** -mono-, di-, and triester, respectively- in PEG-400 solvent was in accordance with the increase of PEG conjugations. Final compounds **2**−**9** were prepared in 18% to 57% yields from the corresponding phenolic Lam-D precursors.

Lastly, the conjugates were further evaluated biologically, and in vitro drug delivery assays were carried out.

Cytotoxicity and Cellular Uptake. The cytotoxicity of Lam-D (**1**) and its analogues (**2**−**9**) was evaluated against BJ human skin fibroblasts, and a panel of three human tumor cell lines: HT-29, A-549, and MDA-MB-231. A conventional colorimetric assay was used to estimate values of GI_{50} (i.e., the drug concentration that causes 50% of cell growth inhibition after 72 h of continuous exposure to the test molecule (*17*)). The results are shown in Table 1.

Conjugates **2**−**9** are all active against the cell lines: HT-29, the cytotoxicity of **2**−**9** is similar to that of Lam-D; in A-549 and MDA-MB-231 cell lines, the activity of **2**−**4** and **6**−**9** is 1.4−4.3-fold better than that of Lam-D. Furthermore, BJ skin fibroblasts were used in the present study to evaluate the effects of the drug and its conjugates in normal cells. In this non-tumoral cellular culture, conjugates **3**, **6**, and **7** maintained the same order of magnitude of cytotoxicities than Lam-D. Besides,

[2]Lactonization of methyl 2-(2,4-dihydroxy-5-methoxyphenyl)-8-hydroxy-1-(4-(2-(2-(2-methoxyethoxy)ethoxy)acetoxy)-3-methoxyphenyl)-9-methoxypyrrolo[2,1-*a*]isoquinoline-3-carboxylate did not provide compound **4**; rather, it led exclusively to formation of Lam-D.

[3]The conjugates are more soluble in water, EtOH, and PEG-400 than Lam-D. See Table SI1 in the Supporting Information.

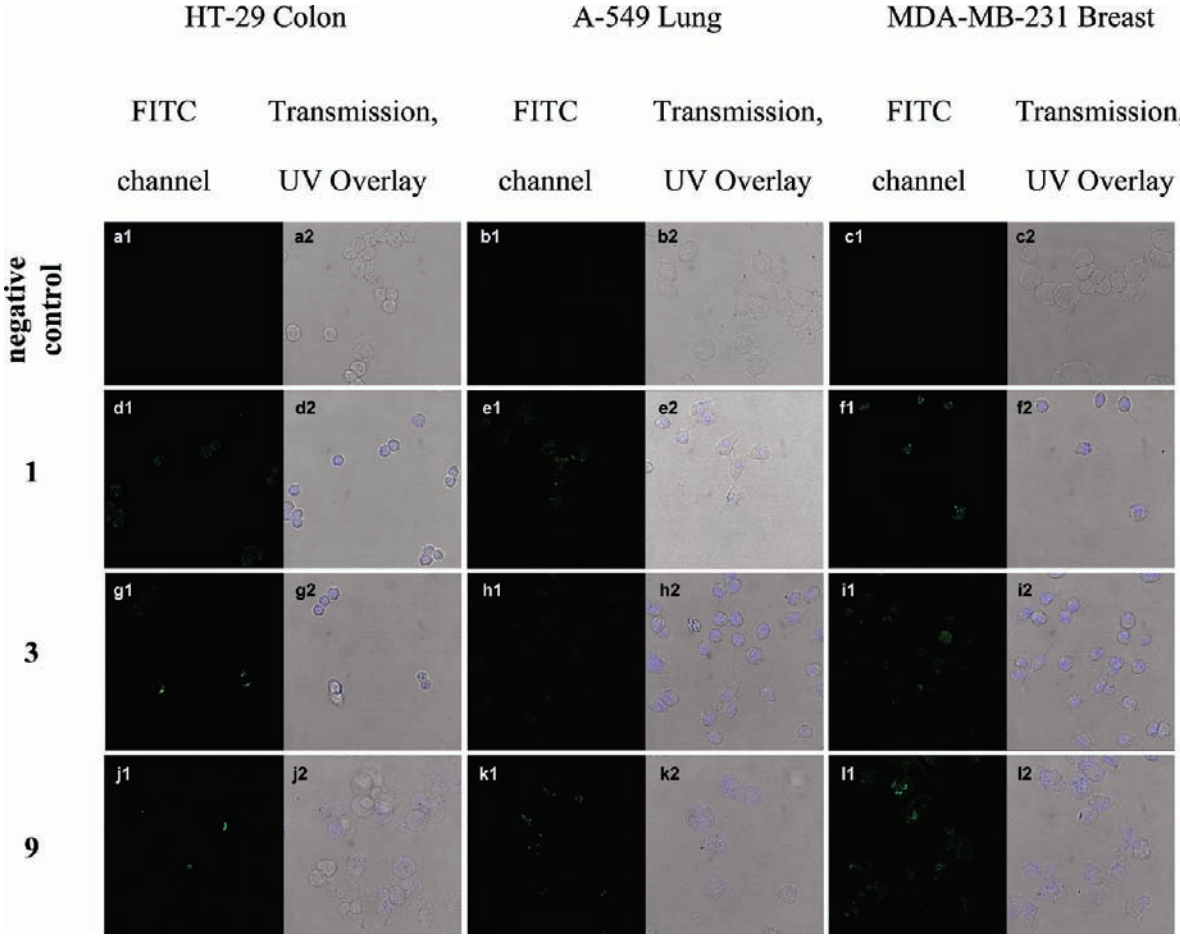

Figure 4. Detection of apoptosis by CaspaTag green fluorescence.

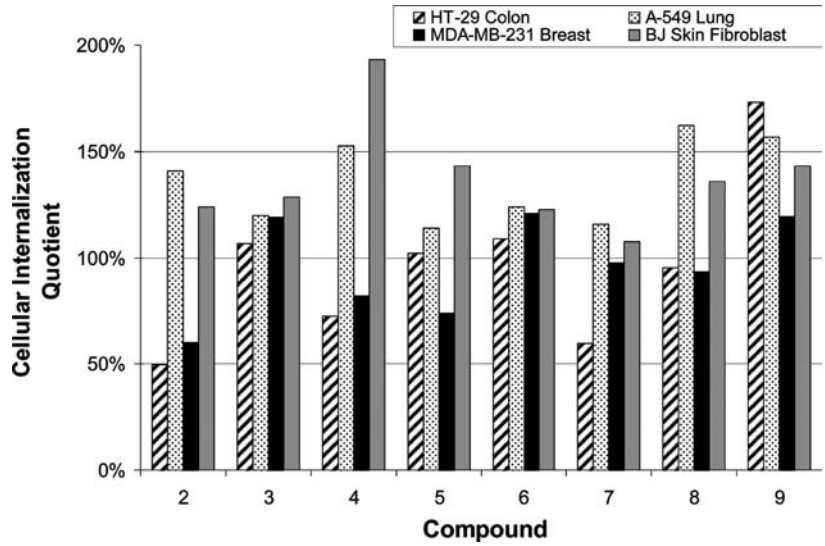
Chart 1. Cellular Internalization Quotient



conjugates **2**, **4**, **5**, **8**, and **9** showed a decrease of 4- to 500-fold in their cytotoxic activity for BJ skin fibroblasts.

The results of initial cellular internalization experiments in HeLa cells at different compound concentrations and exposure times were encouraging for Lam-D and **7** (see Figure SI1 and Figure SI2 in the Supporting Information). Compound **9** was selected as one of the best compounds of the series for colocalization experiments. Cell cultures were incubated with compound **9** for 48 h. WGA-FITC and Mitotracker were then employed for the selective staining of cell membrane-Golgi apparatus (green fluorescence) and mitochondria (red fluorescence), respectively. Likewise, UV fluorescence corresponding to **9** was observed in the cytoplasm;[4] however, no fluorescence was observed in the nuclear region of any of the cells for compound **9** (Figure 2).

[4]The Lam-D UV spectrum presents four characteristic absorption maxima: 237, 267, 356, and 382 nm. Excitation at 267 nm of **1** led to three emission maximum wavelengths: 319, 430, and 490 nm. The authors assumed that any minor deviation in the molar extinction

The internalization of compounds **1**−**9** was measured by FACS flow cytometry (see Table 2). Conjugates **3**, **6**, and **9** underwent the greatest cellular uptake in HT-29 and MDA-MB-231. Furthermore, conjugates **2**−**9** all had higher internalization in A-549 than did Lam-D. Results were normalized in function of Lam-D uptake; thus, the CIQ was calculated relative to 100% internalization for Lam-D (**1**). The comparative study showed that all the PEG conjugation motifs introduced enabled greater internalization in A-549 and BJ cell lines. For compounds **4**, **8**, and **9**, the ratio was greater than 150%. Although compounds **3**, **6**, and **9** exhibited greater internalization than did Lam-D (**1**) in HT-29 and MDA-MB-231, the differences observed for these cell lines were not as dramatic. Likewise, as observed in the results for **3**, monoconjugation enables greater uptake. The introduction of the PEG-NH_2 backbone at phenolic position 3 of Lam-D (compound **3**) led to better GI_{50} cytotoxicity and internalization than at position 4′ (compound **5**).

Effects of 1 on Cell Cycle Progression of HT-29 Cells. Lam-D was tested for effects on cell cycle progression in HT-29 tumor cells (Figure 3). Cells were treated with the product (see Experimental Section) and then analyzed by flow cytometry to determine if the cell cycle had been arrested at a specific phase. A control set of untreated cells was also used.

Compared to the control cells (Figure 3, panels **1a**,**c**), the cells treated with **1** (Figure 3, panels **1b**,**c**) showed an arrest in G2/M progression. Hence, it was concluded that Lam-D inhibits cell cycle progression. Furthermore, conjugates **3** and **9** provoked cell cycle arrest in a greater extent. The results showed one single peak corresponding to the G2/M phase (see Figure SI3 in the Supporting Information).

Induction of Apoptosis by 1, 3, and 9 in HT-29, A-549, and MDA-MB-231 Cell Lines. Many anticancer drugs induce cell cycle arrest and apoptosis. Apoptotic cells undergo characteristic morphological changes. Among these, the cell surface often bends and breaks up into membrane-enclosed fragments called apoptotic bodies. This process depends on a cascade of proteolytic enzymes called caspases (*24*).

To analyze whether Lam-D induces apoptosis, HT-29, A-549, and MDA-MB-231 cell lines were incubated with a single compound and then qualitatively measured for apoptosis (Figure 4, see Experimental Section). The assay consists of detecting active caspases (caspase-3/7) using a commercially available colorimetric test.

All cell lines showed a high level of apoptotic cell death after treatment with compounds **1**, **3**, and **9** (Figure 4d−l). A negative control of the assay was performed by analyzing untreated cells under the same experimental conditions (Figure 4a−c). Altogether, these results indicate that Lam-D and derivatives **3** and **9** induce cell cycle arrest and apoptosis.

DISCUSSION

A procedure for preparing PEGylated Lam-D pro-drugs has been described for the first time. One, two, or three phenol groups were selectively conjugated to the Lam-D in mild reaction conditions employing selective orthogonal protection (benzyloxy and isopropoxy groups).

The feasibility of the selective modification of the phenolic moieties of Lam-D has been demonstrated with readily available and inexpensive PEG-carboxylic acid as starting material. Conjugates functionalized with only a single phenolic residue of **2**−**5** (C-3 or C-4′ OH groups) are much more soluble than Lam-D in various solvents. Notwithstanding, di- and tri-PEG conjugates were also synthesized. Di- and tri-PEG conjugates—which imply greater steric hindrance—were also synthesized, thereby demonstrating the robustness of our method. The pH-labile ester conjugates were prepared in 18% to 57% yields from the corresponding Lam-D phenolic precursors.

Conjugates (**2**−**9**), screened against normal BJ skin fibroblasts and three human cancer cell lines, exhibited better internalization than Lam-D (**1**) did. Conjugation provided cytotoxicity amelioration for the cancerous cell lines. Indeed, the GI_{50} of conjugates **2**−**4**, **6**, **7**, and **9** (bearing mono-, di-, and tri-PEG backbones) in MDA-MB-231 and A549 cancer cell lines were 1 order of magnitude lower than that of Lam-D (**1**). Comparison of cytotoxic activity in BJ skin fibroblast between Lam-D and compounds **2**−**9** shown that bioconjugates are equal or less toxic than Lam-D. Compounds **2**, **4**, and **9** with higher cytotoxycity than Lam-D in A-549 and MDA-MB-231 tumor cell lines displayed less cytotoxyc-activity in the BJ normal cell line. Although these compounds **2**, **4**, and **9** possess better internalization in normal cells. These results indicate that these compounds have better affinity to components of tumor cell lines. Confocal microscopy revealed that Lam-D (**1**) and the conjugates (**2**−**9**) were internalized in the cytoplasmatic region. Furthermore, Lam-D induces cell cycle arrest at the G2 phase. Lam-D, and derivatives **3** and **9**, produce caspase-3,7-dependent apoptosis in all cell lines tested.

ACKNOWLEDGMENT

This study was partially supported by CICYT (Grant BQU 2006-03794), *Generalitat de Catalunya*, and the Barcelona Science Park. We gratefully the Networking Centre on Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN). This study was partially supported by the Industrial Consortium "NanoFarma" from the Spanish grants of CENIT program. We also thank Dr. J. Comas from Flow Cytometry Facility - SCT (UB) and M. Bosch from Confocal Microscopy Unit - SCT (UB) for their valuable discussions regarding this work. We also thank Ramon Eritja for recording Lam-D UV-emission spectra.

Supporting Information Available: Materials and methods, experimental procedures, characterization data of the precursor compounds. This material is available free of charge via the Internet at http://pubs.acs.org.

TABLE OF CONTENTS

SI3	General data.
SI4-SI6	General methods and characterization of precursor compounds.
SI7-SI14	^{1}H, ^{13}C-NMR spectra of final compounds **2-9**.
SI15	Table of solubility for compounds **1**, **3**, **7** and **9**.
SI16-SI17	Initial internalization assays in HeLa Cells.

General Data:

Reagents and solvents were purified according to *Purification of Laboratory Chemicals,* Armarego, W. and Chai C., Elsevier (2003). Melting points (mp) were determined in a Büchi Melting Point B540 in open capillaries and are uncorrected. Automatic flash chromatography was done in an Isco Combiflash medium pressure liquid chromatograph with Redisep silica gel columns (47-60 μm). A Branson ultrasound bath was used to perform sonication. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Varian Mercury 400 MHz spectrometer and a Gemini 200 MHz spectrometer. Multiplicity of the carbons was assigned with DEPT and gHSQC experiments, although the usual abbreviations according to off-resonance decoupling are used: (s) singlet, (d) doublet, (t) triplet, and (q) quartet. The same abbreviations were used for the multiplicity of signals in H-NMR and also: (m) multiplet, (bs) broad singlet, (bd) broad doublet. Spectra were referenced to appropriate residual solvent peaks (d_6-acetone, d_6-DMSO, d_4-MeOH or $CDCl_3$). IR spectra were obtained on a Thermo Nicolet FT-IR spectrometer. HRMS were performed on a Bruker Autoflex high resolution mass spectometer by Unidad de Espectrometría de Masas (Universidad de Santiago de Compostela) and by Servei d'Espectrometria de Masses (Universitat de Barcelona). Microwave-assisted reactions were carried out in a CEM Discover microwave. The automatic syringe pump was used as specified for controlled addition of some reactants. Reversed phase analytical HPLC was performed on a Waters Alliance separation module 2695 using a Waters Xterra MS C_{18} column (150 x 4.6 mm, 5 μm) and a Waters 996 PDA detector at 254 nm.

General Methods and Characterization of Synthesized Precursor Compounds:

2-(4-Benzyloxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (11a)

K_2CO_3 (2.49 g, 18.0 mmol) and BnBr (1.2 mL, 1.43 g/mL, 9.9 mmol) were added to a solution of 2-(4-hydroxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (2.25 g, 9.0 mmol) in dry THF (25 mL) and DMF (0.5 mL). The mixture was stirred at 80 ºC under Ar for 16 h. The mixture was then cooled to r.t. and the solvent was removed *in vacuo*. EtOAc was added and the organic solution was washed with sat. aq. Na_2CO_3, water and brine. The organic layer was dried and concentrated, affording 3.06 g (quantitative yield) of the title compound as a white solid. mp (MeCN) 89-92 ºC. IR (film) ν 2977, 2931, 1598, 1410, 1354, 1138 cm^{-1}. ^1H NMR ($CDCl_3$, 200 MHz) δ 1.33 (s, 12H); 3.92 (s, 3H, OMe); 5.182 (s, 2H); 6.88 (d, J = 8.0 Hz, 1H); 7.27-7.44 (m, 7H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 24.9 (4q); 56.0 (q); 70.6 (t); 83.6 (s); 112.9 (d); 117.1 (d); 127.1 (2d); 127.7 (d); 128.4 (2d); 128.9 (s); 136.9 (s); 148.9 (s); 150.7 (s). MS (ESI) 341 (M+1, 100); 342 (M+2, 10).

General Procedure for Bromination of Polialcoxybenzenes. Solid NBS (1 mmol) was added to a cooled solution (–78 ºC) of the aromatic compound (1 mmol) in THF (5 mL), and the reaction mixture was stirred until complete consumption of starting material. The reaction mixture was allowed to reach r.t., and the solvent was then evaporated under reduced pressure. CH_2Cl_2 was added to the remaining residue, and the resulting solution was filtered through a pad of neutral alumina. After solvent removal, pure products were obtained (99%-quant. yield).

1-Bromo-2,4-dibenzyloxy-5-methoxybenzene

Starting from 1,3-dibenzyloxy-4-methoxybenzene (7.2 g, 22.4 mmol), a white solid (9.0 g, quant. yield) was obtained. mp (MeCN) 105-106 ºC. IR (film) ν 2929, 1505, 1382, 1212, 843 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ 3.84 (s, 3H, OMe); 4.99 (s, 2H); 5.07 (s,

2H); 6.59 (s, 1H); 7.08 (s, 1H); 7.31-7.41 (m, 10H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ 56.7 (q); 71.5 (t); 72.2 (t); 103.1 (s); 104.1 (d); 116.7 (d); 127.2 (4d); 127.8 (d); 127.9 (d); 128.4 (2d); 128.5 (2d); 136.5 (s); 144.9 (s); 147.7 (s); 149.0 (s). MS (ESI) 399 (MBr^{79}+1, 97); 400 (MBr^{79}+2, 23); 401 (MBr^{81}+1, 100); 402 (MBr^{81}+2, 21).

1-Bromo-2-benzyloxy-4-isopropoxy-5-methoxybenzene

Starting from 1-benzyloxy-3-isopropoxy-4-methoxybenzene (11.3 g, 41.5 mmol), a white solid (14.4 g, 99%) was obtained. mp (MeCN) 73-75 ºC. IR (film) ν 2975, 2933, 1504, 1251, 844 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ 1.28 (d, *J* = 6.2 Hz, 6H); 3.80 (s, 3H, OMe); 4.39 (h, *J* = 6.2 Hz, 1H); 5.08 (s, 2H); 6.58 (s, 1H); 7.05 (s, 1H); 7.30-7.49 (m, 5H). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ 22.0 (2q); 56.7 (q); 72.1 (d); 72.3 (t); 103.2 (s); 106.0 (d); 117.0 (d); 127.3 (2d); 127.9 (d); 128.5 (2d); 145.8 (s); 147.0 (s); 149.0 (s). MS (ESI) 351 (MBr^{79}+1, 95); 352 (MBr^{79}+2, 15); 353 (MBr^{81}+1, 100); 354 (MBr^{81}+2, 12).

General Procedure for Pd (0) Catalyzed Borylations 3. A mixture of bromoalcoxybenzene (1 mmol), $Pd(OAc)_2$ (5%), DPEphos (0.1 mmol), and pinacolborane (3.0 mmol) in dry Et_3N-dioxane (83:17, 6 mL/mmol) was heated at 100 °C for 13.5 h. The cooled reaction mixture was quenched with saturated NH_4Cl, and the aq. solution was extracted with Et_2O. The organic solution was dried, filtered and concentrated. The resulting oil was purified by flash chromatography (SiO_2 previously deactivated with 5% Et_3N). Elution with hexane/EtOAc (70:30) afforded the title compounds **3a-3b** (62-88% yield).

2-(2-Benzyloxy-4-isopropoxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (12a)

Starting from 1-bromo-2-benzyloxy-4-isopropoxy-5-methoxybenzene (7.37 g, 21.0 mmol), a white solid (7.31 g, 88%) was obtained. mp (MeCN) 98-99 ºC. IR (film) ν

2979, 2931, 1601, 1409, 1139, 1040 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.33 (d, *J* = 6.0 Hz, 6H); 1.36 (s, 12H); 3.84 (s, 3H, OMe); 4.56 (h, *J* = 6.0 Hz, 1H); 5.07 (s, 2H); 6.59 (s, 1H); 7.28-7.40 (m, 4H); 7.61 (d, *J* = 7.5 Hz, 2H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 21.7 (2q); 24.6 (4q); 56.2 (s); 70.8 (d); 71.7 (t); 82.8 (2s); 103.1 (d); 119.5 (d); 126.7 (2d); 127.0 (d); 127.7 (2d); 137.4 (s); 144.2 (s); 150.4 (s); 158.6 (s). MS (ESI) 399 (M+1, 100); 400 (M+2, 12).

2-(2,4-Dibenzyloxy-5-methoxyphenyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (12b)

Starting from 1-bromo-2,4-dibenzyloxy-5-methoxybenzene (1.00 g, 2.5 mmol), a yellow syrup (694 mg, 62%) was obtained. IR (film) ν 2925, 2853, 1596, 1433, 1272, 1134 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.33 (s, 12H); 1.35 (d, *J* = 6.0 Hz, 6H, 2Me); 3.89 (s, 3H, OMe); 4.95 (s, 2H); 5.15 (s, 2H); 6.54 (s, 1H); 7.22 (s, 1H); 7.30-7.39 (m, 8H); 7.50-7.54 (m, 2H). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 25.0 (4q); 56.7 (q); 70.9 (t); 71.9 (t); 83.3 (s); 102.1 (d); 119.4 (d); 127.0 (2d); 127.2 (2d); 127.3 (d); 127.8 (d); 128.0 (2d); 128.5 (2d); 136.7 (s); 137.6 (s); 151.4 (s); 158.8 (s). MS (ESI) 447 (M+1, 100); 448 (M+2, 18).

Received November 24, 2008; Revised Manuscript Received March 24, 2009

The design and synthesis of Lamellarin D conjugates with a nuclear localization signal peptide and a poly(ethylene glycol)-based dendrimer are described. Conjugates **1**−**4** were obtained in 8−84% overall yields from the corresponding protected Lamellarin D. Conjugates **1** and **4** are 1.4- to 3.3-fold more cytotoxic than the parent compound against three human tumor cell lines (MDA-MB-231 breast, A-549 lung, and HT-29 colon). Besides, conjugates **3** and **4** showed a decrease in activity potency in BJ skin fibroblasts, a normal cell culture. Cellular internalization was analyzed, and a nuclear distribution pattern was observed for **4**, which contains a nuclear localization signaling sequence.

INTRODUCTION

Actively mediated cellular delivery of biomolecules (*1*) has garnered great interest as a strategy for delivering cancer chemotherapeutics (*2*−*5*). Conjugates of a drug and a macromolecular vehicle such as NLS[1] peptidic sequences (*5*−*8*), PEG carriers (*9*), and dendrimers (*10*) may have better cellular internalization than the drug alone and, in some cases, may produce passive accumulation of the drug in tumors by the EPR effect (*11*). In addition, the therapeutic activity of these conjugates is associated with their capacity to release the drug at a specific subcellular target. Thus, the suitability of macromolecules as vehicles also extends to their propensity to deliver the drug to a predetermined intracellular location.

The marine alkaloid Lam-D (*12*−*15*) is a promising drug candidate due to its Topo I inhibition activity. Topoisomerases are nuclear enzymes crucial in cellular replication. They change the topology of DNA before and after the replication and transcription processes. Therefore, they are especially attractive targets for cancer therapy (*16*−*19*). Lam-D is limited by its insolubility in common solvent media, especially in water. Therefore, it has been used to investigate its conjugation to macromolecules. In the previous paper, we have described the first generation of Lam D-bioconjugates based on PEG esters such as **1** (*9*). In this paper, we describe a second generation of Lam-D conjugates (Figure 1) based on esterification with either a poly(ethylene glycol)-based dendrimer (in **2**) or NLS oligopeptide sequences (in **3** and **4**). The peptide NLS H-Pro-Pro-Lys-Lys-Lys-Arg-Lys-Val-OH, which has been demonstrated (*20*) to shuttle compounds to the nucleus, was used in the present work.

The introduction of such oligomeric systems to Lam D demanded an integrated and robust synthetic scheme with a collection of suitable orthogonal protecting groups, in terms of selective removal and compatibility with the presence of other functional groups (*21*).

EXPERIMENTAL PROCEDURES

General Data. Reagents and solvents were purified according to *Purification of Laboratory Chemicals*, Armarego, W. and Chai C., Elsevier (2003). Melting points (m.p.) were determined

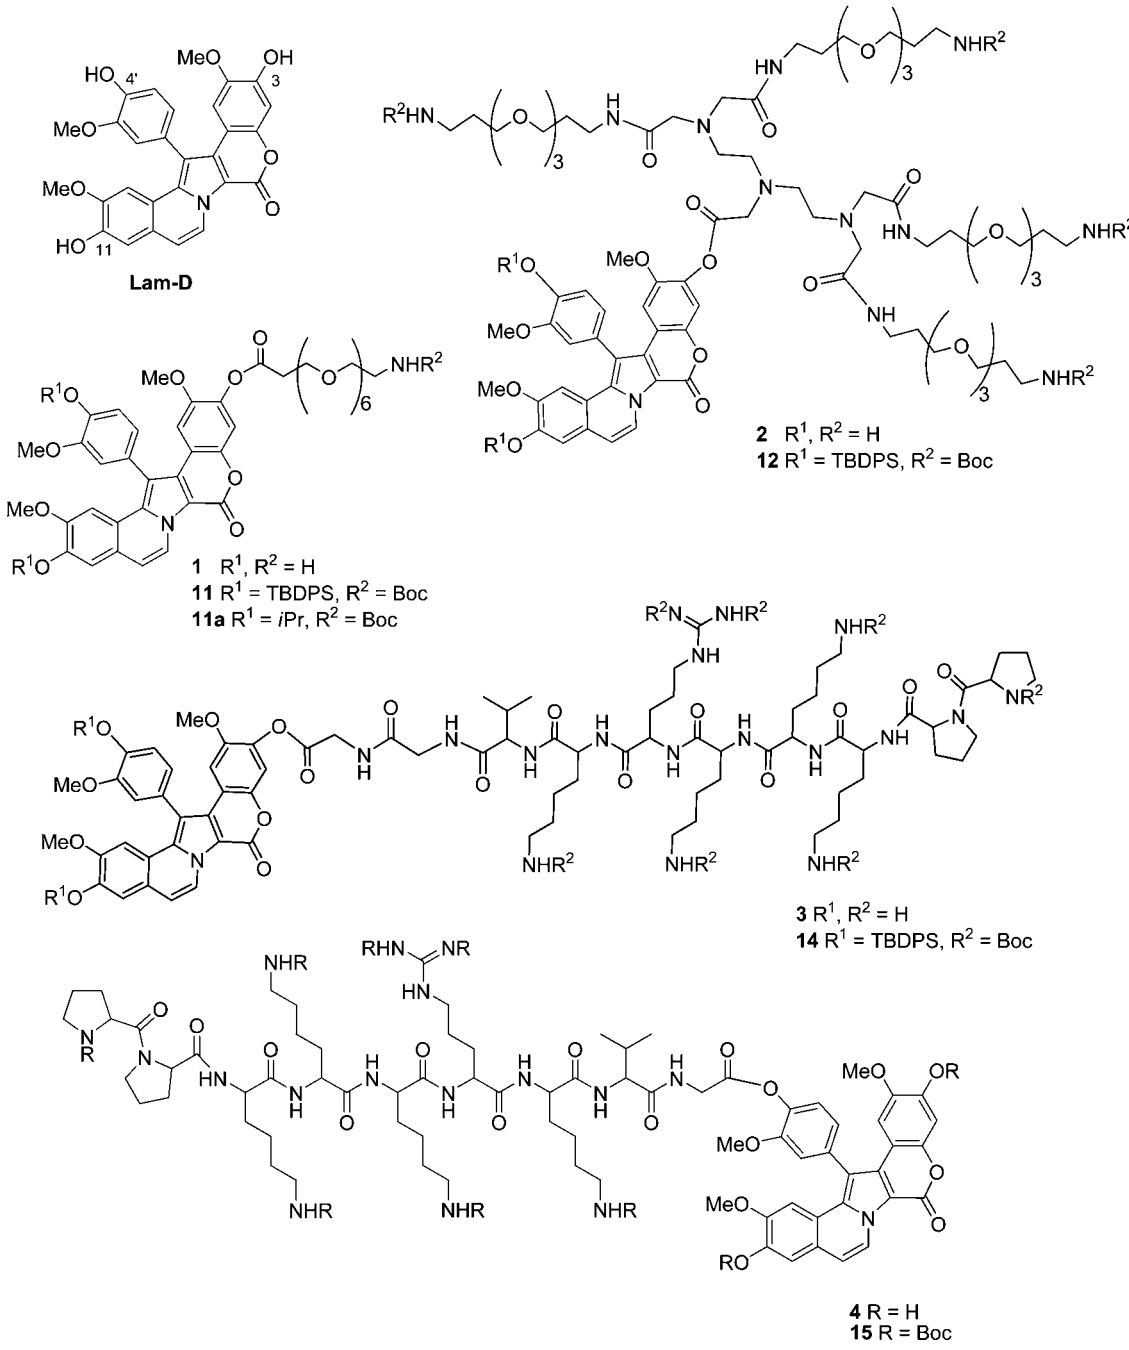

Figure 1. Structures of Lam-D conjugates.

in a Büchi Melting Point B540 in open capillaries and are uncorrected. Automatic flash chromatography was done in an Isco Combiflash medium-pressure liquid chromatograph with Redisep silica gel columns (47−60 μm). Sonication was performed in a Branson ultrasound bath. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Varian Mercury 400 MHz spectrometer and a Gemini 200 MHz spectrometer. Multiplicity of the carbons was assigned with DEPT and gHSQC experiments, using standard abbreviations for off-resonance decoupling: (s) singlet, (d) doublet, (t) triplet, (q) quartet. The same abbreviations were also used for the multiplicity of signals in ^{1}H NMR, plus (m) multiplet, (bs) broad singlet, (bd) broad doublet. Spectra were referenced to appropriate residual solvent peaks (d_6-acetone, d_6-DMSO, d_4-MeOH, or $CDCl_3$). IR spectra were obtained on a Thermo Nicolet FT-IR spectrometer. HRMS were performed on a Bruker Autoflex high-resolution mass spectrometer by *Unidad de Espectrometría de Masas* (Universidad de Santiago de Compostela) and by *Servei d'Espectrometria de Masses* (Universitat de Barcelona). Microwave-assisted reactions were carried out in a CEM Discover microwave. The automatic syringe pump was used as specified for controlled addition of some reactants. Reversed-phase analytical HPLC was performed on a Waters Alliance separation module 2695 using a Waters Xterra MS C_{18} column (150 × 4.6 mm, 5 μm) and a Waters 996 PDA detector at 254 nm.

General Procedures. *A. General Method for Simultaneous Removal of TBDPSO and N-Boc.* HF (5 mL) at −196 °C was poured over solid **11**, **12**, or **14** (0.05−0.08 mmol). The solution was stirred for 1 min, and the solvent was immediately removed under vacuum at low temperature. MeCN was added to the crude, and the deprotected compound was precipitated by addition of MTBE, cooling to 0 °C and centrifugation (10 min, 2000 rpm). The residue was dried in vacuo to give the final Lam-D conjugates **1**−**3**.

B. General Method for MOMO Deprotection. Me_3SiI (142 μL, 3.00 mmol) was added at r.t. to a solution of **10a** or **10b** (1.00 mmol) in CH_2Cl_2 (225 mL), and the resulting orange solution was stirred at r.t. for 20 min. The solvent was removed in vacuo, and the residue was dissolved with EtOAc and then washed three times with sat NH_4Cl and brine. The organic phase was dried over anhydrous $MgSO_4$, and the solvent was removed in vacuo. Purification by column chromatography on silica gel by elution with hexane/EtOAc (80:20 to 60:40) gave the title compounds (84% quant yield).

C. General Method for Esterification. Synthesis of Conjugates. DMAP (0.6 mmol) and **5** (1 mmol) in dry CH_2Cl_2 (45 mL) were added to a solution of NHBocPEG$_6$-OH, or Boc-NLS-Gly-OH (4 mmol), and EDC·HCl (4 mmol) in dry CH_2Cl_2 (5 mL). The resulting solution was stirred at r.t. for 2 h. The reaction mixture was diluted with CH_2Cl_2 and washed with sat $NaHCO_3$ solution and brine. The organic phase was dried over anhydrous $MgSO_4$ and the solvent removed under vacuum, to provide the title compounds **11** and **13** (89% quant yield).

3-[3-(2-(2-(2-(2-(2-(2-Aminoethoxy)ethoxy)ethoxy)ethoxy)-ethoxy)ethoxy)propanoyloxy]Lam-D (*22*) (1). Following the general procedure **A** and starting from **11** (24, 23, and 23 mg, 0.05 mmol), a yellow solid (35 mg, 84%) was obtained. The spectroscopic data are in accordance with previous reports (*9*).

3-[2-(Bis(2-(bis(2-(3-(2-(2-(3-aminopropoxy)ethoxy)ethoxy)propylamino)-2-oxoethyl)amino)ethyl)amino)acetyl]Lam-D (*22*) (2). Following the general procedure **A** and starting from **12** (17 and 15 mg, 0.12 mmol), **2** as a yellow solid (8 mg, 36%) was obtained. ^{1}H NMR (D_2O, 400 MHz) δ 1.54 and 1.67 (2m, J = 6.6 Hz, 8H); 1.76 and 1.83 (2m, J = 6.6 Hz, 8H); 2.93 (2t, J = 7.2 Hz, 4H); 2.97 (2t, J = 7.2 Hz, 4H); 3.02−3.10 (m, 8H); 3.16−3.29 (m, 11H, OMe); 3.33−3.43 (m, 43H, OMe); 3.52−3.56 (m, 18H); 3.70 (br, 3H, OMe); 6.43 (s, 1H); 6.57 (br, 1H); 6.71 (br, 1H); 6.81−6.88 (m, 4H); 6.99 (br, 1H); 8.35 (br, 1H). ^{13}C NMR (D_2O, 100 MHz) δ 26.6 (t); 26.7 (t); 28.5 (t); 28.6 (t); 36.4 (t); 36.5 (t); 37.7 (t); 37.8 (t); 55.2 (q); 55.5 (q); 55.7 (q); 57.6 (t); 57.7 (t); 68.3 (t); 68.4 (t); 68.5 (t); 69.4 (t); 69.5 (t); 69.6 (t); 69.7 (t); 107.7 (d); 111.5 (d); 111.7 (d); 122.2 (d); 122.4 (d); 122.8 (d); 127.6 (d); 145.6 (d); 146.7 (d); 147.4 (s); 149.5 (s); 149.9 (s); 150.3 (s); 151.1 (s); 171.0 (s); 171.1 (s). MS (MALDI-TOF) 1684 (M+1, 100), 1685 (M+2, 93) 1686 (M+3, 49). HRMS *m*/*z* calcd for $C_{82}H_{131}N_{12}O_{25}$ 1683.9342, found 1683.9346. HPLC analysis: 6.9 min retention time (94% purity), with a gradient of 0% to 100% of eluent **B** over 15 min using the solvent system: H_2O/0.045% TFA (**A**) and MeCN/0.036% TFA (**B**).

3-[Gly-Gly-NLS]Lam-D (*22*) (3). Following the general procedure **A** and starting from **14** (28 and 17 mg, 0.16 mmol), **3** as a white solid (10 mg, 38%) was obtained. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 0.83−0.88 (m, 6H, 2CH$_3$); 1.22−1.36 (m, 10H, 5CH$_2$); 1.42−1.54 (m, 8H, 4CH$_2$); 1.56−1.62 (m, 8H, 4CH$_2$); 1.88−1.93 (m, 4H, 2CH$_2$); 2.05 (br, 2H, CH$_2$); 2.07 (br, 2H, CH$_2$); 2.33 (t, J = 1.8 Hz, 2H, CH$_2$); 2.55 (br, 1H, CH); 2.67 (t, J = 1.8 Hz, 2H, CH$_2$); 2.69−2.75 (m, 16H, 3CH$_2$); 3.36 (2s, 6H, 2OMe); 3.75 (s, 3H, OMe); 3.99−4.05 (m, 3H, CH); 4.14−4.25 (m, 7H, 3CH, 2CH$_2$); 4.58 (br, 1H, CH); 5.93 (br, 1H); 5.76 (br, 1H); 5.47 (br, 1H); 6.70 (s, 1H); 6.87 (s, 1H); 7.01 (dd, J = 8.0, 1.7 Hz, 1H); 7.10 (d, J = 8.0 Hz, 1H); 7.12−7.13 (m, 2H); 7.19 (s, 1H); 7.21 (br, 1H); 9.00 (d, J = 7.4 Hz, 1H, H8). MS (MALDI-TOF) 1575 (M+1, 100), 1576 (M+2, 92). HRMS *m*/*z* calcd. for $C_{77}H_{111}N_{18}O_{18}$ 1575.8324, found 1575.8319. HPLC analysis: 1.8 min retention time (96.7% purity), with 15 min isocratic MeCN/0.036% TFA.

4′-[Gly-NLS]Lam-D (*22*) (4). Peptide **8** (392 mg, 0.23 mmol) was preactivated for 15 min at r.t. with TCFH (63 mg, 23 mmol) and NEt_3 (32 μL, 23 mmol) in dry CH_2Cl_2 (15 mL). Compound **6** (53 mg, 0.08 mmol) and DMAP (9 mg, 0.08 mmol) in dry CH_2Cl_2 (5 mL) were then added. The resulting solution was stirred at r.t. for 120 h. The reaction mixture was diluted with CH_2Cl_2 and washed with sat $NaHCO_3$ solution and brine. The organic phase was dried over anhydrous $MgSO_4$, and the solvent was removed under vacuum. The residue was purified by flash chromatography: elution with CH_2Cl_2/MeOH (99:1 to 95:5) gave **15** (45% yield based on 40% transformation of **6**). The Boc protected compound **15** was then treated with 40% TFA in CH_2Cl_2 (10 mL) at r.t. for 1 h. The solvent was removed under reduced pressure, and the residue was purified by reverse-phase chromatography. Elution with H_2O/MeCN (60:40 to 40:60) gave **4** as a yellow solid (3 mg, 17%). ^{1}H NMR (D_2O, 500 MHz) δ 1.04 (d, J = 6.5 Hz, 3H, CH$_3$); 1.16 (d, J = 6.5 Hz, 3H, CH$_3$); 1.39−1.56 (m, 8H, 4CH$_2$); 1.66−1.77 (m, 10H, 5CH$_2$); 1.78−1.88 (m, 8H, 4CH$_2$); 2.00−2.12 (m, 4H, 2CH$_2$); 2.17 and 2.36 (2br, 2H, CH$_2$); 2.44 and 2.58 (2br, 2H, CH$_2$); 2.84 (br, 1H, CH); 2.96−3.05 (m, 10H, 5CH$_2$); 3.40 (br, 3H, OMe); 3.44 (s, 3H, OMe); 3.45 (s, 3H, OMe); 3.22 (t, J = 7.5 Hz, 1H, CH$_2$); 3.59 (t, J = 7.0 Hz, 1H, CH$_2$); 3.81 (br, 2H, CH$_2$); 4.23−4.42 (m, 5H, 5CH); 4.51 (t, J = 8.3 Hz, 1H, CH); 4.65 (dd, J = 9.0, 8.4 Hz, 1H, CH); 6.38 (s, 1H); 6.64−6.87 (m, 4H); 6.99 (br, 1H); 7.01 (br, 1H); 7.32 (br, 1H); 8.54 (br, 1H). MS (MALDI-TOF) 1518 (M+1, 100), 1519 (M+2, 82). HRMS *m*/*z* calcd. for $C_{75}H_{108}N_{17}O_{17}$ 1518.8109, found 1518.8114. HPLC analysis: 6.9 min retention time (95% purity), with a gradient of 50% to 100% of eluent **B** over 15 min using the solvent system: H_2O/0.045% TFA (**A**) and MeCN/0.036% TFA (**B**).

4′,11-Bis(*tert*-butyldiphenylsilyl)Lam-D (*22*) (5). Following the general procedure **B** and starting from **10b** (1.06 g, 1.04 mmol), **5** as a yellow solid (856 mg, 84%) was obtained. mp (MeCN) 278−280 °C. IR (film) ν 1704, 1487, 1428, 1284, 1111 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.15 (s, 9H); 1.17 (s, 9H); 3.18 (s, 3H, OMe); 3.47 (s, 3H, OMe); 3.64 (s, 3H, OMe); 5.89 (s, 1H); 6.68 (d, J = 7.4 Hz, 1H, H9); 6.69 (s, 1H); 6.91−6.93 (m, 3H); 6.95 (s, 1H); 7.05 (br, 1H); 7.06 (br, 1H); 7.37−7.48 (m, 10H); 7.71−7.79 (m, 10H); 9.04 (d, J = 7.4 Hz, 1H, H8). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 19.9 (s); 26.6 (q); 26.7 (q); 54.5 (q); 55.5 (q); 55.7 (q); 103.4 (d); 104.7 (d); 105.9 (d); 107.6 (s); 109.8 (s); 111.0 (s); 112.1 (d); 115.4 (d); 116.5 (d); 119.7 (s); 120.3 (d); 122.7 (d); 123.7 (d); 124.4 (s); 127.5 (d); 127.6 (d); 128.5 (s); 129.1 (s); 129.7 (d); 129.9 (d); 132.9 (s); 133.0 (s); 133.4 (s); 134.1 (s); 135.0 (d); 135.1 (d); 143.1 (s); 144.9 (s); 146.1 (s); 146.8 (s); 150.7 (s); 151.1 (s); 155.3 (s). MS (MALDI-TOF) 976 (M+1, 100), 977 (M+1, 57), 978 (M+2, 38).

3,11-Di-*tert*-butoxycarbonyl-Lam-D (*22*) (6). A solution of TBAF in THF (1 M, 1.64 mmol) was added to a −78 °C solution of **10d** (771 mg, 0.82 mmol), in MeOH-THF (100 mL, 80:20). The mixture was stirred at −78 °C for 15 min. Solvents were removed under vacuum, and the residue was dissolved in CH_2Cl_2. The organic solution was washed with water and brine. The organic phase was dried over anhydrous $MgSO_4$ and the solvent removed under vacuum. The residue was purified by flash chromatography: elution with hexane/EtOAc (60:40 to 40:60) gave **6** as a white solid (491 mg, 85%). mp (MeCN) 149−150 °C. IR (film) ν 1760, 1709, 1275, 1255 cm^{-1}. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.54 (s, 9H); 1.55 (s, 9H); 3.455 (s, 3H, OMe); 3.463 (s, 3H, OMe); 3.91 (s, 3H, OMe); 5.93 (br, 1H, OH); 6.83 (s, 1H); 6.97 (d, J = 7.4 Hz, 1H, H9); 7.11 (br, 1H); 7.15 (dd, J = 8.0, 1.8 Hz, 1H); 7.18 (br, 1H); 7.24−7.26 (m, 2H); 7.44 (br, 1H); 9.14 (d, J = 7.4 Hz, 1H, H8). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 27.5 (q); 55.3 (q); 55.6 (q); 56.3 (q); 83.89 (s); 83.95 (s); 106.4 (d); 106.6 (d); 108.8 (s); 111.8 (d); 112.6 (d); 113.0 (s); 113.5 (d); 115.4 (d); 115.7 (s); 120.3 (d); 123.0 (d); 123.6 (s); 123.8 (s); 124.0 (s); 124.4 (d); 128.1 (s); 128.3 (s); 133.6 (s); 140.0 (s); 141.0 (s); 145.4 (s); 145.9 (s); 147.7

(s); 147.9 (s); 150.9 (s); 151.0 (s); 151.1 (s); 155.0 (s). MS (MALDI-TOF) 699 (M, 56), 700 (M+1, 100).

Boc-Pro-Pro-Lys(Boc)-Lys(Boc)-Lys(Boc)-Arg(Boc$_2$)-Lys-(Boc)-Val-Gly-OH (8). The Boc protected peptide was synthesized manually on solid phase in a polypropylene syringe fitted with a porous polyethylene disk. Solvents and soluble reagents were removed by suction. Washings between deprotection, coupling, and subsequent deprotection steps were carried out with DMF (5 × 1 min) and CH_2Cl_2 (5 × 1 min) using 10 mL solvent/g resin each time. Standard Fmoc/*t*Bu chemistry and chlorotrityl resin (0.5 g, 1.5 mmol/g) were used. The resin was preswollen in anhydrous CH_2Cl_2 and then in DMF. The first Fmoc-protected amino acid (Fmoc-L-Gly-OH) (155 mg, 0.7 equiv) was introduced in the presence of DIEA (635 μL, 5 equiv) in DMF. After 1 h, MeOH (0.5 mL) was added and the mixture was stirred for 30 min. The resin was then washed with DMF and CH_2Cl_2, and the synthesis continued as described below. The peptide was elongated through successive iterations of Fmoc removal and amino acid coupling. The Fmoc protecting group was removed with several treatments of 20% piperidine in DMF (1 × 1 min + 2 × 15 min). The resin was then washed with DMF and CH_2Cl_2. The corresponding Fmoc-protected amino acid (5 equiv) was introduced using DIPCDI (310 μL, 5 equiv) and HOBt (305 mg, 5 equiv) as coupling agents. After 2 h, the resin was washed with DMF and CH_2Cl_2, and the coupling was monitored using the Kaiser test. Recouplings were done when needed. Boc-L-Pro-OH (430 mg, 5 equiv) was used as a last amino acid. The peptide was finally cleaved from the resin using 3% TFA in CH_2Cl_2, (5 × 1 min). Washes were collected in a flask containing 50 mL of water. The CH_2Cl_2 was then evaporated under reduced pressure, MeCN (30 mL) was added to the aqueous solution, and the resulting mixture was then lyophilized. Peptide **8** (590 mg, 94%) was obtained as a white solid. HPLC analysis: 6.2 min retention time (92% purity), with a gradient of 50% to 100% of eluent **B** in 7 min using the solvent system: H_2O/0.045% TFA (**A**) and MeCN/0.036% TFA (**B**). HPLC ESI-MS calcd. for $C_{82}H_{144}N_{16}O_{24}$ $[M+H]^+$ 1738, found: $[M+2]^{2+}/2$, 870.

11-Benzyl-4′-*tert*-butyldiphenylsilyl-3-methoxymethyl-Lam-D (*22*) (10). A mixture of **9** (*27*) (1.54 g, 1.76 mmol) and DDQ (400 mg, 1.76 mmol) in dry $CHCl_3$ (25 mL) was purged with Ar in a sealed vessel and microwaved at 120 °C for 10 min. The organic solution was washed with water, and brine, dried over $MgSO_4$, filtered, and then concentrated in vacuo. Purification by column chromatography on silica gel by elution with hexane/EtOAc (80:20 to 60:40) gave **10** as a white solid (2.27 g, 81%). mp (MeCN) 144−145 °C. IR (film) ν 1705, 1429, 1267, 1223 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 1.17 (s, 9H); 3.43 (s, 3H, OMe); 3.46 (s, 3H, OMe); 3.50 (s, 3H, OMe); 3.65 (s, 3H, OMe); 5.23 (s, 2H); 5.24 (s, 2H); 6.77 (s, 1H); 6.92−6.96 (m, 3H); 7.06−7.08 (m, 2H); 7.19 (s, 1H); 7.25 (d, J = 5.4 Hz, 1H); 7.32−7.47 (m, 11H); 7.75−7.79 (m, 4H); 9.16 (d, J = 7.2 Hz, 1H, H8). ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ 19.9 (s); 26.7 (q); 55.2 (q); 55.5 (q); 55.7 (q); 56.3 (q); 70.7 (t); 95.4 (t); 105.1 (d); 105.5 (d); 105.6 (d); 109.4 (d); 111.3 (s); 111.4 (s); 112.3 (d); 115.4 (d); 119.3 (s); 120.3 (d); 123.1 (d); 123.7 (d); 124.5 (s); 127.2 (d); 127.7 (d); 128.0 (d); 128.4 (s); 128.5 (s); 128.6 (d); 128.9 (s); 129.9 (d); 133.3 (s); 134.1 (s); 135.1 (d); 136.2 (s); 145.0 (s); 146.0 (s); 146.2 (s); 146.6 (s); 149.0 (s); 149.5 (s); 151.2 (s); 155.3 (s). 4′,11-Bis(*tert*-butyldiphenylsilyl)-3-[Gly-Gly-Boc-NLS]-Lam-D (*22*) (14). Lamellarin **13** (32 mg, 29 mmol) was treated with 40% TFA in CH_2Cl_2 (10 mL) at 0 °C for 10 min. The solvent was removed under reduced pressure, and the crude was used without further purification. A solution of this residue and DIPEA (4.9 μL, 29 mmol) in dry CH_2Cl_2 (3 mL) was added to a solution of **8** (50 mg, 29 mmol), HOBt (5 mg, 34 mmol), DIPEA (4.9 μL, 29 mmol), and EDC·HCl (7 mg, 34 mmol) in dry CH_2Cl_2 (2 mL). The resulting solution was stirred at r.t. for 4 h. The reaction mixture was diluted with CH_2Cl_2 and washed with sat $NaHCO_3$ solution and brine. The organic phase was dried over anhydrous $MgSO_4$, and the solvent was removed under vacuum. The residue was purified by flash chromatography with neutral alumina: elution with CH_2Cl_2/MeOH (98:2 to 95:5) gave **14** as a yellow oil (46 mg, 58%). IR (film) 3328, 1650, 1534, 1429, 1365, 1281, 1166 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.92−1.00 (m, 6H, $2CH_3$); 1.11 (s, 3H, CH_3); 1.13 (s, 3H, CH_3); 1.23−1.33 (m, 8H, $4CH_2$); 1.36−1.37 (m, 4H, $2CH_2$); 1.39 (s, 3H, CH_3); 1.41 (s, 18H, $6CH_3$); 1.44−1.50 (m, 4H, $2CH_2$); 1.46−1.50 (m, 8H, $4CH_2$); 1.84 (br, 4H, $2CH_2$); 2.07 (br, 4H, $2CH_2$); 2.43 (br, 4H, $2CH_2$); 2.71 (h, J = 6.8 Hz, 1H); 3.00 and 3.07 (2br, 8H, $4CH_2$); 3.14 (s, 3H, OMe); 3.34−3.41 (m, 2H, CH_2); 3.44 (s, 3H, OMe); 3.59 (s, 3H, OMe); 3.62−3.74 (m, 2H, CH_2); 3.92−4.23 (m, 5H, 5CH); 4.28 (br, 2H, CH_2); 4.47−4.53 (m, 2H, CH_2); 4.67−4.71 (m, 3H, 3CH); 4.77 (br, 1H); 4.86 (br, 1H); 6.67 (s, 1H); 6.71 (d, J = 7.4 Hz, 1H, H9); 6.80−6.89 (m, 2H); 6.91 (d, J = 1.8 Hz, 1H); 6.95−6.99 (m, 2H); 7.02 (d, J = 8.2 Hz, 1H); 7.32−7.47 (m, 10H); 7.56−7.75 (m, 10H); 8.2 (br, 1H); 8.3 (br, 1H); 8.4 (br, 1H); 8.5 (br, 1H); 9.07 (d, J = 7.4 Hz, 1H, H8). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 19.8 (s); 23.6 (t); 23.7 (t); 24.6 (t); 26.2 (t); 26.6 (q); 26.7 (q); 28.0 (q); 28.3 (q); 28.4 (q); 29.5 (t); 29.7 (t); 30.2 (t); 40.4 (t); 47.1 (t); 54.4 (q); 55.48 (q); 55.53 (t); 55.6 (q); 56.4 (d); 56.5 (d); 56.6 (d); 56.7 (t); 63.1 (d); 63.6 (d); 83.2 (s); 103.5 (d); 104.8 (d); 105.9 (d); 109.8 (s); 111.1 (s); 112.2 (d); 115.4 (d); 116.6 (d); 119.7 (s); 120.3 (d); 122.7 (s); 123.7 (d); 124.4 (s); 127.5 (d); 127.6 (d); 127.7 (s); 128.6 (s); 129.2 (s); 129.8 (d); 129.9 (d); 130.0 (s); 132.9 (s); 133.0 (s); 133.4 (s); 135.0 (d); 135.2 (d); 143.3 (s); 145.0 (s); 146.2 (s); 146.3 (s); 146.9 (s); 150.8 (s); 151.2 (s); 153.4 (s); 155.2 (s); 155.9 (s); 156.0 (s); 156.1 (s); 157.4 (s); 170.4 (s); 171.9 (s); 173.1 (s); 174.7 (s); 175.3 (s). MS (ESI) 884 ([M-Boc+3]/3, 24), 1326 ([M-Boc+2]/2, 77).

Cell Lines and Culture. Human-derived established cell lines used in this study were purchased from ATCC (American type Culture Collection): A-549, human lung carcinoma (ATCC no. CCL-185); BJ, skin fibroblast (ATCC no. CRL-2522); HT-29, human colorectal adenocarcinoma (ATCC no. HTB-38); and MDA-MB 231, human breast adenocarcinoma (ATCC no. HTB-26). All cell lines were maintained in DMEM supplemented

with 10% FBS and 100 units/mL penicillin and streptomycin at 37 °C and 5% CO_2.

GI_{50} Analysis. Triplicate cultures were incubated for 72 h in the presence or absence of test compounds Lam-D, **1**, **2**, **4**, and **15** (at ten concentrations, typically ranging from 0.0026 to 10 μg/mL).

A colorimetric assay using SRB was adapted for quantitative measurement of cell growth and viability, following a previously described method (*23*). Cells were plated in 96-well microtiter plates at a density of 5×10^3/well and incubated for 24 h. One plate from each different cell line was fixed, stained, and used for Tz reference (see next paragraph). The cells were then treated with vehicle alone (control) or compounds at the concentrations indicated. Treated cells were incubated for an additional 72 h, and then evaluated for cytotoxicity via colorimetric analysis. The cells were washed twice with PBS, fixed for 15 min in 1% glutaraldehyde solution, rinsed twice in PBS, and stained in 0.4% SRB solution for 30 min at room temperature. The cells were then rinsed several times in 1% acetic acid solution and air-dried. SRB was then extracted in 10 mM trizma base solution and the absorbance measured at 490 nm. Cell survival is expressed as a percentage of control cell growth.

Dose−response curves were obtained by using the NCI algorithm (*24*): Tz = number of control cells at time t_0; C = number of control cells at time t; and T = number of treated cells at time t.

If $Tz < T < C$ (growth inhibition), then the result is $100 \times ([T - Tz]/[C - Tz])$.

If $T < Tz$ (net cell death), then the result is $100 \times ([T - Tz]/Tz)$.

After dose−curve generation, the results were expressed as GI_{50} (the concentration that causes 50% cell growth inhibition, compared to control cultures).

General Treatments for Imaging. A-549, MDA-MB-231, and HT-29 cells were seeded onto MatTek (Ashland, USA) glass-bottomed microwell dishes at 30×10^3 cells/cm^2. After 24 h, the culture medium was discarded and replaced by fresh DMEM medium containing Lam-D, **1**, or **4** at 1 μM. Absence of compound was used as a negative control. Cells were then incubated for 12 h at 37 °C.

Topo I-GFP Visualization. Procedure for a single microwell dish transfection: A-549, MDA-MB-231, and HT-29 cells were seeded onto a MatTek (Ashland, USA) glass-bottomed microwell dish at 30×10^3 cells/cm^2. Culture medium was discarded after 24 h, cells were washed 3 × PBS, and 1400 μL of reduced serum media Opti-MEM I (Invitrogen, USA) were added. The preparation of DNA for transfection required previous dilution of 3 μL FuGENE (Roche Molecular Biochemicals, Indianapolis, IN) in 100 μL of reduced serum media Opti-MEM I (Invitrogen, USA), and further addition of 6.7 μL of the plasmid solution encoding green fluorescent protein GFP with full-length Topo I (*25*). The mixture was mixed thoroughly and incubated for 30 min at r.t., before addition to the dish. Samples were incubated at 37 °C and 5% CO_2 for 10 h. Afterward, medium was discarded, cells were washed three times with PBS, and new DMEM solution containing 1 μM Lam-D, **1**, or **4** was added. Absence of compound was used as a negative control. The cells were incubated for an additional 12 h at 37 °C and then analyzed by confocal microscopy.

Confocal Laser Scanning Microscopy. Confocal laser scanning microscopy was performed with a Leica TCS SPII microscope (Leica Microsystems Heidelberg GmbH, Mannheim, Germany), using a 63× objective. GFP fluorescence was excited with an Ar laser excitation at 488 nm. Lam-D and its derivatives were excited at 351 nm. The same microscope settings were used for each conjugate and concentration. To avoid crosstalk, the two-fluorescence scanning was performed in a sequential mode.

Uptake Measurements by Fluorescence-Activated Cell Sorting Flow Cytometry. 1×10^6 A-549, BJ, MDA-MB-231, and HT-29 cells were seeded onto 25 cm^2 cell culture flasks (Nalgene Nunc International, Naperville, USA) with 10 mL of DMEM. After 12 h, the culture medium was discarded and replaced by fresh DMEM medium containing compounds 1 μM Lam-D, **1**, **2**, or **4**. Absence of compound was used as a negative control. The cells were then incubated for 12 h at 37 °C. After incubation, the cells were washed three times with PBS, detached with trypsin−EDTA 0.25%, and centrifuged at 1000× rpm. Finally, the medium was decanted, and the cellular pellet was resuspended in PBS and kept at 0 °C until measurements were performed. Fluorescence analysis was performed with a MoFlo cytometer (DakoCytomation, Colorado, USA), using the 351 nm excitation line of an Ar laser (25 mW) and emission detection at 450 nm (tolerance range ±65 nm). CIQ is expressed as a percentage value in reference to Lam-D. It was calculated by dividing the fluorescence value of the test compound by the fluorescence value obtained with the Lam-D control under the same experimental conditions.

RESULTS

Orthogonal protecting groups had to be used for the three phenol groups of Lam-D and for the functional groups presented into the conjugation building blocks. *N*-Boc was used to protect the amino and guanidino groups of the oligomeric building blocks **7** and **8**. Synthesis of compounds **2**−**4** required the preparation of different building blocks: the protected Lam-D derivatives **5** and **6**, the DTPA-PEG dendrimer **7**, and the peptide **8** (Figure 2). Compounds **5** and **6** are the precursors for the conjugates at positions 3 and 4′, respectively, and contain two phenolic groups protected as either TBDPS ethers or Boc esters, respectively. In the protected peptide **8**, a glycine was introduced as spacer at the C-terminal position to avoid the steric hindrance caused by the C-terminal Val residue during coupling.

Synthesis of Protected Lamellarins 5 and 6. The protecting groups *Oi*Pr/*O*Bn used in earlier strategies (*9*) required harsh deprotection conditions incompatible with the synthesis of more complex Lam-D conjugates such as **4**.[2] The previously described lamellarin **9** (*26*, *27*), for which three different and orthogonal protecting groups were employed (MOM, Bn, and TBDPS), was used as the precursor to Lam derivatives **5** and **6** (Scheme 1).[3] Lam **9** was prepared following Banwell's strategy for the total synthesis of Lam-K (*28*). Oxidation of **9** under MW irradiation using DDQ in $CHCl_3$ gave **10** with good yield. Compound **10** was subjected to changes of protecting groups (see Scheme 1). Catalytic hydrogenation of **10** over Pd−C in methanolic EtOAc gave **10a**, which was successfully converted into **10b** by TBDPS protection of the phenol. Removal of the MOM protecting group at position 3 of **10b** with trimethylsilyl iodide in $CHCl_2$ gave **5** in excellent yield. Moreover, compound **10a** was subjected to the latter conditions, which afforded the 4′-*O*TBDPS mono-protected Lam-D **10c** in quantitative yield. The free phenol groups of **10c** were protected as *tert*-butyl carbonates using Boc_2O, DMAP, and CH_2Cl_2 to give **10d** in quantitative yield. Finally, *O*TBDPS deprotection of **10d** with TBAF in MeOH gave the 4′-OH Lam-D intermediate **6** (85%).

As a side note, compounds **10a** and **10c** are privileged synthetic intermediates for the construction of additional mono-

[2]Conjugate **4** protected with *Oi*Pr on positions 3 and 11, and Boc-Lys, Boc-Pro and Pbf-Arg gave only mixtures on deprotection assays.

[3]The ester bonds of the protected Lam-D conjugates were labile; hence, to avoid problems with hydrolysis, we minimized the deprotection steps after condensation.

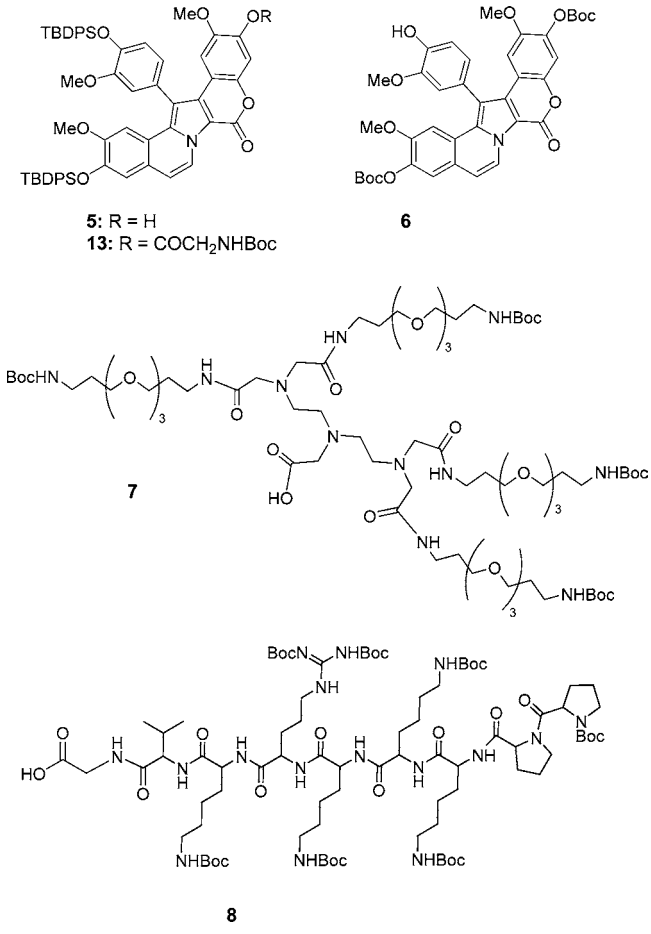

Figure 2. Building blocks for the synthesis. The UV emissions corresponding to Lam-D, **1**, and **4** are arbitrarily represented in red tones. The test compounds were seeded at a concentration of 1 μM and then incubated for 12 h.

and diconjugates at positions 11-OH and 3,11-OHs of Lam-D, respectively.

Synthesis of Poly(ethylene glycol)-Based Dendrimer 7. PEG-based dendrimer **7** was synthesized by coupling 1-(*tert*-butyloxycarbonylamino)-4,7,10-trioxa-13-tridecanamine to monobenzyl-protected diethylenetriamine pentaacetic acid with PyBOP and DIPEA. The tetracarboxylic moiety derivative was prepared from an orthogonally protected DTPA derivative (one benzyl and four *tert*-butyl protecting groups). The *t*Bu groups were eliminated using 4.0 M HCl in dioxane, and then, the benzyl group was eliminated by hydrogenolysis with Pd/C to render dendrimer **7** (*29*).

Synthesis of the Peptide NLS 8. The protected peptide **8** was synthesized on chlorotrityl resin following standard Fmoc/*t*Bu solid-phase chemistry, with 20% piperidine-DMF for the deprotection steps, and DIPCDI and HOBt as coupling reagents.

N-α-Fmoc-*N*-ω,*N*-ω′-bis-*tert*-butoxycarbonyl-L-arginine was used for the synthesis of the NLS peptide sequence. Attempts to use Fmoc-*N*-ω-Pbf-L-arginine resulted in harsher deprotection conditions and complex reaction crudes. The last amino acid used was Boc-L-Pro-OH (as the desired building block had to be completely protected). The peptide was cleaved from the resin using 3% TFA in CH_2Cl_2, and after solvent evaporation, it was lyophilized.

Esterification and Synthesis of Conjugates 1−4. To test the efficacy of the protecting scheme, the synthesis of bioconjugate **1** was repeated using the following strategy (*21*). An ester bond between **5** and BocNH-$CH_2(CH_2OCH_2)_6CH_2$COOH was formed using EDC·HCl with a catalytic amount of DMAP to afford compound **11** (Figure 1) in quantitative yield. Compound **11** was considered a good model for the deprotection assays, because it contains the critical protecting groups and the ester functional group. Hence, it was used for the optimization of procedures and to test the success of the deprotection steps. Initial assays of sequential TBAF-TFA, two-step deprotection led to complex crude products. Furthermore, purification on SiO_2 gave low yields of **1**. The best results were obtained via simultaneous deprotection of both groups, using liquid HF at low temperature. Highly pure final product was obtained from the reaction crude by precipitation with MTBE. Notwithstanding, the scope of the reaction was limited to small amounts of starting material.[4] Compound **1** was synthesized in 84% overall yield from its precursor **5**. This is a major improvement over previous *Oi*Pr/*O*Bn strategies (45% yield, from 4′,11-diisopropyl-Lam-D) (*9*).

Formation of an ester bond between **5** and **7** (*29*) afforded compound **12** (Figure 1) in 26% yield, using EDC·HCl with a catalytic amount of PS solid supported DMAP in CH_2Cl_2. Deprotection of compound **12** using HF provided **2** in 36% yield.

Ester bond formation between **8** and protected lamellarin **5** or **6** using EDC·HCl was unsuccessful. The inaccessibility of the carboxylic acid in the *N*-Boc protected oligopeptide sequence **8** or steric hindrance of the free phenolic group in Lam-D building blocks **5** and **6** may have been decisive to the lack of reaction. Various attempts at ester bond formation between **8** and the scaffold **5** were also unsuccessful.[5] Therefore, taking advantage of the relatively easy amide bond formation (i.e., compared to ester bonds), an *N*-Boc-Gly-OH spacer was introduced at position 3 of **5** (affording **13** in 89% yield, Figure 2) for subsequent amide bond formation with **8**. *N*-Boc deprotection of **13** with 40% TFA followed by reaction with **8** in EDC·HCl, HOBt, and DIPEA as base gave **14** (Figure 1, 58% yield). Deprotection of **14** with HF under standard conditions afforded the NLS peptidic conjugate **3** in 38% yield.

The NLS conjugate at position 4′ of Lam-D could not be formed using the same conditions employed for ester bond formation between **6** and **8**.[6,7] Instead, preactivation of **8** with TCFH (*30*) and NEt_3 followed by the addition of a solution of **6** and DMAP were required, affording **15** (Figure 1) in 45% yield (relative to 40% transformation of **6**). Elimination of the nine Boc protecting groups with 40% TFA in CH_2Cl_2 gave compound **4** in 17% yield.

The ester bond of compound **3**, which has a double Gly spacer, is more susceptible to nucleophilic attack by nucleophiles from the medium than that of compound **4**, which has a single Gly spacer. Thus, the final conjugate **3** (derived from **14**) was water-labile. The rapid degradation of **3** made biological tests with this compound impossible.[8]

Cytotoxicity and Cellular Uptake. The cytotoxicity of Lam-D and its analogues (**1**, **2**, **4**, and **15**) was evaluated against BJ human skin fibroblasts, and a panel of three human tumor

[4]The yield for the deprotection was 84% working on a 20−30 mg scale. However, the procedure could not be scaled up. The stability **1** was studied in DMEM supplemented with 10% FBS and 100 units/mL penicillin and streptomycin at 37 °C. HPLC analysis indicates 97% of Lam-D liberation after 360 min of incubation.

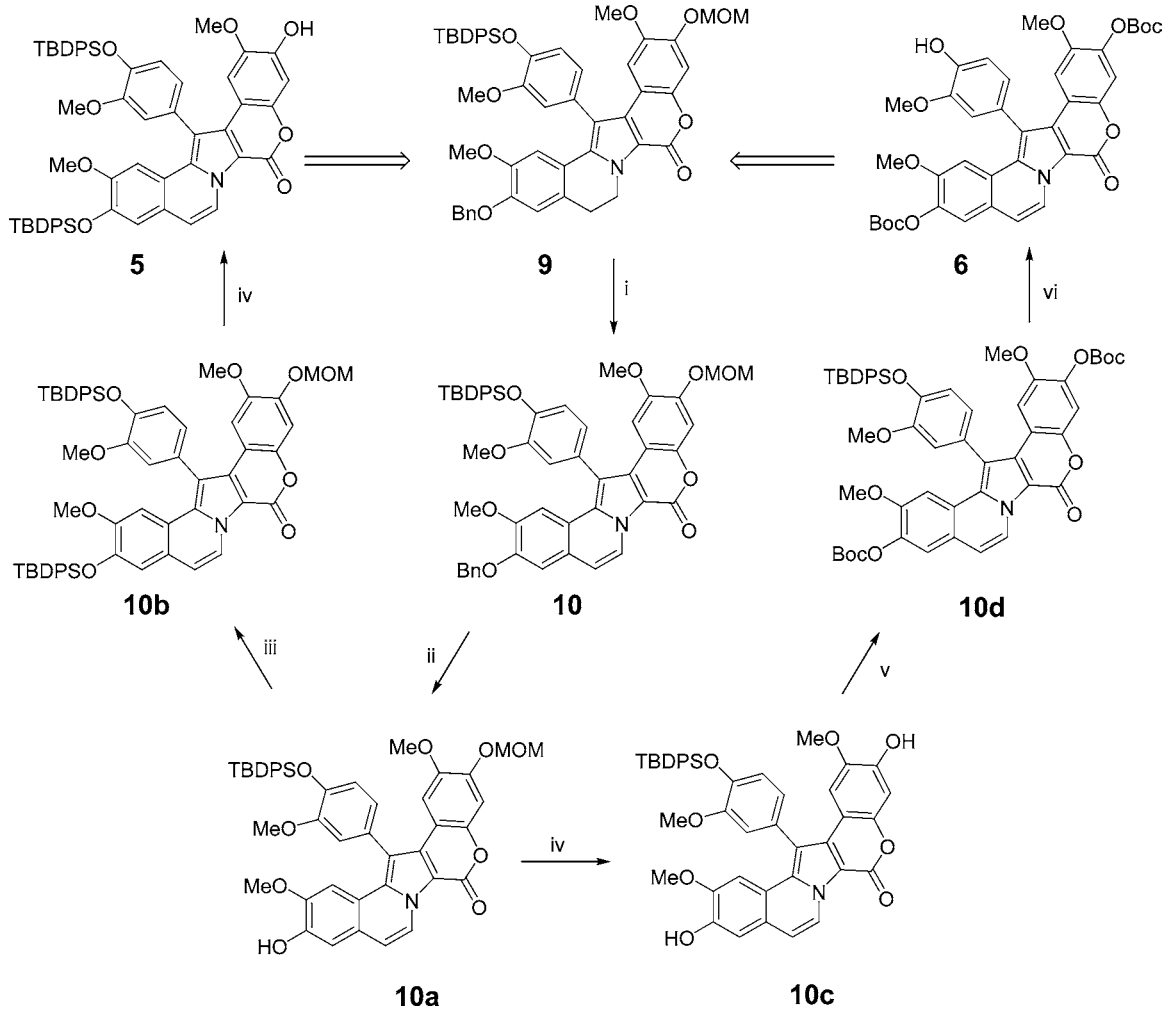
[5]Esterification of **5** was tested with EDC·HCl, TCFH, or *N*,*N*,*N*′,*N*′-tetramethylcholorformamidyl chloride as activating agent.

[6]*N*-Cbz-Gly-OH was anchored to **6** in quantitative yield. However, further Cbz deprotection could not be performed without concomitant hydrolysis of the conjugate ester bond.

[7]Other coupling reagents such as EDC·HCl, DIPCDI, TFFH, PyBOP with HOAt, and MSNT with NMI failed in ester bond formation.

[8]Compound **3** quickly hydrolyzes and liberates Lam-D into the medium, even on the time scale of an HPLC analysis.

Scheme 1[a]



[a] Reagents and conditions: (i) DDQ, $CHCl_3$, MW, 120 °C, 10 min (81%); (ii) H_2, Pd−C, EtOAc, MeOH, r.t., 16 h (95%); (iii) TBDPSCl, Im, DMAP, DMF, r.t., 24 h (58%); (iv) Me_3SiI, CH_2Cl_2 r.t., 20 min (84% for **5**; quant. yield for **10c**); (v) Boc_2O, DMAP, CH_2Cl_2 r.t., 16 h (quant.); (vi) 1M TBAF in THF, MeOH, −78 °C, 15 min (85%).

Table 1. Cytotoxicity of Compounds 1, 2, 4, and 15 in Three Human Cancer Cell Lines

	cytotoxicity (M)			
compound	HT-29 colon	A-549 lung	MDA-MB-231 breast	BJ skin fibroblast
Lam-D	3.00×10^{-6}	1.22×10^{-7}	1.34×10^{-7}	6.37×10^{-9}
1	1.68×10^{-6}	8.86×10^{-8}	4.07×10^{-8}	6.51×10^{-9}
2	3.92×10^{-6}	2.20×10^{-7}	8.31×10^{-8}	1.54×10^{-8}
4	1.01×10^{-6}	4.79×10^{-8}	4.79×10^{-8}	3.14×10^{-8}

cell lines: A-549, HT-29, and MDA-MB-231 (Table 1). A conventional colorimetric assay was used to estimate values of GI_{50} (defined here as the drug concentration that causes 50% of cell growth inhibition after 72 h of continuous exposure to the test molecule). Lam-D was included for comparison. The results are shown in Table 1. The tested compounds in the tumor cell lines exhibited cytotoxicities from 4 μM to 40.7 nM, except for the Boc protected derivative **15**, which only had micromolar activity for the HT-29 and MDA-MB-231 cell cultures. BJ skin fibroblasts were used in the present study to evaluate the effects of the drug and its conjugates in normal cells. In this non-tumoral cellular culture, conjugate **1** citotoxicity was similar to that of Lam-D, or even 2.4−4.9-fold less for **2** and **4**.

FACS flow cytometry was used to measure cellular uptake quantification (*9*). The results are shown in Table 2. Interestingly, the cellular internalization quotient for the PEGylated derivatives **1** and **2** were higher than that of Lam-D in all cancer cell lines. Indeed, compound **4**, with an NLS sequence, was 10 times more active than Lam-D in A-549 and MDA-MB-231 cell lines and retained CIQ, despite having the highly charged NLS peptide. CIQ of conjugates in BJ cellular culture were from 76.8% to 128.6%.

Table 2. Cellular Internalization as Measured by FACS

	cellular internalization (AU)				cellular internalization quotient (CIQ)[a]			
compound	HT-29 colon	A-549 lung	MDA-MB-231 breast	BJ skin fibroblast	HT-29 colon	A-549 lung	MDA-MB-231 breast	BJ skin fibroblast

4	88.5	377.7	434.9	240.6	107%	115%	98%	92.8%

[a] CIQ was calculated in reference to the cellular uptake of Lam-D.

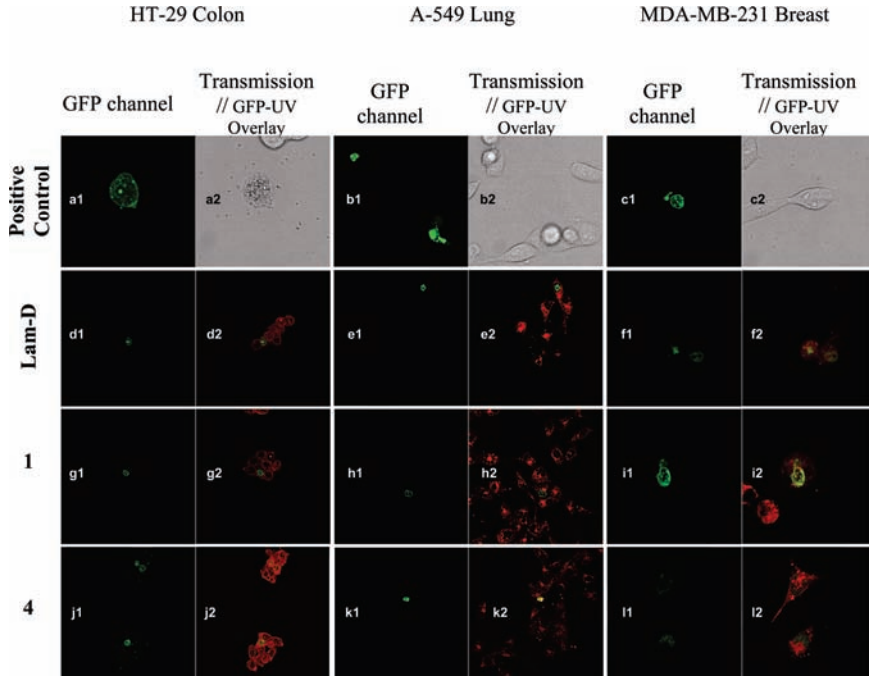

Figure 3. Internalization of Lam-D and conjugates **1** and **4** by Topo I-GFP transfected cells.

Cellular Distribution of Lam-D, 1 and 4. Tracking in GFP-Topo I Transfected Cell Cultures. Lam-D is a Topo I inhibitor. To determine whether Lam-D, **1**, and **4** localize to the same subcellular compartment as Topo I, a cellular localization assay was performed. A functional chimera of the green fluorescent protein EGFP with full-length Topo I (GFP-Topo I) was expressed in HT-29, A-549, and MDA-MD-231 cells, which were then treated with either Lam-D, **1**, or **4**. As described, GFP-Topo I was located in the nucleus (*25*) in all cell types (Figure 3, positive control). Conjugate **4**, carrying the NLS signal, was localized to the nucleus in HT-29 and A-549 cells (Figure 3, **j1**, **j2**, **k1**, and **k2**), suggesting that its higher activity could correlate to subcellular colocalization with its target, Topo I.

Interestingly, Lam-D and **1** showed both higher activity and greater nuclear localization in MDA-MB-231 cells than **4** did (Figure 3, **f1**, **f2**, **i1**, and **i2**).

DISCUSSION

We have described the synthesis of Lam-D conjugates with well-defined, water-soluble peptidic and dendritic systems as potential nontoxic drug delivery vehicles. Interestingly, the Lam-D conjugate containing a single backbone attached to a phenolic residue of Lam-D has very different solubility compared to Lam-D alone. Scaffold **10**, with three orthogonal protecting groups, has proven to be a good starting material, enabling synthesis of **5** and **6**, via protection group interchange, on a multigram scale and in good overall yield. New protected derivatives of Lam-D, which can be conjugated to one (C^{11}−OH, **10a**) or two (C^{3}−OH and C^{11}−OH, **10b**) phenol groups, have been isolated in good yields with this strategy. Compound **1** was synthesized in 84% overall yield from its precursor **5**; this constitutes an important improvement over previous strategies (45% yield, from 4′,11-diisopropyl-Lam-D) (*9*). Simultaneous removal of TBDPS*O* and *N*Boc with HF is a new and highly efficient deprotection scheme for compounds with labile ester bonds. The *O*Boc and TBDPS*O* protecting groups used in lamellarins **5** and **6** permitted optimization of the final deprotection conditions and represented adequate choices for total deprotection in the last step. Thus, single-step HF deprotection was the cleanest method for preparing Lam-D **1-3** (9−84% overall yields from **5**).

The new Lam-D conjugates reported here are excellent candidates for further biological evaluation. The evaluation of conjugates **3** and **4** in BJ skin fibroblasts as normal cells was used in the present study. In this cellular culture, no significant variation or even less cytotoxicity was obtained for conjugates **3** and **4** than the parent compound Lam-D. PEGylated conjugates **1** and **2** have much higher cytotoxicity to MDA-MB-231 cells than Lam-D alone. Surprisingly, compound **4** had nanomolar GI_{50} for MDA-MB-231 and A-549, representing 10-fold-lower GI_{50}, respectively, compared to Lam-D. These results in the A-549 cancer cell line could correlate to colocalization of **4** in nuclear regions where GFP−Topo I accumulated (Figure 3k). The NLS peptidic sequence is at least partly responsible for nuclear import of **4** in A-549 and HT-29 cell lines. In contrast, Lam-D and **1** were able to weakly reach the nucleus in only MDA-MB-231 cells. Altogether, we conclude that better cytotoxicity correlates with greater nuclear localization.

In summary, the use of a robust chemistry strategy, with a combination of solid-phase and solution strategies and a myriad of orthogonal and/or compatible protecting groups, has allowed the preparation of several Lam-D bioconjugates. All of them show some improved characteristics when compared with the parent lamellarin D. Particularly, **4**, which contains the NLS-peptide, shows a clearly improved cytotoxicity and a colocalization in the nucleus. To the best of our knowledge, **4** is one of the first examples of NLS peptide conjugation with small molecules.

Our results (*9*) indicate that Lam-D derivatives obtained through various chemical modifications may have markedly higher activity than the parent compound in certain tumor cell lines, increasing the selectivity between the tumor cell lines.

ACKNOWLEDGMENT

This study was partially supported by CICYT (Grant BQU 2006-03794 and BQU2005-00315), *Generalitat de Catalunya*, and the Barcelona Science Park. We gratefully acknowledge PharmaMar S.A. for performing the preliminary biological tests, and the Networking Centre on Bioengineering, Biomaterials and

Nanomedicine (CIBER-BBN). This study was partially supported by the Industrial Consortium "NanoFarma" from the Spanish grants of CENIT program. We thank Dr. J. Comas from Flow Cytometry Facility − SCT (UB) for valuable discussions regarding the present work. We also thank Prof. C. Mielke (Heinrich-Heine University, Medical School, Düsseldorf) for generous donation of a sample of GFP−Topo I plasmid.

A new strategy is described for functionalizing the ω-terminal end of polymers synthesized by reversible addition−fragmentation chain transfer (RAFT) polymerization that provides spatially controlled bioconjugation sites. Traditional methods for preparing ω-functional polymers require the reduction of the RAFT chain-transfer agent to yield secondary or tertiary thiols of low reactivity or the synthesis of novel chain-transfer agents that contain reactive groups. As an additional strategy, N-substituted maleimido monomers have been used in a modified block polymerization to add a single maleimido unit onto the RAFT polymer with nearly quantitative efficiency. Unique reactive groups contained in the N-substituent are thereby added to the ω-terminal end of the polymer and are subsequently available for conjugation reactions. This technique has been demonstrated using *N*-(2-aminoethyl)maleimide trifluoroacetate to introduce a single primary amine to the ω-terminus of poly(dimethylaminoethyl methacrylate) and poly(*N*-isopropyl acrylamide) and to a specialized block copolymer for siRNA delivery. Evidence for retention of functional RAFT endgroups is provided by synthesis results where chain-extended polyDMAEMA (M_n = 10 600 g/mol, M_w/M_n = 1.14) was used as a macro chain transfer agent for the polymerization of styrene, yielding a diblock polymer of low polydispersity (M_n = 20 300 g/mol, M_w/M_n = 1.11). It is thus also possible to construct diblock copolymers with a bioconjugation site precisely located at the junction between the two blocks. The chain-extended polymers are functionalized with an amine-reactive fluorescent dye or folic acid at conjugation efficiencies of 86 and 94%, respectively. The versatile chain-extension technique described here offers unique opportunities for the synthesis of well-defined polymeric conjugates to molecules of biological and targeting interest.

INTRODUCTION

Controlled radical polymerization (CRP) techniques such as nitroxide-mediated polymerization (NMP) (*1*), atom transfer radical polymerization (ATRP) (*2*), and reversible addition−fragmentation chain transfer polymerization (RAFT) (*3, 4*) offer the ability to produce polymers with predetermined molecular weights, narrow molecular weight distributions, and advanced architectures. For RAFT polymerizations, numerous groups have reported the incorporation of diverse monomers in both organic and aqueous conditions (*5*−*11*). One particularly significant feature of RAFT is that it allows a facile route to prepare telechelic polymers with distinct α and ω functionalities. This feature provides a useful tool for the tailored design of novel polymeric conjugates via coupling to fluorescent dyes, nanoparticles, drugs, peptides, proteins, or targeting moieties (*12*−*17*). In particular, reactive α and ω endgroups offer unique opportunities for the synthesis of well-defined polymeric drug carriers that incorporate both targeting and therapeutic moieties.

Functional endgroups can be prepared using ATRP by modifying the initiator (*18, 19*) or by RAFT through modifications to the chain transfer agent (CTA). The majority of literature reports have focused on RAFT CTAs with functional R groups (*16, 17, 20*−*23*), largely due to the greater stability of the R group following polymerization. Notable examples of RAFT agents with functional Z groups also exist. Liu et al. (*24*) prepared a novel trithiocarbonate CTA containing a pyridyl disulfide group in the Z position that allows for direct coupling to thiol-bearing molecules without postpolymerization modifications. Similarly, Carter et al. prepared a highly branched polymer with imidazole endgroups by employing a Z-functional dithioester (*25*). However, preparation of Z-functionalized RAFT CTAs often requires more difficult synthetic protocols, and many desirable chemical moieties are unsuitable for incorporation into CTA moieties.

RAFT CTAs based on xanthates, dithioesters, dithiocarabamates, and trithiocarbonates can be reduced with primary amines (*26*−*28*) or $NaBH_4$ (*12, 13*) to yield a polymeric thiol endgroup that can be used for conjugation reactions (*29*−*33*). While conjugations to secondary thiols (from styrenic and non-α-substituted monomers) or tertiary thiols (from α-substituted monomers) have been described (*11, 13, 14, 26, 34, 35*), these reactions typically require elevated temperatures, long reaction times, and stoichiometric ratios that can be problematic for many molecules of biological interest due to their expense or instability. A route around this reactivity barrier was described by Scales et al. (*13*), who showed that a secondary thiol could be reacted with a small linker-like molecule for subsequent conjugations. Similarly, York et al. (*34*) obtained 80% conjugation of a fluorescent dye to an α-substituted *N*-(2-hydroxypropyl) methacrylamide block copolymer following reduction of the CTA and subsequent conversion of the tertiary thiol to a primary amine. However, these conversions require reaction conditions that may prove impractical for many polymer compositions. Additional routes to the ω-functionalization of RAFT polymers are needed that are compatible with a wide range of monomers and can be conducted at the time of synthesis under mild conditions.

Our research group has been interested in applications of stimuli-responsive "smart" polymers for therapeutic and diag-

nostic/bioanalytical applications. The therapeutic applications utilize pH-responsive polymers for intracellular delivery of macromolecular biologics such as proteins, peptides, antisense DNA, and small interfering RNA (siRNA) (*36*−*42*). Additionally, we have worked on the development of stimuli-responsive polymers for bioseparations and diagnostic applications (*43*−*45*). These applications would benefit from more efficient chemistries for spatially controlled ω (or Z)-end conjugations, and here, we describe a technique for functionalizing the ω-terminal end of RAFT polymers by chain extension using N-substituted maleimides. Maleimido monomers readily undergo copolymerization with other species but do not efficiently homopolymerize under typical RAFT conditions (*46*−*50*). We show that this property can be exploited in a block polymerization in order to add a single amine-substituted maleimido unit to the end of a RAFT polymer. Because a high percentage of the maleimido-terminated chains are living and a second block can be polymerized from this macro-CTA, the reactive amine can also be positioned precisely at the junction of AA or AB block segments, providing spatial control over the position of a branched bioconjugation site.

EXPERIMENTAL DETAILS

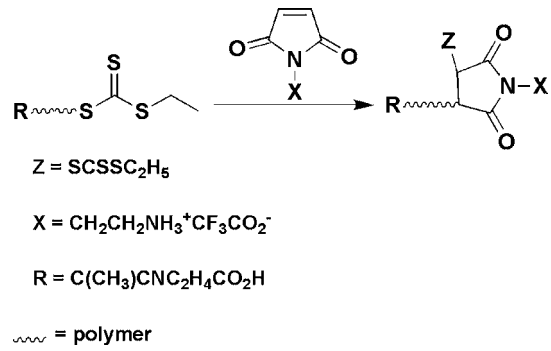
Materials. All reagents were purchased from Sigma-Aldrich and used without further purification unless otherwise noted. Dimethylaminoethyl methacrylate (DMAEMA), butyl methacrylate (BMA), and styrene were purified by vacuum distillation. *N*-Isopropylacrylamide (NIPAM) was recrystallized from hexanes. Propylacrylic acid (PAA) was synthesized as previously published (*51*). Unless noted otherwise, the primary radical source used in all polymerizations was 2,2-azobisisobutyronitrile (AIBN), which was recrystalized from methanol. The trithiocarbonate CTA ethyl cyanovaleric trithiocarbonate (ECT) was synthesized as previously described (*41*) and used as the CTA in all RAFT polymerizations. All polymerizations were conducted under N_2 atmosphere.

RAFT polymerization of pDMAEMA and p(DMAEMA-*b*-DMAEMA/BMA/PAA). Poly(DMAEMA) was obtained by RAFT polymerization using experimental conditions appropriate to target the various molecular weights used in this study. As an example of typical conditions, the $[CTA_o]/[I_o]$ ratio was10:1, the $[CTA_o]/[M_o]$ ratio was 1:150, and the monomer was 50 wt % in *N*,*N*′-dimethylformamide (DMF). The polymerization was conducted at 60 °C for 7 h. The molecular weight and polydispersity were 8100 g/mol and 1.21, respectively. All DMAEMA polymers were isolated by precipitation in an 80/20 v/v pentane/ether mixture, followed by repeated cycles of dissolution in ether and precipitation in pentane. The polymer was dried under vacuum overnight. Molecular weight distributions were determined by gel permeation chromatography (GPC).

The block copolymer p(DMAMEA-*b*-DMAEMA/BMA/PAA) was prepared following previously described protocols (*41*). Briefly, a pDMAEMA macro CTA (M_n = 9000 g/mol, M_w/M_n = 1.30) was employed for the polymerization of the copolymer block using a $[CTA_o]/[I_o]$ ratio of 10:1 and a $[CTA_o]/[M_o]$ ratio of 1:250 in DMF at 40 wt % monomer. The composition of the feed was 40 mol % butylmethacrylate (BMA), 30 mol % propylacrylic acid (PAA), and 30 mol % DMAEMA. 2,2′-Azobis(4-methoxy-2,4-dimethylvaleronitrile) (V70) was the radical source, and the polymerization time was 18 h at 30 °C. The block copolymer was isolated by multiple precipitations in an 80/20 v/v pentane and ether mixture, followed by precipitation in pentane.

RAFT Polymerization of pNIPAM. Poly(NIPAM) was obtained by RAFT polymerization based on previously published conditions (*52*) using a $[CTA_o]/[I_o]$ ratio of 20:1, a $[CTA_o]/[M_o]$ ratio of 1:100, and the monomer was 33 wt % in *p*-dioxane. The polymerization was conducted at 70 °C for 120 min. pNIPAM was isolated by repeated cycles of precipitation into ethyl ether, followed by dissolution in acetone, and dried under vacuum overnight.

Scheme 1. Synthetic Pathway for Maleimido Chain Extension of RAFT Polymers



Maleimido Chain Extension. Maleimide chain extension was performed at 60 °C in DMF for 16 h using *N*-(2-aminoethyl)-maleimide trifluoroacetate (AM) as the monomer and poly(DMAEMA), poly(NIPAM), or poly(DMAEMA-*b*-DMAEMA/BMA/PAA) as the macro-CTA (Scheme 1). The polymerizations were conducted with a $[CTA_o]/[I_o]$ ratio of 10:1 and a $[CTA_o]/[M_o]$ ratio of 1:100. The polymerization solution was 60 wt % solvent. As an example of polymerization, 400 mg pDMAEMA (49 μmol) and 1.26 g AM (4.9 mmol) were polymerized with 0.81 mg AIBN (4.9 μmol) in 2.5 g DMF. ^{1}H NMR was used to confirm that the macro-CTAs were free of residual monomer prior to chain extension in order to eliminate the possibility of copolymerization during maleimide chain extension.

Chain-extended pDMAEMA-AM was isolated by six cycles of precipitation in an 80/20 solution of pentane/ether. Between precipitations, the polymer was redissolved in acetone and separated from any insoluble AM by centrifugation and filtration through 0.2 μm syringe filters. Following precipitation, a solution of pDMAEMA-AM was prepared in deionized water (DI) and the polymer was further purified from residual AM monomer using two PD-10 desalting columns (Amersham, Piscataway NJ) in series and lyophilized. Chain-extended pNIPAM-AM was purified from AM by running the reaction mixture through two PD-10 columns following 1:2 dilution in DI, then lyophilized. The extent of AM chain extension was determined using ^{1}H NMR, and the molecular weight distribution was characterized by GPC.

Styrene Polymerization from pDMAEMA-AM. Chain-extended pDMAEMA-AM was used as a macro-CTA for the polymerization of styrene (pDMAEMA-AM-STY) in order to demonstrate retention of functional RAFT chain ends. The $[CTA_o]/[I_o]$ ratio was10:1, the $[CTA_o]/[M_o]$ ratio was 1:250, and the monomer was 50 wt % in DMF. The polymerization was conducted at 60 °C for 24 h, and the polymer was isolated by precipitation in 80/20 v/v pentane/ether as previously described.

Fluorescent Labeling. Amine functionalized pDMAEMA-AM and pDMAEMA-AM-STY were labeled with 1-pyrenebutanoic acid succimidyl ester (PNHS) (Invitrogen). pDMAEMA-AM (75 mg, 10 μmol) was dissolved in 1 mL of anhydrous DMF. Subsequently, diisopropylethylamine (123 mg, 0.96 mmol) was added at 2-fold molar excess relative to the number of DMAEMA residues to ensure removal of the triflate salt from the pDMAEMA-AM primary amine. After 60 min, PNHS (20 mg, 70 μmol) was added to the solution at 7-fold molar excess relative to the number of pDMAEMA-AM chains, and the reaction was allowed to proceed in the dark at room temperature for 18 h under anhydrous conditions. At the end of the reaction

time, free PNHS was precipitated from solution by the addition of 4 mL of DI water and separated by centrifugation. The supernatant was filtered through a 0.2 μm syringe filter, eluted through 2 PD-10 desalting columns, and dried. The sample was then dissolved in 2.5 mL of 50% v/v DI/DMF and eluted through two additional PD-10 columns in series, and frozen and lyophilized. The percent conjugation was determined by GPC using online UV and RI detectors.

pDMAEMA-AM-STY was labeled using a similar procedure, but PNHS was added at 50-fold molar excess to compensate for the increased steric hindrance of the amine caused by the presence of the styrene block. Following labeling, the reaction mixture was added to 50 mL anhydrous ether causing the precipitation of PNHS, which was removed by centrifugation. pDMAEMA-AM-STY was subsequently precipitated from the ether by the addition of 50 vol % pentane and recovered by centrifugation.

To determine the concentration of pyrene associated with pDMAEMA-AM or pDMAEMA-AM-STY, a linear pyrene calibration curve was generated by injecting multiple known concentrations of pyrene on the GPC column and plotting their corresponding UV peak areas at 338 nm. The concentration of pyrene associated with the polymers was subsequently determined by comparison of the polymer conjugate UV peak area ($\lambda = 338$) to the pyrene calibration curve. The UV peak area of the unlabeled polymers was used to account for the contribution of the RAFT CTA to the absorption at 338 nm while maintaining constant RI peak area between the two samples.

Folic Acid Conjugation. Folic acid was activated with dicyclocarbodiimide (DCC) in dry dimethylsulfoxide (DMSO) at a molar ratio of 1:1.1 for 60 min at 4 °C. A solution of pDMAEMA-*b*-DMAEMA/BMA/PAA that had been chain-extended with *N*-(2-aminoethyl)maleimide and TEA (1:1 mol ratio with PAA and AM) in DMSO was added to the activated folate solution (10:1 folate/polymer ratio) and reacted overnight at room temperature. The polymer−folate conjugate was purified by extensive dialysis in water, then lyophilized. The remaining folic acid was separated from the lyophilized conjugate using a series of 5 PD-10 desalting columns until no further reduction in folic acid absorbance ($\lambda = 363$ nm) was observed in the column flow-through. The purified polymer−folate conjugate was dried by lyophilization, and the amount of folate present in the conjugate was determined by UV absorbance relative to a standard curve of free folic acid. No shift in the folate absorbance spectrum was observed as a result of conjugation to the polymer. UV measurements were done in phosphate buffered saline (PBS), pH = 7.4. Concentrations of the polymer−folate conjugate were between 0.1 and 1 mg/mL.

Instrumentation. The polymers in this study were characterized by gel permeation chromatography using three Tosoh TSK-GEL columns (TSK-α3000, α3000, α4000) connected in series to a Viscotek GPCmax VE2001 and Viscotek RI and UV detectors (VE3580 and VE3210, respectively) (Viscotek, Houston, TX). The mobile phase was HPLC-grade DMF containing 0.1 wt % LiBr. Molecular weight distributions were determined relative to a series of poly(methyl methacrylate) standards. Characterization of polymer−folate conjugates was performed on an HP Agilent 8453 UV−vis spectrophotometer. All NMR spectroscopy was done on a Bruker DRX499 system in D_2O.

RESULTS AND DISCUSSION

A single N-substituted maleimido repeat unit can be added to the ω-terminal end of a polymer using RAFT and the common techniques of block polymerization. By varying the identity of the N-substituent, maleimido chain extension provides a method to introduce highly reactive chemical groups at the ω-(Z)-end (Scheme 1). The technique is versatile in that it is compatible with a wide variety of polymers, does not require post-polymerization processing to obtain reactive moieties, and yields functional groups for bioconjugations that are significantly more reactive than the polymeric thiols that can be obtained by CTA reduction. Using the chain extension technique, we have successfully introduced primary amine ω-endgroups to acrylamido and α-substituted methacrylic polymers and at the junction between diblock segments (Figure 1). The utility of the amines has been shown by conjugations to an optical dye and to the targeting moiety folic acid.

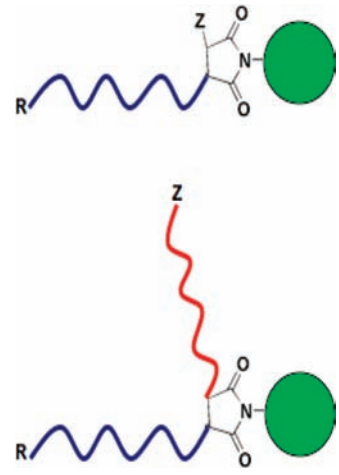


Figure 1. Schematic design of functionalized telechelic RAFT-polymers that provide a convenient route to controlled bioconjugations at the ω(Z)-chain end, or at the branched junction between two block segments. Using the CTA described in the text, the R group is a reactive carboxylate and the Z-group is an unreduced trithiocarbonate or reduced polymeric thiol.

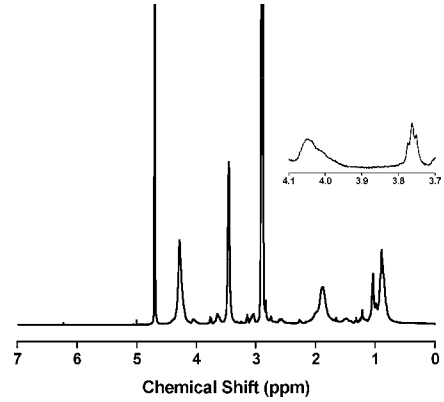

Figure 2. ^{1}H NMR of pDMAEMA after chain extension with *N*-(2-aminoethyl)maleimide trifluoroacetate (AM). The inset shows the triplet at $\delta = 3.77$ that results from the addition of AM to the polymer chain.

Primary amines are highly nucleophilic and have significant synthetic utility in the preparation of polymeric bioconjugates. However, primary amines are commonly used for the reduction of trithiocarbonates and dithiocarbamates, and therefore difficult to incorporate into RAFT polymers or RAFT CTAs. As shown in Scheme 1, we have used the triflate salt of *N*-(2-aminoethyl)maleimide (AM) to introduce primary amine functionality on the ω-end of polymer chains. The triflate salt prevents reduction of the RAFT CTA during chain extension with the maleimide, but does not interfere with subsequent conjugation reactions. The success of this technique can be shown using ^{1}H NMR. Figure 2 shows the spectrum of a chain extended pDMAEMA-AM macro-CTA. The emergence of the triplet at $\delta = 3.77$ corresponding to the ($NC\mathbf{H}_2CH_2$) group in AM and

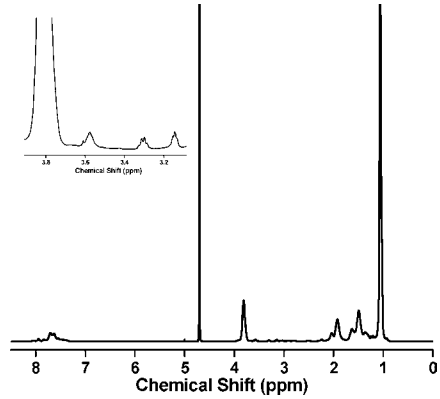

Figure 3. The ^{1}H NMR spectrum of pNIPAM following chain extension with AM. The inset shows the triplet at $\delta = 3.15$ that results from the addition of AM to the polymer chain and the quartet at $\delta = 3.31$ that indicates the presence of intact RAFT Z groups.

the absence of free vinyl peaks at $\delta = 6.8$ shows that AM is incorporated into the pDMAEMA polymer and not present as a contaminating monomer. By comparing the pDMAEMA ($CO_2C\mathbf{H}_2$) peak area at $\delta = 4.1$ to the AM peak area at $\delta = 3.77$, and using the molecular weight of pDMAEMA determined by GPC, the number of AM residues incorporated into each polymer chain is calculated at 1.02 (P1, Table 1). This result clearly shows the addition of a single functional maleimide to the ω-end of the polymer chain.

The chain extension technique is not limited to the preparation of ω-functional methacrylic polymers. Using the thermally responsive polymer poly(*N*-isopropylacrylamide) (pNIPAM), we have shown that acrylamido polymers may be functionalized by maleimido chain extension. Figure 3 shows the ^{1}H NMR spectrum of a chain-extended pNIPAM-AM macro-CTA. The triplet at $\delta = 3.15$ corresponds to the ($CH_2C\mathbf{H}_2NH_2$) group in AM and the spectrum is free of vinyl peaks, indicating incorporation of AM into the pNIPAM polymer. The number of AM residues incorporated into each polymer was determined to be 0.97 (P3, Table 1) by comparing the pNIPAM methine peak area ($NHC\mathbf{H}(CH_3)_2$) at $\delta = 3.81$ to the AM peak area at $\delta = 3.15$ and using the molecular weight of pNIPAM determined by GPC. Moreover, the AM peak area can be compared directly to the ($SC\mathbf{H}_2CH_3$) peak from the Z-group of the CTA at $\delta = 3.31$, indicating that the CTA and AM are present on the polymer in a 1:1 ratio. Calculation of the degree of polymerization based on the pNIPAM methine peak and the CTA peak at $\delta = 3.31$ yields the degree of polymerization expected from GPC measurements, providing further evidence that pNIPAM has been successfully functionalized by a single AM residue and that functional CTA moieties are retained on the polymer chain end. Together with the results of the pDMAEMA chain extension, these results indicate that maleimido chain extension may not be restricted by monomer class and will have synthetic utility with a wide array of commonly used polymers (e.g., (meth)acrylic and (meth)acrylamido).

The chain extension conditions we describe do not result in changes to the molecular weight distribution of the polymer undergoing extension. Figure 4A shows the RI traces for pDMAEMA and pDMAEMA-AM (P1, Table 1) following chain extension. No apparent shift in the peak elution volume results from chain extension, consistent with the addition of a single monomer to the chain end, and no change was observed in the calculated M_n (8100 g/mol) upon chain extension. Moreover, no peak broadening is exhibited in the RI traces, as would be expected if significant polymer−polymer coupling or formation of homomaleimide polymer fragments were to occur ($M_w/M_n = 1.21$ and 1.26 before and after chain extension, respectively). Similarly, no significant changes in molecular weight distribution were observed after chain extension of pNIPAM ($M_n = 8000$ g/mol $M_w/M_n = 1.16$, and $M_n = 8000$ g/mol $M_w/M_n = 1.17$) or the block copolymer pDMAEMA-*b*-DMAEMA/BMA/PAA ($M_n = 19\,400$ g/mol $M_w/M_n = 1.42$, and $M_n = 19\,500$ g/mol $M_w/M_n = 1.45$) (P4, Table 1).

A possible complication of chain extension with a primary amine containing monomer is destruction of the RAFT moiety through aminolysis. If this undesirable reaction were to occur, it would yield polymeric thiols that might result in polymer−polymer coupling by disulfide formation or reaction with maleimide monomers. Although GPC traces provided no evidence of polymer coupling following chain extension, we prepared an additional chain-extended pDMAEMA-AM to serve as a macro-CTA in a subsequent styrene polymerization ($M_n = 10\,600$ g/mol, $M_w/M_n = 1.14$). If destruction of some or all of the RAFT CTA were to occur during chain extension, subsequent block formation using the pDMAEMA-AM macro-CTA would be impossible or would yield polymers with broad or multimodal molecular weight distributions due to the presence of nonfunctional macro-CTA. Figure 4B shows RI traces for the pDMAEMA-AM macro-CTA and for the triblock polymer obtained by block polymerization, pDMAEMA-AM-STY (P2, Table 1). A clear shift in the retention volume of the polymer is observed following polymerization, and the molecular weight distribution of the triblock polymer is characteristically narrow ($M_n = 20\,300$ g/mol and $M_w/M_n = 1.11$). These results strongly suggest that significant aminolysis of the CTA is not occurring. Further evidence in support of this point can be seen by examining the ^{1}H NMR spectrum of pNIPAM-AM, shown in Figure 3.

This spectrum clearly shows the methylene peak from the Z-group of the CTA at $\delta = 3.31$. The ratio of this peak area to the methine peak area in chain-extended pNIPAM-AM is the same as the corresponding ratio in the parent pNIPAM, indicating that no detectable aminolysis of the CTA occurs during chain extension.

The retention of functional RAFT moieties on the polymer following chain extension offers unique synthetic opportunities. The maleimido-terminated chains are living and can be used in subsequent block polymerizations, as illustrated by our polymerization of pDMAEMA-AM-STY. Such polymerizations have the effect of positioning a bioconjugation site precisely at the junction of the AA or AB blocks, whose length and composition can also be readily controlled. Moreover, multiple rounds of block polymerizations could potentially be used to position multiple bioconjugation sites at defined intervals along a polymer backbone of hetero- or homogeneous composition. These materials could be used to prepare therapeutic and diagnostic polymer conjugates with uniquely defined architectures.

To confirm that the amines introduced to the polymers by chain extension were reactive and available, a fluorescent dye was used as a model compound for imaging agent conjugations. Amine-reactive 1-pyrenebutanoic acid succimidyl ester (PNHS) was used

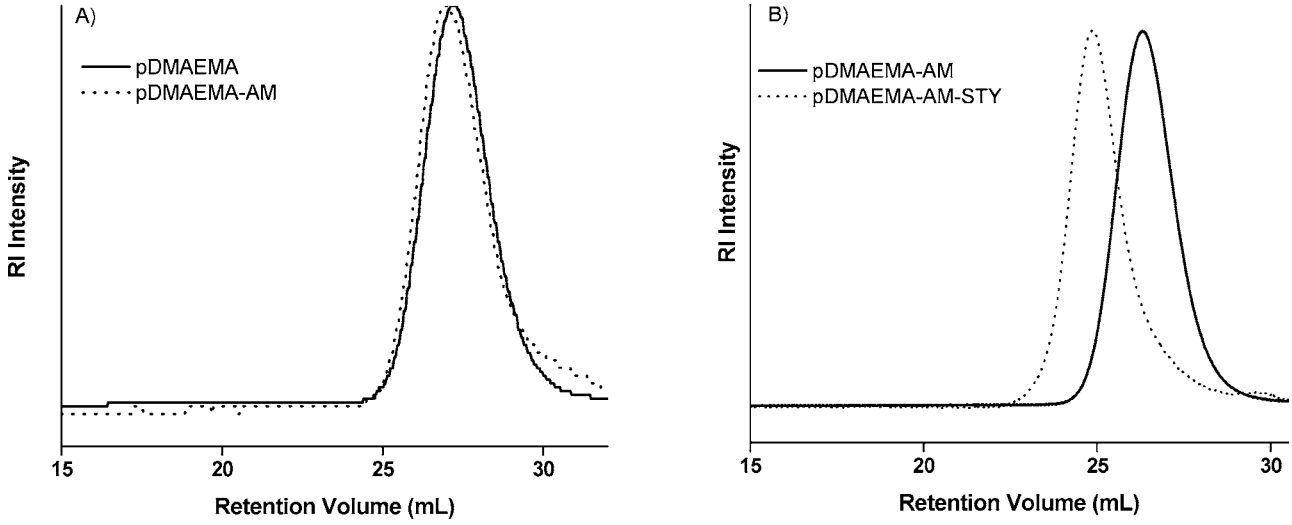

Figure 4. (A) GPC traces showing the molecular weight distribution of pDMAEMA and pDMAEMA-AM following chain extension. (B) GPC traces of a pDMAEMA-AM-STY triblock polymer and the corresponding pDMAEMA-AM macro-CTA.

to label pDMAEMA-AM, and the amount of pyrene conjugated was evaluated by GPC and UV spectroscopy following purification. Figure 5A shows normalized RI and UV traces for pyrene-labeled pDMAEMA-AM. Upon reaction with PNHS, an intense UV signal is observed with polymer elution that is not present in unconjugated pDMAEMA-AM, indicating that the pDMAEMA-AM chains were successfully labeled with pyrene. Figure 5B shows the UV absorbance spectra of pyrene-labeled pDMAEMA-AM and unlabeled pDMAEMA-AM, illustrating the significant increase in absorptivity that occurs upon pyrene addition. The percentage of pDMAEMA-AM chains conjugated to pyrene was determined to be 86.1% (P1, Table 1) by comparing the UV peak area associated with polymer elution to a calibration curve. Similarly, PNHS was also used to label the primary amine located at the maleimido junction of the DMAEMA and STY block segments in pDMAEMA-AM-STY (P2, Table 1). The degree of conjugation to this polymer was 44%, suggesting that the steric effects of the large styrene block reduce the conjugation efficiency.

Recently, our group described the use of the block copolymer pDMAEMA-*b*-DMAEMA/BMA/PAA as a siRNA delivery vehicle (*41*). The positively charged pDMAEMA block functions to condense nucleic acid residues, while the pH-responsive and membrane-disruptive copolymer block mediates intracellular delivery of the complexes following endosomal uptake. Though the block copolymer mediated excellent gene knockdown (up to 80%) (*41*), incorporation of targeting ligands can further enhance knockdown in vitro and facilitate more efficient in vivo delivery (*53, 54*). Folic acid is a commonly used targeting ligand, mediating greater internalization for cells that express or overexpress the folic acid receptor (*55, 56*). As a demonstration of the utility of maleimido chain extension, we conjugated folic acid to the AM chain-extended pDMAEMA-*b*-DMAEMA/BMA/PAA block copolymer. Figure 6A shows the RI and UV GPC traces of the unmodified copolymer, while Figure 6B shows the RI and UV GPC traces of the copolymer−folate conjugate. The unmodified copolymer shows negligible UV absorbance at 363 nm (Figure 6A), while an intense UV signal is associated with polymer elution in the case of the copolymer−folate conjugate (Figure 6B). The degree of folate conjugation to the copolymer was determined by comparison to a calibration curve of free folic acid and found to be 94% (P4, Table 1).

It is important to note that the highly efficient conjugation reactions demonstrated here were conducted for less than 24 h at room temperature and relatively low stoichiometric ratios. These reaction conditions are possible because maleimide chain extension provides a functional group with far greater reactivity than the

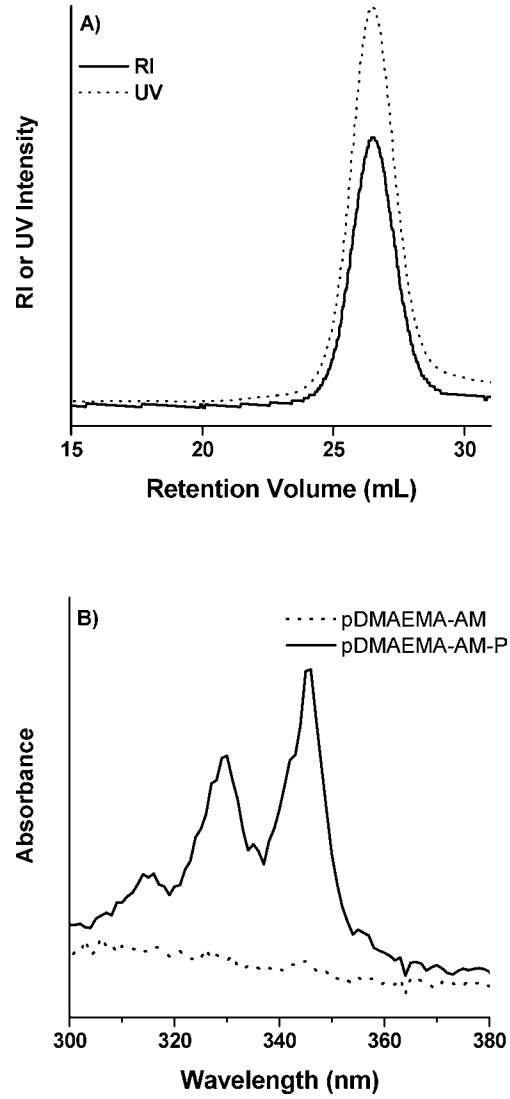

Figure 5. Chain-extended polymers were labeled with an amine-reactive pyrene. (A) RI and UV traces of pDMAEMA-AM-P following pyrene conjugation. (B) Unmodified pDMAEMA-AM shows limited UV absorbance due to the trithiocarbonate moiety on the chain end, while pyrene-labeled pDMAEMA-AM-P exhibits significantly increased absorption.

tertiary thiols that can be obtained following reduction of the CTA. For this reason, chain extension is particularly well suited for functionalizing polymers with molecules of biological interest that may be insufficiently stable or prohibitively expensive for use with other ω-functionalization strategies.

CONCLUSION

A facile method to achieve end-functionalization of RAFT polymers with moieties for bioconjugation was demonstrated. Using an N-substituted maleimido monomer, a unique functional group was introduced to the ω-terminal end of RAFT polymers. Specifically, *N*-(2-aminoethyl)maleimide trifluoroacetate (AM) was used to introduce a single primary amine to an α-substituted polymer, dimethylaminoethyl methacrylate (pDMAEMA), *N*-isopropyl acrylamide (pNIPAM) and a block copolymer of DMAEMA, butyl methacrylate (BMA), and propylacrylic acid (PAA), (pDMAEMA-*block*-DMAEMA/BMA/PAA). The primary amine was active, and conjugation efficiencies of 86% to pyrene and 94% to folic acid were readily achieved at room temperature and low stoichiometric ratios. This synthetic approach should provide a versatile method for ω-end functionalization of RAFT polymers, since alternate ω-end functionalities could be readily prepared by altering the identity of the maleimido N-substituent.

The Cu(I)-catalyzed azide−alkyne cycloaddition (CuAAC) has recently proven to be a powerful synthetic tool in various fields of chemistry, including protein−polymer conjugation. In this article, we describe a fluorogenic CuAAC, which allows for efficient monitoring of protein−polymer conjugation. We show that profluorescent 3-azido coumarin-terminated polymers can be reacted with an alkyne-functionalized protein to produce a strongly fluorescent triazole-linked conjugate. Upon formation of the product, the evolution of fluorescence can accurately be determined, providing information about the course of the CuAAC. As a proof of concept, we synthesized several 3-azido coumarin terminated poly(ethylene glycol) (PEG) chains and investigated their conjugation with alkyne-functionalized bovine serum albumin (BSA) as a model protein. CuAAC conjugation was shown to be very efficient and proceeded rapidly. Conversion plots were constructed from measuring the fluorescence as function of reaction time. An additional benefit of the fluorogenic CuAAC is the *in situ* labeling of bioconjugates. We envision that the fluorogenic protein−polymer conjugation is not restricted to the reaction system reported in this work, but may also be ideal to screen for optimal reaction conditions of various other systems.

INTRODUCTION

The modification of proteins with synthetic polymers has been demonstrated to be beneficial for applications in medicine and biotechnology (*1*−*5*). A well-known example in this respect is the conjugation of proteins with poly(ethylene glycol) (PEG), termed PEGylation (*6*−*11*). In comparison to native proteins, PEGylated derivatives often exhibit improved biodistribution and pharmacokinetics, reduced immunogenicity, prolonged plasma half-life, and increased solubility (*12, 13*). As a result, several therapeutic protein−PEG conjugates are currently on the market or in clinical development (*10*, *14*). Besides PEGylated proteins, other types of protein−polymer conjugates have also gained much interest. In particular, bioconjugates that comprise stimuli-responsive polymers (e.g., poly(*N*-isopropylacrylamide), pNIPAM) have been widely investigated for their reversible phase transition behavior (*3, 15*−*17*). Somewhat less deeply studied are the conjugates of hydrophobic polymers (e.g., polystyrene; PS) and proteins, which have been shown to act as giant amphiphiles and form bioactive assemblies in water (*18*−*24*).

As protein−polymer conjugates constitute a versatile and interesting class of materials, their synthesis has attracted a lot of attention. Several synthetic routes have now been established, mainly following two approaches: (i) the propagation of a polymer from a protein equipped with initiator moieties (i.e., grafting-from), and (ii) the coupling of an end-functionalized polymer to peripheral amino acid side chains of a protein (i.e., grafting-to) (*25*−*27*). The latter approach is most commonly applied and allows the polymer segment to be presynthesized under conventional, optimized conditions. Obviously, the success of the grafting-to method strongly relies on the selection of an efficient coupling strategy for the joining of bulky building blocks. In the choice of chemistry, it should furthermore be taken into consideration that site-specific conjugation may be required to retain maximum biological activity. Therefore, a frequently used strategy is to couple thiol-reactive polymers to unpaired cysteine residues, which are naturally very scarce (*23, 28, 29*). In fact, many proteins lack free thiol groups, but in those cases, genetic engineering can be used to introduce cysteines residues at specific positions (*30*). Another strategy to create a handle for site-specific conjugation is via the incorporation of non-natural amino acids (*31*). In this way, functional groups such as ketones, azides, and alkynes can be installed, facilitating a bioorthogonal derivatization by oxime ligation (*32*−*36*) or the recently developed Cu(I) catalyzed azide−alkyne 1,3-dipolar cycloaddition (CuAAC) (*37*−*40*). The latter can be considered as a prototypical click reaction (*41*) and has proven to be a powerful synthetic tool in the fields of biohybrid chemistry (*42*−*44*) and materials science (*45, 46*). In terms of protein−polymer conjugation, the CuAAC has successfully been employed in grafting-to approaches to prepare PEGylated enzymes (*47, 48*), glycopolymer−virus particles (*49*), stimuli-responsive bioconjugates (*50*), and giant amphiphiles (*22*).

Protein−polymer conjugation is generally monitored by characterization techniques that discriminate between the size of the starting materials and products, e.g., sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) or size exclusion chromatography (SEC). However, we realized that using the CuAAC would also allow for monitoring of the bioconjugation process by a fluorogenic assay. That is, exploiting the fact that profluorescent 3-azido coumarin derivatives become strongly fluorescent upon undergoing a cylcoaddition reaction, as depicted in Figure 1. 3-Azido coumarin derivatives have been developed by Wang and co-workers (*51*) and proved to be very useful to signal for an effective CuAAC with alkynes (*52*−*55*) and cycloaddition with oxanorbornadienes (*56*). Extending on the signaling purposes, it should be possible to determine the progress of coupling 3-azido coumarin-terminated polymers to alkyne-functionalized proteins by simply measuring the increase in fluorescence intensity. In addition, the newly formed bioconjugate would instantly be labeled with

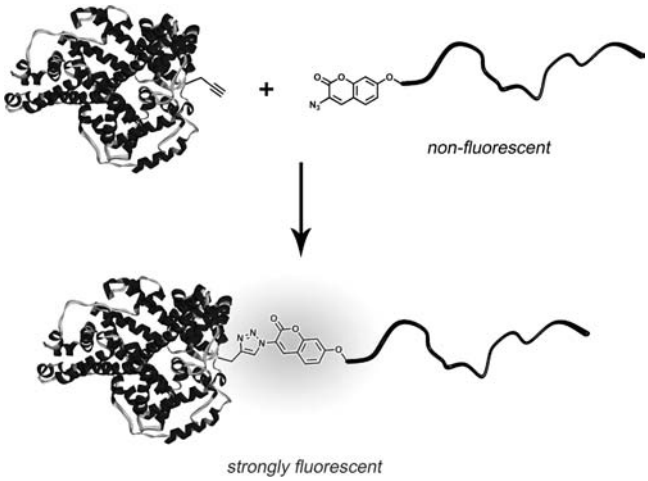

Figure 1. Schematic representation of a fluorogenic Cu(I)-catalyzed azide−alkyne 1,3-dipolar cycloaddition between a protein and a polymer.

a fluorescent probe, which is of great assistance in tracking the materials with established characterization techniques (e.g., SEC and SDS−PAGE). For the reasons described above, we decided to further develop the concept of monitoring protein−polymer conjugation by a fluorogenic CuAAC. Considering the great technological relevance of protein PEGylation, we focused in our proof of concept on the coupling of 3-azido coumarin terminated PEG to an alkyne-functionalized model protein. Bovine serum albumin (BSA) was selected as a model protein because it is readily available and easy to functionalize with a single alkyne group (*22*). In this article, we concentrate on 3-azido coumarin derivatives, but it should be noted that other azide/alkyne-bearing profluorescent probes also may be selected for the same purpose (*57, 58*).

RESULTS AND DISCUSSION

Synthesis of 3-Azido Coumarin Terminated PEG. Nowadays, a range of well-defined PEG derivatives is commercially available. Commonly, these polymers are equipped with hydroxyl end groups, which allow for their functionalization by straightforward modifications. We envisioned that a 3-azido coumarin compound carrying a carboxyl acid group (i.e., compound **3**) would be ideal for coupling to hydroxyl-terminated PEG as well as to other end-functional polymers in future studies. Therefore, acid derivative **3** was synthesized starting from 3-azido-7-hydroxy coumarin (**1**) reported by Wang and co-workers (Scheme 1) (*51*). First, a *tert*-butyl ester was introduced, which could subsequently be deprotected to a carboxylic acid under mild conditions, i.e., treatment with trifluoro acetic acid (TFA). Both reaction steps proceeded smoothly and in good yield. However, a similar route employing a methyl ester was found to be unsuccessful, and no azide-containing coumarin could be recovered after deprotection attempts with 1 M NaOH in THF.

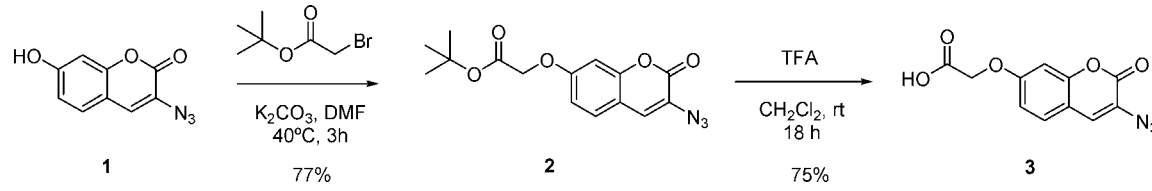
Coumarin **3** was coupled to hydroxyl-terminated PEG (M_n = 2000 and 5000 Da) using 1-ethyl-3-(3′-dimethylaminopropyl) carbodiimide (EDCI) as a coupling reagent. This resulted in end-functional polymers **4** and **5** containing an ester linkage (Scheme 2). Additionally, hydroxyl PEG (M_n = 2000 Da) was used as a starting material for the preparation of amide-linked 3-azido coumarin terminated PEG **8**, which is expected to be more stable under physiological conditions. To this end, the PEG was first reacted with acrylonitrile to give polymer **6**. After reduction of the nitrile to the corresponding amine (**7**), the polymer was coupled to coumarin **3** using EDCI under conditions similar to those employed for the ester derivatives. All 3-azido coumarin terminated polymers were characterized by ^{1}H NMR spectroscopy and SEC. Figure 2 displays the ^{1}H NMR spectra of PEG **4** and **8** (both with M_n = 2000 Da), which clearly show the signals corresponding to the coumarin end groups. It should be noted that for the amide-linked PEG **8**, traces corresponding to ester-linked PEG **4** were observed in the ^{1}H NMR spectrum. This shows that not all chains of PEG **7** were amine terminated, which might be caused by an incomplete Michael addition with acrylonitrile or the occurrence of the reversed reaction. Integration of the α-terminal methoxy signal (*a*) and the protons neighboring the carbonyl (*f* and *h* for **4**/**5** and **8**, respectively) gave a ratio close to 3:2, pointing to quantitative functionalization. For all polymers, the covalent attachment of the coumarin moiety to PEG was confirmed further by SEC using UV detection at λ = 340 nm. The coupled products clearly showed a signal at the expected elution times, while the starting PEG gave no response. As expected, detection by refractive index (RI) afforded comparable results for PEG and the corresponding functionalized derivatives.

Synthesis of Alkyne-Functionalized BSA. To evaluate the concept of monitoring protein−polymer conjugation by a fluorogenic CuAAC, we selected alkyne-functionalized BSA **10** as a model protein. Following up on previous work (*22*), commercially available BSA was coupled to *N*-propargyl maleimide. A CuAAC with 3-azido-7-hydroxy-coumarin (**1**) was successfully conducted to check for functionalization of the protein (see Supporting Information).

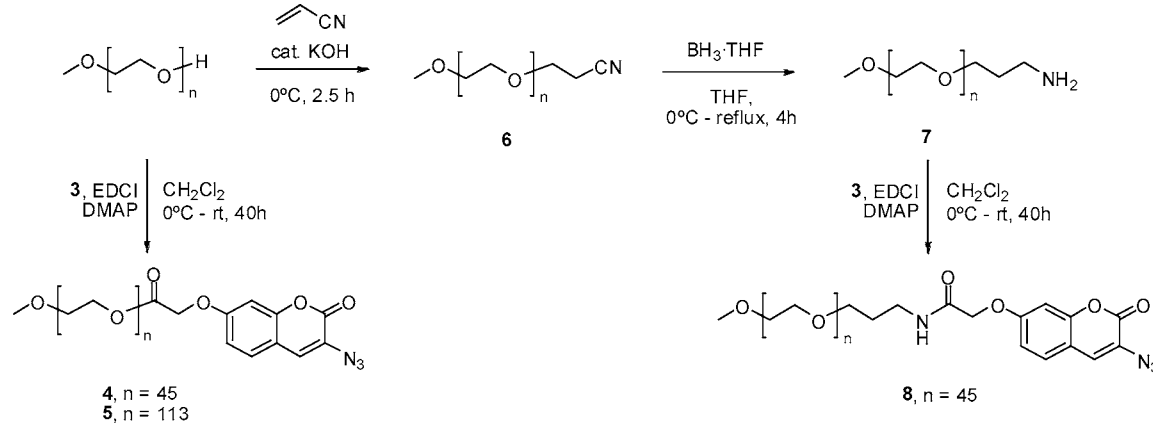
Fluorogenic PEGylation via the CuAAC. Before carrying out the PEGylation of BSA, we decided to examine the reactivity of the azido end group of PEG using low molecular weight alkyne **12**. This alkyne derivative was taken as a model for **10**, and was synthesized by reacting *N*-propargyl maleimide with β-mercapto ethanol (Scheme 3). With the help of $CuSO_4$/Na-ascorbate, alkyne **12** was reacted with PEG **4** using THF/water (3:2) as a solvent system. The reaction was accompanied by a clear evolution of fluorescence (when irradiated under a hand-held UV lamp, λ = 366 nm), indicating that the azide moiety was successfully converted into a triazole. Complete conversion of the reaction was confirmed by ^{1}H NMR spectroscopy, which showed a full shift of coumarin H_4 from δ = 7.16 ppm to δ = 8.49 ppm. Furthermore, a distinct signal of the triazole proton was detected at δ = 8.60 ppm. Analysis by matrix-assisted laser desorption/ionization time-of-flight (MALDI-ToF) mass spectrometry showed a single molecular weight distribution (Figure 3) corresponding to the expected mass of a sodium adduct of the clicked polymer **13** (calcd for $[M + Na]^+$ n = 45; 2492.3, found; 2492.1). Consequently, it was confirmed that the coumarin end group is accessible and participates in a fluorgenic CuAAC in aqueous media. The fluorescence properties of the clicked PEG were evaluated in a phosphate buffer (PB), comparable to the conditions of the bioconjugation experiments described below. Figure 4 displays the excitation and emission spectra of the polymer. The emission intensity at λ_{max} = 418 nm was found to depend linearly on the concentration in the range of 16−140 ng/mL. The excitation wavelength of λ = 340 nm was also used for analysis of the reported PEGylation experiments.

In bioconjugation experiments, typically an excess of reagents is used in order to drive the reaction to completion, especially if bulky substrates are to be conjugated. For our fluorogenic PEGylation experiments (Scheme 4), we therefore started off by using 20 equiv of 3-azido coumarin terminated PEG **4** compared to a 10 mg/mL solution of alkyne-functioanlized BSA **10** (0.15 mM) in the presence of 3 mM $CuSO_4$ and 4.5 mM Na-ascorbate. Under these conditions, a significant evolution of fluorescence was evident upon irradiation by a standard UV lamp (λ = 366 nm), within few minutes after the addition of

Scheme 1. Synthesis of an Acid Functionalized 3-Azido Coumarin Derivative 3



Scheme 2. Preparation of 3-Azido Coumarin Terminated PEG with Ester or Amide Linkage



the copper/Na-ascorbate mixture (Figure 5A). A control experiment in which no copper was added hardly showed fluorescence. The fluorescence intensity of the reaction mixture did not seem to increase further after 5 min, and at that point, the fluorescence emission spectrum was measured as depicted in Figure 5B.

The spectrum of the reaction mixture was comparable to that found for PEG **13**. Compared to the model compound PEG **13** (the emission intensity at $\lambda_{max} = 418$ nm was found to depend linearly on the concentration in the range of 16-140 ng/mL); however, the quantified intensity at $\lambda = 418$ nm was found to be approximately three times higher than expected. This implies that either PEG **13** is not a good model for the BSA−PEG conjugate or the number of alkyne moieties in the protein sample was higher than expected. The latter is unlikely because maleimides react ∼1000 times faster with free thiols compared to amines (*28*), and moreover, the excess of *N*-propargyl

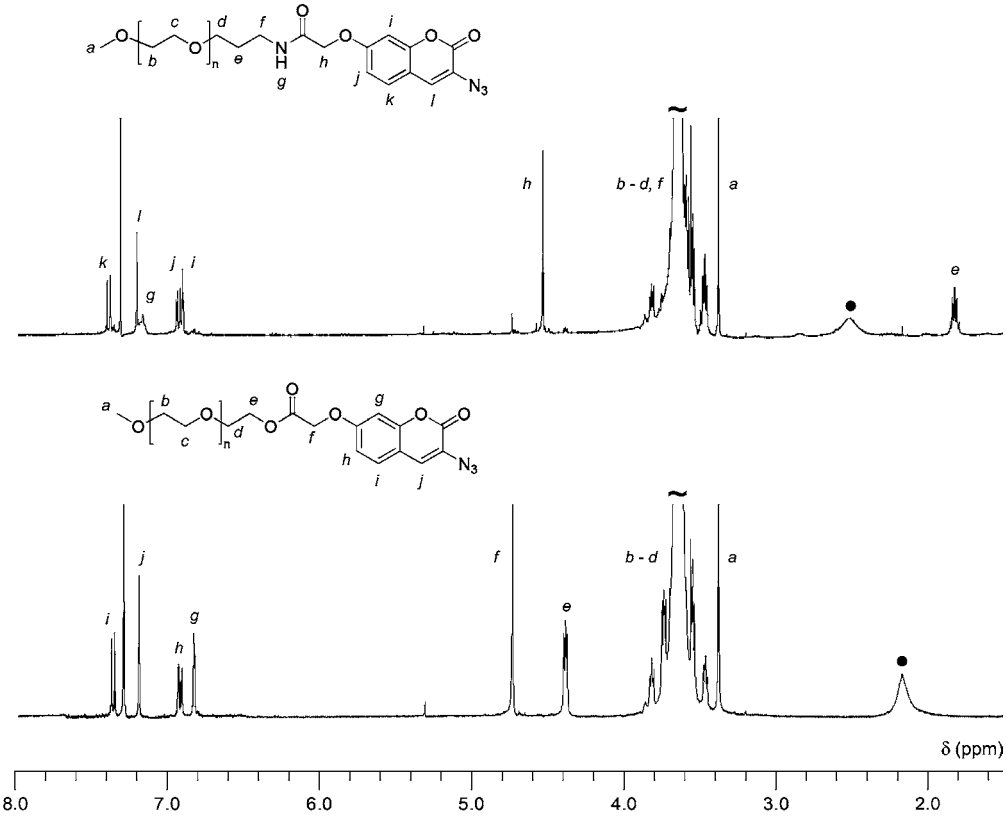


Figure 2. 1H NMR ($CDCl_3$, 400 MHz) spectra of 3-azido coumarin terminated PEG **4** and **8**. The broad signal indicated by ● is assigned to water.

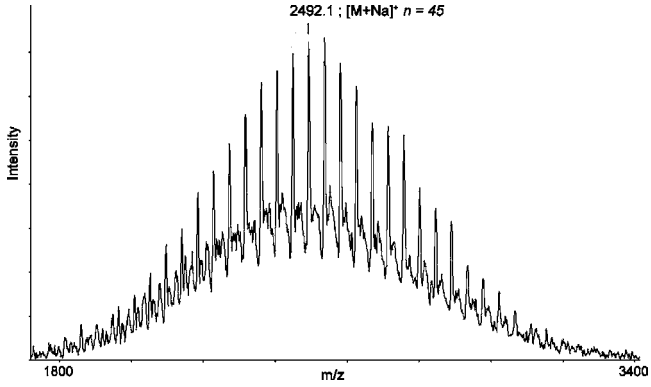

Figure 3. MALDI-ToF mass spectrum of the clicked PEG derivative **13**.

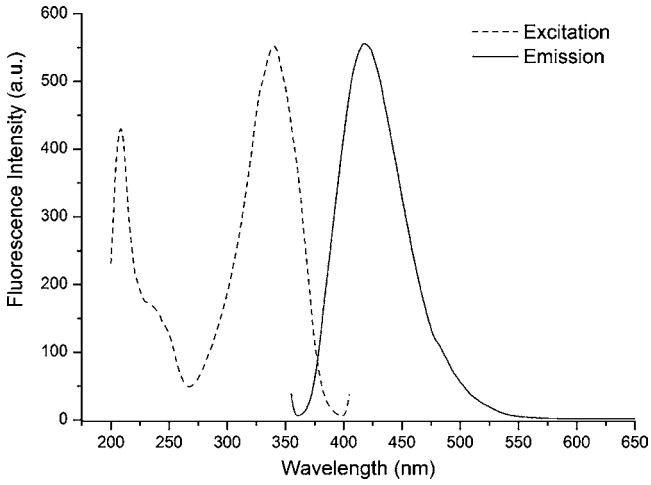

Figure 4. Fluorescence excitation (dashed) and emission (solid) spectra of clicked PEG **13** in PB (50 mM, pH 7.5); $\lambda_{ex.max} = 340$ nm, $\lambda_{em.max} = 418$ nm.

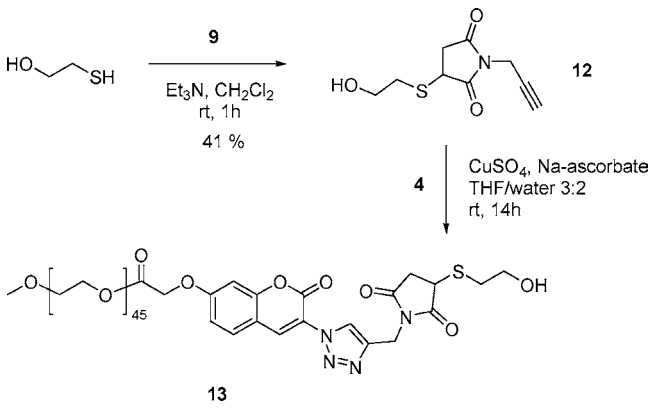
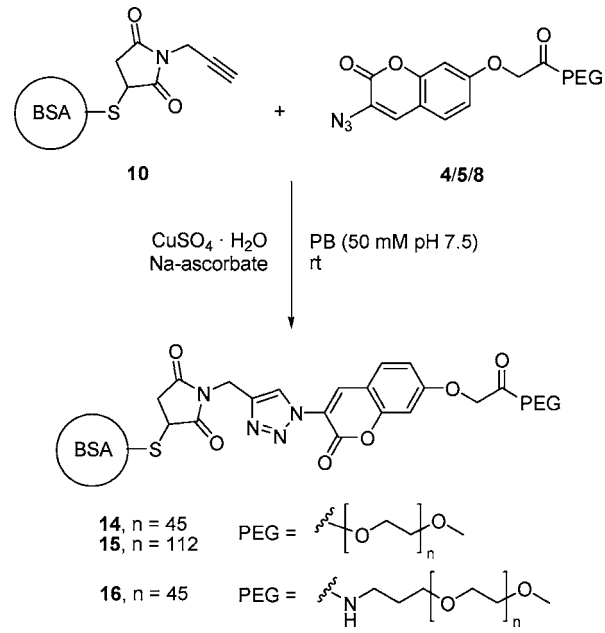
maleimide was removed by size exclusion chromatography (Sephadex G50). Furthermore, aqueous size exclusion does not point to the formation of higher molecular weight polymer−protein conjugates (see below). Another explanation for the difference in fluorescence intensity could be that the protein environment influences the photochemical properties of the coumarin, similar to effects caused by different solvents. Measuring the fluorescence spectra of PEG **13** in different solvents resulted in considerable differences in fluorescence intensity, with toluene giving a 2.3 times lower emission than ethanol or THF and 1.5 times lower than phosphate buffer. The

Scheme 3. Fluorogenic CuAAC at the 3-Azido Coumarin End Group of PEG 4



Scheme 4. CuAAC between 3-Azido Coumarin Terminated PEG (4/5/8) and Alkyne-Bearing BSA 10



polarity of the environment evidently influences the fluorescence properties of coumarin.

As a consequence, the fluorescence evolving from the protein−polymer conjugation cannot directly be quantified in terms of an absolute conversion. Nevertheless, a relative increase of intensity could be determined, which also provides information about the course of the reaction. The PEGylation reaction was therefore monitored by periodically removing samples from the reaction mixture for spectroscopic analysis. The excess of PEG was lowered to 10 equiv because the initial CuAAC appeared to be extremely fast. Again, a rapid increase in fluorescence intensity (at $\lambda = 418$ nm) was observed, and around 15 min, the measured emission was found not to increase further. Upon addition of an extra amount of catalyst, the fluorescence intensity remained constant, suggesting that the reaction was complete. Plotting the relative fluorescence intensity against time resulted in a curve comparable to a conversion plot (Figure 6). As can be seen from Figure 6, the CuAAC between PEG and BSA is very fast and reaches completion in approximately 15 min. Repeating the reaction with halved concentrations still resulted in a fast conjugation (Figure 6), which seemed to be complete after 40 min. To confirm the covalent attachment of PEG to BSA, the crude mixture at 60 min was subjected to aqueous SEC (Figure 7). This clearly showed the formation of a product with a higher molecular weight than that of starting BSA. Additionally, the newly formed compound showed UV absorbance at both $\lambda = 340$ nm and $\lambda = 280$ nm, whereas starting BSA only shows absorbance at the lower wavelength, confirming the presence of the coumarin moiety. The SEC trace of the conjugate showed some tailing, which may be caused by a residual amount of unreacted BSA; this is inevitable because in commercial batches of BSA, not all thiol groups are available for functionalization (*28*).

Next, the fluorogenic PEGylation of BSA **10** was carried out with PEG **5** and **8**, using the same conditions as discussed above. Plotting the fluorescence emission against reaction time resulted in similar curves (Figure 8), despite the differences in molecular weight between **5** and **8**/**4**. The conjugation product of the higher molecular weight PEG was analyzed by aqueous SEC, and as expected, a peak at higher molecular weight than those of BSA **10** and BSA−PEG **14** was observed. Like conjugate **14**, the peak of **15** showed UV absorbance at both $\lambda = 340$ nm and λ

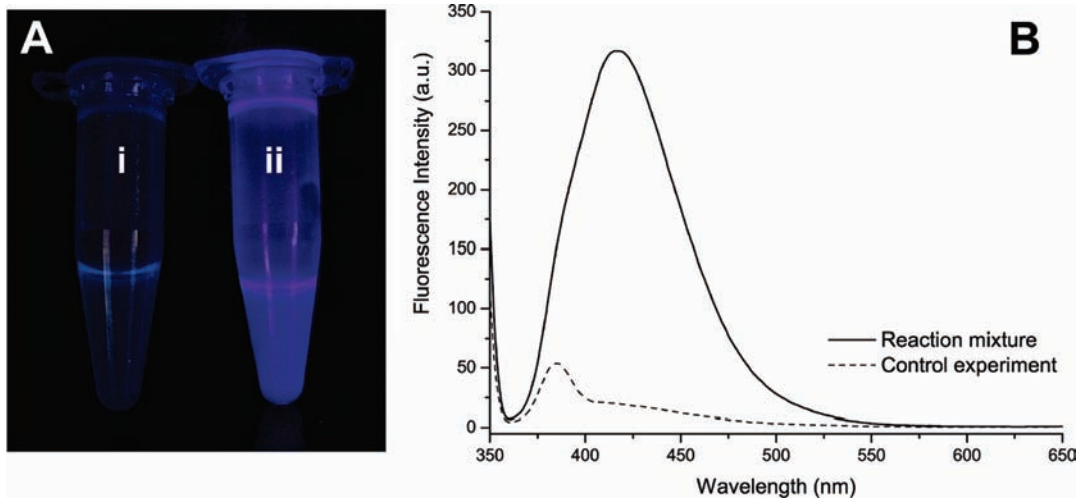


Figure 5. (A) Image taken under UV irradiation (λ = 366 nm) of fluorogenic CuAAC between PEG **4** and BSA **10**; i, control experiment without copper catalyst; ii, conjugation experiment at equal concentration of the other reactants. (B) Fluorescence emission spectrum of the conjugation reaction between **4** and **10** after 5 min (λ_{exc} = 340 nm).

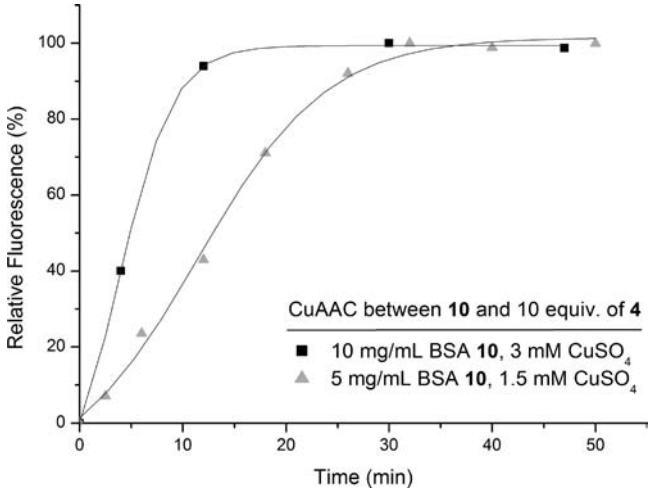

Figure 6. Increase of the fluorescence emission ($\lambda_{em.}$ = 418 nm) during the CuAAC between **4** and **10**, λ_{ex} = 340 nm. Ten equiv of PEG were used. The molar ratio of $CuSO_4$/Na-ascorbate was 1:1.5. Fluoresence is reported relative to the intensity at maximum conversion.

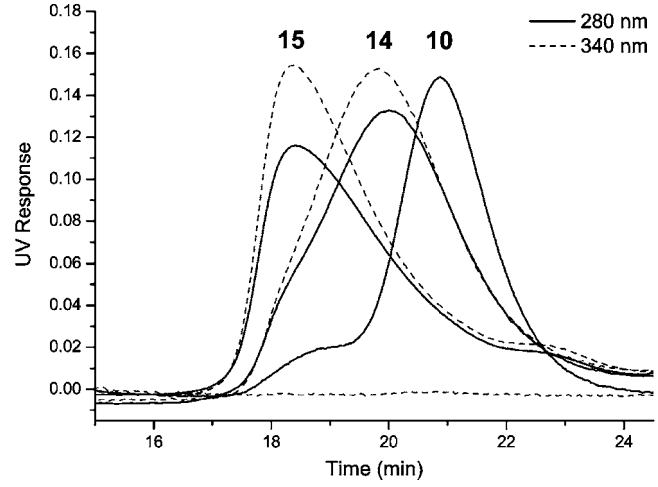

Figure 7. FPLC traces of alkyne-functionalized BSA (**10**) and crude mixtures of BSA−PEG conjugates **14** and **15** after 60 min of reaction time. Phosphate buffer (20 mM, pH 7.5) was used as the eluent in combination with UV detection at λ = 340 nm (dashed lines) and at λ = 280 nm (solid lines).

= 280 nm. The SEC results depicted in Figure 7 demonstrate that the PEGylation had effectively occurred when the fluorescence emission reached a constant level. Accordingly, the fluorescence−time plots (Figures 6 and 8) are considered to be representative for the progression of the bioconjugation reaction.

CONCLUSIONS

A fluorogenic PEGylation reaction via the CuAAC has been described. Several 3-azido coumarin terminated PEG derivatives were synthesized by coupling an acid-functionalized coumarin to a hydroxyl or amine terminus of PEG. The resulting 3-azido coumarin end group was demonstrated to participate in the CuAAC with a low molecular weight alkyne, under clear evolution of fluorescence. Likewise, the polymers were coupled to alkyne-bearing BSA, serving as a model protein. Upon bioconjugation, a clear increase in fluorescence emission was observed. Determination of the fluorescence intensity as a function of reaction time resulted in a conversion plot of the PEGylation process. Completion of the reaction could accurately be determined from the conversion curve and the covalent attachment of PEG to BSA was confirmed by aqueous SEC. Because of the presence of the coumarin moiety, the bioconjugates could easily be traced by SEC.

In summary, the CuAAC of proteins and 3-azido coumarin terminated polymers offers the possibility to monitor the bioconjugation process by a quick fluorogenic assay that is based on the progression of the reaction. This is a procedure that is fast compared to, for example, size exclusion or gel electrophoresis and furthermore allows for a visual check. Although, strictly speaking, the reported procedure at this point does not provide a tool to quantify polymer conjugation, in combination with the highly orthogonal character of the CuAAC it is reasonable to assume that polymers only couple to the acetylene groups on the protein. This is particularly the case when the acetylene groups are incorporated in the aimed protein by residue-specific introduction of noncanonical amino acids (*48*). We believe that the concept is not limited to the PEGylation example used as a proof of principle in this research. In fact, the reported concept may be ideal to screen for optimal reaction conditions in various systems, even in the more laborious coupling of immiscible polymer segments such as in the formation of protein−polymer biohybrid amphiphiles (*18*).

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, all chemicals were obtained from commercial sources and used without further

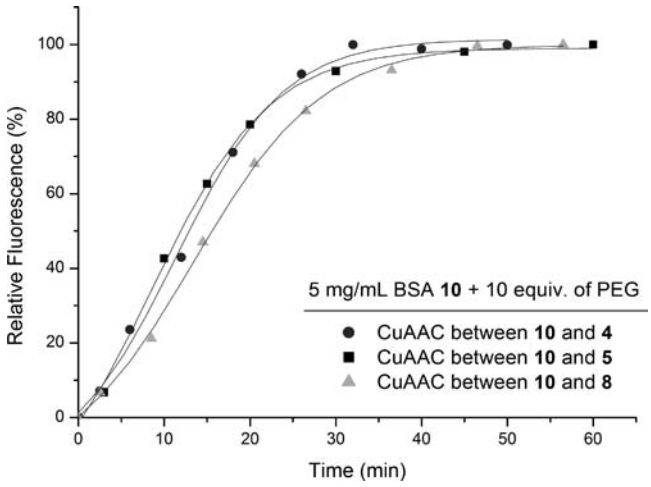

Figure 8. Increase of the fluorescence emission ($\lambda_{em.} = 418$ nm) during the CuAAC between **10** and **4**/**5**/**8**, $\lambda_{em.} = 340$ nm. The concentration of protein and $CuSO_4$ were 5 mg/mL and 1.5 mM, respectively. Ten equiv of PEG were used. The molar ratio of $CuSO_4$/Na-ascorbate was 1:2. Fluoresence is reported relative to the intensity at maximum conversion.

purification. Analytical thin layer chromatography (TLC) was performed on Merck precoated silica gel 60 F254 plates (layer thickness 0.25 mm) with visualization by ultraviolet (UV) irradiation at $\lambda = 254$ nm and/or $\lambda = 366$ nm and/or staining with $KMnO_4$ or Ninhydrin. Purifications by silica gel chromatography were performed using Acros (0.035−0.070 mm, pore diameter ca. 6 nm) silica gel. The water used in the experiments with bovine serum albumin (BSA) was deionized using a Labconco Water Pro PS purification system. THF and Et_2O were distilled under nitrogen from sodium/benzophenone. CH_2Cl_2 was distilled under nitrogen from CaH_2. Styrene was distilled under reduced pressure. Anhydrous DMF was obtained from Biosolve. BSA was obtained from Sigma.

General Instrumentation. NMR spectra were recorded on Bruker DMX300 (300 and 75 MHz for ^1H and ^{13}C, respectively) and Varian Inova 400 (400 MHz) spectrometers. ^1H NMR chemical shifts (δ) are reported in parts per million (ppm) relative to a residual proton peak of the solvent, $\delta = 7.26$ for $CDCl_3$, and $\delta = 2.50$ for DMSO-d_6. Multiplicities are reported as follows: s (singlet), d (doublet), t (triplet), q (quartet), dd (doublet of doublets), dt (doublet of triplets), dq (double quartet), ddd (double, double doublet), ddt (double, double triplet), or m (multiplet). Broad peaks are indicated by the addition of br. Coupling constants are reported as a *J* value in hertz (Hz). The number of protons (*n*) for a given resonance is indicated as *n*H and is based on spectral integration values. ^{13}C NMR chemical shifts (δ) are reported in ppm relative to DMSO-d_6 ($\delta = 39.5$) or $CDCl_3$ ($\delta = 77.0$). IR spectra were recorded on an ATI Matson Genesis Series FTIR spectrometer fitted with an ATR cell. The vibrations (ν) are given in cm^{-1}. Molecular weight distributions were measured with a Shimadzu SEC, equipped with a guard column and a PL gel 5 μm mixed D column (Polymer Laboratories) with differential refractive index (RI) and UV ($\lambda = 254$ nm and $\lambda = 340$ nm) detection using THF as an eluent (1 mL/min at 35 °C). Poly(ethylene glycol) (PEG) standards were used for calibration. Matrix assisted laser desorption/ionization time-of-flight (MALDI-ToF) spectra were measured on a Bruker Biflex III spectrometer, and samples were prepared from THF solutions using indoleacrylic acid (IAA) (20 mg/mL) as a matrix. High resolution mass spectra were recorded on a JEOL AccuToF (ESI) or a MAT900 (EI, CI, and ESI). UV−vis spectra were measured on a Varian Cary 50 spectrophotometer equipped with a RM6 Lauda temperature controller using a 1 cm path-length quartz cuvette. Protein conjugates mixtures were analyzed with a Pharmacia SMART high performance liquid chromatography (HPLC) system, equipped with a Superdex 75 PC 3.2/30 column (optimal separation 3−70 kDa) (Pharmacia) using phosphate buffer (20 mM, pH 7.5) as an eluent (50 μL/min at room temperature) in combination with UV detection ($\lambda = 280$ nm and $\lambda = 340$ nm). Prior to injection, crude reaction mixtures were diluted to a protein concentration of 1.25 mg/mL and filtered over a 0.2 μm nylon filter. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was performed using 10% polyacrylamide gels. To denaturate the samples, β-mercapto ethanol was added, and the samples were heated at 95 °C for 10 min. Staining was accomplished using Coomassie blue.

Fluorescence Experiments. Fluorescence measurements were performed on a Perkin-Elmer luminescence spectrometer LS 55 equipped with a RM6 Lauda temperature controller fixed at 23 °C. A 1 cm path-length quartz cuvette was used, and after measurements of protein containing samples, the cuvette was washed thoroughly with deionized water and EtOH. Samples from the bioconjugation experiments were prepared by withdrawing 40 μL of reaction medium followed by dilution in the reaction buffer to a protein concentration of 0.59 μg/mL. The excitation wavelength was set at 340 nm, and the spectra were recorded using excitation and emission slits of 10 nm.

3-Azido-7-hydroxy Coumarin (1). This compound was prepared according to a literature procedure and was obtained as a light brown solid (12% yield). ^1H NMR (DMSO-d_6, 400 MHz): $\delta = 10.53$ (s, 1 H, O*H*), 7.60 (s, 1 H, coumarin H_4), 7.48 (d, $J = 8.5$ Hz, 1 H, coumarin H_5), 6.81 (dd, $J = 8.5$, 2.3 Hz, 1 H, coumarin H_6), 6.76 (d, $J = 2.3$ Hz, 1 H, coumarin H_8). ^{13}C NMR (DMSO, 75 MHz): $\delta = 160.3$, 157.3, 152.7, 129.1, 127.8, 121.1, 113.8, 111.3, 102.0. FT-IR (ATR): 3291, 2115 (νN_3), 1679, 1616, 1303.

3-Azido-7-(*tert*-butylcarboxy methoxy) Coumarin (2). 3-Azido-7-hydroxy-coumarin (803 mg; 3.95 mmol) and K_2CO_3 (580 mg; 4.20 mmol) were suspended in anhydrous DMF (15 mL) under an argon atmosphere and stirred for 10 min at room temperature. The mixture was heated to 40 °C, and *tert*-butyl-2-bromoacetate (584 μL; 3.96 mmol) was added. The mixture was stirred for 3.5 h at 40 °C, after which completion of the reaction was determined by TLC (EtOAc/heptane; 1:1 v/v). After dilution with EtOAc (200 mL), the mixture was washed with water (2 × 150 mL). The aqueous phases were extracted with EtOAc (100 mL), and the combined organic phases were dried over anhydrous Na_2SO_4 and filtered. Upon concentration under reduced pressure, the crude product was obtained as a brown oil. The oil was dissolved in CH_2Cl_2 (10 mL), and this solution was added dropwise to *n*-pentane (400 mL) under stirring, forming a brown precipitate and a yellow solution. After filtration, the precipitation procedure was repeated for the residue. The filtrates were combined and concentrated under reduced pressure, affording the product as a yellowish-brown solid (960 mg, 77%) $R_f = 0.7$ (EtOAc/heptane; 1/1), ^1H NMR (DMSO-d_6, 300 MHz): $\delta = 7.63$ (s, 1H, coumarin H_4), 7.58 (d, $J = 8.6$ Hz, 1H, coumarin H_5), 7.02 (d, $J = 2.4$ Hz, 1H, coumarin H_8), 6.97 (dd, $J = 2.5$, 8.6 Hz, 1H, coumarin H_6), 4.8 (s, 2H, OC*H*$_2$CO$_2$), 1.43 (s, 9H, O^{t}Bu). ^{13}C NMR (DMSO-d_6, 75 MHz): $\delta = 167.3$, 159.7, 157.1, 152.4, 128.8, 127.1, 122.6, 113.2, 101.4, 81.7, 65.3, 27,7. FT-IR (ATR): 2120 (νN_3), 1744, 1722, 1618, 1139.

3-Azido-7-(carboxy methoxy) Coumarin (3). To a solution of 3-azido-7-(*tert*-butylcarboxy methoxy) coumarin (**2**; 700 mg, 2.21 mmol) in CH_2Cl_2 (30 mL) was added trifluoro acetic acid (TFA; 1.5 mL, 20 mmol), and the mixture was stirred at room temperature for 18 h. The reaction was determined to be almost complete by TLC (EtOAC/heptane, 1/1). An extra amount of TFA (1.5 mL, 20 mmol) was added, and the mixture was

allowed to stir for an additional 3 h. The reaction mixture was diluted with CH_2Cl_2 (150 mL) and washed with water (75 mL) and a 10% aqueous solution of citric acid (75 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*, yielding an brownish-orange solid (434 mg, 75%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ = 13.13 (br s, 1H, COO*H*), 7.64 (s, 1H, coumarin H_4), 7.58 (d, J = 8.6 Hz, 1H, coumarin H_5), 7.03 (d, J = 2.5 Hz, 1H, coumarin H_8), 6.98 (dd, J = 2.5, 8.6 Hz, 1H, coumarin H_6), 4.81 (s, 2H, OC*H*$_2$COOH). ^{13}C NMR (DMSO-d_6, 75 MHz): δ = 169.6, 159.8, 157.1, 152.4, 128.8, 127.2, 122.5, 113.2, 112.9, 101.4, 64.9. FT-IR (ATR): 2152 (νN$_3$), 1748, 1725, 1621, 1245, 1221, 1156. HRMS (ESI-) calcd for $C_{11}H_6N_3O_5$ $(M - H)^-$: 260.03075; found, 260.03172.

Ester-Linked 3-Azido-coumarin Terminated Poly(ethylene glycol). Polymers **4** and **5** were prepared following a similar procedure. Procedure for **4**: To a flame-dried Schlenk vessel were added α-methoxy poly(ethylene glycol) (mPEG, M_n = 2000 g/mol; 259 mg, 0.130 mmol), 3-azido-7-(carboxy methoxy) coumarin (**3**; 51 mg, 0.20 mmol), 4-(dimethylamino)-pyridine (DMAP; 9 mg, 0.07 mmol), and anhydrous CH_2Cl_2 (4 mL) under an argon atmosphere. Next, the mixture was cooled to 0 °C and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC·HCl; 38 mg, 0.20 mmol) was added. The mixture was stirred at 0 °C for 1 h followed by 40 h at room temperature. After dilution with CH_2Cl_2 (150 mL), the mixture was washed with a saturated aqueous solution of $NaHCO_3$ (2 × 100 mL) and a saturated aqueous solution of NH_4Cl (100 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure until approximately 5 mL of the mixture remained. Upon precipitation in Et_2O (450 mL), the product was obtained as a yellow−orange solid (216 mg, 73%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 7.35 (d, J = 8.7 Hz, 1H, coumarin H_5), 7.18 (s, 1H, coumarin H_4), 6.92 (dd, J = 2.5, 8.7 Hz, 1H, coumarin H_6), 6.82 (d, J = 2.4 Hz, 1H, coumarin H_8), 4.73 (s, 2H, OC*H*$_2$CO$_2$), 4.41−4.36 (m, 2H, CH$_2$C*H*$_2$OCO), 3.64 (br s, 180H, PEG backbone), 3.38 (s, 3H, OC*H*$_3$). FT-IR (ATR): 2883, 2123 (νN$_3$), 1960, 1725, 1619, 1466, 1341, 1102. SEC (THF): M_n = 1830 g/mol; M_n/M_w = 1.22.

α-Methoxy ω-(2-Cyanoethyl) Poly(ethylene glycol) (6). A solution of α-methoxy poly(ethylene glycol) (mPEG, M_n = 2000 g/mol; 4.0 g, 2.0 mmol) in acrylonitrile (20 mL) was cooled to 0 °C before adding KOH (10 mg, 0.18 mmol). The mixture was stirred at 0 °C for 2.5 h, after which the mixture turned slightly yellow. At this point, the reaction was quenched by the addition of a drop of concentrated HCl. Subsequently, the mixture was concentrated under reduced pressure resulting in an off-white solid (3.94 g, 96%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 3.73 (t, J = 6.4 Hz, 2H, overlap with signal at 3.64 ppm, OC*H*$_2$CH$_2$CN), 3.64 (br s, 180H, PEG backbone), 3.38 (s, 3H, OC*H*$_3$), 2.64 (t, J = 6.4 Hz, 2H, OCH$_2$C*H*$_2$CN). FT-IR (ATR): 2883, 2249, 1960, 1466, 1340, 1106.

α-Methoxy ω-(3-Aminopropyl) Poly(ethylene glycol) (7). To a cooled (0 °C) solution of borane−THF complex (5 mL 1 M in THF, 5 mmol) in anhydrous THF (15 mL) was added a solution of α-methoxy ω-(2-cyanoethyl) PEG (**6**; 2.01 g, 0.979 mmol) in anhydrous THF (10 mL) under an argon atmosphere. The mixture was stirred at 0 °C for 30 min, after which it was heated to reflux for 4 h. The mixture was cooled again to 0 °C, and MeOH (5 mL) was added dropwise (resulting in the evolution of hydrogen gas). Next, HCl (0.25 mL) was added slowly, and the mixture was stirred for 1 h, after which it was concentrated under reduced pressure. Trimethyl borate was removed by coevaporation with MeOH (3 × 50 mL). An aqueous solution of NaOH (1 M, 50 mL) was added to the residue, and the resulting mixture was extracted with CH_2Cl_2 (2 × 100 mL). The organic phases were dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*, yielding a white solid (1.94 g, 96%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 3.64 (br s, 180H, PEG backbone), 3.55 (m, 2H, overlap with signal at 3.64 ppm, OC*H*$_2$CH$_2$CH$_2$), 3.38 (s, 3H, OC*H*$_3$), 2.80 (t, J = 6.2 Hz, 2 H, CH$_2$C*H*$_2$NH$_2$), 1.73 (m, 2H, OCH$_2$C*H*$_2$CH$_2$). FT-IR (ATR): 2882, 1960, 1466, 1340, 1101.

Amide-Linked 3-Azido Coumarin Terminated Poly(ethylene glycol) (8). To a flame-dried Schlenk vessel were added α-methoxy ω-(3-aminopropyl) poly(ethylene glycol) (**7**; 252 mg, 0.122 mmol), 3-azido-7-(carboxy methoxy) coumarin (**3**; 48 mg, 0.18 mmol), 4-(dimethylamino)-pyridine (DMAP; 38 mg, 0.31 mmol), and anhydrous CH_2Cl_2 (4 mL) under an argon atmosphere. Next, the mixture was cooled to 0 °C and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC·HCl; 36 mg, 0.19 mmol) was added. The mixture was stirred at 0 °C for 1 h followed by 40 h at room temperature. After dilution with CH_2Cl_2 (150 mL), the mixture was washed with a saturated aqueous solution of $NaHCO_3$ (2 × 100 mL) and a 10% aqueous solution of citric acid (100 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure, affording a yellow−orange solid (249 mg, 88%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 7.39 (d, J = 8.6 Hz, 1H, coumarin H_5), 7.2 (s, 1H, coumarin H_4), 7.16 (br s, 1H, CH$_2$N*H*CO), 6.93 (dd, J = 2.5, 8.6 Hz, 1H, coumarin H_6), 6.90 (d, J = 2.4 Hz, 1H, coumarin H_8), 4.53 (s, 2H, OC*H*$_2$CONH), 3.64 (br s, 180H, PEG backbone), 3.60−3.53 (m, overlaps with signal at 3.64 ppm), 3.38 (s, 3H, OC*H*$_3$), 1.83 (q, J = 5.9 Hz, 2H, OCH$_2$C*H*$_2$CH$_2$). FT-IR (ATR): 2883, 2125 (νN$_3$), 1964, 1714, 1666, 1619, 1466, 1341. 1104. SEC (THF): M_n = 1830 g/mol; M_n/M_w = 1.24.

***N*-Propargyl Maleimide (9).** Propargylamine (330 μL, 4.84 mmol) was dissolved in a saturated aqueous solution of $NaHCO_3$ (40 mL) and cooled on an ice bath. Then *N*-(methoxy carbonyl) maleimide (751 mg, 4.81 mmol) was added in portions over 20 min under vigorous stirring. The mixture was stirred for 30 min at 0 °C, followed by 45 min at room temperature. After extraction with CH_2Cl_2 (3 × 50 mL), the organic phase was dried over anhydrous Na_2SO_4, filtered, and concentrated *in vacuo*. Purification by silica gel column chromatography (EtOAc/heptane, 1:2) yielded the product as a colorless oil after coevaporation with CH_2Cl_2 and would eventually lead to white crystals (291 mg, 45% yield). R_f = 0.56 (EtOAc/heptane, 1:1 v/v) ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 6.76 (s, 2H, *H*C=C*H*); 4.30 (d, J = 2.5 Hz, 2H, C*H*$_2$C'CH); 2.22 (t, J = 2.5 Hz, 1H, C'C*H*) ^{13}C NMR (75 MHz, $CHCl_3$): δ = 169.2, 134.4, 76.9, 71.5, 26.8. FT-IR (ATR): 3272, 3100, 2972, 2127, 1698, 1430, 1402, 1315, 1348, 1154 cm^{-1}. HRMS (EI+) *m/z* calcd for $C_7H_5NO_2$: 135.0320; found, 135.0324.

3-(2-Hydroxy ethylsulfanyl)-*N*-propargyl-succinimide (18). 2-Mercaptoethanol (25 μL, 0.36 mmol) was added to a solution of *N*-propargyl-maleimide (40 mg, 0.30 mmol) and Et_3N (50 μL, 0.36 mmol) in anhydrous CH_2Cl_2 (2 mL), under an argon atmosphere. The mixture was stirred at room temperature for 1 h. After dilution with CH_2Cl_2 (10 mL), the mixture was washed with 1 M aqueous HCl (2 × 10 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure, affording the crude product as a colorless oil. Purification by preparative TLC (EtOAc/heptane, 4:1 v/v) yielded the desired compound as a colorless oil (26 mg, 41% yield). R_f = 0.41 (EtOAc/heptane, 4:1 v/v) ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 4.28 (d, J = 2.5 Hz, 2H, C*H*$_2$C'CH), 3.91 (dd, J = 4.1, 9.3 Hz, 1H, CH$_2$C*H*S), 3.92−3.87 (m, 2H, CH$_2$C*H*$_2$OH), 3.22 (dd, J = 9.3, 18.8 Hz, 1H, C*H*$_2$CHS), 3.16 (ddd, J = 4.8, 6.1, 14.4 Hz, 1H, SC*H*$_2$), 2.91 (ddd, J = 4.9, 6.4, 14.4 Hz, 1H, SC*H*$_2$), 2.60 (dd, J = 4.1, 18.8 Hz, 1H, C*H*$_2$CHS) 2.63−2.58 (br m, 1H, O*H*), 2.22 (t, J = 2.5 Hz, 1H,

C'C$\underline{H}$). ^{13}C NMR (75 MHz, $CHCl_3$): δ = 176.2, 173.0, 76.1, 71.8, 61.8, 39.5, 36.3, 35.7, 28.2. FT-IR (ATR): 3421, 3282, 2925, 2850, 2565, 2250, 2127, 1703, 1422, 1392, 1343, 1174, 1060 cm^{-1}. HRMS (ESI+) *m/z* calcd for $C_7H_{11}NO_3SNa$: 236.03544 $(M + Na)^+$; found, 236.03573.

CuAAC between 3-(2-Hydroxy ethylsulfanyl)-*N*-propargyl-succinimide (12) and 3-Azido-coumarin Terminated Poly(ethylene glycol) (4). To a solution of 3-(2-hydroxy ethylsulfanyl)-*N*-propargyl-succinimide (12.5 mg, 58.6 μmol) and 3-azido coumarin terminated PEG **4** (50 mg, 22 μmol) in THF (1.5 mL) was added a mixture of $CuSO_4 \cdot 5H_2O$ (7.0 mg, 28 μmol) and Na-ascorbate (8.3 mg, 42 μmol) in water (1 mL). Upon stirring for 14 h at room temperature, the mixture showed a strong fluorescence when irradiated with UV light (λ = 366 nm). The mixture was diluted with an aqueous solution of ethylenediaminetetraacetic acid (EDTA; 25 mL, 0.065 M) and extracted with CH_2Cl_2 (3 × 25 mL). The combined organic layers were washed with water (25 mL) and dried over anhydrous Na_2SO_4. After filtering and drying *in vacuo*, the crude product was taken up in CH_2Cl_2 (1 mL) and precipitated in Et_2O (15 mL). Upon centrifugation, a yellowish pellet was obtained, which was washed with Et_2O and dried *in vacuo* to yield an off-white to yellowish solid (26 mg, 47% yield). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 8.60 (s, 1H, triazole H), 8.49 (s, 1H, coumarin H_4), 7.59 (d, J = 8.8 Hz, 1H, coumarin H_5), 7.01 (dd, J = 2.5, 8.7 Hz, 1H, coumarin H_6), 6.89 (d, J = 2.4 Hz, 1H, coumarin H_8), 4.91 (s, 1H, OC$\underline{H}_2$CO$_2$), 4.78 (s, 1H, NC$\underline{H}_2$C=CH), 4.41−4.38 (m, 2H, CH$_2$C$\underline{H}_2$OCO), 3.91 (dd, J = 4.0, 9.3 Hz, 1H, CH$_2$C$\underline{H}$S), 3.89−3.83 (m, 2H, CH$_2$C$\underline{H}_2$OH), 3.65 (br s, PEG backbone), 3.37 (s, 3H, OC$\underline{H}_3$), 3.22 (dd, J = 9.3, 18.8 Hz, 1H, C$\underline{H}_2$CHS), 3.09 (ddd, J = 4.7, 6.1, 14.4 Hz, 1H, SC$\underline{H}_2$), 2.89 (ddd, J = 4.9, 6.4, 14.4 Hz, 1H, SC$\underline{H}_2$), 2.67 (dd, J = 4.0, 18.8 Hz, 1H, C$\underline{H}_2$CHS). MALDI-ToF MS (IAA): calcd for $[M + Na]^+$ n = 45; 2492.3, *m/z* found = 2492.1.

Alkyne-Functionalized Bovine Serum Albumin (10). BSA (66 mg, 1.0 μmol) was placed in a Greiner tube and dissolved in phosphate buffer (PB) (1.5 mL; 50 mM, pH 7.5) by gently mixing for 30 min. Next, a solution of *N*-propargyl maleimide (8 mg, 59 μmol) in THF (0.5 mL) was added, and the mixture was gently mixed on a roller bank for 1.5 h, with exclusion of light. Excess *N*-propargyl maleimide was removed by passing the mixture through a sephadex (G50) column using phosphate buffer (50 mM, pH 7.5) as the eluent. The fractions containing BSA (judged by UV−vis spectroscopy) were combined and stored at 4 °C until further use (typically within a few days). The final concentration was determined by UV−vis spectroscopy using a molar extinction coefficient of 42316 M^{-1} cm^{-1}.

CuAAC of Alkyne-Functionalized BSA (10) and 3-Azido-7-hydroxy-coumarin (1). To an Eppendorf tube was added a solution of alkyne-functionalized BSA **10** (2.1 mg, $3.2 \cdot 10^{-2}$ μmol) in PB (250 μL, 50 mM, pH 7.5) and a solution of 3-azido-7-hydroxy-coumarin (0.18 mg, 0.89 μmol) in THF (54 μL). After the addition of a catalyst mixture (54 μL) containing $CuSO_4 \cdot 5H_2O$ (0.16 mg, 0.63 μmol) and Na-ascorbate (0.19 mg, 0.95 μmol) in PB (50 mM, pH 7.5), the reaction vial was placed on a roller bank for 18 h. The mixture was analyzed by fluorescence spectroscopy and SDS−PAGE without further purification.

Typical Procedure for CuAAC between Alkyne-Functionalized BSA (10) and 3-Azido-coumarin Terminated PEGs. A Greiner tube was loaded with an argon-purged solution of alkyne-functionalized BSA **10** (2.5 mg, $3.8 \cdot 10^{-2}$ μmol) in PB (300 μL, 50 mM, pH 7.5) and a solution of PEG **4** (0.93 mg, 0.41 μmol) in argon-purged PB (100 μL). After the addition of a catalyst mixture (100 μL) containing $CuSO_4 \cdot 5H_2O$ (0.19 mg, 0.76 μmol) and Na-ascorbate (0.29 mg, 1.46 μmol) in argon-purged PB (50 mM, pH 7.5), the reaction mixture was gently shaken, and samples were withdrawn periodically for spectroscopic analysis. Reactions between alkyne-functionalized BSA **10** and PEG **5** or **6** were carried out using a comparable protocol.

ACKNOWLEDGMENT

We thank Eva Sans i Atxer and Eline Mol for their assistance at the initial stage of this research. This work was financially supported by the research school NRSC-Catalysis, the Chemical Council of The Netherlands Organization for Scientific Research (CW-NWO), the European Science Foundation (ESF), and the Royal Netherlands Academy of Arts and Sciences (KNAW).

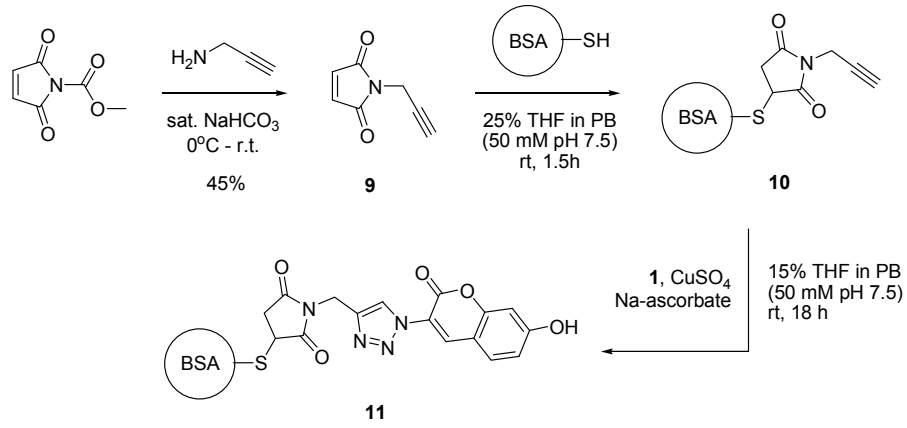
To evaluate the concept of monitoring protein-polymer conjugation by a fluorogenic CuAAC, we selected alkyne-functionalized BSA **10** as a model protein, this protein can readily be prepared by coupling *N*-propargyl maleimide (**9**) to residue CYS34 of commercially available BSA. Previously, *N*-propargyl maleimide was prepared in a two-step procedure, involving the opening of maleic anhydride with propargyl amine followed by a ring closure (*1*). However, an alternative protocol starting from *N*-methoxycarbonyl maleimide (Scheme S1) was later found to rapidly produce the desired maleimide **9** in one clean reaction step. Conjugation of maleimide **9** to BSA was achieved by mixing the reaction partners in phosphate buffer (50 mM, pH 7.5) containing 25 % (v/v) of THF. The resulting alkyne-bearing BSA was purified over a sephadex (G50) column. Subsequently, a CuAAC with 3-azido-7-hydroxy-coumarin (**1**) was conducted to check for a successful functionalization of the protein (Scheme S1). Analysis by fluorescence spectroscopy clearly showed an increase in fluorescence intensity (at $\lambda_{em.}$ = 385 nm, using $\lambda_{ex.}$ = 475 nm) upon the cycloaddition reaction, indicating the presence of the alkyne moiety. Additional analysis by SDS-PAGE showed a fluorescent band at the position of BSA under irradiation with a hand-held UV lamp (λ = 366 nm) (Figure S1). Since a control experiment in which the catalyst was left out did not show a fluorescent band, the results confirm the formation of covalently linked protein-coumarin conjugate **11** *via* the formation of **10**. For the thiol-maleimide coupling to prepare BSA **10**, reduction of the reaction time from 18h, as we previously reported (*2*), to 1.5 h resulted in an equally efficient functionalization reaction.



Scheme S1. Synthesis of alkyne-functionalized BSA and subsequent labeling by a CuAAC reaction with 3-azido-7-hydroxy-coumarin (**1**).

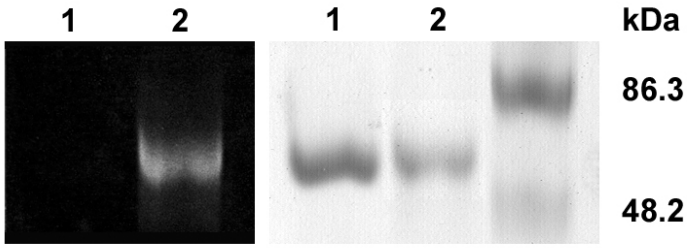


Figure 3. SDS-PAGE (10% running gel) analysis of BSA-coumarin conjugate **11** (lane 2) and a control experiment in which the catalyst was left out (lane 1). The SDS-PAGE gel was first photographed under exposure to UV light (λ = 366 nm) (left image) and subsequently stained with Coomassie Blue (right image).

17-[4-(2-[^{18}F]Fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoic Acid: A Potential Radiotracer for the Evaluation of Myocardial Fatty Acid Metabolism

Dong Hyun Kim, Yearn Seong Choe,* Joon Young Choi, Yong Choi, Kyung-Han Lee, and Byung-Tae Kim

Department of Nuclear Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, 50 Ilwon-dong, Kangnam-ku, Seoul 135-710, Korea. Received October 30, 2008; Revised Manuscript Received May 8, 2009

In this study, we synthesized 17-[4-(2-[^{18}F]fluoroethyl)−1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoic acid ([^{18}F]**1**), a PET radiotracer for the evaluation of fatty acid metabolism. [^{18}F]**1** was synthesized in 20−26% decay-corrected radiochemical yields from 17-azido 6-thia-heptadecanoic acid (**9**) and 4-[^{18}F]fluoro-1-butyne using click chemistry. The tissue distribution of [^{18}F]**1** in mice showed high radioactivity accumulation in heart (3.70%ID/g at 1 min, 3.28%ID/g at 10 min, and 3.01%ID/g at 60 min postinjection), a prolonged myocardial elimination half-life (>60 min), and a maximal heart-to-blood uptake ratio at 5 min postinjection (5.55). Pretreatment with etomoxir, a carnitine palmitoyl transferase (CPT) I inhibitor, reduced myocardial radioactivity uptake at 30 min postinjection by 53%, suggesting that [^{18}F]**1** was transported into the mitochondria. Analyses of heart tissue samples showed that most of the radioactivity was present in a tissue pellet (62−63%) after homogenization in $CHCl_3$−CH_3OH followed by extraction with 40% urea and 5% H_2SO_4, which was mostly precipitated with addition of 50% trichloroacetic acid (TCA). These results suggest that [^{18}F]**1** undergoes metabolic trapping via β-oxidation in myocardium and, thus, suggest that it has potential use as a PET radiotracer for the evaluation of myocardial fatty acid metabolism.

INTRODUCTION

Free fatty acids are myocardial energy substrates under aerobic conditions (*1*). In the fasting state, fatty acids undergo β-oxidation, whereas in the nonfasting state, fatty acid oxidation decreases and glucose is utilized as an energy source (*2*−*4*). Therefore, radiolabeled fatty acid analogues can be used to evaluate fatty acid metabolism in myocardium using positron emission tomography (PET) or single photon emission computed tomography (SPECT).

Radioiodinated fatty acid analogues have been previously investigated in this context. 15-(*p*-[^{123}I]Iodophenyl)pentadecanoic acid ([^{123}I]IPPA) was synthesized to overcome some of the drawbacks of [^{123}I]iodoalkyl fatty acid analogues, such as in vivo deiodination and a short myocardial clearance half-time (*5*−*7*). Fatty acid analogues labeled with positron emitting radionuclides have also been developed. 1-[^{11}C]Palmitate was found to show biexponential clearance, composed of rapid washout resulting from β-oxidation and slow washout due to intracellular lipid pool turnover, and ω-[^{11}C]palmitate showed greater heart uptake than 1-[^{11}C]palmitate due to its reduced metabolism in rats (*8*−*10*). To prolong myocardial retention of fatty acid analogues, two different strategies such as methyl group substitution or the insertion of a sulfur atom at a fatty acid chain have been used. As expected, methyl group substitution at C3 of IPPA retarded its myocardial metabolism, and 15-(*p*-[^{123}I]iodophenyl)-3-methylpentadecanoic acid ([^{123}I]BMIPP) and 15-(*p*-[^{123}I]iodophenyl)-3,3-dimethylpentadecanoic acid ([^{123}I]DMIPP) were found to have prolonged myocardial retention as compared with that of [^{123}I]IPPA (*11*). [^{123}I]BMIPP showed more promise than [^{123}I]DMIPP in terms of diagnosing various myocardial disease due to its lower liver uptake (*12*). A similar effect was observed in methyl branched ω-[^{18}F]fluoroheptadecanoic acids at C3 (3-[^{18}F]MFHA) or C5 (5-[^{18}F]MFHA), and these showed higher and prolonged myocardial uptake than unsubstituted ω-[^{18}F]fluoropalmitic acid, except at initial time point (1 min) (*13*). As an alternative strategy, 4- and 6-thiafatty acid analogues were developed and shown to prolong its myocardial retention (*14*−*16*), e.g., 14-[^{18}F]fluoro-6-thia-heptadecanoic acid ([^{18}F]FTHA) was found to have excellent biological properties, e.g., high heart uptake in mice and prolonged myocardial retention (*15*). It has been proposed that [^{18}F]FTHA undergoes β-oxidation and is then metabolically trapped in myocardium. However, none of these metabolites have been identified.

Click chemistry represents triazole formation via the Cu(I)-catalyzed 1,3-cycloaddition of azides and terminal alkynes (*17*) and has been shown to be useful for synthesis of new compounds due to its simple reaction conditions, stereospecificity, wide scope of application, and so forth. Therefore, click chemistry has been used to synthesize various radiotracers, including small organic molecules and peptides (*18*−*23*).

Hence, in the present study, we applied click chemistry to synthesis of 17-[4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoic acid ([^{18}F]**1**) and evaluated the fatty acid analogue in mouse heart.

EXPERIMENTAL SECTION

Materials and Methods. Chemicals were obtained from Sigma-Aldrich (St. Louis, MO, USA). ^{1}H NMR spectra were obtained on a Varian Unity Inova 500NB (500 MHz) spectrometer (Palo Alto, CA, USA) at the Cooperative Center for Research Facilities, Sungkyunkwan University (Suwon, Korea). Chemical shifts (δ) are reported as ppm downfield of tetramethylsilane. Electron impact (EI) and fast atom bombardment (FAB) mass spectra were obtained on a JMS-700 Mstation (JEOL Ltd., Tokyo, Japan) at the Korea Basic Science Institute (Seoul, Korea). HPLC was carried out using a Thermo Separa-

tion Products System (Fremont, CA, USA) equipped with a semipreparative column (YMC C18, 5 μ, 10 × 250 mm) or an analytical column (YMC C18, 5 μ, 4.6 × 250 mm). Eluates were simultaneously monitored using a UV (220 nm) detector and a NaI(T1) radioactivity detector. TLC was performed on Merck F_{254} silica plates and analyzed using a Bioscan radio-TLC scanner (Washington, DC, USA). microPET imaging of mice was acquired using an Inveon microPET (Siemens Medical Solutions, Malvern, PA, USA).

[^{18}F]Fluoride was produced by the ^{18}O(p,n)^{18}F reaction using a cyclotron (GE Healthcare PETtrace, Uppsala, Sweden). Radioactivities were measured using a dose calibrator (Biodex Medical Systems, Shirley, NY, USA) and tissue radioactivities using a Wallac automated gamma counter (Boston, MA, USA). All animal experiments were performed in compliance with the requirements of the Samsung Medical Center Laboratory Animal Care, in accord with NIH guidelines.

Synthesis of Methyl 17-Hydroxy-6-thia-heptadecanoate (2). 11-Mercapto-1-undecanol (540 mg, 2.64 mmol) and *N*,*N*-diisopropylethylamine (DIEA; 920 μL, 5.28 mmol) were added to methyl 5-bromovalerate (413 μL, 2.91 mmol) in CH_3CN (5 mL), and the reaction mixture was stirred under N_2 at 85 °C for 18 h. After solvent had been removed in vacuo, the residue was extracted with CH_2Cl_2, washed with water, and dried over anhydrous Na_2SO_4. Flash column chromatography (3:1 hexane/ethyl acetate) gave **2** (597 mg, 71%) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.67 (s, 3H), 3.64 (t, 2H, J = 6.5 Hz), 2.53−2.48 (m, 4H), 2.33 (t, 2H, J = 7.0 Hz), 1.76−1.70 (m, 2H), 1.65−1.54 (m, 6H), 1.38−1.24 (m, 14H); MS (EI) *m*/*z* 318 (100), (M^+); HRMS calcd for $C_{17}H_{34}O_3S$ 318.2229, found 318.2230.

Synthesis of Methyl 17-Methanesulfonyloxy-6-thia-heptadecanoate (3). Compound **2** (500 mg, 1.57 mmol) was dissolved in CH_2Cl_2 (7 mL), and to this solution was added triethylamine (438 μL, 3.14 mmol). After stirring for 10 min at room temperature, methanesulfonyl chloride (243 μL, 3.14 mmol) was added dropwise at 0 °C. The reaction mixture was then stirred under N_2 at room temperature for 2 h. After quenching with 1 N HCl, the mixture was extracted with CH_2Cl_2, washed with water, and dried over anhydrous Na_2SO_4. The oily residue so obtained was purified by flash column chromatography (3:1 hexane/ethyl acetate) to give **3** (504 mg, 81%) as a pale yellow solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.22 (t, 2H, J = 7.0 Hz), 3.67 (s, 3H), 3.00 (s, 3H), 2.53−2.48 (m, 4H), 2.34 (t, 2H, J = 7.0 Hz), 1.78−1.70 (m, 4H), 1.65−1.54 (m, 4H), 1.42−1.28 (m, 14H); MS (EI) *m*/*z* 396 (9.6) (M^+); HRMS calcd for $C_{18}H_{36}O_5S$ 396.2004, found 396.2011.

Synthesis of Methyl 17-Azido-6-thia-heptadecanoate (4). Sodium azide (224 mg, 3.44 mmol) was added to **3** (455 mg, 1.15 mmol) in EtOH (6 mL), and the reaction mixture was stirred at 85 °C for 10 h. After removing solvent in vacuo, the residue was extracted with CH_2Cl_2, washed with water, and dried over anhydrous Na_2SO_4. The oily residue obtained was purified by flash column chromatography (3:1 hexane/ethyl acetate) to give **4** (327 mg, 83%) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.67 (s, 3H), 3.25 (t, 2H, J = 7.0 Hz), 2.53−2.48 (m, 4H), 2.33 (t, 2H, J = 7.0 Hz), 1.76−1.70 (m, 2H), 1.65−1.54 (m, 6H), 1.37−1.26 (m, 14H); MS (EI) *m*/*z* 343 (3.1) (M^+); HRMS calcd for $C_{17}H_{33}O_2N_3S$ 343.2293, found 343.2288.

Synthesis of Methyl 17-[4-(2-Hydroxyethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoate (5). Compound **4** (100 mg, 0.291 mmol) was added to 3-butyn-1-ol (22.1 μL, 0.291 mmol) in a mixture of *tert*-butanol (2 mL) and water (1 mL). To this solution was then added a water solution (1 mL) containing $CuSO_4 \cdot 5H_2O$ (26.8 mg, 0.08 mmol) and sodium ascorbate (40 mg, 0.20 mmol). The reaction mixture was then stirred at room temperature for 1 h, and at the end of reaction, it was extracted with CH_2Cl_2, washed with water, and dried over Na_2SO_4. The crude product obtained was purified by flash column chromatography (30:1 CH_2Cl_2/methanol) to give **5** (96 mg, 80%) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.39 (br s, 1H), 4.33 (t, 2H, J = 7.0 Hz), 3.67 (s, 3H), 2.97−2.95 (m, 2H), 2.53−2.48 (m, 4H), 2.33 (t, 2H, J = 7.5 Hz), 1.91−1.88 (m, 4H), 1.76−1.70 (m, 2H), 1.65−1.53 (m, 4H), 1.38−1.26 (m, 14H); MS (EI) *m*/*z* 413 (32.1) (M^+); HRMS calcd for $C_{21}H_{39}O_3N_3S$ 413.2712, found 413.2709.

Synthesis of Methyl 17-[4-(2-Fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoate (6). Compound **5** (80 mg, 0.19 mmol) was dissolved in CH_2Cl_2 (5 mL), and diethylaminosulfur trifluoride (DAST; 51.1 μL, 0.39 mmol) was added at −40 °C. After stirring the reaction mixture under N_2 at −40 °C for 2 h, it was warmed up to room temperature, concentrated in vacuo, and purified by flash column chromatography (1:2 hexane/ethyl acetate) to give **6** (41 mg, 52%) as a pale yellow solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.48−7.46 (m, 1H), 4.72 (dt, 2H, J = 47.0, 6.0 Hz), 4.37−4.34 (m, 2H), 3.67 (s, 3H), 3.18 (dt, 2H, J = 26.0, 6.0 Hz), 2.75−2.64 (m, 2H), 2.55−2.50 (m, 2H), 2.42−2.34 (m, 2H), 1.93−1.91 (m, 2H), 1.87−1.55 (m, 6H), 1.38−1.28 (m, 14H); MS (EI) *m*/*z* 415 (22.2) (M^+); HRMS calcd for $C_{21}H_{38}O_2N_3FS$ 415.2669, found 415.2674.

Synthesis of 17-[4-(2-Fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoic Acid (1). Compound **6** (35 mg, 0.084 mmol) was dissolved in ethanol (4 mL) and treated with 0.5 N NaOH (1 mL). After stirring at 80 °C for 2 h, the reaction mixture was cooled, neutralized with 0.1 N HCl in an ice bath, and then extracted with CH_2Cl_2. The organic fraction was dried over anhydrous Na_2SO_4 and purified by flash column chromatography (10:1 CH_2Cl_2/MeOH) to give **1** (15 mg, 44%) as a pale yellow solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.52 (s, 1H), 4.69 (dt, 2H, J = 47.0, 6.0 Hz), 4.34 (t, 2H, J = 7.5 Hz), 3.12(dt, 2H, J = 26.0, 6.0 Hz), 2.75−2.67 (m, 2H), 2.55−2.50 (m, 2H), 2.39−2.31 (m, 2H), 1.93−1.88 (m, 2H), 1.86−1.54 (m, 6H), 1.39−1.22 (m, 14H); MS (FAB) *m*/*z* 402 (16.3), (M^++H); HRMS calcd for $C_{20}H_{37}O_2N_3FS$ 402.5900, found 402.5891.

Synthesis of 17-Hydroxy-6-thia-heptadecanoic Acid (7). Compound **7** was synthesized as described in the literature (*24*). 11-Mercapto-1-undecanol (800 mg, 3.91 mmol) and KOH (439 mg, 7.83 mmol) in EtOH (8 mL) were added to 5-bromovaleric acid (711.8 mg, 3.91 mmol), and stirred under N_2 at 85 °C for 18 h. At the end of the reaction, the mixture was acidified with 2.5 M H_2SO_4. After removing solvent in vacuo, the residue was extracted with chloroform, washed with water, and dried over anhydrous Na_2SO_4. Flash column chromatography (30:1 CH_2Cl_2/methanol) gave **7** (821 mg, 69%) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.65 (t, 2H, J = 6.5 Hz), 2.54−2.49 (m, 4H), 2.50 (t, 2H, J = 7.5 Hz), 2.38 (t, 2H, J = 7.5 Hz), 1.78−1.72 (m, 2H), 1.68−1.51(m, 6H), 1.39−1.28 (m, 14H); MS (FAB) *m*/*z* 305 (100), (M^++H); HRMS calcd for $C_{16}H_{33}O_3S$ 305.2150, found 305.2155.

Synthesis of 17-Methanesulfonyloxy-6-thia-heptadecanoic Acid (8). Compound **8** was prepared using the procedure described for **3**. Flash column chromatography (2:1 hexane/ethyl acetate) gave **8** (350 mg, 63%) as a pale yellow solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 4.22 (t, 2H, J = 6.5 Hz), 3.00 (s, 3H), 2.54−2.49 (m, 4H), 2.39 (t, 2H, J = 7.0 Hz), 1.78−1.72 (m, 4H), 1.66−1.57 (m, 4H), 1.40−1.24 (m, 14H); MS (FAB) *m*/*z* 383 (22.0), (M^++H); HRMS calcd for $C_{17}H_{35}O_5S_2$ 383.1926, found 383.1931.

Synthesis of 17-Azido-6-thia-heptadecanoic Acid (9). Compound **9** was prepared using the procedure described for **4**. Flash column chromatography (50:1 CH_2Cl_2/methanol) gave **9** (165 mg, 64%) as a pale yellow solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 3.25 (t, 2H, J = 7.0 Hz), 2.54−2.49 (m, 4H), 2.39 (t, 2H, J = 7.0 Hz), 1.77−1.73 (m, 4H), 1.68−1.56 (m, 4H), 1.54−1.27

(m, 14H); MS (FAB) *m*/*z* 330 (55.0), (M^++H); HRMS calcd for $C_{16}H_{32}O_2N_3S$ 330.2215, found 330.2204.

Synthesis of 4-Tosyloxy-1-butyne (10). 3-Butyn-1-ol (175 μL, 2.31 mmol) was dissolved in distilled CH_2Cl_2 (5 mL), and to this solution was added triethylamine (323 μL, 2.31 mmol). After stirring at room temperature for 1 h, the solution was reacted with tosyl chloride (90 mg, 0.45 mmol) for 3 h at 0 °C. The mixture was then extracted with CH_2Cl_2 (30 mL × 3), washed with water, and dried over Na_2SO_4. Flash column chromatography (4:1 hexane/ethyl acetate) gave **10** (374.2 mg, 72%) as a pale yellow oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.97 (t, 1H, J = 3.0 Hz), 2.46 (s, 3H), 2.54−2.58 (m, 2H), 4.11 (t, 2H, J = 7.5 Hz), 7.35 (d, 2H, J = 8.0 Hz), 7.81 (d, 2H, J = 8.5 Hz); MS (FAB) *m*/*z* 225 (100), ($M + H)^+$; HRMS calcd for $C_{11}H_{13}O_3S$ 225.0586, found 225.0585.

Radiochemical Synthesis of [^{18}F]1. After loading a QMA cartridge with [^{18}F]F^-, radioactivity was eluted using a 1:1 solution of water and CH_3CN (600 μL) containing $K_{2,2,2}$ (13 mg, 0.03 mmol) and K_2CO_3 (3 mg, 0.02 mmol). Solvents were removed under N_2 at 90 °C, and the remaining water was removed by two azeotropic distillations using 100−200 μL aliquots of CH_3CN at 90 °C under a gentle stream of N_2. The resulting K[^{18}F]F was dissolved in CH_3CN (1 mL) and transferred to a vial containing 4-tosyloxy-1-butyne (*23*). This reaction mixture was then stirred at 100 °C for 20 min, while 4-[^{18}F]fluoro-1-butyne was distilled with acetonitrile into the second vial containing the azido precursor **9** (1.1 mg, 5.36 μmol), CuI (3.1 mg, 0.02 mmol), and sodium ascorbate (21 mg, 0.11 mmol) at −50 °C (dry ice in an acetone bath). After completing the distillation, 4-[^{18}F]fluoro-1-butyne was obtained in 43−47% decay-corrected radiochemical yields based on [^{18}F]fluoride ion. The reaction mixture was then warmed to room temperature, and DIEA (14 μL, 0.12 mmol) and water (250 μL) were added. After stirring for 15 min at 90 °C, the resulting mixture was concentrated to remove acetonitrile under N_2 at 50 °C (water bath), diluted with water (500 μL), and then injected onto a HPLC column, which was then eluted with a linear gradient (from 30:70 to 0:100) of water containing acetic acid (2.6%) and methanol over 30 min at a flow rate of 3 mL/min. The desired fraction, which eluted at 20−21 min, was collected, and solvents were removed using a rotary evaporator. Overall, decay-corrected radiochemical yields of [^{18}F]**1** from [^{18}F]fluoride ion were 20−26%. Radiotracer [^{18}F]**1** was then redissolved in ethanol and diluted in saline containing 1% bovine serum albumin (BSA) at 40 °C to give a final solution of 10% ethanol in saline containing 1% BSA. Specific activity was determined by comparing the UV peak area of the desired radiolabeled HPLC peak with those of the standard curve obtained from HPLC analyses of different concentrations of nonradiolabeled compound **1**. This HPLC analysis was performed, as described above using an analytical column at a flow rate of 1 mL/min. An aliquot of [^{18}F]**1** was coinjected with **1** into a HPLC system to confirm its identity.

Tissue Distribution. Institute of Cancer Research (ICR) mice (male, 25−28 g, 4 mice per time point) were fasted for 14 h before injecting [^{18}F]**1** (3.0 MBq/mouse) in 0.2 mL of 10% ethanol−saline containing 1% BSA via a tail vein. Mice were sacrificed by cervical dislocation at 1, 5, 10, 30, and 60 min postinjection. Samples of blood, heart, lung, liver, kidney, and bone were removed, weighed, and counted. Data were expressed as percentages of injected dose per gram of tissue (%ID/g).

In another set of experiments, 14 h fasted ICR mice (male, 25−28 g, 4 mice per time point) were injected intraperitoneally with etomoxir (40 mg/kg) at 2 h prior to a tail-vein injection of [^{18}F]**1** (3.0 MBq/mouse) (*16*). The mice were sacrificed by cervical dislocation at 10 and 30 min postinjection. The remainder of the procedure was the same as that described above.

Metabolite Analysis in Mouse Hearts. ICR mice were injected with [^{18}F]**1** (14.3 MBq) and heart tissue and urine samples were collected at 10 and 30 min postinjection. Separately, a group of mice were injected intraperitoneally with etomoxir (40 mg/kg) at 2 h before a tail-vein injection of radiotracer, and heart tissue and urine samples were collected at 30 min postinjection. Heart tissue samples were homogenized with a 2:1 mixture of $CHCl_3$−CH_3OH (1.25 mL) at 0 °C, and to this homogenate were added 40% urea (0.35 mL) and 5% H_2SO_4 (0.35 mL). This mixture was then vortexed and centrifuged at 3000 *g* for 5 min (*15*). The resulting organic and aqueous fractions, and tissue pellets were then counted. Aqueous fractions and urine samples were analyzed by HPLC using a linear gradient (from 30:70 to 0:100) of water containing acetic acid (2.6%) and methanol over 30 min at a flow rate of 1 mL/min. Organic fractions were then analyzed by TLC using CH_2Cl_2−CH_3OH (15:1) as the developing solvent. An aliquot of the organic fractions were treated with 10 N KOH at 60 °C for 1 h and analyzed by TLC as described above. On the other hand, residual tissue pellet was dissolved in 1 N NaOH at 90 °C for 1 h and treated with 50% TCA, and supernatants and precipitates were counted (*15*).

microPET Imaging of [^{18}F]1 in Normal Mice. ICR mice were fasted for 14 h before injecting [^{18}F]**1** (22.9 MBq), and microPET imaging of two anesthesized mice (28 g) was performed using an Inveon microPET. Dynamic scan of the mice was obtained for 30 min (12 frames × 10 s, 6 frames × 30 s, 5 frames × 60 s, 5 frames × 120 s, and 2 frames × 300 s), and the reconstruction was performed using ordered subset expectation maximization 3D (OSEM3D).

RESULTS

Chemistry. Nonradiolabeled compound **1** was synthesized by the Cu(I)-catalyzed 1,3-cycloaddition of azido precursor **4** and 3-butyn-1-ol, followed by OH group fluorination and methyl ester removal (Scheme 1). The methyl ester at the other end of **5** was found to be necessary for OH group fluorination using DAST to avoid side product formation. The resulting fluoro compound **6** was obtained in higher yield at low temperature (52% at −40 °C vs 11% at 0 °C). Radiotracer [^{18}F]**1** was synthesized as above using click chemistry from the 17-azido-6-thia fatty acid analogue **9** and 4-[^{18}F]fluoro-1-butyne (Scheme 2) and purified by reverse-phase HPLC; although [^{18}F]**1** was purifiable by normal-phase HPLC, the eluted peak was very broad. The radiotracer [^{18}F]**1** obtained using this technique had high radiochemical purity (>99%) and specific activity (55.4 ± 4.2 GBq/μmol), probably because unreacted 4-[^{18}F]fluoro-1-butyne was easily removed due to its low boiling point (45 °C) (*25*). The decay-corrected radiochemical yields of [^{18}F]**1** were 20−26%, and the total synthesis time required, including HPLC purification, was 80−85 min. Radiotracer [^{18}F]**1** was identified by coeluting it with nonradiolabeled compound **1** on HPLC. Use of 4-[^{18}F]fluoro-1-butyne for click chemistry with azide has advantages, such as a little perturbation of biomolecule properties and purification by distillation of 4-[^{18}F]fluoro-1-butyne, although one of the reasons for relatively low yield of [^{18}F]**1** could be derived from incomplete transfer of 4-[^{18}F]fluoro-1-butyne to the second reaction vial, due to its low boiling point.

Tissue Distribution. Since fatty acids are predominantly metabolized in the fasting state, mice were fasted for 14 h prior to experiments. After injecting [^{18}F]**1** into mice, high levels of radioactivity accumulated in blood, heart, lung, liver, and kidneys, and this heart uptake washed out slowly (3.70%ID/g at 1 min, 3.44%ID/g at 5 min, 3.28%ID/g at 10 min, 3.26%ID/g

at 30 min, and 3.01%ID/g at 60 min postinjection) with an elimination half-life of >60 min (Table 1). On the other hand, blood clearance of radioactivity was almost complete within 5 min, and the heart-to-blood uptake ratios of [^{18}F]**1** were 5.55 at 5 min and 4.97 at 10 min postinjection. Constant and low bone uptake suggested that [^{18}F]**1** underwent little metabolic defluorination in vivo (0.53−0.77%ID/g up to 30 min and 1.19%ID/g at 60 min postinjection). Moreover, pretreatment of mice with etomoxir (a CPT I inhibitor) decreased the myocardial uptake of [^{18}F]**1** by 30% and 53% at 10 and 30 min, respectively (Table 2).

Metabolite Analysis in Mouse Hearts. When heart tissues were homogenized in and extracted with a 2:1 mixture of $CHCl_3$−CH_3OH, 40% urea, and 5% H_2SO_4 (extraction efficiency of 93%), most of the radioactivity in heart tissues was found in tissue pellet (63.4:32.8:3.8 and 62.1:33.4:4.5 (tissue pellet/organic fraction/aqueous fraction) at 10 and 30 min postinjection, respectively) (Table 3). Analysis of aqueous fractions showed a radioactive peak with an HPLC retention time of 19.4−20.1 min, which was identified as [^{18}F]**1** (Figure 1A,C), although most of the radioactivity was not extracted into the aqueous fraction. HPLC analysis of the urine samples also showed the unmetabolized [^{18}F]**1** (Figure 1B,C). TLC analyses of the organic fractions showed that [^{18}F]**1** was being converted into an unidentified nonpolar compound (41:59 and 35:65 at 10 and 30 min postinjection) (Figure 2). The residual tissue pellets were dissolved in 1 N NaOH at 90 °C, which was mostly precipitated with addition of 50% TCA (88%). In addition, the amount to precipitate was reduced to 71% when mice were pretreated with etomoxir at 2 h before [^{18}F]**1** administration.

microPET Imaging of [^{18}F]1 in Normal Mice. Early PET images (first 2 min) of mice injected with [^{18}F]**1** showed high accumulation of the radioactivity in blood pool, which decreased

Table 3. Distribution of Radioactivity in the Heart Homogenates Obtained after Injecting Mice with [^{18}F]1

	% organic fraction	% aqueous fraction	% tissue pellet
10 min	32.8	3.8	63.4
30 min	33.4	4.5	62.1
30 min (etomoxir-pretreated)	54.0	7.2	38.8

rapidly with time. Heart uptake of [^{18}F]**1** was clearly shown during the whole time of the study (30 min after radiotracer injection) (Figure 3), although a high level of radioactivity was also accumulated in liver and kidneys. This result showed high myocardial uptake and prolonged myocardial retention of [^{18}F]**1** in mice.

DISCUSSION

Click chemistry concerns triazole formation via the Cu(I)-catalyzed 1,3-cycloaddition of azides and terminal alkynes and has been found to be useful for synthesizing various triazole-containing compounds (*17*). Furthermore, we synthesized 4-[^{18}F]fluoro-1-butyne, a synthon for click chemistry, and found that the 4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazolyl group is metabolically stable (*23*). The radiotracer [^{18}F]**1** was prepared from precursor **9** and 4-[^{18}F]fluoro-1-butyne using click chemistry, which did not require carboxylic acid protection (Scheme 2). Because unsubsitituted fatty acid analogues undergo rapid myocardial clearance, a sulfur atom was inserted into the fatty acid chain to stop β-oxidation beyond the sulfur-containing site. The tissue distribution of [^{18}F]**1** showed high uptake by heart tissue (3.44%ID/g at 5 min) and high heart-to-blood uptake ratios in mice. In addition, [^{18}F]**1** underwent little in vivo defluorination, whereas odd-numbered ω-[^{18}F]fluorofatty acid and ω-[^{18}F]fluoro-4-thia-hexadecanoic acid have been shown to suffer from in vivo defluorination in rodents (*16, 26*). In the present study, myocardial retention of [^{18}F]**1** was found to be greater than that of other unsubstituted fatty acid analogues (<10 min), and its elimination half-time could not be determined because it was not reached during this 60 min long study (Table 1). [^{123}I]BMIPP showed prolonged myocardial retention in rats (4.62%ID/g at 5 min, 3.63%ID/g at 30 min, 4.26%ID/g at 60 min, and 2.27%ID/g at 240 min postinjection) with an elimination half-life of ca. 4 h (*11*). 5-Methyl branched ω-[^{18}F]fluorofatty acid (5-[^{18}F]MFHA) had a heart uptake of 3.04%ID/g at 5 min postinjection in rats and an elimination half-life of ca. 30 min (*13*). [^{18}F]FTHA, 6-thiafatty acid analogue, showed high heart uptake of 39.8%ID/g at 5 min postinjection in mice with an elimination half-time of approximately 2 h (*15*).

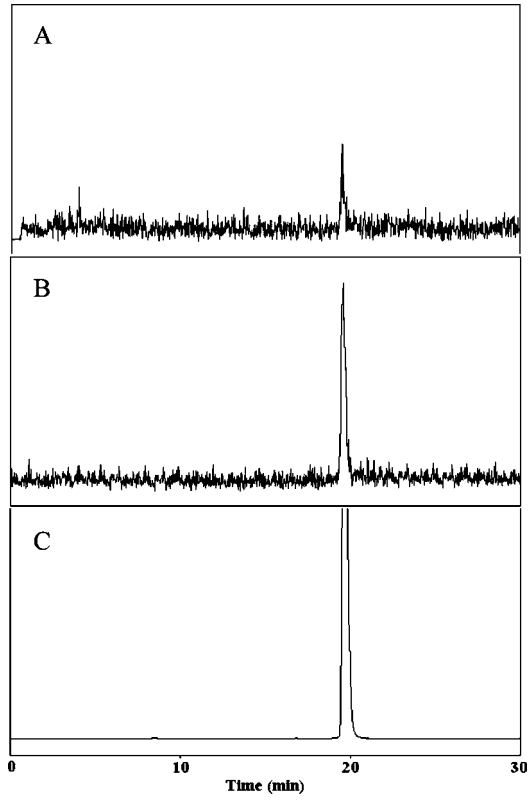

Figure 1. HPLC profiles of a water-soluble heart tissue sample (A) and a urine sample (B) obtained at 10 min after injecting mice with [^{18}F]**1** and HPLC profile of [^{18}F]**1** (C). HPLC analysis was conducted using an analytical column (YMC C18, 5 μ, 4.6 $\times$ 250 mm) and a NaI(T1) radioactivity detector.

CPT I is located in the outer membrane of mitochondria and is responsible for the transportation of long-chain fatty acids into the mitochondria. In the present study, pretreatment of mice with etomoxir (a CPT I inhibitor), prior to injecting radiotracer, was found to reduce myocardial uptake at 30 min postinjection by 53% (Table 2). In the case of [^{18}F]FTHA, 2[5(4-chlorophenyl)pentyl]oxirane-2-carboxylate, POCA (also a CPT I inhibitor) reduced myocardial uptake of radioactivity at 1 and 60 min postinjection by 81% and 87%, respectively (*15*). In addition, the myocardial uptake of 16-[^{18}F]fluoro-4-thia-hexadecanoic acid was also reduced by 81% at 30 min postinjection by etomoxir pretreatment (*16*). Although the extent of myocardial uptake inhibition by CPT I inhibitors is different, these results suggest that the fatty acid analogues are transported into the mitochondria.

It has been proposed that [^{18}F]FTHA undergoes β-oxidation and then is metabolically trapped in myocardium. DeGrado et al. suggested that [^{18}F]FTHA may be metabolized to 12-[^{18}F]fluoro-4-thia-2-pentadecanoyl-CoA and 12-[^{18}F]fluoro-4-thia-3-hydroxy-pentadecanoyl-CoA in the mitochondria (*15*). As shown in the studies by Lau et al., 4-thia-octanoyl-CoA is converted to 4-thia-octenoyl-CoA by acyl-CoA dehydrogenase and accumulates in the mitochondria, in which it is then slowly converted to β-hydroxy-4-thia-octanoyl-CoA by enoyl-CoA hydratase, and then the product splits nonenzymatically into alkyl thiol and malonylsemialdehyde CoA (*27*). As such, 12-[^{18}F]fluoro-4-thia-3-hydroxypentadecanoyl-CoA would be further converted into 8-[^{18}F]fluoroundecane-1-thiol, which has, however, not yet been confirmed (*15*). Therefore, in order to investigate the metabolites of 6-thiafatty acid analogue, metabolites of [^{18}F]**1** were analyzed using mouse heart and urine samples. When the heart tissues were homogenized in a 2:1 mixture of $CHCl_3-CH_3OH$ and subsequently extracted with 40% urea and 5% H_2SO_4, radioactivity was predominantly retained in tissue pellet, and smaller amounts were retained in the organic and the aqueous fractions. We synthesized the proposed β-oxidation metabolite of [^{18}F]**1** (15-[4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-4-thia-pentadecanoic acid) to see whether the metabolite is further used as a substrate for the subsequent β-oxidation steps in the mitochondria. The β-oxidation metabolite, 4-thia-fatty acid analogue, was not detected in either the aqueous or the organic fractions obtained from heart tissues or urine samples (Figures 1 and 2) (HPLC t_R of 15-[4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-4-thia-pentadecanoic acid = 14.2−15.1 min under the same conditions used for metabolite analysis), although a single cycle of β-oxidation was expected to occur, because the sulfur atom was inserted between C5 and C7 of [^{18}F]**1**. This result suggests that the 4-thia-fatty acid analogue could be formed and further used as a substrate for the subsequent β-oxidation steps. In the organic extracts of the heart tissue, [^{18}F]**1** was converted into the more nonpolar radiolabeled metabolite with time (Figure 2). However, our HPLC analysis showed that this nonpolar

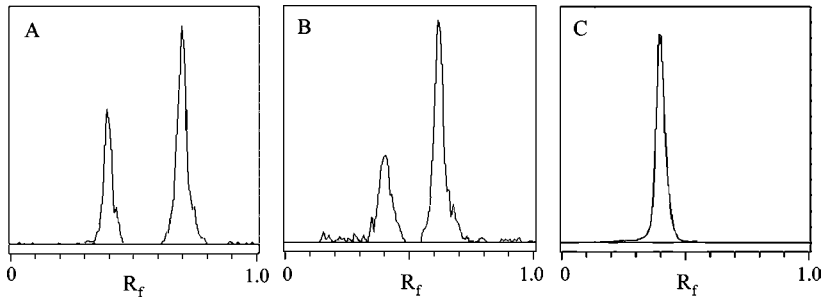

Figure 2. TLC analyses of 10 min (A) and 30 min (B) heart samples extracted with organic solvent after injecting mice with [^{18}F]**1** (R_fs = 0.4 and 0.7) and TLC analysis of [^{18}F]**1** (C) (R_f = 0.4).

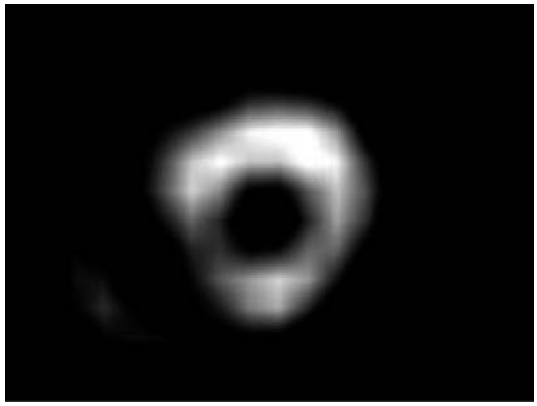

Figure 3. microPET image of midventricular short-axis slice of normal mouse heart acquired 10−20 min postinjection with [^{18}F]**1** (22.9 MBq).

radiolabeled peak did not match with 11-[4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-undecane-1-thiol, which can be obtained from β-oxidation followed by nonenzymatic fragmentation, because the peak was eluted almost 2 min before the nonradiolabeled standard thiol peak by HPLC (t_R = 16.4 min vs 18.1 min; 20:80 aqueous acetic acid (2.6%)/methanol, 1 mL/min) (data not shown). In order to identify the nature of the radiolabeled metabolite, the sulfoxide and sulfone analogues of **1** were synthesized, which were found to be more polar than [^{18}F]**1**, indicating that the radiolabeled metabolite is not the sulfoxide or sulfone analogue of [^{18}F]**1**. Furthermore, this metabolite was not hydrolyzed to [^{18}F]**1** under hot basic conditions (10 N KOH, 60 °C, 1 h), which suggests that it is not the triglyceride form of [^{18}F]**1** (*15*). Therefore, this nonpolar radiolabeled metabolite in the organic fraction remains to be identified. When residual tissue pellets were treated with TCA after dissolution in hot basic solution (1 N NaOH, 90 °C, 1 h), most of the radioactivity precipitated (88%), and the amount of precipitate was reduced to 71% with etomoxir pretreatment (Table 3). This result suggests that most of the radioactivity in the tissue pellet may be derived from protein-bound β-oxidation metabolites or alkyl thiols and that its formation is CPT I dependent. In addition, microPET image of [^{18}F]**1** in mice showed high radioactivity accumulation in heart, liver, and kidneys during the time of study, which is well-correlated with its tissue distribution data (Table 1).

CONCLUSION

Radiotracer [^{18}F]**1** was prepared using click chemistry from azido fatty acid analogue **9** and 4-[^{18}F]fluoro-1-butyne. Tissue distribution studies in mice showed high radioactivity accumulation in heart, high heart-to-blood uptake ratios, and prolonged myocardial retention. Furthermore, our analysis of heart tissue samples suggests that most of the [^{18}F]**1** is metabolically trapped via β-oxidation in myocardium, which indicates that [^{18}F]**1** should be viewed as a potential PET radiotracer for visualizing fatty acid metabolism in myocardium.

^{68}Ga-Labeling of Biotin Analogues and their Characterization

Elisabeth Blom,[†] Bengt Långström,[†,‡,§] and Irina Velikyan*[,†,‡]

Department of Biochemistry and Organic Chemistry, Box 576, Husargatan 3, BMC, S-751 23 Uppsala, Sweden, and Uppsala Applied Science Lab and Uppsala Imanet, GEHC, Box 967, S-751 09 Uppsala, Sweden. Received December 12, 2008; Revised Manuscript Received April 29, 2009

Biotin- and ^{68}Ga-based tracers have been suggested as tools that could be used to monitor the survival of avidin-coated islets of Langerhans isolated from pancreas and used in transplantation, i.e., to liver. Three biotin analogues with various alkyl and poly(ethylene glycol) (PEG) chains coupled to DOTA were synthesized and labeled with ^{68}Ga. The ^{68}Ga labeling was studied at room temperature as well as elevated temperature using either conventional or microwave heating. Radioactivity incorporation reached 95% within 5 and 2 min using the, respectively, conventional and microwave heating modes. The specific activity of the tracers was improved by preconcentration and purification of the generator eluate. The binding of the labeled and nonlabeled conjugates to avidin in solution was compared to the binding of native biotin. All compounds maintained good affinity for avidin, though introducing the linkers and chelator, especially the PEG-groups, somewhat decreased the binding affinity. The extent of binding of the labeled compounds to avidin was 54−91% after 5 min. Blocking experiments were performed confirming the specificity of the binding of biotin analogues to avidin. The stability of the three labeled compounds in human serum was studied. The stability of the biotin analogue **8** (65% within 30 min) and avidin−biotin complex (80% within 120 min) might be sufficient for the monitoring of the islets of Langerhans. The tracers will be evaluated in *in vitro* experiments of avidin-coated islets of Langerhans and in transplantation models *in vivo*.

INTRODUCTION

The transplantation of islets isolated from a donor pancreas into patients with type I diabetes for therapeutic purposes has been studied for decades, with considerable progress. However, obstacles like low graft survival and islet rejection preclude the widespread application of this strategy (*1*). An understanding of the underlying mechanisms and the ability to monitor the procedure *in vivo* would contribute considerably to development of the field. A noninvasive imaging technique like positron emission tomography (PET) may become a useful tool, to evaluate, monitor, and optimize graft survival during islet transplantation (*2*). We have explored a tracer containing ^{68}Ga as the positron emitting radionuclide on biotin analogues as the targeting compounds.

The positron-emitting radionuclide ^{68}Ga ($T_{1/2}$ = 68 min; 89% β^+-emission) is available from a long shelf-life ^{68}Ge/^{68}Ga-generator with 1−2-year shelf life provided by 270 day half-life of the parent ^{68}Ge. The half-life of ^{68}Ga permits ^{68}Ga-based radiopharmaceuticals to be produced and used. The chelator-mediated labeling chemistry is straightforward and site-specific. Biotin (5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanoic acid) is a naturally occurring vitamin that is generally found in its protein-bound form. It acts as a carboxyl carrier in four carboxylase enzymes in animals and is important in lipid, glucose, energy, and amino acid metabolism (*3*). Biotin possesses a strong binding affinity to avidin and streptavidin ($K_d \approx 10^{-15}$ M) (*4*). The quarternary structure of avidin ($M_w \approx$ 66 kDa) consists of four noncovalently bound units that combine into the active form (*5*, *6*). Therefore, each avidin unit is capable of binding four biotin molecules (*6*, *7*). This binding property can be exploited to develop a universal tracer that could be used, for example, in the management of various tumor types (*8*) based on pretargeting concept as well as in organ-transplantation medicine. The development of such a tracer would require physiological half-life of the biotin tracer to be prolonged. This feature can be tuned by the introduction of poly(ethylene glycol) (PEG) chains. The PEG polymer is linear, hydrophilic due to the hydrogen bonds to water from the ether oxygens, uncharged and flexible (*9*). It has been investigated for use as a covalent modification of biological macromolecules and surfaces for many pharmaceutical and biotechnology applications (*10, 11*). It is well-known that PEG modifications to therapeutically useful proteins and peptides improve *in vivo* stability, pharmacokinetic, immunogenic, and antigenic properties and show little toxicity (*10, 12, 13*).

The biotin−^{68}Ga-based tracer development and application is exemplified here by the exploration of a tracer that could be used for labeling islets of Langerhans in order to monitor the survival of transplanted avidin-coated islets.

In this study, three biotin counterparts with various alkyl, PEG, and DOTA modifications were synthesized, labeled with ^{68}Ga, and characterized.

EXPERIMENTAL PROCEDURES

Materials. *N*-(5-Aminopentyl)-5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanamide, *N*-{2-[2-(2-aminoethoxy)ethoxy]ethyl}-5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanamide, and *N*-(2-{2-[2-(2-aminoethoxy)ethoxy]ethoxy}ethyl)-5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanamide were obtained from Pierce Biotechnology, Inc. (Rockford, USA) and (+)-biotin was purchased from Alfa Aesar, Chemtronica. 2,2′,2″-(10-{2-[(2,5-Dioxopyrrolidin-1-yl)oxy]-2-oxoethyl}-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic acid HPF_6·TFA (DOTA-NHS-ester) was purchased from Macrocyclics (Dallas, USA). 2-[4-(2-Hydroxyethyl)piperazin-1-yl]ethane-

sulfonic acid (HEPES), trifluoroacetic acid (TFA), double-distilled hydrochloric acid (Riedel de Haën), avidin (lyophilized powder, from egg white), sodium tetraborate decahydrate (Borax), and gallium (III) chloride were obtained from Sigma-Aldrich. Sodium dihydrogen phosphate disodium hydrogen phosphate and sodium chloride were obtained from Merck eurolab. The purchased chemicals were used without further purification.

Analytical Methods. HPLC analyses of radiolabeled compounds were performed on a Beckman Nouveau HPLC system equipped with a Beckman 166 variable-wavelength UV detector and a Bioscan β^+-flow detector, using an isocratic elution with water (A) (92%) and acetonitrile (B) (8%), both containing 0.05% TFA, as mobile phase and UV detection at 223 nm. For analytical HPLC, a Grace Vydac C18 Protein and Peptide column (150 × 4.6, 5 μ) was used, with a flow of 1 mL/min. For semipreparative HPLC, a Grace Vydac C18 Protein and Peptide column (150 × 10, 10 μ), 300 Å TP silica, was used on a Gilson HPLC system at a flow of 5 mL/min. Millipore water (18 mΩ) from Purelab Maxima Elga system (Bucks, UK) was used throughout the synthesis. NMR spectra were recorded on a Varian Unity spectrometer at 400 MHz for ^{1}H or 100 MHz for ^{13}C, at 25 °C, in CD_3OD (solvent peak used as reference, ^{1}H 3.31 ppm, ^{13}C 49.00 ppm). LC-MS analysis was performed using a Micromass VG Quattro mass spectrometer with electrospray ionization. The same analytical HPLC column and mobile phases were used at a flow of 0.3 mL/min. The radioactivity was measured in an ion chamber, Veenstra Instrumenten bv, VDC-202.

Microwave Heating. Microwave heating was performed in a SmithCreator monomodal cavity (Biotage AB, Uppsala, Sweden) producing continuous irradiation at 2450 MHz (Biotage AB, Sweden). The temperature, pressure, and microwave power were monitored and controlled. Smith Process Vial microwave vials of 200−1000 μL volume were used.

Preparation of ^{68}Ga. ^{68}Ga ($T_{1/2}$ = 68 min, β^+ = 89%, and EC = 11%) was available from a ^{68}Ge/^{68}Ga generator system (Cyclotron Co., Ltd., Obinsk, Russia) in which ^{68}Ge ($T_{1/2}$ = 270 d) was attached to a column of an inorganic matrix based on titanium dioxide. The initial ^{68}Ge radioactivity loaded onto the generator column was 1850 MBq. The specified shelf-life of the generator was 1−2 years. The ^{68}Ga was eluted with 6 mL of 0.1 M hydrochloric acid.

Preconcentration Procedure (*14*). The ^{68}Ge/^{68}Ga generator was eluted with 6 mL of a 0.1 M HCl (aq) solution. To this eluate solution, 5 mL of 30% HCl was added. The resulting solution was passed through an anion-exchange column (Chromafix 30-PS-HCO_3, Macharey-Nagel (Germany)) at a flow rate of 4 mL/min. Thereafter, the ^{68}Ga ions were eluted with deionized water (4 × 50 μL) at a flow rate of 0.5 mL/min. The final solution was used for labeling reactions.

General Labeling Procedure. HEPES (0.048 g, 0.20 mmol) was dissolved in 200 μL of ^{68}Ga eluate (in 0.1 M HCl (aq)) in a 2 mL Eppendorf tube. Thereafter, an aqueous solution of biotin−DOTA conjugates (**4**−**6**) (1−70 nmol) was added, and the total volume was adjusted to 280 μL by addition of water. The pH was adjusted to 4.6−5 by adding 2 M NaOH (aq) if necessary. The reaction was conducted at room temperature or

Table 1. Retention Times on Analytical HPLC for Compounds 4−9, and log *D* Values

compound	retention time[a] (min)	compound	retention time[a] (min)	log D[b]
4	6.9	**7**	9.4	-1.71 ± 0.07
5	6.1	**8**	7.3	-1.05 ± 0.10
6	9.5	**9**	12.4	-1.50 ± 0.10

[a] Retention time on analytical HPLC column. [b] Partion coefficient for the respective ^{68}Ga-labeled compounds at pH 7.4 between 1-octanol and PBS, experiments performed in triplicate.

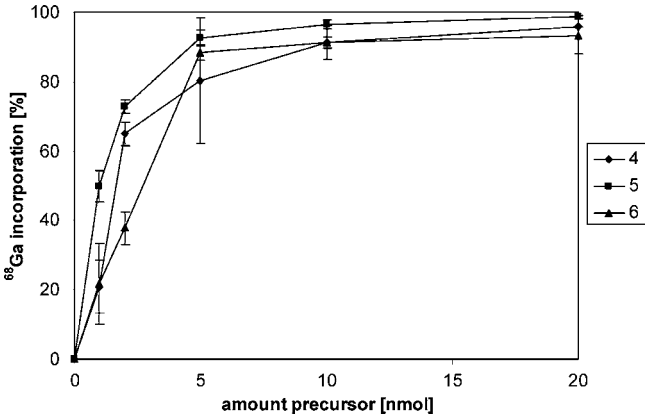

Figure 1. Percent ^{68}Ga(III) incorporation versus amount precursor (compounds **4**−**6**) used in labeling reaction. Heating was performed at 90 ± 5 °C for 5 min, in heating block. The reaction volume was 280 μL. Data are presented as mean ± SD (n = 3).

by using conventional heating at 90 ± 5 °C for 5 min or microwave heating at 90 ± 5 °C for 2 min.

Recovery. The recovery of ^{68}Ga eluate sample on the HPLC system was 88% when an analytical HPLC column was attached and 98% with no column attached. The recovery of a ^{68}Ga-Biotin-DOTA-conjugate sample was 59 ± 4% (n = 2) with column.

Synthesis of ^{69,71}Ga-Reference Compounds. HEPES (0.048 g, 0.20 mmol) was dissolved in 200 μL of ^{68}Ga eluate and the pH was adjusted to 4.6−5 by adding 2 M NaOH (aq). Thereafter, an aqueous solution of the respective precursor **4**−**6** (70 nmol) and $^{69,71}GaCl_3$ (56 mM, 2 μL, 112 nmol) was added. The reaction mixture was heated at 90 °C for 5 min.

ESI-MS: ^{69,71}Ga-**4** *m/z* 784 $[M+H]^+$, 393 $[M+2H]^{2+}$, ^{69,71}Ga-**5** *m/z* 827 $[M+H]^+$, 414 $[M+2H]^{2+}$, ^{69,71}Ga-**6** *m/z* 874 $[M+H]^+$, 438 $[M+2H]^{2+}$.

Lipophilicity. The log D (pH = 7.4) values were determined by the following procedure: a solution of the ^{68}Ga-labeled compounds **7**−**9** (20 μL, 48 μM) was added to a solution of 1-octanol and phosphate buffered saline (PBS) (presaturated with each other), containing 500 μL of each, in a 2 mL Eppendorf tube. After vortexing the obtained solutions, they were centrifuged at 3000 rpm for 10 min. Aliquots (100 μL) were removed from the two phases and the radioactivity was measured in a γ-counter. The experiments were performed in triplicate. The method was published previously (*15*).

Avidin Binding Reactions. Various amounts of biotin, compounds **4**−**6** or ^{69,71}Ga-biotin-**4**−**6** (2−128 nmol) were incubated with a constant amount of avidin (2 nmol) for 5 min at room temperature in water (150 μL total volume). The percentage binding was determined by HPLC analysis monitoring the consumption of avidin. HPLC program: 8% (B) for 12 min, then up to 80% in 10 min for compounds **4** and **5**; 8% (B) for 15 min, then up to 80% in 18 min for compound **6**. The labeled compounds **7**−**9** were incubated with avidin for 5 min at room temperature and analyzed by the same HPLC programs.

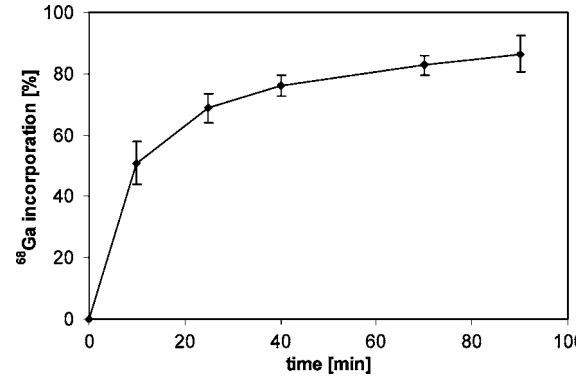

Figure 2. Percent ^{68}Ga(III) incorporation versus reaction time at room temperature, using 10 nmol of compound **5** and a reaction volume of 280 μL. Data are presented as mean ± SD (n = 3).

Blocking Experiment. Avidin (2 nmol) was incubated together with biotin (400 nmol) in water (100 μL) for 10 min. HPLC analysis confirmed the blocking. Thereafter, one of compounds **7**−**9** (8 nmol) was added and incubated together with the blocked avidin for 5 min (total volume 360 μL) before the solution was again analyzed by HPLC. HPLC program: 8% (B) for 12 min, then up to 80% in 10 min for compounds **7** and **8**; 8% (B) for 15 min, then up to 80% in 18 min for compound **9**.

Stability Studies. The stability studies were conducted using modified protocol published elsewhere (*8*). Solutions containing compounds **7**−**9** (10 μL, 0.5 nmol) were incubated for 0, 10, 30, 60, and 120 min at 37 °C together with human serum/saline 1:1 (500 μL). Thereafter, avidin (12 nmol) was added and incubated for 5 min at room temperature. Aliquots (50 μL) were withdrawn, diluted to a total volume of 500 μL with water, subsequently centrifuged in Microcon YM-10 at 14 000 rpm for 30 min, and finally washed with saline (500 μL) and centrifuged again. The fraction of intact ^{68}Ga tracer−avidin complex was determined by radioactivity counts of Microcon filter and vials (γ-counter, in house). In the case of study of the stability of the complex between compound **8** and avidin, compound **8** (8 nmol) was first incubated with avidin (2 nmol) for 5 min at room temperature. Thereafter, diluted serum (500 μL) was added; the mixtures were incubated for 0, 10, 30, 60, and 120 min at 37 °C and analyzed as described previously. The experiments were performed in triplicate.

Chemical Synthesis. *2,2′,2″-[10-(2-Oxo-2-{[5-({5-[(3aR,4R,6aS)-2-oxohexahydro-1H-thieno[3,4-d]imidazol-4-yl]pentanoyl}-amino)pentyl]amino}ethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl]triacetic Acid* (**4**). *N*-(5-Aminopentyl)-5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanamide (**1**) (0.015 g, 46 μmol) was dissolved in 250 μL aqueous sodium tetraborate decahydrate (Borax) (0.08 M, pH 9.3). The solution was cooled to 0 °C and 2,2′,2″-(10-{2-[(2,5-dioxopyrrolidin-1-yl)oxy]-2-oxoethyl}-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic acid HPF_6·TFA (0.057 g, 69 μmol) was added. The pH of the resulting solution was 2. The pH was raised to 7 by adding 200 μL of a 1:1 v/v mixture of 1 M NaOH (aq) and Borax (aq). The reaction mixture was warmed to room temperature and stirred for 24 h. Purification by semipreparative HPLC (6% (B) isocratic) gave the desired product as a colorless oil (0.011 g, 34% yield). ^{1}H NMR (400 MHz, CD_3OD, 25 °C): δ = 4.51 (dd, J = 5.1, 7.9 Hz, 1H), 4.31 (dd, J = 4.6, 7.9 Hz, 1H), 3.98 (m, 4H), 3.83 (m, 12H), 3.25−3.16 (m, 13H), 2.94 (dd, J = 4.9, 12.6 Hz, 1H), 2.73 (d, J = 12.6 Hz, 1H), 2.21 (t, J = 7.2 Hz, 2H), 1.80−1.27 (m, 12H).^{13}C NMR (100 MHz, CD_3OD, 25 °C): δ = 176.0, 165.8, 162.9, 162.0, 63.4, 61.7, 57.0, 54.6, 51.6, 51.1, 50.7, 41.0, 40.5, 40.2, 36.8, 30.1, 29.9,

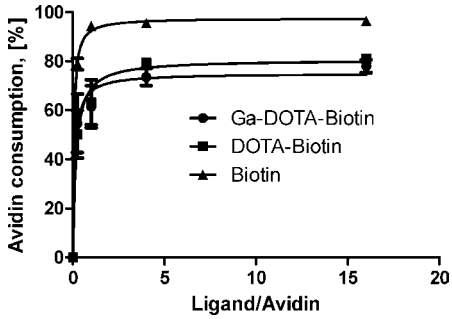

Figure 3. Saturation of the binding of a series of biotin-based counterparts (biotin, compound **5** (DOTA−biotin), and ^{69,71}Ga-labeled **5** (Ga−DOTA−biotin)) to avidin in solution, as determined by HPLC analysis. The incubation was carried out for 5 min at room temperature with varied ligand concentrations resulting in ligand/avidin ratios of 0.25, 1, 4, and 16. Data are presented as mean ± SD (n = 2).

29.7, 29.5, 26.9, 25.2. ESI-MS: *m*/*z* 715 $[M+H]^+$, 358 $[M+2H]^{2+}$. HPLC purity >99%.

*2,2′,2″-(10-{2,13-Dioxo-17-[(3aR,4R,6aS)-2-oxohexahydro-1H-thieno[3,4-d]imidazol-4-yl]-6,9-dioxa-3,12-diazaheptadec-1-yl}-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic Acid (***5***).* *N*-{2-[2-(2-Aminoethoxy)ethoxy]ethyl}-5-[(3*aR*,4*R*,6*aS*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl]pentanamide (**2**) (0.011 g, 29 μmol) was dissolved in 250 μL aqueous sodium tetraborate decahydrate (Borax) (0.08 M, pH 9.3) or 250 μL aqueous sodium dihydrogen phosphate (*16*) (0.2 M, pH 8.5). The solution was cooled to 0 °C and 2,2′,2″-(10-{2-[(2,5-dioxopyrrolidin-1-yl)oxy]-2-oxoethyl}-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic acid HPF_6·TFA (0.030 g, 36 μmol) was added. The pH of the resulting solution was 4. The pH was raised to 8 by adding 100 μL of a 1:5 v/v mixture of 1 M NaOH (aq) and Borax (aq). The reaction mixture was warmed to room temperature and stirred for 24 h. Purification by semipreparative HPLC (6% (B) isocratic) gave the desired product as a colorless oil (0.010 g, 47% yield). ^{1}H NMR (400 MHz, CD_3OD, 25 °C): δ = 4.50 (dd, J = 5.0, 8.0 Hz, 1H), 4.31 (dd, J = 4.5, 8.0 Hz, 1H), 3.92 (m, 4H), 3.83 (m, 12H), 3.64−3.62 (m, 4H), 3.60−3.54 (m, 6H), 3.41 (t, J = 5.4 Hz, 2H), 3.39−3.33 (m, 8H), 3.25−3.19 (m, 1H), 2.94 (dd, J = 5.0, 12.8 Hz, 1H), 2.72 (d, J = 12.8 Hz, 1H), 2.23 (t, J = 7.5 Hz, 2H), 1.81−1.54 (m, 4H), 1.50−1.41 (m, 2H). ^{13}C NMR (100 MHz, CD_3OD, 25 °C): δ = 176.3, 166.1, 163.3, 162.5, 71.3, 71.2, 70.6, 70.4, 63.4, 61.7, 57.0, 51.9, 49.8, 41.0, 40.4, 40.3, 36.8, 29.7, 29.5, 26.8. RESULTS AND DISCUSSION

Conjugation. The biotin−DOTA (DOTA = 2,2′,2″,2‴-(1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl)tetraacetic acid) conjugates **4**−**6** were prepared by reacting the 2,2′,2″-(10-{2-[(2,5-dioxopyrrolidin-1-yl)oxy]-2-oxoethyl}-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic acid (DOTA-NHS-ester) with the corresponding biotin−amines (**1**−**3**) in water at pH 7−8 using a mixture of sodium tetraborate decahydrate (Borax) and sodium hydroxide as buffer (Scheme 1). The yield of the product after purification by semipreparative HPLC was 34−47%. When the synthesis of compound **5** was attempted at pH 4, using sodium dihydrogen phosphate and no added sodium hydroxide as buffer, the yield was only 7%.

Labeling. The biotin conjugates were labeled with ^{68}Ga(III) cation using a solution in hydrochloric acid of the radiometal eluted from the ^{68}Ge/^{68}Ga generator system and 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonic acid (HEPES) as a buffer, as shown in Scheme 2. This buffer is biocompatible and does not need to be removed prior to biological experiments. The labeling reaction was performed at pH 4.6−5.0 at room temperature as well as 90 ± 5 °C, provided by conventional or microwave heating mode (2450 MHz). The radioactivity incorporation of ^{68}Ga(III) could reach 90% within 5 min with conventional heating, and when microwave heating was applied, the reaction time was reduced to 2 min. No major differences in incorporation yield were observed between the two heating modes. When the labeling was performed at room temperature, on the other hand, at least 90 min reaction time was required to reach 90% incorporation. The entire synthesis of the ^{68}Ga-labeled compound under elevated temperature and including subsequent HPLC analysis was accomplished within 30 min. Since the incorporation exceeded 90%, and the solution was buffered with HEPES no further purification was performed. The ^{68}Ga half-life of 68 min in combination with the short synthesis time may allow the use of the resulted tracers for biology experiments during 3−4 h.

Different linkers between the biotin and DOTA moieties of the tracer were used to explore the variability in avidin binding. An alkyl linker was used in compound **7**, and two poly(ethylene glycol) (PEG) linkers of different length were used in compounds **8** and **9**. The retention times for the ^{68}Ga-labeled compounds on the analytical HPLC column increased in the order **8** < **7** < **9**, as shown in Table 1. The "shake-flask" method, with 1-octanol and PBS (pH = 7.4), was used to determine the log D values, which are also shown in Table 1. The order of the determined log D values, **7** < **9** < **8**, was not in agreement with the retention times in HPLC analysis. One could speculate that the two analogues having PEG spacers **8** and **9** would have similar lipophilicites, and also lower compared to the analogue with an alkyl linker **7**, but this was not the case. The size of the molecules can also make contributions.

The incorporation of ^{68}Ga(III) into 1−20 nmol of compounds **4**−**6** by conventional heating at 90 ± 5 °C for 5 min was investigated. The plateau at 95% incorporation was reached at 10 nmol using the described setup, as shown in Figure 1. This amount (10 nmol) was thereafter used in the subsequent labeling reactions. The specific activity when using 10 nmol of compound **5** in labeling reactions was 9 ± 3 GBq/μmol starting from 140 ± 30 MBq (n = 4).

The incorporation kinetics of ^{68}Ga(III) at room temperature was explored using 10 nmol of compound **5** (Figure 2).

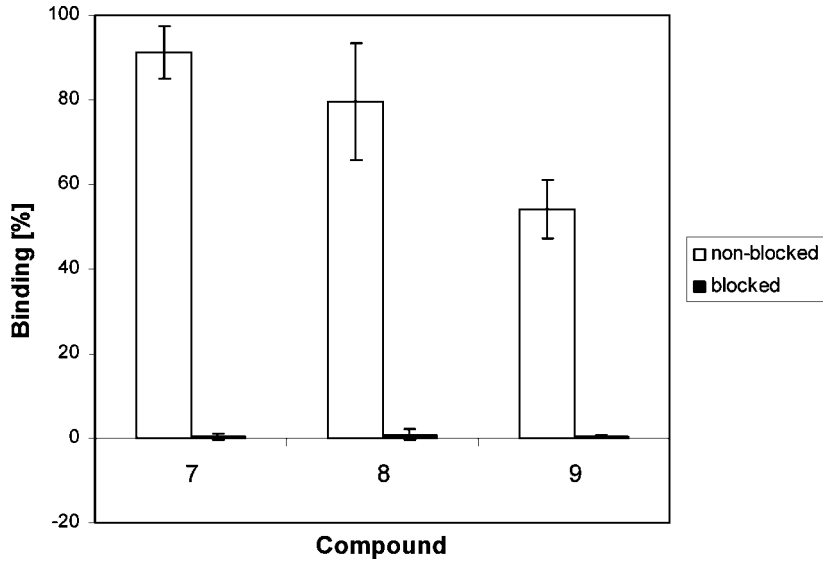

Figure 4. Percent binding of compounds **7**−**9** to avidin, blocked and nonblocked. Data are presented as mean ± SD ($n = 2$).

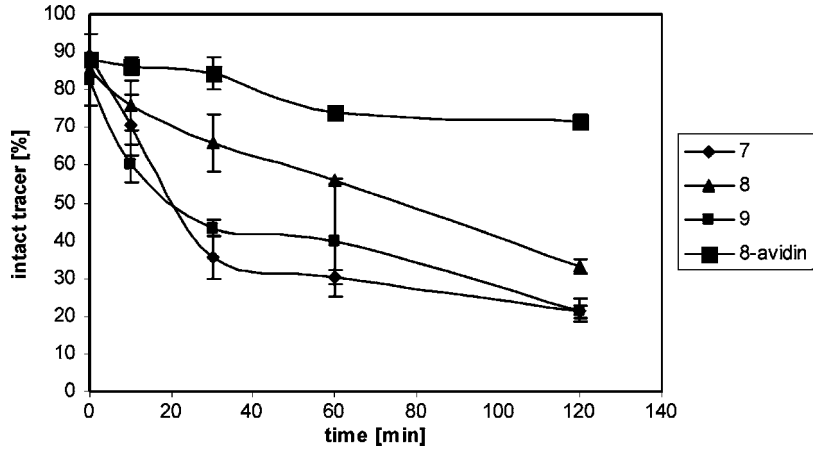

Figure 5. Stability of ^{68}Ga-labeled compounds **7**−**9** and **8**-avidin complex in human serum. Data are presented as mean ± SD ($n = 3$).

Stable gallium isotope (^{69,71}Ga) was introduced to the biotin−DOTA conjugates using an aqueous solution of $GaCl_3$ at 90 ± 5 °C for 5 min and the reaction conditions shown in Scheme 2. The synthesis was conducted under the same conditions using a mixture of ^{68}Ga and ^{69,71}Ga cations. The use of a mixture of radioactive and stable gallium isotopes was twofold: to create a reaction condition identical to the labeling procedure; to make it possible to follow the reaction. The identity of the compounds was confirmed by LC-ESI-MS. The stable gallium-labeled conjugates were added as authentic reference compounds in the LC analysis of labeling reactions in order to identify of the ^{68}Ga-labeled compounds.

The retention times on the analytical HPLC column for **4**−**6** (Table 1) increased when gallium(III) ion coordinated to the conjugate (**7**−**9**), most probably because of the change of the geometry and overall charge of the DOTA chelator upon the complexation.

The ^{68}Ga(III) is eluted from the ^{68}Ge/^{68}Ga generator using 6 mL of a solution of hydrochloric acid. The high volume decreases the radioactivity incorporation and, consequently, specific radioactivity of the product. The reduction of the volume to 200 μL using eluate preconcentration on an anion exchange column (*14*) prior to the labeling experiments improved the specific activity of the products approximately 4-fold.

Binding. The influence of the introduction of alkyl or PEG chains, the DOTA chelator, and radioactive and stable gallium isotopes on the biotin binding capacity was studied. All of the ligands **4**−**9** retained their binding ability to avidin in solution. The results of avidin saturation experiment with the biotin compounds: native biotin, DOTA−biotin (**5**), and Ga−DOTA−biotin (^{69,71}Ga-**5**) are shown in Figure 3. Various amounts of the biotin or its analogues (2−128 nmol) were incubated together with a constant amount of avidin (2 nmol), at room temperature for 5 min. The binding experiments were carried out in both water and HEPES buffer solutions, and the buffer did not affect the binding. The specific binding presented as the avidin consumption on percentage basis was plotted against the ratio of the total molar concentration of added ligands and avidin. The result was analyzed by nonlinear regression using the *GraphPad Prism* software. All the curves reached a maximum value, indicating saturation. Native biotin showed the highest binding, and analogues **4** and **5** reached saturation at approximately 15% below biotin. Compound **6**, with the longer PEG-linker, had the lowest binding, reaching saturation approximately 40% below biotin. In all cases, the binding was somewhat lower when ^{69,71}Ga was inserted into the DOTA chelator, and the molecule became neutral. (Without the gallium ion, the molecule has a −3 charge.) Increasing the incubation time to 40 min did not increase the binding of any of the analogues.

Thus, the modifications of biotin did not deteriorate its avidin-binding ability and the binding of the conjugates might be sufficient to allow their use in labeling avidin-treated islets of Langerhans.

The binding of equimolar amounts of the ^{68}Ga-labeled conjugates and avidin (67 mM each) was studied using HPLC. The biotin analogues **7**−**9** were incubated with avidin at room temperature. Approximately 80−90% of the labeled compounds **7** and **8**, but only 50% of compound **9**, were bound to avidin within 5 min, as shown in Figure 4. The lower binding of compound **9** was also seen in the saturation experiments with avidin (see above). The pegylation, which increases the size of the molecule, especially in the case of compound **9**, led to lower binding. In order to demonstrate that the binding was receptor-specific, a 50-fold excess of native biotin was added to avidin solutions and incubated at room temperature for 10 min, in order to saturate the binding sites of the avidin. Thereafter, an equimolar amount (67 mM) of the labeled compounds **7**−**9** was added and incubated together with the blocked avidin for 5 min. HPLC analysis showed approximately 0.5−1.5% binding of the ^{68}Ga-labeled compounds to the blocked avidin (Figure 4). The binding was therefore site-specific, as it could be precluded by presaturation of avidin with the native ligand, biotin. We were not able to perform these studies at concentration levels corresponding to the K_D of the native biotin−avidin affinity (10^{-15} M) due to the limited sensitivity of the UV and radiodetectors.

The biotin-based tracer could be different from [^{18}F]FDG (*17*, *18*) in terms of binding specificity, accumulation, and longer residence. For example, in porcine islets *in vitro*, [^{18}F]FDG was retained with a half-life of 141.5 min (*17*). The ultimate aim is to provide monitoring and quantification of the transplanted avidin-coated islets of Langerhans.

Stability Studies. The stability in human serum of the three ^{68}Ga-labeled compounds **7**−**9** was studied. The results are presented in Figure 5. After 120 min, approximately 20−30% of the tracers were intact. The stability of the complex between avidin and compound **8** was higher; over 80% of the complex was intact after 120 min. The localization of the avidin target by biotin *in vivo* requires 5−60 min (*19*). Thus, the stability of the analogue **8** (60−75% within 60 min) in combination with the high stability of avidin−biotin complex might be sufficient for the monitoring of the islets of Langerhans within the time frame of the ^{68}Ga half-life.

CONCLUSION

Three ^{68}Ga-labeled biotin−DOTA conjugates with different linkers were synthesized and characterized. The binding of all the analogues to avidin in solution was saturable and specific. All analogues showed binding to avidin in solution. The stability in serum of the biotin analogue **8** (65% within 30 min) and avidin−biotin complex (80% within 120 min) might be sufficient for the monitoring of the islets of Langerhans *in vivo*. The tracers will be evaluated in *in vitro* experiments of avidin-coated islets of Langerhans and in transplantation models *in vivo*.

The modification of ubiquitin to defined oligo-ubiquitinated conjugates has received considerable interest due to the finding that isomeric oligo-ubiquitin conjugates exhibit distinct differences in their biochemical functions, depending on the specific lysine-ε-amino linkage used for conjugate formation. Here, we report the design and development of a thioether linkage-based approach for the synthesis of oligo-ubiquitin conjugates with lysine-specific branching by thioether ligation of a linear ubiquitin peptide containing a C-terminal cysteine residue as the "donor" component, with a corresponding lysine-ε-amino-branched haloacyl-activated ubiquitin "acceptor" peptide. This approach was successfully used for the synthesis of a lysine-63-linked diubiquitin conjugate by ligation of the modified ubiquitin(1−52)-Cys- donor peptide to the N-terminal Arg-54 residue of the branched Lys-63-linked acceptor peptide, ubiquitin$(54-76)_2$. Advantages of the present approach are as follows: (i) the conjugation reaction is performed in solution using suitable preformed donor ubiquitin peptides with a C-terminal Cys residue, and (ii) different corresponding N-chloroacetylated ubiquitin acceptor peptides containing the branched Lys residue are employed, providing broad applicability to the preparation of isomeric oligo-ubiquitin conjugates. The Lys-63-diubiquitin conjugate **7** described here was purified by semipreparative HPLC, and its structure and homogeneity ascertained by HPLC and high-resolution MALDI and electrospray-mass spectrometry. CD spectra and molecular modeling indicate a conformationally stable structure of the conjugate with spatial separation of the ubiquitin parts of the Lys-63 linkage. Moreover, the activity of the thioether-linked diubiquitin conjugate was ascertained by *in vitro* autoubiquitination assay. These results indicate the feasibility of this approach for the preparation of functional oligo-ubiquitin conjugates.

INTRODUCTION

Ubiquitin is an essential eukaryotic protein of 76 amino acids that is highly conserved in all eukaryotes and plays a fundamental role in the control of many biological processes including cell cycle regulation, transcription, DNA repair, and apoptosis (*1*−*4*). Ubiquitin occurs in two general forms within cells, free (monomeric) ubiquitin and ubiquitin molecules that are covalently linked to other proteins. Modification of proteins with ubiquitin, a reaction type termed "ubiquitylation" or "ubiquitination", involves the concerted action of three classes of enzymes, ubiquitin-activating enzymes E1, ubiquitin-conjugating enzymes E2, and ubiquitin ligases E3 (*1*−*4*). In a simplified view, ubiquitinated proteins can be classified into two groups, monoubiquitinated and poly- (or oligo-)ubiquitinated conjugates. In monoubiquitinated proteins, single ubiquitin moieties are attached to one or several lysine residue of the substrate. Polyubiquitinated proteins are modified by so-called ubiquitin chains that consist of several ubiquitin moieties (*5*−*7*). Ubiquitin contains seven lysine residues (K 6, 11, 27, 29, 33, 48, 63), and mass spectrometric analysis of ubiquitinated proteins derived from yeast revealed that each of these lysine residues can be employed for ubiquitin chain formation (*8*). Of particular interest has been the observation that, depending on the specific lysine residue of ubiquitin used for conjugate formation, the corresponding isomeric ubiquitin conjugates exhibit distinct differences in their biochemical functions (*5*−*7*).

The best understood function of ubiquitin chains is as a signal targeting the modified protein to the 26S proteasome for degradation (*1*−*7*). However, it has recently become evident that ubiquitin conjugation may also serve nonproteolytic functions. In fact, the biochemical function of a poly-ubiquitinated protein appears to be critically determined by the specific lysine residue of ubiquitin used for chain formation (*5*−*7*), thus requiring a detailed chemical structure−function evaluation of the respective ubiquitin conjugates. The modification of substrate proteins with K48-linked and, possibly, with K11-linked and K29-linked ubiquitin chains targets these proteins for proteasome-mediated degradation (*5*−*7, 9, 10*). By contrast, K63-linked ubiquitin conjugates have not been found to be substrates for proteasome-mediated degradation but have been suggested to be involved in endocytosis and in other biochemical activities of the modified proteins (*7, 11*−*14*). Beyond the K48-linked ("proteasome flags") and K63-linked ubiquitin chains, the functions of ubiquitin conjugates linked by other lysine residues are presently unclear. NMR studies of K48-linked and K63-linked diubiquitin indicate differences in tertiary structures, which may reflect their different biochemical functions (*15, 16*). This notion (different ubiquitin chains adopt different tertiary structures that, in turn, mediate different functions) is supported by the observation that several proteins have been reported to differentially interact with K48-linked and K63-linked ubiquitin chains (*17*−*21*).

Studies to obtain insight into the biochemical and physiological functions of different ubiquitin chains are hampered by the fact that, besides K48-linked and K63-linked ubiquitin chains, defined chemical or biochemical preparation procedures are not available for isomeric oligo-ubiquitin conjugate formation. Here, we report the design and development of a thioether linkage-based approach for the synthesis of oligo-ubiquitin conjugates with defined lysine-specific linkages. This approach was successfully used for the preparation of K63-linked diubiquitin by ligation of a linear ubiquitin-derived peptide with a C-terminal cysteine as "donor" component with a corresponding K63-branched bis-haloacyl-activated ubiquitin "acceptor" peptide (Figure 1). The K63-branched diubiquitin conjugate prepared was purified and its homogeneity characterized by HPLC, mass spectrometry, and circular dichroism spectroscopy. A corresponding thioether-linked linear ubiquitin conjugate was active in *in vitro* autoubiquitination assays indicating the feasibility of this approach for the preparation of active oligo-ubiquitin conjugates. Thus, the present synthetic pathway should be applicable as a general route for the preparation of oligo-ubiquitin conjugates that can be used (i) to evaluate the biochemical properties of isomeric poly-ubiquitin conjugates and (ii) for the preparation of antibodies that selectively recognize isomeric ubiquitin chains depending on the specific lysine residue of ubiquitin used for chain formation.

EXPERIMENTAL SECTION

Materials. Amino acid derivatives, NovaSyn TGA resins, and benzotriazole-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP) were obtained from NovaBiochem (Läufelfingen, Switzerland) and from GL Biochemicals (Shanghai, China). Triisopropylsilane, 4-methylmorpholine (NMM), piperidine, 1,8-diazabicyclo-[*5.4.0*]undec-7-ene (DBU), trifluoroacetic acid (TFA), 1,4-dithiothreitol (DTT), diisopropylcarbodiimide (DIC), and 4-dimethylaminopyridine (DMAP) were obtained from Fluka (Buchs, Switzerland). Dimethyl formamide (DMF) was purchased from Acros Organics (Geel, Belgium). *tert*-Butyl methyl ether, acetonitrile, and other reagents and solvents were obtained from Riedel-deHäen (Seelze, Germany) at analytical grade or highest available purity.

Synthesis of Chloroacetylated Ubiquitin(54−76) Acceptor Peptides 1. The chloroacetylated acceptor peptides, *N*-chloroacetyl ubiquitin(54−76) **1** ((ClAc)-^{54}RTLSDYNIQ**K**ESTLHLVLRLRGG^{76}-OH) and the N^{α}-(N^{ε}-K63)-bis-chloroacetyl-ubiquitin(54−76)$_2$ **2** ((ClAc)-^{54}RTLSDYNIQ**K**ε((ClAc)-^{54}RTLSDYNIQ**K**ESTLHLVLRLRG G^{76}CO-)ESTLHLVLRLRGG^{76}-OH) were synthesized manually by solid-phase peptide synthesis on a NovaSyn TGA resin (0.29 mmol/g coupling capacity) according to the Fmoc strategy. The following side chain protected amino acid derivatives were used: Fmoc-Arg(Pbf[1])-OH, Fmoc-His(Trt)-OH, Fmoc-Ser(*t*Bu)-OH, Fmoc-Glu(O*t*Bu)-OH, Fmoc-Lys(Boc)-OH, Fmoc-Gln(Trt)-OH, Fmoc-Asn(Trt)-OH, Fmoc-Tyr(*t*Bu)-OH, Fmoc-Asp(O*t*Bu)-OH, Fmoc-Thr(*t*Bu)-OH, and Dde-Lys(Fmoc)-OH. The C-terminal G76 residue was preactivated with DIC and attached to the TGA resin in the presence of DMAP. A coupling capacity of 0.19 mmol/g was determined spectrophotometrically at 290 nm. The following synthetic protocol was generally employed for the attachment of the other amino acids: (i) DMF washing for 4 × 1 min; (ii) Fmoc deprotection for 15 min using 2% DBU and 2% piperidine in DMF; (iii) DMF washing for 8 × 1 min; (iv) double coupling using 5 equiv of Fmoc-amino acid/ PyBOP/NMM in DMF for 60 min; (v) DMF washing for 4 × 1 min; (vi) DCM washing for 2 × 1 min. The bromophenol blue test was used to assess the presence of free amines. After completion of the synthesis of ubiquitin(54−76) **1**, the N-terminus of R54 was chloroacetylated using chloroacetic acid-pentachlorophenyl ester in DMF/DCM at 5 mol equiv (*28*). Cleavage of the peptide from the resin was performed for 3 h at 25 °C using a mixture of TFA, triisopropylsilane, and deionized water (90:5:5, v/v/v). The product was then precipitated with cold *tert*-butyl methyl ether, washed three times with diethyl ether, and solubilized in 5% aqueous acetic acid prior to freeze−drying. The crude peptide was purified by reversed-phase HPLC on a preparative C4 column, and the purified peptide characterized by analytical HPLC and mass spectrometry.

The chloroacetylated K63-branched ubiquitin(54−76)$_2$ **2** was synthesized manually on a NovaSyn TGA resin (0.29 mmol/g coupling capacity) described above using the combined Fmoc/*t*Bu protecting chemistry and the analogous side chain protected amino acid derivatives (Figure 2). The C-terminal G76 residue was first preactivated with DIC and attached to the TGA resin as described above, and the subsequent amino acids coupled with incorporation of Dde-K(ε-Fmoc)-OH in position 63. After completion of the linear ubiquitin(63−76), the Fmoc-ε-amino protecting group of K63 was removed by treatment with 2% piperidine/2% DBU in DMF for 20 min and the synthesis of the branching sequence, ubiquitin(63−76) was built up on the free ε-amino group of the K63 residue. After completion of the synthesis of the branched diubiquitin(63−76)$_2$ sequence, the N-terminal Fmoc protecting group of the K63 residue of the branched peptide sequence was removed by treatment with 2% piperidine/2% DBU, and the *N*-α-terminal Dde-protecting group of K63 removed by treatment with 2% hydrazine in DCM for 2 min. The amino acids ubiquitin(54−62) were coupled, and the chloroacetyl group introduced at the N-terminal amino group of both R54 residues by treatment with a 5 mol excess/Arg residue of chloroacetic acid-pentachlorophenyl ester (ClAcOPcp) for 3 h at 25 °C. The final peptide **2** was cleaved from the resin at 25 °C for 3 h using a mixture of TFA, triisopropylsilane, and deionized water (90:5:5, v/v/v). The crude peptide was precipitated with ice-cold *tert*-butyl methyl ether, washed three times with diethyl ether, and solubilized in 5% aqueous acetic acid prior to freeze−drying. The peptide was then redissolved in 0.1% TFA and purified by HPLC on a preparative C4 column; the purified peptide was then characterized by analytical HPLC and FTICR mass spectrometry.

Expression and Isolation of His-Tagged Ubiquitin(1−52)-C 4. A cDNA encoding GSSHHHHHHSSGLVPRGSH-ubiquitin(1−52)-C **4** that consists of an N-terminal His-tag for affinity purification, ubiquitin amino residues 1−52, and a C-terminal cysteine residue was generated by PCR using the primers 5′-GAGATATACATATGCAGATCTTCGTGAAGAC-3′ (forward primer) and 5′-GCGGGATCCTTAACAGTCCTC-GAGCTGCTTACCG (reverse primer). The product was cloned by 5′NdeI and 3′*Bam*HI into the bacterial expression vector pET3a (Novagen) and the ubiquitin peptide **4** expressed in *E. coli* BL21-CodonPlus(DE3)-RIL (Stratagene). For isolation and purification of **4**, cells were lysed in PBS buffer, pH 8.7, with 1% Triton X100 (Sigma) by sonication, and the clarified lysate incubated for 20 min at 75 °C and then cooled on ice for 10 min. Under these conditions, ubiquitin remains in a native-like conformation, while most other proteins in the lysate denature and precipitate. After removal of denatured proteins by centrifugation, DTT was added for removal of possible mixed-disulfide formation at the C-terminal cysteine residue, and the solution was acidified to pH 3. The polypeptide was purified from residual byproducts and detergent by preparative HPLC,

[1]Abbreviations: FTICR-MS, Fourier transform-ion cyclotron resonance mass spectrometry; Pbf, (2,2,4,6,7-Pentamethyldihydro-benzofuran-5-sulfonyl); tBu, *tert*-butyl; OtBu, *tert*-butyl ester; Trt, trityl; Boc, *tert*-butoxycarbonyl; Dde, (1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl).

and the purified peptide **4** characterized by analytical HPLC and ESI mass spectrometry.

Halide Exchange of Chloroacetylated Ubiquitin(54−76)-Acceptor Peptide and Conjugation of His-Tagged-Ubiquitin(1−52)-C 4. *In situ* halide exchange for the preparation of iodoacetylated ubiquitin-acceptor peptides was performed using chloroacetylated ubiquitin(54−76) (0.3 mg) dissolved in 1 mL of a mixture of 8 M urea, pH 8.7, and 0.1 M Tris buffer, pH 8 (1:1; v/v), and then 1 mL of a saturated solution of KI prepared in 0.1 M Tris buffer was added. After 30 min reaction, a solution of 2 mol equiv of His-tagged ubiquitin(1−52)-C peptide **4** (dissolved in 1 mL of 8 M urea, pH 8.7, and 0.1 M Tris buffer, pH 8 (1:1 v/v)) was added dropwise for 20 min. After 20 h, the conjugation reaction mixture was acidified with TFA to pH 3 and purified by preparative RP-HPLC (Figure 3).

Conjugation of chloroacetylated branched ubiquitin$(54-76)_2$ acceptor peptide **2** ((ClAc)-^{54}RTLSDYNIQKESTLHLVLRL-RGG^{76}-OH)$_2$ (0.3 mg) was performed by dropwise addition of a solution of GSSHHHHHHSSGLVPRGSH-ubiquitin(1−52)-C **4** (0.875 mg) in 500 μL of a 1:10 mixture of 6 M guanidinium hydrochloride and 1 M potassium carbonate. The reaction mixture was stirred for 3 h at 25 °C in a sealed reaction tube, and the ligation reaction was monitored by analytical HPLC (Figure 5). Aliquots of 20−50 μL from the reaction mixtures were isolated and injected into an analytical HPLC; eluted fractions were isolated and analyzed by MALDI and ESI ion trap mass spectrometry. After completion of the reaction, the solution was acidified to pH 3 using 0.1% TFA and subjected to purification by semipreparative HPLC (see below).

High-Performance Liquid Chromatography. Analytical reversed-phase HPLC was performed on a Bio-Rad system (Bio-Rad Laboratories, Richmond, CA) using a Vydac C4 column (250 × 4.6 mm I.D., 5 μm silica, 300 Å pore size) (Hesperia, CA). The samples were dissolved in 200 μL 0.1% TFA (aqueous solution), and peptides were separated using a linear gradient elution (0 min, 0% B; 5 min, 0% B; 105 min, 100% B; 110 min, 100% B; 115 min, 0% B; 120 min, 0% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20 v/v)). The flow rate was 1 mL/min and the peaks were detected at 220 nm wavelength. Preparative HPLC separations of ubiquitin peptides were carried out on a Knauer HPLC system (Knauer, Berlin, Germany) using a preparative Vydac C4 column (250 nm × 10 mm I.D., 10 μm, 300 Å pore size). The same mobile phases and gradient as described above were employed at a flow rate of 10 mL/min.

The purification of diubiquitin conjugate **7** was carried out on a Bio-Rad system (Bio-Rad Laboratories, Richmond, CA) using a semipreparative Nucleosil 300-7 C_8 column (250 nm × 10 mm, 7 μm, 300 Å) (Macherey-Nagel, Düren, Germany) as a stationary phase. Linear gradient elution (0 min, 0% B; 15 min, 35% B; 45 min, 45% B, 65 min, 50% B, 100 min, 100% B; 105 min, 100% B; 110 min, 0% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water, (80:20, v/v)) was used at a flow rate of 2 mL/min and the peaks were detected at 220 nm. Purified diubiquitin conjugate **7** was analyzed by analytical RP-HPLC on a Vydac C8 column (250 × 4.6 mm I.D., 5 μm silica, 300 Å pore size) (Hesperia, CA) using the same gradient employed for purification.

Mass Spectrometry. ESI-FTICR mass spectrometry was performed with a Bruker Apex II FTICR mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with a 7.0 T actively shielded superconducting magnet (Magnex, Oxford, UK), and an APOLLO-II electrospray ionization source (Bruker Daltonics). Nano-ESI-FTICR mass spectrometry was performed with a modified APOLLO electrospray source (Bruker Daltonics) to accommodate a custom-made nanospray system (*35, 43*). A stable spray was obtained by application of a capillary entrance voltage between −880 and −1120 V, while the nanospray needle was grounded. Calibration was performed externally using fragment ions of angiotension I (Bachem, Bubendorf, Switzerland) produced by in-source CID. Acquisition of spectra was performed with the Bruker Daltonics software XMASS and corresponding programs for mass calculation, data calibration, and processing. A 10 μM solution of peptides in 50% methanol/2% aqueous acetic acid (1:1, v/v) was used for sample preparation.

ESI-ion trap mass spectra were recorded on a Bruker Esquire 3000+ ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with a direct infusion and ESI-LC-MS source (*33*). In addition, LC-MS experiments were carried out using an Agilent 1100 HPLC with binary pump system and a Zorbox 300SB-C8 column (Agilent, Waldbronn, Germany) with the dimensions as follows: 1.0 × 150 mm, 3.5 μm. *HyStar 3.1* (Bruker Daltonik, Bremen, Germany) control software was used. Samples were introduced by direct infusion with a syringe pump at flow rates 3−5 μL/min, using nitrogen both as nebulizer and as drying gas. The ion source voltages were used as follows: capillary exit −200 V, skimmer 40 V; scanned mass range m/z = 200−3000. For sample preparation, the samples were dissolved in 0.1% formic acid before injection.

MALDI-TOF mass spectrometric analyses were carried out with a Bruker Biflex TOF mass spectrometer (Bruker Daltonics, Bremen, Germany) equipped with a nitrogen UV laser (337 nm), a dual channel plate detector, a 26 sample SCOUT source, a video system, and an XMASS data system for spectra acquisition and instrument control (*42*). A saturated solution of α-cyano-4-hydroxycinnamic acid (HCCA) in acetonitrile/0.1% trifluoroacetic acid in water (2:1, v/v) was used as the matrix. An aliquot of 1 μL of the sample solution and 1 μL of a saturated matrix solution were mixed on the stainless steel MALDI target and allowed to dry. Acquisition of spectra was carried out at an acceleration voltage of 20 kV and a detector voltage of 1.5 kV.

Circular Dichroism Spectroscopy. CD spectra were recorded with a Jasco model J-720 spectropolarimeter at 25 °C in 0.05 cm quartz cells under constant nitrogen flush. The instrument was calibrated with 0.06% (w/v) ammonium-d-camphor-10-sulfonate (Katayama Chemical, Osaka, Japan) in double-distilled water; the sample concentrations were 0.5 μg/μL. The spectra were averages of six scans between 190 and 260 nm, respectively.

Molecular Modeling. The *Hyperchem* 7.01 software was used for the molecular modeling calculations. Geometry optimizations (*in vacuo*) were performed using the Amber99 parameter set for the force field and the Polak-Ribiere algorithm with a rms gradient of 0.1 kcal/(Å*mol).

RESULTS AND DISCUSSION

General Concept for Synthesis of Ubiquitin Conjugates by Thioether Ligation. Due to the well-known problems in solid-phase chemical synthesis of peptides with increasing chain lengths, chemoselective ligation using linear and lysine-branched precursor peptides as building blocks appears appropriate for ubiquitin conjugate synthesis. A number of chemoselective ligation methods have been recently developed and applied in polypeptide synthesis, such as via formation of thioether, oxime, thioester, and hydrazone bonds (*22−27*); and differences in reaction rates and chemical stabilities for several linkages have been determined (*28, 29*). The general approach employed in the present study for the synthesis of specific lysine-linked ubiquitin conjugates by (i) preparation of a linear ubiquitin−"donor" peptide with a C-terminal cysteine and (ii) its conjugation with a corresponding lysine-specific branched bis-haloacyl-ubiquitin "acceptor" peptide by thioether alkylation is shown

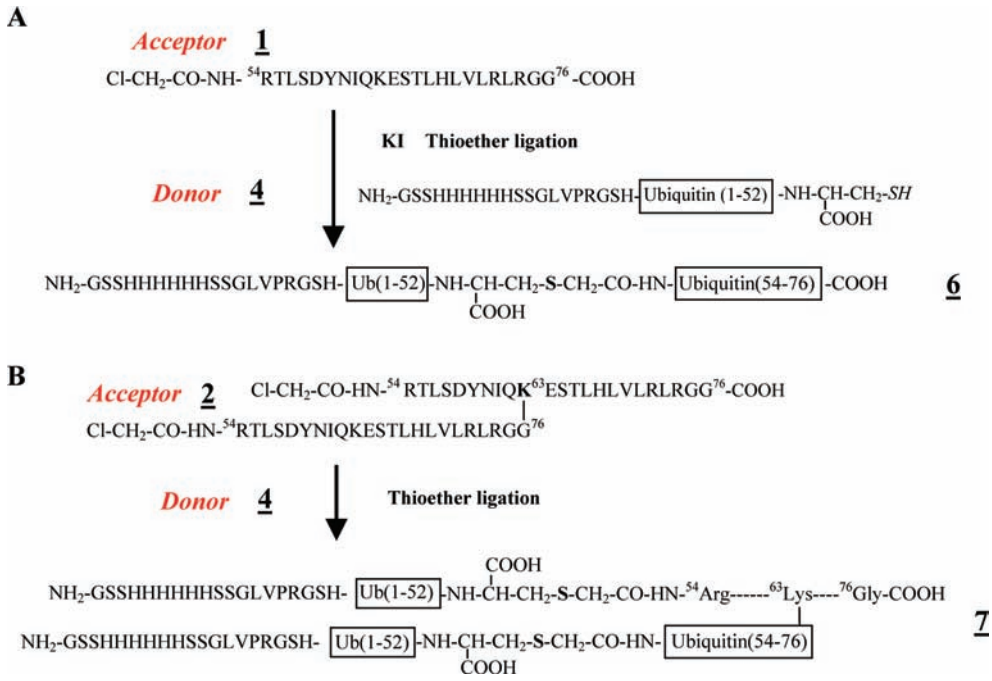

Figure 1. General scheme for the synthesis of oligo-ubiquitin conjugates. (A) Synthesis of linear ubiquitin peptide **6** by thioether ligation of acceptor peptide ubiquitin(54−76) **1** and His-tag-ubiquitin(1−52)-Cys **4**. (B) Thioether ligation of Lys-63-branched acceptor peptide ubiquitin(54−76)$_2$ **2** with ubiquitin donor peptide **4**.

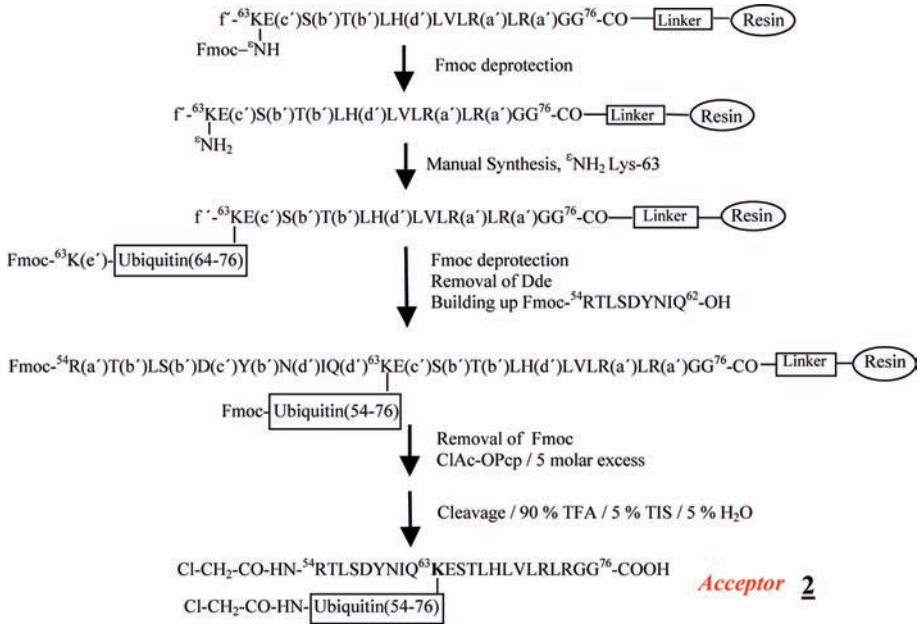

Figure 2. Pathways for the manual synthesis of the branched K63-linked bis-chloroacetylated ubiquitin(54−76)$_2$ acceptor peptide **2**. The protecting groups used are as follows: a′, Pbf, (2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl); b′, tBu, *tert*-butyl; c′, OtBu, *tert*-butyl ester; d′, Trt, trityl; e′, Boc, *tert*-butoxycarbonyl; f′, Dde, (1-(4,4-Dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl).

in Figure 1. Due to the high chemical and biological stability of thioether bonds and their lack of immunogenicity (*21*, *30*), we decided to use this approach that allows specific ligation between cysteine-thiol and halo-acetylated amino groups for ubiquitin conjugate synthesis.

Synthesis of N-Chloroacetylated Ubiquitin−Acceptor Peptides with Lys-NH$_2^{\varepsilon}$-specific linkage. N-Chloroacetylated ubiquitin peptides comprising the designated Lys-NH$_2^{\varepsilon}$-specific linkage were prepared as "acceptor" components in the first step of the general thioether conjugation approach (Figure 1) by manual synthesis on a NovaSyn TGA resin, using the scheme of insertion of lysine-branching sequences and orthogonal protecting groups shown in Figure 2. The linear N-chloroacetyl−ubiquitin(54−76) **1** containing the N-terminal amino group of Arg54 was prepared using a 5-molar excess of chloroacetic acid pentachlorophenyl ester in DMF/DCM. For isolation and characterization of the N-chloroacetyl-ubiquitin(54−76) **1**, the peptide was cleaved from the resin using a cleavage mixture containing 90% TFA, 5% water and 5% TIS, and the crude product purified by HPLC on a preparative C4 column. The ESI ion trap mass spectrum showed a single homogeneous peptide product with the experimental molecular mass of 2746.02 Da (Table 1; $C_{118}H_{198}N_{37}O_{36}Cl_1$; calculated mass: 2746.52 Da). Further, the N-chloroacetylated peptide **1** was converted into the N-iodoacetylated peptide **3** upon KI treatment,

which was used in the thioether ligation with ubiquitin donor peptides (see below).

The designated K63-NH_2^{ε}-branching site was protected with N^{α}-Dde and N^{ε}-Fmoc groups. After completion of the synthesis of the linear ubiquitin(63−76) component and removal of the N^{ε}-Fmoc protecting group, the second branching sequence ubiquitin(63−76) was built up on the K63-ε-amino group using NH_2^{α}-Fmoc-NH_2^{ε}-Boc protection of the branching K63 residue. After completion of the synthesis of the branched diubiquitin(63−76)$_2$ peptide, the N-terminal Dde protecting group of K63 was removed with 2% hydrazine in DCM. The second N^{α}-Fmoc group of K63 was subsequently removed, followed by manual coupling of amino acids (54−62) for both sequences (Figure 2). Following removal of the N-terminal Fmoc protecting groups, the chloroacetyl group was introduced at each N-terminal R54 residue using chloroacetic acid pentachlorophenyl ester. The peptide was cleaved from the resin, and the crude product was purified by HPLC on a preparative C4 column. The purified peptide **2** showed a single homogeneous peak by HPLC at a retention time of 31.49 min and provided molecular ions both by ESI-ion trap and MALDI-TOF mass spectrometry (*31*−*37*) due to a average molecular mass of 5474.99 Da, consistent with the calculated molecular mass of 5475.02 Da ($C_{236}H_{394}N_{74}O_{71}Cl_2$) (Table 1, Figure 5).

Preparation and Characterization of Cysteinyl−Ubiquitin Peptides As Donor Components. A ubiquitin peptide comprising an N-terminal His-tag sequence (GSSHHHHHHSSGLVPRGSH-ubiquitin(1−52)-C) **4** was prepared by bacterial expression as donor component for thioether ligation by replacing the C-terminal G53 with a cysteine residue (cf. Figure 1). Following bacterial expression, isolation, and purification as described in the Experimental Section, the His-tag-G53C mutant ubiquitin peptide **4** was analyzed by HPLC and MALDI-TOF-MS, which provided a singly charged molecular ion corresponding to a molecular mass 7990.94 Da, consistent with the expected molecular mass of the product ($C_{348}H_{558}N_{104}O_{108}S_2$; 7990.20). The HPLC separation of the crude product revealed the presence of an additional peak with a slightly lower retention time (29.2 min) relative to the main component (29.9 min), which was identified by MALDI-TOF-MS as the mixed disulfide of **4** with glutathione (molecular mass 8296.24 Da), present in excess in the biological medium upon isolation (data not shown). Consistent with this finding, HPLC analyses and MALDI-MS characterization of further mutant cysteinyl−ubiquitin peptides prepared with an identical procedure (i.e., ubiquitin-N60C) showed the formation of the mixed GSH-disulfide adducts as major product (data not shown). In order to remove the GSH, the disulfide linkage was reduced with DTT for 1.5 h at 25 °C and the peptide then purified from the residual byproducts and detergent by preparative HPLC (not shown). The structure and homogeneity of the purified ubiquitin peptide **4** was ascertained by ESI-FTICR-MS (*32*, *34*, *37*, *38*), which provided a single homogeneous molecular ion series with the most abundant 10+ charged ion, corresponding to the molecular mass of 7985.64 Da (Table 1). The functional activity of the cysteinyl-containing mutant ubiquitin peptides, G53C, as well as the N60C was ascertained by an auto-ubiquitination assay using two different E3 ligases as described below.

Conjugation of Cysteinyl−Ubiquitin Donor Peptides with K-NH_2^{ε}-Linked Ubiquitin−Acceptor Peptides by Thioether Ligation. The His-tag-ubiquitin donor peptides containing a carboxy-terminal Cys residue were subjected to coupling with the chloroacetylated ubiquitin acceptor peptides via thioether conjugation, as described in the Experimental Section. Due to the relatively low reactivity of the chloroacetylated ubiquitin peptides found in initial experiments, the N-chloroacetyl−acceptor peptide component was activated *in situ* by conversion to the iodoacetyl derivative using a saturated potassium iodide solution in Tris-buffer (pH 8), which increased the reaction rate due to the highly reactive iodoacetyl group (*39*, *40*). The time course of the conjugation reaction was monitored by analytical HPLC on a C4 column, and HPLC fractions were characterized by mass spectrometry, as shown in Figure 3 for the activation and thioether ligation of the His-tag−ubiquitin(1−52)-Cys donor peptide **4** with the N-chloro/iodoacetylated ubiquitin(54−76) acceptor **1** after 6 h. Oxidation of the C-terminal Cys residue and formation of the ubiquitin(1−52)-cystinyl-53 dimer **5** was observed as a significant side reaction competing with the thioether ligation (molecular mass, **5**, 15 979.86 Da; see Figure 3). The monoubiquitin peptide **6** was isolated by preparative

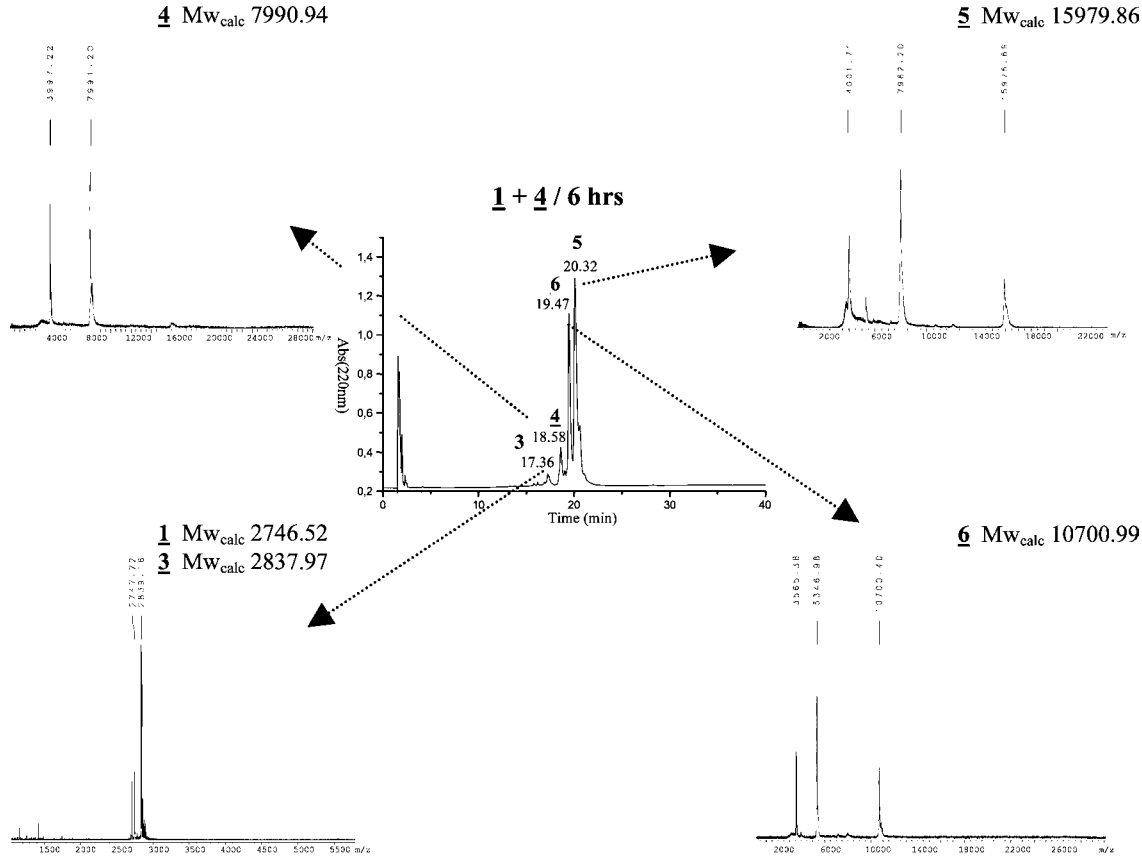

Figure 3. HPLC monitoring and MALDI mass spectrometric characterization of the conjugation of His-tagged ubiquitin(1−52)-Cys donor peptide **4** with N-chloroacetylated ubiquitin(54−76) acceptor peptide **1**, using *in situ* activation to the N-iodoacetyl-ubiquitin(54−76) **3** and thioether ligation. MALDI-mass spectra of the HPLC peaks of residual peptides **1** and **3** are shown on the left, the MALDI spectrum of the cystinyl-dimer oxidation product **5** of the donor peptide is shown on the upper right side.

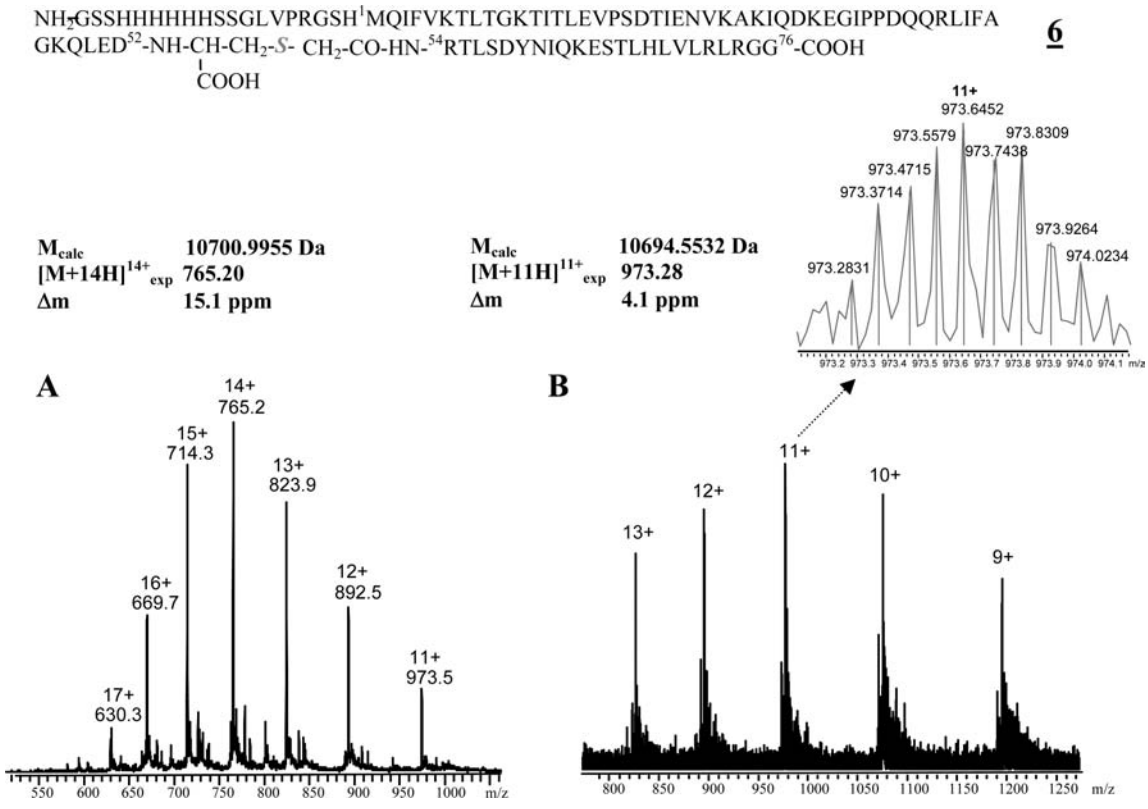

Figure 4. Mass spectrometric characterization of the HPLC-purified monoubiquitin conjugate **6** by thioether ligation of linear His-tagged ubiquitin(1−52)-Cys donor peptide **4** with N-chloroacetylated ubiquitin(54−76) acceptor peptide **1**. (A) ESI-ion trap mass spectrum (average molecular mass). (B) High-resolution Nano-ESI-FTICR mass spectrum (monoisotopic molecular mass).

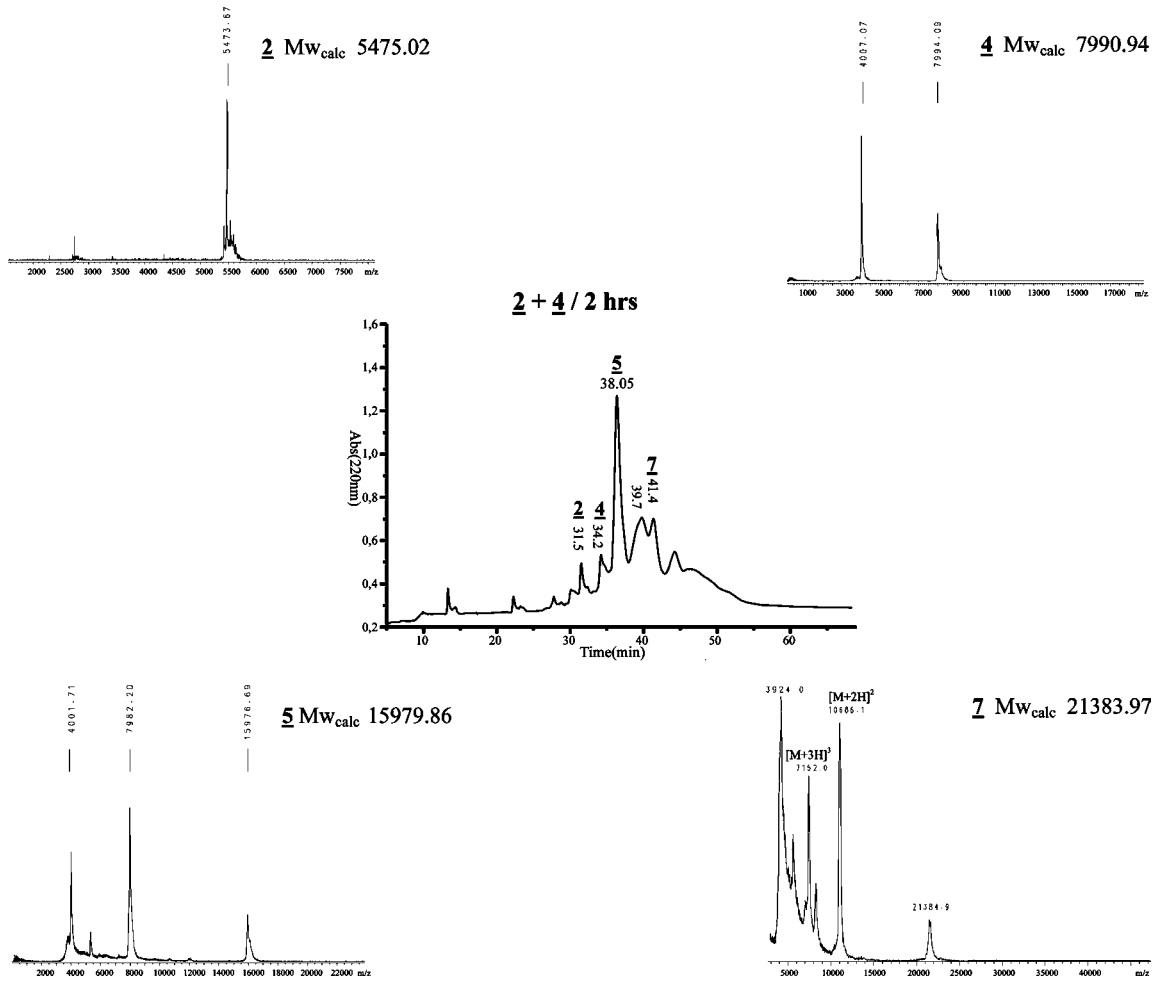

Figure 5. HPLC monitoring and MALDI mass spectrometric characterization of the thioether ligation of His-tagged ubiquitin(1−52)-Cys donor peptide **4** with K63-branched bis-N-chloroacetylated ubiquitin(54−76)$_2$ acceptor peptide **2**, at 2 h reaction time. The MALDI mass spectra of the diubiquitin conjugate **7** and the disulfide dimer **5** are shown on the lower right and left sides, respectively.

HPLC and characterized by mass spectrometry (Figure 4). Both the ESI-ion trap and the high-resolution FT-ICR mass spectra showed the corresponding multiply charged (*37, 38, 41*−*44*), protonated ion series yielding a molecular weight ($C_{466}H_{755}N_{141}O_{144}S_2$; average molecular weight 10 700.99 Da, monoisotopic molecular weight 10 694.55 Da) consistent with the correct sequence of **6**.

Initial studies of the thioether conjugation of the His-tag cysteinyl−ubiquitin donor peptides with the K63-branched ubiquitin(54−76)$_2$ acceptor peptide indicated solubility problems in standard aqueous solution at slightly alkaline pH, in addition to the disulfide oxidation as a side reaction. The chloroacetylated ubiquitin(54−76)$_2$ acceptor component **2** and the mutant ubiquitin(1−52)-C donor peptide **4** were dissolved in a 1:10 (v/v) mixture of 6 M guanidinium hydrochloride and 1 M potassium carbonate as described in the Experimental Section, and the reaction course monitored by analytical HPLC and mass spectrometry (Figure 5). At these conditions, the HPLC profile and MALDI-TOF-MS clearly showed the formation of the diubiquitin conjugate **7** (average molecular weight 21 383.97 Da; found 21 384.30 Da) after 2 h reaction, in addition to the unreacted peptides, chloroacetylated ubiquitin(54−76)$_2$ **2** and His-tag-ubiquitin(1−52)-C **4**, and the disulfide−dimer byproduct **5**. However, purification of the diubiquitin conjugate **7** in homogeneous form was obtained by semipreparative HPLC on a Nucleosil 300−7 C_8 column, as described in the Experimental Section. At the reaction conditions described above, a yield of approximately 29% of conjugate **7** relative to acceptor peptide **2** was obtained after 6 h. The analytical HPLC profile and ESI-ion-trap mass spectrum of the purified diubiquitin conjugate **7** are shown in Figures 6 and 7, respectively; the purity of **7** was estimated to approximately 92%. The deconvolution of the multiply protonated ions in the ESI-ion trap MS (see insert in Figure 7) provided a molecular weight of 21 385.5 Da, consistent with the correct structure ($C_{932}H_{1508}N_{282}O_{287}S_4$; 21 383.97 Da). In addition, the sequence was ascertained by partial ESI-MS/MS of tryptic peptide fragments (data not shown).

A structural model of the diubiquitin conjugate **7**, obtained by molecular modeling using the Hyperchem-7 software, is shown in Figure 9. The Lys-63 linkage is highlighted in the insert, and the thioether bonds used for the conjugation are marked in pink. The overall structure calculated for the conjugate suggests conformational stability with spatial separation of both parts of the Lys-63 branching, in agreement with the CD spectroscopic data (see below).

Conformational Analysis of Thioether-Conjugated Mutant Ubiquitin Peptides by Circular Dichroism Spectroscopy. The monoubiquitin conjugate **6** containing a thioether bond and wild-type bovine ubiquitin (Sigma, Germany) were examined by circular dichroism spectroscopy in water (*45, 46*). Both compounds adopted predominantly helical conformation characterized by two negative bands around 207 and 220 nm (data not shown). No significant differences in the CD spectra of the synthetic, mutant, and wild-type bovine ubiquitin were

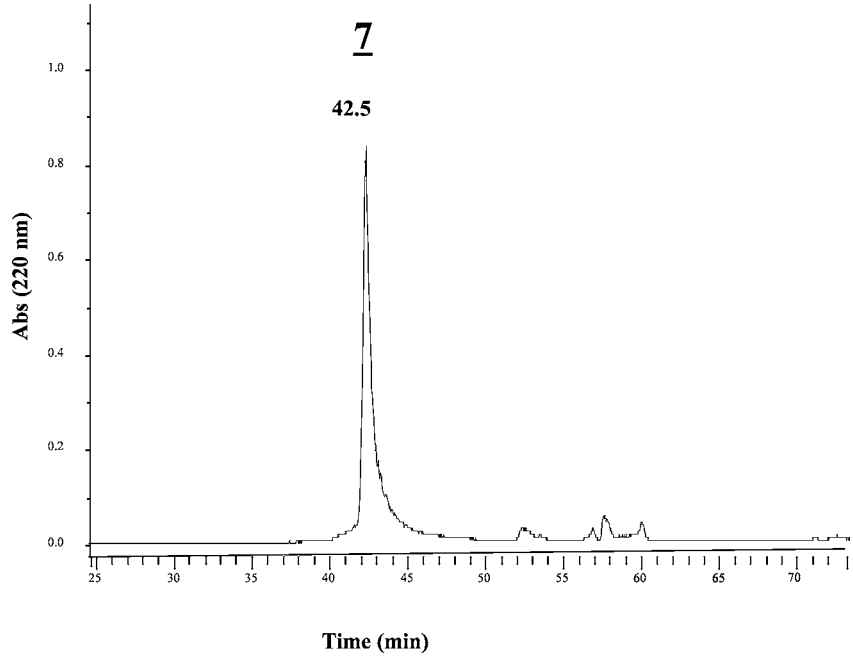

Figure 6. Analytical RP-HPLC profile of purified K63-branched diubiquitin conjugate **7**. Eluents: 0.1% TFA in water (A), 0.1% TFA in MeCN−water 80:20 v/v (B); flow rate, 1 mL/min; gradient, 0 min 0% B, 15 min 35% B, 45 min 45% B, 65 min 50% B, 100 min 100% B.

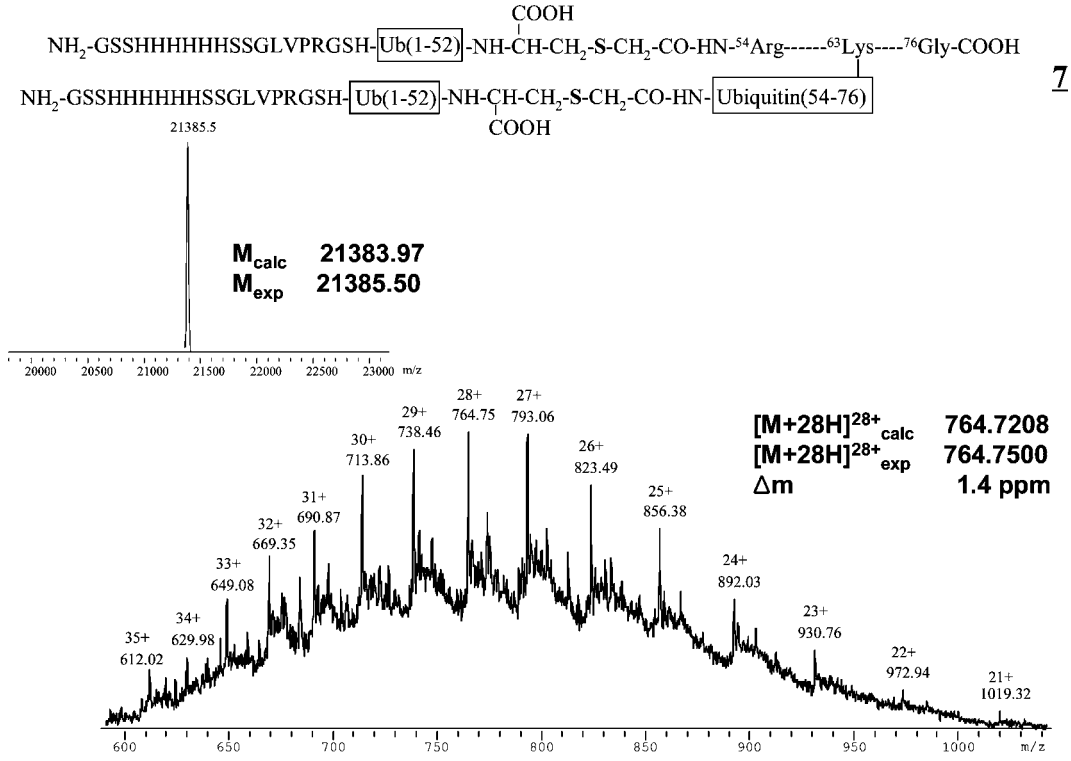

Figure 7. ESI-ion-trap mass spectrum of purified K63-branched diubiquitin conjugate **7**. The insert shows the deconvoluted molecular ion obtained from the series of multiply protonated ions, yielding a molecular weight of 21 385.5 Da.

found, indicating that the presence of a thioether bond in the structure of ubiquitin does not lead to a conformational change.

Functional Characterization of Thioether-Conjugated Mutant Ubiquitin Peptides by *in Vitro* Auto-Ubiquitination. Potential drawbacks of the approach described above are the replacement of G53 of ubiquitin by a cysteine residue and the linkage of C53 to R54 via a thioether bond rather than a peptide bond, as these alterations may result in a ubiquitin mutant that is biochemically inactive (i.e., the mutant cannot be activated and covalently attached by the ubiquitin conjugation system to substrate proteins). To assess the biochemical activity of the mutant cysteinyl−ubiquitin conjugates, the linear monoconjugate **6** of ubiquitin(1−52)-Cys was prepared by ligation with the chloro/iodoacetylated ubiquitin(54−76) peptide (G53C-ubiquitin). The mutant ubiquitin **6** was then analyzed *in vitro* in auto-ubiquitination assays using two different ubiquitin ligases (purified baculovirus-expressed E6AP, data not shown; purified bacterially expressed HectH9, Figure 8) as previously described (*47, 48*).

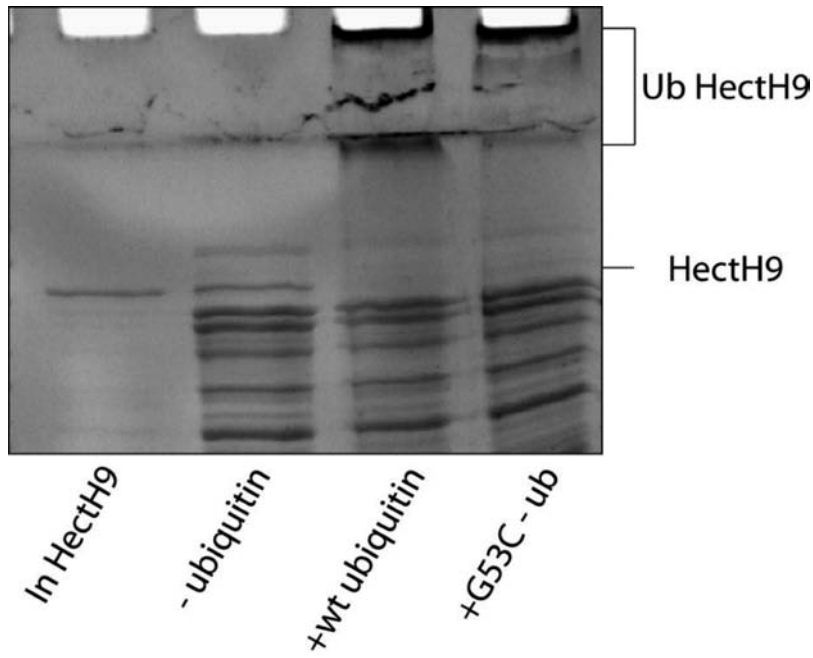

Figure 8. *In vitro* autoubiquitination assay of HectH9 using the mutant monoubiquitin conjugate (G53C-ubiquitin) derived by thioether ligation of His-tagged ubiquitin(1−52)-Cys donor peptide **4** with N-chloroacetylated ubiquitin(54−76) acceptor peptide **1**. The running positions of the nonmodified form of HectH9 (HectH9) and the ubiquitinated forms of HectH9 (Ub HectH9) are indicated. In HectH9, input of bacterially expressed HectH9; − ubiquitin, reaction in the absence of ubiquitin; +wt ubiquitin, reaction in the presence of wild-type ubiquitin; +G53C-ub, reaction in the presence of G53C-ubiquitin.

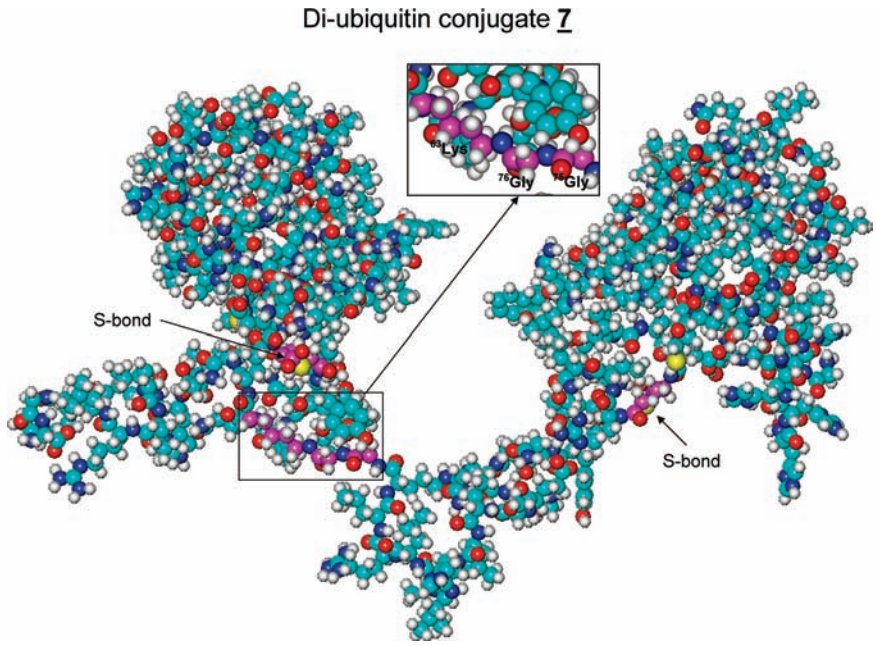

Figure 9. Structure model of the diubiquitin conjugate **7**. The lys-63 linkage is highlighted in the insert; thioether linkages in the conjugate are marked in violet.

As shown in Figure 8, the synthetic cysteinyl−ubiquitin conjugate is used by the ubiquitin conjugation system with an efficiency similar to wild-type ubiquitin, indicating the feasibility of the cystein mutation and thioether ligation approaches in producing biochemically active conjugates.

CONCLUSIONS

In this study, a general approach was developed for the synthesis of oligo−ubiquitin conjugates with defined Lys-ε-amino branching sites. The preparation of specific isomeric Lys-branched conjugates utilizes a chemoselective ligation approach with stable thioether linkages using (i) an activated N-chloroacylated partial ubiquitin acceptor peptide containing the specific Lys-branching residue, prepared by manual synthesis, and (ii) thioether ligation to a ubiquitin peptide donor component that contains a C-terminal Cys residue at the defined conjugation site. In a first example, a K63-branched diubiquitin conjugate was successfully prepared and purified, and the structure of the 21 kDa polypeptide adduct ascertained by ESI mass spectrometry. Although the concomitant oxidation by dimerization at the cysteinyl residues was found as a byproduct, a homogeneous Lys63−diubiquitin conjugate was obtained by HPLC isolation

with a purity of >90% and a yield of approximately 30% at optimized reaction times. The reaction conditions developed here are presently used to the preparation of oligomeric ubiquitin conjugates with amounts suitable to enable (i) their detailed structural characterization by NMR spectroscopy and (ii) the generation of antibodies selectively recognizing ubiquitin chains linked by different lysine residues.

ACKNOWLEDGMENT

This work was supported by grants from the Deutsche Forschungsgemeinschaft (DFG), Bonn, Germany (to M.S. and M.P.). We are grateful to Reinhold Weber for the expert assistance with the high resolution mass spectrometric characterization.

Note Added after ASAP Publication: This paper was published ASAP on May 27, 2009 with an error in the reverse primer in the Experimental Section. The revised version was published on May 29, 2009.

Preparation of Multifunctional Drug Carrier for Tumor-Specific Uptake and Enhanced Intracellular Delivery through the Conjugation of Weak Acid Labile Linker

Caixia Ding, Jingxia Gu, Xiaozhong Qu,* and Zhenzhong Yang*

State Key Laboratory of Polymer Physics and Chemistry, Institute of Chemistry, Chinese Academy of Sciences, Beijing 100190, China. Received December 24, 2008; Revised Manuscript Received April 19, 2009

We demonstrate that multifuctional drug carriers, e.g., polymeric micelles, for tumor-specific uptake and intracellular delivery can be generated from the pH-dependent progressive hydrolysis of a novel benzoic-imine linker in the micelle-forming amphiphilic polymer. The linker, hence the micelle, is stable at physiological pH, partially hydrolyzes at the extracellular pH of the solid tumor, and completely hydrolyzes at the endosomal pH. Meanwhile, the surface property of the micelle converts from neutral to positively charged due to the generation of amino groups from the cleavage of the imine bond at tumor pH. The ionization on the surface facilitates the cellular uptake of the micelles through the electrostatic interaction between the micelle and the cell membrane. Subsequently, at the endosomal pH, with more complete cleavage of the polymer the micellar structure dissociates, and the system becomes very membrane-disruptive, inferring an enhanced intracellular delivery capability via the endosomal pathway.

INTRODUCTION

The ultimate goal of controlled drug delivery is to achieve a desired therapeutic concentration at the targeting site while the drug concentrations at other tissues are kept at safe levels (*1*). An ideal controlled delivery vehicle for antitumor drugs should have long circulation duration, the ability to catch tumor cells, and eventually the ability to efficiently deliver the drug into the cytoplasm (*2, 3*). Therefore, a key issue is to construct multifunctional drug carriers with the ability to tune their interactions with different biological membranes following the change of environmental conditions during the entire delivery procedure (*4*). In addition to the conjugation of various targeting antibodies and ligands (*5*−*8*), surface charge conversion of a drug carrier in response to the change of external pH around 6.8−7.4 would also help to gain smart antitumor drug delivery systems, since the extracellular environment of solid tumors is slightly acidic (pH ∼6.8) compared with the physiological pH (7.4) (*9*−*12*). Recently, a few such multifunctional antitumor drug delivery systems have been reported based on some charge conversion polymers (*4*), such as poly(L-histidine) ($pK_b = 6.5$) (*9*) and poly(sulfonamide) ($pK_a \sim 7.0$) (*10*).

On the other hand, in nanosized delivery systems a protective layer on the surface, usually a PEG corona, is required to prevent nonspecific interaction and stimulation to the immune system during circulation (*13, 14*). However, the PEG corona brings a controversial to hamper the intracellular transport (*14, 15*). In order to enhance the bioavailability of the therapeutic agents, many strategies have focused on the development of intelligent polymeric colloidal systems and liposomes with low-pH triggered membrane disrupting ability (*16*−*19*), because nanosized carriers are mainly taken up by cells via endocytosis and the pH values in endosomes (5.0−6.5) are much lower than the physiological pH (*20*). It is reasonable to insert acid-cleavable linkers in a nanocarrier to induce the destabilization of the carrier in endosome (*21*−*24*), hence the disruption of the endosomal membrane to facilitate the release of incorporated drug into cytoplasm (*16*). So far, acid-labile covalent bonds such as hydrazone (*25*−*28*), acetal (*16, 21, 22, 29*), and orthoester (*30, 31*), which hydrolyze rapidly in the endosomal compartment (pH ∼5), are extensively used to build the intracellular delivery systems. However, unlike the charge conversion polymers, tumor specificity has rarely been gained from the inclusion of these linkers, since the gap between physiological pH (7.4) and the extracellular pH of the tumor (6.8) is so subtle that the degree of the linker cleavage at tumor pH could not cause a significant property change of the carriers (*17*).

Imine bond hydrolyzes under very weak acidic conditions; however, it is scarcely used to construct pH-triggered delivery vehicles, since it is unstable at physiological pH (*32*). However, early studies mainly on Schiff base amphiphiles have shown that $\pi-\pi$ conjugation can significantly improve the stability of imine bond in water (*33, 34*). Thus, the investigation of the pH sensitivity of those structures around physiological pH is interesting and helpful for the design of pH-triggered delivery systems, since the hydrolysis of an imine bond generates an amino group, which could affect the charge property of the system. We have previously studied a benzoic-imine linker and found that it hydrolyzes under very slightly acidic conditions whereas it is stable at neutral and basic pH due to the proper $\pi-\pi$ conjugation extent (*35*). Amphiphilic poly(L-lysine) micelles were PEGylated via the benzoic-imine linker and showed a neutral zeta potential at physiological pH (7.4) but were positively charged under weak acidic conditions. In the present work, another advantage of the benzoic-imine bond was that the hydrolysis level is significantly influenced by the solution pH within a very narrow pH interval (7.4−5.0). In a drug nanocarrier, the pH-dependent hydrolysis of the benzoic-imine bond suggests an internal structural evolution of the carrier, e.g., production of more positively charged groups, with the acidity in body sites such as solid tumors (pH ∼6.8) and endosome (pH ∼5.0−6.5), hence the increase of electrostatic interaction between the carrier and biological membranes. This will probably generate multifunctional nature of the carrier for tumor-

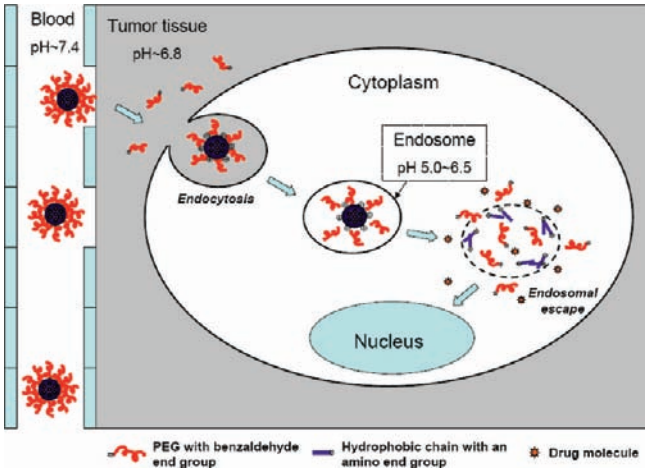

Figure 1. Schematic representation of a multifunctional drug carrier with tumor-targeting capability and intracellular delivery ability originated from the pH-dependent progressive hydrolysis of a chemical bond, e.g., benzoic-imine, in the carrier-forming polymer. The particle has a PEG corona to obtain prolonged circulation in the blood. A suitable particle size would accumulate the carrier in tumor tissue by the "enhanced permeation and retention effect" (EPR). Under the weak acidic condition in a tumor, the particle surface becomes positively charged due to partial hydrolysis of the imine linker, facilitating cellular uptake through adsorptive endocytosis. Subsequently, in the more acidic environment of the endosome, the complete hydrolysis of the imine bond causes the particle to dissociate and destabilize the endosomal membrane to release the therapeutics rapidly into the cytoplasm.

specific uptake and enhanced intracellular delivery even without the inclusion of a biological ligand. The schematic strategy of such a system, i.e., a model polymeric micelle, is shown in Figure 1.

EXPERIMENTAL PROCEDURES

Materials. Methoxy poly(ethylene glycol) (mPEG) (MW = 2k Da), *n*-octadecane amine, dicyclohexyl carbodiimide (DCC), 4-(dimethylamino) pyridine (DMAP), sodium borohydride ($NaBH_4$), pyrene, Triton X-100, doxorubicin (DOX), chloroform-*d* ($CDCl_3$), deuterated water (D_2O), and phosphate buffered saline (PBS) were all purchased from Sigma-Aldrich (St. Louis, US). *p*-Formylbenzoic acid was a generous gift from Beijing Prina Chemical Industry Co., Ltd., China. Solvents and other compounds were obtained form Beijing Chemical Reagents Company, China. All reagents were used as received.

Synthesis of Amphiphilic Polymers (PEG-b-C18 and PEG-C18). Methoxy poly(ethylene glycol) benzaldehyde (PEG-CHO) was synthesized as previously described (*35*). Typically, *p*-formylbenzoic acid (6 g, 10 equiv), DCC (8.2 g, 10 equiv), and DMAP (1.2 g, 2.5 equiv) were added to a solution of mPEG (8 g, 1 equiv) in dichloromethane (DCM) (150 mL). After stirring for 24 h, the solution was filtered. The filtrate was concentrated, dissolved in isopropanol (80 mL), and cooled at 0 °C for 2 h. The resulting crystals were collected by filtration and washed with isopropanol and diethyl ether with 80% yield. ^{1}H NMR ($CDCl_3$): δ 10.12 (s, 1H), 8.23 (d, 2H), 7.95 (d, 2H), 3.65 (m, CH_2 of PEG), 3.32 (s, 3H).

n-Octadecane amine (300 mg, 1 equiv) was dissolved in 10 mL of DMSO. To this solution was added a desired amount of the functionalized PEG (2 g, 0.9 equiv) which was dissolved in 50 mL of DMSO. The mixture was stirred and heated to 40 °C for 4 h before the solvent was evaporated by a rotary evaporator. The rough product was washed with diethyl ether and methanol, and dried under reduced pressure at 40 °C to gain a white powder-like PEG-b-C18 in an 80% yield. ^{1}H NMR ($CDCl_3$): δ 8.34 (d, 1H), 8.10 (d, 2H), 7.80 (d, 2H), 3.66 (m, CH_2 of PEG), 3.40 (s, 3H), 2.06 (m, 2H), 1.63 (m, 2H), 1.28 (m, CH_2 of *n*-octadecane amine), 0.90 (t, 3H).

200 mg of the PEG-b-C18 (1 equiv) was dissolved in 10 mL of ethanol with stirring followed by the addition of 6.5 mg of $NaBH_4$ (2 equiv) to reduce the imine bond to amine. The mixture was stirred overnight, dialyzed against 0.05 M HCl and then water (molecular weight cutoff 2 kDa), and freeze−dried. The resultant white powder was washed with diethyl ether and dried under reduced pressure to gain the non-acid-labile PEG-C18 as a control polymer of the PEG-b-C18 for the property characterizations. The yield was 70%. ^{1}H NMR ($CDCl_3$): δ 8.05 (d, 2H), 7.53 (d, 2H), 4.37 (m, 2H), 3.65 (m, CH_2 of PEG), 3.40 (s, 3H), 2.68 (t, 2H), 1.63 (m, 2H), 1.28 (m, CH_2 of *n*-octadecane amine), 0.90 (t, 3H).

Characterization. ^{1}H NMR analysis was performed on polymer solutions in $CDCl_3$ or in deuterated water (D_2O) at a required pH adjusted by DCl and/or NaOD using a Bruker AMX 600 MHz spectrometer. Infrared spectroscopy (FTIR) of the polymers was recorded using a Bruker Equinox 55 FT-IR spectrometer. Freeze−dried polymer was pressed with KBr under vacuum and scanned from 4000 to 400 cm^{-1} with a resolution of 2 cm^{-1}. To monitor the hydrolysis of the benzoic imine linkage at acidic pH, PEG-b-C18 was dispersed in water at an acidic pH (e.g., 5.0, adjusted by adding 0.1 M HCl), and then aliquots of the dispersion were dropped on KBr, dried, and recorded.

Micelle Formation of the Amphiphilic Polymers. Polymer samples were dispersed in water or PBS buffer with a desired pH by probe sonication using a JY96-II probe sonicator (Zhejiang Xin-Zhi, China) with the output set at 150 W. The solution pH was checked by a Delta 320 pH meter (Mettler-Toledo Instrument Ltd., Switzerland) after sonication.

Dynamic Light Scattering and Zeta Potential Measurement. Particle size measurement was carried out with a Brookhaven Zetaplus analyzer (Brookhaven Instruments Corporation, US), and the zeta potential was measured using a Zetasizer 3000 HS (Malvern Instruments, UK). All samples were passed through a membrane filter (pore size: 450 nm, Millipore) before detection.

Fluorescence Spectrophotometry. Aliquots of pyrene stock solution (1.54×10^{-5} M in acetone, 200 μL) were added to 5 mL volumetric flasks, and acetone was evaporated. Five milliliters of the aqueous polymer solution was then added to the volumetric flasks containing the pyrene residue. The solutions were equilibrated for 4 h at 60 °C. Fluorescence spectra of the polymer solutions were then recorded on a fluorescence spectrometer (Cary Eclipse, Varian, US). The emission spectra were recorded from 350 to 500 nm with an excitation wavelength of 340 nm. The first inflection point of the intensity ratio plot of the third band to the first band (I_3/I_1) against polymer concentration was determined as the critical micelle concentration (cmc).

Drug Loading and Release. Doxorubicin hydrochloride (1−5 mg, 1 equiv) was stirred with TEA (3 equiv) in DMSO for overnight before the solvent was evaporated using a rotary evaporator. An aqueous solution of the polymers (PEG-b-C18 or PEG-C18, 5 mL, 1 mg/mL) was then added, and the mixture was sonicated using a bath sonicator for 20 min. The dispersion was transferred into a dialysis tube (molecular weight cutoff 2 kDa) and dialyzed against water for 24 h at pH = 7.4. The entrapped drug amount was determined by measuring the UV absorbance at 480 nm (UV-1601PC, Shimadzu, Japan). Freeze−dried drug-loaded micelles were dispersed in PBS at different pHs (7.4 and 6.8). Three milliliters of the dispersion was transferred into a dialysis bag (molecular weight cutoff 2 kDa), and the bag was subsequently placed in a 50 mL flask containing 30 mL of PBS adjusted to a required pH. One

milliliter of solution was collected from the flask periodically, and the released drug was determined spectrophotometrically. Volume of the release medium in the flask was kept constant by adding 1 mL of fresh medium after each sampling.

Cell Culture. HepG2 cell, a human hepatocellular liver carcinoma cell line, was purchased from European Collection of Cell Cultures (ECACC), UK, and used for the cell uptake studies. The cells were grown in 75 cm^2 culture flasks as a monolayer using Dulbecco's Modified Eagle Medium (DMEM, Invitrogen, US) supplemented with 10% fetal bovine serum (FBS, Invitrogen, US) at 37 °C in 5% CO_2, 95% humidified atmosphere in an incubator. The cells were subcultured every 48 h and, before testing, were harvested by trypsinization using a 0.05% (w/v) trypsin/0.03% (w/v) EDTA solution.

Confocal Laser Scanning Microscopy Observation. HepG2 cells (2×10^5 cells/well) were cultured onto a plate with six wells; each was placed by a coverslip. They were maintained in DMEM media supplemented with 10% FBS in a humidified atmosphere of 5% CO_2 at 37 °C for 24 h. The medium was then removed, and fresh DMEM was added at a desired pH, adjusted by adding 0.1 M aqueous HCl or NaOH, containing the drug-loaded polymeric micelles (5 wt %) with an equivalent doxorubicin concentration of 10 μg/mL. The cells were incubated for 0.5 to 2 h and were fixed using 4% paraformaldehyde for 30 min at room temperature. The coverslips were then mounted on the glass microscope slide with a drop of 80% glycerol PBS solution. The DOX distribution was observed using a confocal laser scanning microscope (CLSM, Leica TCS-sp2, Germany) at excitation and emission wavelengths of 490 and 590 nm, respectively.

Flow Cytometry. HepG2 cells (2×10^5) were maintained in DMEM supplemented with 10% fetal bovine serum for 24 h at 37 °C in 5% CO_2, 95% humidified atmosphere on a 24-well plate. The medium was then changed by freshly prepared DMEM containing the drug-loaded polymeric micelles with an equivalent doxorubicin concentration of 10 μg/mL at pH 6.8 and 7.4. The cells were incubated for desired time, harvested and washed three times with PBS, and suspended with PBS. Flow cytometry was performed on a FACS calibur (BD Biosciences US).

Hemolysis. Approximately 5 mL of porcine blood was poured into a centrifuge tube. PBS (pH 7.4) was added to 50 mL, and the solution was mixed. The tube was centrifuged (Heraeus Labofuge 400R Centrifuge) at 2500 rpm for 10 min at 4 °C. The erythrocyte pellet was isolated, washed twice with phosphate buffer by resuspending the pellet in PBS (pH 7.4), and centrifuged. The pellet was weighed, and 3 wt % dispersion of the erythrocyte was prepared in PBS. 80 μL of the erythrocyte suspension was pippetted into a 96-microwell plate, followed by adding 80 μL of polymer solution of different concentration in each well. PBS and Triton X-100 (1 vol %) served as the negative and positive control, respectively. The 96-microwell plate was incubated at 37 °C for 1 h and then centrifuged at 2500 rpm for 10 min at 4 °C. The absorbance of the supernatant (100 μL) was measured at 570 nm using a microplate reader (Versamax Tunable Microplate Reader). The results were expressed as percentage hemolysis with the assumption that Triton X-100 causes 100% hemolysis and PBS, 0% hemolysis. The above experiment was repeated at different pHs (6.8, 6.5, and 5.0).

RESULTS AND DISCUSSION

Characterization of Polymer Structure and the pH-Dependent Hydrolysis of PEG-b-C18. The synthesis procedure of the PEG-b-C18 polymer is illustrated in Figure 2. The chemical structure of the polymer was examined using FTIR and ^{1}H NMR in chloroform. In the NMR spectrum,

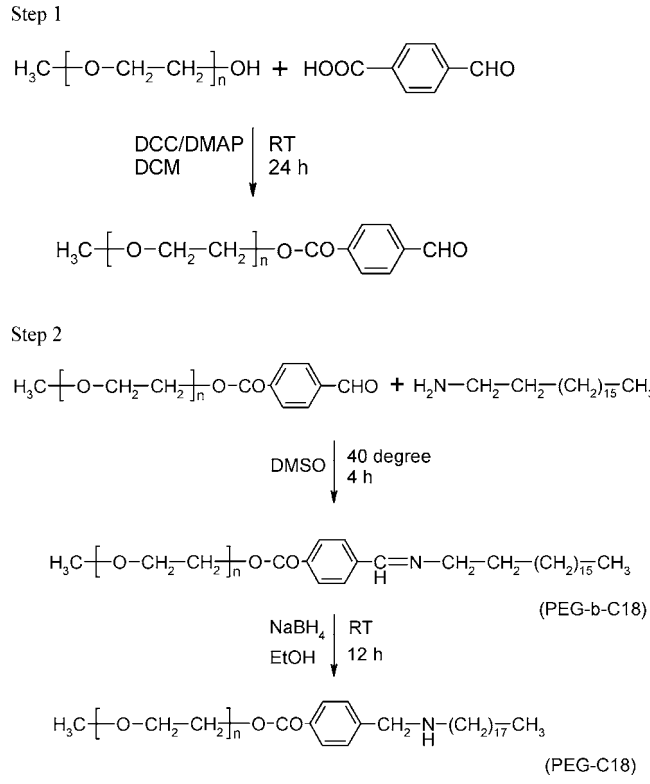

Figure 2. Schematic description of the synthesis of the amphiphilic PEG-b-C18. Further reduction of imine bond in the PEG-b-C18 to amine gets the non-acid-labile PEG-C18.

the aldehyde peak at 9.7 ppm of PEG-CHO was not observed from the purified PEG-b-C18, while the imine proton at 8.1 ppm was clearly seen. The appearance of a specific band at 1648 cm^{-1} in the FTIR spectrum further confirmed the formation of the benzoic imine linkage in the PEG-b-C18 (see Supporting Information) (*35, 36*). The purification of the polymer was also checked by thin layer chromatography (TLC) on a silica plate.

The hydrolysis kinetics as well as the hydrolysis bonding equilibrium of an imine bond is significantly influenced by environmental pH and the substitute groups (*37, 38*). While the imine bond formed from aliphatic amine and aldehyde hydrolyzes in neutral aqueous solution, the imine linkage in a Schiff base amphiphile made from aromatic amine and aldehyde is more stable due to the $\pi-\pi$ conjugation (*32*−*34*). However, for the purpose of pH-triggered drug release, it requires an acid-labile bond in the carrier-building polymer responsive to a subtle pH difference under the physiological conditions, e.g., pH 4.5−7.4 (*39, 40*). Herein, we synthesized the amphiphilic polymer by an aromatic aldehyde (PEG-benzaldehyde) and an aliphatic amine (*n*-octadecane amine) for the formation of a derivate imine linker with proper conjugation extent. The stability and pH-dependent hydrolysis of the benzoic-imine bond in the PEG-b-C18 was monitored using ^{1}H NMR, by dissolving the polymer in aqueous solution at different pHs (see Supporting Information). The aldehyde peak was not detected from the polymer in deuterated water at pH 7.4 for up to 24 h, indicating that the benzoic-imine bond is stable. At a pH of 6.5, the aldehyde peaks appeared where the imine peak still existed, an indication of partial hydrolysis of the polymer. By comparing the integrals of the aldehyde and imine peaks in the NMR spectra, it was shown that the hydrolysis extent of PEG-b-C18 increased with the decrease of solution pH. In addition, the hydrolysis reaction was rapid and reached equilibrium within 10 min, similar to our previous study (*35*). At a more acidic pH, i.e., 5.0, the

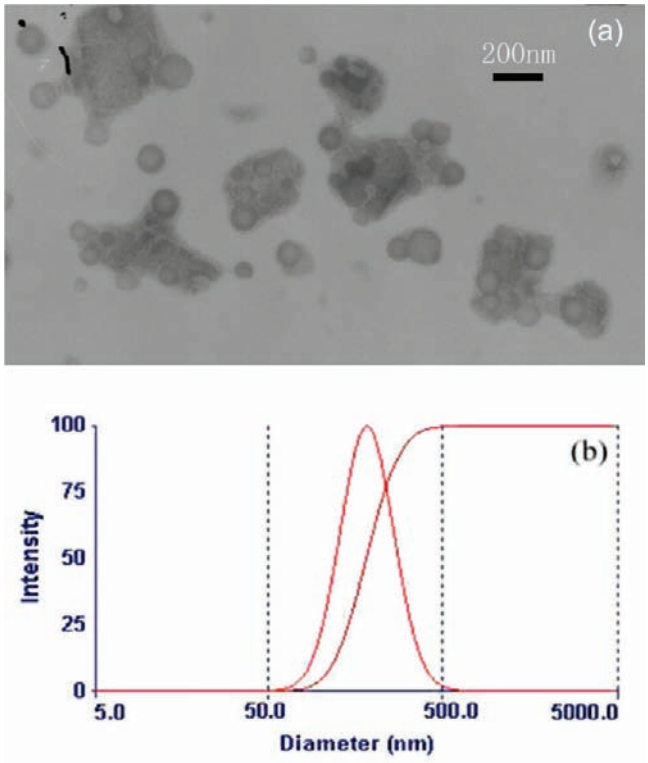

Figure 3. TEM image (a) and DLS diagram (b) of PEG-b-C18 aggregates prepared at pH 7.4.

benzoic imine linker completely hydrolyzed, evidenced by the disappearance of the imine proton peak (8.1 ppm) accompanied by the recovery of the integral of the aldehyde proton at 9.7 ppm in the ^{1}H NMR. FTIR of the PEG-b-C18 dried from a solution at acidic pH (~5.0) further confirmed hydrolysis of the imine linkage by the comparison of the specific band at 1648 cm^{-1} with that of the untreated sample.

Aggregate Formation and pH-Mediated Structural Evolution of PEG-b-C18. Micelles were formed from the PEG-b-C18 in aqueous solution at neutral and basic pH. The cmc was determined as 0.019 mg/mL at pH 7.4 using fluorescence spectrophotometry with pyrene as the probe. The aggregates are spherically shaped in the TEM image (Figure 3a) and have an average size of 181 nm measured by DLS (Figure 3b), implying the formation of a multicore structure through the entanglement of the PEG chains (*41*). The pH dependence of zeta potential and the core polarity of the aggregates, determined by fluorescence emission of pyrene, were plotted in Figure 4. At a pH higher than 7.4, the I_3/I_1 of the PEG-b-C18 micelles is larger than 1 and the zeta potential is nearly zero, because the benzoic imine linker is stable; thus, the micelles contain no charged moiety.

A sharp increase of zeta potential from 0 to 30 mV is observed with the pH decrease from 7.0 to 6.5 for the PEG-b-C18, attributed to the cleavage of PEG chains generating positively charged octadecane amine (pK_a ~11), whereas the zeta potentials of the nondegradable PEG-C18 micelles are nearly constant at different pHs (Figure 4). However, since the I_3/I_1 ratio of pyrene emission remains at a higher value, i.e., 1.15, the micellar structure should be maintained for the PEG-b-C18 at pH 6.5−5.0, while the zeta potential reaches a plateau at 30 mV. The average particle size of the PEG-b-C18 micelle at pH 6.5 is 183 nm (DLS), almost the same as the original 181 nm at pH 7.4. As described above, an acidic pH higher than 5.0 would not cause a complete cleavage of the benzoic-imine bond. It is understandable that the portion of uncleaved PEG-b-C18 molecules prevented

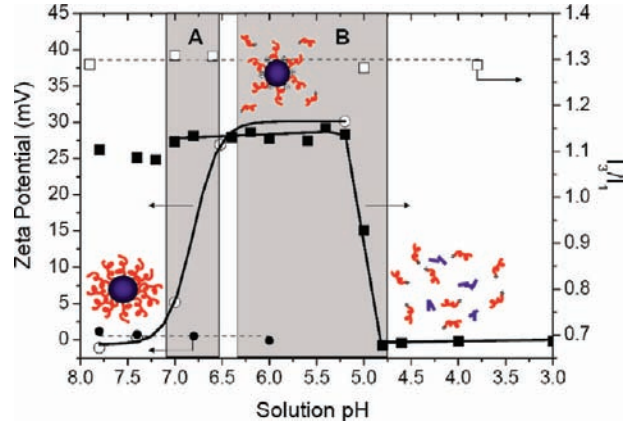

Figure 4. Zeta potential of PEG-b-C18 (○) and PEG-C18 (•) micelles, and I_3/I_1 of pyrene fluorescence emission in PEG-b-C18 (■) and PEG-C18 (□) solution as a function of solution pH. The polymer concentration is fixed at 0.5 mg/mL. pH range A, extracellular pH of solid tumor; B, endosomal pH.

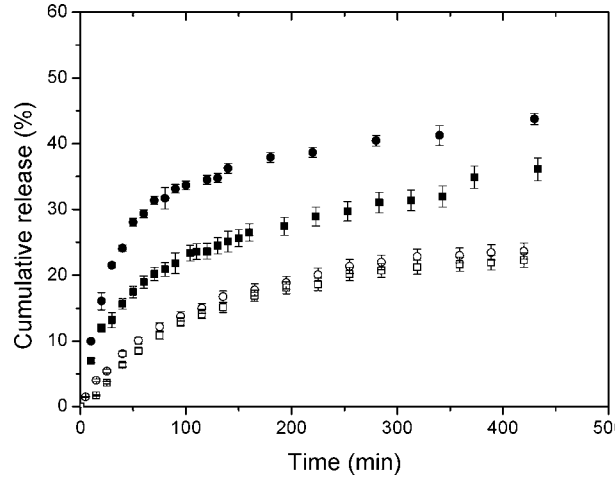

Figure 5. Cumulative release of doxorubicin from the PEG-b-C18 micelles at pH 7.4 (■) and 6.8 (•) and from the PEG-C18 micelles at pH 7.4 (□) and 6.8 (○).

the micellar structure from dissociating, and the residual octadecane amine from the cleaved polymer was solubilized in the core of the micelle with amino groups exposed on the surface leading to a positive zeta potential. The transition pH of the zeta potential is 6.7, defined as the middle value between the two inflections of the curve (Figure 4), lying in the extracellular pH region of solid tumors. The positively charged surface of the PEG-b-C18 micelles will be conducive for cell absorption in the tumor site (*10*).

At a lower pH, i.e., the endosomal pH ~5.0, further cleavage of the PEG-b-C18 will cause dissociation of the micelles. As shown in Figure 4, the I_3/I_1 ratio of the PEG-b-C18 decreases abruptly to a value close to that for water, i.e.. 0.7, an indication of demicellization (*42*). The fluorescence intensity was also reduced significantly at pH 5.0 due to the decrease of the quantum yield and the quenching of fluorescence by the primary amino group of the produced octadecane amine (*43*). Thus, with the environmental pH changing from physiological to tumor and endosomal pHs, the progressive hydrolysis of the benzoic-imine bond in the PEG-b-C18 leads to a surface property change and furthermore a structural change of the aggregates, i.e., from PEG-shielded to positively charged and finally dissociated (Figure 4).

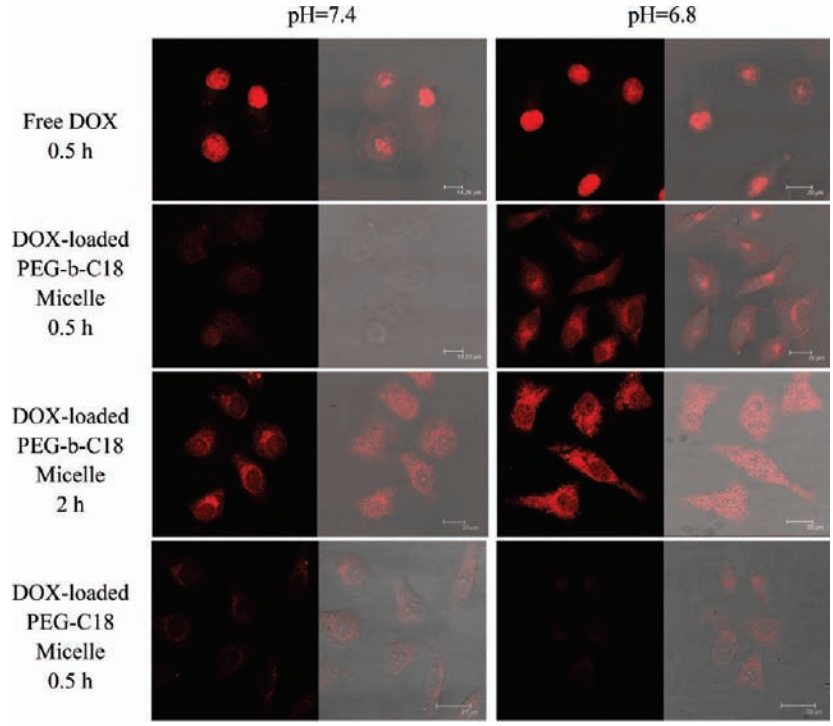

Figure 6. Confocal fluorescence microscopy images (in each column: left, doxorubicin channel; right, overlap of doxorubicin and transmittance channels) of HepG2 cells being treated with free DOX, DOX-loaded PEG-b-C18 micelles, and DOX-loaded PEG-C18 micelles with incubation time of 0.5 and 2 h at pH 7.4 and 6.8.

Drug Loading and in Vitro Release. Doxorubicin was encapsulated in the micelles using the solvent evaporation method. The PEG-b-C18 micelle with a drug loading capacity of 30 wt % has a mean size of 216 nm (DLS), slightly bigger than that of the bare micelle (181 nm). The size increase is attributed to the solubilization of drug within the hydrophobic core. Figure 5 shows the DOX release from the PEG-b-C18 and the PEG-C18 micelles at different pHs. A burst release is observed at early stage of the profiles, which may be explained by the relatively low molecular weight of the polymer especially for the hydrophobic segment, leading to a lower stability of the entrapped drug molecules in the hydrophobic cores (*1*). Nevertheless, by comparison with the PEG-C18 micelles, it could be clearly seen that the release of DOX from the PEG-b-C18 micelles was accelerated by changing the environmental pH from neutral to slightly acidic, i.e., 7.4 to 6.8 (Figure 5). Similar pH dependence on the release of prednisolone, a drug with constant water solubility in the tested pHs, from the PEG-b-C18 micelles was also observed, indicating that the PEG-b-C18 formulations are able to respond to a very subtle change of the environmental pH.

In Vitro Cellular Uptake of DOX-Loaded PEG-b-C18 Micelles at Tumor and Physiological pHs. The intracellular localization of DOX-loaded PEG-b-C18 micelles was investigated using confocal fluorescence microscopy on HepG2 cells (Figure 6). As expected, DOX is mainly distributed in the nuclear region of cells after being treated with free drug solution (*9, 26*). Differently, the fluorescence intensity was detectable in both nucleus and cytoplasm after the cells were incubated with the DOX-loaded PEG-b-C18 micelles. This proves that the internalization mechanism of the PEG-b-C18 micelle is endocytosis (*44*). However, the amount of DOX uptake showed strong pH dependence for the DOX-loaded PEG-b-C18 formulations. Flow cytometry shows that the mean fluorescence intensity is much higher in the cells treated with the drug-loaded PEG-b-C18 micelles at pH 6.8 than that at physiological pH 7.4, whereas it has little difference and stays at a low level after treatment with the noncleavable PEG-C18 formulations at the two pHs (Figure 7). The internalization of noncharged nanoparticles, for example, with a PEGylated surface, normally undergoes a fluid-phase endocytosis mechanism, while positively charged nanoparticles will be taken up by cells through a more efficient adsorptive endocytosis due to the electrostatic interaction between the carrier and the negatively charged cell membrane (*45*). However, both of the processes are nonspecific. In our studied system, the hydrolysis of the benzoic-imine bond in PEG-b-C18 occurs at tumor pH and the micelle surface converts from neutral to positively charged with the micellar structure preserved (Figure 4). Therefore, the adsorptive endocytosis is favored only at the tumor pH (6.8) to the PEG-b-C18 micelles, which would lead to the acceleration of DOX uptake under the tumor condition.

pH-Dependent Membrane Disruption of PEG-b-C18. After being endocytosed, a rapid endosomal escape of the carrier is required for protecting the carried drug from degradation during the lysosome transport. The pH-dependent membrane disruption of the micelle from physiological to endosomal pH was evaluated using porcine erythrocytes as the biological model membrane (*22*, *46*). Under physiological and tumor conditions (pH = 7.4−6.5), hemolysis of the PEG-b-C18 micelle increases slightly with the decrease of pH (Figure 8). This proves again that the positive ionization of the PEG-b-C18 micelle at tumor pH indeed increases the electrostatic interaction between the micelle and the cell membrane. The hemolysis is 22% at pH 7.4 with a polymer concentration of 10 mg/mL, in a reasonable range for intravenous administration, and remains at relatively low levels (<40%) at pH higher than 6.5 possibly due to the existence of residue PEG chains on the micelle surface. With further pH decrease to endosomal pH (5.0), a more complete hydrolysis of the benzoic-imine bond leads to the collapse of the micellar structure of the PEG-b-C18, and the system becomes rather hemolytic. At pH 5.0, hemolysis reaches as high as 60% and 100% for the PEG-b-C18 at

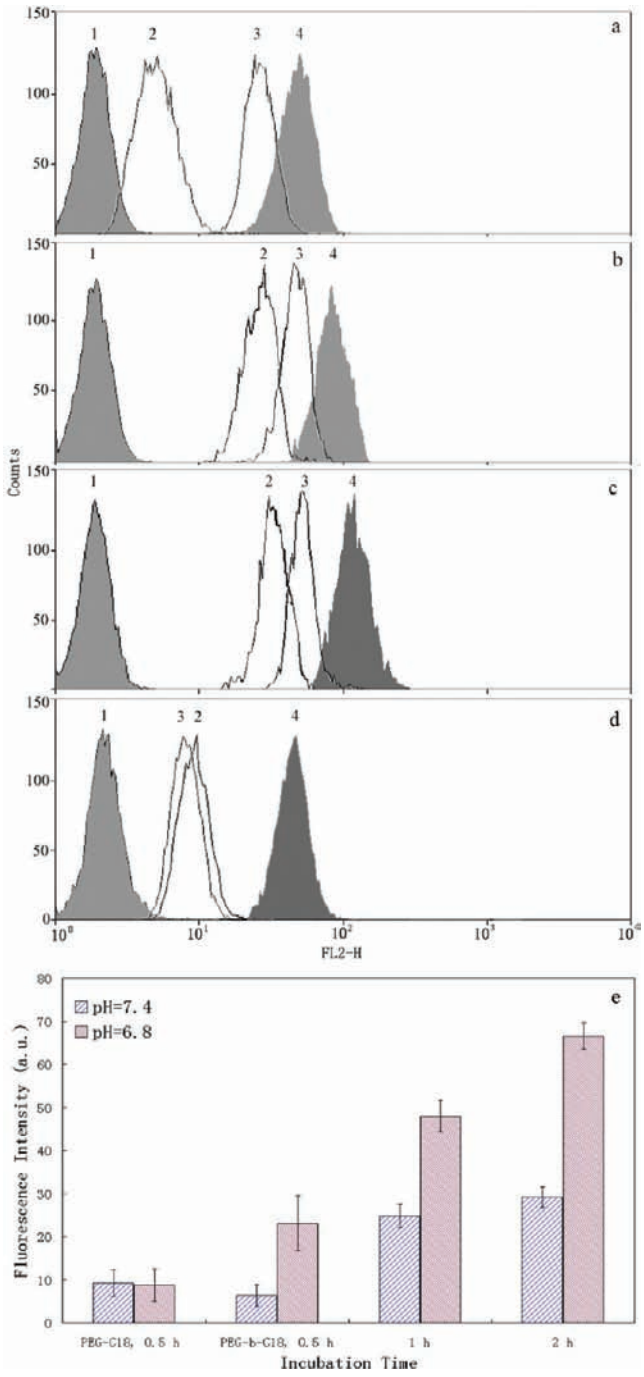

Figure 7. Flow cytometric analysis of HepG2 cells being treated with DOX-loaded PEG-b-C18 for 0.5 h (a), 1 h (b), and 2 h (c), and treated with DOX-loaded PEG-C18 for 0.5 h (d) (1, Medium; 2, DOX-loaded micelles at pH 7.4; 3, DOX-loaded micelles at pH 6.8; 4, free DOX at pH 7.4). (e) Mean fluorescence intensity on HepG2 cells after treatment with DOX-loaded PEG-b-C18 or PEG-C18 micelles at different incubation time and pH measured by flow cytometry.

concentrations of 2.5 mg/mL and 10 mg/mL, respectively (Figure 8), compared to the maximum value of 13% for the nondegradable PEG-C18, inferring the pH-triggered membrane-disrupting ability of the PEG-b-C18 micelle after it was endocytosed, which will help the system to overcome the intracellular barrier and allow the drug to release rapidly into the cytoplasm and then to the nucleus via diffusion. As shown in the CLSM images (Figure 6), DOX is found in the nuclear region only after a short incubation of 0.5 h when treated with the drug-loaded PEG-b-C18 micelles.

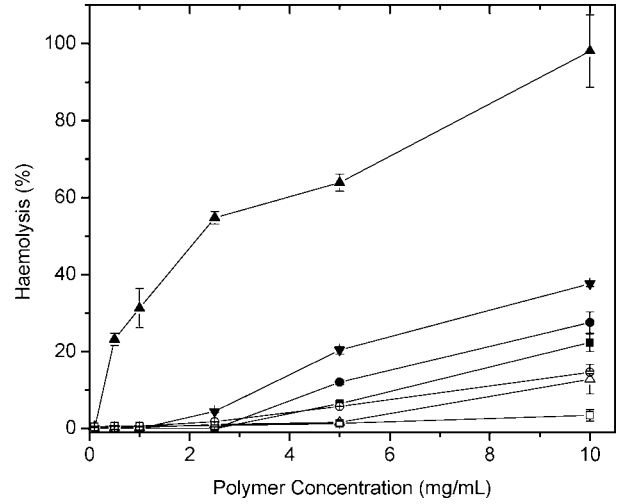

Figure 8. Hemolysis of PEG-b-C18 at pH 7.4 (■), 6.8 (•), 6.5 (▼), 5.0 (▲), and PEG-C18 at pH 7.4 (□), 6.8 (○), and 5.0 (△).

In summary, an amphiphilic polymer PEG-b-C18 was synthesized by conjugating a hydrophilic and a hydrophobic block via a novel pH-responsive benzoic-imine bond. The benzoic-imine linker was stable at physiological pH and cleaves with increasing magnitude following the decrease of pH progressively to tumor and endosomal pHs. Meanwhile, the polymer self-assembled into noncharged micellar aggregates in aqueous solution at physiological pH, which is positively charged on the surface at tumor pH and dissociates at endosomal pH. As a result, the PEG-b-C18 micelle is more easily taken up by cells under tumor condition and has an enhanced membrane disrupting capability in endosomes. The conjugation of benzoic-imine bond will be promising for future design of delivery systems with both tumor-specific uptake and intracellular delivery ability.

Bracco Research USA Inc., 305 College Road East, Princeton, New Jersey 08540. Received January 26, 2009; Revised Manuscript Received April 27, 2009

The metabolism of ^{177}Lu-AMBA (AMBA = DO3A-CH_2CO-G-(4-aminobenzoyl)-QWAVGHLM-NH_2), a radiotherapeutic compound in clinical development that binds to GRP and NMB receptors, was studied in vitro (mouse, rat and human plasma, mouse kidney homogenate) and in vivo (by analysis of mouse and rat plasma and urine following IV injection of ^{177}Lu-AMBA). The primary metabolites were Lu-DO3A-CH_2CO-G-Abz4-R, where R = -Q-OH (A), -QW-OH (B), and -QWAVGH-OH (C). Minor amounts of (D) where R = -QWAVGHLM-OH and (E) -QWAVGHL-OH were also observed. Clearance of ^{177}Lu-AMBA and of radioactivity from mouse and rat blood was rapid in vivo. In mouse and rat urine, only metabolites Lu-A and Lu-B were found—no parent drug was excreted. Unmetalated ligands and ^{nat}Lu and ^{177}Lu complexes for Lu-AMBA metabolites A−E were synthesized, characterized by HPLC and MS, and used to perform in vitro competition and direct binding studies on GRP receptor-positive PC-3 (human prostate) cancer cells. Biodistribution studies with ^{177}Lu-labeled metabolites A−E were performed in PC-3 tumor-bearing mice and the results compared with intact ^{177}Lu-AMBA. IC_{50} values for unmetalated metabolite ligands A−E were >400 nM in PC-3 cells in competition binding studies against ^{177}Lu-AMBA. No direct binding to PC-3 cells was observed with ^{177}Lu-labeled A−C, confirming IC_{50} results. ^{177}Lu-labeled metabolites A−E showed no uptake in GRP-receptor positive tumor or pancreas in PC-3 tumor bearing mice. All metabolites were rapidly excreted via the renal route (~78−87%) within 1 h. These results demonstrate that the tumor uptake observed with ^{177}Lu-AMBA is due to parent drug and not due to any of its identified metabolites.

INTRODUCTION

Bombesin, a 14-amino acid peptide, is an analogue of human gastrin-releasing peptide (GRP) and binds GRP receptors with high affinity and specificity (*1*). ^{177}Lu-AMBA (Figure 1) is a bombesin (7−14) derivative that binds to and is internalized by cells expressing gastrin-releasing peptide (GRP) and Neuromedin B (NMB) receptors (*2, 3*).

GRP receptors are overexpressed in many types of cancers, notably breast, prostate, pancreatic, and lung (*4*−*7*). They are an attractive target for molecular imaging and targeted radiotherapy of cancer, as they are located on the cell membrane and are frequently expressed in high numbers. When an agonist ligand binds to them, the receptor/ligand complex is internalized, thus facilitating either peptide receptor scintigraphy or targeted radiotherapy (*8*−*10*). Many radiolabeled bombesin derivatives have been investigated by different groups, using full-length peptide, bombesin (7−14), or analogues modified to bind to all four receptor subtypes of the bombesin receptor family (*2, 8, 9, 11*−*13*).

Lantry et al. (*2*) have demonstrated that ^{177}Lu-AMBA (AMBA = DO3A-CH_2CO-G-(4-aminobenzoyl)-QWAVGHLM-NH_2) binds with nanomolar affinity to GRP receptors. Preclinical studies demonstrated its therapeutic efficacy in a GRP-R positive PC-3 human prostate tumor-bearing mouse model. ^{177}Lu-AMBA is now in clinical trials for the radiotherapeutic treatment of prostate cancer.

This paper describes the identification of the metabolites of ^{177}Lu-AMBA, their receptor-binding characteristics, and their biodistribution and routes of excretion. The synthesis and characterization of the proposed metabolites and their unmetalated ligands and in vitro and in vivo studies with these authentic standards are also described.

EXPERIMENTAL PROCEDURES

Synthesis of AMBA and Metabolite Ligands A, B, C, D, and E. AMBA [(DO3A-CH_2CO-G-(4-aminobenzoyl)-QWAVGHLM-NH_2), DO3A = (1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)-cyclododecyl)-acetyl] was synthesized using solid-phase peptide synthesis chemistry as described by Lantry et al. (*2*). The Fmoc-protected amino acids used were purchased from Nova-Biochem (San Diego, CA), Advanced ChemTech (Louisville, KY), Chem-Impex International (Wood Dale, Ill), and Multiple Peptide Systems (San Diego, CA). Other chemicals, reagents, and adsorbents were procured from Aldrich Chemical Co. (Milwaukee, WI) and VWR Scientific Products (Bridgeport, NJ).

The peptide chains for unmetalated metabolite ligands A−E (Table 1) were assembled by either of two methods (methods A and B, below) of solid-phase peptide synthesis. For all constructs, the coupling of the glycine to the 4-aminobenzoyl attached resin and the DO3A-acetyl chelating moiety and cleavage from the resin were performed manually as indicated below.

Method A. DIC (4 equiv) was added to a solution of amino acid (4 equiv, 0.25 M in NMP) and HOBT (4 equiv, 0.5 M in NMP). After 5 min, the solution was added to the resin in NMP (15 mL NMP/g of resin). After 4 h of shaking, the resin was filtered and washed 3× with NMP. For the next coupling, the Fmoc group was removed from the resin-bound peptide with 20% piperidine in DMF (15 mL/g resin) with shaking 2× for

[a] System 3: XTerra MS C-18 (4.6 × 50 mm, 5 μ particle size): A = H_20 (0.1%TFA), B = ACN (0.1% TFA). Gradient = 0−40% B over 8 min, 3 mL/min. UV detection 220 nm. System 4: Initial condition: 10% B. Gradient = 10−40% B over 10 min.

15 min. The resin was filtered and washed 4× with NMP. The next coupling was repeated as above until the Fmoc-4-aminobenzoic acid had been added to the resin.

Method B. Synthesis of the peptides was carried out using a 0.25 mmol FastMoc protocol on an ABI 433A peptide synthesizer under N_2. In each cycle of this protocol, 1.0 mmol of a dry protected amino acid in a cartridge was dissolved in a solution of 0.9 mmol of HBTU, 2 mmol of DIEA, and 0.9 mmol of HOBT in DMF with additional NMP added. The activated Fmoc-amino acid was transferred directly to the reaction vessel. In the reaction vessel, 0.18 mmol of the C-terminal amino acid on 2-chlorotrityl resin (Novabiochem, resin substitution 0.42 mmol/g) was used. All couplings in this protocol were of 21 min duration. Fmoc deprotection was carried out with 20% piperidine in NMP. The peptide resin was finally washed with NMP for further manual derivatization.

Coupling of Glycine to 4-Aminobenzoic Acid Portion of the Peptide Chain. Fmoc-Gly-OH (10 equiv) was dissolved in NMP (5.0 mL/g) and treated with 10 equiv of HATU. The mixture was stirred under N_2 at 0 °C. DIEA (20 equiv) was directly added to the mixture and stirred for 10 min more before transferring the activated acid to the resin. The coupling was continued for 10 h at RT. The resin was drained of the reactants, and the above coupling procedure was repeated one more time. After draining the resin, it was washed with NMP (3×) and the resin was then taken to the cleavage step.

General Coupling Procedure for DOTA-tri-*t*-Butyl Ester. DOTA-tri-*t*-butyl-OH (8 equiv) was dissolved in NMP (5 mL/g). HBTU (8 equiv) was added and stirred under N_2. DIEA (16 equiv) was added neat to the above mixture and stirred for 10 min at RT before transferring the activated acid to the resin. The total volume of the reaction mixture was adjusted to about 15 mL/g of the resin used. The coupling was continued overnight (20 h). The resin was drained, washed with NMP (3×), and then washed twice with CH_2Cl_2.

Cleavage Procedure. Reagent B (15.0 mL, 88:5:5:2 TFA/water/phenol/TIPS v/v/wt/v) was added to about 1.0 g of the resin, and the vessel was shaken for 4 h at RT. The resin was filtered and then washed twice with TFA (5 mL/g of resin). The filtrates were combined, concentrated to a syrup, triturated with 20 mL of ether/g of the resin used, and centrifuged. The supernatant was decanted, and the process was repeated three times. Crude peptides were purified with a Shimadzu HPLC system using a YMC C-18 or Waters X Terra MS-C18 preparative column. The fractions were analyzed by reversed-phase HPLC and MS; appropriate fractions were combined and lyophilized.

Synthesis of ^{177}Lu and ^{nat}Lu Complexes. All commercial reagents and solvents were of reagent grade or better and used as received. L-(+)-Selenomethionine (Se-Met) was obtained from Sabinsa Corp. Bacteriostatic 0.9% sodium chloride injection (U.S.P.) was purchased from Abbott Laboratories. ASCOR L500 ascorbic acid injection (U.S.P.) [containing 500 mg/mL ascorbic acid and 0.025% (w/v) Na_2EDTA] was obtained from McGuff Pharmaceuticals, Inc. $^{177}LuCl_3$ in 0.05 N HCl was purchased from Missouri University Research Reactor (MURR). Lutetium trichloride·$6H_2O$, 99.9%, was obtained from Alfa Aesar.

^{177}Lu-AMBA. ^{177}Lu-AMBA was prepared and characterized as described by Chen et al. (*14*). For HPLC-purified product, the radiocomplex was separated from free ligand and radioactive and nonradioactive impurities by HPLC (Zorbax Bonus-RP Column, 5 μm, 80 Å pore, 250 mm × 4.6 mm, Agilent). For non-HPLC-purified product, the reaction mixture was diluted to the desired concentration using a 9:1 mixture of Bacteriostatic 0.9% sodium chloride injection USP and ASCOR L500 ascorbic acid injection USP to prevent radiolysis. HPLC-purified product had a specific activity of ∼3−4 Ci/μmol and a radiochemical purity (RCP) of >95%. Non-HPLC-purified product had a specific activity of ∼1.4 Ci/μmol and an RCP of ≥91%.

^{nat}Lu-AMBA and ^{nat}Lu-Labeled Metabolites A−E. $LuCl_3$·$6H_2O$ (14 mg, 0.036 mmol, 1.5 equiv) was added to AMBA (36.5 mg, 0.024 mmol, 1 equiv) dissolved in 5 mL of 0.2 M NaOAc buffer, pH 4.5. The solution was refluxed for 15 min and then cooled to room temperature. The metalated product was purified by HPLC on a Vydac C-18 column (10 × 250 mm) using a gradient of 80% H_2O (0.1% TFA)/20% CH_3CN (0.1% TFA) to 76%/24% in 15 min, a flow rate of 4.5 mL/min and a column temperature of 37 °C. The desired fractions were lyophilized to yield 38 mg (75%) of Lu-AMBA·2TFA·$10H_2O$ as a white solid, based on elemental analysis (C, H, N, S, F, H_2O). Authentic standards of ^{nat}Lu-labeled metabolites ^{nat}Lu-A, -B, -C, -D, and -E were similarly prepared and isolated.

Preparation of ^{177}Lu-Labeled Metabolites A−E for Biodistribution Studies. Ligand C (10 μg in 10 μL of 0.2 M NaOAc, pH 4.8) was mixed with $^{177}LuCl_3$ (5 μL, 2.11 mCi) and 0.2 M

NaOAc pH 4.8 (100 μL). The solution was heated at 100 °C for 10 min, cooled for 2 min in a water bath, and 5 μL of 5% Na_2EDTA solution in water was added. The reaction mixture was purified by HPLC to remove unchelated ligand, and the desired peak was collected into a 9:1 mixture of bacteriostatic saline/Ascor solution containing 0.2% human serum albumin (HSA), evaporated to near dryness, and diluted to 50 μCi/mL for biodistribution studies. ^{177}Lu-labeled metabolites A, B, D, and E were similarly prepared using the appropriate ligand.

Hydrolysis of ^{177}Lu-AMBA in Kidney Homogenate. Kidneys from nude mice were washed in PBS (all operations on ice), minced with scissors in Tris buffer (25 mM Tris, 150 mM NaCl, pH 7.4), and then Dounce-homogenized. The total volume of the homogenate was adjusted to contain 4 mL of Tris buffer for each gram of original tissue and then centrifuged at ~4000 × *g* for 10 min at 4 °C. The supernatant was aliquoted (200 μL) and stored at −80 °C until use. HPLC-purified ^{177}Lu-AMBA (25 μL, 3.50 Ci/μmol, 2.25 μCi, 0.00064 nmol) was incubated at 37 °C in 200 μL of kidney homogenate that was diluted 1:5 in Tris buffer immediately before use. Aliquots were removed and heat-denatured (100 °C, 10 min) at 10, 20, 30, and 60 min. The control was no homogenate, heated at 100 °C for 10 min. All samples were centrifuged at 20 000 × *g* for 6 min at 4 °C, and the supernates were analyzed by HPLC, using radiodetection.

Hydrolysis of ^{nat}Lu-AMBA in Kidney Homogenate. Kidney homogenate (25 μL), Tris buffer (15 μL), and ^{nat}Lu-AMBA (30 μL, 6.9 mg/mL) were incubated at 37 °C. At 0, 30, or 60 min, 23 μL of the mixture was removed, combined with 46 μL of cold methanol on ice, and centrifuged at 4 °C for 10 min at 20 000 × *g* to remove the protein. Preliminary LC/MS analyses were performed on the supernatants using an Agilent 1100 Series LC/MSD and a Waters XTerra C18 column (50 × 4.6 mm, 5 μm pore size) eluted with a gradient of H_2O (0.1% TFA)/ACN (0.1% TFA) at a flow rate of 0.5 mL/min. To confirm the identity of the metabolites, each metabolite peak was isolated from the supernate solution by preparative HPLC on a Vydac C18 column (5 μm, 4.6 × 250 mm) eluted at 1.5 mL/min with a gradient of 0−36% B over 26 min, where A = H_2O (0.1% TFA) and B = ACN (0.085% TFA). The desired peaks were detected at 280 nm. Solvents were evaporated; the samples were redissolved in 1:1 H_2O/ACN and analyzed by direct-injection MS.

In Vitro Metabolism in Mouse, Rat, and Human Plasma. Pooled normal human, rat, and mouse plasma (sodium citrate form) was obtained from Innovative Research, Inc. (Southfield, MI). ^{177}Lu-AMBA was radiolabeled as described above, but bacteriostatic saline and Ascor were omitted to avoid possible interference from EDTA and ascorbic acid. Immediately after labeling, 10 μL (1 mCi) of ^{177}Lu-AMBA was mixed with 0.99 mL of plasma and incubated at 37 °C (n = 4 per time point). At various times, sample solution (200 μL) was mixed with 10 μL of 10 mM DTPA, proteins were precipitated by treatment with 0.1 mL of 50% ice-cold EtOH (containing 5 mg/mL Se-Met) and 0.3 mL of ice-cold ACN, followed by centrifugation for 20 min at 20 000 × *g* at 4 °C. Recovery of radioactivity in the supernates was ~90%; the isolated supernates showed good stability (18 h at RT). These samples were analyzed using HPLC System 1.

HPLC Analysis of in Vitro Plasma Samples (System 1). HPLC analysis of in vitro plasma supernates was performed on a Zorbax Bonus-RP column (4.6 × 250 mm; 5 μm, Agilent) using the gradient in Table 2, where A, H_2O; B, 30 mM $(NH_4)_2SO_4$/0.1% TFA (v/v); C, acetonitrile (ACN); D, methanol (MeOH); flow rate = 1.5 mL/min, with a column temperature of 37 °C.

The amounts of ^{177}Lu-AMBA (% RCP) and metabolites were determined at each time-point from HPLC radiochromatograms.

Table 2

	mobile phases and percentage (%)			
time	A	B	C	D
0−5 min	70	30	0	0
15 min	44	30	13	13
30 min	30	30	20	20
35−40 min	0	30	35	35
45 min	70	30	0	0

A one- or two-compartment open model was used to fit the standard deviation-weighted, mean % RCP data in human, rat, and mouse plasma, using eq 1 [$C = Ae^{-at} + Be^{-bt}$], which was solved using the SAAM II program (*19*−*21*). The Lu-AMBA half-life was then interpolated from the fitted curves.

^{177}Lu-AMBA Metabolism in Normal Mouse and Rats. Animal studies were conducted in accordance with the U.S. Public Health Service Policy on Human Care and Use of Laboratory Animals as well as institutional guidelines. Non-HPLC purified ^{177}Lu-AMBA was diluted to 100 μCi/ 0.1 mL using 9:1 bacteriostatic saline/Ascor solution (RCP = 91%) for studies in mice and 750 μCi/ 0.1 mL (RCP ~94.0%) for studies in rats. ^{177}Lu-AMBA (100 μCi, 0.1 mL) was injected into a lateral tail vein of each of six mice (CD-1 normal males, Charles River Laboratories, ~8 weeks old, 35 g). Two mice each were sacrificed at 2 and 10 min. Urine was collected from the bladders of the sacrificed animals at t = 10 min and pooled. At 30 and 60 min, urine samples were taken from the bladder of one additional mouse each. Blood was taken from the descending aorta following CO_2 asphyxiation and stored on ice. Within 10 min, it was centrifuged at 4 °C for 15 min at 1000 × *g* to remove the cellular fraction, and the plasma fraction was removed and kept on ice. Urine samples were immediately placed on ice and treated in the same fashion as the plasma samples. An accurate aliquot of the plasma or urine was vortexed on ice with an equal volume of 50% EtOH containing 0.1% TFA (v/v), 0.05 mg/mL of Se-Met, and 0.05 mg/mL EDTA; treated with 3 parts of ice-chilled ACN and centrifuged at 4 °C for 15 min at 20 000 × *g*. Extracts were transferred to glass autosampler vials for HPLC analysis.

For studies in normal male CD rats (Charles River Laboratories), 0.1 mL (750 μCi) of ^{177}Lu-AMBA was injected into a lateral tail vein. In the first study, three rats were injected, each ~4 weeks in age and 90 g. In the followup study, a single rat ~6 weeks in age and 150 g was injected in the same manner. Blood was collected from conscious animals restrained in a soft plastic cone from the contralateral tail vein using heparin-rinsed syringes fitted with 21-gauge infusion sets. A separate syringe and infusion set was used for each time point. Urine samples were collected at 30 min and 2 h post injection (n = 1/time point).

HPLC analysis of ^{177}Lu-Labeled Metabolites in Vivo (HPLC System 2). Plasma extracts and urine samples were analyzed by HPLC using an Agilent 1100 series quaternary HPLC equipped with an autosampler and variable wavelength detector. Radioactivity was monitored using a Canberra NaI detector (model 802−2 × 2W) with high-voltage power supply (model 3102D), single channel analyzer (model 2015A), and a linear/logarithmic ratemeter (model 1481LA). Column: Vydac C18 (250 mm × 4.6 mm); column temp 37 ± 1 °C; mobile phase A, H_2O with 0.1% TFA (v/v); mobile phase B, ACN with 0.085% TFA; flow rate, 1.5 mL/min. Gradient: 0% B at 0 min, 20% B at 15 min, 23% B at 27 min, 67% B at 30 min, return to initial conditions at 36 min.

In Vivo Biodistribution of Isolated Metabolites. TAC:Cr:(NCr)-Foxn1^{nu} homozygous 4−5 week old male mice (Taconic Farms Inc.) were xenografted with human prostate cancer PC-3 cells (2 × 10^6). Studies were performed with tumors ranging

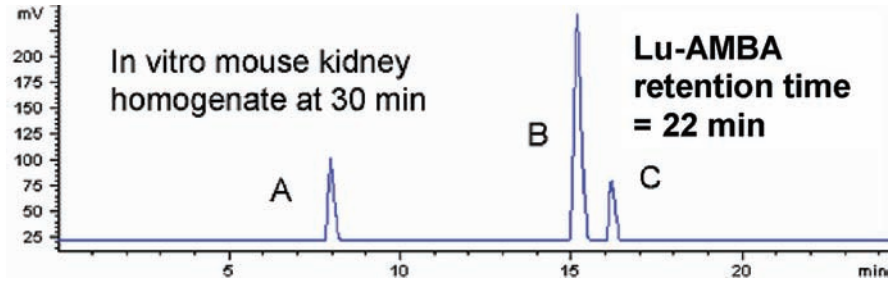

Figure 2. HPLC chromatogram of ^{177}Lu-AMBA (^{177}Lu-DO3A-CH_2CO-QWAVGHLM-NH_2) after 30 min incubation in mouse kidney homogenate at 37 °C. Metabolites A, B, and C are ^{177}Lu-DO3A-CH_2CO-R, where R = -Q-OH, -QW-OH, and -QWAVGH-OH. HPLC System 2 was used for this analysis.

from 125−1800 mm^3. Each subject (n = 4/group) was administered, via i.v. tail vein, a 0.1 mL (5 μCi) dose of HPLC-purified ^{177}Lu-AMBA or ^{177}Lu-labeled metabolite A−E (RCP > 96%, specific activity 1.9−3.54 Ci/μmol). Animals were sacrificed at 1 or 24 h via cervical dislocation, and tissues were harvested, weighed, and assayed for residual radioactivity in a Perkin-Elmer model 1480 Wizard gamma counter.

In Vitro Binding Studies - Cell Culture. Competition and direct binding studies were performed at 4 °C using the human prostate cancer cell line PC-3 (androgen-resistant prostate adenocarcinoma; American type Culture Collection) following procedures described previously (*2*). Plates were used for competition and direct binding studies on day 3 postplating, at which time the cells were confluent. Assays were performed in binding buffer containing protease inhibitors (RPMI-1640 supplemented with 0.2% BSA, 0.5 mM [4-(2-aminoethyl) benzenesulfonyl fluoride] (AEBSF) and Bacitracin (50 mg/500 mL), pH 7.4).

IC_{50} Determination. AMBA or metabolite ligands (A−E) (without added Lutetium) were diluted to concentrations ranging from 1.25× 10^{-9} M to 5× 10^{-7} M in binding buffer. Competition binding studies were performed to determine their inhibitory concentration (IC_{50}) against binding of ^{177}Lu-AMBA. After the addition of the appropriate solutions, plates were incubated for 1 h at 4 °C (n = 3 wells/data point). Incubation was ended by the addition of 200 μL of ice-cold binding buffer. Plates were washed five times, blotted dry, and counted in either an LKB CompuGamma counter or a microplate scintillation counter. Bound cpm (^{177}Lu) was plotted against concentration of metabolites to determine the concentration of the metabolite at 50% inhibition (IC_{50}).

Direct Binding of ^{177}Lu-AMBA Metabolites to PC-3 Cells. HPLC-purified ^{177}Lu-labeled metabolite A, B, or C (75 μL, RCP >98%) was added to triplicate wells at final concentrations of 0−10 μCi/mL in binding buffer. The cells were incubated for 1 h at room temperature. After washing off the unbound radioactivity (0.1% BSA in PBS, pH 7.4), total radioactivity bound to the cells was determined. In a parallel experiment, cells were incubated with various concentrations of ^{177}Lu-labeled metabolites in the presence of their respective unmetalated ligand (2 μM) to determine any nonspecific binding.

RESULTS

In Vitro Metabolism in Liver and Kidney Homogenate. The enzymatic cleavage of ^{177}Lu-AMBA was initially studied in mouse kidney homogenates for up to 60 min, followed by TLC analysis. These studies indicated that ^{177}Lu-AMBA was readily degraded in a time-dependent manner into radioactive products that were more polar than the parent ^{177}Lu-AMBA (data not shown). To identify the hydrolysis/cleavage products, nonradioactive ^{nat}Lu-AMBA or ^{177}Lu-AMBA was incubated with mouse kidney homogenate at 37 °C for 0, 30, and 60 min, and the incubation mixtures analyzed by LC-MS or HPLC. The major products were identified as Lu-DO3A-CH_2CO-G-Abz-Q-OH [m/z 881.3, M+H$^+$], Lu-DO3A-CH_2CO-G-Abz-QW-OH [m/z 1067, M+H$^+$], and Lu-DO3A-CH_2CO-G-Abz4-QWAVGH-OH [m/z 1431, M+H$^+$] based on LC-MS results. The time course for this study (data not shown) suggested that Lu-AMBA was first cleaved to Lu-DO3A-CH_2CO-G-Abz4-R, where R = QWAVGH-OH (Metabolite C), which was in turn further hydrolyzed into smaller metabolites, where R = QW-OH and -Q-OH (Metabolites B and A). After 30 min at 37 °C, ^{177}Lu-AMBA had been completely converted to ^{177}Lu-containing metabolites Lu-A, -B, and -C, as shown in the radiochromatogram in Figure 2.

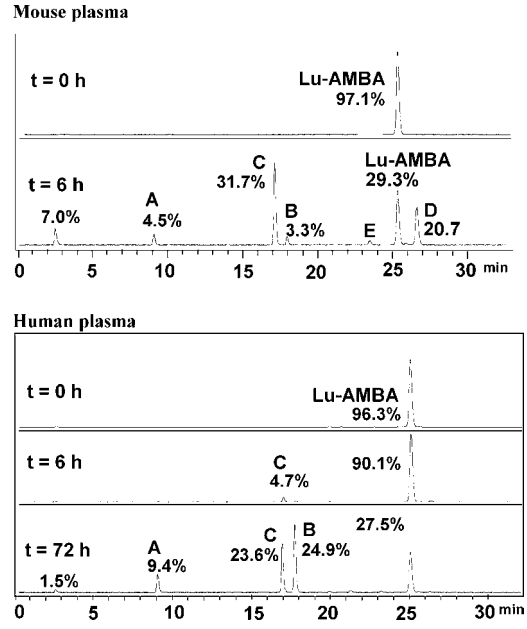

Figure 3. Comparison of the in vitro metabolism of ^{177}Lu-AMBA at 37 °C (retention time = 25 min) in mouse plasma (t = 0 and 6 h) and in human plasma (t = 0, 6, and 72 h). Metabolism is significantly slower in human plasma. The metabolites observed were Lu-DO3A-CH_2CO-G-Abz4-R, where R = Q-OH (A), QW-OH (B), QWAVGH-OH (C), QWAVGHLM-OH (D), and QWAVGHL-OH (E). HPLC System 1 was used for this analysis.

In Vitro Studies in Mouse, Rat and Human Plasma. In contrast to the results obtained with kidney and liver homogenate, the metabolism of ^{177}Lu-AMBA in plasma in vitro was very slow. Figure 3 shows typical radiochromatograms of the time course in these studies in mouse and human plasma. Full data sets for studies in mouse, rat, and human plasma are provided in the Supporting Information (Tables S1−2 and Figures 1−3S).

^{177}Lu-AMBA was metabolized faster in mouse and rat plasma than in human plasma. Radiochemical purity (RCP) data from these studies were used to calculate the half-lives of ^{177}Lu-

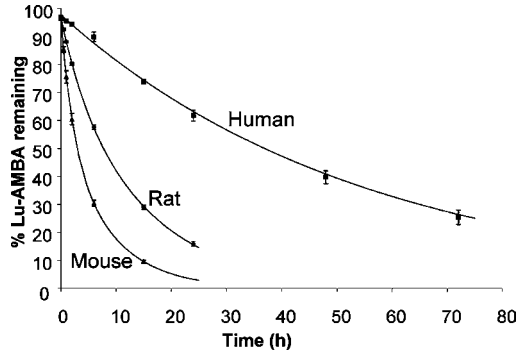

Figure 4. Disappearance of intact ^{177}Lu-AMBA in human, rat, and mouse plasma in vitro. Error bars on experimental data are indicated.

AMBA in human, rat and mouse plasma in vitro. Figure 4 shows the fits to the data. The half-lives of ^{177}Lu-AMBA in human, rat, and mouse plasma in vitro were found to be 38.8 ± 1.3 h, 8.1 ± 3.8 h, and 3.1 ± 0.1 h, respectively.

Nature of Metabolites. Table 3 summarizes the five ^{177}Lu-AMBA metabolites observed in plasma in vitro. Lu-AMBA has a retention time of 25 min in the HPLC system used for analysis of in vitro plasma samples (HPLC System 1). The peaks at t_R =18 min and t_R = 17 min corresponded to the metabolites identified by LC/MS from studies in mouse kidney homogenate: Lu-DO3A-CH_2CO-G-Abz4-QW-OH (B) and Lu-DO3A-CH_2CO-G-Abz4-QWAVGH-OH (C), respectively. The metabolite that elutes after Lu-AMBA (D, t_R = 26 min) coeluted with an authentic standard of Lu-DO3A-CH_2CO-G-Abz4-QWAVGHLM-OH, a compound in which the terminal amide of Lu-AMBA is converted to a carboxylic acid. This metabolite was especially predominant in rat plasma in vitro. The polar metabolite labeled A, t_R= 9 min, coeluted with an authentic standard of Lu-DO3A-CH_2CO-G-Abz4-Q-OH. Minor metabolite E coeluted with an authentic standard of Lu-DO3A-CH_2CO-G-Abz4-QWAVGHL-OH (Lu-AMBA without its terminal methioninamide residue). All assignments were confirmed by coinjection of authentic standards of the proposed metabolites.

Chemical Synthesis of Metabolites. Standards of the unmetalated ligands for Lu-AMBA metabolites A−E were readily synthesized by automated solid-phase peptide synthesis and/or manual methods as described above. HPLC analysis of the peptides showed them all to be >95% pure; the appropriate molecular weight was observed by API-ES mass spectra in all cases (Table 1). Their ^{nat}Lu analogues were prepared by heating excess $LuCl_3 \cdot 6H_2O$ with the appropriate ligand in acetate buffer, followed by HPLC purification and lyophilization. These ^{nat}Lu-metabolite standards showed the appropriate mass spectra and coeluted with their ^{177}Lu analogs, using HPLC Systems 1 and 2 (Table 3).

In Vitro Cell Binding Studies with Synthesized Metabolite Ligands. In vitro competition binding of AMBA metabolites to GRP receptors in PC-3 cells were performed by competing ^{177}Lu-AMBA with increasing concentrations of each of the unmetalated metabolite ligands. The results are shown in Table 4. While AMBA ligand competed with ^{177}Lu-AMBA at 5 nM (IC_{50}), the five metabolite ligands showed little or no competition, with IC_{50} >400−500 nM. Furthermore, direct binding studies performed with the ^{177}Lu-labeled metabolites A, B, and C did not demonstrate any specific binding to PC-3 cells.

In Vivo PK Studies on ^{177}Lu-AMBA - Metabolites in Mouse/Rat Plasma and Urine. The clearance and metabolism of ^{177}Lu-AMBA following injection into male CD-1 mice was studied to determine its pharmacokinetics and the rate at which metabolites formed in vivo. HPLC traces obtained from mouse plasma samples obtained at 2 and 10 min are shown in Figure 5. Fit-functions for ^{177}Lu-AMBA in rats showed an initial clearance phase ($t_{1/2}$ of 0.66 min) and a terminal clearance phase with a $t_{1/2}$ of 8.64 min. Modeling results for the metabolism of Lu-AMBA in rat plasma are shown in Figure 6.

A radiochromatogram of mouse urine at 10 min post-injection is shown in Figure 5. Mouse urine at 60 min and rat urine at 30 min had a similar appearance. No parent ^{177}Lu-AMBA was found in the urine at any time point; only ^{177}Lu-A and ^{177}Lu−B were observed.

In Vivo Biodistribution of Lu-AMBA and Its Metabolites. Biodistribution results for ^{177}Lu-AMBA and its five metabolites at 1 and 24 h are shown in Table 5. The major elimination route for all ^{177}Lu-AMBA metabolites was by renal excretion (78−87%). As reported previously (*2*), ^{177}Lu-AMBA showed high uptake in PC-3 tumors and mouse pancreas, both of which express high numbers of GRP receptors. No significant uptake in tumor or pancreas was noted for any of the ^{177}Lu-AMBA metabolites, confirming the in vitro IC_{50} and direct binding study results.

DISCUSSION

In Vitro Plasma. The metabolites formed from ^{177}Lu-AMBA in mouse, rat, and human plasma in vitro were the same across species, but the relative amounts of the various metabolites formed were different. At intermediate time points in mouse and rat plasma, Lu-labeled metabolites C and D predominated, with only small amounts of Lu-A and -B observed. In contrast, human plasma samples in vitro formed only trace amounts of Lu-labeled D; Metabolites Lu-B and Lu-C were the predominant species observed. Lu-A formed slowly in all cases. In vitro metabolism was slow in all three types of plasma, with observed half-lives of hours (Figure 4).

In vitro metabolism half-lives were significantly slower if performed in plasma containing EDTA as an anticoagulant (data not shown). Inhibition of ^{177}Lu-AMBA metabolism by EDTA strongly suggests that metalloenzymes are responsible for the metabolism of this peptide complex, as EDTA can bind to the metals found in the active site of metalloenzymes, thus inactivating them.

In Vivo Mouse and Rat. In contrast to in vitro results, the metabolism of ^{177}Lu-AMBA in vivo was rapid. Two minutes after IV administration to normal mice, only ∼45% of the radioactivity in the plasma was present as ^{177}Lu-AMBA. The remainder was present as metabolites Lu-A, -B, -C, -D, and -E, the products previously identified from in vitro studies. By 10 min post-injection, 78−87% of the radioactivity in mouse plasma had been converted to these metabolites. Similar results were obtained in the normal rat, although the rate of ^{177}Lu-AMBA metabolism was somewhat slower. By 1 h post-injection, no ^{177}Lu-AMBA was detectable. In both species, metabolites Lu-A, -B, and -C were found in the plasma. Lu-D was also a predominant species in mice, but was much less prominent in samples of rat plasma. Lu-E was found only in trace amounts.

Radioactivity cleared rapidly into the urine in both mouse and rat. For all urine samples analyzed, ∼95−100% of the radioactivity detected was due to metabolites Lu-A and -B. No parent ^{177}Lu-AMBA was excreted into any urine sample.

Nature of the Metabolites. All metabolites identified were due to selective cleavage of the -QWAVGHLM-NH_2 peptide chain responsible for binding to the GRP receptor, including removal of the terminal amide from the methioninamide residue to form metabolite D, loss of methionine to form E, cleavage of the H↑L bond to form C, cleavage of the W↑A bond to form B, and cleavage of the Q↑W bond, forming A. Consistent with the concept of enzymatic control of small bioactive peptides, we note that the metabolites reported here are inactive. Thus, it is clear that attempts to stabilize such

Table 3. Summary of Lu-AMBA Metabolites and Their Sequences[a]

Lu metabolite	Lu-DO3A-CH_2CO-G-Abz4-R R =	MW	mass spectrum	HPLC System 1 t_R (min) (in vitro studies)	HPLC System 2 t_R (min) (in vivo studies)
Parent Lu-AMBA	-QWAVGHLM-NH_2	1674.9	$[M+H]^+$: 1675.3 $[M+2H]^{2+}/2$: 837.9 $[M+Na+H]^{2+}/2$: 848.8	25.2	22.5
Metabolite Lu-A	-Q-OH	880.7	$[M+H]^+$: 881.3 $[M+Na]^+$: 903.4 $[M+2Na]^{2+}/2$: 463.2	9.0	7.9
Metabolite Lu-B	-QW-OH	1066.9	$[M+H]^+$: 1067.5 $[M+Na]^+$: 1089.5 $[M+2Na]^{2+}/2$: 556.2	17.8	14.8
Metabolite Lu-C	-QWAVGH-OH	1431.3	$[M+H]^+$: 1431.4 $[2M+3H]^{3+}/3$: 954.9 $[M+2H]^{2+}/2$: 716.2	17.0	15.6
Metabolite Lu-D	-QWAVGHLM-OH	1675.9	$[M+H]^+$: 1675.4 $[M+2H]^{2+}/2$: 837.8	26.6	23.2
Metabolite Lu-E	-QWAVGHL-OH	1544.4	ND	23	19

[a] ND = not determined; NI = not identified.

Table 4. Competition of Unmetalated Lu-AMBA Metabolite Ligands with ^{177}Lu-AMBA for GRP-R Binding in PC-3 Cells

symbol	metabolite ligands	IC_{50} [nM]
AMBA	DO3A-CH_2CO-G-Abz4-QWAVGHLM-NH_2	5
A	DO3A-CH_2CO-G-Abz4-Q-OH	>500
B	DO3A-CH_2CO-G-Abz4-QW-OH	>500
C	DO3A-CH_2CO-G-Abz4-QWAVGH-OH	>500
D	DO3A-CH_2CO-G-Abz4-QWAVGHLM-OH	>500
E	DO3A-CH_2CO-G-Abz4-QWAVGHL-OH	400

derivatives should focus on stabilization of these bonds. Garoyoa et al. attempted such a strategy in the synthesis of $^{99m}Tc(CO)_3$ derivatives bound to a modified histidyl residue bearing various analogues of -QWAVGHLM-NH_2. Replacement of Leu with the unnatural amino acid cyclohexylalanine (Cha) and/or the replacement of Met with norleucine (Nle) reportedly led to derivatives that had significantly improved stability when incubated in human plasma at 37 °C (*22*). These compounds still showed significant binding to the GRP receptor in vitro, and comparable or improved uptake in GRP receptor-positive pancreas and tumor in PC-3 tumor-bearing mice relative to unstabilized analogues, especially when a suitable spacer was inserted between the targeting group and the *retro*N^{α}-carboxylmethyl histidine residue responsible for coordination to the $Tc(CO)_3$ core. However, for the biodistributions reported, washout of the compounds from such tissues was faster than that observed for ^{177}Lu-AMBA (ref 2 and Table 5), a finding that is not ideal for radiotherapeutic applications. Similarly Höhne et al. (*23*) chose to modify the Leu residue to Statin [(3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid], along with N-methylation of the glycyl amide bond for their ^{18}F-labeled derivative 2-(4-(di-*tert*-butylfluorosilyl)phenyl)acetyl-Arg-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2. This group reported little metabolism of this construct either in vitro or in vivo. However, this agent showed relatively low uptake in GRP-receptor positive pancreas in nude mice (4.67% I.D./g at 1 h), and even lower uptake in PC-3 tumors (0.63% I.D./g), although retention in these tissues over 4 h was good. Thus, the stabilizing effects of the modifications made will need to be balanced by their effects on receptor-binding affinity, internalization, biodistribution, and clearance characteristics.

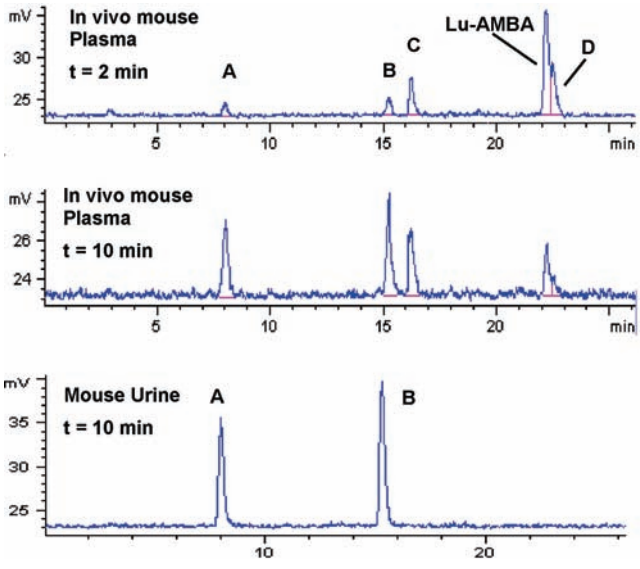

Figure 5. Radiochromatograms of in vivo mouse plasma and urine samples. HPLC System 2 was used for this analysis.

That bombesin and its analogues are readily metabolized has been known for some time. Rapid cleavage is not unexpected, as bombesin-like peptides have potent biological effects, stimulating gastric acid and pancreatic enzyme secretion, gall bladder contraction, modifying gut motility and affecting behavior, food and water intake, and thermoregulation (*1*). Rapid and highly selective proteolytic cleavage of bioactive peptides is common and allows close control over their effects (*15*). Two of the major metabolites observed are consistent with those observed by Shipp et al. (*16*), who studied the hydrolysis of bombesin, GRP, and GRP (14−27) with purified samples of the metalloprotease known as neutral endopeptidase 24.11 (NEP) or neprilysin. They found that cleavage occurred at the Trp-Ala and His-Leu peptide bonds in the conserved 7-amino acid C terminus region of these peptides [i.e., Q/H−W↑AVGH↑LM-NH_2. In Lu-AMBA, such metabolism would give rise to metabolites Lu-B and Lu-C.

Little has been reported on the metabolism of other radiolabeled bombesin derivatives. Zhang et al. (*9*) found that the modified bombesin (6−14) derivative ^{111}In-DTPA-GABA-[D-Tyr^6-QWAV-β-Ala^{11}-H-Thi^{13}Nle^{14} was cleaved in human serum between Ala^{11} and the His residue, followed by metabolism to ^{111}In-DTPA-GABA-D-Tyr-Q-OH and ^{111}In-DTPA. Addition of EDTA slowed the rate of metabolism, suggesting the involvement of a metalloprotease. The enzyme carnosinase was suggested to be the active enzyme responsible for cleavage. The ^{111}In-DTPA-GABA-D-Tyr-Q-OH metabolite is analogous to metabolite Lu-A with Lu-AMBA, but no other similarities were seen. Nock et al. (*17*) reported that the ^{99m}Tc complex of a tetraamime ligand coupled to the bombesin antagonist sequence DPhe^6-QWAVGHL-NHEt showed two polar metabolites in the urine following IV

injection, but the nature of these compounds was not determined, except to confirm that the products were not $^{99m}TcO_4^-$.

In summary, Lu-AMBA is a derivative of bombesin and is expected to be metabolized relatively rapidly in vivo. Our in vivo results confirm this expectation. Of the radioactivity remaining in mouse plasma in vivo at 10 min post-injection, an average of 18% was parent ^{177}Lu-AMBA, supporting a plasma half-life of <4 min. Of the radioactivity remaining in rat plasma at 10 min, an average of ∼40% was parent ^{177}Lu-AMBA, supporting a plasma half-life of <8 min in rat. No parent ^{177}Lu-AMBA remained in samples of rat plasma at 60 or 120 min post-injection.

The primary metabolites formed in vivo were ^{177}Lu-labeled A, B, and C. ^{177}Lu-D was also seen in mouse plasma, and to a much lesser extent in the rat plasma. Only minor amounts of E were observed. The only radioactive products observed in mouse and rat urine were metabolites Lu-A and Lu-B.

Neither the metabolite ligands nor their ^{177}Lu-labeled analogues showed any significant binding to GRP-R in PC-3 cells. All metabolite ligands had IC_{50} values >400−500 nM vs unmetabolized ^{177}Lu-AMBA, which was previously demonstrated (*2*) to have a high affinity for the GRP-R (K_d, 1.02 nmol/L).

Biodistributions of the five known metabolites of ^{177}Lu-AMBA, which showed little or no uptake in GRP receptor-positive tissues, confirmed that intact ^{177}Lu-AMBA alone is responsible for the uptake and retention in target and nontarget tissues and that the metabolites were eliminated rapidly via renal excretion. Although it showed rapid in vivo metabolism in these preclinical studies, ^{177}Lu-AMBA showed good radiotherapeutic efficacy in GRP-R(+) PC-3 tumor-bearing nude mice (*2*) and effective targeting of prostate cancer metastases in humans (*18*).

Tailored PEG for rh-G-CSF Analogue Site-Specific Conjugation

Stefano Salmaso, Sara Bersani, Anna Scomparin, Francesca Mastrotto, Rodolfo Scherpfer, Giancarlo Tonon, and Paolo Caliceti*

Department of Pharmaceutical Sciences, University of Padua, Via F. Marzolo, 5, 35131 Padova, Italy, and Bio-Ker, Scientific Park "Polaris", Località Piscinamanna, Pula (Cagliari), Italy. Received January 30, 2009; Revised Manuscript Received April 17, 2009

A new end-tailored monomethoxypoly(ethylene glycol) (PEG) for site-directed protein conjugation was synthesized according to a three-step procedure: (1) linear 20 kDa PEG-NH_2 was conjugated to 12-(Boc-amino)dodecanoic acid; (2) PEG-NHCO$(CH_2)_{11}$-Boc was deprotected by TFA treatment; (3) PEG-NHCO$(CH_2)_{11}$-NH_2 was conjugated to 6-maleimidohexanoic acid to yield PEG-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-Mal (PEG-C_{18}-Mal). The chemical intermediates as well as the final product were purified by solvent precipitation/extraction and characterized by ^{1}H NMR spectroscopy and colorimetric analysis. The synthesis procedure yielded over 90% activated product [PEG-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-Mal/PEG-NH_2 molar ratio, %]. Both PEG-C_{18}-Mal and the commercial maleimido activated 20 kDa linear PEG (PEG-Mal) were used for conjugation to ^{17}Cys of recombinant human granulocyte colony stimulating factor (rh-G-CSF). Under denaturing conditions, at pH 7.0, both activated PEGs yielded over 90% protein conjugation. Under native conditions, about 55% and 7% PEGylated protein were obtained with PEG-C_{18}-Mal and PEG-Mal, respectively. Circular dichroism analysis showed that the PEGylation does not induce detectable alteration of the protein secondary structure. On the other hand, the PEGylation conditions were found to affect significantly the protein stability. The derivatives obtained either with the two polymers by unfolding/refolding process or with PEG-Mal under native conditions displayed rapid aggregation with half-life ranging from 30 to 90 min. The derivative obtained with PEG-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-Mal in the absence of guanidinium chloride displayed remarkably higher stability with aggregation half-life of about 60 h.

INTRODUCTION

The increased demand for more potent and tailored performing biotech drugs has boosted from one side the production of engineered proteins and from the other suitable delivery techniques. PEGylation has become a valuable tool for overcoming poor physicochemical, pharmacokinetic, and immunological properties of many therapeutically useful proteins such as cytokines, hormones, enzymes, antibodies, and other biomodulators (*1*−*3*). Nevertheless, the therapeutic performance of bioconjugates strictly depends upon the polymer features and conjugation strategy: polymer size and shape, extensive or limited modification, site-directed or random conjugation (*3, 4*).

Bioconjugates with well-defined and unique chemical structure are usually difficult to obtain by classical amino-PEGylation protocols. Nevertheless, single site-specific conjugation is essential to endow derivatives with high therapeutic value such as hormones and cytokines, whose activity is dramatically decreased by multipoint/random modification that may hamper the receptor recognition (*5, 6*). In the recent years, few interesting site-specific PEGylation procedures have been indicated to produce mono-PEGylated derivatives. These techniques take advantage of chemical- or enzyme-mediated conjugation to specific amino acids in the protein sequence (*7*−*9*).

A typical example of the advantages of site-directed mono-PEGylation is offered by the recombinant human granulocyte colony stimulating factor (rh-G-CSF), a deglycosylated 19 kDa protein encoded by *Escherichia coli*, which displays its biological activity by controlling the development and proliferation of predominantly neutrophilic granulocyte colony in mammalians. Despite its pharmacological activity, the use of this protein in myelosuppressive chemotherapy and bone marrow transplantation (*10, 11*) is limited by its short half-life in the bloodstream, which requires daily injections with counteract poor patient acceptability and compliance. Furthermore, similarly to many deglycosylated proteins, rh-G-CSF is susceptible to aggregation either in long-term storage or under physiological conditions (*12*). Multiple random PEG attachments were found to enhance the pharmacokinetic properties of this cytokine, but reduced dramatically its biological activity (*8, 13, 14*). On the contrary, the rh-G-CSF conjugate obtained by reductive site-directed attachment of 20 kDaPEG to the terminal α-amino group, which is not directly involved in the receptor recognition, maintains high biological activity and provides for sustained therapeutic levels (*15, 16*).

Cysteine bioconjugation by maleimide, vinyl sulfone, dithiopyridine or iodoacetamide activated PEG represents the most interesting strategy to obtain stable site-directed mono-PEGylated derivatives (*7*). Cys is, in fact, an infrequent amino acid in the protein structure. When natively present, only one Cys residue is usually available for conjugation, as it is engaged in a disulfide bond. Furthermore, Cys can be introduced by site-directed mutagenesis into peptide sequences not directly involved in the biological activity mechanism, thus playing as a unique PEGylation site.

In most proteins, Cys is located inside deep hydrophobic pockets that avoid protein dimerization through disulfide bonding. This Cys inaccessibility prevents the penetration of large hydrated molecules like PEG, making its modification difficult. Protein denaturation under controlled conditions can be successfully used to yield the exposition and modification of hidden amino acids. Nevertheless, the unfolding/refolding process and the access of a hydrophilic macromolecule into a hydrophobic pocket can induce conformational protein alteration, which may

reflect in decreased activity and stability, thus precluding its therapeutic application.

In order to overcome the problems generated by the use of the commercial activated PEG, we prepared a new PEG derivative suitable for modification of low-accessibility amino acids under nondenaturing conditions. Since the use of hydrophobic PEG for modification of amino acids bundled into hydrophobic clefts has not been reported to our knowledge, we investigated this bioconjugation approach using rh-G-CSF as the protein model. A convenient chemical procedure for PEG hydrophobization and activation for Cys conjugation was set up, and rh-G-CSF was modified under different reaction conditions. The effect of the polymer attachment on the protein physicochemical and biological properties was investigated. For comparison, a parallel study was performed by using the commercial PEG-Mal.

MATERIALS AND METHODS

Recombinant human granulocyte colony stimulating factor (rh-G-CSF) (173 AA) was a kind gift of Bio-Ker (Pula, Italy). Linear 20 kDa monoammino-monomethoxy-poly(ethylene glycol) (PEG-NH_2) and linear 20 kDa monomethoxy-poly(ethylene glycol)-maleimide (PEG-Mal) were obtained from Nektar (Huntsville, AL). 12-(Terbutoxycarbonate-amino)dodecanoic acid [Boc-NH-$(CH_2)_{11}$-COOH], dicyclohexylcarbodiimide (DCC), and *N*-hydroxysuccinimide (NHS) were purchased from Fluka Chemika (Buchs, Switzerland). β-Mercaptoethanol was obtained from Merck (Rahway, NJ). Triethylamine (TEA) and trinitrobenzenesulfonic acid (TNBS) were furnished by Aldrich (Milwaukee, WI). 6-Maleimidohexanoic acid, 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), and all other reagents were supplied by Sigma (St. Louis, MO). Ultrafiltration was carried out using an Amicon system operating with Millipore 10 kDa cutoff membranes (Billerica, MA, USA). ^{1}H NMR analyses were carried out in $CDCl_3$ using a Bruker Spectrospin 300 (Fallanden, Switzerland)). Circular dichroism studies were performed using a J-810 Jasco spectrodichrograph (Tokyo, Japan). Light scattering studies were carried out by a Nicomp 380/ZLS photon correlation spectrometer (Particle Sizing Systems, St. Barbara, CA). The ELISA microplate reader was a Bio-Tek Instrument (Winooski, VT, USA).

Synthesis of PEG-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-Mal (PEG-C_{18}-Mal). *PEG-NHCO-$(CH_2)_{11}$-NH-Boc.* Linear 20 kDa PEG-NH_2 (500 mg, 25 μmol) was dissolved in 3 mL CH_2Cl_2 solution of dicyclohexylcarbodiimide (DCC) (103 mg, 500 μmol) and Boc-NH-C_{11}-COOH (78.8 mg, 250 μmol). The reaction was maintained overnight under anhydrous conditions and mild stirring at room temperature. Afterward, the mixture was filtered through a sintered filter funnel and added dropwise to 40 mL of ice-cooled diethyl ether. The product was recovered by centrifugation at 5000 rpm, washed three times with diethyl ether, and finally desiccated under reduced pressure.

The product was finally tested for the primary amino group evaluation (*17*).

^{1}H NMR analysis ($CDCl_3$). δ 1.25 [bs, 14H of PEG-NH-CO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NH-Boc]; δ 1.44 (s, 9H, -CH_3 of Boc); δ 2.16 (t, 2H of PEG-NH-CO-CH_2-); δ 3.04 (t, 2H of CH_2-NH-Boc); δ 3.38 (s, 3H of CH_3O-PEG-); δ 3.64 (bs, 1818 H of -CH_2CH_2-O of PEG chain). Other signals, namely, peaks corresponding to PEG-NH-CO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NH-Boc], could not be clearly identified and/or integrated.

PEG-NHCO-$(CH_2)_{11}$-NH_2. PEG-NHCO-$(CH_2)_{11}$-NH-Boc (400 mg, 19.7 μmol) was dissolved in 3 mL of TFA/water mixture (95/5, v/v) and maintained for 1 h at room temperature. The mixture was reduced to half volume under vacuum and poured into 40 mL of ice-cooled diethyl ether. The precipitate was recovered by centrifugation at 5000 rpm, washed three times with diethyl ether, and desiccated under reduced pressure. The product was finally tested for the primary amino group evaluation (*18*).

^{1}H NMR analysis ($CDCl_3$). δ 1.25 [bs, 14H of PEG-NHCO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NH_2]; δ 2.16 [t, 2H of PEG-NH-CO$CH_2CH_2(CH_2)_7CH_2CH_2$-NH_2]; δ 3.04 (t, 2H of CH_2-NH_2); δ 3.38 (s, 3H of CH_3O- of PEG); δ 3.64 (bs, 1818 H of -CH_2CH_2-O of PEG chain).

PEG-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-Mal (PEG-C_{18}-Mal). PEG-NHCO-$(CH_2)_{11}$-NH_2 (300 mg, 14.8 μmol) was dissolved in 3 mL of CH_2Cl_2 containing 6-maleimidohexanoic acid (31.2 mg, 0.148 mmol) and DCC (61 mg, 0.296 mmol). The reaction mixture was maintained overnight under stirring at room temperature and then filtered. The solution was added dropwise to 30 mL of ice-cooled diethyl ether. The precipitate was recovered by centrifugation at 5000 rpm, washed three times with diethyl ether, and desiccated under vacuum. The final product was tested for the determination of the primary amino groups and the maleimido groups (*19*). The Ellman assay was carried out as follows: 30 μL of 10 mM DTNB solution in 50 mM phosphate buffer pH 8.0 were added to 300 μL of 0.1 M phosphate buffer, 3 M guanidinium HCl, pH 7.0, containing 2 mM of activated PEG preincubated with 2 mM of β-mercaptoethanol. The reaction was maintained at room temperature for 15 min and analyzed at 405 nm by a Bio-Tek Instruments microplate reader.

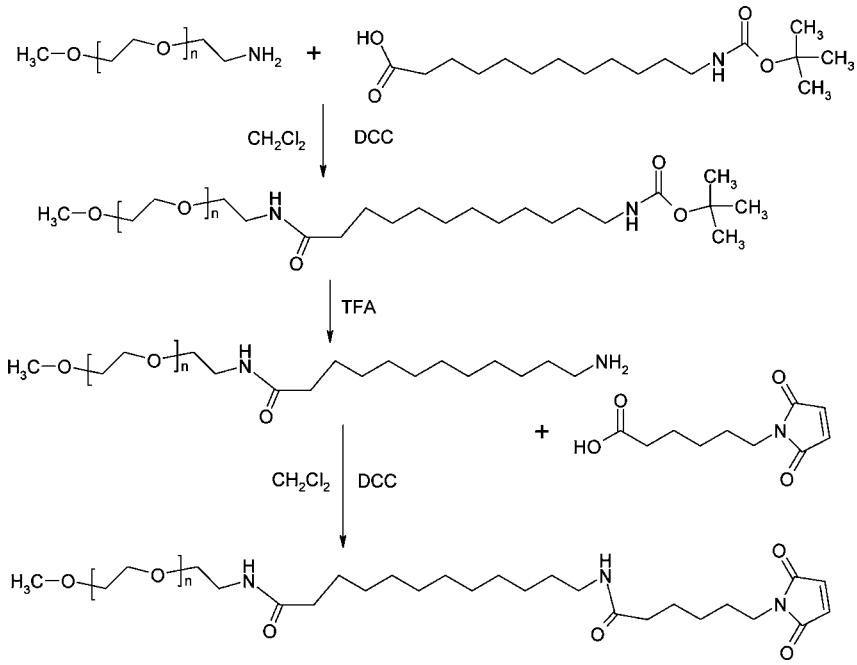
^{1}H NMR analysis ($CDCl_3$). δ 1.26 [bs, 18H of PEG-NHCO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NHCO-$CH_2(CH_2)_2CH_2CH_2$-Mal]; δ 1.47−1.73 [m, 6H of PEG-NHCO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NHCO-$CH_2(CH_2)_2CH_2CH_2$-Mal]; δ 2.17 [t, 2H PEG-NHCO-$CH_2CH_2(CH_2)_7CH_2CH_2$-NHCO-]; δ 2.35 [t, 2H -NHCO-$CH_2(CH_2)_2CH_2CH_2$-Mal]; δ 3.38 (s, 3H of CH_3O-PEG); δ 3.63 (bs, 1818H of -CH_2CH_2-O of PEG chain); δ 6.68 (s, 2H of -CH=CH- of maleimide).

Light Scattering Analysis. Photon correlation spectroscopy studies were carried out using a Nicomp 380/ZLS instrument with a fixed 90° scattering and external fiber angle. PEG-C_{18}-Mal solutions (0.2−5.0 mg/mL, 0.01−0.25 mM) were prepared by dissolving the polymer solutions in 0.1 M phosphate buffer, pH 7.0, or in 0.1 M phosphate buffer, 3 M guanidinium HCl, pH 7.0. The polymer solutions were filtered with 0.22 μm filters and then analyzed. Analyses were performed also by using 0.2−5.0 mg/mL (0.01−0.25 mM) PEG-C_{18}-Mal solutions in CH_2Cl_2.

rh-G-CSF PEGylation in Guanidinium Chloride. Two milliliter solutions of 4 mg/mL (0.2 mM) of PEG-Mal or PEG-C_{18}-Mal in 0.1 M Tris HCl, 6 M guanidinium chloride, 10 mM EDTA at pH 5.5, 6.0, 7.0, or 8.0 were added to 2 mL solutions of 4 mg/mL (0.2 mM) of rh-G-CSF in 0.1 M Tris HCl, 10 mM EDTA at the same pH. At scheduled times, the native rh-G-CSF and rh-G-CSF-PEG content in the solutions was monitored by RP-HPLC performed by a Jupiter C18 column from Phenomenex (5 μm, 250 × 4.6 mm, 300 Å) thermostatted at 55 °C. The column was eluted with 0.05% TFA in water (eluent A) and 0.05% TFA in acetonitrile (eluent B) in a gradient mode: 0−3 min, 35% eluent B; 3−23 min from 35% to 75% eluent B. The elution flow rate was set at 1 mL/min and UV detector at 280 nm. After 4 h reaction, the samples were purified by gel filtration chromatography using a Sephadex G75 superfine resin eluted with 0.1 M acetate buffer, pH 5.5. The elution fractions were analyzed by UV−vis at 280 nm for protein detection and by iodine test for PEG determination (*20*). The fractions corresponding to the PEGylated rh-G-CSF were collected, pooled, and concentrated by ultrafiltration.

rh-G-CSF PEGylation under Native Conditions. PEG-Mal or PEG-C_{18}-Mal (8 mg, 0.4 μmol) was added to 2 mL solutions of rh-G-CSF (2 mg/mL, 0.1 mM) in 0.1 M TRIS buffer, 10

Scheme 1



mM EDTA, pH 6.0. The solutions were maintained under gentle upside down mixing at 4 or 25 °C. At scheduled times, aliquot samples were analyzed by RP-HPLC. Once conjugation equilibrium was reached, the rh-G-CSF-PEG derivatives were purified by semipreparative gel filtration as reported above.

Conjugation studies were carried out in the same conditions reported above by ten sequential additions of 100 μL volumes of a 4 mg/mL polymer solution in the same buffer. The samples were analyzed by RP-HPLC.

Structural Studies. Circular dichroism spectra were recorded in the far UV (195−250 nm) using 0.1 mg/mL (5.3 μM) rh-G-CSF solutions or equimolar quantity of PEGylated rh-G-CSF in 20 mM phosphate buffer, 0.15 M NaCl, pH 7.2. The analysis were carried out using a J-810 Jasco spectrodichrograph (Tokyo, Japan).

Stability Study. Native rh-G-CSF or equimolar amounts of PEG conjugated rh-G-CSF solutions (0.33 mg/mL, 0.018 mM) in 0.1 M phosphate buffer, pH 7.2, were incubated at 4, 25, and 37 °C. At scheduled times, the solutions were sampled, centrifuged at 3500 rpm for 3 min, and finally analyzed by gel filtration HPLC using a Zorbax GF-250 analytical column (4 μm, 250 × 4.6 mm) eluted with 63 mM phosphate buffer, 3% isopropanol, pH 7.2. The flow rate was set at 0.3 mL/min and UV detector at 280 nm.

Cell Culture Studies. NFS-60 cells (CLS Cell Line Service, Eppelheim, Germany) were cultured in RPMI 1640 medium supplemented with 5.1 mL L-glutamine (200 mM), 1 mM Na-pyruvate, 10% fetal bovine serum, and 33 IU/ml IL-3 at 37 °C, under humidified atmosphere containing 5% CO_2. The cells were then incubated for 17 h in FBS and IL-3 free medium and seeded in 96-wells tissue culture plates in 100 μL of IL-3 free medium containing 10% FBS at a density of 1×10^4 cells/well. Increasing amounts of rh-G-CSF, Neulasta, or PEG-C_{18}-Mal modified rh-G-GSF ranging from 0 to 10 000 pg/mL in 100 μL volume were serially added to the wells and incubated for 44 h. To the wells were added 20 μL aliquots of WST-1 (Roche 1644807), and the material was further incubated for 4 h and then analyzed by a microplate reader set at 450 and 595 nm. The optical density at 450 nm was subtracted from the value obtained at 595 nm and plotted as function of the cytokine concentration (*21*).

RESULTS

PEG-C_{18}-Mal Synthesis. The three-step chemical procedure used for preparation of PEG-C_{18}-maleimide derivative is depicted in Scheme 1.

In the first step, the linear 20 kDa PEG-NH_2 was reacted with 12-(Boc-amino)dodecanoic acid in the presence of the condensing agent dicyclohexylcarbodiimide (DCC). The excess of 12-(Boc-amino)dodecanoic and DCC used in the reaction was completely removed by extraction in ethyl ether where both reagents are highly soluble. The degree of polymer functionalization, evaluated by the free amino group analysis and ^{1}H NMR, was 98−99% [PEG-NHCO-$(CH_2)_{11}$-NH-Boc/PEG-NH_2 molar ratio, %] and the final product yield was 87−89% (molar yield, %).

In the second step, the Boc group of PEG-NHCO-$(CH_2)_{11}$-NH-Boc was removed using a TFA/water mixture (95/5, v/v), which is typically used in peptide synthesis protocols. After volume reduction, the water content, which was less than 150 μL, did not interfere with the polymer precipitation in 40 mL of diethyl ether. The amino group analysis by the TNBS test showed that the deprotection procedure yielded 97−99% free amino groups [PEG-NHCO-$(CH_2)_{11}$-NH_2/PEG-NHCO-$(CH_2)_{11}$-NH-Boc molar ratio, %]. The ^{1}H NMR spectra did not show the characteristic Boc signal at δ 1.43 confirming that Boc was completely removed by the TFA treatment. The product yield was 80% (molar yield, %).

In the third step, PEG-NHCO-$(CH_2)_{11}$-NH_2 was reacted in the presence of excess of condensing agent DCC. Unreacted 6-maleimidohexanoic acid and DCC were completely removed by extraction in ethyl ether where both reagents are highly soluble. Dicyclohexyl urea produced during condensation reaction was eliminated by filtration.The degree of amino group conjugation [PEG-C_{18}-Mal/PEG-NHCO-$(CH_2)_{11}$-NH_2 molar ratio, %], assessed by the colorimetric TNBS test, was in the range 96−98%. The Ellman assay performed to evaluate the maleimido functions was carried out either in plain phosphate buffer or in buffer containing 3 M guanidinium chloride. In plain

Table 1. rh-G-CSF PEGylation Degree Obtained with PEG-C_{18}-Mal and PEG-Mal in the Presence of 3 M Guanidinium HCl at pH 8.0, 7.2, 6.0, and 5.5

	rh-G-CSF PEGylation degree (%)	
pH	PEG-C_{18}-Mal	PEG-Mal
8.0	50%	55%
7.2	96%	93%
6.0	88%	90%
5.5	75%	70%

buffer, the degree of polymer activation was about 30%, while in the presence of guanidinium chloride, the activation degree was found to be about 96%. The ^{1}H NMR spectra confirmed that the chemical procedure yielded 94−97% polymer activation. The final product yield was about 84% (molar yield, %).

Light scattering analysis demonstrated that, in 0.1 M phosphate buffer, pH 7.0, PEG-C_{18}-Mal can assemble into 30 nm size micelles. In organic solvent or in the presence of guanidinium chloride, the signal corresponding to the micelle disappeared.

pH Effect on rh-G-CSF PEGylation. Under denaturant conditions, PEG-C_{18}-Mal and the PEG-Mal displayed similar reactivity toward rh-G-CSF and the reaction was complete in 30 min. Table 1 shows the conjugation degree obtained after 1 h reaction with the two polymer at different pH values. The maximal polymer reactivity was obtained at pH 7.2 and was fairly unaltered at pH 6.0, while it decreased at higher and lower pH.

rh-G-CSF PEGylation under Nondenaturant Conditions. The rh-G-CSF PEGylation under nondenaturant conditions at pH 6.0 was carried out either at 4 or 21 °C. At 4 °C, the protein modification was very low, as after 200 h, only 5% and 2% of protein was modified with PEG-C_{18}-Mal and PEG-Mal, respectively. At 21 °C, the conjugation reaction was faster than at 4 °C, and it occurred according to first-order kinetics. Figure 1 shows that, after 150 h reaction, about 55% and 7% of rh-G-CSF was modified with PEG-C_{18}-Mal and PEG-Mal, respectively.

Figure 2 shows the bioconjugation kinetics and the native protein disappearance when serial PEG aliquots are added to the protein solution. After 265 h, about 58% and 16% of PEGylated rh-G-CSF were obtained with PEG-C_{18}-Mal (Figure 2A) and PEG-Mal (Figure 2B), respectively. The figures show that the native rh-G-CSF disappearance was more rapid than the bioconjugate formation. After 265 h, the residual native rh-G-CSF was 33% and 22% with PEG-C_{18}-Mal and PEG-Mal, respectively.

Structural Studies. Circular dichroism spectra of native rh-G-CSF and the various bioconjugated derivatives registered in the far-UV are reported in Figure 3. The superimposable spectra indicate that PEGylation does not induce significant alteration of the secondary protein structure.

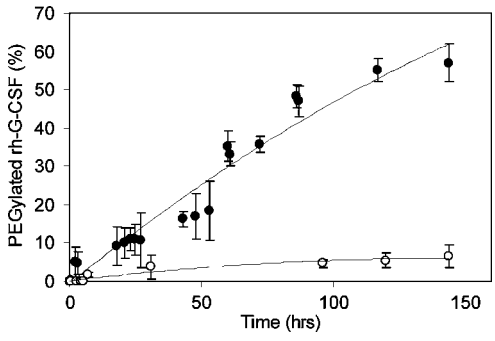


Figure 1. PEGylation profile of rh-G-CSF conjugation with PEG-C_{18}-Mal (•) or PEG-Mal (○). The time point mean values and standard deviation have been calculated on the basis of 5 experiments.

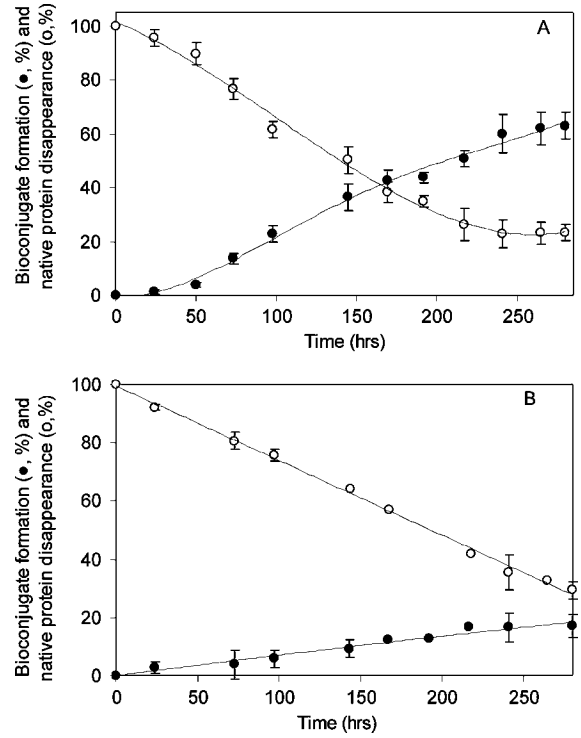

Figure 2. A. Time course PEGylation profile of rh-G-CSF by serial addition of PEG-C_{18}-Mal (A) and PEG-Mal (B). Native rh-G-CSF (○) and PEGylated rh-G-CSF (•). B. The experimental mean values and standard deviation were calculated on the basis of five experiments.

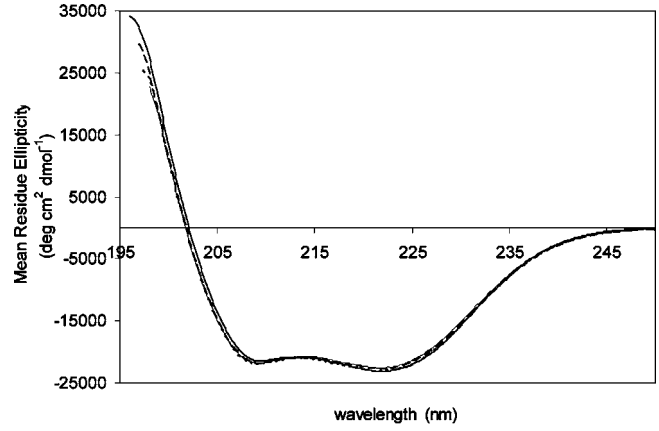

Figure 3. Circular dichroism profile of native rh-G-CSF (—), rh-G-CSF modified with PEG-C_{18} Mal under nondenaturing conditions (- -) or denaturant conditions (------) and rh-G-CSF modified with PEG-C_{18}-Mal under nondenaturing conditions (- -) or denaturant conditions (.....).

Stability Study. Stability studies were performed by incubation of native and PEGylated rh-G-CSF in physiologic medium at 4, 21, and 37 °C. The disappearance of the starting protein due to physical aggregation phenomena was evaluated by gel filtration chromatography. At 4 and 21 °C, all the rh-G-CSF forms displayed a remarkable stability, as neither native nor PEGylated rh-G-CSF underwent significant aggregation throughout 10 days incubation (data not shown).

The aggregation profiles at 37 °C reported in Figure 4 show that all the rh-G-CSF species undergo aggregation according to first-order kinetics. Native rh-G-CSF was the most stable form, as only 3% starting material underwent aggregation in 24 h. The derivatives obtained under denaturing conditions displayed a rapid aggregation with complete disappearance of the bioconjugate in about 6 h. The aggregation half-time was

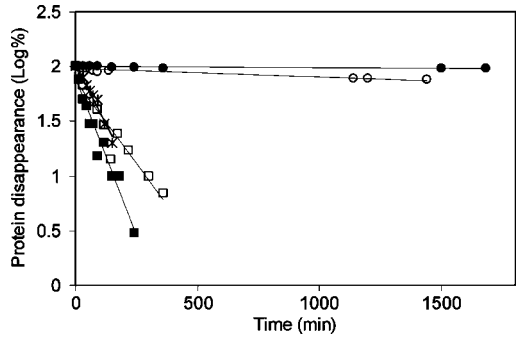

Figure 4. Stability profile of native and PEGylated rh-G-CSF at 37 °C in phosphate buffer pH 7.2: native rh-G-CSF (•, $y = (-8 \times 10^{-5})x + 1.9813$), rh-G-CSF-PEG obtained with PEG-C_{18}-Mal under nondenaturing conditions (○, $y = -(1 \times 10^{-5})x + 1.998$), rh-G-CSF-PEG obtained with PEG-Mal under nondenaturing conditions (*x*, $y = -0.0044x + 2.0247$), rh-G-CSF-PEG obtained with PEG-C_{18}-Mal in the presence of guanidinium chloride (□, $y = -0.0058x + 1.9047$), rh-G-CSF- PEG obtained PEG-Mal in the presence of guanidinium chloride (■, $y = -0.003x + 1.8712$). The time point mean values were calculated on the basis of four experiments.

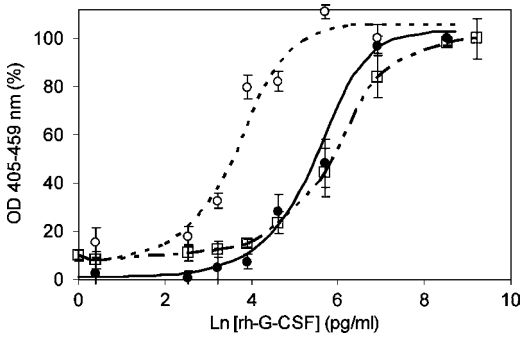

Figure 5. Biological activity of rh-G-CSF (○), Neulasta (•) and rh-G-CSF PEGylated with PEG-C_{18}-Mal under native conditions (□).

30 and 60 min for the derivatives obtained with PEG-Mal and PEG-C_{18}-Mal, respectively. Also, the PEG derivative obtained with PEG-Mal under nondenaturant conditions displayed a rapid aggregation profile. In such a case, the aggregation half-life was about 90 min. On the contrary, the PEGylated rh-G-CSF obtained with PEG-C_{18}-Mal under nondenaturing conditions displayed high stability with an aggregation half-life of about 60 h.

Biological Studies. The biological activity of the rh-G-CSF, rh-G-CSF modified with PEG-C_{18}-Mal under native conditions, and Neulasta was evaluated using NFS-60 cells whose growth responds to this cytokine. The study could not be carried out using the PEGylated rh-G-CSF forms obtained with PEG-Mal or with PEG-C_{18}-Mal under denaturant conditions because of the physical instability of these bioconjugates.

The bioassay profiles reported in Figure 5 show that native rh-G-CSF has higher bioactivity than the PEGylated cytokine, either G-CSF modified with PEG-C_{18}-Mal under native conditions or Neulasta. rh-G-CSF-PEG and Neulasta did not display significant biological activity differences. The EC_{50} values calculated for rh-G-CSF and rh-G-CSF-C_{18}-PEG were found to be about 50 and 250 pM, respectively.

DISCUSSION

Aimed at modifying selectively the ^{17}Cys bundled into a deep hydrophobic pocket of rh-G-CSF (*22*), a new end-hydrophobized maleimido-PEG (PEG-C_{18}-Mal) was designed. Preliminary studies showed that commercial PEGs failed in modifying this low-accessible amino acid under native conditions, probably because of the high hydrodynamic size, flexibility, and bulk energy of the polyoxyethylene chains. On the other hand, the Cys derivatization performed according to an unfolding/refolding procedure in guanidinium chloride solutions was found to induce microstructural protein alterations, which yielded a bioconjugate with poor stability properties.

Linear PEG was used to avoid hindrance problems typical of branched or fork-like polymers that make difficult the modification of amino acids unexposed on the protein surface (*23*). The high molecular weight (20 kDa) was chosen to endow a mono-PEGylated derivative with sustained pharmacokinetic profile. Indeed, several studies demonstrated that the prolonged permanence in the bloodstream of PEGylated proteins depends mainly on a critical polymer mass, which can be achieved either by using multiple polymer attachment or by conjugating high molecular weight PEGs (*24*). Finally, it is worth noting that linear 20 kDa PEG was also successfully used for preparation of the rh-G-CSF-PEG derivative marketed as Neulasta. This derivative, obtained by selective α-amino group conjugation of the terminal amino acid, displays a prolonged permanence in the bloodstream and improved therapeutic performance as compared to the native protein (*25*, *26*).

In order to facilitate the PEG docking to the cysteine residue of rh-G-CSF, the polymer was end-functionalized with a spacer possessing proper length, volume, hydrophobicity, and rigidity. The spacer arm was selected on the basis of the structural properties of the rh-G-CSF analogue, which is a well-structured globular protein presenting antiparallel four-α-helix bundle with a left-handed twist and overall dimensions of 45 Å × 26 Å × 26 Å (*27*).

The length of the diamidoalkyl [-NHCO-$(CH_2)_{11}$-NHCO$(CH_2)_5$-] spacer (26 Å) was calculated as being suitable for reaching the deep protein pocket where the ^{17}Cys residue is hosted. The spacer possesses a smaller volume (350 Å^3) as compared to the oligo-ethylene oxide fragment of similar length (450 Å^3). Furthermore, each ethylene oxide coordinates three water molecules that dramatically increase the hydrodynamic size of the oligomer fragment (*24*). The diamidoalkyl function possesses higher oil/water partitioning coefficient (log $P = 5.2$) and lower polar surface area (PSA = 72) than the oligo-ethylene oxide fragment (log $P = 2.2$, PSA = 96) indicating that the former has more affinity for hydrophobic pockets. Finally, the diamidoalkyl chain possesses higher rigidity than the flexible oligo-ethylene oxide fragment, which should favor the docking into the protein grooves. By virtue of these features, the hydrophobic diamidoalkyl spacer was expected to penetrate into the tightly packed protein structure under physiological conditions without forcing the pocket hosting ^{17}Cys to open up and allowing for the crypted ^{17}Cys residue conjugation via the terminal maleimido group.

As expected, under denaturant conditions, the PEG-C_{18}-Mal and PEG-Mal displayed similar reactivity toward the Cys of the rh-G-CSF analogue. In such a case, in fact, the protein unfolding allows for ^{17}Cys exposure to the bulk (*28*). The differences in the bioconjugation degree obtained at different pH values are due to the dissimilar maleimide stability and to the Cys thiol group nucleophilicty that decreases as the pH decreases. Therefore, the maximal bioconjugation efficiency was obtained at neutral pH where the maleimido hydrolysis and the -SH reactivity are balanced (*29*).

The rh-G-CSF modification under nondenaturing conditions was performed at pH 6.0 to guarantee the maleimido and protein stability over several days. rh-G-CSF was, in fact, demonstrated to display monotonic increase instability as the pH decreases from 7.0 to 4.0 (*12*, *30*). Furthermore, at this pH the conjugation selectivity is maintained, since possible reaction with other nucleophile groups, namely, amino groups of Lys, are minimized.

The rh-G-CSF PEGylation under native conditions was found to depend significantly on both the reaction temperature and the polymer physicochemical properties. At 4 °C, the rh-G-CSF modification was negligible with either PEG-C_{18}-Mal or PEG-Mal. This low reactivity may be ascribed to the low system energy and protein rigidity that may prevent the approach and penetration into the pocket hosting the target ^{17}Cys. As the temperature increased to 21 °C, a higher protein PEGylation degree was obtained with the PEG-C_{18}-Mal as compared to PEG-Mal, indicating that the spacer can easily penetrate into the hydrophobic protein site thus allowing for the Cys bioconjugation. However, the PEGylation was found to proceed slowly probably because of the bulk energy of the PEG chain, which partially hampers the protein interaction. Furthermore, by a kinetic point of view, maleimide inactivation in the reaction medium can compete with polymer conjugation reaction, which requires time for the polymer docking into the hydrophobic cleft.

The serial addition of polymer aliquots to the protein solution resulted in higher PEGylation yield as compared to the one-shot polymer addition, while in the case of PEG-C_{18}-Mal, only negligible differences were observed between the two methods of polymer addition. This result may be explained with the higher PEG-C_{18}-Mal stability in buffer as compared to the PEG-Mal, which undergoes faster inactivation than the former. Light scattering studies demonstrated that PEG-C_{18}-Mal, according to its amphiphilic structure, undergoes assembly forming micelles. Alkyl-terminating PEGs possess, in fact, surfactant properties and, depending on their polymer length and the alkyl structure, may form micelles once dissolved in water (*31*). It is conceivable that the formation of micelle structures, where the maleimide end group of the PEG-C_{18}-Mal is chased into the hydrophobic core of polymeric assemblies, preserves the polymer reactivity toward thiol groups with respect to non-forming micelles PEG-Mal. This hypothesis is supported by the low PEG-C_{18}-Mal reactivity toward the small substrate β-mercaptoethanol observed in plain buffer (only 30%), while in the presence of guanidinium chloride, which disassembled the micelle structure, the polymer was highly reactive (96%).

All the rh-G-CSF-PEG derivatives were found to be fairly stable at 4 and 21 °C, but the stability under physiological conditions (37 °C) was found to depend strictly on the physicochemical properties of the polymer as well as on the bioconjugation conditions. Nevertheless, the protein stability at this temperature is paramount to the pharmaceutical exploitation of the bioconjugate.

Polymer conjugation by the unfolding/refolding process was found to endow derivatives that rapidly aggregate, suggesting that the protein undergoes a misfolding process regardless of the polymer used for the protein PEGylation. Therefore, despite the spectroscopic analysis showing that the native protein structure was substantially recovered after PEGylation and refolding, the process seems to provoke microstructural but relevant conformational alterations, which induce protein aggregation. In particular, subtle tertiary structural changes involving the exposition of hydrophobic amino acids such as Trp have been found to promote cytokine aggregation (*32*). However, the slightly higher stability displayed by the PEG-C_{18}-Mal modified rh-G-CSF seems to indicate that the physicochemical properties of the macromolecule fragment, namely, size, hydrophobicity, and rigidity, directly bound to the Cys has an important role in the protein structure recovery.

The derivative obtained with the PEG-C_{18}-Mal under native conditions was found to be much more stable than the bioconjugate prepared with PEG-Mal. The low stability of the derivative obtained with PEG-Mal was also observed during the bioconjugation reaction where the concentration of the native protein in solution decrease was not balanced by the formation of bioconjugate, which was hampered by aggregation. These results indicate that the penetration of the hydrophobic spacer of PEG-C_{18}-Mal into the protein bundle does not provoke dramatic structural alterations, thus preserving its conformational integrity, which is paramount for the protein stability and activity.

Finally, the biological studies demonstrated that the polymer conjugation slightly decreases the cytokine activity, which is similar to that of Neulasta, probably because of the steric hindrance of the high molecular weight of the polymer. Possibly, the Cys residue is close to the recognition site of the protein; thus, the polymer hampers the receptor/protein interaction. However, similar to what was reported for the PEGylated interferon α 2a and 2b, the biological activity decrease should be largely compensated by the enhanced biopharmaceutical properties of the bioconjugate. Data reported in the literature show, in fact, PEGylated rh-G-CSF to display prolonged permanence in the body upon subcutaneous administration, thus producing a long-lasting therapeutic effect (*26*).

CONCLUSIONS

Nowadays, PEGnology is considered a mature and routine technique for delivering poorly performing proteins. Nevertheless, the demanding requisites for new therapeutically efficient derivatives makes critical a proper design of the PEGylation strategy, which must be tailored according to the protein physicochemical, biopharmaceutical, and therapeutic properties.

PEG tailoring with hydrophobic molecular functions has been found to achieve unexpected conjugation. In particular, shielded seldom amino acids can be selectively conjugated without alteration of the protein conformation, which could result in poor stability and loss of activity of the final product. Therefore, the use of end-hydrophobized polymers can be added to the arsenal of protein PEGylation techniques, which can be properly adopted to produce effective therapeutics.

A new magnetic resonance imaging (MRI) contrast agent based on the trimetallic nitride templated (TNT) metallofullerene $Gd_3N@C_{80}$ was synthesized by a facile method in high yield. The observed longitudinal and transverse relaxivities r_1 and r_2 for water hydrogens in the presence of the water-soluble gadofullerene **2** $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ (M = Na or H) are 207 and 282 $mM^{-1}\ s^{-1}$ (per C_{80} cage) at 2.4 T, respectively; these values are 50 times larger than those of Gd^{3+} poly(aminocarboxylate) complexes, such as commercial Omniscan and Magnevist. This high ^{1}H relaxivity for this new hydroxylated and carboxylated gadofullerene derivative provides high signal enhancement at significantly lower Gd concentration as demonstrated by *in vitro* and *in vivo* MRI studies. Dynamic light scattering data reveal a unimodal size distribution with an average hydrodynamic radius of ca. 78 nm in pure water (pH = 7), which is significantly different from other hydroxylated or carboxylated fullerene and metallofullerene derivatives reported to date. Agarose gel infusion results indicate that the gadofullerene **2** displayed diffusion properties different from those of commercial Omniscan and those of PEG5000 modified $Gd_3N@C_{80}$. The reactive carboxyl functionality present on this highly efficient contrast agent may also serve as a precursor for biomarker tissue-targeting purposes.

INTRODUCTION

Magnetic resonance imaging (MRI) is a rapidly evolving noninvasive diagnostic tool that provides high-quality anatomical images of soft tissue and, with the application of contrast enhancement agents, clear delineation of tumors and other pathological processes (*1*). Currently used MRI contrast agents are mainly gadolinium poly(aminocarboxylate) chelates with nontargeted biodistribution and limited chelate−site interaction with water, resulting in reduced flexibility. These nonspecific agents accumulate passively throughout the body and are normally excreted intact through the kidneys. In brain imaging, impairment of the blood−brain barrier allows for preferential contrast accumulation in tumor areas and hence for improved lesion delineation if sufficient contrast agent is present. Since the free metal ion is toxic, complexation with a multidentate diethylenetriaminepentaacetic acid (DTPA) ligand (*2, 3*) provides a high safety margin against dissociation of the contrast complex. However, recent reports show that the use of these agents increases the risk of development of a serious medical condition, nephrogenic systemic fibrosis, (NSF) in patients with acute or chronic severe renal insufficiency and patients with renal dysfunction (*4*). Therefore, there is a continuing need for safer gadolinium-based contrast agents with higher sensitivity (relaxivity) and target specificity to increase the ability for molecular/cellular diagnosis (*5*−*8*). To address these issues, efforts have been directed mainly toward the development of alternative contrast materials. For example, Gd-chelated contrast agents with higher relaxivity than Gd-DTPA or Gd-DTPA-BMA, gadobenate dimeglumine (Gd-BOPTA, MultiHance; Bracco Imaging SpA, Milan, Italy) (*9, 10*) have been approved. Though the structure of the gadobenate ion (one extra benzyloxymethyl group) differs slightly from that of the widely used gadopentetate ion, this leads to a slightly higher longitudinal relaxivity for the gadobenate ion (4.39 ± 0.01 vs 3.77 ± 0.01 $mM^{-1}\ s^{-1}$, 0.5 T) (*10*). More importantly, the same gadobenate dimeglumine concentration in serum causes a markedly higher r_1 relaxivity than is observed in water or saline in comparison with other conventional gadopentetate dimeglumine (9.7 vs 4.8 $mM^{-1}\ s^{-1}$) as a result of weak and transient interactions with serum albumin (*10*−*12*). Another important example is gadofosveset (MS-325), which is the first representative member of receptor-induced magnetization enhancement (RIME) contrast agents targeted to the vasculature by exploiting noncovalent binding to the plasma protein of human serum albumin (HSA) (*13*−*15*) and has been approved in the EU. The relaxivity of MS-325 in human plasma is not constant as a function of concentration and decreases from 45 to 30 $mM^{-1}\ s^{-1}$ (20 MHz) from 0.1 to 1 mmol L^{-1}, respectively (*14*), much higher than that of clinically used Gd-DTPA (4.6 $mM^{-1}\ s^{-1}$) (*14*).

Very recently, it has been found that water-soluble gadofullerenes (*16*−*25*) and gadonanotubes (*26*) exhibit much higher relaxivities than commercial Magnevist (gadolinium-diethylenetriaminepentaacetic acid, Gd-DTPA) and Ominiscan (Gd-diethylenetriaminepentaacetate-bismethylamide). Most significantly, the fullerene cage is believed to hinder both chemical attack on the lanthanide ion and the escape of the lanthanide ion, which should effectively suppress the toxicity of naked Gd^{3+} ions. Moreover, the biodistribution can be improved by modifying the cages with biologically active groups that exhibit high and specific affinity for a particular tissue, resulting in accumulation of targeting probes and thus local contrast enhancement (*27, 28*). To date, there are three basic types of Gd-based metallofullerenes reported as potential MRI contrast agents, i.e.,

$Gd@C_{82}$ (*16*−*20*, *22*, *27*), $Gd@C_{60}$ (*21*), $Sc_xGd_{3-x}@C_{80}$ ($x = 0$, 1, 2) (*23*, *24*, *29*). Among these materials, $Gd_3N@C_{80}$ potentially exhibits the highest relaxivity in units of mM^{-1} s^{-1} per mM of contrast agent because of the presence of three Gd^{3+} ions/molecule.

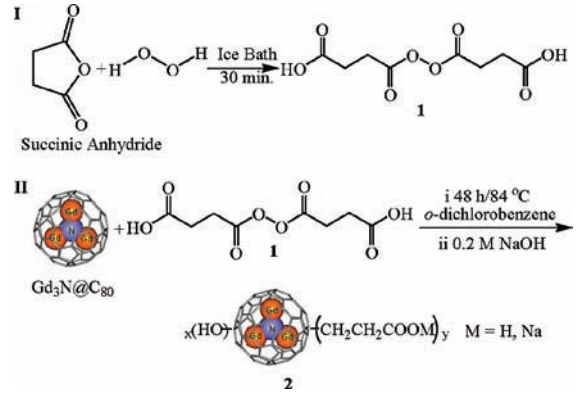
Herein, we report that $Gd_3N@C_{80}$ reacts with an acyl peroxide to produce a highly water-soluble derivative, $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ (M = H or Na) in high yield. Since the paramagnetic Gd atoms preclude using standard high-resolution NMR to confirm the structure of these nanomaterials, we have employed $Sc_3N@C_{80}$ as a diamagnetic model and synthesized its analogue, $Sc_3N@C_{80}(OH)_{\sim 33}(CH_2CH_2COOM)_{\sim 19}$, M = Na or H. This acyl peroxide free radical procedure allows for the chemical attachment of a variety of functional groups to the carbon cage through covalent carbon−carbon bonds without destroying the cage. Most importantly, the functionalized $Gd_3N@C_{80}$ exhibited promising properties as an MRI contrast agent, such as significantly high relaxivity, narrow size distribution, and diffusion properties different from Ominiscan in agarose gel, a brain-mimicking material. The *in vivo* experimental results suggest that the long-term stability of this contrast agent around the tumor will be a benefit for long-term diagnostics. On the basis of other examples in the literature (*30*,*31*), these functionalized $Gd_3N@C_{80}$ compounds also could exhibit antioxidative properties.

MATERIALS AND METHODS

$Gd_3N@C_{80}$ was synthesized and purified as reported (*32*, *33*). Succinic acid acyl peroxide (**1**) was synthesized according the literature (*34*).

Fourier transform infrared spectroscopic (FTIR) measurements were performed using a Nicolet magna-IR750 spectrometer. X-ray photoelectron spectroscopy (XPS) measurements were taken with a PHI Quantera SXM scanning photoelectron spectrometer microprobe using Al Kα radiation. The concentration of Gd^{3+} ion in the aqueous solutions was determined by inductively coupled plasma atomic emission spectroscopy (ICP-OES, VARIAN) at 342.247 nm. The relaxation times were measured at three different magnetic field strengths: 0.35 T with a TEACH SPIN PS1-B instrument, 2.4 T with a Bruker/Biospec system, and 9.4 T with a Varian Inova 400 unit. The inversion−recovery method was used to measure T_1 and the Carr-Pucell-Meiboom-Gill method was used for measurement of T_2. The relaxivities (r_1 and r_2 in mM^{-1} s^{-1}) in aqueous solution (pH = 7) and phosphate buffered saline (PBS, pH = 7.4) solution were obtained from linear least-squares determinations of the slopes of relaxation rates ($1/T_1$ and $1/T_2$) vs [Gd_3N] plots. T_1-weighted and T_2-weighted images of gadofullerene solutions were obtained at a 34, 14, and 7 μM of $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ in pure water and PBS solutions, compared with 1.0 and 0.5 mM Omniscan on the 2.4 T MR instrument using a spin−echo pulse sequence with pulse repetition time/echo times T_R/T_E, 700 ms/13 ms and 6000 ms/100 ms, respectively. Dynamic light scattering (DLS) measurements were carried out with a Spectra-Physics HeNe laser producing vertically polarized light of $\lambda_0 = 632.8$ nm and the correlator consisting ca. 288 exponentially spaced channels (ALV/CGS-3 multiple τ correlator) at six different scattering angles (30°, 45°, 60°, 75°, 90°, and 105°). Each sample was filtered with a 0.2 μm cellulose acetate membrane filter. The CONTIN analysis was used to obtain a hydrodynamic radius based on a diffusion coefficient and size distribution. Infusion into 0.6% agarose gel was carried out with solutions of gadofullerene **2** and the commercial agent Omniscan using the convection-enhanced delivery (CED) method.

Scheme 1. Synthesis of Succinic Acid Acyl Peroxide (1) (*34*) and $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) (2)



RESULTS AND DISCUSSION

Synthesis of $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) (2). For the biomedical application of the fullerenes and endofullerenes, modification of these hydrophobic materials to provide water solubility is essential. Several methods have been reported to modify the precursors of MRI contrast agents, including strong base treatment (*18*), electrophilic reaction or radical reaction (*22*, *24*), and multistep Bingel reaction (*21*, *23*). However, to date, carboxylic acid and amino-functionalized $Gd_3N@C_{80}$ have not been reported, even though these functional groups are of special importance for the tissue-targeting purposes (*23*, *24*). Herein, we report a facile method to modify $Gd_3N@C_{80}$ with carboxylic acid terminal groups (Scheme 1). Briefly, to $Gd_3N@C_{80}$ (4 mg) in 5 mL of *o*-dichlorobenzene was added succinic acid acyl peroxide (**1**) (3.2 mg, 5 equiv). The resultant solution was deaerated with flowing argon and heated at 84 °C for 48 h. In intervals of 12 h, more **1** (3.2 mg, 5 equiv) was added. After the reaction, a brown sludge precipitated from the solution. Then, 8 mL of 0.2 M NaOH aqueous solution was added to extract the water-soluble product. Two layers were obtained; the top layer was deep brown and the bottom layer was colorless (Supporting Information Figure S1a). The top layer was concentrated, and the residue was purified via a Sephadex G-25 (Parmacia) size-exclusion gel column with pure water as eluent to obtain a narrow brown band with pH = 6−7 (Supporting Information Figure S1b). The yield was 95% estimated from the ICP calibration. The solubility of the final product in pure water is ca. 13.2 mg/mL. This fraction were characterized by XPS and FT-IR and studied in detail as an MRI contrast agent.

In a separate experiment, the $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) sample **2** was placed in a dialysis membrane (MW cutoff 500 D) and dialyzed for 24 h. The resulting solution outside the membrane was subjected to ICP analysis and Gd^{3+} ion was not detected.

Structural Characterization. The electronic structure of the functionalized gadofullerene **2** was analyzed by measuring the binding energy spectrum for the C_{1s} electrons. The main line of the XPS spectrum (Supporting Information Figure S2a) exhibits a broad and asymmetric line-shape. Gaussian analysis suggests the presence of at least three components (indicated by blue, green, and purple lines, respectively). The intensities of C_{1s} components in **2** were estimated from integration of the peak area under each line to be 66.4%, 20.9%, and 12.7% for the sp^2 nonfunctionalized carbon (C═C) and sp^3 hybridized carbons (C−C and -CH_2−CH_2-), hydroxylated carbon (C−OH), and carboxylate carbon (O═C−O), respectively. Thus, gado-

fullerene **2** can be designated as $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ (M = Na, H). It was reported that the molecular stability of fullerenols largely depends on the quantity of highly oxygenated carbons, but less on the number of hydroxyl groups (*35*). In compound **2**, there are no highly oxygenated carbons based on the XPS analysis, which may be helpful to stabilize the carbon cage and thus protect the Gd_3N clusters inside from leakage (*36*). Xiao et al. reported the synthesis of [59]fullerenones starting from the fullerene mixed peroxide, $C_{60}(OO\text{-}t\text{-}Bu)_6$ (*37*). They suggested a reaction mechanism of peroxide-mediated stepwise cleavage of fullerene skeletal bonds. However, acyl peroxides, RC(O)OO(O)CR (R = aliphatic, aromatic, or another group), readily decompose to release carbon dioxide and form free radicals R″ upon mild heating (*38*). Yoshida et al. reported a reaction of C_{60} with diacyl peroxides containing perfluoroalkyl groups to yield $C_{60}(R_FOH)$ and $C_{60}(R_FCO_3H)$ (*39*). Succinic acid peroxide, **1**, decomposes to form a $HOOCCH_2CH_2COO^{\cdot}$ radical (*40*), which can subsequently lose CO_2 to yield a 2-carboxyethyl radical and add on the C═C double bonds of metallofullerenes. This method has been successfully applied to the modification of SWNTs (*41*).

The IR spectrum of **2** (Supporting Information Figure S3) displays intense bands at 1576 cm^{-1} and 1402 cm^{-1} (overlap with O—H bending vibration) for the carboxylate ion asymmetrical and symmetrical stretching vibrations, respectively. The C—O stretching absorptions at about 1120 and 1014 cm^{-1}, an intense broad O—H band at ca. 3169 cm^{-1}, and a very strong O—H bending vibration frequency at 1402 cm^{-1} indicated the —C—O—H structure of the compound. The weak peaks at 1649 cm^{-1} and 2893/2826 cm^{-1} are from C═C and C—H vibrations, respectively. It is noteworthy that the antisymmetric Gd—N stretching vibration can be observed at 689 cm^{-1}, a frequency increase of 32 cm^{-1} compared to that of pristine $Gd_3N@C_{80}$, which appears at 657 cm^{-1} (*42*). The higher vibrational energy in **2** reflects a stronger Gd—N bond relative to pristine $Gd_3N@C_{80}$. The broad absorption at 3618 cm^{-1} is from bonded water. These IR absorptions are consistent with the results from XPS analysis.

The UV—vis absorption spectra of **2** and $Gd_3N@C_{80}$ (Supporting Information Figure S4) were measured in water and toluene, respectively. The UV—vis spectra reveal that the $Gd_3N@C_{80}$ derivative **2** has lost most of the characteristic absorbance for $Gd_3N@C_{80}$ that was centered at 706 and 676 nm (*42*, *43*), indicating that the removal of p-orbitals from the π system of the cage by introduction of the hydroxyl and ethylenecarboxyl groups changes the electronic structure.

***In Vitro* MRI Study.** In order to explore the potential of compound **2** as an MRI contrast agent, the proton relaxivities (*1*), r_1 and r_2 values (the paramagnetic longitudinal and transverse relaxation rate enhancement of water protons, respectively, referred to 1 mM concentration), were measured at three different magnetic fields, 0.35, 2.4, and 9.4 T. Generally, the relaxivity, r_i, can be defined by eq 1:

$$\frac{1}{T_{i,\mathrm{obsd}}} = \frac{1}{T_{i,\mathrm{d}}} + \frac{1}{T_{i,\mathrm{para}}} = \frac{1}{T_{i,\mathrm{d}}} + r_i[\mathrm{M}] \quad i = 1, 2 \qquad (1)$$

in which $1/T_1$ and $1/T_2$ are the longitudinal and transverse relaxation rates of the solvent. $1/T_{i,\mathrm{obsd}}$, $1/T_{i,\mathrm{d}}$, and $1/T_{i,\mathrm{para}}$ are the observed relaxation rates in the presence of the paramagnetic species, the values in the absence of the paramagnetic species, and the contribution from the paramagnetic compound, respectively. [M] is the concentration of the paramagnetic species.

As shown in Table 1, the r_1 and r_2 of **2** at 2.4 T (close to clinical used magnetic fields) are 50 and 60 times larger than those of commercial Omniscan (Gd-DTPA BMA, $r_1/r_2 = 4.1/4.7$ mM^{-1} s^{-1} as shown in Table 2) under the same conditions. In contrast, these values decrease greatly in PBS solution, which we ascribe to deaggregation, leading to smaller and faster tumbling complexes and correspondingly lower relaxivities. It can be seen that the r_2/r_1 ratio of the present compound **2** increases as the magnetic field increases. This observation and the high r_2 value strongly suggest that gadofullerene **2** could also be used as a T_2-enhancing MRI contrast agent at higher magnetic fields. Toth and coauthors have reported the first relaxometric studies on $Gd@C_{60}[C(COOH)_2]_{10}$ and $Gd@C_{60}(OH)_x$ and discovered a maximum in the high-field (10—100 MHz) region of their nuclear magnetic resonance dispersion (NMRD) profiles (*36*). They suggest that the relaxivity maxima could arise from an increase in the rotational correlation time, τ_R, of the contrast agent (*46*, *47*). Although a more detailed NMRD profile measurement was not performed in the current study, the maximum at 2.4 T (100 MHz) rather than 0.35 T (15 MHz) and 9.4 T (400 MHz) suggests that the relaxivity maxima may also be due to an increase in the rotational time resulting

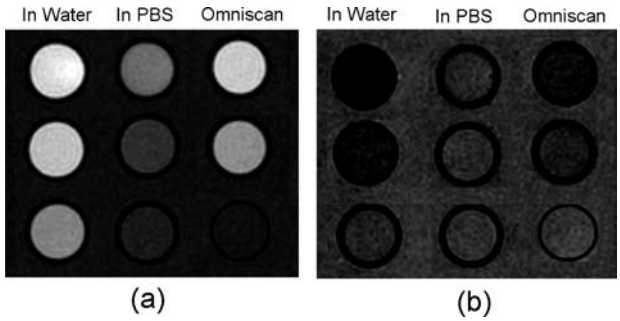

Figure 1. T_1-weighted images with T_R/T_E = 700 ms/13 ms, number of acquisitions (NA) = 4 (a); and T_2-weighted images T_R/T_E = 6000 ms/100 ms, NA = 1 (b); of **2** in pure water and PBS with concentrations of 34, 14, and 7 μM [Gd_3N] from top to bottom, respectively; and Omniscan at [Gd] concentrations of 1.0, 0.5, and 0 mM (pure water) from top to bottom. Matrix: 192 × 192; slice thickness = 2 mm.

from an increase in aggregation of the gadofullerenes in aqueous solution relative to PBS (*vide infra*).

In Table 2, the relaxivities of **2** are compared with those of other gadofullerenes under different conditions as well as the newly approved Gd-based complex in human serum plasma. It should also be noted that another Gd-based carbonaceous nanomaterial, ultrashort (20−80 nm) gadonanotubes, is reported to exhibit very high relaxivities (r_1 = 180, 1.5 T) at pH 6.5 and 37 °C (*26*). The unprecedented relaxivity and corresponding variable-field NMRDs of the latter material are not readily rationalized using classic Solomon-Bloembergen-Morgan (SBM) theory (*46*). Wilson and co-workers suggested that gadonanotubes are likely an example of special properties (magnetic/relaxivity) arising from the nanoscalar confinement of Gd^{3+} ion clusters within their carbon capsule sheaths (*26*). At clinically used field strengths (1.0−3 T), polyhydroxylated Gd@C_{82} (*18*) and Gd@C_{60} (*44*) exhibit higher relaxivities due to the larger aggregates and fast exchange with water via OH groups. The Gd_3N@C_{80} derivatives are the second member of agents with high relaxivities, but the C_{80} cage can entrap three gadolinium ions and concentrate them safely, thus providing substantially higher relaxivities (r_1/r_2 from 69/94 per Gd and 207/282 per cage). The new compound **2** together with reported Gd_3N@$C_{80}R_x$ (R = N(OH)$(CH_2CH_2O)_6CH_3$) (*24*) exhibits higher relaxivity than Gd_3N@C_{80}[Peg5000$(OH)_x$] (*23*). Additionally, compound **2** with carboxylic groups may provide a unique platform for coupling with molecular targeting moieties. Under similar conditions, Gd-BOPTA and MS-325 exhibit great advantages in human plasma relative to the routinely used Gd-DTPA-BMA, but their relaxivities are still significantly lower than those of gadofullerenes.

To confirm the large MRI signal enhancement of **2** at lower Gd concentration over that required for the commercial contrast agent Omniscan, T_1- and T_2-weighted MR images of Gd_3N@$C_{80}$$(OH)_{\sim 26}$$(CH_2CH_2COOM)_{\sim 16}$ solutions at concentrations of 34, 14, and 7 μM [Gd_3N] and Omniscan at concentrations of 1.0 and 0.5 mmol Gd/L were generated using a spin−echo pulse sequence. A strong MRI signal enhancement was observed for **2** at 14 μM, whereas Omniscan exhibits similar contrast at a concentration of 0.5 mM (over 2 magnitudes higher concentration), confirming that the MRI signal-enhancing efficiency of gadofullerene **2** is indeed much higher than that of Omniscan (Figure 1) and gadofullerene **2** is also a good T_2-enhancing contrast agent (Figure 1b). These MRI data are in conformity with the high r_1 and r_2 values reported in Table 1.

So far, several types of functionalized MRI contrast agents based on classical metallofullerenes Gd@C_{2n} ($2n$ = 60, 82) and TNT metallofullerene Gd_3N@C_{80} have been reported, such as the polyhydroxylated (*16−18, 20, 29*) and the carboxylated Gd@C_{2n} ($2n$ = 60, 82) (*21, 22*), sulfonated (*48*), and phosphated

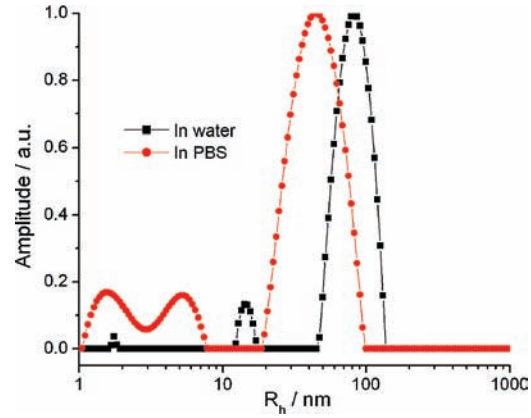

Figure 2. Intensity-weighted (intensity percent) size distribution profiles of **2** in pure water, pH = 7.0, (black line) and PBS, pH = 7.4, (red dash) at 90° scattering angle. Temperature = 25 °C.

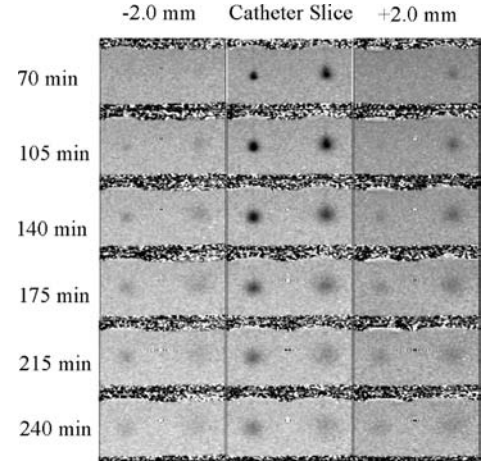

Figure 3. T_1 computed map images of bilaterial infusion into 0.6% agarose gel of 0.005 mM Gd_3N@$C_{80}$$(OH)_{\sim 26}$$(CH_2CH_2COOM)_{\sim 16}$ (left side of each image) and 0.25 mM Omniscan (right side of each image). Displayed times are in minutes post-beginning of infusion. Infusion was applied for 120 min at 0.2 μL/min on both ports. At each time point, three contiguous slices are shown with infusion carried out in the middle slice.

(*27*) Gd@C_{82}, the PEGylated hydroxylated Gd_3N@C_{80} (*23*) and Gd_3N@$C_{80}R_x$ (R = N(OH)$(CH_2CH_2O)_6CH_3$) (*24*). Polyhydroxylated metallofullerenes with high reticuloendothelial system (RES) uptake exhibited much higher relaxivity than the sulfonated and carboxylated systems, which exhibit a favorable non-RES distribution. Although water molecules are not directly coordinated to the encapsulated metal ion, these gadofullerene-based MRI contrast agents exhibit much higher relaxivities than the Gd chelates. The mechanisms ascribed to these high relaxivities include (a) the presence of three Gd^{3+} ions within the cage; the charge transfer between the Gd_3N cluster and the C_{80} cage leads to a very stable nanoparticle and the ferromagnetic coupling gives rise to a large magnetic moment, 21 μB (*49, 50*); (b) a large number of hydroxyl groups attached to the carbon cage, which facilitate exchange of protons with surrounding water protons; this exchange transmits the paramagnetic relaxation to the bulk water; (c) a longer rotational correlation time τ_R (the order of nanoseconds) as a result of aggregation; and (d) the presence of a pool of water molecules that are trapped within the aggregates are relaxed by the gadofullerenes and exchange rapidly with the bulk water molecules (*51*). This is in contrast to the conventional Gd-DTPA complex, which has a single water molecule bound in the first coordination sphere of the metal ion and the entire complex tumbles very rapidly ($\tau_R \sim$ 58 ps) (*1*).

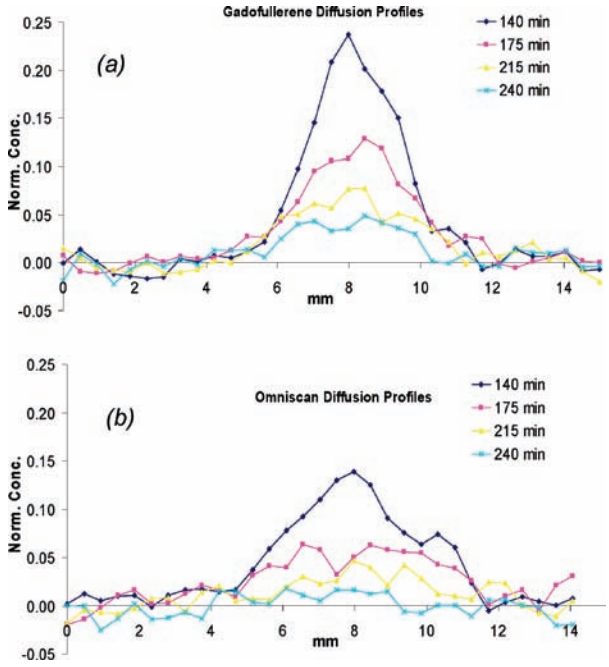

Figure 4. Concentration profiles normalized to the infused concentrations through the gadofullerene infusate (a) and Omniscan infusate (b) at different time points.

Notably, the hydrodynamic diameter distribution of as-synthesized $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ in water is unimodal. This is significantly different from the results found for $Gd@C_{60}(OH)_x$ and $Gd@C_{60}[C(COOH)_2]_{10}$ (*52*), but is similar to that of our formerly synthesized $Gd@C_{82}O_6(OH)_{16}$-$(NHCH_2CH_2COOH)_8$ (*53*). In the PBS medium, the relatively larger aggregates were reduced in size by the intercalation of phosphate, since the $H_2PO_4^-$ and HPO_4^{2-} ions can break up intermolecular H-bonding (*44*); the resulting smaller size aggregate distribution relative to that in pure water leads to faster tumbling entities and correspondingly lower ^1H relaxivity. This interpretation is consistent with the multimodal distributions in PBS (Figure 2), which indicate a dynamic aggregation/deaggregation process. The downward shift of the intensity-weighted size distribution in PBS solution (Figure 2) led to a marked decrease of proton relaxivities (r_1/r_2 = 35/62 mM^{-1} s^{-1} at 2.4 T) relative to those in pure water (r_1/r_2 = 207/282 mM^{-1} s^{-1}), indicating that the aggregation size in this range is not large enough to increase the rotational time of entities to the nanosecond range. Recently, Fatouros et al. (*23*) reported an MRI contrast agent based on a trimetallic nitride templated metallofullerene (TNT EMF), $Gd_3N@C_{80}$, which was PEGylated and hydroxylated. This compound also exhibited extremely high relaxivities due to the advantages described above. However, the small size distribution (less than 10 nm) of $Gd_3N@C_{80}[Peg5000(OH)_x]$ leads to a lower relaxivity compared to compound **2** (48 mM^{-1} s^{-1} vs 69 mM^{-1} s^{-1} at 2.4 T), which exhibits an average hydrodynamic diameter of ca. 78 nm (Figure 2). Notably, $Gd_3N@C_{80}R_x$ (R = $N(OH)(CH_2CH_2O)_6CH_3$) was found to have small particle size of 10−15 nm but high relaxivity (68 mM^{-1} s^{-1} at 0.47 T**)** (*24*). These $Gd_3N@C_{80}$-based derivatives may lead to different tissue uptake (*21*) due to the different aggregating behaviors.

Agarose Gel Infusion Experiment. In order to understand the distribution of the new gadofullerene compound **2** upon direct infusion by convection-enhanced delivery (CED) into the extracellular space of the brain, agarose gel (0.6%) was used as a surrogate for *in vivo* brain tissues. With the CED method, a bilateral infusion of 0.005 mM gadofullerene **2** and 0.25 mM Ominscan was administered into the agarose gel phantom. The infusion was applied for 120 min at 0.2 μL/min. To obtain comparable T_1-weighted images, the concentration values of the infusates (0.005 mM of gadofullerene and 0.25 mM of Gd-DTPA-BMA, respectively) were adjusted using our measured r_1 values (ratio = 207/4.1 = 50).

Figure 3 displays successive T_1 computed maps of $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ and Omniscan in the agarose gel. The displayed times are in minutes after the start of infusion. The T_1 maps shown demonstrate different diffusion patterns. That is, the gadofullerene **2** bolus is more compact, diffuses more slowly, and lingers longer—see the higher residual at 240 min vs the Omniscan. To investigate the diffusion of the new compound quantitatively, we have converted these T_1 maps into concentration maps by means of eq $1/T_1 = 1/T_{10} + r_1[M]$. Concentration profiles normalized to the infused concentrations through the two infusates at different time points are shown in Figure 4. The slower diffusion of the gadofullerene

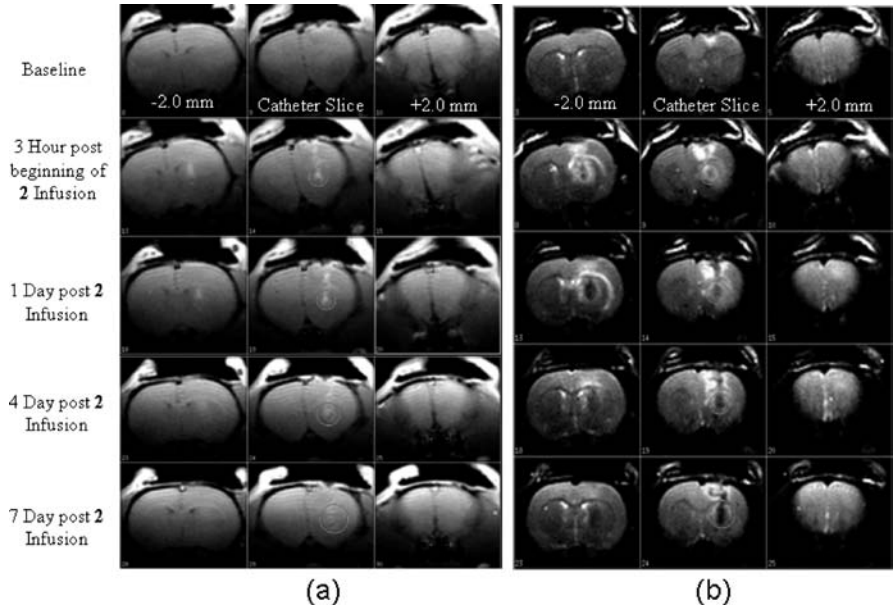

Figure 5. T_1 weighted images (T_R/T_E = 700 ms/10 ms) (a) and T_2 weighted images (T_R/T_E = 6000 ms/100 ms) (b) of direct infusion into T9 tumor-bearing rat brain of 0.0475 mM $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COO_m)_{\sim 16}$ (**2**). Infusion was applied for 120 min at 0.2 μL/min.

is consistent with the dependence of the width of the diffusion profile on diffusion coefficient D and time of diffusion t: full-width at half-maximum (fwhm) $\propto (D \cdot t)^{1/2}$ assuming an approximate Gaussian profile. From the Stokes−Einstein equation and the known particle radii, the diffusion coefficient for the gadofullerene **2** is 40−50 times smaller than Omniscan; hence, the gadofullerene **2** diffusion time is 40−50 times longer. Our present study further qualified the diffusion time of compound **2** relative to formerly reported $Gd_3N@C_{80}$[Peg5000$(OH)_x$] (*23*), which may have a shorter diffusion time due to the small size distribution.

***In Vivo* Infusion Experiment.** To further document and quantitate the diffusion profile of the infused gadofullerene *in vivo*, we have used a Fischer 344 female rat as an animal model of an experimental brain glioma tumor: 5×10^4 T9 glioblastoma cells were directly deposited into the brain parenchyma through a guide cannula. Before direct infusion of $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COO_m)_{\sim 16}$ (**2**) into T9 tumor-bearing rat brain on day 13 post cell implantation, a baseline image of the anesthetized animal was acquired for comparison. Then, direct infusion of 0.0475 mM $Gd_3N@C_{80}(OH)_{26}(CH_2CH_2COO_m)_{16}$ (**2**) into the brain at the nascent tumor site was applied for 120 min at 0.2 μL/min using a slow, low-pressure process. The anesthetized animal was imaged in a 2.4 T/40 cm MR Bruker/Biospec system at days 13, 14, 17, and 20 post cell implantation (or at 3 h, 1 d, 4 d, and 7d post **2** infusions). Seven days after the injection, an established tumor was clearly identifiable at the implantation site.

Figure 5 shows T_1 weighted images (T_R/T_E = 700 ms/10 ms) and T_2 weighted images (T_R/T_E = 6000 ms/100 ms). From these successive images, we can see clearly that the new contrast agent provides contrast enhancement (red circles) at very low concentration (0.0475 mM, 24 μL). Notice that a larger tumor bolus can be imaged clearly even after 7 days post-injection, indicating that a prolonged stay of this contrast agent in the tumor can work as a long-term diagnostic agent.

CONCLUSION

In conclusion, a new gadofullerene-based MRI contrast was synthesized by a facile method in high yield. This new MRI contrast agent exhibited equivalent contrast enhancement at dosage levels 1/50 of that of the commercial MRI contrast agent, Omniscan. DLS results displayed a particle size shift from 78 nm in pure water to 44 nm in PBS solutions. Agarose gel infusion experiments revealed different diffusion properties of gadofullerene **2** from clinically used Omniscan. The functional carboxyl terminal groups, -COOH, may enable the conjugation of biomarkers for future tissue-targeting studies. The *in vivo* experimental results demonstrate that this new contrast agent can provide high contrast enhancement at very low concentration and work as long-term diagnostic agent due to its slow diffusion behavior relative to Omniscan.

Experimental Details

Succinic acid acyl peroxide (1): Succinic anhydride (4 g) as a fine powder was added to 10 mL of ice cold hydrogen peroxide (8 %) and stirred for 30 min until all of the powder dissolved and a white gel-like solution formed (**Scheme 1-I**). The solution was filtered with a 0.45 μm pore size PTFE membrane filter (PALL); the solid was washed with a small amount of water and air-dried for 10 min. The white peroxide product, mp 106° [lit.(*1*) mp 105-107°] was transferred to a glass vial and vacuum-dried at room temperature for 24 h. Approximately 2.4 g of peroxide **1** was obtained using this one-step procedure reported by Clover et al.(*1*). ^{1}H NMR (500 MHz, acetone-d_6): 2.71 ppm (m); ^{13}C NMR (125 MHz, acetone-d_6): 24.84, 28.03, 168.54, 172.44 ppm.

$Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) (2): To $Gd_3N@C_{80}$ (4 mg) in 5 mL of *o*-dichlorobenzene was added succinic acid acyl peroxide (**1**) (3.2 mg, 5 eq). The resultant solution was deaerated with flowing argon and heated at 84 °C for 48 h. In intervals of 12 h, more **1** (3.2 mg, 5 eq) was added. After the reaction, a brown sludge precipitated from the solution. Then 8 mL of 0.2 M NaOH aqueous solution were added to extract the water soluble product. Two layers were obtained; the top layer was deep brown and the bottom layer was colorless (Figure S1a). The top layer was concentrated and the residue was purified via a Sephadex G-25 (Parmacia) size-exclusion gel column with pure water as eluent to obtain a narrow brown band with pH = 6~7 (Figure S1b). The yield was 95 % estimated from the ICP calibration. The solubility of the final product in pure water is ca. 13.2 mg/mL. This fraction was characterized by XPS, FT-IR and studied in detail as an MRI contrast agent.

In a separate experiment, the $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) sample **2**, was placed in a dialysis membrane (MW cutoff 500 D) and dialyzed for 24 hours. The resulting solution outside the membrane was subjected to ICP analysis and no Gd ion was detected.

$Sc_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na): To $Sc_3N@C_{80}$ (4 mg) in 5 mL of *o*-dichlorobenzene was added succinic acid acyl peroxide (**1**) (4.2 mg, 5 eq). The resultant solution was deaerated with flowing argon and heated at 84 °C for 48 h. In intervals of 12 h, more **1** (4.2 mg, 5 eq) was added. After the reaction, a brown sludge precipitated from the solution. Then 8 mL of 0.2 M NaOH aqueous solution were added to extract the water soluble product. Two layers were obtained; the top layer was deep brown and the bottom layer was colorless. The top layer was concentrated and the residue was purified via a Sephadex G-25 (Parmacia) size-exclusion gel column with pure water as eluent to obtain a narrow brown band with pH = 6~7. This fraction was characterized by XPS, FT-IR together with ^{1}H NMR and ^{13}C NMR. ^{1}H NMR (500 MHz, D_2O): 2.4 ppm (br.); ^{13}C NMR (125 MHz, D_2O/ acetone-d_6): 180 (*C*OOM), 160~120 (C=C), 60~85 (*C*OH), 20~40 ppm (CH_2CH_2).

In a separate experiment, the $Sc_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (M = H, Na) was placed in a dialysis membrane (MW cutoff 500 D) and dialyzed for 24 hours. The resulting solution outside the membrane was subjected to ICP analysis and no Sc ion

was detected.

Agarose gel (0.6 %)(*2*): A mixture of agarose powder and 1X TBE (89 mmol/L of tris(hydroxymethyl)aminomethane (Tris, T), 89 mmol/L of boric acid (B) and 2 mmol/L of ethylenediaminetetraacetic acid (E), pH of 8.4) was heated until all the powder had dissolved, and then boiled for 5 min. After it had cooled to 50 ^{o}C, the resulting solution (20 mL) was poured into a thin-wall container mounted with a guide cannula serving as the guidance path for the infusion cannula. The agarose gel solidified as it cooled to room temperature.

(2006) In vitro and in vivo imaging studies of a new endohedral metallofullerene nanoparticle. *Radiology 240*, 756-764.

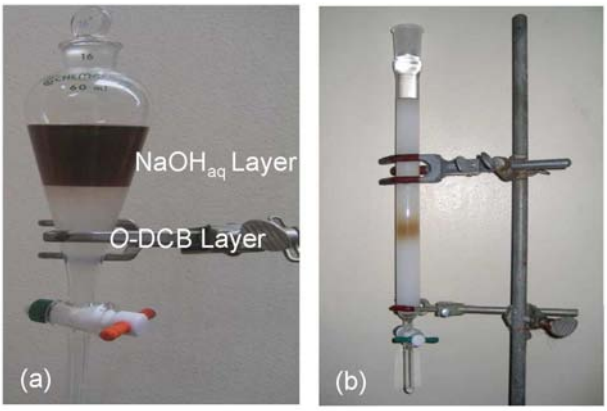

Figure S1. Graphic illustration of the extraction and isolation of $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$, M = Na or H.

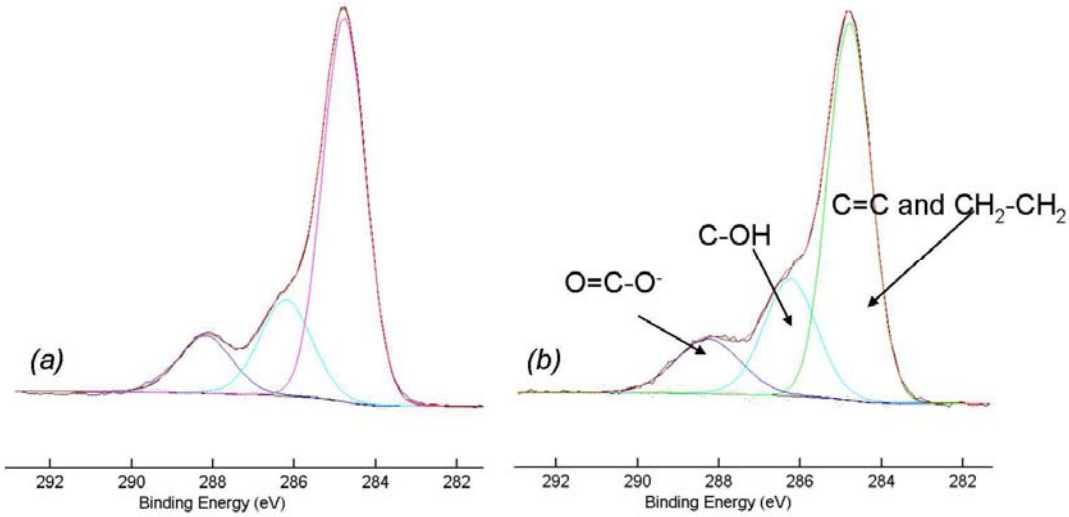

Figure S2. C_{1s} XPS spectrum of $Gd_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$, **2**, (a); and $Sc_3N@C_{80}(OH)_x(CH_2CH_2COOM)_y$ (b). M = H or Na. The curve-fitting analysis reveals at least three different types of carbon atoms centered at binding energies of 284.8, 286.2 and 288.2 eV, respectively.

The electronic structure of the functionalized gadofullerene **2** was analyzed by measuring the binding energy spectrum for the C_{1s} electrons. The main line of the XPS spectrum (**Figure S2a**) exhibits a broad and asymmetric line-shape. Gaussian analysis suggests the presence of at least three components (indicated by blue, green and purple lines, respectively). The C_{1s} binding energies observed for nonfunctionalized sp^2 carbons and some sp^3 hybridized carbons (C–C and $–CH_2–CH_2–$) are centered at 284.8

eV. Those for hydroxylated (C–OH) and carboxylate (O=C–O) carbons are centered at 286.2 and 288.2 eV, respectively. The intensities of C_{1s} components in **2** were estimated from integration of the peak area under each line. The relative intensities for the sp^2 nonfunctionalized carbon (C=C) and sp^3 hybridized carbons (C–C and $–CH_2–CH_2–$), hydroxylated carbon (C–OH), and carboxylate carbon (O=C–O) are 66.4, 20.9 and 12.7%, respectively. Thus, gadofullerene **2** can be designated as $Gd_3N@C_{80}(OH)_{\sim 26}(CH_2CH_2COOM)_{\sim 16}$ (M = Na, H). As for the water-soluble derivative of $Sc_3N@C_{80}$ (**Figure S2b**), three fitting peaks for C_{1s} were found at 284.8 (61.8%), 286.2 eV (24.3%) and 288.3 eV (13.9%). Therefore, its molecular formula is proposed as $Sc_3N@C_{80}(OH)_{33}(CH_2CH_2COOM)_{19}$, M = Na or H.

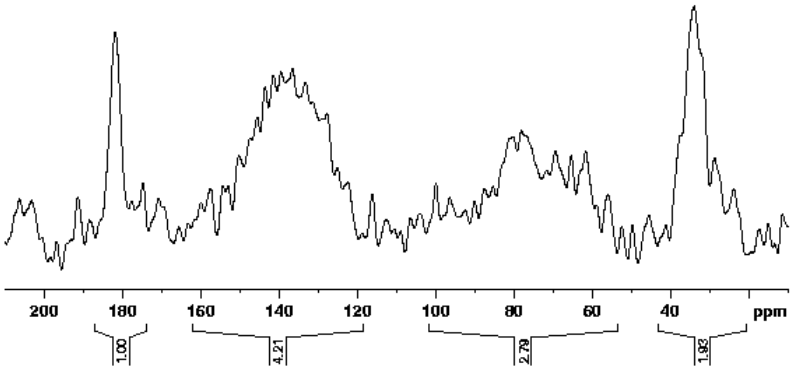

Figure S3. ^{13}C NMR (125 MHz) of $Sc_3N@C_{80}(OH)_{33}(CH_2CH_2COOM)_{19}$, M=Na or H in D_2O/ acetone-d_6.

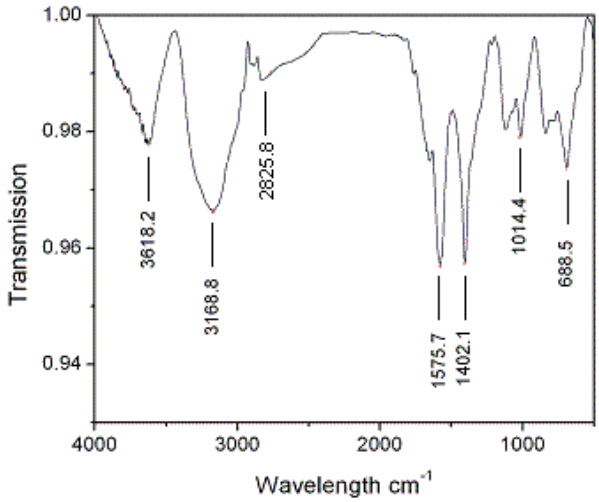

Figure S4. FTIR spectrum of **2** in a KBr pellet.

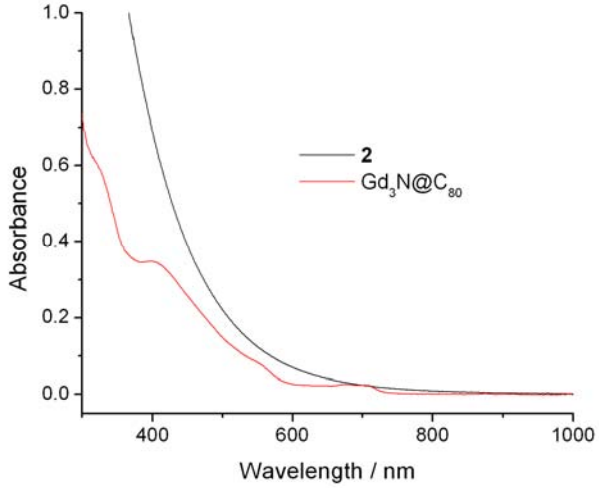

Figure S5. UV-visible spectral comparison between $Gd_3N@C_{80}$ in toluene (red line) and **2** in water (black line).

Synthesis and Immunological Characterization of Toll-Like Receptor 7 Agonistic Conjugates

Michael Chan,[†] Tomoko Hayashi,*[,†] Crystal S. Kuy,[†] Christine S. Gray,[†] Christina C. N. Wu,[†] Maripat Corr,[‡] Wolfgang Wrasidlo,[†] Howard B. Cottam,[†] and Dennis A. Carson[†]

Moores Cancer Center and Department of Medicine, University of California, San Diego. Received February 3, 2009; Revised Manuscript Received March 30, 2009

Activation of toll-like receptors (TLRs) on cells of the innate immune system initiates, amplifies, and directs the antigen-specific acquired immune response. Ligands that stimulate TLRs, therefore, represent potential immune adjuvants. In this study, a potent TLR7 agonist was conjugated to phospholipids, poly(ethylene glycol) (PEG), or phospholipid-PEG via a versatile benzoic acid functional group. Compared to the unmodified TLR7 agonist, each conjugate displayed a distinctive immunological profile in vitro and in vivo. In mouse macrophages and human peripheral blood mononuclear cells, the phospholipid TLR7 agonist conjugate was at least 100-fold more potent than the free TLR7 ligands, while the potency of PEG−phospholipid conjugate was similar to that of the unmodified TLR7 agonist. When administered systemically in mice, the phospholipid and phospholipid−PEG TLR7 conjugates induced prolonged increases in the levels of proinflammatory cytokines in serum, compared to the unmodified TLR7 activator. When the conjugates were used as adjuvants during vaccination, only the phospholipid TLR7 agonist conjugates induced both Th1 and Th2 antigen-specific immune responses. These data show that the immunostimulatory activity of a TLR7 ligand can be amplified and focused by conjugation, thus broadening the potential therapeutic application of these agents.

INTRODUCTION

Toll-like receptors (TLRs) are pattern recognition molecules present on diverse cell types that recognize common ligands in microbes such as bacteria, viruses, and fungi (*1*). Various TLRs interact with lipoprotein (TLR2), double-stranded RNA (TLR3), lipopolysaccharide (LPS, TLR4), flagellin (TLR5), single-stranded RNA (TLR7/8), and unmethylated CpG DNA (TLR9). All TLRs, except TLR3, signal through the myeloid differentiation primary response gene 88 (MyD88) adapter protein, resulting in the activation of NF-κB and the cytokine genes that it regulates (*2*).

The active form of TLR7 is located mainly in the endosomal compartment of innate immune cells, including dendritic cells, mast cells, and B lymphocytes (*3, 4*). The natural ligand for TLR7 was identified as guanine and uridine-rich single-stranded RNA (*5*). In addition, several low molecular weight activators of TLR7 have been discovered, including imidazoquinolines, and purine-like molecules (*3, 6, 7*). Among the latter, 9-benzyl-8-hydroxy-2-(2-methoxyethoxy) adenine (SM360320; designated here as **SM**) has been shown to be a potent and specific TLR7 agonist (*8*). In a previous study, we synthesized a derivative of SM-designated UC1V150, in which the aldehyde functional group on the benzyl moiety enabled coupling the agonist to different auxiliary chemical entities through a bifunctional linker molecule containing a hydrazine and *N*-hydroxysuccinimide activated ester function (*9*). Conjugation to mouse serum albumin (MSA) increased potency by 10- to 100-fold and improved in vivo pharmacodynamics, compared with the free drug (**9**). Moreover, the conjugate (MSA-UC1 V150) could be delivered effectively to the respiratory system by intranasal or intratracheal administration, without inducing a systemic cytokine syndrome. Drug delivery by the intranasal route was effective in reducing mortality in mouse models of bacterial and viral infection (*9*).

An important aspect of TLR biology is the connection between receptor localization, cell activation, and cytokine production. TLR7 and TLR9 are only active when proteolytically processed and loaded into endosomes (*10–12*). The conjugation of various chemical entities to phospholipids is known to facilitate endocytosis. Therefore, we hypothesized that conjugation of a TLR7 activator to a phospholipid would enhance innate immune activation. The conjugation of drugs to poly(ethylene glycol) can promote their circulation time in the blood and potentially increase solubility in water (*13*). It was therefore of interest to determine if conjugation of a TLR7 agonist to PEG could alter its in vivo pharmacodynamics.

EXPERIMENTAL PROCEDURES

Materials. 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) was purchased from Avanti Polar Lipids (Alabaster, AL). All other reagents were purchased as at least reagent grade from Sigma-Aldrich (St. Louis, MO) without further purification. Solvents were purchased from Fischer Scientific (Pittsburgh, PA) and were either used as purchased or redistilled with an appropriate drying agent. Ovalbumin (OVA, grade V) was purchased from Sigma-Aldrich.

Endotoxin levels in the reagents and conjugates for experiments of immunological activities were measured using the QCL1000 end point chromogenic Limulus Amoebocyte Lysate (LAL) assay purchased from BioWhittaker (Walkerville, MD). Reagents that contained less than 1 pg endotoxin per μg protein or drug were used throughout the experiments. Since DOPE gave false positive results in the chromogenic endotoxin assay, bone marrow derived macrophages (BMDM) from lipopolysaccharide unresponsive mutant mice (C3H/HeJ) were used to test

contamination by endotoxin (Supporting Information Figure 1). The levels of cytokine production by bone marrow derived mononuclear cells from C3H/HeJ mice were similar to the levels in cells derived from the wild-type C3H/HeOuJ strain, indicating that endotoxin contamination was negligible (Supporting Information Figure 1).

All conjugates were stored at −80 C° as dry powders. The conjugates were dissolved in DMSO at 100 mM and further diluted before immunological assays.

Instrumentation. Analytical TLC was performed using precoated TLC silica gel 60 F_{254} aluminum sheets purchased from EMD (Gibbstown, NJ) and visualized using UV light. Flash chromatography was carried out on EMD silica gel 60 (40−63 μm) using the specified solvent system. Chromatography and mass spectra (ESI) for compounds without phospholipids were recorded on a 1100 LC/MSD (Agilent Technologies, Inc., Santa Clara, CA) with a Supelco Discovery HS C18 column (Sigma-Aldrich) with purity above 98% by percent area. Mass spectra (ESI) of phospholipid-containing compounds were recorded on a Finnigan LCQDECA (Thermo Fisher Scientific Inc., Waltham, MA). ^{1}H NMR spectra were obtained on a Varian Mercury Plus 400 (Varian, Inc., Palo Alto, CA). The chemical shifts are expressed in parts per million (ppm) using suitable deuterated NMR solvents in reference to TMS at 0 ppm. UV absorbance for solubility experiments were measured using a NanoDrop ND-1000 spectrophotometer (Wilmington, DE).

4-{[6-Amino-2-(2-methoxyethoxy)-8-oxo-7*H*-purin-9(8*H*)-yl]methyl}benzoic Acid (5). To 4-{[6-amino-8-methoxy-2-(2-methoxyethoxy)-9*H*-purin-9-yl]methyl}benzonitrile (**1**) (0.10 g, 0.28 mmol) was added 1:1 ethanol/10M NaOH (20 mL) and refluxed for 8 h. The reaction mixture was allowed to cool and acidified to pH 2 with conc HCl. The aqueous solution was extracted with dichloromethane (DCM) (3 × 20 mL), dried over $MgSO_4$, and evaporated in vitro to yield a mixture of the 8-oxo-9-benzoic acid (**5**), 8-methoxy-9-benzoic acid, and 8-oxo-9-ethyl benzoate. Once dried, the products were dissolved in CH_3CN (25 mL) and NaI (0.14 g, 0.96 mmol) was added. To this solution was added chlorotrimethylsilane (12 μL, 0.96 mmol) dropwise with stirring. The reaction mixture was heated at 40 °C for 4 h, then cooled, filtered, and washed with water (20 mL) and then diethyl ether (20 mL) to obtain a white solid in 85% yield. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 10.33 (s, 1H), 7.89 (d, J = 8 Hz, 2H), 7.37 (d, J = 8 Hz, 2H), 6.65 (s, 2H), 4.92 (s, 2H), 4.24 (t, J = 4 Hz, 2H), 3.56 (t, J = 4 Hz, 2H), 3.25 (s, 3H). Retention time (Rt) on HPLC = 14.3 min. ESI-MS (positive ion mode): calculated for $C_{16}H_{17}N_5O_5$ m/z [M+1] 360.34; found 360.24.

2-(4-{[6-Amino-2-(2-methoxyethoxy)-8-oxo-7*H*-purin-9(8*H*)-yl]methyl}benzamido)ethyl 2,3-Bis(oleoyloxy)propyl Phosphate (6). To a solution of compound **5** (0.022 g, 0.06 mmol) in anhydrous *N*,*N*-dimethylmethanamide (DMF) (1 mL) was added *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU) (0.026 g, 0.067 mmol) and anhydrous triethylamine (TEA) (17.0 μL, 0.12 mmol). A solution of 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (0.05 g, 0.067 mmol) in anhydrous 1:1 DCM/DMF (1 mL) was prepared and slowly added to the reaction mixture. The reaction mixture was stirred at room temperature until completion and then evaporated in vitro. The product was purified by flash chromatography using 15% methanol (MeOH) in DCM to give 0.038 g of white solid in 58% yield. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 9.7 (s, 1H), 7.87 (d, J = 8.3 Hz, 2H), 7.32 (d, J = 8.3 Hz, 2H), 6.61 (s, 2H), 5.30 (m, 4H), 5.05 (m, 1H), 4.88 (s, 2H), 4.26 (m, 4H), 4.06 (m, 1H), 3.77 (m, 4H), 3.57 (m, 2H), 3.35 (m, 2H), 3.26 (s, 3H), 2.23 (m, 4H), 1.95 (m, 8H), 1.46 (m, 4H), 1.22 (m, 40H), 0.83 (m, 6H). ESI-MS (negative ion mode): calculated for $C_{57}H_{92}N_6O_{12}P$ m/z [M−1] 1083.35; found 1083.75. HR-ESI-FT-MS (positive ion mode): calculated for $C_{57}H_{92}N_6O_{12}PNa$ m/z [M+Na+1] 1107.6481; found 1107.6477.

4-{[6-Amino-8-hydroxy-2-(2-methoxyethoxy)-9*H*-purin-9-yl]-methyl}-*N*-(32-azido-3,6,9,12,15,18,21,24,27,30-decaoxadotriacontyl)benzamide (7). To a solution of compound **5** (0.100 g, 0.278 mmol) in anhydrous DMF (5 mL) was added HATU (0.117 g, 0.306 mmol) and anhydrous TEA (77.014 μL, 0.556 mmol). A solution of *O*-(2-aminoethyl)-*O*′-(2-azidoethyl)nonaethylene glycol (0.150 g, 0.306 mmol) in anhydrous DMF (1 mL) was prepared and slowly added to the reaction mixture. The reaction mixture was stirred at room temperature until completion and then evaporated in vitro. The product was purified by flash chromatography using 5% MeOH in DCM to give 0.224 g of an opaque oil in 93% yield. Rt = 12 min. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 10.01 (s, 1H), 8.45 (t, J = 5.6 Hz, 1H), 7.78 (d, J = 8.3 Hz, 2H), 7.35 (d, J = 8.3 Hz, 2H), 6.49 (s, 2H), 4.90 (s, 2H), 4.25 (t, J = 4 Hz, 2H), 3.57 (m, 4H), 3.5 (m, 36H), 3.4 (M, 6H), 3.26 (s, 3H). ESI-MS (positive ion mode): calculated for $C_{38}H_{61}N_9O_{14}$ m/z [M+1] 868.94; found 868.59.

3-{1-[1-(4-{[6-Amino-8-hydroxy-2-(2-methoxyethoxy)-9*H*-purin-9-yl]methyl}phenyl)-1-oxo-5,8,11,14,17,20,23,26,29,32-decaoxa-2-azatetratriacontan-34-yl]-1*H*-1,2,3-triazol-4-yl}propanoic Acid (8). Compound **7** (0.218 g, 0.251 mmol) and 4-pentynoic acid (0.074 g, 0.753 mmol) was dissolved in 1:1 *t*-butanol/H_2O (3 mL). Sodium ascorbate (0.02 g, 100 mmol) and $Cu(OAc)_2$ (0.009 g,50 mmol) in 1:1 *t*-butanol/H_2O (1 mL) was slowly added to the reaction mixture and stirred at room temperature until compound **7** was fully reacted by TLC. The product was extracted with DCM (10 mL) and H_2O (10 mL), and the organic layer was dried over $MgSO_4$ to give 0.230 g of an opaque oil in 95% yield. Rt = 11.5 min. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 13.48 (s, 1H), 7.76 (d, J = 8.29 Hz, 2H), 7.75 (s, 1H), 7.23 (d, J = 8.29, 2H), 4.88 (s, 2H), 4.41 (t, J = 5.12 Hz, 2H), 4.23 (t, J = 4 Hz, 2H), 3.74 (t, J = 5.12 Hz, 2H), 3.57 (t, J = 4 Hz, 2H), 3.51 (m, 8H), 3.42 (m, 36H), 3.26 (s, 3H), 2.79 (t, J = 7.56 Hz, 2H), 2.24 (t, J = 7.56 Hz, 2H). ESI-MS (positive ion mode): calculated for $C_{43}H_{67}N_9O_{16}$ m/z [M+1] 966.04; found 966.67.

2-(3-{1-[1-(4-{[6-Amino-8-hydroxy-2-(2-methoxyethoxy)-9*H*-purin-9-yl]methyl}phenyl)-1-oxo-5,8,11,14,17,20,23,26,29,32-decaoxa-2-azatetratriacontan-34-yl]-1*H*-1,2,3triazole-4-yl}propanamido)ethyl 2,3-Bis(oleoyloxy)propyl Phosphate (9). To a solution of compound **8** (96 mg, 0.1 mmol) and HATU (42 mg, 0.11 mmol) in anhydrous DMF (1 mL) was added anhydrous TEA (2.7 uL, 0.2 mmol). A solution of DOPE (81.4 mg, 0.11 mmol) in 1:1 DCM/DMF (1 mL) was added dropwise to the reaction mixture and stirred at room temperature until completion. Upon completion, the product was isolated by evaporation in vitro followed by flash chromatography using 15% MeOH in DCM to give 155 mg of opaque oil in 92% yield. ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 8.5 (s, 2H), 8.39 (s, 1H), 7.79 (m, 3H), 7.33 (d, J = 6.23 Hz, 2H), 6.91 (s, 2H), 5.31 (m, 4H), 5.05 (m, 1H), 4.89 (s, 2H), 4.46 (m, 2H), 4.23 (m, 4H), 4.08 (t, J = 8 Hz, 2 H), 3.76 (m, 4H), 3.63 (t, J = 8 Hz, 2H), 3.56 (t, J = 8 Hz, 2H), 3.48 (m, 36H), 3.26 (m, 5H), 3.17 (m, 2H), 2.82 (t, J = 8 Hz, 2H), 2.39 (t, J = 8 Hz, 2H), 2.24 (m, 4H), 1.96 (m, 8H), 1.48 (m, 4H), 1.23 (m, 40H), 0.84 (m, 6H). ESI-MS (positive ion mode): calculated for $C_{84}H_{142}N_{10}O_{23}P$ m/z [M+1] 1691.05; found 1692.82.

Mice. 6−8 week old female C57BL/6 mice were purchased from Charles River Laboratories (San Diego, CA). C3H/HeJ and C3H/HeOuJ mice were purchased from The Jackson Laboratories (Bar Harbor, ME). TLR7 deficient mice were a gift from Dr. S. Akira, (Osaka University, Osaka, Japan) and were backcrossed ten generations onto the C57BL/6 background. Animals were bred and maintained at UCSD in rooms at 22 ±

0.5 °C on a 12/12 h light−dark cycle from 7 a.m. to 7 p.m. All procedures and protocols were approved by the Institutional Animal Care and Use Committee.

In Vitro Measurements of Cytokine Induction. The RAW264.7 (mouse leukemic monocyte macrophage cell line) was obtained from the ATCC (Rockville, MD) and cultured in DMEM (Irvine Scientific, Irvine, CA) supplemented with 10% heat-inactivated fetal bovine serum, 2 mM L-glutamine, and 100 U/mL penicillin/100 μg/mL streptomycin. BMDM were prepared from C57BL/6, TLR7 deficient, C3H/HeJ, and C3H/HeOuJ mice as described (*9*). The cells (1×10^6/mL) were incubated with the conjugates for 18 h at 37 °C, 5% CO_2, and culture supernatants were collected. The levels of cytokines (IL-6, IL-12, or TNFα) in the supernatants were determined by ELISA (BD Biosciences Pharmingen, La Jolla, CA) (*12*). Minimum detection levels of these cytokines were 15 pg/mL, respectively.

Human blood peripheral mononuclear cells (PBMC) were isolated from human buffy coats obtained from The San Diego Blood Bank (San Diego, CA) as described previously (*11*). PBMC (1×10^6/mL) were incubated with various compounds for 18 h at 37 °C, 5% CO_2, and culture supernatants were collected. The levels of cytokines (IL-6, TNFα, or IFNα1) in the supernatants were determined by Luminex bead assays (Invitrogen, Carlesbad, CA) due to the relatively small sample volume. The minimum detection levels of IL-6, TNFα, and IFNα1 were 6 pg/mL, 10 pg/mL, and 15 pg/mL, respectively.

In Vivo Experimental Procedures. For in vivo pharmacokinetic experiments, 6 to 8 week old C57BL/6 mice were intravenously injected with the TLR7 agonist and its conjugates (40 nmol **4a** or 200 nmol **SM**, **6**, **8**, or **9** per mouse as described in the figure legends). The solubility was measured in 10% DMSO in saline at room temperature for 30 min at a maximum theoretical concentration of 1 mM. The aqueous concentrations of compounds **SM**, **6**, **8**, and **9** were measured by UV absorption, and the concentration was derived by comparison to standard curves with four calibration concentrations in DMSO (Supporting Information Table 1). The solutions were homogeneous, and no precipitates were noted prior to i.v. administration. Blood samples were collected 2, 4, 6, 24, or 48 h after the injections. Sera were separated and kept at −20 °C until use. The levels of cytokines in the sera were measured by Luminex bead microassay due to the small sample volume. The minimum detection levels of IL-6 and TNFα were 5 pg/mL and 10 pg/mL, respectively.

For the adjuvanticity experiments, mice were subcutaneously immunized with 20 μg ovalbumin (OVA) with 10 nmol of TLR7 equivalent dose per mouse in various TLR7 conjugates on days 0 and 7. A TLR9 activating immunostimulatory oligonucleotide sequence (ISS-ODN, 1018) was used as a positive control for a Th1 inducing adjuvant (*10*). Sera were collected on days 0, 7, 14, 21, 28, 42, and 56. Mice immunized with saline or OVA mixed with vehicle served as controls. Mice were sacrificed on day 56, and the spleens were harvested. Approximately 2.5×10^6/mL spleen cells were aliquoted into round-bottom tissue culture microtiter plates in triplicate in a total volume of 200 μL RPMI 1640 complete medium [RPMI1640 (Irvine Scientific, Irvine, CA) supplemented with 10% heat-inactivated FCS, 2 mM L-glutamine, and 100 U/mL penicillin/100 μg/mL streptomycin] and restimulated with either 100 μg/mL OVA or medium alone. Cultures were then incubated at 37 °C, 5% CO_2, and supernatants harvested after 72 h. The levels of IFNγ in the culture supernatants were measured by ELISA (BD Bioscience PharMingen) as per the manufacturer's instructions (*14*). The average total spleen cell numbers in each group were calculated and compared to the control group to monitor spleen cell proliferation.

Anti-OVA antibodies of the IgG subclasses, IgGl and IgG2a, were measured by ELISA, as described (*12*). Each ELISA plate contained a titration of a previously quantitated serum to generate a standard curve. The titer of this standard was calculated as the highest dilution of serum that gave an absorbance reading that was double the background. The various sera samples were tested at a 1:100 dilution. The results are expressed in units per mL, calculated based on the units/mL of the standard serum, and represent the mean ± SEM of five animals in each group.

In some experiments, the site of injection was examined 24 h after immunization for signs of inflammation or local reaction. Mice were observed for locomotor activity to assess a "sickness" response to immunization and then weighed weekly.

Histological Examination. In the adjuvanticity experiments, the spleens, lungs, livers, hearts, and kidneys were collected on day 56. The organs were fixed in 10% buffered formalin (Fisher Scientific) and embedded in paraffin. Sections 5 μm thick were stained with hematoxylin and eosin (H&E) and evaluated under the microscope.

Statistical Analysis. A software package (*Prism 4.0*, GraphPad, San Diego CA) was used for statistical analyses including regression analyses. Data were plotted and fitted by nonlinear regression assuming a Gaussian distribution with uniform standard deviations between groups. The statistical differences were analyzed by two-way ANOVA with Bonferroni's post hoc, Dunnett's post hoc, or Student's *t* test. A value of $P < 0.05$ was considered statistically significant.

RESULTS

Chemical Synthesis. The synthesis of compound **4** from compound **1** yielded a consistent conjugation ratio of 5:1 UC1 V150 to MSA protein (*9*). Basic hydrolysis of the 9-benzylnitrile of compound **1** (*8*) provided a versatile benzoic acid functional group (*5*) in 85% yield and allowed for the assembly of conjugates **6**, **8**, and **9** (Scheme 1). The benzoic acid was coupled with DOPE by activation with HATU in the presence of TEA in anhydrous DMF to give compound **6** in 58% yield. Due to the difficulty in dissolution of compound **6** in suitable solvents for testing, a PEG spacer was coupled to provide improved solubility. A readily available amine/azide bifunctional PEG was coupled to the benzoic acid by activation with HATU in the presence of TEA in anhydrous DMF to give compound **7** in 93% yield. The formation of a 1,2,3-triazole through a copper(I)-catalyzed azide−alkyne cycloaddition with 4-pentynoic acid gave compound **8** in 95% yield. Finally, compound **9** was prepared by HATU activated amide formation with DOPE and compound **8** (92% yield).

Cytokine Induction by a Phospholipid-Conjugated TLR7 Agonist. The in vitro potency of the phospholipids TLR agonist conjugate (**6**), PEG-TLR7 agonist conjugate (**8**), PEG-phospholipid (**9**) conjugate, and the MSA-TLR7 agonist conjugate were compared using the murine macrophage cell line, RAW264, and primary bone marrow derived macrophages (BMDM) (Figure 1A,B). The respective cells were stimulated for 18 h with serially diluted TLR7 agonist conjugates, and the levels of cytokines released in the media were measured by ELISA and compared to the unconjugated TLR7 agonist (**SM**).

As previously shown, the MSA-TLR7 agonist conjugate (**4a**) was approximately 100-fold more potent as a cytokine inducer compared to the unconjugated agonist. In the same system, the phospholipid-TLR7 conjugate was 10-fold more potent, when normalized to the molar level of the pharmacophore ($P < 0.0001$ compared to unconjugated TLR7 agonist in RAW cells and BMDM). Although the PEG-TLR7 agonist conjugates (**8**) showed less potency compared to the unconjugated TLR7 agonist (**SM**) ($P < 0.001$ in RAW cells), the hybrid phospho-

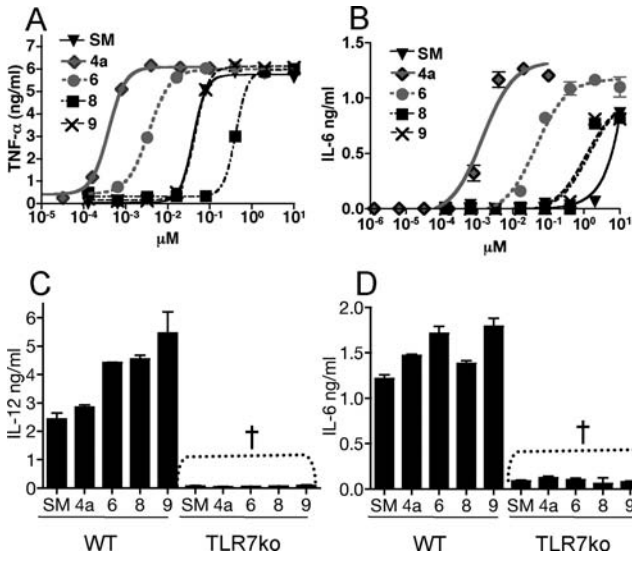

Figure 1. In vitro immunological characterization of TLR7 conjugates in murine macrophages. 1×10^6/mL RAW 264.7 cells (A), or 0.5×10^6/mL BMDM derived from wild-type (B−D) or TLR7 deficient mice (C,D) were incubated with serially diluted TLR7 conjugates for 18 h. Serial dilutions of **SM** (triangle), **6** (gray circle), **8** (solid square), and **9** (ex) were prepared (steps of 1:5) starting from 10 μM. **4a** (gray rhombus) was serially diluted (steps of 1:5), starting from 0.1 μM. The levels of TNFα, IL-6, and IL-12 in the culture supernatants were measured by ELISA. Data are mean ± SEM of triplicates and are representatives of three independent experiments. $P < 0.001$ by two-way ANOVA with Bonferroni post hoc test in comparison between **SM** and **6**. * denotes $P < 0.01$ by Student's *t* test compared to the corresponding data of wild-type macrophages.

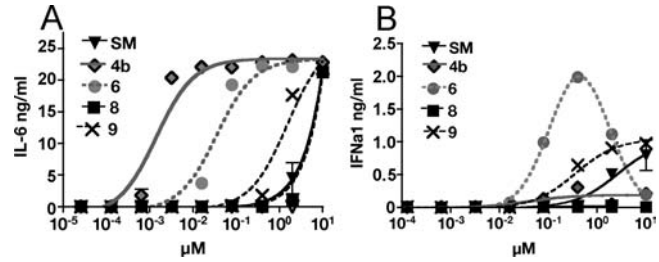

Figure 2. In vitro immunological characterization of TLR7 conjugates in human PBMC. 2×10^6/mL human PBMC were incubated with serially diluted TLR7 conjugates for 18 h. Serial dilutions of SM (triangle), 6 (gray circle), 8 (solid square), and 9 (ex) were prepared (steps of 1:5) starting from 10 μM. **4a** (gray rhombus) was serially diluted (steps of 1:5), starting from 0.1 μM. The levels of IL-6 (A) and IFNα1 (B) in the culture supernatants were determined by Luminex assay in duplicate. Data are means ± SEM and are representative of three independent experiments. The order of potency is **4b** > **6** > **9** > **SM** = **8** ($P < 0.0005$ by two-way ANOVA test for compounds **4b**, **6**, **9**, and **SM**; $P = 0.2$ by two-way ANOVA test for compound **8**).

lipid-PEG-TLR7 agonist was as potent as the unconjugated drug (**SM**). Equivalent concentrations of MSA, phospholipid, or PEG, processed without TLR7 conjugation, induced minimal or no cytokine levels in RAW264.7 cells and BMDM, respectively (data not shown).

To confirm that the conjugated forms of the TLR7 agonist stimulated exclusively via TLR7 activation, BMDM derived from TLR7 deficient mice were analyzed (Figure 1C,D). Compounds **4a**, **6**, **8**, **9**, and **SM** induced little or no IL-12 and IL-6 production in the TLR7 deficient cells, whereas these conjugates were active in wild-type BMDM. To assess the immunological effects of the conjugates in human cells, PBMC from three separate donors were treated with the different agents, and the levels of IL-6 and IFNα1 released into the supernatants were determined (Figure 2A,B). Human serum albumin (HSA) conjugated to the TLR7 agonist (**4b**) was used instead of MSA-

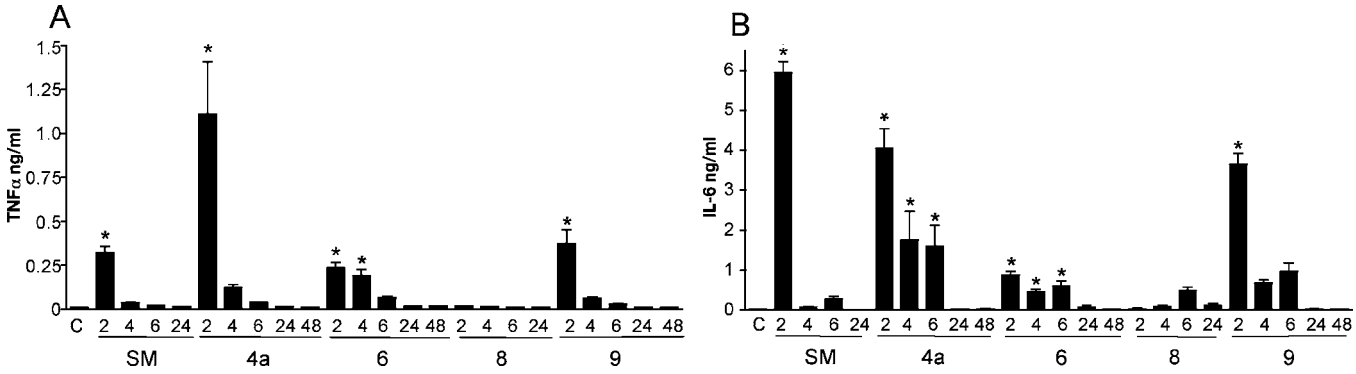

Figure 3. Kinetics of proinflammatory cytokine induction by TLR7 conjugates in vivo. C57BL/6 mice ($n = 5$ per group) were intravenously injected TLR7 conjugates (**SM**, 200 nmol; **4a**, 40 nmol; **6**, 200 nmol; **8**, 200 nmol; **9**, 200 nmol). Serum samples were collected 2, 4, 6, 24, and 48 h after injection. The levels of TNFα (A) and IL-6 (B) were measured by Luminex assay. Data are means ± SEM of five mice and are representative of two independent experiments. (C) Control naïve mice. * denotes $p < 0.05$ compared to the naïve mice by one-way ANOVA tests with Bonferroni post hoc testing.

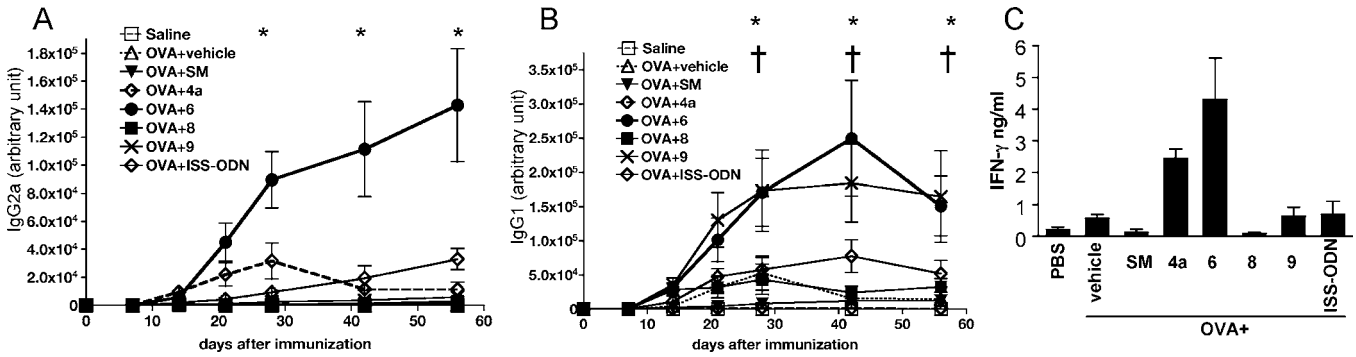

Figure 4. Adjuvanticity of TLR7 conjugates in vivo. Groups of C57BL/6 ($n = 5$ per group) were subcutaneously immunized with 20 μg OVA mixed with TLR7 conjugates (10 nmol TLR7 equivalent dose per mouse) on days 0 and 7. Sera were collected days 0, 7, 14, 21, 28, 42, and 56. OVA specific IgG1 and IgG2a were measured by ELISA (A and B). On day 56, mice were sacrificed, and splenocytes were cultured with OVA (100 μg/mL) in RPMI1640 for 3 d. IFNγ level in the supernatant was measured by ELISA (C). Data are means ± SEM of 5 mice/group and are representative of 3 independent experiments. * and † denote $P < 0.05$ and $P < 0.01$ by one-way ANOVA with Dunnett's post hoc comparison to the mice immunized with OVA mixed with vehicle, respectively.

conjugates (**4a**) for this experiment, to avoid any effects of anti-MSA antibodies. The order of potency of the conjugates was similar in human PBMC and mouse BMDM (**4b** > **6** > **9** > **SM** = **8**) (Figure 2A). Compound **4b** induced minimal levels of IFNα1 in all of the human PBMC samples tested (Figure 2B).

In Vivo Kinetics of Induction of Pro-Inflammatory Cytokines by TLR Agonist Conjugates. To compare the in vivo immunological properties of the different TLR7 agonist conjugates, C57BL/6 mice were injected intravenously with the agents, and cytokine levels in sera were assayed at various time intervals (Figure 3A,B). On the basis of the results of a previous study (*9*), compound **4a** was used at a lower concentration (40 nmol per animal) than compounds **SM**, **6**, **8**, and **9** (200 nmol per animal). The maximum induction of TNFα and IL-6 was observed 2 h after injection with all the TLR7 conjugates (Figure 3A,B). Although the levels of the cytokines induced by the unconjugated TLR7 agonist (**SM**) declined rapidly after 2 h, cytokine induction by compounds **4a**, **6**, and **9** was sustained for up to 6 h. Compound **8** induced only a low level of IL-6, and undetectable TNFα, 6 h after injection (Figure 3B). Sera from control mice that received saline, MSA, or DOPE revealed little or no detectable cytokine levels (data not shown).

Phospholipid-TLR7 Agonist Conjugates Promote Rapid and Long-Lasting Humoral Immune Responses. The adjuvanticity of the different conjugates was assessed by the levels and isotypes of antigen-specific IgG induced after immunization of mice with ovalbumin (OVA) and drug (*15*), as well as by antigen-induced synthesis of interferon γ (IFNγ). Groups of C57BL/6 ($n = 5$ animals per group) were subcutaneously injected with OVA mixed with the various TLR7 conjugates. A TLR9 activating immunostimulatory oligonucleotide sequence (ISS-ODN, 1018) is known to stimulate Th1 immune response and was used as a positive control for a Th1 inducing adjuvant (*10*). The kinetics of OVA-specific serum IgG1 and G2a on days 0, 7, 14, 21, 28, 42, and 56 were monitored by immunoassay (Figure 4A,B). Induction of IgG was observed as early as 14 days in mice immunized with OVA and compound **4a** or compound **6** (Figure 4A). The anti-OVA IgG2a levels increased thereafter in mice immunized with OVA and compound **6**, while the levels in mice immunized with OVA and compound **4a** mixture declined progressively. The spleen cells of mice immunized with OVA combined with compound **4a** or **6** displayed enhanced OVA-specific IFNγ secretion, compared to mice immunized with OVA alone or OVA and a TLR9 agonist (Figure 4C).

Adverse Effects. We previously reported that 150 nmol of the TLR7 agonist **SM** induced anorexia and weight loss in mice after intranasal administration (*16*). We, therefore, monitored both body weights and local skin inflammation in mice immunized with the phospholipid-TLR7 agonist conjugate. At the dose of TLR7 agonist that was an effective adjuvant (10 nmol per mouse), no weight loss or behavioral changes were noted. Chronic administration of TLR7 agonists can also stimulate hematopoietic cell proliferation, leading to spleen and lymph node hyperplasia (*17*). However, there were no significant differences in the numbers of splenocytes or myeloid cells between mice immunized with OVA alone, compared to TLR7 agonist conjugates and the saline control mice (Figure 5A).

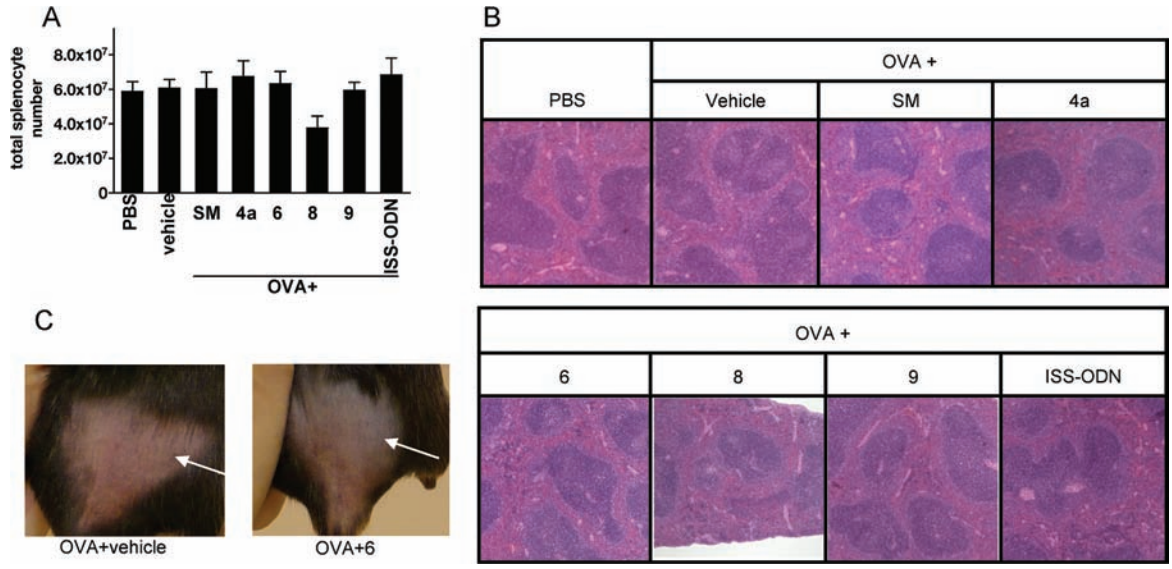

Figure 5. Evaluation of possible adverse effects of TLR7 conjugates. C57BL/6 mice were immunized with OVA 20 μg with TLR7 conjugate. On day 56, mice were sacrificed, and the number of total splenocytes was determined (A). The spleens were collected and submitted for histological examination ($\times$100) (B). The skin at injection sites was inspected 24 h after injection (C). There was no significant difference in the splenocyte number between the mice immunized with OVA plus TLR7 conjugates and the mice immunized with OVA alone (A). Histological examination of the spleens from mice immunized with OVA mixed with TLR7 conjugates did not show any disruption of the white pulps or increased cellularity in red pulp (B). The skin at injection sites did not have visible redness (C).

Histological examination of spleens from mice immunized with OVA plus TLR7 agonist conjugate showed no structural disruption of the white pulp and no increased cellularity in the red pulp (Figure 5B). Moreover, no significant differences were observed in the histological appearance of the liver, lung, heart, and kidney samples collected from each group (data not shown). There was also no significant erythema or warmth at the sites of injection (Figure 5C).

DISCUSSION

TLR7 agonists are not active unless delivered to endosomal vesicles where the active receptor resides (*18*). Previous experiments showed that the conjugation of a TLR7 agonist to serum albumin greatly increased potency, compared to the unconjugated drug (**9**). Presumably, the modified albumin quickly interacted with scavenger receptors on macrophages and dendritic cells, followed by endocytosis. However, modified proteins are not generally suitable for adjuvants, as they are difficult to standardize, store, and administer, and may be immunogenic. Therefore, we conjugated a TLR7 agonist to phospholipids (**6**), which are widely used to deliver drugs to cells. The phospholipid-TLR7 conjugated was 10-fold more potent as a cytokine inducer in mouse and human cells, compared to the unconjugated TLR7 agonist. More importantly, the phospholipid conjugate was a rapidly acting and potent adjuvant for vaccination. It induced antibody responses by 14 days after primary immunization and stimulated both antibody production and antigen specific interferon production. In contrast, the conjugation of the same TLR7 agonist to PEG (**8**) reduced its potency in vitro, unless a phospholipid moiety was included in the conjugated molecule (**9**). Experiments using TLR7 deficient mouse cells confirmed that all the conjugates used in this study stimulated immune responses exclusively through TLR7.

One would normally expect that the same TLR7 activating pharmacophore, conjugated to different delivery molecules, would induce comparable patterns of cytokine synthesis. However, this was clearly not the case. The TLR7 agonist albumin conjugates (**4b**) induced high levels of IL-6 in human blood leukocytes but very low levels of type I interferons. In contrast, the TLR7 agonist phospholipid conjugate (**6**) induced abundant IL-6 and type I interferon. In humans and mice, the major source of type 1 interferon is plasmacytoid dendritic cells (pDC) (*19*), while other dendritic cells, mast cells, and B lymphocytes can produce IL-6. Furthermore, it is mainly TLRs in early, newly formed endosomes that are linked to type I interferon synthesis (*20*). Interaction of a TLR agonist and its receptor in the early endosome triggers the interferon induction pathway, whereas interaction in the late endosome induces cytokines dependent on the NF-κB pathway, such as TNFα and IL-6 (*20*). The results emphasize the complexity of TLR7 signal transduction, which may be regulated by target cell type, endosomal localization, and receptor occupancy time. The conjugation of a TLR7 pharmacophore to different accessory molecules could affect all these parameters. In particular, the TLR7 phospholipid conjugate could promote uptake by plasmacytoid dendritic cells or enhance intracellular persistence of the ligand in early endosomal vesicles.

It is well-established that the antibody class and subtype induced by vaccination can be influenced by the type of coadministered adjuvant (*21*). In mice, IgG2 production is a surrogate marker for activation of Th1-type cells, which also promote delayed hypersensitivity responses. In contrast, Th2-type cells preferentially enhance IgG1 synthesis and do not foster delayed hypersensitivity. However, both antibody and T-cell mediated delayed hypersensitivity responses are optimally needed to control many infections. The TLR7 agonist conjugated to albumin or phospholipid caused rapid elevation of IgG2a antibodies. However, levels of IgG2a in the mice receiving the albumin conjugate (**4a**) declined by three weeks after the last immunization, while the mice immunized with the phospholipid conjugates sustained and even increased antigen-specific IgG2a levels without further boosting. One possible explanation for the divergent effects is that the phospholipid conjugate acted as a depo, delivering the TLR7 activating pharmacophore over a more prolonged period.

The unconjugated TLR7 active SM molecule is very poorly soluble in aqueous solutions. Conjugation to poly(ethylene glycol) (PEG) improved its solubility but decreased its ability to induce cytokines (Figure 3). However, a hybrid conjugate

containing both PEG and a phospholipid retained cytokine inducing activity. Vaccination with the hybrid conjugate as adjuvant induced a significant Th2 immune response but a minimal Th1 response.

Imiquimod, a specific but relatively weak TLR7 agonist, is currently approved for treatment of skin disorders such as viral warts and superficial basal cell carcinomas (*22*, *23*). The TLR7 phospholipid conjugate described here is approximately 1000-fold more potent as a cytokine inducer. Although the hybrid conjugate containing both phospholipids and PEG was somewhat less potent, its water solubility renders it useful for systemic administration. In contrast, the phospholipid conjugate may be preferable for local administration, where persistent stimulation of in situ immune cells is desirable. The phospholipid moiety may also facilitate drug penetration through the epidermal barrier. Thus, the conjugation of a TLR7 agonist to phospholipid or PEG moieties is a promising strategy to expand the clinical uses of these agents for infectious, malignant, or atopic diseases.

Supplementary Figure 1. Evaluation of endotoxin contamination using LPS unresponsive mutant and wild type macrophages.

0.5×10^6/ml BMDM derived from C3H/HeJ (LPS unresponsive mutant) or C3H/HeOuJ(wild type) were incubated with TLR7 conjugates (10 μM SM, 0.1 μM 4a, 10 μM 6, 10 μM 8 or 10 μM 9) for 18 hours. The levels of IL-6 or IL-12 in the culture supernatants were measured by ELISA. Each TLR7 conjugates induced similar levels of IL-6 both in TLR4 mutant and wild type mice, indicating LPS contamination of these conjugates is minimum.

Supplementary Table 1.

Received February 9, 2009; Revised Manuscript Received April 16, 2009

Affibody molecules are small and stable antigen-binding molecules derived from the B domain of protein A. We applied a bivalent, high-affinity epidermal growth factor receptor (EGFR)-specific affibody molecule for the generation of targeted PEGylated liposomes. These sterically stabilized affibody liposomes (SAL) were produced by chemical coupling of the cysteine-modified affibody molecule to maleimide-PEG_{2000}-DSPE and subsequent insertion into PEGylated liposomes. These SAL showed strong and selective binding to EGFR-expressing tumor cell lines. Binding was dependent on the amount of inserted affibody molecule−lipid conjugates and could be blocked by soluble EGF. Approximately 30% of binding activity was still retained after 6 days of incubation in human plasma at 37 °C. Binding of SAL to cells led to efficient internalization of the liposomes. Using mitoxantrone-loaded liposomes, we observed for SAL, compared to untargeted liposomes, an enhanced cytotoxicity toward EGFR-expressing cells. In summary, we show that SAL can be easily prepared from affibody molecules and thus may be suitable for the development of carrier systems for targeted delivery of drugs.

INTRODUCTION

The epidermal growth factor receptor (EGFR) is a transmembrane glycoprotein and a member of the erbB receptor tyrosine kinase family. Dysregulation of EGFR signaling has been shown to contribute to malignant transformation (*1*). Elevated levels of EGFR are found on different types of solid tumors, e.g., breast, ovarian, lung, head and neck, prostate, and colorectal cancers, and have been proposed as prognostic marker for disease progression and survival (*2*). Consequently, strategies targeting EGFR have been developed as treatment option, including monoclonal antibodies, small molecule inhibitors of EGFR signal transduction, and antibody-based immunoconjugates, e.g., immunotoxins (*3*). Some of these reagents have already been approved for therapy, such as monoclonal antibodies (cetuximab, panitumumab) and small molecule inhibitors (gefitinib, erlotinib) (*4*).

Antibodies recognizing EGFR have also been applied for the targeting of drug-loaded liposomes. Liposomes are small, vesicular carrier systems consisting of one or more lipid bilayers composed of natural or synthetic lipids, e.g., phospholipids and cholesterol (*5*). Encapsulation of drugs into the liposomal interior or the lipid bilayer alters the drug pharmacokinetics, e.g., protects the drug from rapid elimination and degradation, and has been shown to improve efficacy and safety (*6*). Half-life of liposomal drugs can be drastically improved by incorporating polymers such as poly(ethylene glycol) into the lipid bilayer, thus sterically stabilizing the liposomes. Coupling of antibodies to the surface results in immunoliposomes allowing for an active targeting to tumor cells and receptor-mediated internalization (*7*−*9*). In order to avoid Fc-mediated uptake of immunoliposomes by phagocytic cells, recent applications focused on the use of antibody fragments (Fab′) and recombinant formats (e.g., scFv)[1](for review, see 10). Both, anti-EGFR Fab′ and scFv molecules have been employed for the preparation of anti-EGFR immunoliposomes (*11*−*13*). Selective binding and internalization into EGFR-overexpressing tumor cells as well as selective cytotoxicity of drug-loaded anti-EGFR immunoliposomes has been demonstrated in vitro in these studies. Superiority of immunoliposomal delivery of various drugs, e.g., doxorubicin, epirubicin, and vinorelbine, over free drug and nontargeted liposomal formulations was confirmed in xenograft tumor models (*12*).

Obviously, the antigen-binding moiety of an antibody is sufficient and advantageous to confer target specificity of immunoliposomes. Recently, various antibody mimetics based on nonimmunoglobulin scaffolds have been proposed as an alternative for antibodies (*14*). Several of these antibody mimetics have been developed into high-affinity antigen binders. For example, affibody molecules are small molecules (7 kDa) based on a 58 amino acid residue three-helix bundle domain from staphylococcal protein A (*15*−*17*). Anti-EGFR affibody molecules were selected from a phage display library and further affinity matured into molecules with low nanomolar affinity (*18,19*). One of these anti-EGFR affibody molecules, $(Z_{EGFR:955})_2$, was shown to be efficiently internalized into EGFR-overexpressing A431 squamous carcinoma cells similar to monoclonal antibody cetuximab (*20*).

Here, we applied a bivalent anti-EGFR affibody molecule for the generation of targeted liposomes. This was achieved by chemical coupling of the cysteine-modified affibody molecule to maleimide-PEG_{2000}-DSPE and subsequent insertion into sterically stabilized liposomes. The resulting sterically stabilized

affibody liposomes (SAL) showed strong and selective binding to various EGFR-expressing tumor cell lines and subsequent internalization. Furthermore, compared to untargeted drug-loaded liposomes, targeting led to a selective increase in cytotoxicity of mitoxantrone-loaded SAL toward EGFR-expressing tumor cell lines. These findings demonstrate that affibody molecules are useful molecules for the generation of targeted nanocarrier systems suitable for delivery of drugs and other agents, e.g., for diagnostic purposes.

MATERIALS AND METHODS

Materials. Phospholipids were purchased from Avanti Polar Lipids (Alabaster, USA) and cholesterol from Calbiochem (Gibbstown, USA). DiI and mitoxantrone were purchased from Sigma-Aldrich (Taufkirchen, Germany). Human plasma (stabilized with citrate-phosphate-dextrose solution (CPD)) was kindly provided by the blood donation center of the Katharinenhospital (Stuttgart, Germany). A PE-labeled anti-EGFR monoclonal antibody (clone EGFR.1) was purchased from BD Pharmingen (San Jose, USA). A431, MDA-MB-468, MDA-MB-231, SKBR3, and MCF-7 were grown in RPMI, 10% FCS, 2 mM glutamine. Colo205, LS174T, and HEK293 were grown in RPMI, 5% FCS, 2 mM glutamine.

Expression and Purification of $(Z_{EGFR:1907})_2$-cys. The non his-tagged dimeric EGFR-binding affibody molecule $(Z_{EGFR:1907})_2$-cys was expressed in *Escherichia coli* BL21(DE3) cells as previously described (*21*). Pelleted bacterial cells harboring $(Z_{EGFR:1907})_2$-cys were suspended in 20 mM Tris-HCl pH 7.1 and heat-treated at 85 °C for 3 min to disrupt the cells and release the intracellular content. The lysate was clarified by centrifugation followed by filtration and loaded on 25 mL Q Sepharose FF (GE Healthcare), previously equilibrated with 20 mM Tris−HCl pH 7.1. After wash with 20 mM Tris−HCl pH 7.1, bound protein was eluted with a linear gradient 0−0.5 M NaCl in 20 mM Tris−HCl pH 7.1. Fractions containing $(Z_{EGFR:1907})_2$-cys were pooled and pH was adjusted to 8.0 by addition of 1 M Tris−HCl pH 8.0 to a final concentration of 50 mM. The C-terminal cysteine was reduced by addition of DTT to 20 mM, followed by incubation at 40 °C for 3 min. After reduction, acetonitrile (ACN) was added to a final concentration of 5% and reduced $(Z_{EGFR:1907})_2$-cys was loaded on 1 mL Resource 15 RPC columns (GE Healthcare), previously equilibrated with RPC A-buffer (0.1% TFA, 5% ACN, 95% water). After wash with RPC A-buffer, bound proteins were eluted with a linear gradient 0−40% RPC B-buffer (0.1% TFA, 80% ACN, 20% water). Fractions containing pure $(Z_{EGFR:1907})_2$-cys were identified by SDS-PAGE analysis and pooled. The buffer was exchanged to 10 mM ammonium hydrogen carbonate pH 8.0 using a PD-10 desalting column (GE Healthcare). Finally, $(Z_{EGFR:1907})_2$-cys was lyophilized and stored at 4 °C until use. Determination of the concentration of $(Z_{EGFR:1907})_2$-cys solutions was performed by measuring the absorbance at 280 nm. The purity of $(Z_{EGFR:1907})_2$-cys was assessed in SDS-PAGE analysis using approximately 10 μg $(Z_{EGFR:1907})_2$-cys. The identity was verified with LC/MS-analyses using an Agilent 1100 LC/MSD system, equipped with API-ESI and single quadruple mass analyzator.

Determination of Protein Melting Point. The melting point of the affibody molecule was determined with the ZetaSizer Nano ZS (Malvern, Herrenberg, Germany). 50 μg of purified affibody molecule was diluted in PBS to a total volume of 500 μL and sterile filtered into a quartz cuvette. Dynamic laser light scattering intensity was measured while the temperature was increased in 1 °C intervals from 30 to 70 °C with 2 min equilibration for each temperature step. The melting point was defined as the temperature at which the light scattering intensity and size dramatically increased.

Size Exclusion Chromatography. HPLC size exclusion chromatography of the affibody molecule was performed on a BioSep-Sec-S3000 column (Phenomenex, Torrance, CA). Mobil phase was PBS, 1 M NaCl, with a flow rate of 0.5 mL/min. The following standard molecules were employed: thyroglobulin, apoferritin, β-amylase, bovine serum albumin, carbonic anhydrase, cytochrome c, and aprotinin.

Generation of Sterically Stabilized Affibody Liposomes (SAL). Affibody liposomes were generated by postinsertion of affibody molecule-conjugated micelles into preformed PEG-liposomes as described previously for the generation of scFv immunoliposomes (*22*). In brief, liposomes composed of EPC/Chol/$mPEG_{2000}$-DSPE at a molar ratio of 6.5:3:0.5 were prepared by the film hydration−extrusion method. For binding studies, 0.3 mol % DiI was included. The lipid film was hydrated with 1 mL 10 mM Hepes buffer pH 6.7 with a final lipid concentration of 10 μmol lipid per ml buffer. The resulting multilamellar vesicle dispersion was extruded 21 times through 50 nm polycarbonate membranes using a LiposoFast extruder (Avestin, Ottawa, Canada). Mal-PEG_{2000}-DSPE micelles were prepared dissolving dried lipid in ddH_2O at 65 °C to a final concentration of 10 mg/mL. Purified affibody molecules were reduced in 2 mM tris(2-carboxyethyl)phosphine (TCEP) for 2 h at room temperature followed by removal of TCEP by dialysis against oxygen-free 10 mM Na_2HPO_4/NaH_2PO_4 buffer, 0.2 mM EDTA, 30 mM NaCl (pH 6.7) overnight at 4 °C. Micellar lipid and reduced affibody molecule were mixed at a molar ratio of 4.67:1 and incubated at room temperature for 30 min. The coupling reaction was quenched with 1 mM L-cysteine, 0.02 mM EDTA, pH 5.5. Coupling efficiency was determined by SDS-PAGE analysis and quantification of Coomassie-stained bands of free and lipid-conjugated affibody molecule. The affibody molecule-coupled micelles were inserted into preformed PEGylated liposomes by incubation at 55 °C for 30 min (0.02 mol % to 2 mol % micellar lipid in respect to liposomal lipid). Unbound affibody molecules were removed by gel-filtration using a Sepharose CL4B column (Amersham, Braunschweig, Germany). Liposome size (ζ-average) and ζ-potential were measured using a ZetaSizer Nano ZS (Malvern, Herrenberg).

Generation of Drug-Loaded Affibody Liposomes. Mitoxantrone-loaded liposomes were produced by remote loading (*23*). Sterically stabilized liposomes (SL) composed of DOPC, Chol, and $mPEG_{2000}$-DSPE (45:50:5) were prepared as described above (final conc. 100 μmol lipid/mL) using 300 mM citrate buffer (pH 4) for rehydration. After extrusion, liposomes were neutralized by adding 200 μL 0.5 M Na_2HPO_4 and 49 μ 2 N NaOH to 200 μL liposomes, adjusting the pH to 7.5. Liposomes were then preheated to 55 °C in a water bath for 5 min, and 120 μL mitoxantrone (10 mg/mL in water) was added resulting in a drug/lipid ratio of 0.12. After further incubation for 10 min at 55 °C and 20 min at room temperature, affibody molecules coupled to Mal-PEG_{2000}-DSPE micelles were inserted as described above using 0.6 mol % micellar lipid in respect to liposomal lipid. Drug-loaded affibody liposomes were separated from free drug and uninserted micelles by gel filtration on a sepharose CL4B column. Encapsulated drug was quantified measuring absorption at 590 nm after lysis of liposomes with 2% Triton-X 100. Encapsulation efficiency was between 99−100%.

Flow Cytometry. Cells were detached from cell culture dishes using 0.05% trypsin, 0.02% EDTA (GIBCO). Approximately 200 000 cells were incubated with DiI-labeled affibody liposomes (10 nmol lipid) in PBS containing 2% FBS, 0.02% sodium azide (PBA) for 1 h at 4 °C in the dark. After washing cells three times with PBA buffer (4 °C), cells were resuspended in 500 μL PBA buffer and analyzed by flow cytometry (Cytomics FC 500, Beckmann-Coulter). Binding of

PE-labeled anti-EGFR antibody was determined by incubating detached cells with antibody (diluted 1:20) in PBA buffer for 1 h at 4 °C. Cells were then washed three times with PBA as described and analyzed for binding by flow cytometry. Data were evaluated with *WinMDI 2.9*.

In Vitro Plasma Stability. To analyze plasma stability, SAL were preincubated in the presence of 50% human plasma for up to 6 days at 37 °C in a total volume of 60 μL. Subsequently, binding of SALs to cells was analyzed by flow cytometry as described above.

Internalization Studies. A431 cells were seeded onto collagen-coated coverslips (100 000 cells/well) and allowed to adhere overnight. Cells were then incubated with DiI-labeled SAL (50 nmol lipid) for 1 h at 37 °C, washed, and incubated for additional 8 h. Coverslips were washed twice with PBS, fixed with 4% PFA for 20 min at room temperature, and washed again twice with PBS. Cells were then counter-stained with Alexa-488-labeled cetuximab (0.8 μg/mL) and fixed again with 4% PFA. Nuclei were stained by subsequent incubation of cells with DAPI (1 μg/mL) for 20 min at RT. Coverslips were mounted with Moviol and analyzed by fluorescence microscopy (Zeiss Cell Observer) and confocal fluorescence microscopy (Leica TCS SP 2). Alternatively, A431 cells were grown in a 12 well plate (200 000 cells/well). The next day, DiI-labeled anti-EGFR SAL were added (50 nmol lipid) and incubated for up to 8 h. Cells were washed twice with 1 mL ice-cold PBS or 50 mM glycine, 150 mM NaCl, pH 2.7, respectively. Cells were washed again with PBS, trypsinized, and analyzed by flow cytometry as described above.

In Vitro Cytotoxicity Assay. Cells were grown in 96 well plates (15 000 cells/well) for 24 h, and varying amounts of free drug or drug-loaded liposomes were added. After incubation for 20 h, wells were washed 3 times with ice-cold PBS, and viable cells were determined using an MTT ([3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide]) assay. In brief, microtiter plates were incubated with 50 μL/well RPMI + 10% FCS and 5 μL/well MTT (5 mg/mL) for 2 h at 37 °C. Then, the cells were lysed by adding 45 μL/well 10% SDS, 50% *N*,*N*-dimethylformamide, pH 4.7, overnight by shaking at room temperature. Absorbance was measured at 570 and 660 nm. For analysis, the 660 nm values were subtracted as unspecific background from the 570 nm values.

RESULTS

Anti-EGFR affibody ($Z_{EGFR:1907}$)$_2$-cys. SDS-PAGE analysis of purified ($Z_{EGFR:1907}$)$_2$-cys revealed a single band of 14 kDa under reducing conditions and a major band (approximately 96%) corresponding to dimeric molecules (25 kDa) under nonreducing conditions (Figure 1a). The presence of dimeric molecules was confirmed by size exclusion chromatography (SEC) (Figure 1c). Here, ($Z_{EGFR:1907}$)$_2$-cys eluted at a major peak corresponding to a molecular mass of 28 kDa. A melting point of 46 °C was determined for ($Z_{EGFR:1907}$)$_2$-cys by dynamic light scattering analysis (Figure 1b).

Sterically Stabilized Anti-EGFR Affibody Liposomes. Anti-EGFR sterically stabilized affibody liposomes (SAL) were produced by coupling reduced ($Z_{EGFR:1907}$)$_2$-cys to Mal-PEG$_{2000}$-DSPE micelles and subsequent insertion into preformed PE-Gylated liposomes using 2 mol % micellar lipid in relation to liposomal lipid. Efficiency of coupling of ($Z_{EGFR:1907}$)$_2$-cys to Mal-PEG$_{2000}$-DSPE micelles was determined to be 53 ± 5% (n = 5). Postinsertion was performed at 55 °C for 30 min. Although the melting point of ($Z_{EGFR:1907}$)$_2$-cys is only 46 °C, the resulting SAL showed binding to a panel of EGFR-expressing tumor cell lines (Figure 2). For most cell lines analyzed, binding strength correlated with expression of EGFR as determined by flow cytometry analysis with an anti-EGFR monoclonal antibody.

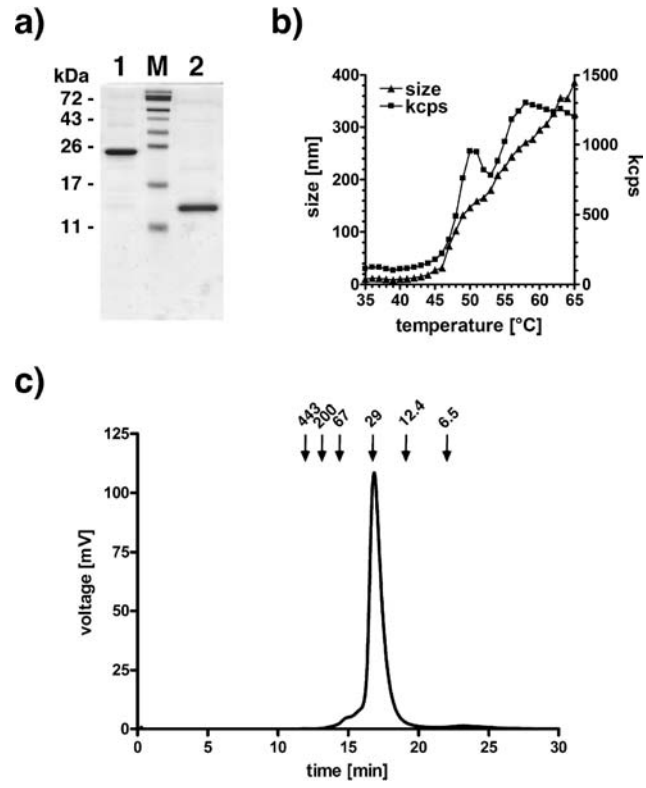

Figure 1. (a) SDS-PAGE analysis of purified affibody ($Z_{EGFR:1907}$)$_2$-cys. Affibody (5 μg/lane) was separated on a 20% SDS-polyacrylamide gel under nonreducing (1) and reducing (2) conditions, respectively, and stained with Coomassie blue. (b) Determination of protein melting point by dynamic light scattering (kcps, kilocounts per second). (c) Size exclusion chromatography of purified affibody ($Z_{EGFR:1907}$)$_2$-cys.

Exceptions were cell lines MDA-MB-231 and Colo 205, which expressed moderate to low levels of EGFR but did not bind anti-EGFR SAL. Binding was strongest with human squamous carcinoma cell line A431. Binding to this cell line was analyzed in more detail using anti-EGFR SAL produced by postinsertion of 0.02 to 2 mol % affibody molecule-coupled micellar lipid, corresponding to approximately 2 to 200 pmol affibody molecule/μmol lipid. All liposomes had a size in the range 90−97 nm and a slightly negative ζ potential (Table 1). Flow cytometry showed that binding to A431 cells increases with increasing concentrations of lipid and affibody molecule density, i.e., inserted micellar lipid (Figure 3a). At the highest lipid concentration (100 nmol lipid/assay), we observed a reduction in binding for SAL prepared by insertion of 0.6 and 2 mol % micellar lipid, which was most pronounced for SAL with 2 mol % micellar lipid. Binding of anti-EGFR SAL (10 nmol lipid, 2 mol % inserted micellar lipid) to A431 was blocked by excess amounts (10 μg/mL) of soluble ($Z_{EGFR:1907}$)$_2$-cys as well as soluble EGF (EGF$_{m1}$) (*24*) but not by an irrelevant affibody molecule, (Z_{Taq})$_2$-cys (Figure 3b). Furthermore, SAL produced from (Z_{Taq})$_2$-cys directed against Taq polymerase did not show any binding to A431 (Figure 3c).

Stability and Internalization of anti-EGFR SAL. In order to determine stability of SAL under physiological conditions, anti-EGFR SAL (2 mol % inserted micellar lipid) were incubated with human plasma at 37 °C for up to 6 days and subsequently analyzed for cell binding by flow cytometry. Approximately 70% of the initial binding activity of the anti-EGFR-SAL was retained after 1 day of incubation, which gradually decreased to a value of approximately 30% after 6 days (Figure 4). Anti-EGFR SAL were efficiently internalized as shown by flow cytometry analysis. A431 were incubated for up to 8 h at 37 °C with DiI-labeled anti-EGFR SAL and then

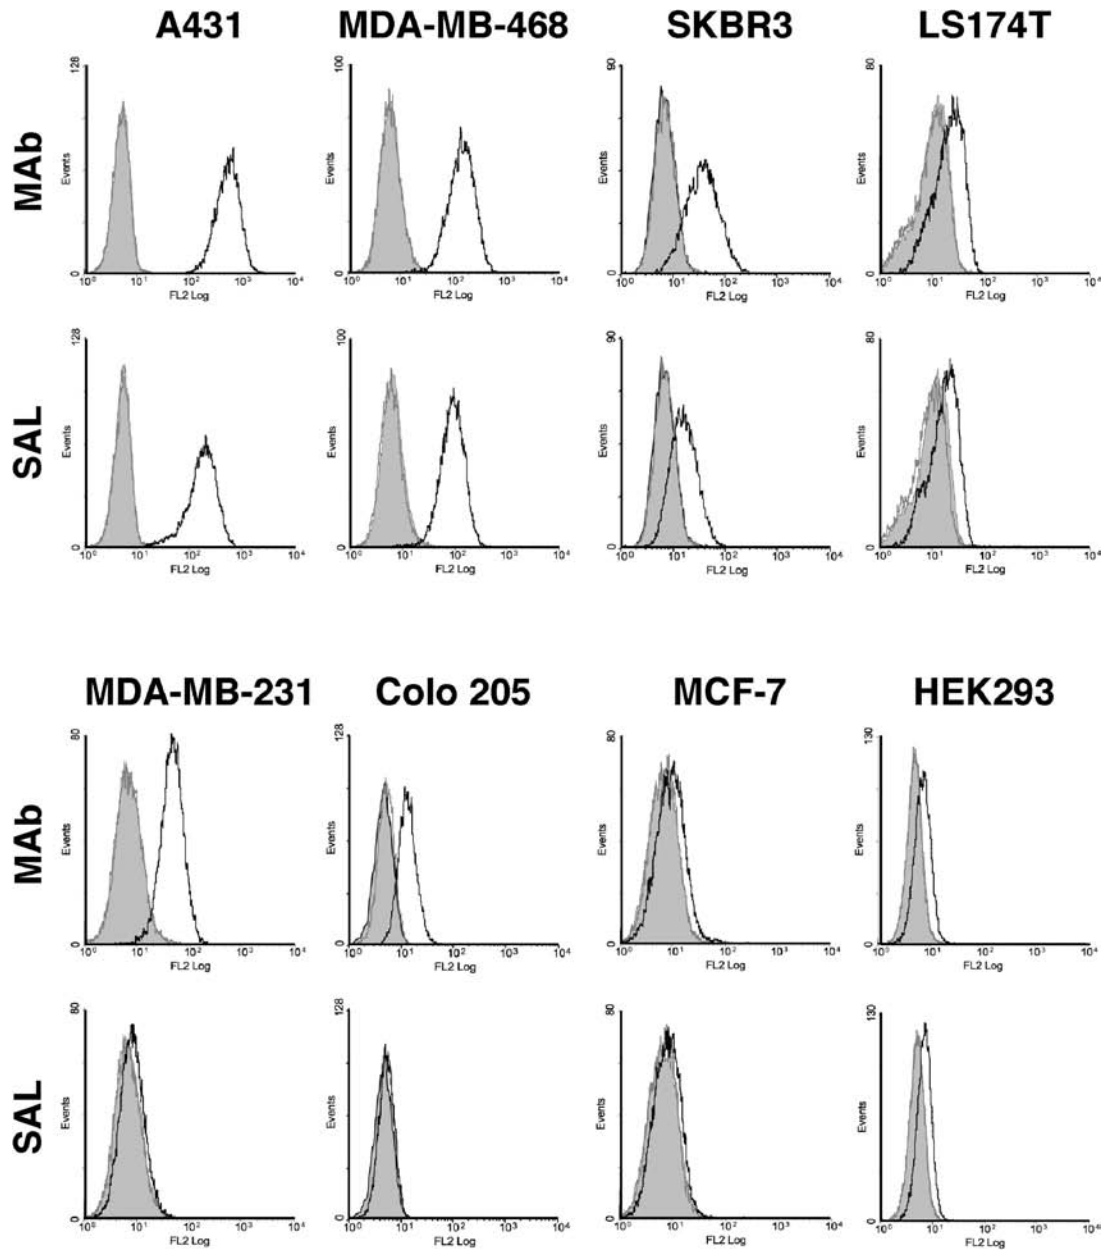

Figure 2. Binding of SAL to EGFR-expressing cells. Flow cytometry analysis of binding of PE-labeled anti-EGFR monoclonal antibody (mAb) or sterically stabilized anti-EGFR affibody liposomes (SAL) to various cell lines (A431, MDA-MB-468, SKBR3, LS174T, MDA-MB-231, Colo 205, MCF-7, HEK293). 200 000 cells were incubated with 10 nmol lipid or 10 μg/mL anti-EGFR mAb, respectively, (gray, cells alone; bold line, cells incubated with antibody or SAL).

Table 1. Characterization of anti-EGFR SAL

inserted micelles (mol %)	affibody molecule	size (nm)	polydispersity index	ζ-potential (mV)
2.0	−	99.6 ± 0.6	0.20	−0.57
2.0	+	93.9 ± 1.5	0.08	−0.04
0.6	+	96.9 ± 1.3	0.14	−0.90
0.2	+	92.9 ± 0.6	0.10	−2.24
0.06	+	95.1 ± 0.8	0.09	−0.46
0.02	+	90.2 ± 0.4	0.07	0.12

washed with PBS (pH 7.4) or acidic glycine buffer (pH 2.7). An increase of fluorescence was observed over time (Figure 5). Fluorescence of cells washed with acidic buffer, which removes liposomes bound to the cell membrane (*25*), was weaker than that measured for cells washed with PBS but also increased over time to approximately 90% of fluorescence of PBS-washed cells after 8 h indicating that the majority of SALs was internalized. Internalization was further shown by conventional and confocal fluorescence microscopy of A431 cells incubated for 9 h with DiI-labeled anti-EGFR SAL (Figure 6a,d). A431 incubated with SAL at 4 °C showed only binding to the cell surface (Figure 6b). Furthermore, no binding and internalization was observed for nontargeted SL included as negative control (Figure 6c).

In Vitro Cytotoxicity. In order to analyze the effects of affibody-mediated delivery of liposomal drugs, we prepared mitoxantrone (MTO)-loaded SL (MTO-SL) and SAL (MTO-SAL). Because SAL prepared by insertion of 2 mol % micellar lipid show a strong reduction of binding at very high lipid concentrations, we used SAL prepared by the insertion of 0.6 mol % affibody molecule-coupled micelles for cytotoxicity assays. The size of the drug-loaded liposomes was 116 ± 5 nm for MTO-SL and 110 ± 1 nm for MTO-SAL (n = 9). MTO-SL and anti-EGFR MTO-SAL were tested for cytotoxicity on A431, MDA-MB-468, and MCF-7, the latter included as negative cell line (see Figure 2). In these experiments, cells were incubated with drug for 20 h and the viability of remaining cells

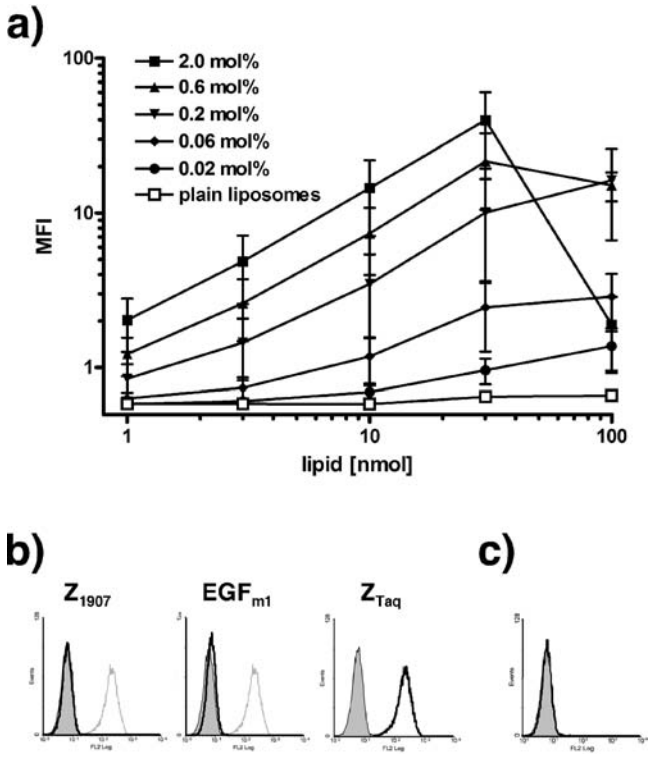

Figure 3. (a) Binding to A431 cells of anti-EGFR SAL generated by insertion of different micellar-conjugated affibody $(Z_{EGFR:\ 1907})_2$-cys (2 to 0.02 mol %) at varying lipid concentrations (1 to 100 nmol lipid per 200 000 cells). Plain liposomes (incubated with cysteine to block the maleimide group) were included as negative control. Shown is the mean fluorescence intensity (MFI) of cells incubated with liposomes and analyzed by flow cytometry ($n = 2$). (b) Blocking of binding of anti-EGFR SAL to A431 cells by soluble affibody $(Z_{EGFR:1907})_2$-cys or a EGF variant (EGFm1) but not with an irrelevant affibody (Z_{Taq}) (gray, cells alone; gray thin line, cells incubated with anti-EGFR SAL; bold line, cells incubated with anti-EGFR SAL + soluble proteins as indicated. (c) Flow cytometry analysis of SAL generated from control affibody Z_{Taq} tested for binding to A431 cells at 10 nmol lipid/200 000 cells (gray, cells alone; bold line, cells incubated with SAL).

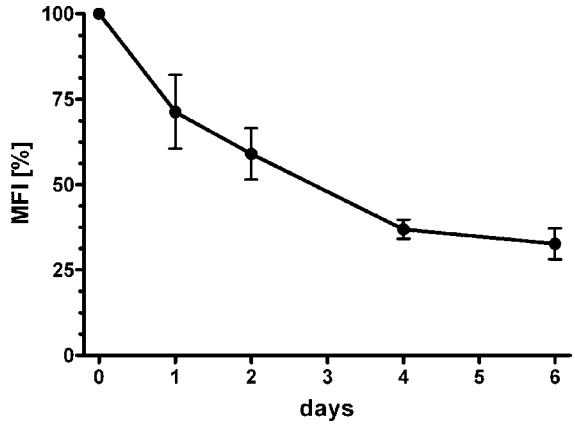

Figure 4. Stability of anti-EGFR SAL. Anti-EGFR SAL were incubated with human plasma at 37 °C for up to 6 days and subsequently analyzed for binding to A431 cells. Shown is the mean fluorescence intensity (% of untreated SAL) of cells incubated with liposomes ($n = 3$).

was determined by MTT assay. All 3 cell lines were sensitive for MTO with IC_{50} values between 1.3−18 μM (Figure 7; Table 2). MTO-loaded liposomes (MTO-SL) showed a reduced cytotoxicity demonstrating the protective properties of encapsulation of drug into PEGylated liposomes. Compared to MTO-SL, an increased cytotoxicity of MTO-SAL was observed for the two EGFR-expressing cell lines (A431, MDA-MB-468),

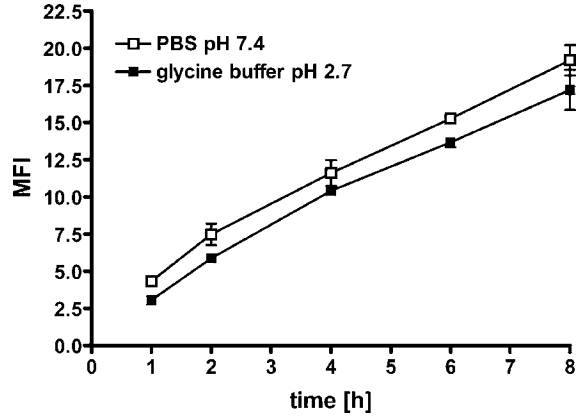

Figure 5. Internalization of anti-EGFR SAL. A431 cells were incubated with anti-EGFR SAL for up to 8 h at 37 °C, washed either with PBS or with glycine buffer (pH 2.7), respectively, and subsequently analyzed by flow cytometry ($n = 3$).

while no differences were found for the EGFR-negative cell line (MCF-7) (Figure 7, Table 2). Anti-EGFR SAL not loaded with drug showed no growth inhibition on MDA-MB-468 cells and only little cytotoxicity on A431 cells up to a concentration of 33 μmol lipid/mL (corresponding to the highest lipid concentration used for the MTO-loaded SAL) (Figure 8a). Furthermore, soluble $(Z_{EGFR:1907})_2$-cys did not inhibit growth of MDA-MB-468 cells and was only slightly inhibitory on A431 cells up to a concentration of 6.7 μg/mL (Figure 8b).

DISCUSSION

We applied a bivalent affibody molecule directed against EGFR and possessing a free cysteine residue at the C-terminus, $(Z_{EGFR:1907})_2$-cys for the generation of targeted liposomes. The resulting affibody liposomes (SAL), which were sterically stabilized by incorporating mPEG into the lipid bilayer, showed selective and strong binding to a variety of EGFR-expressing tumor cell lines. Thus, coupling of the affibody molecule to Mal-PEG_{2000}-DSPE and insertion into PEGylated liposomes does not interfere with antigen-binding activity. This is comparable to recent findings for an anti-HER2 affibody molecule, which was used for the production of targeted nanoparticle-affibody molecule bioconjugates composed of poly(D,L-lactic acid), PEG, and Mal-PEG (*26*). These nanoparticles also showed selective binding to HER2-expressing cell lines and efficient internalization. In another study, HER2-specific affibody molecule-conjugated thermosensitive liposomes, composed of DPPC, Mal-PEG_{2000}-DSPE, and PEG_{2000}-DSPE, were produced, however, no binding data were reported (*27*). Binding of anti-EGFR SAL to A431 was efficiently blocked by soluble $(Z_{EGFR:1907})_2$ as well as EGF. This is in accordance with recent binding studies of the low-affinity precursor of $Z_{EGFR:1907}$, $(Z_{EGFR:955})_2$, where binding of the affibody molecule was blocked by EGF and anti-EGFR mAb cetuximab (*20*). We also observed efficient internalization of anti-EGFR SAL into A431 cells, which gradually increased over time. Internalization of a bivalent, ^{125}I-labeled anti-EGFR affibody molecule ($(Z_{EGFR:955})_2$) was recently shown to reach a maximum after 8 h, similar to that of cetuximab, while internalization of EGF occurred more rapidly with a maximum reached already after 2 h (20). Thus, anti-EGFR SAL behave similarly to free affibody molecule in terms of internalization.

Applying dynamic light scattering, a melting point of approximately 46 °C was determined for purified $(Z_{EGFR:1907})_2$. Interestingly, the affibody molecule retained its antigen-binding activity after the postinsertion step, which was performed for 30 min at 55 °C. This indicates that the affibody molecule is

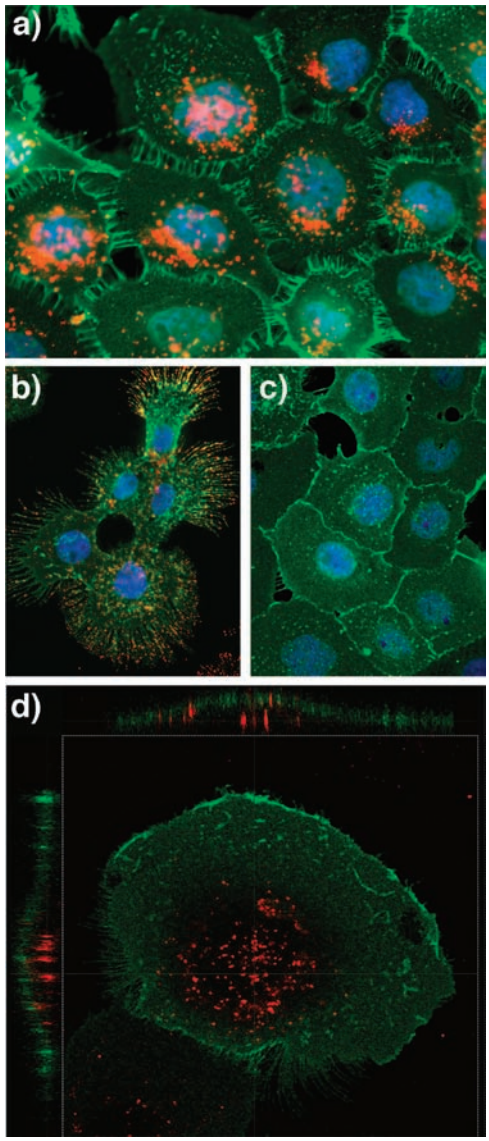

Figure 6. Internalization of anti-EGFR SAL. (a) Fluorescence microscopy of A431 cells incubated with anti-EGFR SAL (red) for 9 h at 37 °C. (b) Fluorescence microscopy of A431 cells incubated with anti-EGFR SAL (red) for 1 h at 4 °C. (c) Fluorescence microscopy of A431 cells incubated with control SL (red) for 9 h at 37 °C. (d) Confocal fluorescence microscopy of a representative A431 cell as shown in (a) including sections through the *z* axes. In all images, fixed cells were counterstained with Alexa-488-labeled cetuximab (green) to visualize the cell membrane. Nuclei in (a−c) are stained with DAPI (blue).

capable of refolding into its native configuration after the postinsertion. The capacity to refold after denaturation is a general feature observed for affibody molecules (*28, 29*). In this regard, affibody molecules behave differently from antibody molecules. For example, scFv molecules with a similar melting point did not survive the postinsertion step performed at 50 °C or higher temperatures, thus were not capable of refolding into active molecules (unpublished personal data). Compared to antibodies, affibody molecules possess several further advantages for the generation of targeted liposomes and other nanocarriers. First, they do not require any disulfide bonds to assemble into stable and active molecules. Hence, a single cysteine residue can be easily introduced and used for site-directed and defined conjugation, e.g., the formation of stable thioether bonds, without interfering with domain assembly and stability. Second, affibody molecules have been shown to possess similar selectivity and picomolar to low nanomolar affinities as antibodies (*19, 30*) but lack the Fc-mediated

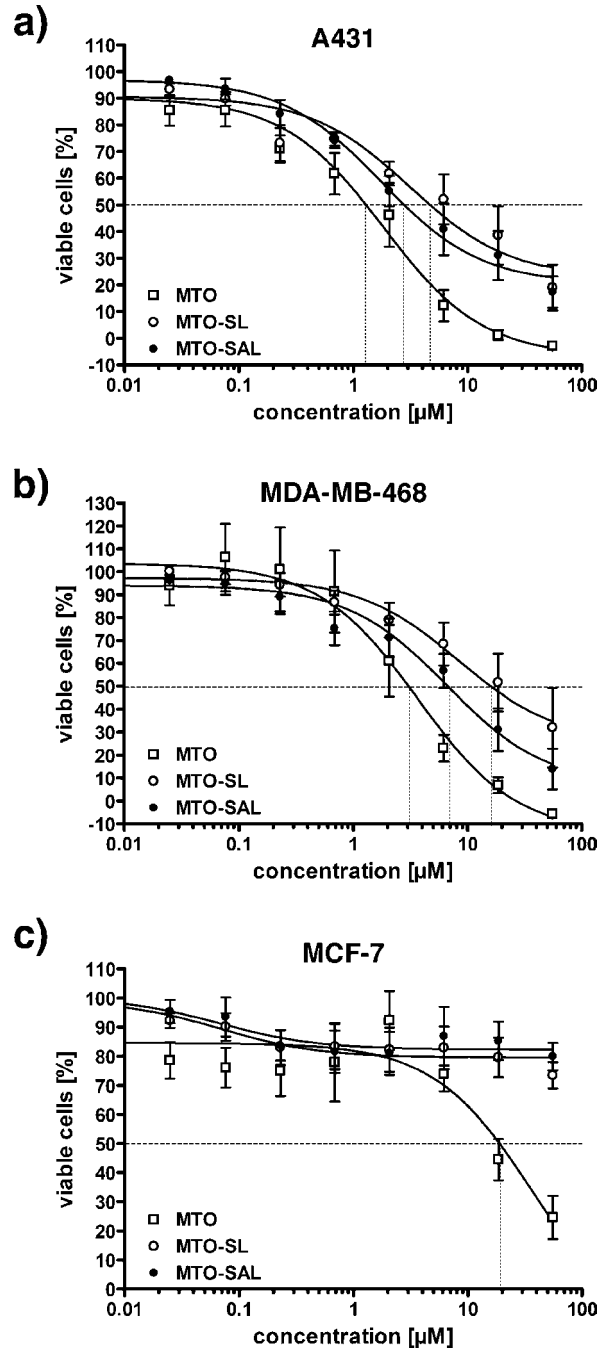

Figure 7. Cytotoxicity. (a) A431 ($n = 6$), (b) MDA-MB-468 ($n = 6$), and (c) MCF-7 ($n = 6$) were incubated with free mitoxantrone (MTO), mitoxantrone-loaded liposomes (MTO-SL), or mitoxantrone-loaded anti-EGFR SAL (MTO-SAL) for 20 h, and cell viability was determined by MTT assay.

Table 2. IC_{50} Values of Mitoxantrone and Mitoxantrone-Loaded Liposomes (in μM)

cell line	free MTO	MTO-SL	MTO-SAL
A431	1.3	4.7	2.8
MDA-MB-468	3	16	6.8
MCF-7	18	>100	>100

activities, which have been shown to be involved in rapid clearance of immunoliposomes produced from whole antibodies. Finally, they can be produced at large quantities in bacteria without the need for periplasmic secretion as required for recombinant antibody molecules.

Using mitoxantrone-loaded anti-EGFR SAL, we showed that binding to EGFR-expressing cells translates into increased

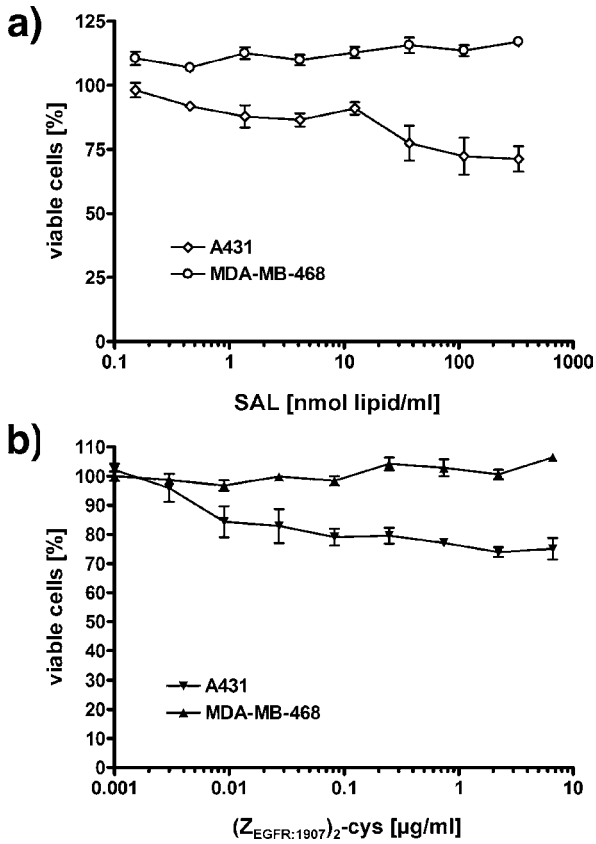

Figure 8. Effects of SAL and soluble affibody molecules on cell growth. MDA-MB-468 and A431 were incubated for 20 h with increasing concentrations of anti-EGFR SAL (a) or soluble affibody molecule (ZEGFR: 1907)$_2$-cys (b) and viable cells were determined by MTT assay.

cytotoxicity compared to drug-loaded SL. Anti-EGFR SAL not loaded with drug were nontoxic, indicating that cytotoxicity was not mediated by the affibody molecule displayed on the liposome surface. The MTO-SAL formulation used in this study did not reach the cytotoxicity of the free drug. This is in accordance with studies for anti-EGFR immunoliposomal formulations of doxorubicin, which also reported IC_{50} values between those of free drug and nontargeted liposomes (*13*). These findings indicate that there is room for improvement, e.g., by increasing stability and thus reducing nonspecific cytotoxicity probably mediated by drug leakage. Furthermore, intracellular drug release from internalized liposomes is a subject for further improvement, e.g., by the incorporation of pH-dependent release mechanisms or by increasing fluidity of lipid bilayer through incorporation of short-chain phospholipids (*31*−*33*). In vivo efficacy of targeted liposomal drug formulations might also be influenced by other factors (*34*). For instance, the kind of drug can determine efficacy, as shown for anti-CD19 immunoliposomes loaded with doxorubicin and vincristine, respectively (*35*). Finally, the affibody molecule itself might influence efficacy of SAL. For example, affibody molecules with strong internalization capacity should result in increased intracellular delivery of the liposomal drug, as shown for anti-ErbB2 scFv immunoliposomes (*36*−*39*).

In summary, we have established a method to produce targeted liposomes from cysteine-modified affibody molecules as ligands. This method should be broadly applicable to the generation of affibody liposomes and other carrier systems for targeted delivery of drugs or other reagents.

ACKNOWLEDGMENT

The authors would like to thank doctors Per Jonasson and Nina Bandmann (Affibody AB, Stockholm, Schweden), for valuable assistance with purification of $(Z_{EGFR:1907})_2$-cys, and Dr. Thomas Mürdter (Dr. Margarete Fischer-Bosch Institut für Klinische Pharmakologie, Stuttgart, Germany) for providing Alexa-488-labeled cetuximab.

Radiolabeling of Biodegradable Polymeric Microspheres with $[^{99m}Tc(CO)_3]^+$ and *in Vivo* Biodistribution Evaluation using MicroSPECT/CT Imaging

Katayoun Saatchi and Urs O. Häfeli*

Faculty of Pharmaceutical Sciences, University of British Columbia, 2146 East Mall, Vancouver, BC V6T 1Z3, Canada.
Received February 11, 2009; Revised Manuscript Received April 22, 2009

Poly(L-lactide) (PLA) microspheres tailored with a tridentate chelating group were radiolabeled with $[^{99m}Tc(H_2O)_3(CO)_3]^+$ and optimized for labeling efficiency and stability. Various ligand−polymer blend compositions with commercial PLA (from 2% to 100%) were evaluated. Labeling efficiencies over 95% were achieved in a 5 min reaction using 100% of the ligand−polymer or within 15 min using a 5% ligand−polymer blend. The addition of 1.5% of PEGylated copolymer to the blend did not affect the labeling efficiency of these particles but changed their *in vivo* behavior. MicroSPECT/CT imaging showed significant uptake of non-PEGylated microspheres by the murine lung, while only the liver and spleen took up PEGylated microspheres. Such ^{99m}Tc radiolabeled biodegradable microspheres will be useful diagnostic imaging agents for visualization of the functioning reticuloendothelial system (RES). Similarly, other sizes of the same microspheres will allow imaging of lung perfusion, bone marrow, lymph and inflammation scintigraphy, and radioembolization therapy.

INTRODUCTION

In nuclear medicine, particles of various sizes are radiolabeled to diagnose different conditions (*1*). The particle-bound radioactivity is made visible by imaging, typically with a single photon emission computed tomography (SPECT) instrument. Examples of such particle-based imaging include lung perfusion imaging with ^{99m}Tc-labeled macroaggregated albumin (MAA) particles sized between 10−90 μm (*2, 3*) liver and spleen function imaging with ^{99m}Tc-sulfur colloid sized 0.1−1 μm (*4, 5*) or with ^{99m}Tc-albumin colloid sized 0.4−2 μm (*6, 7*), both of which are taken up by the reticulo-endothelial system (RES); and bone marrow, inflammation, and lymph scintigraphy which uses even smaller, less than 0.08 μm, ^{99m}Tc-albumin colloid (*8, 9*).

A major drawback of these imaging methods is that the main material used to prepare the diagnostic radiopharmaceuticals is albumin, a human protein with all the inherent risks (e.g., hepatitis C, HIV) associated with blood products. To eliminate these risks and their associated liability, several manufacturers have taken albumin-based products (e.g., Technescan, Microlite, and Isojex) off the market.

Particulate radiopharmaceuticals used in nuclear medicine, including the nonalbumin ones (Table 1), are associated with a second disadvantage. Specifically, their wide size distribution results in an uptake by other than the target tissue or organ. As a result, higher background activities are seen in these areas, leading to the deterioration of the imaging signal and resulting in the need for higher injection activities in order to obtain statistically sound images from the imaging region. The high background makes it thus impossible to minimize the injected activity and, therefore, the radiation dose received by the patient.

To circumvent the problems associated with particulate albumin radiopharmaceuticals, we sought to develop a replacement particle of narrowly controlled size. Such particles would form the basis of a radiolabeling kit for the preparation of radioactive microspheres for both diagnostic and therapeutic applications. A successful radiolabeling kit must, in addition to containing nontoxic biodegradable microparticles of narrow size distribution, show excellent labeling efficiency and stability. Diagnostic applications of such radiopharmaceuticals in nuclear medicine include lung perfusion imaging, imaging of the reticuloendothelial system (RES) and of bone marrow, as well as inflammation and deep vein thrombosis imaging (Table 1). Therapeutic applications of such radiopharmaceuticals in radiation oncology include the radioembolization of liver tumors, uterine fibroids, meningiomas and arteriovenous malformations, and the local treatment of leftover and recurring disease (Table 1).

We have previously developed biodegradable microspheres (made of FDA-approved polylactide or polylactide-*co*-glycolide) that can be made in different sizes (*10, 11*) with relatively narrow size distributions. We have also synthesized tailored polymers to accommodate metal coordination using a simple one-pot synthesis of biodegradable tailored polylactide with a built-in tridentate ligand to coordinate selected metal ions, "polymers with a grip" (*12*) (Figure 1). To follow up on both of these studies, and to investigate a potential replacement product for the discontinued albumin-based particles (e.g., Microlite, Table 1), this work describes the radiolabeling of these custom polymers or a blend thereof with commercially available polymers in the shape of microspheres (0.5−1.5 μm) with $[^{99m}Tc(CO)_3]^+$ (Figure 1). The labeling conditions were also investigated and optimized for microspheres containing additional poly(ethylene glycol) (PEG) groups and then compared for their biological distribution in mice.

EXPERIMENTAL PROCEDURES

Materials. Poly(L-lactide) (PLA) with a molecular weight (MW) of 2 kDa was purchased from Boehringer Ingelheim (Resomer L104; Ingelheim, Germany). Poly(vinyl alcohol) (PVA) with a MW of 13−23 kDa and 98% hydrolyzed was obtained from Aldrich. All other chemicals were purchased from Sigma/Aldrich and used as received. The PEGylated copolymer $MePEG_{17}$-b-PCL_{10} was kindly provided by the Burt lab in the Faculty of Pharmaceutical Sciences at The University of British Columbia (*13*). Double-distilled water was used in all experiments.

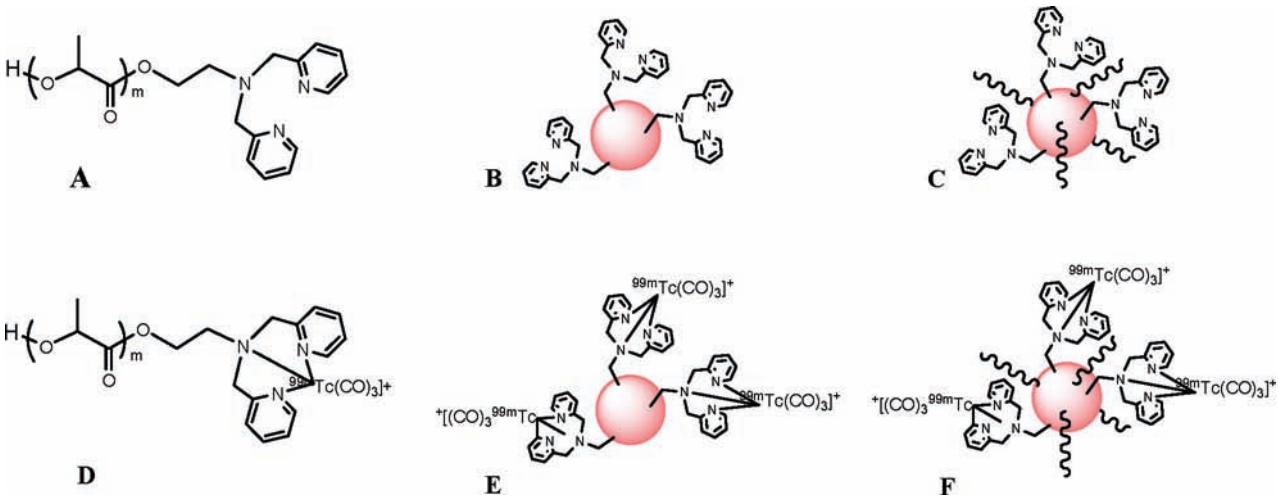

Figure 1. (A) Structure of "chelomer"; (B) cartoon of a microsphere with ligands on the surface; (C) PEGylated blend chelomer (wiggly line, PEG); D,E,F) Matching coordinated/radiolabeled chelomer and microspheres.

The radioisotope used herein,^{99m}Tc, is present in almost all particle-based radiopharmaceuticals including Technescan and Microlite and is currently the most used imaging agent in nuclear medicine due to its ideal physical properties ($t_{1/2}$ = 6 h, E = 140 keV, 89% abundance), suitable dosimetry (low radiation dose) and high specific activity. It is generator produced (^{99}Mo/^{99m}Tc) and available at a reasonable cost. The most recent labeling precursor to yield ^{99m}Tc radiopharmaceuticals is the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ complex cation (*14, 15*). This complex is suitable for coordination to a wide variety of ligands, because it has a robust [*fac*-$Tc(CO)_3]^+$ core, a small size, and is kinetically inert and thermodynamically stable. Its three potential binding sites are readily available for coordination, since the aqua ligands are labile and easily replaced (*16*−*18*). We prepared the $[^{99m}Tc(H_2O)_3(CO)_3]^+$ precursor from Isolink kits generously provided by Mallinckrodt (now Covidien, St. Louis, MO).

Thin layer chromatography (TLC) was performed on black TEC-Control strips (Cat# 150−005; Biodex, Shirley, NY, USA) using saline as the mobile phase. The radioactive TLCs were made visible using a phosphor imager (Cyclone storage phosphor imager with 20 × 25 cm^2 phosphor screen, Perkin-Elmer, Waltham, MA, USA) and analyzed using OptiQuest software. Microspheres were separated by centrifugation using an Eppendorf Centrifuge 5415 C at 6000 rpm (6611 g). A polytron (PT 10/35; Kinematica, Lucerne, Switzerland) was used for homogenization during microsphere preparation. Scanning electron microscopy (SEM) was performed on a Hitachi S-3000N (acceleration voltage 20.0 KV, SE mode, 15.0 mm working distance). The particles were sputtered with a 10 nm layer of Au/Pd (60:40) prior to imaging. Activity measurements were carried out using a Packard Cobra II gamma counter (Perkin-Elmer).

Chelomer Preparation. The ligand-polymer, nick-named "*Chelomer*" in our laboratories (***Chel***ating P**o**ly***mer*) (Figure 1A), was prepared by ring-opening polymerization of L-lactide as previously reported (*12*). Briefly, L-lactide was polymerized

using bis(2-(aminomethyl)pyridine)ethanol for the initiator and tin(octoate) as the catalyst at 125 °C for 3.5 h. The product was completely characterized before use by ^{1}H NMR, ^{13}C NMR, MALDI-TOF MS, and FTIR (*12*).

Microsphere Preparation. All microspheres were made using a double emulsion solvent evaporation technique (*19*). Briefly, the polymer(s) were dissolved in 4 mL of CH_2Cl_2. The first emulsion (w/o) was prepared by homogenization (27 000 rpm) of 400 μL H_2O in the polymer CH_2Cl_2 solution for 2.5 min in an ice bath. PVA (1% w/v, 15 mL) was added to this mixture and homogenized for another 2.5 min to make the second emulsion (w/o/w). This mixture was quickly poured into a stirred 1% solution of PVA (85 mL) at 2000 rpm for 5 min. Stirring continued for 2.5 h, after which the mixing speed was reduced to 500 rpm, and the suspension was stirred long enough for the foam to settle. The microspheres were washed several times in water by serial centrifugation at 5000 rpm (2683 g) and then resuspended in 1 mL water and stored at 4 °C. Since the microsphere preparation is just a physical transformation, no characterization was carried out to determine the nature of particles. However, the size and shape of the particles were measured using scanning electron microscopy.

Functionalized Microspheres. The chelomer and various blends (wt % mixture of the chelomer with commercial PLA) of chelomer with PLA were used to produce chelating microspheres. The 2% chelomer microspheres were, for example, made by dissolving 4 mg chelomer and 196 mg of PLA in 4 mL CH_2Cl_2. Additional microspheres containing 5%, 10%, 25%, and 100% chelomer were also produced, while 0% chelomer (= 100% PLA) microspheres were used as controls in all studies. Pegylated microspheres were made by blending (a) 5% chelomer, 1.5% $MePEG_{17}$-*b*-PCL_{10} with 93.5% PLA; and (b) 10% chelomer, 3% $MePEG_{17}$-*b*-PCL_{10} with 87% PLA.

Radiolabeling. The precursor complex $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was prepared by injecting a saline solution of $Na[^{99m}TcO_4]$ (740−1850 MBq), diluted to 1 mL total volume with water, into the Isolink vial and heating for 25 min in boiling water. After cooling, the vial was vented and 0.2 mL HCl (0.1 M) added to neutralize the solution (pH = 7). The volume was adjusted to 2 mL with water. A >94% yield for the reaction was confirmed by TLC of the reaction mixture in saline, in agreement with the information provided by Covidien.

After addition of the desired activity A_T (9−260 MBq) to a 2 mg suspension of microspheres (total combined volume $V_T \leq 300$ μL), the mixture was heated to 75 °C, shaken at 1000 rpm for varying times (2 min to 2 h), and cooled to room temperature. At each time point, the suspension was centrifuged for 15 min at 6611 *g* and a known volume V_S (50 μL) of supernatant removed and its activity A_S measured. The labeling efficiency was then calculated with time-corrected activities as

$$\text{labeling efficiency}(\%) = \frac{A_S \times V_T}{V_S \times A_T} \times 100 \qquad (1)$$

Each experiment was performed with a minimum of 3 and up to 6 replicates. Microspheres made from commercial PLA were used as controls in all studies. Variables affecting labeling (heating time, heating temperature, chelomer fraction) were optimized to achieve maximum labeling efficiency at minimum heating time.

Cysteine Challenge. After radiolabeling, a 1 mM cysteine solution in PBS was added to the labeled microspheres to a total of 1 mL. The samples were shaken at 1000 rpm and 37 °C for 1 h, centrifuged, and the activity in 300 μL supernatant aliquots measured. Dissociation of $[^{99m}Tc(CO)_3]^+$ was measured by TLC. The remaining cysteine solution (700 μL) was shaken for an additional 23 h and another 300 μL supernatant aliquot analyzed. After the 48 h time point, the last aliquot was sampled, the radioactivity of all aliquots analyzed in a gamma counter, and the percentage of microsphere-bound activity calculated.

Biodistribution. To investigate if the microspheres were appropriate for RES imaging, the biodistribution of the 5% blended microspheres, with and without 1.5% of the PEGylated block copolymer, was determined using microSPECT/CT imaging on an X-SPECT instrument (Gamma Medica, Northridge, CA; now Siemens) at McMaster University's Centre for Preclinical and Translational Imaging in Hamilton, Ontario. Microspheres were labeled as explained above immediately prior to the imaging studies at the Nuclear Medicine Department's Radiopharmacy. Groups of four female PyVMT transgenic mice with mammary tumors and four female C57BL/6 mice with subcutaneous neck tumors grown from a primary cell line at passage six of PyVMT mouse tumors were injected intravenously into the tail vein with 18.5 MBq of the non-PEGylated microspheres and with 18.5 MBq of the ^{99m}Tc-tricarbonyl precursor, respectively. These mice were predestined to be sacrificed, so rather than healthy mice, they were used to give us the additional benefit of investigating tumor uptake for the precursor ^{99m}Tc-tricarbonyl complex and confirming no particle uptake in the tumor. Later, an additional group of four female C57BL/six mice without tumors received 18.5 MBq of the ^{99m}Tc-labeled PEGylated microspheres. At 2, 4, and 6 h after injection, a SPECT scan (32 projections for initially 18 s and at the later two time points 46 s) was performed under isoflurane anesthesia in the supine position, followed by a CT scan (512 projections), after which the animals were sacrificed and the organs removed, weighed, and their activity determined using a Packard Cobra II auto gamma-counter. Results were expressed as the percentage of the injected dose per organ and per gram of tissue (%ID/g), and the tumor-to-blood ratios calculated from the %ID/g values. The biodistribution of the precursor complex $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was investigated and compared to that of the microspheres as a control.

RESULTS AND DISCUSSION

Biodegradable polymers for the delivery of radiation have been seriously under-investigated in nuclear medicine. Such polymers if designed properly are suitable tools for many different diagnostic or therapeutic applications. Depending on the polymer's physical shape, for example, in the form of microspheres and nanospheres, and the radioisotope used, these compounds can replace currently used products such as macroaggregated albumin particles, nonbiodegradable sulfur colloids, or even TheraSphere and SIR-Spheres (Table 1). In a different physical shape, for example, in the form of films, disks, and wafers, such a radiolabeled polymer could be used to deliver local radiation, in a similar way as the Gliadel wafers deliver an anticancer drug for the prevention of recurring disease.

Our goal in this work was to create a simple microsphere radiolabeling kit suitable for various *in vivo* applications. For this purpose, we prepared particles in the 0.5−2 μm size range that would be appropriate for RES imaging and could therefore replace the discontinued albumin colloids (Microlite). Our microspheres (Figure 1B and 2A) were made from the chelomer, or a blend of chelomer and a nonchelating commercial polymer, using a double emulsion, solvent extraction/evaporation procedure (*20*). In this water-in-oil-in-water (w/o/w) process, water-soluble or water-dispersible components are dissolved or dispersed in an aqueous solution, which is then emulsified in an organic solvent containing the chelomer. The primary water-in-oil emulsion (w/o) is then dispersed in a second aqueous phase, containing a suitable emulsifier, and forms a double emulsion (w/o/w). Solid microspheres are collected following the complete removal of the volatile organic solvent by

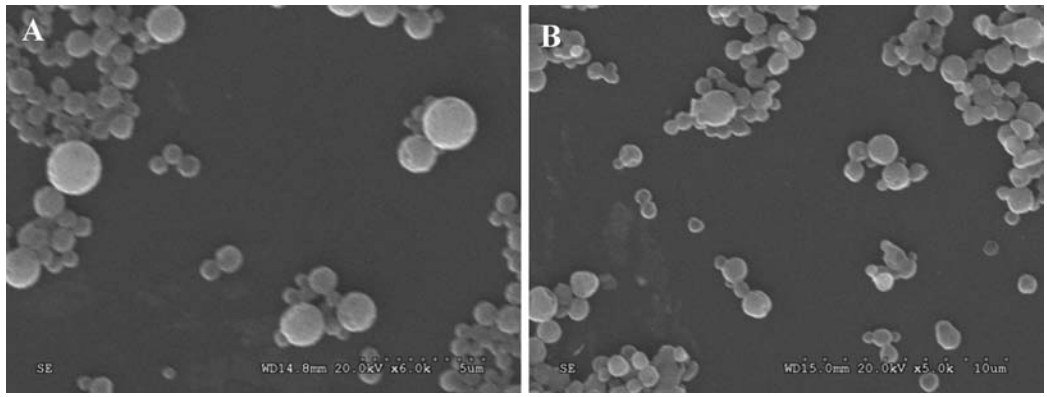

Figure 2. SEM pictures of the 10% blend PEGylated microspheres (A) before (scale bar 5 μm) and (B) after (scale bar 10 μm) radiolabeling.

extraction into the surrounding water phase and evaporation. The first (inner) emulsion allows drug loading, and the second solidifies the particles. In the present studies, no drug was loaded into the microspheres. Instead, the microspheres consisted of a PLA core with the ligand bis(picolylamine) at the outer surface having the capability to bind metals. This technique of making microspheres does not involve chemical or physicochemical changes to the polymeric material; it is just a physical transformation of shape from a solid powder to microspheres.

Radiolabeling was readily achieved with the 100% chelomer microspheres. These microspheres suspended in the $[^{99m}Tc(H_2O)_3(CO)_3]^+$ solution and heated to 75 °C for 30 min took up 94.8 ± 1.5% of the radioactivity compared to 79.9 ± 7.4% for the control microspheres. The reaction conditions, especially heating at 75 °C, did not affect the physical appearance of the microspheres (Figure 2B). This is important for *in vivo* applications, as any changes in size and shape affect microsphere biodistribution (*21*).

Figure 3 compares the TLC of the chelomer-containing microspheres to that of control microspheres. Chelomer microsphere activity was found exclusively at $R_f = 0$, whereas an additional spot was observed for the control microspheres. The R_f of the additional spot was similar to that of $[^{99m}Tc(H_2O)_3(CO)_3]^+$, indicating random release. The labeling efficiency of the control polymer varied from sample to sample, as a result of nonspecific weak binding of $[^{99m}Tc(CO)_3]^+$ to the particles.

Once the initial radiochemical stability was confirmed, the labeling conditions were optimized in terms of chelomer fraction, heating time, and temperature. Table 2 shows the labeling efficiency for various blend compositions of microspheres reacted for varying times with $[^{99m}Tc(H_2O)_3(CO)_3]^+$. For all polymer blends containing more than 5% of the chelomer, the average labeling efficiency was about 95%, whereas the labeling efficiency for the 2% blend and the control (100% commercial PLA) were only slightly higher than 80%. Although low, the labeling efficiency for the 2% chelomer microspheres was consistent, while the results for the control (0% chelomer) varied wildly. This is depicted in Figure 4 by plotting the labeling efficiency of chelomer blends vs heating times for a subset of these experiments. Blended polymers containing 100% (A), 25% (B), or 10% (C) of the chelomer showed excellent labeling efficiency and high stability in the cysteine challenge. The control microspheres, 0% (D), however, were labeled less efficiently and could not withstand the cysteine challenge, as most of the radioactivity was released within 24 h.

For additional reaction times of 2, 5, and 120 min, only the 100% and 0% blends were examined. The 100% chelomer microspheres showed 86.8 ± 9.4%, 96.7 ± 0.5%, and 96.8 ± 3.1% radiolabeling efficiency, respectively, while the control microspheres took up only 62.3 ± 11.5%, 75.8 ± 11.8%, and 65.1 ± 6.1%. This indicates that a minimum reaction time of 5 min is needed to achieve labeling efficiencies suitable for clinical applications.

The thermodynamic stability of the radiolabeled complex for *in vivo* applications is generally evaluated by cysteine or histidine challenges, where the radioactive metal complex is placed in a concentrated solution of the competitive *in vivo* ligands cysteine or histidine (*22*). We performed a cysteine challenge after each labeling experiment. After 30 min of radiolabeling (Table 2), the cysteine challenge to microspheres consisting of 100% chelomer resulted in microsphere-bound activity of 89.3 ± 1.9% and 81.2 ± 2.2% at the 1 and 24 h time points, respectively. For the 0% chelomer microspheres (controls), only 37.9 ± 2.3% and 1.9 ± 3.6% of the activity remained microsphere-bound at the 1 and 24 h time points, respectively. This confirmed the stability of the complexation of $[^{99m}Tc(CO)_3]^+$ to the chelomer's bis(picolylamine) binding site after 24 h. Overall, for microspheres consisting of a more than 5% chelomer blend, stability after 15 to 60 min reaction time was approximately 95% activity as determined by the cysteine challenge. An average of 90% activity remained after 24 h of cysteine competition for the same groups.

To evaluate how much activity could be loaded onto the microspheres, the 5%, 10% and 25% chelomer blends were radiolabeled with increasing amounts of $[Tc(CO)_3]^+$ (74, 128, and 260 MBq). For all activities, the 10% blend chelomer had ≥93% labeling efficiency (Figure 5), with good cysteine

challenge results at 1 and 24 h. The 5% and 25% chelomer blends were only labeled with 74 and 128 MBq of activity and had 98% and 93% labeling efficiency, respectively.

We also evaluated the temperature of the radiolabeling reaction. As expected, lowering the radiolabeling temperature to less than 75 °C decreased thermal energy and led to increased reaction time or decreased labeling efficiency. For example, heating microspheres with 100% chelomer to 50 °C for 30 min resulted in a labeling efficiency of 50%. Since the biodegradable microspheres are sensitive to heat, we determined that 75 °C was the upper temperature limit to achieve labeling without affecting the polymer matrix integrity. Further shortening of the overall radiolabeling procedure would be possible only by speeding up the radiolabeling of the precursor $[Tc(H_2O)_3(CO)_3]^+$ using microwave heating (*23*).

The biodistribution of the 10% chelomer microspheres radiolabeled with 18.5 MBq of ^{99m}Tc (labeling efficiency 94%) (Figure 1E) was then investigated in mice after tail vein injection using microSPECT/CT imaging (Figure 6B) and organ activity analysis at the end of the experiment (Figure 7). Most microspheres accumulated in the liver, with additional substantial uptake in the lungs. The high lung uptake was unexpected since the microspheres sized between 1 and 2 μm (Figure 2A) were not large enough to clog the lung capillaries of between 5 and 7 μm. Two factors could be potential contributors to this uptake: the charge of the complex cation on the particle surface or *in vivo* agglomeration of the particles and accumulation in the lung capillaries. Upon checking, no *in vitro* aggregation of the radiolabeled microspheres was observed microscopically. No other organs received significant amounts of microspheres, and the tumors virtually excluded them.

As mentioned earlier, our experimental design did not include tumor-bearing mice initially, but since there were tumor-mice available destined to be sacrificed, we chose to use them for two main reasons. First, from literature data, it is well-known that microspheres are in general captured by the RES in the liver and spleen (*24*). Micrometer-sized particles are not expected to be taken up by a tumor—for that, they would have to be smaller than about 200 nm, which would increase their blood circulation time and make it possible for the particles to nonspecifically accumulate in newly grown tumors' leaky vasculature by the enhanced permeation and retention (EPR) effect (*25*). Using tumor-bearing animals would confirm this expectation. The second reason for using the available mice with tumors was that there is no published report about the biodistribution of the ^{99m}Tc-tricarbonyl precursor in the literature. Investigating this in mice with tumors might add more information to the reader than by doing it in normal mice. However, since there was no indication of tumor uptake with the microspheres, the later biodistribution study with the PEGylated microspheres was performed in mice without tumors.

To further investigate the significant lung uptake of the microspheres, we decided to make microspheres with additional PEGylated polymers incorporated into the surface (Figure 1C). PEGylation has been shown to enhance surface hydrophilicity of microspheres and to prevent agglomeration and clumping, not only *in vitro*, but also *in vivo* (*26*). To prepare PEGylated microspheres, 1.5% of a PEGylated polymer was simply added to the polymer blend during the preparation of the microspheres. The good labeling efficiency seen in non-PEGylated microspheres was maintained, as 2 mg of the PEGylated microspheres radiolabeled with 40 MBq of $[Tc(CO)_3]^+$ achieved a 97.8 ±

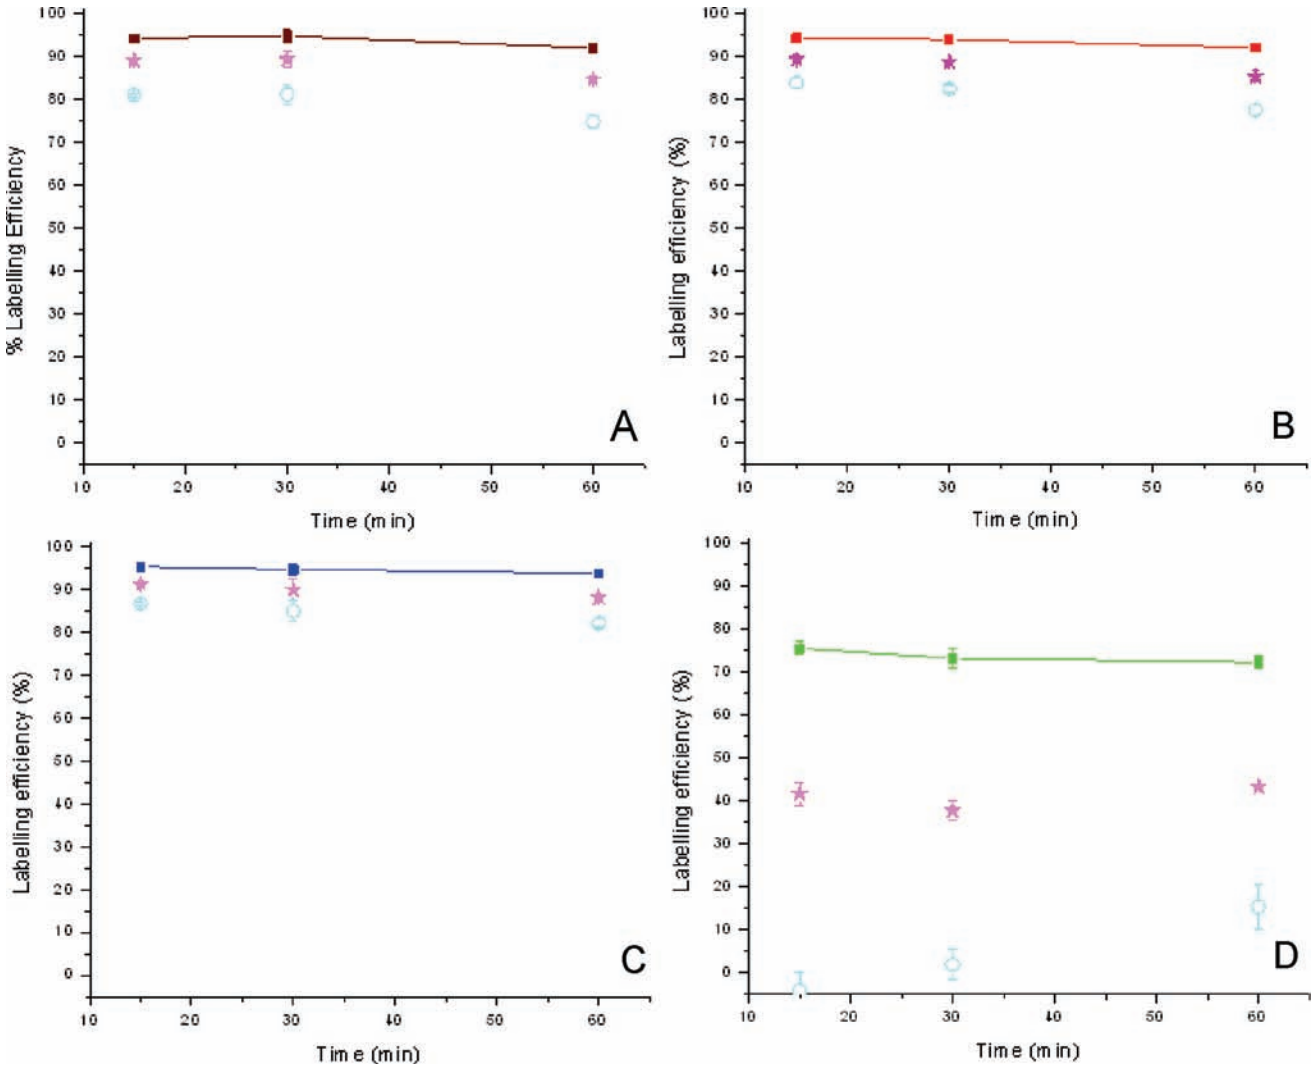

Figure 4. Plots of labeling efficiency vs initial reaction time along with the stability testing against cysteine for (A) 100%, (B) 25%, (C) 10%, and (D) 0%. Cysteine challenge results are given at 1 h (stars) and 24 h (hollow circles). For all experiments, 2 mg of microspheres were radiolabeled with 9.5 MBq (250 μCi) of $[Tc(CO)_3]^+$.

0.4% labeling efficiency. The radiochemical stability of these microspheres was as good as that of non-PEGylated microspheres: the cysteine challenge showed that 97% and 93% of the activity were still microsphere-bound after 1 and 24 h, respectively.

The biodistribution of PEGylated 10% chelomer microspheres radiolabeled with 18.5 MBq of ^{99m}Tc (Figure 1F) was also investigated in mice after tail vein injection. As seen by microSPECT/CT imaging (Figure 6C), almost all lung uptake could be avoided by using PEGylated microspheres. The charge on the microspheres was, therefore, not responsible for the lung uptake of microspheres observed previously. Uptake of the PEGylated microspheres by the liver increased, and all other organs received proportionally less of the radioactive microspheres (Figure 7).

To be able to evaluate the *in vivo* stability of the $[^{99m}Tc(CO)_3]^+$ complexation to the chelomer, an additional group of 4 animals received the same activity of the precursor complex $[^{99m}Tc(CO)_3(H_2O)_3]^+$ so that the biodistribution of the complex could be compared to that of the radiolabeled microspheres (Figure 6A). After 6 h, approximately one-third of the injected charged tricarbonyl compound was still found in the animals, mainly circulating in the blood. The heart with the highest blood concentration was, thus, highly visible in the SPECT scan. While a large part of the precursor complex $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was

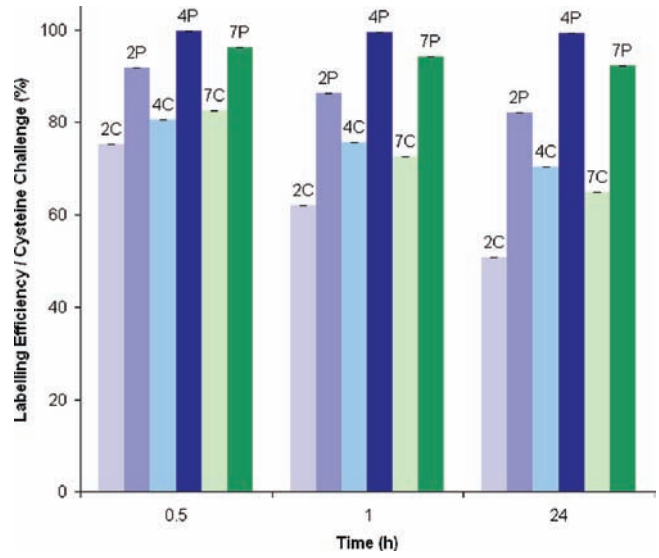

Figure 5. Graph showing labeling efficiency by increasing initial labeling activity from 74 MB (2 mCi) to 260 MBq (7 mCi) for 10% chelomer (P) vs control (C) microspheres. The first time point at 0.5 h is the labeling efficiency, while the 1 and 24 h time point are results of the cysteine challenge.

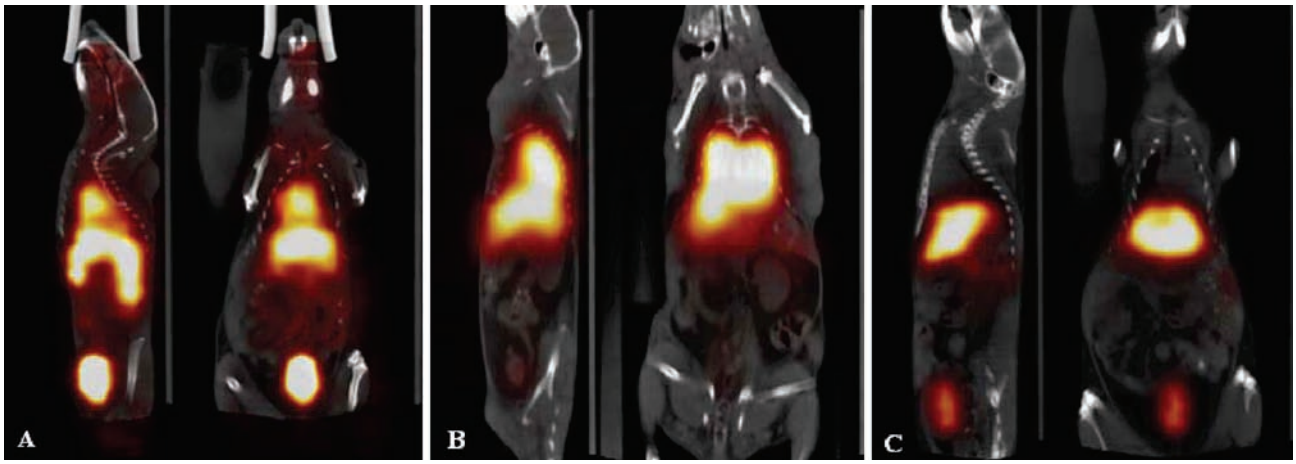

Figure 6. Sagittal (left) and coronal (right) microSPECT/CT images of (A) $[^{99m}Tc(H_2O)_3(CO)_3]^+$, (B) non-PEGylated microspheres, and (C) PEGylated microspheres 6 h after tail vein injection.

excreted through the urine, some may have rapidly exchanged its three labile water molecules and ended up in coordination with potential donors from serum proteins, for example, transferrin, to coordinate the $[^{99m}Tc(CO)_3]^+$ core. Since transferrin is excreted and/or stored in the liver, the 11% of the activity found in the liver at the 6 h time point could further implicate transferrin as a carrier protein for $[^{99m}Tc(CO)_3]^+$.

The transferrin proteins are the most prominent metal binding proteins in the body fluids (*27*). Although it is the Fe^{3+} ion that is normally found in the active site of transferrin, this protein also has a high affinity for many other metal ions (*27*, *28*). Transferrin's metal binding depends mainly on its structural organization. Both the C and the N lobes in the transferrins contain the same four donor atoms to bind various metal ions, two phenolic O from two tyrosines, an N from the histidine imidazole, and a carboxylate O from aspartic acid. It has been reported that accommodating metal ions depends on the conformation of both the apoprotein (metal-free protein) as well as the metal bound protein. Transferrin conformation changes from the initial open state to the closed state after metal binding. It is likely that the protein can accommodate $[^{99m}Tc(CO)_3]^+$ binding in the open state, since it acts as a potential tetra dentate ligand able to readily fill the three vacant positions around ^{99m}Tc. However, whether this binding puts much stress on the structure and hinders the conformational change (from open to closed), due to the size of $[^{99m}Tc(CO)_3]^+$, requires a thorough investigation. If transferrin's binding site cannot properly close, then the metal ion might be removed easily.

Biodistribution analysis at the 6 h time point via the organ/blood ratios (Table 3) confirmed that both PEGylated and non-PEGylated microspheres were mainly taken up by the monophagocytic system in the liver and spleen, and to a very similar extent. The only difference between the two types of microspheres was the 20-fold higher accumulation of the more hydrophobic, non-PEGylated microspheres in the lungs. While the reason for this lung accumulation is not known, the charge of the metal complex can be excluded as the cause, since both PEGylated and non-PEGylated microspheres had the same ligand moiety and generated similar complex cations. Agglomeration is more likely related to hydrophobic interactions with blood proteins, which can, for the most part, be prevented by PEGylation of the microspheres. Changes in the poly(ethylene glycol) chain length or in the total amount used (currently only 1.5%) might further reduce agglomeration in the lungs. The kidney to blood ratio of $[^{99m}Tc(CO)_3]^+$ after 6 h confirmed that the urinary system was its main path of excretion. The initially expected uptake of the positively charged $[Tc(CO)_3(H_2O)_3]^+$ in the heart, similar to that seen in the also positively charged radiopharmaceuticals sestamibi and tetrofosmin (*29*), was not confirmed (Table 3)—the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ compound is likely not sufficiently lipophilic. The low heart to blood ratio of 0.30 suggests that the highly visible heart during SPECT imaging at the 6 h time point was due to the large volume of radioactive blood in the heart and not due to local binding of the radioactive compound to the myocardium.

Unfortunately, colloidal albumin kits in the same size range as our particles are no longer available, making direct comparison of our labeling and biodistribution results difficult. We have, however, compared our findings to those by Scheffel et al., who described the preparation of human serum albumin (HSA) microspheres with an average size of 0.6 μm (*24*). The values for the percentage of injected dose per organ measured after 4.25 h were similar to our findings measured after 6 h (Figure 7). For example, the blood activity was 0.9% vs 2.5%; the liver uptake was 73.2% vs 57.6%; the spleen uptake was 1.0% vs 2.5%, and finally the lung uptake was 0.3% vs 0.7%, accordingly (Scheffel et al. vs our data for the PEGylated microspheres). Differences might have mainly to do with the different size distribution and/or time point of analysis.

In conclusion, chelomer-formulated microspheres are promising candidates for imaging, as they exhibit excellent radiolabeling efficiency and radiochemical stability. The PEGylated microspheres showed no agglomeration, a key factor for *in vivo* utilization of these particles. Therefore, the PEGylated chelomer microspheres are excellent tools for RES imaging. Other potential applications with the same microspheres of larger size (around 10 μm) include lung perfusion imaging. And even larger, around 40 μm, the biodegradable microspheres could be radiolabeled with the β-emitter ^{188}Re and used for the therapeutic radioembolization of liver tumors. The easy and complete kit-based labeling and the fact that the particles do not agglomerate will allow for reliable and repeatable imaging, and potentially even therapy. Furthermore, all biohazards connected with the handling of blood products are eliminated with these nontoxic, biocompatible, and biodegradable microspheres.

ACKNOWLEDGMENT

We thank Dr. Troy Farncombe, Chantal Saab, and Rod Rhem at McMaster's Centre for Preclinical and Translational Imaging in Hamilton, Ontario, Canada, for excellent imaging support. We also thank Scott McNaughton, radiopharmacist at McMaster's University Health Centre, for providing ^{99m}Tc and space for the radiolabeling, and Dr. Don Lyster, at Vancouver General Hospital, Vancouver, British Columbia, Canada for many discussions. We appreciate support for this research from a Natural Sciences and Engineering Research Council of Canada (NSERC) grant.

Rapid Synthesis of DNA-Functionalized Gold Nanoparticles in Salt Solution Using Mononucleotide-Mediated Conjugation

Wenting Zhao,[†] Li Lin,[†] and I-Ming Hsing*[,†,‡]

Bioengineering Graduate Program and Department of Chemical and Biomolecular Engineering, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong SAR. Received February 20, 2009; Revised Manuscript Received April 8, 2009

DNA functionalized gold-nanoparticles (Au-nps) have been broadly used as labeling reagents in the development of molecular diagnostics as well as building blocks in nanotechnology. Conventional methods for the synthesis of DNA functionalized Au-nps require long incubation, typically overnight, and delicate control of the ionic strength to compensate for the charge repulsion between the nanoparticles surface and the DNA strands, which generally affect the stability of the nanoparticles and the DNA loading density. In this study, we present a novel mononucleotide-mediated conjugation approach to synthesize DNA-functionalized Au-nps within 4 h in a high ionic strength environment. Au-nps covered with a thermally tunable stabilization layer through mononucleotide adsorption were shown to readily conjugate with thiol-DNAs in 0.1 M NaCl solution upon heating. Monitoring this mononucleotide-mediated conjugation reaction through dynamic light scattering and UV−vis spectroscopy demonstrated the formation of stable DNA/Au-nps conjugates. The resulting conjugates, as characterized by fluorescence spectroscopy, are loaded by ∼80 strands per particle, comparable to the DNA loading density of current approaches. The general applicability of this approach was further verified in a nanoparticle-bound DNA hybridization test. Our results show that mononucleotide-mediated thermal conjugation is an attractive alternative that allows temperature-controlled and salt-enhanced functionalization of gold nanoparticles with DNAs in just a few hours.

INTRODUCTION

DNA-functionalized gold nanoparticles (Au-nps) play an important role in biosensing and nanobiotechnology. A synergistic combination of the sequence-specific hybridization-based molecular recognition of DNA molecules and the size-dependent chemical, physical, and plasmonic properties of Au-nps has enabled DNA/Au-nps conjugates to find many critical applications in molecular diagnostics (*1–5*), nanofabrication (*6–9*), molecular nanoelectronics (*10–12*), cell imaging (*13*), and gene regulation (*14*). The use of DNA-functionalized gold nanoparticles is still in its infancy, and many more interesting approaches are expected. One of the key essentials to fully developing their application potentials is the fast and reproducible synthesis of stable DNA/Au-nps conjugates.

On the basis of the chemistry of thiol self-assembly on gold, a widely accepted protocol to immobilize specific DNAs onto Au-nps surfaces was developed by Mirkin and co-workers (*15*). In their approach, a 2 day incubation process was needed to directly link thiol-terminated oligonucleotides to citrate-stabilized Au-nps (referred to as direct conjugation approach). Specifically, salt was added after an initial overnight incubation to neutralize the charge repulsion, and then, a 40 h aging step was performed to achieve a high DNA loading density, which is critical for the stabilization of the conjugates. Improvement on the direct conjugation approach was later reported by Brust and co-workers, who applied vacuum centrifugation instead of a long aging step to speed up the formation of stable conjugates, and the conjugation process was completed in ∼20 h (*16*). They suggested that the vacuum centrifugation step was essential to ensure a gradual and simultaneous rise of solution DNA concentration and ionic strength with a concomitant increase of DNA loading density on particles. Other than the direct conjugation method, Alivisatos and co-workers reported a strategy to minimize the salt effect on the particle stability by the complexation of Au-nps with bis(*p*-sulfonatophenyl)phenylphosphine dehydrate dipotassium salt (BSPP) prior to the immobilization of thiol-DNA molecules (referred to as BSPP coating approach) (*17, 18*). With BSPP protection, the salt-dependent aggregation of Au-nps was controlled and the conjugation process could be done in ∼12 h. However, this process is suitable for the synthesis of mono or low DNA conjugated Au-nps, but not intended for preparing DNA/Au-nps conjugates with a high DNA loading density.

In this study, we report a new conjugation method enabling a rapid immobilization of high-density DNAs on stable Au-nps in a salt environment, which to our knowledge has never been reported in the literature. The essence of our strategy relies on the fast and reversible binding of mononucleotides to Au-nps surfaces. This binding was used to quickly stabilize Au-nps in salt solution by forming a mononucleotide layer on particle surface, and the adsorption/desorption of this layer is also thermally tunable (*19*). As shown in Scheme 1, our conjugation process starts with a reversible adsorption of mononucleotides on the Au-nps for nanoparticle stabilization in salt solutions, followed by a temperature-facilitated ligand-exchange reaction between the incoming thiol-DNA and the protecting mononucleotides on Au-nps surface. Our experimental characterization data will show that the synthesis of DNA/Au-nps conjugates by our method could be achieved within several hours and the resulting conjugates have similar or better characteristic attributes (DNA loading density and stability) in comparison with those synthesized by conventional methods. The ability to modify Au-nps with specific DNAs in an efficient

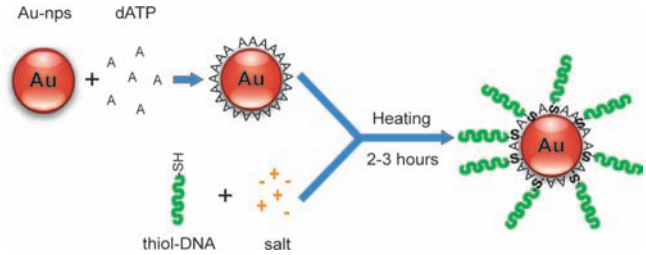
Scheme 1. Mononucleotide-Mediated Conjugation of Thiol-DNA to Gold Nanoparticles



and controlled manner opens up opportunities in molecular diagnostics and bionanotechnology.

EXPERIMENTAL PROCEDURES

Materials. Thirteen nanometer Au-nps were prepared by reduction of tetrachloroaurate as reported previously (*20, 21*), while 20 nm Au-nps, hydrogen tetrachloroaurate trihydrate ($HAuCl_4 \cdot 3H_2O$), sodium citrate, and poly(L-lysine) were purchased from Sigma. dATP (10 mM) was purchased from Invitrogen, and oligonucleotides were synthesized by Integrated DNA Technologies. Other salts were provided by USB Corporation. The water used in all experiments was purified with NANOpure Diamond TOC Analytical Ultrapure Water System (Barnstead, U.S.A.) and autoclaved by ES-215/ES-315 Autoclaves (Tomy, Japan) prior to use.

Conjugation of DNA/Au-nps. The procedure for mononucleotide-mediated conjugation of DNA/Au-nps is illustrated in Scheme 1. Citrate-stabilized Au-nps were first incubated with dATP in a molar ratio (dATP/Au-nps) of 1000 for 15 min. The mixture was then brought to 10 mM sodium phosphate buffer (pH 8.0) and 0.1 M NaCl. After brief vortexing, thiol-DNA (thiol-T30, 5′-TTT TTT TTT TTT TTT TTT TTT TTT TTT TTT TTT-C3-thiol-3′, 500 μM) was introduced in a molar ratio (thiol-DNA to Au-nps) of 500, followed by heating (Eppendorf Mastercycler personal thermal cycler) at a constant temperature for 3 h. Except for the temperature effect study, all the heating steps were conducted at 60 °C. Afterward, the particles were washed three times in 10 mM sodium phosphate buffer (pH 8.0) with 0.1 M NaCl through centrifugation (13 200 rpm, 20 min) to remove excess reagents. Finally, the resulting conjugates were resuspended in 100 μL sodium phosphate buffer (10 mM, pH 8.0) with NaCl (0.3 M). For the direct conjugation and BSPP coating approaches, the procedure is the same as previously reported (*15, 17, 18*).

Hybridization of Au-nps Linked DNAs. Hybridization test was performed using DNA/Au-nps conjugates of different sizes and labeled with DNAs of complementary sequences. Specifically, two conjugates were prepared using the mononucleotide-mediated approach: Au-nps of 13 and 20 nm functionalized with respective cDNA sequences (thiol-T30, 5′-TTT TTT TTT TTT TTT TTT TTT TTT TTT TTT TTT-C3-thiol-3′, to Au-nps of 20 nm (**thiol-T30/Au20**) and thiol-A30, 5′-AAA AAA AAA AAA AAA AAA AAA AAA AAA AAA AAA-C3-thiol-3′, to Au-nps of 13 nm (**thiol-A30/Au13**)). Two conjugates were mixed overnight at a molar ratio of 1:10 (thiol-T30/Au20:thiol-A30/Au13) in 10 mM sodium phosphate buffer with 0.3 M NaCl (pH 8.0). In the negative control, the thiol-A30 was substituted with a nonthiol-DNA (nonthiol-A24, 5′-AAA AAA AAA AAA AAA AAA AAA AAA-3′, forming nonthiol-A24/Au13). The resulting solutions of hybrids were imaged with TEM.

UV−vis Spectroscopy. A 1 mL cuvette (Bragg and Co.) was used, and all spectra were obtained through Ultrospec 4300 pro UV−vis spectrophotometer (Amersham Biosciences).

Dynamic Light Scattering (DLS). Measurements were performed using a ZetaPlus (Brookhaven Instruments Corporation). Incident light was provided by a 35 mW solid state laser (660 nm). Scattered light was collected at a fixed angle of 90°. All samples were filtered through a 0.22 μm acetate membrane filter prior to measure. Five runs were performed per sample with 30 s per run.

Fluorescence-Based Quantification of the DNA Loading Density on Au-nps. Centrifugation pellets of 300 μL Cy3-A20-thiol/Au13 conjugates were incubated overnight with 50 μL mercaptoethanol (ME) (12 mM in 0.3 M PBS). The solution containing displaced Cy3-A20-thiol was separated from the Au-nps by centrifugation. The fluorescence signal of each sample was measured using Applied Biosystems 7300 real-time PCR system. Standard curves were prepared to convert the fluorescence reading to molar concentration.

Transmission Electron Microscopy (TEM). Specimens were prepared by deposition of a drop of colloidal solutions on 0.01% poly(L-lysine) pretreated carbon-nonporous film supported by copper grid (SPI Supplies Inc., 400 mesh). All the samples were examined in a JEM 2010 transmission electron microscope (JEOL) operated at 200 kV. Images were taken by GATAN MSC 794 CCD Camera and analyzed with *GATAN Digital Microscopy* software.

RESULTS

Scheme 1 illustrates our strategy for the synthesis of DNA/Au-nps conjugates. As shown, the process involves the protection of Au-nps from salt-induced aggregation by the mononucleotide adsorption and the thermally enhanced ligand exchange reaction between the surface-bound mononucleotides and the incoming DNA molecules. Deoxyadenosine triphosphate (dATP) was chosen among the four different mononucleotides, as in our previous study dATP-covered Au-nps were found to have a higher salt tolerance than the Au-nps protected by other mononucleotides (*19*). A detailed working procedure for conjugate synthesis is described in the Experimental Procedures. Critical characterization results of this conjugation approach are delineated in the following paragraphs.

Conjugate Stability. It would be useful to understand the stability of the synthesized DNA/Au-nps conjugates, since the conjugates might also be vulnerable to the irreversible salt-induced aggregation at high temperature and high ionic strength as the mononucleotide-coated Au-nps do. From the measurement of surface plasmon resonance (SPR) using UV−vis spectroscopy, it is clear in Figure 1 that our DNA/Au-nps conjugates (thiol-T30/Au13) are stable at a salt solution (0.1 M NaCl) and exhibit a characteristic adsorption peak at 520 nm before and after the heat treatment at 80 °C. On the other hand, dATP-covered Au-nps without thiol-DNA attachments were found to suffer aggregation with an obvious color change from red to blue and a significant shift of the adsorptive peak to a higher wavelength (e.g., 650 nm), which is consistent with the previous report (*19*). The conjugate stability of the 20 nm Au-nps was also evaluated using UV−vis spectroscopy. Similar stability results (see Supporting Information) were observed. It is believed that the enhanced stability of the DNA/Au-nps conjugate comes from the ligand replacement of the initial dATP protection layer by thiol-DNA linkage, that stabilizes the conjugate even at high ionic strength and at elevated temperature. Other than a few-nanometer red shift caused by the newly formed thiol-DNA/Au linkage, the conjugate shows a similar SPR peak to that of the citrate Au-nps without salt.

Effective Diameter of DNA/Au-nps Conjugates. In addition to assessing the dispersion of Au-nps, effectiveness of the dATP-mediated conjugation method could also be reflected by measuring the "effective diameter" of DNA and nanoparticle conjugates using the dynamic light scattering (DLS) technique. The effective diameter of the DNA/Au-nps conjugates should

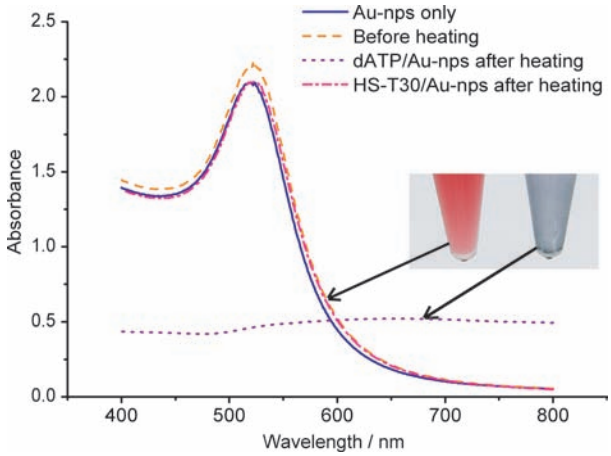


Figure 1. UV−vis spectra of the solution mixture in the mononucleotide-mediated conjugation approach. Solid line (blue), Au-nps (13 nm) serving as control without dATP and salt; dashed line (yellow), thiol-T30 and dATP protected Au-nps (thiol-T30/Au13) with 0.1 M NaCl before heat treatment; dotted line (purple), dATP protected Au-nps with 0.1 M NaCl after 3 h heat treatment at 80 °C; dash−dotted line (pink), thiol-T30 and dATP protected Au-nps (thiol-T30/Au13) with 0.1 M NaCl after 3 h heat treatment at 80 °C. The inset image shows the observed colors of the dATP protected Au-nps (right, blue) and the mixture of thiol-T30 and dATP protected Au-nps (left, red) after the heat treatment.

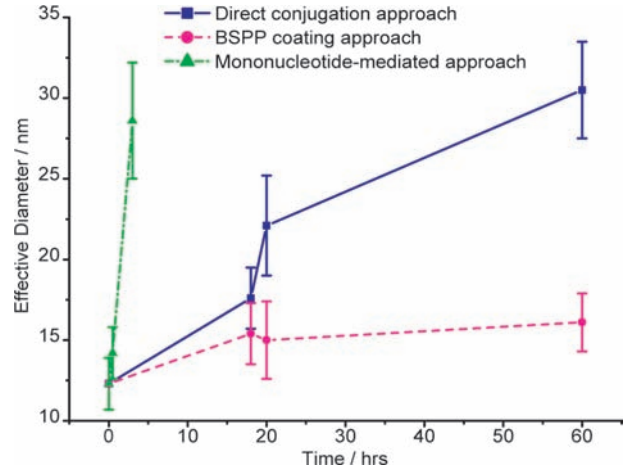

Figure 2. Effective diameter of thiol-DNA/Au-nps conjugate during the time course of conjugate synthesis. Solid line (blue) with square mark (■), direct conjugation approach; dashed line (pink) with circle mark (•), BSPP coating approach; dash−dotted line (green) with triangle mark (▲), mononucleotide-mediated approach. The starting size of bare Au-nps is 13 nm, and the error bars represent standard deviation for five independent measurements.

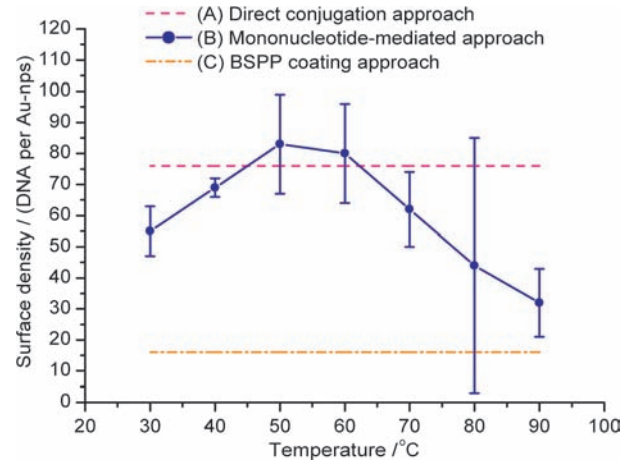

Figure 3. Temperature effect on DNA surface loading density. (A) dashed line (pink), direct conjugation approach; (B) solid line (blue) with circle mark (•), mononucleotide-mediated approach; (C) dash−dotted line (yellow), BSPP coating approach. The error bars represent standard deviation for three independent fluorescence measurements.

be significantly larger than that of the bare gold particles. Although the salt concentration might have influence on the effective diameter through its impact on the DNA inter/intrastrand repulsion, the overall size of the conjugate is dominated by the surface loading density of thiol DNAs on Au-nps (*22*). The higher the density, the larger is the size. In Figure 2,[1] the effective diameters of our conjugates during the time course of conjugate synthesis was benchmarked with the ones synthesized by the conventional direct conjugation and BSPP-based methods. The effective diameter of the conjugates by the BSPP coating method was found to be the smallest among the three methods, and there is no significant size change of the conjugate during the synthesis. The limited size growth could be due to the low salt concentration and the hindered diffusion of DNAs during the synthesis. The conjugates prepared by our approach and the direct conjugation show very significant size increase (from 13 nm to ∼30 nm). However, the direct conjugation approach requires a much higher synthesis time, while the mononucleotide-mediated approach achieves a similar effective diameter in just 3 h.

Temperature Effect on the Mononucleotide-Mediated Conjugation. The effect of temperature on the mononucleotide-mediated conjugation process was evaluated using fluorescence techniques (*23*), by which the surface density of DNA per particle could be measured as a function of the conjugation temperature. As shown in Figure 3, the DNA loading densities on DNA/Au-nps synthesized by the three different approaches are compared. Straight lines (Figure 3A,C) were used here to represent the DNA surface density achieved by the conventional isothermal methods (direct conjugation approach and BSPP coating approach, respectively) for the convenience in comparison with the values achieved by mononucleotide-based approach under different temperatures. Our approach shows an increase of DNA density per particle (up to 80 oligo strands per particle) with temperature rising from 30 to 60 °C, and the density drops at higher temperatures, which indicates that the DNA loading on Au-nps could be optimized at an elevated temperature of ∼50 °C (Figure 3B).

Validation of Hybridization by DNA/Au-np Conjugates. As the molecular orientation of immobilized DNAs may greatly affect the sensitivity in many hybridization-based biosensing applications (*3, 24*), hybridization experiments were therefore conducted to verify the functionality of immobilized DNAs. As shown by the TEM micrographs (Figure 4B), star-shaped aggregates were observed for the DNA/Au-nps conjugates with complementary thiol-DNA sequences (thiol-A30/Au13 and thiol-T30/Au20). However, in the negative control experiments, the hybridization between the thiol-T30/Au-20 conjugate and the 13 nm Au-with nonthiol-DNAs (nonthiol-A24/Au13) was not successful, and thus, no aggregates were found in Figure 4A. Misorientation of the nonthiol-DNA or the nonspecific

[1]The data were taken in the following operating time points: the first data point was taken at 0 h for the citrate-coated Au-nps for all the three methods. In the direct conjugation, the data points (A) at overnight incubation of thiol-DNA and Au-nps (18 h), salt concentration adjusting to 0.1 M NaCl (20 h) and after 40 h aging step (60 h) were taken. In BSPP method, the data points (B) at the formation of BSPP coating layer (18 h) and thiol-DNA incubation (20 and 60 h) were taken. In the mononucleotide-mediated approach, the data points (C) at the introduction of dATP and salts (0.5 h) and after thermal treatment (3 h) were taken.

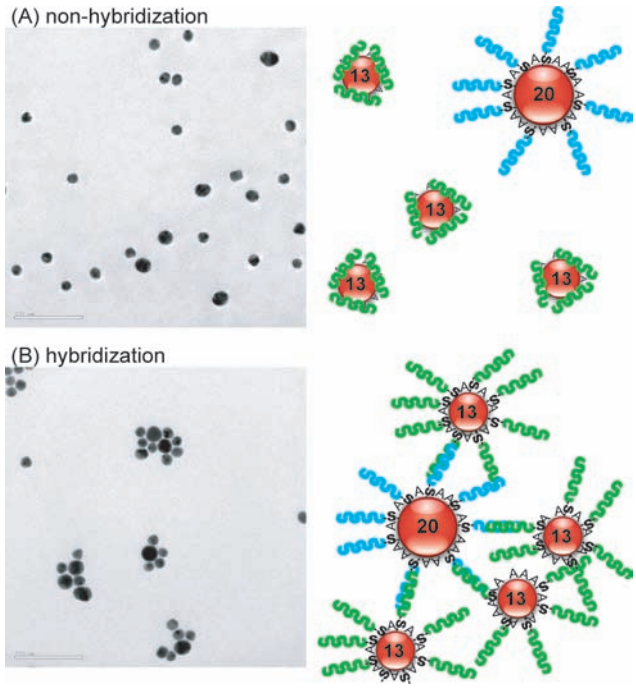

Figure 4. TEM images of DNA/Au-nps conjugates after hybridization. (A) thiol-T30/Au20 conjugates with nonthiol A24/Au13 particles; (B) thiol-T30/Au20 conjugates with thiol-A30/Au13 conjugates. All the conjugates were synthesized through mononucleotide-mediated conjugation approach. (Scale bar: 100 nm.) Schematic representations of scenarios (A) and (B) are placed next to the TEM micrographs.

adsorption of DNA on Au-nps could result in hybridization failure, as demonstrated in the negative control group. DNA/Au-nps conjugates synthesized by the dATP-mediated approach retain DNA functionality and possess rich DNA strands per particle for hybridization-based medical diagnostic and biosensing applications.

DISCUSSION

In the direct conjugation approach, careful control of the salt concentration is needed. Diffusion of thiol-linked DNA to citrate-covered Au-nps would require salt ions to reduce the repulsive force between the negatively charged incoming DNA molecules and the negatively charged citrate-capping on Au-nps surface. However, too much salt could cause an irreversible aggregation of nanoparticles. Therefore, gradual addition of salts and long incubation are generally required in the direct conjugation approach in order to balance the need for DNA conjugation without causing particle aggregation. To address the long-standing issue related to salt tolerance, our approach utilizes the adsorbed mononucleotides as a mediating layer on Au-nps to perform the conjugation of thiol-DNA to citrate Au-nps in salt solutions. The conjugates prepared by our approach and the direct conjugation show very significant size increase (from 13 nm to ~30 nm). However, the direct conjugation approach requires a much higher synthesis time, while the mononucleotide-mediated approach achieves a similar effective diameter in just 3 h. The mediating component dATP plays an important role in shortening the synthesis time. Without the need for overnight incubation and a long aging step, the salt concentration in our approach can be adjusted to a higher value prior to the introduction of thiol-DNA, as the dATP-covered Au-nps could resist a much higher salt concentration without the salt-induced aggregation than that of the citrate-based counterpart. The controlled salt concentration and the temperature-monitored removal of mononucleotide from Au-nps facilitate the ligand exchange reaction between the incoming thiol-DNA and the outgoing dATP.

Temperature plays an important role in the mononucleotide-mediated conjugation. Although the removal rate of dATP is larger at higher temperatures (i.e., >60 °C), the re-exposed Au-np surfaces without dATP protection would suffer salt-induced aggregation and the bond of Au-thiol DNA might not survive at high-temperature (*25*). The increased loading density of thiol-DNA on Au-nps due to the high dATP removal rate could be compromised by the unstable Au-thiol bonding at higher temperatures, which could result in the temperature dependence described earlier. In comparison with the DNA loading densities per Au-np particle in the direct conjugation method (~76 oligo strands) and in the BSPP method (~16 oligo strands) measured using the same procedure, we believe that the dATP-mediated approach, which demonstrates a loading density of 80 oligo strand, offers a synthesis strategy for rapid DNA/Au-nps conjugation with comparable quality of the established methods. In the direct conjugation method, other researchers reported loading density of ~70 strands per 15 nm particle for a oligo DNA sample with poly dA spacer and 100 ± 30 DNA per 15 nm Au-np with the vacuum evaporation enhancement (*16*, *23*, *26*). Their results are consistent with ours (~76 per 13 nm Au-np) for the direct conjugation approach. By balancing dATP displacement at a specific temperature and ion strength, stable DNA/Au-nps conjugates could be made within 4 h, which is much shorter than the conventional approaches. Moreover, dATP, a monomer unit of nucleic acids, shares similar nonthiol functional groups in DNA, and thus, dATP residues on Au-nps help to reduce the nonspecific DNA binding to the particle through the nonthiol entities. The reduction of nonspecific binding by dATPs contributes to the right molecular orientation of the immobilized DNAs for hybridization.

Our study has demonstrated that a novel mononucleotide-mediated conjugation approach enables the rapid DNA functionalization of Au-nps with DNA surface coverage comparable to that obtained by the direct conjugation method. The stable conjugates with about 80 DNA strands per particle can be formed in salt solution (0.1 M NaCl) at 60 °C without special equipment required, and the resulting conjugates are able to hybridize. We envision that this mononucleotide-mediated method will offer an attractive alternative for the preparation of DNA/Au-nps conjugates, and similar methodology can be readily applicable for the synthesis of nanoparticle conjugates with various biomolecules (e.g., DNA and peptides). The ability to modify Au-nps with biomolecules in a rapid and controlled manner would provide more opportunities in nanobiotechnology.

ACKNOWLEDGMENT

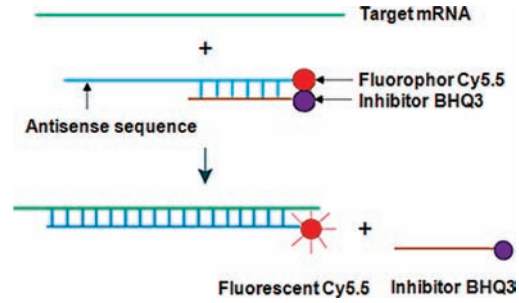
Fluorescent conjugated DNA oligonucleotides for antisense targeting of mRNA has the potential of improving tumor/normal tissue ratios over that achievable by nuclear antisense imaging. By conjugating the Cy5.5 emitter to the 3′ equivalent end of a 25 mer phosphorothioate (PS) antisense major DNA and hybridizing with a shorter 18 mer phosphodiester (PO) complementary minor DNA (cDNA) with the Black Hole inhibitor BHQ3 on its 5′ end (i.e., PS DNA25-Cy5.5/PO cDNA18-BHQ3), we previously achieved antisense optical imaging in mice as a proof of this concept. In a process of optimization, we have now evaluated the stability of a small series of duplexes with variable-length minor strands. From these results, a new study anti-mdr1 antisense duplex was selected with a 10 mer minor strand (i.e., PS DNA25-Cy5.5/PO cDNA10-BHQ3). The new study duplex shows stability in serum environments at 37 °C and provides a dramatically enhanced fluorescence in KB-G2 (pgp++) cells when compared with KB-31 (pgp±) as evidence of antisense dissociation at its mdr1 mRNA target. The duplex was also administered to KB-G2 tumor bearing mice, and when compared to the duplex used previously, the fluorescence from the tumor thigh was more obvious and the tumor-to-background fluorescence ratio was improved. In conclusion, by a process designed to optimize the duplex for optical antisense tumor targeting, the fluorescence signal was improved both in cells and in tumored mice.

INTRODUCTION

Oligomers such as DNA for antisense imaging of mRNA are potentially powerful candidates for detection of endogenous gene expression in vivo (*1*−*5*). In conventional imaging of mRNA expression in vivo, antisense oligonucleotides are usually radiolabeled with gamma ray emitting radionuclides. However, our experience and that of other laboratories suggest that achieving adequate tumor/normal radioactivity ratios by antisense nuclear imaging is often problematic (*6*). As an alternative to nuclear imaging, optical imaging has the potential to improve tumor/normal tissue ratio by modulating the detectable signal in the target through the judicious use of fluorescence resonance energy transfer (FRET) (*7*−*11*). We have been developing an approach to optical antisense imaging that in principle should provide fluorescence images in tumored subjects by an antisense mechanism that are free of background fluorescence (*12*). In this method, linear fluorophor-conjugated oligomer duplexes are arranged to inhibit fluorescence and to dissociate only in the presence of their target mRNA. Thus, the fluorescence signal should in principle be inhibited everywhere except in the target cell. The approach is illustrated in Scheme 1.

Recently, we reported on our first optical DNA duplex consisting of a Cy5.5 conjugated 25 mer phosphorothioate (PS) DNA hybridized to a BHQ3 conjugated complementary 18 mer phosphodiester (PO) cDNA for optical antisense imaging (i.e., PS DNA25-Cy5.5/PO cDNA18-BHQ3) (*12*). Although fluorescence in the tumor was clearly evident, this duplex also provided a fluorescence background making obvious the need for duplex optimization. In a process of optimization, we now report that five DNA duplexes differing in the length of the complementary minor strand were compared for stability using a simple thiazole orange (TO) fluorescence assay (*13*). On the basis of the screening results, the shortest minor strand (10 mer) was selected and, after hybridization to the 25 mer PS antisense major strand, was studied in cells and in tumored animals in comparison to that of the 18 mer major strand used previously.

Scheme 1. Schematic Diagram Illustrating the Principle of Antisense Optical Imaging



MATERIALS AND METHODS

As in our earlier investigation, all duplexes used the 25 mer anti-mdr1 uniform PS antisense (5′-AAG-ATC-CAT-CCC-GAC-CTC-GCG-CTC-C-3′) major strand (*14*−*16*), either native or conjugated with the Cy5.5 fluorophor on the 3′ end attached via a three carbon linker. The native duplexes were formed by hybridization with a complementary uniform native PO minor strand with one of five chain lengths. The study conjugated duplexes were formed by hybridization of the same major strand with either a 10 or 18 mer PO minor strand conjugated with a Black Hole Quencher 3 (BHQ3) quencher on the 5′ end attached via a two carbon linker. Controls for the two study conjugated duplexes were identical except that the two fluorophors were reversed:

Native Duplexes.
PS-DNA25/PO-cDNA25
PS-DNA25/PO-cDNA22
PS-DNA25/PO-cDNA18
PS-DNA25/PO-cDNA14
PS-DNA25/PO-cDNA10

Conjugated Study and Control Duplexes.
PS-DNA25-Cy5.5/PO-cDNA10-BHQ3 (study duplex)
PS-DNA25-BHQ3/PO-cDNA10-Cy5.5 (control)
PS-DNA25-Cy5.5/PO-cDNA18-BHQ3 (comparison duplex)
PS-DNA25-BHQ3/PO-cDNA18-Cy5.5 (control)

The native DNAs (Integrated DNA Technologies, Coralville, IA) and the conjugated DNAs (Biosearch Technologies, Novato, CA) were purchased HPLC purified. The TO dye was obtained from Sigma-Aldrich (St Louis, MO) and was used as received. The KB-G2 (pgp++) and KB-31 (pgp±) human epidermoid carcinoma cell lines were a gift from Isamu Sugawara (Research Institute of Tuberculosis, Tokyo, Japan) and were cultured overnight at 37 °C, 5% CO_2, in Dulbecco's modified Eagle's medium (DMEM, Invitrogen, Carlsbad, CA, USA) containing 10% fetal bovine serum (FBS). The cells were incubated with DNAs in 1% FBS/DMEM medium.

Measurement of Native Duplexes. The five native duplexes were screened for stability in serum using a simple TO assay developed in this laboratory (*13*). Each duplex was added to a 96 well microplate at 100 μL per well and incubated at 500 nM in 70% normal mouse serum (Jackson Immuno Research Laboratories, Inc., West Grove, PA) at 37 °C for different times before the addition of the indicator TO at 6 μM. Fluorescence intensities were measured at room temperature on a Fluorescence Microplate Reader (Safire, Tecan Group Ltd.). In this case, 504 nm was used for excitation and 527 nm for detection of TO fluorescence. The TO concentration that was just sufficient to saturate the duplexes was determined by trial and error to be 6 μM. In the screening assay, decreased fluorescence was an indication of TO release and therefore of duplex instability due to dissociation and/or degradation.

Measurement of Conjugated Duplexes in Solution. Both the 10 mer and 18 mer conjugated study duplexes were prepared at different molar ratios by mixing the 10 or 18 mer cDNA with the DNA25-Cy5.5 at a molar ratio of 1:1, 2:1, 3:1, 5:1, 8:1, and 10:1 in wells of a 96 well microplate before the fluorescence was measured on the Microplate Reader. In this case, 685 nm was used for excitation and 706 nm for detection of Cy5.5 fluorescence. The DNA25-Cy5.5 concentration was 50 nM in all cases to provide a convenient fluorescence intensity.

The stability in serum of the DNA25-Cy5.5/cDNA10-BHQ3 duplex was measured by adding 100 μL of each duplex solution in a 96 well plate in quadruplicate to a final duplex concentration of 50 nM in 70% normal mouse serum (Jackson Immuno Research Laboratories, Inc., West Grove, PA) and incubated at 37 °C for up to 25 h. As control, the singlet DNA25-Cy5.5 was added to serum at the identical molar concentration in the identical manner. The fluorescence intensity was measured at each time point on the Microplate Reader.

Measurement of Conjugated Duplexes in Cells. The cell studies were performed in KB-G2 and KB-31 cells in quadruplicate in 96 well plates seeded at 10 000 cells per well and incubated with 10% FBS/DMEM culture medium overnight. In one experiment, both study and control duplexes were incubated in KB-G2 cells in 1% FBS/DMEM medium at 50, 100, 300, and 500 nM for 3 h at 37 °C. In another experiment, all four conjugated duplexes were incubated with both KB-G2 and KB-31 cells in 1% FBS/DMEM medium at 500 nM for 3 h at 37 °C. In all cases, the cells were washed twice with 1% FBS/DMEM culture medium and twice with PBS. To improve the reproducibility of the measurement, the cells were lysed before measuring the fluorescence. The lysis buffer (150 mM PBS, pH 7.2, 1% Triton X-100) was added at 100 μL per well, and the cells were incubated for 1 h at 37 °C. The fluorescence intensity of each lysis solution was measured on the Microplate Reader.

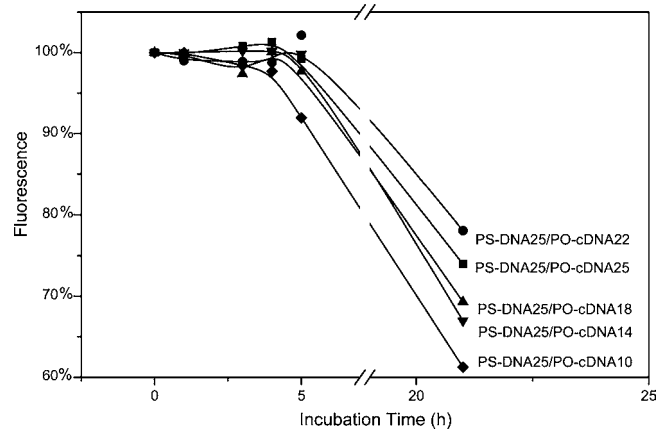

Figure 1. Percent fluorescence change for five duplexes in 70% serum at 37 °C as a function of incubation time. In each case, the fluorescence at time zero was set as 100%.

Animal Studies. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee. Male nude mice (NIH Swiss, Taconic Farms, Germantown, NY) at 7 weeks of age were each injected subcutaneously in the left thigh with 100 μL suspension containing 10^6 KB-G2 cells with greater than 95% viability. Mice were used for imaging studies when tumors were about 0.7 cm in any dimension and after having been on a chlorophyll-free diet (AIN-93G Purified Diet, Harlan Teklad, Madison, WI) for 5 days prior to imaging. Mice bearing KB-G2 tumor were administered 3 nmol of DNA25-Cy5.5/cDNA10-BHQ3 duplex in 100 μL of PBS via a tail vein. In vivo fluorescence imaging was performed on an IVIS 100 small animal imaging system (Xenogen, Alameda, CA) using a Cy5.5 filter set. During imaging, the animals were lightly anesthetized with 1.5% isoflurane in 2 L/min oxygen. Fluorescence images were acquired at 20 min, 2 h, 7 h, and 23 h after injection using a 0.5 s exposure time (f/stop 4). Image presentation and quantification were performed using *Living Image 2.5* software (Xenogen). Ellipsoid regions of interest (ROI) of equal area were drawn on the tumor and on the contralateral muscle in the normal thigh.

RESULTS

Measurement of Native Duplexes. The five native DNA duplexes, each with the same 25 mer major strand but different length of minor strand, were incubated at 37 °C in 70% normal mouse serum at 500 nM for different times before the addition of the TO indicator. The fluorescence was measured immediately after TO addition with shaking. Instability of the DNA duplex will result in a decreased fluorescence signal as denaturation of the duplex will reduce TO intercalation. Figure 1 presents the change of fluorescence intensity as a function of the incubation time in 37 °C serum and shows in all cases no change in fluorescence for at least 5 h of incubation. Thus, all duplexes appear to be stable in serum for a period sufficiently long for tumor targeting in vivo. Because of the similar stabilities, the duplex with the shortest minor strand (i.e., PS-DNA25/PO-cDNA10) was selected for further study on the assumption that it would exhibit the least stability in the presence of its mRNA target. The duplex of our earlier investigation (i.e., PS-DNA25/PO-cDNA18) was used for comparison.

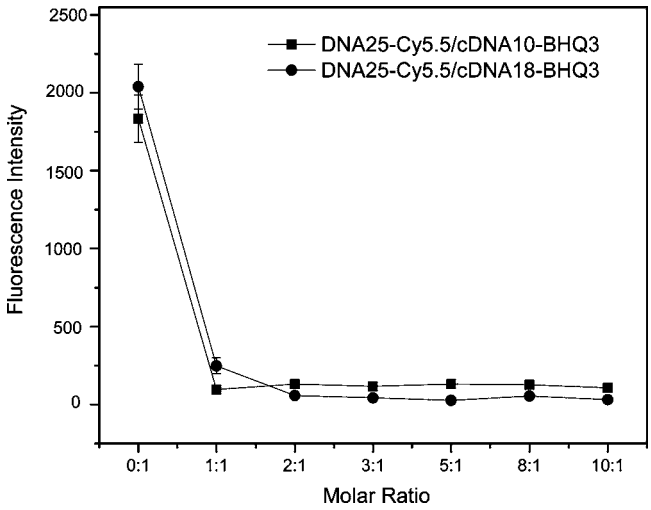

Figure 2. Fluorescence intensity of DNA25-Cy5.5 in PBS solution alone and after hybridized with increasing molar ratios of cDNA10-BHQ3 or cDNA18-BHQ3. Error bars represent standard deviations for three replicates and are too small to be visible on most data points.

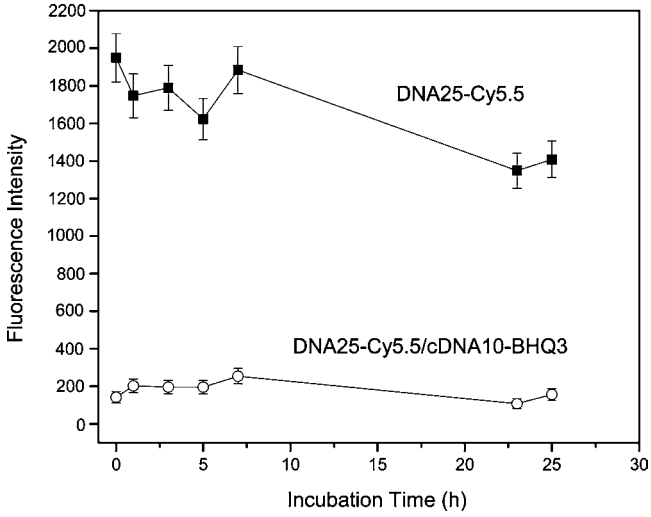

Figure 3. Fluorescence intensity showing stability of DNA25-Cy5.5/cDNA10-BHQ3 duplex compared to the DNA25-Cy5.5 single strand in 70% normal mouse serum at 37 °C over 25 h. Error bars represent standard deviations for three replicates.

Measurement of Conjugated Duplexes in Solution. Figure 2 presents the fluorescence intensity of DNA-Cy5.5 when different molar ratios of cDNA10-BHQ3 or cDNA18-BHQ3 were added. The results show that about 90% of the fluorescence signal of Cy5.5 is quenched when hybridized with either cDNA at a 1:1 molar ratio.

As mentioned above, the duplex with the shortest minor strand (i.e., PS-DNA25/PO-cDNA10) was selected as the study duplex on the assumption that it would exhibit the least stability in the presence of its mRNA target. The stability of this conjugated duplex was therefore evaluated over 25 h, again at 100 nM in 70% normal mouse serum at 37 °C, and the results compared to that of the singlet DNA25-Cy5.5. As shown in Figure 3, the study duplex did not show a substantial change in fluorescence over 25 h, suggesting duplex stability over this period.

Measurement of Conjugated Duplexes in Cells. The KB-G2 cells were incubated with the study anti mdr1 mRNA antisense DNA25-Cy5.5/cDNA10-BHQ3 duplex and its control duplex in which the fluorophors were reversed. For comparison, the antisense DNA25-Cy5.5/cDNA18-BHQ3 duplex of our previous investigation (*12*) was also studied as a comparison

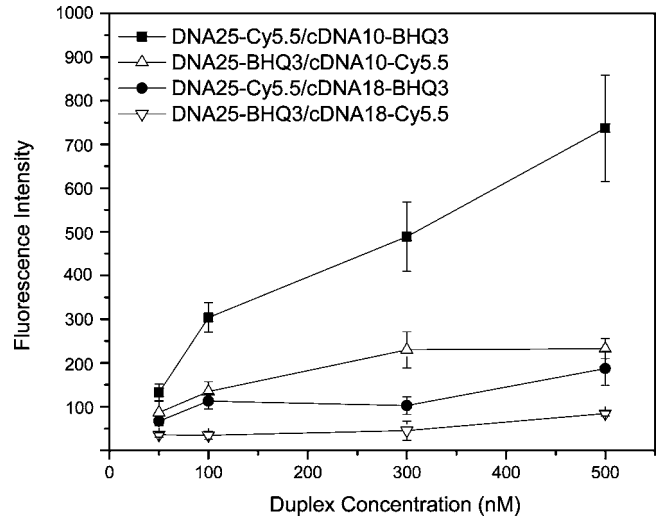

Figure 4. Cellular fluorescence of KB-G2 cells after incubation for 3 h with the 10 mer anti-mdr1 study duplex (DNA25-Cy5.5/cDNA10-BHQ3), its 10 mer control duplex with fluorophors reversed (DNA25-BHQ3/cDNA10-Cy5.5) and the 18 mer comparison duplex and its control at four concentrations. Error bars represent standard deviations for four replicates.

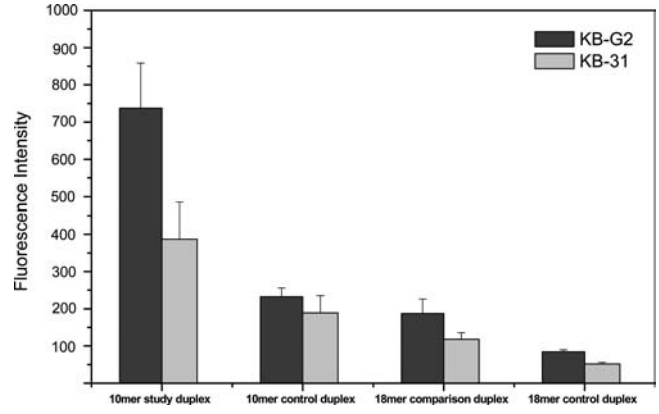

Figure 5. Cellular fluorescence of KB-G2 and KB-31 cells after incubation for 3 h with the 10 mer anti-mdr1 study duplex (DNA25-Cy5.5/cDNA10-BHQ3), its 10 mer control duplex with fluorophors reversed (DNA25-BHQ3/cDNA10-Cy5.5), and the corresponding 18 mer comparison duplex and its control duplex at 500 nM. (Error bars represent standard deviations for four replicates.)

duplex along with its similar control. Incubations were for 3 h at 37 °C at concentrations between 50 nM and 500 nM. Figure 4 presents the cellular fluorescence intensity vs duplex concentration and shows that the fluorescence signal of the cells is in all cases significantly higher ($p < 0.05$) when incubated with the 10 mer study or 18 mer comparison duplex compared to their respective control duplexes that differ only in reversed fluorophors. However, the fluorescence of cells incubated with the 10 mer study duplex is about 4-fold higher than cells incubated with the 18 mer comparison duplex as evidence of the decreased stability of the 10 mer compared to the 18 mer duplex, most probably due to antisense targeting.

If the higher fluorescence of KB-G2 cells incubated with the study compared to the 18 mer comparison duplex was due to antisense dissociation as is likely, then the fluorescence should be reduced in KB-31 cells because of its limited mdr1 expression. Figure 5 presents the results of incubating both the KB-G2 and KB-31 cells with the same four duplexes as above at 500 nM. No significant differences in fluorescence were observed between the two cell lines when incubated with either the 10 mer or 18 mer control duplexes presumably because the

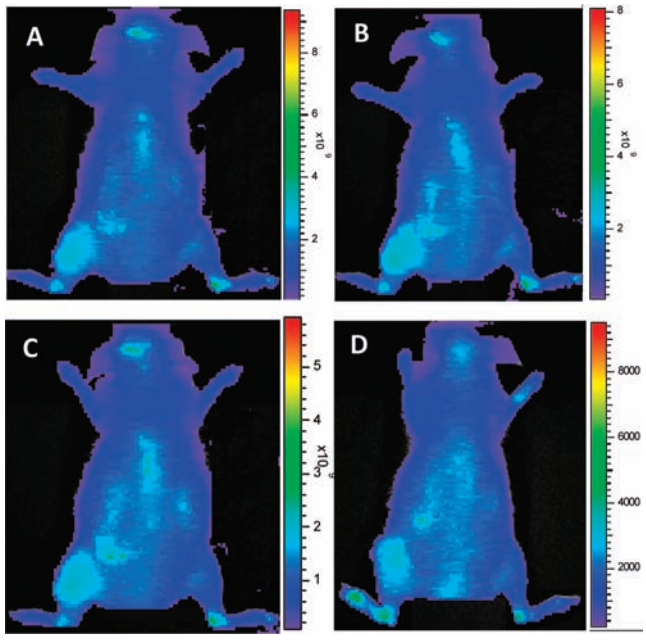

Figure 6. Whole-body dorsal fluorescence images of one mouse bearing a KB-G2 tumor in the left thigh at (A) 20 min; (B) 2 h; (C) 7 h; and (D) 23 h postinjection of 3 nmol study duplex (DNA25-Cy5.5/cDNA10-BHQ3).

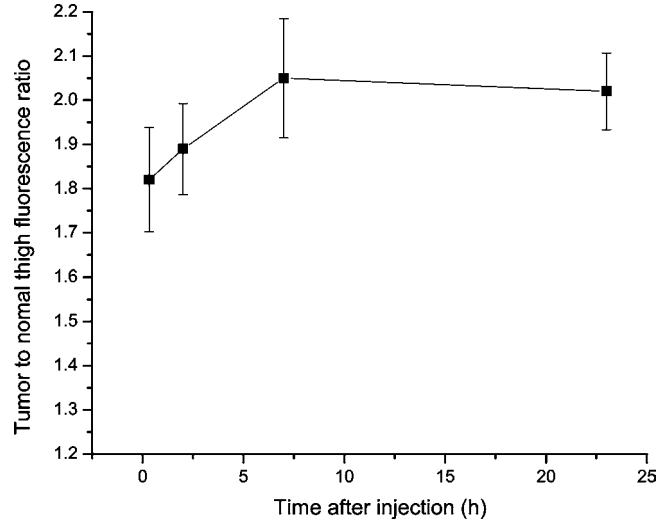

Figure 7. Average tumor-to-normal thigh fluorescence ratios vs time after injection of the study duplex. Error bars represent standard deviations for three animals. Fluorescence quantitation was accomplished using *Living Image 2.5* software (Xenogen).

Cy5.5 fluorophor is, in these cases, on the minor strand of each duplex that are either not dissociated (presumably in KB-31 cells) or are dissociated and released from the cell if binding does occur (presumably in KB-G2 cells). In both cases, the results would be the same: an absence of fluorescence. By contrast, the fluorescence of KB-G2 cells was statistically higher ($p < 0.05$) compared to the KB-31 cells when incubated with either the study 10 mer or 18 mer comparison duplex presumably because of the limited expression of the mRNA targets in KB-31. However, compared to the 18 mer duplex, the shorter 10 mer study duplex produces a much stronger fluorescence signal.

Animal Study. Three nude mice each bearing KB-G2 tumors in the left thigh received an injection of 3 nmol DNA25-Cy5.5/cDNA10-BHQ3 study duplex and were imaged at different times over 2 days. Images of one mouse obtained without contrast manipulation are shown in Figure 6. Tumor fluorescence is evident at all times. The fluorescence intensity ratios at four postinjection time points were calculated for the three animals, and the averages are shown in Figure 7. A positive tumor/normal thigh ratio was achieved as early as 20 min postinjection and was followed by a constant increase until a maximum at 2.05 was reached at 7 h postinjection and was constant thereafter.

Compared to the images obtained earlier in the same mouse tumor model following administration of the comparison DNA25-Cy5.5/cDNA18-BHQ3 duplex (*12*), the study DNA25-Cy5.5/cDNA10-BHQ3 duplex of this investigation provided images with a more intense fluorescence in the tumor thigh and an averaged tumor-to-background ratio superior to the 1.6 ratio observed by us previously (*12*). The most likely explanation for the improved results is increased instability of the duplex with the shorter minor strand in the presence of the target mRNA.

DISCUSSION

Optical imaging is a rapidly developing biomedical technology that enables the investigation of biological/molecular events in both cell culture and small live animals and is already practical in the clinic for imaging surface cancers and those accessible by endoscopy. However, self-absorption of the optical signal can seriously complicate optical imaging even when employing near-infrared fluorescence (NIRF) imaging probes with fluorescence emission in the near-infrared where tissue hemoglobin and water, the major absorbers of visible and infrared light, respectively, have their lowest absorption coefficients (*17*−*19*). While self-absorption of γ rays in connection with nuclear imaging is much more limited, nuclear imaging, unlike optical imaging, does not offer the possibility of modulating the signal at its target site. Through the judicious use of fluorescence resonance energy transfer (FRET), optical imaging has the potential to improve the tumor/normal tissue ratio and thus become an attractive alternative to nuclear imaging (*20*−*23*).

Previously, we reported on a successful optical antisense imaging study using a Cy5.5 conjugated 25 mer antisense PS−DNA hybridized to a BHQ3 conjugated complementary 18 mer PO−DNA showing fluorescence only upon dissociation (*12*). The duplex was designed to resist dissociation except by an antisense mechanism in the presence of its target mRNA in tumor. Although there was obvious tumor fluorescence obtained with this duplex, there was also a background in normal tissue and therefore a less than optimal tumor/nontarget ratio. The low tumor/nontarget ratio was attributed to a combination of excessive duplex stability in the presence of the mRNA target and excessive duplex instability in circulation and in tissues and led to the conclusion that optimization was required. In this investigation, optimization was focused on varying the DNA chain length rather than changing the backbone of the phosphorothioate and phosphdiester DNAs to that of second generation oligomer analogues such as phosphodiamidate morpholinos. While keeping the antisense major strand at 25 mer, the complementary sense minor strand was varied from 25 to 10 mer and the stabilities of the duplexes measured in 37 °C serum by the TO assay. Complementary chain lengths of less than 10 mer were not considered due to concerns of low duplex binding specificity and low stability (*24*, *25*). The results, shown in Figure 1, demonstrate that all five native duplexes were sufficiently stable by this assay in serum, and therefore, the shortest 10 mer chain length was selected for further investigation.

The results presented in Figures 4 and 5 both provide evidence of antisense targeting for both the 10 and 18 mer study duplexes. In the first instance, a significantly higher fluorescence was observed in the mdr1 expressing KB-G2 cells for the study

duplexes compared to the control duplexes with fluorophors reversed, a result that would not be expected by nonspecific accumulation. In the case of the control duplexes, presumably after dissociation, the Cy5.5 PO cDNA is rapidly degraded and the fluorophor cleared from the cell. In the second instance, the fluorescence intensity of the mdr1 expressing KB-G2 cells was significantly higher than that of the control low level mdr1 expressing KB-31 cells especially in the case of the 10 mer study duplex, again providing evidence of antisense targeting.

Furthermore, the shorter DNA25-Cy5.5/cDNA10-BHQ3 study duplex provided a much higher fluorescence in cells compared to the 18 mer DNA25-Cy5.5/cDNA18-BHQ3 comparison duplex, presumably due to a lower stability toward dissociation of the study duplex in the presence of its target mRNA. Finally, the whole-body fluorescence images in KB-G2 tumor bearing mice, one of which is presented in Figure 6, show obvious fluorescence in tumor at all time points, and an improvement in the average tumor/background fluorescence ratio of 2.05 for this duplex compared to an average value of 1.6 obtained previously in the same mouse model with the comparison duplex (*12*).

Taken together, the work presented here provides further evidence that optical antisense imaging with fluorescent duplexes is possible and our results have been improved by the process described herein designed to optimize duplex stabilities for this application. However, it is noteworthy that there is still some unexpected fluorescence background in animals administered the optimized duplex. Obviously, the Cy5.5 in these animals is not quenched completely by the BHQ3 inhibitor, indicating that the duplex has partly dissociated in some nontarget tissues such as liver due to instability of the fluorophors and/or duplex instability to nucleases therein. A better understanding of the properties of these duplex probes in vivo will be required to further optimize this approach.

ACKNOWLEDGMENT

We thank Dr. Isamu Sugawara (Research Institute of Tuberculosis, Tokyo, Japan) for providing the KB-G2 and KB-31 cell lines for this investigation. This investigation was funded by the NIH (CA-12959).

The Fc N-glycan chains of four therapeutic monoclonal antibodies (mAbs), namely, Avastin, Rituxan, Remicade, and Herceptin, released by PNGase F, show by MALDI analysis that these biantennary N-glycans are a mixture of G0, G1, and G2 glycoforms. The G0 glycoform has no galactose on the terminal GlcNAc residues, and the G1 and G2 glycoforms have one or two terminal galactose residues, respectively, while no N-glycan with terminal sialic acid residue is observed. We show here that under native conditions we can convert the N-glycans of these mAbs to a homogeneous population of G0 glycoform using β1,4 galactosidase from *Streptococcus pneumoniae*. The G0 glycoforms of mAbs can be galactosylated with a modified galactose having a chemical handle at the C2 position, such as ketone or azide, using a mutant β1,4-galactosyltransferase (β1,4Gal-T1-Y289L). The addition of the modified galactose at a specific glycan residue of a mAb permits the coupling of a biomolecule that carries an orthogonal reactive group. The linking of a biotinylated or a fluorescent dye carrying derivatives selectively occurs with the modified galactose, C2-keto-Gal, at the heavy chain of these mAbs, without altering their antigen binding activities, as shown by indirect enzyme linked immunosorbent assay (ELISA) and fluorescence activated cell sorting (FACS) methods. Our results demonstrate that the linking of cargo molecules to mAbs via glycans could prove to be an invaluable tool for potential drug targeting by immunotherapeutic methods.

INTRODUCTION

Monoclonal antibodies are increasingly becoming important therapeutic agents to target drugs to the tissue in need of treatment, leaving the normal tissue unharmed (*1*). They are commonly used in combination with chemotherapeutic agents for cancer treatment (*2*). The concept of making of antibody−drug conjugates (ADC) by which the antibody is used as a vehicle to deliver a cargo molecule to the tumor cell is gaining immense interest (*3*−*5*). Generally, the ADCs are antibodies conjugated to cytotoxic substances, such as drugs, toxins, and radioisotopes. The conjugated antibody recognizes and binds to cell surface antigen(s). At this point, the cargo molecules must be internalized into the target cells and released from the antibodies for activation of the drug.

All licensed therapeutic antibodies are of the IgG class; these are complex glycoproteins with two main functions, including a multivalent antigen binding through the Fab variable domains and effector functions through the Fc constant domain. IgG molecules are N-glycosylated in the CH_2 domain of the Fc fragment at the conserved Asn 297. In human IgG1, which is the main subtype used for therapeutics, the majority of the Fc glycans are complex biantennary structures with variable galactosylation: 0, 1, or 2 terminal galactoses corresponding to G0, G1, and G2 glycoforms, respectively, and <10−14% are sialylated (*6*, *7*). Only 15−20% of human IgG1 are also glycosylated in the Fab region of the molecule (*7*, *8*). Recent in vitro studies have established the importance of the Fc glycosylation profile of the IgG molecule on its effector functions: complement-dependent, cell-mediated cytotoxicity (CDC) and antibody-dependent, cell-mediated cytotoxicity (ADCC), such that removal of terminal galactose from the IgG can reduce the CDC but not affect ADCC activity (*9*). However, the use of rat hybridoma YB2/0 cells has permitted the production of mAbs that lack fucose in the conserved core oligosaccharide increasing the ADCC activity of the IgG, allowing the antibody to be effective at lower doses (*10*). Thus, glycosylation of recombinant monoclonal antibodies has been the focus of attention of the pharmaceutical industry to produce a homogeneous human-type glycosylation product, irrespective of the system/means by which the antibodies are produced.

After years of work to produce successful monoclonal antibodies as targeted drug therapeutics, researchers have developed 6 unconjugated and 3 antibody−drug conjugates that are currently approved for cancer treatment (*11*). Generally, the labeling of antibodies with the cargo molecules involves chemical methods which are difficult to control because the chemical reactions occur at tyrosine, lysine, aspartic, and glutamic acid residues that are distributed randomly on the surface of the protein. The result is the production of proteins with compromised activities (*12*). In order to maintain the biological activity of the protein and to optimize the production of homogeneous proteins, several methods have been developed for site-specific modification of the carriers. In the monoclonal antibodies, this site should be selected such that it is away from the antigen binding site. The oligosaccharide moieties of

immunoglobulins are not involved in the process of antigen binding and are N-linked to Asn297 on the heavy chain in the Fc domain of the immunoglobulin far from the antigen binding site. The conjugation of monoclonal antibodies to the cargo molecules via the oligosaccharides has been carried out by chemical or enzymatic methods, resulting in the formation of aldehydes (*13, 14*). Generally, the chemistry used for the modification of the sugar moieties present on glycoproteins such as the immunoglobulin's is mild periodate oxidation of sialic acid residues, resulting in the generation of aldehyde groups, which can then be used for coupling (*15, 16*). However, less than 10−14% of mAbs are sialylated (*6, 7*). An alternative method for the generation of aldehyde groups on the oligosaccharide moieties of glycoproteins is the use of enzymes (*16−18*). However, the maximum number of aldehyde groups is dictated by the structure/linkage of the sugar; thus, the heterogeneous nature of the sugar moieties on the monoclonal antibodies can result in poor conjugation.

Recently, new chemoenzymatic methods for conjugation have been developed for site-specific conjugation (*19−21*). We have shown the utility of the galactosyltransferase mutant to transfer a sugar residue with a chemically reactive functional group (e.g., C2-keto-Gal or GalNAz) from their UDP derivatives to the N-acetylglucosamine residue of glycoproteins or glycopeptides (*20, 21*). Using this method, we have shown that the N-glycan moiety of the IgG molecule can be used as the substrate for the transfer of C2-keto-Gal sugar by the mutant β1,4Gal-T1-Y289L (*20*). After the transfer of the modified sugar residue, the chemical handle is used for selective conjugation with a biomolecule that has an orthogonal reactive group, such as an aminooxy linked to biotin (*19−21*).

Here, we show that one can take advantage of the unique heterogeneous oligosaccharide linked at Asn297 in the mAbs that can be made homogeneous by a simple enzymatic procedure and obtain a population of mAbs having a set of glycans of the G0 glycoform that are subsequently fully galactosylated to a G2 glycoform, with the modified C2-keto-Gal as monitored by MALDI-TOF analysis of the PNGase F-treated samples. The transferred C2-keto-Gal is coupled to an aminooxy-biotin, which was previously detected by chemiluminescence techniques (*20, 22*) and here by MALDI-TOF analysis of the N-glycans. Using ELISA methodology, we show that the coupling of aminooxy-biotin to C2-keto-Gal does not compromise the antigen (Ag) binding site. Furthermore, Herceptin with C2-keto-Gal modified N-glycans coupled to Alexa Fluor 488 C_5-aminooxyacetamide binds to HER2-receptor-expressing cells, as shown by FACS methodology. Therefore, our conjugation technology presents a viable method to quantify the cargo molecules to be used for detection and targeting therapies.

EXPERIMENTAL PROCEDURES

REAGENTS. Rituxan (Rituximab) and Remicade (Infliximab) are recombinant chimeric monoclonal antibodies (mAbs), and Avastin (Bevacizumab) and Herceptin (Trastuzumab) are recombinant humanized mAbs (Genentech, Inc., South San Francisco, CA), purchased via the NIH pharmacy (Bethesda, MD). FITC-conjugated goat antihuman IgG (whole molecule) was from Sigma-Aldrich (St. Louis, MO). Alexa Fluor 488 C_5-aminooxyacetamide, bis (triethylammonium) salt (Alexa Fluor 488 hydroxylamine) was from Invitrogen (Eugene, OR). Recombinant β1,4-galactosidase from *Streptococcus pneumoniae* was from Calbiochem (San Diego, CA). Peptide *N*-glycoside F (PNGase F) was from New England Biolabs (Ipswich, MA). Microcon Ultracel YM-50 centrifugation devices came from Millipore Corporation, (Bedford, MA). Protein A-Sepharose 4B conjugate was from Invitrogen (Eugene, OR). 2,5-Dihydrobenzoic acid (DHB) came from Sigma-Aldrich (St. Louis, MO). Micro biospin chromatography columns P-30 were from Bio-Rad (Hercules, CA). Recombinant human vascular endothelial growth factor (VEGF) was from Thermo Scientific and *p*-nitrophenyl phosphate from Sigma-Aldrich (St. Louis, MO). UDP-C2-keto-Gal was synthesized as described previously (*19*).

β 1,4 Galactosyltransferase Expression in *E. coli* and in Vitro Folding of Inclusion Bodies. The enzymes β1,4Gal-T1[1] and β1,4Gal-T1-Y289L used in this study have been previously described (*23, 24*). Inclusion bodies were purified from the bacterial pellet as described earlier (*23, 24*). The in vitro folding of the enzymes was carried out in a way similar to that of β1,4Gal-T1 (*23*), with a few modifications. Typically, 100 mg of sulfonated protein were folded for 48 h in 1 L of folding solution that contained oxido-shuffling reagents and 550 mM arginine-HCL (*23*). The presence of arginine in the folding solution enhances the folding efficiency of β1,4Gal-T1-Y289L.

Degalactosylation of Monoclonal Antibodies. Avastin, Rituxan, Remicade, or Herceptin were washed with 50 mM sodium phosphate pH 6.0, using a Microcon Ultracel YM-50 centrifugation device. The samples at 8 mg mL^{-1} were incubated with 100 mU of recombinant *Streptococcus pneumoniae* β1,4-galactosidase for 24 h at 37 °C. Removal of terminal galactose residues was confirmed by analysis of the N-glycans released after PNGAse F treatment by MALDI TOF spectrometry. Approximately 3 μg of mAbs was incubated in the presence or absence of PNGase F (2500 units), 16 h at 37 °C in 10 μL of G7 buffer. Samples were then purified on microspin charcoal columns (Harvard Apparatus, MA). Samples were eluted with 30% acetonitrile and analyzed by mass spectrometry. Degalactosylated monoclonal antibodies were then purified by protein A affinity chromatography.

Protein A Affinity Chromatography of mAbs. Degalactosylated samples were diluted 1:1 with 1 × PBS, pH 7.4 (binding buffer), and then added to the protein A columns (Invitrogen). The columns were washed several times with binding buffer and the mAbs were eluted with 100 mM glycine-HCL, pH 2.7. The eluted mAbs were neutralized with 1 M Tris−HCl buffer pH 8.0, concentrated, and washed with 1 × PBS, pH 7.4, using the Microcon Ultracel YM-50 centrifugation device. Protein amounts were determined using the Bio-Rad protein assay kit based on the method of Bradford (BIO-RAD), and the purity of all mAbs further verified by SDS-PAGE electrophoresis.

Transfer of C-2 keto Galactose from Its UDP-Derivative to Free GlcNAc Residues on mAbs using the Mutant β1,4Gal-T1-Y289L and Biotinylation of the mAbs. Monoclonal antibodies (12 μg) were incubated with 2 mM UDP-C2 keto-Gal and 12 μg of the mutant β1,4Gal-T1-Y289L in a 25 μL final incubation mixture containing 10 mM $MnCl_2$ and 25 mM Tris−HCl (pH 8.0). Reactions were incubated at 30 °C for 12 h. The ketone-labeled proteins were subsequently diluted to 30 μL in a mixture containing 50 mM NaOAc (pH 3.9) and 3 mM *N*-aminooxy-methylcarbonylhydrazino-D-biotin (AOB), purchased from Dojindo Laboratories. The biotinylation reactions were incubated with gentle shaking for 12−16 h at 25

[1]Abbreviations: β1,4-Gal-T1, β1,4-galactosyltransferase; ELISA, enzyme linked immunosorbent assay; FACS, fluorescence activated cell sorting; PNGase F, peptide N-glycosidase F; DHB, 2,5-dihydrobenzoic acid; DMA, *N*,*N*-dimethylaniline; Gal, galactose; GlcNAc, *N*-acetylglucosamine; *N*-acetyl-azido-galactosamine (Gal-2-NHCO-CH_2-N_3), GalNAz; UDP-Gal, uridine 5′-diphosphogalactose; UDP-2-keto-Gal, Uridine 5′-diphospho-2-acetonyl-2-deoxy-galactose; UDP-GalNAc, uridine 5′-diphospho-*N*-acetylgalactosamine; UDP-GalNAz, uridine 5′-diphospho-*N*-acetyl-azido-galactosamine; MALDI, matrix-assisted laser desorption ionization; MS, mass spectra; AOB, *N*-aminooxy-methylcarbonylhydrazino-D-biotin; HRP, horseradish peroxidase; FBS, fetal bovine serum; BSA, bovine serum albumin; PBS, phosphate buffer saline.

°C. A portion of the sample was treated with PNGase F for the MALDI-TOF analysis of the glycan chain, and a portion was boiled in Tris-Glycine-SDS sample buffer containing β-mercaptoethanol and analyzed by Western blot analysis as described (*19*−*21*).

SDS-PAGE Analysis of mAbs and Western Blotting of IgGs. The SDS-PAGE analyses of native or biotinylated mAbs, respectively, before and after PNGase F treatment, were performed in 14% Tris−glycine gels (Invitrogen). For Western blotting analysis, the proteins from the gels were then transferred by electrophoresis to nitrocellulose paper (0.45 μm pore size) for 2 h at 25 V and biotinylated protein bands identified as described previously (*20*).

Fluorescent Labeling of Herceptin. Fluorescent labeling reactions were carried out by treating 10 μg of C2-keto-Gal labeled Herceptin with 400 μM of Alexa Fluor 488 C_5-aminooxyacetamide in 27 μL containing 166 mM NaOAc (pH 4.9). The reactions were incubated for 2−6 h at 37 °C. The unreacted fluorescent dye was removed by purification on micro biospin chromatography columns P-30 from Bio-Rad (Hercules, CA), as per manufacturer's directions. Purified samples were separated by SDS-PAGE and fluorescence was detected using a multi view FMBIO II scanner (Hitachi).

Indirect ELISA. The binding activity of Avastin to recombinant human vascular endothelial growth factor (VEGF) was determined in a solid-phase binding assay using soluble Avastin and coated VEGF. Binding of antibodies was then detected by a specific secondary antibody in an enzyme-linked immunosorbent assay. Briefly, flat-bottom 96-well microtiter plates (Costar 3690, Corning Inc., NY) were coated with the appropriate amounts of VEGF overnight at 4 °C and were washed three times with phosphate buffer saline (PBS) pH 7.4 containing 0.05% Tween-20 and 0.1% sodium azide. The plates were blocked with 3% bovine serum albumin (BSA) in PBS with 0.05% Tween-20 for 1 h at room temperature. A serial dilution of native or modified Avastin was added to the VEGF-coated plate and incubated for 1 h at room temperature. The detection antibody conjugate (antihuman-Fc-phosphatase) (Thermo Scientific) was then applied for 1 h at room temperature. The detection of alkaline phosphatase was performed with *p*-nitrophenyl phosphate (Sigma). Samples were measured at 405 nm with a plate reader.

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry. Typically 1−2 μL of sample was mixed with an equal volume of 2,5-dihydrobenzoic acid (DHB) matrix solution prepared by dissolving 100 mg of DHB (Sigma Chemicals) in 1 mL of a 1:1 solution of water and acetonitrile. In some instances, a matrix solution of a mixture of DHB/DMA (*N*,*N*-dimethylaniline) was used, which was prepared by adding 30 μL of distilled DMA to the DHB matrix (*25*). Mixtures were spotted onto a stainless steel plate after mixing the samples and matrix solutions (1 μL each). The samples were dried by evaporation at room temperature. A hybrid triple-quad time-of-flight (QqTOF) mass spectrometer (QSTAR XL, Applied Biosystems, Inc., Framingham, MA) was configured for matrix-assisted laser desorption/ionization (MALDI). Mass spectrometry (MS) data was obtained using a laser intensity = 21 000 μj, pulse rate = 20 Hz, collision gas (CAD) = 3 (high purity argon, Airgas, Inc., Frederick, MD), focusing potential (FP) = 35 V, declustering potential (DP) = 0 V, declustering potential 2 (DP2) = 20 V, and ion energy (IE1) = 0.8 V. All samples were analyzed in the positive mode with a 3 min accumulation time over an *m*/*z* range of 150−3000 amu.

Cell Surface Immunostaining of HER2 Receptor by FACS Analysis. To determine if the modifications in Herceptin influenced its ability to bind to the cellular HER2 receptor, we used either indirect immunostaining (when using modified Herceptin) or direct immunostaining of cells when using Alexa-conjugated-Herceptin. HER2 receptor expressing human breast adenocarcinoma cells (SKBR-3) and HER2 receptor negative human breast adenocarcinoma cells (MDA-MB-468) were purchased from the American type Culture Collection (ATCC, Manassas, VA). The cells were cultured in DMEM/F12 medium supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) and penicillin/streptomycin as antibiotics at 37 °C in a humidified atmosphere containing 5% CO_2. Other culture reagents were bought from Invitrogen (Carlsbad, CA). For immunostaining experiments, cells were harvested using a PBS-based, enzyme-free cell dissociation buffer, and suspended to a concentration of 10^7 cells per mL in PBS containing 5% FBS. The cells were further incubated for 15 min at room temperature, centrifuged and washed twice with cold PBS supplemented with 0.1% BSA (PBS−BSA), and resuspended in PBS−FBS at a concentration of 10^7 per mL. For incubation with antibodies, 100 μL cell suspension (containing 10^6 cells) were placed in 1.5 mL Eppendorf tubes. Native Herceptin, modified Herceptin, or Alexa-conjugated Herceptin (4 μg each) was added to individual samples, and incubations were continued for 1 h at 4 °C in the dark with constant shaking. At the end of incubations, samples were washed twice with cold PBS−BSA, and resuspended in 100 μL PBS−FBS. The samples incubated with Alexa-conjugated Heceptin were analyzed by FACS. The cells incubated with native Herceptin or modified Herceptin were incubated with a 1:32 dilution of FITC-conjugated goat antihuman IgG for 1 h at 4 °C in the dark with constant shaking. Cells were washed twice with PBS−BSA, and resuspended in PBS−BSA (1 mL per sample). Control samples were incubated without any primary antibody, with only the FITC-conjugated goat antihuman IgG. Cells were analyzed using a FACS Calibur flow cytometer (Becton Dickinson, San Jose, CA). Each sample was analyzed for 10 000 counts of viable cells, and all samples were run at least in duplicate.

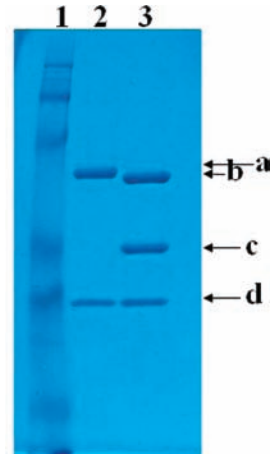

Figure 1. SDS-PAGE analysis of monoclonal antibody before and after PNGase F treatment. (1) Kaleidoscope prestained standards; (2) the native IgG; (3) IgG after treatment with PNGase F. Arrows show from top to bottom: (a) heavy chain of native IgG, (b) deglycosylated heavy chain of IgG, (c) PNGase F used for deglycosylation, and (d) light chain of IgG.

RESULTS

Glycoforms of Therapeutic Monoclonal Antibodies; MS Analysis of Native and β-galactosidase-treated IgGs. The human IgGs are N-glycosylated in the CH_2 domain of the Fc fragment and only ∼15−20% are also glycosylated in the Fab domain (*7*, *8*). SDS-PAGE analysis of mAbs, Avastin, Rituxan, Remicade, and Herceptin, before and after the PNGase F treatment, shows the mobility difference only in the heavy chain

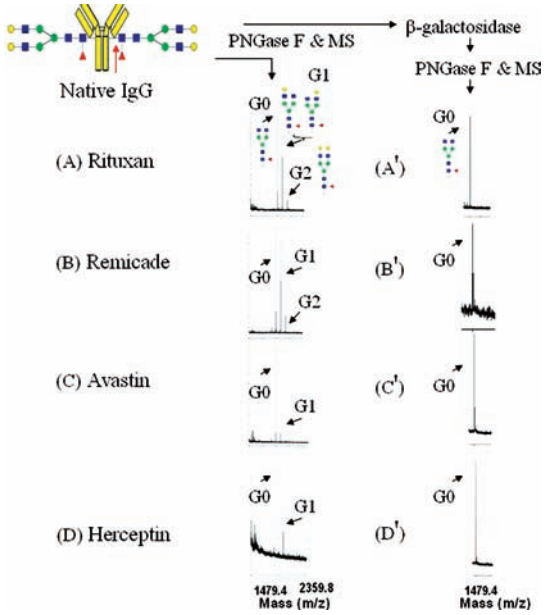

Figure 2. Glycoforms of therapeutic monoclonal antibodies; MS analysis of N-glycans after β-galactosidase treatment of IgG's. (A−D) MALDI-TOF MS analysis of N-glycans released by PNGase F treatment (red arrow shows the cleavage site) of native Rituxan (A), Remicade (B), Avastin (C), and Herceptin (D). G0 glycoform with a peak at 1485.6 *m/z*, the G1 glycoform with a peak at 1647.6 *m/z*, and G2 glycoform with a peak at 1809.6 *m/z*. mAbs were treated with β-galactosidase to obtain a homogeneous G0 glycoform population (A′−D′) MALDI-TOF analysis of N-glycans released by PNGase F treatment of β-galactosidase treated Rituxan (A′), Remicade (B′), Avastin (C′), and Herceptin (D′), respectively. Only the G0 glycoform with a peak at 1485.6 *m/z* is seen after treatment. Major peaks are annotated with the carbohydrate structure shown in the symbols for monosaccharides, according to the nomenclature adopted by the consortium for functional glycomics: GlcNAc (blue squares), mannose (green spheres), galactose (yellow spheres), and fucose (red triangles). The symbols were drawn using the GlycoWorkbench program found in the Eurocarb database http://www. Eurocarb.org/.

protein band, and not in the light chain, indicating that the oligosaccharide chain is released only from the IgG heavy chain, and not from the light chain (Figure 1).

The degree of heterogeneity of the oligosaccharides in the native mAbs was determined by carrying out the MALDI-TOF analysis of the oligosaccharide released after PNGase F treatment of mAbs. MS analysis of oligosaccharides released after PNGase F treatment of native forms of Rituxan and Remicade show that they carry oligosaccharides of G0, G1, and G2 glycoforms (Figure 2A,B), corresponding to 0, 1, and 2 galactose residues, respectively, while Avastin and Herceptin have only G0 and G1 glycoforms (Figure 2C,D). None had sialylated structures as observed with some mAbs (*6*). To selectively remodel the oligosaccharide of the monoclonal antibodies at Asn 297 in the Fc domain and to obtain a homogeneous population of glycoforms, the IgGs were degalactosylated by β1,4-galactosidase from *S. pneumoniae* for 24 h. After galactosidase treatment, the degree to which the mAbs glycans were degalactosylated was confirmed by MALDI-TOF analysis of the N-glycans after PNGase F treatment. 24 h incubation of 8 mg/mL^{-1} of mAbs with 100 mU units of galactosidase in 50 μL incubation mixture completely converts the IgG in G0 glycoform (Figure 2A′−D′).

Reglycosylation of G0 Glycoform of mAbs Using Either UDP-Gal or UDP-GalNAc as Sugar Donors. The mutant β1,4Gal-T1-Y289L enzyme, in contrast to the wild-type enzyme β1,4Gal-T1, exhibits both β1,4Gal transferase and β1,4GalNAc transferase activities (*24*). Using chemoenzymatic methods, it was shown that the mutant enzyme can transfer the C2-keto-Gal from its UDP-derivative to the GlcNAc residue on the N-glycan chain of an asialo-agalacto IgG molecule (*20*). In the present studies, we investigated the transfer of UDP-sugars to the protein A purified G0 glycoform of Herceptin by the wild-type and a mutant β1,4-galactosyltransferse. Figure 3 shows the MALDI-TOF profile of the oligosaccharide after the transfer of galactose by the wild-type β1,4Gal-T1 (Figure 3A) and the transfer of N-acetylgalactosamine (Figure 3B) by the mutant enzyme β1,4Gal-T1-Y289L to the free GlcNAc residues on the G0 glycoforms of Herceptin (Figure 2D′). Nearly 100% galactosylation of both arms of the N-glycan of the IgG-G0 glycoform

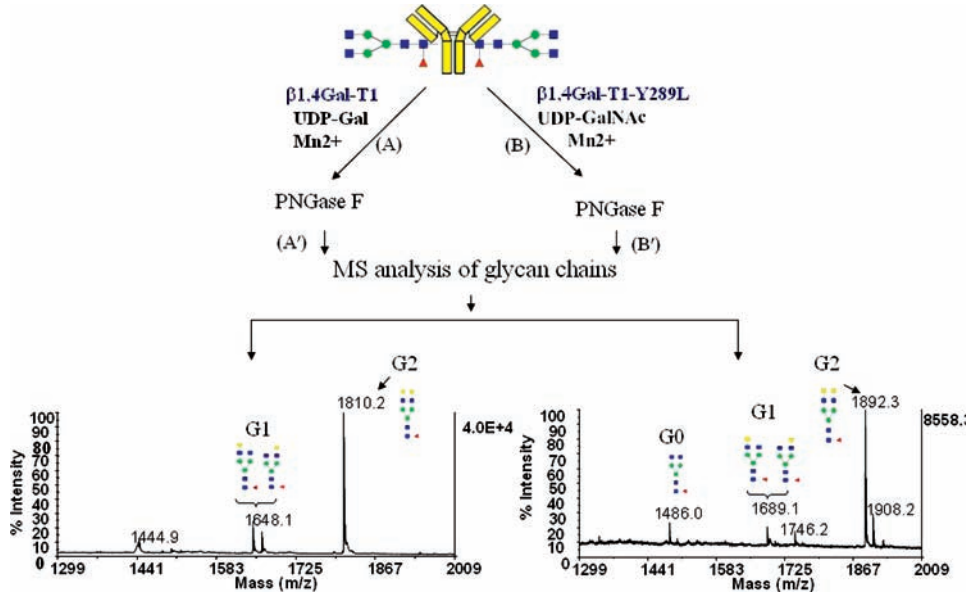

Figure 3. Reglycosylation of β-galactosidase treated mAbs using natural UDP-sugar donors. To the degalactosylated G0 glycoform of the IgG, (A) galactose moiety was transferred from UDP-Galactose using the wild-type enzyme β1,4Gal-T1 or (B) GalNAc moiety was transferred from UDP-GalNAc using the mutant β1,4Gal-T1-Y289L. After overnight incubation, mixtures were treated with PNGase F prior to MS analysis. (A′) After galactose transfer, ions at 1648.1 *m/z* and 1810.2 are assigned to G1 and G2 glycoforms, respectively, and (B′) after GalNAc transfer, ions at 1486.0 *m/z*, 1689.1 *m/z*, and 1892.3 *m/z* are assigned to G0, G1, and G2 glycoforms, respectively.

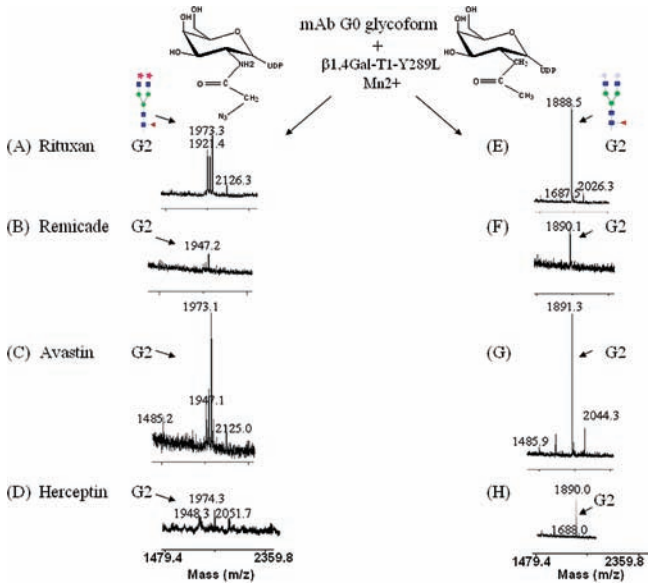

Figure 4. Reglycosylation of G0 glycoform using C-2 modified sugar donors: The mutant enzyme β1,4Gal-T1-Y289L was used to transfer the C-2 modified sugars from their respective UDP-sugar nucleotides to the degalactosylated mAbs; UDP-2-keto-Gal (right panel) and UDP-2-azido-Gal (left panel). MALDI mass analysis after treatment of N-glycans with a mixture of sialydase and β-galactosidase (not shown), gave the same G0 glycoform profile, upon PNGase F treatment, as did the β-galactosidase treatment alone. The transfer of the modified sugar nucleotide was analyzed by mass spectrometry of the modified N-glycans released after PNGase F treatment. β-Galactosidase treated mAbs having a G0 glycoform are fully galactosylated to the G2 glycoform after transfer of GalNaz moiety to the terminal GlcNAc residues showing a peak of 1973 *m/z* (left panel A, C, and D). The G2 glycoform peak at 1947 *m/z* in (B) is due to partial fragmentation of the azido group that can take place during mass spectrometry analysis. The peak at 2126 *m/z* corresponds to the matrix DHB adduct. Right panel (E−H) shows the transfer of C2-keto-Gal moiety to the terminal GlcNAc residues in the G0 glycoform (middle panel). A peak at ~1891 *m/z* corresponds to the G2 glycoform and peaks at 2026 *m/z* and 2044 *m/z* correspond to the DHB adduct. GalNAz (pink stars) and C2-keto-Gal (purple circles).

(Figure 2D′) was observed when 80 pmol of IgG (12 μg) were incubated at 30 °C for 12 h with 120 pmol of β1,4Gal-T1 enzyme (4 μg) at 1.5 mM concentration of the sugar donor substrate UDP-Gal (Figure 3A′). A peak occurred at *m/z* 1810.2, corresponding to the G2 form, and a very small peak at *m/z* 1648.1, corresponding to the G1 form where galactosylation is on either the 1,3 or 1,6 arm of the N-glycan. The transfer of GalNAc (Figure 3B′) by the mutant enzyme β1,4Gal-T1-Y289L to both arms of the G0 glycoform (Figure 2 D′) is observed as a main peak at *m/z* 1892.3 corresponding to the G2 glycoform of the mAb. Minor peaks at *m/z* 1486 and 1689 correspond to the G0 and G1 glycoforms, respectively. Under the conditions described here, the transfer of galactose and of GalNAc to both GlcNAc residues on each arm of the N-linked structure is observed.

Transfer of C2-keto-Gal to the Free GlcNAc Residues on the N-Glycan Chains of mAbs by the Mutant Enzyme β1,4Gal-T1-Y289L. In a previous study, we showed that the transfer of C2-keto-Gal to the N-linked oligosaccharides of the IgG by the mutant β1,4Gal-T1-Y289L (*20*) can be detected by the chemoenzymatic method. In this study, we followed the transfer of C2-keto-Gal to mAbs by the MALDI-TOF of the PNGase F-released oligosaccharides. There is nearly full conversion of 80 pmol of the G0 form of IgG (12 μg) to the G2 form with either C2-GalNAz (Figure 4A−D) or C2-keto-Gal (Figure 4E−G) using 2 mM concentration of sugar donor substrate UDP-C2-GalNAz or UDP-2-keto-Gal, respectively, with ~360 pmol of β1,4Gal-T1-Y289L mutant enzyme (12 μg) in a 25 μL incubation mixture. The appearance of a major peak at *m/z* 1973.5 after the transfer of C2-GalNAz (Figure 4A−D), and at *m/z* 1890.0 after the transfer of C2-keto-Gal (Figure 4E−G), shows that the transfer occurs under these conditions on both arms of the G0 glycoform.

Biotinylation of the Glycosylated IgG. The transfer of C2-keto-Gal has been followed by coupling the biotinylated aminooxy biotin to the ketone group at the C2 position of the galactose (Figure 5A) and detected by a sensitive chemiluminescence assay (*19*−*21*). MALDI-TOF analysis of the oligosaccharides released after PNGase F treatment of the C2-keto-galactosylated mAbs showed a major peak at *m/z* 2519, corresponding to the G2 glycoform of the antibodies (Figure 5B) having 4 molecules of C2-keto-Gal transferred per IgG molecule. The conjugated proteins were also analyzed by SDS-PAGE, followed by Western blotting and detection by the streptavidin-HRP technique, as previously described (*19*−*21*). The lack of chemiluminescence band in the Western blot analysis after PNGase F treatment of the mAbs (Figure 5C) supports the conclusion that the biotinylated aminooxy ligand is linked only to the C2-keto-Gal modified N-glycan chain of the IgG heavy chain.

Comparing the Binding of Native and Modified Avastin to VEGF by the ELISA Method. We used an indirect ELISA method described previously (*26*) to analyze the binding of native and modified Avastin to VEFG immobilized on a microtiter plate surface. Remodeling of the Fc N-glycans of Avastin did not change the binding to VEGF, when compared to the binding of the native mAb (Figure 6).

Herceptin Labeling with Alexa Fluor 488 C_5−Aminooxyacetamide. Since C2-keto galactosylated mAbs could be successfully coupled to aminooxy containing ligands (Figure 5B,C) without affecting the antigen binding, as observed by the ELISA method (Figure 6), we linked the C2-keto-Gal modified Herceptin (Figure 4H) to the Alexa Fluor 488 C_5-aminooxyacetamide and analyzed the protein by fluorescence imaging of the SDS-PAGE (Figure 7A), and subsequent staining of the gel with Coomassie blue (Figure 7B). Results from the fluorescence imaging indicate that there is a selective labeling of the heavy chain of the mAb, and this signal is almost lost following PNGase F treatment of the fluorescent-tagged antibody, which removes the N-linked sugars in the Fc domain of the IgG (Figure 7A). No fluorescence was detected at other protein bands seen after Coomassie blue staining of the SDS-PAGE gel (Figure 7B). Conjugation of Alexa Fluor 488 to enzyme-modified Herceptin was further confirmed using a spectrofluorometer (model FluoroMax 3, HORIBA Jobin Yvon Inc., NJ) to measure fluorescence at Ex/Em 494/518 nm (not shown).

Effect of Herceptin Modification(s) on its Binding to HER2 Receptor. To evaluate the effect of carbohydrate modifications in Herceptin on its biological activity, we examined its binding to HER2 receptor using a human breast adenocarcinoma cancer cell line (SKBR-3) that overexpresses this receptor. MDA-MB-468 cells, that do not express the HER2 receptor, were used as controls. The immunostaining with Alexa Fluor 488 C_5-aminooxyacetamide-conjugated Herceptin or modified Herceptin was performed as described in the Methods section. The results are presented in Figures 8 and 9, respectively.

Alexa-conjugated Herceptin showed binding only to SKBR-3 cells (receptor expressing) (Figure 8B). In contrast, under identical conditions, we did not observe any binding above background for MDA-MB-468 cells (receptor negative) (Figure 8A). Therefore, the conjugation of Alexa Fluor 488 and

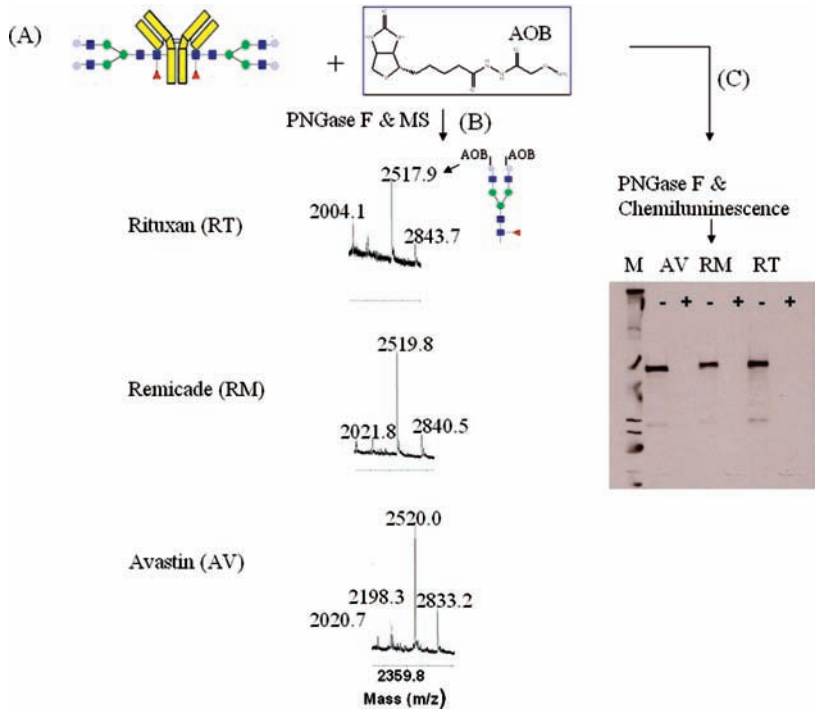

Figure 5. Detection by chemiluminescence technique of the transfer of the C2-keto-Gal to free GlcNAc residues on the N-glycan chains of mAbs. (A) The C2-keto-Gal has been transferred to the free GlcNAc residues in the N-linked carbohydrate of IgG. (B) Detection of the transferred C2-keto-Gal is accomplished by linking to aminooxy biotin followed by PNGase F treatment and MS analysis of the N-glycans. The peaks at 2517.9 *m*/*z*, 2519.8 *m*/*z*, and 2520.0 *m*/*z* correspond to AOB being transferred to both arms of N-glycans carrying C2-keto-Gal in Rituxan (RT), Remicade (RM), and Avatin (AV), respectively. The peaks at 2843.7 *m*/*z*, 2840.5 *m*/*z*, and 2833.2 *m*/*z* correspond to AOB transferred to the sugars at the reducing end. (C) The linked AOB-C2-keto-Gal of AV, RM, and RT is also detected on Western blots by chemiluminescence. In contrast to the samples that were not treated with PNGase F (−), the samples treated with PNGase F (+) showed no chemiluminescence. C2-keto-Gal (purple circles).

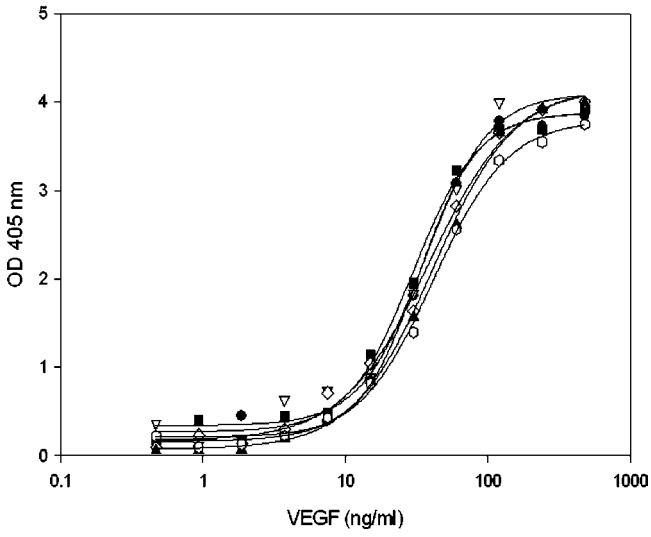

Figure 6. VEGF ELISA comparing the binding of modified Avastin. Avastin, native or modified, was bound to VEGF immobilized on a microtiter plate surface, and was detected with an antihuman Fc antibody conjugated to alkaline phosphatase. The transfer of various substrates by the mutant β1,4Gal-T1-Y289L, namely, GalNAc and C2-keto-Gal to Avastin did not perturb the binding to VEGF. Aminooxy biotin is also linked to the modified C2-keto-Gal without perturbing the Fab domain. (●) Avastin native. (▽) Degalactosylated Avastin. (□) Degalactosylated Avastin+ GalNAc. (◇) Degalactosylated Avastin+ no UDP-GalNAc+β1,4Gal-T1-Y289L. (□) Degalactosylated Avastin+ C2-keto-Gal. (⬡) Degalactosylated Avastin+ C2-keto-Gal +AOB.

Herceptin did not have any effect on its receptor-binding activity, suggesting that these conjugates may serve as suitable tools for imaging.

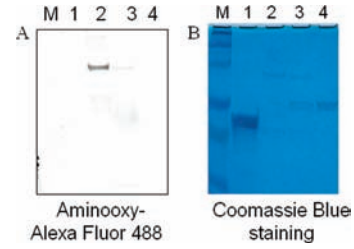

Figure 7. Herceptin labeling with Alexa Fluor 488 C_5-aminooxy acetamide. C2-keto-Gal modified Herceptin was conjugated with Alexa Fluor 488 C_5-aminooxyacetamide and analyzed by SDS-PAGE (see Materials and Methods). (A) Fluorescence imaging of the SDS-PAGE. (B) The gel was subsequently stained with Coomassie blue. (M) Kaleidoscope standard, (1) β1,4Gal-T1-Y289L, (2) C2-keto-Gal modified Herceptin conjugated to Alexa Fluor 488 C_5-aminooxy acetamide, (3) C2-keto-Gal modified Herceptin conjugated to Alexa Fluor 488 C_5-aminooxyacetamide digested with PNGase F, and (4) PNGase F.

Next, we examined the effect of carbohydrate modifications in Herceptin, other than Alexa Fluor 488, on the binding to the HER2 receptor expressing cells. We performed cell sorting experiments using indirect immunostaining (using the FITC-conjugated goat antihuman IgG, see Methods). The results are presented in Figure 9. SKBR-3 (receptor positive) cells bound to native and to modified Herceptin conjugates with similar efficiency (Figure 9 F−H). In contrast, FITC-conjugated goat antihuman IgG alone did not show any significant binding above background (Figure 9 E). Our data also show that MDA-MB-468 cells (receptor negative) did not bind to Herceptin (or modified Herceptin) above background (Figure 9A−D). Therefore, carbohydrate modifications and/or subsequent conjugation

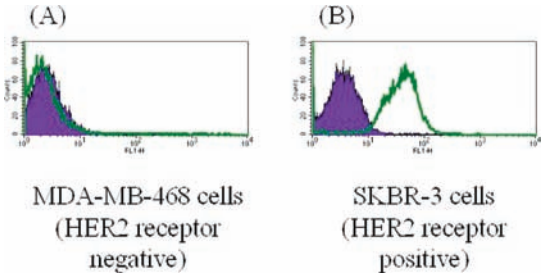

Figure 8. Binding of Alexa Fluor 488 conjugated Herceptin to HER2-receptor expressing cells. Herceptin was enzymatically modified with C2-keto-Gal and conjugated with Alexa Fluor 488 C_5-aminooxyacetamide. Alexa-conjugated Herceptin (4 μg) was incubated with 10^6 cells/100 μL PBS−FBS for 60 min at 4 °C while shaking in the dark. The cells were washed twice with PBS−BSA and resuspended in 1 mL PBS−BSA. Samples were analyzed by FACS (see Materials and Methods). (A) MDA-MB-468 control cells and (B) SKBR-3 cells. The purple area indicates the background value. The empty area defines the fluorescence of Herceptin conjugated Alexa Fluor 488 C_5-aminooxyacetamide (green line).

via the introduced functional groups do not alter their receptor binding activity.

DISCUSSION

The mAbs are used as powerful therapeutic agents for the treatment of various diseases. They can be used "naked" with their inherent effector functions or as targeting vehicles. Here, we used an enzymatic method (*19*−*21*) for the production of the conjugated targeting vehicle of mAbs that has the advantage (I) of being site-specific and accessible for conjugation; (II) the cargo does not interfere with or modify the Fab domain; (III) the conjugation of a cargo molecule to a mAb makes it possible to direct the cargo to the desired site; (IV) mAb conjugated with fluoroprobes via glycan chains are suitable probes for imaging and clinical applications.

We have previously shown that the mutant enzyme β1,4Gal-T1-Y289L can transfer GalNAc and galactose from its UDP-derivatives to GlcNAc residues present at the nonreducing end of proteins (*24*). We have also shown that this mutant can transfer modified sugars such as 2-keto-Gal from their UDP derivatives for detection of O-GlcNAc modifications in proteins (*19*) or detection of free GlcNAc residues at the nonreducing end of the N-glycans of proteins (*20*). Our findings led us to propose that two glycoproteins having modified sugars with unique chemical handles could be conjugated via linkers having orthogonal chemical reactive groups, allowing the design of novel mAb-drug conjugates and imaging agents (*27*).

The present study extends our previous work by showing: (1) Fc N-glycans of native therapeutic antibodies are highly heterogeneous; (2) it is possible to modify the therapeutic monoclonal antibodies from a heterogeneous to a homogeneous glycoform population; (3) the modification at the N-linked oligosaccharide occurs in a site-specific manner without compromising the antigen binding site; and (4) we have been able to produce mAb-fluoroprobes conjugates for imaging applications.

The glycosylation profile of recombinant mAbs has been well-characterized and is known to be highly heterogeneous with respect to core fucosylation, terminal sialylation, and galactosylation (*28*). The difference between the observed glycoform types depends on the enzymes/host cell type, substrates, and culture conditions utilized for their production. The MALDI-TOF analysis of PNGase F-released oligosaccharides of the mAbs used in our study concur with the published data (*28*). These N-glycans are core-fucosylated with differences in the terminal sugars having a mixture of G0, G1, and G2 glycoforms. None of the mAb used here had terminal sialic acids. Previously, we showed that the C2-keto-Gal from its UDP derivative was transferred by β1,4-Gal-T1-Y289L to free GlcNAc residues on the N-linked glycan chains of a heterogeneous population of IgG molecules (*20*). An important issue in this study was the transfer of the modified sugar to each available GlcNAc present in a homogeneous mAb glycoform population. In order to obtain a population of mAb having a single G0 glycoform with 2 mol of GlcNAc available for transfer to each IgG heavy chain, we tested galactosidases from various sources to remove the

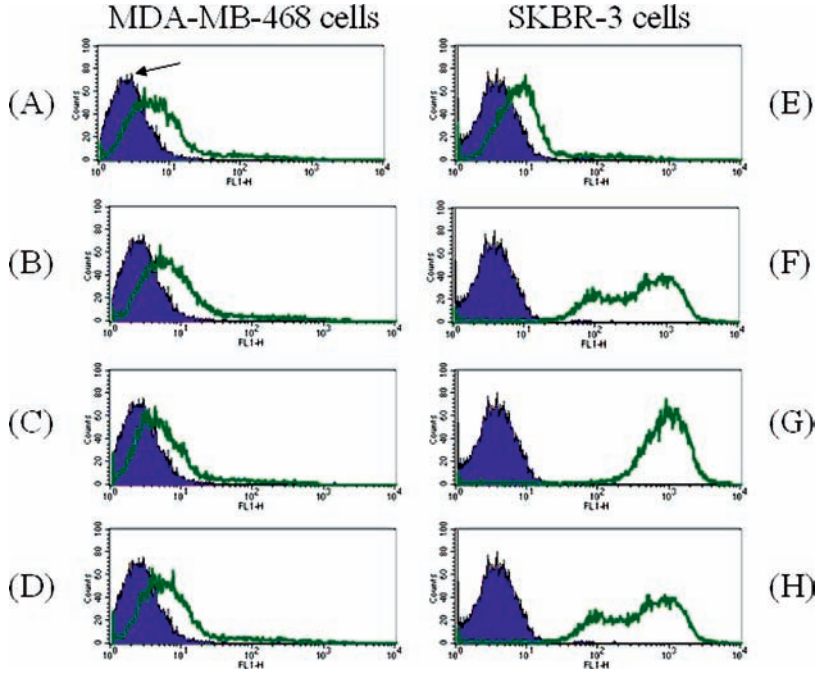

Figure 9. Effect of carbohydrate modification of Herceptin on its binding to HER2-receptor expressing cells. Herceptin was subjected to various enzyme treatments (see Materials and Methods). Native and modified Herceptin molecules were incubated with MDA-MB-468 cells or SKBR-3, followed by incubation with FITC-conjugated goat antihuman IgG. The samples were analyzed by FACS (see Methods section). (A,E) secondary antibody alone; (B,F) Herceptin untreated; (C,G) Herceptin treated with β-galactosidase; (D,H) Herceptin treated with β-galactosidase + C2-keto-Gal. The arrow indicates background fluorescence of cells in the absence of antibodies.

nonreducing end galactose residues in the G1 and G2 glycoforms. Only after using β1,4 galactosidase from *Streptococcus pneumoniae* (*9*), we were able to show, by MALDI-TOF analysis of the PNGase F-released carbohydrates, a single-type G0 glycoform. The β1,4 galactosidase from other sources did not yield 100% fully degalactosylated glycoforms. Having demonstrated the production of a single glycoform, the G0 form, by enzymatic degalactosylation, we explored the transfer of the modified sugar and the coupling of the ketone handle to aminooxy-biotin, which was then detected by MALDI-TOF analysis of N-glycan chains or by chemiluminescence (*20*), or coupling to aminooxi Alexa Fluor 488, which was detected by a fluorescence technique after SDS-PAGE and FACS analysis. Both chemiluminescence and fluorescence analysis showed that the method of coupling described here is highly specific; almost all the chemiluminescence and fluorescence from the antibody conjugates were associated with binding to the heavy chain. Thus, the cargo is linked in a site-directed manner and only occurs where the sugar binds in the Fc domain of the IgG.

This study also shows that the linking of the target agent, either biotin or Alexa Fluor 488, to the mAb via the N-linked carbohydrates does not modify the antibody affinity for the antigen. One important goal in using this conjugation method is to generate a delivering agent: an antibody−cargo conjugate that will not interfere in its binding to the target cells. The results from ELISA assays using native mAb showed no detectable loss of antigen (Ag) binding activity. Moreover, all antibodies described in this study, obtained either by removal or by addition of sugars, when conjugated via glycan chains, did not show a loss of Ag binding activity. The Ag binding activity of the Fc-N-glycan modified antibodies was comparable to the results obtained with the native mAb. Also, the results obtained by FACS are consistent with the ELISA assay in that the binding of mAb conjugate to HER-2-expressing cells was not affected by the modification.

In conclusion, the present study describes an enzymatic method for conjugation of monoclonal antibodies at a unique site, away from the Ag binding domain. This method using modified sugars for conjugation provides a specific labeling with 4 molecules of fluorescent dyes if the IgG molecule has free GlcNAc residues available on the Fc N-glycan chains. To our knowledge, this is the first report on the site-specific conjugation of fluoroprobes to the N-linked glycans of intact mAb using an enzymatic method. Other laboratories have reports on the use of molecular imaging probes using mAbs; however, they use chemical conjugation methods, which lead to random labeling (*29, 30*). Thus, this conjugated fluoroprobe may be used as a probe for imaging and clinical applications.

ACKNOWLEDGMENT

We thank Dr. Natalia Mercer for critical reading of the manuscript and Dr. Linda Hsieh-Wilson, CalTech, for helping Dr. Maria Manzoni during the synthesis of UDP-C2-keto-Gal. We also thank Dr. John T. Simpson, Protein Chemistry Laboratory, NCI-Frederick, for helping with mass spectrometric analysis. Received March 10, 2009; Revised Manuscript Received April 27, 2009

Fluorescent proteins from the green fluorescent protein family strongly interact with CdSe/ZnS and ZnSe/ZnS nanocrystals at neutral pH. Green emitting CdSe/ZnS nanocrystals and red emitting fluorescent protein dTomato constitute a 72% efficiency FRET system with the largest alteration of the overall photoluminescence profile, following complex formation, observed so far. The substitution of ZnSe/ZnS for CdSe/ZnS nanocrystals as energy donors enabled the use of a green fluorescent protein, GFP5, as energy acceptor. Violet emitting ZnSe/ZnS nanocrystals and green GFP5 constitute a system with 43% FRET efficiency and an unusually strong sensitized emission. ZnSe/ZnS-GFP5 provides a cadmium-free, high-contrast FRET system that covers only the high-energy part of the visible spectrum, leaving room for simultaneous use of the yellow and red color channels. Anisotropic fluorescence measurements confirmed the depolarization of GFP5 sensitized emission.

INTRODUCTION

Semiconductor nanocrystals and fluorescent proteins can be assembled in fluorescence (or Förster) energy transfer (FRET) systems. Both nanocrystals and fluorescent proteins present outstanding properties as biological probes (*1*), and their coupled use provides a research tool of promising potential.

Semiconductor nanocrystals have large absorption cross sections, high photoluminescence (PL) quantum yields (QY), size-tunable PL spectra, exceptional photochemical stability (*2, 3*), and good dispersibility in biological fluids (*3*−*7*). The green fluorescent protein (GFP) family is composed of a group of homologous, colored, compact proteins that spontaneously generate their own fluorophore (*8*−*10*). They have been extensively used as gene-based probes in molecular and cell biology (*11*). The diversity of emission and absorption profiles of these elements provide a variety of possible donor−acceptor FRET pairs.

The nanocrystal−fluorescent protein FRET pairs commonly used to date are composed of green emitting CdSe/ZnS nanocrystals and yellow or red emitting fluorescent proteins (*12*−*15*). Such systems have been used to create three chromophore FRET systems (*13*) and to research cell penetration and nanoparticle mediated drug delivery (*14*).

In the present work, we extend the available nanocrystal−fluorescent protein FRET pairs by substituting the previously used red emitting protein HcRed1 (quantum yield 5% (*12*)) with the high quantum yield dTomato (quantum yield 69% (*16*)) and by introducing ZnSe/ZnS as a cadmium-free, blue-shifted nanocrystal donor substitute for CdSe/ZnS. The CdSe/ZnS−dTomato system exhibits highly efficient FRET with larger overall PL alteration under complex formation than nanocrystal−fluorescent protein pairs used previously (*12*−*15*). ZnSe/ZnS nanocrystals are advantageous not only because they are free of toxic cadmium (*17*), but also because their emission peak is blue-shifted to 400 nm, leaving all color channels from blue to red available for other probes. The ZnSe/ZnS−GFP5 system presents particularly attractive characteristics such as unusually intense sensitized emission and excellent contrast due to the large separation, 100 nm, between donor and acceptor PL peaks.

EXPERIMENTAL PROCEDURES

Nanocrystals. Mercaptoundecanoic acid (MUA) coated CdSe/ZnS nanocrystals were purchased from NN Laboratories. The emission spectrum of these CdSe/ZnS nanocrystals is provided in Figure 1. Mercaptopropionic acid (MPA) coated ZnSe/ZnS nanocrystals were synthesized in accordance with a protocol derived from ref 18. MPA was added to 60 mL of Milli-Q water containing 1 mM zinc perchlorate, to a final concentration of 2.4 mM. The pH of the solution was raised to 10.5 by the addition of sodium hydroxide. The solution was then stirred and put under a nitrogen flux for 10 min. In parallel, 9.6 mg of selenium powder and 10 mg of sodium borohydride were mixed in a 15 mL Falcon flask. To this mixture 2 mL of Milli-Q water was added, and the solution was sonicated for 5 min, keeping the Falcon's cap loose to let the evolving gas escape. 0.5 mL of this solution was injected in the zinc perchlorate solution and stirred. Thirty milliliters of the resulting solution were collected and poured inside a 50 mL total volume Teflon-lined autoclave. The Teflon set was then placed inside an oven at 70 °C for 24 h. 0.85 mL of the autoclaved solution was collected and placed inside a 1 mL quartz cuvette. 4.4 μL of MPA were diluted in 1 mL of Milli-Q water containing 0.1 mM sodium hydroxide, and 0.15 mL of this solution was also

added to the quartz cuvette. The cuvette was then capped and placed 20 cm from a commercial 27 W UV light (emission peak at 370 nm) inside an oven held at 60 °C, where it was kept for 4 h. Absorption and emission spectra of the ZnSe/ZnS nanocrystals are shown in Figures 2 and 5. The approximate concentration, 2.7 nM, and diameter, 3 nm, of the nanocrystals were inferred in accordance to *refs* 19 *and* 20. The quantum yield of the colloidal solution, 50%, was estimated by comparison with quinine in aqueous 0.5 M sulfuric acid (quantum yield: 54.5% (*21*)).

Fluorescent Proteins. HcRed1 on plasmid pHcRed1 was purchased from Clontech. Plasmid pHcRed1 was used without modifications. HcRed1 does not encode a hexa-histidine sequence. dTomato was generously provided by R. Y. Tsien (University of California at San Diego) on plasmid pRSET-B dTomato. pRSET-B (Invitrogen) encodes a hexa-histidine sequence at the N-terminus of the dTomato coding sequence. pRSET-B dTomato plasmid was used without modification. GFP5 was generously provided by J. Haseloff (University of Cambridge) on plasmid pBIN m-GFP5-ER. The gene encoding GFP5 was excised by digestion with *Eco*RI and *Sac*I and ligated in the same sites at the multiple cloning site of the pET-28a (+) (Novagen). pET-28a (+) also encodes a hexa-histidine sequence at the N-terminus of the GFP5 coding sequence. Each plasmid was respectively introduced into BL21(DE3) *E. coli* cells (Invitrogen) and expression induced with 0.16 mM isopropyl-β-D-thiogalactopyranoside (IPTG, Sigma) for 20 h at 30 °C, before harvesting the cells by centrifugation. His-tagged proteins were purified from soluble cell lysates using Ni-NTA Resin (Qiagen) eluted with 500 mM imidazole and dialyzed. The absorption spectrum of GFP5 is shown in Figure 2. Figure 3 shows the emission spectrum of the ZnSe/ZnS-GFP5 system as a function of the GFP5 (G) to ZnSe/ZnS molar ratio.

Nanocrystal−Fluorescent Protein Conjugates. To assemble CdSe/ZnS-HcRed1 and CdSe-dTomato, the proteins at the appropriate molar ratios were added to 33 nM of CdSe/ZnS (capped with MUA) in 5 mM phosphate, 5 mM NaCl, pH 6 at room temperature. To assemble ZnSe/ZnS-GFP5, GFP5 at the appropriate molar ratios was added to 120 nM of ZnSe/ZnS (capped with MPA) in phosphate buffered saline (137 mM NaCl, 10 mM phosphate, 2.7 mM KCl, pH 7.4, PBS) at room temperature. Conjugates were characterized through the quenching of the nanocrystals' fluorescence and enhancement of the proteins' fluorescence, which was monitored by measuring the steady-state fluorescence using a SPEX Fluorolog 1691 (Spex industries) spectrophotometer equipped with a 450 W Xenon lamp. The SPEX software MCORRECT.SPT was used to correct the responsivity of the spectrophotometer. Polarizers were introduced into the SPEX to measure the polarization anisotropy (r). Anisotropy was calculated using the equation:

$$r = \frac{VV - gVH}{VV + 2gVH}$$

Vertically polarized excitation of the donor was used in combination with capture of both horizontal (*VH*) and vertical (*VV*) polarizations. The factor g corrects for polarization bias in the instrument (*22*, *23*). g was calculated using the equation

$$g = \frac{HV}{HH}$$

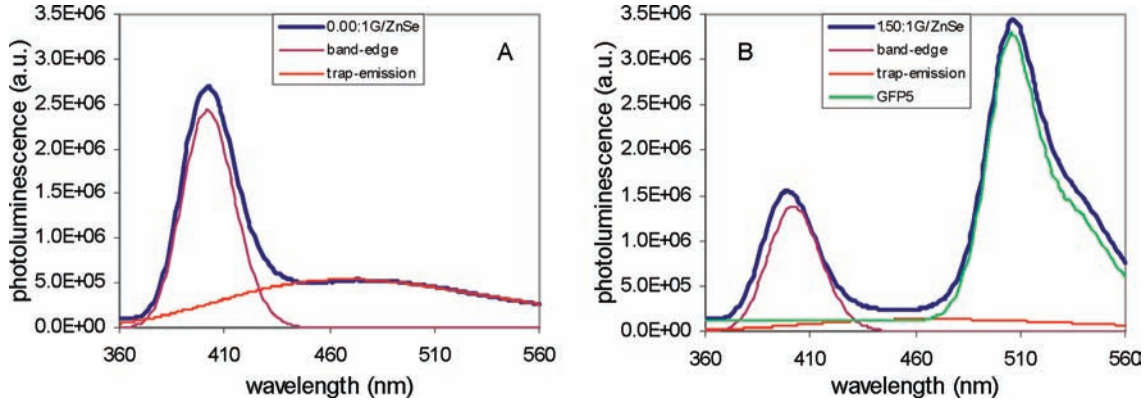

Figure 4. (A) Deconvolution of the ZnSe/ZnS nanocrystals photoluminescence spectrum with two Gaussians corresponding to band-edge and trap emission. (B) Deconvolution of the ZnSe/ZnS−GFP assembly photoluminescence spectrum at GFP5 (G) saturation.

In this case, horizontally polarized excitation of the donor was used in combination with capture of both vertical (*HV*) and horizontal (*HH*) polarizations.

RESULTS AND DISCUSSION

We have previously reported the occurrence of FRET from green emitting CdSe/ZnS nanocrystals to the red emitting protein HcRed1 (*12*), as shown in Figure 1A. At that time it was pointed out that the low quantum yield of HcRed1, 5%, was the reason for the weak intensity of the sensitized emission. We have now replaced HcRed1 with the red emitting protein dTomato (*16*), which has a quantum yield of 69%, and a substantial increase of the sensitized emission intensity was observed, as shown in Figure 1B.

In both cases, the titration was conducted at pH 6. The FRET efficiency for the pair CdSe/ZnS−dTomato, calculated by using the relative fluorescence intensity of the donor, in the absence and presence of acceptor is 72% (*22*). The strong overall fluorescence transition undergone by the CdSe/ZnS−dTomato system during complex formation makes it an excellent tool for FRET-based characterization.

Bulk CdSe exhibits band gap emission centered at 713 nm. Due to quantum confinement, it is possible to tune the emission of CdSe nanocrystals over the visible spectrum by controlling their diameter. However, blue emitting CdSe nanocrystals require very small diameters, which renders them unstable and restricts their commercial availability (*20*). This limitation is the primary reason there are no reports of CdSe nanocrystals as FRET donors in the blue spectral region. To overcome this limitation, we have substituted CdSe nanocrystals. Bulk ZnSe emits at 459 nm, and there are a large number of references reporting aqueous synthesis of efficient ZnSe/ZnS nanocrystals (*18*, *20*, *24*). We decided to synthesize ZnSe/ZnS nanocrystals at our lab, which demanded a considerable effort in refining the available protocols and adapting them to the lab conditions. At pH 10.5, immediately after synthesis, our nanocrystals presented a quantum yield of 50%, with emission centered at 400 nm. The quantum yield slowly decreases with time and was 25% one month after synthesis. Such a decrease in quantum yield is possibly related to the long-term dynamics undergone by the MPA ligand at the nanocrystal surface (*25*). ZnSe/ZnS nanocrystals are promising candidates for FRET donors at the shorter wavelength end of the visible spectrum. Moreover, the violet emission of these nanocrystals overlaps well with the GFP5 absorption spectrum, as can be seen in Figure 2. GFP5 is a mutant form of GFP especially designed to be expressed in *E. coli* (*26*).

Unlike the MUA coated CdSe/ZnS nanocrystals, the lab synthesized ZnSe/ZnS nanocrystals were coated with MPA. MPA, however, confers poor protection for pH changes. At a pH below 7, the ZnSe/ZnS nanocrystals barely fluoresce. Consequently, assays with ZnSe/ZnS were made in PBS buffer at pH 7.4, whereas assays made with CdSe/ZnS nanocrystals had been conducted at pH 6. At pH 7.4, the ZnSe/ZnS nanocrystals present a quantum yield of 15%, which is substantially smaller than the quantum yield of 50% at pH 10.5 but is still satisfactory for FRET characterization, as can be seen in Figure 3. Actually, there is a tradeoff between lowering the pH to increase the electrostatic attraction among nanocrystals and fluorescent proteins (*12*) and augmenting the pH to increase the nanocrystal fluorescence quantum yield. As a compromise, we decided to conduct the assays at an intermediate pH value, 7.4.

The calculated FRET efficiency using the relative fluorescence intensity of the donor, in the absence and presence of acceptor, is 43% (*22*). Despite the lower FRET efficiency when compared to the CdSe/ZnS−dTomato pair, the high intensity of the sensitized emission is an outstanding characteristic of the new system. GFP5 has an elevated quantum yield, 77% (*26*, *27*), and the nanocrystals, at pH 7.4, have a quantum yield of only 15%. Probably, some of the nanocrystal energy is being rapidly transferred to the GFP5 before it is emitted or nonradiatively recombined, causing the substantial enhancement of the GFP5 emission (*28*). Bidentate anchors like dihydrolipoic acid (DHLA) confer superior stability for the nanocrystals than single sulfur molecules like MPA, improving their quantum yield at neutral pH (*13*, *14*). Tests are being conducted to verify the effect of DHLA on the energy transfer among ZnSe/ZnS and GFP5. Preliminary results show that the addition of 5 mM DHLA, after the UV processing, immediately increases the nanocrystal emission intensity as well as has a positive effect on retaining the nanocrystal quantum yield at neutral pH. Studies concerning the long-term stability and dilution effects over the nanocrystal quantum yield at neutral pH are being conducted.

The ZnSe/ZnS nanocrystal emission spectrum has two components, one related to the band-edge emission, centered at 402 nm, and the other related to the trap emission, centered at 468 nm (*18*), which can be represented by two Gaussians, as shown in Figure 4A. In Figure 4B, the two Gaussians, together with a curve corresponding to pure GFP5, are used to deconvolute the emission spectrum of a ZnSe/ZnS−GFP5 assembly at a saturating concentration of GFP5. Analyzing Figure 4B, two considerations were made. First, the nanocrystals suffer a blue shift of 3 nm when put into close proximity to GFP5, which is characteristic of an environment change at the nanocrystal surface (*15*). Second, comparing the deconvolution curves for the emission spectra of ZnSe/

ZnS alone and for the assembly ZnSe/ZnS−GFP5 it comes out that the deconvolution factor for the trap emission was more strongly reduced, 75%, than the deconvolution factor for the band-edge emission, which was reduced by only 43%, possibly because the ratio of the Förster exchange rate from the traps to the GFP5 is proportionally larger than the Förster exchange rate from the band-edge states to the GFP5. In spite of the possible high trap emission Förster exchange rate, we intend to improve the postprocessing protocol for the ZnSe/ZnS nanocrystals to further reduce the trap emission. As can be seen in Figure 4B, the trap emission causes a signal contamination in the GFP5 emission spectrum, and its elimination would override any spectral overlapping, further improving the resolution of this FRET system.

The ZnSe/ZnS−GFP5 constitutes a sensitive and well-resolved, cadmium-free nanocrystal−fluorescent protein FRET system. Moreover, due to its low wavelength position in the visible spectrum, this system is particularly suitable for extension to a multifluorophore FRET system. For example, GFP5 emits at 506 nm, and a ternary FRET system having yellow fluorescent protein as the second energy acceptor can be envisioned. Such a system would include FRET among fluorescent proteins along with nanocrystal donors. Multifluorophore FRET systems are useful for the elucidation of multicomponent molecular assemblies, characteristic of highly coordinated biological supramolecular interactions (*13*).

The enhanced fluorescence emission of GFP5 was also characterized by polarization fluorimetry to confirm the FRET. The direct emission of fluorescent proteins is highly polarized, while the depolarization of its fluorescence is observed only in the presence of energy transfer (*22*, *23*). This characteristic provides the means to detect the FRET with great accuracy in high-throughput screening assays (*23*). In Figure 5, it is possible to verify that the anisotropy of GFP5 complexed with the ZnSe/ZnS tends to zero when the absorption of the nanocrystals becomes strong, i.e., when the emission of GFP5 is mainly due to energy transfer. The anisotropy of GFP5 alone, on the other hand, is essentially wavelength independent.

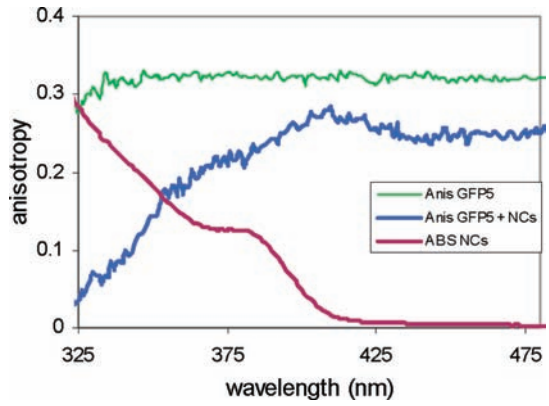

Figure 5. Steady-state anisotropy was calculated from fluorescence excitation spectra with emission set at 506 nm for solutions containing GFP5 alone and GFP5 complexed with ZnSe/ZnS nanocrystals. The absorbance spectrum of the nanocrystals is also depicted.

ACKNOWLEDGMENT

The authors thank Dr. Jim Haseloff for providing the gene coding for GFP5 and Dr. R. Y. Tsien for providing the gene coding for dTomato. The authors wish to express their gratitude to the Brazilian funding agencies CNQP, FAPESP, CAPES, and CONICET being also thankful for the support from the Biochemistry Department of the Chemistry Institute of the University of São Paulo, Brazil.

Antibody−drug conjugates (ADCs) were prepared with potent camptothecin analogues attached to monoclonal antibodies (mAbs) via dipeptide or glucuronide-based linkers. Aniline-containing camptothecin analogues were employed to provide a site of linker attachment via carbamate bonds that would be stable in circulation. The camptothecin analogues, 7-butyl-10-amino-camptothecin and 7-butyl-9-amino-10,11-methylenedioxy-camptothecin, are generally 10−1000 times more potent than camptothecin. Dipeptide and glucuronide drug linkers were employed containing self-immolative spacers that release drug following lysosomal degradation upon ADC internalization into antigen-positive cell lines. The camptothecin drug linkers were conjugated to three antibodies: chimeric BR96, chimeric AC10, and humanized 1F6, which bind to the Lewis-Y antigen on carcinomas, CD30 on hematologic malignancies, and CD70 present on hematologic malignancies and renal cell carcinoma, respectively. ADCs bearing the potent camptothecin analogue, 7-butyl-9-amino-10,11-methylenedioxy-camptothecin, were highly potent and immunologically specific on a panel of cancer cell lines in vitro, and efficacious at well-tolerated doses in a renal cell carcinoma xenograft model.

INTRODUCTION

In an attempt to enhance activity and mitigate toxicity of cancer chemotherapy, there has been a great deal of interest in the use of monoclonal antibodies (mAbs) for the targeted delivery of cytotoxic agents to cancer cells (*1*−*3*). The principle behind this approach is that, by covalent attachment of a cytotoxic drug to a mAb that binds selectively to a tumor-specific antigen, the activity of the drug could be enhanced through high intratumoral concentrations while sparing normal, nontarget tissue from indiscriminant damage. Early-generation ADCs[1] have demonstrated that several parameters are important for efficient targeted cell kill, such as drug potency, drug linker stability, efficient on-target drug release, mAb immunogenicity, and normal tissue expression of the tumor antigen (*1*−*3*). More recently, significant progress in ADC design has led to the clinical advancement of two new immunoconjugates: SGN-35 for CD30-positive hematologic malignancies (*3*−*5*) and trastuzumab-DM1 for HER2-positive metastatic breast cancer (*6, 7*). In phase I clinical trials both ADCs induced tumor regressions at well-tolerated doses (*6, 8*−*10*), providing further validation of the use of ADCs as an emerging treatment modality.

We are interested in all classes of drugs that may be suitable for empowering mAbs. Early immunoconjugates used clinically approved cytotoxic agents due to their availability and known toxicological properties. This approach is exemplified by BR96-doxorubicin ADC targeted to the Lewis-Y antigen present on human carcinomas. Doxorubicin was attached to the mAb via an acid-sensitive hydrazone linker, and free drug was released upon ADC internalization into acidic lysosomes (*11*). In vivo efficacy was observed in tumor-bearing mice, albeit at elevated (>100 mg ADC/kg) dose levels. Clinical trials revealed low levels of activity in patients with Lewis-Y positive carcinomas (*11*−*13*). The limitations associated with this ADC included drug linker instability, antigen expression on normal tissues, and low drug potency. It has been proposed that optimized ADCs must address these issues to achieve maximal therapeutic efficacy (*1, 2*).

As part of our search for new chemotypes suitable for use in ADCs, we sought to evaluate conjugates consisting of potent camptothecin (CPT) analogues. Camptothecin (**1**) is a natural product that exerts cytotoxic activity through the inhibition of topoisomerase I, leading to cell death (*14*). As a consequence of its broad-spectrum antitumor activity and cytotoxic mechanism, there has been a substantial effort toward the development of clinical camptothecin analogues. To date, two water-soluble analogues have received FDA approval: topotecan and irinotecan. Topotecan is used primarily in the treatment of advanced ovarian cancer and non-small cell lung cancer and was recently approved for cervical cancer (*15*). Irinotecan is a prodrug that is converted into SN-38, a more potent CPT analogue, under the action of carboxylesterases (*16*) and is used primarily in the treatment of colorectal cancer (*15*). Clinical studies with irinotecan, topotecan, and other camptothecin analogues in development indicate that optimal efficacy is achieved with dosing regimens that provide for prolonged exposure to low levels of camptothecin (*17*). This suggests that camptothecin, or potent CPT analogues, may be ideally suited for mAb targeting, as antibodies often have extended circulation half-lives, ranging from many days to weeks (*1, 3*).

An ADC of CPT has already been described (*18*). It was found that BR96-CPT had a similar level of potency as BR96-DOX (*18, 19*). In addition, the CPT-containing ADC was relatively unstable, due to the use of a labile carbonate linker (*18*). Other camptothecin ADCs bearing SN-38 were more potent, but were also composed of labile linkers (*20*). On the basis of our previous work with optimized auristatin-containing ADCs (*4*), we felt that it was necessary to use camptothecin analogues with much higher potency than CPT, and to incorporate linkers that provide high serum stability.

Camptothecins have been subjected to extensive structure−activity relationship studies (*21*), which indicate that 7-position alkyl substituents and a methylenedioxy group spanning the 10 and 11 positions confer enhanced biochemical and cellular potency (*22, 23*). The selected camptothecin analogues, 7-butyl-10-amino-CPT (**2**) and the des-amino precursor (**12**) to 7-butyl-9-amino-10,11-methylenedioxy-CPT (**3**), are substantially more potent (1−3 logs) than camptothecin (*22, 24, 25*). These molecules are ideally suited for ADC application, not only because of their potencies, but also because they (**2** and **3**) contain functional groups that allow for stable mAb attachment. We now report the design, synthesis, and biological evaluation of ADCs comprising highly potent camptothecin analogues. This investigation resulted in CPT ADCs that were well-defined, potent, and immunologically specific in vitro and displayed good in vivo efficacy at well-tolerated doses.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All commercially available anhydrous solvents were used without further purification and were stored under a nitrogen atmosphere. NMR spectral data were collected on a Varian Mercury 400 MHz spectrometer. Chemical shifts (δ) were reported in ppm and referenced off the deuterium solvent signal. Coupling constants (*J*) are reported in hertz. Mass spectral data were obtained on a ZMD Micromass mass spectrometer interfaced to an HP Agilent 1100 HPLC instrument configured for LC-MS analysis. 7-Butyl-10-amino-camptothecin (**2**) and 7-butyl-10,11-methylenedioxy-camptothecin (**12**) were prepared via Friedlander condensation as previously described (*23*).

Analytical HPLC was performed on two different HPLC systems. Data collected by "gradient A" were obtained on an HP Agilent 1100 HPLC equipped with a C12 Phenomenex Synergi 2.0 × 150 mm, 4 μm, 80 Å reverse-phase column. The acidic eluent consisted of a linear gradient of acetonitrile from 5% to 95% in 0.1% aqueous formic acid over 10 min, followed by isocratic 95% acetonitrile for 5 min (flow rate = 0.4 mL/min). Data collected by "gradient B" were obtained on a Waters 2690 HPLC interfaced with a Waters 996 PDA and Millenium[32] software. Samples were eluted over a C12 Phenomenex Synergi 2.0 × 150 mm, 4 μm, 80 Å reverse-phase column. The neutral eluent consisted of a linear gradient of acetonitrile from 10% to 90% in 5 mM ammonium phosphate pH 7 over 10 min, followed by isocratic 90% acetonitrile for 5 min (flow rate = 1.0 mL/min).

Preparative HPLC was carried out on a Varian ProStar 210 solvent delivery system configured with a Varian ProStar 330 PDA detector. Products were purified over a C12 Phenomenex Synergi 10.0 × 250 mm, 4 μm, 80 Å reverse-phase column eluting with 0.05% TFA in water (solvent A) and 0.05% TFA in acetonitrile (solvent B). Purification Method A consisted of the following gradient of solvent A to solvent B: 90:10 from 0 to 5 min; 90:10 to 40:60 from 5 to 45 min; 40:60 to 10:90 from 45 to 50 min; followed by isocratic 10:90 for 5 min. The flow rate was 4.6 mL/min with monitoring at 254 nm. Purification Method B consisted of the following gradient of solvent A to

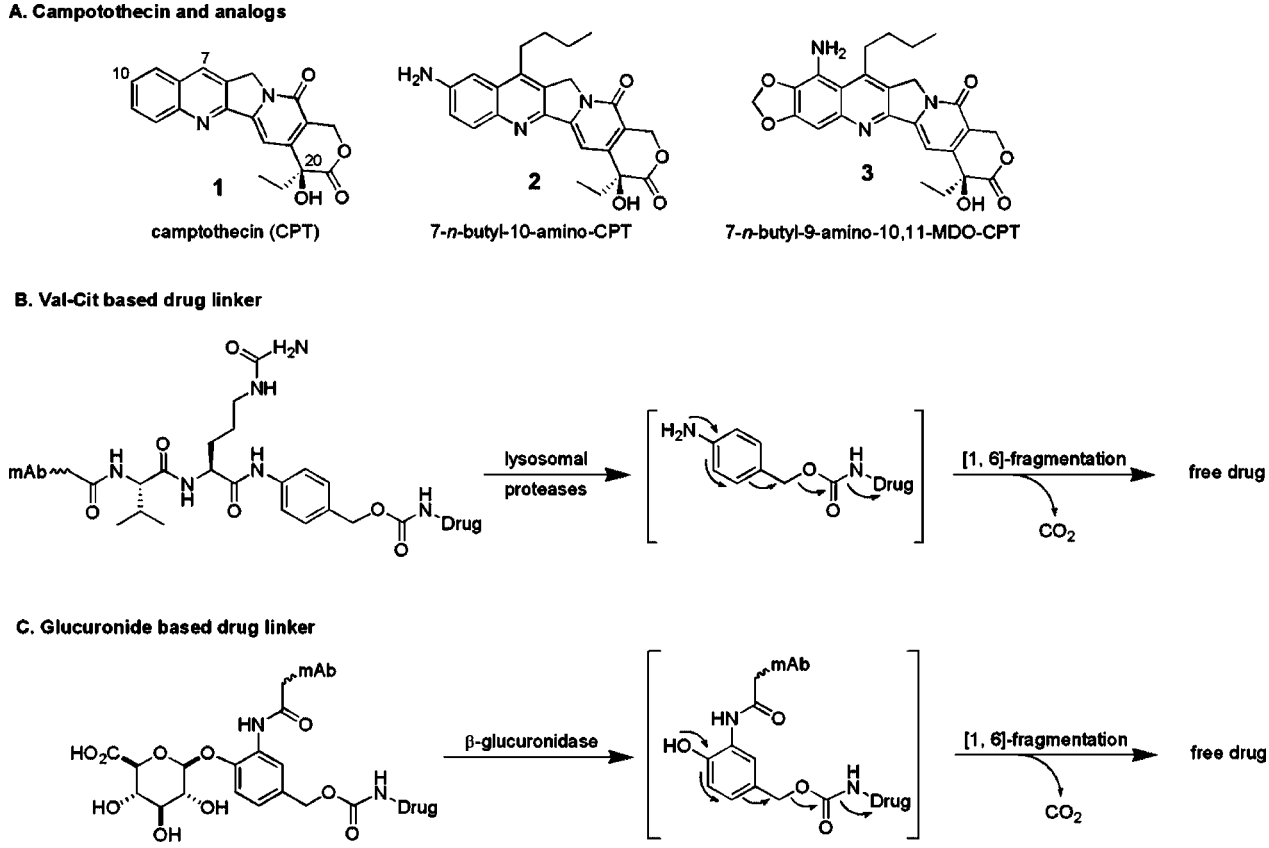

Figure 1. Structures and mechanism of release of active CPT drugs; (A) camptothecin and potent analogues prepared via Friedlander condensation; (B) val-cit dipeptide based drug linker; (C) glucuronide based drug linker.

solvent B: isocratic 90:10 from 0 to 5 min; 90:10 to 60:40 from 5 to 45 min; 60:40 to 10:90 from 45 to 50 min; followed by isocratic 10:90 for 5 min. The flow rate was 4.6 mL/min with monitoring at 254 nm.

Analytical thin layer chromatography was performed on silica gel 60 F_{254} aluminum sheets (EMD Chemicals, Gibbstown, NJ). Whatman 60 Å 230−400 mesh silica gel was used for flash chromatographic purification. Radial chromatography was performed on a Chromatotron instrument (Harris Research, Palo Alto, CA).

7-Butyl-9-amino-10,11-methylenedioxy-camptothecin (3). To a stirred solution of 7-butyl-10,11-methylenedioxy-camptothecin (**12**, 50 mg, 112 μmol) was added 2 mL of concentrated sulfuric acid. The reaction was cooled to 0 °C and sodium nitrate (14 mg, 166 μmol) was added. The reaction was warmed to room temperature and stirred for 30 min, at which time LC/MS revealed complete conversion to product. The reaction was then poured into ice-water and extracted with methylene chloride. The combined extracts were washed with water and concentrated under reduced pressure to provide the nitrated material (54 mg, 98%). UV λ_{max}: 225, 305, and 385 nm. LC-MS: *m/z* (ES^+) found 494.14 $(M+H)^+$, *m/z* (ES^-) found 492.10 $(M-H)^-$. The material was carried forward without further characterization. A stirred solution of the nitrated material (54 mg, 110 μmol) in ethanol was warmed to facilitate dissolution, and then the reaction vessel was purged with nitrogen. At room temperature, 10% palladium on carbon (100 mg) was added, and the reaction mixture was exposed to a hydrogen atmosphere. After 30 min, LC-MS indicated conversion to product. The reaction was filtered through a plug of Celite that was subsequently washed with 300 mL methanol. The filtrate was concentrated under reduced pressure and purified by radial chromatography on a 1 mm plate eluted with a CH_2Cl_2/MeOH mixture (97:3 to 95:5 CH_2Cl_2/MeOH) to provide **3** (29 mg, 57%). ^1H NMR ($CDCl_3$) δ (ppm): 1.02 (m, 6H), 1.57 (m, 3H, under HOD), 1.82 (m, 2H), 1.87 (m, 3H), 3.35 (m, 3H), 3.73 (m, 1H), 5.21 (s, 1H), 5.22 (s, 1H), 5.51 (AB, $J = 16.4$ Hz, 2H), 6.17 (d, $J = 2.0$ Hz, 2H). UV λ_{max} 229, 280, 335, and 381 nm. Analytical HPLC: gradient A, t_R = 12.56 min, $AUC_{255} = 97.9\%$; gradient B, $t_R = 8.35$ min, $AUC_{255} = 97.5\%$. LC-MS: *m/z* (ES^+) found 464.00 $(M+H)^+$, *m/z* (ES^-) found 461.97 $(M-H)^-$.

4-((*S*)-2-((*S*)-2-(6-(2,5-Dioxo-2*H*-pyrrol-1(5*H*)-yl)hexanamido)-3-methylbutanamido)-5-ureidopentanamido)benzyl-(7-butyl-10-aminocamptothecin)carbamate (4). An oven-dried flask was charged with a solution of **2** (10 mg, 23.8 μmol) in 0.5 mL anhydrous CH_2Cl_2. The solution was stirred at room temperature under nitrogen, and 0.4 mL of a 20% phosgene solution in toluene was added. The resultant brown suspension was stirred for 18 h at room temperature. The solution was then evaporated to dryness with a stream of nitrogen gas and further concentrated by rotary evaporation. To the residue obtained was added maleimidocaproyl-valine-citrulline-*para*-aminobenzyl alcohol (**13**, 20.5 mg, 35.7 μmol) (henceforth called mcVal-Cit-PABA (*26*)) dissolved in 0.5 mL anhydrous DMF. The solution was then heated to 45 °C under nitrogen. LC/MS revealed the formation of a product corresponding to the desired molecular weight. The reaction was diluted with 1.5 mL of DMSO and desired product isolated by preparative HPLC (Method A) to give **4** (3.6 mg, 15%). ^1H NMR (DMSO-d_6) δ (ppm): 0.87 (m, 9H), 0.97 (t, $J = 7.6$ Hz, 3H), 1.19 (m, 2H), 1.48 (m, 8H), 1.70 (m, 4H), 1.85 (m, 4H), 2.15 (m, 4H), 3.10 (m, 5H), 4.19 (m, 1H), 4.38 (m, 1H), 5.17 (s, 2H), 5.29 (s, 2H), 5.43 (s, 2H), 5.98 (m, 1H), 7.00 (s, 2H), 7.28 (s, 1H), 7.41 (d, $J = 8.6$ Hz, 2H), 7.65 (d, $J = 8.0$ Hz, 2H), 7.81 (d, $J = 9.2$ Hz, 1H), 7.90 (m, 1H), 8.10 (d, $J = 9.0$ Hz, 2H), 8.43 (s, 2H), 10.03 (s, 1H), 10.27 (s, 1H). UV λ_{max}: 225, 267, and 385 nm. Analytical HPLC: gradient A, $t_R = 12.38$ min, $AUC_{255} = 98.5\%$; gradient B, t_R = 7.81 min, $AUC_{255} = 93.9\%$. LC-MS: *m/z* (ES^+) found 1018.33 $(M+H)^+$, *m/z* (ES^-) found 1017.06 $(M-H)^-$.

4-((*S*)-2-((*S*)-2-(6-(2,5-Dioxo-2*H*-pyrrol-1(5*H*)-yl)hexanamido)-3-methylbutanamido)-5-ureidopentanamido)benzyl-(7-butyl-9-amino-10,11-methylendioxycamptothecin)carbamate (5). Drug linker **5** was prepared from CPT **3** (24 mg, 51.8 μmol) in an analogous reaction to that described for **4**. The crude reaction material was purified by flash chromatography on silica gel eluted with MeOH in CH_2Cl_2 (98:2 to 95:5 to 90:10 CH_2Cl_2/MeOH) to yield **5** (11.2 mg, 20%). ^1H NMR (DMF-d_7) δ (ppm): 0.96 (m, 9H), 1.28 (m, 3H), 1.56 (m, 8H), 2.00 (m, 3H), 2.16 (m, 1H), 2.29 (m, 2H), 3.08 (q, $J = 6.2$ Hz, 1H), 3.26 (m, 3 H), 3.46 (t, $J = 6.8$ Hz, 2H), 4.36 (t, $J = 7.6$ Hz, 1H), 4.63 (bt, 1H), 5.20 (s, 2H), 5.31 (s, 2H), 5.51 (s, 2H), 5.66 (m, 1H), 6.27 (bt, 1H), 6.37 (s, 1H), 6.49 (s, 1H), 7.02 (s, 2H), 7.37 (s, 1H), 7.45 (d, $J = 8.0$ Hz, 1H), 7.55 (s, 1H), 7.84 (d, $J = 8.0$ Hz, 1H), 7.90 (d, $J = 8.4$ Hz, 1H), 8.16 (d, $J = 7.6$ Hz, 1H), 9.37 (s, 1H), 10.11 (s, 1H). UV λ_{max}: 227, 253, and 383 nm. Analytical HPLC: gradient A, $t_R = 12.11$ min, $AUC_{255} = 96.2\%$; gradient B, $t_R = 7.41$ min, $AUC_{255} = 94.9\%$. LC-MS: *m/z* (ES^+) found 1062.45 $(M+H)^+$, *m/z* (ES^-) found 1060.29 $(M-H)^-$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-Methyl 6-(2-(3-(((9*H*-fluoren-9-yl)methoxy)-carbonylamino)propanamido)-4-(((7-butyl-10-aminocamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-triacetoxy-tetrahydro-2*H*-pyran-2-carboxylate (6). A flame-dried flask was charged with the known (*27*) protected glucuronide linker fragment (**14**, 28.5 mg, 38.1 μmol) dissolved in 1.5 mL anhydrous CH_2Cl_2. Anhydrous pyridine (37 μL, 457 μmol) was added, and the solution was cooled to −78 °C under a nitrogen atmosphere. Diphosgene (5.5 μL, 46 μmol) was added; the light yellow, limpid solution was stirred for 3 h at −78 °C. A solution of **2** (16.0 mg, 38.1 μmol) in 1.5 mL anhydrous THF was then added, and the reaction was warmed to 0 °C over 1 h. Analytical HPLC at 1 h revealed the formation of product. The reaction was poured into 50 mL EtOAc, and the organic phase was washed with 20 mL water, then 20 mL brine. The organic layer was dried over Na_2SO_4, filtered, and concentrated. The residue so obtained was purified by flash chromatography on silica gel eluted with a CH_2Cl_2/MeOH mixture (98:2 to 97:3 CH_2Cl_2/MeOH) to provide **6** (28.8 mg, 64%). ^1H NMR ($CDCl_3$) δ (ppm) 0.95 (t, $J = 7.6$ Hz, 3H), 0.99 (t, $J = 7.2$ Hz, 3H), 1.46 (m, 3H), 1.66 (m, 3H), 1.86 (m, 3H), 2.03 (s, 3H), 2.05 (s, 6H), 2.73 (m, 2H), 3.05 (q, $J = 8.0$ Hz, 1H), 3.57 (m, 2H), 3.72 (s, 3H), 4.12 (t, $J = 7.2$ Hz, 1H), 4.31 (m, 4H), 5.15 (m, 7H), 5.42 (m, 1H), 5.59 (m, 1H), 5.76 (bt, 1H), 6.95 (d, $J = 8.4$ Hz, 1H), 7.04 (d, $J = 8.0$ Hz, 1H), 7.21 (m, 1H), 7.22 (s, 1H), 7.32 (t, $J = 7.2$ Hz, 2H), 7.52 (d, $J = 7.2$ Hz, 2H), 7.59 (d, $J = 8.4$ Hz, 1H), 7.68 (m, 3H), 8.06 (m, 2H), 8.29 (s, 1H), 8.41 (s, 1H). UV λ_{max}: 267 and 385 nm. LC-MS: *m/z* (ES^+) found 1194.84 $(M+H)^+$, *m/z* (ES^-) found 1192.57 $(M-H)^-$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-Methyl 6-(2-(3-(((9*H*-fluoren-9-yl)methoxy)-carbonylamino)propanamido)-4-(((7-butyl-9-amino-10,11-methylendioxycamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-triacetoxy-tetrahydro-2*H*-pyran-2-carboxylate (7). A flame-dried flask was charged with **3** (10 mg, 21 μmol) dissolved in 0.5 mL anhydrous CH_2Cl_2. The solution was stirred at room temperature under nitrogen, and 0.4 mL of a 20% phosgene solution in toluene was added. The reaction was stirred for 18 h at room temperature; a small aliquot of the reaction was quenched with methanol, and the methyl carbamate (indicating formation of the isocyanate) was detected by LC-MS. The solution was then evaporated to dryness with a stream of nitrogen gas and further concentrated by rotary evaporation. To the residue obtained was added the known (*27*) protected glucuronide linker fragment (**14**, 30 mg, 40 μmol) dissolved in 0.2 mL anhydrous DMF. The reaction was stirred at room

temperature for 2 h, after which time LC-MS revealed conversion to product. The reaction was then concentrated, redissolved in minimal CH_2Cl_2, and purified by radial chromatography eluting CH_2Cl_2/MeOH (97:3 to 95:5 CH_2Cl_2/MeOH) to give **7** (10 mg, 38%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.88 (m, 3H), 1.00 (t, J = 7.6 Hz, 3H), 1.26 (s, 2H), 1.42 (m, 3H), 1.87 (m, 2H), 2.06 (s, 9H), 2.74 (m, 2H), 2.99 (bs, 1H), 3.18 (bs, 1H), 3.61 (m, 2H), 3.74 (s, 3H), 4.19 (q, J = 6.8 Hz, 2H), 4.39 (q, J = 10 Hz, 2H), 5.16 (m, 9H), 5.43 (q, J = 8.8 Hz, 1H), 5.65 (d, J = 16.4 Hz, 1H), 5.85 (s, 1H), 6.17 (s, 3H), 6.96 (m, 3H), 7.22 (s, 1H), 7.32 (t, J = 6.8 Hz, 2H), 7.45 (s, 1H), 7.59 (m, 3H), 7.67 (d, J = 7.2 Hz, 2H), 8.14 (s, 1H), 8.47 (s, 1H). UV λ_{max}: 229, 263, and 383 nm. LC-MS: *m/z* (ES^+) found 1237.95 $(M+H)^+$, *m/z* (ES^-) found 1236.85 $(M-H)^-$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-Aminopropanamido)-4-(((7-butyl-10-aminocamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid (8). A flask charged with **6** (24.0 mg, 20.1 μmol) dissolved in a solvent mixture of 2.5 mL MeOH, 3.0 mL THF, and 2.5 mL water, was cooled to 0 °C. To the stirred solution was added LiOH monohydrate (8.6 mg, 212 μmol) and the reaction was warmed to room temperature. After 3 h, LC-MS revealed complete conversion to product. Glacial acetic acid (12.7 μL, 222 μmol) was added, and the reaction was evaporated to dryness. Purification of residue by preparative HPLC using Method B gave **8** (12.7 mg, 67%). ^{1}H NMR (CD_3OD) δ (ppm) 0.96 (t, J = 7.6 Hz, 3H), 0.99 (t, J = 7.2 Hz, 3H), 1.49 (q, J = 7.2 Hz, 2H), 1.65 (m, 2H), 1.89 (m, 2H), 2.62 (s, 1H), 2.86 (t, J = 6.0 Hz, 2H), 2.95 (bt, 2H), 3.53 (m, 3H), 3.93 (m, 1H), 4.84 (d, J = 7.6 Hz, 1H), 4.91 (s, 2H), 5.11 (s, 2H), 5.34 (AB, J = 16.0 Hz, 2H), 7.20 (m, 2H), 7.40 (s, 1H), 7.60 (m, 1H), 7.82 (d, J = 8.8 Hz, 1H), 8.12 (s, 1H), 8.22 (s, 1H), 9.63 (s, 1H). UV λ_{max}: 227, 267, 385 nm. LC-MS: *m/z* (ES^+) found 832.20 $(M+H)^+$, *m/z* (ES^-) found 830.27 $(M-H)^-$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-Aminopropanamido)-4-(((7-butyl-9-amino-10,11-methylendioxycamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid (9). Drug linker **9** was prepared from **7** (25.0 mg, 25.2 μmol) in the same manner as that described for **8**. The reaction gave **9** (17.6 mg, 92%). UV λ_{max}: 223 and 383 nm. LC-MS: *m/z* (ES^+) found 875.94 $(M+H)^+$, *m/z* (ES^-) found 873.95 $(M-H)^-$. The material was carried forward without further characterization.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-(6-(2,5-Dioxo-2*H*-pyrrol-1-(5*H*)-yl)hexanamido)propanamido)-4-(((7-butyl-10-aminocamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid (10). To a solution of **8** (23.0 mg, 27.6 μmol) dissolved in 1.5 mL anhydrous DMF was added maleimidocaproyl NHS ester (12.8 mg, 41.4 μmol), followed by DIPEA (14.4 μL, 82.8 μmol). The reaction was stirred at room temperature under nitrogen for 4 h, at which time LC-MS revealed conversion to product. The crude reaction was diluted in DMSO and purified by preparative HPLC (Method A) to give **10** (20.5 mg, 72%). ^{1}H NMR (DMF-d_7) δ (ppm): 0.99 (m, 6H), 1.26 (p, J = 8.4 Hz, 2H), 1.57 (m, 6H), 1.81 (p, J = 7.2 Hz, 2H), 2.01 (m, 2H), 2.16 (t, J = 7.2 Hz, 2H), 2.68 (t, J = 6.8 Hz, 2H), 3.21 (t, J = 8.0 Hz, 2H), 3.57 (m, 10H), 4.10 (d, J = 9.6 Hz, 2H), 5.03 (m, 1H), 5.23 (s, 2H), 5.36 (s, 2H), 5.52 (d, J = 2.4 Hz, 2H), 6.52 (bs, 1H), 7.01 (s, 2H), 7.19 (dd, J = 8.4, 2.0 Hz, 1H), 7.27 (d, J = 8.4 Hz, 1H), 7.43 (s, 1H), 7.94 (t, J = 5.6 Hz, 1H), 8.09 (dd, J = 9.2, 2.0 Hz, 1H), 8.18 (d, J = 9.2 Hz, 1H), 8.48 (s, 1H), 8.57 (s, 1H), 9.36 (s, 1H), 10.37 (s, 1H). UV λ_{max}: 267 and 385 nm. Analytical HPLC: gradient A, t_R = 11.93 min, AUC_{255} = 94.7%; gradient B, t_R = 5.76 min, AUC_{255} = 97.1%. LC-MS: *m/z* (ES^+) found 1025.40 $(M+H)^+$, *m/z* (ES^-) found 1023.29 $(M-H)^-$.

(2*S*,3*S*,4*S*,5*R*,6*S*)-6-(2-(3-(6-(2,5-Dioxo-2*H*-pyrrol-1-(5*H*)-yl)hexanamido)propanamido)-4-(((7-butyl-9-amino-10,11-methylendioxycamptothecin)carbamoyloxy)methyl)phenoxy)-3,4,5-trihydroxy-tetrahydro-2*H*-pyran-2-carboxylic Acid (11). Drug linker **11** was prepared from **9** (16.3 mg, 18.6 μmol) in the same manner as that described for **10**. The reaction gave **11** (12.9 mg, 65%). ^{1}H NMR (DMF-d_7) δ (ppm): 0.93 (t, J = 7.2 Hz, 3H), 0.99 (t, J = 8.0 Hz, 3H), 1.27 (m, 2H), 1.56 (m, 8H), 1.70 (m, 2H), 1.98 (m, 2H), 2.17 (t, J = 7.6 Hz, 2H), 2.69 (m, 2H), 3.52 (m, 10H), 4.10 (d, J = 9.2 Hz, 2H), 5.03 (d, J = 6.4 Hz, 2H), 5.19 (s, 2H), 5.30 (s, 2H), 5.51 (d, J = 2.8 Hz, 2H), 6.37 (m, 3H), 7.02 (d, J = 3.6 Hz, 2H), 7.18 (d, J = 8.4 Hz, 1H), 7.28 (d, J = 8.4 Hz, 1H), 7.37 (s, 1H), 7.55 (s, 1H), 8.50 (s, 1H), 9.36 (s, 1H), 9.43 (s, 1H). UV λ_{max}: 223 and 383 nm. Analytical HPLC: gradient A, t_R = 11.70 min, AUC_{255} = 97.2%; gradient B, t_R = 5.47 min, AUC_{255} = 97.7%. LC-MS: *m/z* (ES^+) found 1069.44 $(M+H)^+$, *m/z* (ES^-) found 1067.37 $(M-H)^-$.

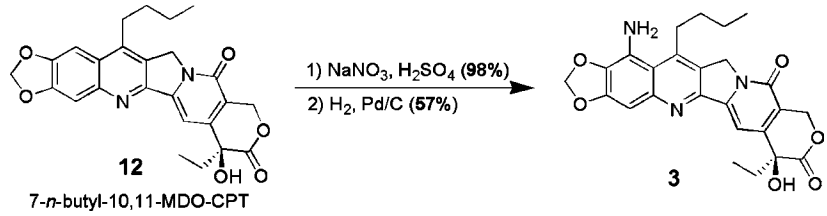
Antibody−Drug Conjugate Preparation. The immunoconjugates were prepared as previously described (*4*, *28*). Briefly, the mAbs (4−5 mg/mL) in PBS containing 50 mM sodium borate at pH 7.4 were reduced with tris(carboxyethyl)phosphine hydrochloride at 37 °C. The progress of the reaction, which reduces interchain disulfides, was monitored by reaction with 5,5′-dithiobis(2-nitrobenzoic acid) and allowed to proceed until the desired level of thiols/mAb was achieved. The reduced antibody was then cooled to 0 °C and alkylated with 1.5 equiv of maleimide drug linker per antibody thiol. After 1 h, the reaction was quenched by the addition of 5 equiv of *N*-acetyl cysteine (NAC). Quenched drug linker was removed by gel filtration over a PD-10 column. The ADC was then sterile-filtered through a 0.22 μm syringe filter. Protein concentration and drug loading were determined by spectral analysis at 280 and 375 nm, respectively, with correction for the contribution of drug absorbance at 280 nm. Size-exclusion chromatography was used to determine the extent of antibody aggregation, and RP-HPLC confirmed the absence of remaining NAC-quenched drug linker.

ADC Binding Assay. Karpas 299 cells were treated with serial dilutions of cAC10 or cAC10-**10** in PBS. cBR96-**10** was also included as a nonbinding control. After 30 min on ice, the cells were washed and resuspended in 4 °C PBS. Secondary goat antibody-FITC was added to detect bound mAb or ADC. The cells were then washed, fixed with paraformaldehyde, and analyzed by flow cytometry.

Stability Assay. The stability of cBR96-**10** was assessed by incubation in citrated CD-1 mouse plasma. cBR96-**10** was incubated at 37 °C in plasma over the course of two weeks. Aliquots were withdrawn as a function of time and protein precipitated through the addition of 5 volumes ice-cold methanol containing 0.1% formic acid and spiked with a camptothecin reference standard. The protein was then removed by centrifugation for 5 min at 16 100 *g*; the supernatant was collected and analyzed by LC-MS (ES^+ mode) using gradient A for the detection of counts at *m/z* 420.2 $(M+H)^+$ at a retention time of 11.78 min, corresponding to free drug **2**. A standard calibration curve spanning the range 1−100% drug release was employed to convert the *m/z* 420.2 AUC at 11.78 min to a concentration value.

In Vitro Growth Inhibition. The cytotoxic activity of the immunoconjugates was assessed using a resazurin (Sigma, St. Louis, MO, USA) reduction assay (*4*). Karpas 299 (2000 cells/well), H3396 (2000 cells/well), L540cy (7000 cells/well), and Caki-1 (1000 cells/well) cells cultured in log-phase growth were seeded for 24 h in 96-well plates containing 150 μL RPMI 1640 supplemented with 20% FBS. Serial dilutions of ADC in cell culture media were prepared at 4× working concentration; 50 μL of each dilution was added to the 96-well plates. Following

Scheme 1



addition of ADC, the cells were incubated with test articles for 4 or 8 d at 37 °C. Resazurin was then added to each well to achieve a 50 μM final concentration, and the plates were incubated for an additional 4 h at 37 °C. The plates were then read for the extent of dye reduction on a Fusion HT plate reader (Packard Instruments, Meridien, CT, USA) with excitation and emission wavelengths of 530 and 590 nm, respectively. The IC_{50} value, determined in triplicate, is defined here as the concentration that results in a 50% reduction in cell growth relative to untreated controls.

In Vivo Therapy Experiments. All experiments were conducted in concordance with the Animal Care and Use Committee in a facility fully accredited by the Association for Assessment and Accreditation of Laboratory Animal Care. In vivo tolerability was first assessed to ensure that the conjugates were tolerated at clinically relevant doses. BALB/c mice were treated with escalating doses of ADC formulated in PBS with 0.01% Tween 20. Mice were monitored for weight loss following drug treatment; those that experienced 20% weight loss or other signs of morbidity were euthanized.

The efficacy experiment was conducted in a renal cell carcinoma xenograft model. Caki-1 tumor fragments were implanted into the right flank of Nude mice. Mice were randomized to study groups ($n = 5$) on day nine with each group averaging around 100 mm^3 tumor volume. The ADC or controls were dosed ip according to a q4dx4 schedule. Tumor volume as a function of time was determined using the formula ($L \times W^2$)/2. Animals were euthanized when tumor volumes reached 1000 mm^3. Mice showing durable regressions were terminated on day 96 post-implant.

RESULTS

Drug Linker Design. There are two significant challenges associated with designing an immunoconjugate with camptothecin: lack of a suitable functional group for conjugation, and hydrophobicity, which can cause antibody aggregation. The first obstacle requires designing a drug linker that combines a high level of stability in circulation with rapid drug release upon internalization into targeted cells. The only readily accessible functional group in camptothecin is the C20 tertiary hydroxyl. The use of ester or carbonate linkages to assemble conjugates with aliphatic alcohols is common (*18, 20, 29*−*31*). However, as cited earlier, this can be a liability, as mouse plasma contains high levels of esterase activity and readily cleaves ester and carbonate functional groups (*32*).

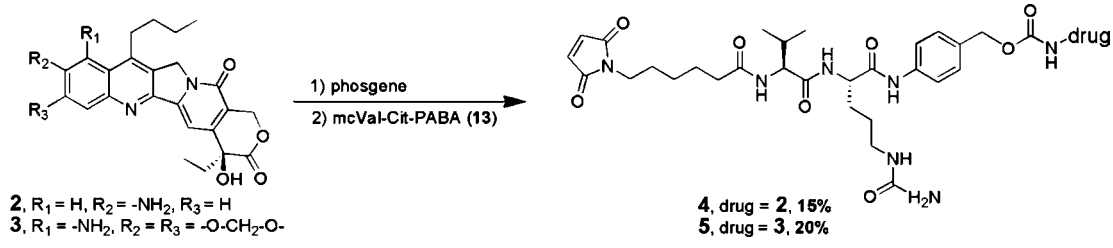
To address drug linker stability, we envisioned employing a carbamate bond to an amine-containing camptothecin such as 7-butyl-10-amino-CPT (**2**) shown in Figure 1. Carbamate bonds typically provide superior stability relative to ester and carbonate bonds with respect to hydrolysis (*33*). Alternatively, we installed an amine into the known (*23, 24*) analogue 7-butyl-10,11-methylenedioxy-CPT (**12**, Scheme 1). In both cases, the presence of the amine provided for the use of a cathepsin B-cleavable valine-citrulline-PABA dipeptide linker (val-cit) system (Figure 1B). The val-cit dipeptide linker system is designed to achieve circulation stability and rapid lysosomal drug release upon internalization into the targeted cancer cells (*4, 34*).

A second obstacle associated with this class is manifest in the hydrophobic nature of these compounds. Camptothecins possess a rigid, extended aromatic ring system that confers limited aqueous solubility and can induce significant antibody aggregation. To address this issue, hydrophilic glucuronide-based CPT drug linkers (Figure 1C) were pursued in addition to dipeptide drug linkers. The glucuronide linker system is characterized by its ability to provide monomeric ADCs with a high degree of circulation stability and rapid drug release in the presence of endogenous β-glucuronidase at the target site (*27*).

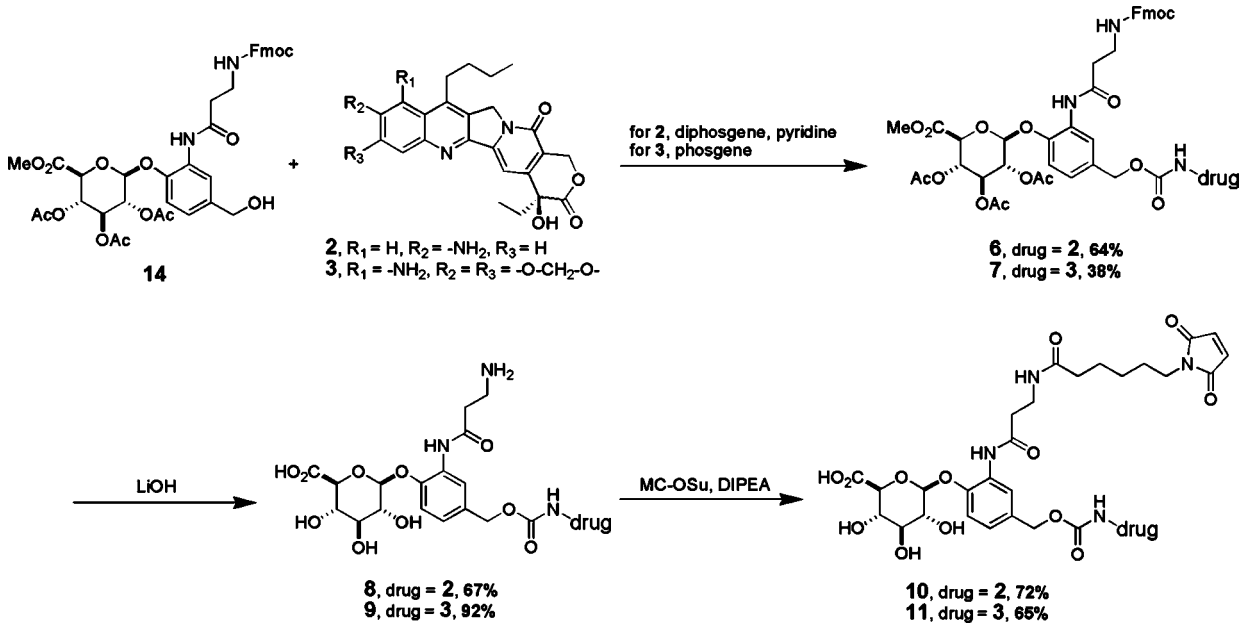
Drug Linker Synthesis. The syntheses of CPT analogues **2** and **12** were achieved by the well-precedented Friedlander condensation route (*23, 25*). Regioselective nitration and subsequent hydrogenation of **12** provided the 9-amino analogue **3** in 56% overall yield, as shown in Scheme 1. The protease-cleavable dipeptide drug linkers were prepared in two synthetic steps (Scheme 2). Camptothecins **2** and **3** were treated with phosgene to convert their respective amines to isocyanates in situ. The isocyanates were subsequently trapped by benzyl alcohol linker **13** (*26*) (mcVal-Cit-PABA), forming the carbamate linkages in drug linkers **4** and **5**, respectively.

The glucuronide drug linkers were prepared according to the synthetic sequence in Scheme 3. The synthesis commenced by converting the protected glucuronide benzyl alcohol **14** (*27*) to the chloroformate with diphosgene, which was then trapped in situ with camptothecin **2** to provide intermediate **6**. The more sterically hindered amine in **3** was converted to the isocyanate with phosgene and trapped with glucuronide benzyl alcohol **14**. Exhaustive saponification and simultaneous Fmoc-deprotection of **6** and **7** yielded free amines **8** and **9**, respectively. The synthetic sequence was then completed via the coupling of amines **8** and **9** with the NHS ester of maleimidocaproic acid

Scheme 2



Scheme 3



(MC-OSu), providing drug linkers **10** and **11**, respectively, in moderate overall yield.

Preparation of Antibody−Drug Conjugates. Conjugates comprising antibodies cBR96, cAC10, and h1F6 and drug linkers **4**, **5**, **10**, and **11** were prepared following standard protocols (*4, 28*). Reduced interchain disulfides were alkylated with drug linker, forming Michael adducts between the mAb cysteines and drug linker maleimide. Upon completion of the conjugation reaction, excess drug linker was quenched with *N*-acetylcysteine and removed by gel filtration, which was confirmed by HPLC. Drug loading was assessed by chromatographic analysis and UV absorption of the ADCs with correction for the contribution of the camptothecin chromophore at 280 nm.

The extent of ADC aggregation was determined by size-exclusion chromatography. Glucuronide drug linkers **10** and **11** provided ADCs with 4 drugs or 8 drugs per antibody with minimal (<5%) aggregation (Tables 1 and 2). The dipeptide drug linkers **4** and **5** led to antibody aggregation to a greater extent than the more hydrophilic glucuronide drug linkers. ADCs loaded with 4 drugs per antibody contained 4−16% aggregate. ADCs comprising **4** or **5** loaded with 8 drugs/mAb gave much higher levels of aggregation. For example, cAC10 loaded with drug linker **4** was >80% aggregated (Table 1). Highly aggregated (>20%) ADCs were excluded from the biological evaluation.

ADC Binding. As previously shown (*4*), alkylation of interchain disulfides typically has negligible effect on ADC antigen binding activity. To ensure that this was the case with the camptothecins, cAC10-**10** (7 drug/mAb) was assayed for binding affinity relative to unconjugated mAb with CD30+ Karpas 299 cells. The results, shown in Figure 2, indicate that conjugation did not significantly impact the antigen binding. Antigen-negative cBR96 displayed no appreciable binding.

Drug Linker Stability. Val-Cit-PAB and glucuronide carbamate drug linkers have been previously shown to be highly stable toward hydrolysis in various matrices, including plasma (*4,28*). To corroborate these observations with the camptothecin series, cBR96-**10** (7 drug/mAb) was incubated in mouse plasma, and the appearance of free drug was assessed by a calibrated LC/MS assay. After 14 d at 37 °C, the free drug (**2**) signal was below the limit of detection of the assay, which is <1% of the theoretical maximum drug release. This suggests that the carbamate linkage is stable to hydrolysis in mouse plasma. Control experiments established efficient recovery of free drug from the matrix.

In Vitro Biological Evaluation. The activities of ADCs containing 7-butyl-10-amino-CPT (**2**) incorporated via dipeptide (**4**) or glucuronide (**10**) drug linker were assessed on Karpas 299 (CD30+) ALCL and H3396 (LeY+) breast carcinoma cell lines following 4 or 8 d treatment (Table 1). ADCs comprising dipeptide drug linker **4** displayed negligible activity following a 4 d treatment (data not shown). When the treatment time was extended to 8 d, modest immunologically specific activity was observed. ADCs bearing glucuronide drug linker **10** were weakly

[a] Cells were treated with test articles for 4 d, and cell viability was determined by resazurin conversion. The IC_{50} values represent the concentrations (nM) of the drug component of the ADC. [b] IC_{50} values are greater than the highest concentration tested.

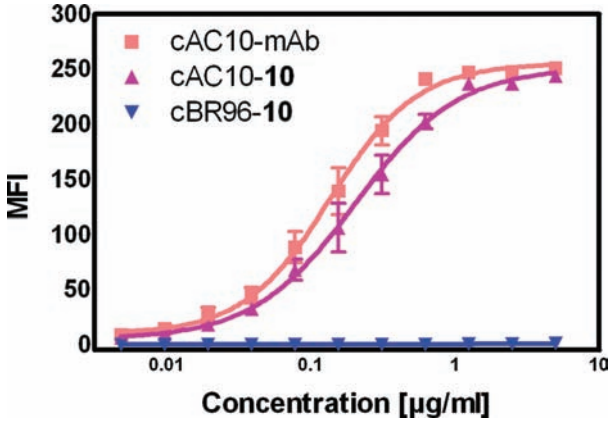

Figure 2. FACS analysis of antigen binding of glucuronide drug linker cAC10-**10** relative to cAC10 mAb and nonbinding cBR96-**10** on CD30+ Karpas 299 cells.

active, albeit more potent than mAb−**4** conjugates, over the course of a 4 d drug treatment with IC_{50} values of 160 nM and 22 nM on Karpas 299 and H3396, respectively. When drug treatment was extended to 8 d, cAC10−**10** displayed a substantial increase in potency on Karpas 299. An analogous increase in potency on H3396 cells was not observed. The activities of conjugates comprising h1F6 or cAC10 and **5** and **11** were tested on Karpas 299, L540cy (Hodgkin lymphoma), and Caki-1 (renal cell carcinoma) following a 4 d treatment (Table 2). The conjugates were immunologically specific and highly potent on the three cell lines, with IC_{50} values ranging from 0.23 to 4.4 nM across the panel.

In Vivo Biological Evaluation. In light of the superior in vitro potency of ADCs armed with camptothecin analogue **3** relative to **2**, in vivo evaluation focused on ADCs bearing drug linkers **5** and **11**. ADCs were initially evaluated for mouse tolerability prior to efficacy experiments. BALB/c mice were injected once ip with cAC10−**5** (4 drug/mAb) or cAC10−**11** (4 drug/mAb) and evaluated for weight loss and morbidity. Both the glucuronide (cAC10−**11**) and the val-cit dipeptide (cAC10−**5**) conjugates were well-tolerated at 50 mg/kg. At 100 mg/kg, cAC10−**5** resulted in moderate weight loss (5−10%) and cAC10−**11** was toxic. From these results, the maximum tolerated doses (MTD) for cAC10−**5** and cAC10−**11** are approximately 100 mg/kg and 50 mg/kg, respectively.

An efficacy experiment with immunoconjugates h1F6−**5** and h1F6−**11** was carried out in the Caki-1 renal cell carcinoma model. Nude mice bearing Caki-1 tumors were treated four times every 4 d (q4d × 4) with ADCs once the average tumor size was approximately 100 mm^3 (Figure 3). At 3 mg/kg, the val-cit immunoconjugate (h1F6−**5**) had no effect on tumor growth. In contrast, the glucuronide conjugate (h1F6−**11**) induced substantial tumor growth delay. At 10 mg/kg, the glucuronide conjugate again

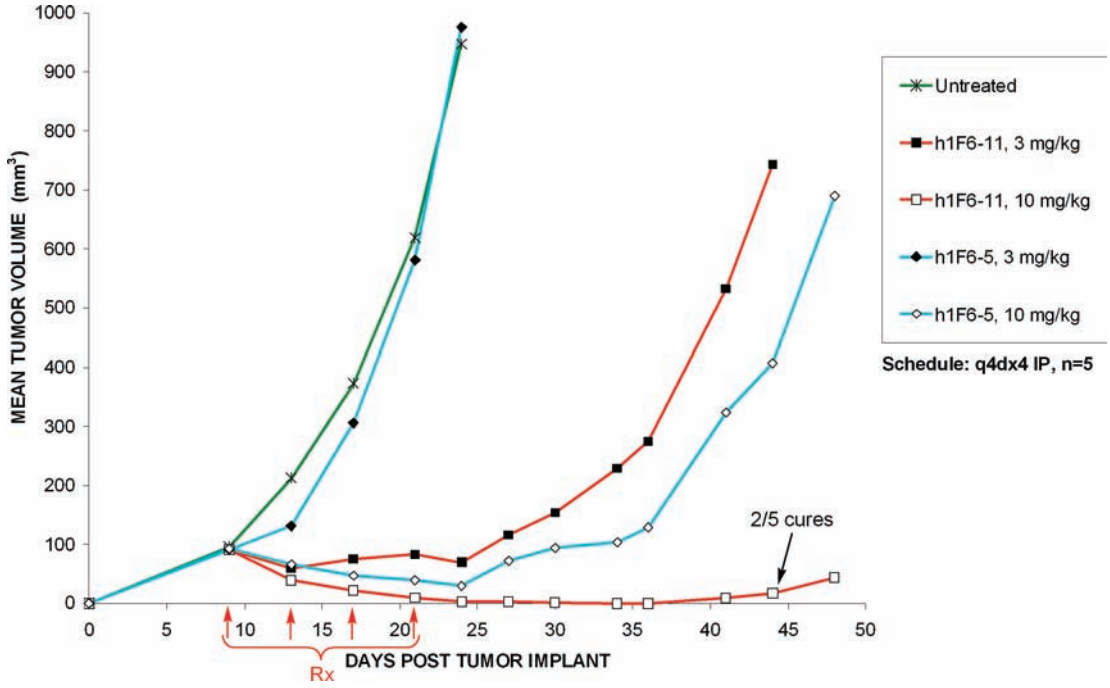

Figure 3. In vivo efficacy of camptothecin ADCs in a Caki-1 renal cell carcinoma xenograft model; all ADCs contain 4 dr/mAb.

outperformed the val-cit conjugate. Mice treated with h1F6−**5** achieved 5/5 partial regressions, while mice treated with h1F6−**11** had 5/5 complete regressions with 2/5 mice cured.

DISCUSSION

Early work on ADCs established drug potency as an important parameter contributing to the conjugate activity. The camptothecin analogues employed here are substantially more potent than CPT or related clinical analogues, irinotecan and topotecan. Among the two CPT analogues evaluated, the more potent analogue (**3**) provided significantly more potent ADCs (Tables 1 and 2). ADCs bearing **3** provided in vitro potencies 20- to 400-fold greater than CPT ADCs (*18*). More recently, ADCs bearing SN-38 were reported to be active at the single-digit nM level (*20*). Specificity controls were not included, however, and it is possible that nonspecific drug release from the carbonate or ester drug linker significantly contributed to the observed conjugate potency. The ADCs bearing **3** led to high levels of immunologically specific cell kill at subsaturating doses (Table 2). Immunological specificity implies that the linker is stable since the cells were continuously exposed to the ADCs for 96 h. The binding ADCs were less potent than the respective free drugs (Tables 1 and 2). It is possible that free drug accumulation via passive cellular uptake over the course of the 96 h treatment exceeds the intracellular drug concentration achieved through antigen-mediated delivery. This has been previously observed with other ADCs (*5*, *35*, *36*).

Camptothecins are an especially compelling drug class for ADCs because they can be produced synthetically, modified to give analogues with high potency, and have been shown to possess pronounced clinical activity. However, aqueous insolubility presents a significant challenge in utilizing the CPT drug class. Clinical camptothecins, irinotecan and topotecan, were designed to overcome this by inclusion of solubilizing amine groups (*15*). From the standpoint of ADC development, upon conjugation, CPT hydrophobicity can lead to significant mAb aggregation. The glucuronide linker system is ideal in addressing this issue. The glucuronide drug linkers consistently provided monomeric ADCs when loaded at 4 and 8 drug/mAb, whereas the dipeptide drug linkers tended to provide ADCs with a greater degree of aggregation (Tables 1 and 2). This is consistent with our previous work with hydrophobic minor groove binders (*37*).

We have described the preparation and biological evaluation of ADCs empowered with camptothecin analogues that were selected on the basis of the presence of an amine functional group and enhanced cellular potency. The amine functional group was deemed important because it facilitated the use of carbamate-based linkers such as the val-cit dipeptide and the glucuronide linker systems. On the basis of these results, immunoconjugates comprising the more potent analogue (**3**) linked via val-cit dipeptide or glucuronide drug linker systems are well-suited for further development.

Received March 14, 2009; Revised Manuscript Received April 30, 2009

Thrombosis underlies numerous life-threatening cardiovascular syndromes. Development of thrombosis-specific molecular imaging agents to detect and monitor thrombogenesis and fibrinolysis in vivo could improve the diagnosis, risk stratification, and treatment of thrombosis syndromes. To this end, we have synthesized efficient multimodal nanoagents targeted to two different constituents of thrombi, namely, fibrin and activated factor XIII. These agents are targeted via the conjugation of peptide-targeting ligands to the surface of fluorescently labeled magnetic nanoparticles. As demonstrated by in vitro and in vivo studies, both nanoagents possess high affinities for thrombi, and enable mutimodal fluorescence and magnetic resonance imaging.

INTRODUCTION

Thrombosis is characterized by the accumulation of platelets and fibrin induced by the activation of coagulation factors. Thrombosis underlies several life-threatening cardiovascular syndromes including myocardial infarction, stroke, and pulmonary embolism, leading causes of mortality in the developed world (*1*). It is thus important to localize and characterize thrombi in vivo, in order to determine treatment options and their resultant efficacy.

Several conventional and molecular imaging strategies have been developed in order to visualize thrombus formation (*2*). Platelets, which adhere to the damaged vessel wall, have been fluorescently or radioactively labeled in order to visualize their accumulation (*3*−*5*). Alternately, agents targeted to specific molecules within the thrombus have been investigated (*3, 4, 6*−*9*). We have previously reported on the synthesis of a peptide-based fluorescent imaging agent targeted to activated factor XIII (FXIIIa) (*9*). FXIIIa is responsible for the cross-linking of fibrin α- and γ-chains, increasing fibrinolytic resistance, and is a hallmark of biologically acute thrombi, as its activity diminishes over time. This peptide agent is covalently cross-linked into clots actively undergoing thrombogenesis by FXIIIa, thereby exhibiting a time-dependent increase in the fluorescence signal and as such may be utilized to distinguish acute from subacute thrombi in vivo.

Another thrombosis-targeting strategy utilizes the noncovalent binding of a fibrin-avid peptide to thrombi. The tripeptide Gly-Pro-Arg comprises the N-terminal sequence of the α-chain of fibrin, and can inhibit fibrin and thrombin clotting (*10*). Subsequent iterations have identified the peptide Gly-Pro-Arg-Pro-Pro (GPRPP) as a highly avid fibrin-binding agent possessing increased resistance to proteolysis (*8, 11*). This pentapeptide has previously been used to scintigraphically image pulmonary emboli in swine by the addition of a C-terminal radionuclide binding sequence, Gly-(D)-Ala-Gly-Gly (GAGG), and labeling with ^{99m}Tc. However, few fibrin-targeted molecular imaging agents are available for high-resolution in vivo optical/near-infrared fluorescence (NIRF) imaging, a modality that offers utility in noninvasive imaging (*12*), intravital microscopy (*2*), as well as high-resolution intravascular molecular imaging catheters compatible with human coronary arteries (*13*).

Table 1. Thrombus-Targeted Imaging Agents

agent	targeting sequence	target	fluorophore
CLIO-Cy7	n/a	n/a	Cy7
CLIO-GPRPP	GP**R**PPGGSKGC-NH2	fibrin	Cy7
CLIO-GPSPP	GP**S**PPGGSKGC-NH2	fibrin control	Cy7
CLIO-VT680	n/a	n/a	VT680
CLIO-FXIII	GN**Q**EQVSPLTLLKC-NH2	FXIIIa	VT680
CLIO-CXIII	GN**A**EQVSPLTLLKC-NH2	FXIIIa control	VT680

Herein, we discuss the synthesis and characterization of two multimodal thrombus-targeted nanoagents exhibiting either covalent or noncovalent binding to thrombi. Functionalization of fluorescently labeled cross-linked iron oxide (CLIO) nanoparticles with targeting peptides for fibrin or FXIIIa yields thrombus-targeted agents detectable by both magnetic resonance (MR) and optical imaging modalities (Table 1). These agents utilize two spectrally distinct fluorescence channels, which allows for the simultaneous monitoring of thrombus formation, the determination of biological thrombus age, and the efficacy of thrombolytic therapies.

EXPERIMENTAL PROCEDURES

General. All solvents and reagents used were of reagent grade or better and were used as received. Cross-linked iron oxide nanoparticles (CLIO) were synthesized as described previously and obtained from the Center for Molecular Imaging Research Chemistry Core (*14, 15*). All peptides were synthesized by the Peptide Synthesis/Protein Sequencing Core at the Massachusetts General Hospital using conventional Fmoc synthesis strategies on Rink amide resin. The peptides (0.1 mmol scale) were received on Rink amide resin with the N-terminus *t*-butoxucarbonyl (Boc)-protected. High performance liquid chromatography (HPLC) was performed on a Varian ProStar HPLC. Gradients were run with buffer A (H_2O/0.1% trifluoroacetic acid (TFA)) and buffer B (acetonitrile/10% buffer A). For analytical HPLC, a Varian C-18 reversed-phase column was used with

dimensions of 250 mm × 4.6 mm. For semipreparative HPLC, a Varian C-18 reversed-phase column was used with dimensions of 250 mm × 21.2 mm. UV−vis spectra were recorded on a Cary 50 spectrophotometer and fluorescence emission spectra on a Cary Eclipse spectrofluorometer. Electrospray ionization (ESI) mass spectra were recorded on a Waters Micromass ZQ mass spectrometer in the solvents indicated. Near-infrared fluorophores in the far-red (VT680, 660 nm excitation and 735 nm emission) or near-infrared channel (Cy7, 762 nm excitation and 800 nm emission) were employed for agent synthesis to enable translatable near-infrared fluorescence imaging. Fluorescence reflectance imaging was accomplished on either a Siemens BonSAI or Olympus OV100 system. To augment spin dephasing-induced MRI signal changes from iron oxide nanoparticles, T_2*-weighted MR imaging was conducted on a 4.7 T Bruker Pharmascan.

Peptide Cleavage and Purification. The peptide resin was swelled in *N*,*N*-dimethylformamide (DMF) for 15 min and filtered. The peptide was then cleaved from the resin and deprotected by reaction with TFA/triisopropylsilane/water (95:2.5:2.5, 5 mL) for 3 h. The resin was filtered, and the peptide contained in the supernatant was precipitated by the addition of excess methyl *tert*-butyl ether (MTBE). The precipitate was recovered following centrifugation and washed twice more with MTBE. The resulting crude peptide was purified by HPLC.

GNQEQVSPLTLLKC Peptide for Factor XIII (FXIII) Targeting. The peptide was purified by HPLC (gradient, 80% buffer A to 20% buffer A over 30 min; retention time (*rt*) = 12.8 min). ESI+ MS (30 V, H_2O/0.1% TFA) *m*/*z* = 1715.0 (MH^+).

GNAEQVSPLTLLKC Peptide Control (CXIII). The above FXIII peptide underwent a single amino acid substitution (Q → A) to generate a control peptide with weak binding by FXIII (*9*). The CXIII peptide was purified by HPLC (gradient, 80% buffer A to 20% buffer A over 30 min; *rt* = 13.3 min). ESI+ MS (30 V, H_2O/0.1% TFA) *m*/*z* = 1658.1 (MH^+).

GPRPPGGSKGC Peptide for Fibrin Targeting (GPRPP). The peptide was purified by HPLC (gradient, 100% buffer A to 60% buffer A over 30 min; *rt* = 10.1 min). ESI+ MS (30 V, H_2O/0.1% TFA) *m*/*z* = 941.8 (MH^+).

GPSPPGGSKGC Peptide Control Peptide (GPSPP). The control peptide with minimal binding to fibrin was purified by HPLC (gradient, 100% buffer A to 60% buffer A over 30 min; *rt* = 11.1 min). ESI+ MS (30 V, H_2O/0.1% TFA) *m*/*z* = 1011.8 (MH^+).

CLIO-VT680. To CLIO (20 mg) in PBS (2.37 mL) was added the succinimidyl ester of VivoTag 680 (1 mg, VisEn Medical) dissolved in 400 μL of dimethylsulfoxide (DMSO). The reaction was allowed to proceed for 16 h, at which time it was purified by filtration through Sephadex G-25 to yield 3 dyes per CLIO, as determined spectrophotometrically.

CLIO-Cy7. To CLIO (20 mg) in PBS (2.37 mL) was added the succinimidyl ester of Cy7 (1 mg, GE Healthcare) dissolved in 400 μL of dimethylsulfoxide (DMSO). The reaction was allowed to proceed for 16 h, at which time it was purified by filtration through Sephadex G-25 to yield 2 dyes per CLIO, as determined spectrophotometrically.

FXIII-CLIO-VT680 (CLIO-FXIII). To CLIO-VT680 (5 mg) in PBS (602 μL) was added succinimidyl iodoacetate (SIA, 5 mg) dissolved in DMSO (100 μL) The reaction proceeded for 4 h, at which time it was purified by filtration through Sephadex G-25. To the resulting particle was added the **FXIII** peptide (5 mg) dissolved in DMSO (200 μL). The reaction was allowed to proceed for 16 h, at which time it was purified by filtration through Sephadex G-25. This procedure typically conjugates 10−12 peptides per particle, as described previously (*16*).

CXIII-CLIO-VT680 (CLIO-CXIII). CLIO-CXIII was synthesized as described above for **CLIO-FXIII** using the **CXIII** peptide.

GPRPPGGSKGC-CLIO-Cy7 (CLIO-GPRPP). To CLIO-Cy7 (5 mg) in PBS (531 μL) was added succinimidyl iodoacetate (SIA, 5 mg) dissolved in DMSO (100 μL) The reaction proceeded for 3 h, at which time it was purified by filtration through Sephadex G-25. To the resulting particle was added the **GPRPP** peptide (5 mg) dissolved in DMSO (200 μL). The reaction was allowed to proceed for 16 h, at which time it was purified by filtration through Sephadex G-25. This procedure typically conjugates 10−12 peptides per particle, as described previously (*16*).

GPSPPGGSKGC-CLIO-Cy7 (*CLIO-GPSPP*). CLIO-GPSPP was synthesized as described above for **CLIO-GPRPP** using the **GPSPP** peptide.

In Vitro Clot Binding. Clots were created from fresh frozen plasma (FFP) in 96 well plates. Each well received 180 μL of FFP, 10 μL of 0.4 M $CaCl_2$, and 10 μL of thrombin (0.1 U/μL PBS). The plate was incubated at 37 °C for 90 min to form plasma clots. Thereafter, 6 μg of various nanoparticle preparations (∼2 mg Fe/mL) was added to respective wells and then incubated at 37 °C for an additional 30 min. The clots were then washed twice with PBS and centrifuged at 500 rpm for 10 min. They were then washed twice more with PBS and imaged by fluorescence reflectance imaging on the BonSAI system in the Cy7 or VT680 channels (exposure times from 1−10 s).

For magnetic resonance (MR) imaging, representative clots from the above FRI experiment were embedded in 2% agar and imaged using a T_2*-weighted pulse sequence with the following imaging parameters: multislice 2D fast low angle shot (FLASH) sequence, repetition time (*TR*) 500 ms, echo time (*TE*) 8 ms, flip angle 30°, matrix 128 × 128, in-plane resolution 0.3 × 0.3 mm, slice thickness 0.8 mm, and 8 averages. Following MR imaging, the gel was imaged on the OV100 system for correlation of fluorescence and magnetic resonance images.

In Vivo Thrombosis Binding. Animal studies were approved by the Hospital Subcommittee of Research Animal Care. In vivo thrombi were induced by ferric chloride ($FeCl_3$) injury to the jugular vein (*6*, *9*). Mice were anesthetized using an intraperiotenal (IP) ketamine (50 mg/mL, 330 μL), xylazine (100 mg/mL, 50 μL), and sterile saline (380 μL) mixture. Each mouse received a 60 μL IP induction dose of the resulting mixture, followed by 30−50 μL IP hourly for continued anesthesia. A paramedian neck incision was then made exposing approximately 1 cm of the jugular vein. $FeCl_3$ was locally applied to the jugular vein using a 2 mm × 1 mm strip of Whatman No. 1 filter paper soaked in 10% $FeCl_3$ in distilled water. The filter paper was applied to the anterior surface of the vein for 5 min. Thereafter, the filter paper was removed, and the injured vessel was irrigated with sterile saline. At 30 min after injury, a respective thrombus-targeted agent (CLIO-GPRPP, CLIO-FXIII) or control agent (CLIO-GPSPP, CLIO-CXIII) was injected i.v. via a tail vein catheter. All agents were injected at 7.5 mg Fe/kg mouse (200 μL total volume). Thrombus binding by imaging agents was determined by ex vivo fluorescence reflectance imaging (FRI) of the resected thrombosed and contralateral control jugular veins. At 30 min after injection of the agent, the mice were sacrificed by cervical dislocation and perfused with 20 mL saline. The jugular vein containing the thrombus and contralateral control jugular vein were then excised and imaged in the Cy7 (fibrin) or VT680 (FXIII) channel on an OV100 FRI system.

Image Analysis. Image analyses were performed with ImageJ 1.37v software (NIH) using manual region-of-interest tracing. Signal-to-background ratios (SBRs) were determined using the formula SBR = mean thrombus signal/mean background signal.

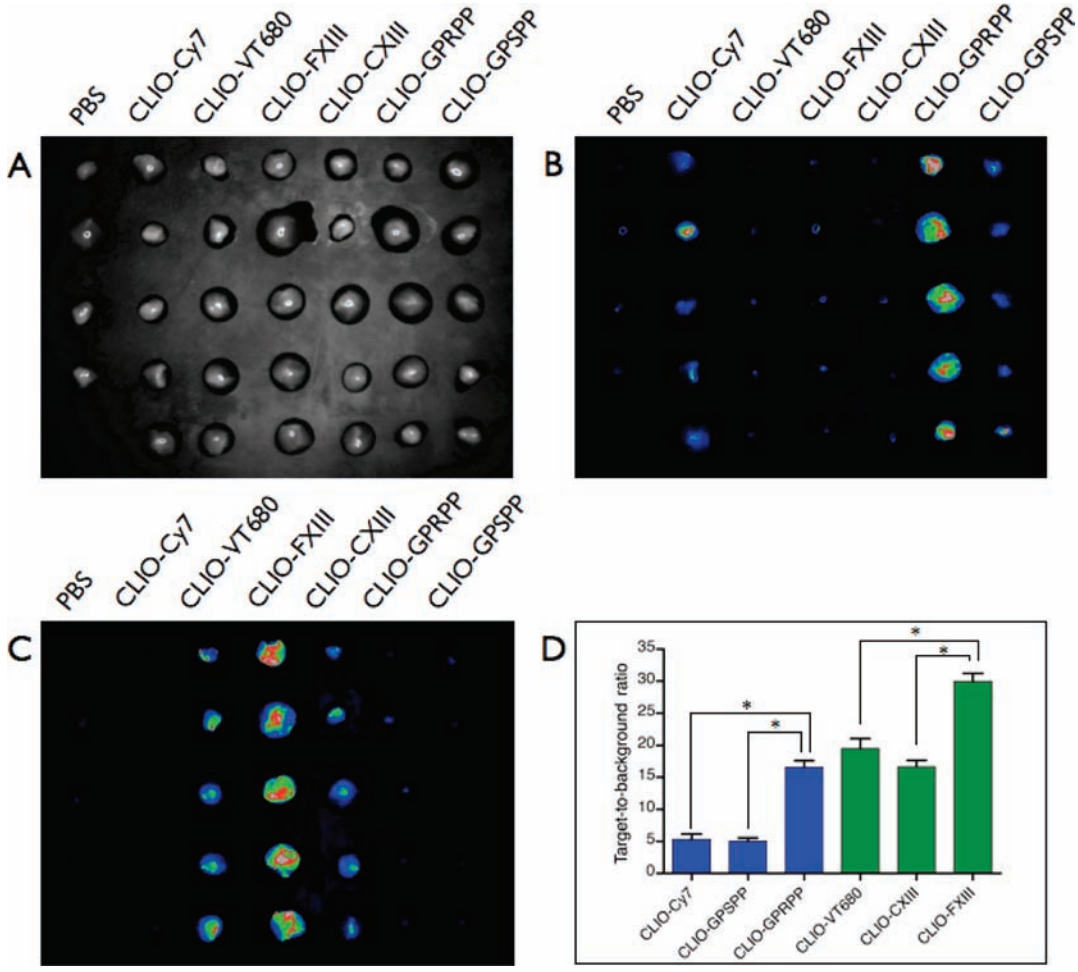

Figure 1. Fluorescence reflectance imaging of in vitro binding of agents to FFP clots (A, bright field image) as imaged in the (B) Cy7 and (C) VT680 channels. (D) The target-to-background ratios of the targeted agents were significantly greater than those of the control agents. All differences were statistically significant (*$P < 0.0001$).

For in vitro FRI studies, background was defined as the fluorescence signal from the clots incubated with PBS. For ex vivo FRI studies, background was defined as the nonthrombosed contralateral jugular vein. The statistical significance of the results was calculated using either a one way ANOVA or unpaired *t*-test, depending upon the number of groups in the comparison.

RESULTS AND DISCUSSION

Thrombus-Targeted Probe Synthesis. The fibrin-avid pentapeptide Gly-Pro-Arg-Pro-Pro was synthesized with the addition of the C-terminal sequence Gly-Gly-Ser-Lys-Gly-Cys (GGSKGC), in order to impart functionality on the peptide. GGSKGC has been used with peptides derived from phage screening libraries and contains an amine for modification via amide bond formation as well as a free thiol for conjugation via disulfide or thioester bonds. The peptide, Gly-Pro-Arg-Pro-Pro-Gly-Gly-Ser-Lys-Gly-Cys (**GPRPP** peptide) was synthesized by typical Fmoc methods, with Boc-protection at the N-terminus. This allows for the glycine to remain unmodified after cleavage from the resin, preventing a possible loss of binding affinity due to steric interference. Similar to the fibrin-targeting peptide, an analogous control peptide with scant FXIII avidity was synthesized with one amino acid replaced (*9*). The sequence Gly-Pro-Ser-Pro was previously shown to have minimal fibrin binding (*10*) and thus served as a suitable control peptide. This peptide sequence was initially identified in defective human fibrinogen (fibrinogen Detroit) (*17*). The peptide, Gly-Pro-Ser-Pro-Pro-Gly-Gly-Ser-Lys-Gly-Cys (**GPSPP** peptide), was synthesized as described above for the **GPRPP** peptide.

The fibrin-targeted nanoparticulate agents (**GPRPP-CLIO** and **GPSPP-CLIO**) were synthesized by modification of cross-linked iron oxide (CLIO) nanoparticles with the respective peptides. CLIO consists of a 5 nm iron oxide core surrounded by a dextran coating that has been cross-linked with epichlorohydrin and aminated (*14*). Initially, the particles were appended with Cy7 by reaction of the amines with the succinimidyl ester of the dye to yield 2 fluorophores per particle, as determined spectrophotometrically. The resulting magnetofluorescent particle was then reacted with succinimidyl iodoacetate (SIA) in order to impart reactivity toward sulfhydryl groups and subsequently reacted with the C-terminal cysteine of the peptide. Often, peptides are modified with a chromophore, such as fluorescein (FITC), prior to conjugation to the particle, in order to calculate the number of peptides per particle. In this case, this is not possible as the ultimate utility of these particles is the monitoring of clot formation in vivo, and the FITC channel is often necessary for fluorescence angiography during multichannel intravital microscopy. As the procedure for the conjugation of the peptide to the particle is well established, it is assumed that there are approximately 10 peptides per nanoparticle (*16*).

The nanoagent targeted to FXIIIa and its corresponding control (CXIII) were synthesized using the peptide sequences previously reported (*9, 18*). The N-terminus of α_2-antiplasmin,

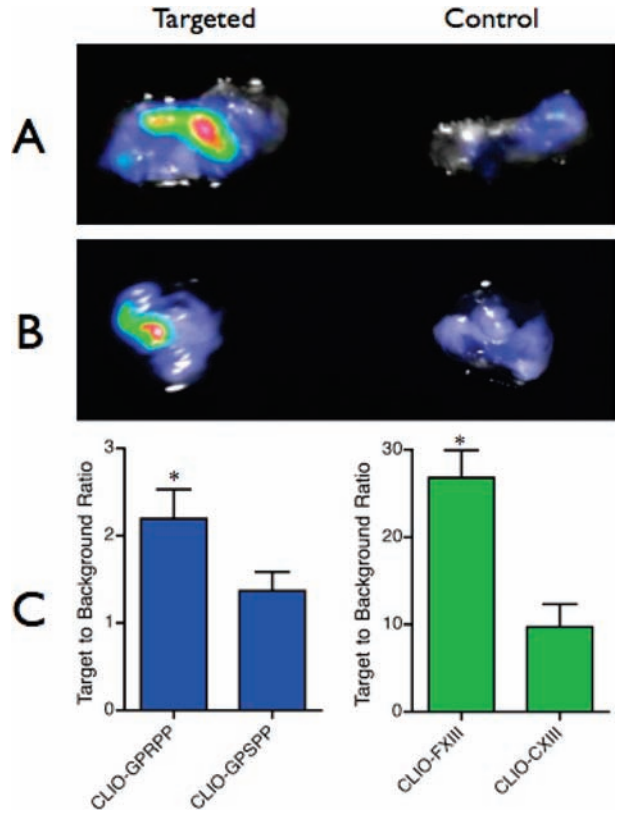

Figure 3. In vivo targeting of acute thrombi. Representative ex vivo FRI composite images of fibrin-targeted (A) and FXIII-targeted (B) nanoagents, and their respective control agents. The fluorescence images of the fibrin-targeted agent were acquired in the Cy7 channel and the FXIII-targeted agent in the VT680 channel. (C) Ex vivo FRI signal-to-background ratios for all agents studied (*$P < 0.05$).

N_{13}QEQVSPLTLLK$_{24}$, is specifically cross-linked into thrombi by the transglutaminase FXIIIa via a covalent bond between the glutamine 14 residue and the ε-amino group of a lysine residing within fibrin. In order to facilitate use as an imaging agent, this sequence was modified at its N-terminus with a glycine and at its C-terminus with a tryptophan spacer and a cysteine, to allow for conjugation to a particle. The control peptide sequence was identical to the FXIII peptide with the exception of an alanine replacement of glutamine 14. This modification results in negligible binding of the peptide to FXIII (*9*, *18*).

Analogous to the fibrin-targeted nanoparticle synthesis, the FXIII and CXIII peptides were conjugated to CLIO via the C-terminal cysteine after modification of the particle surface with SIA. The main difference between the nanoplatforms utilized for FXIIIa and fibrin is the wavelength of the fluorescent dye. For CLIO-FXIII, we chose to utilize VT680-labeled CLIO, as this will allow for simultaneous in vivo imaging of the accumulation of the two agents as the excitation and emission wavelengths of Cy7 and VT680 are spectrally distinct, which enables simultaneous fluorescence imaging of FXIII and fibrin via multichannel fluorescence imaging approaches. Specifically, these agents can be utilized to localize thrombi via the fibrin-targeted nanoparticle and determine thrombus age and lysis potential via the FXIII-targeted agent.

In Vitro Clot Binding. The targeting ability of the synthesized agents was tested with fresh frozen plasma (FFP) clots. Clots were formed in 96-well plates by the addition of $CaCl_2$ and thrombin to FFP, followed by incubation for 90 min. The agents were then incubated with the clots for an additional 30 min and were washed and centrifuged to remove the unbound agent.

Fibrin. The plate was initially imaged by FRI in the Cy7 channel. Clots incubated with the fibrin-targeted imaging agent (**CLIO-GPRPP**) demonstrated considerably greater NIRF signal than clots incubated with control agents **CLIO-GPSPP** and **CLIO-Cy7** (Figure 1B). The signal-to-background ratio (SBR) of **CLIO-GPRPP** clots (16.6 $\pm$ 1.7) was more than 3-fold the SBR of control **CLIO-GPSPP** (5.0 $\pm$ 1.2) and **CLIO-Cy7** (5.3 $\pm$ 0.8).

FXIIIa. When imaged in the VT680 channel, clots incubated with the FXIIIa-targeted imaging agent (**CLIO-FXIII**) demonstrated considerably greater NIRF signal than clots incubated with control agents **CLIO-CXIII** and **CLIO-VT680** (Figure 1C). The SBR of **CLIO-FXIII** clots (30 $\pm$ 2.8) was more than 1.5-fold higher than the SBR of control **CLIO-CXIII** (16.6 $\pm$ 2.3) and **CLIO-VT680** (19.5 $\pm$ 3.4). This high level of control agent background suggests an intrinsic avidity of VT680-bearing CLIO for thrombi, given the much lower SBRs obtained for **CLIO-Cy7** incubated clots.

MRI. The multimodal capabilities of the nanoagents was next tested by MRI. Representative FFP clots from the above experiments were embedded within 2% agar (Figure 2A) and then underwent T_2*-weighted MR imaging at 4.7 T. Consistent with the well-known MRI signal effects of iron oxide nanoparticles, clots binding targeted CLIO agents (**CLIO-GPRPPP** and **CLIO-FXIII**) demonstrated strong MRI signal loss on T2*-weighted images resulting in high thrombus-to-agar contrast-to-noise ratios (CNR) of 50.4 and 30.6, respectively (Figure 2B). In contrast, clots incubated with the control agents (**CLIO-CXIII** and **CLIO-GPSPP**) demonstrated negligible signal changes resulting in low CNR values (8.6 and -1.2, respectively) (Figure 2B). FRI of the agar clot phantom after MRI confirmed increased deposition of the targeted FXIII nanoparticle in the VT680 channel (Figure 2C) and targeted fibrin nanoparticles in the Cy7 channel (Figure 2D), further illustrating the multimodal nature of the agents.

In Vivo Thrombosis Binding. The targeting ability of the nanoagents was tested in vivo in an $FeCl_3$-induced thrombosis

model in wild-type C57Bl6 mice. Application of 10% $FeCl_3$ laden filter paper directly to the jugular vein for 5 min induced thrombus formation. After 30 min, mice were injected intravenously with targeted or control agents, followed by a 30 min circulation time. The thombosed jugular vein and contralateral normal jugular vein were resected and imaged by FRI. As is evident in Figure 3, the fibrin and FXIII-targeted agents preferentially accumulated within thrombi and generated higher SBR ratios as compared to those of their respective control agents. **CLIO-GPRPP** displayed a 1.6-fold greater SBR than the control particle, **CLIO-GPSPP** (SBR $= 2.19 \pm 0.33$ vs 1.37 ± 0.21, respectively), while the SBR for **CLIO-FXIII** was 2.7-fold greater than that of **CLIO-CXIII** (SBR $= 26.8 \pm 3.2$ vs 9.7 ± 2.6, respectively). The differences in the magnitude of the SBRs can be attributed to the sensitivity of the instrument in the distinct fluorescent channels. The longest wavelength channel, Cy7, is much less sensitive than the VT680 channel due to fewer photons being transmitted by the OV100 broadband light source. Longer acquisition times are thus required for image formation, which concomitantly produces greater background signals.

CONCLUSIONS

In this work, we demonstrate the synthesis of two novel multimodal nanoagents targeted to key molecules in thrombi, namely, fibrin and FXIIIa. In vitro clot studies demonstrated strong binding of the agents, which is detectable by near-infrared fluorescence and magnetic resonance imaging. In vivo thrombosis studies in mice further demonstrated that these nanoagents readily accumulated within vascular thrombi preferentially over analogously synthesized control agents. Further in vivo studies will utilize these agents to image the biological expression of fibrin and factor XIII in acute and subacute thrombi, to examine the role of fibrin and FXIIIa in predicting fibrinolysis and stent thrombosis.

ACKNOWLEDGMENT

This work was supported by NIH grants U24-CA092782 (to R.W.) and U01-HL080731 (to J.R.M., F.A.J., and R.W.), American Heart Association Scientist Development Grant (to F.A.J.), Howard Hughes Medical Institute Career Development Award (to F.A.J.), and NIH grants U54-CA119349 (to R.W.) and U54-CA126515 (to R.W.). We thank Dr. Ashok Khatri for synthesizing the peptide, Dr. Matthias Nahrendorf and Gregory Wojtkiewicz, MS for assistance with MRI, and Zach Mueller for assistance with FRI.

Received March 18, 2009; Revised Manuscript Received April 8, 2009

Nuclease-resistant hybridization probes for long-term intracellular RNA imaging were synthesized. Newly designed probes with a 2′-*O*-MeRNA structure showed high resistance against nucleases, which is in contrast to the low resistance of DNA probes. These modified probes retained the function on the on−off switching of fluorescence emission in sensitive response to RNA recognition, based on the mechanism of interdye excitonic interaction, and functioned effectively for the long-term monitoring of RNA-stained living cells.

INTRODUCTION

Recent developments of techniques for visualizing compounds, organs, and processes in the living cell have paved the way for advanced studies of cell function. The visualization of intracellular RNA is, however, still immature, compared to the analysis of live cells using proteins fused with fluorescent proteins. It is mainly the fluorescence-labeled nucleic acid probes that are used for the visualization of RNA (*1*−*5*). Conventional probes always emit fluorescence when excitation light is shone on probe-containing RNA samples. Therefore, fluorescence from probes that do not take part in labeling of the target RNA causes strong background fluorescence. Furthermore, the DNA backbone of probes is readily digested by intracellular nucleases in a short time, and thus conventional probes, even well-known molecular beacon DNA probes (*6, 7*), are not suitable for long-term RNA monitoring in a living cell.

We recently developed a doubly thiazole orange-labeled probe to achieve high fluorescence intensity for a hybrid with the target DNA or RNA, and effective quenching for a single-strand state of the probe (*8*−*10*). Emission from the probe was controlled by interdye excitonic interaction. The clear change in fluorescence intensity depending on hybridization is useful for visible RNA analysis (*10*). However, this probe has a 2′-deoxyribose backbone and will therefore be unstable under conditions where nucleases are present. The usefulness of the probe may be limited to in vitro or short-term experiments in cells before degradation by cellular nucleases. For the long-term observation of target RNA in living cells, a new type of the probe structure is required that is not degraded by nucleases and maintains the hybridization-sensitive on−off fluorescence switching function.

Here, we report on the novel design of an RNA detection probe that is tolerant to exposure to intracellular nucleases. A sugar-modified structure (2′-*O*-MeRNA) was adopted for a new exciton-controlled probe. The probe showed high resistance against nucleases and maintained a high on−off performance as a hybridization-sensitive fluorescent probe.

EXPERIMENTAL PROCEDURES

Probe Synthesis. Probes were synthesized by a conventional phosphoramidite method. The diamino-modified nucleoside phosphoramidite was synthesized as described in our previous paper (*8*). The synthesized oligomer was cleaved from the support with 28% aqueous ammonia and deprotected at 55 °C for 8 h. After removal of ammonia from the solution under reduced pressure, the unlabeled oligomer was purified by reversed-phase HPLC on a 5-ODS-H column (10 mm × 150 mm, elution with a solvent mixture of 0.1 M triethylammonium acetate (TEAA), pH 7.0, linear gradient over 30 min from 5% to 37.5% acetonitrile at a flow rate of 3.0 mL/min).

[a] X denotes a doubly thiazole orange-labeled deoxyuridine as shown in Figure 1. [b] Probes have 2′-*O*-methylribose backbones, except X that has a 2′-deoxyribose.

A solution of the succinimidyl ester of dye (50 equiv to an active amino group of the synthesized oligomer) in DMF was added to a solution of deprotected oligomer in 100 mM sodium carbonate buffer (pH 9.0) and incubated at 25 °C for 16 h. The reaction mixture was diluted with ethanol. After centrifuging at 4 °C for 20 min, the supernatant was removed. The residue was dissolved in a small volume of water, and then, the solution was passed through a 0.45 μm filter. The product was purified by reversed-phase HPLC on a 5-ODS-H column (10 mm × 150 mm, elution with a solvent mixture of 0.1 M TEAA, pH 7.0, linear gradient over 30 min from 5% to 37.5% acetonitrile at a flow rate of 3.0 mL/min). The synthesized probes are listed in Table 1. They were identified by MALDI-TOF mass spectrometry. Melting Temperature. All melting temperature (T_m) values of probe−RNA duplexes (1 μM, final duplex concentration) were recorded in a HEPES-buffered solution (120 mM KCl, 5 mM NaCl, 25 mM HEPES, pH 7.2). Absorbance vs temperature profiles were measured at 260 nm. The absorbance of the samples at 260 nm was monitored from 10 to 90 °C at a heating rate of 0.5 °C/min. First derivatives were calculated from these profiles to determine the T_m values.

Absorption and Fluorescence Data. Absorption and fluorescence spectra of the probes (1.0 μM single-stranded or duplex concentration) were measured in a HEPES-buffered solution (120 mM KCl, 5 mM NaCl, 25 mM HEPES, pH 7.2), using a quartz cuvette with a 1 cm path length. The excitation and emission bandwidths were 1.5 nm. The fluorescence quantum yield (Φ) was determined using 9,10-diphenylanthracene as a reference, with a known value of $\Phi = 0.95$ in ethanol. The quantum yield was calculated using the following equation.

$$\Phi_{(S)}/\Phi_{(R)} = [A_{(S)}/A_{(R)}] \times [(Abs)_{(R)}/(Abs)_{(S)}] \times [n_{(S)}^2/n_{(R)}^2] \quad (1)$$

Here, $\Phi_{(S)}$ and $\Phi_{(R)}$ are the fluorescence quantum yields of the sample and the reference, respectively. The terms $A_{(S)}$ and $A_{(R)}$ are the areas under the fluorescence spectra of the sample and the reference, respectively; $(Abs)_{(S)}$ and $(Abs)_{(R)}$ are the optical densities of the sample and the reference solution at the wavelength of excitation, respectively; and $n_{(S)}$ and $n_{(R)}$ are the values of the refractive index for the solvents used for the sample ($n_{(S)} = 1.333$) and the reference ($n_{(R)} = 1.383$).

Cell Culture. Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were purchased from GIBCO. HeLa cells were cultured at 37 °C in DMEM containing 10% heat-inactivated FBS, 25 U/mL penicillin, and 25 mg/mL streptomycin, under a humidified atmosphere with 5% CO_2. For experimental use, cells (passage numbers 5−9) were cultured in glass-based dishes. Prior to microscope observation, the culture medium was washed and exchanged to phenol red free DMEM.

Transfection and Cell Imaging. A probe solution in water (50 μM, 2 μL) was introduced using 2 μL of lipofectamine 2000 (Invitrogen). After incubation for 1 h in a solution of lipofectamine 2000 and probe, cells were washed twice with PBS and observed in phenol red free DMEM. Cells were maintained under culturing conditions using an incubation system during the observation. Images were acquired with a motorized inverted microscope (Axio Observer Z1; Zeiss) equipped with a 20× objective and a filter set (ex 500/24−25, dm 520, em 542/25−27). Acquired images were analyzed and processed with *AxioVision 4.2*.

Digestion of Probe by Nucleases. Nuclease sensitivity was analyzed with single-stranded probes (200 pmol). Digestion of the probes with an exonuclease (Exonuclease I, Takara, 1.5 U) was performed at 37 °C in 67 mM glycine−KOH (pH 9.5, 50 μL), 6.7 mM $MgCl_2$, 1 mM dithiothreitol. Digestion of the probes with an endonuclease (S1 nuclease, Takara, 0.5 U) was performed at 37 °C in 50 μL buffer of 30 mM NaOAc (pH 4.6), 280 mM NaCl, 1 mM $ZnSO_4$. After the digestion treatment, the mixture was diluted with 500 μL ice-cold water and analyzed immediately by reversed-phase HPLC on a 5-ODS-H column (10 mm × 150 mm, elution with a solvent mixture of 0.1 M TEAA, pH 7.0, with a linear gradient over 24 min from 5% to 35% acetonitrile, at a flow rate of 3.0 mL/min). Probes were detected at 480 nm, and the quantities determined from the absorption peak areas. For the fluorescent spectra of single-stranded and hybridized probes, the reaction samples were used after 10 times dilution with HEPES buffer.

Digestion of RNA by RNaseH. A solution containing a probe and the complementary RNA (0.1 μM each) in 1600 μL HEPES buffer containing 5 mM magnesium chloride was prepared. The

time course data were recorded at 25 °C for 1 h, with and without 4 U RNaseH.

RESULTS AND DISCUSSION

Design and Synthesis. We designed a new hybridization-sensitive probe, which has both a 2′-*O*-methylribose backbone and a doubly fluorescence-labeled deoxyuridine unit (Figure 1). A modified nucleic acid containing 2′-*O*-methyl-RNA (2′-*O*-MeRNA) is known to bind more tightly to complementary RNA sequences than analogous DNA oligomers, and it has improved resistance to degradation by nucleases (*11, 12*). Four nucleoside phosphoramidites for 2′-*O*-MeRNA synthesis and a phosphoramidite of the 2′-deoxyuridine derivative with two amino linkers at C5 were used for probe synthesis using a conventional DNA synthesis method (*8*). Double fluorescence labeling was carried out by mixing the diamino-modified oligomer with the thiazole orange derivative with a carboxy-activated alkyl linker. Synthesized DNA and 2′-*O*-MeRNA probes are listed in Table 1.

Duplex Stability and Photophysics. 2′-*O*-MeRNA is known to exhibit higher affinity for RNA targets than the corresponding DNA, resulting in higher T_m values (*13, 14*). The T_m values of the hybrids of our new 2′-*O*-MeRNA probes with the complementary RNA (1 μM) were initially measured in a HEPES buffer solution (pH 7.2). The absorbance of the hybrids was monitored at 260 nm from 10 to 90 °C, and from these profiles, the first derivatives were calculated to determine the value of T_m. The hybrid of the 2′-*O*-MeRNA probe with the complementary RNA strand was thermally stable (Table 2). For example, a 2′-*O*-MeRNA probe, **Probe$_{omr}$1**, exhibited a 6 °C higher T_m value when bound to an RNA target **RNA1** than a DNA probe, **Probe$_{dna}$1**. Other 2′-*O*-MeRNA probes also showed similarly higher T_m values, except in the case of the polypyrimidine/polypurine hybrid, **Probe$_{omr}$5/RNA5**. The T_m values of probe−RNA hybrids were 4−16 °C higher compared with those

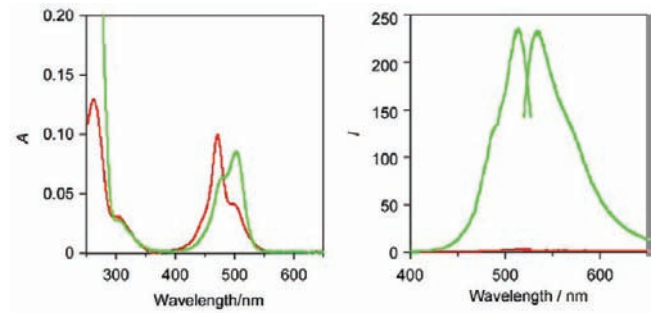

Figure 2. Absorption, and excitation and fluorescence spectra of a 2′-*O*-MeRNA probe. Absorption spectra of **Probe$_{omr}$5** (1 μM) are shown in the left panel and the excitation and fluorescence spectra (1 μM) are shown in the right panel. The spectra for single strand (ss, red) and hybrid with 1 equiv of **RNA5** (ds, green) were measured in 5 mM NaCl, 120 mM KCl, and 25 mM HEPES (pH 7.2)−KOH at 25 °C. Excitation spectra for ss and ds were measured for emission at 536 and 534 nm, respectively. The samples, ss and ds, for emission spectra were excited at 517 and 514 nm, respectively.

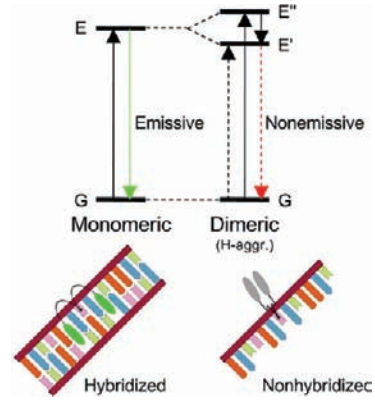

Figure 3. Schematic representation of the energy levels of the single- and double-stranded states of the hybridization probe controlled by excitonic interaction between thiazole orange dyes.

of the corresponding natural DNA/RNA duplexes, suggesting that two cationic probe dyes effectively bind to duplexes formed with the target sequence (*8*).

We next measured the absorption, excitation, and emission spectra of 2′-*O*-MeRNA probes before and after hybridization with the complementary RNA strands. Absorption spectra of the 2′-*O*-MeRNA probes exhibited the hybridization-dependent shift of absorption maximum. For example, the absorption band of **Probe$_{omr}$5** appeared at shorter wavelength (477 nm) more strongly when probes were in a single-stranded state, whereas an absorption band at longer wavelength (509 nm) became predominant when the probe was hybridized with the complementary RNA strand (Figure 2, left).

The shift of absorption maxima observed in the single-strand state can be explained in terms of the exciton coupling theory (*15*), in which the excited state of the dye H-aggregate (*16*−*18*) splits into two energy levels (Figure 3). On the basis of this theory, the transition to the upper excitonic state is allowed for the H-aggregates, which rapidly deactivate to the lower excitonic state. However, emission from the lower energy level is forbidden. On the other hand, hybridization with the complementary strand will result in dissociation of dye aggregates. The aggregate dissociation at the hybrid state was indicated by a shift of the absorption maximum to longer wavelength. Disruption of the excitonic interaction in the aggregate gave strong emission from the hybrid (Figure 2, right). The emission spectra of the 2′-*O*-MeRNA probes hybridized with the target RNA strands were observed at approximately 530 nm as a single broad

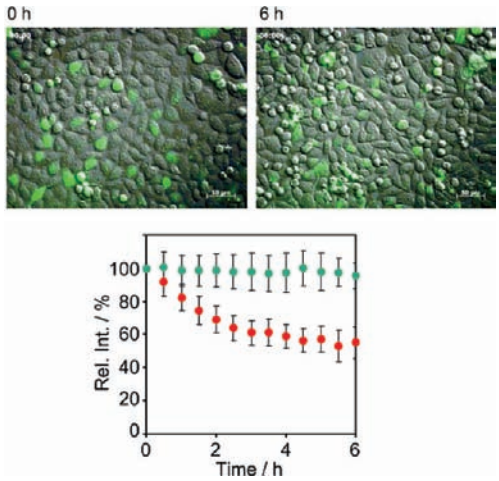

Figure 4. Differential interference contrast and fluorescence images of probe-transfected HeLa cells. The sample was excited through a 500/24−25 band-pass filter, and the fluorescence was collected through a 542 ± 25 nm band-pass filter. Bar: 50 μm. Above: an example of the transfection of 2′-*O*-MeRNA probe **Probe$_{omr}$5** to HeLa cells (0 and 6 h after 1 h incubation and washing processes). Below: plots of the average of fluorescence intensities (mean ± SD) observed for several transfected cells (**Probe$_{dna}$5** (red), $n = 10$; **Probe$_{omr}$5** (green), $n = 7$).

band. The strong emission of the hybrid of the 2′-*O*-MeRNA probe and RNA was at similar level to that of DNA probes. In contrast, the emission intensity of the probes before hybridization was much weaker. The excitation spectra displayed a single broad peak at approximately 510 nm, regardless of their structural states. This wavelength is in good agreement with the absorption band at the longer wavelength, indicating that the absorption participating in the fluorescence emission is only the band corresponding to the state released from excitonic interaction.

The on−off switching of 2′-*O*-MeRNA probes by hybridization with the complementary RNA is adequately effective to detect the complementary RNA. It is especially the fluorescence intensity ratio of the hybrid and nonhybrid of **Probe$_{omr}$2** and **Probe$_{omr}$3** that increased drastically, because of effective quenching in the nonhybrid state (Table 2). The sequence dependence of the fluorescence intensity ratio of the hybrid and nonhybrid did not deviate from the "self-dimer avoidance" rule for effective design of hybridization-sensitive fluorescent probes described in our previous paper (*9*). The modification of the sugar moiety from a hydrogen atom to a methoxy group did not inhibit fluorescence control by the excitonic interaction of thiazole orange dyes in a probe.

Fluorescence in Long-Term Cell Observation. Having established that the 2′-*O*-MeRNA probe is an effective RNA detection probe, the fluorescence behavior of the probe in living cells was investigated next. The probes capable of binding to the polyA tail of mRNA, **Probe$_{dna}$5** and **Probe$_{omr}$5**, were transfected to HeLa cells using one of the common transfection reagents, lipofectamine 2000. After incubation for 1 h, the cells were washed twice with PBS buffer. In this incubation, approximately 37% of cells in the observation field emitted fluorescence at about 542 nm, which was observed mainly in nuclei. The retention of the fluorescence intensity was determined using the average of the total intensity of fluorescence from several cells (**Probe$_{dna}$5**, $n = 10$; **Probe$_{omr}$5**, $n = 7$) (Figure 4). The fluorescence from cells where the 2′-*O*-MeRNA probe **Probe$_{omr}$5** was incorporated almost retained the initial intensity over 6 h observation, whereas the fluorescence of cells labeled with DNA probe **Probe$_{dna}$5** gradually decreased to about 50% of the initial intensity within 6 h. **Probe$_{omr}$5**-transfected cells

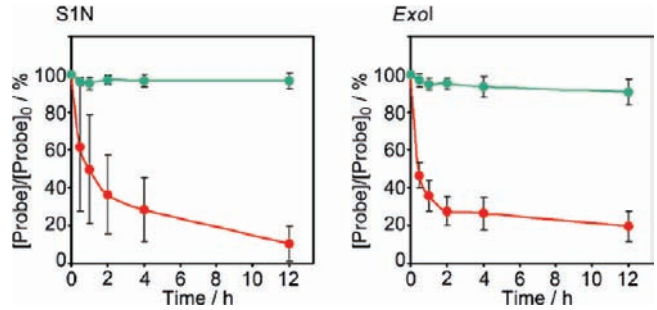

Figure 5. Probe degradation by nuclease digestion. The results of HPLC signal analysis after treatment with S1 nuclease are shown in the left panel, and the results after exonuclease I treatment are shown in the right panel. The average data for five DNA probes **Probe$_{dna}$1−5** (red) and five 2′-*O*-MeRNA probes **Probe$_{omr}$1−5** (green) are plotted (mean ± SD, $n = 5$).

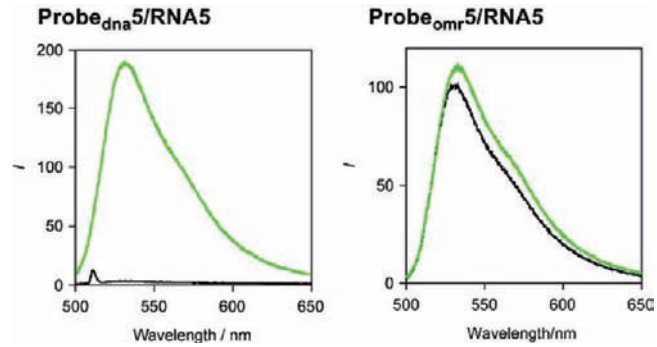

Figure 6. Fluorescence spectra of the mixture of the S1N-digested probe and the complementary RNA. The spectra for the mixture of DNA probe **Probe$_{dna}$5** and **RNA5** (0.5 μM) are shown in the left panel, and the spectra for the mixture of 2′-*O*-MeRNA probe **Probe$_{omr}$5** and **RNA5** (0.5 μM) are shown in the right panel. These spectra were measured in 5 mM NaCl, 120 mM KCl, and 25 mM HEPES (pH 7.2)−KOH at 25 °C. The mixture of the nondigested probe and RNA (green) and the mixture of the S1N-digested probe and RNA (black). The samples were excited at 514 nm.

emitted strong fluorescence, even after 24 h monitoring under culturing conditions.

Nuclease Resistance. It has been shown that the stability of the 2′-*O*-MeRNA probe fluorescence is much higher in the cell compared with the low stability of the DNA probe fluorescence. This may be because of the high nuclease resistance of the 2′-*O*-MeRNA probe. The 2′-*O*-MeRNA structure is known to have many advantages over DNA probes for detecting RNA targets, including increased stability of the hybrid with RNA and higher resistance against nucleases (*19*). These advantages may render 2′-*O*-MeRNA probes superior to DNA probes for use in assays that detectthe target RNA in a cell. In order to investigate the nuclease resistance ability of probes, both 2′-*O*-MeRNA and

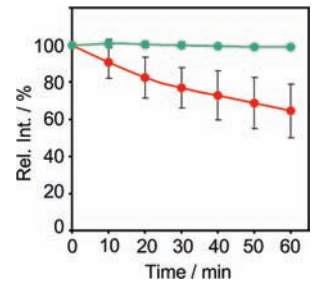

Figure 7. RNA degradation by RNaseH. The probe fluorescence at 530 nm was monitored on the excitation at 514 nm. The average data for five DNA probes **Probe$_{dna}$1−5** (red) and five 2′-*O*-MeRNA probes **Probe$_{omr}$1−5** (green) are plotted (mean ± SD, $n = 5$).

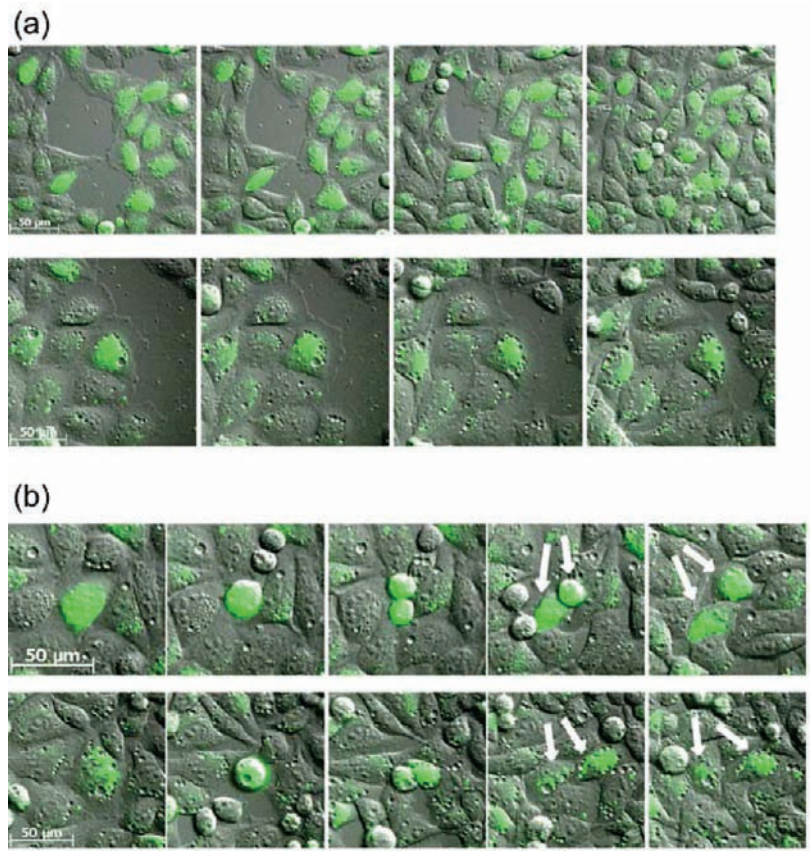

Figure 8. Differential interference contrast and fluorescence images of **Probe$_{omr}$5**-transfected HeLa cells. The sample was excited through a 500/24−25 band-pass filter, and the fluorescence was collected through a 542 ± 25 nm band-pass filter. Bar: 50 μm. (a) Two examples of cell migration: from left, initial state, and 2, 4, and 6 h later. (b) Two examples of cell division: from left, initial state, and 1, 1.5, 2.5, and 4 h later. Divided cells are indicated by white arrows.

DNA probes were treated with an endonuclease and an exonuclease, and then the decrease in the HPLC peak area of undigested probe was analyzed. S1 nuclease (S1N) is an endonuclease that catalyzes the specific degradation of single-stranded DNA or RNA to 5′-mononucleotides (*20*, *21*). Degradation curves were drawn by plotting the quantity of undigested probe as the function of the incubation time with S1N (Figure 5, left). S1N (500 mU) degraded about 90% of DNA probes (200 pmol) within 12 h, whereas about 95% of 2′-*O*-MeRNA probes (200 pmol) were still undigested after 12 h incubation. 2′-*O*-MeRNA probes showed high resistance against not only an endonuclease, but also an exonuclease (Figure 5, right). Exonuclease I (*Exo*I) is 3′→5′ exonuclease specific for a single-stranded polynucleotide, and it results in the production of 5′-mononucleotides (*22*, *23*). Digestion of the DNA probes proceeded rapidly, and only 20% of the DNA probes were undigested after 12 h. On the other hand, digestion of 2′-*O*-MeRNA probes was suppressed.

Probe degradation caused a significant decrease in fluorescence intensity in a solution containing the target RNA. Digestion of a DNA probe by S1N resulted in loss of fluorescence intensity because of a decrease in the binding ability to RNA (Figure 6). In contrast, 2′-*O*-MeRNA probes retained fluorescence in the presence of RNA, even after 12 h S1N treatment, suggesting that the probes maintain the function of RNA detection in this nuclease condition.

Inhibition of RNA Degradation. DNA probes are exposed to attack by nucleases even after hybridization with RNA. As a typical example, ribonuclease H (RNaseH) is known to catalyze the specific degradation of the RNA strand binding to DNA (*24*). Damage of the probe-hybridizing RNA by RNaseH may spoil the original function of RNA as well as reduce the probe fluorescence. In order to investigate the influence of RNaseH on the maintenance of RNA and the fluorescence intensity of a probe for a probe-RNA hybrid, RNaseH (4 U) was added to a solution containing the probe and the complementary RNA, and the fluorescence of the mixture was measured after 1 h. The hybrids of DNA probes and RNA strands showed a gradual fluorescent decrease to about 65% within 1 h (Figure 7). No decrease in fluorescence intensity of the hybrids was observed in the absence of RNaseH, and probes were not degraded by RNaseH. Therefore, the fluorescent decrease was attributed to RNA damage by RNaseH and dissociation of probes from damaged RNA. In contrast, when 2′-*O*-MeRNA probes were used, a significant decrease of fluorescence was not observed, even in the presence of RNaseH. 2′-*O*-MeRNA probes prevented RNaseH from degrading RNA in the hybrid.

Live Cell Imaging. The high resistance of 2′-*O*-MeRNA probes against nucleases makes long-term live cell RNA imaging possible. The probe showed no severe cytotoxicity, by appropriately selecting the sequence that does not obstruct the RNA activity. Cell life events, for example, migration and division of **Probe$_{omr}$5**-transfected cells, were also observed in a long-term monitoring and were similar to those observed for normal cells (Figure 8). During cell migration and division, the probe fluorescence was detected mainly from nuclei, and translocation of fluorescence to the cytoplasm region was also observed. In cell division, the fluorescence in the mother cell was evenly distributed to two daughter cells. In addition, stronger fluorescence was observed for the cell at the mitotic phase compared with the fluorescence at the interphase, sug-

gesting that a huge amount of mRNA expresses and works during cell division.

CONCLUSION

In conclusion, we have reported on nuclease-resistant probes for long-term intracellular RNA imaging. The 2′-*O*-MeRNA probes that we synthesized showed high resistance against nucleases, in contrast to the low resistance of DNA probes. Furthermore, this modified probe retained the function on the on−off switching of fluorescence emission in sensitive response to RNA recognition, based on interdye excitonic interaction. The long-term monitoring of the migration and division of RNA-stained living cells was attained using this highly functional fluorescent probe. Our probe settled the issue of probe damage by nucleases, and now, we anticipate that it will be a practical tool for effective monitoring of the spatiotemporal characteristics of RNAs in living cells.

Received March 26, 2009; Revised Manuscript Received April 30, 2009

The objective of our study was to develop a novel nonviral gene silencing system using small interfering RNA (siRNA) or short hairpin RNA (shRNA) complexes using star vector (SV), which is a star-shaped, four-branched, cationic−nonionic-blocked copolymer, as the water-soluble delivery system. This vector was previously designed as a carrier for high-efficiency gene delivery of plasmid DNA. The lamin gene was used as the target for developing siRNAs. SV was shown to condense and interact with siRNAs to yield SV/siRNA polyion complexes with a diameter of ca. 90 nm and having considerable stability. By using these complexes, siRNA was successfully delivered to almost all human hepatocellular carcinoma cells used in this study, and both siRNAs and shRNAs could produce significant gene silencing in these cells without affecting cell viability. The silencing efficacy of these complexes was similar to that of commercially available high-efficiency siRNA transfection reagent (Darmafect-4). After injecting SV/siRNA complexes into mice, effective gene silencing was also observed in vivo in the liver and lung, suggesting that the SV/siRNA complexes were stable under in vivo conditions, and their transfection efficiency was retained after intravenous administration. Thus, SV was a potential carrier for siRNA and shRNA delivery in both in vitro and in vivo conditions; this finding suggests that it may offer a new clinical therapeutic approach in gene therapy.

INTRODUCTION

Gene therapy is an attractive new approach for the treatment of inherited disorders (*1, 2*). However, current gene therapy techniques have not yielded successful results in clinical trials. Generally, there are two kinds of gene delivery systems—viral and nonviral. Viral vectors such as retrovirus, lentivirus, and adenovirus have been proven to be efficient means for gene delivery (*3*−*5*); however, the possibility of negative outcomes resulting from viral transformations cannot be completely ruled out (*6*). On the other hand, various types of nonviral vectors have been reported recently. These vectors are attracting considerable attention, since they are easier to handle and induce weaker immune responses (*7*−*9*).

Recently, in order to improve the efficiency of gene transfection, we designed a novel nonviral vector, namely, star vector (SV), which is a star-shaped and cation-based polymer (*10, 11*), or its cross-linked complexes (*12*). These vectors have been shown to be effective in inducing gene expression from plasmid DNA (pDNA). In addition, in combination with ligands such as C45D18 peptide, which promotes nuclear trafficking (*13*), or an integrin-binding RGD peptide (*14*), DNA could be selectively delivered to macrophages or endothelial cells, respectively.

RNA interfering (RNAi) is the process by which double-stranded RNA (dsRNA) directs the sequence-specific degradation of complementary mRNA (*15*−*18*). RNAi is an effective method for gene-function analysis as well as a powerful therapeutic agent for silencing pathogenic gene products associated with diseases, including cancer, viral infections, and autoimmune disorders. Small interfering RNAs (siRNAs) can be directly introduced into cells in the form of synthetic siRNAs or short hairpin RNAs (shRNAs) (*19*). RNA polymerase III-driven expression cassettes can be used for the constitutive expression of shRNA molecules. Although both viral and nonviral vectors can be used to deliver siRNA into cells, viral vectors are not sufficiently capable of delivering siRNA-expressing constructs such as shRNA. Commercially available cationic lipids such as oligofectamine can effectively deliver siRNAs into cells (*20*); however, such cationic lipids are highly toxic and hence cannot be effectively used for systemic delivery of siRNAs in vivo.

In this study, the possibility of using SVs as carriers for RNA delivery was evaluated both in vitro and in vivo. One of the most effective pDNA carriers among the various SVs (*11*), i.e., a four-branched diblock copolymer containing an inner domain of cationic poly(*N*,*N*-dimethylaminopropylacrylamide) chains (chain length, ca. 50 kDa) and an outer domain of nonionic poly(*N*,*N*-dimethylacrylamide) chains (chain length, ca. 33 kDa), was selected as an RNA carrier in this study. The in vitro gene

silencing efficacy of SV/siRNA or SV/shRNA complexes was evaluated using human hepatocellular carcinoma cell line. In addition, the in vivo gene silencing efficacy was evaluated by injecting SV/siRNA complexes in mice and investigating their effects in the liver and lung. The possibility of using SV/RNA complexes as therapeutic agents has also been discussed.

EXPERIMENTAL PROCEDURES

Materials. *N,N*-Dimethylacrylamide was purchased from Wako Pure Chemical Ind., Ltd. (Osaka, Japan) and 3-(*N,N*-dimethylamino)propyl acrylamide from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). Other chemical reagents were commercially obtained from Wako. Monomers were distilled under reduced pressure before use in order to remove the stabilizer, and if required, other reagents were also purified before use.

Preparation of SV. SV—poly(3-(*N,N*-dimethylamino)propyl acrylamide)-*block*-poly(*N,N*-dimethylacrylamide), four-branched block copolymer—was synthesized by iniferter-based photoliving radical polymerization of 1,2,4,5-tetrakis(*N,N*-diethyldithiocarbamylmethyl)benzene, which was used as a four-functional iniferter, with 3-(*N,N*-dimethylamino)propyl acrylamide and *N,N*-dimethylacrylamide, which were used as cationic and nonionic monomers, respectively, in accordance with our previously reported method (*11*).

Briefly, 1,2,4,5-tetrakis(*N,N*-diethyldithiocarbamylmethyl)-benzene (72 mg, 0.1 mmol) and 3-(*N,N*-dimethylamino)propyl acrylamide (3.43 g, 22.0 mmol) were dissolved in 20 mL of methanol and irradiated using a 200 W high-pressure mercury lamp (1 mW/cm^2 at 250 nm; SPOT CURE, USHIO, Tokyo, Japan) for 30 min under bubbling with N_2 gas (99.9999%) at room temperature. The reaction mixture was purified by precipitating it in a large amount of ether. Reprecipitation was carried out using methanol ether to yield a four-branched cationic polymer (conv. 40%). The molecular weight was M_n 50 kDa, as determined by gel permeation chromatography (GPC). ^{1}H NMR (300 MHz, D_2O, ppm) δ: 1.7−1.5 (-C$\underline{H}_2$-CH- and -CH$_2$-C$\underline{H}_2$-CH$_2$-), 2.0−1.8 (-C$\underline{H}$-CO), 2.2−2.1 (-N-C$\underline{H}_3$), 2.4−2.2 (-C$\underline{H}_2$-N(CH$_3$)$_2$), 3.2−3.0 (-NH-C$\underline{H}_2$-), 7.8−7.4 (-NH).

The resultant four-branched cationic polymer (M_n 50 kDa, 125 mg, 2.5 μmol) and *N,N*-dimethylacrylamide (2.97 g, 30 mmol) were dissolved in 20 mL of methanol solution and irradiated for 30 min under the above-mentioned conditions. After reprecipitation in a methanol-ether system, the four-branched block copolymer, namely, star vector (SV), was obtained (conv. 19%). The total molecular weight was 83 kDa, as determined by ^{1}H NMR. ^{1}H NMR (300 MHz, D_2O, ppm) δ: 1.0−1.7 (-C$\underline{H}_2$CH- and -CH$_2$C$\underline{H}_2$CH$_2$-), 1.9 (-CH$_2$C$\underline{H}$- of PDMAPAAm), 2.1 (-N(C$\underline{H}_3$)$_2$ of PDMAPAAm), 2.3 (-C$\underline{H}_2$N-(CH$_3$)$_2$), 2.4−2.7 (-CH$_2$C$\underline{H}$- of PDMAAm), 2.8−2.9 (-N(C$\underline{H}_3$)$_2$ of PDMAAm), 3.0 (-CONHC$\underline{H}_2$-).

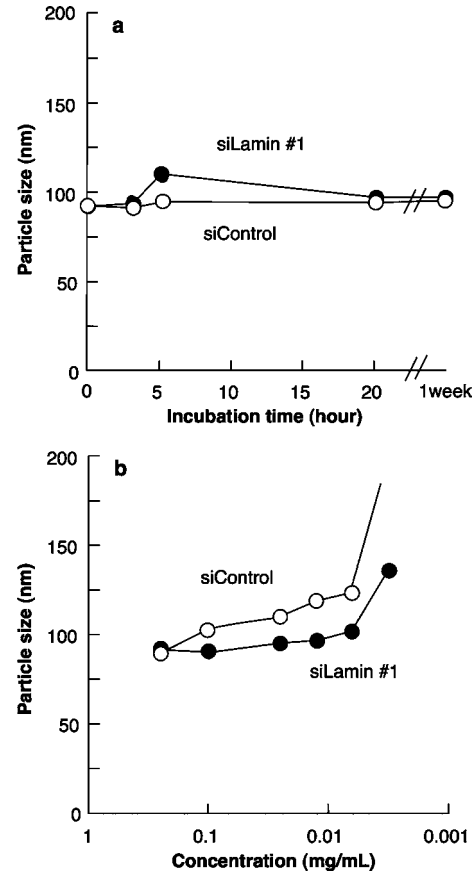

Figure 2. Changes in mean diameter of SV/siRNA complexes in aqueous solutions at 37 °C depending on incubation time (a) and after dilution in biological saline (b). The SV/siRNA complexes were prepared by mixing SV (20 μg/50 μL) and siLamin #1 or siControl (5 μg/50 μL) at an N/P ratio of 5.

Biophysical Characterization of SV/siRNA Complexes. The SVs were dissolved in biological saline. An aliquot of the saline solution containing SV (20 μg/50 μL) was added to the saline solution containing siRNA (5 μg/50 μL) to obtain SV/siRNA complexes with the N/P ratio of 5. The mean diameters of the complexes were measured by the dynamic light scattering (DLS) method using an ELS-8000 system (Otuska Electronics Co., Osaka, Japan) equipped with a 10-mW He−Ne laser. The concentration-dependent colloidal stability of SV/siRNA complexes was studied by the DLS method at 37 °C.

Real-Time Quantitative RT-PCR Analysis. Real-time quantitative-polymerase chain reaction (qRT-PCR) analysis was performed as described previously (*21*). The primer sets used were as follows: for human lamin A/C, 5′-GCCTACCG-CAAGCTCTTGGA-3′ (forward) and 5′-CTAGTGCGTGCGT-GCTGTGA-3′ (reverse); and for mouse lamin A/C, 5′-TTCCC-ACCGAAGTTCACCCTAA-3′ (forward) and 5′-ATGGTCA-GTGAGCGCACCAG-3′ (reverse). In order to standardize the amount of RNA, the expression level of glyceradehyde-3-phosphate dehydrogenase (GAPDH) in each sample was quantified by using the following primer sets: for human GAPDH, 5′-GAAGGTGAAGGTCGGAGTC-3′ (forward) and 5-CCCG-AATCACATTCTCCAAGAA-3′ (reverse); and for mouse GAPDH, 5′-AAATGGTGAAGGTCGGTGTG-3′ (forward) and 5′-

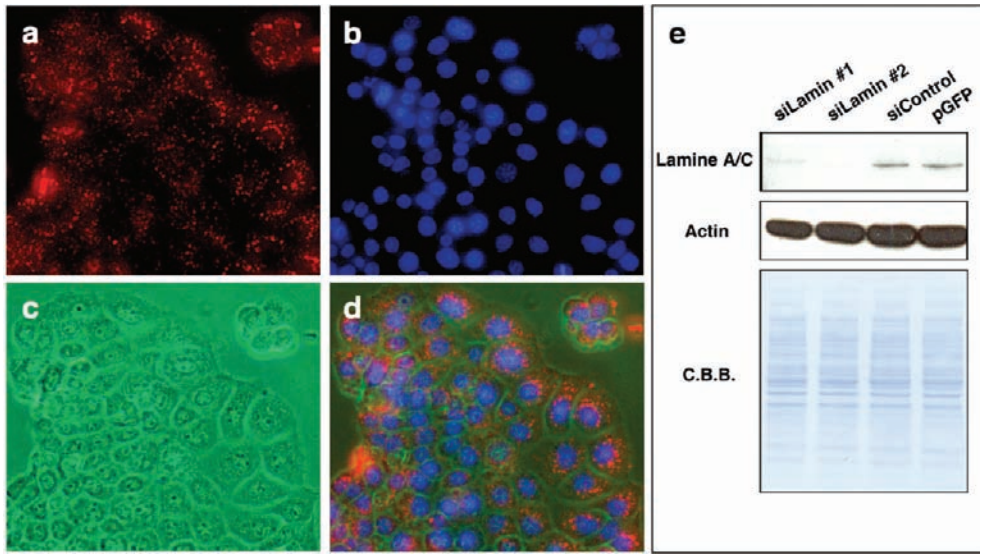

Figure 3. (a) Fluorescence microscopic image of Cy3-labeled siLamin #1 in human hepatocellular carcinoma cells delivered by SV/siRNA complexes, (b) after diaminophenylindole (DAPI) staining, (c) phase-contrast microscopic image, and (d) all three images merged into one. (e) Immunoblotting of Lamin A/C after treatment of human hepatocellular carcinoma cells with SV/siRNA or SV/pGFP complexes. Actin expression levels and coomassie brilliant blue (CBB) staining were used as loading controls.

TGAAGGGGTCGTTGATGG-3′ (reverse). All PCR reactions were performed using a SYBR RT-PCR kit (Takara Bio, Tokyo, Japan).

Western Blot Analysis. Western blot analysis of the Lamin A/C (sc-7292) and actin (using a mouse monoclonal Ab: 1:1000 dilution; Santa Cruz Biotechnology Inc., CA, USA) from human hepatocellular carcinoma cell lines (PLC/PRF/5: Alexander) was performed, as described previously (*22*).

RNA Interference (siRNA Duplexes). All purified and pre-annealed siRNA molecules were obtained from Dharmacon Research, Inc. (Lafayette, CO). siGL2 Lamin A/C siRNA (human/mouse/rat) (Cy3-labeled siLamin A/C #1: sense, 5′-GGUGGUGACGACGAUCUGGGCUdTdT-3′; antisense, 5′-AGCCCAGAUCGUCACCACCdTdT-3′), siGL2 Lamin A/C siRNA human (Cy3-labeled siLamin A/C #2: sense, 5′-ACCAGGUGGAGCAGUAUAAdTdT-3′; antisense, 5′-UUAUACUGCUCCACCUGGUdTdT-3′), and siControl nontargeting siRNA #1 (siControl: sense, 5′-UAGCGACUAAACACAUCAAUU-3′; antisense, 5′-UUGAUGUGUUUAGUCGCUAUU-3′) are unmodified siRNA duplexes bioinformatically designed to minimize the potential for targeting any known human or mouse genes.

Vector Construction. shRNA expression vector, pDEST-CL-SI-MSCVpuro (previously designated as pSI-CMSCVpuroDEST), and the entry vector, pENTR-H1R-stuffer, were constructed in accordance with the previous report (*23*).

In Vitro Transfection. Human hepatocellular carcinoma (PLC/PRF/5: Alexander) cells were seeded into 6-well plates (5×10^4 to 1×10^5 cells per well) 2 days prior to transfection and grown in RPMI-1640 (Sigma, St. Louis, MO) medium supplemented with 10% fetal bovine serum (FBS) and antibiotics. SV/RNA or SV/DNA complexes were prepared by mixing an aliquot of phosphate buffered saline (PBS) containing SV (10 μg for RNA and 4 μg for DNA) with an aliquot of PBS containing siRNA or shRNA (2.5 μg/well) and plasmid green fluorescent protein (pGFP) DNA (pmaxGFP, Amaxa Inc., MD) (1 μg /well) at a N/P ratio of 5. The resultant complexes were maintained at room temperature for 30 min. On the other hand, complexes of siRNA (2.5 μg/well) and Dharmafect-4 (TR; Dharmacon Research, Inc., Lafayette, CO, USA) (TR/siRNA complexes) were prepared according to the manufacturer's instructions. All the complexes were applied to each well in a total volume of 2 mL. The transfection medium (Opti-MEM, Invitrogen, Carlsbad, CA) was replaced with the complete medium after 4 h.

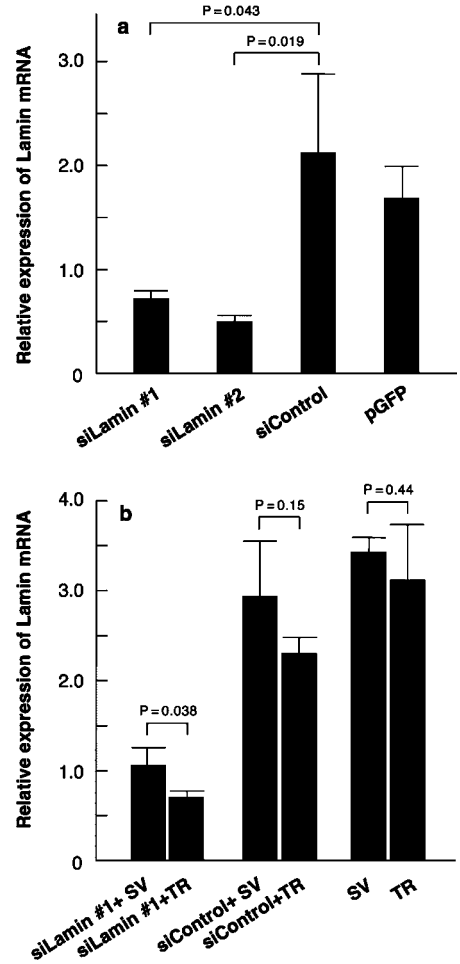

Figure 4. In vitro lamin mRNA silencing efficiency of SV/siRNA complexes in human hepatocellular carcinoma cells, as analyzed by quantitative RT-PCR. (a) Comparison between siLamin #1 and siLamin #2. (b) Comparison between SV and TR (Darmafect-4) using siLamin #1.

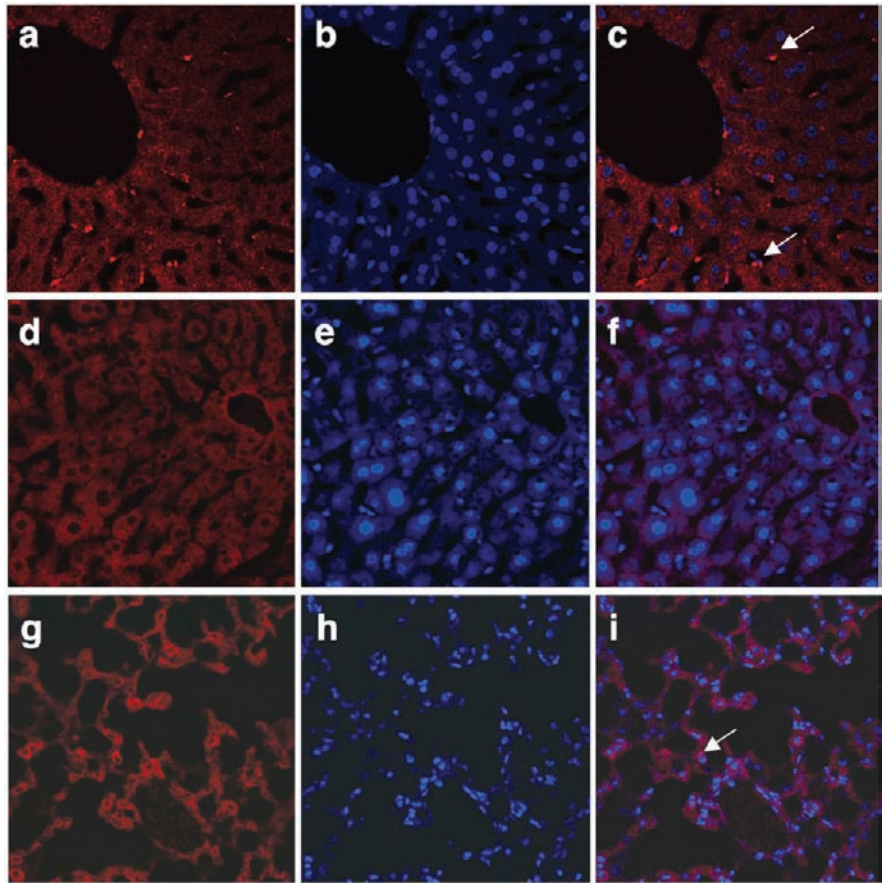

Figure 5. Images of mice liver and lung tissues transfected with SV/siRNA complexes observed under confocal microscope. Cy3-labeled siRNA detected in the mouse tissues (a−c, Cy3-labeled siLamin-injected liver specimen; d−f, nonlabeled siControl-injected liver specimen; g−i, Cy3-labeled siLamin-injected lung specimen). Cy3 labeling (a,d,g), DAPI staining (b,e,h), and merged image (c,f,i). Cy3-labeled siLamins were detected in the liver and lung tissues (white arrows in c and i).

In Vivo Transfection (Tail-Vein Injection of SV/siRNA Complexes). Male CH3/HeN mice (7−9-week old) weighing about 20 g were used ($n = 8$). Using the animal protocols that were approved by the institutional Animal Care and Use Committee of Keio University School of Medicine (approval #060042), 200 μL of SV/siRNA complex was injected into each mouse via the tail vein over a period of 5 s (10 μg siRNA per 20 g mouse). The N/P ratio was set at 5. Mice were euthanized 48 h after the injection, and the livers and lungs were dissected and rapidly frozen for subsequent mRNA and protein analysis. For immunofluorescence study, dissected specimens were fixed in 4% paraformaldehyde (PFA) and analyzed under a confocal laser-scanning microscope (LSM 510; Carl Zeiss, Oberkochen, Germany) after staining with 4,6-diamidino-2-phenylindole (DAPI) (Wako) at 1:1000 dilution.

Statistical Analysis. Data are expressed as mean ± standard error (SE). The relative mRNA expression levels were compared using unpaired *t*-test, and all statistical analyses were performed using *Statcel* software (OSM, Tokyo, Japan).

RESULTS

Formation of SV/siRNA Complexes and Their Stability. The chemical structure of the SV used in this study was four-branched, blocked copolymer, with an inner domain of cationic chains (chain length, ca. 50 kDa) and an outer domain of nonionic chains (chain length, ca. 33 kDa), as shown in Figure 1. When the saline solution of SV was mixed with the saline solution of siRNA at the N/P ratio of 5, highly scattered intensity was observed in the DLS analysis for both lamin and control siRNAs, indicating the formation of SV/siRNA complexes. These complexes were considered polyion complexes that were formed by nonspecific electrostatic interactions between the cationic SVs and anionic RNAs.

The effective diameters of the resultant SV/siRNA complexes of both lamin and control RNAs were found to be approximately 90 nm, as revealed by DLS analysis, and their size remained smaller even 1 week after complex formation (Figure 2A). There was a small change in the size of the complexes after an approximately 40-fold dilution with PBS (Figure 2B). SV-based complexes of both the RNAs clearly showed good colloidal stability.

SV/siRNA-Mediated Lamin Knockdown in Vitro. Induction efficiency in vitro, which was mediated by SV/siRNA, was evaluated by monitoring Cy3-labeled siRNA. In order to eliminate serum effects, the human hepatocellular carcinoma cells were cultured in serum-free media, and the media was changed every 4 h after transfection with SV/siRNA complexes to avoid nonspecific interaction. Fluorescence microscopic examination revealed Cy3 labeling in almost all cells (Figure 3a−d). In other words, SV was able to deliver siRNA to almost all cells.

The gene silencing efficiency of the SV/siRNA complex was evaluated as follows. First, two different alignments of siRNA against lamin (siLamin #1 for human/mouse/rat and siLamin #2 for human) were designed; these were used as positive controls. A nontargeting control siRNA (siControl) or a green fluorescent protein (GFP)-expression vector (pGFP) was used as a negative control. After 24 h of transfection with SV/siRNA complexes, lamin mRNA expression levels in the human hepatocellular carcinoma cells were evaluated. The results of

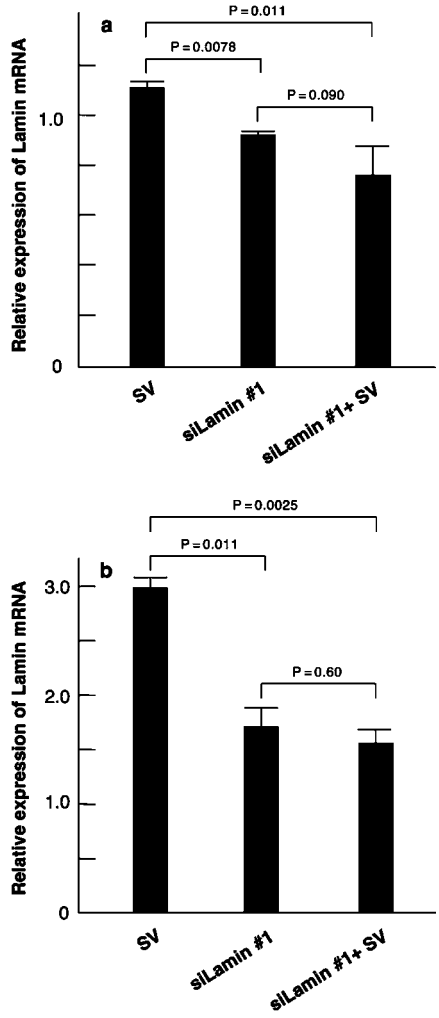

Figure 6. In vivo lamin mRNA silencing efficiency of SV/siRNA complexes in mice liver or lung tissue, as analyzed by quantitative RT-PCR. SV/siRNA was transfected by tail vain injection. Comparison of siLamin before and after the SV/siLamin #1 complex formation in the liver (a) or the lung (b).

qRT-PCR indicated that the lamin mRNA expression levels were significantly reduced in the cells transfected with siLamin #1 and #2 compared to those in the cells transfected with the control siRNA (siLamin #1 vs siControl, $P = 0.043$; siLamin #2 vs siControl, $P = 0.019$) (Figure 4a). A significant decrease in the levels of lamin protein was also observed in the cells transfected with siLamin #1 and #2 compared with those transfected with the controls (Figure 3e).

The transduction efficiency of SV was compared with a commercially available high-efficiency siRNA transfection reagent (TR; Darmafect-4). Both SV and TR could effectively down-regulate lamin expression mRNA levels (mean relative expression levels: SV/siLamin #1 vs TR/siLamin #1, 1.06 vs 0.71, $P = 0.038$; SV/siCont vs TR/siCont. = 2.93 vs 2.29, $P = 0.145$; SV vs TR = 3.40 vs 3.09, $P = 0.44$) (Figure 4b).

SV/siRNA-Mediated Gene Silencing in Vivo. The in vivo gene silencing efficiency of SV/siRNA complex was assessed by using Cy3-labeled siLamin #1 or Cy3-labeled siControl. Cy3-labeled SV/siLamin #1 or SV/siControl complexes were injected into each mouse via the tail vein. Mice were euthanized 48 h after injection, and the liver or lung was dissected for subsequent analysis.

Cy3-labeled siRNAs were detected in all the liver and lung specimens, as observed under the confocal laser-scanning microscope (Figure 5). In addition, Cy3-labeled siRNAs were observed in the kidney/renal tubules (data not shown). This confirms that the siRNAs were effectively delivered into the liver and lung by using SV. The silencing efficacy of SV (without siLamin), naked-siLamin (without SV), and SV/siLamin complex were quantitatively analyzed in the liver and lung specimens by measuring the lamin mRNA levels. Lamin expression levels were efficiently down-regulated after transfection with both siLamin groups with or without SV in both the tissues (mean relative lamin mRNA levels in the liver, SV vs siLamin (naked) vs siLamin/SV = 1.11 vs 0.92 vs 0.76; mean relative lamin mRNA levels in the lung, SV vs siLamin (naked) vs siLamin/SV = 3.00 vs 1.71 vs 1.54). There was no statistical difference between the transfection efficiency of SV and of naked siLamin ($n = 3$; $P > 0.05$) (Figure 6).

SV/shRNA-Mediated Lamin Knockdown in Vitro. The possibility of SV-induced gene silencing using shRNAs (plasmid DNA) was also evaluated. Confocal laser scanning microscopy showed that shRNA was delivered to almost all carcinoma cells treated with SV/shRNA complexes, including about 30% of cells showing strong shRNA induction (Figure 7). In the preliminal experiment, the lamin gene expression level was strongly down-regulated by SV/shRNA complexes (Figure 8). Although statistical analysis was not performed for the lack of experimental number, the inhibition efficacy of SV/shRNA complex was almost similar to that of TR/shRNA complex (mean relative lamin levels, SV/shLamin vs SV/shCont. = 1.17 vs 2.40; TR/shLamin vs TR/shCont. = 0.82 vs 2.02).

DISCUSSION

We showed that SV promotes siRNA- or shRNA-mediated gene silencing in vitro in human hepatocellular carcinoma cells and also in vivo in mice liver or lung. SV is a synthetic cation-based polymer that was previously developed as a carrier for DNA delivery. The gene transfection efficiency of SV was 10-fold higher than that of polyethyleneimine (PEI), which is one of the best vectors popularly used for gene transfer. Recently, several types of SVs were bioinformatically designed to enhance gene transfection efficacy or develop novel transfection methods. Among the various types of SV, the four-branched poly(*N*,*N*-dimethylaminopropylacrylamide)-*block*-poly(*N*,*N*-dimethyacrylamide) that was used in this study is the standard structure; this SV is one of the most effective gene delivery vectors.

SV could be used to form siRNA/SV complexes merely by mixing siRNA and SV in aqueous media even though the molecular weight of RNA is smaller than that of DNA. Since in our previous study a minimum N/P ratio of 5 was required for stable complex formation between SV and DNA, the N/P ratio was fixed at 5; cellular toxicity was minimal at this N/P ratio. The complex may be formed by electrostatic interactions between cationic SV and anionic RNAs in a manner similar to the complex formation between DNA complexes and SV. SV is easy to handle, does not require specific conditions for complex formation with RNAs, and is considerably water-soluble; hence, no organic solvent was required for preparing its aqueous solution. Thus, solvent-based toxicity was avoided. The complexes had a small particle size and were stable in saline for at least up to 1 week and even after dilution up to approximately 40-fold (Figure 2); this feature is of great advantage for use in animal studies. Almost all cationic polymers can conjugate with anionic RNAs to prepare polymer/RNA polyion complexes immediately after mixing by electrostatic affinity. However, the complexes are gradually aggregated with an increase in incubation time to grow micrometer size by similar electrostatic affinity. Therefore, in general, it was reported that gene silencing efficacy was low in large particles due to difficulty internalizing polyion complexes into the cells, which is one of key steps in polyion-complex-mediated gene

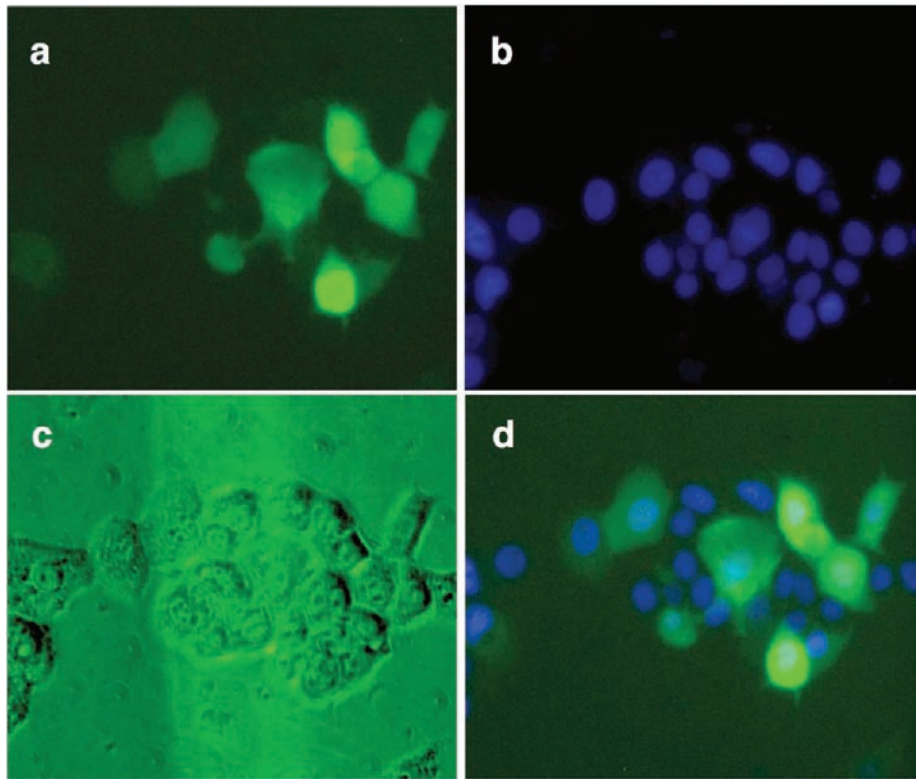

Figure 7. Fluorescence microscopic image of GFP expression in human hepatocellular carcinoma cells after transfection with plasmid DNA using SV/shRNA complexes. (a) GFP, (b) DAPI, (c) phase-contrast microscope image, and (d) all three images merged into one.

silencing. On the other hand, in SV with a combination of cationic and nonionic chains the aggregation of the complexes was prevented by nonionic chains, which might exist at the outermost surfaces of the complexes. In addition, complexes formed from RNA and cationic homopolymer may be generally more rigid than those from RNA and SV, because nonionic chains in SV can function as a buffer layer between RNA and polymer. Therefore, it is considered that the only cationic polymer-based polyion complexes may not dissociate easily. That is, this may prevent RNA release from the complexes, which is also one of key steps in gene silencing. For these two reasons, SV is considered to have higher gene silencing efficiency.

RNAi is an effective tool for gene silencing and can be used as a potential therapeutic agent against many diseases, including cancer (*16*). RNAi effector molecules can be directly introduced into cells as synthetic siRNAs or indirectly as shRNAs. Although in vitro transfection methods using commercially available cationic lipids such as oligofectamine can deliver siRNA into cells with high efficiency, they are highly toxic, and hence, their usage in in vivo systemic delivery systems is generally avoided. In addition, previous reports showed that the delivery of siRNA into subcutaneous tumors for gene silencing was possible by using the tail vein approach (*23, 24*). However, the concentration of siRNA used in the above-mentioned study was 5-fold higher (50 μg/20 g body weight in mice) than that used in our study, and this result may have included artifacts or drug (siRNA and/or reagents) side effects. Thus, it is not feasible to use this approach in clinical interventions. In fact, we observed that 2 of the 9 mice died within 24 h after in vivo oligofectamin transfection.

The transfection efficiency of SV was similar to that obtained using cationic lipids as vectors such as TR (Dramafect-4) that are commonly used for siRNA-mediated gene silencing (Figures 3 and 4). We selected the lamin gene as the target for siRNA-mediated gene silencing. The lamin siRNA was established for siRNA positive correlation of fluorescence with transfection efficiency and target gene silencing. Moreover, Lamin A/C is abundantly expressed in most of the human, mouse, and rat cells, and knockdown of the mRNA corresponding to lamin does not affect cell viability. In order to investigate the accuracy of the siRNAs, two different conformations of siRNAs with varying sequences, i.e., siLamin #1 designed to target human, mouse, and rat lamin and siLamin #2 designed to target only human lamin, were used. Both siRNAs showed similar high-performance gene silencing in the in vitro study (Figure 4). In addition, our in vitro study also demonstrated that SV could be a beneficial tool for gene silencing using shRNA as a plasmid DNA vector (Figure 8). In the in vivo study, we chose to examine effects on the liver, which is one of the reticuloendothelial organs that can trap foreign particles entering through

the veins, and we observed that the SV/siRNA complexes were effective even at low doses. After the tail vein injection, the complexes flowed through the venous return and were trapped by the reticuloendothelial system of the liver. We hypothesized that the complexes were initially trapped in the interstitial region and some of them were phagocytosed by the Kupffer cells, following which they entered the surrounding cells. The lamin mRNA expression level in the entire liver was less than 10% after injection of the complexes compared with the expression levels of the control livers. These results suggest that gene silencing was effective not only in the Kupffer cells but also in other liver cells such as the hepatocytes, endothelial cells, and all liver architectonic cells. In addition, there was no incidence of sudden death in the treated mice caused by embolism resulting from the injected materials.

Our results demonstrate that SV can be a promising tool for gene therapy against cancer, although we did not investigate the effectiveness of the complexes against in vivo tumors. Therefore, further studies need to be performed in the future to elucidate this new approach. Most of the cervical cancers are associated with HPV-16 infection, which results in the expression of *E6* and *E7* genes encoded by the viral genome. The expression of these oncogenes is imperative for tumor development and the maintenance of malignancy. Recently, Yoshinouchi et al. reported that siRNA-mediated gene silencing suppressed the expression of *E6* and *E7* genes in HPV-16-positive cancer cells and had a remarkable effect on reducing tumor size (*26*). Thus, these genes are ideal targets for cancer gene therapy. Other candidate genes that may be targeted are *LMP-1* (Epstein−Barr (EB) virus genome) (*27*−*29*) and retinoblastoma gene (*Rb*) (*30*). At present, we are investigating two different approaches for targeting genes. The first approach is by the inhibition of inducer genes involved in early-stage carcinogenesis, and the second is by the inhibition of transmembrane receptors such as multidrug resistance receptor (MDR). Furthermore, we would also be evaluating whether gene transfection using SV could cause organ-specific injury (i.e., in the heart, brain, liver, and kidney) due to drug accumulation.

In conclusion, we have developed a novel nonviral gene silencing system based on our previously developed polymeric four-branched, cationic-blocked star vector (SV), which can efficiently deliver both siRNAs and shRNAs in vitro and in vivo. These results suggest that SV can be a potential nonviral vector and also offer a new clinical therapeutic approach for the treatment and management of disease.

ACKNOWLEDGMENT

We would like to express our sincere thanks to Shinji Saito (Bridgestone Corp., Yokohama, Japan) for support throughout the work, M. Fujiwara, M. Morioka, and M. Konno for providing expert technical assistance. This work was supported in part by a Keio University Grant-in-Aid for Encouragement of Young Medical Scientists, special grant for Keio Health Counseling, and Grant-in-Aid for Young Scientists (B), The Ministry of Education, Culture, Sports, Science and Technology (MEXT) to TM.

Integrin $\alpha_v\beta_3$ Targeted Gene Delivery Using RGD Peptidomimetic Conjugates with Copolymers of PEGylated Poly(ethylene imine)

Olivia M. Merkel,[†] Oliver Germershaus,[†] Carol K. Wada,[‡] Peter J. Tarcha,[‡] Thomas Merdan,[‡] and Thomas Kissel*[,†]

Department of Pharmaceutics and Biopharmacy, Philipps-Universität Marburg, Ketzerbach 63, 35032 Marburg, Germany, and Abbott Laboratories Incorporated, 200 Abbott Park Road, Abbot Park, Illinois 60064. Received April 14, 2009; Revised Manuscript Received May 12, 2009

This study describes the synthesis and characterization of five conjugates of poly(ethylene glycol) modified polyethylenimine (PEG-PEIs) coupled in two different synthesis routes to a nonpeptidic pentacyclic RDG-mimetic for integrin receptor-targeted gene delivery. Synthesis of this panel of different conjugates allowed for systematic analysis of structure−activity relationships. Conjugates were therefore characterized regarding molecular composition, DNA condensation, size, and zeta potential of self-assembled polyplexes. In vitro characterization included investigation of blood compatibility, binding affinity to receptor-positive and receptor-negative cells measured by flow cytometry, cellular uptake quantified by scintillation counting, and efficiency and specificity of transfection assayed by reporter gene expression. In a first synthetic approach, low molecular weight PEI (LMW-PEI) was PEGylated using a heterobifunctional PEG linker and coupling of the RGD-mimetic was achieved at the distal end of PEG chains. In a second synthesis route, the RGD-mimetic was directly coupled to AB-block-copolymers of PEI (25 kDa) and PEG (30 kDa). Interactions of RGD-PEG-LMW-PEI conjugates with DNA were strongly impaired, whereas PEG-PEI-RGD conjugates were more promising candidates due to their physicochemical properties and higher receptor specificity. The binding, uptake, and transfection efficiency in receptor-positive cells was strongly increased upon conjugation of the RGD-mimetic to AB-block-copolymers of PEG-PEI and depended on the degree of peptide substitution. The conjugates of PEG-PEI AB-block-copolymers with low ligand density of the RGD-mimetic appear to be promising candidates for in vivo cancer gene therapy.

INTRODUCTION

The integrin receptor $\alpha_v\beta_3$ is a known marker of angiogenic vascular tissue (*1*). The so-called vitronectin receptor represents a highly interesting therapeutic target because of its role in a wide range of pathologies which have been reviewed elsewhere, e.g., angiogenesis (*2*). Vitronectin, fibronectin and fibrinogen, contains the tripeptide motif Arg-Gly-Asp, abbreviated as RGD, which is recognized by integrin receptors. Extensive neovascularization in tumors makes integrin receptor $\alpha_v\beta_3$ a promising target for cancer gene therapy. Targeted delivery of pDNA (*3*−*5*) and siRNA (*6*) condensed by poly(ethylene imine)-*graft*-poly(ethylene glycol) (PEG-PEI) copolymers bearing cyclic RGD peptides was reported earlier in the context of cancer gene therapy. In fact, the N-alkylated cyclic pentapeptide c(-RGD-f[NMe]V-) is currently being tested in phase II clinical trials under the name "Cilengitide" as an angiogenesis inhibitor in glioblastoma multiforme (*7*). Because of metabolic instability of peptides and bioavailability reasons, nonpeptidic small molecule RGD-mimetics were developed, such as β-amino acid-based azacarba analogues with increased lipophilicity (*8*), hydantoin scaffolds (*9*), aminobenzoyl and isonipecotyl groups as arginine mimetic, and C-terminal tryptophan to maintain ionic and hydrophobic interaction (*10*) or attachment of aliphatic carbamate linkers (*11*). Another class of substances which is similar to the one used in our study was described by Ishikawa et al. (*12*), suggesting that a cyclic guanidine at the N-terminus generates suitable adhesion, receptor inhibition, and water solubility. None of the RGD-mimetics mentioned above have so far been used for targeted gene delivery.

In this study, we used as a targeting ligand thiol and maleimide derivatives of a pentaycyclic peptidomimetic substance of a class of 1-α-*Z*-2,3-diaminopropionic acid substituted 4-amino-1*H*-pyrimidin-2-ones previously reported to exhibit high affinities to the vitronectin receptor in the nanomolar range (*13*). This ligand was coupled to different derivatives of PEI using two different synthetic approaches to generate five different bioconjugates for targeted gene delivery based on a novel RGD-mimetic. The position and ligand density were varied to identify the most suitable synthetic strategy and composition of the conjugates.

MATERIALS AND METHODS

Materials. PEI 25 kDa (Polymin, 25 kDa) was a gift from BASF (Ludwigshafen, Germany); low molecular weight poly(ethylene imine) (LMW-PEI) with a low degree of branching (*14*) and the block copolymer poly(ethylene glycol)-poly(ethylene imine) (PEI25k-PEG30k) (*15*) were synthesized as described earlier.

RGD-mimetics (RGD-M) were obtained as maleimide derivative ($C_{34}H_{36}N_8O_7$, M_w 668.70 g/mol) or as sulfhydryl derivative ($C_{30}H_{35}N_7O_5S$, M_w 605.71 g/mol) from Abbott Laboratories (Abbott Park, IL, USA) as shown in Figure 1. Orthopyridyl-disulfide poly(ethylene glycol)-succinimidyl propionic acid (NHS-PEG2 kDa-OPSS) was purchased from Nektar Therapeutics (San Carlos, CA, USA), the luciferase encoding plasmid pCMV-Luc from The Plasmid Factory (Bielefeld, Germany), Luciferase Assay Reagent (LAR) and Cell Culture

Figure 1. (A) Maleimide and (B) thiol derivatives of the 1-α-*Z*-2,3-diaminopropionic acid substituted 4-amino-1*H*-pyrimidin-2-one RGD-mimetic with a 2-aminobenzimidazole moiety connected to the piperidine ring via one methylene group, which was used for coupling via PEG-linker (A) or direct coupling (B).

Lysis Reagent (CCLR) were bought from Promega (Mannheim, Germany), ion exchange columns SP Sepharose HP from Amersham Pharmacia Biotech (Freiburg, Germany), and centricon YM-30 from Millipore (Millipore, Schwalbach, Germany). Fluorescein-5-isothiocyanate (FITC), dithiothreitol (DTT), and 2,4,6-trinitrobenzenesulfonic acid (TNBS) were purchased from Sigma-Aldrich Laborchemikalien GmbH (Seelze, Germany); dimethylacetamide (DMAc) and all other chemicals were used of analytical grade.

Conjugate Synthesis. Conjugates were synthesized using two different approaches. Either (i) prePEGylated PEI (PEI25k-PEG30k), synthesized as described previously (*15*), was coupled directly with a maleimide-derivative of the RGD-M, or (ii) LMW-PEI (PEI 5 kDa) was PEGylated with a 2 kDa SPA-PEG2k-OPSS linker which was activated with DTT before coupling to a thiol derivative of the RGD-M. For the first synthetic approach (i), shown in Figure 2, 23.3 mg PEG-PEI, corresponding to 10 mg PEI (0.4 μmol), was diluted to 500 μL in either double distilled water (conjugate 10−1) or HEPES buffered saline (HBS, 20 mM HEPES, 150 mM NaCl, pH 7.5) (conjugates 10−2 and 5−2) in a 1.5 mL Eppendorf cup. RGD-M was dissolved in dimethylacetamide (DMAc) and amounts of 2.67 mg (4.0 μmol) (conjugates 10−1 and 10−2) or 1.33 mg (2.0 μmol) (conjugate 5−2) were added to the polymer solution, vortexed for 30 s and incubated under constant shaking on a sample shaker TH 15 (Edmund Bühler, Hechingen, Germany) at room temperature for 24 h. After incubation, purification was accomplished by ultrafiltration using centricon YM-30 spin columns.

The second synthetic approach (ii; Figure 3) involved coupling of a PEG linker to LMW-PEI. For this step, 5 mg LMW-PEI (1 μmol) was dissolved in HEPES buffered saline, pH 7.5, and reacted for 8 h with either 11.5 mg (5 μmol) (conjugate I) or 23 mg (10 μmol) (conjugate II) PEG linker, which had been dissolved in 200 μL absolute ethanol. Purification of the conjugates was achieved by modified ion exchange chromatography on an ÄKTA FPLC system equipped with 2 SP Sepharose HP cation exchange columns (ÄKTA Prime, Amersham Pharmacia Biotech, Freiburg, Germany) as previously described (*16*, *17*). The intermediate products, namely, the PEGylated PEI precursors, which were eluted with a high ionic strength buffer (3 M NaCl, 20 mM HEPES) from the ion exchange column, were desalted using centricon YM-3 spin columns as recommended by the manufacturer. They were characterized regarding their PEI concentration by copper complexation (*18*, *19*) and regarding their coupling degree by a pyridon-2-thion release assay (*20*). For this assay and for activation of the PEG-linker, PEG-PEIs were treated with a 10-fold molar excess of DTT for 4 h at room temperature. Pyridon-2-thion release was measured spectrophotometrically at 343 nm, and the activated PEG-PEIs were purified using centricon YM-3 spin columns

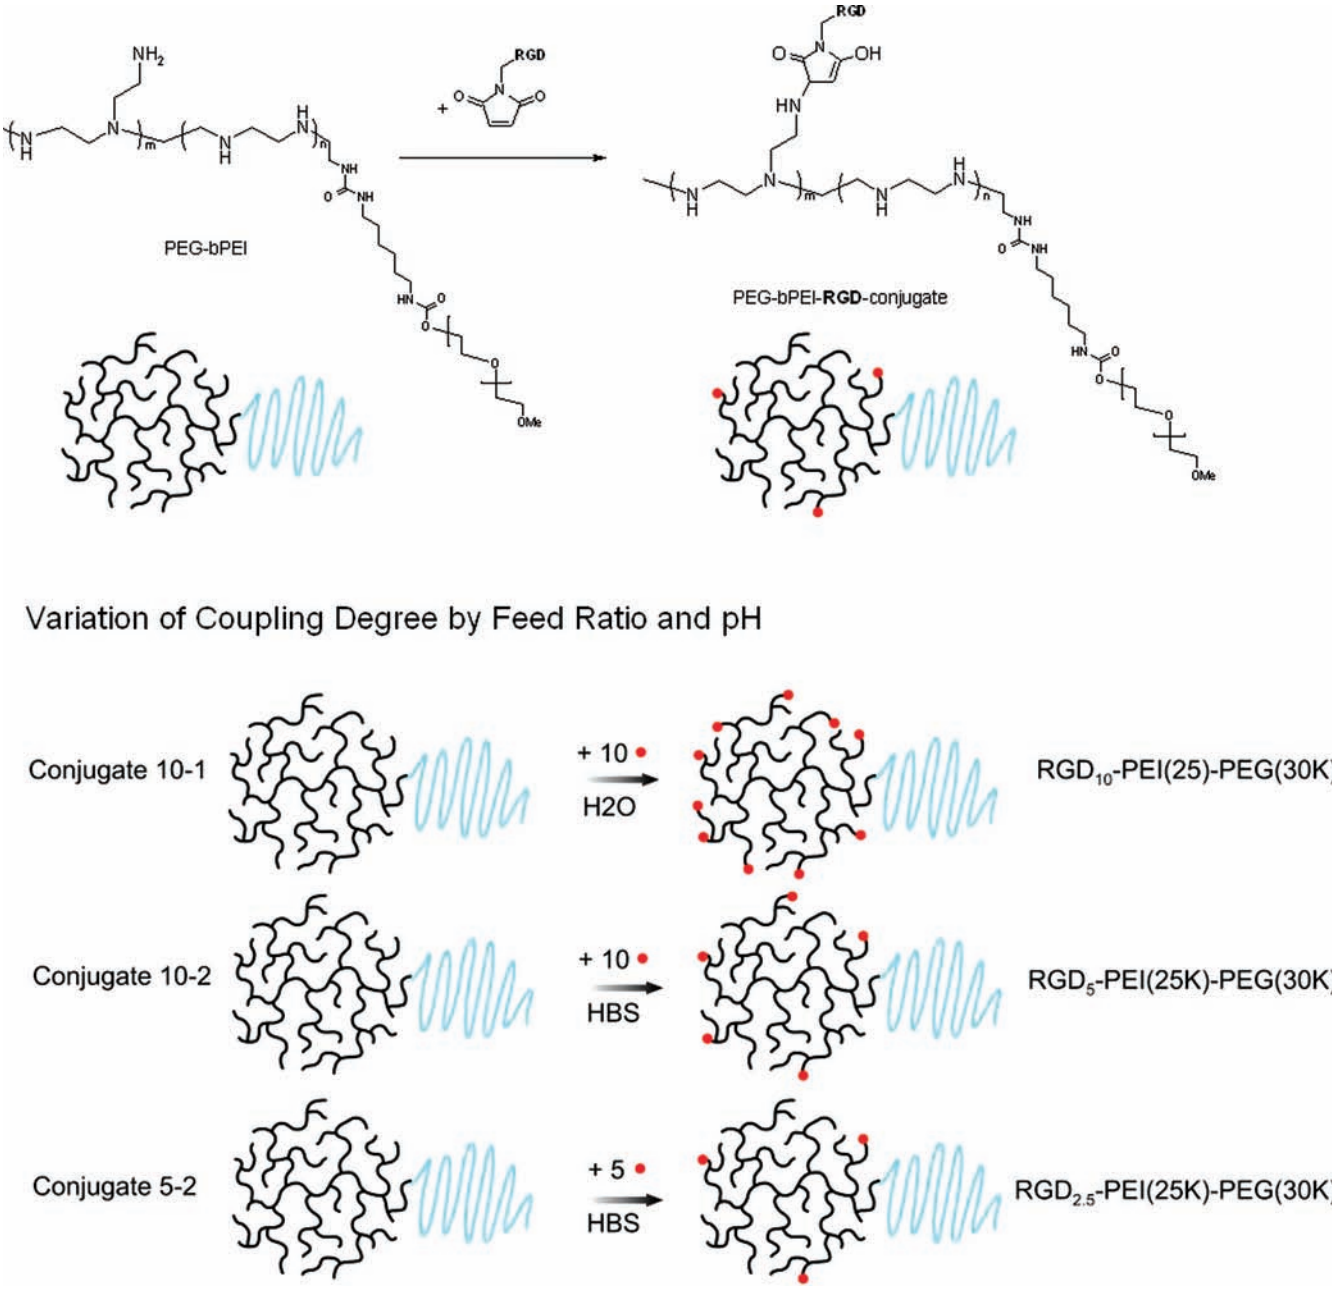

Figure 2. Synthesis of PEG-bPEI-RGD conjugates via direct coupling. Feeds of different excesses of RGD-Mimetic and synthesis at different pH values yielded three conjugates (Conjugate 10−1, 10−2, and 5−2) schematically illustrated below the synthesis scheme.

in the presence of 10 mM EDTA to avoid metal-catalyzed sulfhydryl oxidation (*21*). The activated, purified, and characterized precursors were mixed with a 3-fold (Conjugate I) or 10-fold (Conjugate II) molar excess of a sulfhydryl derivative of the RGD-M dissolved in DMAc and were coupled by formation of disulfide bonds. After another ultrafiltration step, coupling degree of all conjugates was determined spectrophotometrically at 297 nm, the wavelength that had shown maximal absorption in a wavescan of RGD-M. Measured absorption was compensated with the blank value of the noncoupled precursor.

Fluorescent Labeling of Polymers and Conjugates. Polymers were labeled as previously reported (*22*). Briefly, 20 mg polymer was dissolved in 2 mL 0.1 M sodium bicarbonate buffer, pH 9.0, and mixed with 1 mg FITC in 200 mL DMSO, stirred in the dark for 3 h at room temperature, and purified by ultrafiltration using centricon YM-10 spin columns with a MWCO of 10 kDa. The concentration of the purified sample was determined at 405 nm after formation of a picrate with 2,4,6-trinitrobenzenesulfonic acid (TNBS) in an assay previously described (*23*). The absorbance of the fluorescent dye was found not to interfere with the results from the TNBS assay.

FITC-labeled conjugates were obtained by labeling the presynthesized conjugates as described above. Since the targeting ligand, namely, the RGD-M, does not contain primary amines, we presumed that postlabeling would not negatively affect the conjugates, whereas prelabeling could interfere with the coupling steps of either RGD-Mal or the PEG-linker.

Radioactive Labeling of Conjugate 5−2. Similar to the fluorescent labeling, conjugate 5−2 was dissolved in 1 mL 0.1 M sodium bicarbonate buffer, pH 9.0, at a concentration of 10 mg/mL, mixed with p-SCN-Bn-DTPA (Macrocyclics, Dallas, TX, USA) in DMSO at a final concentration of 1 mg/mL and reacted for 1 h at room temperature. The reaction was stopped by addition of 0.1 M citrate buffer, pH 5.0, before the reaction

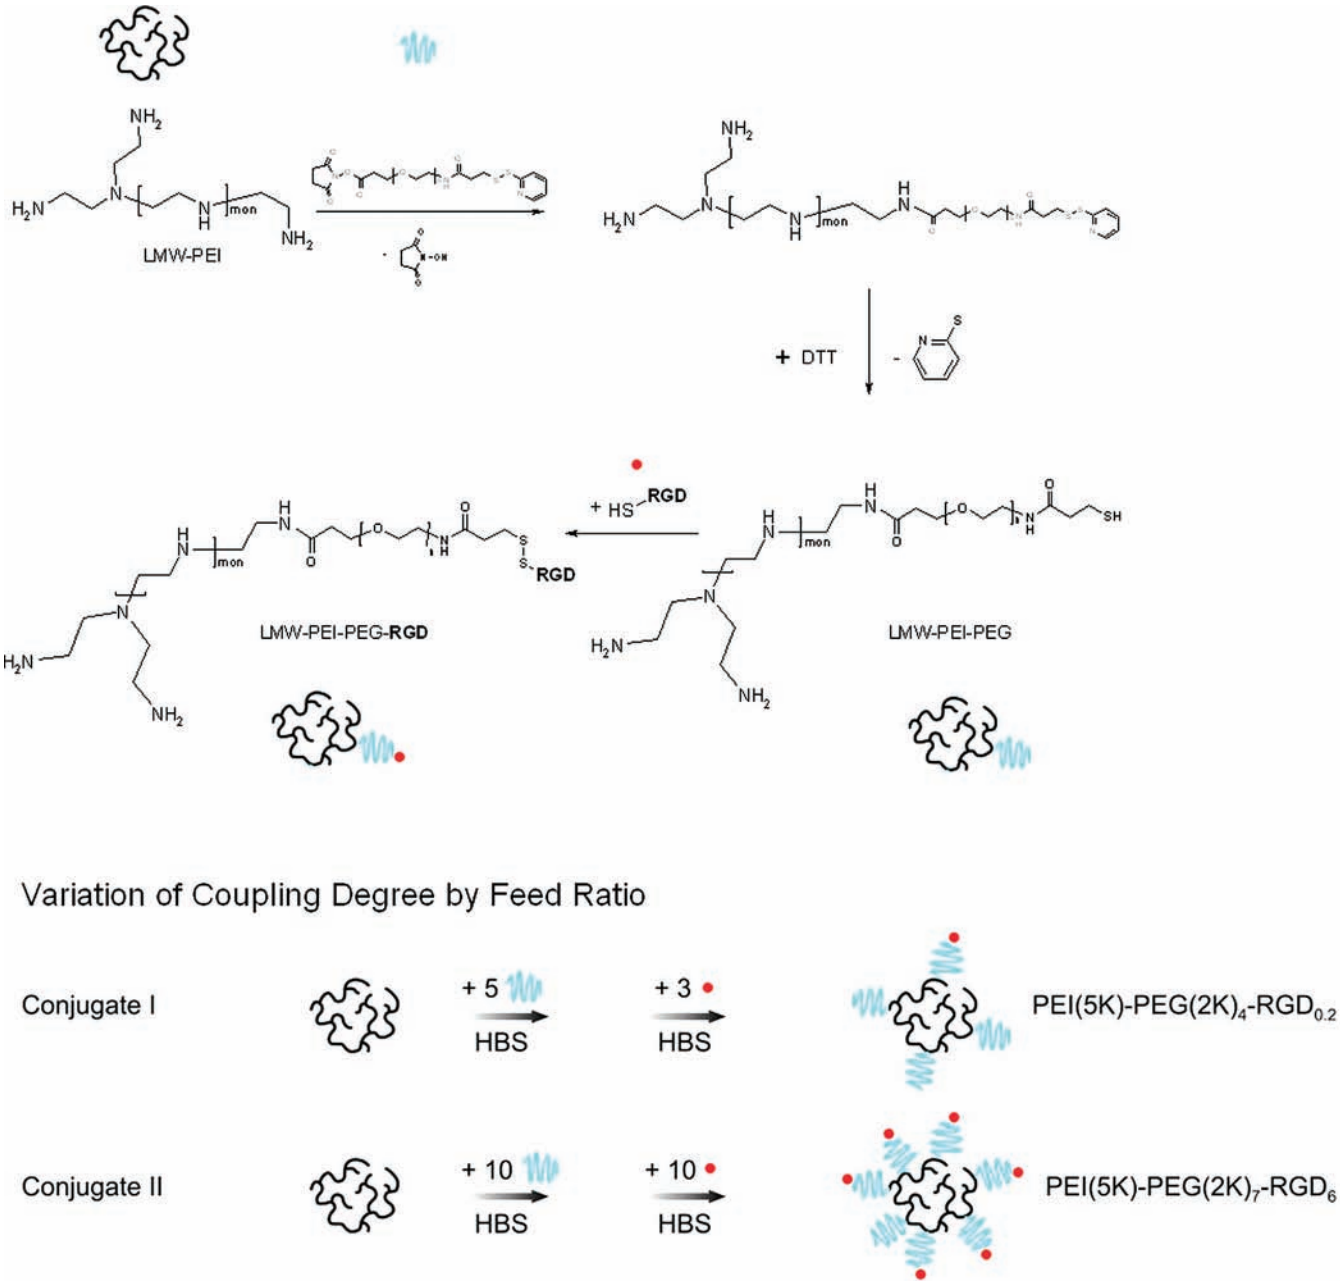

Figure 3. Synthesis of LMW-PEI-PEG-RGD conjugates via heterobifunctional PEG. Feeds of different excesses of RGD-Mimetic and PEG linker yielded two different conjugates (Conjugates I and II) schematically illustrated below the synthesis scheme.

mixture was purified by ultrafiltration using centricon YM-10 spin columns with a MWCO of 10 kDa. The concentration of the purified sample was determined at 405 nm using the TNBS-assay (*23*).

An amount of 100 μg of DTPA coupled polymer or conjugate was diluted in 0.1 M acetate buffer, pH 4.5, and mixed with 10 MBq $^{111}InCl_3$ for 30 min at room temperature, followed by size exclusion chromatography using a PD-10 Sephadex G25 prepacked column from Amersham Pharmacia Biotech (Freiburg, Germany).

Polyplex Formation. Polyplexes were formed by mixing equal volumes (25 μL each) of pDNA and polymer or conjugate diluted in 150 mM NaCl solution to obtain the desired nitrogen to DNA phosphate ratio (N/P ratio). Briefly, the appropriate amount of polymer was added to a pDNA dilution (0.04 μg/μL) to yield a final concentration of 0.02 μg DNA per μL, vortexed for 10 s, and incubated for equilibration for 10 min.

Dynamic Light Scattering (DLS) and Laser Doppler Anemometry (LDA). For measurements of hydrodynamic diameters, polyplexes were prepared as described above. 50 μL of the polyplex solution was pipetted into a disposable cuvette (UVette, Eppendorf, Wesseling-Berzdorf, Germany) and measured in the "General Purpose" mode, which best fits the correlation function of sizes measured with polyplexes. Attenuator and position were optimized by the device. Subsequently, polyplex solutions were diluted with 5% glucose solution to 800 μL and pipetted into a folded capillary cell (Malvern Instruments, Herrenberg, Germany) for zeta potential measurement. Measurements were performed in replicates of five using a Zetasizer Nano ZS (Malvern Instruments, Herrenberg, Germany) equipped with a 4 mW He−Ne laser at a wavelength of 633 nm at 25 °C. Scattered light was detected at a 173° backward scattering angle. The viscosity and refractive index of water at 25 °C was used for data analysis with the Dispersion

Technology Software 5.00 (Malvern Instruments, Herrenberg, Germany). The accuracy of the instrument was validated using reference polymer particles (Nanosphere Size Standards of 50, 100, and 200 nm, Duke Scientific Corp., Palo Alto, CA, USA) and with Zeta Potential Transfer Standard (Malvern Instruments, Herrenberg, Germany).

Ethidium Bromide Quenching Assay. To investigate if condensation efficiency of the polymers used for conjugate synthesis would be influenced by coupling of PEG or the targeting ligand, 4 μg of herring testes DNA (Sigma-Aldrich Chemie GmbH, Schnelldorf, Germany) were complexed with polymers or conjugates at different N/P ratios. After incubation for 20 min at room temperature, 20 μL of a 0.1 mg/mL ethidium bromide solution (Carl Roth GmbH, Karlsruhe, Germany) was added and the samples incubated briefly in the dark after intensive mixing. Intercalation-caused fluorescence was quantified using a fluorescence plate reader (LS 50 B, Perkin-Elmer, Rodgau-Jügesheim, Germany) at 518 nm excitation and 605 nm emission wavelengths. Experiments were performed in triplicate; results are given as mean relative fluorescence intensity values where intercalation of free DNA represents 100% fluorescence and nonintercalating ethidium bromide in buffer represents 0% remaining fluorescence.

Hemolytic Activity. Surface activity leading to hemolysis was quantified after treating human erythrocytes with polyplexes made of polymers or conjugates. Therefore, erythrocytes were isolated from fresh citrated blood from healthy volunteers by centrifugation, washed with PBS buffer, and diluted to 5×10^8 cells/mL. Polyplexes of 0.1 μg pDNA per mL were prepared at N/P 5, and 50 μL aliquots of polyplex solutions, 1% Triton-X 100 (100% lysis), or 150 mM NaCl (0% lysis) were mixed with 50 μL erythrocyte suspension. After incubation for 30 min at 37 °C, samples were centrifuged at 400 *g*. Hemolysis of replicates of three was measured spectrophotometrically in supernatants at 541 nm and is given as mean percentage of the released hemoglobin normalized to total hemolysis induced by 1% Triton-X 100.

Cell Culture. MeWo (human malignant skin melanoma; ATCC: HTB-65) and A549 (human non-small-cell lung carcinoma; ATCC: CCL-185) cells were purchased from ATCC (Teddington, UK) and maintained in DMEM (PAA Laboratories, Cölbe, Germany) supplemented with 10% fetal calf serum (Cytogen, Sinn, Germany) in humidified atmosphere with 5% CO_2 at 37 °C.

Immunofluorescence Staining of Integrin $\alpha_v\beta_3$ Receptors on the Cell Surface. MeWo and A549 cells were seeded with 60 000 cells per well on 24 well plates (Nunc, Wiesbaden, Germany). After incubation for 24 h, cells were washed with Earle's Balanced Salt Solution (EBSS, Hyclone, Thermo Fisher, Schwerte, Germany) and incubated with either 3% bovine serum albumin in phosphate buffered saline (PBS/BSA) only (blank cells and secondary antibody only cells) or with integrin $\alpha_v\beta_3$ antibody ([BV3] (ab7166), Abcam, Cambridge, MA, USA) at a concentration of 1 μg/mL in PBS/BSA for 1 h in the dark. Cells were washed three times with ice cold PBS before all wells except for blanks were treated with a 1:100 dilution of a FITC-labeled goat polyclonal to mouse IgG H&L (ab6785, Abcam, Cambridge, MA, USA) antibody in PBS/BSA for 30 min in the dark. Afterward, cells were washed three times with ice-cold PBS before they were trypsinized with 100 μL trypsin/EDTA (PAA Laboratories, Cölbe, Germany) and fixed with 200 μL of a 1:1 mixture of FACSFlow (BD Biosciences, San Jose, CA) and 4% paraformaldehyde in PBS. Cell suspensions were stored refrigerated in the dark until analysis by flow cytometry. All experiments were performed with replicates of three.

Binding Assay. MeWo and A549 cells were seeded with 60 000 cells per well in 24 well plates (Nunc, Wiesbaden, Germany). After incubation for 24 h, medium was aspirated and cells were supplied with cold serum-containing medium before they were transfected with polyplexes containing 1 μg DNA per well and FITC-labeled polymer or conjugate at N/P 5. Triplicates of cells were incubated with the polyplexes for 15 min at 4 °C before they were washed three times with PBS, trypsinized, and fixed with a 1:1 mixture of FACSFlow (BD Biosciences, San Jose, CA) and 4% paraformaldehyde in PBS. Cell suspensions were stored refrigerated in the dark until analysis by flow cytometry.

Flow Cytometry. Suspensions of fixed cells were measured on a FACScan (BD Biosciences, San Jose, CA) with excitation at 488 nm and the emission filter set to a 530/30 bandpass. Cells were gated, 10,000 viable cells were evaluated in each experiment, and results are given as the mean of 3 independent measurements. Data acquisition and analysis was performed using CellQuest Pro (BD Biosciences, San Jose, CA) and FCS Express V3.00 (DeNovo Software, Thornhill, Canada). Results were statistically analyzed using one-way ANOVA with Bonferroni posthoc test.

Quantification of Uptake. MeWo and A549 cells were seeded with 60 000 cells per well in 24 well plates (Nunc, Wiesbaden, Germany). After incubation for 24 h, triplicates of cells were treated with polyplexes prepared of various amounts of pCMV-Luc and radiolabeled conjugate 5−2 at N/P 5. Cells were incubated for 4 h before they were treated as described by Haigler et al. (*24*) to make sure only internalized activity was measured. Briefly, the cells were first treated with 0.5 mL acetic acid (0.2 M NaAc containing 0.5 M NaCl, pH 2.5) for 6 min at 4 °C followed by a quick washing with an additional amount of 0.5 mL acetic acid to remove any remaining membrane-bound activity. The cell-associated activity, which was extracted by treating the cells with 0.5 mL 1 M NaOH for 80 min at 37 °C, was considered to be internalized. The extracts in 0.5 mL NaOH were collected, and the wells were then washed with an additional 0.5 mL NaOH. Before analysis in the gamma counter, the samples were adjusted to neutral pH by adding drops of 3 M HCl.

In Vitro Cell Transfection. MeWo and A549 cells were seeded with 30 000 cells per well in 24 well plates (Nunc, Wiesbaden, Germany). After incubation for 24 h, cells were treated with polyplexes prepared of the "gold standard" PEI 25 kDa, LMW-PEI, PEG-PEI, or the various conjugates at N/P 5. After 4 h of incubation, medium was changed and cells were incubated for another 44 h before they were washed with PBS and lysed with cell culture lysis reagent (CCLR, Promega, Mannheim, Germany). Lysates of triplicates were assayed for luciferase expression with a commercial luciferase assay reagent (LAR, Promega, Mannheim, Germany) on a luminescence plate reader LUMIstar OPTIMA (BMG Labtech, Offenburg, Germany).

Competitive Inhibition of in Vitro Cell Transfection. For competitive inhibition of cell transfection, MeWo and A549 cells were seeded with 30 000 cells per well in 24 well plates (Nunc, Wiesbaden, Germany). After incubation for 24 h, cells were pretreated with increasing amounts increasing from 0.05 to 1.5 nmol per mL of the free targeting ligand for 15 min at 37 °C. Polyplexes prepared of PEG-PEI or conjugate 5−2 at N/P 5 were added into the RGD-M containing medium. Replicates of 3 were incubated for 4 h before medium was changed and thereafter treated as described above.

RESULTS AND DISCUSSION

Synthetic Outcome. RGD-peptides were reported to be good targeting ligands for tumor endothelium using nonviral lipoplexes (*25, 26*) or polyplexes containing siRNA (*6, 27, 28*) and pDNA (*4, 5*) or protein delivery systems bearing antisense

Table 1. Molecular Composition of Polymers and Conjugates, and Size and Zeta Potential of Their Complexes with pDNA

	PEI 25k	PEG-PEI	Con 5−2	Con 10−2	Con 10−1	LMW-PEI	Con I	Con II

oligonucleotides (*29*). Integrin targeting is an approach adopted from nature: several pathogenic organisms, such as adenoviruses (*30*), use the integrin receptor to promote their cellular internalization. While RGD-PEG-PEI has successfully been reported to efficiently deliver nucleic acids into tumors (*6*), cRGD bearing micelles did not show enhanced uptake but modulated intracellular trafficking (*4*). RGD-mimetics, on the other hand, have, to our knowledge, so far only been used as therapeutic agents, e.g., as angiogenesis inhibitors (*31*), inhibitors of monocyte-derived macrophages (*32*), enhancers of osseointegration (*33*), and imaging tracers for atheriosclerotic plaques (*34*), and they were were recently described as ligands for 5-FU (*35*) or TNFα carrying liposomes (*36*). In this study, we describe for the first time synthesis of five RGD-M conjugates of different molecular composition in two different coupling approaches (compare Figures 2 and 3) for nonviral gene delivery by coupling of a 1-α-*Z*-2,3-diaminopropionic acid substituted 4-amino-1*H*-pyrimidin-2-one. This small molecule (*13*) exhibits nanomolar affinity to the vitronectin receptor (IC50 = 1.3 nM) as determined by ELISA and therefore binds more strongly than the physiologic ligand vitronectin (IC50 = 6 nM (*37*)) and is comparable to the cyclic pentapeptide Cilengitide (IC50 = 0.86 nM (*38*)) which is being studied in clinical trials. The advantages of this targeting ligand compared to peptides are its metabolic stability and low molecular weight. Two types of conjugates were synthesized consisting either of AB-block-copolymers of PEI (25 kDa) and PEG (30 kDa) directly coupled with RGD-M ligands attached to PEI amines (Figure 2) or of a low molecular weight PEI core, which was PEGylated using a heterobifunctional PEG linker that was decorated with RGD-M molecules at the distal end of the PEG chains (Figure 3), similar to (*6*, *28*). Coupling of PEG to LMW-PEI in HBS buffer, pH 7.5, yielded coupling degrees of 70−80% of the feed, as shown in Figure 3. Coupling of RGD-M to activated PEG depended not only on the excess of RGD-M, but also on the amount of PEG-linker present. Synthesis of Conjugate I, for which a 5-fold molar excess of PEG over PEI and 3-fold molar excess of RGD-M over PEI was used, resulted in a conjugate that can be described as LMW-PEI-$(PEG2k)_4$-$RGD_{0.2}$ (final yield of LMW-PEI: 10.0%), whereas Conjugate II, for which the feed contained a 10-fold molar excess of PEG linker and a 10-fold molar excess of RGD-M over PEI, yielded the conjugate LMW-PEI-$(PEG2k)_7$-RGD_6 (final yield of LMW-PEI: 5.8%). Coupling of RGD-mimetic-maleimide turned out to be strongly influenced by pH. PEG-PEI dissolved in double-distilled water produced a pH of 10, where most of the amines in PEI are deprotonated and available for addition to RGD-mimetic-maleimide. Mixing the two components yielded quantitative reaction, whereas only 50% of the feed reacted with PEG-PEI in HEPES buffered saline adjusted to pH 7.5. Thus, Conjugate 10−1, where a 10-fold molar excess of RGD-M over PEI was added to PEG-PEI in water, reacted to a compound which can be described as PEG30k-PEI25k-RGD_{10} (final yield of PEG-PEI: 86.0%). Conjugates 10−2 and 5−2, where 10- and 5-fold excesses of RGD-M, respectively, were added to PEG-PEI in HBS, resulted in PEG30k-PEI25k-RGD_5 (final yield of PEG-PEI: 84.0%) and PEG30k-PEI25k-$RGD_{2.5}$ (final yield of PEG-PEI: 88.0%). While LMW-PEI-PEG-RGD conjugates were purified in several steps by ion exchange chromatography and buffer was additionally exchanged by ultrafiltration, PEG-PEI-RGD conjugates were only ultrafiltered and revealed much higher yields. All conjugates and their syntheses are depicted schematically in Figures 2 and 3 and Table 1.

Hydrodynamic Diameter and Zeta Potential. Both PEI and PEGylated PEIs are known to efficiently form polyplexes with p-DNA (*39*); hence, we measured hydrodynamic diameters of self-assembled complexes containing plasmid DNA and conjugates and compared their sizes to polyplexes prepared with the polymers that had been used for synthesis. It was reported earlier that PEI 25 kDa formed smaller particles than LMW-PEI at low N/P ratios (*40*), which is in good agreement with our findings (compare Figure 4). Interestingly, conjugation of RGD-M to PEG-PEI influenced size of particles in different ways. In theory, conjugation shifts the ratio of primary/secondary/tertiary amines and thus the protonation profile. Additionally, the targeting ligand itself can be protonated and influence interaction with polyanions. Therefore, its spatial orientation is most relevant. In our case, Conjugate 10−1, bearing 10 molecules RGD-M, formed particles that are smaller (92.1 ± 3.23 nm) than unmodified PEG-PEI (162 ± 5.34 nm). Conjugate 5−2, on the other hand, which bears the smallest amount of RGD-M molecules, formed larger complexes (387 ± 101 nm) than PEG-PEI, and Conjugate 10−2 (271 ± 6.3 nm), bearing twice as many RGD-M molecules as Conjugate 5−2 and half as many as Conjugate 10−1, still formed bigger complexes than PEG-PEI but smaller ones than the conjugate bearing the least targeting ligands. Obviously, the targeting moiety affected complex formation, which resulted in the smallest complexes formed by the conjugate bearing the highest density of RGD-M. Surprisingly, conjugates of lower coupling degree formed significantly larger particles. This can be explained by spatial orientation of the targeting ligands, which do not seem to be involved in complex formation if coupled in low density but may be oriented toward the surface of the complexes yielding nonspherical particles which can only be measured via hydrodynamic diameters by dynamic light scattering. Conjugates I and II, on the other hand, both exhibited a

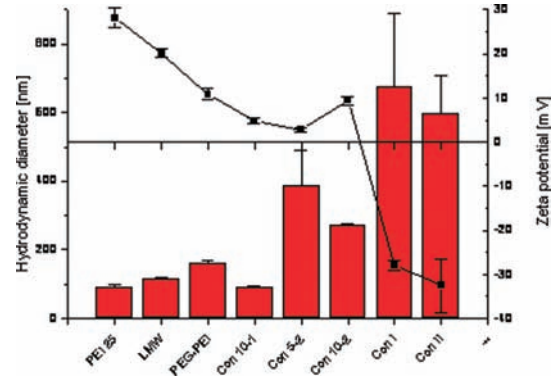

Figure 4. Size (bars) and zeta potential (squares) of pDNA complexes formed with polymers and conjugates at N/P 5 were significantly affected by conjugation. Conjugates I and II synthesized by PEGylation of LMW-PEI were not able to condense DNA into small particles, also shown by the negative zeta potential, whereas sizes of directly coupled PEG-PEI-RGD conjugates decrease with increasing ligand density and exhibit only slight differences in surface charge.

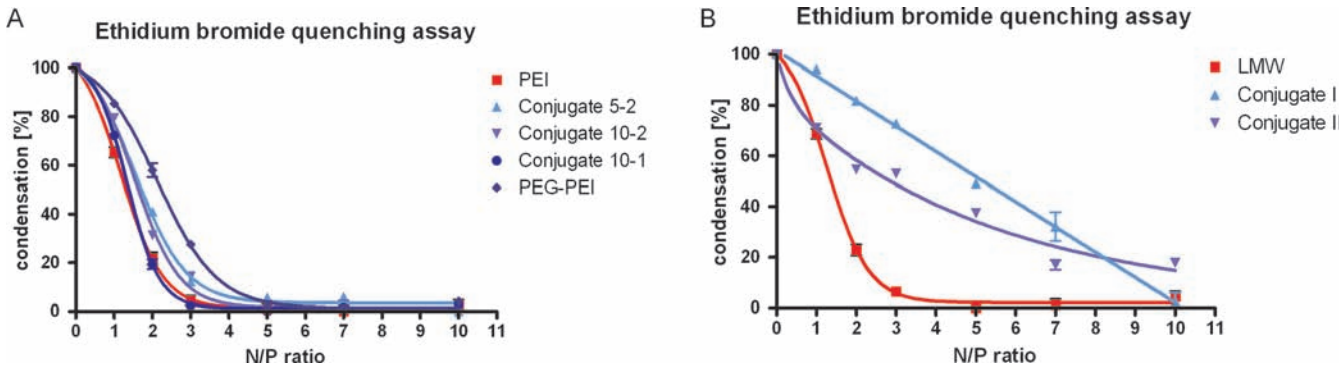

Figure 5. Quenching of intercalation caused ethidium bromide fluorescence upon condensation of DNA with (A) PEI 25k, PEG-PEI, or PEG-PEI conjugates and (B) LMW-PEI or LMW-PEI-PEG conjugates. Increase of ligand density increased condensation of DNA. While only minor differences were observed among PEG-PEI and its conjugates, condensation of LMW-PEI was strongly influenced upon conjugation.

strong hindrance in nanoplex formation compared to LWM-PEI. The LMW-PEI used in our study was less branched than PEI 25 kDa, and coupling of PEG decreased electrostatic interaction of LMW-PEI with negatively charged DNA both by a shift of the ratio of primary/secondary/tertiary amines and by modification of a small (5 kDa) ionic polymer with a relatively large (2 kDa) nonionic polymer, yielding a small portion of PEI in the overall copolymer conjugates, in fact, less than 50%. The increased number of targeting ligands in Conjugate II seemed to decrease the size of the polyplexes, which is a indication of interaction between the targeting ligand and DNA. However, differences in size between Conjugates I (677 ± 211 nm) and II (597 ± 111 nm) were not significant. In a previously published paper, it was reported that branched PEI 25k even after coupling of 40 molecules PEG and RGD peptide still formed small particles of about 200 nm at N/P ratio >1 (*28*). Therefore, we hypothesized that LMW-PEI, which in addition to its shorter chain length contains a lower branching degree, is not suitable for DNA condensation after PEGylation. It is known that particles <200 nm in size are taken up by most cell lines and that larger particles sediment faster, thereby enhancing transfection efficiency under in vitro conditions (*41*). Polyplexes showing aggregation, on the other hand, are not suitable for systemic administration. Aggregation tendency, of course, has to be evaluated in the context of surface charge. Therefore, zeta potentials of the various complexes were measured by LDA, as shown in Figure 4. Polyplexes formed with PEI25k revealed the highest surface charge, which can easily be understood as a function of the high number of protonable amines. LMW-PEI polyplexes, which have a lower branching degree (*14*) and therefore a smaller number of primary amines, exhibited a decreased zeta potential, followed by PEG-PEI polyplexes, where the positive surface charge is believed to be shielded by nonionic PEG (*42*, *43*). Polyplexes prepared with RGD-PEG-PEI conjugates showed slightly lower surface charges compared to PEG-PEI. This could be explained by the coupling of the targeting ligands, which most probably are attached to secondary amines, which exhibit a high electron density but lower steric hindrance than tertiary amines. By coupling, secondary amines are turned into tertiary ones, which are less prone to protonation than secondary amines, decreasing the protonation of the conjugate compared to the polymer. Additionally, it is possible that the targeting ligand, if oriented toward the surface of the polyplex, may shield the positive surface charges of the polyplexes as described for transferrin-PEI polyplexes (*44*), PEG-PEI conjugates with anti-OA3 Fab′ (*45*), and PEG-PEI conjugates with trastuzumab (*46*). LMW-PEI-PEG conjugates, on the other hand, formed polyplexes with net negative surface charge, which was probably caused by insufficient condensation of DNA. As already seen in size measurements, PEGylation of LMW-PEI impaired condensation

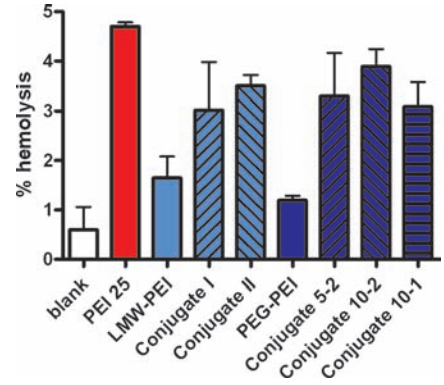

Figure 6. Percentage of hemolytic activity of pDNA complexes formed with PEI 25k, LMW-PEI, LMWPEI-PEG conjugates, PEG-PEI, or PEG-PEI conjugates compared to total hemolysis caused by 1% Triton X. Both LMW-PEI and PEG-PEI caused fewer hemolytic effects than PEI 25 kDa, while their conjugates displayed lower biocompatibility but still less hemolysis than PEI 25 kDa.

of DNA. In the case of LMW-PEI conjugates, a relatively small polymer (5 kDa) was substantially modified with several comparably large PEG chains (2 kDa). Although the targeting moiety is a small molecule, the assumption that conjugation can influence complex formation (*47*) explained the differences in sizes between LMW-PEI conjugate complexes and LMW-PEI complexes.

Condensation of DNA. A means to quantify condensation and protection of DNA inside the core of polyplexes is detection of intercalation-caused fluorescence of double strands that are available for reaction with ethidium bromide. DNA condensation efficiency of the different polymers and conjugates at different N/P ratios was therefore measured in ethidium bromide quenching assays. PEG-PEI conjugates (see Figure 5A) showed an obvious trend: Unmodified PEI25k incorporated and protected DNA best, showing full condensation at N/P 3, whereas PEG-PEI reached full condensation at N/P > 5. By increasing the amount of RGD-M molecules per PEG-PEI, condensation efficiency was gradually increased, and Conjugate 10−1 showed similar values to PEI25k. This was in line with the trends observed in dynamic light scattering, where Conjugate 10−1 formed polyplexes as small as PEI25k. Better condensation and higher stability of PEG-PEI conjugate complexes compared to their unmodified counterpart were previously described for trastuzumab-coupled PEG-PEI conjugates (*46*). LMW-PEI-PEG conjugates (Figure 5B) yielded condensation properties much different from those of LMW-PEI. The latter exhibited condensation efficiency almost as good as PEI 25k with complete condensation above N/P of 5. Conjugate I, on the other hand, did not show sigmoidal dose−response condensation efficiency but a linear trend, which proves impairment of the usual

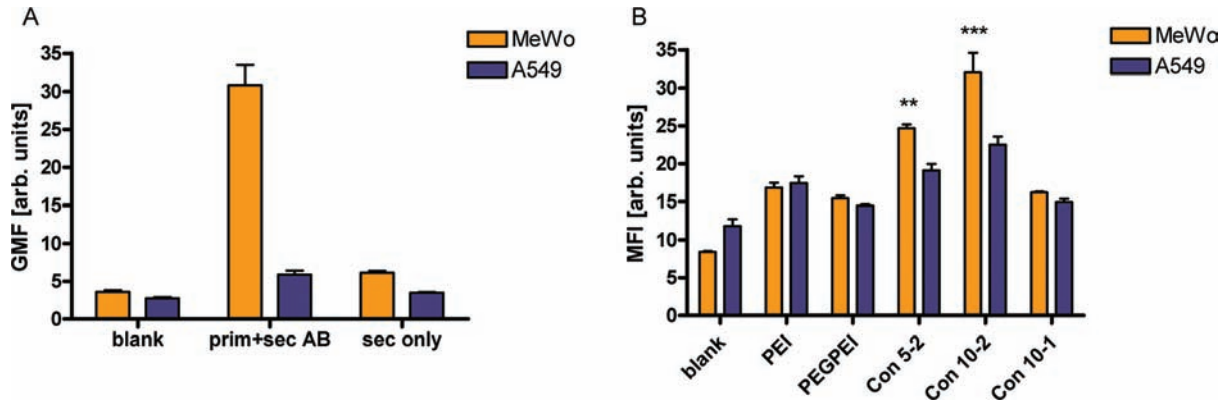

Figure 7. (A) Flow cytometric analysis of relative expression of integrin $\alpha_v\beta_3$ in A549 and MeWo cells compared to blank cells and cells treated with the fluorescently labeled secondary antibody only. MeWo cells known to express a noticeable amount of integrin receptors proved significantly stronger binding of the primary antibody. (B) Flow cytometric binding analysis of fluorescently labeled polymer and conjugate complexes to the surface of A549 and MeWo cells. Conjugate 10−2 with a medium ligand density shows the strongest differences concerning binding to receptor positive and receptor negative cells. Cells treated with Conjugate 10−1 were macroscopically observed to be detached from the plate.

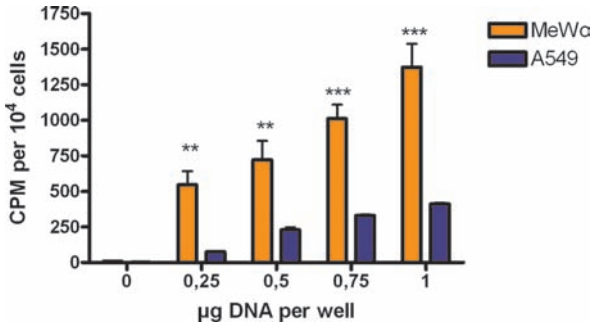

Figure 8. Radioactive internalization analysis of radiolabeled conjugate 5−2 complexes into A549 and MeWo cells at different concentrations. Up to 1 mg DNA per mL, increasing uptake of radiolabeled polyplex is maintained with increasing concentration.

condensation behavior of DNA by PEI. As already seen in size and zeta potential measurements, DNA seemed to be loosely bound to the conjugates at N/P 5 and was not well-condensed into small polyplexes. Interestingly, at N/P = 10, full condensation was reached, and it can be hypothesized that the small amount of targeting ligand in this conjugate gained importance only at higher N/P ratios. Conjugate II exhibited another profile, which was attributed to the higher graft density of RGD-M. At low N/P ratios, Conjugate II showed better condensation than Conjugate I, but full condensation was not reached at N/P of 10. This assay of course only mirrors in vitro condensation. Complex stability in the presence of serum is currently being addressed in our present study, and in vivo stability will eventually be the subject of an in vivo study if biocompatibility of the conjugates proves suitable.

Biocompatibility. Nonspecific interaction of polyplexes with cell surfaces is known for polycations such as PEI, PPI, PLL, or PAMAM and can provoke nano hole formation caused toxicity (*48*). PEGylation of polycations is an effective shielding approach to decrease interaction with blood components (*15*). Since all of the conjugates showed nearly neutral or even negative zeta potentials, a strong decrease of nonspecific interactions was expected. In order to investigate blood compatibility of the conjugates, red blood cells were treated with polyplexes composed of DNA and polymers or conjugates and analyzed for hemolysis (see Figure 6). Polyplexes prepared with PEI25k caused the strongest hemolytic effects; LMW-PEI and PEG-PEI polyplexes showed significantly (*** $p < 0.001$) decreased hemolytic activity. Interestingly, conjugation with the targeting ligand increased hemolysis: Conjugate II, despite its negative surface charge, caused significantly (* $p < 0.05$) higher hemolysis than LMW-PEI, and Conjugates 10−1 (* $p < 0.05$), 10−2 (** $p < 0.01$), and 5−2 (*** $p < 0.001$) showed stronger hemolysis than PEG-PEI. This could be an indication of surface activity or different spatial orientation of the targeting ligand depending on the coupling degree. RGD sequences do not only interact with integrin $\alpha_v\beta_3$ (*49*). Since erythrocytes do not carry integrins but rather an integrin-associated protein (IAP) CD47 (*50*), nonspecific interactions in this assay could lead to cross reactivity of the conjugates with CD47. Agglutination of the red blood was strongly observed in cells treated with unmodified PEI25k and slightly in LMW-PEI treated cells. PEG-PEI and conjugates did not cause agglutination despite the slightly higher hemolytic effects of the conjugates (data not shown). In order to test the conjugates in an in vivo study, minimal hemolysis and cross-linking of cells is a prerequisite. Further toxicity assays will show whether the conjugates we synthesized are safe enough to be applied intravenously in a tumor model. Other options could be intratumoral injections or local administration.

Expression of Integrin Receptor. To test specific bioactivity of the conjugates in $\alpha_v\beta_3$ integrin overexpressing cells compared to cells that do not show overexpression of this receptor, expression status of MeWo human melanoma and A549 carcinomic human alveolar basal epithelial cells, two cell lines previously used for integrin targeted gene delivery (*51*), was quantified after immunostaining by flow cytometry (Figure 7A). A549 cells treated with primary and secondary antibody did not show significantly stronger fluorescence than after treatment with secondary antibody only, proving that fluorescence was only caused by nonspecific binding of the secondary antibody. MeWo cells, on the other hand, showed clear overexpression of CD51/CD61. A549 cells were therefore considered receptor-negative, whereas MeWo cells were considered receptor-positive.

Cell Binding of Polyplexes. Binding of fluorescently labeled polyplexes to the receptor expressing or nonexpressing cell surface of MeWo or A549 cells, respectively, was tested at 4 °C, where energy-dependent processes such as receptor-mediated endocytosis are deactivated. Flow cytometric analysis proved that only Conjugates 10−2 and 5−2 with substitution degrees of 5 and 2.5 RGD-M per molecule displayed differences concerning binding to receptor-positive or receptor-negative cells (Figure 7B). Conjugate 10−1, on the other hand, which bears the highest number of RGD-M molecules, did not show significantly higher binding to MeWo compared to A549 cells. Due to higher stability of the complex, possibly at least parts of the targeting ligand in Conjugate 10−1 are involved in complex formation and are therefore either oriented toward the inside of the complex or hidden by DNA with which they interact. Therefore, Conjugate 10−1 forms the smallest particles, condenses DNA as well as PEI25k, and does not bind to MeWo

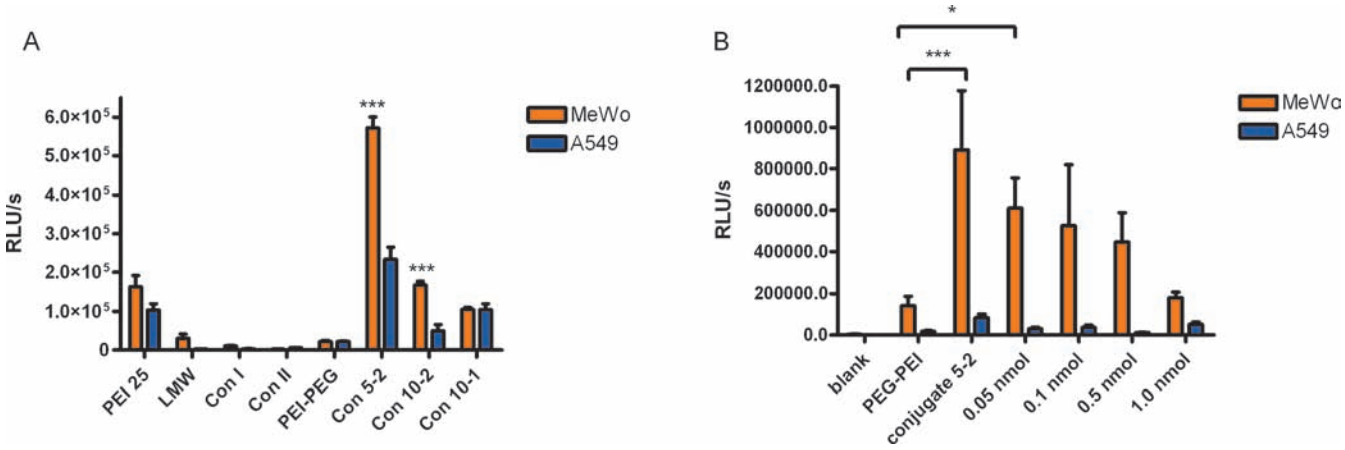

Figure 9. (A) Transfection efficiency of polymer and conjugate complexes in A549 and MeWo cells. Conjugate 5−2 with the lowest ligand density revealed the highest transgene expression. (B) Competitive inhibition of transfection efficiency of conjugate complexes in A549 and MeWo cells. At a concentration of 0.1 nmol/mL of free targeting ligand or higher, transfection efficiency of Conjugate 5−2 could be comparatively inhibited to values significantly higher than that of PEG-PEI.

cells specifically more strongly than to A549 cells. Concerning substitution degree, linker chemistry, and their correlation to specificity, there are contrary reports in literature. While Garg et al. (*35*) reported increasing specific uptake with increasing amounts of targeting ligand in a range of coupling degree below 8−10 mol %, they also described lipoplex destabilization above that degree. This amount is still much below the coupling degree of all the conjugates in our study, and it is possible that polyplexes could as well be destabilized at high coupling degrees. It must also be kept in mind that the RGD-M used for conjugate synthesis is a receptor antagonist. Vitronectin-receptor antagonists are known to cause detachment of cells. The high amount of RGD-M present in Conjugate 10−1 therefore detached cells effectively interacting with Conjugate 10−1, which could be observed macroscopically. The detached cells were aspirated in one of the washing steps leading to low fluorescence values measured by flow cytometry. It was reported earlier that integrin dimerization, cluster formation, and activation of downstream effects depend on ligand density and affinity (*52*). This could explain that conjugates bearing a higher ligand density have a stronger inhibitory effect on cell attachment than those with lower ligand density.

Transfection Efficacy. To investigate whether the strong interaction of the conjugates with MeWo cells was only a concentration-dependent surface effect of the targeting ligand, uptake, which was assumed to be receptor-mediated endocytosis due to a previous report (*53*), was studied in a radioactive assay. Here, surface-bound material could be removed and distinct information about internalization could be obtained. In order to test for concentration-dependent effects, MeWo and A549 cells were treated with increasing concentrations of Conjugate 5−2/DNA polyplexes, which had caused strong nonspecific effects in the hemolysis assay, which could be interpreted as an indication of a surface effect. However, scintillation counting of cell lysates confirmed cell specificity of uptake at each concentration as shown in Figure 8. Up to 1 μg of DNA per well, an increasing abundance of RGD-M leads to increasing uptake of polyplexes without any sign of cell detachment.

Finally, transgene expression after transfection of receptor-positive and receptor-negative cells with polymer and conjugate complexes was measured. PEI 25k, the "gold standard" in polymeric nonviral gene delivery, was used for comparison in each experiment (compare Figure 9A). LMW-PEI and PEG-PEI complexes exhibited lower transfection efficiency compared to PEI25 kDa, due to decreased nonspecific cell interaction. LMW-PEI-PEG conjugates were even inferior to LMW-PEI concerning transfection efficiency, which can be explained by insufficient condensation and protection of DNA inside the complex. In a previous study, it was shown that attaching the targeting ligand to PEI via PEG spacer achieved higher transfection efficiency than direct coupling (*46*), but in this panel of conjugates, PEGylated LMW-PEI conjugates did not exhibit desirable qualities. By PEGylation of LWM-PEI, the interaction between polycation and polyanion was obviously impaired, shown by poor condensation and large polyplex sizes. In another report, conjugation of an RGD peptide to PEI via PEG was inefficient, whereas coupling via SPDP-mediated efficient and specific transfection efficiency (*51*) is in accordance with our results. Directly coupled Conjugate 10−1 yielded higher transfection efficiency than PEG-PEI but no specific differences between the cell lines. This comparably low transfection efficacy of Conjugate 10−1 can again be explained by cell detachment, which falsified the results. Conjugate 5−2, on the other hand, showed 28-fold higher transgene expression in MeWo cells than PEG-PEI and highly significantly (*** $p < 0.001$) stronger expression than in A549. The low ligand density in this conjugate obviously did not cause any inhibitory effects on cell attachment. Conjugate 10−2 achieved very good and specific (** $p < 0.01$) transfection efficiency in MeWo as well, which was comparable to that of the PEI 25 kDa but might be decreased compared to Conjugate 5−2 due to cell detachment. The fact that some of the conjugates also showed better transfection efficiency in A549 cells compared to nontargeted PEG-PEI can be explained by a constitutive expression of integrin receptor on almost all cells which was shown to be much lower in A549 than in MeWo cells but not fully absent (Figure 7A).

Specificity of Transfection Efficacy. To ascertain receptor specificity of transfection efficiency, which had also yielded higher values for conjugates in A549 cells, uptake of conjugate complexes was competitively inhibited by free ligand. Eventually, transfection efficiency was measured and compared to that of nontargeted PEG-PEI complexes, as shown in Figure 9B. Conjugate 5−2 complexes again caused significantly higher (*** $p < 0.001$) transfection efficiency in MeWo than PEG-PEI complexes, but transgene expression was decreased by increasing amounts of free ligand. At 0.1 nmol inhibitor per mL and higher concentrations, transfection efficiency in MeWo cells was not significantly different from that of PEG-PEI complexes. Interestingly, Conjugate 5−2 complexes also again caused slightly higher transgene expression in A549 cells than PEG-PEI complexes, and this increase was reversed in A549 cells, too, in the presence of free targeting ligand. Since A549 cells do express a low number of integrin receptors, this result is not

very surprising. Conjugate 5−2 was exemplarily investigated in this assay, as it has shown the highest transfection efficacy in the absence of competing free RGD-M. Since we were able to prove the specificity of its receptor-mediated delivery of pDNA, we hypothesize that this uptake route is also true in case of the other conjugates.

CONCLUSIONS

In conclusion, with our panel of differently synthesized conjugates, we have been able to investigate structure−function relationships. The high-affinity small molecule we used for integrin receptor targeting proved to be a suitable coupling reagent for in vitro gene delivery systems. Depending on the coupling route, more and less effective conjugates were obtained. Obviously, LMW-PEI lost its ability to condense DNA into small particles and to protect it upon coupling of substantial amounts of PEG. The RGD-M-coupled LMW-PEI-PEG conjugates therefore did not perform well in vitro and did not generate high transgene expression. The PEG-PEI conjugates, where the targeting ligand was coupled to the PEI domain of a diblock-like copolymer, on the other hand, seemed to be very promising compounds. PEG-PEI was not strongly affected concerning DNA condensation upon conjugation, which is shown by ethidium bromide quenching and size measurements of the polyplexes. The coupling degree of the targeting moiety had an impact on sizes, zeta potentials, and complexation of DNA but even more strongly influenced bioactivity. Whereas Conjugate 10−1 lacked specific interaction with MeWo cells, Conjugates 10−2 and 5−2 exhibited significantly higher binding and transgene expression in integrin receptor overexpressing cells, which could be inhibited by free targeting ligand. In these conjugates, DNA was tightly bound, but targeting ligands were obviously easily accessible for interaction with cell surface receptors. Considering the biologic effect of the RGD-M, conjugates with a rather low coupling degree revealed the best results in vitro, with transfection efficacy inversely correlating with coupling degree. In this study, we were able to identify Conjugates 10−2 and especially 5−2 as promising candidates for in vivo cancer gene therapy.

ACKNOWLEDGMENT

We are grateful to Dr. Cornelia Brendel (FACS laboratory, Department of Hematology, Oncology and Immunology, University Hospital Marburg) and Prof. Dr. Thomas Behr (Nuclear Medicine Department, University Hospital Marburg) for the generous use of equipment and facilities and to Eva Mohr (Department of Pharmaceutics and Biopharmacy, Philipps-Universität Marburg) for excellent technical support.

REVIEWS

Nonnatural Amino Acids for Site-Specific Protein Conjugation

Albert J. de Graaf,[†] Marlous Kooijman,[†] Wim E. Hennink, and Enrico Mastrobattista*

Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Sciences (UIPS), Faculty of Science, Utrecht University, P.O. Box 80.082, 3508 TB Utrecht, The Netherlands. Received July 12, 2008; Revised Manuscript Received November 17, 2008

Over the years, several chemical reactions have been developed that enable the covalent conjugation of synthetic molecules to natural proteins. The resulting bioconjugates have become important tools in the study of natural proteins. Furthermore, they form a new class of protein-based pharmaceuticals and biomaterials. However, classical bioconjugation reactions to natural amino acids suffer from poor site-specificity. To overcome this problem, a variety of uniquely reactive non-natural amino acids have recently been designed. These can be incorporated into proteins by specifically engineered bacterial strains. Such reactive non-natural amino acids create new possibilities for bio-orthogonal conjugation to proteins. This review first gives an overview of the various methods for site-specific introduction of non-natural amino acids into proteins. Both semisynthetic and entirely recombinant methods are addressed. Then, a detailed description is given of the reactive non-natural amino acids that have already been recombinantly introduced into proteins. The bio-orthogonal reactions that can be used for conjugation to these reactive non-natural amino acids are also discussed. These include the alkyne/azide 'click' reaction, carbonyl condensations, Michael-type additions, and Mizoroki-Heck substitutions.

INTRODUCTION

Proteins are responsible for the majority of functional attributes of all living organisms. They act as building blocks of the cell structure and as catalysts in the metabolism of cells. Furthermore, signal transduction within and between cells, as well as cell morphology and stability, are dependent on a large number of proteins. Many of these functions are dependent on post-translational modifications (e.g., glycosylation or lipidation) at specific sites of the proteins involved.

Scientists have long been inspired by the mechanisms of nature to couple different molecules to proteins and have explored them in order to synthesize (nonnatural) protein bioconjugates. As a result of this research, different chemoselective conjugation methods have been developed in the last decades. These chemoselective conjugation methods have proven to be very useful, e.g., to attach probes or drugs to proteins. Another application is the attachment of hydrophilic polymers (e.g., poly(ethylene glycol) (PEG)) to therapeutic proteins. PEGylation reduces the immunogenicity and antibody recognition of therapeutic proteins. This leads to increased stability and body residence time. PEGylation has also improved the targeting and tissue penetration of protein pharmaceuticals (*1*−*5*).

Furthermore, fusion proteins and proteins with new functionalities have been developed using bioconjugation reactions (*2*−*8*). Finally, chemoselective conjugation reactions are useful tools for the design of new biomaterials (*9*−*12*).

A drawback of the conventional chemoselective bioconjugation reactions is the heterogeneity of the product that is

Table 1. Reactive Natural Amino Acid Side Chains

Amino acid	Side chain	pKa
Aspartic acid		3.7-4.0
Glutamic acid		4.2-4.5
Histidine		6.7-7.1
Lysine		9.3-9.5
Arginine		>12
Tyrosine		9.7-10.1
Cysteine		8.8-9.1
Methionine		
Tryptophan		
C-terminus		2.1-2.4
N-terminus		7.6-8.0

formed. This is due to the fact that more than one residue of the targeted amino acid species may be present in a protein. To overcome this limitation, orthogonally reactive nonnatural amino acids can be introduced into proteins. Various methods to incorporate nonnatural amino acids into proteins are outlined below. Being able to attach molecules only to the introduced nonnatural amino acid, without derivatizing the natural amino acids in the protein, one can achieve exact control over the site and number of conjugations to a protein. In this way, highly defined products can be obtained. In principle, such bio-orthogonal conjugation reactions can be carried out in the presence of other proteins that contain only natural amino acids.

This review analyzes the potential of bio-orthogonal conjugation reactions to proteins containing nonnatural amino acids. First, the most common techniques for incorporation of nonnatural amino acids into proteins are discussed. Then, an overview is given of chemically reactive nonnatural amino acids that have been introduced into proteins, together with a discussion of the reactions that can be used for conjugation to these amino acids.

CONJUGATION TO NATURAL AMINO ACIDS

Most bioconjugation reactions make use of the reactivities of natural amino acids. Though not the scope of this review, a short account of these reactions is given here to clarify the need for nonnatural amino acids with bio-orthogonal reactivities.

There are nine canonical amino acids that may in principle be derivatized at their side chains, since these amino acids possess functional groups (Table 1).
