Antibody-based therapy is one of the promising treatments for AIDS. In recent years, AIDS antibodies have been produced by immunization (*1*) and by de novo engineering of monoclonal antibodies (mAb) with molecular evolution tactics such as phage display (*2*). Despite enormous efforts, however, only a limited number of highly and broadly HIV-neutralizing human mAbs have been isolated and characterized. These antibodies include gp41 Abs, 2F5 (*3*−*6*) and 4E10 (*5*−*7*), and gp120 Abs, 2G12 (*8*) and b12 (*9*). gp41 is a transmembrane envelope glycoprotein, which is divided into an endodomain and an ectodomain by the transmembrane region; the latter contains a hydrophobic amino-terminal fusion peptide, followed by amino-terminal and carboxy-terminal leucine/isoleucine heptad repeat domains with helical structures (HR1 and HR2, respectively). In the membrane fusion process of HIV-1, these subunits form a "pre-bundle" complex. The HR1 and HR2 regions are termed the N-terminal helix (N36) and C-terminal helix (C34), respectively. These helices form a six-helical bundle consisting of a central parallel trimeric coiled-coil of N36 surrounded by C34 in an antiparallel hairpin fashion. In design of immunogens that elicit broadly neutralizing antibodies, a useful strategy is to produce molecules that mimic the natural trimer on the virion surface. Previous studies show that these molecules could be proteins expressed as a recombinant form or on the surface of particles such as pseudovirions or proteoliposomes (*10*−*12*). The X-ray crystallographic study of gp41 shows that the distances between any two residues at the N-terminus of N-region are almost equal at approximately 10 Å (Figure 1A). A chemically synthetic template could be useful in connection with the design of a peptidomimetic corresponding to the native structure of gp41. To date, several gp41 mimetics have been synthesized as inhibitors or antigens and subjected to inhibition or neutralization assays (*13*−*16*). However, the templates for assembly of these helical peptides contain branched peptide linkers, which are not exactly equivalent in length (*14*). The N-terminal peptides constrained by another threefold linker showed high affinity for C-terminal peptides, although its biological advantages have not been determined (*15*). The mimicry can be estimated using the broadly neutralizing mAbs; suitable mimetics will bind neutralizing mAbs efficiently, but they will bind non-neutralizing mAbs poorly. In the present study, we designed and synthesized a novel three-helical bundle mimetic, which corresponds to the trimeric form of N36. We investigated whether mice immunized with the equivalent trimeric form of N36 mimetic can produce antibodies with stronger binding affinity for N36 trimer than for N36 monomer. This approach demonstrates the possibility of producing structure-specific antibodies by immunization of synthetic antigens corresponding to the natural form of viral proteins.

EXPERIMENTAL PROCEDURES

Conjugation of N36REGC and the Template to Produce triN36e. Compound **6** (100 μg, 0.174 μmol) and N36REGC (3.4 mg, 0.574 μmol) were dissolved in a mixture of 300 μL of 200 mM acetate buffer (pH 5.2) and 300 μL of TFE under a nitrogen atmosphere, then TCEP·HCl was added. The reaction was stirred for 72 h at room temperature and monitored by HPLC. The ligation product (triN36e) was separated as an HPLC peak and was characterized by ESI-TOF-MS, *m*/*z* calcd for $C_{690}H_{1160}N_{226}O_{201}S_3$ 15933.1, found 15933.8. The purification was performed by reverse phase HPLC (YMC-Pack ODS-A column, 10 × 250 mm). Elution was carried out with a 40−50% linear gradient of acetonitrile (0.1% TFA) over 50 min. Purified triN36e, obtained in 16% yield, was identified by ESI-TOF-MS. The detailed synthesis of peptides is described in the Supporting Information (SI).

CD Spectra. CD measurements were performed with a J-720 circular dichroism spectrolarimeter equipped with a thermoregulator (JASCO). The wavelength dependence of molar ellipticity [θ] was monitored at 25 °C from 190 to 250 nm. Peptides were dissolved in 20 mM acetate buffer (pH 4.0) containing 40% MeOH (*23, 24*). The experimental helicity was calculated as reported previously (*17*−*19*).

Immunization and Sample Collection. Six-week-old male BALB/c mice were purchased from Sankyo Laboratory Service Corp. (Tokyo, Japan) and maintained under specific pathogen-free conditions in an animal facility. The experimental protocol was approved by the ethical review committee of Tokyo Medical and Dental University. Freund incomplete adjuvant and PBS

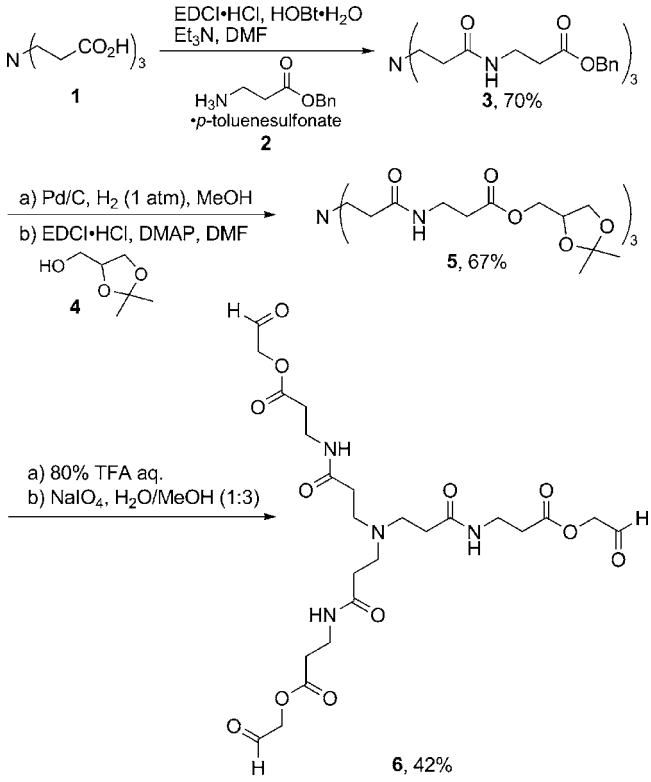
(D) Conjugated structure of trimeric N36 after thiazolidine ligation.

were purchased from Wako Pure Chemical Industries (Osaka, Japan). DMSO (endotoxin free) was purchased from Sigma-Aldrich (St. Louis, MO).

All mice were bled one week before immunization. One hundred micrograms of antigen was dissolved in 1 μL of DMSO. The solution was mixed with 50 μL of PBS and 50 μL of Freund incomplete adjuvant. The mixture was injected subcutaneously under anesthesia on days 0, 14, 28, 42, and 58. Mice were bled on days 21, 35, 49, and 65. Serum was separated by centrifugation (15 000 rpm) at 4 °C for 15 min and inactivated at 56 °C for 30 min. Sera were stored at −80 °C before use.



Serum Titer ELISA. Tween-20 (polyoxyethylene (20) sorbitan monolaurate) and hydrogen peroxide (30%) were purchased from Wako. ABTS (2,2-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt) was purchased from Sigma-Aldrich. Antimouse IgG (H+L)(goat)-HRP was purchased from EMD Chemicals (San Diego, CA). Ninty-six-well microplates were coated with 25 μL of a synthetic peptide at 10 μg/mL in PBS at 4 °C for overnight. The coated plates were washed 10 times with deionized water and blocked with 150 μL of blocking buffer (0.02% PBST, PBS with 0.02% Tween 20, containing 5% skim milk) at 37 °C for 1 h. The plates were washed with deionized water 10 times. Mice sera were diluted in 0.02% PBST with 1% skim milk, and 50 μL of 2-fold serial dilutions of sera from 1/200 to 1/102400 were added to the wells and allowed to incubate at 37 °C for 2 h. The plates were washed 10 times with deionized water. Twenty-five microliters of HRP-conjugated antimouse IgG, diluted 1:2000 in 0.02% PBST, was added to each well. After 45 min incubation, the plates were washed 10 times and 25 μL of HRP substrate, prepared by dissolving 10 mg ABTS to 200 μLof HRP staining buffer—a mixture of 0.5 M citrate buffer (pH 4.0, 1 mL), H_2O_2 (3 μL), and H_2O (8.8 mL)—was added. After 30 min incubation, the reaction was stopped by addition of 25 μL/well 0.5 M H_2SO_4, and optical densities were measured at 405 nm.

Virus Preparation. The pNL4-3 construct (8 μg) was transfected into 293T cells by Lipofectamine LTX (Invitrogen, Carlsbad, CA) followed by changing medium at 12 h after transfection. At 48 h after changing medium, the supernatant was collected, passed through a 0.45 μm filter, and stored at −80 °C as HIV-1_{NL4-3} strain before use. For titration, MT-4 cells were infected with serially 3-fold diluted virus from 1/10 to 1/196830, and cultured for 7 days. HIV-1 p24 levels in supernatants were measured, and then the titer of virus solution was calculated.

Anti-HIV Assay. Virus was prepared as described above except that the transfection of pNL4-3 was performed by the calcium phosphate method. Anti-HIV-1 activity was determined on the basis of protection against HIV-1-induced cytopathogenicity in MT-4 cells. Various concentrations of AZT, N36RE, and triN36e (The starting concentrations are 100, 10, and 1 μM, respectively) were added to HIV-1-infected MT-4 cells (MOI = 0.01) by 2-fold serial dilution and placed in wells of a flat-bottomed microtiter plate (2.0×10^4 cells/well). After 5 days' incubation at 37 °C in a CO_2 incubator, the number of viable cells was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) method (EC_{50}). Cytotoxicity of compounds was determined on the basis of viability of mock-infected cells using the MTT method (CC_{50}). Each experiment was performed three times independently.

Neutralizing Assay. MT4-cells (1×10^5 cells/100 μL) were incubated in 100 μL medium containing 10 μL sera from immunized or preimmunized mice for 1 h at 37 °C, then pretreated MT-4 cells were infected with HIV-1_{NL4-3} (MOI = 0.05). At 3 days after infection, cells were collected by centrifuge at 4000 rpm for 10 min at 4 °C. After discarding supernatant, pellets were lysed with 30 μL of lysis buffer (50 mM Tris·HCl (pH 7.5), 150 mM NaCl, 1% NP-40), then 30 μL of 2 × SDS buffer (125 mM Tris·HCl (pH 6.8), 4% SDS, 20% glycerol, 10% 2-ME, 0.004% BPB) were added and boiled for 10 min. The samples (5 μL) were subjected to SDS-page to perform Western blotting. The HIV-1 gag p24 was detected by using Western lightning ECL kit (PerkinElmer, MA) according to manufacturer's instruction after treatment of HIV-1 p24

antibody (2C2; 1:2000 dilution) (*20*) and anti- mouse IgG (H+L)-HRP (Millipore, MA). The band intensity of p24 was calculated with post/pre-immunized samples by using *ImageJ* image analyzing software.

RESULTS AND DISCUSSION

The N-region of gp41 is known to be an aggregation site involving a trimeric coiled-coil conformation. In design of an N36-derived peptide (N36RE), the triplet repeat of arginine and glutamic acid was fused to the N-terminus to increase the solubility in buffer solution (Figure 1B). In order to form a triple helix corresponding precisely to the gp41 prefusion form, we designed the novel C3-symmetric template depicted in Figure 1C. This designed template linker has three branches of equal length and possesses the hydrophilic structure and ligation site for coupling with N36RE. The template was synthesized from the commercially available 3-[bis(2-carboxyethyl)amino]propanoic acid **1** as shown in Scheme 1. Coupling of **1** with β-alanine benzyl ester **2** gave the corresponding triamide **3** in 77% yield. Cleavage of three benzyl esters by hydrogenation and coupling with solketal **4** produced the corresponding triester **5**. Deprotection of the acetonides with aqueous 80% TFA followed by oxidative cleavage of diol group led to the desired template **6**. This approach uses thiazolidine ligation for chemoselective coupling of Cys-containing unprotected N36RE (N36REGC) with a three-armed aldehyde scaffold producing triN36e (Figure 1D). Thiazolidine ligation is a peptide segment coupling strategy which does not require side chain protecting groups (*22*−*26*). The reaction consists of three steps: (i) aldehyde introduction, in which a masked glycolaldehyde ester is linked to the carboxyl terminus of an unprotected peptide by reverse proteolysis; (ii) ring formation, in which the unmasked aldehyde reacts at acidic pH with the α-amino group of an N-terminal cysteine residue of the second unprotected peptide forming a thiazolidine ring; and (iii) rearrangement at higher pH in which O-acyl ester linkage is converted to an N-acyl amide linkage forming a peptide bond with a pseudoproline structure (Figure 2).

Circular dichroism (CD) spectra of triN36e and N36RE, which is a monomer form without N-terminal Cys-Gly residues, are shown in Figure 3A. The peptides were dissolved in 20 mM acetate buffer with 40% MeOH, pH4.0, suitable for measurement of CD spectra of membrane proteins (*27, 28*). Both spectra display double minima at 208 and 222 nm and showed high molar ellipticity as absolute values (Table 1). The results indicate that these peptides form a highly structured α-helix and that the helical content of the trimer triN36e is higher than that of the monomer N36RE. Furthermore, to assess the interaction of triN36e with C34, CD spectra of the peptide mixture with C34-derived peptide, C34RE, were measured (Figure 3B,C). The spectrum of triN36e and C34RE mixture showed high molecular ellipticity as an absolute value comparable with that of triN36e alone. This supports the conclusion that C34RE interacts with tri36e and thereby induces a higher helical form as shown previously (*29*).

Mice were immunized with these synthetic gp41 mimetics and antibody production was successfully induced (the detailed titer increase in 5 weeks' immunization is given in the Supporting Information). Two out of three mice showed induction of antibodies against either antigen (N36RE or triN36e). Antibody titers and selectivity of antisera isolated from mice immunized with N36RE or triN36e were evaluated by serum titer ELISA against coated synthetic antigens. The most active antiserum for each antigen was utilized for the evaluation of binding activity by ELISA (Figure 4). The N36RE-induced antibody showed approximately 5 times higher affinity for N36RE than for triN36e, as 50% bound serum dilutions are 3.88×10^{-4} and 2.14×10^{-3} to N36RE and triN36e, respectively. It is noteworthy that the triN36e-induced antibody showed approximately 30 times higher preference in binding affinity for triN36e antigen than for N36RE (serum dilutions at 50% bound are 3.83×10^{-3} to N36RE and 1.33×10^{-4} to triN36e). Although this evaluation was not determined with purified mAbs, it is clear that the antibodies produced exploit a structural preference for antigens. The mechanism of induction

of structure-specific antibody is still not clear, but the results could suggest the efficacy of producing antibodies with structural specificity and that the synthesis of structure-involving antigens is an effective strategy when higher specificity is required.

Neutralizing activity of sera against HIV-1 infection was assessed by p24 assays utilizing antisera from two mice that showed antibody production for each antigen (Figure 5). Sera

	$[\theta]_{222}$	$[\theta]_{222}/[\theta]_{208}$	α-helicity
N36RE	−30 957	0.87	73%
triN36e	−38 998	0.96	95%

Table 2. EC_{50} and CC_{50} Values Calculated from Inhibition Assays of Peptidomimetics

	AZT	triN36e	N36RE
EC_{50} (μM)[a]	0.047	0.49	1.4
CC_{50} (μM)[b]	>50	>1	>10

[a] EC_{50} values are based on the inhibition of HIV-induced cytopathogenicity in MT-4 cells. [b] CC_{50} values are based on the reduction of the viability of MT-4 cells. All data are the mean values for at least three experiments.

from mice immunized with the same antigen showed similar inhibitory activity against viral infection (12.5% and 14.8% for N36RE, 40.3% and 52.1% for triN36e). A trend was observed that the sera from triN36e immunization shows higher inhibition than those from N36RE immunization. This suggests that the synthetic antigen corresponding to the N36 trimeric form induces antibody with neutralization activity superior to that of the monomer peptide antigen and implies a restricted response of B-cells upon immunization to the trimeric form of N36RE. In order to assess the compatibility of induced antibodies in HIV-1 entry inhibition, the HIV-1 inhibitory activities of peptidomimetics (N36RE and triN36e) have been evaluated by viral infection and cytotoxicity assays. A C-terminal region peptide known as Enfuvirtide (T20, Roche/Trimeris) has been used clinically as a fusion inhibitor, and its success indicates that gp41-derived peptides might be potent inhibitors, useful against HIV-1 infection (*30*). In the development of anti-HIV peptides, several mimetics such as Enfuvirtide, CD4 binding site of gp120 (*31*), and protein-nucleic acid interactions (*32*), which disrupt protein−protein interactions, have been produced. As indicated in Table 2, N36 and triN36e showed modest inhibitory activity as reported in previous studies (*33*−*35*). The potency of triN36e was three times higher than that of N36RE indicating that the active structure of monomer N36RE is a trimeric form. Cytotoxicity of the antigens was not observed at concentrations of 1 μM of triN36e and 10 μM of N36RE.

CONCLUSIONS

In summary, a mimic of HIV-1 gp41-N36 designed as a new vaccine has been synthesized utilizing a novel template with three branched linkers of equal lengths. Thiazolidine-forming ligation attached the esteraldehyde of three-branched template with N-terminal cysteine of peptides in an aqueous medium. The resulting peptide antigen successfully induces antibodies with neutralization activity against HIV-1 infection. It is of special interest that the antibody produced acquires structural preference to antigen, which showed 30 times higher binding affinity for trimer than for monomer. This indicates the effectiveness of the design based on the structural dynamics of HIV-1 fusion mechanism of an antigen which could elicit neutralizing antibodies. In a design based on the N36 region of gp41, the exposed timing of epitopes is limited during HIV-1 entry (*36*), and carbohydrates, which could make accession of antibodies to epitopes difficult, are not associated with the amino acid residues of the native protein. These two advantages could further enhance the potential of a vaccine design based on the N36 region. During preparation of the manuscript, a new HIV vaccine strategy was reported by Burton's group (*37*). The report describes the importance of antibody recognition for the trimer form of surface protein. The trimer-specific antibodies indicate broad and potent neutralization. The gp41 trimer-form specific antibody produced in this study could also obtain the corresponding properties. The elucidation of antibody-producing mechanisms and epitope recognition mode of antibodies in antiserum during HIV-1 entry will be addressed in future studies.

ACKNOWLEDGMENT

The authors deeply thank Prof. K. Akiyoshi (Tokyo Medical and Dental Univ.) for allowing access to CD spectroporalimeter.

In Vivo Evaluation of ^{64}Cu-Labeled Magnetic Nanoparticles as a Dual-Modality PET/MR Imaging Agent

Charles Glaus,[†] Raffaella Rossin,[‡] Michael J. Welch,[‡] and Gang Bao*,[†]

Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, Georgia, and Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri. Received November 19, 2009; Revised Manuscript Received February 25, 2010

A novel nanoparticle-based dual-modality positron emission tomograph/magnetic resonance imaging (PET/MRI) contrast agent was developed. The probe consisted of a superparamagnetic iron oxide (SPIO) core coated with PEGylated phospholipids. The chelator 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid (DOTA) was conjugated to PEG termini to allow labeling with positron-emitting ^{64}Cu. Radiolabeling with ^{64}Cu at high yield and high purity was readily achieved. The ^{64}Cu-SPIO probes produced strong MR and PET signals and were stable in mouse serum for 24 h at 37 °C. Biodistribution and in vivo PET/CT imaging studies of the probes showed a circulation half-life of 143 min and high initial blood retention with moderate liver uptake, making them an attractive contrast agent for disease studies.

INTRODUCTION

Multimodality imaging combines two or more distinct imaging modalities in a way that leverages the respective strengths and weaknesses of each imaging technology. Examples include combined PET-CT (*1*), PET-MR (*2, 3*), and MR-fluorescence imaging (*4, 5*), which often generate results superior to both modalities operating separately. The combination of positron emission tomography (PET) with X-ray computed tomography (CT) has become the gold standard in oncologic imaging (*1*). Positron emission tomography is the most sensitive human molecular imaging modality and produces whole body images of functional and molecular information. CT rapidly acquires whole-body images at high resolution but exposes patients and experimental animals to substantial doses of ionizing radiation. Magnetic resonance imaging (MRI), in comparison, uses no ionizing radiation and provides soft tissue contrast superior to CT. Combining PET with the high-resolution, spectroscopic, or contrast enhanced abilities of MRI would produce a breakthrough in the detection and monitoring of disease (*2*).

Nanoparticles possess unique characteristics that make them well-suited as probes for molecular imaging (*6*). Particles can be synthesized in a systematic fashion with tight control over nanoparticle diameter to produce particles with narrow size distributions. As particles become smaller, their surface area to volume ratio increases significantly. Engineering of nanoparticle surface chemistry allows the surface area to be decorated with therapeutic molecules, imaging agents, targeting ligands, or nucleic acids. Distinct ligands and reporters can be attached to a single particle to allow multiplexing and multifunctionality. A single nanoparticle can be conjugated with a large number of targeting ligands, increasing the affinity of the nanoparticle to its biological target through a phenomenon known as multivalency. Additionally, a nanoparticle can be conjugated with a large number of reporter molecules (e.g., fluorophores, radionuclides), increasing signal-to-noise in imaging applications.

The unique qualities of nanoparticles described above make them superior in many ways to traditional low molecular weight MRI contrast agents and PET probes (*7*). Compared to gadolinium-based MRI contrast agents, nanoparticle MRI contrast agents circulate in the blood for longer periods of time, offer greater sensitivity, and may produce fewer side effects (*8*). Radiolabeled nanoparticles can circulate for longer periods of time than small molecule PET tracers and can carry greater numbers of radionuclides (*9*). Nanoparticles are therefore a promising material for the construction and evaluation of combined PET/MRI probes.

Herein, we report the development of a novel dual-modality nanoparticle for PET/MR imaging. The probe in this work has a superparamagnetic iron oxide nanoparticle (SPIO) core with a micelle coating composed of functionalized PEGylated lipids. The nanoparticles were modified with DOTA to allow chelation of copper-64 for PET imaging. The nanoparticles were labeled at high specific activity and produced strong PET and MRI contrast. The pharmacokinetics of this novel probe was measured using microPET/CT and organ biodistribution.

EXPERIMENTAL PROCEDURES

Materials. Superparamagnetic iron oxide (SPIO) crystalline cores (generously provided by Dr. Charles O'Connor, University of New Orleans) were synthesized using a reverse micelle process (*10, 11*). 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)2000] (DSPE-PEG2000-amine) and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethylene glycol)-5000] (DSPE-mPEG5000) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL). 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid mono(*N*-hydroxysuccinimide ester) (DOTA-NHS) was purchased from Macrocyclics Inc. (Dallas, TX). ^{64}Cu was produced on a Washington University School of Medicine Cyclotron (Model CS-15, Cyclotron Corp.) by the ^{64}Ni(p,n)^{64}Cu reaction with the nuclide having a specific activity of 220 ± 55 mCi/μg at the end of bombardment, as previously described (*12*). All buffers used for ^{64}Cu labeling were passed through a Chelex 100 column before use. Water was deionized to 18 MΩ cm using an E-Pure water filtration system (Barnstead International, Dubuque, IA). Wiretrol II capillary micropipets were purchased from the

Drummond Scientific Company (Broomall, PA). Chelex 100 resin (50−100 mesh), hydrochloric acid, hydroxylamine hydrochloride, ferrous ammonium sulfate hexahydrate, 1,10-phenanthroline, ethylenediaminetetraacetic acid (EDTA), 10 mM phosphate buffered saline (PBS), chloroform, and mouse serum were purchased from Sigma-Aldrich Inc. (St. Louis, MO).

Preparation of Micelle-Coated SPIOs. Micelle-coated SPIOs (mSPIOs) were prepared as previously described (*13*) with slight modifications. DSPE-PEG2000-amine and DSPE-mPEG5000 were individually dispersed in chloroform at 25 mg/mL and stored at −20 °C prior to the coating procedure. To prepare amino-functionalized mSPIOs, DSPE-PEG2000-amine (9 μmol) and DSPE-mPEG5000 (34 μmol) were added to 24 mL chloroform in a round-bottomed flask. Uncoated SPIOs suspended in toluene (20 mg Fe) were then added to the flask, and the mixture was placed in a rotary evaporator. Pressure was slowly reduced to 10 mTorr to remove all solvents, resulting in a dry film of nanoparticles and PEG-phospholipids. The physical adsorption of PEGylated lipids onto particles was due to a hydrophobic interaction between cetyltrimethylammonium bromide capping ligands on the nanoparticle surface and acyl chains of phospholipids. The film was heated at 60 °C for 30 min under vacuum. Next, the flask was removed from vacuum and the film hydrated using deionized water with gentle agitation followed by sonication, producing a clear, brown solution of mSPIOs. Empty PEG-phospholipid micelles were separated from mSPIOs by ultracentrifugation (Optima XL-100K; Beckman Coulter Inc., Fullerton, CA) for 10 h at 280 000 *g* (4 °C). The supernatant containing empty micelles was removed and the nanoparticle pellet was resuspended in PBS to 10 mg Fe/mL and passed through a 0.1 μm Anotop syringe filter (Whatman International Ltd., UK).

Conjugation of mSPIOs with DOTA-NHS-Ester. DOTA-NHS-ester was reacted with 1 mL of 10 mg Fe/mL amino-functionalized mSPIOs at 1 mM in PBS (pH 7.5) overnight at 4 °C. The product, DOTA-mSPIO, was separated from excess DOTA-NHS-ester by dialysis using a 100 kD Float-A-Lyzer (Spectrum Laboratories, Inc., Rancho Dominguez, CA) against 2 L of phosphate buffer for 48 h at 4 °C with a total of 8 buffer changes. The number of DOTA groups per mSPIO, estimated at 5−10, is proportional to the percentage of initial DSPE-PEG2000-amine present during the micelle coating procedure (*14, 15*).

Iron Concentration Determination. Iron concentration of DOTA-mSPIO solutions were determined using a 1,10-phenanthroline assay after conjugation of DOTA to mSPIOs (*16, 17*). Solutions of hydroxylamine hydrochloride (10 mg/mL), sodium acetate (125 mg/mL), 1,10-phenanthroline (1 mg/mL), and hydrochloric acid (6 M) were freshly prepared using deionized water. In a 200 μL PCR tube, 17 μL of hydrochloric acid was added to 18 μL of dilute nanoparticles and incubated in a thermocycler at 100 °C for 10 min. The resulting solution of dissolved mSPIOs was combined with 10 μL of hydroxylamine hydrochloride and 855 μL of sodium acetate, followed by addition of 100 μL 1,10-phenanthroline. After 10 min, the absorbance of the sample at 510 nm was measured using a Safire microplate reader (Tecan Group Ltd., Männedorf, Switzerland) and compared to the absorbance of a standard curve created using a ferrous ammonium sulfate hexahydrate solution.

Relaxation Measurement. Relaxation measurements were carried out using a 0.47 T Minispec mq20 (Bruker Optics, Billerica, MA) according to previous studies (*13*). Briefly, transverse magnetization decay curves were acquired using a Carr-Purcell-Meiboom-Gill sequence, while longitudinal magnetization recovery curves were acquired using an inversion−recovery sequence. Curves were fit using *Origin 6* analysis software (OriginLab Corp., Northampton, MA) to obtain T_2 time constants. Relaxivity values (r_2) were calculated using T_2 time constants and the iron concentration of measured samples.

Radiolabeling of DOTA-mSPIO with ^{64}Cu. In general, DOTA-mSPIOs were labeled with ^{64}Cu and analyzed according to Rossin et al (*18*). DOTA-mSPIOs (5 mg in 610 μL) were incubated with $^{64}CuCl_2$ (3 mCi in 2.2 μL, 0.1 M HCl) in 0.1 M ammonium acetate buffer (pH 5.5) at 37 °C for 1 h in a thermomixer. The solution was then challenged with 5 μL of 10 mM EDTA or DTPA at 37 °C for 5 min with mixing to remove nonspecifically bound ^{64}Cu. Labeling yield was determined by radiochemical thin layer chromatography (radio-TLC). A small amount of the ^{64}Cu-labeled mSPIO (^{64}Cu-mSPIO) solution was applied to an ITLC-SG plate (Pall Corporation, East Hills, NY) and developed using a 1:1 mixture (v/v) of 10% (w/v) ammonium acetate and methanol. The TLC plate was then measured using a Bioscan 200 imaging scanner (Bioscan Inc., Washington, DC, and the labeling yield was found to be 94%. The ^{64}Cu-labeled mSPIOs were then passed through a centrifugal desalting column (Pierce Biotechnology, Inc., Rockford, IL) to remove the small amount of unbound ^{64}Cu contained in the sample.

Radiochemical purity (RCP, the percentage of the total radioactivity that was due to DOTA-mSPIOs) of ^{64}Cu-mSPIO was evaluated by radio-fast protein liquid chromatography (radio-FPLC) using an Amersham Biosciences ÄKTA FLPC system (GE Healthcare, Piscataway, NJ) equipped with a UV detector (280 nm) and fitted with an in-line model 170 radioisotope detector (Beckman Coulter Inc., Fullerton, CA). A 100 μL sample of dilute ^{64}Cu-mSPIO was applied to a Superose 12 gel filtration column (GE Healthcare, Piscataway, NJ) and eluted with 20 mM HEPES and 150 mM NaCl at a flow rate of 0.8 mL/min. The RCP of ^{64}Cu-labeled mSPIO was found to be >95%, indicating that less than 5% of the total radioactivity present in the sample was due to free ^{64}Cu. The nanoparticle solution was then diluted with PBS to obtain doses suitable for biodistribution and imaging studies. The serum stability of ^{64}Cu-mSPIO was determined by incubating labeled nanoparticles in mouse serum at 37 °C with constant shaking for up to 24 h. The samples were subjected to radio-TLC analysis after 0, 1, 3, 6, and 24 h incubation to measure the amount of radioactivity due to ^{64}Cu dissociated from ^{64}Cu-mSPIOs.

Size Determination. Dynamic light scattering (DLS) was used to measure the hydrodynamic diameter of uncoated SPIOs and DOTA-mSPIOs using a NICOMP 380 ZLS Submicrometer Particle Sizer (Particle Sizing Systems, Inc., Santa Barbara, CA) equipped with a 632.8 nm He−Ne laser and an Avalanche Photodiode detector at a fixed 90° scattering angle. DLS measurements were performed on DOTA-mSPIO samples chelated with "cold" (i.e., stable) isotopes of copper (Cu-mSPIO) according to the same procedure used for radiolabeling with copper-64. DLS of uncoated, hydrophobic SPIOs was performed in toluene. Dilute nanoparticle samples (0.4 mL) were placed in prewashed cylindrical optical cells and incident laser light was adjusted using a neutral density filter to obtain a scattering intensity of 300 kHz. Samples were scanned at 23 °C for 30 min in a temperature-controlled sample chamber, and data are reported as the volume-weighted hydrodynamic diameter.

Uncoated SPIOs were stored in toluene prior to surface modification and were analyzed using transmission electron microscopy (TEM) to ensure monodispersity. TEM micrographs were produced by applying dilute SPIO samples to copper TEM grids allowing the organic solvent to evaporate. Grids were then imaged using a Hitachi H-7500 TEM. Micrographs were analyzed for particle size and distribution using NIH *ImageJ*.

Biodistribution. All animal studies were performed in compliance with guidelines set by the Washington University

Animal Studies Committee. Female BALB/c mice (Charles River Laboratories, Inc., Wilmington, MA) weighing approximately 20 g were anesthetized using 1−2% isoflurane and given tail vein injections of 100 μCi of purified ^{64}Cu-mSPIO at a dose of 10 mg Fe/kg body weight. Mice ($n = 4$ per time point) were sacrificed by cervical dislocation at 10 min, 1 h, 4 h, and 24 h postinjection, and organs of interest were collected, blotted dry, weighed, and assessed for radioactivity by counting for one minute in a Gamma 8000 scintillation counter (Beckman Coulter Inc., Fullerton, CA). A standard dose was prepared and measured along with the samples to allow calculation of the percentage injected dose (%ID) for the various tissues and organs. Data were corrected for ^{64}Cu decay and the percentage injected dose per gram of tissue (%ID/g) and the percentage injected dose per organ (%ID/organ) were calculated according to the following equations:

$$\%\text{ID/g} = \frac{(\text{cpm in sample} - \text{background}) \times 10^2}{(\text{decay correction factor}) \times (\text{sample weight}) \times (\text{cpm in standard dose})} \quad (1)$$

$$\%\text{ID/organ} = \frac{(\text{cpm in sample} - \text{background}) \times 10^2}{(\text{decay correction factor}) \times (\text{cpm in standard dose})} \quad (2)$$

Small-Animal PET/CT Imaging Studies of ^{64}Cu-mSPIOs. MicroPET imaging scans were performed using a microPET Focus 120 (Siemens Medical Solutions USA, Inc., Malvern, PA). Female BALB/c mice (20−25 g) were anesthetized using 1−2% isoflurane and given tail vein injections with 100 μCi of purified ^{64}Cu-mSPIO (10 mg Fe/kg body weight) in 100 μL PBS. The anesthetized animals were monitored for physiological signs. Mice were reanesthetized and imaged in the supine position at 1 h, 4 h, and 24 h postinjection. PET scan acquisition time for the 10 min, 1 h, and 4 h images was 10 min, while the PET scan acquisition time for the 24 h image was 20 min. Mice were scanned on a microCAT II (Siemens Medical Solutions USA, Inc., Malvern, PA) immediately after microPET. Analysis of microPET images was accomplished using vendor software (ASIPro, Siemens Medical Solutions USA, Inc.) on decay-corrected images. Coregistration of microPET and microCT images was performed using fiducial markers in the animal transfer bed and the *Amira* software package (Mercury Computer Systems, Inc., Chelmsford, MA). The small animal studies were performed following an IACUC-approved protocol.

Phantom Study. To demonstrate the ability of mSPIOs to function as a dual imaging agent, we prepared microcentrifuge tubes of ^{64}Cu-mSPIOs for PET and MR imaging. Radiolabeled nanoparticles were added to a tubes containing PBS to a final concentrations of 10 and 25 μg Fe/mL. The tubes were placed upright in the bed of a Focus 120 microPET and scanned for 10 min. After a sufficient amount of time to allow ^{64}Cu to decay, the samples were then imaged in a 7.0-T Pharmascan magnet (Bruker BioSpin, Billerica, MA). A T_2-weighted proton density scan was obtained using a multislice multiecho sequence (MSME-PD-T2, Bruker Paravision 4) using the following parameters: 1000 ms repetition time (TR); 12 echo times (TE) ranging from 12−144 ms; 180° flip angle, 3 cm FOV; 1 mm slice thickness, 2 averages.

RESULTS

Nanoparticle Formation and Characterization. Dual PET/MRI nanoparticles (Figure 1A) were prepared by first encapsulating monocrystalline superparamagnetic iron oxide nanoparticles (SPIOs) in PEG-phospholipid micelles (*13, 19, 20*). This technique exploited the hydrophobic interaction between

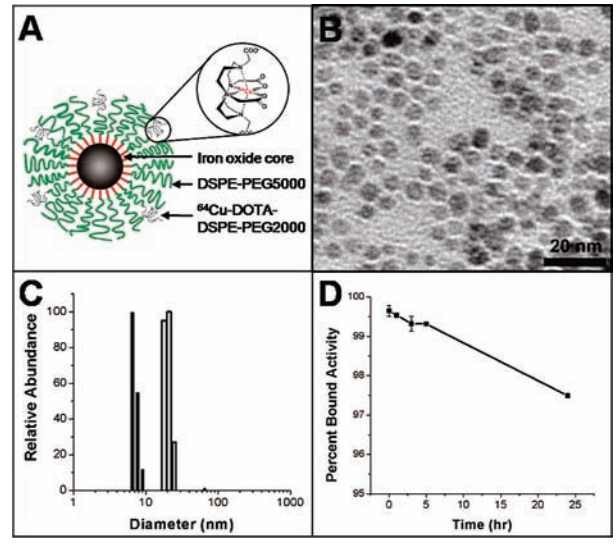

Figure 1. (A) Schematic representation of dual-modality ^{64}Cu-mSPIO. (B) Transmission electron micrograph of uniform monocrystalline superparamagnetic iron oxide nanoparticles. (C) Dynamic light scattering showing highly monodisperse populations of SPIO before (closed bars) and after (open bars) encapsulation in PEGylated lipid micelle. (D) In vitro stability of ^{64}Cu-mSPIO over the course of 24 h incubation in mouse serum at 37 °C.

capping ligands on the nanoparticle surface and hydrocarbon chains of PEGylated phospholipids, leaving the PEG moieties exposed to confer water solubility and reduce protein absorption. High magnetic field gradients surround the surface of the iron oxide core, allowing sensitive detection by MRI. The DOTA-functionalized PEG-phospholipid coating permits labeling with ^{64}Cu for sensitive detection by PET imaging. SPIOs used in this experiment were highly monodisperse (Figure 1B), having an average diameter of 6.2 nm with size variation of 9%, as determined by TEM. Functionalized micelle-coated SPIOs (mSPIOs) were prepared by coating nanoparticles with a 1:5 molar ratio of amino-PEG2000 phospholipids to methoxy-terminated mPEG5000 phospholipids. Empty micelles were separated from mSPIOs using ultracentrifugation, and the yield, calculated from Fe concentration measurements, was found to be 44%. The r_2 relaxivity of mSPIOs, measured using a 0.47 T Bruker Minispec, was 209 ± 26 mM^{-1} s^{-1}.

Amine-modified mSPIOs were conjugated with DOTA-NHS-ester to allow incorporation of PET imaging isotopes. Dialysis was used to separate DOTA-mSPIOs from excess DOTA-NHS-ester, and dynamic light scattering was employed to measure the hydrodynamic diameter of the DOTA-mSPIO (Figure 1C). We found that DOTA-mSPIOs had a hydrodynamic diameter of 20.3 ± 1.9 nm as determined by dynamic light scattering, while prior to lipid-PEG encapsulation, the SPIO cores had an average diameter of 7.1 ± 0.7 nm, consistent with the TEM measurement.

^{64}Cu-Radiolabeling of DOTA-mSPIO. To construct the dual-modality PET/MR contrast agent, the positron-emitting radionuclide ^{64}Cu ($t_{1/2} = 12.7$ h; $\beta^+ = 0.653$ MeV, 17.4%; $\beta^- = 0.578$ MeV, 39%) was used to radiolabel mSPIOs to allow small animal PET imaging and biodistribution studies. Copper-64 is commonly used in PET imaging and radiopharmaceuticals (*21*) because it can be produced at high specific activity in biomedical cyclotrons (*22, 23*), and chelation of ^{64}Cu to various macrocyclic ligands can provide an efficient route for radiolabeling a wide variety of macromolecules and nanoparticles.

Labeling of DOTA-mSPIOs was achieved by incubation with ^{64}Cu at 37 °C for 1 h in 0.1 M ammonium acetate buffer, pH 5.5 (radiolabeling in acetate buffer was found to be superior to

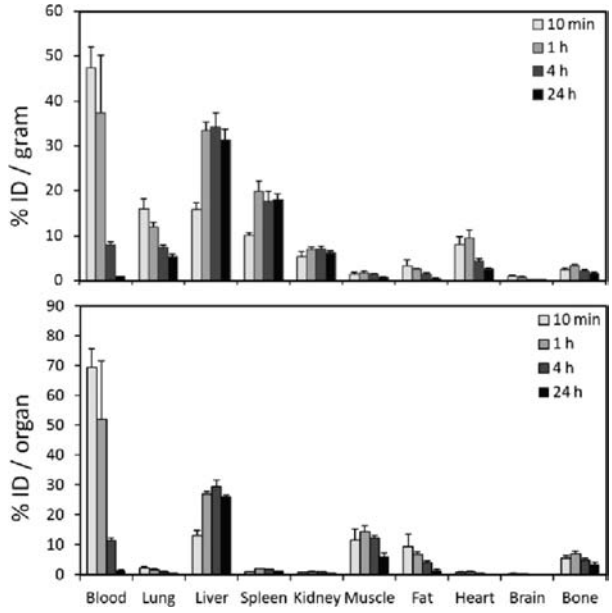

Figure 2. Biodistribution data of dual-PET/MRI ^{64}Cu-mSPIO (10 mg Fe/kg body weight) in BALB/c mice. Groups of mice ($n = 4$) were sacrificed at 10 min, 1 h, 4 h, and 24 h, and select organs were measured for activity. Data are expressed as percent injected dose per gram tissue (%ID/g, top) and percent injected dose per organ (%ID/organ, bottom) ± one standard deviation.

Table 1. Organ Biodistribution as Percent Injected Dose per Gram Tissue

organ	10 min	1 h	4 h	24 h
blood	47.47 ± 4.64	37.31 ± 12.87	7.89 ± 0.76	1.01 ± 0.05
lung	16.06 ± 2.03	11.98 ± 1.01	7.29 ± 0.64	5.37 ± 0.52
liver	15.85 ± 1.41	33.42 ± 1.85	34.20 ± 3.08	31.33 ± 2.33
spleen	10.07 ± 0.56	19.96 ± 2.27	17.52 ± 2.32	18.05 ± 1.27
kidney	5.26 ± 1.16	6.87 ± 0.63	7.03 ± 0.65	6.20 ± 0.38
muscle	1.37 ± 0.49	1.78 ± 0.30	1.45 ± 0.14	0.72 ± 0.13
fat	3.23 ± 1.40	2.51 ± 0.16	1.41 ± 0.28	0.49 ± 0.12
heart	8.00 ± 1.72	9.46 ± 1.76	4.29 ± 0.66	2.52 ± 0.35
brain	0.95 ± 0.14	0.77 ± 0.20	0.31 ± 0.01	0.30 ± 0.02
bone	2.47 ± 0.39	3.28 ± 0.29	2.17 ± 0.28	1.62 ± 0.27

labeling in 0.1 mM ammonium citrate buffer, pH 5.5). It was found that DOTA-mSPIOs could be labeled to a specific activity of at least 2−4 GBq/mmol Fe (10−20 μCi/μg Fe) with a yield of 94%. Nonspecifically bound ^{64}Cu was removed from ^{64}Cu-mSPIOs by addition of excess EDTA following completion of the labeling reaction, and ^{64}Cu-EDTA was separated from ^{64}Cu-mSPIOs using a desalting column. The radiochemical purity of the labeled nanoparticles, defined as the percentage of the total radioactivity that was bound to DOTA-mSPIOs, was determined by radio-FPLC to be >95%. Incubation of ^{64}Cu-mSPIOs at 37 °C for 24 h in mouse serum indicated high in vitro stability of ^{64}Cu radiolabeling (Figure 1D).

Biodistribution Studies. The pharmacokinetics and biodistribution of ^{64}Cu-mSPIO were studied to evaluate the nanoparticle's potential as a dual-PET/MRI in vivo imaging probe. Radiolabeled nanoparticles were administered via tail vein injection, and circulation half-life and accumulation in major organs were investigated; the results of organ biodistribution, presented as percent injected dose per gram tissue, are shown in Figure 2 and Table 1. To allow dual PET/MR imaging with ^{64}Cu-mSPIOs, the dose of particles administered needed to be within the detection limits of both modalities. Because PET is more sensitive than MRI (*24*), the amount of administered iron oxide was the limiting factor when formulating doses for injection. Mice ($n = 4$) weighing approximately 20 g were injected with a 10 mg Fe/kg dose of ^{64}Cu-mSPIOs (100 μCi, radiochemical purity >95%), an amount of iron oxide used for typical in vivo magnetic resonance imaging experiments. Each dose of particles contained 100 μCi of ^{64}Cu ($t_{1/2} = 12.7$ h) to allow imaging up to 24 h postinjection. ^{64}Cu-labeled mSPIOs exhibited high blood retention at 10 min and 1 h postinjection of 47.5 ± 4.6 and 37.3 ± 12.9%ID/g, respectively. Blood retention of ^{64}Cu-labeled mSPIOs decreased to 7.9 ± 0.8%ID/g at 4 h postinjection and to 1.0 ± 0.05%ID/g by 24 h postinjection. Accumulation in the heavily vascularized tissues of the heart and lungs generally followed the pattern of blood retention. The circulation half-life of labeled nanoparticles was 143 ± 21 min, substantially longer than ^{64}Cu-DOTA alone, which undergoes rapid renal excretion (circulation half-life ~6 min) (*25, 26*).

Organs of the reticuloendothelial system (RES) experienced moderate nanoparticle uptake. The liver and spleen showed a low initial accumulation of 15.8 ± 1.4 and 10.1 ± 0.6%ID/g, respectively. At 1 h postinjection, the liver and spleen uptake reached 33.4 ± 1.8 and 20.0 ± 2.3%ID/g, respectively, and generally maintained those values for the remainder of the study. It has been shown previously that ^{64}Cu dissociated from the ^{64}Cu-DOTA complex will undergo transchelation by proteins such as superoxide dismutase, metallothionein, and ceruloplasmin (*27–29*) in the liver. Therefore, while liver uptake at later time points was prominent, some contribution may have been due to an accumulation of disassociated ^{64}Cu.

Kidney uptake remained relatively constant, averaging 5−7%ID/g for all time points. Renal excretion of ^{64}Cu-labeled mSPIOs was assessed by measuring urine activity using a metabolism cage. The activity of urine at 4 h postinjection was 1.1%ID/g at 4 h postinjection and 5.0%ID/g at 24 h postinjection. This implies that although ^{64}Cu-labeled mSPIOs were larger than the cutoff for glomerular filtration (*30*), their individual ^{64}Cu-DOTA-PEGylated lipids were able to traverse the fenestrae of glomerular capillaries when disassociated from the nanoparticle surface. All other organs evaluated showed low (muscle, fat, bone) or negligible (brain) uptake. Animals were not perfused prior to counting, so some contribution of activity in the harvested organs may have been due to remaining blood.

Small Animal PET Imaging Studies. The PET imaging capabilities of dual-modality ^{64}Cu-labled mSPIOs were analyzed by small animal microPET imaging performed using a microPET Focus 120. In this study, BALB/c mice were administered 100 μCi of ^{64}Cu-mSPIO (10 mg Fe/kg body weight) in 100 μL PBS via tail vein injection and imaged at 1 h, 4 h, and 24 h postinjection. Accurate comparison of microPET images with ex vivo biodistribution data required additional anatomical information that was provided by microCT scans. Mice were scanned on a microCAT II immediately after acquisition of microPET images, and coregistration was accomplished using fiducial landmarks on the animal bed. Examples of coregistered images obtained after administration of ^{64}Cu-mSPIO are shown in Figure 3.

MicroPET images showed general agreement with the results of the nanoparticle biodistribution studies. High levels of activity were observed in the heart and carotid arteries at 1 h postinjection (Figure 3A,B), indicating a large amount of nanoparticles in circulation. The strong presence of circulating nanoparticles was also observed in the descending abdominal aorta, aortic bifurcation, and common iliac arteries. Less activity was observed in the heart at 4 h postinjection (Figure 3C,D). This absence of activity in the heart indicated a marked decrease in circulating nanoparticles relative to levels at 1 h postinjection, corresponding well to the decrease in blood activity observed from the 1 to 4 h ex vivo biodistribution. Uptake of ^{64}Cu-mSPIOs by the liver was also clearly apparent, suggesting that

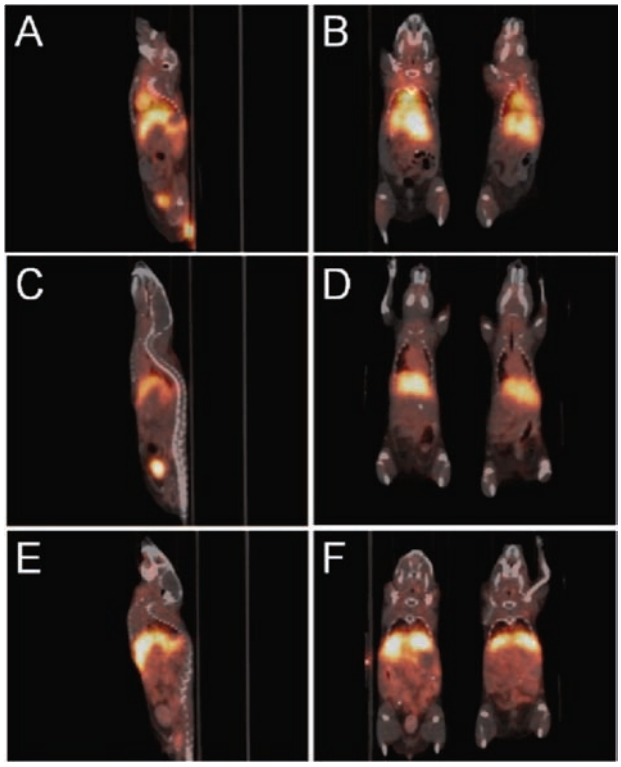

Figure 3. Coregistered microPET/microCT of BALB/c mice administered 100 μCi of ^{64}Cu-mSPIOs (10 mg Fe/kg body weight, 100 μL injection volume). Whole body sagittal (A−E) and coronal (B−F) PET images are decay corrected and scaled by min/max frame: (A, B) 1 h; (C, D) 4 h; and (E, F) 24 h postinjection.

significant amounts of nanoparticles were sequestered by the RES at 4 h postinjection.

By 24 h postinjection, microPET images showed little activity in the heart (Figure 3E,F), corresponding to negligible amounts of circulating nanoparticles. While the liver and spleen showed high uptake at 24 h, widespread activity could also be observed in gastrointestinal (GI) tract. This activity indicated that ^{64}Cu-mSPIOs (and their metabolic products) present in the liver underwent biliary excretion into the GI tract to be eliminated in the feces.

Phantom Studies. To verify the dual imaging capability of ^{64}Cu-mSPIOs, nanoparticle samples underwent PET and MR scans using standard techniques. Figure 4 shows T_2-weighted and microPET images of 10 and 25 μg Fe/mL samples of labeled magnetic nanoparticles. Iron oxide cores in ^{64}Cu-mSPIO produced a characteristic darkening (signal hypointensity) at increasing iron concentrations, seen in Figure 4A. A strong PET signal was produced from ^{64}Cu chelated to PEG-phospholipid micelle coating (Figure 4B).

DISCUSSION

The combination of positron emission tomography (PET) with magnetic resonance imaging (MRI) offers many opportunities (*31–34*). MRI produces high-resolution soft tissue images as well as functional and spectroscopic information. PET provides quantitative, whole-body imaging with high sensitivity. Interest in combining PET with MRI has surged (*2, 35–37*), and structured nanomaterials have emerged as a possible platform for the development of dual-PET/MR imaging agents. Although dual modality PET/MRI imaging does not necessarily require a combined PET/MRI contrast agent, the use of ^{64}Cu-mSPIO in dual modality PET/MRI imaging offers certain potential advantages, including enhanced PET contrast, better circulation half-life, and better correlation between functional (PET) and

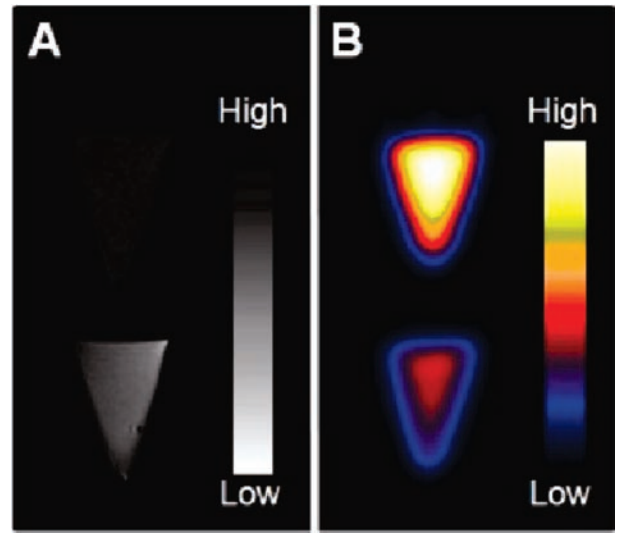

Figure 4. PET and MR imaging of ^{64}Cu-mSPIO phantoms. (A) T_2-weighted image of 25 μg Fe/mL (top) and 10 μg Fe/mL (bottom) of ^{64}Cu-labeled magnetic nanoparticles (scale bar corresponds to high and low iron concentration). (B) Decay-corrected microPET image of 25 μg Fe/mL (top) and 10 μg Fe/mL (bottom) of ^{64}Cu-labeled magnetic nanoparticles (scale bar corresponds to high and low copper-64 concentration).

morphological (MRI) information. While magnetic nanoparticles have been used extensively with MRI to study a wide range of biological phenomena such stem cell tracking (*13, 38*), cancer detection (*39–41*), and atherosclerotic monitoring (*42–44*), the synthesis and use of nanoparticles as PET molecular imaging agents have only recently been explored in detail (*45–48*). Nanoparticles are well-suited to the design of PET probes, because their relatively large surface area (as compared with small-molecule PET agents) can be labeled to a high specific activity, allowing for increased sensitivity of detection and increased payload of targeting ligands and therapeutic isotopes.

Encapsulation of magnetic nanoparticles in micelles of PEGylated lipids has many advantages over traditional polymer- and carbohydrate-based approaches. Unlike polymeric encapsulation, the modular nature of this coating scheme allows the functionalization of nanoparticle surfaces with multiple lipid species and alternative chemical groups on PEG termini to be achieved in situ by simple adjustment of the stoichiometry of the initial lipid solution. Additionally, polymer coatings commonly applied to nanoparticles are relatively bulky and possess surface chemistry that results in nanoparticles that experience high RES uptake (*26*). Carbohydrate coatings traditionally used in precipitation-based nanoparticle synthesis limit the core size that can be encapsulated (*49*) and generally require postsynthesis surface functionalization. Several functionalized PEG-phospholipids are commercially available and inexpensive, and PEGylated lipid coatings have been applied to nanoparticles ranging from 3 nm (*50*) to 35 nm (*51*) using multiple chemical functionalities (*20, 52*).

^{64}Cu-mSPIOs produced strong MR and PET signals (Figure 4) and were found to be stable in serum for 24 h (Figure 1D). The potential of this nanoparticle as a novel imaging agent was investigated by ex vivo biodistribution and in vivo PET imaging. Biodistribution results showed high initial blood retention with moderate liver uptake (Figure 2). ^{64}Cu-mSPIO had a circulation lifetime of 143 min, a value that compares well with previous reports of quantum dots and silica nanoparticles with PEGylated lipid coatings (*53, 54*). This result suggests that the circulation profile is dominated by the coating and that lipid-PEG coatings can be generalized to other classes of nanoparticle cores with differing chemistries.

PET/CT imaging showed high levels of ^{64}Cu in several regions. In general, microPET imaging correlated well with biodistribution findings. The heart and carotid arteries were clearly visible at early time points, indicating a high level of ^{64}Cu-mSPIO blood retention (Figure 3A,B). While the liver and spleen showed high uptake at 24 h postinjection, widespread activity could also be observed in gastrointestinal (GI) tract (Figure 3E,F). This activity was an indication that ^{64}Cu-mSPIOs (and their metabolic products) sequestered in the liver at earlier time points underwent biliary excretion into the GI tract to be eliminated in the feces. Since iron oxide nanoparticles have been used in humans with few observed side effects (*55, 56*), and ^{64}Cu has been used in patients (*57–60*) and showed no toxicity, ^{64}Cu-mSPIO probes have a high potential for clinical applications.

In summary, we report the development and in vivo evaluation of a novel dual-PET/MRI nanoparticle probe composed of a monocrystalline superparamagnetic iron oxide (SPIO) core and a physically adsorbed layer of PEGylated lipids. This is in contrast to the published reports of dual-modality PET/MRI nanoparticles that used either dextran-based (*61, 62*) or protein-based (*7, 63*) coatings. We have characterized the physical and pharmacokinetic properties of ^{64}Cu-mSPIO probes and evaluated their potential as a dual-modality imaging agent using quantitative ex vivo biodistribution and in vivo microPET/CT imaging. We are currently investigating the targeting abilities of these and other dual-PET/MRI nanoparticle probes and their application to disease detection and treatment in atherosclerosis and cancer models.

ACKNOWLEDGMENT

This work was supported by the National Heart Lung and Blood Institute of the NIH as Programs of Excellence in Nanotechnology (HL80711 to G.B. and HL080729 to M.J.W.), and as a Center of Cancer Nanotechnology Excellence (CA119338 to G.B.). The production of ^{64}Cu was supported by the National Cancer Institute (CA86307 to M.J.W.).

Discovery of Metabolically Stabilized Electronegative Polyacridine-PEG Peptide DNA Open Polyplexes

Christian A. Fernandez, Nicholas J. Baumhover, Kevin Anderson, and Kevin G. Rice*

Divisions of Pharmaceutics and Medicinal & Natural Products Chemistry, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242. Received November 20, 2009; Revised Manuscript Received January 29, 2010

Cationic condensing peptides and polymers bind electrostatically to DNA to form cationic polyplexes. While many cationic polyplexes are able to achieve in vitro transfection mediated through electrostatic interactions, few have been able to mediate gene transfer in vivo. The present study describes the development and testing of polyacridine PEG-peptides that bind to plasmid DNA by intercalation resulting in electronegative open polyplex DNA. Polyacridine PEG-peptides were prepared by chemically conjugating 6-(9-acridinylamino) hexanoic acid onto side chains of Lys in PEG-Cys-Trp-$(Lys)_{3, 4, or 5}$. The resulting PEG-Cys-Trp-$(Lys\text{-}(Acr))_{3, 4, or 5}$ peptides bound tightly to DNA by polyintercalation, rather than electrostatic binding. Unlike polycationic polyplexes, polyacridine PEG-peptide polyplexes were anionic and open coiled, as revealed by zeta potential and atomic force microscopy. PEG-Cys-Trp-$(Lys\text{-}(Acr))_5$ showed the highest DNA binding affinity and the greatest ability to protect DNA from metabolism by DNase. Polyacridine PEG-peptide DNA open polyplexes were dosed intramuscularly and electroporated in mice to demonstrate their functional activity in gene transfer. These results establish polyacridine PEG-peptide DNA open polyplexes as a novel gene delivery method for in vivo use.

INTRODUCTION

Nonviral gene delivery systems have traditionally relied on reversible binding between cationic carriers and anionic oligonucleotides (*1*−*3*). The resulting lipoplexes and polyplexes typically possess a positive surface charge as determined by zeta potential measurements. While cationic DNA lipoplexes and polyplexes have shown the ability to mediate in vitro gene transfer through electrostatic binding to cell surfaces, they exhibit poor gene transfer properties in vivo, in part due to their overall cationic charge (*4, 5*). There have been many attempts to mask the positive charge of cationic polyplexes with polyethylene glycol (PEG) to improve blood compatibility (*6*−*11*).

Alternatively, it is difficult to prepare an electronegative DNA polyplex using cationic polymers. This has been attempted by either partially titrating a polycationic polymer with plasmid DNA or using a layer-by-layer addition of oppositely charged polymers in an attempt to reverse the charge of polyplexes (*12*−*14*). The resulting electronegative polyplexes are formed in a delicate and unstable equilibrium (*15*). Attempting to reverse the charge of a cationic polyplex with the addition of an anionic polymer can lead to dissociation of the DNA. Similarly, if titrated to below the charge equivalency point, the polyplex is not completely protected against DNase, whereas if titrated to charge equivalency, the resulting neutral polyplexes are hydrophobic and aggregate. Titration past the equivalency point results in collapse of a polyplex into a cationic colloidal particle that is relatively stable but highly cationic and thereby less compatible with blood components (*5*). Consequently, we sought to find an alternative approach to ionic binding to DNA that would result in stable electronegative polyplexes.

In principle, the high affinity DNA binding achieved by polyintercalation could result in metabolically stable electronegative polyplexes (*16*). Electronegative polyplexes may bind to fewer proteins and thereby be more blood and tissue compatible to allow delivery via intramuscle electroporation (IM-EP) (*17*−*20*).

Polyacridine containing polymers have been previously investigated as gene transfer agents by Szoka, Vierling, and Neilsen (*21*−*23*). Their studies utilized polyacridine polymers possessing one, two, or three acridine units conjugated to either a neoglycopeptide or a nuclear localizing sequence. While these polyacridine carriers could bind to DNA, they possessed modest gene transfer activity in vitro (*22, 23*). Alternatively, we have recently reported that a polyacridine peptide modified with a melittin fusogenic peptide is a potent in vitro gene transfer agent (*24*). The most potent polyacridine-melittin gene delivery peptide contained four acridines and possessed a sequence of Lys(Acr)-Arg-Lys(Acr)-Arg-Lys(Acr)-Arg-Lys(Acr)-Arg-Cys joined to melittin by a disulfide bond. Polyacridine-melittin bioconjugates formed electropositive DNA polyplexes in which their potency was dependent upon the number of acridines, the identity of the spacing amino acid, and the presence of a reducible disulfide bond between polyacridine and melittin.

To date, there are no reports of polyacridine peptides modified with PEG. The present study demonstrates a synthetic strategy to modify the side chains of Lys in PEG-Cys-Trp-$(Lys)_n$ peptides with acridine. The resulting PEG-Cys-Trp-$(Lys(Acr))_n$ peptides bind reversibly to DNA through intercalation and demonstrate the ability to form a unique electronegative open polyplex DNA structure that is protected from DNase and maintains transfection competency in vivo. The unique properties of PEGylated polyacridine DNA electronegative open polyplexes afford desirable characteristics that are more compatible with in vivo nonviral gene delivery compared to cationic polyplexes.

MATERIALS AND METHODS

N-terminal Fmoc protected amino acids, 9-hydroxybenzotriazole (HOBt), diisopropylcarbodiimide (DIC), and Wang resin were purchased from Advanced ChemTech (Lexington, KY). Sephadex G-25, HEPES buffer, tris(2-carboxyethyl)-phosphine hydrochloride (TCEP), diisopropylethylamine (DIPEA), piperdine, acetic anhydride, triisopropylsilane (TIS), DNase I (EC

3.1.21.1), 9-chloroacridine, and thiazole orange were obtained from Sigma Chemical Co (St. Louis, MO). Acetonitrile, *N*,*N*-dimethylformamide (DMF), and trifluoroacetic acid (TFA) were purchased from Fisher Scientific (Pittsburgh, PA). Agarose was obtained from Gibco-BRL. mPEG-maleimide 5000 Da was purchased from Nektar (Huntsville, AL), mPEG-amine (5000 Da) was purchased from Creative Biotechnology (Winston-Salem, NC), and bis-amino PEG (2000 Da) was purchased from Iris Biotech GmbH (Marktredwitz, Germany). The 5.3 kb luciferase plasmid, pGL3 control vector, containing a SV40 promoter and enhancer was obtained from Promega (Madison, WI). Plasmid DNA was amplified in DH5α strain of *E. coli* and purified according to the manufacturer's instructions.

Synthesis and Characterization of PEGylated Cys-Trp-Lys$_n$ Peptides. Cys-Trp-Lys$_n$ synthesis was carried out using standard Fmoc chemistry on a computer interfaced Advanced Chemtech APEX 396 solid-phase peptide synthesizer with 9-hydroxybenzotriazole and diisopropylcarbodiimide double couplings followed by N-capping with acetic anhydride as described previously (*25*). Cleavage and deprotection were accomplished by reacting the resin with TFA/TIS/water (95:2.5:2.5) at RT for 3 h. The crude peptide was precipitated in cold diethyl ether, centrifuged, and the supernatant was decanted. Crude peptides were reconstituted in 0.1% TFA and purified on a preparatory RP-HPLC using a Vydac C18 column (2 × 25 cm) eluted at 10 mL/min with 0.1 v/v % TFA and a gradient of acetonitrile of 5−25% over 30 min while monitoring Abs 280 nm. Purified peptides were reconstituted in 0.1% TFA and quantified by Abs (Trp $\varepsilon_{280nm} = 5600\ M^{-1}\ cm^{-1}$) to determine the isolated yield of 30%. The purified peptides were characterized using LC-MS by separation on a Vydac C18 analytical column (0.47 × 25 cm) eluted at 0.7 mL/min with 0.1% TFA and a gradient of acetonitrile of 5−25% over 30 min while detecting ESI-MS in the positive ion mode.

PEGylation of the Cys residue on Cys-Trp-Lys$_{3,4and5}$ was achieved by reacting 0.9 mol equiv of peptide with 1 mol equiv of PEG$_{5000Da}$-maleimide in 100 mM sodium phosphate buffer pH 7 for 1 h at RT (*25*). PEGylated peptides were purified on a G-25 column (2.5 × 50 cm) eluted with 0.1% acetic acid while monitoring Abs 280 nm. The peak corresponding to the PEG-peptide eluted in the void volume (100 mL), was pooled, concentrated by rotary evaporation, and freeze−dried. The PEG-peptide was reconstituted in 0.1% TFA, and quantified by Abs (Trp $\varepsilon_{280nm} = 5600\ M^{-1}\ cm^{-1}$) to determine an isolated yield of 80%. PEG-peptides were characterized by MALDI-TOF MS by combining 1 nmol with α-cyano-4-hydroxycinnamic acid (CHCA) prepared in 50% (v/v) acetonitrile and 0.1% TFA. Samples were spotted onto the target and ionized on a Bruker Biflex III mass spectrometer operated in the positive ion mode.

Synthesis of Polyacridine PEG Peptides and Mono- and Bis-Acridine PEGs. 6-(9-Acridinylamino)hexanoic acid was prepared according to a prior published procedure (*26*). The carboxyl group on 6-(9-acridinylamino) hexanoic acid was activated with 1.1 mol equiv of DIC and HOBt in DMF. Activated 6-(9-acridinylamino) hexanoic acid (12 mol equiv) was reacted with 2.5 μmol of PEG-Cys-Trp-Lys$_{3,4,and5}$ in 3 mL of DMF at RT for 24 h. The PEG-Cys-Trp-(Lys(Acr))$_{3,4,and5}$ peptides were purified using a G-25 column (2.5 × 50 cm) eluted with 0.1% acetic acid while monitoring Abs 280 nm. The product peak eluting at 100 mL was pooled, freeze−dried, and characterized using MALDI-TOF MS as described above. A yield of 42% of PEG-Cys-Trp-(Lys(Acr))$_{3,4,and5}$ peptides was determined by acridine Abs ($\varepsilon_{409nm} = 9266\ M^{-1}\ cm^{-1}$) assuming additivity of acridine molar absorptivity and complete conjugation to the ϵ-amine of Lys. Similarly, mono- and bis-acridinylated PEGs were prepared by reacting 6 mol equiv of activated 6-(9-acridinylamino) hexanoic acid with PEG-amine or bis-amino PEG (2 μmol) in 2 mL of DMF. The acridinylated PEGs were purified by G-25 column and characterized by MALDI-TOF MS.

Thiazole Orange Displacement Assay. The binding of polyacridine PEG-peptides to DNA was determined using an intercalator dye displacement assay (*27*). pGL3 (1 μg) was prepared in 5 mM Hepes pH 7.4 containing 40 nM thiazole orange. Polyacridine PEG-peptides were added to pGL3 to prepare samples of 0, 0.25, 0.5, 1, 2, 3, and 4 nmol per μg of DNA in a final volume of 500 μL. The fluorescence intensity of each sample was measured using an LS50B fluorometer (Perkin-Elmer, UK) with an excitation wavelength of 500 nm while monitoring emission at 530 nm. The data were converted to percent by comparison to the fluorescence intensity of thiazole orange in buffer (0%) and pGL3 with fully bound thiazole orange (100%).

Gel Band Shift and DNase Protection Assay. pGL3 (1 μg) or DNA polyplexed (1 μg) prepared in 18 μL of normal saline were combined with 1 nmol of mono-acridine PEG, bis-acridine PEG, PEG-Cys-(Lys-Acr)$_3$, PEG-Cys-(Lys-Acr)$_4$, or PEG-Cys-(Lys-Acr)$_5$ and 2 μL of loading buffer (*28*). The samples were loaded onto a 1% agarose gel (50 mL) and electrophoresed in TAE buffer at 80 V for 90 min. The gel was stained in 2 mg/mL ethidium bromide at 5 °C overnight, and the transilluminated gels were photographed using Polaroid 667 film. pGL3 (1 μg) or DNA polyplexes (1 μg) prepared with 1 nmol of mono-acridine PEG, bis-acridine PEG, PEG-Cys-(Lys-Acr)$_3$, PEG-Cys-(Lys-Acr)$_4$, or PEG-Cys-(Lys-Acr)$_5$ in 20 μL of normal saline was incubated with 0.06 U of DNase I at 37 °C for 0−20 min (*29*). The samples were applied to a 1% agarose gel and electrophoresed as described above.

Particle Size and Zeta Potential of Polyacridine PEG-Peptide DNA Open Polyplexes. Polyacridine PEG-peptide DNA polyplexes were formed by combining 10 μg of pGL3 (in 500 μL of 5 mM Hepes pH 7.4) with an equal volume containing 1, 2, 4, 8, 12, 16, or 20 nmol of polyacridine PEG-peptide while vortexing. The polyplexes were equilibrated at RT for 30 min prior to analysis of particle size (QELS) and zeta potential using a Brookhaven ZetaPlus (Brookhaven Instruments, Holtsville, NY). The particle size diameter and zeta potential are reported as the mean and standard deviation of ten measurements.

Atomic Force Microscopic Analysis of Polyacridine PEG-Peptide DNA Open Polyplexes. pGL3 was prepared at a concentration of 100 μg per ml in 10 mM Tris containing 1 mM EDTA pH 8. DNA polyplexes were prepared identically with the addition of PEG-Cys-Trp-(Lys(Acr))$_5$ at either 0.2 or 1 nmol per μg of DNA. pGL3 and DNA polyplexes were diluted 10-fold in 40 mM Hepes containing 5 mM nickel chloride pH 6.7, then deposited on a freshly cleaved mica surface and incubated for 10 min, followed by washing with deionized water (*30*). Alternatively, polyacridine-melittin DNA polyplexes were prepared at 0.5 nmol of peptide per μg of DNA at a concentration of 100 μg per ml of DNA and directly deposited on a freshly cleaved mica surface and allowed to bind for 10 min prior to washing with deionized water (*24*). Images were captured using an Asylum atomic force microscope (AFM) MFP3D (Santa Barbara, CA) operated in ac-mode using a silicon cantilever (Ultrasharp NSC15/AIBS, Mikro Masch).

Intramuscle-Electroporation Dosing. Male ICR mice (Harlan), weighing 25−30 g, were prepared for IM-EP dosing by anesthetization with an intraperitoneal dose of 200 μL of ketamine/xylazine (20 mg/mL and 2 mg/mL, respectively). The hamstring muscles were sheared and swabbed with 70% ethanol prior to administering a 50 μL dose over 10 s in normal saline to both gastrocnemius muscles in 2 mice by a 1 mL monoject syringe (1 cm^3, 28 G × 1/2). After dosing, the BTX 2-Needle

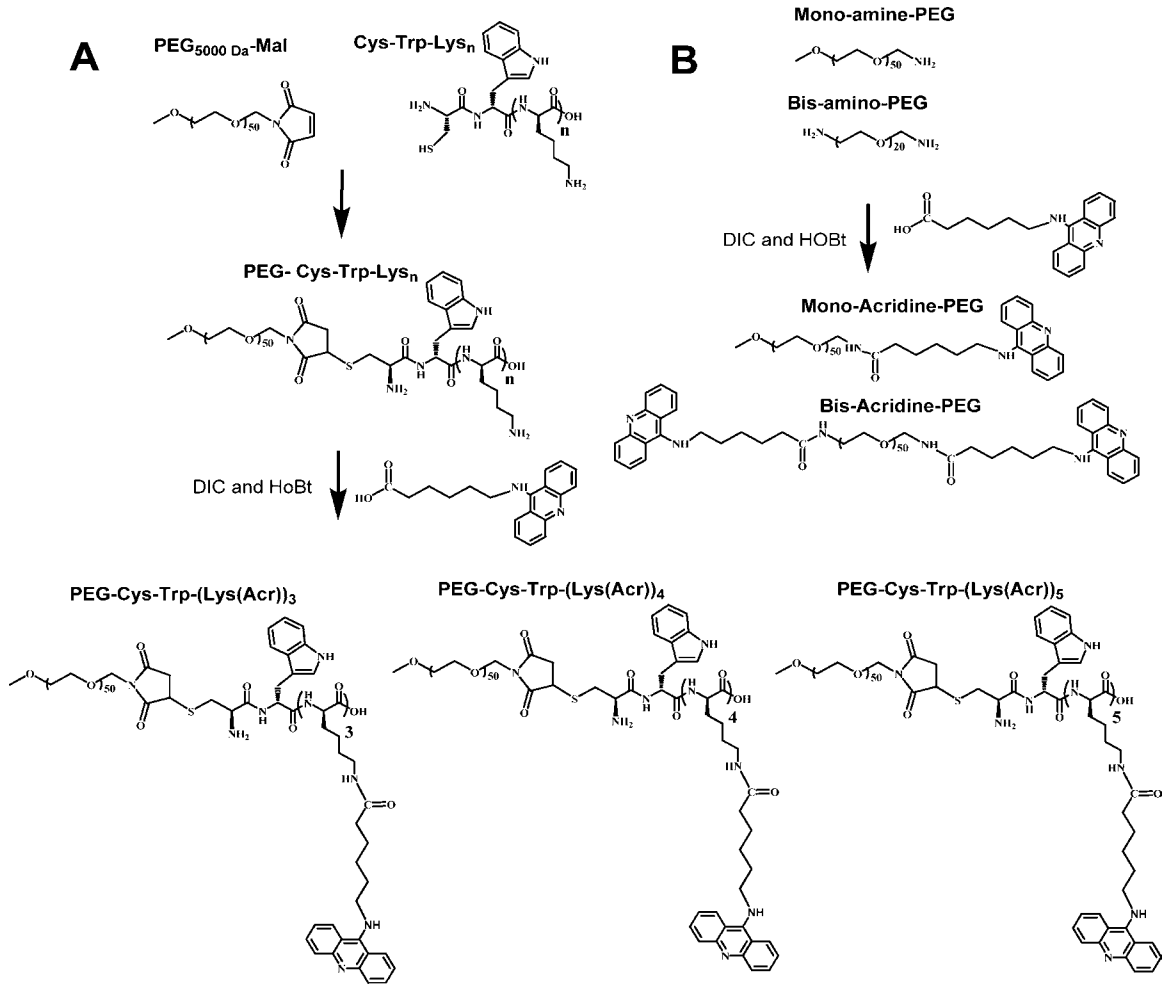

Figure 1. Preparation of PEGylated polyacridine bioconjugates. PEG_{5000Da}-maleimide was reacted with the Cys residue on Cys-Trp-Lys_3, Cys-Trp-Lys_4, and Cys-Trp-Lys_5 to form PEG-Cys-Trp-$(Lys)_{3,\,4,\,\text{and}\,5}$. Activated 6-(9-acridinylamino) hexanoic acid was reacted with ε-amines of Lys to form PEG-Cys-Trp-$(Lys\text{-}(Acr))_{3,\,4,\,\text{and}\,5}$. Alternatively, mono and bis PEG-amine were reacted with activated 6-(9-acridinylamino) hexanoic acid to prepare mono-Acr-PEG and bis-Acr-PEG.

Array Electrode was inserted into the skin with the electrodes straddling the dosing site. Successive electronic stimulation was generated by the EMC BTX 830, Square-Wave Pulse Generator (BTX, Harvard Apparatus) as the power source. At 1 min postadministration of the DNA dose, the pulse generator delivered six successive 100 V pulses over 20 ms with a 100 ms interval between pulses (*31*).

Bioluminescence Imaging. Luciferase reporter gene expression was quantified by bioluminescence imaging (BLI) at 2−14 days following IM-EP using an IVIS Imaging System 200 series (Xenogen) (*32*). Mice were anesthetized by isofluorane (2% flow with oxygen) and dosed intramuscularly with 40 μL of 30 mg per ml D-luciferin (GoldBio). Bioluminescent images were acquired 5 min post substrate administration and acquired for 1 min with a 24.6 cm field of view. The resultant grayscale images with a colormap overlay were analyzed using the *IgorPro 4.09* software (LivingImage). Luciferase expression is reported as photons/s/cm^2/steradian within a uniformly defined region of interest.

RESULTS

Several polyintercalator constructs that bind to double-stranded DNA have been reported in prior studies aimed at delivering plasmid DNA (*21*−*23*). These studies designed and tested delivery molecules possessing one to three acridine dyes displayed on a branched polymer modified with a neoglycopeptide or a nuclear localizing peptide, the later of which were shown to mediate in vitro gene expression (*22, 23*). These studies established that two to three acridines were required to achieved sufficient DNA binding affinity for in vitro transfection.

In the present study, we sought to use a synthetic strategy that would allow for the incorporation of more than three acridines by covalent modification of the side chain of PEGylated polylysine. This was accomplished by first modifying acridine to possess a 6-amino hexanoic acid and then activating the carboxyl group to allow coupling to the ϵ-amines of PEG-Cys-Trp-$(Lys)_{3,\,4,\,\text{and}\,5}$ to afford PEG-Cys-Trp-$(Lys(Acr))_{3,\,4,\,\text{and}\,5}$ (Figure 1). In addition, conjugation of acridine 6-amino hexanoic acid directly to PEG-amine and bis amino PEG afforded constructs with either one or two acridines (Figure 1). This strategy provided an advantage by allowing the comparison of DNA binding affinity with PEGs modified with 1−5 acridines.

Chromatographic evidence supporting the synthesis of PEG-Cys-Trp-$(Lys(Acr))_5$ is illustrated in Figure 2. Modification of Cys-Trp-$(Lys)_5$ with PEG results in a significant delay in elution on RP-HPLC compared to Cys-Trp-$(Lys)_5$. However, upon conjugation of five acridines to PEG-Cys-Trp-$(Lys)_5$, the resulting PEG-Cys-Trp-$(Lys(Acr))_5$ elutes only slightly later, and is detected at Abs $_{409nm}$.

The complete conjugation of acridine to the each Lys side chain was established using MALDI-TOF MS analysis. Conjugation of Cys-Trp-$(Lys)_5$ (948.8 g/mol) with polydisperse PEG of average mass of 5425 Da results in a PEG-Cys-Trp-$(Lys)_5$ with an apparent average mass of 6546 Da (Figure 3A−C).

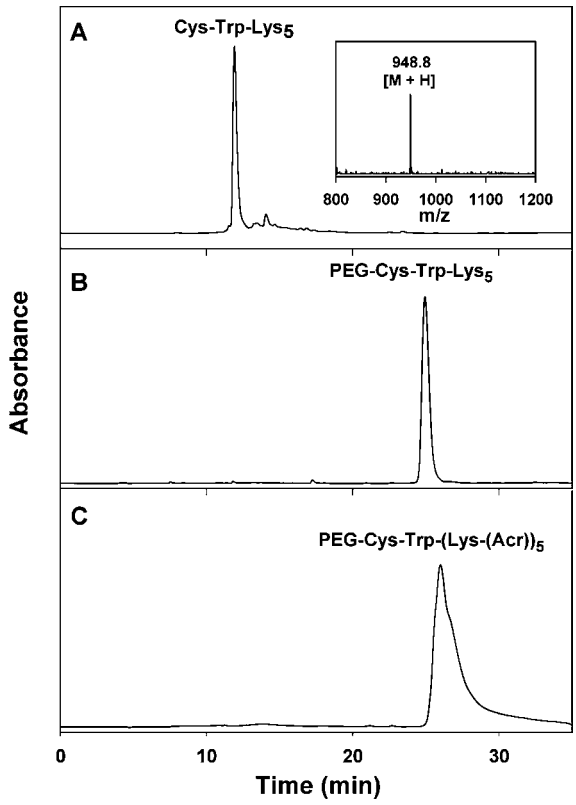

Figure 2. RP-HPLC Analysis of PEG-Cys-Trp-(Lys-(Acr))$_5$. Cys-Trp-(Lys)$_5$ elutes at 10 min on RP-HPLC eluted with 0.1% TFA and an acetonitrile gradient 5−60% over 30 min while detecting Trp by Abs at 280 nm (panel A). The inset shows the ESI-MS of Cys-Trp-Lys$_5$ with an [M+H] = 982.8 Da. Purified PEG-Cys-Trp-(Lys)$_5$ elutes at 24 min under identical gradient and detection (panel B). Purified PEG-Cys-Trp-(Lys(Acr))$_5$ elutes as a broad peak at 25 min and is detected by Abs 409 nm due to acridine (panel C).

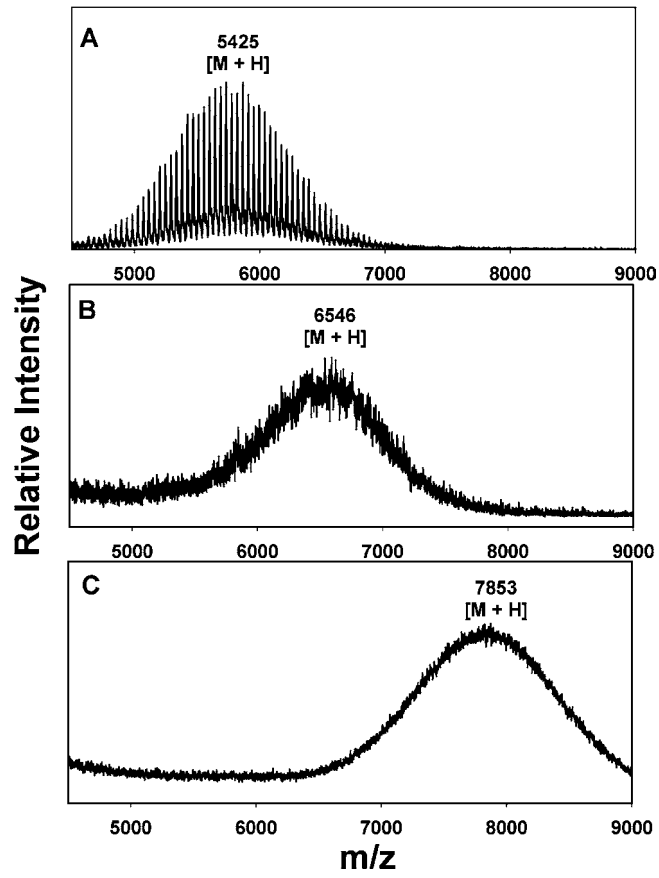

Figure 3. Mass spectral analysis of PEG-Cys-Trp-(Lys(Acr))$_5$. MALDI-TOF MS analysis PEG$_{5000Da}$-maleimide resulted in an average mass with *m/z* of 5425 (panel A). MS analysis of PEG-Cys-Trp-(Lys)$_5$ resulted in a mass shift of 1121 Da, consistent with the formation of the PEG-peptide with *m/z* of 6546 (panel B). Following conjugation of five 6-(9-acridinylamino) hexanoic acid residues (290 g/mol), the average mass increases by 1307 Da, consistent with the formation of PEG-Cys-Trp-(Lys(Acr))$_5$ with *m/z* of 7853 (panel C).

Purified PEG-Cys-Trp-(Lys(Acr))$_5$ produced an average mass of 7853 Da (Figure 3D), consistent with the conjugation of 4.4 acridines. Similar mass spectral results were obtained when preparing PEG-Cys-Trp-(Lys(Acr))$_3$ and PEG-Cys-Trp-(Lys(Acr))$_4$ as summarized in Table 1.

The relative DNA binding affinity of mono and bis-acridine PEG compared to polyacridine PEG-peptides was established using a thiazole orange displacement assay (*33*) (Figure 4A). Titration of 0.2−4 nmols of mono-acridine PEG with 1 μg of pGL3 resulted in minimal displacement of thiazole orange. By comparison, bis-acridine PEG demonstrated higher affinity, resulting in a decrease in fluorescence intensity by approximately 40% at 1 nmol per μg of DNA. The apparent DNA binding affinity of PEG-Cys-Trp-(Lys(Acr))$_{3-5}$ was higher than either mono- or bis-acridine PEG, resulting in approximately 10% fluorescence intensity at a stoichiometry of 1 nmol per μg of DNA (Figure 4A).

The DNA binding affinity was also compared by a band shift assay performed at a constant stoichiometry of 1 nmol per μg of DNA (Figure 4B). Monoacridine PEG failed to produce a band shift relative to plasmid DNA (Figure 4B, lanes 1 and 2), whereas bis-acridine PEG partially retarded the migration of DNA (Figure 4B, lane 3). PEG-Cys-Trp-(Lys(Acr))$_{3and4}$ both further retarded DNA migration to a similar extent (lanes 4 and 5), whereas PEG-Cys-Trp-(Lys(Acr))$_5$ led to complete retardation of DNA migration and also inhibited intense ethidium staining (Figure 4B, lane 6). Conversely, PEG-Cys-Trp-(Lys)$_5$ was unable to cause a band DNA shift (not shown).

A further demonstration of polyacridine binding to DNA binding utilized a titration experiment while monitoring both the particle size and zeta potential of DNA polyplexes as a function of increasing concentration of polyacridine (Figure 5). The titration of PEG-Cys-Trp-(Lys(Acr))$_3$ with pGL3 results in a decrease in the apparent particle diameter to approximately 200 at 0.2 nmols per μg of DNA but then plateaued at higher stoichiometries. The zeta potential gradually increased from −15 to −5 mV when titrating with 0.1 to 2 nmol of PEG-Cys-Trp-(Lys(Acr))$_3$ per μg of DNA, indicating that the polyplexes remained electronegative (Figure 5A). A nearly identical trend was observed when titrating pGL3 with PEG-Cys-Trp-

Table 1. MS Analysis of Polyacridine PEG-Peptides and Mono- and Bis-Acridine PEG.

sample	mass (g/mol)	mass difference[b]
Mono-amine-PEG	5385	
Mono-acridine-PEG	5626	241 (0.8)[c]
Bis-amine-PEG	2000	
Bis-acridine-PEG	2813	813 (2.8)[c]
Cys-Trp-Lys$_3$[a]	691.4	
PEG-Cys-Trp-Lys$_3$	6524	
PEG-Cys-Trp-(Lys(Acr))$_3$	7238	714 (2.5)[c]
Cys-Trp-Lys$_4$[a]	819.5	
PEG-Cys-Trp-Lys$_4$	6623	
PEG-Cys-Trp-(Lys(Acr))$_4$	7533	910 (3.1)[c]
Cys-Trp-Lys$_5$[a]	948.5	
PEG-Cys-Trp-Lys$_5$	6555	
PEG-Cys-Trp-(Lys(Acr))$_5$	7822	1267 (4.4)[c]

[a] Determined by ESI-MS. [b] Measured mean difference in MALDI-TOF mass due to the addition of acridine. [c] Calculated number of acridine-6-amino-hexanoic acids based on 291 g/mol.

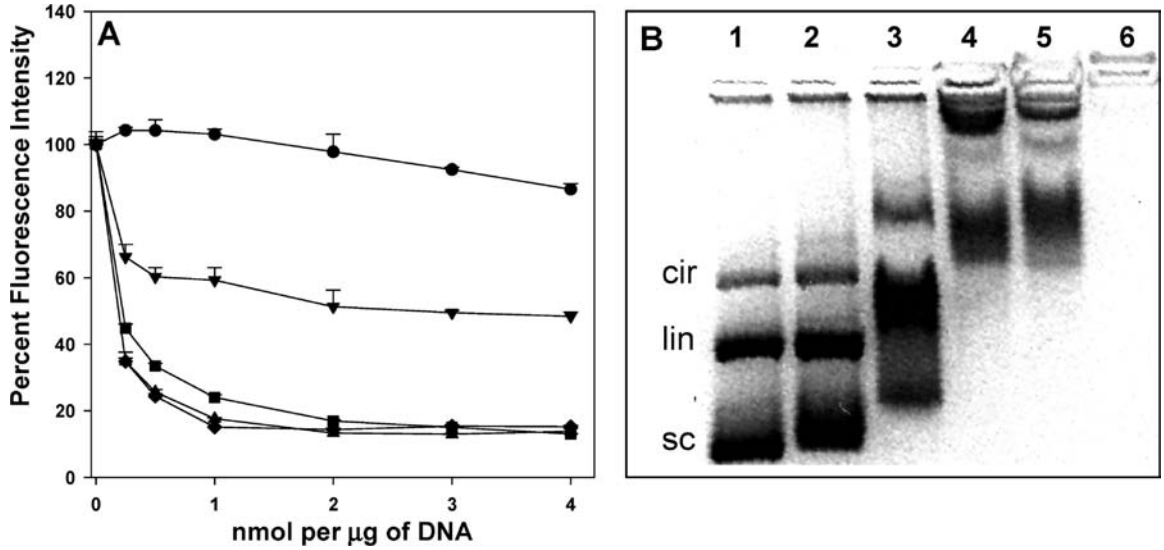

Figure 4. Relative binding affinity of mono-acridine-PEG, bis-acridine-PEG, and polyacridine peptides with DNA. The relative binding affinity of mono- and bis-acridine-PEG, and PEG-Cys-Trp-(Lys(Acr))$_{3,\ 4,\ \text{and}\ 5}$ for DNA was determined using a thiazole orange dye displacement assay and agarose gel band shift assay. Thiazole orange displacement established weak DNA binding for mono- (•) and bis-acridine-PEG (▼), with higher and indistinguishable affinity determined for PEG-Cys-Trp-(Lys(Acr))$_3$ (■), 4 (▲), and 5 (♦) (panel A). The DNA binding affinity was also compared by agarose gel electrophoresis DNA migration (1 μg) (lane 1) relative to polyplexes prepared with 1 nmol each of mono-acridine PEG (lane 2), bis-acridine PEG (lane 3), PEG-Cys-(Lys(Acr))$_3$ (lane 4), PEG-Cys-(Lys(Acr))$_4$ (lane 5), or PEG-Cys-(Lys(Acr))$_5$ (lane 6) (panel B). The results established maximal binding affinity with PEG-Cys-(Lys(Acr))$_5$ (lane 6).

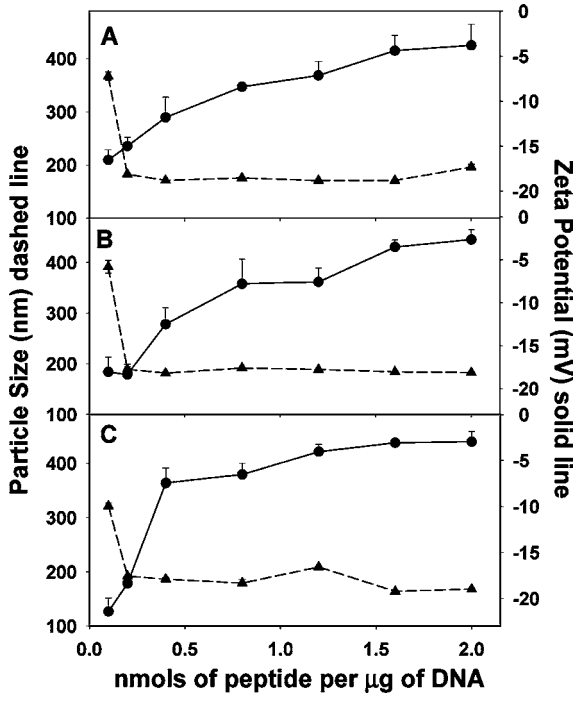

Figure 5. Particle size and zeta potential of polyacridine-peptide DNA polyplexes. The mean diameter size and zeta potential of DNA polyplexes prepared with 0.1, 0.2, 0.4, 0.8, 1.2, 1.6, or 2 nmol of PEG-Cys-(Lys(Acr))$_{3,\ 4,\ \text{and}\ 5}$ per μg of DNA were compared. At 0.2 nmol of polyacridine peptide or higher, PEG-Cys-(Lys(Acr))$_3$ formed polyplexes of apparent mean diameter of 200 nm that remained unchanged throughout the titration (panel A, dashed line). In contrast, the zeta potential progressively increased from −15 mV to approximately −2 mV when titrating from 0.1−2 nmol per μg of DNA (panel A, solid line). Nearly identical results were obtained when titrating with PEG-Cys-(Lys(Acr))$_4$ (panel B) and PEG-Cys-(Lys(Acr))$_5$ (panel C).

(Lys(Acr))$_4$ and PEG-Cys-Trp-(Lys(Acr))$_5$ (Figure 5B,C), with the exception that the latter reached an asymptote of −5 mV at 1 nmol per μg of DNA due to its greater DNA binding affinity.

The unusual zeta potential properties of the polyacridine DNA polyplexes prompted an investigation into their morphology using atomic force microscopy. Under analysis by AFM, plasmid DNA is observed as an open circular structure when immobilized onto electropositive mica prepared with immobilized Ni (Figure 6A). By comparison, PEG-Cys-Trp-(Lys(Acr))$_5$ DNA polyplexes prepared at either 0.2 or 1 nmol per μg of DNA also resulted in a open circular structure, which we term open polyplexes (Figure 6B,C). Comparison of the size and shape of open polyplexes with plasmid DNA reveals a slightly more compact structure that becomes progressively more tightly wound at higher stoichiometry of polyacridine. The appearance of smaller particles in Figure 6B,C is the result of AFM tip irregularities (*34*). Finer analysis of the data in Figure 6B,C suggests that the thickness of the open polyplex DNA is reduced by 20% relative to naked DNA. The open polyplex structure observed by AFM is quite unique when compared to an electropositive polyplex prepared with polyacridine melittin (Figure 6D).

We conjectured that the DNA in open polyplexes may be protected from metabolic degradation by serum endonucleases. The metabolic stability was evaluated by treating pGL3 with DNase followed by gel electrophoresis. Unprotected pGL3 is significantly degraded by DNase in 5 min and completely degraded by 10 min (Figure 7A, lanes 2 and 3). The weak binding affinity afforded by mono- or bis-acridine PEG failed to protect DNA from metabolism (Figure 7B,C). Comparison of the metabolic stability of PEG-Cys-Trp-(Lys(Acr))$_{3,4\text{and}5}$ DNA open polyplexes demonstrated that PEG-Cys-Trp-(Lys(Acr))$_3$ and PEG-Cys-Trp-(Lys(Acr))$_4$ provided partial protection (Figure 7D,E), whereas PEG-Cys-Trp-(Lys(Acr))$_5$ provided complete protection (Figure 7F). Decreasing the stoichiometry from 1 nmol of PEG-Cys-Trp-(Lys(Acr))$_5$ to 0.4 or 0.2 nmol per μg of DNA established that at lower stoichiometries the DNA was more susceptible to metabolism (Figure 7G,H).

The in vivo gene transfer properties of PEG-Cys-(Lys-(Acr))$_5$-DNA open polyplexes were evaluated in mice following IM-EP. pGL3 and pGL3 PEG-Cys-(Lys-(Acr))$_5$ open polyplexes prepared at 0.2, 2, and 4 nmol per μg of DNA formulations were administered by IM-EP, and the expression was monitored

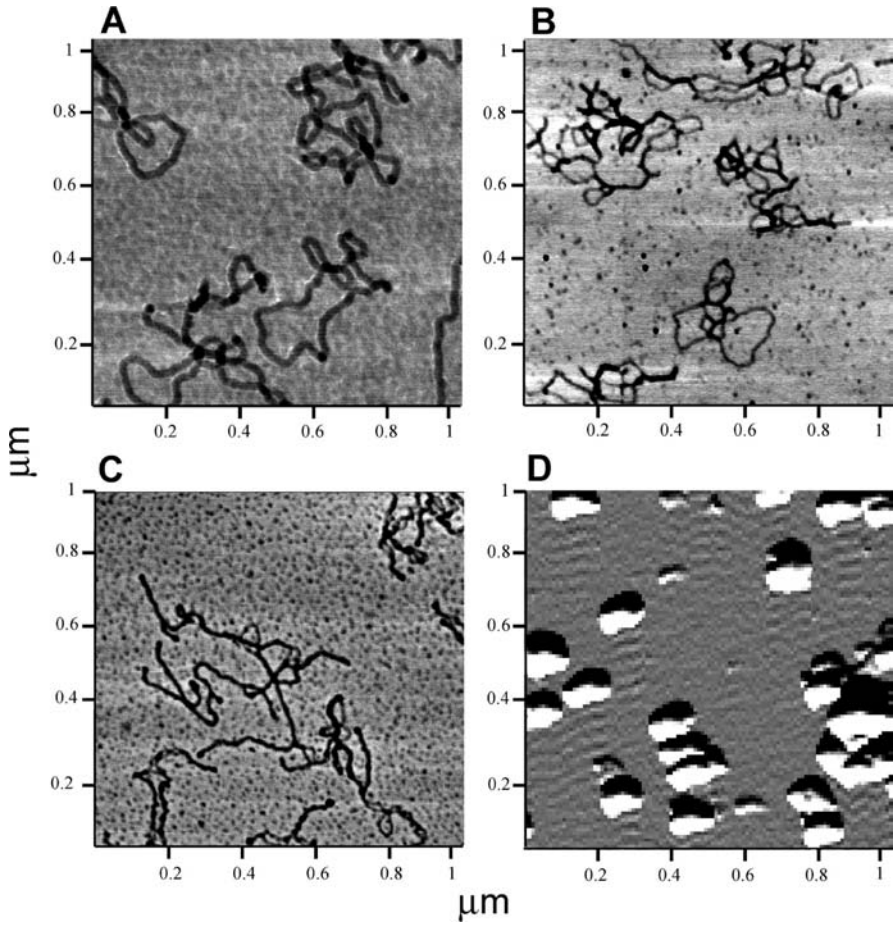

Figure 6. Atomic force microscopy analysis of plasmid DNA and polyacridine DNA polyplexes. AFM was used to compare the relative morphology of plasmid DNA or PEG-Cys-Trp-(Lys(Acr))$_5$ DNA polyplexes bound to electropositively charged mica in panels A−C. Plasmid DNA appears as an open circular structure (panel A) of comparable dimensions relative to PEG-Cys-Trp-(Lys-Acr)$_5$ DNA polyplexes prepared at either 0.2 nmol per μg of DNA (panel B) or 1 nmol per μg of DNA (panel C). Alternatively, a cationic polyplex prepared with polyacridine melittin binds to electronegative mica and appears as a collapsed structure (panel D). The results establish polyacridine PEG peptides bind to DNA to form electronegative open polyplexes that possess similar morphology as plasmid DNA.

for two weeks by bioluminescence imaging (Figure 8). At day 2 following dosing, pGL3 and the DNA open polyplexes prepared at 2 nmol per μg of DNA produced identical expression levels. Open polyplexes prepared at 4 nmol per μg of DNA showed approximately 10-fold lower expression, whereas a formulation prepared with 0.2 nmol per μg of DNA resulted in a 100-fold decrease in expression. A similar expression time course was observed for pGL3 and DNA open polyplexes prepared with 0.2 and 2 nmol of PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA resulting in a 10-fold decrease over 14 days. The expression time-course for open polyplexes prepared at 4 nmol of PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA was extended, resulting in only a 2−3-fold loss in expression across the 14 day sampling period.

DISCUSSION

An important function of a gene delivery carrier is to protect DNA from premature metabolism during transit (*35*). The present study demonstrates that polyintercalation provides strong and reversible binding to DNA that delays metabolic degradation. The main advantage of this approach over polycationic polymer binding to DNA is that high affinity can be achieved with a short polyacridine and that the charge of the resulting DNA polyplexes can be controlled to be either positive or negative, depending on intended applications in vitro or in vivo (*24*). Prior reports of the cellular toxicity of known intercalators demonstrate a dependency on both chemical structure and dose (*36*). Little or no information is available regarding the toxicity of PEGylated polyacridine peptides.

To evaluate the relationship between DNA binding affinity and metabolic stability, five DNA carriers were prepared that varied the number of acridines from 1 to 5. The synthetic strategy conjugated 6-(9-acridinylamino) hexanoic acid with the primary amine(s) on PEG-amine, bis-amino PEG, and the ε-amines on PEG-Cys-Trp-(Lys)$_{3,\ 4,\ \text{or}\ 5}$. This strategy not only simplified the chemical preparation of the delivery molecules, but also allowed for a long 12 atom tether between each acridine and the peptide backbone to facilitate flexible multivalent binding of acridine with DNA.

The DNA binding affinity significantly increased for PEG-Cys-(Lys-(Acr))$_{3,\ 4,\ \text{and}\ 5}$ compared to mono- and bis-acridine PEG as determined by both fluorophore displacement and DNA band shift on agarose gel electrophoresis (Figure 4A,B). While the QELS particle size suggested the formation of large polyplexes with an apparent diameter of 200 nm, the zeta potential revealed that for PEG-Cys-(Lys-(Acr))$_{3,\ 4,\ \text{and}\ 5}$ polyplexes were negatively charged. AFM images established that the shape of PEG-Cys-(Lys-(Acr))$_{3,\ 4,\ \text{and}\ 5}$ DNA polyplexes were open-coiled structures that closely resemble plasmid DNA (Figure 6). The observed electronegative open polyplexes are distinct from electropositive condensed polyplexes that are formed by polycation binding with DNA. The metabolic stability afforded by comparing PEG-Cys-(Lys-(Acr))$_{3,\ 4,\ \text{and}\ 5}$ establish a relationship between the apparent DNA binding affinity and the degree of protection from

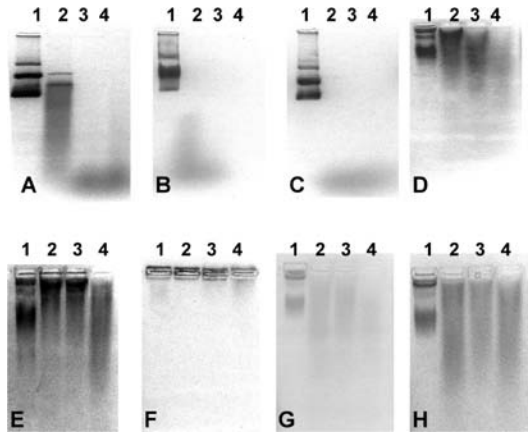

Figure 7. Relative metabolic stability of mono-acridine-PEG, bis-acridine-PEG, and polyacridine peptides DNA polyplexes. The relative metabolic stability of DNA polyplexes was compared with plasmid DNA by agarose gel electrophoresis. Plasmid DNA (1 μg) (panel A), or DNA polyplexes prepared with 1 nmol each of mono-acridine PEG (panel B), bis-acridine PEG (panel C), PEG-Cys-(Lys(Acr))$_3$ (panel D), PEG-Cys-(Lys(Acr))$_4$ (panel E), or PEG-Cys-(Lys-(Acr))$_5$ (panel) were incubated with 0.06 U of DNase at 37 °C for 0 (lane 1), 5 (lane 2), 10 (lane 3), and 20 (lane 4) min. PEG-Cys-(Lys(Acr))$_5$ DNA polyplexes were also prepared at 0.2 (panel G) and 0.4 (panel H) nmol of polyacridine peptide per μg of DNA and digested with DNase. The results demonstrate that PEG-Cys-(Lys-(Acr))$_5$ provided the greatest protection at 1 nmol per μg of DNA, (panel F) while the lower stoichiometries of 0.2 or 0.4 nmol per μg of DNA (panel G and H) resulted in less stability.

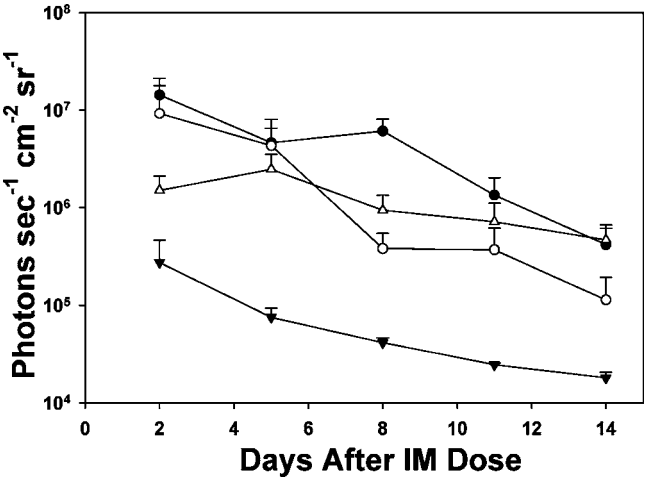

Figure 8. In vivo gene expression mediated by polyacridine peptide DNA polyplexes. The gene transfer efficiencies of naked DNA (•) or polyacridine peptide DNA polyplexes prepared with 0.2 (▲), 2 (○), or 4 (Δ) nmol of PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA were determined following i.m. dosing and electroporation of 1 μg of pGL3 in the gastrocnemius muscle of ICR male mice (n = 4). The luciferase expression was quantified at times ranging from 2−14 days by bioluminescence imaging (BLI) following an i.m. dose of luciferin. Open polyplexes prepared at 0.2 nmol (▲) of PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA showed the lowest transfection efficiency, while polyplexes prepared at 2 nmol (○) of PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA showed similar expression levels to that of naked DNA. Increasing the stoichiometry to 4 nmol (Δ) PEG-Cys-(Lys-(Acr))$_5$ per μg of DNA resulted in a more sustained expression. The results represent the mean and standard deviation of four doses.

DNase. Additionally, the metabolic protection of DNA afforded by PEG-Cys-(Lys-(Acr))$_5$ was concentration-dependent.

IM-EP of cationic DNA polyplexes results in lower gene expression levels compared to naked DNA alone (*20, 37, 38*). This may be due to the charge of cationic polyplexes that are unable to electromigrate through the transient pore formed during electroporation (*20*). In contrast, the IM-EP of DNA versus PEG-Cys-(Lys-(Acr))$_5$ DNA open polyplexes resulted in very similar levels and duration of expression in mice over two weeks. However, at an elevated stoichiometry of PEG-Cys-(Lys-(Acr))$_5$, a lower but more sustained expression was determined, perhaps due to the metabolic protection afforded by the peptide at higher stoichiometries.

The results of this study establish a new family of PEGylated polyacridine gene delivery carriers that bind to DNA and provide protection against DNase. The unique anionic open polyplex structure is compatible with IM-EP. Given the flexibility of design, polyacridine gene delivery systems could be optimized for a variety of other nonviral gene delivery applications.

Imaging Human Pancreatic Cancer Xenografts by Targeting Mutant *KRAS2* mRNA with [^{111}In]DOTA$_n$-Poly(diamidopropanoyl)^m-*KRAS2* PNA-D(Cys-Ser-Lys-Cys) Nanoparticles

Nariman V. Amirkhanov,[†,‡] Kaijun Zhang,[§] Mohan R. Aruva,[§] Mathew L. Thakur,[§,||] and Eric Wickstrom*[,‡,||]

Received November 27, 2009; Revised Manuscript Received February 16, 2010

95% of patients with ductal pancreatic cancer carry 12th codon activating mutations in their *KRAS2* oncogenes. Early whole body imaging of mutant *KRAS2* mRNA activation in pancreatic cancer would contribute to disease management. Scintigraphic hybridization probes to visualize gene activity in vivo constitute a new paradigm in molecular imaging. We have previously imaged mutant *KRAS2* mRNA activation in pancreatic cancer xenografts by positron emission tomography (PET) based on a single radiometal, ^{64}Cu, chelated to a 1,4,7,10-tetra(carboxymethylaza)cyclododecane (DOTA) chelator, connected via a flexible, hydrophilic spacer, aminoethoxyethoxyacetate (AEEA), to the N-terminus of a mutant *KRAS2* peptide nucleic acid (PNA) hybridization probe. A peptide analogue of insulin-like growth factor 1 (IGF1), connected to a C-terminal AEEA, enabled receptor-mediated endocytosis. We hypothesized that a polydiamidopropanoyl (PDAP) dendrimer (generation *m*), with increasing numbers (*n*) of DOTA chelators, extended via an N-terminal AEEA from a mutant *KRAS2* PNA with a C-terminal AEEA and IGF1 analogue could enable more intense external imaging of pancreatic cancer xenografts that overexpress IGF1 receptor and mutant *KRAS2* mRNA. ([^{111}In]DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-*KRAS2* PNA-AEEA-IGF1 analogues were prepared and administered intravenously into immunocompromised mice bearing human AsPC1 (G12D) pancreatic cancer xenografts. CAPAN2 (G12 V) pancreatic cancer xenografts served as a cellular *KRAS2* mismatch control. Scintigraphic tumor/muscle image intensity ratios for complementary [^{111}In]$_n$-PDAP^m-*KRAS2* G12D probes increased from 3.1 ± 0.2 at $n = 2$, $m = 1$, to 4.1 ± 0.3 at $n = 8$, $m = 3$, to 6.2 ± 0.4 at $n = 16$, $m = 4$, in AsPC1 (G12D) xenografts. Single mismatch [^{111}In]$_n$-PDAP^m-*KRAS2* G12 V control probes showed lower tumor/muscle ratios (3.0 ± 0.6 at $n = 2$, $m = 1$, 2.6 ± 0.9 at $n = 8$, $m = 3$, and 3.7 ± 0.3 at $n = 16$, $m = 4$). The mismatch results were comparable to the PNA-free [^{111}In]DOTA control results. Simultaneous administration of nonradioactive Gd$_n$-*KRAS2* G12 V probes ($n = 2$ or 8) increased accumulation of [^{111}In]$_8$*KRAS2* G12 V probes 3−6-fold in pancreatic cancer CAPAN2 xenografts and other tissues, except for a 2-fold decrease in the kidneys. As a result, tissue distribution tumor/muscle ratios of ^{111}In uptake increased from 3.1 ± 0.5 to 6.5 ± 1.0, and the kidney/tumor ratio of ^{111}In uptake decreased by more than 5-fold from 174.8 ± 17.5 to 30.8 ± 3.1. Thus, PDAP dendrimers with up to 16 DOTA chelators attached to PNA-IGF1 analogs, as well as simultaneous administration of the elevated dose of nonradioactive Gd$_n$-*KRAS2* G12 V probes, enhanced tumor uptake of [^{111}In]$_n$*KRAS2* PNA probes. These results also imply that Gd(III) dendrimeric hybridization probes might be suitable for magnetic resonance imaging of gene expression in tumors, because the higher generations of the dendrimers, including the NMR contrast Gd$_n$-*KRAS2* G12 V probes, improved tumor accumulation of the probes and specificity of tumor imaging.

INTRODUCTION

Pancreatic cancer will kill over 30 000 US men and women in 2010 (*1*). The vast majority of patients with pancreatic cancer present at an advanced, incurable stage. Even before an enlarged mass can be seen by magnetic resonance imaging (MRI) or computerized tomography (CT), early stage pancreatic intraepithelial neoplasia cells contain high levels of mRNAs copied from hyperactive cancer genes such as *KRAS2* and *HER2* (*2*). 95% of patients with ductal pancreatic cancer carry 12th codon activating mutations in their *KRAS2* oncogenes (*2*). Specific detection of pancreatic intraepithelial neoplasia by molecular imaging would enable resection of ductal pancreatic cancer at a survivable stage. Monitoring oncogene expression by radiohybridization imaging might also provide the earliest possible evidence for therapeutic efficacy, or resistance, sooner than FDG-PET.

Scintigraphic imaging, such as planar or PET, is very sensitive, but only appropriate in a human subject when suspect masses are evident or highly likely. Nonradioactive fluorescent imaging and luminescent imaging are impractical for any suspect mass more than 2 cm below the surface of the skin. Nonradioactive MRI could be effective for molecular imaging of deep-seated malignant foci, particularly due to the high spatial resolution (up to 25−100 μm) of MRI (*3*). However, disadvantages of MRI include relatively low specificity and the requirement for large quantities of the injected probes containing gadolinium.

Noninvasive scintigraphic imaging of gene expression by detection of specific mRNAs in cells to diagnose cancer and

other diseases in living systems has been attempted with antisense oligonucleotides (*3*−*14*). Specific imaging of target gene mRNA requires multiple steps: probe permeation into tissue, endocytosis into the cells, probe hybridization with the target mRNA, probe:mRNA accumulation in the specific cells, and effluxing of unbound probes. Nonhybridized probes must efflux from cells with little or no expression of the target mRNA in order to permit a specific image in the targeted cells.

We used peptide nucleic acids (PNA[1]) (*15*) because PNA is resistant to biological degradation and binds complementary mRNA with affinity, specificity, and stability exceeding those of corresponding DNA/RNA duplexes (*16*). PNA oligomers are uncharged, resulting in poor cellular uptake, which minimizes nonspecific binding to cells (*17*).

Receptor-mediated endocytosis of PNA drugs or diagnostic probes into malignant cells that overexpress insulin-like growth factor 1 (IGF1) receptors can be accomplished with a short, cyclized IGF1 peptide analogue, D(Cys-Ser-Lys-Cys), separated from the C-terminus of the PNA by a flexible, hydrophilic aminoethoxyethoxyacetic acid (AEEA) spacer (*9, 10, 13, 18*). Alanine replacements in the peptide (*9, 10, 12, 13, 18*), or peptide blocking by native IGF1 (*13*), minimized internalization. Bonding radioactive metal cations to specific chelator-PNA-IGF1 analogues enabled their delivery to cells for radioimaging in xenografts in living subjects (*9, 10, 12, 13*).

In the case of activated *KRAS2* G12D mRNA overexpressed in pancreatic cancer AsPC1 cells, the melting temperature, T_m, of the complementary *KRAS2* G12D PNA 12-mer with a *KRAS2* G12D RNA 20-mer was 80 °C, independent of the peptide ligand sequence (*12*), following the typical behavior of PNA:RNA duplexes (*19, 20*). A single mismatch, corresponding to the difference between the *KRAS2* G12D mutant sequence and the *KRAS2* G12 wild-type sequence, lowered the T_m by 20 °C. Three mismatches lowered the T_m by 30 °C. Those thermodynamic results predicted single mismatch hybridization specificity under intracellular conditions.

Uptake of [^{99m}Tc]SBTG$_2$-DAP-AEEA-*KRAS2* PNA-AEEA-IGF1 analogue by AsPC1 cells at 37 °C was 3-fold greater than accumulation of a corresponding *CCND1* probe (*21*). Those results are consistent with greater cellular retention due to *KRAS2* complementarity. Confocal fluorescence microscopic measurements of the mass transfer coefficients of AsPC1 cellular uptake of fluorescent analogues of the *KRAS2* G12D PNA probes revealed 10-fold less uptake by dual amino acid mismatch probes (*22*).

[^{64}Cu]DOTA-AEEA-*KRAS2* PNA-AEEA-IGF1 analogues enabled PET imaging in pancreatic cancer AsPC1 G12D xenografts, with single base mismatch precision in the PNA. Tumor core PET contrast intensities were 8-fold greater than contralateral muscle PET intensities for the *KRAS2* G12D complementary probe. Much lower tumor core PET intensities in the cases of G12 wild-type (one mismatch), G12 V (one mismatch), G12K (two mismatches), and G12E (three mismatches) sequence controls implied that PET imaging intensity depended upon accurate mRNA hybridization (*12*).

Similarly, a dual amino acid mismatch sequence in the IGF1 analogue, with a fully matched PNA sequence, reduced PET contrast intensities (*12*). Furthermore, reduced PET intensities were observed in G12 V single mismatch pancreatic CAPAN2 xenografts, after administration of the G12D probe, and in *KRAS2*$^-$ breast cancer BT474 xenografts. Four hours of distribution, cellular efflux, and systemic excretion were necessary before clear images could be obtained (*12*).

Those *KRAS2* PET imaging experiments all depended on probes with a single chelator binding a single radionuclide. To increase mRNA-specific contrast by genetic probes, particularly for less abundant mRNAs, it would be desirable to increase the number of metal ions per hybridization probe. For that purpose, we designed novel polydiamidopropanoyl (PDAP) dendrimers with increasing numbers of primary amines by coupling Fmoc-AEEA monomers and Fmoc-diaminopropanoate (DAP) monomers to the N-terminus of PNA−peptide chimeras extended from polymer supports (*23*). To each amine, we coupled a DOTA chelator by one of its carboxylates, converting it into a DOTA moiety.

Recently, we reported the synthesis of (Gd-DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-*KRAS2* PNA-AEEA-IGF1 analogue MRI contrast agents (*24*). MRI phantom experiments showed proportional increase of the MRI intensity and T1 relaxivity with increases in the number of Gd(III) chelated to those probes. To estimate the fraction of internalized Gd$_n$*KRAS2* PNA agents that would be hybridized to available *KRAS2* mRNAs in live tumor cells, the T_m of each probe was measured with increasing generations of the PDAP dendrimers hybridized to *KRAS2* G12D 20-mer RNA. Fully matched (Gd-DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-*KRAS* G12D PNA-IGF1 analogues formed stable complementary PNA/RNA hybrid complexes with melting temperatures (T_m) of 79−80 °C. The generation of the PDAP dendrimers did not influence the T_m values of PNA/RNA hybrid duplexes. A single mismatch, corresponding to the single base difference between the G12D mutant sequence and the G12 V mutant sequence, lowered the T_m by 12 °C (*24*). These thermodynamic results predict single mismatch hybridization specificity for the dendrimeric PNA probes under intracellular conditions.

However, before evaluation of such dendrimeric probes for noninvasive molecular imaging of intracellular mRNA and oncogene expression, several questions must be addressed. First of all, how does the number of metal cations chelated to the PNA probes or the generation of PDAP dendrimers influence their uptake and accumulation in the tumor-targeted tissue and in other tissues? Second, how does the concentration of the dendrimeric PNA probes influence the imaging of the tumor? As a result of the sensitivity limitations of MRI with Gd(III) contrast, we chose to label the dendrimeric hybridization probes with ^{111}In(III) [γ, 0.171, 0.245 MeV, half-life 67.32 h (2.8 d)] for scintigraphic imaging. Free, unchelated ^{111}In(III) accumulates nonspecifically in the kidneys, liver, spleen, bone, and tumors of mice bearing colon, lung, or neuroblastoma xenografts (*25*). However, chelated ^{111}In(III) is exceedingly stable, dissociating by no more than 1% in 10 days at 37 °C in the presence of serum, correlating with a binding constant of $\sim 10^{24}$ (*26*).

Here, we report the sensitivity of noninvasive scintigraphic imaging of overexpressed oncogene *KRAS2* mRNA with γ-emitting ([^{111}In]DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-*KRAS2* PNA-IGF1 analogues, **WT5195**, **WT8900**, and **WT13842**, specific for *KRAS2* G12D or *KRAS2* G12 V mRNA, with up to $n = 16$ ^{111}In(III) per probe. We investigated the accumulation of the [^{111}In]$_n$*KRAS2* probes in immunocompromised mice bearing human AsPC1 (G12D) or CAPAN2 (G12 V) pancreatic cancer xenografts. We also investigated the effect of administering mixtures of ^{111}In(III)-chelated PNA hybridization probes with increasing doses of nonradioactive Gd(III)-chelated hybridization probes in order to saturate nonspecific tissue binding sites. This approach permitted us to determine how the concentration and

^{a} Masses were measured by MALDI TOF MS or ESI-MS. Yields were calculated with respect to initial amino acid loading of the resin beads. Melting temperatures are shown ± standard errors of the means. ND: not done.

dendrimer generation of our Gd(III)-chelated agents influenced the specificity and intensity of *KRAS2* mRNA scintigraphic imaging.

MATERIALS AND METHODS

Synthesis of (DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-KRAS2 PNA-AEEA-IGF1 Analogue Nanoparticles. The unlabeled hybridization probes (Scheme 1, Table 1) containing 12-base PNAs flanked by the dendrimeric radionuclide chelators $DOTA_2$, $DOTA_8$, or $DOTA_{16}$ at the N-terminus, and a short retro-inverso cyclized fragment of IGF1, D(Cys-Ser-Lys-Cys), at the C-terminus (Figure 1), were assembled by solid-phase synthesis from Fmoc-monomers, purified, and characterized as described (*24*), and in the Supporting Information.

Radiolabeling of DOTA$_n$-KRAS2 PNA Probes with ^{111}In(III). DOTA$_n$-*KRAS2* PNA probes (n = 2, 8, 16; G12D and G12 V *KRAS2* mutants, Table 1) were labeled with ^{111}In(III) essentially as described (*6*). Briefly, 5−10 μL of $^{111}InCl_3$ at 3.7−7.4 MBq/μL (100−200 μCi/μL) in 0.05 M HCl (MDS Nordion, Kanata, ON, Canada) containing 37 MBq (1 mCi) (~21 pmol, assuming the specific activity for carrier-free $^{111}InCl_3$, 1.723 GBq/nmol, 46.6 Ci/μmol), were incubated with 45 μL of 0.10−0.15 mM (~6 nmol) of the indicated DOTA$_n$-*KRAS2* PNA probes in 0.10 M NaOAc, pH 7.0, for 15 min at 80 °C. The radiolabeling yield (typically >95%) was analyzed by HPLC as below. Thus, the final specific activity of the PNA probes, assuming stoichiometric chelation, was ~6 MBq/nmol (0.17 Ci/μmol). Similarly, 500 nmol of DOTA was labeled with 74 MBq (2 mCi) (~42 pmol) of ^{111}In as a control probe, with a calculated specific activity of ~0.15 MBq/nmol (0.004 Ci/μmol) in a final volume of 100 μL.

Solutions were diluted with 100 μL of 0.9% saline. Aliquots of each labeling mixture (10−14 μCi, 0.37−0.52 MBq) were analyzed by reversed-phase HPLC on a 4.6 × 150 mm C_{18} column (Altima, Alltech) coupled to a UV detector, NaI (Tl) radioactivity monitor, and a rate meter. The column was eluted with a 30 min gradient from 4% to 72% CH_3CN in aqueous 0.1% CF_3CO_2H, at 1 mL/min, at 23 °C. Other aliquots of the labeling mixtures (250−350 μCi, 9.0−13.0 MBq) after dilution with 0.9% saline up to a total volume of 200 μL were used for tail vein administration into mice to image tumors.

In Vitro Stability. Labeled probes were tested for stability in 0.9% saline, and with 100-fold molar excesses of diethylenetriaminepentaacetic acid (DTPA), human serum albumin, or cysteine at 22 °C for more than 2 days. Stability was determined by HPLC as above.

Chelation of DOTA$_n$-KRAS2 PNA Probes with Gd(III). DOTA$_n$-*KRAS2* PNA probes (n = 2, 8, 16; G12 V *KRAS2* mutants, Table 1), 0.5 mM in 0.1 M NaOAc, pH 6.0, were incubated with at least a 10-fold excess of $GdCl_3$ at 80 °C for 15 min to maximize chelation, as described (*24*). Spectrophotometric quantitation of remaining unchelated Gd(III) ions was carried out by titration with 1 mM DTPA solution in water in the presence of arsenazo III dye, which changes from a cherry-red color with a peak at 665 nm to a blue color after forming a specific Gd(arsenazo III)$_2$ complex in 0.15 M NaOAc, pH 4 (*27, 28*). 90−98% of the DOTA residues in the hybridization probes were occupied by Gd(III) ions. The final Gd-chelated products were purified on a 22 × 250 mm Alltima C_{18} column eluted with a linear 30 min gradient from 0% to 30% CH_3CN in aqueous 0.1% CF_3CO_2H, at 10 mL/min, at 50 °C, monitored at 260 nm (*24*).

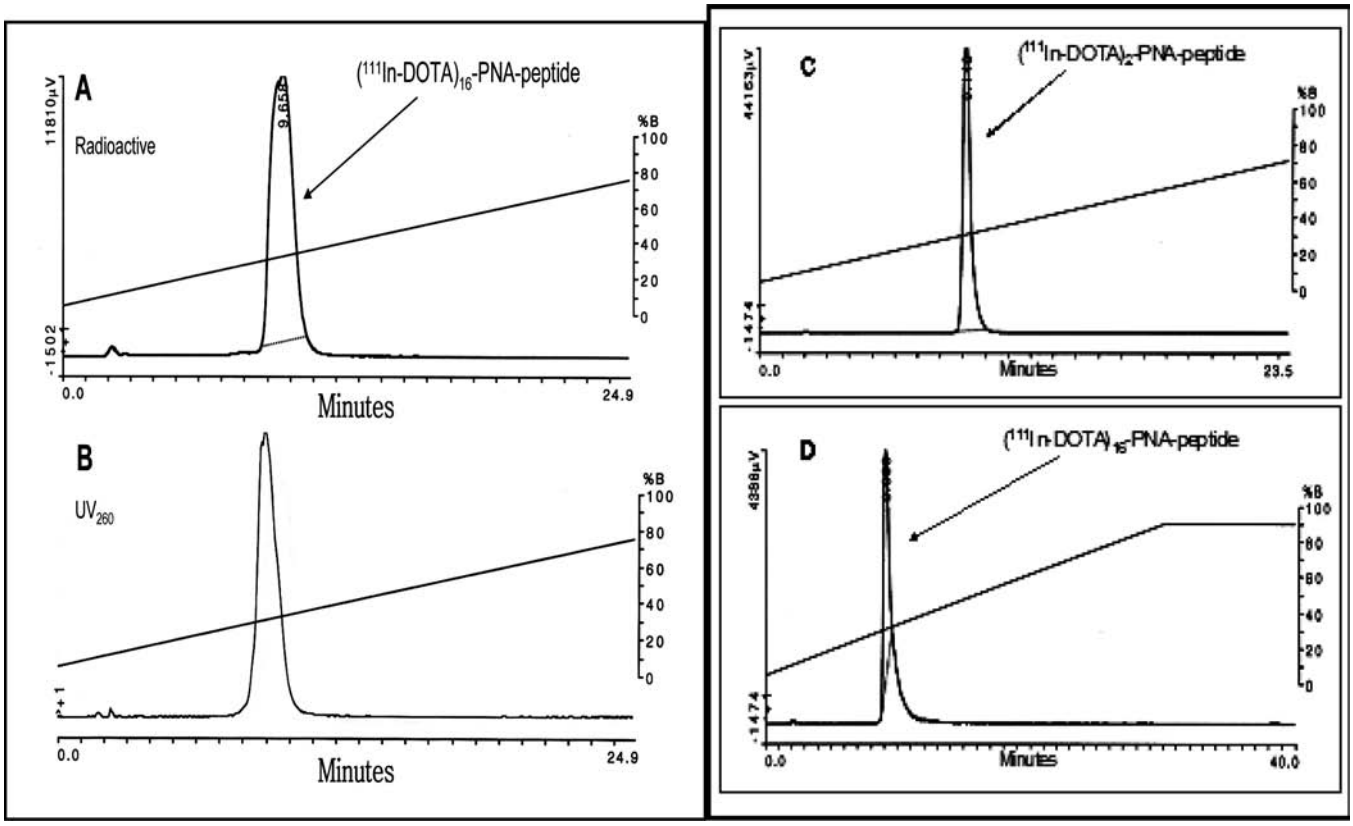

Figure 1. C_{18} HPLC profiles of $[^{111}In]_n$*KRAS2* G12D probes, eluted as described in Materials and Methods. (A) Analytical radioactivity profile of $[^{111}In]_{16}$*KRAS2* G12D, **WT13842**. (B) Analytical absorbance profile at 260 nm of $[^{111}In]_{16}$*KRAS2* G12D, **WT13842**. (C) Analytical radioactivity profile of $[^{111}In]_2$*KRAS2* G12D, **WT5195**, in the combined urine from 3 immunocompromised mice bearing AsPC1 xenografts 3.5 h after tail vein administration. (D) Analytical radioactivity profile of $[^{111}In]_{16}$*KRAS2* G12D, **WT13842**, in the combined urine from 3 immunocompromised mice bearing AsPC1 xenografts 3.5 h after tail vein administration.

Cell Culture and Xenografts. The human pancreatic cancer cell line AsPC1 (American Type Culture Collection, Rockville, MD), isolated from ascites of a female patient with invasive pancreatic adenocarcinoma (*29*), expresses a 12th codon GGT→GAT, G12D mutant *KRAS2* oncogene (*30*), and overexpresses IGF1R (*31*). As a *KRAS2* sequence control, the human pancreatic cancer cell line CAPAN2 (American Type Culture Collection, Rockville, MD), which was isolated from a male patient with invasive pancreatic adenocarcinoma (*32*), expresses a 12th codon GGT→GTT, G12 V mutant *KRAS2* oncogene (*33*), and overexpresses IGF1R (*34*). Pancreatic cancer cells were maintained in log phase in RPMI 1640 (AsPC1) or McCoy's 5a (CAPAN2) media supplemented with 2 mM glutamine, 5000 U/mL penicillin, 50 μg/mL streptomycin, 10% fetal bovine serum (Sigma Chemical Co., St. Louis, MO), incubated at 37 °C in a humidified incubator containing 5% CO_2/95% air and cultured to 80% confluence prior to splitting or implantation. Quantitative RT-PCR analysis of total RNA from AsPC1 cells yielded about 20 000 *KRAS2* mRNA per cell (*12*).

For tumor induction, approximately (5−6) × 10^6 cells in 0.2 mL of culture medium were implanted intramuscularly through a sterile 27 gauge needle into the thighs of 6−8-week-old 20−25 g female immunocompromised NCR mice obtained from NCI. Tumors were grown to no more than 1 cm in diameter. All animal studies were conducted in accordance with federal and state guidelines governing the laboratory use of animals, and under approved protocols reviewed by the Animal Care and Use Committee at Thomas Jefferson University. All animals were anesthetized by approved methods, and when required, the animals were restrained using methods and devices specifically designed to provide a minimum of discomfort to the animal. Animals were euthanized in a halothane chamber, consistent with USDA regulations and American Veterinary Medical Association recommendations.

Systematic Administration and Tissue Distribution of Labeled Probes. To assess *KRAS2* probe imaging and distribution, 7.4−11.1 MBq (200−300 μCi), ∼2 nmol, of the $[^{111}In]_n$-*KRAS2* G12D and G12 V probes in 0.2 mL of sterile 0.14 M NaCl, pH 7, was administered to groups of 3−5 mice with xenografts each through a lateral tail vein using a sterile 27 gauge needle. Distributions were also measured for mixtures of $[^{111}In]_n$*KRAS2* G12 V probes with an additional 11, 48, or 94 nmol of Gd_n-*KRAS2* G12 V probes. ∼11 MBq (∼300 μCi), 80 nmol, of [^{111}In]DOTA was administered as a control. Free, unchelated ^{111}In(III) was not used as a control due to its nonspecific accumulation in the kidneys, liver, spleen, bone, and tumors of mice bearing a variety of xenografts (*25*).

At 4, 8, and 24 h postinjection, mice were lightly anesthetized with a mixture of ketamine (200 mg/kg), xylazine (10 mg/kg), and acetopromazine (2 mg/kg), then imaged using a Starcam (GE Medical, Milwaukee, WI) gamma camera equipped with a parallel hole collimator. For each image, 300 000 counts were collected. Digital scanning of region-of-interest intensities with the interfaced Integra computer (GE Medical) across each scintigraphic image from the tumor-free left flank to the tumor-bearing right flank provided quantitation of tumor images. Statistical significance was assessed by standard error of the means, assuming normal distributions.

After 24 h, mice were euthanized. Portions of muscle, intestine, heart, lungs, blood, spleen, kidneys, liver, and tumor were collected. We did not attempt to dissect out the pancreas, because in mice, the pancreas is remarkably small and wrapped tightly around the small intestine. Portions of tail were not collected separately from muscle, because previous imaging

experiments had not shown excess residual probe remaining in the tails. The dissected tissues were washed free of blood, blotted dry, and weighed, and radioactivity associated with each tissue was counted in an automatic gamma counter (Packard Series 5000, Meridien, CT), together with a standard radioactive solution of a known quantity prepared at the time of injection. Results were expressed as percent of injected dose per gram of tissue (% ID/g). Null probabilities were calculated by Student's *t* test.

In Vivo Stability. Analysis of urine samples will reveal catabolism of labeled probes occurring throughout the body of the animals. [^{111}In]chelates are so strong as to preclude transchelation to serum proteins (*26*). Urine was collected up to 3.5 h postinjection from groups of 3−5 mice injected with radiohybridization probes for assessment of probe stability. The urine samples were combined, sedimented at 2000 × *g* for 10 min, filtered through Millipore HAWP 025 membranes with 0.22 μm pores, and analyzed by RP-HPLC as described in Radiolabeling.

RESULTS

Characterization of (DOTA-AEEA)$_n$-PDAP^m-AEEA$_2$-KRAS2 PNA-AEEA-IGF1 Nanoparticles. Theoretically, the number of free amino groups on the growing PDAP dendrimers on the polymer support at each generation should double at each coupling. The number of amino groups available at each generation was determined by measuring the absorbance of the dibenzofulvene-piperidine adduct (ε_{301} = 7800 M^{-1} cm^{-1}) released upon Fmoc deprotection after each coupling of (Fmoc)$_2$-DAP-COOH as described (*24*). The number of Fmoc deprotection residues released from the growing PDAP dendrimers at each step increased from 1.00 to 2.00, 3.98, then 7.61 (95.0% yield) for PDAP^3 with 8 theoretical amines, as reported (*24*). For PDAP^4 dendrimers with 16 theoretical amines, Fmoc deprotection residues released increased from 1.00 to 1.95, 3.82, 7.58, then 14.16 (88.5% yield) (*24*).

Analysis of [^{111}In]$_n$KRAS2 PNA Probes. A ≥600-fold excess of DOTA residues (≥15 nmol) over ∼21 pmol of $^{111}InCl_3$ promoted chelation of ^{111}In(III) to DOTA-dendrimer PNA probes. The lack of free ^{111}In(III) permitted administration of [^{111}In]$_n$*KRAS2* PNA probes directly after labeling. Before administration to mice, aliquots of radiolabeled probes were analyzed by HPLC, monitoring with both UV detector at 260 nm and with NaI (Tl) radioactivity monitoring detector. Analytical HPLC of the [^{111}In]$_{16}$*KRAS2* G12D probe **WT13842** is shown as an example (Figure 1AB). Generations 1 and 3 are shown in Figures S1 and S2 in the Supporting Information. On the basis of the HPLC results, routine radiochemical yields of more than 95% with specific activities of ∼6 MBq/nmol (0.17 mCi/nmol) of [^{111}In]$_n$*KRAS2* PNA probes were obtained. Theoretically, >600-fold greater specific activity of [^{111}In]$_n$-*KRAS2* PNA probes could be obtained, if stoichiometric amounts of $^{111}InCl_3$ were used.

Radiohybridization Probe Stability in Vitro. These preparations were stable at 22 °C for more than 2 days, as determined by HPLC, and were stable to challenges with 100-fold molar excesses of diethylenetriaminepentaacetic acid (DTPA), human serum albumin, or cysteine. The analyses indicated that essentially all of the ^{111}In(III) was bound to DOTA$_n$-*KRAS2* PNA probes. These results made it possible to administer the labeled probes directly without the necessity for further purification. Due to the efficiency of labeling observed, each labeled probe was used directly for administration into the tail veins of immunocompromised mice bearing AsPC1 xenografts.

Radiohybridization Probe Stability in Vivo. To check the in vivo stability of radiohybridization probe, [^{111}In]$_n$*KRAS2* PNA probes were injected into the tail veins of immunocompromised mice bearing AsPC1 pancreatic cancer xenografts. HPLC analysis of radioactivity in the combined 3.5 h urine sample from mice injected with [^{111}In]$_2$*KRAS2* G12D probe, **WT5195** (Figure 1C) and [^{111}In]$_{16}$*KRAS2* G12D probe, **WT13842** (Figure 1D) revealed a void volume peak of free ^{111}In that included less than 1% of radioactivity and a probe peak eluting at 9 min with more than 99% of the radioactivity.

Breakdown fragments of [^{111}In]**WT5195** and [^{111}In]**WT13842** were not detected. In a comparable study with [^{64}Cu]DOTA-AEEA-*CCND1* PNA-AEEA-IGF1 analogue in immunocompromised mice bearing breast cancer xenografts, no evidence was seen for transchelation to serum or tissue proteins (*13*).

Systemic Administration of Radiohybridization Probes. Scintigraphic images of γ-particles emitted from immunocompromised mice bearing pancreatic cancer xenografts 24 h after administration of [^{111}In]$_n$*KRAS2* PNA probes are shown in Figure 2A for the fully matched [^{111}In]$_n$*KRAS2* G12D probes and in Figure 2B for the single mismatch [^{111}In]$_n$*KRAS2* G12 V probes. Imaging of PNA-free [^{111}In]DOTA as a control is also presented in Figure 2A.

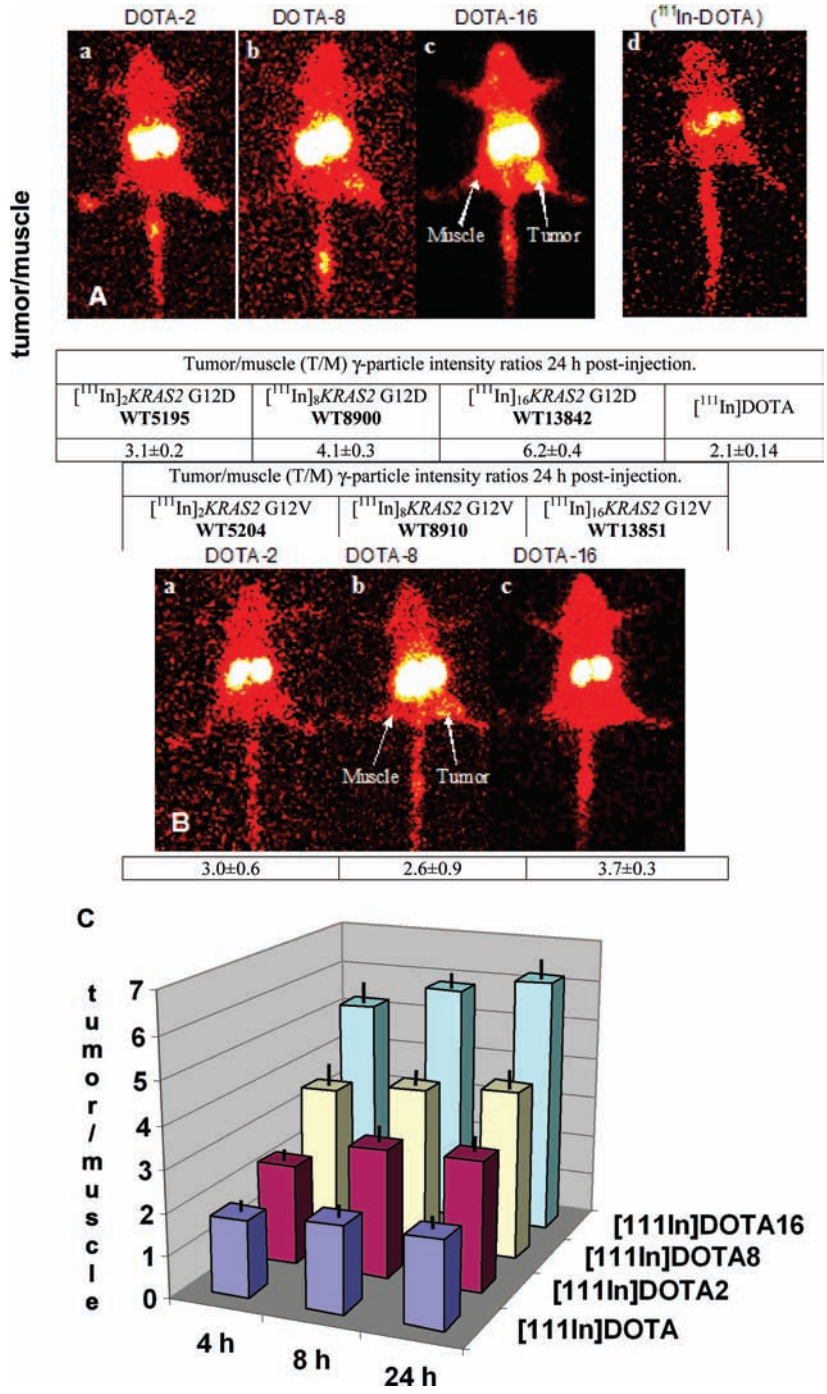
Digital scanning of the xenograft region-of-interest on the right flank vs the mirror image tumor-free region-of-interest on the left flank (muscle) was carried out to determine the tumor/muscle (T/M) intensity ratios of each subject. The intensity averages and standard deviations of the T/M ratios are shown at the bottoms of each image in Figure 2 and in Table S1 in the Supporting Information.

In the case of imaging with fully matched [^{111}In]$_n$*KRAS2* G12D PNA sequences, the T/M ratios increased from 3.1 ± 0.2 at n = 2, **WT5195**; to 4.1 ± 0.3 at n = 8, **WT8900**; to 6.2 ± 0.4 at n = 16, **WT13842**. Kruskal−Wallis one-way analysis of variance on ranks indicated that the differences in the mean values among the four treatment groups were greater than would be expected by chance ($p < 0.001$). Comparison of each treatment group with every other treatment group by the Holm-Sidak all-pairwise multiple comparison procedure revealed that each group was statistically significantly different from the others ($p \leq 0.05$).

On the other hand, imaging with single mismatch [^{111}In]$_n$-*KRAS2* G12 V PNA control probes showed lower T/M ratios (3.0 ± 0.6 at n = 2, **WT5204**; 2.6 ± 0.9 at n = 8, **WT8910**; and 3.7 ± 0.3 at n = 16, **WT13851**). Kruskal−Wallis one-way analysis of variance on ranks indicated that the three treatment groups were indistinguishable from each other. T/M ratios from single mismatch [^{111}In]$_n$*KRAS2* G12 V control probes were comparable to the T/M ratios for the PNA-free [^{111}In]DOTA control (Figure 2A). The single mismatch control results established a basis for determination of PNA sequence specificity for the accumulation of fully matched [^{111}In]$_n$*KRAS2* G12D probes in the xenografts.

Upon comparing the image intensity T/M ratios obtained for fully matched [^{111}In]$_n$*KRAS2* G12D probes in AsPC1 xenografts in mice (Figure 2C), it is apparent that the T/M ratio for [^{111}In]$_2$*KRAS2* G12D remained at ∼3 at 4, 8, and 24 h after injection, while T/M for [^{111}In]$_8$*KRAS2* G12D remained at ∼4, and T/M for [^{111}In]$_{16}$*KRAS2* G12D remained at ∼6. This result implies that the avidity of the xenografts for the [^{111}In]$_n$*KRAS2* G12D probes, relative to the avidity of the contralateral muscle, had already leveled out by 4 h after administration.

Dose Dependence of Radiohybridization Probe Administration. In view of our intent to use Gd(III)-chelated probes for MRI of mRNA expression (*24*), we assessed the effect of elevated doses of Gd$_n$*KRAS2* G12 V probes with constant doses of [^{111}In]$_8$*KRAS2* G12 V probes on scintigraphic image intensity. Nonradioactive Gd$_n$*KRAS2* G12 V probes (n = 2 or 8) (1.9, 11, 48, and 94 nmol) were mixed with ∼2 nmol (300−350 μCi, 11−13 MBq) of fully matched [^{111}In]$_8$*KRAS2* G12 V probe, then admin-



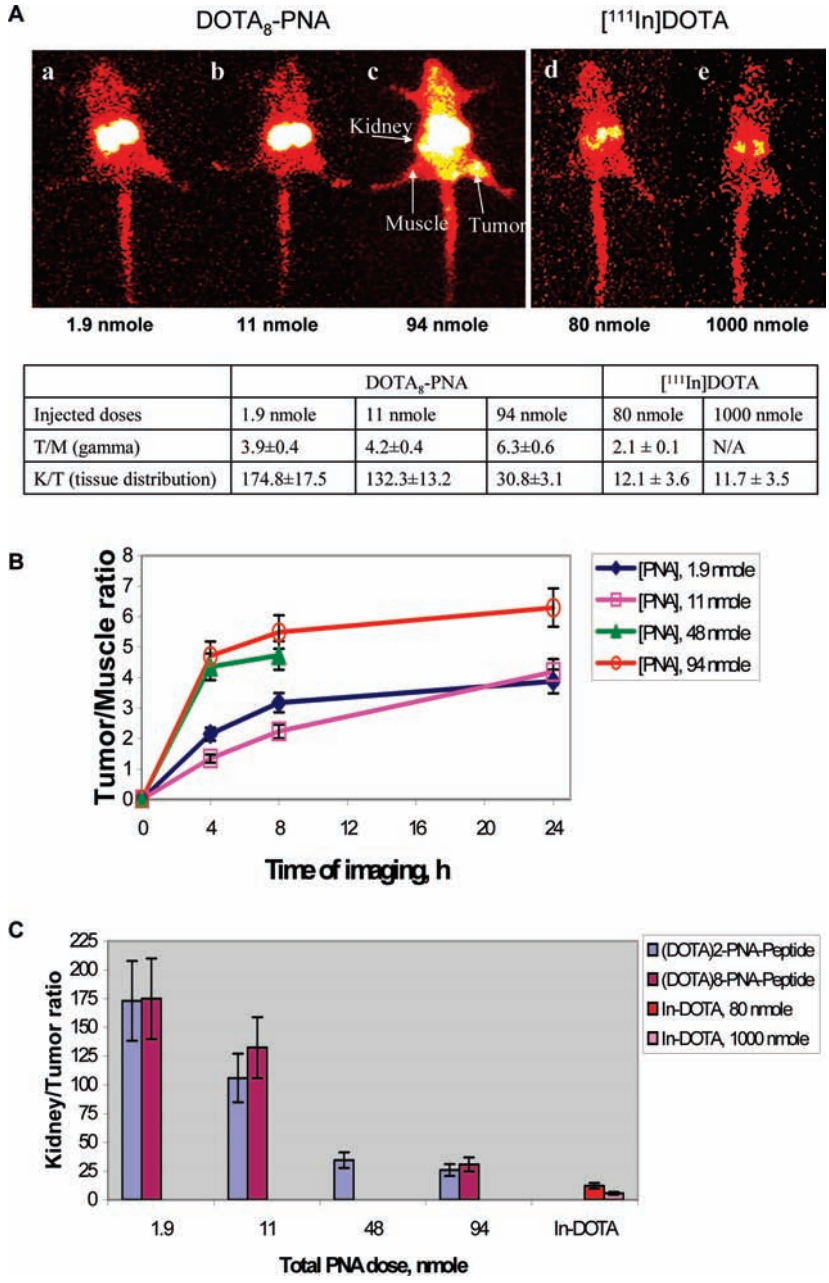


Figure 2. Scintigraphic images of immunocompromised mice bearing human AsPC1 pancreatic cancer xenografts at 24 h after tail vein administration of ~2 nmol (300−350 μCi, 11−13 MBq) of $[^{111}In]_n$*KRAS2* probes to groups of 3 mice. (A) Fully matched G12D probe images (a) $[^{111}In]_2$*KRAS2* G12D, **WT5195**; (b) $[^{111}In]_8$*KRAS2* G12D, **WT8900**; (c) $[^{111}In]_{16}$*KRAS2* G12D, **WT13842**; (d) 80 nmol [^{111}In]DOTA (~11 MBq, ~300 μCi) control. Tumor/Muscle (T/M) γ-particle intensity ratios were calculated for each group of 3 mice. Holm-Sidak all pairwise multiple comparison revealed that each group was statistically significantly different from the others ($p \leq 0.05$). (B) Single mismatch G12 V probes images (a) $[^{111}In]_2$*KRAS2* G12 V, **WT5204**; (b) $[^{111}In]_8$*KRAS2* G12 V, **WT8910**; (c) $[^{111}In]_{16}$*KRAS2* G12 V, **WT13851**. Kruskal−Wallis one-way analysis of variance on ranks indicated that the three treatment groups were indistinguishable from each other. (C) Histograms of tumor/muscle (T/M) γ-particle intensity ratios of G12D fully matched probes calculated from scintigraphic image intensities. Solid black lines show standard deviations. Each group was statistically significantly different from the other three ($p \leq 0.05$).

istered to immunocompromised mice bearing CAPAN2 (G12 V) pancreatic cancer xenografts. Scintigraphic images recorded 24 h after administration of $[^{111}In]_8$*KRAS2* G12 V probes are shown in Figure 3A for added Gd_8*KRAS2* G12 V probe, **WT8910**, and in Figure S3 of the Supporting Information for Gd_2*KRAS2* G12 V probe, **WT5204**. Elevated doses of Gd_8*KRAS2* G12 V probes increased accumulation of the fully matched $[^{111}In]_8$*KRAS2* G12 V probe in CAPAN2 (G12 V) xenografts, thereby increasing the T/M ratio from 3.9 ± 0.4 to 6.3 ± 0.6 (Figure 3A).

The time courses of $[^{111}In]_8$*KRAS2* G12 V probe accumulation in tumor and muscle were similar for 1.9 and 11 additional nanomoles of nonradioactive probe, but shifted up markedly for 48 and 94 additional nanomoles (Figure 3B). The effect of additional nonradioactive probe was apparent as early as 4 h after administration. Tissue distribution data for all time points are shown in Table S2 in Supporting Information.

Tissue Distribution of Radiohybridization Probes. Tissue distribution of each of the $[^{111}In]_n$*KRAS2* PNA probes in

	DOTA$_8$-PNA			[^{111}In]DOTA	
Injected doses	1.9 nmole	11 nmole	94 nmole	80 nmole	1000 nmole
T/M (gamma)	3.9±0.4	4.2±0.4	6.3±0.6	2.1 ± 0.1	N/A
K/T (tissue distribution)	174.8±17.5	132.3±13.2	30.8±3.1	12.1 ± 3.6	11.7 ± 3.5

Figure 3. Immunocompromised mice bearing human CAPAN2 (G12 V) pancreatic cancer xenografts at 24 h after tail vein administration of ~2 nmol (300−350 μCi, 11−13 MBq) of fully matched [^{111}In]$_8$-*KRAS2* G12 V, **WT8910**, mixed with increasing doses of Gd$_2$-*KRAS2* G12 V, **WT5512**, or Gd$_8$-*KRAS2* G12 V, **WT10144**. (A) Scintigraphic images of mice that received (a) 1.9 nmol, (b) 11 nmol, or (c) 94 nmol of nonradioactive Gd$_8$ probes. Additional tumor-bearing mice were injected with (d) 80 nmol (~11 MBq, ~300 μCi) or (e) 1000 nmol (~11 MBq, ~300 μCi) of [^{111}In]DOTA as controls. Tumor/Muscle (T/M) ratios were calculated from γ-particle intensity data. Kidney/Tumor (K/T) ratios were calculated from tissue distribution data. (B) Time course of Tumor/Muscle (T/M) ratios from γ-particle intensity data. (C) Dependence of kidney/tumor (K/T) tissue distribution ratios on elevated Gd$_n$ probe dose. The decrease of K/T with added nonradioactive Gd$_n$ probes were the same for Gd$_2$ probes or Gd$_8$ probes. The Mann−Whitney rank sum test indicated that there was not a statistically significant difference ($p = 0.886$).

immunocompromised mice bearing human AsPC1 pancreatic cancer xenografts was measured at 24 h after administration. The measured tissue distribution data are presented in Table 2. Tissue distribution data for [^{111}In]$_n$*KRAS2* G12 V probes in CAPAN2 xenografts are presented in Table S2 in the Supporting Information. Probe distribution into the mouse pancreas was not measured, because it is wrapped around the intestine in a thin layer, unlike the human pancreas.

In addition to typical measurements of percent of injected dose per gram of tissue (%ID/g) for individual tissues, we calculated the total percent of injected dose per gram of tissue. The total percent of injected dose per gram of tissue informs us of the total radioactivity that remains in the body after injection. That number reports how quickly the radioactive probes can be utilized or excreted. Interestingly, we found that this value, total percent of injected dose per gram of tissue, is different for different generations of dendrimers and different kinds of radioactive probes.

At 24 h after injection, the total %ID/g increased in all tissues with the size of the dendrimer and number of ^{111}In per probe, which implies that larger probes are retained longer in the tissues prior to renal excretion. This phenomenon was seen with both the fully matched [^{111}In]$_n$*KRAS2* G12D probes (Table 2A) and with the single mismatch [^{111}In]$_n$*KRAS2* G12 V probes (Table 2B). Tumor %ID also increased with dendrimer size, particularly for $n = 16$ (Table 2A). The muscle %ID also increased in the

Table 2. Tissue Distribution (% injected dose/g) of [^{111}In]$_n$*KRAS2* PNA Probes vs [^{111}In]DOTA, in Immunocompromised Mice Bearing Human AsPC1 (G12D) Pancreatic Cancer Xenografts[a]

[a] Tissue samples were analyzed 24 h after tail vein administration of ~2 nmol doses of each [^{111}In]$_n$*KRAS2* probe, or 80 nmol (~11 MBq, 300 μCi) of [^{111}In]DOTA control, to immunocompromised mice bearing human AsPC1 (G12D) pancreatic cancer xenografts (n = 3).

same order, which correlates with little change in the tumor/muscle (T/M) ratios as a function of n (Table 2A). On the other hand, the kidney/tumor ratios (K/T) were least for n = 16 (Table 2AB).

In contrast, the total %ID/g for the PNA-free [^{111}In]DOTA control was 26−83 times less than the total %ID/g for the [^{111}In]$_n$*KRAS2* PNA probes (Table 2A), which implies that the low molecular mass [^{111}In]DOTA does not accumulate readily in tissues, unlike the significant nonspecific organ accumulation of free ^{111}In(III) (*25*), and is cleared much more rapidly than high molecular weight probes like [^{111}In]$_n$*KRAS2* PNA probes. The [^{111}In]DOTA complex does not dissociate appreciably over the time course of the experiment, precluding redistribution to naturally occurring proteins in blood and tissues. As a result, the chemically stable and neutral [^{111}In]DOTA complex exits the body quickly by renal excretion. The T/M ratios for [^{111}In]DOTA were comparable to that for [^{111}In]$_n$*KRAS2* PNA probes (Table 2).

Elevated doses of nonradioactive Gd$_8$-*KRAS2* G12 V probe, 1.9 to 94 nmol, added to [^{111}In]$_8$*KRAS2* G12 V probe, increased image intensity of the fully matched [^{111}In]$_8$PNA probe in CAPAN2 (G12 V) xenografts 24 h after administration (Figure 3A). As a result, T/M ratios of ^{111}In image intensity at 24 h increased from 3.9 ± 0.4 to 6.3 ± 0.6 (Figure 3A). T/M ratios for all time points increased upon addition of Gd$_{2,8}$-*KRAS2* G12 V probes (Figure 3B, and Table S2 in Supporting Information).

Tissue distribution measurements (Table S2 in Supporting Information) showed increased accumulation of the fully matched [^{111}In]$_8$PNA probe, in combination with elevated doses of nonradioactive Gd$_{2,8}$-*KRAS2* G12 V probe in CAPAN2 (G12 V) xenografts, as well as in other tissues, by 3−6-fold, except for a 2-fold decrease in kidney accumulation. The K/T ratio decreased dramatically and significantly, more than 5-fold, from 174 ± 17 to 28 ± 3, 24 h after coinjecting 94 nmol of nonradioactive Gd$_{2,8}$-*KRAS2* G12 V probe with 2 nmol of [^{111}In]$_8$*KRAS2* G12 V probe (Figure 3C). K/T reduction by the Gd$_2$-*KRAS2* G12 V probe vs the Gd$_8$-*KRAS2* G12 V probe, analyzed by the Mann−Whitney rank sum test, was not significantly different (p = 0.886).

DISCUSSION

These studies revealed that [^{111}In]$_n$*KRAS2* PNA-IGF1 analogue nanoparticles permeated xenografts, entered cancer cells, and accumulated in a sequence-specific manner. We observed that the relative T/M intensity of scintigraphic images of AsPC1 pancreatic cancer xenografts increased with the size of the dendrimer and the number of DOTA chelating groups, up to n = 16, but only for fully matched [^{111}In]$_n$*KRAS2* G12D probes. In contrast, the relative T/M intensity of scintigraphic images of AsPC1 pancreatic cancer xenografts stayed constant for single mismatch [^{111}In]$_n$*KRAS2* G12 V probes, independent of size and number of chelated ^{111}In cations.

Tissue distribution measurements of total %ID/g, reaching 45−60%, imply that the largest [^{111}In]$_{16}$*KRAS2* PNA probes exhibit longer clearance times than the smaller probes. In the n = 16 case, renal excretion was apparently reduced, relative to smaller probes. That hypothesis agrees with the reduction in K/T ratios with increasing "n" of DOTA residues per PNA probe. For MRI, as well as for scintigraphic imaging, extended retention will increase signal intensity over 24−48 h, for which we already observed a preliminary indication (*24*).

The average diameter of gyration for the Gd$_{16}$-*KRAS2* G12D probe, g/mol, was previously calculated to be 3.3 ± 0.1 nm (*24*). In contrast, the single chelator [^{64}Cu]*KRAS2* G12D probe, g/mol, was previously calculated to be 2.2 ± 0.1 nm (*12*). On the nanoparticle scale, 2−3 nm is still small, minimizing the probability of nanoparticle toxicity. DOTA holds Gd(III) so

strongly (*35*) that toxicity by transchelation is most unlikely. In practice, Gd-chelator toxicity occurs only in the context of poor kidney function (*36*). Considering potential toxicity of the PNA, no hepatic or renal toxicity was observed in mice after administration of 2.5 mg/kg of PNA (*37*), nor immunogenicity (*38*), mutagenicity, or clastogenicity (*39*).

In our previous report (*24*), we noted that concentration of *KRAS2* PNA hybridization probes in AsPC1 cells should approach a maximum, based on our QRT-PCR analysis (*12*), of 2×10^4 *KRAS2* mRNAs in a 1 pL pancreas cancer cell, or ~30 nM. At 1 ^{111}In(III) or Gd(III) per DOTA chelator, 480 nM intracellular ^{111}In(III) or Gd(III) might thus be achieved at 16 Gd(III) per probe. These calculated concentrations of intracellular Gd(III) are in accord with the minimum concentration of 300 nM Gd-nanoparticle calculated for molecular MR visualization in T1-weighted imaging (*40*). That estimate was confirmed in turn for fourth-generation polyamidoamine dendrimers conjugated with 40 Gd(III)-DTPA chelators and a fluorescently labeled anti-EGFR antibody. That large, slowly rotating probe displayed a relaxivity of 323.5/mM•s (*40*). Furthermore, we discussed at length (*24*) the phenomena of restricted mobility and degrees of freedom for Gd_n-*KRAS2* PNA probes bound to high molecular mass *KRAS2* mRNA/polyribosome complexes in viscous cytoplasm that would all contribute to increased relaxivity, relative to Gd-DTPA. This analysis predicts favorable tumor accumulation of the Gd_8-chelated *KRAS2* probe at elevated doses, which correlates with the positive preliminary MRI result we reported earlier (*24*).

After finding sequence-specific images of *KRAS2* mRNA expression in pancreatic cancer xenografts with 2 nmol doses of complementary [^{111}In]$_n$*KRAS2* G12D probes, we modeled the circumstances of MRI, requiring higher doses of nonradioactive Gd-chelated probes. Upon mixing increasing doses of Gd_n-*KRAS2* G12 V probe with constant [^{111}In]$_8$*KRAS2* G12 V probe prior to administration, we observed more intense CAPAN2 G12 V xenograft ^{111}In images, and less intense kidney images, as the nonradioactive Gd_n-*KRAS2* G12 V probe dose increased. In parallel, elevated doses of $Gd_{2.8}$-*KRAS2* G12 V probe added to [^{111}In]$_8$*KRAS2* G12 V probe significantly decreased K/T.

This phenomenon suggests that nonspecific binding sites in the kidney consume a significant portion of the 2 nmol doses of undiluted [^{111}In]$_8$*KRAS2* G12 V probes, but only a small portion of the 96 nmol doses of the [^{111}In]$_8$*KRAS2* G12 V-Gd_n-*KRAS2* G12 V mixture. In the AsPC1 xenograft, however, IGF1R turns over continuously over the 48 h of these experiments, continually delivering probes with IGF1 analogues into the cytoplasm of AsPC1 cells. Furthermore, continuous transcription of new *KRAS2* mRNAs over the 48 h of these experiments suggests that available *KRAS2* mRNA binding sites are not saturated. If the intracellular *KRAS2* mRNAs are not saturated, then both labeled and unlabeled PNA probes can accumulate inside pancreatic cancer cells over time, yielding our observation of significantly decreased K/T at 24−48 h.

CONCLUSIONS

(1) mRNA expression in pancreatic cancer xenografts can be selectively imaged with ([^{111}In]DOTA-AEEA)$_n$-PDAP^m-$AEEA_2$-*KRAS2* PNA-AEEA-IGF1 analogue probes with single mismatch specificity. (2) Tumor/Muscle image intensity ratios for ([^{111}In]DOTA)$_n$*KRAS2* G12D PNA probes increased from 3 to 6, in the order $DOTA_2 < DOTA_8 < DOTA_{16}$. (3) Elevated doses of Gd_8-*KRAS2* G12 V probes increased the image intensity of [^{111}In]$_8$*KRAS2* G12 V probes in xenografts, thereby increasing the tumor-to-muscle ratios from 3.9 ± 0.4 to 6.3 ± 0.6. Elevated doses of $Gd_{2,8}$-*KRAS2* G12 V probes decreased the kidney-to-tumor ratios more than 5-fold from 174 ± 17 to 28 ± 3.

These experiments supported the hypothesis that PDAP dendrimers with up to 16 DOTA chelators coupled to PNA-IGF1 analogue probes do not inhibit tumor uptake of PNA-IGF1 analogue probes. Thus, dendrimeric PNA genetic imaging agents can be used directly for preclinical scintigraphic imaging. In addition, dendrimeric PNA genetic imaging agents can be used for preliminary radionuclide testing of targeting specificity prior to full preclinical development of Gd-chelated PNA agents for magnetic resonance imaging (MRI) of pathogenic mRNA in vivo.

ACKNOWLEDGMENT

We thank Dr. Richard Wassell for assistance in measuring mass spectra of DOTA-PDAP-PNA-IGF1 analogues. Grant support: This work was supported in part by NCI contract N01 CO27175 and NCI subaward CA105008 to E.W., and NCI grant CA109231 to M.L.T. Conflicts of interest: E.W. and MLT founded GeneSeen LLC, which might ultimately benefit from the results of this investigation, but did not support the work.

Supporting Information Available: Additional data on synthesis and experimental results with additional *KRAS2* probes. This material is available free of charge via the Internet at http://pubs.acs.org.

Received November 30, 2009; Revised Manuscript Received March 4, 2010

A new haptenated derivative of α-galactosyl ceramide (α-GalCer) has been synthesized to assist in the study of the mechanism of T cell help for the production of B cell antibodies. Our synthetic route provides access to an amine intermediate which can easily be extended to generate an array of compounds, useful in various ongoing studies. Herein, we also describe the biological evaluation of the nitrophenyl (NP) haptenated α-GalCer and demonstrate its importance in such mechanistic studies. For instance, *in vitro* studies showed that NP-α-GalCer stimulates both T and B cell proliferation while *in vivo* studies in immunized mice showed the production of IgG anti-NP antibodies after exposure to NP-α-GalCer. The interpretation of these results helps toward a better understanding of T cell help for the production of antibodies.

INTRODUCTION

Antigen-presenting cells (APC) [1]and lymphocytes are two major cell types that work together to ensure an effective immune response through the recognition and elimination or neutralization of pathogenic organisms and other foreign invaders in mammals (*1*−*4*). APC include macrophages, B lymphocytes, and dendritic cells, while T cells, invariant natural killer (*i*NKT), and natural killer (NK) cells are three major types of lymphocytes important for immune defense. Specifically, B cells recognize their epitopes as a part of either an intact protein, lipid molecule, or polysaccharide, whereas T cells only recognize epitopes which are subcomponents of an intact molecule and are found in association with antigen-presenting molecules, such as MHC class II or CD1.

A distinctive class of T cells, known as invariant Natural Killer T (*i*NKT) cells, display characteristics of both T cells and NK cells and play a crucial role in diverse immune responses and other pathologic conditions (*5*). The synthetic glycolipid α-galactosyl ceramide (α-GalCer) (*6*), known as KRN7000 (**1**), is a powerful agonist for these cells. When it is presented by CD1d, it activates *i*NKT cells to release diverse cytokines, including both Th1 and Th2 cytokines (*7*−*9*). It is believed that the release of Th1 cytokines may contribute to antitumor and antimicrobial functions, while Th2 cytokines may help alleviate autoimmune diseases (*10*−*12*), such as multiple sclerosis (*13*) and arthritis (*14*) or helminth infections. Once stimulated, *i*NKT cells also activate other cells, such as dendritic cells, NK cells, peptide-reactive T cells, and B cells (*2*).

The detection of IgG antilipid antibodies, generated by lipid-specific B cells during infection and autoimmune disease, such as malaria (*15*) and systemic lupus erythematosus (*16*), respectively, suggests the existence of cooperation between *i*NKT cells and B cells (*17*). To better understand the mechanism of *i*NKT cell help for the production of antilipid antibodies, haptenated lipid antigens, containing both a B cell recognition component and an *i*NKT cell agonist are useful tools (Figure 1) (*17*). As part of ongoing studies on the emerging role for CD1d and *i*NKT cells/B cell responses that are crucial in defense against infection, autoimmunity, and tumor immunity, easy access to hybrid haptenated lipids is therefore desired. Here, we propose that the modified α-GalCer derivative **2** (Figure 2) represents an ideal template which is easily amenable to such molecules. We believe that the amine functionality in compound **2** allows conjugation to different haptens, e.g., biotin or 4-hydroxy-3-nitrophenyl (NP) to yield substrates such as compound **3**, thereby making it an ideal scaffold. In this paper, we describe the syntheses of compounds **2** and **3** and describe the biological activities of compounds **3** and **4** (Figure 2). The hapten, 4-hydroxy-3-nitrophenyl (NP), was chosen as the B cell recognition component because the anti-NP B cell response has been extensively studied in mice and there are a number of B-cell specific immunologic tools available to investigate this response (*18*−*20*). Conversely, α-GalCer was selected as the *i*NKT cell component of this conjugated molecule because it is also a well-studied antigen which stimulates robust activation

of *i*NKT cells and for which there are a number of important immunologic tools available.

EXPERIMENTAL PROCEDURES

General Experimental Procedures. ^{1}H NMR spectra were recorded at 400 or 300 MHz, using Bruker AMX 400, Bruker AV 400, Bruker AV 300, and Bruker AC 300 spectrometers. ^{13}C NMR spectra were recorded at 100 or 75 MHz, respectively, using Bruker AMX 400, Bruker AV 400, Bruker AV 300, and Bruker AC 300 spectrometers. Chemical shifts are reported as δ values (ppm) referenced to the following solvent signals: $CHCl_3$, δ H 7.26; $CDCl_3$, δ C 77.0; CH_3OH, δ H 3.34; CD_3OD, δ C 49.9. Quaternary carbons were reported only when observed. HRMS were recorded on a Micromass LCT spectrometer using a lock mass incorporated into the mobile phase. All reagents were obtained from commercial sources and were used without further purification unless stated otherwise. Anhydrous solvents were purchased from Sigma-Aldrich, U.K., stored over 4 Å molecular sieves and under an argon atmosphere. Analytical thin layer chromatography (TLC) was performed on aluminum plates precoated with Merck silica gel 60A F-254 as adsorbent. The developed plates were air-dried, visualized by UV detection (at 254 nm) and/or stained with 5% phosphomolybdic acid in EtOH (MPA spray). Compounds were purified by flash column chromatography on Merck silica gel (particle size 40−63 lm mesh) or Fluka 60 (40−60 lm mesh) silica gel.

Phenyl 3,4-*O*-Isopropylidene-6-*O*-*tert*-butyldiphenylsilyl-2-*O*-(5-azapentyl)-1-thio-β-D-galactopyranoside 13. To a cold solution of phenyl 3,4-*O*-isopropylidene-6-*O*-*tert*-butyldiphenylsilyl-1-thio-β-D-galactopyranoside **12** (2.00 g, 3.64 mmol) in dry DMF (30 mL) was added sodium hydride (0.44 g, 18.2 mmol, 5 equiv) in small amounts at 0 °C. The solution was allowed to stir for 20 min before the addition of 1,5-dibromopentane (4 mL, 18.2 mmol, 5 equiv). The reaction mixture was stirred at room temperature for two hours, and then taken up in water (50 mL). The resulting mixture was then extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layers were washed with brine (30 mL), dried over anhydrous Na_2SO_4, and concentrated in vacuo. The crude bromide was further dissolved in DMSO (30 mL) and sodium azide (1.20 g, 18.2 mmol, 5 equiv) was added. The reaction was stirred overnight at 60 °C, after which it was taken up in water (50 mL) and extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layers were then washed with brine (30 mL), dried over anhydrous Na_2SO_4, and evaporated. The residue was then purified by flash chromatography using hexanes/EtOAc (4:1) to give the desired product as a colorless oil (1.80 g, 2.72 mmol, 75%). ^{1}H NMR ($CDCl_3$): δ 7.65−7.75 (3H, m, Ar-*H*), 7.49−7.55 (2H, m, Ar-*H*), 7.32−7.44 (8H, m, Ar-*H*), 7.19−7.27 (2H, m, Ar-*H*), 4.55 (1H, d, $J_{1,2}$ = 9.72 Hz, H-1), 4.28 (1H, dd, $J_{4,3}$ = 5.6, $J_{4,5}$ = 1.9 Hz, H-4), 4.15 (1H, dd, $J_{3,2}$ = 6.5 Hz, H-3), 3.96−3.83 (3H, m, H-5, H-6a, H-6b), 3.72 (1H, ddd, $J_{1a',1b'}$ = 10.7, $J_{1a',2a'}$ = $J_{1a',2b'}$ = 6.1 Hz, $OCH_2C_3H_6CH_2N_3$), 3.59 (1H, ddd, $J_{1b',2a'}$ = 8.1, $J_{1b',2b'}$= 5.2 Hz, $OCH_2C_3H_6CH_2N_3$), 3.34−3.39 (1H, m, H-2), 3.26−3.31 (2H, m, $OCH_2C_3H_6CH_2N_3$), 1.56−1.70 (4H, m, CH_2), 1.34, 1.47 (6H, 2s, $C(CH_3)_2$), 1.09 (2H, s, CH_2), 1.06 (9H, s, *t*-Bu). ^{13}C NMR (75 MHz, $CDCl_3$): δ 135.6, 134.8, 133.4, 131.4, 131.5, 129.7, 128.8, 127.7, 127.6, 127.2 (18 C_{Ar}), 109.8 ($O_2C(CH3)_2$), 86.6 (C-1), 79.7, 79.2, 76.7, 73.4 (C-2, C-3, C-4, C-5), 71.7 ($OCH_2C_3H_6CH_2N_3$), 63.0 (C-6), 51.4 ($OCH_2C_3H_6CH_2N_3$), 29.5, 28.6 (2 × CH_2), 28.0, 26.8, 26.6, 26.3 ($C(CH_3)_3$, $C(CH_3)_2$), 23.3 (CH_2), 19.2 ($C(CH_3)_3$). HRMS calcd for $C_{36}H_{47}N_3O_5SiS$ $[M+Na]^+$: 684.2904, found 684.2908.

Phenyl 2-*O*-(5-Azapentyl)-1-thio-β-D-galactopyranoside 10. To a solution of **13** (1.50 g, 2.27 mmol) in THF (30 mL) was added a 1 M solution of tetrabutylammonium fluoride (4.50 mL, 2 equiv). The reaction mixture was stirred at room temperature for 4 h. Upon completion of the reaction, the reaction mixture was diluted with EtOAc (20 mL) and washed successively with water (20 mL) and brine (20 mL). The organic layer was dried over anhydrous Na_2SO_4 and evaporated. The residue was then dissolved in CH_2Cl_2, and TFA (5 mL) was added. The mixture was stirred at room temperature for 2 h, after which time TLC analysis indicated that the reaction was complete. The solvents were removed in vacuo, and the residue was purified by flash chromatography using EtOAc to give the desired product as a colorless oil (0.68 g, 1.78 mmol, 78%). ^{1}H NMR ($CDCl_3$): δ 7.48−7.54 (2H, m, Ar-*H*), 7.26−7.35 (3H, m, Ar-*H*), 4.59 (1H, d, H-1, $J_{1,2}$ = 9.7 Hz), 4.06 (1H, d, $J_{4,3}$ = 3.1 Hz, H-4), 3.95 (1H, dd, $J_{6a,6b}$ = 11.9, $J_{6a,5}$ = 5.9 Hz, H-6a), 3.90 (1H, dd, H-6b), 3.80−3.69 (2H, m, $OCH_2C_3H_6CH_2N_3$), 3.63 (1H, dd, $J_{3,2}$ = 8.9 Hz, H-3), 3.58 (1H, m, H-5), 3.45 (1H, t, H-2), 3.28 (2H, t, $OCH_2C_3H_6CH_2N_3$), 1.56−1.71 (4H, m, CH_2), 1.07 (2H, s, CH_2). ^{13}C NMR (75 MHz, $CDCl_3$): δ 134.0, 131.1, 129.0, 127.4 (6 C_{Ar}), 87.7 (C-1), 78.5, 77.9, 75.1, 69.8 (C-2, C-3, C-4, C-5), 73.2 ($OCH_2C_3H_6CH_2N_3$), 62.6 (C-6), 51.4 ($OCH_2C_3H_6CH_2N_3$), 29.7, 28.6 (2 × CH_2), 23.2 (CH_2), 19.2 ($C(CH_3)_3$). HRMS calcd for $C_{17}H_{25}N_3O_5S$ $[M+Na]^+$: 406.1413, found 406.1426.

Phenyl 3-*O*-Benzyloxy-4,6-*O*-di-*tert*-butylsilylene-2-*O*-(5-azapentyl)-1-thio-β-D-galactopyranoside 8. To a solution of **10** (0.52 g, 1.36 mmol) in dry DMF (15 mL) was added di-*tert*-butylsilyl bis(trifluoromethanesulfonate) (0.90 g, 2.04 mmol, 1.5 equiv) at 0 °C, and the mixture was stirred for 30 min, then neutralized with Et_3N. The solution was taken up in water and extracted with EtOAc (3 × 20 mL). The organic layers were combined, washed with brine (20 mL), dried over anhydrous Na_2SO_4, and evaporated. The residue was then dissolved in pyridine (20 mL) and benzoyl chloride (0.27 g, 1.92 mmol, 1.4 equiv) was added. The mixture was stirred at room temperature for 2 h, after which time TLC analysis indicated that the reaction was complete. The reaction was quenched with methanol, diluted with CH_2Cl_2 (30 mL), washed successively with 1 M HCl (3 × 20 mL), water (2 × 20 mL), brine (20 mL), dried over anhydrous Na_2SO_4, and concentrated in vacuo. The residue was finally purified by flash chromatography using hexanes/EtOAc (4:1) to give the desired product as a colorless oil (0.82 g, 1.31 mmol, 96%). ^{1}H NMR ($CDCl_3$): δ 8.06−8.13 (2H, m, Ar-*H*), 7.41−7.65 (6H, m, Ar-*H*), 7.27−7.34 (2H, m, Ar-*H*), 5.03 (1H, dd, $J_{3,2}$ = 9.4, $J_{3,2}$ = 3.1 Hz, H-3), 4.69−4.75 (2H, m, H-1, H-4), 4.22−4.28 (2H, m, H-6a, H-6b), 3.82−3.94 (2H, m, H-2, $OCH_2C_3H_6CH_2N_3$), 3.66 (1H, ddd, $J_{1a',1b'}$ = 9.0, $J_{1a',2a'}$ = $J_{1a',2b'}$

= 6.2 Hz, $OCH_2C_3H_6CH_2N_3$), 3.50 (1H, s, H-5), 3.05−3.18 (2H, m, $OCH_2C_3H_6CH_2N_3$) 1.26−1.57 (4H, m, CH_2), 1.09 (2H, s, CH_2), 1.16, 0.97 (18H, 2s, 2 × *t*-Bu). ^{13}C NMR (75 MHz, $CDCl_3$): δ 133.2, 132.0, 131.9, 129.6, 128.8, 128.5, 127.4 (12 C_{Ar}), 88.5 (C-1), 77.3 (C-3), 76.7, 74.6, 70.6 (C-2, C-4, C-5), 73.3 ($OCH_2C_3H_6CH_2N_3$), 67.2 (C-6), 51.2 ($OCH_2C_3H_6CH_2N_3$), 29.7, 28.5 (2 × CH_2), 27.7, 27.4 (2 × $C(CH_3)_3$), 23.3, 20.7 (2 × $C(CH_3)_3$). HRMS calcd for $C_{32}H_{45}N_3O_6SiS$ $[M+Na]^+$: 650.2696, found 650.2693.

(2*S*,3*S*,4*R*)-2-*N*-*tert*-Butoxycarbonylamino-3,4-di(benzyloxy)1-[3-*O*-benzyloxy-4,6-*O*-di-*tert*-butylsilylene-2-*O*-(5-azapentyl)-α-D-galactopyranosyloxy)]-octadecane 14. A suspension of **10** (0.75 g, 1.20 mmol), **9** (0.90 g, 1.44 mmol, 1.2 equiv), silver triflate (0.18 g, 2.4 mmol), and 4 Å molecular sieves in anhydrous CH_2Cl_2 (10 mL) was stirred, with the exclusion of light for 10 min at room temperature under Ar before it was cooled to −78 °C. A solution of *p*-nitrobenzenesulfenyl chloride (0.24 g, 1.20 mmol, 95% purity) in anhydrous CH_2Cl_2 (2 mL) was dropped into the above suspension at −78 °C. The reaction mixture was maintained at −78 °C for 30 min and allowed to warm up to 0 °C over the following 30 min, after which TLC analysis showed that the reaction was complete. The reaction was quenched with saturated $NaHCO_3$ (2 mL) and diluted with CH_2Cl_2 (5 mL) to give a suspension, which was filtered through Celite, and the Celite pad was washed with CH_2Cl_2 (10 mL). The filtrate was separated, and the organic phase was dried over anhydrous Na_2SO_4 and evaporated. The residue was purified by flash chromatography using hexanes/EtOAc (5:1) to give the glycosylated compound **14** as a light yellow oil (1.02 g, 0.89 mmol, 75%). ^{1}H NMR ($CDCl_3$): δ 7.89−8.13 (6H, m, Ar-*H*), 7.32−7.64 (12H, m, Ar-*H*), 5.64 (1H, dd, $J_{3,2}$ = 8.5, $J_{3,4}$ = 3.4 Hz, H-3^{Cer}), 5.39−5.52 (2H, m, N*H*BOC, H-4^{Cer}), 5.24 (1H, dd, $J_{3,2}$ = 10.3, $J_{3,2}$ = 3.1 Hz, H-3), 5.00 (1H, d, $J_{1,2}$ = 3.5 Hz, H-1), 4.27 (1H, d, H-4), 4.06−4.32 (3H, m, H-6a, H-6b, H-2^{Cer}), 4.00 (1H, dd, H-2), 3.73−3.84 (2H, m, H-5, H-1a^{Cer}), 3.60−3.71 (2H, m, $OCH_2C_3H_6CH_2N_3$, H-1b^{Cer}), 3.44 (1H, ddd, $J_{1a',1b'}$ = 8.9, $J_{1a',2a'}$ = $J_{1a',2b'}$ = 6.6 Hz, $OCH_2C_3H_6CH_2N_3$), 2.84−3.06 (2H, m, $OCH_2C_3H_6CH_2N_3$), 1.80−2.02 (2H, m, H-5a^{Cer}, H-5b^{Cer}), 1.49 (9H, s, $NHCO_2C(CH_3)_3$), 1.15−1.13 (24H, m, CH_2), 1.06−1.14 (2H, m, CH_2), 0.94−098 (2H, m, CH_2), 1.03, 0.92 (18H, 2s, 2 × *t*-Bu), 0.87 (3H, t, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ 133.3, 132.9, 133.2, 132.0, 131.9, 129.9, 129.7, 129.6, 129.4, 128.8, 128.5, 127.4 (18 C_{Ar}), 97.4 (C-1), 80.3 ($NHCOOC(CH_3)_3$), 77.1 (C-3), 76.5, 74.8, 70.2 (C-2, C-4, C-5), 73.8 (C-3^{Cer}), 73.2 ($OCH_2C_3H_6CH_2N_3$), 71.8 (C-4^{Cer}), 67.0 (C-6), 61.7 (C-1^{Cer}), 51.2 ($OCH_2C_3H_6CH_2N_3$), 49.9 (C-2^{Cer}), 32.1−22.8 (13 × CH_2^{Cer}), 29.8, 28.4 (2 × CH_2), 27.6, 27.3 (2 × $C(CH_3)_3$), 23.1, 20.5 (2 × $C(CH_3)_3$), 14.8 (CH_3^{Cer}). (2*S*,3*S*,4*R*)-2-*N*-*tert*-Butoxycarbonylamino-1-[2-*O*-(5-azapentyl)-α-D-galactopyranosyloxy)]-octadecanediol 15. To a solution of **14** (0.93 g, 0.814 mmol) in THF was added a 1 M solution of tetrabutylammonium fluoride (2 mL, 2 equiv). The reaction mixture was stirred at room temperature for 6 h. Upon completion of the reaction, the reaction mixture was diluted with EtOAc (20 mL) and washed successively with water (20 mL) and brine (20 mL). The organic layer was dried over anhydrous Na_2SO_4 and evaporated. The residue was then dissolved in MeOH and a 1 M solution of NaOMe (5 mL) was added. The mixture was stirred at room temperature for 2 h, after which time TLC analysis indicated that the reaction was complete. The reaction was neutralized by the addition of Dowex 50WX8−200 resin. The latter was then filtered and the filtrate concentrated to give a residue, which was purified by flash chromatography using EtOAc/MeOH (7:1) to give the title compound as a colorless syrup (0.49 g, 0.710 mmol, 88%). ^{1}H NMR ($CDCl_3$): δ 4.90 (1H, d, $J_{1,2}$ = 3.8 Hz, H-1), 3.81 (1H, d, $J_{4,3}$ = 3.1 Hz, H-4), 3.70 (1H, dd, $J_{1a',1b'}$ = 10.9, $J_{1a',2a'}$ = 4.4 Hz, H-1a^{Cer}), 3.65 (1H, dd $J_{3,2}$ = 9.8 Hz, H-3), 3.54−3.62 (5H, m, H-1b^{Cer}, H-2^{Cer}, H-3^{Cer}, H-4^{Cer}, H-5), 3.43 (1H, dd, H-2), 3.31−3.37 (2H, m, H-6a, H-6b), 3.20 (2H, ddd, $J_{1a',1b'}$ = 8.9, $J_{1a',2a'}$ = $J_{1a',2b'}$ = 6.8 Hz, $OCH_2C_3H_6CH_2N_3$), 2.02−2.11 (2H, m, $OCH_2C_3H_6CH_2N_3$), 1.50 (9H, s, $NHCO_2C(CH_3)_3$) 1.35−1.60 (m, 8H, CH_2), 1.22−1.32 (2H, m, CH_2), 1.20−1.23 (68H, m, CH_2), 0.71 (6H, t, *J* = 6.8 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ 98.1 (C-1), 78.2, 76.1, 75.2, 71.4, 70.2, 69.2 (C-2, C-3, C-4, C-5, C-4^{Cer}, C-3^{Cer}), 71.2 ($OCH_2C_3H_6CH_2N_3$), 68.2 (C-1^{Cer}), 61.4 (C-6), 51.3 ($OCH_2C_3H_6CH_2N_3$), 50.1 (C-2^{Cer}), 36.5−22.0 (17 × CH_2), 27.5, 27.3 (2 × $C(CH_3)_3$), 14.0 (CH_3^{Cer}). HRMS calcd for $C_{34}H_{66}N_4O_{10}[M+Na]^+$: 713.4677, found 713.4676.

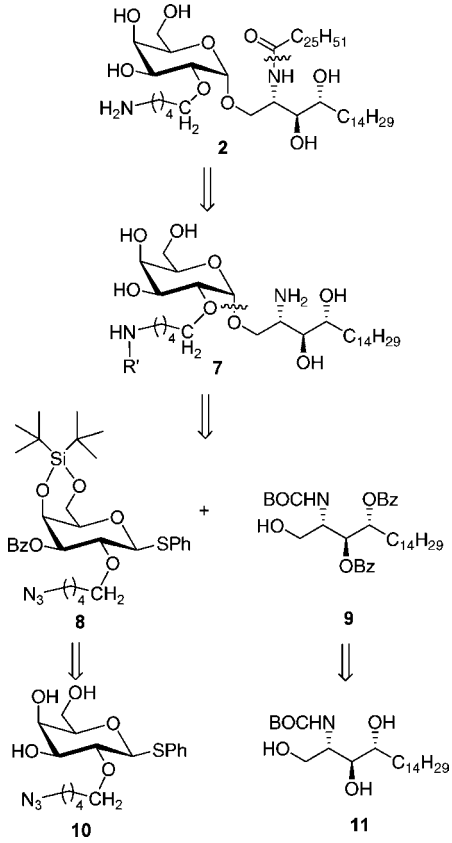
(2*S*,3*S*,4*R*)-2-Amino-*N*-hexacosanoyl-1-[2-*O*-(5-azapentyl)-α-D-galactopyranosyloxy)]-3,4-octadecanediol 16. Compound **15** (0.38 g, 0.550 mmol) was dissolved in CH_2Cl_2/MeOH (2:1) (10 mL) and TFA (2 mL) was added. The reaction was stirred for 2 h and concentrated in vacuo to give the crude amine which was used in the next step without purification. The crude amine was then dissolved in a 1:1 mixture of THF/NaOAC (saturated solution) (5 mL) and the freshly prepared acid chloride of hexacosanoic acid (0.25 g, 0.603 mmol, 1.1 equiv) was added. The reaction was allowed to stir overnight at room temperature. The organic phase was then concentrated, and the residue was purified by flash chromatography (gradient from $CHCl_3$ to 15% MeOH in $CHCl_3$) to give the acylated compound **16** as a white solid (0.38 g, 0.39 mmol, 71%). ^{1}H NMR ($CDCl_3$/CD_3OD 2:1): δ 4.86 (1H, d, $J_{1,2}$ = 3.6 Hz, H-1), 3.79 (1H, d, $J_{4,3}$ = 3.2 Hz, H-4), 3.72 (1H, dd, $J_{1a',1b'}$ = 10.9, $J_{1a',2a'}$ = 4.6 Hz, H-1a^{Cer}), 3.64 (1H, dd $J_{3,2}$ = 9.8 Hz, H-3), 3.52−3.60 (5H, m, H-1b^{Cer}, H-2^{Cer}, H-3^{Cer}, H-4^{Cer}, H-5), 3.43 (1H, dd, H-2), 3.31−3.37 (2H, m, H-6a, H-6b), 3.20 (2H, ddd, $J_{1a',1b'}$ = 8.9, $J_{1a',2a'}$ = $J_{1a',2b'}$ = 6.8 Hz, $OCH_2C_3H_6CH_2N_3$), 2.00−2.10 (2H, m, $OCH_2C_3H_6CH_2N_3$), 1.36−1.59 (m, 8H, CH_2), 1.25−1.35 (2H, m, CH_2), 1.20−1.24 (68H, m, CH_2), 0.73 (6H, t, *J* = 6.8 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ 97.7 (C-1), 77.2, 75.2, 72.1, 70.4, 69.6, 69.3 (C-2, C-3, C-4, C-5, C-4^{Cer}, C-3^{Cer}), 71.2 ($OCH_2C_3H_6CH_2N_3$), 67.4 (C-1^{Cer}), 61.5 (C-6), 51.1 ($OCH_2C_3H_6CH_2N_3$), 49.8 (C-2^{Cer}), 36.2, 32.9, 31.6, 29.4, 29.1, 28.3, 25.6, 22.8, 22.4 (CH_2), 13.7(CH_3^{Cer}). HRMS calcd for $C_{55}H_{108}N_4O_9$ $[M+Na]^+$: 991.8014, found 991.8018.



(2*S*,3*S*,4*R*)-2-Amino-*N*-hexacosanoyl-1-[2-*O*-(5-aminopentyl)-α-D-galactopyranosyloxy)]-3,4-octadecanediol 3. Compound **16** (0.32 g, 0.33 mmol) was dissolved in MeOH (10 mL) and stirred with Pd−C (5 mg) under H_2 overnight, after which time it was filtered through a pad of Celite, which was subsequently washed with MeOH. The combined filtrates were concentrated and the target compound **3** was obtained as a white solid (0.28 g, 0.297 mmol, 90%). The crude amine was used without any further purification in the following acylation reactions. **Acylation to give compound 3:** (3-hydroxy-4-nitrophenyl) acetic acid (17 mg, 0.09 mmol) was added to neat oxalyl chloride (1 mL) and stirred at 70 °C for 2 h, after which time the solution was cooled to rt and the unreacted oxalyl chloride was removed under a stream of argon. The residual volatiles were removed under reduced pressure. The resulting crude acyl chloride was dissolved in THF (1 mL) and added to a solution of amine **3** (50 mg, 0.05 mmol) in THF/NaOAc(sat) (1:1, 1 mL). The reaction was stirred vigorously overnight after which the organic phase was removed. The aqueous phase was further extracted with THF (2 × 1 mL), and the combined organic phases were concentrated. The residue was finally purified by flash chromatography (gradient from $CHCl_3$ to 15% MeOH in $CHCl_3$) to give the acylated compound **17** as a yellow solid (42 mg, 0.39 mmol, 71%). ^{1}H NMR ($CDCl_3$/CD_3OD 2:1): δ 7.85 (1H, d, *J* = 2.4 Hz), 7.36 (1H, dd, *J* = 8.6, *J* = 2.4 Hz), 6.90 (1H, d, *J*

= 8.6 Hz), 4.81 (1H, d, $J_{1,2}$ = 3.6 Hz, H-1), 3.74 (1H, d, $J_{4,3}$ = 3.1 Hz, H-4), 3.25−3.69 (10H, m, H-1a^{Cer}, H-1b^{Cer}, H-2^{Cer}, H-3^{Cer}, H-4^{Cer}, H-2, H-3, H-5, H-6a, H-6b), 3.00 (2H, t, $J_{1a',2a'}$ = $J_{1a',2b'}$ = 6.4 Hz, OCH_2C$_3$H$_6$CH$_2$NHCO), 2.00−2.06 (2H, m, OCH$_2$C$_3$H$_6$CH_2NHCO), 1.32−1.50 (m, 8H, CH_2), 1.20−1.24 (68H, m, CH_2), 0.68 (6H, t, J = 6.5 Hz, CH_3). ^{13}C NMR (75 MHz, CDCl$_3$): δ 173.2 (C═O), 138.8, 125.1, 120.4 (C$_{Ar}$), 98.1 (C-1), 77.3, 75.2, 72.9, 70.5, 69.8, 69.2 (C-2, C-3, C-4, C-5, C-4^{Cer}, C-3^{Cer}), 71.1 (OCH_2C$_3$H$_6$CH$_2$NHCO), 63.1 (C-1^{Cer}), 60.4 (C-6), 49.9 (C-2^{Cer}), 42.0 (COCH_2Ar), 39.5 (OCH$_2$C$_3$H$_6$CH_2NHCO), 31.9−21.1 (CH_2), 14.1 (CH_3^{Cer}). HRMS calcd for C$_{63}$H$_{115}$N$_3$O$_{13}$ [M+Na]$^+$: 1144.8328, found 1144.8326.

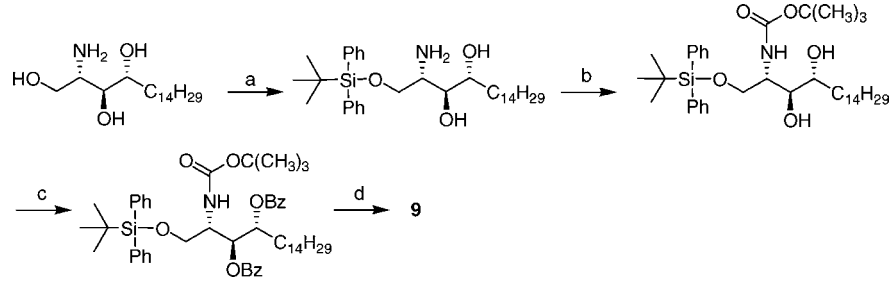
Scheme 2. Retrosynthetic Ananlysis of Target Compound 3

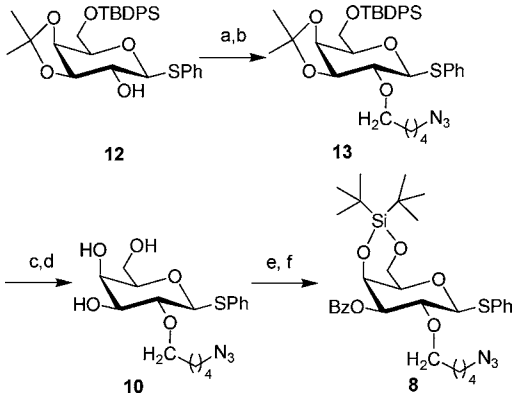
Mice. All mice were maintained in Dana Farber Animal Facility according to IACUC guidelines. C57BL/6 WT were obtained from Jackson Laboratories. C57BL/6 Vα14 Tg mice (iNK T TcR Tg) created by A. Bendelac (University of Chicago, Chicago) were provided by Mark Exley (Beth Israel Hospital, Boston). C57BL/6.SJL congenic B1−8^{hi} B cell receptor knock-in mice, previously created by insertion of a high-affinity NP-specific BcR transgene into the BCR coding region to maintain class switch components, were provided by M. Nussenzweig (Rockefeller University, New York). Mice were immunized as noted with 200 μL intraperitoneally (IP) in PBS/0.1%BSA. Serum was collected by retro-orbital bleed and stored at −20 °C until evaluation.



Murine Serum Antibody ELISA. NP-conjugated antigen challenge induces a heteroclitic response, where the resulting antibodies have higher affinity for NIP, so antibody is detected with an NIP-specific ELISA. Plates (Immulon 2 HB) were coated with 1 mg NIP (5)-OVAL in PBS and blocked with 10% soy milk/0.05% Tween/PBS. Serum was serially diluted in 0.1% soy milk/PBS and antibody detected with HRP-labeled goat antimouse IgG, IgM (Southern Biotech) developed with ABTS (Sigma A-1888). Concentration was extrapolated from IgG anti-NP (clone Pevchγ1) or IgM anti-NP (clone J558) (provided by A. Ferguson, Boston University School of Medicine, Boston) standard curves.

In Vitro Proliferation Assay. B and T cells were purified by pan-B or pan-T MACS bead separation (Milteny-Biotec) according to the manufacturer's instructions. iNK T TcR Tg total splenic T cells were approx 40% iNK T cells (data not shown). Purified B and T cells were mixed at 1:1 ratio (1×10^5 cells per well each) and labeled with 0.5 μM CFSE (Sigma 21888) for 9 min in PBS, then quenched with FCS and washed extensively before culture. Proliferation was assessed by FACs as CFSE dilution on day 3. Murine-specific antibodies were anti-CD19 PerCP-Cy5.5 (1D3), anti-Thy1.2 APC(53−2.1), NA/LE anti-CD3 (145−2C11), and isotype controls (all BD Biosciences PharMingen). Cells were preblocked with unlabeled anti-FcγRIII, II (clone 2.4G2).

RESULTS AND DISCUSSION



Compound **4** was synthesized as reported via a pseudoglycosylation reaction of compound **6** with a suitably protected α-GalCer **5** (Scheme 1) (*17*). In this route, the six-carbon linker was first attached to the hapten (*p*-nitrophenol) before being added onto the sugar residue. While this remains an effective strategy for synthesizing derivatives of α-GalCer, we have observed that glycosylation reactions at this slightly hindered C-2 position can sometimes be tricky and dependent upon various factors, such as the reactivity of the donor, thus offering

limited scope for hapten diversity. Therefore, we reason that the introduction of a linker into the sugar residue via a reaction other than glycosylation is worth exploring. Also, in the interest of adaptability, the linker should facilitate the introduction of different haptens or other molecules via simple and diverse reactions.

Retrosynthetic analysis (Scheme 2) indicated that target compound **3** can be obtained by acylation of compound **7**, which in turn can be accessed from the coupling of sugar donor **8** with the sphingosine derivative **9**. This route is quite efficient as it entails the introduction of the linker at C-2 prior to glycosylation via an alkylation reaction, thereby eliminating the complications discussed above. It is noteworthy that compound **7** bears amine functionalities on both the sugar and the sphingosine base moieties. Judicious orthogonal protection of the two amino groups is therefore required, as they are to be acylated with different carboxylic acids at distinct stages in the course of the synthetic route. Since the sugar moiety is to be subjected to a wider range of chemical reactions, we chose to protect the amino group as the corresponding azide. The latter is known to be very stable and compliant to diverse reaction conditions. As for the amino group on the sphingosine moiety, we opted for the acid-sensitive BOC protecting group, which is also compatible with the benzoate protecting group. To ensure α-selectivity in the crucial glycosylation step, we relied on the directing effect of the bulky 4,6-*O*-di-*tert*-butylsilylene (DTBS) group on the sugar moiety (*21*).

Scheme 6. [a]

[a] (a) THF/NaOAc (1:1), 71%.

The phytosphingosine acceptor **9** (*22*) was synthesized from (2*S*,3*S*,4*R*)-2-amino-1,3,4-octadecanetriol using standard procedures summarized in Scheme 3. The spectroscopic data of compound **9** matched those previously reported (*22*). Regarding the synthesis of **10**, an appropriately protected galactosyl derivative had to be carefully chosen at the outset. Importantly, the protecting groups should withstand the basic reaction conditions for the formation of an alkoxide at C-2. In galactose, the cis-orientation of the hydroxyl groups at C-3 and C-4 facilitate their simultaneous protection as the acetonide, while the primary hydroxyl group at C-6 can be selectively blocked using diphenyltertiarybutylsilyl chloride, thereby leaving C-2 free for modification.

The crucial intermediate **12** was thus synthesized from β-D-galactopyranose pentaacetate according to published report (*23*). The alkoxide of **12**, which was generated in situ by treatment with NaH in DMF, was then reacted with commercially available 1,5-dibromopentane to afford the bromide. The amine functional group was then introduced into the molecule by an S_N2 displacement of the bromide with sodium azide in DMSO. With the linker in place at C-2, we then proceeded to the preparation of the glycosyl donor **8**. The protecting groups were sequentially removed to give **10** in quantitative yields. Finally, introduction of the α-directing bulky DTBS group at C-4 and C-6, followed by benzoylation at C-3, gave compound **8** as colorless syrup in 96% yield after purification.

With both the donor **8** and the acceptor **9** in hand, we next turned our attention to the glycosylation reaction. Because of the possible cleavage of the acid-sensitive BOC group on the acceptor, we preferred avoiding the usual method of activation of the thioglycoside with NIS/TfOH. When using Crich's (*24*) relatively new method of activation with the commercially available *p*-nitrobenzenesulfenyl chloride (*p*-NO_2PhSCl) in conjunction with silver triflate in anhydrous CH_2Cl_2 at −78 °C over 2 h, we were pleased to observe that the desired glycoslated product **14** was obtained as the α-anomer exclusively in 75% yield after purification by flash chromatography. The formation of the α-linkage was confirmed by the H-1 and C-1 signals in ^1H and ^{13}C NMR, respectively.

Stepwise deprotection of compound **14** was then carried out. To avoid any probable base-induced migration of the benzoate to the free amine, we chose to remove the BOC protecting group on the aglycon last. Hence, treatment with TBAF and Zemplen's deprotection of the benzoate protecting groups produced the intermediate **15** as a thick syrup in quantitative yields. The BOC group was subsequently cleaved with TFA and the resulting free amine was acylated with the fully saturated fatty acid, hexacosanoic acid. This was achieved by the reaction of the corresponding acid chloride with the free amine in a 1:1 mixture of THF and saturated sodium acetate solution. The azide intermediate **16** was obtained as a white solid after concentration of the organic phase and purification of the residue by flash

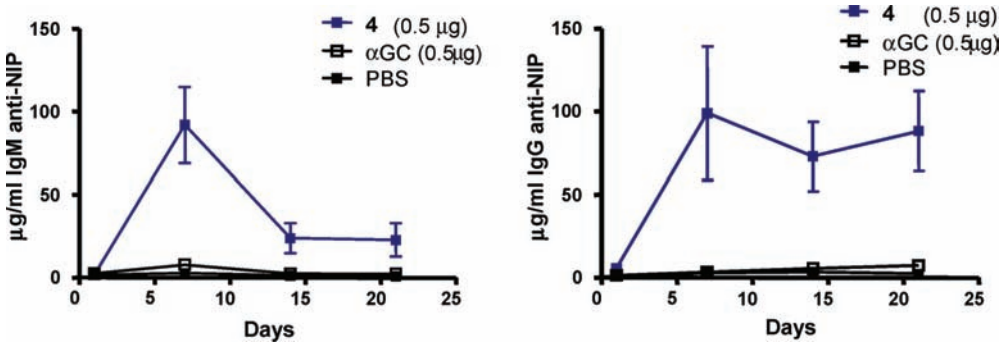

Figure 3. NP-haptenated derivative (**4**) of αGalCer, but not αGalCer, stimulates in vivo production of NP-specific IgM (left panel) and IgG (right panel) by B1−8 BcR Tg mice. (n = 2−4 mice/group, representative example from more than 2 experiments).

chromatography. Ultimately, hydrogenation of the azide in methanol provided the desired scaffold **2**. Conjugation of the amine with the NP hapten was then accomplished by acylation with its corresponding activated carboxylic acid group. Compound **3** was obtained after stirring freshly prepared acid chloride of the (3-hydroxy-4-nitrophenyl) acetic acid with **2** in a 1:1 mixture of THF and saturated sodium acetate solution for 12 h (Scheme 6).

Following successful synthesis, the NP-derivatives (**3** and **4**) were tested *in vivo* and *in vitro* for recognition by *i*NKT and B cells. Mice expressing an increased frequency of B cells with an NP-specific B cell receptor (B1−8 BcR Tg) were found to develop high titers of both IgM and IgG anti-NP antibodies in their serum (Figure 3) when immunized with **4**, but not αGalCer or PBS/0.1%BSA. Because T cell help is required for class switch to IgG, the presence of NP-specific IgG antibodies following immunization with **4** suggests T cell help is being provided, most likely by *i*NKT cells recognizing the α-GalCer component of the compound (Figure 1). In depth investigations of this immunologic cooperation have been published elsewhere (*17*). Furthermore, the requirement of *i*NKT activation and response for both the specific antibody production and class-switch was demonstrated by Batista et al. (*25*) in their *in vivo* studies using α-GalCer conjugated with the antigen CGG (chicken gamma globulin). Therefore, it can be inferred that *i*NKT cells help anti-lipid antibody production.

The biological functions of **3** and **4** haptenated with NP (3-hydroxy-4-nitrophenyl) using the two different approaches described above were then compared in vitro. To compare functional recognition of **3** and **4** by *i*NKT cells and B cells, isolated cell populations were mixed, labeled with CFSE, incubated in vitro, and then assessed for proliferation after three days of culture. Proliferation in response to control stimuli (Figure 4, lower panel) confirms the specificity of the assay, since only B cells respond to the B cell stimulus, LPS (*Salmonella enterica,* Sigma); *i*NKT cells respond more strongly to the T cell stimulus, anti-CD3; and neither cell type responds to the media alone. *i*NKT cells respond to αGalCer, and while there is no selective advantage for NP-specific B cells, there are likely some B cells specific for α-GalCer in any population which contribute to the low level of proliferation observed in the αGalCer stimulated group. Our data show that proliferative responses by *i*NKT cells and B cells were predominantly comparable following stimulation with **3** and **4** despite their slight structural differences. (Figure 4, upper panel). Importantly, previous in vitro experiments (*17*) showed that NP-α-GalCer **4** stimulated 3.2 μg/mL anti-NP IgG by day 7, whereas α-GalCer

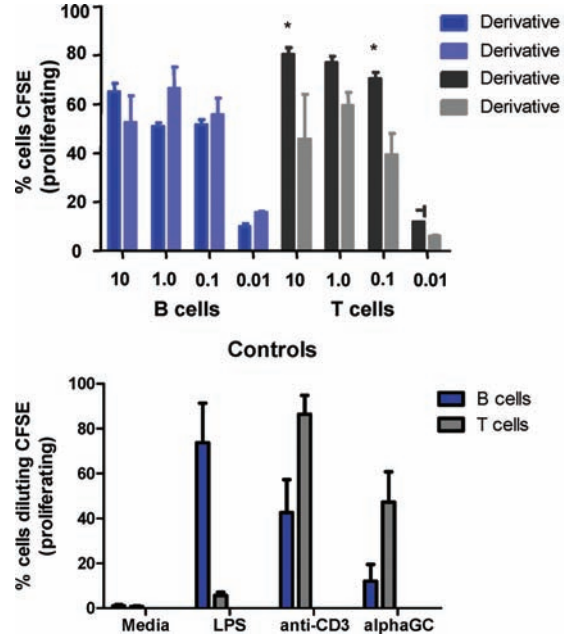

Figure 4. Alternatively synthesized NP-haptenated compounds **3** and **4** stimulate similar levels of iNKT and B cell proliferation. Mixtures of T cells from Vα14 Tg mouse and B cells from B1−8 BcR Tg mouse were stimulated with 10−0.01 ng/mL NP-αGalCer (top panel), or media, 1 μg/mLLPS, 10 μg/mL anti-CD3, 10 ng/mL αGalCer as controls (bottom panel). Proliferation is measured as % B and T cells diluting CFSE. Statistics performed by *Prism* software ANOVA analysis (* = $p < 0.05$ for 2 vs 17). Each bar represents the mean of pools of triplicate wells from two experiments.

stimulated <0.05 μg/mL IgG anti NP, clearly indicating that both **3** and **4** induce substantial proliferation of both B and T cells.

CONCLUSION

We have described the synthesis of a highly biologically attractive glycolipid template **2**, which can be conjugated to multiple molecules, exemplified by the synthesis of compound **3**. Furthermore, the biological evaluation of the haptenated derivatives of α-GalCer showed that the biologic recognition of **3** and **4** is virtually the same and that they are both important tools in studying the mechanism of *i*NKT cell help for the production of anti-lipid antibodies.

ACKNOWLEDGMENT

We thank Michel Nussenzweig and Mark Exley for generously providing transgenic mice. This work was supported by the Irvington Institute for Immunological Research (E.A.L.) and National Institutes of Health Grant T32 AR007530-21(to

Synthesis of Oligonucleotide Glycoconjugates Using Sequential Click and Oximation Ligations

Marika Karskela,* Mia Helkearo, Pasi Virta, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received December 2, 2009; Revised Manuscript Received January 7, 2010

Oligodeoxyribonucleotide glycoconjugates bearing two trivalent glycoclusters have been synthesized by two alternative methods based on solid-supported oximation of aminooxy functionalized oligonucleotides with glycoclusters constructed by click chemistry. In more detail, the trivalent glycoclusters (**5** and **6**) bearing three sugar pendants were first assembled by treating a 4-[tri-*O*-propargylpentaerythrityloxy]benzaldehyde scaffold with methyl 6-azido-6-deoxyglycopyranoside under the click reaction conditions. Two phosphoramidite reagents containing a phthaloyl protected aminooxy function, viz., 2-cyanoethyl *N*,*N*-diisopropylphosphoramidites derived from 3-[3,5-bis(phthalimidoxymethyl)phenoxy]propanol (**12**) and 5-(4,4′-dimethoxytrityl)-1,2-dideoxy-1-*C*-(2-phthalimidoxyethyl)-*β*-D-*erythro*-pentofuranose (**16**), were synthesized and incorporated as branching units in appropriate places of the oligonucleotide chains. On using **12**, the phthaloyl protections of the branching unit were removed and two identical glycoclusters were attached via oxime linkage to the 5′-terminus of the support-bound oligonucleotide chain. With branching unit **16**, the phosphoramidite coupling and the oximation were carried out alternately, allowing introduction of two dissimilar trivalent glycoclusters close to the 3′-end of the oligonucleotide chain. The products (**20**, **26**) were released and deprotected by ammonolysis and purified by HPLC chromatography.

INTRODUCTION

Oligonucleotide-based drugs show promise as a novel form of chemotherapy, although several thresholds must still be overcome on the way to applicable nucleic acid therapeutics (*1–14*). Poor cellular uptake, in particular, limits the applicability of both antisense oligonucleotides and siRNA. A possible way to combat this drawback is to conjugate the therapeutic oligonucleotide to an agent expected to exhibit cell-type organ specificity (*15–20*). The oligonucleotide conjugate, hence, is enriched on the cell-surface and internalized by endocytosis. It is well-known that carbohydrate−protein interactions play a major role in recognition of cells by pathogens (*21–23*). These interactions are multipodal; high-affinity binding is achieved by multiple simultaneous interactions, a phenomenon known as a glycocluster effect (*24–26*). Usually, multiantennary carbohydrates anchored to cell membranes recognize extracellular proteins (*27–29*), but the opposite is also possible. Trivalent *N*-acetylgalactosamine conjugate of oligodeoxynucleotide methylphosphonate (*30*) and phosphorothioate (*31*), tetravalent galactose conjugates of oligodeoxynucleotides (*32, 33*), and monovalent galactose conjugates of oligodeoxynucleotide phosphorothioates (*34*) have all shown enhanced uptake in liver via the galactose-specific asialoglycoprotein receptor-mediated endocytosis. It has also been shown that a transmembrane glycoprotein CD44 recognizes hyaluronic oligomers (*35*) and glycoconjugation may be exploited to target antigenic peptides to dendritic cells (*36*). Accordingly, glycotargeting appears to be a feasible approach (*37*) and development of reproducible methods for convenient preparation of various types of oligonucleotide glycoconjugates appears worthwhile. Workable chemistry is a prerequisite for extensive biological studies.

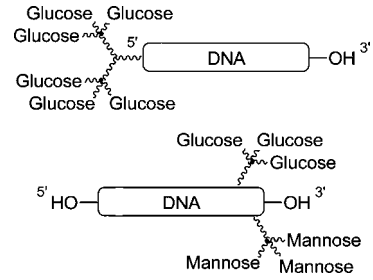

Figure 1. Oligonucleotide glycoconjugates prepared.

Solid-phase oximation, click chemistry, and phosphoramidite coupling are the methods most extensively applied to preparation of oligonucleotide glycoconjugates on a solid support (*19, 38, 39*). Apart from coupling of some aminoglycosides (*40, 41*) and trigalactosylated tetrahydroxycholane (*42*) by phosphoramidite chemistry, the approaches described so far allow attachment of mono- or disaccharides along the oligonucleotide chain using either nucleosidic (*43–45*) or non-nucleosidic (*46–49*) branching units or their conjugation to the internucleosidic phosphodiester linkages (*50*). The examples of oligonucleotide conjugates bearing a multiantennary terminal glycocluster are limited to prepration of a spruce-like tetramannosyl 5′-conjugate (*51*), a trivalent 5′-terminal conjugate containing three different sugars (*52*), and a 3′-cyclodextrin conjugate (*53*). High-affinity binding to membrane lectins may, however, require simultaneous interaction with even more than three or four appropriately situated sugar ligands. For this reason, we now report a protocol for solid-phase synthesis of an oligonucleotide conjugate bearing a hexavalent cluster at the 5′-terminus (Figure 1). In addition, we describe a protocol for attachment of various prefabricated trivalent clusters at desired sites of the oligonucleotide chain. Both methods are based on preparation of aldehyde functionalized trivalent clusters in

solution by click chemistry and attachment of these clusters to the support-anchored oligonucleotide by oximation.

EXPERIMENTAL PROCEDURES

General Methods and Materials. CH_2Cl_2, 1,4-dioxane, and MeCN were dried over 4 Å molecular sieves, THF over 3 Å sieves. Diethyl ether was dried over sodium. Triethylamine was dried by consecutive distillations from ninhydrin and potassium hydroxide, and then stored over CaH_2. The NMR spectra were recorded at 500 MHz. The chemical shifts are given in ppm using internal TMS as a reference. Appropriate 2D NMR methods (COSY, HSQC, and HMBC) were used for peak assignment. The mass spectra were recorded using EI and ESI ionization methods. C18 RP HPLC analyses of oligonucleotide conjugates were performed using Thermo ODS Hypersil (250 × 4.6 mm, 5 μm) analytical column, a gradient elution from 0% to 50% MeCN in 0.05 mol L^{-1} NH_4OAc (aq) buffer over 30 min (conjugates **20**, **23**, and purified **26**) or 60 min (conjugates **25** and crude **26**), flow rate 1 mL min^{-1}, and detection at 260 nm. For purifications, Thermo ODS Hypersil (250 × 10 mm, 5 μm) column and flow rate 3 mL min^{-1} were used.

4-(Tri-*O*-propargylpentaerythrityloxy)benzaldehyde (2). To a solution of tri-*O*-propargyl pentaerythritol (*54*) (**1**, 0.50 g, 2.0 mmol) in dry THF (10 mL), 4-hydroxybenzaldehyde (0.29 g, 2.4 mmol) and triphenylphosphine (0.63 g, 2.4 mmol) were added. The mixture was cooled to 0 °C and diisopropylazodicarboxylate (DIAD, 0.50 mL, 2.4 mmol) was added dropwise. The mixture was stirred at 70 °C for 10 h and evaporated to dryness. Crude product was purified by silica gel chromatography (30% ethyl acetate in petroleum ether) to yield 0.38 g (53%) of **2.** ^{1}H NMR 500 MHz, $CDCl_3$): δ_{ppm} 9.88 (s, 1H, CHO), 7.82 (m, 2H, Ar), 7.02 (m, 2H, Ar), 4.14 (d, 6H, J = 2.4 Hz, 3 × CH_2CCH), 4.08 (s, 2H, CH_2OAr), 3.66 (s, 6H, 3 × CH_2O), 2.40 (t, 3H, J = 2.4 Hz, 3 × CH_2CCH); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 190.8, 164.2, 131.9, 129.9, 115.0, 79.8, 74.3, 68.5, 67.1, 58.8, 44.7; HRMS (EI): M^+ $C_{21}H_{22}O_5$ requires 354.1467, found 354.1455.

Glucoside Cluster (5). Compound **2** (64 mg, 0.18 mmol) was dissolved in 1,4-dioxane (1.3 mL) together with methyl 2,3,4-tri-*O*-acetyl-6-azido-6-deoxy-α-D-glucopyranoside (**3**, 310 mg, 0.90 mmol). $CuSO_4$ as 0.05 mol L^{-1} aqueous solution (36 μL 1.8 μmol) and sodium ascorbate as 0.1 mol L^{-1} aqueous solution (0.90 mL, 0.090 mmol) were added. The mixture was stirred at 50 °C for 4.5 h and then at room temperature overnight. The volatiles were evaporated and the residue was dissolved in ethyl acetate and washed twice with brine. The aqueous layer was extracted twice with ethyl acetate. The combined organic layers were dried with Na_2SO_4 and evaporated to dryness. The residue was purified by silica gel chromatography (5% MeOH in CH_2Cl_2) to yield 140 mg (56%) of **5**. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 9.89 (s, 1H, CHO), 7.83 (m, 2H, Ar), 7.64 (s, 3H, 3 × CH triazole), 6.95 (m, 2H, Ar), 5.47 (m, 3H, 3 × H-3 Glc), 4.88−4.81 [m, 9H, 3 × (H-1, H-4, and H-2 Glc)], 4.58 (s, 6H, 3 × OCH_2C═), 4.56 (dd, 3H, J = 2.4 and 14.4 Hz, 3 × H-6a Glc), 4.38 (dd, 3H, J = 8.3 and 14.4 Hz, 3 × H-6b Glc), 4.17 (m, 3H, 3 × H-5 Glc), 3.99 (s, 2H, CH_2OAr), 3.56 (s, 6H, 3 × CCH_2O), 3.09 (s, 9H, 3 × OCH_3), 2.10 (s, 9H, 3 × CH_3), 2.07 (s, 9H, 3 × CH_3), 2.01 (s, 9H, 3 × CH_3); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 190.7, 170.1, 169.8, 169.8, 163.9, 145.0, 131.9, 129.9, 124.1, 114.7, 96.5, 70.6, 69.9, 69.7, 68.5, 67.7, 67.0, 64.8, 55.3, 50.5, 45.0, 20.6, 20.6; HRMS (ESI): $[M + Na]^+$ $C_{60}H_{79}N_9NaO_{29}$ requires 1412.4882, found 1412.4879.

Mannoside Cluster (6). was synthesized from **2** (64 mg, 0.18 mmol) and methyl 2,3,4-tri-*O*-acetyl-6-azido-6-deoxy-α-D-mannopyranoside (*55*) (**4**, 310 mg, 0.90 mmol) as described for **5** to yield 142 mg (57%) of **6**. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 9.90 (s, 1H, CHO), 7.83 (m, 2H, Ar), 7.65 (s, 3H, 3 × CH triazole), 6.93 (m, 2H, Ar), 5.32 (dd, 3H, J = 3.4 and 10.0 Hz, 3 × H-3 Man), 5.21 (dd, 3H, J = 1.6 and 3.4 Hz, 3 × H-2 Man), 5.14 (m, 3H, 3 × H-4 Man), 4.62 (d, 3H, J = 1.6 Hz, 3 × H-1 Man), 4.59−4.56 [m, 9H, 3 × (H-6a Man and OCH_2C═)], 4.36 (dd, 3H, J = 9.1 and 14.3 Hz, 3 × H-6b Man), 4.15−4.11 (m, 3H, 3 × H-5 Man), 3.96 (s, 2H, CH_2OAr), 3.54 (s, 6H, 3 × CCH_2O), 3.04 (s, 9H, 3 × OCH_3), 2.14 (s, 9H, 3 × CH_3), 2.11 (s, 9H, 3 × CH_3), 2.00 (s, 9H, 3 × CH_3); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 190.7, 170.1, 169.8, 169.7, 163.9, 144.8, 131.9, 130.0, 124.1, 114.8, 98.4, 69.4, 69.1, 68.7, 68.6, 67.5, 67.0, 64.8, 55.1, 50.9, 45.0, 20.8, 20.8, 20.6; HRMS (ESI): $[M + H]^+$ $C_{60}H_{80}N_9O_{29}$ requires 1390.5062, found 1390.5033.

Dimethyl 5-[3-(4-Methoxytrityl)propoxy]isophthalate (8). Dimethyl 5-hydroxyisophthalate (**7**, 2.10 g, 10.0 mmol) and 3-(4-methoxytrityl)propan-1-ol [prepared as corresponding tritylated propanediol (*56*)] (3.78 g, 10.8 mmol) were dissolved in dry THF (70 mL) and triphenylphosphine (2.85 g, 10.8 mmol) was added. The mixture was cooled to 0 °C and diethylazodicarboxylate (DEAD, 1.68 mL, 10.8 mmol) in dry THF (7 mL) was added dropwise. The reaction was allowed to proceed at room temperature for 19 h, followed by addition of triphenylphosphine (0.53 g, 2.0 mmol) and DEAD (0.31 mL, 2.0 mmol) and the stirring was continued for 2 h. The mixture was evaporated to dryness and the residue was purified by silica gel chromatography (25% ethyl acetate in petroleum ether) to yield 4.14 g (77%) of **8** as colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 8.27 (m, 1H, Ar), 7.71 (br d, 2H, Ar), 7.43 (m, 4H, MMTr), 7.30 (m, 2H, MMTr), 7.25 (m, 4H, MMTr), 7.20 (m, 2H, MMTr), 6.79 (m, 2H, MMTr), 4.19 (t, 2H, J = 6.2 Hz, CH_2OAr), 3.94 (s, 6H, 2 × $COOCH_3$), 3.77 (s, 3H, OCH_3), 3.30 (t, 2H, J = 6.0 Hz, MMTrOCH_2), 2.07 (tt, 2H, J = 6.0 and 6.2 Hz, $CH_2CH_2CH_2$); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 166.2, 159.0, 158.5, 144.6, 135.8, 131.7, 130.3, 128.4, 127.7, 126.8, 122.8, 119.8, 113.0, 86.2, 65.5, 59.5, 55.2, 52.4, 29.8; HRMS (ESI): $[M + Na]^+$ $C_{33}H_{32}NaO_7$ requires 563.2046, found 563.2043.

5-[3-(4-Methoxytrityl)propoxy]-1,3-phenylenedimethanol (9). Compound **8** (4.14 g, 7.66 mmol) was dried over P_2O_5, dissolved in dry diethyl ether (80 mL), and cooled to 0 °C. Lithium aluminum hydride (0.87 g, 23 mmol) was slowly added and stirring was continued for 2.5 h at room temperature. The excess hydride was destroyed by careful addition of water and the solids were filtered. The product containing filtrate was diluted with ethyl acetate and washed with brine. The organic layer was dried with Na_2SO_4 and evaporated to dryness to yield 3.50 g (94%) of **9** as colorless oil. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 7.42 (m, 4H, MMTr), 7.29 (m, 2H, MMTr), 7.25 (m, 4H, MMTr), 7.20 (m, 2H, MMTr), 6.91 (br s, 1H, Ar), 6.79 (br s, 2H, Ar), 6.77 (m, 2H, MMTr), 4.63 (s, 4H, 2 × CH_2OH), 4.12 (t, 2H, J = 6.2 Hz, CH_2OAr), 3.77 (s, 3H, OCH_3), 3.27 (t, 2H, J = 6.0 Hz, MMTrOCH_2), 2.05 (tt, 2H, J = 6.0 and 6.2 Hz, $CH_2CH_2CH_2$), 1.90 (br s, 2H, 2 × OH); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 159.5, 158.4, 144.7, 142.7, 135.9, 130.4, 128.4, 127.7, 126.8, 117.4, 113.0, 112.2, 86.2, 65.2, 64.9, 59.8, 55.2, 29.9; HRMS (ESI) $[M + Na]^+$ $C_{31}H_{32}NaO_5$ requires 507.2147, found 507.2169.

5-[3-(4-Methoxytrityl)propoxy]-1,3-phenylenebis(methyleneoxyphthalimide) (10). To a solution of **9** (3.50 g, 7.22 mmol) in dry THF (80 mL) *N*-hydroxyphthalimide (2.35 g, 14.4 mmol) and triphenylphosphine (3.77 g, 14.4 mmol) were added. The mixture was cooled to 0 °C and diethylazodicarboxylate (DEAD, 2.24 mL, 14.4 mmol) in dry THF (10 mL) was added dropwise. The mixture was stirred for 20 h

at room temperature and evaporated to dryness. Crude product was purified by silica gel chromatography (1% MeOH in CH_2Cl_2) to yield 3.01 g (53%) of **10** as white foam. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 7.71 (m, 8H, Pht), 7.44 (m, 4H, MMTr), 7.31 (m, 2H, MMTr), 7.26−7.16 (m, 7H, MMTr and Ar), 7.12 (br d, 2H, Ar), 6.78 (m, 2H, MMTr), 5.18 (s, 4H, 2 × CH_2ON), 4.19 (t, 2H, J = 6.2 Hz, CH_2OAr), 3.76 (s, 3H, CH_3), 3.27 (t, 2H, J = 6.0 Hz, MMTrOCH_2), 2.06 (tt, 2H, J = 6.0 and 6.2 Hz, $CH_2CH_2CH_2$); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 163.4, 159.2, 158.4, 144.7, 136.0, 135.4, 134.4, 130.3, 128.9, 128.4, 127.7, 126.7, 123.5, 122.7, 116.5, 113.0, 86.2, 79.4, 65.0, 59.8, 55.2, 29.9; HRMS (ESI) $[M + Na]^+$ $C_{47}H_{38}N_2NaO_9$ requires 797.2475, found 797.2512.

3-[3,5-Bis(phthalimidoxymethyl)phenoxy]propanol (11). Compound **10** (3.01 g, 3.88 mmol) was suspended in 80% aqueous acetic acid (40 mL) and stirred for 4.5 h. The mixture was evaporated to dryness, and the residue was dissolved in CH_2Cl_2 and washed with saturated $NaHCO_3$. The organic layer was separated and the aqueous layer was extracted four times with CH_2Cl_2. The combined organic layers were dried with Na_2SO_4 and evaporated to dryness. The residue was purified by silica gel chromatography (4−5% MeOH in CH_2Cl_2) to yield 1.61 g (82%) of **11** as white powder. ^{1}H NMR [500 MHz, $(CD_3)_2SO$]: δ_{ppm} 7.86 (s, 8H, Pht), 7.22 (br s, 1H, Ar), 7.15 (br d, 2H, Ar), 5.16 (s, 4H, 2 × CH_2ON), 4.58 (t, 1H, J = 5.2 Hz, OH), 4.08 (t, 2H, J = 6.4 Hz, CH_2OAr), 3.56 (dt, 2H, J = 5.2 and 6.2 Hz, CH_2OH), 1.87 (tt, 2H, J = 6.2 and 6.4 Hz, $CH_2CH_2CH_2$); ^{13}C NMR [125 MHz, $(CD_3)_2SO$]: δ_{ppm} 163.6, 159.1, 136.4, 135.3, 129.0, 123.7, 122.8, 116.4, 79.3, 65.3, 57.7, 32.5; HRMS (ESI): $[M + Na]^+$ $C_{27}H_{22}N_2NaO_8$ requires 525.1274, found 525.1305.

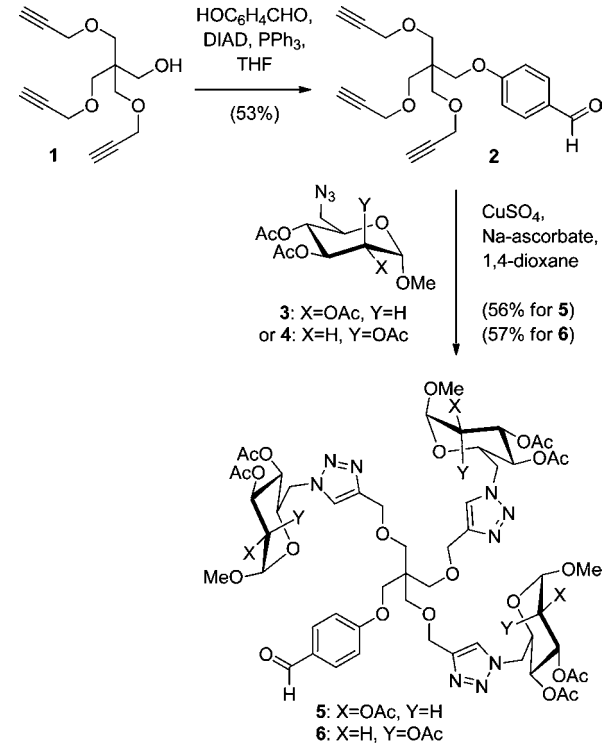
3-[3,5-Bis(phthalimidoxymethyl)phenoxy]propyl 2-cyanoethyl *N,N*-Diisopropylphosphoramidite (12). Compound **11** (290 mg, 0.578 mmol) was dried over P_2O_5 and suspended in dry 1,4-dioxane (3 mL). Dry triethylamine (287 μL, 2.07 mmol) and 2-cyanoethyl *N,N*-diisopropylphosphonamidic chloride (141 μL, 0.632 mmol) were added under nitrogen. The mixture was stirred for 2.5 h and then subjected directly to a silica gel column. Elution with 1% triethylamine and 29% petroleum ether in ethyl acetate yielded 284 mg (70%) of **12** as white powder. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 7.81 (m, 4H, Pht), 7.73 (m, 4H, Pht), 7.21 (m, 1H, Ar), 7.16 (br d, 2H, Ar), 5.17 (s, 4H, 2 × CH_2ON), 4.15 (t, 2H, J = 6.1 Hz, CH_2OAr), 3.91−3.76 (m, 4H, 2 × $POCH_2$), 3.61 [m, 2H, 2 × CH(CH_3)$_2$], 2.64 (t, 2H, J = 6.5 Hz, CH_2CN), 2.10 (m, 2H, $CH_2CH_2CH_2$), 1.19 (s, 3H, CH_3), 1.18 (s, 3H, CH_3), 1.18 (s, 3H, CH_3), 1.17 (s, 3H, CH_3); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 163.4, 159.2, 135.4, 134.4, 128.9, 123.5, 122.7, 117.7, 116.5, 79.5, 64.7, 60.1 [d, J(^{13}C, ^{31}P) = 17.6 Hz], 58.4 [d, J(^{13}C, ^{31}P) = 19.2 Hz], 43.0 [d, J(^{13}C, ^{31}P) = 12.5 Hz], 30.9 [d, J(^{13}C, ^{31}P) = 7.2 Hz], 24.6 (m), 20.4 [d, J(^{13}C, ^{31}P) = 7.1 Hz]; ^{31}P NMR (200 MHz, $CDCl_3$): δ_{ppm} 147.7; HRMS (ESI): $[M + Na]^+$ $C_{36}H_{39}N_4NaO_9P$ requires 725.2353, found 725.2371.

5-(4,4′-Dimethoxytrityl)-3-*O*-*tert*-butyldimethylsilyloxy-1,2-dideoxy-1-C-(2-phthalimidoxyethyl)-β-D-erythro-pentofuranose (14). 5-(4,4′-Dimethoxytrityl)-3-*O*-*tert*-butyldimethylsilyloxy-1,2-dideoxy-1-*C*-(2-hydroxyethyl)-β-D-*erythro*-pentofuranose (*40*) (**13**, 1.64 g, 2.84 mmol), *N*-hydroxyphthalimide (0.557 g, 3.42 mmol), and triphenylphosphine (0.896 g, 3.41 mmol) were dissolved in dry THF (40 mL). Diethylazodicarboxylate (DEAD, 573 μL, 3.68 mmol) was added dropwise and the mixture was stirred for 89 h at room temperature. After evaporation, the residue was dissolved in CH_2Cl_2 and washed three times with saturated $NaHCO_3$. The combined aqueous layers were extracted with CH_2Cl_2, and then the organic layers were combined, dried with Na_2SO_4, and evaporated. Crude product was purified by silica gel chromatography (0.1% triethylamine and 3% MeOH in CH_2Cl_2) to yield 1.90 g (93%) of **14**. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 7.82 (m, 2H, Pht), 7.73 (m, 2H, Pht), 7.44 (m, 2H, DMTr), 7.33 (m, 4H, DMTr), 7.27 (m, 2H, DMTr), 7.18 (m, 1H, DMTr), 6.82 (m, 4H, DMTr), 4.40−4.31 (m, 3H, CH_2ON and H-1), 4.25 (m, 1H, H-3), 3.88 (m, 1H, H-4), 3.79 (s, 6H, 2 × OCH_3), 3.07 (m, 2H, H-5), 2.08 (m, 2H, CH_2CH_2ON), 1.94 (m, 1H, H-2a), 1.74 (m, 1H, H-2b), 0.84 [s, 9H, C(CH_3)$_3$], 0.01 (s, 3H, CH_3Si), −0.02 (s, 3H, CH_3Si); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 163.6, 158.4, 145.0, 136.2, 134.4, 130.1, 128.9, 128.2, 127.7, 126.6, 123.5, 113.0, 86.4, 85.9, 76.1, 75.2, 74.3, 64.3, 55.2, 41.3, 34.2, 25.8, 18.0, −4.6, −4.8; HRMS (ESI) $[M + Na]^+$ $C_{42}H_{49}NNaO_8Si$ requires 746.3125, found 746.3147.

5-(4,4′-Dimethoxytrityl)-1,2-dideoxy-1-*C*-(2-phthalimidoxyethyl)-β-D-erythro-pentofuranose (15). Triethylamine trihydrofluoride (409 μL, 2.51 mmol) was added to a solution of **14** (1.21 g, 1.67 mmol) in dry THF (15 mL). The mixture was stirred at room temperature for 24 h, after which another portion of triethylamine trihydrofluoride (408 μL, 2.50 mmol) was added. The reaction was allowed to proceed for another 24 h, followed by addition of triethylamine (200 μL, 1.43 mmol) and evaporation. The crude product was purified by silica gel chromatography (0.1% triethylamine and 3% MeOH in CH_2Cl_2) to yield 0.538 g (53%) of **15**. ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 7.82 (m, 2H, Pht), 7.73 (m, 2H, Pht), 7.42 (m, 2H, DMTr), 7.32 (m, 4H, DMTr), 7.27 (m, 2H, DMTr), 7.19 (m, 1H, DMTr), 6.82 (m, 4H, DMTr), 4.42−4.29 (m, 4H, CH_2ON, H-1, and H-3), 3.91 (m, 1H, H-4), 3.79 (s, 6H, 2 × OCH_3), 3.23 (dd, 1H, J = 4.6 and 9.6 Hz, H-5a), 3.08 (dd, 1H, J = 5.9 and 9.6 Hz, H-5b), 2.10−2.05 (m, 3H, CH_2CH_2ON and H-2a), 1.90−1.84 (m, 2H, H-2b and OH); ^{13}C NMR (125 MHz, $CDCl_3$): δ_{ppm} 163.6, 158.5, 144.9, 136.1, 134.5, 130.1, 128.9, 128.2, 127.8, 126.8, 123.5, 113.1, 86.1, 85.8, 75.9, 75.3, 74.7, 64.7, 55.2, 40.9, 34.2; HRMS (ESI): $[M + Na]^+$ $C_{36}H_{35}NNaO_8$ requires 632.2261, found 632.2268.

5-(4,4′-Dimethoxytrityl)-1,2-dideoxy-1-*C*-(2-phthalimidoxyethyl)-β-D-erythro-pentofuranosyl-3-(2-cyanoethyl-*N,N*-diisopropylphosphoramidite) (16). 2-Cyanoethyl *N,N,N′,N′*-tetraisopropylphosphordiamidite (365 μL, 1.15 mmol) was added to a solution of **15** (0.538 g, 0.884 mmol) in dry MeCN (1 mL), followed by addition of tetrazole as 0.45 mol L^{-1} solution in MeCN (2.0 mL, 0.90 mmol). After 80 min, the mixture was evaporated to dryness, saturated $NaHCO_3$ was added, and the product was extracted twice with CH_2Cl_2. The combined organic layers were dried with Na_2SO_4 and evaporated to yield 0.618 g (86%) of **16**. ^{1}H NMR (500 MHz, CD_3CN): δ_{ppm} 7.83 (m, 4H, Pht), 7.49−7.46 (m, 2H, DMTr), 7.37−7.30 (m, 6H, DMTr), 7.25−7.21 (m, 1H, DMTr), 6.91−6.86 (m, 4H, DMTr), 4.42 (m, 1H, CHHON), 4.38−4.32 (m, 3H, CHHON, H-1, and H-3), 4.01 (m, 1H, H-4), 3.84−3.67 (m, 8H, $POCH_2$ and 2 × OCH_3), 3.60 (m, 2H, H-2), 3.15 (m, 1H, H-5a), 3.05 (m, 1H, H-5b), 2.66 (t, 1H, J = 6.0 Hz, CHHCN), 2.55 (t, 1H, J = 6.0 Hz, CHHCN), 2.24−2.00 [m, 3H, CH(CH_3)$_3$ and CH_2CH_2ON], 1.93−1.85 [m, 1H, CH(CH_3)$_3$], 1.19−1.03 (m, 12H, 4 × CH_3); ^{31}P NMR (200 MHz, CD_3CN): δ_{ppm} 147.2; HRMS (ESI): $[M + Na]^+$ $C_{45}H_{52}N_3NaO_9P$ requires 832.3339, found 832.3311.

Synthesis of Oligodeoxyribonucleotide 5′-Glycoconjugate (20). The oligodeoxyribonucleotide **18** was synthesized on an Applied Biosystems 392 DNA synthesizer on 1.0 μmol scale using commercial 1000 Å CPG-succinyl-thymidine support and conventional phosphoramidite chemistry. Standard DNA coupling protocol was used except for a prolonged coupling time for phosphoramidite **12** (600 s, 0.13 mol L^{-1} solution in dry MeCN). After the oligonucleotide assembly, the support-bound material was removed from the synthesizer

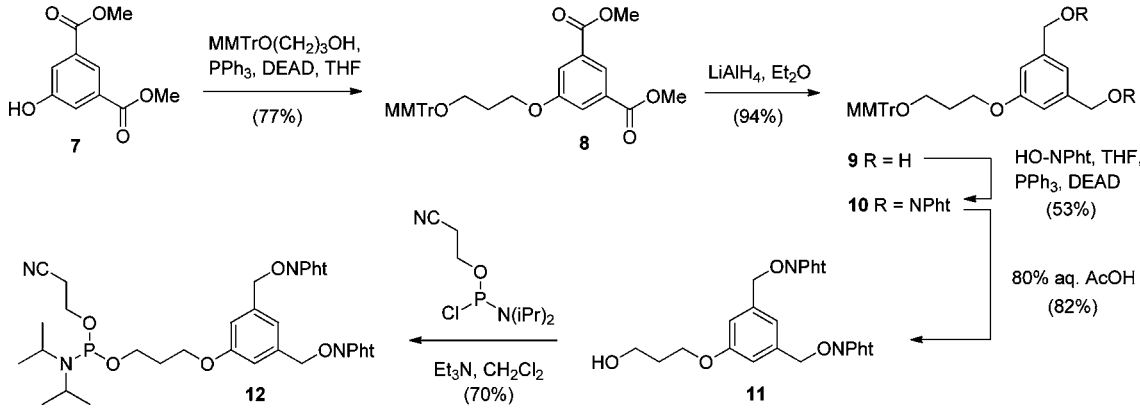


and the phthaloyl protections were removed by 0.5 mol L^{-1} hydrazinium acetate treatment; i.e., the support was suspended in a mixture of $NH_2NH_2 \cdot H_2O$, pyridine, and AcOH (0.124/4/1 v/v/v) for 30 min, washed with pyridine and MeCN, and dried. An aliquot of the support **19** (6.9 mg, 0.21 μmol) was transferred to microcentrifuge tube, and the glucoside cluster **5** was coupled to the aminooxy groups by adding the glycocluster as a 0.08 mol L^{-1} solution (55 μL, 4.2 μmol) in MeCN to the support. The mixture was shaken at ambient temperature for 24 h, filtered, washed with MeCN, and dried. To ensure the completeness of the reaction, oximation was repeated twice. The unreacted aminooxy groups were capped with acetone (1 h), and the support was dried. The oligodeoxyribonucleotide glycoconjugate was released from the support and deprotected with concentrated ammonia (33% aqueous NH_3, 16 h at 55 °C). The crude product was evaporated, dissolved in 30% aqueous MeCN, and purified by C18 RP HPLC. The authenticity of the conjugate **20** was verified by MS (ESI) spectroscopy: required 6817.2, found 6816.5.

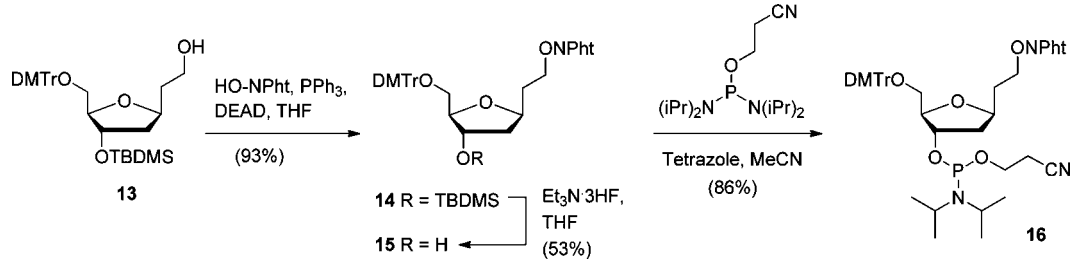
Synthesis of Oligodeoxyribonucleotide 3′-Glycoconjugate (26). The general procedures were as described for **20**. Phosphoramidite **16** (0.11 mol L^{-1} solution in dry MeCN) was coupled to CPG-succinyl-thymidine support using a prolonged coupling time of 1200 s and 6 extra detritylations. The support-bound material **22** was removed from the synthesizer, and the phthaloyl protection was removed by hydrazinium acetate treatment as described for **20**. The support (18.8 mg, 0.56 μmol) was transferred to microcentrifuge tube, and the mannoside cluster **6** was coupled to the aminooxy group by adding the glycocluster as a 0.07 mol L^{-1} solution (80 μL, 5.7 μmol) in MeCN to the support. The mixture was shaken at ambient temperature for 24 h, filtered, washed with MeCN, and dried. Oximation with the glycocluster was repeated twice, followed by acetone treatment (1 h). The support **23** was dried and reloaded to the DNA synthesizer. The oligonucleotide chain assembly was continued by coupling of a thymidine residue (two consecutive couplings, 600 s each) and phosphoramidite **16** (three consecutive couplings, 1200 s each). The support-bound **24** was again removed from the synthesizer, the phthaloyl protection was removed, and the glucoside cluster **5** was coupled three times as a 0.09 mol L^{-1} solution (60 μL, 5.1 μmol) in MeCN to the support as described above. After acetone treatment (1 h) and drying, the support **25** was reloaded to the DNA synthesizer for the assembly of the remaining chain. Two consecutive couplings were again performed with the adjacent thymidine residue, whereas the rest of the chain was assembled using standard DNA coupling protocol. The oligodeoxyribonucleotide glycoconjugate was released from the support and deprotected with concentrated ammonia (33% aqueous NH_3, 16 h at 55 °C). The crude product was evaporated, dissolved in 30% aqueous MeCN, and purified by C18 RP HPLC. The authenticity of the conjugate **26** was verified by MS (ESI) spectroscopy: required 7599.6, found 7599.0.

RESULTS AND DISCUSSION

Synthesis of Glycoclusters (5,6). Previously (*54*) published tri-*O*-propargyl pentaerythritol (**1**) was used as a core molecule in the synthesis of trivalent glycoclusters (Scheme 1). First, an aldehyde functionality was introduced in the core to allow ligation of the clusters to aminooxy functionalized oligonucleotides. For this purpose, the free hydroxyl group of **1** was subjected to Mitsunobu reaction with 4-hydroxybenzaldehyde, which gave the desired scaffold **2** in 53% yield. Methyl 6-azido-6-deoxy-α-D-gluco- (**3**) and -α-D-mannopyranoside (**4**) (*55*) were used for construction of the clusters. Accordingly, copper(I)-catalyzed 1,3-dipolar cycloaddition (*57, 58*), the so-called click reaction, was applied to attach the sugarazide units to scaffold **2** to obtain glycoclusters **5** (56%) and **6** (57%). The advantage of clustering the sugars via the 6-position of the carbohydrate ring is that it allows variation of the aglycone moiety, which may in some cases affect the efficiency of lectin binding (*29*).



Scheme 1. Synthesis of Glycoclusters 5 and 6



Synthesis of the 5′-Branching Unit (12). To enable conjugation of two trivalent glycoclusters to the 5′-end of an oligonucleotide, a phosphoramidite reagent bearing two phthaloyl-protected aminooxy functions (**12**, Scheme 2) was synthesized. This building block is compatible with conventional solid-phase oligonucleotide synthesis by the phosphoramidite strategy and it can be attached to the oligonucleotide chain by a somewhat elongated coupling cycle. Commercially available dimethyl 5-hydroxyisophthalate **7** was used as the starting material to which 4-methoxytrityl protected propanediol arm (prepared as corresponding tritylated propanediol (*56*)) was attached by Mitsunobu reaction (→ **8**, 77%). The methyl ester functions were then reduced to primary alcohols with lithium aluminum hydride to obtain **9** (94%). The phthaloyl protected aminooxy groups were generated by Mitsunobu reaction with *N*-hydroxyphthalimide (→ **10**, 53%). The 4-methoxytrityl protection was finally removed with acetic acid (→ **11**, 82%) and the exposed hydroxyl group was phosphitylated to give **12** (70%).

Synthesis of the Intrachain Branching Unit (16). To enable conjugation of trivalent clusters in desired positions within the oligonucleotide chain and, in particular, to allow introduction of dissimilar glycoclusters in different sites within the chain, a deoxyribose-derived C-glycosidic phosphoramidite reagent **16** (Scheme 3) bearing a phthaloyl protected aminooxy function was synthesized. Previously (*40*) prepared 5-(4,4′-dimethoxytrityl)-3-*O*-*tert*-butyldimethylsilyloxy-1,2-dideoxy-1-*C*-(2-hydroxyethyl)-β-D-*erythro*-pentofuranose (**13**) was used as a starting material. The primary hydroxyl group was converted to a phthaloyl protected aminooxy group by the Mitsunobu reaction to obtain **14** (93%). *tert-*

Scheme 3. Synthesis of the Intrachain Branching Unit 16

Scheme 4. Synthesis of Oligonucleotide 5′-Glycoconjugate 20[a]

[a] Abbreviation Pr used for the fully protected oligodeoxyribonucleotide.

Butyldimethylsilyl protection was removed (→ **15**, 53%), and the hydroxyl group was phosphitylated to give **16** (86%).

Preparation of an Oligonucleotide 5′-Glycoconjugate (20). The synthesis of the oligonucleotide conjugate containing two trivalent glucopyranosyl clusters at the 5′-terminus was initiated by coupling phosphoramidite **12** to the 5′-hydroxy of otherwise fully protected support-bound oligonucleotide (**17**, Scheme 4). The support was removed from the synthesizer and the phthaloyl protections were removed from the solid-supported oligomer (**18**) by treatment with hydrazinium acetate in pyridine. The exposed aminooxy groups of **19** were then oximated with 20 equiv of the aldehyde functionalized glucoside cluster **5** in acetonitrile for 24 h. To ensure the efficiency of oximation, the treatment was repeated twice. The remaining

Scheme 5. Synthesis of Oligonucleotide 3′-Glycoconjugate 26

unreacted aminooxy groups were capped with acetone, after which the conjugate was released from the support and deprotected by standard ammonolysis (16 h, at 55 °C). The crude product was purified by RP HPLC (Figure 2) and analyzed by MS (ESI) spectroscopy. As seen from the HPLC trace, the desired conjugate **20** was the main product. In addition, an incompletely oximated conjugate, i.e., conjugate having only one sugar cluster attached, was detected in a minor amount. All in all, the method proved to be successful in the preparation of glycoconjugates bearing six sugars that may adopt a more or less parallel orientation in space.

Preparation of an Intrachain Oligonucleotide Glycoconjugate (26). Intrachain branching unit **16** was used for preparation of a glycoconjugate with two dissimilar glycoclusters attached close to the 3′-terminus of the oligonucleotide (**26**, Scheme 5). The first branching unit was coupled to CPG-succinyl-thymidine support after which the support (**22**) was removed from the synthesizer and the phthaloyl protection was removed by the hydrazinium acetate treatment discussed above. The exposed aminooxy group was oximated with 10 equiv of the mannoside cluster **6** in acetonitrile for 24 h. Oximation was repeated twice followed by capping with acetone. HPLC trace of the crude conjugate released by ammonolysis from an aliquot of support **23** can be seen in Figure 3. The support (**23**) was reloaded to the synthesizer and one thymidine unit and another branching unit **16** were coupled using consecutive couplings for both compounds to enhance the coupling efficiency. The support was again removed from the synthesizer and the phthaloyl protection was removed from the tetrameric structure (**24**) as before. The second oximation step was carried out three times using now the glucoside cluster **5**. After acetone capping, the support **25** was again reloaded to the synthesizer. The first thymidine residue following the branching unit was introduced by two consecutive couplings, while the rest of the oligonucleotide chain was assembled by standard DNA coupling protocol. The conjugate was released and deprotected by ammonolysis (16 h, at

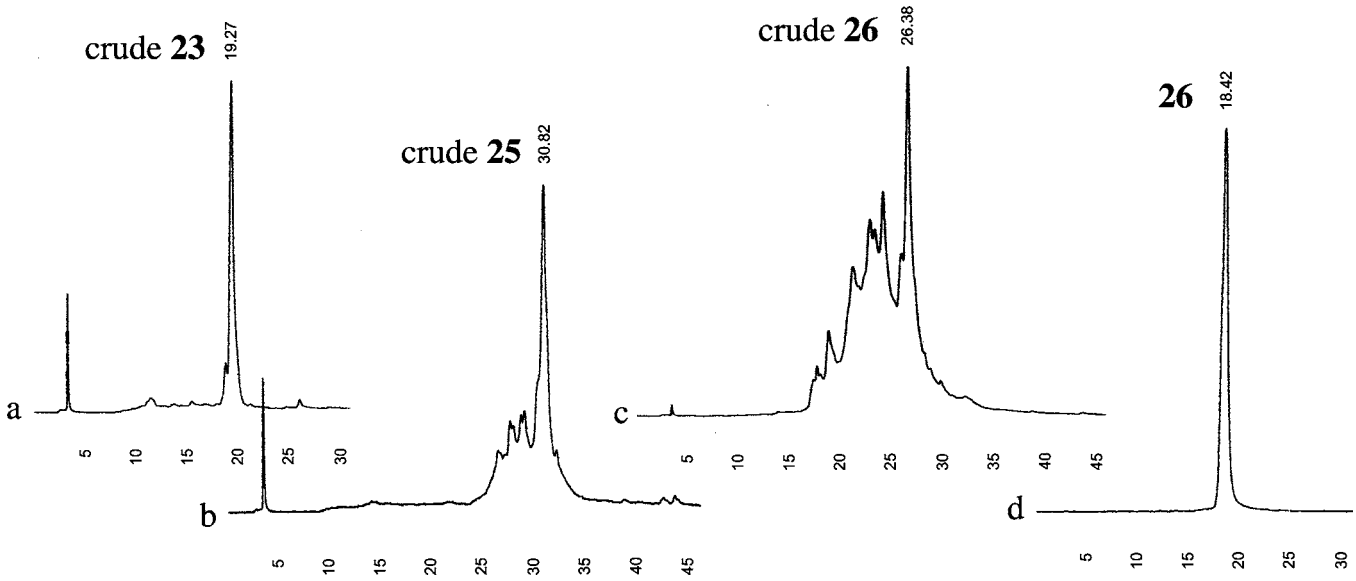

Figure 3. RP HPLC traces of the crude oligonucleotide glycoconjugates released by ammonolysis from aliquots of supports **23** (a), and **25** (b), and the HPLC trace of the crude (c) and purified (d) oligonucleotide glycoconjugate **26**. For the chromatographic conditions, see experimental procedures.

55 °C), followed by purification by RP HPLC (Figure 3) and analysis by MS (ESI) spectroscopy. Conjugate **26** was the main product although numerous side products could be detected, especially due to incomplete coupling of the second branching unit. Oxidation on the other hand seemed to proceed almost to completion on the basis of the HPLC traces of the crude intermediates released by ammonolysis from aliquots of supports **23** and **25** (Figure 3).

CONCLUSION

It has been shown that trivalent glycoclusters bearing a benzaldehyde moiety for subsequent conjugation (**5**, **6**) may be conveniently prepared from tri-*O*-propargylpentaerythritol in two steps by applying sequentially the Mitsunobu and click reactions. These clusters may rather efficiently be conjugated to solid supported oligonucleotides incorporating aminooxy functionalized branching units. On using a 5′-terminal 3,5-bis(aminooxymethyl)phenyl group (**12**) for branching, a conjugate bearing six sugars having a more or less parallel orientation is conveniently obtained. When a 2′-deoxyribose-derived aminooxyethyl *C*-glycoside (**16**) is inserted into the oligonucleotide chain, the prefabricated clusters may be attached to desired sites within the chain. This can be done in a stepwise manner, and hence, more than one type of clusters may be introduced.

ACKNOWLEDGMENT

The authors thank M.Sc. Teija Niittymäki and Ms. Miriam von Usedom for their help in preparation of some of the compounds. The Graduate School of Organic Chemistry and Chemical Biology is gratefully acknowledged for financial support.

Received December 7, 2009; Revised Manuscript Received February 8, 2010

Pharmacokinetic study of small interfering RNA (siRNA) is an important issue for the development of siRNAs for use as a medicine. For this purpose, a novel and favorable positron emitter-labeled siRNA was prepared by amino group-modification using *N*-succinimidyl 4-[fluorine-18] fluorobenzoate ([^{18}F]SFB), and real-time analysis of siRNA trafficking was performed by using positron emission tomography (PET). Naked [^{18}F]-labeled siRNA or cationic liposome/[^{18}F]-labeled siRNA complexes were administered to mice, and differential biodistribution of the label was imaged by PET. The former was cleared quite rapidly from the bloodstream and excreted from the kidneys; but in contrast, the latter tended to accumulate in the lungs. We also confirmed the biodistribution of fluorescence-labeled naked siRNA and cationic liposome/siRNA complexes by use of a near-infrared fluorescence imaging system. As a result, a similar biodistribution was observed, although quantitative data were obtained only by planar positron imaging system (PPIS) analysis but not by fluorescence in vivo imaging. Our results indicate that PET imaging of siRNA provides important information for the development of siRNA medicines.

INTRODUCTION

Small interfering RNA (siRNA) is a short double-stranded nucleic acid molecule that induces sequence-dependent gene silencing (*1, 2*), and gene therapy using siRNA is expected to be a novel treatment strategy for various diseases (*3*). However, the degradation of naked siRNA after administration into the bloodstream of human and animals readily occurs due to nucleases in the blood. Furthermore, siRNA poorly penetrates the plasma membranes of target cells, thus making difficult the delivery to the cytosol of targeted cells for effective gene knockdown. Therefore, a delivery system of siRNA molecules is considered to be indispensable for establishing siRNA therapy. Many studies on the in vivo application of siRNA using chemical modification (*4*) or drug delivery system (DDS) carriers such as liposomes (*5*) and micelles (*6*) for efficacious delivery and gene silencing have been reported. Cationic liposomes or micelles are representative carriers having electric charges on their surface. Because siRNA possesses polyanionic charges, it electrostatically interacts with cationic carriers used for RNA interference (RNAi). Pharmacokinetic studies on siRNA/carrier complexes have been performed by using fluorescence- or radioisotope-labeled carriers or carrier-entrapped imaging agents for magnetic resonance imaging. The techniques of carrier-labeling, however, do not always reflect the biodistribution of siRNA, since there is a chance that the siRNA may become detached from the carrier in the bloodstream, especially when the siRNA is bound to the surface of cationic carriers. To evaluate the in vivo behavior of siRNA itself, the trafficking of it is carried out by near-infrared fluorescence (NIRF) imaging (*7*). However, like fluorescence imaging, NIRF imaging is affected by tissue depth to some extent, and therefore, quantitative data are difficult to obtain. In addition, although the NIRF imaging method is applicable for use on nonhuman primates, the method for human use has not yet been established.

To obtain precise pharmacokinetic information on siRNA molecules or their carriers in vivo, positron emission tomography (PET) is one of the ideal techniques. PET enables the determination of the real-time biodistribution and topical accumulation of positron emitter-labeled compound noninvasively. This technique can be applied in preclinical studies, in which a drug candidate labeled with a positron emitter is injected into animals. The circulation profile, biodistribution in various tissues, and eventual elimination of the drug candidate from the body can be monitored noninvasively in the same animal. Furthermore, certain positron emitter-labeled new drug candidates can be used for microdosing studies in humans. Such phase zero studies enable the investigator to reduce the rate of dropout of drug candidates in further clinical studies. For the pharmacokinetic study of DDS carriers, we previously reported a novel [^{18}F]-probe for labeling the lipid assembly carriers for PET analysis (*8*). As mentioned above, since siRNA may possibly dissociate from its carrier and be degraded by plasma nucleases after injection into the bloodstream, we have sought to label siRNA with a positron emitter for the analysis of siRNA trafficking in vivo. The pharmacokinetic information on siRNA molecules, like that of the carrier, is considered to be critical and indispensable for the development of siRNA medicines.

Recently, Bartlett et al. labeled the sense strand of siRNA with copper-64 by using 1,4,7,10-tetraazacyclododecane-*N,N′,N″,N‴*-tetraacetic acid (DOTA) and then annealed this modified strand with the unmodified antisense strand for the determining biodistribution of siRNA in micellar carriers (*9*).

Viel et al. reported the conjugation of ^{18}F to oligonucleotide by using (*N*-[3-(2-[^{18}F]fluoropyridin-3-yloxy)-propyl]-2-bromoacetamide ([^{18}F]FRyBrA), and this method also required the annealing process (*10, 11*). In spite of their efforts, detail pharmacokinetic information about naked siRNA or siRNA in DDS carriers is still largely lacking.

In the present study, we developed a novel technique for labeling siRNA with a positron emitter, ^{18}F, in which double-stranded siRNA was labeled to gain conformational accuracy for examining the pharmacokinetics of siRNA by using [^{18}F]SFB as an ^{18}F labeling reagent. [^{18}F]SFB have been widely used to form a stable amide bond by reacting with primary amino groups for a short time and very easily for labeling certain peptides (*12*), antibodies (*13*), or DNA oligonucleotides (*14*). Because ^{18}F has an extremely short half-life (109 min), avoidance of the annealing process by labeling of double-stranded siRNA is favorable. [^{18}F]-labeled siRNA thus prepared was identified by ESI-TOF-MS, HPLC, and autoradiography after electrophoresis. By use of this positron emitter-labeled siRNA, we actually examined the biodistribution of siRNA by PPIS in the presence or absence of cationic liposome, a DDS carrier of siRNA. We also performed NIRF imaging for verifying the in vivo behavior of siRNA and discussed the correspondence of the imaging results obtained from NIRF imaging and PPIS imaging.

EXPERIMENTAL PROCEDURES

Materials. 4,7,13,16,21,24-Hexaoxa-1,10-diazabicyclo[8.8.8]-hexacosane (K[2.2.2]), tetra-*n*-propyl-ammonium hydroxide (Pr_4NOH), *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(*N*-succinimidyl)uronium tetrafluoroborate (TSTU), CH_3CN (anhydrous), and fetal bovine serum were obtained from Sigma-Aldrich (Saint Louis, MO, USA). Potassium carbonate·$1.5H_2O$ was purchased from Merck (Darmstadt, Germany). Anion-exchange resin AG1-X8 (OH^- form, 100−200 mesh) was from Bio-Rad Laboratories (Hercules, USA). *N,N*-Dimethylformamide (DMF) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). A cationic lipid for transgene use, 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP), was purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA). Cholesterol was kindly provided by Nippon Fine Chemical Co., Ltd. (Takasago, Hyogo, Japan). Trizol reagent was obtained from Invitrogen Co. (Carlsbad, CA). An alfalfa-free feed was purchased from Oriental Yeast co. Ltd. (Tokyo, Japan). Escain was purchased from Mylan Pharmaceuticals (Morgantown, WV). All other chemicals and solvents were analytical grade and were used without further purification unless otherwise stated. [^{18}F]Fluoride was produced with a cyclotron (HM-18, Sumitomo Heavy Industries, Tokyo, Japan) at Hamamatsu Photonics PET Center by the ^{18}O(p,n)^{18}F nuclear reaction using [^{18}O]H_2O. Labeled compounds were synthesized by using modified CUPID system (Sumitomo Heavy Industries, Tokyo, Japan). The HPLC column used for the purification of succinimidyl 4-[^{18}F] fluorobenzoate ([^{18}F]SFB) was an Inertsil ODS3 (10 × 250 mm, 5 μm, GL Sciences Inc., Tokyo, JAPAN). Nonradioactive fluorine-conjugated siRNA was identified by using a UPLC/ESI-QTOF-MS system, which consisted of an ACQUITY ultraperformance liquid chromatography (UPLC) system and an electrospray ionization quadrupole time-of-flight mass spectrometer (SYNAPT High Definition Mass Spectrometry system; Waters, Milford, MA, USA). An ultraviolet−visible (UV/vis) detector (ACQUITY TUV, Waters) was used. The UPLC column used for the identification of fluorine-labeled siRNA was an Acquity UPLC BEH C18 column (2.1 × 100 mm, 1.7 μm, Waters Corp.). The particle size and zeta-potential of nanoparticles were measured by using a Zetasizer Nano ZS (Malvern, Worcs, UK). Gel for obtaining an autoradiogram of ^{18}F and siRNA after electrophoresis was used an FLA-7000 (FUJIFILM Corporation, Tokyo, Japan) and LAS-3000 mini system (Fuji Film, Tokyo, Japan), respectively. Fluorescence imaging was performed by using a Xenogen IVIS Lumina System coupled to *Living Image* software for data acquisition (Xenogen Corp., Alameda, CA). PET imaging was performed by using a planar positron imaging system (PPIS, Hamamatsu Photonics, Shizuoka, Japan). Radioactivities in each organs were measured by gamma-counter (ARC-2000, Aloka, Tokyo, Japan).

Experimental Animals. Five-week-old male BALB/c mice male were purchased from Japan SLC Inc. (Shizuoka, Japan). The animals were cared for according to the Animal Facility Guidelines of the University of Shizuoka. All animal experiments were approved by the Animal and Ethics Review Committee of the University of Shizuoka.

siRNA Sequence. Alexa Fluor 750-labeled siRNA (AF750-siRNA) was purchased from Japan Bio Services Co., Ltd. (Saitama, Japan). Antisense strand contained a fluorescence at the 3′ end of the strand. siRNA for positron emitter-labeling was synthesized and purified by Hokkaido System Science. The nucleotide sequences of the siRNA were those of an unspecific scrambled RNA, and the antisense strand contained a 3′ amino C6 linker for the radioactive labeling of the siRNA duplex (Scheme 1). The sequences of the siRNA used were 5′-CGAUUCGCUAGACCGGCUUCAUUGCAG-3′ (sense) and 5′-GCAAUGAAGCCGGUCUAGCGAAUCGAU-3′ (antisense).

Synthesis of Ethyl-(4-Trimethylammonium)benzoate Trifluoromethanesulfonate. Ethyl 4-dimethylaminobenzoate was synthesized according to the procedure reported by Haka et al. (*15*). The synthetic compound was assigned by ^{1}H NMR and ^{13}C NMR. Ethyl 4-dimethylaminobenzoate 11.4 g (59 mmol) was dissolved in 70 mL anhydrous CH_2Cl_2. Ten grams of $CF_3SO_3CH_3$ (64.9 mmol) was added dropwise to the solution, and the mixture was stirred overnight at room temperature. A crystalline precipitate was formed by the addition of Et_2O (100 mL) and collected by suction filtration. Recrystallization from CH_2Cl_2/Et_2O gave 10.2 g (48%) of ethyl 4-trimethylammoniumbenzoate trifluoromethanesulfonate.

Radiosynthesis of [^{18}F]KF/K[2,2,2] Complex. [^{18}F]KF/K-[2,2,2] was obtained by use of a previously reported method (*16*). In brief, [^{18}F]fluoride was trapped by ion-exchange resin AG1-X8 and eluted from the resin by 0.5 mL of 40 mM K_2CO_3. To this fluoride solution, 15 mg of K[2,2,2] in CH_3CN (2 mL) was added. Water was removed by azeotropic distillation at 110 °C under He flow (400 mL/min) for 5 min. To the residue, the addition of CH_3CN (1 mL) and azeotropic distillation were repeated twice. Then, the residue was dried under reduced pressure for 1 min, and the reaction vessel was purged with a flow of He (50 mL/min) for 1 min to ensure complete dryness. Finally, the reaction vessel was cooled to room temperature and used for further labeling.

Preparation of Succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]-SFB). [^{18}F]SFB was prepared according to the one-pot procedure of Tang et al. (*17*) with some modifications. The precursor (5 mg) in 1.5 mL of CH_3CN was added to the dried [^{18}F]KF/K[2,2,2] complex mentioned above and reacted at 80 °C for 10 min. After the reaction mixture had been cooled, 20 μL of 1 M Pr_4NOH in 0.5 mL of CH_3CN was added; and hydrolysis was carried out at 120 °C for 5 min. Then, to the reaction mixture, TSTU (15 mg) in 0.5 mL of CH_3CN was added and converted to [^{18}F]SFB at 80 °C for 5 min. The reaction mixture was diluted with 2.0 mL of 5% CH_3COOH and transferred to the HPLC injector. Crude product was purified by semipreparative HPLC (CH_3CN:H_2O = 300:700, 6 mL/min, 254 nm). The radioactive peak eluted at 25.7 min was collected, diluted with 30 mL of H_2O, and passed through a Sep-Pak C18 cartridge (Waters). [^{18}F]SFB retained on the cartridge was released with 4 mL of CH_2Cl_2 and recovered into a V-vial by passage through a Sep-Pak Dry cartridge (Waters). Then, the [^{18}F]SFB was concen-

Scheme 1. Synthesis of the [^{18}F]SFB and [^{18}F]-Labeled siRNA

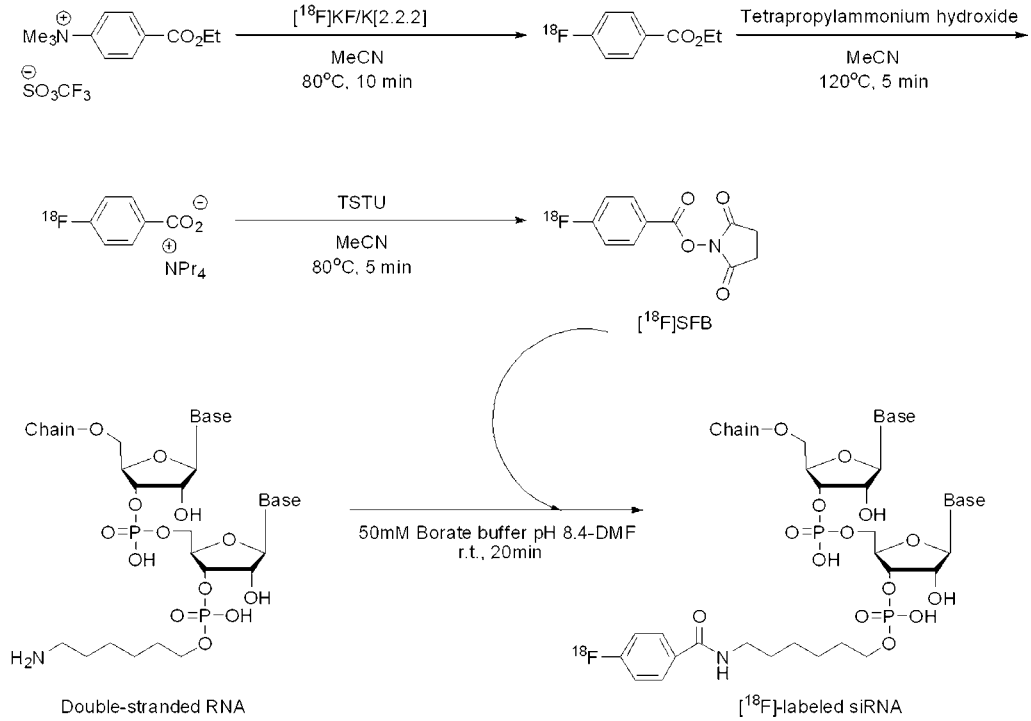

Table 1. Gradient Flow Table

time (min)	0.1 M TEAA (%)	CH_3CN (%)	flow rate (mL/min)
0−2	95−90	5−10	0.3
2−3	90−75	10−25	0.3
3−7	75−60	25−40	0.3
7−10	60−0	40−100	0.3

trated by a flow of He (200 mL/min) at 60 °C and used for labeling. [^{18}F]SFB with (a specific radioactivity of 51.4 GBq/μmol, a radiochemical yield of 21.1%) was obtained.

Radiolabeling of siRNA with [^{18}F]SFB. siRNA (40 nmol) in 16 μL of 50 mM borate buffer, pH 8.5, was added to the [^{18}F]SFB (60 nmol) in 3.6 μL of DMF. The mixture was vortexed for a few seconds and then incubated at room temperature for 20 min. The reaction mixture was purified and concentrated by ultrafiltration through a 10 000 molecular weight cutoff filter (Amicon, Millipore, Bedford, MA, USA). The mixture was centrifuged at 4000 × *g* with RNase-free phosphate-buffered saline (PBS). [^{18}F]-labeled siRNA with a radiochemical yield of 37.9% and a specific activity of 25.5 GBq/μmol was obtained. Nonradioactive fluorine-conjugated siRNA was synthesized in a similar manner except that 150 nmol cold SFB was used instead of 60 nmol [^{18}F]SFB.

Analytical Methods. Nonradioactive fluorine-conjugated siRNA was identified by using a UPLC/ESI-QTOF-MS system. The analytical column was maintained at 40 °C. A ultraviolet−visible (UV/vis) detector, equipped with a 500 nL flow cell, was also directly connected between the column outlet and the QTOF-MS instrument. Fractionation of fluorine-conjugated siRNA was performed at a flow rate of 0.3 mL/min using as the eluent the gradient of 0.1 M triethylammonium acetate (TEAA, pH 7.0) and CH_3CN. Gradient profile is presented in the Table 1.

Evaluation of siRNA Labeling. Precursor siRNA, fluorine-conjugated siRNA (non-RI), and [^{18}F]-labeled siRNA (0.5 μg) were applied to a 15% polyacrylamide gel and electrophoresed. Then, the gel was exposed to an imaging plate for obtaining an autoradiogram of ^{18}F by using an FLA-7000; the gel was stained for 5 min in ethidium bromide (EtBr), and siRNA was detected by using a LAS-3000 mini system.

Preparation of Cationic Liposomes and Their Complexes with siRNA. DOTAP and cholesterol (1:1 as a molar ratio) were dissolved in *tert*-butyl alcohol for freeze−drying and hydrated in RNase-free PBS. The liposomes were frozen and thawed for 3 cycles using liquid nitrogen and extruded 10 times through a polycarbonate membrane filter having a pore size of 100 nm (Nucleopore, Maidstone, UK). Then, the cationic liposome and siRNA were mixed gently and incubated for 10 min at room temperature to form liposome/siRNA complexes. The nitrogen moiety of cationic liposome to the phosphorus of siRNA (N/P ratio) was 24:1 in the complexes. The particle size and zeta-potential of liposome/siRNA complexes diluted with RNase-free PBS were measured. The particle size of liposome/siRNA complexes was 218 ± 3.0 nm (n = 3), and the particles showed monodispersion (polydispersity index = 0.16). The zeta-potential was 36.3 ± 1.9 mV.

Near-Infrared Fluorescence Imaging in Vivo. The biodistribution of AF750-siRNA was assessed by using an IVIS Lumina System. Mice were fed an alfalfa-free feed to reduce the effect of background fluorescence. The animals were anesthetized continuously via inhalation of 2% escain. siRNA or liposome/siRNA complexes containing 15 μg AF750-siRNA were injected via a tail vein under anesthesia. Alexa Fluor 750 fluorescence was acquired every 10 min for up to 60 min after the injection. After monitoring, the mice were sacrificed under anesthesia. Then, the organs, namely, heart, lungs, liver, spleen, and kidneys, were collected and imaged ex vivo with the IVIS.

PPIS Imaging of [^{18}F]-Labeled siRNA. Biodistribution of [^{18}F]-labeled siRNA was imaged noninvasively by using a PPIS (*18*−*20*). Animals were anesthetized with an intraperitoneal injection of pentobarbital at 50 mg/kg, and then fixed on an animal holder. To determine the whole-body biodistribution of siRNA, we administered the [^{18}F]-labeled siRNA intravenously (2.5 MBq/mouse). The scan was started immediately after the administration and performed for 60 min. Images were analyzed by using software *ImageJ*. After the PPIS scan, the mice were sacrificed for the collection of the blood from a carotid artery under anesthesia. Then, the heart, lungs, liver, spleen, and kidneys were removed, and the biodistribution of

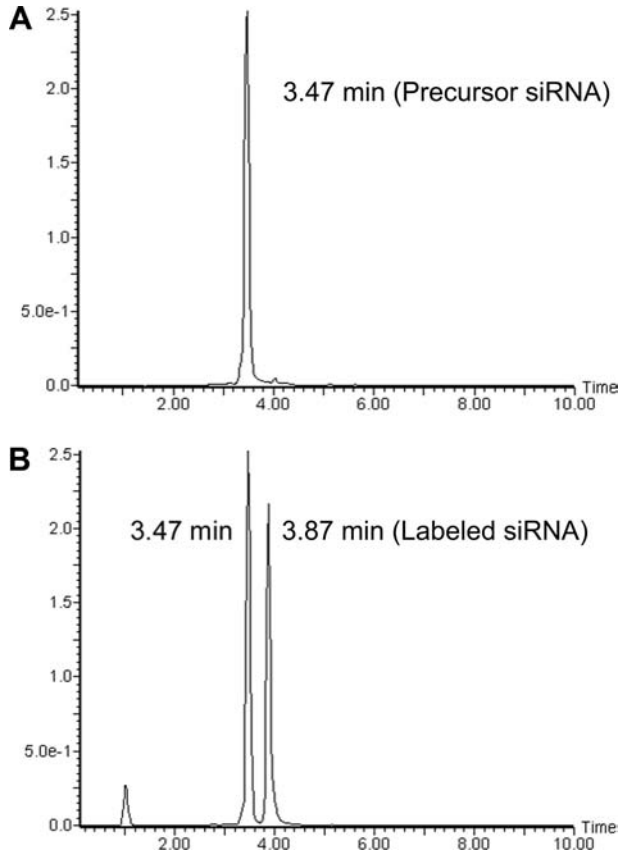

Figure 1. UPLC analysis of fluorine-conjugated siRNA. Nonradioactive fluorine was conjugated to siRNA and separated with the UPLC system. (A) Peak of precursor siRNA at 3.47 min. (B) Peaks of unreacted siRNA at 3.47 min and fluorine-labeled siRNA at 3.87 min after the reaction.

[18F]-labeled siRNA was measured with a gamma counter. Distribution data were presented as percent dose per wet tissue. The total volume of blood was assumed to be 7.56% of the body weight. A time−activity curve was obtained from the mean pixel radioactivity in the region of interest (ROI) of the PPIS images.

Evaluation of siRNA Stability against Serum-Mediated Degradation. Fluorine-conjugated (0.5 μg) naked siRNA or that complexed with liposomes was incubated in 90% fetal bovine serum for 60 min at 37 °C. The siRNA was extracted from the serum by using Trizol reagent and subjected to 15% polyacrylamide gel electrophoresis. The gel was stained for 5 min in EtBr, and siRNA was detected by using a LAS-3000 mini system.

RESULTS

[18F]-Labeling of siRNA and Its Radiochemistry. The methods for synthesis of [18F]SFB and [18F]-labeling of siRNA are shown in Scheme 1. At first, we prepared non-radioisotope (non-RI) fluorine-conjugated siRNA and identified the compound by using LC/ESI-TOF-MS (Table 1). Unreacted siRNA showed a peak at 3.47 min (Figure 1A). After the reaction, HPLC analysis indicated 2 main peaks, namely, labeled siRNA at 3.87 min and precursor siRNA at 3.47 min, respectively (Figure 1B). These peaks were fractionated by HPLC and analyzed by ESI-TOF-MS, giving multiply charged ion peaks of *m*/*z* $[M\text{-}8H]^{8-}$ 2196.1, $[M\text{-}7H]^{7-}$ 2510.9, and $[M\text{-}6H]^{6-}$ 2930.0 (data not shown), which corresponded to the labeled siRNA (expected mass of *m*/*z* $[M\text{-}8H]^{8-}$ 2196.7, $[M\text{-}7H]^{7-}$ 2510.7, and $[M\text{-}6H]^{6-}$ 2929.3). The overall yield of labeled siRNA was greater than 30% based on the peak area. On the basis of the result from non-RI fluorine-grafting to siRNA, [18F]-labeled siRNA was prepared according to the same procedure, and then electrophoresis assay and subsequent autoradiography were performed to confirm the production of [18F]-labeled siRNA. Electrophoresis assay with an imaging plate showed that the siRNA was labeled with [18F]-fluorine without any other exposure bands (Figure 2). In addition, the main band visualized by EtBr staining showed the same position as the band on the same polyacrylamide gel observed by autoradiography. As a result, [18F]-labeled siRNA was successfully prepared without any positron emitter-labeled byproducts, and the labeled siRNA was not degraded under the experimental conditions used.

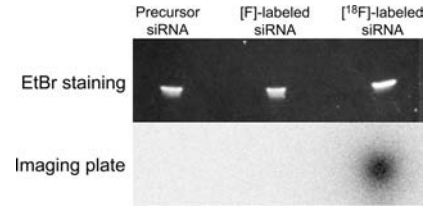

Figure 2. Demonstration of [18F] labeling of siRNA. Precursor siRNA, fluorine-conjugated siRNA, and [18F]-labeled siRNA were applied to a 15% polyacrylamide gel, electrophoresed, and stained with ethidium bromide. The gel was exposed to an imaging plate for detecting 18F.

Biodistribution of siRNA Determined with near-Infrared Fluorescence Imaging in Vivo. We examined the in vivo behavior of siRNA by use of the NIRF imaging system. Mice were intravenously administered naked AF750-siRNA or liposome/AF750-siRNA complexes via a tail vein. The fluorescence imaging of AF750-siRNA was started immediately after the injection and monitored for 60 min. The biodistribution of AF750-siRNA is shown in Figure 3. The results indicated that the fluorescence compound was accumulated in the bladder immediately after the administration of naked AF750-siRNA and then excreted in the urine (Figure 3A). On the contrary, fluorescence was observed at the upper part of the body where the lung was positioned after the administration of liposome/AF750-siRNA complexes. The total fluorescence intensity of the image of mice injected with naked AF750-siRNA was apparently higher than that obtained with the liposomal formulation: Fluorescence in bladder after injection of naked siRNA was quite intense because bladder is located near the body surface, while that in lungs after injection of cationic liposome complexes was weak because lungs are located more deep from body surface compared with bladder.

The ex vivo imaging showed that a small amount of fluorescence remained in the kidneys but that no fluorescence was detected in the other tissues examined (Figure 3B). In contrast, the fluorescence of the cationic liposome/AF750-siRNA complexes accumulated in the lungs, being consistent with the in vivo imaging data.

Stability of Fluorine-Conjugated siRNA against Serum-Mediated Degradation. We evaluated the stability of naked fluorine-conjugated siRNA and cationic liposome/fluorine-conjugated siRNA complexes in serum for 60 min (Figure 4). The naked fluorine-conjugated siRNA incubated in PBS (control) was not decomposed. However, the band of naked siRNA obtained by electrophoresis of the sample that had been incubated in the presence of serum disappeared, indicating that the siRNA had been degraded by RNase within 60 min. In contrast, the band of siRNA was detected in the case of the cationic liposome/siRNA complexes exposed to the serum, indicating that complex formation protected siRNA from RNase in the serum.

In Vivo PPIS Imaging of siRNA Trafficking. Next, we examined [18F]-labeled siRNA trafficking by use of PPIS. Mice were intravenously administered naked [18F]-labeled siRNA in

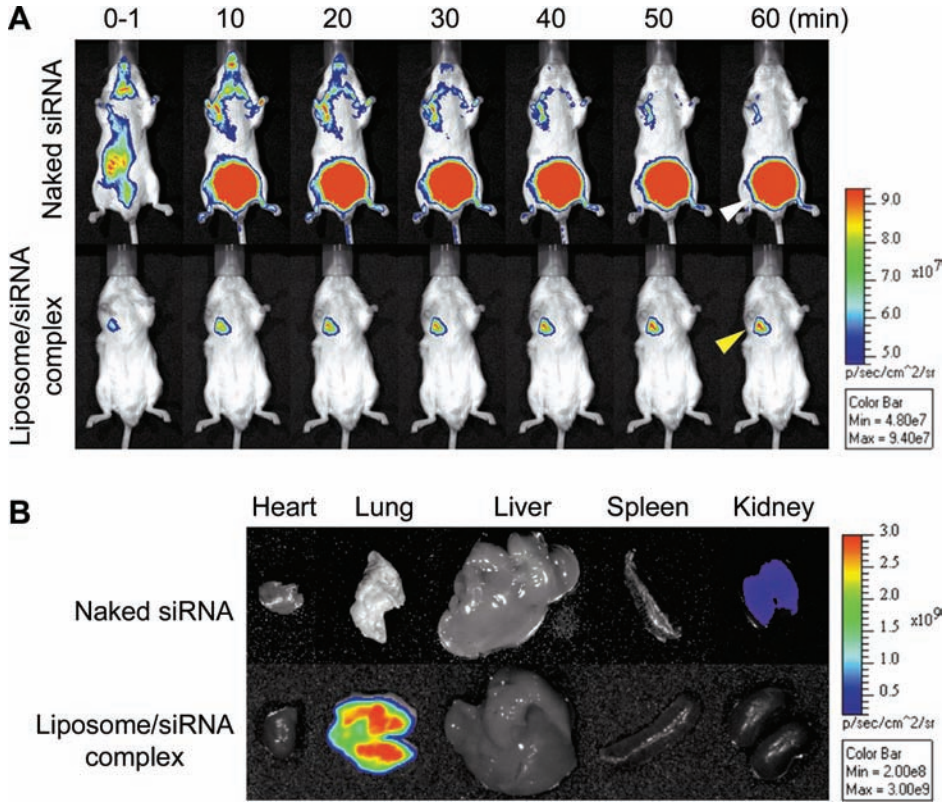

Figure 3. NIRF in vivo imaging with AF750-siRNA and liposome/AF750-siRNA complexes. (A) AF750- siRNA (top) or liposome/AF750-siRNA complexes (bottom) were intravenously administered to BALB/c mice. Images were acquired every 10 min for up to 60 min after the administration. The white arrowhead shows the bladder region, and the yellow arrowhead, the lung region. (B) Ex vivo imaging of AF750-siRNA and liposome/AF750-siRNA complexes at 60 min after administration.

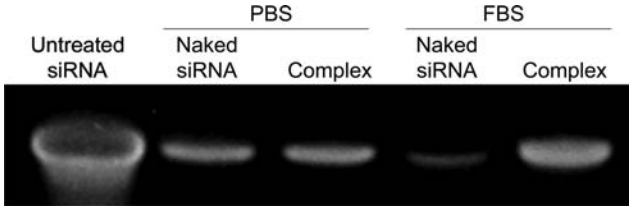

Figure 4. Stability of naked siRNA or liposome/siRNA complexes in FBS. siRNA (0.5 μg) was incubated with PBS (−) or 90% FBS at 37 °C for 60 min. siRNA was extracted and electrophoresed on a 15% polyacrylamide gel after a 60 min incubation and stained with EtBr. Untreated siRNA was used as a control marker.

PBS (−) or liposome/[^{18}F]-labeled siRNA complexes via a tail vein. The real-time imaging of [^{18}F]-labeled siRNA using PPIS was acquired for 60 min, and images were integrated every 5 min (Figure 5A). The ^{18}F radioactivity of the naked [^{18}F]-labeled siRNA accumulated inside the kidneys immediately after administration. This accumulation was not detected in NIRF in vivo imaging because of the influence of tissue depth. Then, ^{18}F was transferred to the bladder and subsequently excreted in the urine. In contrast, most of the ^{18}F radioactivity after the administration of cationic liposome/[^{18}F]-labeled siRNA complexes were retained in the lungs for 60 min, and only insignificant accumulation of them was observed in the bladder. The time−activity curve of ^{18}F in naked siRNA showed transient accumulation in kidney immediately after injection (19% injected dose/tissue at 2 min), and half of that was transferred to bladder at 21 min, and then the excretion of ^{18}F to bladder was gradually increased (Figure 5B). In contrast, the most of the ^{18}F after injection of liposome/siRNA complexes immediately accumulated in lungs and was maintained up to 60 min (76% injected dose/tissue). The biodistribution data obtained with a gamma counter after organ dissection showed that the ^{18}F after administration of naked [^{18}F]-labeled siRNA had not been distributed in any tissues tested, whereas the radioactivity after the injection of the cationic liposome/[^{18}F]-labeled siRNA complexes was highly distributed in the lungs (Figure 5C). These results corresponded roughly to the data obtained from the fluorescence ex vivo imaging.

Moreover, to confirm whether the accumulation of ^{18}F in the lungs after administration of cationic liposome/[^{18}F]-labeled siRNA reflected the accumulation of the liposomes of the complex, we examined the biodistribution of cationic liposome/siRNA complexes prepared with [^{3}H]cholesterylhexadecyl ether as a component. As a result, the liposomal complexes with siRNA were distributed in the lungs quite similarly to the distribution of the ^{18}F, suggesting that cationic liposome/siRNA accumulated in lungs as the complex form (Supporting Information Figure S1).

DISCUSSION

Recently, the topical application of siRNA medicines has reached clinical trial, and siRNA delivery systems for systemic injection have been extensively studied for the next generation of siRNA medicines (*21*). Pharmacokinetic information on siRNA molecules is considered to be particularly important for the acceleration of the development of siRNA medicine. Among the technologies for pharmacokinetic analysis, PET imaging technique is considered to be applicable to both preclinical trial and microdosing study (human phase 0 study). Using subtoxic and subpharmacologic doses, PET microdosing studies can be performed to screen for drug candidates for clinical trials on the basis of their pharmacokinetic properties (*22, 23*).

In the present study, we labeled double-stranded siRNA with^{18}F to obtain pharmacokinetics information about siRNA and siRNA in DDS carriers. We used [^{18}F]-fluorine as a short-

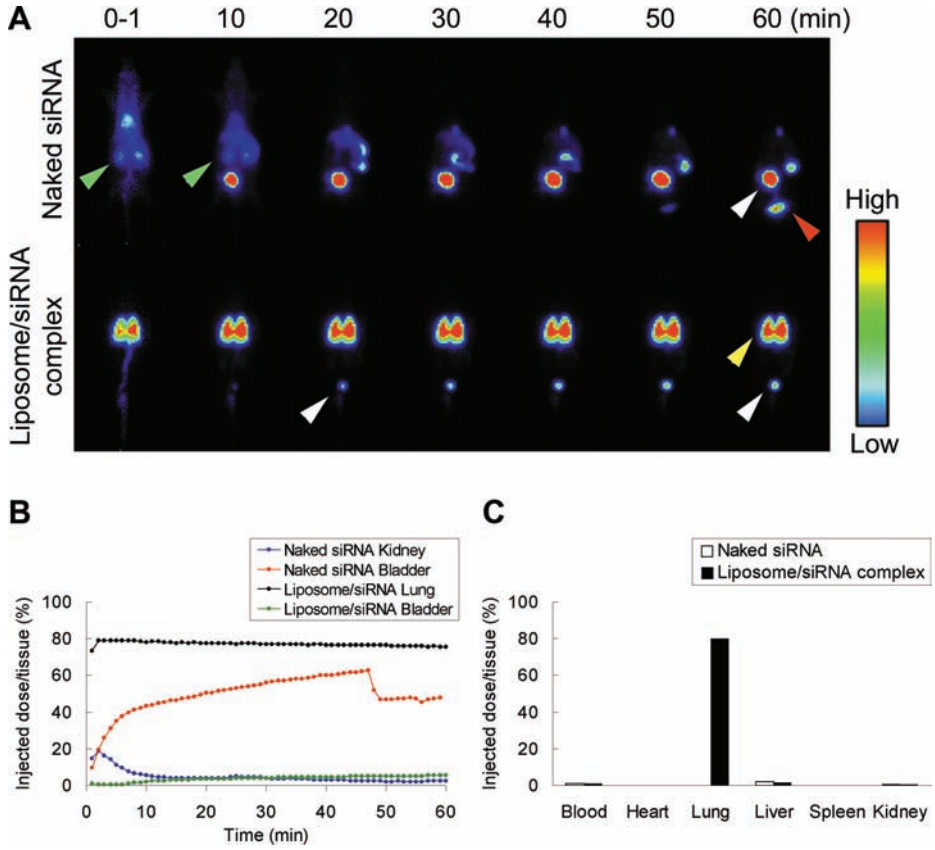

Figure 5. PPIS imaging with [18F]-labeled siRNA and liposome/[18F]-labeled siRNA complexes. (A) Naked siRNA (top) or liposome/siRNA complexes (bottom) at 2.5 MBq in 0.2 mL were intravenously administered to BALB/c mice. Images were acquired with a 1 min frame at 1, 10, 20, 30, 40, 50, and 60 min after the administration. The green arrowhead shows kidneys; the white one, the bladder; the red one, urine; and the yellow one, the lungs. (B) Real-time changes in [18F]-labeled siRNA and liposomal [18F]-labeled siRNA. Time activity curves of 18F with naked siRNA shows kidney (blue) and bladder (red) and that of 18F with cationic liposome/siRNA shows lung (black) and bladder (green). (C) After the PPIS scan, the mice were sacrificed, and biodistribution of 18F in each organ was then measured with a gamma counter.

lived positron-emitting radionuclide (half-life: 109 min), which has been applied to humans for cancer diagnosis in the form of [2-18F]2-deoxy-2-fluoroglucose ([18F]FDG). The advantages of the present methodology to label siRNA are that (1) the modification of double-stranded RNA with amino group enables fast preparation and purification without the time-consuming process of annealing and (2) the methodology maintains the conformational accuracy of the siRNA. Indeed, reaction of siRNA and [18F]SFB was complete within 20 min. In addition, fluorine-conjugated siRNA was identified by LC and ESI-TOF-MS (Figure 1) and did not decompose during the reaction or purification process (Figure 2).

It is well-known that one of the most important factors regarding the biodistribution of liposomes in vivo is the charge of the liposomal surface. Positively charged complexes aggregate in the presence of serum proteins (*24*), are entrapped in the lung capillaries, and thus accumulate in the lung tissue (*25, 26*) after intravenous administration. In fact, when liposomes were labeled with [3H]cholesterylhexadecyl ether, the radioactivity of cationic liposome/siRNA complexes accumulated in the lungs (Supporting Information Figure S1). However, since nucleic acids such as siRNAs and oligodeoxynucleotides (ODNs) are known to be eliminated from the circulation via the kidneys and excreted into the urine 60 min after administration via a tail vein (*27, 28*), distribution studies on siRNAs or ODNs besides on their carriers are important for the development of nucleic acid medicines. In the distribution study, [3H]cholesterylhexadecyl ether was accumulated in the liver to some extent, although the accumulation of siRNA was not observed after injection of cationic liposome/siRNA complex. We speculate that siRNA was degraded in the liver and excreted, while cholesterylhexadecyl ether did not.

In the present study, we first used AF750-siRNA and examined its in vivo behavior by using NIRF fluorescence imaging. NIRF fluorescence was rapidly cleared from the bloodstream and excreted in the bladder after the administration of naked AF750-siRNA (Figure 3). In contrast, the fluorescence of cationic liposome/siRNA complexes accumulated in the lungs. However, the differential fluorescence intensities between in vivo images and ex vivo ones indicated the limitation of NIRF imaging. Quantitative analysis could not be applied due to the influence of tissue depth on the fluorescence intensity. Moreover, it is possible that fluorescence self-quenching and/or resonance energy transfer affect the intensity.

In contrast to NIRF imaging, PPIS or PET technology provides quantitative analytic data with high spatial resolution. 18F was observed in the kidneys until 10 min after the administration of naked [18F]-labeled siRNA, and subsequently, it was transferred to the bladder and excreted into urine (Figure 5). This result is consistent with previous result reported by Viel et al. who used 18F-labeled naked siRNA (*11*). Other reports also presented the renal excretion of siRNA (*27, 29, 30*). In addition, Bartlett et al. reported that the excretion of 64Cu-labeled naked siRNA was quite fast (*9*). They indicated that the siRNA in a complex with cyclodextrin-containing polycation excreted quite rapidly and suggested the instability of the complex. Therefore, determination of siRNA trafficking instead of carrier trafficking is important for the development of siRNA medicines. In contrast to the in vivo fate of naked siRNA, the 18F of

cationic liposome/[^{18}F]-labeled siRNA complexes was spread throughout the lungs and was retained in them at least up to 60 min.

Next, we investigated the stability of siRNA in the presence of serum by performing an electrophoresis assay. The data indicated that naked siRNA was degraded when incubated for 60 min in serum, whereas the liposome/siRNA complexes were not (Figure 4). These results suggest that naked siRNA has a short half-life in vivo and is rapidly eliminated by renal excretion as a degraded form. However, further study is needed to clarify whether the excreted siRNA is in the intact form or degraded form. On the other hand, a part of the ^{18}F showed enterohepatic circulation. This enterohepatic circulation would be mediated by some of the fragmented siRNA having the polar moiety (the alkyl chain on the 3′ end of the antisense strand) and nonpolar moiety (siRNA).

As indicated above, the serum stability study showed that the liposomal siRNA was not degraded in the presence of serum. Furthermore, the ^{18}F distribution of liposomal [^{18}F]-labeled siRNA was similar to the distribution of the [^{3}H]-labeled liposome carrier: Both were accumulated in the lungs after intravenous administration. Taken together, our data strongly suggest that liposomal siRNA would be delivered to the lungs in its intact form. In conclusion, we developed a novel positron emitter-labeling methodology for siRNA and evaluated the in vivo trafficking of [^{18}F]-labeled siRNA by PPIS. The results of present study suggest that siRNA is stable as a complex with liposomes and should be deliverable specific tissues depending on the characteristics of the carrier. Therefore, designing the DDS carrier expands the usefulness of siRNA in vivo, and the present technology might support the development of siRNA medicines.

ACKNOWLEDGMENT

This study was financially supported by the Health and Labor Sciences Research Grants from the Ministry of Health, Labour, and Welfare of Japan. Synthesis of positron emitter-labeled siRNA was supported in part by Hokkaido System Science Co. Ltd. We thank Drs. T. Kakiuchi and H. Uchida at Hamamatsu Photonics K.K. PET Center for PET study for their technical assistance. They also thank Drs. S. Akai and T. Toyo'oka at the University Shizuoka for their valuable discussions as well as for allowing us to use their facilities. We also acknowledge Dr. S. Inagaki for helpful discussions and excellent technical assistance.

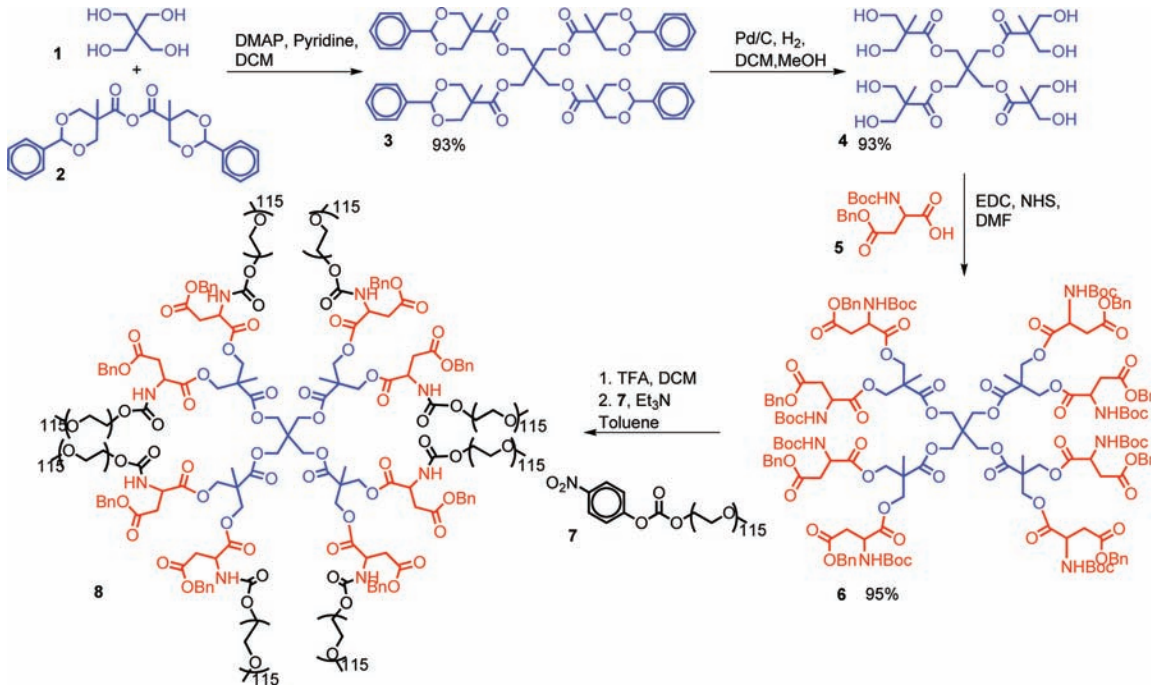
PEGylated dendrimers are attractive for biological applications due to their tunable pharmacokinetics and ability to carry multiple copies of bioactive molecules. The rapid and efficient synthesis of a robust and biodegradable PEGylated dendrimer based on a polyester−polyamide hybrid core is described. The architecture is designed to avoid destructive side reactions during dendrimer preparation while maintaining biodegradability. Therefore, a dendrimer functionalized with doxorubicin (Dox) was prepared from commercial starting materials in nine, high-yielding linear steps. Both the dendrimer and Doxil were evaluated in parallel using equimolar dosage in the treatment of C26 murine colon carcinoma, leading to statistically equivalent results with most mice tumor-free at the end of the 60 day experiment. The attractive features of this dendritic drug carrier are its simple synthesis, biodegradability, and versatility for application to a variety of drug payloads with high drug loadings.

INTRODUCTION

The use of macromolecular carriers for the delivery of chemotherapeutics originated from the hypothesis that polymers may be used to improve both the solubility and the blood circulation time of small molecule drugs (*1, 2*). It was later discovered that macromolecules have the additional benefit of increased accumulation in tumor tissue as a result of the leaky vasculature surrounding rapidly growing neoplasm—a concept known as the enhanced permeation and retention (EPR) effect (*3, 4*). Thus, macromolecular carriers can provide both enhanced pharmacokinetics and a passive targeting mechanism, characteristics that may be used to increase the efficacy of small molecule drugs. To this end, carrier systems such as linear polymers, micellar assemblies, liposomes, polymersomes, and dendrimers have been studied in an effort to identify an ideal drug carrier (*5*−*14*). Important design features (*9*) include a long blood circulation time, high tumor accumulation, high drug loading, low toxicity, low polydispersity index, and simple preparation. Considering the above criteria, PEGylated dendrimers (*15, 16*) constitute an attractive platform, because their size and degree of branching can be precisely controlled and they possess multiple functional appendages for the attachment of both drugs and solubilizing groups. Dendritic drug carriers based on polyesters (*17*−*19*), polyamines (*20, 21*), melamines or triazines (*22*−*24*), PAMAM (*25*−*30*), and other polyamides (*31*−*33*) have all been explored and recently reviewed (*14*). Polyesters constitute a very attractive class of materials because they are biodegradable; however, the hydrolytic susceptibility of the ester bond can make the synthesis of drug conjugates somewhat challenging. The hydrolysis rates of polyesters can vary dramatically depending on the hydrophobicity of the monomer, steric environment, and the reactivity of functional groups located within the dendrimer (*34*). In contrast, polyamide and polyamine dendrimers can withstand a much wider selection of synthetic manipulations, but they do not degrade as easily in the body and thus they may be more prone to long-term accumulation in vivo (*35*). Currently, challenges facing the biological application of dendrimers are their lengthy syntheses and the need to develop nontoxic, biodegradable dendrimers that are still resilient to the reaction conditions encountered during their synthesis and modification. As a result, accessing a universal, biodegradable, highly soluble, unimolecular carrier capable of achieving a high drug loading and low polydispersity has remained a challenge.

In recent studies, we have determined that a family of polyester-core dendrimer based on a 2,2-bis(hydroxymethyl) propanoic acid (bis-HMPA) monomer unit, typically functionalized with eight 5 kDa poly(ethylene glycol) (PEG) chains (*18*), is biocompatible and that it is capable of high drug loading while facilitating high tumor accumulation through its long circulation half-life. An asymmetric bis-HMPA PEGylated dendrimer functionalized with doxorubicin via a pH-sensitive acyl hydrazone bond demonstrated outstanding antitumor activity in mice bearing murine C26 colon carcinoma (*17*). Despite these promising in vivo results, further evaluation of this asymmetric carrier in biological models was slowed by its lengthy synthesis (*37*). Therefore, we sought to transpose the beneficial features (*9*) of this PEGylated dendrimer onto a simpler and more readily prepared carrier. Initial approaches involved simplified multifunctional dendrimers based on bis-HMPA (*38, 39*); however, some issues still remained, as undesired degradation of the polyester backbone was observed during the attachment of certain drugs.

Herein, we describe the design evolution of three dendrimers that resulted in the creation of a new PEGylated dendrimer, which circumvented the synthetic and biological limitations uncovered in previous studies. We report a very efficient synthesis that combines the biocompatibility of bis-HMPA dendrimers with the robustness of polyamide dendrimers, yielding a hybrid scaffold capable of translation into clinical studies.



MATERIALS AND METHODS

Materials. Materials were used as obtained from commercial sources unless otherwise noted. Poly(ethylene glycol) was purchased from Laysan Biosciences Inc. Amino acid derivatives

Scheme 1. Synthesis of Symmetrically PEGylated Dendrimer

were purchased from Bachem. Dimethylformamide (DMF), pyridine, and dichloromethane (DCM) for syntheses were purged 1 h with nitrogen and further dried by passing them through commercially available push stills (Glass Contour). Solvents were removed under reduced pressure using a rotary evaporator or by vacuum pump evacuation. Compounds **2**, **3**, **4** (*19*), **6**, **8**, **9** (*39*), **10** (*40*), **15**, **17**, **18**, and **19** (*41*) were synthesized according to published procedures.

Characterization. NMR spectra were recorded on Bruker AV 300, AVB 400, AVQ 400, or DRX 500 MHz instruments. Spectra were recorded in $CDCl_3$ or D_2O solutions and were referenced to TMS or the solvent residual peak and taken at ambient temperature. Elemental analyses were performed at the UC Berkeley Mass Spectrometry Facility. MALDI-TOF MS was performed on a PerSeptive Biosystems Voyager-DE using the following matrices: *trans*-3-indoleacrylic acid (IAA) for *tert*-butyloxycarbonyl (Boc) protected dendrimers; or 2,5-dihyroxybenzoic acid (DHB) for amine-terminated dendrimers. Samples were prepared by diluting dendrimer solutions (~1 M) 40-fold in 100 mM matrix solutions in tetrahydrofuran and spotting 0.5 μL on the sample plate. Size exclusion chromatography (SEC) was performed using one of three systems:

SEC System A: a Waters 515 pump, a Waters 717 auto sampler, a Waters 996 Photodiode Array detector (210−600 nm), and a Waters 2414 differential refractive index (RI) detector. SEC was performed at 1.0 mL/min in a PLgel Mixed B (10 μm) and a PLgel Mixed C (5 μm) column (Polymer Laboratories, both 300 × 7.5 mm), in that order, using DMF with 0.2% LiBr as the mobile phase and linear PEO (4200−478 000 MW) as the calibration standards. The columns were thermostatted at 70 °C.

SEC System B: The same equipment as System A, but performed at 1.0 mL/min in two SDV Linear S (5 μm) columns (Polymer Standards Service, 300 × 8 mm) using DMF with 0.2% LiBr as the mobile phase.

SEC System C: A Waters Alliance separation module 2695 (sample compartment maintained at 37.0 ± 3.0 °C), a Waters 410 differential RI detector, a Waters 996 photodiode array detector (λ = 486 nm), and a Shodex OHpak SB-804 HQ SEC column. An isocratic flow rate of 0.7 mL/min was used with a mobile phase composed of 70%/30%/0.05% water/acetonitrile/formic acid.

Doxorubicin loading was quantified using a Lambda 35 UV−vis spectrometer (PerkinElmer, Wellesley, MA). Measurements were performed in sealed, standard 1 cm quartz cells in Millipore water at room temperature.

Animal and Tumor Models. All animal experiments were performed in compliance with National Institutes of Health guidelines for animal research under a protocol approved by the Committee on Animal Research at the University of California (San Francisco, CA) (UCSF). C26 colon carcinoma cells obtained from the UCSF cell culture facility were cultured in RPMI medium 1640 containing 10% FBS. Female BALB/c mice were obtained from Simonsen Laboratories, Inc. (Gilroy, CA).

EA-G$_1$-Lys(Boc)$_8$ (22). Pentaerythritol (353 mg, 2.6 mmol), BocLys(Boc)-ONp (5.500 g, 11.8 mmol), and 4-dimethylaminopyridine (DMAP) (125 mg, 1.0 mmol) were added to a 20 mL reaction vial. Under a nitrogen atmosphere, DMF (5.5 mL) and triethylamine (1.6 mL, 11.5 mmol) were added and the reaction stirred for 48 h. MALDI-TOF analysis confirmed the reaction had gone to completion. *N,N*-Dimethylethylene diamine (300 μL, 4.1 mmol) was added to quench excess PNP esters. After 10 min, the mixture was diluted with ether (200 mL) and washed with three 100 mL portions of 1 M NaOH, three 100 mL portions of 1 M $NaHSO_4$, 100 mL DI water, and 100 mL of brine. The organic layer was dried over Na_2SO_4 and evaporated to dryness to give **22** (3.455 g, 93% yield) as a white foam. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.26−1.49 (m, 88H), 1.58−1.83 (m, 8H), 3.09−3.11 (m, 8H), 4.08−4.18 (m, 12H), 4.80 (s, 4H), 5.3−5.6 (br d, 4H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 22.5, 28.3, 28.4, 29.6, 31.5, 39.9, 53.4, 62.2, 79.0, 79.8, 155.7, 156.1. Calc $[M]^+$ ($C_{69}H_{124}N_8O_{24}$) m/z = 1448.87. Found MALDI-TOF $[M+Na]^+$ m/z = 1470.0.

EA-G$_1$-Lys(NH$_3$TFA)$_8$ (22a). Compound **22** (209 mg, 144 μmol) was dissolved in 1:1 trifluoroacetic acid (TFA)/DCM for 1 h. Quantitative deprotection was confirmed by MALDI-TOF analysis. The solvents were removed under reduced pressure to give **22a** as a gummy solid in quantitative yield. ^{1}H NMR

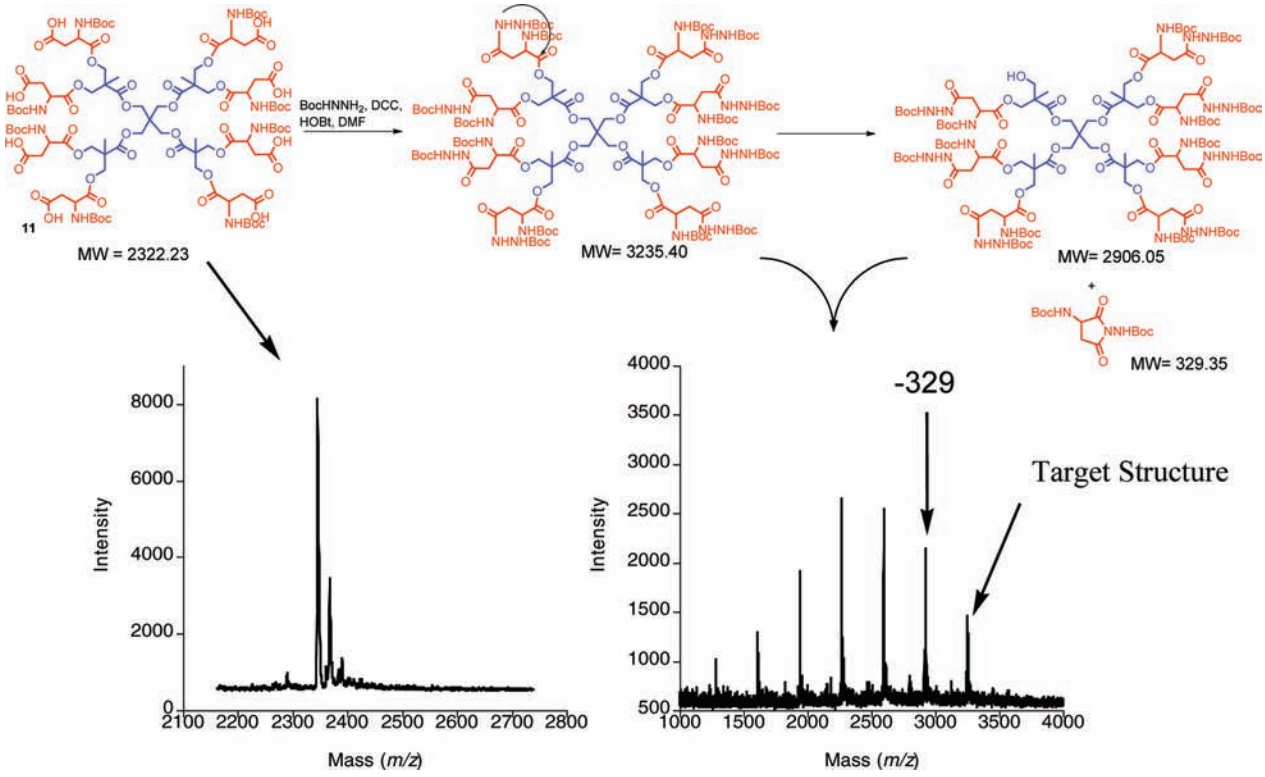

Figure 1. Proposed degradation pathway for polyester dendrimer.

(400 MHz, MeOD): δ 1.40−1.60 (m, 8H), 1.67−1.75 (m, 8H), 1.87−2.10 (m, 8H), 2.99 (t, J = 8 Hz, 8H), 4.21 (t, J = 6 Hz, 4H), 4.40 (s, 8H). ^{13}C NMR (100 MHz, MeOD): δ 21.8, 26.5, 29.5, 38.7, 42.5, 52.3, 62.9, 161.4, 161.7, 168.6. Calc $[M]^+$ ($C_{29}H_{60}N_8O_8$) m/z = 648.45. Found MALDI-TOF $[M+H]^+$ m/z = 649.6.

EA-G$_1$-Lys(Glu(Bn)Boc)$_8$ (24). Compound **22a** (89 mg, 63 μmol) and BocGlu(OBz)-ONp (290 mg, 632 μmol) were added to a 20 mL reaction vial. Under a nitrogen atmosphere, DMF (1 mL) and triethylamine (140 μL, 1.0 mmol) were added and the reaction was allowed to stir for 4 h. MALDI-TOF analysis showed a single peak corresponding to the fully functionalized dendrimer. *N,N*-Dimethylethylene diamine (50 μL, 690 μmol) was added to quench excess PNP esters. The reaction was diluted with ethyl acetate (100 mL) and washed with three 50 mL portions of 1 M $NaHSO_4$, three 50 mL portions of saturated K_2CO_3, 50 mL of DI water, and 50 mL brine. The organic layer was dried over Na_2SO_4 and evaporated to dryness to give **24** (171 mg, 87% yield) as a white foam. ^{1}H NMR (400 MHz, MeOD): δ 1.41−1.56 (bm, 96H), 1.60−1.75 (m, 4H), 1.70−2.13 (m, 16H), 2.25−2.40 (m, 4H), 2.44−2.51 (m, 12H), 2.58−2.61 (m, 4H), 3.10−3.20 (m, 8H), 4.09−4.25 (m, 12H), 4.35−4.40 (m, 4H) 5.08−5.09 (2s, 16H), 7.28−7.38 (m, 40H). ^{13}C NMR (100 MHz, MeOD): δ 23.8, 28.6, 31.5, 40.8, 44.6, 49.0, 54.4, 64.9, 163.4, 163.8, 170.7. Calc $[M]^+$ ($C_{165}H_{228}N_{16}O_{48}$) m/z = 3201.59. Found MALDI-TOF $[M+Na]^+$ m/z = 3223.3.

EA-G$_1$-Lys(Glu(Bn)NH$_3$TFA)$_8$ (24a). Compound **24** (100 mg, 31 μmol) was dissolved in 1:1 TFA/DCM for 1 h. Quantitative deprotection was confirmed by MALDI-TOF analysis. The solvents were removed under reduced pressure to give **24a** as a gummy solid in quantitative yield. ^{1}H NMR (400 MHz, MeOD): δ 1.19−1.35 (m, 16H), 1.45−1.65 (m, 8H), 2.04−2.20 (m, 16H), 2.38−2.46 (m, 8H), 2.51−2.63 (m, 8H), 2.89−2.93 (m, 4H), 3.09−3.12 (m, 4H), 3.89−3.96 (m, 12H), 4.11 (t, J = 4.4 Hz, 4H), 4.30−4.33 (m, 4H), 4.80−5.00 (m, 16H), 7.17−7.26 (m, 40H). ^{13}C NMR (100 MHz, MeOD): δ = 24.1, 27.7, 29.7, 30.3, 30.5, 31.6, 40.2, 53.5, 53.9, 54.1, 63.9, 67.8, 116.7, 119.6, 129.2, 129.3, 129.6, 137.3, 162.8, 163.2, 169.8, 170.3, 172.7, 173.6, 173.8. Calc $[M]^+$ ($C_{125}H_{164}N_{16}O_{32}$) m/z = 2402.73. Found MALDI-TOF $[M+Na]^+$ m/z = 2424.8.

EA-G$_1$-Lys(Glu(Bn)PEO)$_8$ (25). PNP-PEG carbonate (986 mg, 192 μmol) and **24a** (81 mg, 203 μmol NH_3) were added to a 20 mL reaction vial. Under a nitrogen atmosphere, DMF (3 mL) was added. After using a warm water bath to dissolve the starting material, triethylamine (120 μL, 0.863 mmol) was added. After stirring for 48 h (reaction monitored by SEC analysis), no further increase in the molecular weight was observed and the reaction was considered complete. Piperidine (50 μL, 0.506 mmol) was added to quench remaining PNP carbonate. After 1 h, acetic anhydride (400 μL, 4.24 mmol) was added to acylate any remaining primary amines on the dendrimer that had not reacted with the PNP-PEG carbonate. After stirring an additional hour, the reaction mixture was precipitated into ether (300 mL) and **25** (999 mg) was collected by filtration as a fluffy white solid. In some cases, residual 5 kDa PEG was observed after the PEGylation was considered complete. This could be removed by dialysis using 100 000 MWCO tubing against water for 24 h. ^{1}H NMR (500 MHz, D_2O): δ 1.20−1.80 (br m, 24H), 1.80−2.10 (br d, 16H), 2.35−2.55 (br s, 16H), 3.05−3.20 (br s, 8H), 3.38 (s, 24H), 3.40−3.90 (br m, ∼3900H), 4.00−4.40 (br m, 36H), 5.09−5.15 (br s, 16H), 7.25−7.40 (br m, 40H). DMF SEC: M_n: 32 000 Da, M_w: 35 000 Da, PDI: 1.09.

EA-G$_1$-Lys(GluPEO)$_8$ (25a). Compound **25** (402 mg, 10.1 μmol) was added to a 20 mL reaction vial and dissolved in MeOH (9 mL). Activated Pd/C (10 wt %, 50 mg) was added and the reaction put under hydrogen atmosphere. The reaction was stirred overnight, then filtered and solvent removed via rotary evaporation to give **25a** (387 mg) as a white solid. ^{1}H NMR (500 MHz, D_2O): δ 1.20−1.80 (br m, 24H), 1.80−2.1 (br d, 16H), 2.40−2.51 (m, 16H), 3.15−3.25 (br s, 8H), 3.38 (s, 24H), 3.40−3.90 (br m, ∼3900H), 4.00−4.40 (br m, ∼36H).

EA-G$_1$-Lys(Glu(NNBoc)PEO)$_8$ (26). Compound **25a** (710 mg, 142 μmol COOH), *t*-butyl carbazate (94 mg, 711 μmol), and DMAP (10 mg, 81 μmol) was added to a 20 mL reaction

vial. Under a nitrogen atmosphere, DCM (8 mL) was added dropwise. The solution was cooled to 0 °C followed by the addition of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) (136 mg, 709 μmol). The reaction was allowed to warm to room temperature and stirred overnight. The reaction was dialyzed against MeOH in 12 kDa−14 kDa MWCO dialysis with 3 solvent changes over 18 h. Concentration of the bag contents in vacuo gave **26** (660 mg) as a white solid. ^{1}H NMR (500 MHz, D_2O): δ 1.30−1.60 (br m, 100H), 1.65−2.20 (br m, 20H), 2.30−2.45 (br s, 16H), 3.15−3.25 (br s, 8H), 3.38 (s, 24H), 3.50−3.90 (br m, ∼3900H), 4.00−4.45 (br m, 40H).

EA-G$_1$-Lys(Glu(NNH$_3$TFA)PEO)$_8$ (26a). Compound **26** (102 mg) was dissolved in 1:1 TFA/DCM for 1 h. The solvents were removed under reduced pressure to give 100 mg of **26a** as a gummy solid. ^{1}H NMR (500 MHz, D_2O): δ 1.15−1.80 (br m, 24H), 1.85−2.00 (br m,16), 2.05−2.15 (br m, 16H), 2.15−2.25 (br m, 16H), 3.05−3.15 (br s,8H), 3.38 (s, 24H), 3.50−3.90 (br m, ∼3900H), 4.00−4.45 (br m, 40H).

EA-G$_1$-Lys(Glu(NNDox)PEO)$_8$ (27). Compound **26a** (72 mg, 14 μmol NNBoc) and doxorubicin (50 mg, 92 μmol) were added to a 20 mL reaction vial and were dissolved in MeOH (3 mL), pyridine (100 μL), and acetic acid (100 μL). The reaction was purged with nitrogen and stirred at 60 °C in the dark for 18 h. The reaction mixture was loaded directly onto a Sephadex LH-20 column and eluted with methanol. The first dark red band was collected and the solvent removed by rotary evaporation. The solid material was further purified using a Biorad PD-10 column with water as the eluent. After lyophilization, 67.2 mg of red powder remained. The Dox loading was quantified using the absorbance at 486 nm (ε = 11 500) (*42*) to be 9.6 wt %, or 88% of the maximum theoretical loading.

Polymer Degradation Study. Compound **26** (20 mg) was dissolved in 1.5 mL of 1× PBS buffer and incubated at 37 °C. At t = 0, 1, 2, 3, 6, 15, and 20 days, 100 μL aliquots were taken out and immediately frozen followed by lyophilization. At the end of the experiment, each sample was dissolved in 0.5 mL DMF from the System A mobile phase, filtered though a 0.2 μm PVTF filter, and measured by the RI detector on system A.

Hydrolysis of Dox from Compound 27 at pH 7.4 and pH 5. Drug release rates were determined by a modified published procedure (*43*). Compound **27** was dissolved in either 1× PBS or pH 5 acetate buffer (30 mM with 70 mM $NaNO_3$), at 1 mg/mL. Buffers were preheated to 37 °C before dissolving polymer and maintained at this temperature throughout the experiment. At each time point, 25 μL was injected onto SEC system C for analysis.

Cytotoxicity Studies in Cells. The cytotoxicities of free Dox, **26**, and **27** were determined by using the MTT assay with C26 cells. Cells were seeded onto a 96-well plate at a density of 5.0 × 10^3 cells per well in 100 μL of medium and incubated overnight (37 °C, 5% CO_2, and 80% humidity). An additional 100 μL of new medium (RPMI medium 1640, 10% FBS, 1% penicillin−streptomycin, 1% Glutamax) containing varying concentrations of Dox, **26**, or **27** were added to each well. After incubation for 72 h, 40 μL of media containing thiazolyl blue tetrazolium bromide (5 mg/mL) was added. The cells were incubated for 3 h, after which time the medium was carefully removed. To the resulting purple crystals was added 200 μL of DMSO and 25 μL of pH 10.5 glycine buffer (0.1 M glycine/0.1 M NaCl). Optical densities were measure at 570 nm by a SpectraMAX 190 microplate reader (Molecular Devices, Sunnyvale, CA). Optical densities measured for wells containing cells that received neither dendrimer nor drug were considered to represent 100% viability. IC_{50} values were obtained from sigmoidal fits of the data using *Origin 7* SR4 8.0552 software (OriginLab, Northampton, MA).

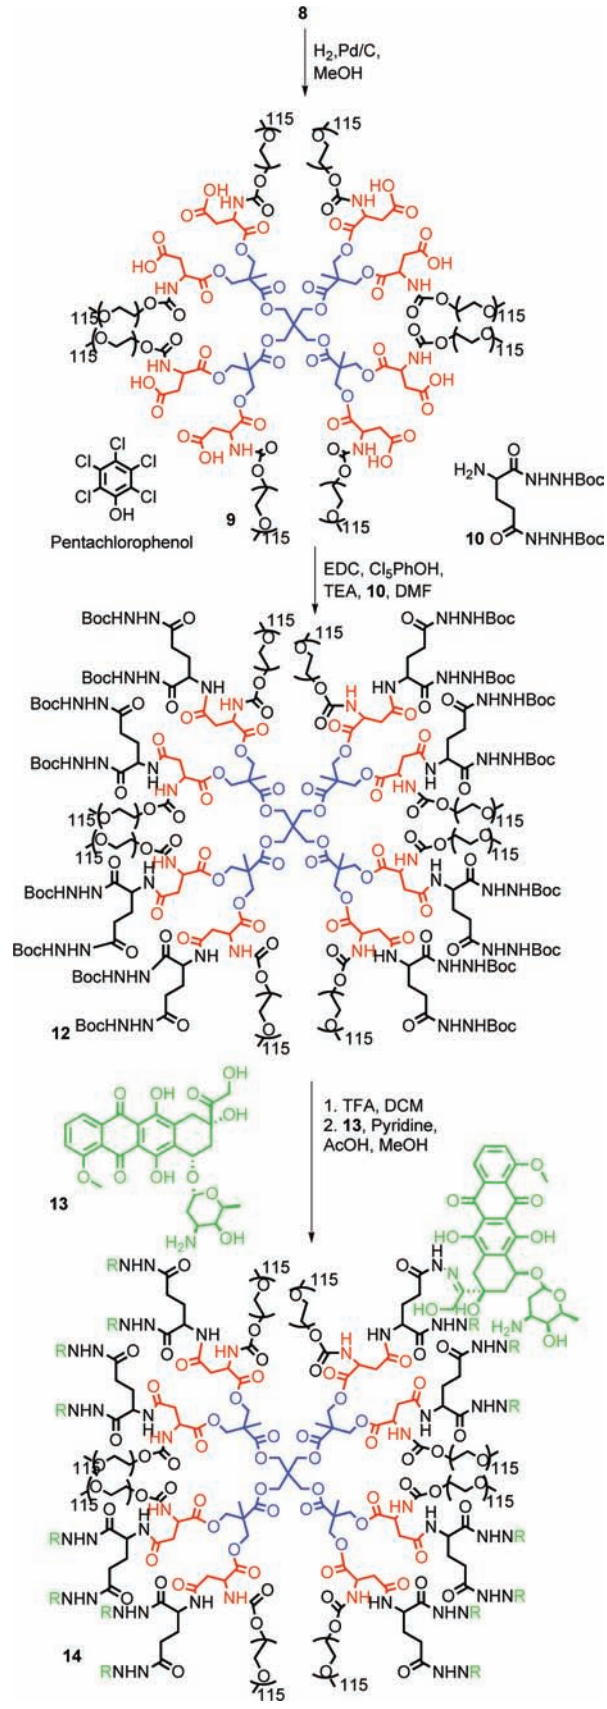
Biodistribution Study in Xenograph Mice. Six- to eight-week-old female Balb/C mice were injected in the right hind flank with 3 × 10^5 C26 cells. Twelve days after tumor inoculation, mice were randomized into two groups. Mice were injected by means of the tail vein either with Doxil (8 mg Dox eq/kg; 3 mice) or with **27** (8 mg Dox eq/kg; 6 mice) in ∼200 μL of PBS. Blood was collected from half of the mice injected with polymer by submandibular bleeds 60 and 1440 min after dosing (data not shown); after 2880 min, the three mice were sacrificed. The remaining six mice were sacrificed at 1 wk postinjection. The blood (collected by heart puncture), heart, liver, spleen, kidney, muscle, and tumor were collected for analysis. Each organ was weighed and 200−300 mg of the collected organs were homogenized with zirconium beads and 1 mL acidified isopropyl alcohol (0.075 M HCl, 90% IPA). The samples then incubated at 4 °C for 24 h. Serum was collected using Microtainer serum separator vials and processed in the same manner as the organs. The samples were frozen in a −80 °C freezer until measurements could be made. At measurement time, samples were thawed, briefly vortexed, and centrifuged for 3 min at 8000 rpm. Then, 80 μL of supernatant was combined with 920 μL of acidified IPA for fluorescence measurements. Dox fluorescence (excitation 490 nm; emission 590 nm) was measured on a PTI fluorimeter (Birmingham, NJ). Calibration curves were made from organ samples collected from an untreated mouse.

Chemotherapy Experiments. While under anesthesia, female Balb/C mice were shaved, and C26 cells (3 × 10^5 cells in 50 μL) were injected subcutaneously in the right-hand flank. At eight days post-tumor implantation, mice were randomly distributed into treatment groups of 10 animals. Mice were injected by means of the tail vein with Doxil (20 mg Dox/kg) or **27** (10, 15, and 20 mg Dox/kg) in approximately 200 μL of solution. Mice were weighed and tumors measured every other day. The tumor volume was estimated by measuring the tumor volume in three dimensions with calipers and calculated using the formula tumor volume = length × width × height. Mice were removed from the study when (i) a mouse lost 15% of its initial weight, (ii) any tumor dimension was >20 mm, or (iii) the mouse was found dead. The mice were followed until day 60 post-tumor inoculation. Statistical analysis was performed as previously described (*41*) using *MedCalc 8.2.1.0* for Windows (MedCalc Software, Mariakerke, Belgium). The tumor growth delay was calculated based upon a designated tumor volume of 400 mm^3.

RESULTS AND DISCUSSION

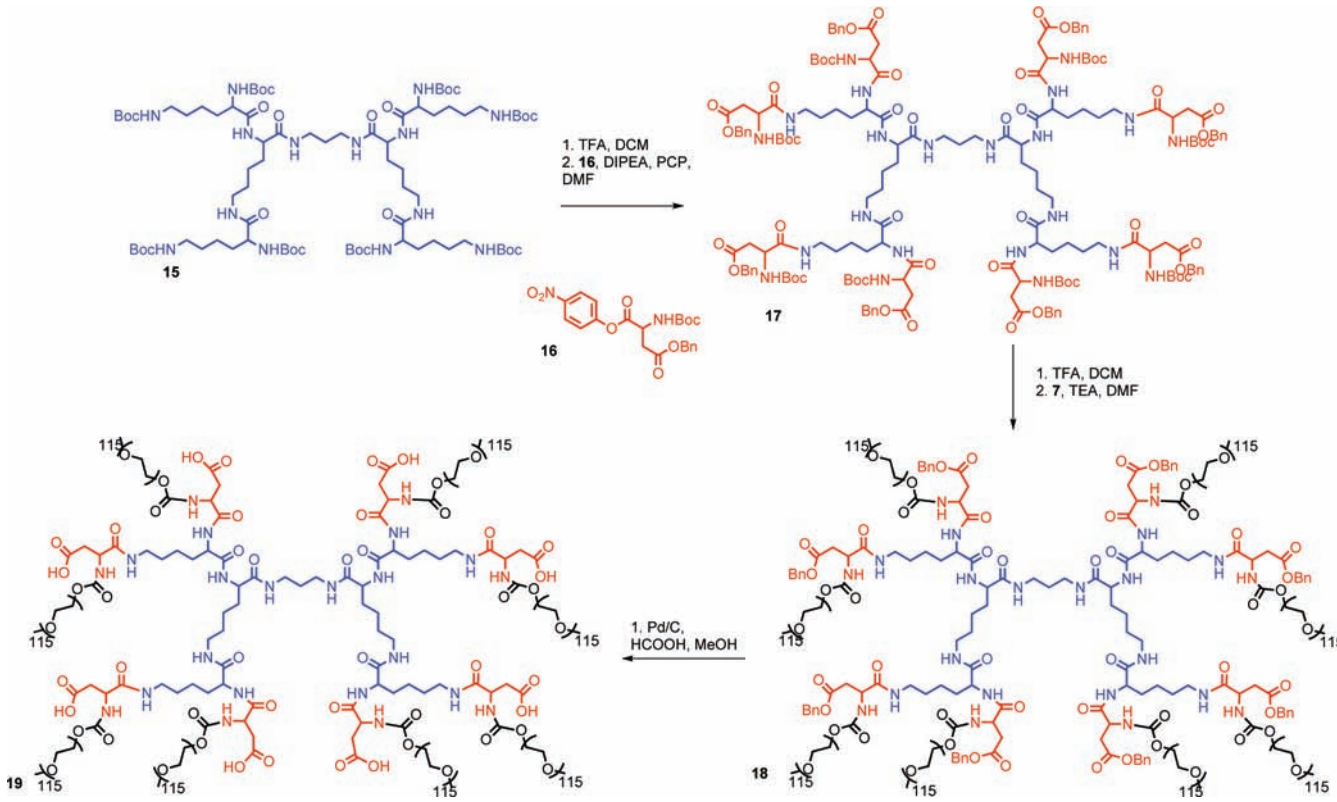
Exploring Polyester-Core Dendrimers. Polyester dendrimers based on bis(HMPA) monomer units are an attractive scaffold for biological applications because they are nonimmunogenic, biodegradable, and nontoxic (*36*). Scheme 1 outlines the synthesis of a core-functionalized PEGylated dendrimer we have developed earlier (*39*). Briefly, the tetrafunctional pentaerythritol core **1** was modified with a benzylidene-protected bis(HMPA) monomer **2** to afford the first-generation dendrimer **3**. After removal of the protecting groups via hydrogenolysis, the eight peripheral hydroxyl groups were functionalized with orthogonally protected aspartic acid to give **6**. Subsequent deprotection of the amino groups of **6** followed by PEGylation with the 5 kDa PEG electrophiles gave dendrimer **8**. Removal of the benzyl ester protecting groups of **8** via hydrogenolysis afforded dendrimer **9** with eight carboxylic acids moieties available for potential drug attachment. However, early attempts at the functionalization of this dendrimer with *t*-butyl carbazate or glutamic acid derivative **10** were unsuccessful as degradation of the dendrimer was observed during this reaction.

In order to gain insight into the degradation pathway, we prepared the dendrimer probe **11** and attempted to functionalize



its aspartic acid chain-ends with *t*-butyl carbazate. Probe molecule **11** was selected instead of PEGylated dendrimer **9** as progress of its reaction could be more easily monitored by MALDI-TOF since it does not contain PEG chains (Figure 1). As a result of a degradation side reaction, only a small amount of the target product was formed, leading to the appearance of lower molecular weight products with molecular weights that decreased in increments of 329 amu, likely as a result of intramolecular cyclization reactions as proposed in Figure 1. This type of cyclization reaction on benzyl ester-protected aspartic acid residues is documented in the peptide literature and additives have been developed to suppress such reactions (*44*). For example, pentachlorophenol (PCP) has been used to decrease the production of the aminosuccinyl byproduct by inhibiting amide deprotonation. Under these buffered conditions, the primary amines are still available to react with *p*-nitrophenyl (PNP) carbonates and other electrophiles. The use of PCP as an additive proved beneficial in our hands as it allowed the functionalization of the carboxylic acid side chains of dendrimer **9** with protected nucleophile**10** to give dendrimer **12** (Scheme 2). Finally, doxorubicin hydrazone conjugate **14** was obtained after removal of the Boc groups from the hydrazide linkers in **12** and condensation of the resulting amines with the ketone group of doxorubicin **13**. In order to determine how rapidly this polyester architecture breaks down under physiological conditions, **12** was incubated in PBS buffer at 37 °C and the evolution of its molecular weight with time was monitored by SEC. This revealed that the α-amino esters located did not survive long enough for use of **12** in vivo as significant degradation was observed after only 10 h. For this reason, we began exploring alternative dendrimer scaffolds based on more robust polyamide cores.

Exploring Polylysine-Core Dendrimers. In contrast to polyester dendrimers, polyamide dendrimers are less susceptible to hydrolysis, but this increased stability may hamper their break down in vivo. Recently, Fox et al. functionalized a PEGylated polylysine with camptothecin and observed 100% survival in transgenic mice with HT-29 human colon carcinoma over a 70 day experiment (*41*). While the degradation of amide bonds in linear peptides in vivo is well established, the fate of branched, acylated, and PEGylated polyamide dendrimers is less certain as proteases may not be able to access amide bonds near the core of the structure. However, even slow or incomplete degradation of the carrier may be permissible for drug delivery applications if the byproduct are nontoxic and small in size (*45, 46*). In order to apply the polylysine carrier used by Fox (*41*) to the delivery of doxorubicin, dendrimer **18** with a protected hydrazide had to be prepared.



Lysine dendrimer **15**, first described by Denkewalter (*47*) in 1982, was used as the starting material. Its peripheral amines were acylated with PNP-Asp(Bn)Boc to afford dendrimer **17** (Scheme 3). It is worth noting that the PCP additive was also needed when attaching aspartic acid to the G_2 lysine periphery. Otherwise, a five-membered amino succinyl byproduct can form via amidolysis of the benzyl ester protected side chain. Deprotection of the amino groups of the aspartate termini and PEGylation with PEG-*p*-nitrophenyl carbonate afforded **18**. Unfortunately, the coupling of *t*-butyl carbazate to the deprotected side chain carboxylic acid terminal moieties (*19*) led to the appearance of degradation byproducts such as **20** (Figure 2). Monitoring of the reaction by size exclusion chromatography (Figure 2) showed the formation of lower molecular weight by products—presumably formed as a result of attack of the hydrazide nitrogens onto the carbamate linkers to PEG, thus forming a six-membered cyclic byproduct and releasing PEG.

This side reaction could be circumvented in two ways (see Supporting Information): (i) replacement of the carbamate in **18** with a more stable amide linkage by using carboxymethyl terminated PEG instead of a PNP carbamate; or (ii) use of a glutamic acid spacer between the nucleophilic hydrazides and the relatively labile carbamate linkages to PEG. The latter route requires more synthetic operations, but has the added benefit

Scheme 2. Linker Attachment and Dox Loading

Scheme 3. PEGylated Polylysine Synthesis

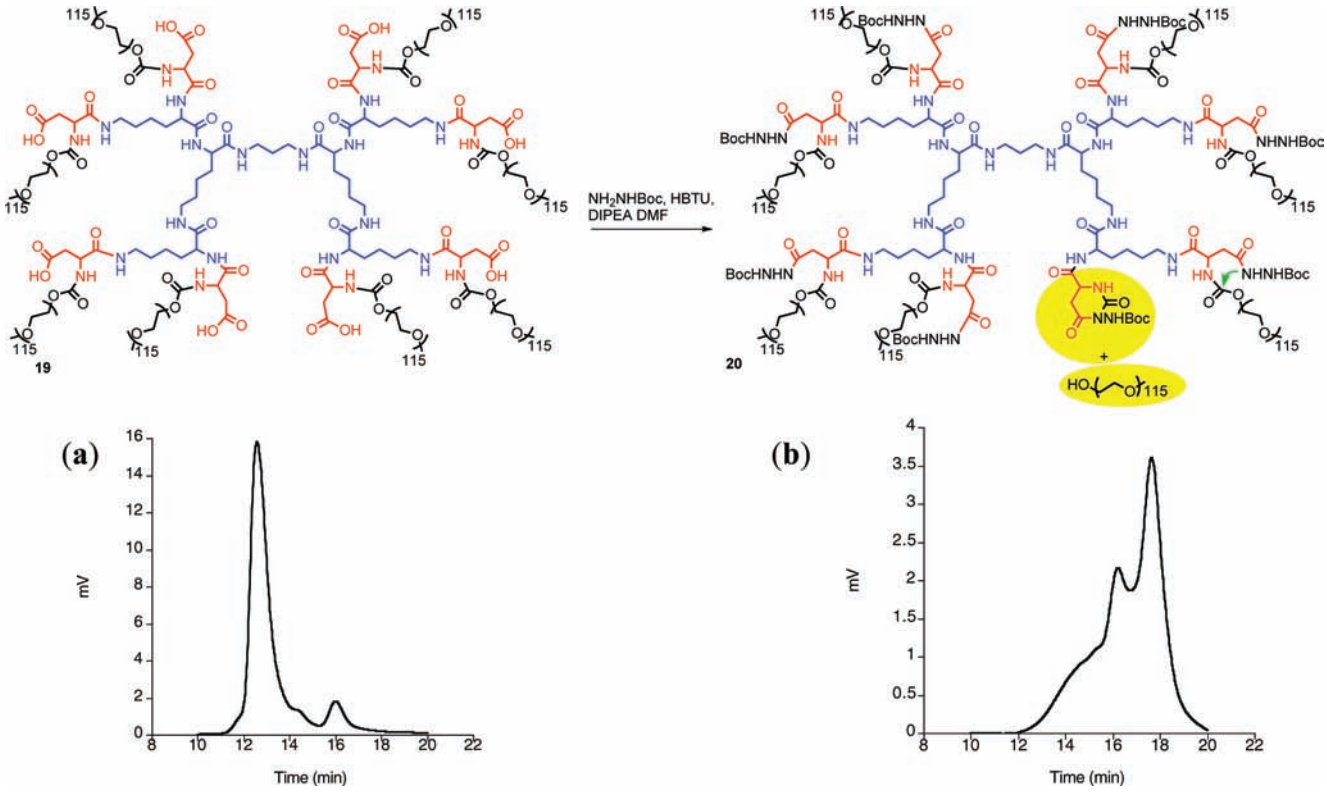
of doubling the number of hydrazides through which drug molecules can be attached. Overall, while feasible, this route did not fully meet our criteria for an optimized dendritic drug carrier.

Exploring Hybrid Ester-Amide-Core Dendrimers. The important lessons learned from the synthesis of both the polyester and polyamide carriers ultimately led us to consider a hybrid approach that combines their separate virtues in one scaffold. It appears that the combination of a hydrolytically degradable ester core and a more chemically resistant amide periphery might be ideal for the construction of PEGylated drug conjugates. Furthermore, the early designs we tested (vide supra) also underscored the importance of avoiding the positioning nucleophilic sites at a 5- or 6-atom distance from potential leaving groups (*43*). Hybrid dendrimer **24** (Scheme 4), representing such an architecture was obtained in three simple steps and 81% overall yield without any chromatographic purification.

Synthesis of the hybrid carrier began by treatment of pentaerythritol **1** with the *p*-nitrophenyl ester of lysine **21** (Scheme 4). The amine protecting groups of the resulting dendrimer **22** were then removed and the molecule was provided with "differentiated end functionalities" by reacting each of its eight primary amino groups with orthogonally protected PNP-glutamic acid **23**. Glutamic acid was selected over aspartic acid for the following reasons: (i) pentachlorophenol was no longer needed to prevent amidolysis of the benzyl ester group, since formation of the 6-membered amino succinyl byproduct was not observed; and (ii) *t*-butyl carbazate could be attached directly to the glutamic acid side chain without any degradation as cyclization of the acyl hydrazide onto the carbamate to form a seven-membered ring was not an issue. Eight 5 kDa PEG chains were then installed on the dendrimer periphery via a carbamate linkage. This was accomplished by quantitative removal of the Boc protecting groups and subsequent PEGylation with 1 equiv (per amine) of PNP-PEG (Scheme 4). The PEGylation reaction was extended over two days, at which time, piperidine was added to quench any unreacted PNP-PEG, and then acetic anhydride was added to acylate any remaining primary amines on the dendrimer scaffold. The resulting PEGylated dendrimer **25** was purified via precipitation into ether to give a polymer with MW ~40 000 Da and PDI < 1.1, with an average particle size of 12 nm as determined by dynamic light scattering (DLS). Finally, residual linear PEG could be removed by dialysis using 100 000 MW cutoff dialysis tubing in water.

The benzyl ester protected side chains of the glutamic acid moieties in **25** were removed via hydrogenolysis, and the resultant carboxylic acids were treated with *t*-butyl carbazate and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) to give dendrimer **26** with eight protected hydrazides available for drug attachment. Finally, target drug conjugate **27** was successfully obtained from the protected precursor **26** by removal of the Boc groups and subsequent condensation with doxorubicin in 5% pyridine/acetic acid solution of methanol at 60 °C.

The degradation profile of the ester-amide dendrimer hybrid was evaluated under physiological conditions. Polymer **26** was incubated at 37 °C in phosphate buffer at physiological pH and the molecular weight was monitored over 20 days by size exclusion chromatography (Figure 3a). As expected, the polymer degraded into 10 kDa and 5 kDa fragments as a result of the slow hydrolysis of both ester and carbamate moieties. Given that the threshold for renal clearance for linear polymers is estimated to be near 45 000 Da (*48*), cleavage of the 40 000 Da branched polymer following delivery of its payload contributes to prevent its long-term accumulation. The observed degradation profile is promising, as it suggests that hybrid dendrimer **26** is sufficiently stable to allow for selective tumor uptake, yet can be eventually broken down and cleared (*9*). It is also noteworthy that the drug is attached to a narrow population of polymeric material and that no significant amount of free drug is present as confirmed by the absence of a peak corresponding to free drug at 590 nm in the UV−vis trace of the conjugate (Figure 3b).



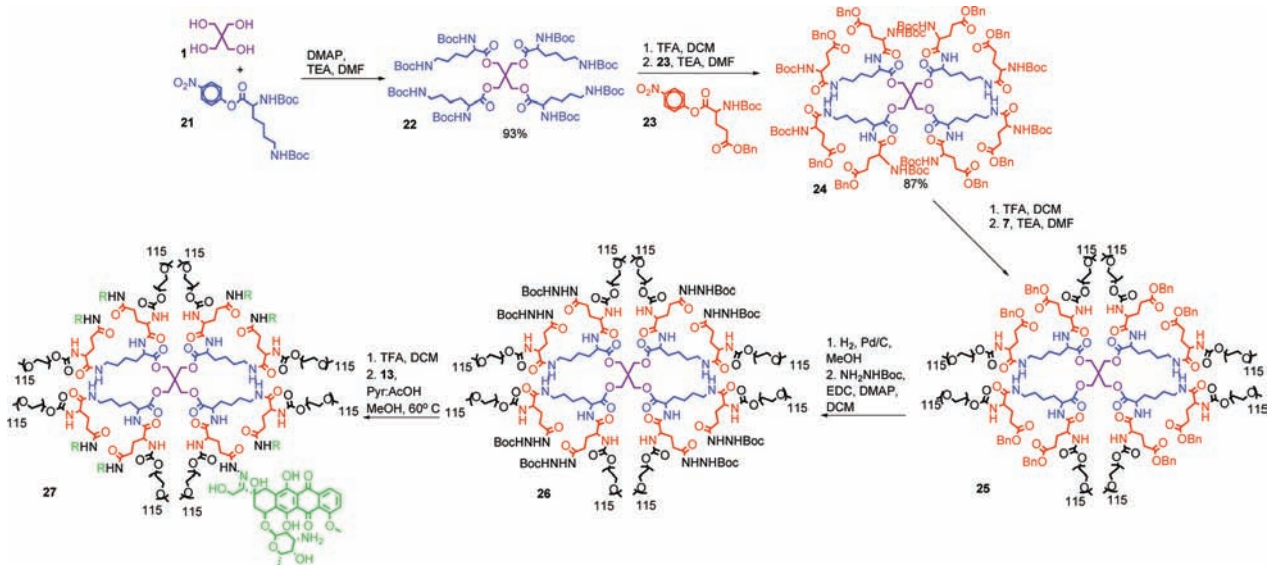


Figure 2. PEGylated polylysine degradation: (a) SEC of compound **19**, (b) SEC of reaction mixture with byproduct **20**.

Scheme 4. Synthesis of Drug Loaded PEGylated Ester-Amide Dendrimer

Carrier drug loading was determined via UV−vis spectroscopy and could be varied from 6−10 wt/wt% depending on how many equivalents of doxorubicin were used in the loading step. This correlates to 55−92% of the theoretical maximum doxorubicin loading for a ~40 kDa polymer with 8 sites for drug attachment. Doxorubicin was chosen for attachment because it is a well-established and highly effective chemotherapeutic agent (*49*) that can benefit from conjugation to a carrier to decrease its innate cardiotoxicity. It is important to note that a variety of drugs, prodrugs, or other biological agents may potentially be attached to dendritic carriers based on **25** through its latent carboxylic acid side chains. The pH-dependence for the rate of hydrolysis of the hydrazone bond we formed is well-studied (*43, 50, 51*), and we could confirm that the drug would be selectively released under acidic conditions similar to those found in the lysosome (*43*). At pH 7.4, less than 5% of drug was released over 48 h, while the half-life of hydrolysis at pH 5 was 22 h.

In Vitro Toxicity of Ester-Amide Dendrimer. The in vitro cytotoxicity tests showed that **26** remained nontoxic toward C26 cells at a concentration of 5 mg/mL. When Dox was conjugated to the carrier, a 10-fold decrease in toxicity was observed over the free Dox ($IC_{50(27)}$ = 529.6 ± 3.8 nM; $IC_{50(Dox)}$ = 52.4 ± 12.7 nM). The decrease in toxicity may be attributed to the slower rate of uptake of the ester-amide carrier compared to free Dox and the slow hydrolysis of the drug from the carrier.

Biodistribution in Tumored Mice. The biodistribution of the ester-amide dendrimer was determined in C26 tumored female Balb/C mice (Figure 4). Mice were injected with 8 mg Dox eq/kg, formulated as Doxil or **27**. After 48 h, Dox

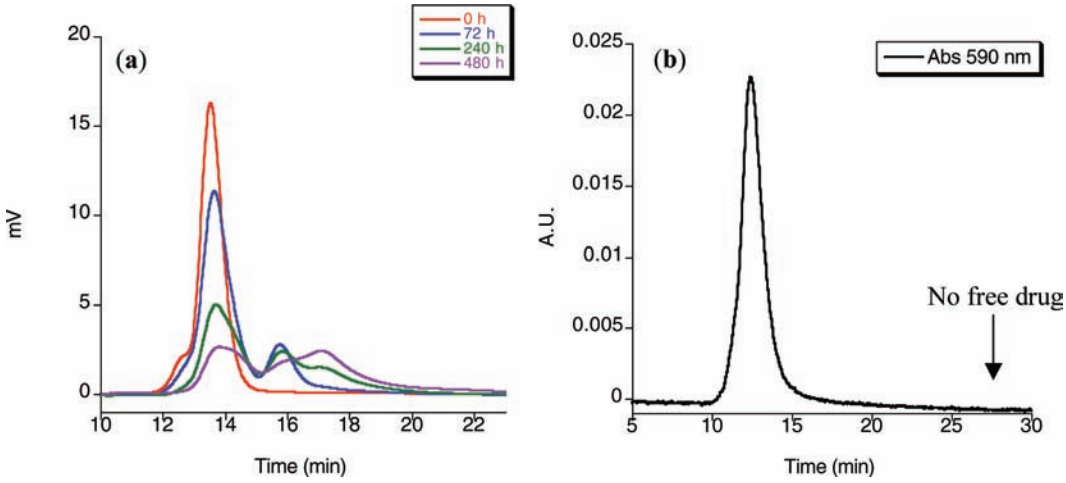

Figure 3. (a) Size exclusion chromatographs of **26** in pH 7.4 PBS buffer at 37 °C. (b) UV−vis size exclusion chromatograph of **27** at 590 nm.

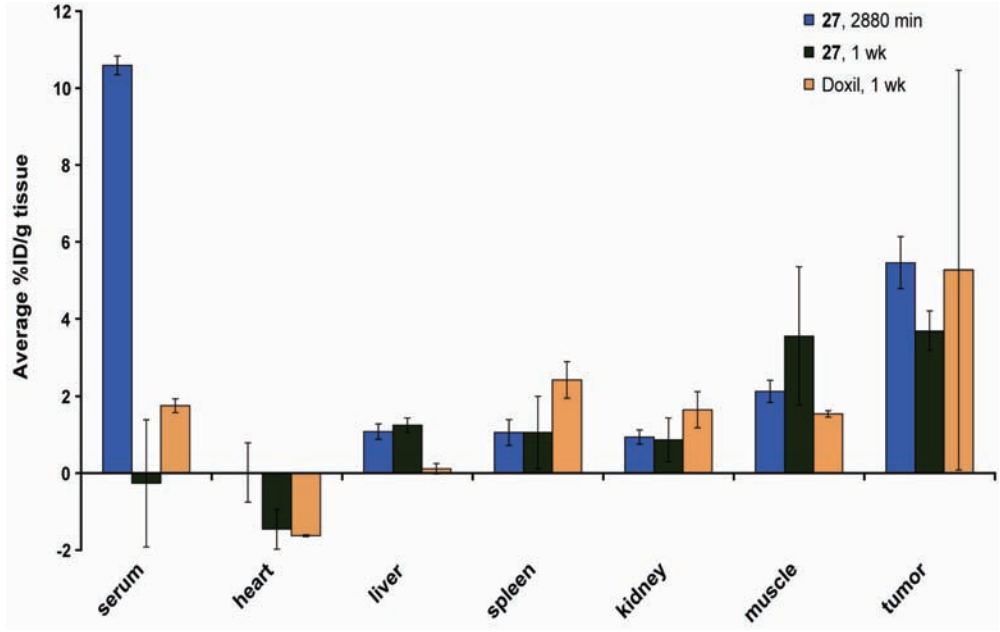

Figure 4. 48 h and 1 week biodistribution of **27** and 1 week biodistribution of Doxil in mice with s.c. C26 colon carcinoma.

accumulation within the tumor was 5.5 ± 0.7% ID/g of tissue (compared to vital organs, $p < 0.001$), whereas accumulation in the vital organs was less than 2% ID/g of tissue. This result is comparable to the levels of accumulation we have previously observed for related macromolecules (*36, 39*). Furthermore, we were pleased to find a measurable level of Dox still remained within the tumor tissue (compared to vital organs, $p < 0.05$) after one week with little accumulation within the vital organs. Mice injected with **27** or Doxil had comparable tumor accumulation after one week, 3.7 ± 0.51% ID/g of tissue and 5.27 ± 5.19% ID/g of tissue respectively. The ester-amide dendrimer showed lower accumulation within the spleen than Doxil. Lowering Dox accumulation in the vital organs is important for reducing systemic toxicity, while uptake by tumor tissue must be maintained to promote treatment efficacy.

Chemotherapy Study in Tumored Mice. A dose−response experiment was performed in C26 tumored Balb/C mice; four treatment groups were investigated, Doxil (20 mg Dox/kg) and **27** (10, 15, and 20 mg Dox/kg). Dose-dependent survival was observed and all three groups treated with **27** showed significant tumor growth delay (TGD) and prolonged survival (Table 1, Figure 5). Mice treated with **27** at 20 mg Dox/kg had 9 out of 10 mice tumor free at the end of the study (day 60), with TGD of 229% ($p < 0.0001$) and median survival time of 60 days. For **27** administered at 15 mg Dox/kg and 10 mg Dox/kg, the treatment groups had 175% ($p < 0.0001$) and 74% TGD ($p < 0.0001$) and a median survival time of 60 and 33 days, respectively. Doxil had 8 out of 10 mice alive at day 60, but the two deaths appeared to be due to treatment-related toxicity. Weight loss due to treatment toxicity was on average not severe, with a mean weight loss of 6.4% for Doxil and 4.3% for **27** (20 mg Dox/kg). This result is comparable to the chemotherapy experiment with the asymmetrically PEGylated dendrimer vs Doxil, both administered at 20 mg Dox/kg (*17*). In this earlier study, there was complete tumor regression with the asymmetrically PEGylated dendrimer carrier with a single toxic death observed in the parallel Doxil experiment. Therefore, both the current and the earlier studies confirm that Dox-loaded PEGylated dendrimer carriers are as effective as Doxil against the C26 tumor model. The ester-amide dendrimer **27** may exhibit less toxicity than Doxil at equivalent Dox dosages and its biodegradability, streamlined synthesis, and facile

Table 1. In Vivo Efficacy of Ester Amide Dendrimer Conjugate and Controls against Balb/C Mice with C26 Colon Carcinoma[a]

storage as a dry powder offer significant advantages over existing treatments.

CONCLUSION

In conclusion, the attractive features of polyester and polyamide dendrimers have been combined to form a robust yet degradable polyvalent macromolecular scaffold that can be prepared in a scalable fashion. The final drug-loaded dendrimer is made entirely from commercial starting materials in nine high-yielding steps, four of which are near-quantitative deprotection steps. No chromatographic steps are required during the dendrimer preparation. This scaffold will be studied with additional tumor models and drugs as it shows promise as a clinically relevant delivery vehicle.

Received December 30, 2009; Revised Manuscript Received February 17, 2010

Despite increasing interest in cell-penetrating peptides (CPPs) as carriers for drugs and in gene therapy, the current understanding of their exact internalization mechanism is still far from complete. The cellular translocation of CPPs and their payloads has been mostly described by fluorescence- and activity-based methods, leaving the more detailed characterization at the ultrastructural level almost out of attention. Herein, we used transmission electron microscopy to characterize the membrane interaction and internalization of a cell-penetrating peptide $S4_{13}$-PV. We demonstrate that $S4_{13}$-PV peptide forms spherical nanoparticle-like regular structures upon association with cell surface glycosaminoglycans on the plasma membrane. Insertion of $S4_{13}$-PV particles into plasma membrane induces disturbances and leads to the vesicular uptake of peptides by cells. We propose that for efficient cellular translocation $S4_{13}$-PV peptides have to assemble into particles of specific size and shape. The spherical peptide particles are not dissociated in intracellular vesicles but often retain their organization and remain associated with the membrane of vesicles, destabilizing them and promoting the escape of peptides into cytosol. Lowering the temperature and inhibition of dynamins' activity reduce the internalization of $S4_{13}$-PV peptides, but do not block it completely. Our results provide an ultrastructural insight into the interaction mode of CPPs with the plasma membrane and the distribution in cells, which might help to better understand how CPPs cross the biological membranes and gain access into cells.

INTRODUCTION

Cell-penetrating peptides (CPPs) [1]constitute an expanding peptide family with a common denominator—the ability to cross biological membranes and gain access into living cells. These peptides have been applied to drag various molecules into cells, like siRNA (*1, 2*), PNA oligomers (*3, 4*), peptides (*5*), proteins (*6, 7*), plasmids (*8*), and bigger particles (*9–11*). Although the mechanism of CPP cellular uptake is far from being fully understood yet, their potential to target cargo molecules into cells has been widely appreciated and used. Nevertheless, unraveling of the uptake mechanism of CPPs is of high importance for both achieving the specific targeting and increasing the biological response, i.e., the activity of delivered cargo in the cellular interior.

Initially, the internalization of CPPs was suggested to occur by direct translocation across the plasma membrane and not by receptor-mediated endocytosis. After the discovery of artifactual redistribution of membrane-associated CPPs into cells and nucleus upon fixation, the "endocytosis only" concept was introduced, and ideas about passage of peptides directly across the plasma membrane were neglected (*12, 13*). Experiments in living nonfixed cells implicated the involvement of different endocytic pathways in the internalization of CPPs and their conjugates: clathrin-mediated endocytosis (*14*), lipid raft/caveolae-mediated endocytosis (*15, 16*), and macropinocytosis (*17, 18*). However, a number of recent studies demonstrated the switching between different cellular distribution patterns of CPPs (from the punctuate/vesicular to the diffuse/uniform characteristic to penetration mechanism) in response to the shift of experimental conditions, like the concentration of CPP, the temperature, and the size of cargo (*5, 19–21*). Currently, CPPs are considered to use a combination of multiple mechanisms for cell entry—direct translocation and endocytosis.

Due to the high positive charge, CPPs interact electrostatically with the negatively charged extracellular matrix, probably glycosaminogycans (GAG) at the cell surface. Membrane-associated heparan sulfate containing proteoglycans has been shown to be a primary interaction site of CPPs with the plasma membrane mediating their uptake by cells (*14, 18, 22, 23*). Moreover, recent investigations indicate that cationic peptides reorganize the extracellular matrix and the binding of CPPs to the negatively charged GAGs induces their clustering at the surface of cells thereby stimulating the endocytotic uptake of formed aggregates (*24, 25*). Although it is generally appreciated that GAGs are essential for cellular translocation of CPPs, information about other anionic molecules, which are also suggested as possible uptake mediators of CPPs, is still lacking.

In our study, we focused on the $S4_{13}$-PV peptide, its interaction with the cell surface, and translocation into cells. $S4_{13}$-PV is a chimeric CPP that contains a 13 amino acid sequence derived from dermaseptin S4 and the nuclear localization signal

of the simian virus 40 (SV40) large T antigen (*26*). We have previously shown that the $S4_{13}$-PV peptide is efficiently taken up by cells in a rapid dose-dependent manner, which is distinct from endocytosis and most likely involves direct penetration across cell membranes (*19, 27*). Circular dichroism analysis and the change in fluorescence emission spectra of the $S4_{13}$-PV peptide upon interaction with target membranes implicated that the peptide acquires a helical conformation in the presence of target membranes and is partially inserted in the hydrophobic environment of lipid bilayer (*28*). The high translocation ability and the cellular delivery potential of $S4_{13}$-PV peptide was recently corroborated by successful transfection of cells with plasmid DNA (*8*).

The vast majority of studies examining the CPPs' uptake and cellular localization have used fluorophore-labeled peptides. Fluorescence microscopy is a very powerful technique for visualizing the uptake and location of peptides in cells. However, it does not provide sufficiently detailed information regarding whether CPPs associate first with the extracellular matrix or directly with the plasma membrane, what is the size and shape of loci of initial contacts of CPPs with cells, which type of vesicles mediate the uptake, and so forth. In addition, the fluorescence signal might be quenched in the cellular environment, especially in vesicles with low pH or when associated with polyanions, as well as on the cell surface upon interaction with heparan sulfate proteoglycans (HSPGs) (*29*) complicating the interpretation of fluorescence microscopy results. Transmission electron microscopy, on the other hand, provides resolution necessary to unambiguously assign the localization of CPPs in relation to subcellular compartments and, moreover, to examine how peptides interact with the plasma membrane and extracellular matrix components. Still, quite a few studies have used electron microscopy to assess the mechanism of CPP uptake.

In this study, we used transmission electron microscopy to characterize the cellular uptake of a cell-penetrating peptide $S4_{13}$-PV and its analogues with reversed NLS and scrambled sequence. We demonstrate that $S4_{13}$-PV peptides form nanoparticle-like regular spheric structures on the cell surface to enter HeLa cells. Our data indicate that these CPPs associate first with the cell surface anionic glycosaminoglycans and assemble in spherical clusters followed by the interaction with the plasma membrane. Accumulation of $S4_{13}$-PV particles on/in the plasma membrane leads to their cell entry and membrane repair response, which is only induced at high peptide concentrations. The cellular uptake of $S4_{13}$-PV peptide is markedly reduced at low temperature or by the inhibition of dynamins' activity, but not completely ceased. We provide ultrastructural insight into the membrane interaction and cellular uptake of $S4_{13}$-PV peptides, which will contribute to our current understanding of how CPPs cross biological membranes and enter cells.

EXPERIMENTAL PROCEDURES

Cell Culture. Human cervical carcinoma cell line HeLa was cultured in Iscove's Modified Dulbecco's Medium (IMDM) (Gibco, Invitrogen, UK) supplemented with 10% fetal bovine serum (FBS) (PAA Laboratories, Austria), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Gibco, Invitrogen, UK). Wild-type CHO-K1 and glycosaminoglycan mutant CHO cell line pgsA-745 was cultured in Ham's F12 culture medium (Gibco, Invitrogen, UK) containing 10% FBS, 100 IU/mL penicillin, and 100 μg/mL streptomycin. Cells were grown in a humidified atmosphere containing 5% CO_2 at 37 °C.

Peptides. High-purity (>95%) $S4_{13}$-PV peptide (ALWKTLLKKVLKAPKKKRKVC), reverse NLS peptide (ALWKTLLKKVLKAVKRKKKPC), and scrambled sequence (KTLKVAKWLKKAKPLRKLVKC) were obtained from Thermo Electron (Thermo Electron GmbH, Karlsruhe, Germany). The peptides were modified with an acetyl group at the N-terminus and had an amide group at the C-terminus. Peptides were tagged with Nanogold (Monomaleimido Nanogold, Nanoprobes, NY, *d* 1.4 nm) by forming a covalent bond between the thiol group of peptide and the maleimide group of label by incubation at a molar ratio 2.5:1 in 50% methanol at 30 °C for 90 min. Methanol was removed and the conjugate concentrated by speed-vac to reach 50−100 μM concentration of labeled peptide. The conjugate with 1:1 peptide/Nanogold ratio was purified to homogeneity by size-exclusion chromatography on Superdex Peptide HR10/30 in buffer containing 35 mM Tris-HCl pH 7.5, 105 mM NaCl, and 30% (v/v) acetonitrile or by reversed phase chromatography on Pro RPC HR5/2 (Pharmacia, Sweden) in water−acetonitrile gradient in the presence of 0.1% TFA and concentrated again. The analysis of conjugate by both above-mentioned chromatography methods yielded a single peak.

Treatment of Cells with Peptides. Cells were seeded onto glass coverslips in 24-well plates, grown to 80−90% confluence, and incubated with culture medium containing 0.1−3 μM gold-labeled peptides at 37 °C for 10 min to 24 h depending on the experimental setup. After incubation, the cells were washed twice with cell culture medium and processed for electron microscopy (see below). For low-temperature experiments, cells were preincubated in culture medium at 10 °C for 30 min, followed by treatment with peptides at the same temperature for 1 h.

Staining of Cell Surface Acidic Mucopolysaccharides with Ruthenium Red. After incubation with Nanogold-labeled peptides, cells were washed twice with cell culture medium and fixed with 2.5% glutaraldehyde containing 1 mg/mL ruthenium red (Sigma-Aldrich, Germany) in the cacodylate buffer (0.1 M sodium cacodylate, pH 7.4) for 1 h. The ruthenium red-stained cells were then washed twice for 10 min with the cacodylate buffer and processed for TEM as described below.

Treatment of Cells with Hyaluronidase. Hyaluronan chains were removed from the surface of pgsA-745 CHO cells by treating with 300 μg/mL hyaluronidase (Sigma-Aldrich, Germany) in serum-free (SF) medium at 37 °C for 30 min. Thereafter, the cells were incubated with 1 μM gold-labeled peptides for 1 h in fresh SF medium containing 300 μg/mL hyaluronidase.

Plasma Membrane Repair Assay. Cells were washed with SF culture medium and incubated with 0.5−10 μM peptides in SF medium for 30 min at 37 °C. Treated cells were washed with PBS, fixed with 3% paraformaldehyde in phosphate buffer (0.1 M, pH 7.4) for 30 min, and washed with PBS. The control cells were permeabilized with methanol at −20 °C for 15 min to expose all intracellular LAMP-2 antigens. The sites of unspecific binding were blocked with 10% nonfat dry milk in PBS for 1 h. LAMP-2 was stained with monoclonal antibody (H4B4, DSHB, 1:100) for 1 h and Alexa Fluor 488-conjugated goat antimouse antibody (Invitrogen, 1:400) for 30 min at room temperature in dark. The solution of secondary antibody was supplemented with 1 μg/mL propidium iodide to assess the intactness of plasma membrane. The coverslips were washed, mounted on glass slides with Fluoromount G (Electron Microscopy Sciences, Hatfield, PA, USA), and analyzed with fluorescence microscopy. Images were recorded using an Olympus BX61 microscope equipped with CCD camera DP70 or Olympus FV1000 confocal microscope (Olympus, Tokyo, Japan). Obtained images were processed with *Adobe Photoshop 7.0* (Adobe Systems, San Jose, CA, USA).

Transmission Electron Microscopy. After treatment with Nanogold-labeled or unlabeled peptides, the cells were fixed with 2.5% glutaraldehyde in cacodylate buffer at room temperature for 1 h and washed two times for 10 min with cacodylate buffer. The Nanogold label of peptides was magnified

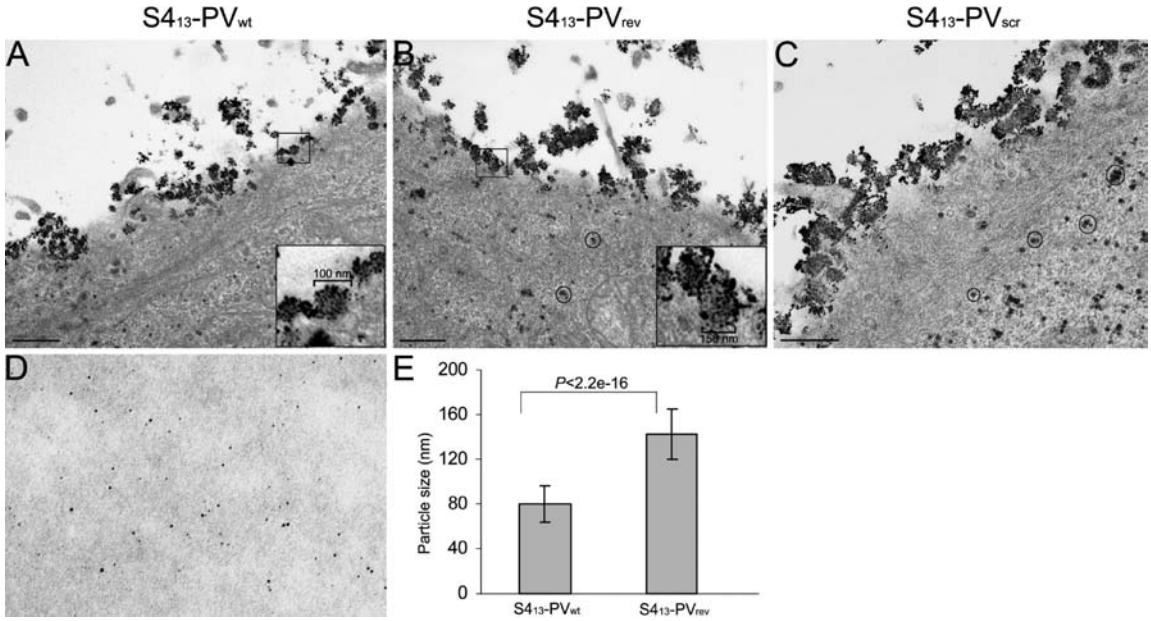

Figure 1. Interaction of S4$_{13}$-PV$_{wt}$ and its analogues with the plasma membrane of HeLa cells. Cells were incubated with 1 μM Nanogold-labeled S4$_{13}$-PV$_{wt}$ (A), S4$_{13}$-PV$_{rev}$ (B), and S4$_{13}$-PV$_{scr}$ (C) for 30 min. Insets in A and B illustrate the enlarged nanoparticles of S4$_{13}$-PV$_{wt}$ (100 nm) and S4$_{13}$-PV$_{rev}$ (150 nm) peptides, respectively. For clarity, note that the black circles in B and C indicate some glycogen granules, which may misleadingly be referred to as the peptide nanoparticles. (D) Distribution of S4$_{13}$-PV$_{wt}$ peptide in cell-free system. Two micromolar Nanogold-labeled S4$_{13}$-PV$_{wt}$ in cell culture medium was placed onto blank sections on TEM grid and allowed to air-dry. The Nanogold (1.4 nm) particles were magnified by silver deposition to ~10 nm. (E) Quantitative analysis of the size of the nanoparticles formed by S4$_{13}$-PV$_{wt}$ and S4$_{13}$-PV$_{rev}$ peptide. Scale bars 0.5 μm.

by silver enhancement for 2−5 min with HQ Silver kit from Nanoprobes (Yaphank, NY, USA) following the protocol suggested by manufacturers. The silver deposition was stabilized by toning with 0.05% gold chloride (*30*). Cells were postfixed with 1% osmium tetroxide in the cacodylate buffer containing 15 mg/mL potassium ferrocyanate at room temperature for 1 h. After osmification, the cells were washed three times for 5 min with cacodylate buffer and dehydrated with 70%, 96%, and twice with 100% ethanol. Finally, the coverslips were dipped into acetone and embedded in epoxy resin (TAAB Laboratories Equipment Ltd., UK). Ultrathin sections were cut in parallel with the coverslip and contrasted in 2% uranyl acetate in 50% ethanol for 2 min and in lead citrate for 2 min. The sections were examined with a JEM-100S (JEOL, Tokyo, Japan) transmission electron microscope at 80 kV. The scanned electron microphotos were analyzed and processed with *Adobe Photoshop 7.0* software. Statistical analysis was performed using program R 2.6.0.

Treatment of Cells with Dynasore and Transferrin. For electron microscopy, the activity of dynamins was inhibited by pretreating cells with 80 μM dynasore (AKos GmbH, Steinen, Germany) in SF culture medium at 37 °C for 30 min (*31*). The peptides were diluted to the concentration of 1 μM in the same solution and incubated for 1 h.

For transferrin uptake, 5×10^4 HeLa cells were seeded onto glass coverslips in 24-well plate one day before experiment. Cells were washed twice with SF medium and pretreated for 30 min at 37 °C with 80 μM dynasore in SF culture medium or SF medium only. For visualizing endosomes, cells were incubated with 10 μg/mL transferrin labeled with Alexa Fluor 594 (Molecular Probes, Invitrogen, OR, USA) in the corresponding medium for 2 min at room temperature, washed 3 times with the corresponding medium without transferrin, and incubated for an additional 15 min at 37 °C. Treated cells were washed twice with cold 0.2 M glycine buffer containing 0.15 M NaCl (pH 3.0) for 30 s, followed by washing with cold PBS, and fixed with 4% paraformaldehyde in PBS on ice for 30 min. Fixed cells were washed with PBS and mounted to microscope slides with 30% glycerol in PBS. The images were recorded and processed as described above.

RESULTS

S4$_{13}$-PV Peptides Assemble into Small Nanoparticle-Like Spherical Structures Upon Interaction with the Plasma Membrane of HeLa Cells. In order to characterize the cellular uptake of the S4$_{13}$-PV peptides at the ultrastructural level, we tagged the original "wild-type" peptide (S4$_{13}$-PV$_{wt}$) and its analogues with reversed NLS (S4$_{13}$-PV$_{rev}$) and scrambled sequence (S4$_{13}$-PV$_{scr}$) covalently with Nanogold clusters of 1.4 nm in diameter. Incubation of HeLa cells with 1 μM S4$_{13}$-PV$_{wt}$-nanogold conjugates led to the association of peptides into spherical structures, which accumulated on the plasma membrane and entered cells. These structures had regular shape and relatively uniform size of about 80−100 nm reminiscent of nanoparticles (Figure 1A). The assembly of wild-type peptide into nanoparticles was rather prevailing, but still a fraction of peptides bound to the extracellular matrix without formation of spherical structures. S4$_{13}$-PV$_{rev}$ peptide formed similar nanoparticle-like structures, albeit somewhat bigger and more variable in size and shape (Figure 1B). Quantitative analysis revealed that the average size of particles formed by S4$_{13}$-PV$_{rev}$ peptide was about 1.8 times bigger (142.6 ± 22.7 nm) than those formed by wild-type peptide (79.8 ± 16.4 nm) (Figure 1E). In contrast to S4$_{13}$-PV$_{wt}$ and S4$_{13}$-PV$_{rev}$, the peptide with scrambled sequence (S4$_{13}$-PV$_{scr}$) could not assemble into spherical structures and typically formed bigger irregular aggregates on the plasma membrane of cells (Figure 1C). This suggests that the peptide with scrambled sequence cannot acquire a regular structure similar to the wild-type and reverse NLS peptides.

The spherical structures of wild-type and reversed NLS peptides seem to form only in the presence of cell membranes, since the incubation of peptides in the cell culture medium (Figure 1D) with or without calf serum did not lead to assembly of nanoparticles. Next, we assessed whether the characteristic spherical assemblies are induced by the Nanogold cluster used

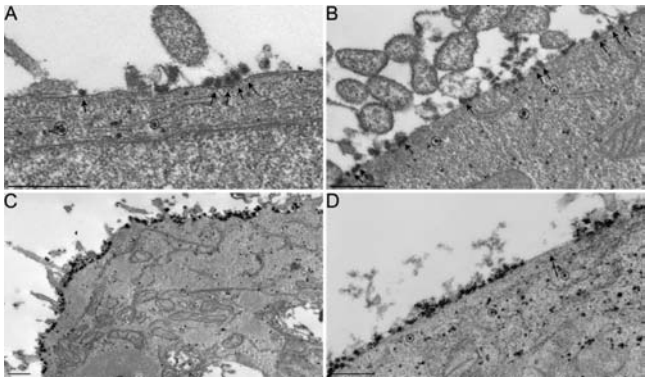

Figure 2. Association of the nanoparticles of $S4_{13}$-PV_{wt} with cell surface mucopolysaccharides. Nanoparticles on the surface of HeLa cells after incubation with 4 μM unlabeled (A,B) or 1 μM Nanogold-labeled (C,D) $S4_{13}$-PV_{wt} peptides for 1 h and stained with ruthenium red (RR). Arrows in A and B indicate the $S4_{13}$-PV_{wt} nanoparticles formed by unlabeled peptide. Arrow in D points to the surface region lacking both the binding of $S4_{13}$-PV_{wt} peptides and RR-staining. Note that the glycogen granules in the cytoplasm (some of them surrounded by black circles in A, B, and C) may look similar to the peptide nanoparticles. Scale bars 0.5 μm.

for peptide labeling and not by the peptide. As expected, the cationized Nanogold was rarely detected in association with cells after incubation in identical conditions, and no spherical assemblies were ever detected (data not shown), showing that the specific clustering was indeed induced by the peptides. To further confirm this, we incubated cells with 1 μM of gold-labeled peptide and added unlabeled peptide at 2, 4, or 9 μM concentration. At all used concentrations, similar regular structures formed on/in the cell surface in analogy with the gold-labeled peptides only. However, in the presence of unlabeled peptide the number of gold labels per nanosphere was lower than in nanostructures obtained by incubating cells with Nanogold-labeled peptide only (data not shown). This demonstrates that both the gold-labeled and unlabeled $S4_{13}$-PV_{wt} peptides are capable of forming nanoparticles and intermix with one another. In line with this, when we incubated cells with unlabeled peptides only, either at 4 (Figure 2A,B) or 10 μM concentration, we also detected similar distinct electron-dense spherical structures on the surface of HeLa cells, which probably represent the same particles. Analogous results were also obtained with $S4_{13}$-PV peptide with reversed NLS sequence (data not shown).

Cell Surface Glycosaminoglycans Are Involved in the Formation of Peptide Nanostructures. The electron microphotos revealed that the peptide nanoparticles always had an electron-dense background. Binding of polycationic molecules, e.g., cell-penetrating peptides, to the HSPGs is known to induce the clustering and concentration of peptides to the cell surface as dense aggregates followed by their internalization (*24, 25*). Therefore, we visualized the extracellular matrix with ruthenium red (RR), a polycationic cytochemical stain for cell surface mucopolysaccharides. Ruthenium red markedly increased the staining of the plasma membrane and especially the extracellular matrix surrounding cells. In line with the staining of extracellular matrix, the electron density of $S4_{13}$-PV clusters' background was markedly increased by RR treatment (Figure 2C,D). In addition, we noticed that $S4_{13}$-PV peptides associated preferentially with the membrane areas marked with ruthenium red, but not with regions lacking the intense stain of RR (arrow in Figure 2D).

To further assess the involvement of glycosaminoglycans, we analyzed the association of $S4_{13}$-PV_{wt} with the cell surface and internalization in wild-type and glycosaminoglycan-deficient Chinese hamster ovary (CHO) cells. In wild-type CHO cells,

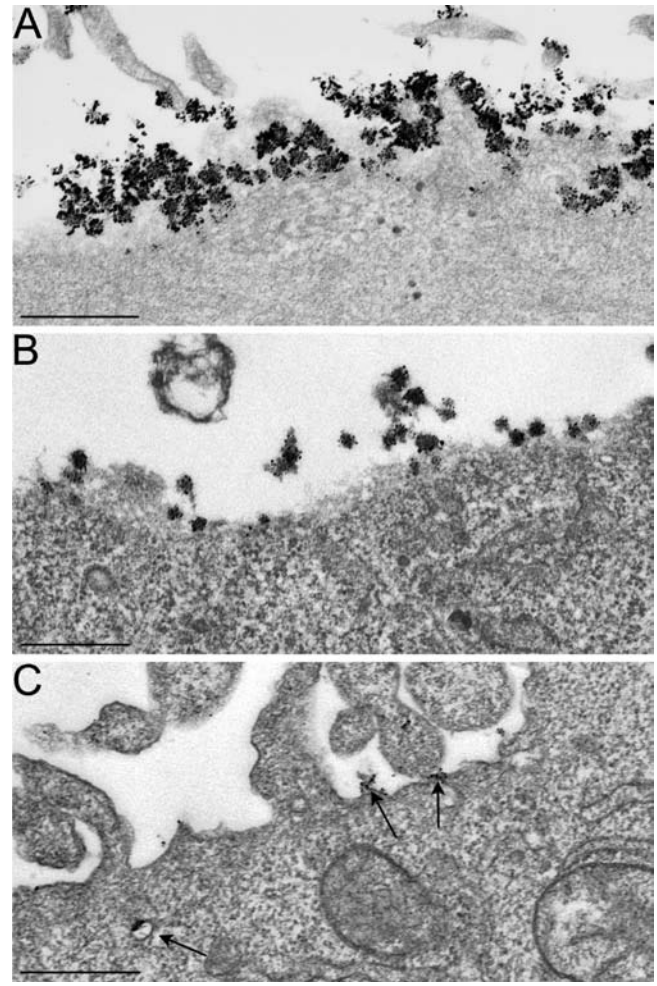

Figure 3. Effect of hyaluronidase treatment on the formation of $S4_{13}$-PV nanostructures. Wild-type CHO-K1 (A) and glycosaminoglycan (GAG) mutant CHO cells (pgsA-745) (B,C) were incubated with 1 μM Nanogold-labeled $S4_{13}$-PV_{wt} peptide for 1 h. (C) The GAG-deficient CHO cells were pretreated with 300 μg/mL hyaluronidase in serum-free medium for 30 min at 37 °C to remove hyaluronan chains from the cell surface and incubated with 1 μM gold-labeled $S4_{13}$-PV_{wt} in the same solution for 1 h. Arrows in C indicate the few peptides that bound to the plasma membrane and internalize into cells after hyaluronidase treatment. Scale bars 0.5 μm.

the peptide accumulated extensively to the cell surface and formed nanospheres with similar size and shape as in HeLa cells (Figure 3A). The nanoparticles of $S4_{13}$-PV were also present at the surface of mutant CHO-pgsA-745 cells, which are defective in glycosaminoglycan biosynthesis (*32*) and lack specific GAG assemblies (Figure 3B). However, the amount of peptide particles on the surface of GAG deficient cells was markedly reduced in comparison to the wild-type CHO. Treatment of mutant CHO cells with hyaluronidase, which specifically cleaves glycosidic bonds in hyaluronic acid and thereby removes the hyaluronan strands and the hyaluronan filament-associated proteoglycans from the cell surface abolished the formation of $S4_{13}$-PV nanoparticles. However, some peptide particles were able to associate with the cell surface and internalize into cells even after treatment with hyaluronidase (arrows in Figure 3C).

In order to determine more specifically the electron-dense membrane constituents associating with $S4_{13}$-PV nanostructures on the cell surface, we incubated peptides in a cell-free system with different isolated acidic glycosaminoglycans (i.e., chondroitin sulfate, heparin, hyaluronan) in the cell culture medium. Unexpectedly, under these conditions none of the examined

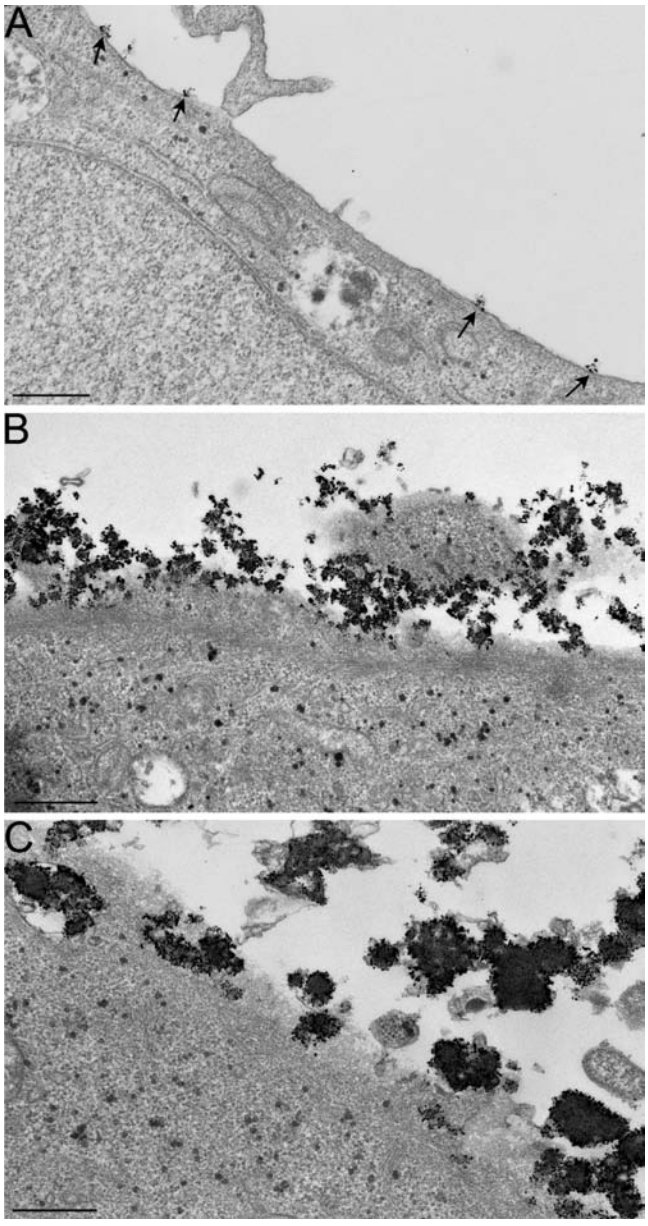

Figure 4. Concentration- and time-dependent formation of $S4_{13}$-PV nanostructures. HeLa cells were incubated with 0.1 μM $S4_{13}$-PV_{wt} for 10 min (A), 0.5 μM (B) or 3 μM $S4_{13}$-PV_{wt} (C) for 1 h. Single clusters of $S4_{13}$-PV_{wt} (arrows in A) at the cell surface formed at a lower concentration; peptide particles of typical size (B) and large irregular aggregates (C) formed at higher concentrations, 0.5 μM and 3 μM respectively. Scale bars 0.5 μm.

GAGs alone were sufficient to induce the formation of nanoparticle-like structures of this peptide (data not shown).

Formation of $S4_{13}$-PV Nanostructures Is Dependent on the Peptide Concentration and Incubation Time. The clusters of $S4_{13}$-PV were detectable by electron microscopy as early as 10 min after the addition of peptides to HeLa cells at the concentration of 0.1 μM. As expected, at low concentration only the "germs" of the nanostructures were detected attached to the cell membrane (arrows in Figure 4A). The peptide-containing structures were small and contained only a few gold particles per cluster. Peptides were taken up by cells also at this concentration and they localized in small ($\leq$50 nm) vesicles under the plasma membrane. Longer incubation (1 h) at this peptide concentration resulted in a slight increase in the surface-bound as well as internalized $S4_{13}$-PV particles. Upon longer incubation, the size of peptide-containing structures did not increase and remained similar to that observed after 10 min incubation. However, at 0.5 and 1 μM concentrations the assemblies of $S4_{13}$-PV peptides exhibited a characteristic spherical shape and size, had higher background density, and comprised more gold particles (Figure 4B). These peptide nanoparticles accumulated extensively at the plasma membrane during 1 to 24 h of continuous incubation with cells. A negligible fraction of peptide particles at 1 μM concentration formed bigger conglomerates during 4 to 24 h, but most of these still retained regularity and a uniform size in bigger structures. However, when we increased the concentration of labeled peptides to 2−3 μM, the large aggregates (up to 0.5−1 μm diameter) started to form already in 1 h (Figure 4C).

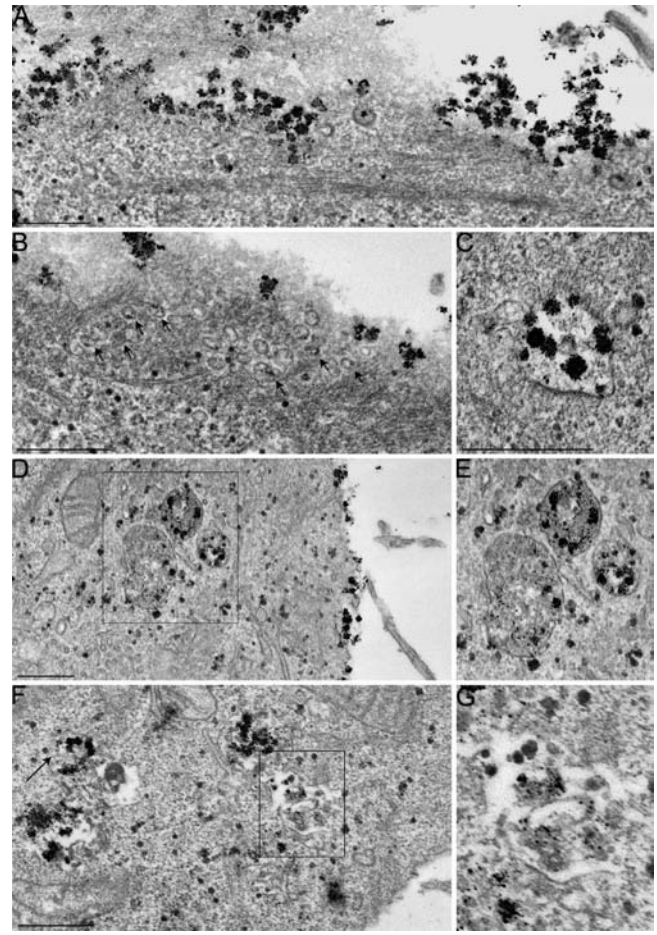

Figure 5. Translocation and intracellular localization of $S4_{13}$-PV_{wt} peptide. HeLa cells were incubated with 0.5 μM (A,B) or 1 μM $S4_{13}$-PV_{wt} (D,E) for 1 h, and with 1 μM $S4_{13}$-PV_{wt} for 24 h (C,F). Accumulation of $S4_{13}$-PV_{wt} nanoparticles to the cell surface (A), internalization in small vesicles (arrows in B), and localization in caveosome-like structures (C) or multivesicular bodies (D,E). Arrow in F and enlarged section (G) indicate the peptide-containing vesicles with a discontinuous membrane after 24 h of $S4_{13}$-PV_{wt} incubation with cells. Scale bars 0.5 μm.

$S4_{13}$-PV Peptides Interfere with the Organization of the Plasma Membrane and Efficiently Enter the Cells. The $S4_{13}$-PV_{wt} and $S4_{13}$-PV_{rev} peptides associated preferentially with specific loci on the plasma membrane. Upon longer incubation, the peptide nanostructures continued to accumulate in these particular regions on the cell surface. Accumulation of peptides interfered with the distinct ultrastructure of the lipid bilayer turning it hardly detectable by electron microscopy. In parallel with the destabilization of the lipid bilayer, the peptide particles inserted into the cortical cytoplasm (Figure 5A) and entered deeper into cells.

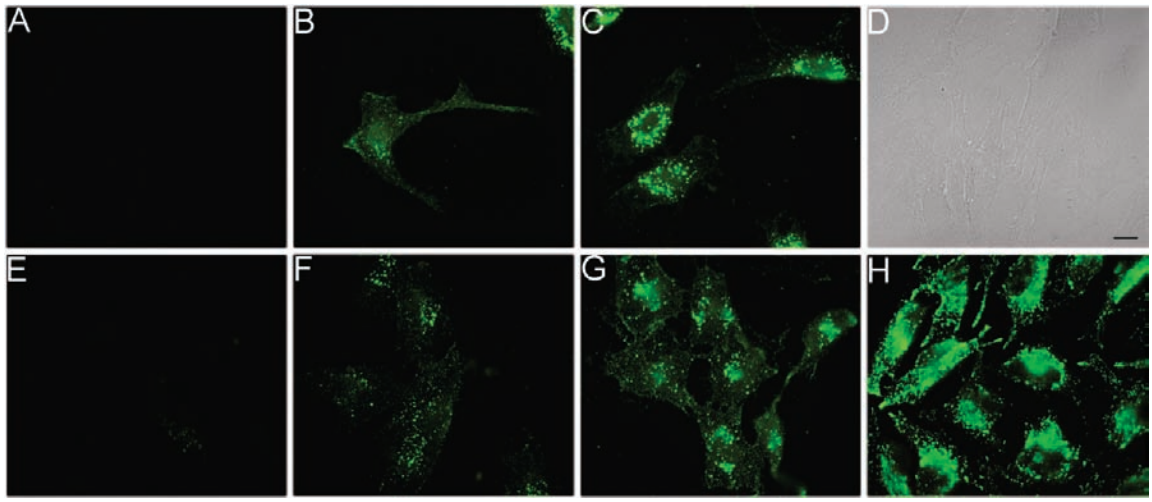

Figure 6. Induction of the membrane repair response by $S4_{13}$-PV peptide. HeLa cells were incubated with 1 μM (A), 3 μM (B), 5 μM (C) $S4_{13}$-PV_{wt} or 1 μM (E), 3 μM (F), 5 μM (G) $S4_{13}$-PV_{rev} at 37 °C for 30 min. LAMP-2 was visualized with monoclonal LAMP-2 antibody and Alexa Flour 488-conjugated antimouse antibody. The membrane repair response is not induced at lower concentration of $S4_{13}$-PV_{wt} (A) and $S4_{13}$-PV_{rev} (E) peptides. LAMP-2 signal appeared at the plasma membrane higher concentrations of $S4_{13}$-PV_{wt} (B,C) and $S4_{13}$-PV_{rev} (F,G) peptides. (D) DIC image of cells in panel A. Localization of LAMP-2 protein in control cells permeabilized with methanol (H). Scale bar 10 μm.

In parallel with the interaction of $S4_{13}$-PV nanostructures with the plasma membrane, the formation and pinching off of small vesicles with diameter of 50−100 nm into cells was induced and some of these also contained peptides (Figure 5B). In addition, peptides were found in bigger rosette-like structures, morphologically reminiscent of caveosomes (Figure 5C). The peptide nanoparticles were present also in multivesicular bodies (MVB), especially after longer incubation. Interestingly, even inside the MVB the distinct spherical organization of peptides was retained for at least 1−4 h (Figure 5D,E). The peptide structures usually located on the inner surface of the vesicle and were mostly in direct contact with the membrane of vesicles. Continuous uptake of $S4_{13}$-PV peptides by cells during 24 h led to their high accumulation in large vacuoles (Figure 5F). This was accompanied by impaired membrane integrity of some peptide-containing vesicles (arrow in Figure 5F,G) indicating that the high concentration of $S4_{13}$-PV can destabilize the membrane and induce the escape of peptides into the cytosol.

$S4_{13}$-PV Peptides Enter Cells without Triggering the Membrane Repair Response, which Requires Higher Peptide Concentrations. Next, we assessed whether $S4_{13}$-PV peptides caused plasma membrane disturbances at the extent of enabling calcium influx into cells and thereby triggering the plasma membrane repair response (MRR). Under these circumstances, the intracellular vesicles donate membranes to reseal the injured plasma membrane, and this can be detected by the exposure of lysosomal membrane protein LAMP-2 to the plasma membrane of intact cells (*33*).

Incubation of HeLa cells with 0.5−1 μM wild-type $S4_{13}$-PV did not trigger the plasma membrane repair response (Figure 6A). It is remarkable that efficient cellular uptake of $S4_{13}$-PV_{wt} peptide takes place without disturbing the ordered packing of the plasma membrane or evoking the membrane repair response. Higher concentrations of peptide starting from 3 μM led to marked fusion of lysosomal membranes with the plasma membrane, and LAMP-2 was detected all over the plasma membrane as distinct punctae (Figure 6B,C). At 10 μM concentration, the plasma membrane resealing was triggered in more than 80% of cells.

The peptide with reversed NLS sequence induced MRR at somewhat lower concentration than the wild-type peptide. LAMP-2 was targeted to the plasma membrane in about 10% of cells already after incubation with 2 μM peptide (data not shown). At 3 μM peptide concentration, LAMP-2 was present at the plasma membrane of 50% of cells (Figure 6F). Increasing the $S4_{13}$-PV_{rev} concentration to 5 μM induced appearance of LAMP-2 on the plasma membrane of almost all cells in specimen (Figure 6G). However, even at 5 μM $S4_{13}$-PV_{rev} concentration the integrity of the plasma membrane was not impaired since propidium iodide could not enter cells (data not shown).

$S4_{13}$-PV analogue with scrambled sequence was the least potent to induce targeting of LAMP-2 to the outer leaflet of the plasma membrane. Very few cells became positive for the lysosomal protein at the cell surface starting from 5 μM concentration and reaching a maximum at 10 μM concentration where almost all of the population was stained. However, not all LAMP-2 antigens became accessible to antibodies at the peptide concentration with the highest induction ability (in case of all used peptides), because the removal of membrane lipids by methanol fixation led to a drastically elevated staining of this lysosomal protein all over the cell (Figure 6H).

Cellular Uptake of $S4_{13}$-PV Peptides Is Reduced at Low Temperature. At 10 °C, the $S4_{13}$-PV_{wt} and both of its analogues associated with the plasma membrane to a lesser extent than at the physiological temperature, and their translocation into cells was diminished. The $S4_{13}$-PV_{wt} and $S4_{13}$-PV_{rev} peptides were still able to assemble into nanostructures, although the size of peptide clusters was more variable and their shape less uniform (Figure 7A,B). At low-temperature condition, the peptides associated with the plasma membrane/extracellular matrix as either irregular aggregates or single clusters. Surprisingly, despite the markedly decreased amount of surface-bound peptides the vesicular uptake of $S4_{13}$-PV peptides was not blocked at 10 °C. However, only a few or single gold particles were in small vesicles or bigger vesicular structures (arrows in Figure 7B,C), which located in the cortical cytoplasm or in the close proximity of the plasma membrane but not deeper in cells.

Dynamin Inhibition Does Not Abolish the Vesicular Uptake of $S4_{13}$-PV by HeLa Cells. Dynasore, an inhibitor of dynamin GTPase activity, blocks the formation and fission of endocytic vesicles in most pathways (*31*). Therefore, we examined the effect of dynasore on the translocation efficiency of $S4_{13}$-PV. Inhibition of dynamins decreased but did not abolish the vesicular uptake of $S4_{13}$-PV nanoparticles. Even in the presence of dynasore, the $S4_{13}$-PV peptides induced the formation and

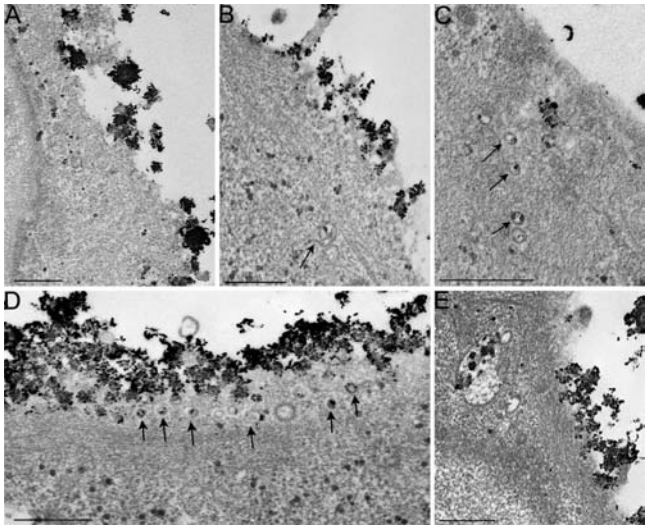

Figure 7. Effect of low temperature and dynamin inhibition on cellular translocation of $S4_{13}$-PV peptides. HeLa cells were incubated with 1 μM $S4_{13}$-PV_{wt} (A), $S4_{13}$-PV_{rev} (B), or $S4_{13}$-PV_{scr} (C) at 10 °C for 1 h. HeLa cells incubated with 1 μM $S4_{13}$-PV_{wt} for 1 h in the presence of dynasore (80 μM) at 37 °C (D,E). Arrows indicate internalized peptides in small vesicles formed at low temperature (B,C) and in dynasore-treated cells (D). Scale bars 0.5 μm.

fission of small vesicles. The formed small vesicles localized mainly in the cortical cytoplasm near the plasma membrane and contained typically a few labeled peptides (Figure 7D). Remarkably, $S4_{13}$-PV_{wt} peptides were also taken up into large endosomal structures ($\geq$0.5 μm) despite the presence of dynasore (Figure 7E). The control cells incubated with Alexa Fluor 594 conjugated transferrin, as a marker for dynamin-dependent endocytic pathway, corroborated the inhibition of endocytosis by dynasore, since only a negligible part of protein was taken up by cells (Supporting Information Figure S1). These findings suggest that $S4_{13}$-PV peptides can also gain entry into cells by endocytic processes that do not necessarily require dynamin.

DISCUSSION

Cell-penetrating peptides have been under intense investigation from the moment of their discovery 15 years ago, but the discussion about their mechanism of association with cells, uptake, and cargo delivery is still continuing, and consensus has not yet been reached in some key questions. Currently, a growing number of studies support the view that CPPs enter cells by different mechanisms, which act in parallel, and for most CPPs, more than one cellular pathway exists. Previously, we have shown that the internalization of $S4_{13}$-PV cell-penetrating peptide proceeds by at least two different mechanisms: an endocytic pathway, which prevails at lower peptide concentrations, and an alternative endocytosis-independent mechanism that is induced preferentially at higher peptide concentrations (*19*). In addition, we demonstrated that the localization of this peptide is not markedly changed upon fixation with aldehydes (*19*), which enables studies at an ultrastructural level by transmission electron microscopy in fixed specimen.

Electron microphotos revealed that the Nanogold-labeled (1.4 nm gold cluster) $S4_{13}$-PV_{wt} peptide assembles into small spherical structures at the plasma membrane of HeLa cells. Considering the relatively uniform size of 80−100 nm and regular shape of the particles formed by $S4_{13}$-PV peptides, we called these structures "nanoparticles" for brevity. The ability to form nanoparticles was also observed for analog of $S4_{13}$-PV peptide with reversed NLS sequence, which clustered in regular spherical structures although with bigger and less uniform size (~140 nm). In contrast, the peptide with scrambled sequence, $S4_{13}$-PV_{scr}, failed to form such spherical structures despite having an identical amino acid composition. The scrambled analogue of $S4_{13}$-PV formed bigger irregular aggregates and entered cells less efficiently than $S4_{13}$-PV_{wt} and $S4_{13}$-PV_{rev} peptides, indicating that not only the amino acid composition, but also their positions influence the mode of interaction with cell surface and subsequent internalization. In general, we observed that the formation of small and regular peptide-containing structures is in good correlation with their ability to enter cells, i.e., the peptides forming regular particles are more efficiently taken into cells. This observation could explain our earlier reports (*27, 28*) demonstrating that the cellular uptake of the scrambled peptide was significantly less efficient than that of $S4_{13}$-PV_{wt} or with reversed NLS peptides. On the basis of the study of peptide conformational changes, we have previously attributed the better internalization properties of the $S4_{13}$-PV and reverse NLS peptide, compared to the scrambled peptide, to the ability of these peptides to adopt an amphipathic α-helical conformation upon interaction with the negatively charged membranes. The changes in the secondary structure of CPPs could in turn induce rearrangement of the plasma membrane lipids leading to peptide internalization (*27*). The electron microscopy results described here are quite well in line with this concept—the plasma membrane of HeLa cells becomes less distinct upon interaction with $S4_{13}$-PV_{wt} or $S4_{13}$-PV_{rev} but not with $S4_{13}$-PV_{scr}. Both the modulation of plasma membrane properties and the different size of peptide assemblies on the cell surface might be responsible for differences in cell-translocation ability of $S4_{13}$-PV peptides.

The first hint that CPPs may assemble in clusters upon association with cells can be found in a publication demonstrating the receptor-independent internalization of the third helix of the Antennapedia homeodomain in 1996 (*34*). Although it was not discussed by the authors at that time, the visualization of Antp(43−58) by colloidal gold particles in electron microscopy reveals that this peptide tends to localize in cells as small clusters in parallel to its even/diffuse distribution. The clustering of peptides to produce particles or aggregates has also been described for other CPPs. Some amphipathic CPPs, like SAP and Pep-1, self-assemble in aqueous solution (*35–37*). On the other hand, the aggregation and clustering can be induced by the binding of CPPs to HSPGs on the cell surface (*24*). Remarkably, not only CPPs, but also some amyloidogenic polypeptides form aggregates to gain access into cells. For example, the large fibrillar polyglutamine peptide aggregates (0.2−0.5 μm in diameter) are able to penetrate the cytosolic compartment of mammalian cells where they can nucleate the aggregation of other soluble proteins containing polyglutamine sequence (*38*).

The cell-penetrating peptide Pep-1, which analogously to $S4_{13}$-PV peptide is amphipathic and comprises a NLS sequence, forms discrete nanometer-sized particles when complexed with cargo protein in solution (*37*). The Pep-1/cargo nanoparticles were of about 80−120 nm diameter as characterized by scanning electron microscopy and light scattering measurements. Analogously to Pep-1, some other short amphipathic peptides, e.g., MPG and CADY, have been demonstrated to form stable nanoparticles with proteins and/or nucleic acids in solution (*39*). Considering these results and taking into account that different cargo molecules can influence the properties of its carrier peptide (*40*), we assessed whether the Nanogold tag, which we conjugated to the peptide could induce/facilitate the assembly of $S4_{13}$-PV nanoparticles or determine their size and structure. The Nanogold cluster is very stable, has no overall charge, and is considered of no affinity to proteins. Still, its diameter is 1.4

nm, and it could alter the bulk properties of peptide more than typically used fluorophores. Although we cannot completely exclude some impact of the gold label on the formation of $S4_{13}$-PV nanoparticles, it cannot be the main assembling force, since after incubation of cells with unlabeled peptides, we were still able to clearly detect the distinct spherical structures. The particles of "naked" $S4_{13}$-PV were reminiscent of structures formed with $S4_{13}$-PV-Nanogold conjugates. The similar size of formed particles suggests that the Nanogold tag does not contribute markedly to the assembly of $S4_{13}$-PV nanoparticle-like structures. It remains nonetheless unclear whether the formation of the nanoparticle-like structures by the $S4_{13}$-PV_{wt} or $S4_{13}$-PV_{rev} peptides is somehow related to the ability of these peptides to adopt a helical conformation.

CPPs may also bunch on the surface of cultured mammalian cells. Ziegler et al. demonstrated that peptides and other cationic compounds can cluster GAGs and induce formation of particles on the surface of cells (*24, 25*). The initial study revealed the presence of strongly absorbing aggregates (<5 μm) of Tat peptide bound to membrane-associated HS on the surface of mouse fibroblasts in fluorescence microscopy experiments (*24*). Moreover, the interaction of CPPs with heparin in cell-free system produced particles, which size ranged from 80 to 130 nm depending on peptide as revealed by light scattering (*25*). In order to distinguish whether the formation of $S4_{13}$-PV peptide nanoparticles is taking place in solution or on the cell surface only, we first examined peptides in a cell-free system. Nanogold-labeled $S4_{13}$-PV did not form nanoparticles in culture medium either in the presence or in the absence of fetal bovine serum and peptides were detected by TEM as single dots distributed evenly on the grid. Somewhat surprisingly, the incubation of $S4_{13}$-PV peptides with different anionic glycosaminoglycans, like heparin, chondroitin sulfate, and hyaluronan, did not lead to the formation of nanoparticles. The absence of $S4_{13}$-PV nanoparticles in solution suggests that a specific environment or a direct interaction with the cell surface is required for the clustering of this peptide. We have shown that the presence of heparan sulfate proteoglycans at cell surface facilitates the cellular uptake of the $S4_{13}$-PV peptide at lower concentration (*27*). By now, the convincing evidence of HSPGs as true internalizing receptors of macromolecular cargo has been provided (*41*). Wittrup et al. showed that the sorting of cell-surface HSPGs to endocytic vesicles is heparan sulfate epitope specific and mediated by both PG core proteins, a transmembrane syndecan, as well as GPI-anchored glypican. Moreover, HIV-1 Tat CPP competes for the internalizing PG population and delivers its cargo through the same vesicular compartments as HSPGs ligands (*41*). To probe the presence of glycosaminoglycans in the content of $S4_{13}$-PV nanoparticles, we used ruthenium red, a polycationic stain for the visualization of acidic polysaccharides on the outer surface of cells. The increase in the electron density of $S4_{13}$-PV nanoparticles after ruthenium red staining corroborated the presence of carbohydrate components in particles and their significance in accumulation of CPPs at the cell membrane and uptake. However, the fact that $S4_{13}$-PV peptide was able to form nanoparticles even on the surface of glycosaminoglycan mutant CHO cells (pgsA-745) lacking xylosyltransferase suggests that the formation of nanoparticles is not merely dependent on the presence of heparan sulfate and/or chondroitin sulfate. Surprisingly, enzymatic cleavage of hyaluronan filaments from the surface of glycan-deficient CHO cells completely abolished the formation of $S4_{13}$-PV nanoparticles, and only a negligible part of peptide was taken up by cells. These data further confirm that the glycosidic component is required for the formation of peptide nanoparticles, and the hyaluronic acid together with hyaluronan-associated proteoglycans might contribute to the formation of these particles.

Experiments with model membranes have demonstrated that $S4_{13}$-PV peptides become buried in the lipid bilayer upon interaction with negatively charged lipid vesicles (*28*). Our electron microscopy results revealed that the clearly distinguishable lipid bilayer of the plasma membrane becomes hazy and is mostly undetectable at the accumulation sites of peptides, suggesting that the association of $S4_{13}$-PV nanoparticles to the plasma membrane interferes with the ordered packing of lipids in the membrane. We demonstrated recently that the accumulation of some CPPs on/in the plasma membrane introduces disturbances, which might be compensated by the membrane repair response (MRR) mechanism (*33*). The plasma membrane resealing is usually activated by the influx of calcium ions from the exterior into cytoplasm, which triggers the exocytosis of intracellular vesicles to reseal the injured plasma membrane or replace the damaged regions. Most commonly, lysosomes donate their membrane for plasma membrane repair, which is accompanied with the exposure of lysosomal lumenal proteins, like LAMP-1 or LAMP-2, to cell surface (*42, 43*). The fluorescence microscopy results demonstrate that $S4_{13}$-PV peptides can indeed induce the membrane repair response, since LAMP-2 protein is targeted to plasma membrane and is detectable in nonpermeabilized cells, but this only occurs at high peptide concentrations. However, the very efficient uptake of $S4_{13}$-PV wild-type and reversed NLS peptides takes place also at lower concentrations than those necessary for triggering the MRR at considerable extent. The emergence of LAMP-2 on the plasma membrane correlates with the size and heterogeneity of $S4_{13}$-PV particles recorded by TEM. More specifically, the $S4_{13}$-PV_{wt} peptide forms the uniform particles with 80−100 nm diameters and evokes MRR only in a small population of cells starting from 3 μM concentration. $S4_{13}$-PV_{rev} formed somewhat bigger and more heterogeneous nanoparticles than wild-type peptide and induced emergence of LAMP-2 already from 2 μM peptide concentration, suggesting higher interference with the membrane integrity by bigger and more variable particles. At the higher concentrations, both these peptides produced large particles with highly varying size and induced MRR all over the plasma membrane in all cells in culture. $S4_{13}$-PV with the scrambled sequence associated with cells without disturbing the integrity of lipid bilayer, and as expected, no induction of MRR was detected up to 10 μM concentration.

The association of $S4_{13}$-PV nanoparticles with the plasma membrane also induced vesicle formation and a partial uptake of $S4_{13}$-PV peptides by small vesicles, which resemble caveosomal structures. Later, the $S4_{13}$-PV peptides were targeted to multivesicular bodies, suggesting that this pathway leads to late endosomal structures. On the other hand, the association of other CPPs with glycosaminoglycans was shown to induce their energy-dependent uptake via clathrin-mediated endocytic pathway (*12, 14*). Both these pathways are dynamin-dependent and could be inhibited with the small cell-permeable drug dynasore (*31*) or by lowering temperature below 18 °C. As expected, the presence of dynasore did not markedly interfere with the assembly of $S4_{13}$-PV nanoparticles, their insertion into plasma membrane, or its destabilization and blurring detected by TEM. However, treatment with dynasore drastically decreased the vesicle formation, but still did not completely abolish it, suggesting that mostly dynamin-dependent processes are active in the uptake of $S4_{13}$-PV peptide, in analogy with Tat and oligoarginine as shown earlier (*21*). Several endocytosis pathways, for example, macropinocytosis, fluid-phase endocytosis, and some other less well understood uptake mechanisms, are dynamin-independent (*44–47*). Although the vesicles, which could by morphology be assigned to these pathways, were present in electron microphotos of dynasore-treated cells, their impact to the uptake of $S4_{13}$-PV_{wt} peptides remained low.

Lowering of incubation temperature, which decreases the plasma membrane fluidity and flexibility, and abolishes most endocytic processes, had a contrasting effect. The association of $S4_{13}$-PV peptide with the extracellular matrix, the formation of nanoparticles, as well as the uniformity of latter were markedly decreased. The cellular uptake of $S4_{13}$-PV peptide was diminished at 10 °C but still not completely stopped, in analogy with our earlier study of other CPPs (*48*). These results support the endocytic uptake mechanism of $S4_{13}$-PV peptides by cells and emphasize the significance of plasma membrane fluidity and dynamic rearrangement of underlying cytoskeleton for the internalization of peptide nanoparticles.

Interestingly, the $S4_{13}$-PV nanoparticles retained their spherical organization within endocytic vesicles for at least 1−4 h, suggesting that the peptide is not dissociated from anionic GAG molecules and its degradation is inhibited. This is also consistent with the observation about HSPGs, which cointernalize with their ligands and remain intact in isolated vesicles for more than three hours (*41*). When the MVBs fuse with lysosomes, their lumenal content is usually degraded or condensed. However, the $S4_{13}$-PV nanoparticles were rather intact even after 24 h incubation. In some vesicles, the high concentration of CPPs had interfered with the integrity of their membrane, since a fraction of vesicles were broken or had lost the continuous membrane and peptides had escaped to the cytosol.

In conclusion, our data demonstrate that $S4_{13}$-PV peptides assemble into spherical structures with diameter of 80−100 nm clustering acidic polysaccharides on cell surface. These nanoparticle-like structures insert into the plasma membrane and by destabilizing and rearranging it induce formation and fission of small endocytic vesicles, but are conveyed toward cell center in large vesicles. The ability of $S4_{13}$-PV peptides to form nanoparticles with about 80−100 nm diameter correlates with the efficacy of their cellular uptake.

ACKNOWLEDGMENT

We thank M. Kure for an excellent technical assistance in electron microscopy and H. Räägel for fruitful discussions and critical reading of manuscript. The work was supported by grants from Estonian Science Foundation (ESF 7058) and from Portuguese Science Foundation (PTDC/BIO/65627/2006).

Rates and Equilibria for Probe Capture by an Antibody with Infinite Affinity

Tolulope A. Aweda[†], Heather E. Beck[†], Anna M. Wu[‡], Liu H. Wei[‡], Wolfgang A. Weber[§], and Claude F. Meares*[,†]

Chemistry Department, University of California, Davis, California, Department of Molecular and Medical Pharmacology, David Geffen School of Medicine, University of California, Los Angeles, California, and Department of Nuclear Medicine, University of Freiburg, Freiburg, Germany. Received January 23, 2010; Revised Manuscript Received March 11, 2010

Probe-capture systems based on proteins and synthetic ligands have become important for new analytical and imaging applications. We have used kinetic measurements of luminescence and measurements of binding by isothermal calorimetry to determine essential rate and equilibrium constants for a system that permanently captures modified DOTA chelates for positron imaging. We used that information along with previous results to quantitatively characterize the behavior of this system in vitro and in vivo. Under physiological conditions at 37 °C, the equilibrium dissociation constant for yttrium *S*-2-(4-aminobenzyl)-1,4,7,10-tetraazacyclododecanetetraacetate from antibody 2D12.5 is 2.0 (± 0.4) × 10^{-9} M and the dissociation rate constant is 7.0 (± 0.7) × 10^{-3} s^{-1}, leading to an inferred association rate constant of 3.5 × 10^{6} M^{-1} s^{-1}. Using these values to interpret data from earlier experiments leads to the rate constant 2.5 × 10^{-2} s^{-1} for covalent attachment of bound yttrium *S*-2-(4-acrylamidobenzyl)-1,4,7,10-tetraazacyclododecanetetraacetate to the G54C mutant of antibody 2D12.5. These values lead to a model for the detailed behavior of the latter system for tumor imaging in vivo that is consistent with experimental observations.

INTRODUCTION

The capture of probe molecules by receptors has an established and increasing role in the biomedical applications of bioconjugate chemistry. Biotinylated probes bind to avidin or streptavidin (*1*); hexahistidine tags bind to NTA[1]chelates (*2*); antibodies bind to haptens (*3*); and a number of engineered proteins bind to synthetic tags (*4*). These systems display a variety of properties, which dictate their applicability to specific problems. Their quantitative rates and equilibria of binding—and, if applicable, attachment—are fundamentally important but not always known. Here, we describe measurements and interpretation of a set of values for the engineered antibody binding site 2D12.5 G54C, which captures labeled acrylamidobenzyl-DOTA (AABD) metal chelates with infinite affinity. This system is highly promising for pretargeted imaging and therapy applications in vivo, and has recently been demonstrated to have potential as a reporter gene (*5*).

EXPERIMENTAL PROCEDURES

Reagents. DOTA and aminobenzyl-DOTA (ABD) were purchased from Macrocyclics (Dallas, TX). TEA and plastic backed thin layer silica (TLC) plates were purchased from EMD Chemicals. Rare earth salts were purchased from Sigma Aldrich (St Louis, MO). Fetal bovine serum and G418 selection antibiotic were also purchased from Sigma Aldrich. Biotechnical grade glycine, DEAE-cellulose, lithium dodecyl sulfate, and glycerol were purchased from Fisher Scientific (Waltham, MA). DTPA and EDTA were purchased from Acros Organics (Geel, Belgium). Microtiter plates were purchased from Greiner Bio-One (Monroe, NC). DMEM, PBS based enzyme-free cell dissociation buffer, and 4−20% Tris-glycine Novex gels were purchased from Invitrogen (Carlsbad, CA). PVDF membrane was purchased from Millipore (Billerica, MA) and SuperSignal West Dura Extended Duration substrate was purchased from Thermo Scientific (Waltham, MA). All buffers were made using 18 mΩ cm water and thoroughly degassed for all experiments. Rabbit antihuman Fc fragment antibody was purchased from Jackson Immuno Research (West Grove, PA), while the horseradish peroxidase conjugated goat antirabbit antibody was purchased from Pierce (Rockford, IL). Tris-HCl was purchased from USB (Cleveland, OH). Bromophenol Blue was purchased from Bio-Rad (Hercules, CA).

Metalation of Chelates. The concentration of stock ABD and DOTA was measured using a Co-57 metal binding assay as previously described (*6*). Briefly, 200 μM stock YCl_3 and $Co(NO_3)_2$ were prepared in metal-free 0.05 N HCl. Next, 80 mM ABD (0.048 mmol, 600 μL) was chelated with 1.5 equiv of YCl_3 or $Co(NO_3)_2$ at 37 °C for 2 h in 0.5 M triethylamine acetate, pH 6.0. Also, 80 mM DOTA (0.048 mmol, 600 μL) was chelated with 1.5 equiv $TbCl_3$ using the same conditions. The percent chelation was measured using competitive metal-binding assay with Co-57. The unreacted excess metal was scavenged with DTPA (0.2 M, 300 μL). In order to remove excess salts, the metal chelates were passed through an anionic DEAE-cellulose column, eluted in ammonium acetate (gradient: 0.1 to 1 M), and then lyophilized four times to remove ammonium acetate, being redissolved in water and re-lyophilized each day. The dry, desalted metal chelate was dissolved in 0.1

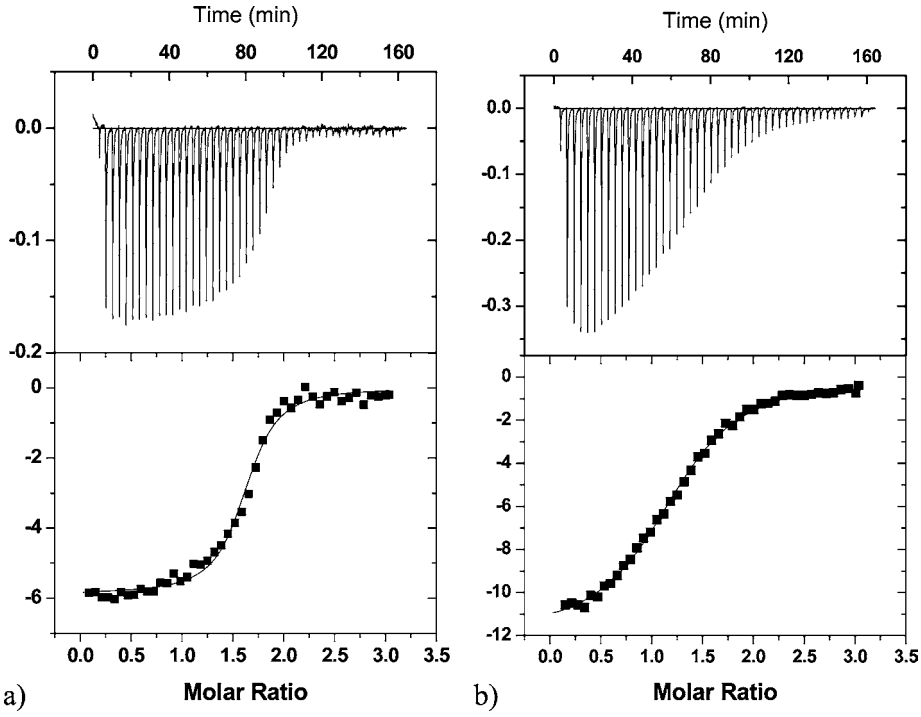

Figure 1. Calorimetric titrations of wild-type 2D12.5 monoclonal antibody (12.5 μM for ABD(Co) or 16.1 μM for competitive titration) with (a) the chelate ABD(Y) (150 μM) in the presence of ABD(Co) (100 μM) (competitive titration), (b) chelate ABD(Co) (150 μM). The upper vertical axis represents the raw differential power in μcal/s between the reference and sample cells, while the lower vertical axis represents the normalized kcal/mol of injected ABD chelate. The experiments were performed at 30 °C in 0.1 M sodium phosphate, pH 7.0.

M sodium phosphate buffer, pH 7.0. The concentration of the metal chelate was confirmed by measuring its absorbance at 286 nm using $\varepsilon_{286} = 1430\ M^{-1}\ cm^{-1}$, as determined from titrations of ABD with standard metal solutions.

Protein Preparation. Wild-type 2D12.5 monoclonal antibody (whole IgG, 50 μM) was dialyzed into the same buffer as the chelates and filtered through a 0.22 μm. The concentration was measured by A_{280} as 48.3 μM ($\varepsilon_{280} = 194\ 900$) and diluted to the appropriate concentration in the sodium phosphate buffer.

Isothermal Titration Calorimetry. This was carried out according to the manufacturer's instructions, using a VP-ITC titration calorimeter (Microcal Inc., Northampton, MA). All thermodynamic data were analyzed with MicroCal software, *Origin 7.0*, which performs nonlinear least-squares curve fitting.

Blank Experiment. ABD(Co) (150 μM) or ABD(Y) (128 μM) in the syringe was titrated in 46 injections into the sample buffer, 0.1 M sodium phosphate (pH 7.0). The small heat change produced was used for blank subtraction from the analyte-ligand experiments.

Competitive Binding Experiments. The high affinity between ABD(Y) and 2D12.5 mAb led to results from direct binding experiments that were not sufficiently accurate to yield a reliable value for the equilibrium constant. The method of Velazquez et al. (*7*) employs a competitive or displacement method using a competing weaker ligand to lower the apparent affinity of the stronger ligand. This approach involves two sets of experiments, as described below.

Direct Titration of Weak Competitor with 2D12.5 mAb. ABD(Co) (150 μM, 12 times molar concentration of the antibody) placed in the syringe was titrated in 45 injections into 12.5 μM 2D12.5 mAb (analyte in the cell, 1.45 mL). The volume for each injection was 6 μL. This experiment was carried out at 30 and 37 °C.

Competitive Binding with Excess of Stronger Competitor in the Syringe. After the first direct titration of the monoclonal antibody 2D12.5 with ABD(Co), the cell was cleaned out and a second titration involving the strong ligand was carried out. 150 μM ABD(Y) in the syringe was titrated in 46 injections against a mixture of 100 μM ABD(Co)−16.1 μM 2D12.5 (analyte in the cell, 1.45 mL). The volume for each injection was 6 μL. Experiments were carried out at 30 and 37 °C. Titrations are shown in Figure 1 and Figure 2.

Time-Resolved Fluorescence. Time-resolved fluorescence measurements were made on a Fluostar Fluorescence microplate reader (BMG Lab Technologies) using the 280 nm excitation and 550 nm emission filters, each with ±10 nm bandpass.

Off-Rate Determination Using 2D12.5 Enhanced Luminescence of Tb^{3+}. The UV excitation of the 2D12.5-DOTA(Tb) complex at 280 nm leads to energy transfer from aromatic amino acid side chains in the antibody to the bound DOTA(Tb), producing an enhanced green Tb luminescence at 545 nm (*8*). We used this phenomenon to measure the dissociation rate of ABD(Y) from the antibody. Monoclonal antibody 2D12.5 (10 μM) was incubated with 100 μM ABD(Y) overnight to ensure that equilibrium association was attained. At the beginning of the luminescence experiment, the DOTA(Tb) complex was quickly added in large excess, so that each ABD(Y) dissociating from the 2D12.5 antibody binding pocket would be replaced immediately by DOTA(Tb). In the experiment, 50 μL of 2 mM DOTA(Tb) was autoinjected into 50 μL of 10 μM 2D12.5+ABD(Y) in TBS (50 mM Tris-HCl, 150 mM NaCl), pH 7.4.This was done at 30 °C and also at 37 °C in 96-well black round-bottom microplates with 5 sets of controls: 2D12.5, 2D12.5+ ABD(Y), 2D12.5+DOTA(Tb), DOTA(Tb) only, and TBS buffer only. In all the wells, total volume was kept at 100 μL and the final concentration of 2D12.5 mAb kept at 5 μM in the appropriate wells. The time-resolved fluorescence was read at 550 ± 10 nm, 40 μs delay, with 200 scans every 15 s. Each reading was blanked with the buffer and DOTA(Tb) readings. Also, increasing concentrations of DOTA(Tb) (2 mM and 4 mM final concentrations) were evaluated in order to ensure that sufficient excess was being used. The experiments were carried

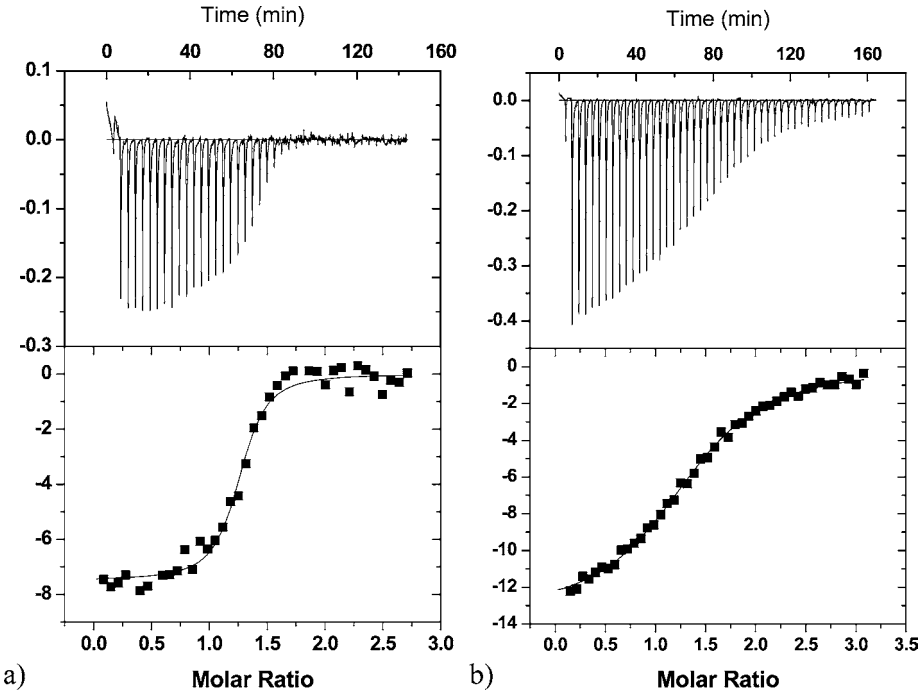

Figure 2. Calorimetric titrations of wild-type 2D12.5 monoclonal antibody (15.6 μM for ABD(Co) or 12.4 μM for competitive titration) with (a) the chelate ABD(Y) (150 μM) in the presence of ABD(Co) (100 μM) (competitive titration) and (b) the chelate ABD(Co) (150 μM). The upper vertical axis represents the raw differential power in μcal/s between the reference and sample cells, while the lower vertical axis represents the normalized kcal/mol of injected ABD chelate. The experiments were performed at 37 °C in 0.1 M sodium phosphate, pH 7.0.

out in triplicate. As a control, nonspecific mouse IgG was incubated with ABD(Y) and analyzed the same way as 2D12.5 mAb. Data are presented in Figure 3.

Western Blots to Evaluate the Number of Binding Sites on DAbR1-Transfected U-87 Glioma Cells. Glioblastoma (U87) cells stably transfected with the DAbR1 gene and the scFv-human Fc minibody standard protein were prepared as described (*5*). Cells were maintained at 37 °C in a humidified CO_2 incubator (5% CO_2) in complete Dulbecco's modified Eagle's medium containing 10% (v/v) heat inactivated fetal bovine serum and G418 selection antibiotic (250 μg/mL). Cells were dissociated for Western blots using PBS based enzyme-free cell dissociation buffer and pelleted by centrifugation (1000 × *g* for 5 min). Cell pellets were resuspended in phosphate-buffered saline and diluted 1:1 with 5× concentrated SDS PAGE sample application buffer consisting of 125 mM Tris-HCl pH 8, 25 M EDTA, 10% (w/v) lithium dodecyl sulfate, 50% (v/v) glycerol, 0.05% (w/v) bromophenol blue, and 0.5% (v/v) β-mercaptoethanol. Resuspended cells were boiled for 10 min and sonicated in an ice bath in 5 s bursts until samples were completely soluble (5 to 6 min). Reduced whole cell lysates were loaded into 4−20% Tris-glycine Novex gel and electrophoresed at 150 V for 1.5 h. Protein was transferred to a polyvinylidene difluoride membrane and blocked overnight at 4 °C in Tris-buffered saline, pH 7.4, with 5% nonfat milk. The membranes were probed for 2 h with rabbit antihuman Fc antibody (1:5000) in TBST. The membranes were washed 6× with 50 mL of TBST and probed for 2 h with a horseradish peroxidase conjugated goat antirabbit antibody (1:5000). Blots were washed 6× with 50 mL of TBST and were treated with SuperSignal West Dura Extended Duration substrate according to manufacturer instructions and imaged with a Typhoon Trio variable mode imaging system (GE Healthcare Life Sciences) using the chemiluminescent setting. The band density of triplicate whole cell lysate samples were measured and compared with a human IgG Fc standard curve using Bio-Rad Quantity One software. Results are shown in Figure 4.

Mathematical Modeling of Kinetic Behavior. The systems of differential eqs 1−4 and 5−9 (see below) were solved numerically, and Figures 5−8 were prepared, using Mathematica 7 software.

RESULTS AND DISCUSSION

In what follows, we build up a simple mathematical description of the behavior of this probe-capture system that is consistent with all the data available. This begins with calorimetric measurements of the equilibrium thermodynamics of reversible binding of aminobenzyl-DOTA(Y) to mouse 2D12.5 IgG. We turned to calorimetry after surface plasmon resonance experiments failed to give reliable results; this appeared to result primarily from the small size of the DOTA chelate, which led to a lack of sensitivity to binding. Alternative surface plasmon resonance strategies were not successful in our hands. On the other hand, calorimetry generally is suitable for small molecules as well as macromolecules.

Thermodynamic Parameters Obtained from ITC. Using isothermal titration calorimetry, we measured the binding affinity

Table 1. Thermodynamic Parameters for the Reversible Association of Aminobenzyl-DOTA Chelates to Antibody 2D12.5 at 30 and 37 °C[a]

chelate	T, °C	K_A, M^{-1}	ΔG, kcal/mol	ΔH, kcal/mol	ΔS, cal/(mol K)	K_D, M
ABD(Co)	30	$8.2(\pm0.9) \times 10^5$	−8.2(±0.1)	−12.2(±0.4)	−13.2(±1.3)	$1.2(\pm0.1) \times 10^{-6}$
ABD(Co)	37	$7.1(\pm0.4) \times 10^5$	−8.3(±0.1)	−12.4(±4.8)	−13.3(±4.8)	$1.4(\pm0.1) \times 10^{-6}$
ABD(Y)	30	$3.3(\pm2.1) \times 10^8$	−11.7(±0.4)	−18.2(±0.5)	−21.5(±2.9)	$3.1(\pm2.0) \times 10^{-9}$
ABD(Y)	37	$5.2(\pm0.9) \times 10^8$	−12.4(±0.2)	−20.1(±1.2)	−24.9(±4.1)	$2.0(\pm0.4) \times 10^{-9}$

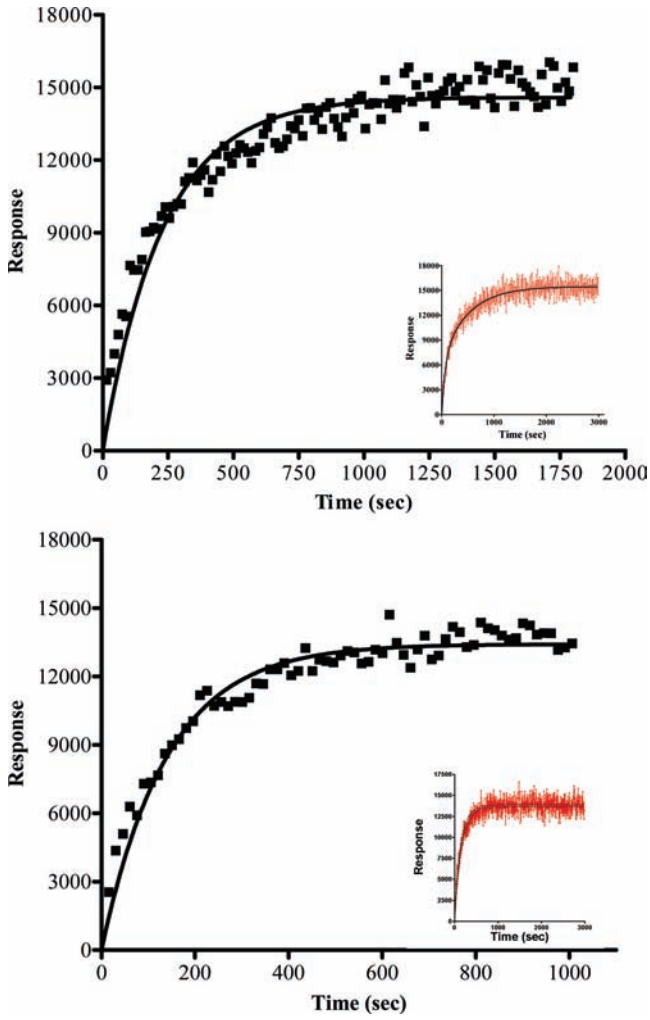

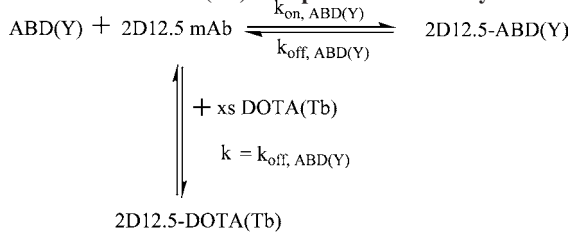

Figure 3. Curve fits from the determination of the dissociation rate constant between ABD(Y) and parental 2D12.5 antibody. Upper panel, 30 °C; lower panel 37 °C (note: time scales are different). 1, 2, and 4 mM DOTA(Tb) was used to competitively replace the ABD(Y) when it dissociated from the 2D12.5 binding site. Triplicate experiments were done at each DOTA(Tb) concentration, and all the data were combined for the fits and plots. Insets show longer total time courses, which indicate that equilibrium has been reached.

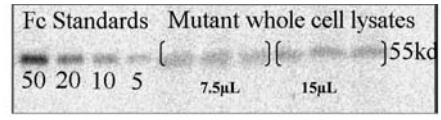
Scheme 1. Competition Experiment to Measure k_{off} by Forming the Luminescent DOTA(Tb) Complex with Antibody 2D12.5[a]

[a] First, the antibody was saturated with ABD(Y), then it was mixed with a large excess of DOTA(Tb).



and other thermodynamic parameters involved in the reversible interaction of ABD(Y) and parental 2D12.5 monoclonal antibody. From previous reports (*9*), we expected that the K_D should be on the order of 10^{-8} M, indicating that the binding interaction is strong. In the direct titration of ABD(Y) with 2D12.5, the binding curve was difficult to fit because of high binding affinity. However, as shown by Velazquez et al. (*7*), the apparent affinity of a strong ligand can be lowered by the presence of a weaker ligand so that a more accurate binding affinity can be measured for the strong ligand. Sigurskjold (*10*) provides a complete mathematical analysis of the displacement or competitive isothermal titration calorimetric technique. These experiments were carried out at 30 °C (Figure 1) and 37 °C (Figure 2); results are summarized in Table 1.

Having the equilibrium constant in hand, we measured the dissociation rate constant k_{off} at 30 and 37 °C; we did this indirectly, by measuring the luminescence of DOTA(Tb) as it bound to the antibody when ABD(Y) dissociated, as described below.

Statistical Analysis of Fluorescence Time-Resolved Data. As shown in Scheme 1, the rate of association of the excess DOTA(Tb) with 2D12.5 was taken to equal the rate of dissociation of ABD(Y) from 2D12.5 mAb. The terbium luminescence response at 545 nm for DOTA(Tb) bound to 2D12.5 mAb (*8*) was monitored as a function of time. To ensure that excess DOTA(Tb) was present, three different concentrations were used. Similar results were obtained in all cases, and all three sets of triplicate results were fitted to one curve. The k_{off} was obtained from a fit of the following equation that describes the pseudo-first-order association kinetics: $Y = Y_{max}(1 - e^{-kt})$, where Y is the terbium luminescence intensity and the pseudo-first-order rate constant for binding DOTA(Tb) is $k = k_{off}$ s^{-1} (with t in seconds).

The dissociation rate constant of ABD(Y) with 2D12.5 antibody was determined from the plot of the fluorescence signal growth of 2D12.5-DOTA(Tb) complex with time (Figure 3). Attempts to fit the data to more than one rate constant gave inferior results. Having measured k_{off} and K_D, we can calculate $k_{on} = (k_{off}/K_D)$ M^{-1} s^{-1} (Table 2).

With these results, we are now able to model the behavior of this infinite affinity system, explaining previous observations in vitro and in vivo. Corneillie et al. (*11*) studied the rate of formation of the covalent bond between the acryloyl group of

Whole cell lysate	Band Density ODu/mm^2	Average band density ODu/mm^2	Average Band mass in ng	Average # Fc/cell ±SD
7.5µL samples	4924; 4944; 4367	4745 (±328)	3.4 (± 1.3)	$5.5(\pm2.2)\times10^4$
15µL samples	5435; 5708; 5737	5626 (±167)	6.9 (±0.7)	$5.7(\pm0.6)\times10^4$

Figure 4. Western blot of reduced whole cell lysate vs human Fc standard. Calculations were performed for 4.4×10^4cell/μL and a formula weight of 110 kDa for the protein, using the equation $y = 0.004x - 15.63$ obtained by fitting the standards. There are 2 binding sites per 110 kDa protein, implying $\sim10^5$ binding sites per cell.

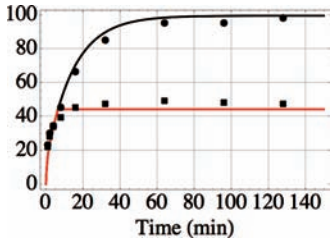


Figure 5. Formation of the covalent bond between AABD(Y) and the G54C mutant of DOTA-binding Fab 2D12.5 in vitro at 37 °C, pH 7.5, as a function of time; nonlinear least-squares fit of data from ref *11* using eqs 1−4. The top data (●) are for bond formation in the absence of competitor, while the bottom data (■) are the result of adding excess unlabeled competitor after 6 min. The values $k_{on} = 3.5 \times 10^6$ M^{-1} s^{-1} and $k_{off} = 7.0 \times 10^{-3}$ M^{-3} s^{-1} determined in this work lead to the nonlinear least-squares value $k_{irr} = 2.5 \times 10^{-2}$ s^{-1} for formation of the covalent bond, and probability $x = 0.2$ of binding in a reactive conformation, all of which were used to construct the black curve. The red curve was drawn using the same values, with the added constraint of no association or reassociation after 6 min.

AABD(Y) and the cysteine of the G54C mutant of antibody 2D12.5. As shown in Figure 5, we were able to fit Corneillie's results with the following set of kinetic equations:

$$\frac{d[AABD(Y)]}{dt} = \frac{d[G54C]}{dt} = k_{on}[AABD(Y)][G54C] + k_{off}[C_R] + k_{off}[C_{NR}] \quad (1)$$

$$\frac{d[C_R]}{dt} = xk_{on}[AABD(Y)][G54C] - k_{off}[C_R] - k_{irr}[C_R] \quad (2)$$

$$\frac{d[C_{NR}]}{dt} = (1 - x)k_{on}[AABD(Y)][G54C] - k_{off}[C_{NR}] \quad (3)$$

$$\frac{d[P]}{dt} = k_{irr}[C_R] \quad (4)$$

In order to fit the complex kinetic behavior observed in ref *11*, it is necessary to assume that AABD(Y) can form either a reactive complex C_R (which can form the product P) or a nonreactive complex C_{NR} with the G54C antibody binding site. This is consistent with the observation of two modes of binding in crystal structures of the parental antibody complex (*12*). The fit in Figure 5 gives the value $k_{irr} = 1.5$ min $^{-1} = 2.5 \times 10^{-2}$ s^{-1} derived using the nonlinear least-squares method. The partitioning of complex formation between the nonreactive C_{NR}, with probability $1 - x = 0.8$, and the reactive C_R, with probability $x = 0.2$, is also necessary to fit these data.

It is expected that the different binding modes should have different values for k_{on} and k_{off}. However, the values of k_{on} and k_{off} are not sufficiently different to be measured separately by the methods available to us. The crystal structures show two binding modes in which the antibody−DOTA interactions are almost identical but the DOTA side chain is oriented differently (*12*). On the basis of the proximity of the DOTA side chain to residue 54 in one structure but not the other, these could plausibly correspond to the reactive and unreactive binding observed kinetically in ref *11*. The goodness of fit in Figure 5 justifies the use of this minimal set of rate constants to model the processes of tumor uptake discussed below.

We have found that the 2D12.5 G54C Fab expressed in *D. melanogaster* S2 cells (*11*) is largely cysteinylated (has a cysteine monomer attached to Cys-54 by a disulfide bond), which protects the Cys-54 side chain from reaction with electrophiles such as AABD(Y) (*13*). The experiments in ref *11* were carried out using an excess of radiolabeled AABD(Y) to detect the rate of covalent bond formation by Michael addition; thus, the results were sensitive only to protein with a free thiol at G54C, and the value of k_{irr} is not affected by the presence of cysteinylated protein.

Reviewing the values of these new rate constants shows that the second-order association reaction controlled by $k_{on} = 3.5 \times 10^6$ M^{-1} s^{-1} is rather rapid compared to the more typical values of $k_{on} \approx 10^5$ M^{-1} s^{-1} observed for antibody−protein association (*14*). However, it is not as fast as the biotin−streptavidin association, for which the rate constant is reported to be $k_{on} = 7.5 \times 10^7$ M^{-1} s^{-1} at 25 °C (*15*). This comparison is important because the streptavidin−biotin system has been widely used for pretargeted delivery of small probes for imaging and therapy of cancer (*16*). However, streptavidin is immunogenic in human patients (*17*), so the irreversible antibody capture system may provide a desirable alternative: currently, making antibodies minimally immunogenic is less challenging than doing the same for streptavidin (*5*).

The rate constant for reversible dissociation of nonelectrophilic ABD(Y) from parental antibody 2D12.5, $k_{off} = (7.0 \pm 0.7) \times 10^{-3}$ s^{-1}, is quite fast compared to that for dissociation of biotin from streptavidin, which is reported to be $k_{off} = (4.1 \pm 0.3) \times 10^{-5}$ s^{-1} at 37 °C under comparable conditions (*18*). This rapid dissociation, combined with the effects of irreversible binding and the branching between reactive and nonreactive complexes, makes the behavior of the reactive AABD(Y) with the G54C binding site quite unusual. The results above imply that in a homogeneous solution approximately $x \cdot (k_{irr})/(k_{irr} + k_{off}) = 0.2 \cdot (25)/(25 + 7) \cong 16\%$ of the AABD(Y) molecules will form permanent bonds with the receptor site the first time they bind, without ever dissociating, while the majority (~80%) will dissociate, diffuse, and rebind. Because the results in vivo will depend on additional factors such as effective target site concentration on cell surfaces and transport behavior of the probe in a tumor, it was important to observe this system in an animal model to see if it would exhibit biological properties useful for imaging and perhaps therapy.

Wei et al. (*5*) prepared an engineered version of the 2D12.5 G54C antibody with infinite affinity, termed DAbR1, in which the binding site was expressed as part of an scFv-Fc fusion protein on the surface of U-87 human glioma cells implanted in the flanks of SCID mice. The behavior of AABD(^{86}Y) after injection into the tail vein was monitored by microPET imaging, with highly successful results; some experimental data from ref *5* are used in Figure 6. Having determined values for k_{on}, k_{off}, k_{irr}, and x under physiological conditions in vitro, we sought to use these numbers to fit the data for in vivo tumor uptake in order to understand how this system behaves relative to reversible ligand−receptor pairs.

It is convenient to describe the basic unit of a glioma tumor as a "cord", a cylindrical array of cancer cells surrounding a blood capillary (*19*), from which the tumor tissue receives nutrients and also small molecules such as the PET probe AABD(^{86}Y). Characterizing the behavior of cells around one capillary can lead to a useful description of the main features of the tumor (*20*). Our goal here is to consider the major consequences of irreversible binding of the probe to its receptor, in order to gain insight into the essentials of this chemistry in a living organism.

The immediate requirement is the formulation and solution of a set of partial differential equations to describe not only the chemistry already considered in vitro but also the diffusion of the AABD(Y) probe in vivo to its receptors on the tumor cell surface. Assuming cylindrical symmetry and considering a small segment of a long cylinder reduces the geometry to one

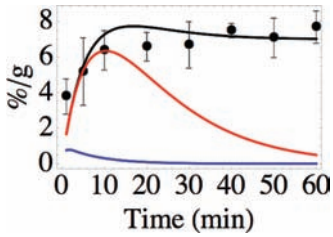

Figure 6. Experimental tumor uptake data (● ± SD) from ref *5*, showing the results of injection of AABD(^{86}Y) into the tail veins of SCID mice bearing xenograft U-87 human glioma tumors expressing the DAbR1 reporter gene, plotted as average % dose per gram tissue vs time. The black curve shows how these data are fit by the solutions to the concentrations of all labeled species in eqs 5−9. The red curve shows the behavior predicted if irreversible binding did not occur ($k_{irr}\rightarrow 0$), and the blue curve shows the behavior predicted if there were no binding of the probe at all ($k_{on}\rightarrow 0$), which is consistent with experimental observations of mice bearing xenograft U-87 human glioma tumors that do not carry the DAbR1 gene.

dimension: the radial distance r from the center of the capillary (*20*). The appropriate reaction-diffusion equations are given below as eqs 5−9; only the probe diffuses, but the concentration of each species depends on both r and t:

$$\frac{\partial[\mathrm{AABD(Y)}]}{\partial t} = D\left\{\frac{\partial^2[\mathrm{AABD(Y)}]}{\partial r^2} + r^{-1}\cdot\frac{\partial[\mathrm{AABD(Y)}]}{\partial r}\right\} - k_{on}[\mathrm{AABD(Y)}][\mathrm{DAbR1}] + k_{off}[C_R] + k_{off}[C_{NR}] \quad (5)$$

$$\frac{\partial[\mathrm{DAbR1}]}{\partial t} = -k_{on}[\mathrm{AABD(Y)}][\mathrm{DAbR1}] + k_{off}[C_R] + k_{off}[C_{NR}] \quad (6)$$

$$\frac{\partial[C_{NR}]}{\partial t} = (1 - x)k_{on}[\mathrm{AABD(Y)}][\mathrm{DAbR1}] - k_{off}[C_{NR}] \quad (7)$$

$$\frac{\partial[C_R]}{\partial t} = xk_{on}[\mathrm{AABD(Y)}][\mathrm{DAbR1}] - k_{off}[C_{NR}] - k_{irr}[C_R] \quad (8)$$

$$\frac{\partial[P]}{\partial t} = k_{irr}[C_R] \quad (9)$$

We sought realistic solutions to these equations by fitting the in vivo tumor uptake data from ref *5*, using nonlinear least-squares with the concentration of AABD(Y) at the periphery of the capillary as the only adjustable parameter, along with literature values for the typical radius of a capillary (10 μ) and a tumor cord (∼100 μ) (*20, 21*), the diffusion coefficient of a metal chelate in brain tissue (3.4×10^{-6}cm^2/s) (*22*), and the observed ∼5 min circulatory half-life of the AABD(Y) probe (*5*). The calculated behavior is compared to experimental data in Figure 6; it is important to emphasize that the values for k_{on}, k_{off}, k_{irr}, and x were those determined from in vitro experiments described above, with no adjustments. An important underlying assumption throughout is that, consistent with the crystal structures of parental Fab-DOTA complexes (*12*), the complex tolerates molecular changes at positions peripheral to the sites of van der Waals contact between protein and DOTA. Thus, the most important interactions between receptor and ligand persist through genetic substitution of Cys for Gly at position 54, reformatting of the mouse IgG to chimeric G54C Fab or to G54C scFv, and chemical changes at the *para* position of the DOTA side chain.

Figure 6 also illustrates the predicted effects of eliminating irreversible binding of the AABD(Y) probe in the tumor while

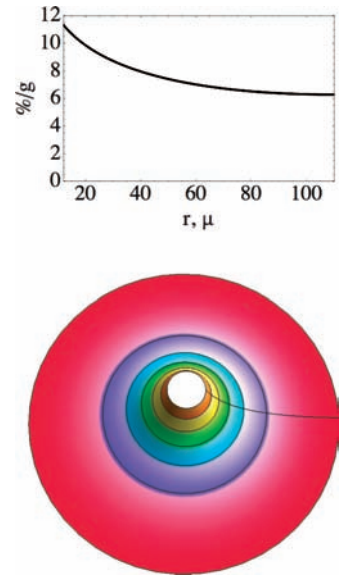

Figure 7. Top: predicted concentration of the probe 60 min after injection, as a function of distance from just outside the boundary of the capillary (12 μ) to the outer periphery of the tumor cord (110 μ from the center of the coordinate system). Bottom: contour plot of probe concentration in a transaxial slice of the tumor from 12 μ (∼12%/g) to 110 μ (∼6%/g); color of contour changes at approximately 1%/g intervals. The capillary (radius 10 μ) is within the empty space in the center, and the concentration profile along the radial line is given by the graph above.

maintaining reversible binding (setting $k_{irr}\rightarrow 0$) or eliminating probe binding altogether (setting $k_{on}\rightarrow 0$). The fit to the in vivo experimental data in Figure 6 was made with the assumption that all the G54C binding sites expressed on cell surfaces have the side chain of Cys-54 free to react with the acryloyl group of AABD(Y), which would not be true for the highly cysteinylated antibody expressed in S2 cells (*13*). Changing the calculation to assume a significant degree of blocked Cys-54 leads to curves that resemble the red curve ($k_{irr}\rightarrow 0$) in Figure 6, diverging markedly from experimental observation. Thus, the binding sites expressed on the surface of U-87 cells in vivo exhibit little or no blockage of the Cys-54 side chain. Because there is no established way to change the oxidation state of the expressed G54C side chain on cell surfaces in vivo, this information is crucial to the design of future experiments. It also illustrates the diversity of post-translational modification in eukaryotic cells.

One of the central issues of molecular targeting is the transport of probe molecules, whether large or small, from the blood into the target tissue (*21*). A number of interesting experiments have been carried out to demonstrate the effects of various parameters on this process (e.g., *refs* 23, 24). The results in ref *5* demonstrate rapid, durable uptake in a xenograft tumor but lack the spatial resolution to provide information about whether the irreversible binding occurs at the edge of the capillary or throughout the tumor. The model developed here predicts that probe molecules present in the tumor 1 h after administration will all be irreversibly bound to the engineered receptor, with a spatial distribution plotted in Figure 7. While the average concentration of probe in the tumor at 1 h was observed to be approximately 7%/g, the predicted concentration near the capillary is almost 12%/g, declining to slightly more than 6%/g near the periphery of the tumor cord.

It is informative to use the solutions of eqs 5−9 to gain a sense of how the concentrations of the different probe-containing species vary with time and position in the tissue. The curves in Figure 8 imply that the free probe AABD(Y) is quickly incorporated into complexes C_{NR} and C_R, with the latter rapidly

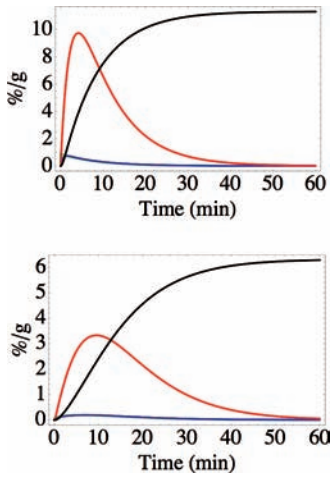

Figure 8. Predicted speciation of the probe in the tumor at two positions, as a function of time. Top: near the capillary surface (12 μ from the center of the coordinate system, for which the capillary radius is 10 μ). Bottom: near the outer periphery of the tumor cord (distance 110 μ from the center of the coordinate system, 100 μ from the edge of the capillary). The curves represent product P (black), nonreactive complex C_{NR} (red), and, practically superimposed, the reactive complex C_R (blue) and free probe AABD(Y) (green). The product P dominates the concentrations of the other species after about 20 min.

converted to P. Because of the short lifetime of either complex, the product P becomes the dominant species within a short period. Rapid clearance of the probe from the circulation leads to disappearance of the other species from the tumor before 60 min has elapsed. The behavior illustrated in Figure 8 for positions near the capillary and near the outer periphery of the tumor cord is predicted to be qualitatively similar at intermediate distances from the capillary, with no remarkable differences except that the final concentration of P varies with r according to Figure 7, and the concentrations of all the species are predicted to change more slowly farther from the capillary.

The interplay between molecular transport and ligand−receptor binding provides an almost inexhaustible range of possibilities for molecular imaging probes. This is true when irreversible binding may take place, as in the case of antibodies with infinite affinity (*3, 25*). In the most extreme manifestation, an irreversible probe molecule would encounter its receptor and become permanently attached immediately after entering tumor tissue; in that case, the curve in Figure 7 would be a narrow peak at the left side, falling to zero with increasing distance. In the case examined here, the probe has both reactive and nonreactive modes of binding to the receptor, and the latter is more probable; nonreactive binding and dissociation can serve to further spread the probe through the tissue before it becomes permanently fixed on a receptor.

If we compare this to purely reversible binding, we see the possibility that it can offer a useful middle ground encompassing the most desirable aspects of opposing extremes. Very strong (though reversible) binding such as provided by the streptavidin−biotin pair would be expected to yield a zone of stably bound probe molecules near the capillary, as long as streptavidin is in excess over biotinylated probe molecules. This nonuniform distribution of probes in tissue, referred to as the binding-site barrier, could be ameliorated if the concentration of avidin molecules were too low to efficiently capture the probes or if the concentration of probe molecules was large enough to saturate the streptavidin sites, allowing other probe molecules to diffuse past. On the other hand, weaker reversible binding naturally allows small probe molecules to penetrate into tissue by virtue of repeated dissociation, diffusion, and association. This might eventually lead to uniform distribution in tissue, but since the binding is not durable, the concentration of the probe falls to zero in an inconveniently short time. The contour plot in Figure 7 implies a combination of durable binding and broad distribution that would be difficult to produce by other means.

ACKNOWLEDGMENT

We thank Dr. Andrew Fisher for sharing his isothermal calorimeter and instructions for its use, Dr. Mark McCoy and Dr. Michael Toney for insightful discussion and help on the kinetics experiments, and Dr. Tove Olafsen for the human IgG standard. Microencapsulation of islets with a semipermeable membrane, i.e., bioartificial pancreas, is a promising way to transplant islets without the need for immunosuppressive therapy for insulin-dependent diabetes mellitus (type I diabetes). However, materials composing a bioartificial pancreas are not ideal and might activate defense reactions against foreign materials. In this study, we propose an original method for microencapsulation of islets with living cells using an amphiphilic poly(ethylene glyocol)-conjugated phospholipid derivative (PEG-lipid) and DNA hybridization. PolyA and polyT were introduced onto the surfaces of the islets and HEK 293 cells, respectively, using amphiphilic PEG-lipid derivatives. PolyA20 modified HEK cells were immobilized onto the islet surface where polyT20-PEG-lipid was incorporated. The cells spread and proliferated on the islet surface, and the islet surface was completely encapsulated with a cell layer after culture. The encapsulated islets retained the ability to control insulin release in response to glucose concentration changes.

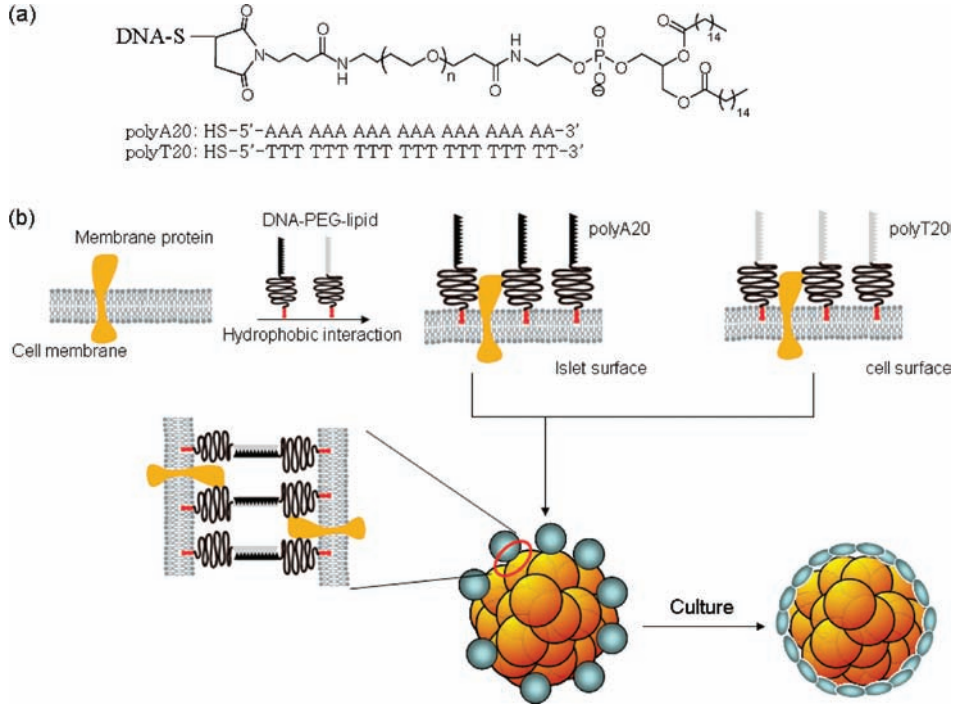
INTRODUCTION

The bioartificial pancreas, which encapsulates islets of Langerhans (islets) within a semipermeable membrane, is one of the therapeutic devices for patients with insulin-dependent diabetes mellitus (type I diabetes). It is a safe and simple way to transplant islets without the need for immunosuppressive therapy. The semipermeable membrane protects the islets from the immune system of a recipient patient, and thus, the islets are expected to survive and release insulin for a long period of time and thereby control glucose metabolism. Various types of bioartificial pancreas have been proposed and developed (*1*−*3*), with the microencapsulated type being a promising model. In this example, islets are microencapsulated within an alginate/poly(L-lysine) polyion complex membrane (*4*) or an agarose hydrogel (*5*−*8*). Our group has used the agarose system and has demonstrated its efficacy in diabetic animals (*5*−*8*). Recently, we also have developed an original design for a bioartificial pancreas for transplantation into the liver through the portal vein (*9*−*15*). However, materials composing a bioartificial pancreas have not been ideal and might activate defense reactions against foreign materials. Compatibility of the membrane with the recipient patient should be improved.

We proposed to enclose islets from a donor under a layer of cells from a recipient to increase compatibility with the patient. Since the outermost surface is the recipient's own cells, the host immune defense system will not be provoked. In our previous study, we developed a method to enclose islets with living cells (*15*). Amphiphilic poly(ethylene glycol)-conjugated phospholipid derivatives (PEG-lipid) and biotin/streptavidin reactions were employed (*15*). Although the biotin/streptavidin reaction worked well to cover the islets with living cells, streptavidin is a xenogeneic protein and is expected to activate the host immune system. We sought to improve this technique with the use of biocompatible materials.

In this study, we employed DNA hybridization instead of the biotin/streptavidin reaction. Polyadenine (polyA) and polythymine (polyT) were introduced onto the surfaces of the islets and HEK 293 cells, respectively, by using polyA or polyT-conjugated PEG-lipid. We already succeeded in the cell−cell attachment induced by hybridization of DNA-conjugated PEG-lipid (*18*). The hybridization of DNA-conjugated PEG-lipid was effectively used for the cell−cell attachment and cell-immobilization to the substrate. The HEK 293 cells were thereby immobilized on the surface of the islets through hybridization of polyA and polyT. A layer of living HEK cells was formed on the surface of islets.

EXPERIMENTAL PROCEDURES



Materials. α-*N*-Hydroxysuccinimidyl-*ω*-maleimidyl poly(ethylene glycol) (NHS-PEG-Mal, M_w: 5000) was purchased from Nektar Therapeutics (San Carlos, USA). 1, 2-Dipalmitoyl-*sn*-glycerol-3-phosphatidylethanolamine (DPPE) was purchased from NOF Corporation (Tokyo, Japan). Dichloromethane, triethylamine, sucrose, and diethyl ether were purchased from Nacalai Tesuque (Kyoto, Japan). Hoechst 33342 nuclear stain was purchased from Dojindo Laboratories (Kumamoto, Japan). Alexa 488-labeled goat antiguinea pig IgG, minimum essential medium (MEM), HEPES buffer solution, Hanks' balanced salt solution(HBSS), Medium 199, RPMI-1640 medium, penicillin, and streptomycin were purchased from Invitrogen Co. (Carlsbad, CA, USA). Fetal bovine serum (FBS) was obtained from Equitech-Bio, Inc. (TX, USA), and phosphate-buffered saline (PBS) from Nissui Pharmaceutical Co. Ltd. (Tokyo, Japan). Enzyme-linked immunosorbent assay (ELISA) kits for the insulin assay were purchased from Shibayagi Co., Ltd. (Gunma, Japan). Tissue-Tek was purchased from Sakura Fine Technical Co. Ltd. (Tokyo, Japan). Goat normal serum and polyclonal guinea pig anti-insulin serum were purchased from Dako (Glostrup, Denmark). The 10% formalin solution, dithiothreitol (DTT), and Triton X-100 were purchased from Wako Pure Chemical (Osaka, Japan). NAP-5 column was purchased from GE health care (GE Healthcare UK Ltd., Buckinghamshire, UK).

Synthesis of polyDNA-PEG-Phospholipid Conjugate (polyDNA-PEG-lipid). Mal-PEG-lipid was synthesized by first dissolving NHS-PEG-Mal (180 mg), triethylamine (50 μL) and

Scheme 1[a]

[a] (a) Chemical structure of DNA-conjugated PEG-DPPE (polyDNA-PEG-lipid) and the DNA sequence of polyA20 and polyT20. (b) Schematic illustration of interaction between polyDNA-PEG-lipid and a lipid bilayer of the cell membrane, and immobilization of living cells to the islet surface. DNA (polyA20 or polyT20)-PEG-lipid has hydrophobic acyl chains which anchor into the cell membrane. After mixing polyT-PEG-lipid-modified GFP-HEK cells and polyA-PEG-lipid-modified islets, they were suspended in medium and cultured at 37 °C and 5% CO_2. During culture, GFP-HEK cells spread and grew on the islet surface.

DPPE (20 mg) in dichloromethane and stirring for 36 h at room temperature as shown in Scheme S1 (Supporting Information) (rt) (*12*). After precipitation with diethyl ether, Mal-PEG-lipid was obtained as a white powder (190 mg, yield 80%). ^{1}H NMR ($CDCl_3$, 400 MHz, δ ppm): 0.88 (t, 6H, $-CH_3$), 1.25 (br, 56H, $-CH_2-$) 3.64 (br, 480H, PEG), 6.71 (s, 2H, $-HC{=}CH-$, maleimide).

The structure of polyDNA-PEG-lipid was shown in Scheme 1a. PolyA20 and polyT20 which carry $(CH_2)_6$-SS-$(CH_2)_6$-OH at 5′ end were purchased from Sigma-Aldrich Chemical Co (see Scheme S1 in Supporting Information). PolyDNA-SH was prepared by reduction of the disulfide bond with DTT in accordance with the instructions of the manufacturer. Briefly, polyDNA-disulfide conjugate (in 10 mM Tris-HCl, 1 mM EDTA, pH 8.0) was mixed with DTT (0.04 M) for 16 h at rt for removal of protection group for thiol. After purification with NAP-5 column, polyDNA-SH was obtained.

The SH groups at the 5′-ends of polyDNAs were used to form conjugates with the Mal-PEG-lipid. A PBS solution of polyDNA-SH (1.0 mg) was mixed with Mal-PEG-lipid (5.0 mg) and the reaction mixture was left for 24 h at rt to form conjugations. polyDNA-PEG-lipid (500 μg/mL in PBS) was used for surface modification of cells and islets without any further purification.

Encapsulation of Islets with GFP-HEK Cells. HEK293, which stably expressed enhanced green fluorescence protein (EGFP) (GFP-HEK), was kindly supplied by Dr. K. Kato (Institute for Frontier Medical Sciences, Kyoto University). The GFP-HEK cells were routinely maintained in MEM supplemented with 10% FBS, 100 U/mL penicillin, and 0.1 mg/mL streptomycin. GFP-HEK cells were collected by centrifugation (180 × *g*, 5 min, rt) after treatment with trypsin. The cells were washed with HBSS to remove the medium. A cell pellet (2×10^6 cells) was obtained by centrifugation. After the addition of polyT20-PEG-lipid solution (50 μL, 500 μg/mL) to the cell suspension, the suspension was incubated for 1 h with gentle agitation at rt. The cells were then suspended in 10 mL HBSS and collected by centrifugation (180 × *g*, 5 min, 25 °C, twice) to obtain polyT20-PEG-lipid-modified cells.

Islets were isolated from the pancreas of female Syrian hamsters (7−8 weeks old, Japan SLC, Inc., Shizuoka, Japan) using the collagenase digestion method. The islets were cultured for 7 d after isolation to remove cells damaged by the isolation procedure. The islets were maintained in culture medium (Medium 199 with 10% FBS, 8.8 mM HEPES buffer, 100 units/mL penicillin, 100 μg/mL streptomycin, and 8.8 U/mL heparin). A solution of polyA20-PEG-lipid solution (500 μg/mL, 100 μL of PBS) was added to suspension of the islets in serum-free medium (200 islets), and the mixture was incubated at rt for 1 h. After washing three times with serum-free medium, polyA20-PEG-lipid-modified islets were obtained. Finally, polyT20-PEG-lipid-modified GFP-HEK cells (2×10^6) and polyA20-PEG-lipid-modified islets (200 islets) were mixed in serum-free medium (300 μL), and the mixture was incubated for 60 min with gentle agitation at rt. The GFP-HEK cell-immobilized islets were picked up by hand using a Pasteur pipet (inside diameter: 1 mm) under a stereomicroscope and cultured on a nontreated dish at 37 °C under 5% CO_2 in Medium 199 supplemented with 10% FBS. Islets were observed by a confocal laser scanning microscope (FLUOVIEW, FV500, Olympus Optical Co. Ltd., Tokyo, Japan) and a phase-contrast microscope (IX71, Olympus). The FITC and GFP were excited by an argon laser (488 nm) and the fluorescence was detected though a bandpass filter (510−550 nm).

Histochemical Analysis. GFP-HEK cells-immobilized islets were washed with PBS and then transferred to 10% formalin solution and incubated for 1 d at rt. The formalin solution was removed, and the islets were sequentially kept in 3% and 10% sucrose in PBS for 1 d, followed by incubation in 20% sucrose in PBS for an additional 1 d at rt. The islets were embedded in

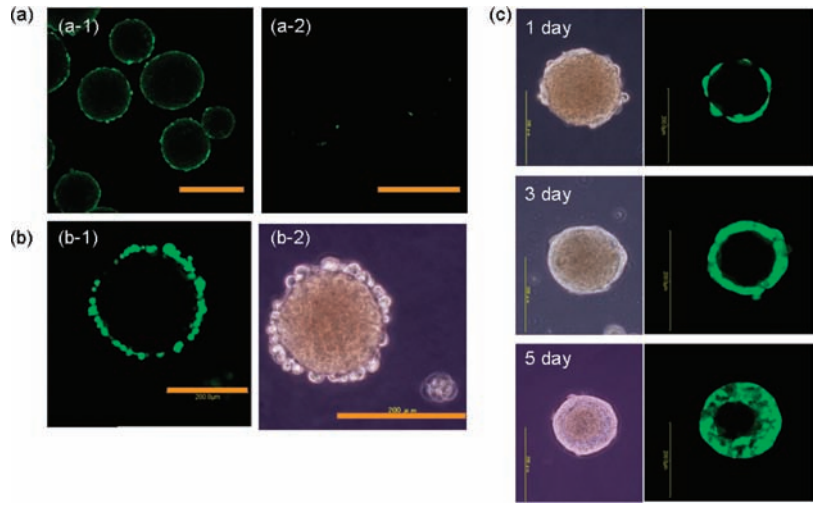

Figure 1. Encapsulation of islets with living cells. (a) Hamster islets modified with polyA20-PEG-lipid were treated with (a-1, FITC) FITC-labeled polyT20. (a-2) Naked islets were treated with FITC-labeled polyT20. These islets were observed by a confocal laser scanning microscope. (b) Attachment of polyT20-PEG-lipid modified GFP-HEK cells onto the surface of polyA20-PEG-lipid modified hamster islets. An islet was observed by a confocal laser scanning microscope for (b-1, GFP) and a phase contrast microscope (b-2). (c) GFP-HEK cells-immobilized islets were cultured in Medium 199 supplemented 10% FBS at 37 °C under 5% CO_2 for 1, 3, and 5 days. Islets were observed by a phase contrast microscope (left panels) and a confocal laser scanning microscope (right panels, GFP). Scale bars: 200 μm.

Tissue-Tek for freezing. The frozen specimens were sliced (6 μm thick) using a cryostat (CM 3050S IV, Leica, Solms, Germany). The sliced sections were permeabilized by treatment with 0.2% Triton X-100 in PBS at rt for 15 min. The samples were first treated with a 10% normal goat serum in PBS for 1 h to block the nonspecific binding of antibodies. The samples were then treated with 1% guinea pig anti-insulin serum in PBS containing 3% goat normal serum for 3.5 h at rt, and then washed with PBS. The samples were incubated with fluorescently labeled secondary antibody, 0.2% Alexa 488 Goat antiguinea pig IgG in PBS containing 3% goat normal serum, at rt for 1.5 h. Cell nuclei were counterstained with Hoechst 33342. The localization of secondary antibodies and the Hoechst dye was analyzed by a fluorescence upright microscope (BX51, Olympus). The sliced sections were also stained with hematoxylin-eosin (HE) using a conventional staining method.

Insulin Secretion from GFP-HEK Cell-Encapsulated Islets on Glucose Stimulation. Static insulin secretion tests were performed on GFP-HEK cell-immobilized islets (50 islets) after culturing for 3 days to evaluate their insulin-secreting ability in response to changes in glucose concentration. As a control experiment, this assay was performed on islets without enclosure with HEK cells (naïve islets). GFP-HEK cell-immobilized islets and naïve islets were exposed to solutions of glucose in Krebs-Ringer's buffer (KRB) at concentrations of 0.1 g/dL, then 0.3 g/dL, and finally 0.1 g/dL glucose for intervals of 1 h in each solution at 37 °C. The supernatants were collected after each 1 h incubation, and the insulin concentrations in the KRB solutions were determined by ELISA.

Statistical Analysis. Comparisons between two groups were made using Student's *t*-tests. $p < 0.05$ was considered statistically significant. All statistical calculations were performed using the software *KaleidaGraph 4.0J*.

RESULTS

Islet Encapsulation with Living GFP-HEK Cells. Islets were treated with polyA20-PEG-lipid, followed by treatment with FITC-labeled polyT20 (Figure 1a). Fluorescence from FITC-labeled polyT20 was clearly seen at the periphery of each islet (Figure 1a-1). No fluorescence was observed in naked islets treated with FITC-labeled polyT20 (Figure 1a-2). Thus, polyA20 can be immobilized onto the surface of islets using polyA20-PEG-lipid without damaging islet morphology, and polyA20 on the cell surface can hybridized with polyT20.

GFP-HEK cells were immobilized onto the surface of islets by DNA hybridization between polyA20 on the islets and polyT20 on the GFP-HEK cells. Figure 1b shows a microscopic image of a GFP-HEK cell-islet complex just after preparation. The HEK cells on the islet surface appeared as white cells under a phase contrast microsope (Figure 1b-2) and were more clearly identified as green cells of GFP-HEK under a confocal laser scanning microscope (Figure 1,b-1). Single HEK cells were recognized on the islets, indicating that the GFP-HEK cells had become immobilized on the islet surface by DNA hybridization. The inhibition study was also performed. When polyA20-islets and polyT20-GFP-HEK were previously incubated with polyT20 and polyA20, respectively, no specific immobilization of GFP-HEK cells on islets was observed (see Figure S1 of Supporting Information).

The modified islets were cultured in medium in a culture dish and observed at 1, 3, and 5 days after the complex was formed (Figure 1c). Although GFP-HEK cells were attached and spread on the surface after 1 day of culture, the islet surface was not completely covered with cells. The HEK cells spread and gradually proliferated on the islet surface, and by 3 days in culture, the islet surface was fully covered with a layer of HEK cells (Figure 1c). As seen Figure 1c and Figure 2, HEK cells proliferated continuously and form a thicker multicell layer due to lack of contact inhibition as the culture period proceeded.

Histochemical Analysis. The GFP-HEK cell-encapsulated islets were histochemically analyzed by HE and insulin staining (Figure 2). In HE staining, a layer of GFP-HEK cells was observed around the islet surface after culturing for 3 and 5 days (left panel in Figure 2). The nuclei of GFP-HEK cells were slightly larger than that of islets. The multilayers of GFP-HEK cells were formed on the islet surface after culturing for 3 and 5 days. Necrosis of islet cells was not observed even at the center of the complex at 5 days. Figure 2 also shows images of insulin-stained GFP-HEK cell-encapsulated islets (right panel). Islets stained green with anti-insulin antibody were found in a core cell aggregate. These results indicate that GFP-HEK cell-encapsulation did not impair the morphology of islets.

Insulin Secretion by Glucose Stimulation. We examined the abilities of the islets modified with or without HEK cell-

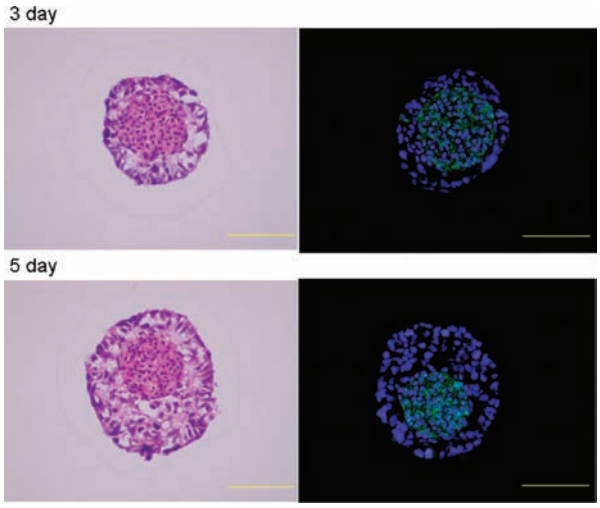

Figure 2. Histochemical analyses of GFP-HEK cell-immobilized islets cultured for 3 and 5 days. Frozen sections of GFP-HEK cell-immobilized islets were stained with (left panels) hematoxylin-eosin (HE) or (right panels) Alexa 488-labeled anti-insulin antibody and Hoechst 33342 dye for nuclear staining. Right panels show merged microscopic images of insulin (green fluorescence) and Hoechst 33342 staining (blue fluorescence). Scale bars: 100 μm.

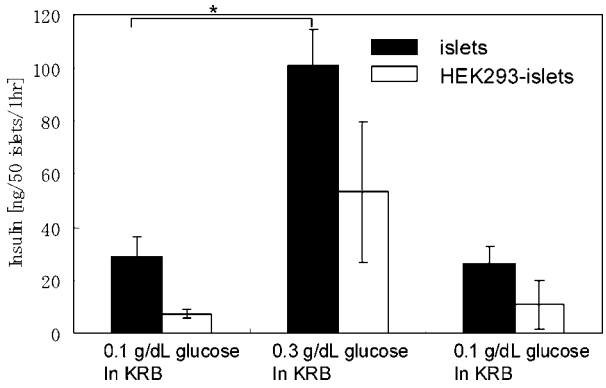

Figure 3. Glucose stimulation test of islets encapsulated HEK cells after 3 days culture. As a control experiment, the assay was performed on naive islets. The amounts of insulin secreted from the islets in response to glucose concentration changes (0.1, 0.3, 0.1 g/dL) were determined by ELISA. Results are expressed as mean ± SD for $n = 3$. KRB: Krebs-Ringer buffer. An asterisk represents a significant difference ($p < 0.05$) between two groups.

encapsulation to release insulin. At the basal glucose concentration, 0.1 g/dL, insulin release by the encapsulated islets was less than that by naïve islets. We also performed a glucose stimulation test to examine the ability of the modified islets to regulate insulin release in response to changes in the glucose level. When the glucose concentration in the medium was increased from 0.1 g/dL to 0.3 g/dL, islets of both groups increased insulin release above basal levels (Figure 3). Insulin release returned to basal levels when the islets were re-exposed to 0.1 g/dL glucose. Glucose stimulation indexes (insulin release at 0.3 g/dL glucose/insulin release at 0.1 g/dL glucose) calculated from these results were 7.3 ± 5.3 and 3.6 ± 1.0 for the encapsulated islets and naïve islets, respectively. Although there was no significant difference between two groups for glucose stimulation index, the amount of insulin secretion of the encapsulated islets tended to be lower than that of native islets at 0.1 g/dL and 0.3 g/dL glucose in KRB. These results indicate that the HEK cell layer did not influence the islets' ability to regulate insulin release in response to glucose concentration, although the cause of decreased insulin release by encapsulated islets was not clear. It might be attributed to the oxygen consumption by the HEK293 cells since low oxygen tension can decrease islet cell function. The decrease of basal insulin release in encapsulated islets is a topic that requires further study.

DISCUSSION

There were some fundamental studies on improvement of biocompatibility by using cells such as chondrocyte (*16, 17*). Pollok et al. first reported the macroencapsulation of rat islets with porcine chondrocyte membrane (*16*). Porcine chondrocytes were cultured to form a confluent monolayer for use as a matrix upon which to deposit islets. After the islets were attached to poly(glycolic acid) polymer fibers, the islet−polymer composite was wrapped with chondrocyte membrane by hand. Lee et al. also demonstrated enclosure of islets with chondrocyte membranes using the cell sheet engineering technique (*17*). However, the increase of total volume after enclosure and aggregate formation of islets inside the membrane led to necrosis of islet cells at the center. Lee et al. also demonstrated enclosure of islets with chondrocyte membranes using the cell sheet engineering technique (*17*). The issue of islet necrosis still remains to be resolved. They expected that chondrocyte membrane would work as an immuno-isolation membrane of bioartificial pancreas, although unfortunately, they have not yet reported results of animal experiments.

To overcome this problem, we studied methods to enclose islets singly with living cells. Herein, we have used amphiphilic polyDNA-PEG-lipid to immobilize GFP-HEK cells on the surface of islets through hybridization between polyA20 and polyT20. The surface of the islets was completely covered with a cell layer after 3 to 5 days in culture without central necrosis of the islet cells (Figure 2). Insulin secretion upon glucose stimulation was well maintained in the cell-encapsulated islets complex, although total insulin secretion was reduced as compared to normal islets (Figure 3). HEK cells which formed a multicell layer on islets consume oxygen and thus islet cells were exposed to low concentration of oxygen. We thought that the reduction of insulin secretion was due to the insufficient oxygen supply to β-cells of islets. The same phenomena were observed in islets encapsulated with HEK cells using the biotin/streptavidin reaction. However, we might evade this issue by encapsulation with endothelial cells because they are expected to form a single cell layer.

We have reported immobilization of cells onto the islet surface by using biotin/streptavidin reaction (*15*). Although the specific biotin/streptavidin reaction worked well to cover the islets with living cells, streptavidin is expected to activate the host immune system because it is a xenogeneic protein isolated from bacteria. Therefore, we improved the technique compatible to future clinical application. There was no difference in islet encapsulation efficiency between these two techniques.

Many shortcomings remain to be overcome prior to clinical application. The cells employed are HEK293 cells, which proliferate rapidly and form a multicellular layer. Most primary cells, that is, cells isolated from normal animals, proliferate much more slowly than HEK cells and cannot form a multicellular layer. Thus, we should select types of primary cells which can effectively form a cell layer on islets. The short- and long-term effects of the covered cells on islet functions should be carefully examined. We also should follow the fate of cells after transplantation. In addition, the efficiency and biocompatibility of cell-based microencapsulation should be examined carefully by using animal experiments early. Although these issues should be addressed, the technology developed in this study will be

useful in preparation of future bioartificial pancreas and studies on cell−cell interaction.

CONCLUSIONS

Islets can be individually encapsulated with living cells through hybridization between polyA and polyT which can be introduced onto the surfaces of islets and cells, respectively, using amphiphilic PEG-lipid derivatives. No central necrosis was observed after encapsulation. The encapsulated islets still retained the ability to control insulin release in response to changes in glucose concentration.

ACKNOWLEDGMENT

This study was supported in part by a Grant-in-Aid for Scientific Research (A) (No. 21240051) and a Challenging Exploratory Research grant (No. 21650118) from the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of Japan and by the Ministry of Health, Labor, and Welfare of Japan (H20-007).

This paper briefly documents the history of the discovery of the EPR (enhanced permeability and retention) effect and elucidates an analogy between bacterial infection involving proteases that trigger kinin generation and cancer. The EPR effect of macromolecules in cancer tissues is defined, and the distinction between the EPR effect (with reference to clearance of macromolecules from the interstitial space of tumor tissues) and the simple passive targeting of drugs to tumors is described. Additional points of discussion include the uniqueness of tumor vessels, the influence of kinin and other vascular mediators such as nitric oxide (NO) and prostaglandins, and the heterogeneity of the EPR effect. Two different strategies to augment the EPR effect that were discovered are elevating blood pressure artificially via slow infusion of angiotensin II and applying nitroglycerin or other NO donors. Use of the nitroagent increased not only the blood flow of the tumor, but also the delivery of drug to the tumor and the drug's therapeutic effect. This finding shows an intriguing analogy to hypoxic cardiac infarct tissue, in that both are improved by NO. These two methods were applied to treatment of rodents and human cancers, in combination with other anticancer agents, with successful results achieved in rodents as well as humans. These data suggest very appealing prospects for utilization of the EPR effect in future development of cancer therapeutics.

NATURE OF THE EPR EFFECT AND FACTORS AFFECTING THE EPR EFFECT

In 1964, I had started to work on a proteinaceous anticancer agent called neocarzinostatin (NCS[1]; MW = 12 kDa) (*1*). My initial research on NCS was extended to the development of an NCS conjugate with a polymer (styrene-maleic acid, or SMA), which I named SMANCS (MW of about 16 kDa) (*2*, *3*). SMANCS could bind to plasma albumin (67 kDa), so that it would become a larger molecule, about 83 kDa (*3*, *4*). This development of the albumin-bound SMANCS formed the basis for my continuing work on what would be now called the EPR (enhanced permeability and retention) effect (see later).

Another focus of my research was the molecular mechanism of bacterial infection involving bacterial proteases, because of their pathogenic potential. During this work, we demonstrated that bacterial proteases could activate the bradykinin-generating cascade called the kallikrein-kinin cascade (*5–10*), which facilitated vascular leakage.

Human blood plasma contains no effective inhibitors of bacterial proteases. As a result, a number of precursor proteases (proenzymes) could be activated by limited proteolysis such as that occurring in the coagulation system (which forms fibrin gel or blood clots) (*7–9*). We found that bacterial proteases in blood plasma could generate the endogenous nonapeptide bradykinin (a member of the kinin family); the bradykinin was liberated from its precursor kininogen in the plasma via limited proteolysis. This kinin causes very potent pain and induces vascular permeability (or edema) in vivo at the site of its generation (*5–10*) (Figure 1A). This vascular permeability, or extravasation of this dye out of the vessels and into interstitial tissue space, can be quantified by determining the amount of dye extracted from the tissue. The Evans blue is so tightly bound to albumin that the extravasation can be regarded as macromolecular extravasation from the vasculature. We also found that similar extravasation occurred in most experimental solid tumors via bradykinin generation (*10–15*) (Figure 1B). Both normal inflammatory and tumor tissues exhibit similar enhanced vascular permeability (Figure 1). The difference between these tissues is related to the clearance rates of the Evans blue−albumin complex from each tissue, which are quite dissimilar. Clearance of Evans blue−albumin complex from normal tissue is much faster (usually within 1 wk) than clearance from tumor tissue, which is much slower and takes more than 3−4 wk (*11–20*). I named the enhanced permeability and retention (EPR) effect of macromolecules in tumor tissues (*11*).

The EPR effect was more marked when the lipid contrast agent Lipiodol (with SMANCS dissolved in it) was injected via the tumor-feeding artery (*16–20*). In the clinical setting, this EPR effect has been observed with gamma ray-emitting gallium in radioscintigraphy, in which gallium-67 bound to the plasma protein transferrin (MW = 90 kDa) demonstrated the EPR effect, as shown in radioscintigraphic images of tumors.

During the past 25 years, considerable evidence supporting the EPR effect has been accumulated. The EPR effect has been

[1]Abbreviations: NCS, neocarzinostatin; SMA, styrene-maleic acid copolymer; EPR, enhanced permeability and retention; NO, nitric oxide; CT, computed tomography; AT-II, angiotensin II.

[2]Biocompatible in this case means being inert with reference to the immune system, that is, free from removal by macrophages or the reticuloendothelial system. Polycations are readily captured by the negatively charged laminar surface of blood vessels or by the liver or kidney. Conformational changes (denaturation) of plasma proteins or other biocompatible molecules are detected, and they can be rapidly cleared. For instance, α_2-macroglobulin has a $t_{1/2}$ in mice of more than 144 h, but when it is complexed with a protease, its $t_{1/2}$ is only 2.5 min (*47*).

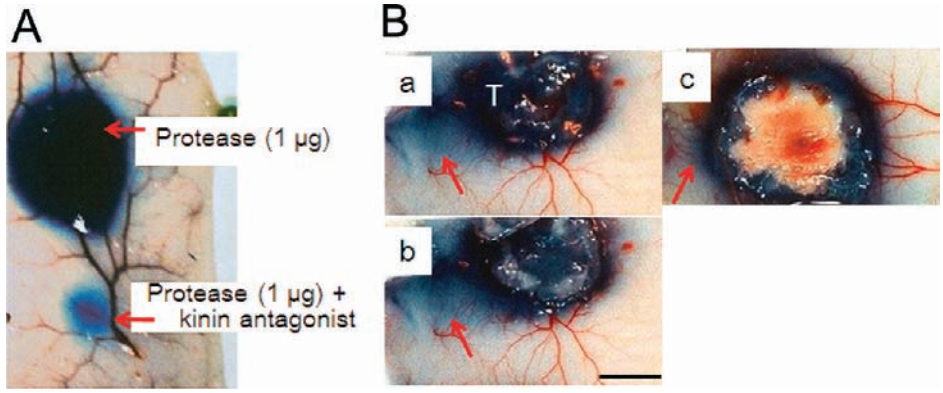

Figure 1. (A) Extravasation of Evans blue−albumin induced by 1 μg of bacterial protease (serratial 56 kDa) as a result of kinin generation or 1 μg of protease plus the kinin antagonist SQ 20881 (50 μmol), injected at the site of protease injection. The protease-induced vascular permeability was inhibited by the kinin antagonist. (B) Extravasation in murine S-180 solid tumor. (a) Macroscopic tumor (T) under the skin, after intravenous (i.v.) Evans blue injection. (b) Horizontally cut surface of the same tumor, also after i.v. Evans blue injection. In (b), the tumor tissue shows heterogeneous staining of Evans blue as inhomogeneous extravasation of the blue dye−albumin complex. (c) Another example of a horizontally cut surface of an S-180 tumor. The center of the tumor shows no EPR effect, but the intense permeability of tumor vessels is clear at the periphery, which has a pattern similar to that found in human metastatic liver cancer (see Figure 4 Case 2B and ref *19*). This type of peripheral uptake of SMANCS/Lipiodol is seen via computed tomography (CT) in metastatic human tumors and is classified as B-type staining (see ref *19* and Figure 4 Case 2B). Arrows in B point to areas in which the EPR effect also occurred in normal tissue as a result of the generation of vascular mediators such as bradykinin. Figure 1B is adapted with permission from ref *14*.

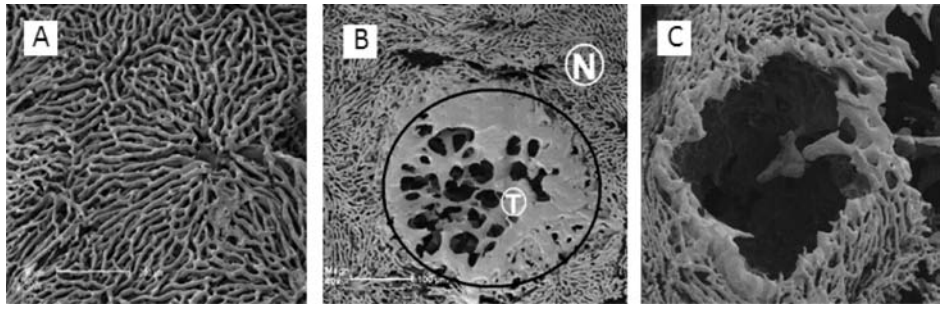

Figure 2. Scanning electron micrographs of vascular casts of plastic resin in the liver. (A) Normal capillary structure. (B) Vascular structure of the liver with a metastatic microtumor nodule, as indicated by T. Polymer resin extravasated only into the vascular bed of the tumor, whereas the normal vasculature (N) did not show such polymer leakage. (C) In the same murine tumor model as that used for B, a macromolecular drug (SMA-pirarubicin micelles) (*23*) had been injected i.v. 1 week earlier, and that caused selective disintegration of the tumor blood vessel bed (seen as an empty void, equivalent to the circled area containing the T in B). The tumor had been chemically induced by dimethylhydrazine in the colon of CBA mice, and a metastasis model was generated (*45*). Tumor-selective drug delivery and damage could be achieved in the mouse even with a tumor size as small as 200 μm, i.e., micronodules. Tumor nodules as small as 200 μm already have unique blood vasculature, which is evidence of tumor angiogenesis. These pictures are courtesy of Prof. C. Christophi and Ms. J. Daruwalla, University of Melbourne. Parts A and B are adapted with permission from ref *45*.

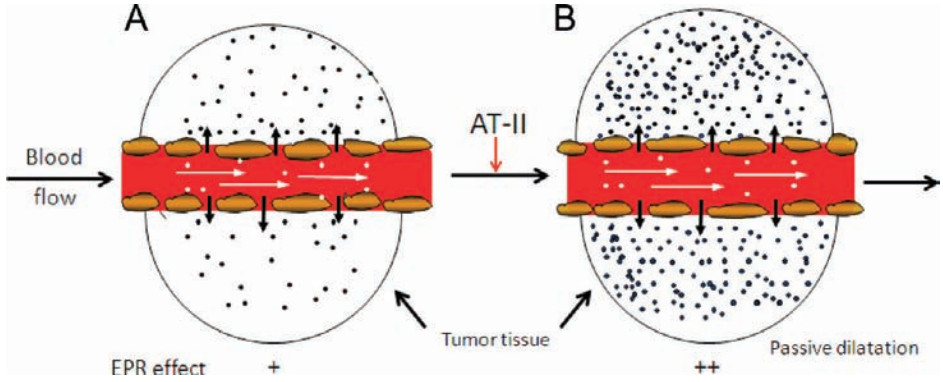

Figure 3. Diagrammatic representation of blood vasculature in tumor tissue under normotensive (A) and hypertensive (B) conditions (adapted from ref *20* with permission). Angiotensin II (AT-II)-induced enhanced extravasation of macromolecular drugs (dark dots) is shown in B. A greater EPR effect occurred in tumor tissue after AT-II-induced systemic hypertension, with tumor vessels opening wider, whereas normal blood vessels constricted and showed small openings of endothelial cell−cell gaps.

observed with biocompatible[2] macromolecules or nanoparticles with a molecular size of more than 40 kDa and up to the size of bacteria (approximately 1 μm) in most experimental solid tumor (see Figure 2). Professor Folkman first observed neoangiogenesis in tumor tissue when a tumor cell cluster (nodule) reached a size of about 2−3 mm (*21*). More detailed

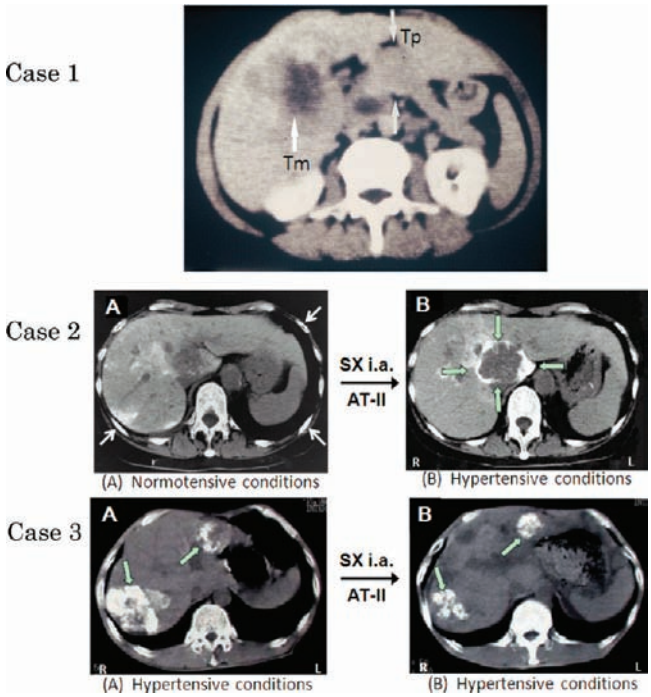

Figure 4. CT scans showing metastatic liver cancer in humans. Case 1. Metastatic tumor originating from pancreatic cancer. Arrows indicate dark low-density areas or hypovascular tumor areas; Tp points to the site of the primary pancreatic tumor, and Tm, the metastatic tumor in the liver. Case 2. CT scans demonstrating colon cancer metastasized to the liver. Arrows at the periphery of Case 2A are ribs (bones). (A) SMANCS/Lipiodol was infused via the hepatic artery under normotension. (B) SMANCS/Lipiodol was infused via the hepatic artery but under AT-II-induced hypertension (*20*). The arrows point to the main metastatic tumor in the liver. Note the more effective drug delivery only in the periphery of the tumor mass, which was defined as type B staining (*19*) (see Figure 1Bc). The intensity of the SMANCS/Lipiodol staining (white area) at the periphery of the tumor depended on the dose, the pressure applied, and the duration of the induced hypertension during arterial infusion, among other factors. Case 3. CT scans of stomach cancer metastatic to the liver. Note the white high-density areas (arrows) in which accumulation of SMANCS/Lipiodol was tumor-selective. This SMANCS/Lipiodol infusion was also performed under AT-II-induced hypertension (*20*) (see text). The CT scan in B was obtained 8 months after the scan in A. Note the considerable tumor size reduction (white areas), even in the liver metastatic lesion. The staining seen in A somewhat resembles the B-type staining seen in Case 2B (*19*), that is, circumferential low-density staining after AT-II infusion induced hypertension. As in Case 2, more complete filling of tumor with drug was achieved with AT-II-induced hypertension. Figure 4 is adapted with permission from ref *20*.

scanning electron microscopic observations of metastatic tumor nodules in the liver, in which vascular casts of blood vessels were obtained with plastic resin, indicated that tumor nodules of 100 μm have a highly permeable vascular bed (ref *22* and others) that is not seen in normal blood vasculature (Figure 2). Administration of a micellar drug (SMA-pirarubicin) (*23*) selectively destroyed the tumor micronodules by means of the EPR effect and did not damage normal blood vessels (Figure 2c).

The EPR effect with macromolecular drugs or lipid particles is clearly different from the so-called passive targeting of drugs to tumors, in that the drug retention period in tumors showing the EPR effect is more than days to weeks, whereas that of passive targeting may be only a few minutes, or no more than 10 min, as routinely observed during tumor angiography. Radiology clinics normally use low-molecular-weight angiographic contrast agents, which usually do not remain in tumor tissues for more than 10 min, so that the radiographic image is visible for only a short time, and no retention as seen in the case of the EPR effect.

One of our review articles in *Bioconjugate Chemistry* with good numbers of citations on this matter appeared in 1992 (*24*). The EPR effect was observed not only with plasma proteins, but also with micelles composed of block copolymers of n(PEG-poly Asp), as reported by Yokoyama et al. (*25*); with HPMA (hydroxypropyl methacrylate) copolymer conjugated with drugs (*26*); and with our micelles composed of SMA copolymer and various encapsulated drugs (*23, 27*). In addition, similar results have been obtained with liposomes (*28*), IgG and other plasma proteins (*11*), DNA-complexes, PEGylated proteins (ref *29* and others), and bacteria with diameters of 1−2 μm (*30, 31*).

In additional studies, we identified nitric oxide (NO), prostaglandins, peroxynitrite, collagenase, and bradykinin, among others, as factors facilitating the EPR effect (*33–36*).

INDUCED ARTIFICIAL AUGMENTATION OF THE EPR EFFECT, OVERCOMING OF THE HETEROGENEITY, AND CLINICAL OUTLOOK

Our interest is now focused on the artificial augmentation of the EPR effect for more efficient tumor-selective drug delivery. One method that we utilized for this purpose of enhancing drug delivery is elevation of systemic blood pressure by means of angiotensin II (AT-II) (*20, 37*) (Figure 3). The method was originally described by Suzuki et al. (*38*). Indeed, we discovered that this method improved drug delivery as well as therapeutic efficacy markedly against highly refractory solid tumors such as metastatic liver cancer, and even cancers of the gallbladder and pancreas (*20*) (Figures 3 and 4).

The second method used to enhance drug delivery involved nitroglycerin and other NO-releasing agents (*39, 40*). This method is unique because in hypoxic tumor tissue nitroglycerin can be converted into nitrite, which can then be reduced to NO (*41*) (Figure 5A). As stated above, NO is one of the potent mediators of vascular extravasation. Thus, topical application of nitroglycerin at any skin site resulted in a 2−3-fold increase in drug delivery (Figure 5B,C), which also potentiated the therapeutic effect in experimental tumors (*39, 40*) as well as in human cancers (*42, 43*).

Both Yasuda et al. (*42, 43*) and Graham's group (*44*), in agreement with our findings, independently reported an advantage of nitroglycerin or nitroagents for improving therapeutic efficacy. It is interesting to note that hypoxia and the low pH of tumor tissues are analogous to conditions in cardiac tissue in the presence of angina pectoris (*41*). In such cardiac tissues, release of nitrite from nitroglycerin and conversion of nitrite to NO (Figure 5A) facilitated vascular blood flow and hence elevated pO_2, with a consequent enhancement of the EPR effect and drug delivery (*39, 40*).

Despite the heterogeneity of drug distribution (on the EPR effect) in tumor tissues (Figure 1B,b and c), the just-described methods of augmenting the EPR effect, i.e., elevation of blood pressure and use of nitroglycerin, did indeed enhance drug delivery and therapeutic efficacy in a more ubiquitous manner, that is, for solid tumors in general. The EPR effect may therefore become increasingly realized as useful for cancer therapy and diagnosis that would have more universal application than the antibody-dependent selectivity of a single molecular target species. Furthermore, this enhanced EPR effect, induced by either elevating blood pressure or utilizing nitroglycerin, appears to be effective in apparently hypovascular tumors, such as metastatic liver cancer and pancreatic cancer; in tumors refractory to radiotherapy and most of chemotherapy (*39, 40, 42, 43*); and even in minute tumor nodules as small as 100 μm (Figure

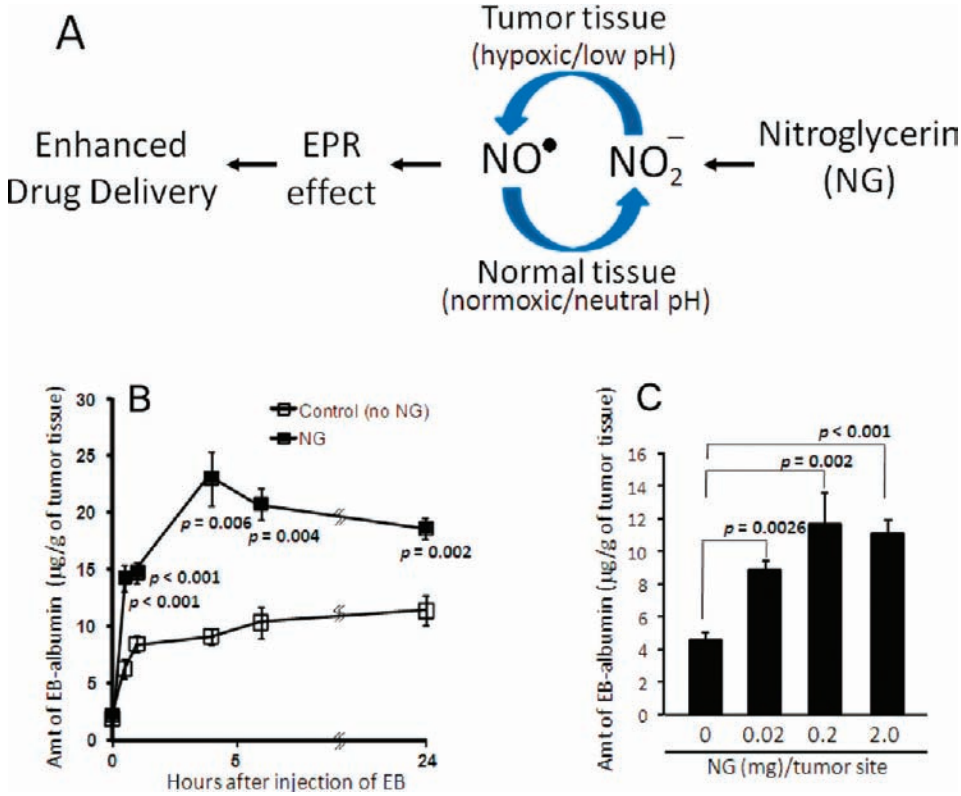

Figure 5. (A) Mechanism of NO generation from nitroglycerin (NG). NO_2^- is generated from NG, to a greater degree in hypoxic tumor tissues than in normal tissues. NO_2^- is then reduced to NO˙ in tumor and hypoxic tissues, which contributes to the EPR effect (*14*, *33*). (B) Time-dependent increase in delivery of Evans blue (EB)-albumin to tumors after topical application of NG ointment to the skin (1 mg/mouse). This effect lasted more than 24 h. (C) Dose-dependent increase in delivery of Evans blue-albumin to tumors in mice. Tumor diameters were 5−8 mm; dye concentration was determined after extraction of the dye and measuring absorption. Adapted with permission from ref *40*.

2), so that invisible metastatic tumor foci in the liver may be more selectively targeted (*45*, *46*).

CONCLUSIONS

The EPR effect is mediated by various vascular mediators including bradykinin and NO, among others. Some tumors undergo active angiogenesis, which results in high vascular density, whereas others are dormant or hypovascular. Many other tumors exhibit heterogeneous vascular features. However, we can effectively enhance drug delivery to most of these tumors, if not all, via augmenting the EPR effect, by elevating systemic blood pressure with AT-II. Another method of enhancing drug delivery is application of nitroglycerin, which we discovered generates NO in hypoxic tumor tissues and facilitates drug delivery. Both methods have been demonstrated to work in clinical settings.

ACKNOWLEDGMENT

The author would like to thank the generosity of Ms. J. Daruwella and Prof. C. Christophi of University of Melbourne, Australia, for providing the electron micrographs of Figure 2, and my colleagues, the late Dr. T. Konno of Kumamoto University for Figure 1, Case 1, and Dr. A. Nagamitsu of Nagamitsu Clinic, Fukuoka, for Figure 4, Cases 2 and 3. I also acknowledge the help and assistance of my previous and present colleagues including Ms. A. Takaki and Ms. J. Gandy for their typing and editing of the manuscript.

RNA interference (RNAi) is a sequence-specific gene silencing technique that has been applied to multiple pathological conditions. In this report, we describe the generation and in vitro characterization of an RNAi-based fluorescent probe for use as a therapeutic in the setting of ischemic stroke. Probe delivery to bEnd.3 brain endothelial cells and primary cortical neurons and astrocytes was promoted by incorporating small interfering RNA (siRNA) into complexes with fluorescently labeled myristoylated polyarginine peptides. The resulting probe was partially protected from serum nuclease degradation and was efficiently internalized by cells as confirmed by flow cytometry and confocal microscopy. In addition, application of the siRNA probe directed against c-Src, a protein implicated in stroke pathology, led to statistically significant reduction of endogenous *c-src* mRNA levels in all cell types tested. Results demonstrate the proof-of-principle that functionalized peptide−siRNA probes can be used as potential tools for dual imaging and therapeutic applications.

INTRODUCTION

In the past decade, RNA interference (RNAi) technology has been rapidly integrated into basic biomedical research, emerging as a premier method for regulating gene expression in a variety of model systems. As RNAi-based therapies progress to clinical trials and are applied to increasingly complex human diseases, the need for more robust strategies for small RNA delivery and monitoring becomes critical (*1*). These considerations are particularly relevant in neurological pathologies, for which an intact blood brain barrier (BBB) opposes direct contact between diseased cells and most systemically administered agents. One approach for overcoming biological membranes exploits naturally occurring membrane translocation peptides (*2, 3*) known as cell penetrating peptides (CPPs), cationic peptides that have been adapted to accommodate diverse molecular cargoes, including proteins (*4*), liposomes (*5*), and nanoparticles (*6*). Recently, it was demonstrated that intravenously injected small interfering RNA (siRNA), when used in conjunction with a peptide sequence from rabies virus glycoprotein, is delivered to the brain and retains its gene silencing capabilities (*7*).

In the present study, we utilized optically labeled polyarginine peptides modified with a 14-carbon myristic acid moiety (MPAP) for siRNA delivery. It has been shown previously that myristoylation increases the affinity of the peptide for lipid bilayer membranes, enhancing peptide entry into cells by several-fold relative to Tat and unmodified polyarginine cell penetrating peptides (*8*). This peptide was used by us to promote cellular delivery of nanoparticle imaging agents to solid tumors after intravenous injection (*9, 10*). Furthermore, MPAP is BBB permeable in vivo, where it was shown to localize to neurons, astrocytes, and endothelial cells after intravascular administration (*11*). These properties make MPAP ideally suited for use with siRNA to form a dual optical imaging and therapeutic probe for neurological applications, provided that a method of complexation is developed that does not interfere with the bioactivity of siRNA molecules.

This work details the generation and in vitro testing of an MPAP and siRNA (MPAP-siRNA) imaging probe complex for the treatment of ischemic stroke. In the setting of ischemic stroke, disruption of blood flow to the brain induces a cascade of pathological cell signaling events, culminating in widespread death of neurons and supporting cells (*12*). We hypothesize that if siRNA directed against proteins implicated in stroke pathology were effectively delivered to primary neurons and astrocytes to intercede in this process, neuroprotection could be elicited. With this in mind, we developed dual MPAP-siRNA optical imaging probes directed against c-Src, a protein tyrosine kinase that becomes upregulated after stroke and is associated with increased tissue damage in cerebral ischemia models (*13, 14*). Probes were assembled by utilizing the natural affinity of cationic peptides for oligonucleotides, a process that was optimized to ensure maximum siRNA incorporation. MPAP-siRNA complexes were tested for stability and their internalization by primary cells and an endothelial cell line was monitored by flow cytometry and confocal microscopy. The probes were also evaluated for their cytotoxic effects and siRNA silencing efficiency. Results confirm that MPAP-siRNA complexes become internalized by cells and cause statistically significant reductions in endogenous *c-src* levels without significantly affecting cell viability, paving the way for the future studies of the dual imaging and therapeutic probe in vivo.

EXPERIMENTAL PROCEDURES

Myristoylated polyarginine peptide (MPAP), C14-βAla-$(Arg)_7$-Cys(SH)-NH_2, was synthesized as described previously

(*11*) and conjugated to Cy5.5 fluorescent dye (Amersham, Piscataway, NJ) to form MPAP−Cy5.5. To promote probe complex formation, MPAP−Cy5.5 was mixed through gentle aspiration with a solution of siRNA conjugated to Dy547 (siRNA−Dy547), a fluorescent tag with absorbance/emission max of 548/562 nm. The resulting probe mixture was incubated for 20 min at room temperature to induce complete complexation of the two components.

To optimize stoichiometry of MPAP−Cy5.5 and siRNA−Dy547 complexes, we performed polyacrylamide gel electrophoresis. Various dilutions of MPAP−Cy5.5 solution were added to siRNA−Dy547 (20 pmol) to obtain 1:10, 1:5, 1:2.5, 1:1, 2.5:1, 5:1, and 10:1 siRNA-to-peptide molar ratios. Samples were run on polyacrylamide gels and stained with ethidium bromide for visualization of uncomplexed siRNA.

Solutions of free siRNA−Dy547 or complexes of siRNA−Dy547 and MPAP−Cy5.5, hereafter termed MPAP-Src, were incubated in mouse serum to evaluate the protective effect of MPAP−Cy5.5 on nuclease digestion of siRNA. MPAP−Cy5.5 and c-Src siRNA were combined at a 1:5 siRNA-to-peptide molar ratio to form MPAP-Src. MPAP-Src was incubated in fresh mouse serum for 0, 0.5, 1, 2, 4, or 8 h. The amount of siRNA spared from nuclease digestion was determined by gel electrophoresis, SYBR Gold (Molecular Probes, Invitrogen, Eugene OR) staining, and quantification using *ImageJ* software (NIH).

Cortical neuron cultures were generated from embryonic day 18 C57BL/6 mouse fetuses (see Supporting Information). Cell culture of cortical astrocytes was performed using a slight modification of the procedure for neurons, with cortices dissected from C57BL/6 mouse pups, postnatal days 1−2 (see Supporting Information). A brain endothelial cell line, bEnd.3, was obtained from American Type Culture Collection (Manassas, VA) and maintained according to the vendor's instructions (see Supporting Information). To promote probe internalization by cells, MPAP-Src solutions were added to primary astrocytes, primary neurons, or bEnd.3 cells plated in 12-well plates in serum-free media and incubated for 24 h. To determine the cytotoxicity of probe incubation, cells exposed to MPAP-Src for 48 h or untreated cells were processed using MTT and CASP-3-C (Sigma, St. Louis, MO) caspase-3 assays (see Supporting Information).

The extent of probe internalization by cells was investigated using FACS analysis and confocal microscopy (see Supporting Information). Confocal microscopy was also used in conjunction with LysoSensor Green staining of living cells to evaluate the mechanism of MPAP-Src uptake. To assess the effect of MPAP-Src internalization, total RNA was purified from cells treated with MPAP-Src or scrambled control siRNA probes (MPAP-ctrl) and subjected to real-time quantitative RT-PCR (TaqMan) to determine relative levels of *c-src* mRNA.

RESULTS AND DISCUSSION

MPAP has proven effective as a membrane translocation moiety when covalently linked to optical probes and iron oxide nanoparticles (*9, 10*). In this report, we wished to extend the use of optically labeled MPAP further, by taking advantage of the potential for its polyarginine residues to electrostatically interact with negatively charged siRNA molecules. To promote the formation of siRNA dual optical imaging probes, c-Src siRNA−Dy547 and MPAP−Cy5.5 were mixed in several molar ratios. The efficiency of MPAP binding to siRNA was determined by performing gel electrophoresis on the resulting MPAP-Src solutions to assess the proportion of free siRNA in each mixture. MPAP-Src complexes remained in the loading well during gel electrophoresis, while uncomplexed siRNA readily entered the gel and stained with ethidium bromide (Figure 1).

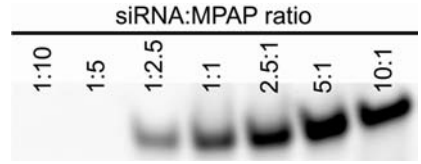

Figure 1. Gel mobility shift assay. MPAP-Cy5.5 was incubated with c-Src siRNA at several molar ratios to form MPAP-Src probes. At the 1:5 siRNA-to-MPAP ratio, most siRNA was incorporated into complexes.

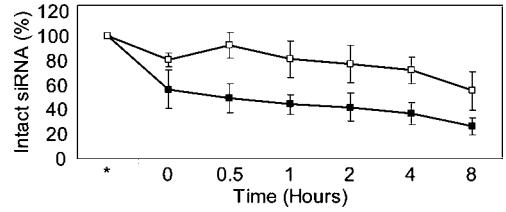

Figure 2. Serum stability. Stability of MPAP-Src (open squares) in serum relative to Dy547-labeled c-Src siRNA alone (closed squares) was investigated by incubating probes in 75% mouse serum for 0−8 h. MPAP complexation to siRNA confers partial protection from serum nucleases, yielding a higher percentage of intact siRNA after incubation in serum than siRNA alone (mean ± s.d.) relative to undigested controls (*).

In solutions containing a 1:5 siRNA-to-MPAP molar ratio or higher peptide content, the vast majority of siRNA was associated with MPAP. Full incorporation of siRNA into probes was deemed important to maximize siRNA internalization and silencing potential. Thus, the siRNA-to-peptide ratio at which no discernible siRNA remained unassociated with MPAP−Cy5.5, 1:5, was used for subsequent experiments.

Ultimate utility of MPAP-Src in vivo requires protection of siRNA from nucleases in the bloodstream. Generally, siRNAs are chemically modified to extend their serum half-life relative to naked siRNA, which becomes degraded and inactivated within minutes of blood exposure (*15, 16*). To investigate the stability of the siRNA incorporated into MPAP-Src, siRNA complexes and naked siRNA−Dy547 were exposed to serum for up to 8 h. Following removal of serum proteins and MPAP with proteinase K (1 mg/mL), intact siRNA was analyzed by gel electrophoresis and quantified (Figure 2). It was observed that the optical label Dy547 conjugated to c-Src siRNA partially protects it from degradation by nucleases, with just over 25% of the total siRNA retained after 8 h. The presence of MPAP appears to confer an additional measure of protection, such that the amount of free siRNA after 8 h of MPAP-Src incubation in serum was close to 55%. These results indicate that MPAP complexation has a stabilizing effect on c-Src siRNA.

Internalization of MPAP-Src probes was evaluated in vitro in a variety of cell types implicated in ischemic stroke pathology, including primary cortical neurons, astrocytes, and the bEnd.3 brain endothelial cell line. Cells incubated for 24 h with MPAP-Src or MPAP associated with scrambled control siRNA (MPAP-ctrl) were subjected to flow cytometry and monitored for Cy5.5 and Dy547 fluorescence. Figure 3 shows significant signal from both siRNA and MPAP relative to untreated controls in all cell types. Internalization of MPAP-Src and MPAP-ctrl occurred in similar patterns, indicating that MPAP association with c-Src siRNA is not sequence-dependent. Furthermore, flow cytometry scatter plots (data not shown) showed that roughly 46% of bEnd3 cells, 77% of neurons, and 78% of astrocytes with MPAP uptake also contained c-Src siRNA, suggesting that siRNA did not dissociate from MPAP but formed a stable complex in solution.

To confirm that MPAP-Src probe was internalized by cells and not passively associated with the cell membrane, confocal

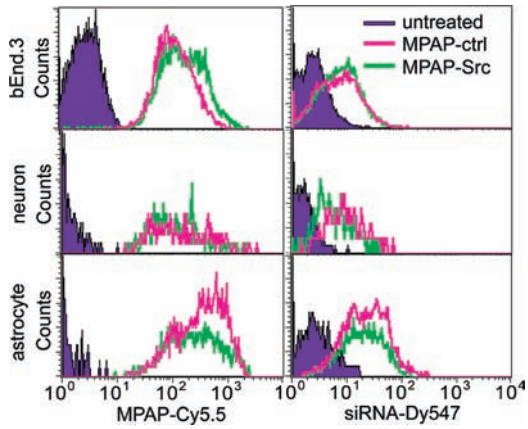

Figure 3. Flow cytometry. Astrocytes, neurons, and bEnd.3 cells were subjected to MPAP-Src or MPAP-ctrl incubation for 24 h, followed by flow cytometry. All cell types were positive for the presence of both MPAP−Cy5.5 and siRNA−Dy547.

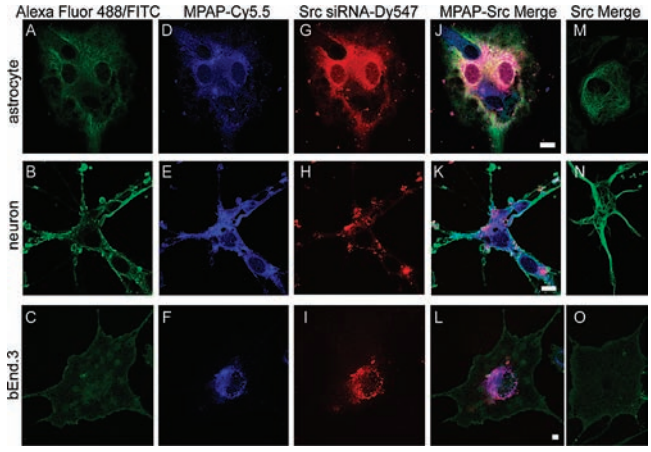

Figure 4. Confocal microscopy of astrocytes, neurons, and bEnd.3 stained with GFAP (A), β-III tubulin (B), and CD31 (C), respectively. Following incubation with MPAP-Src probe for 24 h and cell-specific staining, cells were visualized by confocal microscopy. MPAP (D−F) and c-SRC siRNA (G−I) were taken up by cells following MPAP-Src incubation, whereas incubation with 100 pmol of c-Src siRNA alone resulted in no significant siRNA uptake (M−O). Scale bar = 10 μm.

microscopy was performed. Neurons, astrocytes, and bEnd.3 cells stained with cell-specific antibodies (Figure 4A−C) were positive for the presence of both MPAP (Figure 4D−F) and c-Src siRNA (Figure 4G−I). In general, c-Src siRNA colocalized with MPAP (Figure 4J−L), though, for neurons in particular, there was evidence that MPAP and siRNA become dissociated to some degree when taken up by cells (Figure 4K). The presence of MPAP was crucial for internalization, as is evident by the complete absence of c-Src siRNA uptake relative to MPAP-Src when cells were incubated with equivalent quantities of siRNA alone (Figure 4M−O).

The mechanism of cellular internalization was investigated in unfixed astrocytes, bEnd.3 cells, and neurons using Lysosensor Green staining that is specific for endosomal vesicles (Figure 5D−F). As in fixed cells, MPAP-Src substantially entered cells (Figure 5M−O). A significant portion of c-Src and MPAP signal appeared to originate from vesicles in all cell types, suggesting that a dominant mechanism of MPAP uptake is endocytosis. These findings prompt concerns that MPAP-Src becomes sequestered in vesicles where it would be unable to access RNAi machinery to achieve successful c-Src silencing. To address this, expression levels of endogenous *c-src* mRNA were evaluated by RT-PCR following MPAP-Src uptake. Total

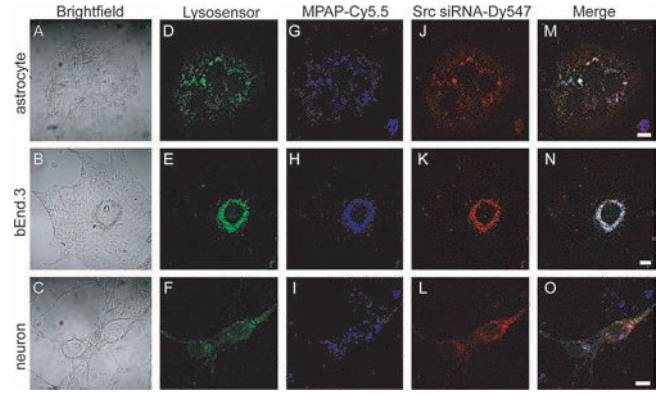

Figure 5. Cells were visualized using confocal microscopy following Lysosensor Green staining of unfixed astrocytes, bEnd.3 cells, and neurons (D−F) to determine the mechanism of cellular uptake of MPAP-Src. MPAP (G−I) and c-Src siRNA (J−L) generally colocalize with endosomal vesicles. Scale bar = 10 μm.

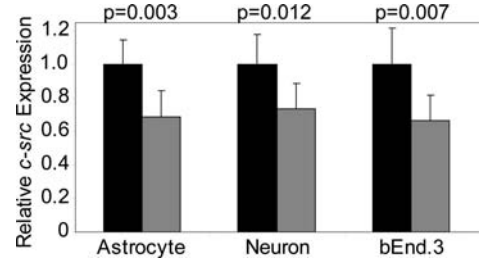

Figure 6. Quantitative RT-PCR analysis of endogenous *c-src* mRNA expression levels (mean ± s.d., $n = 7$) in astrocytes, neurons, and bEnd.3 cells treated with MPAP-ctrl (black bars) or MPAP-Src (gray bars) for 48 h. After administration of MPAP-Src, there was a significant reduction in *c-src* levels in all cell types tested.

c-src expression after MPAP-Src treatment was compared to expression after treatment with MPAP-ctrl, a control used to differentiate siRNA-induced *c-src* inhibition from off-target effects potentially caused by the MPAP method of siRNA delivery. Endogenous *c-src* levels were reduced to a statistically significant degree in all cell types subjected to MPAP-Src treatment for 48 h relative to controls (Figure 6). For astrocytes and bEnd.3 cells, *c-src* expression decreased to approximately 66% of controls, while in neurons, the decrease was to 75%. Similar reductions in *c-src* levels were achieved following 24-h MPAP-Src treatment in astrocytes and bEnd.3 cells (data not shown). Thus, despite the observation that MPAP-Src appears to traffic to some extent in endosomal vesicles, the endosomal escape of siRNA and its separation from MPAP is sufficient to mediate a significant degree of endogenous gene inhibition. To determine if MPAP-Src mediated siRNA delivery was cytotoxic, MTT and caspase-3 assays were performed (Figure 7). MPAP-Src treatment resulted in no discernible increase in cytotoxicity in either astrocytes or bEnd.3 cells relative to untreated controls as assessed by MTT and caspase-3 analysis. Likewise, MTT analysis showed no relative decrease in viability in neurons. Although caspase-3 levels appeared elevated in neurons, suggesting the presence of apoptosis following 48 h of MPAP incubation, the effect was not statistically significant. These data indicate that MPAP-Src treatment induced partial endogenous gene silencing without the cytotoxic effects that are often observed in other peptide-based delivery systems (*17*).

This report details the characterization and in vitro testing of a fluorescent siRNA imaging probe for application to ischemic stroke. MPAP, an amphipathic membrane translocation peptide derivative capable of crossing the blood−brain barrier, was shown to form stable complexes with siRNA and mediate cell

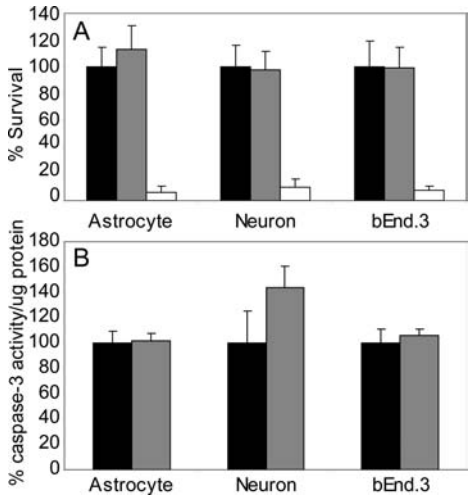

Figure 7. A. The percent survival (mean ± s.d.) of cells treated with MPAP-Src or staurosporine (gray and white bars, respectively) relative to untreated controls (black bars) was obtained by MTT analysis. MPAP-Src treatment resulted in no significant increase in cytotoxicity in any of the cell types. B. Caspase-3 activity (mean ± s.d.) in cells treated with MPAP-Src (gray bars) presented relative to activity in untreated cells (black bars). Though slight increases in caspase-3 signal were apparent, particularly in neurons, these were not statistically significant in any of the cells tested.

entry in primary neurons and astrocytes and an endothelial cell line without significant cytotoxicity. The internalized probe was biologically active, reducing endogenous levels of *c-src* mRNA that codes for a protein associated with detrimental outcome following ischemic stroke.

Previous studies have shown successful noncovalent complexation of siRNA to cell penetrating peptides for delivery to model and therapeutic targets (*7, 18*−*20*). Here, we demonstrate the proof-of-principle that simple complexation techniques can be employed to produce a dual optical imaging and therapeutic probe. We intend to investigate the probe as a method of monitoring siRNA delivery and treatment of cerebral ischemia in vivo.

Solid-Phase Synthesis of PEGylated Lipopeptides Using Click Chemistry

Rasmus I. Jølck, Rolf H. Berg, and Thomas L. Andresen*

Technical University of Denmark, DTU Nanotech, Department of Micro- and Nanotechnology, Frederiksborgvej 399, 4000 Roskilde, Denmark. Received January 2, 2010; Revised Manuscript Received March 29, 2010

A versatile methodology for efficient synthesis of PEGylated lipopeptides via CuAAC "Click" conjugation between alkyne-bearing solid-supported lipopeptides and azido-functionalized PEGs is described. This new and very robust method offers a unique platform for synthesizing PEGylated lipopeptides with a high level of complexity. These molecules, obtained in a single purification step, are ideally suited for functionalization of solid-supported lipid bilayers and liposomal drug delivery systems and are particularly valuable in enzyme activation strategies.

We report for the first time a highly efficient and versatile methodology for the synthesis of PEGylated lipopeptides on solid-phase support by use of the Cu(I) catalyzed azide/alkyne Huisgen 1,3-dipolar cycloaddition (CuAAC "Click" conjugation) developed by the Meldal (*1*) and the Sharpless (*2*) laboratories. This approach allows for an efficient synthesis of highly functionalized PEGylated lipopeptides, which are particularly interesting in the field of drug delivery. Current research in advanced liposomal drug delivery systems is increasingly focused on materials with a high complexity and functionality. Functionalized lipids can be difficult and expensive to synthesize, which is highly problematic for their utilization in drug delivery systems in a clinical setting. This creates a crucial need for the development of new approaches for obtaining complex lipids efficiently. Conjugates with the general composition of lipid-peptide-PEG have drawn particular interest due to their use as triggering molecules in enzymatically sensitive drug delivery systems (*3*−*7*). Such conjugates are particularly difficult to synthesize due to the diverse properties of the peptidyl side chains, the high molecular mass of the poly(ethylene glycol) (PEG) polymer, and the amphiphilic character of the compounds, which results in difficult purification procedures. Currently, such molecules are predominantly synthesized by postassembly of the lipid, peptide, and PEG-polymer fragments using *N*-hydroxysuccinimide (NHS) and *N*,*N*″-dicyclohexylcarboiimide (DCC) chemistry in solution (*3*, *4*). This approach may result in unspecific binding if multiple binding sites are present within the peptide. Furthermore, it often results in moderate yields and time-consuming purification steps.

In the present communication, we report a novel approach for the synthesis of complex PEGylated lipopeptides solely on solid-phase support. The method is based on the known advantages of solid phase peptide synthesis (SPPS) (*8*) and the unique features of the CuAAC reaction. By adopting SPPS methodology, excess reagents can easily be removed by washing and the required purification steps are greatly reduced. In addition, the CuAAC reaction is one of the most useful and robust ligation reactions available and offers unique flexibility due to the high level of orthogonality to other chemical functionalities. We have developed a general methodology for achieving PEGylated lipopeptides on solid-phase support by using the CuAAC reaction with the solvent, the choice of resin, and the reaction time as the optimization parameters.

The resin-bound diacylated lipopeptide **1** (Figure 1) was chosen as an immobilized model substrate for the on-resin CuAAC reaction. A bulky peptide with large side-chain protection groups was chosen in order to demonstrate the versatility of the developed method. The alkyne functionality at the C-terminal of the peptide serves as a site specific conjugation site, whereas the tryptophan residue was chosen as a UV-marker for HPLC monitoring at 280 nm. The model lipopeptide **1** was synthesized on both PS (1% DVB cross-linked) resin and NovaSyn TentaGel resin both equipped with the Rink amide linker in order to elucidate the effect of the solid-phase support.

Lipopeptide **1** was synthesized manually by employing standard Fmoc chemistry (*9*) (see Supporting Information). The alkyne functionality was introduced at the C-terminal of the lipopeptide by using (*S*)-2-(Fmoc-amino)-4-pentynoic acid. The diacyl lipid anchor was achieved by conjugation of N_{α},N_{β}-di-Fmoc-L-2,3-diaminopropionic acid (Fmoc-dap(Fmoc)-OH) to the *N*-terminal of the peptide followed by diacylation with myristic acid (Scheme 1). After diacylation with myristic acid, a test cleavage of **1** from the resin was conducted in order to confirm the peptide sequence by MALDI-TOF MS and RP-HPLC (see Supporting Information).

The methoxy poly(ethylene glycol) azides **3a**−**c** needed for the on-resin CuAAC reaction were synthesized from the commercially available corresponding monomethoxy poly(ethylene glycol)s by either tosylation or mesylation of the alcohol, followed by a nucleophilic substitution with sodium azide, as illustrated in Scheme 2. This approach was easily scaled up and resulted in good yields. Azide formation was confirmed by ^{1}H NMR, ^{13}C NMR, MALDI-TOF MS, and FT-IR (see Supporting Information).

The efficiency of the CuAAC reaction between the resin-bound lipopeptide **1** and the monomethoxy poly(ethylene glycol) azides **3a**−**c** was studied as a function of time, choice of resin, and solvent. The reactions were carried out in 2.5 mL reaction vessels by using 50 mg lipopeptide modified resin (12.5−15 μmol lipopeptide), 5 equiv of the azide functionalized polymer, 5 equiv copper(I) iodide, and 5 equiv sodium ascorbate in either DMF/piperidine (4:1) or CH_2Cl_2/piperidine (4:1). The total reaction volume was adjusted in all cases to give a final concentration of the above-mentioned reagents of 61.25 mM (Scheme 3).

Small samples of resin were taken out after 1, 2, 5, 24, 48, and 72 h respectively. The PEGylated lipopeptides were cleaved from the resin with a mixture of TFA/TIS/H_2O, lyophilized, and analyzed by analytical RP-HPLC, employing a Waters XTerra RP_{18} 5 μm (4.6 × 150 mm) column with water/

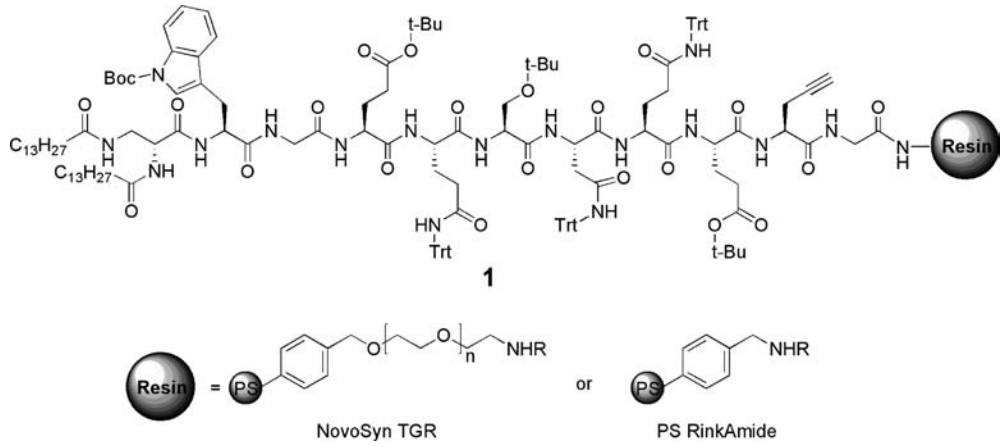

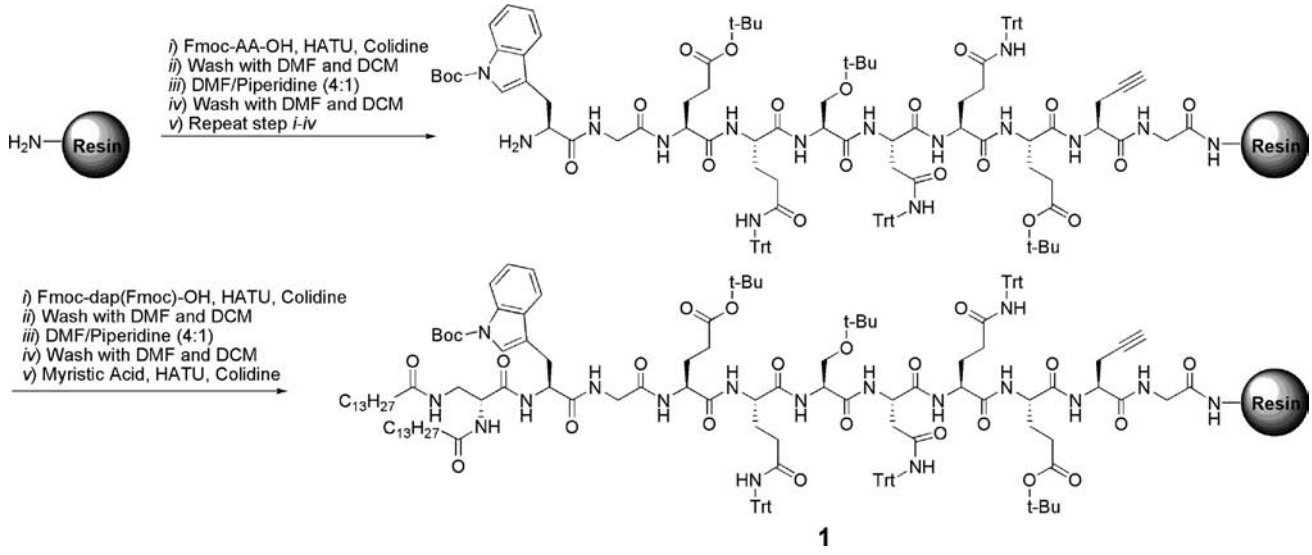

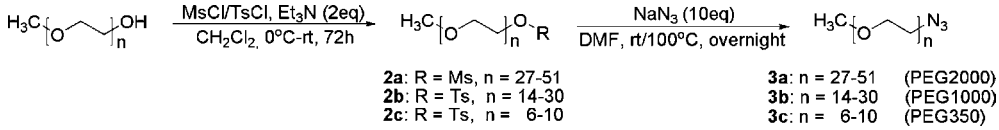

Figure 1. Fully protected diacylated lipopeptide **1** was employed as an immobilized model substrate for the on-resin CuAAC "Click" reaction with PEG. **1** was synthesized on both PS- and TentaGel resin equipped with Rink amide linker.

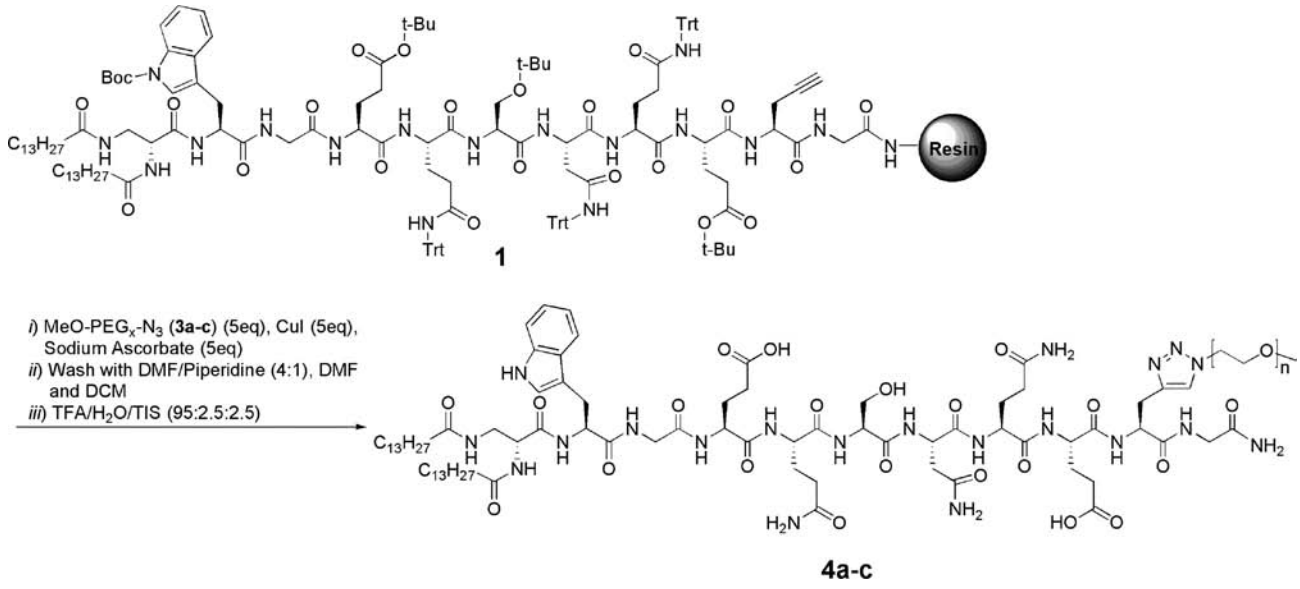
Scheme 1. Synthetic Pathway to the Resin-Bound Lipopeptide 1

Scheme 2. Synthetic Pathway to the Methoxy Poly(Ethylene Glycol) Azides 3a−c Used for On-Resin CuAAC Reaction



acetonitrile as the mobile phase. The degree of PEGylation was calculated from the area under the curve (AUC) from the two peaks corresponding to the lipopeptide and the PEGylated lipopeptide, respectively, at 280 nm by the formula given in eq 1.

$$\text{PEGylation degree} = \frac{\text{AUC}_{\text{lipid-peptide-PEG}}}{\text{AUC}_{\text{lipid-peptide-PEG}} + \text{AUC}_{\text{lipid-peptide}}} \times 100\% \quad (1)$$

The obtained results from the on-resin CuAAC on PS-RinkAmide resin with the synthesized PEG azides **3a**−**c** are given in Figure 2a. As Figure 2a clearly illustrates, the average size of the PEG-azide used for the CuAAC reaction has a significant influence on both the reaction rate and the degree of conversion. Complete PEGylation with MeO-PEG_{350}-N_3 (**3c**) was observed within the first hour, whereas MeO-PEG_{1000}-N_3 (**3b**) and MeO-PEG_{2000}-N_3 (**3a**) resulted in 80% and 50% PEGylation degree in 48 h, respectively. Since 99% of the available reaction sites on the resin are present inside the polystyrene matrix, diffusion of the reacting species is usually the limiting factor (*10*). This effect gets progressively more dominant with higher molecular weight polymers, which is clearly illustrated by the observed conversion. Similar observations have been reported by Klok et al. (*11*) and Mutter et al. (*12*), who studied *N*-terminal PEGylation with α-methoxy-*ω*-carbonyl functionalized PEG to PS-supported peptides. They reported quantitative conversion with MeO-PEG_{700}-COOH, whereas only 40% conversion was achieved when the average molecular weight was increased to 1800 Da. The strong decrease in the conversion degree was explained by the lower reactivity of the polymer, by the

Scheme 3. Employed Reaction Conditions for the On-Resin PEGylation of 1, Followed by Deprotection and Cleavage from Solid Support

decrease in diffusion into the PS-matrix, and by the increasing incompatibility of the polymer with the solid support. We have therefore compared the coupling efficiency of PEG on the PS-RinkAmide resin with the efficiency on NovaSyn TentaGel resin. The TentaGel resin was chosen because of its hydrophilic character due to the high content of PEG (approximately 70 mass%), which should improve the compatibility of the PEG-azides with the solid support. Furthermore, enzymes such as porcine pancreatic trypsin (23.5 kDa) and various lipases (30−40 kDa) have been reported to be able to penetrate to the core of TentaGel resins (*13, 14*), which clearly illustrates the easy accessibility of this class of resins. However, although the TentaGel resin should be more compatible and accessible to the reacting PEG-azides, no significant improvement of the PEGylation degree was observed (Figure 2b). Again, complete PEGylation with MeO-PEG_{350}-N_3 (**3c**) was observed within the first hour, whereas MeO-PEG_{1000}-N_3 (**3b**) and MeO-PEG_{2000}-N_3 (**3a**) resulted in 85% and 55% PEGylation degree in 48 h, respectively. Due to the lack of success in increasing the yield for the longer PEGs by choice of resin, we attempted to improve the degree of conversion by changing the solvent mixture for the on-resin CuAAC reaction. The swelling behavior of the resin is highly dependent on the solvent polarity, which will affect the diffusion of solute molecules within the matrix (*10*, *15*). By changing the solvent system from DMF/piperidine (4:1) to CH_2Cl_2/piperidine (4:1), the degree of conversion was improved from 85% to quantitative yield for MeO-PEG_{1000}-N_3 (**3b**) and from 55% to 85% for MeO-PEG_{2000}-N_3 (**3a**) (Figure 2c). Precipitation of a small amount of 1-(chloromethyl)-piperidine was observed, but did not effect the CuAAC reaction. Furthermore, addition of the Cu(I)-stabilizing ligand bathophenanthroline disulfonic acid (*16*) or an increase of temperature to 50 °C did not result in an improved conversion degree (data not shown). No evidence of alkyne−alkyne homocoupling (Glaser-coupling) was observed by MALDI-TOF MS at any time during the reaction, most likely due to the pseudo dilution effect (*17*). Excess of reagents and Cu(I) was easily washed away resulting in high purity of the crude products.

In conclusion, we have demonstrated a novel approach for the synthesis of PEGylated lipopeptides via the CuAAC "Click" reaction between an alkyne-bearing solid-supported diacylated lipopeptide and α-methoxy-*ω*-azido functionalized PEGs. The alkyne functionality was easily inserted into the peptide and served as a site-specific conjugation site, without the need for complex protective group strategies. The α-methoxy-*ω*-azido functionalized PEGs were readily available from the corresponding alcohols, and the on-resin CuAAC with the large polymers proved to be fully compatible with Fmoc-SPPS methodology. HPLC analysis of the cycloaddition products demonstrated a clear polymer size dependent conversion degree. Small polymers such as MeO-PEG_{350}-N_3 (**3c**) reacted readily and resulted in full conversion regardless of the choice of resin and solvent mixture. Full conversion was also achieved after 24 h with MeO-PEG_{1000}-N_3 (**3b**) when applying the NovaSyn TentaGel resin in a mixture of CH_2Cl_2/piperidine (4:1), whereas 85% conversion was achieved with MeO-PEG_{2000}-N_3 (**3a**) under the same conditions. The employed strategy allows for PEG insertion (and other molecules) in the final step of the synthesis to any position that is desired in the peptide, and importantly provides the possibility of verifying possible amino acid deletions before PEGylation, which can otherwise be very difficult to detect.

The method described here enables easy synthesis of molecules with a high level of complexity which, after a single purification step, is ideally suited for functionalization of solid-supported lipid bilayers and liposomal drug delivery systems and is particularly valuable in enzyme activation strategies. Additional targeting ligands or functional groups can easily be attached to the distal end of the PEG-azide, resulting in an even higher level of complexity, if needed. Furthermore, this method also enables easy synthesis of asymmetric diacyl lipopeptides by choosing a 2,3-diaminopropionic acid derivate with two orthogonal amine protection groups. This allows for optimization of the lipopeptide properties with respect to its integration and compatibility with lipid bilayers, which has been shown to be a crucial parameter in controlling the release of encapsulated content in liposomal drug delivery systems (*18*).

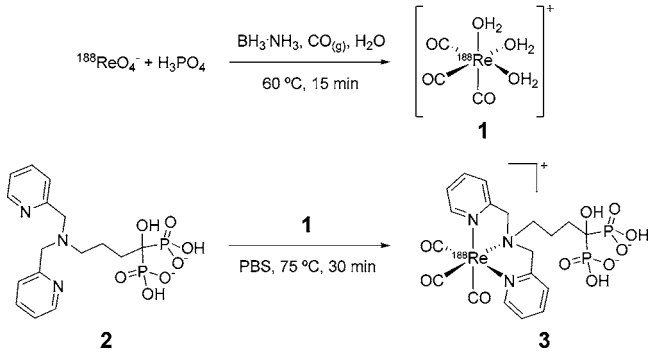
Received February 5, 2010; Revised Manuscript Received March 31, 2010

The palliation of pain due to bone metastases using targeted compounds containing β-emitters such as rhenium-188 (^{188}Re) is an accepted and effective form of treatment. Here, we describe the efficient synthesis and preclinical evaluation of $^{188}Re(CO)_3$-dipicolylamine(DPA)-alendronate, a novel bifunctional bisphosphonate for the palliative treatment of bone metastases. $^{188}Re(CO)_3$-DPA-alendronate can be easily synthesized with high specific activities and yields (18.8 GBq/mg, radiochemical yield $\geq$96%) in two steps using kit-based methodology, and in contrast with the clinically approved bisphosphonate $^{186/188}$Re-HEDP, it forms inert, single species that have been well-characterized. In vivo imaging and biodistribution studies demonstrate that $^{188}Re(CO)_3$-DPA-alendronate is superior to ^{188}Re-HEDP in targeting and accumulating in areas of high metabolic bone activity while having low soft-tissue uptake. In addition to these studies, a simple and convenient new method for purifying its precursor, *fac*-$[^{188}Re(CO)_3(H_2O)_3]^+$, is described.

Bone metastases arise most commonly from malignancy of breast, prostate, and lung cancers with an estimated 80% of patients eventually developing these secondary tumors (*1*). Other types of cancers such as melanoma, ovarian, thyroid, kidney, and head and neck are also likely to present these complications. One of the most distressing effects of bone metastases is extensive pain which severely impairs the quality of life of these patients. Palliation of the pain is usually managed by using strong opioid analgesics such as morphine. With ongoing administration, however, these drugs may induce severe side effects such as nausea, respiratory depression, and addiction/withdrawal syndrome. Palliative treatment using external beam radiation therapy is also commonly employed. This modality, however, is not recommended when the metastases have spread to several distant sites of the skeleton, as harmful radiation of essential organs cannot be avoided.

A very effective way of palliating the pain of these tumors is by internal radiotherapy using β^--emitting radionuclides (*2*). In this modality, a targeted radioactive pharmaceutical is taken up selectively by the bone metastases giving a high localized dose of radiotherapy to these areas. Several clinical trials have demonstrated its usefulness. In fact, several β^--emitting radiopharmaceuticals are currently being used in the clinic, of which the most popular are $^{89}SrCl_2$ (Metastron) and ^{153}Sm-ethylenediamine tetra(methylene phosphonic acid) (^{153}Sm-EDTMP or Quadramet) (*3*−*5*). Their clinical efficacy is proven, but they are not without disadvantages. ^{89}Sr and ^{153}Sm can only be produced in specialized nuclear reactors which are decreasing in number. Another concern is economic, as a single dose of one of these agents costs ca. $2900 per dose (*6*). Furthermore, neither is carrier-free, and the low stability of ^{153}Sm-EDTMP requires coadministration of a high concentration of unlabeled EDTMP. As a consequence, there has been a growing interest in developing therapeutic bone-seeking radiopharmaceuticals using generator-produced isotopes. Generator technologies not only provide straightforward availability of radioisotopes in any laboratory or clinical center around the world, but also reduce costs dramatically, as a single generator can potentially provide hundreds of doses.



Rhenium-188 (^{188}Re) is arguably the most promising generator-produced β^--emitting radionuclide for the radiotherapy of bone metastases. ^{188}Re (E_{max} 2.12 MeV, 100%) is readily available using commercially available generators and shows favorable therapeutic properties. It also emits γ-photons (155 keV, 15%) that allow imaging using single photon emission computed tomography (SPECT) (*7, 8*). It has a medium-short half-life (16.9 h) and similar chemistry to technetium-99m (^{99m}Tc), the most widely used radionuclide in biomedical imaging. It was this Tc−Re analogy that drove forward the development of $^{186/188}$Rehydroxyethylidene-1,1-diphosphonate ($^{186/188}$Re-HEDP), the therapeutic "analogues" of the ^{99m}Tc-bisphosphonates (^{99m}Tc-BPs) routinely used as bone imaging agents. ^{186}Re-HEDP and ^{188}Re-HEDP have shown promise as palliative and therapeutic agents for bone metastases in recent clinical trials (*9*−*14*), but their properties are far from optimal from a chemical and pharmaceutical point of view. Their main drawback is that their chemical structures and compositions remain unidentified, although there are clear indications that they are composed of a mixture of anionic polymers (*15*). Also, these complexes are not entirely analogous to their technetium "analogues" since additional nonradioactive Re needs to be added as a "carrier" to achieve bone targeting (*14, 16, 17*). Furthermore, a large fraction of the injected complexes degrade to perrhenate (ReO_4^-) in vivo within 24 h and thus are not retained in bone metastases.

These drawbacks are attributable to poor chemical design. In these complexes, the BP acts as both radionuclide-binding ligand and targeting group, compromising both roles. We believe that to improve upon current Re-BPs a more logical approach is the use of targeted bifunctional ligands in which the targeting (BP) and metal chelating groups are separated within the molecule so that they can each function independently and effectively. A few recent reports describe such a bifunctional

Scheme 1

approach based on BPs (*18*−*20*). These BP conjugates, however, require complicated multistep synthetic strategies, show high plasma protein binding, and often form enantiomeric mixtures. To address these issues, we recently developed dipicolylamine(DPA)-alendronate (**2**, Scheme 1), an easily synthesized and well-characterized bifunctional bisphosphonate that forms single, well-defined isostructural Tc(I) and Re(I) tricarbonyl complexes that efficiently accumulate in bone tissue in vivo (*21*). Herein, we describe the synthesis, characterization, and preclinical in vivo studies of its ^{188}Re complex, $^{188}Re(CO)_3$-DPA-alendronate (**3**, Scheme 1), in comparison with ^{188}Re-HEDP to evaluate its potential as a new improved radiopharmaceutical for the therapy of bone metastases.

3 was easily made from generator-eluted $^{188}ReO_4^-$ in two steps (Scheme 1). The precursor *fac*-$[^{188}Re(CO)_3(H_2O)_3]^+$ (**1**, Scheme 1) was synthesized following the method of Schibli et al. (*22*). The radiochemical yields of **1** ranged between 80% and 85%, in agreement with the published method, with the remaining byproduct being unreduced and/or reoxidized $^{188}ReO_4^-$ and colloidal "$^{188}ReO_2$". A new purification method was required, since none was described in the original report. We reasoned that ionic chromatography could be used to separate the two byproducts based on their ionic and colloidal character. Thus, the crude solution was passed through a system composed of two solid-phase extraction columns connected in series, an OnGuard II Ag column (Dionex) to remove chloride ions from the saline solution, followed by a strong anion exchange (SAX) column (SAX Varian Bond Elut 100 mg) to retain $^{188}ReO_4^-$. Using this system, **1** is obtained in the eluate in good radiochemical yields (65%, based on initial $^{188}ReO_4^-$ activity) and excellent purities (≥99%) (Figure 1). The OnGuard II Ag column was proven necessary in order to remove the chloride ions from the saline solution that otherwise compete with $^{188}ReO_4^-$ in the SAX column, at the expense of **1** being retained to some extent in the OnGuard II Ag column (10%). Attempts to release trapped **1** using increasing concentrations of NaCl were unsuccessful, suggesting that the interaction between **1** and the OnGuard II Ag column is not ionic.

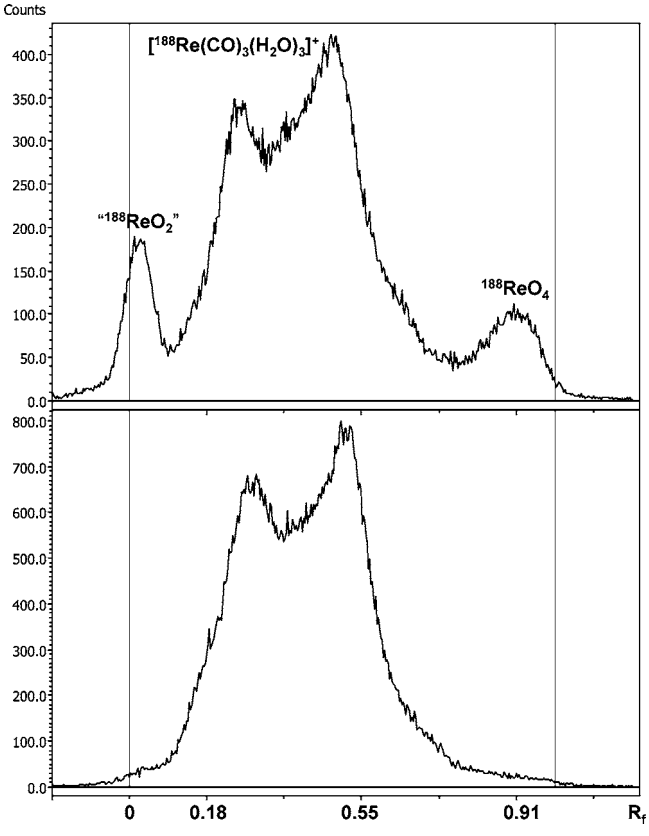

Figure 1. Silica gel TLC analyses of $[^{188}Re(CO)_3(H_2O)_3]^+$ (**1**) in the crude reaction solution (top) and after purification (bottom). Vertical lines indicate origin and solvent front. Using MeOH/HCl_{conc} (99%:1%) as the mobile phase, "$^{188}ReO_2$" colloids appear at $R_F = 0.05$, **1** appears as two broad peaks with $R_F = 0.20-0.50$, and $^{188}ReO_4^-$ appears at $R_F = 0.90$).

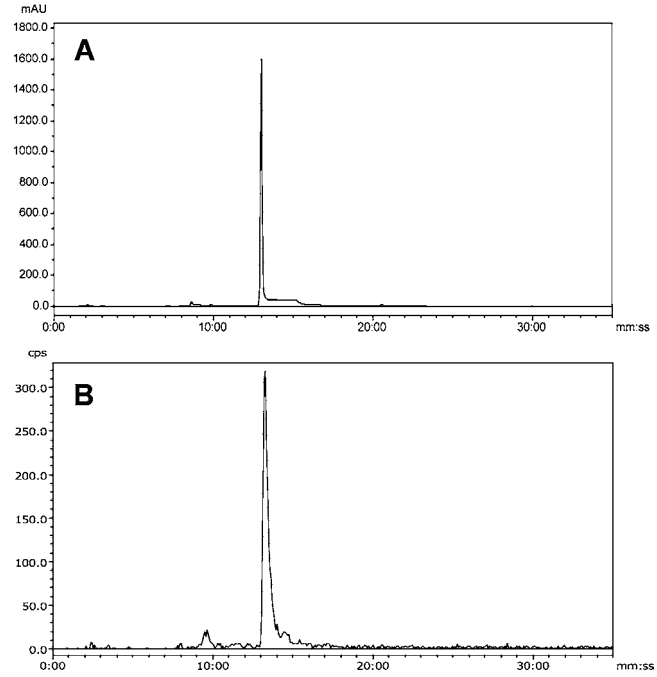

Figure 2. RP-HPLC chromatograms of nonradioactive $Re(CO)_3$-DPA-alendronate (A, UV detection (254 nm), t_R = 13:12 mm:ss) and **3** (B, β detection, t_R = 13:12 mm:ss). The difference in peak width is due to the larger cell volume of the γ/β^- detector.

3 was synthesized by mixing a solution of freshly made **1** (100 μL, 150 MBq) with **2** (0.01 mg/mL in PBS, 100 μL) in a N_2-purged vial followed by heating at 75 °C for 30 min. RP-HPLC analysis of the reaction solution revealed the formation of **3** with a specific activity of 18.8 GBq/mg and ≥96% radiochemical yield with the remainder of the activity being $^{188}ReO_4^-$. In contrast to $[^{99m}Tc(CO)_3(OH_2)_3]^+$, reoxidation of **1** to $^{188}ReO_4^-$ during labeling conditions has been observed previously with other ligands and can be rationalized to be the result of the lower redox potential of Re compared to that of Tc (*22*). Longer reaction times (up to 60 min) and lower reaction temperatures (60 °C) led to lower yields of **3**. A comparison with the chromatogram of the well-characterized nonradioactive $Re(CO)_3$-DPA-alendronate complex, and its ^{99m}Tc analogue, demonstrates the formation of the desired compound as a single species (Figure 2) (*21*).

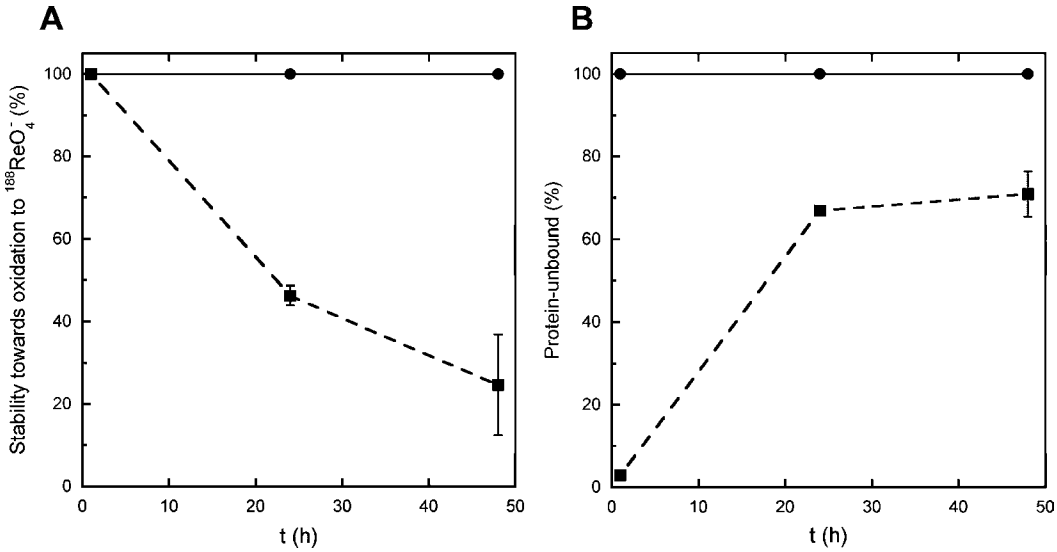

Figure 3. Stability study (toward oxidation to $^{188}ReO_4^-$) in PBS (A) and serum protein binding study (B), of **3** (black circles) and ^{188}Re-HEDP (black squares). See Supporting Information for methods.

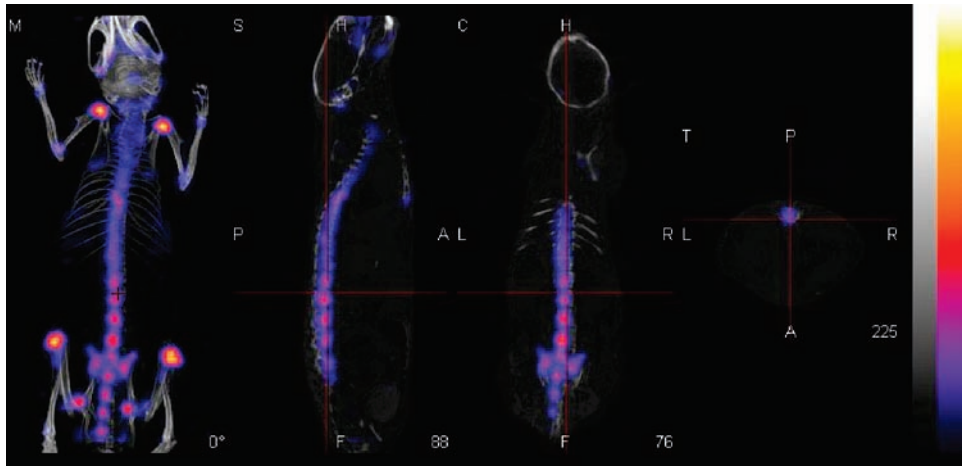

Figure 4. SPECT (color)/CT (grayscale) image taken 24 h postinjection showing the high uptake of **3** in bone tissue, particularly at the joints. From left to right, maximum intensity projection (M), sagittal (S), coronal (C), and transverse (T) sections.

In order to achieve the maximum therapeutic efficiency, ^{188}Re compounds must remain stable and bound to the target during at least one to three half-lives of ^{188}Re (16.9 h). One of the most important drawbacks of ^{188}Re-HEDP is its lack of stability both in vivo and in vitro. In order to assess the in vitro stability of **3** in comparison with ^{188}Re-HEDP, both compounds were incubated in PBS for 48 h at 37 °C. RP-HPLC and TLC analyses demonstrated that **3** did not degrade over this time, whereas most of ^{188}Re-HEDP oxidized to $^{188}ReO_4^-$ (up to 75%) (Figure 3A). Incubation of both compounds in human serum show most of the radioactivity from the ^{188}Re-HEDP sample remains bound to serum proteins during the first 24 h. After this time, ~70% of the radioactivity was free in solution. ITLC analyses demonstrated, however, that the non-protein-bound radioactivity was $^{188}ReO_4^-$, the decomposition product of ^{188}Re-HEDP. **3**, on the other hand, remained non-protein-bound and unmodified throughout the 48 h incubation period (Figure 3B).

In vivo imaging studies with **3** and ^{188}Re-HEDP were carried out at 1, 5, 24, and 48 h postinjection with adult BALB/c female mice (9 weeks old for **3** and 8 weeks old for ^{188}Re-HEDP) using a nanoSPECT/CT scanner (Figure 4). These studies confirmed the ability of **3** to accumulate in areas of metabolically active bone such as the joints, while soft-tissue organ uptake was very low throughout the experiment. Quantification of the images provided an interesting comparison of the pharmacokinetics of each compound (Figure 5). Thus, both compounds show an increase in uptake in the knee for the first 5 h. After this time, however, the uptake of **3** increased during the next 24 h, whereas that of ^{188}Re-HEDP diminished until the end of the 48 h experiment. We speculate that the increased uptake in bone of **3** during the first 24 h is the result of recycling of the unmetabolized, chemically intact complex from soft tissues, coupled with its excellent retention and slow release from bone compared to ^{188}Re-HEDP. This is in agreement with the biodistribution profiles at 48 h (vide infra) as well as with previous in vitro experiments with its ^{99m}Tc analogue, demonstrating the superior capabilities of Re/Tc-DPA-alendronate for binding and remaining bound to the main component of bone mineral (hydroxyapatite) (*21*). Further experiments, however, would be needed to confirm this hypothesis.

Ex vivo biodistribution studies at 48 h demonstrate that **3** exhibits higher uptake in bone tissue than ^{188}Re-HEDP (percentage of injected dose per gram of tissue (% ID/g) in one whole femur: 21.2 ± 6.6% for **3**; cf. 13.4 ± 0.2% for ^{188}Re-HEDP), consistent with its higher stability and/or better targeting properties (Figure 6). As shown in the above-mentioned imaging studies, soft-tissue uptake was very low for both compounds with most organs having an uptake of less than 0.6% ID/g. **3** consistently shows higher uptake than ^{188}Re-HEDP in these organs, especially in the liver (0.96 ± 0.2% ID/g). This may

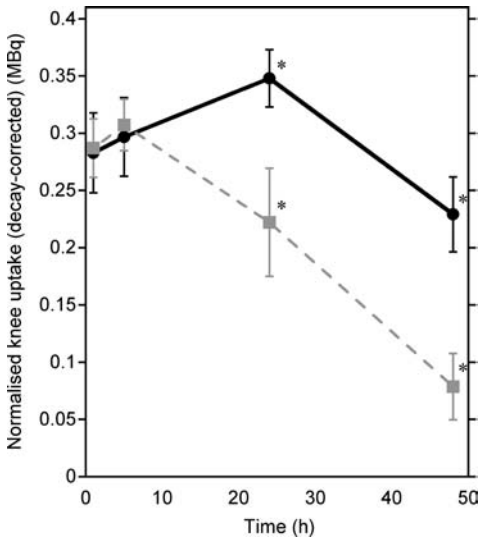

Figure 5. Uptake in the left knee (decay-corrected) after injection of **3** (33 MBq, black circles, continuous line) or ^{188}Re-HEDP (29 MBq, gray squares, dashed line) obtained from ROI analysis of the imaging data. The data from **3** were scaled by a factor of 29/33 to take into account the different injected activity. Values represent the mean ± SD (n = 3 mice). * indicates a significant difference ($P < 0.05$, Student's paired t-test) between the two radiotracers.

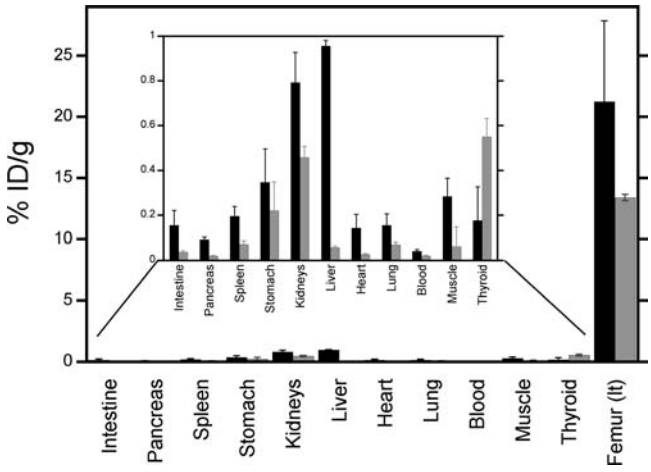

Figure 6. Biodistribution profile of **3** (black bars) and ^{188}Re-HEDP (gray bars) at t = 48 h postinjection. Values represent the mean ± SD (n = 3 mice).

be explained by the lipophilic nature of the carbonyl and dipicolylamine groups. An interesting exception, however, is the lower uptake of **3** in the thyroid. We attribute this to the tendency of ^{188}Re-HEDP, but not **3**, to decompose into $^{188}ReO_4^-$, which is known to be taken up by sodium-iodide symporter (NIS)-expressing organs such as the thyroid (*23*).

In conclusion, we have described a simple and convenient method to purify **1** that will facilitate the labeling of other small molecules and biomolecules such as His-tagged peptides/proteins with ^{188}Re in high radiochemical yields and purities (*24*). We have also described the synthesis of **3** as a new radiopharmaceutical for the radionuclide therapy of bone metastases. **3** can be easily synthesized with high specific activities in two steps using kit-based methodology, and in contrast with the clinically approved $^{186/188}$Re-HEDP, it forms an inert, single species that has been well-characterized. The strategy of using a designed chelating agent for rhenium rather than relying on the chelating properties of the bisphosphonate group is vindicated in that **3** displays superior stability, bone targeting, and retention properties. **3** is therefore an attractive candidate for further clinical studies.

PDT Center, Cell Stress Biology, Preclinical Imaging Facility, and Department of Dermatology, Roswell Park Cancer Institute, Buffalo, New York 14263. Received December 2, 2009; Revised Manuscript Received March 8, 2010

To develop novel bifunctional agents for tumor imaging (MR) and photodynamic therapy (PDT), certain tumor-avid photosensitizers derived from chlorophyll-a were conjugated with variable number of Gd(III)aminobenzyl DTPA moieties. All the conjugates containing three or six gadolinium units showed significant T_1 and T_2 relaxivities. However, as a bifunctional agent, the 3-(1′-hexyloxyethyl)pyropheophorbide-a (HPPH) containing 3Gd(III) aminophenyl DTPA was most promising with possible applications in tumor-imaging and PDT. Compared to HPPH, the corresponding 3- and 6Gd(III)aminobenzyl DTPA conjugates exhibited similar electronic absorption characteristics with a slightly decreased intensity of the absorption band at 660 nm. However, compared to HPPH, the excitation of the broad "Soret" band (near 400 nm) of the corresponding 3Gd(III)aminobenzyl-DTPA analogues showed a significant decrease in the fluorescence intensity at 667 nm.

INTRODUCTION

Magnetic resonance imaging (MRI) is a medical imaging technique commonly used in radiology to visualize the internal structure and function of the body (*1*). MRI provides greater contrast between the different soft tissues of the body than computed tomography (CT), making it especially useful in neurological (brain), musculoskeletal, cardiovascular, and oncological (cancer) imaging (*2*). However, MR imaging has some practical disadvantages. For example, benign tumors may be difficult to distinguish from malignant lesions. The fibrocystic disease of the breast, fibroadenomas, sclerosing adenosis, atypical hyperplasia, lobular carcinoma in situ (LCIS), and breast papillomas can all produce contrast enhancement patterns that are hard to distinguish from malignant processes. In addition, some benign processes such as proliferative dysplasia, inflammation, wounds, and benign tumors can enhance in a similar fashion to malignant tumors (*3*). These shortcomings of MRI in measuring tissue properties offer opportunities that may be satisfied with information provided by optical fluorescence imaging with near-infrared light (*4*). Optical techniques offer the potential to contribute greatly to the expansion of clinical multimodality techniques. Their ability to image structural, functional, and molecular information at different spatial and temporal scales makes them very attractive. In this case, the multimodality approach can be used as the combination of multiple optical techniques in one instrument and/or the fusion of an optical technique with another well-established clinical modality, such as PET, CT, or MRI (*5, 6*).

Clinically, optical imaging modality has been employed to enable or improve PDT (*7*). Most of the porphyrin-based photosensitizers generally fluoresce and the fluorescent nature of these porphyrins has been exploited for the detection of early stage cancers in the lung, bladder, and other sites (*8*). In addition, for treatment of early disease or for deep-seated tumors the fluorescence can be used to guide the activated light. Most of the porphyrin-based compounds are not optimal fluorophores for tumor detection for several reasons, especially a small shift between the long-wavelength absorption and emission bands, which make it technically difficult to separate the fluorescence from excitation wavelength (*9*). However, certain pyropheophorbide-a analogues (e.g., HPPH) produce very high fluorescence quantum yields and exciting them at their long-wavelength absorption (665 nm) produces two emission bands: a strong peak at 670 nm, and a weaker band at 720 nm. This characteristic of HPPH has been used for in vivo fluorescence imaging of canine and other tumors (*10*). In recent years, integrating the strengths of each imaging modality has become a major research area. The research in our laboratory has also been focused on designing certain porphyrin-based compounds as "multifunctional agents" for tumor imaging and photodynamic therapy (PDT) (*11*−*15*).

We have previously shown that HPPH (*16*−*21*) a tumor-avid photosensitizer (currently undergoing phase I/II human clinical trials) on conjugating with Gd(III)aminobenzyl DTPA [Gd(III)ADTPA] can be used for both tumor MR imaging and PDT (*22, 23*). In our initial study, among the compounds investigated, the conjugates with two Gd(III)ADTPA moieties showed greater tumor contrast than the corresponding mono-Gd(III)ADTPA derivative. However, poor solubility of these agents in various clinically acceptable formulations restricted their use for detailed in vivo studies, including toxicity. To investigate the effect of increased number of GD(III)ADTPA moieties in tumor imaging/PDT and also to improve water solubility, we decided to extend this approach further, and a series of tumor-avid long-wavelength absorbing chlorophyll-a analogues (pyropheophorbide-a and purpurinimide) containing three or six Gd(III)ADTPA moieties with variable lipophilicity were synthesized. For developing "bifunctional agents" with longer wavelength absorption than HPPH (λ_{max}: 660 nm), a related conjugate containing a highly tumor-avid purpurinimide (λ_{max}: 700 nm) (*24*) was also prepared. In this manuscript, the synthesis, photophysical properties, T_1/T_2 relaxivity, and in vitro photosensitizing efficacy of a series of novel photosensitizer-

Gd(III)ADTPA conjugates are discussed. The second part of our study (see the following paper in this issue) is focused on selecting the optimal "multifunctional agent" for tumor-imaging (MRI, fluorescence imaging) and PDT. In vivo PDT response is discussed in terms of long-term cure rate and monitoring of the vascular response via immunohistochemistry. Finally, the biodistribution and organ-specific toxicity of the lead compound (C-14 labeled) at variable time points is also discussed.

EXPERIMENTAL PROCEDURES

Chemistry. The synthetic intermediates and the final products were characterized by NMR (400 MHz), mass spectrometry (EIMS and HRMS) and elemental analysis. ^{1}H NMR spectra were recorded on a Bruker AMX-400 spectrometer. Chemical shifts are expressed in δ ppm. All photophysical experiments were carried out using spectroscopic-grade solvents. The reactions were monitored by TLC and/or spectrophotometrically. Column chromatography was performed either over Silica Gel 60 (70−230 mesh) or neutral Alumina (Brockmann grade III, 50 mesh). UV−visible spectra were recorded on Varian Cary 50 Bio UV−visible spectrophotometer using dichloromethane as solvent unless otherwise specified. Fluorescence spectra were recorded on a Varian Cary Eclipse fluorescence spectrophotometer with an excitation wavelength in the "Soret" band region between 410 and 425 nm.

Compound 1. HPPH (100.0 mg, 0.157 mmol), amine **A** (97.8 mg, 0.235 mmol), EDCI (1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride) (60.2 mg, 0.314 mmol), and DMAP (4-dimethylaminopyridine) (38.36 mg, 0.314 mmol) were taken in a dry, round-bottom flask (100 mL). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at room temperature for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 1−3% methanol/dichloromethane mixture as eluent to give product **1**. Yield: 130.0 mg (80.0%). UV−vis (λ_{max}, dichloromethane): 318, 412, 506, 537, 604, and 660 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.78 (s, 1H, H-5), 9.41 (s, 1H, H-10), 8.54 (s, 1H, H-20), 5.96−5.91 (m, 2H, $CH_3\underline{CH}$Ohexyl, NH), 5.33 (d, 1H, CH-15^1, J = 19.6 Hz), 5.14 (d, 1H, CH-15^1, J = 19.6 Hz), 4.53 (q, 1H, H-17, J = 7.2 Hz), 4.32 (m, 1H, H-18), 3.71−3.67 (m, 2H, -O$\underline{CH_2}$-hexyl), 3.63−3.60 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.52 (s, 3H, 7-CH_3), 3.39 (s, 3H, 2-CH_3), 3.27 (s, 3H, 12-CH_3), 2.67 (m, 1H, CH-17^2), 2.37 (m, 1H, H-17^2), 2.26 (m, 1H, H-17^1), 2.15−2.13 (m, 9H, 3CH_2-chain and $\underline{CH_3}$CHOhexyl), 1.97 (m, 1H, H-17^1), 1.92 (t, 6H, 3CH_2-chain, J = 7.6 Hz), 1.80 (d, 3H, 18-CH_3, J = 7.2 Hz), 1.73 (m, 2H, CH_2hexyl), 1.66 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.6 Hz), 1.44 (m, 2H, CH_2hexyl), 1.30 (s, 27H, 3$CO_2{}^t$Bu), 1.24 (m, 4H, 2CH_2hexyl), 0.78 (t, 3H, CH_3hexyl, J = 6.8 Hz), 0.04 (brs, 1H, NH), −1.68 (brs, 1H, NH). EIMS: 1035 (MH^+). HRMS: Calcd for $C_{61}H_{87}N_5O_9$, 1033.6503; found 1034.6564 (MH^+).

Compound 2. Compound **1** (73.0 mg, 0.07 mmol) was stirred with 70% trifluoroacetic acid (TFA)/dichloromethane (DCM, 5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove traces of TFA. To this crude preparation were added amino-benzyl-DTPA-penta-*tert*-butyl ester (219.0 mg, 0.282 mmol), EDCI (67.0 mg, 0.352 mmol), and DMAP (43.0 mg, 0.352 mmol). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over alumina G (III) using 1−3% methanol/dichloromethane mixture as eluent to give product **2**. Yield: 130.0 mg (58.47%). UV−vis (λ_{max}, dichloromethane): 319, 411, 506, 537, 604, 661. ^{1}HNMR (400 MHz, $CDCl_3$): δ 9.74 (splitted s, 1H, H-5), 9.36 (splitted s, 1H, H-10), 8.54 (splitted s, 1H, H-20), 8.17 (brs, 1H, NH), 7.74 (m, 1H, Ph-DTPA), 7.61−7.56 (m, 2H, Ph-DTPA), 7.43 (m, 4H, Ph-DTPA), 7.12 (m, 5H, Ph-DTPA), 6.96 (brs, 1H, NH), 5.96 (m, 1H, $CH_3\underline{CH}$Ohexyl), 5.29 (d, 1H, CH-15^1, J = 19.2 Hz), 5.11 (d, 1H, CH-15^1, J = 19.2 Hz), 4.47 (m, 1H, H-17), 4.26 (m, 1H, H-18), 3.64 (m, 2H, and O$\underline{CH_2}$hexyl), 3.54 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.45−3.38 (m, 30H, 15CH_2-DTPA), 3.36 (s, 3H, 7-CH_3), 3.32 (s, 3H, 2-CH_3), 3.22 (s, 3H, 12-CH_3), 3.12 (m, 3H, CH-DTPA), 2.84−2.70 (m, 19H, 9CH_2-DTPA and CH-17^2), 2.59 (m, 6H, 6CH_2-benzyl), 2.47−2.41 (m, 8H, 3CH_2-chain, CH-17^2 and CH-17^1), 2.19−2.15 (m, 9H, 3CH_2-chain, $\underline{CH_3}$CH−Ohexyl), 2.06 (d, 3H, 18-CH_3, J = 7.6 Hz), 2.00 (m, 1H, CH-17^1), 1.74 (m, 4H, 2CH_2-hexyl), 1.66 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.2 Hz), 1.60 (m, 135H for 15 $CO_2{}^t$Bu), 1.26 (m, 4H, 2CH_2-hexyl), 0.77 (m, 3H, CH_3-Ohexyl), 0.55 (brs, 1H, NH), −0.24 (brs, 1H, NH). HRMS: Calcd for $C_{172}H_{267}N_{17}O_{36}$, 3149.053; found 3150.10 (MH^+).

Compound 3. Compound **2** (110.0 mg, 0.034 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude preparation thus obtained was dissolved in pyridine (10 mL), and while stirring, $GdCl_3 \cdot 6H_2O$ (77.9 mg, 0.21 mmol) in 1 mL of water was added slowly, and the resultant mixture was stirred for 16 h. The reaction mixture was concentrated to dryness under high vacuum. The residue was washed with water (10 mL × 3) and acetone (10 mL × 3) and finally dried under high vacuum using P_2O_5 as drying agent. Yield: 75.0 mg (77.55%). UV−vis (λ_{max}, MeOH): 620, 408, 504, 537, 604, and 660 nm. Elemental analysis: Calcd for $C_{113}H_{151}Gd_3N_{17}O_{36}$: C, 48.55; H, 5.44; Gd, 16.88; N, 8.52; O, 20.61. Found: C, 48.68; H, 5.49; N, 8.57.

Compound 5. Acid **4** (100.0 mg, 0.143 mmol), amine **A** (89.1 mg, 0.214 mmol), EDCI (54.9 mg, 0.28 mmol), and DMAP (34.9 mg, 0.28 mmol) were taken in a dry, round-bottom flask (RBF, 100 mL). Dry dichloromethane (30 mL) was added to it, and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 1−2% methanol/dichloromethane mixture as eluent to give product **5**. Yield: 134.0 mg (85.3%). UV−vis (λ_{max} nm, dichloromethane): 318, 411, 506, 536, 604, and 661. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.76 (splitted s, 1H, H-5), 9.38 (splitted s, 1H, H-10), 8.55 (s, 1H, H-20), 6.02 (d, 1H, $CH_3\underline{CH}$OTEG, J = 6.4 Hz), 5.99 (brs, 1H, NH), 5.34 (d, 1H, CH-15^1, J = 20.0 Hz), 5.15 (d, 1H, CH-15^1, J = 20.0 Hz), 4.58 (q, 1H, H-17, J = 6.8 Hz), 4.33 (m, 1H, H-18), 3.88−3.75 (m, 4H, 2$\underline{CH_2}$-O-TEG), 3.70−3.62 (m, 6H, 3$\underline{CH_2}$-O-TEG), 3.55 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.47−3.44 (m, 2H, $\underline{CH_2}$-O-TEG), 3.40 (s, 3H, 7-CH_3), 3.39 (s, 3H, 2-CH_3), 3.29 (s, 3H, 12-CH_3), 3.27 (s, 3H, $\underline{CH_3}$-O-TEG), 2.69 (m, 1H, CH-17^2), 2.39 (m, 1H, CH-17^2), 2.31 (m, 1H, CH-17^1), 2.14 (m, 8H, 4CH_2-chain), 2.00 (m, 1H, CH-17^1), 1.92 (m, 7H, 2CH_2-chain, $\underline{CH_3}$CHOTEG), 1.82 (d, 3H, 18-CH_3, J = 7.2 Hz), 1.68 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.6 Hz), 1.31 (s, 27H, 3$CO_2{}^t$Bu), 0.42 (brs, 1H, NH), −1.69 (brs, 1H, NH). EIMS: 1097 (MH^+). Calcd for $C_{62}H_{89}N_5O_{12}$, 1095.6507; found 1096.6571 (MH^+).

Compound 6. Compound **5** (100.0 mg, 0.091 mmol) was stirred with 80% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude preparation were added amino-benzyl-DTPA-penta-*tert*-butyl ester (285.0 mg, 0.365 mmol), EDCI (105.0 mg, 0.54 mmol), and DMAP (66.8 mg, 0.54 mmol). Dry dichloromethane (30 mL) was added, and the reaction mixture was stirred at RT for 16 h under N_2

atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over alumina Gr(III) using 1−3% methanol/dichloromethane mixture as eluent to give product **6**. Yield: 250.0 mg (85.3%). UV−vis (λ_{max} nm, dichloromethane): 319, 411, 506, 537, 606, 661. ^{1}HNMR (400 MHz, $CDCl_3$): δ 9.70 (splitted s, 1H, H-5), 9.44 (splitted s, 1H, H-10), 9.37 (brs, 1H, NH), 9.20 (brs, 1H, NH), 8.56 (m, 1H, NH), 8.47 (s, 1H, H-20), 7.77 (m, 1H, Ph-DTPA), 7.59 (m, 2H, Ph-DTPA), 7.44 (m, 2H, Ph-DTPA), 7.10 (m, 6H, Ph-DTPA), 6.81 (m, 1H, Ph-DTPA), 5.97 (m, 1H, $CH_3\underline{CH}$OTEG), 5.20 (m, 2H, CH_2-15^1), 4.60 (m, 1H, H-17), 4.22 (m, 1H, H-18), 3.81−3.64 (m, 4H, 2CH_2−OTEG), 3.57−3.50 (m, 4H, 8-$\underline{CH_2}CH_3$, $\underline{CH_2}$-OTEG), 3.60 (m, 6H, 3CH_2OTEG), 3.38 (s, 30H, 15CH_2-DTPA), 3.35 (s, 3H, 7-CH_3), 3.23 (m, 6H, 12-CH_3, OCH_3-TEG), 3.04 (m, 3H, 3CH-DTPA), 2.70 (m, 19H, 9CH_2-DTPA, CH-17^2), 2.55 (m, 7H, 3CH_2-benzyl and CH-17^2), 2.32 (t, 6H, 3CH_2-chain, J = 6.8 Hz), 2.23 (m, 1H, CH-17^1), 2.10 (d, 3H, $\underline{CH_3}$CH−OTEG, J = 6.4 Hz), 2.01 (m, 1H, CH-17^1), 1.77 (d, 3H, 18-CH_3, J = 7.2 Hz), 1.68 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.6 Hz), 1.59 (t, 6H, 3CH_2-chain, J = 6.4 Hz), 1.44 (m, 135H, 15CO_2^{t}Bu), −1.75 (brs, 1H, NH). HRMS: Calcd for $C_{173}H_{269}N_{17}O_{39}$, 3211.077; found 3212.20 (MH^+).

Compound 7. Compound **6** (226.0 mg, 0.07 mmol) was stirred with 80% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude mixture thus obtained was dissolved in pyridine (10 mL), and while stirring, $GdCl_3\cdot 6H_2O$ (156.9 mg, 0.422 mmol) in 1 mL of water was added slowly, and the resultant mixture was stirred for 16 h. The reaction mixture was concentrated to dryness under high vacuum. The residue was washed with water (10 mL × 3) and acetone (10 mL × 3) and finally dried under high vacuum using P_2O_5 as drying agent. Yield: 165.0 mg (82.5%). UV−vis (λ_{max} nm, MeOH): 320, 408, 505, 537, 605, and 660 nm. Elemental analysis: Calcd for $C_{113}H_{149}Gd_3N_{17}O_{39}$: C, 47.77; H, 5.29; Gd, 16.60; N, 8.38; O, 21.96. Found: C, 47.85; H, 5.30; N, 8.43.

Compound 9. Acid **8** (82.0 mg, 0.118 mmol), amine **A** (73.6 mg, 0.177 mmol), EDCI (45.3 mg, 0.236 mmol), and DMAP (28.8 mg, 0.236 mmol) were taken in a dry RBF (100 mL). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 1−2% methanol/dichloromethane mixture as eluent to give product **9**. Yield: 90.0 mg (69.8%). UV−vis (λ_{max}, dichloromethane): 365, 418, 509, 545, and 699 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.75 (splitted s, 1H, meso-H), 9.64 (s, 1H, meso-H), 8.55 (s, 1H, meso-H), 6.25 (m, 1H, CONH), 5.79 (q, 1H, $CH_3\underline{CH}$Obutyl, J = 6.4 Hz), 5.34 (m, 1H, H-17), 4.52 (t, 2H, -N$\underline{CH_2}$butyl, J = 7.2 Hz), 4.42 (m, 1H, H-18), 3.84 (s, 3H, ring-CH_3), 3.70−3.59 (m, 4H, -O$\underline{CH_2}$-butyl, 8-$\underline{CH_2}CH_3$), 3.32 (s, 3H, ring-CH_3), 3.17 (s, 3H, ring-CH_3), 2.61 (m, 1H, CH-17^2), 2.43 (m, 1H, H-17^2), 2.27 (m, 1H, H-17^1), 2.20 (t, 6H, 3$\underline{CH_2}$-chain, J = 7.2 Hz), 2.06 (m, 3H, $\underline{CH_3}$CHObutyl), 2.01 (t, 6H, 3$\underline{CH_2}$-chain, J = 7.6 Hz), 1.82 (m, 1H, H-17^1), 1.75 (d, 3H, 18-CH_3, J = 6.0 Hz), 1.68 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.6 Hz), 1.62 (m, 8H, 4$\underline{CH_2}$butyl), 1.34 (s, 27H, 3CO_2^{t}Bu), 1.10 (t, 3H, $\underline{CH_3}$-obutyl, J = 7.2 Hz), 0.87 (t, 3H, $\underline{CH_3}$-Nbutyl, J = 7.2 Hz), 0.40 (brs, 1H, NH), −0.06 (brs, 1H, NH). EIMS: 1092 (MH^+). HRMS: Calcd for $C_{63}H_{90}N_6O_{10}$, 1090.6718; found 1091.6823 (MH^+).

Compound 10. Compound **9** (80.0 mg, 0.073 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude mixture were added, amino-benzyl-DTPA-penta-*tert*-butyl ester (286.0 mg, 0.366 mmol), EDCI (84.4 mg, 0.44 mmol), and DMAP (53.7 mg, 0.44 mmol). Dry dichloromethane (30 mL) was added, and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over alumina G (III) using 1−3% methanol/dichloromethane mixture as eluent to give product **10**. Yield: 140.0 mg (59.57%). UV−vis (λ_{max}, dichloromethane): 365, 418, 509, 546, 699 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.75 (splitted s, 1H, meso-H), 9.63 (splitted s, 1H, meso-H), 9.33 (brs, 1H, NH), 8.60 (splitted s, 1H, meso-H), 7.61 (m, 2H, Ph-DTPA), 7.58 (m, 1H, Ph-DTPA), 7.37 (m, 3H, Ph-DTPA), 7.12 (m, 5H, Ph-DTPA), 6.84 (m, 1H, Ph-DTPA), 5.76 (m, 1H, $CH_3\underline{CH}$Obutyl), 5.39 (m, 1H, H-17), 4.45 (m, 3H, H-18 and N$\underline{CH_2}$butyl), 3.82 (s, 3H, ring-CH_3), 3.65 (m, 4H, 8-$\underline{CH_2}CH_3$ and O$\underline{CH_2}$butyl), 3.38 (m, 22H, 11CH_2-DTPA), 3.31 (m, 11H, 4CH_2-DTPA and ring-CH_3), 3.17 (s, 3H, ring-CH_3), 3.03 (m, 3H, CH-DTPA), 2.84−2.61 (m, 19H, 9CH_2-DTPA and CH-17^2), 2.47 (m, 8H, 6CH_2-benzyl and CH-17^2 and CH-17^1), 2.20 (m, 6H, 3CH_2-chain), 2.04 (d, 3H, $\underline{CH_3}$CHObutyl, J = 6.8 Hz), 1.96 (m, 6H, 3CH_2-chain), 1.84 (m, 1H, CH-17^1), 1.73 (s, 3H, 17-CH_3), 1.67 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.2 Hz), 1.60 (m, 4H, 2CH_2-Obutyl), 1.41 (m, 135H for 15 CO_2^{t}Bu), 1.37 (m, 4H, 2CH_2-N-butyl), 1.03 (t, 3H, CH_3-Obutyl, J = 6.8 Hz), 0.86 (t, 3H, CH_3-N-butyl, J = 6.8 Hz), −0.09 (brs, 1H, NH). HRMS: Calcd for $C_{174}H_{270}N_{18}O_{37}$, 3206.104; found 3207.250 (MH^+).

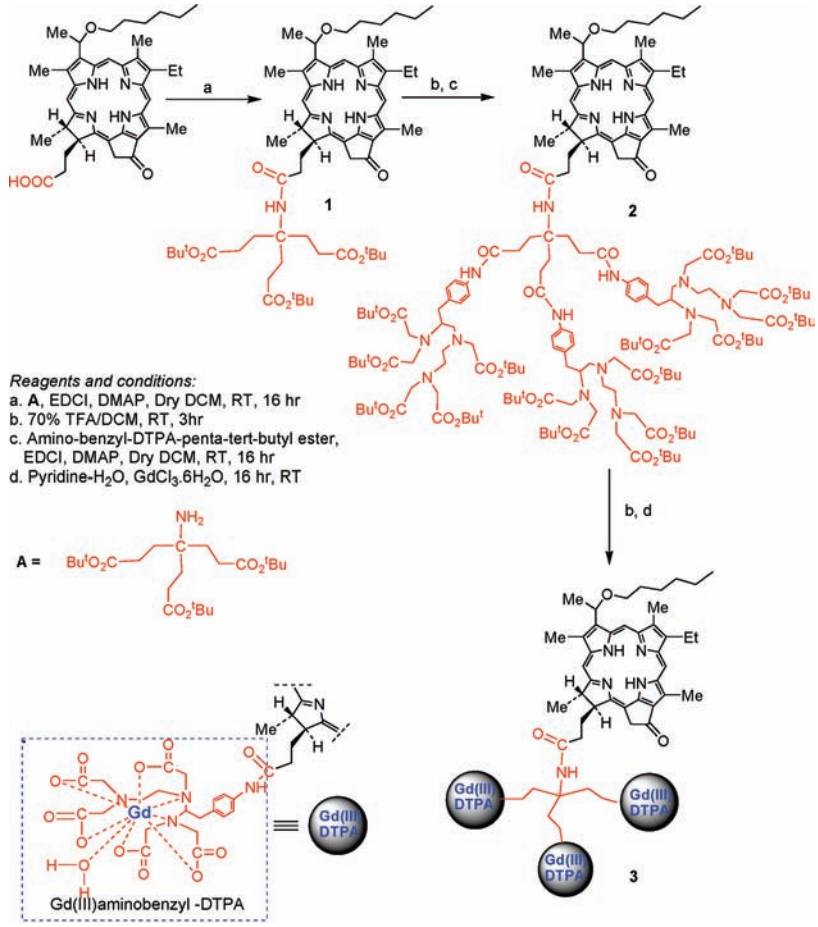
Compound 11. Compound **10** (130.0 mg, 0.04 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude preparation thus obtained was dissolved in pyridine (10 mL), and while stirring, $GdCl_3\cdot 6H_2O$ (90.3 mg, 0.243 mmol) in 1 mL of water was added slowly and the resultant mixture was stirred for 16 h. The reaction mixture was concentrated to dryness under high vacuum. The residue was washed with water (10 mL × 3), acetone (10 mL × 3), and finally dried under high vacuum using P_2O_5 as drying agent. Yield: 80.0 mg (69.9%). UV−vis (λ_{max}, MeOH): 364, 415, 546, and 700 nm. Elemental analysis: Calcd for $C_{114}H_{150}Gd_3N_{18}O_{37}$: C, 48.28; H, 5.33; Gd, 16.63; N, 8.89; O, 20.87. Found: C, 48.14; H, 5.40; N, 8.93.

Compound 12. HPPH (100.0 mg, 0.157 mmol), di-*tert*-butyl iminodiacetate (77.0 mg, 0.314 mmol), EDCI (60.2 mg, 0.314 mmol), and DMAP (38.36 mg, 0.314 mmol) were taken in a dry RBF (100 mL). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at room temperature for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 1−1.5% methanol/dichloromethane mixture as eluent to give product **12**. Yield: 120.0 mg (88.3%). UV−vis (λ_{max} nm, dichloromethane): 317, 411, 506, 538, 605, and 660 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.80 (s, 1H, H-5), 9.51 (s, 1H, H-10), 8.55 (s, 1H, H-20), 5.94 (q, 1H, $CH_3\underline{CH}$Ohexyl, J = 6.4 Hz), 5.33 (d, 1H, CH-15^1, J = 20.0 Hz), 5.17 (d, 1H, CH-15^1, J = 20.0 Hz), 4.52 (q, 1H, H-17, J = 7.6 Hz), 4.41 (m, 1H, H-18), 4.04 (m, 2H, CH_2chain), 3.75 (m, 2H, -O$\underline{CH_2}$-hexyl), 3.67 (s, 3H, 7-CH_3), 3.62 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.42 (s, 3H, 2-CH_3), 3.37 (m, 2H, CH_2chain), 3.29 (s, 3H, 12-CH_3), 2.77 (m, 1H, CH-17^2), 2.46 (m, 1H, CH-17^2), 2.16 (m, 1H, CH-17^1), 2.13 (m, 3H, and $\underline{CH_3}$CHOhexyl), 1.97 (m, 1H, CH-17^1), 1.84 (d, 3H, 18-CH_3, J = 7.2 Hz), 1.78 (m, 2H, CH_2hexyl), 1.72 (t, 3H, 8-$CH_2\underline{CH_3}$, J = 7.6 Hz), 1.49 (s, 9H, CO_2^{t}Bu), 1.46 (m, 2H, CH_2hexyl), 1.45 (s, 9H, CO_2^{t}Bu), 1.25 (m, 4H,

2CH_2hexyl), 0.8 (t, 3H, CH_3hexyl, $J = 6.8$ Hz), 0.42 (brs, 1H, NH), −1.7 (brs, 1H, NH). EIMS: 865 (MH^+) (*25*).

Compound 13. Compound **12** (120.0 mg, 0.139 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude preparation were added amine **A** (144.2 mg, 0.34 mmol), EDCI (106.6 mg, 0.556 mmol), and DMAP (67.8 mg, 0.556 mmol). Dry dichloromethane (30 mL) was added, and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The cude mixture was chromatographed over silica gel using 2−6% methanol/dichloromethane mixture as eluent to give product **13**. Yield: 190.0 mg (88.3%). UV−vis (λ_{max}, dichloromethane): 318, 411, 506, 537, 605, and 660 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.78 (s, 1H, H-5), 9.52 (s, 1H, H-10), 8.3 (s, 1H, H-20), 8.27 (brs, 1H, NH), 8.17 (brs, 1H, NH), 6.59 (brs, 1H, NH), 5.90 (m, 1H, $CH_3\underline{CH}$Ohexyl), 5.34 (d, 1H, CH-15^1, $J = 20.0$ Hz), 5.15 (d, 1H, CH-15^1, $J = 20.0$ Hz), 4.53 (q, 1H, H-17, $J = 6.0$ Hz), 4.36 (m, 1H, H-18), 3.77 (m, 2H, -O$\underline{CH_2}$-hexyl), 3.69 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.67 (s, 3H, 7-CH_3), 3.61 (m, 4H, 2CH_2chain), 3.36 (s, 3H, 2-CH_3), 3.26 (s, 3H, 12-CH_3), 2.77 (m, 1H, CH-17^2), 2.66 (m, 1H, CH-17^2), 2.52 (m, 1H, CH-17^1), 2.23 (m, 12H, 6CH_2-chain), 2.11 (d, 3H, $\underline{CH_3}$CHOhexyl, $J = 6.4$ Hz), 2.07 (m, 6H, 3CH_2-chain), 1.95 (m, 6H, 3CH_2-chain), 1.93 (m, 1H, CH-17^1), 1.81 (d, 3H, 18-CH_3, $J = 7.2$ Hz), 1.75 (m, 2H, CH_2hexyl), 1.71 (t, 3H, 8-$CH_2\underline{CH_3}$, $J = 8.0$ Hz), 1.43 (m, 2H, CH_2hexyl), 1.41 (s, 27H, 3$CO_2{}^t$Bu), 1.32 (s, 27H, 3$CO_2{}^t$Bu), 1.24 (m, 4H, 2CH_2hexyl), 0.77 (t, 3H, CH_3hexyl, $J = 6.8$ Hz). EIMS: 1548 (MH^+). HRMS: Calculated for $C_{87}H_{131}N_7O_{17}$, 1545.9601, found 1545.9574 (M^+).

Compound 14. Compound **13** (100.0 mg, 0.064 mmol) was stirred with 80% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude preparation were added amino-benzyl-DTPA-penta-*tert*-butyl ester (503.5 mg, 0.64 mmol), EDCI (123.9 mg, 0.64 mmol), and DMAP (78.8 mg, 0.64 mmol). Dry *N*,*N*-dimethylformamide (15 mL) was added and reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was concentrated under vacuum, dichloromethane added (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over alumina G (III) using 1−3% methanol/dichloromethane mixture as eluent to give product **14**. Yield: 250.0 mg (70.0%). UV−vis (λ_{max}, dichloromethane): 318, 413, 507, 539, 606, and 660. Elemental analysis: Calcd for $C_{309}H_{491}N_{31}O_{71}$: C, 64.25; H, 8.57; N, 7.52; O, 19.67. Found: C, 64.30; H, 8.59; N, 7.56.



Compound 15. Compound **14** (225.0 mg, 0.038 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude preparation thus obtained was dissolved in pyridine (10 mL), and while stirring, $GdCl_3 \cdot 6H_2O$ (173.7 mg, 0.46 mmol) in 1 mL of water was added slowly, and the resultant mixture was stirred for 16 h. The reaction mixture was concentrated to dryness under high vacuum. The residue was washed with water (10 mL × 3) and acetone (10 mL × 3) and finally dried under high vacuum using P_2O_5 as drying agent. Yield: 170.0 mg (86.7%). UV−vis (λ_{max}, MeOH): 320, 411, 507, 539, 606, and 660 nm. Elemental analysis: Calcd for $C_{189}H_{251}Gd_6N_{31}O_{71}$: C, 45.07; H, 5.02; Gd, 18.73; N, 8.62; O, 22.55. Found: C, 45.15; H, 5.10; N, 8.58.

Compound 16. Acid **4** (150.0 mg, 0.214 mmol), di-*tert*-butyl iminodiacetate (105.0 mg, 0.429 mmol), EDCI (82.3 mg, 0.429 mmol), and DMAP (52.0 mg, 0.429 mmol) were taken into a dry RBF (100 mL). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer was separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 1−1.5% methanol/dichloromethane mixture as eluent to give product **16**. Yield: 165.0 mg (82.9%). UV−vis (λ_{max}, dichloromethane): 318, 411, 506, 536, 605, and 661 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.75 (splitted s, 1H, H-5), 9.52 (splitted s, 1H, H-10), 8.53 (s, 1H, H-20), 6.01 (m, 1H, $CH_3\underline{CH}$OTEG), 5.31 (d, 1H, CH-15^1, $J = 20.0$ Hz), 5.13 (d, 1H, CH-15^1, $J = 20.0$ Hz), 4.50 (q, 1H, H-17, $J = 7.2$ Hz), 4.36 (m, 1H, H-18), 4.02 (m, 2H, CH_2chain), 3.85 (m, 2H, $\underline{CH_2}$-O-TEG), 3.79 (m, 2H, $\underline{CH_2}$-O-TEG), 3.73 (m, 4H, 3$\underline{CH_2}$-O-TEG), 3.68 (s, 3H, 7-CH_3), 3.66 (m, 2H, 8-$\underline{CH_2}CH_3$), 3.55 (m, 2H, $\underline{CH_2}$-O-TEG), 3.39 (s, 3H, 2-CH_3), 3.27 (s, 6H, 12-CH_3 and $\underline{OCH_3}$-TEG), 2.75 (m, 1H, CH-17^2), 2.44 (m, 1H, CH-17^2), 2.41 (m, 1H, CH-17^1), 2.16 (m, 1H, CH-17^1), 2.14 (d, 3H, $\underline{CH_3}$CHOTEG, $J = 6.4$ Hz), 1.81 (d, 3H, 18-CH_3, $J = 7.6$ Hz), 1.71 (t, 3H, 8-$CH_2\underline{CH_3}$, $J = 7.6$ Hz), 1.44 (splitted s, 9H, $CO_2{}^t$Bu), 1.06 (splitted s, 9H, $CO_2{}^t$Bu), 0.39 (brs, 1H, NH), −1.80 (brs, 1H, NH). EIMS: 927 (MH^+). HRMS: Calcd for $C_{52}H_{71}N_5O_{10}$, 925.5201, found 926.5288 (MH^+).

Compound 17. Compound **16** (140.0 mg, 0.151 mmol) was stirred with 70% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude preparation were added amine **A** (188.2 mg, 0.453 mmol), EDCI (115.9 mg, 0.604 mmol), and DMAP (73.7 mg, 0.604 mmol). Dry dichloromethane (30 mL) was added and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was diluted with dichloromethane (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over silica gel using 3−7% methanol/dichloromethane mixture as eluent to give product **17**. Yield: 210.0 mg (86.4%). UV−vis (λ_{max}, dichloromethane): 318, 411, 506, 536, 604, and 661 nm. ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.76 (splitted s, 1H, H-5), 9.53 (s, 1H, H-10), 8.63 (s, 1H, H-20), 8.31 (splitted s, 1H, CONH), 6.56 (splitted s, 1H, CONH), 6.00 (m, 1H, $CH_3\underline{CH}$OTEG), 5.35 (d, 1H, CH-15^1, $J = 20.0$ Hz), 5.16 (d, 1H, CH-15^1, $J = 20.0$ Hz), 4.53 (q, 1H, H-17, $J = 7.6$ Hz), 4.36 (d, 1H, H-18, $J = 10.4$ Hz), 3.85−3.80 (m, 4H, 2$\underline{CH_2}$-O-TEG), 3.74−3.71 (m, 6H, 2CH_2chain, $\underline{CH_2}$-O-TEG), 3.67 (s, 3H, 7-CH_3), 3.66 (m, 4H, 8-$\underline{CH_2}CH_3$, $\underline{CH_2}$-O-TEG), 3.53 (m, 2H, $\underline{CH_2}$-O-TEG), 3.42−3.39 (m, 5H, $\underline{CH_2}$-O-TEG, 2-CH_3), 3.27−3.26 (m, 6H, 12-CH_3, $\underline{OCH_3}$TEG), 2.75 (m, 1H, CH-17^2), 2.67 (m, 1H, CH-17^2), 2.52 (m, 1H, CH-17^1), 2.24−2.22 (m, 13H, 6$\underline{CH_2}$-chain, CH-17^1), 2.14 (d, 3H, $\underline{CH_3}$CHOTEG, $J = 6.8$ Hz), 2.09−2.04 (m, 6H, 3$\underline{CH_2}$-chain), 1.96 (m, 6H, 3$\underline{CH_2}$-chain), 1.81 (d, 3H, 18-CH_3, $J = 7.2$ Hz), 1.71 (t, 3H, 8-$CH_2\underline{CH_3}$, $J = 8.0$ Hz), 1.41 (s, 27H, 3$CO_2{}^t$Bu), 1.33 (s, 27H, 3$CO_2{}^t$Bu), 0.39 (brs, 1H, NH), −1.79 (brs, 1H, NH). EIMS: 1610 (MH^+). HRMS: Calcd for $C_{88}H_{133}N_7O_{20}$, 1607.9605, found: 1607.9650 (M^+).

Compound 18. Compound **17** (100.0 mg, 0.06 mmol) was stirred with 80% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude preparation were added amino-benzyl-DTPA-penta-*tert*-butyl ester (471.0 mg, 0.60 mmol), EDCI (115.9 mg, 0.60 mmol), and DMAP (73.8 mg, 0.60 mmol). Dry *N*,*N*-dimethylformamide (15 mL) was added and the reaction mixture was stirred at RT for 16 h under N_2 atm. The reaction mixture was concentrated under vacuum, dichloromethane added (100 mL), washed with brine solution, the organic layer separated, dried over sodium sulfate, and concentrated. The crude mixture was chromatographed over alumina G (III) using 1−3% methanol/dichloromethane mixture

Scheme 1

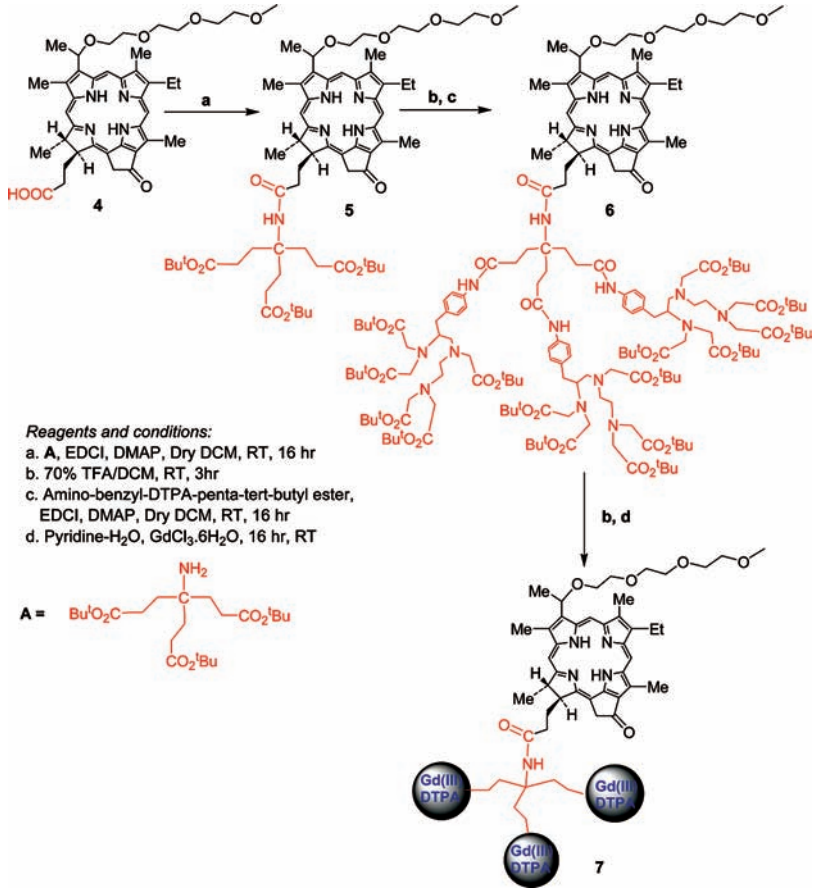
as eluent to give product **18**. Yield: 250.0 mg (69.0%). UV−vis (λ_{max}, dichloromethane): 319, 412, 508, 538, 606, and 661 nm. Elemental analysis: Calcd for $C_{309}H_{491}N_{31}O_{74}$: C, 63.72; H, 8.50; N, 7.46; O, 20.33. Found: C, 63.67; H, 8.57; N, 7.46.

Compound 19. Compound **18** (215.0 mg, 0.0369 mmol) was stirred with 80% TFA/DCM (5.0 mL) at room temperature for 3 h. The resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude preparation thus obtained was dissolved in pyridine (10 mL), and while stirring, $GdCl_3 \cdot 6H_2O$ (164.6 mg, 0.44 mmol) in 1 mL of water was added slowly, and the resultant mixture was stirred for 16 h. The reaction mixture was concentrated to dryness under high vacuum. The residue was washed with water (10 mL × 3) and acetone (10 mL × 3), and finally dried under high vacuum using P_2O_5 as drying agent. Yield: 160.0 mg (85.0%). UV−vis (λ_{max}, MeOH): 320, 410, 507, 539, 606, and 661 nm. Elemental analysis: Calcd for $C_{190}H_{253}Gd_6N_{31}O_{74}$: C, 44.76; H, 5.00; Gd, 18.50; N, 8.52; O. Found: C, 44.80; H, 5.07; N, 8.51.

Calculation of In Vitro Relaxivities. MRI acquisitions were performed using a General Electric 4.7T/33 cm horizontal bore magnet (GE NMR instruments, Fremont, CA) incorporating AVANCE digital electronics (Bruker BioSpec platform with *ParaVision* v 3.0.2 acquisition software, Bruker Medical, Billerica, MA).

Each conjugate was diluted with phosphate-buffered saline (pH 7.4) to a concentration ranging from 0.02 mM to 0.10 mM and imaged at 25 °C. T_1 relaxation rates (R_1) were acquired utilizing a saturation recovery, spin−echo (SE) sequence with a fixed echo time (T_E) = 10 ms and repetition times (T_R) ranging from 75 to 8000 ms. Additional MR acquisition parameters were as follows: field of view (FOV) 32 × 32 mm^2, slice thickness = 1 mm, slices = 3, interslice gap = 2 mm, matrix = 192 × 192, number of averages (NEX) = 1. Signal intensities at each repetition time were sampled by taking the mean intensity within regions of interest (ROI's) using commercially available image processing software (*Analyze 7.0*, AnalyzeDirect, Overland, KS), and R_1 and S_{MAX} were calculated by nonlinear fitting of the equation

$$S_{(TR)} = S_{MAX}(1 - e^{-(R1 \cdot TR)}) + \text{background noise}$$



using Matlab's Curve Fitting Toolbox (*Matlab 7.0*, MathWorks Inc., Natick, MA). The T_1 relaxivity for each conjugate was then determined by obtaining the slope of the compound's molar concentration vs R_1 via linear regression fitting of the data. Similarly, T_2 relaxation rates (R_2) were acquired using a multiecho, Carr-Purcell-Meiboom Gill (CPMG) SE sequence with a fixed T_R of 2500 ms and T_E times ranging from 15 to 300 ms, NEX = 2. R_2 and S_{MAX} were calculated as described above using the equation

$$S_{(TE)} = S_{MAX}(e^{-(R2 \cdot TE)}) + \text{background noise}$$

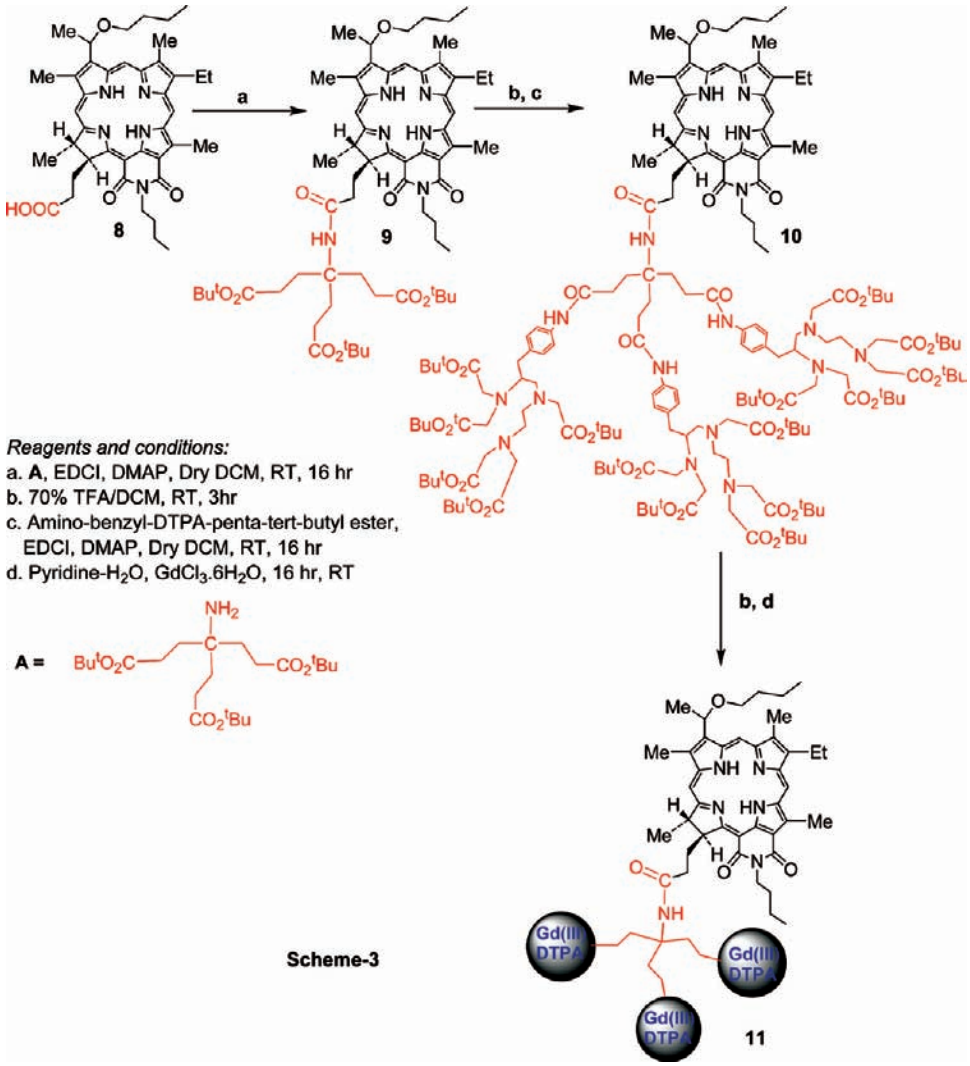
As before, the T_2 relaxivity was determined by obtaining the slope of concentration vs R_2 via linear regression fitting of the data.

Determination of in Vitro Photobleaching. In vitro photobleaching (*26*) of each compound was performed using a continuous light source at 665 nm at a power of 500 mW and a dose rate of 75 mW/cm^2. Samples were prepared in 17% bovine calf serum. Individual 2.5 mL samples in 17% bovine calf serum were irradiated in quartz cuvettes and monitored via UV−vis spectroscopy (Varian Cary Bio 50 spectrophotometer,

Scheme 2

Palo Alto, CA) at 665 nm until the peak had been reduced to a minimum of 70%.

Evaluation of Phototoxicity Viability. The compounds were tested for photodynamic efficacy at 4 μM and variable light doses (at 665 nm for HPPH analogues and 705 nm for purpurinimides) after incubating for 24 h with (Colon26) cells seeded in 96 well plates. Viability was measured 48 h later using the 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazoliumbromide (MTT) assay (*26*). The results were plotted as percent survival compared with the untreated dark control (no drug, no light) at each light dose (in J/cm^2).



Determination of in Vitro Intracellular Localization. Colon26 cells were seeded at 1×10^5 cells in 2 mL growth medium on poly(L-lysine) coated glass coverslips in 6-well plates and cultured for 48 h to allow attachment and spreading. The photosensitizer (1.0 μM) was incubated with the cells in the dark at 37 °C for 4 or 24 h. The cells were coincubated with organelle specific dyes MitoTracker Green FM for 30 min at 0.5 μM, Lysotracker Green at 1 μM for 2 h, and Bodipy Ceramide C5-albumin complexes at 5 μM (*27*) according to manufacturer's instructions (Invitrogen). Prior to microscopy, the cells were rinsed with PBS and mounted with PBS containing 1 μM DAPI. Live cells were examined with a Zeiss Axiovert 200 inverted fluorescence with a Fluoarc mercury vapor shortarc lamp as light source. Fluorescent images from the same fields were captured successively in detector channels using suitable filter sets (Chromatechnology) for the PS and the organelle probes with an AxioCam MR-MRGrab frame grabber and a monochromatic CCD camera (Zeiss AxioCam MRm). Filter cubes contained 410/40 nm excitation, beamsplitter 505, and bandpass emission 675/50 nm for the PS; excitation bandpass 470/40 nm, beamsplitter 495, and bandpass emission 525/50 nm for MitoTracker Green and Lysotracker Green; excitation bandpass 565/30 nm, beamsplitter 585, and bandpass emission 620/60 nm for the Bodipy C5 ceramide and excitation 390/22 nm, beamsplitter 420 nm, and bandpass emission 460/50 nm. Images were digitally processed with the Zeiss *AxioVision LE* v 4.1 software.

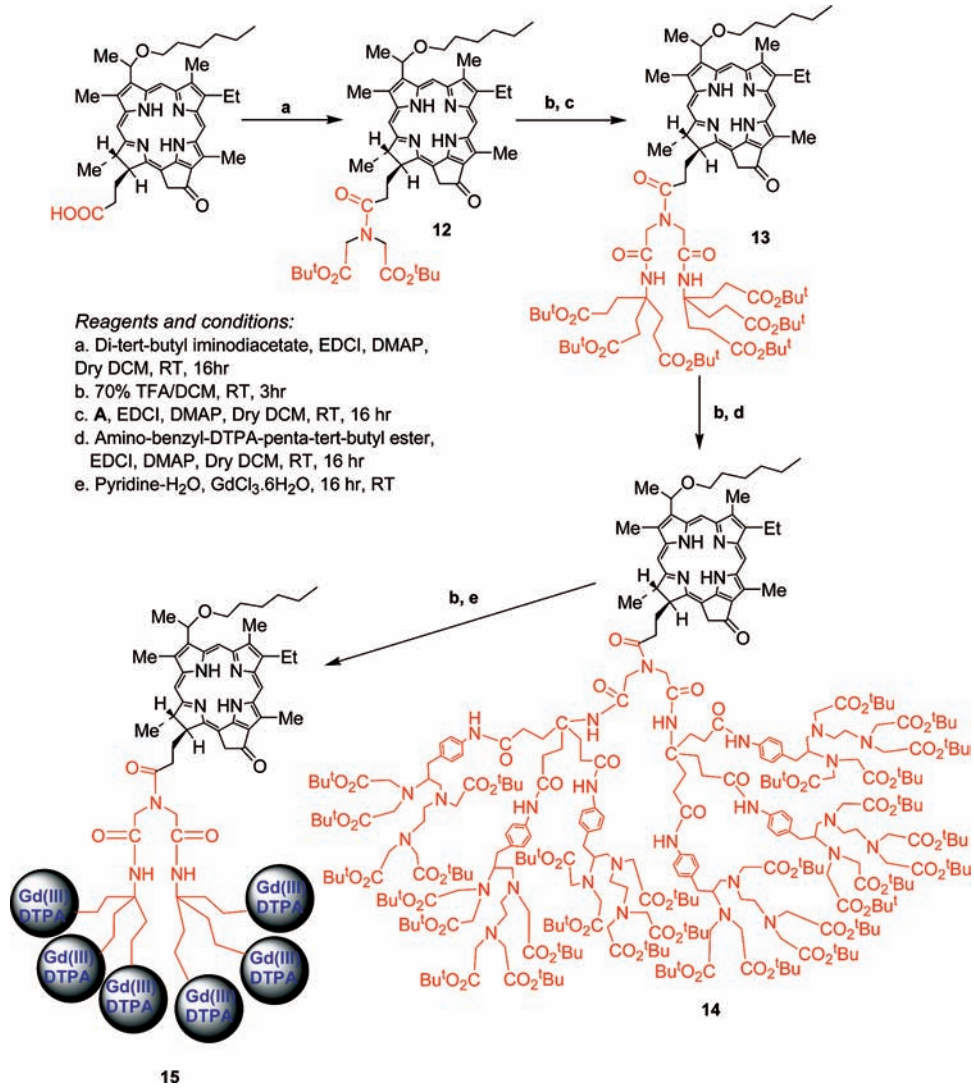
Statistical Evaluation. In vitro PDT of the compounds was presented as the mean and standard deviation of three replicate experiments. In vivo PDT of the compounds was compared in Kaplan−Meier plots. *GraphPad Prism 5.0* was utilized to compare tumor response curves.

RESULTS AND DISCUSSION

Chemistry. For the preparation of photosensitizer-Gd(III) ADTPA conjugates, 3-(1′-hexyloxyethyl)-3-devinylpyropheophorbide-a (HPPH) HPPH and 3-(1′-butyloxyethyl)3-devinyl-purpurin-18-*N*-butylbutylimide **8** were synthesized by following the methodologies developed in our laboratory (*28*). For the synthesis of HPPH-3Gd(III)ADTPA **3**, HPPH was reacted with aminotriester **1** (Scheme 1which on treating with trifluoroacetic acid (TFA) and further reaction with aminobenzylDTPA butyl ester gave the desired conjugate. To investigate the effect of lipophilicity of the conjugate in tumor-imaging (MRI) and PDT, we synthesized a series of compounds with increasing/decreasing lipophilicity/hydrophilicity by modifying the position-17 of pyropheophorbide with alkyl ether (butyl or hexyl) or poly-(ethylene glycol) moieties. We started with compound **4** containing an ethylene glycol group at position-3, which on a sequence of reactions illustrated in Scheme 2 produced the corresponding 3Gd(III)aminobenzyl DTPA conjugate **7** in modest yield. For the synthesis of a bifunctional agent with longer wavelength absorption, pyropheophorbide-a analogues (HPPH or compound **4**) were replaced with a highly effective photosensitizer **8** (Scheme 3) (developed on the basis of structure−activity relationships studies) exhibiting longer wave-

Scheme 3

length absorption near 700 nm, and the corresponding 3Gd(III)-ADTPA conjugate **11** was synthesized. To further investigate the effect of increased Gd(III) units in MR imaging ability and the effect of overall lipophilicity in pharmacokinetic/pharmacodynamic characteristics, pyropheophorbide-6Gd(III)aminobenzyl conjugates **15** and **19** containing a hexyl ether or an ethylene glycol group at position-3 were synthesized by following the methodology as depicted in Schemes 4 and 5, respectively. The structures of all the intermediates and the final products were confirmed by NMR, mass spectrometry, and elemental analyses.



Effect of Gadolinium Chelates in Absorption and Fluorescence Properties of HPPH. To investigate the effect of the number of Gd(III) units in absorption and fluorescence properties of the conjugates, HPPH and the corresponding conjugates **3** and **15** containing three- and six gadolinium chelates were dissolved in methanol, and the electronic absorption spectra and fluorescence spectra were measured at equimolar concentrations. As can be seen from Figure 1A, subtle deviations were observed among the UV−vis spectra of HPPH, **3** (HPPH-3Gd(III) chelate, and **15** (HPPH-6Gd(III)chelate). The Soret band region in compound **15** was much broader. The long wavelength absorption intensity at 660 nm for conjugates **3** and **15** was slightly lower (ε = 35 000, 33 000, respectively) than that observed for HPPH (ε = 45 000).

Compared to HPPH, the emission spectra (Figure 1B) of the metalated analogues **3** and **15** showed a significant decrease in fluorescence intensity. Excitations of these compounds in the "Soret" band region (410−425 nm) exhibited an emission peak at 667 nm, and as can be seen from Figure 1B, compared to HPPH the corresponding Gd(ADTPA) analogues decrease the fluorescence intensity. A sharp decrease in fluorescence intensity indicates a possible interaction between the gadolinium chelates and the HPPH moiety, and detailed photophysical studies of this phenomenon are currently in progress.

Effect of Gd(III)aminobenzyl DTPA Moiety in Photobleaching of HPPH. The singlet oxygen produced on exposing photosensitizer within a tumor to light is responsible for the destruction of tumor and also the photosensitizer (*29, 30*). In order to achieve an optimal PDT response, it is extremely important to make the maximum use of the tumor oxygen supply and also to understand the photobleaching characteristics of the photosensitizer by the single oxygen produced in situ. In this study, HPPH and the corresponding gadolinium analogues **3** and **15** with 3 and 6 Gd(III)aminobenzyl DTPA units, respectively, were dissolved in 17% bovine calf serum (BCS) solution and irradiated with laser light at 665 nm. The absorption spectra were measured at regular intervals and the observed peak intensity values at λ_{max} 665 nm were plotted against the light exposure time.

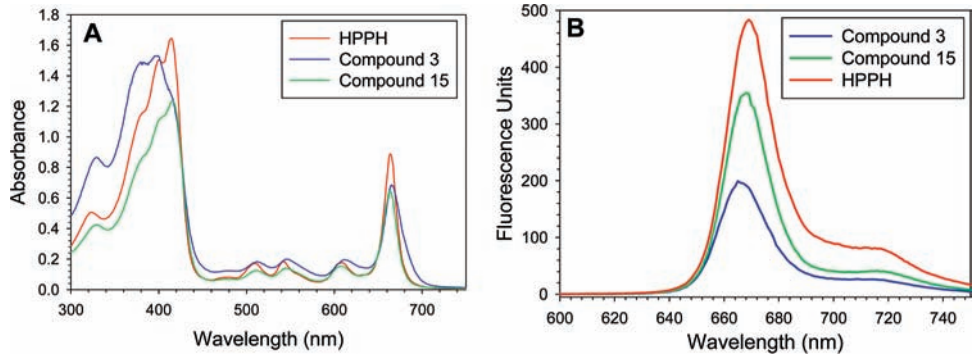
As can be seen from the results summarized in Figure 2, the presence of Gd(III)aminobenzl DTPA moieties in both conjugates **3** and **15** significantly reduced the rate of photobleaching of the HPPH. The longer stability of the Gd(III) containing photosensitizers provides an opportunity for an additional light

Scheme 4

treatment to those cancer patients, which did not produce a satisfactory response after initial treatment without injecting more PDT agent.

T_1 and T_2 Relaxivity of HPPH-Gd(III)aminobenzylDTPA Conjugates. The T_1 and T_2 relaxivity values of the photosensitizer-Gd(III)ADTPA conjugates are summarized in Table 1. Compared to Magnevist, the relaxivity values were higher for compounds containing 3- or 6Gd-ADTPA moieties. However, the increase in relaxivity was nonlinear with the increase in the number of Gd(III) units. The reason for the lack of linearity is attributed to the relative close proximity of Gd-ADTPA groups, which may be reducing the degree of relaxation enhancement by limiting the hydration of the molecule.

In selection of a lead candidate, T_1 relaxivity was favored over T_2, as an increase in T_1 relaxation rate reduces saturation of signal, leading to brighter intensity in tumors, while an increase in T_2 relaxation rate causes loss of signal intensity, producing poorer contrast. Although all compounds exhibited adequate T_1/T_2 ratios, compounds **15** and **19** displayed the highest T_1/T_2 ratios but limited photosensitizing efficacy.



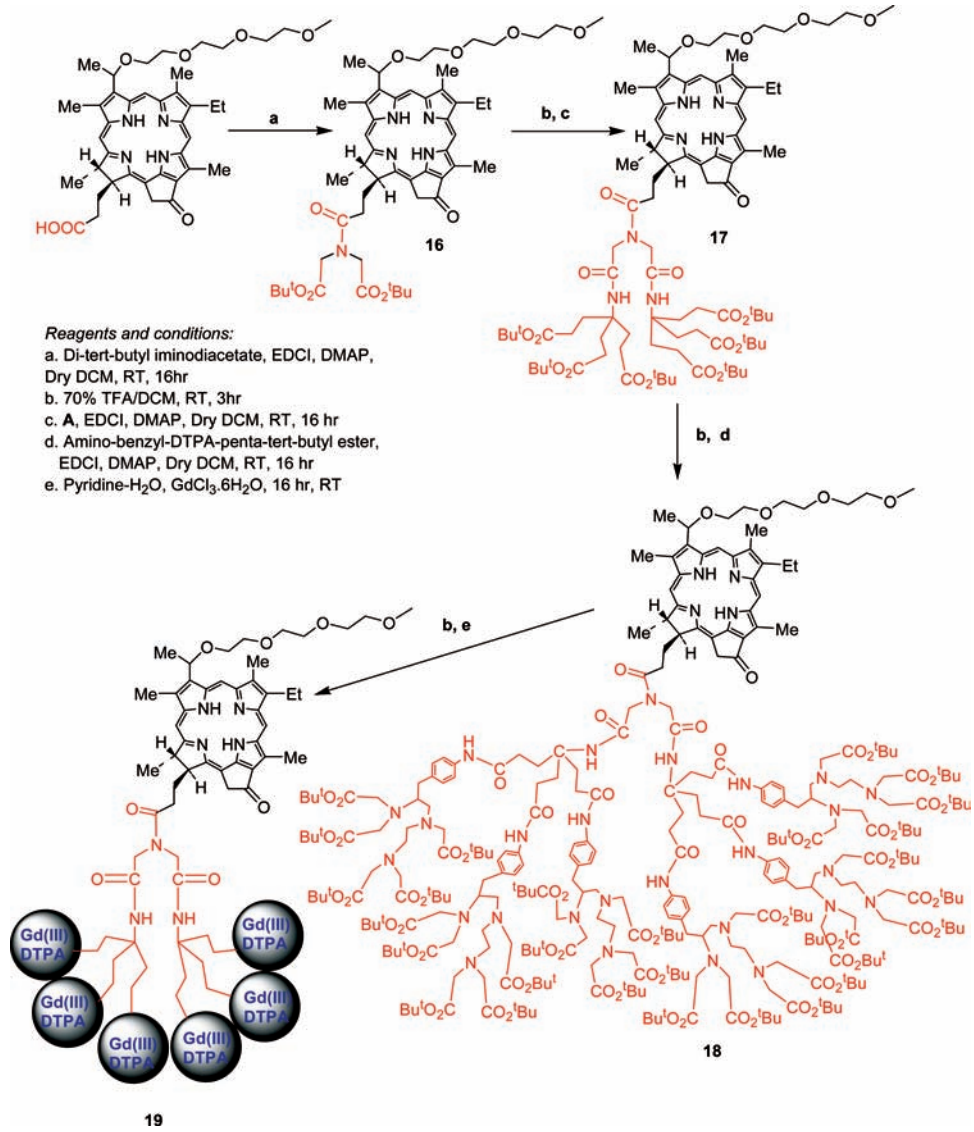


Figure 1. Comparative absorption (A) and fluorescence spectra (B) of HPPH and the corresponding 3 Gd(III)aminobenzyl DTPA **3** and 6Gd(III)aminobenzyl DTPA conjugate **15** in methanol (conc. 19.6 μM).

Scheme 5

In Vitro Photosensitizing Activity. To determine the effect of the nature of photosensitizer and the number of Gd(III)-ADTPA moieties on photosensitizing efficacy, conjugates **3**, **7**, **11**, **15**, and **19** were evaluated in RIF cells at various concentrations and light doses. The results obtained at a fixed concentration of the conjugates (4.0 μM) but at variable light doses are shown in Figure 3. As can be seen, among all the derivatives both HPPH and purpurinimide linked with 3Gd(III)ADTPA moieties (**3** and **11**, respectively) were more effective than those containing 6Gd(III)ADTPA moieties (**15** and **19**, respectively). Interestingly, replacing the hexyl ether functionality at position-3 with PEG (**7** and **19**) reduced the in vitro efficacy.

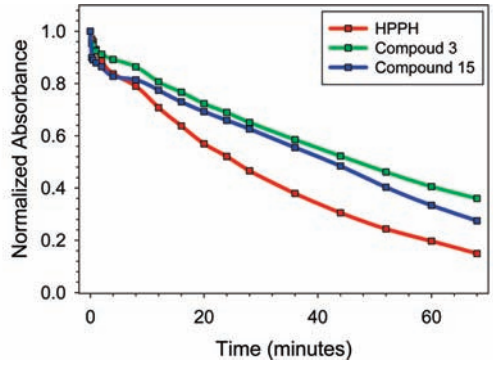

Figure 2. Comparative photobleaching characteristics of HPPH and the corresponding 3 and 6Gd(III) aminobenzyl DTPA **3** and **15**, respectively, at (9.8 μM) in 17% BCS. The solutions were exposed with a laser light (500 mW, 665 nm, 75 mW/cm^2) and the absorption peak at 665 nm were recorded at variable time points.

Table 1. Comparative T_1 and T_2 Relaxivity Values of the Conjugates and Magnevist

	$(mM \cdot s)^{-1}$	
Compound	T_1	T_2
3	13.50	81.37
15	24.72	66.54
11	14.14	85.32
7	13.58	40.11
Magnevist	4.33	5.10
19	25.09	69.19

Intracellular Localization of HPPH vs HPPH-3Gd(III)ADTPA Conjugate. Most of the porphyrin-based compounds can be observed intracellularly with a fluorescence microscope. It has been shown that photosensitizers localize to cytosolic targets such as Golgi, endoplasmic reticulum, mitochondria, lysosomes, and membranes (*31*, *32*). Efforts have been made to investigate a correlation between the site(s) of localization and PDT activity

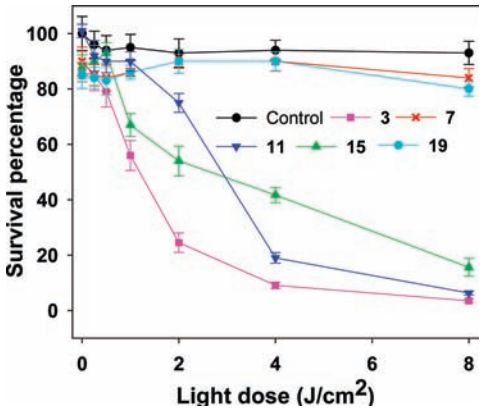

Figure 3. In vitro photosensitizing activity of photosensitizer-Gd(III)ADTPA conjugates (4.0 μM) in RIF cells. The cells were incubated for 24 h and then exposed to light at a dose of 3.2 mW/cm^2. Control cells were exposed to light only.

of photosensitizers. Moan et al. (*33*) suggested that lysosomes are a primary localization site but not the photodynamic target. However, it has not been determined whether the lysosomes rupture after PDT damage and release the compound or whether some other cellular damage, caused by unobservable functions of the photosensitizer elsewhere in the cell, cause the lysosome to rupture and subsequently release the photosensitizer. We have previously shown that most of the effective PDT agents, including HPPH developed in our laboratory, localize either in mitochondria or in lysosomes (*34*). We have also observed that, besides the overall lipophilicity, the nature of the substituents introduced in photosensitizers also makes a remarkable difference in intracellular localization characteristics (*35*).

To determine the impact of Gd(III)ADTPA moieties in site of localization of HPPH, the intracellular localization of both the compounds was investigated by using various site-specific probes. Although some of the conjugates were also found in the mitochondra and lysosomes (see Figure 4 and the Supporting Information), localization of the lead Gd-containing compound **3** appeared to be primarily in the Golgi apparatus as determined by its colocalization with a probe for that organelle. Addition of Gd alone may not account for the shift from mitochondria observed with HPPH to the Golgi, but may be partly due to the position at which the additional moieties are attached and a significant change in overall lipophilicity of the molecule. Primarily, photosensitizers which localize to the mitochondria are more effective at evoking cell death (*34*); however, photosensitizers which localize to alternative cellular organelles also exhibit the ability to induce cell mortality upon light irradiation (*36*). Further studies to establish a correlation between the site(s) of localization and cell death (apoptosis vs necrosis) are currently in progress.

CONCLUSION

Our studies indicate that tumor-avid photosensitizers can be used as vehicles for delivering the MR imaging agents to tumors. Compared to Magnevist, a clinical standard, most of the conjugates showed enhanced tumor-imaging potential (T_1/T_2 relaxivity) which increased by increasing the number of Gd(III)ADTPA units. However, as a "multifunctional agent" for tumor-imaging (MR and fluorescence) and PDT, HPPH containing 3Gd(III)ADTPA showed the best PDT efficacy (in vivo results are presented in the following paper of this journal). Our approach has great potential for developing dual-function agents for MR imaging and phototherapy with increased sensitivity by reducing false-positive and false-negative results in screening, diagnosis, treatment monitoring, or image-guided intervention.

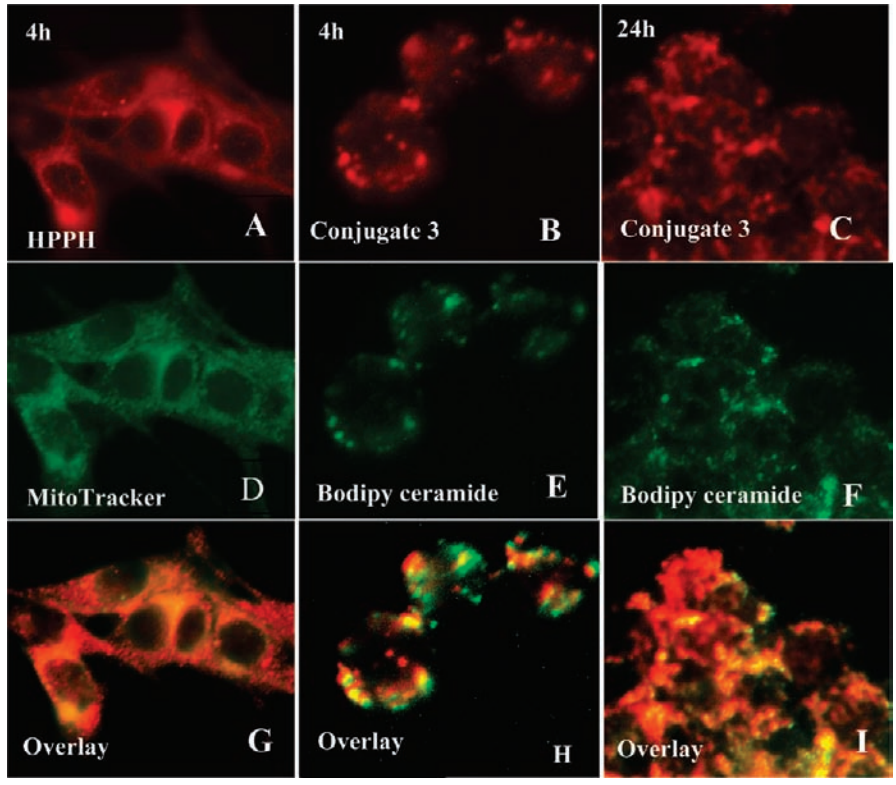

Figure 4. False-color images showing subcellular localization of HPPH and compound **3** (red) in Colon26 cells after 4 h (B) or 24 h incubations (A and C), respectively. Localization was determined by fluorescence microscopy by coincubation with fluorescent organelle probes (green). Subcellular areas of colocalization in the overlay of compound **3** or HPPH with the probes are yellowish orange. A, HPPH; B,C, compound **3**; D, MitoTracker Green; E,F, Bodipy ceramide C5-albumin complex; G, overlay of HPPH and MitoTracker Green; H,I, overlays of compound **3** and Bodipy ceramide C5-albumin complex.

Hexylether Derivative of Pyropheophorbide-a (HPPH) on Conjugating with 3Gadolinium(III) Aminobenzyldiethylenetriaminepentaacetic Acid Shows Potential for in Vivo Tumor Imaging (MR, Fluorescence) and Photodynamic Therapy

Joseph A. Spernyak,[†] William H. White III,[‡] Manivannan Ethirajan,[‡] Nayan J. Patel,[‡,§] Lalit Goswami,[‡] Yihui Chen,[‡] Steven Turowski,[†] Joseph R. Missert,[‡] Carrie Batt,[‡] Richard Mazurchuk,[†] and Ravindra K. Pandey*[,‡]

Preclinical Imaging Facility, PDT Center, Cell Stress Biology, and Molecular Pharmacology and Cancer Therapeutics, Roswell Park Cancer Institute, Buffalo, New York 14263. Received December 2, 2009; Revised Manuscript Received March 8, 2010

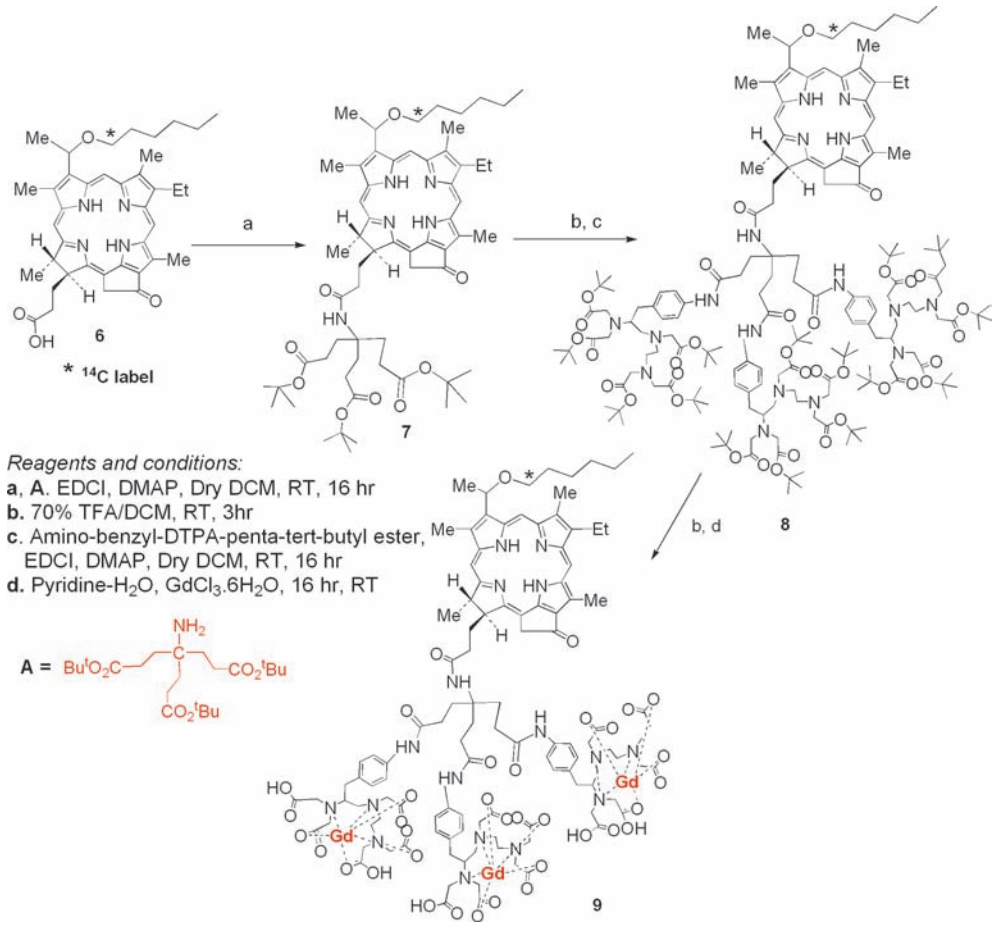
Conjugates of 3-(1′-hexyloxyethyl)-3-devinyl pyropheophorbide-a (HPPH) with multiple Gd(III)aminobenzyl diethylenetriamine pentacetic acid (ADTPA) moieties were evaluated for tumor imaging and photodynamic therapy (PDT). In vivo studies performed in both mice and rat tumor models resulted in a significant MR signal enhancement of tumors relative to surrounding tissues at 24 h postinjection. The water-soluble (pH: 7.4) HPPH-3Gd(III) ADTPA conjugate demonstrated high potential for tumor imaging by MR and fluorescence. This agent also produced long-term tumor cures via PDT. An in vivo biodistribution study with the corresponding ^{14}C-analogue also showed significant tumor uptake 24 h postinjection. Toxicological evaluations of HPHH-3Gd(III)ADTPA administered at and above imaging/therapeutic doses did not show any evidence of organ toxicity. Our present study illustrates a novel approach for the development of water-soluble "multifunctional agents", demonstrating efficacy for tumor imaging (MR and fluorescence) and phototherapy.

INTRODUCTION

Early detection and treatment of cancer presents numerous clinical benefits. While the disease is well-localized and neoplastic growths are small, highly localized therapies have the potential advantage of reduced side effects and minimal damage to normal tissues (as opposed to systemic chemotherapy or invasive surgery). One example of localized therapy is photodynamic therapy, or PDT. PDT works via the creation of cytotoxic singlet oxygen formed by exposing a photosensitizing agent with an appropriate wavelength of a laser light (*1*).

One of the first photosensitizing agents approved for treatment of cancer was porfimir sodium (Photofrin). Photofrin is considered a first-generation photosensitizer and has been used in the treatment of Barrett's esophagus (*2*), cervical cancer (*3*), endobronchial cancer (*4*), and papillary bladder cancer (*5*). However, Photofrin has several inherent limitations, namely, its low molar absorption coefficient (1170 M^{-1} cm^{-1}) (*6*), as well as skin photosensitivity resulting from residual photosensitizer delocalized throughout the skin (*7*). These limitations have led to the development of "second generation" sensitizers which absorb energy efficiently at longer wavelengths and localize more effectively within the tumor. One such compound is 3-[1′-hexyloxyethyl]-3-devinyl pyropheophorbide-a (HPPH), which has a peak absorbance at 665 nm (in vivo absorption) and is currently in phase II clinical trials for the treatment of esophageal, lung, and cutaneous tumors (*8*, *9*). In contrast to most porphyrin-based agents, HPPH does not show any significant skin phototoxicity in patients.

A typical treatment regimen involves the single injection of agent followed by light illumination of the tumor after time has passed to allow for tumor uptake of the PDT agent. As PDT requires direct illumination of light onto the photosensitizer, image-guided therapy may be an effective way to efficiently (a) determine the size and extent of the tumor and (b) assist the clinician in localizing the light source onto the tumor. While still relatively novel in application, image-guided PDT has shown efficacy as a primary treatment in head and neck cancer (*10*) or as an adjuvant treatment to fluorescence-guided resection in high-grade gliomas (*11*) and melanomas that have metastasized to the brain (*12*). To this end, we have explored the feasibility of incorporating imaging functionality into porphyrin-based PDT agents to develop compounds that can be used in both diagnosis and therapy.



Magnetic resonance imaging (MRI) is well-suited for image guided therapy, as it does not require ionizing radiation, is noninvasive, and provides three-dimensional tomographic data sets with excellent soft tissue contrast. Use of gadolinium-based contrast agents has shown utility in the diagnosis of cancer (*13*−*16*) and in the study of numerous other disease states (*17*, *18*). Gadolinium, or Gd(III), has seven unpaired electrons within inner orbital shells, giving it a high degree of paramagnetism, which causes an increase in the T_1 relaxation rates (R_1) of nearby water molecules, thereby enhancing the MR signal.

Magnetic resonance imaging has numerous limitations, however. Detection sensitivity of MR contrast agents is relatively poor, requiring levels of Gd(III) to be at micromolar concentrations within the tissues. Determination of the degree of tissue signal enhancement requires comparison of preinjection and postinjection images. In comparison to contrast-enhanced MRI, fluorescence imaging has a much higher sensitivity in the detection of imaging agents and does not require multiple imaging time points. Fluorescence imaging is relatively inexpensive and can be employed in situations where MRI is ill-suited for use, such as such imaging subjects with metal embedded within their bodies or who cannot remain motionless. Therefore, incorporating both optical and MR imaging functionality into an effective photosensitizer allows one to incorporate the complementary strengths of each imaging modality.

Scheme 1. Synthesis of ^{14}C-Labeled HPPH-3Gd(III)ADTPA

Previously, we reported on the utility of tumor-avid HPPH in developing "multifunctional agents" (*19*) where HPPH was conjugated with Gd(III)-DTPA and showed in vivo tumor enhancement at 24 h postinjection on MR images. However, due to its low water solubility it was difficult to formulate at higher concentrations.

In this report, we describe the comparative in vivo tumor imaging and PDT efficacy of a series of conjugates containing 3- or 6-Gd(III)aminobenzyl DTPA units with the expectation that the additional number of Gd(III) units would improve solubility and increase tumor conspicuity. Among the compounds evaluated, the HPPH-3 Gd(III)aminobenzyl DTPA was selected as a lead compound on the basis of its imaging potential, in vitro PDT efficacy, and ease of synthesis. The utility of the conjugate was further evaluated for in vivo fluorescence imaging, in vivo PDT efficacy, organ toxicity, and PDT-induced mechanism of action. In addition, an in vivo biodistribution study of the lead conjugate was performed with the corresponding ^{14}C-labeled analogue.

EXPERIMENTAL PROCEDURES

Chemistry. A detailed report on the synthesis, characterization, in vitro intracellular localization, and T_1 relaxivity of the multifunctional agents is reported in our preceding publication of this journal. In brief, three groups of compounds were synthesized (Figure 1): (i) HPPH with 3- or 6-Gd(III)-aminobenzylDTPA, (ii) Pyro-based photosensitizer with 3- or 6-Gd(III)-aminobenzylDTPA groups in which the hexyl chain of HPPH is replaced with an ether-linked tri(ethylene glycol) functionality (OTEG), (iii) a purpurinimide analogue [longer wavelength photosensitizer (λ_{max}: 700 nm)] linked with 3-Gd(III)-aminobenzylDTPA. Although all the conjugates showed potential for tumor imaging (MRI), HPPH conjugated with 3Gd(III)ADTPA (Figure 1) was found to be most promising as a multifunctional agent for tumor imaging and phototherapy, and therefore was investigated further for detailed biological evaluation.

Selection Criteria of the Best Candidate for Tumor Imaging and PDT. In our preceding paper, we discussed the synthesis, photophysical characteristics, in vitro T_1/T_2 MR relaxivity, and in vitro/in vivo PDT efficacy of a series of HPPH-Gd(III)ADTPA conjugates. Some of the analogues showed enhanced tumor contrast, but limited PDT efficacy. Because the objective of our research was focused on developing "multifunctional agents" for tumor imaging and phototherapy, we selected only those candidates which showed both imaging and therapeutic potential. The selection criteria we used for identification of the lead compound are summarized in Figure 2.

Synthesis of ^{14}C-Labeled HPPH Aminotriester Derivative 7. ^{14}C-HPPH **6** (15.0 mg, 0.023 mmol; specific activity: 5.2 μCi/μmol), aminotriester (15 mg, 0.036 mmol), EDCI (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride) (9 mg, 0.05 mmol), and DMAP (4-dimethylaminopyridine) (6 mg, 0.05 mmol) were taken in a dry, round-bottom flask (25 mL). Dry dichloromethane (DCM, 5 mL) was added and reaction mixture was stirred at room temperature (RT) for 12 h under N_2 atm. Reaction mixture was diluted with DCM (10 mL), washed with brine solution, organic layer separated, dried over sodium sulfate, and concentrated. Crude mixture was purified over preparative thin layer chromatography (silica gel) using 1% MeOH/DCM mixture to give the desired product **7**. Yield: 18.0 mg (76.0%).

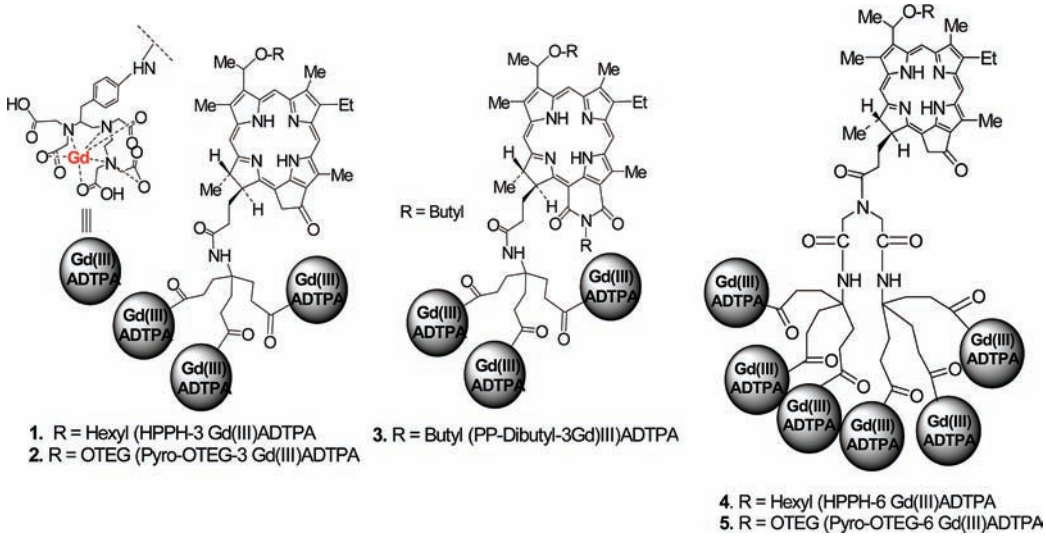

Figure 1. Gd(III)ADTPA conjugates of photosensitizers with variable lipophilicity.

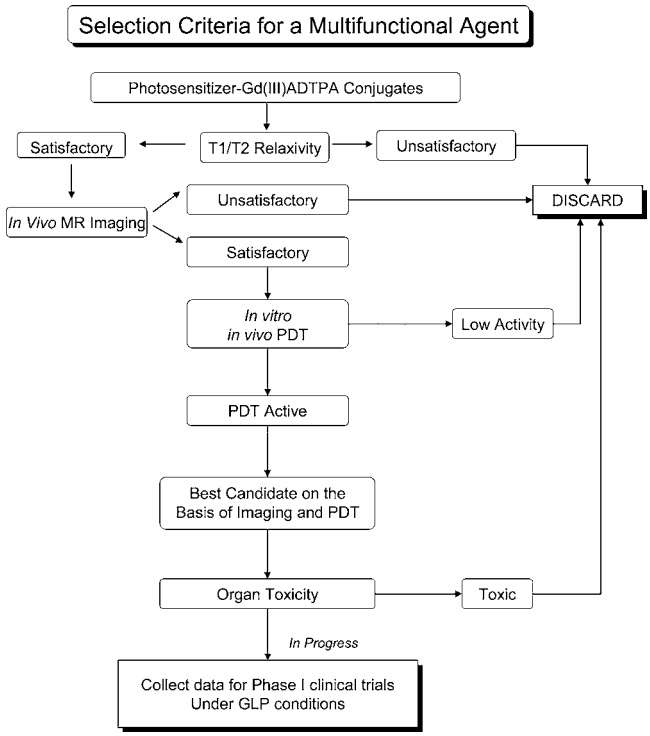

Figure 2. Selection criteria for identifying the best candidate for MR imaging and therapy.

Synthesis of ^{14}C-Labeled HPPH tri-AminobenzylDTPA Ester 8. Compound **7** (17.0 mg, 0.016 mmol) was stirred with 70% trifluoroacetic acid (TFA) / DCM (2.0 mL) at room temperature for 5 h. Resultant mixture was concentrated and dried under high vacuum to remove trace TFA. To this crude were added amino-benzyl-DTPA-penta-*tert*-butyl ester (54.0 mg, 0.069 mmol), EDCI (20.0 mg, 0.103 mmol), and DMAP (12.0 mg, 0.103 mmol). Dry dichloromethane (5 mL) was added and reaction mixture was stirred at RT for 16 h under N_2 atm. Reaction mixture was further diluted with dichloromethane (10 mL), washed with brine solution, organic layer separated, dried over sodium sulfate, and concentrated. Crude mixture was purified over short column (0.5 cm width, 12 cm height) containing grade-III alumina as a stationary phase and a 3% MeOH/DCM mixture as eluent to give product **8**. Yield (2 steps): 31.0 mg (61.0%).

Synthesis of ^{14}C-Labeled HPPH 3Gd(III)-AminobenzylDTPA Complex 9. Compound **8** (30.0 mg, 0.009 mmol) was stirred with 70% TFA/DCM (2.0 mL) at RT for 5 h. Resultant mixture was concentrated and dried under high vacuum to remove trace TFA. The crude obtained was dissolved in pyridine (2 mL) and put under continuous stirring. $GdCl_3 \cdot 6H_2O$ (20.0 mg, 0.054 mmol) in 0.5 mL of water was slowly added to this solution and resultant mixture was stirred for an additional 16 h. Reaction mixture was filtered and the residue obtained was washed with water (10 mL $\times$ 3) and acetone (10 mL $\times$ 3) and then dried under high vacuum to yield gadolinium complex **9**. Yield: 18.0 mg (72.0%). Specific activity: 3.9 μCi/μmol.

Animal Models. In vivo PDT experiments were performed in two tumor models, C3H mice bearing radiation induced fibroblast (RIF) tumors and BALB/c mice bearing Colon 26 tumors (NCI, Bethesda, MD). These tumor models were chosen as they have been extensively characterized in our lab in determining the PDT efficacy of numerous photosensitizers. In both models, tumor cells (1×10^6 Colon 26 cells in 50 μL PBS, 4×10^5 RIF cells in 50 μL PBS) were implanted subcutaneously and were allowed to grow to an approximate diameter of 5−7 mm. For MR imaging of the most promising candidates, Ward tumor cells were implanted subcutaneously above the intraperitoneal cavity of adolescent Fischer 344 rats (Harlan Laboratories) (150−200 g). Tumors were allowed to grow to ~1 cm in diameter prior to MR imaging. The in vivo biodistribution of the ^{14}C-labeled lead compound was also performed in rats bearing Ward tumors. Due to the size limitation of the in vivo fluorescence instrument, the fluorescence imaging of the lead compound was performed in BALB/c mice bearing Colon 26 tumors. All animal procedures were carried out in accordance with guidelines approved by the Institute Animal Use and Care Committee.

MR Imaging Potential of the Conjugates. Among the compounds investigated, the conjugates containing three Gd(III)-ADTPA moieties had better in vitro PDT activity than those containing six Gd(III)ADTPA (see the preceding paper in this issue). Therefore, only those conjugates bearing three Gd(III)-ADTPA chelates were examined for detailed in vivo MR imaging ability (tumor contrast enhancement) in rats bearing Ward tumors. Prior to imaging, anesthesia was induced in the animals with 4% isoflurane and maintained with 2% isoflurane during imaging. Animal temperature and respiration rate were monitored with an MR-compatible small animal monitoring system (model 1025, SAII, Stony Brook, NY), and temperature

was maintained at 32 °C with warm air. A sealed tube containing 150 μM Gd(III)-DTPA (Magnevist, Bayer HealthCare Pharmaceuticals) was placed on each side of each animal to serve as an MR signal intensity calibration standard.

Prior to tail vein administration of each agent (dose:10 μmol/kg), MRI data sets were acquired for each animal to serve as baseline controls, and then animals were rescanned 24 h after injection. An additional MRI data set was acquired at 8 h post injection of conjugate **2** (Pyro-OTEG-3Gd) because a faster clearance rate from the body was anticipated. For comparison to clinically administered MRI contrast agents, two separate groups of rats ($n = 3$ per group) were imaged immediately before and after the administration of Gd(III)-DTPA via tail vein catheter at the clinically recommended dose of 100 μmol/kg, as well as at 10 μmol/kg to compare imaging results with our multifunctional agents.

Two SE imaging protocols were used with identical slice prescription parameters [5−6 axial slices, 1.5 mm slice thickness, 6 × 6 cm FOV(field of view), 256 × 192 acquisition matrix zero-filled to 256 × 256]: first, a moderately T_1-weighted scan acquired with a T_E/T_R of 10/1200 ms (echo and repetition time, respectively) and, second, a heavily T_1-weighted scan acquired with chemical shift selective (CHESS) fat suppression with a T_E/T_R of 10/356 ms.

Additionally, T_1 relaxation rates for tissues were determined by acquiring a series of 6 fast spin−echo encoded scans with T_R's ranging from 360 to 6000 ms.

Last, in vivo testing of HPPH-3Gd(III)ADTPA was performed with an orthotopic RIF tumor model implanted into the thigh muscle of C57bl/6 mice. Imaging parameters were modified to achieve higher resolution required for imaging mice (FOV = 32 mm, matrix size =160 × 160, slice thickness =1 mm). All other data acquisition parameters were identical to the MR imaging protocol described above.

In vivo MR data sets were processed with commercially available software (*Analyze 7.0*, Analyze Direct, Overland Park, KS) by defining a region of interest (ROI) for tumor, muscle surrounding the backbone, and the 150 μM Gd-DTPA calibration standards. Following segmentation, the mean signal intensities for each ROI were sampled. To normalize signal intensity values acquired at different time points, all signal intensity values were divided by the average intensity value of the two Gd-DTPA phantoms. Normalized contrast between tumor and muscle was then determined by subtraction of the mean signal intensity of the two regions. T_1 relaxation rates of tumor and back muscle were calculated by taking the mean intensity within ROI's, and R_1 and S_{MAX} were calculated by nonlinear fitting of the equation

$$S_{(TR)} = S_{MAX}(1 - e^{-(R1 \cdot TR)}) + \text{background noise}$$

using Matlab's Curve Fitting Toolbox (*Matlab 7.0*, MathWorks Inc., Natick, MA). Tissue concentrations of agents were estimated using the following equation

$$[CA] = (R_{1post\text{-}inj} - R_{1pre\text{-}inj}) \div \text{relaxivity}$$

where the compound relaxivity was determined and reported in the accompanying paper.

Fluorescence Imaging. Fluorescence imaging of photosensitizer accumulation in the tumor was carried out using a Nuance optical imaging camera system (Cambridge Research Inc., Woburn, MA). When the tumor reached 4−5 mm in diameter, mice were anesthetized with either a ketamine/xylene mixture (100/10 mg/kg) or 8 mg/kg of pentobarbitol sodium. Prior to imaging, Nair was used to remove hair from the skin surrounding the Colon 26 tumors. Fluorescent excitation was achieved using a spectrum between 525−555 nm using a tungsten−halogen light source. Spectral emission images were acquired from the range 550−700 nm prior to and 24 h postadministration of HPPH-3Gd(III)ADTPA. HPPH-specific images were spectrally unmixed using the Nuance software and represented in false color images.

In Vivo PDT Efficacy and Assessment of Response. When tumor reached 4−5 mm in diameter, the mice were injected with HPPH-3Gd(III)ADTPA at the imaging dose (10 μmol/kg). Prior to PDT treatment, Nair was used to remove all hair surrounding the tumor site. At 24 h postinjection, the mice were restrained in plastic plexiglass holders without anesthesia, treated with a laser light (70 J/cm^2, 70 mW/cm^2). Following treatment, mice were observed daily for tumor regrowth or tumor cure. Visible tumors were measured using two orthogonal measurements, L and W (L perpendicular to W) and the volumes were calculated using the Microsoft *Excel* formula $V = L \times W^2/2$ and recorded. Mice were considered cured if there was no palpable tumor by day 60. Mice were euthanized if the tumor reached 400 mm^3 due to tumor burden.

In Vivo Biodistribution Studies. The ^{14}C-labeled photosensitizers (0.2 mL/0.08 μCi) were individually administered to mice through a lateral tail vein [3 mice/group (BALB/c mice bearing Colon 26 tumors and C3H mice bearing RIF tumors)]. At 24 and 48 h postinjection, 3 mice per time point were sacrificed by CO_2 asphyxiation. The blood was collected into heparinized syringes and immediately centrifuged to obtain plasma. The plasma was transferred to a scintillation vial for ^{14}C counting. The organs of interest (skin, muscle, tumor, heart, lung, liver, kidney, and spleen) were removed. Sample weights were recorded and 1 mL of Solvable (PerkinElmer, Waltham, Massachusetts) was added to each sample and incubated overnight at 53 °C. The samples were allowed to dissolve before adding 80 μL of peroxide (20 μL at a time). After samples were sufficiently bleached, 15 mL of scintillation fluid was added and the samples were run on a Beckman LS 6000LL scintillation counter. Raw data were then converted to counts per gram tissue weight and plotted using *SigmaPlot 10.0* software.

Toxicology Study. To assess the possible toxicity effects of our lead imaging agent, HPPH-3Gd(III)ADTPA was injected into 27 rats (9 rats/group) at concentrations of 5 μmol/kg (lower than the imaging dose), 10 μmol/kg (imaging dose), and 25 μmol/kg (higher than the imaging dose). An additional 3 rats were used as control. Animals were sacrificed 14 days postinjection; liver, spleen, kidney, skin, heart, and lung were collected and fixed in formalin. Fixed tissue specimens were embedded in paraffin, sectioned, and subsequently stained with hematoxylin and eosin (H&E). Individual tissue sections were examined by light-field microscopy for evidence of toxicity.

RESULTS

^{14}C-Labeled HPPH-3GD(III)-DTPA 9. The ^{14}C-labeled HPPH was synthesized from methyl pyropheophorbide-a by following the reported procedure. It was then converted into the corresponding 3Gd(III)-ADTPA (specific activity: 3.9 μCi/μmol) analogue by following the methodology reported for the nonlabeled conjugate in our preceding paper in this issue.

In Vivo Tumor Enhancement by MR Imaging. All HPPH-Gd(III)-ADTPA conjugates containing either three or six gadolinium units showed tumor contrast enhancement 24 h after administration. However, our objective was to develop dual-function agents which could be used for both tumor imaging and therapy. Unfortunately, the conjugates with six gadolinium units showed limited photosensitizing efficacy. Therefore, only those conjugates containing 3Gd(III)-ADTPA groups were investigated for in vivo assessment of tumor contrast enhancement. Figure 3 shows the increase in the normalized contrast between tumor and muscle at 24 h postinjection of each of the

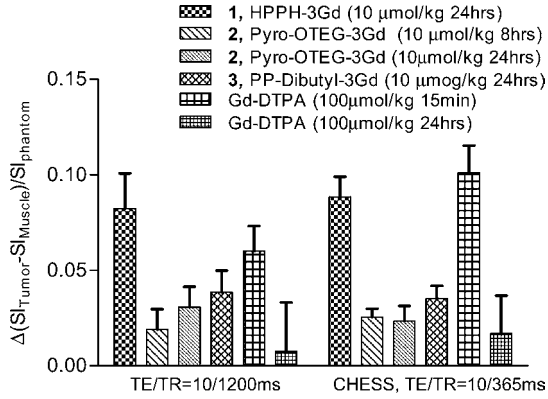

Figure 3. Comparison of the relative increases in contrast between tumor and back muscle for the MR contrast/PDT agents and a clinical dose of Gd(III)-DTPA. The tumor-to-muscle-contrast enhancement caused by the HPPH-3Gd(III)ADTPA (10 μmol/kg) was comparable to the enhancement from clinical Gd(III)-DTPA (100 μmol/kg) seen immediately after injections, despite HPPH-3Gd(III)ADTPA being administered at one-tenth the concentration of Gd(III)-DTPA, and imaged 24 h postinjection.

Table 1. Dose Dependence of HPPH-3Gd(III) ADTPA on Increase in Contrast and T_1 Relaxation Rate

Scan Protocol	10 μmol/kg	5 μmol/kg	2.5 μmol/kg
T_E/T_R = 10/1200 ms (% increase of contrast)	101.5	40.1	−2.71
CHESS fat saturation (% increase of contrast)	130.3	51.4	8.60
ΔR_1 $(s)^{-1}$	0.12	0.08	0.05

3Gd(III)-ADTPA containing agents (Pyro-OTEG-3Gd(III)-ADTPA was also imaged at 8 h postinjection).

All of the multifunctional agents showed increased tumor-to-muscle contrast as compared to baseline values. HPPH-3Gd(III)ADTPA showed the greatest increase in tumor conspicuity administered at 10 μmol/kg (C) at 24 h postinjection in both T_1-weighted scans. As a result, HPPH-3Gd(III)ADTPA was

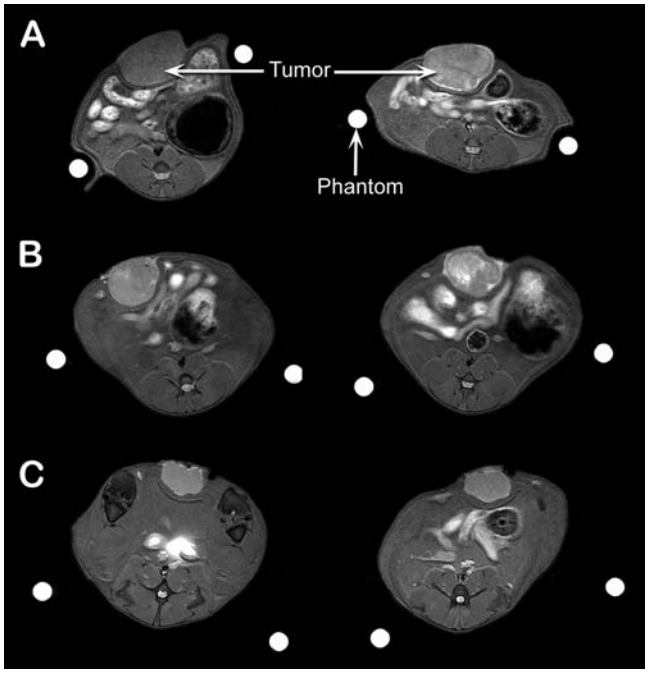

Figure 4. Visible increase in signal intensity was seen in rat Ward Colon tumors (arrow) from preinjection (left) to postinjection (right, 24 h postinjection) of conjugate **1** (HPPH-3Gd) at 10 μmol/kg (A) and at 5 μmol/kg (B). Tumor contrast enhancement of HPPH-3Gd compares favorably to Gd-DTPA.

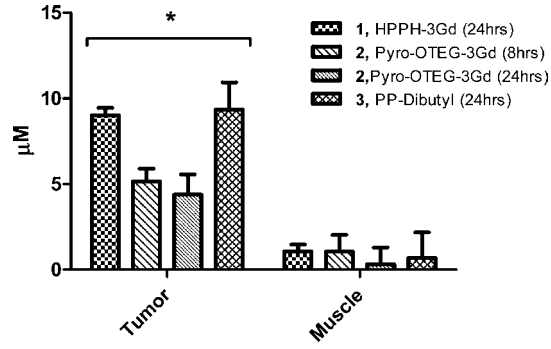

Figure 5. Preferential tumor uptake of multifunctional agents was seen 24 h post administration as compared to muscle (dose = 10 μmol/kg of each conjugate). Concentrations of agents were determined by dividing by change in T_1 relaxation rate by the relaxivity of each agent as determined in vitro. Each compound showed a statistically greater amount of uptake in the tumor as compared to muscle (* $p < 0.05$, unpaired Student's t test.)

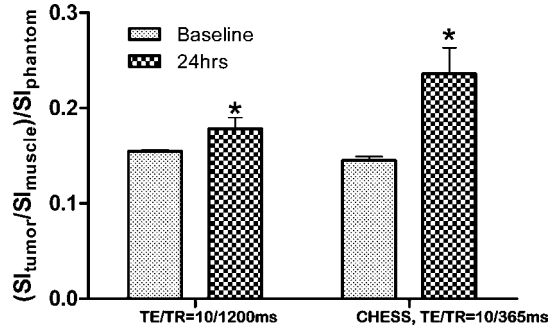

Figure 6. Increase in contrast between RIF tumor and leg muscle was significant for conjugate **1**, HPPH-3Gd (dose = 10 μmol/kg; * $p < 0.05$, paired, one-way Student's t test.)

selected for further characterization at lower doses and in an additional tumor model.

HPPH-3Gd(III)ADTPA also showed quantifiable increases in tumor to muscle contrast and T_1 relaxation rates at 5 and 2.5 μmol/kg, albeit lower than the increases from the 10 μmol/kg dose. Percent increases in tumor to muscle contrast from baseline values for each dose are shown in Table 1, as well as the average increase in T_1 relaxation rate of the tumor. At administered doses of 10 and 5 μmol/kg of HPPH-3Gd(III)ADTPA, the increase in tumor signal intensity could be seen clearly (Figure 4). However, at a dose of 2.5 μmol/kg, tumor signal enhancement was not discernible visually (not shown). T_1 relaxometry of tumor and muscle before and after injection showed preferential tumor uptake of all of the 3Gd(III)ADTPA conjugates tested (Figure 5). Only minimal increases in T_1 relaxation rates compared to baseline values were observed in normal tissue (muscle) 24 h after injection. Tumor-specific enhancement by HPPH-3Gd(III)ADTPA was also seen in an orthotopic RIF tumor model. A significant increase in contrast between tumor and adjacent leg muscle was exhibited (Figure 6). Contrast between tumor and leg muscle increased an average of 36% for the two scan protocols employed.

In Vivo Fluorescence Imaging. Fluorescence imaging potential of HPPH-3Gd(III)ADTPA was evaluated at the imaging dose (10 μmol/kg) in BALB/c mice bearing Colon 26 tumors at 24, 48, and 72 h postinjection. The fluorescence intensity measured in the tumor was maximum at the 24 h postinjection, but was still visible at 48 h. At 72 h, the majority of the drug has cleared out leaving only minimal fluorescence. Tumor enhancement was highest in the 24 h image with a tumor to skin intensity ratio of 3.79 compared with only 2.73 at 48 h (Figure 7).

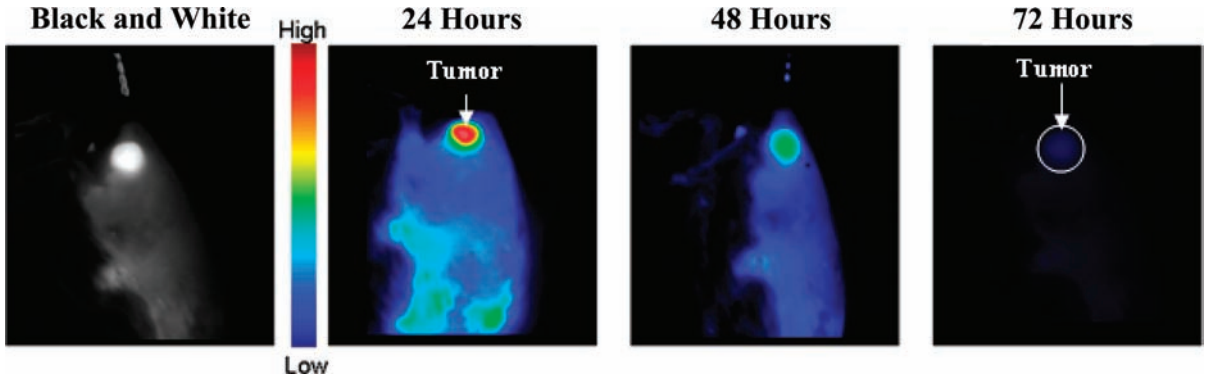

Figure 7. In vivo fluorescent images of conjugate **1** (HPPH-3Gd) in BALB/c mice at 24, 48, and 72 h with an imaging/therapeutic dose of 10 μmol/kg. Spectrally unmixed images are presented with a false color representing fluorescence intensity of the imaging agent. Best tumor images were obtained at 24 h post injection. A preanalysis black and white image at 24 h is given for comparison with the false color images provided.

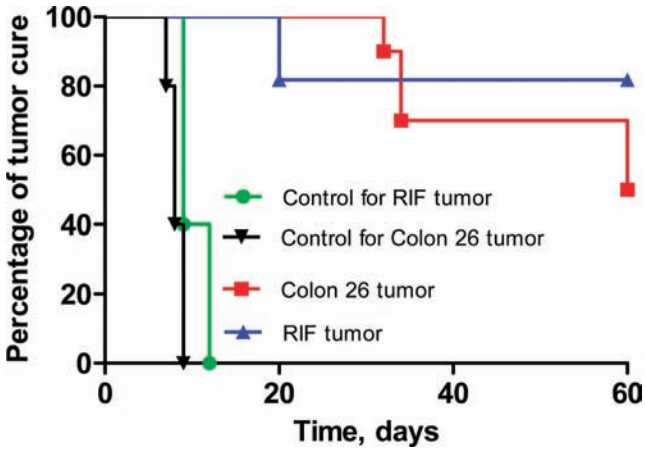

Figure 8. In vivo PDT efficacy of HPPH-3GD(III)ADTPA **1** in (A) C3H mice bearing RIF tumors and (B) BALB/c mice bearing Colon 26 tumors at an imaging dose (10 μmol/kg). Mice were irradiated with a laser light (70 J/cm^2, 70 mW/cm^2) and the tumor size was measured daily.

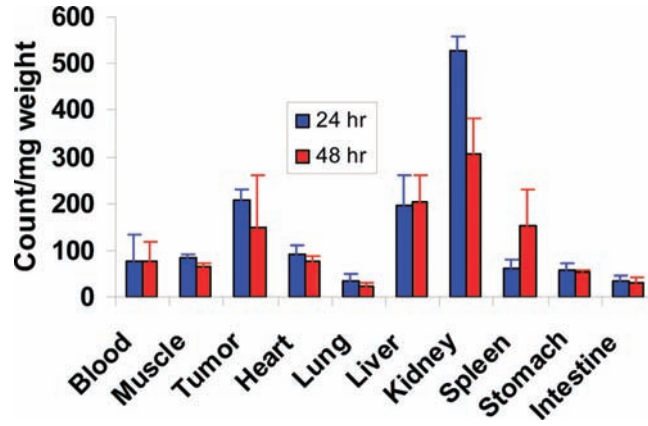

Figure 9. In vivo biodistribution of ^{14}C-labeled HPPH-3Gd(III)ADTPA in Ward colon tumors (3 rats/group): The ^{14}C-labeled conjugate (0.2 mL/0.8 μCi) was administered to 3 rats/group. At 24 and 48 h after injection, 3 rats/time point were sacrificed. Preferable uptake of conjugate **1** in the tumor was seen at 24 and 48 h compared to most normal tissues.

In Vivo PDT Efficacy. For in vivo screening, 6Gd(III)-ADTPA-HPPH conjugate **4** which showed the best T_1 and T_2 relaxivity was initially evaluated at variable doses (2.5, 5.0, and 10.0 μmol/kg) in mice bearing RIF tumors.

Tumors were exposed to a laser light (135 J/cm^2, 75 mW/cm^2) at 24 h postinjection, and tumor growth was recorded daily. Even at such a higher dose, conjugate **4** did not show any significant photosensitizing efficacy. Under similar treatment parameters, conjugates **1**−**3** and **5** were also evaluated. Interestingly, compounds **2** and **5** produced minimal tumor response, whereas the mice injected with **1** and **3** on exposure to light produced 100% mortality. This could possibly be due to high singlet oxygen formation in organs such as liver and spleen (due to high uptake of conjugates) on exposing the tumor (which is in close proximity to tumors) to the light. However, at the same imaging dose (10 μmol/kg), but at a lower light dose compared to **3**, conjugate **1** [HPPH-3Gd(III)aminobenzyl DTPA] was quite effective in both RIF and Colon 26 tumor models. The best tumor response was obtained after exposing the tumors to a laser light (665 nm at 70 J/cm^2, 70 mW/cm^2) at 24 h post treatment (Figure 8).

In Vivo Biodistribution of HPPH-3Gd(III)ADTPA Conjugate. The biodistribution of HPPH-3Gd(III)ADTPA conjugate was evaluated in vivo using Ward tumors in Fischer 344 rats. The distribution of the conjugate to tumor was higher than blood, muscle, heart, lung, spleen, stomach, and intestine, and similar to that of liver (Figure 9). However, kidney showed a significant uptake of the conjugate at 24 h, with a considerable decrease seen at 48 h postinjection, suggesting glomerular filtration of the conjugate by the kidneys.

Toxicological Study (a Range-Finding Study). For a 14 day range-finding toxicity study, male and female SD rats (3 per sex per group) were treated with vehicle (phosphate buffered saline), 5, 10, and 25 μmol HPPH-3Gd(III)ADTPA/kg (a total of 24 rats). The lowest dose chosen coincided with lowest dose required for MR imaging efficacy, and the upper dose was five times that. Higher doses could not be obtained because of solubility limitations. No infusional toxicities were seen, and the rats showed no acute toxicities. As is standard in single dose studies, the rats were sacrificed 14 days after treatment.

Full hematological and serum chemistry evaluation was conducted on an individual animal basis at the time of necropsy, and histopathological evaluation of all major organs (20 tissues per rat) was carried out. Representative toxicological results in tissues of an animal that received 25 μmol/kg (2.5× higher than the imaging/therapeutic dose) are shown in Figure 10. H&E results obtained from liver, spleen, kidney, skin, heart, and lungs following HPPH-3Gd(III)ADTPA administration demonstrated that each tissue appeared normal, well-preserved, and devoid of toxicological lesions.

DISCUSSION

With advances in the early detection of cancerous lesions, highly localized therapies such as photodynamic therapy present a favorable alternative to invasive surgery or systemic chemo-

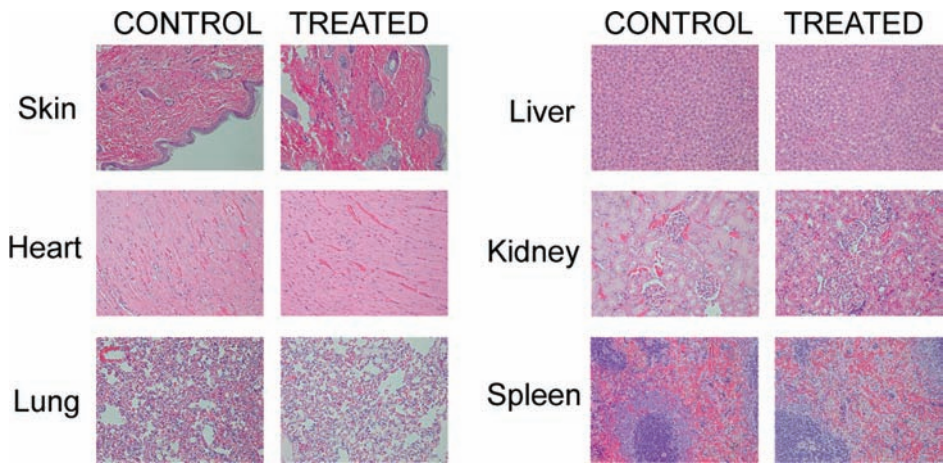

Figure 10. In vivo histochemical staining of HPPH-3Gd(III)-ADTPA conjugate. No histologic evidence of toxicity was observed in the animals (rats) administered with HPPH-3Gd(III)-ADTPA at a dose of 25 μmol/kg (2.5-fold higher than the imaging dose). Histological structure of every organ was preserved.

therapy. In this paper, we report the advancement of combined MR contrast/PDT agents. The combination of diagnostic and therapeutic efficacy into a single compound offers multiple advantages. In the case of deep-seated tumors, the ability to use noninvasive imaging to better delineate tumor boundaries or metastatic spread immediately prior to or during PDT would be a valuable tool to the clinician. Furthermore, the inclusion of MR contrast enhancing groups into the therapeutic agent provides a probe to determine intratumoral concentration of the PDT agent. To a first approximation, the T_1 relaxation rate (R_1) of tissue increases linearly with contrast agent concentration within the tissue (*20*). Therefore, measuring baseline relaxation rates and monitoring the increase in R_1 allows for individualized measurements of the pharmacokinetics of the agent within the tumor. In the past, the time requirements for in vivo T_1 relaxometry were prohibitive for routine assessment of changes in T_1 rates. However, through rapid measurement techniques, T_1 rates can be measured well under 5 min in a patient (*21*−*23*). These advances, as well as the lack of nonionizing radiation associated with MRI, allow for serial assessment of multifunctional agent concentration. Thus, light dosing parameters may potentially be adjusted on a per patient basis, maximizing efficacy while reducing phototoxicity to surrounding normal tissue. Furthermore, if these multifunctional agents can be modified for more effective uptake into tumors, MRI may be used serially to measure individual tumor uptake at variable time points, and PDT treatment can begin as soon as intratumoral levels reach a predetermined threshold.

As determined by T_1 relaxometry, there was minimal uptake in muscle at 24 h postinjection. Biodistribution studies of ^{14}C labeled compound displayed similar preferential uptake of HPPH-3Gd(III)ADTPA in the tumor. Using the relaxivity 13.50 $(mM \cdot s)^{-1}$ for HPPH-3Gd(III)ADTPA (as determined in vitro), mean tumor concentration of the conjugate at 24 h was 9.0 μM. The primary cause of preferential tumor accumulation is believed to be the result of the enhanced permeability and retention effect associated with tumor vasculature. It has been reported that Gadophrin-2, another porphyrin-based compound, binds with the serum protein albumin and accumulates preferentially in the rim of necrotic regions (*24*, *25*).

At the MR imaging dose (10 μmol/kg), the utility of the conjugate **1** was also investigated for in vivo fluorescence imaging and PDT. As can be seen from Figures 7 and 8, the conjugate produced significant tumor contrast and long-term PDT activity in two tumor models. However, HPPH-3Gd(III)-ADTPA produced excellent PDT response and tumor-imaging potential at lower doses as well (data not shown). The difference between the MR imaging dose required for HPPH-Gd(III)-ADTPA is 10- to 20-fold less than the clinical MR imaging agent Gd(III)-DTPA in mice and rat models. This study further indicates that the conjugates in which tumor-avid photosensitizer (HPPH) was used as a vehicle for MR imaging require a much higher dose than required for fluorescence imaging and therapy. However, even at higher doses required for MR imaging, no histologic evidence of toxicity was seen by detailed in vivo organ toxicological studies in rats. Thus, the development of such multifunctional conjugates with tumor-avid photosensitizer presents a clear potential for a "see and treat" approach in photodynamic therapy.

CONCLUSION

In summary, our study indicates that tumor-avid photosensitizers can be used as vehicles to deliver the desired imaging agent to tumor. The presence of three Gd(III)ADTPA moieties increased tumor conspicuity during MR imaging while maintaining antitumor PDT efficacy. The fluorescent characteristic of the HPPH-based conjugate (Ex: 665 nm, Em: 715 nm) also showed a great potential for complementary optical imaging of the tumor. Thus, the HPPH-3Gd(III)ADTPA as a single moiety can be used for tumor imaging by MR and fluorescence with an option of photodynamic therapy. Our next goal is to increase the tumor specificity of these multifunctional agents by introducing variable number of tumor-targeting moieties such as (a) cyclic RGD peptide which binds preferably to the $\alpha_v\beta_3$ integrin expressed in the neoangiogenic vasculatures of tumors (*7*, *26*, *27*), (b) folic acid to target folate receptors known for their high expressions in breast cancers, and (c) certain β-galactosides for binding to integrin-3 to target metastatic brain tumors. A target-specific approach may help to reduce the dose required for MR imaging efficacy, which is already 10-fold less than that of the typical dose of Gd-DTPA (100 μmol/kg) used clinically.

ACKNOWLEDGMENT

The authors are highly thankful to Dr. Peter Kanter for animal toxicological studies, Dr. Toth, pathologist (RPCI) for analyzing the in vivo toxicological data, and Dr. Rustum (Chair, Department of Cancer Biology) for valuable discussions. Financial support from the NIH (Grants R21/33 CA109914 and PO1, CA55791), Roswell Park Alliance Foundation, and the shared resources of the RPCI Support Grant (P30CA16056) is highly appreciated.

Low Molecular Weight Polyethylenimine Conjugated Gold Nanoparticles as Efficient Gene Vectors

Chu Hu, Qi Peng, Fujie Chen, Zhenlin Zhong,* and Renxi Zhuo*

Key Laboratory of Biomedical Polymers of Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, P. R. China. Received August 22, 2009; Revised Manuscript Received March 7, 2010

Gold nanoparticles (GNPs) conjugated with low molecular weight polyethylenimine (PEI 800 Da) were synthesized, and their characteristics as gene transfection vectors were investigated. The polyethylenimine conjugated GNPs (GNP-PEI800s) can retard plasmid DNA completely at N/P ratios above 4 in electrophoresis on agarose gel, and they also render effective protection of DNA from attack by DNase. TEM imaging revealed that GNP-PEI800s with higher PEI grafting density resulted in more compact and smaller complexes with plasmid DNA, compared to those obtained with lower grafting density ones. These complexes showed high efficiency in gene delivery in monkey kidney cells in vitro. In the absence of serum, GNP-PEI800s can transfect pGL-3 to COS-7 cells 3 to 4 orders more efficient than unmodified PEI800, reaching almost the same magnitude of PEI 25 kDa. More importantly, in contrast to the dramatically lowered efficiency of high molecular weight PEIs such as PEI 25 kDa in the presence of serum, the efficiency of GNP-PEI800s can be retained or even enhanced in serum-containing media. GNP-PEI800 1.3 exhibited transfection efficiency exceeding 60-fold that of PEI 25 kDa in 10% serum medium. All GNP-PEI800s exhibit mild cytotoxicity in comparison with that of PEI 25 kDa.

INTRODUCTION

Substantial effort has been focused on synthetic nonviral vector systems such as cationic lipids (*1*), dendrimers (*2*), and cationic polymers (*3*). Among them, polyethylenimine (PEI) is one of the most extensively studied polycations (*4*). The relatively high transfection efficiency of PEI has led to intense research in terms of both understanding (*5, 6*) and improving (*7, 8*) gene delivery by PEI. The efficiency and toxicity of PEI are strongly correlated with its molecular weight (MW) (*9*). High molecular weight PEI such as PEI with molecular weight of 25 000 Da (PEI 25 kDa) leads to high transgene expression, but its acute cytotoxicity and significantly lower efficiency in the presence of serum (*10*) has restricted its clinical development (*11*). Meanwhile, low molecular weight PEI, which has been demonstrated to be nontoxic in cell culture studies, displays very poor transfection activity (*12*), presumably because of its inability to condense DNA effectively (*13*). To achieve a useful level of transfection efficiency while minimizing the toxicity, low molecular weight PEIs such as PEI with molecular weight of 800 Da (PEI800) are modified by cross-linking via biodegradable linkages (*14*−*16*).

Recently, efforts have been made for construction of inorganic nanoparticles as alternate nonviral vectors including silica (*17*), iron oxide (*18*), carbon nanotube (*19*), and gold nanoparticles (GNPs) (*20*−*24*). GNPs provide attractive scaffolds for gene delivery vectors (*25*−*29*). GNPs can be readily synthesized varying in diameter from about 5 nm to around 150 nm and conjugated with targeting molecules through thiol linkages. GNPs of small size provide a high surface-to-volume ratio, maximizing grafting density of target molecules, which allow further tuning of the surface charge and hydrophobicity. Moreover, GNPs are bioinert and nontoxic (*30*). Various GNPs functionalized with cationic quaternary ammonium (*20*), cationic lipid (*21*), chitosans (*22*), amino acids (*23*), and polyethylenimine (*24*) were demonstrated to be excellent vehicles for the delivery of genetic material into cells.

Thomas and Klibanov covalently conjugated branched PEI of 2 kDa to GNPs and found that conjugation to GNPs greatly enhances PEI's transfer of plasmid DNA into mammalian cells (*24*). We recently reported a convenient procedure for preparation of thiolated PEI with controllable amounts of thiol groups by ring-opening reaction of thiiranes (*16a*) and found that disulfide cross-linked PEI800 is superior to the cross-linked PEI 1.8 kDa and 25 kDa for use as gene vectors (*16b*). Efficient gene delivery systems based on low molecular weight PEIs such as PEI800 are attractive because of lower toxicity and easier clearance from body than higher molecular weight ones. In the present study, we devised a series of PEI800 conjugated GNPs (GNP-PEI800) at different PEI/Au molar ratios as nonviral vectors. The effect of PEI grafting density on DNA binding capacity, DNA protection ability, surface charge and size of GNP-PEI800s/DNA complexes, cytotoxicity, and in vitro transfection efficiency of nanoparticles were investigated.

MATERIALS AND METHODS

Materials. Branched PEI with molecular weights of 25 kDa and 800 Da were purchased from Aldrich. Methylthiirane was synthesized by literature procedure (*31*). $HAuCl_4$ tetrahydrate and $NaBH_4$ were obtained from Shanghai Chemical Co (China). GelRed was purchased from Biotium (CA, USA). Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), Dulbecco's phosphate buffered saline (PBS), and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were purchased from Invitrogen Corp. The Micro BCA protein assay kit was purchased from Pierce. DNase, DNase reaction buffer, and stop reaction buffer were purchased from (Promega, USA). Ultrapure water (18.0 MΩ, Millipore) was used throughout the experiment. Plasmid pGL3 was propagated at 37 °C in *Escherichia colia* in Luria−Bertani (LB) medium containing 50 μg/mL kanamycin or 60 μg/mL ampicillin. The mixture was shaken overnight at 250 rpm. The plasmid was purified using E.Z.N.A. Fastfilter Endo-Free Plasmid Midi Kits (Omega)

according to the manufacturer's instruction. The DNA concentration was determined by measuring the UV absorbance at 260 nm. The purity of DNA was assessed spectrophotometrically by measuring absorbance at wavelengths of 260 and 280 nm (OD_{260}/OD_{280} 1.8 or greater). DNA aliquots were stored at −20 °C prior to use.

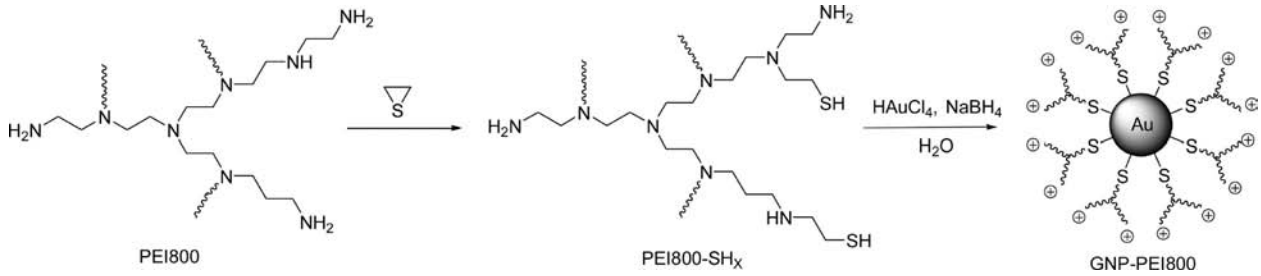
Synthesis of Thiolated PEI (PEI-SH). In a 25 mL flask, 1.00 g of PEI800 was dissolved in 5 mL of deionized water. Hydrochloric acid (0.1 M) was added to the PEI solution until pH was regulated to 7.2. After removal of water, the neutralized PEI was redissolved in 10 mL of CH_3OH. The assigned amount of thiirane was added after the container was purged with argon. The flask was kept in a 50 °C oil bath for 24 h under magnetic stirring. The solution was evaporated to remove CH_3OH and the yellow solid thus obtained was kept under argon. Two kinds of thiolated PEIs varying in thiol group content were synthesized, and the thiol group contents were determined to be 0.8 and 1.7, respectively, by Ellman's method (*32*, *33*).

General Procedure for the Synthesis of GNP-PEI800. $HAuCl_4$ (tetrahydrate, 0.10 g, 0.24 mmol) was mixed with calculated amount of PEI-SH in 10 mL of water and stirred for 15 min; then, freshly prepared $NaBH_4$ solution (0.45 g, 12 mmol in 5 mL of water) was added dropwise. Within 90 s, the solution turned dark purple signaling the onset of gold nanoparticles formation. The mixture was stirred at room temperature for an extra 24 h. The conjugates were dialyzed extensively against water with 12 kDa cutoff dialysis tubes. The solution was filtered through a 0.22 mm pore size polyether sulfone membrane and stored at room temperature for use. A measured portion was lyophilized and submitted for elemental analysis. On the basis of nitrogen content from elemental analysis and gold content from ICP measurements, the ratios of gold/PEI800 were calculated and summarized in Table 1.

Instrumentation. Elemental analysis was performed by using Vario EL III (Germany). UV−vis spectra were recorded on a Perkin Elmer UV−vis spectrophotometer with a quartz cuvette with a 10 mm optical path length. The ICP-AES was carried on a Thermo IRIS Intrepid II XSP spectrometer (USA). The morphologies of GNP-PEI800s and GNP-PEI800/DNA complexes were observed on transmission electron microscope (TEM JEM-100CXa) with an acceleration voltage of 100 kV.

Particle Size and Zeta Potential Measurements. The particle size and zeta potential were measured with a Nano-ZS ZEN3600 (Malvern) at room temperature. The relative amount of GNP-PEI800s/DNA was express as N/P molar ratio which is calculated with the N content in GNP-PEI800s based on the elemental analysis and the P content in the DNA solution of known concentration. The GNP-PEI800s/DNA complexes at various N/P ratios ranging from 30 to 180 were prepared by adding appropriate volumes of GNP-PEI800s to 50 μL of pGL-3 DNA (20 ng/mL in 40 mM Tris-HCl buffer solution), and then the complexes were diluted to a total volume of 1 mL with 150 mM NaCl and vortexed for 15 s. After that, the complexes were incubated at room temperature for 30 min before measurements of particle sizes or zeta potentials.

Agarose Gel Retardation Assay. GNP-PEI800/DNA complexes at predetermined N/P ratios were loaded on 0.7% (w/v) agarose gel containing GelRed and electrophoresed with Tris-acetate (TAE) running buffer at 80 V for 80 min. DNA was visualized with a UV lamp using a Vilber Lourmat imaging system (France).



DNase Protection Assay. The concentration of DNase enzyme was 1 U/μg DNA. Reaction mixture for DNase digestion contained 1.0 μL of 10× reaction buffers, 8.0 μL of either DNA or GNP-PEI800s/DNA complex with an amount of DNA of 0.2 μg, and 1.0 μL of DNase enzyme (1 U/μL). The digestions were incubated at 37 °C for 30 min and halted by addition of 1.0 μL of stop solution followed by heating at 65 °C for 30 min. The complexes were then analyzed by agarose gel electrophoresis. The integrity of DNA in each formulation was compared with untreated DNA as a control.

Cytotoxicity Assay. The cytotoxicity assay was carried out on the basis of an MTT assay on COS-7 cells. Cells were seeded in 96-well plates at an initial density of 5000 cells/well in DMEM complete medium. The cells were allowed to grow for 24 h. The original media were then replaced with 100 μL of fresh DMEM complete media. The GNP-PEI800s, PEI 800 Da, or PEI 25 kDa solution were added to the media. Each dosage was replicated in 4 wells. Treated cells were incubated at 37 °C under a humidified atmosphere of 95% air and 5% CO_2 for 24 h. MTT reagent (20 μL in PBS, 5 mg/mL) was added to each well, and the cells were incubated for another 4 h at 37 °C. The liquid in each well was removed with cautions to avoid disturbing the crystals on the well wall. 100 μL of DMSO was added to each well to dissolve the crystals. The absorbance at 570 nm of the solution in each well was recorded using a Microplate Reader (Bio-Rad model 550).

In addition to the general control experiment of cell culturing in the absence of the polycation samples, control experiment using GNP-PEI800s in medium without cells was carried out to exclude the interference caused by the absorbance of gold nanoparticles at 570 nm. Cell viability was calculated according to the following equation: Cell viability (%) = $(OD_{sample} - OD_{GNP} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100$ where OD_{sample} is the absorbance of the solution of the cells cultured with GNP-PEIs and PEI; OD_{blank} is the absorbance of the medium, $OD_{control}$ is the absorbance of the solution of the cells cultured with the medium only, and OD_{GNP} is the absorbance of the control solution of GNP-PEI800s in medium without cells.

Luciferase Assay. For in vitro transfection study, COS-7 cells were plated in 24-well plates at a density of 5×10^4 cells/well. They were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2 until the cells reached about 70% confluence. At the time of transfection, the medium in each well was replaced with 1 mL of DMEM without FBS. The cells were transfected with gene-loaded complexes containing 1 μg of plasmid DNA at 37 °C for 4 h. Then, the complexes were removed, and the cells were washed by PBS three times. The cells were then incubated in fresh DMEM with 10% FBS at 37 °C for another 48 h and lysed with the reporter lysis buffer (Promega, USA). The luciferase activity in cell extracts was measured using a luciferase assay kit (Promega, USA). The relative light units (RLU) were normalized by the total protein concentration of the cell extracts, and the total protein was

Scheme 1

measured with a BCA protein assay kit (PERBIO, USA). Luciferase activity was expressed as RLU/mg protein.

Cell Uptake Tracing Assay. GelRed was used as molecular probe to label pGL-3. The GNP-PEI800s/DNA complexes at N/P ratio of 90 were prepared. After the complexes were incubated for 4 h at 37 °C, the medium was replaced with GelRed solution (in 1/10 000 (v/v) DMEM with 10% FBS) and incubated for 10 min at 37 °C. Then, the GelRed solution was replaced with fresh DMEM with 10% FBS. After incubating for an extra 4 h, the cells were directly visualized on a laser confocal scanning microscope (Eclipse C1Si, Nikon, Japan).

RESULTS AND DISCUSSION

Preparation and Characterization of GNP-PEI800s. As shown in Scheme 1, thiolated PEIs (PEI-SH) were synthesized via the ring-opening reaction of methylthiirane on low molecular weight PEI with an M_w of 800 Da. PEI conjugated golden nanoparticles (GNP-PEI800s) were prepared by the simple one-pot reduction of tetrachloroaurate with sodium borohydrate in the presence of PEI-SH. To explore the effect of PEI grafting density on transfection efficiency, we fabricated GNPs with varied Au/PEI molar feed ratios. The elemental composition of the GNP-PEI800s was measured by using a Vario EL III elemental analyzer (for CHN) and ICP-AES measurement (for Au). On the basis of the nitrogen and gold contents, the molar ratio composition of the GNP-PEI800s was calculated and summarized in Table 1. The UV−vis spectra of GNP-PEI800s were shown in Figure 1. These spectra have a strong absorption feature at 520 nm due to the characteristic surface plasmon resonance of GNPs (*34*). Though the GNP-PEI800s were at the same weight concentration of 0.15 mg/mL, the absorbance strength was different, because the absorbance of the conjugates is proportional to the content of GNP cores other than the weight of the total conjugates. Actually, the absorbance strength in Figure 1 is in good agreement with the Au/PEI composition ratios in Table 1. Electron micrographs of GNP-PEI800s and those of their complexes with the plasmid pGL3 DNA are presented in Figure 2. All PEI800-GNPs exhibited no apparent

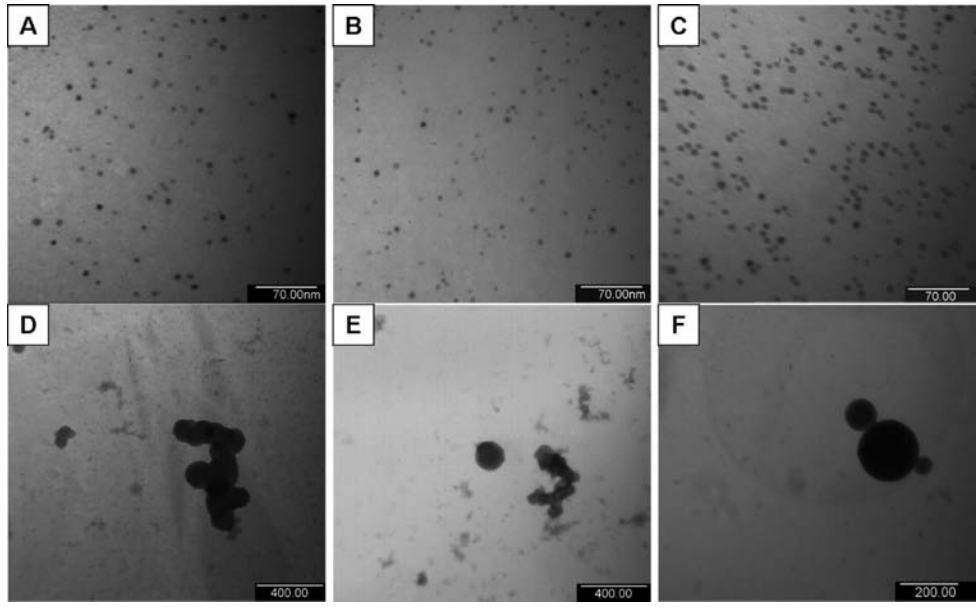

Figure 2. TEM micrographs of (A) GNP-PEI800 5.6, (B) GNP-PEI800 4.3, (C) GNP-PEI800 1.3, (D) GNP-PEI800 5.6/pGL3 complex, (E) GNP-PEI800 4.3/pGL3 complex, and (F) GNP-PEI800 1.3/pGL3 complex. The GNP−PEI800/pGL3 complexes were prepared at N/P ratio of 30.

signs of aggregation. The sizes of the gold core deduced from TEM were 5.7 ± 1.5 nm for GNP-PEI800 5.6, 5.4 ± 0.8 nm for GNP-PEI800 4.3, and 7.7 ± 1.8 nm for GNP-PEI800 1.3, respectively.

GNP conjugates with thiolated PEI 2 kDa were previously prepared and studied for enhanced gene tansfection (*24*). Compared with the literature procedure of making thiolated PEI by reduction of disulfide cross-linked PEI, our thiirane ring-opening procedure is more direct and controllable without need of time-consuming dialysis. The GNP-PEI800s have higher PEI content that is beneficial to higher gene loading capacity. It is worth noting that GNP-PEI800s are very stable. After 6 months of stocking at room temperature, no obvious changes were observed with GNP-PEI800 solutions.

Determination of Graft Density of PEI800 on GNPs. The number of gold atoms in each nanoparticle (U) was calculated according to eq 1 (*35*).The number of PEI molecules per nanoparticle (N) and grafting density of PEI (δ) can be determined using eqs 2−5, and the results are shown in Table 1.

$$U = \frac{2}{3}\pi\left(\frac{D}{\alpha}\right)^3 \tag{1}$$

$$N_{\mathrm{GNPs}} = \frac{W_{\mathrm{Au}}}{M_{\mathrm{Au}}U} \tag{2}$$

$$N_{\mathrm{PEI}} = \frac{W_{\mathrm{PEI}}}{MW_{\mathrm{PEI}}} \tag{3}$$

$$N = \frac{N_{\mathrm{PEI}}}{N_{\mathrm{GNPs}}} \tag{4}$$

$$\delta = \frac{N}{\pi D^2} \tag{5}$$

where α refers to the edge of a unit cell, which has a value of 4.0786 Å on the edge; there are four gold atoms per unit cell. D is the diameter of nanoparticles. W_{Au} and W_{PEI} are the gold content and PEI content, and N_{GNPs} and N_{PEI} are the molar number of gold nanoparticles and PEI. MW_{PEI} and M_{Au} are the molecular weight of PEI and gold.

Characterization of Complexes. The morphology of the complexes was also monitored by TEM. Upon the addition of DNA, GNP−PEI conjugates tended to aggregate with DNA forming submicrometer particles. At N/P ratio of 30, all of the complexes exhibited diameters below 400 nm. The structure of the complexes varied as a function of PEI grafting density on the GNPs. While mainly anomalous loose aggregations with a size of around 400 nm were observed in the images of GNP-PEI800 5.6/DNA (Figure 2D), both anomalous loose and spherical structures were found in GNP-PEI800 4.3/DNA (Figure 2E), and when GNP-PEI800 1.3/DNA complexes were formed, compact and ordered spherical granules were the primary structure as shown in Figure 2F.

The particle sizes of the complexes were further determined by DLS (Figure 3). At low N/P ratios, the complex size decreases rapidly with the increase in the amount of GNP-PEI800. At higher N/P ratios, however, the size becomes less sensitive or even independent of the ratio. As for GNP-PEI800 4.3 and GNP-PEI800 1.3, the sizes were around 200 nm and fairly consistent at N/P ratios ranging from 30 to 180. For complexes with GNP-PEI800 5.6, the particle size showed no obvious differences at high N/P ratios over 90. This phenomenon could be interpreted as the complexation of DNA by the GNP-PEI800 conjugate is saturated above a certain N/P ratio. The results of size measurement by DLS were in accordance with

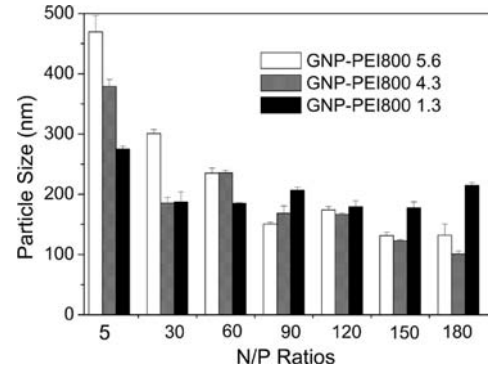

Figure 3. Particle size of GNP-PEI800/pGL3 complexes at various N/P ratios in 150 mM NaCl solution.

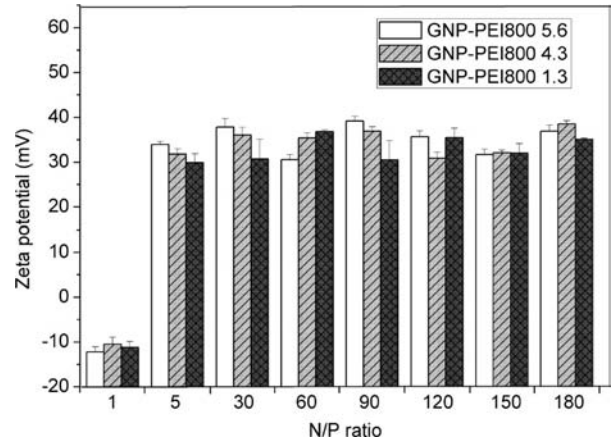

Figure 4. Surface charge of GNP-PEI800/pGL3 complexes at various N/P ratios with fixed pGL3 concentration of 1 μg/mL.

TEM results that a higher PEI grafting density would promote condensation more efficiently.

Surface charge of DNA complexes is another important parameter in determining the efficiency of cellular uptake. Zeta potentials of the complexes were shown in Figure 4. Regardless of the Au/PEI composition, all DNA complexes of the three GNP-PEI800 conjugates showed very similar surface charge profiles. At very low N/P ratio of 1, the particles had zeta potential of about −10 mV, implying that the negative charge of DNA is not completely neutralized. With increasing N/P ratio, zeta potentials of the complexes increased and reached plateaus between +30 and +40 mV at N/P ratios above 5. Complexes of GNP-PEI800s bearing positive surface potentials that should promote initial adhesion on a negatively charged cell surface (*31*).

The ability of GNP-PEI800s to interact with DNA was characterized by agarose gel electrophoresis. In good agreement with zeta potential measurements, the migration of pDNA was completely retarded at a relatively low N/P ratio of 4 (Figure 5), which indicated high DNA binding capacity of all the conjugates. Intensities of DNA staining decreased obviously at higher N/P ratios. Condensation of DNA with GNP-PEI800s might result in exclusion of the dye due to alterations in the double helix leading to reduced fluorescence emission (*37*). As a result, the intensities of DNA staining decrease with increasing DNA condensation ability at higher N/P ratios.

To investigate whether GNP-PEI800s are efficient in protecting DNA from enzyme cleavage, an in vitro DNase protection assay was performed by agarose gel electrophoresis. An amount of enzyme equal to 5 units (1 U/μg DNA) was fixed in the experiment. DNase was added to naked plasmid DNA and GNP-PEI800/DNA complexes (N/P = 20), followed by incubation

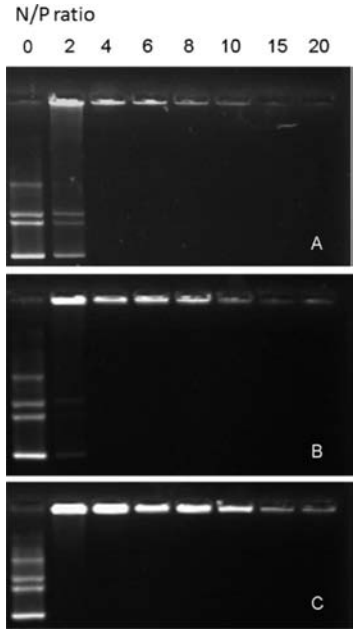

Figure 5. Agarose gel electrophoresis assay of the complexes of pGL3 plasmid DNA (100 ng/well) with (A) GNP-PEI800 5.6, (B) GNP-PEI800 4.3, and (C) GNP-PEI800 1.3 at various N/P ratios. The line of N/P = 0 refers to pGL3 in the absence of GNP-PEI800.

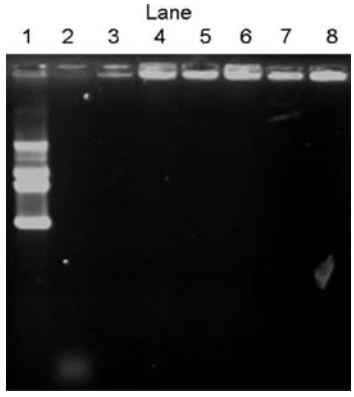

Figure 6. Agarose gel showing DNase digestion results. Lanes 1, 3, 5, 7 are undigested samples of naked DNA, GNP-PEI800 5.6/DNA, GNP-PEI800 4.3/DNA, and GNP-PEI800 1.3/DNA, respectively. Lanes 2, 4, 6, 8 are the above samples exposed to enzyme. Five units of enzyme were used for each reaction. The amount of DNA was 200 ng/well.

for 15 min at 37 °C. As shown in Figure 6 (lane 2), when exposed to the same amount of enzyme under the same conditions, free plasmid DNA alone was digested thoroughly, while plasmid DNA complexed with GNP-PEI800s remained intact.

Cytotoxicity. The cytotoxicity of GNP-PEI800s was evaluated by MTT assay. It should be noted that the absorbance of GNP obviously affects the assay accuracy especially at high concentration. Control experiment using GNP-PEI800s in medium without cells was carried out to get rid of the interference of the absorbance of gold nanoparticles on the color intensity of the assay at 570 nm. The results are presented in Figure 7. In the case of GNP-PEI800 5.6 and GNP-PEI800 4.3, half of the cells were still metabolically active when exposed to a concentration of 300 mg/L, which was almost the same as unmodified PEI 800 Da. In contrast, GNP-PEI800 1.3 with higher PEI content showed greatly increased cytotoxicity compared to the other two GNP-PEI800s, though its half-cell viability concentration was still three times higher than that of PEI 25 kDa. The relatively higher cytotoxicity of GNP-PEI 1.3 may be caused by its high PEI grafting density of 57 chains/nm^2. High cationic charge densities and compact structure, as well as high molecular weight, usually result in high cytotoxicity.

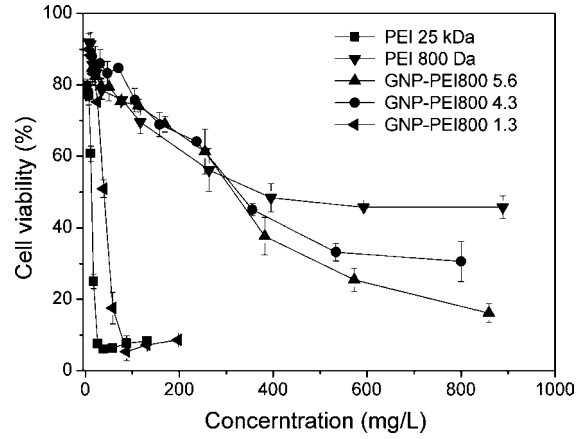

Figure 7. Cell viability at 24 h after the addition of GNPs, PEI 25 kDa, and PEI 800 Da.

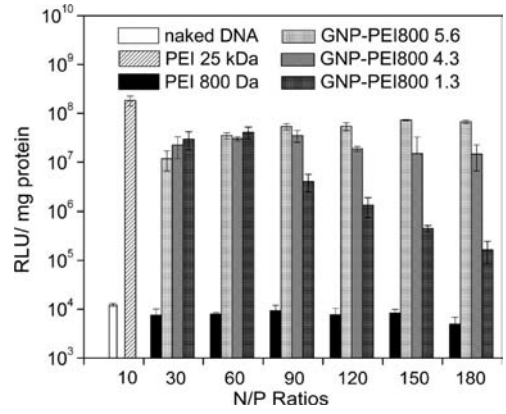

Figure 8. In vitro transfection efficiency of complexes of pGL3 with GNPs in COS-7 cells in comparison with PEI 25 kDa and PEI 800 Da in serum-free medium.

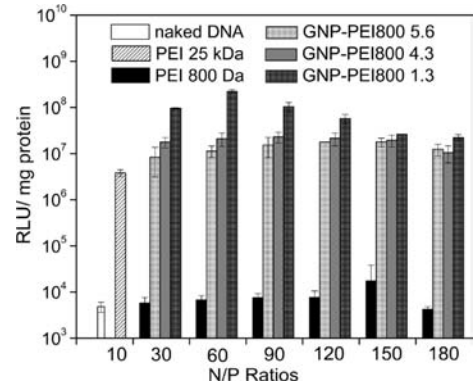

Figure 9. In vitro transfection efficiency of complexes of pGL3 with GNPs in COS-7 cells in comparison with PEI 25 kDa and PEI 800 Da in medium containing 10% serum.

GNP-PEI800 Conjugates Mediated in Vitro Transfection. Transfection efficiency of GNP-PEI800 conjugates was evaluated by luciferase expression of pGL3 plasmid DNA in monkey kidney (COS-7) cells. Complexes were prepared with N/P ratios ranging from 30 to 180, among which the optimal ratio of each complex was determined. Branched PEI 25 kDa at its optimal N/P ratio of 10 and unmodified PEI 800 Da were used for comparison.

Figure 8 shows luciferase expression mediated by the conjugates in the serum-free medium. Under this condition,

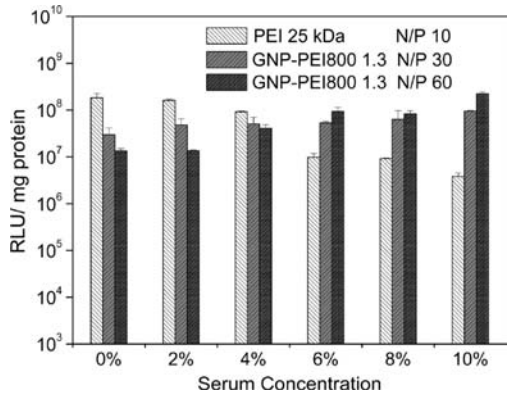

Figure 10. In vitro transfection efficiency of complexes of pGL3 with GNP-PEI800 1.3 at different serum concentrations (v/v) in comparison with PEI 25 kDa.

GNP-PEI800 4.3/DNA complexes at N/P ratio of 90 exhibited the highest efficiency, while GNP-PEI800 5.6 and GNP-PEI800 1.3 reached their maxima at N/P ratio of 150 and 60, respectively. The optimal N/P ratio of each GNP-PEI800 decreased with the increase of PEI grafting density on the GNPs, indicating that GNPs with higher PEI density may achieve efficient transfection at lower N/P ratios. At its best ratio, GNP-PEI800 4.3 achieved nearly half the luciferase expression of PEI 25 kDa, which was worth mentioning, since unmodified PEI 800 was 1000 times less efficient even at a relatively high N/P ratio of 150. In the case of GNP-PEI800 1.3, complexes prepared at N/P ratio of 90 or higher ratios led to abnormal sharply reduced efficiency, possibly ascribed to the increased cytotoxicity, which may also explain why its efficiency was not the highest among the three.

It is known that transfection efficiency of high molecular weight PEI decreased in serum supplemented medium (*31*). Therefore, the development of nonviral gene vectors that can retain efficiency in serum is important. Thus, we tested transfection efficiency of GNP-PEI800s in the presence of serum. As shown in Figure 9, when 10% serum was supplemented in the media, the strong dependence of transfection activity on PEI grafting density became more obvious. The transfection efficiencies declined in the order GNP-PEI800

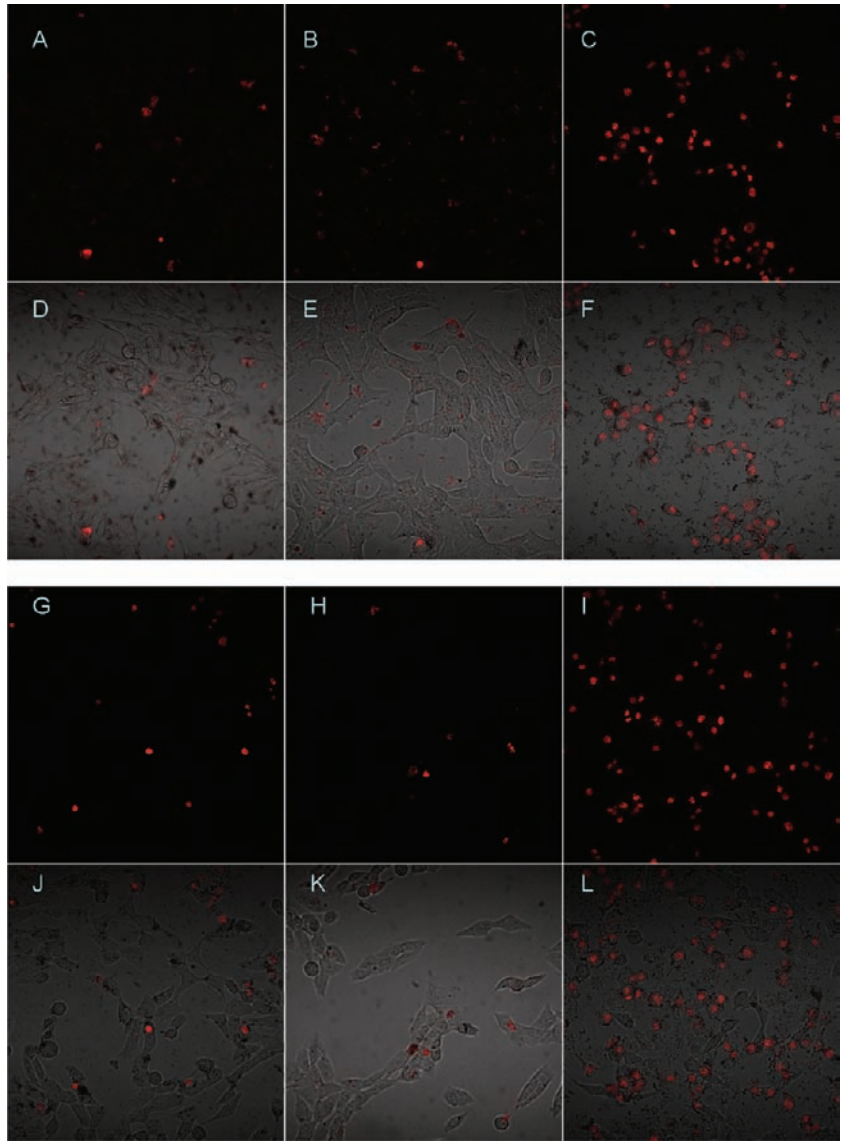

Figure 11. Confocal cell images showing tracking of GelRed labeled GNP-PEI800/DNA complexes. (A−C) Complexes of GNP-PEI800 5.6/DNA, GNP-PEI800 4.3/DNA, and GNP-PEI800 1.3/DNA at N/P ratio of 90 after 4 h post-transfection in serum-free medium. (G−I) Complexes of GNP-PEI800 5.6/DNA, GNP-PEI800 4.3/DNA, and GNP-PEI800 1.3/DNA at N/P ratio of 90 after 4 h post-transfection in medium containing 10% serum. The light inverted micrographs are D−F and J−L, respectively. The micrographs were obtained at magnification of 400×.

1.3 > GNP-PEI800 4.3 > GNP-PEI 800 5.6 (at optimal N/P ratios of 60, 90, and 150, respectively). This sequence is consistent with the PEI grafting density of the GNP-PEI800 conjugates. Specifically, GNP-PEI800 1.3 exhibited efficiency 10 times higher than that of GNP-PEI800 4.3 and PEI800-GNP 5.6 at their optimal N/P ratios. Moreover, the efficiency of GNP-PEI800 1.3 was found to significantly exceed that of PEI 25 kDa. It is interesting that the presence of serum resulted in significant enhancement of gene transfer efficiency of GNP-PEI800 1.3, while GNP-PEI800 4.3 and PEI800-GNP 5.6 could also retain their efficiency under the same conditions. In contrast, the efficiency of PEI 25 kDa was greatly decreased by the presence of serum.

To get further insight into the effect of serum on efficiency, we performed transfection at different serum concentrations. Since GNP-PEI800 1.3 exhibited the most striking distinction between its efficiency in the absence and presence of serum, it was selected for the subsequent experiment. Two N/P ratios of 30 and 60 were chosen to exclude the impact of cytotoxicity at higher ratios. Branched PEI 25 kDa at the optimal N/P ratio of 10 was used for comparison. Figure 10 shows the comparative gene transfection efficiencies of GNP-PEI800 1.3 and PEI 25 kDa in the presence of various percentages of serum. There was a gradual decrease in the transfection efficacy with increase in serum concentrations in the case of PEI 25 kDa, while GNP-PEI800 1.3 showed a completely opposite tendency. For example, at 6% serum concentration, only 5% of its transfection efficiency in serum-free medium was observed for PEI 25 kDa, whereas gene expression with GNP-PEI800 1.3 was promoted about 7 times higher than that without serum. The result clearly shows that GNP-PEI800 1.3 is a better transfection agent in the presence of serum than PEI 25 kDa.

The enhancement of transfection efficiency of GNP-PEI800 1.3 in serum might be related to lowered cytotoxicity. The high PEI grafting density in GNP-PEI800 1.3 can largely increase the effective molecular weight of PEI 800 Da, which consequently leads to more efficient DNA condensation and thus more efficient transfection. However, it induced inevitable cytotoxicity simultaneously. At the same concentration as in its complex, the cell viability of GNP-PEI800 1.3 alone decreased with an increase in N/P ratio, which was greater than 80% cell viability at N/P ratios of 30 and 60, nearly 60% at N/P ratios of 90 and 120, and 20% at N/P ratios of 150 and 180. These results revealed that the cytotoxicity of the GNP-PEI800 conjugates is remarkable under the transfection conditions. Thus, the enhancement of transfection efficiency in serum-containing medium might be related to the cell function raised by the addition of serum.

Cell Uptake Tracing. The capacity of GNP-PEI800s to internalize plasmid DNA into cells was additionally observed by confocal laser scanning microscopy (CLSM). GelRed was used as a molecular probe to label pGL-3. Complexes of all three GNP-PEI800 samples at N/P ratio of 90 were incubated in the medium in the absence and presence of serum, respectively, and examined at 4 h post-transfection. Control experiments with labeled naked DNA showed no signs of cellular uptake (data not shown). As shown in Figure 11, the uptake of complexes in the absence and presence of serum exhibited subtle differences. In the case of GNP-PEI800 1.3, the percentage of cells showing complex uptake was high, which probably contributed to its high transfection efficiency. However, the high absorption of GNP-PEI800 1.3 may also impair plasma membrane dramatically and result in high cytotoxicity. In fact, a significant level of cellular dysfunction or even cell death was observed in the images. By comparison of the two images in Figure 11F and L, it is obvious the cells in the serum-containing medium were better in morphology than those in serum-free medium. The results imply that the cytotoxicity of the PEI conjugated GNP was reduced by the presence of serum, while the cell uptake capacity was retained. Generally, the qualitative results of CLSM are in good agreement with the results of luciferase assay and cytotoxicity assay.

CONCLUSION

In closing, we have synthesized a series of hybrid GNP-PEI800s by conjugating PEI 800 Da to gold nanoparticles at three PEI/Au molar ratios. GNP-PEI800s possesses many outstanding features in favor of polycation-mediated gene delivery, including efficient DNA condensation, high DNA binding capability and DNA protection against degradation by DNase. In consequence, GNP-PEI800s can transfect COS-7 cells 3 to 4 orders more efficient than unmodified PEI800, reaching almost the same magnitude of PEI 25 kDa. Moreover, in contrast to the dramatically lowered efficiency of high molecular weight PEIs such as PEI 25 kDa in the presence of serum, the efficiency of GNP-PEI800s can be retained or even enhanced, reaching 60-fold higher than that of PEI 25 kDa in 10% serum medium. The research demonstrated that GNP−PEI conjugates are very promising as gene delivery vectors.

Synthetic cationic lipids are promising transfection agents for gene therapy. We report here that polyamine conjugates of dialkyl phosphates, combined with natural lipids and assembled in the form of liposomes (polycationic liposome: PCL), possess high transfection activity in the COS-1 cell line. Furthermore, we describe the functional morphology of the PCL/DNA complexes as revealed by atomic force microscopy (AFM). The conjugates were synthesized from dialkyl phosphates (with alkyl chain lengths of 12, 14, or 16 carbons) by reaction with the polyamine molecules, spermidine, spermine, or polyethylenimine (PEI(1800)). [Dewa, T., et al. *Bioconjugate Chem.* **2004**, *15*, 824]. The PCL composed of the spermidine and C16 conjugate combined with phospholipid and cholesterol (conjugate/phospholipid/cholesterol = 1/1/1 as a molar ratio) exhibited 3.6 times higher activity than that of a popular commercial product. Systematic tests revealed clear correlations of the transgene activity with physical properties of the polyamine, in particular, that longer alkyl chains and the lower molecular weight polyamines (spermidine, spermine) favor high efficacy at the higher nitrogen/phosphate ratio = 24 (N/P, stoichiometric ratio of nitrogen in the conjugate to phosphate in DNA). The low molecular weight polyamine-based PCLs, which formed 150−400 nm particles with plasmid DNA (lipoplexes), exhibited ∼3-fold higher gene transfer activity than micellar aggregates (lacking phospholipid and cholesterol) of the corresponding conjugate. In contrast, the PEI-based PCL formed large aggregates (∼1 μm), that, like the micellar aggregate form, had low activity. Activity of the low molecular weight polyamine-based PCLs increased linearly with the N/P of the lipoplex up to N/P = 24. Formation of lipoplexes was examined by agarose gel electrophoresis, dynamic light scattering (DLS), and AFM. At the lower N/P = 5, large aggregates of complex (∼1 μm), in which DNA molecules were loosely packed, were observed. At higher N/P, lipoplexes were converted into smaller particles (150−400 nm) having a lamellar structure, in which DNA molecules were tightly packed. Such morphological features of the lipoplex correlate with the dependence of transfection on the N/P in that the lamellar structures gave superior transfection. AFM also indicated that the lipoplexes disassembled significantly, releasing DNA, when the lipoplexes were exposed to acidic conditions (pH 4). The significance for transfection activity of the metamorphosis of bilayer lipoplexes is discussed relative to that of the less active micellar aggregate form, which is unresponsive to pH change.

INTRODUCTION

Development of more efficient and safer gene carriers using nonviral compounds is one of the most challenging aspects of gene therapy (*1, 2*). Compared to viral carrier systems, nonviral gene carrier systems have advantages in simplicity of use, lack of specific immune response, and ease of mass production due to the low cost of preparation; however, they have the disadvantage of low transfection efficiency, which needs to be overcome (*3, 4*). To improve the efficiency of nonviral carriers, many synthetic organic compounds, including cationic lipids (*5*−*9*), polycations (*10*−*15*), and combinations thereof (*16*−*22*), have been developed as nonviral gene carriers (*23*). Substantial research has been reported on structure−activity relationships for cationic amphiphiles concerning the cationic and hydrophobic portions (*24*−*28*). Such amphiphiles form self-assembling micelles and liposomes in an aqueous phase, the structures of which have been investigated using small-angle X-ray scattering (SAXS)[1], transmission electron microscopy (TEM), and atomic force microscopy (AFM) to gain knowledge about structure−activity relationship, particularly those involving ordered structures (lamellar, inverted hexagonal, and cubic phases) and their morphological changes (*29*, *30*) as well as about the size of complexes (*31*).

The mechanism of gene delivery by such cationic carriers probably involves an endosomal pathway (*32*): (i) cellular uptake via endocytosis, (ii) DNA release from endosome, and (iii) entry

Scheme 1. Polyamine-Dialkyl Phosphate Conjugates As Gene Carriers[a]

[a] NH_2-(Polyamine) represents polyamines and their primary amine portion that reacts with the phosphate portion.

into the nucleus. Many researchers have devised cationic compounds that facilitate the process, for example, ligand-conjugated molecules targeting a receptor such as integrin (*33, 34*), pH-responsive or cleavable molecules that enable escape of DNA from endosome (*13, 35*−*38*), and conjugation of nuclear localization signal peptides (NLS) (*39, 40*) for steps (i)−(iii), respectively. For cationic lipids/DNA complexes (lipoplexes), it has been proposed that a morphological change from lamellar to inverted hexagonal phase in the acidic endosomal environment facilitates the endosomal release and escape of DNA (*41, 42*). In addition to investigation of intracellular trafficking of polycation−DNA complexes (polyplexes and lipoplexes), observation of morphology and metamorphosis of the complexes is very important to shed light on the mechanism of gene transfer and provide information for development of novel synthetic carriers (*30, 43, 44*).

We have reported that polycationic liposomes (PCL) containing cetylated polyethylenimine (cetyl-PEI) possess high gene transfer activity (*45*−*47*). The cetyl-PEI molecule is anchored by the hydrophobic cetyl portion and is distributed over the liposomal surface. In our previous report, we proposed a possible mechanism of PCL-mediated gene transfer, in which PCL/DNA complexes are taken up by the endosomal pathway (based on tracking of fluorescence-labeled components, PCL lipid, cetyl-PEI, and DNA), after which the cetyl-PEI/DNA complex is released and transferred into the nucleus via the cytosol (*48*). Compaction of DNA is therefore crucial, and both electrostatic and hydrophobic interactions in the cetyl-PEI/DNA complex are responsible for its effective compaction.

We have previously described novel polyamine (spermidine, spermine, or PEI)-dicetyl phosphate conjugates, prepared via a facile synthetic route (Scheme 1) (*49*) in which the polyamine and phosphate portions are linked through a P−N bond. When suspended in aqueous solution, they form micellar aggregates and exhibit moderate gene-transfer activity, the magnitude of which is relatively insensitive to the modification of the polyamine portion. In the present report, we present (1) evidence demonstrating that the transgene activity is dramatically enhanced when the conjugates are assembled into liposomes containing cholesterol and phospholipid and that the activity is susceptible to the chemical modification of the conjugate both in the polyamine and in the hydrophobic chain portions (Scheme 1). We show further that (2) gene transfer activity of the corresponding PCLs strongly depends on the type of polyamine in the conjugate, with notable differences between the lower molecular weight polyamines (spermidine and spermine) on one hand and the polymer type (PEI(1800)) on the other.

We also examined (3) the morphology of the lipoplexes by AFM and discuss the relationship between the structure of lipoplexes and their transfection efficiency. AFM analysis has a considerable advantage for observation of lipoplex morphology, especially for less ordered structures (*50*); however, until now little clear evidence has been reported on the relationship between morphological change and DNA release. In this research, DNA release as a result of disassociation of the complex was revealed by AFM. We discuss morphology−activity relationships on the basis of electrophoresis analysis, dynamic light scattering (DLS), and AFM observation.

EXPERIMENTAL PROCEDURES

General Methods. Unless stated otherwise, all chemicals and reagents were obtained commercially and used without further purification. Dialkyl phosphates, dilauryl phosphate (DLP), dimyristyl phosphate (DMP), and dicetyl phosphate (DCP) were synthesized from corresponding alcohols, i.e., lauryl (C12), myristyl (C14), and cetyl (C16) alcohols, and $POCl_3$ in accordance with the reported method (*51*). The polyamine−dicetyl phosphate conjugates, DCP-spermidine (**DCP-spd**), DCP-spermine (**DCP-spm**), and DCP-PEI(1800) (**DCP-PEI**) were synthesized as described previously (*49*). Other conjugates, DLP-spermidine (**DLP-spd**), DLP-spermine (**DLP-spm**), DLP-PEI(1800) (**DLP-PEI**), DMP-spermidine (**DMP-spd**), DMP-spermine (**DMP-spm**), and DMP-PEI(1800) (**DMP-PEI**), were also synthesized using analogous procedures. Spectral data are given below. (Note: The asymmetric molecule, spermidine, has two distinguishable primary amines. Products, **DLP-spd**, **DMP-spd**, and **DCP-spd**, bearing a spermidine moiety, have two isomers, which, to date, have not been identified spectroscopically. Similarly, the content of primary amine of PEI(1800) in the products DLP-PEI, DMP-PEI, and DCP-PEI is 25% in total amino moieties (on the basis of theoretical calculation); thus, some structural uncertainty cannot be avoided.)

DLP-spermidine conjugate (**DLP-spd**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 36H), 1.51−1.95 (br m, 12H), 2.65−3.05 (br m, 6H), 3.98 (br m, 4H), 4.50 (br s, 4H). MALDI-TOF-MS for $(C_{31}H_{69}N_3O_3P)^+$: calcd 562.9, found 563.0.

DLP-spermine conjugate (**DLP-spm**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 36H), 1.49−2.00 (br m, 15H), 2.63−3.05 (br m, 14H), 3.95 (br m, 4H). MALDI-TOF-MS for $(C_{34}H_{76}N_4O_3P)^+$: calcd 620.0, found 620.2.

DLP-PEI(1800) conjugate (**DLP-PEI**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 36H), 1.58−1.65 (br m, 4H), 2.55−3.80 (br m, 209H), 3.95 (br m, 4H).

DMP-spermidine conjugate (**DMP-spd**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 44H), 1.50−1.71 (br m, 10H), 2.61−3.02 (br m, 12H), 3.98 (br m, 4H). MALDI-TOF-MS for $(C_{35}H_{77}N_3O_3P)^+$: calcd 619.0, found 618.9.

DMP-spermine conjugate (**DMP-spm**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 44H), 1.61−2.00 (br m, 17H), 2.63−3.04 (br m, 12H), 3.97 (br m, 4H). MALDI-TOF-MS for $(C_{38}H_{84}N_4O_3P)^+$: calcd 676.1, found 676.1.

DMP-PEI(1800) conjugate (**DMP-PEI**). ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 6H), 1.26 (s, 44H), 1.56−1.65 (br m, 4H), 2.55−3.82 (br m, 209H), 3.95 (br m, 4H).

Preparation of Polycation Liposome (PCL). Polycation liposome suspensions were typically prepared as follows: polyamine conjugate, phospholipid (either 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) or 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC)), and cholesterol (1/1/1 as a molar ratio) were dissolved in chloroform/*t*-butyl alcohol (2/1). After removal of chloroform under reduced pressure, the residual solvent was removed by freeze−drying overnight. The lyophilized powder was hydrated with Tris-HCl buffer (20 mM, pH 8.0) followed by three freeze−thaw cycles, and the resultant suspension was then subsequently extruded through polycarbonate membranes of 0.4, 0.2, and 0.1 μm pore diameter at room temperature. For vesicles composed of DPPC, the hydration and extrusion were carried out at 60 °C. Unless stated otherwise, PCL refers to the DOPE-based polycation liposome. A suspension of the polyamine conjugate alone was prepared in the Tris-HCl buffer (20 mM, pH 8.0) by ultrasonication for 3 min. For convenience, particles so prepared are termed "micellar aggregates". Hereafter, polycation liposomes (PCL) and micellar aggregates (M) composed of the conjugates are described as "**conjugate**(PCL)", such as **DCP-spd**(PCL), and "**conjugate**(M)", such as **DCP-spd**(M), respectively.

Lipoplex Formation with Plasmid DNA. A plasmid encoding luciferase gene, pCAG-luc3 (6480 bp, a gift of DNAVEC Institute, Tsukuba, Japan), was amplified in *E. coli* JM109 (Nippon Gene, Toyama, Japan) and purified as described before (*47*). One microgram of the plasmid DNA in a TE buffer was added to a suspension of PCL containing 1 mM of polyamine conjugate so as to give the desired nitrogen/phosphate ratio, N/P. The mixture was incubated for 20 min at room temperature when used for transfection. A plasmid, ColE1 DNA (6646 bp, Nippon Gene), was used for an assay of ethidium bromide intercalation and morphological observation of lipoplexes with AFMs (JSPM-4210, JEOL, and PicoPlus, Molecular Imaging), using the AC mode under ambient air conditions. A sample was deposited on a mica surface by spin coating, followed by drying in a desiccator for 1 h under reduced pressure to remove water from the mica surface. A freshly cleaved mica surface is negatively charged. As appropriate, the mica was treated with poly(L-lysine) (PLL) to provide positively charged surface. Hereafter, the negatively and positively charged mica substrates are described as bare mica and PLL-mica, respectively.

The sizes of PCLs, micellar aggregates, and their lipoplexes were analyzed by dynamic light scattering (DLS) with a NICOMP particle sizing system (model 370, Santa Barbara, CA, USA). The ζ-potentials of the cationic vectors were measured with ZETA SIZER Nano-ZS (MALVERN, Worcestershire, U.K.). Agarose-gel electrophoretic analysis was conducted by using 0.8% agarose (UltraPure agarose, Invitrogen) and 1 kb DNA ladder marker (Invitrogen). Electrophoresed DNA bands were stained with ethidium bromide.

For observation of morphological change of lipoplex by acidification, to a solution of lipoplex (pH 8.0) was added acetic acid so as to acidify down to pH 4. The solution was incubated for 1 h at room temperature.

Transfection Procedure. COS-1 cells were cultured in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum (FBS, Japan Bioserum Co. Ltd.) under a humidified atmosphere of 5% CO_2 in air. One day before a transfection experiment, 1×10^5 COS-1 cells were seeded onto each of several 35 mm dishes and incubated overnight in a CO_2 incubator. Then, the cells were washed twice with DMEM, and a suspension of lipoplex (1 μg DNA) was added to them in the presence of 10% FBS-DMEM. After 3 h incubation (37 °C, 5% CO_2), the cells were washed twice with DMEM and cultured for another 48 h in 10% FBS-DMEM. The cells in the 35 mm dishes were washed twice with phosphate-buffered saline at 37 °C, and 200 μL of cell lysis buffer (LC-β, TOYO B-Net Co. Ltd., Tokyo) was added. After 15 min incubation, the cells were collected with a cell scraper, frozen at −80 °C, and then thawed at room temperature. The lysate was centrifuged at 15 000 rpm for 5 min at 4 °C. The supernatant was subjected to the luciferase assay (Pica Gene, TOYO B-Net Co. Ltd., Tokyo) using a luminophotometer (Luminescencer-PSN AB-2200, ATTO). The observed intensity in instrument light units was normalized to the amount of protein determined by BCA protein assay kit (PIERCE) to give relative light units (RLU/mg protein).

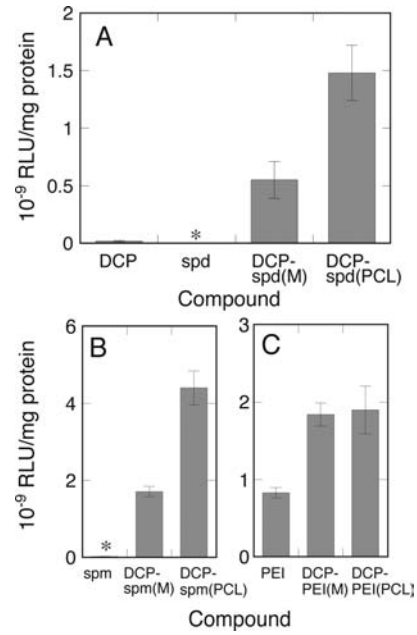

Figure 1. Transfection efficacy of polyamine−lipid conjugates, **DCP-spd** (A), **DCP-spm** (B), and **DCP-PEI** (C), and their constituents, DCP (A) and polyamines, spermidine (spd, A), spermine (spm, B), and PEI(1800) (PEI, C), on COS-1 cells. Efficacy was evaluated with the luciferase activity. The observed values for spermidine and spermine indicated by the asterisks (*) were apparently negligible on the activity scale shown. The conjugates **DCP-spd**(M), **DCP-spm**(M), and **DCP-PEI**(M) represent their micellar aggregate forms, and **DCP-spd**(PCL), **DCP-spm**(PCL), and **DCP-PEI**(PCL) represent the conjugate-based PCLs (conjugate/DOPE/cholesterol = 1/1/1 (mol/mol/mol)). The nitrogen/phosphate (N/P) ratio was 16/1 for the polyamine conjugate/DNA complexes. For the monoanionic DCP, the molar ratio, DCP/nucleotide = 16/1, was applied as a negative control experiment. Transfection was conducted in the presence of 10% FBS.

RESULTS

Transfection Efficacy of Micellar Aggregates and PCL Vectors: Comparison of the Dicetyl Phosphate Derivatives of Spermidine, Spermine, and Polyamine. Figure 1A shows the transfection efficacy of the polyamine conjugate, **DCP-spd**(M), and its constituent molecules, DCP and spermidine (spd). The conjugate (in this case an aqueous micellar suspension) shows greatly increased efficacy relative to the constituent molecules, DCP and spermidine. For these polyamine/DNA complexes, the nitrogen/phosphorus ratio (N/P) was 16. The data of the figure indicate that coupling the lipophilic and cationic portions is essential to obtain gene transfer. Such an

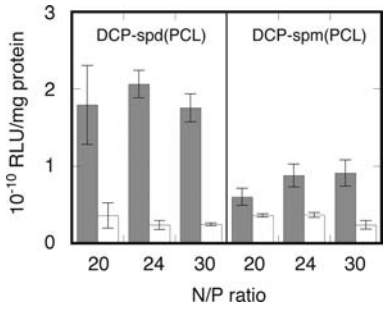

Figure 2. Transfection efficacy of spermidine and spermine conjugates (**DCP-spd** and **DCP-spm**, respectively) incorporated into DOPE-based (closed bar) and DPPC-based (open bar) liposomes. Polyamine conjugate/phospholipid/cholesterol = 1/1/1 (mol/mol/mol). Transfection was conducted in the presence of 10% FBS.

effect of conjugating these two moieties was also observed for the spermine conjugate, **DCP-spm**(M) (Figure 1B). When the conjugates were further formulated with DOPE and cholesterol (conjugate/DOPE/cholesterol = 1/1/1 (mol/mol/mol)) to generate polycation liposomes (PCL) (**DCP-spd**(PCL) and **DCP-spm**(PCL)), efficacies were further enhanced by a factor of 2−3 relative to the micellar aggregate suspensions (**DCP-spd**(M) and **DCP-spm**(M)). The polycation PEI(1800) itself showed moderate activity and the conjugate, **DCP-PEI**(M), exhibited even greater activity. However, in contrast to the other conjugates, the activity of the liposomal form, **DCP-PEI**(PCL), was comparable to that of the micellar version, **DCP-PEI**(M). The cytotoxicity of the conjugates, as both micellar aggregates and PCLs, was low; the latter vectors, which exhibited higher activity, also had slightly higher toxicity than the former (Supporting Information Figure S1).

Effect of the Phospholipid Components of PCLs on Their Transfection Efficacy. Figure 2 shows the transfection efficacy of **DCP-spd**(PCL) and **DCP-spm**(PCL) composed of either DOPE (dark bar) or DPPC (bright bar) in the N/P range 20−30. It is clear that the DOPE-based PCL exhibits significantly greater activity than the DPPC-based compound for both the **DCP-spd**(PCL) and the **DCP-spm**(PCL). This is indicative of a lipid-mediated gene transfer mechanism; DOPE is well-known as a "helper" lipid, which is believed to facilitate membrane fusion and endosomal escape of the DNA (*52*). DOPE in the present PCL systems presumably also plays a role in the mechanism to expedite membrane fusion and destabilization of the endosomal membrane. DPPC, whose T_m is 41.5 °C (*53*), renders the PCL more stable and more rigid than does DOPE. Thus, it is likely that the fusogenic property of DOPE is responsible for the enhanced transfection activity of its complexes relative to those containing DPPC.

Optimal Structure of the Conjugate Molecules for Gene Transfer. The facile synthetic route provides a variety of polycationic compounds that can be exploited to examine the effect of the polycationic and hydrophobic portions on transfection efficiency. We hence examined the effect on transfection activity of different polyamine conjugates incorporated into PCLs: C12, C14, or C16 alkyl chain in the lipophilic portion and spermidine, spermine, or PEI(1800) as the polycationic headgroup of the conjugate. The data on these compounds are shown in Figure 3. This result reveals clear tendencies of longer length of the alkyl group and the lower molecular weight of the polyamines (spermidine, spermine) to enhance transfection. When compared with a commercial product, Lipofectamine 2000, the **DCP-spd**(PCL) possessed 3.6-fold higher activity. The transfection activity of **DCP-spd**(PCL) and **DCP-spm**(PCL) depends on cell lines tested (Figure 3B): **DCP-spd**(PCL) < **DCP-spm**(PCL) for Lewis lung carcinoma (LLC) and **DCP-spd**(PCL) > **DCP-spm**(PCL) for B16BL6.

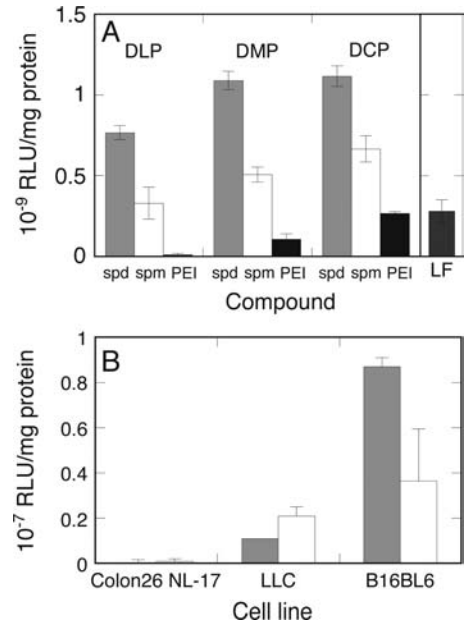

Figure 3. (A) Effect of polyamine and hydrophobic portions on PCL-mediated gene transfer efficiency. PCL were composed of polyamine conjugate/DOPE/cholesterol (1/1/1 (mol/mol/mol)). N/P ratio was 24. Transfection was done in the presence of 10% FBS. LF represents Lipofectamine 2000 as a positive control experiment. (B) Transfection efficiency of **DCP-spd**(PCL) (dark bar) and **DCP-spm**(PCL) (open bar) for various murine cancer cells. In the presence of 10% serum, lipoplexes (N/P = 24) were applied to Colon26 NL-17, Lewis lung carcinoma (LLC), and B16BL6 melanoma cells. Transfection procedure was carried out as described in the Experimental Section.

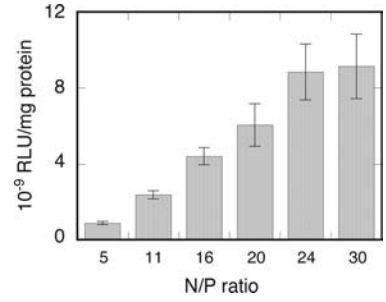

Figure 4. Effect of the N/P ratio on the transfection efficacy of **DCP-spm**(PCL) (**DCP-spm**/DOPE/cholesterol = 1/1/1 (mol/mol/mol)). Transfection was in the presence of 10% FBS.

N/P-Dependent Efficacy and Complexation of PCL with DNA. Figure 4 shows the dependence of **DCP-spm**(PCL) efficacy on the ratio of the number of nitrogen atoms in the conjugate to that of phosphate in the DNA (N/P). The efficacy increases with the N/P ratio essentially linearly up to 24. A similar N/P dependence has been also observed for **DCP-spd**(PCL) (data not shown for clarity), indicating that excess polyamine relative to DNA is needed for effective gene transfer by PCLs. In contrast, the transfection activity of micellar aggregates **DCP-spd**(M) and **DCP-spm**(M) reaches plateau values in the N/P range 11−16 ($1-2 \times 10^9$ of RLU/mg protein). This tendency is consistent with our previous data obtained with the β-galactosidase expression system (*49*).

To elucidate the characteristics of N/P dependence, formation of **DCP-spd**(PCL)/DNA and **DCP-spm**(PCL)/DNA lipoplexes was analyzed by agarose gel electrophoreses (Figure 5A,B) and DLS analysis (Table 1). In Figure 5, lane 2 of the plasmid DNA (pCAG-luc3) shows free-DNA bands (supercoiled and open circular DNAs). Lane 3 represents **DCP-spd**(PCL) and **DCP-spm**(PCL) alone as a control experiment. In the lower N/P range

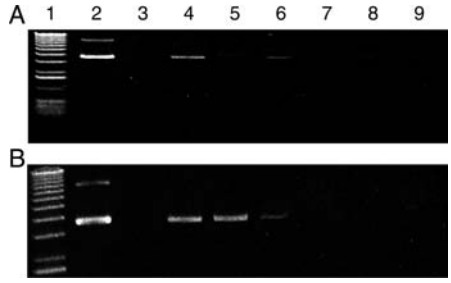

Figure 5. Agarose gel electrophoresis of PCL/plasmid DNA (pCAG-luc3: 6480 bp) lipoplexes. **DCP-spd**(PCL) (A) and **DCP-spm**(PCL) (B) were mixed with the DNA in the N/P range 5−30. Lane 1, 1 kb DNA ladder marker; lane 2, plasmid DNA (6480 bp) alone; lane 3, PCL alone. Lanes 4−9 represent PCL/DNA lipoplexes at N/P = 5, 11, 16, 20, 24, and 30, respectively.

Table 1. DLS Analysis of Various Polyamine-Dialkyl Phosphate Conjugate/DNA Complexes

				size (nm)	
entry	compound	N/P ratio	pH	PCL	micelle
1	**DCP-spd**	−	8	158 ± 56	249 ± 106
2		2	8	231 ± 89	
3		5	8	651 ± 501	1181 ± 1057
4		16	8	190 ± 83	
5		24	8	261 ± 114	1791 ± 1630
6		24	4	985 ± 1437	1624 ± 1566
7	**DCP-spm**	−	8	159 ± 30	225 ± 102
8		2	8	293 ± 112	
9		5	8	764 ± 378	321 ± 181
10		16	8	296 ± 168	
11		24	8	256 ± 116	1767 ± 1284
12		24	4	1033 ± 1060	1209 ± 949
13	**DCP-PEI**	−	8	214 ± 90	275 ± 184
14		24	8	1062 ± 783	317 ± 243

5−16 (lanes 4−6), the open circular DNA band vanished and the supercoiled DNA band gradually faded for both of **DCP-spd**(PCL) and **DCP-spm**(PCL). In the higher N/P range (20−30, lanes 7−9), the latter DNA band totally disappeared, indicating that the DNA molecules are completely entrapped within the lipoplex. Ethidium bromide (EtBr) replacement experiments also reveal condensation of DNA in the N/P range 5−30 (Supporting Information Figure S2).

The particle size of lipoplexes estimated by DLS analysis is summarized in Table 1. The diameters of the **DCP-spd**(PCL) and **DCP-spm**(PCL) alone are 158 ± 56 and 159 ± 30 nm, respectively (entries 1 and 7). Lipoplexes were larger and their size increased with increasing N/P up to 5 (entries 2 and 8 at N/P = 2 and entries 3 and 9 at N/P = 5). At N/P = 5, the PCL/DNA lipoplexes became larger with a broad distribution from 650 nm to over 1 μm (entries 3 and 9). In the higher N/P range (N/P = 16−24), sizes were reduced, converging at 261 ± 114 nm (**DCP-spd**(PCL), entry 5) and 256 ± 116 nm (**DCP-spm**(PCL), entry 11). ζ-potential measurements indicated the polarity of surface charge of lipoplexes inverts from negative in the lower N/P (5−11) to positive in the higher N/P (>16) regions.

AFM images revealed characteristic morphologies of lipoplexes in the both low and high N/P ranges (Figure 6A−D). When the **DCP-spd**(PCL)/DNA and **DCP-spm**(PCL)/DNA lipoplexes at N/P = 5 were put on PLL-treated mica (positively charged surface), large aggregates in the sub-micrometer size range (600−1200 nm, Figure 6A,B) were observed. These structures resembled by bead-like aggregates (*54*) composed of small particles (80−120 nm in diameter, 8−20 nm in height) connected to one another. Such aggregates were not observed on a negatively charged bare mica. This is understandable since the lipoplex at N/P = 5 is negatively charged, and the lipoplex

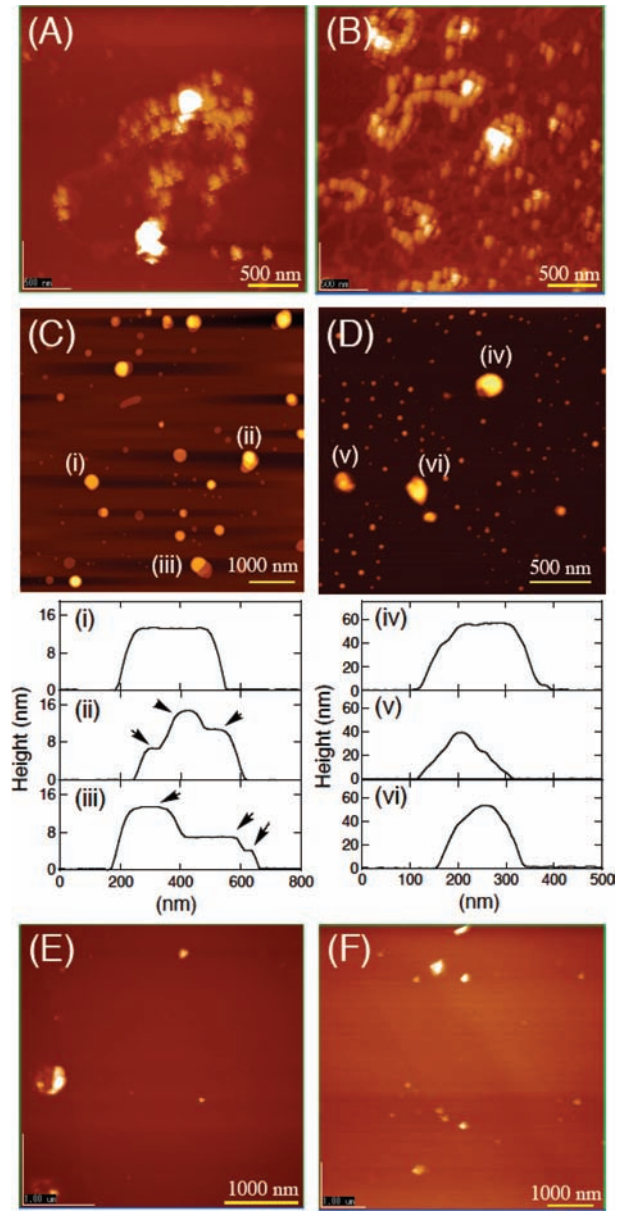

Figure 6. AFM images of PCL/plasmid DNA (ColE1; 6646 bp) lipoplexes: (A), **DCP-spd**(PCL)/DNA (N/P = 5); (B), **DCP-spm**(PCL)/DNA (N/P = 5); (C), **DCP-spd**(PCL)/DNA (N/P = 24); (D), **DCP-spm**(PCL)/DNA (N/P = 24); (E and F), **DCP-PEI**(PCL)/DNA complex (N/P = 24). Scale bars shown in the images are 500 nm (A,B,D) and 1000 nm (C,E,F). The PCL/DNA complexes were applied to PLL-mica (A,B) and bare mica (C,D,E,F). All images were taken under an ambient air conditions. Height profiles of the objects (i)−(iii) in C and (iv)−(v) in D are shown below these images. Arrows in (ii) and (iii) indicate step-like profiles discussed in the text. Images E and F for **DCP-PEI**(PCL)/DNA were taken from a different area of the bare mica surface.

must be adsorbed on the PLL-mica surface through electrostatic interaction to be imaged. The outer periphery of the large aggregates is rich in DNA molecules, presumably those were so loosely attached that they were liberated from the aggregates during electrophoresis.

At the high N/P = 24, spherical complexes were observed for **DCP-spd**(PCL) and **DCP-spm**(PCL) complexes; their diameters were 200−400 nm for **DCP-spd**(PCL)/DNA (C) and 150−250 nm for **DCP-spm**(PCL)/DNA lipoplexes (D), and their heights were 12−30 and 27−60 nm, respectively. The size of the complexes is in good agreement with the values observed by DLS. The detailed topography of these **DCP-spd**(PCL)/DNA

and **DCP-spm**(PCL)/DNA lipoplexes showed flat-topped spheres and spherical structures (line profiles (i)−(iii) for (C) and (iv)−(vi) for (D)). The profiles (ii) and (iii) are characteristically "step-like" (arrows). The heights indicated in (ii) are 6, 10, and 14 nm. Considering the thickness of lipid bilayer (4 nm) and the diameter of DNA (2 nm), these three values correspond to one bilayer (4 nm) + DNA (2 nm) = 6 nm, a double bilayer (8 nm) + DNA = 10 nm, and a triple bilayer (12 nm) + DNA = 14 nm, respectively. Thus, the step-like structure is reasonably indicative of a smectic lamellar assembly, where DNA molecules are laminated between bilayers.

Compared with **DCP-spd**(PCL) and **DCP-spm**(PCL) lipoplexes, the size of the **DCP-PEI**(PCL)/DNA lipoplex (N/P = 24) is large and has a broad distribution (1062 ± 783 nm, Table 1, entry 14). AFM images of the **DCP-PEI**(PCL)/DNA lipoplex show aggregates with heterogeneous and featureless shapes (Figure 6E,F). EtBr replacement experiments revealed DNA condensation in a similar manner to that of **DCP-spd**(PCL) and **DCP-spm**(PCL) (Supporting Information Figure S2).

Disruption of the PCL/DNA Lipoplexes. When the **DCP-spd**(PCL)/DNA and **DCP-spm**(PCL)/DNA lipoplexes (N/P = 24) were incubated in acidic solution (down to pH 4), the particle sizes measured by DLS became significantly larger and exhibited broad distributions (Table 1, entries 6 and 12). AFM imaging revealed morphological transformation of the PCL/DNA complexes upon acidification. When the dispersion of **DCP-spd**(PCL)/DNA lipoplexes (N/P = 24) was acidified at pH 4 for 1 h by addition of acetic acid, deformed structures were observed on bare mica (Figure 7A). Relative to the original structure (Figure 6C), the complex is decisively deformed by the acid treatment. Although some of the flat-topped sphere complexes remain, the predominant morphology is particles connected with strings. The height of the clusters is 25−53 nm and they are connected with string portions that are 6−10 nm high. When the acid-treated complex solution was put on PLL-mica, additional deformed objects appeared on the surface (Figure 7B). A "beads on a string" deformed structure is composed of very small particles (50−100 nm in diameter) and string parts (∼70 nm in width and 2−5 nm in height). The beads on a string structure observed on the positively charged surface must consist of DNA-rich fragments associated with some lipid components. The **DCP-spm**(PCL)/DNA lipoplex maintains its spherical structure on bare mica (Figure 7C). On the PLL-mica, on the other hand, deformed structures were observed as in the case of **DCP-spm**(PCL)/DNA lipoplex (Figure 7D). Such morphological changes upon acidification result from disassembly of the lipoplexes and the accompanying DNA release. Gel electrophoretic analysis provided evidence for the DNA release; the released plasmid band increased with the acidification from pH 8 to pH 4 (Supporting Information Figure S4). In sharp contrast, such a morphological change was not observed for the micellar aggregate **DCP-spd**(M) (Figure 7E,F). DLS analysis indicates an insensitivity of the micellar aggregates to acidification (Table 1, entries 6 and 12).

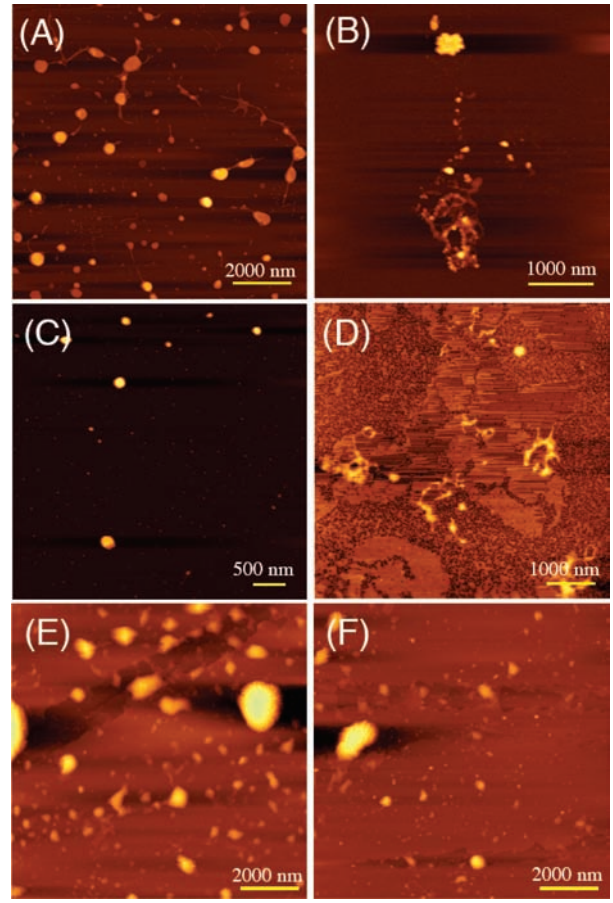

Figure 7. AFM images of disassembled lipoplexes, **DCP-spd**(PCL)/DNA (A and B) and **DCP-spm**(PCL)/DNA (C and D) by acidification at pH 4. Images (E) and (F) represent the micellar aggregate **DCP-spd**(M)/DNA complex before and after the acid treatment, respectively. The acid-treated suspensions of complexes were put on bare mica (A,C,E,F) and PLL-mica (B,D). After removal of the solution, the images were acquired. Scale bars: 2000 nm (A), 1000 nm (B), 500 nm (C), 1000 nm (D), 2000 nm (E) and (F).

DISCUSSION

Chemical Structure of the Polyamine Conjugates. The polyamine-dialkyl phosphate conjugates can be readily synthesized via a two-step reaction: (i) formation of dimerized dialkyl phosphate anhydride and (ii) its nucleophilic substitution with polyamines. The synthetic strategy gives access to a wide variety of polyamine−dialkyl phosphate derivatives. Conjugation of the polyamine and hydrophobic portions is required for an effective gene carrier (Figure 1). Such amphiphilicity is essential to condense DNA molecules, which requires both electrostatic and hydrophobic interactions (*45*, *49*). We tested a number of combinations of dialkyl and polyamine portions for their activity in gene transfection. The longer alkyl chain exhibited higher efficiency (Figure 3). The ζ-potential of the DOPE-based PCL increased with alkyl chain length, for example, 27.6, 33.4, and 37.1 mV for **DLP-spd**, **DMP-spd**, and **DCP-spd**, respectively, showing that the conjugate with the longer chain length provides the higher positive potential. The hydrophobic interaction results in stable incorporation of the conjugate into the PCL, consistent with transfection activity in the order of C16 ≥ C14 > C12. We found that the micellar aggregate of **DCP-PEI** conjugate exhibited slightly higher transfection activity than the low-molecular-weight amine conjugates, **DCP-spd**(M) and **DCP-spm**(M); however, the activity of **DCP-PEI**(PCL) was marginal. The size of **DCP-PEI**(PCL)/DNA lipoplex is significantly greater than that of the other lipoplexes (Table 1, entry 14). The **DCP-PEI** conjugate is composed of DCP/PEI(1800) = ∼1/1, judged by ^{1}H NMR (*49*). As previously reported, the cetyl-PEI, whose PCL possesses high transfection activity, consists of 10 cetyl portions in the polymer (*47*). The cetyl-PEI can attach to the PCL surface via the anchoring of cetyl portions in the lipid bilayer. However, that is not the case for **DCP-PEI**(PCL); the single hydrophobic portion in the conjugate is not enough to provide adequate covering of PEI over the PCL surface. This may cause "PEI-protrusion" from the surface, which gives rise to the large and heterogeneous aggregation seen upon combination with DNA molecules. This is likely the reason for the lower activity of the **DCP-PEI**(PCL). Taken together, these consid-

erations suggest that a homogeneous positive charge distribution on the PCL surface is important to the transfection activity.

Effect of Bilayer Structure on the Transfection Activity. In the series of polyamines tested in this study, the low-molecular-weight polyamines were found to be more effective gene carriers when these conjugates were assembled into PCLs. The transfection activity of the PCL was ~3 times larger than as the corresponding micellar aggregate (Figure 1). The effect of the helper lipid, DOPE, was clearly substantial, as is shown in Figure 2. DOPE, a predominantly nonlamellar lipid, is thought to facilitate fusion and destabilization of the endosomal membrane after uptake of cationic lipid/DNA complexes into a cell. In our previous report, we described intercellular trafficking of PCL (composed of cetyl-PEI and DOPE)-DNA complexes, which were taken up into cells by endosomal pathway (*48*), followed by endosomal escape. In fact, transfection activity of the present PCLs was inhibited by nigericin, which is able to dissipate the pH gradient across the endosomal membranes, by 30−50%, suggesting that endosomal pathway is likely involved in the mechanism in the present lipoplex system. It appears, therefore, that the mechanism of the lipofection by the compounds in this study may be similar to that of this and other agents known to be enhanced by DOPE. The lipoplexes made from the bilayer-structured PCLs evidently involve lamellar assemblies, given that AFM images reveal the presence of step-like profiles ((ii) and (iii) in Figure 6). The step-like profiles imply a lamellar complex, in which DNA rods (2 nm in diameter) are laminated between bilayers (4 nm thickness). Such an intrinsic bilayer structure may predispose lipoplexes to interact with cell and endosomal membranes. This is not the case for micellar aggregates, whose morphology is large spheres (Figure 7E and Table 1 entry 5), in which polyamine conjugate and DNA molecules likely aggregate randomly. This may be one of the reasons for the higher activity of PCL-based lipoplex, whose size is more favorable to transfection.

The linear dependence of activity on N/P (Figure 4) is related to the morphology of the lipoplex. The electrophoresis experiment (Figure 5) and AFM images (Figure 6A−D) suggest a reasonable explanation of the dependence, namely, the following: In the low N/P range (~5), the PCLs inadequately condense DNA molecules, giving the bead-like structures (Figure 6A,B). The DNA molecules loosely packed in the complex are readily released during electrophoresis. Such a complex, whose ζ-potential is negative, is too large to be introduced into the cell membrane via endocytosis; therefore, the transfection level is low. With increasing N/P ratio, the morphology of the lipoplex transforms from large bead-like structure into smaller particles, wherein DNA molecules are condensed more tightly (Figure 6C,D). The size of the lipoplexes, whose ζ-potential is positive, is 150−400 nm, more favorable for cellular uptake via endocytosis (*30*). Given that the lamellar assembly in the lipoplex is responsible for its effectiveness as a gene carrier (*29*, *30*), the population of active species for gene transfer would increase with increasing in the N/P. Although highly positive-charged carriers are generally toxic, the PCL described here exhibit low cytotoxicity, an advantage for in vitro and in vivo applications.

Disassembly of the Lipoplexes and DNA Release. Facile escape from the acidic endosomal compartment is necessary for efficient gene transfer. Disassembly of the lipoplex associated with DNA release has been clearly observed by AFM imaging (Figure 7) and by electrophoretic analyses (Supporting Information Figure S3). Upon acidification (down to pH 4), the extent of protonation of the polyamine portion is increased. Assuming that the lipoplex forms smectic lamella, electrostatic repulsion between layers must be increased with such protonation, resulting in the disruption of the lipoplex. For lipoplexes composed of **DCP-spd**(PCL) and **DCP-spm**(PCL), disruption accompanying DNA release has been confirmed. In sharp contrast, the size and shape of micellar aggregate/DNA complexes composed of **DCP-spd** and **DCP-spm** are insensitive to acidification (Figure 7F and Table 1, entries 6 and 12). This would be due to their amorphous structure, which does not respond to pH change. Thus, the disassembly of the lipoplex composed of the bilayer-structured PCL is essential in effective gene transfer, especially in the process of endosomal escape, where lipid exchange and flip−flop are involved in disrupting the membrane and leading to DNA release (*42*). Although the acidity of this experimental condition (pH 4) seems higher than that in endosome (pH 5.5), such a protonation process on the polyamines should be involved in the endosomal environment, because the protonation on the polyamines whose pK_a values are >8 may proceed rather gradually in the acidic region, especially in the self-assembled lamellar structure, where polyamines are densely packed. This finding suggests a strategy for molecular design—especially in the polyamine portion—in which a morphological transformation of lipoplexes is taken advantage of for new nonviral transfection strategies.

CONCLUSION

We have demonstrated that PCL composed of the low-molecular-weight polyamine conjugates, DCP-spermidine (**DCP-spd**) and DCP-spermine (**DCP-spm**), exhibit much higher gene transfer activity than PEI(1800) conjugate-based **DCP-PEI**(PCL). The former compounds generate 150−400 nm diameter lipoplexes, whereas the latter gives rise to large aggregates. In the case of the former compounds, AFM images clearly reveal a morphological change upon acidification, indicating DNA release from the lipoplexes, whereas in contrast, the morphology of micellar aggregates is insensitive to pH change. A pH-dependent transformation is crucial in gene transfer, and the chemical structure of the polyamine portion may therefore play an important role in the acidification-induced transformation. We have also described the relation between the N/P dependence of transfection activity and the morphology of the lipoplexes as revealed by AFM. Morphological study with AFM provided useful information for understanding the basis of lipoplexes with superior activity and for design strategies leading to optimally efficient gene carriers.

ACKNOWLEDGMENT

The authors thank Dr. Robert C. MacDonald for helpful comments and discussion. The present work was partially supported by "Grant-in-Aid for Scientific Research on Innovative Areas 2006 (Molecular Science of Fluctuations toward Biological Functions)" (21107510) from the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of the Japanese Government.

Site-Specific, Orthogonal Labeling of Proteins in Intact Cells with Two Small Biarsenical Fluorophores

Alexander Zürn,[§] Christoph Klenk,[§] Ulrike Zabel,[§,#] Susanne Reiner,[§] Martin J. Lohse,*[,§,#] and Carsten Hoffmann[§]

Institute of Pharmacology and Toxicology, Rudolf Virchow Center University of Würzburg, Versbacher Strasse 9, 97078 Würzburg, Germany. Received September 7, 2009; Revised Manuscript Received January 19, 2010

The fusion of fluorescent proteins to proteins of interest has greatly advanced fluorescence microscopy, but is often limited by their large size. Here, we report site-specific, orthogonal labeling of two cellular proteins in intact cells with two small fluorescent dyes: fluorescein arsenical hairpin binder, FlAsH, and its red analogue, ReAsH, which bind to tetracysteine motifs. Development of a sequential labeling method to two different motifs, CCPGCC and FLNCCPGCCMEP, allowed site-specific labeling with FlAsH and ReAsH, respectively. Using the cell surface receptor for parathyroid hormone and its cytosolic binding protein, β-arrestin2, we show their selective visualization in intact cells and analyze their interaction by colocalization and fluorescence resonance energy transfer (FRET). We propose that this method may be widely applied to label intracellular proteins and to study their interactions in intact cells with minimal disturbance of their function.

INTRODUCTION

Fluorescence microscopy of cellular and subcellular structures generally requires the use of fluorophores. These fluorophores can be attached, for example, to antibodies in order to visualize specific proteins and structures. However, in intact cells this approach is mostly limited to cell surface proteins, because the labeled antibodies cannot pass the cell membrane. This situation has been greatly advanced by the discovery of the green fluorescent protein (GFP) and its many colored variants, which can be fused to proteins of interest and permit their visualization (*1*). To date, numerous variants of GFP and other fluorescent proteins, characterized by different fluorescent properties, have been described, and permit various fluorescence techniques to study the localization and interaction of proteins in intact cells, including fluorescence resonance energy transfer (FRET) (*2*). However, protein function may be disturbed by fusion with the ~27 kDa GFP molecule and limit their use for in vivo imaging (*3–5*). Moreover, GFPs are often fused to proteins via a flexible linker, and this together with the size of GFPs makes it difficult to predict the exact position of the central fluorophore in relation to the protein of interest.

Alternatives to GFPs include fusions with an O^6-alkylguanine-DNA-alkyltransferase (AGT), which binds covalently O^6-benzylguanine that can be chemically coupled with various fluorescent dyes. While this technique offers the advantage of using highly fluorescent dyes, the AGT tags are also of considerable size (~20 kDa). Depending on the dye used and its membrane permeability, this method can be used to label cell surface as well as intracellular proteins (*6–9*). Other enzymes that can be fused to proteins and permit labeling with a variety of fluorescent dyes include dihydrofolate reductase (together with fluorescent trimethoprim derivatives (*10*)) and a modified haloalkane dehalogenase designed to covalently bind to synthetic ligands (*11*).

A technique to minimize the size of the fluorescent dyes involves the insertion of an oligo-histidine tag into the target protein. This motif can form a complex with a nitrilo triacetic acid (NTA)-Ni^{2+}, which can again be coupled to fluorophores. By combining different fluorescently labeled NTA-variants, FRET measurements have been done with purified proteins (*12*). Labeling of proteins at the extracellular face of intact cells has also been shown, but the fluorophores did not cross the cell membrane and thus did not permit labeling of intracellular proteins (*13*). With sizes of 2−5 kDa, these complexes are much smaller than the GFP-variants or the AGT-tag, but their low affinity results in a low stability of the complex (*14*).

To circumvent these problems, a much smaller, chemical fluorescent label was reported as an alternative. The 700 Da fluorescein derivative FlAsH (fluorescein arsenical hairpin binder) and the resorufin derivative ReAsH (red arsenical hairpin binder) have been shown to bind to a tetracysteine motif (CCPGCC) with high affinity and specificity (*15, 16*). Such tetracysteine motifs can be genetically introduced into proteins. Labeling of tetracysteine-motif containing proteins requires a labeling step that results in a complex formation between the label and the tetracysteine motif. This needs to be followed by a washing procedure to minimize unspecific background staining. This labeling technique has been used for cytosolic as well as membrane proteins (*17, 18*). FlAsH can be used as an alternative to YFP and forms a FRET pair with CFP. Using FlAsH instead of YFP, we were able to rescue the functionality of a G-protein coupled receptor (GPCR), which was inactive when labeled with YFP in its third intracellular loop (*3*).

However, for FRET (or colocalization) studies, this approach still required CFP (or a similar protein) as a second label, and it would seem attractive to also replace this second label by a small one. Therefore, further studies have been undertaken to simultaneously label and visualize two different proteins within a cell using two small fluorophores. Different approaches for simultaneous labeling with FlAsH and ReAsH have been described. Robia et al. (*19*) cloned two CCPGCC sequences into the sarcoplasmic reticulum protein phospholamban and stained cells expressing this construct by simultaneous incubation with ReAsH and FlAsH; this resulted in random labeling of phospholamban with either FlAsH or ReAsH. Interestingly,

phospholamban, a small protein of 5 kDa, still formed pentamers after labeling, indicating that the protein had remained functional (*19*). Roberti et al. (*20*) performed nondirected labeling with the two small fluorophores of α-synuclein aggregates in vitro and in cells. Finally, Squier et al. presented a tetracysteine motif, CCKACC, with different binding rates and affinities for FlAsH and ReAsH compared to the CCPGCC motif; this allowed sequential labeling, but this approach has so far been done only with purified proteins (*21*).

Despite these studies demonstrating the value of biarsenical dyes, site-specific labeling of two different proteins with FlAsH and ReAsH in intact cells has not yet been achieved. However, such specific labeling would be necessary to distinguish two different proteins by different labels in order to achieve the full power of fluorescence microscopy and FRET techniques. Therefore, we set out to develop such specific labeling of intracellular proteins. To do so, we utilized different tetracysteine motifs (*22*) and developed a selective and specific labeling protocol. We show that a cell surface and a cytosolic protein—the parathyroid hormone (PTH) receptor and its binding protein β-arrestin2—can be specifically labeled with FlAsH and ReAsH in the same cell and their known interaction (*23*) can then be visualized by colocalization and FRET studies.

EXPERIMENTAL PROCEDURES

Reagents. FlAsH and ReAsH are commercially available from Invitrogen as TC-FlAsH and TC-ReAsH, respectively. Human [$Nle^{8,18}$,Tyr^{34}]PTH(1−34), abbreviated as PTH(1−34), was obtained from Bachem. 1,2-Ethane dithiol (EDT) was from Sigma-Aldrich and British anti-Lewisite (BAL; 1,2-dimercaptopropanol) from Fluka. All other reagents were of the highest available grade from standard sources, generally from Sigma-Aldrich.

Molecular Biology. cDNA-sequences coding for a FLNCCPGCCMEP or a HRWCCPGCCKTF sequence (*22*) followed by those for CFP or YFP were fused to the very C-terminus of the A_{2A}-receptor cDNA. These constructs served for the analysis of the affinities for the twelve amino acid FlAsH binding motifs. The six amino acid motif CCPGCC was inserted in the third intracellular loop the A_{2A}-receptor after the position 215 (*3*), resulting in a sequence MESCCPGCCARS, and a CFP or YFP was fused to the receptor sequence after position 340.

Similarly, a FLNCCPGCCMEP motif (or a CCPGCC motif) was inserted into the C-terminus of the human PTH receptor following amino acid position 515. Likewise, a CCPGCC motif (or a FLNCCPGCCMEP motif) with a linker sequence was fused to the very C-terminus of β-arrestin2, resulting in an addition of KQMESCCPGCCARSTLQ (or KQMESFLNCCPGCCMEPARSTLQ), i.e., the same amino acid motifs as above. Site-directed mutagenesis was achieved using standard polymerase chain reaction techniques followed by DNA-sequencing for verification. For transient expression in mammalian cells, all cDNAs were cloned into the pcDNA3 vector (Invitrogen).

Cell Culture. HEK cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum, 100 000 U/L penicillin and 100 mg/L streptomycin at 37 °C and 7% CO_2. For fluorescence measurements, cells were seeded on round polylysine-coated coverslips in 6-well plates 6 h prior to transfection. Cells were transfected using Effectene (Quiagen) according to the manufacturer's instructions. Assays were performed 48 h after transfection.

FlAsH and ReAsH Labeling. Transfected cells grown on polylysine-coated 24 mm coverslips to a confluence of about 70% were washed twice with 1 mL Phenol red-free Hank's balanced salt solution containing 1.8 g/L glucose (HBSS; Invitrogen) and incubated at 37 °C and 7% CO_2 for 1 h with 1 mL 2.5 μM ReAsH, 12.5 μM EDT in HBSS. Subsequently, cells were washed once with 1 mL HBSS. To reduce nonspecific labeling, cells were next incubated for 10 min at 37 °C and 7% CO_2 with 1 mL 250 μM BAL in HBSS and washed again with 1 mL HBSS. Subsequently, cells were incubated at 37 °C and 7% CO_2 for 1 h with 1 mL 250 nM FlAsH, 12.5 μM EDT in HBSS, washed again with HBSS, incubated for 10 min with 1 mL 250 μM EDT in HBSS, and finally washed twice with HBSS.

Determination of FlAsH and ReAsH Affinities. As a measure of the affinity of FlAsH and ReAsH to different binding motifs, we determined the concentration−response curves of the removal of the fluorophore by BAL. After labeling of transfected HEK cells, crude cell membranes were prepared by lysis with an Ultra-Turrax device and centrifugation at 120 000 × *g*. The membranes were resuspended in 500 μL of 50 mM Tris-buffer, pH 7.4, and FlAsH or ReAsH fluorescence were measured in a spectrofluorometer (Perkin-Elmer LS50B) in a 600 μL cuvette. The excitation wavelength for the CFP-FlAsH constructs was 436 nm and the emission spectrum was measured at 460−600 nm. For the YFP-ReAsH constructs, the excitation wavelength was 490 nm and the emission spectrum was measured at 500−700 nm. To determine the affinity of the fluorophores to the individual binding motifs, the concentration of BAL was increased stepwise. FRET between the two labels in a given construct was determined as the ratio between the emission of the donor (CFP or YFP; at 490 or 525 nm) and the emission of the acceptor (FlAsH or ReAsH; at 525 or 608 nm).

Confocal Microscopy. HEK cells were transfected with cDNA constructs coding for the PTH receptor or β-arrestin2, respectively, and labeled with FlAsH and ReAsH as described above. Coverslips were mounted using an Attofluor holder (Molecular Probes).

Images were taken on a Leica TCS SP5 confocal microscope with a 63 × 1.4 oil objective. For excitation of FlAsH, the 514 nm line of an argon laser was used, and fluorescence intensities were recorded from 520 to 560 nm. ReAsH was excited using a 594 nm laser line, and fluorescence intensities were recorded from 600 to 700 nm. Settings for image acquisition were kept constant at 1024 × 1024 pixel format and 400 Hz. Time series were recorded using the standard Leica software package. The pictures were taken sequentially at 3 min intervals. For the β-arrestin2 translocation, the time series were stopped after 9 min, and for receptor internalization, image acquisition was terminated after 18 min.

Measurement of Intracellular Free Calcium Responses. HEK cells were grown on polylysine-coated 24 mm coverslips to a confluence of about 70%. The cells were transfected with PTH-receptor cDNA constructs using Effectene (Quiagen) according to the manufacturer's instructions. Assays were performed 48 h after transfection. To load the calcium indicator, cells were incubated for 35 min at 37 °C in loading buffer (10 mM HEPES, 140 mM NaCl, 5.4 mM KCl, 1 mM $MgCl_2$, 2 mM $CaCl_2$) containing the calcium-sensitive dye, Fura-2 a.m. (1 μM), washed three times with loading buffer, and incubated at room temperature in the dark for 40 min. To determine Fura-2-fluorescence, an inverted fluorescence microscope was used (dichroic mirror, 455DCLP; filter set, 340 and 380 nm excitation filters and 520/20 emission filter), and the Ca^{2+} responses in single cells to stimulation with 10 nM PTH (1−34), added with a pipet, were measured by recording the Fura-2 fluorescence using *MetaMorph/MetaFluor* software (Visitron) and calculating the ratio of Fura-2 emission when excited at 340 nm and at 380 nm.

FRET Measurements with FlAsH and ReAsH. Dynamic FRET measurements using FlAsH as the donor and ReAsH as the acceptor were performed with a custom-built Zeiss Observ-

er.Z1 microscope equipped with a Visitron dual view, a DCLP 565 nm beam splitter, and 535/30 nm and 595/70 nm emission filters to monitor the FlAsH and ReAsH signals, respectively. An EXFO X-cite 120 lamp was used as the excitation source at a wavelength of 500 nm. Under these conditions, no direct excitation of ReAsH was measured. For bleedthrough of FlAsH into the ReAsH channel, a correction of 25% was determined in control experiments and applied. Data were measured using the *MetaFluor* software (Visitron), and *Origin6.1* (OriginLab) was used for analysis.

RESULTS

Affinity Measurements. In order to achieve selective binding of two small fluorophores to specific motifs, we aimed to identify motifs with different affinities toward FlAsH and ReAsH. Initially, we set out to assess the individual binding affinities of two recently described (*22*) 12-amino-acid high-affinity motifs (FLNCCPGCCMEP and HRWCCPGCCKTF). In order to study labeling and affinities in intact cells, we assessed these motifs in the context of the A_{2A} adenosine receptor, a prototypical G-protein coupled receptor (*3*). The two motifs were fused to C-terminus of the receptor, followed directly by CFP or YFP, respectively (Figure 1A). All constructs were expressed in HEK cells and showed specific membrane localization as measured by confocal microscopy (data not shown). In addition, to introduce a second label (for FRET studies) to a site with lower affinity, we expressed the similar A_{2A} adenosine receptor constructs carrying the core CCPGCC motif in their third intracellular loop (Figure 1A).

All constructs were labeled in HEK cells with either FlAsH or ReAsH, respectively, in order to allow intramolecular FRET between either CFP and FlAsH or YFP and ReAsH. Membranes were then prepared from the cells, and the emission spectra of each construct were measured. Figure 1B shows the emission spectra of a CFP- and FlAsH-labeled A_{2A} adenosine receptor (construct #5). The emission of both fluorophores, CFP (emission maximum at 480 nm) and FlAsH (emission maximum at 525 nm), were both clearly detectable in this spectrum when CFP was excited (436 nm). The strong emission of FlAsH under these conditions is indicative of FRET. Similarly, FRET was detected in membranes with an A_{2A} adenosine receptor labeled with YFP and ReAsH (construct #6; Supporting Information Figure 1).

FlAsH and ReAsH are fluorescent only when bound covalently to their tetracysteine motifs. British anti-Lewisite (BAL, dimercaptopropanol) can compete for binding and thus reduce their fluorescence signals (*22*). As a consequence, in the FRET-reporter constructs increasing BAL concentrations should decrease the emission of FlAsH or ReAsH, respectively, and because of ensuing lack of FRET increase the emission of the respective GFP-variant. This was indeed observed, with increasing concentrations of BAL causing the spectrum to shift progressively from two peaks of equal height (green curve) to one with a dominant CFP-emission and lacking FlAsH emission (cyan curve) (Figure 1B). The ratio between the emissions of CFP/FlAsH (or YFP/ReAsH) can be used to generate a kind of "competition curve" for BAL, and the IC_{50} value reflect the stability of FlAsH and ReAsH binding to the respective motif (i.e., a high IC_{50} value of BAL corresponds to a high stability).

These IC_{50} values were ~5.6 mM of BAL for FlAsH at the FLNCCPGCCMEP-motif, whereas the affinity for FlAsH at the HRWCCPGCCKTF motif was 2.3 mM of BAL. A clearly lower affinity for FlAsH was determined for the 6-amino-acid motif CCPGCC with 0.7 mM of BAL. For ReAsH, 3-fold lower affinities were determined for each motif, with IC_{50} values of 2.0 mM, 0.8 mM, and 0.2 mM of BAL, respectively (Supporting Information Table 1). Thus, the three tetracysteine motifs can be exploited for the development of a selective labeling protocol.

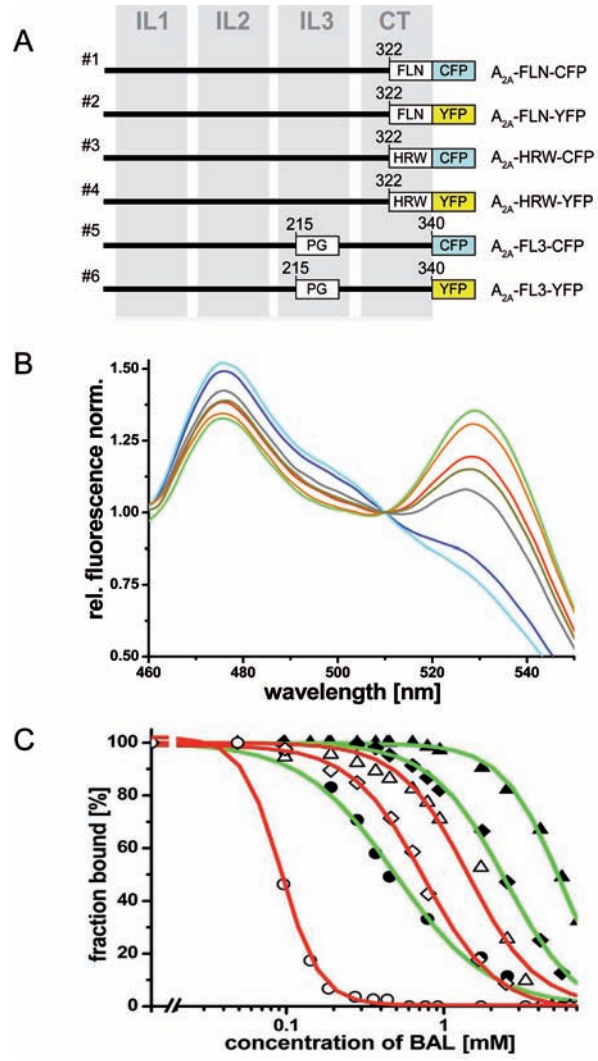

Figure 1. Characterization of FlAsH and ReAsH binding motifs in A2A-adenosine receptors. (A) Schematic representation of the different constructs. CFP or YFP were attached C-terminally after the indicated amino acid position. The 12-amino-acid tetracysteine motifs are denoted "FLN"for FLNCCPGCCMEP and "HRW" for HRWCCPGCCKTF. The 6-amino-acid tetracysteine motif CCPGCC is denoted "PG". Additional numbers denote the sites (amino acid number) of motif insertion. IL and CT denote intracellular loops and C-terminus, respectively. (B) Fluorescence emission spectrum of FlAsH-labeled A2A-FL3-CFP (construct #5) and disruption of FRET by increasing concentrations of BAL (0−4 mM), measured with 436 nm excitation. (C) Reduction of ReAsH and FlAsH binding to the different tetracysteine motifs by BAL. Shown is the fraction of the indicated motifs occupied by the respective label (FlAsH green curves, ReAsH red curves) as a function of the BAL concentration used to displace binding. Data are derived from experiments as shown in (B). Symbols denote: open circle, A2A-Fl3-YFP (construct #6), filled circle, A2A-Fl3-CFP (construct #5); open diamond, A2AHRW-YFP (construct #4); filled diamond, A2A-HRW-CFP (construct #3); open triangle, A2A-FLN-YFP (construct #2); filled triangle, A2A-FLN-CFP (construct #1). Data are representative measurements of three independent experiments. IC_{50} values are given in Supporting Information Table 1.

Selective Labeling in Intact Cells. In order to develop a double labeling protocol, we used two proteins, localized in two different cellular compartments in resting cells, that display a well-described, agonist dependent interaction: the cell surface parathyroid hormone receptor (PTH receptor, a G-protein coupled receptor) and its cytosolic binding protein β-arrestin2 (*23*). The motif with the highest affinity, FLNCCPGCCMEP, was inserted into the C-terminus of the PTH receptor, and the motif with the lowest affinity, CCPGCC, was fused to the

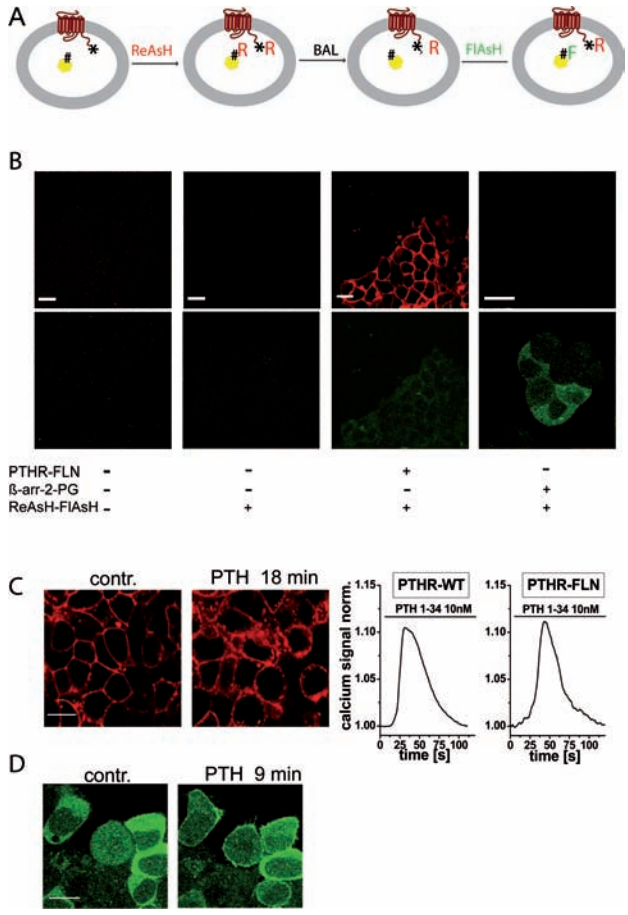

Figure 2. Specific labeling of the PTH receptor and β-arrestin2 in intact cells with ReAsH and FlAsH. (A) Schematic representation of the labeling protocol. Initially, the FLNCCPGCCMEP motif in the PTH receptor (*) as well as the CCPGCC motif in β-arrestin2 (#) were both covalently labeled with ReAsH (R). In a washing step with BAL, ReAsH was selectively removed from the CCPGCC motif in β-arrestin2. Finally, the latter motif was again labeled with FlAsH (F). (B) Specificity and completeness of labeling. The upper row of panels shows the ReAsH emission (594 nm laser line excitation, 600−700 nm emission); the lower row shows the FlAsH fluorescence (514 nm laser line excitation, 520−560 nm emission). The panels (from left to right) show nontransfected HEK cells before (left) and after (second from left) the labeling protocol (as depicted in (A)), HEK cells expressing only the PTH receptor construct (second from right) or the β-arrestin2 construct (both labeled as depicted in (A)). (C) Functional integrity of the ReAsH labeled PTH receptor. The left panels show receptor internalization in HEK cells in response to PTH (1 μM, 18 min; right) compared to unstimulated controls (left). The right panels show Ca^{2+}-responses to PTH (measured with Fura-2) in HEK cells transiently expressing wild-type or FLNCCPGCCMEP labeled receptors. (D) Functional integrity of FlAsH-labeled β-arrestin2. HEK cells transiently expressing unlabeled PTH receptors and FlAsH-labeled β-arrestin2 were stimulated with PTH (1 μM, 9 min; right) to induce translocation of β arrestin2 to the plasma membrane. White scale bars represent 10 μm.

C-terminus of β-arrestin2. HEK cells expressing both constructs were sequentially labeled with FlAsH and ReAsH with various protocols, resulting in the following optimal procedure (Figure 2A; see Experimental Procedures for further details). First, cells were incubated with 2.5 μM ReAsH for 1 h and then washed with 250 μM BAL for 10 min. This BAL concentration left >95% of FLNCCPGCCMEP motif in the PTH receptor bound with ReAsH, while almost all ReAsH was removed from the CCPGCC motif in β-arrestin2 (compare open circles and open triangles in Figure 1C). Subsequently, cells were incubated for another hour with 250 nM FlAsH, which allowed full labeling of the CCPGCC motif, while the FLNCCPGCCMEP motif remained "protected" by the already bound ReAsH. Finally, cells were subjected to a washing procedure using 250 μM 1,2-ethane dithiol (EDT) to reduce nonspecific labeling.

The specificity of this labeling protocol was ascertained in various control experiments (Figure 2B). First, we showed that background labeling, i.e., when no tetracysteine containing proteins were transfected, was negligible (Figure 2B, second from left), and in fact, fluorescence in both channels was not much different from totally unlabeled cells (Figure 2B, left). Furthermore, we confirmed that the two labels were bound to the correct sites, i.e., that indeed ReAsH already bound to the FLNCCPGCCMEP motif would protect this motif from subsequent labeling with FlAsH. To do so, we transfected HEK cells with the PTH receptor-FLNCCPGCCMEP construct alone and subjected these cells to the labeling protocol. Figure 2B (second from right) shows that indeed this resulted in clear cell surface staining with ReAsH, but essentially no labeling with FlAsH. This illustrates that despite its higher affinity FlAsH does not displace ReAsH from the FLNCCPGCCMEP motif and confirms the site specificity of the labeling procedure. Conversely, when HEK cells were transfected with the β-arrestin-2-CCPGCC construct alone and then labeled, this resulted in clear labeling of the cytosolic β-arrestin-2 with FlAsH but essentially no labeling with ReAsH (Figure 2B, right). Protein synthesis ongoing during the labeling process did not appear to cause a significant resynthesis of the first labeling motifs, as evidenced by very low background staining (Figure 2B, second from left), low FlAsH binding to receptors nearing the ReAsH motif (Figure 2B, second from right) and a lack of improvement when the labeling was done in the presence of the protein synthesis inhibitor cycloheximide (not shown). Taken together, these data indicate both negligible background staining and highly specific, orthogonal labeling of the two tetracysteine motifs with FlAsH or ReAsH, respectively.

The functional integrity of the labeled proteins after this labeling procedure was verified along several lines. First, the ReAsH-labeled PTH receptors were localized at the cell surface and internalized in response to stimulation with PTH (Figure 2C), indicating an intact activation switch and internalization process of the receptor construct. Second, the ReAsH-labeled receptors generated intracellular Ca^{2+} signals that were not different from the signals mediated by wild-type receptors (Figure 2C**)**, indicating intact coupling to G-proteins and downstream signaling. Finally, FlAsH-labeled β-arrestin2 translocated from the cytosol to the cell surface in response to stimulation of the PTH receptor (Figure 2D**)**, indicating an intact interaction between the two proteins and normal β-arrestin2 behavior (*23*).

Co-Localization and FRET Measurements. A number of experiments were then carried out to assess whether this site-specific labeling protocol allowed the study of protein colocalization and protein−protein interactions, using again the PTH receptor/β-arrestin2 interaction as a model. HEK cells, expressing PTH receptor-LNCCPGCCMEP and β-arrestin2-CCPGCC, were labeled as above. Analysis by confocal microscopy with the appropriate wavelengths showed the ReAsH-labeled receptors at the cell surface and the FlAsH-labeled β-arrestin2 in the cytosol. Stimulation of the cells with PTH caused translocation of β-arrestin to the cell surface, and this was visualized by an overlay of the ReAsH and FlAsH emissions (Figure 3A).

Scanning of such cells expressing the two labeled proteins allowed a quantification of the ReAsH label at the cell surface and of the cytosolic (control) vs cell surface (PTH-stimulated) localization of β-arrestin2 (Figure 3B). While the PTH receptors were primarily localized to the cell surface under both conditions, β-arrestin2 was evenly distributed throughout the cell under control conditions, but showed a preferential localization

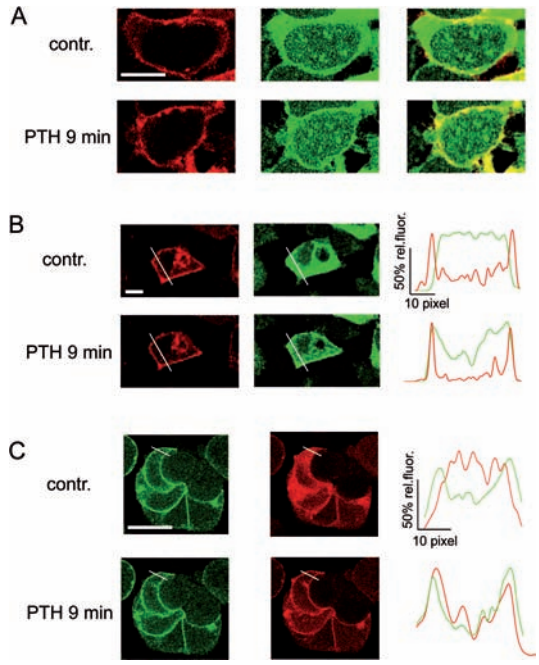

Figure 3. Interaction of ReAsH-labeled PTH receptors with FlAsH-labeled β-arrestin2 in HEK cells. (A) PTH-induced colocalization of receptors and β-arrestin2 at the plasma membrane. HEK cells expressing both ReAsH-labeled PTH receptors (FLNCCPGCCMEP motif) and FlAsH-labeled β-arrestin2 (CCPGCC motif) are shown prior to stimulation (top) or 9 min after stimulation with PTH (1 μM, bottom). Shown are the images of ReAsH emission (left), FlAsH emission (center), and the corresponding overlay images. The yellow color in the overlay images indicates co-localization of FlAsH and ReAsH labeled proteins. (B) PTH-induced translocation of β-arrestin2 to the plasma membrane represented by relative distribution of fluorescence intensity. FlAsH or ReAsH emission coming from labeled β-arrestin2 or labeled PTH receptor was quantified along the indicated white line before (top right) and after (bottom right) stimulation of the cells with PTH as in (A). The relative fluorescence intensity traces indicate a uniform distribution of FlAsH under control conditions and clear plasma membrane preponderance after receptor stimulation. (C) Same experiment as in (B), but with β-arrestin2 equipped with the FLNCCPGCCMEP motif and labeled with ReAsH, and the PTH receptor with the lower-affinity CCPGCC motif labeled with FlAsH. PTH-induced translocation of β-arrestin2 to the plasma membrane represented by confocal images (left) and relative distribution of fluorescence intensity (right). The relative fluorescence intensity traces indicate a uniform distribution of ReAsH under control conditions, and clear cell surface preponderance after receptor stimulation.

at the cell surface after stimulation with PTH. These experiments document that ReAsH and FlAsH can be used for selective labeling of specific proteins and to visualize their intracelluar (co)localization.

To demonstrate the versatility of our technique, we exchanged the tetracysteine tags, i.e., β-arrestin2 was equipped with the FLNCCPGCCMEP sequence (ReAsH motif), and the PTH receptor with the lower affinity CCPGCC sequence (FlAsH motif). Labeling was done as before and resulted in clear cytosolic ReAsH-labeling of β-arrestin2 and cell surface labeling of the PTH receptor with FlAsH (Figure 3C). The ReAsH-labeled β-arrestin2 again translocated to the cell surface upon receptor stimulation as visualized by confocal imaging (Figure 3C, left) and fluorescence quantification (Figure 3C, right).

To show that FRET can be measured between FlAsH and ReAsH, we first studied intramolecular FRET and labeled again an A_{2A}-adenosine receptor (as in Figure 1), carrying a CCPGCC sequence (FlAsH motif) in the third intracellular loop, and a FLNCCPGCCMEP sequence at the C-terminus, which was labeled at both sites as before. Partial acceptor photobleaching (550 nm, 500 s) caused an increase of donor fluorescence by almost 10%, indicative of FRET (Supporting Information Figure 2). Ratiometric quantification of agonist-induced changes in FRET was then used to study the dynamics of the interaction between β-arrestin2 and PTH receptors and to show that direct protein−protein interactions were the basis for their colocalization in cells stimulated with PTH (Figure 4). HEK cells transfected and labeled as in Figure 3A were excited at the appropriate wavelength for FlAsH (500 nm) and observed under wide-field conditions equipped to simultaneously image emission of FlAsH (535/30 nm) and ReAsH (595/70 nm). Addition of the agonist PTH caused a decrease of the FlAsH fluorescence, while the ReAsH fluorescence increased in a reciprocal manner with the same time course (Figure 4, left). As a consequence, the FRET ratio increased (Figure 4, right) and the time course of this increase corresponded to the previously described kinetics of the PTH receptor/β-arrestin2 interaction (*23, 24*). This behavior is indicative of the progressive development of FRET and illustrates that site-selective labeling with ReAsH and FlAsH can be used for specific FRET measurements.

DISCUSSION

Labeling of intracellular proteins with GFP and other fluorescent proteins variants has become an extremely popular tool in fluorescence microscopy. However, the limitations mentioned above have prompted a search for alternatives, most

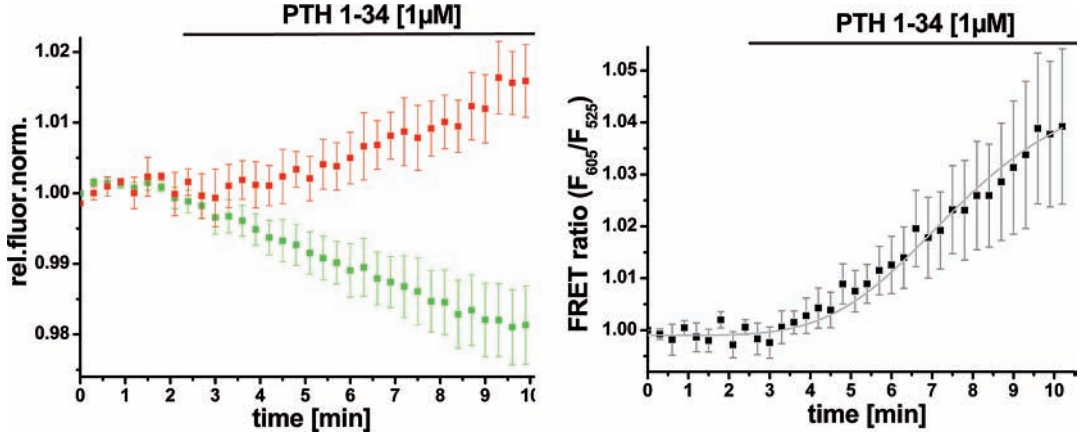

Figure 4. FRET between ReAsH-labeled PTH receptors (FLNCCPGCCMEP motif) and FlAsH-labeled β-arrestin2 (CCPGCC motif) in HEK cells. Exposure to PTH (1 μM) causes a decrease in FlAsH emission and a simultaneous increase in ReAsH emission (left), resulting in an increase in the emission ratio (595 nm/535 nm), which is indicative for FRET (right). Every time point shows the mean of five independent measurements and the SEM.

notably smaller labels, an issue that appears particularly important when labeling small and/or multifunctional proteins (*25, 26*). To achieve labeling of intracellular proteins with small labels in intact cells, the technique of tetracysteine motif labeling with FlAsH (or ReAsH) appears at present the most attractive approach, due to the small size of the labels (~0.7 kDa). An additional, and particularly useful property of these dyes is that they become fluorescent only when bound to these tetracysteine motifs (*2, 15*). Analogues with brighter fluorescence have also been synthesized (*27, 28*) and will add to the attractiveness of this technology. Applied to GPCRs, FlAsH-labels have not only been used to report agonist-induced conformational changes of receptors (*3, 29*), but also to pick up differences in agonist-induced changes in different positions of the third intracellular loop (*30*), illustrating the versatility of this label and the usefulness of its small size and the fixed binding to its recognition sequence.

In FRET studies using FlAsH, usually CFP (or a similar variant) is employed as the second label. Attempts to measure FRET between FlAsH and ReAsH have been reported, but they were based on nonselective, i.e., random labeling of tetracysteine motifs by the two labels (*20*). Such random labeling does not permit the identification of different proteins by specific labels; furthermore, it reduces the signal/noise ratio and complicates the molecular interpretation of FRET changes. With an isolated protein in vitro, Wilkins et al. (*31*) have recently achieved site-specific labeling with FlAsH using protection of sites with photocaged amino acids, but this approach has so far been used only with in vitro translated proteins and a single label.

To overcome these problems, we have developed here a sequential labeling procedure that results in site-specific, orthogonal labeling of two different tetracysteine motifs in intact cells. Applying this procedure to a cell surface GPCR and its cytosolic binding protein, β-arrestin2, we observed that the labeled proteins retained essential functions. Furthermore, we showed that the labeling was clearly site-specific, as evidenced by the cell surface vs cytosolic localization of the two labels and their distinct movements upon receptor stimulation. Finally, the specific labeling permitted the demonstration of the agonist-dependent interaction of the two proteins by co-localization and by FRET between the labels; the kinetics of this translocation and interaction agree with the well-known time course, which occurs over several minutes (*24, 32*).

The labeling procedure resulted in virtually no background labeling, but essentially complete labeling of the two sites, as evidenced by our inability to label the "ReAsH-site" with FlAsH after the ReAsH labeling step (see Figure 2B). The specificity and wide applicability of this method should also make the development of FlAsH analogues with improved fluorescent properties an attractive goal, to achieve wider variability of colors and combinations of different fluorophores. Our data suggest that with this method specific labeling of intracellular proteins may be generally achievable and may permit the study of intracellular proteins with minimal disturbance of their function.

ACKNOWLEDGMENT

Exchange Kinetics of Protein-Functionalized Micelles and Liposomes Studied by Förster Resonance Energy Transfer

Sanne W. A. Reulen and Maarten Merkx*

Laboratory of Chemical Biology, Department of Biomedical Engineering, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands. Received September 13, 2009; Revised Manuscript Received April 2, 2010

Protein-functionalized micelles and liposomes are attractive delivery systems for applications ranging from targeted drug delivery to molecular imaging. In particular, systems that use pegylated phospholipids have become popular, but little is known about the stability of these lipid-functionalized proteins toward exchange. In this study, Förster resonance energy transfer (FRET) between the fluorescent proteins ECFP and EYFP was used to investigate the lipid exchange behavior of protein-functionalized liposomes and micelles. Native chemical ligation was used as an efficient method to site-specifically couple varying amounts of proteins to pegylated phospholipids. No exchange was observed between protein-functionalized phospholipids in sterically stabilized liposomes. In micelles, however, protein-functionalized lipids were found to exchange with a half-time of exchange ranging from almost 2 h at room temperature to 4 min at 37 °C. These pegylated micelles remained intact at lipid concentrations down to 0.15 μM, indicating that they are even more stable than previously assumed. The results obtained in this study provide a useful frame of reference for assessing the potential role of protein exchange in biomedical applications of these lipid-based nanoparticles.

INTRODUCTION

Lipid-based nanoparticles such as micelles and liposomes are attractive delivery systems in a variety of biomedical applications including targeted drug delivery and molecular imaging (*1, 2*). An important development in this area has been the use of poly(ethylene glycol) (PEG) modified phospholipids. Incorporation of PEG-modified phospholipids in liposomes was shown to improve their biodistribution and half-time of circulation (*3*), most likely because the PEG shell prevents adsorption of proteins and cells. Pegylated phospholipids are also known to form relatively stable and well-defined micelles, allowing applications ranging from targeted delivery of hydrophobic drugs to their use as relatively small, macromolecular MRI contrast agents (*4*−*6*). Active targeting of micelles and liposomes has been accomplished by coupling targeting ligands such as proteins (*4, 7, 8*), peptides (*9, 10*), and carbohydrates (*11*−*13*) to the end of the PEG-chain, ensuring good accessibility of the targeting ligand. Typically, peptides and proteins are coupled to pegylated phospholipids by reaction of lysine or cysteine side chains to active esters or maleimide functionalities. However, the limited control of these classical bioconjugation reactions often yields heterogeneous conjugates and sometimes leads to protein inactivation.

An important property of protein-functionalized micelles and liposomes that has received little attention is their stability toward exchange of lipidated proteins. Successful therapeutic application of liposomes and micelles requires that the protein-functionalized phospholipids remain associated with the nanoparticle within the time frame of the experiment. While exchange of lipidated proteins has been studied previously for vesicles and other biologically relevant bilayer systems (*14*−*16*), such studies have not been reported for protein-functionalized micelles or sterically stabilized liposomes. Work by Silvius et al. showed that derivatization of phospholipids with PEG chains or protein domains can substantially enhance phospholipid transfer rates between egg phosphatidyl choline vesicles (*14*). However, phospholipid exchange was found to be much slower in the liposome preparations that are typically used for molecular imaging applications, which are stabilized by the incorporation of PEG-modified phospholipids and high concentrations of cholesterol (>30%). Exchange rates were also found to be highly dependent on the acyl chain length, with Li and co-workers reporting essentially no exchange for PEG2000-DSPE (*17*). The latter study used biotinylated PEG2000-DSPE, however, and the effect of protein conjugation was not taken into account. Desorption rates of pegylated phospholipids in PEG2000-DSPE micelles have recently been shown to be highly temperature dependent, with half-lives ranging from several days at 5 °C to less than 1 h at 30 °C (*6*).

We and others have recently explored the use of native chemical ligation (NCL) as an attractive chemoselective conjugation reaction to couple proteins site-specifically via their C-terminus to supported lipid bilayers, micelles, and liposomes (*18*−*20*). In this study, we applied Förster resonance energy transfer (FRET) between donor and acceptor fluorescent proteins (ECFP and EYFP, respectively) as a tool to study protein exchange in protein-functionalized micelles and liposomes. Micelles and liposomes with high and tunable protein/particle ratios were obtained by NCL of fluorescent proteins to cysteine-functionalized PEG2000-distearoylphosphatidyl-ethanolamine (DSPE) phospholipids (Figure 1a). The availability of these well-defined protein-functionalized micelles and liposomes allowed an in-depth characterization of the exchange kinetics of lipidated proteins under a variety of conditions (Figure 1b). Micelles containing a 1:1 ratio of ECFP and EYFP also provided an opportunity to investigate structural properties of micelles such as aggregation number and stability (Figure 1c,d).

N-(Lissamine rhodamine B sulfonyl) (rhodamine-DPPE), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (NBD-DPPE), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG2000-DSPE) were purchased from Avanti Polar Lipids. Cysteine-functionalized 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))2000] (Cys-PEG2000-DSPE) was synthesized as described previously (*19*). 4-(Carboxylmethyl) thiophenol (MPAA), Tris(2-carboxyethyl) phosphine hydrochloride (TCEP), and sodium 2-mercaptoethanesulfonate (MESNA) were purchased from Sigma.

Protein Expression and Purification. ECFP and EYFP with a C-terminal thioester were expressed using the IMPACT system (New England Biolabs) as previously described (*21*). Briefly, proteins were expressed in *E. coli BL21* (DE3) cells using IPTG induction. After protein expression, the cell pellet was harvested and proteins were extracted using the BugBuster protocol (Novagen). The proteins were obtained with C-terminal MESNA thioester using chitin affinity chromatography, followed by MESNA-induced cleavage of the protein−intein bond. The concentrations of ECFP with a C-terminal MESNA thioester (ECFP-MESNA) and EYFP with a C-terminal MESNA thioester (EYFP-MESNA) were determined by UV−vis using $\varepsilon_{434\ nm} = 29\,000\ M^{-1}\ cm^{-1}$ (*22*) and $\varepsilon_{514\ nm} = 84\,000\ M^{-1}\ cm^{-1}$ (*23*), respectively.

Cysteine−Liposome Preparation. Liposomes were prepared by lipid film hydration as described previously (*19*). A mixture of DSPC (37 μmol), Gd-DTPA-bis(stearylamide) (25 μmol), cholesterol (33 μmol), PEG2000-DSPE (2.5 μmol), and Cys-PEG2000-DSPE (2.5 μmol) was dissolved in $CHCl_3$/MeOH 4:1 (v/v) and concentrated under reduced pressure at room temperature. The obtained lipid film was hydrated in 2.5 mL HBS (10 mM HEPES, 135 mM NaCl, pH 7.4). This dispersion was extruded five times at 65 °C through 200 nm polycarbonate

membrane filters. Cysteine−liposomes were stored at 4 °C before further modification.

Synthesis of Protein-Functionalized Liposomes. Native chemical ligation of EYFP-MESNA (97 μM) to cysteine−liposomes (581 μM Cys-PEG2000-DSPE) was done for 24 h at 20 °C in HBS containing 50 mM MPAA and 10 mM TCEP and pH of 6.2. Similar conditions were used to ligate ECFP-MESNA (103 μM) to cysteine−liposomes (620 μM Cys-PEG2000-DSPE). The amount of lipidated protein was determined from SDS-PAGE analysis by integration of the bands of unreacted and lipidated protein. The liposome concentration was calculated from the lipid concentration that was determined via phosphate analysis, using the assumption of unilamellar liposomes and a lipid surface area of 0.6 nm^2 (*24, 25*). The number of proteins per liposome was then obtained by dividing the concentration of lipidated protein by the liposome concentration. The protein-functionalized liposomes were separated from nonreacted protein by ultracentrifugation for 1 h at 270 000 *g* and 20 °C using a Kontron Centrikon T-2060 ultracentrifuge with a TFT 70.38 rotor. The liposomal pellet was resuspended in HBS pH 7.4, and pellet and supernatant were analyzed using SDS-PAGE to confirm the separation between lipidated and unreacted protein. Protein-functionalized liposomes were stored at 4 °C.

Synthesis of Protein-Functionalized Micelles. 0.3 μmol Cys-PEG2000-DSPE was dissolved in chloroform and placed in a glass vial. After chloroform evaporation, the obtained lipid film was rehydrated in 0.1 M sodium phosphate pH 8.5 with 50 mM MPAA and 10 mM TCEP, vortexed for 2 min, followed by 5 min sonication. ECFP-MESNA and EYFP-MESNA were added in varying amounts depending on the required protein load per micelle and the pH was adjusted to ∼6.5 with 1 M sodium phosphate pH 9.2. After overnight incubation at room temperature, the protein micelles were analyzed using SDS-PAGE to check for complete conversion to the lipidated protein. Upon complete conversion, the average amount of proteins per micelle was calculated by simply dividing the protein concentration over the micelle concentration. The latter was calculated from the total amount of lipids and the previously reported aggregation number of 90 lipids per micelle. Protein-functionalized micelles were stored at 4 °C.

Preparation of NBD and Rhodamine-Containing Micelles. 0.9 μmol of Cys-PEG2000-DSPE and 0.02 μmol NBD-DPPE or 0.02 μmol rhodamine-DPPE in chloroform were placed in a vial. After chloroform evaporation, the obtained lipid film was rehydrated in HBS with 50 mM MPAA and 10 mM TCEP and vortexed for 2 min, followed by 5 min sonication. Micelles were stored at 4 °C.

Fluorescence Spectroscopy. Fluorescence emission spectra were recorded on a Varian Cary Eclipse photoluminescence spectrometer, equipped with a cuvette holder that was temperature controlled by a Peltier element. Liposomes and micelles were diluted separately and prewarmed in cuvettes. The liposomes or micelles were mixed in a 1:1 ratio, and protein−lipid or dye−lipid transfer was monitored by exciting the donor and monitoring the emission of the donor and acceptor for a certain time period. All spectra were corrected for wavelength-dependent efficiency of the instrument. The observed rates of exchange were obtained by fitting the emission ratio as a function of time using eq 1

$$\text{ratio}(t) = (\text{ratio}_{\text{end}} - \text{ratio}_{\text{start}}) \times (1 - \exp^{-kt}) + \text{ratio}_{\text{start}} \quad (1)$$

RESULTS AND DISCUSSION

Protein−Phospholipid Exchange between Liposomes. Liposomes were prepared containing 2.5% Cys-PEG2000-DSPE, 2.5% PEG2000-DSPE, 25% Gd-DTPA-bis(stearylamide), 37% DSPC, and 33% cholesterol by lipid film hydration as described previously (*19*). These sterically stabilized liposomes have previously been thoroughly characterized using both DLS and cryoTEM, showing very stable liposomes with an average diameter of 200 nm (*26*). The liposomes obtained in this manner were subsequently functionalized with thioester-modified ECFP or EYFP using native chemical ligation in the presence of the thiol MPAA (*27*) as a catalyst. After removal of unreacted proteins via ultracentrifugation, protein-functionalized liposomes were obtained containing ∼1300 ECFP/liposome or ∼1000 EYFP/liposome (Supporting Information Figure S1).

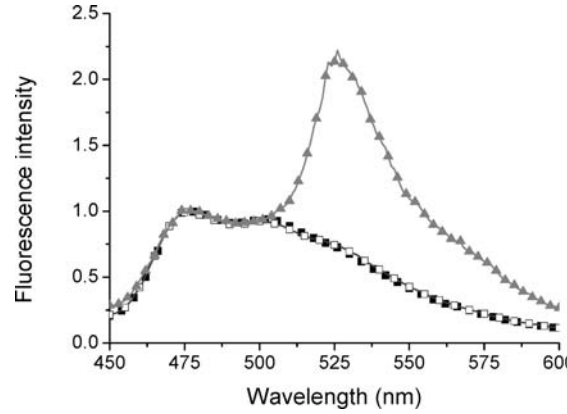

Figure 2. Characterization of protein−phospholipid transfer between ECFP-liposomes and EYFP/liposomes using steady-state fluorescence spectroscopy. All measurements were performed at 37 °C in 10 mM HEPES, 135 mM NaCl, pH 7.4, with a total protein concentration of 2.3 μM ([liposome] = 1.9 nM). Emission spectra were obtained using an excitation wavelength of 420 nm with a slit width of 10 nm, monitoring the emission from 450 to 600 nm with a slit width of 5 nm. The plot with the black squares shows a summation of the emission spectra of ECFP and EYFP liposomes measured before mixing (black squares). The spectrum labeled with open squares shows the emission spectrum obtained 23 h after mixing, while the emission spectrum labeled with gray triangles is from liposomes that contained approx 630 copies of ECFP and 630 copies of EYFP per liposome. All spectra were normalized to ECFP emission at 475 nm.

ECFP and EYFP liposomes were mixed at a 1:1 ratio, and emission spectra were monitored in time (Figure 2). Even after 24 h of incubation at 37 °C, the emission spectrum remained identical to the summation of the emission spectra of the separate ECFP and EYFP liposomes, consistent with the absence of any protein exchange between the liposomes under these conditions. Experiments at higher temperatures (55 °C) were hampered by the instability of the ECFP domain under these conditions, which prevented reliable measurements over prolonged periods of time. To establish that the surface density of proteins used here was sufficient to allow significant energy transfer between ECFP and EYFP when present on the same liposome, we also prepared liposomes that were reacted with a 1:1 mixture of ECFP- and EYFP-thioester. The emission spectrum of this control liposome, which contained approx 630 copies of ECFP and 630 copies of EYFP, indeed showed an intense EYFP peak at 527 nm when excited at 420 nm, providing clear evidence for energy transfer between ECFP and EYFP (Figure 2). Li et al. previously also did not observe any lipid exchange when monitoring the reaction at 37 °C for up to 25 h for biotinylated PEG2000-DSPE using a more indirect assay in the same type of liposomes (*17*). We thus conclude that in these liposomes protein functionalization does not result in an enhanced exchange of PEG2000-DSPE, at least not under the conditions and the time scale that are relevant for molecular imaging applications.

Protein−phospholipid Exchange between Micelles. Several studies have reported efficient transfer of pegylated phospholids from micelles to liposomes (*17, 28, 29*). In addition, Tirrell and

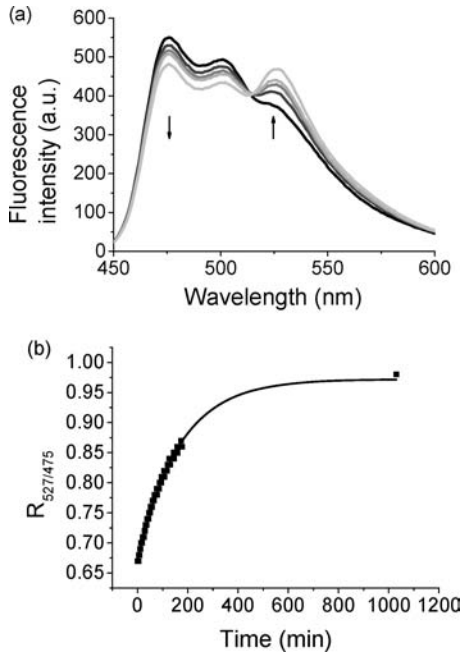

Figure 3. Monitoring protein exchange between ECFP-micelles and EYFP-micelles at 20 °C using steady-state fluorescence spectroscopy. All measurements were performed in HBS pH 7.4 with a protein−lipid concentration of 4.8 μM and a total lipid concentration of 40 μM. Emission spectra were obtained using an excitation wavelength of 420 nm with a slit width of 5 nm. Emission spectra (a) are shown after 0 min (black), 60 min (dark gray), 120 min (medium gray), 178 min (gray), and overnight incubation (light gray). (b) Plot showing the increase in emission ratio R527/475 as a function of time. The solid line represents a fit to eq 1 using a rate constant $k_{obs} = 1.0 \times 10^{-4}$ s^{-1}.

co-workers recently showed a desorption rate of ~3 h^{-1} at 30 °C for PEG2000-DSPE micelles (*6*). However, as far as we know exchange of pegylated phospholipids between micelles has not been studied for protein functionalized systems. Micelles containing an average of 11 copies of EYFP or ECFP were prepared via native chemical ligation with MPAA as the catalyst (*20*). SDS-PAGE analysis showed essentially complete conversion of ECFP and EYFP to their lipidated forms (Supporting Information Figure S2). Structural characterization of these preparations using dynamic light scattering (DLS) showed the presence of well-defined protein micelles with an average diameter of 14 nm and only a very small amount of larger aggregates (Supporting Information Figure S3). These ECFP- and EYFP-functionalized micelles are thus similar to the previously characterized CNA35-micelles, and do not show a higher tendency to form other aggregates (*20*). Protein exchange was observed after mixing the ECFP and EYFP micelles at room temperature as evidenced by the decrease in ECFP emission at 475 nm and the concomitant increase in EYFP emission at 527 nm (Figure 3). However, at 20 °C the exchange is still slow. A fit of the emission ratio as a function of time yielded an observed rate of 1.0×10^{-4} s^{-1}, corresponding to a half-life of almost 2 h at room temperature (Table 1). Since protein micelles are typically used at higher temperatures, we also monitored the exchange reaction at 28 and 37 °C (Figure 4). Protein exchange was strongly dependent on the temperature, showing a half-life of only 4 min at 37 °C. Please note that the final emission ratio that is reached at equilibrium is different at various temperatures, probably reflecting differences in temperature-dependent fluorescent properties of ECFP and EYFP. Exchange experiments were also performed at lower protein functionalization levels to exclude the possibility that interactions between donor and acceptor proteins influenced the exchange kinetics. Similar exchange rates were observed for micelles carrying on average 5 and 2 proteins per micelle (Table 1), suggesting that protein−protein interactions did not affect the rate-limiting step in the exchange reaction. (Supporting Information Figure S4).

To understand the contribution of the protein and the PEG chain on the protein−phospholipid transfer rate, we also studied the exchange of phospholipids that contained nitrobenzoxazole (NBD) and rhodamine as donor and acceptor dyes directly attached to the phosphate ester headgroup. Cys-PEG2000-DSPE micelles were prepared containing either 2.5 mol % of rhodamine-DPPE or NBD-DPPE and exchange was monitored at 37 and 55 °C (Supporting Information Figure S5). At 37 °C, the exchange of the dye-labeled phospholipids was observed to be 50× slower than the exchange of the protein-PEG2000-DSPE conjugates under otherwise similar conditions (Table 1). Very similar exchange rates were observed for micelles containing PEG2000-DSPE lacking the cysteine functionality, thus excluding the possibility that the slow exchange rate was affected by possible disulfide bond formation. Direct comparison of the exchange rates between the dye−lipid system and the protein-PEG2000-lipid system is difficult because the acyl tail in the dye−lipid system is two carbon atoms shorter. Since lipid exchange rates are highly dependent on the acyl length of the lipid tail and exhibit slower transfer rates upon increasing tail lengths (*30*), we expect that the half-time of exchange of dye−DSPE lipids would be even slower. This in turn implies that introduction of protein and PEG chain together enhanced the rate of phospholipid exchange more than 50-fold.

Concentration Dependence of Protein−Phospholipid Transfer between Micelles. Dissociation of amphiphiles from micelles into solution is generally considered to be the rate limiting step in phospholipid exchange (*31*). However, some studies on mixed micelles have found an increase in exchange rates at high micelle concentrations, suggesting a role for micelle collisions in the transfer reaction (*32*). To investigate the role of such collisions on the exchange rate of protein−phospholipid in micelles, additional exchange experiments were performed at higher lipid concentrations. Micelles containing an equimolar amount of ECFP and EYFP were first prepared by mixing ECFP and EYFP micelles at 37 °C until full exchange was reached. Next, a large excess of nonfunctionalized PEG2000-DSPE micelles was added and the transfer of fluorescent proteins was monitored by the decrease in FRET. Figure 5 shows the emission ratio as a function of time after adding PEG2000-DSPE micelles (594 μM PEG2000-DSPE) to the mixed ECFP−EYFP micelles (40 μM Cys-PEG2000-DSPE) at 20 °C, 28 °C, and 37 °C. The exchange rates observed at these high PEG2000-DSPE concentrations are similar to the rates obtained in the initial experiments where the formation of mixed micelles was monitored at 15-fold lower PEG2000-DSPE concentrations (Table 1). This observation shows that collisions between micelles do not play a significant role in protein exchange, rendering dissociation of the protein-PEG2000-DSPE from the micelle the most likely rate-limiting step in the transfer reaction. In addition, the exchange rates observed in this study for ECFP- and EYFP-functionalized Cys-PEG2000-DSPE micelles are similar to the desorption rates reported by Tirrell and co-workers for PEG2000-DSPE micelles at 20 and 28 °C (*6*). This finding thus confirms that desorption of protein-functionalized PEG2000-DSPE is the rate-limiting step in the exchange process and suggests that protein functionalization does not significantly increase exchange rates for these pegylated phospholipids.

Structural Properties of Protein-Functionalized Micelles. Micelles functionalized with ECFP and EYFP not only provide a straightforward manner to study the kinetics of protein exchange, but they also offer an opportunity to probe structural properties of these micelles. The protein−micelle ratios reported

Table 1. Characteristics of the Transfer Process between Micelles Using ECFP and EYFP or Rhodamine and NBD as Probes

mixing process between	[total lipid] (μM)	T (°C)	k_{obs} (s^{-1})[a]	$t_{1/2}$ (min)[b]
ECFP ($n = 11$) + EYFP ($n = 11$) micelles	40	20	$1.0 \times 10^{-4} \pm 1.5 \times 10^{-6}$	115.5
ECFP ($n = 11$) + EYFP ($n = 11$) micelles	40	28	$6.0 \times 10^{-4} \pm 8.1 \times 10^{-6}$	19.3
ECFP ($n = 11$) + EYFP ($n = 11$) micelles	40	37	$2.9 \times 10^{-3} \pm 6.9 \times 10^{-5}$	4.0
ECFP ($n = 5$) + EYFP ($n = 5$) micelles	40	37	$1.7 \times 10^{-3} \pm 5.2 \times 10^{-5}$	6.8
ECFP ($n = 2$) + EYFP ($n = 2$) micelles	40	37	$2.2 \times 10^{-3} \pm 2.6 \times 10^{-4}$	5.3
rhodamine + NBD micelles	40	37	$5.6 \times 10^{-5} \pm 1.3 \times 10^{-6}$	206.3

ECFP-EYFP micel + unfunctionalized micelles	627	20	$1.7 \times 10^{-4} \pm 3.8 \times 10^{-6}$	68.0
ECFP-EYFP micel + unfunctionalized micelles	627	28	$4.7 \times 10^{-4} \pm 2.9 \times 10^{-6}$	24.6
ECFP-EYFP micel + unfunctionalized micelles	627	37	$2.6 \times 10^{-3} \pm 2.6 \times 10^{-5}$	4.5

[a] The observed rate constants (k_{obs}) were calculated using eq 1. [b] The half-times of decay ($t_{1/2}$) were calculated using the relation $\ln 2/k_{obs}$.

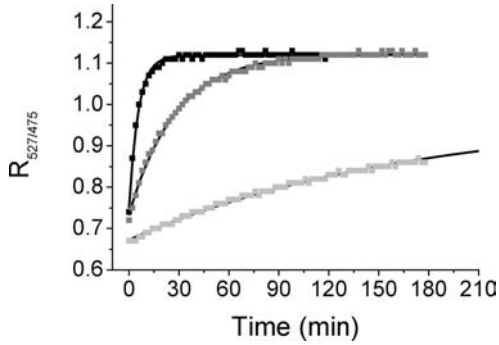

Figure 4. Comparison of protein exchange between ECFP-micelles and EYFP-micelles at 20 °C (light gray), 28 °C (dark gray), and 37 °C (black) using steady-state fluorescence spectroscopy. All measurements were performed in HBS pH 7.4 with a protein−lipid concentration of 4.8 μM and a total lipid concentration of 40 μM. The exchange was monitored by exciting ECFP at 420 nm and monitoring the EYFP to ECFP ratio (527 nm/475 nm) over time with excitation and emission slit widths of 5 nm. Plots of the emission ratio as a function of time were fitted to eq 1 (black lines).

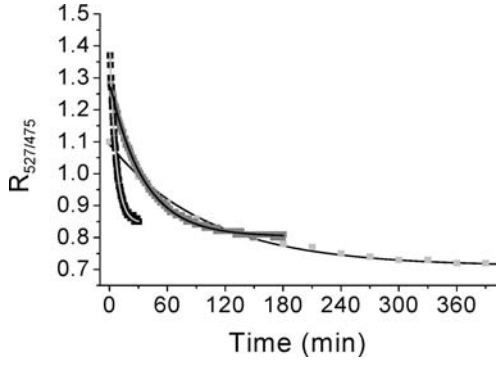

Figure 5. Exchange of ECFP-EYFP micelles with high concentrations of unfunctionalized PEG2000-DSPE micelles monitored using steady-state fluorescence spectroscopy. All measurements were performed in HBS pH 7.4 with a protein−lipid concentration of 4.0 μM and a total lipid concentration of 627 μM. The exchange was monitored by exciting ECFP at 420 nm and monitoring the EYFP to ECFP ratio (R527 nm/475 nm) over time at 20 °C (light gray), 28 °C (gray), and 37 °C (black). Plots of the emission ratio as a function of time were fitted to eq 1 (solid lines).

here were calculated assuming an aggregation number (N_a) of 90 lipids per micelle, a number that is based on previous SANS measurements on (nonfunctionalized) PEG2000-DSPE micelles (*33*). Since the amount of energy transfer is correlated to the presence of ECFP and EYFP on a single micelle, titration of PEG2000-DSPE to mixed ECFP−EYFP micelles should result in a decrease in emission ratio until a regime is reached where the average protein−micelle ratio is less than two. Figure 6A shows the results of such a titration experiment in which increasing concentrations of PEG2000-DSPE were added to ECFP−EYFP micelles. Indeed, a strong decrease in FRET is

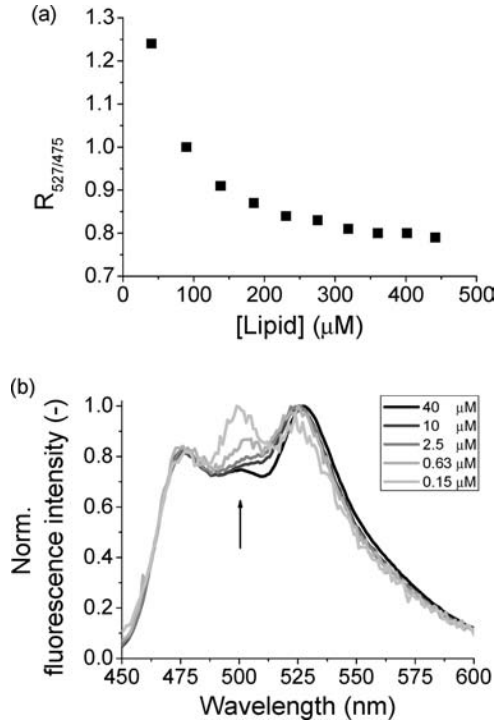

Figure 6. Structural properties of mixed ECFP−EYFP micelles studied using FRET. Mixed ECFP−EYFP micelles were prepared by mixing ECFP-micelles and EYFP-micelles in a 1:1 ratio yielding a starting concentration of 2.4 μM ECFP-PEG2000-DSPE, 2.4 μM EYFP-PEG2000-DSPE, and 35 μM Cys-PEG2000-DSPE. All measurements were performed in HBS pH 7.4 at 37 °C. (A) Decrease of FRET observed in ECFP−EYFP micelles by the addition of increasing concentrations of PEG2000-DSPE. Emission spectra were measured after 20 min incubation at 37 °C to allow complete exchange of lipidated proteins. (B) Determination of the CMC by stepwise dilution of mixed ECFP−EYFP-micelles in buffer. After each dilution step, micelles were left to equilibrate for 30 min before measuring an emission spectrum using an excitation wavelength of 430 nm. The arrow indicates the appearance of a Raman scatter band that increases in relative intensity at low protein concentrations.

observed up to a total PEG2000-DSPE concentration of 150−200 μM, after which the ratio stabilizes. The observation of an inflection point around 200 μM is consistent with the aggregation numbers of 72−90 that were reported in previous studies, suggesting that protein functionalization did not significantly alter the aggregation number (*33*−*35*).

Micelles functionalized with a combination of donor and acceptor fluorescent proteins also provide an alternative method to assess the stability of protein-functionalized micelles by monitoring FRET upon dilution of these micelles in buffer. The critical micelle concentration is typically measured by employing methods that rely on solubilization of fluorescent dyes in the micellar interior, but it has been argued that these methods could be less reliable for stable micelles (*36*). The ratio of EYFP and

ECFP emission was determined as a function of Cys-PEG2000-DSPE concentration after time was taken to allow equilibration at 37 °C. Figure 6B shows the emission spectra normalized for dilution up to a Cys-PEG2000-DSPE concentration of 0.15 μM. Surprisingly, no significant change was observed in the ratio between EYFP emission and ECFP emission, showing that micelles remained intact under these conditions even at 0.15 μM PEG2000-DSPE. Unfortunately, no reliable measurements could be obtained at concentrations below lipid concentrations of 0.15 μM (corresponding to 10 nM ECFP and EYFP) due to the increasing intensity of a Raman scatter at 500 nm. Nonetheless, the CMC determined in this manner is at least 10-fold lower than the 1−10 μM CMC values that were previously reported for (protein functionalized) PEG2000-DSPE micelles (*20, 33, 37*). It is unclear whether this difference is being caused by the more direct measurement of the CMC or reflects a possible stabilization of the micelles induced by the presence of ECFP and EYFP.

CONCLUSION

Functionalization of pegylated phospholipids with donor and acceptor fluorescent domains provides a straightforward approach to study the stability of protein-functionalized liposomes and micelles with respect to protein−lipid transfer. Even after incubation for 24 h at 37 °C, no protein exchange is observed for sterically stabilized liposomes. Protein exchange is relatively fast for PEG2000-DSPE micelles at 37 °C, but much slower at room temperature. The similar exchange rates obtained for protein-functionalized PEG2000-DSPE found here and non-functionalized PEG2000-DSPE micelles reported previously suggest that protein functionalization does not result in an additional enhancement of lipid-exchange rates. Nonetheless, the short half-life of 4 min observed at 37 °C shows that these micellar systems are kinetically unstable under physiological conditions and might rapidly exchange their protein-functionalized lipids with other lipid pools such as cellular membranes.

ACKNOWLEDGMENT

The authors thank Wouter Habraken for his help with DLS, Marcel Rooijackers for initial exploratory research with the fluorescent protein micelles, Ilmar Kruis for exploratory work with the fluorescent protein liposomes, Erik Sanders for liposome preparation, and Bert Meijer and Luc Brunsveld for support and useful discussions. This work was supported by an NWO VIDI grant 700.56.428 to M.M. and the BSIK program entitled Molecular Imaging of Ischemic Heart Disease (project number BSIK03033).

In this article, we present our results on the design of new polymeric carriers for antibodies. Polymer colloids based on poly(styrene-*co*-glycidyl methacrylate) were synthesized by surfactant-free emulsion polymerization. Obtained polymer particles stabilized by grafted poly(ethylene glycol) (PEG) chains and carrying active epoxy groups were used for the covalent immobilization of activating antibodies against the human surface proteins CD (cluster of differentiation) 3 and CD28. The particle−antibody conjugates were employed for the stimulation of human CD4 memory T cells. This was analyzed by the up-regulation of the activation markers CD69 and CD25 on T cells and T cell proliferation as assessed by the dilution of a fluorescent dye on dividing daughter T cells. The particle−antibody conjugates were able to stimulate T cells at least as efficiently as conventional methods, e.g., surface-immobilized antibodies. Furthermore, an increase of the PEG chain length of the particles decreased the efficiency of the particle−antibody conjugates to activate T cells.

INTRODUCTION

Polymeric particles are very versatile objects whose properties can be tailor-made during synthesis by varying different parameters such as the nature of the monomer, the polymerization procedure, or additives. In biomedicine, for example, particles can be used as carriers in drug delivery systems, as well as for agglutination tests and in the area of biosensors. However, due to the complexity of biological systems there is still a need for the development of new reactive polymeric carriers.

Most synthesis strategies employ surfactants that are noncovalently bound. Therefore, they can desorb under certain circumstances like high ionic strength, freezing, or mechanical stress leading to unstable dispersions and undesired interactions with other substances. One aim of this work was the synthesis of highly reactive particles avoiding classical surfactants by using surfactant-free heterophase polymerization. This technique employs functional monomers such as acetoacetoxyethyl methacrylate (*1*) or poly(ethylene glycol) methacrylate (*2*) that are able to stabilize the prepared particles. Furthermore, PEG derivatives are known for their biocompatibility and the reduction of unspecific protein adsorption and cell adhesion (*3*−*5*).

The covalent attachment of biomolecules can be realized by a posterior grafting of molecules with desired functionalities or by direct functionalization during polymerization (*6*). The use of glycidyl methacrylate (GMA) for immobilization of biomolecules has been known for a long time because its epoxy groups are able to react with several functional groups such as thiol, amino, or hydroxy groups without further activation. A lot of work in this area has been done by Horák and co-workers (*7, 8*) who synthesized magnetic particles containing GMA and used these for the immobilization of biomolecules.

Several other publications deal with copolymers of GMA and 2-hydroxyethyl methacrylate and their use for the immobilization of enzymes (*9*−*12*). In contrast, little research has so far been done in the field of immobilization of antibodies using GMA. Faure et al. (*13*) prepared miniaturized immunoextraction columns by bonding of anti-ochratoxin A antibodies on poly(glycidyl methacrylate-*co*-ethylene dimethacrylate) monoliths. Iwata et al. (*14*) immobilized goat anti-mouse immunglobulin-(Ig) G Fab′ fragments on GMA-containing polymer brushes in a defined orientation.

To explain processes of the human immune system, it is necessary to examine single steps of an immune response in vitro. Furthermore, the amount of primary cells from blood donations is limited. Analysis of immunological systems in vitro frequently requires expansion and activation of the desired cell species, e.g., T cells. Another application for T cell expansion is for therapeutic purposes, e.g., for the treatment of cancer (*15*) or autoimmune diseases (*16*−*18*).

Stimulation of T cells with immobilized antibodies to surface proteins, such as the polymorphic T cell receptor (TCR) or the nonpolymorphic CD (cluster of differentiation) 3 complex, mimics binding of the major histocompatibility class II/peptide complex (MHC class II/peptide) on the surface of antigen-presenting cells to T cells and hence initiates the T cell activation program (*19*). To stimulate T cells effectively, two activation signals are required. The first signal occurs via the T cell receptor complex, whereas the second, so-called co-stimulatory signal, can be provided by engaging the nonpolymorphic surface receptor CD28. A conventional method for polyclonal stimulation of memory T cells (T_{mem}) in vitro employs antibodies to CD3 adsorbed on plastic cell culture plates in combination with

antibodies to CD28. The immobilization of the antibodies to CD3 is necessary, as it effectively permits cross-linking of the CD3 complexes on the surface of T cells, a prerequisite for T cell activation. Soluble antibodies to CD3, in fact, are not sufficient to induce T cell activation in most experimental settings (*20*−*22*). In contrast, CD28 mediated signals are rather independent of cross-linking, and stimulation of CD28 can be provided by soluble or immobilized antibodies to CD28. As cross-linking of CD3 can be employed upon contact with any carrier on which antibodies to CD3 can be immobilized in adequate densities, effective T cell activation can be initiated by CD3 and CD28 antibodies immobilized on polymeric particles.

The aim of the present work was the development of a simple and cheap polymeric carrier system for antibodies. The important challenge was a proper design of the particle surface, e.g., the presence of reactive functional groups able to bind antibodies, the presence of hydrophilic polymer chains for enhanced colloidal stability to avoid particle aggregation, as well as adjustment of particle size in submicrometer range. In the present study, we used particles immobilized with anti-CD3 and anti-CD28 antibodies to stimulate T cells and compared this method to the activating effect of plate bound antibodies to CD3 in concert with soluble anti-CD28 (control sample). Furthermore, we assessed whether particle−antibody conjugates without poly(ethylene glycol) methyl ether methacrylate (PEGMEMA) chains or with PEGMEMA chains of different length vary in their capacity to stimulate T cells.

EXPERIMENTAL PROCEDURES

Materials. Styrene (S, Fluka) was purified using an inhibitor remover (Aldrich) according to the manufacturer's description. Glycidyl methacrylate (GMA, Fluka) was purified by vacuum distillation. Poly(ethylene glycol) methyl ether methacrylate (PEGMEMA, Aldrich), 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AMPA, Aldrich), dimethyl sulfoxide (Merck), 5-(and 6-) carboxyfluoresceine-diacetate-succinimidylester (CFSE, Molecular Probes), tris(hydroxymethyl)-aminomethane (Tris, Merck), ethanol (Aldrich), sodium azide (Merck), cresol red (Chemapol Praha), 1,4-dioxane (Riedel-de Haën), hydrogen chloride dioxane solution (Fluka), potassium chloride solution in methanol (Grüssing), tris(hydroxymethyl)-aminomethane (Merck), Hanks' solution (Apotheke Innenstadt, LMU Munich), phosphate buffer solution (PBS, Invitrogen), Ficoll-Hypaque-solution/Lymphoflot (Biotest), fetal calf serum (FCS, Invitrogen), sheep erythrocytes (SBRC, Fiebig-Nährstofftechnik), Penicillin G/Streptomycin (Invitrogen), L-glutamine (Invitrogen), Interleukin 2 (Chiron), and RPMI 1640 (Invitrogen) were used as received. For the preparation of FACS (fluorescence activated cell sorting)−PBS, 500 mL PBS, 10 mL FCS, and 0.5 mL of NaN_3 solution in water (10%) were mixed. Deionized water was employed as reaction medium for emulsion polymerization.

The following monoclonal antibodies (mAbs) were used for cell purification and cell culture: anti-CD3 (OKT3), anti-CD8 (OKT8), anti-CD16 (3g8FcIII), anti-HLA-DR (L243; all from American Type Culture Collection), anti-CD28 (28.2; BD Pharmigen), anti-CD19 (HD37, Dako Diagnostika), anti-CD45RA (111.1 C5; a gift from Dr. R. Vilella, Barcelona, Spain), anti-CD56 (MOC-1, Dako Cytomation), and polyclonal antimouse IgG (MP Biomedicals).

For cell staining, fluorescein isothiocyanate (FITC)-conjugated or phycoerythrin (PE)-conjugated mAbs were applied: FITC-anti-CD3 (UCHT1), PE-anti-CD4 (Q4120), FITC-anti-CD4 (Q4120, all from Sigma), and PE-anti-CD3 (UCHT1), PE-anti-CD28 (CD28.2), PE-anti-CD25 (M-A251), FITC-anti-CD27 (M-T271), PE-anti-CD45RO (UCHL1), FITC-anti-CD69 (FN50, all from BD Pharmigen).

Synthesis of Polymeric Particles. A monomer mixture containing appropriate amounts of styrene and GMA was prepared. A double-walled glass reactor equipped with stirrer was filled with 170 mL distilled water. For the preparation of PEGMEMA containing particles, appropriate amounts of PEGMEMA were previously dissolved in the water. Then, the monomer mixture was added to the water phase under stirring. The obtained pre-emulsion was heated to 60 °C and stirred for 1 h while purging with nitrogen. To start the polymerization process, 10 mL of water with 1.5 wt % of initiator was added. Latexes were prepared at 10% solid content. The reaction time was 8 h at 60 °C.

Titration of Epoxy Groups. Water-based particle dispersions were freeze−dried. 0.5 g of dried particles were redispersed in 20 mL 1,4-dioxane. Then, 5 mL of a solution of hydrogen chloride in dioxane were added. The mixture was stirred for 8 h at room temperature. Remaining hydrogen chloride was determined by titration with a solution of potassium hydroxide in methanol. The equivalence point was determined by either potentiometric titration or with 1 mL of a solution of 0.1 g cresol red in 100 mL ethanol−water mixture (volume ratio = 1:1) as color indicator.

Attachment of Antibodies to Polymeric Particles. *Fluorescence-Labeled Antibodies.* The particle dispersions were diluted 1:100 with 50 mM Tris-HCl (pH 9.5). 25 μL of fluorescence-labeled antibodies were added to 100 μL of diluted particle dispersion. Then, the samples were incubated at 37 °C for 2 h. After washing with 50 mM Tris buffer, the particle−antibody conjugates were resuspended in 150 μL FACS-PBS and analyzed by flow cytometry.

Antibodies for Cell Activation. The particle dispersions were sterilized by washing with ethanol twice and diluted with 50 mM Tris (pH 9.5) 1:500. 150 μL of the antibody solution in 50 mM Tris with the desired antibody concentrations was added. The final concentration of antibodies was 1 μg/mL. The samples were incubated at 37 °C for 2 h, afterward washed twice with deionized water, and transferred to the cell culture medium. The particle amount in each sample corresponded to the surface area of one well of the cell culture plate.

Attachment of Antibodies to Cell Culture Plates (Control Sample). Each well of a 48-well plate was filled with 150 μL of an antibody solution of appropriate concentration (1 μg/mL in 50 mM Tris-HCl) and incubated at 37 °C in a humidified atmosphere containing 5% CO_2 for 2 h. The plates were washed twice with Hanks' solution to remove unbound antibodies and obtain a neutral pH and used for further cell culture.

Cell Purification. Mononuclear cells were obtained from heparinized peripheral blood of one healthy individual. Ethical approval was obtained by the local Institutional Review Board, and all subjects enrolled gave their written informed consent. After gradient centrifugation (20 min, 400*g*) over a Ficoll-Hypaque layer followed by washing with PBS, cells were incubated with sheep red blood cells (rosetting) (*23*). The rosette-positive cells were further purified by negative selection using saturating amounts of mAbs against CD8, CD16, and CD19, followed by panning on plastic Petri dishes coated with goat antimouse IgG for 15 min at room temperature as previously described (*24*, *25*). CD4 T cells were harvested by gently washing the dishes with a solution of 4% NHS (normal human serum)/RPMI 1640 in PBS and centrifugation. In the last step, resting CD4 T_{mem} were isolated by negative selection using anti-HLA-DR, anti-CD45RA, anti-CD56, and anti-CD8 antibodies. Recovered cells were washed with PBS and resuspended in 10% NHS/RPMI 1640. The homogeneity and purity of isolated T cells were assessed by flow cytometry. Routinely, ≥90% T cells were positive for CD3 and CD4.

Table 1. Ingredients Used in Emulsion Polymerization (Reaction Temperature: 60 °C)

N	*S* [g]	GMA [g]	GMA [wt%]	PEGMEMA [g]	PEGMEMA [wt%]	M_n, [g/mol] PEGMEMA	initiator [g]	water [g]
1	19	1	5	-	-	-	0.3	180
2	19	0.5	2.5	0.5	2.5	~475	0.3	180
3	19	0.5	2.5	0.5	2.5	~1100	0.3	180
4	19	0.5	2.5	0.5	2.5	~2080	0.3	180

Cell Culture. Culturing of the cells was carried out in RPMI 1640 medium supplemented with penicillin G/streptomycin (50 U/mL), L-glutamine (2 mM), 10% NHS, and 10 ng/mL IL-2. Cell cultures were maintained at 37 °C in a humidified atmosphere containing 5% CO_2. Memory CD4 T cells were aliquoted at a concentration of 0.75×10^6 cells/mL in the cell culture medium. 300 μL of the cell suspension were pipetted in each well of a 48-well cell culture plate (Costar) and diluted with the same volume of cell culture medium containing the particle−antibody conjugates.

Alternatively, the same amount of T cells was stimulated with Dynabeads CD3/CD28 T Cell Expander beads (Dynal Biotech) according to the manufacturer instruction at a 3:1 beads per T cell ratio.

Flow Cytometry. 1×10^5 T cells/sample were washed with FACS-PBS, resuspended in 50 μL FACS-PBS, and incubated with saturating amounts of directly fluorochrome labeled mAb against different surface molecules (CD25 or CD69) for 15 min at 4 °C in the dark. Afterward, cells were washed twice with 1 mL FACS-PBS and resuspended in 300 μL FACS-PBS. To obtain quantitative data with very high reliability, at least 1×10^4 T cells/sample were analyzed as recommended (*26*) and the mean fluorescence intensity (MFI) and standard deviation were calculated for the entire population of 1×10^4 T cells.

Analysis of Cell Division. 1 μL of the CD4 T_{mem} cell suspension (10×10^6 cells/mL) in PBS was incubated with a 10 mM solution of CFSE in dimethyl sulfoxide for 8 min at room temperature, with a final CFSE concentration of 10 μM. Labeling was stopped by adding of 1 mL NHS. Cells were washed twice with RPMI 1640 supplemented as described above. At indicated time points of cell culture, cells were harvested, washed with FACS-PBS, resuspended with 250 μL FACS-PBS, and analyzed by flow cytometry. The proliferation index of the cells was calculated as 1/MFI × 100%.

Characterization Methods. SEM images were taken with a Gemini microscope (Zeiss, Germany). For sample preparation, particle dispersions were diluted with deionized water, dropped onto aluminum support, and dried at room temperature. Samples were coated with a thin Au/Pd layer to increase the contrast and quality of the images. Images were obtained at a voltage of 4 kV. Dynamic light scattering measurements were performed with a Zetasizer Nanoseries ZEN3600 (Malvern Instruments, UK). Stability measurements of particle dispersions were performed with the separation analyzer LUMiFuge 114 (LUM GmbH, Germany). Measurements were made in glass tubes at an acceleration velocity of 3000 rpm. The slopes of the sedimentation curves were used to calculate the sedimentation velocities and to get information about the stability of the samples. Flow cytometry analysis was done with a Cytomics FC500, Beckman Coulter. Fluorescence was excited with an Ar-ion laser at a wavelength of 488 nm. Fluorescence signals were determined using appropriate electronic compensation to exclude emission spectra overlap. For extracellular staining, 0.1×10^6 cells/staining were washed with 1 mL FACS-PBS, resuspended in 50 μL FACS-PBS, and incubated with saturating amounts of PE- or FITC-labeled antibodies for 15 min at 4 °C in the dark. Afterward, the cells were washed twice with 1 mL FACS-PBS, resuspended with 250 μL FACS-PBS, and analyzed by flow cytometry. Light microscopy was performed with an Axiovert 25 microscope (Zeiss, Germany).

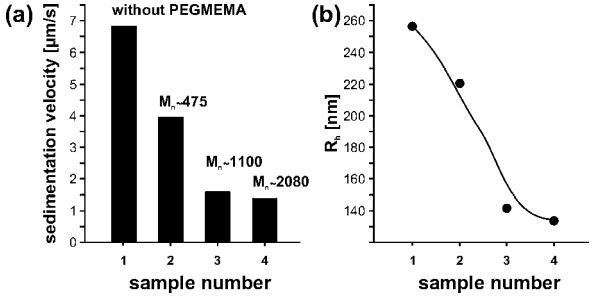

Figure 1. Sedimentation velocities (a) and hydrodynamic radius (b) of polymer particles prepared with PEGMEMA macromonomers of different molecular weights.

RESULTS AND DISCUSSION

Particle Size and Morphology. Poly(styrene-*co*-glycidyl methacrylate) (PS-PGMA) and PS-PEGMEMA-PGMA particles were prepared by surfactant-free heterophase polymerization. Interestingly, this technique could be used although GMA is regarded as a rather hydrophobic monomer. But in comparison to styrene, the difference in hydrophobicity is big enough for sufficient particle stabilization. Hence, the obtained dispersions were stable and showed no precipitation during storage. In all runs, the final monomer conversion was between 80% and 85%. An overview of the reaction recipes for emulsion polymerization is given in Table 1.

For further evaluation of colloidal stability, sedimentation experiments with an analytical centrifuge were performed (Figure 1a). As expected, the best stability (lowest sedimentation velocity) was observed for dispersions with the highest molecular weight of PEGMEMA, because poly(ethylene glycol) and its derivatives are known as effective sterical stabilizers (*27*, *28*).

Figure 1b shows results of dynamic light scattering indicating that the molecular weight of the PEGMEMA macromonomer has a strong influence on the final size of polymer colloids. It is obvious that the particle size decreases with an increase of the PEGMEMA molecular weight. Obtained polymer particles are monodisperse and possess a spherical shape as shown in SEM images (Figure 2).

Furthermore, it is believed that the particles possess a core−shell structure due to different hydrophilicity and reactivity of monomers. In the presence of a water-soluble initiator, polymerization in the water phase likely involves a homogeneous nucleation mechanism because the functional monomer has a low ability to form defined micelles in water. As both functional monomers, PEGMEMA and GMA, are more reactive than styrene, formed oligoradicals will contain more GMA and PEGMEMA units leading to enhanced heterogeneity of copolymers. Addition of styrene leads to the formation of amphiphilic polymer chains which can act as stabilizers during polymerization of residual styrene. Thus, final particles probably consist of a polystyrene-rich dense core and a more diffuse shell containing PEGMEMA and GMA units, respectively, as confirmed for similar particles (*2*). This leads to the assumption that the epoxy groups should be mainly located in the outer region of synthesized particles.

The amount of reactive epoxy groups of polymerized particles was determined by titration using the HCl−dioxane method (*29*). About 85% of the epoxy groups were still intact and available

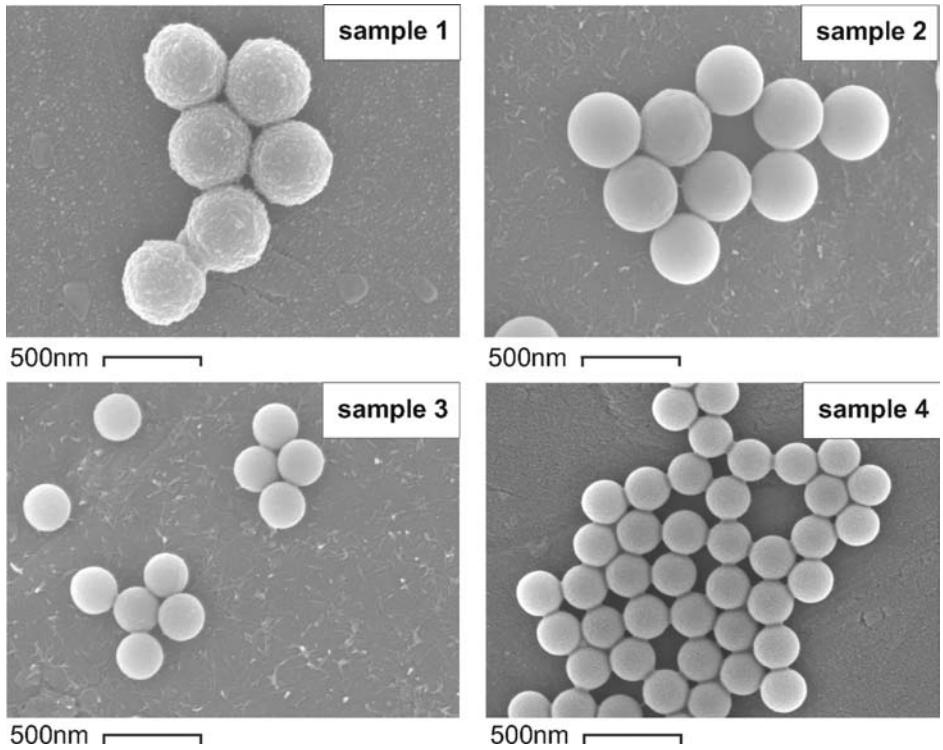

Figure 2. SEM images of polymer colloids (numbers correspond to sample numbers in Table 1).

for further reactions, e.g., immobilization of antibodies after polymerization.

Immobilization of Antibodies. Most standard methods bind proteins only by adsorption which usually leads to a high degree of protein denaturation (*30, 31*). In order to enhance the activity of bound antibodies and therefore minimize the amount needed for a certain cell activation, we chose to immobilize antibodies by covalent bonding via epoxy groups. In this context, PEGMEMA was incorporated into the particles not only for enhanced stability, but also for the prevention of protein adsorption. The ability of the synthesized polymeric particles to bind antibodies was demonstrated by immobilization of fluorescence-labeled antibodies (FITC labeled anti-CD3 and PE labeled anti-CD28) followed by flow cytometry analysis. As shown in Figure 3a, light scattering provides information about the size (forward scatter) and the surface characteristics (sideward scatter) of the particles. The scatter plots are then used to gate on the particle population of interest, and fluorescence signals of this population are measured in the different channels according to the fluorescent dye. Figure 3b,c demonstrates the corresponding flow cytometry plots of pure PS-PGMA particles. The particles did not show signals themselves, in either the FITC or the PE channel, verifying that the particles have no significant autofluorescence.

In contrast, Figures 3d,e presents the flow cytometry plots for PS-PGMA particles after immobilization of saturating amounts of fluorescence-labeled antibodies to CD3 (FITC) and to CD28 (PE), respectively. The peaks in Figure 3d,e are shifted to higher fluorescence signals in FITC/PE channels compared to Figure 3b,c indicating fluorescent particle−antibody conjugates. FACS analysis showed that 99.5% of the particles were FITC-positive and 98.7% of the particles were positive for PE. Therefore, PS-PGMA particles are able to immobilize both antibodies to CD3 and CD28 effectively. Similar results were obtained for PS-PEGMEMA-PGMA particles (data not shown).

Light Microscopy Investigation of Cell Culture. Since the particles effectively bind fluorescending antibodies as demonstrated by flow cytometric analysis, we immobilized particles with activating antibodies (1 μg/mL) against human CD3 and CD28 and analyzed their effect on human T cells by light microscopy. As shown in Figure 4a, purified T cells alone exhibit a round shape and an equal distribution throughout the cell culture plate. The conventional T cell stimulation by plate-bound antibodies in the control sample results in the characteristic pattern of activated T cells (*32*) (Figure 4b). T cell activation induces the formation of cell clusters and changed cell morphology. Upon contact with particle−antibody conjugates (Figure 4c), the same effects can be observed as compared with conventional plate-bound antibodies confirming a proper T cell activation by particle−antibody conjugates. Interestingly, endocytosis of the particles by the human T cells was not observed in contrast to human monocytes, which show strong endocytotic activity when incubated with the particles (data not shown).

Assessment of T Cell Stimulation. After antibody immobilization on the particles, we furthermore studied the influence of the particle surface properties on the ability of the antibodies to stimulate human CD4 memory T cells as monitored by their expression of the activation markers CD69 and CD25 and by their proliferation upon contact with the particle−antibody conjugates. The amount of activated T cells expressing the T cell activation markers CD69 and CD25 was determined by specific labeling of the T cells with fluorescent antibodies and further flow cytometric analysis of T cells on days 2, 3, and 4 after contact with particle−antibody conjugates. As already shown in other studies, expression of CD69 in activated T cells starts earlier than that of CD25 (*33, 34*). Figure 5 confirms successful cell activation in case of samples 1 and 2, whereas samples 3 and 4 (higher molecular weight of PEGMEMA) comprise significantly less activated cells. As all different particles (samples 1−4) were immobilized with the same amounts of antibodies, a comparable antibody density on the surface of the different particle is supposed. Therefore, the lower capacity of samples 3 and 4 to activate T cells possibly occurs due to restricted antibody−cell contact because longer PEGMEMA chains on the particle surface may prevent contact

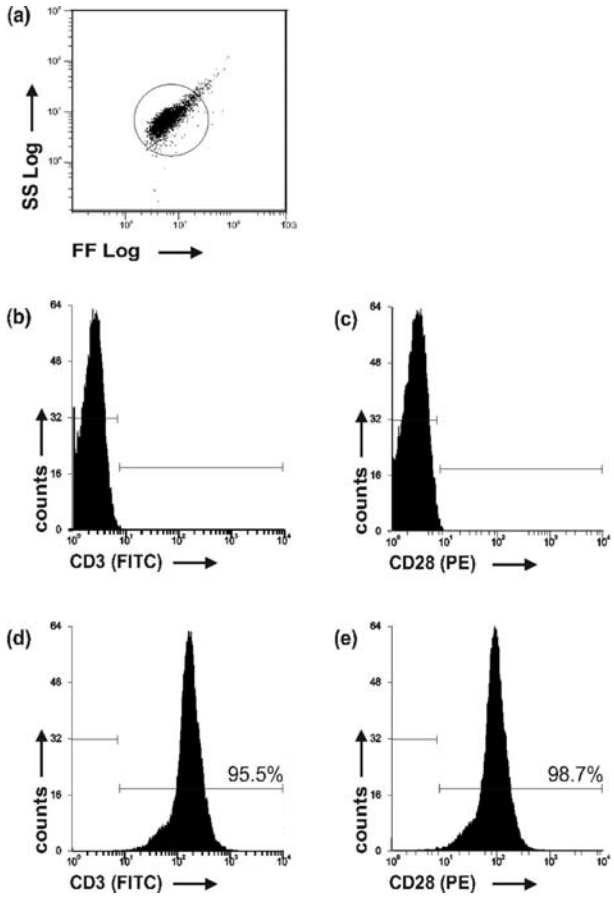

Figure 3. Flow cytometry analysis was performed for PS-PGMA particles (sample 1). (a) Forward scatter (FF) and sideward scatter (SS) of the PS-PGMA particles are plotted on a logarithmic scale, and the region of interest was selected based on the size and surface structure of the particles. Fluorescence signals in the FITC (b) or PE (c) channel of PS-PGMA particles alone or for PSPGMA particles with immobilized fluorescence-labeled anti-CD3-FITC (d) and anti-CD28-PE (e) are shown for the population selected in (a).

with the T cells. Of note, particles alone without antibodies on the surface have no influence on T cell activation or proliferation at all, because the measured data for CD69, CD25, and proliferation were similar to the data observed for T cells alone (blank). T cell activation by PS-PGMA particle−antibody conjugates (sample 1) is at least as sufficient as activation by conventional methods. In comparison to plate-bound antibodies (control sample), the frequencies of activated T cells were slightly enhanced after stimulation with particle−antibody conjugates especially at early time points of T cell activation. Since the surface areas of the particles and the cell culture plate in the control samples are identical, the applied polymeric particles may possess a higher density or better cross-linking of CD3 compared to the conventional method.

For our study, we used the same antibody concentration that is routinely used for the immobilization of activating antibodies on plastic (1 μg/mL) (*25, 35*). However, our interest was also to evaluate if different amounts of antibodies on the surface of the particles or on the cell culture plate may have an influence on the activation of the T cells. As shown in Supporting Information Figure S1, the chosen antibody concentration of 1 μg/mL is in the saturating region for an appropriate activation of T cells. Interestingly, higher amounts of antibody did not increase cell activation, but rather showed a tendency to decrease the activation of memory T cells. This observation is in correlation with reports from the literature, that high levels of anti-CD3 antibodies and prolonged T cell receptor stimulation

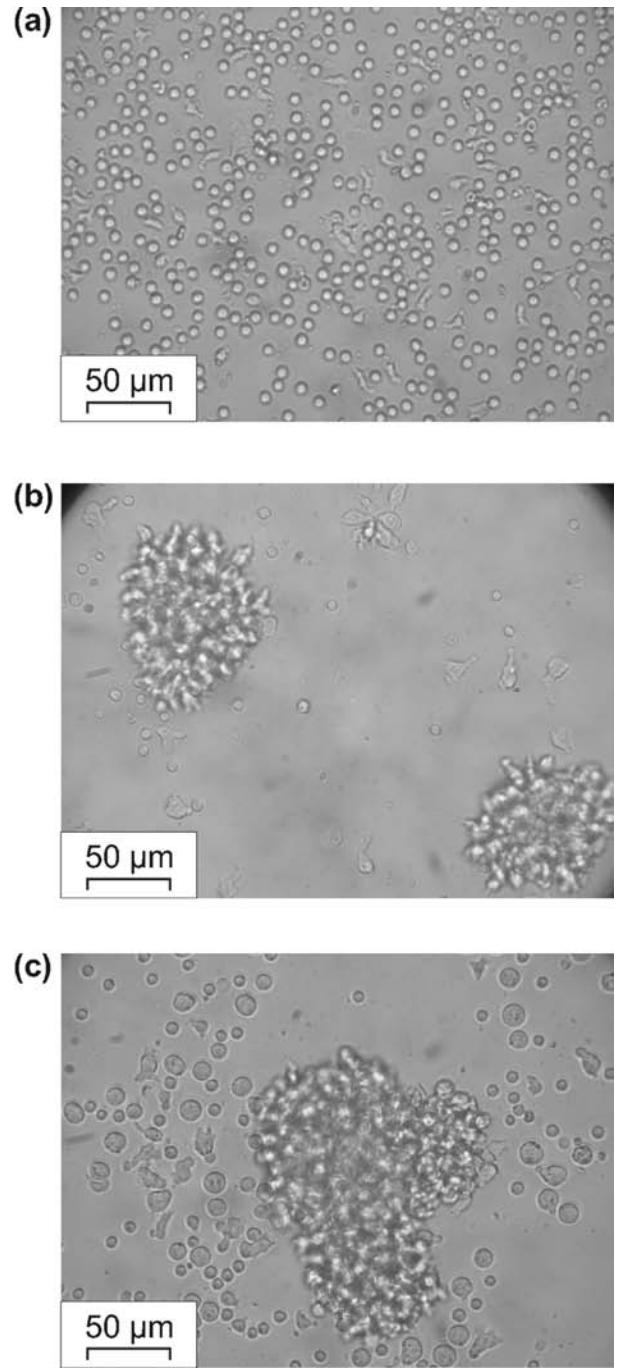

Figure 4. Light microscopy image of T cell culture: (a) purified nonstimulated T cells, (b) T cells conventionally stimulated with plate-bound antibodies (control sample), (c) T cells after contact with PS-PGMA particles with bound antibodies (note that particle−antibody conjugates are too small to be visualized by light microscopy).

may reduce T cell expansion and increase activation-induced apoptosis (*36, 37*).

Cell proliferation was analyzed by equal distribution of the dye CFSE to daughter cells after cell division. The corresponding fluorescence signal was investigated by flow cytometry. Analysis of cell proliferation revealed similar tendencies (Figure 6) and, therefore, is in line with the results from the determination of activation markers. In addition, we compared the proliferation of T cells stimulated with plate-bound antibodies to CD3 or with antibodies bound to different particles with the effects of commercially available Dynabeads CD3/CD28 T Cell Expander beads on T cell proliferation. Dynabeads are 4.5 μm

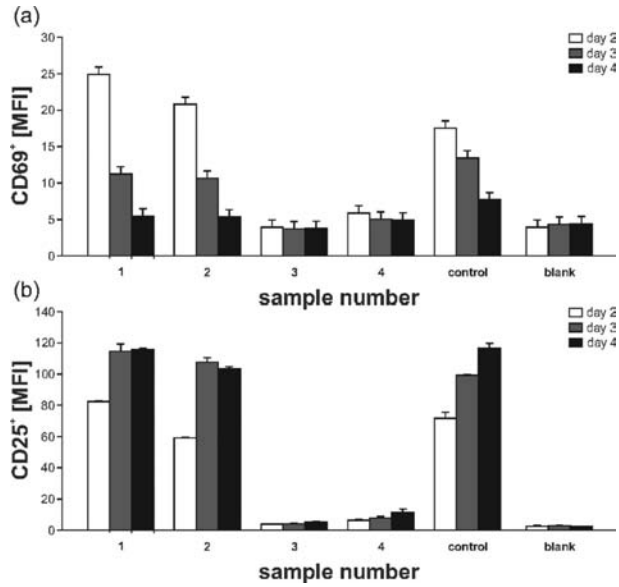

Figure 5. Mean fluorescence intensity of cells exhibiting the T cell activation markers CD69 (a) and CD25 (b) after contact with particle-bound antibodies. Sample numbers correspond to Table 1. The control represents conventional activation of T cells with plate-bound antibodies to CD3 and soluble anti-CD28. The blank denotes nonstimulated T cells without contact to antibodies or particles.

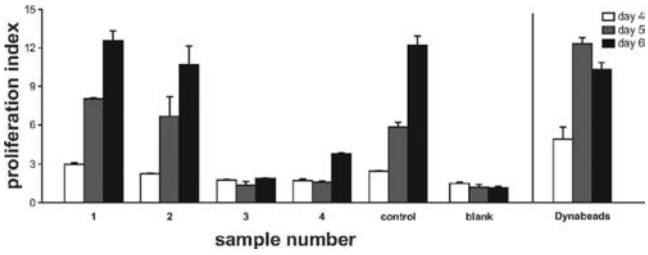

Figure 6. Proliferation of cells after contact with particle-bound antibodies. Sample numbers correspond to Table 1. Dynabeads represents T cells stimulated with Dynabeads CD3/CD28 T Cell Expander beads.

superparamagnetic microparticles with covalently bound antibodies available for different applications. Here, we used CD3/CD28 T Cell Expander Dynabeads for the expansion of human T cells, with antibodies to CD3 and CD28 coupled to the beads. Of note, the Dynabeads indeed showed an increased proliferation at early time points but reaching a plateau at later time points.

CONCLUSIONS

Up to now, most methods for T cell expansion are time-consuming, and large amounts of cells are needed. Improvements were achieved by using Dynabeads for the expansion of human T cells (*38*), but one potential disadvantage of these particles are surfactant residues. With regard to an application in complex biological systems, the negative effects of surfactants on skin permeability (*39*), on cell membrane structure (*40*), or on their cytotoxic effects (*41*) should be considered. Besides, normal microparticles must be separated from the cell population before flow cytometry analysis due to their large size. The benefit of Dynabeads for the expansion of T cells is undoubted, and this technique is now routinely used for the expansion of distinct T cell subsets with regulatory functions (*42*). We could also observe a robust proliferation induced by the Dynabeads, but excessive proliferation is often linked to a decreased differentiation of cells (*43*). Indeed, we observed reduced cytokine levels in T cells stimulated with Dynabeads (data not shown). Therefore, other tools for specific applications such as expansion of highly differentiated effector T cells would be desirable.

To overcome those limitations, surfactant-free emulsion polymerization was used to synthesize poly(styrene-*co*-glycidyl methacrylate) particles. Employing this technique, particles with size in the submicrometer range could be obtained. The use of glycidyl methacrylate as a functional co-monomer ensured incorporation of reactive epoxy-groups into particle surface. The use of poly(ethylene glycol) methyl ether methacrylate (PEGMEMA) macromonomers in the polymerization process improved the colloidal stability of particles. Additionally, the size of polymer colloids could be adjusted by varying the PEGMEMA molecular weight. Active epoxy groups on the particle surface were applied for immobilization of antibodies to CD3 and CD28 by covalent bonding. By flow cytometric analysis, we could demonstrate that more than 95% of the particles effectively bound the antibodies. These particle−antibody conjugates were used for stimulation of human CD4 memory T cells. Effective T cell responses after contact with particle−antibody conjugates were assessed by light microscopy of the T cells showing a characteristic pattern of activation. Furthermore, T cell activation was observed by evaluating the expression of the activation markers CD69 and CD25 and cell proliferation. For the PGMA particle−antibody conjugates, T cell activation is at least as sufficient as activation by conventional methods. Interestingly, at early time points frequencies of activated T cells were enhanced after stimulation with PGMA particle−antibody conjugates as compared with conventional activation (25 MFI vs 17.6 MFI for CD69 and 82.8 MFI vs 72 MFI for CD25). At higher PEG chain lengths, cell activation with particle−antibody conjugates was less efficient, possibly due to restricted antibody−cell contact.

In summary synthesized particle−antibody conjugates can be used as an alternative for other techniques of T cell activation and therefore may have potential for therapeutic applications.

ACKNOWLEDGMENT

Expression, Glycoform Characterization, and Antibody-Binding of HIV-1 V3 Glycopeptide Domain Fused with Human IgG1-Fc

Qiang Yang, Cishan Li, Yadong Wei, Wei Huang, and Lai-Xi Wang*

Institute of Human Virology and Department of Biochemistry and Molecular Biology, University of Maryland School of Medicine, 725 West Lombard Street, Baltimore, Maryland 21201. Received September 24, 2009; Revised Manuscript Received March 18, 2010

The third variable (V3) domain of HIV-1 gp120 envelope glycoprotein is critical for HIV-1 entry and represents an attractive target for vaccine design. There are three conserved *N*-glycans within or around the V3 loop. The N295 and N332 glycans at the base of V3 are usually characterized as high-mannose type in gp120, and the N301 glycan is a complex type. We report in this paper the expression and characterization of glycosylated, full-size V3 domain derived from HIV-1_{Bal} strain as an IgG1-Fc fusion protein, including its binding to two broadly HIV-neutralizing antibodies 2G12 and 447-52D. It was found that expressing the V3-Fc fusion protein in the HEK293T cells resulted in the production of a glycoform in which all the *N*-glycans were complex type, in contrast to the glycosylation pattern of V3 in the context of gp120, where the N295 and N332 glycans are high-mannose type. Controlling the glycosylation to restore an epitope of antibody 2G12 was achieved by using an inhibitor of glycan processing enzymes. Mutational studies indicate that the glycan at N301 slightly decreases the binding of V3-Fc to antibody 447-52D, but it can significantly enhance the binding of the V3-Fc to antibody 2G12 when it is changed to a high-mannose type *N*-glycan. The high-mannose type V3-Fc fusion protein that includes both the 2G12 and 447-52D epitopes represents an interesting immunogen that may be able to raise anti-HIV neutralizing antibodies.

INTRODUCTION

Neutralizing antibodies are an important component of protective immunity against HIV-1 infection (*1–3*). So far, a few human monoclonal antibodies (MAbs) have been characterized, suggesting the presence of conserved neutralizing epitopes in the HIV-1 envelope glycoproteins. Thus, characterization and reconstitution of the neutralizing epitopes for these broadly neutralizing antibodies constitute an important step for HIV-1 vaccine design. The third variable (V3) domain of HIV-1 gp120 envelope glycoprotein was once considered "the principal neutralization determinant (PND)" for vaccine development (*4, 5*). While the sequence variation resulted in the production of most anti-V3 antibodies that are strain-specific and neutralize only T-cell line adapted viruses or a very narrow range of primary isolates, there is accumulating evidence showing that broadly reactive anti-V3 antibodies capable of neutralizing HIV-1 primary isolates across clades do exist (*2*). For example, the anti-V3 monoclonal antibody (mAb) 447-52D is able to neutralize HIV-1 primary isolates of clades A, B, and F, regardless of the sequence variability of the V3 loop (*6–8*). In fact, despite the sequence variations flanking the tip of the loop, V3 domains from different viral strains do share conserved sequence and structural features in order to function as a key determinant in recognizing chemokine coreceptor (CCR5 or CXCR4) during HIV-1 infection (*9–12*). In addition to those conserved elements, such as a fixed size (30−35 amino acids) of the loop, a conserved disulfide bond at the base, and a β-turn structure at the conserved tip (GPGR or GPGQ) (*5, 13*), V3 domains from many different strains also carry three conserved *N*-glycans, within or adjacent to the loop, at the N295, N301, and N332 glycosylation sites (HXB2 numbering, http://hiv-web.lanl.gov). In the context of gp120, the N301 glycosylation site within the V3 loop usually carries a complex type *N*-glycan, while the N295 and N332 sites at the base normally bear high-mannose type *N*-glycans (*14, 15*). The two high-mannose type *N*-glycans at N295 and N332 sites are particularly interesting, as they were proposed to be an essential component of the epitope of the broadly neutralizing antibody 2G12 (*16, 17*). The human mAb 2G12 is the only broadly neutralizing antibody so far discovered that recognizes a novel cluster of high-mannose type *N*-glycans with terminal Manα1,2Man motifs in gp120 (*16–19*).

As part of our research program on HIV-1 vaccine, we are interested in reconstituting a V3 domain immunogen that integrates both the carbohydrate and peptide epitopes of the broadly neutralizing antibodies 2G12 and 447-52D. V3 domain has been previously expressed in the context of different fusion proteins for biochemical and immunological studies (*20–24*). But most of the V3 fusion proteins previously described were not glycosylated, as they were usually overproduced in *E. coli* that lacks protein glycosylation machinery (*20–23*). A large outdomain (aa 251−481) of a clade C gp120, which consists of V3 and other domains (C3, V4, C4, V5, and C5), was expressed in baculovirus infected insect cells as a glycosylated Fc-fusion protein (*24*). This study confirms the importance of the *N*-glycans around the V3 domain for 2G12 recognition, but the nature of the glycans (complex type vs high-mannose type) attached to V3 and other domains in the recombinant protein is yet to be characterized. We describe in this paper the expression of a glycosylated V3 domain as an IgG1-Fc fusion protein in the human embryonic kidney 293T (HEK293T) cell line. A V3 domain corresponding to the sequence aa 291−336 (46 amino acid residues) of HIV-1_{Bal} gp120 was chosen, which was fused to the C-terminus of the human IgG1-Fc domain (232 amino acid residues). The resulting V3-Fc fusion protein contains four glycosylation sites: three (N295, N301, and N332) are in the V3 domain and one is in the Fc domain (Fc-N297) (Figure 1). The advantage of making the IgG1-Fc fusion protein was

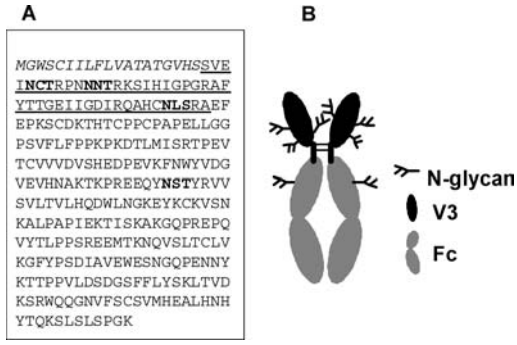

Figure 1. Schematic presentation of the glycosylated V3-Fc fusion protein. (A) Amino acid sequence of the V3-Fc fusion protein. The signal peptide sequence is italic, the V3 domain is underlined, and the glycosylation sites are in bold. (B) Homodimer of V3-Fc, in which the *N*-glycans at the N295 and N332 glycosylation sites in V3 domain are expected to be high-mannose type (HM), the glycan at N301 site in V3 domain is expected to be complex type (CT), and the *N*-glycan at the Fc region is expected to be complex type (CT).

several-fold. In addition to the easiness of purification of the Fc-tagged fusion protein via protein A affinity chromatography, fusing the small V3 polypeptide to the Fc is likely to stabilize the resulting recombinant protein and prevent degradation, as previously demonstrated for the Fc-fused gp41 ectodomain (*25*). Moreover, it has been suggested that the Fc domain could enhance the immunogenicity of the Fc-fusion protein by facilitating the uptake of antigens via Fc-mediated interactions with Fcγ receptors on antigen presenting cells (*24–26*). We report here the expression, characterization, and antibody-binding of different glycoforms of the recombinant V3-Fc fusion protein. Our results suggest that the high-mannose type V3-Fc fusion protein, which constitutes the epitopes of both the neutralizing antibodies 2G12 and 447-52D, may be a valuable immunogen for raising broadly neutralizing antibodies against HIV-1.

EXPERIMENTAL PROCEDURES

Strains, Cell Line, Media, and Enzymes. *Escherichia coli* DH5α was used for all molecular cloning steps. It was grown in LB broth (1% casein peptone, 0.5% yeast extract, and 1% NaCl). Human HEK293T cell line was used for the expression of V3-Fc fusion protein. It was cultured in DMEM medium supplemented with 10% low IgG fetal bovine serum (HyClone, Logan, UT) and 12.5 mM HEPES buffer.

Construction of pcDNA-LV3Fc Expression Vector and Site-Directed Mutagenesis. A 46 amino acid V3 domain was chosen from the sequence (aa 291−336, HXB2 numbering) of the gp120 derived from the HIV-1 BAL strain (R5 tropic). This domain includes the two glycosylation sites at the base of the V3 loop. The fusion protein was arranged by adding the Fc domain of human IgG1 to the C-terminus of the V3 domain. The human CD5 antigen leader sequence (*27*) was added to the N-terminus of fusion protein. The whole fusion construct was assembled in pGEM-T vector (Promega, Madison, WI). First, the coding fragments for human IgG1-Fc, V3, and CD5 leader were amplified by PCR with respective primer pairs and cloned into pGEM-T vector. The Fc coding fragment was amplified by a primer pair, (forward) CGA ATT CGA GCC CAA ATC TTG TGA C, (reverse) GTA GCG GCC GCT TAT TTA CCC GGG GAC AGG GAG. V3 fragment was amplified by the following primers, (forward) TCT CGA GCG TGG AGA TCA ACT GCA C and (reverse) TGA ATT CGG CGC GGC TCA GGT TGC. CD5 leader was amplified with (forward) CGG TAC CAT GGG ATG GTC ATG TAT CAT C and (reverse) GCT CGA GTG TAC ACC GGT TGC AGT. Each fragment was inserted into the pGEM-T vector, resulting in three plasmids: pT-Fc, pT-V3, and pT-CD5. To assemble the final expression construct, the Fc fragment was released from pT-Fc with *Eco*R I and *Not* I and cloned into corresponding sites of pT-V3, resulting in pT-V3Fc. Subsequently, V3Fc fragment was released with *Xho* I and *Not* I from the pT-V3Fc and cloned into corresponding site of pT-L, resulting in pT-LV3Fc. Finally, the assembled LV3Fc fragment was released from pT-LV3Fc and cloned into *Kpn*I and Not I site of mammalian expression vector pcDNA3.1+ (Invitrogen, Carlsbad, CA), resulting in the expression vector pcDNA-LV3Fc. To generate the single mutants of N-glycosylation sites in fusion protein, site-directed mutagenesis was carried out by using a commercial site-directed mutagenesis kit (QuickChange, Stratagene). All mutants were confirmed by DNA sequencing.

Transfection and Expression of V3-Fc in HEK293T Cells. The phenol-free pcDNA-LV3Fc plasmid for transfection was prepared with HiSpeed Plasmid Midi Kit or QIAfilter Maxi Kit (Qiagen). Transient transfection was performed using Fugene6 transfection reagent (Roche) following the manufacture's protocol. After transfection, the expression of fusion protein was periodically monitored using an antihuman IgG1 Fc ELISA assay kit (human IgG ELISA quantitation kit, BETHYL Laboratories Inc., Montgomery, TX). Complex type V3-Fc was expressed without the addition of mannosidase inhibitor. For generation of HM type V3-Fc, kifunensine (Caltech), the mannosidase inhibitor, was added into the culture system immediately after the transfection.

Purification of the Fusion Glycoprotein. The culture supernatant was collected 4 days after transfection. The fusion protein was purified by affinity chromatography using a protein A-agarose resin (Pierce). The cell-free culture supernatant was loaded on the protein A column pre-equilibrated with the binding buffer (pH 8.0, Thermo Scientific, Rockford, IL). After an extensive wash with the same buffer, V3-Fc was eluted with IgG elution buffer (pH3.0, Thermo Scientific, Rockford, IL). Each elution fraction was immediately neutralized with 1 M Tris-HCl, pH 8.8. Subsequently, all fractions were combined and concentrated with centrifugal filtration (Amicon Ultra centrifugal filter, Millipore, Billerica, MA). The integrity and purity of protein were checked by SDS−PAGE. The protein A column was regenerated with the elution buffer.

Size Exclusion Chromatography (SEC). The SEC chromatography was performed on an AKTA FPLC system (GE Healthcare) at 4 °C. The purified V3-Fc was loaded on a Superdex 200 10/300 GL size exclusion column (GE Healthcare). The column was eluted with a buffer containing 150 mM NaCl and 20 mM Tris-HCl (pH 8.0) at a flow rate of 0.5 mL/min. The sizes of proteins were estimated by using thyroglobulin (670 kDa) γ-globulin (158 kDa), ovalbumin (44 kDa), and myoglobin (17 kDa) as standards.

Enzymatic Deglycosylation. Purified V3-Fc proteins in various glycoforms were deglycosylated by different glycosidase treatment. PNGase F and Endo H (New England Biolabs) treatments were performed according to the manufacture's instruction, respectively. Deglycosyaltion of high mannose type V3-Fc was carried out by incubation of the V3-Fc fusion protein with endo-β-*N*-acetylglucosaminidase from *Arthrobacter* (Endo-A) (1/100, by weight) in a 25 mM Tris-Cl buffer (pH 8.0) at 37 °C for 2 h. Endo-A was expressed according to the reported method (*28*).

MALDI-TOF Mass Spectrometry. For the MALDI-TOF MS analysis of *N*-glycans, the total *N*-glycans of V3-Fc were released from 60 μg of glycoprotein by 10 U of PNGase F with incubation at 37 °C for 48 h. The reaction mixture was then treated with 10 mU of neuraminidase (from *Clostridium perfringens*, Sigma) and incubation at 37 °C for 2 h for

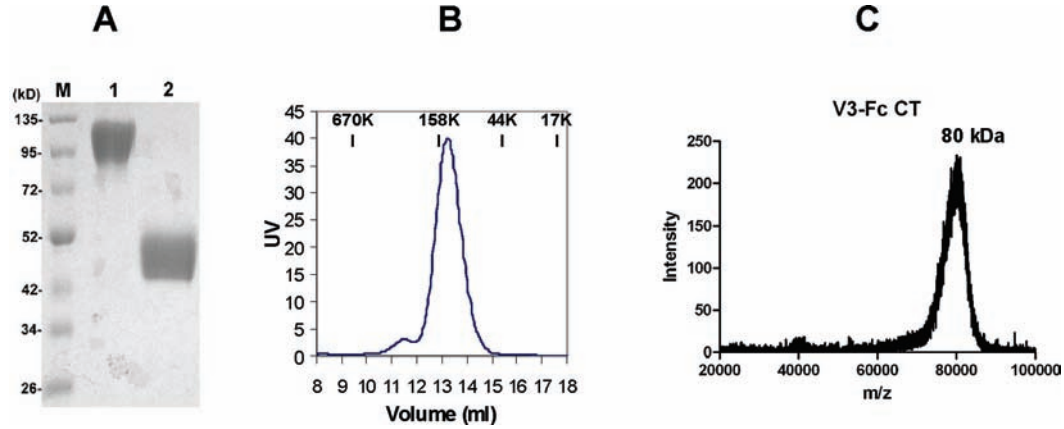

Figure 2. Analysis of the expressed V3-Fc fusion protein: (A) SDS−PAGE of the V3-Fc fusion protein under nonreducing (lane 1) and reducing conditions (lane 2); (B) gel-filtration chromatography of the V3-Fc under native condition; (C) MALDI-TOF MS analysis of the native V3-Fc.

desialylation. The released *N*-glycans were separated with centrifuge filtration (Microcon centrifugal filter, 10 KDa cutoff, Millipore), desalted by treatment with anion-exchange resin (DOWEX 1X2-100, Sigma-Aldrich) and cation-exchange resin (DOWEX 50WX8-100, Sigma-Aldrich), and finally lyophilized. The *N*-glycans were analyzed using a Bruker Autoflex II linear MALDI-TOF mass spectrometer (Bruker Daltonics) with 2,5-dihydroxybenzoic acid (DHB) as the matrix. The MALDI-TOF analysis of V3-Fc fusion protein was performed with the same machine, with sinapinic acid as matrix.

Surface Plasmon Resonance (SPR) Measurement. The interactions between the glycoforms of V3-Fc fusion protein and antibodies 2G12 and 447-52D were evaluated using a BIAcore T100 system (GE Healthcare). Monoclonal antibodies 2G12 and 447-52D (NIH AIDS Research and Reference reagent program) were immobilized respectively on CM5 sensor chips in an acetate buffer (10 mM, pH 5.0) by use of the amine coupling kit provided by the manufacturer, until the targeted response unit (RU) was reached. The reaction was quenched by the addition of ethanolamine HCl (1 M, pH 8.5). A reference cell without the antibody was prepared by similar procedures. Analyses were performed at 25 °C by injecting a solution of the respective V3-Fc glycoforms in a HBS-P buffer (10 mM HEPES, 150 mM NaCl, and 0.05% surfactant P20, pH 7.4) at a flow rate of 30 μL/min for 2 min, followed by wash for 5 min with HBS-P buffer for dissociation. The sensor surface was regenerated through a two-step wash (first wash, 3.5 M $MgCl_2$ for 0.5 min; second wash, HBS-P for 1 min). Data processing was carried out using the BIAcore T100 software.

RESULTS AND DISCUSSION

Expression, Purification, and Characterization of the V3-Fc Fusion Protein. The expression vector encoding the fusion protein was introduced into HEK293T cells by transient transfection. The culture supernatant was collected 4 days after transfection, and the V3-Fc fusion protein was purified with protein A affinity chromatography. The fusion protein appeared as a broad band at ∼49 kDa under reduced conditions (Figure 2A, lane 2) on SDS−PAGE. The broad band implicates a significant heterogeneity in the *N*-glycans attached. Under nonreducing (native) conditions, the fusion protein migrated on SDS−PAGE as a broad band at 110 kDa (Figure 2A, lane 1). These results suggest that the fusion protein is present as a homodimer in aqueous solution. This is expected, as the hinge-containing IgG-Fc turns to form a covalently linked homodimer through the formation of two pairs of disulfide bonds (*29*). The dimer format of the fusion protein under native conditions was further confirmed by size-exclusion chromatography. The V3-Fc fusion protein was eluted as a peak at ∼110 kDa, suggesting that it exists as a homodimer (Figure 2B). However, it was observed that the apparent molecular weight of the fusion protein was significantly bigger than the calculated molecular weight. On the basis of the assumption that the V3-Fc fusion protein (31 kDa for the protein backbone) carries four *N*-glycans and each *N*-glycan has an average molecular weight of 2 kDa, the estimated molecular weight should be around 39 kDa. The apparent molecular size (∼49 kDa) of the monomeric fusion protein on SDS−PAGE was clearly larger than the calculated data. The homodimer also showed a much larger size on SDS−PADE (under native condition) as well as in size-exclusion chromatography. One possible explanation is that the heavily glycosylated protein might have an extensive hydration to give a large hydration volume. To verify the actual molecular mass, the native V3-Fc fusion protein was subject to MALDI-TOF MS analysis (Figure 2C). While the fusion protein appeared as a broad signal, indicating the heterogeneity of the attached *N*-glycans, the average molecular mass is ∼80 kDa, which is consistent with the expected molecular weight of the heterogeneous dimeric V3-Fc glycoprotein (78−82 kDa).

To characterize the N-glycosylation status of the V3-Fc, the fusion protein was treated with PNGase F, which would remove all *N*-glycans attached. SDS−PAGE showed that the deglycosylated V3-Fc appeared as a sharp band with a size of ∼38 kDa (Figure 3A, lane 2). An 11 kDa difference between the glycosylated V3-Fc (∼49 kDa) and deglycosylated V3-Fc (∼38 kDa) suggests that the monomeric V3-Fc carries at least four *N*-glycans. Thus, all the glycosylation sites (three in the V3 domain and one in the Fc domain) in the expressed fusion protein should be glycosylated. Treatment of the fusion protein with Endo-H, an endo-glycosidase that cleaves only high-mannose type or hybrid type *N*-glycans, did not cause any change in the molecular size of the protein (comparing lane 3 and lane 1, Figure 3A). These results suggest that the V3-Fc fusion protein does not contain any high-mannose type or hybrid type *N*-glycans.

To validate the glycan profiles of the expressed fusion protein, the total *N*-glycans were released by PNGase F treatment. The released *N*-glycans were subjected to MALDI-TOF MS analysis after desialylation by sialidase, which simplifies the profiles of complex type *N*-glycans and also enhances the detection sensitivity. It was found that all the *N*-glycans in the V3-Fc fusion protein were complex type composed of bi-, tri-, and tetraantennary complex *N*-glycans, and no high-mannose type or hybrid type sugars were present (Figure 3B). The found molecular mass and proposed structures of the released *N*-glycans were listed in Table 1. These MS analysis data

confirmed the results from the Endo-H treatment. This is an interesting observation. In HIV-1 gp120, the two conserved *N*-glycans at the base of the V3 loop, N295 and N332, are usually high-mannose type, and the one within the V3 loop (N301) is conserved as a complex type *N*-glycan (*14*, *15*). We have shown here that when the V3 domain was expressed in the context of Fc-fusion protein, all the *N*-glycans were processed to form complex type sugars. These results suggest that the two *N*-glycans at N295 and N332 might be inaccessible for further processing by ER and Golgi α-mannosidases in the context of gp120, but in the Fc-fusion protein, the *N*-glycans at the two sites are more exposed so that further trimming and modifications could be achieved to form complex type sugars. These results also suggest that the microenvironment of the N-glycosylation sites, e.g., the steric hindrance around the sites due to the presence of other proximal domains, is critical for determining the nature of the *N*-glycans attached. This glycoform of the V3-Fc fusion protein, in which all the *N*-glycans are complex type, is named as V3-Fc-CT.

Expression and Characterization of High-Mannose Glycoforms of V3-Fc and Its Selected N-Glycosylation Mutants. It is known that antibody 2G12 recognizes a cluster of high-mannose type *N*-glycans around the V3 domain, and the *N*-glycans at the N295 and N332 sites of HIV-1 gp120 are the essential components for the epitope (*16*, *17*, *30*, *31*). The unexpected results that all the *N*-glycans attached to the V3-Fc fusion protein are complex type sugars when expressed in the HEK293 cell line prompted us to restore high-mannose type *N*-glycans in the V3-Fc fusion protein by controlling the glycan processing with a specific glycosidase inhibitor. It was previously reported that expression of glycoproteins in HEK293 cell lines in the presence of kifunensine, a potent α-mannosidase inhibitor, could efficiently control the glycosylation at the high-mannose type stage, thus leading to the formation of high-mannose glycoforms of recombinant glycoproteins (*32*–*34*). In particular, Scanlan and co-workers have successfully expressed HIV-1_{IIIB} gp120 in CHO cell line in the presence of kifunensine, which produced a novel glycoform of HIV-1_{IIIB} gp120 that carries high-mannose type sugars (*33*). Thus, we expressed the V3-Fc fusion protein in the HEK293T culture system in the presence of kifunensine (2 μg/mL). The expressed fusion protein, named as V3-Fc-HM, appeared at ∼95 kDa in SDS−PAGE under nonreducing condition (data not shown) and at ∼45 kDa under reduced condition as a clear band (Figure 4A, lane 1). This result indicates that the fusion protein

expressed is a homodimer. The dimeric form of the fusion protein was also confirmed by size-exclusion chromatography, which appeared as a single peak larger than 90 kDa (data not shown). In contrast to the complex type fusion protein V3-Fc-CT that appeared as a broad band in SDS−PAGE, the high-mannose type fusion protein V3-Fc HM appeared as a much sharper band, suggesting that the glycans attached are more uniformed. Removal of the V3-Fc-HM by PNGase F gave the deglycosylated fusion protein that appeared as a single band at 38 kDa (Figure 4A, lane 2), which is at the same size of the deglycosylated fusion protein from V3-Fc-CT. In addition, treatment of V3-Fc-HM with Endo-H resulted in a single band in SDS−PAGE (Figure 4A, lane 3) that had a similar size of the PNGase-F treated protein. This result indicates that all the glycans attached in V3-Fc-HM are Endo-H-sensitive, high-mannose type *N*-glycans. The MALDI-TOF MS of the V3-Fc-HM (Figure 4B) showed an average molecular mass of 77 050 Da, which is consistent with a V3-Fc homodimer carrying four high-mannose *N*-glycans (calculated, $M = 77\,000$ Da, for the Man8GlcNAc2 glycofrom). The observed *m*/*z* data from the MALDI-TOF MS of the Endo-H deglycosylated fusion protein (Figure 4C) are also in agreement with the calculated molecular weight of the deglycosylated protein (observed, 64 271 Da, calculated, $M = 64\,355$ Da). Finally the *N*-glycans released from the V3-Fc-HM by PNGase F were analyzed by MS. It was found that most of the glycoforms were Man9GlcNAc2 and Man8GlcNAc2, together with minor fractions of Man7GlcNAc2 and Man6GlcNAc2 glycoforms (Figure 5A and Table 2). Thus, the use of 2 μg/mL of kifunensine in the expression system could efficiently control the glycosylation processing at the high-mannose stage. To produce a homogeneous high-mannose type glycoform of V3-Fc, we increased the concentration of kifunensine in the HEK293 expression system to 10 μg/mL. Interestingly, we found that the fusion protein obtained under this condition was almost the Man9GlcNAc2 glycoform, with only a minor amount of the Man8GlcNAc2 (Figure 5B). No glycans smaller than Man8GlcNAc2 were formed under this expression condition. Thus, a new glycoform, V3-Fc-Man9 was obtained that appeared as a homogeneous glycoprotein, as indicated by SDS−PAGE (Figure 5B, inlet).

We also produced two mutants, N301A and Fc-N297A, in which the N301 glycosylation site in the V3 and the N297 site in the Fc domain were deleted, respectively. Both mutants were expressed in HEK293T cells in the presence of 2 μg/mL kifunensine to provide the high-mannose type glycoforms. SDS−PAGE analysis indicated that the two mutants were about 2 kDa smaller in size than that of the high-mannose glycoform of the wild type fusion protein (V3-Fc-HM) (Figure 6A, lane 1, V3-Fc-HM; lane 2, N301A; lane 3, Fc-N297A). These data suggest the deletion of one *N*-glycan in the two mutants. The *N*-glycan profiles of the two mutants are shown in Figure 6B and Figure 6C. Both have very similar profiles as that of the V3-Fc-HM, with Man9GlcNAc2 and Man8GlcNAc2 as the major glycoforms.

Binding of V3-Fc Glycoforms with Broadly Neutralizing Antibody 2G12. Monoclonal antibody 2G12 is a broadly HIV-neutralizing antibody that recognizes a cluster of high-mannose type *N*-glycans in HIV-1 gp120 (*16–18, 30*). We measured the interactions between 2G12 and the various glycoforms of V3-Fc with Biacore surface plasmon resonance (SPR) technology. 2G12 was immobilized on the SPR chip, and its real-time association and dissociation with V3-Fc at various concentrations were examined. It was observed that the complex type glycoform V3-Fc-CT did not show measurable interaction with 2G12 (Figure 7A). This result was expected, as 2G12 was previously shown to recognize only those *N*-glycans that bear terminal Manα1,2Man motifs (*16–19*). In contrast, the high-

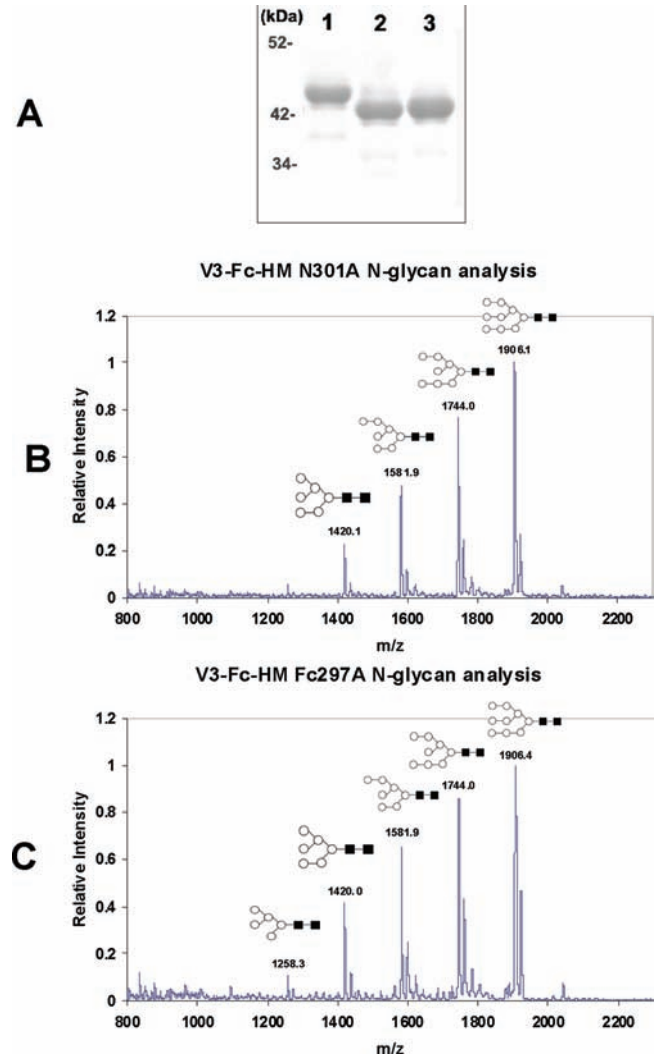

Figure 6. Characterization of V3-Fc mutants and their glycoprofiles. (A) SDS−PAGE analysis of V3-Fc mutants: lane 1, wild type V3-Fc HM); lane 2, V3-Fc N301A; lane 3, V3-Fc Fc-N297A. (B, C) MALDI-TOF MS analysis of PNGase F released *N*-glycan from N301A and Fc-N297A mutants, respectively.

mannose type glycoforms of V3-Fc demonstrated significant affinity to 2G12. The binding profiles of the V3-Fc-HM, V3-Fc-M9, and the two mutants (N301A and Fc-N297A) are shown in Figure 7B−E, respectively. The binding profile of gp120 derived from the HIV-1_{Bal} strain is shown in Figure 7F. It was found that the binding of antibody 2G12 to the four high-mannose glycoforms of V3-Fc fusion protein (including the two mutants) followed a quick association/dissociation kinetic process. Unfortunately, an attempt to fit the SPR data to possible kinetic equations failed to provide an accurate dissociation constant (K_d), making it difficult to have a quantitative comparison of the binding of 2G12 with different V3-Fc glycoforms. Nevertheless, a comparison of the sensorgrams of the various glycoforms indicated that the V3-Fc-HM and V3-Fc-M9 had a comparable affinity to 2G12 and followed a very similar kinetic profile (Figure 7B vs Figure 7C). Since both glycoforms carry Man9GlcNAc2 and Man8GlcNAc2 as the major *N*-glycans, these results are consistent with previous observations that Man9GlcNAc2 and Man8GlcNAc2 interacted with 2G12 equally efficiently through the D1 arm contact (*18, 19*). Interestingly, removal of the *N*-glycan at the N301 site significantly reduced the affinity to antibody 2G12 (Figure 7D). In native HIV-1 gp120, the glycan at the N301 site of V3 is a conserved complex type sugar that did not positively contribute

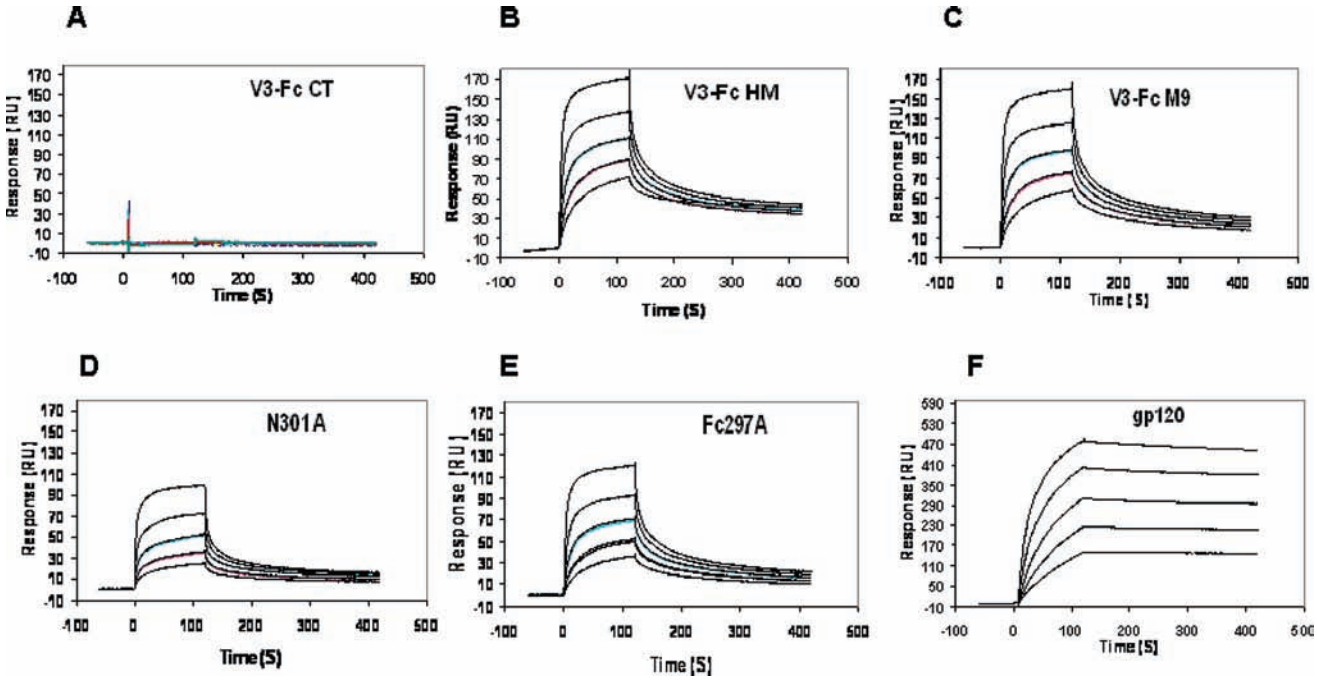

Figure 7. SPR sensorgram of the binding of different glycoforms of V3-Fc and its mutants with immobilized 2G12 antibody. V3-Fc was applied to analysis with a serial concentration of 2-fold dilution, with the highest concentration set at 2 μM. The interaction between gp120 and immobilized 2G12 was analyzed in a similar manner except that the highest concentration of gp120 was set at 1 μM.

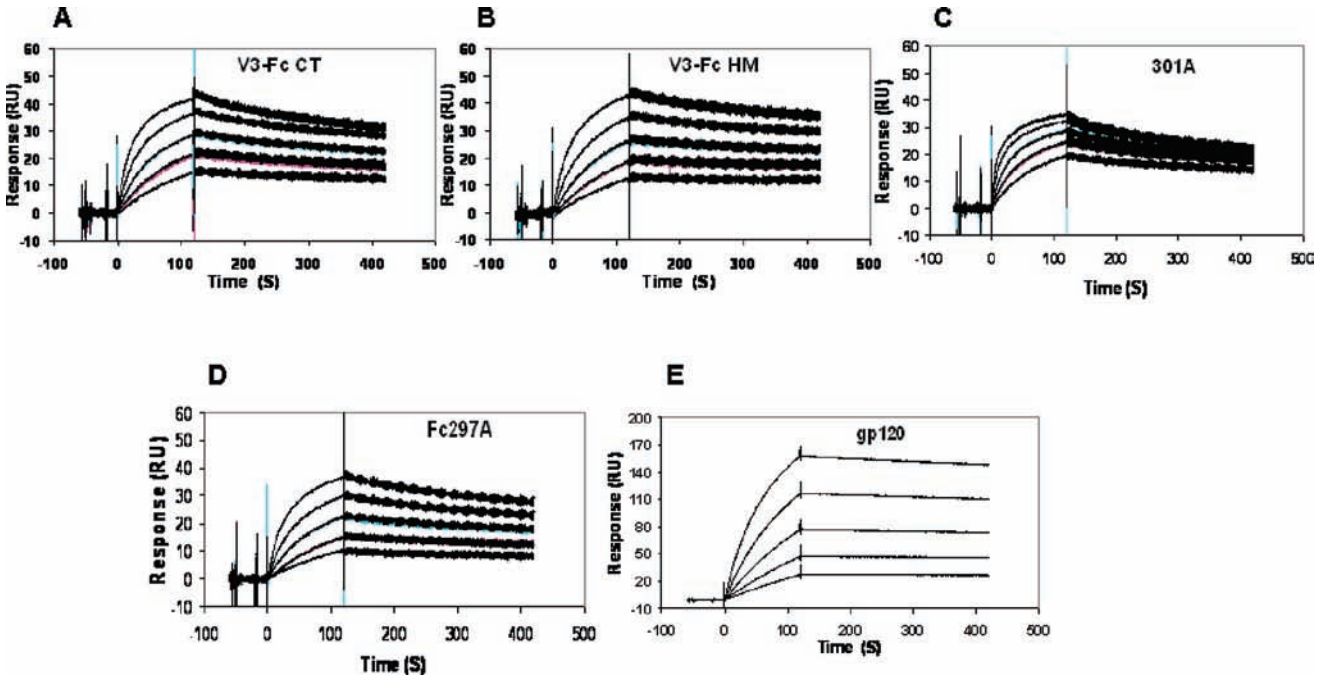

Figure 8. SPR sensorgram of the binding of different glycoforms of V3-Fc with immobilized 447-52D antibody. Both V3-Fc and gp120 were applied to the analysis with a serial concentration of 2-fold dilution. The highest concentration was set at 200 nM.

to the binding of 2G12 (*14*, *15*). Thus, changing this *N*-glycan to a high-mannose type glycan seemed to create a new epitope (likely a cluster of the three *N*-glycans at N295, N301, and N332) for 2G12 that has a much higher affinity to 2G12 than the epitope formed only by the two glycans at N295 and N332. As for the Fc glycosylation, we also observed that removal of the *N*-glycan at the Fc domain resulted in the reduction of the binding of the resulting mutant (Fc-N297A) to 2G12 (Figure 7E), albeit to a lesser extent than the N301A mutant. This result implicated that the Fc domain *N*-glycan was also involved in the interaction of the V3-Fc fusion protein with 2G12. In contrast to those recombinant V3-Fc fusion proteins, the dissociation between gp120 and 2G12 was found to be extremely slow (Figure 7F), although its association rate was comparable to those of the V3-Fc fusion proteins (Figure 7F). A typical HIV-1 gp120 carries 24 *N*-glycans, among which 11 are high-mannose type and 13 are complex type *N*-glycans (*14*, *15*). The extremely slow dissociation rate for the gp120-2G12 interaction suggests that other key elements, e.g., some protein domains or additional high-mannose type *N*-glycans in the context of gp120, might be also be involved in subsequent interactions to strengthen the binding, after initiate recognition with gp120. The difficulty of fitting the binding data to any appropriate kinetic equations also implicates a complex process for the 2G12−glycan interactions.

Although the high-mannose *N*-glycans at the N295 and N332 sites in gp120 are essential for 2G12 recognition, the precise epitope of antibody 2G12 is still not fully characterized.

Binding of V3-Fc Glycoforms with Broadly Neutralizing Antibody 447-52D. Monoclonal antibody 447-52D is another broadly neutralizing antibody that is specific for the V3 loop. It is a conformation-sensitive antibody. X-ray structural studies indicated that 447-52D Fab recognized the V3 peptide by binding to two domains: the conserved β-turn at the tip (GPGR) of the V3 loop and the peptide amide backbone, rather than the variable side chains of the surrounding sequence (*35*). Although extensive structural and biochemical studies have been performed for the interactions between 447-52D and various V3 antigens, it is hitherto not clear how the conserved *N*-glycans within or around the V3 loop affect the antibody−epitope interaction. This is partly attributed to the difficulty of obtaining structurally defined, glycosylated full-size V3 domains. To examine the effects of glycosylation on the antibody binding, we tested the interaction of different glycoforms of V3-Fc with antibody 447-52D using SPR technology. Interestingly, both the complex type (V3-Fc-CT) and the high-mannose type glycoforms (V3-Fc-HM) of the fusion protein could bind 447-52D with a high affinity and with a very similar association/dissociation pattern (Figure 8A and Figure 8B). Fitting of the binding data to a steady-state mode equation gave an estimated K_d of 46 and 72 nM for the V3-Fc-CT and V3-Fc-HM, respectively. The data suggest that the nature of the glycosylations at the N295, N301, and N332 sites did not significantly affect the recognition of the antibody to its epitope. On the other hand, the binding of the N301A and F-N297A mutants with 447-52D was assessed by SPR (Figure 8C and Figure 8D) and the dissociation constants (K_d) for N301A and Fc-N297A were estimated to be 21 and 67 nM, respectively. Interestingly, the N301A mutant (K_d = 21 nM) showed a 2-fold increase in affinity to 447-52D in comparison with the V3-Fc-CT (K_d = 46 nM), while the Fc-N297A (K_d = 67 nM) had essentially the same affinity as V3-Fc-HM (K_d = 72 nM). These data suggest that an *N*-glycan at N301 might partially hinder the interaction between antibody 447-52D and the V3 antigen. Nevertheless, all the glycoforms of V3-Fc could still bind antibody 447-52D with very high affinity at nanomolar concentrations. The affinity of the glycosylated V3-Fc with 447-52D is comparable to that of the nonglycosylated V3 inserted at the surface loop location of *E. coli* thioredoxin (*22*). For comparison, we measured the binding of HIV-1_{Bal} gp120 to 447-52D (Figure 8E). The K_d was estimated to be 23 nM. Taken together, these data suggest that the nature and the presence of the three conserved *N*-glycans at N295, N301, and N332 sites that are near the epitope do not significantly affect the antibody recognition of its epitope, although deletion of the *N*-glycan at N301 does increase the affinity to some extent. Moreover, the comparable binding affinity among the various Fc fusion proteins and the HIV-1 gp120 suggests that the fusion protein could present a similar conformational epitope of 447-52D as that existing in native gp120. Thus, the high-mannose type fusion proteins (V3-Fc-HM and V3-Fc-M9), which include both the epitopes of 2G12 and 447-52D, could represent an interesting immunogen that may be used to elicit neutralizing antibodies against HIV-1.

CONCLUSION

Several glycoforms of the V3-Fc fusion protein were successfully expressed and characterized. Our studies demonstrate that the nature of the V3 glycosylation depends on the protein context where the V3 domain is present. Antibody binding studies revealed that the nature and presence of the glycan at N301 within the V3 loop did not significantly affect the recognition of antibody 447-52D with the V3 domain. On the other hand, controlling the glycosylation at the three sites (N295, N301, and N332) at high-mannose type *N*-glycans could partially reconstitute the epitope of antibody 2G12. In particular, mutational studies indicate that installing a high-mannose type *N*-glycan at the N301, which is usually occupied by a complex type *N*-glycan in gp120, significantly enhances the binding to 2G12. The resulting high-mannose type V3-Fc fusion protein that includes both the 2G12 and 447-52D epitopes thus represents an interesting immunogen that may be able to raise neutralizing antibodies against HIV-1.

ACKNOWLEDGMENT

We thank Drs. Anthony L. DeVico, George K. Lewis, and Yongjun Guan for helpful discussions during the work. The human antibodies 2G12 and 447-52D were provided by the National Institutes of Health (NIH)'s AIDS Research and Reference Reagent Program. This work was supported by the National Institutes of Health (NIH Grant R01 AI067111).

The induction of apoptosis is frequently accompanied by the exposure of phosphatidylserine (PS) on the cell surface, which has been detected using radionuclide and fluorescently labeled derivatives of the PS-binding protein, Annexin V. The fluorescently labeled protein has been used extensively in vitro as a diagnostic reagent for detecting cell death, and radionuclide-labeled derivatives have undergone clinical trials for detecting tumor cell death in vivo following treatment. We show here that the C2A domain of Synaptotagmin-I, which had been fluorescently labeled at a single cysteine residue introduced by site-directed mutagenesis, detected the same levels of cell death as a similarly labeled Annexin-V derivative, in drug-treated murine lymphoma and human breast cancer cell lines in vitro. However, the C2A derivative showed significantly less binding to viable cells and, as a consequence, up to 4-fold more specific binding to apoptotic and necrotic cells when compared with Annexin-V. C2A offers a potential route for the development of a new generation of more specific imaging probes for the detection of tumor cell death in the clinic.

INTRODUCTION

The detection of cell death in the clinic is of considerable interest for assessing the effectiveness of therapy and for determining the progression of disease (*1, 2*). In oncology, the induction of tumor cell death following treatment can be a good predictive indicator of treatment outcome, a positive correlation having been observed, for example, between the levels of tumor cell death post treatment and patient survival rates, in human breast cancer (*3, 4*). Apoptosis is frequently associated with the externalization of negatively charged phospholipids, such as phosphatidylserine (PS), on the outer leaflet of the plasma membrane bilayer, where they direct engulfment of the apoptotic cell by neighboring phagocytes (*5*). PS is also exposed during subsequent necrosis, due to disruption of plasma membrane integrity. The detection of PS exposure by Annexin V (AnxV) has often been used to detect apoptosis. AnxV is a 36 kDa protein that binds with high affinity and in a Ca^{2+}-dependent manner to the PS exposed on dying cells. Radionuclide derivatives of AnxV reached early-stage clinical trials and were shown to detect cell death in patients with myocardial infarcts (*6*), lymphoma, and lung cancer (*7, 8*). There were, however, problems with biodistribution (*9, 10*).

The C2A domain of Synaptotagmin I is a 14.7 kDa protein, which like AnxV binds to PS in a Ca^{2+}-dependent manner (*11, 12*). A glutathione-S-transferase (GST)-tagged version of C2A was shown to detect cell death in vitro and in vivo using radionuclide and MR imaging techniques (*13*−*15*). The protein is of interest since, due to its smaller size, it may show better penetration of tumor tissue than AnxV and also better clearance of unbound material, thus generating better tissue contrast.

In previous studies with the C2A domain of synaptotagmin, an MRI contrast agent was attached to the ε-amino group of surface lysine residues (*13, 15, 16*). There are 14 lysine residues in C2A and a total of 35 in the C2A-GST fusion protein (*15*). Attachment of labels to multiple lysine residues inevitably results in a reagent that consists of a heterogeneous mixture of molecular species. Moreover, in the case of an MRI agent based on C2A-GST, modification of these lysine residues with MR-detectable Gd^{3+}-chelates was shown to lower the affinity of the protein for phosphatidylserine (PS) (*15*). We describe here a site-directed mutant of C2A, C2Am, in which we have replaced a serine residue that is distant from the PS-binding site, with a single cysteine residue (S78C). Since there are no other cysteine residues in the protein, this provides a unique site for the modification of the protein with fluorescent, radionuclide, or MR-detectable labels. In this study, we have assessed the potential of a fluorescent derivative of C2Am to detect cell death in murine lymphoma and human breast cancer cell lines, by comparing both its sensitivity and specificity for detection of apoptotic and necrotic cells with that of a fluorescent derivative of AnxV that is available commercially.

EXPERIMENTAL PROCEDURES

Materials. All tissue culture reagents, SYTOX Green dead cell stain, and Annexin V-Alexa Fluor647 (AnxV-AlxF647) were from Invitrogen (Paisley, Renfrewshire, UK). The green Polycaspases FLICA kit was from Immunochemistry Technologies LLC (Bloomington, MN, USA). All chemicals were of analytical grade from Sigma-Aldrich Co. Ltd. (Poole, Dorset, UK), unless stated otherwise. Etoposide (EPOSIN) was from PCH Pharmachemie, (Haarlem, Netherlands). Murine lymphoma (EL-4) cells were obtained from the American Type Culture Collection (Teddington, Middlesex, UK) and MDA-MB-231 cells were from European Collection of Cell Cultures (Salisbury, Wiltshire, UK).

Construction, Overexpression, and Purification of C2A(S78C). The *Rattus norvegicus* synaptotagmin I sequence was obtained from the NCBI Genbank service (sequence NM_001033680).

Appropriate primers for mutagenesis were designed using Quikchange Primer Design software. The C2A-containing pGEX-2T vector (GE Healthcare, Chalfont St Giles, UK) was isolated from *E. coli* BL21 cells and mutagenesis performed using the QuikChange Site-Directed Mutagenesis kit (Stratagene, La Jolla, CA, USA). *E. coli* DH5a competent cells were transformed with the mutant plasmid by heat shock and the amplified vector then isolated and sequenced. Finally, *E. coli* BL21 cells were transformed with the vector by electroporation. The proteins were expressed as 42-kDa GST-tagged fusion proteins, following induction using isopropyl-β-D-thiogalactoside (IPTG), and the S78C mutant was purified using affinity chromatography (see Methods 1 in Supporting Information). The extent of purification was analyzed using SDS-PAGE. Protein concentrations were determined using a Non-Interfering Protein AssayTM kit (NIPA from Merck Chemicals Ltd., Nottingham, UK) and by densitometry for AnxV-AlxF647 (see Methods 2 in Supporting Information).

Production of Fluorescently Labeled Protein. The mutant protein (C2Am) was covalently labeled with the fluorophore Alexa Fluor 647 (AF647), by reaction of the cysteine-78 residue with the maleimide group of Alexa Fluor 647 C2 maleimide (Invitrogen). Briefly, the protein was reduced using 10 mM DTT for half an hour at room temperature. The protein was then washed in a 5 kDa vivaspin concentrator (Sartorius, Epsom, UK) in HNE buffer (20 mM HEPES, 100 mM NaCl, 5 mM EDTA, pH 7.4). The protein was kept at a concentration in the range 50−100 μM, and an approximately 10-fold molar excess of the fluorescent maleimide dye was added. The reaction was allowed to proceed on a magnetic stirrer at 4 °C overnight. The modified protein was separated from unreacted dye by gel filtration using a Hi Load Superdex 75 26/60 prep grade column (GE Healthcare). Electrospray ionization (ESI) mass spectrometry was used to confirm modification of the protein, which showed a single species of approximately 17 204 Da (C2Am-AF647) (see Methods 3 and Figure S1 in Supporting Information).

Surface Plasmon Resonance (SPR). Protein affinity of C2Am and C2Am-AF647 for PS-containing liposomes was estimated using the Biacore T100 (Biacore, GE Healthcare). (See Methods 4 in Supporting Information).

Cell Culture. EL4 murine lymphoma and MDA-MB-231 human breast cancer cells were propagated in RPMI 1640 media, supplemented with 10% fetal calf serum and 2 mM L-glutamine. Cell number and viability were monitored using Trypan blue dye staining. EL4 cell death was induced by addition of 5 μM etoposide for up to 24 h and MDA cell death by treatment with doxorubicin (1 μg/mL) for up to 96 h.

Detection of Cell Death Using Flow Cytometry. Cell pellets (10^6 cells) were washed in ice-cold HEPES-buffered saline (10 mM HEPES, 150 mM NaCl, 2 mM $CaCl_2$, pH 7.4) with 1% fetal calf serum and resuspended in 100 μL of the same buffer containing C2Am-AF647, which was used at concentrations between 50 nM to 1.0 μM, or AnnexinV-AF647 (Invitrogen), which was used at concentrations between 1 and 20 nM, in combination with SYTOX Green (Invitrogen; 50 nM), and incubated for 15 min at 37 °C. The resulting mixture was washed twice, kept briefly on ice, and then analyzed in an LSRII cytometer (BD Biosciences, Rockville, MD USA), with 20 000 cells counted per event.

For detection of active caspases, EL4 or MDA cells were washed and then incubated with Poly Caspases FLICA for 30 min at 37 °C (300-fold diluted stock). A further wash step was performed before incubation with C2Am and AnxV. The same washing steps were applied as in all the other flow cytometry studies. All experiments were performed at least three times.

Image Analysis of C2Am and AnxV Binding to Dying Cells. EL4 cell pellets (5×10^6 cells) were washed in ice-cold HEPES-buffered saline. The pellets were resuspended in 1 mL of warm buffer containing the mitochondrial stain MitoTracker Orange CMTMRos (Invitrogen, 100 nM) and incubated for 30 min at 37 °C. Cells were washed once and resuspended in ice-cold HEPES-buffered saline with 3% BSA for 30 min at 4 °C. Cells were then resuspended in 100 μL HEPES-buffered saline containing either C2Am-AF647 or AnxV-AF647 (Invitrogen), which were used at concentrations of 200 nM and 4 nM, respectively, and incubated for 15 min at 37 °C. The resulting mixture was then washed twice and resuspended in 100 μL ice-cold buffer containing the nucleic acid stain, 7-amino-actinomycin D (7-AAD) (Invitrogen, 20 μg/mL) and kept on ice briefly before samples were loaded into an ImageStream system (Amnis Corporation, Seattle, WA, USA), and a file of 5000 cells was collected in the standard collection mode. Data files were analyzed using *IDEAS* software (Amnis, Seattle, WA) to obtain fluorescence images of individual cells.

Statistical Analysis. Two-way ANOVA and subsequent Mann−Whitney's test were used for all analyses. *P*-values below 0.05 were considered to be statistically significant.

RESULTS

Preparation of C2A(S78C). The serine residue at position 78 of the C2A domain of Synaptotagmin-I (position 217 of Synaptotagmin-I), was replaced with a cysteine residue, using site-directed mutagenesis. Three candidate amino acid residues were selected for replacement: Ser217, Gln154, Asn248. SDS PAGE of the three GST-C2A mutants (S217C, N248C, and Q154C) was used to assess the levels of expression before and after IPTG induction. All vector-transformed bacteria expressed the mutant proteins to some degree, but a much higher level of overexpression was obtained for S217C. The isolated C2A domain [C2A(S78C)] was prepared as described in Experimental Procedures.

Synthesis and Characterization of C2A(S78C)-Alexa Fluor 647. C2A(S78C) was reacted with a maleimide derivative of Alexa Fluor 647. The modified protein (C2Am), gave a single peak on electrospray ionization mass spectrometry, with the expected mass of 17 204 Da (see Figure S1 in Supporting Information). SDS-PAGE also showed a single band of the expected mass (see Figure S2 in Supporting Information). Surface plasmon resonance (SPR) measurements gave similar dissociation constants (K_d) for the unmodified and modified proteins for PS of 55.4 ± 3.5 nM and 71.0 ± 6.9 nM, respectively. The dissociation constant of wild-type C2A for PS is approximately 20 nM (*16*). These dissociation constants were corroborated by kinetic analysis of the SPR data (see Table ST1 in Supporting Information). The k_{on} values determined from the kinetic analysis for the unmodified and modified proteins were 2.01×10^6 M^{-1} s^{-1} and 2.14×10^6 M^{-1} s^{-1}, respectively, and the k_{off} values were 0.110 s^{-1} and 0.188 s^{-1}, respectively.

Analysis of Fluorescently Labeled Annexin V. A commercial preparation of Annexin V (AnxV), that had been labeled with the same fluorophore (Alexa Fluor 647, or AF647) as C2Am, was analyzed by SDS-PAGE, which showed bands at ca. 35 kDa and ca. 65 kDa, which were thought to be AnxV and BSA, respectively (see Figure S3a in Supporting Information). The latter is an additive in the preparation, at 0.1% (w/v). Fluorescent imaging of the same gel showed that the band at ca. 35 kDa was fluorescent (647 nm excitation), confirming it as AF647-labeled AnxV (see Figure S3b in Supporting Information). The intensity of this band indicated that it was approximately 2% (w/w) of the total protein concentration (determined to be 800 μg/mL), and therefore, the concentration of AnxV was estimated to be approximately 460 nM in this commercial preparation of the protein.

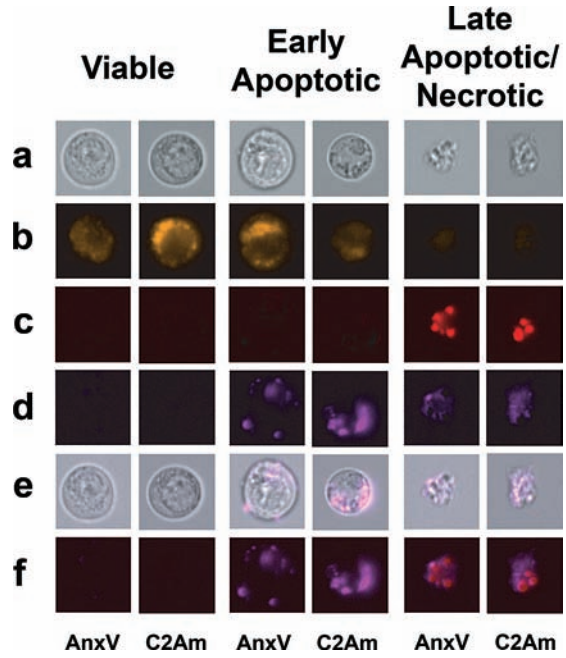

Figure 1. Images of EL4 cells at different stages of cell death. Bright field images (A); fluorescent images of cells stained with MitoTracker orange (B); fluorescent images of cells stained with the DNA stain, 7AAD (7-amino-actinomycin) (C); fluorescent images of cells stained with AnxV-AF647 or C2Am-AF647 (D); overlays of images shown in A and D (E); overlays of images shown in C and D (F). C2Am was used at a concentration of 200 nM and AnxV at 4 nM.

Flow Cytometry of Dying Cells Stained with C2Am or AnxV. Images were acquired from etoposide-treated EL4 cells that had been sorted according to the level of binding of C2Am or AnxV. Viable cells, which did not stain with C2Am or AnxV (Figure 1d), had a rounded morphology and an intact plasma membrane (Figure 1a), showed mitochondrial activity (Figure 1b) and no nucleic acid staining (Figure 1c). In contrast, early apoptotic cells that stained with C2Am or AnxV (Figure 1d) appeared irregular, with blebbing of the plasma membrane (Figure 1a), but still showed mitochondrial activity (Figure 1b) and no nucleic acid staining (Figure 1c). Late apoptotic/necrotic cells showed no detectable mitochondrial activity (Figure 1b), pronounced nucleic acid staining (Figure 1c), which demonstrated loss of plasma membrane integrity, and C2Am or AnxV staining (Figure 1d). Overlays of C2Am or AnxV staining with the bright field images are shown in Figure 1e, demonstrating that both probes stain the EL4 cell membrane of early apoptotic cells. Overlays of nucleic acid staining with the corresponding images of C2Am and AnxV staining are shown in Figure 1f, demonstrating that both C2Am and AnxV accumulate intracellularly in late apoptotic/necrotic EL4 cells.

Detection of Cell Death Using Flow Cytometry and C2Am or AnxV. The facility of C2Am to detect cell death by flow cytometry in drug-treated murine lymphoma (EL4) and human breast cancer (MDA-MB-231, hereafter referred to as MDA) cell lines was compared with detection using AnxV. Cell death was induced by treatment of EL4 and MDA cells with etoposide or doxorubicin, respectively (Figures 2 and 3).

Treatment of cells with DNA damaging agents, such as etoposide and doxorubicin, results in activation of poly ADP-ribose polymerase (PARP) and, since NAD^+ is a substrate for PARP, depletion of the cellular NAD(H) pool (*17*). As a consequence, NADH autofluorescence is decreased considerably upon the induction of cell death using DNA damaging agents, and this decrease occurs relatively early after etoposide treatment in EL4 cells (*18*). Therefore, we identified apoptotic cells by their low NADH autofluorescence (green symbols), necrotic cells by their low NADH autofluorescence and high SYTOX green fluorescence (SYTOX green is a marker of cell necrosis) (orange symbols), and viable cells by their high NADH autofluorescence and low SYTOX green fluorescence (blue symbols) (Figure 3a,b and i,j). In this study, we have not tried to distinguish between primary necrosis, that is cells that have become necrotic without engaging the apoptotic pathway, and secondary necrosis, in which late apoptotic cells have become necrotic (*19*). Instead, when we refer to late apoptotic or necrotic cells, we are referring to cells with compromised plasma

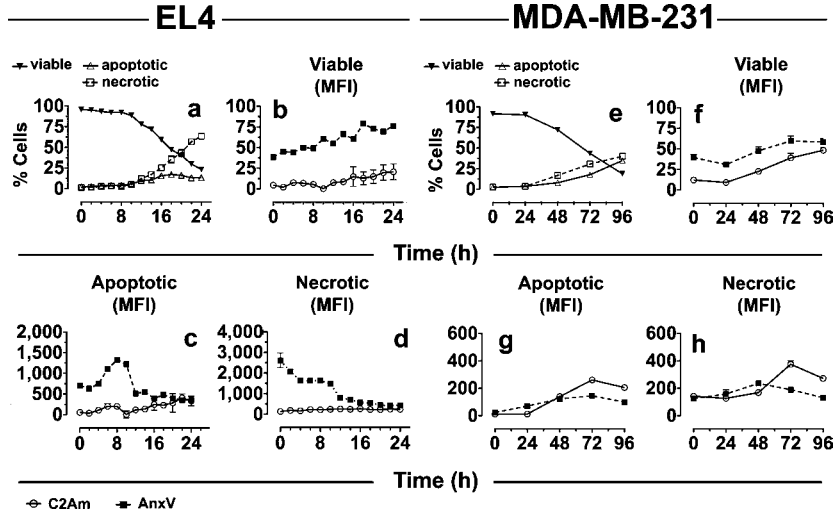

Figure 2. Binding of C2Am and AnxV to viable, apoptotic, and necrotic EL4 and MDA cell populations. Cell death was induced in EL4 and MDA cells by treatment with etoposide or doxorubicin, respectively, for the specified times. The fractions of apoptotic (△), necrotic (□), and viable cells (▼) were assessed by flow cytometric measurements of NADH autofluorescence (Exc, $\lambda = 350$; Em, $\lambda = 475$ nm) and Sytox green staining (Exc, $\lambda = 504$; Em, $\lambda = 523$ nm) (a and e). Binding of fluorescently labeled derivatives of C2Am (○) and AnxV (■) to the viable (b,f), apoptotic (c,g), and necrotic (d,h) cell populations was also assessed by flow cytometry, where binding is expressed as the mean fluorescence intensity (the total fluorescent signal for this population was divided by the number of cells and is expressed in arbitrary units). The fluorescence intensities used to calculate the MFIs were standardized to autofluorescence levels in the Alexa Fluor 647 channel. Data shown are means ± SEM ($n = 3$; error bars lie within the symbols when not visible) for each time point. C2Am was used at a concentration of 200 nM and AnxV at a concentration of 4 nM. Differences were significant at the following: $^*P < 0.05$, plot a-6 and 12 h, b-2 h, c-24 h; $^{**}P < 0.01$, a-8 h, b-4 and 14 h, d-48 h; $^{***}P < 0.001$, a-10 and 14 to 24 h, b-0 and 12 h, c-48 to 96 h, d-0, 24, 72, and 96 h.

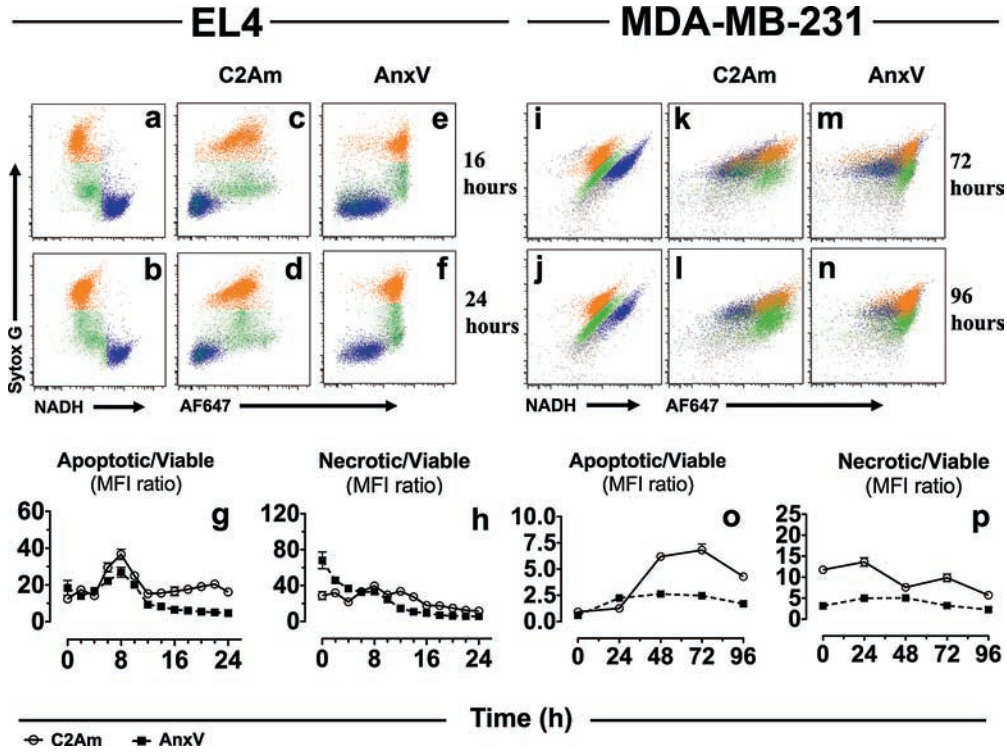

Figure 3. Specificity of C2Am and AnxV binding to viable, apoptotic, and necrotic EL4 and MDA cell populations. Cell death was induced by treatment of EL4 and MDA cells with etoposide or doxorubicin, respectively, for the specified times. The fractions of apoptotic (green symbols), necrotic (orange symbols), and viable cells (blue symbols) were assessed by flow cytometric measurements of NADH autofluorescence (Exc, λ = 350; Em, λ = 475 nm, *x*-axis) and Sytox green nuclear staining (Exc, λ = 504; Em, λ = 523 nm, *y*-axis) (a, b, i, and j). Binding of Alexa Fluor 647-labeled C2Am or AnxV (Exc, λ = 647; Em, λ = 670 nm, *x*-axis) to these cell populations is shown in c and d and k and l for C2Am and in e and f and m and n for AnxV. The specificity of binding was assessed by plotting the mean fluorescence intensity (MFI) ratios for the Alexa Fluor 647 following binding of C2Am (○) and AnxV (■) to the indicated cell populations, where these cell populations were identified by their NADH autofluorescence and Sytox green nuclear staining (g,h and o,p). The fluorescence intensities used to calculate the MFIs were standardized to autofluorescence levels in the Alexa Fluor 647 channel. Data shown are means ± SEM (n = 3, error bars lie within the symbols when not visible) for each time point. Differences were significant at the following: *$P < 0.05$, plot s-48 h; **$P < 0.01$, h-12 h, i-14 h, q-24 and 72 h, r-24 h; ***$P < 0.001$, g-0 to 24 h, h-0 to 10 and 14 h, i-0 to 12 h, q-0 and 48 h, r-72 and 96 h, s-72 and 96 h. Sytox SYTOX green; AF647 = Alexa Fluor 647.

Table 1. Correlation Factors (R^2) for Best Fit of EL4 or MDA Cell Populations (% Cells) Identified by C2Am or AnxV and by Measurements of NADH UV Autofluorescence and SYTOX Green Staining

	viable	apoptotic	necrotic
	C2Am vs AnxV		
EL4	0.9641	0.9333	0.9919
MDA	0.9947	0.9913	0.9936
	C2Am vs NADH and SYTOX Green		
EL4	0.9983	0.9859	0.9969
MDA	0.9734	0.9965	0.9840
	AnxV vs NADH and SYTOX Green		
EL4	0.9975	0.9568	0.9986
MDA	0.9677	0.9913	0.9936

membrane integrity and which therefore stain with the nucleic acid stains SYTOX green or 7-AAD.

Both C2Am (Figure 3c,d and k,l) and AnxV (Figure 3e,f and m,n) bound to the apoptotic and necrotic cell fractions identified by measurements of NADH autofluorescence and SYTOX green staining. Moreover, the cell populations identified by either protein were well-correlated with each other and with the cell populations identified by measurements of NADH autofluorescence and SYTOX green staining (Table 1). However, C2Am showed better specificity for detecting apoptotic and necrotic cells, when compared with AnxV, which can be explained by the greater binding of AnxV to viable cells. Viable EL4 and MDA cells (Figure 2b and f, respectively) showed consistently higher absolute staining with AnxV (up to 4-fold, $P < 0.001$, for EL4 cells and up to 2-fold, $P < 0.01$, for MDA cells) when compared with C2Am, despite being used at a 50-fold lower concentration (4 nM AnxV and 200 nM C2Am). Although apoptotic and necrotic EL4 and MDA cells generally showed more labeling with AnxV than C2Am (Figure 2c,d and g,h), the effects of this on the specificity of detection of apoptotic and necrotic cells was more than offset by the greater binding of AnxV to the viable cells. This improved specificity can readily be appreciated from plots of the ratios of the mean fluorescence intensities (apoptotic and necrotic versus viable) following binding of C2Am and AnxV. The ratios of the mean fluorescence intensities (MFI) for apoptotic/viable (Figure 3g and o) and necrotic/viable (Figures 3 h and p) cells were higher for C2Am than for AnxV for the majority of the time following drug treatment, for both EL4 and MDA cells. C2Am showed greater specificity for apoptotic cells ($P < 0.05$ for EL4 and MDA cells) and necrotic cells ($P < 0.05$ for EL4 cells and $P < 0.01$ for MDA cells) when compared to AnxV.

Apoptotic and necrotic MDA cells (Figure 3i and j, represented by the green and orange symbols) showed similar levels of SYTOX green staining to viable cells (in blue). Compare Figure 3a and b for EL4 cells with Figure 3i and j for MDA cells. However, doxorubicin is fluorescent and its emission overlaps with that of SYTOX Green (*20*), and therefore, this effect was probably due to the presence of the drug in the viable MDA cells in this particular experiment.

Comparison of Cell Labeling with C2A and AnxV with Caspase Activation. As a further independent measure of cell death, we assessed caspase activation using a Poly Caspases

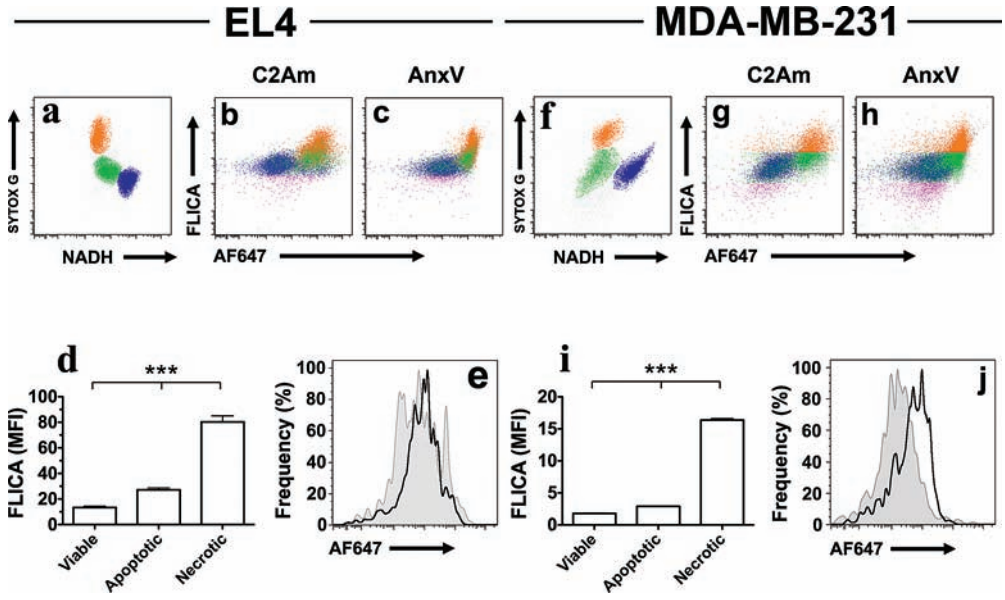

Figure 4. Dual scatter plots of active caspase labeling (Poly Caspases FLICA carboxyfluorescein; Exc, $\lambda = 490$; Em, $\lambda = 530$ nm, *y*-axis) versus labeling with C2Am (b and g) or AnxV (c and h) (Alexa Fluor 647; Exc, $\lambda = 647$; Em, $\lambda = 670$ nm, *x*-axis) of EL4 cells treated with etoposide (5 μM) for 16 h (a−c) and MDA cells treated with doxorubicin (1 μg/mL) for 72 h (f−h). Apoptotic (green), late apoptotic/necrotic (orange), and viable (blue) EL4 or MDA cells were identified based on their levels of NADH autofluorescence and staining with SYTOX green (a, EL4 cells; f, MDA cells). Mean fluorescence intensities (MFI) following FLICA-labeling of the different EL4 and MDA cell populations is shown in (d) and (i), respectively. Data shown are means ± SEM ($n = 3$) (***$P < 0.001$). C2Am and AnxV labeling (Alexa Fluor 647; Exc, $\lambda = 647$; Em, $\lambda = 670$ nm, *x*-axis) of the 5% of the viable cell population (purple in b and c and g and h) that showed the lowest FLICA labeling are shown for EL4 (e) and MDA (j) cells against the frequency of events. Viable EL4 and MDA cells stained more with AnxV (black line) than C2Am (shaded gray area) ($P < 0.05$, for EL4 and $P < 0.001$, for MDA). MFI values, in arbitrary units (a.u.), were standardized to green autofluorescence levels. C2Am was used at a concentration of 200 nM and AnxV at a concentration of 4 nM.

FLICA (fluorescent-labeled inhibitor of caspases) kit, which is based on caspase inhibitors that are linked to a green (carboxyfluorescein) fluorophore. FLICA is cell-permeant and is thought to bind only to active caspases within cells. Plots of SYTOX Green labeling as a function of NAD(H) autofluorescence were used, as before, to identify three cell populations: apoptotic cells (represented by the green symbols), late apoptotic/necrotic cells (orange symbols), and viable cells (blue symbols) (Figure 4). Dual scatter plots of drug-treated EL4 and MDA cells stained with FLICA and C2Am are shown in Figure 4b and g, respectively, and with FLICA and AnxV in Figure 4c and h, respectively. In EL4 cell populations treated with etoposide for 24 h, the MFIs for apoptotic and late apoptotic/necrotic cells stained with FLICA were up to 2-fold ($P < 0.001$) and 6-fold ($P < 0.01$) more, respectively, when compared with viable cells (Figure 4d). In MDA cells treated for 72 h with doxorubicin, these differences were up to 2-fold ($P < 0.01$) and 10-fold ($P < 0.001$) more for apoptotic and late apoptotic/necrotic cells, respectively, when compared with viable cells (Figure 4i). The binding of C2Am and AnxV to the viable cell population was examined by selecting the 5% of the viable cell population that showed the lowest FLICA labeling (Figure 4b,c and g,h) and analyzing the binding of C2Am and AnxV to this population. This is shown for EL4 cells in Figure 4e and for MDA cells in Figure 4j. This analysis confirmed that both C2Am and AnxV show low levels of binding to viable cells, which show the lowest FLICA labeling, but that AnxV binding to these cells was significantly greater than that of C2Am ($P < 0.05$, EL4 and $P < 0.001$, MDA).

Effects of C2Am and AnxV Concentration on Their Binding to Drug-Treated Cells. The proteins were used at concentrations of between 0.05 and 1.0 μM for C2Am and 1−20 nM, for AnxV. The AnxV concentration recommended by the manufacturer is approximately 20 nM. Again, the three different cell populations, viable, apoptotic, and late apoptotic/necrotic, were selected based on SYTOX Green staining and NAD(H)

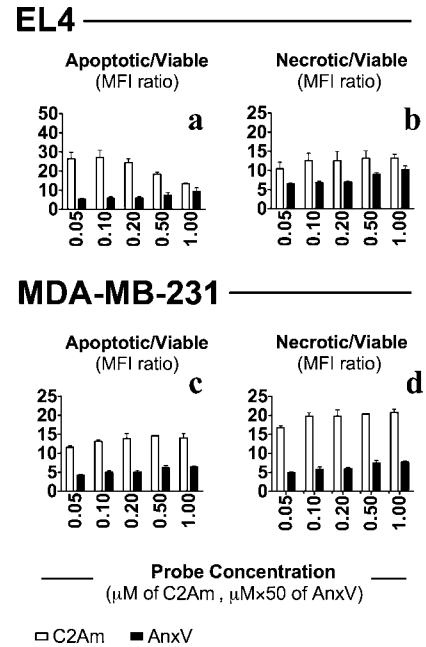

Figure 5. Effect of probe concentration on the specificity of labeling with C2Am and AnxV. C2Am was used at concentrations between 0.05 and 1.0 μM. AnxV was used at 50× lower concentrations, between 1 and 20 nM. EL4 cells were treated with etoposide (5 μM) for 16 h and MDA cells were treated with doxorubicin (1 μg/mL) for 72 h. MFI ratios for apoptotic/viable and necrotic/viable are shown for EL4 cells (a and b) and for MDA cells (c and d) following labeling with C2Am (open bars) or AnxV (closed bars). The different cell populations were identified based on their NADH autofluorescence and staining with SYTOX green, as in Figures 2−4. Data are shown as means ± SEM ($n = 3$). The differences in MFI ratios between C2Am and AnxV were significant at *$P < 0.05$, plot b-0.1 and 0.2 μM; **$P < 0.01$, a-0.5 μM; ***$P < 0.001$, a-0.05 to 0.2 μM, c-0.05 to 1.0 μM, d-0.05 to 1.0 μM.

autofluorescence. The levels of AnxV staining were consistently higher ($P < 0.05$) than C2Am for all cell populations (see Figure S4a−c in Supporting Information), above a concentration of 0.5 μM for C2Am and 10 nM for AnxV. This included the viable cell population, where the mean fluorescence intensity (MFI) for cells stained with AnxV was significantly higher ($P < 0.01$) than for those stained with C2Am (see Figure S4a in Supporting Information), despite AnxV being used at 50-fold lower concentrations. As a consequence, the mean fluorescence intensity (MFI) ratios for apoptotic/viable (Figure 5a) and necrotic/viable (Figure 5b) EL4 cells were significantly higher for C2Am than AnxV, at all the concentrations tested, indicating more specific labeling of both apoptotic ($P < 0.01$) and necrotic cells ($P < 0.05$) by C2Am. Similar results were obtained for the MDA line, for which the MFI of viable cells stained by AnxV was also significantly higher ($P < 0.01$) than for those stained with C2Am (see Figure S4d in Supporting Information), again despite being used at 50-fold lower concentrations. The levels of AnxV and C2Am staining of apoptotic and necrotic MDA cells were similar at these concentrations (see Figure S4e,f in Supporting Information), and like EL4 cells, the ratios of apoptotic/viable (Figure 5c) and necrotic/viable (Figure 5d) MDA cell staining were significantly higher for C2Am ($P < 0.001$), indicating again more specific labeling of both apoptotic and necrotic cells compared to viable cells.

On the basis of the concentration dependency of C2Am binding to apoptotic EL4 (see Figure S4b in Supporting Information) and MDA cells (see Figure S4e in Supporting Information), which shows partial or total saturation of the MFI value, we estimated the concentration of PS exposed on these dying cells. Assuming a 1:1 binding model of C2Am to PS, this gave values of 277 ± 42 and 127 ± 10 pmol of PS per million apoptotic EL4 and MDA cells, respectively.

Ca^{2+}-Dependence of C2Am and AnxV Binding to Dying Cells. Binding of C2Am and AnxV to the PS exposed on dying cells is calcium-dependent. However, both proteins are also known to bind other plasma membrane phospholipids in a Ca^{2+}-independent manner (*21, 22*). Drug-treated EL4 and MDA cells were incubated in the presence of Ca^{2+} (2 mM) or EDTA (10 mM) and binding of C2Am (200 nM) and AnxV (4 nM) was assessed by flow cytometry. The MFI ratios for binding to apoptotic versus viable and necrotic versus viable cells are shown in Figure 6. Binding to apoptotic EL4 cells was largely Ca^{2+}-dependent for both proteins, and significantly higher than in the absence of Ca^{2+} (Figure 6a) ($P < 0.001$ and $P < 0.05$, for C2Am and AnxV, respectively). The mean MFI ratio for apoptotic/viable in the absence of Ca^{2+} was 0.04 and 0.12 for C2Am and AnxV, respectively. C2Am, however, showed a more pronounced Ca^{2+}-independent binding to necrotic EL4 cells (Figure 6b) (a mean MFI ratio for necrotic/viable of 0.52 versus 0.16 for AnxV). This was also the case for necrotic MDA cells, where C2Am showed more Ca^{2+}-independent binding (with a MFI ratio for necrotic/viable of 0.58 versus 0.08 for AnxV). However, in these cells, C2Am also showed relatively high levels of Ca^{2+}-independent binding to apoptotic cells as well.

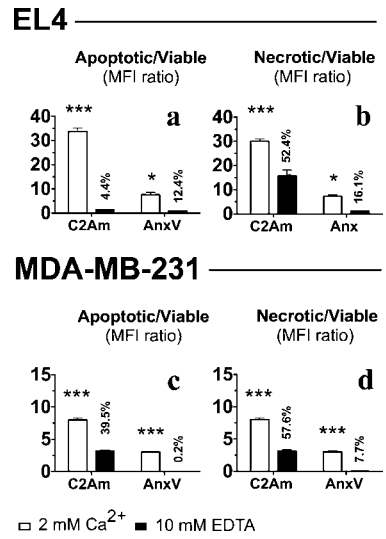

Figure 6. Effect of Ca^{2+} concentration on binding of C2Am and AnxV to apoptotic and necrotic cells. EL4 cells were treated with etoposide (5 μM) for 16 h and MDA cells were treated for 72 h with doxorubicin (1 μg/ml). MFI ratios for apoptotic/viable and necrotic/viable cells are shown for EL4 cells (a and b) and for MDA cells (c and d) following labeling with C2Am or AnxV in the presence of 2 mM Ca^{2+} (open bars) or 10 mM EDTA (filled bars). The different cell populations were identified based on their NADH autofluorescence and staining with SYTOX green, as in Figures 2−4. The ratios obtained in the absence of Ca^{2+} are also shown as a percentage of the ratios obtained in the presence of Ca^{2+}. The data are shown as means ± SEM ($n = 3$). *$P < 0.05$, ***$P < 0.001$.

DISCUSSION

Detection of PS with fluorescently labeled AnxV is a commonly used method for detecting apoptotic cell death in vitro (*23, 24*). Fluorescent, paramagnetic, and radionuclide-labeled derivatives of AnxV have also been used to detect cell death in vivo (*25−30*). In this study, we have evaluated, in comparison with AnxV, a novel probe for cell death detection based on the C2A domain of Synaptotagmin-I (*11, 31*). A GST-C2A fusion protein has been labeled previously with paramagnetic and radionuclide labels and used to detect apoptotic cells in vivo using magnetic resonance and radionuclide imaging, respectively (*13−15, 32*). A problem with these early derivatives of C2A was that they were labeled on one or more of the ε-amino groups of the 35 lysine residues in the fusion protein, and thus, the imaging agent was a heterogeneous mixture of labeled molecules (*15, 32*). Moreover, in the case of the agent labeled with Gd^{3+}-chelates, increased labeling led to a loss of affinity for PS and increased nonspecific binding (*15*). In this study, we have produced a site-directed mutant of C2A, containing a single cysteine residue C2A(S78C), which was labeled stoichiometrically with a fluorophore to yield a single chemical species (C2Am). The unmodified protein showed a comparable dissociation constant to the wild-type protein for PS (55 nM vs 20 nM, respectively) (*16*), and this was increased only slightly by modification of the cysteine residue with the fluorophore ($K_d = 71$ nM). We have shown that this fluorescently labeled derivative was able to detect PS on apoptotic and necrotic murine lymphoma and human breast cancer cells in vitro by flow cytometry. Although the C2Am derivative showed less labeling of apoptotic and necrotic cells than a similarly labeled commercial preparation of AnxV, the C2Am derivative showed lower binding to viable cells, despite being used at 50-fold higher concentrations and, as a consequence, better specificity for the detection of apoptotic and necrotic cells. This was reflected in the consistently higher ratios for the apoptotic/viable and necrotic/viable mean fluorescence intensities (MFI) for cells labeled with C2Am as compared with AnxV.

Titration of apoptotic EL4 and MDA cells with increasing concentrations of C2Am led to saturation of the bound fluorescence intensity and enabled us to estimate the abundance of PS, which for EL4 was 277 ± 42 pmol/10^6 cells and for MDA 127 ± 10 pmol/10^6 cells. The concentration of PS on EL4 cells is comparable to the level reported for apoptotic Jurkat cells of 240 pmol/10^6 cells, which is a human lymphoid cell line (*33*).

In order to investigate further the apparent binding of AnxV to viable cells, we used a fluorescently labeled inhibitor of

activated caspases (FLICA) to confirm that this cell population, which was identified as viable from measurements of NADH autofluorescence, was indeed viable. There has been some discussion as to whether FLICA detects activated caspases or the cell damage mediated by activated caspases (*34*, *35*). Regardless of the mechanism responsible, we expect viable cells to show only low levels of FLICA staining. The viable cell population, identified from measurements of NADH autofluorescence in drug-treated cell preparations, showed 2-fold and 6-fold less labeling with FLICA, when compared with apoptotic and late apoptotic/necrotic cells, respectively, in EL4 cells and 2-fold and 10-fold less labeling, respectively, in MDA cells, confirming that this was a genuinely viable cell population. When we analyzed C2m and AnxV binding to the 5% of the viable cell population that showed the lowest labeling with FLICA, there was considerably more labeling with AnxV (up to 5-fold) than with C2Am.

The Ca^{2+}-dependent binding of C2A and AnxV to PS is well-documented (*12*, *23*). Binding of both probes to the apoptotic cell fraction was largely quenched (60−99%) by the addition of EDTA (10 mM). This was also the case for AnxV binding to necrotic cells (8−16% of Ca^{2+}-independent binding). However, a large component of C2Am binding to necrotic cells was Ca^{2+}-independent (53% for EL4 and 58% for MDA). Since there is no evidence that C2A has any detectable affinity for PS in the absence of Ca^{2+} (*36*), the reason for this binding is unclear, although it could relate to the smaller size of C2Am making it better able to cross the ruptured cell membranes of necrotic cells. The Ca^{2+}-independent binding observed for both proteins may be due to binding to other phospholipids that are externalized during apoptosis (e.g., phosphatidylethanolamine or phosphatidylinositol) (*37*).

Although both proteins exhibit Ca^{2+}-dependent binding of anionic phospholipids, their three-dimensional structures, mechanisms of binding, and ultimately their affinities for PS differ appreciably. The C2A domain is a compact eight-stranded β-sheet structure interconnected by seven loops (*31*). The Ca^{2+} and PS binding sites are formed by the three loops at the top of the domain. There are three sites for Ca^{2+} in the Ca^{2+} binding pocket of C2A, and this binding stabilizes the loops but produces no significant conformational changes (*38*). The empty coordination sites on the bound Ca^{2+} ions are filled by direct interaction with anionic phospholipids. In contrast, AnxV is composed of four compact α-helical domains. Each domain contains a Ca^{2+} and phospholipid binding site (*39*). Two Ca^{2+} ions are bound at each binding site (*40*) and Ca^{2+}-induced conformational changes allow these multiple PS binding sites to interact in a cooperative manner, giving rise to the high affinity for PS (*41*). Furthermore, chemical cross-linking studies have shown that Annexin-V can form calcium-induced trimers, hexamers, and larger aggregates on phospholipid membranes (*42*). This multivalent binding likely explains the very high affinities reported for AnxV binding to PS, in the range 0.03−15 nM (*43*, *44*). This range is considerably lower than that reported previously for C2A (*16*) and that measured here. The much higher affinity of AnxV for PS may explain the binding of this protein to viable cells, which could express low levels of PS. The lower affinity of C2Am for PS may reduce binding to viable cells and hence explain why it is a more specific probe for cell death detection than AnxV.

CONCLUSIONS

We have synthesized a chemically well-defined fluorescent derivative of a site-directed mutant of the C2A domain of Synaptotagmin-I (S78C), which shows lower binding to viable cells than a similarly labeled Annexin V derivative and consequently has better specificity for detecting cell death. The lower binding to viable cells may be due to the lower affinity of C2A for PS. The lower binding of C2A to viable cells may be important when radionuclide derivatives of this protein are used to detect cell death in vivo, since this may reduce the nonspecific tissue accumulation observed with radionuclide-labeled derivatives of Annexin-V.

ACKNOWLEDGMENT

The work was supported by a Cancer Research UK Programme grant (to K.M.B.; C197/A3514) and by a Translational Research Program Award from The Leukemia & Lymphoma Society. T.H.W. was in receipt of BBSRC CASE studentship with GE Healthcare. We thank Dr. Len Packman at the Department of Biochemistry, University of Cambridge, for mass spectrometric analysis and Dr. Maaike de Backer, also at the Department of Biochemistry, for suggesting candidate mutations.

Supporting Information Available: Expression and purification of C2A(S78C), the protein assay, electrospray ionization (ESI) mass spectrometry, and surface plasmon resonance (SPR) measurements are described in more detail. There is a table showing the dissociation constants derived from affinity and kinetic analysis of the SPR data, a figure showing the ESI−mass spectrum of the C2Am-AlxF647 conjugate, figures showing the SDS-PAGE gels of the C2Am-AlxF647 and AnxV-AlxF647 conjugates and a figure demonstrating the effect of probe concentration on the specificity of labeling with C2Am and AnxV. Influence of Multivalent Nitrilotriacetic Acid Lipid−Ligand Affinity on the Circulation Half-Life in Mice of a Liposome-Attached His_6-Protein

Virginia Platt, Zhaohua Huang, Limin Cao, Matthew Tiffany, Kareen Riviere, and Francis C. Szoka, Jr.*

Received October 13, 2009; Revised Manuscript Received March 23, 2010

Metal chelation−ligand interactions, such as occur between nitrilotriacetic acid (NTA)-nickel and multihistidines, enable the noncovalent attachment of histidine-modified proteins to liposomes and other particles. We compared three lipids: a mono-NTA lipid (ca. 10 μM affinity) and two tris-NTA lipid derivatives (ca. 3 nM and 0.2 nM affinity) in their ability to retain two different his_6-containing proteins on NTA-liposomes in the presence of serum or plasma and after intravenous injection in mice. At nanomolar affinities, the off-rate of a his_6-ligand is sufficiently long so that his_6-proteins attached to particle surfaces will remain with the particle for hours; thus, we hypothesized that the increased his_6 affinity of multivalent NTA-modified liposomes would retain his_6-proteins longer both *in vitro* and *in vivo*. For each of the three lipids, we found a robust association and complete activity retention of two his_6-modified proteins: a far red-fluorescent protein, monomeric Katushka (mKate), and a prodrug-converting enzyme, yeast cytosine deaminase (yCD). Proteins associated more tightly *in vitro* with tris-NTA liposomes than with mono-NTA liposomes in the presence of refiltered fetal calf serum and mouse plasma. Free yCD exchanged with previously associated mKate for tris-NTA binding sites on the liposome surface. This exchange was due to the exchange of the proteins for NTA occupancy and not due to the exchange of tris-NTA lipid out of the liposome. The amount of yCD on the surface was similar if the proteins were co-associated or if mKate was pre-associated. This exchange confirms that NTA associated proteins are in a dynamic state and can exchange with multihistidine proteins in the biological milieu. There was no difference in circulation time of the protein when it was intravenously administered by itself or attached to any of the NTA-modified liposomes because *in vivo* the protein was rapidly released from the NTA liposomes. Upon recovery from blood, liposomes containing tris-NTA accumulated a different plasma protein profile than control liposomes, suggesting that Ni-NTA specifically interacts with some plasma proteins. The reason for the rapid protein dissociation from the liposome *in vivo* is not clear; it could be due to displacement by endogenous histidine-containing proteins or to natural chelators that remove nickel from the NTA. Regardless of the cause, improvements in chelator or ligand design are needed before metal chelation will be capable of retaining histidine-modified proteins on NTA liposomes after *in vivo* administration.

INTRODUCTION

Nickel chelation chromatography, and similar technologies that depend upon noncovalent interactions between a nickel chelator and a multihistidine-ligand, are widely used to purify proteins and associate proteins with surfaces (*1, 2*). The affinity of first-generation nitrilotriacetic acid (NTAs) is about 10 μM, whereas affinities of newer trivalent-NTAs (tris-NTAs) are in the nanomolar range (*3*−*6*).

NTA-mediated protein association is a useful investigative tool that is mild enough to retain protein activity and requires only a simple modification of the amino acid sequence—the addition of a string of histidines (*1, 7*). This interaction is reversible by stripping the chelated nickel from the NTA or allowing molecules to compete with the protein for NTA association (*2*). Proteins remain in a lateral surface orientation (*8*−*10*) and free of surface involvement (*11*). The stable, well-defined orientation allows proteins to be imaged and their structure or function investigated (*12, 13*). NTA coated surfaces improve AFM-based protein imaging and have been used to measure real-time substrate degradation (*14*). Active, surface-immobilized proteins can also be used to exploit the activity of these proteins in microarrays and biosensors (*7, 8, 15, 16*).

Modifications to the linkage area of the NTA headgroups change the molecules affinity for his-tagged proteins. The addition of poly(ethylene glycol) (PEG) increases protein capture efficiency (*15, 16*). Multivalent NTAs improve affinity by allowing multiple chelated nickels within the NTA cluster to interact with a single his-tag (*6, 17*−*19*).

Advances in protein production by recombinant techniques have largely removed protein availability as a limitation for protein-related therapies (*20*). The stability and rapid clearance of proteins *in vivo* are barriers that can reduce their therapeutic potential (*21*). These limitations can be overcome, in part, by using nanocarriers to alter protein pharmacokinetics or increase protein stability (*22*−*24*). Additional problems arise as chemical conjugation of proteins to carrier surfaces can damage the protein and the percent of protein attached to the carrier can be low (*25*). Multivalent NTAs have the potential to increase the efficiency, simplify the modification of nanocarriers and enable a "toolkit" approach for *in vivo* therapeutic use. Coupling proteins to carriers using a noncovalent NTA also avoids harsh conjugation chemistries. At low nanomolar affinities, the off-rate of a his_6 ligand from an NTA-nickel is sufficiently long so that the his_6-proteins bound to particle surfaces will remain with

the particle for hours. Thus, an appropriate NTA-lipid would enable the creation of NTA-modified liposomes that could be functionalized with any his_6-containing protein.

The increased affinity of a multivalent NTA for a his-tagged protein is strong enough to make the interactions stable *in vitro* (*3*−*5*, *18*, *19*, *26*−*28*). Immunoliposomes generated by associating single-chain antibody fragments to liposomes with mono-NTA lipids were found to be suitable for rapid *in vitro* screening (*27*, *28*). However, incubation with human plasma as a surrogate for *in vivo* studies caused the protein to dissociate from the mono-NTA (*29*).

Other groups have shown success *in vivo*. His-tagged epitopes have been associated with both mono- and multivalent-NTA nanoparticles to mediate immunotherapies (*3*, *26*, *30*). A his-tagged peptide designed to be membrane penetrating and immunostimulatory was shown to induce splenocytic immune stimulation in BALB/c mice when associated with NTA-DOGS-liposomes (*26*). Using the same NTA-DOGS-lipid, an NTA-wax nanoparticle induced immune response against an HIV Gag protein (*30*). Potential vaccines were also formulated from plasma membrane vesicles derived from tumor cells modified to contain tris-NTA lipid (*3*). When mice were immunized by subcutaneous injection of these vesicles, containing encapsulated cytokines, they exhibited decreased tumor growth when challenged two weeks after immunization (*3*). In all three studies, the nanoparticles were injected subcutaneously and were not exposed to blood. The stability of the protein−vesicle association *in vivo* was not monitored, so the duration of protein retention is not known.

In this study, we compare the behavior of liposomes modified with three different NTA-lipids of increasing affinities for his-tagged proteins: mono-NTA-DOGS, tris-NTA-LYS-DOD, and tris-NTA-DAP-DOD (Figure 1). Liposome formulations containing NTA-lipids robustly associated both yCD and mKate without decreasing protein activity but association with the NTA liposomes did not increase the protein's circulation time.

EXPERIMENTAL PROCEDURES

Materials. All reagents and solvents obtained from commercial suppliers were used without further purification. Palmitoyloleoylphosphatidyl choline (POPC), palmitoyloleoylphosphatidyl glycerol (POPG), methoxy poly(ethylene glycol) 2000 disteroylphosphatidyl ethanolamine (mPEG (2000)-DSPE), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(Lissamine Rhodamine B Sulfonyl) (rhodamine-DOPE) and cholesterol were obtained from Avanti Polar Lipids (Alabaster, AL). Ni-NTA-DOGS (1,2-dioleoyl-*sn*-glycero-3-{(*N*-(5-amino-1-carboxypentyl)iminodiacetic acid)succinyl}) was purchased from Avanti Polar Lipids preloaded with nickel. Frozen, refiltered fetal calf serum (FCS) was obtained from the UCSF Cell Culture Facility and was prepared by filter-purifying serum, not heat inactivation, thus retaining active portions of the complement cascade.

Synthesis of Tris-NTA-LYS-DOD and Tris-NTA-DAP-DOD. The tris-NTA-lipids were synthesized via the methods described by Huang et al. (*4*, *5*). Tris-NTA-lipids are constructed from a base of dioctadececyl (DOD) lipid chains and diaminopropionic acid (DAP) or lysine (LYS) for tris-NTA-DAP-DOD and tris-NTA-LYS-DOD, respectively (Figure 1). Lipids were stored dry and dissolved in organic solvents immediately prior to use. To load the NTA_3 head groups with nickel, $NiCl_2$ was dissolved in minimal H_2O followed by methanol. NTA_3-lipids were incubated with nickel in the methanol−water solution (3 mol equiv $NiCl_2$ per mol NTA_3) at 60 °C for 15 min. The solution was allowed to cool to room temperature before adding it to the lipid formulation mixture. Preloading the nickel prior to liposome formation prevented dilution during removal of the excess nickel. Ni-NTA-DOGS was used as received from Avanti Polar Lipids.

Synthesis of FITC-DSPE. The fluorescent lipid was synthesized via direct coupling of FITC to DSPE. To a solution of DSPE (50 mg) in dry chloroform (5 mL) and triethylamine (37.3 μL) was added FITC (52.1 mg, 2 equiv) in minimal dimethyl sulfoxide (DSMO). The mixture reacted overnight at room temperature in the dark. Crude product solution was concentrated by rotary evaporation and purified on a Biotage Horizon HPFC system with prepacked silica columns (Biotage; Charlottesville, VA). The elution gradient consisted of 3 segments (solvent A, chloroform; B, methanol); 0−20% B, 24 mL; 20−20% B, 48 mL; 20−30% B, 72 mL. Fractions of pure product were pooled, evaporated, and dried under high vacuum overnight. Rf = 0.38 in chloroform/methanol (4:1 v/v). The product was dissolved and stored in chloroform at −40 °C. During synthesis, handling, and use, FITC-DSPE was protected from photobleaching by minimizing exposure to light and heat. Structure of the product was confirmed with ^{1}H NMR and MALDI mass spectrometry.

Formation of Liposomes. Liposomes were prepared by the sonication and extrusion method (*31*). Briefly, lipids dissolved in organic solvents were added to depyrogenated borosilicate glass tubes. Solvent was evaporated while rotating under reduced pressure at room temperature to form a lipid film. Residual

solvent was removed under high vacuum overnight. Films were then rehydrated in 1 mL HEPES buffer (20 mM HEPES, 140 mM NaCl, pH 7.4) with intermittent vortexing and sonicated under argon for 10 min at 23 °C to form vesicles. Liposome diameter was reduced by serially extruding 11 times through 200, 100, and 80 nm polycarbonate membranes with a hand-held extruder (Avestin; Ontario, Canada). Formulations contained either NTA_3-LYS-DOD, NTA_3-DAP-DOD, or NTA-Ni-DOGS (POPC/Chol/mPEG/NTA 55:40:5:*n*, molar ratio, where *n* corresponds to the mole percent NTA for each formulation). All liposomes contained 5 mol % mPEG(2000), unless noted. Control liposomes contained 1.5 mol % POPG to mimic the charge density of a 0.3% NTA_3-containing liposome formulation.

In some experiments, a tris-NTA-containing formulation without nickel was also used as a negative control. Liposome diameter and zeta potential were measured using a Zetasizer 3000 (Malvern Instruments; UK) for 3 or more liposome preparations of each formulation. The fluorescent signal from FITC-DSPE lipid, incorporated into the formulation to allow for tracking of the liposome (at 0.05 mol % unless noted), was not significantly decreased once liposomes formed. Lipid concentration in solution was calculated from the FITC signal based on control liposomes containing the same NTA concentration. Inclusion of NTA lipids caused both a slight fluorescence decrease and a negative charge.

Transfer of Tris-NTA Lipids between Lipid Membranes. Liposomes were prepared as described above (20 μmol/mL total lipid) that contained 3% tris-NTA-DAP, POPC, cholesterol, and 0.1 mol % FITC-DSPE (3:60:40:0.1 mol ratio) or POPC, cholesterol, and rhodamine-DOPE (60:40:0.05 mol ratio). Liposomes containing tris-NTA-DAP were mixed with liposomes without NTA lipids (1:1 v/v) and incubated at 37 °C for 3 h. Liposome mixtures (3 μmol total lipid) were then passed over an AG 1-X2 anion exchange column (1 × 6 cm bed volume, Bio-Rad Laboratories, Inc.; Hercules, CA) pre-equilibrated with 20 mM HEPES, 140 mM NaCl (pH 7.4). Uncharged rhodamine-containing liposomes were not retained by the column and appeared in the void volume fractions. Negatively charged, tris-NTA-DAP, FITC-containing liposomes were retained by the column and eluted with 20 mM Tris-HCl, 1 M NaCl (pH 9.5). Presence of liposomes was determined on the basis of rhodamine or FITC fluorescence (excitation/emission 544/590 nm and 490/520 nm, respectively). The charge of neutral, rhodamine-containing liposomes was monitored (Zetasizer 3000, Malvern Instruments; UK) before and after incubation with NTA-liposomes.

Protein Production. Genes for thermostabilized yeast cytosine deaminase (yCD; 18 kDa) (*32*) and monomeric Katushka (mKate; 27 kDa) (*33*) were constructed from gene fragments. Briefly, an optimized gene sequence for *E. coli* K12 (high) codon bias was designed and 27 or 32 primers (for yCD and mKate respectively) were used to construct a complete gene sequence using PCR. PCR was performed with GoTaq DNA polymerase (Promega; Madison, WI) in a GeneAmp PCR system 2400 thermal cycler (Perkin-Elmer; Waltham, MA). Synthesized genes were then ligated into pET15b vector for amplification and expression.

Protein was expressed in BL21-Codon Plus (DE3)-RIPL *E. coli* cells (Stratagene; La Jolla, CA). *E. coli* were grown in LB culture medium containing 30 μg/mL kanamycin and 50 μg/mL chloramphenicol at 37 °C until the OD600 nm reached 0.6−0.9. Protein expression was induced with 1 mM isopropyl α-D-1-thiogalactopyranoside (IPTG) with 0.5 mM zinc acetate. After overnight expression at room temperature, protein was purified from the cell supernatant by lysing the cells using freeze−thaw followed by sonication. His-tagged proteins were purified from other cellular proteins on a HisTrapFF affinity column (Amersham Biosciences; Piscataway, NJ) and eluted with 300 mM imidazole. The remaining yCD protein contaminants were removed by size exclusion chromatography on a HiPrep Sepharose S-100HR 16/60 size exclusion column (Amersham Biosciences; Piscataway, NJ). Buffers were exchanged using a PD10 desalting column (GE Healthcare; UK). OD280 nm was measured to obtain the fractions containing protein.

Liposome−Protein Association. His-tagged proteins were associated with liposomes at room temperature. Liposomes (2 μmol total lipid) were incubated with 270 μg mKate-his_6 or 180 μg yCD-his_6 in 0.2 mL HEPES buffer. For a 1% NTA containing formulation, this solution corresponds to a 1:1 molar ratio of surface NTA to his_6. To quantitate the extent of protein−liposome association, samples containing at least 2 μmol total lipid were passed through a pre-equilibrated 1 × 20 cm Sepharose CL-4B column under gravity flow. Fractions collected every 20 s (0.5 mL) were assayed for the presence of protein and liposomes. Liposomes eluted in the void volume and were measured by fluorescence (excitation/emission 490/520 nm). Protein concentration was quantified with a Bradford Protein Assay (Biorad Laboratories; Hercules, CA). This experiment was performed in triplicate for each protein/liposome formulation to ensure reproducibility.

Protein Activity. mKate activity was measured by fluorescence (excitation/emission 544/590 nm) in a Fluorostar 403 microplate reader (BMG Lab Technologies; Durham, NC). Enzymatic conversion of 5-FC to 5-FU per microgram of yCD was measured using previously described methods (*34*). Briefly, 1 μg yCD or yCD on liposomes was incubated in 1 mL PBS containing 5 mM 5-FC at 37 °C. Aliquots of the reaction mixture (20 μL) were removed at 10, 20, and 30 min and enzymatic conversion quenched by dilution to 1 mL in 0.1 M HCl in PBS. The amount of 5-FU formed in the reaction was determined by measuring the UV absorbance at 255 and 290 nm. Concentration (mM) of 5-FU was calculated as 0.185 × (Abs 255) − 0.049 × (Abs 290) to adjust for the presence of unconverted 5-FC. The activity of each sample was measured in triplicate.

Amount of enzyme activity per unit of lipid was measured after free protein was removed to ensure that all active protein was associated with the surface of the liposome. Liposome concentration was estimated on the basis of the presence of a FITC-DSPE fluorophore within the membrane.

Protein Dissociation in Serum or Plasma. The dissociation of protein from liposomes was measured by challenging already associated protein with refiltered fetal calf serum (FCS). Liposomes with associated protein were mixed 1:1 in refiltered FCS and incubated at 37 °C for a predetermined time. After incubation, samples were passed through a 1 × 20 cm Sepharose CL-4B column under gravity flow to separate free from bound protein. Liposome-containing fractions were collected and yCD concentrations were measured on the basis of conversion activity. mKate activity was measured by fluorescence. The experiment, including liposome formulation, was performed in triplicate.

For studies using mouse plasma, whole blood was collected using a heart puncture technique in BALB/c mice with a heparin (Sigma Aldrich; St. Louis, MO) loaded syringe. Plasma was clarified at 14 000 × *g* (Eppendorf Centrifuge 5415C, Brinkman Instruments, Inc.; Westbury, NY) for 20 min and stored at 4 °C for no longer than 2 days. Liposomes containing 1% tris-NTA-DAP were incubated with mKate for 1 h prior to addition of mouse plasma. Liposomes, with preassociated mKate, were mixed 1:1 with mouse plasma and incubated at 37 °C for 24 h. Samples were prepared in triplicate.

His-Tagged Protein Competition. Liposomes were prepared as described above and incubated to give 1:1 surface NTA to

mKate ratio. After 1 h, surface association was challenged with yCD. Proteins were allowed to equilibrate for an additional hour at room temperature and then passed over a Sepharose CL-4B column. Total protein was measured using the Bradford Protein Assay. Fluorescence of mKate and liposomes were monitored as described above. The competition assay was performed in triplicate for each formulation.

Protein Half-Life *in Vivo.* Liposomes were prepared at 20 mM lipid by hydrating films in sterile PBS, as described above. Once liposome diameter was reduced to approximately 80 nm, liposomes were sterilized with 0.2 μm filters. Each protein was iodinated following the Iodogen iodination protocol (Pierce Biotechnology; Rockford IL). Briefly, an iodination tube was washed with 1 mL PBS. To the tube was added 0.1 mL 0.2 M HEPES, pH 7.4, and 10 μL NaI^{125} ($\sim$1 mCi). Approximately 0.5 mg protein was added to the tube and the solution was reacted at room temperature for 10 min. The reaction mixture was diluted with nonradioactive protein and serially purified on a prepacked PD10 desalting column followed by a 1 $\times$ 15 cm Sephadex G-50 column. Fractions containing radioactive protein were collected and reaction efficiency calculated. The protein was then further diluted to give one million counts per dose of protein. Diluted, iodinated protein was mixed with liposomes to give one protein per surface available NTA and incubated for 1 h at room temperature prior to injection.

All animal procedures were conducted in accordance with the policies of the UCSF Institutional Animal Care and Use Committee. Mice (Jackson Laboratories; Bar Harbor, ME) were housed in an official UCSF facility. For periods of less than 48 h, during experimentation, mice were housed in UCSF approved laboratory conditions. BALB/c or Swiss-Webster mice (6−8 weeks old) were divided into treatment groups of 3 animals. Each group received 10 mM total lipid with 1.35 mg/mL iodinated mKate or 0.89 mg/mL iodinate yCD in 200 μL PBS via tail vein injection (one million I^{125} counts per dose; injection accounts for approximately a 15% increase in total blood volume).

Radioactivity in the blood obtained from submandibular cheek pouch bleeds at 5 min and 1 h (50 μL; less than 5% total blood volume) with a final bleed at 6 h (0.5 to 1 mL; 30−60% total blood volume) was quantified by gamma scintillation counting (Wallac Wizard, Perkin-Elmer; Waltham, MA). Liver, lung, and spleen were collected and analyzed for accumulation of radioactivity.

Noniodinated mKate and liposomes containing 0.5% FITC-DSPE were monitored in the blood by heart puncture at 15 min. Plasma was collected by centrifugation at 14 000 $\times$ *g* and liposomes were separated from the bulk free protein with a Sepharose CL-4B column. mKate fluorescence was measured (excitation/emission 544/590 nm) to quantify mKate remaining with the liposomes.

Association of Endogenous Proteins with NTA-Liposomes After Intravenous Administration. Liposomes containing either 1% tris-NTA-DAP or 1.5% POPG and 0.5% FITC-DSPE, 5% mPEG-DSPE were recovered from the blood of BALB/c mice. Whole blood was collected 10 min after liposome injection (2 μmol lipid in 200 μL PBS) by heart puncture using a heparin loaded syringe. Plasma was collected by sedimenting blood cells at 14 000 $\times$ *g* and liposomes were separated from unassociated protein using a Sepharose CL-4B column. Fractions containing liposomes were collected on the basis of FITC fluorescence (excitation/emission 490/520 nm). Liposome concentration was calculated on the basis of a FITC fluorescence standard curve constructed from serially diluted liposomes of the same lipid formulation. Protein concentration was measured using the Bradford Protein Assay (Biorad Laboratories; Hercules, CA).

Liposome fractions containing liposome-associated proteins were mixed with SDS gel-loading buffer (1:1 v/v) (*35*) and boiled for 10 min. Approximately 5 μg protein was loaded per well onto a 15-well, 4−15% tris-Glycine, SDS-PAGE gel (Biorad Laboratories; Hercules, CA). Protein bands were separated at 120 V for approximately 1 h and the gel was stained (Silver Stain Plus, Biorad Laboratories; Hercules, CA). Prestained protein ladders (10−230 kDa, New England Biolabs; Ipswich, MA) were included to estimate protein molecular weight. Relative protein quantity in each band was estimated using *ImageJ* gel analysis software (NIH *ImageJ* 1.42q; Bethesda, MD). For statistical comparisons, lanes were equalized to the 37 kDa protein band.

mKate Association with NTA-Liposomes Recovered after Intravenous Administration. BALB/c mice were injected with liposomes containing 1.0% tris-NTA-DAP and 5% mPEG-DSPE. Whole blood was collected and plasma was clarified via centrifugation as described previously. Free protein was separated from liposome-bound protein and liposome-containing fractions were collected on the basis of fluorescence. Liposomes were concentrated using a microcon concentrator (YM10, 10 000 MWCO, Millipore; Bedford, MA) pre-equilibrated with untreated tris-NTA-DAP-containing liposomes. Liposome fractions were concentrated for 30 min at 14 000 $\times$ *g*. Final liposome concentration was estimated on the basis of liposome fluorescence. Liposomes were then incubated with 5-fold excess of mKate (5 mKate per 1 surface available tris-NTA-DAP) for 3 h at room temperature. Free mKate was separated from liposome-associated mKate on a Sepharose CL-4B column. mKate fluorescence was measured (excitation/emission 544/590 nm) in liposome-containing fractions.

Hemopexin Interactions with NTA-Liposomes *in Vitro.* Hemopexin (HPX, Human, 70 kDa, Cell Sciences; Canton, MA) was dissolved in PBS (to 1 mg/mL) and incubated with liposomes (5 μmol/mL) containing 1.0% tris-NTA-DAP and 5% mPEG-DSPE for 3 h at room temperature. The final ratio of HPX to tris-NTA-DAP available on the liposome surface was 1:2 (a 2-fold excess tris-NTA-DAP). Following incubation, free HPX was separated from liposome-associated protein on a Sepharose CL-4B column pre-equilibrated in PBS. Liposome concentration was determined by FITC-fluorescence. Protein concentration in each fraction was determined by Bradford Protein Assay.

The dissociation of mKate from liposomes was measured by challenging liposomes containing preassociated mKate with HPX. Liposomes were incubated with mKate for 1 h prior to HPX addition. Liposomes containing preassociated mKate (3 μmol/mL with 0.4 mg/mL mKate) were incubated with a 1.5 volume excess HPX (at 1 mg/mL). The final ratio of HPX to tris-NTA-DAP available on the liposome surface was 1.5:1. The molar ratio of HPX to mKate in solution was also 1.5:1. Samples were incubated at 37 °C for 3 h. After incubation, samples were passed through a 1 $\times$ 20 cm Sepharose CL-4B column under gravity flow to separate free from bound protein. Fractions containing mKate were assayed on the basis of fluorescence (excitation/emission 544/590 nm). The ratio of mKate fluorescence to μmol/lipid was based upon a FITC standard curve prepared from liposomes of the same lipid formulation. Samples were assayed in triplicate.

RESULTS

Liposome Formulation and Construction. An illustration of a liposome and the NTA lipids used in this study is shown in Figure 1. The reported equilibrium dissociation constants for each lipid with a multihistidine peptide are also given (*4, 18*). Liposome diameter and stability was largely unaffected by the presence of NTA lipids (up to 3 mol %). We estimated, using

Table 1. Liposome Diameter and Zeta-Potential of NTA-Containing Liposomes with 3%, 1%, or 0.3% NTA and 5 mol % mPEG or 1% NTA without mPEG[a]

	3% NTA, 5% mPEG	1% NTA, 5% mPEG	1% NTA, 0% mPEG	0.3% NTA, 5% mPEG
		Tris-NTA-DAP		
diameter (nm)	88.0 ± 6.4	82.1 ± 2.5	88.3 ± 6.6	95.2 ± 15.1
ζ potential (mV)	−21.0	−18.3 ± 2.7	−18.6 ± 1.3	−19.3
		Tris-NTA-LYS		
diameter (nm)	107.9 ± 3.8	96.0 ± 11.5	96.6 ± 12.1	82.9 ± 7.6
ζ potential (mV)	−22.8	−18.6 ± 0.2	−20.1	−15.3
		NTA-DOGS		
diameter (nm)	78.7 ± 14.7	75.4 ± 12.3	85.0 ± 7.8	71.5 ± 1.0
ζ potential (mV)	−18.9	−16.9 ± 0.6	−16.1	−12.6
		Control (1.5% POPG, 5% mPEG)		
diameter (nm)		80.5 ± 6.5		
ζ potential (mV)		−15.6 ± 1.6		

[a] Control liposomes contained 1.5 mol % POPG to mimic the charge of 0.3% NTA-containing liposomes. ($n = 3$).

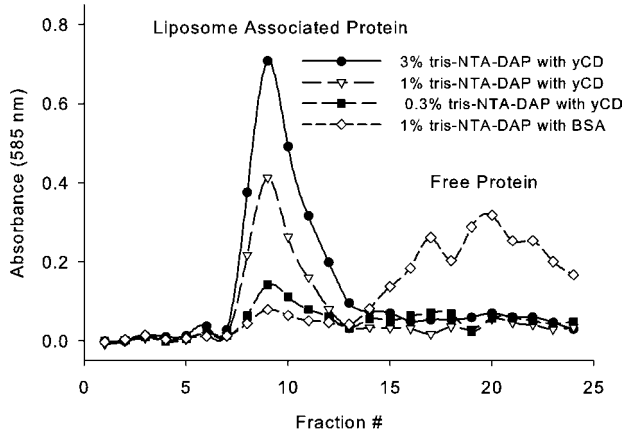

Figure 2. Representative association of proteins with the surface of NTA-liposomes. Liposomes bearing tris-NTA-DAP at 3% (circles), 1% (triangles), or 0.3% (squares) were associated with his-tagged yCD to saturate the available surface NTA. BSA was associated with 1% tris-NTA-DAP liposomes as a control (diamonds).

the protein diameter (UCSF Chimera; San Francisco, California) and NTA-lipid surface density on the liposome (*36*), that steric hindrance between adjacent NTA binding sites should effect association around 3% NTA with a 1:1 surface NTA to protein loading ratio. The liposome diameter and charge as measured by the zeta potential were similar for all formulations (Table 1).

His-Tagged Protein Association with Surface Displayed NTA on Liposomes. Liposomes containing any of the three NTA-lipids associated with protein to near the maximal expected amount. Free protein was separated from liposome-bound protein to determine the extent of association. Liposomes, along with their associated protein, elute in the void volume of a Sepharose CL-4B size exclusion column; nonassociated protein elutes at a larger volume. A representative example of protein separation in each fraction is shown in Figure 2. Liposomes with 3%, 1%, or 0.3% NTA_3-DAP associated with yCD to near saturation, with no free yCD visible in later fractions. BSA did not associate with 1% NTA_3-DAP liposomes.

The concentration of liposomes in each fraction was calculated on the basis of FITC-DSPE fluorescence. It was assumed that NTA lipids would distribute evenly between the inner and outer liposome surfaces. Hence, complete association was deemed to be a 1:1 ratio of his-tagged protein to expected surface-available NTA (Table 2).

Liposomes that contained NTA but not nickel did not associate with protein. BSA, which does not contain a his-tag, did not associate with NTA-nickel-containing liposomes. Control liposomes, containing both mPEG and POPG and having a similar surface charge as 0.3% NTA liposomes, associated with a minor amount of protein. The addition of EDTA, a strong chelator for nickel, to any NTA-containing liposome eliminated protein binding. Thus, a chelated nickel on the liposome surface and a his-tagged protein are necessary for this technology to be effective. When those elements are present, the amount of bound protein is stoichiometric with the amount of Ni-NTA on the liposome surface. yCD is a dimer, so it might be expected that greater than 100% association would occur, but this was rarely seen. This indicates that both his-tags of the dimer are engaged to the NTAs on the liposome surface. The amounts of mKate associated with 3, 1, and 0.3 mol % NTA containing liposomes are given in Figure 3.

Activity Retention of Surface Associated Proteins. Covalent attachment methods often partially or fully inactivate proteins (*25*). We measured the retention of activity of both yCD and mKate after binding to the NTA liposome. yCD converts the prodrug 5-FC to the cytotoxic drug 5-FU and the association of yCD with the surface of liposomes does not hinder 5-FC prodrug conversion. yCD retains full enzymatic activity when on the surface of a liposome (Figure 4A). Some proteins exhibit increased function and experience less product inhibition (to which yCD is susceptible) when in close proximity to a lipid bilayer (*22*); a slight increase in activity is observed in the liposome-bound yCD.

mKate also completely occupied all of the available sites on NTA-bearing liposomes at the NTA surface densities studied (Figure 4B). The activity of these liposomes was based on the fluorescence of the mKate. Unlike the observed increase in yCD activity when associated with the NTA-liposome, there was no increase in fluorescence for mKate.

Protein Dissociation in the Presence of Serum or Plasma. Liposomes bearing NTA preassociated with mKate or yCD were mixed at a 1:1 volume ratio with refiltered FCS. Figure 5 shows the retained protein on the surface of 1% NTA, 5% mPEG liposomes. The estimated amount of protein retained by the liposome is based on active protein and thermostabilized yCD has an activity half-life of over 50 h (*32*). The decrease in fluorescent activity of mKate over 24 h in FCS corresponds to approximately 5−10% of the total mKate fluorescence. This fluorescence decrease is equivalent to that seen in the loss of total fluorescence from free mKate in FCS at 37 °C over the same time period.

Dissociation of mKate from tris-NTA-DAP containing liposomes was also measured in the presence of mouse plasma. Plasma was prepared, stored at 4 °C, and used within 2 days. More mKate disassociated from the surface of NTA-

Table 2. yCD Association with NTA-Containing Liposomes[a]

mol % NTA with 5% mPEG (NTA:protein) ratio		tris-NTA-DAP mg/μmol lipid	tris-NTA-DAP % of expected	tris-NTA-LYS mg/μmol lipid	tris-NTA-LYS % of expected	NTA-DOGS mg/μmol lipid	NTA-DOGS % of expected
3.0% (1:1)		0.28 ± 0.02	103 ± 7	0.28 ± 0.03	102 ± 12	0.27 ± 0.05	99 ± 16.8
3.0% (3:1)		0.09 ± 0.02	91 ± 16	0.10 ± 0.01	105 ± 9	0.09 ± 0.01	94 ± 7.3

1.5% POPG	No NTA[e]	0.01 ± 0.00	13 ± 3				

[a] Protein association was measured using the Bradford Protein Assay after unbound protein removal on a Sepharose CL-4B size exclusion column. Two variables are indicated for each NTA formulation: percent NTA present in the liposome is indicated by mol % NTA, protein added to formed liposomes is indicated as a ratio (NTA:protein). Data represent analysis of liposome-containing fractions. Control liposomes of various formulations were used to validate NTA-nickel-his-tag interactions. [b] Liposomes formulated without a 5% mPEG coat associated similar amounts of yCD as those containing mPEG. [c] BSA, a control protein that does not contain a his-tag, had limited association with liposomes containing NTA-nickel. [d] Liposomes formulated with NTA, but without nickel, associated less yCD than those with nickel. [e] Liposomes containing POPG, to mimic the charge of NTA-containing liposomes, had minimal yCD association.

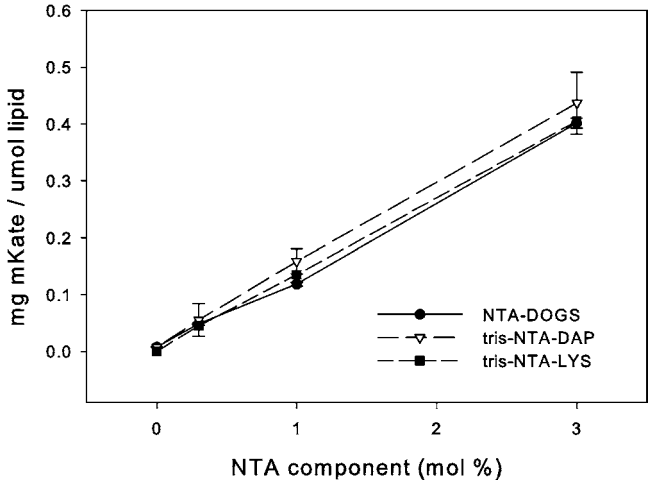

Figure 3. Association of mKate with the surface of NTA-liposomes. The amount of protein per μmol liposomes containing 3, 1, and 0.3 mol % NTA-DOGS (circles), tris-NTA-DAP (triangles), or tris-NTA-LYS (squares) ($n = 3$).

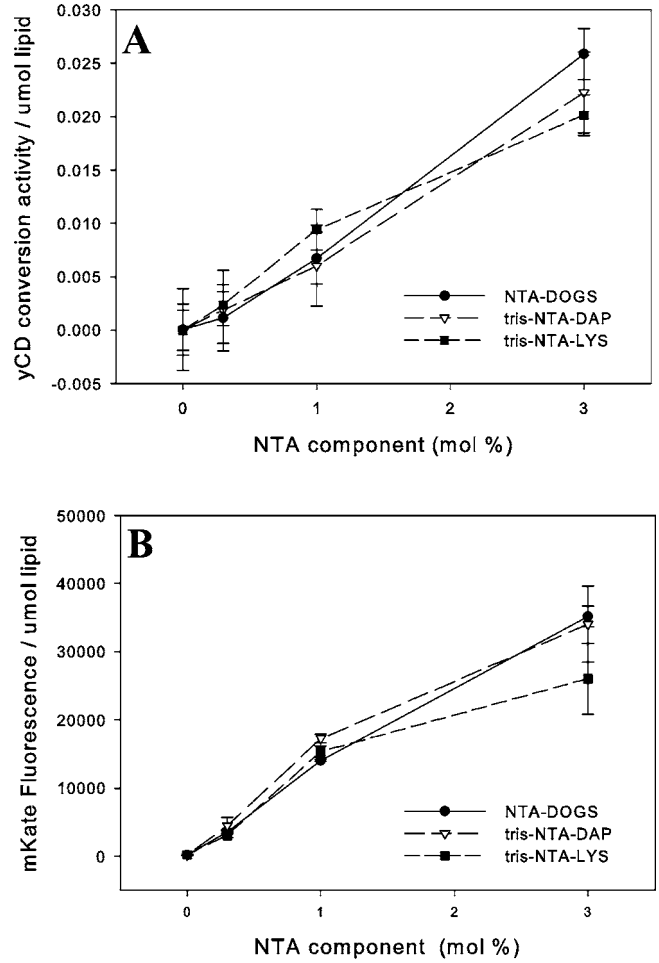

Figure 4. Retained protein activity of yCD (A) or mKate (B) on the surface of NTA-liposomes. The protein activity per μmol liposomes containing 3, 1, and 0.3 mol % NTA-DOGS (circles), tris-NTA-DAP (triangles), or tris-NTA-LYS (squares) ($n = 3$).

containing liposomes after 24 h (Figure 5C) than disassociated from liposomes exposed to FCS (Figure 5B). Tris-NTA-DAP-liposomes exposed to mouse plasma retained 30 ± 4% of the initial mKate after 24 h.

NTA_3-DAP has a higher affinity for histidine-tags than does NTA_3-LYS (*5*). Tris-NTAs in turn have significantly higher affinity (0.2−10 nM) than mono-NTA (10 μM) (*18*). For both yCD and mKate, retention in refiltered FCS or mouse plasma is related, but not directly proportional to, the relative affinity for the NTA lipids.

Competition between NTA-Liposome Bound His_6-Proteins and Subsequently Added His_6-Proteins. mKate that was stably associated with the liposome surface was challenged with added his_6-yCD. Despite the slightly higher affinity of tris-NTA-lipids for mKate ($K_d = 0.69$ nM) than for yCD ($K_d = 3.02$ nM) (*5*), yCD exchanged with preassociated mKate for positions on the liposome surface (Figure 6). Upon addition of a competing protein, proteins redistributed to yield the stoichiometric distribution of proteins on the surface of the liposome regardless of their reported affinity. For example, if yCD and mKate are at the same final concentration in solution, there will be an equal amount of yCD and mKate on the surface of the liposome and in solution. This arrangement will occur regardless of which protein is first incubated with the liposomes. When prebound mKate was challenged with BSA, which lacked a his-tag, no mKate dissociated; however, BSA nonspecifically associated with the liposome so that the total amount of liposome-bound protein increased.

Retention of Tris-NTA-Lipids in Liposomes. Liposomes containing 3% tris-NTA-DAP (−23.6 mV) were retained on a highly charged anion exchange column, while neutral liposomes (−4.1 mV) passed through the column in the void volume. The tris-NTA-DAP-DOD lipid did not transfer between labile lipid bilayers to a measurable degree. After 3 h at 37 °C, the neutral

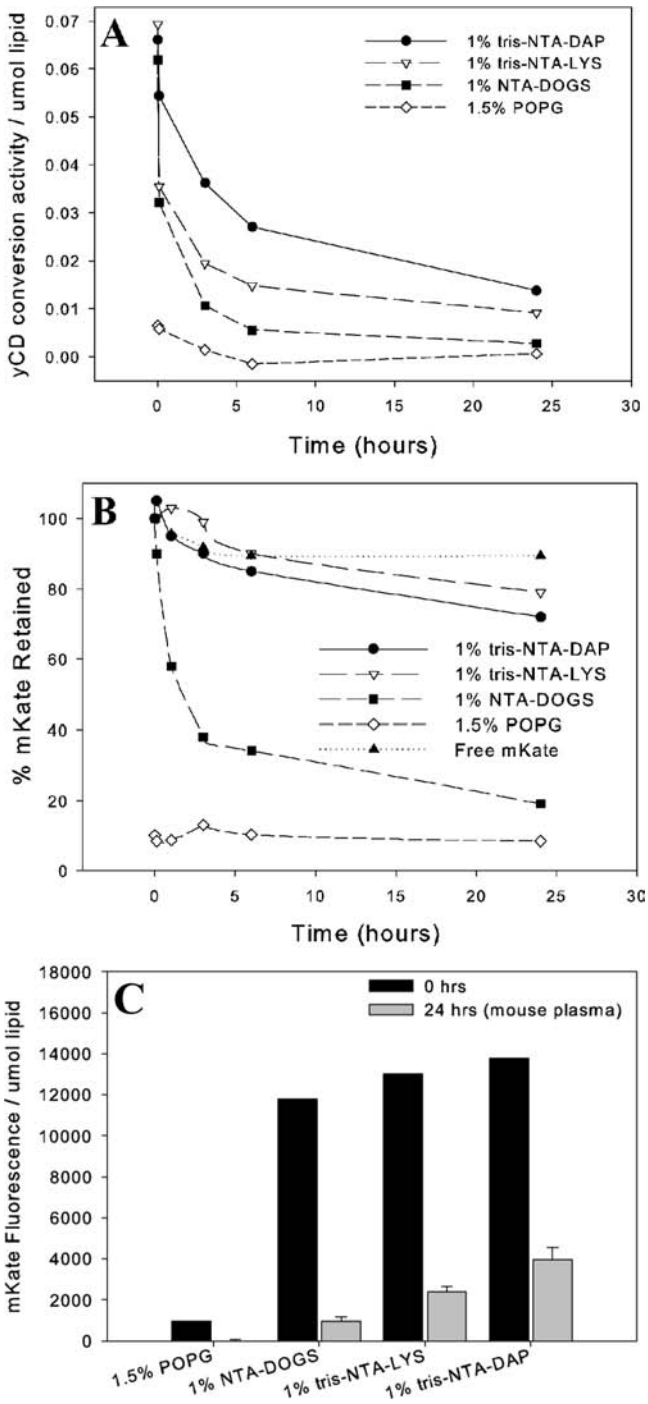

Figure 5. Dissociation of yCD (A) or mKate (B,C) from NTA-liposomes in serum or plasma. Enzyme activity per unit of liposome (for yCD) or percent retained mKate fluorescence after unbound protein has been removed for each of four liposome types: 1% tris-NTA-DAP (circles), 1% tris-NTA-LYS (triangles), 1% NTA-DOGS (filled squares), and control liposomes containing 1.5% POPG (diamonds). Time-course studies were done in the presence of refiltered fetal calf serum (A,B). Dissociation in the presences of mouse plasma was studied at 24 h (C) (yCD, $n = 1$; mKate, $n = 3$).

liposomes passed through the anion exchange column in the same fraction and retained the same surface charge (-4.8 ± 1.3) as neutral liposomes that were not incubated with NTA-containing liposomes (-3.8 ± 1.4). Neutral liposomes were fully recovered in the void volume (105 537 ± 13 546 au fluorescence or 105 ± 14% of the expected fluorescence based on untreated, neutral liposomes).

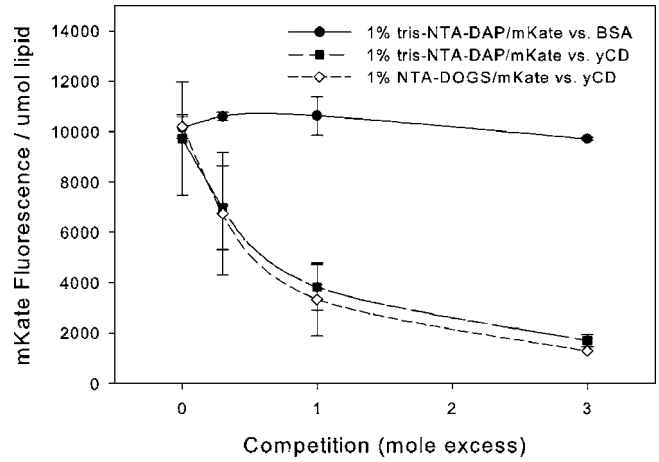

Figure 6. Competition of proteins with pre-associated mKate. Competition of BSA for pre-associated mKate on 1% tris-NTA-DAP (circles) or yCD for pre-associated mKate on 1% tris-NTA-DAP (squares) and 1% NTA-DOGS (diamonds) ($n = 3$).

Half-Life of NTA-Liposome Associated Proteins Upon Intravenous Administration. The association of iodinated protein with NTA-liposomes did not increase the residence time of either protein in the blood after intravenous injection (Figure 7). To ensure that iodination was not responsible for protein loss from the liposome, noniodinated mKate was associated with fluorescent tris-DAP-NTA-liposomes and injected into mice. After 15 min, blood was collected and the mKate-NTA liposomes remaining in plasma were separated on a Sepharose CL-4B column. A majority of the liposomes remained in circulation, but only a small fraction of the injected mKate was associated with the liposome fractions from the column (Figure 7B, inset). This verified that the mKate rapidly dissociated from the liposome upon contact with blood.

Endogenous Protein Binding to NTA-Liposomes Upon Intravenous Administration. When recovered from blood, tris-NTA-DAP containing liposomes had a different protein profile than liposomes with a similar charge (1.5% POPG, Figure 8A). In this experiment, three mice were injected per group with each liposome formulation. Unassociated plasma proteins were removed from liposome fractions based on size exclusion on a Sepharose CL-4B column. Tris-NTA-DAP-containing liposomes associated more protein (420 ± 90 μg/μmol lipid) than did POPG-containing liposomes (320 ± 60 μg/μmol lipid); however, this difference was not significant ($p = 0.19$). Lower molecular weight bands at approximately 12, 28, 58−60, and 75−90 kDa were enriched in tris-NTA-DAP-containing liposomes compared to POPG-containing liposomes (Figure 8A).

The quantity of protein present in the bands at approximately 12, 27, 37, and 60 (as a doublet) kDa was estimated using *ImageJ* gel analysis software and the area under the histogram peaks was calculated (Figure 8B). Equalizing the values based on the protein band at 37 kDa suggests that tris-NTA-DAP liposomes associate the 12 kDa and 60 kDa proteins significantly more than POPG containing liposomes ($p = 0.048$, 0.040, respectively). Association of the 27 kDa protein was higher with tris-NTA-liposomes than POPG; however, the difference was not significant.

Liposomes recovered from the blood of mice associated mKate after separation from plasma proteins. Liposomes containing tris-NTA-DAP were purified from unassociated plasma proteins, concentrated, and then mixed with a 5-fold excess of mKate. Liposomes associated approximately 70% of the mKate that would be expected based on liposome fluorescence (7000 units fluorescent/μmol lipid) compared to liposomes that were not exposed to mouse blood. This confirms that the

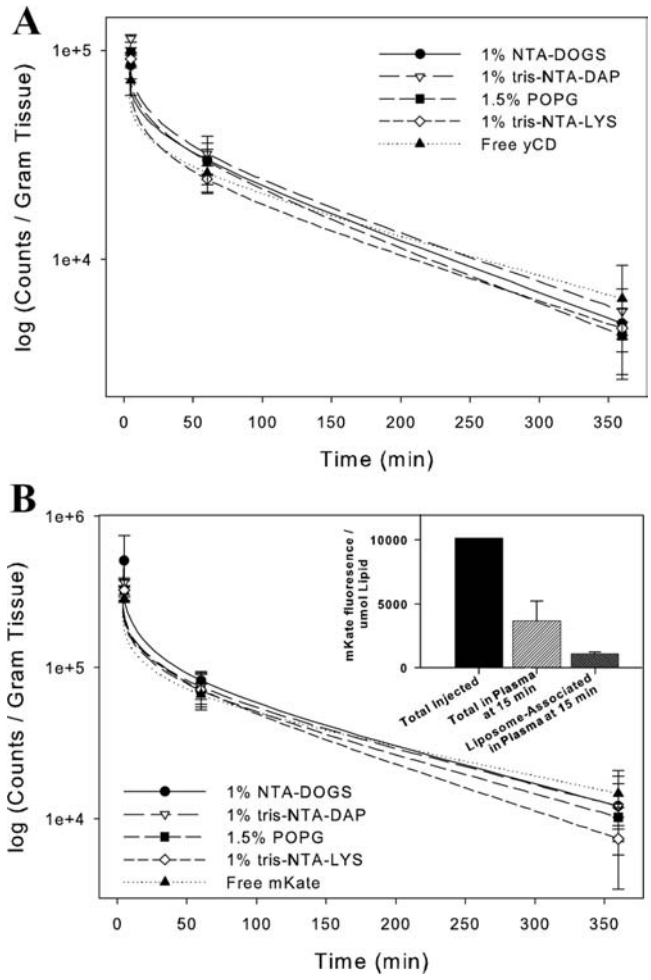

Figure 7. Disappearance of iodinated yCD (A) or mKate (B) after intravenous injection in mice (filled triangles) on four liposome types: 1% tris-NTA-DAP (open triangles), 1% tris-NTA-LYS (diamonds), 1% NTA-DOGS (circles), or control liposomes containing 1.5% POPG (squares). Each animal was injected with one million I^{125} counts per dose. Non-iodinated mKate (B**,** inset) fluorescence remaining bound 15 min after injection on 1% tris-NTA-DAP liposomes ($n = 3$).

tris-NTA lipid was not removed from the liposome during circulation in mice.

Hemopexin, a plasma protein which scavenges heme from the blood, was identified as a candidate for removing nickel from tris-NTA containing liposomes (*37*). Exposure of tris-NTA-DAP-liposomes to hemopexin did not effect mKate association. Hemopexin bound to tris-NTA-DAP-liposomes at approximately 25 μg/μmol lipid; this binding quantity (approximately 8% of 1:1 surface available NTA:HPX) is considered nonspecific binding and is similar to the quantity seen for BSA association to NTA-liposomes or his-tagged protein association to POPG control liposomes.

DISCUSSION

We characterized the effect of increasing affinity in a series of Ni-NTA/his_6 pairs, on his_6-protein-NTA liposome association, his_6-protein activity, and his_6-protein retention on NTA-liposomes under a variety of conditions. The surprising finding is that, despite the retention of the his_6-proteins on the NTA liposomes in FCS and mouse plasma, the NTA-liposome-attached protein rapidly dissociated from the liposome upon intravenous administration and hence was eliminated from circulation as rapidly as the injected "free" protein. The rapid elimination occurred regardless of whether the liposome contained a low affinity NTA lipid or a high affinity NTA lipid and was not consistent with the measured off-rates of the same protein on a NTA Biacore chip.

Our experiments were enabled by the synthesis of a series of tris-NTA chelators with increasing affinity for the his_6-tag (*5*). We synthesized tris-NTA-lipids with two different carbon lengths between each NTA headgroup to examine the effect of linker spacing on binding affinity. yCD and mKate retained activity when associated with the surface of NTA-containing liposomes, so the interaction holds forth the prospect of a modular system for easily constructing liposomes modified with any protein that has a his_6-tag.

Retention time for the his_6-proteins on the surface of a Biacore chip modified with the various NTA derivatives increased as NTA linker length decreased. Dissociation rates for the same NTA derivative also varied between his_6-proteins; this was ascribed to differences in the accessibility of the his-tag (*5*). Assuming that the protein is rapidly eliminated when released from the liposome, the blood residence time of a his_6-protein attached to an NTA-liposome after intravenous administration can be calculated from the dissociation rate. For the tris-NTA-LYS headgroup, with four carbons in the linker region, the half-time of release from the surface of a Biacore chip was 14 min with yCD ($k_d = 0.83 \times 10^{-3}$/s). If the linker is decreased by one carbon, the half-time was 20 min with yCD ($k_d = 0.59 \times 10^{-3}$/s) and 50 min with mKate ($k_d = 0.22 \times 10^{-3}$/s). When the linker region was decreased by another carbon, the computed half-time with mKate increased to over 2 h ($k_d = 0.89 \times 10^{-3}$/s) (*5*).

Proteins associated with the higher affinity NTA-liposomes were retained on the liposome much better when exposed to FCS than when on the mono-NTA modified liposomes (Figure 5). The magnitude of this increased association time is related to the affinity of each NTA−protein pair (Figure 5). At 24 h, approximately 80% of the initially bound mKate remained associated with either the tris-NTA-LYS and tris-NTA-DAP liposomes, whereas only 20% mKate remained bound to liposomes containing NTA-DOGS. yCD dissociated to a greater extent from the surface of the liposome than did mKate, which is consistent with the difference in affinity ($K_d = 0.69$ and 3.02 nM) for mKate and yCD, respectively. When plasma was obtained from mice, approximately 30% of the initially bound mKate remained associated with the tris-NTA-DAP liposomes at 24 h (Figure 5C). However, as expected for a reversible interaction, his_6-proteins could exchange with proteins in solution even from the lipid with the highest affinity, the tris-NTA-DAP. This reflects the dynamic nature of this system (Figure 6).

While tris-NTA-DAP increased retention of both proteins as compared to NTA-DOGS in FCS, it did not improve protein association *in vivo* (Figure 7). All of the formulations studied exhibited a similar clearance rate to that of free protein. PEGylated liposomes of this diameter have a circulation half-life of half a day or more (*38*). If the dissociation rate was the prime determinant of protein loss from the liposome, tris-NTA association should have afforded some improvement in circulation time for the liposome-bound protein over the free protein. The dynamic nature of noncovalent protein association with NTA may allow any multihistidine-containing protein in the body to actively compete with the associated protein, even if the affinity of the nascent, competing protein is much lower than that of the associated protein. However, if loss of protein is a simple equilibrium phenomenon, the off rate would still control the residence time of the protein on the liposome. Therefore, there must be other factors that contribute to the rapid dissociation after intravenous injection.

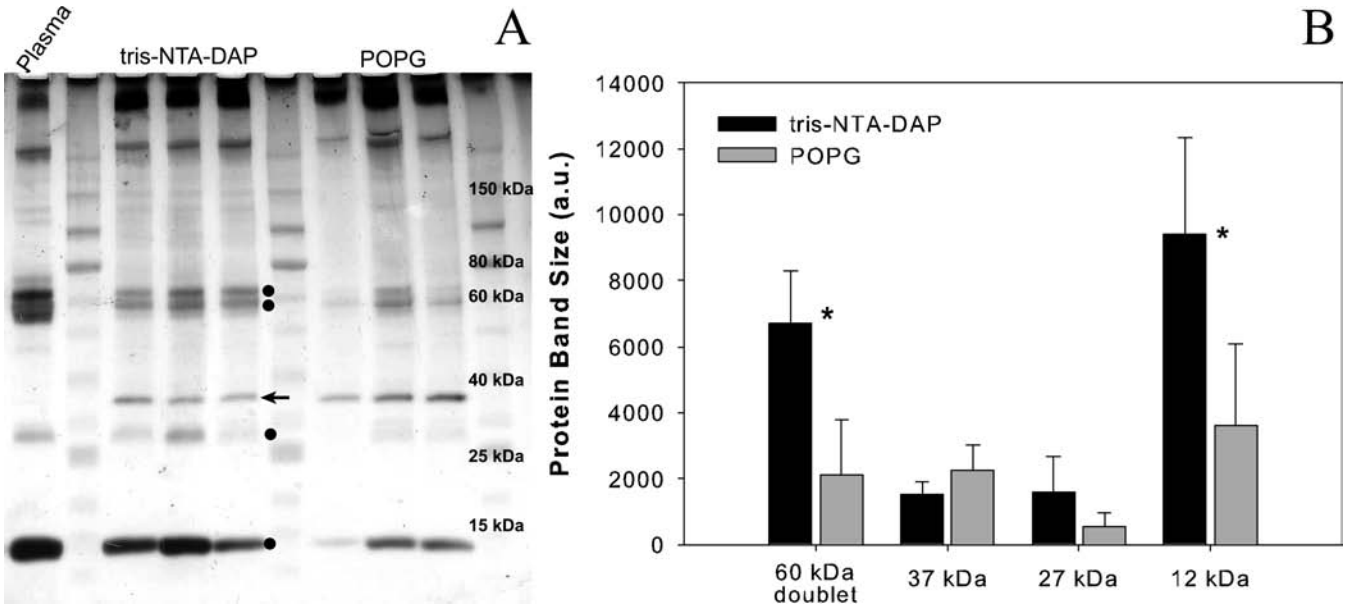

Figure 8. Analysis of protein interactions with NTA-modified and control liposomes. Liposomes containing either 1% tris-NTA-DAP or 1.5% POPG with 5% mPEG were recovered from the plasma of mice after intravenous injection. Each lane represents recovery of liposomes from an individual mouse, which accounts for the variable amount of total protein per well. Liposomes were purified to remove unassociated proteins and run on a 4−15% tris-Glycine SDS Page Gel. Circles (•) denote proteins that were substantially more visible in tris-NTA-DAP containing fractions than in control fractions after silver staining (A). The relative amount of protein in each band was quantified using *ImageJ* software. Association of the proteins at 60 kDa and 12 kDa are statistically greater for the tris-NTA-DAP-liposome than control liposomes (* $p < 0.05$) (B).

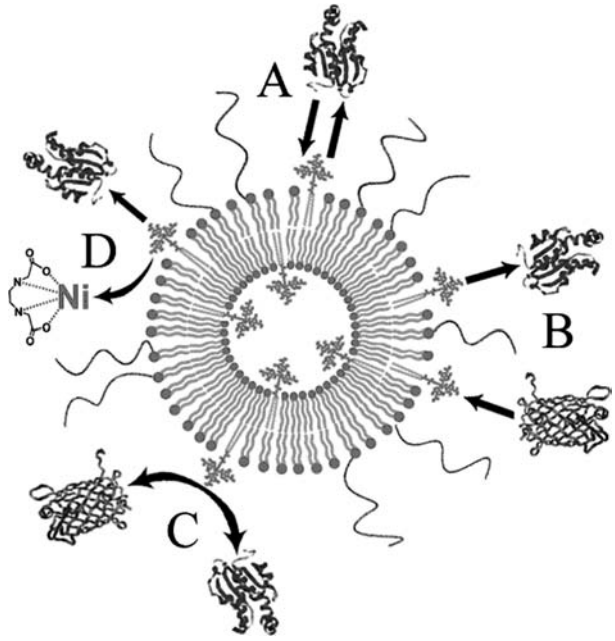

Figure 9. Modes of interaction of His-tagged proteins with NTA-containing PEGylated liposomes. Proteins bearing a his-tag associate and dissociate from the liposome surface (A). Upon dissociation, other proteins may associate with the newly available NTAs (B), proteins may directly compete for NTA binding (C), or nickel may be removed by endogenous chelators (D).

Plasma proteins may play a crucial role in the disruption of his_6-NTA association (Figure 9). Some plasma proteins may interact preferentially with the surface of NTA-liposomes (Figure 8A) (*29*) and may contribute to protein dissociation or loss of nickel from the chelator. Tris-NTA-DAP-containing liposomes recovered from mouse blood contained several proteins that were less present on liposomes containing POPG. These proteins may include metal-scavenging and histidine-rich plasma proteins, such as thioredoxin (12 kDa), Hemopexin (HPX, approximately 60 kDa) and histidine-rich glycoprotein (HRG, 75−95 kDa) (*37*, *39*, *40*). HPX scavenges heme within the blood, partially due to a high-affinity binding site containing eight histidines (*37*). This protein also binds divalent metal ions, including nickel (*41*), and has been shown to interact with immobilized metal-affinity columns (*42*). Although HPX did not bind tris-NTA-DAP liposomes or cause mKate dissociation under the conditions studied, similar metal-scavenging plasma proteins may interact with liposome-displayed NTA *in vivo*. HRG, another abundant plasma protein, has also been shown to scavenge heme, interact with metal ions, and bind to nickel-NTA with high affinity (*39*, *43*). Endogenous biochelators may act as an additional destabilizing factor by removing bound nickel from the NTA (*44*). Although NTA-liposomes recovered from blood could associate mKate (Figure 8C) without addition of exogenous nickel, removal of nickel from the NTA in blood may act to partially disassociate proteins. Competition for NTA occupancy by endogenous histidine-rich proteins, along with loss of nickel, may cause the initial protein dissociation from the liposome upon exposure to blood.

Several groups have published the robust association of his-tagged proteins with NTA containing nano-lipoparticles (*3*, *4*, *26*, *29*, *30*, *45*). Our findings must be reconciled with a number of papers where proteins associated with liposomes or lipid particles containing mono-NTA or tris-NTA mediate a number of immune responses (*3*, *26*, *30*). Protein-NTA particles generated a measurable immune response based on specific serum IgG levels (*30*) or an increase in splenocytes secreting cytokines (*26*). Mice immunized with tris-NTA containing plasma membrane vesicles showed decreased tumor growth (*3*). In these studies, the NTA particle was injected via the subcutaneous route. After subcutaneous administration, the particles are exposed to an order of magnitude lower concentration of endogenous proteins and the NTA liposome and its attached protein are eliminated more slowly than after intravenous administration. Second, the immune response is exquisitely sensitive to a protein antigen and even small quantities of protein that remained associated with the particle might have been responsible for the observed effects. Thus, it is not possible to

deduce the amount of protein that these various particles delivered from the observed immune responses.

Many *in vitro* cellular studies using protein-his_6/NTA-lipooparticles are performed in the presence of FCS-rich cell culture media. Under these conditions, Herringson et al. state that the his_6-protein/tris-NTA association is sufficiently robust so that *in vitro* retention will translate to *in vivo* protein/particle stability (*46*). However, our results indicate that improvements in metal chelation methodologies are required if metal chelation technology is to be useful for *in vivo* particle applications. Our group is exploring methods to improve the affinity of the system and reduce loss of nickel chelation. One approach is to increase the shielding in the vicinity of the acetic acid moiety by incorporating branched methyl groups. This might provide a hydrophobic wall that impedes removal of the chelated metal. An alternative approach is to synthesize a "clamp" for the chelated nickel. Chemically, this can be easily accomplished by covalently attaching histamines to a triacetic acid scaffold, such as the building blocks used to synthesize tris-NTA. The imidazole groups would then form a triad complementary structure to interact with the chelated nickel on the lipids. Although the triad histamine could not be incorporated into a recombinant protein, it could be used as a high-affinity binding partner for the chelated nickel. It remains to be discovered whether such improvements will be sufficient to stabilize NTA-protein-his_6 complexes *in vivo*.

ACKNOWLEDGMENT

We gratefully thank Katherine Jerger for her assistance with animal experiments. This work was supported by grant NIH R01 GM061851. Protein production and the salary of Dr. Cao were supported by UC discovery grant Bio 60−10618 and Halozyme, Inc. Our appreciation is extended to Greg Frost for suggesting hemopexin might interfere with his_6/NTA interactions in plasma and Christopher Cullander for helpful discussions regarding this manuscript.

Membrane receptors for steroid hormones are currently a subject of considerable debate. One approach to selectively target these putative receptors has been to couple ligands to substances that restrict cell permeability. Using this approach, an analogue of the estrogen receptor ligand 4-hydroxytamoxifen was attached to fluorescent dyes with differing degrees of predicted cell permeability. The conjugates bound to estrogen receptor in vitro, but all three conjugates, including one predicted to be cell-impermeable, inhibited estradiol-induced transcriptional activation. Fluorescence microscopy revealed cytoplasmic localization for all three conjugates. We further characterized a 4-hydroxytamoxifen analogue conjugated to a BODIPY fluorophore in breast cancer cell lines. Those experiments suggested a similar, but not identical, mode of action to 4-hydroxytamoxifen, as the fluorescent conjugate was equally effective at inhibiting proliferation of both tamoxifen-sensitive and tamoxifen-resistant breast cancer cell lines. While these findings point to significant complicating factors in designing steroid hormone mimics targeted to the plasma membrane, the results also reveal a possible new direction for designing estrogen receptor modulators.

INTRODUCTION

Estrogens, including 17β-estradiol (Scheme 1), are known to play key roles in female reproductive tissues such as the breast and uterus (*1*), and compounds that modulate estrogen signaling are clinically valuable for relieving menopausal symptoms or treating diseases such as breast cancer (*2*). However, current estrogen-based therapies have serious side effects in nontarget tissues, presenting significant therapeutic challenges. Breast cancer therapies such as tamoxifen (Scheme 1) can cause hot flashes in patients, and estrogen replacement therapies can increase the risk of breast cancer to unacceptable levels (*3, 4*). As a result, in order for progress in the field of estrogen drug design and discovery to continue to move forward, the key mechanisms of estrogen signaling and their roles in specific physiological responses to estrogen signaling modulators need to be identified.

There are multiple types of receptors in a cell that bind estrogens (*5*). The classical estrogen receptors and two major subtypes of the nuclear receptors are estrogen receptor (ER) alpha and ER beta (*6, 7*). Other receptors that can bind to estrogen ligands include the G-protein coupled receptor (GPCR) known as GPR30 (*8*) and variants of ER alpha (*9*). The possibility that some of these receptors may be associated with the plasma membrane has been an area of considerable debate, especially since certain cellular responses to estrogen such as the activation of kinase signaling cascades are typical downstream events of membrane receptor activation (*10*). Additional receptors have been identified based on homology with the classical estrogen receptors, but their activity does not appear to be directly regulated by physiological estrogens (*11*).

Scheme 1

Membrane-associated ERs have been postulated for a long time (*12*), but identifying and characterizing those receptors has been difficult and controversial (*13*). One strategy to selectively target membrane ERs has been to increase the polarity of known ER ligands until they become cell-impermeable, but confirming the localization of these molecules has proven to be difficult (*14,15*). Conjugating the ligand to proteins such as bovine serum albumin allows for tracking, since a fluorescent tag can also be attached to the protein (*16, 17*), but the use of the protein conjugates has been controversial for a number of reasons, including the purity of the conjugates and their unusual binding kinetics for ER (*18, 19*).

A potentially useful strategy that combines the ability to alter cell permeability with the ability to track localization is the conjugation of ER ligands to fluorescent dyes. Fluorescent ER ligand conjugates have been used for quite some time to try to determine the ER content of the cell (*20, 21*), but the growing library of available fluorophores now includes compounds that are cell-impermeable, making it possible to generate cell-impermeable fluorescent conjugates to target membrane steroid hormone receptors. Toward this objective, a cell-impermeable fluorescent estradiol conjugate has recently been used to

determine GPR30 localization of the estrogen-binding GPCR (*22*). In the current study, we use a similar strategy with a well-known ER ligand, 4-hydroxytamoxifen, to develop a novel set of fluorescent conjugates. These conjugates bind with good affinity to the estrogen receptor in vitro, and show remarkable differences in receptor localization and effects on estrogen signaling in cell-based assays when compared to the previously reported estradiol conjugate. We also show for the first time that even the ethinyl estradiol conjugate displays significant uptake over time, complicating the use of this type of chemical probe for longer-term studies of plasma membrane-initiated, estrogen signaling.

EXPERIMENTAL PROCEDURES

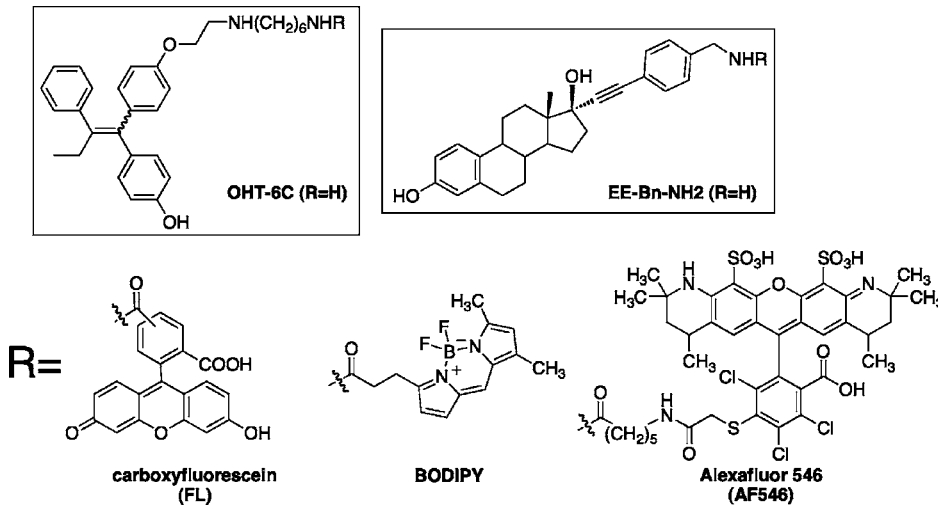
General Procedures. All reagents were purchased from Sigma-Aldrich. Routine proton nuclear magnetic resonance spectra (^{1}H NMR) were obtained on a Bruker DRX500 (500 MHz) instrument. ^{1}H NMR chemical shifts are reported as δ values in parts per million (ppm) downfield from internal tetramethylsilane. NMR instruments were provided by the Shared Resource Center of the Purdue Cancer Center. The plasmids used in the reporter gene assays, pSG5-ERalpha, pSG5-ERbeta, and estrogen response element (ERE)-luciferase, have been described elsewhere (*23, 24*). Analytical HPLC was performed using a 4.6 × 150 mm Agilent Eclipse XDB-C8 5 μm reverse-phase column with UV signal detection at 280 nm and fluorescence detection at excitation/emission of 488/508 nm. Preparative HPLC was performed using a 25 × 250 mm Vydac C8 15 μm semipreparative column with signal detection at 280 nm. Nonlinear regression analysis of binding and reporter assay curves was performed using *Prism 4* software. Images were acquired using either a Nikon TE2000 inverted microscope or a Zeiss LSM 710 upright microscope. Images on both microscopes were acquired sequentially using a 60× oil 1.4 NA lens. OHT-6C-BODIPY images were obtained by exciting with the 488 nm line of a 4-line argon laser. Alexa Fluor 546-labeled conjugates were excited at 543 nm using a green HeNe laser, and emission wavelengths greater than 560 nm were collected.

Conjugate Synthesis. The synthesis of OHT-6C has been described elsewhere (*25*). The ethinyl estradiol Alexa Fluor 546 was made by following a previously reported procedure (*22*). For the conjugation reactions, the commercially available *N*-hydroxysuccinimide ester of each fluorophore (5 mg for the carboxyfluorescein and BODIPY-FL esters and 2.5 mg for each of the Alexa Fluor esters) was dissolved in DMSO (0.25 mL). To each solution was added 10 mg of OHT-6C dissolved in DMSO (0.25 mL). The reaction proceeded in the dark at room temperature overnight. The sample was then purified by preparative HPLC with a water/acetonitrile eluent gradient starting at 20% acetonitrile and ending at 100% acetonitrile at 70 min. The eluent also contained 0.1% trifluoroacetic acid. The fractions containing the appropriate product were then freeze−dried using a lyophilizer. Characterization of each conjugate is included in the Supporting Information.

Radiolabeled Ligand Receptor Binding Assay. In each well of a 96 well plate, 25 μL of a solution containing binding buffer (100 mM potassium phosphate (pH 7.4), 100 μg/mL bovine gamma globulin, and 0.02% sodium azide) plus 2 nM [2,4,6,7,16,17-^{3}H] estradiol (GE Healthcare) and different concentrations of competitor were added to a 25 μL solution containing 30 nM of full-length recombinant estrogen receptor alpha or beta (Invitrogen) in binding buffer. After 2 h incubation at room temperature, the mixture was transferred to a MultiScreen HTS Filter Plate (Millipore) and washed with binding buffer to remove unbound ligand. Plates were allowed to dry overnight. Microscint 0 scintillation fluid (Perkin-Elmer) was added, and the radioactivity was counted on a Packard TopCount scintillation counter. Each drug concentration was tested three times each in three different experiments. Data were analyzed using *Prism* software.

Cell Culture. The ER-positive MCF-7 cell line was grown in phenol red free DMEM F-12 HAM medium supplemented with 0.876 g/L glutamine, 100 mg/L streptomycin sulfate, 100 units/mL of penicillin G, and 10% fetal bovine serum (FBS) at 37 °C in an air/carbon dioxide (95:5) atmosphere. MDA-MB-231 and SKBR3 breast cell lines were grown in phenol red free RPMI 1640 medium supplemented with 0.876 g/L glutamine, 100 mg/L streptomycin sulfate, 100 units/mL of penicillin G, and 10% fetal bovine serum (FBS) at 37 °C in an air/carbon dioxide (95:5) atmosphere. Transfection assays were run with the same media conditions except serum free media was used.

Luciferase Reporter Assays. Cells were plated in 24 well plates (2×10^6 cells per plate). Transfections were performed according to the protocol for Lipofectamine 2000. In order to normalize for the transfection efficiency in each well, the dual luciferase system was used in which a constitutively expressed, chemically orthogonal luciferase expression vector was also transfected. The total amount of DNA/well for each plasmid was as follows: ERE-luciferase 0.3 μg/well, and *Renilla*-luciferase 0.1 μg/well. The ratio of total DNA/Lipofectamine 2000 ratio was 1:3. After transfection, the plates were incubated at 37 °C for 6 h before replacing the media with serum free media for 24 h. The serum free media was then replaced with fresh serum free media and the ligands. All ligands were delivered in DMSO or ethanol and the total concentration of organic solvent in each was 0.1% or less. For competition experiments with 4-hydroxytamoxifen compounds, the ligand was added to media already containing 10 nM estradiol. For the ethinyl estradiol conjugates, ligand was added to media containing 5 nM raloxifene, an antagonist of ER in the ERE assay. After 18 h, the cells were lysed and assayed for dual luciferase activity in a Packard TopCount luminometer according to the protocol provided by Promega. The relative light units (RLU) were then calculated by dividing the output of the ERE-driven luciferase in each well by the output of the *Renilla* luciferase. For antagonist experiments, the percent transcriptional activation was calculated using the RLU value obtained with 10 nM estradiol as 100% and the RLU value obtained with 1 μM fulvestrant as 0%. Each drug concentration was tested in triplicate, and each experiment was repeated at least three times.



Uptake Studies. MCF-7 (ER-positive cell line) and MDA-MB-231 and SKBR3 (both ER-negative cell lines) were seeded on poly(L-lysine) coverslips and grown to 90% confluency. Drugs were dosed in serum free medium for the appropriate time point. Cells were washed and fixed using 4% paraformaldehyde. Coverslips were washed and mounted using ProLong Gold Antifade Reagent containing DAPI and then imaged.

Timed Uptake Studies. For the timed uptake studies in Figure 3, 3×10^5 MCF7 cells were seeded into each chamber of an 8-chambered, CC2-coated LabTek slide and grown to 90% confluency. The timed conjugate uptake assay was performed following a previously reported procedure (*22*).

Proliferation Studies. MCF-7 or tamoxifen-resistant MCF-7 cells (*26*) were plated in 96 well dishes (2000 cells per well) in steroid-free medium and treated with 1 nM of estradiol and various doses of 4-hydroxytamoxifen or OHT-6C-BODIPY. Cell numbers were determined by MTT assay after 7 days of treatment.

Receptor Stability Studies. MCF7 cells (5×10^5/dish) were plated in 60 mm dishes in steroid-free medium for 3 days prior to drug exposure. Whole cell extracts were prepared by suspending cells in 0.1 mL of lysis buffer (62 mM Tris, pH 6.8, 2% sodium dodecyl sulfate; 10% glycerol; 10 μL protease inhibitor cocktail set III). After sonication (3 × 10 s), insoluble

Scheme 2

material was removed by centrifugation (15 min at 12 000 *g*), and protein concentration in the supernatant was determined using a protein assay kit (Bio-Rad Laboratories, Inc.). The protein extracts were mixed with 1/4 vol of 5× electrophoresis sample buffer and boiled for 5 min at 90 °C. Protein extract (50 μg per lane) was then fractionated by SDS-PAGE, transferred to polyvinylidene difluoride membrane, and probed with antibodies. Primary antibody was detected by horseradish peroxidase-conjugated second antibody and visualized using enhanced SuperSignal West Pico Chemiluminescent Substrate (Pierce Chemical Co., Rockford, IL). The band density of exposed films was evaluated with *ImageJ* software (http://rsb.info.nih.gov/ij/).

RESULTS

Design and Synthesis of the Conjugates. While there has been success in generating inherently fluorescent ER ligands (*27*), we opted for the traditional conjugation strategy of attaching the fluorescent dye to an ER ligand through a flexible linker. The keys to success with this strategy are (1) the choice of the ER ligand and (2) identifying a location on the drug where linker attachment is well-tolerated. Tamoxifen, one of the most studied ER ligands, shows a mixed agonist/antagonist profile therapeutically (*3*) and has long been associated with possible plasma membrane binding sites, including some that might not bind estradiol itself (*28*). We have previously shown that potential linkers can be attached to the more potent tamoxifen metabolite, 4-hydroxytamoxifen (OHT), through the basic side chain with only small losses in binding affinity for ER and inhibitory potency in cell-based gene reporter assays (*29*). We have also shown that an analogue with a 1,6-diaminohexane linker known as OHT-6C (Scheme 2), showed strong ER binding affinity when coupled to a poly(methacrylic acid) polymer (*25*). For the cell-impermeable fluorescent dye, Alexa Fluor 546 was chosen. For comparison, we also chose two dyes, carboxyfluorescein and BODIPY FL, that have been well-characterized as cell-permeable fluorophores. Amine-reactive analogues of all three fluorophores were purchased as activated *N*-hydroxysuccinimide esters and linked to the primary amine of the OHT-6C analogue to generate three different conjugates (Scheme 2). The resulting conjugates (and OHT-6C itself) are generated as mixtures of *E* and *Z* isomers—the two forms readily interconvert at room temperature. Previous work with 4-hydroxytamoxifen has shown that, despite this interconversion, the *Z* isomer is almost exclusively bound by the receptor both in vitro and in vivo (*30*, *31*). All three of the conjugates showed nearly identical fluorescence spectra in solution as their parent fluorophores, although the overall fluorescence intensity of each conjugate was somewhat decreased (likely due to a change in the overall chemical environment of the fluorophore).

ER Binding and Effects on ER-Mediated Transcription. The conjugates were compared for their ability to bind to ER in solution using competition binding experiments with tritium-labeled estradiol. As predicted, all of the conjugates still retained their ability to bind to both ER alpha and ER beta in vitro at submicromolar concentrations, although there was some loss in affinity compared to the parent compound and to estradiol and OHT (Figure 1A and Table 1). In the published structures of the ER ligand binding domain bound to OHT, the basic side chain extends away from the binding pocket and into solution (*32*), which could explain the general tolerance in binding for the bulky OHT substitutions conjugates, although the weaker binding affinity suggests that there could be some somewhat unfavorable interactions with the fluorophore. This possibility seems likely considering that the largest fluorophore, Alexa Fluor 546, has the worst binding potency.

The conjugates were also tested for their ability to inhibit estradiol-induced activation of ER-mediated transcription using a cell-based luciferase reporter gene assay. In this assay, ER-positive MCF7 cells were transiently transfected with a reporter plasmid containing the luciferase gene under the control of a consensus estrogen response element-containing promoter. In this reporter system, dosing the cells with estradiol typically activates transcription of the reporter gene, while OHT acts as an antagonist. On the basis of the predicted cell permeability of the conjugates, we expected the carboxyfluorescein and BODIPY-labeled conjugates to still act as antagonists and the Alexa Fluor 546-labeled conjugate to have no effect due to its inability to enter the cell and interact with the ER. As shown in Figure 1B, all three conjugates antagonized ER-mediated transcription with roughly the same inhibitory IC_{50} (100−900 nM concentration range), 10−50-fold worse than OHT or OHT-6C. The conjugates were also rechecked for purity by analytical HPLC. No free OHT ligand was detected, suggesting that the conjugates enter the cell and modulate receptor function by an undetermined mechanism.

Conjugate Uptake and Localization. Confocal laser scanning microscopy was used to monitor the cellular uptake and localization of the conjugates at different time points. Previous studies using fluorescent ER ligands capable of modulating ER-mediated transcription reported observing the fluorescence in the nucleus (*33*). In addition, our work (*34*) along with multiple

other studies demonstrated that ER localizes to the nucleus in the presence of agonists or antagonists (reviewed in *refs* 35, 36). Since all three conjugates were ER antagonists, we expected to see similar nuclear localization patterns; however, the fluorescence localized to the cytoplasm in a number of the ER-positive MCF7 cell lines and was clearly excluded from the nucleus at 100 nM and 10 μM (Figure 2). To our knowledge, this pattern of cellular localization has not been previously reported for any fluorescent ER ligand.

Comparison with 17α-Ethynyl Estradiol Conjugates. In order to compare the unusual localization of the OHT-derived conjugates to a conjugate with a known localization pattern, we also synthesized the previously reported 17α-ethinyl estradiol analogue conjugated to Alexa Fluor 546. This conjugate which has been reported to be cell impermeable (*22*) was first tested

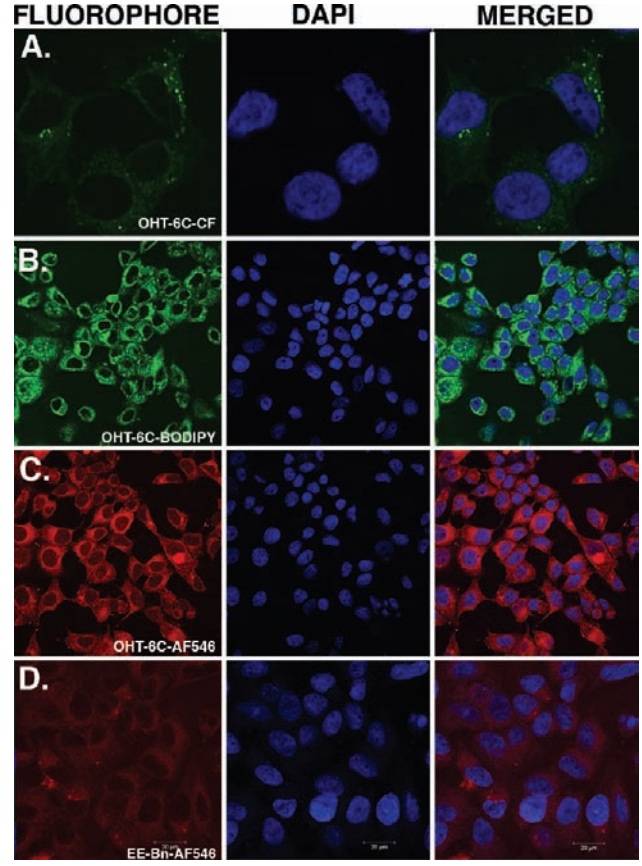

Figure 2. Images of uptake of conjugates by ER-positive MCF7 cell line after 6 h of dosing. Row A, 10 μM OHT-6C−CF; Row B, 100 nM OHT-6C-BODIPY; Row C, 10 μM OHT-6C-AF546; Row D, 1 μM EE-Bn-AF546. The first image of each row is the emission of the fluorophore. The second image of each row is the image of the DAPI nuclear stain, and the third image is the merged picture of the first two images. Due to the relatively low brightness of the carboxyfluorescein conjugate, we have shown an image at higher magnification than the other fluorophores.

for its ability to bind to ER alpha and ER beta in vitro. We observed sufficient binding affinity for both receptor subtypes (Table 1) and subsequently tested the conjugate for its effect on ER-mediated transcription in the ER-positive MCF7 breast cancer cell line. Surprisingly, the conjugate, at submicromolar concentrations, activated ER-mediated transcription from a consensus estrogen response element (Supporting Information Figure S1), in contrast to the original report describing the 17α-ethinyl estradiol−Alexa Fluor conjugate as a cell-impermeable probe (*22*). It should be noted, however, that, in the first report, the conjugate was tested at lower concentrations and for much shorter time periods than used for the transcriptional activation assays in the present study.

In order to attempt to reconcile the apparent differences in the permeability of our ethinyl estradiol conjugate compared to the previous report, we examined the cellular localization of both the OHT and ethinyl estradiol−Alexa Fluor 546 conjugates, as well as the Alexa Fluor546 dye itself, at different time periods using the original experimental conditions in the MCF7 breast cancer cell line (ref *22* and described in the Experimental Procedures). After 15 min, no uptake was apparent for either the ethinyl estradiol conjugate or the Alexa Fluor dye; however, significant uptake of the OHT-6C conjugate was observed (Figure 3). Thus, the results for the ethinyl estradiol conjugate are consistent with a previous report (*22*), although after a 2 h incubation, cytoplasmic localization was seen for all of the compounds (Figure 3).

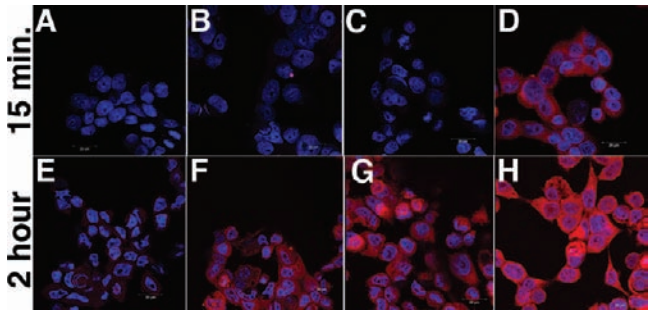

Figure 3. MCF7 cells were treated with different Alexa Fluor 546 conjugates for either 15 min (A−D) or 2 h (E−H) and imaged as described in the experimental procedures. The conjugates used are as follows: images A and E, DMSO; images B and F, 1 μM Alexa Fluor 546 dye alone; images C and G, 1 μM EE-Bn-AF; images D and H, 1 μM OHT-6C-AF. The images represent merged images of the emission from the DAPI stain of the nucleus (blue) and the emission of the Alexa Fluor dye (red).

Characterization of Conjugate Uptake and Localization. On the basis of brightness and potency qualities, the OHT-6C-BODIPY conjugate was chosen to further examine the mechanisms of uptake and cytoplasmic localization. Similar to the OHT-6C-AF conjugate, uptake of the OHT-6C-BODIPY by ER positive MCF7 cells could be detected as soon as 15 min after dosing using confocal laser microscopy and uptake increased over time (Supporting Information Figure S2). The fluorescence in the cytoplasm was stable, as no conspicuous change in fluorescence was observed 12 h after the media containing the conjugate with conjugate-free media was replaced (data not shown).

Uptake of the BODIPY-labeled conjugate in the ER-positive MCF7 breast cell line was compared to the ER-negative MDA-MB-231 and SKBR3 breast cell lines using confocal laser microscopy. No difference in the degree of uptake was seen (Supporting Information Figure S3), suggesting that ER does not play a significant role in conjugate uptake or localization. Moreover, uptake and localization were not altered in the presence of the ER ligands estradiol or OHT (Figure 4), suggesting a "non-receptor mediated" mechanism of uptake. We also considered the possibility of an endocytic mechanism. However, even at the earliest time points, fluorescence from the conjugate was seen in the cytoplasm, and the fluorescence did not colocalize with a commercially available, fluorescent endosomal or lysosomal markers (data not shown). Taken together, these observations suggest that, while there may be some endocytic conjugate uptake, the majority of the conjugate appears to enter the cell through either passive diffusion or pinocytosis.

Effects of the Conjugate on ER Activity. The unusual cytoplasmic localization of the OHT-6C-BODIPY conjugate prompted us to investigate whether this localization had any effect on ER function. To address this key question, we first compared classical ER responses to OHT-6C-BODIPY and tamoxifen. The effect of the conjugate on proliferation of both tamoxifen-sensitive and tamoxifen-resistant breast cancer cell lines were measured. The growth of ER-positive MCF7 breast cancer cells are stimulated by estradiol, and either tamoxifen or OHT block that stimulation. As shown in Figure 5, both OHT and OHT-6C-BODIPY were able to block estradiol-induced growth in tamoxifen-sensitive MCF7 cells, indicating that the conjugate is still capable of classic ER antagonism. The compounds were also tested against a subline of MCF7 cells that were grown in the presence of tamoxifen until they developed a resistance to the drug (*26*). The conjugate, in contrast to OHT, showed equal effectiveness in the tamoxifen-resistant line as it did in the parental MCF7 cell line (Figure 5), suggesting that the conjugate has an overlapping, but not identical, mechanism of action to 4-hydroxytamoxifen.

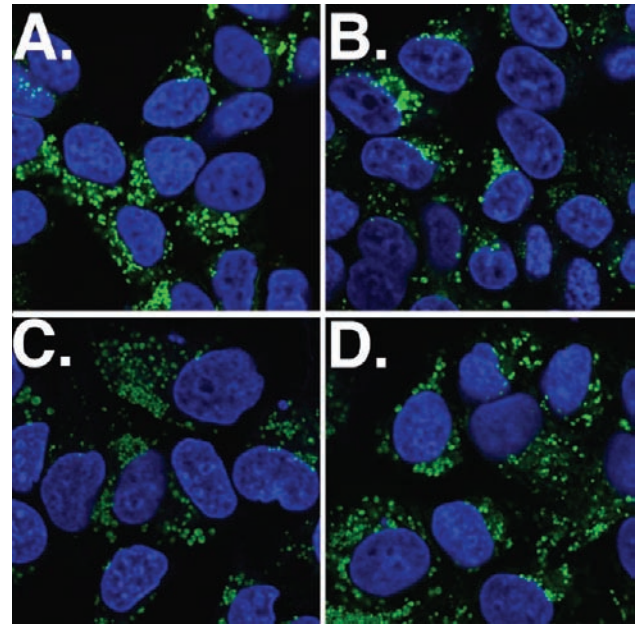

Figure 4. Uptake by MCF7 cells of 100 nM OHT-6C-BODIPY in the presence of competing ER ligands as analyzed by confocal scanning laser microscopy. The competing drugs are as follows: A, DMSO; B, 1 μM estradiol; C, 1 μM 4-hydroxytamoxifen; D, 1 μM OHT-6C. Images represent merged fluorescent images of emission from DAPI nuclear stain (blue) and the emission from the BODIPY fluorophore (green).

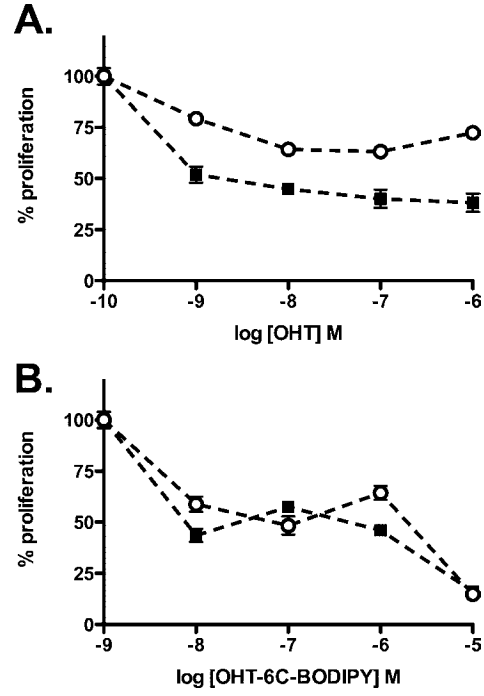

Figure 5. Effect of OHT (A) and OHT-6C-BODIPY (B) on proliferation of tamoxifen-sensitive, parental MCF7 cells (closed squares) and a tamoxifen-resistant MCF7 cell subline (open circles). Cells were seeded in hormone-free medium and treated in the presence of 1 nM E2. Seven days after treatment, cell number was determined by MTT assay. Experiments were performed twice in triplicate.

We next examined the effect of these conjugates on cellular ER levels, a key determinant of hormone sensitivity. One of the critical differences between the mechanism of action of selective estrogen receptor modulators (SERMs) like OHT and

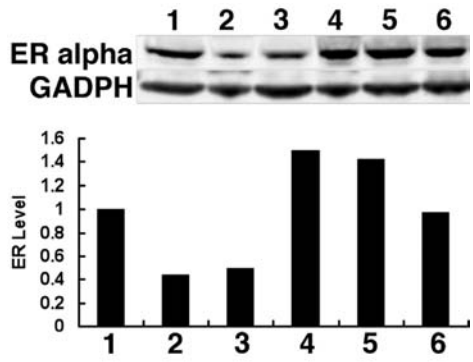

Figure 6. Effects of the OHT-6C-BODIPY conjugate on ER alpha stability. MCF7 cells were seeded in hormone-free medium for three days, then treated with different compounds for 24 h. Lane 1, DMSO; lane 2, 10 nM estradiol; lane 3, 100 nM fulvestrant; lane 4, 100 nM 4-hydroxytamoxifen; lane 5, 1 μM OHT-6C; lane 6, 10 μM OHT-6C-BODIPY. ER alpha levels in whole cell extracts were determined by immunoblotting with anti-ERα antibody. GAPDH was used as the loading control. Relative ER alpha levels (versus untreated cells) are shown in the corresponding histogram.

another class of drugs known as SERDs (selective ER down-regulators) such as fulvestrant is that OHT stabilizes cellular ER levels, while fulvestrant causes rapid receptor degradation (*37,38*). Whereas both estradiol and fulvestrant induced marked receptor downregulation in MCF7 cells after a 24 h incubation, no receptor degradation was observed after treatment with the OHT-6C-BODIPY conjugate (Figure 6), indicating that OHT-6C-BODIPY is more similar in mechanism of action to SERMs rather than compounds in the SERD class.

DISCUSSION

The design and synthesis of fluorescent conjugates for estrogen signaling modulators has previously focused on targeting activity either in the nucleus or the membrane. Although the compounds described in this paper were intended to target either of these locations, they instead localized to the cytoplasm. The only compounds for which specific cytoplasmic localization has been previously reported are a highly useful set of dendrimer-based estradiol analogues (*39, 40*). The uptake of those analogues appears to be mediated by ER and nuclear exclusion and seems to derive from the overall size and charge of the dendrimers (*39, 40*). For the fluorescent conjugates described in this current study, the mechanism of conjugate uptake and apparent exclusion from the nucleus is not as clear. ER does not appear to play a significant role in cellular uptake of the conjugates, which was similar in ER± breast cancer cell lines and not affected by the addition of competing ER ligands in ER+ cells (Figures 2−4, Supporting Information Figure S3). Furthermore, it is unlikely that conjugate size is a contributing factor to the observed cytoplasmic accumulation, as all of the conjugates are small enough to easily enter the nucleus.

We also found that the ethinyl estradiol Alexa Fluor conjugate, previously reported to be cell-impermeable (*22*), showed similar uptake to the OHT conjugates, with accumulation time being the only difference between these conjugates (Figure 3), indicating a slower mode of uptake. Although this observation would apparently contradict earlier claims regarding cell impermeability of the ethinyl estradiol conjugate, by using the reported concentrations and time intervals (*22*), we also found that no uptake was detected, consistent with those previous results. This lag in uptake has been indirectly seen with other highly polar ethinyl estradiol analogues. In ER alpha expressing COS7 cells, a longer time period was required to observe cellular uptake of compounds that did not stimulate rapid calcium mobilization, as these more polar ethinyl estradiol analogues showed a slower increase in mobilization (*15*).

It is difficult to exactly rationalize why the fluorescent conjugates all showed similar levels of cellular uptake and why the localization was almost entirely in the cytoplasm of the cells. One of the difficulties in trying to understand uptake is the fact that the conjugates are not particularly potent compared to their in vitro binding affinity. In addition, the fluorescence of the conjugates cannot be detected easily at lower nanomolar concetration ranges. As a result, localization only can be studied at higher concentrations where events such as aggregation could be playing a role. Aggregate formation would be consistent with the long-term stability and general punctate pattern of fluorescence seen in OHT-6C-BODIPY fluorophore treated cells, providing a possible reason the conjugate is excluded from the nucleus. Tamoxifen is known to interact with membranes (*41*), which could serve or initiate a nucleation event, leading to internalization of even the relatively more polar Alexa Fluor conjugates. Evidence for aggregation was not seen using standard fluorimetry of conjugates in solution, although we acknowledge that the level of sensitivity of the fluorimeters available to us does not approach that of confocal laser scanning microscopy.

A mechanism that also explains why the fluorescent conjugates are able to inhibit ER-mediated transcription is unclear. The dendrimer conjugates described by the Katzenellenbogen laboratories localize to the cytoplasm and have little to no effect on ER-mediated transcription (*39, 42*). The antagonist activity of the fluorescent OHT conjugates could arise from ER binding to the conjugate in the cytoplasm and being sequestered away from the nucleus. Alternatively, conjugate degradation within the cell could release free ligand from the fluorescent dye and subsequent transport of ligand to the nucleus. Toward these possibilities, we determined the hydrolytic susceptibility of the amide bond common to all of the conjugates by performing pH stability experiments in solution (various pHs at 37 °C for multiple days; data not shown). No release of OHT-6C was detected by HPLC, and no other nonfluorescent products were observed, but it is always possible with ligands as potent as OHT-6C that some level of hydrolysis undetectable by HPLC or any other standard analytical technique is still occurring and is responsible for the transcriptional inhibition. In addition, subcellular fractionation studies performed in ER-positive MCF7 cells dosed with OHT-6C-BODIPY revealed the presence of ER only in the nucleus, thereby contradicting the sequestration hypothesis. Another explanation is that, despite the apparent nuclear exclusion of the fluorescent conjugate, a small amount of nonaggregated conjugate is free to enter the nucleus. The concentration of this soluble conjugate is below detection sensitivity by microscopy in the presence of the much brighter cytoplasmic aggregates but able to inhibit ER transcription in a manner similar to the nonconjugated OHT6C ligand itself.

Overall, our findings indicate that a hydrophobic and planar drug portion of a conjugate can significantly complicate the use of fluorescent dyes to dictate subcellular localization. Considering that most drugs targeting steroid hormone receptors fit this description, care should be taken when using this type of approach to selectively target plasma membrane-initiated steroid hormone signaling. While it may be possible to obtain the desired localization by only studying very rapid signaling or by connecting the drug and fluorophore with a linker that prevents aggregation, we contend that thorough testing of the conjugates at different concentrations and time points is necessary before conclusions about selectivity can be drawn.

In addition to the unusual localization pattern, another unique property of the OHT conjugates is their ability to effectively inhibit proliferation of ER-positive, tamoxifen-resistant breast

cancer cells. Whether this activity is the result of altered ER function due to the added bulk of the fluorophore attachment in a manner similar to but distinct from compounds like fulvestrant or to changes in the intracellular drug concentrations due to the aggregate is unknown at this time. At this point, ongoing work to improve the potency of the compounds is necessary before more detailed mechanistic work can be pursued. Nonetheless, either mechanism could have significant impact on the discovery and development of hormone therapies for ER-positive, antiestrogen resistant breast cancer, the focus of our ongoing studies.

ACKNOWLEDGMENT

To increase the therapeutic index of chemotherapeutic drugs, prodrugs have been investigated as anticancer agents, as they may present fewer cytotoxic side effects than conventional cytotoxic drugs, while therapeutic efficacy is maintained or even increased. Extracellular β-glucuronidase (β-GUS) in the tumors has been investigated as a target enzyme for prodrug therapy, as it can convert nontoxic prodrugs into cytostatic drugs. To optimize β-GUS-based prodrug therapies, PET imaging could be a useful tool by providing information regarding the localization and quantification of β-GUS. Here, we describe our first PET tracer for extracellular β-GUS, [^{18}F]-FEAnGA, which consists of a 2-[^{18}F]fluoroethylamine ([^{18}F]-FEA) group bound to a glucuronic acid via a self-immolative nitrophenyl spacer. [^{18}F]-FEAnGA was synthesized by alkylation of its imidazole carbamate precursor with [^{18}F]-FEA, followed by deprotection of the sugar moiety with NaOH in 10−20% overall radiochemical yield. [^{18}F]-FEAnGA is about 10-fold more hydrophilic than the cleavage product [^{18}F]-FEA, and it is stable in PBS and rat plasma for at least 3 h. In the presence of either *Escherichia coli* β-GUS or bovine liver β-GUS, in vitro cleavage of [^{18}F]-FEAnGA with complete release of [^{18}F]-FEA was observed within 30 min. C6 glioma cells incubated with the tracer and *Escherichia coli* β-GUS or bovine liver β-GUS showed a 4- and 1.5-fold higher uptake of radioactivity, respectively, as compared to control C6 cells without β-GUS. Incubation of CT26 murine colon adenocarcinoma cells or the genetically engineered CT26mβGUS cells, which expressed membrane-anchored GUS on the outer cell membrane, with the tracer, resulted in a 3-fold higher uptake into GUS-expressing cells as compared to control cells. In a preliminary microPET study in mice bearing both CT26 and CT26mβGUS tumors, [^{18}F]-FEAnGA exhibited a 2-fold higher retention of radioactivity in the tumor expressing β-GUS than in the control tumor. [^{18}F]-FEA did not show any difference in tracer uptake between tumors. These results suggest that [^{18}F]-FEAnGA may be a suitable PET tracer for evaluation of β-GUS activity, since it is specifically cleaved by β-GUS and the released [^{18}F]-FEA remains attached to targeted cells.

INTRODUCTION

To overcome the limitation of toxicity associated with chemotherapeutic drugs, local conversion of a nontoxic prodrug (PD) to the active cytotoxic drug in or in the vicinity of tumors provides a means for delivering active drugs selectively to tumor cells while sparing the normal cells of a host.

β-glucuronidase (β-GUS) (EC 3.2.1.31) belongs to a group of isoenzymes that catalyze the hydrolysis of β-D-glucuronides to the corresponding alcohol and D-glucuronate. The enzyme is present in virtually all tissues and can be found in microsomes (endoplasmic reticulum) and lysosomes (Fishman). The human enzyme has a pH optimum of 4 to 5. Under normal tissue pH, only about 10% of the maximum activity is retained. β-GUS concentrations are low in human serum and the extracellular compartment of normal tissue (*1*). However, increased levels of extracellular β-GUS have been reported in a number of pathological conditions, such as rheumatoid arthritis, leprosy, myocardial infarction, liver fibrosis, bacterial infection, and various inflammatory processes (*2*). It is also known that tumors have high extracellular levels of β-GUS, due to invading monocytes and granulocytes (*3*). Extracellular β-GUS is also associated with tumor invasiveness and metastatic potential (*3*). Therefore, β-GUS seems to be a promising candidate for a PD-converting enzyme.

Glucuronide−drug conjugates exhibit improved water solubility, stability, and lower toxicity toward normal cells than the native drug. However, glucuronide−drug conjugates are susceptible to enzymatic cleavage by β-GUS, resulting in the in situ generation of highly cytotoxic drugs that can selective incorporate into targeted tumor cells (*1, 4, 5*). A number of prodrugs for β-GUS have been designed. These prodrugs generally consist of three distinct parts: a trigger, a linker, and an effector unit. For β-GUS targeted prodrugs, the trigger and effector units consist of a glucuronide moiety and the cytostatic drug, respectively. They are joined together by the linker unit, which should release the drug as fast as possible after prodrug activation via a chemical breakdown (*6*−*8*).

Encouraging results were obtained with the prodrugs DOX-GA3 and HMR1826 both carrying para-substituted aromatic spacers, which were able to release doxorubicin after enzymatic cleavage of the glucuronide moiety by extracellular β-GUS (Scheme 1).

As follows from the above, bioactivation of the glucuronide prodrug by β-GUS is an attractive approach in prodrug therapy.

Scheme 2. General Structure of the PET Tracer and Its Mechanism of Activation

However, interindividual and intertissue variability of β-GUS activity, as well as factors modulating the enzyme's expression and activity, are key determinants for the success of these therapeutic strategies (*9*, *10*).

For a better understanding of the mechanisms of action and metabolic conversion of these PD, some in vivo optical measurements of gene/enzyme expression have been done using substrates with fluorescent or bioluminescent properties. These optical imaging modalities are useful in superficial tissues and have extensive application in small animals, but application to larger animals or humans is limited by the depth of light penetration (*11*−*13*). Monitoring enzyme or gene expression in larger animals and ultimately in humans is possible with the use of specific radiotracers combined with nuclear imaging techniques like PET or SPECT (*14*−*17*). Among these techniques, PET is of particular interest for drug development because of its high sensitivity and ability to provide quantitative kinetic data (*18*, *19*).

For PET imaging of β-GUS activity, a suitable tracer is necessary (*20*). Therefore, we aimed to develop a PET tracer that allows repetitive noninvasive imaging of β-GUS activity in living subjects. Thus, we designed a potential PET tracer with a structure based on HMR1826. In the PET tracer, the doxorubicin moiety is replaced by a [^{18}F]-fluoroalkylamine group.

Due to the highly hydrophilic character of the glucuronide, the intact tracer will be rapidly cleared from plasma and from tissues that do not have extracellular β-GUS. However, in tissues with high levels of β-GUS, the enzyme should cleave the glucuronic acid moiety from the PET tracer. As a result, the less hydrophilic [^{18}F]-fluoroethylamine will be released after self-immolation of the spacer, and we hypothesized that [^{18}F]-fluoroethylamine will be trapped in the target tissue (Scheme 2).

This study aimed to provide a proof of principle of this tracer design. The tracer may be further optimized by replacing the

[18F]-fluoroethylamine moiety with, for example, a more lipophilic or targeted moiety in order to increase trapping efficiency as a result of increased nonspecific binding.

MATERIALS AND METHODS

Reagents and solvents were obtained from commercial suppliers (Aldrich, Fluka, Sigma, and Merck) and used without further purification. A glucose, magnesium, and calcium solution (GMC-PBS) was prepared by adding 5.6 mM D-glucose, 0.49 mM $MgCl_2$, and 0.68 mM $CaCl_2$ to 100 mL phosphate-buffered saline (PBS). Flash chromatography was performed on silica gel 60 (0.040−0.063, Merck). All reactions were monitored by thin layer chromatography on Merck F-254 silica gel plates. Detection of the compounds on the TLC plates was performed with UV light (254 nm). Sugar compounds were additionally visualized by staining the TLC strip with 8% H_2SO_4 followed by heating. For radiolabeled compounds, the detection on the TLC was performed with Cyclone phosphor storage screens (multisensitive, Packard). These screens were exposed to the TLC strips for a few seconds and subsequently read out using a Cyclone phosphor storage imager (PerkinElmer) and analyzed with OptiQuant software. ^{1}H and ^{19}F NMR were recorded on a Varian 300 and 200 MHz, respectively. Chemical shifts were determined relative to the signal of the solvent, converted to the TMS scale, and expressed in δ units (ppm) downfield from TMS. Coupling constants were reported in Hertz (Hz). Splitting patterns are defined as s (singlet), d (doublet), dd (double−doublet), t (triplet), dt (double−triplet), or m (multiplet). HPLC purifications were performed with an Elite LaChrom VWR Hitachi L-2130 pump system using a Phenomenex Prodigy C18-column, connected to a UV-spectrometer (Elite LaChrom VWR Hitachi L-2400 UV detector) set at 254 nm and a Bicron frisk-tech radiation detector. Radioactivity measurements for log *D* determination and cell studies were done using an automated gamma counter (Compugamma, LKB Wallac). Absorbance measurements in the enzyme assays were obtained with a UV spectrophotometer (Waters 2487 dual wavelength absorbance detector). CT26mβGUS murine colon adenocarcinoma cells were kindly provided by Steve Roffler (*11*), Institute of Biomedical Science, Academia Sinica, Academia Road, Section 2 No128, 11529 Taipei, Taiwan.

Synthesis. *Methyl 1-O-(4-((2-Fluoroethylcarbamoyloxy) methyl)-2-nitrophenyl)-2,3,4-tri-O-acetyl-β-D-glucopyronuronate (***2***).* Methyl 1-O-(4-(1*H*-imidazole-carbamoyloxymethyl)-2-nitrophenyl)-2,3,4-tri-*O*-acetyl-β-D-glucopyronuronate (**1**) was synthesized in 3 steps according to the procedure described by Duimstra et al. (*21*). Carbamate **1** (0.2 g, 0.35 mmol) was dissolved in 3 mL anhydrous CH_2Cl_2 under a N_2 atmosphere and cooled to 0 °C. Methyl triflate (45 μL, 0.40 mmol) was added to the reaction mixture. After stirring for 30 min at 0 °C, the reaction mixture was diluted with 2 mL Et_2O and cooled to −20 °C to allow the methylated product to precipitate. The white solid was collected by filtration, washed with Et_2O, and dried in vacuo. The methylated compound was resuspended in 2.5 mL CH_2Cl_2 under a N_2 atmosphere, and 2-fluoroethylamine hydrochloride (0.05 g, 0.54 mmol) and tryethylamine (75 μL, 0.54 mmol) were added. The slurry was stirred for 5 h at room temperature and then washed with water and brine. The organic layer was dried on Na_2SO_4, concentrated in vacuo, and purified by flash chromatography (silica, EtOAc−Hex 1:1 + 0.1% Et_3N) to give 81 mg (41%) of **2** as a white solid. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.97 (s, 3H, OAc), 1.99 (s. 6H, OAc), 3.23 (m, 2H, CH_2N), 3.61 (s, 3H, $COOCH_3$), 4.38 (dt, 2H, J = 47.2 Hz, J = 10 Hz, CH_2F), 4.71 (d, 1H, J = 9.5 Hz, H-5), 5.01−5.12 (m, 4H, benzylic CH_2, H-2, H-4), 5.43 (t, 1H, J = 19 Hz, H-3), 5.71 (d, 1H, J = 7.7 Hz, H-1), 7.40 (d, 1H, J = 8.4 Hz, ArH), 7.56 (m, 1H, NH), 7.65 (d, 1H, J = 9.5 Hz, ArH), 7.87 (s. 1H, ArH). ^{19}F NMR (200 MHz, DMSO-d_6) δ −217.84. ESI-MS *m/z* 592.3 $[M+NH_4]^+$, 597.3 $[M+Na]^+$.

*Methyl 1-O-(4-((2-Fluoroethylcarbamoyloxy)methyl)-2-nitrophenyl)-β-D-glucopyronuronate (***3***).* 12.6 μL 30% w/v NaOMe in MeOH was added to a solution of **2** (50 mg, 0.087 mmol) in anhydrous MeOH at 0 °C. After 2 h of stirring under nitrogen atmosphere, the reaction was quenched with acetic acid and concentrated in vacuo. The crude residue was purified by flask column chromatography (silica, 10% MeOH in CH_2Cl_2). The resulting solid was dissolved in acetone and filtered through a 0.2 μm PTFE filter to remove any remaining silica. Trituration of the solid in diethyl ether yielded 30.3 mg of **3** (78%) as a white solid.

^{1}H NMR (300 MHz, DMSO-d_6) δ 3.2 (m, 2H, CH_2N, 3.63 (s, 3H, $COOCH_3$), 4.10 (d, 1H, J = 9.1 Hz, H-5), 4.38 (dt, 2H, J = 47.6 Hz, J = 10 Hz, CH_2F), 5.00 (s, 2H, benzylic CH_2), 5.3 (d, 2H, J = 7 Hz, H-2, H-4), 5.51 (s, 2H, H-3, H-1), 7.42 (d, 1H, J = 8.8 Hz, ArH), 7.56 (m, 1H, NH), 7.65 (m, 2H, NH, ArH), 7.84 (s, 1H, ArH). ^{19}F NMR (200 MHz, DMSO-d_6) δ −232. ESI-MS *m/z* 455.3 $[M+Li]^+$.

*1-O-(4-(2-Fluoroethyl-carbamoyloxymethyl)-2-nitrophenyl)-O-β-D-glucopyronuronate (FEAnGA) (***4***).* A solution of **3** (20 mg, 0.047 mmol) in acetone (1 mL) was stirred in the presence of a 1 M NaOH (380 μL) solution at 0 °C. After 10 min, the mixture was neutralized with 1 M HCl, concentrated in vacuo, and purified by flash chromatography (Silica, MeCN/H_2O 7:3) to give 17.3 mg of a light yellow solid (91%).

^{1}H NMR (300 MHz, DMSO-d_6) δ 3.2 (m, 2H, CH_2N), 3.55 (d, 1H, J = 9.4 Hz, H-5), 4.38 (dt, 2H, J = 47.6 and 10 Hz, CH_2F), 5.01 (s, 2H, benzylic CH_2), 5.11 (d, 2H, J = 6.8 Hz, H-2, H-4), 5.30 (d, 2H, J = 4.4 Hz, H-3, H-1), 7.41 (d, 1H, J = 9.1 Hz, ArH), 7.60 (m, 2H, NH, ArH), 7.83 (s. 1H, ArH). ^{19}F NMR (200 MHz, DMSO-d_6) δ −225; *m/z* 457.2 $[M+Na]^+$.

Radiolabeling. *Radiosynthesis of [*^{18}*F]-FEAnGA ([*^{18}*F]-***4***).* Aqueous [18F]-fluoride was produced by irradiation of [18O] water with a Scanditronix MC-17 cyclotron via the ^{18}O (p,n)^{18}F nuclear reaction. The [18F]-fluoride solution was passed through a SepPak Light Accell plus QMA anion exchange cartridge (Waters) to recover the ^{18}O-enriched water. The [18F]-fluoride was eluted from the cartridge with 1 mL of K_2CO_3 (5 mg/mL) and collected in a vial with 20 mg Kryptofix 2.2.2. To this solution, 1 mL acetonitrile was added and the solvents were evaporated at 130 °C. The ^{18}F-KF/Kryptofix complex was dried 3 times by the addition of 0.5 mL acetonitrile, followed by evaporation of the solvent.

[18F]-FEA ([18F]-7) was prepared by fluorination of *N*-[2-(toluene-4-sulfonyloxy)ethyl]phthalimide (30 mg, 0.09 mmol) in acetonitrile at 110 °C, followed by deprotection with hydrazine hydrate (50 μL, 1.03 mmol) as described in the literature (*22*). The resulting amine was distilled at 75 °C into an ice-cold solution of **1** (5 mg, 0.009 mmol) in acetonitrile (0.2 mL). The mixture was allowed to react at room temperature for 30 min. The product was diluted with 20 mL of water and passed through a tC18 cartridge (activated with 5 mL EtOH and 10 mL H_2O). Deprotection of the hydroxyl groups was done on the tC18 cartridge by addition of 1 mL 2 M NaOH and incubation for 7 min at room temperature. The product was eluted from the cartridge with 4 mL of water and purified by HPLC (10% EtOH in NaH_2PO_4 0.025 M (pH 6.3); 4 mL/min; retention time: [18F]-FEAnGA = 10 min).

The radiolabeled compound [18F]-FEAnGA ([18F]-**4**) was obtained in 5−20% radiochemical yield from [18F]-fluoride (decay-corrected) in 150 min. At the end of synthesis (EOS), the specific activity was 5−10 GBq/μmol and the radiochemical purity was >95%.

Stability of [$^{18/19}$F]-FEAnGA. Samples of [$^{18/19}$F]-FEAnGA were taken for stability testing. The sample of FEAnGA was dissolved in PBS (1 mL) and incubated at 37 °C. After 60 min, the solution was analyzed by HPLC (retention time: FEAnGA = 3.2 min, HNBA = 10.4 min) (20% CH_3CN/NaH_2PO_4 0.025 M (pH 6.3); 4 mL/min).

A sample of radiolabeled [^{18}F]-FEAnGA was dissolved in PBS (1 mL) and rat plasma (1 mL) and incubated at 37 °C. After 1 h and 3 h of incubation, respectively, the stability of the radiolabeled [^{18}F]-FEAnGA was followed by Radio-TLC (R_f FEA = 0.0, R_f FEAnGA = 0.4) (eluent: MeOH/CH_2Cl_2 2:8 + 0.1% Et_3N). After elution, the TLCs were analyzed by phosphor storage imaging. The screens were scanned with Cyclone phosphor storage system (PerkinElmer), and the percentage of conversion of [^{18}F]-FEAnGA as a function of the incubation period was calculated by ROI analysis using Opti-Quant software.

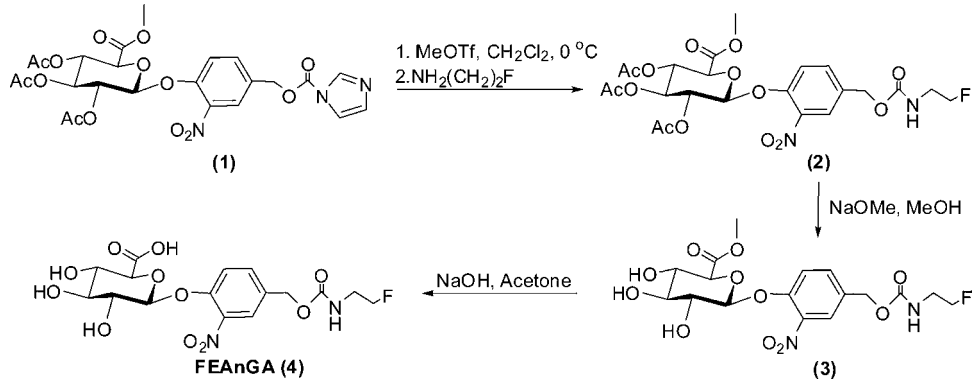
In order to not underestimate the amounts of [^{18}F]-FEA due to its volatile nature, we created a calibration curve of the amount of [^{18}F]-FEA evaporated over time in the radio TLC ($y = -0.2141x + 103.11$, $R^2 = 0.72$, $P = 0.03$) and corrected all values. The calibration curve was prepared by pipetting 1.5 μL of a stock [^{18}F]-FEA solution at different time points in a TLC plate. The TLC was read out by storage phosphorus imaging. Images were analyzed by Optiquant software and the percentage of evaporated activity was calculated. At 60 min, approximately 10% of [^{18}F]-FEA has evaporated.

Distribution Coefficient (Log $D_{7.4}$). To determine the Log $D_{7.4}$ of [^{18}F]-FEA and [^{18}F]-FEAnGA, an aliquot of 1 mL of HPLC purified [^{18}F]-FEA or [^{18}F]-FEAnGA solution was added to a mixture of *n*-octanol/PBS (5 mL/5 mL) at pH 3 and 7 for [^{18}F]-FEAnGA and at pH 7 and 10 for [^{18}F]-FEA. The tubes were vortexed at room temperature for 1 min, followed by 30 min shaking in a water bath at 37 °C. Aliquots of 1000 and 25 μL were drawn from the *n*-octanol and aqueous phase, respectively, and the radioactivity was counted using an automated gamma counter. The experiments were performed at least in triplicate.

In Vitro Hydrolysis of FEAnGA. To assess the kinetics parameters for the β-GUS-catalyzed hydrolysis of FEAnGA, aliquots of FEAnGA were prepared with concentrations ranging from 0.001 to 0.01 M in PBS buffer (pH 7.4). To a 0.950 mL solution containing 0.1% BSA in PBS (pH = 7.4), 3.7 μg (74U) *Escherichia coli* β-GUS (E.C.3.2.1.31, 20 000 U/mg Aldrich) and 50 μL of FEAnGA were added. The solution was incubated at 37 °C in a water bath, and 75 μL samples were collected at different time points ranging from 30 s to 30 min after the start of incubation. Each sample was immediately added to 500 μL acetonitrile in ice to stop the reaction. The release of 4-hydroxy-3-nitrobenzyl alcohol (HNBA) ($\varepsilon = 3460\ M^{-1}\ cm^{-1}$) was monitored by measuring the UV absorbance at 420 nm. The initial velocities of the reactions were determined from the slope of the absorbance curve at time = 0.The kinetic parameters K_M and V_{max} were obtained from a Lineweaver−Burk plot (*12, 23, 24*).

The kinetic parameters of the hydrolysis of FEAnGA by bovine liver β-GUS were determined as described above, but with minor modifications. Briefly, to a 0.8 mL solution containing 0.1% BSA in PBS (pH = 5), 95.2 μg (952U) bovine liver β-GUS (B-10, E.C.3.2.1.31, 10 000 U/mg Sigma) and 200 μL of FEAnGA were added. The same assay was also performed for a control sample solution (without enzyme) under the same conditions, and it showed negligible absorption for the duration of the experiment. For comparison, the kinetic parameters of a reference substrate, *p*-nitrophenyl-β-D-glucuronide (PNPG) ($\varepsilon = 7578\ M^{-1}\ cm^{-1}$) were determined using the same conditions as for FEAnGA. The experiment was preformed in triplicate.

In Vitro Hydrolysis of [^{18}F]-FEAnGA. To a 0.6 mL solution of 0.1% BSA in PBS (pH = 7), 3.7 μg (74U) *Escherichia coli* β-GUS or 95.2 μg (952U) bovine liver β-GUS and 0.4 mL of HPLC purified [^{18}F]-FEAnGA (0.68−1.28 MBq) were added. The solutions were incubated in a water bath at 37 °C, and 75 μL samples were collected at different time points ranging from 30 s to 30 min after the start of incubation. The enzymatic activity was stopped by dilution of the samples in 0.5 mL of acetonitrile and cooling of the samples in ice. The degradation of the radiolabeled [^{18}F]-FEAnGA was followed by Radio-TLC (eluent: MeOH/CH_2Cl_2 2:8 + 0.1% Et_3N). After elution, the TLCs were analyzed by phosphor storage imaging as described earlier.



Cellular Uptake of [^{18}F]-FEAnGA in C6 Glioma Cells. C6 glioma cells were maintained in 5 mL Dulbecco's Modified Eagle Medium (DMEM) supplemented with 7.5% fetal bovine serum (FBS) in 25 cm^3 culture flasks. Cells were grown in a humidified atmosphere containing 5% CO_2 and were passaged every 3−4 days. For uptake experiments, cells were plated in triplicate in a 12-well plate at a density of 7×10^5 cells per well. After 24 h, the medium was discarded and 1 mL of PBS-GMC buffer per well was added, followed by the addition of 200 μL [^{18}F]-FEAnGA (ca. 250 kBq) or 10 μL [^{18}F]-FEA (ca. 125 kBq). In 2 series of 3 wells, an excess of *E. coli* β-GUS (740U) or bovine liver β-GUS (340U) was added, respectively. After 60 min of incubation at 37 °C, the medium was collected and the cells washed with cold PBS (3 × 1 mL/well), harvested with trypsin (250 μL), and resuspended in 1750 μL of DMEM. The cell suspensions as well as the supernatant fractions were collected separately for each well, and the radioactivity was measured using a gamma counter. For each well, the medium was analyzed for conversion of [^{18}F]-FEAnGA into [^{18}F]-FEA as described earlier.

Cellular Uptake of [^{18}F]-FEAnGA in CT26 Adenocarcinoma Cells. CT26 control cells as well as the genetically engineered CT26mβGUS murine colon adenocarcinoma cells that express membrane-anchored GUS on the outer cell membrane were maintained in 10 mL DMEM medium supplemented with 10% FBS and 1% penicillin−streptomycin in 75 cm^3 culture flasks. Cells were grown in a humidified atmosphere containing 5% CO_2 and were passaged every 3−4 days. For uptake experiments, cells were plated in triplicate in a 12-well plate at a density of 7×10^5 cells per well. After 24 h, the medium was discarded and 1 mL of PBS-GMC buffer per well was added followed by the addition of 200 μL [^{18}F]-FEAnGA (ca. 250 kBq) or 10 μL [^{18}F]-FEA (ca. 125 kBq). The rest of the tracer uptake experiment was performed as described above.

Efflux Analysis of [^{18}F]-FEA in C6 Glioma Cells. C6 glioma cells were plated in triplicate in a 12-well plate at a density of 7×10^5 cells per well. After 24 h, the medium was discarded and 1 mL of PBS-GMC buffer per well was added, followed by the addition of 10 μL [^{18}F]-FEA (ca. 1.3 MBq). After 60 min of incubation at 37 °C, the medium was discarded, the cells washed with cold PBS (3 × 1 mL/well), and 1 mL of PBS-GMC buffer per well was added. At different time points, the medium was collected and the cells harvested with trypsin (250 μL) and resuspended in 1750 μL of DMEM. The cell suspensions as well as the supernatant fractions were collected separately for each well, and the radioactivity was measured using a gamma counter.

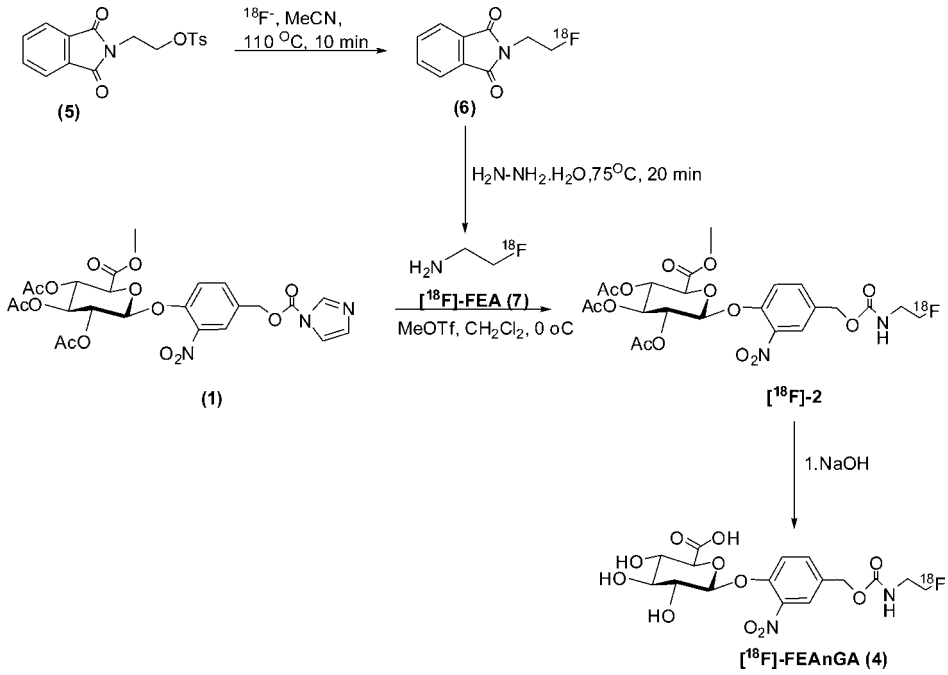
MicroPET Imaging in a β-GUS Expressing Tumor (CT26mβGUS) Mouse Model. The animals were provided with standard laboratory chow and tap water ad libitum. All studies were carried out in compliance with the local ethical guidelines for animal experiments. The protocol was approved by the local

Scheme 3. Synthesis of Compound FEAnGA

Animal Ethics Committee. CT26 and CT26mβGUS cells [(1−1.6) × 10^6, in a 1:1 mixture of Matrigel and DMEM with 10% FBS] were subcutaneously injected into the right and left shoulders of two male Balb/c mice (6−8 weeks old), respectively. On day 7 after inoculation of the mice with CT26 and CT26mβGUS cells, the mice were anesthetized with 2% Isoflurane and fixed to the bed in the small animal PET camera in transaxial position. A 20 min transmission scan with a Co-57 point source was obtained for the correction of attenuation of 511 keV photons by tissue. After the transmission scan was completed, the PET tracer [18F]-FEAnGA (4.4 MBq) or [18F]-FEA (4.2 MBq) was injected via the penile vein of the animal. A 60 min static image was acquired with a Focus 220 rodent scanner (CTI Siemens, Munich, Germany). Emission sinograms were iteratively reconstructed (OSEM2D) after being normalized, corrected for attenuation, and corrected for decay of radioactivity. Subsequent to the μPET imaging, the animal fixed to the bed was positioned in the microCT scanner (MicroCT II, CTI Siemens) and a microCT image (exposure time = 1050 ms; X-ray voltage = 55 kvp; anode current = 500 μA; number of rotation steps = 500; total rotation = 360°) was acquired for 15 min for anatomic localization. From the difference in bed positions from the PET to the CT, a transformation matrix was constructed, which describes the translation between both images. This transformation matrix was used for precise fusion of both images, using Inveon Research Workplace (Siemens) software.

Data Analysis. Apparent kinetic constants (V_{max} and K_M) were determined from Lineweaver-Buck plots of the initial rates ($1/V_0$) against the reciprocal substrate concentration 1/[S] generated in *Sigmaplot* software. The comparison between cells with and without β-GUS was performed using a two-sided *t* test that was paired for the different conditions in a single experiment. In all cases, $P \leq 0.05$ was considered significant.

RESULTS AND DISCUSSION



Prior studies with DOX-GA3 and HMR 1826, which have a β-glucuronyl group attached to doxorubicin via a para-substituted aromatic group showed promising preclinical results for PD therapy. Their low general toxicity has been clearly demonstrated in mice and rats studies with human tumor xenografts such as lungs, colon, breast, ovary, stomach, and pancreatic cancer. Experiments in ex vivo human lung tumor specimens have demonstrated that HMR1826 leads to increased levels of free DOX in tumor tissues and decreased levels in normal tissues compared to native DOX, while DOX-GA3 showed enhanced efficacy in ovarian cancer xenografts in comparison to native DOX. Inspired by the structures of the doxorubicin prodrugs, we designed an 18F-labeled PET tracer for imaging of β-GUS (Scheme 2). In this PET tracer, the DOX moiety is replaced by a lipophilic labeled molecule; after cleavage of the PET tracer by β-GUS, the labeled lipophilic part of the molecule is supposed to be trapped at the cleavage site by nonspecific binding.

Compound **1** was prepared in 3 steps from methyl 1-bromo-2,3,4-tri-*O*-acetyl-α-D-glucopyronuronate according to the procedure described by Duimstra et al. (*21*). Activation of the imidazole intermediate with methyltriflate followed by the reaction with fluoroethylamine gave compound **2** in 30% yield. It was observed that the amount of methyl triflate used was critical in this step, since higher amounts than 1.1 mol equiv led to lower yields of compound **2**. This could be due to the reaction of fluorethylamine with the excess of methyl triflate instead of compound **1**. The deprotection of the sugar moiety in 2 in a single step did not give product **4** in the desired yield, as the reaction was incomplete and led to the formation of multiple side products. Moreover, the purification of product FEAnGA by flash chromatography proved difficult, and consequently, it was decided to perform the synthesis of FEAnGA by a two-step procedure as depicted in Scheme 3. First, deacetylation of the hydroxyl groups was achieved using sodium methoxide. Then, the basic hydrolysis of the carboxylic ester was performed with NaOH, which afforded the unlabeled reference compound FEAnGA in 50% yield. The overall yield of this procedure was 23%. The identity of the compound was confirmed by low-resolution mass spectroscopy (LRMS) and the disappearance of the methoxy and acetyl groups of the glucuronic moiety in ^{1}H NMR.

The anomeric β-configuration, essential for substrate affinity for β-GUS, was confirmed by the NMR, which showed the H-1 proton as a doublet at a chemical shift $\delta_{H\text{-}1}$ of 5.71 ppm with a characteristic coupling constant J_{H1-H2} of 7.7 Hz. Typically, the H1−H2 coupling constants of the α anomer are 2−5 Hz, whereas the coupling constant of the β anomer is between 6 and 10 Hz (*19*, *25*, *26*).

The synthesis of [18F]-FEAnGA is a 3-step procedure consisting of the preparation of [18F]-FEA followed by the coupling of the amine with compound **1** and the removal of the protecting groups. [18F]-FEA was prepared according to the procedure described by Tewson (*22*) by reaction of the tosylate **5** with [18F]fluoride and subsequent removal of the phthalimide group **6** with hydrazine. This last step is of critical importance with regard to the final labeling yield. In order to obtain distilled [18F]-FEA in 48 ± 9% (n = 8) yield, it is necessary to use hydrated hydrazine in a reaction mixture that is free of acetonitrile to avoid the evaporation of the hydrazine associated water, which is required for the hydrolysis of the phthalimide moiety. On the other hand, distillation should not be performed at higher temperatures than 75 °C or longer than 15 min to avoid the distillation of hydrazine into the second reaction vial. Hydrazine competes with [18F]-FEA in the carbamate formation reaction, thus

Scheme 4. Radiosynthesis of Compound [^{18}F]FEAnGA

decreasing the final yield. The carbamate formation of compound **1** with the distilled [^{18}F]-FEA gives compound [^{18}F]-FEAnGA in 33 ± 19% (n = 8) yield after 30 min of reaction at room temperature. Deprotection of the hydroxyl groups was done on the tC18 cartridge by addition of 1 mL 2 M NaOH and incubation for 7 min at room temperature. The product was eluted from the cartridge with 4 mL of water and was purified by HPLC in 79 ± 9% (n = 8) yield. In contrast to the deprotection of the reference compound **2** which was obtained in 2 steps, surprisingly it was possible to deprotect [^{18}F]-**2** in a single step giving our final product in good yield. Thus, the final product [^{18}F]-FEAnGA was obtained in 13 ± 7% (n = 8) overall radiochemical yield (corrected for decay, based on [^{18}F]-fluoride) with a total synthesis time of 150 min (Scheme 4). The identity of the tracer was confirmed by coelution with an authentic sample of the nonradioactive compound by RP-HPLC.

The stability of [$^{18/19}$F]-FEAnGA in PBS was determined at 37 °C. After 1 h of incubation, HPLC analysis showed that 98% of the tracer was still intact. The stability of [^{18}F]-FEAnGA in PBS and rat plasma were also determined at 37 °C. After 1 and 3 h of incubation, 98% and 99% (Radio-TLC) of the radioactivity still corresponded to the intact tracer, respectively. This indicates that the tracer is highly stable in vitro.

The lipophilicities of [^{18}F]-FEAnGA and [^{18}F]-FEA were determined by measuring their *n*-octanol/water distribution coefficient at pH 7.4; the Log D was found to be −1.61 ± 0.01 for [^{18}F]-FEAnGA and −0.69 ± 0.02 for [^{18}F]-FEA. As expected, [^{18}F]-FEAnGA is about 10 times more hydrophilic than [^{18}F]-FEA due to the presence of the glucuronic acid moiety. Moreover, [^{18}F]-FEAnGA is less hydrophilic at pH 3 (Log $D_{3.0}$ −1.01 ± 0.03) than at pH 7.4, because the glucuronic acid is partially protonated at acidic pH (pK_a ≈ 3). In contrast,

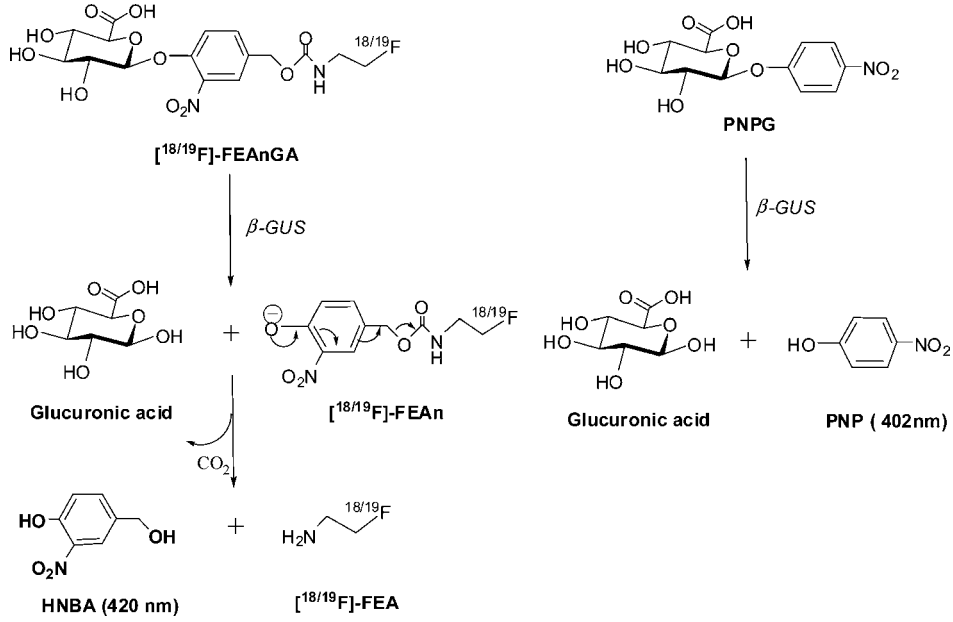


Figure 1. Mechanism of activation of [$^{18/19}$F]-FEAnGA and PNPG by β-GUS.

Table 1. Enzyme Kinetic Parameters for FEAnGA Represented by the Mean Values of Triplicate Samples ± SD

enzyme	substrate	K_M (μM)	V_{max} (μmol min^{-1} mg^{-1})	k_{cat} (s^{-1})	k_{cat}/K_M (10^6 M^{-1} s^{-1})
E. coli β-GUS	PNPG	8.2 ± 1.6	1366 ± 68	660	80.3
	FEAnGA	7.1 ± 0.9	348 ± 24	134	24.6
bovine liver β-GUS	PNPG	34.0 ± 16.5	56.9 ± 23	19	0.6
	FEAnGA	5.7 ± 2.7	25.8 ± 9	10	1.8

the log *D* of [^{18}F]-FEA was increased at pH 10 (−0.42 ± 0.03) as compared to pH 7.4, due to the fact that [^{18}F]-FEA is no longer protonated at basic pH (p$K_a \approx 8.8$) (*15*, *19*, *27*−*30*).

The enzymatic processing of FEAnGA was studied using commercially available bacterial *Escherichia coli* β-GUS and mammalian bovine liver β-GUS. The water-soluble FEAnGA is stable in aqueous buffer in the absence of β-GUS, and as a result, a solution of FEAnGA remains colorless. However, in the presence of β-GUS it undergoes rapid hydrolysis, resulting in the spontaneous release of [^{18}F]-FEA and the self-immolating spacer, which immediately colors the solution yellow. The liberation of 4-hydroxy-3-nitrobenzyl alcohol (HNBA) can be measured with a UV spectrophotometer at 420 nm. In a similar manner, the commercially available reference substrate, PNPG, is cleaved by β-GUS, producing *p*-nitrophenol (PNP) which can also be measured by UV spectrophotometer at 402 nm (Figure 1.)

Thus, the kinetic parameters for the hydrolysis of FEAnGA were determined by measuring the release of HNBA under physiological conditions. The kinetic parameters of PNPG were also determined under the same conditions for comparison. In general, the kinetic parameters of FEAnGA are on the same order of magnitude as those of PNPG, which indicates that FEAnGA is a good substrate of β-GUS as well. The maximum hydrolysis rate (V_{max}) of PNPG by *Escherichia coli* β-GUS and bovine liver β-GUS was 4 and 2 times higher than that of FEAnGA, respectively (Table 1). FEAnGA and PNPG show similar affinity for *E. coli* β-GUS ($K_M \approx 7$ μM). However, FEAnGA ($K_M = 5.8$ μM) has 6 times higher affinity than PNPG ($K_M = 34$ μM) toward bovine liver-β-GUS. Thus, despite the slightly lower turnover (K_{cat}) of FEAnGA by bovine liver-β-GUS as compared to PNPG, FEAnGA will still undergo relatively fast hydrolysis at low concentrations of substrate and enzyme, as is demonstrated by higher catalytic efficiency, K_{cat}/K_M. Although FEAnGA is a slightly less efficient substrate for *E. coli* β-GUS compared to PNPG, it proves to be a better

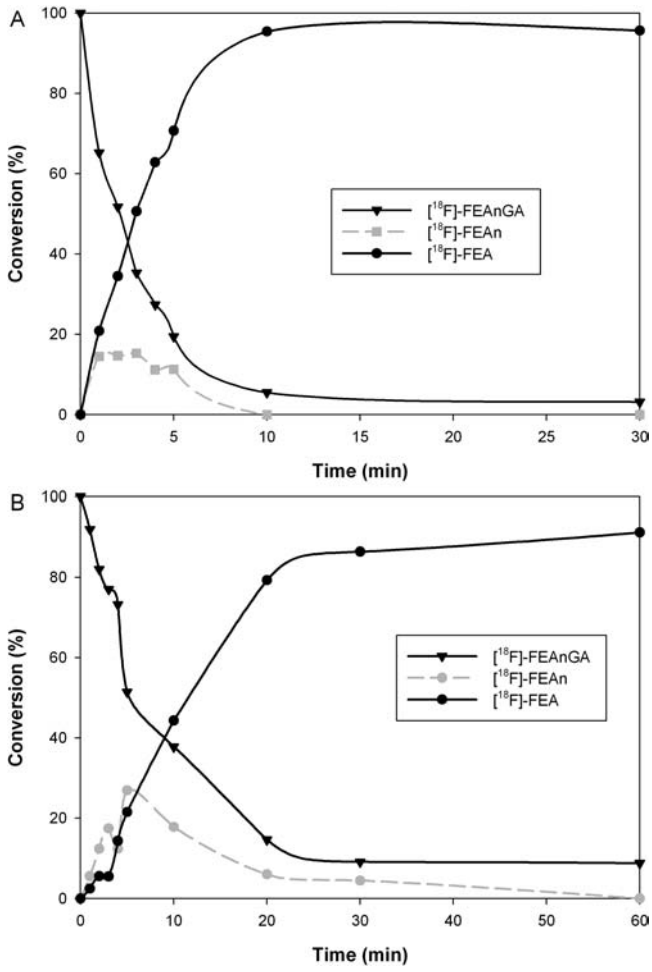

Figure 2. Cleavage of [^{18}F]-FEAnGA by (A) *E. coli* β-GUS ($n = 1$), (B) bovine liver β-GUS ($n = 1$).

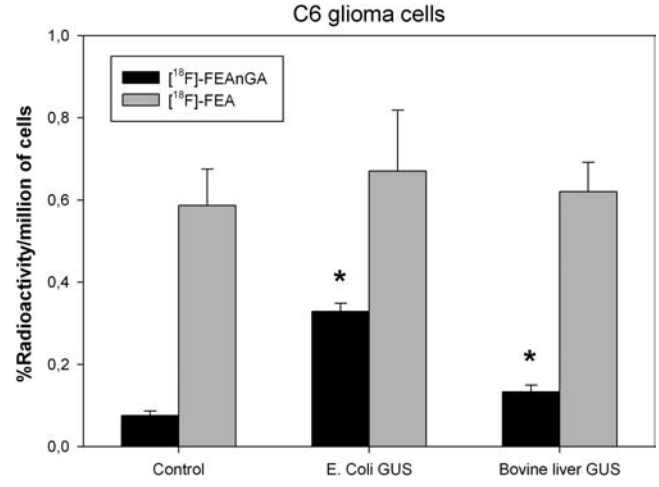

Figure 3. Cell-associated radioactivity of [^{18}F]-FEAnGA and [^{18}F]-FEA in control C6 cells and in C6 cells in the presence of *E. coli* β-GUS and bovine liver β-GUS. Data are expressed as % radioactivity/million cells and are mean values of triplicate samples ± SD.* $P < 0.05$, paired bidirectional Student's *t* test.

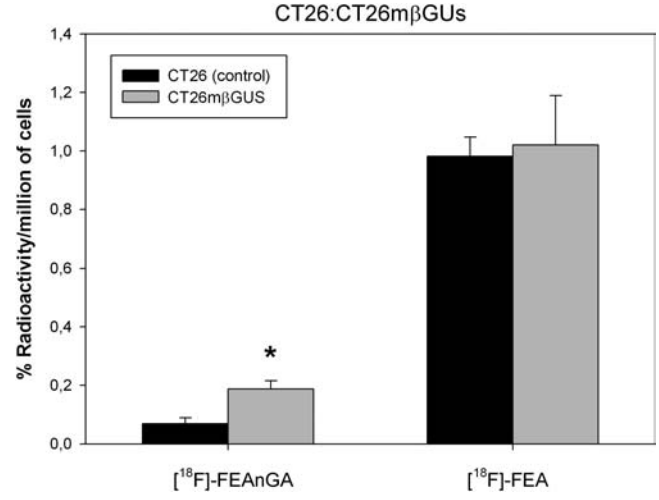

Figure 4. Cell-associated radioactivity of [^{18}F]-FEAnGA and [^{18}F]-FEA in control (CT26) and CT26mβGUS cells. Data are expressed as % radioactivity/million cells and are mean values of triplicate samples ± SD. *$P < 0.05$, paired bidirectional Student's *t* test.

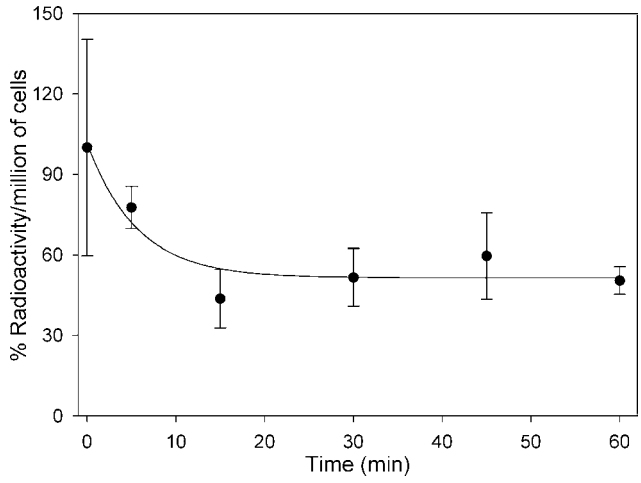

Figure 5. Cell-associated radioactivity of [^{18}F]-FEA in C6 cells. Data are expressed as % radioactivity/million cells and are mean values of triplicate samples ± SD. The efflux follows an exponential decay ($y = 51.47 + 50.06\ e^{(-0.18x)}$, $R^2 = 0.90$; $P = 0.03$).

substrate for bovine liver β-GUS (high K_{cat}/K_M) (Table 1). In a control experiment under identical conditions, but in the absence of β-GUS, no hydrolysis of FEAnGA was observed. These results indicate that FEAnGA is specifically hydrolyzed by β-GUS (*21*, *27*, *31*, *32*).

Radiolabeled [^{18}F]-FEAnGA was rapidly cleaved by both *Escherichia coli* β-GUS and bovine liver β-GUS. Radio-TLC analysis confirmed that the cleavage of [^{18}F]-FEAnGA by both enzymes is a two-step process (*33*). The consumption of [^{18}F]-FEAnGA leads to the formation of an intermediate which we hypothesized being the 4-(hydroxymethyl)-2-nitrophenol self-immolative spacer attached to [^{18}F]-FEA ([^{18}F]-FEAn). The intermediate ([^{18}F]-FEAn) is subsequently converted to [^{18}F]-FEA resulting in almost complete cleavage of the tracer into [^{18}F]-FEA within 10 min of incubation with *Escherichia coli* β-GUS (95% conversion) and 30 min of incubation with bovine liver β-GUS (86% conversion) (Figure 2).

C6 glioma cells were incubated with [^{18}F]-FEAnGA or [^{18}F]-FEA for 60 min at 37 °C, in the presence of either *E. coli* β-GUS (740 U) or bovine liver β-GUS (340 U) or in the absence of the enzyme (control). As depicted in Figure 3, the cell associated radioactivity was 6 times higher when C6 cells are incubated with [^{18}F]-FEA than when the C6 cells were incubated with [^{18}F]-FEAnGA in the absence of β-GUS. This increase in uptake is most likely due to the small size of [^{18}F]-FEA that enables the crossing of the cell membrane by passive diffusion. As expected, there is no significant difference in the cell-associated radioactivity of C6 cells incubated with [^{18}F]-FEA in the presence or absence of β-GUS. However, when C6 cells are incubated with [^{18}F]-FEAnGA the cell-associated radioactivity increases 4 and 1.5 times in the presence of *E. coli* β-GUS and bovine liver β-GUS, respectively. The higher tracer uptake in the presence of *E. coli* β-GUS compared to the uptake in the presence of bovine liver β-GUS could be explained by the fact that the catalytic rate of bovine liver β-GUS toward [^{18}F]-FEAnGA is 13 times lower than the catalytic rate of *E. coli* β-GUS.

Indeed, the radio-TLC of the medium samples shows that in the presence of *E. coli* β-GUS the conversion of [^{18}F]-FEAnGA into [^{18}F]-FEA is 99%, while with bovine liver β-GUS, there is only 37% of conversion into [^{18}F]-FEA (Supporting Information). These results suggest that the increase in cell-associated radioactivity is associated with the conversion of [^{18}F]-FEAnGA into [^{18}F]-FEA.

In addition to the uptake in C6 cells, [^{18}F]-FEAnGA and [^{18}F]-FEA were evaluated in genetically engineered CT26mβGUS murine colon adenocarcinoma cells that expressed membrane-anchored β-GUS on the outer cell membrane. Therefore, CT26 cells and CT26mβGUS were incubated with [^{18}F]-FEAnGA or [^{18}F]-FEA for 60 min at 37 °C. Incubation with [^{18}F]-FEA resulted in a 14-fold higher cell-associated radioactivity in

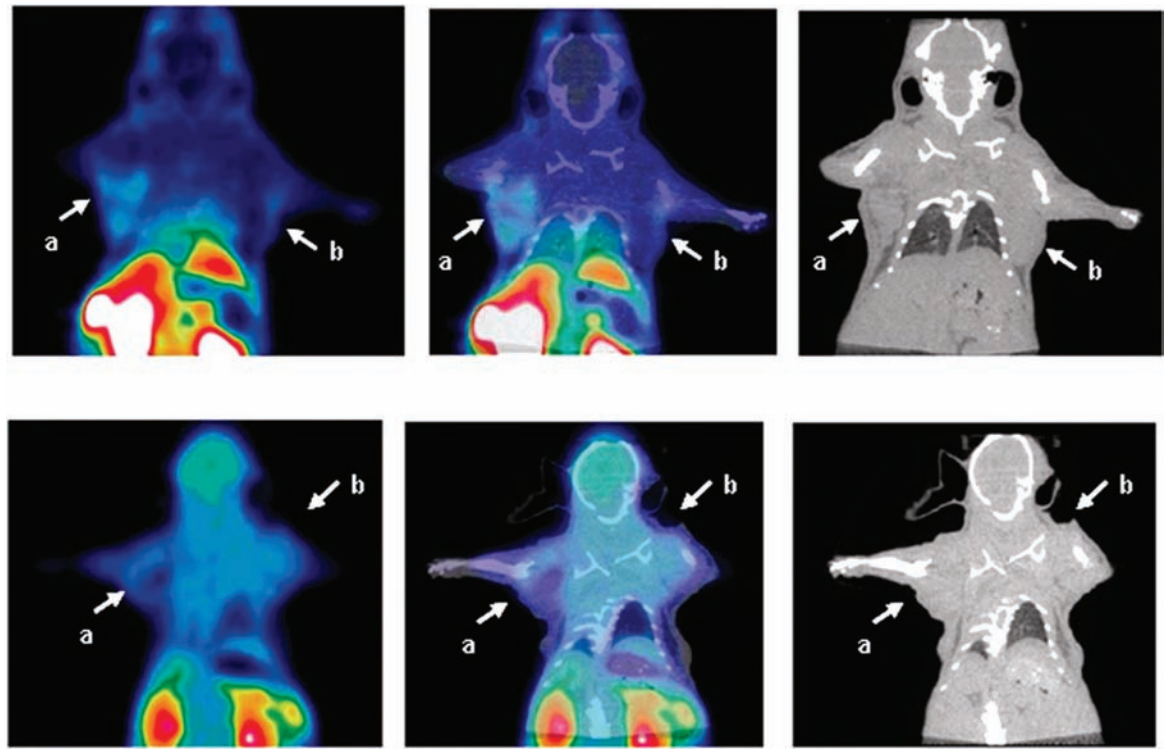

Figure 6. MicroPET image (left), microPET/CT fusion image (middle), and microCT image (right) of a mouse bearing a CT26mβGUS tumor (a) and a CT26 tumor (b) injected with either [^{18}F]-FEAnGA (upper row) or [^{18}F]-FEA (lower row).

control CT26 cells than incubation with [^{18}F]-FEAnGA. There is no significant difference between CT26 and CT26mβGUS associated radioactivity when incubated with [^{18}F]-FEA, while incubation with [^{18}F]-FEAnGA caused 3-fold higher uptake in β-glucuronidase expressing cells (CT26mβGUS) than control CT26 cells (Figure 4). Radio-TLC of the medium showed that [^{18}F]-FEAnGA was converted into [^{18}F]-FEA (20%) by the enzyme expressing cells only (Supporting Information).

For a good PET tracer, not only tracer uptake, but also its retention is important. To evaluate whether the tracer after cleavage of β-GUS is retained by C6 cells, the efflux of [^{18}F]-FEA was investigated as shown in Figure 5, the efflux analysis seems to indicate that 50% of the cell-associated radioactivity is bound loosely to the extracellular domain. Nevertheless, it was observed that, in the absence of radioactivity in the medium, 50% of the radioactivity still remains trapped in the cells.

To test the potential of [^{18}F]-FEAnGA as a PET tracer probe for detecting β-GUS expression in vivo, a preliminary PET study was performed in two mice bearing CT26 and CT26mβGUS tumors. Mice were injected with either [^{18}F]-FEAnGA or [^{18}F]-FEA, and a microPET scan was acquired for 60 min followed by a 15 min microCT scan.

When injected with [^{18}F]-FEAnGA, the CT26mβGUS tumor had more retention of radioactivity than the control tumor (CT26). The tracer uptake ratio between the CT26mβGUS tumor and the control CT26 tumor was 2 at 1 h post injection. This enhanced tumor uptake was ascribed to the selective production of [^{18}F]-FEA due to the cleavage of [^{18}F]-FEAnGA by β-GUS that is expressed extracellularly in the CT26mβGUS tumor only. The uncleaved [^{18}F]-FEAnGA was rapidly excreted out of the body through the kidneys leading to a very clear image with a good tumor-to-background ratio. On the other hand, the animal injected with [^{18}F]-FEA did not show specific accumulation in the CT26mβGUS tumor (Figure 6). It is possible to observe an absence of uptake in the center of the CT26mβGUS tumor due to the advanced necrosis of the tumor.

These preliminary imaging results suggest that extracellular β-GUS efficiently cleaves the tracer, resulting in the formation of [^{18}F]-FEA, which is retained in the tumor. The increased retention of radioactivity in the tumor that expresses β-glucuronidase extracellularly can be visualized in the image; additional animal experiments are in progress to further evaluate the properties of [^{18}F]-FEAnGA in vivo.

CONCLUSION

[^{18}F]-FEAnGA was efficiently labeled with [^{18}F]-fluoride in good yield. [$^{18/19}$F]-FEAnGA showed high in vitro stability in PBS and rat plasma. Kinetic studies indicate that [$^{18/19}$F]-FEAnGA is a good substrate for *E. coli* β-GUS and bovine liver β-GUS. Cleavage of the tracer by β-GUS caused an increase in cell-associated radioactivity in rodent tumor cells. Initial animal studies showed that [^{18}F]-FEAnGA is specially retained in CT26mβGUS tumors with high tumor uptake and good tumor-to-background ratio. Therefore, [^{18}F]-FEAnGA has proven to be a promising PET tracer for imaging of extracellular β-glucuronidase activity.

ACKNOWLEDGMENT

We gratefully thank Annie van Dam and Margot Jeronimus-Stratingh for performing all LRMS analysis, Katica Stojanov for her help in the C6 glioma cell studies, Dr. Steve Roffler for providing the CT26mβGUS cells, and Jurgen Sijbesma for the help in the in vivo study.

Supporting Information Available: ^{1}H NMR, ^{19}F NMR spectra, and the raw LRMS of compounds **2**, **3**, and **4**. Radio-TLC of the medium of C6 glioma cells and CT26/CT26mβGUS. This material is available free of charge via the Internet at http://pubs.acs.org.

Conjugation of Fluorescent Proteins with DNA Oligonucleotides

Vidmantas Lapiene, Florian Kukolka,* Kathrin Kiko, Andreas Arndt, and Christof M. Niemeyer*

Technische Universität Dortmund, Fakultät Chemie, Biologisch-Chemische Mikrostrukturtechnik, Otto-Hahn Str. 6, D-44227 Dortmund, Germany. Received October 28, 2009; Revised Manuscript Received March 1, 2010

This work describes the synthesis of covalent ssDNA conjugates of six fluorescent proteins, ECFP, EGFP, E^2GFP, mDsRed, Dronpa, and mCherry, which were cloned with an accessible C-terminal cystein residue to enable site-selective coupling using a heterobispecific cross-linker. The resulting conjugates revealed similar fluorescence emission intensity to the unconjugated proteins, and the functionality of the tethered oligonucleotide was proven by specific Watson−Crick base pairing to cDNA-modified gold nanoparticles. Fluorescence spectroscopy analysis indicated that the fluorescence of the FP is quenched by the gold particle, and the extent of quenching varied with the intrinsic spectroscopic properties of FP as well as with the configuration of surface attachment. Since this study demonstrates that biological fluorophores can be selectively incorporated into and optically coupled with nanoparticle-based devices, applications in DNA-based nanofabrication can be foreseen.

INTRODUCTION

The investigation of the fundamental principles of photosynthesis is of great current interest. In this context, the synthesis of artificial light harvesting devices from multiple chromophoric units and the study of energy transfer processes occurring in these systems aims to mimic natural photosynthesis and to develop materials and devices with complex spectroscopic properties. Recent approaches to assemble light harvesting complexes included the use of small molecule chromophors, such as porphyrin derivatives (*1*), polypyridine complexes of d^6 metal ions (*2*), perylene-based polyphenyl dendrimers (*3, 4*), or supramolecular assemblies of functional dyes (*5*). On the other hand, significant research is currently devoted to the exploitation of biomolecules for the assembly of functional devices. In this young field of science, the bioconjugation of short DNA oligonucleotides to various molecular compounds and materials has already been established as a means to fabricate nanoscaled functional devices (*6*). The approach is based on the extraordinary specific molecular recognition properties of short ssDNA oligonucleotides, which can be harnessed as structure-directing agents for the rational assembly of proteins, nanoparticles, and other components (*7*−*9*).

In view of synthetic energy transfer systems, the naturally occurring family of fluorescent proteins (FPs) is currently attracting increasing interest (*6*). Starting with the initial discovery of naturally occurring *Aequorea victoria* green fluorescent protein (GFP) (*10*), nowadays a large number of structural variants of GFP are available and they are routinely used as genetically encoded markers for cell biology and the study of biomolecular interactions by means of Förster resonance energy transfer (FRET) (*11*−*14*). Moreover, FPs are currently being exploited in materials research as chromophors for the fabrication of nanoscaled optically addressable devices. For instance, FPs have been used to decorate semiconductor nanoparticles, often termed "quantum dots" (QD), to study FRET mechanisms occurring in such light-addressable nanodevices (*15*−*19*). Also, it has recently been demonstrated that the color of natural fluorescent proteins can be controlled by photonic crystals (*20*).

In these examples, the decoration of the inorganic materials with FPs was achieved by adsorption and electrostatic interactions (*21*), thus allowing only limited control of the assembly process. To extend controlability of supramolecular FP assembly and enable rational design of FP-based FRET systems, we have previously established the synthesis of a covalent ssDNA conjugate, using the enhanced yellow fluorescent protein (EYFP) (*22*). The use of this conjugate indeed enabled the DNA-based assembly of FRET systems, in which the spatial proximity of the chromophors can be controlled by the helicity of the dsDNA carrier backbone (*23, 24*). Moreover, the ssDNA−EYFP conjugate was used to explore FRET processes in three-chromophore QD assemblages (*17*) and to investigate particle−protein interactions, taking advantage of EYFP fluorescence emission quenching by gold nanoparticles (*25*). Very recently, a ssDNA conjugate of the photoswitchable FP Dronpa, one of the conjugates developed in the course of the work reported here, was used in a single-molecule FRET study (*26*).

In this full paper, we describe the synthesis of six novel DNA oligonucleotide−FP conjugates, based on mutant variants of the native FPs (Figure 1). In particular, the fluorescent proteins ECFP, a cyan mutant of jellyfish *Aequorea victoria* GFP (*27*), EGFP (*28*), E^2GFP (*29*), mDsRed, a monomeric variant of tetrameric DsRed (*30, 31*), available from Clontech, photoswitchable Dronpa (*32*), and mCherry (*33*) were cloned with an N-terminal hexahistidine sequence and a C-terminal cystein residue. The engineered cystein residue was positioned at the C-terminal region of the FPs because known crystal structures suggest that this region is easily accessible for chemical conjugation. Indeed, all six proteins could be derivatized with maleimide-activated DNA oligomers to yield the desired ssDNA−FP conjugates. These hybrid molecules were characterized and then used for the investigation of fluorescence emission quenching as a result of their specific hybridization with ssDNA-modified gold nanoparticles (DNA-AuNP), bearing the complementary oligonucleotides. Determination of hybridization kinetics and quenching efficiency revealed slight but distinct differences between the six DNA−FP conjugates, as a consequence of the optical and steric properties of the individual FPs.

EXPERIMENTAL PROCEDURES

Molecular cloning and overexpression of the recombinant FPs was carried out similar to previously described methods (*22, 34*).

[a] Calculated with respect to the amount of ssDNA oligonucleotide.

Synthesis of ssDNA−FP conjugates was achieved from 5′-alkylamino-modified DNA using the heterobispecific cross-linker sulfosuccinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (sSMCC) (*22*). Preparation of 23 nm diameter ssDNA-modified gold nanoparticles and hybridization with ssDNA−FP conjugates was carried out as described before (*25*). Full details on cloning and expression of FPs, experimental protocols for conjugate synthesis, and binding studies with DNA-AuNP are available in the Supporting Information.

RESULTS AND DISCUSSION

To facilitate site-selective conjugation with DNA oligonucleotides, we followed the bioconjugation approach previously explored for the coupling of the fluorescent protein EYFP with alkylamino-modified DNA (*22*). This method is based on the cloning and heterologous expression of a mutant FP, containing an N-terminal hexahistidine sequence and a C-terminal cystein residue. While the His_6-tag allows for convenient purification of the recombinant FP, the accessible C-terminal Cys residue enabled conjugation with thiol-reactive DNA oligonucleotides. Genetic engineering of the cystein residue into the FP genes was achieved by PCR techniques. Detailed information on the cloning of the expression vectors is given in the Supporting Information. Transformation of *E. coli* BL21 and overexpression of the recombinant FPs was followed by Ni-NTA affinity chromatography. Expression yields obtained ranged 70−260 μg/mL cell culture (Table 1). Gel electrophoretic analysis of the recombinant FPs revealed that the proteins were sufficiently pure (>85%) to enable chemical coupling with DNA oligomers.

Site-selective chemical coupling of the mutant FPs with DNA oligomers was achieved by using the heterobispecific cross-linker sulfosuccinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (sSMCC), which contains a thiol-reactive maleimide functionality in addition to an amino-reactive NHS group (Figure 1). To this end, commercially available alkylamino-modified oligonucleotide cA24 was reacted with an excess of sSMCC to install a maleimide group at the 5′-end of the oligomer. Subsequent to purification by gel filtration chromatography, the oligomer was allowed to react with the recombinant FP, and crude reaction products were purified by ultrafiltration and anion-exchange chromatography (Figure S1, in the Supporting Information). Isolated yields, determined by UV/vis spectroscopy after alkaline denaturation (*35*−*37*), ranging 15−36% (Table 1), thus indicating that the synthetic protocol allows ready production of the desired DNA−FP conjugates. Gel electrophoretic analysis of the conjugates (Figure 2) showed that the products essentially contained a single molecular species, with only slight impurities of the unconjugated protein. Denaturing SDS-gel electrophoresis indicated the expected increase in molecular weight of ∼8 kDa due to the attachement of one oligonucleotide per FP molecule (Figure 2A). This result was also obtained for Dronpa, which contains an additional Cys residue at position 113. We assume that the exclusive generation of the monoconjugated cA24-Dronpa is due to our optimized

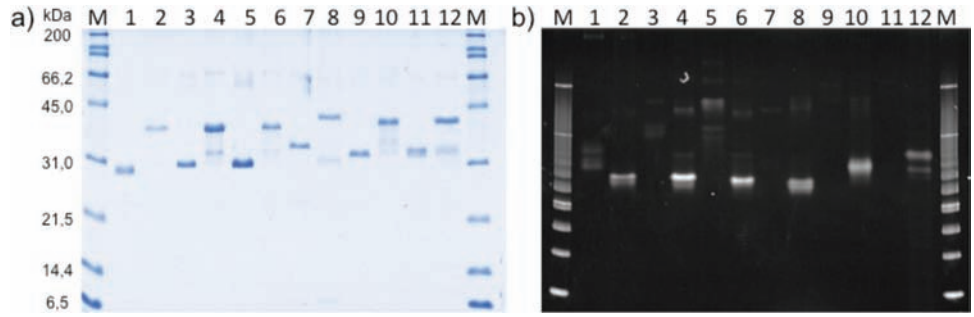

Figure 2. Gel electrophoretic analysis of recombinant FPs and their respective ssDNA conjugates. (A) 14% denaturing SDS polyacrylamide gel, stained with Coomassie: lane M, SDS Broadrange Marker (Bio-Rad); lane 1, EGFP; 2, cA24-EGFP; 3, E^2GFP; 4, cA24-E^2GFP; 5, ECFP; 6, cA24-ECFP; 7, mDsRed; 8, cA24-mDsRed; 9, Dronpa; 10, cA24-Dronpa; 11, mCherry; 12, cA24-mCherry. (B) 14% nondenaturing polyacrylamide gel after DNA staining with SybrGold: lane M, O'RangeRuler 50bp DNA ladder (Fermentas); lanes 1−12, same samples as in (A). Note that, although SybrGold dye is usually selective for nucleic acid staining, some FPs are visible as weak bands (e.g., lanes 1, 5, 7). This phenomenon has previously been observed (*22*), and it results from the native FP fluorescence at the filter settings used for SybrGold imaging (λ_{Exc} = 365 nm, λ_{Em} = 520 nm, see also Figure S7 in the Supporting Information).

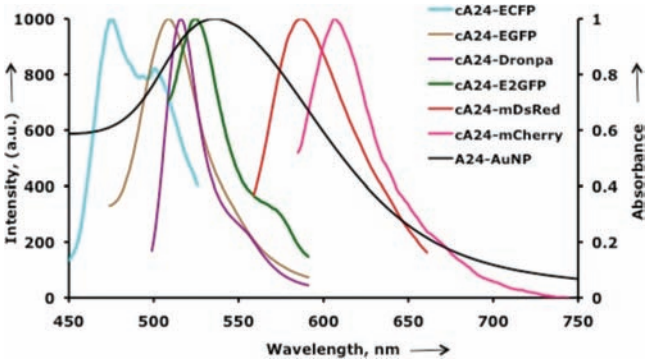

Figure 3. Fluorescence emission spectra of the DNA−FP conjugates cA24-ECFP (cyan), cA24-EGFP (brown), cA24-Dronpa (purple), cA24-E^2GFP green), cA24-mDsRed (red), and cA24-mCherry (pink). For comparison, the absorbance spectrum of AuNP is shown as the black curve.

reaction conditions (i.e., excess of protein and short reaction time) in addition to careful purification by gradient anion-exchange chromatography. Analysis under nondenaturing conditions (Figure 2B) showed that the electrophoretic mobility of the DNA−FP conjugates was increased, as compared to the individual native FPs, due to the appended negatively charged oligonucleotide.

The DNA−FP conjugates were analyzed by fluorescence spectroscopy (Figure 3), their fluorescence emission and UV/vis absorbance spectra were compared to those of the native FPs (Figures S2, S3, in the Supporting Information), and quantum yields were determined (Table S3, in the Supporting Information). The spectroscopic properties of all DNA−FP conjugates were basically identical to those of the unconjugated FPs, thus confirming that (i) all FPs under investigation here were fully maturated and (ii) conjugation with ssDNA did not significantly affected the chromophore of the native FP.

With the desired DNA−FP conjugates in hand, we investigated their nucleic acid hybridization with gold nanoparticles (AuNPs), containing the complementary ssDNA oligomer A24. It should be noted that the generation of protein-functionalized gold nanoparticles is of great current interest, due to their applications in biosensing and diagnostics (*8*, *9*). While protein−AuNPs are long known as versatile probes in immunohistochemistry and related techniques (*7*), mixed hybrid nanoparticles containing both nucleic acid fragments and proteins have only recently been established (*25*, *38*−*42*), because they offer additional functionality due to the presence of both classes of biomolecular recognition elements. We had previously demonstrated that such hybrid particles can be readily prepared by specific DNA hybridization using DNA−AuNPs and appropriate ssDNA−protein conjugates bearing the complementary sequence (*25*, *38*, *41*, *43*), and here we applied this method to investigate whether the various ssDNA−FP conjugates are functional with respect to both the FP fluorescence and their specific Watson−Crick hybridization capability.

Similar to that reported for small-molecule organic fluorescent dyes (*44*−*50*), the FP fluorescence should be quenched upon binding to the AuNP, and it was interesting to see whether and how quenching would be influenced by the optical properties of the various FPs under investigation here. To this end, binding of the various covalent DNA−FP conjugates was investigated, using three different kinds of DNA-coated 23 nm AuNPs (Figure 4a). 5′A24-AuNP contained the complementary oligomer A24 bound via its 5′-end, while 3′A24-AuNP contained the A24 sequence attached via its 3′-end. Due to the directionality of the DNA double helical spacer, the distance between the gold surface and the FP is greater in the case of 5′A24-AuNP than for 3′A24-AuNP. Moreover, the noncomplementary oligonucleotide AuNP-dT124b was used as control. Gel electrophoretic analysis was used to initially confirm specificity of binding (Figure S4, in the Supporting Information). In the case of DNA−AuNPs bearing complementary oligomers, a decrease in electrophoretic mobility of the nanoparticle bands indicated formation of the respective FP−AuNPs, while incubation with dT124b-AuNP only revealed very small shifts of the particle bands (lanes 11−15, in Supporting Information Figure S4; see also Figure S6). This confirmed that the binding of all ssDNA−FP conjugates to the DNA−AuNPs primarily occurred due to specific Watson−Crick base-pairing of the oligonucleotides.

We then investigated whether and to what extent the binding of the various ssDNA−FP conjugates to the DNA−AuNP leads to the quenching of FP fluorescence. In an initial set of experiments, solutions of the DNA−FP conjugate (1.2 pmol in TETBS buffer, pH 7.3, containing 150 mM NaCl) were mixed with solutions of the various DNA−AuNP (36 fmol in TETBS buffer containing 150 mM NaCl, corresponding to 32 mol equiv of DNA−FP to DNA−AuNP) and incubated for 6 h at room temperature. While the entire data is represented in Supporting Information Figure S4, it is examplified here for cA24-EGFP and cA24-mCherry (Figure 4b) that end-point determination of the fluorescence showed marked differences between the samples. The fluorescence of the pure ssDNA−FP conjugates (blue curves) is significantly decreased upon addition of noncomplementary dT124b-AuNP, and this effect occurrs due to strong absorption and scattering caused by the AuNPs. The extent of decrease differed clearly for the various FPs under investigation, which is a logical consequence of the different wavelenghts used for FP excitation. The absorption spectrum of AuNP (Figure 3) indicates that the particle's broad plasmon

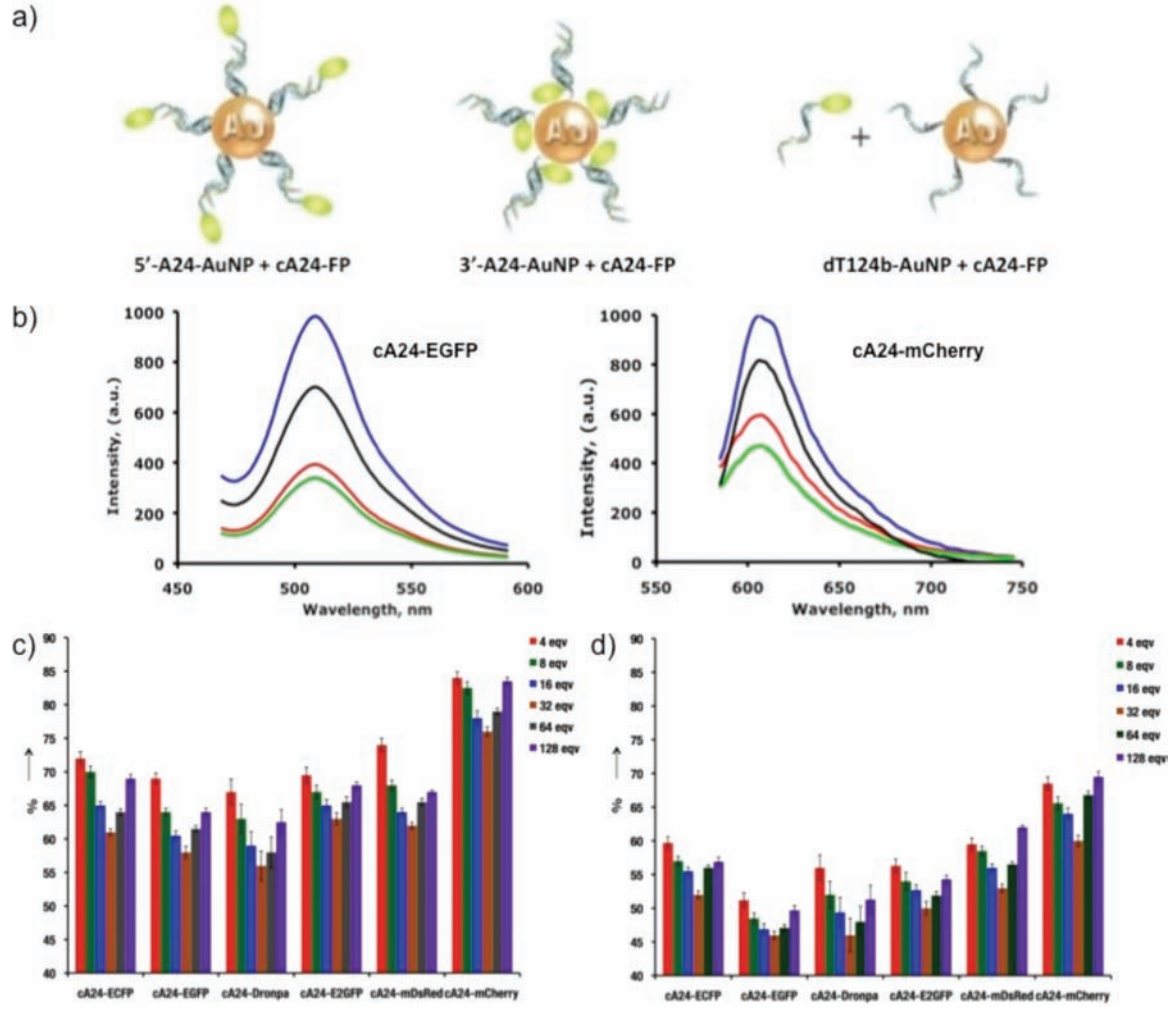

Figure 4. AuNP-induced quenching of FP fluoresence. (A) Schematic representations of DNA-directed binding of ssDNA−FP conjugates to DNA−AuNPs and the DNA−AuNPs used for immobilization of cA24−FP conjugates to DNA−AuNPs and the DNA−AuNPs used for immobilization of cA24−FP conjugates. (B) End point determination of the fluorescence measured for cA24-EGFP and cA24-mCherry before (blue curves) and after incubation with 5′A24-AuNP (red), 3′A24-AuNP (green), or dT124b-AuNP (black). (C,D) Variation of coupling ratio FP/AuNP; fluorescence values of the ssDNA−FP conjugates after binding to 5′A24-AuNP (C) or 3′A24-AuNP (D) were normalized with respect to the fluorescence of analogous samples after incubation with noncomplementary dT124b-AuNP.

absorption has its maximum at about 540 nm. This wavelength almost coincides with the excitation/emission wavelenghts of mDsRed (558/583 nm). In contrast, plasmon absorption is significantly less effective at the excitation/emission wavelenghts of ECFP (434/476 nm), EGFP (488/508 nm), or mCherry (587/615 nm). Consequently, the amount of scattering induced by addition of dT124b-AuNP, and thus immediate decrease in FP fluorescence, is much higher for mDsRed than for ECFP, EGFP, or mCherry.

Normalized values of ssDNA−FP conjugate's fluorescence, measured in the presence of dT124b-AuNP, 5′A24-AuNP, or 3′A24-AuNP, are summarized in Table 2. To account for the aforementioned wavelength-dependent differences in scattering, fluorescence of the ssDNA−FP conjugate in the presence 5′A24-AuNP or 3′A24-AuNP was normalized with respect to the value measured in the presence of noncomplementary dT124b-AuNP, set as 100%. It is clearly evident from the data of Table 2 as well as from the original data (Figure 4b and Supporting Information Figure S5) that addition of the complementary AuNPs led to a significantly higher quenching of the fluorescence of the FP, and this effect was markedly different for particles 5′A24-AuNP and 3′A24-AuNP (red and green curves, in Figure 4b). This result is in aggreement with the expectation that Watson−Crick hybridization with 5′A24-AuNP should lead to the formation of a 24 base-pair dsDNA spacer of approximately 8.5 nm in length between the protein and the gold surface, while the hybridization with 3′A24-AuNP should localize the protein in closer proximity to the particle's surface.

Table 2. Numerical Values of ssDNA−FP Conjugate Fluorescence, Measured in the Presence of Gold Nanoparticles[a]

entry	conjugate	dT124b-AuNP[b]	5′A24-AuNP[c]	3′A24-AuNP[c]
1	cA24-ECFP	70	61	52
2	cA24-EGFP	72	58	46
3	cA24-Dronpa	61	56	45
4	cA24-E^{2}GFP	55	63	50
5	cA24-mDsRed	42	62	53
6	cA24-mCherry	82	76	60

[a] End point determination after 6 h of incubation with 32 mol equiv of AuNP. [b] Normalized values [%] with respect to the fluorescence of pure cA24-FP in the absence of AuNP (100%). [c] Normalized values [%] with respect to the fluorescence of cA24-FP in the presence of noncomplementary dT124b-AuNP set as 100%.

The difference in quenching efficiency observed for the two different configurations, however, is relatively small. This suggests that binding and quenching aspects are involved. The fundamental mechanisms of the quenching of organic fluorophores by metal nanoparticles are still under investigation (*44*−*50*), and one important factor concerns the knowledge of real distances between the chromophore and the metal surface. The AuNP-bound DNA should be able to adopt a number of different conformations, such as being fully stretched and

pointing perpendicular from the surface, adopting a random coil shape, or possibly being tilted and interacting with the AuNP surface (*51*). Hence, the aforementioned nominal difference in distance of about 8.5 nm is most likely affected by the presence of various conformational states. Moreover, slight changes in protein loading should also induce different distances and/or different dynamics and, thus, might affect the quenching efficiency.

To further analyze the system, we also studied the influence of surface coverage of AuNP with ssDNA−FP conjugate on the quenching efficiency. To this end, particles 5′A24-AuNP (Figure 4c) and 3′A24-AuNP (Figure 4d) were incubated with various molar equivalents of ssDNA−FP conjugate, and fluorescence emission was determined after 15 h. The fluorescence emission values measured were normalized to that of similar samples incubated with noncomplementary dT124b-AuNP. It is evident that the nature of FP did not markedly influence the stoichiometry of binding. In all cases, the fluorescence decreased for the binding of up to about 32 mol equiv of ssDNA−FP conjugate, and a further increase led to an increase in fluorescence, due to increasing amounts of free conjugate in the solution. It should be noted that the about 32 mol equiv of ssDNA−FP conjugate, which hybridizes to the 25 nm AuNP, correlates with an approximately 18% hybridization efficiency of the in total about 175 oligonucleotide molecules bound at the AuNP (see Supporting Information). This result is in good agreement with earlier studies concerning the hybridization efficiency of DNA−AuNPs (*52*,*53*).

As expected, the extent of quenching differed significantly with the configuration of binding (Figure 4c vs d), and interestingly, the quenching efficiency was different for the various FPs studied (see also Table 2). In particular, strongest quenching was observed for binding of EGFP- and Dronpa-conjugate to either 5′A24-AuNP or 3′A24-AuNP, and this maximum was slightly more pronounced in the case of 3′A24-AuNP. The relative quenching efficiency observed for the six ssDNA−FP conjugates is in good aggreement with what one would expect from the overlap of FP fluorescence emission and AuNP plasmon absorption (Figure 3).

It was also analyzed whether the two different configurations, realized in the binding to either 5′A24-AuNP or 3′A24-AuNP, affect the kinetics of protein immobilization (Supporting Information Figure S5). Time-dependent fluorescence measurements showed that the ssDNA−FP conjugates rapidly hybridize with 5′A24-AuNP, and the reaction was completed within less than 4 h. The curves also suggest that the binding of ssDNA-FP to 3′A24-AuNP was slightly slower than binding to 5′A24-AuNP. This observation is in agreement with the proposed configuration, since binding to 3′A24-AuNP requires the bulky FP to penetrate, at least partially, the dense layer of DNA oligomers attached to the particle's surface.

In conclusion, we have shown that fluorescent proteins can be effectively conjugated with DNA oligonucleotides, using a combination of genetic engineering and heterobispecific cross-linking chemistry. The resulting ssDNA−FP conjugates revealed similar spectroscopic properties than the unconjugated FPs. Moreover, the functionality of the tethered oligonucleotide was proven by specific Watson−Crick base pairing to cDNA-modified gold nanoparticles. Fluorescence spectroscopy analysis indicated that the FP fluorescence is quenched by the gold particle and the extent of quenching varied with the intrinsic spectroscopic properties of FP as well as with the configuration of surface attachement. Thus, this study demonstrates that these biological fluorophores can be incorporated into and optically coupled with nanoparticle-based devices using DNA-based assembly schemes. Given the enormous power of structural DNA nanotechnology and nanofabrication, we therefore anticipate that further elaboration on covalent DNA−FP conjugates might open up ways toward nanostructured materials with programmable functionalities for a broad range of applications in nanobiotechnology.

ACKNOWLEDGMENT

This work was supported in part by Deutsche Forschungsgemeinschaft (DFG, grants Ni-399/6-1/6-2) Max-Planck Research School in Chemical Biology (IMPRS-CB), Dortmund, and the project SMD in the course of FP7-NMP-2008-SMALL-2, founded by European Comission. We thank Martina Reibner for preparation of DNA-conjugated gold nanoparticles. We are also grateful to the reviewer for very important comments on the manuscript.

Supporting Information Available: Full details on experimental protocols for molecular cloning of FPs, conjugate and nanoparticle synthesis, hybridization assays, characterization of ssDNA−FP conjugates, and spectroscopic analysis of their binding to DNA−AuNP. This material is available free of charge via the Internet at http://pubs.acs.org.

$^{99m}Tc(N)$-DBODC5 is a cationic mixed compound under clinical investigation as potential myocardial imaging agent. In spite of this, analogously to the other cationic ^{99m}Tc-agents, presents a *relatively* low first-pass extraction. Thus, modification of $^{99m}Tc(N)$-DBODC(5) direct to increase its first-pass extraction keeping unaltered the favorable imaging properties would be desirable. This work describes the synthesis and biological evaluation of a series of novel cationic ^{99m}Tc-nitrido complexes, of general formula $[^{99m}TcN(DTC\text{-}Ln)(PNP)]^+$ (DTC-Ln= alicyclic dithiocarbamates; PNP = diphosphinoamine), as potential radiotracers for myocardial perfusion imaging. The synthesis of cationic ^{99m}Tc-(N)-complexes were accomplished in two steps. Biodistribution studies were performed in rats and compared with the distribution profiles of $^{99m}Tc(N)$-DBODC5 and ^{99m}Tc-Sestamibi. The metabolisms of the most promising compounds were evaluated by HPLC methods. Biological studies revealed that most of the complexes have a high initial and persistent heart uptake with rapid clearance from nontarget tissues. Among tested compounds, **2** and **12** showed improved heart uptake with respect to the gold standard ^{99m}Tc-complexes with favorable heart-to-liver and slightly lower heart-to-lung ratios. Chromatographic profiles of $^{99m}Tc(N)$-radioactivity extracted from tissues and fluids were coincident with the native compound evidencing remarkable *in vivo* stability of these agents. This study shows that the incorporation of alicyclic dithiocarbamate in the $[^{99m}Tc(N)(PNP)]^+$ building block yields to a significant increase of the heart uptake at early injection point suggesting that the first-pass extraction fraction of these novel complexes may be increased with respect to the other cationic ^{99m}Tc-agents keeping almost unaltered the favorable target/nontarget ratios.

INTRODUCTION

In spite of the great strides in developing myocardial perfusion scintigraphy, there is a general agreement about the fact that an improved myocardial agent having imaging characteristics much closer to those of an ideal perfusion indicator still needs to be found (*1*). An ideal perfusion imaging agent should possess a few important properties, such as a high first-pass extraction, a rapid elimination from critical nontarget tissues such as lungs and liver, and a rapid blood clearance to allow a clear visualization of the cardiac region. Moreover, the myocardial uptake should be linear over the whole range of blood flow passing through the organ (*2*). Despite their widespread clinical application, ^{99m}Tc-Sestamibi (Cardiolite) and ^{99m}Tc-Tetrofosmin (Myoview) do not meet all these requirements, in part due to their high liver uptake which makes it very difficult to interpret heart activity in the inferior and left ventricular wall (*3*−*5*).

Over the past few years, novel examples of myocardial tracers, characterized by the presence of a terminal technetium–nitrogen multiple bond, have been reported (*6, 7*). One of these included a new class of monocationic compounds of the type $[^{99m}Tc(N)(DTC)(PNP)]^+$, where DTC is an aliphatic dithiocarbamate ligand and PNP a diphosphinoamine. Among the tested compounds, $[^{99m}Tc(N)(DBODC)(PNP5)]^+$ and $[^{99m}Tc(N)(DBODC)(PNP3)]^+$ [DBODC = bis(*N*-ethoxyethyl)-dithiocarbamato; PNP5 = bis(dimethoxypropylphosphinoethyl)-ethoxyethylamine]; PNP3 = bis(dimethoxypropylphosphinoethyl)-methoxyethylamine)] complexes, namely, ^{99m}Tc-(N)-DBODC5 and ^{99m}Tc-(N)-DBODC3, respectively, showed the most interesting biodistribution properties (*8, 9*). In particular, animal studies of ^{99m}Tc-(N)-DBODC5 revealed singular biodistribution profiles characterized by a high and persistent myocardial accumulation, with an uptake mechanism and a kinetic behavior identical to those of the commercially available myocardial imaging agents (*10*). The most interesting properties lie in its rapid lungs and liver clearance and consequently in its favorable heart/lungs and heart/liver ratios, thus exhibiting unprecedented imaging characteristics with respect to the commercially available myocardial imaging agents, ^{99m}Tc-Sestamibi and ^{99m}Tc-Tetrofosmin (*8*−*12*).

Similar results were found in humans. Preliminary phase I study data in healthy volunteers showed that both rest and peak stress administration of ^{99m}Tc-(N)-DBODC5 can yield high-quality myocardial images starting from 5 min p.i., suggesting a promising diagnostic value of this new tracer (*13*).

As for other cationic ^{99m}Tc-complexes, the favorable properties of ^{99m}Tc-(N)-DBODC5 are somehow negatively counterbalanced by its *relatively* low first-pass extraction (approximately 60%) and minimal redistribution (*12, 14*−*16*), if compared to those of neutral ^{99m}Tc-complexes, such as ^{99m}Tc-Teboroxime

(88−91%) and ^{99m}Tc(N)NOET (NOET = *N*-ethoxy,*N*-ethyl dithiocarbamate) (∼80−90%) (*17*−*19*). For the two latter compounds, the high initial heart extraction [3.44 ± 0.32% ID/organ at 1 min p.i. for ^{99m}Tc-Teboroxime and 4.28 ± 0.18% ID/organ at 5 min p.i. for ^{99m}Tc(N)NOET] and the redistribution properties seem to be correlated to the higher lipophilic character which allows, through a passive diffusion mechanism, a rapid diffusion/penetration of the complexes across the cell membrane and to the higher circulating blood activity with respect to those exhibited by monocationic compounds (*6*, *20*, *21*). Tracers with higher first-pass extraction will accurately track blood flows over a wide range than tracers with lower first-pass extraction, and thus, they may potentially be more sensitive for the quantitative evaluation of milder flow-limiting coronary stenosis under stress conditions; in addition, a nonlinear behavior could be preferred for a qualitative assessment.

On the basis of these considerations, a rational modification of the ^{99m}Tc-(N)-DBODC5 compound directly to produce new ^{99m}Tc-agents with high initial heart uptake, which is correlated with the first-pass extraction, but maintaining the favorable pharmacokinetic properties of ^{99m}Tc-(N)-DBODC5 can be considered.

Over the last years, different ^{99m}Tc-mixed compounds containing alkoxy-alkyl amino-diphosphine ligands such as [^{99m}Tc(N)-(L)(PNP)]$^{+}$ (L = linear-chain- or crown ether-containing dithiocarbamate or thiomaltol derivates), [^{99m}Tc(NNPh)(L)-(PNP)]$^{+}$ (DTC = crown ether-containing dithiocarbamate), and [^{99m}Tc(CO)$_3$(PNP)]$^{+}$ have been reported as potential myocardial imaging agents (*8*, *22*−*28*). The evidence that all of these compounds maintain similar favorable biodistribution patterns, characterized by a rapid elimination of the activity from nontarget tissues, regardless of the presence of the terminal technetium−nitrogen multiple bond and regardless of the nature of the dithiocarbamate, maltol, or the CO coligand suggests that this behavior may be mainly correlated to the [Tc(PNP)]$^{n+}$ scaffold and in particular to the chemical structure of the PNP ligand as well as to the presence of alkoxy-alkyl pendant groups.

Recently, we reported a new class of neutral nitrido mixed ligand complexes of the type [^{99m}Tc(N)(DTC-Ln)(PS)] where (PS) is a branched phosphinoethanethiolate ligand and (DTC-Ln) an alicyclic dithiocarbamate. Biodistribution studies carried out in rats of some of these lipophilic compounds exhibited remarkably high, but transient, myocardial uptake (*29*). Comparison of the myocardial uptakes at early injection times (2 min, which may correspond to a certain extent to a first-pass extraction) evidenced that [^{99m}Tc(N)(DTC-Ln)(PS)] complexes with dithiocarbamates containing pyrrolidine (4.78 ± 0.76% ID/g), piperidine (3.79 ± 1.99% ID/g), and *N*-ethyl-piperazine (4.81 ± 0.73% ID/g) substituents showed higher initial heart activity than those exhibited by compounds incorporating dithiocarbamate with linear chains such as diethyldithiocarbamate (2.48 ± 0.35% ID/g) or DBODC (2.93 ± 0.72% ID/g).

The prominent back diffusion of these [^{99m}Tc(N)(DTC-Ln)(PS)] compounds is likely related to their neutral and lipophilic properties and to the fact that they are not joined intracellularly owing to the lack of an appropriate trapping mechanism that may be connected to the absence of the cationic charge. These observations prompted us to combine the biological properties of the well studied monocationic [^{99m}Tc(N)(DTC)(P-NP)]$^{+}$ with those of the neutral [^{99m}Tc(N)(DTC-Ln)(PS)] complexes by introducing a dithiocarbamate containing pyrrolidine, piperidine, or *N*-ethylpiperazine into the [^{99m}Tc(N)-(PNP)]$^{2+}$ building block.

In this preliminary study, our goal was to verify if the novelty to include alicyclic dithiocarbamates into a cationic species of the type [^{99m}Tc(N)(DTC)(PNP)]$^{+}$ may favor high initial heart uptake, as observed for neutral [^{99m}Tc(N)(DTC-Ln)(PS)] compounds, along with a prolonged retention. Moreover, considering that in these asymmetrical compounds variation of both DTC and PNP showed significant impact on their distribution properties (*8*, *23*) additional newly synthesized diphosphine ligands were evaluated.

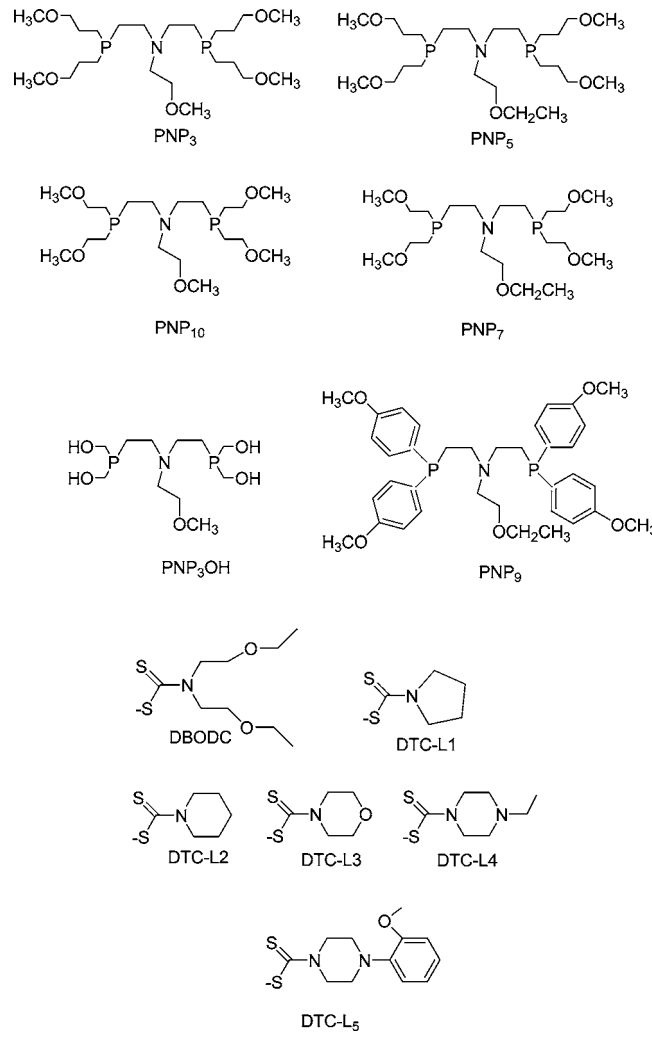

Figure 1. Diphosphinoamine and dithiocarbamate used in our experiments.

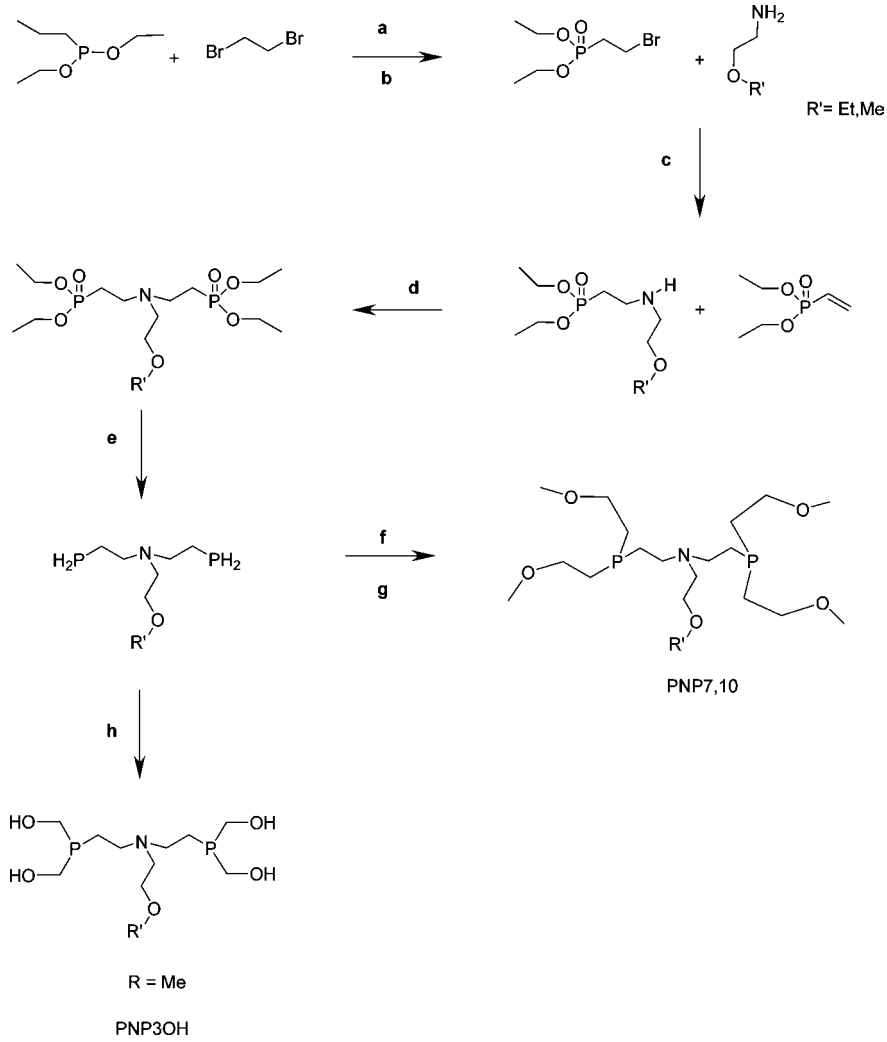


In this article, we describe the synthesis and chromatographic characterization of a series of new monocationic mixed compounds of the general formula [^{99m}Tc(N)(DTC-Ln)(PNP)]$^{+}$. Diphosphinoamine (PNP) and dithiocarbamate (DTC-Ln) ligands utilized in this investigation are illustrated in Figure 1.

The *in vitro* stability and transchelation toward an excess of cysteine of all synthesized compounds were evaluated. Comparison of the biodistribution data of these new compounds with the biological profiles of the ^{99m}Tc-(N)-DBODC5,3 complexes and of the commercially available ^{99m}Tc-Sestamibi is presented. In addition the *in vitro* and *in vivo* stability of the most promising compounds of the new series was assessed.

EXPERIMENTAL PROCEDURES

General. All chemicals and reagents were purchased from Aldrich Chemicals (Milano, Italy). All solvents were of reagent grade and were used without further purification. PNP3 and PNP5 were purchased from Argus Chemicals (Prato, Italy). Diphosphinoamine PNP7 (bis(dimethoxyethylphosphinoethyl)-ethoxyethylamine), PNP9 (bis(*p*-methoxyphenylphosphinoethyl)-methoxyethylamine), PNP10 (bis(dimethoxyethylphosphinoethyl)-methoxyethylamine), and PNP3OH (bis(2-

Scheme 1[a]

[a] Reagents and conditions: (a) Δ, 2 h; (b) distil. 1 mm Hg, 75 °C; (c) MeCN, K_2CO_3, 65 °C, 3 h; (d) $LiClO_4$, 75 °C, 7 h; (e) $LiAlH_4$, Et_2O_{dry}, 0 °C; (f) *n*-BuLi, THF_{dry}, −78 °C, N_2; g) Cl-$CH_2CH_2OCH_3$, 0 °C, N_2; (h) EtOH, CH_2O.

dihydroxymethylene)phosphinoethyl)-methoxyethylamine) were synthesized according to reported procedures (*30*, *31*). The general way of synthesis of the ligands is exemplified in Scheme 1. PNP3OH was utilized as the phosphonium salt PNP3OH × HCl and converted *in situ* into the corresponding diphosphinoamine.

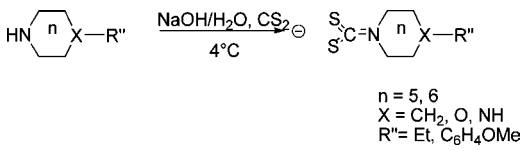
To avoid oxidation, all of the solvents used in reactions with the alkyl diphosphinoamine were previously degassed. DBODC, as sodium salt, was acquired from Alchemy (Bologna, Italy). DTC-L1 (pyrrolidinedithiocarbamate) as ammonium salt was purchased from Merck (Milano, Italy). Other DTC-Ln were prepared as detailed below. ^{99m}Tc as Na[$^{99m}TcO_4$] was eluted from a Drytec ^{99} Mo/^{99m}Tc generator provided by GE Healthcare (Milano, Italy).

For comparison studies, both ^{99m}Tc-(N)-DBODC5,3 complexes were synthesized according to the literature methods (*7*, *8*), whereas ^{99m}Tc-Sestamibi (Bristol-Myers Squibb) was prepared through reconstitution of the commercially available kits.

Analysis. Elemental analyses (C, H, N, and S) were performed on a Carlo Erba 1106 elemental analyzer. ^{1}H and ^{13}C NMR spectra were collected on a Bruker 300 instrument, using $SiMe_4$ as internal reference (^{1}H and ^{13}C).

Thin-layer chromatography (TLC) and high performance liquid chromatography (HPLC) analyses were used to evaluate the radiochemical purity (RCP) and the stability of the compounds. TLC analysis was performed on C18 F_{254S} plates (Merck, Milano, Italy) using a mixture of Saline/MeOH/THF/$HAc_{(g)}$ (2/8/1/1) as mobile phase or alternatively on SiO_2 F_{254} plates (Merck, Milano, Italy) using a mixture of EtOH/$CHCl_3$/Tol/NH_4Ac 0.5 M (5/3/3/1). The activity on the plates was detected and measured using a Cyclone Instrument equipped with a phosphorus imaging screen and OptiQuant image analysis software (Packard, Meridian, CT).

HPLC was performed on a Beckman System Gold instrument equipped with a programmable solvent Model 126, a sample injection valve 210A, a scanning detector Module 166, and a radioisotope detector Model B-FC-3200 Bioscan. HPLC analysis was carried out using a reversed-phase Beckman ODS precolumn (5 μm, 4.6 × 45 mm), and a reversed-phase Beckman ODS column (5 μm, 4.6 × 250 mm). log k'_0 of the complexes were determined by HPLC chromatography as previously reported (*8*) and compared with the log k'_0 value of ^{99m}Tc-Sestamibi.



Serum protein binding affinity was evaluated through chromatographic methods using HPLC and a size-exclusion Microspin G50 column (Amersham Biosciences). Analytical RP HPLC was performed with a Symmetry 300 C4 precolumn (5 μm, 3.9 × 20 mm) and a Symmetry 300 C4 column (5 μm, 4.6 × 150 mm). Solvent A = H_2O (0.1% TFA; pH 3.0), solvent B = CH_3CN (0.1% TFA). Gradient: 0−2 min B 15%; 2−20 min B 65%; 20−22 B 15%; 22−25 B 15%. The flow rate was 1 mL/min.

Scheme 2

Measured physical properties of [^{99m}Tc(N)(DTC-Ln)(PNP)]$^{+}$ agents are reported in Table 1, including HPLC capacity factors and rat plasma protein binding. Images were collected using a gamma camera PRISM 3000 XP.

Ligands Synthesis. *Dithiocarbamate DTC-Ln.* Basically, the dithiocarbamate ligands DTC-L2−5 were prepared by reaction of the relevant secondary amine with an equivalent amount of carbon disulfide in NaOH solution, as detailed below. The general pathway of synthesis is shown in Scheme 2.

In a water-bath cooled vessel, 1.6 mmol of the appropriate secondary amine were suspended in water (10 mL), and an aqueous solution of NaOH (1.6 mmol/1.5 mL) was slowly added followed by dropwise addition of carbon disulfide (1.6 mmol/, 100 μL, 4 × 25 μL). The reaction mixture was stirred at room temperature for 1 h to obtain a yellow−orange solution. The solvent was removed under reduced pressure, and the resulting crude residue was recrystallized from ethanol/diethyl ether to give white crystals of the corresponding dithiocarbamate as sodium salt.

DTC-L2 (Piperidin Dithiocarbamate). The yield was 41%. Anal. Calcd for $C_6H_{10}NNaS_2$ (MW 183.27): C 39.32, H 5.50, N 7.64, S 34.99. Found: C 40.97, H 6.01, N 7.56, S 35.24. IR (KBr cm^{-1}) 2930 (−CH_2); 2852 (−CH_2); 1449 (CH_2); 1409 (C−N); 1218 (C═S). ^{1}H NMR (D_2O) δ: 4.19−4.15 (t, 4H, J = 5.3 Hz −$CH_2CH_2C\underline{H_2}$N-), 1.72−1.65 (m, 4H, −$CH_2C\underline{H_2}$-CH_2N-), 1.58−1.64 (m, 2H, -$C\underline{H_2}CH_2CH_2$N-).^{13}C NMR (D_2O) δ: 202.2 (C═S), 52.6 ($CH_2CH_2\underline{C}H_2$N-), 25.2 (−$CH_2\underline{C}H_2$-CH_2N-), 21.9 ($\underline{C}H_2CH_2CH_2$N-).

DTC-L3 (Morfolin Dithiocarbamate). The yield was 48%. Calcd for $C_5H_8NNaOS_2$ (MW 185.25): C 32.42, H 4.35, N 7.56, O 8.64, S 34.62. Found: C 31.97, H 4.58, N 7.06, O 8.94, S 35.24. IR (KBr cm^{-1}) 2930 (−CH_2); 1418 (C−N); 1219 (C═S). ^{1}H NMR (D_2O) δ: 4.24 (m, 4H, -$OCH_2C\underline{H_2}$N-), 3.62 (m, 4H, -$OC\underline{H_2}CH_2$N-). ^{13}C NMR (D_2O) δ: 212.0 (C═S), 68.91 (−OCH_2-$\underline{C}H_2$N-), 54.15 (-$O\underline{C}H_2CH_2$N-).

DTC-L4 (1-Ethyl-piperazine Dithiocarbamate). The yield was 60%. Calcd for $C_7H_{13}N_2NaS_2$ (MW 212.04): C 39.60, H 6.17, N 13.19, S 30.21. Found: C 40.97, H 7.58, N 13.86, S 30.54. IR (KBr cm^{-1}) 2969(−CH_3); 2818 (−CH_2); 1415 (C−N); 1227 (C═S). ^{1}H NMR (D_2O) δ: 4.32−4.16 (m, b, 4H, $CH_2C\underline{H_2}$N(CS_2)), 2.52 (m, b, 4H (CH_3CH_2)N$C\underline{H_2}CH_2$N-), 2.47−2.39 (q, b, 2H, J = 7.3 Hz $CH_3C\underline{H_2}N$ <), 1.05−0.98 (t, 3H, $C\underline{H_3}CH_2N$ <).^{13}C NMR (D_2O) δ: 202,10 (C═S), 50,91 ((CH_3CH_2)N$\underline{C}H_2CH_2$), 50.75 ($CH_3\underline{C}H_2N$ <), 49.81 (−CH_2-$\underline{C}H_2$N(CS_2)), 10.00 ($\underline{C}H_3CH_2N$ <).

DTC-L5 (4-N-(2 Methoxyphenyl)-piperazine Dithiocarbamate). The yield was 76%. Calcd for $C_{12}H_{15}N_2NaOS_2$ (MW 290.05): C 49.63, H 5.21, N 9.65, O 5.51, S 22.08. Found: C 50.97, H 5.99, N 9.89, O 5.94, S 23.24. IR (KBr cm^{-1}) 1464 (F, C−N); 1236 (F, C═S). ^{1}H NMR (D_2O) δ: 7.01−6.96 (m, 4H, Ar), 4.37 (m, 4H, $CH_2C\underline{H_2}$N(CS_2)), 3.74 (s, 3H, O$C\underline{H3}$), 2.95 (m, 4H, $CH_2C\underline{H_2}$N−Ar).^{13}C NMR (D_2O) δ: 214,10 (C═S), 155.21, 143.42 (2C, -*Ar*) 125.35−115.53 (4C, -*Ar*), 62.03 (2C, $CH_2\underline{C}H_2$N(CS_2)), 57.95 (-O$\underline{C}$H3), 53.21 (−$CH_2\underline{C}H_2$N−Ar).

Preparation of the ^{99m}Tc(N)-Complexes. Na[^{99m}TcO_4] (0.25 mL, 50.0 MBq−2.2 GBq) was added to a vial containing 5.0 mg of succinic dihydrazide (SDH = $NH_2NHC(O)CH_2CH_2$-$C(O)NHNH_2$), 5.0 mg of ethylenediamine tetraacetic acid (EDTA), and 0.1 mg of $SnCl_2$ (tin chloride) suspended in 0.1 mL of saline and 1 mL of EtOH. The vial was kept at room temperature for 30 min giving a mixture of ^{99m}Tc-nitrido precursors, [^{99m}Tc≡N]$_{mix}^{2+}$. Then, 1.0 mg of the selected diphosphinoamine (dissolved in 0.1 mL of EtOH) and 2.0 mg of the appropriate dithiocarbamate (dissolved in 0.2 mL of saline) were simultaneously added to the reaction vial. The radiochemical yield (RCY), of each compound, determined by TLC and HPLC chromatography, after 15 min at 80 °C, is reported in Table 1.

*Preparation of [^{99m}Tc(N)(DBODC)(PNP3OH)]$^{+}$ (**9**).* To a mixture of [^{99m}Tc≡N]$_{mix}^{2+}$ prepared as described above, 2.0 mg of PNP3OH × HCl dissolved in 0.5 mL of phosphate buffer (0.1 M and pH 7.4) and 1.0 mg of DBODC dissolved in 0.2 mL of saline were simultaneously added. The radiochemical yield (RCY) determined by TLC and HPLC, after 15 min at 80 °C, is reported in Table 1.

Dose Preparation of ^{99m}Tc(N)-Complexes. A Sep-Pak C18 cartridge (Waters) was activated with 5 mL of EtOH and 5 mL of deionized water. Then, the reaction solution containing the selected ^{99m}Tc(N)-complex was diluted with 8.0 mL of deionized water and loaded on the cartridge. Approximately 90% of the initial activity was retained on the cartridge. After washing the cartridge with water (20.0 mL) and 35% ethanol (5.0 mL), the complex was eluted using a mixture of ethanol and saline 90/10 (0.250 mL × 1; 0.750 mL × 1). Ninety percent of the loaded activity was collected in the second fraction. The solvent was eliminated under dinitrogen stream; the complex was dissolved in saline and utilized for *in vitro* and *in vivo* stability studies.

Compound **9.** For biodistribution studies, the complex was purified by HPLC, concentrated on a preactivated Sep Pak C18 cartridge, rinsed with H_2O (10 mL), and eluted using a mixture of EtOH/NBu_4Br (0.1 M) 50/50 (0.5 mL × 2). The second fraction containing all of the activity was diluted with saline and utilized for *in vitro* and *in vivo* studies. After purification, the radiochemical purity (RCP), evaluated by HPLC chromatography, was >95%. The stability of the isolated complex was evaluated over time.

In Vitro Studies. *Solution Stability of the ^{99m}Tc(N)-Complexes.* Aliquots of each reaction mixture containing the relevant ^{99m}Tc(N)-complex were analyzed by HPLC at 1, 2, and 18 h postlabeling.

For the cysteine (Cys) challenge experiment, an aliquot (50.0 μL) of a 10.0 mM stock aqueous solution of Cys was added to a polypropylene test tube (5.0 mL) containing 0.2 M phosphate buffer (250.0 μL and pH 7.4), water (100.0 μL), and the selected ^{99m}Tc(N)-complex (100.0 μL). The mixture was vortexed and incubated at 37 °C for 18 h. A blank reaction containing an equal volume of water instead of Cys was also accomplished. At 15 min, 1, 2, and 18 h aliquots of the reaction mixture were withdrawn and analyzed by TLC and HPLC chromatography.

Protein Binding. Considering the rapid blood clearance of these compounds, the affinity of the complexes toward the serum protein was evaluated after 2, 10, and 60 min of incubation at 37 °C in human and in rat serum by chromatographic methods using the procedures reported below.

Purified ^{99m}Tc(N)-complex (100.0 μL) (50−100 MBq) was added to 900.0 μL of human or rat serum; 150.0 μL of each sample was withdrawn and diluted in 1350.0 μL of phosphate buffer (0.02 M and pH 7.4). Aliquots of this solution were treated and analyzed as follows:

Method a. 100.0 μL was analyzed by HPLC, without further purification, using a RP Symmetry C4.

Method b. 25.0 μL was loaded on a prespun (2,000*g* for 1 min) Sephadex G-50 mini-column. The column was centrifuged at 2,000*g* for 1 min. The collected eluate and the column were counted in a γ-counter. The protein-bound complex was calculated as the percentage of total activity. HPLC analysis performed on the eluate revealed only the presence of the proteic fraction. All activity was found associated to the column.

As the blank 25.0 μL of the ^{99m}Tc(N)-complex was controlled after incubation in PBS at 37 °C for 60 min.

Metabolism. The *in vitro* metabolism studies of the agents were evaluated by monitoring the radiochemical purity (RCP) at different time points using the following procedures. In a polypropylene test tube, 50.0 μL of the purified Tc-99 m complex (50−100 MBq) was added to (a) 450.0 μL of rat serum, (b) 450.0 μL of human serum, (c) 450.0 μL of rat liver homogenate, and (d) 950.0 μL of saline as a blank. The resulting mixtures were incubated at 37 °C for 2 h. At 15 min, 1 and 2 h aliquots (200.0 μL) of each solution were withdrawn, diluted with 800.0 μL of phosphate buffer (0.2 M and pH 7.4), and filtered using an OASIS HLB extraction cartridge before HPLC injection. In detail, the sample was loaded on cartridges conditioned with MeOH (1 mL) and equilibrated with water (1 mL) and washed with MeOH 5% (3.0 mL). Ninety percent of the starting activity was eluted using a mixture of ethanol and an aqueous solution of 90/10 (1.0 mL) NBu_4Br (0.1 M); 100.0 μL of this fraction was analyzed by TLC and HPLC chromatography.

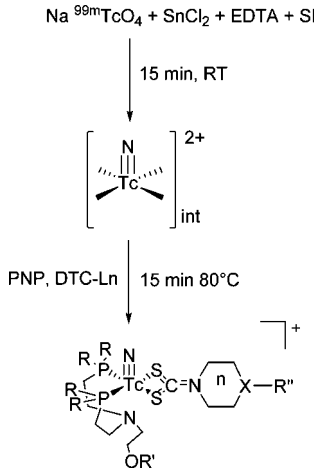
In Vivo Studies. Animal experiments were carried out in compliance with the national laws relating to the conduct of animal experimentation.

Biodistribution Studies. Before injection, each ^{99m}Tc(N)-complex was purified using the procedure outlined above. After purification, the activity recovered was further diluted with saline to obtain a final solution which was <5% in ethanol content. Female Sprague−Dawley rats weighing 180−200 g were anesthetized with an intraperitoneal injection of a mixture of Zoletil (40 mg kg^{-1}) and xilazine (2 mg kg^{-1}). The jugular vein was surgically exposed, and 100.0 μL (300−370 kBq) of the solution containing the radioactive complex was injected. The animals (n = 3) were sacrificed by cervical dislocation at different times postinjection. The blood was withdrawn from the heart through a syringe immediately after sacrifice, weighed, and counted. Organs were excised, rinsed in saline, weighed, and counted in a γ-counter. Results normalized as percent injected dose per gram (% ID/g) are reported in Tables 1S−3S (see Supporting Information). For comparison purposes, ^{99m}Tc-(N)(DBODC)(3/5), ^{99m}Tc-Sestamibi, and ^{99m}Tc-Tetrofosmin were evaluated using the same procedure.

In Vivo Stability and Metabolism. For the most promising compounds **2** and **12**, the extraction of the complex from rat tissues and urine was performed using the following procedure. One hundred microliters of the solution containing the radioactive complex (370−500 MBq) was injected into the jugular vein of anesthetized rats (200−250 g). At 30 and 120 min postinjection, the animals were sacrificed. The heart, kidneys, and small intestine were excised, rinsed with water, weighed, and counted in a NaI well counter. Results were normalized as percent injected dose per gram (% ID/g).

Extraction from the Heart and from the Kidneys. The extraction of the complex from the myocardial and renal tissue was performed following the previously reported procedures (*10*).

Metabolites in the Intestine. The intestinal lumen was rinsed with 2 mL of water; 90% of the total activity was collected in the endoluminal content. The liquid fraction was separated from the intestinal content by centrifugation (3.000*g* for 10 min) and counted. Fifty percent of the activity was found in the first liquid fraction (Fraction I). Exhaustive extraction of the residual activity from the solid fraction was performed by using MeCN (2 mL) followed by centrifugation (3.000*g* for 10 min) (Fraction II). An aliquot of each fraction (1 mL) was eluted through an OASIS HLB extraction cartridge and the eluate analyzed by TLC and HPLC.



Metabolites in the Urine. The urine was collected from the bladder and loaded directly onto an activated OASIS HLB extraction cartridge. The complex was eluted with a mixture of EtOH and saline 90/10 (0.5 mL) and analyzed by TLC and HPLC.

In Vivo Whole-Body γ-Camera Imaging. Serial *in vivo* γ-camera imaging was performed in 12 additional anesthetized rats. Compound **2** (n = 3) (44.4−59.2 MBq), **12** (n = 3), ^{99m}Tc(N)(DBODC)(5) (n = 3), or ^{99m}Tc-Sestamibi (n= *3*) was injected via the jugular vein, after which the rats were placed supine directly on the surface of the collimator. Whole body images where acquired at 2, 30, and 60 min postinjection using a 15% window centered on the 140 keV ^{99m}Tc photopeak. Imaging acquisition time was 5 min at each time point, resulting in approximately 1.2−1.0 × 10^6 counts in each image. The images were then quantified by regions of interest drawn on the heart, lung, and liver regions on each image.

RESULTS

$[^{99m}Tc(N)(DTC\text{-}Ln)(PNP)]^+$ mixed compounds were efficiently prepared, starting from $[Na^{99m}TcO_4]$ following the synthesis pathway sketched in Scheme 3. The labeling procedure entailed the preliminary formation of a mixture of $[^{99m}Tc{\equiv}N]^{2+}$nitrido precursors, through the reduction of ^{99m}Tc pertechnetate with tin(II) chloride in the presence of SDH as a nitride nitrogen donor. In the second step, the mixture was transformed, at 80 °C, into the final heterocomplex, by simultaneous addition of the two ligands at neutral pH.

Scheme 3

In all cases, the reactions were completed after 15 min of heating at 80 °C, and no improvement of the RCY was obtained modifying the reactions conditions. The RCY of all synthesized compounds, along with their chromatographic properties are reported in Table 1. log k'_0 values were determined for each compound by reversed-phase HPLC and compared with the log k'_0 of the analogous mixed-compounds ^{99m}Tc-(N)-DBODC(3/5) and commercially available ^{99m}Tc-Sestamibi (Table 1). Excluding **11**, all of the compounds are less lipophilic than ^{99m}Tc-(N)-DBODC(3/5). As expected, in [^{99m}Tc(N)(DBODC)(PNP)]$^{+}$ the replacement of PNP3 or PNP5 with a more hydrophilic diphosphinoamine such as PNP3OH, PNP7, and PNP10 had a significant impact on the lipophilicity of the final heterocomplexes. In accordance, the retention times (R_t) of the corresponding complexes moved consistently to lower values (Table 1) according to their variation in log k'_0 values.

The complexes remained stable in reaction solution for >8 h postlabeling and for 18 h after purification in injectable solution. No significant change of radiochemical purity (RCP) was observed after 18 h of incubation at 37 °C with an excess of cysteine. No ^{99m}Tc activity was coeluted with any protein, and essentially all activity was eluted in a single peak as the native compound showing that no degradation processes had occurred (HPLC profiles of rat serum incubated with the more representative ^{99m}Tc(N)-complexes at 1 h are shown in Figure 1S, Supporting Information).

These results were confirmed by size exclusion chromatography experiments (Table 1). In both cases, no significant serum protein binding was found by chromatographic methods in both human and rat sera. This behavior was in agreement with the extremely rapid blood clearance of these agents.

Biodistribution studies of all asymmetrical complexes were carried out in rats. Before the injection, the radiolabeled compounds were purified following the procedure described in the Experimental Procedures section. The RCP and the stability of the purified complexes were evaluated at 15 min prior to *in vivo* administration and for the succeeding 18 h. The tissue uptake and the target-to-background ratio of the complexes are reported in Table 2 and Tables S1−S3 (see Supporting Information).

In general, the ^{99m}Tc(N)-compounds evidenced high and persistent heart uptake (3.98 ± 0.34−1.74 ± 0.06% ID/g at 2 min p.i.; 3.67 ± 0.55−2.40 ± 0.08% ID/g at 120 min p.i.) (Figure 2). Only **9** and **11** presented a low myocardial activity followed by rapid washout: 0.30 ± 0.04% ID/g at 2 min p.i.; 0.06 ± 0.00% ID/g at 10 min p.i. for **9**; 0.52 ± 0.07% ID/g at 2 min. p.i.; 0.28 ± 0.04% ID/g at 120 min p.i. for **11**.

The blood clearance was rapid (in the ranges 0.64 ± 0.13−0.16 ± 0.04% ID/g at 2 min p.i.; 0.28 ± 0.01−0.01 ± 0.00% ID/g at 60 min p.i.), and the activity was eliminated through both the hepatic system and urinary tract.

More accurately, a low lung uptake followed by a rapid washout was observed for the two [^{99m}Tc(N)(DBODC)(PNP)]$^{+}$compounds (PNP = PNP7(**10**), PNP10(**12**)). Similar low lung accumulation was shown by the other complexes but without detectable washout. The liver uptake was transient, and the elimination of the activity from this tissue was fast and quantitative for all complexes with the exception of the most lipophilic complexes of the series **8** (1.43 ± 0.11 ID/g at 120 min p.i.) and **11** (9.93 ± 0.78 ID/g at 120 min p.i.). It is interesting to note that, in spite of the enhanced hydrophilicity of **9**, biodistribution data showed a greater excretion of the tracer into the intestine (i.e., 30.53 ± 1.36% ID/g at 120 min p.i.) than into the urine (13.53 ± 2.33% ID/g at 120 min p.i.). A less favorable kinetic of elimination from the nontarget tissues with corresponding low heart-to-lung and heart-to-liver ratios was observed for **5**.

***In Vivo* Whole-Body γ-Camera Imaging.** Although the *ex vivo* biodistribution studies give a quantitative assessment of the organ uptake of a specific tracer, whole-body imaging allows a direct comparison of both the imaging quality and T/B ratio of the different tracers in living animals.

Considering their high myocardial uptake and heart/liver ratio, we selected **2** and **12** for imaging studies in rats (Table 2). For comparative purposes, we also collected the images of ^{99m}Tc-(N)-DBODC5 and ^{99m}Tc-Sestamibi.

Figure 3 displays *in vivo* whole body planar images acquired at different time points after injection. On all images acquired at 2 min p.i., high liver uptake was observed neighboring the heart, but the lung activity was low for all tracers. After 30 min, the liver uptake of the Tc(N)-complexes was visibly decreased and nearly disappeared at 60 min p.i., while the level of the liver activity for ^{99m}Tc-Sestamibi remained high.

Metabolism Studies of 2 and 12. Because of the fast blood clearance and the low liver uptake followed by rapid washout, extraction of the complexes from these tissues was not accomplished at the same times of interest. Thus, the stability of the two most promising agents in these tissues was evaluated *in vitro*, incubating the purified compounds both in human and rat sera as well as in the rat liver homogenate, at 37 °C for 120 min. The complexes were stable in all conditions; in particular, no transformation of the native compounds into more hydrophilic species as a result of metabolic actions was observed.

Extraction of the activity localized in the heart tissue after endovenous injection of the tracer was accomplished using the procedure reported in the Experimental Procedures section. In both cases, approximately 90% of the activity initially localized in the myocardial tissue was recovered in the organic phase (MeCN) and analyzed by TLC and HPLC, in order to investigate the influence of the uptake process on the chemical identity of the complexes (Figure 4b). The myocardial uptake/trapping process did not involve a change in the chemical nature of the tracer; indeed, the activity extracted from the myocardial tissue coincided exactly with the control peak.

The *in vivo* stability and metabolism of these agents were evaluated comparing the chromatographic profiles of the injected compounds with that of the activity extracted from the endoluminal content of the small intestine, kidneys, and urine from animals administrated 30 and 120 min earlier.

Approximately, 80% of the initial activity localized in the tissues or in the liquids was taken out and analyzed. The chromatographic profiles evidenced the presence of a single peak

which perfectly overlapped the control compounds indicating that any metabolic transformation occurred (Figure 4c,d,e).

DISCUSSION

In this study, a new series of monocationic mixed ^{99m}Tc(N)-compounds incorporating alicyclic dithiocarbamate and alternative diphosphinoamine ligand was reported. These compounds were stable in solution and inert toward transchelation with an excess of free cysteine, demonstrating their remarkable stability and kinetic inertness.

The complexes appeared to possess promising biological properties exhibiting high and persistent heart localization, low lungs accumulation, and rapid blood clearance. The liver washout was fast, and the activity of the excreted tracer quickly moved from the hepatic tissue to the gastrointestinal area showing high activity in the intestine at 10 min p.i. The fast decrease of the circulating activity, due to high intestinal accumulation, led to rapid elimination from blood and from critical nontarget tissues such as lungs and liver, resulting in high heart-to-lung and heart-to-liver ratios. As observed in other

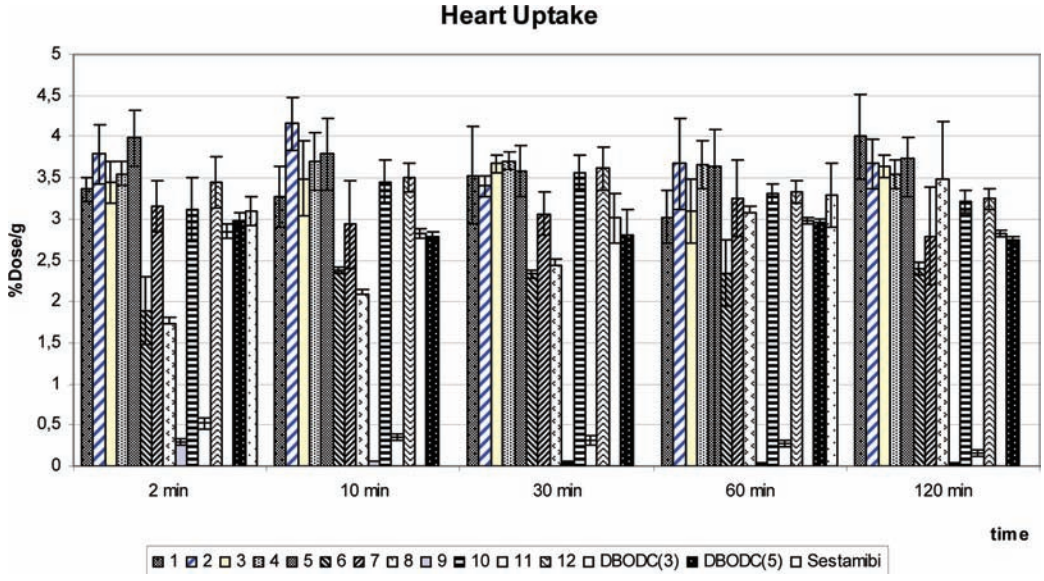

Figure 2. Comparison of heart activity over time of ^{99m}Tc-complexes.

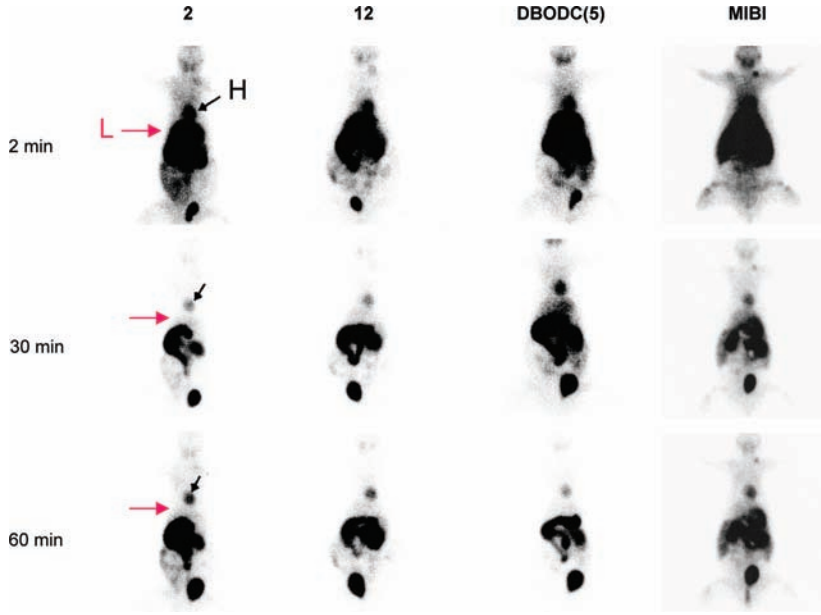

Figure 3. Planar imaging of the rats administrated with 55.0 MBq of **2**, **12**, ^{99m}Tc-DBODC5, and ^{99m}Tc-Sestamibi.

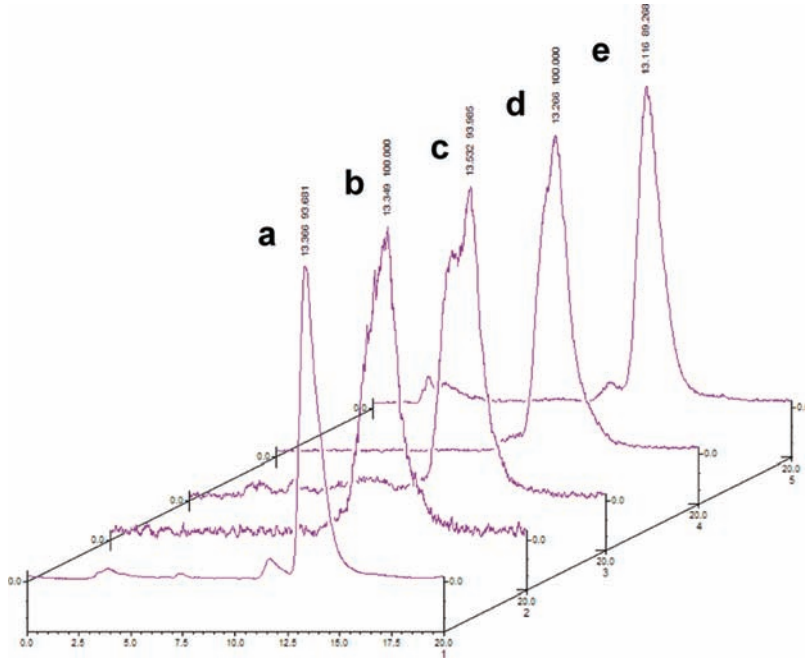

Figure 4. HPLC profile of **2** after tissue extraction: (a) control; (b) activity extracted from myocardial tissue; (c) activity extracted from endoluminal content; (d) activity extracted from kidneys; (e) urine. Similar results were obtained for **12**.

[^{99m}Tc(N)(DTC)(PNP)]$^{+}$ compounds, differences in biological behavior were found to be dependent on the nature of the dithiocarbamate ligands and on the modifications of the functional group attached either to the phosphorus or to the nitrogen atom of the PNP ligand (*8, 23*).

Considering the [^{99m}Tc(N)(DTC-Ln)(PNP3)]$^{+}$ series of complexes, we observed that variations in distribution properties were related to the nature of the dithiocarbamate ligand. The most important effects of modifications were changes in heart accumulation. In particular, the replacement in DBODC of the linear chain with alicyclic groups was responsible, in spite of their low log k'_0 values, for a significant increase in myocardial uptake (in the order DTC-L2 > DTC-L1 > DTC-L4) which resulted, at 2 min p.i., in 10−20% higher accumulation than that of both ^{99m}Tc-(N)-DBODC(3/5) and ^{99m}Tc-Sestamibi (Figure 2). Meanwhile, a considerable decrease of heart activity was observed after the administration of **6** and of **8** which correspond to the least and most lipophilic compounds, respectively.

A parallel increase in myocardial accumulation was also detected for [^{99m}Tc(N)(DBODC)(PNP)]$^{+}$ series of complexes, where PNP was PNP5,7 or PNP10 alternatively, when the linear dithiocarbamate ligand (DBODC) was replaced with the alicyclic DTC-L2.

The incorporation, in the [^{99m}Tc(N)(PNP)]$^{2+}$ synthon, of alicyclic dithiocarbamates should be consistent with a significant variation of the hydration sphere of the final mixed compounds and probably with an enhancement of their asymmetry.

In particular, the lack of a polar center (O, N) in saturated alicyclic dithiocarbamate such as DTC-L1 and DTC-L2 reduced the hydration possibility of this domain of the complex which therefore should appear less hydrated with respect to the (more polar) diphosphinoamine fragment. As a result, the exposition

of the less hydrated portion of the molecule to the hydrophobic cellular components may facilitate the interaction and the diffusion of the agents through the cellular membrane, increasing their extraction from the myocytes at early injection point.

In view of the series of the $[^{99m}Tc(N)(DBODC)(PNP)]^+$ complexes, the replacement of the diphosphine ligands PNP3 or PNP5 with PNP7 or PNP10 (replacement of four methoxypropyl with four methoxyethyl pendant groups at P donors) caused a considerable reduction of liver activity and consequently a reduction in activity in the intestinal tract, and a concomitant increased uptake in the urinary tract. This outcome is due to the enhanced hydrophilic properties of the molecules as a result of the shortening of the ether groups.

For both compounds, myocardial uptake was high and invariable over time; in particular, **12** showed heart activity comparable to that of **2** and was consequently higher with respect to the lead $^{99m}Tc(N)$-compounds, and showed favorable heart-to-lung and heart-to-liver ratios.

Unexpectedly, in **9** (log k'_0 1.09) the introduction of the highly hydrophilic hydroxymethyl groups in the PNP3OH ligand, led to a greater intestinal excretion of the activity with respect to urine. The heart uptake was initially very low, with additional wash-out.

These findings evidenced that lipophilicity remains an important factor influencing the biodistribution profile of these classes of tracers. In addition, slight differences in tissue biodistribution were also found depending on the nature of the chain attached to the tertiary amino group of the PNP ligand (PNP3/PNP10 = $-CH_2CH_2OCH_3$; PNP5/PNP7 = $-CH_2CH_2OCH_2CH_3$). Meanwhile, the heart uptake of these complexes was almost the same, and differences in lungs and liver uptake and washout were evidenced. In fact, as previously observed for $^{99m}Tc(N)(DBODC)(3/5)$ or for other cationic asymmetrical dithiocarbamate $^{99m}Tc(N)$-compounds bearing PNP3 or PNP5 diphosphinoamine (*8*), the replacement of the terminal $-OCH_3$ group on the nitrogen chain of PNP ligand with the $-OCH_2CH_3$ one led to a slight enhancement of the nontarget tissue uptake and to a reduction of the rate of elimination of the complex from the pulmonary and hepatic districts corresponding to a reduction of the heart-to-lung or the heart-to-liver ratios.

On the basis of all these results, we thought to combine in **5** the best pharmacokinetic properties of the corresponding homologue compounds **2** and **12**. Actually, the placing of DTC-L2 instead of DBODC produced a notable increase of myocardial uptake in comparison with that of complex **12** (3.98 ± 0.34 vs 3.45 ± 0.31), but its biodistributive pattern was affected by an augmented activity accumulation in nontarget tissues, such as lungs and liver, followed by a reduced washout, thus giving low target-to-nontarget ratios if compared with those of **2** and

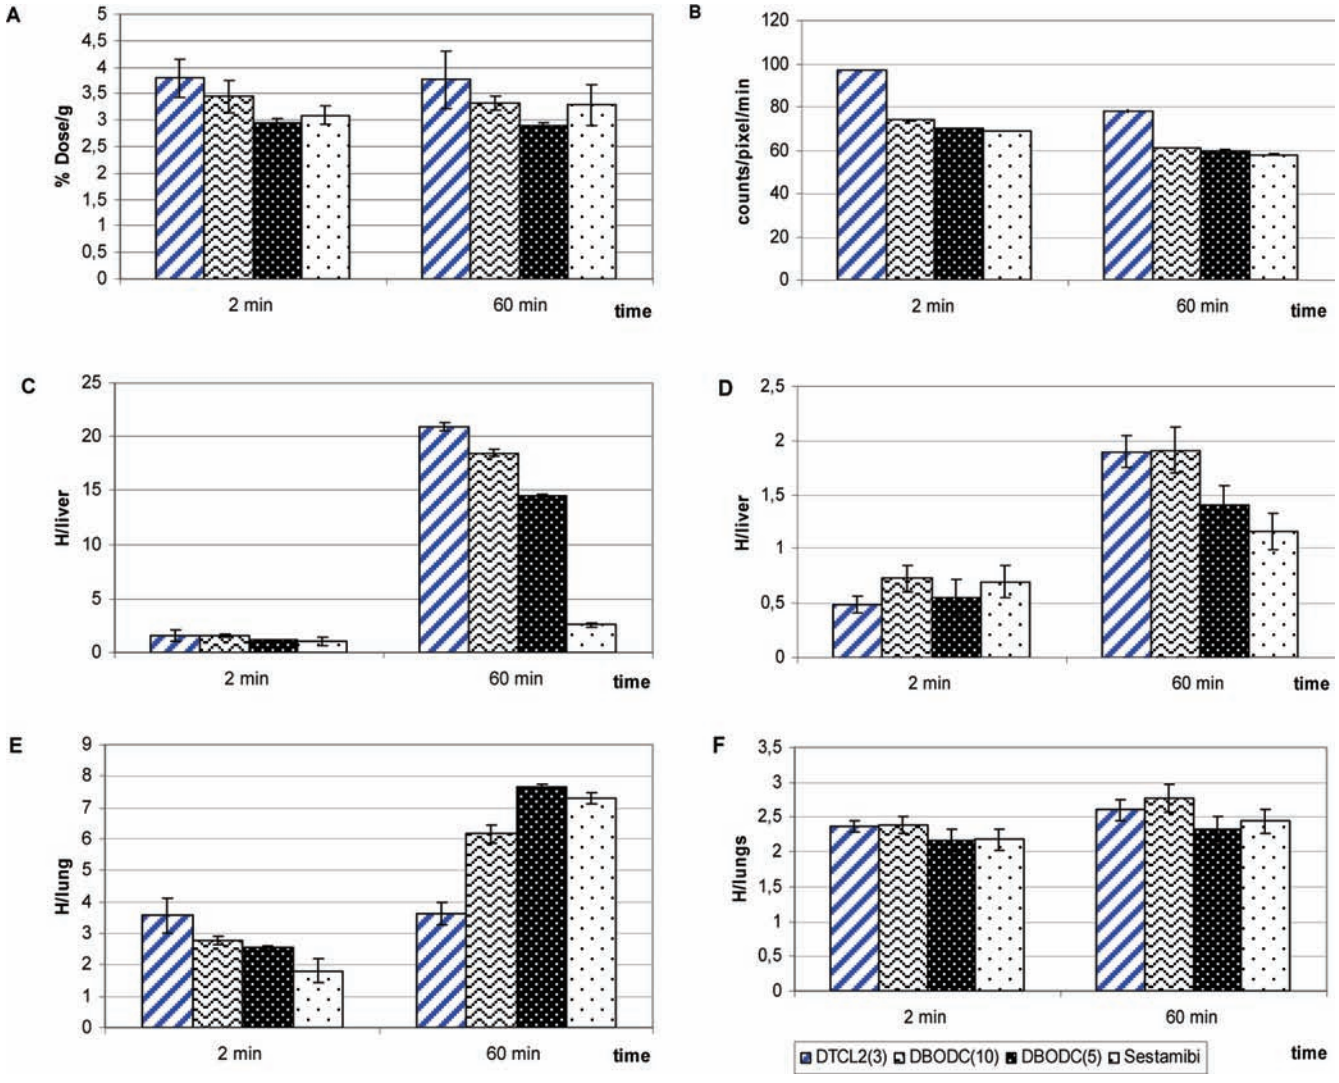

Figure 5. Comparison of (a) heart activity; (b) heart-to-liver activity ratios; and (c) heart-to-lung activity ratios over time from γ-well counting (A, C, and E); and *in vivo* image quantification (B, D, and F) of the most promising $^{99m}Tc(N)$compounds [**2**-DTC-L2(3) and **12**-DBODC(10)] with ^{99m}Tc-DBODC5 and ^{99m}Tc-Sestamibi.

12. This fact suggested for **5** a different clearance pathway with respect to the other complexes, thus evidencing that dimension and shape can significantly affect the biodistribution properties of this class of tracers.

Comparison with Gold Standard ^{99m}Tc-Agents. As previously indicated, among a series of several properties an ideal perfusion tracer should have a high first-pass extraction fraction with stable myocardial retention. Since the first-pass extraction takes place within the first 2 min after injection, the 2 min heart uptake may be used for a rough assessment of the first-pass extraction fraction of these new compounds. In general, higher heart uptake at 2 min p.i. suggests a better first-pass extraction fraction.

Amid the tested compounds, **2** and **12** presented superior biological profiles. Comparison of the heart activity uptake over time of the best candidates with respect to ^{99m}Tc-(N)-DBODC5 and to the commercially available agent ^{99m}Tc-Sestamibi is reported in Figure 5a. Variations of the heart-to-liver uptake and the heart-to-lung uptake are reported in Figure 5b,c.

Data at 2 min p.i. showed that the myocardial uptakes of both **2** and **12** were higher than the accumulation of ^{99m}Tc-(N)-DBODC5 and ^{99m}Tc-Sestamibi. These findings prompted us to believe that these new compounds might possess a first-pass extraction fraction superior to that of the standard cationic ^{99m}Tc-(N)-DBODC5, ^{99m}Tc-Sestamibi, and ^{99m}Tc-Tetrofosmin tracers. Accurate determination should be performed in more appropriate animal models.

For both **2** and **12**, the heart-to-liver ratio, at 1 h p.i., was much more favorable in comparison with ^{99m}Tc-Sestamibi ratios and similar to that found for ^{99m}Tc-(N)-DBODC5 (Figure 5 c). From a clinical point of view, the remarkably rapid efflux of these new agents from the liver without reducing myocardial uptake would be a great advance, allowing a more accurate assessment of myocardial perfusion. In fact, fast liver clearance may significantly reduce photon scatter from the liver into the inferior and in the inferoapical walls on myocardial perfusion images, thus reducing artifacts and potentially improving the diagnostic accuracy for the detection of coronary artery disease compared with that of the other ^{99m}Tc-perfusion tracers (*11*).

The heart-to-lung ratio of **12** was comparable with those of the reference tracers, whereas the **2** ratios were slight lower. In spite of this, the collected whole-body imaging of this latter complex showed a good heart-to-lung contrast comparable to those of the other compounds.

Recently, we investigated the mechanism of distribution, retention, and excretion of ^{99m}Tc-(N)-DBODC5 (*10*). Considering the close equivalence in chemical structure of these novel ^{99m}Tc(N)-complexes (**2** and **12**) with ^{99m}Tc-(N)-DBODC5, it is reasonable to assume for these tracers a similar mechanism of heart accumulation: lipophilicity modulates the penetration of the complexes into the cellular membrane, while electronic charge is responsible for irreversible tissue uptake, which is mediated by the negative mitochondrial transmembrane potential. Consequently, it is also realistic to believe that the better myocardial uptake of these agents was likely caused by the enhanced capability to cross the plasma membrane. In general, the aptitude of a monocationic compound to diffuse freely through the cell membrane is correlated with the lipophilicity of the complexes evaluated as log *P* values (*23, 24, 32*−*34*). Data obtained in this investigation suggested that despite the fact that lipophilicity remained an important factor influencing the pharmacokinetic properties of these agents, dimension, shape, and changes in the hydration sphere of the molecules have an important role in heart uptake.

In addition, metabolic studies aimed to clarify the reasons behind the rapid excretion of these new ^{99m}Tc(N)-complexes from nontarget tissues revealed that the agents were eliminated in the native (unmetabolized) form, indicating that metabolization of these ^{99m}Tc(N)-compounds cannot explain their favorable pharmacokinetic properties and rapid efflux from nontarget tissues.

Pgp and MRP are important determinants of the pharmacokinetic profile of different drugs. In addition to their overexpression in tumors, Pgp/MRP are normally located in several tissues involved in excretory functions, including the biliary surface of hepatocytes, the apical surface of mucosal cells in the small intestine and colon, and the brush border of proximal tubule cells in the kidney (*35*−*37*). In a recent study, we found that the rapid efflux of ^{99m}Tc-(N)-DBODC5 from nontarget tissues is correlated to Pgp/MRP function (*10*). Thus, the close equivalence in the metabolic profile of **2**, **12**, and ^{99m}Tc-(N)-DBODC5 suggested that the markedly rapid efflux from the principal organs of metabolism may be correlated to the Pgp/MRP transport function of these sites (*10*). This common behavior supports the possibility that the diagnostic application of this class of ^{99m}Tc(N)-complexes could be extended to oncology as in tumor and in MDR imaging studies (*38*).

CONCLUSIONS

The synthesis and the biological evaluation of novel cationic mixed ligand compounds of the type [^{99m}Tc(N)(DTC)-(PNP)]$^{+}$(DTC = DTC-Ln or DBODC) as potential myocardial imaging agents were described. In these compounds, modifications of the dithiocarbamate and PNP ligands led to a fine modulation of the lipophilic properties of the final complex. Notably, the introduction of alicyclic dithiocarbamate determined a significant increase of the heart uptake at early injection point, suggesting that the first-pass extraction fraction of such complexes may be augmented with respect to the other cationic ^{99m}Tc-agents.

This preliminary study clearly shows that through an appropriate modification of molecular properties such as lipophilicity, volume, and shape it is possible to design and develop new myocardial imaging agents with improved biodistribution profile with respect to the ^{99m}Tc-(N)-DBODC5 lead compound.

ACKNOWLEDGMENT

We thank Dr. G. Gerardi from the Department of Veterinary Clinical Science of Padua and Dr. G. Saladini from the Nuclear Medicine Service, Istituto Oncologico Veneto (IOV) of Padua for their collaboration in imaging studies, Mr. Mariano Schiavon for his assistance in the biological studies, and Mrs. Anna Rosa Moresco for her work in the elemental analysis. We also thank Nihon Medi-Physic, Tokyo, Japan, for the financial support of this work.

Synthesis of biologically active antibody conjugated quantum dots (QDs) has been of great importance in cellular imaging and diagnostics. Cetuximab (or Erbitux) is the first monoclonal antibody drug which targets the epidermal growth factor receptor (EGFR) overexpressed in most cancer cells. In the present work, we investigated three different conjugation strategies to obtain the biologically functional QD−cetuximab conjugates for the tumor-specific imaging. Successful conjugation of cetuximab to QDs was achieved using PEG conjugated polymer-coated QDs and two long-chain heterobifunctional linkers, sulfo-LC-SPDP and sulfo-SMCC. The dissociation constant of the QD−cetuximab conjugates to EGFR was determined to be 0.61 ± 0.28 nM. The cancer cell-specific binding ability of the QD−cetuximab conjugates was evaluated in vitro, and the cellular internalization of the QD−cetuximab conjugates was clearly demonstrated in live cells by confocal microscopy. The cellular imaging experiments using the QD−cetuximab conjugates showed a clear endocytosis pathway, which was evidenced by the colocalization of the QD−cetuximab conjugates with dye-labeled transferrin. These results suggest that the QD−cetuximab conjugates as an imaging modality for tumor EGFR overexpression can be expected to provide important information on the expression levels of EGFR on the cancer cells.

INTRODUCTION

Synthesis of biologically active quantum dot (QD) conjugates with a variety of biomolecules has been of great importance in cellular imaging and diagnostics (*1–3*). The conventional labeling methods using organic fluorophores or fluorescent proteins have exhibited several problems such as photobleaching or low quantum yield despite their great success. Semiconductor QD nanocrystals with unique photochemical properties such as high photoluminescence and photostability have shown great potential to overcome currently existing shortcomings for a cellular labeling agent in biological and medical applications (*4*). QD bioconjugates have demonstrated successful application in various cellular targeting and imaging studies (*3*). Optimized methodologies for obtaining biofunctional QD−antibody conjugates have become more important. Recently, Pathak et al. (*5*) claimed that the conjugation and blocking conditions for antibodies should be optimized in order to avoid nonspecific artifact labeling and maintain their original binding affinity.

Recently, commercially available activators or functional linkers have been routinely used to perform various conjugation reactions. Among them, a covalent cross-linking agent, 1-ethyl-3-(3-dimethylaminoprophyl)carbodiimide hydrochloride (EDC) has been extensively used to prepare antibody-conjugated nanoparticles (*6*). However, this method has sometimes been found to result in low quantum yield and aggregates of the final nanoparticle conjugate. To improve this chemical-induced instability, a variety of conjugation reactions should be optimized depending on the nature of antibodies and characteristics of the nanoparticles.

Cetuximab (or Erbitux) is the first monoclonal antibody (mAb) drug which targets the epidermal growth factor receptor (EGFR) overexpressed in most cancer cells (*7*) and has been widely used for the treatment of patients with metastatic colorectal carcinoma (*8, 9*). EGFR has been recognized as a biomarker of cancer cells since activation of EGFR is associated with the tumorigenic mechanisms such as autonomous cell growth, invasion, angiogenesis, and metastasis (*10, 11*). Elevated levels of EGFR are found on various types of tumors, such as breast, ovarian, lung, prostate, and colorectal cancers, and have been proposed as a prognostic marker. In this context, the recent reports exploiting cetuximab as a targeting modality for cancer diagnostics have been of great interest (*12–14*).

In the present work, we investigated three different conjugation strategies to obtain the biologically functional QD−cetuximab conjugates for the tumor-specific imaging. The conjugation efficiency, binding specificity, and cellular internalization process were also compared according to the conjugation methods. The cancer cell-specific binding ability of the QD−cetuximab conjugates was evaluated in vitro, and the cellular internalization of the QD−cetuximab conjugates was clearly demonstrated in live cells by confocal laser scanning fluorescence microscope.

EXPERIMENTAL PROCEDURES

Materials. 2,2′-(Ethylenedioxy) bis-(ethylamine), (*N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC), and dithiothreitol (DTT) were purchased from Sigma. Sulfosuccinimidyl 6-[3′-(2-pyridyldithio)propionamido]hexanoate (Sulfo-LC-SPDP) and sulfosuccinimidyl-*trans*-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC) were purchased from Pierce. *O*,*O*′-Bis(2-aminoethyl) octadecaethylene glycol was

purchased from Fluka and poly(ethylene glycol) (PEG) diamines (M_w = 2000 and 5000) were obtained from SunBio. Dulbecco's Modification of Eagle's Medium (DMEM), Roswell Park Memorial Institute (RPMI), fetal bovin serum, penicillin−streptomysin, and phosphate buffered saline (PBS, pH 7.4) were obtained from Gibco. Cy5 mono-NHS ester was purchased from Amersham, and Alexa Fluor 633 conjugated transferrin was purchased from Molecular Probe. Cetuximab (Erbitux) was purchased from Merck. The cancer cell lines (A549 and CT26.WT) were kindly provided by KIRAMS (Korea Institute of Radiological & Medical Sciences).

Preparation of CdSe/ZnS Nanocrystals. The starting core/shell CdSe/ZnS nanocrystals were prepared by the previously reported method (*15, 16*) with a slight modification (see Supporting Information S1).

Preparation of PEG-Conjugated Polymer Coated QDs 2. To the solution of the polymer coated QDs **1** (500 μL of 3 μM) were added diamino poly(ethylene glycol) and EDC to obtain amine functionalized QDs (see Supporting Information S2).

Preparation of QD−Cetuximab Conjugates Using Two Bifunctional Cross-Linkers. Amine functionalized QDs **2** reacted with 1000 equiv of sulfo-LC-SPDP. DTT (3.5 μL of 1 M) was then added to the solution under nitrogen flow to reduce the disulfide bond of LC-SPDP attached to QDs **3**. After 3 h of the reaction at room temperature, the excess of sulfo-LC-SPDP was removed using a NAP-5 desalting column pre-equilibrated with a conjugation buffer (1× PBS, pH 7.4). At the same time, cetuximab antibody **5** (500 μL of 2 mg/mL) was activated by 1000 equiv of sulfo-SMCC to give SMCC activated antibody **6**. After 30 min of the reaction, the excess of sulfo-SMCC was removed by membrane filtration (MWCO, 30 kDa). Finally, the LC-SPDP modified QD **4** and the SMCC activated cetuximab **6** were mixed and incubated at room temperature for 3 h. This reaction mixture was purified by removing the unreacted antibodies using a Superdex 200 size exclusion column. The final concentration of the resulting QD−cetuximab conjugates **7** was determined by measuring the absorbance using a reported extinction coefficient (ε_{600}, 1.7×10^7 M^{-1} cm^{-1}) of the QD (*17*).

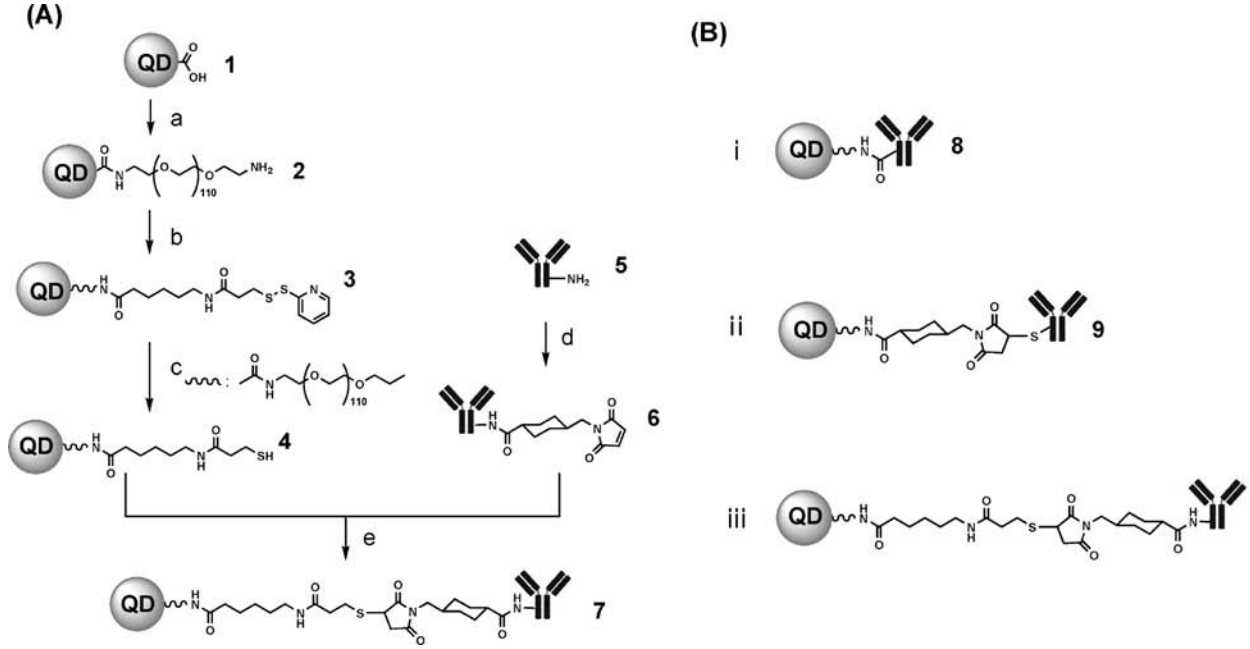
Preparation of QD−Cetuximab Conjugates 8 Using Zero-Order Cross-Linker, EDC. Another type of QD−cetuximab conjugates was prepared using a widely used coupling reagent, EDC. To 500 μL of cetuximab solution (2 mg/mL), 1000 equiv of EDC was added. After 30 min incubation, excess EDC was removed by membrane filtration (MWCO, 30 kDa). Amine-functionalized QDs were then added and incubated at room temperature for 3 h. Finally, QD−cetuximab conjugates were purified using the Superdex 200 size exclusion column.

Preparation of QD−Cetuximab Conjugates 9 Using a Short Chain Cross-Linker, Sulfo-SMCC. Cetuximab antibody (500 μL of 2 mg/mL) was reacted with DTT (65 μL of 1 M) for 2 h to reduce the disulfide bond, and excess DTT was removed by membrane filtration (MWCO, 30 kDa). 200 μL of amine functionalized QDs (3.5 μM) was reacted with 1000 equiv of sulfo-SMCC for 30 min, and SMCC-modified QDs were purified using a NAP-5 desalting column. SMCC modified QDs and reduced cetuximab antibodies were mixed and reacted at room temperature for 3 h and the final mixture was purified by using the Superdex 200 size exclusion column.

Preparation of Cy5-Labeled Cetuximab Antibody. Cy5-labeled cetuximab was prepared to study the binding affinity of cetuximab in comparison with Cy5 and nanoparticle conjugates. To 600 μL of cetuximab antibody solution (2 mg/mL), 400 μL of Cy5-mono *N*-hydroxysuccinimide (NHS) solution (2.5 mg/mL in DMSO) was added and incubated at room temperature for 3 h. Then, the Cy5-labeled cetuximab was purified by membrane filtration (MWCO, 30 kDa). The concentration of Cy5-labeled cetuximab conjugate was determined at the protein absorption peak (280 nm).

General Characterization Methods. All absorption spectra were obtained in a quartz cuvette using Cary 5000 UV−vis spectrometer (Varian Inc., CA, USA) with a spectral range 200−800 nm, a scan rate of 600 nm/min, and a slit width of 2 nm. Photoluminescence was measured by a Fluorolog−3 spectrofluorimeter (HORIBA, Jobin Yvon, UK) with excitation at 480 nm at an integration time of 0.1 s and an excitation and emission slit width of 1 nm. Agarose gel electrophoresis was performed in 1% agarose in 0.5× Tris-borate EDTA buffer (pH 8.0) at 50 V cm^{-1} for 40 min. The resulting gel image was obtained on LAS 3000 gel imager (Fuji, Japan). For identification of antibodies, the gel was poststained with Colloidal Blue solution (Invitrogen, USA). The number of cetuximab antibodies per QDs was determined by BCA protein assay, following the protocol suggested by the supplier (Thermo). For the hydrodynamic size measurement of the QD−antibody conjugates, dynamic light scattering (DLS) analysis was performed using Nano-ZS (Malvern, UK) at room temperature.

Cell Culture. The human lung carcinoma cell line, A549, which overexpresses the epidermal grow factor receptor (EGFR) was grown in Dulbeco's modified Eagle's medium (DMEM) with 10% heat-inactivated fetal bovine serum (FBS) and 0.5% penicillin (100 units/mL)−streptomycin (100 μg/mL). As a control cell line that does not express EGFR, the mouse colon carcinoma cell line CT26.WT was cultured in supplemented RPMI with 10% heat-inactivated FBS and 0.5% penicillin (100 units/mL)−streptomycin (100 μg/mL).



Flow Cytometry. For the specific cellular binding study, both A549 and CT26.WT cells (6×10^5 cells per tube) were incubated at 4 °C for 1 h with the solution of QD or QD−cetuximab conjugates in the final concentration of 10 nM. For the quantitative binding study, different concentrations of QD−cetuximab conjugates (0−50 nM) or Cy5-labeled cetuximab conjugates were used. The cells were then fixed with 4% paraformaldehyde at room temperature, followed by washing with fresh FACS buffer (1× PBS with 5% BSA). Cell-associated fluorescence intensity was measured using a Beckton Dickinson FACS Canto II (BD Bioscience, USA) through the PE channel (564−606 nm band-pass filter) for QD600 and APC channel (650−670 nm bandpass filter) for Cy5. FL1 fluorescence of at least 10 000 cells per sample was acquired and the mean fluorescence of the viable cells was analyzed in triplets. The data processing for K_d determination was done with *GraphPad Prism 5* software.

Cell Imaging. Cellular uptake of QD−cetuximab conjugates was investigated by confocal fluorescence microscope (Zeiss LSM5 Live). A549 cells (5000 cells/well) were seeded in glass-bottomed 8-well chamber slide (Lab-Tek) with 0.4 mL DMEM medium. After 24 h incubation at 37 °C, the cells were treated with 1 μM QD−cetuximab conjugate solution (QD final concentration = 2.5 nM). Consecutively, 1 μL of AlexaFluor (AF) 633-labeled transferrin (1 mg/mL in PBS; Invitrogen) was also added to the cell medium as an endosomal labeling reagent. After incubation at 37 °C for 20 min, the cells were washed with fresh DMEM medium three times. Fluorescence images of the cells were obtained with confocal microscope at 37 °C using a 63× oil immersion objective and a scan speed of 1 frame/s. For the excitation of QD, 488 Ar-ion laser line was used with emission bandpass filer (550−615 nm), while the AF633−transferrin conjugate was excited with 633 He−Ne laser and observed with long pass filter (650 nm).

RESULTS AND DISCUSSION

Preparation and Characterization of QD−Cetuximab Conjugates. The conjugation of biomolecules to QDs has been often a challenge due to the decreased water-solubility, quantum yield, and stability of the resulting conjugates, and the con-

Scheme 1. Synthesis of QD−Cetuximab Conjugates[a]

[a] (A) Carboxylated polymer-coated QDs were modified to amine-functionalized QDs by reacting with diamino-PEG (MW = 5000) and EDC; amine-functionalized QDs were produced by reacting with diamino-PEG molecules (a) and first activated with sulfo-LC-SPDP (b) and thiolated by a reducing reagent, DTT (c). At the same time, the cetuximab antibody was activated by sulfo-SMCC (d). After mixing two solutions, QD−cetuximab conjugates were produced (e). (B) The structures of three QD−cetuximab conjugates were presented.

comitant loss of binding affinity of biomolecules due to the steric hindrance of the nanoparticles (*18*). In this regard, our major effort was concentrated to prepare stable QD−antibody conjugates to maintain the original solubility and high binding affinity of the antibody. We prepared PEG conjugated QDs by reacting amino PEG5000 moiety with the polymer-coated QDs to improve the solubility and stability in the biological medium. This reaction allowed to introduce the amine functional groups on the QD surface (see Supporting Information S2). Many reports have demonstrated successful conjugation of protein to the nanoparticles by using EDC or sulfo-SMCC (*1, 19–21*). However, the conjugation efficiency, reactivity, and binding affinity of the resulting conjugates varied considerably depending on the reactivity of the reagents, nanoparticles, and antibodies used. Therefore, various conjugation strategies need to be tested and optimized, considering the different reactivity of the reagents and molecular characteristics of antibodies. In addition to the EDC and sulfo-SMCC for the conjugation, two different heterobifunctional linkers were also employed in order to obtain optimal antibody−QDs conjugates. This coupling strategy by using sulfo-LC-SPDP and sulfo-SMCC linkers was chosen to reduce the antibody stress and the steric hindrance of the bulky QD nanoparticles (Scheme 1). First, 10 000 equiv of sulfo-LC-SPDP were reacted with the amino PEG-functionalized QD **2** at room temperature for 1 h to give the linker attached QD **3**. After finishing the reaction, the disulfide bond at the end of the linker was cleaved by adding an excess amount of DTT. The resulting QDs **4** having the monothiol functionality were purified using a desalting column (NAP-5) equilibrated with PBS buffer (pH 7.4) to remove unreacted sulfo-LC-SPDP and DTT molecules. On the other hand, to introduce the thiol-reactive maleimido group, the amine groups of cetuximab **5** were also activated by using 10 equiv of sulfo-SMCC. Excess SMCC linker was removed by membrane filtration (MWCO 30 kDa) using 1× PBS. Finally, the maleimido-functionalized cetuximab **6** was reacted with the monothiolated QDs **4** with 10:1 molar ratio for 1 h in PBS (pH 7.4). The resulting QD−cetuximab conjugates **7** were purified by size exclusion column chromatography using the Superdex 200 equilibrated with 1× PBS (pH 7.4). Approximately 70% of the first elution fraction was collected under ultraviolet lamp (365 nm wavelength).

The first evidence of successful conjugation of QD with cetuximab was obtained from agarose gel electrophoresis (Figure 1). In gel running conditions (pH 8.5), the starting QDs barely moved on the gel because of the decreased negative charges due to the amino-PEG5k conjugation (see Supporting Information). Cetuximab antibodies (pI = 8.48) (http://www.drugbank.ca/drugs/DB00002) are slightly positively charged in the gel running buffer condition, migrating toward the negative electrode (lane 5; lower panel). On the other hand, sulfo SMCC-activated cetuximab showed net negative charges (lane 6; lower panel). The reaction of the sulfo LC-SPDP modified QDs with the sulfo SMCC activated cetuximab via thiol-maleimide coupling chemistry resulted in the formation of negatively charged QD-cetuximab conjugate. The colocalization of QDs fluorescence and cetuximab stained by Colloidal Blue (lane 3) indicated the successful attachment of QDs to the cetuximab. The simple mixture of QDs and the cetuximab did not show any migration changes (data not shown). DLS analysis indicated that the hydrodynamic size of the QD-cetuximab (27.9 ± 7.8 nm) increased compared with the starting QDs (18.4 ± 5.4 nm) (Figure 1B). The number of cetuximab bound per QD was determined to be 6.27 ± 0.62 based on the BCA protein assay with 63% conjugation efficiency.

We also tried two other conjugation methods to prepare QD−cetuximab conjugates. The reaction with EDC proved to be unsuccessful in our case as shown in the gel electrophoresis analysis (Figure 1A, lane 4). This may be due to the fact that the carboxyl residues of the cetuximab are not readily available for EDC activation or due to the accessibility issue of the amino groups of the bulky QD nanoparticles to the carboxyl residues of the antibody (the number of amino groups is ∼1.5× more than that of carboxyl group on the cetuximab antibody molecule: histidine, 26; lysine, 88; arginine, 36; aspartic acid, 52; glutamic acid, 60). In addition, these experiments sometimes resulted in

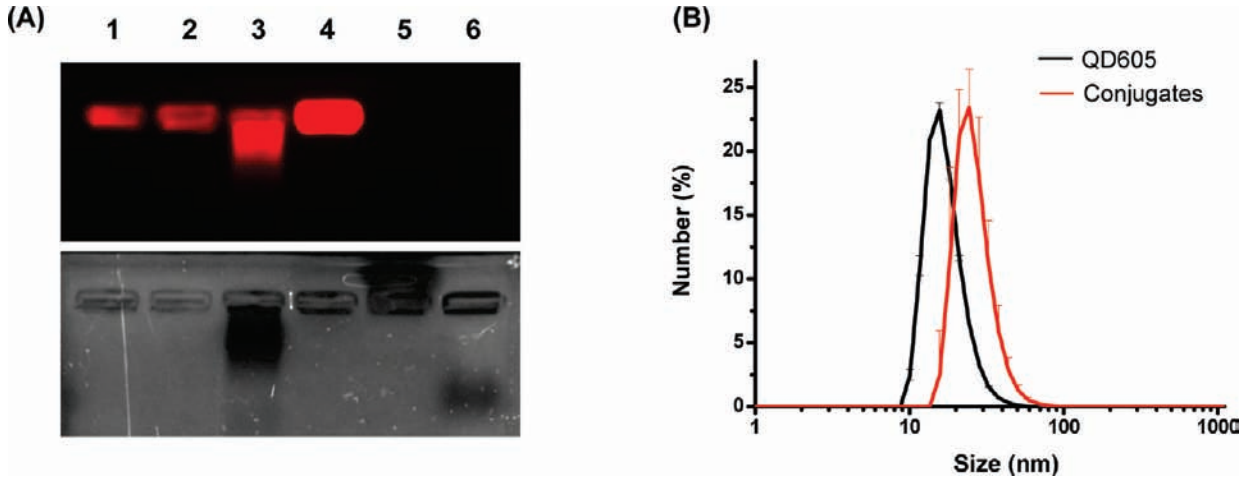


Figure 1. Confirmation of QD−cetuximab conjugates by agarose gel electrophoresis (A) and dynamic light scattering (DLS) measurement (B). QD-cetuximab conjugates	Conc. of QD (μM)	Conc. of Cetuximab (μM)	Cetuximab/QD
EDC coupling	0.61	0.05 ± 0.19	0.08 ± 0.31
SMCC linker	2.43	11.76 ± 0.82	4.84 ± 0.34
LC-SPDP/SMCC linker	0.78	4.89 ± 0.48	6.27 ± 0.62

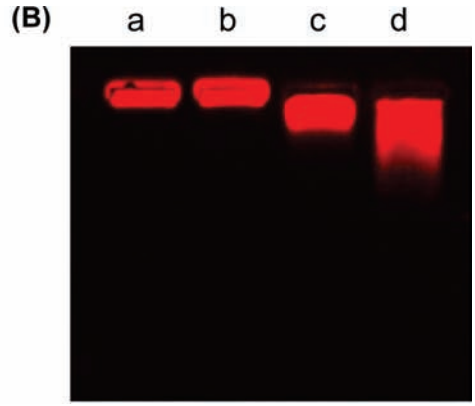

Figure 2. Molar ratio of cetuximab per QD (A) and gel electrophoresis (B): a, QD-PEG5000-NH_2; b, QD−cetuximab conjugates (EDC coupling); c, QD−cetuximab conjugates (SMCC linker), QD−cetuximab conjugates (LC-SPDP/SMCC linker).

the formation of aggregates. When the SMCC linker was used, the treatment of DTT generated the thiol groups of the cetuximab, which was then allowed to react with QD-SMCC conjugates. This approach yielded QD−cetuximab conjugate formation with 48% conjugation efficiency, which is much lower than that of the LC-SPDP-SMCC two-linker strategy. Also, these conjugates did not show any effective binding affinity to EGFR in A549 cells (see Supporting Information S3).

The low binding affinity of these conjugates can be explained by (i) the conjugation reaction by EDC resulted in extremely low conjugation efficiency, (ii) the sulfo-SMCC reaction requires the prereduction of the antibody to yield antibody fragment bearing free SH functionalities, which may reduce the original affinity of the antibody, and (iii) the steric hindrance induced by the nanoparticles can affect the affinity of the antibody by the use of short linker. The bifunctional linkers used in this study are composed of the freely rotatable sp^3 carbon (except heterocyclic ring), allowing to maximize the flexibility of the linker to diminish the steric hindrance. In this condition, the difference of the length of the linker should influence the accessibility of the QDs to antibodies.

The number of cetuximab per QD depending on the three different preparations was shown in Figure 2. While the reaction using EDC was unsuccessful, the reaction with the other two activated linkers resulted in QD−cetuximab conjugates with cetuximab molar ratio of 5−6 cetuximab/QD.

Specific Labeling of EGFR-Positive A549 Cells with QD−Cetuximab Conjugates. Cetuximab has been known to bind with EGFR-expressing cell lines such as A549 with high binding affinity (K_d = 4.54 nM) (*22*). To confirm the specificity of cetuximab toward the extracellular domain of EGFR, EGFR-positive A549 and EGFR-negative CT26.WT cells were incubated with QD−cetuximab conjugates. FACS analysis was carried out to see whether the targeting specificity of the QD−antibody conjugates toward EGFR is maintained (Figure 3A,B). QDs without cetuximab were used as a negative control. Fluorescence intensity of A549 cells incubated with QD−cetuximab conjugates **7** showed an increase of 2 orders of magnitude compared to the control CT26.WT cells. These results suggested the strong and selective binding of QD−cetuximab conjugates to EGFR expressing tumor cells. Furthermore, three types of conjugates, **7**, **8**, and **9**, were tested in EGFR-positive A549 cell solution (see Supporting Information S3).

The binding affinity of QD−cetuximab conjugates **7** was determined in A549 cells. Figure 3D shows the concentration-dependent saturation binding curve with the apparent dissociation constant (K_d) of 0.61 ± 0.28 nM. This result shows very high binding affinity of cetuximab on the QD toward A549 cells. On the other hand, that of the Cy5-labeled cetuximab was determined to be K_d = 0.22 ± 0.09 nM in identical experimental conditions (see Supporting Information S4). The slightly lower binding efficacy of the QD−cetuximab conjugate **7** than Cy5-labeled cetuximab was anticipated due to the large size of the

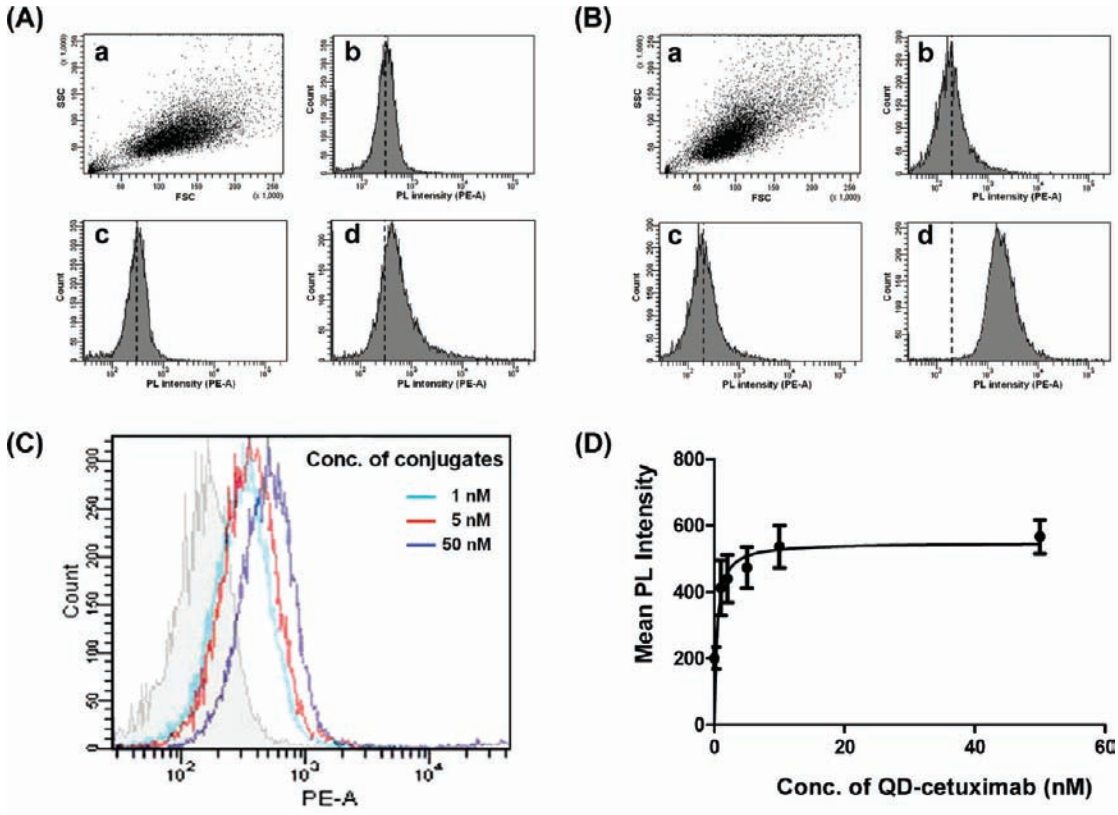

Figure 3. Specific binding of QD−cetuximab conjugates (A,B) and concentration-dependent binding (C,D) treated into the cells. Bright field image (left) and fluorescence image (right).

QDs. Wen et al. (*23*) also observed that DTPA(PEG)−cetuximab conjugate showed 66% of the binding affinity of original cetuximab. Our results represent the first quantitative analysis on the binding affinity of a nanoparticle-conjugated cetuximab for EGFR-positive cells. In our case, the specificity of QD−cetuximab conjugates **7** among the conjugates was not significantly altered after the chemical conjugation reactions. These results clearly suggested that the binding of the QD−cetuximab conjugates prepared by optimized conjugation protocol are mediated by EGFR, which leads us to implement specific detection and imaging of the EGFR overexpressed cancer cells taking advantage of the high luminescence and photostability of QD.

EGFR Imaging in Live Cell Using QD−Cetuximab Conjugates. The specific binding ability of the QD−cetuximab conjugates was tested in live cell experiments using a confocal microscope (Figure 4). The binding of QD−cetuximab conjugates to EGFR on the A549 cells occurred within 20 min (Figure

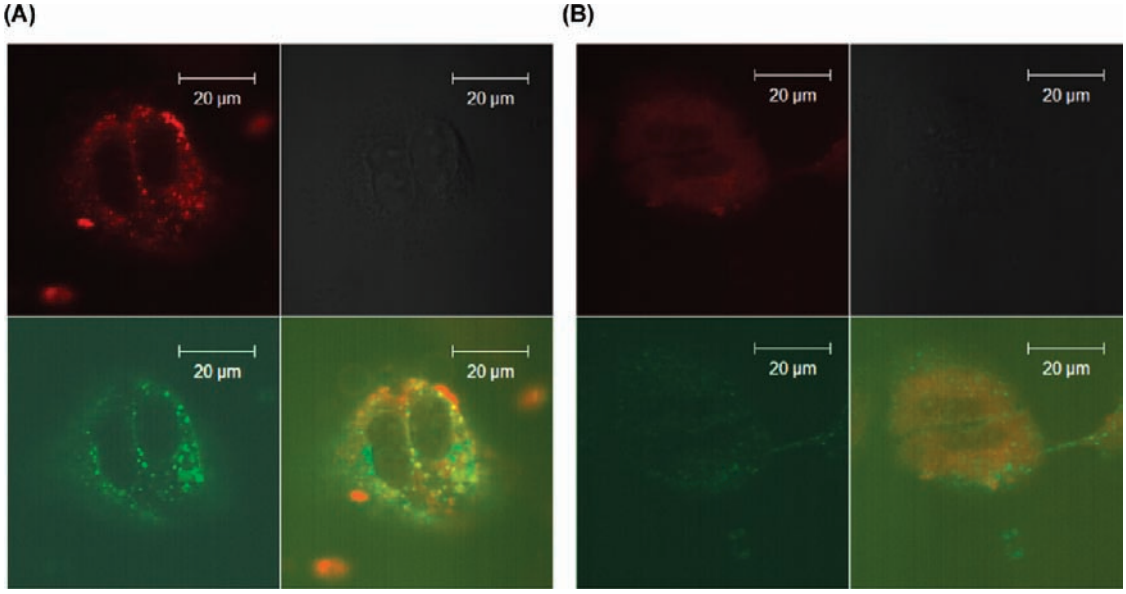

Figure 5. Fluorescence images of A549 cell treated with QD−cetuximab conjugates and Alexa633 conjugated transferrin. (A) QD−cetuximab conjugates treatment. (B) QD without cetuximab treatment. Images: QD fluorescence (up left), bright field image (up right), Alexa633 labeled transferrin (down left, pseudocolored), merge (down right).

4C). QD−cetuximab conjugate was found to bind competitively to the extracellular domain of EGFR showing exactly the same binding as cetuximab. Cetuximab binding has been known to inhibit the autophosphorylation of EGFR and induces its internalization. After 1 h incubation, most QD−cetuximab conjugates were internalized into the cytoplasm (Figure 4D). When the cells were pretreated with free cetuximab before adding the QD−cetuximab conjugates, the binding of QD−cetuximab conjugates to the cell membrane was completely blocked (Figure 4B).

The photostability of QD−cetuximab conjugates was also examined in the course of the cellular imaging (see the Supporting Information S5 and S6). QD−cetuximab conjugates clearly exhibited high photostability, of which the PL of Cy5−cetuximab decreased about 50% after 30 min of incubation. The high photostability of the QDs allowed us to observe the endocytotic pathway of QD−cetuximab conjugates in live A549 cells (Figure 5). The colocalized fluorescence images of A549 cells incubated with the QD−cetuximab conjugates and the Alexa633-labeled transferrin demonstrated that the internalization of QD−cetuximab conjugates occurred by well-known endocytosis and QD−cetuximab conjugates were trapped in endosome. Most QD−cetuximab conjugates were internalized via EGFR binding in 1 h 30 min. In a control experiment with the amine functionalized QDs without cetuximab, nonspecific binding was not observed; colocalization of QD and endosome was not detected either.

CONCLUSIONS

Successful conjugation of monoclonal anti-EGFR antibody (cetuximab) to QDs was achieved using PEG-conjugated polymer-coated QDs and two long-chain heterobifunctional linkers, sulfo-LC-SPDP and sulfo-SMCC. The dissociation constant of the QD−cetuximab conjugates to EGFR overexpressing A549 cancer cells was reproducibly determined to be 0.61 ± 0.28 nM. There was no significant nonspecific binding toward EGFR-negative CT26.WT cells. Competitive inhibition of the QD−cetuximab binding by free antibodies strongly suggested the binding specificity of the conjugates to EGFR-expressing cancer cells. As cetuximab has been known to induce internalization of EGFR, live cell imaging was performed to examine whether the QD−cetuximab conjugates were internalized by endocytosis. The cellular imaging experiments using the QD−cetuximab conjugates showed clear endocytosis pathway, which was evidenced by the colocalization of the QD−cetuximab conjugates with dye-labeled transferrin. These results suggest that the QD−cetuximab conjugates as an imaging modality for tumor EGFR overexpression can be expected to provide important information on the expression levels of EGFR on the cancer cells, including in vitro assay, cellular imaging, and in vivo imaging applications.

Small-Animal PET Imaging of Human Epidermal Growth Factor Receptor Positive Tumor with a ^{64}Cu Labeled Affibody Protein

Zheng Miao,[†,‡,§] Gang Ren,[†,‡,§] Hongguang Liu,[†,‡,§] Lei Jiang,[†,‡,§] and Zhen Cheng*[,†,‡,§]

Molecular Imaging Program at Stanford (MIPS), Department of Radiology, and Bio-X Program, Stanford University, Stanford, California 94305-5344. Received November 20, 2009; Revised Manuscript Received February 25, 2010

Epidermal growth factor receptor (EGFR) has become an attractive target for cancer molecular imaging and therapy. Affibody proteins against EGFR have been reported, and thus, we were interested in evaluating their potential for positron emission tomography (PET) imaging of EGFR positive cancer. An Affibody analogue (Ac-Cys-$Z_{EGFR:1907}$) binding to EGFR was made through conventional solid phase peptide synthesis. The purified protein was site-specifically coupled with the 1,4,7,10-tetraazacyclododecane-1,4,7-tris-aceticacid-10-maleimidethylacetamide (maleimido-mono-amide-DOTA) to produce the bioconjugate, DOTA-$Z_{EGFR:1907}$. ^{64}Cu labeled probe ^{64}Cu-DOTA-$Z_{EGFR:1907}$ displayed a moderate specific activity (5−8 MBq/nmol, 22−35 μCi/μg). Cell uptake assays by pre-incubating without or with 300 times excess unlabeled Ac-Cys-$Z_{EGFR:1907}$ showed high EGFR-specific uptake (20% applied activity at 0.5 h) in A431 epidermoid carcinoma cancer cells. The affinity (K_D) of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ as tested by cell saturation analysis was 20 nM. The serum stability test showed excellent stability of the probe with >95% intact after 4 h of incubation in mouse serum. In vivo small-animal PET imaging showed fast tumor targeting, high tumor accumulation (~10% ID/g at 1 h p.i.), and good tumor-to-normal tissue contrast of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ spiked with a wide dose range of Ac-Cys-$Z_{EGFR:1907}$. Bio-distribution studies further demonstrated that the probe had high tumor, blood, liver, and kidney uptakes, while blood radioactivity concentration dropped dramatically at increased spiking doses. Co-injection of the probe with 500 μg of Ac-Cys-$Z_{EGFR:1907}$ for blocking significantly reduced the tumor uptake. Thus, ^{64}Cu-DOTA-$Z_{EGFR:1907}$ showed potential as a high tumor contrast EGFR PET imaging reagent. The probe spiked with 50 μg of Ac-Cys-$Z_{EGFR:1907}$ improved tumor imaging contrast which may have important clinical applications.

INTRODUCTION

Epidermal growth factor receptor 1 (EGFR) is a transmembrane protein belonging to the ErbB receptor kinase family. Overexpression of EGFR has been frequently detected in a wide range of human tumors, for example, small cell lung cancer, small cell carcinoma of the head and neck, esophageal cancer, gastric cancer, gliomas, colon cancer, pancreas cancer, breast cancer, ovarian cancer, bladder cancer, kidney cancer, prostate cancer, etc. (*1, 2*). Cetuximab, Lapatinib, Gefitinib, and Erlotinib have shown clinical benefits in lung, colorectal, pancreatic, and breast cancer patients by targeting over-expressed/activated EGFR (*3*−*5*). Furthermore, increasing evidence has demonstrated that there is a correlation between EGFR overexpression and tumor metastasis formation, therapy resistance, poor prognosis, and short survival for some cancer types. It has been found that EGFR expression level is a strong prognostic indicator for head and neck, ovarian, cervical, bladder, and esophageal cancer (*6, 7*). Therefore, EGFR has become an attractive target for cancer molecular imaging and therapy.

A variety of small molecules based upon EGFR substrates and EGF have been labeled with different radionuclides for molecular imaging of EGFR expression and activity. However, the small molecules and EGF based probes generally show rapid blood clearance and very low tumor uptake; thus, the imaging quality is poor (*8*−*10*). Radiolabeled monoclonal antibodies (MAbs) against EGFR demonstrate good tumor uptake, but the tumors can only be visualized at several hours or even days after the injection of probes because of both slow tumor targeting ability and slow clearance of the radiolabeled MAbs (*11, 12*). Recently, small protein scaffolds have shown great potential for recognizing a variety of biomarkers (*13*−*17*). Among them, Affibody molecules have demonstrated to be a promising universal platform for developing imaging or therapeutic agents for different molecular targets (*17*−*19*). Affibody molecules are small, engineered proteins with 58-amino acid residues and a three-helix bundle scaffold structure, yet at the same time they display a binding surface as large as that of antibodies. In our previous research, Affibody $Z_{HER2:477}$ site-specifically labeled with ^{18}F and ^{64}Cu has shown rapid human epidermal growth factor receptor 2 (HER2) positive tumor targeting ability and good tumor-to-normal tissue imaging contrast at even 1 h post-injection (p.i.) of the probe (*20, 21*). These results have encouraged us to further explore this type of protein scaffold for positron emission tomography (PET[2]) imaging of many other important tumor biomarkers including EGFR.

Several anti-EGFR Affibody proteins (Z_{EGFR}) with high affinities have been reported recently (*22, 23*). Some of them were radiolabeled with ^{111}In in a nonsite-specific manner and evaluated using EGFR-expressing A431 tumor xenografts. Biodistribution studies demonstrated that these Affibody molecules displayed specific and good tumor accumulation; especially, $Z_{EGFR:1907}$ was reported to show the best in vivo tumor

targeting properties. In this study, we aimed to develop an Affibody based PET probe for the imaging of an EGFR positive tumor. A $Z_{EGFR:1907}$ analogue, Ac-Cys-$Z_{EGFR:1907}$, was first synthesized so that the protein can be site-specifically conjugated with 1,4,7,10-tetraazacyclododecane-1,4,7-tris-aceticacid-10-maleimidethylacetamide (Malei mido-mono-amide-DOTA) through the cysteine residue (Figure 1). The resulting bioconjugate, Ac-Cys(DOTA)-$Z_{EGFR:1907}$ (abbreviated as DOTA-$Z_{EGFR:1907}$), was then radiolabeled with a positron emitter ^{64}Cu (half-life $t_{1/2}$ = 12.7 h, $E_\beta{}^+{}_{max}$ = 656 keV, and β^+ decay = 19%) because it can be produced in large quantities and high specific activity. The ability of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ to image the EGFR positive tumor using small-animal-PET was then evaluated on the epidermoid carcinoma A431 tumor xenograft mice model.

MATERIALS AND METHODS

General. Maleimido-mono-amide-DOTA was purchased from Macrocyclics Inc. Dimethylsulfoxide (DMSO) and ethyl acetate were purchased from Fisher Scientific. Dichloromethane (DCM), trifluoroacetic acid (TFA), thioanisole (TIS), ethanedithiol (EDT), ethylene-diamine-tetra-acetic acid (EDTA), triethylamine, octanol, *N*-hydroxybenzotriazole hydrate (HOBT), 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide (EDC), *N*,*N*-diisopropylethylamine (DIEA), ethyl acetate, dithiothriotol (DTT), and all other standard synthesis reagents were purchased from Sigma-Aldrich Chemical Co. The fluorescent dye 7-diethylamino-3-(4′-maleimidylphenyl)-4-methylcoumarin (CPM) was purchased from Molecular Probes Inc. All chemicals were used without further purification. The radionuclide, ^{64}Cu, was provided by the Department of Medical Physics, University of Wisconsin at Madison. Human epidermoid carcinoma cancer cell line A431 was obtained from the American Type Tissue Culture Collection. Analytical RP-HPLC columns (Dionex, Acclaim-120 C18, 4.6 mm ×250 mm) with a guard column were used for analysis of ^{64}Cu labeled protein and unlabeled protein. The mobile phase was solvent A, 0.1% trifluoroacetic acid (TFA)/H_2O, and solvent B, 0.1%TFA/acetonitrile. The flow rate was 1 mL/min, with the mobile phase starting from 95% solvent A and 5% solvent B (0−3 min) to 35% solvent A and 65% solvent B at 33 min, then going to 15% solvent A and 85% solvent B (33−36 min), maintaining this solvent composition for another 3 min (36−39 min) and returning to initial solvent composition by 42 min. All other general materials (e.g., mice) and instruments (e.g., radioactive dose calibrator and matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF-MS), liquid chromatography electrospray ionization mass spectrometer (LC-ESI-MS), etc.) were the same as those previously reported (*20*).

Conjugation of DOTA-$Z_{EGFR:1907}$. Ac-Cys-$Z_{EGFR:1907}$ (Ac-CVDNKFNKEMWAAWEEIRNLPNLNGWQMTAFIA SLVD-DPSQSANLLAEAKKLNDAQAPK-NH_2) was synthesized on an automatic peptide synthesizer (CS Bio, CS 336X). Briefly, Rink Amide LS resin (200 mg, 40 μmol, Advanced ChemTech, 0.2 mmol/g loading) was swollen in *N*,*N*-dimethylformamide (DMF) for 30 min. Fmoc-protected amino acids were purchased from Novabiochem/EMD Chemicals Inc. Fmoc groups were removed with 20% piperidine in DMF. The aliquots of amino acids (0.20 mmol) were activated in a solution containing 0.20 mmol of HOBt and 0.5 M diisopropylcarbodiimide (DIC) in DMF. The small protein was N-terminal-acetylated by activation of acetic anhydride with HOBt/DIEA after deprotection of the Fmoc protection group of the last amino acid residue. Peptide cleavage and deprotection were carried out by a 3-h incubation in a mixture of TFA/TIS/EDT/H_2O (94:2:2:2). The mixture was filtered, and the peptide in solution was precipitated with anhydrous diethyl ether. The resulting peptide was washed four times with ice-cold anhydrous diethyl ether, dried, and dissolved in 1 mM DTT. The peptide was purified by RP-HPLC on a C-18 column. Fractions were collected and lyophilized. The target product was characterized by ESI-MS and was ready for use in the next step in the reaction.

The general procedure for the conjugation of maleimido-mono-amide-DOTA with Ac-Cys-$Z_{EGFR:1907}$ is as follows: Ac-Cys-$Z_{EGFR:1907}$ was dissolved with freshly degassed phosphate buffer (pH 7.4) at a concentration of 1 mg/mL. The bifunctional chelator maleimido-mono-amide-DOTA dissolved in DMSO (10 mM) was added at 20 equivalents per equivalent of the Affibody. After mixing by vortexing for 2 h, we purified the reaction mixture by a Dionex HPLC with a protein-and-peptide C4 column (Grace Vydac 214TP54). Characterization of the products was confirmed using MALDI-TOF-MS or LC-ESI-MS. The purity of the bioconjugate DOTA-$Z_{EGFR:1907}$ was confirmed by HPLC. The concentration of free cysteine side chains was determined with the fluorescent reagent CPM on both unconjugated and conjugated proteins. The method of Greiner et al. (*24*) was slightly modified as follows: β-mercaptoethanol standard solutions were prepared in MOPS buffer (1 mM MOPS, pH 7.9, 120 mM NaCl, 10 mM $MgCl_2$, and 1.0 mM EDTA) at concentrations of 30, 20, 10, 5, 3, 1, 0.3, and 0.1 μM. The protein concentration was determined by the micro-Bradford assay. A 15 μL aliquot of 0.4 mM CPM in DMF was added to 15 μL of each standard and each protein sample. After a 1-h incubation time at room temperature, triton X-100 (3 mL, 1%) was added to each reaction. The intensity of fluorescence emission was measured on 50 μL of samples on a NUNC plate, using a TECAN SAFIRE fluorescence plate reader. The excitation and emission wavelengths were 390 and 473 nm, respectively.

^{64}Cu Radiolabeling of DOTA-$Z_{EGFR:1907}$. The Affibody conjugate DOTA-$Z_{EGFR:1907}$ was radiolabeled with ^{64}Cu by the addition of 66.6−148 MBq (2−4 mCi) $^{64}CuCl_2$ (1 μg of DOTA-$Z_{EGFR:1907}$ per 2.96 MBq ^{64}Cu) in 0.1 N sodium acetate (NaOAc, pH 6.3) buffer followed by a 1-h incubation at 45 °C. EDTA

(5 μL, 10 mM) was then added to quench the free ^{64}Cu. The radiolabeled complex was purified by a PD-10 column (GE Healthcare). The product was washed out by phosphate-buffered saline (PBS, pH 7.4) and passed through a 0.22-μm Millipore filter into a sterile vial for in vitro and animal experiments. Radioanalytical HPLC was used to analyze the purified ^{64}Cu-DOTA-$Z_{EGFR:1907}$.

Octanol/Water Partition Coefficient. To determine the lipophilicity of ^{64}Cu-DOTA-$Z_{EGFR:1907}$, approximately 370 kBq of the probe in 500 μL of PBS (0.01 M, pH 7.4) was added to 500 μL of octanol in an Eppendorf microcentrifuge tube. The resulting biphasic system was mixed vigorously for 0.5 h and left at room temperature for another 0.5 h. The two phases were then separated by centrifugation at 3000*g* for 5 min (model 5415R Eppendorf microcentrifuge; Brinkman). From each layer, an aliquot of 100 μL was removed and counted in a γ-counter (Packard Instrument). The partition coefficient (log *P*) was then calculated as a ratio of counts in the octanol fraction to the counts in the water fraction. The experiment was repeated 3 times.

Serum Stability. ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (6.7 MBq, 180 μCi) in 250 μL of PBS was added to 1 mL of mouse serum (Sigma). After incubation at 37 °C for 1 h, 4 h, and 23 h, 74 kBq−118 kBq (20−40 μCi) solution was precipitated with 300 μL of ethanol. After centrifugation, the supernatant was transferred to a new Eppendorf tube, and DMF (300 μL) was added to precipitate the residue of serum protein. After centrifugation, the supernatant was acidified with 300 μL of buffer A (water + 0.1% TFA) and filtered through a Spin-X centrifuge tube filter (0.22 μm nylon, COSTAR). The filtrate was then injected into the radio-HPLC under conditions identical to the ones used for analyzing the original ^{64}Cu-DOTA-$Z_{EGFR:1907}$.

In Vitro Cell Assays. The EGFR positive A431 cell line was cultured in high glucose DMEM supplemented with 10% fetal bovine serum (FBS) and 1% penicillin−streptomycin (Invitrogen Life Technologies). The cells were maintained in a humidified atmosphere of 5% CO_2 at 37 °C, with the medium changed every two days. A 70−80% confluent monolayer was detached by 0.1% trypsin and dissociated into a single cell suspension for further cell culture.

The in vitro cell uptake assays of the ^{64}Cu-DOTA-$Z_{EGFR:1907}$ were performed as previously described with minor modifications (*23*, *25*). Briefly, the A431 cells were washed three times with PBS and dissociated with 0.25% trypsin-EDTA. DMEM medium was then added to neutralize trypsin-EDTA. Cells were spun down and resuspended with serum free DMEM. 5×10^5 cells were incubated at 37 °C for 0.25 to 2 h with the radioactive probe (7.4 kBq, ∼7 ng of Affibody) in 0.5 mL of serum-free DMEM medium. The nonspecific binding of the probes with A431 cells was determined by coincubation with nonradiolabeled DOTA-$Z_{EGFR:1907}$ (final concentration 0.6 μM). The cells were washed three times with 0.01 M PBS (pH 7.4). Cells were then washed three times with chilled PBS and spun down at a speed of 7000−8000 rpm. The cell pellets at the bottom of the tube were spliced, and the radioactivity of the pellets was measured using a γ-counter (PerkinElmer 1470, Waltham, MA). The uptake (counts/min) was normalized to the percentage of binding for analysis using Excel (Microsoft).

The receptor saturation assay of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ was conducted with the A431 cells, and 3×10^5 cells were plated on 6-well plates one day before the experiment. Cells were washed with PBS three times. Serum free DMEM (1 mL) was added to each well, and 8.9 kBq−532.8 kBq (0.24 μCi −14.4 μCi, 2 nM−120nM final concentration) of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ with or without 100 times excess of Ac-Cys-$Z_{EGFR:1907}$ was added to the plates. The plates were incubated on ice for 2 h. Then cells were washed with cold PBS three times and detached with TrypLE-Express (Invitrogen, San Diego, CA). The radioactivity of the cells was measured in a γ-counter. The data was analyzed using GraphPad Prism (GraphPad Software, Inc., San Diego, CA, USA), and the K_D value of DOTA-$Z_{EGFR:1907}$ was calculated from a one-site fit binding curve.

Biodistribution Studies. All animal studies were carried out in compliance with federal and local institutional rules for the conduct of animal experimentation. The A431 cells (5×10^6) suspended in PBS were implanted subcutaneously in the right upper shoulders of nude mice. Tumors were allowed to grow to around 0.4−0.6 cm in diameter (1−2 weeks). The tumor bearing mice were subject to in vivo biodistribution and imaging studies.

For biodistribution studies, the A431 tumor-bearing mice ($n = 3$ for each group) were injected with ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.11−1.85 MBq, 30−50 μCi, 1−2 μg) spiked with different doses of nonradioactive Ac-Cys-$Z_{EGFR:1907}$ (0, 5, 50, and 500 μg) through the tail vein and sacrificed at different time points (1, 4, and 24 h) p.i. Tumor and normal tissues of interest were removed and weighed, and their radioactivity was measured in a γ-counter. The radioactivity uptake in the tumor and normal tissues was expressed as a percentage of the injected radioactivity (decay corrected) per gram of tissue (% ID/g).

Small-Animal PET Imaging. PET imaging of tumor-bearing mice was performed on a microPET R4 rodent model scanner (Siemens Medical Solutions USA, Inc.). The mice bearing A431 were injected with ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.11−1.85 MBq, 30−50 μCi, 1−2 μg) spiked with cold Ac-Cys-$Z_{EGFR:1907}$ (0, 5, 50, and 500 μg) via the tail vein. At different times after the injection, the mice were anesthetized with 2% isoflurane and placed in the prone position and near the center of the field of view of a microPET. The 3-min static scans were obtained, and the images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. No background correction was performed. The method for quantification analysis of the images was the same as that reported previously (*20*).

EGFR Western Analysis of Tumor Cells and Tissues. Tumor, liver, and kidneys from A431 xenografted mice were harvested and immediately frozen in dry ice. Thawed tissues were sliced into pieces. RIPA cell lysis buffer (Sigma) supplemented with protease inhibitor cocktail was added to the sliced tissue samples and incubated for 10 min in ice. The supernatant was collected by centrifuging at 14,000 rpm for 10 min at 4 °C. The protein concentrations of the samples were measured using the Bradford assay (BioRad, Hercules, CA). An equal amount of protein from each sample was loaded onto a 10% NuPAGE Bis-Tris gel and electroblotted to a PVDF membrane. After blocking with Tris buffered saline (TBS) plus 0.05% Tween 20 containing 5% powdered milk, the membrane was divided into two pieces at the 60 kDa marker. The top and bottom membranes were incubated separately with a rabbit monoclonal anti-human EGFR antibody (Cell Signal Technology) (1:1000) or mouse monoclonal anti-actin (Sigma-Aldrich) (1:1000) overnight, followed by incubation with horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG (Invitrogen) (1:1,000) or HRP-conjugated goat anti-mouse IgG (1:1,000), respectively for 1 h. After extensive washing, the protein bands were visualized using ECL plus (Invitrogen).

Statistical Methods. Statistical analysis was performed using Student's two-tailed *t*-test for unpaired data. A 95% confidence level was chosen to determine the significance between groups, with $P < 0.05$ being significantly different.

RESULTS

Chemistry and Radiochemistry. Ac-Cys-$Z_{EGFR:1907}$ with a cysteine residue at the N-terminal was successfully synthesized

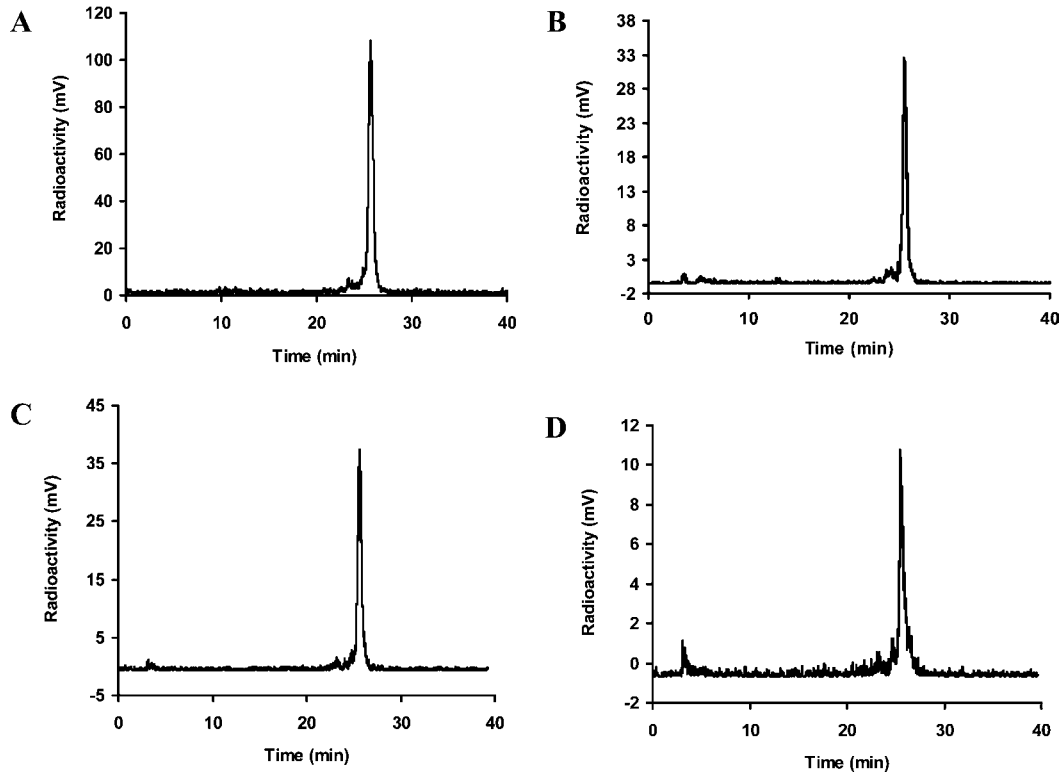

Figure 2. HPLC radiochromatograms of purified ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (A) and radiolabeled probe after 1 h (B), 4 h (C), and 23 h (D) of incubation with mouse serum.

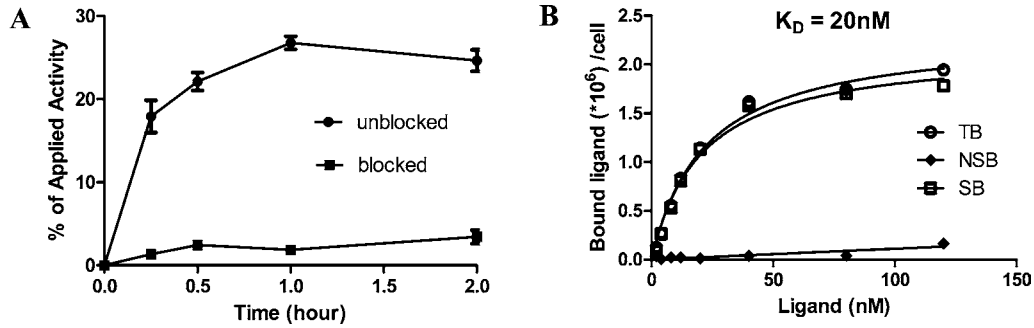

Figure 3. Characterization of EGFR-specific binding. (A) Cell uptakes of ^{64}Cu-DOTA- $Z_{EGFR:1907}$ in A431 cells over time at 37 °C with or without the presence of nonradioactive Affibody molecules DOTA-$Z_{EGFR:1907}$. All results are expressed as the mean of triplicate measurements ± standard deviation. (B) Saturation assay using SKOV3 cells plotted by concentration of total radioligands versus bound radioligand. through conventional solid phase peptide synthesis and purified by semi-preparative HPLC. The purified peptide was generally obtained in about 10% yield. The retention time on analytical HPLC for Ac-Cys-$Z_{EGFR:1907}$ was found to be 26 min. The purified Ac-Cys-$Z_{EGFR:1907}$ was characterized by MALDI-TOF-MS. The measured molecular weight (MW) was consistent with the expected MW: m/z = 6690.0 for $[M + H]^+$ (calculated $MW_{[M+H]}^+ = 6689.6$). Ac-Cys-$Z_{EGFR:1907}$ was then conjugated with maleimido-mono-amide-DOTA and purified by C4 analytical HPLC. Analysis of free thiol of the DOTA-$Z_{EGFR:1907}$ confirmed the absence of unreacted Ac-Cys-$Z_{EGFR:1907}$ (data not shown). Furthermore, mass spectrometry analysis of the final product also only showed the expected mass peak for DOTA-$Z_{EGFR:1907}$. The measured MW was m/z = 7215 for $[M + H]^+$ (calculated $MW_{[M+H]}^+ = 7215.1$). The recovery yield was 47% after purification, and the purity for the final product was over 95% (retention time: 26 min).

DOTA-$Z_{EGFR:1907}$ was successfully labeled with ^{64}Cu at 45 °C for a 1-h incubation (Figure 1). The labeling yield with ^{64}Cu was generally over 50%. The purification of radiolabeling solution using a PD-10 column afforded ^{64}Cu-DOTA-$Z_{EGFR:1907}$ with >95% radiochemical purity (Figure 2A, retention time =26 min) with modest specific activity (5−8 MBq/nmol, 22−35 μCi/μg) at the end of synthesis (EOS). From the octanol−water partition coefficient measurements, the log P value of ^{64}Cu-DOTA- $Z_{EGFR:1907}$ was determined to be −1.01 ± 0.09, indicating a moderate hydrophilicity of the radiolabeled Affibody.

In Vitro Assay of ^{64}Cu-DOTA-$Z_{EGFR:1907}$. The serum stability study showed that ^{64}Cu-DOTA-$Z_{EGFR:1907}$ had excellent resistance to proteolysis and transchelation with >95% of the probe intact after a 4-h incubation in the serum, and there was ∼85% intact ^{64}Cu-DOTA-$Z_{EGFR:1907}$ after 24 h of incubation (Figure 2). The receptor-binding affinity study of ^{64}Cu -DOTA-$Z_{EGFR:1907}$ for EGFR was performed using A431 cells (Figure 3B). The K_D value of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ was determined to be 20 nM from the saturation assay. Figure 3A shows the cell uptake of ^{64}Cu-DOTA- $Z_{EGFR:1907}$ in A431 cells at 37 °C over a 2-h incubation period. It was observed that the radiola-

[a] Data are expressed as the percentage of administered activity (injected probe) per gram of tissue (% ID/g) after intravenous injection of the probe (1.11−1.85 MBq, 30−50 μCi, 1−2 μg) spiked with 0, 5, 50, and 500 μg of Ac-Cys-$Z_{EGFR:1907}$ at 1, 4, or 24 h (n = 3). ^{64}Cu-DOTA-$Z_{EGFR:1907}$ demonstrates significantly higher uptake in A431 tumor mice than that of the blocked group (500 μg) at 4 h p.i. ($P < 0.05$). Student's unpaired two tailed t-test was conducted. $P < 0.05$ was considered significant. [b] $P < 0.05$, comparing 5 μg of spike tracer biodistribution 1 h and 24 h p.i. [c] $P < 0.05$, comparing 0 μg and 5 μg of spike tracer biodistribution at 4 h p.i. [d] $P < 0.05$, comparing 5 μg and 50 μg of spike tracer biodistribution at 4 h p.i. [e] $P < 0.05$, comparing 50 μg spike and 500 μg (block) of dose tracer biodistribution at 4 h p.i. [f] $>P < 0.05$, comparing 5 μg spike and 500 μg (block) of dose tracer biodistribution at 4 h p.i.

beled peptide steadily increased over the 2-h incubation time, and it reached an EGFR specific uptake of ~20% applied activity in 0.5 h. Pre-incubation with 300 time excess of DOTA-$Z_{EGFR:1907}$ significantly blocked ^{64}Cu-DOTA-$Z_{EGFR:1907}$ uptake ($P < 0.05$ at all time points), demonstrating the receptor binding specificity of the PET probe.

In Vivo Biodistribution Studies. The in vivo biodistribution studies of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ were examined in a A431 xenograft mouse model, and the biodistribution data and statistical analysis results are presented in Table 1. For the probe spiked with 5 μg of Ac-Cys-$Z_{EGFR:1907}$, high activity accumulation in the tumor was observed at early time points, with 9.72 ± 4.89 and 11.02 ± 1.41% ID/g uptake at 1 and 4 h p.i., respectively. ^{64}Cu-DOTA-$Z_{EGFR:1907}$ also showed good tumor retention with uptake of 10.46 ± 2.11% ID/g at 24 h. Blood radioactivity concentration was high at early time with 10.03 ± 3.80% ID/g at 1 h and dropped to 4.84 ± 0.26% ID/g at 4 h and 1.99 ± 0.59% ID/g at 24 h. High liver uptake and retention were also found (20.03 ± 3.03 and 12.83 ± 3.27%ID/g at 4 and 24 h p.i., respectively). At later time points such as 24 h p.i., ^{64}Cu-DOTA-$Z_{EGFR:1907}$ displayed a good tumor to blood ratio of 5.39 ± 0.69 (Table 1, 5 μg spiking dose). Excellent tumor-to-muscle ratios (>16) were found for all the time points studied.

To study the spiking dose-dependent biodistribution of ^{64}Cu-DOTA-$Z_{EGFR:1907}$, ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.11−1.85 MBq) was co-injected with 0, 5, and 50 μg of Ac-Cys-$Z_{EGFR:1907}$ into A431 tumor bearing mice (Table 1). Tumor uptakes were maintained over 10% ID/g at 4 h p.i. for all different spiking doses. However, the blood radioactivity concentration of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ was very different with uptake values of 11.68 ± 1.39, 4.84 ± 0.26, and 1.81 ± 0.44% ID/g at 0, 5, and 50 μg spiking dose respectively (4 h p.i., $P < 0.05$). Thus, high specific activity of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ could not increase the tumor uptake, and the tumor-to-blood ratios at 0 and 5 μg were low (Table 1). Liver uptakes were also relatively high (18.99 ± 2.88 and 20.03 ± 3.03% ID/g, 4 h) at 0 and 5 μg spiking doses. In contrast, at 50 μg spiking dose the liver uptake (13.87 ± 1.43% ID/g, 4 h) was significantly reduced ($P < 0.05$). Tumor-to-liver ratio at 4 h thus increased from 0.62 ± 0.07 (0 μg spiking dose) and 0.56 ± 0.09 (5 μg spiking dose) to 1.32 ± 0.37 (50 μg spiking dose) ($P < 0.05$). Moreover, tumor-to-blood ratios at 4 h also improved from 1.04 ± 0.01 (0 μg spiking dose) and 2.29 ± 0.43 (5 μg spiking dose) to 9.87 ± 2.99 (50 μg spiking dose) ($P < 0.05$) (Figure 4).

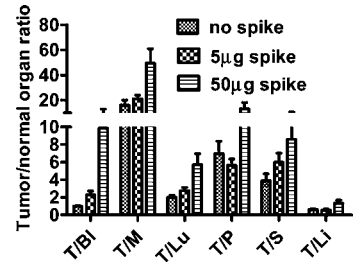

Figure 4. Tumor-to-normal organ ratios of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ in mice bearing the A431 tumor at 4 h p.i. (n = 3).

The in vivo tumor targeting specificity was confirmed by co-injection of the probe with 500 μg of Ac-Cys-$Z_{EGFR:1907}$. It was found that the tumor had a significantly reduced uptake of 6.15 ± 0.49% ID/g, compared with 17.35 ± 4.48% ID/g at 50 μg spiking dose (4 h p.i., $P < 0.05$). Liver uptake was also significantly decreased (6.47 vs 13.27% ID/g at 50 μg spiking dose, 4 h, $P < 0.05$).

Small-Animal PET Imaging. Imaging studies were conducted at 1, 2, 4, and 24 h after tail vein injection of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ with or without co-injection of 5, 50, and 500 μg (block) of cold Ac-Cys-$Z_{EGFR:1907}$. Decay-corrected coronal microPET images are shown in Figure 5. At 5 μg spiking dose, the tumor was clearly visible up to 24 h p.i. with good tumor-to-background contrast. Also, high activity accumulation in the kidneys and liver for ^{64}Cu-DOTA-$Z_{EGFR:1907}$ was observed (Figure 5E). At 0 and 50 μg spiking dose, tumors are both clearly visible at 4 h p.i., while much better tumor imaging contrast was obtained for 50 μg spiking dose at early time points (1 and 2 h p.i.) (Figure 5A and B). For the blocking group (500 μg), the tumor was barely visible on micro-PET images at all time points (Figure 5C). Quantification analysis of PET images

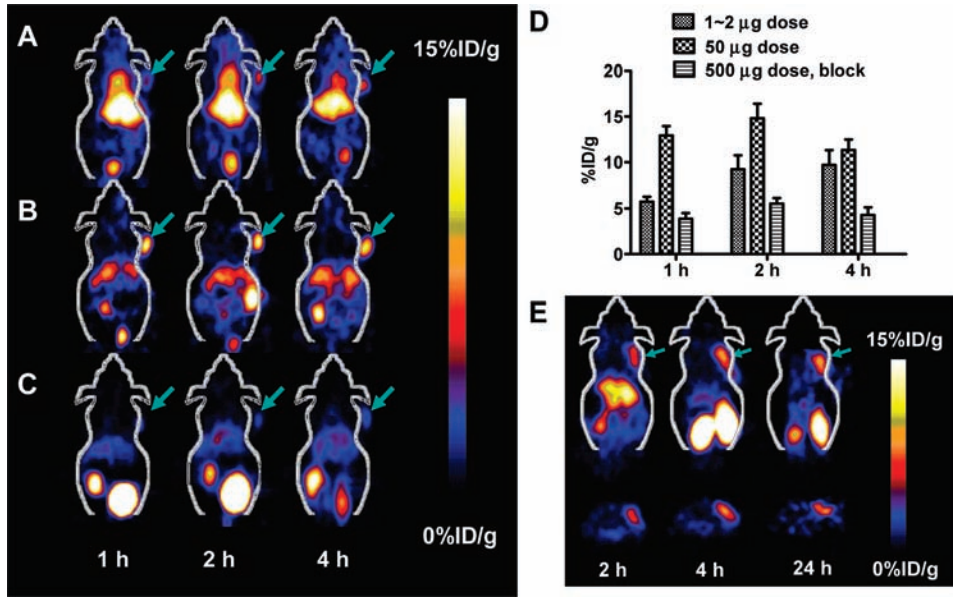

Figure 5. Representative images of decay corrected coronal microPET images of nude mice bearing the A431 tumor on the right shoulder at 1, 2, and 4 h after tail vein injection of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.11−1.85 MBq, 30−50 μCi) spiked with 0 μg (A), 50 μg (B), and 500 μg (C) of Ac-Cys-$Z_{EGFR:1907}$. Arrows indicate the location of tumors. Quantitative analysis of tumor uptakes at 1, 2, and 4 h p.i. (D) ROI was drawn on coronal images. Uptake was calculated with the mean uptake value (n = 3). (E) Representative images of decay corrected coronal (top) and transaxial (bottom) microPET images of nude mice bearing the A431 tumor on the right shoulder at 2, 4, and 24 h after tail vein injection of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.11−1.85 MBq, 30−50 μCi, spiked with 5 μg of Ac-Cys-$Z_{EGFR:1907}$). Arrows indicate the location of tumors.

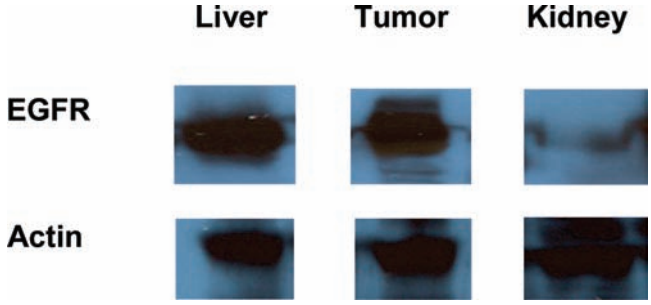

Figure 6. Representative western blot detection of EGFR expression in liver, tumor, and kidney tissue samples. Liver, A431 tumor, and kidney homogenates were prepared, and 50 μg of protein was detected with the rabbit antihuman EGFR monoclonal antibody.

showed much lower tumor uptake for mice injected with 500 μg spiking dose compared with 50 μg spiking dose ($P < 0.05$) at all time points (1−4 h p.i.) (Figure 5D). Western blot analysis is shown in Figure 6. High EGFR expression was detected for both liver and A431 tumor samples, which explained the blocking effects in the tumor and liver observed in microPET imaging studies.

DISCUSSION

Molecular imaging techniques have been demonstrated to be powerful noninvasive tools to address many important clinical questions. PET imaging is particularly useful because of its high sensitivity, high spatial resolution, strong quantification ability, and its great potential for clinical translation. The EGFR targeted PET molecular probes are expected to provide a real-time assay of EGFR expression in all tumor sites (primary and metastatic lesions) in living subjects. These imaging probes could potentially be used for early detection of EGFR positive tumor recurrence, stratification of cancer patients and optimization of the dose for EGFR targeted therapy, and monitoring the efficacy of EGFR based tumor treatment.

Affibody scaffold proteins are chemically robust like small molecules. They have good in vivo stability and bioavailability (*18*−*20*). In this study, we site-specifically conjugated an Affibody analogue Ac-Cys-$Z_{EGFR:1907}$ with a versatile chelator DOTA-monomaleimide and measured the binding specificity and affinity to EGFR. The conjugated DOTA-$Z_{EGFR:1907}$ has good binding affinity with a K_D of 20 nM. In vitro cell uptake experiments showed that ^{64}Cu-DOTA-$Z_{EGFR:1907}$ had rapid accumulation in the A431 cells. The uptake reached a plateau in 0.5 h. This accumulation is EGFR specific since blocking with cold DOTA-$Z_{EGFR:1907}$ significantly reduced cell uptake from 26.77% ± 1.35% to 1.86% ± 0.67% of applied activity (1 h) ($P < 0.05$). It is reported that in EGFR over expression tumors the concentration of EGFR is about 100 nM (*26*, *27*); thus, 20 nM affinity was considered efficient for the in vivo imaging application.

Site-specifically labeled ^{64}Cu-DOTA-$Z_{EGFR:1907}$ showed good in vivo pharmacokinetics for EGFR targeted PET imaging. Good contrast imaging of the EGFR positive A431 tumor xenograft model were obtained with optimized spiking doses (5−50 μg) at early time (1 h p.i.) after the injection of ^{64}Cu-DOTA-$Z_{EGFR:1907}$. High tumor uptake (~10% ID/g, 5 μg spiking dose) at 1 h p.i. confirmed the fast tumor targeting ability of the probe. The biodistribution study showed that optimal good tumor/blood ratio was obtained with partially blocking with 5−50 μg unlabeled Affibody (9.87 ± 2.99 at 4 h p.i., 50 μg spiking dose; 5.39 ± 0.69 at 24 h p.i., 5 μg spiking dose), which was consistent with reports that radioiodine labeled EGF with large (3 mg) spiking dose of cold EGF can give improved imaging quality in clinics (*11*).This observation may be attributed to the fact that the liver has high expression of EGFR (Figure 6) and could retain significant amount of the radiolabeled ligand (Figure 5). When spiked with an optimized amount of the cold ligand, the availability of the probe in the circulation would be increased. Because of the relatively small size of the scaffold protein, majority of the probe was quickly cleared through the kidney−urinary system. EGFR targeting specificity of ^{64}Cu-DOTA-$Z_{EGFR:1907}$ was also proven in vivo. When 500 μg of

Ac-Cys-$Z_{EGFR:1907}$ was co-injected, uptakes in high EGFR expression organs/tissues, such as the tumor and liver, were both significantly reduced at 4 h p.i. ($P < 0.05$).

High liver accumulation of radioactivity (>10% ID/g, 4 h p.i.) was also observed, which is mainly caused by the high EGFR expression in the liver, as well as nonspecific clearance of the probe through the hepatobiliary system and transchelation of ^{64}Cu in the liver. Recently, the Affibody $Z_{EGFR:1907}$ has been modified with a chelator Bz-DTPA through lysine residues and then labeled with ^{111}In (*28*). The resulting single photon emission computed tomography (SPECT) probe ^{111}In-Bz-DTPA-$Z_{EGFR:1907}$ showed much lower blood and liver uptakes (0.23 and 1.5% ID/g, repectively, at 4 h p.i., with 50 μg spiking dose). However, tumor uptake of ^{111}In-Bz-DTPA-$Z_{EGFR:1907}$ was also much lower (3−4% ID/g at 4 h p.i., with 50 μg spiking dose). This may be caused by the nonspecific labeling strategy used in the study, which could lead to reduced affinity of the probe and low tumor uptake. This is a disadvantage, especially because it may result in low sensitivity for the detection of the tumors with moderate or low EGFR expression, such as breast carcinoma (only about 3% of A431 EGFR expression level) (*2*). Further studies are required to compare these two EGFR imaging probes to conclude which one would be better for a specific application. ^{64}Cu-DOTA-$Z_{EGFR:1907}$ also showed extremely high kidney uptake (196 ± 4% ID/g vs 207.35 ± 101.16% ID/g at 4 h, with 50 μg spiking dose). Thus, radioactive coppers with higher fraction of positron emission and shorter half-life such as ^{60}Cu ($t_{1/2}$ = 24.5 min, 93% β^+) and ^{61}Cu ($t_{1/2}$ = 3.333 h, 60% β^+) will be more favorable for future clinical translation (*29*). ^{18}F ($t_{1/2}$ =109.8 min, 98% decay by positron emission) labeled Affibody could also have significantly reduced kidney radiation because of the nonresidualizing properties of radiohalogen (*30*).

On the basis of the biodistribution and microPET imaging results, it has been found that Affibody molecule based probe ^{64}Cu-DOTA-$Z_{EGFR:1907}$ shows much better properties for PET imaging than ^{64}Cu labeled monoclonal antibody Cetuximab. Affibody protein $Z_{EGFR:1907}$ is much smaller than Cetuximab (7 kDa vs 150 kDa). $Z_{EGFR:1907}$ site specifically modified with DOTA still has low-nanomolar affinity to EGFR (IC_{50} = 26.1 ± 8.8 nM). High tumor uptake (over 9% ID/g) could be obtained at as early as 1 h p.i. of the ^{64}Cu-DOTA-$Z_{EGFR:1907}$, while it takes ~24 h for ^{64}Cu labeled DOTA-Cetuximab to achieve over 10% ID/g tumor uptake (A431, U87MG, and PC-3 tumors) (*31*, *32*). In addition, blood clearance was much faster for ^{64}Cu-DOTA-$Z_{EGFR:1907}$ (1.96 ± 0.30% ID/g at 50 μg spiking dose, 4 h p.i. vs 9.4 ± 1.2, 5.7 ± 1.9% ID/g for ^{64}Cu-DOTA-cetuximab at 16 and 48 h p.i., respectively); thus, much better contrast was obtained for the Affibody based PET probe at early time. Compared with Affibody protein based probes, antibody based PET probes have poorer tumor penetration and higher nonspecific uptake because of their bulky size. Recently, in a quantitative PET imaging study of EGFR using a ^{64}Cu-labeled antibody, it was found that EGFR expression level measured in head and neck cancer cells was not correlated with the PET signal at all (*33*), suggesting that a bulky antibody based PET probe may not be suitable for quantitative imaging of EGFR. It is expected that an Affibody based PET probe such as ^{64}Cu-DOTA-$Z_{EGFR:1907}$ may overcome this problem. Further research is ongoing in our group to address this important question.

CONCLUSIONS

In conclusion, a novel Affibody based PET probe, ^{64}Cu-DOTA-$Z_{EGFR:1907}$, has been successfully developed for molecular imaging of EGFR in vivo. This probe provides high specificity, sensitivity, and excellent tumor contrast as early as 1 h p.i.. It may find important applications in cancer PET molecular imaging.

Received December 9, 2009; Revised Manuscript Received January 17, 2010

Paramagnetic nanomaterials for use as magnetic resonance imaging (MRI) contrast agents have higher relaxivity than conventional low molecular weight MRI agents. However, the biocompatibility and pharmacokinetics of such nanomaterials will strongly affect the likelihood of clinical approval. We synthesized MRI contrast agents based on biocompatible lysine-dendri-grafts: Gd-BzDTPA-lysineG2 and Gd-BzDTPA-lysineG3. The relaxivity of Gd-BzDTPA-lysineG2 and Gd-BzDTPA-lysineG3 increased with sample temperature, while the relaxivity of Gd-BzDTPA-PAMAMG4 decreased with increasing sample temperature. The increase in relaxivity with increasing temperature may be attributed to accessibility of water to the internal Gd chelates with lysine-dendri-grafts, which does not occur with PAMAM dendrimers. Gd-BzDTPA-lysineG3 had a long intravascular half-life but were largely excreted by the kidneys. Therefore, Gd-BzDTPA-lysineG3 enhanced the blood vessels for longer periods than Gd-BzDTPA-PAMAMG4, but was still excreted through the kidney. Because of their biocompatibility, desirable magneto-physical characteristics and favorable pharmacokinetics, which are derived from different interior structures rather than the physical size, lysine-dendri-graft MR contrast agents may be feasible for clinical use.

INTRODUCTION

There are distinct physical and chemical characteristics of nanosized macromolecules, such as size, charge, and hydrophobicity that greatly influence their behavior, in vivo (*1, 2*). Nanosized macromolecules can be finely tuned to have optimal characteristics for biological applications (*3*−*5*). Although in vivo behavior of nanosized macromolecules is not easy to predict (*6*), precise physical and biological characteristics of specific nanoparticles must be verified with animal studies.

Nanosized magnetic resonance imaging (MRI) contrast agents are attractive because they have numerous attachment sites for chelated gadolinium (or other chelated lanthanides) and favorable physical properties that lead to higher T1 relaxivity compared with conventional small molecular weight contrast agents. Lysine-dendri-graft is a new nanosized soft material that is thought to have favorable physicochemical features, which should increase relaxivity. However, the physicochemical characteristics, biocompatibility, and pharmacokinetics of such nanoparticles must be determined before clinical translation (*7, 8*).

In this paper, we synthesized two new MRI contrast agents based on generation-2 and -3 lysine-dendri-grafts, and studied their physical and biological characteristics in vitro and in vivo.

MATERIALS AND METHODS

Reagents. The poly(L-lysine) dendri-grafts (generation-2; G2 and generation-3; G3) were purchased from COLCOM SAS (Montpellier, France). The G2 and G3 dendri-grafts have 50 and 127 terminal primary amino groups, respectively. 2-(4-Isothiocyanatobenzyl)-diethylenetriamine pentaacetic acid (*p*-SCN-BzDTPA) was purchased from Macrocyclics (Dallas, TX). Carrier-free $^{111}InCl_3$ was purchased from Perkin-Elmer Health Sciences, Inc. (North Billerica, MA). All other chemicals used were of reagent grade. A generation-4 PAMAM dendrimer, which has 64 terminal primary amino groups, was purchased from Aldrich Chemical Co. (Milwaukee, WI).

Conjugation of Chelates to the Lysine-Dendri-Grafts. Synthetic scheme is shown in Figure 1. The poly(L-lysine) dendri-graft G2 (1.2 μmol, 1 equiv) was reacted with *p*-SCN-BzDTPA (55.8 μmol, 48 equiv) in a bicarbonate buffer (pH 9, 2 mL) at 40 °C. Following this, *p*-SCN-BzDTPA (55.8 μmol, 48 equiv) was added 48 h later to the reaction solution and maintained at pH 9. The reaction mixture was kept at 40 °C for 48 h. The resulting solution was purified by diafiltration using Centricon 10 (Millipore, Billerica, MA) to obtain BzDTPA conjugated poly(L-lysine) dendri-graft G2 (BzDTPA-lysineG2), and the buffer was changed to PBS. The number of chelates on a dendri-graft was determined using HPLC (column, TSKgel G2000SW (7.8 × 300 mm, Tosoh Bioscience LLC.); flow rate = 0.5 mL/min; eluent, PBS (pH 7.2)) by comparing the UV peak area of BzDTPA-lysineG2 and *p*-SCN-BzDTPA. An average of 20 BzDTPA chelates was conjugated to a dendri-graft.

After the buffer was changed to the 0.5 M ammonium citrate (pH 4.8), the BzDTPA-lysineG2 (23 μmol) was reacted with Gd(III) acetate (46 μmol) overnight at 37 °C. Excess Gd(III) was removed by diafiltration using Centricon 10, and the buffer was changed to PBS. The number of chelated Gd was measured by ICP-OES (Columbia Analytical Services, Tucson, AZ). The number of available chelates for binding Gd atom was 17.

Gd-BzDTPA-lysineG3 was prepared in a similar manner to Gd-BzDTPA-lysineG2, by treating G3 poly(L-lysine) dendri-graft (0.45 μmol, 1 equiv) with two separated additions of *p*-SCN-BzDTPA (55.8 μmol, 48 equiv). The resulting BzDTPA-lysineG3 (21 μmol) was treated with Gd(III) acetate (42 μmol)

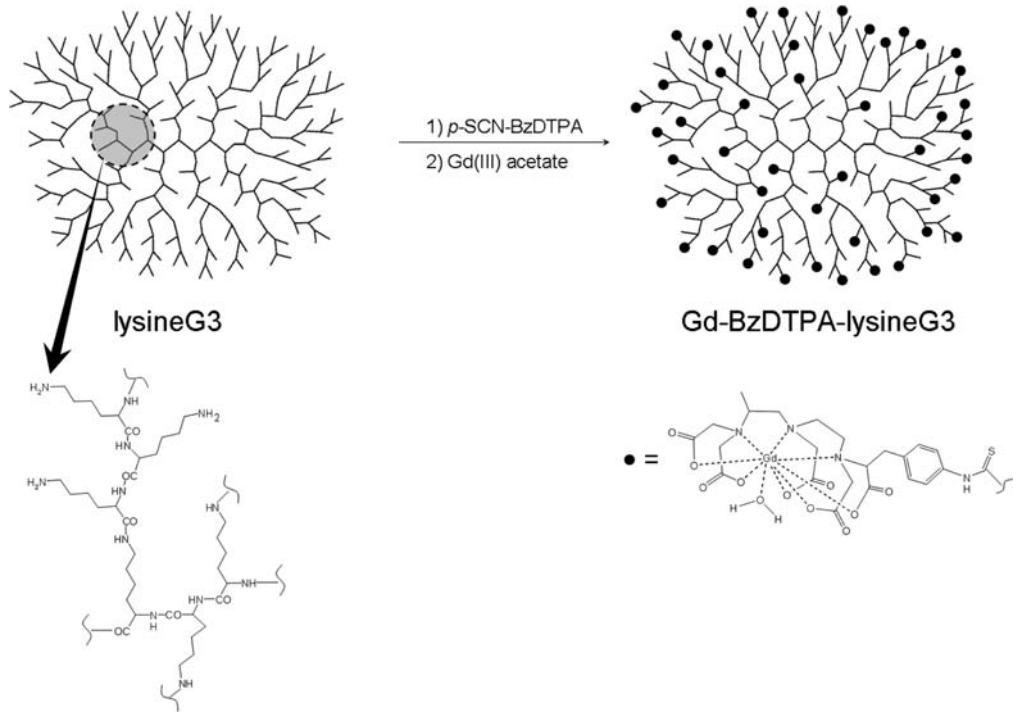

Figure 1. Synthetic scheme of Gd-BzDTPA-lysineG3.

to obtain Gd-BzDTPA-lysineG3. The number of chelates on the dendri-graft was 46, and the number of available chelates for binding Gd atom was 38.

Gd-BzDTPA-PAMAMG4 was also prepared as a control by treating PAMAM G4 dendrimer with *p*-SCN-BzDTPA as previously described (*1*). The number of chelates per dendrimer was 59, and number of available chelates for binding Gd atom was 57. Molecular weights of synthesized Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3 and Gd-BzDTPA-PAMAMG4 are 25.3, 40.4, and 64.5 kDa, respectively.

Size Measurement of Gd-BzDTPA-LysineG2 and Gd-BzDTPA-LysineG3. The sizes of Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4 were measured by dynamic light scattering (DLS) using Malvern Zeta Sizer Nano instrument (Malven Instruments Ltd., Malvern, UK) and by size exclusion HPLC (column, TSKgel G2000SW (7.8 × 300 mm, Tosoh Bioscience LLC.); flow rate = 0.5 mL/min; eluent, PBS (pH 7.2)).

Radiolabeling of Lysine-Dendri-Grafts. The Gd-BzDTPA-lysine dendri-grafts (~200 μg) were reacted with carrier-free ^{111}In in 0.15 M NH_4OAc pH 4.25 for 1 h at room temperature. To remove any non-incorporated free radiometal, 10 μL of 0.1 M EDTA was added and purified using an Amicon Ultra-4 centrifuge with Ultracel-10 (MWCO 10k) (Millipore, Billerica, MA) with an average radiolabeling yield of ~85%.

All radiolabeled [^{111}In]-Gd-BzDTPA dendri-grafts were analyzed by HPLC using TSK 2000SW (Toso Haas) size-exclusion columns connected to Flow-count radio-HPLC detector (Bioscan, Washington, DC, USA). Samples were eluted using 1× PBS (10 mM phosphate buffer at pH 7.4 in 0.15 M NaCl) at a flow rate of 0.5 mL/min. Radiochemical purity was also assessed using radio-ITLC and was found to be >98%.

Biodistribution of [^{111}In]BzDTPA-LysineG2 and [^{111}In]-BzDTPA-LysineG3. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the NIH Animal Care and Use Committee. The carrier molecule, Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, or Gd-BzDTPA-PAMAMG4, was added to the radiolabeled solution; and [^{111}In]Gd-BzDTPA-lysineG2 (185 kBq, 300 μg), [^{111}In]Gd-BzDTPA-lysineG3 (185 kBq, 300 μg), or [^{111}In]Gd-BzDTPA-PAMAMG4 (185 kBq, 300 μg) was injected intravenously into female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). The mice were sacrificed at 15 min, 1 h, 4 h, and 24 h, and the organs were weighed and counted in a gamma counter to calculate %ID/g.

Relaxivity. Relaxivity was measured by a custom-designed variable field T1-T2 analyzer (Southwest Research Institute, San Antonio, TX) and a 3T MR system (Signa LX, GE Healthcare, Waukesha, WI, USA).

For the variable field analyzer, the field strength was varied from 0.035 to 1.5 T (1.5−62 MHz) and the sample temperature was set at 23 °C. Solutions of Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, Gd-BzDTPA-PAMAMG4, and Gd_DTPA (Magnevist, Berlex, Princeton, NJ) (1 mMGd, PBS, pH 7.4) were prepared, and T1 was measured using a saturation recovery pulse sequence with 32 incremental recovery times. T2 was measured using a Carr-Purcel-Meiboom-Gill pulse sequence of 500 echoes and an interecho time of 2 ms. To investigate the temperature dependency, additional measurements were performed at 0.8 T field strength by changing the temperature to 16, 23, and 37 °C.

We also measured the relaxivity at 22 °C using a 3.0T clinical scanner (Signa Excite, GE Healthcare, Waukesha, WI, USA) equipped with a rectangular single loop receiver coil (84 × 126 × 6 mm). Phantom solutions in 1× PBS consisting of 0, 0.1, 0.25, 0.5, 0.75, and 1 mM in Gd(III) together with Gd-DTPA as reference controls were prepared. A series of single-slice 2D inversion recovery (IR) fast spin−echo images of all solutions were obtained at an echo time (TE) of about 7.54 ms using different inversion recovery times (TI) of 50, 100, 350, 750, 1250, 2500, and 5000 ms for r1 calculation, an 8-echo 2D-SE sequence with a TR = 5000 ms and an echo time interval of 8.5 ms for r2 calculation. The r1 values for each dilution were determined by fitting ROI intensity values from variable IR images using Igor Pro (http://www.wavemetrics.com). r2 values were measured from ROI values from T2 maps, which were

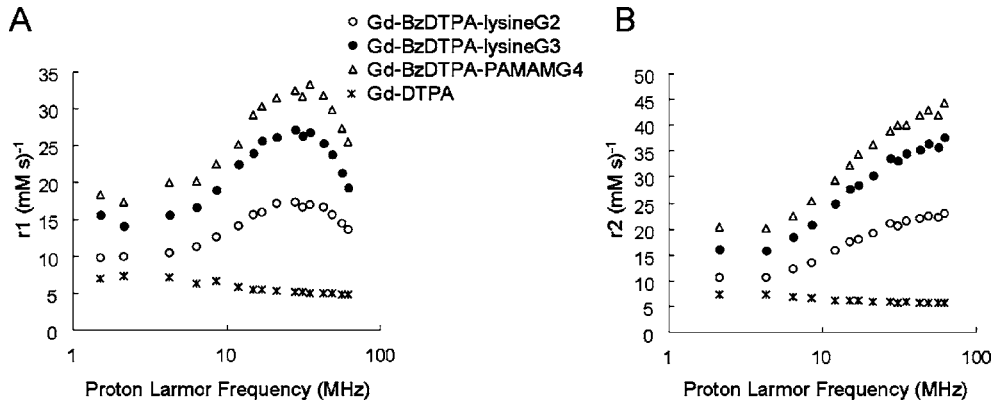

Figure 2. Frequency dependency of r1 (A) and r2 (B) profiles for each contrast agent at 23 °C.

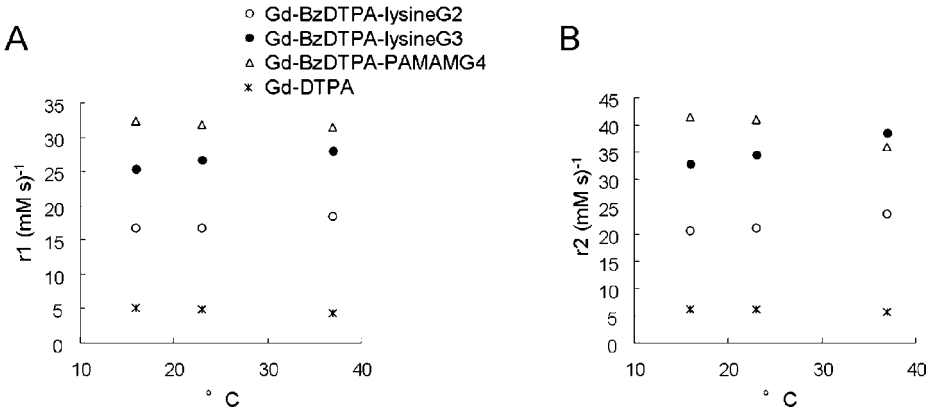

Figure 3. Temperature dependency r1 (A) and r2 (B) profiles for each contrast agent at 35 MHz.

calculated from the multiecho images in *ImageJ* (http://rsb.info.nih.gov/ij) using the MRI analysis plug-in (http://rsb.info.nih.gov/ij/plugins/mri-analysis.html). The molar relaxivities, r1 and r2, were obtained from the slope of 1/T1 or 1/T2 vs [Gd(III)] plots determined from region of interest measurements.

Contrast-Enhanced Dynamic 3D-Micro MRI of Mice. All dynamic micro-MRI images were obtained at 3 T with a 1 in round receive-only modified Alderman-Grant resonators. Mice were chemically restrained with 2% isoflurane (Abbott Laboratories, NJ) in O_2 delivered using a Summit Anesthesia Solutions vaporizer (Bend, OR) at a flow rate of 0.8 L/min. Respiration rate was maintained at 25−30 respirations per min and monitored using a Biopac System MP150 (Biopac Inc., Goleta, CA). The temperature of the mouse was maintained at 32 ± 1 °C using a Polyscience Model 210 heating recirculator with 3 M Fluorinert Electronic Liquid FC-77 with body temperature monitored using FOT-M fiberoptic sensors (Fiso Technologies Inc., San Jose, CA) and a UMI-8 multichannel instrument (Fiso Technologies Inc.). A tail vein cannula consisting of a 30-gauge needle attached to Tygon tubing (0.01 in i.d.) was then established. Prior to injection of the contrast agent, a T1 map was obtained by using a 3D-fast spoiled gradient echo image (3D-fSPGR) sequence at two different flip angles (repetition time/echo time 10.888/3.86 ms; flip angles 8° and 24°; bandwidth 31.25 kHz; matrix size 512 × 128 × 40; voxel resolution 156 × 156 × 600 μm; slice thickness 0.6 mm; two averages; scan time ~2 min). One hundred microliters (100 μL) of the Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, or Gd-BzDTPA-PAMAMG4 was injected (0.03 mmol Gd/kg) from the tail vain. The region of interest was placed on the liver, the cortex and medulla of the kidney, the muscle at the femoral region, and the jugular vein, and the time−intensity curves were made. In addition, the slice data were processed into 3D images with the maximum intensity protection (MIP) method.

RESULTS

Size. The size of Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4, measured by dynamic light scattering (DLS), was 8.58, 14.59, and 9.28 nm, respectively. The retention time by size-exclusion HPLC was 15.2, 12.4, and 14.3 min for Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4, respectively, and the results were matched with the DLS results.

Relaxivity. The r1 profiles of the Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, Gd-DTPA, and Gd-BzDTPA-PAMAMG4 at 23 °C are plotted in Figure 2. The profiles are similar for Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4 and exhibit an increase in peak relaxivity at about 35 MHz as observed previously for macromolecular MRI contrast agents. The low molecular weight contrast agent Gd-BzDTPA exhibits dispersion at around 10 MHz and slightly decreases over 10 MHz in this frequency range. All samples exhibited characteristic T1 and T2 profiles. Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4 had peak relaxivities around 35 MHz (0.8 T). The Gd-BzDTPA-lysineG2 and Gd-BzDTPA showed lowest r1 values. The r2 values of Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, and Gd-BzDTPA-PAMAMG4 increased with frequency as expected.

The r1 values of Gd-BzDTPA-lysineG2 and Gd-BzDTPA-lysineG3 increased with sample temperature; in contrast, r1 decreased with temperature for Gd-BzDTPA-PAMAMG4 and Gd-DTPA. The similar tendency was observed for r2 values (Figure 3). However, the magnitude of r2 for the G3 lysine was greater than G4 PAMAM at 35 °C. This has been attributed to

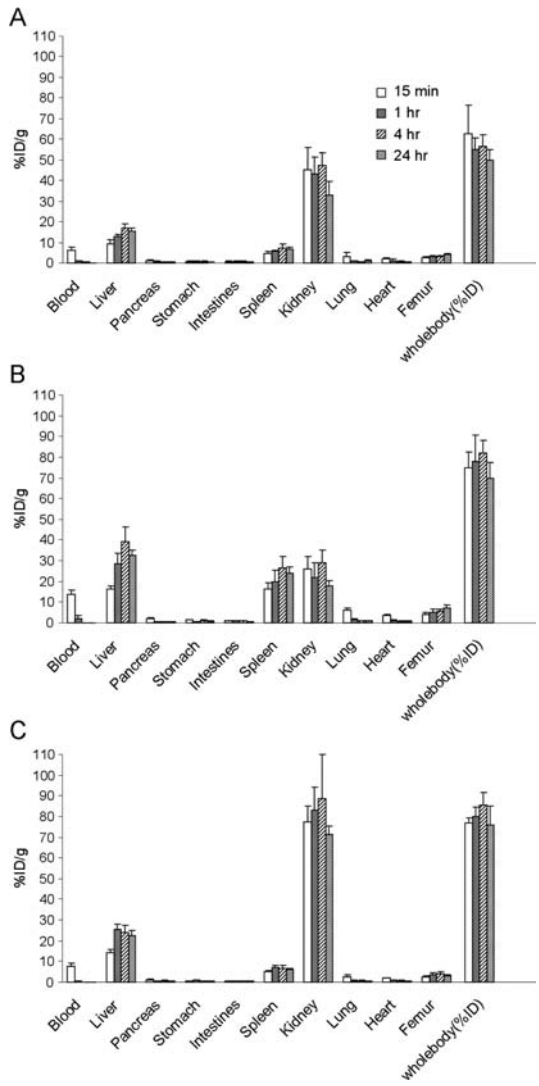

Figure 4. Biodistribution of [^{111}In]Gd-BzDTPA-lysineG2 (A), [^{111}In]Gd-BzDTPA-lysineG3 (B), and [^{111}In]Gd-BzDTPA-PAMAMG4 (C) in mice.

improved access of water to the interior Gd chelates in the lysine-dendri-graft. The r1 and r2 values of Gd-BzDTPA-lysineG2, Gd-BzDTPA-lysineG3, Gd-BzDTPA-PAMAMG4, and Gd-DTPA measured by 3T clinical scanner were 7.53, 6.86, 11.04, and 4.44 /s/mM for r1, and 25.72, 26.38, 30.64, and 5.46 /s/mM for r2, respectively.

Biodistribution of [^{111}In]Gd-BzDTPA-LysineG2, [^{111}In]Gd-BzDTPA-LysineG3, and [^{111}In]Gd-BzDTPA-PAMAMG4. The results of biodistribution experiments are summarized in Figure 4. High kidney activity for all agents, but was highest for [^{111}In]Gd-BzDTPA-PAMAMG4 and lowest for [^{111}In]Gd-BzDTPA-lysineG2. The liver accumulation was highest for [^{111}In]Gd-BzDTPA-lysineG3. [^{111}In]Gd-BzDTPA-lysineG3 also showed high splenic uptake. The blood clearance was slowest for [^{111}In]Gd-BzDTPA-lysineG3. The clearance from the body was fastest for [^{111}In]Gd-BzDTPA-lysineG2.

3D-Micro-MR. The time−intensity curve and MIP images are shown in Figures 5 and 6, respectively. The blood retention was greatest for Gd-BzDTPA-lysineG3. The profiles of signal intensity in blood were similar for Gd-BzDTPA-lysineG2 and Gd-BzDTPA-PAMAMG4. Relatively high signal intensity was detected in the cortex of the kidneys for Gd-BzDTPA-lysineG2. The signal intensities in the renal pelvis were high for both the G2 and G3 lysine-dendri-grafts, while it was lower for Gd-BzDTPA-PAMAMG4. Gd-BzDTPA-lysineG3 showed higher signal intensity than Gd-BzDTPA-lysineG2 and PAMAMG4 in the liver. The signal in muscle was low for all compounds.

DISCUSSION

An interesting physical characteristic of lysine-dendri-graft based MRI contrast agents is their relaxivity behavior relative to PAMAM-based dendrimers of similar sizes or small molecular weight chelates. Since the Gd-chelates are located on the surface of low-generation PAMAM-based dendrimer contrast agents, they constantly interact with water, the rotational correlation time of the chelated Gd ions increases as the temperature decreases leading to an increase in r1 for these contrast agents. Similar results were previously obtained by Jaszberenyi et al. (*9*) Low molecular weight gadolinium chelates behave similarly. Conversely, an increase in temperature results in a decrease in r1 because of the decrease in the rotational correlation time of the single Gd chelate or the Gd chelates on the surface of the low generation dendrimers. In contrast, lysine-dendri-grafts demonstrate higher r1's as the temperature increases, as has been previously observed for high-generation PAMAM dendrimers (*10*). In addition, the overall r1 of the lysine-dendri-graft based MRI contrast agents was lower than that of PAMAM-based dendrimer contrast agents with similar size especially at the low temperature. The lysine-dendri-grafts potentially have terminal amines in the interior structure. Therefore, some of the chelated Gd ions might not be fully accessible by water. As the temperature increases, however, water can access the internal chelates which lead to an increase in relaxivity. Furthermore, the increase in water exchange between the (interior) bound water and the exterior bulk water with rising temperature would also result in an increased relaxivity. However, it is difficult to know the exact extent of the interplay between water accessibility and the water exchange and additional studies are needed over a larger range of lysine-based dendri-graft generations. However, the exchange time of the water bound to the interior Gd chelates and in bulk solution also increases, because now, the water has to go inside the dendrimer and then back out. With PAMAM, it only has to go to the exterior and then back to the bulk water. So, this increases the water exchange time for the lysine-dendri-graft compared to the PAMAM dendrimer and increases even further with rising temperature. The effect on increasing the water exchange time is the same effect as increasing the rotational correlation time—an increase in relaxivity. As was observed for the high-generation PAMAM, if the water exchange time is increased too much, it actually will start to decrease the relaxivity. Therefore, this unique relaxivity behavior of the contrast agents based on the lysine-dendri-graft compared with the PAMAM-based contrast agent of the similar size could be derived from the less packed, therefore, better flexible interior of the lysine-dendri-grafts than that of PAMAM dendrimer (*9*−*11*). The relaxivity change of the macromolecular contrast agents was mostly focused on the size of the molecule because of the rotational correlation time; however, our findings suggested that the flexibility of the interior can also affect the relaxivity change. This theory can be useful for designing nanosized contrast agents with high relaxivity or chemical exchange saturation transfer (CEST) contrast using various soft nanomaterials.

Accelerated renal excretion is important to minimize the potential toxicity of Gd-chelated agents. It is known that excretion by glomerular filtration primarily depends on molecular size (*12*). The lysine-dendri-graft based MRI contrast agents are relatively larger in hydrodynamic physical size than the PAMAM-based dendrimer contrast agents. Nevertheless, lysine-dendri-grafts demonstrate renal excretion, an observation likely related to the flexibility of the molecule. In addition, it is known that lysine administration can block renal tubular reabsorption

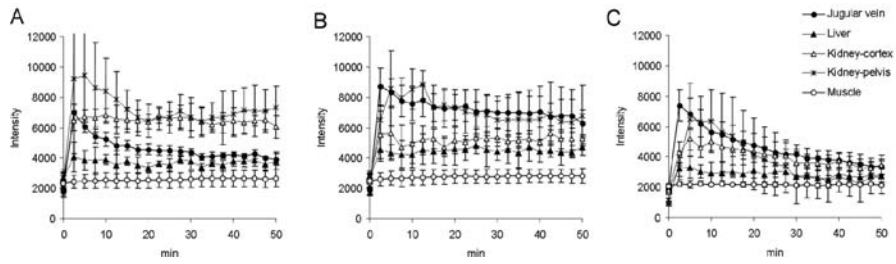

Figure 5. Plots of the signal intensity in the jugular vein, the liver, the cortex and medulla of the kidney, and the muscle at the femoral region obtained from the contrast enhanced dynamic MRI of mice: Gd-BzDTPA-lysineG2 (A), Gd-BzDTPA-lysineG3 (B), and Gd-BzDTPA-PAMAMG4 (C).

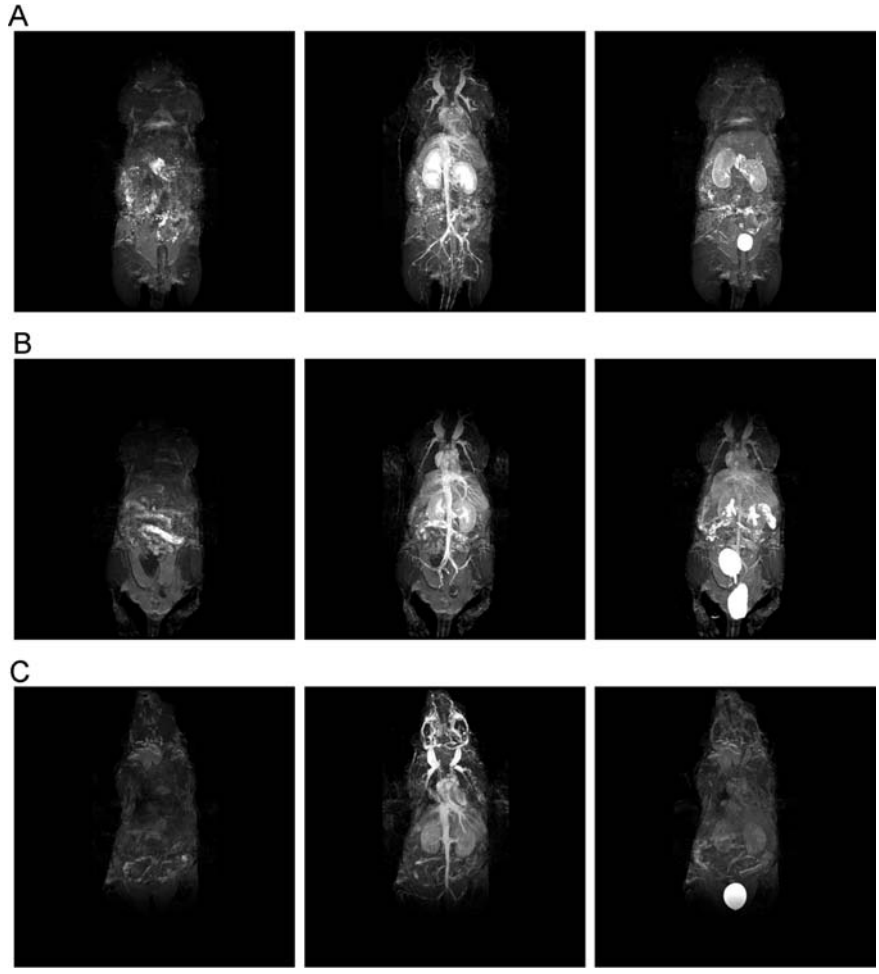

Figure 6. Whole body 3D MR images of mice, which were constructed with the MIP method with preinjection (left), immediately after (middle), and 50 min after (right) injection of Gd-BzDTPA-lysineG2 (A), Gd-BzDTPA-lysineG3 (B), or Gd-BzDTPA-PAMAMG4 (C).

of small-molecular-weight proteins (*13*, *14*), and Kobayashi et al. previously reported that lysine coinjection can accelerate the renal excretion of Gd-chelated PAMAMG4 (*15*). Therefore, Gd-BzDTPA-lysineG3 can visualize the blood vessels longer than Gd-BzDTPA-PAMAMG4, but still can be excreted through the kidney. Since the G8 PAMAM-based dendrimer contrast agent with similar size to Gd-BzDTPA-lysineG3 is not excreted from the kidney, this pharmacokinetic characteristic of lysine-dendri-graft based MRI contrast agents is potentially advantageous.

In conclusion, we have synthesized nanosized MRI contrast agents using lysine-dendri-graft platforms and compared their physical and pharmacological characteristics with those of a PAMAM-based dendrimer contrast agent of comparable size. Nanosized MRI contrast agents using lysine-dendri-graft platforms showed different relaxivity characteristics from the PAMAM-based agents of the similar size. In addition to its biocompatibility, preferable physical characteristics and pharmacokinetics of nano-sized MRI contrast agents with lysine-dendri-graft, which are derived from different interior structures rather than the physical size, might make these agents clinically feasible.

Folate receptor-α (FR) is a promising cellular marker for tumor-specific drug delivery. Conjugation of folic acid to therapeutic and imaging agents has been shown to enhance their delivery to FR (+) cancer cells in vitro and in tumor-bearing mice via an FR-mediated cellular uptake mechanism. In this study, immunoglobulin G (IgG) was conjugated to folate and evaluated as a therapeutic antibody against folate receptor (FR)-positive tumors. Murine IgG (mIgG) was conjugated to folate via an amide bond to yield folate-conjugated mIgG (f-mIgG) that contained an average of ∼2.6 folates per molecule. Selective uptake of f-IgG by FR (+) tumor cells was determined by fluorescence microscopy and by flow cytometry. Lysis of L1210JF cells by NK cells from murine donors was increased 1.4−9.0-fold at the effector:target (E:T) ratio of 25:1, relative to control mIgG. In mice bearing L1210JF tumors, f-mIgG was found to significantly inhibit tumor growth and to have prolonged the median survival time (MeST). Significantly, the antitumor efficacy of f-mIgG was greatly increased when combined with liposomal G3139, an 18-mer phosphorothioate oligonucleotide. In fact, the combination resulted in a 100% cure rate among the tumor-bearing mice. Injection of f-mIgG significantly increased serum INF-γ and IL-6 level in mice compared with mIgG and dramatically increased serum INF-γ and IL-6 level when combined with liposomal G3139. These results suggested that f-IgG, a novel immunotherapy agent, has potent activity as a therapeutic antibody to the FR-positive cancer, and the therapeutic activity is enhanced by immunomodulatory agents.

INTRODUCTION

Folate receptor-α (FR) is a promising cellular marker for tumor-specific drug delivery, because it is up-regulated in many types of human epithelial cancers. These include tumors arising in the ovary, lung, kidney, mesothelium, head and neck, and brain (*1*−*5*). Conjugation of folic acid to therapeutic and imaging agents has been shown to enhance their delivery to FR(+) cancer cells in vitro and in tumor-bearing mice via an FR-mediated cellular uptake mechanism (*6*−*8*) and are currently being developed in the clinic by Endocyte Inc. Some folate conjugates have shown significant antitumor activities as immunotherapeutic agents (*9*−*12*). For example, folate−fluorescein was shown to eliminate FR(+) tumors in fluorescein-immunized mice (*11, 12*). Moreover, co-administration of interleukin 2 (IL-2) and interferon-α (IFN-α) was shown to enhance the therapeutic efficiency of the folate−fluorescein conjugate (*11*). In other studies, anti-FR-α monoclonal antibodies such as Mov-18 (*13, 14*) and MORAb-003 (Farletuzumab) (*15*) have been reported to target ovarian cancer and have undergone clinical evaluation as therapeutic agents with promising initial results. In addition, a folate-conjugated anti-TCR antibody was shown to re-target cytotoxic T lymphocytes to FR(+) tumors resulting in significant therapeutic activity (*16*−*18*).

G3139 (oblimersen or Genasense) is an 18-mer phosphorothioate oligonucleotide that was designed as an antisense agent against antiapoptotic factor bcl-2 (*19*−*21*). G3139 contains 2 CpG dinucleotides (*22*−*24*) and has been shown to induce a potent cytokine response, presumably through activation of toll-like receptor 9 (TLR9) (*25, 26*). Liposomal encapsulation of G3139 has recently been shown by us to further enhance the immunomodulatory effect of G3139 (*27*).

The objective of this study was to evaluate the therapeutic efficacy of folate conjugated IgG (f-IgG) as a therapeutic antibody against FR(+) tumors. F-mIgG conjugates was synthesized and evaluated in vitro as well as in vivo. Furthermore, the combined effect of f-mIgG and liposomal G3139 was also examined.

EXPERIMENTAL SECTION

Materials. Murine IgG (mIgG) was purchased from Equitech-Bio Inc. (Kerrville, TX). Folic acid, fluorescein isothiocyanate (FITC isomer I), *N*,*N*′-dicyclohexylcarbodiimide (DCC), and *N*-hydroxysuccinimide (NHS) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). G3139 was synthesized by Alpha DNA (Montreal, CA). Phosphatidylcholine from egg yolk (EPC), 3β-[*N*-(*N*′,*N*′-dimethylaminoethane)carbamoyl] cholesterol hydrochloride (DC-Chol), and methoxy-poly(ethylene glycol) (MW = 2000) distearoyl phosphatidylethanolamine (mPEG-DSPE) were purchased from Avanti Polar Lipids (Alabaster, AL). All chemicals used were of analytical or HPLC grade. Recombinant IL-2 with specific activity of 1×10^6 IU/mL was obtained from Hoffmann-La Roche Pharmaceuticals (Nutley, NJ).

Cell Lines. KB and K562 cells were purchased from American Type Culture Collection (Rockville, MD). L1210JF cells were provided by Dr. Manohar Ratnam at University of Toledo (Toledo, OH). KB, L1210JF cells were grown in folate-

free RPMI 1640 medium, and K562 cells were grown in RPMI1640 medium (Invitrogen Life Technologies Inc.). The media were supplemented with 10% heat-inactivated fetal bovine serum (FBS), 2 mM L-glutamine, 100 U/mL penicillin, and 100 mg/mL streptomycin. The cells were maintained in a humidified incubator at 37 °C in 5% CO_2.

Synthesis of Folate-Conjugated Antibodies. The f-IgG was synthesized as previously described (*28*) with minor modifications. Briefly, folate was reacted with *N*,*N*′-dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) in DMSO at molar ratios of folate/DCC/NHS = 1/1.5/1.1 for 3 h at room temperature. The product f-NHS was centrifuged to remove byproducts and then was added to IgG in a pH 8.0 PBS buffer solution at a folate-to-IgG molar ratio of 12:1 for 2 h at room temperature. For the preparation of FITC labeled f-IgG (f-IgG-FITC) or IgG (IgG-FITC), 5× FITC dissolved in a small volume of DMSO was added to the protein solution at pH 8. To purify the conjugates, the reaction mixture was passed through a PD-10 column equilibrated in PBS (pH 8.0) and the product was collected in the void volume fractions. Folate content of the product was determined by UV spectrometry at 371 nm, and the antibody protein concentration was determined using the Pierce BCA Protein Assay Kit. A synthetic scheme is described in Figure 1.

Uptake of f-IgG-FITC by Tumor Cells. The cellular uptake of f-IgG was determined in FR(+) KB, L1210JF, and FR(-) K562 cells. Approximately 1×10^6 cells were incubated with 200 nM FITC labeled IgG or f-IgG in 1 mL folate-free RPMI1640 at 37 °C for 30 min. The cells were then washed three times with cold PBS containing 1% BSA and examined by fluorescence microscopy or by flow cytometry. For receptor blocking studies, 200 μM of free folate was added to media during f-IgG-FITC exposure.

Antibody Dependent Cellular Cytotoxicity (ADCC) Mediated by f-IgG in L1210JF Cells. Murine NK cells were isolated from splenocytes of DBA/2 mice (Charles River, Wilmington, MA) via mechanical digestion followed by lysis of red blood cells. Spleenocytes were then incubated with phycoerythrin-labeled anti-DX5 antibody (BD PharMingen, San Diego, CA) for 30 min at 4 °C. Following this, the cells were washed and incubated with antiphycoerythrin antibody-coated magnetic microbeads (Miltenyi Biotech, Auburn, CA) for an additional 30 min at 4 °C according to the instructions of the manufacturer. NK cells were isolated via positive selection through an LS+ magnetic column (Miltenyi Biotech). Isolated murine NK cells were >90% $DX5^+$ by FACS analysis. Purified murine NK cells were plated in 96-well V-bottom plates in 10% HAB containing glutamine free, folate-free RPMI 1640 medium supplemented with a low dose of IL-2 (1 nM), and incubated overnight at 37 °C. For ADCC assays, mIgG or f-mIgG treated, ^{51}Cr-labeled L1210JF tumor cells were added to NK cells at effector:target (E:T) ratios of 25:1 and 12.5:1 and 6.25:1, and cytotoxic interactions were allowed to proceed for 4 h at 37 °C. Target cell lysis was determined by counting 100 μL of supernatant in a scintillation counter after removal of intact cells by centrifugation. Spontaneous and maximum lysis were determined by incubating radiolabeled target cells in the absence of effector cells or by adding 10% SDS to the radiolabeled target cells, respectively. The percentage of cell lysis was calculated by the following formula: Lysis (%) = 100 × (experimental release − spontaneous release)/(maximal release − spontaneous release).

Preparation of Liposomal G3139. Liposomes containing G3139 were prepared by the EtOH dilution/diafiltration method, as described previously (*27*). DC-Chol, egg PC, and mPEG-DSPE were dissolved in ethanol and mixed at a molar ratio of 30:65:5. The lipid mixture (20 mg/mL) was mixed with protamine solution in citrate buffer (pH 4.0, 20 mM) and then slowly added to G3139 solution in citrate buffer (pH 4.0, 20 mM) under vortex mixing to achieve a final ethanol concentration of 40% and a G3139, lipid, and protamine ratio of 1:12.5:0.3 (w/w/w). The preparation was then dialyzed against citrate buffer (pH 4.0, 20 mM) for 1 h and then against HEPES-buffered saline (HBS, pH 7.5) overnight to remove ethanol. Final product was stored at 4 °C before use. The mean particle size was determined by dynamic light scattering on a Nicomp model 370 Submicrometer Particle Sizer (Particle Sizing Systems, Santa Barbara, CA). Zeta potential (ζ) of liposomal G3139 was measured on a Brookhaven 90plus Particle Analyzer (Holtsville, NY).

Therapeutic Efficacy in Murine Leukemia Model. Therapeutic efficacy in murine leukemia model was evaluated in DBA/2 mice (Charles River, Wilmington, MA). Female mice (18−22 g) were injected subcutaneously on day 0 with 1×10^6 L1210JF cells and then randomized to different treatment groups to eliminate cage effects. Before leukemia cell inoculation, mice were placed on a folate-free diet (AIN-90G, Dyets, Bethlehem, PA) for 1 week. Normal rodent chow was not used because it contains approximately 3.19 mg/kg folic acid, which leads to supra-physiological serum folate concentration. When a tumor reached a volume of ~25 mm^3, the mice were treated with the desired immunotherapy regimens 4 times every 4 days (q4dx4). In the first treatment regimen, mice were given 100 mg/kg mIgG or f-mIgG intraperitoneally. In the second treatment regimen, mice were treated with 1 mg/kg free G3139 or liposomal G3139. In the third treatment regimen, mice were given 100 mg/kg f-mIgG combined with free G3139 or liposomal G3139. Tumor dimensions were determined by measuring with a caliper, and the tumor volume (in mm^3) was calculated by the formula 0.5 × (length × width × height). Mice were sacrificed once the tumor size reached greater than 1500 mm^3. Tumor inhibition ratio was calculated by $(C - T)/C \times 100\%$, where T and C represent the mean tumor volume of the treated and control animals, respectively. Animal survival was evaluated by Kaplan−Meier analysis and increase-in-

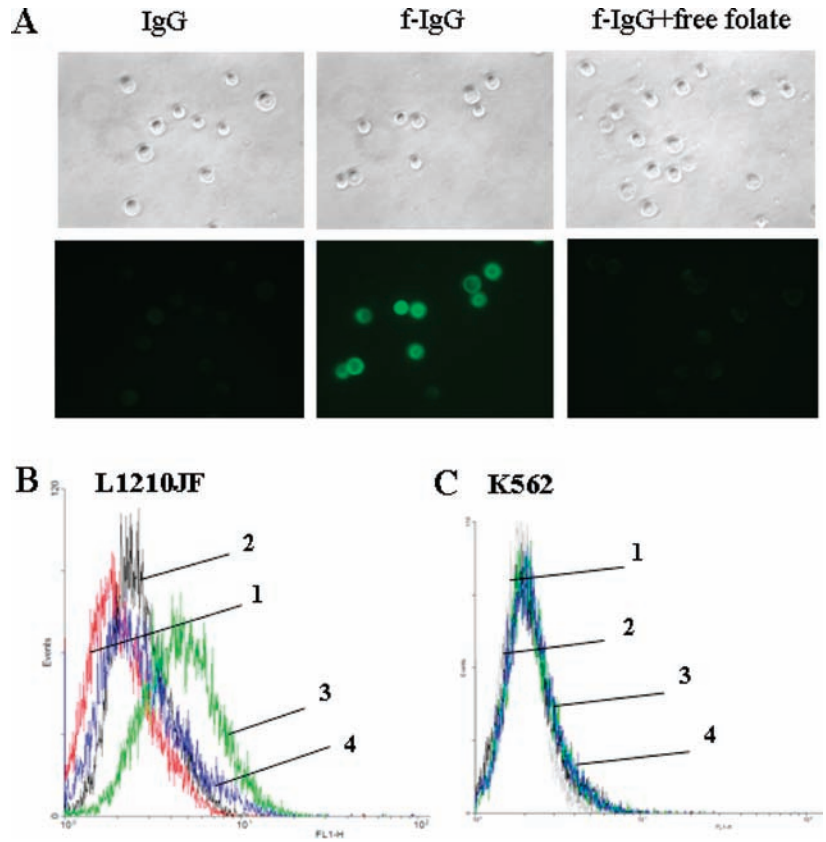

Figure 2. Uptake of f-IgG-FITC in KB (A), L1210JF (B), and K562 (C) cells. Cells were treated with 200 nM FITC labeled IgG or f-IgG in folate-free RPMI1640 at 37 °C for 30 min. For the receptor blocking study, 200 μM of free folate was added to media during f-IgG-FITC exposure. f-IgG-FITC binding in KB cells by fluorescence microscopy. After treatment, KB cells were photographed in both phase-contrast (upper panels) and fluorescence (lower panels) mode on a Nikon Eclipse 800 fluorescence microscopy. Uptake of f-IgG-FITC in L1210JF and K562 cells by flow cytometry. (1) Untreated cells. (2) Cells were treated with IgG-FITC. (3) Cells were treated with f-IgG-FITC. (4) Cells were treated with f-IgG-FITC and free folate.

lifespan (ILS, %) was calculated by ILS = (mean survival time of the treated mice/mean survival time of control mice − 1) × 100%.

Serum Cytokine Levels in Murine Leukemia Model. The serum cytokine levels were investigated in L1210JF tumor-bearing DBA/2 mice (Charles River, Wilmington, MA). Before leukemia cell inoculation, mice were placed on a folate-deficient diet (AIN-90G, Dyets, Bethlehem, PA) for at least 1 week. At 5 days after tumor cells inoculation, the mice were injected intraperitoneally with 100 mg/kg mIgG and f-mIgG. For the therapeutic combination study, f-mIgG was intraperitoneally administered with free G3139 or liposomal G3139. Blood samples were collected at 2, 6, and 24 h after injection. Serum was obtained by centrifugation of blood samples at 7000 × *g* for 10 min and stored −20 °C until the time of assay. IL-6 and INF-γ was determined by ELISA Ready-Set-Go kits.

Statistical Analysis. Statistical analysis of survival data was performed using the log-rank test. Comparisons between groups were made by Student's *t* tests using the MiniTAB software (Minitab Inc., State College, PA). Difference in survival or tumor growth were considered significant when the *p* value was <0.05.

RESULTS

Characterization of f-IgG Conjugates. The concentrations of IgG and folate were determined by BCA protein assay and UV spectrometry at 371 nm, respectively. Conjugation reactions performed at IgG-to-folate-NHS ratios of 12:1 and 100:1 yielded preparations containing an average molar ratio of 2.6 folates per IgG and 9.0 folates per IgG, respectively. Because excessive folate conjugation may adversely affect the effector function of the IgG, a lower conjugation level was desirable. Therefore, f-IgG with the lower conjugation level was selected for subsequent studies. The presence of folate on IgG was further confirmed by MALDI-TOF mass spectroscopy (data not shown).

To evaluate the FR targeting efficiency of f-IgG, tumor cell uptake of f-IgG-FITC was determined by fluorescence microscopy or by flow cytometry. In FR(+) KB cells, f-IgG-FITC was shown to be taken up much more compared to IgG-FITC (Figure 2A). The uptake of f-IgG-FITC was blocked by 200 μM free folate (Figure 2A). The results from flow cytometry were consistent with those obtained by fluorescence microscopy. In FR(+) murine L1210JF cells, incubation of f-IgG-FITC with cells resulted in greater fluorescence intensity compared with that of cells treated with IgG-FITC (Figure 2B). No increased fluorescence was observed when cells were incubated with f-IgG-FITC in the presence of 200 μM free folate (Figure 2B). In contrast, in FR(-) K562 cells, the uptake of f-IgG-FITC and of IgG-FITC were similar, and the uptake was not affected by 200 μM free folate (Figure 2C). These results indicated that f-IgG-FITC selectively targeted FR (+) tumor cells and was taken up via the FR.

F-IgG Enhanced NK Mediated ADCC against L1210JF Cells. The effects of f-IgG on NK cell lytic activity were examined in an ADCC assay using L1210JF tumor cells as targets. Murine NK cells were activated overnight in medium supplemented with IL-2 (1nM). These cells were then used as effectors against ^{51}Cr labeled target cells that were treated with either mIgG or f-mIgG. As shown in Figure 3A, f-IgG markedly enhanced the ADCC activity of NK cells at all E:T ratios

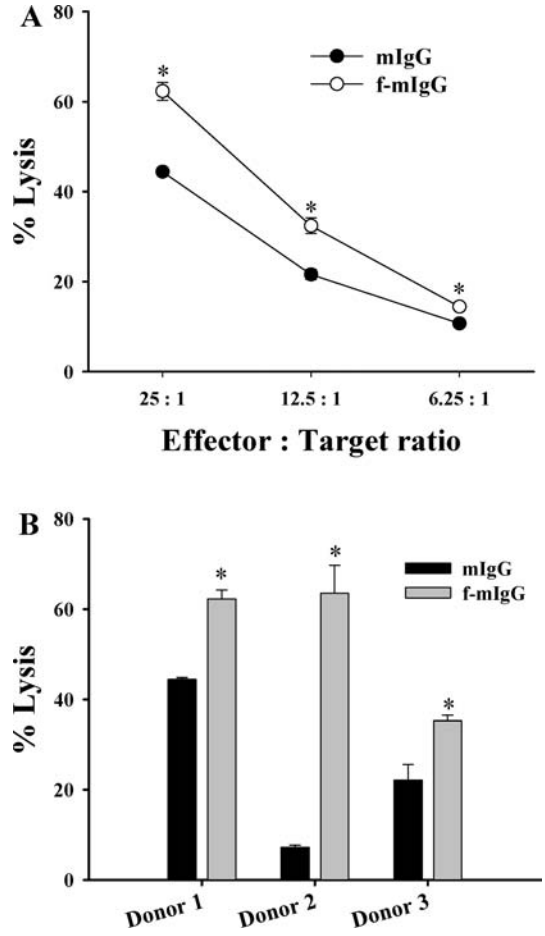

Figure 3. Effect of f-IgG on ADCC activity against FR-positive L1210JF cells at different effector:target ratio (A) and different donor from different mice (B). The NK cell lytic activity was assessed in a standard 4 h chromium release assay using f-mIgG-coated L1210JF cancer cells. The percentage of lysis was calculated as described in Experimental Section. Data represent the mean ± SD ($n = 3$).

examined compared with IgG (Figure 3A). Similar results was observed at E:T ratio of 25:1 for each of the three donors (Figure 3B). However, a relatively large variation was observed among different donors, presumably due to the variability in effector cell activities from different mice.

Characterization of Liposomal G3139. Liposomes containing G3139 was prepared by the EtOH dilution/diafiltration method. The G3139 liposomes showed mean diameter of 92.4 ± 43.6 nm, encapsulation efficiencies of >95%, and zeta potential of 5.02 ± 0.4 mV.

Therapeutic Activity of f-IgG in the Murine Leukemia Model. f-IgG was evaluated in the FR (+) L1210JF murine leukemia model. Mice bearing L1210JF tumors of ~25 mm^3 in size were treated with PBS, 100 mg/kg of mIgG, or 100 mg/kg of f-mIgG by intraperitoneal injection every 4 days for a total of 4 injections. The mice treated with f-mIgG had 59.6% reduction in tumor volume by day 24 after the engraftment of L1210JF cells compared with mIgG treated mice ($p < 0.05$) (Figure 4A). However, tumor-bearing mice treated with mIgG did not show any difference in tumor volume compared to the mice treated with PBS. The median survival time (MeST) for PBS, mIgG, or f-mIgG groups was 24, 27, and 39 days, respectively (Figure 4B, Table 1). Percentage ILS values are 62.5% for f-mIgG and 12.5% for mIgG. Moreover, 1 out of 5 mice was completely cured following treatment with f-mIgG (Figure 4B). The data indicated that f-IgG was more therapeutically effective than IgG or PBS in inhibiting tumor growth and prolonging animal survival ($p = 0.004\,01$; by log-rank test).

In order to investigate whether the anticancer activity was due to FR targeting, anticancer activity of f-mIgG was evaluated in the FR (-) L1210 murine leukemia model. As shown in Figure 4C, f -mIgG slightly decreased tumor volume by day 23 after the engraftment of L1210 cells compared with mIgG and PBS, although no significant differences were observed among f-mIgG, mIgG, and PBS. The median survival times (MeST) for PBS, mIgG, and f-mIgG were 25, 28, and 28, respectively. Similar to data on tumor inhibition, survival time was not significantly prolonged by treatment of f-mIgG compared with mIgG ($p = 0.535$; by log-rank test). Taken together, these results suggested that anticancer activity of f-mIgG in FR positive L1210JF tumor-bearing mice was likely due to the FR targeting.

Therapeutic Efficacy of Liposomal G3139 in Murine Leukemia Model. Previous studies have shown that the cellular uptake and the immunomodulatory effect of G3139 can be significantly enhanced when delivered in a liposomal form (*29*). In order to compare the antitumor efficacy of free G3139 and liposomal G3139, mice carrying L1210JF tumors were treated with 1 mg/kg of G3139 in free form or in liposomal form. As shown in Figure 5, tumor-bearing mice treated with liposomal G3139 had a 45.5% reduction in tumor volume compared with PBS-treated mice ($p < 0.05$). In contrast, free G3139 did not decrease tumor growth compared with PBS. The median survival times (MeST) for PBS, free G3139, or liposomal G3139 were 24, 36, and 36 days, respectively (Figure 5). However, there was no significant difference between free G3139 and liposomal G3139 ($p = 0.252$; by log-rank test). These data suggested that liposomal G3139 was more effective than free G3139 or PBS in mediating tumor regression but not in prolonging survival time of mice compared with free G3139.

Synergistic Effect of f-IgG Combined with Liposomal G3139. Loomis et al. (*30*) has shown that antitumor efficacy of G3139 significantly increased when combined with rituximab, a monoclonal antibody directed against CD20 in a SCID mouse xenograft model. Since f-IgG is being evaluated as a therapeutic antibody, we examined the antitumor efficacy of free and liposomal G3139 coadministered with mIgG or f-mIgG in the murine L1210JF leukemia model. Treatment of IgG combined with liposomal G3139 significantly increased MeST of the mice compared with the treatment of IgG combined with free G3139 (data not shown). With regard to tumor growth inhibition, liposomal G3139 further increased the antitumor efficacy of f-IgG (Figure 5A, Table 1). Importantly, all of the mice were rendered tumor-free after combined treatment with liposomal G3139 and f-IgG (Figure 5B). In comparison, less impressive 20% and 25% cure rates were observed following treatment with f-mIgG alone and following combined treatment with f-mIgG and free G3139, respectively (Figure 5B). These data indicate a strong synergistic effect between f-IgG and liposomal G3139.

Serum Cytokine Levels in Murine Leukemia Model. In order to investigate the effect of cytokine production on anticancer activity, the serum cytokine was determined in DBA/2 mice after administration of mIgG or f-mIgG and combined with free G3139 or liposomal G3139. As shown in Figure 6, levels of INF-γ peaked at 8 h, while levels of IL-6 peaked at 2 h. After 24 h, all cytokine levels were diminished. Compared with mIgG, f-mIgG showed significant cytokine (INF-γ and IL-6) production (Figure 6A,B). In combination with free G3139 and liposomal G3139, f-mIgG induced 2.3-fold and 6.1-fold higher INF-γ production than f-mIgG alone at 6 h postinjection, respectively. Similar results were observed from IL-6 induction in L1210JF murine leukemia model. These data suggested that increased uptake of f-mIgG might elevate the

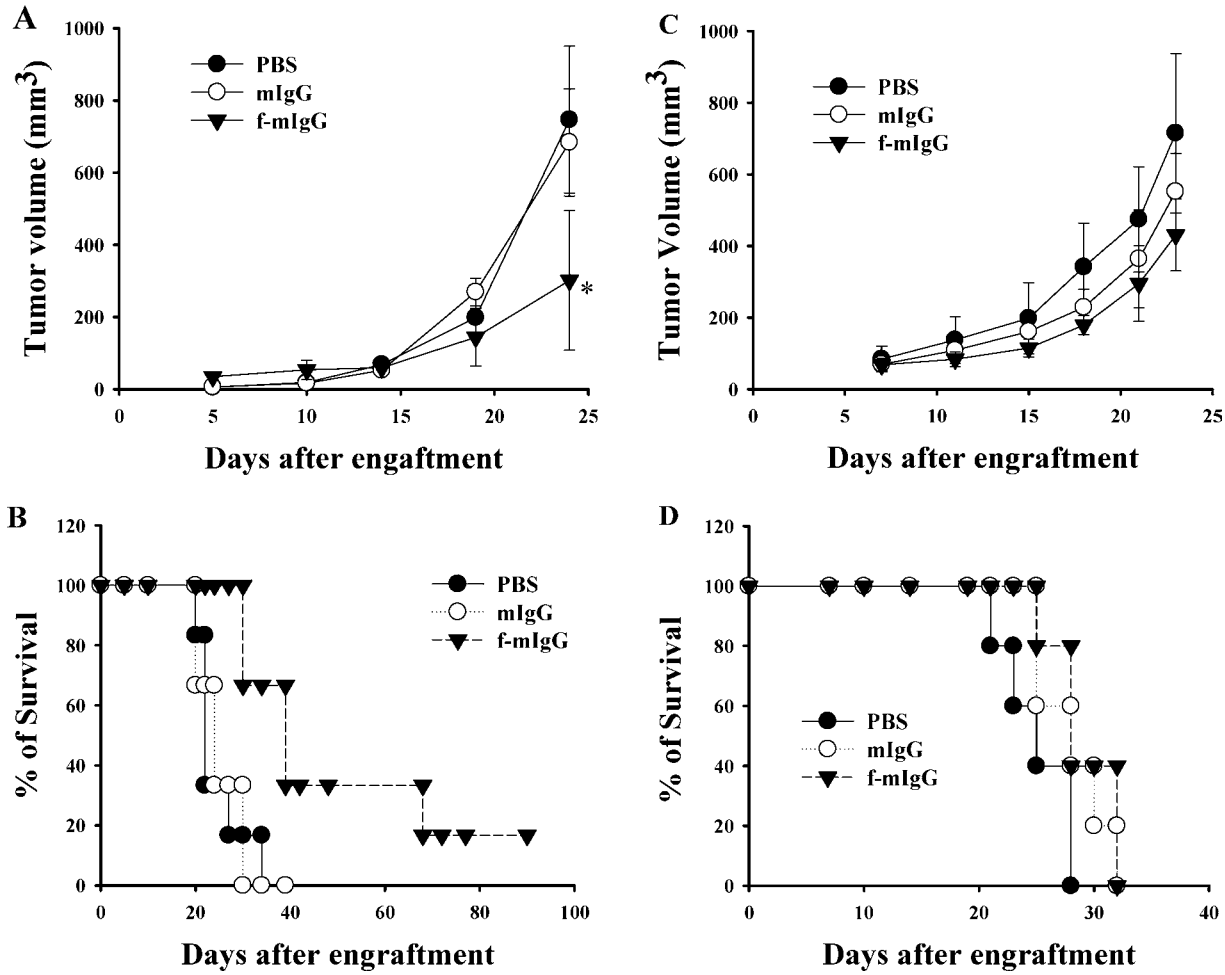

Figure 4. In vivo efficacy of folate receptor mediated immunotherapy in L1210JF (A,B) and L1210 (C,D) bearing DBA/2 mice. Mice (5−6 per group) were implanted subcutaneously on day 0 with 1×10^6 L1210JF cells. On day 5 or 7, animals were treated with 100 mg/kg of mIgG or f-mIgG. The treatment was continued every 4 days for four times. (A,C) Inhibition of tumor growth. Tumor dimensions were measured every 2 days using calipers. (B,D) Survival of L1210JF and L1210 tumor-bearing mice after treatment with mIgG or f-mIgG. PBS was injected as a vehicle control. (*, $P < 0.01$ compared with PBS group.)

Table 1. Survival of Mice after Treatment with mIgG and f-mIgG Alone or in Combination with Free or Liposomal G3139 (L-G3139) in L1210JF Tumor-Bearing Mice[a]

treatment	tumor inhibition ratio[b] (%)	MeST (days)	ILS[c] (%)	Log-rank *p* value
PBS	0	24	0	-
mIgG	8.4	27	12.5	0.901
f-mIgG	59.6	39	62.5	0.00401
G3139	5.6	36	50.0	0.0209
L-G3139	45.5	36	50.0	0.00804
f-mIgG+G3139	83.1	70	191.7	0.000495 (0.198)[d]
f-mIgG+L-G3139	100.0	∞	∞	0.000495 (0.00432)[d]

[a] $n = 6$ for each treatment group. [b] Tumor inhibition ratio was calculated by $(C - T)/C \times 100\%$, where T and C represent the mean tumor volume of the treated and control mice, respectively. [c] ILS(%) was calculated by (MeST of the treated mice/MeST of control mice − 1) × 100%, where MeST represents the mean survival time. [d] The *p* value was calculated in comparison to f-mIgG.

level of cytokines and combined with liposomal G3139 more potently increased the level of cytokines.

DISCUSSION

FR is a promising target for tumor-specific drug delivery. In this study, we describe a novel immunotherapy agent that combines the FR-targeting properties of folate and the effector functions of the IgG. Although folate−hapten's activities have been reported previously (*11*, *12*), that strategy involves preimmunization of the animal and in vivo coupling of the folate−hapten and the endogenous antihapten antibody, which may present an challenging issue. The f-IgG strategy is more analogous to FRα monoclonal antibodies such as MOv-18 (*13*, *14*) and Morab-003 (*15*) currently under clinical development. Compared with FRα monoclonal antibodies, f-IgG targets both FR subtypes, and the underlying IgG used is human and polyclonal, which may be less immunogenic.

f-IgG showed much stronger antitumor effect than IgG in the FR(+) L1210JF tumor-bearing mice (Figure 4A,B) but not in the FR(-) L1210 tumor-bearing mice (Figure 4C,D). These results presumably were due to FR-mediated tumor cell targeting. Tissue toxicity and splenomegaly was not founded by treatment of f-IgG in tumor-bearing mice. Selective folate receptor binding was also observed in the FR(+) L1210JF and KB cells in vitro (Figure 3). Besides folate receptor binding, Fc receptor (FcR) is critical in f-IgG mediated immunotherapy (*31*). FcR-expressing immune cells that recognize a constant (Fc) region of IgG and induce immune response such as ADCC, phagocytosis, neutrophil activation, and the paradoxical inhibition of B cell activation (*31*−*34*). The potential role of NK cell-mediated ADCC of f-IgG was examined. The results showed that lysis of L1210JF tumor cells by NK cells was increased 1.4−9.0-fold by treatment of f-IgG as compared with IgG (Figure 3). In contrast, f-IgG did not bind to FR(-) cell lines (e.g., A549 human alveolar basal epithelial) and did not enhance their lysis by NK cells (data not shown). These results suggested

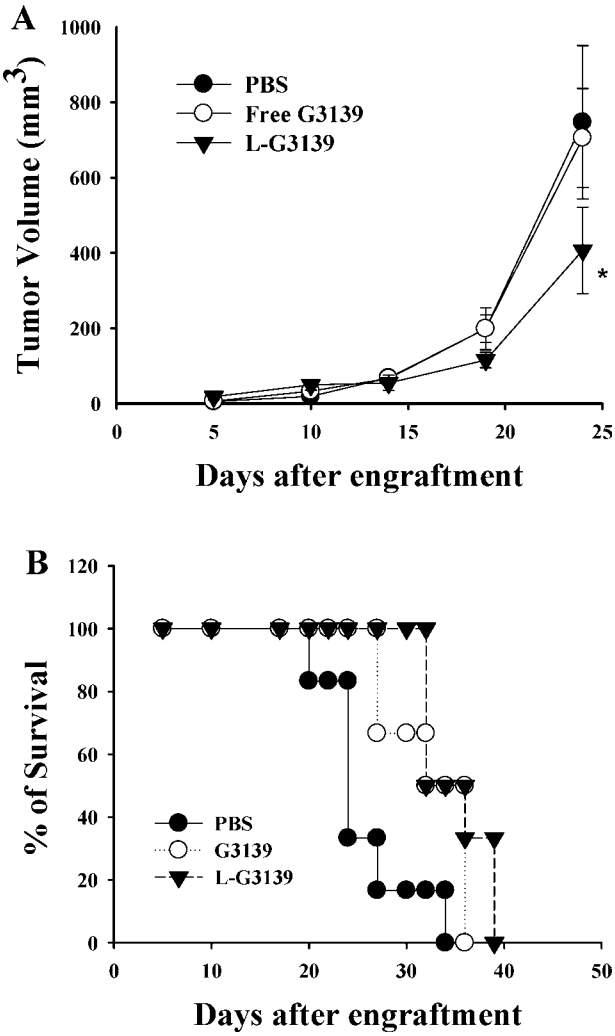

Figure 5. In vivo antitumor efficacy of G3139 in L1210JF bearing DBA/2 mice. Mice (6 per group) were implanted subcutaneously on day 0 with 1×10^6 L1210JF cells. On day 5, animals were treated with with 1 mg/kg of free G3139 or liposomal G3139. The treatment was continued every 4 days for four times. (A) Inhibition of tumor growth. Tumor dimensions were measured every 2 days using caliper. (B) Survival of L1210JF bearing mice after treatment with free G3139 or liposomal G3139. PBS was injected as a vehicle control. (*; $P < 0.05$ compared with PBS group.)

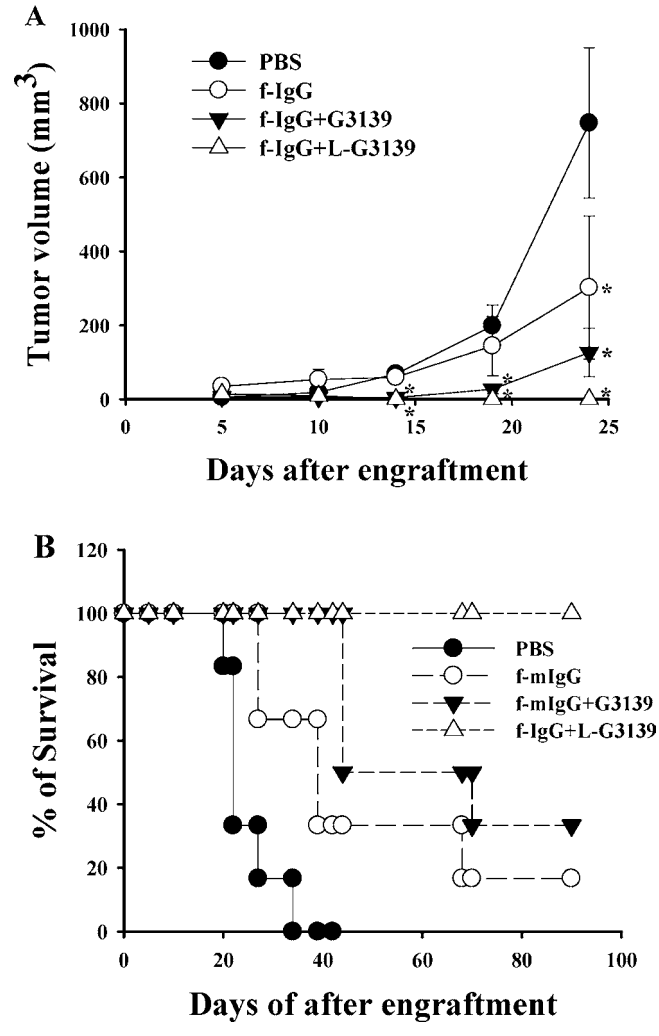

Figure 6. In vivo antitumor efficacy of f-mIgG combined with free G3139 or liposomal G3139 in L1210JF bearing DBA/2 mice. Mice (6 per group) were implanted subcutaneously on day 0 with 1×10^6 L1210JF cells. On day 5, animals were treated with 100 mg/kg of f-mIgG alone or combined with 1 mg/kg of free G3139 or liposomal G3139. The treatment was continued every 4 days for four times. (A) Inhibition of tumor growth. Tumor dimensions were measured every 2 days using caliper. (B) Survival of L1210JF bearing mice after treatment with free G3139 or liposomal G3139. that NK-mediated ADCC was FR-specific. Moreover, we demonstrated enhanced INF-γ production by NK cells when NK cells were co-cultured with f-IgG coated FR(+) tumor cells (*35*). Consistent with this, high levels of INF-γ and IL-6 were observed in the FR(+) tumor-bearing mice after administration of f-IgG compared with IgG (Figure 6), indicating that increased binding of f-IgG to tumor might elevate the level of cytokines. These results suggested that f-IgG might form a bispecific molecular bridge between the FR(+) tumor cells and immune effector cells that mediates tumor cell killing, through NK cell ADCC and cytokine production by NK cells, i.e., the same mechanism of a therapeutic antibody. A similar mechanism was reported by Lu et al. with a combination of a folate−hapten conjugate and endogenous antihapten antibody (*11, 12*). Therefore, the potent anticancer activity of f-IgG in FR(+) tumor-bearing mice observed was likely the result of FcR mediated ADCC and cytokine production, stimulated by f-IgG coated tumor cells via the bispecific molecular bridge. In addition, activated macrophages are known to express folate receptor (*36, 37*). Recently, Turk and Low showed that livers and spleens of tumor-bearing mice preferentially accumulated folate-targeted liposomes, presumably due to the FR-mediated targeting of agents to macrophages in livers and spleens (*38, 39*). Therefore, cytokine production by f-IgG accumulated macrophages in liver and spleen may also contribute to the anticancer activity of f-IgG in tumor-bearing mice. This mechanism remains to be investigated in the future studies.

G3139 was originally designed as a human bcl-2 mRNA antisense and has been investigated in phase I to III clinical trials as a monotherapy or combination with chemotherapy for treatment of chronic lymphocytic leukemia (CLL) (*40, 41*). Importantly, G3139 contains two CpG motifs, which have been shown to activate cytokine production via TLR9 (*25*). We therefore hypothesized that G3139 administration could enhance the antitumor effects of f-IgG. Free G3139 or liposomal G3139 have been shown to prolong animal survival. Compared to free G3139, liposomal G3139 was shown to be significantly more active in tumor inhibition (Figure 5). Recent studies in our lab have demonstrated that liposomal G3139 significantly increased plasma concentration of IFN-γ and IL-6 in mice, and increased proliferation of the DCs and NK cells (*27*). In contrast, no down-regulation of bcl-2 in murine L1210JF cells was observed, presumably due to sequence mismatches between G3139 and

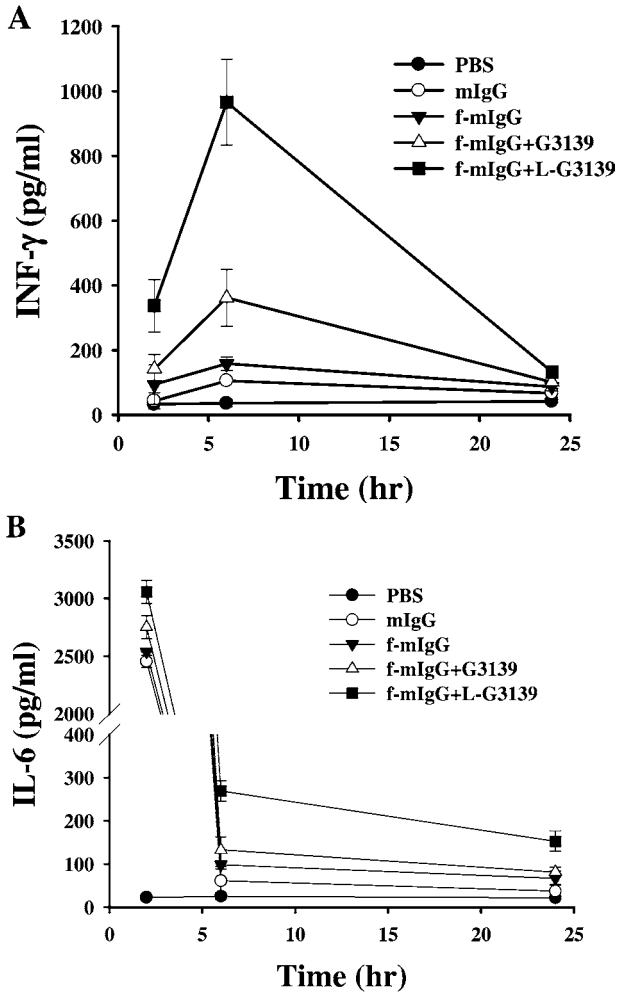

Figure 7. In vivo serum INF-γ (A) and IL-6 (B) production in L1210JF tumor-bearing mice. The tumor-bearing mice were treated with mIgG, f-mIgG alone or in combination with free or liposomal G3139. Blood samples were collected at 2, 6, and 24 h after injection. Serum was obtained by centrifugation and analyzed for INF-γ and IL-6 content by ELISA.

murine bcl-2 (*27*). These results suggested that the antitumor activity was not due to bcl-2 down-regulation but rather the immunomodulatory effect of G3139, which was amplified by liposomal delivery.

Moreover, a strong synergistic antitumor activity was observed when liposomal G3139 was used in combination with f-IgG (Figure 5). Consistent with this result, serum cytokine (INF-γ and IL-6) level was dramatically increased when f-IgG was combined with liposomal G3139 than combined with free G3139 (Figure 6). These results suggested that the synergic antitumor activity was due to the synergistically amplified cytokine (INF-α and IL-6) production in combination with liposomal G3139 and f-IgG. These results were consistent with previous reports (*11*), in which ADCC-activating cytokines such as interleukin 2 (IL-2) or interferon-alpha (IFN-α) have been shown to synergize with the folate receptor targeted immunotherapy.

CONCLUSIONS

F-IgG was shown to specifically target FR(+) tumor cells and be more effective against tumor compared to IgG in a murine tumor model. Moreover, the antitumor efficacy and the serum cytokine level were synergistically increased when co-administrated with liposomal G3139. A series of immunological assays indicated f-IgG's ability to mediate ADCC and cytokine production by immune cells. Therefore, f-IgG exhibits the characteristics of a therapeutic antibody. In addition, folate targeted f-IgG immunotherapy, combined with liposomal G3139, is a promising strategy for treatment of FR(+) cancers.

Evaluation of ^{111}In-Labeled Cyclic RGD Peptides: Tetrameric not Tetravalent

Sudipta Chakraborty,[†] Jiyun Shi,[†,‡] Young-Seung Kim,[†] Yang Zhou,[†] Bing Jia,[‡] Fan Wang,[‡] and Shuang Liu*[,†]

School of Health Sciences, Purdue University, Indiana 47907, and Medical Isotopes Research Center, Peking University, Beijing 100191, China. Received December 14, 2009; Revised Manuscript Received March 17, 2010

This report presents the synthesis and evaluation of ^{111}In(DOTA-6G-RGD$_4$) (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracetic acid; 6G-RGD$_4$ = E{G$_3$-E[G$_3$-c(RGDfK)]$_2$}$_2$ and G$_3$ = Gly-Gly-Gly), ^{111}In(DOTA-RGD$_4$) (RGD$_4$ = E{E[c(RGDfK)]$_2$}$_2$) and ^{111}In(DOTA-3G-RGD$_2$) (3G-RGD$_2$ = G$_3$-E[G$_3$-c(RGDfK)]$_2$) as new radiotracers for imaging integrin $\alpha_v\beta_3$-positive tumors. The IC$_{50}$ values of DOTA-6G-RGD$_4$, DOTA-RGD$_4$, and DOTA-3G-RGD$_2$ were determined to be 0.4 ± 0.1, 1.4 ± 0.1 and 1.1 ± 0.1 nM against ^{125}I-c(RGDyK) bound to integrin $\alpha_v\beta_3$-positive U87MG human glioma cells. ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) were prepared by reacting ^{111}InCl$_3$ with the respective DOTA conjugate in NH$_4$OAc buffer (100 mM, pH = 5.5). Radiolabeling could be completed by heating the reaction mixture at 100 °C for 15−20 min. The specific activity was ∼1850 MBq/μmol for ^{111}In(DOTA-3G-RGD$_2$) and ∼1480 MBq/μmol for ^{111}In(DOTA-6G-RGD$_4$). The athymic nude mice bearing U87MG human glioma xenografts were used to evaluate tumor uptake and excretion kinetics of ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$). The results from both the integrin $\alpha_v\beta_3$ binding assay and biodistribution studies suggest that the tetrameric cyclic RGD peptides, such as RGD$_4$ and 6G-RGD$_4$, are most likely bivalent in binding to the integrin $\alpha_v\beta_3$. Both ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) had significantly higher tumor uptake than ^{111}In(DOTA-3G-RGD$_2$) at 24−72 h postinjection due to the extra RGD motifs in RGD$_4$ and 6G-RGD$_4$. ^{111}In(DOTA-3G-RGD$_2$) had very little metabolism, while ^{111}In(DOTA-6G-RGD$_4$) had significant metabolism during its excretion via both renal and hepatobiliary routes over the 2 h period, probably due to its much larger size. The combination of high tumor uptake with long tumor retention suggests that their corresponding ^{90}Y and ^{177}Lu analogues M(DOTA-6G-RGD$_4$) (M = ^{90}Y and ^{177}Lu) might be useful as therapeutic radiotracers for treatment of integrin $\alpha_v\beta_3$-positive solid tumors.

INTRODUCTION

Radiolabeled cyclic RGD (Arg-Gly-Asp) peptides represent a new class of radiotracers that target the integrin $\alpha_v\beta_3$ overexpressed on both tumor cells and activated endothelial cells of the neovasculature during tumor growth, invasion, and metastasis (*1*−*9*). Over the past several years, many multimeric cyclic RGD peptides, such as E[c(RGDfK)]$_2$ (RGD$_2$) and E{E[c(RGDfK)]$_2$}$_2$ (RGD$_4$), have been used to maximize the integrin $\alpha_v\beta_3$ binding affinity and improve the radiotracer tumor uptake (*10*−*30*). The results from in vitro assays, ex vivo biodistribution, and in vivo imaging studies clearly demonstrated that radiolabeled (^{99m}Tc, ^{18}F, ^{64}Cu, and ^{68}Ga) cyclic RGD peptide tetramers, such as E{E[c(RGD*x*K)]$_2$}$_2$ (*x* = f and y), have better tumor targeting capability as evidenced by their higher tumor uptake and longer tumor retention times than their dimeric and monomeric counterparts (*25*, *26*, *29*, *30*). In our previous studies (*31*−*37*), we found that RGD$_2$ was monodentate while PEG$_4$-E[PEG$_4$-c(RGDfK)]$_2$ (3P-RGD$_2$: PEG$_4$ = 15-amino-4,7,10,13-tetraoxapentadecanoic acid) and (G$_3$-E[G$_3$-c(RGDfK)]$_2$ (3G-RGD$_2$: G$_3$ = Gly-Gly-Gly) were bivalent due to the longer distance between two RGD motifs. However, it remains unclear if the cyclic RGD tetramers, such as RGD$_4$, are tetravalent in binding to integrin $\alpha_v\beta_3$.

To answer this fundamental question, we prepared a new RGD tetramer conjugate, DOTA-E{G$_3$-E[G$_3$-c(RGDfK)]$_2$}$_2$ (Figure 1: DOTA-6G-RGD$_4$, DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and its ^{111}In complex ^{11}In(DOTA-6G-RGD$_4$). A competitive displacement assay was used to determine the integrin $\alpha_v\beta_3$ binding affinity of DOTA-3G-RGD$_2$, DOTA-RGD$_4$, and DOTA-6G-RGD$_4$ against ^{125}I-c(RGDyK) bound to the integrin $\alpha_v\beta_3$-positive U87MG glioma cells. Biodistribution and imaging studies were carried out in athymic nude mice bearing U87MG glioma xenografts. For comparison purposes, we also evaluated DOTA-RGD$_4$, DOTA-3G-RGD$_2$,^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) using the same assays. The comparison of IC$_{50}$ values of DOTA-3G-RGD$_2$, DOTA-RGD$_4$, and DOTA-6G-RGD$_4$ and tumor uptake of ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) will allow us to determine the valency of RGD$_4$ and 6G-RGD$_4$.

EXPERIMENTAL SECTION

Materials and Instruments. Chemicals were purchased from Sigma/Aldrich (St. Louis, MO). Cyclic RGD peptide 3G-RGD$_2$ was purchased from the Peptides International, Inc. (Louisville, KY). DOTA-OSu (1,4,7,10-tetraazacyclododecane-4,7,10-triacetic acid-1-acetate-(*N*-hydroxysuccinamide)) was purchased from Macrocyclics (Dallas, TX). DOTA-3G-RGD$_2$ and DOTA-RGD$_4$ were prepared according to the literature methods (*14*, *26*, *33*). MALDI (matrix assisted laser desorption ionization) mass spectral data were collected using an Applied Biosystems Voyager DE PRO mass spectrometer (Framingham, MA), Department of Chemistry, Purdue University. ^{111}InCl$_3$ was obtained from Perkin-Elmer Life and Analytical Sciences (North Billerica, MA). The NH$_4$OAc buffer for ^{111}In-labeling studies

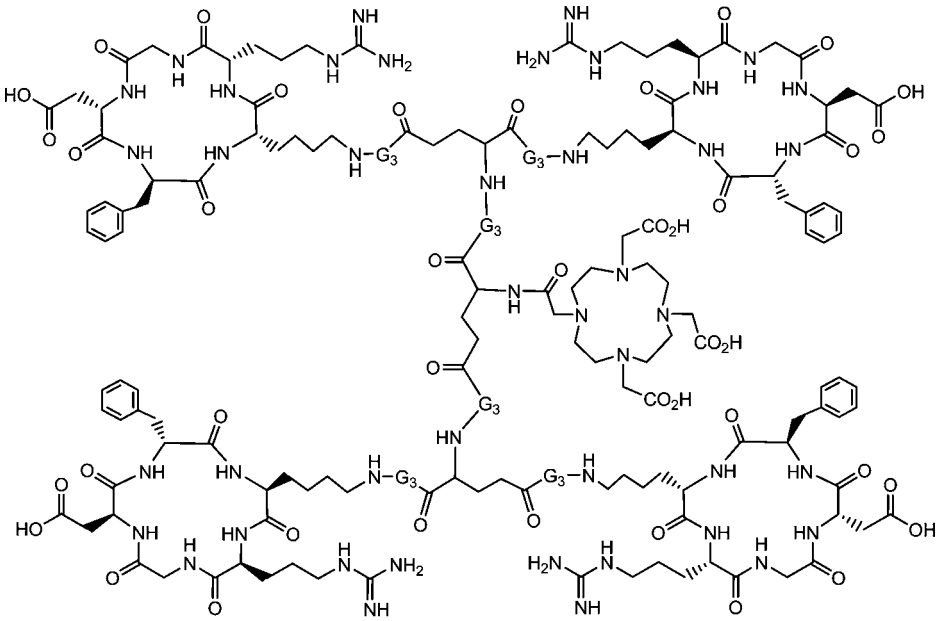

Figure 1. Structure of a new cyclic RGD tetramer conjugate: DOTA-6G-RGD_4.

was passed over a Chelex-100 column (1 × 15 cm) to minimize the trace metal contaminants.

HPLC Methods. Method 1 used a LabAlliance HPLC system equipped with a UV/vis detector ($\lambda = 254$ nm) and Zorbax C_{18} semiprep column (9.4 mm × 250 mm, 100 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 2.5 mL/min, and the mobile phase was isocratic with 90% A (0.1% TFA in water) and 10% B (0.1% TFA in acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 10% B at 5 min to 40% B at 20 min. Method 2 used the LabAlliance HPLC system equipped with a β-ram IN/US detector (Tampa, FL) and Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% A (25 mM NH_4OAc, pH = 6.8) and 10% B (acetonitrile) at 0−5 min, followed by a gradient mobile phase from 10% B at 5 min to 20% B at 15 min and to 50% B at 20 min.

Boc-E{G_3-E[G_3-c(RGDfK)]$_2$}$_2$ (Boc-6G-RGD_4). The succinimidyl ester of Boc-protected glutamic acid (Boc-E$(OSu)_2$) was prepared according to the literature method (*12*). To a solution of Boc-E$(OSu)_2$ (2.1 mg, 4.75 μmol) in DMF (2 mL) was added 3G-RGD_2 (21 mg, 11.5 μmol). After addition of DIEA (3 drops), the reaction mixture was stirred for 2 h at room temperature. The reaction was terminated by addition of 3 mL NH_4OAc buffer (100 mM, pH = 7.0). The product was isolated by HPLC (Method 1). Lyophilization of the collected fractions at 15.8 min afforded desired product Boc-6G-RGD_4. The yield was 7.6 mg (∼41%). MALDI-MS: $m/z = 3877$ for $[M + H]^+$ ($M = 3875$ calcd. for $[C_{164}H_{241}N_{57}O_{54}]^+$).

E{G_3-E[G_3-c(RGDfK)]$_2$}$_2$ (6G-RGD_4). Boc-6G-RGD_4 was dissolved in TFA (2 mL). After standing at room temperature for 5 min, excess TFA was removed. The residue was dissolved in 2 mL of 0.1 M NH_4OAc buffer (100 mM, pH = 7.0). The product was separated from the mixture by HPLC (Method 1). Lyophilization of the collected fractions at 14.2 min afforded 6G-RGD_4. The yield was 5.6 mg (∼76%). MALDI-MS: $m/z = 3777$ for $[M + H]^+$ ($M = 3775$ calcd. for $[C_{159}H_{233}N_{57}O_{52}]^+$).

DOTA-E{G_3-E[G_3-c(RGDfK)]$_2$}$_2$ (DOTA-6G-RGD_4). DOTA-OSu (5.0 mg, 10.0 μmol) and 6G-RGD_4 (3.8 mg, 1.0 μmol) were dissolved in anhydrous DMF (1 mL). After addition of excess DIEA (3 drops), the reaction mixture was stirred for 2 h at room temperature. Upon addition of 2 mL NH_4OAc buffer (100 mM, pH = 7.0), the product was separated by HPLC (Method 1). Lyophilization of the collected fractions at 14.5 min afforded DOTA-6G-RGD_4 with >95% purity. The yield was 3.2 mg (∼76%). MALDI-MS: $m/z = 4163$ for $[M + H]^+$ ($M = 4161$ calcd. for $[C_{175}H_{259}N_{61}O_{59}]^+$).

^{111}In-Labeling and Dose Preparation. To a clean Eppendorf tube were added 200−300 μL of the DOTA conjugate solution (0.1 mg/mL in 0.1 M NaOAc buffer, pH = 5.5) and 20 μL of $^{111}InCl_3$ solution (∼18.5 MBq in 0.05 M HCl). The vial was heated in a water bath at 100 °C for ∼15 min. After heating, the Eppendorf tube was allowed to stand at room temperature for ∼10 min. A sample of the resulting solution was analyzed by radio-HPLC (Method 2). For biodistribution studies, the ^{111}In radiotracer was purified by HPLC (Method 2). Volatiles in the mobile phase were removed under vacuum (∼5 mmHg) at room temperature. Doses were prepared by dissolving the purified radiotracer in saline to a concentration of ∼1.1 MBq/mL. For imaging studies, doses were prepared by dissolving the radiotracer in saline to ∼37 MBq/mL. The resulting solution was filtered with a 0.20 μm Millex-LG filter before being injected into animals. Each animal was injected with ∼0.1 mL of the dose solution.

Determination of Octanol/Water Partition Coefficients. The octanol/water partition coefficients were determined using the following procedure. In short, the ^{111}In radiotracer was purified by HPLC. Volatiles were removed completely under vacuum. The residue was dissolved in an equal volume (3 mL/3 mL) mixture of *n*-octanol and 25 mM phosphate buffer (pH = 7.4). After stirring vigorously for ∼20 min, the mixture was centrifuged at a speed of 8000 rpm for 5 min. Samples (in triplets) from both *n*-octanol and aqueous layers were counted in a Perkin-Elmer Wizard -1480 γ-counter (Shelton, CT). The partition coefficients were calculated. The log P values were measured three different times and reported as an average of three independent measurements plus the standard deviation.

In Vitro Whole-Cell Integrin $\alpha_v\beta_3$ Binding Assay. The in vitro integrin binding affinity and specificity of RGD peptides were assessed using ^{125}I-c(RGDyK) as the integrin-specific radioligand. Briefly, U87MG human glioma cells were grown in Gibco's Dulbecco's medium supplemented with 10% fetal

bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co, Carlsbad, CA), at 37 °C in humidified atmosphere containing 5% CO_2. Filter multiscreen DV plates were seeded with 10^5 glioma cells in binding buffer and incubated with ^{125}I-c(RGDyK) in the presence of increasing concentrations of the RGD conjugate. After removing the unbound ^{125}I-c(RGDyK), hydrophilic PVDF filters were collected. The radioactivity was determined using a γ-counter (Packard, Meriden, CT). The IC_{50} values were calculated by fitting the data by nonlinear regression using GraphPad Prism (GraphPad Software, Inc., San Diego, CA). Experiments were carried out twice with triplicate samples. The IC_{50} values are reported as an average plus the standard deviation.

Animal Model. Biodistribution and imaging studies were performed using the athymic nude mice bearing U87MG human glioma xenografts in compliance with NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86−23, revised 1985). The animal protocol was approved by the Purdue University Animal Care and Use Committee. U87MG cells were cultured in the Minimum Essential Medium, Eagle with Earle's Balanced Salt Solution (nonessential amino acids sodium pyruvate) (ATCC, Manassas, VA) in humidified atmosphere of 5% carbon dioxide, and were supplemented with 10% fetal bovine serum and 1% penicillin and streptomycin solution (GIBCO, Grand Island, NY). Female athymic nu/nu mice were purchased from Harlan (Indianapolis, IN) at 4−5 weeks of age. Each mouse was implanted subcutaneously with 5×10^6 tumor cells into the left and right upper flanks. In this way, one could assess the impact of tumor size on the radiotracer imaging quality in a single tumor-bearing mouse. All procedures will be performed in a laminar flow cabinet using aseptic technique. Three to four weeks after inoculation, the tumor size was 0.05−0.4 g, and animals were used for biodistribution and imaging studies.

Biodistribution Protocol. Twenty-five tumor-bearing mice (20−25 g) were randomly divided into five groups. Each tumor-bearing mouse was administered with ~111 KBq of the ^{111}In radiotracer by tail vein injection. Five animals were sacrificed by sodium pentobarbital overdose (~200 mg/kg) at 0.5, 1, 4, 24, and 72 h postinjection (p.i.). Blood samples were withdrawn from the heart of the tumor-bearing mice. Tumor and normal organs (brain, eyes, heart, spleen, lungs, liver, kidneys, muscle, and intestine) were harvested, washed with saline, dried with absorbent tissue, weighed, and counted on a γ-counter (Perkin-Elmer Wizard -1480, Shelton, CT). The organ uptake was calculated as the percentage of injected dose per gram of organ mass (%ID/g) or the percentage of injected dose per organ (%ID/organ). For the blocking experiment, five tumor-bearing athymic nude mice (20−25 g) were used, and each animal was administered with ~111 KBq of ^{111}In(DOTA-6G-RGD$_4$) along with ~350 μg (~14 mg/kg) of RGD_2. Such a high dose of blocking agent was used to make sure that the integrin $\alpha_v\beta_3$ binding was completely blocked. At 1 h p.i., all five tumor-bearing animals were sacrificed for organ biodistribution. Biodistribution data (%ID/g) and target-to-background (T/B) ratios are reported as an average plus the standard deviation based on the results from five tumor-bearing mice (10 tumors) at each time point. Comparison between two radiotracers was made using the two-way ANOVA test (GraphPad Prim 5.0, San Diego, CA). The level of significance was set at $p < 0.05$.

Planar Imaging. The athymic nude mice ($n = 3$) bearing U87MG glioma xenografts were used for imaging studies of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-3G-RGD$_2$). Each tumor-bearing mouse was administered with ~3.7 MBq of ^{111}In radiotracer via tail vein injection. Animals were anesthetized with intraperitoneal injection of ketamine (80 mg/kg) and xylazine (19 mg/kg), and were then placed supine on a single head mini γ-camera (Diagnostic Services Inc., NJ) equipped with a parallel-hole, medium-energy, and high-resolution collimator. Anterior images were acquired at 0.5, 1, 4, 24, and 72 h p.i. and stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 200 K. After completion of imaging, animals were sacrificed by sodium pentobarbital overdose (~200 mg/kg).

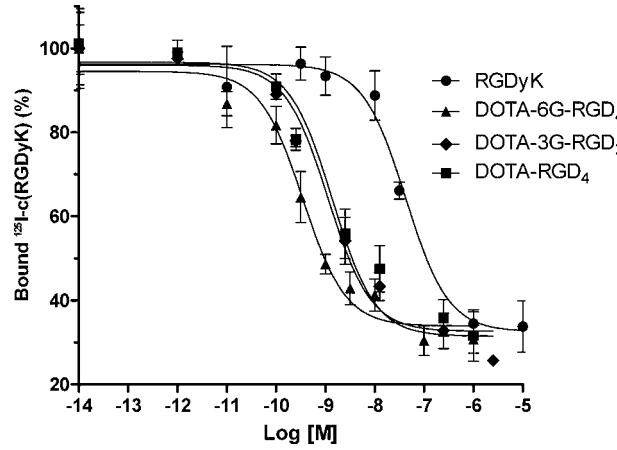

Figure 2. Competitive inhibition curves of ^{125}I-c(RGDyK) bound to the U87MG human glioma cells by c(RGDyK), DOTA-3G-RGD$_2$, DOTA-RGD$_4$, and DOTA-6G-RGD$_4$. Their IC_{50} values were calculated to be 42.2 ± 5.2, 1.1 ± 0.1, 1.4 ± 0.1 and 0.4 ± 0.1 nM, respectively.

Metabolism. Normal nude mice were used for metabolism studies. Each mouse was administered with ~3.7 MBq of ^{111}In(DOTA-3G-RGD$_2$) and ^{111}In(DOTA-6G-RGD$_4$) via tail vein. The urine samples were collected at 30 and 120 min p.i. by manual void and were mixed with equal volume of 50% acetonitrile aqueous solution. The mixture was centrifuged at 8000 rpm. The supernatant was collected and passed through a 0.20 μ Millex-LG filter unit. The filtrate was analyzed by HPLC (Method 2). Feces, liver, and kidney samples were collected at 120 min p.i. and suspended in 20% acetonitrile aqueous solution after homogenization. The resulting mixture was vortexed for 5−10 min. After centrifuging at 8000 rpm, the supernatant was collected and passed through a 0.20 μ Millex-LG filter unit. The filtrate was analyzed by radio-HPLC (Method 2). The percentage radioactivity recovery was >95% (by γ-counting) for both urine and feces samples.

RESULTS

DOTA-6G-RGD$_4$. Synthesis of DOTA-6G-RGD$_4$ was straightforward. The key step was the deprotection of Boc-6G-RGD$_4$. The excess TFA must be removed within 10 min of the reaction. Otherwise, the major product was the hydrolyzed product E-3G-RGD$_2$ (E-G$_3$-E[G$_3$-c(RGDfK)]$_2$), not 6G-RGD$_4$. Conjugation of 6G-RGD$_4$ with excess DOTA-OSu in DMF in the presence of excess DIEA afforded DOTA-6G-RGD$_4$ in high yield (76%). Its identity has been confirmed by MALDI-MS.

In Vitro Integrin $\alpha_v\beta_3$ Binding Affinity. The integrin $\alpha_v\beta_3$ binding affinities of c(RGDyK), DOTA-3G-RGD$_2$, DOTA-RGD$_4$, and DOTA-6G-RGD$_4$ were determined using the integrin $\alpha_v\beta_3$-positive U87MG human glioma cells. Figure 2 shows displacement curves of ^{125}I-c(RGDyK) by c(RGDyK), DOTA-3G-RGD$_2$, DOTA-RGD$_4$, and DOTA-6G-RGD$_4$. Their IC_{50} values were calculated to be 42.2 ± 5.2, 1.1 ± 0.1, 1.4 ± 0.1 and 0.4 ± 0.1 nM, respectively.

Radiochemistry. ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) were prepared by reacting $^{111}InCl_3$ with DOTA-6G-RGD$_4$, DOTA-RGD$_4$, and DOTA-3G-RGD$_2$, respectively, in NH_4OAc buffer (100 mM, pH = 5.5).

Table 1. Radiochemical Purity (RCP), HPLC Retention Time and Log P Values for ^{111}In-Labeled Cyclic RGD Peptides

compound	RCP (%)	retention time (min)	log P value
^{111}In(DOTA-3G-RGD$_2$)	>95	13.9	−4.13 ± 0.08
^{111}In(DOTA-6G-RGD$_4$)	>92	17.1	−4.40 ± 0.04
^{111}In(DOTA-RGD$_4$)	>92	19.1	−3.41 ± 0.13

Radiolabeling was completed by heating the reaction mixture at 100 °C for ∼15 min. The radiochemical purity was >92% for all three ^{111}In radiotracers. The specific activity was ∼925 MBq/mg (∼1850 MBq/μmol) for ^{111}In(DOTA-3G-RGD$_2$). They were analyzed using the same method (Method 2). Their HPLC retention times and log P values were listed in Table 1.

Biodistribution Characteristics. Selected biodistribution data are listed in Tables 2−4 for ^{111}In(DOTA-6G-RGD$_4$), ^{111}In-(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$). Figure 3 compares their uptake (%ID/g) in the tumor and intestine, as well as their tumor/kidney and tumor/liver ratios in the athymic nude mice bearing U87MG human glioma xenografts. The comparison of their tumor uptake in combination with the IC_{50} values of cyclic RGD peptide DOTA conjugates will allow us to determine if they are actually tetravalent in binding to the integrin $\alpha_v\beta_3$.

In general, ^{111}In(DOTA-6G-RGD$_4$) excreted predominantly via the renal route with >75% of the injected radioactivity recovered from urine and <10% of the injected radioactivity recovered from feces at 2 h p.i. ^{111}In(DOTA-6G-RGD$_4$) had a

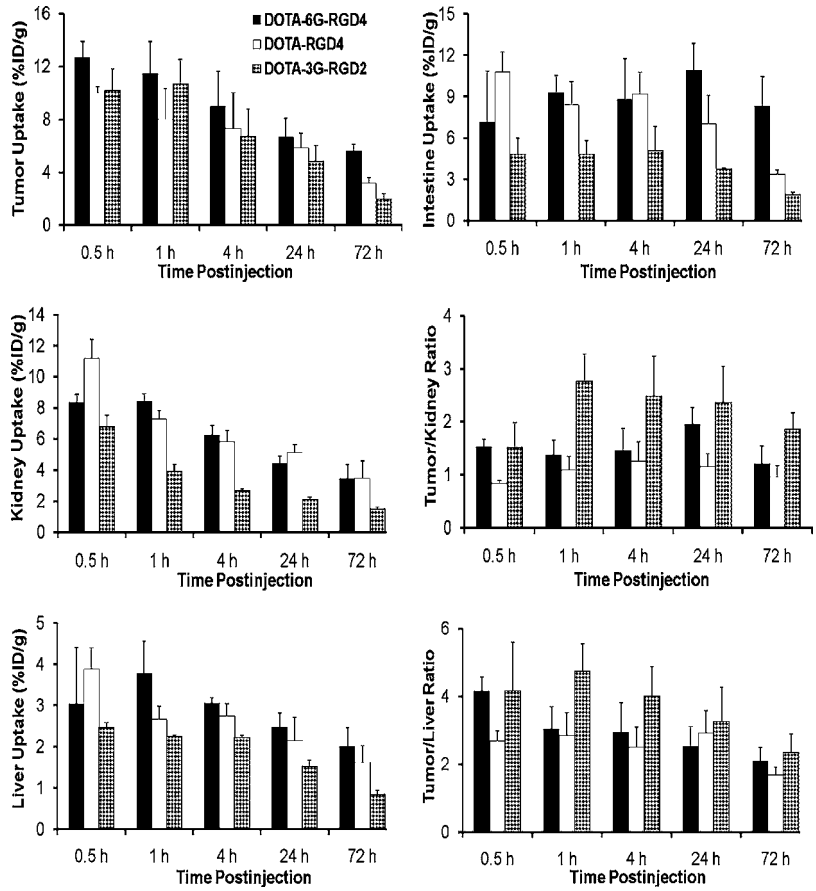

Figure 3. Direct comparison of the tumor and intestine uptake (%ID/g), tumor/kidney, and tumor/liver ratios between ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) in the athymic nude mice ($n = 5$) bearing U87MG human glioma xenografts.

rapid blood clearance with high tumor/blood ratios (Table 2). It had a high initial tumor uptake (12.66 ± 1.25%ID/g at 0.5 h p.i.) with a slow washout (11.45 ± 2.46, 8.99 ± 2.61, 6.68 ± 1.42, and 5.59 ± 0.54%ID/g at 1, 4, 24, and 72 h p.i., respectively). The liver uptake of ^{111}In(DOTA-6G-RGD$_4$) was low (3.04 ± 1.38, 3.77 ± 0.79, 3.05 ± 0.14, 2.46 ± 0.36, and 2.01 ± 0.45%ID/g at 0.5, 1, 4, 24, and 72 h p.i., respectively), and its tumor/liver ratios were high (4.16 ± 0.41, 3.04 ± 0.65, 2.95 ± 0.86, 3.53 ± 0.58, and 2.09 ± 1.41 at 0.5, 1, 4, 24, and 72 h p.i., respectively). The kidney and muscle uptake of ^{111}In(DOTA-6G-RGD$_4$) was also low with high tumor/kidney and tumor/muscle ratios (Table 2). The tumor uptake of ^{111}In(DOTA-RGD$_4$) was high (8.97 ± 0.52, 7.98 ± 2.36, 7.32 ± 2.66, 5.84 ± 1.09, and 3.16 ± 0.43%ID/g at 0.5, 1, 4, 24, and 72 h p.i., respectively), but its tumor retention time was not as long as that of ^{111}In(DOTA-6G-RGD4) (Figure 3). ^{111}In(DOTA-RGD$_4$) had a rapid blood clearance with high tumor/blood ratios over the 72 h period (Table 3). The initial kidney uptake (Figure 3) of ^{111}In(DOTA-RGD$_4$) was significantly higher than that of ^{111}In(DOTA-6G-RGD$_4$). However, there was no significant difference between ^{111}In(DOTA-RGD$_4$) and ^{111}In(DOTA-6G-RGD$_4$) in their kidney uptake at >1 h p.i. ^{111}In(DOTA-RGD$_4$) and ^{111}In(DOTA-6G-RGD$_4$) shared very similar liver uptake and tumor/liver ratio (Figure 3). ^{111}In-(DOTA-3G-RGD$_2$) also had a rapid blood clearance with high tumor/blood ratios (Table 4). Its initial tumor uptake (10.19 ± 3.61%ID/g at 0.5 h p.i.) was comparable to that of^{111}In(DOTA-RGD$_4$) and ^{111}In(DOTA-6G-RGD$_4$) within the experimental error, but its tumor uptake was significantly ($p < 0.01$) lower (Figure 3: tumor uptake = 5.59 ± 0.54%ID/g for ^{111}In(DOTA-6G-RGD4), 3.16 ± 0.43%ID/g for ^{111}In(DOTA-RGD$_4$), and 1.99 ± 0.39%ID/g for ^{111}In(DOTA-3G-RGD$_2$) at 72 h p.i.). The uptake of ^{111}In(DOTA-3G-RGD$_2$) in intestine, kidneys, and liver was also significantly ($p < 0.05$) lower than that of ^{111}In(DOTA-RGD$_4$) and ^{111}In(DOTA-6G-RGD$_4$). As a result, the tumor/kidney and tumor/liver ratios of ^{111}In(DOTA-3G-RGD$_2$) were higher than that of both ^{111}In(DOTA-RGD$_4$) and ^{111}In(DOTA-6G-RGD$_4$) (Figure 3).

Tumor Size vs Tumor Uptake. As illustrated in Figure 4A, there was a linear relationship between the %ID tumor uptake of ^{111}In(DOTA-3G-RGD$_2$) at 60 min p.i. and tumor size (0.03−0.60 g; $n = 12$) with $R^2 = 0.959$. As the tumor became larger, the total tumor uptake of ^{111}In(DOTA-3G-RGD$_2$) increased. In contrast, the %ID/g tumor uptake (Figure 4B) of ^{111}In(DOTA-3G-RGD$_2$) decreased as the tumor size increased. For example, ^{111}In(DOTA-3G-RGD$_2$) has tumor uptake in the range 8.0−15%ID/g with the tumor size 0.05−0.30 g. When the tumor size is in the range 0.5−0.6 g, the tumor uptake of ^{111}In(DOTA-3G-RGD$_2$) is only ∼6.0%ID/g.

Integrin $\alpha_v\beta_3$ Specificity. Figure 5 compares the 60 min organ uptake of ^{111}In(DOTA-6G-RGD$_4$) in the absence/presence of RGD$_2$. Clearly, coinjection of RGD$_2$ significantly blocked the tumor uptake of ^{111}In(DOTA-6G-RGD$_4$) (1.23 ± 0.26%ID/g with RGD$_2$ vs 11.45 ± 2.46%ID/g without RGD$_2$ at 1 h p.i.). Its uptake in normal organs was also significantly blocked by coinjection of excess RGD$_2$. For example, the uptake of ^{111}In(DOTA-6G-RGD$_4$) in eyes, heart, intestine, liver, lungs, and spleen was 1.54 ± 0.22, 1.49 ± 0.29, 9.25 ± 1.27, 3.77 ± 0.79, 3.44 ± 1.86, and 2.38 ± 0.49%ID/g, respectively, without RGD$_2$, while its uptake in the same organs was only 0.33 ± 0.06, 0.66 ± 0.18, 0.79 ± 0.10, 0.79 ± 0.20, 2.06 ± 1.12, and 0.54 ± 0.09%ID/g, respectively, in the presence of excess RGD$_2$.

Planar Imaging. Figure 6 illustrates the planar images of the glioma-bearing mice administered with ∼3.7 MBq of ^{111}In(DOTA-6G-RGD$_4$) (top), ^{111}In(DOTA-3G-RGD$_2$) (bottom) and at 1, 4, 24, and 72 h p.i. The tumors could be clearly

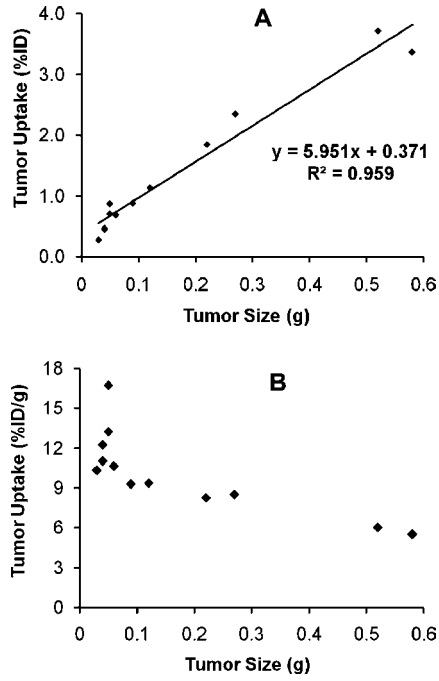

Figure 4. Relationship between the tumor size and tumor uptake of ^{111}In(DOTA-3G-RGD$_2$) at 60 min p.i. in the athymic nude mice (n = 12) bearing the U87MG glioma xenografts.

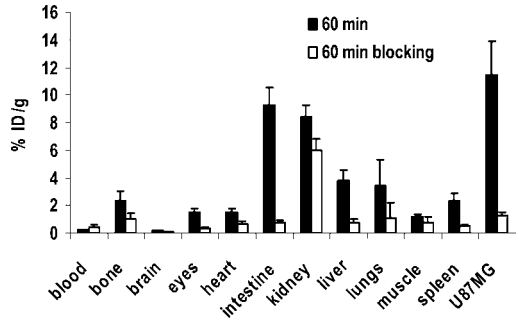

Figure 5. Comparison of the 60 min biodistribution data of ^{111}In(DOTA-6G-RGD$_4$) in athymic nude mice (n = 5) bearing U87MG glioma xenografts in the absence/presence of excess RGD$_2$ to demonstrate its integrin $\alpha_v\beta_3$-specificity.

visualized with excellent T/B contrast as early as 1 h p.i. in the glioma-bearing mice administered with ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-3G-RGD$_2$). Both ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-3G-RGD$_2$) had a very long tumor retention time ($t_{1/2}$ > 30 h), which was consistent with the results obtained from biodistribution studies (Tables 2 and 4). In addition, we also observed that the tumor distribution of ^{111}In(DOTA-3G-RGD$_2$) is quite heterogeneous most likely due to the heterogeneity of integrin $\alpha_v\beta_3$ overexpressed on tumor tissues.

Metabolism. Figure 7 shows representative radio-HPLC chromatograms of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-3G-RGD$_2$) in saline before injection, in urine at 30 and 120 min p.i., and in feces at 120 min p.i. The percentage radioactivity recovery from the urine and feces samples was >95% for both radiotracers. Attempts to extract radioactivity from the liver and kidneys were not successful due to limited radioactivity accumulation in both organs. There was very little metabolite detected in either urine or feces samples over the 2 h period for ^{111}In(DOTA-3G-RGD$_2$). For ^{111}In(DOTA-6G-RGD$_4$), however, there was significant metabolism during its excretion via both renal and hepatobiliary routes. Only ~25% of ^{111}In(DOTA-6G-RGD$_4$) remained intact in the feces sample.

DISCUSSION

In this study, we prepared ^{111}In complexes of DOTA-6G-RGD$_4$, DOTA-RGD$_4$, and DOTA-3G-RGD$_2$. It was found that the integrin $\alpha_v\beta_3$ binding affinity follows the order of DOTA-6G-RGD$_4$ > DOTA-RGD$_4$ ~ DOTA-3G-RGD$_2$ ≫ c(RGDyK). Two factors contribute to the higher integrin $\alpha_v\beta_3$ binding affinity of DOTA-6G-RGD$_4$, DOTA-RGD$_4$, and DOTA-3G-RGD$_2$ as compared to c(RGDyK). Previously, we have clearly demonstrated that 3G-RGD$_2$ binds to the integrin $\alpha_v\beta_3$ in a bivalent fashion while RGD$_2$ is only monovalent due to the short distance (6 bonds excluding K residues) between two RGD motifs (*31*, *33*, *37*). The fact that DOTA-RGD$_4$ (IC$_{50}$ = 1.5 ± 0.2 nM) and DOTA-3G-RGD$_2$ (IC$_{50}$ = 1.3 ± 0.2 nM) shared almost identical IC$_{50}$ values strongly suggests that DOTA-RGD$_4$ is bivalent in binding to integrin $\alpha_v\beta_3$. This conclusion is supported by their similar tumor uptake (Figure 3) and is completely consistent with the biodistribution data obtained for the ^{99m}Tc-labeled cyclic RGD peptides 3G-RGD$_2$ and RGD$_4$ (*31*, *37*). Were DOTA-RGD$_4$ tetravalent, it would have had significantly higher integrin $\alpha_v\beta_3$ binding affinity than DOTA-3G-RGD$_2$, whereas ^{111}In(DOTA-RGD$_4$) would have had higher initial tumor uptake than ^{111}In(DOTA-3G-RGD$_2$).

DOTA-6G-RGD$_4$ (IC$_{50}$ = 0.4 ± 0.1 nM) has higher integrin $\alpha_v\beta_3$ binding affinity than DOTA-RGD$_4$ (IC$_{50}$ = 1.5 ± 0.2 nM). As a result, ^{111}In(DOTA-6G-RGD$_4$) has slightly higher initial tumor uptake (Figure 3) than ^{111}In(DOTA-RGD$_4$). Previously, we found that both bivalency and the "locally enhanced RGD concentration" contribute to the higher integrin $\alpha_v\beta_3$ binding affinity of 3G-RGD$_2$ and 3P-RGD$_2$ as compared to that of c(RGDfK) (*31*−*37*). We also found that the contribution from the bivalency to integrin $\alpha_v\beta_3$ binding affinity and radiotracer tumor uptake are much more significant than that from the "locally enhanced RGD concentration" (*31*, *32*). For example, the tumor uptake of the ^{99m}Tc-labeled 3G-RGD$_2$ was almost 3× higher than that of the ^{99m}Tc-labeled c(RGDfK) in the same model (*31*). Thus, we believe that the differences in the integrin $\alpha_v\beta_3$ binding affinity of DOTA-6G-RGD$_4$ and DOTA-RGD$_4$ and the initial tumor uptake of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) are most likely caused by the number of possibilities to achieve simultaneous integrin $\alpha_v\beta_3$ binding for 6G-RGD$_4$ and RGD$_4$. The concentration factor exists in both DOTA-6G-RGD$_4$ and DOTA-RGD$_4$. The difference is that there are only two possibilities for DOTA-RGD$_4$ to achieve bivalency while any two of the four RGD motifs in DOTA-6G-RGD$_4$ can achieve bivalency due to the longer distance between RGD motifs. If DOTA-6G-RGD$_4$ were tetravalent or trivalent, it would have had much higher integrin $\alpha_v\beta_3$ binding affinity than DOTA-RGD$_4$, whereas ^{111}In(DOTA-6G-RGD$_4$) would have shown much higher initial tumor uptake than ^{111}In(DOTA-RGD$_4$). This conclusion is supported by the fact that ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-3G-RGD$_2$) share a similar initial tumor uptake (Figure 3: 12.66 ± 1.25%ID/g and 10.19 ± 3.61%ID/g, respectively) at 0.5 h p.i. Even though DOTA-6G-RGD$_4$ and DOTA-RGD$_4$ may not be tetravalent, the extra cyclic RGD motifs in DOTA-6G-RGD$_4$ and DOTA-RGD$_4$ contribute significantly to the higher tumor uptake of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) than that of ^{111}In(DOTA-3G-RGD$_2$) at 24−72 h p.i. (Figure 3). The concentration factor might also explain why ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) had higher uptake than ^{111}In(DOTA-3G-RGD$_2$) (Figure 3) in the intestine, liver, and kidneys, all of which are integrin $\alpha_v\beta_3$-positive (*15*, *16*). From this point of view, we believe that ^{111}In(DOTA-6G-RGD$_4$) is most likely bivalent in binding to the integrin $\alpha_v\beta_3$. However, the IC$_{50}$ values and ex

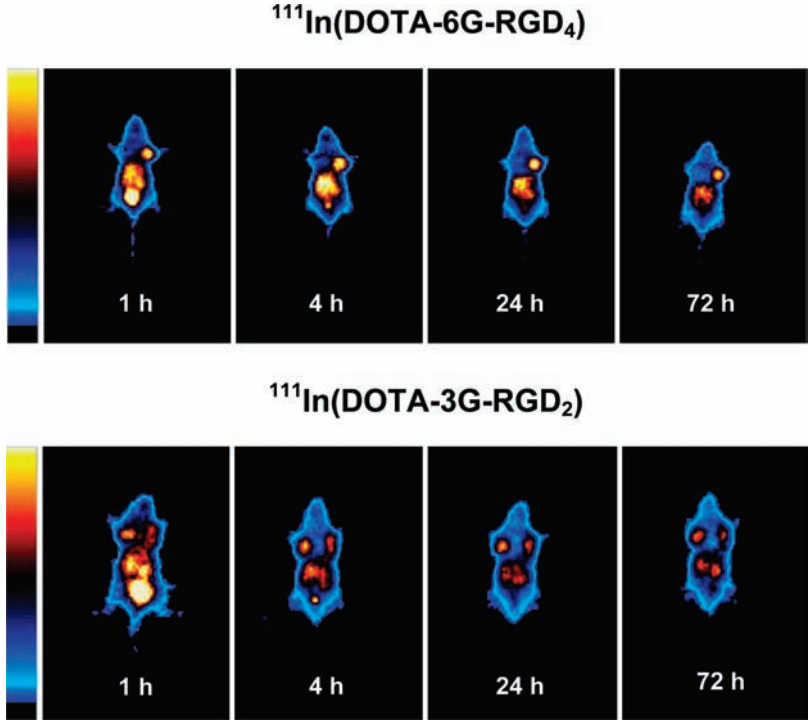

Figure 6. Whole-body planar images of the tumor-bearing mice administered with ~3.7 Mbq of ^{111}In(DOTA-6G-RGD$_4$) (top) and ^{111}In(DOTA-3G-RGD$_2$) (bottom) at 1, 4, 24, and 72 h p.i.

vivo biodistribution data cannot completely eliminate the possibility of trivalency or tetravalency for ^{111}In(DOTA-6G-RGD$_4$).

For diagnostic radiotracers, the tumor retention time may not be as critical as tumor uptake and T/B ratios. For the ^{90}Y and ^{177}Lu radiotracers, however, the longer tumor retention time will result in higher radiation dose to the integrin $\alpha_v\beta_3$-positive tumors during the same period of time. It must be noted that the ability of a multimeric RGD peptide to achieve bivalency also depends on the integrin $\alpha_v\beta_3$ density. If the tumor integrin $\alpha_v\beta_3$ density is high, the distance between two neighboring integrin $\alpha_v\beta_3$ sites will be short, and it is easier for the multimeric RGD peptide to achieve bivalency. If the integrin $\alpha_v\beta_3$ density is very low, the distance between two neighboring integrin $\alpha_v\beta_3$ sites will be long, and it might be more difficult for the same multimeric RGD peptide to achieve simultaneous integrin $\alpha_v\beta_3$ binding.

The integrin $\alpha_v\beta_3$-specificity of ^{111}In(DOTA-6G-RGD$_4$) is demonstrated by the "blocking experiment" (Figure 5). The blockage of radiotracer uptake strongly suggests that its glioma localization is indeed integrin $\alpha_v\beta_3$-mediated. The partial uptake blockage in the eyes, heart, intestine, lungs, liver, and spleen indicates that the accumulation of ^{111}In(DOTA-6G-RGD$_4$) in these organs is in large part integrin $\alpha_v\beta_3$-mediated. This conclusion is supported by the immunohistopathological studies (*15, 16*), which showed a strong positive staining of endothelial cells of small glomeruli vessels in kidneys and weak staining in branches of the hepatic portal vein. Similar results were also obtained for radiolabeled (^{99m}Tc and ^{64}Cu) cyclic RGD peptide dimers, such as 3G-RGD$_2$ and 3P-RGD$_2$ (*31*−*33, 36, 37*).

It is well-established that multimerization of cyclic RGD peptides can significantly improve the integrin $\alpha_v\beta_3$-targeting capability as evidenced by their higher integrin $\alpha_v\beta_3$ binding affinity and better tumor uptake with better tumor uptake than their monomeric counterparts (*26, 30*−*37*). However, this also leads to more radioactivity accumulation of radiolabeled multimeric cyclic RGD peptides in normal organs, as evidenced by the higher uptake of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In-(DOTA-RGD$_4$) than ^{111}In(DOTA-3G-RGD$_2$) in the intestine, liver, and kidneys. As a result, the tumor/liver and tumor/kidney ratios of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) are significantly ($p < 0.01$) lower than those of ^{111}In(DOTA-3G-RGD$_2$) at >1 h p.i. This is consistent with greater accumulation in the abdominal region of tumor-bearing mice administered with ^{111}In(DOTA-6G-RGD$_4$) (Figure 6: top) than that with ^{111}In(DOTA-3G-RGD$_2$) (Figure 6: bottom). Thus, ^{111}In(DOTA-3G-RGD$_2$) is a better radiotracer than ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) for diagnostic purposes. For the integrin $\alpha_v\beta_3$-targeted therapeutic radiotracers, however, 6G-RGD$_4$ has advantages over RGD$_4$ and 3G-RGD$_2$, because ^{111}In(DOTA-6G-RGD$_4$) has a longer tumor retention time than both ^{111}In-(DOTA-3G-RGD$_2$) and ^{111}In(DOTA-RGD$_4$). At this moment, it is not clear why ^{111}In(DOTA-3G-RGD$_2$) is able to maintain its integrity during its excretion from both renal and hepatobiliary routes while ^{111}In(DOTA-6G-RGD$_4$) has significant degradation during its excretion from the hepatobiliary route (Figure 7). It is likely that the metabolic instability of ^{111}In-(DOTA-6G-RGD$_4$) during its hepatobiliary excretion is caused by its much larger size (MW = 4269 Da) than that of ^{111}In(DOTA-3G-RGD$_2$) (MW = 2326 Da).

The %ID tumor uptake reflects the total integrin $\alpha_v\beta_3$ expression level on tumor cells and tumor neovasculature, while the %ID/g tumor uptake reflects the integrin $\alpha_v\beta_3$ density. When tumor is small (<0.05 g or 50 mm^3), there is little tumor mass and angiogenesis. As a result, ^{111}In(DOTA-3G-RGD$_2$) has low %ID tumor uptake (Figure 4A). As tumor grows, the integrin $\alpha_v\beta_3$ level becomes higher, and the %ID tumor uptake of ^{111}In(DOTA-3G-RGD$_2$) increases (Figure 4A). However, the microvessel density decreases due to the maturation of blood vessels, and the integrin $\alpha_v\beta_3$ density also decreases due to larger interstitial space and higher collagen concentrations (*38*). In addition, parts of the tumor may become necrotic, leading to lower integrin $\alpha_v\beta_3$ density.

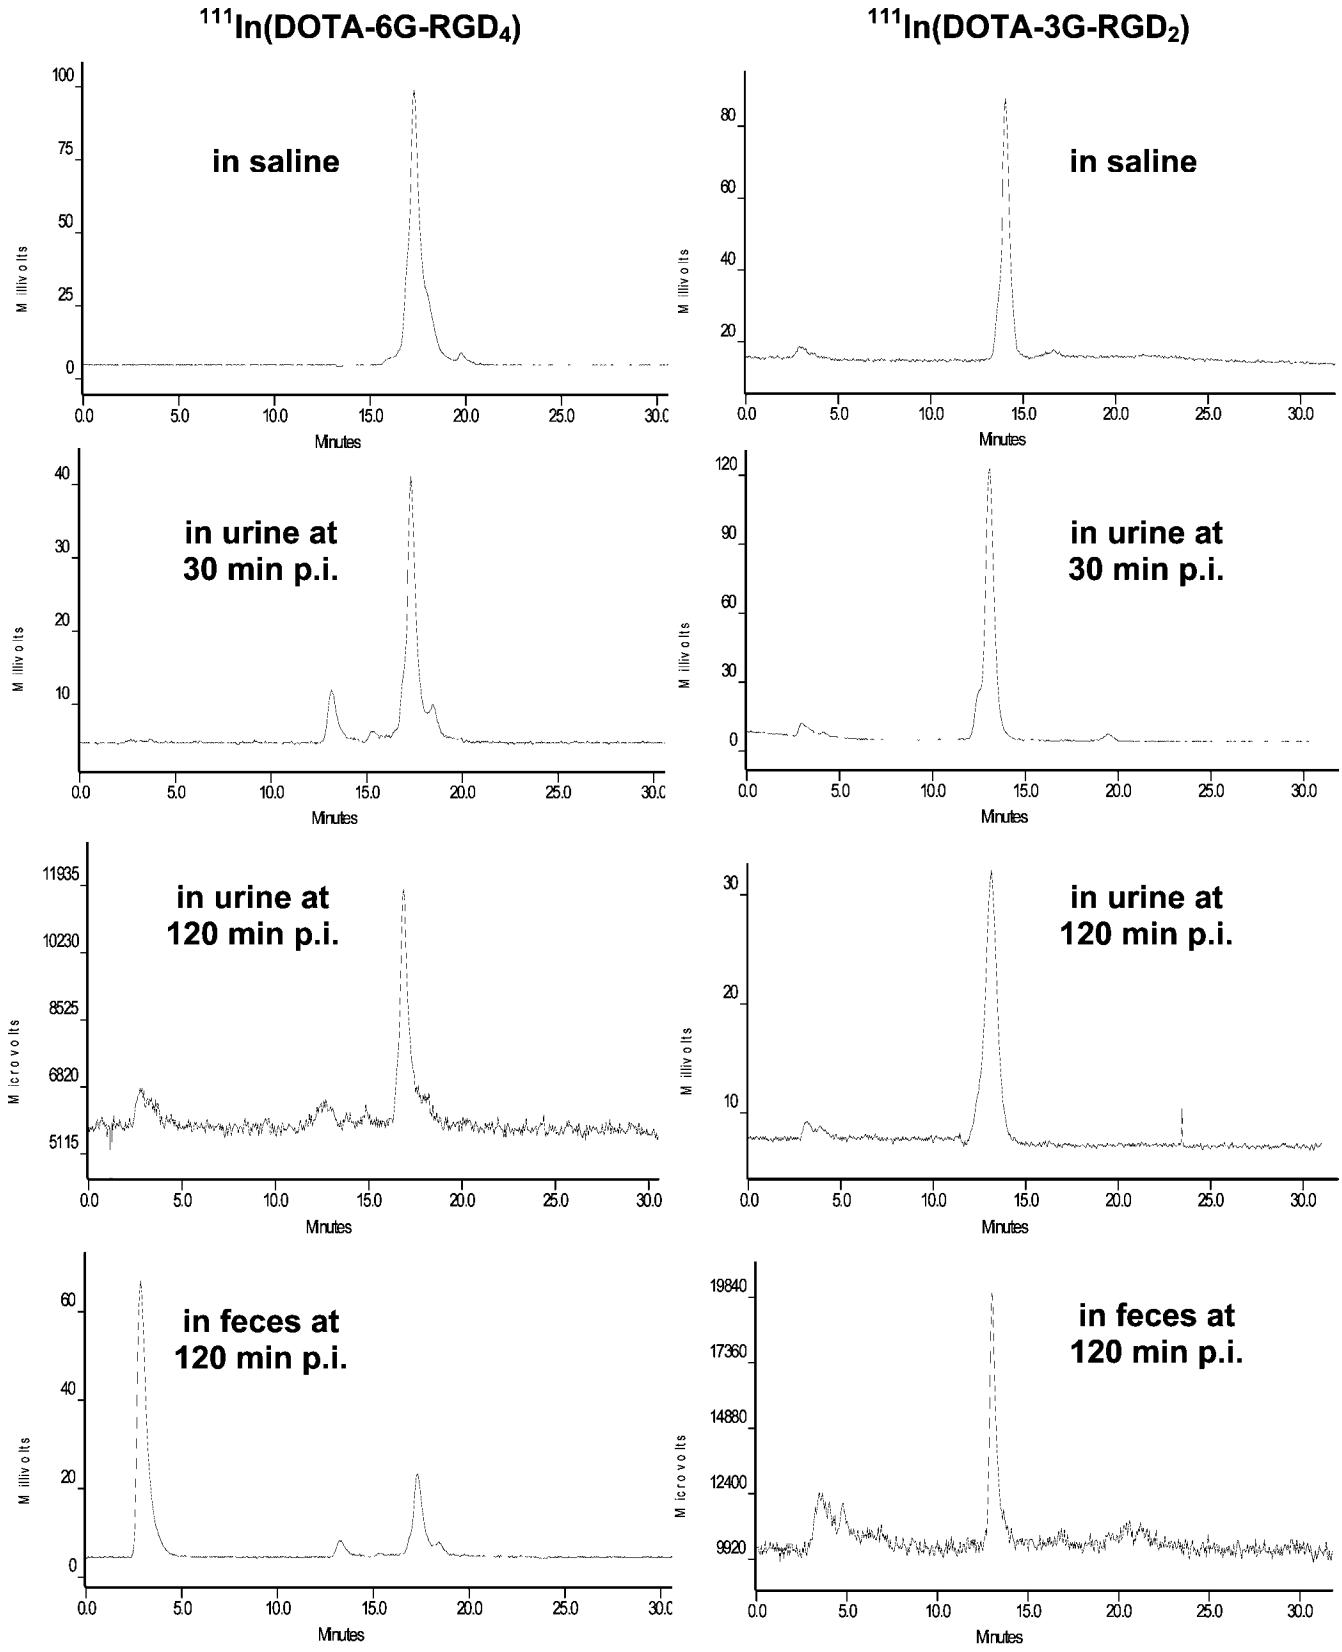

Figure 7. Typical radio-HPLC chromatograms of ^{111}In(DOTA-6G-RGD$_4$) (left) and ^{111}In(DOTA-3G-RGD$_2$) (right) in saline before injection, in urine at 30 and 120 min p.i., and in feces at 120 min p.i. Each mouse was administered with ~3.7 Mbq radiotracer.

It is not surprising that ^{111}In(DOTA-3G-RGD$_2$) had significantly less %ID/g uptake in larger tumors (Figure 4B). Similar results were also reported for ^{64}Cu(DOTA-3P-RGD$_2$) (*33*). The linear relationship between the tumor size and %ID tumor uptake suggests that ^{111}In(DOTA-3G-RGD$_2$) might have the potential for monitoring tumor growth or shrinkage. However, the relationship between the radiotracer uptake and integrin $\alpha_v\beta_3$ levels needs to be further established in our

future studies. The ability to noninvasively quantify integrin $\alpha_v\beta_3$ level will provide a useful tool to select the patients more appropriately for antiangiogenic therapy (*39, 40*).

CONCLUSION

In this study, we evaluated ^{111}In(DOTA-6G-RGD$_4$), ^{111}In(DOTA-RGD$_4$), and ^{111}In(DOTA-3G-RGD$_2$) for their potential as new integrin $\alpha_v\beta_3$-targeted radiotracers. On the basis of results from the integrin $\alpha_v\beta_3$ binding assay and biodistribution studies, it is concluded that (1) tetrameric RGD peptides 6G-RGD$_4$ and RGD$_4$ are not tetravalent; (2) 6G-RGD$_4$, RGD$_4$ and 3G-RGD$_2$ most likely bind to the integrin $\alpha_v\beta_3$ in a bivalent fashion; (3) two extra cyclic RGD motifs in 6G-RGD$_4$ and RGD$_4$ contribute significantly to the longer tumor retention times of ^{111}In(DOTA-6G-RGD$_4$) and ^{111}In(DOTA-RGD$_4$) than that of ^{111}In(DOTA-3G-RGD$_2$); (4) further increase of multiplicity from cyclic RGD dimers, such as 3G-RGD$_2$, has an adverse impact on T/B ratios due to the increased radioactivity accumulation in normal organs; and (5) the combination of high tumor uptake and prolonged tumor retention of ^{111}In(DOTA-6G-RGD$_4$) suggests that its ^{90}Y and ^{177}Lu analogues, M(DOTA-6G-RGD$_4$) (M = ^{90}Y and ^{177}Lu), might have potential for targeted radiotherapy of glioblastoma.

Received December 20, 2009; Revised Manuscript Received April 6, 2010

An efficient mechanism-based tumor-targeting drug delivery system, based on tumor-specific vitamin-receptor mediated endocytosis, has been developed. The tumor-targeting drug delivery system is a conjugate of a tumor-targeting molecule (biotin: vitamin H or vitamin B-7), a mechanism-based self-immolative linker and a second-generation taxoid (SB-T-1214) as the cytotoxic agent. This conjugate (**1**) is designed to be (i) specific to the vitamin receptors overexpressed on tumor cell surface and (ii) internalized efficiently through receptor-mediated endocytosis, followed by smooth drug release via glutathione-triggered self-immolation of the linker. In order to monitor and validate the sequence of events hypothesized, i.e., receptor-mediated endocytosis of the conjugate, drug release, and drug-binding to the target protein (microtubules), three fluorescent/fluorogenic molecular probes (**2**, **3**, and **4**) were designed and synthesized. The actual occurrence of these processes was unambiguously confirmed by means of confocal fluorescence microscopy (CFM) and flow cytometry using L1210FR leukemia cells, overexpressing biotin receptors. The molecular probe **4**, bearing the taxoid linked to fluorescein, was also used to examine the cell specificity (i.e., efficacy of receptor-based cell targeting) for three cell lines, L1210FR (biotin receptors overexpressed), L1210 (biotin receptors not overexpressed), and WI38 (normal human lung fibroblast, biotin receptor negative). As anticipated, the molecular probe **4** exhibited high specificity only to L1210FR. To confirm the direct correlation between the cell-specific drug delivery and anticancer activity of the probe **4**, its cytotoxicity against these three cell lines was also examined. The results clearly showed a good correlation between the two methods. In the same manner, excellent cell-specific cytotoxicity of the conjugate **1** (without fluorescein attachment to the taxoid) against the same three cell lines was confirmed. This mechanism-based tumor-targeting drug delivery system will find a range of applications.

INTRODUCTION

Cancer is the second leading cause of death (the number 1 cause of death under the age of 85) in the U.S. and remains one of the most challenging diseases to combat. Traditional cancer chemotherapy is based on the premise that tumor cells are more likely to be killed by anticancer drugs because of the faster proliferation of those cancer cells (*1*). However, in reality, the representative cytotoxic chemotherapeutic agents, such as paclitaxel, cisplatin, and doxorubicin, cannot distinguish cancer cells from normal cells. This lack of selectivity leads to undesirable side effects associated with these drugs (*2*), i.e., patients would be at risk of systemic cytotoxicity if exposed to the high doses of cytotoxic agents required to eradicate the tumor. Accordingly, the development of tumor-specific delivery systems for anticancer agents, recognizing the intrinsic differences between normal and tumor cells, is an urgent need for efficacious cancer chemotherapy, and has been receiving increasing attention in recent years (*3*).

In general, a tumor-targeting drug delivery system (DDS) consists of a tumor recognition moiety and a cytotoxic agent connected directly or through a suitable linker to form a conjugate (*4*). The tumor-targeting DDS should be systemically nontoxic. This means that the linker must be stable in blood circulation, but upon internalization into the tumor cells, the conjugate should be readily cleaved to regenerate the active cytotoxic agent.

Cancer cells overexpress many tumor-specific receptors, which can be used as targets to deliver cytotoxic agents into tumors (*3*). For example, monoclonal antibodies (*1, 2, 5*−*7*), polyunsaturated fatty acids (*8, 9*), folic acid (*10*−*12*), aptamers (*13, 14*), transferrin (*15*), oligopeptides (*16*), and hyaluronic acid (*17*) have been employed as tumor-specific "guiding modules" to construct tumor-targeting drug conjugates.

We have constructed efficacious tumor-targeting DDS based on highly potent new-generation taxoids, which were discovered and developed in our laboratory, in combination with monoclonal antibodies (mAb's: targeting epidermal growth factor receptor) as well as omega-3 polyunsaturated fatty acids (*2, 4, 9*). These tumor-targeting drug conjugates exhibited remarkable efficacy against tumor xenografts in mouse models (*2, 4, 9*), and the mAb-taxoid conjugates demonstrated exceptional tumor-targeting specificity (*2, 4*). However, mAb's are very large (ca. 150 kD) and expensive, containing modification sites that are difficult to pinpoint, and are potentially immunogenic, while drug conjugates with omega-3 fatty acids provide only passive tumor-targeting delivery, although efficacious in vivo. Accordingly, we turned our attention to explore small molecules as tumor-targeting molecules and found that vitamins would serve as excellent guiding molecules (*4, 18*).

Although all living cells require vitamins for their survival, rapidly dividing cancer cells, in particular, require certain vitamins to sustain their rapid growth (*19, 20*). Consequently, the receptors involved in uptake of the vitamins are overexpressed on the cancer cell surface. Therefore, those vitamin receptors serve as useful biomarkers for the imaging and identification of tumor cells as well as tumor-targeting drug delivery. Vitamin B12, folic acid, biotin, and riboflavin are essential vitamins for the division of all cells, but particularly for the growth of cancer cells. The folate receptors were recognized as potentially excellent biomarkers for targeted drug delivery, and significant advancement has been made to date (*10, 11, 21, 22*). In contrast, the biotin receptors were not investigated for this purpose until recently. Biotin (vitamin H or B-7) is a growth promoter at the cellular level, and its content in tumors is substantially higher than that in normal tissues (*19*). Recently, it has been shown that the biotin receptors are overexpressed more than the folate and/or vitamin B-12 receptors in many cancer cells, e.g., leukemia (L1210FR), ovarian (Ov2008, ID8), Colon (Colo-26), mastocytoma (P815), lung (M109), renal (RENCA, RD0995), and breast (4T1, JC, MMT06056) cancer cell lines (*19, 20*). Accordingly, we chose biotin as the tumor-targeting molecule for our tumor-targeting DDS bearing a self-immolative disulfide linker with a second-generation taxoid as the cytotoxic agent (*4, 18*).

We describe here a mechanistic study on the validation of tumor-targeting DDS by monitoring (i) the internalization through receptor-mediated endocytosis (RME), (ii) drug release triggered by an intracellular thiol, e.g., glutathione (GSH), and (iii) drug binding to the molecular target in cancer cells, using fluorescent and fluorogenic molecular probes of the biotin-linker-taxoid conjugate. The efficacy and cell-specificity of the biotin-linker-taxoid conjugate is also evaluated based on cytotoxicity of the conjugate against cells that overexpress the biotin receptor, as well as those do not express this vitamin receptor, including normal human cells.

EXPERIMENTAL SECTION

Chemical Syntheses, Procedures, and Characterization Data for Conjugates 1−4. See Supporting Information.

Cell Culture. L1210 (ATCC) and L1210FR (a gift from Dr. Gregory Russell-Jones, Access Pharmaceuticals Australia Pty Ltd., Australia) cell lines were grown as a suspension in the RPMI-1640 cell culture medium (Gibco) in the absence of folic acid (FA) but supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) as well as 1% (v/v) penicillin and streptomycin (P/S) at 37 °C in a humidified atmosphere with 5% CO_2. WI-38 human lung fibroblast cells (ATCC) were cultured as monolayers on 100 mm tissue culture dishes in a DMEM cell culture medium (Gibco) that was supplemented with 10% (v/v) heat-inactivated FBS and 1% (v/v) P/S at 37 °C in a humidified atmosphere with 5% CO_2. The cells were harvested, collected by centrifugation at 1000 rpm for 6 min, and finally resuspended in fresh cell culture medium containing different cell densities for subsequent biological experiments and analysis.

Incubation of Cells with the Biotin−FITC Conjugate 2. The cell suspension (1 mL) at 5×10^5 cells/mL was added to a 1.5 mL microcentrifuge tube first. The biotin−FITC conjugate **2** (10 μM) in DMSO (10 μL) was then injected into the microcentrifuge tube to provide the final concentration of 100 nM, and the resultant suspension was incubated at 37 °C for 3 h. For low-temperature experiments, the incubation of cells (L1210FR) with conjugate **2** was carried out in the cold room at 4 °C for 3 h. For the assessment of the effect of NaN_3 addition, the cells were initially preincubated at 37 °C for 0.5 h with 0.05% (w/v) of NaN_3, prior to the addition of conjugate **2**. For the assessment of the effect of excess biotin addition, the cells were treated with 2 mM of biotin (at the final concentration) at 37 °C for 1 h prior to incubation with conjugate **2**. After incubation, the cells were washed twice with PBS, collected by centrifugation, and resuspended in 100 μL PBS for imaging.

Incubation of Cells with the Biotin-Linker-Coumarin Conjugate 3. The cell suspension (1 mL: 5×10^5 cells/mL) was added to 1.5 mL microcentrifuge tube. The conjugate **3** (100 μM) in DMSO (10 μL) was added to the microcentrifuge tube at the final concentration of 1 μM. After incubation at 37 °C for 3 h, the cells were washed twice by PBS to remove excess conjugates and resuspended in the medium. To observe the release of coumarin in a short period of time, GSH-OEt (10 μL) was added to the L1210FR cell suspension at the final concentration of 2 mM and incubated for another 2 h. Excess GSH-OEt was removed by washing twice with PBS, and the cells were collected by centrifugation. Then, the cells were resuspended in 100 μL PBS prior to imaging. In the control experiment, DMSO (10 μL) was added to the suspension and incubated for another 2 h. After incubation, cells were washed with PBS twice, collected by centrifugation, and resuspended in 100 μL PBS prior to imaging.

Incubation of Cells with the Biotin-Linker-SB-T-1214-Fluorescein Conjugate 4. The cell suspension (1 mL: 5×10^5 cells/mL) was added to a 1.5 mL microcentrifuge tube. The biotin-linker-SB-T-1214-fluorescein conjugate **4** (2 mM) in DMSO (10 μL) was added to the microcentrifuge tube at the final concentration of 20 μM. After incubation at 37 °C for 2 h, the cells were washed twice with PBS to remove excess conjugates and resuspended in the medium. For observation of the release of taxoid in a short period of time, GSH-OEt (10 μL) was added to the L1210FR cell suspension at the final concentration of 2 mM and incubated for another 1 h. Excess GSH-OEt was removed by washing twice with PBS, and the cells were collected by centrifugation. Then, the cells were resuspended in 100 μL PBS prior to imaging. In the control experiment, DMSO (10 μL) was added to the suspension and incubated for another 1 h. After incubation, cells were washed with PBS twice, collected by centrifugation, and resuspended in 100 μL PBS prior to imaging.

Confocal Microscopy Imaging of the Treated Cells. Cells treated as described above were resuspended in 100 μL of PBS after each experiment, and dropped onto an uncoated glass dish (MatTek Corp.). Confocal fluorescence microscopy (CFM) experiments were performed using a Zeiss LSM 510 META NLO two-photon laser scanning confocal microscope system, operating at a 488 nm excitation wavelength and at 527 ± 23 nm detecting emission wavelength using a 505−550 nm bandpass filter. Images were captured using a C-Apochromat 63×/1.2 water (corr.) objective or a Plan-Apochromat 100×/1.45 oil objective. Acquired data were analyzed using LSM 510 META software.

Flow Cytometry Fluorescent Measurements of the Cells. Flow cytometry analysis of the treated cells was performed with a flow cytometer, FACSCalibur, operating at a 488 nm excitation wavelength and detecting emission wavelengths with a 530/30 nm bandpass filter. Cells treated as described above were resuspended in 0.5 mL of PBS. At least 10 000 cells were counted for each experiment using *CellQuest 3.3* software (Becton Dickinson) and the distribution of FITC fluorescence was analyzed using *WinMDI 2.8* freeware (Joseph Trotter, Scripps Research Institute). Propidium iodide staining was used in all experiments to rule out dead cell count in the analysis.

In Vitro Cytotoxicity Assay. The cytotoxicities of biotin-linker-SB-T-1214 (**1**), biotin-linker-SB-T-1214-fluorescein (**4**), SB-T-1214, SB-T-1214-fluorescein (**24**), and paclitaxel were evaluated in vitro against murine leukemia cell lines, L1210FR and L1210, as well as a human lung blastoma cell line, WI38, by means of a quantitative colorimetric assay using a tetrazolium

salt-based analysis ("MTT assay" (*23*); MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; Sigma Chemical Co.). The inhibitory activity of each compound is represented by the IC_{50} value, which is defined as the concentration required for inhibiting 50% of the cell growth. Cells were harvested, collected, and resuspended in 100 μL medium at a concentration of $\sim 2 \times 10^4$ cells per well over a 96-well plate. For the adhesive cell type, cells were allowed to descend to the bottom of the plates overnight and fresh medium was added to each well upon removal of the old medium. A conjugate (**1** or **4**), taxoid (SB-T-1214 or **24**), or paclitaxel in DMSO stock solution was diluted to a series of concentrations in the cell culture medium without FBS to prepare test solutions. These test solutions at different concentrations ranging from 0.1 to 100 nM (10 μL each) were added to the wells in the 96-well plate and cells were subsequently cultured for 72 h. After spinning down the cells and removing the old medium, the fresh medium containing MTT (e.g., 100 μL of 0.5 mg/mL) was added and incubated at 37 °C for 4 h. The resulting medium was then removed and as-produced insoluble violet formazan crystals were dissolved into 0.1 N HCl in isopropanol with 10% Triton X-100 to give a violet solution. The spectrophotometric absorbance measurement of each well in the 96-well plate was run at 570 nm. The IC_{50} values and their standard errors were calculated from the viability−concentration curve using the Four Parameter Logistic Model of *Sigmaplot*. The concentration of DMSO per well was ≤1% in all cases. The control experiment, i.e., adding 1% DMSO to the cells, indicated that 1% DMSO was not cytotoxic, and thus, all the cells treated remained virtually 100% positive.

RESULTS AND DISCUSSION

Design of an Efficient Tumor-Targeting DDS and Its Molecular Probes. Our tumor-targeting DDS consists of a tumor recognition moiety (biotin in the present study) and a cytotoxic agent connected through a self-immolative linker. The drug conjugate should be nontoxic systemically but release the cytotoxic agent upon internalization to cancer cells, as mentioned above.

Self-Immolative Disulfide Linker. In order to develop efficacious tumor-targeting DDS's, efficient mechanism-based linkers are critically important since the tumor-targeting DDS should be stable in blood circulation while readily cleavable in the tumor. These linkers should be bifunctional so that the cytotoxic agent can be connected to the linker at one end and the tumor-targeting module at the other end. Previously, we designed and examined mAb−taxoid conjugates as tumor-targeting DDS, which exhibited extremely promising results against human cancer xenografts in SCID mice (*2*). The results clearly demonstrated the tumor-specific delivery of a taxoid anticancer agent, curing all animals tested without any noticeable toxicity to the animals (*2*). As the linker for these mAb-taxoid DDS's, a simple disulfide linker was employed, which was stable in blood circulation but efficiently cleaved by intracellular reducing substances in the tumor. However, in this first-generation mAb-taxoid DDS, the original taxoid molecule was not released because of the compromised modification of the taxoid molecule to accommodate the disulfide linker. Thus, the cytotoxicity of the taxoid released (SB-T-12136-SH) was 8 times weaker than the parent taxoid (SB-T-1213) (*2*).

As a solution to this problem, we devised the second-generation mechanism-based bifunctional disulfide linkers, which can be connected to various cytotoxic agents and tumor-targeting molecules. We designed self-immolative disulfide linkers wherein the intracellular thiol-triggered cascade drug release should generate the original anticancer agent via thiolactone formation and ester bond cleavage (Figure 1) (*24*).

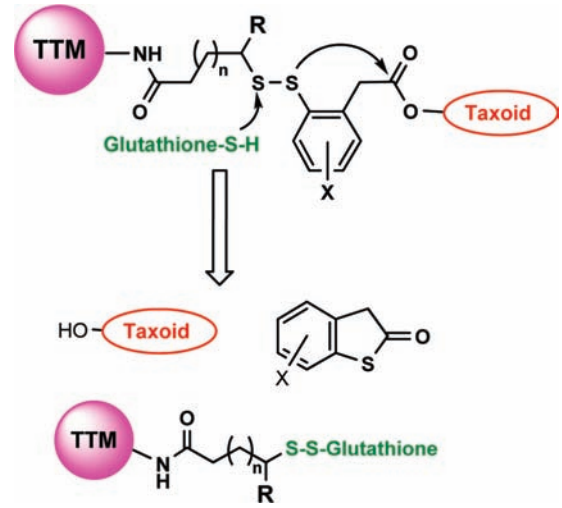

Figure 1. Second-generation self-immolative disulfide linkers (TTM = tumor-targeting module).

The designed mechanism-based drug release has been proven in a fluorine-labeled model system by monitoring the reaction with ^{19}F NMR (*24*). The strategic placement of a phenyl group attached to the disulfide linkage should direct the cleavage of this linkage by a thiol to generate the desirable thiophenolate or sulfhydrylphenyl species for thiolactonization. The disulfide linkage should be cleaved by endogenous thiols, e.g., GSH and thioredoxin. It has been shown that the GSH level in cancer cells is >1000 times higher than that in blood plasma (*25*−*29*). The resulting thiol undergoes an intramolecular nucleophilic substitution at the ester moiety, forming a 5-membered ring thiolactone and releasing the taxoid in its original form. This type of self-immolative disulfide linker can readily be applied to a variety of tumor-targeting drug conjugates. We chose a rather simple linker (R = X = H, $n = 0$) in the present study.

Cytotoxic Agent. Although paclitaxel and docetaxel have brought about significant impact on cancer chemotherapy, mainly because of their unique mechanism of action (*30*), these drugs seriously suffer from the lack of tumor specificity and multidrug resistance (MDR). These taxane drugs are effective against breast, ovary, and lung cancers, while they do not show efficacy against colon, pancreatic, melanoma, and renal cancers. As an example, human colon carcinoma is inherently multidrug-resistant due to the overexpression of P-glycoprotein (Pgp), which is an effective ATP-binding cassette (ABC) transporter and effluxes out hydrophobic anticancer agents, such as paclitaxel and docetaxel (*31*).

We have developed a series of highly potent second- and third-generation taxoids through structure−activity relationship study of taxoids (*32*−*37*). Most of these taxoids exhibited 2−3 orders of magnitude higher potency than those of paclitaxel and docetaxel against MDR cell lines expressing Pgp. Accordingly, these highly potent taxoids have been used as cytotoxic agents of our tumor-targeting DDS's. Among these new-generation taxoids, we chose SB-T-1214, a second-generation taxoid, as the warhead for the present study.

Molecular Probes of the Biotin-Linker-Taxoid Conjugate. The structure of a "guided molecular missile", biotin-linker-SB-T-1214 (**1**), is shown in Figure 2. In order to monitor the sequence of events involved in tumor-targeting drug delivery of conjugate **1**, it was necessary for us to design and synthesize three fluorescence-labeled biotin conjugates, i.e., biotin-fluorescein (**2**), biotin-linker-coumarin (**3**) (fluorogenic probe), and biotin-linker-taxoid-fluorescein (**4**) (Figure 3).

Conjugate **2** was designed to observe RME (Figure 4), while conjugate **3** was designed for confirming the internalization of

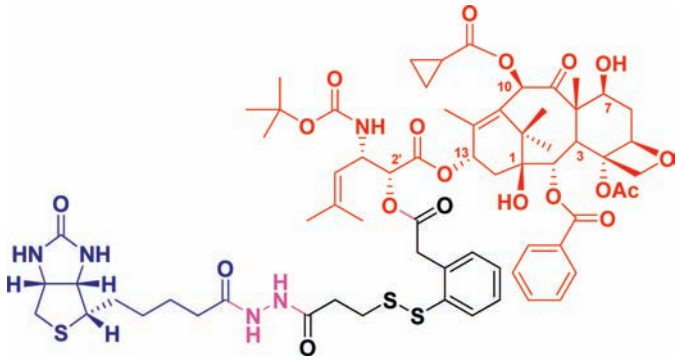

Figure 2. Biotin-linker-SB-T-1214 conjugate (**1**).

the conjugate via RME and the release of coumarin, which becomes fluorescent only when it is released as a free molecule via disulfide cleavage. Fluorogenic molecules, such as coumarin derivatives, have been widely utilized as model systems for probing drug release (*38*). Conjugate **4** was designed to validate the whole internalization by RME and drug release processes, wherein the released fluorescent taxoid should bind to the target protein, microtubules, in the cancer cells (Figure 4).

Figure 4 illustrates the internalization and drug release mechanism of a biotin-linker-taxoid conjugate. Once localized at the tumor site, the drug-conjugate binds to its complementary receptor on the tumor cell surface and is further internalized via RME. The disulfide linkage of the drug-conjugate is cleaved by endogenous reducing agents (e.g., GSH) to generate a thiol group. The resulting thiol group undergoes thiolactonization to release the taxoid warhead in its original form (i.e., SB-T-1214). When a fluorescent taxoid (i.e., SB-T-1214-fluorescein) is used, it should bind to microtubules, visualizing the fluorescent microtubule network.

Chemical Synthesis. The fluorescent probe, biotin-FITC **2**, was synthesized via coupling of fluorescein isothiocyanate (FITC) to biotin-$NHNH_2$ (**5**), which was readily prepared from biotin through esterification and subsequent reaction with hydrazine, as shown in Scheme 1.

The synthesis of the fluorogenic probe, biotin-linker-coumarin **3**, is illustrated in Scheme 2. First, triisopropylsilyl(TIPS) pyridine-2-yldisulfanylpropanoate (**8**) was prepared through thiol-disulfide exchange reaction of pyridine disulfide (**6**) with 3-sulfhydrylpropanoic acid, giving **7**, followed by TIPS protection of the carboxylic acid moiety of **7**. Second, 2-sulfhydrylphenylacetic acid (**11**) was prepared from benzothiophene-2-boronic acid (**9**) through hydrogen peroxide oxidation to benzothiophen-2-one (**10**), followed by hydrolysis with lithium hydroxide. The reaction of **8** with **11** via thiol-disulfide exchange reaction gave 2-(TIPSO-carbonylethyl)disulfanylphenylacetic acid (**12**). The coupling of **12** with 7-hydroxy-4-methylcoumarin (**13**) gave coumarin-linker (TIPS) conjugate (**14**), which was deprotected to afford coumarin-linker conjugate **15**. The DCC-coupling of **15** with *N*-hydroxysuccinimide (HOSu) afforded coumarin-linker-OSu active ester **16**. The amide coupling of **5** with **16** gave conjugate **3**.

The synthesis of biotin-linker-taxoid-fluorescein **4** is illustrated in Schemes 3−5. First, commercially available fluorescein was converted to the corresponding methyl ester **17** (*39*), while succinic acid mono-*tert*-butyl ester (**18**) was reduced to *tert*-butyl 4-hydroxybutanoate (**19**) (*40*). The Mitsunobu coupling of **17** with **19** afforded modified fluorescein diester **20** (*39*). Selective deprotection of the *tert*-butyl group of **20** with trifluoroacetic acid afforded 6-tethered fluorescein methyl ester **21** (Scheme 3). Next, the C2′ hydroxy group of taxoid SB-T-1214 was protected as *tert*-butyldimethylsilyl (TBS) ether to give **22**, which was coupled with **21** under DIC/DMAP conditions, followed by deprotection of the C2′-TBDMS group to afford 7-fluorescein-tethered taxoid **24** (Scheme 4). Subsequently, SB-T-1214-fluorescein **24** was coupled with disulfanylacetic acid **12** using DIC/DMAP to give **25**, which was deprotected with HF-pyridine to afford (SB-T-1214-fluorescein)-linker-CO_2H conjugate **26** (Scheme 5). The carboxylic acid moiety of **26** was converted to the corresponding activated ester **27** via esterification with HOSu in the presence of DIC. Finally, activated ester **27** was reacted with **5** to give biotin-linker-SB-T-1214-fluorescein conjugate **4** in high yield (Scheme 5).

Following the same synthetic protocol, biotin-linker-SB-T-1214 **1** was synthesized by using SB-T-1214 without the fluorescein tether, as shown in Scheme 6.

Probing Receptor-Mediated Endocytosis (RME), Drug Release, and Drug Binding to Target. Internalization of these fluorescent and fluorogenic probes **2**−**4** was monitored by confocal fluorescence microscopy (CFM) and the fluorescence was quantified by flow cytometry, using ca. 10 000 treated live cells. Results are shown in Figures 5−8.

Figure 5A shows the intense fluorescence observed when the L1210FR cell was incubated with the probe **2** (100 nM) at 37 °C for 3 h, followed by thorough washing of the cells by phosphate-buffered saline (PBS) and CFM analysis. The result clearly indicates the efficient internalization of the fluorescent probe **2** into the leukemia cells. It has been shown that endocytosis is an energy-dependent process and should be inhibited either at low temperature (4 °C) or in the presence of the metabolism inhibitor, typically NaN_3 (*41*−*43*). The CFM image of the probe **2**, incubated at 4 °C (100 nM, 3 h) showed dramatically diminished (ca. 6 times by flow cytometry) fluorescence in the cells (Figure 5B). When L1210FR cells were incubated with probe **2** (100 nM, 3 h) in the presence of 0.05% (w/v) NaN_3 at 37 °C, a substantial decrease (ca. 4 times) in fluorescence occurred inside the cells as well (Figure 5C). These results unambiguously show that probe **2** was internalized through endocytosis. To validate that this was a RME process, excess free biotin (2 mM) was preincubated for 1 h to saturate the biotin receptors on the cancer cell surface, and subsequently, probe **2** (100 nM, 37 °C, 3 h) was added. The CFM image revealed a substantial decrease (ca. 4.5 times) in fluorescence. The result confirms that this is indeed the receptor-mediated endocytosis (Figure 5D).

Next, the fluorogenic probe **3** (1 μM) was incubated with L1210FR cells at 37 °C for 3 h, and afterward, the cells were washed thoroughly with PBS. Then, glutathione ethyl ester (GSH-OEt, 2 mM) was added to the medium and cells were incubated for another 2 h at 37 °C. The addition of GSH-OEt was to ensure the cleavage of the self-immolative disulfide linker to release free coumarin, as designed. [Note: It has been shown that GSH-OEt is internalized into cells to generate GSH inside the cell (*44*). GSH-OEt also acts as a reducing agent.] As Figure 6A shows, fluorescent coumarin molecules (blue) are indeed released in L1210FR cells. The result unambiguously demonstrates that the intracellular release of coumarin (a drug surrogate) via cleavage of the disulfide linkage by GSH and the subsequent thiolactonization, took place as designed. In the absence of additional GSH (or GSH-OEt), the observed blue fluorescence was drastically weaker (Figure 6B). This means that the concentration of intracellular GSH in this leukemia L1210FR cell line is rather low, especially in the 3 h time frame, under the in vitro experimental conditions, which are significantly different from those in vivo where the GSH supply in tumor tissues is more than adequate (*26*, *27*). On the other hand, this experiment using additional GSH (as GSH-OEt) confirmed that the cleavage of the self-immolative disulfide linkage and subsequent drug release was caused by GSH.

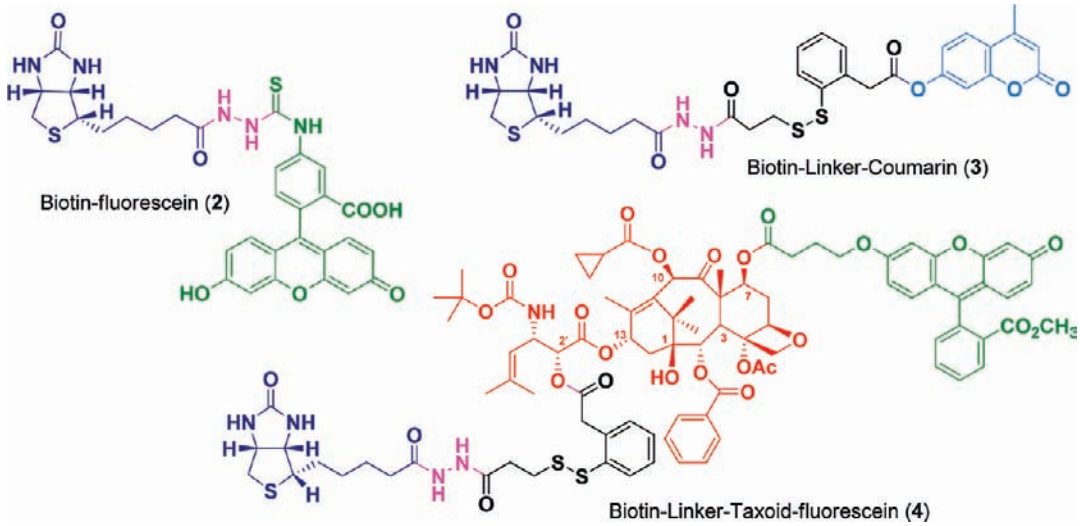

Figure 3. Fluorescent and fluorogenic probes for the internalization and drug-release.

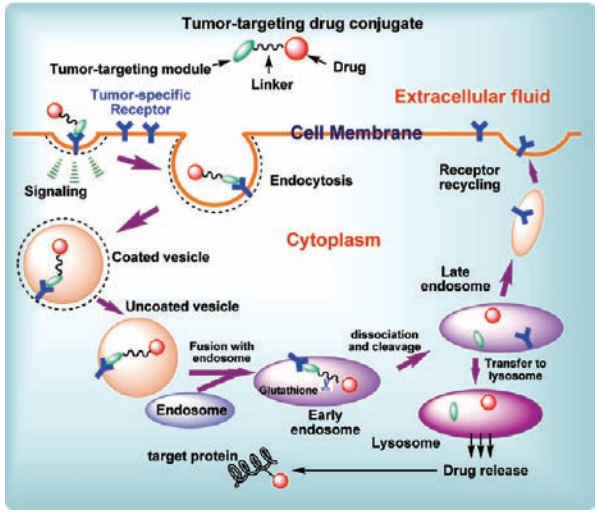

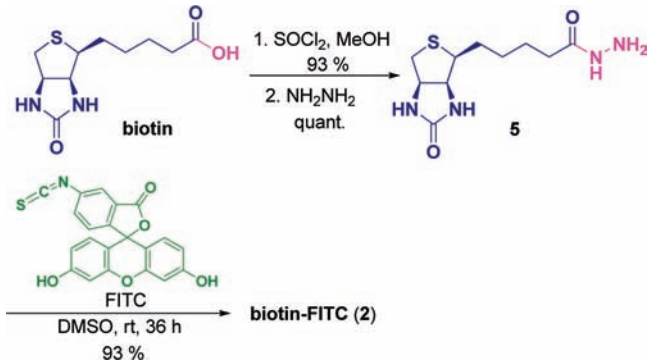

Figure 4. Schematic representation of the RME of a tumor-targeting drug conjugate, drug release, and drug-binding to the target protein.

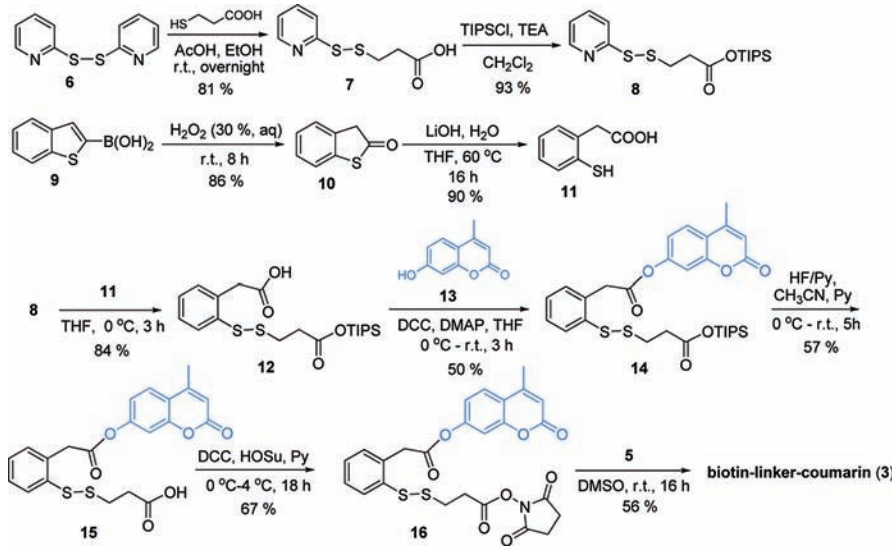
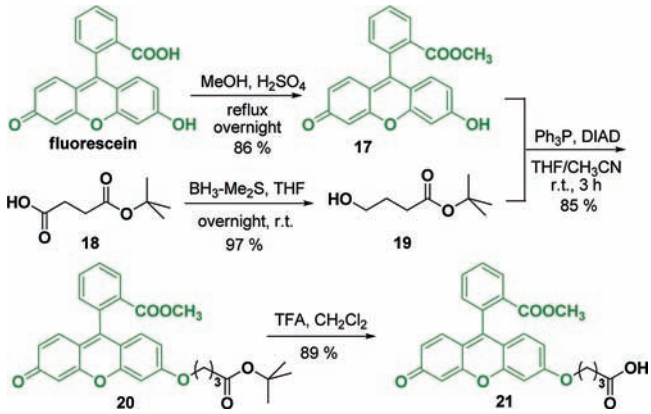
Scheme 1. Synthesis of Biotin−FITC Conjugate 2

Finally, the internalization and drug release of probe **4** was examined. Probe **4** (20 μM) was incubated with L1210FR cells at 37 °C for 2 h and analyzed by CFM. As Figure 7A shows, the whole conjugate was internalized in the same manner as that described above for the probe **2** (see Figure 5A). Next, GSH-OEt (2 mM) was added to the medium, and the cells were incubated for another 1 h to ensure the drug release. As Figure 7B shows, the CFM image of this system is dramatically different from that shown in Figure 7A. The CFM image in Figure 7B indicates that the released fluorescent taxoid binds to the microtubules that are the drug target of the taxoid and highlights the fluorescence-labeled microtubule bundles. The result confirms that the release of the taxoid proceeded through the designed mechanism (see Figure 1) in the same manner as that observed for the fluorogenic probe **3**. To double-check the morphology of microtubules with the fluorescence-labeled taxoid, the CFM image of the L1210FR cells treated with SB-T-1214-fluorescein (**24**) was taken. As Figure 7C shows, the morphology of treated cells is indeed virtually identical to that treated with the conjugate **4**. This provides additional evidence of efficient release of **24** from the conjugate **4**.



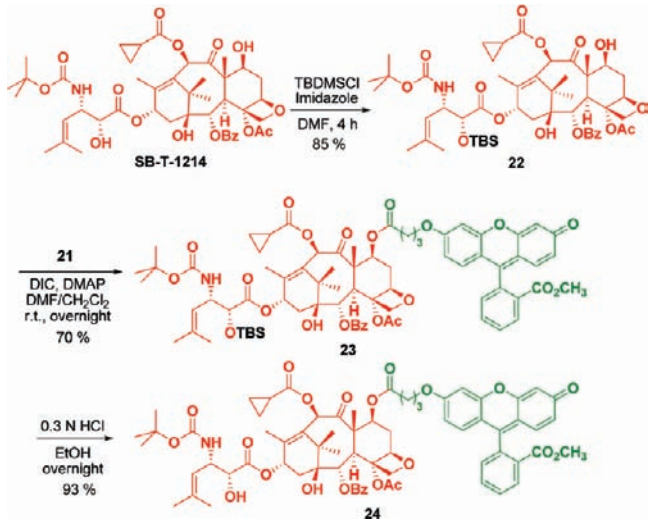
It should be noted that the intracellular GSH in L1210FR would also be able to cleave the disulfide linkage with longer incubation time (vide infra), but the endogenous GSH level in cancer cells varies due to the significant difference in the physiological conditions in the actual leukemia or solid tumors. Accordingly, the extracellular addition of excess GSH-OEt was beneficial for rapid visualization of the drug release inside the leukemia cells.

Consequently, we can safely conclude that the tumor-targeting DDS successfully delivered the active cytotoxic agent to the drug target, as designed, through RME and GSH-triggered intracellular drug release via cleavage of self-immolative disulfide linker and thiolactonization.



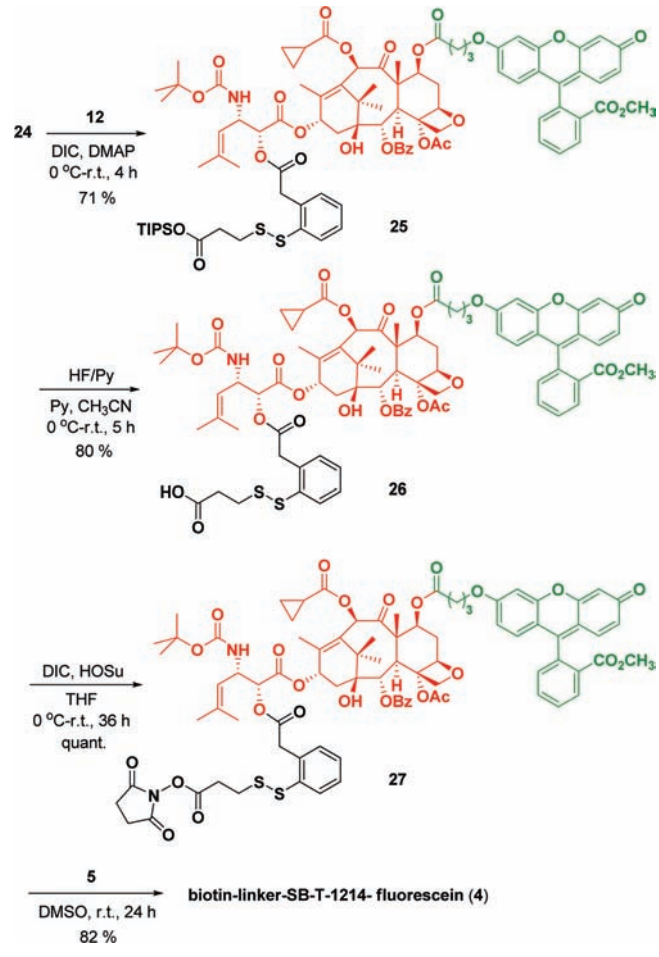
Evaluation of Tumor-Targeting Specificity of Biotin-Linker-Taxoid Conjugates by CFM and Cytotoxicity Assay. To evaluate the tumor specificity of the biotin-mediated RME, two other cell lines, i.e., L1210 murine leukemia cell line and WI38 noncancerous human lung fibroblast cell line, were chosen to compare results with that for L1210FR cell line. Both L1210 and WI38 cell lines do not overexpress biotin receptors on their cell surfaces. Accordingly, this comparison should provide a fair and definitive information about the efficacy of tumor-targeting using biotin as the "guiding" module for our "guided molecular missile".

As Figure 8 clearly shows, much stronger (ca. 12−13 times) fluorescence was indeed observed in L1210FR cells (Figure 8A) as compared to that in L1210 cells (Figure 8B) as well as WI38 cells (Figure 8C) upon incubation with the probe **4** under identical conditions (20 μM at 37 °C for 2 h) by CFM and flow cytometry analyses. Thus, the results confirm the validity of our tumor-targeting design based on this vitamin and its receptors, which can clearly distinguish cancer cells overexpressing the vitamin receptors from other cells which do not, including human normal cells.

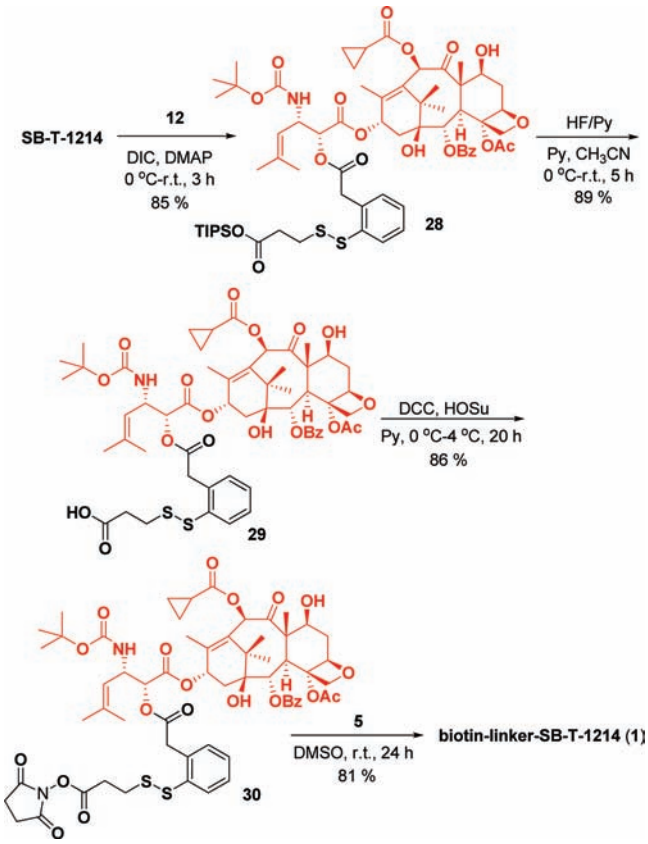


Scheme 2. Synthesis of Biotin-Linker-Coumarin Conjugate (3)

Scheme 3. Preparation of Fluorescein Derivative with Carboxylic Acid Tether



Scheme 4. Synthesis of SB-T-1214 Linked to Fluorescein (24)



As described above, the mechanistic investigation into the cancer cell specificity, RME, drug release, and drug binding to the target protein with the use of fluorescent and fluorogenic molecular probes were successfully executed by means of CFM and flow cytometry. However, these observations should be correlated to the cancer cell specific cytotoxicity of the originally designed biotin-linker-taxoid conjugate **1** against three cell lines examined by CFM and flow cytometry.

Scheme 5. Synthesis Diagram of Biotin-Linker-SB-T-1214-Fluorescein Conjugate (4)

Accordingly, the cytotoxicity assays (MTT method (*23*)) of conjugate **1** against L1210FR, L1210, and WI38 cell lines were performed. For comparison purpose, the parent taxoid (SB-T-1214), its fluorescein conjugate **24**, and paclitaxel were assayed as well. It should be noted that, in these assays, no GSH-OEt was added to the medium, since the exposure time is much longer (72 h) than that for CFM and flow cytometry analyses

Scheme 6. Synthesis of Biotin-Linker-SB-T-1214 (1)

(2−3 h), and hence, the amount of endogenous GSH should be sufficient to release the taxoid warhead (SB-T-1214) from conjugate **1**. Results are summarized in Table 1.

As Table 1 shows, conjugate **1** exhibited high potency (IC_{50} 8.8 nM) against L1210FR, overexpressing biotin receptors, while those against L1210 (IC_{50} 522 nM) and WI38 (IC_{50} 570 nM) cell lines were 59 times and 65 times less. For comparison, the parent taxoid (SB-T-1214) was also assayed against those three cell lines. As anticipated, SB-T-1214 cannot distinguish these cell lines, resulting in very similar IC_{50} values, i.e., 9.5 nM for L1210FR, 9.7 nM for L1210, and 10.7 nM for WI38. The results clearly indicate that highly efficient vitamin-receptor specific drug delivery to cancer cells has been achieved by conjugate **1**, and also, the drug release by endogenous GSH (and possibly by some other thiols) is efficient as well in 72 h incubation.

As Table 1 shows, the IC_{50} values of SB-T-1214, SB-T-1214-fluorescein, (**24**) and paclitaxel against L1210FR are 9.5 nM, 87.6 nM, and 122 nM, respectively. Thus, SB-T-1214 is ca. 13 times more potent than paclitaxel, and fluorescently labeled **24** is ca. 9 times less potent than the parent SB-T-1214 against L1210FR. As mentioned above, SB-T-1214 exhibited very similar IC_{50} values against these three cell lines. SB-T-1214-fluorescein **24** and paclitaxel showed slight to small differences in their IC_{50} values against the three cell lines, but differences are less than 45% at most (see Table 1). Thus, it is safe to say that these two taxanes cannot distinguish targeted cancer cells from normal cells, as anticipated.

We also assayed the cytotoxicity of the probe **4** against the same three cell lines. As Table 1 shows, virtually the same differences in IC_{50} values were observed, i.e., 81.7 nM for L1210FR and >5 μM for L1210 as well as WI38 (>61 times difference), as those for the conjugate **1**. Thus, the drug delivery to L1210FR is highly specific through vitamin-receptor recognition and RME in this conjugate (probe **4**), as well. As mentioned above, the cell specificity of probe **4** quantified by flow

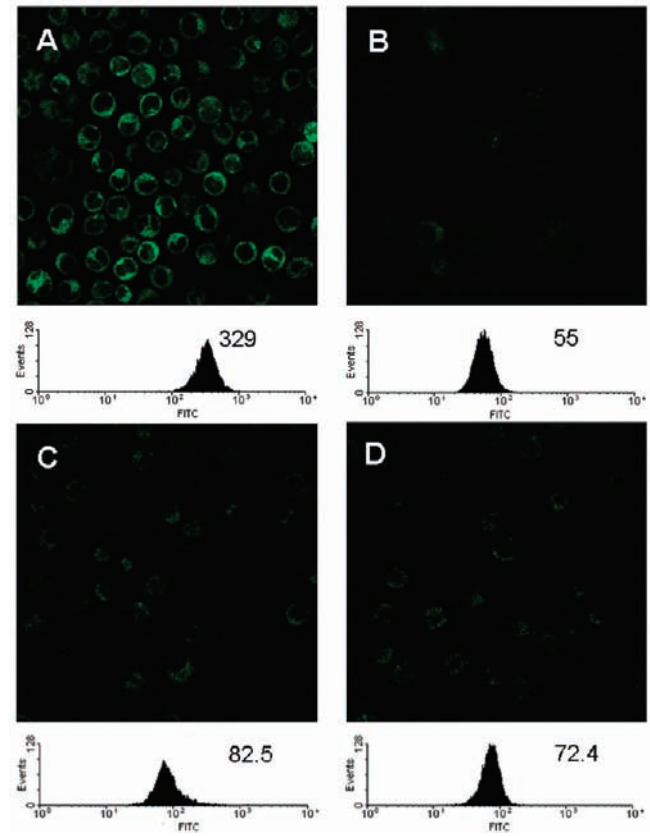


Figure 5. CFM images and flow cytometry analysis of L1210FR cells after incubation with the probe **2** under different conditions: (A) 100 nM, 37 °C, 3 h; (B) 100 nM, 4 °C, 3 h; (C) 100 nM, 37 °C, 0.05% NaN_3, 3 h; (D) 100 nM, 37 °C, 3 h, pretreated with excess biotin (2 mM).

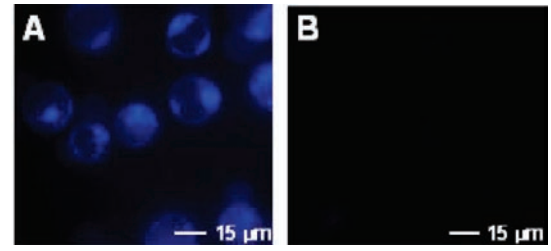

Figure 6. (A) Epifluorescence image of L1210FR cells that were initially incubated with the probe **3** (nonfluorescent form), followed by treatment with GSH-OEt to trigger the self-immolation of the linker. The released coumarin showed blue fluorescence. (B) Epifluorescence image of L1210FR cells after incubation with the probe **3** (nonfluorescent form).

cytometry was 11.7 for L1210FR/L1210 and 13.2 for L1210FR/WI38, which is more modest as compared to that based on cytotoxicity. It is most likely that this difference is attributed to the substantially shorter exposure time for the flow cytometry analysis (2 h) than that for the cytotoxicity assay (72 h), i.e., the internalization of the probe **4** has not been completed in 2 h. At any rate, the observation by CFM and flow cytometry corresponds well to the cytotoxicity assay results.

CONCLUSIONS

A highly efficient mechanism-based tumor-targeting DDS, consisting of a tumor-targeting molecule, self-immolative linker, and a cytotoxic agent, was designed and successfully developed. The proof of concept was obtained by using a drug conjugate, bearing biotin as the cell-targeting moiety, a mechanism-based

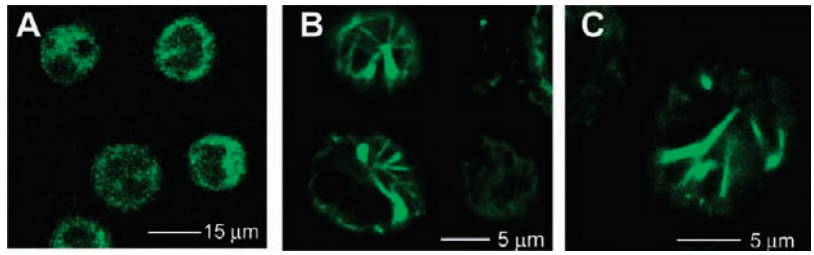

Figure 7. (A) CFM image of L1210FR cells after incubation with the probe **4**. (B) CFM image of L1210FR cells that were initially incubated with the probe **4**, followed by treatment with GSH-OEt to release the fluorescent taxoid **24**. Then, the microtubule network in the cells was fluorescently labeled by **24** and visualized. (C) CFM image of L1210FR cells after incubation with **24** as a control experiment.

Table 1. Cytotoxicities (IC_{50}, nM) of Paclitaxel, SB-T-1214, and Its Conjugates

	L1210FR	L1210	WI38
paclitaxel	121	151	157
SB-T-1214	9.50	9.72	10.7
24	87.6	107	127
1	8.80	522	570
4	81.7	>5000	>5000

disulfide linker, and a second-generation taxoid linked to fluorescein by means of CFM and flow cytometry. The result was confirmed by cytotoxicity assay using the drug conjugates with and without a link to fluorescein. Both conjugates exhibited excellent cell-specificity against three cell lines, L1210FR (biotin receptor +++), L1210 (biotin receptor ±), and WI38 (biotin receptor ±) based on the expression of biotin receptors on the cell surfaces. Efficient internalization of the drug conjugate into the targeted cancer cells via RME, smooth drug release via GSH-triggered self-immolation of disulfide linker, and drug binding to the target protein (microtubules) were monitored and validated by means of CFM using three fluorescent/fluorogenic molecular probes. This tumor-targeting DDS is applicable to a variety of drug conjugates consisting of various tumor-targeting molecules, e.g., monoclonal antibodies, aptamers, vitamins, peptides, and proteins, as well as cytotoxic agents. Further studies along this line are actively underway in these laboratories (*18*).

ACKNOWLEDGMENT

The Effect of Charge-Reversal Amphiphile Spacer Composition on DNA and siRNA Delivery

Xiao-Xiang Zhang,[†] Carla A. H. Prata,[†] Thomas J. McIntosh,[‡] Philippe Barthélémy,[§] and Mark W. Grinstaff*,[†]

Departments of Biomedical Engineering and Chemistry, Boston University, Boston, Massachusetts 02215, Department of Cell Biology, Duke University Medical Center, Durham, North Carolina 27710, and Inserm, U-869, Université de Bordeaux, Bordeaux, F-33076, France. Received December 9, 2009; Revised Manuscript Received April 7, 2010

A series of charge-reversal amphiphiles with different spacers separating the headgroup from the hydrophobic chains are described for delivery of DNA and siRNA. Among them, the amphiphiles possessing a glycine spacer (e.g., **B-GlyGly**) showed effective DNA transfection in CHO and NIH 3T3 cells, as well as siRNA gene knockdown in HepG2 and UASMC cells. Ethidium bromide quenching assays revealed that DNA was released the fastest from the lipoplex of **B-GlyGly** in the presence of esterase. Also, X-ray diffraction results indicated that the DNA was located between the adjacent lipid bilayers in the lipoplex of **B-GlyGly**. These distinct features appear to be required for high transfection activity.

INTRODUCTION

Gene therapy has received significant attention in the past decade due to its advantages over traditional therapies. The two most common methods for gene delivery use either synthetic (*1*−*5*) or viral (*6*−*10*) vectors. Compared to viral vectors, nonviral vectors have lower toxicity and high load capacity and are easy to synthesize. Consequently, there has been a significant effort to develop and evaluate nonviral vectors, which include cationic amphiphiles and polymers (*11*−*15*) and, more recently, anionic amphiphiles (*16*). Yet, synthetic vectors also have a number of limitations including low transfection efficiencies both in vitro and in vivo, significant cytotoxicity, and inactivation in the presence of serum. To overcome these limitations, investigators are modifying the amphiphile structure, and for small cationic amphiphiles, this entails alternative cationic head groups, linkers, and hydrophobic moieties. Examples of different cationic head groups explored include choline (*17, 18*), spermine (*19*), di- and tripeptides (*20, 21*), carbohydrates (*22, 23*), and nucleosides (*24*−*32*). With regard to the hydrophobic moiety, long chain ester and ether linked hydrocarbons have been extensively studied. The fluorinated analogues of cationic lipids, like DOTMA, have also been explored, and these amphiphiles exhibited higher transfection activities in vitro (*33*) and in vivo compared to their hydrocarbon analogues (*34*). In addition, researchers have used combinatorial approaches to screen large libraries of amphiphiles in order to identify key structural components of the amphiphile responsible for high transfection activity (*35, 36*).

Although significant research has been conducted regarding the structure−property relationships of a wide range of cationic lipids, only a few studies can be found that systematically investigate the effect of spacers within the headgroup, and include cationic lipids derived from betaine glycine (*37*), cationic glycolipids (*38*), and cholesterol-based cationic lipids (*39*). These studies, along with others, have begun to provide design parameters for optimizing the chemical structure for efficient nucleic acid delivery with minimal cytotoxicity.

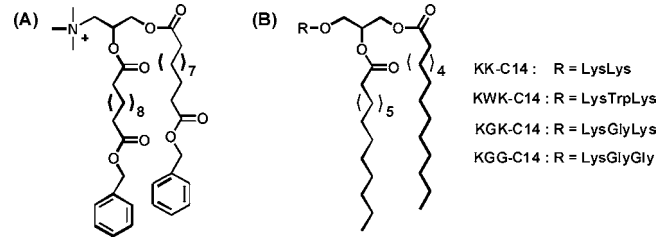

Figure 1. Amphiphiles previously studied.

In previous research in our lab, we found that a charge-reversal amphiphile (Figure 1A) which possesses benzyl esters at the end of alkyl chains showed high transfection activity (*40*). The total charge of this amphiphile was capable of switching from +1 to −1 when the benzyl esters are hydrolyzed. This charge-reversal effect was implemented to facilitate the release of DNA from the amphiphiles. In a separate study, we also found that spacing of the cationic charges within the headgroup in a series of peptide-based amphiphiles can afford improved transfection performance with amphiphiles **KWK-C14**, **KGK-C14**, and **KGG-C14** showing higher transfection compared to **KK-C14** (Figure 1B) (*21*). To take advantage of the charge-reversal effect, as well as to further understand how spacer length and composition affect transfection efficacy, here we present a study on a series of charge-reversal amphiphiles with different spacers separating the headgroup from the hydrophobic chains.

All the amphiphiles studied (Figure 2) possess a quaternary ammonium as a cationic headgroup (**B**) and the same alkyl chains ending with benzyl esters, but have spacers of different lengths: two, five, or seven atoms. The nature of the spacers is also varied: (1) the glycine and alanine spacers are relatively rigid, hydrophilic, and capable of hydrogen bonding (**B-Gly**, **B-GlyGly, B-AlaAla**; (2) the ethylene oxide spacers are flexible and hydrophilic (**B-EO**, **B-(EO)$_2$**); and (3) the alkyl chain spacers are flexible and hydrophobic (**B-(CH$_2$)$_4$**, **B-(CH$_2$)$_7$**).

RESULTS AND DISCUSSION

The synthetic routes to the different amphiphiles can be found in Scheme 1, and a detailed procedure can be found in the Supporting Information. In general, the different spacers

containing the headgroup were first synthesized and then coupled to **1** or **2** to afford the desired products. As a representative example, the synthesis of the **B-GlyGly** amphiphile is described next. *N*,*N*-Dimethylglycine hydrochloride and glycine benzyl ester hydrochloride were reacted in the presence of DCC and DMAP at RT for 16 h. Benzyl 2-(2-(dimethylamino)acetamido)acetate was purified as yellow oil (76%). The benzyl group

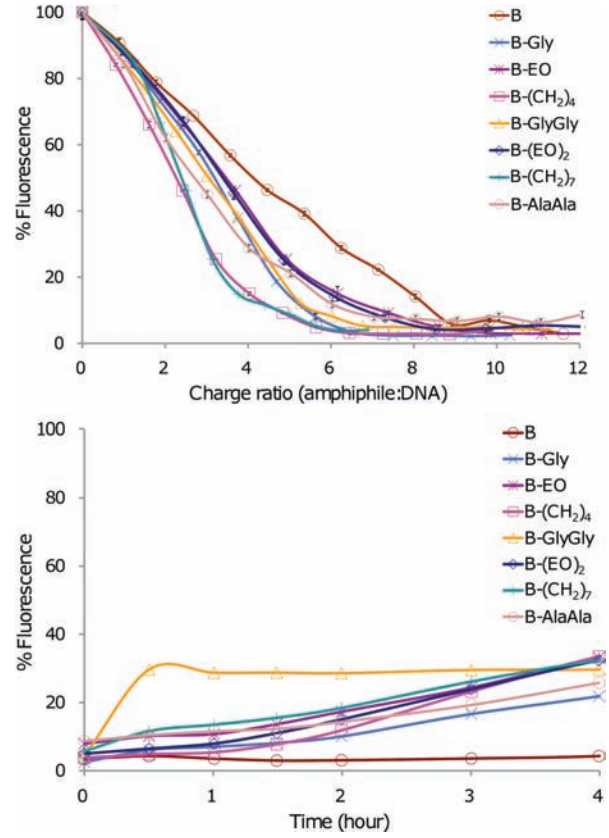

Figure 3. EtBr displacement assay showing the fluorescence intensity. Top: as a function of amphiphile/DNA charge ratio. Bottom: as a function of time in presence of porcine liver esterase (300 units/mL).

was removed in the presence of a catalytic amount of Pd(II) on carbon at RT under 50 psi H_2 for 16 h to afford the intermediate, in 84% yield. The deprotected 2-(2-(dimethylamino)acetamido)acetic acid was then coupled with **2** followed by reaction with CH_3I to afford the **B-GlyGly** amphiphile as a viscous oil in 80% yield. The characterization data for **B-GlyGly**, as well as all of the amphiphiles, can be found in the Supporting Information.

To determine whether the amphiphiles would bind DNA, a standard ethidium bromide (EtBr)-DNA fluorescence quenching assay was performed, as shown in Figure 3 (top). DNA binding was observed for all the amphiphiles with similar affinity. Among the amphiphiles, **B-$(CH_2)_4$** and **B-$(CH_2)_7$** showed the strongest binding affinity with a ± charge ratio of 6:1, and **B** bound the weakest with a charge ratio of 9:1. Next, the above DNA/EtBr/amphiphile solution was incubated with esterase at pH 7.4 (100 mM Tris, 100 mM NaCl buffer, 300 units/mL). The intensity of fluorescence, which reflects the dissociation of the amphiphile from the DNA as a consequence of the hydrolysis of the terminal benzyl esters, increased at slightly different rates for the amphiphiles, as shown in Figure 3 (bottom). DNA was released the fastest from the **B-GlyGly** complex with around 30% fluorescence recovered in the first 30 min, while less than 10% fluorescence recovery was observed for all the other complexes. During the 4 h period, fluorescence intensity increased slowly and reached ∼20−35% for all other complexes, except for **B** where the fluorescence did not change significantly.

Given their polar headgroup and long hydrophobic alkyl chains, these amphiphiles are likely to form bilayer vesicles in aqueous solution. Differential scanning calorimetry (DSC) traces of hydrated amphiphiles showed phase-transition temperatures between ∼−22 and −15 °C, except for **B**, which was 60.6 °C

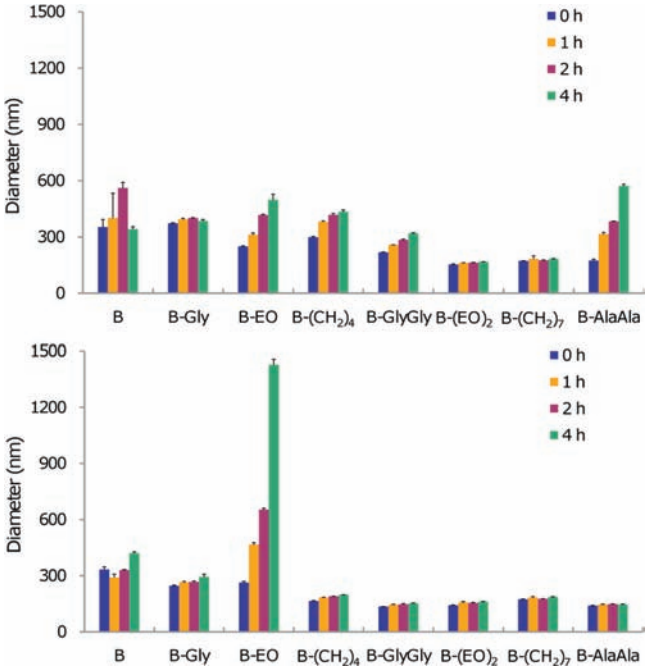

Figure 4. Sizes of lipoplexes (nm) at pH 7.4 (top) and pH 5 (bottom). $N = 3$, mean ± SD.

Table 1. Phase Transition Temperatures of the Amphiphiles and Repeat Periods without and with DNA

		repeating period (nm)	
amphiphiles	T_m (°C)	without DNA	with DNA
B	60.6	5.9	6.2
B-Gly	−15.4	5.4	5.6
B-EO	−22.2	5.7	6.7
B-$(CH_2)_4$	−17.3	7.6	7.8
B-GlyGly	−16.8	6.1	7.9
B-$(EO)_2$	−19.6	6.4	6.5
B-$(CH_2)_7$	−14.8	1.4	5.8
B-AlaAla	−19.3	6.4	7.0

(Table 1). We subsequently prepared liposome solutions of all the amphiphiles by sonicating a hydrated film of the amphiphile in an aqueous solution (see Supporting Information for details). Dynamic light scattering measurements revealed that the sizes of liposomes in the presence of DNA varied from 154 to 353 nm in pH 7.4 solution (100 mM NaCl, 100 mM Tris buffer). The stability of the liposomes over time was examined by measuring their sizes at 0, 1, 2, and 4 h (Figure 4 top). The size of liposomes formed from **B-Gly**, **B-$(EO)_2$**, and **B-$(CH_2)_7$** remained almost constant during the 4 h period, while those of other amphiphiles increased moderately. Given that these increasing rates are very small, all the liposomes appeared to be stable.

Since endocytosis is one of the major cell uptake pathways for internalization of nonviral vectors (*41*−*44*), liposomes were incubated in a solution (100 mM NaCl, 100 mM phosphate buffer) of pH 5, which resembles the pH of the endosome, and analyzed at 0, 1, 2, 4 h (Figure 4 bottom). Generally, the size of liposomes at pH 5 is slightly smaller than those at pH 7.4. During the 4 h period, all the liposomes were stable except for the liposome formed with **B-EO**, which quickly increased in size. The size increased from 264 to 468 nm in 1 h, and further to 655 and 1428 nm in 2 and 4 h. These findings demonstrated that the liposomes formed from the amphiphiles were stable under pH 7.4 and mildly acidic conditions, except those formed from **B-EO**.

Next, to characterize the supramolecular structures, X-ray diffraction experiments were performed at 22 °C on all of the

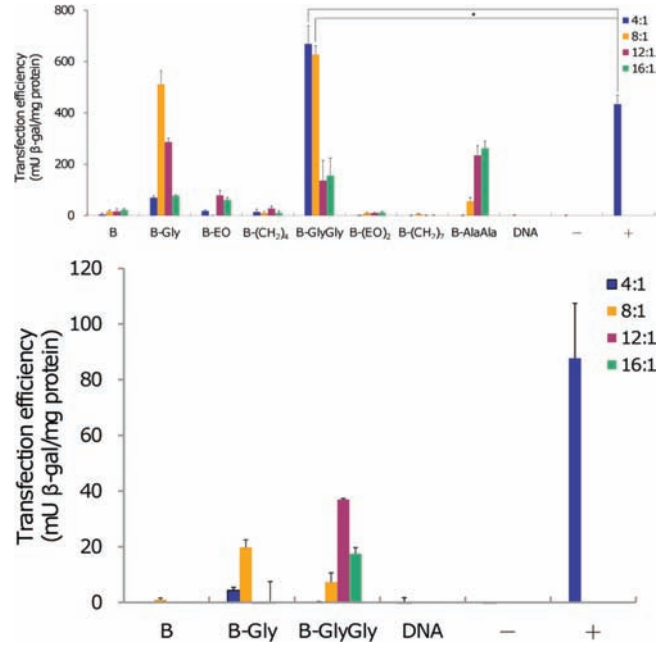

Figure 5. DNA transfection after 48 h in CHO (top) and NIH3T3 (bottom) cells as a function of amphiphiles and DNA molar ratio. Lipofectamine 2000 was used as positive control. $N = 3$, mean ± SD, * $p < 0.05$.

samples in the absence and presence of DNA. A hydrated vesicle pellet was obtained for all samples, and oriented multilayers were prepared for X-ray analysis by placing the pellets on a curved glass substrate and incubating at 66% relative humidity. All of the samples showed multiple reflection indexing as orders of lamellar repeat periods, characteristic of lipid bilayers (Table 1).

The repeat periods of all samples in the absence of DNA were between 5.4 and 7.6 nm, except for **B-$(CH_2)_7$**, which had a period of 1.4 nm. This period was abnormally small and could be a higher-order reflection from a larger repeat period. The addition of DNA increased the repeat period for all of the assemblies. A smaller increase between 0.1 and 0.6 nm was observed for **B**, **B-Gly**, **B-$(CH_2)_4$**, **B-$(EO)_2$**, and **B-AlaAla**, while for **B-GlyGly**, we observed an increase in the period of 1.8 nm. This larger change would be consistent with a structural model where a smectic phase was formed with the DNA chains located between the adjacent lipid bilayers within the multilamellar liposome. This structural model has been reported for complexes of DNA with DOTAP (*45*) and cationic triesters of phosphatidylcholine (*46*). For the other samples, the repeat periods did not change significantly, indicating that DNA was not located within the lipid multilayers.

Transfection experiments using reporter gene, β-galactosidase (β-gal, pVax-LacZ1, Invitrogen) were performed with CHO and NIH 3T3 cells (Figure 5). Gene transfection results were determined after 48 h as a function of cation/anion ratios (4:1, 8:1, 12:1, 16:1).

In CHO cells, amphiphiles **B-Gly** and **B-GlyGly** showed the highest transfection activity, amphiphile B-AlaAla exhibited moderate activity, and the other amphiphiles showed minimal transfection efficiency. **B-GlyGly** was significantly more active than the positive control, Lipofectamine 2000. However, both amphiphiles **B-Gly** and **B-GlyGly** were less active than Lipofectamine 2000 in NIH 3T3 cells, but still had higher transfection efficiency compared to the other amphiphiles we tested. These results showed that those amphiphiles containing spacers that are hydrophilic, relatively rigid, and capable of hydrogen bonding possessed the highest transfection activity. We also

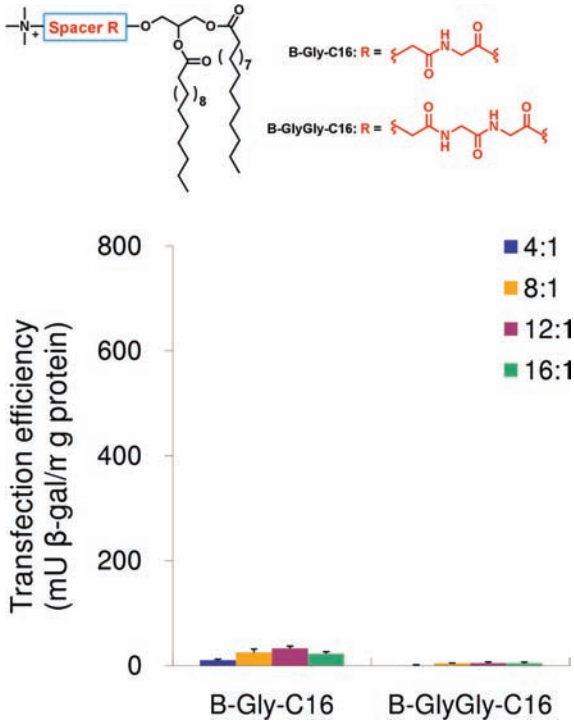

Figure 6. Structures of **B-Gly**-C16 and **B-GlyGly**-C16 and DNA transfection after 48 h in CHO cells as a function of amphiphiles and DNA molar ratio. Lipofectamine 2000 was used as positive control. $N = 3$, mean ± SD.

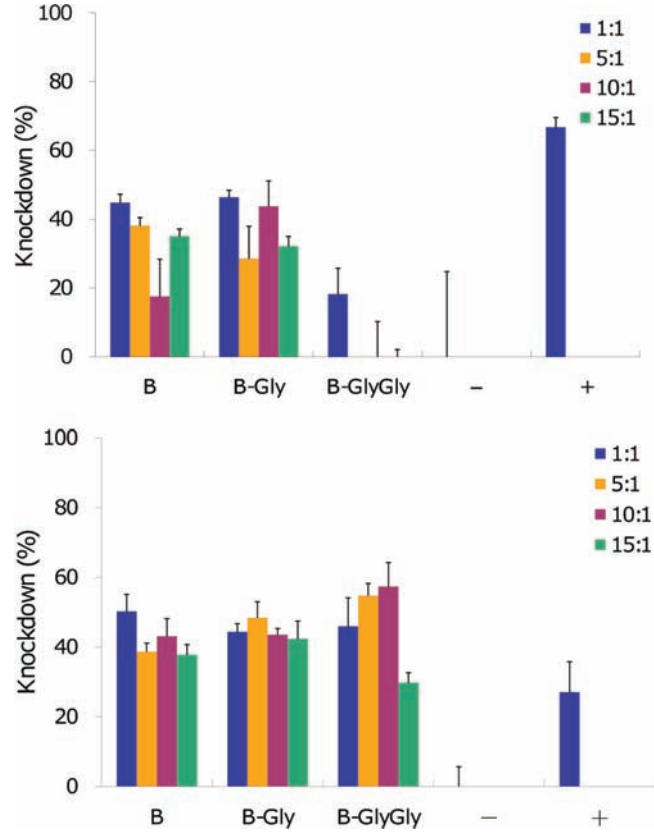

Figure 7. siRNA transfection after 48 h in HepG2 cells (top) and UASMC cells (bottom) as a function of amphiphiles and siRNA molar ratio, NeoFX was used as positive control. $N = 3$, mean ± SD.

prepared the **B-AlaAla** amphiphile, since this amphiphile is similar to the **B-GlyGly** amphiphile but the spacer is slightly more hydrophobic and rigid. The **B-AlaAla** amphiphile showed moderate transfection activity but less than that observed with the **B-GlyGly** amphiphile. To confirm that the benzyl ester linkages on the hydrophobic chains (and the resulting charge-reversal effect) were a contributing factor to the gene delivery efficiency of these amphiphiles, we synthesized two additional control amphiphiles with the Gly or GlyGly spacers, possessing saturated C16 chains instead of the benzyl ester terminated hydrophobic chains. As shown in Figure 6, both amphiphiles displayed minimum transfection activity in CHO cells. This result demonstrated the importance of the charge-reversal effect on the transfection. MTS assays performed with all the amphiphiles showed no significant cytotoxicity in the two cell lines (see Supporting Information).

Next, siRNA transfections were performed with the base amphiphiles **B** and the two best performing amphiphiles, **B-Gly** and **B-GlyGly**, using the KDalert GAPDH assay (Ambion) with HepG2 and UASMC cells (Figure 7) at four different cation/anion ratios (1:1, 5:1, 10:1, 15:1). NeoFX was used as the positive control. After 48 hrs of transfection, in HepG2 cells, **B** and **B-Gly** achieved 50% gene knockdown, while **B-GlyGly** only achieved 20% knockdown. In UASMC cells, **B** and **B-Gly** achieved 50% gene knockdown, while **B-GlyGly** reached 60% knockdown. These results were comparable to those obtained with NeoFX.

CONCLUSION

In summary, a series of amphiphiles with different spacers within the headgroup were evaluated for DNA and siRNA delivery. Among them, the amphiphiles possessing the relatively rigid and hydrophilic glycine or alaine spacers, capable of hydrogen bonding, showed effective DNA transfection in vitro. As for siRNA transfection, **B**, **B-Gly** and **B-GlyGly** showed gene knockdown. The binding affinity for the amphiphiles with the peptide spacers was similar to all the other amphiphiles, but DNA was released the fastest from **B-GlyGly** in the presence of esterase. Also, X-ray diffraction results indicate that DNA is located between the adjacent lipid bilayers in the complex formed with **B-GlyGly**. It is clear that many factors can influence transfection efficiency and that small perturbations in structure can have a significant effect. In this study, we found that the best performing amphiphile has a peptide linker separating the headgroup from the chains, complexes with DNA to afford a bilayer structure, and forms lipoplexes of 200 nm in diameter. This study highlights the importance and sensitivity of the spacer group in DNA/amphiphile assembly, liposome stability, and gene transfection activity. Continued studies with different amphiphile compositions will facilitate the development of a set of design requirements for efficient DNA and RNA delivery.

Small interfering RNAs offer novel opportunities to inhibit gene expression in a highly selective and efficient manner but depend on cytosolic translocation with synthetic delivery systems. The polyethylenimine (PEI) is widely used for plasmid DNA transfection. However, the water-soluble PEI does not form siRNA polyplexes stable enough in extracellular media for effective delivery. We previously showed that rendering PEI insoluble in physiological media, without modifying drastically its overall cationic charge density, by simple conjugation with natural hydrophobic α-amino acids, can lead to effective siRNA delivery in mammalian cells. In here, we comprehensively investigated the mechanism behind the excellent efficacy of the leading PEIY vector. Our data revealed that the underlining proton sponge property is key to the effectiveness of the tyrosine−polyethylenimine conjugate as it may allow both endosomal rupture and siRNA liberation via an optimal pH-sensitive dissolution of the PEIY self-aggregates. Altogether, these results should facilitate the development of novel and more sophisticated siRNA delivery systems.

INTRODUCTION

RNA interference (RNAi) is a sequence-specific and post-transcriptional gene silencing process present in animals and in plants and is mediated by 21−22nt long RNA duplexes, called small interfering RNA (siRNA) (*1*). This gene silencing mechanism appears to be particularly effective and holds great potential for decoding gene function and in gene-specific therapeutics (*2*). However, oligonucleotides do not diffuse freely across plasma membrane and imperiously depend on formulation within synthetic delivery systems (*3, 4*).

Nonviral delivery vehicles were initially developed for plasmid delivery (*5, 6*). They are generally cationic lipids or cationic polymers that interact electrostatically with the nucleic acid phosphate backbone to form stable complexes (*7, 8*). These cationic complexes in turn bind to anionic proteoglycans present on cell surfaces, enter cells within membrane-coated vesicles, and experience acidification on their road to degradative compartments. Escape from this pathway is required and relies on the incorporation of fusogenic lipids or endosomolytic functions within the complexes. Among the cationic polymers, PEI[1] is certainly the most used plasmid DNA transfection agent because its high buffering capacity in the pH range between 5.0 and 7.5 facilitates rupture of endosomal membranes via a "proton sponge" mechanism (*9, 10*). However, PEI was shown to be a poor siRNA delivery agent (*11*), especially in comparison to lipids (*12, 13*).

Numerous approaches and hypotheses have been investigated to create efficient polymer-based delivery vehicles dedicated to siRNA (*14*−*21*). While siRNA duplexes and genes share a similar anionic charge density, the reduced number of anionic charges of a siRNA duplex (40) in comparison to a plasmid DNA (average anionic charge of 7000) reduces the electrostatic cohesion of the soluble PEI with siRNA. Polyanionic proteoglycans present outside the cells and on the cell surfaces may then effectively displace PEI from the complexes, resulting in release of siRNA in the extracellular medium (*22*). No delivery and siRNA-mediated gene silencing can consequently occur.

Increased stability of oligonucleotide polyplexes may be performed by three means. siRNA duplexes could be artificially transformed into long structures, like plasmid DNA, by equipment with self-complementary and overhanging nucleotides (*22*). Oligonucleotides could be conjugated with cholesterol for enhanced anchorage to cationic micelles (*23*) or to cationic peptide so as to obtain an overall self-aggregating and cationic species (*24*). Finally, transformation of the water-soluble PEI into an insoluble molecule, similar to cationic lipids, could also favor overall siRNA delivery. We have previously reported that the latter approach was successful (*25*). Simple modification of the commercial branched 25 kDa PEI with various α-amino acids, at a modification degree of 30% per ethylenimine, maintains the proton sponge and siRNA binding properties of the vector, but confers self-aggregation and siRNA delivery aptitude to the polymers (Figure 1). The tyrosine-modified PEI (PEIY) appeared particularly effective relative to the other self-aggregating polymers as it led to more than 90% luciferase expression silencing versus only about 50% with the other ones. The effectiveness of the PEIY could not be explained by a molecular specificity of the tyrosine. Indeed, decreasing the content of the PEIY from 30% to 20% (PEIY20) diminishes the delivery potential, while an opposite trend is observed with

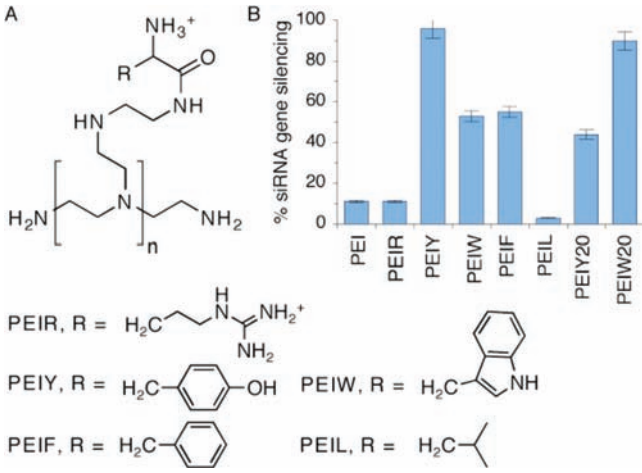

Figure 1. A. Chemical structure of the α-amino acid−polyethylenimine conjugates. B. siRNA delivery abilities of the various polymers in a model cell line, as judged by inhibition of a reporter gene expression. siRNA (10 nM) was delivered to A549Luc cells with 20 μM of the indicated polymer.

the tryptophan-modified PEI (PEIW) for which 20% amino acid content generated a polymer with almost the same efficiency as the PEIY.

In the present work, we comprehensively investigated the mechanism behind the excellent efficacy of the leading PEIY vector. We measured the hydrophobicity of several representative polymers using a fluorescent probe and evaluated their hemolytic, cytotoxic, self-aggregating, and siRNA delivery abilities. Results revealed that the acidic environment encountered in PEI-loaded endosomes can direct dissolution of tyrosine−polyethylenimine aggregates and mediate disassembly of siRNA polyplexes through protonation of the polymer.

EXPERIMENTAL PROCEDURES

Materials. The amino acid-modified PEIs were prepared as previously described (*25*). Succinimidyl ester of N-Boc protected α-amino acids were purchased from Novabiochem, Merck KgaA (Darmstadt, Germany). Branched PEI (40,872−7, batch 09529KD-466; 25 kDa) was from Aldrich (St. Quentin, France). Water was deionized on a Millipore Milli-Q apparatus. All other chemicals were at least of analytical grade and were used as supplied. NMR spectra were performed on Bruker DPX 300 or 200 MHz spectrometers. HiPerfect (Qiagen) was used according to manufacturer's protocol. Before use, dialysis membranes were soaked in Milli-Q water (200 mL, 3 times, 8 h each) to remove preservatives.

Synthesis of Fluorescently Labeled PEIY (Green-PEI). 6-Carboxyfluorescein *N*-hydroxysuccinimide ester (2.4 μmol), freshly dissolved in methanol (1 mL), was added at once to a solution of PEIY (0.2 M in ethylenimine, 1.0 mL), which was first buffered to pH 7.0 by addition of 0.6 equiv NaOH. The solution was stirred in the dark overnight at room temperature and the solution subjected to dialysis using a SpectraPor 12−14 kDa membrane against methanol/water 1/1 mixture (0.1 L, 2 changes over a 48 h period), aqueous 100 mM HCl (0.1 L, 24 h), followed by water (0.2 L, 2 changes over a 48 h period).

Size Measurement. The apparent sizes were determined via dynamic light scattering measurements using a NanoZS apparatus (Malvern instruments, Paris, France) with the following specifications: sampling time = 90 s; refractive index of medium = 1.3402; refractive index of particles = 1.47; medium viscosity = 1.145 cP; and temperature = 25 °C. Data were analyzed using the multimodal number distribution software included with the instrument.

Determination of the Polymer Hydrophobicity. A stock solution of Nile Red was prepared in DMSO at a concentration of 0.4 mM and stored at −20 °C. Stock solutions of polymer were in water at a 0.2 M concentration in ethylenimine. Each polymer (2 μL) was first added to 1 mL RPMI solution to final concentration of 400 μM. Increment (0.2 μL) of the Nile Red solution was then added between measurements. The excitation wavelength was set at 540 nm (bandpass: 5 nm) and emission was recorded from 580 to 700 nm (bandpass: 5 nm) using a fluorescent spectrophotometer. Representative emission spectra were extracted from experiments containing 0.56 μM Nile Red.

Determination of Polymer Aggregation pH. Self-aggregation was determined by turbidity. Each polymer (HCl salt) was first solubilized in water at a 20 mM concentration (0.5 mL volume). The solution was then titrated by addition of NaOH solution (0.25 M, 1 μL increment) until occurrence of aggregate as seen by turbidity. pH of the solution was then measured with a calibrated pH meter. The turbid solution was then titrated with HCl (0.1 M, 1 μL increment) up to full dissolution and the pH measured again. For all polymers, the transition was relatively narrow and within 0.2 pH unit.

Hemolysis Experiments. For recovery from washing steps, sheep red blood cells (RBC) (Eurobio, Courtaboeuf, France) were centrifuged at 400 RCF for 10 min. Before experiments, cells were washed three times with NaCl aqueous solution (150 mM). RBC were then resuspended in phosphate buffer (100 mM, pH 7.4), prepared to be isoosmotic to the inside of a RBC and caused negligible hemolysis, and plated in 96 well plates to obtain 15×10^6 cells in 50 μL. 50 μL aliquots of polymer solutions at different concentrations, also prepared in the same phosphate buffer, were added to the erythrocytes and incubated for 2 h at 37 °C and 5% CO_2. The release of hemoglobin was determined after centrifugation at 700 RCF for 10 min by spectrophotometric analysis of the supernatant at 550 nm (Bio-Rad model 550, Marnes-la-Coquette, France). Complete hemolysis was achieved using deionized water yielding the 100% control value. The negative control was obtained by suspension of RBC in phosphate buffer alone. The experiments were performed in triplicate.

siRNA Polyplexes Preparation. PAGE-purified siRNA were purchased from Eurogentec (Seraing, Belgique) and stored at −20 °C as a 20 μM solution in RNase-free water as indicated by the manufacturer. The luciferase gene originating from pGL3 plasmid was silenced with a RNA duplex of the sense sequence: 5′-CUUACGCUGAGUACUUCGA. Untargeted pGL2luc RNA duplex was of sequence 5′-C**G**UACGC**G**GA**A**UACUUCGA (bold marks showed mismatches by comparison to pGL3 sequence). Human papillomavirus 18 E6 oncoprotein from infected HeLa cells was silenced with a RNA duplex of sense sequence 5′-CUAACUAACACUGGGUUAU.

To prepare polyplexes, appropriate quantities of siRNA and polymer were separately diluted in RPMI medium (Eurobio, Courtaboeuf, France). After 10 min equilibration, the polymer solution was added to the siRNA solution. Then, the mixture was vortexed for 10 s and incubated at room temperature for 30 min.

Determination of Polyplex Stability. 50 pmol of siRNA and 100 nmol of polymer buffered to pH 6.0 were prepared either in RPMI (15 μL, final pH of 7.8) or in water (15 μL, final pH of 6.0). Complexes were then incubated for 30 min with increasing charge excess of heparin (Sigma-Aldrich, Saint-Quentin-Fallavier, France). The mixture was then loaded onto a 2% agarose gel containing 1 mM EDTA and 40 mM Tris acetate buffer pH 8.0, and subjected to electrophoresis for 30 min at 90 V. After staining with ethidium bromide solution (0.5 μg/mL) for 15 min, siRNA released from polyplexes by heparin

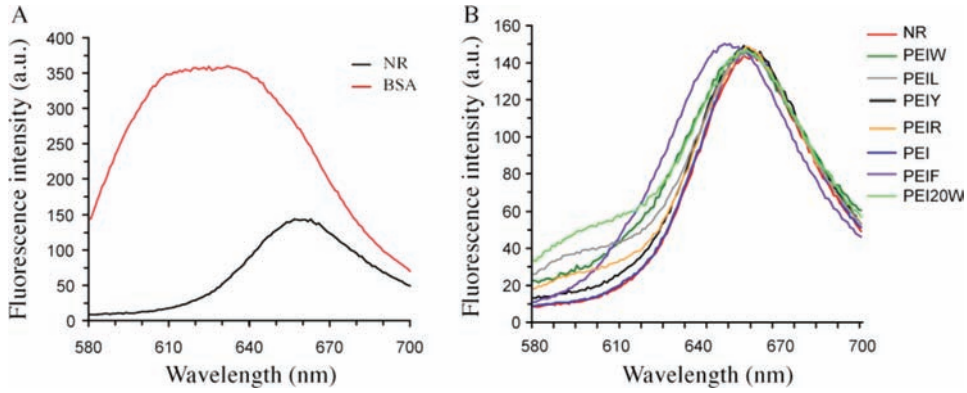

Figure 2. Determination of polymer hydophobicity using a fluorescent probe. Fluorescence emission spectra of Nile Red (0.56 μM) in the presence of bovine serum albumin (5 μM) (A) or with the indicated polymer (0.4 mM) (B). Excitation was at 540 nm and polymers were in RPMI medium.

was visualized with a UV transilluminator and quantified using picture analysis software (NIH *ImageJ*).

Cell Culture. All cell culture media were supplemented with 10% FBS (Perbio, Brebières, France), 100 units/mL penicillin, and 100 μg/mL streptomycin (Eurobio, Courtaboeuf, France). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere.

A549 cells (human lung carcinoma; CCL-185; ATCC) were transformed to stably express the *Photinus pyralis* luciferase gene originating from the pGL3 plasmid (Clontech, Mountain View, CA) and selected on G418. The transfectants A549Luc were grown in RPMI 1640 medium containing 2 mM L-glutamine (Eurobio, Courtaboeuf, France) and 0.8 mg/mL G418 (Promega, Charbonnières, France). HeLa cells (human cervix epithelial adenocarcinoma; CCL-2; ATCC) were grown in Eagle's MEM medium.

Delivery Experiments. The procedure is for 24-well plates or 4-well-chambered cover glass experiments. The day before experiment, cells were plated at 25 000 cells per well for A549Luc cells and 50 000 cells per well for HeLa cells. 100 μL of polyplexes, prepared as described above, were added in each well by dilution with the cell medium containing serum (0.5 mL). To ensure optimal cell growth, 24 h after polyplex addition each well was filled with an optional addition of serum-containing growth medium (0.5 mL). In the case of experiments with high concentrations of serum, growth medium was added 4 h after polyplex addition to achieve 10% serum-containing medium. The gene expression profiles were analyzed 48 h after addition of the complexes.

Confocal Microscopy. A549Luc cells were cultured on 4-well-chambered cover glasses (Lab-Tek, Nunc). Complexes were prepared and added to cells as described above except that siRNA and PEIY were replaced with Cy-3-siRNA and carboxyfluorescein-PEIY, respectively. After 4 h of incubation, the cell culture medium was removed and replaced with complete growth medium containing no phenol red (Sigma-Aldrich, Saint-Quentin Fallavier, France). Living cells were analyzed with a Leica TCS SP2 AOBS confocal microscope coupled to the Leica Confocal Software (Leica Microsystems), using 63× oil-immersion objective and excitation at 488 and 543 nm. Confocal sections were taken every 1 μm. Images showing one section of the middle of cells were processed by Photoshop (Adobe Systems Incorporated).

Luciferase Profile Analysis. Luciferase gene expression was determined 48 h after delivery with a commercial kit using manufacturer's protocol (Promega, Charbonnières, France). The luminescence was measured from 1 μL of lysate during 1 s with a luminometer (Centro LB960 XS; Berthold, Thoiry, France). Luciferase activity was expressed as light units integrated over 10 s (RLU) and normalized per milligram of cell protein by using the BCA assay (Pierce, Brebières, France). The error bars represent standard deviation derived from triplicate experiments. Luciferase silencing efficiency of pGL3luc with siRNA was calculated relative to cells treated with a nonspecific siRNA (GL2luc).

Detection of p53 Level. For immunohistochemistry imaging, cells were washed with PBS and fixed with 4% paraformaldehyde solution 48 h after addition of the complexes. p53 was detected with anti-p53 rabbit polyclonal serum FL-393 (Santa Cruz Biotechnology) followed by Alexa Fluor 488 labeled goat antirabbit immunoglobulins (Molecular Probes). DAPI was used for counterstaining nuclei. For Western blot analysis, cells were washed with PBS and harvested by trypsination. Each cell pellet was lysed in 50 mM Tris-HCl buffer, pH 8, containing 150 mM NaCl, 0.1% SDS, 1% NP40, 1 mM DTT, and protease inhibitors (Complete, Roche). Protein levels were next quantified using a Bradford assay and 50 μg lysate from each sample was subjected to 12% SDS−polyacrylamide gel electrophoresis and electro-transferred to nitrocellulose membrane. p53 and actin polypeptides were revealed using monoclonal anti-p53 (DO-7, Santa Cruz Biotechnology) and rabbit polyclonal anti-actin (Sigma-Aldrich) antibodies, respectively, using enhanced chemiluminescence kit (ECL kit, Millipore).

RESULTS AND DISCUSSION

Hydrophobic Character of the Polymers. The hydrophobic character of each α-aa-PEI was evaluated using Nile Red (NR) as a fluorescent probe. Nile red is a zwitterionic fluorescent molecule that is sensitive to local polarity but pH-insensitive, and has been used to monitor hydrophobic surfaces of proteins (*26*). In a polar environment, Nile Red is weakly fluorescent. In a more hydrophobic environment, its quantum yield increases and its maximum emission is progressively blue-shifted. For example, interaction of Nile Red with hydrophobic surfaces of bovine serum protein (BSA) led to a 2.5-fold increase in its quantum yield as well as a remarkable blue shift of the emission maximum from 660 to 630 nm (Figure 2A). No modification of the NR emission spectrum was observed for PEI alone or for PEIs modified with the hydrosympathetic amino acids R or mixed Y (Figure 2B). The probe did not sense large hydrophobic domains on PEIL, even if this residue has a high hydropathy index, probably because the aliphatic chain is too short for formation of stable micelles/domains for NR insertion (*27*). A slight shoulder in the NR spectrum below 630 nm is seen and may be tentatively attributed to highly labile and weak interactions between the probe and solvated aliphatic chains. The impact of PEIW on the NR spectrum is a function of the modification degree. As previously seen with PEIL, interaction

Table 1. Self-Aggregation Abilities of α-Amino Acid Modified Polyethylenimines

polymer	PEI	PEIR	PEIY	PEIW	PEIF	PEIL	PEIY20[a]	PEIW20[a]
hydropathy index[b]		−4.5	−1.3	−0.9	2.8	3.8		
aggregation pH[c]	[d]	[d]	6.3	5.2	6.9	[d]	7.25	6.4
sizes of the polymer self-aggregates (nm)[e]	[d]	[d]	325 ± 28	475 ± 11	700 ± 34	[d]	160 ± 40	218 ± 2

[a] Polymer with a 20% degree of modification. [b] Obtained from ref 40. [c] Corresponds to the pH for which polymer goes for a soluble to an aggregated state. The value was estimated by turbidity upon titration of a 20 mM polymer HCl solution with NaOH. [d] No DLS signal detected. [e] Estimated in RPMI media, pH 7.8, from DLS data with 120 μM of the polymer.

of NR with the indoles of PEIW20 also leads to an NR spectrum with a similar shoulder but of higher intensity, presumably for the same reason as previously indicated. No shoulder is observed with the PEIW that was modified at a 30% content, indicating that the indoles of the PEIW are no longer accessible (not solvated) for interaction with the NR probe and they probably interact together in domains without affinity for the NR. Only PEIF (hydropathy index of 2.8) induces a modest 7 nm blue shift of the NR spectrum but without enhancement of the probe quantum yield. Overall, these results indicated that modification of PEI with the selected amino acids does not lead to extensive hydrophobic domains or pockets in which Nile Red can bind. With the notable exception of aliphatic leucine, this method did nonetheless make it possible to confirm the direct transfer of the hydropathy character from the individual amino acid to the modified PEIs.

Aggregation Properties of the Polymers. As hydrochloride salts, all polymers are fully soluble in water even at 0.5 M concentration and can be stored in solution for extensive periods at 0−4 °C or at −20 °C. However, the amino acid modified PEIs exist in a wide variety of protonation states, which can affect their solvation in aqueous media. For example, addition of these polymers in RMPI cell growth medium, pH 7.8, provokes self-aggregation of the polymers PEIY, PEIW, PEIF, PEIY20, and PEIW20 (Table 1). In the next experiment, we determined precisely the pH value where aggregation occurs. Each polymer−HCl salt (20 mM) was carefully deprotonated with NaOH until turbidity and the pH value was measured (Table 1). PEI, the hydrophilic PEIR, and the aliphatic PEIL do not aggregate up to pH 9.0. On the other hand, the aromatic amino acid modified PEIY, PEIW, and PEIF lead to aggregation at pH of 6.3, 5.2, and 6.9, respectively, and in a narrow range (transition from a limpid to a turbid solution occurred within 0.1 pH unit). Decreasing the tyrosine or tryptophane content from 30% to 20% is conducive to aggregation at higher pH (around 1 pH unit higher) and to a softer transition. These results indicate that the aggregation abilities of the modified PEIs vary as functions of the pH and of the nature of the amino acid.

Evaluation of the Membrane-Destabilizing Properties and Cytotoxicity of the Polymers. Technically, nucleic acid translocation into the cell must involve a rupture of the lipid membrane integrity. Some amino acid−PEI conjugates may induce direct membrane destabilization via interfacial activity of the amino acid side chains (*28*). We therefore evaluated the effect of the polymers on mammalian plasma cell membranes by monitoring the release of hemoglobin from sheep erythrocytes (Figure 3A). PEIF is the only polymer with important hemolytic activity at 1 mM concentration. At higher concentration (10 mM), PEIL shows partial hemolysis, whereas all other PEIs have no hemolytic activity. One important property that was unique to PEIW but not to PEIW20 was that it resulted in red cells becoming brownish at pH 7.4, without apparent release of heme in solution, suggesting interference with membrane stability.

In parallel, we evaluated the toxicity level of the polymers on A459Luc cells by measuring the mitochondrial activity using the MTT assay and reported the maximum polymer concentration for which cells remained 100% viable (Figure 3B).

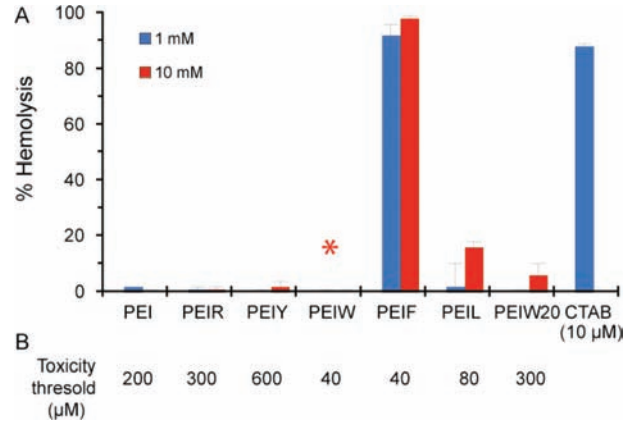

Figure 3. A. Permeation effect of polymers on mammalian cell membranes at extracellular pH. Sheep erythrocytes were incubated for 2 h at 37 °C with 1 and 10 mM of the various polymers in PBS, pH 7.4. Cells were then centrifuged and rupture of erythrocyte membranes was monitored by release of hemoglobin in the supernatant. Cationic detergent cetyl trimethylammonium bromide (CTAB) was used at 10 μM. [*] PEIW modifies the color of the cells from red to brown at pH 7.4 at both concentrations. B. Maximum concentration of polymer which did not provoke cell toxicity as measured by MTT assay on A549Luc cells.

Membrane-perturbing polymers PEIF, PEIL, and PEIW affect considerably the cell viability, while the others are friendlier to cells. In particular, PEIY offers an important cushion between its effective concentration (20 μM) and its toxicity threshold (600 μM). Altogether, these experiments show that PEIY does not possess any hemolytic activity and that the polymers with membrane-perturbing activity at extracellular pH rather lead to cell lethality.

Evaluation of siRNA/PEIY Polyplexes Suitability for Entry into the Cellular Degradative Endosomal/Lysosomal Compartment. The previous experiment showed that direct permeation of the plasma membrane is not an efficient translocation method. Translocation should rather be a consequence of a more localized rupture of lipid membranes surrounding endocytosed complexes. To take this route, most synthetic delivery systems use initial electrostatic anchorage to sulfated (polyanionic) proteoglycans present on membranes of adherent cells. While polyanions may effectively displace siRNA from polyplexes, we investigated the stability of the siRNA polyplexes in the presence of heparin, a natural polymer with high anionic density. siRNA polyplexes were prepared in RPMI medium (pH 7.8) at an N/P ratio of 50 to ensure full complexation and then incubated for 30 min with increasing quantities of heparin. The mixtures were then subjected to analysis by agarose gel electrophoresis. Release of siRNA was monitored after ethidium bromide staining and quantified (Figure 4). Heparin effectively displaces PEI from the weakly cohesive siRNA/PEI complexes and provokes a quantitative liberation of siRNA, even at a low heparin to ethylenimine ratio. According to the working hypothesis, transformation of the soluble PEI into cohesive species does indeed allow the stabilization of the polyplexes against electrostatic displacement, but to various extents. PEIY20 and PEIF, for which aggregation in water occurs at

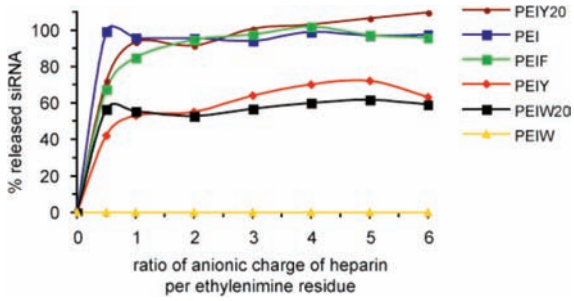

Figure 4. Evaluation of the electrostatic stability of the polyplexes. siRNA polyplexes (N/P 50, 0.7 μg siRNA) were incubated for 30 min with increasing amounts of heparin in RPMI medium, and release of siRNA was determined from agarose gel electrophoresis analyses.

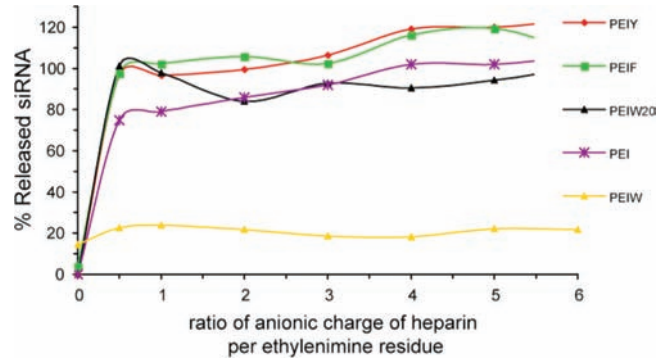

Figure 6. Evaluation of the electrostatic stability of the polyplexes at endosomal pH. siRNA polyplexes (N/P 50, 0.7 μg siRNA) were incubated for 30 min at pH 6.0 with increasing amounts of heparin. Release of siRNA was determined from agarose gel electrophoresis analyses.

pH 7.25 and 6.9, respectively, form moderately stable siRNA polyplexes against electrostatic displacement. On the other hand, PEIW assembles and entraps siRNA into an extremely resistant shell, as judged by the absence of siRNA liberation even at high heparin amount. An intermediate siRNA release profile is observed for the two most effective siRNA polyplexes made with PEIY or PEIW20. A fast siRNA release, obtained by displacement of superficially polyplex-bound siRNA, is followed by a plateau, for which about 40% of the RNA duplexes remained entrapped, presumably within the insoluble complex cores. These experiments suggest that the relatively low efficiency of PEIF and PEIY20 is due to instability of their self-assemblies, leading to impaired cell anchorage. Self-aggregation of PEIY, PEIW20, and PEIW is cohesive enough to protect siRNA from dissociation against electrostatic competition in an extracellular medium.

Intracellular Fate of siRNA/PEIY Complexes. We next followed delivery of the siRNA/PEIY complexes using Cy3-labeled fluorescent siRNA and fluorescein-labeled PEIY (green-PEIY). First, the delivery efficacy of the green-PEIY was compared to that of native PEIY using A549 cell line that stably express the pGL3 luciferase gene (A549Luc) (*22*). The polymer (12 nmol in ethylenimine residue) was mixed with siRNA (6 pmol in duplex of either targeting or untargeting sequence) in RPMI cell growth medium (100 μL) and the cationic complexes added to cells that were grown in 10% serum-containing RPMI medium. Cells were lysed 48 h later. Measured luciferase activity showed that the fluorescent tag does not significantly modify the delivery properties of PEIY (Figure 5A). Fluorescent polyplexes were then prepared and incubated under identical conditions. The fluorescent species were observed with a scanning fluorescent microscope 4 h later on living cells (Figure 5B,C). Tracking the siRNA/PEIY from the PEIY species (Figure 5B) provides images similar to those previously observed for PEI/DNA complexes (*29*). Indeed, PEIY appears as discrete spots located on the cell surfaces and in the cytoplasm in perinuclear areas, indicating that these complexes enter via the same degradative lysosomal pathway. The siRNA displays a different pattern (Figure 5C) with intracellular patches, corresponding to PEIY complexes, and a diffuse fluorescence in the cytosol. Observation of siRNA diffusion in the cytosol to that extent was quite surprising because siRNA delivered with a cationic lipid did not show such a diffuse pattern (*22*), even if the size of siRNA duplexes does not restrict cytosolic diffusion (*30*).

To explain this phenomenon, we hypothesized that acidity of the endosome may render the PEIY soluble and lose the siRNA/PEIY polyplexes. Sulfated proteoglycan receptors, which are concomitantly engulfed in endosomes, may play a favorable role here by favoring siRNA release from polyplexes. We therefore investigated once again the stability of the siRNA polyplexes in the presence of heparin but at an endosomal pH. Complexes that enter the degradative lysosomal trafficking pathway undergo progressive acidification (within 3 to 4 h) of their environments from pH 7.4 to as low as 4.5. The buffering capacity of PEI nonetheless blocks acidification of PEI-loaded endosomes at measured pHs of 5.9 (*31*) or 6.1 (*32*). siRNA polyplexes were hence incubated in the presence of increasing proportion of heparin at pH 6.0 and siRNA release reported in Figure 6. Even if low pH environments increase the cationic charge density of the PEI and strengthen the electrostatic polyplex cohesion (*33*), heparin effectively dissociates siRNA polyplexes made from the now soluble polymers PEIY and PEIW20. As previously observed at higher pH, still insoluble PEIW retains siRNA within its self-assemblies, explaining why this polymer leads to modest siRNA-mediated luciferase silencing. To complete this study, we evaluated the hemolytic activities of the polymers at pH 6.0. Results (Supporting Information, Figure S6) confirmed that PEIY has no hemolytic activity at 1 and 10 mM concentrations, suggesting that endo-

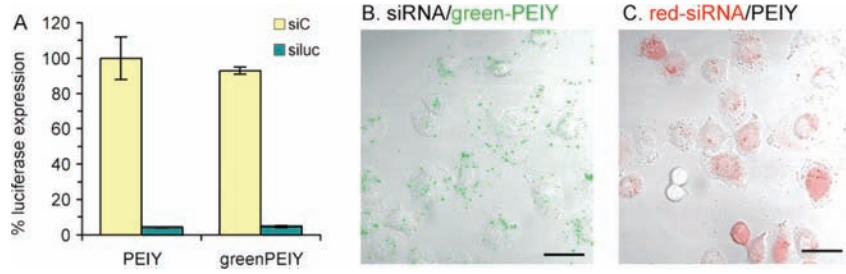

Figure 5. Evaluation of the PEIY delivery efficiency and intracellular fate of siRNA and PEIY following application of complexes onto cells. A. Targeting (siluc) or untargeting (siC) siRNA (10 nM) were delivered to A549Luc cells with 20 μM of PEIY or green-PEIY. Luciferase expression was measured 48 h later. For images A and B, complexes of fluorescently Cy3-labeled siRNA (red, 6 pmol) and fluorescein-labeled PEIY (green, 12 nmol) were applied to A549Luc cells grown in RPMI medium containing serum. The living cells were analyzed 4 h later by scanning fluorescence microscopy. The scale bars represent 40 μm.

somal membrane rupture for this polymer results purely from the PEI proton sponge mechanism.

Altogether, these experiments suggest that sticky PEIY and PEIW20 possess just the right hydrophobic/hydrophilic balance for carrying siRNA into endosomes and for directing siRNA release at endosomal pH values.

Impact of Self-Aggregation on siRNA-Mediated Delivery. Electrostatic condensation of a plasmid DNA with soluble polycations is a kinetically driven and almost irreversible process. When initial electrostatic stoichiometry between DNA phosphates and PEI is in favor of the latter, PEI molecules entangle in large excess with plasmid DNA molecules and form thermodynamically unstable cationic complexes. For the branched PEI, which is weakly protonated at pH 7.4, assembly at a PEI nitrogen amine (N) to DNA phosphate (P) ratio of 13 appeared to offer complexes with optimal gene transfection activities in vitro (*9*), presumably because this N/P ratio both permits an accurate cationic particle formation process (100% DNA condensation in cationic particles) and limits the occurrence of free PEI in solution.

The ability of PEIY to self-aggregate in extracellular medium implies that there is no free entity left in the solution. We therefore investigated the PEIY dose dependency of siRNA delivery by using three different siRNA concentrations (Figure 7). Regardless of the siRNA concentrations and of the N/P ratio, the histograms present a U-shape with an optimal gene silencing efficiency in a narrow quantity range of PEIY (7.6 to 12 nmol) for about 25 000 cells. This behavior emphasizes the importance of the dose of the active carrier for an effective endosomal rupture and subsequent siRNA activity (*34*−*37*). The U-shape is likely a combination of two opposite trends. A gradual decrease in luciferase activity with increasing PEIY quantity presumably corresponds to progressive titration of the particle's cell surface receptors up to full occupancy. The subsequent increase in PEIY to siRNA ratio in turn dilutes the siRNA within PEIY containing particles and diminishes the quantity of delivered siRNA into the cytosol. Decreased luciferase silencing activity is then observed and is amplified at low siRNA inputs. Although the mechanism of siRNA-mediated silencing also depends on the siRNA concentration, it is worth mentioning that 75% silencing efficiency was obtained with extracellular siRNA duplex concentration as low as 0.1 nM, reflecting nonetheless the effectiveness of such a mechanism.

PEIY versus a Cationic Lipid Formulation for siRNA-Mediated Silencing of a Viral Oncoprotein. To evaluate the potential of PEIY as a general siRNA delivery reagent, we next compare it to HiPerfect, a commercially available siRNA-optimized, "second-generation", cationic lipid formulation for the delivery of oncoprotein-targeting siRNAs. A majority of cervical cancers is caused by high-risk types of human papillomaviruses (HPV) and derives from genetic integration of viral E6 and E7 oncoproteins into infected cells. These two oncoproteins disrupt several cellular growth control mechanisms. Malignancy due to E6 is attributed to its ability to induce proteasomal degradation of the p53 tumor suppressor protein. The cervical cancer cells HeLa harbor copies of the HPV-18 genome, and in vitro studies showed that p53 levels can be restored by silencing E6 expression with an E6-selective siRNA (siE6) (*38*). siE6/PEIY complexes were prepared as described earlier, and the cationic lipid formulation was used according to the manufacturer's instructions. Complexes were simply added to the cells grown in complete MEM medium. The p53 level was monitored by immunohistochemistry and Western blot analysis (Figure 8). A siE6-mediated increase of nuclear p53 is observed in almost all cell nuclei to the same extent as the lipid formulation, although nonspecific antibody binding to PEIY aggregates is also seen (Figure 8A). Quantification of p53 level in the immunoblot after delivery with an untargeted siRNA (siC) or without carrier (Figure 8B) confirms that PEIY does not interfere with the cellular cascade leading to the p53 increase. These results suggest that PEIY represents an alternative siRNA delivery reagent to the lipidic ones and can be applied for silencing malignant gene expression.

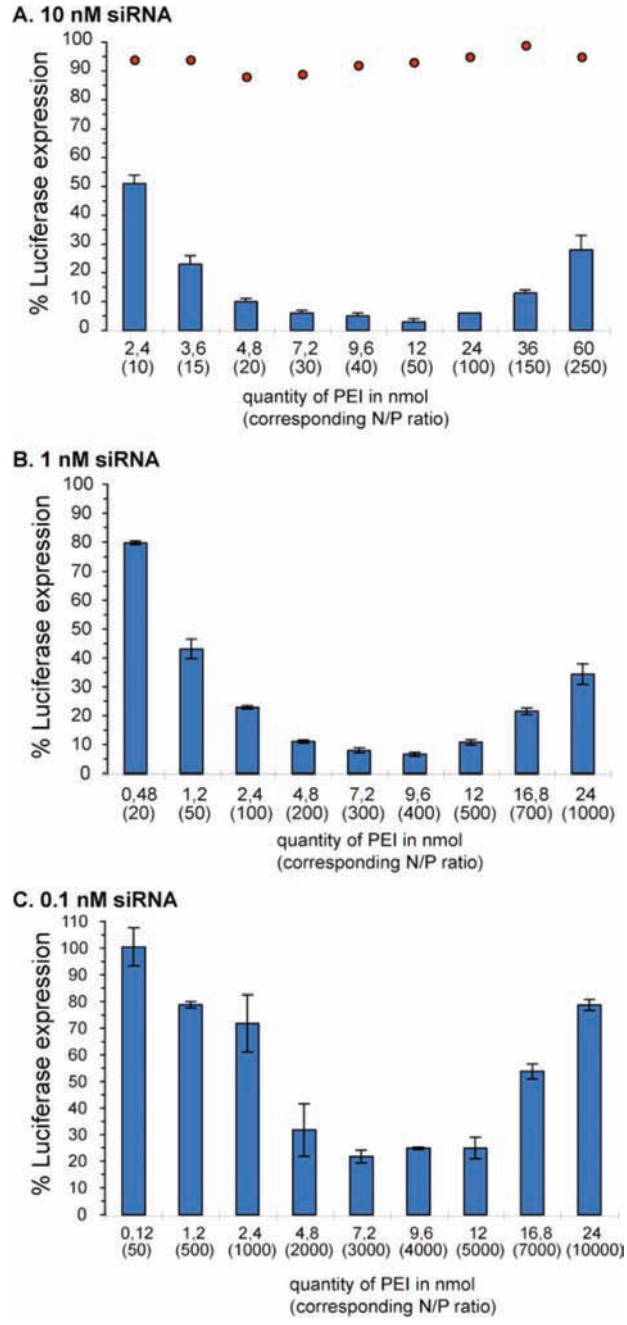

Figure 7. Evaluation of the siRNA delivery efficacy as a function of the PEIY quantity. The polymer at the indicated quantity was mixed with siRNA (6 pmol (A), 0.6 pmol (B), or 0.06 pmol (C)) in 0.1 mL RPMI and added to A549Luc cells grown in medium containing serum (0.5 mL). Luciferase expression was measured 48 h after addition of polyplexes. The bar represents the residual luciferase activity. The red points measured the percentage of cell protein levels relative to mock (same scale as luciferase expression).

Stability of siRNA/PEIY Complexes in High Serum Content. In this final experiment, we examined the stability of the siRNA/PEIY complexes in the presence of varying amounts of serum from luciferase silencing experiments.

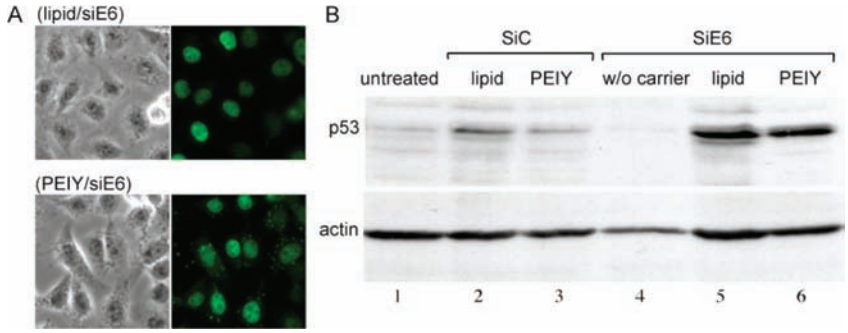

Figure 8. Inhibition of the HPV18 E6 oncoprotein in HeLa cells using siRNA (6 pmol) delivered with either PEIY (12 nmol) or a commercial cationic lipid (HiPerfect). The resulting increase of p53 was visualized by immunohistochemistry (A) and Western blotting (B). SiC: untargeted siRNA. siE6: E6 targeted siRNA.

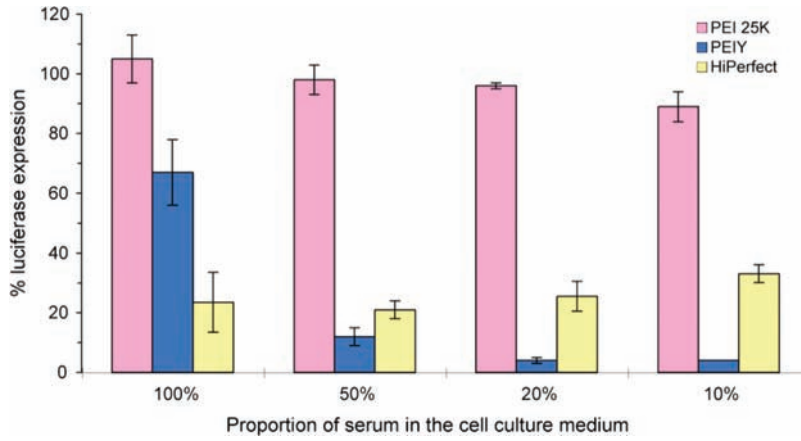

Figure 9. Evaluation of the PEIY delivery efficacy in the presence of high serum concentration. siRNA (10 nM) were delivered to A549Luc cells with PEI 25K (pink bars), PEIY (blue bars), or HiPerfect (yellow bars) in the presence of 100%, 50%, and 20% serum, respectively. After 4 h, the medium was replaced with the optimal cell growth medium (RPMI containing 10% serum) and luciferase expression was measured 48 h later. The results are relative to cells treated with nonspecific siRNA.

Indeed, extracellular serum contains many amphiphiles with hydrophobic surfaces, such as seric albumin, that can potentially interfere with the tyrosine-tyrosine interactions and hence diminish the cohesion of the polyplexes. Figure 9 shows that PEIY remains a remarkable siRNA delivery agent up to a 50% serum content (90% luciferase inhibition) but loses its efficiency in 100% serum. By comparison, HiPerfect-based lipoplexes appear less effective in delivering siRNA to A549 cells than to Hela cells but are fully insensitive to serum proportion in the cell culture media. These results, in combination with the absence of hemolytic activity, suggest that PEIY may be suitable for in vivo administration but is not tailored for intravenous delivery.

CONCLUSION

Our results show that tyrosine−polyethylenimine conjugate has a favorable efficiency/toxicity balance and is able to convey effectively low quantities of siRNA, even in the presence of high serum content. The success of tyrosine−polyethylenimine does not derive from membrane-perturbing activity but may originate from a disassembly sensitivity at pH 6.0, a pH value that is found in PEI-buffered endosomes. This property emanates from the PEI proton sponge ability and favors siRNA release from polyplexes at moments when PEI conducts osmotic pressure increase on endosomal membranes. Subsequent siRNA diffusion into the cytosol may hence not be restricted when endosome swelling/lysis events take place. Regardless of its mechanism, ease of preparation at low cost and high delivery efficacies should be appreciated for gene silencing experiments in cell culture. More experiments are currently underway to address usefulness of such modified PEIs in vivo for administration and pathologies for which cell surfaces are accessible to large delivery systems (*36*, *39*).

ACKNOWLEDGMENT

This work is dedicated to J.-P. Behr and was funded by the CEFIPRA and by a MRT fellowship to GC. We are grateful to Guy Duportail for assistance with the Nile Red assay and Jean-Luc Vonesh (IGMBC, Strasbourg) for access to the IGMBC imaging facilities. We also thank Dr. Coll and Giliane Coupin for kindly providing the A549Luc cells and red sheep erythrocytes, respectively.

Supporting Information Available: Detailed discussion on the synthetic design of the polymers, procedures for polymer synthesis and toxicity assay. Figure S1 shows NR spectra in presence of the various polymers in 150 mM NaCl. Figures S2−3 are the cell viability dose response to the polymers. Figure S4 shows the efficiency of PEIY to deliver siRNA following siRNA/PEIY polyplexes assembly in various media. Figure S5 shows confocal image analysis of A549Luc cells that were treated with Cy3-siRNA and its corresponding PEI polyplexes. Figure S6 is the hemolysis assay at pH 6.0. Figures S7 and S8 are the agarose gels used to plot the Figures 4 and 6. Figure S9 shows siRNA-mediated cyclinD1 silencing using PEIY as the delivery carrier. Hybrids of Nonviral Vectors for Gene Delivery

Shubiao Zhang,* Yinan Zhao, Budiao Zhao, and Bing Wang

SEAC-ME Key Laboratory of Biotechnology and Bioresources Utilization, College of Life Science, Dalian Nationalities University, Dalian 116600, Liaoning, China. Received June 12, 2009; Revised Manuscript Received December 27, 2009

Gene transfer has been a critical step for gene therapy. Viral vectors and nonviral vectors are commonly used for gene transfer. It has been shown that nonviral vectors have the advantage over viral ones, as they are nonimmunogenic, easy to produce, and not oncogenic. However, they have the major limitation of inefficient transfection; the hybridized usage of nonviral vectors may provide a partial solution. This article reviews the hybrids (different materials used in one delivery system) of nonviral vectors for gene delivery including hybrids between cationic lipids and helper lipids, conjugates of peptides or targeting moieties and lipids, and hybrids of cationic liposomes and polymers.

INTRODUCTION

Gene therapy has been developed for treatment of both acquired and inherited diseases such as severe combined immunodeficiency (*1*), cystic fibrosis (*2*), and Parkinson's disease (*3*), as well as an alternative method to traditional chemotherapy used in treating cancer (*4*). This approach is based on the principle of correcting the basis of diseases at their origin by delivery and subsequent expression of exogenous DNA, which encodes for a missing or defective gene product (*5*). Naked nucleic acids are easily degraded when used either *in vitro* or *in vivo*, so vectors are employed in many methods to protect nucleic acids and deliver them to targeted cells. These vectors can be generally divided into two categories, viral vectors and nonviral vectors.

After several accidents (*6–8*), nonviral vectors gained great attention for they are nonimmunogenic, not oncogenic, easy to produce in large scale, and capable of delivering large genetic material. However, unlike viral analogues that have evolved to overcome cellular barriers and immune defense mechanisms, nonviral gene carriers consistently exhibit significantly lower transfection efficiency compared with viral ones.

People have been designing and synthesizing a large number of new compounds (*9, 10*); at the same time, the hybridized utilization of nonviral vectors may provide a solution to the problem. We could combine cationic lipids and helper lipids, hybridize cationic lipsomes and polymers, and introduce peptides and targeting moieties into lipids to approach the requirements of gene therapy. Though many high-quality reviews have been published recently (*11–13*), we found it necessary to demonstrate the status of hybrids of nonviral vectors.

HYBRIDS BETWEEN CATIONIC LIPIDS AND HELPER LIPIDS

Though some cationic lipids show transfection ability when used alone in cationic liposomes, in many cases helper lipids are required to be incorporated into the formulations to yield high transfection efficiency. Among helper lipids, DOPE has been researched very extensively for it often presents a super synergistic effect when used in cationic liposomes. In early study, people have realized that DOPE destabilized lipid bilayers, and it was believed to be involved in endosomal disruption (*14*). Then, an endocytosis model of DNA delivery by cationic liposomes was proposed in which the principal function of the chase liposomes was to destabilize the endosome membrane and allow the release of DNA into the cytosol (*15*). When compared with other helper lipids, such as DOPC, DOPE shows superior activity. It has been proven that the replacement of DOPE with DOPC abolished most of the transfection activity of cationic liposomes (*16–19*). The difference in their head groups can be the reason, as DOPC contains a choline headgroup instead of the ethanolamine headgroup in DOPE (*14*). All the studies support DOPE as a strong destabilizer of lipid bilayers.

Recent studies disclosed by Safinya et al. (*20*) further gave the reason in the level of phase transition. They used synchrotron small-angle X-ray scattering (SAXS) and optical microscopy to find a completely different columnar inverted hexagonal H_{II}^C liquid-crystalline state in cationic liposome−DNA complexes. In this process, DOPE induced the phase transition from L_α^C to H_{II}^C by controlling the spontaneous curvature $C_o = 1/R_o$ of the lipid monolayer. It has been concluded that DOPE facilitates endosomal escape by forming an unstable inverted hexagonal phase at the endosomal pH that destabilizes both the complex and the endosomal membrane. Conversely, it would be expected that lipids such as dioleoylphosphatidylcholine (DOPC) would hinder the ability of cationic lipids to induce nonbilayer structure (*21*).

Another helper lipid, cholesterol, could also promote H_{II}^C organization as DOPE. Usage of cholesterol and its derivatives as helper lipids allowed one to attain higher transfection levels in vivo (*22, 23*). Reliably higher expression in many organs was revealed upon the application of cholesterol-containing liposomes (*24, 25*) as compared to other liposomes. Some studies indicated that in in vivo applications cholesterol was a more effective helper lipid than DOPE (*26*). Needless to say, the structure of cationic lipids plays a very important role in various phase structures. Safinya (*27*) also found that hexagonally arranged tubular lipid micelles (H_I^C) surrounded by DNA rods were formed though DOPC was used in the dendritic lipid-based cationic liposome. Helper lipid is indispensable for many cationic liposome formulations; the hybrids of helper lipids and cationic lipids would continue to be a research highlight.

CONJUGATES OF PEPTIDES AND LIPIDS

One of the most challenge things for gene delivery by cationic liposome method is the toxicity of cationic lipids originated in the cationic nature. The cationic lipids can become cytotoxic by interacting with critical enzymes such as PKC. It has been

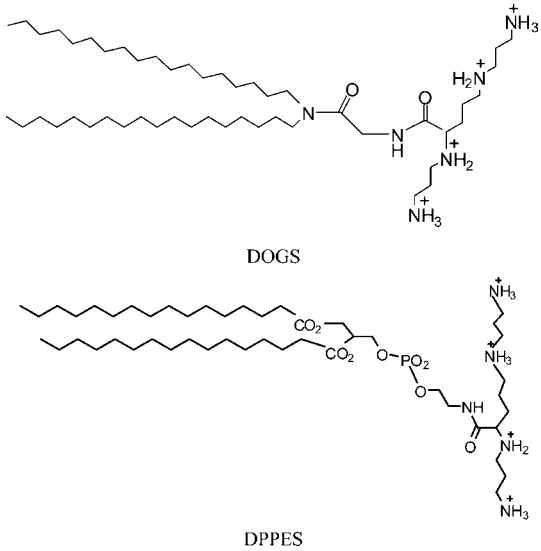

Figure 2. Chemical structures of DOGS and DPPES.

proven that many derivatives of cholesterol can inhibit PKC activity, which contained tertiary or quaternary nitrogen head groups (*28*). So, the replacement of cationic head groups has been a major trend with other more biocompatible groups, such as peptides, in recent years. The conjugates of peptides and lipids are much less toxic, while keeping the same transfection efficiency. The early examples (*29*) are DOGS (dioctadecylamidoglycylspermine) and DPPES (dipalmitoyl phosphatidylethanolamidospermine) in which spermine as headgroup was attached to lipids through peptide bonds. A variety of eukaryotic cell cultures also have been transfected with success for transient and stable expression. Even a single-tailed and ornithine-based cationic lipid, OLON (a cationic lipid-oleoyl ornithinate), has been proven to be less toxic and more than 10 times the transgene expression than other liposomes when used with DOPE (*30*).

Such a combination of peptides and lipids has been reported to produce superior transfection of genes. A compound which contained cholesterol and a dipeptide consisting of glycine and sterically protected arginine has been proven to be suitable for in vitro transfection in the presence of 10% serum more efficiently than other cholesterol derivatives (*31*). The structure−activity study has proven that a change in peptide groups would cause very different transfection efficiency. In a structure−activity investigation, cationic lipids with alanine and β-alanine headgroups were found to be remarkably more transfection efficient than their serine headgroup counterparts, and some of the conjugates in combination with cholesterol as auxiliary lipid were much more effective than Lipofectamine 2000 (*32*). In a later study, they studied three novel nontoxic cationic transfection amphiphiles containing mono-, di-, and trihistidine functionalities in their headgroup regions in multiple cultured cells for elucidating the structure−activity relationship (*33*). Yosuke Obata et al (*34*) have proven that the lysine- or arginine-type lipids exhibited higher gene expression efficiencies than Lipofectamine 2000, against COS-7 cells. The gene expression efficiency in relation to the cationic headgroup of the lipids was as follows: lysine > arginine > histidine. Peptide-based gemini surfactants GS (Figure 3) could lead to an increase in levels of gene expression in vitro compared to well-established nonviral reagents (*35*).

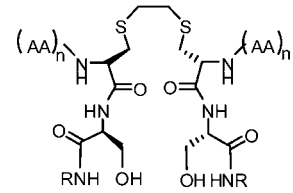

Figure 3. Chemical structure of GS.

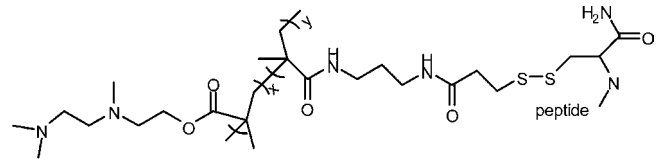

Figure 4. Chemical structure of INF7 peptide−polymer conjugates.

A series of new lipophilic peptides possessing a cationic tripeptide headgroup were effective nonviral vectors for gene delivery. Cytotoxity experiments performed with all the tripeptide lipophilic peptides showed no significant cytotoxicity, significantly better than Lipofectamine 2000 when exposed to chinese hamster ovarian (CHO) or NIH 3T3 cells (*36*). A subset of lipitoids with a repeated side chain trimer motif conjugated with dimyristoyl phosphatidyl-ethanolamine (DMPE) mediated DNA were also found to transfer cells with high efficiency (*37*).

Some peptide headgroups could endow additional functions to the lipids, such as membrane-disturbing ability. In a hybrid molecule, the covalent coupling of an amphipathic and membrane-disturbing peptide to a lipid moiety might create a stable and efficient peptide-based gene transfer system. The luciferase activity induced by the dioleoylmelittin/DNA complex was 5−500-fold higher than that induced by a cationic lipid/DNA complex, depending on the cationic lipid and the cell line (*38*). A membrane-disrupting peptide derived from the influenza virus was covalently linked to different polymethacrylates using *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) as a coupling agent to increase the transfection efficiency of polyplexes based on these polymers (Figure 4). In vitro transfection and toxicity were tested in COS-7 cells, and these experiments showed that the polyplexes with grafted peptides had a substantially higher transfection activity than the control polyplexes, while the toxicity remained unchanged (*39*).

Moreover, some peptide type cationic lipids are not serum-sensitive, which is crucial in in vivo applications (*40–42*). Dioleoylmelittin represented a new class of efficient peptide-based transfection reagents, especially suited for serum-sensitive cells, in which the presence of 10−50% fetal calf serum during dioleoylmelittin-mediated transfection enhanced 1.5−3-fold gene expression (*38*). The headgroups of asymmetric diether lipids have been varied by the coupling of the four naturally occurring amino acids with cationic side chains, sarginine, histidine, lysine, and tryptophan, and several formulations have

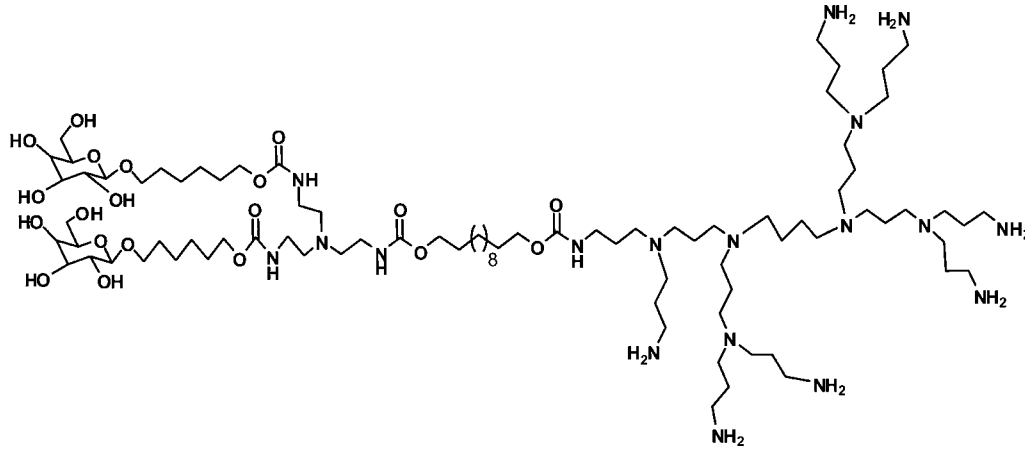

Figure 5. Chemical structure of DAB-dendr-$(NH_2)_8$.

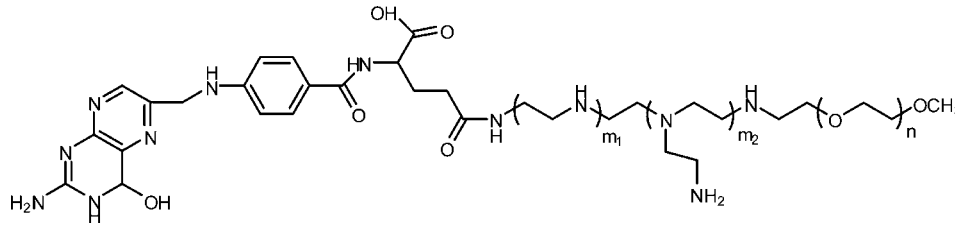

Figure 6. Chemical structure of FOL-PEI-b-PEG.

been shown to transfect different cell lines with up to 10 times the efficacy of the commonly used DC-Chol/DOPE formulation (*43*).

CONJUGATES OF TARGETING MOIETIES AND NONVIRAL VECTORS

The incorporation of targeting moieties into liposomes by direct formulation, with no covalent bond to any lipid (*44*); conjugated to helper lipid (*45, 46*), or connected directly to the cationic lipids (*47, 48*) can increase uptake and selectivity of liposomes for certain tissues. The targeting groups often used include folate (*45, 46*), galactose (*47, 48*), mannose (*49, 50*), and proteins such as antibodies (*51*) and transferrin (*44*).

The hepatic asialoglycoprotein receptor could recognize and bind to β-D-galactoside terminated glycoproteins (*52*). By using this physical and biological feature, asialoglycoprotein receptor has been studied as a target for gene delivery into hepatocytes. Hashida et al (*53*) synthesized novel galactosylated cholesterol derivatives, cholesten-5-yloxy-*N*-(4-((1-imino-c-β-D-thiogalactosylethyl)amino)alkylformamide, for gene delivery to hepatocytes. In HepG2 cells, the liposomes containing galactosylated cholesterol derivatives showed higher transfection activities than DC-Chol liposomes based on a receptor-mediated mechanism. Later, they used galactosylated cationic liposomes to target liver cells asialo-glycoprotein receptors in vivo (*48*). Liu et al (*54*) developed an efficient route toward the synthesis of bifunctional cationic compounds with DAB-dendr-$(NH_2)_8$ (Figure 5) as the DNA binding domain and galactose ligand for binding to the asialoglycoprotein receptor to prove that the galactosyl compounds Di-Gal and Tri-Gal could effectively deliver DNA into HepG2 cells.

The folate receptor (FR) is a tumor marker overexpressed in large numbers of cancer cells. As a low molecular weight ligand, folic acid has the advantages of being stable and nonimmunogenic compared to monoclonal antibodies (*55*), and still having a relatively high receptor affinity. Folate-targeted liposomes have been successfully used in the tumor cell specific delivery of anticancer drugs and antisense oligodeoxynucleotides in vitro (*56*). In a study, folate was connected to polyethylenimine-*block*-poly(ethylene glycol) to form a copolymer, FOL-PEI-b-PEG (Figure 6), which showed less toxicity in comparison with that of 25 kDa PEI and effective transfection efficiency (*57*). Huang et al (*58, 59*) developed vectors in which poly(lysine)-condensed DNA was entrapped into folate-targeted cationic liposomes (LPD). They found LPD vector to be more efficient and less cytotoxic compared to conventional cationic liposomal vectors.

The physical and biological features of mannosylated vectors offer them the opportunity to deliver plasmid DNA (pDNA) to the liver NPC via mannose receptor mediated endocytosis. The application of poly(lysine) linked to mannose with naked pDNA has been reported to enhance gene expression in macrophages (*60*). Hashida et al. (*61*) have developed a novel mannosylated cholesterol derivative, Man-C4-Chol, consisting of modified cationic liposomes with mannose moieties for NPC-selective gene delivery via mannose receptors on NPC. The mannosylated cationic liposomes can deliver pDNA to liver nonparenchymal cells (*61*) and splenic DCs and improve immune activation in DNA vaccines (*62*). They also proved that DOPE could improve gene expression of the mannosylated cationic liposomes after intraportal administration into mice, and DOPE complex was accumulated in the liver more efficiently through intravenous administration (*63*).

Targeting proteins such as antibodies or transferrin were conjugated to cationic polymers (e.g., poly(lysine) (*64*) or polyethylenimine *65–67*) to mediate uptake of plasmid DNA and antisense oligonucleotides. Since antibodies feature a highly selective binding to their antigen, they are of particular interest as targeting moieties. PEI was modified with G250 mAb to gain targeting effect and enhanced gene delivery to tumor cells that express G250 antigen. The conjugate showed targeted gene delivery to RCC and Hela cells, even in the presence of serum, but with restricted reactivity to G250 negative cells or normal cells (*51*). Transferrin was covalently linked to protamine to deliver functional plasmid DNA to erythroblasts (*68, 69*). Hormone receptors, such as the epidermal growth factor receptor family member ErbB2, expressed on the cell surface can serve

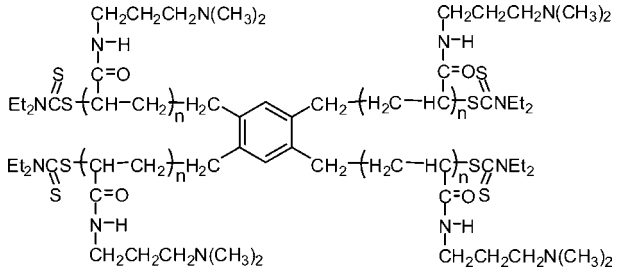

Figure 7. Chemical structure of PDMAPAAm-branched polymer.

as target structures for nucleic acid delivery. A recombinant fusion protein of an ErbB2-specific single-chain antibody fused to protamine successfully transported plasmid DNA to ErbB2 antigen expressing cells (*69, 70*).

Peptides containing the amino acid sequence Arg-Gly-Asp (RGD) can be used for specific targeting to integrin receptors, including the vitronectin receptor $\alpha v\beta 3$, which is known to be highly upregulated in certain tumors (*71*). Anderson et al. (*72*) used RGD containing peptide to coat nanoparticles; the noncovalent peptide coated nanoparticles were found to have favorable biophysical characteristics including small particle size, near-neutral ζ potential, and stability in serum. At appropriate formulation conditions, the coated nanoparticles enabled effective ligand-specific gene delivery to human primary endothelial cells in serum-containing media.

Nakayama (*73*) also proved the fact of RGD peptide enhancing gene expression of a cationic nonviral gene carrier, poly(*N*,*N*-dimethylaminopropylacrylamide) (Figure 7), in endothelial cells. The addition of the RGD-containing peptide to the polyplex solution led to a decrease in the ζ-potential and particle size, and an increase of transfection against endothelial cells and reduction of cellular cytotoxicity.

HYBRIDS OF CATIONIC LIPOSOMES AND POLYMERS

Cationic liposomes, cationic polymers, micelles, or nanoparticles are often researched for gene delivery, but none of them seem to meet the need of the theoretical study or clinical trials for gene therapy. The combination of them may provide a synergistic effect on the transfection efficiency and a promising solution to the problem frustrating us.

Serum is a major hurdle for nucleic delivery of cationic liposomes, as the binding of negatively charged serum components to positively charged DNA complexes can significantly decrease transfection efficiency (*74, 75*). To decrease or reverse the overall particle charge and hence reduce serum opsonization, anionic polymers have been employed as an additional component of the delivery vector (*76–78*). Roth (*79*) showed that the addition of a synthetic, pH-sensitive, membrane-disrupting polyanion, poly(propylacrylic acid) (PPAA), improved the in vitro efficiency of the cationic lipid, DOTAP, with regard to oligonucleotide delivery and antisense activity.

Low-molecular-weight PEIs and cationic liposomes can be combined resulting in a synergistic increase in transfection efficiency. PEI2K-DNA-Dosper complexes showed much more cellular uptake of DNA than PEI2K-DNA complexes and two times higher transfection than Dosper-DNA complexes. It has been hypothesized that Dosper improved the cellular uptake of PEI2K-DNA complexes and PEI2K improved a transfer of the complexes from lysosomes to nucleus (*80*). In a study, the combination of PEI and DOTAP-Chol caused more than 10-fold increase in the transfection efficiency in many cells compared with using polymer or liposome alone. Minimal toxicity was also shown in these cultured cells in vitro (*81*).

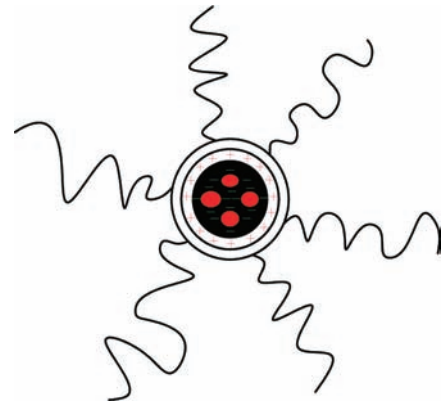

Figure 8. PEGylated LPD through the hybridization of polyplex, liposome and PEG based lipid (This figure was adapted from Huang et al's illustration in ref *84*).

It has been reported that liposome-mediated gene transfer could be improved by natural polycations such as protamine sulfate (PS), poly(L-lysine) (PLL), and spermine (*57, 82*). The addition of poly(L-lysine) and protamine dramatically reduced the particle size of the complex formed between DNA and cationic liposomes and rendered DNA resistant to the nuclease activity (*58*). As copolymers, they can markedly enhance the transfection efficiency of several types of cationic liposomes by 2−28-fold in a number of cell lines in vitro (*58*) and in vivo (*82*). These polycations are known to form a complex with DNA and condense DNA from extended conformation to highly compact structure into 30−100 nm in size. They exhibit a synergistic effect when combined with several different types of cationic LPs in delivering plasmid DNA into several different types of cells (*58*).

Moreover, three natural polycations, protamine sulfate (PS), poly(L-lysine), and spermine, were selected as DNA condensing active agents to enhance the in vitro and in vivo transfection activity of the cationic lipid emulsion (LE). The transfection activity of the ternary complex increased by at least 2.5−5-fold in vitro cell culture system in the presence of 80% serum, as well as in vivo mouse system, as compared with LE/DNA binary complexes. More importantly, after intravenous and intranasal administrations, the in vivo transfection efficiency of the LE/PS/DNA complex was ca. 30 and 50 times higher than that of the liposome (LP)/DNA complex in spleen and lung, respectively. On the other hand, cell toxicity of the ternary complex is lower than that of binary complex (*83*).

We have stated already that Huang et al (*58, 59*) developed vectors in which poly(lysine)-condensed DNA was entrapped into folate-targeted cationic liposomes (LPD). Later, they modified LPDs through different cationic liposomes wherein LPDS were used to deliver antisense oligodeoxynucleotide and siRNA (*84, 85*). Though they used DOTAP and *N*,*N*-distearyl-*N*-methyl-*N*-2[*N*-(*N*2-guanidino-L-lysinyl)] aminoethyl ammonium chloride (DSGLA), a novel non-glycerol-based cationic lipid, which contained both a guanidinium and a lysine residue as the cationic headgroup and downregulated pERK more efficiently in H460 cells than DOTAP as cationic liposomes in the process of LPD preparation, the procedure is very similar. Nucleic acids were mixed with a carrier DNA, calf thymus DNA, before complexing with protamine, a highly positively charged peptide. The resulting particles were coated with cationic liposomes to obtain LPD (liposome−polycation−DNA) nanoparticles. Ligand targeting and steric stabilization were then introduced by incubating preformed LPD nanoparticles with PEGylated ligand lipid (Figure 8).

Maitani et al (*86*) developed cell-penetrating peptide-based gene delivery vectors. A novel oligoarginine lipid ($(Arg)_n$-B, *n*

= 4, 10) conjugated to 3,5-bis(dodecyloxy)benzamide (BDB) lipid with a poly(ethylene glycol) (PEG) spacer was synthesized. Oligoarginine lipid-coated vector was prepared by the addition of $(Arg)_n$-B to DNA/protamine complex (PD) ($(Arg)_n$-B-PD). This result suggested that negatively charged tetraarginine conjugated-PEG lipid-coated PD is a promising gene delivery vector for intratumoral injection.

In another study (*87*), polyamidoamine (PAMAM) dendrimer/DNA complexes encapsulated in a water-soluble polymer, poly-α,β-[*N*-(2-hydroxyethyl)-L-aspartamide) (PHEA), were supported on a cholic acid functionalized star poly(DL-lactide) film with a fast degradation rate to mediate localized gene delivery. The star poly(DL-lactide) supported PHEA encapsulated PAMAM/DNA complexes could effectively mediate transfection to indicate that the existence of PHEA played an important role in the efficient transfection. pH-sensitive fusogenic polymer-modified liposomes exhibited higher transfection activity toward DC2.4 cells than some commercial reagents and hence may be useful as a gene vector for DCs (*88*).

Recently, hybrids of nonviral and viral carriers have been extended to deliver genes, though they have mainly been used for drug delivery systems (*89, 90*). Bionanocapsules (BNCs) consisting of hepatitis B virus (HBV) surface antigen (HBsAg) and lipid bilayer and displaying a human hepatocyte-recognizing molecule (pre-S1 peptide) were approximately 50 nm hollow particles which have been used as an HB vaccine (*91, 92*). BNCs could be produced efficiently in recombinant yeast and therefore were free of other components of HBV (*93*). On the basis of these studies, Kuroda et al (*94*) developed a new BNC conjugated with liposomes. The conjugate could deliver large materials (100 nm fluorescence-labeled polystyrene beads and N30 kbp plasmids) to human hepatocytes specifically in vitro and in vivo. The transfection efficiency of the BNC−liposome complex was significantly higher than that of the original BNC.

CONCLUDING REMARKS

Though the past decade has seen tremendous progress in the design and synthesis of nonviral vectors for gene delivery as well as application of a battery of techniques, the hybrids of nonviral vectors provide another route to overcome the low transfection efficiency of nonviral vectors. Cationic lipids themselves are rarely used, as they do not show effective transfection without the addition of helper lipids such as DOPE. The combination between cationic lipids and helper lipids represents the most successful formulations for gene delivery. However, this may not meet the requirements of in vivo transfection, because of the lack of targeting ability. To promote the uptake of vector−DNA complexes by specific cell types, vectors are usually conjugated with a number of cell targeting agents, particularly folate for cancer cell targeting and galactose for hepatic cell targeting. It has been proven that tertiary amine and quaternary ammonium containing vectors show toxicity to some extent; the conjugates of peptides and lipids are being explored to resolve this problem. They show relatively low toxicity, while retaining acceptable transfection efficiency. The combined utilization of cationic liposomes and other nonviral vectors may provide the most exciting solution for gene delivery, for many advantages could concentrate on the delivery systems. Besides the above-mentioned hybrids, other new formulations are being explored, such as the combination of nonviral and viral carriers.

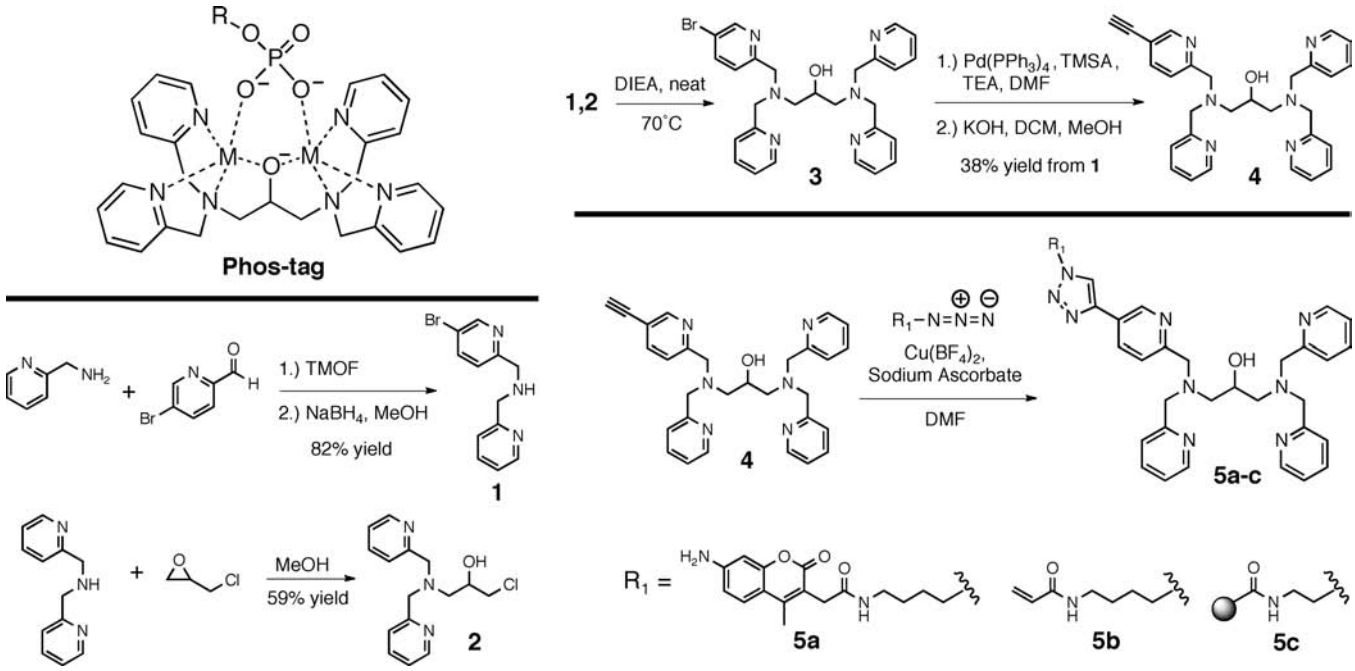
Expedient Synthesis of a Modular Phosphate Affinity Reagent

Nicolas P. Tilmans, Casey J. Krusemark, and Pehr A. B. Harbury*

Department of Biochemistry, Stanford University School of Medicine, California. Received December 6, 2009; Revised Manuscript Received April 12, 2010



Isolation and identification of phosphorylated macromolecules is essential for the deconvolution of most biological regulatory networks. Koike and co-workers recently reported the application of a dinuclear zinc-(pyridylmethyl)-amine complex to phosphate-specific affinity purifications and gave it the shorthand name "phos-tag". This complex is valuable for studying phosphorylation because it binds selectively to phosphate dianion in the presence of acidic functional groups at physiological pH, and because the binding is largely independent of molecular context. These properties of phos-tag recommend it for applications in phosphoproteomics, metabolomics, and nucleic acid biology. The catch has been that the molecule is difficult to make and prohibitively expensive to buy. Here, we describe an efficient and inexpensive synthesis of a phos-tag derivative with a versatile alkyne handle. The alkyne handle allows for attachment of phos-tag to alkyl azides via the copper(I)-catalyzed azide−alkyne cycloaddition reaction ("click chemistry"). We characterize the phosphate binding behavior of the new phos-tag derivative in a variety of experimental assays, including its conjugation to a fluorescent reporter, to acrylamide gels, and to sepharose chromatography resin. The synthesis we report should enable a broader use of phos-tag for phosphate-related biochemistry, as both an analytical and a preparative reagent.

Phosphorylation plays a central regulatory role in many biological networks (*1*−*3*). Understanding such networks requires the detection and purification of different phospho-isoforms of proteins, nucleic acids, lipids, sugars, and small metabolites. Existing work has focused primarily on proteins, and multiple technologies for phospho-peptide enrichment exist (*4*). Importantly, however, most of these techniques require harsh acidic conditions to suppress polyvalent binding of carboxylic acids (*4*). The necessity for acidic pH, which can induce chemical decomposition or denaturation, limits the utility and generality of most known phosphate affinity reagents.

Phos-tag is a phosphate-binding metal chelate complex that operates under milder conditions (*4, 5*). It contains an organic core consisting of two bis(pyridylmethyl)amine moieties attached to the first and third carbon atoms of an isopropanol molecule (Scheme 1). The core chelates a pair of divalent metal

cations (Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, La^{2+}, Mn^{2+}, Ni^{2+}, and Zn^{2+} in literature reports) (*6*−*11*). Some of these metals in turn coordinate tightly to the nonbridging oxygen atoms of phosphate. At physiological pH and salt concentration, phosphate monoester dianion binds to phos-tag(Zn^{2+}) with nanomolar affinity, while sulfate dianion, acetate, chloride, and phosphate monoanion bind with dissociation constants that are 5000- to 800 000-fold weaker (*12*). Phos-tag has been used successfully to produce phospho-specific fluorescent dyes, to retard phosphorylated macromolecules in acrylamide gels, to tag or isolate phosphorylated compounds for mass spectrometry, and to enrich phosphorylated peptides and proteins by column chromatography (*11, 13*−*17*).

Currently, tethered phos-tag is available from a single commercial source in a limited number of formats at a cost of ~$50 000/g (*18*). A single synthesis of phos-tag with an immobilization handle is reported in the patent literature (*19*). The published synthesis proceeds from the cost-limiting reagent 6-methyl nicotinate ($371/g) in a 38% reported yield over four steps. The steps generate product mixtures, and four flash column purifications are required. This cumbersome synthetic scheme, and the expense of the commercially available material, practically limits the use of phos-tag for preparative applications and in novel experimental formats. Here, we present a simple, inexpensive, and convergent synthesis of a phos-tag ligand bearing a versatile alkyne handle for single-point attachment to solid supports and to reporter molecules.

An exploration of the literature for synthetic strategies to the unsubstituted phos-tag ligand (Scheme 1) yielded two prevalent synthetic routes: alkylation of 1,3-diamino-2-propanol with methylpyridines (*20*) and addition of one or two bis(pyridylmethyl)amine units to epichlorohydrin (*21, 22*). In our hands, the alkylation route generated a mixture of products that were difficult to separate. The epichlorohydrin route, on the other hand, promised greater synthetic control. It could be carried out in two steps with sequential addition of a first and second bis(pyridylmethyl)amine unit. Addition of unsubstituted bis(pyridylmethyl)amine followed by a singly functionalized bis(pyridylmethyl)amine would generate a single phos-tag product with a chemically accessible handle (Scheme 1).

A search of commercially available pyridylmethyl derivatives led to 2-formyl,5-bromopyridine (Scheme 1). Reductive amination of this compound with 2-aminomethylpyridine provides an asymmetric, singly brominated bis(pyridylmethyl)amine. Sequential addition of unsubstituted bis(pyridylmethyl)amine and then the brominated bis(pyridylmethyl)amine to epichlorohydrin produces a singly brominated phos-tag derivative. Finally, Sonogashira coupling to (trimethylsilyl)acetylene, followed by base-mediated deprotection, converts the bromine group to a terminal alkyne group (*23, 24*).

The synthesis proceeds in four steps from five commercially available reagents. The overall yield from the cost-limiting reagent, 2-formyl,5-bromo pyridine ($19/g), is 31%. Thus, the cost per gram of the product amounts to approximately $60. The alkyne handle is particularly useful because it can be linked chemoselectively to azide-containing partners by the copper-mediated alkyne−azide cycloaddition reaction (colloquially called the "click" reaction). The resulting linker consists of a triazole.

A first question is whether triazole-linked phos-tag binds to phosphate monoesters with the same affinity as the known amide-linked phos-tag. To address this question, we measured the dissociation constant (K_D) of phos-tag(Zn^{2+})-triazole-aminomethylcoumarin (**5a**) from fluorescein−phosphoethanolamine using a published fluorescence assay (Figure 1 and ref *25*). The fluorescence emission of the aminomethylcoumarin donor chromophore (emission maximum at 445 nm) is suppressed by

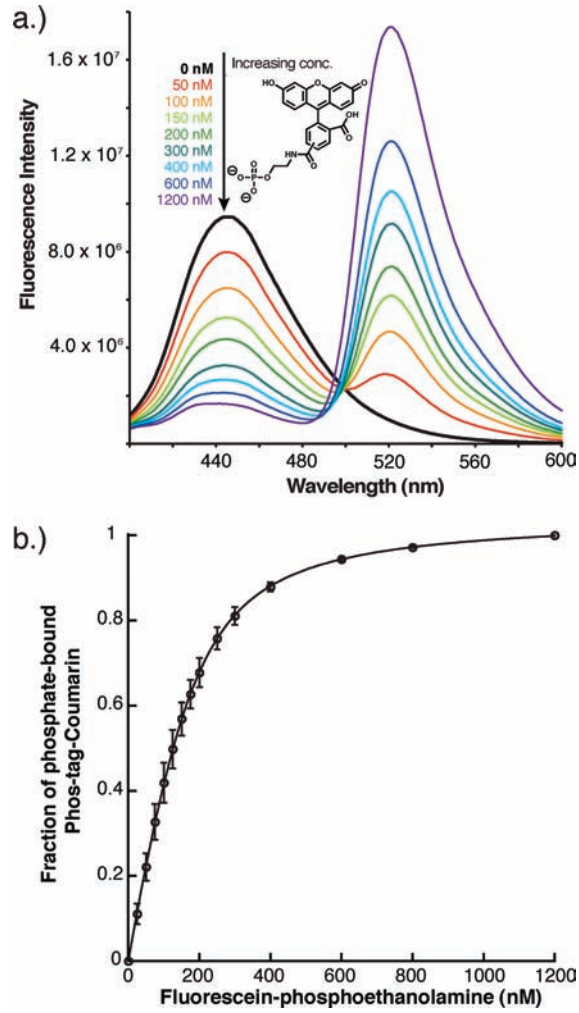

Figure 1. Triazole-linked phos-tag binds phosphate monoesters with an affinity comparable to amide-linked phos-tag. A. Overlaid emission spectra of phos-tag(Zn^{2+})-triazole-aminomethylcoumarin (**5a** at 170 nM concentration, λ_{ex} = 345 nm, 25 °C) with increasing concentrations of fluorescein−phosphoethanolamine. The aminomethylcoumarin fluorophore has an emission maximum at 445 nm, and the fluorescein has an emission maximum at 524 nm. B. Plot of triplicate FRET data with error bars indicating ±1 standard deviation. The fraction of bound phos-tag(Zn^{2+})-triazole-aminomethylcoumarin is plotted vs fluorescein−phosphoethanolamine concentration (0, 25, 50, 75, 100, 125, 150, 175, 200, 250, 300, 400, 600, 800, and 1200 nM). The calculated bimolecular dissociation curve with a K_D of 47 nM is shown as a solid line. Phos-tag(Zn^{2+})-amide-aminomethylcoumarin is reported to bind fluorescein−phosphoserine with a K_D of 70 nM (*25*).

increasing concentrations of the fluorescein acceptor (absorption maximum at 490 nm). The bimolecular dissociation curve that best fits the data has a K_D of 47 ± 10 nM, comparable to the 70 nM K_D measured for the dissociation of phos-tag(Zn^{2+})-amide-aminomethylcoumarin from fluorescein−phosphoserine (*25*). The data suggest that the binding properties of phos-tag are largely unperturbed by the triazole linker.

We next checked whether triazole-linked phos-tag is a practical phosphate-affinity reagent in standard electrophoretic and chromatographic applications. For electrophoresis experiments, the phos-tag alkyne was coupled to an azido-acrylamide moiety (**5b**) and incorporated into native 15% acrylamide gels supplemented with zinc. We compared the migration of two double-stranded PCR amplicons of 200 base-pair length that differed by a single 5′-phosphorylation (Figure 2A). Compound **5b** at 700 nM shifted the phosphorylated amplicon such that it migrated with an apparent size of 275 base pairs, while the amplicon lacking a terminal 5′-phosphate migrated as a 200mer.

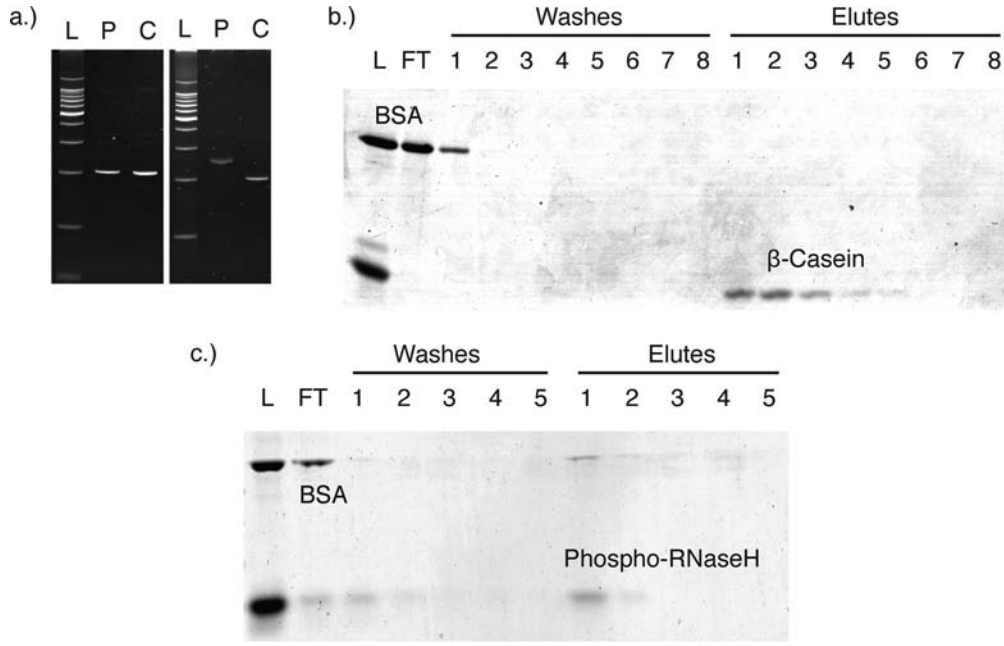

Figure 2. Detection and purification of phosphorylated macromolecules with the triazole-linked phos-tag. A. Phospho-specific DNA gel shift. A conventional 15% native DNA acrylamide gel (left) is compared with an identical gel containing 700 nM phos-tag acrylamide (right). Both gels were cast with 100 μM zinc nitrate. The samples include a 100 base-pair DNA ladder (L), a 200mer DNA with a single 5′-phosphate modification (P), and an identical 200mer DNA with two 5′-hydroxyl termini (C). The migration of the phosphorylated DNA is retarded in the phos-tag-containing gel. B. Phospho-specific protein purification. Load (L), flow-through (FT), wash and elute fractions from a phos-tag sepharose spin column were analyzed on 15% Laemmli gels stained with colloidal coomassie blue. β-casein (a polyphosphorylated protein) is separated away from bovine serum albumin (BSA, a non-phosphorylated acidic protein). The wash buffer was 100 mM citrate and 100 mM Tris-acetate pH 7.4. Elution was accomplished by addition of 100 mM sodium phosphate to the wash buffer. C. Laemmli gel as in **B** showing the partial separation of a monophosphorylated RNase H derivative (engineered to contain a single substrate recognition site for protein kinase A) away from BSA. The wash buffer was 1 M sodium acetate and 100 mM Tris-acetate pH 7.4. Elution was accomplished by addition of 10 mM sodium phosphate to the wash buffer.

The two amplicons migrated identically in a gel containing zinc but lacking compound **5b**.

For phosphate-affinity chromatography experiments, we coupled phos-tag alkyne to azide-derivatized NHS-sepharose at a final substitution level of 5 mM. The phos-tag sepharose resin (**5c**) was placed into 50 μL volume spin columns and loaded with Zn^{2+}. We compared the retention of the polyphosphorylated protein β-casein to the retention of the acidic protein bovine serum albumin (BSA). The use of the highly acidic protein BSA (net charge of -11 at the pH 7.4 used for the separations (*26*)) represents a challenging control. Acidic peptides and proteins are commonly co-purified in phospho-specific purifications, presumably through weak polyvalent interactions of carboxylic acids with the affinity reagent. Nevertheless, the triazole-linked phos-tag(Zn^{2+}) resin cleanly separated β-casein from BSA (Figure 2B), consistent with previous reports for amide-linked phos-tag(Zn^{2+}) (*17*). Thus, triazole-linked phos-tag works well for purification of polyphosphorylated proteins from mixtures.

Previously published phos-tag affinity separations of simple protein mixtures have all used polyphosphorylated proteins as the model phosphorylated species (*5, 17*). To explore the selectivity for monophosphorylated proteins, we measured the retention of a variant of RNase H engineered to include a single substrate recognition site for protein kinase A. The monophosphorylated RNase H bound to the resin but was eluted by citrate wash buffer. It remained bound during washes with 1 M NaCl and could then be eluted by addition of phosphate (Figure 2C). However, BSA was not fully cleared under these milder wash conditions, and some BSA eluted in a phosphate-dependent manner. Alternate wash solutions (1 M sodium acetate and 1 M ethylene diamine) and loading the phos-tag with an alternate metal (Mn^{2+} instead of Zn^{2+}) failed to abolish binding of BSA while retaining complete binding of monophosphorylated RNase H.

Although phos-tag(Zn^{2+}) binds to phosphate dianion 16 000-fold more tightly than it binds to acetate (*12*), in our hands phos-tag sepharose resin cannot cleanly separate a monophosphorylated protein from the acidic protein BSA. Additionally, the tricarboxylic acid citrate at 100 mM concentration competitively displaces monophosphorylated protein from phos-tag sepharose resin, whereas the monocarboxylic acid acetate at 1 M concentration does not. A possible explanation is that multiple weak interactions of carboxylates with the phos-tag sepharose resin are comparable in strength to the interaction with a single phosphate monoester. Increasing the mean distance between phos-tag ligands would suppress such multivalent binding and could be accomplished by reducing the phos-tag substitution level on the resin and by ensuring an even spatial distribution of the ligand. This remedy would presumably improve the specificity with which monophosphorylated proteins could be isolated, at the cost of decreased resin binding capacity. Notably, β-casein remains bound to phos-tag sepharose at high concentrations of citrate. Thus, isolation of polyphosphorylated proteins from complex mixtures is possible using highly substituted resins.

When synthesized as described, phos-tag alkyne is roughly 3 orders of magnitude less expensive than commercially available phosphate-affinity reagents or supports. It recapitulates the published properties of the amide-linked molecule. Our data suggest that phos-tag alkyne can be substituted directly for the commercially available phos-tag, with similar performance. The substantial cost reduction achieved by the new synthesis allows phos-tag to be considered as a practical reagent for preparative

protein purification. The versatility of the alkyne linkage handle should also facilitate new applications of the phos-tag chelate core.

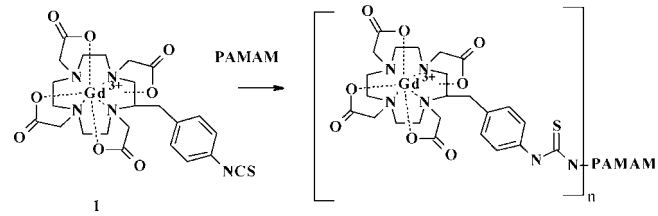
Poly(amidoamine) Dendrimer Based MRI Contrast Agents Exhibiting Enhanced Relaxivities Derived via Metal Preligation Techniques

Kido Nwe,[†] L. Henry Bryant, Jr.,[‡] and Martin W. Brechbiel*,[†]

Radioimmune & Inorganic Chemistry Section, Radiation Oncology Branch, National Cancer Institute, 10 Center Drive, Bethesda, Maryland 20892, and Laboratory of Diagnostic Radiology Research (CC), National Institutes of Health, Bethesda, Maryland 20892. Received February 9, 2010; Revised Manuscript Received April 27, 2010

This report presents the preparation and characterization of three [Gd-*C*-DOTA]$^{-1}$−dendrimer assemblies by way of analysis, NMRD spectroscopy, and photon correlation spectroscopy (PCS). The metal−ligand chelates were preformed in alcohol media prior to conjugation to generation 4, 5, and 6 PAMAM dendrimers. The dendrimer-based agents were purified by Sephadex G-25 column chromatography. The combustion analysis, SE-HPLC, and UV−vis data indicated chelate to dendrimer ratios of 28:1, 61:1 and 115:1, respectively. Molar relaxivity measured at pH 7.4, 22 °C, and 3 T (29.6, 49.8, and 89.1 mM^{-1} s^{-1}) indicated the viability of conjugates as MRI contrast agents. $1/T_1$ NMRD profiles were measured at 23 °C and indicated that at 22 MHz the $1/T_1$ reached a plateau at 60, 85, and 140 mM^{-1} s^{-1} for the generation 4, 5, and 6 dendrimer conjugates, respectively. The PCS data showed the respective sizes of 5.2, 6.5, and 7.8 nm for G-4, 5, and 6 conjugates.



During the development of MRI, contrast agents have been employed to induce additional contrast and increase the sensitivity of MRI scans (*1, 2*). Increased usage of MRI, combined with the necessity for a contrast agent, prompts development of new, efficient agents. Clinically used low molecular weight extracellular contrast agents, e.g., [Gd(DTPA)(H_2O)]$^{-2}$ (Magnevist) suffer from rapid extravasation from blood vessels into interstitial space and fast decrease in concentration in blood vessels, combined with rapid whole body clearance.

In recent years, dendrimers have become an exciting class of polymeric platforms for assembly of multifunctional macromolecular nanomaterials undergoing preclinical development as diagnostics and therapeutic delivery vehicles. There have been reports indicating that dendrimers are applicable as carriers for site-specific delivery of drugs and that they do not alter the function of the molecules attached (*3*−*8*). It has also been discovered that dendrimers can act as drugs themselves (*9, 10*). In the MRI field, dendrimers have not only allowed molecules to retain their function, but also greatly enhanced the signal-to-noise ratio of various imaging modalities; however, this application has never reached its full potential.

The use of Gd(III) chelates conjugated to high molecular weight carriers such as a PAMAM dendrimer prolongs intravascular retention and circulation time, slows down molecular rotation, which results in a short relaxation time, and increases relaxivity (*11*−*13*). Polyamidoamine (PAMAM) dendrimers of different generations conjugated to acyclic diethylenetriamine pentaacetic acid (DTPA) derivatives, e.g., 2-(*p*-isothiocyanatobenzyl)-6-methyl-diethylenetriaminepentaacetic acid (1B4M-DTPA), are versatile in MRI applications due to their monodispersed nature and available range of molecular sizes (*14, 15*).

An acceptable contrast agent must be noncytotoxic and must have high water solubility, most preferably at physiological pH,

and high relaxivity properties. The recent reports regarding nephrogenic systemic fibrosis (NSF) linked to the use of [Gd DTPA]$^{-2}$ derived MR contrast agents provided our laboratory with an impetus to re-evaluate the use of bifunctional DTPA agents for creation of macromolecular MR agents not only with regard to complex stability (*16*−*20*), but also with regard to their inherent extended in vivo residence time. [Gd(DOTA)]$^{-1}$ (1,4,7,10-tetraazacyclododecane-*N,N′,N″,N‴*-tetraacetic acid) is known to be a better contrast agent in terms of complex stability and thus potentially less toxicity as compared to [Gd(DTPA)]$^{-2}$ (*21, 22*). [Gd(DOTA)]$^{-1}$, DOTAREM, has been extensively evaluated in patients with pre-existing renal diseases and to date without clinical side effects (*23*). The higher relaxivity and kinetic stability of [Gd(DOTA)]$^{-1}$ makes it an alternative contrast agent for MRI (*24*). The formation and stability of the [Gd(DOTA)]$^{-1}$ complex has also been thoroughly studied; dissociation of the metal ion was exceedingly slow even at low pH (2−4), on the order of days (*25*), while its thermodynamic stability was comparable to [Gd(III)](DTPA) (*26*). [Gd(DOTA)]$^{-1}$ was previously shown to be 5 orders of magnitude higher in in vitro stability as compared to [Gd(DTPA)]$^{-2}$, which potentially translates to decreased in vivo toxicity (*21*).

Herein, we report the preparation and characterization of three contrast agents with different generation (4, 5, and 6) of dendrimers. The *C*-DOTA (2-(4-nitrobenzyl)-1,4,7,10-tetraazacyclododecane-*N,N′,N″,N‴*-tetraacetic acid) ligand is first used to sequester Gd(III) (Scheme 1), and thereafter, the formed metal complex is covalently attached to the terminal -NH_2 groups of the dendrimer. We have recently reported that premetalation method to be significantly advantageous over conventional

Table 1. Number of Chelates and Molar Relaxivity Values Measured for G4-(*C*-DOTA-Gd)$_{28}$, G5-(*C*-DOTA-Gd)$_{61}$, and G6-(*C*-DOTA-Gd)$_{115}$

agent	no. chelate (analysis)	no. chelate (UV)	r_1 (mM^{-1} s^{-1})
Magnevist	---	---	4.2
G4-(*C*-DOTA-Gd)$_{28}$	28	26	29.6
G5-(*C*-DOTA-Gd)$_{61}$	61	58	49.8
G6-(*C*-DOTA-Gd)$_{115}$	113	107	89.1

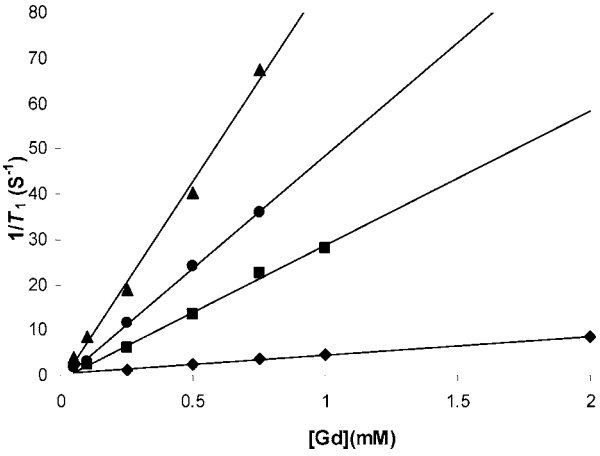

Figure 1. Molar relaxivity plots of G4-(*C*-DOTA-Gd)$_{28}$ (□; 29.6 mM^{-1} s^{-1}), G5-(*C*-DOTA-Gd)$_{61}$) (•; 49.8 mM^{-1} s^{-1}), G6-(*C*-DOTA-Gd)$_{115}$) (▲; 89.1 mM^{-1} s^{-1}), and Magnevist (♦; 4.2 mM^{-1} s^{-1}).

postmetalation methods, resulting in both a more directly characterizable product possessing an ~2-fold enhancement of molar relaxivity when using a bifunctional DTPA chelating agent while also decreasing the overall Gd(III) content by ~30% (*27*). We have also reported the applicability of a *C*-DOTA derivative applied to complex Gd(III) as an agent of choice to replace the use of bifunctional DTPA agents employed to sequester Gd(III) as a component of macromolecular MR contrast agents (*28*).

Table 1 summarizes the number of chelates per dendrimer obtained from analysis and SE-HPLC. For comparison, a UV−vis spectrophotometric titration method was developed. A standard curve using compound **2** (Figure 1 in Supporting Information), which represents a surrogate of the chelate conjugated to an amino surface on the dendrimer, was generated from this method and is shown in Supporting Information Figure 2. The results from assessing the number of chelates per dendrimer were collected in Table 1. Clearly, there is agreement between the two methods within experimental error indicating that spectrophotometric method also to be a viable method for the determination of the number of chelates conjugated to a dendrimer platform.

A plot of the inverse of longitudinal relaxation time ($1/T_1$) versus Gd(III) concentration for the three dendrimer conjugates and Magnevist is shown in Figure 1, while the relaxivity values obtained as a slope of this plot are summarized in Table 1. The data showed that the relaxivity of the three dendrimer based agents are 7−21 times higher than that of Magnevist. This indicates that G6-(*C*-DOTA-Gd)$_{115}$ might be applicable in the submicromolar range and thus also presents the highest potential to eliminate concerns regarding Gd(III) toxicity.

The relaxivity values (30, 50, and 90 mM^{-1} s^{-1}) reported here produced by macromolecules measured at 3 T field strength might seem high, but the reality is that these numbers are not uncommon. A relaxivity range of 139−237 mM^{-1} s^{-1} at 2.4 T field strength, which is close to our field strength, has been reported by Zhang et al. in their contemporary work with fullerene (*29*). The solutions prepared were based on the

gadolinium content from the ICP report of the purified dendrimer conjugate. We reported the efficiency of this macromolecular purification method earlier (*27*), which is also utilized by other researchers (*29*).

In general, conjugation of compound **1** [Gd(*C*-DOTA))$^{-1}$ (Scheme 1) to a higher generation dendrimer such as G6 would result in a more hydrophobic conjugate due to the replacement of exterior primary amines with the complexes. Hydrophobic interaction with solvent molecules is known to slow down the tumbling time (τ_R) which results in increase of the relaxivity (*30*−*32*). On the basis of the combustion analysis, SE-HPLC, and UV−vis data, the agent based on the G6 has the highest free amino sites (141), and thus it is expected to have the highest relaxivity. The experimental data (Table 1) support this position.

Consideration of the nuclear magnetic relaxation dispersion (NMRD) for a given contrast agent is essential, since the field strength of clinical MRI instrumentation ranges from 2 to 180 MHz. The $1/T_1$ NMRD profiles of the G4, G5, and G6 dendrimer conjugates at 23 °C are depicted in Figure 2, wherein the relaxivity for all three agents peaked at ~22 MHz. This behavior is similar to a previously reported measurement using G5, G7, G9, and G10 dendrimers in which the relaxivities peaked at ~22 MHz (*33, 34*). Henry et al. pointed out that the relaxivity of G7 conjugate is comparable to that of G6, which means G6 is the highest generation dendrimer where a significant increase in relaxivity can be observed based on the simple size and amine number of the dendrimers platform (*33, 34*). However, whether that result will hold true for the agents prepared employing the premetalation method presented here remains to be determined in future studies.

The sizes of conjugates determined here are based on 1 μM stock solution prepared in ambient water at pH = 6 to eliminate buffer interference (Table 2). As noted earlier, size measurement based on PCS is concentration dependent (*35*) and also buffer dependent (*36*). As expected, the G6 conjugate has the largest size (Table 2) and thus has the highest impact on the relaxivity (Table 1). This is the first time that our laboratory has measured

the size of PAMAM dendrimer conjugated to [Gd(*C*-DOTA)]$^{-1}$. Relaxivity was observed to be linearly correlated to the size of chelated dendrimer conjugate; the larger the size, the greater the relaxivity (Figure 5; Supporting Information). This is in agreement with a previous report utilizing a similar [Gd(DO3A)]-derivative by Margerum et al. (*36*), and other authors where subsequent increases in size and molecular weight results in increased relaxivity (*33, 34*). This is also a major benefit from attaching a small chelate to a large macromolecule in which the associated tumbling time of the molecule increases leading to increases in relaxation enhancement (*37*). Our NMRD data showed that the relaxivity of G = 6 dendrimer chelate is 140 mM^{-1} s^{-1} at 22 MHz, which is slightly lower than Gd(III)-glutamine synthetase (148 mM^{-1} s^{-1}) at 22.5 MHz (*38, 39*).

The measurement of zeta potential (ζ) reveals the accumulation of ions at the particle surface (*35*). The overall surface charge or ζ potential of the G6 agent is the highest due to the highest density of surface charge as expected. Also, high positive charge ζ potential is indicative of high electrostatic repulsion between particles and provides an energy barrier against aggregation (*35*). Since the differences in ζ potential of the agents is not significant based on the data obtained, one can assume a likelihood of each agent to aggregate to be low. This will be advantageous for in vivo applications where aggregation could interfere with glomerulal filtration clearance through kidney, which would be the preferred route (*40*), especially for larger G5 and G6 conjugates.

In summary, this study indicates that macromolecular-based MRI contrast agents prepared here are efficient and effective in modulating and relaxing water protons when compared to a single Gd(III) chelate. Our study also shows that appending the preformed Gd(III) complex to the dendrimer is far more convenient and significantly more advantageous in areas including species distribution, ease of characterization, stability, and solubility. As reported earlier, this premetalation strategy also produces a more hydrophobic agent that results in high relaxivity and faster blood clearance rate in vivo (*27*). The characterized data provide us with valuable information regarding the nature of the conjugates such as the size and the surface charge, and also enhance our understanding of how these parameters impact the relaxivity and to a certain degree what we can expect from these agents in vivo. These data strongly suggest that the G6-(*C*-DOTA-Gd)$_{115}$ is a superior agent based on its high relaxivity which will also enable use of a much lower injected dose for all future studies thereby facilitating also translation into clinical trial evaluation.

Subunit antigens are attractive candidates for vaccine development, as they are safe, cost-effective, and rapidly produced. Nevertheless, subunit antigens often need to be adjuvanted and/or formulated to produce products with acceptable potency and efficacy. Here, we describe a simple method for improving the potency and efficacy of a recombinant subunit antigen by its immobilization on nickel-chelating nanolipoprotein particles (NiNLPs). NiNLPs are membrane mimetic nanoparticles that provide a delivery and presentation platform amenable to binding any recombinant subunit immunogens featuring a polyhistidine tag. A His-tagged, soluble truncated form of the West Nile virus (WNV) envelope protein (trE-His) was immobilized on NiNLPs. Single inoculations of the NiNLP-trE-His produced superior anti-WNV immune responses and provided significantly improved protection against a live WNV challenge compared to mice inoculated with trE-His alone. These results have broad implications in vaccine development and optimization, as NiNLP technology is well-suited to many types of vaccines, providing a universal platform for enhancing the potency and efficacy of recombinant subunit immunogens.

Rational design of vaccines, made possible by an enhanced understanding of the mechanisms that trigger an effective immune response, includes the optimization of immunogen generation, addition of adjuvants, and improvement of delivery. Numerous vaccine formulations have been very successful, but no single technology covers the key requirements of the ideal vaccine, namely, impeccable safety, low cost, rapid preparation, and high potency (*1*). The three former characteristics are found with subunit antigens (i.e., purified protein components from pathogen candidates) (*2*), though these immunogens suffer from poor potency and thus often are formulated with adjuvants to improved their immunogenicity (*3, 4*). However, adjuvants themselves can have unwanted side effects, and few are approved for use in humans (*4*). The development of an adjuvant-free technology to improve potency through antigen presentation or delivery would accelerate the development of new subunit vaccines.

Multivalency and shape are likely important determinants of vaccine potency and efficacy, since valency may increase affinity and/or aggregate receptors, leading to activation (*5*), and the immune system has likely evolved to react more strongly to particles of the size of invading microorganisms. On the basis of these concepts, multiple investigators have developed multimeric, particulate antigens as vaccine candidates against hepatitis B virus and the human papilloma virus, respectively, produced in yeast and mammalian cells to form 10−20-nm-diameter particles (*6, 7*). While these approaches have been highly effective and widely utilized, their multimeric nature is dictated by the properties of the virus-encoded antigens and is not readily manipulated to produce vaccines for other agents.

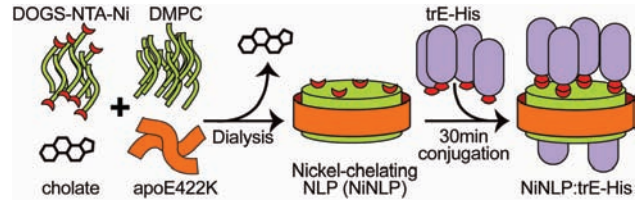

Figure 1. Schematic of NiNLP assembly and His-tagged antigen (trE-His) conjugation.

Other approaches utilizing particulate platforms (*8, 9*) to achieve multivalent presentation of antigens have shown promise, including liposomes (*10*), nanoscale microemulsions (*11*), and nanoparticles (*12*).

Here, we describe a simple method to improve the potency and efficacy of His-tagged recombinant subunit vaccines using nickel-functionalized nanolipoprotein particles (NiNLPs) as a versatile antigen presentation and delivery platform to improve immune response to subunit antigens without requiring adjuvants (Figure 1). To harness multivalent and particulate characteristics for a universal vaccine platform, NiNLPs represent a promising technology. NLPs, also referred to as reconstituted high- or low-density lipoproteins (rHDLs and rLDLs, respectively), are self-assembled, nanometer-sized discoidal particles comprising lipoproteins and phospholipids (*13*−*15*). The lipoproteins are amphipathic, α-helical bundles. Upon lipid binding, the hydrophobic faces of the helices bind the exposed hydrophobic core of the phospholipid bilayer, effectively protecting the lipid patches, producing discrete, soluble particles. The versatility of these biological nanoparticles is underscored by the ability to form NLPs with different apolipoproteins (*13, 16, 17*) and lipids (*13, 18, 19*), including functionalized lipids (*20*−*22*). Traditionally, NLPs have been used as model membrane mimetics for stabilizing and studying membrane proteins (*23*−*27*), although diagnostic (*21, 22, 28*) and drug delivery (*29*−*34*) applications have also been explored.

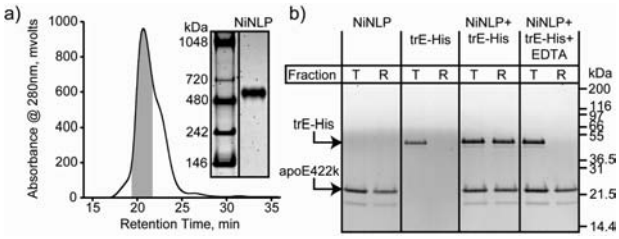

Figure 2. NiNLP characterization and trE-His immobilization. (a) NiNLPs were purified by SEC (shaded region) and analyzed for purity by native gel electrophoresis (inset). (b) Conjugation of WNV trE-His antigen to NiNLPs was verified by centrifugal filtration using a 100 kDa molecular weight cutoff membrane. Total sample (T) and retentate after filtration (R) were resolved by SDS-PAGE and developed using SyproRuby.

We recently reported the facile functionalization of NLPs by incorporating lipids featuring nickel-chelating headgroups during the assembly process (*20*). The resulting particles present a lipid bilayer surface decorated with chelated nickel ions capable of binding recombinant proteins incorporating a poly-His peptide (Figure 1). NiNLPs were prepared by incubating a human apolipoprotein (apoE422K) with a cholate-solubilized mixture of 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC) and the nickel-chelating lipid 1,2-dioleoyl-*sn*-glycero-3-{[*N*-(5-amino-1-carboxypentyl)iminodiacetic acid]succinyl} (nickel salt) (DOGS-NTA-Ni). A 9:1 molar ratio of DMPC to DOGS-NTA-Ni was used to ensure that 10% of the NiNLP bilayer lipids feature chelated nickel (*20*). After dialysis to remove excess cholate, the assembled NiNLPs were purified by size exclusion chromatography (SEC) (Figure 2a). SEC fractions were subsequently analyzed by nondenaturing gradient gel electrophoresis (NDGGE) to identify fractions containing homogeneous populations of NiNLPs, which were then pooled. This approach yields NiNLPs of high purity and homogeneity, as assessed by native gel electrophoresis (Figure 2a, inset). Atomic force microscopy (AFM) confirmed the discoidal nature of the NiNLPs and indicated an average diameter of 23.2 ± 2.3 nm (see Supporting Information). On the basis of previous modeling simulations of apoE422K-based NLPs, the molecular weight of 23.5 nm NLPs is estimated at 860 kDa (*35*), whereas the approximate molecular weight extrapolated from native gel mobility was ~500 kDa (Figure 2a, inset). This discrepancy is due in part to the effects of lipid composition on NLP native gel migration (unpublished observations) as well as the comparison of discoidal NLPs to globular molecular weight markers (*35*).

To determine the ability of NiNLP technology to enhance the antigenicity of recombinant protein immunogens, the envelope protein (E) of West Nile virus (WNV) was identified as a candidate immunogen. Flaviviruses are responsible for serious diseases, including encephalitis (caused by WNV and Japanese encephalitis virus) as well as hemorrhagic fevers (caused by yellow fever virus and dengue viruses) (*36*). Two types of vaccines are currently available against flaviviruses: live-attenuated vaccines (LAVs) and formalin inactivated vaccines (INVs). While effective, LAVs are not recommended for all individuals and have been associated with adverse side effects (*37*). INVs are considered to be a safer type of vaccine, although multiple doses are required to induce high and long-lasting immunity (*38*). Therefore, safer and more potent vaccines need to be developed.

Vaccine-induced immunity to flavivirus infection has been linked to the E protein (*36*). In particular, vaccines based on subviral particles, characterized as 25 nm-diameter cell-derived lipid bilayers coated with E, have been effective against live viral challenges (*39*−*44*). These studies have confirmed the potential of subviral particles as vaccine candidates, but they are currently limited to vaccine formulations against viral targets. Recombinantly expressed E protein has been shown to elicit immunity, however, only in the presence of various adjuvants (*45*−*48*). A broadly adaptable platform for the presentation of antigens from a wide range of pathogens (e.g., viruses, bacteria, and parasites) in the absence of adjuvants would therefore present an important complementary approach to vaccine delivery. To adapt the E protein as a model antigen for use with the NiNLP platforms, a truncated variant of E, in which the native C-terminal membrane-binding domains were substituted with a polyhistidine tag (trE-His), was used in this study (*49*).

We have previously shown that His-tagged proteins are readily immobilized on NiNLPs (*20*). To verify that WNV trE-His was successfully bound to the NiNLPs after 45 min incubation at room temperature, samples were isolated post-conjugation by centrifugal separation using a 100 kDa molecular weight cutoff filter. By this approach, all NiNLP constituents, including apoE422K and any immobilized proteins, are retained by the membrane, whereas unconjugated proteins are removed. Analyses of total (T) and retentate (R) samples by SDS polyacrylamide electrophoresis are shown in Figure 2b, documenting that (1) the NiNLP was retained by the filter, (2) trE-His alone freely passed through the filter, (3) trE-His incubated with NiNLP was retained by the filter, and (4) the presence of EDTA in the mixture disrupted the association of the NiNLP with trE-His, permitting the trE-His to pass through the filter. AFM was used to independently verify immobilization of trE-His on the NiNLPs. An increase in NiNLP height was measured only in the presence of trE-His. No height increase was observed between trE-His and NiNLPs in the presence of EDTA (see Supporting Information).

To determine whether NiNLP conjugation enhanced the immunogenicity of the trE-His to elicit WNV-specific immune responses, a pilot study was performed in 6-week-old mice. The groups of 5 mice were vaccinated once (i.e., no boost) with formulations containing 2.5 μg total trE-His protein, either as free protein (trE-His alone) or conjugated to the NiNLPs (NiNLP-trE-His). In addition, groups of animals were vaccinated with diluent or NiNLP alone. Figure 3a shows the results of the serological trE-His responses detected in the animals in these groups 3 weeks postvaccination. At this dose, only the sera from mice vaccinated with NiNLP-trE-His produced readily detectable IgG responses to trE (Figure 3a). The large standard deviations in the IgG responses are indicative of variable responses by individual mice, rather than experimental error of the ELISAs (see Supporting Information). No response against apoE422K was detected by ELISA assays (data not shown), suggesting either that apoE422K is not immunogenic in mice or that too little protein is used in NLP formation, so an immune response is not observed. To test the ability of NiNLP conjugation to increase the efficacy of trE-His, the animals in this pilot study were challenged with 1000 ffu of live WNV NY99 (corresponding to 10 LD_{50} in 8-week-old mice) two weeks after the collection of sera (5 weeks postvaccination, 11 weeks old), and observed daily for three weeks. The Kaplan−Meier survival curve shown in Figure 3c shows that all mice inoculated with the NiNLP-trE-His preparation survived to 21 days postchallenge when the experiment was terminated (at which time, none of these animals displayed any morbidity—including weight loss; Figure 3e). All of the animals in the other groups succumbed to infection with the exception of two animals that received trE-His, and one animal in each of the NiNLP or diluent groups.

To further assess the efficacy of NiNLP-trE-His, a larger trial using 5-week-old mice in groups of 10 animals was conducted. As with the pilot study, 2.5 μg total trE-His protein, either as free protein or as NiNLP-trE-His, were administered in a single dose. Serological responses were determined 4 weeks postvaccination,

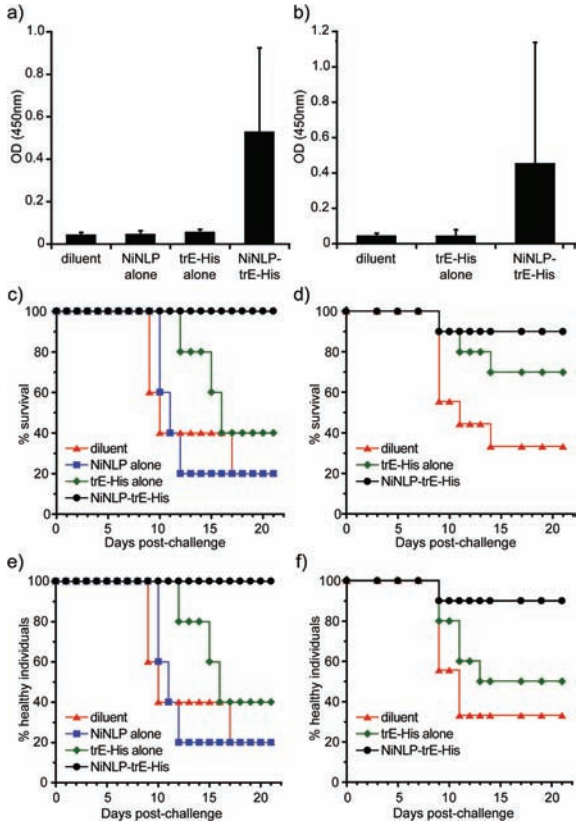

Figure 3. NiNLP conjugation increases the potency of WNV trE vaccines: (a), (c), and (e) first experiment, $n = 5$; (b), (d), and (f) second experiment, $n = 10$. (a) and (b) WNV trE-His ELISA reactivity of sera from mice collected 21 or 28 days postvaccination (first and second experiment, respectively) with various formulations, containing either 2.5 μg of trE-His or no trE-His antigen. Bars represent average OD values obtained from 1:100 dilutions of sera assayed for reactivity to trE-His using standard methods (*37*). Error bars represent s.d. determined from OD values for all animals in each group. (c) and (d) Kaplan−Meier survival curves demonstrating that NiNLP conjugation improved trE-His efficacy. Animals were challenged with 1000 ffu of WNV and observed daily for 21 days. Animals that needed to be euthanized due to disease signs predictive of death within 24 h were scored as dead the following day (*37*). (e) and (f) Morbidity curves reflecting the health of the challenged mice. Individuals were scored as unhealthy if indications of morbidity were observed (weight loss of more than 5%, paralysis, ruffled fur, or inactivity).

and the results mirrored those of the pilot experiment; only those animals receiving the NiNLP-trE-His constructs produced detectable IgG responses to trE (Figure 3b). In contrast to the pilot study, animals were challenged 4 weeks postvaccination. However, exactly the same challenge dose used in the pilot study (1000 ffu of live WNV) was administered. The animals were monitored for 21 days for signs of morbidity and mortality. Importantly, 90% of animals (9/10) receiving the NiNLP-trE-His inoculum survived (Figure 3d) with no indications of morbidity (weight loss of more than 5%, paralysis, ruffled fur, or inactivity) (Figure 3f). Among the animals receiving the unconjugated trE-His subunit in the second experiment, 70% (7/10) survived; however, two animals displayed signs of morbidity (Figure 3f). Of the animals receiving only diluent controls ($n = 9$), only three animals survived.

Taking the health of surviving individuals into account, the two experiments demonstrated a similar outcome. In the first experiment, 100% of NLP-trE-His treated mice survived and were healthy (5/5), whereas only 40% of those receiving trE-His alone (2/5) remained healthy. In the second experiment, 90% of mice receiving the NLP construct (9/10) were healthy following challenge, whereas only 50% of the trE-His vaccinated mice (5/10) remained healthy. Application of Fisher's exact test to the combined 21 day survival data from the two experiments showed a significant difference between the NiNLP-trE-His groups and diluent and a significant difference between the NiNLP-trE-His and trE-His alone (in both cases, $p < 0.01$).

In order for NLPs to gain general use in the preparation of vaccines, a number of items require further investigation, including stability, biodistribution, and elimination. Preliminary stability assessments have demonstrated the ability to lyophilize and rehydrate NiNLPs with no loss in the ability to conjugate His-tagged proteins (data not shown). In vivo applications of rHDLs suggest significant stability over the length of the experiments (*21*). The in vivo fate of NiNLPs will be an important factor in determining the potential of this delivery vehicle. NLPs are most likely eliminated through the same pathway as native HDLs, i.e., processing through the liver. However, toxicology and biodistribution studies are currently underway to address this issue, as are additional stability and storage analyses. Since this vaccine preparation does not require infectious agents, inactivation procedures as well as controlled containment system for infectious agents are avoided, reducing potential costs significantly. Furthermore, we estimate that the process of NLP formation is scalable and the eventual cost of NiNLP-based vaccine platforms will reflect benefits of manufacturing.

We have demonstrated that the immunogenicity of the trE-His antigen is markedly increased when conjugated to NiNLPs. This approach is representative of a more general strategy wherein any protein with a His-tag can be used to generate a NLP-based construct in a matter of a few hours and can be administered to afford protective immunity. Furthermore, NiNLPs offer the potential to codeliver immune stimulators similarly derivatized with a His-tag, providing for enhanced, specific, rapid immune stimulation at the site of delivery and uptake of the NiNLP-antigen construct.

ACKNOWLEDGMENT

The authors thank Dr. Karl Weisgraber for providing apoE422K. Nucleic acid photodynamic molecular beacons (PMBs) are a class of activatable photosensitizers that increase singlet oxygen generation upon binding a specific target sequence. Normally, PMBs are functionalized with multiple solution-phase labeling and purification steps. Here, we make use of a flexible solid-phase approach for completely automated synthesis of PMBs. This enabled the creation of a new type of molecular beacon that uses a linear superquencher architecture. The 3′ terminus was labeled with a photosensitizer by generating pyropheophorbide-labeled solid-phase support. The 5′ terminus was labeled with up to three consecutive additions of a dark quencher phosphoramidite. These photosensitizing and quenching moieties were stable in the harsh DNA synthesis environment and their hydrophobicity facilitated PMB purification by HPLC. Linear superquenchers exhibited highly efficient quenching. This fully automated synthesis method simplifies not only the synthesis and purification of PMBs, but also the creation of new activatable photosensitizer designs.

INTRODUCTION

Activatable photosensitizers modulate singlet oxygen production in response to interactions with a variety of target biomolecules (*1*). Nucleic acid-activatable photosensitizers are based on hybridization to specific nucleic acid target sequences. Nucleic acid photodynamic molecular beacons (PMBs) synthesized with porphyrin or phthalocyanine photosensitizers have recently been developed (*2, 3*). Molecular beacons are hairpin-loop structures that hold a quencher and fluorophore together, until the loop portion hybridizes to a target sequence, causing stem separation and unquenching. PMBs are an extension of prototypical molecular beacons that offer single base mismatch sensitivity and large fluorescence signal differences between the hybridized and nonhybridized states (*4, 5*). Excluding molecular beacons, alternative strategies for DNA control of singlet oxygen have also been proposed. Single-walled nanotubes that bound and quenched a chlorin-*e*6 conjugated aptamer were displaced when the aptamer bound its thrombin target, leading to photosensitizer activation (*6*). Another approach was based on the hybridization and displacement of pyropheophorbide-labeled oligonucleotides to another quenching DNA strand (*7*). These multicomponent systems make use of separate quenching and photosensitizing molecules, which simplifies the synthesis and purification of each individual component but adds a layer of uncertainty of how the subunits behave in diverse hybridization conditions. Here, we report a new synthesis method for PMBs that facilitates their synthesis and purification and also permits the development of novel photodynamic beacon architectures.

Although production of standard molecular beacons is routine, there have been few reports of synthesis and purification of PMBs. Normally, the nucleic acid portion is produced using standard DNA synthesis methods, and then one beacon terminus is labeled with a photosensitizer and the other is labeled with a quenching (or self-quenching) moiety. There are several approaches to the conjugation of these functional groups. To simplify the labeling procedure, previous efforts resulted in the development of a porphyrin phosphoramidite (*7*). While this phosphoramidite is ideal for labeling the 5′ terminus of an oligonucleotide in the final addition cycle of a solid-phase synthesis, no subsequent additions are possible. The most common approach is the incorporation of amine-modified functional groups with different protecting groups that permit sequential deprotection and labeling of each terminus using an activated ester or acid-modified labeling moiety. In the case of self-quenched beacons, only a single type of conjugatable group is required since the same labeling reaction may be repeated at both termini. In some cases, it may be challenging to find a suitable solvent for dissolving the hydrophobic photosensitizer with the hydrophilic nucleic acid. If the oligonucleotide is conjugated at the 3′ prior to synthesis, purification problems can arise using reverse-phase HPLC, because short degradation sequences labeled with a hydrophobic photosensitizer or quencher can elute at the same time as the ion-paired full-length product. Solid-phase synthesis approaches have been described for dual terminal oligonucleotide labeling (*8*) and are applied here to automate PMB synthesis and simplify purification.

RESULTS AND DISCUSSION

To generate a complete solid-phase synthesis approach for PMBs, we first labeled controlled pore glass (CPG) with a photosensitizer. Pyropheophorbide was a suitable choice, since this fluorescent photosensitizer was stable under the harsh conditions of multiple DNA synthesis cycles and oligonucleotide deprotection. The photosensitizer was conjugated to the CPG using a simple dehydration reaction after removing the CPG FMOC group (Figure 1A). After conjugation and washing, the statically charged CPG displayed a dark green color (Figure 1B). A solid-phase packing scheme was developed using a vacuum line, in which empty columns were two-thirds filled to ensure reproducible synthesizer reagent flowthrough during the synthesis (Figure 1C). For the quenching moiety on the opposing 5′ terminus, we employed a commercially available phosphoramidite quencher, BlackBerry quencher dT (BBQ-dT). This is nonterminating and so could be used for multiple additions. As

an example of a useful application of this solid-phase synthesis approach, we generated a new class of PMBs that feature the first linear superquencher.

Superquenchers are assemblies of multiple quenchers that efficiently quench molecular beacon fluorescence when the beacon is in the inactive state (*9*). These have not been previously explored as singlet oxygen quenchers. Standard superquenchers use a trebler phosphoramidite that branches the oligonucleotide, permitting multiple quencher additions in the next addition cycle (Figure 2A, left). While this approach is effective, it requires the use of an additional specialty phosphoramidite (the trebler phosphoramidite, in addition to the quencher phosphoramidite). Instead, we used multiple additions of the BlackBerry quencher phosphoramidite at the 5′ terminus to achieve the first "linear superquencher" (Figure 2A, right) that has multiple quencher moieties attached sequentially (via phosphodiester bonds) in series rather than in parallel. The PMB included pyropheophorbide on the 3′ terminus, the oligonucleotide sequence indicated in the figure (which is a shared stem beacon (*10*) with one stem complementary to a portion the target sequence), and 0, 1, 2, or 3 BlackBerry quenchers linked on the 5′ terminus. After synthesis, the PMBs were deprotected with methylamine/ammonium hydroxide (1:1) for 15 min at 55 °C and were then purified by reverse-phase HPLC. This rapid protocol resulted in PMBs that could be synthesized and purified in a single day. The PMB identities were confirmed with mass spectroscopy. Figure 2B shows the reverse-phase HPLC elution profiles of the beacons. As expected, each additional quencher increased the hydrophobicity and retention times of the beacon. One advantage of the increased retention time was that the linear superquencher could be distinguished from pyropheophorbide-labeled degradation products that tend to elute near the full-length beacon with no quencher or a single quencher (note that Figure 2 shows traces for the purified beacons). The addition of 2 or 3 hydrophobic quenching moieties shifted the elution time so that HPLC purification of the full-length product was straightforward. The absorption profile of the 0, 1, 2, or 3-quencher beacons shown in Figure 2C confirmed that the oligonucleotide (260 nm) and pyropheophorbide (410 and 680 nm) ratios remained constant, while each additional quenching moiety contributed to the broad peak from 500 to 750 nm. The separate spectra of pyropheophorbide and BlackBerry quencher are shown in Supporting Information Figure 1.

The fluorescence response of the beacons was characterized to confirm the beacon activation. As shown in Figure 3A, all

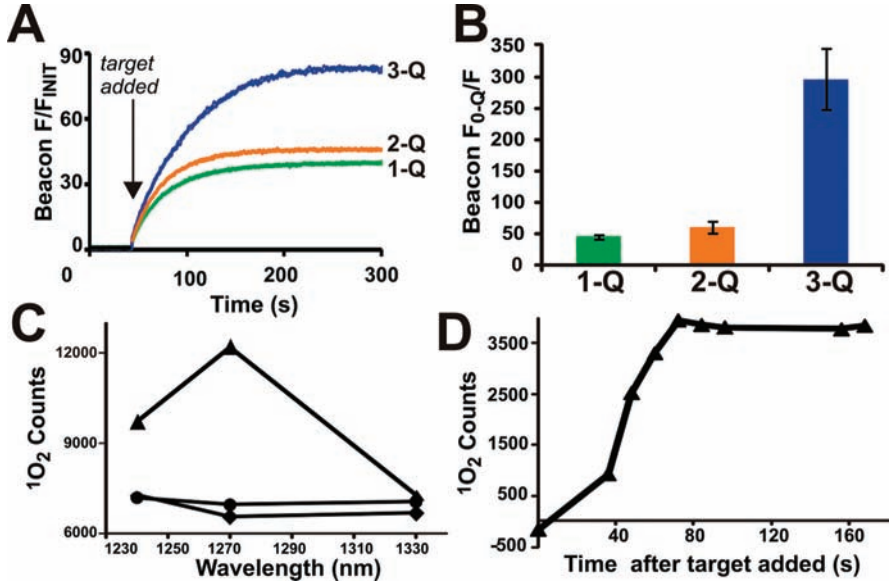

Figure 3. Characterization of linear superquencher (A) 50 nM PMB fluorescence response to addition of a 10-fold excess of target DNA in buffered saline. F is the beacon fluorescence and F_{INIT} is the beacon fluorescence at the initial time point. (B) Beacon fluorescence quenching compared to the 0-Q beacon. (C) Direct measurement of singlet oxygen luminescence for the 1-Q beacon. Triangles: beacon + target. Circles: buffer alone. Diamonds: beacon alone. (D) Singlet oxygen luminescence activation kinetics of the 1-Q beacon measured in buffered saline supplemented with 75% D_2O.

beacons rapidly hybridized to the target nucleic acid, resulting in increased fluorescence. While the single and double quencher were activated 30- and 40-fold, respectively, the triple quencher had a higher activation of approximately 90-fold. This activation is similar to the 100-fold activation observed using gold as a potent molecular beacon quencher (*11*), yet it is not as effective as the 300-fold activation observed with standard branched superquenchers (*9*). However, when the fluorescence intensity of the closed beacon was compared to the 0-Q beacon that lacked any quencher (as opposed to comparing the closed beacon to the target-activated beacon), 300-fold quenching was indeed observed (Figure 3B). This shows that the quenching of the triple quencher was extremely effective, but there was some residual intramolecular quenching in the activated state likely due to the extremely hydrophobic nature of the photosensitizer and quenchers. The singlet oxygen generation of the beacons was next examined. As shown in Figure 3C, in the closed state, the beacon with only 1 quencher generated lower singlet oxygen luminescence than that of the buffer alone. However, when the target was added, a clear singlet oxygen luminescence peak appeared at 1270 nm as expected. Maximum singlet oxygen activation occurred within 80 s of target addition (Figure 3D). Because the singlet oxygen luminescence of the closed-state beacon was below the instrument detection limits with even the 1-Q beacon, we could not accurately determine the activation of the 2-Q or 3-Q PMBs. It would be expected to be similar to the activation of fluorescence, since the degree of fluorescence quenching is highly correlated to the degree of singlet oxygen quenching (*12*).

In summary, the solid-phase approach was effective for generating PMBs that are more convenient to synthesize and purify. By using pyropheophorbide modified CPG, the entire PMB could be synthesized in one run on a standard DNA synthesizer using only one specialty quenching phosphoramidite. Purification was also facilitated by the change in HPLC retention time induced by the presence of multiple quenchers. This synthetic approach permitted the generation of a modified and powerful singlet oxygen superquencher, in which the quenchers were assembled linearly rather than in a branched configuration. The 3-Q PMB displayed favorable characteristics for purification and low-background activation. Fully automated DNA synthesis methods facilitate effective nucleic acid activatable photosensitizer design and implementation.

Received November 10, 2009; Revised Manuscript Received April 11, 2010

Gold/iron oxide magnetic nanoparticles are hybrid nanoparticles containing a core of magnetic iron oxide and surface colloidal gold, which allows for various biomaterials to be immobilized on the surface of the iron oxide nanoparticles *via* colloidal gold. Here, we developed a novel magnetic resonance (MR) imaging agent to broaden the MR tumor-imaging spectrum of superparamagnetic iron oxide nanoparticles (SPIO), e.g., Feridex, a clinical MR imaging agent for diagnosing liver cancer. Au/Feridex was synthesized by electron beam irradiation, and thiol-modified poly(ethylene glycol) (PEG-SH) was easily conjugated to its surface via an Au−S bond without the need for any chemical reactions. PEG conjugation of Au/Feridex enhanced its accumulation in Meth-A tumor tissue and decreased its accumulation in normal liver tissue. In addition, MRI using PEG-Au/Feridex, in contrast to MRI using unmodified Au/Feridex and Feridex, detected B16BL6 and Meth-A tumor tissues *in vivo*. This finding indicates that PEG-Au/Feridex is useful for diagnosing various types of tumors. In addition, because the synthesis of PEG-Au/Feridex is simple and high yields are easily produced, PEG-modified SPIO for tumor diagnosis can be prepared on an industrial scale with low cost.

INTRODUCTION

Superparamagnetic iron oxide (SPIO) is a potent contrast agent for magnetic resonance imaging (MRI) (*1*−*4*), represented by Feridex (AMAG Pharmaceuticals, Inc., MA) and Resovist (Bayer Schering Pharma AG., Germany). These compounds contain a core iron oxide nanoparticle coated with a dextran polymer. SPIO decreases the signal intensity on T_2 (T_2*)-weighted MR images and is clinically used for diagnosing liver cancer (*5*−*7*). SPIO is expected to improve the accuracy and specificity of cancer diagnoses in combination with other diagnostic tools such as computed tomography and ultrasonography (*8*).

SPIO in the blood is rapidly taken up by the reticular endothelial system (RES) like the hepatic specialized macrophages and Kuppfer cells, resulting in a high accumulation in healthy liver tissue (*9, 10*). On the other hand, SPIO does not accumulate in liver tumor tissue lacking Kuppfer cells and does not decrease the signal intensity of tumors, which leads to an increased contrast between healthy liver tissue and tumor tissue (*8*−*10*). Because this mechanism inhibits the distribution of SPIO to other tissues, however, the application of SPIO is limited to the diagnosis of liver cancer. Therefore, many researchers have attempted to develop novel contrast agents for various types of tumors by improving the SPIO (*1, 11, 12*).

Surface modification of SPIO with various biomaterials to inhibit RES uptake is considered effective for targeting tumors (*1*). In particular, conjugation with a water-soluble polymer on the SPIO surface is an effective method of inhibiting RES uptake, subsequently prolonging the half-life of SPIO in the blood. A longer blood half-life of SPIO allows for specific accumulation in tumor tissue by an enhanced permeability and retention effect (EPR effect) (*1, 13*−*18*). Many methods of surface modification have been reported: encapsulation of SPIO into nanoimmunoliposomes (*13*), conjugation of SPIO with polymers such as poly(ethylene glycol) (PEG), poly(ethylene oxide), and dextran (*17, 19*). These approaches, however, require specially designed polymer molecules or complicated preparation methods (*20, 21*). There is therefore strong interest in developing a simple and easy method of conjugating functional molecules to the SPIO surface.

We developed gold/iron magnetic nanoparticles that are easily synthesized by electron beam irradiation of a mixture of iron oxide nanoparticles and Au solution (*22*). Using this method, gold/iron magnetic nanoparticles are obtained in extremely high yield (almost 100%). Colloidal gold forms a strong Au−S bond with a thiol group just by mixing, without any catalysts or linker molecules (*22*−*25*). This property is useful for conjugating various polymers or biomolecules on the nanoparticle surface. As one application, we previously reported that an adenovirus vector (Ad) could be easily immobilized on the gold/iron nanoparticle via the Au−S bond, allowing the Ad/nanoparticle

complex to be introduced into cells by magnetic force, resulting in great improvement in the gene transduction efficacy of the Ad (*23*). In the present study, we synthesized a gold/iron magnetic nanoparticle using Feridex, a clinically available SPIO for liver cancer diagnosis, as its core (Au/Feridex). We coated the surface of Au/Feridex using a thiol-modified PEG to inhibit its accumulation in the liver, thereby extending its half-life in the blood, and to target tumors by the EPR effect. We evaluated the efficacy of PEG-conjugated Au/Feridex (PEG-Au/Feridex) as a tumor contrast agent in tumor-bearing mice.

EXPERIMENTAL PROCEDURES

Au/Feridex Synthesis. Feridex (Advanced Magnetics, Inc.) was dispersed at a concentration of 0.1 g/L in an aqueous solution containing 0.5 mM $AuHCl_4$, 4.125 mM 2-propanol, and 10 g/L poly(vinyl alcohol) (PVA). The dispersion was poured into a glass vial and irradiated with an electron beam at a dose of 6 kGy. Au/Feridex was purified by high-speed centrifugation and redispersed in distilled water. The size was measured using a dynamic light scattering method with a Z-sizer 3000-HS (Malvern Instruments Ltd., UK).

Cell Line. Mouse melanoma cells (B16BL6) were kindly provided from Kobegakuin University. B16BL6 cells were cultured in Minimum Essential Medium (Sigma-Aldrich, St. Louis, MO) containing 7.5% fetal bovine serum (Invitrogen Corporation, Carlsbad, CA) and Antibiotic-Antimycotic Mixed Solution (Nacalai Tesque Inc., Japan). RAW264.7 cells were purchased from American Type Culture Collection. RAW264.7 cells were cultured in Dulbecco's Modified Eagle's Medium (Wako Pure Chemical Industries Ltd., Osaka, Japan) containing 10% fetal bovine serum and Antibiotic-Antimycotic Mixed Solution. Meth-A cells were kindly provided by the Institute of Development, Aging, and Cancer of Tohoku University. Meth-A cells were maintained by intraperitoneal passage in BALB/c mice.

Transmission Electron Microscopy (TEM) Observation of Feridex and Au/Feridex. The morphologies of the Feridex and Au/Feridex were observed by a TEM (H-8100T, Hitachi Ltd., Tokyo, Japan) operated at 200 kV. The typical image from several TEM micrographs is shown in this report.

Preparation of PEG-Conjugated Au/Feridex (PEG-Au/Feridex). Au/Feridex and thiol-modified PEG (PEG-SH, MW = 5000 Da; NOF Corporation, Japan) were mixed at a ratio of 1:1 (1 μmol PEG-SH/mg Fe) in Au/Feridex. The mixture was incubated at room temperature for 1 h and then purified by high-speed centrifugation (28 000 rpm, 30 min). The concentrations of Fe and Au were determined using an inductively coupled plasma (ICP) spectrometer ICPS-7500 (Shimadzu Corporation, Japan).

PVA Test—Cross-Linking of PEGylated Contrast Agents. Contrast agents (Feridex or Au/Feridex) and PEGs (PEG-SH or nonmodified PEG, MW = 5000 Da; Wako Pure Chemical Industries Ltd.) were mixed at a ratio of 1:1 (1 μmol PEGs/mg Fe). After 1 h incubation at room temperature, the mixtures were purified by high-speed centrifugation (100 000 × *g*, 30 min), and the pellet was resuspended with distilled water. An aliquot of 5 mg Fe/mL of these reactants was mixed with an equal volume of 30% PVA (Wako Pure Chemical Industries Ltd.) and incubated at room temperature for 1 h. Cross-linking between PVA and PEG resulted in a precipitate that contained the nanoparticles (*26*).

Quantification of PEG-SH Immobilized on Contrast Agents. Feridex and Au/Feridex were mixed with PEG-SH at a ratio of 1:1 (1 μmol PEGs/mg Fe). After 1 h incubation at room temperature, the mixtures were purified by high-speed centrifugation (100 000 × *g*, 30 min). The amount of sulfur contained in PEG-SH in each sample was then determined using an ICP spectrometer.

***In Vitro* MRI.** Feridex, Au/Feridex, and PEG-Au/Feridex were diluted with distilled water to contain the same iron concentration (50 μg/mL, 10 μg/mL, and 2 μg/mL). T_2-weighted images (multislice spin-echo coronal images; TR = 2000 ms, TE = 69 ms) of these solutions were obtained with a 1.5 T MRI (MRminiSA; DS Pharma Biomedical Co., Ltd., Japan).

***In Vivo* Blood Clearance.** BALB/c mice were intravenously injected with 1 mg Fe in contrast agents (Feridex, Au/Feridex, and PEG-Au/Feridex). Blood samples were collected at 2, 5, 10, 30, and 60 min postinjection. T_2-weighted images of these samples were obtained with a 1.5 T MRI (MRminiSA; DS Pharma Biomedical Co., Ltd., Japan). The signal intensity of each sample on the MR image was analyzed using *Image J* software (National Institutes of Health, USA). The iron concentration of the samples was calculated based on the correlation between the signal intensity and the iron concentration of Feridex. All studies involving animals were approved by the institute's animal care and use committee.

***In Vivo* Distribution.** Meth-A cells (5×10^5 cells/100 μL) were injected intradermally into the abdomen of 6-week-old BALB/c mice. When the tumor size reached 10 mm in diameter, 1 mg Fe/200 μL of each contrast agent (Au/Feridex, PEG-Au/Feridex) was injected intravenously into the mice ($n = 3$ mice per group). The mice were killed, and the tumor and liver were extracted at 1 or 24 h postinjection and immediately freeze-dried. Radiation was counted after irradiation of vials containing samples in a nuclear reactor (JRR-3 in Japan Atomic Energy Agency, Ibaragi, Japan) with a thermal neutron flux of 5.2×10^{17} neutrons/cm/s for 20 min. After a delay of 4 to 5 days, irradiated samples were counted by computer-based γ-ray spectrometry on a Ge detector for 2000 s, and then the peak area of 412 keV γ-rays from ^{198}Au elements was measured using a multichannel pulse height analyzer with automatic dead time (<10%) correction.

***In Vivo* MR Tumor Imaging.** C57BL/6 mice (6 weeks old) were injected intradermally in the abdomen with 5×10^5 cells/100 μL of B16BL6 cells. Meth-A tumor-bearing mice were prepared as described below. When the tumors were 10 mm in diameter, 1 mg Fe/200 μL of each contrast agent (Feridex, Au/Feridex, PEG-Au/Feridex) was injected into the mice ($n = 3$ mice per group). MRI studies were performed with MRminiSA (DS Pharma Biomedical Co., Ltd.). Tumor-bearing mice were anesthetized with a 1.5% isoflurane/air mixture and maintained at 37 °C inside the magnet. All images were obtained as T_2-weighted images (multislice spin-echo axial images; TR = 2000 ms, TE = 69 ms). MRI scans were performed before and 1 h after the injection.

Iron Staining of Tumor Sections. After *in vivo* MRI analysis, the tumor and liver were extracted and fixed with 4% paraformaldehyde followed by sequential immersion in 10%, 20%, and 30% sucrose solutions. Tissues were frozen in OCT compound (Sakura Finetek Inc., Torrance, CA) with liquid nitrogen and sectioned at 10 μm using a cryostat (CM1850; Leica Microsystems GmbH). Sections were stained with Prussian blue to detect the particles of Feridex, Au/Feridex, and PEG-Au/Feridex. Sections were stained with 1% potassium hexacyanoferrate (II)-trihydrate in 0.1 M HCl followed by counterstaining with 0.5% eosin Y ethanol solution.

RESULTS

Synthesis of PEG-Au/Feridex. Au/Feridex was synthesized by electron beam irradiation of the mixture of $AuHCl_4$ and the Feridex solution. Synthesis of Au/Feridex was confirmed by transmission electron microscopy (Figure 1). Au/Feridex was visualized as colloidal gold nanoparticles (black particles) on

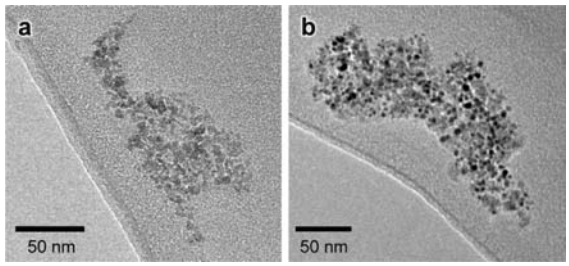

Figure 1. Transmission electron microscopy image of (a) Feridexand (b) Au/Feridex.

the surface of Feridex (gray particles; Figure 1b). Unreacted Feridex, i.e., without colloidal gold, was not observed in this solution. The ratio of Au/Fe was determined as 0.944 Au/Fe by weight using an ICP spectrometer.

PEG conjugation of Au/Feridex was performed by mixing PEG-SH (MW = 5000 Da) with Au/Feridex. PEG conjugation was confirmed by a PVA test, in which PEG-modified particles form a precipitate due to hydrogen bonding between PEG and PVA (*26*). Precipitation was observed only in the PEG-SH and Au/Feridex mixture, and there was no precipitate in the other mixtures (PEG-SH and Feridex, PEG and Au/Feridex, Au/Feridex alone; Figure 2). This findings indicated that PEG modification of Feridex was achieved by an Au−S bond.

Characterization of PEG-Au/Feridex. We measured the amount of PEG-SH immobilized on Au/Feridex using an ICP spectrometer. The amount of immobilized PEG-SH on Au/Feridex was 1.58 mg PEG-SH/mg Fe (1.74 mg PEG-SH/mg Au) and the amount immobilized on Feridex was 0.038 mg. This finding also suggests that PEG-SH was efficiently immobilized on Au/Feridex via Au−S bonds.

We measured the hydrodynamic size of these contrast agents (Feridex, Au/Feridex, and PEG-Au/Feridex) using a dynamic light scattering method. The hydrodynamic size of Feridex, Au/Feridex, and PEG-Au/Feridex was 69.4 nm, 163.9 nm, and 153.6 nm, respectively. Notably, the size of PEG-Au/Feridex (153.6 nm) was smaller than that of Au/Feridex (163.9 nm), suggesting that the state of dispersion was improved by PEG conjugation. The state of dispersion is an important factor in tumor targeting using the EPR effect (*27, 28*). Therefore, this result suggests that PEG-Au/Feridex may be able to effectively target tumors. PEG-Au/Feridex was not cytotoxic to RAW264.7 cells at a concentration of 300 μg Fe/mL (Supporting Information Figure S1). In fetal bovine serum at 37 °C, the Au−S bond remained unbroken after 1 h incubation (Supporting Information Figure S2). Moreover, PEG-Au/Feridex did not aggregate under this condition (data not shown). These results suggested that this conjugation method using the Au−S bond is suitable for *in vivo* applications.

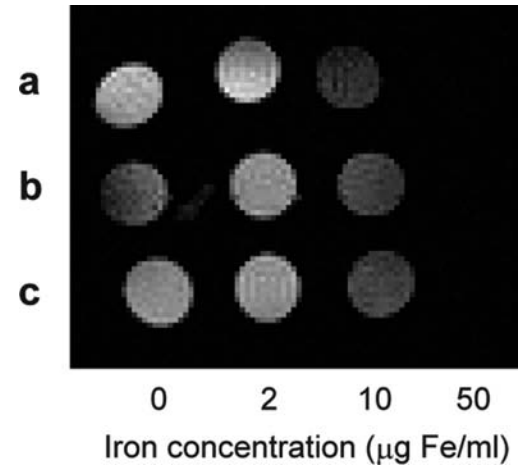

Figure 3. T_2-weighted images of each contrast agent. (a) Feridex, (b) Au/Feridex, and (c) PEG-Au/Feridex were diluted to the same iron concentration with distilled water. T_2-weighted images (spin-echo sequence: TR = 2000 ms, TE = 69 ms) were obtained using MRminiSA.

We then evaluated the transverse T_2 relaxation time of the three contrast agents using *in vitro* MRI images. All the contrast agents showed relaxation at an iron concentration of 10 μg/mL (Figure 3). These results indicate that the T_2 relaxation time was maintained after modification of colloidal gold and PEG-SH, suggesting that PEG-Au/Feridex and Feridex, a clinically used contrast agent, have a nearly equal T_2 relaxation.

Distribution of Each Contrast Agent. The efficacy of PEG modification was estimated by analyzing the blood clearance of Feridex, Au/Feridex, and PEG-Au/Freidex. Blood concentrations of each contrast agent were measured after intravenous injection into mice. The initial Fe concentration in the blood of mice injected with PEG-Au/Feridex was higher than in mice injected with Feridex and Au/Feridex (Figure 4). In addition, the clearance of PEG-Au/Feridex was moderate compared with that of Feridex and Au/Feridex (Figure 4). These findings suggest that the blood concentration of the imaging agent is increased by PEG modification.

We then evaluated the accumulation of the contrast agent in the liver and tumor. Au/Feridex and PEG-Au/Feridex were intravenously injected into Meth-A tumor-bearing BALB/c mice. At 1 h postinjection, the distribution in the liver and tumor tissues was determined by radiochemical neutron

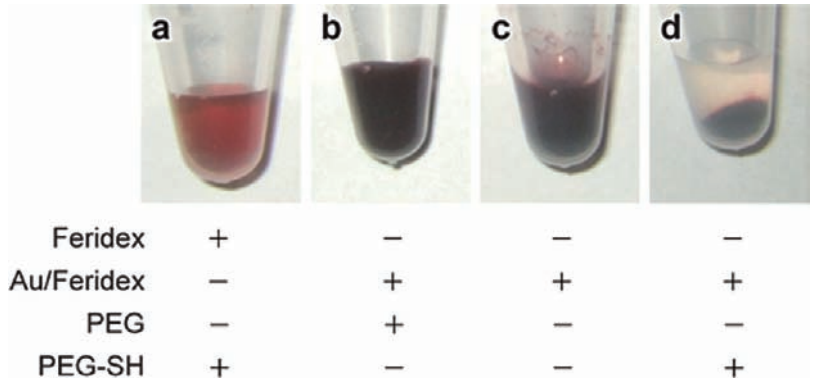

Figure 2. Confirmation of PEG-conjugation to Au/Feridex. PEGs (nonmodified PEG and thiol-modified PEG) were mixed with 5 mg Fe/mL of contrast agents (Feridex and Au/Feridex), as shown in the figure, and purified by high-speed centrifugation. The purified mixtures were mixed with PVA to a final concentration of 15% PVA and incubated overnight at room temperature.

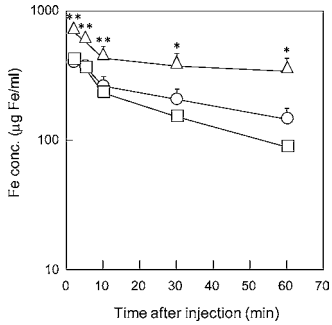

Figure 4. Fe concentration of contrast agents in blood. Fe concentrations were calculated from the intensities of T_2-weighed images (TR = 2000 ms, TE = 69 ms) of mouse blood samples. (o) Feridex, (□) Au/Feridex, and (Δ) PEG-Au/Feridex were intravenously administered and blood samples were collected at 2, 5, 10, 30, and 60 min. The error bars represent the SEM ($n = 5$). *$P < 0.001$, **$P < 0.000\,01$ by two-tailed t-test.

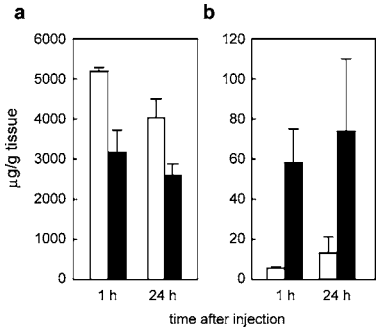

Figure 5. Accumulation of contrast agents in the liver and tumor. Au/Feridex and PEG-Au/Feridex were intravenously injected into tumor-bearing mice, and the livers and tumors were extracted 1 h postinjection. The quantity of (□) Au/Feridex and (■) PEG-Au/Feridex accumulated in the (a) liver or (b) tumor was measured by radiochemical neutron activation analysis of the Au element. Each bar represents SEM ($n = 3$).

activation analysis of the Au element (Figure 5). Liver accumulation of Au/Feridex was decreased by PEG conjugation (Figure 5a), suggesting that PEG conjugation inhibited uptake of the SPIO by the Kupffer cells in the liver. In the tumor, the accumulation of PEG-Au/Feridex was approximately 10-fold higher than that of Au/Feridex (Figure 5b). Accumulation of PEG-Au/Feridex in the tumor at 24 h was slightly increased compared with that at 1 h. The findings suggest that PEG conjugation efficiently enhanced the targeting of Feridex to the tumor.

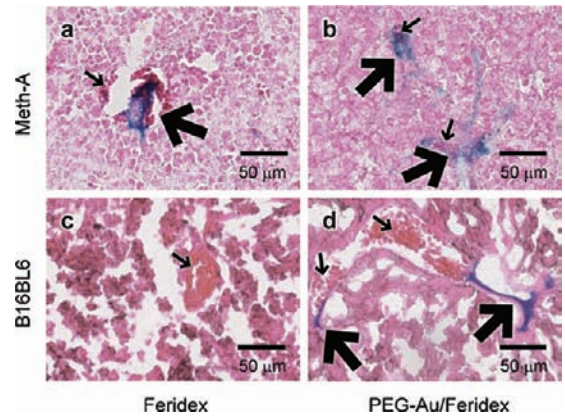

Figure 7. Analysis of tumor-accumulating mechanism of PEG-Au/Feridex. Ex vivo Prussian blue-stained images of tumor tissues extracted from tumor-bearing mice (a,b: Meth-A. c,d: B16BL6) at 1 h postinjection of 1 mg Fe of (a,c) Feridex or (b,d) PEG-Au/Feridex (counterstaining: eosin staining). Narrow arrowhead indicates tumor blood vessel in which erythrocytes are observed. Bold arrowhead indicates location of contrast agents.

PEG-Au/Feridex Enhances Tumor Contrast by an EPR Effect in MR Imaging. We used MR imaging to visualize the efficacy of PEG-conjugated Au/Feridex. MRI of Meth-A tumor-bearing mice was performed 1 h postinjection of Feridex, Au/Feridex, and PEG-Au/Feridex. T_2-weighted images showed that PEG-Au/Feridex decreased the signal intensity of the tumor, leading to the clear identification of a Meth-A tumor, whereas Feridex and Au/Feridex did not improve the tumor contrast (Figure 6a−f). Similar results were obtained using B16BL6 melanoma bearing mice (Figure 6g−l). These results suggested that our PEG-Au/Feridex was effective for identifying various tumor types.

We also tried to determine the mechanism of accumulation in the tumor by analyzing the location of these contrast agents in the tumor tissue. Tumor tissues were extracted from the same mice used to take the MR images, and then slices of the tissues were stained using the Prussian blue staining method to detect the Fe molecules. In both Meth-A and B16BL6-injected mice, PEG-Au/Feridex was distributed around the tumor blood vessels (Figure 7), suggesting that PEG-Au/Feridex leaked from the tumor blood vessels to the outside through the leaky tumor vascular walls. On the other hand, Feridex was not detected in the tumor sections (Figure 6). These results suggest that PEG-Au/Feridex has a decreased liver uptake and accumulated in the tumor by the EPR effect.

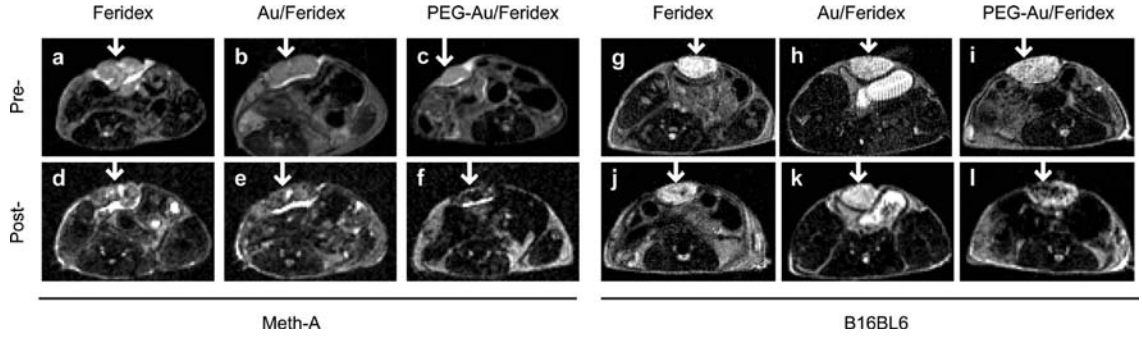

Figure 6. In vivo MRI tumor imaging. T_2-weighted images (1.5 T, spin-echo sequence: TR = 2000 ms, TE = 69 ms) of tumor-bearing mice (a−f, Meth-A; g−l, B16BL6) taken pre- and 1 h postinjection of 1 mg Fe of contrast agent (a,d,g,j: Feridex. b,e,h,k: Au/Feridex. c,f,i,l: PEG-Au/Feridex). Images a−c and g−i were obtained preinjection, and images d−f and j−l were obtained 1 h postinjection. Arrowhead indicates tumor. All images were obtained using MRminiSA.

DISCUSSION

Several studies have been performed in an effort to develop tumor-targeted SPIO (*1*). Most of the previously developed methods, however, require polymers containing special functional groups and some reaction steps that complicate the synthesis of surface-modified SPIO. Moreover, the low yield at each step of the reaction limits the usefulness (*19*). In the present study, these problems were overcome by the use of our original nanomaterial, an Au/Fe magnetic nanoparticle. We designed Au/Feridex from Feridex, a clinically used SPIO coated with dextran. Au immobilization on Feridex was achieved simply (an electron beam irradiation) and its efficiency was almost 100% based on TEM observation (Figure 1). This Au immobilization method is also successful for other iron oxide nanoparticles that do not contain surface dextran (*23*), suggesting that this technology is applicable to various types of SPIO. PEG conjugation via Au−S bonds proceeded under mild conditions at room temperature, without any catalysts or special chemical reactions. The number of PEG-SH molecules on PEG-Au/Feridex was estimated to be approximately 3000 molecules/particle (100 molecules/colloidal gold) based on the assumption that Au/Feridex is a 150-nm-diameter sphere and colloidal gold is a 3.4-nm diameter sphere, which was supported by TEM images (Figure 1). Moreover, the efficiency of PEG conjugation was also estimated to be almost 100%, supported by the clear supernatant in the PVA test (Figure 2). Therefore, this conjugation method is simpler, easier, and more efficient than previously described methods (*13, 14, 16*−*19, 29*). In this aspect, Au/Fe magnetic nanoparticles are an innovative tool that retains the activity of the conjugated molecules (*23*). The efficacy of PEG conjugation was demonstrated by the pharmacokinetics (Figure 4). The higher Fe concentration of PEG-Au/Feridex in the early phase suggests that the distribution volume was decreased and indicates that PEG conjugation inhibited uptake of Au/Feridex into liver (Figure 5). These results clearly show that Au immobilization and surface modification of SPIO is useful for creating a novel MRI tumor contrast agent.

On the other hand, the size of the PEG-conjugated contrast agents is important for tumor targeting (*27*). The size of the gold/iron magnetic nanoparticles can be easily altered by changing the core particle size (*23*). This feature might allow for better control of the pharmacokinetics of the contrast agent (*15, 27*). An effective tumor-targeting method may thus be developed by controlling two parameters: the particle size and the targeting agent. In the future, innovative methods to target various diseases may be developed by synthesizing smaller gold/iron magnetic nanoparticles to decrease the accumulation in the liver, and by applying various targeting agents to control the pharmacokinetics. Our novel MRI contrast agents have high potential for the diagnosis of various diseases.

CONCLUSION

The present paper reports a novel MRI tumor contrast agent (PEG-Au/Feridex) produced using a unique technique. Here, we showed that Au/Feridex can be simply and easily conjugated with PEG-SH. At each reaction step (synthesis of Au/Feridex and modification with PEG-SH), the yield was approximately 100%. PEG-Au/Feridex uptake was decreased in the liver and its accumulation in the tumor was approximately 10-fold greater than that of Au/Feridex, which led to clear identification of the tumor on T_2-weighted images that could not be achieved with Feridex alone. This newly developed contrast agent can be modified with various targeting agents containing a thiol group and will thus be potentially very useful for the diagnosis of various diseases.

ACKNOWLEDGMENT

This study was supported by Research for Promoting Technological Seeds from the Japan Science and Technology Agency (JST); in part by a Grant-in-Aid for Scientific Research and a Grant-in-Aid for Young Scientists (B) from the Ministry of Education, Culture, Sports, Science, and Technology of Japan (MEXT) and the Japan Society for the Promotion of Science (JSPS); in part by a Research Fund Project on Health Sciences focusing on Drug Innovation from the Japan Health Sciences Foundation; and in part by the Magnetic Health Science Foundation. Feridex was kindly provided by Eiken Chemical Co. Ltd. (Tokyo, Japan). Radiochemical neutron activity analysis of the Au element was performed by Dr. Norio Ito at the Osaka Prefecture University (Osaka, Japan).

Novel Polar Single Amino Acid Chelates for Technetium-99m Tricarbonyl-Based Radiopharmaceuticals with Enhanced Renal Clearance: Application to Octreotide

Kevin P. Maresca, John C. Marquis, Shawn M. Hillier, Genliang Lu, Frank J. Femia, Craig N. Zimmerman, William C. Eckelman, John L. Joyal, and John W. Babich*

Molecular Insight Pharmaceuticals, Inc., 160 Second Street, Cambridge, Massachusetts 02142. Received November 23, 2009; Revised Manuscript Received March 10, 2010

Single amino acid chelate (SAAC) systems for the incorporation of the $M(CO)_3$ moiety (M = Tc/Re) have been successfully incorporated into novel synthetic strategies for radiopharmaceuticals and evaluated in a variety of biological applications. However, the lipophilicity of the first generation $Tc(CO)_3$-dipyridyl complexes has resulted in substantial hepatobiliary uptake when either examined as lysine derivatives or integrated into biologically active small molecules and peptides. Here we designed, synthesized, and evaluated novel SAAC systems that have been chemically modified to promote overall $Tc(CO)_3L_3$ complex hydrophilicity with the intent of enhancing renal clearance. A series of lysine derived SAAC systems containing functionalized polar imidazole rings and/or carboxylic acids were synthesized via reductive alkylation of the ε amino group of lysine. The SAAC systems were radiolabeled with ^{99m}Tc, purified, and evaluated for radiochemical stability, lipophilicity, and tissue distribution in rats. The log *P* values of the ^{99m}Tc complexes were determined experimentally and ranged from −0.91 to −2.33. The resulting complexes were stable (>90%) for at least 24 h. Tissue distribution in normal rats of the lead ^{99m}Tc complexes demonstrated decreased liver (<1 %ID/g) and gastrointestinal clearance (<1.5%ID/g) and increased kidney clearance (>15 %ID/g) at 2 h after injection compared to the dipyridyl lysine complex (DpK). One of the new SAAC ligands, [^{99m}Tc]bis-carboxymethylimidazole lysine, was conjugated to the N-terminus of Tyr-3 octreotide and evaluated for localization in nude mice bearing AR42J xenografts to examine tissue distribution, tumor uptake and retention, clearance, and route of excretion for comparison to ^{111}In-DOTA-Tyr-3-octreotide and ^{99m}Tc-DpK-Tyr-3-octreotide. ^{99m}Tc-bis-(carboxymethylimidazole)-lysine-Tyr-3-octreotide exhibited significantly less liver uptake and gastrointestinal clearance compared to ^{99m}Tc-DpK-Tyr-3-octreotide while maintaining tumor uptake in the same mouse model. These novel chelators demonstrate that lipophilicity can be controlled and organ distribution significantly altered, opening up broad application of these novel SAAC systems for radiopharmaceutical design.

INTRODUCTION

The potential to employ the radionuclide technetium-99m with its optimal decay characteristics into targeting molecules has been the foremost consideration in developing diagnostic radiopharmaceuticals (*1*−*3*). ^{99m}Tc-labeled radiopharmaceuticals are preferred over other isotopes because of the ideal nuclear properties of the isotope, as well as its widespread availability from commercial generator columns. ^{99m}Tc emits a 140 keV γ-ray with 89% abundance, which is ideal for imaging with commercial γ cameras. Furthermore, the combination of the medically useful radionuclides, ^{99m}Tc and rhenium-186/188 ($^{186/188}$Re), which have remarkably similar coordination chemistries in terms of the $\{M(CO)_3L_3\}^+$ core thereby yielding isostructural coordination complexes with favorable physical decay characteristics, is attractive for molecular imaging and radiotherapy, respectively (*4, 5*).

We previously described a technology known as the single amino acid chelate (SAAC) (*6*), a radiolabeling platform that has broad utility in radiochemical, fluorescent and dual modality (radio/fluorescent) molecular imaging. SAAC ligands are novel bifunctional chelates constructed from derivatized amino acids modified to provide three donor groups (L_3) for chelation to the $\{M(CO)_3\}^{1+}$ core (M = Tc or Re). SAAC derivatives demonstrate facile labeling with ^{99m}Tc and robust complex stability toward cysteine and histidine challenges, which present major in vivo competition for these ligands (*7*). SAAC avoids the many problems associated with using sulfhydryl containing radioligands and chelating agents that do not fully occupy the coordination sites of Tc and Re or form unstable complexes. In addition, SAAC may be incorporated into bioactive peptides via standard solid phase peptide synthesis and subsequently labeled with ^{99m}Tc and $^{186/188}$Re (*8, 9*).

During the past decade, the field of technetium coordination chemistry has seen both a rising interest in the Tc(I) core (*10*−*15*) and diminishing expectations for its utility, as the core and the subsequent chelators have demonstrated significant deficiencies (*16, 17*). These shortcomings, most notably the hydrophobicity of the metal complexes, are inherent characteristics of the core itself, which are exaggerated by the very nature of the chelators that form the robust complexes. Unfortunately, the lipophilicity of the chelators typically contributes to a poor pharmacokinetic profile of the radiotracer characterized by hepatic accumulation or hepatobiliary clearance. The ability to capitalize on the synthetic flexibility of incorporation, and the stability and inertness of the Tc(I) core, while decreasing the lipophilicity is key to the future success of the technology.

One potential solution to overcome the high hepatobiliary clearance of the complexes is to decrease the lipophilicity surrounding the metal center. Two possible ways to address this issue include (i) derivatizing the metal coordinating ligands with polar, nonlipophilic substituents to counterbalance the lipophilic metal-chelate core or (ii) decreasing the overall size of the ligands used to coordinate the metal core (*18, 19*). The former may be accomplished by modifying imidazole SAAC systems

with polar, water-solubilizing functional groups such as ethers, alcohols, and carboxylic acids, which should alter the pharmacokinetic properties of the SAAC systems, and the biologically relevant molecules to which they are conjugated. In addition, these substitutions will result in metal complexes with neutral, cationic, or anionic charges of the metal complex, which may impact the pharmacokinetic profile. Alternatively, replacing one or more of the ligand donor heteroaromatic rings with a smaller, less hydrophobic donor, i.e., acetic acid, will reduce the size and lipophilicity of the complexes. For example, the nitrilotriacetic acid chelate (NTA) reported by Lipowska et al. (*20*) favored tubular transport rather than hepotobiliary excretion.

In an attempt to address the undesirable liver and gastrointestinal uptake and clearance characteristic of many of the SAAC systems previously designed and evaluated in our laboratory, we have investigated functionalized polar lysine imidazole derivatives with the potential to enhance renal clearance. These novel imidazole SAAC systems can be synthesized with a variety of hydrophilic R-groups via alkylation of imidazole-2-carboxaldehyde with available alkyl halides that contain the desired polar functionality (*21*). In previous work, we functionalized imidazole ligands with ether-containing moieties to investigate cardiac imaging (*22*) resulting in complexes with very low liver uptake and retention. These same principles, expanded to include various alcohols, ethers, and acids, were applied to the SAAC systems to shift the current pharmacokinetic profile from hepatobiliary uptake to higher renal clearance.

Here we describe the synthesis and evaluation of a series of lysine derived SAAC systems with a variety of metal donor ligand groups to form (2-amino-6-(bis((1-X-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid) where X = methyl (**1**), 2,2-dimethoxyethyl (**2**), 2-ethoxyethyl (**3**), carboxymethyl (**4**), 2-hydroxyethyl (**5**), 3-(diethoxyphosphoryl)propyl (**6**), as well as (*S*)-2-amino-6-((carboxymethyl)(thiazol-2-ylmethyl)aminohexanoic acid (**7**), (*S*)-2-amino-6-((carboxymethyl)((1-methyl-1*H*-imidazol-2-yl)methyl)aminohexanoic acid (**8**), 2,2′-(5-amino-5-carboxypentylazanediyl)diacetic acid (**9**) and compared them to 2-amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic acid (DpK) and 2-amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)hexanoic acid (PAMAK). Tissue distribution data obtained with these complexes in normal rats demonstrated greater kidney clearance and significantly less liver and gastrointestinal uptake than first generation SAAC ligands. Two SAAC ligands were subsequently incorporated using solid phase peptide synthesis into Tyr-3-octreotide yielding, ^{99m}Tc-**4**-Tyr-3-octreotide and ^{99m}Tc-DpK-Tyr-3-octreotide. These peptides were evaluated for localization in nude mice bearing AR42J xenografts to examine tissue distribution, tumor uptake and retention, clearance, and route of excretion for comparison to ^{111}In-DOTA-Tyr-3-octreotide, a well established radioimaging agent with excellent pharmacokinetic properties that targets the type 2 somatostatin receptor in neuroendocrine tumors (*23*−*25*).

EXPERIMENTAL SECTION

General Methods. All reactions were carried out in dry glassware under an atmosphere of argon unless otherwise noted. Reactions were purified by column chromatography under medium pressure using a Biotage SP4 or by preparative high pressure liquid chromatography using a Varian Prostar 210 preparative high pressure liquid chromatography (HPLC) system equipped with a semipreparative Vydac C18 reverse-phase column (250 mm ×10 mm × 5 μm) connected to a Varian Prostar model 320 UV−visible detector and monitored at a wavelength of 254 nm. The final technetium SAAC complexes were purified and analyzed using a binary solvent gradient of 5−95% buffer B over 21 min (buffer A = triethylammonium phosphate (TEAP), pH 3, buffer B = methanol). The final ^{99m}Tc-SAAC-peptide conjugates were purified and analyzed on Vydac C18 reverse-phase column (250 mm × 4.6 mm × 5 μm) employing a gradient method of 5−50% buffer B over 30 min (buffer A = water + 0.1% TFA, buffer B = acetonitrile + 0.1% TFA). ^{1}H NMR spectra were obtained on a Bruker 400 MHz instrument. Spectra are reported as ppm and are referenced to the solvent resonances in chloroform-*d* ($CDCl_3$), dimethyl sulfoxide-d_6 (DMSO-d_6), or methanol-d_4 (MeOD). Combustion analyses were performed by Prevalere Life Sciences, Inc. ^{99m}Tc was used as a solution of $Na^{99m}TcO_4$ in saline, as a commercial ^{99}Mo/^{99m}Tc generator eluant (Cardinal Health). The ^{99m}Tc-containing solutions were always kept behind sufficient lead shielding. The $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was prepared from commercially available Isolink kits (Covidien). The ^{111}In was used as an $^{111}InCl_3$ solution commercially available from MDS Nordion. All solvents and reagents were purchased from Sigma Aldrich (St. Louis, MO), Bachem (Switzerland), Akaal (Long Beach, CA), or Anaspec (San Jose, CA). The following abbreviations are used: Fmoc = fluorenylmethyloxycarbonyl, DMAP = *N*,*N*-dimethylaminopyridine, DMF = *N*,*N*-dimethylformamide, DMSO = dimethyl sulfoxide, DCM = dichloromethane, DCE = 1,2-dichloroethane, NaOH = sodium hydroxide, (*S*)-2-(((9*H*-fluoren-9-yl)methoxy)carbonylamino)-6-aminohexanoic acid hydrochloride salt = L-Fmoc-lysine-OH hydrochloride salt, ID/g = injected dose per gram, NTA = nitrilotriacetic acid, PBS = phosphate buffered saline, RCP = radiochemical purity, RCY = radiochemical yield.

Syntheses. *General Procedure for the Alkylations.* To a solution of the imidazole-2-carboxaldehyde dissolved in DMF (1 mL) was added 1 mol equiv of the alkyl bromide, excess potassium carbonate, and a catalytic amount of potassium iodide. The mixture was heated at 110 °C for 18 h followed by evaporation to dryness and purified utilizing a Biotage SP4 with a gradient method of 5−50% methanol in DCM.

General Procedure for the Reductive Aminations. To a solution of L-Fmoc-lysine-OH hydrochloride salt (90 mg, 0.19 mmol) dissolved in DCE (2 mL) was added 2.1 equiv of the aldehyde. The mixture was heated at 50 °C for 1 h whereupon sodium triacetoxyborohydride (36 mg, 0.19 mmol) was added. The mixture was stirred at room temperature for 12 h and was subsequently evaporated to dryness and purified utilizing a Biotage SP4 with a gradient method of 5−50% methanol in DCM. The purified compound (24 mg, 0.034 mmol) was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 2 h. Following evaporation to residue, aqueous extraction and washing with excess DCM afforded the desired compounds as an off-white solid.

*(S)-2-Amino-6-(bis((1-methyl-1H-imidazol-2-yl)methyl)amino)-hexanoic Acid (**1**).* A solution of Fmoc-Lys-OH·HCl (1.8 g, 4.5 mmol) and 1-methyl-1*H*-imidazole-2-carbaldehyde (1.1 g, 10 mmol) in DCE (50 mL) was stirred at 75 °C for 30 min under nitrogen. The reaction mixture was cooled to 0 °C and treated with sodium triacetoxyborohydride (3.2 g, 15 mmol). The reaction mixture was stirred at room temperature overnight and was decomposed with water. The reaction mixture was extracted with DCM. The organic layer was dried and concentrated under reduced pressure. The residue was purified by flash chromatography over silica gel to afford (*S*)-2-(((9*H*-fluoren-9-yl)-methoxy)carbonylamino)-6-(bis((1-methyl-1*H*-imidazol-2-yl)-methyl)amino)hexanoic acid (2.3 g, 92%). MS (ESI), 557 (M + H)$^+$. To a solution of (*S*)-2-(((9*H*-fluoren-9-yl)methoxy)carbonyl-amino)-6-(bis((1-methyl-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid (556 mg, 1.00 mmol) in DMF (4.0 mL) was added piperidine (0.80 mL). The mixture was stirred at room temperature for 2 h. Solvent was evaporated under reduce pressure to afford a residue, which was purified by Amberchrom column chromatography to afford (*S*)-2-

amino-6-(bis((1-methyl-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid (320 mg, 0.958 mmol, 96% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.94 (s, 1 H), 7.04 (d, J = 3, 1.2 Hz, 2H), 6.74 (d, J = 1.2 Hz, 2 H), 3.54 (s, 4 H), 3.98 (brs, 1 H), 2.88 (s, 3 H), 2.72 (s, 3 H), 2.35 (t, J = 6.8 Hz, 2 H), 1.60−1.54 (m, 1 H), 1.43−1.29 (m, 3 H), 1.16−1.11 (m, 2 H). MS (ESI): 335 $(M + H)^+$.

*1-(2,2-Dimethoxyethyl)-1H-imidazole-2-carbaldehyde (**2A**).* To a solution of the imidazole-2-carboxaldehyde (410 mg, 4.3 mmol) dissolved in DMF (1 mL) was added 1.1 equiv of 2-bromo-1,1-dimethoxyethane (800 mg, 4.7 mmol), potassium carbonate, and a catalytic amount of potassium iodide. The mixture was heated at 110 °C for 18 h followed by evaporation to dryness and purified utilizing a Biotage SP4 with a gradient method of 5−50% methanol in DCM to yield the desired compound (250 mg, 1.4 mmol, 32% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.9 (s, H), 7.85 (s, H), 7.55 (s, H), 5.82 (m, H), 4.75 (d, 2H), 3.45 (s, 6H).

*(S)-2-Amino-6-(bis((1-(2,2-dimethoxyethyl)-1H-imidazol-2-yl)-methyl)amino)hexanoic Acid (**2**).* Following the same procedure as utilized in the preparation of **1** yielded the desired compound (93 mg, 0.132 mmol, 54% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.90 (d, 2H), 7.72 (d, 2H), 7.41 (m, 2H), 7.30 (m, 2H), 7.05 (s, H), 6.75 (s, H), 4.45 (m, 3H), 4.2 (m, 4H), 3.95 (d, 2H), 3.80 (m, H), 3.55 (s, 2H), 3.2 (s, 6H), 2.3 (m, 2H), 1.60 (m, H), 1.35 (m, H) 1.15 (m, 2H). ESMS *m*/*z*: 705 $(M + H)^+$.

The purified compound was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 18 h. Following evaporation to residue, aqueous extraction from DCM afforded the desired product (44 mg, 0.093 mmol, 76% yield) as an off-white solid. ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.98 (s, H), 7.05 (s, H), 6.85 (s, H), 4.45 (s, 2H), 3.95 (m, 4H), 3.55 (s, 2H), 3.2 (s, 6H), 2.85 (m, 2H), 2.15 (m, 2H), 1.40 (m, 2H). 1.15 (m, 2H). ESMS *m*/*z*: 483 $(M + H)^+$.

*1-(2-Ethoxyethyl)-1H-imidazole-2-carbaldehyde (**3A**).* Following the same procedure as utilized in the preparation of **2A**, the target compound was prepared from 1-bromo-2-ethoxyethane (3.51 g, 22 mmol) and imidazole-2-carboxaldehyde to yield the desired compound (580 mg, 3.56 mmol, 17% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.63 (s, H), 7.6 (s, H), 7.21 (s, H), 4.45 (dd, 2H), 3.62 (dd, 2H), 3.38 (m, 2H), 1.05 (t, 3H).

*(S)-2-Amino-6-(bis((1-(2-ethoxyethyl)-1H-imidazol-2-yl)methyl)-amino)hexanoic Acid (**3**).* Following the same procedure as utilized in the preparation of **1** yielded the desired Fmoc-protected product (141 mg, 0.210 mmol, 44% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.67 (d, 2H), 7.35 (m, 4H), 7.30 (m, 2H), 7.05 (s, H), 6.75 (s, H), 3.95 (m, 4H), 3.58 (d, 4H), 3.55 (s, 4H), 3.3 (s, 4H), 2.30 (m, 2H), 2.15 (m, 2H), 1.50 (m, 2H). 1.15 (s, 2H), 1.05 (t, 6H). ESMS *m*/*z*: 674 $(M + H)^+$. The purified compound was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 18 h. Following evaporation to residue, aqueous extraction from DCM afforded the desired product (31 mg, 0.069 mmol, 91% yield) as an off-white solid. ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.35 (s, H), 7.98 (s, H), 7.05 (s, H), 6.75 (s, H), 3.95 (m, 4H), 3.58 (d, 4H), 3.55 (s, 4H), 3.3 (s, 4H), 2.30 (m, 2H), 2.15 (m, 2H), 1.50 (m, 2H). 1.15 (s, 2H), 1.05 (t, 6H). ESMS *m*/*z*: 451 $(M + H)^+$.

*tert-Butyl 2-(2-Formyl-1H-imidazol-1-yl)acetate (**4A**).* Following the same procedure as utilized in the preparation of **2A**, the target compound was prepared from *tert*-butyl 2-bromoacetate and imidazole-2-carboxaldehyde to yield the desired compound (850 mg, 4.03 mmol, 39% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.6 (s, H), 7.23 (s, H), 5.15 (s, 2H), 1.40 (s, 9H).

*(S)-2,2′-(2,2′-(5-Amino-5-carboxypentylazanediyl)bis(methylene)-bis(1H-imidazole-2,1-diyl))diacetic Acid (**4**).* Following the same procedure as utilized in the preparation of **1** yielded the desired Fmoc-protected product (155 mg, 0.205 mmol, 42% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.67 (d, 2H), 7.35 (m, 4H), 7.30 (m, 2H), 7.05 (s, H), 6.7 (s, H), 4.70 (s, 4H), 4.2 (m, 4H), 3.4 (d, 2H), 2.4 (m, 2H), 1.8 (s, 2H), 1.39 (s, 18H). 1.2 (m, 2H). ESMS *m*/*z*: 758 $(M + H)^+$. The purified compound was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 18 h. Following evaporation to a residue, aqueous extraction from DCM afforded the desired product (25 mg, 0.047 mmol, 25% yield) as an off-white solid. ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.0 (s, 2H), 6.65 (s, H), 4.70 (s, 4H), 4.2 (m, 4H), 3.2 (d, 2H), 2.4 (m, 2H), 1.8 (s, 2H), 1.39 (s, 18H). 1.15 (m, 2H). ESMS *m*/*z*: 535 $(M + H)^+$.

*(S)-2-Amino-6-(bis((1-(2-hydroxyethyl)-1H-imidazol-2-yl)methyl)-amino)hexanoic Acid (**5**).* To a solution of **3** (25 mg, 0.055 mmol) dissolved in DCM (10 mL) was added 1.0 M boron tribromide in DCM (83 mg, 0.333 mmol) at −20 °C. The mixture was stirred at −20 °C for 2 h and was subsequently quenched with water and washed with excess DCM. The water portion was evaporated to dryness and purified as the product utilizing a Biotage SP4 with a gradient method of 5−50% methanol in DCM (15 mg, 0.038 mmol, 34% yield). ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.40 (m, 2H), 8.16 (d, 2H), 7.70 (d, 2H), 5.50 (s, 2H), 4.20 (s, 2H), 4.05 (m, 4H), 3.68 (d, 2H), 3.15 (m, 5H), 2.46 (s, 2H), 1.70 (m, 2H), 1.65 (m, 2H). 1.21 (m, 2H). ESMS *m*/*z*: 395 $(M + H)^+$.

*Diethyl 3-(2-Formyl-1H-imidazol-1-yl)propylphosphonate (**6A**).* Following the same procedure as utilized in the preparation of **2A**, the target compound was prepared from diethyl (3-bromopropyl)phosphonate (2.96 g, 11.4 mmol) and imidazole-2-carboxaldehyde to yield the desired compound (466 mg, 1.69 mmol, 16% yield). ESMS *m*/*z*: 275 $(M + H)^+$.

*(S)-2-Amino-6-(bis((1-(3-(diethoxyphosphoryl)propyl)-1H-imidazol-2-yl)methyl)amino)hexanoic Acid (**6**).* Following the same procedure as utilized in the preparation of **1** yielded the desired Fmoc-protected product (63 mg, 0.071 mmol, 21% yield). ESMS *m*/*z*: 443 (M/2). The purified compound (53 mg, 0.060 mmol) was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 18 h. Following evaporation to a residue, aqueous extraction from DCM afforded the desired product (32 mg, 0.048 mmol, 80% yield) as an off-white solid. ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.1 (s, 2H), 6.78 (s, 2H), 3.98 (m, 4H), 3.8 (m, 4H), 3.6 (s, 4H), 2.85 (m, 4H), 2.75 (s, H), 2.38 (s, 2H), 1.77 (m, 4H), 1.55 (m, 4H), 1.39 (s, 2H), 1.18 (t, 12H). ESMS *m*/*z*: 664 $(M + H)^+$.

*(S)-2-Amino-6-((carboxymethyl)(thiazol-2-ylmethyl)amino)hexanoic Acid (**7**).* A suspension of Fmoc-Lys-OH·HCl (6.1 g, 15 mmol) and thiazole-2-carbaldehyde (1.697 g, 15 mmol) in DCE (100 mL) was refluxed for 30 min under nitrogen. The reaction mixture was cooled to 0 °C and treated sequentially with sodium triacetoxyborohydride (7.9 g, 38 mmol) and crude *tert*-butyl glyoxalate (3.53 g, 27 mmol) as previously reported (*26*). The reaction mixture was stirred at room temperature overnight and decomposed with water. The reaction mixture was extracted with DCM. The organic layer was dried and concentrated under reduced pressure. The residue was purified by flash chromatography over silica gel to afford (*S*)-1-(9*H*-fluoren-9-yl)-14,14-dimethyl-3,12-dioxo-10-(thiazol-2-ylmethyl)-2,13-dioxa-4,10-diazapentadecane-5-carboxylic acid (1.85 g, 21%). MS (ESI), 580 $(M + H)^+$. To a solution of (*S*)-1-(9*H*-fluoren-9-yl)-14,14-dimethyl-3,12-dioxo-10-(thiazol-2-ylmethyl)-2,13-dioxa-4,10-diazapentadecane-5-carboxylic acid (72.5 mg, 0.125 mmol) in DMF (1.0 mL) was added piperidine (0.20 mL). The mixture was stirred at room temperature for 2 h. Solvent was evaporated under reduced pressure to afford a residue, which was purified by flash chromatography over silica eluting with 10% MeOH in DCM to afford (*S*)-2-amino-6-((2-*tert*-butoxy-2-oxoethyl)(thi-

azol-2-ylmethyl)amino)hexanoic acid (25 mg, 0.083 mmol, 66%). ^{1}H NMR (400 MHz, CD_3OD) δ 7.70 (d, $J = 3.6$ Hz, 1 H), 7.52 (d, $J = 3.6$ Hz, 1 H), 4.15 (s, 2 H), 3.52 (dd, $J = 7.2$, 5.2 Hz, 1 H), 3.39 (s, 2 H), 2.73 (t, $J = 7.2$ Hz, 2 H), 1.91−1.76 (m, 2 H), 1.60−1.57 (m, 2 H), 1.55−1.47 (m, 11 H). MS (ESI): 358 $(M + H)^+$.

*(S)-2-Amino-6-((2-tert-butoxy-2-oxoethyl)((1-methyl-1H-imidazol-2-yl)methyl)amino)hexanoic Acid (**8**).* The title compound was prepared by following the same procedure as described in the preparation of **7** except 1-methyl-1*H*-imidazole-2-carbaldehyde was used in place of thiazole-2-carbaldehyde. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.88 (d, $J = 7.2$ Hz, 2 H), 7.71 (dd, $J = 7.2$, 2.4 Hz, 2 H), 7.55 (d, $J = 8.0$ Hz, 1 H), 7.40 (t, $J = 7.6$ Hz, 2 H), 7.31 (t, $J = 7.6$ Hz, 4 H), 7.01 (s, 1 H), 6.71 (s, 1 H), 4.27−4.18 (m, 3 H), 3.88−3.83 (m, 1 H), 3.72 (s, 2 H), 3.14 (s, 2 H), 1.62−1.50 (m, 2 H), 1.38 (s, 9 H), 1.33−1.21 (m, 4 H). MS (ESI): 577 $(M + H)^+$. To a solution of (*S*)-1-(9*H*-fluoren-9-yl)-14,14-dimethyl-10-((1-methyl-1*H*-imidazol-2-yl)methyl)-3,12-dioxo-2,13-dioxa-4,10-diazapentadecane-5-carboxylic acid (190 mg, 0.33 mmol) in DMF (2 mL) was added piperidine (0.4 mL). The mixture was stirred at room temperature for 2 h. Solvent was evaporated under reduce pressure to afford a residue, which was purified by Amberchrom column chromatography to afford (*S*)-2-amino-6-((2-*tert*-butoxy-2-oxoethyl)((1-methyl-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid (115 mg, 0.32 mmol, 97%). ^{1}H NMR (400 MHz, DMSO) δ 7.27 (brs, 1 H), 7.04 (s, 1 H), 6.72 (s, 1 H), 3.73 (s, 2 H), 3.64 (s, 3 H), 3.15 (s, 2 H), 3.04 (dd, $J = 6.8$, 5.2 Hz, 1 H), 2.47 (t, $J = 7.2$ Hz, 2 H), 1.65−1.46 (m, 2 H), 1.39 (s, 9 H), 1.30−1.21 (m, 4 H). MS (ESI): 355 $(M + H)^+$.

*(S)-2,2′-(5-Amino-5-carboxypentylazanediyl)diacetic Acid (**9**).* (*S*)-10-(2-*tert*-Butoxy-2-oxoethyl)-1-(9*H*-fluoren-9-yl)-14,14-dimethyl-3,12-dioxo-2,13-dioxa-4,10-diazapentadecane-5-carboxylic acid was prepared from a solution of Fmoc-Lys-OH (1.5 g, 4.0 mmol) and crude *tert*-butyl glyoxalate (3.6 g, 27.6 mmol) in DCE (50 mL), and the mixture was stirred at 75 °C for 30 min under nitrogen. The reaction mixture was cooled to 0 °C and treated with sodium triacetoxyborohydride (2.1 g, 10 mmol). The reaction mixture was stirred at room temperature for 3 h and decomposed with water. The reaction mixture was extracted with DCM. The organic layer was dried and concentrated under reduced pressure. The residue was purified by flash chromatography over silica gel to afford (*S*)-10-(2-*tert*-butoxy-2-oxoethyl)-1-(9*H*-fluoren-9-yl)-14,14-dimethyl-3,12-dioxo-2,13-dioxa-4,10-diazapentadecane-5-carboxylic acid (1.70 g, 3.51 mmol 71%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.76 (d, $J = 7.2$ Hz, 2 H), 7.60 (d, $J = 7.2$ Hz, 2 H), 7.40 (t, $J = 7.2$ Hz, 2 H), 7.30 (t, $J = 7.2$ Hz, 2 H), 6.63 (d, $J = 7.6$ Hz, 1 H), 4.40−4.34 (m, 3 H), 4.22 (t, $J = 7.2$ Hz, 1 H), 3.49 (s, 4 H), 2.83−2.64 (m, 4 H), 1.96−1.77 (m, 4 H), 1.40 (s, 18 H). MS (ESI): 598 $(M + H)^+$. The purified compound (12 mg, 0.21 mmol) was deprotected by treatment with piperidine/DMF 1:1 (1 mL), and the mixture was stirred at room temperature for 18 h. Following evaporation to a residue, aqueous extraction from DCM afforded the desired product **9** (3 mg, 0.11 mmol, 55% yield) as an off-white solid. ^{1}H NMR (400 MHz, DMSO-d_6) δ 7.9 (s, 2H), 3.5 (m, H), 3.3 (d, 2H), 2.4 (m, 2H), 1.8 (s, 2H), 1.45 (m, 2H), 1.15 (m, 2H). ESMS *m/z*: 263 $(M + H)^+$.

General Preparation of ^{99m}Tc Complexes and Peptides. The $^{99m}Tc(I)(CO)_3^+$ radiolabeling of the SAAC systems to form the metal complexes was accomplished on either the free α-amino acids or the α-*N*-Fmoc protected lysine derivative utilizing similar methodology. The radiolabeling was accomplished in two steps using commercially available IsoLink kits (Covidien) to form the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ intermediate, which was neutralized and reacted with the appropriate SAAC system (Figure 2) at 10^{-6}−10^{-4} M in an equal volume mixture of acetonitrile and water in a sealed vial. The sealed vial was heated at 100 °C for 30 min, and upon cooling, the mixture was analyzed for purity via reverse-phase HPLC. Purification by HPLC resulted in "carrier-free" products, and the RCP was determined via HPLC and shown to be consistently ≥95% pure. The radiolabeling can be achieved at concentrations as low as 10^{-6} M at 75 °C with RCY ≤ 80% and with RCY > 95% when conducted at 10^{-4} M at 75 °C.

The $^{99m}Tc(I)(CO)_3^+$ radiolabeling of the SAAC-conjugated peptides was achieved and purified in a similar manner with the exception of the heating temperature, which was reduced to 60 °C. The ^{111}In-DOTA-Tyr-3-octreotide was prepared from $^{111}InCl_3$ in an aqueous solution (10^{-4} M of the peptide) by heating at 100 °C for 30 min.

Determination of log *P* Values. The log *P* values of the $^{99m}Tc(I)$ complexes were determined using the following procedure: The ^{99m}Tc radiotracer was prepared and purified by reverse-phase HPLC. The collected mobile phase was evaporated and the residue dissolved in an equal volume mixture of *n*-octanol and 25 mM phosphate buffer (pH 7.4). The samples were extracted as follows: the samples were vortexed for 20 min and centrifuged at 8000 rpm for 5 min, and then aliquots were removed from both the aqueous phosphate buffer and the organic *n*-octanol layers and counted separately in a γ counter (LKB model 1282, Wallac Oy, Finland). The extraction was repeated twice for a total number of three extractions to ensure full extraction of all the organic components. The partition coefficients were then calculated using the equation $P =$ (activity concentration in *n*-octanol)/(activity concentration in aqueous layer). The samples were analyzed in triplicate and the log *P* values determined from the average of the three different measurements.

Rat Tissue Distribution of SAAC Complexes. Tissue distribution studies of the ^{99m}Tc SAAC systems were performed in separate groups of male Sprague−Dawley rats ($n = 5$/time point) administered as a bolus intravenous injection (approximately 10 μCi/rat) in a constant volume of 0.1 mL. Animals were euthanized by carbon dioxide at 5, 30, 60, and 120 min after injection. Blood, heart, lungs, liver, spleen, kidneys, adrenals, stomach (with contents), large and small intestines (with contents), testes, skeletal muscle, bone, brain, and adipose were excised, weighed wet, transferred to plastic tubes, and counted in an automated γ counter (LKB model 1282, Wallac Oy, Finland). Aliquots of the injected dose were also measured to convert the counts per minute in each tissue sample to percent-injected dose per organ. Tissue radioactivity levels, expressed as %ID/g, were determined by converting the decay corrected counts per minute to the percent dose and dividing by the weight of the tissue or organ sample.

Peptide Synthesis. Tyr-3-octreotide analogues {**4**-Tyr-3-octreotide} and {DpK-Tyr-3-octreotide} with the lysine SAAC incorporated at the amino terminus were synthesized by AnaSpec, Inc. (San Jose, CA) using solid phase peptide synthesis employing standard Fmoc coupling techniques with cleavage and deprotection using TFA. Following synthesis, all peptides were purified using reverse phase HPLC and were lyophilized with purity profiles of >90%.

Tumor Cell Lines. AR42J cells were obtained from American Type Culture Collection (Rockville, MD). The cells were grown in Kaighn's F-12 media supplemented with 20% fetal bovine serum, sodium pyruvate, and gentamicin in a humidified atmosphere of 5% CO_2/95% air at 37 °C.

Tissue Distribution in AR42J Bearing Mice. Uptake of radiolabeled peptides in rat tumor xenograft models were performed according to published methods. Briefly, AR42J cells were trypsinized, counted, and suspended in a solution containing 50% Dulbecco's PBS (D-PBS) (with 1 mg/mL D-glucose

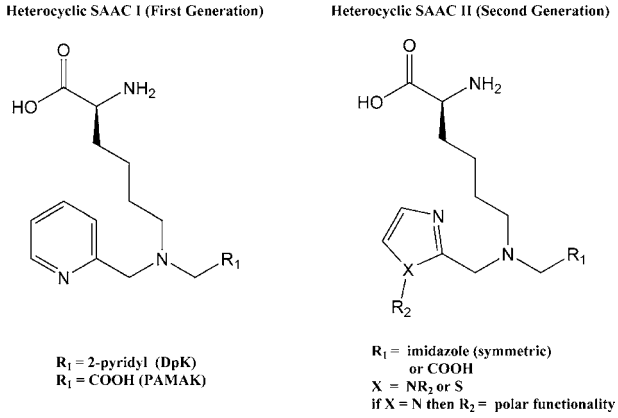

Figure 1. General structures of the first and second generation of heterocyclic SAAC systems.

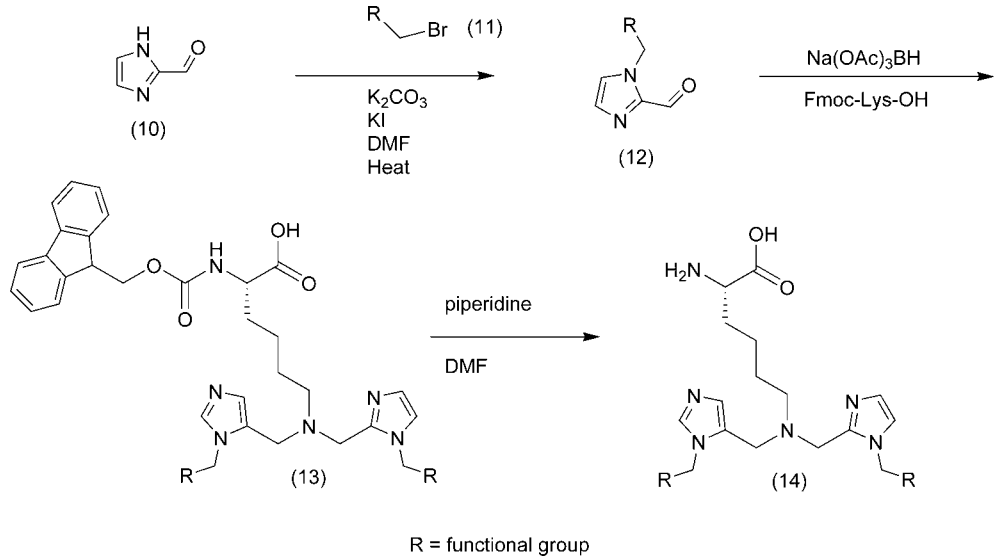
and 36 μg/mL sodium pyruvate) and 50% Matrigel (BD Biosciences, Franklin Lakes, NJ). Male NCr$^{nu/nu}$ mice were anesthetized by intraperitoneal injection of 0.5 mL of Avertin (20 mg/mL) (Sigma-Aldrich, St. Louis, MO) and then inoculated subcutaneously into the hind flank with 2×10^6 cells in a 0.25 mL suspension volume. Studies of tumor uptake were conducted when the tumors reached a size of 600−800 mm^3. Tissue biodistribution studies were conducted by administering, via the tail vein, a bolus injection of 2 μCi/mouse in a constant volume of 0.05 mL of D-PBS containing 1 mg/mL bovine serum albumin. Groups of five animals were euthanized by asphyxiation with carbon dioxide at 1 and 4 h after injection. All tissues from Figure 4, including the tumor, were excised, weighed wet, and transferred to plastic tubes, and radioactivity present was counted in an automated γ-counter (LKB model 1282, Wallac Oy, Finland). Tissue time − radioactivity levels were expressed as % injected dose per gram tissue (%ID/g).

RESULTS AND DISCUSSION

We previously described a technology known as SAAC, a radiolabeling platform that has broad utility in radiochemical, fluorescent, and dual modality (radio/fluorescent) molecular imaging (*6, 9*) and is particularly convenient for developing radiolabeled peptides. One limitation of the $Tc(CO)_3$-dipyridyl complex, characteristic of the original SAAC systems, is the extremely hydrophobic nature of the radiolabeled complexes which has often lead to the liver accumulation and/or hepatobiliary clearance of the bioconjugates. This undesirable pharmacokinetic profile is not unique to the original SAAC systems but a characteristic shared by many bioconjugates (*27, 28*). The goal of this work was to develop a second generation series of hydrophilic lysine-based SAAC systems that have been modified to favor renal clearance of the ^{99m}Tc-SAAC complexes and thus facilitate the development of novel ^{99m}Tc-labeled radiopharmaceuticals that clear the body more readily. This was accomplished, as shown in Figure 1, by modifying the lysine core of SAAC systems in two ways to create novel tridentate chelators with reduced lipophilicity: the addition of polar substituents and the reduction of the ligand size. The N-protected lysine building block of the SAAC systems was derivatized at the ε amine with substituted heterocyclic rings (R_1) that contained distinct polar functional groups (R_2) in an attempt to reduce the lipophilicity of the resulting ^{99m}Tc complexes. The ε amine of lysine allows for the facile synthesis of large numbers of structural variants of SAAC systems with the potential of diverse physiochemical properties. The chemical synthesis of the bifunctional SAAC systems was accomplished via reductive alkylation of *N*-Fmoc protected lysine with the appropriate heterocyclic aldehyde. The availability of a diverse set of heterocyclic aldehydes coupled with the ease of synthesis has led to the preparation of several classes of polar SAAC systems that form cationic ^{99m}Tc complexes with enhanced renal clearance. In addition, incorporation of one acetic acid "arm" onto the ε amine of lysine (R_1) in lieu of the second heterocyclic ligand affords SAAC systems of reduced size with a neutral metal center.

Ligand Design. As illustrated in Figure 1, both first generation (SAAC I) and second generation (SAAC II) SAAC systems were derived from the amino acid lysine. First generation ligands incorporated either two pyridine rings or a pyridine and an acetic acid for R_1. The design of the novel second generation bifunctional chelates explored the concept of increasing the water solubility of the chelate ring systems through the modification of heterocyclic imidazole ring substituents for R_2. The effort focused on the SAAC ligands that form cationic homogeneous tridentate metal complexes as well as the smaller heterogeneous monoacetic acid derivatized compounds which form neutral metal complexes.



Preparation of Homogeneous Tridentate Ligands as Second Generation Lysine Imidazole Derivatived SAAC Systems. The derivatized imidazole SAAC systems were prepared via the alkylation of the commercially available imidazole-2-carboxaldehyde (**10**) with the desired alkyl halide (**11**) to afford the N-substituted imidazole-2-carboxaldehyde analogues (**12**). Reductive amination of *N*-Fmoc lysine with sodium triacetoxyborohydride produces the *N*-Fmoc protected SAAC system (**13**) which following deprotection with piperidine affords the desired SAAC systems (**14**) in good yields as illustrated in Scheme 1.

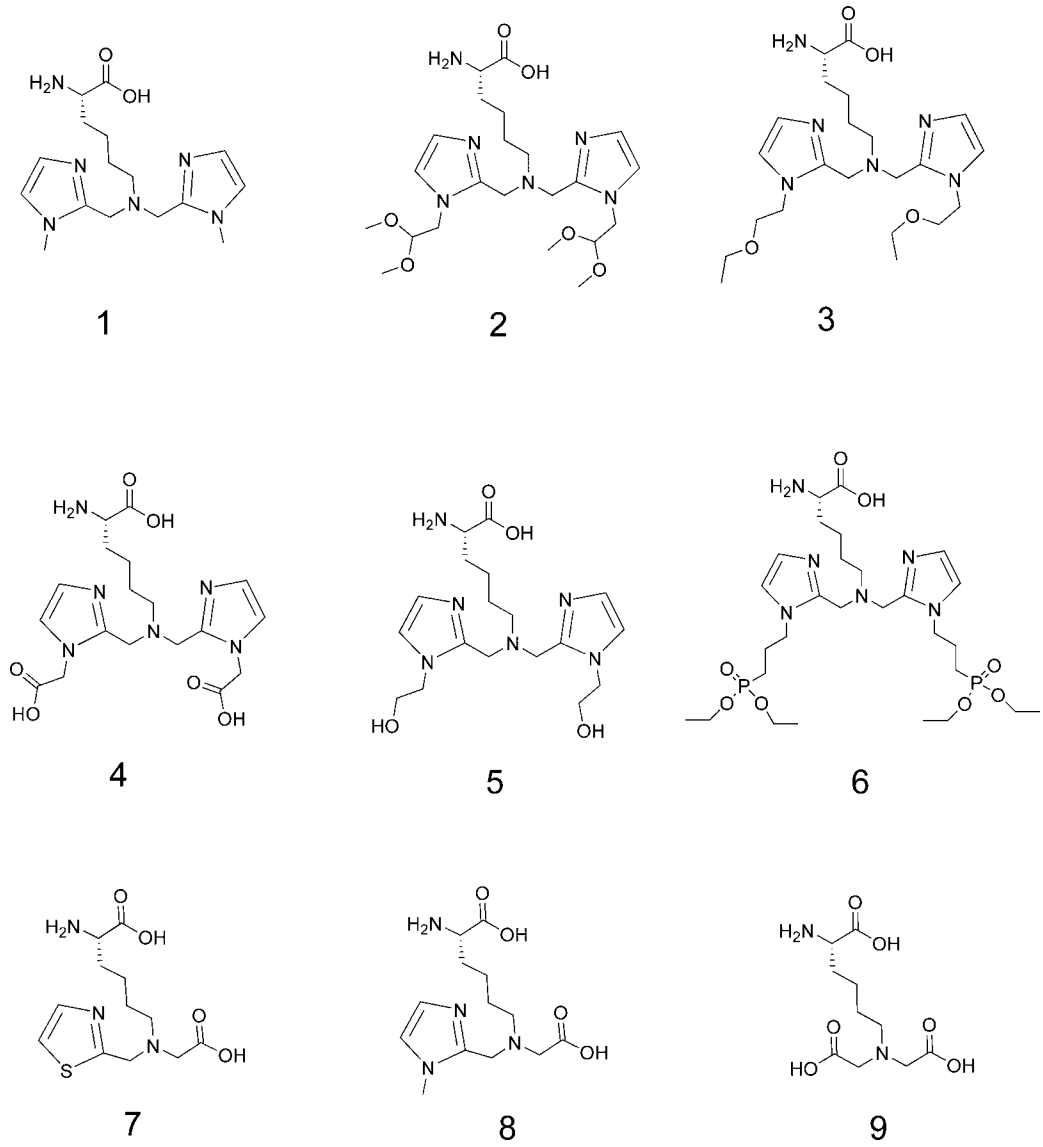
Preparation of Heterogeneous SAAC Systems: Monoacetic Acid Analogues. Several compounds from the homogeneous series described above which exhibited promising pharmacokinetic profiles were prepared as their corresponding monoacetic acid analogues, shown in Figure 2. These new heterogeneous ^{99m}Tc-SAAC complexes were smaller in size, were less hindered complexes, and were uncharged at the metal center, in contrast to the positive charged metal centers of the homogeneous complexes.

The compounds in this series were prepared using the double reductive alkylation sequence on Fmoc-lysine. Addition of the first aldehyde followed by reduction with sodium borohydride affords a monoalkylated intermediate as shown in Scheme 2. Subsequent treatment with *tert*-butyl glyoxalate followed by deprotections with piperidine and trifluoroacetic acid (TFA) afforded the desired series of heterogeneous neutral ligands (*26*).

Radiolabeling of ^{99m}Tc-SAAC. Radiolabeling of the SAAC systems was accomplished on either the free α-amino acids or as the appropriately N-protected amino acid derivative utilizing similar methodology to form ^{99m}Tc-**1**−**9**, demonstrating the flexibility of the radiolabeling and the ease of preparation of these novel SAAC metal complexes. The $^{99m}Tc(I)(CO)_3^+$ radiolabeling was accomplished in two steps using the commercially available IsoLink kits (Covidien) to form the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ intermediate, which was reacted with the appropriate SAAC ligand (ligand concentration of 10^{-6}−10^{-4} M) in an equal volume mixture of 1:1 acetonitrile and phosphate buffer. The sealed vial was heated at 100 °C for 30 min, and upon cooling, the mixture was analyzed for purity via HPLC. The RCP after HPLC purification resulted in "carrier-free" products, with purity determined via HPLC to be consistently ≥95%. While possible to radiolabel at concentrations as low as 10^{-6} M, the RCY at 75 °C was ≤80%. To achieve RCY > 95% at 75 °C, the ligand concentration needed to be increased to 10^{-4} M. This was true for all of the compounds with the exception of 2,2′-(5-amino-5-carboxypentylazanediyl)diacetic acid (**9**) which required 10^{-3} M ligand to achieve >95% RCY.

Scheme 1. Preparation of Homogeneous Bifunctional Imidazole SAAC Systems

SAAC systems 2,2′-(2,2′-(5-amino-5-carboxypentylazanediyl)-bis(methylene)-bis(1*H*-imidazole-2,1-diyl))diacetic acid (**4**) and 2-amino-6-(bis((1-(2-hydroxyethyl)-1*H*-imidazol-2-yl)methyl)-amino)hexanoic acid (**5**) could be radiolabeled with the ester



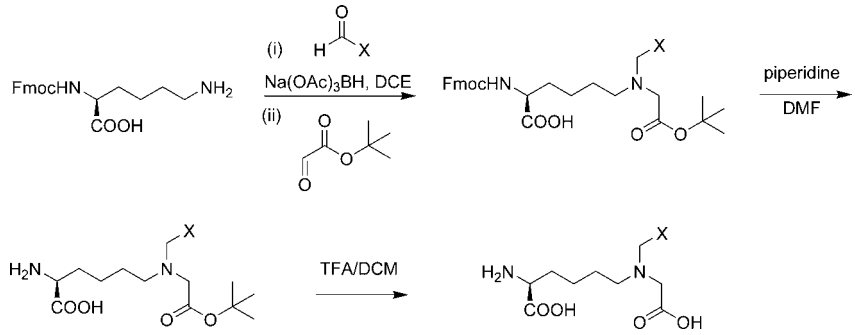


Figure 2. Structures of the novel lysine based SAAC systems.

Scheme 2. Preparation of the Heterogeneous SAAC Systems

protecting groups present on the bis-imidazole derivative or on the fully deprotected ligand. For example, the ^{99m}Tc complex of ligand **4** was prepared in 30 min followed by simple deprotection of the *tert*-butyl ester protecting groups using TFA at room temperature to produce ^{99m}Tc-**4**. The radiolabeling and subsequent deprotection could be followed by HPLC over time, as shown in Figure 3.

The ^{99m}Tc complex of 2-amino-6-(bis((1-(2-hydroxyethyl)-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid (**5**) could be prepared by radiolabeling 2-amino-6-(bis((1-(2-ethoxyethyl)-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid (**3**) followed by subsequent deprotection of the ethyl ethers using BBr_3 to afford the desired metal complex ^{99m}Tc-**5** (Scheme 3). Confirmation of the formation of the ^{99m}Tc-**5** complex was established by independent radiolabeling studies of the compounds **3** and **5** followed by the radiolabeling of **3** with conversion to the ^{99m}Tc-**5** complex.

Rat Tissue Distribution Studies of SAAC Complexes. Rat tissue distribution studies were performed with eight of the novel SAAC complexes, [^{99m}Tc(CO)$_3${η^3-((*S*)-2-amino-6-(bis((1-methyl-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid)}] (^{99m}Tc-**1**), [^{99m}Tc(CO)$_3${η^3-(2-amino-6-(bis((1-(2,2-dimethoxyethyl)-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid)}] (^{99m}Tc-**2**), [^{99m}Tc(CO)$_3${η^3-(2-amino-6-(bis((1-(2-ethoxyethyl)-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid)}] (^{99m}Tc-**3**), [^{99m}Tc(CO)$_3${η^3-(2,2′-(2,2′-(5-amino-5-carboxypentylazanediyl)bis(methylene)-bis(1*H*-imidazole-2,1-diyl))diacetic acid)}] (^{99m}Tc-**4**), [^{99m}Tc(CO)$_3${η^3-(2-amino-6-(bis((1-(2-hydroxyethyl)-1*H*-imidazol-

2-yl)methyl)amino)hexanoic acid)}] (^{99m}Tc-**5**), [^{99m}Tc(CO)$_3$-{η^3-((*S*)-2-amino-6-((carboxymethyl)(thiazol-2-ylmethyl)amino)-hexanoic acid (^{99m}Tc-**7**), [^{99m}Tc(CO)$_3${η^3-((*S*)-2-amino-6-((2-*tert*-butoxy-2-oxoethyl)((1-methyl-1*H*-imidazol-2-yl)methylamino)hexanoic acid (^{99m}Tc-**8**), and [^{99m}Tc(CO)$_3${η^3-(2,2′-(5-amino-5-carboxypentylazanediyl)diacetic acid)}] (^{99m}Tc-**9**). Only [^{99m}Tc(CO)$_3${η^3-(2-amino-6-(bis((1-(3-(diethoxyphosphoryl)propyl)-1*H*-imidazol-2-yl)methyl)amino)hexanoic acid)}] (^{99m}Tc-**6**) was omitted because of the high lipophilicity of the complex. In addition, for comparison, rat tissue distribution studies were performed with previously published SAAC systems (*6*), the cationic bis-pyridine complex [^{99m}Tc(CO)$_3$(η^3-{2-amino-6-(bis(pyridin-2-ylmethyl)amino)hexanoic acid}] [^{99m}Tc-DpK] and the neutral pyridine amine monoacetic acid complex [^{99m}Tc(CO)$_3$(η^3-{2-amino-6-((carboxymethyl)(pyridin-2-ylmethyl)amino)hexanoic acid} [^{99m}Tc-PAMAK]. A summary of the uptake of all of the SAAC complexes examined in selected organs is shown in Table 1.

^{99m}Tc-SAAC imidazole complexes **1**, **2**, **3**, and **5** exhibited rapid clearance from the blood (maximum of 0.14 %ID/g at 2 h for ^{99m}Tc-**5**), relatively low liver uptake (maximum of 1.61 ± 0.32 %ID/g at 5 min for ^{99m}Tc-**3**), and low liver retention (maximum of 0.74 ± 0.14 %ID/g at 2 h for ^{99m}Tc-**1**). In addition, these complexes exhibited a shift from hepatobiliary clearance to a predominantly renal uptake pattern compared to ^{99m}Tc-DpK and ^{99m}Tc-PAMAK. However, the high renal accumulation was in the absence of substantial renal clearance over the 2 h time period of the study. The four complexes displayed >12 %ID/g in the kidneys at the earliest (0.5 h) and latest (2 h) time points tested, demonstrating very little clearance over time. It is not clear whether the undesirable kidney retention was due to nonspecific binding of the complexes in the kidneys or a result of amino acid recycling. Since the goal is to develop chelators that exhibit rapid clearance from all nontarget tissues, the extended retention in the kidneys can be viewed as a significant liability for the complexes and may mitigate their potential application to biologically relevant molecules.

^{99m}Tc-SAAC complex **4**, which contains carboxylic acid functionalized imidazole rings, also exhibited very low liver and gastrointestinal accumulation (0.39 ± 0.07 and 1.22 ± 0.27 %ID/g at 2 h) and high kidney uptake that did not clear over the time course of the study (10.7 ± 2.3 and 10.2 ± 2.5 %ID/g at 0.5 and 2 h, respectively). This complex exhibited the least initial liver uptake (0.52 ± 0.07 %ID/g at 5 min) of any chelate tested. Interestingly, **4** cleared the blood more slowly than any of the chelators examined, potentially because of increased binding to blood proteins.

The complexes of compounds **7** and **8**, the monothiazole and monomethylimidazole analogues, exhibited high kidney uptake, 9.07 ± 0.66 and 17.05 ± 3.17 %ID/g at 0.5 h, respectively, and rapid clearance of 1.63 ± 0.51 and 3.94 ± 0.43 %ID/g at 2 h, respectively. However, these complexes also demonstrated increased accumulation in the gastrointestinal tract (GI) (>2 %ID/g at 2 h) over the 2 h study period. Interestingly, these neutral complexes are similar in nature to ^{99m}Tc-PAMAK, with one heterocyclic chelating moiety and one acetic acid chelating moiety, and displayed a similar clearance pattern to ^{99m}Tc-PAMAK as well.

^{99m}Tc-SAAC complex **9**, the diacetic acid derivative, exhibited high initial kidney uptake with rapid renal clearance (5.68 ± 1.99 and 1.09 ± 0.17 %ID/g at 0.5 and 2 h, respectively) and the least liver and GI accumulation of any of the chelators tested after the initial time point (0.18 ± 0.03 and 0.69 ± 0.19 %ID/g at 2 h, respectively). This complex exhibited an ideal pharmacokinetic clearance profile for development into radiopharmaceuticals; however, this chelator was not studied further because of lower RCY.

[a] Lipowska et al. (*20*).

It is clear that despite the rapid clearance from the blood of the first generation of SAAC complexes, ^{99m}Tc-DpK and ^{99m}Tc-PAMAK, a significant portion of their excretion was via the hepatobiliary route, hindering the potential application of these chelators in the development of radiopharmaceuticals. These limitations are realized in the development of cancer imaging agents where the ability to visualize metastatic lesions in the abdominal cavity with a DpK containing chelator is confounded by the high background signal present in the liver and GI. Through the preparation of a variety of novel polar and/or hydrophilic SAAC systems that are inherently less lipophilic, the pharmacokinetic profiles have been successfully altered to favor renal clearance.

Determination of Partition Coefficients (log *P*) as a Measure of Lipophilicity. The log *P* values (Table 2) of the complexes were determined using the HPLC purified ^{99m}Tc-SAAC complexes by the shake flask method utilizing *n*-octanol and 25 mM phosphate buffer (pH 7.4) as the solvents. NTA was tested as a control based on the published results that the ^{99m}Tc-NTA complex undergoes rapid and efficient renal clearance (*20*).

The lipophilicity of the complexes as measured by the octanol/phosphate buffer (pH 7.4) extinction coefficients followed the general trend of the rat tissue distribution pharmacokinetic profiles whereby the complexes with more negative log *P* values displayed a more desirable pharmacokinetic profile (high kidney/low hepatobiliary clearance). For example, **4** with log *P* of −2.33 cleared primarily by renal excretion, while **7** with a less negative log *P* of −1.75 cleared by combined renal and hepatobiliary routes. However, the correlation between the log *P* measurements and renal uptake and clearance of the radioactive complexes was not perfect because complexes like **3** with a log *P* of −1.10 still have high kidney uptake. Therefore, the log *P* values should only be considered as one of many physiochemical properties of the complexes that govern the in vivo distribution, uptake, metabolism, and excretion.

Incorporation of ^{99m}Tc-SAAC Complexes into Tyr-3-octreotide. One of the most important applications for the SAAC technology is the incorporation of the SAAC ligands directly into clinically relevant peptides. This is readily accomplished using standard solid phase peptide synthesis strategies (*8, 29*). To that end, we have incorporated two SAAC ligands, DpK and **4**, at the N-terminus of Tyr-3-octreotide, a somatostatin receptor 2 (SSTR2) selective peptide agonist. Following complexation with ^{99m}Tc, we evaluated the tissue distribution for comparison to ^{111}In-DOTA-Tyr-3-octreotide, a well established peptide based radiopharmaceutical for the detection of carcinoid and neuroendocrine tumors (*30*−*33*). The SAAC ligand, **4**, was selected for evaluation based on the favorable pharmacokinetic profile in rats demonstrating kidney uptake and GI/liver clearance of the ^{99m}Tc-SAAC complex, high RCY, and prolonged

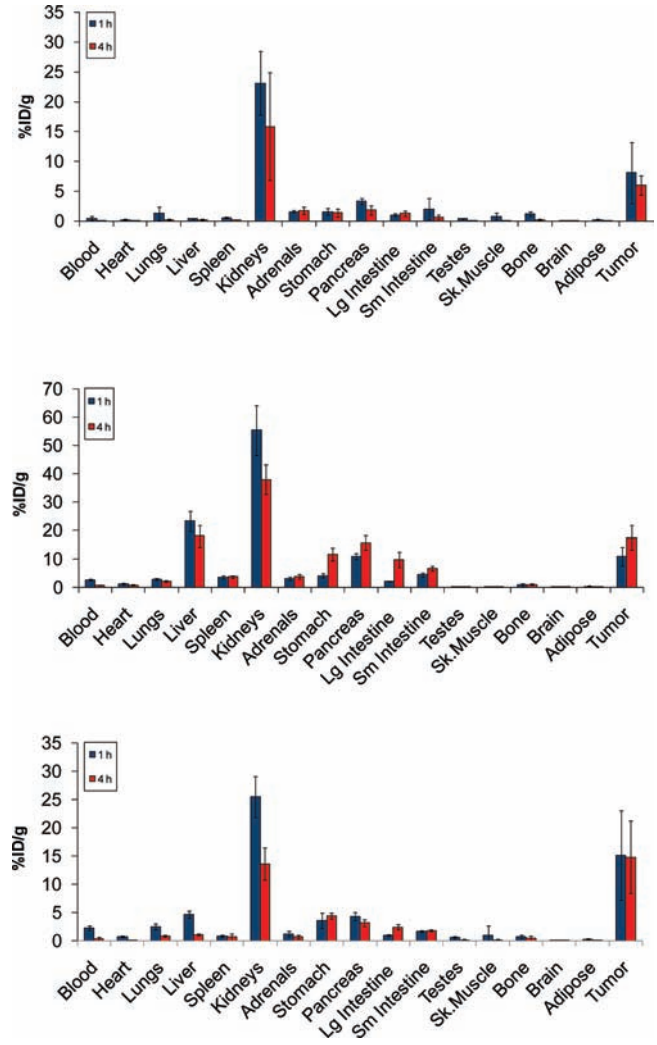

Figure 4. Tissue distribution of SSTR2 receptor mediated ^{111}In-DOTA-Tyr-3-octreotide (top) verses ^{99m}Tc-DpK-Tyr-3-octreotide (middle) and ^{99m}Tc-**4**-Tyr-3-octreotide (bottom) in AR42J mouse tumor model.

chemical stability. The incorporation of DpK was used for a direct comparison of a first generation SAAC with similar size. The results of the tissue distributions are shown in Figure 4. While both ^{99m}Tc-DpK-Tyr-3-octreotide and ^{111}In-DOTA-Tyr-3-octreotide demonstrate specific uptake and retention in target tissues, tumor and pancreas, the liver and GI uptake of ^{99m}Tc-DpK-Tyr-3-octreotide is significantly greater than that of ^{111}In-DOTA-Tyr-3-octreotide, thus highlighting the necessity of developing advanced SAAC ligands with a pharmacokinetic profile that favors renal clearance. In contrast, ^{99m}Tc-**4**-Tyr-3-octreotide exhibited a very similar tissue distribution to the ^{111}In-DOTA-Tyr-3-octreotide with high renal clearance and significantly reduced liver uptake of 4.63 ± 0.65 %ID/g at 1 h compared to 23.31 ± 3.5 %ID/g at 1 h for ^{99m}Tc-DpK-Tyr-3-octreotide ($p < 0.001$). Likewise, both the large and small intestines of the ^{99m}Tc-**4**-Tyr-3-octreotide showed reduced radioactivity at both time points examined compared to ^{99m}Tc-DpK-Tyr-3-octreotide. ^{99m}Tc-**4**-Tyr-3-octreotide also exhibited slightly higher tumor uptake at 1 h (15.15 ± 7.92 %ID/g) compared to the ^{111}In-DOTA-Tyr-3-octreotide (8.08 ± 5.17 %ID/g) and significantly higher tumor uptake at 4 h compared to ^{111}In-DOTA-Tyr-3-octreotide (14.85 ± 6.41 and 5.99 ± 1.65 %ID/g, respectively) ($p < 0.03$). The tumor-to-blood ratio of ^{99m}Tc-**4**-Tyr-3-octreotide was an encouraging 6.7:1 at 1 h and reached a maximum at 4 h with an impressive 35:1 ratio. Thus, the utility of this class of chelators is accentuated by the ability

to maintain high tumor uptake while driving preferential renal clearance of molecules, which would otherwise be dominated by hepatobiliary localization and excretion.

In summary, our ongoing research into the development of novel ^{99m}Tc chelators has led to significant improvements of a key characteristic of the already robust proprietary SAAC radiolabeling platform. The pharmacokinetic profile of the ^{99m}Tc-SAAC metal complex has been significantly altered through the design and synthesis of SAAC systems with the potential to enhance renal clearance and diminish hepatobiliary accumulation and/or clearance. The benefit of the second generation ^{99m}Tc-SAAC technology was realized upon incorporation of ^{99m}Tc-SAAC (**4**) into Tyr-3-octreotide, resulting in a significant decrease of the ^{99m}Tc-SAAC complex in nontarget and hepatobiliary tissues, thus affording the potential to design and develop a superior ^{99m}Tc-SAAC-Tyr-3-octreotide radioimaging agent with the potential to image cancer with improved whole body clearance. Future efforts will focus on applying the novel polar SAAC chelates to additional biologically relevant peptides and small molecules for the development of novel radiopharmaceuticals to image and potentially treat a variety of diseases.

Fluorescent Labeling of (Oligo)Nucleotides by a New Fluoride Cleavable Linker Capable of Versatile Attachment Modes

Diana C. Knapp, Jennifer D'Onofrio, and Joachim W. Engels*

Institut für Organische Chemie und Chemische Biologie, Johann Wolfgang Goethe Universität, Max-von-Laue Strasse 7, 60438 Frankfurt am Main, Germany. Received December 9, 2009; Revised Manuscript Received March 31, 2010

The development of a fluoride cleavable linker **1** for reversibly labeling (oligo)nucleotides is described here. The linker allows different ways of chemical attachment of a reporter molecule, for example, click chemistry or amide formation. The versatile attachment modes of labels are demonstrated by derivatizations with pyrene and fluorescein. Besides the synthesis of the new linker, we also show the derivatization of iodobenzene as a model compound and a nucleoside to demonstrate the applicability. Further, cleavability studies in solution and on a solid-supported oligonucleotide are shown. The linker can be applied in the synthesis of reversible terminators, useful for new DNA sequencing technologies like cyclic reversibly terminating (CRT) sequencing.

INTRODUCTION

The fluorescent labeling of nucleotides is an important tool in biochemistry (*1, 2*). So far a very important application of fluorescently labeled nucleotides is the Sanger DNA-sequencing method (*3*). Novel sequencing approaches (*4, 5*) for future demands on "individualized" diagnostic genome analysis also require reversibly labeled nucleotides. This creates a need for cleavable linkers to reversibly attach a dye to a nucleotide.

These new sequencing techniques include methods for whole genome sequencing (*6*−*8*), as well as for the detection of mutations (mainly SNPs) in minisequencing approaches (*9, 10*). One of these new approaches is the array-based cyclic reversibly terminating (CRT) sequencing (*7, 11*). This technique does not need traditional gel electrophoretic separation but affords direct readout of the sequence by fluorescence detection. The labeled nucleotides are added sequentially to oligonucleotide templates that are immobilized on an array platform, thus sequencing can be performed in a highly parallel fashion. CRT sequencing is based on the use of so-called "reversible terminators" to achieve the defined sequential addition of one base after the other. The structural requirements for these reversible terminators include a reversibly terminating moiety at the 3′-position and a reporter molecule (i.e., a fluorescent dye) reversibly attached via a cleavable linker.

During development of such reversible terminators, one issue is to find a 3′-modification that meets the following demands: reliable termination of the polymerase reaction, quantitative and fast cleavage under reasonable conditions, and acceptance by a DNA polymerase. In a recent publication, we presented the fluoride cleavable 2-cyanoethyl (CE)[1] group as a very promising candidate for a 3′-reversibly terminating group (*12*). The next step is to develop a suitable cleavable linker to connect the nucleotides to the reporter moiety (fluorescent dye). This linker should be efficiently cleavable under the same conditions as the 3′-blocking group to allow the regeneration of the 3′-OH group and the removal of the linker−dye system in a single deprotection step. The dye will be attached to the base moiety of the nucleosides because Sanger sequencing has already demonstrated that modifications at the 7-position of purines and the 5-position of pyrimidines are well tolerated by DNA polymerases.

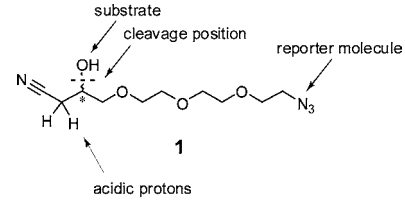

Figure 1. Core structure **1** of the new cleavable linker.

In this publication, we present the design, the synthesis, and the evaluation of a new fluoride cleavable linker for reversible labeling of (oligo)nucleotides. In Figure 1, the core structure **1** of the new linker is displayed.

The linker design was derived from the well-known acidity of protons vicinal to a nitrile function. This motif also plays a key role in the cleavage of other fluoride cleavable protecting groups that are not based on silicon, like the above-mentioned CE (*12, 13*), the 1-(2-cyanoethoxy)methyl (*14*), and the l-(2-cyanoethoxy)ethyl (*15*) protecting groups.

The connection of the substrate (nucleotide) is planned at the secondary alcohol function via a prop-2-ynylcarbamate moiety. The azide group at the end of the triglycol spacer then serves as a juncture for reporter molecules. These molecules can either be attached by click reactions to the existing azide moiety or via amide or carbamate bonds after reduction of the azide to the amine.

First the synthesis of the linker will be shown. For the evaluation of the cleavage properties, a simple model compound **9** was synthesized where the nucleotide moiety is replaced by a phenyl moiety. After defining the cleavage conditions of the model compound a 5-,3′-modified 2′-deoxyuridine derivative **17** was synthesized, bearing the 3′-*O*-(2-cyanoethyl) (CE) group and the cleavable linker at position 5 of the base moiety. Finally

the optimized cleavage conditions were applied to a CPG-bound 8-mer bearing the fluorescently labeled and 3′-*O*-modified 2′-deoxyuridine at the 3′-end.

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents were of the highest commercially available quality and were used as received. Benzoyl chloride and acrylonitrile were distilled before use. Oligonucleotide synthesis was accomplished using an Expedite nucleic acid synthesis system from PerSeptive Biosystems. The 5′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite-3′-(4,4′-dimethoxytrityl)-2′-deoxyribonucleosides building blocks were purchased from Pharmacia; the solid support (dT5′-CPG) was purchased from Glen Research. NMR spectra were recorded on Bruker AM, DPX, and AV instruments at 250, 300, and 400 MHz and 300 K. Chemical shifts (δ) are reported in ppm relative to the solvent signal. The fine structure of proton signals was specified with s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), dd (doublet of doublet), br (broad), and in quotations for pseudo-fine structure. Assignments were made by DEPT, COSY, HSQC, and HMBC experiments. Thin layer chromatograms (TLC) were recorded on Polygram Sil G/UV_{254} by Macherey Nagel & Co., Dueren (thickness of layer 0.2 mm) or 60 F_{254} by Merck KGaA, Darmstadt (thickness of layer 0.2 mm). Flash column chromatography was carried out on silica gel 60 (15−40 μm) by Merck KGaA, Darmstadt at a pressure of 2−3 bar. Reversed phase (RP) HPLC was performed on a Jasco LC-2000Plus HPLC system equipped with a Jasco UV 2075Plus detector (detection at 254 nm) and a Phenomenex Jupiter 4u Proteo 90A 4 μm column (250 mm × 4.6 mm). One molar triethylammonium acetate (TEAA) buffer, pH = 6.5, (A)/water (B)/acetonitrile (C) were used as eluents. Ion-exchange HPLC was performed on a Jasco LC-900 HPLC system equipped with a Jasco UV-970 detector (detection at 254 nm) and a Dionex BioLC DNAPac PA-100 column (250 mm × 9 mm) using water/0.25 M tris(hydroxymethyl)aminomethane hydrochloride (Tris-Cl) buffer, pH = 8/1 M sodium chloride solution as eluent. ESI mass spectrometry was performed on a Fisons instrument equipped with a VG platform II with quadrupole analyzer. MALDI mass spectrometry was performed on a VG TOFSpec from Fisons using 2,5-dihydroxybenzoic acid as matrix for single molecules and 6-aza-2-thiothymin as matrix for oligonucleotides. Fluorescence spectroscopy was performed on a Hitachi F4500 fluorescence spectrometer using 0.3 cm cuvettes. Elemental analyses were recorded on a Foss-Heraeus CHN-O Rapid instrument. The numbering of the atoms in the nucleoside parts is according to the common numbering convention of nucleosides.

2-{2-[2-(2-Azidoethoxy)ethoxy]ethoxymethyl}oxirane, 4. To a suspension of 151 mg of sodium hydride (6.28 mmol, 1.1 equiv) in 6 mL of dry THF, 1 g of compound **3** (5.7 mmol, 1.0 equiv) was added dropwise, and the resulting mixture was stirred for 2 h at room temperature. (±)-Epichlorohydrin (2.3 mL, 28.54 mmol, 5.0 equiv) was added dropwise, and the resulting mixture was stirred for 16 h at room temperature. The reaction mixture then was neutralized with 30% methanolic H_2SO_4 and poured into 40 mL of saturated NaCl solution. The aqueous layer was extracted two times with 30 mL of ethyl acetate and two times with 30 mL of methylene chloride. The combined organic layers were dried over Na_2SO_4 and concentrated under reduced pressure. The resulting oily residue was purified by flash column chromatography using a gradient from *n*-hexane/ether = 1:2 + 1% NH_3 to *n*-hexane/ether = 1:5 + 1% NH_3. Title compound **2** was obtained as colorless oil (884 mg, 67%). R_F = 0.13 (*n*-hexane/ether = 1:2 + 1% NH_3). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.540 (1H, dd, J = 2.7 and 5.1 Hz, CH_2 oxirane ring), 2.724 (1H, dd, J = 4.2 and 5.1 Hz, CH_2 oxirane ring), 3.07−3.11 (1H, m, C*H* oxirane ring), 3.268 (2H, dd, J = 6.4 and 11.6 Hz, CH_2 adjacent oxirane), 3.395 (2H, "t", N_3−CH_2), 3.52−3.63 (10H, m, 5 × CH_2 glycol), 3.714 (1H, dd, J = 2.8 and 11.6 Hz, CH_2 adjacent oxirane) ppm. ^{13}C-NMR (100 MHz, DMSO-d_6, 300 K): δ = 43.39 (*C*H_2 oxirane ring), 50.03 (N_3-*C*H_2), 50.29 (*C*H oxirane ring), 69.27, 69.72, 69.82, 69.84, 69.97 (5 × *C*H_2 glycol), 71.53 (*C*H_2 adjacent oxirane) ppm. FT-IR (NaCl): ν = 3050 (m, epoxide C−H), 2900 (s, >CH_2), 2120 (s, −N_3) cm^{-1}. ESI(+)-MS (*m/z*) Calcd: 231.2 [$C_9H_{17}N_3O_4$]. Found: 254.0 [M + Na]$^+$, 249.0 [M + H_2O]$^+$, 232.0 [M]$^+$. Anal. ($C_9H_{17}N_3O_4$) C, H, N.

4-{2-[2-(2-Azidoethoxy)ethoxy]ethoxy}-3-hydroxybutyronitrile, 1. To a solution of 500 mg of compound **4** (2.16 mmol, 1.0 equiv) in 2 mL of ethanol, 10 mL of water was added. After stirring for 5 min, 153 mg of sodium cyanide (3.03 mmol, 1.4 equiv) was added, and stirring was continued for 16 h at room temperature. The reaction mixture was then concentrated to about half the volume under reduced pressure, extracted two times with 20 mL of ethyl acetate and one time with 20 mL of methylene chloride, dried over Na_2SO_4 and concentrated. The oily residue was purified by flash-column-chromatography using CH_2Cl_2/MeOH = 97:3 as eluent. The desired compound **1** was obtained as colorless oil (498 mg, 89%). R_F = 0.37 (CH_2Cl_2/MeOH = 95:5). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.532 (1H, dd, J = 6.7 and 16.9 Hz, NC−CH_2), 2.655 (1H, dd, J = 4.4 and 16.8 Hz, NC−CH_2), 3.321 (1H, dd, J = 6.2 and 10.0 Hz, NC−CH_2−CH−CH_2), 3.382 (2H, "t", N_3−CH_2), 3.404 (1H, dd, J = 5.3 and 10.0 Hz, NC−CH_2−CH−CH_2), 3.52−3.62 (10H, m, 5 × CH_2 glycol), 3.872 (1H, m, NC−CH_2−C*H*), 5.455 (1H, d, J = 5.2 Hz, O*H*) ppm. ^{13}C-NMR (100 MHz, DMSO-d_6, 300 K): δ = 22.52 (NC-*C*H_2), 49.99 (N_3-*C*H_2), 65.24 (NC−CH_2-*C*H), 69.27, 69.70, 69.71, 69.83, 70.14 (5 × *C*H_2 glycol), 73.37 (NC−CH_2−CH-*C*H_2), 118.86 (N*C*) ppm. (2-{2-[2-(3-Cyano-2-hydroxypropoxy)ethoxy]ethoxy}ethyl)-carbamic Acid *tert*-Butyl Ester, 5. Compound **1** (5 g, 19.36 mmol, 1.0 equiv) was dissolved in dry dioxane, 10.47 g of triphenylphosphine (38.72 mmol, 2.0 equiv) was added, and the mixture was stirred at room temperature. After 8 h, TLC control indicated complete consumption of the starting material, and 100 mL of 25% aqueous ammonia was added. The reaction was left at room temperature for 12 h and subsequently dried in vacuum. The residue was dissolved in 100 mL of methylene chloride and extracted three times with 25 mL of 1 M HCl solution. The water phase was neutralized with solid $NaHCO_3$, and 40 mL of dioxane and another 2.4 g of $NaHCO_3$ (29.00 mmol, 1.5 equiv) were added. The mixture was cooled to 0 °C, and 8.7 g of Boc_2O (38.72 mmol, 2.00 equiv) was added in portions over 20 min. The reaction mixture was allowed to warm to room temperature and stirred for 10 h. After concentration in vacuum, the residue was divided between 100 mL of water and 100 mL of ethyl acetate. The aqueous layer was extracted two times with 70 mL of ethyl acetate. The combined organic layers were dried over Na_2SO_4, and the solvent was removed under reduced pressure. The oily residue was purified by flash column chromatography using CH_2Cl_2/MeOH = 99:1 + 1% $EtMe_2N$ as eluent. Compound **5** was obtained as a slightly yellow oil (6.45 g, 100%). R_F = 0.51 (CH_2Cl_2/MeOH/NH_3 = 90:10:1). ^{1}H NMR (300 MHz, DMSO-d_6, 300 K): δ = 1.368 (9H, s, 3 × CH_3), 2.518 (1H, dd, J = 6.6 and 18.6 Hz, NC−CH_2), 2.645 (1H, dd, J = 4.4 and 16.8 Hz, CN−CH_2), 3.058 (2H, q, J = 5.9 Hz, NH−CH_2), 3.27−3.45 (4H, m, NC−CH_2−CH−CH_2, NH−CH_2−CH_2), 3.48−3.56 (8H, m, 4 × CH_2 glycol), 3.864 (1H, m, NC−CH_2−C*H*), 5.443 (1H, d, J

= 5.2 Hz, O*H*), 6.703 (1H, m, N*H*) ppm. ^{13}C NMR (75 MHz, DMSO-d_6, 300 K): δ = 22.47 (NC−*C*H$_2$), 28.19 (3 × *C*H$_3$), 39.69 (NH−*C*H$_2$), 65.25 (NC−CH$_2$−*C*H), 69.18 (NH−CH−*C*H$_2$), 69.50, 69.67, 69.75, 70.14 (4 × *C*H$_2$ glycol), 73.37 (NC−CH$_2$−CH−*C*H$_2$), 77.56 ((CH$_3$)$_3$*C*), 118.71 (N*C*), 155.54 (*C*O) ppm. 3-Hydroxy-4-(2-{2-[2-(4-phenyl-1,2,3-triazol-1-yl)ethoxy]ethoxy}ethoxy)butyronitrile, 6. Linker **1** (500 mg, 1.94 mmol, 1.0 equiv) was dissolved in 10 mL of methylene chloride and 5 mL of methanol. To the resulting solution, first 31 mg of $CuSO_4$ (0.19 mmol, 0.1 equiv) and then 775 mg of sodium ascorbate (3.87 mmol, 2 equiv) were added, followed by the addition of 1.5 equiv of phenylacetylene (329 mg, 2.90 mmol). The mixture was stirred at room temperature. After 18 h, another 0.5 equiv of phenylacetylene (110 mg, 0.97 mmol) was added, and the mixture was stirred at room temperature for additional 24 h. The reaction mixture then was concentrated under reduced pressure, and the residue was dissolved again in 50 mL of methylene chloride. The solution of the crude product was washed two times with 25 mL of 5% EDTA solution. The organic layer was dried over Na_2SO_4, and the solvent was evaporated in vacuum. The crude product was purified by flash column chromatography (CH_2Cl_2/MeOH = 98:2 to CH_2Cl_2/MeOH = 95:5), yielding 670 mg (96%) of the product **6** as colorless oil. R_F = 0.40 (CH_2Cl_2/MeOH = 90:10). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.498 (1H, dd, J = 7.0 and 16.9 Hz, NC−C*H*$_2$), 2.619 (1H, dd, J = 4.3 and 16.9 Hz, NC−C*H*$_2$), 3.271 (1H, dd, J = 6.2 and 9.8 Hz, NC−CH$_2$−CH−C*H*$_2$), 3.371 (1H, dd, J = 5.5 and 9.8 Hz, NC−CH$_2$−CH−C*H*$_2$), 3.46−3.58 (8H, m, 4 × C*H*$_2$ glycol), 3.79−3.90 (3H, m, NC−CH$_2$−C*H*, triazole−CH$_2$−C*H*$_2$), 4.571 (2H, t, J = 5.1 Hz, triazole−C*H*$_2$), 5.449 (1H, d, J = 5.1 Hz, O*H*), 7.30−7.36 (1H, m, phenyl C*H*$_p$), 7.42−7.49 (2H, m, 2 × phenyl C*H*$_m$), 7.81−7.87 (2H, m, 2 × phenyl C*H*$_o$), 8.522 (1H, s, triazole C*H*) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): δ = 22.47 (NC−*C*H$_2$), 49.58 (triazole−*C*H$_2$), 65.19 (NC−CH$_2$−*C*H), 68.64 (triazole-CH$_2$−*C*H$_2$), 69.61, 70.07 (4 × *C*H$_2$ glycol), 73.33 (NC−CH$_2$−CH−*C*H$_2$), 118.79 (N*C*), 121.71 (triazole *C*H), 125.07 (2 × phenyl *C*H$_o$), 127.76 (phenyl *C*H$_p$), 128.86 (2 × phenyl *C*H$_m$), 130.82 (triazole quaternary *C*), 146.16 (phenyl quaternary *C*) ppm. 3-Hydroxy-4-(2-{2-[2-(4-pyren-1-yl-1,2,3-triazol-1-yl)ethoxy]ethoxy}ethoxy)butyronitrile, 7. *Method a.* Linker **1** (110 mg, 0.43 mmol, 1.0 equiv) was dissolved in 2 mL of methylene chloride and 1 mL of methanol. To the resulting solution, first 7 mg of $CuSO_4$ (0.04 mmol, 0.1 equiv) and then 170 mg of sodium ascorbate (0.85 mmol, 2 equiv) were added. In a separate flask, 146 mg of 1-ethynylpyrene (0.64 mmol, 1.5 equiv) was dissolved in 4 mL of methylene chloride and 2 mL of methanol. The pyrene solution was added to the linker solution via a syringe, and the resulting mixture was stirred for 20 h at room temperature. Because the reaction seemed to be quite slow, it was heated to 40 °C for another 24 h. Afterward the solvents were removed under reduced pressure, and the residue was dissolved in 20 mL of methylene chloride. The solution of the crude product was washed two times with 10 mL of 5% EDTA solution. The organic layer was dried over Na_2SO_4, and the solvent was evaporated in vacuum. The crude product was purified by flash column chromatography (CH_2Cl_2/MeOH = 99:1 to CH_2Cl_2/MeOH = 98:2), yielding 85 mg (41%) of the product **7** as a yellow oil.

Method b. Linker **1** (100 mg, 0.38 mmol, 1.0 equiv), DIPEA (130 μL, 0.77 mmol, 2.0 equiv), and CuI (7.2 mg, 0.038 mmol, 0.1 equiv) were mixed and irradiated for 30 min at 250 W in the microwave. Afterward, the residue was dissolved in methylene chloride and washed two times with 10 mL of 5% EDTA solution. The organic layer was dried over Na_2SO_4, and the solvent was evaporated in vacuum. The crude product was purified by flash column chromatography (CH_2Cl_2/MeOH = 99:1 to CH_2Cl_2/MeOH = 98:2), yielding 110 mg (60%) of the product **7** as yellow oil. R_F = 0.22 (CH_2Cl_2/MeOH = 95:5). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.459 (1H, dd, J = 6.7 and 16.8 Hz, NC−C*H*$_2$), 2.575 (1H, dd, J = 4.3 and 16.9 Hz, NC−C*H*$_2$), 3.226 (1H, dd, J = 6.3 and 10.1 Hz, NC−CH$_2$−CH−C*H*$_2$), 3.30−3.35 (1H, m, NC−CH$_2$−CH−C*H*$_2$), 3.45−3.66 (8H, m, 4 × C*H*$_2$ glycol), 3.807 ("sextet", NC−CH$_2$−C*H*), 3.992 (2H, t, J = 4.9 Hz, triazole−CH$_2$−C*H*$_2$), 4.728 (2H, t, J = 5.1 Hz, triazole−C*H*$_2$), 5.437 (1H, d, J = 5.4 Hz, O*H*), 8.115 (1H, t, J = 7.9 Hz, pyrene C*H*), 8.20−8.45 (7H, m, 7 × pyrene C*H*), 8.742 (1H, s, triazole C*H*), 8.884 (1H, d, J = 9.5 Hz, pyrene C*H*) ppm. ^{13}C-NMR (100 MHz, DMSO-d_6, 300 K): δ = 22.43 (NC−*C*H$_2$), 49.67 (triazole−*C*H$_2$), 65.17 (NC−CH$_2$−*C*H), 68.68 (triazole−CH$_2$−*C*H$_2$), 69.63, 69.64, 69.68, 70.06 (4 × *C*H$_2$ glycol), 73.32 (NC−CH$_2$−CH−*C*H$_2$), 118.77 (N*C*), 124.83, 124.87 (triazole *C*H, pyrene *C*H), 125.12, 125.15, 125.52, 126.46, 126.98, 127.33 127.64, 127.96 (8 × pyrene *C*H), 123.93, 1242.31, 125.46, 127.46, 130.36, 130.52, 130.94, 145.98 (triazole quaternary *C*, 7 × pyrene quaternary *C*) ppm. ESI(+)-MS (*m/z*) Calcd: 484.5 [$C_{28}H_{28}N_4O_4$]. Found: 485.5 [M + H]$^+$, 507.6 [M + Na]$^+$. HR-ESI(−)-MS (*m/z*) Calcd: 483.2038 [$C_{28}H_{27}N_4O_4$]$^-$. Found: 483.2043. Carbonic Acid 1-{2-[2-(2-Azidoethoxy)ethoxy]ethoxymethyl}-2-cyanoethylester 2,5-dioxo-pyrrolidin-1-yl ester, 10. Compound **1** (750 mg, 2.90 mmol, 1.0 equiv) was dissolved in 25 mL of dry ACN and cooled to 0 °C. Then 223 mg of anhydrous K_2CO_3 (1.60 mmol, 0.55 equiv) was added, and the suspension was stirred at 0 °C for 1 h before 1.96 g of di(*N*-succinimidyl)-carbonate (7.26 mmol, 2.5 equiv) was added and the mixture was stirred for another 20 h at 0 °C. The solvent was removed in vacuum, and the residue was divided between 50 mL of ethyl acetate and 50 mL of saturated $NaHCO_3$ solution. The water phase was additionally extracted with 50 mL of ethyl acetate and 50 mL of methylene chloride. The combined organic layers were dried over Na_2SO_4 and concentrated under reduced pressure. The crude product was obtained as yellow oil **10** (1.15 g, 99%) and used without further purification. R_F = 0.35 (CH_2Cl_2/MeOH = 99:1). ^{1}H NMR (400 MHz, $CDCl_3$, 300 K): δ = 2.853 (4H, s, 2 × succinimidyl C*H*$_2$), 2.902 (1H, dd, J = 5.4 and 17.1 Hz, NC−C*H*$_2$), 2.968 (1H, dd, J = 6.0 and 17.0 Hz, NC−C*H*$_2$), 3.38−3.42 (2H, m, N$_3$−C*H*$_2$), 3.65−3.74 (10H, m, 5 × C*H*$_2$ glycol), 3.805 (1H, dd, J = 5.3 and 11.0 Hz, NC−CH$_2$−CH−CH$_2$−O), 3.851 (1H, dd, J = 4.7 and 11.0 Hz, NC−CH$_2$−CH−CH$_2$−O), 5.100 (1H, "quintet", NC−CH$_2$−C*H*) ppm. ^{13}C-NMR (100 MHz, DMSO-d_6, 300 K): δ = 19.77 (NC−*C*H$_2$), 25.50 (succinimidyl *C*H$_2$), 50.74 (N$_3$−*C*H$_2$), 69.36, 70.09, 70.62, 70.73, 70.74, 71.35 (NC−CH$_2$−CH−*C*H$_2$, 5 × *C*H$_2$ glycol), 74.91 (NC−CH$_2$−*C*H), 115.23 (N*C*), 150.86 (carbonate *C*O), 168.28 (succinimidyl *C*O) ppm. ESI(+)-MS (*m/z*) Calcd: 399.4 [$C_{15}H_{21}N_5O_8$]. Found: 417.00 [M + NH$_4$]$^+$, 422.00 [M + Na]$^+$, 372.00 [M − N$_2$+H]$^+$.

Carbonic Acid 1-{2-[2-(2-*tert*-Butoxycarbonylaminoethoxy)-ethoxy]ethoxymethyl}-2-cyano-ethylester 2,5-Dioxopyrrolidin-1-yl Ester, 11. Alcohol **5** (5.27 g, 15.86 mmol, 1.0 equiv) was dissolved in 150 mL of dry ACN and cooled to 0 °C. Anhydrous K_2CO_3 (1.11 g, 7.93 mmol, 0.5 equiv) was added, and the mixture was left at 0 °C for 2 h. Then 10.69 g of di(*N*-succinimidyl)carbonate (39.64 mmol, 2.5 equiv) was added, and stirring at 0 °C was continued for 24 h. The solvent was

evaporated, and the residue was divided between 75 mL of water and 75 mL of ethyl acetate. The aqueous layer was extracted two times with 50 mL of methylene chloride. The combined organic layers were dried over Na_2SO_4 and concentrated under reduced pressure. To the solid residue, first 30 mL of methylene chloride was added and the insoluble parts were filtered off, followed by the addition of 60 mL of ether. The resulting suspension was stored at 4 °C for 2 h and filtered again. The filtrate was concentrated in vacuum to give 6.73 g (90%) of the activated linker **11** as yellow oil. It was used as obtained, without further purification. $R_F = 0.03$ (CH_2Cl_2/MeOH/NH_3 = 90:10:1). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 1.372 (9H, s, 3 × CH_3), 2.817 (4H, s, 2 × succinimidyl CH_2), 3.01−3.11 (4H, m, NC−CH_2, NH−CH_2), 3.374 (2H, t, J = 6.1 Hz, NH−CH_2−CH_2), 3.47−3.61 (8H, m, 4 × CH_2 glycol), 3.654 (1H, dd, J = 6.4 and 11.7 Hz, NC−CH$_2$−CH−CH_2), 3.701 (1H, dd, J = 3.8 and 11.6 Hz, NC−CH$_2$−CH−CH_2), 5.16−5.23 (1H, m, NC−CH$_2$−CH), 6.68−6.77 (1H, m, NH) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): δ = 19.12 (NC−CH$_2$), 25.34 (succinimidyl CH$_2$), 28.19 (3 × CH$_3$), 39.65 (NH−CH$_2$), 69.21 (NH−CH$_2$−CH$_2$), 69.45, 69.57, 69.68, 69.74, 70.27 (5 × CH$_2$ glycol), 75.57 (NC−CH$_2$−CH), 77.55 ((CH$_3$)$_3C$), 116.79 (NC), 150.63 (carbonate CO), 155.54 (carbamate CO), 169.61 (succinimidyl CO) ppm. ESI(+)-MS (*m/z*) Calcd: 473.5 [$C_{20}H_{31}N_3O_{10}$]. Found: 491.0 [M + NH_4]$^+$, 496.2 [M + Na]$^+$, 474.1 [M]$^+$.

Prop-2-ynylcarbamic Acid 1-{2-[2-(2-Azidoethoxy)ethoxy]-ethoxymethyl}-2-cyanoethyl Ester, 8. Compound **1** (130 mg, 0.5 mmol, 1.0 equiv) was dissolved in 10 mL of dry ACN, and the solution was cooled to 0 °C before 70 mg of anhydrous K_2CO_3 (0.5 mmol, 1.0 equiv) was added and the suspension was stirred at 0 °C for 2 h. Afterward 190 mg of di(*N*-succinimidyl)carbonate (0.7 mmol, 1.4 equiv) was added together with another 5 mL of dry ACN. The suspension was stirred at 0 °C for 20 h. After the activation process, 100 mg of $NaHCO_3$ (1.0 mmol, 2.0 equiv) and 72 μL of propargylamine (1.1 mmol, 2.2 equiv) were added. The mixture was stirred at 0 °C for 1 h and at room temperature for 2 h. The solvent was removed under reduced pressure, and the residue was divided between 20 mL of saturated $NaHCO_3$ solution and 20 mL of methylene chloride. The organic layer was washed with 20 mL of saturated $NaHCO_3$ solution and 20 mL of saturated NH_4Cl solution. The combined aqueous layers were extracted two times with 20 mL of methylene chloride, and the combined organic layers were then dried over Na_2SO_4. The solvent was removed under reduced pressure, and the crude product was purified by flash column chromatography (*n*-hexane + 1% $EtMe_2N$ to *n*-hexane/ethyl acetate = 1:1 + 1% $EtMe_2N$). Compound **8** was obtained as slightly yellowish oil (129 mg, 76%). $R_F = 0.27$ (*n*-hexane/ethyl acetate = 1:2). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.832 (1H, dd, J = 6.3 and 17.2 Hz, NC−CH_2), 2.900 (1H, dd, J = 4.8 and 17.2 Hz, NC−CH_2), 3.120 (1H, t, J = 2.4 Hz, alkyne CH), 3.390 (2H, t, J = 5.2 Hz, N$_3$−CH_2), 3.50−3.62 (12H, m, NC−CH$_2$−CH−CH_2, 5 × CH_2 glycol), 3.782 (2H, dd, J = 2.4 and 5.8 Hz, NH−CH_2), 4.947 (1H, "quintet", NC−CH$_2$−CH), 7.891 (1H, t, J = 5.7 Hz, NH) ppm. ^{13}C-NMR (100 MHz, DMSO-d_6, 300 K): δ = 19.72 (NC−CH$_2$), 29.82 (NH−CH$_2$), 50.00 (N$_3$−CH$_2$), 67.89 (NC−CH$_2$−CH), 69.26, 69.67, 69.69, 69.83, 70.20, 70.32 (NC−CH$_2$−CH−CH$_2$, 5 × CH$_2$ glycol), 73.17 (alkyne CCH), 81.08 (alkyne CCH), 117.70 (NC), 154.88 (carbamate CO) ppm. (3-Phenylprop-2-ynyl)carbamic Acid 1-{2-[2-(2-Azidoethoxy-ethoxy]ethoxymethyl}-2-cyanoethyl Ester, 9. Iodobenzene (300 mg, 1.44 mmol, 1.00 equiv) was dissolved in 7 mL of dry methylene chloride and degassed three times using the freeze−pump−thaw technique. Then 28 mg of CuI (0.14 mmol, 0.10 equiv) and 84 mg of $Pd(PPh_3)_4$ (0.07 mmol, 0.05 equiv) were added to the shaded flask. The alkyne **8** (572 mg, 11.69 mmol, 1.17 equiv) was added dropwise in two portions; one-half was added immediately and the other half after 1 h stirring at room temperature. After another 2 h stirring at room temperature, the reaction mixture was diluted by adding 20 mL of methylene chloride and washed two times with 50 mL of 5% EDTA solution and one time with 50 mL of saturated $NaHCO_3$ solution. The organic layer was dried over Na_2SO_4, filtered and the solvent was removed in vacuum. The crude product was purified by flash column chromatography (*n*-hexane + 1% $EtMe_2N$ to *n*-hexane/ethyl acetate = 1:1 + 1% $EtMe_2N$). Compound **9** was obtained as yellow oil (549 mg, 92%). R_F = 0.18 (*n*-hexane/ethyl acetate/$EtMe_2N$ = 1:1:0.02). ^{1}H NMR (300 MHz, DMSO-d_6, 300 K): δ = 2.80−2.96 (2H, m, NC−CH_2), 3.379 (2H, "t", N$_3$−CH_2), 3.51−3.62 (12H, m, NC−CH$_2$−CH−CH_2, 5 × CH_2 glycol), 4.064 (2H, d, J = 5.8 Hz, NH−CH_2), 4.988 (1H, "quintet", NC−CH$_2$−CH), 7.34−7.44 (5H, m, 5 × phenyl CH), 7.964 (1H, t, J = 5.7 Hz, NH) ppm. ^{13}C NMR (75 MHz, DMSO-d_6, 300 K): δ = 19.70 (NC−CH$_2$), 30.57 (NH−CH$_2$), 49.98 (N$_3$−CH$_2$), 67.88 (NC−CH$_2$−CH), 69.21, 69.65, 69.66, 69.79, 70.19, 70.33 (NC−CH$_2$−CH−CH$_2$, 5 × CH$_2$ glycol), 81.79 (alkyne CC−CH$_2$), 86.89 (alkyne CC−CH$_2$), 117.70 (NC), 122.22 (phenyl quaternary C), 128.47, 128.57, 131.28 (5 × phenyl CH), 154.90 (carbamate CO) ppm. ***N*^{3}-Benzoyl-5-iodo-5′-*O*-benzoyl-2′-deoxyuridine, 15.** To a solution of 1.5 g of compound **14** (3.27 mmol, 1.0 equiv) in 15 mL of dry pyridine were added dropwise 1.68 mL of DIPEA (9.82 mmol, 3.0 equiv) and 0.63 mL of TMSCl (4.91 mmol,

1.5 equiv). The reaction mixture was stirred 45 min at room temperature before 0.84 mL of benzoyl chloride (4.91 mmol, 1.5 equiv) was added. The red solution was stirred for another 15 min at room temperature and then poured into 100 mL of ice water and stirred for 10 min, and the organic layer was extracted two times with 40 mL of chloroform, dried over Na_2SO_4, and evaporated to dryness. The crude brown oil was dissolved in 60 mL of $CHCl_3$/MeOH = 1:1, and 75 μL portions of TFA were added every 20 min until the TMS group was cleaved quantitatively (TLC control). TFA (375 μL, 4.89 mmol, 1.5 equiv) was added within 2 h. The reaction mixture was diluted with 30 mL of chloroform and washed two times with 50 mL of 5% $NaHCO_3$ solution. The water phase was extracted three times with 30 mL of chloroform; the combined organic layers were dried over Na_2SO_4 and concentrated in vacuum. The crude product was filtered through silica gel and eluted with a gradient from pure CH_2Cl_2 to CH_2Cl_2/MeOH = 95:5. The product **15** was obtained as yellow foam (1.85 g, 98%). R_F = 0.43 (CH_2Cl_2/MeOH = 95:5). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.271 (1H, ddd, J = 3.7, 6.5, and 13.9 Hz, 2′-CH_2), 2.39−2.47 (1H, m, 2′-CH_2), 4.14−4.18 (1H, m, 4′-C*H*), 4.37−4.42 (1H, m, 3′-C*H*), 4.493 (1H, dd, J = 5.8 and 12.1 Hz, 5′-CH_2), 4.558 (1H, dd, J = 3.6 and 12.1 Hz, 5′-CH_2), 5.487 (1H, d, J = 4.4 Hz, 3′-O*H*), 6.114 (1H, t, J = 6.5 Hz, 1′-C*H*), 7.54−7.62 (4H, m, 2 × 5′-*O*-benzoyl CH_m, 2 × N^3-benzoyl CH_m), 7.67−7.72 (1H, m, N^3-benzoyl CH_p), 7.77−7.81 (1H, m, 5′-*O*-benzoyl CH_p), 8.01−8.05 (4H, m, 2 × 5′-*O*-benzoyl CH_o, 2 × N^3-benzoyl CH_o), 8.202 (1H, s, 6-C*H*) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): δ = 39.36 (2′-*C*H$_2$), 64.31 (5′-*C*H$_2$), 68.54 (5-*C*I), 70.04 (3′-*C*H), 84.43 (4′-*C*H), 86.06 (1′-*C*H), 128.88, 129.26, 129.45, 130.56 (5′-*O*-benzoyl *C*H$_o$, 5′-*O*-benzoyl *C*H$_m$, N^3-benzoyl *C*H$_o$, N^3-benzoyl *C*H$_m$), 130.64 (5′-*O*-benzoyl quaternary *C*, N^3-benzoyl quaternary *C*), 133.53 (N^3-benzoyl *C*H$_p$), 135.65 (5′-*O*-benzoyl *C*H$_p$), 145.28 (6-*C*H), 148.66 (2-*C*O), 159.18 (4-*C*O), 165.61 (N^3-benzoyl *C*O), 168.67 (5′-*O*-benzoyl *C*O) ppm. 5-Iodo-3′-*O*-(2-cyanoethyl)-2′-deoxyuridine, 16. Compound **15** (1.70 g, 3.02 mmol, 1.0 equiv) was dissolved in 4.5 mL of freshly distilled acrylonitrile (68.02 mmol, 22.5 equiv) in a dry 100 mL Erlenmeyer flask, equipped with a big triangle stirring bar and a septum connected to an argon line. The solution was stirred vigorously for 2 min before 9 mL of *t*-BuOH was added, and stirring continued for another 5 min; 990 mg of Cs_2CO_3 (3.02 mmol, 1.0 equiv) was added quickly, and the resulting suspension was stirred vigorously for 2.5 h. The reaction solution was separated from solid components by filtration over silica gel (CH_2Cl_2/MeOH = 95:5) and concentrated in vacuum. Because the purification of compound **16** is difficult because of loss of protecting groups on the column, only a small amount was purified by flash column chromatography for analysis of the fully protected compound N^3-benzoyl-5-iodo-3′-*O*-(2-cyanoethyl)-5′-*O*-benzoyl-2′-deoxyuridine (CH_2Cl_2/MeOH = 99.6:0.4 to CH_2Cl_2/MeOH = 99:1). The rest of the crude product (1.78 g) was directly used for the subsequent deprotection with ammonia. R_F = 0.27 (*n*-hexane/ethyl acetate/$EtMe_2N$ = 1:2:0.03). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): δ = 2.428 (1H, ddd, J = 2.6, 6.1, and 14.0 Hz, 2′-CH_2), 2.47−2.55 (1H, m, 2′-CH_2), 2.793 (2H, t, J = 6.0 Hz, NC−CH_2), 3.695 (2H, t, J = 6.0 Hz, NC−CH$_2$−CH_2), 4.33−4.38 (2H, m, 3′-C*H*, 4′-C*H*), 4.518 (1H, dd, J = 5.2 and 12.0 Hz, 5′-CH_2), 4.578 (1H, dd, J = 3.6 and 12.0 Hz, 5′-CH_2), 6.090 (1H, t, J = 6.8 Hz, 1′-C*H*), 7.54−7.62 (4H, m, 2 × 5′-*O*-benzoyl CH_m, 2 × N^3-benzoyl CH_m), 7.67−7.72 (1H, m, N^3-benzoyl CH_p), 7.76−7.82 (1H, m, 5′-*O*-benzoyl CH_p), 8.01−8.05 (4H, m, 2 × 5′-*O*-benzoyl CH_o, 2 × N^3-benzoyl CH_o), 8.219 (1H, s, 6-C*H*) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): δ = 18.19 (NC−*C*H$_2$), 36.66 (2′-*C*H$_2$), 63.77 (NC−CH$_2$−*C*H$_2$), 64.45 (5′-*C*H$_2$), 68.69 (5-*C*I), 78.68 (3′-*C*H), 81.97 (4′-*C*H), 86.13 (1′-*C*H), 119.56 (N*C*), 128.88, 129.28, 129.45, 130.56 (5′-*O*-benzoyl *C*H$_o$, 5′-*O*-benzoyl *C*H$_m$, N^3-benzoyl *C*H$_o$, N^3-benzoyl *C*H$_m$), 130.62 (5′-*O*-benzoyl quaternary *C*, N^3-benzoyl quaternary *C*), 133.56 (N^3-benzoyl *C*H$_p$), 135.67 (5′-*O*-benzoyl *C*H$_p$), 145.22 (6-*C*H), 148.66 (2-*C*O), 159.15 (4-*C*O), 165.56 (N^3-benzoyl *C*O), 168.61 (5′-*O*-benzoyl *C*O) ppm. 5-(3-Aminoprop-1-ynyl)-3′-*O*-(2-cyanoethyl)-2′-deoxyuridine, 17. Compound **16** (500 mg, 1.23 mmol, 1.0 equiv) was dissolved in 15 mL of dry DMF, and 855 μL of triethylamine (6.14 mmol, 5.0 equiv) was added. The solution was degassed three times by using the freeze−pump−thaw technique. After the solution warmed up, 48 mg of CuI (0.25 mmol, 0.2 equiv) and 143 mg of $Pd(PPh_3)_4$ (0.12 mmol, 0.1 equiv) were added. 2,2,2-Trifluor-*N*-(prop-2-ynyl)acetamid (371 mg, 2.46 mmol, 2.0 equiv) was added in two portions; one-half was injected directly, and the other half was added after stirring at room temperature for 1 h. The resulting mixture was stirred at room temperature in a shaded flask. After 5 h, the solvent was removed under reduced pressure, and the residue was dissolved in 25 mL of methylene chloride and washed two times with 25 mL of 5% EDTA solution. The organic layer was dried over Na_2SO_4 and filtered, and the solvent was removed in vacuum. The crude product, 5-[(2,2,2-trifluoro-acetylamino)-ethynyl]-3′-*O*-(2-cyanoethyl)2′-deoxyuridine, was filtered over silica gel (CH_2Cl_2/MeOH = 98:2), and 344 mg (65%) of the target compound was obtained as a yellow oil. R_F = 0.21 (CH_2Cl_2/MeOH = 90:10). ^{1}H NMR (250 MHz, DMSO-d_6, 300 K): δ = 2.15−2.34 (2H, m, 2′-CH_2), 2.777 (2H, t, J = 5.9 Hz, NC−CH_2), 3.52−3.68 (2H, m, 5′-CH_2), 3.632 (2H, t, J = 6.0 Hz, NC−CH$_2$−CH_2), 3.91−3.99 (1H, m, 4′-C*H*), 4.11−4.17 (1H, m, 3′-C*H*), 4.234 (1H, d, J = 5.5 Hz, NH−CH_2), 5.177 (1H, t, J = 5.0 Hz, 5′-O*H*), 6.068 (1H, t, J = 6.5 Hz, 1′-C*H*), 8.182 (1H, s, 6-C*H*), 10.067 (1H, t, J = 5.3 Hz, N*H*), 11.676 (1H, s, N^3*H*) ppm. ^{13}C NMR (63 MHz, DMSO-d_6, 300 K): δ = 18.22 (NC−*C*H$_2$), 29.42 (NH−*C*H$_2$), 36.93 (2′-*C*H$_2$), 61.08 (5′-*C*H$_2$), 63.54 (NC−CH$_2$−*C*H$_2$), 75.29 (alkyne *C*C−CH$_2$), 79.01 (3′-*C*H), 84.70 (1′-*C*H), 84.90 (4′-*C*H), 87.53 (alkyne C*C*−CH$_2$), 97.80 (5-C), 119.13 (N*C*), 144.00 (6-*C*H), 149.27 (2-*C*O), 161.47 (4-*C*O) ppm, the trifluoroacetate signals are not visible due to their low intensity (quartet structure). ESI(+)-MS (*m*/*z*) Calcd: 430.3 [$C_{17}H_{17}F_3N_4O_6$]. Found: 430.9 [M + H]$^+$.

5-[(2,2,2-Trifluoroacetylamino)ethynyl]-3′-*O*-(2-cyanoethyl)2′-*d*eoxyuridine (300 mg, 0.70 mmol, 1.0 equiv) was dissolved in 40 mL of methanol, and 8.5 mL of concentrated (25%) aqueous ammonia solution was added. The resulting mixture was stirred at room temperature for 12 h. Then the solvent was removed under reduced pressure, and 230 mg (99%) of compound **17** was obtained. The crude product was used without further purification. $R_F = 0.03$ (CH_2Cl_2/MeOH = 90:10). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): $\delta = 2.15-2.24$ (1H, m, 2′-CH_2), 2.278 (1H, ddd, $J = 2.7$, 8.7, and 13.6 Hz, 2′-CH_2), 2.776 (2H, t, $J = 5.8$ Hz, NC−CH_2), 3.547 (2H, s, NH_2−CH_2), 3.59−3.66 (4H, m, 5′-CH_2, NC−CH_2−CH_2), 3.94−3.99 (1H, m, 4′-CH), 4.13−4.18 (1H, m, 3′-CH), 5.04−6.50 (4H, br. s, 5′-OH, N^3H, NH_2), 6.079 (1H, dd, $J = 6.3$ and 7.5 Hz, 1′-CH), 8.153 (1H, s, 6-CH) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): $\delta =$ 18.22 (NC−*C*H_2), 30.63 (NH_2−*C*H_2), 37.02 (2′-*C*H_2), 61.13 (5′-*C*H_2), 63.52 (NC−CH_2−*C*H_2), 74.76 (alkyne *C*C−CH_2), 79.10 (3′-*C*H), 84.66 (1′-*C*H), 84.89 (4′-*C*H), 92.88 (alkyne C*C*−CH_2), 98.29 (5-C), 119.15 (N*C*), 143.43 (6-*C*H), 149.39 (2-*C*O), 161.50 (4-*C*O) ppm. 5-(Prop-2-ynyl)carbamic Acid 1-{2-[2-(2-Azidoethoxy)-ethoxy]ethoxymethyl}-2-cyanoethyl ester]-3′-*O*-(2-cyanoethyl)-2′-desoxyuridine, 18. Activated linker **10** (806 mg, 2.02 mmol, 2.5 equiv) was dissolved in 4.5 mL of dry ACN and cooled to 0 °C. After cooling, 162 mg of $KHCO_3$ (1.62 mmol, 2.0 equiv) was added. In a separate flask, 270 mg of compound **17** (0.81 mmol, 1.0 equiv) was dissolved in another 4 mL of dry ACN and added via a syringe dropwise to the solution of compound **10**. The resulting mixture was stirred at 0 °C for 30 min and at room temperature for 3.5 h. The solvent then was removed under reduced pressure, and the residue was divided between 25 mL of saturated NH_4Cl solution and 25 mL of methylene chloride. The organic layer was washed with 20 mL of saturated NaCl solution, and the combined aqueous layers were extracted two times with 30 mL of methylene chloride. The combined organic layers were dried over Na_2SO_4 and filtered, and the solvent was removed in vacuum. The crude product **18** was purified by flash column chromatography using a gradient from CH_2Cl_2/MeOH = 98:2 to CH_2Cl_2/MeOH = 95:5, yielding 328 mg (66%) of compound **18** as a yellow oil. $R_F = 0.39$ (CH_2Cl_2/MeOH = 90:10). ^{1}H NMR (400 MHz, DMSO-d_6, 300 K): $\delta = 2.17-2.31$ (2H, m, 2′-CH_2), 2.773 (2H, t, $J = 6.1$ Hz, nucleoside NC−CH_2), 2.839 (1H, dd, $J = 6.3$ and 17.3 Hz, linker NC−CH_2), 2.878 (1H, dd, $J = 5.0$ and 17.2 Hz, linker NC−CH_2), 3.387 (2H, t, $J = 5.0$ Hz, N_3−CH_2), 3.51−3.65 (16 H, m, 5′-CH_2, nucleoside NC−CH_2−CH_2, linker NC−CH_2−CH−CH_2, 5 × CH_2 glycol), 3.93−3.97 (1H, m, 4′-CH), 4.022 (2H, d, $J = 5.6$ Hz, NH−CH_2), 4.12−4.16 (1H, m, 3′-CH), 4.954 (1H, "quintet", linker NC−CH_2−CH), 5.169 (1H, t, $J = 5.0$ Hz, 5′-OH), 6.071 (1H, "t", 1′-CH), 7.934 (1H, t, $J = 5.5$ Hz, NH), 8.139 (1H, s, 6-CH), 11.642 (1H, s, N^3H) ppm. ^{13}C NMR (100 MHz, DMSO-d_6, 300 K): $\delta = 18.25$ (nucleoside NC−*C*H_2), 19.73 (linker NC−*C*H_2), 30.69 (NH−*C*H_2), 36.90 (2′-*C*H_2), 50.00 (N_3-*C*H_2), 61.14 (5′-*C*H_2), 63.55 (nucleoside NC−CH_2−*C*H_2), 67.91 (linker NC−CH_2−*C*H), 69.25, 69.66, 69.68, 69.82, 70.21 (5 × *C*H_2 glycol), 70.30 (linker NC−CH_2−CH−*C*H_2), 74.49 (alkyne *C*C−CH_2), 79.09 (3′-*C*H), 84.62 (1′-*C*H), 84.88 (4′-*C*H), 89.61 (alkyne C*C*−CH_2), 98.23 (5-C), 117.71 (linker N*C*), 119.17 (nucleoside N*C*), 143.60 (6-*C*H), 149.42 (2-*C*O), 154.88 (carbamate *C*O), 161.53 (4-*C*O) ppm. FT-IR (NaCl): $\nu = 3650-3120$ (m br., −O−H, >N−H), 3056 (m br., C−H arom.), 2874 (m br., >CH_2), 2252 (m, −C≡N, −C≡C−), 2103 (s, $-N_3$), 1780−1630 (m br., −C═O) cm^{-1}. ESI(+)-MS (*m*/*z*) Calcd: 618.6 [$C_{26}H_{34}N_8O_{10}$]. Found: 636.4 [M + NH_4]$^+$, 641.5 [M + Na]$^+$, 619.5 [M]$^+$. Anal. ($C_{26}H_{34}N_8O_{10}$) C, H, N.

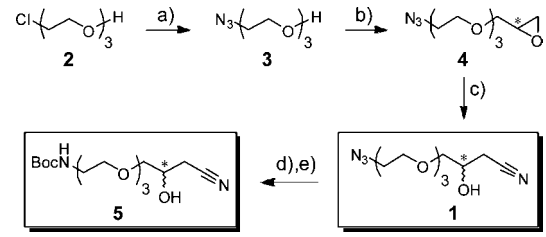
5-(Prop-2-ynyl)carbamic Acid 1-{2-[2-(2-*tert*-Butoxycarbo-nylaminoethoxy)ethoxy]ethoxymethyl}-2-cyanoethyl Ester 3′-*O*-(2-Cyanoethyl)-2′-desoxyuridine, 19. Activated linker **11** (2.24 g, 4.74 mmol, 2.2 equiv) was dissolved in 15 mL of dry ACN and cooled to 0 °C. After cooling, 433 mg of $KHCO_3$ (4.31 mmol, 2.0 equiv) was added. In a separate flask, 1.0 g of compound **17** (2.15 mmol, 1.0 equiv) was dissolved in another 10 mL of dry ACN and added via a syringe dropwise to the solution of compound **11**. The resulting mixture was stirred at 0 °C for 1 h and at room temperature for 3.5 h. The solvent then was removed under reduced pressure, and the residue was divided between 75 mL of water and 100 mL of methylene chloride. The aqueous layer was extracted two times with 75 mL of methylene chloride. The combined organic layers were dried over Na_2SO_4 and filtered, and the solvent was removed in vacuum. The crude product **19** was purified by flash column chromatography using a gradient from CH_2Cl_2/MeOH = 99:1 to CH_2Cl_2/MeOH = 90:10, yielding 1.15 g (77%) of compound **19** as colorless foam. $R_F = 0.34$ (CH_2Cl_2/MeOH = 90:10). ^{1}H NMR (300 MHz, DMSO-d_6, 300 K): $\delta = 1.370$ (9H, s, 3 × CH_3), 2.16−2.31 (2H, m, 2′-CH_2), 2.774 (2H, t, $J = 5.9$ Hz, nucleoside NC−CH_2), 2.876 (2H, m, linker NC−CH_2), 3.055 (2H, q, $J = 6.0$ Hz, Boc-NH−CH_2), 3.370 (2H, t, $J = 6.1$ Hz, Boc-NH−CH_2−CH_2), 3.48−3.65 (14H, m, 5′-CH_2, nucleoside NC−CH_2−CH_2, linker NC−CH_2−CH−CH_2, 4 × CH_2 glycol), 3.93−3.97 (1H, m, 4′-CH), 4.022 (2H, d, $J = 5.9$ Hz, NH−CH_2), 4.138 (1H, quintet, $J = 2.7$ Hz, 3′-CH), 4.953 (1H, quintet, $J = 5.5$ Hz, linker NC−CH_2−CH), 5.13−5.19 (1H, m, 5′-OH), 6.071 (1H, t, $J = 7.3$ Hz, 1′-CH), 6.68−6.77 (1H, m, N^{Boc}H), 7.933 (1H, t, J = 5.7 Hz, NH), 8.137 (1H, s, 6-CH), 11.643 (1H, s, N^3H) ppm. ^{13}C NMR (75 MHz, DMSO-d_6, 300 K): $\delta = 18.23$ (nucleoside NC−*C*H_2), 19.72 (linker NC−*C*H_2), 28.21 (3 × *C*H_3), 30.68 (NH−*C*H_2), 36.90 (2′-*C*H_2), 39.69 (Boc-NH−*C*H_2), 61.14 (5′-*C*H_2), 63.56 (nucleoside NC−CH_2−*C*H_2), 67.91 (linker NC−CH_2−*C*H), 69.17 (Boc-NH−CH_2−*C*H_2), 69.49, 69.60, 69.73, 70.21, 70.30 (linker NC−CH_2−CH−*C*H_2, 4 × CH_2 glycol), 74.49 (alkyne *C*C−CH_2), 77.58 ((CH_3)$_3$*C*), 79.08 (3′-*C*H), 84.64 (1′-*C*H), 84.89 (4′-*C*H), 89.57 (alkyne C*C*−CH_2), 98.23 (5-C), 117.64 (linker N*C*), 119.26 (nucleoside N*C*), 143.40 (2-*C*O), 143.56 (6-*C*H), 154.84 (carbamate *C*O), 155.54 (Boc *C*O), 161.49 (4-*C*O) ppm. ESI(+)-MS (*m*/*z*) Calcd: 692.7 [$C_{31}H_{44}N_6O_{12}$]. Found: 710.5 [M + NH_4]$^+$, 715.4 [M + Na]$^+$. Anal. ($C_{31}H_{44}N_6O_{12}$) C, H, N.



5-(Prop-2-ynyl)carbamic Acid 1-{2-[2-(2-Aminoethoxy)-ethoxy]ethoxymethyl}-2-cyanoethyl Ester 3′-*O*-(2-Cyanoethyl)-2′-deoxyuridine 5′-Phosphoramidite, 21. The well-dried nucleoside **19** (vacuum over 2 days) (200 mg, 0.29 mmol, 1.0 equiv) was dissolved in 5 mL of dry methylene chloride, 138 μL (0.44 mmol, 1.5 equiv) of *N*,*N*,*N*,*N*-tetraisopropyl-*O*-cyanoethyl-phosphoramidite and 40 mg (0.33 mmol, 1.15 equiv) of 4,5-dicyanoimidazole were added, and the reaction mixture was stirred at room temperature for 4 h. The mixture was diluted with methylene chloride to a volume of 25 mL and poured into 25 mL of saturated $NaHCO_3$ solution. After careful mixing, the phases were separated immediately, and the organic layer was washed quickly with saturated NaCl solution, dried over sodium sulfate for 5 min without stirring, filtered, and concentrated in vacuum. The crude product was purified over a short column by flash column chromatography (first CH_2Cl_2/EE/$EtMe_2N$ = 8:2:0.2 then CH_2Cl_2/MeOH/$EtMe_2N$ = 98:2:0.02). The phosphoramidite **21** was obtained as a slightly yellowish foam (260 mg, 100%). The two steroisomers caused by the chiral phosphorus atom (**21a** and **21b**) can be distinguished in the NMR spectra. $R_F = 0.17$ (CH_2Cl_2/MeOH/$EtMe_2N$ = 9:1:0.1). ^{1}H NMR (400 MHz, acetone-d_6, 300 K): $\delta = 1.24-1.31$ (24H, m, N−(CH−(CH_3)$_2$)$_{2,a}$, N−(CH−(CH_3)$_2$)$_{2,b}$), 1.45 (18H, s, Boc-C(CH_3)$_{3,a}$, Boc-C(CH_3)$_{3,b}$), 2.26−2.41 (2H, m, 2′-C$H_{2,a}$, 2′-

$CH_{2,b}$), 2.47−2.57 (2H, m, 2′-$CH_{2,a}$, 2′-$CH_{2,b}$), 2.82 (4H, t, J = 6.2 Hz, nucleoside NC−$CH_{2,a}$, nucleoside NC−$CH_{2,b}$), 2.85−2.99 (8H, m, linker NC−$CH_{2,a}$, linker NC−$CH_{2,b}$, phosphorus NC−$CH_{2,a}$, phosphorus NC−$CH_{2,b}$), 3.26 (4H, q, J = 5.7 Hz, Boc-NH−$CH_{2,a}$, Boc-NH−$CH_{2,b}$), 3.54 (4H, "t", Boc-NH−CH_2−$CH_{2,a}$, Boc-NH−CH_2−$CH_{2,b}$), 3.61−3.80 (24H, m, linker NC−CH_2−CH−$CH_{2,a}$, linker NC−CH_2−CH−$CH_{2,b}$, 4 × $CH_{2,a}$ glycol, 4 × $CH_{2,b}$ glycol, N-(CH)$_{2,a}$, N-(CH)$_{2,b}$), 3.82−3.88 (4H, m, nucleoside NC−CH_2−$CH_{2,a}$, nucleoside NC−CH_2−$CH_{2,b}$), 3.91−4.05 (8H, m, 5′-$CH_{2,a}$, 5′-$CH_{2,b}$, phosphorous NC−CH_2−$CH_{2,a}$, phosphorous NC−CH_2−$CH_{2,b}$), 4.17−4.24 (4H, m, NH−$CH_{2,a}$, NH−$CH_{2,b}$), 4.28/4.31 (each 1H, each "q", 4′-CH_a, 4′-CH_b), 4.34−4.38/4.39−4.43 (each 1H, each m, 3′-CH_a, 3′-CH_b), 5.09 (2H, quintet, J = 5.4 Hz, linker NC−CH_2−CH_a, linker NC−CH_2−CH_b), 5.92 (2H, br. s, Boc-NH_a, Boc-NH_b), 6.24/6.29 (each 1H, each dd, J = 5.7 and 8.6 Hz/J = 5.9 and 8.1 Hz, 1′-CH_a, 1′-CH_b), 7.04 (2H, m, carbamate NH_a, carbamate NH_b), 8.04/8.13 (each 1H, each s, 6-CH_a, 6-CH_b, 10.24 (2H, br. s, N^3H_a, N^3H_b) ppm. ^{13}C NMR (100 MHz, acetone-d_6, 300 K): δ = 19.18/19.20 (nucleoside NC−$CH_{2,a}$, nucleoside NC−$CH_{2,b}$), 20.54 (linker NC−$CH_{2,a}$, linker NC−$CH_{2,b}$), 20.84/20.87 (each d, J = 7.1 Hz/J = 7.1 Hz, phosphorus NC−$CH_{2,a}$, phosphorus NC−$CH_{2,b}$), 24.9−25.1 (4C, m, 2 × N−(CH−(CH_3)$_2$)$_{2,a}$, 2 × N−(CH−(CH_3)$_2$)$_{2,b}$), 28.65 (Boc-C(CH_3)$_{3,a}$, Boc-C(CH_3)$_{3,b}$), 31.87/31.93 (NH−$CH_{2,a}$, NH−$CH_{2,b}$), 38.32/38.47 (2′-$CH_{2,a}$, 2′-$CH_{2,b}$), 41.05 (Boc-NH−$CH_{2,a}$, Boc-NH−$CH_{2,b}$), 43.86 (d, J = 12.4 Hz, N−(CH)$_{2,a}$, N−(CH)$_{2,b}$), 59.63/59.77 (each d, J = 19.9 Hz/J = 19.9 Hz, phosphorus NC−CH_2−$CH_{2,a}$, phosphorus NC−CH_2−$CH_{2,b}$), 64.03/64.81 (each d, J = 8.3 Hz/J = 8.4 Hz, 5′-$CH_{2,a}$, 5′-$CH_{2,b}$), 64.99/65.04 (nucleoside NC−CH_2−$CH_{2,a}$, nucleoside NC−CH_2−$CH_{2,b}$), 69.30 (linker NC−CH_2−CH_a, linker NC−CH_2−CH_b), 70.63 (Boc-NH−CH_2−$CH_{2,a}$, Boc-NH−CH_2−$CH_{2,b}$), 70.91, 71.07, 71.18, 71.31, 71.65 (5 × $CH_{2,a}$ glycol, 5 × $CH_{2,b}$ glycol), 75.36/75.40 (alkyne CC−$CH_{2,a}$, alkyne CC−$CH_{2,b}$), 78.65 (C(CH_3)$_{3,a}$, C(CH_3)$_{3,b}$), 80.91/81.20 (3′-CH_a, 3′-CH_b), 85.09/85.11 (each d, J = 8.3 Hz/J = 8.4 Hz, 4′-CH_a, 4′-CH_b), 86.18/86.50 (1′-CH_a, 1′-CH_b), 90.06/90.20 (5-C_a, 5-C_b), 99.81/99.92 (alkyne CC−$CH_{2,a}$, alkyne CC−$CH_{2,b}$), 117.72 (linker NC_a, linker NC_b), 118.96/118.97 (nucleoside NC_a, nucleoside NC_b), 119.15/119.16 (phosphorus NC_a, phosphorus NC_b), 143.74/143.94 (6-CH_a, 6-CH_b), 150.22/150.29 (2-CO_a, 2-CO_b), 155.85/155.88 (carbamate CO_a, carbamate CO_b), 156.62 (Boc CO_a, Boc CO_b), 162.02 (4-CO_a, 4-CO_b) ppm. ^{31}P NMR (121 MHz, D_2O, 300 K): δ = 148.23, 148.43 (s, a-isomer, b-isomer) ppm. ESI(+)-MS (*m*/*z*) Calcd: 892.9 [$C_{40}H_{61}N_8O_{13}P$]. Found: 910.9 [M + NH_4]$^+$, 915.8 [M + Na]$^+$, 893.8 [M + H]$^+$.

Synthesis of Oligonucleotide 22. The oligonucleotide synthesis was carried out on an Expedite PerSeptive Biosystems DNA synthesizer, using commercially available 5′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite 2′-deoxyribonucleosides and **21** as building blocks and dT5′-CPG as solid support. The protocol was a standard 1 μmol synthesis protocol with prolonged detritylation and coupling times. The sequence 5′-TATGACCT-3′ was assembled, observing in all cases coupling yields greater than 98% as evaluated by DMTr analysis.

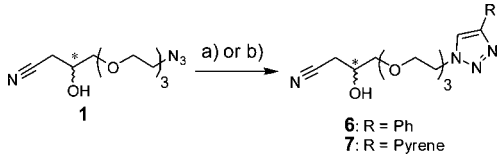
Coupling with Fluorescein to Obtain Oligonucleotide 23. CPG-supported oligonucleotide **22** was treated several times with 3% TCA solution in methylene chloride to remove the Boc protecting group and afterward washed several times with ACN. After drying the support in vacuum, 10 equiv of fluorescein−NHS ester (5 mg, 10 μmol) and 15 equiv of DIPEA (2.6 μL, 15 μmol) in 400 μL of DMF were added to the support, and the reaction was left at room temperature for 20 h. After 20 h, the support was washed thoroughly with DMF, methylene chloride, methanol, and diethyl ether and dried in vacuum.

Scheme 1. Synthesis of the Core Structure 1 of the Cleavable Linker and Its Reduced, Boc-Protected Form 5[a]

[a] Reagents and conditions: (a) NaN_3, NaI, EtOH, reflux, 4 d, 94%; (b) (i) NaH, THF, rt, 2 h, (ii) (±)-epichlorohydrin, rt, 16 h, 70%; (c) NaCN, EtOH/H_2O = 5:1, rt, 16 h, 89%; (d) (i) triphenylphosphine, dry dioxane, rt, 8 h, (ii) 25% aqueous ammonia, rt, 12 h; (e) Boc_2O, $NaHCO_3$, water/dioxane, 0 °C to rt, 10 h, 100%.

Deprotection of the CPG-Supported Oligonucleotide 23. The CPG-support **23** was suspended in 6 mL of DMF and treated with 6 mL of 1 M TBAF/THF solution. The support was shaken for 15 min at 45 °C. Then the supernatant was collected, and its fluorescence was qualitatively analyzed under a UV lamp at 366 nm. The support was washed with methylene chloride and methanol.

Cleavage of Oligonucleotide 24 from the CPG Support. The support was treated with 2 mL of 25% aqueous ammonia at 50 °C for 18 h. The supernatant was filtered, and the support was washed with H_2O. The combined filtrates and washings were concentrated under reduced pressure, redissolved in H_2O, and analyzed and purified by ion exchange HPLC as described in the Materials and Methods using the gradient given below.



The collected fractions were evaporated. The detached oligonucleotide **25** was then dissolved in 1 mL of Millipore water and desalted on a PD-10 desalting column. The desalted oligonucleotide **25** was analyzed by ESI-MS. Ion exchange HPLC: flow rate 5 mL/min, gradient 0 min 85% A, 10% B, 5% C → 20 min 65% A, 10% B, 25% C → 23 min 0% A, 0% B, 100% C → 25 min 0% A, 0% B, 100% C → 27 min 85% A, 10% B, 5% C → 30 min 10% A, 90% B, 0% C; retention time 16.36 min (UV detection at 254 nm). ESI(−)-MS (*m*/*z*) Calcd: 2423.6. Found: 807.3 [M]$^{3-}$, 1211.2 [M]$^{2-}$, 814.5 [M + Na]$^{3-}$, 1222.3 [M + Na]$^{2-}$, 1233.4 [M + 2Na]$^{2-}$, 1244.5 [M + 3Na]$^{2-}$. Calculated masses: 2424.4 [M], 2446.4 [M + Na], 2468.8 [M + 2Na], 2490.8 [M + 3Na].

RESULTS AND DISCUSSION

Synthesis of the Core Structure 1 and the Reduced Form 5. The synthesis of the basic compound **1** and the reduced and Boc-protected form of the linker **5** are shown in Scheme 1. They can easily be synthesized with good to very good yields from inexpensive starting materials.

Starting from the commercially available triglycol monochloride **2**, the azido-modified triglycol **3** could be obtained with 94% yield following a literature procedure (*17*). In the next step, racemic epichlorohydrin was introduced using sodium hydride in dry THF yielding 70% of compound **4**. The epoxide was finally opened using sodium cyanide to build up the cleavage site, yielding 89% of compound **1**. Compound **1** was obtained with an overall yield of 58% over three steps. From the core structure **1**, the reduced linker **5** can easily be obtained in two additional steps. It was synthesized by applying the Staudinger reaction and subsequently protecting the free amino group as *tert*-butyl carbamate without intermediate purification of the free amine. A quantitative yield of compound **5** was obtained over these two steps. By the use of racemic epichlorohydrin, the linker is obtained as racemic mixture. This does not cause any problems as also in further derivatization where diasteroisomers

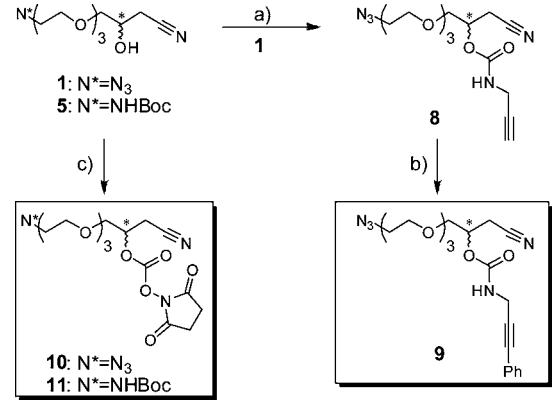
Scheme 2. Modification of the Linker 1 by the Use of Click Reactions[a]

[a] Reagents and conditions: (a) phenylacetylene (**6**) or 1-ethynylpyrene (**7**), $CuSO_4$, sodium ascorbate, CH_2Cl_2/MeOH = 2:1, for **6** rt, 42 h, 96%, for **7** rt, 20 h, 40 °C, 24 h, 41%; (b) 1-ethynylpyrene, CuI, DIPEA, 30 min, 250 W, 60%.

result, no difference in chemical or physical behavior (reactivity, on TLC, or in NMR spectra) was observed.

Click Reactions on the Azido-Modified Linker 1. The core linker **1** was coupled to phenylacetylene in a click reaction to evaluate the effectiveness of this method of attachment. The reaction is shown in Scheme 2. It was accomplished using catalytic amounts of copper(II)sulfate and L-ascorbic acid sodium salt in a 2:1 mixture of methylene chloride and methanol as solvents. The product **6** was obtained with 96% yield and thereby confirms the very good qualities of the linker in click reactions.

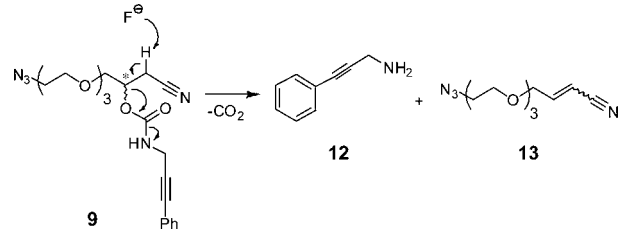
After this successful test reaction, we wanted to introduce a fluorescent label via a click reaction. Because often used dyes like fluorescein or TexasRed are not commercially available as their alkyne derivatives, we used 1-ethynylpyrene as a model dye (**7** in Scheme 2). The conversion was accomplished applying two different methods (a, b). Using very similar conditions as for derivative **6**, we observed that the reaction with pyrene went much slower. After stirring for 20 h at room temperature, there was still starting material left, so we heated it to 40 °C for another 24 h. We could isolate the labeled product **7** with a yield of 41%. An improved yield of 60% could be achieved by performing the reaction in the microwave (30 min, 250 W) without solvents according to a literature procedure (*18*). This demonstrates that the linker is useful for attaching labels by click reactions.



Synthesis and Cleavage of Model Compound 9. To prove the cleavability with fluoride and to investigate the cleavage mechanism, model compound **9** was synthesized where the nucleotide is replaced by a phenyl moiety. The cleavage mechanism is supposed to follow a β-elimination as is also suggested for the above-mentioned fluoride cleavable protecting groups. Fluoride therefore has to act as a base, not as a nucleophile. The synthesis of the model compound **9** is shown in Scheme 3.

Compound **1** was converted to the propargylamine carbamate **8** with 76% yield. In a one-pot procedure, compound **1** was first activated as *N*-succinimidyl carbonate at 0 °C with K_2CO_3 as base followed by the addition of propargylamine and $KHCO_3$ as additional base. The model compound **9** was then synthesized via Sonogashira coupling of the modified linker **8** to iodobenzene with a yield of 92%. From the starting materials **1** and **5**, the *N*-succinimidyl carbonates **10** and **11** were isolated as well by applying the same conditions as described for the transient activation of compound **1**, followed by an aqueous workup. They were used later on for derivatization of a nucleosidic compound (see Scheme 4).

The expected cleavage mechanism and products as well as several cleavage conditions examined using compound **9** are summarized in Table 1. The experiments were performed in a small scale (max. 30 mg of starting material) and analyzed by RP-HPLC where the UV visible compounds were detected (**9** and **12**).



To make a comparison between the cleavage of the linker and our results found for the cleavage of the 3′-*O*-CE group,

Scheme 3. Synthesis of the Model Compound 9 and the Activated Compounds 10 and 11[a]

[a] Reagents and conditions: (a) (i) di-(*N*-succinimdyl)carbonate, anhydrous K_2CO_3, dry ACN, 0 °C, 20 h, (ii) propargylamine, $KHCO_3$, rt, 3 h, 76%; (b) iodobenzene, $Pd(PPh_3)_4$, CuI, Et_3N, dry CH_2Cl_2, rt, 3.5 h, 92%; (c) di(*N*-succinimidyl)carbonate, anhydrous K_2CO_3, dry ACN, 0 °C, **10**, 20 h, 99%; **11**, 24 h, 90%.

Table 1. Expected Cleavage Mechanism and Cleavage Experiments Using Model Compound 9 under Various Conditions[a]

exp. no.	reagent (equiv)/solvent	temp	cleavage/time [min]
1	1 M TBAF (50)[b]/dry THF	60 °C	quant/<1
2	1 M TBAF (50)[b]/dry THF	rt	quant/<1
3	1 M TBAF (5)[b]/dry THF	rt	quant/ca. 10
4	28% aq. NH_3 (100)[b]/MeOH	rt	ca. 60%/>1200
5	$Et_3N \cdot 3HF$ (5)[b]/dry THF	rt	no cleavage
6	aq. TFA/methanol	rt	no cleavage

[a] For following the reaction, 100 μL probes were taken out, diluted with 450 μL of methanol and 50 μL of Millipore water and applied to reversed-phase HPLC column. [b] Numbers in parentheses are the corresponding equivalents of TBAF used.

the first experiment was accomplished at elevated temperature because this is required for effective 3′-*O*-CE cleavage (*12*). A high excess of fluoride is chosen because this mimics the conditions on the chip in a CRT approach. The result for the designed linker was very good because it was cleaved in less than 1 min. Because of this very fast cleavage at 60 °C, the temperature was reduced to room temperature (experiment no. 2, Table 1). Comparing entries 1 and 2 demonstrates that no elevated temperature is needed for this ultrafast cleavage (see also Figure 2). Further the reduction of equivalents decelerated the reaction, but it was still complete in less than 10 min (experiment no. 3 in Table 1). One explanation for the ultrafast cleavage is the release of carbon dioxide.

The linker is also expected to be cleavable by other bases. So the cleavage with high excess of concentrated ammonia was investigated (entry 4, Table 1). The HPLC chromatogram in Figure 3 shows that there is a big difference in effectiveness between fluoride and ammonia. The linker is also cleavable with concentrated ammonia, but it is not complete after 20 h at room temperature (approximately 60% cleavage).

Entry 5 in Table 1 shows that the linker is stable against the slightly acidic fluoride reagent $Et_3N \cdot 3HF$ (Figure 3); no cleavage occurs during 18 h. We further found excellent stability even after 48 h under acidic conditions (TFA solution, entry 6

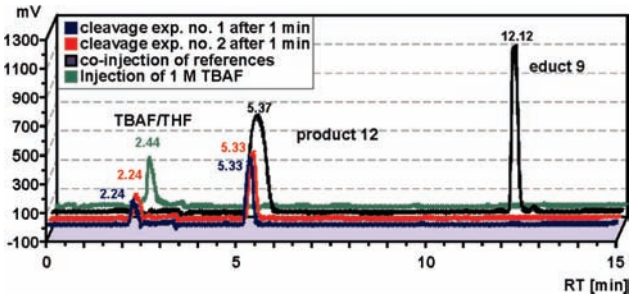


Figure 2. HPLC chromatogram of cleavage experiment nos. 1 and 2 in Table 1.Conditions: Phenomenex Jupiter 4u Proteo 90A 4 μm column 250 mm × 4.6 mm, flow rate 1 mL/min, gradient 0 min 10% A, 70% B, 20% C → 14 min 10% A, 15% B, 75% C → 20 min 10% A, 0% B, 90% C.

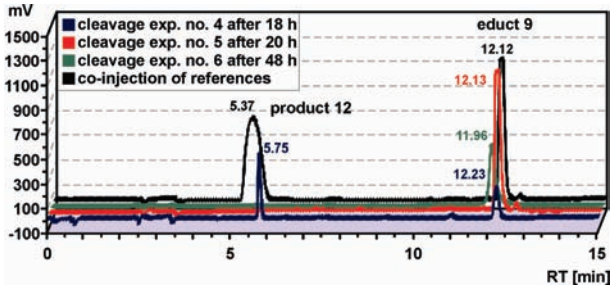

Figure 3. HPLC chromatograms of exp. no. 4, 5, and 6 in Table 1. Condition as described in Figure 2.

and Figure 3). This stability is important for the use of the Boc-protected linker because it has to be deprotected under acidic conditions after attachment to the nucleoside to enable the labeling.

The HPLC chromatograms provide a first hint of the expected cleavage mechanism because they show the appearance of cleavage product **12**. The glycol cleavage product is not UV-active and therefore not detectable by this HPLC system. Another indicator of the β-elimination mechanism is the stability of the linker against $Et_3N \cdot 3HF$. The final proof of the cleavage and its mechanism was achieved by repeating the reaction in a bigger scale to be able to isolate both cleavage products. The reaction was performed using an excess of 5 equiv of TBAF in dry THF at room temperature for 10 min. Both expected products **12** and **13** could be isolated in quantitative yields. The olefin is obtained in a 1:1 ratio of *cis* and *trans* isomers as determined by ^{1}H NMR.

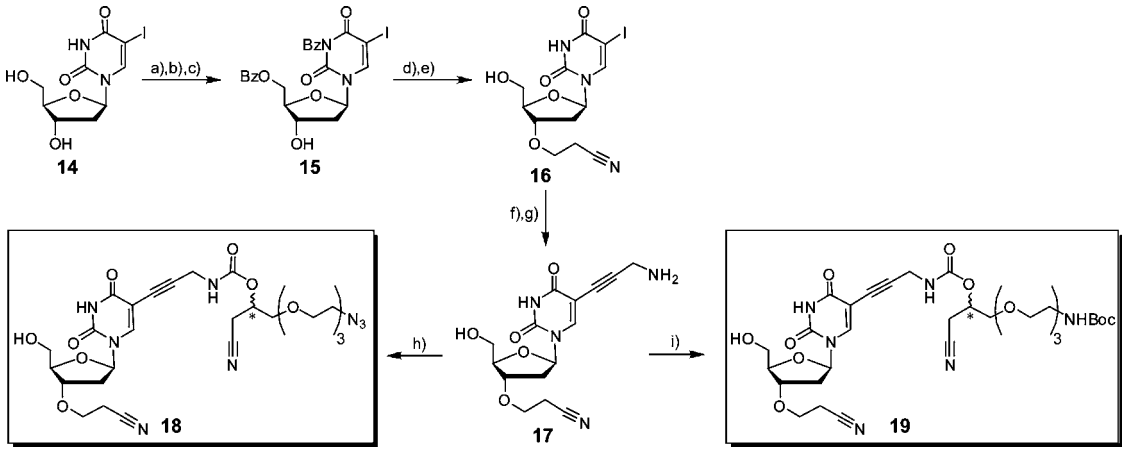
These experiments show that the linker is extraordinarily effectively cleaved with 1 M TBAF in THF following a β-elimination mechanism and that it is completely stable under acidic conditions.

Synthesis and Cleavage of the 5-,3′-Modified 2′-Deoxyuridine Derivatives 18 and 19. To ensure that the cleavage works equally efficiently if the linker is attached to a nucleoside and to analyze the difference in cleavage rate between the 3′-*O*-CE group and the linker, the 5-,3′-modified compound **18** was synthesized (see Scheme 4). To enable the final cleavage experiment on a labeled, CPG-bound 8-mer, compound **19** was also synthesized, bearing the Boc-protected linker at the 5-position (see Scheme 4).

The introduction of the CE group to 5-iodo-2′-deoxyuridine **14** was accomplished in a similar way as described for the thymidine derivative (*12*). The only difference is that for the 5′-*O*-protection the benzoyl group was used instead of the MMTr group to just have one single deprotection step in the end. According to this, the first step was the selective introduction of the benzoyl group at the 5′-OH (*19*). By lowering the temperature to −18 °C we could improve the yield to 77% of 5′-mono protected product as compared with the yield reported in literature (70%). Following conditions described in the literature (*20*), the next step was the benzoyl protection of N^3 by transient TMS protection of the 3′-OH function in a one-pot procedure. The yield of 75% of completely protected nucleoside **15** suggests that two of the three steps mentioned were quantitative, including isolation and purification. The Michael addition was accomplished following the procedure described for the RNA 2′-position (*13*) using freshly distilled acrylonitrile and Cs_2CO_3 as base. The crude product of the Michael addition was directly deprotected and 65% of the 3′-*O*-modified nucleoside **16** was obtained after two steps. To enable the attachment of the cleavable linker, the propargylamine moiety was introduced by the well-known Sonogashira coupling with propargylamine-*N*-(1,1,1-trifluoro)acetate. After deprotection, compound **17** was obtained over the two steps in 65% yield. The coupling of the linker was readily accomplished by adding the activated linker moiety **10** to the modified nucleoside **17** in dry ACN with $KHCO_3$ as base giving 67% of the final compound **18**. Adding the corresponding activated linker **11** to compound **17** yields 77% of compound **19**.

The cleavage experiments using compound **18** were accomplished in the same manner as with model compound **9**. Approximately 30 mg of starting material was used, and the reactions were followed by RP-HPLC. In Table 2, the experiments are summarized.

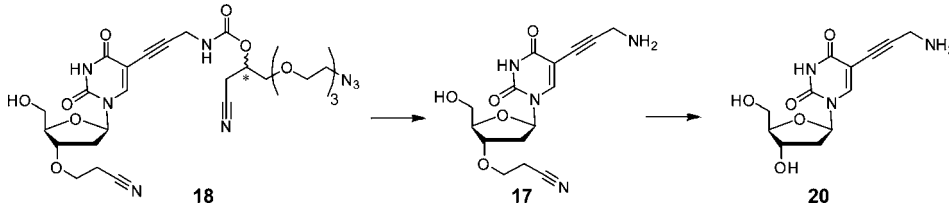
With fluoride, the cleavage proceeds successively as shown in Table 2. For the linker, we observe a very fast cleavage according to the results obtained with the model compound **9**. For the 3′-*O*-CE group, we found a cleavage time of more than 1 h under the conditions applied in entry 1 of Table 2 (*12*). Estimated from these observed times, the linker is cleaved about 100 times faster than the 3′-modification. With ammonia, the cleavage of the linker occurs more slowly, and no cleavage is monitored for the 3′-*O*-CE group.



In Figure 4, the three reference compounds are shown. In Figures 5 and 6, the chromatograms of the two entries in Table 2 at different points of time are displayed.

The results of the HPLC analysis of experiment no. 1 are in accordance with the expectations. Figure 5 shows a very fast cleavage (less than 1 min) of the linker and a complete cleavage after 2 h of the 3′-*O*-CE group. Hence the cleavage is equally effective with the nucleoside compound **18** and the model compound **9**. The cleavage of the linker from the nucleoside **18** with ammonia (entry 2 in Table 2 and Figure 6) is faster than that from the model compound **9**. However it is not completely clear whether this is due to the nucleoside moiety because the conditions were not identical. In experiment no. 2 in Table 2, no additional solvent was used, and the excess was much higher compared with entry 4 in Table 1.

The fluoride cleavage experiment (exp. no. 1 in Table 2) shows that both parts are cleavable under the same conditions. For our future aim to use this combination of 3′-*O*-blocking group and cleavable linker as dye-labeled reversible terminator, it is important that both parts are efficiently cleaved within minutes. At room temperature, the speed of cleavage of the 3′-*O*-CE group does not meet the demands for CRT sequencing. However this problem we already solved and the optimal conditions for cleavage of the 3′-blocking group were found to be at 40 °C with DMF or DMSO as cosolvent (cleavage within 3 min) (*12*).



The future idea for the use of these reversible terminators is to elongate oligonucleotide templates, immobilized on a chip. To mimic these conditions and to show that both modifications can be cleaved in a reasonable time, a final deprotection experiment on a CPG-supported oligonucleotide was ac-

complished. We chose an 8-mer bearing the complete 2′-deoxyuridine-derived reversible terminator at the 3′-end. To be able to detect the cleavage of the linker moiety from the oligonucleotide, the linker was labeled with fluorescein after assembly of the oligonucleotide. For this experiment, nucleoside **19** was used, and the dye was applied as its *N*-hydroxysuccinimidyl active ester.

In order to use the complete reversible terminator **19** in an automated oligonucleotide synthesis, the 5′-*O*-phosphoramidite was synthesized. In Scheme 5, the synthesis of the phosphoramidite **21** is shown. It was carried out using *N*,*N*,*N*,*N*-tetraisopropyl-*O*-cyanoethyl-phosphoramidite as phosphorylating reagent and 4,5-dicyanoimidazole as base. The 3′-modified 5′-phosphoramidite **21** was obtained in quantitative yield.

As a model oligonucleotide, we chose the following 8-mer: 5′-TCCAGTAT$_{mod}$-3′, **22**, where T_{mod} is the 5-,3′-*O*-modified nucleotide. The oligonucleotide synthesis had to be carried out in the inverse way (direction 5′ to 3′, instead of the conventional 3′ to 5′) with commercially available 5′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite-2′-deoxyribonucleosides building blocks. After assembly, the oligonucleotide was left at the CPG support, and the amino group of the linker was deprotected by washing the column 10 times with deblock solution (3% TCA in methylene chloride). To this free amino group, fluorescein was coupled in order to be able to detect the cleavage product of the linker by fluorescence (Scheme 6). The solid phase bound labeled oligonucleotide **23** was washed and dried thoroughly before the treatment with 1 M TBAF in THF and dry DMF as cosolvent at 45 °C for 15 min. After this time, the supernatant

Scheme 5. Synthesis of the 5′-Phosphoramidite 21[a]

[a] Reagents and conditions: (a) *N*,*N*,*N*,*N*-tetraisopropyl-*O*-cyanoethyl-phosphoramidite, 4,5-dicyanoimidazol, dry CH_2Cl_2, rt, 4 h, 100%.

was recovered, concentrated, redissolved in methanol, and irradiated under a UV lamp at 366 nm. At this wavelength, the solution showed a very strong fluorescence (small picture in Scheme 6). This demonstrates the cleavage of the linker−dye system during the fluoride treatment. To prove the cleavage of the 3′-*O*-CE group as well, the oligonucleotide was deprotected and detached from the solid support by treatment with concentrated aqueous ammonia at room temperature. After purification of the oligonucleotide **24** by ion exchange HPLC and desalting by gel filtration, the ESI-MS analysis indeed proved the presence of the completely deprotected oligonucleotide **24** (Scheme 6).

We designed a linker that is rapidly cleaved by fluoride through a β-elimination mechanism. The linker is useful for different modes of attachment, and therefore it is a versatile tool for reversibly labeling (oligo)nucleotides. We showed examples of successful attachment of labels by click reactions and by amide formation.

To prove the use of this linker for a reversible terminator, applicable in a DNA-sequencing approach, the modified nucleosides **18** and **19** were synthesized, and the cleavage properties were analyzed. Initial experiments were performed in solution but with the final cleavage experiment from the CPG-bound oligonucleotide, we could show that also under heterogeneous conditions TBAF efficiently removes the linker−dye system and the 3′-*O*-blocking group in one single step. Further this setup confirmed that oligonucleotides are stable under the applied chemical conditions. These results demonstrate that the developed linker, together with the 3′-*O*-blocking group meets the demands for a reversible terminator.

Attachment of molecules and proteins to surfaces is of great interest for the development of a large variety of applications. We present herein a novel approach to efficiently couple a molecule of choice to biological building blocks. We synthesized and employed a new derivative of 5-bromo-7-nitroindoline to attach nucleophilic molecules and proteins to gold surfaces by photochemical activation. The reaction can be seen as a photoactivated alternative to the activated ester type chemistries that are commonly used to attach proteins or molecules to surfaces. We characterize the reaction by UV−vis and NMR spectroscopy, and as test of principle experiment, we show that we can attach proteins to surfaces and demonstrate that we can functionalize gold nanoparticles by this optically induced cross-linking reaction.

INTRODUCTION

Attachment of proteins and molecules to designated areas on surfaces is crucial for a large variety of biomedical applications such as drug screening platforms, microarrays, solid support protein synthesis, and single molecule experiments (*1*−*9*). Several methods have been developed to randomly or in a selective manner couple (bio)molecules on chemically modified surfaces. In random immobilization methods, the active residues of proteins, such as lysines, are coupled to surfaces containing N-hydroxysuccinimide (NHS) esters (*10*), epoxides (*11*), aldehydes (*8, 12*), oximes (*13*), semicarbazones (*14*), or isothiocyanate (*15*). Oriented immobilization can be obtained by reaction of the free solvent accessible thiols of proteins (*7*), by employing polyhistidine tags (His6)(16), AGT mediated methods (*17*), protein ligation (*18*−*20*), and splicing (*8, 21*). Alternatively, biomolecules can be positioned directly on surfaces by nonspecific adsorption (*22*). To avoid direct interactions with surfaces, enzymes have been coupled to bovine serum albumine (BSA) (*3*) or on streptavidin molecules (*4*) which are then immobilized on surfaces either randomly or by the use of microcontact printing techniques (*1, 2*). To increase coupling efficiency between a surface and a biomolecule, an attractive alternative is the Sharpless (*23, 24*) reaction where an alkyne species is reacting with an azide. Due to conveniently introducing an alkyne group on the amino acids of a protein and an azide group on the surface (or vise versa), this method has been widely employed to couple biomolecules together or covalently attach them on surfaces (*3, 23*−*27*). The advantage of the click-type chemistries is that the reactions are highly chemoselective and can be performed in aqueous media (*23*); a serious disadvantage is that copper and its salts are highly toxic to most living organisms, which can be circumvented by the use of Cu-free methods (*24*). Another shortcoming of the above-mentioned techniques is the limited stability of these reagents (NHS only 2 h (*10*)) or the use of additional proteins such as SAV that may limit or change the properties of the protein one wishes to attach to the surface. We herein present a new, attractive method to efficiently conjugate molecular entities using an in situ photoactivated type of chemistry.

The 5-bromo-7-nitroindolinyl (Bni) group was first reported as a light-sensitive protection group for carboxylic acids (*28*). Through the years, it as been used for a variety of applications, such as natural product synthesis (*29*), peptide synthesis (*30, 31*), and recently as a light sensitive protection group for amines and alcohols (*32*). To demonstrate the utility of the Bni-group for photoinduced cross-coupling reactions, the thiol-functionalized 5-bromo-7-nitroindolinyl molecule **1** was synthesized and explored as a photoactive linker to attach molecules or proteins to gold surfaces. To characterize the efficiency of this linker, we employed UV−vis and NMR techniques to monitor the photoinduced reaction of **1** with 1-aminohexane at various reaction times. To further show the versatility of this concept, we demonstrate that we can functionalize gold nanoparticles with **1** and link these by a photoinduced cross-linking reaction with 1,6- diaminohexane. In a final experiment, we exploited the potential of this method to link proteins through their solvent-accessible lysine groups on functionalized gold surfaces.

EXPERIMENTAL SECTION

^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) NMR spectra were recorded on a Varian instrument. Fast atom bombardment (FAB^{+}) mass spectra were obtained on a Jeol JMS-HX 110 tandem mass spectrometer in the positive ion mode using 3-nitrobenzyl alcohol (NBA) as matrix. EI-MS spectra were recorded on a ZAB-EQ (VG-Analytical) instrument. Elemental analysis was performed by Mrs. Birgitta Kegel at the Microanalytical Laboratory at the Department of Chemistry, University of Copenhagen. Fluorescence micrographs were recorded on a Zeiss Axiocam microscope equipped with fluorescence filter filters. TEM images of AuNPs were obtained from transmission electron microscopes: JEOL JEM 2010F HRTEM (200 kV field emission gun).

$Na_2S_2O_3 \cdot 5H_2O$ (0.54 g, 2.19 mmol) dissolved in water (3 mL). The reaction was followed by TLC (THF/hexane 1:1). The mixture was refluxed for 62 h. The solvents were removed in vacuo and $CHCl_3$ (25 mL) and hydrochoric acid (1 M, 25 mL) was added. After the reaction was complete, the organic phase was separated and dried ($MgSO_4$), filtered, and concentrated in vacuo. The crude material was crystallized from 2-propanol. Yielding *N*-(11-mercaptoundecanoyl)-5-bromo-7-nitroindoline (**1**) as yellow crystals, 0.63 g (70%). Melting point: 82 °C. ^{1}H NMR ($CDCl_3$): δ 1.13−1.32 (b, 12H), 1.50−1.70 (b, 4H), 2.36−2.49 (b, 4H), 3.12−3.18 (t, J = 8.3 Hz, 2H), 4.18−4.20 (t, J = 8.0 Hz, 2H), 7.45−7.46 (b, 1H), 7.71−7.72 (b, 1H). ^{13}C NMR ($CDCl_3$): δ 24.54, 24.69, 28.23−29.59 (7 peaks), 33.92, 35.44, 115.95, 125.35, 131.40, 133.92, 138.31, 171.25. FAB^+ MS: m/z = 443.1 [MH^+] E.A. Calcd. for $C_{19}H_{27}BrN_2O_3S$ (%) C, 51.47; H, 6.14; N, 6.29; found C, 51.10; H, 6.06; N, 6.19.

***N*-(11-Bromoundecanoyl)-5-bromo-7-nitroindoline 2.** 11-Bromoundecanoic acid (1.00 g, 3,77 mmol) was dissolved in thionyl chloride (1 mL). The solution was stirred at room temperature under N_2 for 1 h. A solution of 5-bromo-7-nitroindoline (*33*) (0.30 g, 1.23 mmol) in dry toluene (7 mL) was added, and the reaction mixture was refluxed for 18 h in the dark. The mixture was cooled to room temperature, and CH_2Cl_2 (5 mL) was added. The organic phase was washed with aqueous Na_2CO_3 (10% w/w) until the remaining acids had been removed. The organic phase was dried over $MgSO_4$, filtered, and concentrated in vacuo. The remaining oil was crystallized from 2-propanol, yielding 0.46 g (76%) of the *N*-(11-bromoundecanoyl)-5-bromo-7-nitroindoline (**2**) as yellow crystals. Melting point: 95 °C. ^{1}H NMR ($CDCl_3$): δ (ppm) 1.23−1.49 (b, 12H), 1.59−1.70 (b, 2H), 1.72−1.83 (b, 2H), 2.36−2.42 (t, J = 7.3 Hz, 2H), 3.12−3.18 (t, J = 8.3 Hz, 2H), 3.31−3.37 (t, J = 6.9 Hz, 2H), 4.14−4.20 (t, J = 8.0 Hz, 2H), 7.45−7.46 (b,1H), 7.71−7.72 (b, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 1.12, 24.68, 28.03, 28.60, 28.81, 28.99, 29.20, 32.70, 33.97, 35.42, 49.45, 56.81, 115.95, 125.33, 131.39, 138.31, 171.23. FAB^+ MS: m/z = 490.9 [MH^+] E.A. Calcd. for $C_{19}H_{26}Br_2N_2O_3$ (%) C, 46.6; H, 5.3; N, 5.7; found C, 46.9; H, 5.3; N, 5.7.

Photochemical Cross-Linking Followed by NMR. 1 (0.23 mg, 500 nmol) and aminohexane (0.044 mg, 500 nmol) were dissolved in deuterated chloroform (1.5 mL) and placed in an NMR tube. The NMR tube was then exposed to 380 nm light for 20 min intervals and the NMR spectra were recorded. The concentrations had to be low enough to result in satisfactorily high conversion within a reasonable time period, and just high enough to get reasonable NMR signals with 64 scans. Higher concentrations lead to longer reaction times due to internal filtering of the incoming light by the absorption from the reaction products. The full NMR spectra can be found in Supporting Information Figures S1 and S2.

Preparation of Fluorescently Labeled BSA. BSA was labeled with Alexa Fluor 488 (BSA^{488}) according to manufacturers protocol. Purification of BSA^{488} was performed on FPLC equipped with Superdex G75 size exclusion column. Collection of fractions permitted the isolation of BSA^{488} in HEPES pH = 8 buffer and concentration of ∼5 μM. On average, 4.5 alexa molecules were coupled to every BSA protein.

Attachment of Fluorescently Labeled Protein to the Gold Surface. Gold surfaces were prepared by UHV deposition of a thin layer of chromium (10 nm) followed by a layer of gold (100 nm) to a glass slide. The gold surface was removed from the evaporator and immediately exposed to a 0.1 mM solution of **1** in chloroform. The surface was left to react for 5 h to form a SAM of the nitroindoline on the surface. The surface was exposed to a 5 μM solution of BSA^{488} in HEPES pH = 8 and irradiated for 5 min with a 150 W Xe arc lamp equipped with a monochromator set to a wavelength of 380 nm. The gold surface was washed 3 times with HEPES buffer and 3 times with Milli-Q grade water to remove unreacted material and equilibrated with HEPES. The experiment was accompanied by control experiments where gold surfaces were exposed to BSA^{488} in the dark and experiments where the surface was covered with dodecanethiol and irradiated (Figure 7). Integrating the fluorescent intensity signal revealed a 6-fold increase in the binding of BSA^{488} compared to the control experiments. The relatively low increase in the fluorescent signal may originate from the depletion of the free solvent accessible lysines due to the labeling with Alexa Fluor 488.

Synthesis of Colloidal Gold Nanoparticles. The synthesis of the alkyl thiol stabilized gold nanoparticles (AuNPs) followed a slightly modified procedure from the one initially developed by Brust (*34*), which is a two-phase (toluene−water) reduction of $HAuCl_4$ in the presence of a stabilizing ligand. We used the thiol-functionalized **1** as the stabilizing thiol layer.

To a solution of $HAuCl_4 \cdot 3H_2O$ (0.10 g, 0.25 mmol) in water (8.50 mL) was added a solution of tetraoctyl ammonium bromide (0.35 g, 0.64 mmol) in toluene (25 mL). The reaction mixture was stirred vigorously under nitrogen atmosphere and compound **1** (0.11 g, 0.25 mmol) was added. The reaction mixture was stirred for 10 min and a solution of sodium borohydride (0.11 g, 2.74 mmol) in water (7.5 mL) was added dropwise. After the addition of sodium borohydride, the reaction mixture was left without stirring for 10 min, and the dark brown organic phase was separated and reduced in vacuo to a volume of approximately 5 mL. Ethanol (96%) was added and the reaction mixture was placed at −20 C overnight, allowing the black AuNPs to precipitate. The supernatant was filtered off, and the AuNPs were washed 4 times with ethanol (96%, 2 mL). Finally, the AuNPs was dried under a stream of nitrogen leaving the AuNPs as a black material (120 mg).

^{1}H NMR ($CDCl_3$): δ (ppm) 1.15−1.60 (b, 16 H), 2.36−2.41 (t, 1H, J = 7.18 Hz), 2.57−2.64 (t, 1H, J = 7.28 Hz), 3.12−3.18 (t, J = 8.20 Hz, 2H), 4.14−4.20 (t, J = 8.1 Hz, 2H), 7.45 (b, 1H), 7.70 (b, 1H). ^{13}C NMR ($CDCl_3$): δ (ppm) 13.95, 22.24, 22.47, 24.70, 26.34, 28.37−29.60 (5 peaks), 31.52, 35.44, 49.46, 59.22, 125.30, 131.40, 138.37, 171.26.

The **1** functionalized gold nanoparticles were further functionalized by adding a solution of 1,6-hexanediamine (45 mg, 0.39 mmol in chloroform (1 mL) to a solution of the gold nanoparticles (12 mg) in chloroform (1 mL). The gold nanoparticles were cooled in an ice/acetone bath and irradiated for 4 h with a 150 W Xe arc lamp equipped with a monochromator set to 380 nm. The nanoparticles precipitated leaving a clear solution with a black nanoparticle precipitate. The structure of the precipitate containing the nanoparticles was verified by TEM microscopy (Figure 4).

RESULTS AND DISCUSSION

The coupling reaction using Bni-based linkers does not require any auxiliary reactants such as metal catalysts or activated esters; it proceeds via a photoactivated, reversible transfer of the acyl group to the neighboring nitro group to form a very reactive acyl nitronate intermediate (*32, 35, 36*). If exposed to a nucleophile, the reaction will proceed as outlined in Figure 1. In the absence of nucleophile, the nitroindoline will revert to its initial form. This unique characteristics allows **1** to retain its functional form until the right criteria (nucleophile and light activation) are met (*28, 30*).

Compound **1** was synthesized from available 11-bromo undecanoic acid **3** via the reactive acid chloride **4** as outlined in Figure 2 and in the experimental section.

To test the coupling efficiency of **1**, we initially coupled it to 1-aminohexane in chloroform and monitored the reaction progress by UV−vis spectroscopy. As seen from Figure 3, the

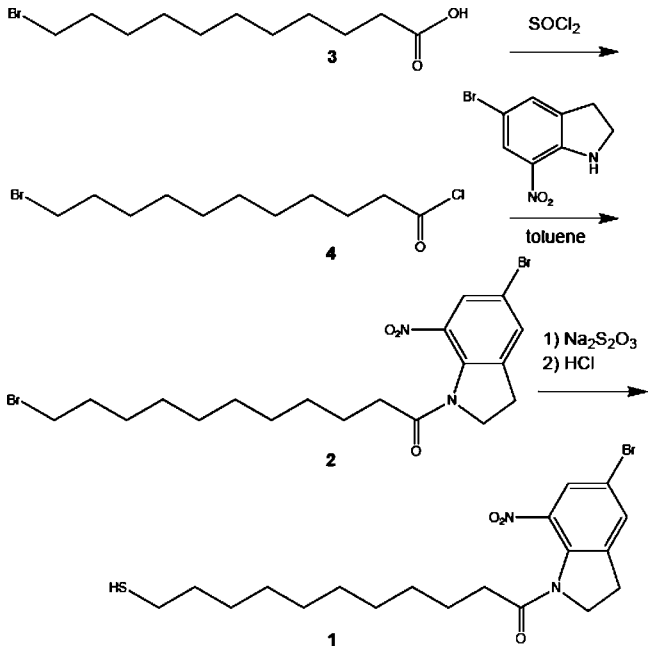

Figure 2. Synthesis of 1-(5-Bromo-7-nitro-2,3-dihydro-indol-1-yl)-11-mercapto-undecan-1-one (**1**).

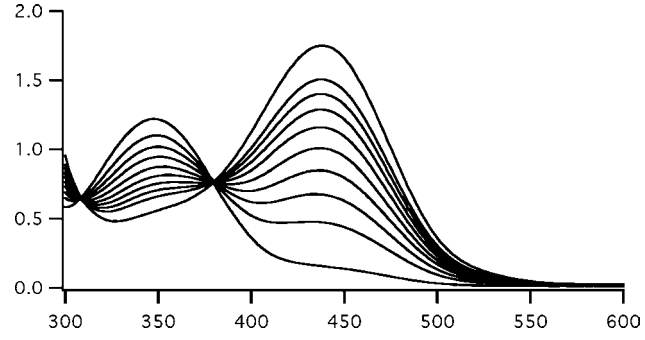

Figure 3. UV−vis spectra of the photoactivated reaction of 7-nitroindolineamide **1** with 1-hexaneamine in chloroform. The absorption band at 340 nm from the 7-nitroindolineamide **1** diminishes as the band at 440 nm from the free indoline rises during a period of 120 min.

absorption band at 340 nm from the 7-nitroindolineamide **1** diminishes as the band at 440 nm from the free indoline rises during a period of 120 min. A test reaction at the same reaction conditions, but without 1-aminohexane, showed no significant degradation of **1**. We further validated our initial observations

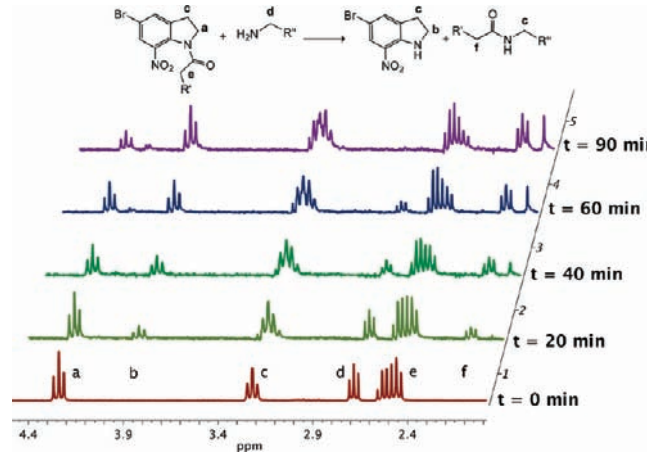

Figure 4. NMR spectra of the photoactivated reaction of 7-nitroindolineamide **1** with 1-aminohexane in chloroform.

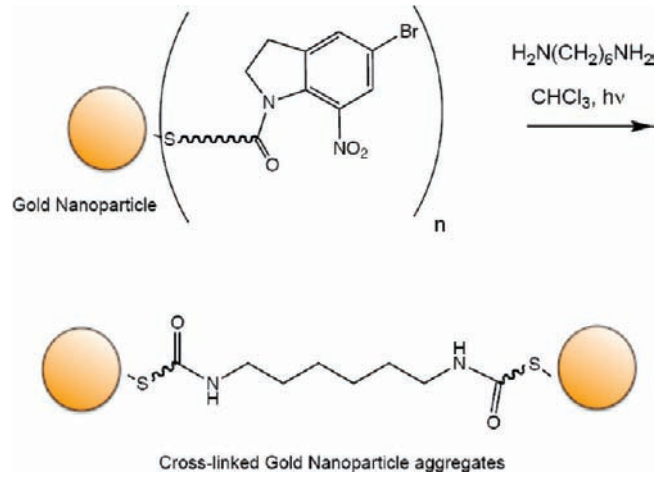

Figure 5. Mechanism for the photochemical cross-linking of the 7-nitroindolineamide-functionalized gold nanoparticles in the presence of 1,6-hexanediamine.

by monitoring the reaction by NMR spectroscopy (Figure 4). The figure represents a selected area (2.0−4.5 ppm) of the NMR spectrum of a mixture of 7-nitroindolineamide and 1-aminohexane at various exposure times (see Supporting Information S1 and S2 for full spectra). The reaction mixture was irradiated for 90 min, and NMR spectra were recorded at 0, 20, 40, 60, and 90 min of irradiation. During this period of time, the signal from the aliphatic protons on the indoline, **a** at 4.25 ppm, together with the α-protons on 1-aminohexane, **d**, were slowly disappearing, demonstrating that both reactants were consumed as the reaction progressed. The signal from the indoline protons **a** did not disappear completely, due to a slight excess of this reactant compared to the 1-aminohexane. Concurrently, new peaks for the aliphatic protons on the indoline product appeared at 3.9 ppm, **b**, together with a triplet at 2.1 ppm from the **f** protons on the newly formed amide, thus confirming the appearance of the two reaction products. The absence of any side products in combination with the quantitative reaction yield (based on NMR) illustrates the high efficiency of the photoactivated coupling reaction.

To test the reactivity of **1** once linked to a metal surface, we performed a simple test experiment: Photoinduced reaction of nanoparticles covered with **1** with a suitable α,ω-diamine should lead to clustering of the particles (Figure 5). Indeed, after exposure to light (380 nm) for 240 min the sample had changed from a dark solution to a clear solution with a dark precipitate. This precipitate was analyzed by TEM (Figure 6b). By

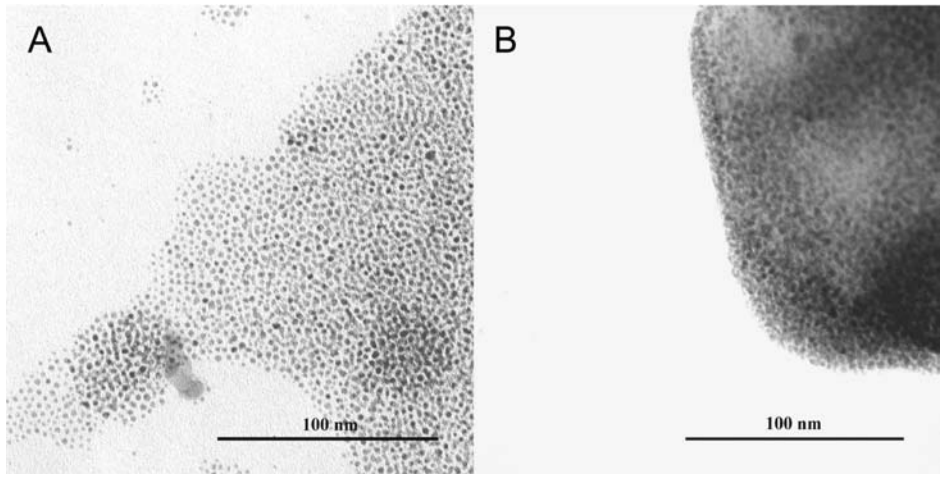

Figure 6. TEM micrographs of the nanoparticles. (A) The nanoparticles before irradiation. (B) One aggregate of gold nanoparticles after irradiation.

comparison of the two TEM pictures, it is evident that the nanoparticles (Figure 6a) were aggregated as a consequence of the reaction with the diamine, as seen in Figure 6b. To verify this result, three control experiments were carried out: (1) A solution of gold nanoparticles covered with **1** did not show any signs of reaction on exposure to light. (2) A mixture of a solution of gold nanoparticles covered with 1-dodecanethiol and 1,6-hexanediamine did not change upon irradiation, thus excluding light-induced ligand exchange, and (3) A solution of gold nanoparticles derivatized with **1** in $CHCl_3$ mixed with excess 1,6-diaminohexane did not change in the absence of light. A sample volume from the third test experiment was removed from the reaction mixture and analyzed by TEM (Figure 6a).

This observation together with the fact that both light and 1,6-diaminohexane are necessary for the precipitation to take place shows that postmodification of thiol-protected gold nanoparticles is possible utilizing **1**.

To further verify the versatility of the reaction, we successfully attached proteins to gold surfaces functionalized with SAMs of **1**. Bovine serum albumin (BSA) labeled with Alexa 488 NHS according to manufacturer's protocol (a fluorescence intensity trace of the FPLC purification is shown in the Supporting Information S3), and was exposed to the functionalized gold surface with and without exposure to a 380 nm wavelength light source. Fluorescence micrographs of the resulting surface are depicted in Figure 7.

Figure 7A shows the image of BSA^{488} coupled to SAM of **1** on gold using UV irradiation. To ensure the validity of our observations, we performed the following control experiments. First, we incubated BSA^{488} over the gold surface without UV activation. As shown in Figure 7B, limited nonspecific binding is obtained demonstrating that reaction only occurs after photoactivation. We then incubated BSA^{488} on a gold surface covered by a SAM of dodecane thiol with UV activation. In Figure 7C, we demonstrate that only limited binding takes place, thus illustrating that both compound **1** and light activation are necessary for the linking of the protein to the surface. To further quantify the degree of attachment of protein to the surfaces, we integrated the fluorescence intensity of a series of samples. The results of three independent experiments are shown in Figure 7D. The error bars represent the standard deviation of individual images. The integrated fluorescence signal form the functionalized surfaces revealed a ~6-fold increased binding of BSA^{488} compared to the controls, thus clearly demonstrating

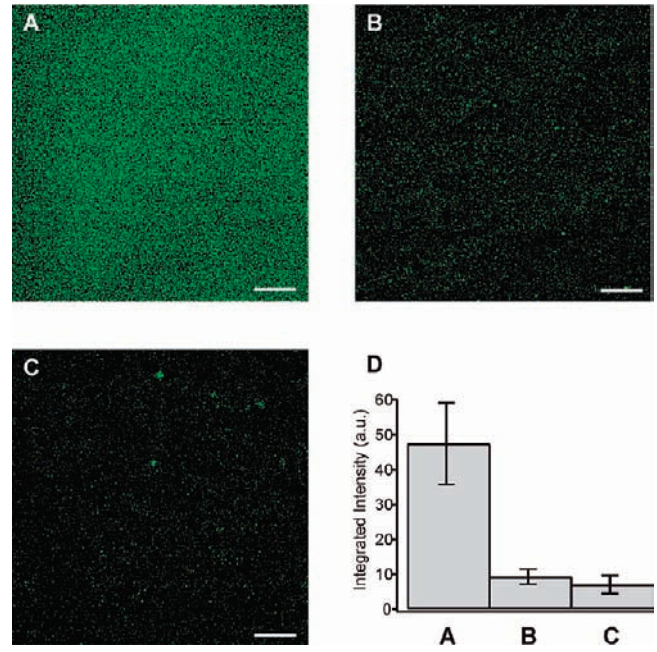

Figure 7. Quantification of the efficiency of **1** to immobilize BSA on gold surfaces using quantitative fluorescent microscopy. (A) Micrograph of Alexa 488 labeled BSA coupled ot SAM of **1** on gold using UV irradiation. (B) Nonspecific binding of BSA on SAMs of **1** in the absence of UV activation. that the Bni SAMs can be used to link proteins to gold surfaces via photoactivation.

CONCLUSION

A versatile method for construction of protein conjugates using optically induced activation has been developed. We have tested the concept by showing that both light activation and a nucleophile are necessary for the reaction to proceed. As a proof of principle, we have used this chemistry to functionalize gold nanoparticles. The reaction has been investigated by the use of UV−vis spectroscopy and TEM imaging of the aggregated gold nanoparticles.

The method is simple to use, and involves only one light-induced reaction step to activate a surface for protein attachment. In contrast to Sharpless-type click chemistries (*23*−*25*), no

auxiliary reagents or heavy metal ions are needed, and in contrast to activated ester strategies such as NHS esters (*10*), the reactive species used here, the Bni group is stable for long periods of time (years of shelf-life time). As a proof of principle, we successfully coupled proteins to gold surfaces. By careful selection of the end group, Bni might also be employed to attach protein or other nucleophile-containing molecules on silicon surfaces or on polymers.

We foresee that this concept can, in a more general way, be used both for the attachment of nucleophiles to surfaces and for the subsequent release of active components by an external stimuli in the form of light. Also, we expect that this photoactive linker molecule will allow for a simple immobilization of arrays of DNA or proteins on surfaces integrated in advanced devices such as microfluidic channels.

Received January 6, 2010; Revised Manuscript Received April 27, 2010

Cationic nucleoside lipids (CNLs) derived from 5-nitroindole and 4-nitroimidazole bases were prepared from D-ribose by using a straightforward chemical synthesis. TEM experiments indicate that these amphiphilic molecules self-assemble to form supramolecular organizations in aqueous solutions. Electrophoresis and standard ethidium bromide (EB) fluorescence displacement assay shows that CNLs are able to bind siRNA. We demonstrated that both the nature of the universal bases and the stereochemistry of the anomeric position (α, β) have an impact on the CNLs-siRNA complex formation. Correlations among chemical structure, stereochemistry, siRNA knockdown effect, and binding affinities for all the compounds were shown and analyzed with a simple molecular modeling study. The best binding affinities for siRNA were found for the β anomer of the 5-nitroindole CNL which exhibits protein knockdown activity similar to the standard siPORT NeoFX positive control. It is noteworthy that no significant cytotoxicity at the tested concentration was observed for the novel CNLs.

INTRODUCTION

Currently, there is substantial interest in the design of bioinspired molecules having a double functionality based on the combination of nucleic acids and lipid characteristics (*1*−*4*). Nucleoside lipids are emerging as tools for constructing both supramolecular assemblies and nucleic acid delivery applications. The 2′-deoxyribosyl derivatives of 3-nitropyrrole and 5-nitroindole represent a new class of compounds known as universal bases. When incorporated into oligonucleotides, they show little discrimination in their base-pairing properties, as they have no hydrogen bonding capability. Recently (*5*), we have described the synthesis and siRNA transfection activities of cationic nucleoside lipids (CNLs) **A** and **B** based on a 3-nitropyrrole universal base (Figure 1). The encouraging biological results with such derivatives prompt us to further investigate the potential of new CNL analogues containing the 5-nitroindole and 4-nitroimidazole universal bases (Figure 2). We hypothesized that the chemical structure of CNLs could have an impact on the siRNA/CNL stability and siRNA delivery. Indeed, puzzling questions are emerging from the siRNA/CNL complexes, for example, how can the structure and/or the stereochemistry of the universal base affect the formation siRNA/CNL or the transfection properties? To address these issues, the following two structural parameters were modulated: (i) the nature of the universal bases (5-nitroindole and 4-nitroimidazole) and (ii) the stereochemistry of the anomeric position.

The target CNLs shown in Figure 2 possess three key components: a quaternized amine at the 5 position, two oleic acid chains linked at the 2 and 3 positions, and a 5-nitroindole or a 4-nitroimidazole attached at the anomeric position. As for the 3-nitropyrrole derivatives **A** and **B** shown in Figure 1, the cationic charge of these new analogues is responsible for electrostatic binding to the nucleic acids, whereas the oleyl chains

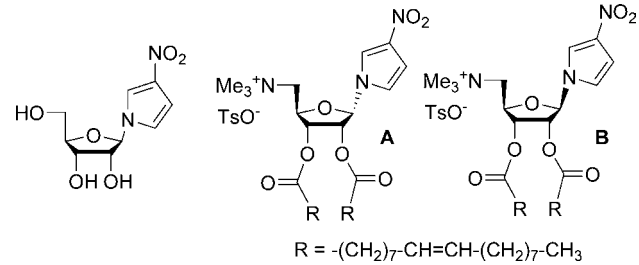

Figure 1. Chemical structures of the (β) universal nucleobase (left) and both CNLs (tosylate salts of 1′-(2′,3′-dioleyl-5′-trimethylammonium-α-D-ribofuranosyl)-3-nitropyrrole **A** and 1′-(2′,3′-dioleyl-5′-trimethylammonium-β-D-ribofuranosyl)-3-nitropyrrole **B** (*2*).

contribute to stabilization of the resulting nucleic acid−nucleolipid assembly through hydrophobic chain−chain interactions.

The 5-nitroindole universal base was selected because 1-(2′-deoxyribofuranosyl)-5-nitroindole has been shown to be generally less destabilizing than 1-(2′-deoxyribofuranosyl)-3-nitropyrrole analogue, with only a 2 °C decrease in melting temperature (T_m) value when incorporated toward the end of a 17mer duplex and 5 °C in the middle (*6*). It was suggested that this stabilization occurs because this nucleoside is sufficiently large to be able to intercalate into the opposite strand. The crystal structure of 1-(2′-deoxyribofuranosyl)-5-nitroindole shows that the base residues stack in columns, with overlap between each aromatic base (*7*). Also, 1-(2′-deoxyribofuranosyl)-5-nitroindole is nondiscriminating toward the natural DNA bases, with a T_m range of 3 °C, similar to that observed with the 3-nitropyrrole analogue.

Herein, we report the synthesis, physicochemical properties, and siRNA transfection efficiency of the universal-base nucleolipids, 2′,3′-dioleyl-5′-*O*-(α,β)-D-ribofuranosyl-5-nitroindole and 2′,3′-dioleyl-5′-*O*-(α-D-ribofuranosyl-4-nitroimidazole.

MATERIAL AND METHODS

Unless noted otherwise, all starting materials were purchased from Sigma-Aldrich, Acros, or Alfa Aesar and used as received.

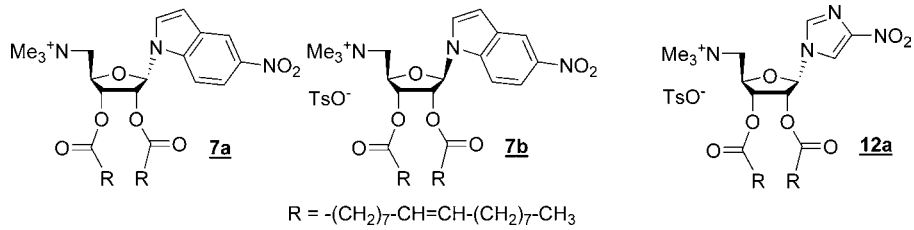

Figure 2. Chemical structures of the universal cationic nucleoside lipids (CNLs) used in this study. Tosylate salts of 1-(2,3-dioleyl-5-trimethylammonium-α-D-ribofuranosyl)-5-nitroindole and 1-(2,3-dioleyl-5-trimethylammonium-*β*-D-ribofuranosyl)-5-nitroindole, **7a** and **7b**, respectively. 1-(2,3-dioleyl-5-trimethylammonium-*β*-D-ribofuranosyl)-4-nitroimidazole) **12a**.

Some solvents were distilled under argon over appropriate drying agent: tetrahydrofuran and diethylether over sodium/benzophenone, dichloromethane over $CaCl_2$. Unless otherwise stated, the other solvents were used as commercially available. All compounds were characterized by ^1H NMR, ^{13}C NMR, and mass spectroscopy. 250 and 62.5 MHz ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AC 250. The spectra were taken at 20 °C and referenced against residual proton-solvent signals (^1H, $CDCl_3$, 7.26 ppm; and ^{13}C, 77 ppm). The ^1H NMR coupling constants (*J*) are reported in hertz. ESI-MS and elemental analyses were performed at the spectropole of the Faculté des Sciences et Techniques de Saint Jerôme, Marseille, France. Electrospray ionization mass spectra (ESI-MS) were recorded with an API///Plus sciex triple quadripole spectrophotometer in the positive mode. Elemental analyses were recorded with a Thermo Finnigan EA 1112 elemental analysis apparatus driven by the Eager 300 software. TEM microscopy experiments were performed on a Philipps CM10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon coated grids). Analytical thin layer chromatography (TLC) was performed on precoated glass plates with Kieselgel 60F254 neutral with aluminum support plate (0.25 mm layer thickness), SDS. The developed plates were air-dried and exposed to UV light and/or sprayed with a solution of cerium sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid and heated at 150 °C. Preparative thin layer chromatography was performed on glass plates with Merck silica gel 60F-254 as the adsorbent (layer thickness 2 mm or 1 mm). Column chromatography was performed on Merck silica gel 60 (0.063−0.200 mm). Melting point (mp) were measured with an Electrothermal 9100. The synthesis of compounds **1**, **2**, and **2′** is described in the Supporting Information.

1-(5-*O*-*tert*-Butyldimethylsilyl-2,3-*O*-isopropylidene-D-ribofuranosyl)-5-nitroindole, 3. *Step 1.* Carbon tetrachloride (433 μL, 4.49 mmol) was added to a stirring solution of **2** (872 mg; 2.87 mmol) in anhydrous THF (10 mL). The solution was cooled to −70 °C and hexamethylphosphorous triamide (700 μL, 3.82 mmol) was added dropwise for 5 min, and the mixture was allowed to stir at the same temperature for 5 min. The resulting chewy compound was allowed to warm to room temperature and further stirred for 2 h. The solvent was evaporated and the residue dissolved in diethyl ether. The resulting insoluble material was removed by decantation and the organic layer was evaporated to give the crude compound **3** as an orange oil.

Step 2. To a cooled solution (0 °C) of 5-nitroindole (906 mg, 5.59 mmol) dissolved in anhydrous acetonitrile (9 mL) was added NaH (60%, 223 mg, 5.61 mmol); the solution was stirred at room temperature for 30 min. To the resulting bright yellow solution, the chlorosugar obtained from the first step was dissolved in anhydrous acetonitrile and transferred via canula. The reaction mixture was then warmed to room temperature and stirred for 40 h. The mixture was poured into H_2O (50 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The organic layers were combined and successively washed with saturated aqueous NH_4Cl and saturated aqueous NaCl. The organic layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was purified by flash column chromatography (90/10: cyclohexane/EtOAc) to give **3** (502 mg, 39%) as a yellow oil (anomeric mixture). ^1H NMR ($CDCl_3$): *δ* 8.57 (1H, d, $J = 2.14$ Hz, H_4); 8.11 (1H, dd, $J = 2.14$ Hz, $J = 9.12$ Hz, H_6); 7.60 (1H, d, $J = 3.43$ Hz, H_3); 7.30 (1H, d, $J = 9.12$ Hz, H_9); 6.71 (1H, d, $J = 3.43$ Hz, H_8); 6.48 (1Hα, d, $J = 4.11$ Hz, $H_{1'\alpha}$); 6.03 (1H*β*, d, $J = 3.38$ Hz, $H_{1'\beta}$); 4.96 (1H, d, $J = 6.06$ Hz, $H_{2'}$); 4.88 (1H, dd, $J = 4.15$ Hz, $J = 6.06$ Hz, $H_{3'}$); 4.45 (1H, m, $H_{4'}$); 3.95 (1H, dd, $J = 2.14$ Hz, $J = 11.05$ Hz, $H_{5'}$); 3.83 (1H, dd, $J = 2.14$ Hz, $J = 11.05$ Hz, $H_{5''}$); 1.43 (3H, s, CH_3−C); 1.30 (3H, s, CH_3−C); 1.00 (9H, s, $(CH_3)_3$−C); 0.15 (6H, s, $Si(CH_3)_2$). ^{13}C NMR ($CDCl_3$) *δ*: 138.34 (C_2); 129.81 (C_5); 128.14 (C_7); 118.08 (C_9); 117.30 (C_6); 113.29 (C_4); 109.24 (C_3); 104.16 (C−$(CH_3)_2$); 100.57 (C_8); 88.33 ($C_{1'}$); 82.76 ($C_{2'}$); 82.74 ($C_{4'}$); 80.53 ($C_{3'}$); 66.06 ($C_{5'}$); 29.69 (CH_3−C); 25.89 (CH_3−C); 25.71 ($(CH_3)_3$−C); 18.13 ($(CH_3)_3$−C); −5.46 ($Si(CH_3)_2$). 1-(2,3-*O*-Isopropylidene-D-ribofuranosyl)-5-nitroindole, 4a and 4b. To a solution of **3** (596 mg, 1.49 mmol) in dry THF (5 mL) was added TBAF (1 M in THF) (3 mL, 2.98 mmol) at room temperature, and the mixture was stirred for 30 min. The solution was evaporated under reduced pressure, diluted with CH_2Cl_2, and washed with brine. The organic layer was dried on $MgSO_4$ and evaporated under reduced pressure. The crude product was purified by flash column chromatography (cyclohexane/EtOAc: 70/30) to give the anomer α **4a** (198 mg, 54%) as a yellow oil and the anomer *β* **4b** (43 mg, 11%) as a yellow oil.

Tosylate Salt of 1-(2,3-Dioleyl-5-trimethylammonium-α-D-ribofuranosyl)-4-nitroimidazole, 12a. Compound **11a** (80 mg, 0.28 mmol) was converted to **12a** according to the procedure described for **7a** to give **11a** as a yellow oil with quantitative yield. ^1H NMR ($CDCl_3$): δ 7.95 (1H, d, $J = 1.46$ Hz, H_5); 7.68 (3H, d+m, $J = 7.90$ Hz, $H_{Ar} + H_2$); 7.15 (2H, d, $J = 7.90$ Hz, H_{Ar}); 5.76 (1H, d, $J = 5.50$ Hz, $H_{1'}$); 5.33 (4H, m, $2 \times CH_2-CH=CH-CH_2$); 4.91 (3H, m, $H_{2'} + H_{3'} + H_{4'}$); 3.37 (9H, s, NCH_3^+); 3.30 (2H, m, $H_{5'} + H_{5''}$); 2.33 (3H, s, CH_3-C_{Ar}); 2.15 (4H, m, CH_2-CO); 1.99 (8H, m, $2 \times CH_2-CH=CH-CH_2$); 1.50 (4H, m, $2 \times CH_2-CH_2-CO$); 1.26 (40H, m, 2×10 CH_2); 0.87 (6H, t, $J = 6.16$ Hz, $2 \times CH_3$). MS (GT, FAB^+): 815 $[M-TsO^-]^+$. Anal. Calcd. 65.63; H, 9.11; N, 5.62; Found C, 65.69; H, 9.19; N, 5.67.

Vesicle Preparation. 1 mg/mL of compounds **7a** or **7b** was dissolved in chloroform. The solution was evaporated and dried under vacuum for 2 h. 1 mL of DI water was added, and the solution was hydrated overnight at 4 °C. The resulting solution was sonicated for 20 min prior to any measurements.

Electrophoresis Studies. Electrophoresis studies were conducted in 2% agarose gels containing ethidium bromide in a 0.5 Tris-Borate-EDTA buffer. Cationic lipoplexes were prepared 10 min before use. 250 ng of siRNA (21 bp, Eurogentec SR-CL010−005) was mixed with lipids at different ratios (final volume is 20 μL). Then, 20 μL of each lipoplexes (samples) were mixed with 4 μL of loading buffer (glycerol 30%, v/v), bromophenol blue 0.25% (w/v), and xylene cyanol 0.25 (w/v) and subjected to agarose gel electrophoresis for 20 min at 100 V. The electrophoresis gel was visualized and digitally photographed using a G.BOX camera.

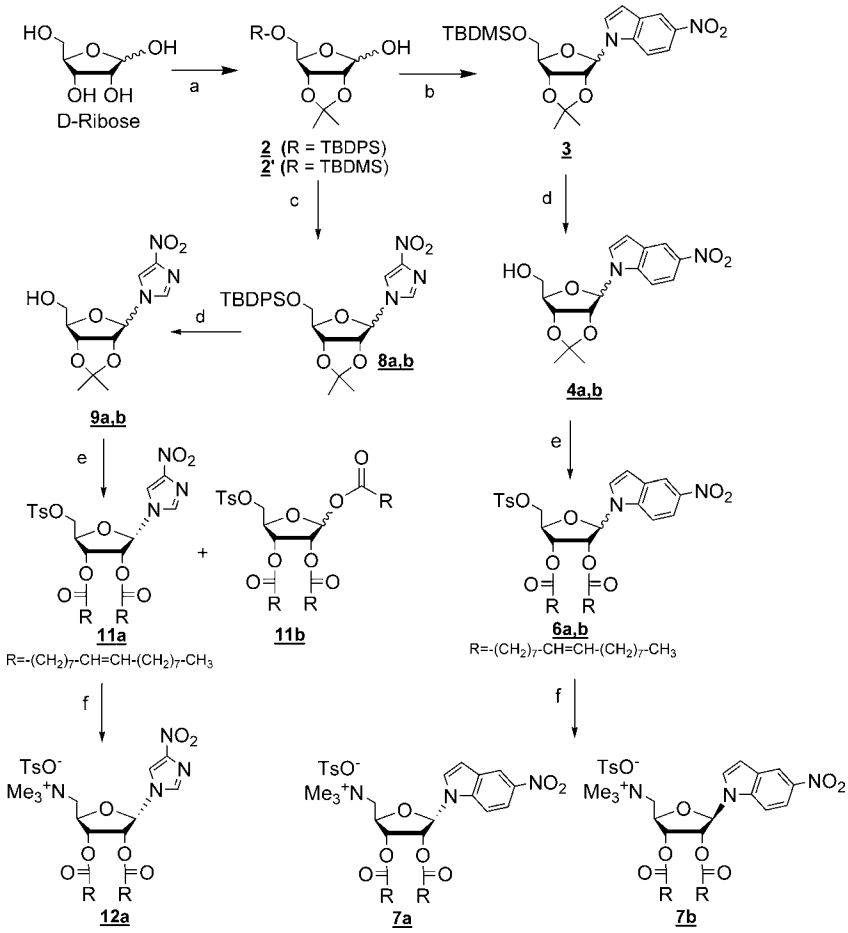
Exclusion Assay. Ten milliliters of EB (10 mg/mL) was diluted in 580 mL in deionized water. Ten microliters of 90 mg/mL solution of siRNA was added. A varying amount of lipid (depending on the siRNA/lipid ratio required) was added to the EB solution finally. The solutions were mixed on a benchtop vortex, and the fluorescence was measured ($\lambda_{exc} = 470$ nm, $\lambda_{em} = 600$ nm; 0.5 cm path length glass cuvette). The fluorescence was expressed as the percentage of the maximum fluorescence signal when EB was bound to the siRNA in the absence of lipid.

ζ Potential and Size Distribution of 7b CNLs (with and without siRNA). Experiments were realized with N/P ratio of 10 (CNLs/siRNA).

Transmission Electronic Microscopy (TEM). TEM experiments were performed on vesicle samples **7a**, **7b**, and **12a** using a Philips CM 10 (negative staining with ammonium molybdate 1% water, Cu/Pd carbon coated grids). Both (α) and (β) anomer nucleolipids formed small vesicles with diameters between 40 and 60 nm, respectively. Cationic lipoplexes were prepared as described above and were visualized by negative staining microscopy. Ten microliter aliquots of samples (either liposomes or lipoplexes) were transferred to a carbon-coated grid for 10 min. Then, the samples were dried and stained with 2.5% (w/w) of uranyl acetate for 30 s. The specimens were observed with a Hitachi H 7650 electron microscope. Both (α) and (β) anomer nucleolipids formed small vesicles with diameters between 40 and 60 nm, respectively.

siRNA Transfection. Trypsine adherent cells were diluted in normal growth medium to 1×10^5 cells per milliliter. The transfectant reagent was diluted in serum free medium and incubated at room temperature for 10 min before use. Next, siRNA (GAPDH siRNA or negative control siRNA, Ambion) was diluted in serum free medium. The siRNA and the tranfection reagent were mixed, incubated for 10 min at room temperature, and dispensed into a culture plate. Depending on the experimental design, the ratio of lipid, siRNA, and incubation time was varied. Cell suspension was overlayed onto the transfection mixture, then incubated at 37 °C and 5% CO_2. Assays for gene knockdown were assessed after 48 h depending on the experimental protocol.

The gene knockdown assay performed was KDalert GAPDH Assay (Ambion) following the manufacturer's protocol. Briefly, 48 h after siRNA transfection, the culture medium was aspirated from transfected cells; 200 μL KDalert Lysis Buffer was added to each sample well and the mixture incubated at 4 °C for 20 min to lyse the cells. The cell lysate was pipeted up and down 4−5 times to homogenize the lysate. 10 μL aliquots of each lysate or GAPDH enzyme dilution (including the GAPDH working stock) were transfered to the wells of a clean 96 well plate. 90 μL aliquots of KDalert master mix were added to each sample using a multichannel pipettor to dispense the KDalert master mix quickly. The increase in fluorescence of the samples was measured at room temperature.



Cytotoxicity. Cytotoxicity was assessed using both a formazan-based proliferation assay (CellTiter 96 AQueous One Solution Cell Proliferation Assay kit, Promega) and a total protein-based assay (Pierce). Briefly, CHO cells were seeded onto a 24 well plate with an appropriate density of 1×10^6 cells per well. After 48 h, the MTS substrate was added to each well, and the plate was incubated for 4 h at 37 °C in a humidified, 5% CO_2 incubator. The amount of soluble formazan produced by cellular reduction of the substrate MTS was recorded at 490 nm using a multiwell plate reader. For the total protein based proliferation assay, cells were lysed at the same time as transfection efficiency was assayed. 10 μL aliquots of lysates were transferred to a separate multiwell plate. Total protein contents were assessed using the Coomassie Blue protein kit (Pierce, Rockford, IL) following the manufacturer protocol. Negative and positive controls were nontreated cells and commercial lipids treated cells, respectively. The proliferation results were expressed as percentages of nontreated cells.

Molecular Modeling. In order to obtain some information about the structure−activity of these universal base analogue nucleolipids, modelization of the five tested compounds was performed at the density functional theory (DFT) level (B3LYP) with a 6-31G* split-valence basis set (*8, 9*). Cavity surface area (CSA) and (polarized solute)-solvent (PSS) are determined within the same methodology in a solvent, water, using a PCM model (*10*). Briefly, cavity surface area (CSA) and (polarized solute)-solvent (PSS) were calculated for all the compounds as well as the quotient MC = |PSS/CSA|.

RESULTS AND DISCUSSION

Synthesis. The (α) and (β) anomers of 2′,3′-dioleyl-5′-*O*-D-ribofuranosyl-3-nitroindole, **7a** and **7b**, respectively, and the (α) anomer 2′,3′-dioleyl-5′-*O*-D-ribofuranosyl-4-nitroimidazole, **12a**, were synthesized from D-ribose as shown in Scheme 1. Accordingly, 5-*O*-*tert*-butyldimethylsilyl-2,3-*O*-isopropylidene-D-ribose **2** and 5-*O*-*tert*-butyldimethylsilyl-2,3-*O*-isopropylidene-D-ribose **2′** were prepared in two steps (see Supporting Information) from D-ribose following a published procedure (*11*). Next, the stereoselective chlorination of the protected

Scheme 1[a]

[a] Reaction conditions: (a) (i) acetone, $CuSO_4$, **1** (94%), (ii) TBDMSCl or TBDPSCl, DMAP, TEA; **2** (35%) and **2′** (46%); (b) (i) CCl_4, HMPT, (ii) 5-nitroindole, NaH, CH_3CN; **3** (40%); (c) (i) CCl_4, HMPT, (ii) 4-nitroimidazole, NaH, CH_3CN; **8a** (22%) and **8b** (11%); (d) TBAF dry THF; **4a/4b** (5/1; 65%); **9a** (46%), **9b** (64%); (e) (i) TsCl, TEA, DCM; **5a** (94%), **5b** (56%) and **10a** (42%), **10b** (46%), (ii) TFA/H_2O, quant., (iii) Oleic acid, DCC/DMAP; **6a** (65%), **6b** (73%), and **11a** (32%); (f) NMe_3, CH_3CN 60°C, 40 h, quantitative.

sugars **2** and **2′** with CCl_4 and hexamethylphosphorus triamide (HMPT) (*12*) was followed by coupling with the anions of 3-nitroindole pyrrole or 4-nitroimidazole. Deprotection of the resulting derivative **3** and **8** afforded the anomeric mixture of (α) **4a** (53%), (*β*) **4b** (18%), and (α) **9a** (53%), (*β*) **9b** (18%). As described previously for nitropyrrole derivatives, the (α) forms were found to be the major isolated polar isomers. The relative stereochemistry of these compounds was assigned by ^{1}H NMR when compared to the chemical shifts of the acetonide methyl group as well as those of the H-1′ (*13*). The anomeric pairs of compounds **4** and **9** were then separately tosylated with TsCl/TEA, deprotected with TFA/H_2O, and coupled with oleic acid using DCC/DMAP to afford the nucleolipids **6a**, **6b**, **11a**, and the side product **11b**. The latter was isolated and characterized by mass spectra. Unfortunately, we were unable to isolate the *β* anomer of **11a**. Indeed, the instability of the sulfonated intermediates has been demonstrated for adenosine analogues with intramolecular cyclization of the 5′-carbon and N3-position of the adenine ring (*14, 15*). It is likely that such an intermolecular cyclization occurs in the case of the nitroindole intermediate **11a**.

Finally, compounds **6a**,**b**, and **11a** were reacted with trimethylamine for two days in a sealed tube to afford the target nucleolipids **7a**, **7b**, and **12a**.

Complexation Studies. In order to determine whether the CNLs **7a**, **7b**, and **12a** bind nucleic acids, we performed (i) siRNA (21 bp) gel electrophoresis and (ii) standard ethidium bromide (EB) fluorescence displacement assays with siRNA (21 bp) as a model system (*16*). The siRNA gel electrophoresis was performed on compounds **7a** and **7b**; as shown in Figure 3, a full complexation occurs for a charge ratio **7b**/siRNA (*β* anomer) of 10/1 (Figure 3 column 6), whereas in the case of the **7a**/siRNA (α anomer), free siRNA is observed for all the ratios investigated (Figure 3 columns 8−12).

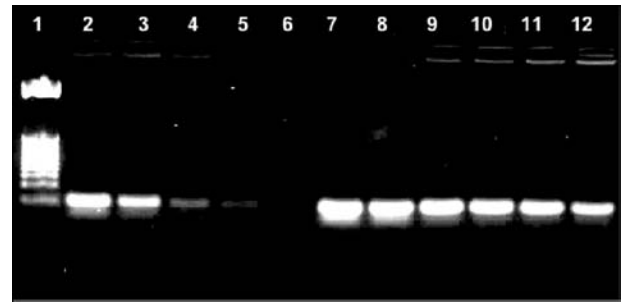


Figure 3. Electrophoretic mobility of **7b** (*β*) and **7a** (α). The lines represent the following (*1*): DNA stepladder 25 pb (*2*−*6*), siRNA with **7b** at different ratios N/P (2, 4, 6, 8, 10 respectively (*7*)), siRNA (*8*−*12*), siRNA with **7a** at different ratios N/P (2, 4, 6, 8, 10, respectively).

The binding affinity of siRNA by CNLs was also investigated by the fluorescence titration of EB with a premixed solution of siRNA and various concentrations of CNLs. In the presence of siRNA, the fluorescence emission of EB is enhanced relative to that in water as a result of EB intercalation between the RNA base pairs. The subsequent addition of CNLs to the siRNA−EB solution results in CNL binding to RNA and displacement of

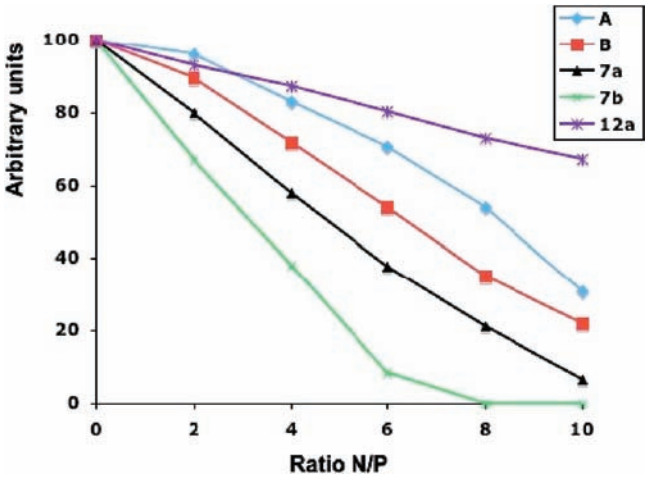

Figure 4. EB exclusion assays with **A**, **B**, **7a**, **7b**, and **12a** in the presence of siRNA (fluorescence intensity arbitrary units versus N/P charge ratio).

EB from the helix to water, which induces a decrease in fluorescence intensity. As shown in Figure 4, the fluorescence intensity decreases rapidly for all the CNLs investigated, including both 5-nitroindole derivatives **7b** (β), **7a** (α), the 4-nitroimidazole **12a**, and nitropyrrole CNLs previously reported (α,β anomers, compounds **A** and **B**, respectively). Interestingly, with a total decrease in fluorescence for N/P ratios higher than 8, the β anomer 5-nitroindole derivative **7b** exhibits the best binding affinity of the CNL series. The α anomer **7a**, which forms **7a**/siRNA complex at higher N/P ratios (higher than 10) compared to β analogue **7b**, shows a lower binding affinity indicating that stereochemistry of the anomeric position has an impact on the complexation with siRNA double helix. Likewise, a higher binding affinity is observed for nitropyrrole CNL **B** (β) compared to CNL **A** (α) confirming the importance of anomeric configuration in the complex formation. As expected, the nature of the CNL universal base has an impact on the formation of CNLs/siRNA complexes. With no residual EB fluorescence for ratio of 10/1, the 5-nitroindole derivatives **7b** (β) and **7a** (α) feature the best binding affinity, whereas 4-nitroimidazole **12a** is the least efficient of the CNLs. It is well-known that intermolecular overlapping of p-orbitals in π-conjugated systems causes $\pi-\pi$ interactions. Hence, these interactions become stronger as the number of π-electrons increases. Accordingly, the best binding affinity observed for the 5-nitroindole universal base can be explained by the 10 π electrons, whereas the 6 π electrons of both nitroindole and nitropyrrole induce fewer $\pi-\pi$ interactions.

Electronic Microscopy Studies, ζ Potential, and Size Distribution. TEM experiments were performed on vesicle samples **7a**, **7b**, and **12a** using a Hitachi H 7650 electron microscope (negative staining with 2.5% (w/w) of uranyl acetate). Both (α) and (β) anomer nucleolipids formed small vesicles with diameters between 40 and 60 nm, respectively (Supporting Information Figure S1). TEM experiments were also performed on samples prepared with siRNA. For these experiments, the CNL vesicles were incubated for 15 min in the presence of siRNA (21 bp). TEM micrographs (Figure 5) of the CNL-siRNA systems exhibited multilamellar vesicles (which are not observed in the case of CNL vesicles; see Supporting Information Figure S2) suggesting that the siRNA molecules are entrapped within the vesicular structures. ζ-potential and size distribution were determined for the CNL vesicles of **7b** with and without siRNA. As expected, the results show a significative decrease of ζ-potential (from 74 to 36.7 mV), as well as an increase of size distribution (from 108 to 360 nm) in the presence of siRNA suggesting its complexation with the CNL vesicles of **7b**.

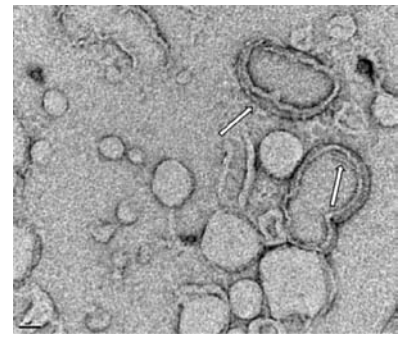

Figure 5. TEM image of CNL-siRNA systems obtained with **7b** (bar = 50 nm).

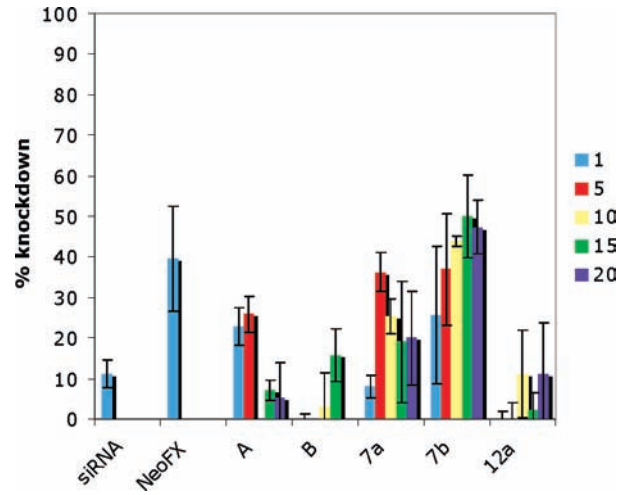

Figure 6. siRNA transfection results after 48 h in HepG2 as a function of nucleolipid (**A**, **B**, **7a**,**7b**, and **12a**) and N/P mole ratio. $n = 3$.

Transfection. The transfection of siRNA with **A**, **B**, **7a**, **7b**, and **12a** was next performed to evaluate the reduction in protein synthesis. Experiments used glyceraldehyde-3-phosphate dehydrogenase (GAPDH) siRNA (Ambion) on human liver (HepG2) cell line, and the complete details can be found in the Supporting Information. siRNA transfection results were accessed after 48 h as a function of both anomer and cation/anion (N/P) mole ratio. In each experiment, controls using GAPDH siRNA and negative control siRNA were used at 30 mM. siPORT NeoFX was used as the positive control, and the previously evaluated 3-nitropyrrole nucleolipids A and B (*2*) (Figure 1) were tested again in the experiment. As shown in Figure 6, siRNA knockdown was observed for most nucleolipids, with values similar to the positive control for compounds **7a** and **7b**. The transfection activity of **7a** was significant vs siRNA with N/P ratios of 5 and 10, whereas for **7b**, it was significant with N/P ratios of 5, 10, 15, and 20. Interestingly, the 5-nitroindole CNL **7b** (β), which features the best binding affinity for siRNA, is also globally the most efficient in term of transfection. In addition, none of the CNLs showed a significant cytotoxicity at these concentrations, similar to that to the negative control (Supporting Information Figure S3).

Molecular Modeling. A basic molecular modeling method described in the section above was used to calculate the MC quotient (MC = |PSS/CSA|). This quotient represents the stabilization in kilojoules per mole per surface unit; it reflects the system's capacity to maintain its cohesion, i.e., the smaller MC values reflect lower membrane cohesion. As shown in Table 1 with N/P ratios of >5, it can be seen that low MC values are correlated both to better transfection activity (Table 1, line 4)

Table 1. Relationship among MC Quotient, % Knockdown, and Fluorescence Intensity for Compounds A, B, 7a−b, and 12a−b[a]

compounds	**12a**	**A**	**B**	**7a**	**7b**

and to binding affinity (Figure 4). These results confirm that to a certain extent (N/P ratio >5) the lowest membrane cohesion of these series of CNLs vesicles are beneficial for the release and the activities of siRNA in the cytoplasm.

It is known that subtle change such as headgroup nature, headgroup charges, counterion nature, and so forth can dramatically affect the transfection properties (*17, 18*). However, for the first time to our knowledge, the results highlight the impact of both stereochemistry and base nature of these nucleoside amphiphiles, i.e., β anomeric configuration, as well as highly π conjugated bases, is likely to improve the transfection efficacy. These findings could provide a rationale for the design of universal base nucleoside amphiphiles for siRNA delivery.

CONCLUSION

In summary, we have synthesized and characterized several new universal base CNLs for siRNA delivery. The results obtained by gel electrophoresis and ethidium bromide exclusion assays clearly indicate that (i) the nature of the universal base (5-nitroindole and 4-nitroimidazole) and (ii) the stereochemistry of the anomeric position (α, β) have an impact on the CNLs-siRNA complex formation. We observed that the CNL featuring the nitroindole as universal base exhibits the best binding affinity for siRNA. We also demonstrated that higher binding affinities for siRNA are observed for β anomers of both nitroindole and nitropyrrole CNLs. Molecular modeling has shown that calculation of simple values (MC) reflecting the system's capacity to maintain its cohesion can be correlated to both binding affinities and transfection efficiencies. On the basis of this rational approach, work is in progress to synthesize and improve the efficacy of new, original cationic nucleoside amphiphiles for siRNA delivery.

Received January 9, 2010; Revised Manuscript Received April 7, 2010

Functionalization of gold nanoparticles (AuNPs) with both a targeting peptide (an analogue of the peptide Bombesin) and a drug peptide ligand (an analogue of the RAF peptide) with the aim of improving selectivity in the delivery of the conjugates as well as the antitumor activity is described. Studies on the internalization mechanism of peptide−AuNP conjugates and viability of cells were carried out. An enhancement of the activity and selectivity of the peptide multifunctionalized conjugates was observed.

INTRODUCTION

Gold nanoparticles (AuNPs) have been extensively used in biological applications because of their biocompatibility, dimension, ease of characterization (*1, 2*), and rich history of surface chemistry. These features make these structures easily exploitable to meet the requirements of biomedical applications (*3*).

The size of AuNPs can be controlled from a few nanometers up to tens of nanometers, thereby placing them at dimensions that are smaller than or comparable to those of a cell (10−100 μm), a virus (20−450 nm), a protein (5−50 nm), or a gene (2 nm wide and 10−100 nm long). These sizes imply that they could get close to a biological target of interest (*4*). For example, AuNPs can be used to deliver a cargo, such as an anticancer drug, or a cohort of radionuclide atoms to a targeted region of the body, such as a tumor (*4*). On the other hand, AuNPs have been used in photothermal therapy for the destruction or molecular surgery of cancer cells or tumors. When irradiated with a focused laser in the near-infrared region (NIR) of suitable wavelength, targeted aggregates of AuNPs, nanorods, or nanoshells can kill bacteria (*5*) and cancer cells (*6*).

Thus, AuNPs provide an excellent intracellular targeting vector for two reasons: they can be synthesized routinely in appropriated sizes adequate for delivery varying from 0.8 to 200 nm with <10% size dispersity and can be modified with a large collection of small molecules, peptides, proteins, DNA, and polymers (*7*).

Surface modifications of AuNPs are often used to increase the functionality of nanoconjugates. These nanoparticle modifiers/conjugants include various peptides which can specifically recognize a target, thus improving cell type uptake (*8*) and ensuring that the AuNPs reach the desired target. Peptides attached to a single nanoparticle make the individual targeting signals more accessible to cell receptors (*9*), thus allowing them to participate in ligand−receptor interactions (*4, 10*).

The design and development of tumor-specific nanoparticles could significantly amplify the delivery capacity to a specific target of interest without affecting healthy cells. The target specificity of nanoparticles could be imparted by tagging with certain biovectors, which navigate them to particular organs or sites under in vivo conditions. The targeting vectors most commonly used are monoclonal antibodies and receptor-specific peptides. Monoclonal antibodies, due to their larger sizes, show poor in vivo mobility and thus delayed and reduced uptake over the desired target (*11–13*). Moreover, these antibodies are highly immunogenic and as such produce harmful side effects. In sharp contrast, peptides, which are smaller, offer various advantages, namely, rapid blood clearance, ease in the penetration of the tumor's vascular endothelium, increased diffusion rates in tissue, and low immunogenicity. Receptors for peptides are highly expressed on a variety of neoplastic and non-neoplastic cells. Furthermore, receptor-targeting peptides have shown a high level of internalization within tumor cells via receptor-mediated endocytosis. The capacity to internalize probes within tumor cells is crucial for delivering maximum payloads to tumor cells (*14–16*). These attractive physical properties coupled with their smaller size make peptides ideal candidates for developing new target-specific nanoparticles. In a recent paper, Chanda et al. conjugated a bombesin/gastrin-releasing peptide (BN/GRP) analogue to gold nanorods, which are internalized in cancer cells for the development of in vivo molecular imaging agents for cancer (*17*).

In the present study, we functionalized AuNPs with both a targeting peptide and a drug peptide ligand with the aim to improve not only the selectivity of the conjugates, but also their antitumor activity over the free drug. Since AuNPs conjugated to a targeting ligand have a higher capacity to enter cells, carrying the antitumor peptide and thus increasing its local concentration will, in turn, enhance the antitumor activity. BN was chosen as a targeting ligand for bombesin gastrin releasing

Scheme 1. Multifunctionalization of Gold Nanoparticles with a Targeting Peptide (BN) and an Antitumoral Peptide (RAF)[a]

[a] BN recognizes the GRP receptor overexpressed in HeLA cells and not in the neuroblastoma line SHSY-5Y. The recognition mediates the penetration into HeLa cells.

peptide receptor (GRPr), which has been found to be overexpressed in prostate, breast, small cell lung, and cervical cancer (*14–20*). Furthermore, AuNPs were functionalized with the drug peptide ligand RAF analogue which inhibits Rb-Raf-1 binding in vivo and therefore inhibits tumor growth and angiogenesis (*21*). In addition, AuNPs were multifunctionalized with a mixture of both peptides with the goal of implementing the targeting vehicle with antitumor activity.

The size of AuNPs may affect the cell permeability as well as toxicity. Taking into account these relevant points in this study, we chose 20-nm-diameter gold nanoparticles for three reasons: (i) they possess a widespread organ distribution (*22–24*) which is very relevant for future drug delivery applications, (ii) they have higher penetration in cells with respect to bigger AuNP (>70 nm) (*25*), and last (iii) AuNPs of this size were reported to pose no inherent toxicity to different cell lines (*26, 27*) and in zebrafish embryos (*28*), in contrast to AuNPs of 1−2 nm that were found to be highly toxic in cell lines (*29, 30*).

The multifunctionalized AuNPs with RAF peptide analogues (Ac-Cys-Ahx-RAF) and BN (Ac-Cys-Ahx-BN) (Scheme 1) were evaluated for their cell internalization properties and in vitro viability in HeLa cells, which overexpress GPRr, and in neuroblastoma SHSH-5Y cells, which do not overexpress these receptors.

RESULTS AND DISCUSSION

BN and RAF Peptide Analogues. A very promising group of small targeting ligands comprises a number of regulatory peptides. Among these, the BN peptide, originally isolated from the skin of a frog, has also shown antitumor activity (*31*). BN-like peptides are known to bind to GRPrs with high affinity and specificity. A high number of GRPrs are overexpressed in various human tumors (*32*) like glioblastoma, small cell lung, gastric, pancreatic, prostate, breast, cervical, and colon cancer (*16, 33–36*), as well as in premalignant cells in the case of prostate, gastric, and lung cancers (*37–39*). These receptors are therefore promising targets for targeted therapy of cancer because of their location on the plasma membrane, which promotes the internalization of the receptor−ligand complex upon binding of a ligand. These findings open up the possibility of applying BN-like peptides as vehicles to deliver cytotoxic drugs (*40, 41*) into tumor cells (*42*). On the basis of studies by Dasgupta et al. (*21*), we selected the RAF peptide as the drug antitumor ligand. The retinoblastoma tumor suppressor protein (Rb) plays a vital role in regulating mammalian cell cycle progression and inactivation of this protein is required for entry into the S phase. Rb is inactivated by phosphorylation upon growth factor stimulation of quiescent cells, thereby facilitating the transition from G_1 to S phase (*43*). Previous studies have shown that the signaling kinase c-Raf (Raf-1) physically and functionally interacts with Rb and contributes to its inactivation, thereby facilitating cell proliferation. Disruption of the Rb-Raf-1 interaction by the 9-amino-acid peptide significantly inhibits Rb phosphorylation and thus cell proliferation (*21*).

Table 1. Structures of the Two Peptides Complexed to Gold Nanoparticles (Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF) and the Two Fluorescently Labeled Peptides (Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF) Used in This Study[a]

name	sequence
Ac-Cys-Ahx-BN	Ac*-Cys-Ahx**-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2
Ac-Cys-Ahx-RAF	Ac*-Cys-Ahx**-Gly-Ile-Ser-Asn-Gly-Phe-Gly-Phe-Lys-NH_2
Ac-Cys-Ahx-Lys (CF)-BN	Ac*-Cys-Ahx**-Lys(CF)-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2
Ac-Cys-Ahx-Lys (CF)-RAF	Ac*-Cys-Ahx**-Lys(CF)-Gly-Ile-Ser-Asn-Gly-Phe-Gly-Phe-Lys-NH_2

[a] * The N-terminus has been acetylated, ** aminohexanoic acid.

The peptides were synthesized using a Fmoc/^{t}Bu solid-phase synthetic strategy (Materials and Methods section) and a free thiol containing Cys was introduced at the end of a spacer to facilitate attachment onto the gold surface (Table 1). As the *C*-terminus of BN is required for high-affinity binding (*44*), the *N*-terminus of the peptide was modified through an aliphatic linker to allow labeling with the cargo (*45*). The spacers have to position the gold conjugate sufficiently far from the GRPr-binding region of BN to prevent hindrance of the binding (affinity) of the BN motif with GRPr (*46, 47*). The optimal hydrocarbon spacer length should vary from 3 to 8 carbon atoms without adversely affecting the resultant binding affinity (*48*). As reported by Hoffman et al. (*49*), an increase in the hydrophobicity of the linker group to excessive levels reduces the receptor-binding affinity (*47, 49, 50*).

Thus, for conjugating both BN and the RAF peptides, a 6-carbon-atom spacer (aminohexanoic acid, Ahx) was selected to be attached to a free thiol containing Cys in order to facilitate anchoring onto the gold surface (Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF) (Table 1). To check whether the free analogue peptides—unconjugated to AuNPs—BN and RAF have the capacity to penetrate the cell, we labeled peptides with a carboxyfluorescein (CF) fluorophore. The CF was introduced into the ε-amino of an additional residue of Lys, which was incorporated at the *N*-terminal of the peptide, before the incorporation of the Ahx residue. Peptides Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF were also produced using a Fmoc/^{t}Bu/Alloc solid-phase strategy (Supporting Information Figure S1, Table S1). The Alloc group was used to block the Lys side chain and was removed once the elongation of the peptide sequence was done to incorporate the CF before the global deprotection and cleavage.

Conjugation of Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF with AuNPs. Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF were conjugated separately and also in an equimolar mixture with a 20 nM AuNP solution to obtain the following conjugates: Ac-Cys-Ahx-BN@AuNPs, Ac-Cys-Ahx-RAF@AuNPs, and Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs (Note: From a peptide point of view, a more correct nomenclature should be Ac-Cys(AuNPs)-Ahx-BN, Ac-Cys(AuNPs)-Ahx-RAF, and Ac-Cys(AuNPs)-Ahx-BN/Ac-Cys(AuNPs)-Ahx-RAF) (Table 1). We then tested the influence of both the targeting and drug ligands on the cell penetration and antitumor activity of these conjugates. AuNPs were obtained via the sodium citrate reduction method (*51–55*), which allows the synthesis of clusters of particles between 6 and 60 nm by adding various amounts of the reducing agent. The AuNPs were characterized by UV−vis (Figure 1) and transmission electron microscopy (TEM)

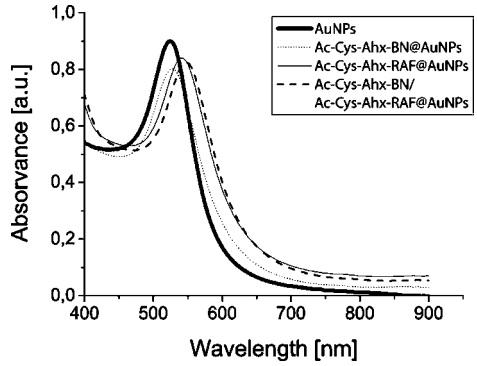

Figure 1. UV−vis spectra of AuNPs and their respective conjugates; a shift in the maximum is representative of the conjugation.

(Supporting Information Figure S3). The peptide-capped AuNPs were prepared by mixing a colloidal gold solution with an excess of peptide to obtain functionalized gold surfaces. The conjugates were characterized by using UV−vis spectroscopy, amino acid analysis (AAA), TEM, and electron energy loss spectroscopy (EELS).

Conjugation of Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF with AuNPs. The same procedure described for the conjugation of Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF to AuNPs was used to prepare Ac-Cys-Ahx-Lys(CF)-BN@AuNPs, Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs, and Ac-Cys-Ahx-Lys(CF)-BN/Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs.

Characterization of Conjugates. *UV−vis Spectroscopy.* The shift of the surface plasmon resonance band (SPR) to a longer wavelength (>522 nm with respect to the SPR of citrate AuNP, Figure 1), as a result of changes in the dielectric properties of the medium in which the AuNPs are found or the presence of materials adsorbed onto their surface, showed the capping of the AuNP surface with the peptide molecules (*4, 56*). The concentration of AuNPs was determined using the molar coefficient of extinction for the 20 nm AuNPs (5.41×10^8 M^{-1} cm^{-1}) as reported in the literature (*57*).

Electron Energy Loss Spectroscopy (EELS). To evaluate the presence of sulfur atoms and thus corroborate the functionalization of the AuNPs with the peptides, spectra between 140 and 220 eV were obtained on the AuNP surfaces for the conjugated and nonconjugated samples. An accurate analysis of the electron energy loss near the edge spectra (ELNES) at the S $L_{2,3}$ edge placed at around 165 eV was performed. All sample spectra show the S $L_{2,3}$ edge slope around 165 eV on the surface of the AuNPs, which is characteristic of peptide functionalization (Figure 2). Given that the nonconjugated sample was assumed to have a low number of S atoms, it was used to evaluate the signal-to-noise ratio in the S $L_{2,3}$ energy region. Table S2 (Supporting Information) shows a comparison of the maximum intensity obtained for the functionalized samples and the control. A slightly higher increment in intensity at 165 eV for the functionalized nanoparticles compared to the bare ones suggests that the thiol moiety of the peptides is attached to the AuNPs.

Determination of the Number of Peptide Molecules/Nanoparticle. To determine the number of peptide molecules per nanoparticle, the conjugates were centrifuged and the supernatants lyophilized, resuspended, and analyzed by HPLC to determine the amount of nonconjugated peptide by interpolation onto a calibration curve (Supporting Information Figure S2). Approximately 40% of the peptides used in the conjugation were attached to the AuNPs. In the case of the equimolar mixture of Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF, 44% of the nonbounded peptide corresponds to Ac-Cys-Ahx-BN and 56% to Ac-Cys-Ahx-RAF. By subtracting the total amount of peptide used for the conjugation, the bounded peptide concentration was found to be about 50 μM and the AuNP solution was about 2 nM (determined spectrophotometrically), which results in a ratio of around 25 000 peptide molecules per AuNP. The large number of peptide molecules/nanoparticle could be attributed to a self-aggregation process that occurs in amphipathic peptides (*58*).

Amino Acid Analysis (AAA). The relationship among the concentrations of the amino acids His, Ile, and Phe give the relative concentration of these two peptides on the AuNPs. The relationship found, 1 for His/Ile and 2 for Phe/His, showed that both peptides were incorporated equimolarly onto the Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs (Supporting Information Table S3).

Cellular Internalization of the Carboxyfluorescinated Peptides as Shown by Confocal Laser Scanning Microscopy (CLSM). Peptides Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF were incubated with HeLa (cervical tumoral cell line which overexpresses GRP receptors) and SHSY-5Y cells for 24 h. As expected, Ac-Cys-Ahx-Lys(CF)-BN was efficiently internalized in HeLa cells and not in SHSY-5Y, while Ac-Cys-Ahx-Lys(CF)-RAF entered both HeLa and SHSY-5Y cell lines, hence showing its lack of specificity (Figure 3).

Accumulation of Peptide−AuNP Conjugates and AuNPs as Shown by CLSM. In order to prove whether the functionalization of AuNPs with BN and RAF—or with both together—favors selectivity in the delivery of the conjugates, the reflection of the nanoparticles was exploited. The red coloration of the nanoconjugates (*9*) of Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF inside cells was observed due to the accumulation and reflection of the AuNP.

An internalization study of the conjugates after 24 h of incubation was performed in the tumoral cell line HeLa and in the SHSY-5Y cell line. The cell membrane was marked in green by WGA, and the nucleus was stained in blue with DRAQ5. The degree of accumulation inside the HeLa cells occurred in the following order Ac-Cys-Ahx-BN@AuNPs > Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs > Ac-Cys-Ahx-RAF@AuNPs (Figure 4). Ac-Cys-Ahx-BN@AuNPs showed the greatest accumulation, suggesting a receptor-mediated internalization mechanism, most likely via endocytosis, as reported in the literature (*17*); however, in this paper we did not study the internalization mechanism. On the contrary, Ac-Cys-Ahx-RAF@AuNPs presented low internalization in HeLa cells due to the fact that the receptor-mediated internalization mechanism is not favored by target peptide. Finally, the conjugates Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs showed an intermediate cell penetration capacity. As expected, gold conjugates did not accumulate in the SHSY-5Y cell line because of the low concentration of GRPr for this cell line.

These results provide an illustration of the power of our strategy. Thus, while the RAF conjugate internalizes poorly into HeLa cells, the AuNPs containing RAF and BN did because of the presence of the BN moiety, which has the capacity to bind to the GRPr of cells. Furthermore, the presence of the BN moiety provides selectivity for the drug−ligand conjugate as shown by the finding that none of the AuNPs penetrated the SHSY-5Y cells. This selectivity is potentially useful in the development of ligand-targeted therapeutics.

Colocalization of the Fluorescence and Gold Reflection Signal Caused by the Conjugate-Labeled Peptides as Shown by CLSM Imaging. The carboxyfluoresceinated conjugates, Ac-Cys-Ahx-Lys(CF)-BN@AuNPs, Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs, and Ac-Cys-Ahx-Lys(CF)-BN/Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs, were incubated with the tumor cell line HeLa for 24 h at 37 °C to colocalize the fluorescence signal caused by the peptide−AuNP conjugate and the reflection of the AuNP.

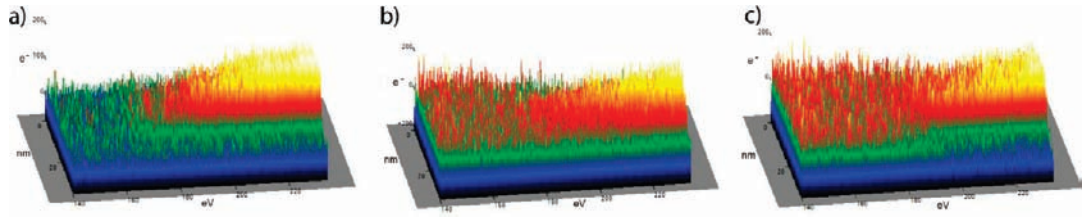

Figure 2. EELS spectrum obtained on the surface of (a) nonfunctionalized 20 nm AuNPs, (b) Ac-Cys-Ahx-BN functionalized AuNPs, and (c) Ac-Cys-Ahx-RAF functionalized AuNPs.

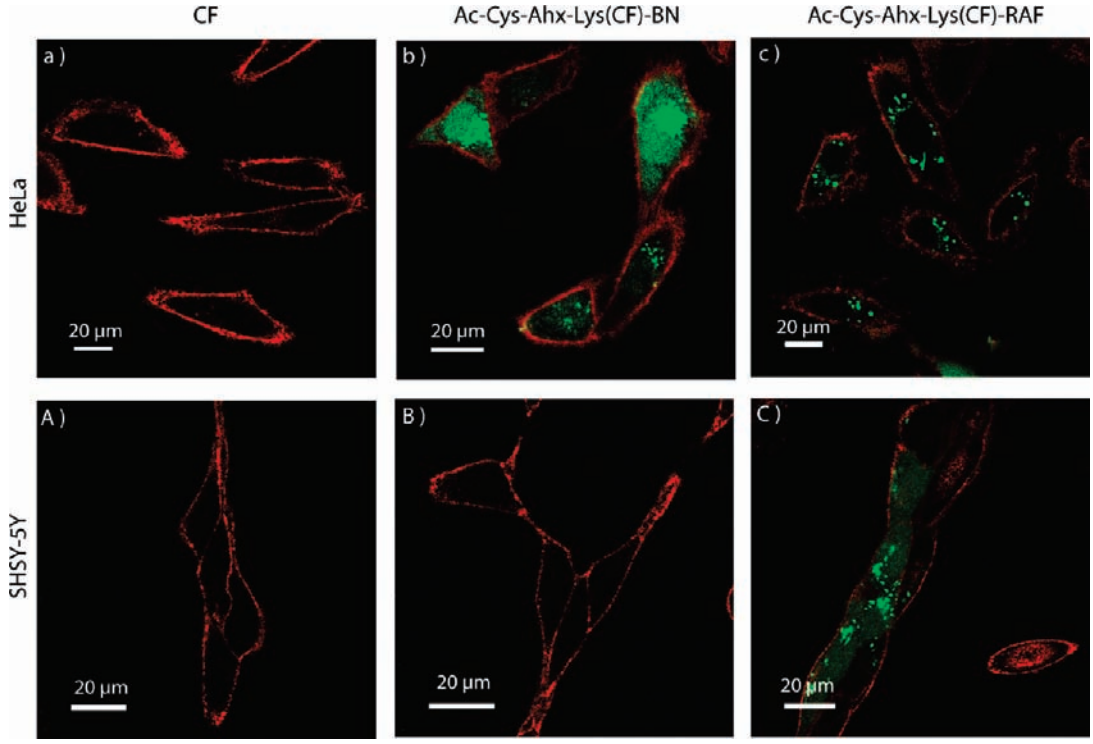

Figure 3. Localization of carboxyfluoresceinated peptides in HeLa cells (a−c) and in SHSY-5Y cells (A−D) incubated for 24 h. Control of CF (a, A), Ac-Cys-Ahx-Lys(CF)-BN (b, B), Ac-Cys-Ahx-Lys(CF)-RAF (c, C). Membranes (green) were stained with a fluorescence marker (WGA). The peptides were added at a final concentration of 1×10^{-5} M.

The membrane of the cells was stained green and the internalization of the fluorinated gold complexes was visualized using CLSM. These observations revealed that nearly all the AuNPs were complexed to the fluorescently labeled peptides (Figure 5) when overlapping the red reflection of the AuNPs with the blue fluorescence of the carboxyfluorinated peptides. These results indicate that the labeled peptides do not detach from the AuNP surface. However, a partial hydrolysis of the peptide in cells may occur. This possibility could not be discarded in the present study because the fluorescence label was found in the *N*-terminal extreme of the peptide, which was bound to the AuNPs surface.

Viability Studies. The degree of viability and effects of the free peptides (Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF), gold conjugates Ac-Cys-Ahx-BN@AuNPs and Ac-Cys-Ahx-RAF@AuNPs, and the equimolar mixture Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs and AuNPs on cell proliferation was determined by MTT assay in HeLa and SHSY-5Y cells following 24 h of incubation (Figure 6). AuNPs did not show any significant effects on HeLa cell viability, while Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF at concentrations of 1×10^{-5} M reduced the viability of cells in 33% and 52%, respectively, with respect to the controls. As expected, the RAF peptide possesses a higher antitumor activity, since it is reported to suppress tumor growth and angiogenesis (*59, 60*). However, to the best of our knowledge, the antitumor activity of both peptides has never been compared in the same conditions. In the case of BN, the conjugation with AuNPs increases the toxicity in cells possibly due to a synergistic effect in the penetration between the AuNP and the peptide, which helps to increase the local concentration which in turn enhances the antitumor activity and is in accordance with the increased delivery of Ac-Cys-Ahx-BN-AuNP to HeLa cells. The conjugates Ac-Cys-Ahx-RAF-AuNP produce similar effects on cell viability with respect to the peptide Ac-Cys-Ahx-RAF-AuNP.

Interestingly, conjugates of the peptides with AuNPs did not show any effect on cell viability in neuroblastoma SHSY-5Y cells. The lack of toxicity could be attributed to the low penetration that the conjugates present in this cell line due to the low expression of GRPr receptors. Remarkably, Ac-Cys-Ahx-RAF is toxic against this cell line which evidences the low selectivity of this peptide against cells in general (as shown by the CLSM of the CF peptide, Figure 3); however, conjugation with AuNP results in increased selectivity (toxicity in HeLa cells but not in SHSY-5Y). The conjugation of this peptide with AuNPs could induce a change in the conformation of the peptide molecules that leads to a reduction of toxicity in neuroblastoma cells. This is an interesting point which we are currently studying.

CONCLUSIONS

In summary, we report herein a strategy to increase the activity and cell selectivity of AuNP−peptide conjugates by

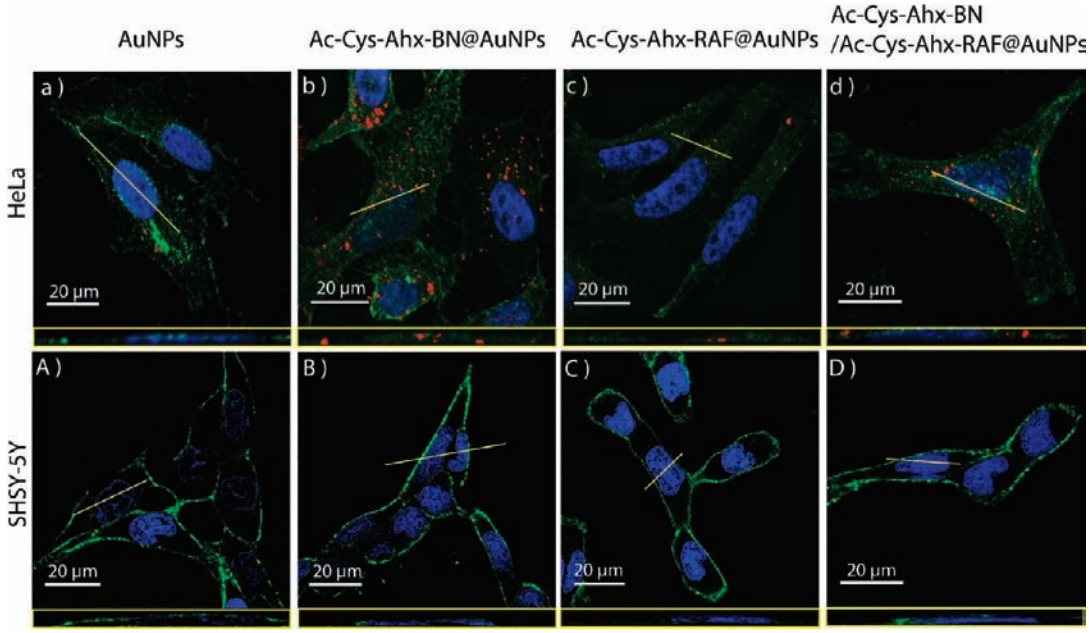

Figure 4. Localization of AuNPs and their conjugates in HeLa cells (a−d) and in SHSY-5Y cells (A−D) incubated for 24 h. AuNPs (a, A), Ac-Cys-Ahx-BN@AuNPs (b, B), Ac-Cys-Ahx-RAF@AuNPs (c, C), Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs (d, D). The red dots represent reflections of groups of nanoparticles. Membranes (green) were stained with a fluorescence marker (WGA), and nuclei (blue) with a DNA marker (DRAQ5). The conjugated peptides were added at final concentrations of 1×10^{-5} M of peptides and 0.4 nM of AuNPs. The insets in yellow squares are the projection of the slides in the *z* axis to corroborate the localization of the gold nanoconjugates inside the cells and not onto the top of the cells.

means of the multifunctionalization of the AuNPs with a targeting peptide (BN) and an antitumor peptide (RAF). This work confirms that the conjugates in which BN is present penetrate cells that overexpress GRPr. However, a more detailed study of the internalization mechanism to confirm a receptor-mediated endocytosis mechanism in HeLa cells for the analogue of BN peptide is currently underway. The enhancement in activity and selectivity could contribute to a potential improvement of the efficacy of RAF for therapy by reducing the therapeutic index. Furthermore, this strategy will provide an opportunity for the controlled delivery of AuNPs used as cargoes for a localized (nanometrically) therapy like the so-called molecular surgery.

MATERIALS AND METHODS

Materials. Rink amide MBHA resin and Fmoc-N^{α}-protected amino acids were purchased from Iris Biotech GmbH (Marktredwitz, Germany). 7-Aza-1-hydroxy-1*H*-benzotriazole (HOAt) was obtained from GL Biochem (Shanghai, China); 1-benzotriazolyloxytris(pyrrolidino)-phosohonium hexafluorophosphate (PyBOP) was purchased from Novabiochem (Laüfelfelfingen, Switzerland); 7-azabenzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyAOP) from Applied Biosystems (Foster City, CA); *N,N*′-diisopropylethylamine (DIEA) from Albatros Chem. Inc. (Montreal, Canada); and *N,N*′-disopropylcarbodiimide (DIC) and triisopropylsilane (TIS) from Fluka Chemika (Buchs, Switzerland). 5(6)-Carboxyfluorescein (CF) was obtained from Acros (Somerville, NJ). Solvents for peptide synthesis and RP-HPLC were obtained from Scharlau (Barcelona, Spain). Trifluoroacetic (TFA) acid was supplied by KaliChemie (Bad Wimpfen, Germany). Dimethylformamide (DMF), dichoromethane (DCM), and acetonitrile (MeCN) were purchased from SDS (Peypin, France). Tetrakis(triphenylphosphine)palladium (0) [$Pd(PPh_3)_4$], phenyl silane ($PhSiH_3$), triisopropylsilane (TIS), and other chemicals used were obtained from Aldrich (Milwaukee, WI, USA) and were of the highest purity commercially available.

Peptide Synthesis and Chromatography. (All reported solvent ratios are expressed as v/v, unless otherwise stated). The four peptides were synthesized manually on Fmoc Rink amide MBHA resin (100 mg, 0.68 mmol/g) using a Fmoc/^{t}Bu strategy in polypropylene syringes, each fitted with a polyethylene porous disk. Solvents and soluble reagents were removed by suction. Washings between deprotection, couplings, and subsequent deprotection steps were carried out with DMF and DCM using around 10 mL solvent per gram of resin each time. The Fmoc group was removed by treatment with a mixture of piperidine−DMF (1:4 v/v) (2 × 10 min). After Fmoc removal, coupling reactions were carried out with Fmoc-amino acids (4 equiv), HOAt (4 equiv), and DIC (4 equiv) in DMF for 1.5 h. Couplings were monitored using the Kaiser test (*61*). When necessary, recouplings were done with PyBOP (4 equiv), HOAt (4 equiv), and DIEA (12 equiv) for 1.5 h. After completing the synthesis, we performed an acetylation step with a mixture of AcOH (10 equiv) and DIC (5 equiv) for 10 min. For fluorescently labeled peptides [Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF], after completion of the peptide sequence, the Alloc (Allyloxycarbonyl) group was removed with $Pd(PPh_3)_4$ (0.1 equiv) in the presence of $PhSiH_3$ (10 equiv) (3 × 15 min) under Ar atmosphere followed by several washes (5 × 1 min) with sodium *N,N*′-diethyldithiocarbamate (0.02 M in DMF) and DMF. CF (5 equiv), PyAOP (5 equiv), HOAt (5 equiv), and DIEA (10 equiv) were dissolved in a mixture of DMF−DCM, preactivated for 10 min, and added to the peptidyl resin. The reaction mixture was stirred for 1.5 h. For the deprotection of side chain groups and concomitant cleavage of the peptides from the support, the resin was washed with DCM (3 × 1 min), dried, and treated with a TFA−H_2O−TIS (95:2.5:2.5) cocktail for 1 h. TFA was then removed by evaporation with a N_2 stream and peptides were precipitated with a mixture of cold anhydrous *tert*-butyl methyl ether (TBME) and hexane (2:1), dissolved in H_2O−MeCN (1:1) and freeze−dried. The crude peptides were purified using a semipreparative RP-HPLC [Waters 2487 Dual λ Absorbance Detector (Waters, MA, USA) equipped with a Waters 2700 Sample Manager, a Waters 600 controller, a Waters Fraction Collector, a Symmetry column (C_{18}, 5 μm, 30 × 100 mm), and Millenium software; flow rate = 10 mL/min, gradient = 0−20% B for 5 min, 20−40% B for 35 min, 40−100% B

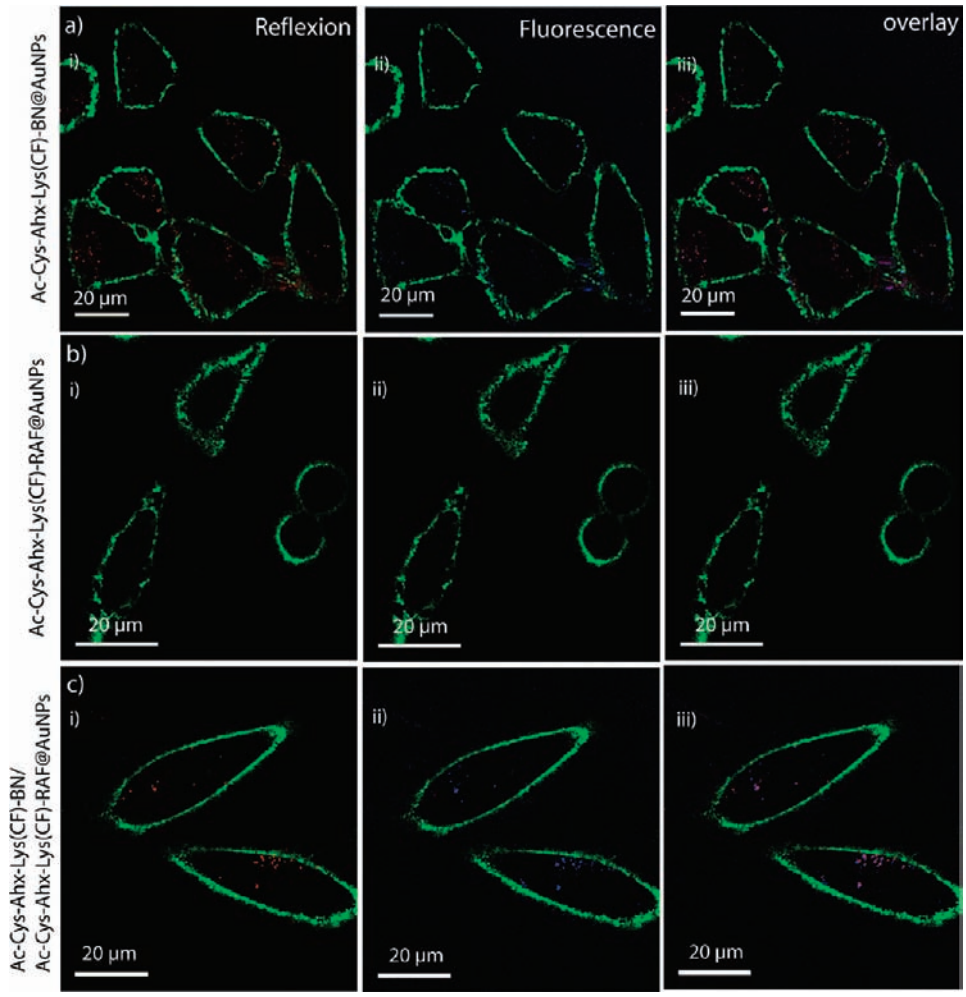

Figure 5. Localization of carboxyfluoresceinated peptides attached to AuNPs in HeLa cells incubated for 24 h. (a) Ac-Cys-Ahx-Lys(CF)-BN@AuNPs, (b) Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs, (c) Ac-Cys-Ahx-Lys(CF)-BN/Ac-Cys-Ahx-Lys(CF)-RAF@AuNPs. Membranes (green) were stained with a fluorescence marker (WGA). Reflection of the AuNPs in red (i), carboxyfluorinated peptides in blue (ii), and the overlay of both channels in purple (iii). The conjugated peptides were added at a final concentration of 1×10^{-5} M of peptides and 0.4 nM of AuNPs.

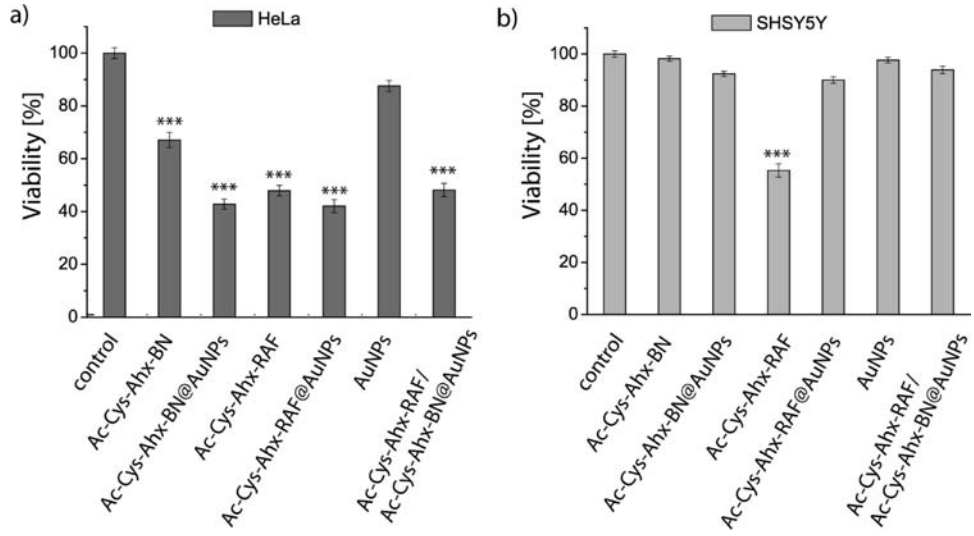

Figure 6. Cell viability assay after incubation of cells with Ac-Cys-Ahx-BN, Ac-Cys-Ahx-RAF, and their gold conjugates for 24 h: (a) HeLa cell line and (b) SHSY-5Y cell line. The conjugated and nonconjugated peptides were added at a final concentration of 1×10^{-5} M of peptides and 0.4 nM of AuNPs. The results are expressed as percentages compared to untreated cells and represent the mean ± standard deviation of three independent experiments (*** $P < 0.001$).

for 5 min (A = 0.1% TFA in H_2O, B = 0.05% TFA in MeCN)]. The purified peptides were identified (Supporting Information Figure S1 ai, bi, ci, di) at $\lambda = 220$ nm by analytical RP-HPLC [Waters 996 photodiode array detector equipped with Waters 2695 separation module, a Symmetry column (C_{18}, 5 μm, 4.6 × 150 mm) and Millennium software; flow rate = 1 mL/min, gradient = 20−40% D for 15 min for Ac-Cys-Ahx-BN, Ac-Cys-Ahx-RAF, Ac-Cys-Ahx-Lys(CF)-RAF, and 20−60% D for

15 min for Ac-Cys-Ahx-Lys(CF)-BN for 15 min (C = 0.045% TFA in H_2O, and D = 0.036% TFA in MeCN)]. Mass spectra were recorded on a MALDI Voyager DE RP time-of-flight (TOF) spectrometer (Applied Biosystems, Foster City, CA, USA) using ACH matrix (Supporting Information Figure S1 aii, bii, cii, dii).

Preparation of AuNPs. AuNPs were produced by reduction of $HAuCl_4 \times H_2O$ obtained from Aldrich (Milwaukee, WI, USA). $HAuCl_4 \times H_2O$ (8.7 mg) was added to a sodium citrate solution (100 mL, 2.2 mM) at reflux. The reducing agent was added rapidly, and the reaction was allowed to continue under uniform and vigorous stirring until a red wine color was observed (*58*).

Conjugation of Peptides with AuNPs. An excess of peptide was used for the conjugation (*62*). 1 mL of peptide solution (1 mg/mL in Milli-Q water) was added dropwise to 10 mL of AuNP solutions at room temperature with magnetic stirring, and the agitation was then maintained for 15 min. The conjugates were then purified by dialysis over three days in a Spectra/Por MWCO membrane: 6−8000 against 1 mM sodium citrate. The solution was refreshed six times to remove the excess peptide (Ac-Cys-Ahx-BN, Ac-Cys-Ahx-RAF, the equimolar mixture of Ac-Cys-Ahx-BN and Ac-Cys-Ahx-RAF or their fluorescently labeled counterparts).

UV−visible. UV−vis absorption spectra were recorded at room temperature with a 2501PC UV−vis recording spectrophotometer (Shimadzu Corporation, Kyoto, Japan).

Electron Energy Loss Spectroscopy (EELS). AuNP or AuNP-peptide (Ac-Cys-Ahx-BN@AuNPs, Ac-Cys-Ahx-RAF@AuNPs, Ac-Cys-Ahx-RAF/Ac-Cys-Ahx-BN@AuNPs) solutions (20 μL × 3) were placed on holley carbon Cu grids and allowed to dry at room temperature. Electron energy loss spectra were obtained in a Gatan Image Filter (GIF 2000) coupled to the JEOL 2010F microscope, with an energy resolution of 1.2 eV.

Amino Acid Analysis (AAA). Amino acid analysis was carried out by the AccQ. Tag method after acid hydrolysis with HCl (6N) for 24 h at 110 °C was used. The analysis was performed in a Waters Delta 600 RP-LC system with UV detection at 254 nm.

Determination of Conjugate Concentration. The number of peptides per particle was calculated by dividing the concentration of grafted peptide by the number of AuNPs in solution, which was determined spectrophotometrically considering the molar extinction coefficients detailed in the literature (*57*). The concentration of grafted peptide was determined by interpolation into a calibration curve (Supporting Information Figure S2) of the area of the HPLC peak of the solution resulting after centrifugation with an amicon filter (Amicon ultra-15, 3 kDa, MilliPore Corporation, Billerica, MA, USA) of a known volume of the conjugates at 13 500 rpm for 30 min. Once the AuNP pellet was removed, the free peptide containing solution was freeze−dried, dissolved again, and injected into the HPLC.

Cell Culture and Incubation with the Conjugates. HeLa and SHSY-5Y cell lines were obtained from ATCC no CCL-2 and ATCC no CRL-2266, respectively (Manasas, VA). Both cell lines were maintained in DMEM (low glucose medium for HeLa cell line and high glucose medium for SHSY-5Y) (Biological Industries) containing 10% fetal calf serum (FCS), 2 mM glutamine, 50 U/mL penicillin, and 0.05 g/mL streptomycin. For experiments, exponentially growing cells were detached from the culture flasks using a trypsin−0.25% ethylenediaminetetraacetic acid (EDTA) solution, and the cell suspensions were seeded at a concentration of 3.5×10^3 cells/cm^2 for the HeLa line and 1×10^3 cells/cm^2 for the SHSY-5Y line onto glass-bottom microwell dishes (35 mm Petri dish, 14 mm microwell, 1.5 mm cover glass) (Nalge Nunc International, Rochester, NY). Experiments were carried out 24 h later, when the confluence was approximately 70−80%. Nonadherent cells were washed away and attached cells were incubated at 37 °C in 5% CO_2 in DMEM with a known concentration of free AuNPs, peptide−AuNP conjugates, and carboxyfluorinated peptides. The conjugated and nonconjugated peptides were added in a 1:4 (conjugate/DMEM) ratio at a final concentration of 1×10^{-5} M of peptides and 0.4 nM of AuNPs.

MTT Assay. HeLa and SHSY-5Y viability in the presence of nonconjugated or conjugated nanoparticles and the free peptides was tested by the reduction of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), including a control with no nanoparticles added. For each assay, 3.5×10^3 cells/cm^2 of the HeLa cell line and 1×10^3 cells/cm^2 of the SHSY-5Y cell line were seeded onto a 96-well plate (Nalge Nunc) and cultured for 24 h. The conjugates were added in a 1:4 (conjugate/DMEM) ratio, and the free peptides were added at the same concentration as the peptide−gold conjugates at a final concentration of 1×10^{-5} M of peptides and 0.4 nM of AuNPs. Cells were incubated for 22 h at 37 °C under a 5% CO_2 atmosphere. After incubation, the medium was removed and the cells were incubated with 200 μL fresh medium containing MTT (0.5 mg/mL) for 2 h. The resulting blue formazan was solubilized in 150 μL acidified isopropanol (0.04 M HCl) and the absorbance was measured at 560 nm using a plate reader (Multiskan Ascent, Thermo Scientific). The values of the untreated cells were taken as 100%, and cell viability was expressed as a percentage of the untreated cells. The data were obtained from three independent experiments performed in triplicate.

Confocal Laser Scanning Microscopy (CLSM). For the cellular localization of AuNP conjugates (Ac-Cys-Ahx-BN@AuNPS, Ac-Cys-Ahx-RAF@AuNPs, Ac-Cys-Ahx-BN/Ac-Cys-Ahx-RAF@AuNPs) and for the carboxyfluorinated peptides (Ac-Cys-Ahx-Lys(CF)-BN and Ac-Cys-Ahx-Lys(CF)-RAF), HeLa and SHSY-5Y cells were plated onto glass coverslips, grown to 60% confluence, and then incubated at 37 °C under a 5% CO_2 atmosphere with either Ac-Cys-Ahx-Lys(CF)-BN, Ac-Cys-Ahx-Lys(CF)-RAF or nanoparticle conjugates for 24 h. WGA as plasma membrane marker and DRAQ5 as a DNA dye were added just before recording the image. The samples were examined using an Olympus Fluoview 500 confocal microscope with a 60×/1.4 NA objective.

ACKNOWLEDGMENT

We gratefully acknowledge Tommaso Cupido for their helpful discussions. We thank Raquel Garcia Olivas, and Elisenda Coll (UB-SCT) for their assistance with CLSM and TEM, respectively. This work was partially supported by AECID, FONDECYT 1090143 CICYT (CTQ2009-07758), the Instituto de Salud Carlos III (CB06_01_0074), the Generalitat de Catalunya (2009SGR 1024), the Institute for Research in Biomedicine, and the Barcelona Science Park.

Aggregation of Alzheimer Amyloid β Peptide (1−42) on the Multivalent Sulfonated Sugar Interface

Tomohiro Fukuda, Erino Matsumoto, Shunsuke Onogi, and Yoshiko Miura*

School of Materials Science, Japan Advanced Institute of Science and Technology, 1-1 Asahidai, Nomi, Ishikawa 923-1292, Japan. Received January 27, 2010; Revised Manuscript Received April 20, 2010

The mechanism of amyloidosis of amyloid β (1−42) (Aβ (1−42)) was investigated by the well-defined glycocluster interface. We prepared monovalent, divalent, and trivalent 6-sulfo-*N*-acetyl-D-glucosamine (6S-GlcNAc) immobilized substrates. The morphology and secondary structure of Aβ (1−42) aggregates on the substrates were investigated by dynamic-mode AFM and FTIR-RAS. Aβ (1−42) interactions with multivalent sugars were evaluated by surface plasmon resonance, and the cytotoxicity of Aβ (1−42) to HeLa cells was evaluated by MTT assay. Morphological images showed, interestingly, that Aβ (1−42) aggregates had a tendency to form globules rather than fibrils as the valency of 6S-GlcNAc on the substrate was increased. The SPR measurements indicated that this morphological change of Aβ (1−42) was related to the change of binding mode, and the binding mode was dependent on the multivalency of the sugar. Globular Aβ (1−42) was more toxic than fibrillar Aβ (1−42) to HeLa cells. These results suggested that the multivalency of sugars for the amyloidosis of Aβ (1−42) was significant in its morphology and aggregation effects at the surface of the cell membrane mimic.

INTRODUCTION

Alzheimer's disease (AD) is a serious dementia, accompanied by the presence of senile plaques (*1*). The main components of senile plaques are amyloid beta (Aβ) peptides of Aβ (1−40) and Aβ (1−42) (*2, 3*). Aβs are produced by cleavage of β- and γ-secretases into amyloid precursor protein (APP) and are present in the cerebral cortex. Since aggregates of Aβs exist in AD patients, it is believed that Aβ aggregates injure the neuron cells. The onset of AD is related to amyloidosis of Aβ (*3, 4*), and Aβ aggregates generally form insoluble fibrils. However, recent research indicated that the morphology of Aβ aggregates varied, and the cytotoxicity of Aβ has been reported to relate to the morphology and aggregation of Aβs as protofibrils, ADDLs, and amylospheroids (*5*−*9*). We were interested in the reason for the change in morphology of Aβ and the relationship of the morphological change to the cytotoxicity of Aβ. It has been reported that amyloidosis is induced by the interaction of Aβ with the cell surface. For example, various sugars on cell surfaces have been reported to be involved in the amyloidosis of Aβ (*10*−*13*). In particular, it is well-known that interactions of Aβ with glycosaminoglycans such as heparin and ganglioside GM1 clusters are also closely related to amyloidosis. Meanwhile, the recognitions where sugars were involved were impossible to regulate due to the clustering effect (*14*−*16*). Consequently, it is possible that the morphologies and biofunctionalities of Aβ are affected by the degree of sugar clustering. However, detailed analyses of amyloidosis with well-defined glyco-clusters have not been reported.

In this study, we investigated the influence of a sugar on the aggregation behavior and cytotoxicity of Aβ with well-ordered glyco-clusters at the surface of a cell membrane mimic. As the target, we selected Aβ (1−42) because it is a predominant biomolecule in the early pathological stage of senile plaque formation (*17*). We chose 6-sulfo-*N*-acetyl-D-glucosamine (6S-GlcNAc), which is the most abundant structure of heparin and has a similar structure to sialic acid, as a representative sugar for this study (*18*). Our group had reported that the linear polymer involving 6S-GlcNAc inhibited Aβ (1−40) (*19, 20*).

We investigated the aggregation behavior, properties, and cytotoxicity of Aβ (1−42) on these SAMs.

EXPERIMENTAL SECTION

Materials. The following reagents were used as received. Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), penicillin−streptomycin solution (Invitrogen Co., GIBCO, Carlsbad, CA), chloroform ($CHCl_3$), copper (0) powder, copper(II) sulfate, *N*,*N*-dimethylformamide (DMF), 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium bromide (MTT), ethanol (EtOH), ethyl acetate (EtOAc), *n*-hexane, methanol (MeOH), sodium L-ascorbate, sodium azide, tetrahydrofuran (THF) (Kanto Chemical Co., Inc., Tokyo, Japan), palladium/charcoal (Pd/C) (Merck & Co., Inc., Whitehouse Station, NJ), amyloid β protein (human, 1−42) (Aβ (1−42)), 2-(7-aza-1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyl uronium hexafluorophosphate (HATU) (Peptide Institute Inc., Osaka, Japan), and *N*,*N*-diisopropylethylamine (DIEPA) (Tokyo Chemical Industry Co., Ltd., Tokyo, Japan).

Other compounds such as multivalent compounds of 6S-GlcNAc (**1**−**3**) were synthesized. The detailed synthetic schemes and characterizations are described in the Supporting Information. NaOH-50 buffer was bought from GE Healthcare Bioscience (Chalfont St. Giles, U.K.), and 50 mM potassium phosphate buffer (pH 7.4) was prepared by the conventional method.

Measurements. The functional SAMs were prepared on gold-coated glass substrates. The substrate, purchased from Moritex Co. (Tokyo, Japan), was used for dynamic mode−atomic force microscope (D-AFM), FTIR-RAS, ellipsometry, X-ray photoelectron spectroscopy (XPS), and water contact angle goniometry, while Au-Kit, the substrate provided by GE Healthcare Bio-Science, was used for SPR analysis. Before the preparation, each gold substrate was prepared by exposure to UV/ozone (UV.TC.NA.003, Bioforce Nanoscience Inc., Ames, IA) and rinsing with EtOH. The surface functional groups were confirmed using an FTIR spectrometer (Perkin-Elmer Inc., Waltham, MA) equipped with an RAS attachment (Reflector 2, Harrick Scientific Products Inc., Pleasantville, NY). The surface was also investigated by XPS using an Ulvac Phi 5600 (Ulvac Inc., Kanagawa, Japan) instrument. Water contact angle was measured with a DropMaster300 (Kyowa Interface Science Co., Ltd., Saitama, Japan) instrument, and the thicknesses of the SAMs were estimated using an ellipsometer (PZ2000, Royal Philips Electronics, Eindhoven, Netherlands). Aβ (1−42) analyses were carried out using SPR, AFM, and FTIR-RAS. SPR binding analysis was performed using a BIACORE 3000 and Au-Kit as probe chip, all provided by GE Healthcare Bio-Sciences Co. D-AFM observation was accomplished using an SPI3800N instrument (Seiko Instruments Inc., Chiba, Japan) equipped with an SPA400 as a probe station, and a DF40P cantilever. The secondary structure of Aβ (1−42) was determined by FTIR-RAS, using the system that was utilized for SAM characterization. Ultracentrifugal separation for Aβ (1−42) preparation was carried out with a Himac CS120FX ultracentrifuge (Hitachi Koki Inc., Ltd., Tokyo, Japan). A microplate reader, Multiscan JX, purchased from ThermoFisher Scientific Inc. (Waltham, MA), was used in MTT assay. Discovery studio 2.0 (Accelrys Inc., San Diego, CA) software was used for molecular modeling.

Syntheses. Initially, *p*NP-6-sulfo-*N*-acetyl-D-glucosamine (*p*NP-6S-GlcNAc), [2-(2-azide-ethoxy)ethoxy]acetate, 3,5-bis(propagyloxy)benzyl chloride, and 3,4,5-tris(propagyloxy)benzyl chloride were synthesized: the synthetic schemes are described in detail in the Supporting Information.

*p-(N-(2-(2-Azide-ethoxy)ethoxy)amido)phenyl 6-sodium sulfo-N-acetyl-β-D-glucosamine (monovalent-6S-GlcNAc (**1**)).* *p*NP-6S-GlcNAc (775 mg, 1.91 mmol, 1.0 equiv) and Pd/C (100 mg) were added to MeOH (50 mL) and stirred under hydrogen at room temperature. After 1 h, the Pd/C was removed and the solution was evaporated to a brownish solid (717 mg). The product and [2-(2-azide-ethoxy) ethoxy]acetate (545 mg, 2.88 mmol, 1.5 equiv) were dissolved in DMF (50 mL) and stirred at 0 °C. Then, HATU (746 mg, 1.96 mmol, 1.0 equiv) and DIPEA (500 μL, 2.88 mmol, 1.5 equiv) were added to the solution. After 8 h, the presence of the product in the reaction mixture was confirmed by rev TLC ($MeOH/H_2O$ = 1:8) and the solution was evaporated to give crude product. A white powder was isolated (1.03 g, 99%) after purification of the crude product by reverse column chromatography (H_2O/MeOH = 10:1).

^{1}H NMR (300 MHz, D_2O, ppm): δ 7.27 (2H, d, J = 9.0 Hz, ArH, meta to 6S-GlcNAc), 6.98 (2H, d, J = 9.3 Hz, ArH, ortho to 6S-GlcNAc), 5.02 (1H, d, J = 8.1 Hz, H-1), 4.27 (1H, dd, J = 2.0 and 11.3 Hz, H-6_{proR}), 4.12 (1H, dd, J = 4.7 and 11.2 Hz, H-6_{proS}), 4.11 (2H, s, -NHCO-$\underline{CH_2}$-), 3.87 (1H, t, J = 9.5 Hz, H-2), 3.76−3.45 (7H, m, H-3, H-4, H-5 and -O$\underline{CH_2CH_2}$-O-), 3.04 (2H, t, J = 4.8 Hz, -O$\underline{CH_2}CH_2N_3$), 3.07 (2H, q, J = 7.4 Hz, $OCH_2\underline{CH_2}N_3$), 1.90 (3H, s, Ac). ^{13}C NMR (75 MHz, DMF-d_7, ppm): δ 169.9 (-NH$\underline{CO}CH_3$), 168.1 (-NHCO-), 154.4 (ArC, ipso to 6S-GlcNAc), 133.4 (ArC, para to 6S-GlcNAc), 121.1 (ArC, meta to 6S-GlcNAc), 116.9 (ArC, ortho to 6S-GlcNAc), 100.2 (C-1), 75.6 (C-5), 74.8 (C-4), 70.0 (-NHCO$\underline{CH_2}$O-, C-3), 69.8 (-$CH_2O\underline{CH_2}CH_2N_3$), 66.1 (C-6), 56.2 (C-2), 54.5 (-NHCOCH$_2$OCH$_2\underline{CH_2}$O-), 54.4 (-NHCOCH$_2$O$\underline{CH_2}$-CH$_2$O-), 50.6 (-$CH_2OCH_2\underline{CH_2}N_3$), 22.7 (-NHCO$\underline{CH_3}$). ESI-MS [negative]: 562.2 $[M-Na^+]^-$ (calculated), 562.3 $[M-Na^+]^-$ (observed).

*Divalent 6S-GlcNAc (**2**).* **1** (266 mg, 0.455 mmol, 3.4 equiv) and 3,5-bis(propargyloxy)benzyl chloride (31 mg, 0.133 mmol, 1.0 equiv) were dissolved in DMF, while sodium L-ascorbate (18 mg, 0.091 mmol, 0.7 equiv) and copper(II) sulfate pentahydrate (7 mg, 0.047 mmol, 0.3 equiv) were dissolved in distilled water. The reaction mixture was prepared by mixing the two solutions with the addition of copper (0) powder (0.4 mg), and stirred under nitrogen at room temperature for 1 day. The object product was confirmed by rev. TLC (H_2O/MeOH = 8:1). Residual copper was removed by centrifugation, and the water layer was removed under reduced pressure. The crude product was dissolved in DMF, and sodium azide (67 mg, 1.03 mmol, 7.7 equiv) was added. After stirring the reaction mixture at 70 °C for 1 day, the solution was evaporated and purified by rev. column chromatography (H_2O/MeOH = 8:1). A white powder was obtained (41 mg, 22%).

^{1}H NMR (300 MHz, D_2O, ppm): δ 7.91 (2H, s, cyclictriazole), 7.03 (2H, d, J = 8.7 Hz, ArH, meta to 6S-GlcNAc), 6.79 (2H, d, J = 9.0 Hz, ArH, ortho to 6S-GlcNAc), 6.39 (2H, s, ArH, cyclictriazole (ortho to benzylazide)), 6.24 (1H, s, ArH, cyclictriazole (para to benzylazide)), 4.92 (2H, d, J = 8.4 Hz, H-1), 4.87 (4H, s, -O$\underline{CH_2}$-cyclictriazole), 4.49 (4H, t, J = 4.6 Hz, -NHCO-$\underline{CH_2}$-), 4.22 (2H, dd, J = 1.7 and 11.3 Hz, H-6_{proR}), 4.10 (2H, s, -$ArCH_2N_3$), 4.08 (2H, dd, J = 5.4 and 11.4 Hz, H-6_{proS}), 3.90−3.81 (2H, m, H-2), 3.87 (4H, t, J = 5.1 Hz, -$CH_2\underline{CH_2}$-cyclictriazole-, 3.84 (4H, t, J = 4.5 Hz, -$\underline{CH_2}CH_2$-cyclictriazole-), 3.71−3.59 (2H, m, H-5), 3.56−3.37 (2H+2H+2H × 4, m, H-3, H-4 and -O$\underline{CH_2CH_2}$O-), 1.89 (3H × 2, s, Ac). ^{13}C NMR (75 MHz, DMF-d_7, ppm): δ 169.9 (-NH$\underline{CO}CH_3$), 168.1 (-NHCO-), 160.1 (ArC, meta to benzylazide), 154.3 (ArC, ipso to 6S-GlcNAc), 143.1 (-N(linker)-N═N-$\underline{C}$(CH_2O-benzylazide)═C-), 138.4 (ArC, ipso to benzylazide), 133.4 (ArC, para to 6S-GlcNAc), 125.2 (-N(linker)-N═N-C(CH_2O-benzylazide)═$\underline{C}$-), 121.1 (ArC, meta to 6S-GlcNAc), 116.9 (ArC, ortho to 6S-GlcNAc), 107.7 (ArC, ortho to benzylazide), 101.3 (C-1), 100.3 (ArC, para to benzylazide), 75.8 (C-5), 74.8 (C-4), 71.2

(-N(linker)-N═N-C(CH$_2$O-benzylazide)═C-), 70.7 (-NHCOCH$_2$-O-), 69.9 (C-3), 66.0 (C-6), 61.7 (-OCH$_2$CH$_2$-cyclictriazole), 56.2 (C-2), 53.8 (-OCH$_2$CH$_2$-cyclictriazole), 54.1 (ArCH$_2$N$_3$), 49.8 (-CH$_2$OCH$_2$CH$_2$-cyclictriazole), 22.7(-NHCOCH$_3$). MALDI-TOF-MS [negative]: 1388.4 [M−Na$^+$]$^-$ (calculated), 1388.5 [M−Na$^+$]$^-$ (observed).

*Trivalent 6S-GlcNAc (**3**).* **1** (420 mg, 0.718 mmol, 3.9 equiv) and 3,4,5-tris(propagyloxy)benzyl chloride (53 mg, 0.227 mmol, 1.0 equiv) were dissolved in DMF while sodium L-ascorbate (8.15 mg, 0.110 mmol, 0.6 equiv) and copper(II) sulfate pentahydrate (20.0 mg, 0.0700 mmol, 0.3 equiv) were dissolved in distilled water. The reaction mixture was prepared by mixing the two solutions with the addition of copper (0) powder (0.05 mg), and stirred under nitrogen at room temperature for 1 day. The object product was confirmed by rev. TLC (H$_2$O/MeOH/CH$_3$COOH = 8:1:1). The copper residue was removed by centrifugation, and the water layer was removed under reduced pressure. The crude compound was dissolved in DMF, and sodium azide (162 mg, 2.48 mmol, 5.8 equiv) was added. After stirring the reaction mixture at 70 °C for 1 day, the solution was evaporated and purified by rev. column chromatography (H$_2$O/MeOH = 8:1). A white powder was obtained (91 mg, 20%).

^{1}H NMR (300 MHz, D$_2$O, ppm): δ 7.91 (2H, s, cyclictriazole (meta to benzylazide)), 7.60 (1H, s, cyclictriazole (para to benzylazide), 7.11 (2H, s, cyclictriazole (ortho to benzylazide)), 7.02 (2H, d, J = 9.0 Hz, ArH, meta to 6S-GlcNAc (para to benzylazide)), 6.98 (4H, d, J = 8.7 Hz, ArH, meta to 6S-GlcNAc (meta to benzylazide)), 6.79 (2H, d, J = 9.0 Hz, ArH, ortho to 6S-GlcNAc (para to benzylazide)), 6.76 (4H, d, J = 8.7 Hz, ArH, ortho to 6S-GlcNAc (meta to benzylazide)), 4.92 (1H, d, J = 8.7 Hz, H-1 (para to benzylazide)), 4.89 (4H, s, -OCH$_2$-cyclictriazole (meta to benzylazide)), 4.89 (2H, d, J = 8.1 Hz, H-1 (meta to benzylazide)), 4.81 (2H, s, -OCH$_2$-cyclictriazole (para to benzylazide), 4.50 (4H, t, J = 4.7 Hz, -NHCOCH$_2$-(meta to benzylazide)), 4.37 (4H, t, J = 4.4 Hz, -NHCO-CH$_2$-(meta to benzylazide)), 4.22 (2H, dd, J = 2.2 and 13.3 Hz, H-6$_{proR}$), 4.21 (2H, m, H-6$_{proR}$ (meta and para to benzylazide)), 4.09 (2H, dd, J = 5.1 and 6.0 Hz, H-6$_{proS}$ (meta to benzylazide)), 4.07 (1H, dd, J = 5.0 and 6.6 Hz, H-6$_{proS}$ (para to benzylazide)), 3.85 (3H, t, J = 7.1 Hz, H-2), 3.88−3.74 (12H, m, -CH$_2$CH$_2$-cyclictriazole), 3.79 (2H, s, -ArCH$_2$N$_3$), 3.67−3.61 (3H, m, H-5), 3.53 (1H, t, J = 9.0 Hz, H-3 (para to benzylazide)), 3.52 (2H, t, J = 8.6 Hz, H-3 (meta to benzylazide)), 3.51 (1H, t, J = 8.6H z, H-4 (para to benzylazide)), 3.53−3.42 (2H+12H, t, J = 8.6 Hz, H-4 (para to benzylazide)) 1.88 (3H, s, Ac (para to benzylazide)), 1.87 (3H × 2, s, Ac (meta to benzylazide)). ^{13}C NMR (75 MHz, DMF-d_7, ppm): δ 169 0.9 (-NHCOCH$_3$), 168.1 (-NHCO-), 154.3 (ArC, ipso to 6S-GlcNAc), 152.4 (ArC, meta to benzylazide), 143.9 (-N(linker)-N═N-C(CH$_2$O-benzylazide)═C-), 143.1 (ArC, para to benzylazide), 133.4 (ArC, para to 6S-GlcNAc), 125.2 (-N(linker)-N═N-C(CH$_2$O-benzylazide)═C-), 125.1 (ArC, ipso to benzylazide), 121.1 (ArC, meta to 6S-GlcNAc), 117.0 (ArC, ortho to 6S-GlcNAc), 109.2 (ArC, ortho to benzylazide), 100.3 (C-1), 75.8 (C-5), 74.8 (C-4), 71.2 (-N(linker)-N═N-C(CH$_2$O-benzylazide)═C-), 70.7 (-NHCOCH$_2$O-), 69.9 (C-3), 66.0 (C-6), 62.9 (-NHCOCH$_2$OCH$_2$CH$_2$O-), 62.5 (-NHCOCH$_2$OCH$_2$CH$_2$O-), 56.2 (C-2), 52.0 (-OCH$_2$CH$_2$-cyclictriazole), 49.9 (ArCH$_2$N$_3$), 49.8 (-CH$_2$OCH$_2$CH$_2$-cyclictriazole), 22.7(-NHCOCH$_3$). ESI-MS [negative]: 1002.3 [M−2Na$^+$]$^{2-}$ and 660.5 [M−3Na$^+$]$^{3-}$ (calculated), 1003.9 [M−2Na$^+$]$^{2-}$ and 661.7 [M−3Na$^+$]$^{3-}$ (observed).

Preparation. *SAM Formation.* An acetylenyl group was attached to the gold substrate by formation of SAMs as described in the literature (*22, 23*); the SAMs comprised acetylenyl- and hydroxyl-terminated disulfides in molar ratio of 1:5. Subsequently, multivalent compounds of 6S-GlcNAc (**1**−**3**) were immobilized on the substrate by click reaction with acetylenyl-terminated SAM.

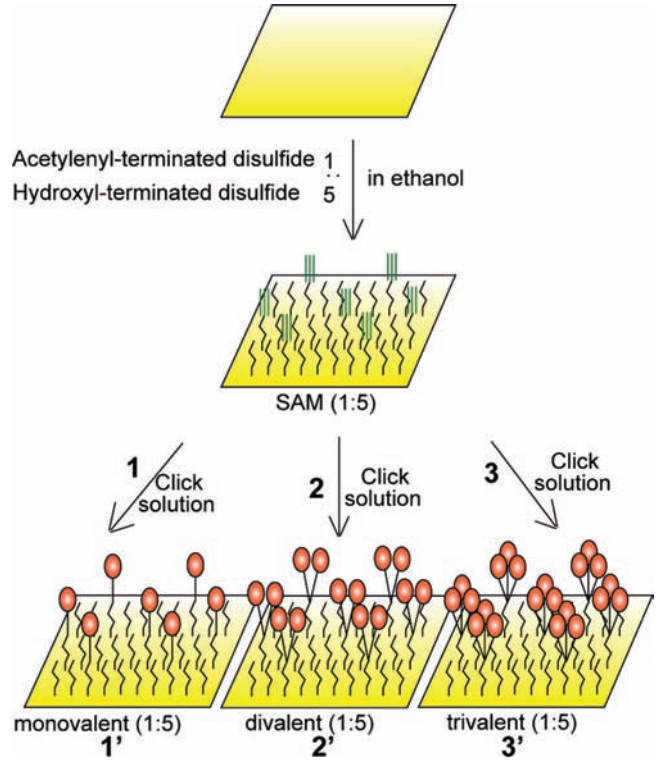

Figure 2. Schematic illustrations of the formation of glyco-clusters on the SAM (acetylenyl-terminated disulfide/hydroxyl-teminated disulfide = 1:5). The click solution was a mixed solution of DMF and water, which included CuSO$_4$, Cu (0) powder, and Na ascorbate.

Acetylenyl-functionalized layers were immobilized by the formation of a SAM. Disulfides with hydroxyl (**S1**) and acetylenyl (**S2**) terminals were dissolved in molar ratio **S1**:**S2** = 5:1 (total 10 mM) in EtOH (**S1** and **S2** were described in the Supporting Information). The gold substrate was immersed in the solution for 12 h and then rinsed several times with EtOH. Subsequently, azide-terminated 6S-GlcNAc derivatives (**1**−**3**) were reacted with acetylenyl-terminated SAM via click chemistry. Each reaction mixture was prepared from 5.0 mM 6S-GlcNAc, 0.10 mM CuSO$_4$, 0.50 mM sodium L-ascorbate, and 0.01 wt % copper (0) powder in an EtOH/H$_2$O = 1:2 (v/v) mixture, and dropped on the acetylenyl-terminated SAMs under N$_2$ gas. After 12 h, each substrate was washed with EtOH and H$_2$O repeatedly, SAMs were characterized by FTIR-RAS, ellipsometry, XPS, and water contact angle goniometry. The substrates with immobilized mono (**1**)-, di (**2**)-, and tri (**3**)-valent 6S-GlcNAc were designated **1′**, **2′**, and **3′**, respectively (Figure 2).

Aβ Sample Preparation. Aβ (1−42) (200 μM) was unfolded with 0.02% aqueous NH$_3$ solution and centrifuged at 4 × 10^4 rpm at 4 °C (*24*). The supernatant solution was separated into suitable volumes in plastic vials. After the vials were rapidly frozen in liquid N$_2$, they were stored at −20 °C. These frozen stock samples were diluted with appropriate buffer solutions just before use. Samples that were prepared from the same batch were used for assay between subsequent measurements.

Functional Analysis. *AFM Observation.* Ten micromolar sample solution was prepared by diluting the stock solution with an aqueous solution containing 0.1 M NaCl, 20 mM potassium phosphate buffer (pH 7.4), and 0.008% NH$_3$. The sample solution of Aβ (1−42) was incubated on **1′**−**3′** for 12 h at 25 °C in static conditions. After incubation, the surface was carefully rinsed several times with H$_2$O to remove excess Aβ

(1−42) and dried by N_2 gas. Images of the aggregates on each surface were collected by D-AFM. The operating parameters for the SI-DF40P-type cantilever were of resonant frequency ca. 330 kHz and spring constant 40 N m^{-1}. The applied voltage was 1.0 V and the scanning frequency was 1 Hz.

FTIR-RAS Measurement. The secondary structure of Aβ (1−42) on the substrates was investigated by Fourier transform−reflection adsorption spectroscopy (FTIR-RAS). To identify the conformation of Aβ (1−42), the sample substrate that was used for D-AFM analysis was also used for FTIR-RAS. Measurements were carried out using an MCT-N detector in dry air, at 4.0 cm^{-1} resolution.

SPR Evaluation. Binding analysis of Aβ (1−42) on multivalent 6S-GlcNAc immobilized surfaces was estimated kinetically by SPR. Flowing buffer solution (0.1 M NaCl, 20 mM potassium phosphate buffer (pH 7.4), 0.008% NH_3) was used for the measurement. The frozen stock sample solution was diluted with the same buffer solution just before measurement, to equalize the NH_{3aq} content for each measurement, and various concentrations of Aβ (1−42) (2.5, 5.0, 10, 20, and 40 μM) were prepared as sample solutions. Measurement was carried out at flow rate 5 μL min^{-1}. The sample solutions from 2.5 to 40 μM Aβ (1−42) were interacted with unmodified substrate and substrates with immobilized monovalent 6S-GlcNAc **1**, divalent 6S-GlcNAc **2,** and trivalent 6S-GlcNAc **3** for 3 or 25 min. The Aβ (1−42) deposited on the substrate was dissociated with three 15 μL aliquots of NaOH-50 solution before next measurement. Measurements were carried out in the order of increasing sample concentration.

MTT Assay. Viability of HeLa cells was evaluated by MTT assay. A cloning ring (d = 5 mm) was first fixed on the modified substrate, and the subsequent assays were carried out in the cloning ring. As a culture medium for HeLa cells, 10% FBS and 1% penicillin−streptomycin solution including DMEM solution were used. A 10 μM sample solution of Aβ (1−42) was incubated on the surface for 12 h at 25 °C. Then, 5×10^3 HeLa cells in the culture medium were added in the ratio of Aβ solution/culture medium of 1:9 and cultured at 37 °C under 5% CO_2 for 1 day. After cultivation, the culture medium was exchanged for 3 h with another assay medium solution which was a composite of 10% MTT (in PBS) and the culture medium solution. After removing the assay medium, the formazan resulting from reduction of MTT was dissolved in DMSO and the absorbance of the solution evaluated at 570 nm.

RESULTS

Preparation and Characterization of SAM. Substrates with mono (**1**)-, di (**2**)-, and tri (**3**)-valent 6S-GlcNAc, denoted **1′**, **2′**, and **3′**, respectively, were fabricated (Figure 2). To avoid reaction complexities due to the hydroxyl groups of the sugar, we synthesized and immobilized the compounds via click reaction (*21, 25*). Immobilization of the multivalent 6S-GlcNAc was confirmed by water contact angle goniometry, X-ray photoelectron spectroscopy (XPS), FTIR-RAS, and ellipsometry. The syntheses of compounds and the characterization of SAMs are described in the Supporting Information. The SAMs involving well-defined glyco-clusters on the substrate were regarded as a cell membrane mimic and used to determine how the multivalency of sugars contributes to amyloidosis of Aβ.

AFM Observation. The morphology of Aβ (1−42) aggregates on the substrate was observed by D-AFM. The shapes and the sizes of Aβ (1−42) on the substrates after preparation are summarized in Table 1 and shown in Figure 3. Interestingly, the morphology of Aβ was dependent on the type of glyco-cluster. When Aβ (1−42) was incubated on **1′**, fibril formation was observed; the fibrils were 4−6 nm high, 8−12 nm wide, and 1−2 μm long (Figure 3A). When incubated on **2′**, the morphology of Aβ (1−42) was changed; both fibrils (as on **1′**) and globular aggregates (7−9 nm high and 200−500 nm in diameter) were observed (Figure 3B). Incubation on **3′** dramatically changed the morphology of Aβ (1−42) aggregate to an exclusively globular form. The globular objects were 10−20 nm high and 500−600 nm in diameter (Figure 3C).

Table 1. Aggregate Patterns and Sizes of Aβ (1−42) on 1′, 2′ and 3′

		1′ (monovalent)	**2′** (divalent)	**3′** (trivalent)
aggregate pattern		fibril	fibril, globule	globule
fibril	width	8−12 nm	8−12 nm	
	length	1−2 μm	1−2 μm	
	height	4−6 nm	4−6 nm	
globule	height		7−9 nm	10−20 nm
	diameter		200−500 nm	500−600 nm

FTIR-RAS Measurement. The secondary structure of Aβ (1−42) aggregates on each substrate was elucidated by FTIR-RAS. The results for amide bands are shown in Figure 4. The amide I band (C═O stretching) at 1670 cm^{-1} was present in

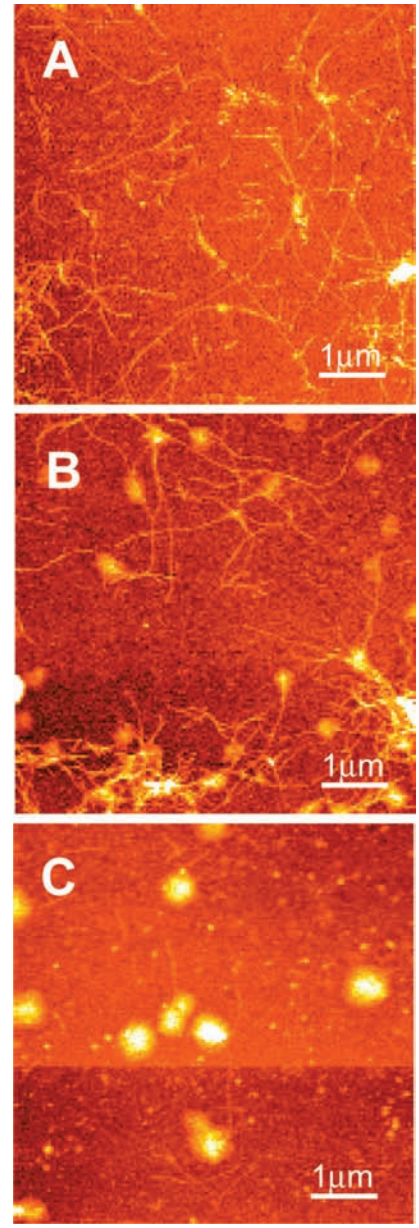

Figure 3. Morphologies observed by D-AFM (top) and aggregate model (bottom) on the (a) monovalent (**1′**), (b) divalent (**2′**), and (c) trivalent (**3′**).

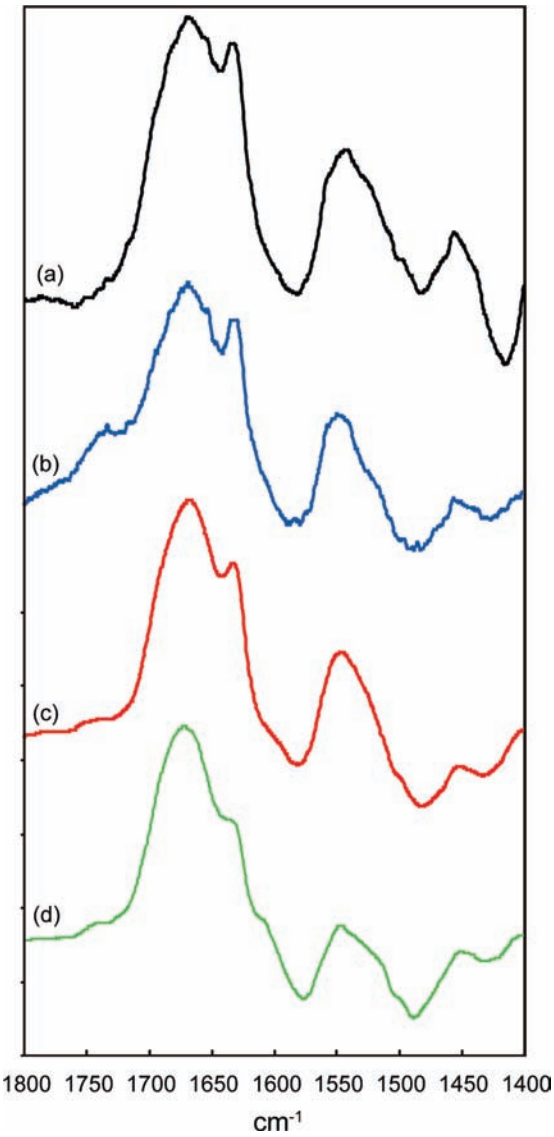

Figure 4. FTIR-RAS spectra of Aβ (1−42) on (a) no-sugar SAM, (b) **1′**, (c) **2′**, and (d) **3′**.

all cases, implying the β-turn structure (*26*). The band at 1632 cm^{-1} showed the existence of antiparallel β-sheet structure (*13, 27*). Remarkably, that band was least intense in the spectrum of the **3′** sample. With AFM observation taken into account, these results indicated that the fibrils on **1′** had predominantly β-sheet structure, and the globules on **3′** had little of the β-sheet structure. Although weak peaks at 1654 and 1648 cm^{-1}, correlated with α-helix and disorder, respectively, were observed on **1′** and on a 6S-GlcNAc-unmodified surface, these peaks disappeared from the spectra for the higher valencies. However, a peak at 1613 cm^{-1} in the β-sheet region was conspicuous in the spectra for the higher valencies.

Interaction Analysis with SPR. The SPR measurements were carried out for two different time schedules (1650 and 300 s), to investigate the initial Aβ (1−42) binding to sugars and the aggregation process of Aβ (1−42).

The interaction was monitored by the change of response unit (RU) on addition of 10 μM Aβ (1−42). The time course of RU change is shown in Figure 5 (A) and indicates responses of Aβ (1−42) in the order **2′** (913 RU) > **3′** (658 RU) ≫ **1′** (388 RU) in the 1650 s measurements, hence a nonlinear RU change with valency. The high level of interaction of **2′** and **3′** suggested the importance of glyco-clusters. The concentration dependence of RU for each substrate is shown in the Supporting Information.

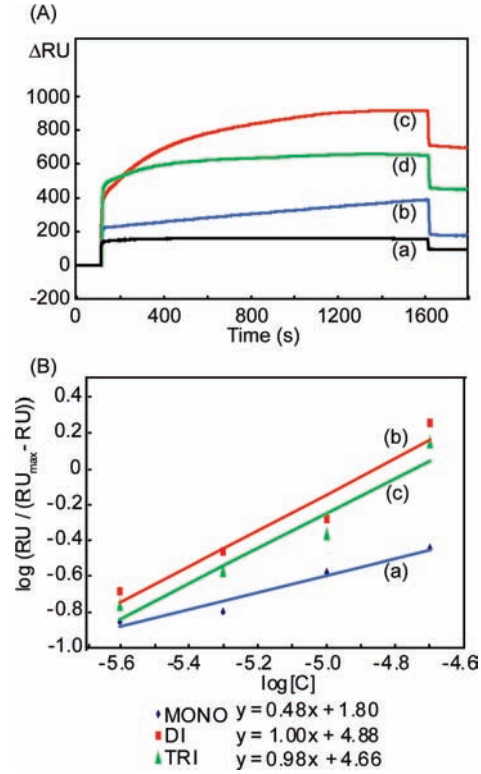

Figure 5. (A) Time courses of ΔRU on (a) no-sugar SAM, (b) **1′**, (c) **2′**, and (d) **3′** for 1800 s. (B) Hill plot analysis using the RU_{eqmax} at 1650 s on (a) no-sugar SAM, (b) **1′**, (c) **2′**, and (d) **3′**.

The interaction between 6S-GlcNAc and Aβ (1−42) was then remeasured for the shorter duration of 300 s; the results are shown in Figure 6. The values of RU_{eqmax} on **1′**, **2′**, and **3′** were 27, 386, and 416 RU, respectively, on the plateaus. Similar to the interaction for the longer time of 1650 s, the multivalent 6S-GlcNAc of **2′** and **3′** showed much stronger interaction than that of monovalent 6S-GlcNAc of **1′**. After 300 s, RU_{eqmax} on **3′** was larger than on **2′**, in contrast to the measurement at 1650 s.

MTT Assay. The cytotoxicity of Aβ (1−42) to HeLa cells was evaluated by MTT assay on the substrate. The results are shown in Figure 7, in which all data are mean values for three replicate experiments. The cell viabilities with Aβ (1−42) on **1′**, **2′**, and **3′** were 104 ± 11%, 84 ± 25%, and 76 ± 11%, respectively.

DISCUSSION

AFM observation of the substrate suggested that Aβ (1−42) had a tendency to form fibrils on the sugars (**1′** and **2′**) with lower valencies, and to form globular aggregates on substrates with higher sugar valencies (**2′** and **3′**). The densely packed sulfonated or acidic sugars strongly induced a morphological change in Aβ (1−42) aggregates. The morphological change of amyloid aggregate from fibrillar to globular objects is consistent with the report of Ban et al., who investigated the morphology of Aβ (1−40) on various sulfonated surfaces (*28*). In the present case, the well-defined nanostructure of multivalent 6S-GlcNAc encouraged Aβ (1−42) to aggregate in a globular morphology, indicating the significance of sugar multivalencies in amyloidosis.

The FTIR-RAS spectra showed that the multivalent sugars influenced not only the morphology of Aβ (1−42), but also its secondary structure. In particular, the band at 1632 cm^{-1} of the antiparallel β-sheet was much weaker in the spectrum of **3′** than that in **1′** and **2′**. The results indicated that Aβ fibrils contained

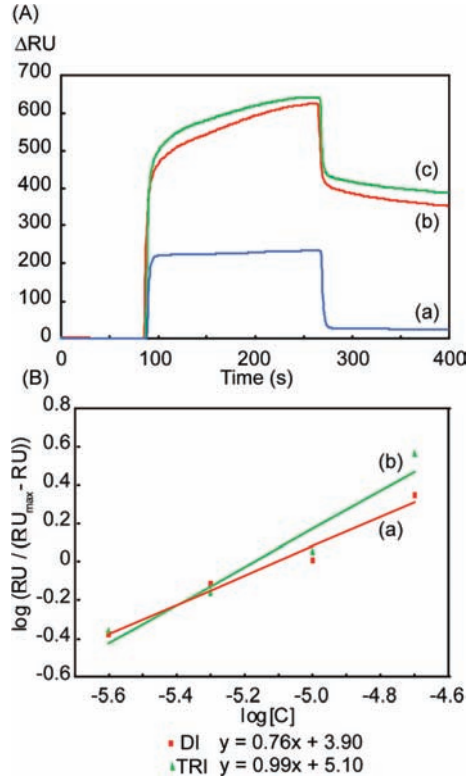

Figure 6. (A) Time courses of ΔRU (a) on no-sugar SAM, (b) **1′**, (c) **2′**, and (d) **3′** for 400 s. (B) Hill plot analysis using the RU_{eqmax} values at 300 s for (a) **2′** and (b) **3′**.

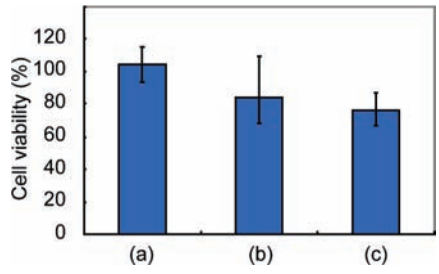

Figure 7. Cytotoxicity of Aβ (1−42) to HeLa cells on (a) **1′**, (b) **2′**, and (c) **3′** by MTT assay.

more antiparallel β-sheet structure than Aβ globular objects. On the other hand, the band at 1613 cm^{-1} appeared in the spectra for the high valencies (**3′**), but the origin of this band is not yet understood in detail. Goto et al. attributed the band at 1613 cm^{-1} to an unknown β-sheet structure (*29*). A similar band was observed by Zurdo et al. in spectra of amorphous aggregates of Aβ (*30*), and Daggett indicated that it was possible that this band implied α-sheet structure (*9*). The FTIR-RAS spectra also showed that the intensity ratio of amide I to amide II was much larger in the spectrum of **3′**. Since FTIR-RAS spectra reflected adsorption of Aβ (1−42) longitudinal to the substrate, the change of amide I to II ratio suggested the specific orientation of Aβ (1−42) to the substrate.

The SPR measurements indicated that the 6S-GlcNAc-immobilized surfaces recognized Aβ (1−42). The amount bound of Aβ (1−42) to the substrate (RU) changed with the valency, and the multivalent sugars were strongly bonded to Aβ (1−42). For the calculation of binding constants, RU_{eqmax} values at 1650 s were plotted against sample concentration (Figure 5B). Subsequently, Hill plots for the long time (1650s) were constructed as shown in Figure 5B, because the curves of RU_{eqmax} versus concentration were not correlated with Langmuir adsorption (*31*). The Hill equation is expressed by eq 1. The equilibrium

Table 2. Binding Mode of Aβ (1−42) to 1′, 2′, and 3′ on Each Time Scale

	binding mode (sugar/Aβ (1−42))		
time scale	**1′** (monovalent)	**2′** (divalent)	**3′** (trivalent)
long (1650s)	2:1	1:1	1:1
short (300s)	no data	2:1 and 1:1	1:1

dissociation constants (K_D) on **1′**, **2′**, and **3′** were 1.49×10^{-4}, 1.16×10^{-5}, and 1.89×10^{-5} [M], respectively. The slopes of the best-fit lines for **1′**, **2′**, and **3′** (i.e., the values of the Hill coefficient, n) were 0.48, 1.00, and 0.98 respectively, which implies that the binding modes between sugar and Aβ (1−42) can be represented as the ratios 2:1, 1:1, and 1:1 (sugar/Aβ (1−42)), respectively. Considering **2′** and **3′** displayed multivalent sugars, the multivalency of the sugars was a key component in binding mode definition.

$$\log\left(\frac{[RU_{eq\ max}]_{C[\mu M]}}{[RU_{eq\ max}]_{40[\mu M]} - [RU_{eq\ max}]_{C[\mu M]}}\right) = n \log[C[\mu M]] - \log K_D \quad (1)$$

The interaction analysis in the short term showed that RU_{eqmax} for **3′** was higher than for **2′**, which implies different trends for the short-time and long-time analyses. The equivalent values (RU_{eqmax}) were introduced into the Hill plot, and the equilibrium dissociation constants (K_D) on **2′** and **3′** were recalculated as 7.82×10^{-6} and 5.80×10^{-6} [M], respectively. The Hill plot for **1′** was not fitted due to the small number of RU_{eqmax} values.

The Hill coefficients for **2′** and **3′** in 300 s were calculated as 0.76 and 0.99, respectively. The different Hill coefficients for **2′** associated with the two time scales suggested that the binding mode changed between 300 and 1650 s, while the binding mode for **3′** was the same in both time scales. The Hill coefficient of 0.76 in the short time for **2′** corresponds to an intermediate value between 2:1 and 1:1 binding modes. The concerted binding mode of 2:1 and 1:1 in the early binding mode was changed into the 1:1 binding in the long-term measurement. The changes of the binding modes are summarized in Table 2. Taking account of the AFM observations, 2:1 binding reaction between sugar and Aβ (1−42) induced fibril formation of Aβ (1−42) on **1′**, and 1:1 binding reaction induced globule formation of Aβ (1−42) such as on **3′**. The mixture of 2:1 and 1:1 binding on **2′** represented both fibril and globule formations. Therefore, the binding mode and the affinities between sugar and Aβ were related to the morphology. The strong binding of **3′** (1:1) might induce the adhesion of Aβ, formation of nucleus, and subsequent globule aggregates.

The sugar intervals were different in the each compound. The multivalent sugars **2** and **3** had a divergence point at the phenyl ring with sugar interval of 5−10 Å, while the intervals of sugars were at least 22 Å on **1′** due to the composition of the SAMs (Figure 8A) (*32*). The net charge of Aβ (1−42) was slightly negative (*28*), but sulfonated sugars are known to interact through the basic residues of the HHQK region (*33*) (Figure 8B). His13, His14, and Lys16 are cationic to interact with Aβ by the electrostatic interaction. The distances between His13 and His14 units are 8−10 Å in the pleated sheet conformation, and the distances between His13 or His14 and Lys16 units are 10−20 Å. From the result of SPR evaluation, the interaction between sulfonated sugar and Aβ (1−42) was of two types (2:1 and 1:1 binding modes). In the 2:1 binding mode, two independent sugars interacted with Aβ (1−42), which indicates a long interaction distance between the sugars on **1′**. We surmised, therefore, that the amino acids that participate in 2:1 binding are His13-Lys16 rather than His13-His14. On the other hand, multivalent sugar clusters participated in 1:1 binding with the HHQK region, because the 1:1 binding mode is superior to

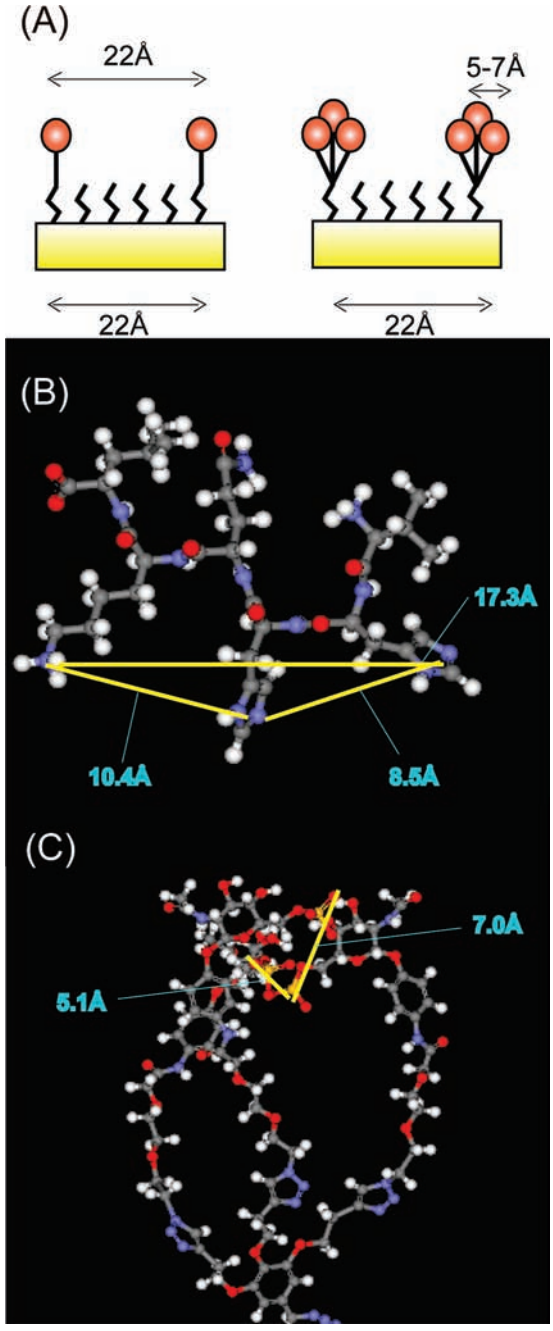

Figure 8. Illustration of sugar intervals on the surface (A). Graphical configurations of multivalent sugars (B) and 12−17 amino acid residues region (C).

the 2:1 binding mode. The sugar intervals of multivalent sugars **2** and **3** are comparable with that of His13-His14 (Figure 8C). Consequently, the multivalent cluster was considered to interact with the His-His region in 1:1 binding due to the steric effect. The change of binding mode allowed the peptide to form an alternative morphology and secondary structure, because peptides were reported to change their conformation in response to the ligand bindings (*34, 35*).

MTT assay showed that the cytotoxicity of Aβ (1−42) varied due to the aggregation process. Aggregation of Aβ (1−42) on **3′** which formed globules gave the highest cytotoxicity, followed by **2′**. By contrast, aggregation of Aβ (1−42) on **1′** formed fibrils and had no cytotoxicity. Lambert et al. reported that cytotoxicity of Aβ (1−42) was attributed to oligomeric, small globules of Aβ (1−42) (*36*), and Hoshi et al. also reported similar results (*8*). That result agreed with our observations in terms of the high cytotoxicity of Aβ (1−42) globules regardless of the difference of the size of Aβ (1−42). The FTIR spectrum of cytotoxic Aβ (1−42) had the characteristic of low-intensity bands at 1632 cm^{-1}, corresponding to β-sheet formation. Zako et al. reported that the insulin peptide with low cytotoxicity did not have the band around 1615 cm^{-1} (*37*). Our results in the band of 1613 cm^{-1} agreed the former results of FTIR spectra and cytotoxicity and suggested that the secondary structure change facilitated the morphological change to globules and cytotoxicity against HeLa cells. Moreover, the multivalency of sugar variously bound to Aβ (1−42) affected the secondary structure, which gives a correlation with the pathogenesis of AD.

FTIR-RAS, D-AFM, and SPR analyses suggested that the binding mode between sugar and Aβ (1−42) was highly affected by sugar valencies, and changed their secondary structure and morphology. Moreover, these changes were correlated to the cytotoxicity of Aβ (1−42). Each result showed that the amyloidosis of Aβ was controllable by the multivalency of sugars. Furthermore, we believe that the results suggest the importance of glyco-cluster formation on cell surfaces in AD.

CONCLUSION

This study revealed the role of sugars in amyloidosis using a well-ordered sugar display. The morphology of Aβ (1−42) was greatly influenced by the sugar valencies, and globular objects were induced to form in the presence of multivalent sugars. The secondary structure was also affected by the presence of multivalent sugars, and the affinity of Aβ (1−42) for sulfonated sugar was likewise highly affected by the valency. Moreover, the binding mode between sugar and Aβ (1−42) was also affected. The result of each D-AFM observation, SPR analysis, and IR evaluation suggested that the multivalency of sugars for the amyloidosis of Aβ had a significant effect on its morphology and aggregation at the surface of the cell membrane mimic. Cell viability assay implied that higher cytotoxicity to HeLa cells was induced by Aβ (1−42) which adsorbed on the multivalent sugars. These results correspond to the introduction of specific behavior of Aβ (1−42) with glycosaminoglycans and gangliosides. Various groups have tried in vain to identify the roles of glyco-clusters; artificial glyco-clusters with a well-defined surface provide a new means by which to clarify the roles of sugars in Alzheimer disease.

ACKNOWLEDGMENT

This work was supported by a Grant-in-Aid for Scientific Research on Innovative Areas (20106003). We thank Prof. Tooru Ooya (Kobe Univ.) and Prof. Shin-ichi Ikushiro (Toyama Pref. Univ.) for the SPR measurement. HeLa cell was kindly donated by Prof. Nobuhiko Yui (Japan Adv. Inst. Sci. Tech.).

Supporting Information Available: Detailed synthetic procedure of **1**−**3**, surface analysis data by FTIR-RAS, XPS, water contact angle, ellipsometry, and concentration-dependent RU curves of Aβ (1−42). This material is available free of charge via the Internet at http://pubs.acs.org.

Chitosan has the potential to be a biocompatible gene carrier. However, the transfection efficiency of chitosan is low because of the slow endosomal escape rate. The buffering capacity of histidine in the endosomal pH range would help the escape of plasmid DNA (pDNA) from endosomes. In this study, histidine was introduced into chitosan to improve the transfection efficiency. Chitosan and histidine were linked by disulfide bonds provided by 2-iminothiolane and cysteine. The complexes were prepared by mixing chitosan or histidine-modified chitosan with plasmid DNA. A broader buffering range of histidine-modified chitosan was observed, and the cellular uptake of histidine-modified chitosan/pDNA complexes was higher than that of chitosan/pDNA complexes. Although chitosan/tetramethylrhodamine (TMR)-pDNA complexes were trapped in the vesicles in cytosol, TMR-pDNA carried by histidine-modified chitosan was more widely distributed in the cytosol. This result suggests that histidine can help pDNA escape from endosomes with the help of the high buffering capacity. The gene expression of histidine-modified chitosan/pDNA complexes was higher than that of chitosan/pDNA complexes. These results suggest that histidine modification improves the transfection efficiency of chitosan.

INTRODUCTION

Chitosan, which is a cationic polysaccharide, has played an important role in biomedicine for more than a decade, being used as a food additive (*1*) and a wound dressing to assist healing (*2*). It is also well-known that chitosan has the potential to act as a gene carrier (*3–6*). The amino groups in the structure of chitosan provide positive charges to form complexes with the negative charges of nucleic acids. The outstanding biocompatibility of chitosan is also an advantage for biomedical applications (*3*). A number of studies have proven that chitosan can be used in vivo with negligible side effects (*7, 8*). These advantages make chitosan a promising material for use as a gene carrier.

However, the gene transfection efficiency of chitosan as a carrier is very low compared with conventional nonviral gene carriers, including liposomes (*4, 9, 10*) and polyethyleneimines (*6, 11*). One reason for the low gene expression efficiency of chitosan is its slow endosomal escape rate (*6, 12*). In fact, chitosan effectively protects and introduces nucleic acids into cells. However, endosomes would be the next barrier to the gene delivery of chitosan. Köping-Höggård et al. showed that chitosan was trapped in endosomes over 24 h (*6*). Therefore, the enzymes in endosomes and lysosomes would gradually degrade the nucleic acids in endosomes or lysosomes over a long period. Other problems including low solubility under physiological conditions and complicated physicochemical properties are also major concerns for the efficient gene transfection of chitosan (*13*). These problems, especially the slow endosomal escape rate, need to be solved to enhance the transfection efficiency of chitosan prior to its application as a gene carrier.

There are several strategies to overcome the endosome barrier. For example, chloroquine, an endosomolytic reagent, can accumulate in lysosomes and disrupt them by increasing the pH (*14, 15*), and pH-sensitive liposomes can escape from endosomes due to membrane disturbance (*16, 17*). Histidine, a nonessential amino acid, contains an imidazole ring (pK_{a3} 6.04) which increases the buffering capacity in endosomes and lysosomes. Histidine and histidine-containing dipeptides, such as carosine and anserine, are known to act as endogenous buffers in skeletal muscle (*18, 19*). For this reason, histidine is commonly used as a modifying group to improve the endosomal escaping rate of several nonviral gene carriers, such as polylysine, liposomes, and poly(amino acid) derivatives (*20–24*). We have demonstrated that histidine can enhance the gene transfection efficiency of liposomes by increasing the buffering capacity (*21*). In addition, the conjugation site on the chitosan structure and the hydrophilicity of histidine itself may help the dissolution of chitosan.

The purpose of this study was to increase the gene transfection efficiency of chitosan/pDNA complexes by enhancing the endosomal escape rate. In this study, we introduced histidine to the amino groups of chitosan via disulfide bonds. The degree of substitution of histidine and the buffering capacity of histidine-modified chitosan were measured. The physicochemical properties of the complexes were evaluated by determination of the particle size and zeta potential, as well as agarose gel electrophoresis. The gene transfection process was examined by confocal microscopy, flow cytometry, and luciferase assay in order to prove the enhanced gene transfection of histidine-modified chitosan by increased cellular uptake and a buffering effect.

EXPERIMENTAL PROCEDURES

Materials. Highly purified chitosan (number-average molecular weight: 173 kDa, degree of deacetylation: 88%) was

Scheme 1. Histidine-Cysteine-OMe (His-Cys-OMe) Synthesis

purchased from SEIKAGAKU Biobusiness (Tokyo, Japan). Cys(Acm)−OH·HCl, Boc-His(Boc)−OH, and hydroxybenzotriazole·H_2O (HOBt·H_2O) were purchased from Watanabe Chemical Industries (Hiroshima, Japan). *O*-Benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluorophosphate (HBTU) was purchased from Peptide Institute (Osaka, Japan). Thionyl chloride ($SOCl_2$), deuterium oxide (D_2O), sodium bicarbonate ($NaHCO_3$), citric acid monohydrate, sodium chloride, chloroform, methanol, ethanol, diethyl ether, trifluoroacetic acid (TFA), potassium diphosphate (KH_2PO_4), dimethyl sulfoxide (DMSO), sodium acetate·$3H_2O$, ninhydrin, hydrindantin·$2H_2O$, and sodium hydroxide (NaOH) were purchased from Nacalai Tesque (Kytoto, Japan). Dehydrated dimethylformamide (DMF), petroleum ether, L-histidine, glucose, magnesium chloride ($MgCl_2$), and 4% paraformaldehyde were purchased from Wako Pure Chemical Industries (Osaka, Japan). Mercury(II) acetate was purchased from Sigma-Aldrich Corporation (Saint Louis, MO). 2-iminothiolane·HCl was purchased from Pierce (Rockford, IL). Alexa Fluor 488 transferrin conjugate, LysoSensor Green DND-189, LysoTracker Green DND-26, Lipofectamine 2000, Opti-MEM I reduced serum medium, Trypan blue stain prepared in 0.85% NaCl, and SYBR Gold nucleic acid gel stain were purchased from Invitrogen (Carlsbad, CA). Agarose X and S were purchased from NIPPON GENE (Osaka, Japan). Label IT fluorescein nucleic acid labeling kit and Label IT TM-rhodamine nucleic acid labeling kit were purchased from Mirus Bio (Madison, WI). jetPEI was purchased from Polyplus-Transfection Inc. (New York, NY). PicaGene luciferase assay kit was purchased from Toyo Corporation (Tokyo, Japan). All solvent and reagents were ACS grade and used directly without further treatment.

His-Cys-OMe Synthesis (Scheme 1). Cys(Acm)−OH·HCl was reacted with $SOCl_2$ to form the methyl ester. Twenty milliliters of methanol was cooled to −30 °C, and then $SOCl_2$ was added to the methanol dropwise. After cooling on ice, the mixture was added with 1 g Cys(Acm)−OH and then stirred at room temperature for 15 h. The methanol in the mixture was removed in an evaporator, and the product, Cys(Acm)-OMe, was recrystallized from ethanol and cold diethyl ether. The coupling reaction of Cys(Acm)-OMe and Boc-His(Boc)−OH was conducted with HBTU and HOBt·H_2O in DMF for 12 h at room temperature. DMF was removed in an evaporator, and the residue was dissolved in chloroform and washed twice with 5% sodium bicarbonate, 10% citric acid, and saturated sodium chloride. Chloroform was removed in an evaporator and the Boc and Acm-protected product was recrystallized using a mixture of ethanol, petroleum ether, and diethyl ether. The deprotection of the Boc groups and Acm groups was carried out by 95% TFA and mercury(II) acetate treatment, respectively. The obtained His-Cys-OMe was confirmed by ESI-MS (Mariner ESI TOF Biospectrometry Workstation, PerSeptive Biosystems, Inc., Framingham, MA).

Synthesis of Histidine-Modified Chitosan (Chi-CH, Scheme 2). The conjugation of chitosan and His-Cys-OMe was carried out according to Masuko et al. (*25*) with slight modification. Chitosan was dissolved in 1% acetic acid (pH 2.0) and potassium phosphate buffer (50 mM KH_2PO_4, 2 mM EDTA·2Na, and 150 mM NaCl, pH 8.0) was mixed with this chitosan solution in the volume ratio of 1:1. Traut's reagent (2-iminothiolane·HCl) was added to the solution directly, and the reaction mixture was stirred for 4 h at room temperature. After purification by dialysis (1000 molecular weight cutoff) for 48 h, the reaction product was immediately reacted with His-Cys-OMe in different weight ratios to 2-iminothiolane·HCl (Table 1). DMSO was added to the reaction mixture in a volume ratio of 10:1 (reaction mixture/DMSO). The reaction mixture was stirred for 12 h, and then purified by dialysis (1000

Scheme 2. Chitosan-Cysteine-Histidine (Chi-CH) synthesis

molecular weight cutoff) for 48 h. The reaction mixture after dialysis was freeze−dried.

Histidine Quantification. The amount of His-Cys-OMe conjugated to chitosan was measured by the ninhydrin test established by S−W Sun et al. (*26*). In brief, Chi-CH was dissolved in sodium acetate buffer (100 mM sodium acetate and 100 mM sodium chloride solution, pH 4.5), and the disulfide bonds were reduced using 75 mM dithiothreitol. The reduction reaction was carried out at room temperature for 1 h, and then the chitosan was removed by Microcon centrifugal filters (3000 molecular weight cutoff). The dipeptide solution in Chi-CH was analyzed by the ninhydrin test. Ninhydrin solution was prepared using 20 mg ninhydrin and 33.35 mg hydrindantin·$2H_2O$ dissolved in DMSO/4 N sodium acetate buffer (7.5 mL/2.5 mL) under nitrogen gas. Histidine standard solution (10−100 μg/mL) was prepared in distilled water. The histidine standard solution and the dipeptide solution were mixed with ninhydrin solution in a volume ratio of 1:1, and then heated at 100 °C for 10 min. After heating, the histidine standard solution and the dipeptide solution were placed on ice for 10 min. Fifty milliliters of the dipeptide solution was added to each well of a 96-well plate, followed by 125 μL 50% ethanol. The absorbance of the solution was determined using a microplate reader (Bio-Rad 550 microplate reader, Foster City, CA) at 570 nm. The degree of substitution was calculated based on a histidine standard curve.

Measurement of Buffering Capacity. Four micromolar chitosan and Chi-CH solutions were prepared in sodium acetate buffer (pH 5.5). The chitosan and Chi-CH solutions were titrated with 0.1 N NaOH. The pH was recorded using a pH meter (Twin pH AS-212, As one, Osaka, Japan), and the buffering capacity was compared.

Preparation and Purification of pCMV-Luc. pCMV-Luc was constructed by subcloning the *Hin*dIII/XbaI firefly luciferase cDNA fragment from a pGL3-control vector (Promega, Madison, WI) into the polylinker of a pcDNA3 vector (Invitrogen, Carlsbad, CA). pDNA was amplified in the *Escherichia coli* strain DH5α, isolated, and purified using a JETSTAR Plasmid Purification Giga Kit (GENOMED GmbH, Löhne, Germany). The concentration of pDNA was measured using a Shimadzu UV−vis spectrometer (Shimadzu, Kyoto, Japan) at 260 nm.

Measurement of Particle Size and Zeta Potential. Chitosan or Chi-CH was dissolved into sodium acetate buffer (pH 5.5) at a concentration of 5 mg/mL, and pDNA was dissolved in 5% glucose at a concentration of 1 mg/mL for use as stock solutions. Chitosan or Chi-CH and pDNA solutions were mixed in the same volume ratio with different concentrations based on the A/P ratio (A: amino groups in chitosan structure; P: phosphate groups in pDNA structure). The size and zeta potential of the complexes were measured using a ZetaNano-Sizer (Malvern ZetaNanoSizer Nano-ZS, Worcestershire, UK).

Evaluation of Complex Stability. The stability of the complexes was evaluated by agarose gel electrophoresis. One microgram of pDNA was mixed with chitosan or Chi-CH at different A/P ratios. The complexes were loaded onto 1% Agarose S gel. For the enzymatic stability assay, the complexes were incubated with 10 U DNase I (Roche, Manheim, Germany) in 5 mM $MgCl_2$ solution for 3 h at 37 °C. DNase I was quenched by TE buffer after a 3 h incubation, then DNA was extracted using phenol/chloroform/isoamyl alcohol (Nacalai Tesque, Kyoto, Japan). The extracted DNA was loaded onto 5% Agarose X gel. The pDNA on the gel was stained using a SYBR Gold nucleic acid gel stain.

pCMV-Luc Labeling. The pDNA was labeled with fluorescein and tetramethylrhodamine (TMR) using a Label IT fluorescein nucleic acid labeling kit or a Label IT TM-rhodamine nucleic acid labeling kit, respectively. The labeling procedure followed the manufacturer's instructions. Briefly, pDNA was incubated with labeling reagents at 37 °C for 2 h. Then, pDNA was precipitated with 100% ethanol and washed with 70% ethanol. The concentration of fluorescence-labeled pDNA was measured by UV absorbance at 260 nm.

Cell Culture and Cellular Uptake. For the uptake study, human embryonic kidney (HEK293) cells (RIKEN Cell Bank, Tsukuba, Japan) were incubated in Dulbecco's modified Eagle's medium (DMEM; Nissui Co., Tokyo, Japan) supplemented with 10% fetal bovine serum (FBS; Invitrogen, Carlsbad, CA), 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine (Invitrogen, Carlsbad, CA). HEK293 cells were seeded onto 12 well plates at a density of 3×10^5 cell/mL. After a 24 h incubation, the medium was changed to Opti-MEM I for complex administration. One microgram per milliliter of fluorescein-labeled pDNA complexed with chitosan, Chi-CH, or Lipofectamine 2000 was added to each well. At 2, 6, and 12 h after incubation, Opti-MEM I containing complexes was removed, and the cells were collected in phosphate buffer and centrifuged at 5000 rpm for 10 min. The cell pellets were fixed and resuspended in 70% ethanol and incubated with Trypan blue for the quenching of the extracellular fluorescein. The resuspended cells were repeatedly centrifuged at 5000 rpm for 10 min and resuspended in phosphate buffer for flow cytometry analysis (Becton Dickinson FACSCalibur, Franklin Lakes, NJ).

Intracellular Distribution of pDNA. HEK293 cells were used as the cell model to monitor the endosomal escape of the complexes. HEK293 cells were seeded on 12 well plates at a cell density of 2×10^5 cells/mL. After a 24 h incubation, HEK293 cells were incubated with 100 μg/mL Alexa Fluor 488 transferrin conjugate for 20 min in Opti-MEM I medium before addition of the complexes. Lysosomes were labeled with 1 μM LysoSensor Green DND-189 and 1 μM LysoTracker Green DND-26 for 30 min in Opti-MEM I medium before addition of the complexes. The complexes containing 2 μg/mL TMR-labeled pDNA were then added to the cells. After a 6 h incubation, HEK293 cells were washed with phosphate buffer and fixed with 4% paraformaldehyde. The endosomal escape was observed using a Nikon Eclipse Ti inverted confocal microscope equipped with a Nikon EZ-C1 observation system (Nikon, Tokyo, Japan). The images were processed using *ImageJ* software. The objective was a 60× water immersion objective.

Proton Pump Inhibition. HEK293 cells were seeded in 12 well plates at a density of 1.5×10^5 cells/mL and incubated at 37 °C, 5% CO_2 for 24 h. Before addition of the complexes, the cells were incubated with 100 nM bafilomycin

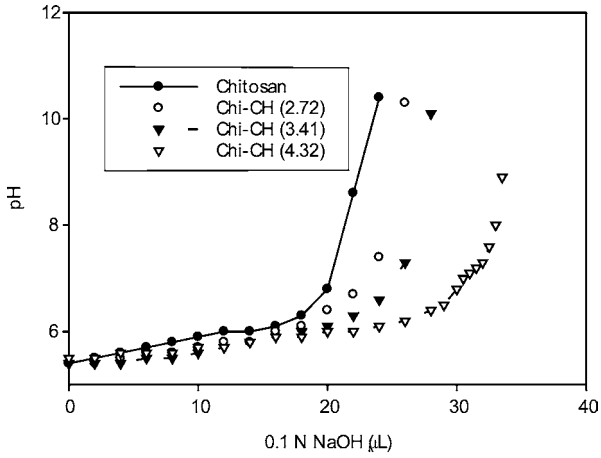

Figure 1. Buffering capacity of chitosan and Chi-CH. Chitosan and Chi-CH were determined after dissolution in sodium acetate buffer at pH 5.5 and then titration with 0.1 N NaOH. The pH was plotted to compare the differences in buffering capacity after treatment with different molar ratios of reactants.

A_1 in Opti-MEM I for 10 min. Then, 6 μg/mL pDNA complexed with chitosan or Chi-CH was added to each well. Lipofectamine 2000 containing 2 μg/mL pDNA was prepared according to the protocol provided by the manufacturer. The dose of pDNA of jetPEI was reduced to half the dose suggested by the protocol, 1 μg/mL, because of concerns about the toxicity of bafilomycin A_1 and polyethylenimine (PEI). The medium was changed to DMEM after a 6 h incubation. The cells were harvested after a 24 h incubation and then lysed. The amount of luciferase was measured using a PicaGene Luciferase Assay Kit.

Measurement of Gene Transfection Efficiency. HEK293 cells were seeded in 12-well plates at a density of 1×10^5 cells/mL. After a 24 h incubation, cells were incubated with complexes containing 6 μg/mL pDNA in Opti-MEM I for 6 h. The medium was changed to DMEM after a 6 h incubation. The cells were harvested at 72 h and then lysed for the measurement of luciferase activity as described previously. The relative luminescence unit (RLU) was measured by luminometer (Lumat Single Tube Luminometers LB 9507, Berthold Technologies GmbH & Co. KG, Wildbad, Germany) and normalized by the protein content, which was measured by Bradford assay.

RESULTS

Synthesis of Chi-CH. Liquid-phase synthesis was used in this study because a greater amount of dipeptide can be produced by liquid-phase synthesis than solid-phase synthesis. Mass calculated for $C_{10}H_{16}N_4O_3S$ (His-Cys-OMe): 272.32. Found by ESI-MS: 273.4 ($M+H^+$). The yields of Cys(Acm)-OMe, Boc-His(Boc)-Cys(Acm)-OMe, and His-Cys-OMe were 99%, 46%, and 90%, respectively, and confirmed by ESI-MS as 204.4 [$M+H^+$], 544.4 [$M+H^+$], and 273.4 [$M+H^+$]. Three different molar ratios of cross-linker and chitosan were designed to produce three types of Chi-CH: Chi-CH A, Chi-CH B, and Chi-CH C (Table 1). The ninhydrin results are shown in Table 1 demonstrating the degree of substitution of dipeptide. Chitosan was also measured in the same process as the control group. The data of the degree of substitution of chitosan were subtracted from that of Chi-CH A, B, and C groups. Chi-CH C showed the highest degree of substitution, 4.32%, compared with Chi-CH A and Chi-CH B, with a substitution of 2.72% and 3.41%, respectively.

Improvement of Buffering Capacity. The titration curve (Figure 1) showed that the Chi-CH C (4.32%) group tolerated more OH^- ions than the other two groups. Chitosan also had some buffering capacity between pH 5 and 6; however, the buffering range of chitosan was narrower than that of the histidine-modified chitosan groups. Therefore, Chi-CH C (4.32%) was chosen for use as a gene carrier for the subsequent experiments.

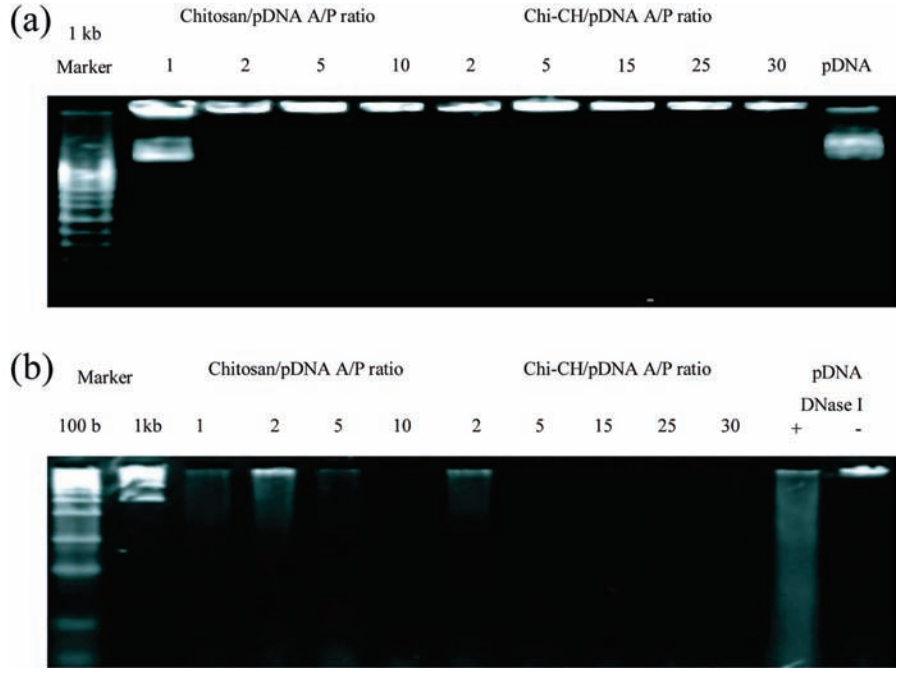

Figure 2. Physical and enzmatic stability of complexes. (a) Chitosan and Chi-CH were dissolved in sodium acetate buffer, pH 5.5, respectively, and mixed with pDNA solution at different A/P ratios.The mixed solutions were incubated at room temperature for 30 min and loaded into the wells of a 1% agarose gel. The gel was stained with SYBR Gold to detect DNA. (b) The complexes prepared at different A/P ratios were incubated with 10 U DNase I at 37 °C for 3 h. The DNA after incubation was extracted using phenol/chloroform/isoamyl alcohol (Nacalai Tesque Inc.) and loaded into the wells of a 1% agarose gel. The gel was stained with SYBR Gold.

[a] Chitosan and Chi-CH were dissolved in sodium acetate buffer and mixed with pDNA solution at different A/P ratios. After 30 minutes incubation at room temperature, the particle size was measured by ZetaNanoSizer at pH 5.5 and pH 7.4 ($n = 3$).

Physicochemical Characterization of Complexes. The particle size of the complexes (Table 2a) was measured at pH 5.5 and 7.4 in order to evaluate the influence of pH on the dispersion of the complexes. At pH 5.5, both chitosan/pDNA and Chi-CH/pDNA had a particle size lower than 200 nm. At pH 7.4, chitosan/pDNA complexes had a small particle size at an A/P ratio less than 10. However, larger chitosan/pDNA complexes were observed at 15 and 25 A/P ratios, respectively, in contrast to the smaller size of the Chi-CH/pDNA complexes at the same A/P ratio. At A/P 25, ZetaNanoSizer could not measure the particle size of chitosan/pDNA complexes due to the aggregation that occurred at a high A/P ratio, which was beyond the detection limit of the instrument. The zeta potential is shown in Table 2b. At both pH 5.5 and 7.4, chitosan/pDNA and Chi-CH/pDNA complexes had the same zeta potential profile at a A/P ratio less than 10. However, the zeta potential of chitosan/pDNA complexes decreased from A/P 15, while that of Chi-CH/pDNA complexes was constant at A/P 15 and 25. The zeta potential of chitosan/pDNA at A/P 25 in pH 7.4 medium could not be measured due to aggregation.

Physical and Enzymatic Stability of Complexes. The physical stability of complexes evaluated by agarose gel electrophoresis (Figure 2a) demonstrated the high stability of both chitosan/pDNA and Chi-CH/pDNA groups, except for chitosan/pDNA at A/P 1. The ability to protect pDNA from enzyme degradation was also evaluated (Figure 2b). Chitosan/pDNA showed some degradation fragments at A/P 1, 2, and 5, while Chi-CH/pDNA showed degradation fragments only at A/P 2.

Enhancement of Cellular Uptake. The uptake of fluorescein-labeled pDNA by HEK293 was measured by flow cytometry at 2, 6, and 12 h (Figure 3). Chitosan/pDNA uptake was low at three time points. Chi-CH/pDNA demonstrated gradually increasing uptake from 2 to 6 h and reached an uptake plateau at 6 h in contrast to the negligible uptake of chitosan/pDNA.

Endosomal Escape. Endosomes (pH 5.0−6.0) and lysosomes (pH 5.0−5.5) in HEK293 cells were labeled with Alexa Fluor 488 transferrin conjugate (Figure 4a), LysoTracker Green DND-26 (Figure 4b), and LysoSensor Green DND-189 (Figure 4c), respectively. Chitosan/pDNA and Chi-CH/pDNA at A/P 2 and 25 were both examined first in endosome-labeling HEK293 cells

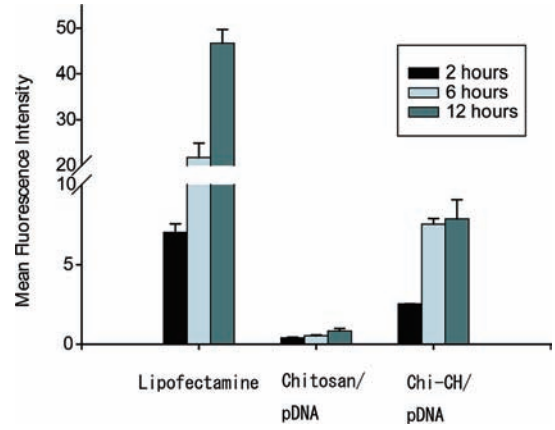

Figure 3. Cellular uptake of complexes. Fluorescein-labeled pDNA (1 μg/mL) complexes prepared by Lipofectamine 2000, chitosan, and Chi-CH were incubated with HEK 293 cells in Opti-MEMI at fixed time points. The extracellular fluorescence was quenched by Trypan blue, and the intracellular fluorescence was measured by flow cytometry. Lipofectamine 2000 was used as a positive control ($n = 3$).

(Figure 4a). We found that chitosan/pDNA at A/P 25 and Chi-CH/pDNA at A/P 2 did not show obvious intracellular distribution of TMR-labeled pDNA. Therefore, we chose chitosan/pDNA at A/P 2 and Chi-CH/pDNA at A/P 25 for the following lysosomal escape (Figure 4b,c). Chi-CH/pDNA showed a wide intracellular distribution of TMR-labeled pDNA at A/P 25 compared with a limited and overlapped intracellular distribution of chitosan/pDNA at A/P 2. These results suggested that chitosan/pDNA complexes may be trapped in the endosomes and lysosomes where the pH is lower than 5.5.

Effect of Proton Pump Inhibitor on Gene Transfection. Bafilomycin A_1 is an H^+-ATPase inhibitor, which inhibits acidification in endosomes and lysosomes (*27*). Generally, bafilomycin A_1 is used to indirectly prove that the buffering capacity of PEI increases the endosomal escape rate. This is because bafilomycin A_1 treatment inhibits the flow of hydrogen ions from cytosol into vesicles and then inhibits the increase of

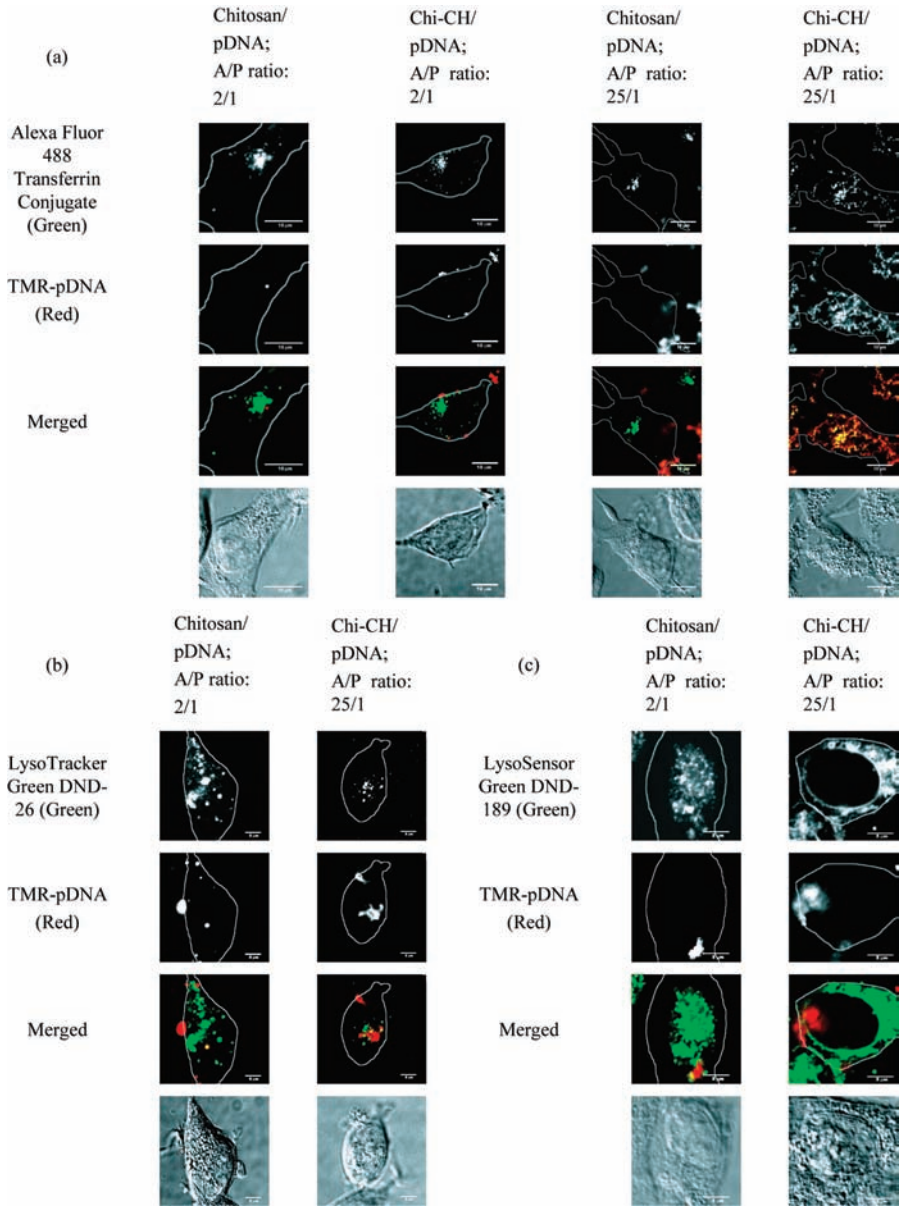

Figure 4. Confocal microscopy of complexes. Chitosan and Chi-CH formed complexes with TMRpDNA in A/P ratios of 2/1 and 25/1. HEK 293 cells were used as models to observe the endosomal escape. Cells were seeded into 12 well plates at 70% confluence. After 24 h incubation, medium of 100 mg/mL Alexa Fluor 488 transferrin conjugate (a), 1 μM LysoTracker Green DND-189 (b), or 1 μM LysoSenser Green DND-26 (c) was added to each well before complex administration. After a 20 to 30 min incubation, chitosan/TMR-pDNA and Chi-CH/TMR-pDNA were added to each well. After a 6 h incubation, the cells were washed by PBS and fixed with 4% paraformaldehyde. The distribution of fluorescence was observed by Nikon confocal microscopy (60× water immersion lens).

osmotic pressure caused by PEI (*28*). The inhibition of gene expression after bafilomycin A_1 treatment (Figure 5) may prove that the hydrogen ion concentration gradient plays an important role in the gene transfection process of Chi-CH/pDNA. After 100 nM bafilomycin A_1 treatment, a significant decrease in gene expression was observed in Chi-CH/pDNA and commercially available jetPEI (data not shown), while a slight but insignificant decrease in gene expression could also be recognized in chitosan/pDNA.

Evaluation of Gene Transfection Efficiency. Chitosan/pDNA and Chi-CH/pDNA complexes at different A/P ratios were prepared and transfected in HEK293 cells for gene expression screening (Figure 6). In the chitosan/pDNA groups, the A/P 2 group showed the highest gene expression after a 72 h incubation. The A/P 25 group of Chi-CH/pDNA showed the highest gene expression compared with other A/P ratios.

DISCUSSION

In this study, we designed His-Cys-OMe after considering three factors. First, the primary amine group in histidine was retained in order to prevent a reduction in nucleic acid binding strength. The positive charge of the primary amino group in histidine could bind to nucleic acids, which would help the formation of chitosan/pDNA complexes. Second, the direct linkage of the amine groups on the chitosan chain and the carboxylic acid group on histidine may reduce the buffering capacity of the histidyl imidazole group. A previous report demonstrated that the buffering range of histidine increased from pH 5−7 to pH 6−8 following conjugation with the acidic group

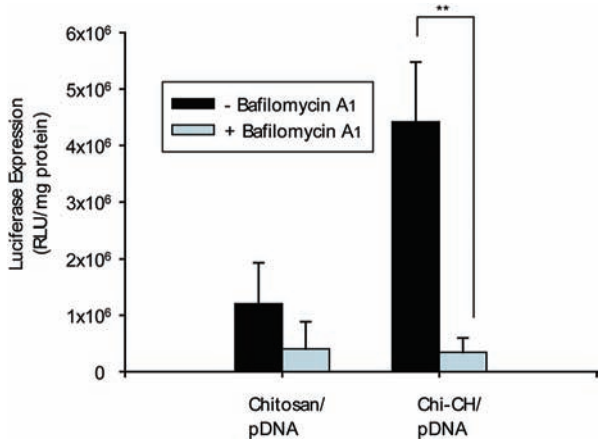

Figure 5. Proton pump inhibition. One hundred nanomolar bafilomycin A1 was added to HEK 293 cells seeded before 24 h into 12-well plates at a density of 1.5×10^4 cells/mL 10 min before complex administration. Complexes and bafilomycin A1 were incubated with the cells for 6 h, and then the medium changed from Opti-MEM I to DMEM(+) and the cells were incubated for another 66 h. The relative light units (RLU) were evaluated by luminometer and calibrated by Bradford protein assay. $^{**}p < 0.01$ ($n = 3$, +Bafilomycin A1 vs −Bafilomycin A1, Student's t test).

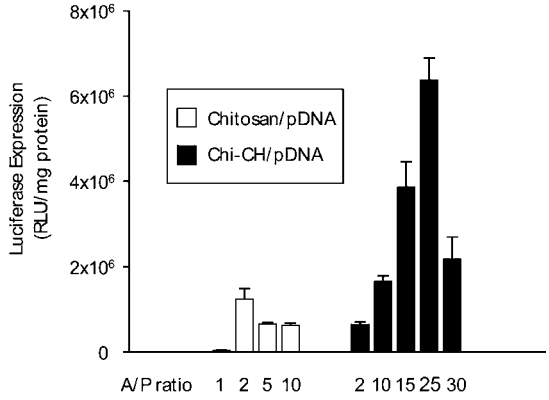

Figure 6. Gene expression of complexes. The gene transfection efficiency of different A/P ratios of chitosan/pDNA and Chi-CH/pDNA was screened by luciferase assay in HEK 293 cells. The RLU were calibrated by Bradford protein assay to obtain an accurate luciferase intensity per milligram protein ($n = 3$).

(*18*). Therefore, chitosan conjugated directly to histidine may increase the pK_a of histidine and then decrease the buffering capacity around the pH range of endosomes and lysosomes. Third, the disulfide bond formed between a cross-linker, 2-iminothiolane, conjugated to chitosan and cysteine linked to histidine can be formed at room temperature and in 10% DMSO. This process did not need any other organic solvent or further reagent treatment. No other side product which could disturb the biocompatibility was produced during the synthesis. This reaction could be performed under mild conditions without influencing the biocompatibility of chitosan (*25, 29*).

Materials with a high buffering capacity in endosomes and lysosomes, such as PEI, polylysine, and polyamidoamine, can trap hydrogen ions in endosomes and lysosomes; then, the H^+-ATPase pump on the membrane of endosomes and lysosomes would introduce more hydrogen ions inside and, finally, disrupt the endosomes and lysosomes because of the high osmotic pressure (*30*). Endosomal escape can be achieved by the high buffering capacity in the pH range of endosomes and lysosomes. In this study, Chi-CH (4.32%) exhibited the highest degree of substitution of the Chi-CH derivatives (Table 1) and have more buffering capacity than chitosan alone in solution (Figure 1). Therefore, Chi-CH (4.32%) was selected for the subsequent analysis and complex preparation. The buffering capacity of Chi-CH was also evaluated in cells by microscopic imaging. LysoSensor Green DND-189 emits a green color when the pH of the vesicles is lower than its pK_a (pK_a 5.2) corresponding to the lysosomal pH (Figure 4c). This result suggests that the TMR-labeled pDNA carried by Chi-CH was not surrounded by a low pH environment. This might be due to the buffering capacity of Chi-CH neutralizing the low pH in late endosomes or lysosomes and then improving the endosomal escape. In order to evaluate this endosomal escape, we examined the intracellular distribution of pDNA from chitosan/pDNA and Chi-CH/pDNA. Chi-CH/pDNA shows independent scattered red spots (TMR-labeled pDNA) without any overlapping green fluorescence (Alexa Fluor 488 transferrin conjugate in Figure 4a or LysoTracker Green DND-26 in Figure 4b), while chitosan/pDNA at an A/P ratio of 2/1 and 25/1 shows overlapping red and green fluorescence and aggregation of red fluorescence on the cell membrane, respectively. This result suggests that Chi-CH/pDNA escaped from endosomes or lysosomes more efficiently than chitosan/pDNA. The endosomal escape ability of Chi-CH/pDNA would be due to the buffering capacity provided by histidine. In addition, the gene expression of Chi-CH/pDNA with bafilomycin A_1 treatment was lower than that without bafilomycin A_1 treatment. This phenomenon could be explained by the higher buffering capacity of Chi-CH compared with chitosan. With these results taken into consideration, histidine modification could increase the endosomal escape of chitosan complexes efficiently by increasing the buffering capacity of chitosan.

The high cellular uptake was also an important factor for improving the gene transfection efficiency of Chi-CH/pDNA. Chitosan/pDNA shows negligible mean fluorescence intensity in cells even after a 12 h incubation (Figure 3). In combination with the result in Figure 4, which showed aggregation on the cell membrane, these results suggest that the low gene expression of chitosan/pDNA was mainly due to the slow pDNA release from the aggregates on the cell membrane. Moreover, the particle size of Chi-CH/pDNA was smaller than that of chitosan/pDNA at A/P ratios higher than 15 under neutral conditions (Table 2). The zeta potential of chitosan/pDNA also indicated a decreasing trend of chitosan/pDNA at a A/P ratio of 15 under neutral conditions (Table 2). These results suggest that chitosan/pDNA may encourage aggregation under neutral conditions. At pH 5.5, although the particle size of chitosan/pDNA did not increase at A/P ratios higher than 15, the zeta potential also shows the decreasing trend. Zeta potential is related to the electrophoretic mobility which was determined by ZetaNanoSizer. At A/P ratio higher than 15, the increasing viscosity of chitosan (*31*) and partial aggregation of chitosan/pDNA may affect the decrease of zeta potential. As far as cellular uptake is concerned, Chi-CH/pDNA shows nearly an 8-fold higher cellular uptake than chitosan/pDNA (Figure 3). The increase in the solubility after histidine conjugation, from nearly 0 mg/mL to 10 mg/mL under neutral conditions (data not shown), also provided a possible explanation for the higher cellular uptake. In several reports, the degree of aggregation of chitosan/pDNA has been shown to be reduced by increasing the water solubility of chitosan, such as modification by hydrophilic groups (*13*) and adjusting the molecular weight of chitosan (*6, 9, 32*). Therefore, the improvement in the cellular uptake of Chi-CH/pDNA might be partly attributed to the higher solubility of Chi-CH compared with chitosan.

In order to solve the problem of the slow endosomal escape rate during the process of drug or gene delivery, other reports have described how chitosan could also be modified with moieties which have a buffering capacity, including imidazole

(*33*) and *N*-α-acetyl-L-histidine (*34*). Our results are in agreement with these reports. The modification of imidazole proved that the increase in buffering capacity can increase the gene transfection efficiency of chitosan (*33*). The modification of *N*-α-acetyl-L-histidine on glycol chitosan also allowed the endosomal escape of paclitaxel (*34*). However, the acetylation on the N terminal end of histidine may increase the pK_a of the imidazole ring and then shift the buffering range of histidine to a higher pH. For example, the pK_a of histidine increases to 7−8 adjacent to an acidic amino acid (*18*), and the pK_a of *N*-α-acetyl-L-histidine is 7.2 (*35*). The shift of buffering range may reduce the buffering capacity of histidine in endosomes and lysosomes. In our design, the primary amino group (pK_a 9.2) and the imidazole ring (pK_a 6.0) could be prevented from basic shift of pK_a because we avoid chemical modification at the N terminal end of histidine.

CONCLUSION

We conjugated histidine to chitosan and increased the gene transfection efficiency of chitosan successfully by increasing the buffering capacity in the pH range of endosomes and lysosomes without affecting the integrity of the complexes. These results suggest that histidine helped the uptake of pDNA by cells and increased the efficiency of escape from endosomes and lysosomes.

Received February 24, 2010; Revised Manuscript Received March 29, 2010

The level of progesterone receptors (PRs) in breast tumors can be used to guide the selection of endocrine therapies for breast cancer patients. To this end, we have prepared a fluorine-18 labeled analogue of Tanaproget, a nonsteroidal progestin with very high PR binding affinity and low affinity for androgen and glucocorticoid receptors, and have studied its tissue distribution in estrogen-primed rats to evaluate its potential for imaging PR levels by positron emission tomography. 4-[^{18}F]Fluoropropyl-Tanaproget ([^{18}F]**9**, **FPTP**) was prepared in three steps, within 140 min at an overall decay-corrected yield of 5% and effective specific activity of >550 Ci/mmol. In biodistribution studies, [^{18}F]**9** uptake was high in target tissues at both 1 and 3 h (uterus, 4.55 and 5.26%ID/g; ovary, 2.32 and 2.20%ID/g, respectively) and was cleanly blocked by coinjection of excess unlabeled compound. Uterus to blood and muscle activity ratios were 9.2 and 5.2 at 1 h and 32 and 26 at 3 h, respectively. The biodistribution of [^{18}F]**9** compares favorably to that of previously prepared F-18 labeled steroidal progestins, FENP and FFNP. Its high target tissue uptake efficiency and selectivity, and prolonged retention, suggest that it has excellent promise as a PET imaging agent for PR-positive breast tumors.

INTRODUCTION

Receptor-targeted radiopharmaceuticals are designed to image specific molecular targets and thereby obtain quantitative information about important metabolic, physiological, and pathological processes in living systems. Steroid receptors, members of the nuclear hormone receptor superfamily, are key regulators of gene expression and cellular function, and have emerged as very attractive targets for imaging (*1*). The activity of certain steroid receptors drives the growth of hormone-responsive cancers, both the estrogen receptor (ER) and the progesterone receptor (PR) in breast cancer, and the androgen receptor (AR) in prostate cancer. Consequently, these receptors are both biomarkers for diagnosis and targets for cancer endocrine therapies (*1*).

Currently, measurements of tumor ER, PR, or AR levels are done in vitro by immunohistochemical assays (*2*−*4*), but there is great interest in developing methods to determine receptor levels by in vivo imaging using positron emission tomography (PET), which could potentially measure receptor levels at all tumor sites, simultaneously and noninvasively (*1, 5*−*8*). This information could be used to select patients most likely to benefit from endocrine therapies, thereby sparing some the morbidity of radiation and chemotherapy. Clinical PET imaging of ER in breast cancer using 16α-[^{18}F]fluoroestradiol (FES) (*9*−*14*) and AR in prostate cancer using 16β-[^{18}F]fluoro-5α-dihydrotestosterone (FDHT) (*15*−*18*) is quite advanced, but thus far, only limited progress has been made with PET imaging of PR (*19*−*22*).

Because PR levels are regulated through ER, breast tumor PR levels have been used, together with ER levels, to predict patient response to ER-targeted therapies (either antiestrogens or aromatase inhibitors) (*2*). In fact, because PR levels are increased by estrogen treatment, measurement of an increase in PR levels in breast tumors by PET, after a brief exposure to estrogen, might be useful in assessing whether the ER is functional and thus capable of mediating endocrine therapies (*19, 23*). PR itself is also a target for endocrine therapy in breast cancer using antiprogestins (*24*).

Currently, most PR ligands are steroidal compounds having similar core structures (Figure 1) (*25, 26*). In the search for diagnostic PR tumor imaging agents, some of these have been labeled with radionuclides such as F-18, I-123, and Br-76 (*1, 21, 27*−*29*). Because fluorine-18 ($t_{1/2}$ = 110 min, β^+ emitting) has the most favorable nuclear and physical properties for PET imaging, we and others have investigated the in vivo behavior of two F-18 labeled steroidal progestins, 21-[^{18}F]fluoro-16α-ethyl-norprogesterone (**[^{18}F]FENP**, **2**) and 21-[^{18}F]fluoro-furanyl-norprogesterone (**[^{18}F]FFNP**, **5**). FENP, based on the well-known, potent Organon progestin, ORG2058 (**1**), has very high binding affinity and showed excellent target tissue uptake efficiency and selectivity in estrogen-primed rats, but surprisingly failed to image PR in humans (*20*). This species difference was traced to 20-hydroxysteroid dehydrogenase (20-HSD) activity, present in the blood of humans but not rodents, that rapidly converts **FENP** into the inactive 20-hydroxy analogue (*27*). **FFNP** (*19*), on the other hand, appears resistant to this dehydrogenase and is currently being evaluated as a PET PR imaging agent in humans.

Despite the continuing promise of **FFNP**, there are potential liabilities in using 20-keto steroids as PR PET imaging agents, because steroidal progestins often show cross reactivity with other steroid receptors, notably the glucocorticoid receptor (GR)

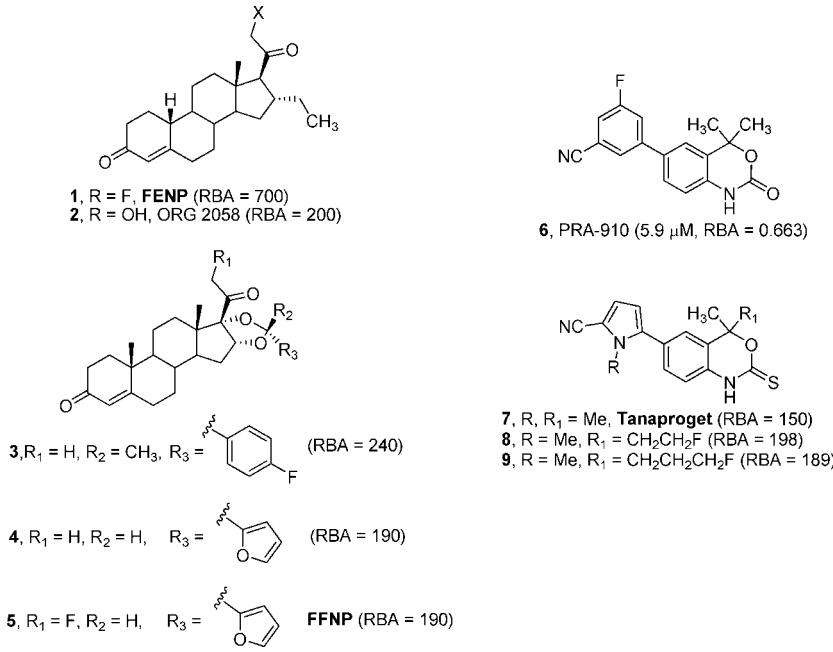

Figure 1. Structure and PR binding affinity of some steroidal (**1**−**5**) and nonsteroidal (**6**−**9**) progestins in the series leading to the F-18 labeled analogues, **FENP** (**2**), **FFNP** (**5**), and **FPTP** (**9**).

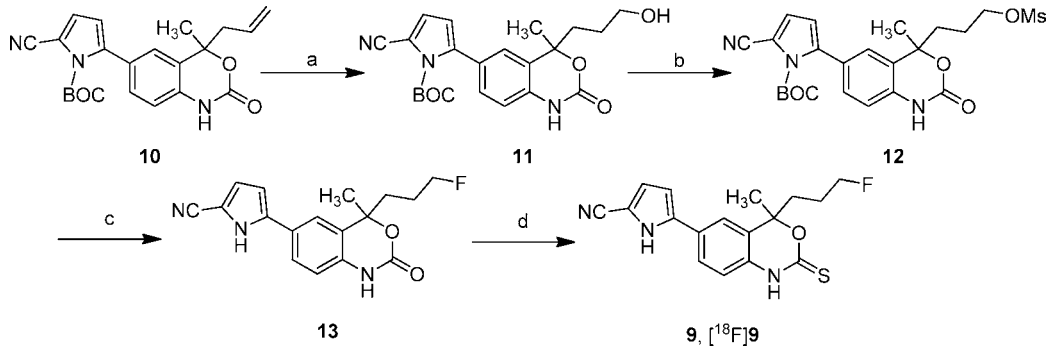
and AR (*30*), and the inactivating metabolism by the 20-HSD is still possible (*27*). Additionally, steroids generally have high lipophilicity, which could increase nonspecific binding.

A number of pharmaceutical companies have reported nonsteroidal progestins with high PR binding affinity and excellent selectivity (*26, 31*−*33*). We were particularly attracted to Tanaproget (**7**), a nonsteroidal progestin developed by Wyeth, that is based on a dihydrobenzoxazinethione core structure. Its PR binding affinity is very high, nearly twice that of the potent steroidal progestin R5020, giving it an estimated K_D of ∼0.2 nM (*34, 35*); its affinity for GR and AR is also very low. Thus, if the F-18 radionuclide could be introduced into Tanaproget or a high-affinity analogue, it might be an effective PET imaging agent for PR-positive tumors.

We recently reported the syntheses and binding affinity of several Tanaproget derivatives containing fluoroethyl or fluoropropyl substituents as potential PET PR imaging agents, including ones having affinities higher than Tanaproget itself (*36*). In this report, we describe synthesis of [^{18}F]fluoropropyl-Tanaproget (**FPTP**, **9**), and we evaluate its tissue distribution in estrogen-primed immature female rats. Its target tissue uptake efficiency, selectivity, and specificity are excellent, and compare favorably with those of **FENP** and **FFNP**. Therefore, it appears to be an excellent prospect for further evaluation as an agent for PET imaging of PR in breast tumors.

RESULTS



Chemistry. *Synthesis of Fluoropropyl Tanaproget Derivatives.* Guided by the structure−affinity relationships in the Tanaproget series, available in the literature, we synthesized a number of Tanaproget analogues containing 2-fluoroethyl and 3-fluoropropyl groups. These are described in our recent publication (*36*). Substitution on the pyrrole nitrogen gave lower-affinity analogues, but replacement of one of the methyl groups on the dihydrobenzoxazinethione core with a 2-fluoroethyl or a 3-fluoropropyl group gave very high affinity Tanaproget analogues (Figure 1). We chose one of these, 3-fluoropropyl-Tanaproget (**FPTP**, **9**), to evaluate further. In competitive radiometric PR binding assays, where the standard progestin, R5020, is given a relative binding affinity (RBA) value of 100, Tanaproget has an RBA value of 150 and **FTPT** of 189 (*36*).

Our original route to unlabeled **FTPT** was not well suited for F-18 labeling, because fluoride ion was introduced early in the sequence, and three subsequent steps were required to produce the final product. In our first approach to develop an alternative synthesis more amenable to F-18 labeling, we tried to prepare a precursor in which F-18 could be introduced in the last step by fluoride ion displacement of a methanesulfonate analogue of **FTPT** itself (or a BOC-protected version). However, the alcohol in the hydroxypropyl group was not stable under the harsh conditions required to convert the carbamate to the thiocarbamate with Lawesson's reagent. It was also very unlikely that the electrophilic methanesulfonate group would have been compatible with the nucleophilic thiocarbamate function under the conditions required for fluoride ion substitution. We therefore turned to the use of the methanesulfonate of the corresponding carbamate (**12**), thinking that the oxygen would be less nucleophilic than the sulfur. As shown in Scheme 1, synthesis of this precursor began with allylcarbmate **10**, which was hydroborated and oxidized to give corresponding hydroxyl compound **11** in good yield (74%). Subsequent treatment with methansulfonyl chloride and triethylamine furnished the desired labeling precursor **12** in good yield (79%).

In model reactions for F-18 labeling, and to prepare authentic samples of the unlabeled compounds, mesylate **12** was treated with tetrabutylammonium fluoride (TBAF) in *tert*-butyl alcohol at 90 °C for 2 h, followed after solvent removal by heating at 160 °C neat for 20 min to remove the BOC protecting group on the pyrrole. This one-pot/two-step sequence provided the fluorinated carbamate **13** in a high yield (81%). As has been observed in other systems (*37*−*41*), use of this protic solvent protocol for the fluoride substitution step was effective in reducing the formation of side products through elimination or hydrolysis, and gave high yields of the fluorinated product. **FPTP** (**9**) itself was then obtained in good yield (70%) by treatment with Lawesson's reagent, which converted the carbamate to the thiocarbamate. However, the reaction required heating in toluene at 100 °C for 2 h, conditions that were subsequently modified to be more suitable for labeling with the short-lived F-18 radionuclide ($t_{1/2}$ = 110 min) (see below).

Synthesis of [^{18}F]Fluoropropyl-Tanaproget. 4-[^{18}F]Fluoropropyl-Tanaproget **9** (**FPTP**) was prepared by the same

Scheme 1[a]

[a] Reagents and conditions: (a) (i) BH_3·THF, THF, −10 °C, N_2, 90 min; (ii) 4 N NaOH, 10 min; (iii) H_2O_2, 2 h, 74%; (b) MsCl, CH_2Cl_2, 0 °C, 2 h, 79%; (c) (i) *n*-Bu_4NF, *tert*-BuOH, 90 °C, 2 h; (ii) neat, 160 °C, 20 min, 81%; (d) Lawesson's reagent, toluene, 100 °C, 2 h, 70%. Radiolabeling conditions: (c) (i) *n*-$Bu_4N[^{18}F]F$, *tert*-amyl alcohol. 130 °C, 20 min, (ii) 160 °C, 10 min; (d) Lawesson's reagent, toluene, 130 °C, 30 min.

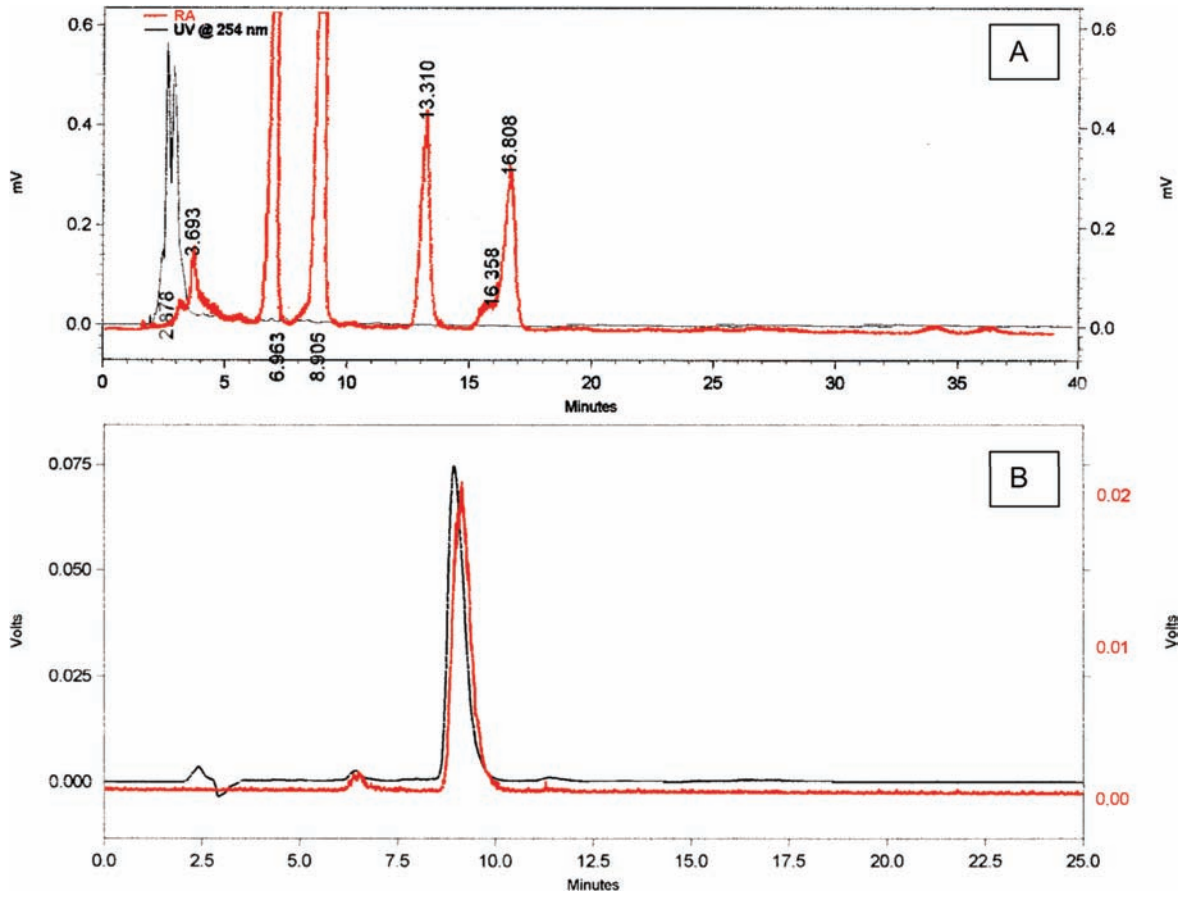


Figure 2. HPLC Profile of reaction mixture from the production of [^{18}F]**9** (Panel A), and purified [^{18}F]**9** coinjected with unlabeled **9** (Panel B). HPLC conditions (Panel A): Altima, C18, 10 μm, 250 × 10 mm, MeOH/water = 65:35, 3.5 mL/min, R_t = 16.8 min; (Panel B): co-injection with standard **9** and [^{18}F]**9**: Econosil, C18, 10 μm, 250 × 4.6 mm, CH_3CN/water = 50:50, 0.8 mL/min, 254 nm.

sequence from methanesulfonate precursor **12**. Treatment with *n*-$Bu_4N[^{18}F]F$ in *tert*-amyl alcohol at 130 °C for 20 min gave the F-18 labeled intermediate, which on further heating in the same vessel after solvent removal (160 °C for 10 min) underwent deprotection to give the penultimate precursor, **13**. Conversion of the carbamate group to the thiocarbamate was achieved by heating with Lawesson's reagent in toluene at 130 °C for 30 min. The final step, producing [^{18}F]**9**, proceeded in 5% yield (decay corrected), after purification by reversed-phase HPLC (see Figure 2).

To accelerate the last step and increase conversion yield, we used 3.0 equiv of Lawesson's reagent, rather than 0.6 equiv, which was sufficient in preparative scale reactions. We also increased the reaction temperature to 130 °C and reduced the reaction volume to 300 μL. Under our original conditions for synthesizing the unlabeled compound (1.2 equiv and 100 °C for 2 h), the carbamate to thiocarbamate conversion proceeded in an overall yield of less than 10%, whereas the modified conditions gave a 40% yield.

With these modifications, the overall radiochemical yield of desired F-18 labeled compound [^{18}F]**8** was 5% (decay-corrected), within a total synthesis time of 140 min from end of bombardment (EOB). The radiochemical purity of [^{18}F]**9** was determined to be >95% by reversed-phase HPLC. The effective specific activity of [^{18}F]**9** was >550 Ci/mmol, determined by a competitive receptor binding assay (*42*).

*Tissue Distribution Studies with [^{18}F]**9** (FPTP).* Purified F-18 fluoropropyl-Tanaproget ([^{18}F]**9**) was reconstituted in 10%

Table 1. Tissue Biodistribution of 3-[18F]Fluoropropyl-Tanaparoget Derivative [18F]9 in Immature Estrogen-Primed Female Rats

	percentage injected dose/gram ± SD[a] ($n = 5$)

ovaries/blood	4.84 ± 0.37	2.67 ± 0.48	13.39 ± 1.65	2.20 ± 0.41
ovaries/muscle	3.95 ± 1.26	1.45 ± 0.24	11.04 ± 1.90	1.90 ± 0.21

[a] SD is standard deviation.

EtOH/saline. This solution was injected (i.v., veil tail) into immature female rats that had been estrogen pretreated to induce the levels of PR in the uterus (*19, 21*). Doses employed were 26 μCi/rat. The tissue distribution was determined at 1 and 3 h postinjection, and tissue activity, as percent injected dose/gram, and target tissue to blood and muscle ratios are given in Table 1. To confirm that the uptake was mediated by a high-affinity, limited-capacity system, one set of rats in each time study was coinjected with the [18F]**9** and 33.3 μg/rat of unlabeled **9**, to saturate the PR (Table 1, 1 and 3 h "blocked").

Labeled **FPTP** ([18F]**9**) showed target tissue uptake that was efficient, selective, and persistent. At 1 h, the %ID/g was 4.55% in the uterus and 2.32% in the ovary; this level of target tissue uptake persisted at 3 h without diminution. While initial uptake in certain nontarget tissues was high (liver, 3.52% ID/g; kidney, 2.56% ID/g), these levels cleared considerably at the later time. Consequently, the ratio of activity in uterus to blood and muscle increased markedly with time, so that at 3 h, the ratios were 32 for uterus/blood and 26 for uterus/muscle; these ratios for the ovary were 13 and 11, respectively.

The selectivity of target tissue uptake was evident from the marked displacement that occurred in uterus and ovary when the unlabeled compound (**9**) was coinjected. At 3 h, uterine activity was blocked by 93% and ovary activity by 86%; no block was observed in nontarget tissues. The uptake in the bone, which, if high and persistent, can be an indicator of in vivo defluorination, was relatively low, 0.93% ID/g at 1 h, and declined at 3 h (0.6% ID/g).

DISCUSSION

In a quest for effective agents for imaging progesterone receptor (PR) in breast tumors by PET, we have synthesized a fluoropropyl analogue of the high affinity, nonsteroidal progestin, Tanaproget (**7**), that we term fluoropropyl-Tanaproget (**FPTP**, **9**) (*36*). We developed a method to label this compound with F-18 at high specific activity ([18F]**FPTP**, **9**), and in an estrogen-primed immature rat animal model, we demonstrated that **[18F]FPTP** (**9**) shows target tissue uptake that is efficient, selective, and persistent. The synthesis of [18F]**9** required two steps after F-18 incorporation, the most challenging of which involved conversion of a carbamate to a thiocarbamate function. The overall process of F-18 labeling and subsequent transformations and purifications took 140 min and gave the final material in 5% radiochemical yield (RCY) with an effective specific activity of >500 Ci/mmol.

It is instructive to compare the biodistribution of [18F]**FPTP** (**9**) with that of two other F-18 labeled progestins that we have studied, 21-[18F]fluoro-16α-ethyl-norprogesterone (**FENP**, **2**) and 21-[18F]fluoro-furanyl-norprogesterone (**FFNP**, **5**) (Figure 3). The ovarian and uterine uptake of [18F]**FPTP** (**9**) at 1 h postinjection was comparable with that of the other progestins, [18F]**FENP** and [18F]**FFNP**; kidney and, in one case, liver uptake of [18F]**FPTP**, however, was somewhat higher. All three compounds showed very good retention in target tissues, so that at 3 h postinjection, activity in the ovaries and uterus is essentially the same as at 1 h, but activity in nontarget tissues (liver, kidney, muscle, and blood) has decreased. Of the three compounds, bone uptake is the least with [18F]**FPTP**, indicating that metabolic defluorination of this compound is minimal. Bone uptake with [18F]**FFNP** is considerable, but some F-18 labeled compounds that show high bone uptake in rats show little bone uptake in primates and humans (*43*).

In previous work, we sometimes compared the biophysical properties of potential PET receptor imaging agents not just in terms of their binding affinities (expressed as relative binding affinity or RBA values), but also in terms of their nonspecific binding (NSB), which we estimated from their lipophilicity, as expressed by their calculated or measured octanol−water partition coefficients (log $P_{o/w}$) (*1, 22*). We also calculated the ratio of these two values, RBA/NSB, which we termed the binding selectivity index (BSI) of the compound. Often, the BSI of a compound proved to be a more accurate predictor of the target tissue uptake characteristics of the compound than its RBA value (*1, 22*). This was true with both estrogens (*44, 45*) and progestins (*19*). Table 2 (left) summarizes these PR biophysical characteristics of the three F-18 labeled progestins and the standard progestin R5020 and (right) gives their GR and AR binding affinities.

The PR binding affinities of all three progestins are greater than that of the standard progestin, R5020, with **FENP** being the highest. The BSI values for all three progestins, however, are very similar, because both **FFNP** and **FPTP** have lower NSB values than **FENP** and R5020. Thus, in terms of these biophysical properties, all three F-18 labeled progestins appear quite comparable.

Although **FPTP** does not have biodistribution characteristics in estrogen-primed immature rat model that are significantly better than those of **FENP** and **FFNP**, it has other very favorable attributes that make it a compound that should be strongly considered for further development: First, **FPTP** is a nonsteroidal progestin and thus would not be a substrate for the 20-hydroxysteroid dehydrogenase found in human blood (*27*); this dehydrogenase led to the failure of **FENP** in humans (*27*), despite the excellent biodistribution of this compound in the rat model (*19* cf., Figure 3). **FFNP** shares a 20-keto group with **FENP**, but although the bulky acetal function fused to the D-ring in **FFNP** is thought to retard or block this inactivating metabolism, this is not certain. Second, **FPTP**, again being a nonsteroidal compound, has very low affinity for other receptors in the same receptor subfamily, namely, AR and GR; **FFNP**, by contrast, binds to GR avidly (Table 2, right). Whether this proves to be an important matter in breast tumor imaging needs to await further studies. Finally, **FPTP** is a chiral compound and thus far has been prepared and studied only as a racemate. Because it is likely that one **FPTP** enantiomer will have higher binding affinity than the other, the high-affinity isomer might have yet more favorable biodistribution properties. We are currently developing methods to separate and/or prepare selectively the **FPTP** enantiomers, and if they have different affinities, we will prepare them in F-18 labeled form for further study.

CONCLUSION

We have prepared a fluoropropyl-Tanaproget derivative, **FPTP** ([18F]**9**), as a potential agent for PET imaging of PR in breast cancer. This nonsteroidal compound has very high PR binding affinity and low affinity for AR and GR and would be

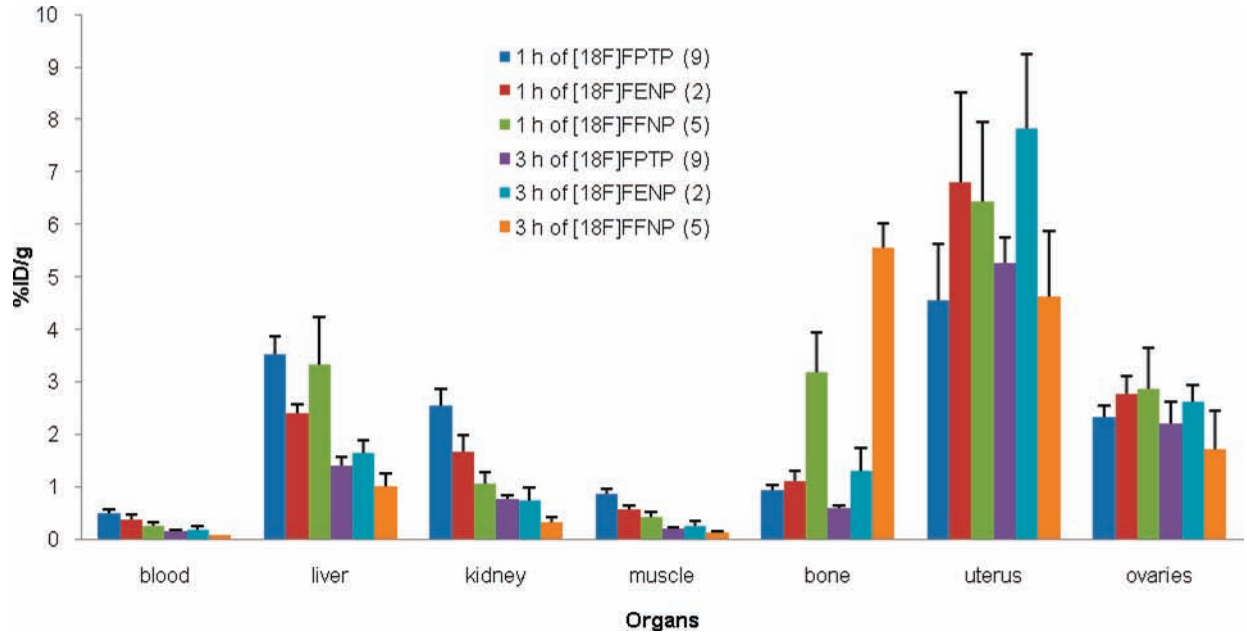

Figure 3. Comparison of tissue biodistribution data of [^{18}F]**FPTP** (**9**), [^{18}F]**FENP** (**2**), and [^{18}F]**FFNP** (**5**) in immature estrogen-primed female rats.

Table 2. Comparison of Receptor Binding Affinities and Biophysical Properties of Three F-18 Labeled Progestins

compd	PR-RBA[a]	cLogP[b]	PR-NSB[c]	PR-BSI[d]	GR-RBA[f]	AR-RBA[g]
FPTP (**9**)	189	3.03	0.400	472	0.9	0.04

R5020	[100]	3.92	[1]	[100]	2.6	0.26

[a] RBA is relative binding affinity value, relative to the standard, R5020 (K_D [R5020] is 0.4 nM). [b] Calculated log $P_{o/w}$ from *ChemDraw*. [c] For calculation of NSB, see ref *46*. [d] BSI = RBA/NSB. [e] These BSI values differ somewhat from those reported earlier (*19*), which were based on experimentally measured log $P_{o/w}$ values. [f] GR-RBA values are relative to the standard, dexamethasone (K_D [dexamethasone] is 20 nM). [g] AR-RBA values are relative to the standard, R1881 (K_D [R1881] is 0.6 nM).

resistant to 20-hydroxysteroid dehydrogenase inactivation. It also shows very favorable target tissue distribution in an estrogen-primed immature rat model. Further studies are planned on this compound and its constituent enantiomers in other animal models.

EXPERIMENTAL SECTION

All chemical was commercially purchased from Sigma-Aldrich Chemical Co. and TCI and used without further purification. Anhydrous THF solvent was obtained from an anhydrous solvent dispensing system (*47*). Flash column chromatography was performed with silica gel (Merck, 230−400 mesh ASTM). Analytical thin layer chromatography (TLC) was performed with Merck silica gel F-254 glass-backed plates. Visualization on TLC was monitored by UV light. ^{1}H and ^{13}C NMR spectra were obtained on Varian Unity 400 (400 MHz) and 500 (500 MHz) and are reported in parts per million downfield from internal tetramethylsilane. Mass spectra were obtained on 70 eV using the micromass 70-VSE mass spectrometer, and ESI mass spectra were achieved using the Quattro mass spectrometer. Melting points obtained using a Thomas-Hoover Uni-Melt capillary melting point apparatus and are uncorrected. High-performance liquid chromatography (HPLC) was carried out on a Thermo Co. system with a semipreparative column. $H_2{}^{18}O$ was purchased from Rotem Industries. The screwcap test tubes used for fluoride incorporation were purchased from Fisher Scientific (Pyrex no. 9825). Oasis HLB-6 cm^3 cartridges (500 mg) as ion exchange cartridge were purchased from Waters Corp. (part no. 186000115). [^{18}F]Fluoride ion was produced at Washington University by ^{18}O(p,n)^{18}F reaction through irradiation of 95% enriched [^{18}O]water, using either the JSW BC16/8 cyclotron (The Japan Steel Works Ltd.) or the CS15 cyclotron (The Cyclotron Corp.). Radiochemical purification of [^{18}F]**9** utilized a reversed-phase semipreparative HPLC column (Alltima C18, 250 × 10 mm, 10 μm, 254 nm, MeOH/water = 65:35, 3.5 mL/min). For quality control, the radiochemical purity of [^{18}F]**9** was determined by analytical HPLC (Econosil C18, 250 × 4.6 mm, 10 μm, 254 nm, CH_3CN/water = 50:50, 0.8 mL/min). TLC plates were analyzed using a Bioscan, Inc., System 200 imaging scanner. Radioactivity was determined with a dose calibrator. Radiochemical yields are decay-corrected to the beginning of synthesis time. *N-tert*-Butoxycarbonylpyrrole-2-boronic acid is commercially available (CAS no 135884−31−0).

Synthesis of 5-(4-(3-Hydroxy)-4-methyl-2-oxo-2,4-dihydro-1*H*-benzo[*d*][1,3]oxazin-6-yl)-*N*-*tert*-buthoxycarbonyl-pyrrole-2-carbonitrile (11). To a solution of 2-(4-allyl-4-methyl-2-oxo-1,4-dihydro-2*H*-benzo[*d*][1,3]oxazin-6-yl)-5-cyano-pyrrole-1-carboxylic acid *tert*-butyl ester (**10**) (*36*) (200 mg, 681.849 μmol) in dried THF (10 mL) was added BH_3·THF (1.0 M, 3.41 mL, 3.409 mmol) at −10 °C and stirred for 90 min. The reaction mixture was added aq. NaOH (4.0 M, 852 μL, 3.409 mmol) and stirred for 10 min, followed by addition of H_2O_2 (30%, 386 μL, 3.409 mmol) and further stirring for 2 h. The reaction mixture was added to water (200 mL) and extracted with EtOAc (20 mL × 3). The combined organic layer was dried over Na_2SO_4 and concentrated under reduced pressure. The residue was purified by flash column chromatography on silica gel to give 3-hydroxypropyl benzo[*d*]oxazines **11** (170 mg, 81%) as a bright yellow oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 9.61 (s, 1H), 7.20 (dd, J = 8.5 Hz, 2.0 Hz, 1H), 7.07 (d, J = 1.5 Hz, 1H), 6.96 (d, J = 3.5 Hz, 1H), 6.93 (d, J = 8.5 Hz, 1H), 6.23 (d, J = 3.5 Hz, 1H), 3.62 (td, J = 6.2 Hz, 1.2 Hz, 2H), 2,23 (br s, 1H), 2.17−2.01 (m, 2H), 1.71 (s, 3H), 1.69−1.62 (m, 2H), 1.52 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 152.7, 147.1, 139.6, 134.4, 129.5, 127.3, 124.6, 124.4, 124.2, 114.3, 113.9, 113.3, 105.4, 87.2, 85.5, 62.1, 37.2, 27.5, 27.1, 26.7; MS (FAB): *m/z*

412.2 $(M+H)^+$, 356.1, 311.1, 289.1, 269.1, 154.2 (100), 136.1, 106.7. HRMS (FAB) calcd for $C_{22}H_{26}N_3O_5$ 412.1872, found 412.1873.

Synthesis of 5-(4-(3-Methylsulfonyloxy)-4-methyl-2-oxo-2,4-dihydro-1*H*-benzo[*d*][1,3]oxazin-6-yl)-*N*-*tert*-buthoxycarbonyl-pyrrole-2-carbonitrile (12). To a solution of 3-hydroxypropyl benzo[*d*]oxazines **11** (170 mg, 413.173 μmol) in CH_2Cl_2 (50 mL) was added triethylamine (173 μL, 1.240 mmol), and the mixture was cooled to 0 °C. Methanesulfonyl chloride (48 μL, 619.759 μmol) was added, and stirring continued for 2 h. The mixture was added to water (100 mL). The organic layer was separated, and aqueous layer was extracted with CH_2Cl_2 (20 mL × 2). The combined organic layer was dried over Na_2SO_4 and concentrated by rotary evaporation. The residue was purified by flash column chromatography on silica gel (70% EtOAc/hexane) to obtain mesylated benzo[*d*]oxazines **12** (136 mg, 67%) as a bright yellow oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 9.54 (s, 1H), 7.23 (dd, J = 8.5 Hz, 2.0 Hz, 1H), 7.06 (d, J = 1.5 Hz, 1H), 6.97 (d, J = 3.5 Hz, 1H), 6.92 (d, J = 8.0 Hz, 1H), 6.25 (d, J = 4.0 Hz, 1H), 4.23 (t, J = 6.0 Hz, 2H), 2.98 (s, 3H), 2.21−2.06 (m, 2H), 1.94−1.83 (m, 2H), 1.71 (s, 3H), 1.51 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 152.4, 147.1, 139.4, 134.3, 129.8, 127.6, 124.45, 124.43, 123.6, 114.4, 114.0, 113.3, 105.5, 87.2, 84.9, 69.4, 37.3, 36.6, 27.5, 27.3, 23.7; MS (FAB): *m*/*z* 490.1 $(M+H)^+$, 460.1, 389.1, 307.1, 289.1, 273.1, 154.2 (100), 136.1, 119.9, 106.7. HRMS (FAB) calcd for $C_{23}H_{28}N_3O_7S$ 490.1648, found 490.1648.

Synthesis of 5-(4-(3-Fluoropropyl)-4-methyl-2-oxo-2,4-dihydro-1*H*-benzo[*d*][1,3]oxazin-6-yl)-1*H*-pyrrole-2-carbonitrile (13). To a solution of mesylated benzo[*d*]oxazines **12** (680 mg, 1.390 mmol) in *tert*-BuOH (100 mL) was added n-$Bu_4NF\cdot 3H_2O$ (658 mg, 2.085 mmol) at room temperature. The reaction mixture was stirred at 90 °C for 2 h. The reaction mixture was heated to 160 °C for 20 min under N_2 gentle stream. The vial was cooled to room temperature, dissolved with EtOAc (50 mL), and absorbed onto a small amount of silica gel. Purification by flash column chromatography on silica gel (60% EtOAc/hexane) gave compound **13** (350 mg, 81%) as a bright yellow oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 10.42 (s, H), 9.14 (s, 1H), 7.44 (dd, J = 8.2 Hz, 1.8 Hz, 1H), 7.35 (d, J = 2.0 Hz, 1H), 6.92−6.90 (m, 2H), 6.46 (dd, J = 4.0 Hz, 2.5 Hz, 1H), 4.47 (dt, J = 47.0 Hz, 5.8 Hz, 2H), 2.89−2.11 (m, 2H). 1.87−1.77 (m, 2H), 1.74 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 152.5, 136.9, 133.8, 126.7, 125.9, 125.0, 121.5, 120.4, 115.43, 115.36, 107.0, 100.9, 85.5, 83.8 (d, J = 164.0 Hz, 1C), 36.5 (d, J = 3.75 Hz, 1C), 27.5, 24.9 (d, J = 20.1 Hz, 1C); MS (FAB): *m*/*z* 314.1 $(M+H)^+$, 307.1, 289.1, 273.1, 258.1, 235.2, 219.3, 195.2, 165.2, 154.1 (100), 136.1, 119.9, 106.7. HRMS (FAB) calcd for $C_{17}H_{17}FN_3O_2$ 314.1305, found 314.1305.

Synthesis of 5-(4-(3-Fluoropropyl)-4-methyl-2-thioxo-2,4-dihydro-1*H*-benzo[*d*][1,3]oxazin-6-yl)-1*H*-pyrrole-2-carbonitrile (9). The mixture of compound **13** (20.0 mg, 63.830 μmol) and Lawesson's reagent (28.4 mg, 70.214 μmol) in toluene was heated at 100 °C for 2 h. The reaction mixture was added to water (10 mL) and extracted with EtOAc (5 mL × 3). The combined organic layer was dried over Na_2SO_4 and concentrated in vacuo. The residue was purified by flash column chromatography on silica gel (30% EtOAc/hexane) to give 3-fluoropropyl benzo[*d*]thiazines **9** (14.7 mg, 70%) as a yellow oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ 9.23 (s, 1H), 9.12 (s, 1H), 7.46 (dd, J = 8.5 Hz, 1.5 Hz, 1H), 7.29 (s, 1H), 6.93 (t, J = 3.0 Hz, 1H), 6.89 (d, J = 8.5 Hz, 1H), 6.51 (t, J = 3.0 Hz, 1H), 3.62−3.54 (m, 2H), 2.36−2.30 (m, 1H), 2.22−2.16 (m, 1H), 2.03−1.96 (m, 1H), 1.92−1.84 (m, 1H), 1.78 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 25.1 (d, J = 20.3 Hz, 1C), 26.0, 36.3 (d, J = 4.0 Hz, 1C), 83.6 (d, J = 162.3 Hz, 1C), 85.8, 107.5, 114.7, 115.1, 120.8, 121.0, 126.0, 126.2, 127.9, 132.2, 135.2, 136.9, 160.6. MS *m*/*z* 329 ($[M]^+$, 15%), HRMS (EI) calcd for $C_{17}H_{16}ON_3SF$ 329.0998, found 329.0998.

General Radiochemical Synthesis of 5-(4-(3-[^{18}F]fluoropropyl)-4-methyl-2-thioxo-2,4-dihydro-1*H*-benzo[*d*][1,3]oxazin-6-yl)-1*H*-pyrrole-2-carbonitrile ([^{18}F]9). The fluorine-18 radionuclide was produced by the ^{18}O(p,n)^{18}F reaction on an enriched water target. Oxygen-18 water containing the [^{18}F]fluoride anion was transferred to a reaction vessel containing tetrabutylammonium bicarbonate ($TBAHCO_3$) (40% in water, 2 μL), and CH_3CN was added. The water in the reaction vessel was removed by azeotropic distillation with CH_3CN under an N_2 stream at 110 °C. The reaction vessel was cooled to room temperature, and the remaining solvent was removed under a gentle N_2 stream at room temperature. The 3-mesylated Tanaproget substrate **12** was added to reaction vessel followed by adding *tert*-amyl alcohol (500 μL). The capped reaction vessel was heated at 130 °C for 20 min and then cooled to room temperature. After radio-TLC analysis to confirm incorporation of the radionuclide, the reaction solvent was removed completely under a stream of N_2 at 110 °C, and the residue in the vessel was heated to 160 °C for 10 min. The reaction mixture was allowed to reach room temperature and dissolved with EtOAc; water (2 mL) and brine (500 μL) were added. The resulting solution was extracted with EtOAc (1 mL × 2). The combined organic layer was evaporated completely under a gentle N_2 stream at 110 °C. The residue was treated with Lawesson's reagent followed by addition of toluene and then heated to 130 °C for 30 min. The solvent removed under N_2 stream at 110 °C. After being cooled to room temperature, the residue was dissolved with CH_3CN followed by passage through an activated silica Sep-Pak. The resulting solution was added to an equal volume of deionized water and purified by reversed-phase semipreparative HPLC (MeOH/water = 65:35, 3.5 mL/min) to give the desired product [^{18}F]**9**, which eluted at 19−21 min (5% decay-corrected radiochemical yield from end of bombardment; a total synthesis time of approximately 140 min). The fractions were collected and diluted with deionized water (50 mL) and passed through an activated C18 Sep-Pak. The radioactivity on C18 Sep-Pak was eluted with EtOH (1.5 mL). The solution was removed under a N_2 stream at room temperature, and the residue was dissolved in 10% EtOH/saline (1.5 mL) for the tissue distribution studies. The radiochemical purity, determined by analytical reversed-phase HPLC, was in all cases greater than 95%. The effective specific activity, determined by a competitive radiometric ligand binding assay (*42*) was >550 mCi/mmol. The identity of the desired product was also confirmed by reversed-phase analytical HPLC (CH_3CN/water = 50:50, 0.8 mL/min, 254 nm), by coinjecting with an authentic sample of compound **9** with [^{18}F]**9**.

Biological Procedures for Relative Binding Affinity (RBA) and Specific Activity Determinations. Relative binding affinities of the progestins were determined in several receptor systems using competitive radiometric binding assays. Measurements were carried out using procedures reported in previous publications for progesterone receptor (*28, 48*), glucocorticoid receptor (*49, 50*), and androgen receptor (*48, 51*). The PR assay used purified recombinant full-length PR B (Invitrogen, Carlsbad, CA) and R5020 as the standard and ^{3}H tracer (Perkin-Elmer, Boston, MA) (K_d = 0.4 nM); GR used adrenalectomized rat liver cytosol and dexamethasone as the standard and ^{3}H tracer (Amersham Biosciences, Piscataway, NJ) (K_d = 20 nM), and for AR, purified recombinant AR ligand binding domain (Invitrogen, Carlsbad, CA) and as the standard and ^{3}H tracer R1881 (Perkin-Elmer, Boston, MA) (K_d = 0.6 nM) for AR. By definition, the standards have RBA values of 100%. Effective specific activities of the ^{18}F-labeled progestins were measured

by in vitro competitive binding assays performed on fully decayed samples (*42*).

Tissue Distribution Studies. The progesterone receptor levels in the uteri of immature Sprague−Dawley rats (21 days old, 40−50 g, five rats per time point) were induced by daily subcutaneous injections for 2 days of 5 μg of estradiol in 0.2 mL of 20% ethanol/sunflower seed oil (*19*). The experiments were begun 24 h after the last injection. The ^{18}F-labeled Tanaproget derivative [^{18}F]**9**, purified by reversed-phase HPLC, concentrated in vacuo, and redissolved in 10% EtOH/isotonic saline, was passed through a filter. Anesthetized rats were injected in the tail vein with 26 μCi/100 μL of the ^{18}F-labeled compound [^{18}F]**9**. At specified time points postinjection, the rats were sacrificed by decapitation, and blood and organs were removed, weighed, and counted in a Beckman Gamma 6000 counter. To determine whether the uptake was mediated by a high-affinity, limited-capacity system, one set of animals was coinjected with the ^{18}F-labeled fluoropropyl-Tanaproget derivative [^{18}F]**9** together with 33.3 μg of unlabeled fluoropropyl-Tanaproget derivative **9** in 14% ethanol/∼30% 2-hydroxypropyl-β-cyclodextrin in saline as standard compound to fully occupy the progesterone receptors.

ACKNOWLEDGMENT

This work has been presented at the 18th International Symposium on Radiopharmaceutical Sciences, S218, Edmonton, Canada, 12−17 July 2009. Supported by grants from the NIH (PHS R01 CA025836 to JAK; R24 CA086307 to MJW). Funding for NMR and MS instrumentation at the University of Illinois is from the Keck Foundation, NIH, and NSF. We are grateful to Terry Sharp, Nicole Fettig, Margaret Morris, Paul Eisenbeis, and Amanda Roth for help with the animal experiments.

Spectroscopic and Calorimetric Studies on the Triplex Formation with Oligonucleotide−Ligand Conjugates

Andrea Eick, Fanny Riechert-Krause, and Klaus Weisz*

Institute of Biochemistry, Ernst-Moritz-Arndt University Greifswald, Felix-Hausdorff-Str. 4, D-17487 Greifswald, Germany.
Received February 25, 2010; Revised Manuscript Received April 13, 2010

Several triplex-forming 9-mer oligonucleotide (TFO) conjugates with a methyl- or methoxy-substituted 5-phenyl-6*H*-indolo[3,2-*b*]quinoline (PIQ) attached at the 5′-terminus or 3′-terminus or at an internal C5 thymine position were synthesized and tested for their ability to form and stabilize a triple helix with a double-helical DNA target employing UV melting experiments, fluorescence titrations, and isothermal titration calorimetry (ITC). A considerable thermal stabilization by up to 14 °C at pH 6.0 was observed for the 5′- and 3′-conjugates with little influence on the type of substituent but also for a conjugate with the ligand tethered by a short linker to the interior of the 9-mer TFO. A detailed thermodynamic characterization of the unmodified TFO and its 5′-conjugate with a methyl-substituted ligand by ITC experiments yielded a $\Delta\Delta G^\circ$ of -1.8 kcal mol^{-1} at pH 6.0 for the TFO-attached PIQ−triplex interaction and also revealed a favorable entropic contribution as the major determinant for the free energy of PIQ binding in the conjugate. The pH dependence of triplex thermal stability highlights the importance of ring protonation of the triplex-bound ligand for its effective interaction and triplex stabilization near physiological conditions.

INTRODUCTION

DNA triple helices formed through the sequence-specific recognition of a DNA duplex by a third-strand oligonucleotide constitute an alternative nucleic acid secondary structure with potential biological relevance (*1, 2*). The formation of a triple-stranded DNA is based on Hoogsteen hydrogen bond interactions between bases of the triplex-forming oligonucleotide (TFO) and available hydrogen bond donor and acceptor groups of purine bases in the double-helical DNA target directed toward its major groove (*3*). The ability of TFOs to bind complementary duplex DNA with a defined base−base recognition code places them among the most specific DNA binding ligands. Currently, TFO-based strategies in biotechnological and gene therapeutic applications focus on the specific regulation of gene expression known as antigene strategy (*4, 5*) and may also include interference with DNA transcription factors (*6, 7*) or site-directed mutagenesis (*8, 9*). However, the exclusive TFO binding to purine bases of the duplex limits effective triplex formation to the presence of oligopyrimidine•oligopurine sequences which are found to be overrepresented especially in promoter regions of the human genome (*10*).

From the two standard types of triplexes, the more extensively studied pyrimidine motif consists of a pyrimidine third strand oriented parallel to the oligopurine strand of the cognate duplex forming isomorphous T•AT and C^+•GC base triplets (*3*). Here, the formation of two Hoogsteen hydrogen bonds requires the protonation of third-strand cytosines resulting in a considerable pH dependence of triplex stability. Given their relatively low stability under physiological conditions, attempts to increase the thermodynamic stability of triple helices in the past have employed various strategies including the addition of triplex binding ligands and multivalent cations to compensate for the charge repulsion between strands, synthetic modification of the nucleobases, deoxyribose sugars or the phosphodiester backbone, (*11, 12*) as well as the covalent attachment of DNA intercalators to the third strand (*13−15*).

On the basis of the latter approach, we have recently designed a TFO conjugated with the benzo-annulated δ-carboline 5-phenyl-6*H*-indolo[3,2-*b*]quinoline (PIQ) that is able to form and to significantly stabilize triple helical structures with a DNA duplex and suggested an intercalative mode of binding at the triplex−duplex junction of this polyaromatic compound (*16*). In the present study, we have covalently tethered methyl- or methoxy-substituted indoloquinoline derivatives to 5′-, 3′-, or internal positions of the TFO with different linkers and examined the ability of the various TFO conjugates to form and stabilize triplexes with a 15-mer target duplex combining different spectroscopic and calorimetric techniques. The results obtained from a detailed thermodynamic characterization of a 5′-conjugate provide for important information on the major driving forces for triplex binding of the indoloquinolines when attached to the TFO and are discussed with respect to the thermodynamics reported for other triplex selective ligands.

EXPERIMENTAL PROCEDURES

Materials. Unmodified and amino-functionalized oligonucleotides were purchased from TIB MOLBIOL (Berlin, Germany) and Eurofins MWG Operon (Ebersberg, Germany). The two phenyl-substituted indolo[3,2-*b*]quinoline derivatives 1,7-dimethyl- and 1,7-dimethoxy-5-(4-succinimido-carboxyphenyl)-6*H*-indolo[3,2-*b*]quinoline were prepared according to previously published procedures (*16*).

The concentration of the oligonucleotides was calculated using molar extinction coefficients at 260 nm derived from the nearest-neighbor model of Tataurov et al. (*17*). The concentration of the TFO-PIQ conjugates was approximated by adding the determined molar extinction coefficient of the free carboxy derivatives of PIQa ($\varepsilon_{260\ nm} = 26\ 818$ M^{-1} cm^{-1}) and PIQb ($\varepsilon_{260\ nm} = 23\ 920$ M^{-1} cm^{-1}) dissolved in a DMSO−water mixture with ≤6% DMSO to the calculated extinction coefficient of the oligonucleotide ($\varepsilon_{260\ nm} = 70\ 800$ M^{-1} cm^{-1}).

Solvents were distilled prior to use. Buffer solutions were prepared using deionized water (Millipore Simplicity 185). All reactions were monitored by TLC using Merck silica gel plates

$60F_{254}$. HPLC separations were carried out with a Hitachi/Knauer system. The purification was performed on a reverse column (Kromasil 100 Å C18 5 μm, 4.6 × 250 mm, Wicom GmbH, Heppenheim, Germany). A gradient was applied using buffer A (0.1 M triethylammonium acetate/CH_3CN = 1:1, pH 6.8) and buffer B (0.1 M triethylammonium acetate/CH_3CN = 98:2, pH 6.8) as eluent. A flow rate of 1.2 mL/min was used and the fractions detected simultaneously at 260, 281, 347, and 406 nm.

Synthesis of the TFO Conjugates. The amino-modified oligonucleotide (5.0 OD, 0.07 μmol) was dissolved in water (150 μL), and 0.1 M sodium phosphate buffer (pH 8.2, 65 μL) containing 50 mM lithium chloride was added. The NHS-ester functionalized phenyl-indoloquinoline PIQa or PIQb (1 mg/100 μL, 2.1 μmol PIQa and 2.0 μmol PIQb, respectively) dissolved in DMF was added. The solution was stirred for 6−8 days at 50 °C and checked by TLC (propanol/H_2O 5:3). Reaction batches showing only modest product formation after 3−4 days (especially reactions with the PIQb analogue as a result of increased NHS−ester hydrolysis) were additionally combined with another portion of NHS−ester (0.5 mg/50 μL, 1 μmol). The final product mixtures were dried in vacuo and the residue dissolved in water. Excessive NHS−ester of PIQa and PIQb was extracted three times by dichloromethane. The TFO−indoloquinoline conjugates were finally purified by HPLC and desalted by using Sep-Pak C18-Cartridges (Waters Corporation, Milford, USA). Final products were characterized by MALDI-TOF mass spectrometry.

Mass Spectrometry. Mass data were recorded on a Bruker Microflex Maldi-TOF with Flexcontrol and Flexanalysis software. A linear detection method and negative ion mode was chosen. The measurements were performed with 400 shots. The HPLC-purified conjugates and the matrix solution (saturated 3-hydroxypicolinic acid in water) were desalted via ammonium-activated cation-exchange resin beads (Dowex 50 W × 8 100−200 mesh; Fluka) and applied on a target plate. The main peak is equivalent to *m/z* M-1.

UV−vis Spectroscopy. All UV measurements were performed on a Cary 100 spectrophotometer equipped with a temperature control unit (Varian Deutschland, Darmstadt). Melting curves were recorded with 1 data point/°C at 260 nm in a temperature interval from 1 to 90 °C. To prevent water condensation at temperatures below 25 °C on the 1 cm cuvettes, the sample chamber was constantly flushed with nitrogen gas. The lyophilized unmodified or conjugated TFO (1.7 μM) and target duplex (1.45 μM) were dissolved in cacodylate buffer pH 6.0 (0.1 M NaCl, 0.02 M cacodylate, 1 mM spermine) and annealed prior to each melting experiment by heating to 90 °C followed by slow cooling to room temperature. For pH-dependent melting experiments, the cacodylate buffer was adjusted with HCl or NaOH within the pH range 5.5−6.5. Measurements included one heating ramp (1 °C/min), followed by one cooling (1 °C/min) and a second heating period (1 °C/min). Heating and cooling curves showed small hysteresis effects due to slow kinetics of 0.5−3 °C depending on the particular TFO conjugate. The melting temperature was determined by the maximum of the first derivative plot of the second heating curve after appropriate smoothing.

The relative hyperchromicity H for the triplex-to-duplex transition is calculated from the melting curve and given as percentage according to $H = (\Delta A_{t\rightarrow d} \times 100)/(\Delta A_{t\rightarrow ss})$.

Fluorescence Measurements. Fluorescence measurements were performed with a Jasco FP-6500 spectrofluorometer (Jasco, Tokyo, Japan). Using an excitation wavelength of 350 nm, emission spectra were acquired from 360 to 650 nm with a scanning speed of 50 nm/min, emission and excitation bandwidths of 5 nm, and a response time of 1 s. The sensitivity was manually adjusted by setting the photomultiplier tube voltage (PMT) to 350 V (400 V for conjugate **S16b**). Fluorescence measurements were carried out with a conjugate concentration between 0.7 and 1.7 μM in cacodylate buffer pH 6.0 (0.1 M NaCl, 0.02 M cacodylate, 1 mM spermine). Relative fluorescence intensities were followed during the addition of the duplex solution (100 μM) in 20 steps to the conjugate to reach a final duplex-to-TFO molar ratio of 2:1. All data were blank and volume corrected.

Binding curves of conjugate **S16a** were constructed by recording the fluorescence emission at 466 or 463 nm after each titration step and fit to a single-site binding model. The mathematical description of this model is represented by

$$\frac{F}{[M_0] \times f_0} = \frac{F_{ML} \times K_a \times [L] + 1}{K_a \times [L] + 1} \quad (1)$$

$$[L]^2 + \left([M_0] - [L_0] + \frac{1}{K_a}\right) \times [L] - \frac{[L_0]}{K_a} = 0 \quad (2)$$

where F is the fluorescence intensity at each titration point, $[M_0]$ and $[L]$ are the total concentration of the conjugate and the concentration of free duplex DNA, respectively, F_{ML} is the fluorescence enhancement factor, f_0 the molar fluorescence of the TFO-PIQ conjugate, and K_a the binding constant. Solving the quadratic eq 2 with the total DNA concentration $[L_0]$ gives the free duplex concentration $[L]$ (*18*).

Isothermal Titration Calorimetry. ITC experiments were performed with a MicroCal VP-ITC instrument (MicroCal, Northampton, USA), and the final data were analyzed with the *Origin* software. All samples were dissolved in cacodylate buffer pH 6.0 (0.1 M NaCl, 0.02 M cacodylate, 1 mM spermine). The smaller first injection volume (4−5 μL) was rejected before data analysis. Subsequent titration steps involved injections with 7−10 μL each and a delay between injections of 4 min. All ITC titrations were performed in triplicate with a reference power of 8 μcal/s at 10 °C. For the ITC experiments on the reference triplex, concentrations of 11−12 μM for the duplex and 140−150 μM for the third-strand oligonucleotide were employed. For the direct determination of binding enthalpies by the excess-site method with modified and unmodified third-strand oligonucleotides, buffer solutions of 130 μM duplex and 136 μM TFO conjugate as well as 130 μM third-strand oligonucleotide were employed, respectively.

Blank titrations were conducted by injecting the TFO into buffer under otherwise identical experimental conditions. The blank-corrected titration curves of the reference triplex were fitted to a model with a single binding site yielding the binding constant K_a and the molar binding enthalpy $\Delta H°$. In the case of the model-independent protocol, the final binding enthalpy was directly determined by peak integration of the power output following each injection, normalization by the number of moles of added ligand, and averaging from three independent experiments with 10 titration steps each. The Gibbs free energy $\Delta G°$ was calculated according to the relationship

$$\Delta G^\circ = -RT \ln K_a \quad (3)$$

The entropic contribution $T\Delta S°$ was calculated from the free energy of binding and the binding enthalpy as determined by the ITC measurements according to the standard thermodynamic relationship

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad (4)$$

RESULTS AND DISCUSSION

Design of the Triple-Helical Construct. In an attempt to limit the size of the triplex construct but nevertheless allow the

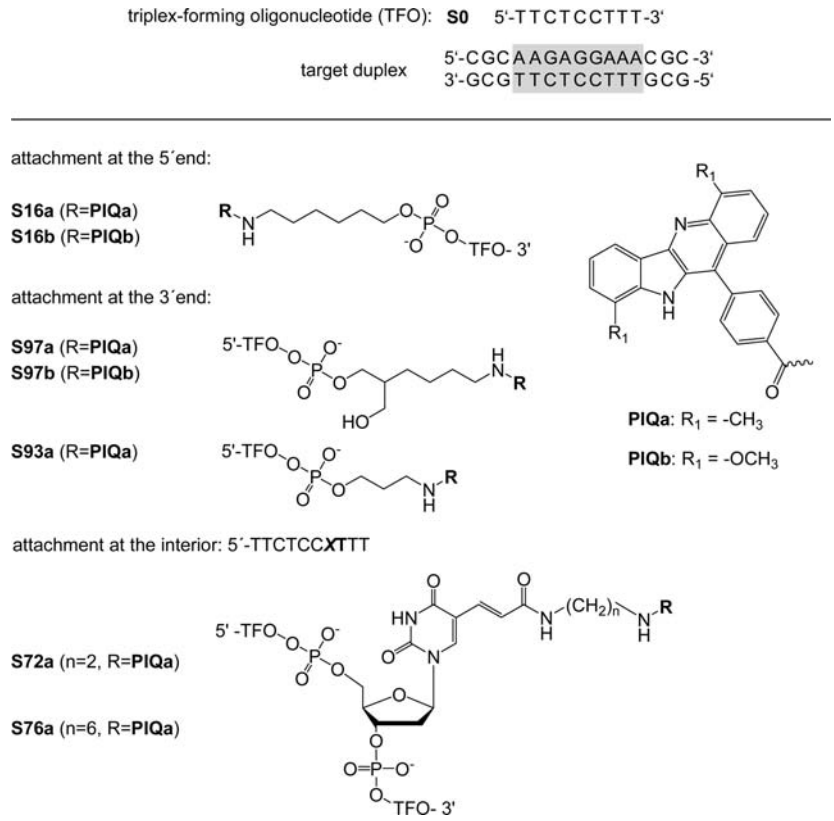

Figure 1. Triple-helical construct formed through the binding of the TFO **S0** to the target duplex (top) and structures of the conjugates with the indoloquinolines PIQa and PIQb.

formation of a stable pyrimidine triplex at pH 6.0 close to physiological conditions, we chose to employ a 9-mer TFO sequence 5′-TTCTCCTTT targeted against a 15-mer duplex as shown in Figure 1. As an added benefit of using shorter oligonucleotides, fewer side reactions occurred during the coupling reaction associated with higher yields of conjugated product. The homopyrimidine TFO binds the homopurine tract of the duplex target in a parallel orientation with the formation of T·AT and C^+·GC triplets. The two all-CG duplex overhangs on either side of the formed triplex strongly stabilize the underlying duplex and clearly separate the onset of triplex and high-temperature duplex denaturation. In addition to their effects on the triplex stability (*19*), 3′- and 5′-overhang sequences provide for triplex−duplex junctions known to constitute a strong binding site for many intercalators (*20, 21*).

Synthesis of the TFO Conjugates. All conjugates (see Figure 1) were synthesized through the coupling of two NHS-activated indoloquinoline (PIQ) derivatives to the various aminoalkyl-functionalized triplex-forming oligonucleotides according to previously published protocols (*16, 22*). For the attachment of the PIQ ligands, amino linkers with various lengths at the 5′- and 3′-ends as well as at the C5-position of a central thymidine within the triplex-forming oligonucleotide were employed. The two derivatives designated in the following as PIQa and PIQb contain either two methyl or two methoxy substituents at the indole and the quinoline moiety. Small modifications for the coupling reaction with derivative PIQb were necessary as a result of increased water solubility and fast NHS−ester hydrolysis. All conjugates were purified by HPLC and characterized by MALDI mass spectrometry. Excellent yields were obtained for the 5′-conjugates, whereas lower yields were generally obtained with 3′-conjugates and conjugates with the ligand attached to an internal position (Table 1).

Thermal Denaturation Studies. Upon third-strand dissociation from the triplex, hyperchromicity is observed at 260 nm in temperature-dependent UV measurements. The melting temperature of the triplex T_m defined by the midpoint of this transition is a measure of the thermal stability of the triple helix. To study the ability of the different TFO-PIQ conjugates to stabilize triplexes, UV thermal melting studies were performed with the 15-mer duplex target and each of the conjugates. Typical UV melting curves are shown in Figure 2 for triple helix formation of the duplex with conjugate **S16a** as well as with unmodified third strand **S0** used as a reference. The results of all measurements are summarized in Table 2.

Table 1. Synthesis and Characterization of the Oligonucleotide−PIQ Conjugates

		MS (*m*/*z*)	
TFO	average yield (%)	found	calcd

S76a	36.7	3132.2	3131.8

Ionic strengths and additives are known to potentially have significant effects on the stability of triple helical structures. Thus, the polyvalent cation spermine present under physiological conditions has been shown to considerably stabilize triplexes. To probe its effect on the conjugate binding, two different cacodylate buffers with and without the addition of 1 mM spermine were prepared and used in initial UV melting experiments. As expected, T_m values for triplexes with the unmodified TFO **S0** and conjugate **S16a** increased by 8 and 11 °C in the presence of spermine, respectively. Interestingly, however, as shown by the difference in ΔT_m of 3 °C, triplex thermal stabilization by the PIQ ligand in **S16a** was further promoted by spermine. For all subsequent measurements, a

S76a	18.5 ± 1.8	1.4	20

[a] All T_m values are given as averages with standard deviations from three independent measurements on a mixture of TFO (1.7 μM) and duplex (1.45 μM) in a 1.2:1 molar ratio. [b] Without spermine in 0.1 M NaCl, 0.02 M cacodylate, pH 6.0. [c] For definition and calculation, see Experimental Procedures. [d] Not determined.

buffer with 1 mM spermine was therefore employed for its triplex stabilizing effect facilitating the analysis of melting profiles with lower transition temperatures.

All conjugates formed more stable triplexes compared to the unmodified third strand. At the same time, the second high-temperature melting transition at 65.5 ± 0.5 °C is independent of the type of third-strand conjugate as expected from duplex melting into single strands. The highest triplex thermal stabilization was observed in the presence of third-strand oligonucleotides with the ligand attached to either the 5′- or 3′-end. Thus, TFO **S16a**, **S16b**, and **S97a** form triplexes with melting temperatures of ~31 °C increasing T_m by 14 °C compared to the unmodified reference triplex. The other two 3′-modified conjugates **S97b** and **S93a** only show a slightly reduced stability with a ΔT_m value of ~12 °C. Most noticeably, however, oligonucleotide **S72a** with the ligand attached to the interior also exhibits substantial stabilizing effects on the triplex with a melting temperature of 28 °C and a ΔT_m of 11 °C. However, whereas a shortening of the linker length in the conjugate in the case of a 3′-attachment has only small effects on the thermal stabilization (compare **S97a** and **S93a** with a C6 and C3 linker, respectively), extending the linker for the internal attachment to thymine C5 by $(CH_2)_4$ has a dramatic effect on the ligand-induced triplex stabilization, and the increase in T_m nearly vanishes for conjugate **S76a** when compared to the unmodified triplex. Thus, a potential intercalation of the thymine C5 tethered ligand within the triplex interior seems to be disfavored by an elongated linker with its increased flexibility. It has to be noted, however, that, in addition to the typical signature of a triple-stranded structure found in circular dichroism (CD) spectra on mixtures of the target duplex with the various conjugates at 10 °C, another negative albeit weak induced CD band centered at the long-wavelength absorbance maximum of the indoloquinoline at about 380 nm is observed for both internally modified conjugates (see Supporting Information). Such induced CD effects are indicative of ligand binding in an asymmetric environment and based on their negative sign together with their low intensity suggest a partial intercalative mode of binding even for conjugate **S76a** (*16, 23*). Consequently, differences in triplex thermal stabilizations may not only reflect variable stacking interactions within the triplex, but also at least partially arise from a variable extent of ligand stacking with bases in the dissociated TFO.

The effect of substituents on the triplex stability can be examined by melting data for PIQa and PIQb. Surprisingly, substituting methyl by methoxy groups has no or only a small effect on triplex stabilization in the case of ligand attachment at the 5′- and 3′-end, respectively. The two substituents differ in hydrophobicity, and theoretical calculations on the HF-6-31G* optimized geometries of the two indoloquinoline chromophores also indicate different dipole moments (3.0 vs 2.5 D for PIQa and PIQb, respectively). In the case of intercalation, stacking interactions with nucleic acid bases are expected to be modulated by the different charge distribution. Also, a different degree of the ring nitrogen protonation in the indoloquinoline structure is likely to have an impact on the binding affinity for the two ligands. Consequently, the lack of a noticeable influence of the substituent on binding may also result from partial compensation of different effects.

There have been few comparative studies on the relative triplex stabilization of intercalators coupled to either a terminal or internal position of the TFO. Except for a strongly triplex stabilizing benzo[*e*]pyridoindole (*14*) and a benzo[*f*]pyridoquinoxaline (*24*) attached through an internucleotide pentamethylene and tetramethylene containing linker in the interior of the TFO, respectively, conjugates with a centrally positioned ligand seem generally less effective in triplex stabilization compared to conjugates with terminal modifications (*25, 26*). In addition to the ligand structure, favorable interactions of internally attached intercalators have also been found to be particularly sensitive to the type and length of the linker in line with the present data. Clearly, ligand orientation and thus steric requirements greatly differ in the case of an internucleotide linkage or a direct coupling to a nucleobase. However, unlike the considerable triplex stabilizing effects of the internally modified **S72a**, UV melting studies reported on benzo[*e*] and benzo[*g*]pyridoindoles similarly tethered via a flexible linker to the 5-position of a modified 2′-deoxyuridine indicate enhanced third-strand binding to a target duplex only when located at the 5′-end of the TFO, but no stabilization was observed with ligands fixed at internal positions (*25*).

In contrast to previous reports that the highest affinity is obtained by intercalators attached to the 5′-end of the triplex-

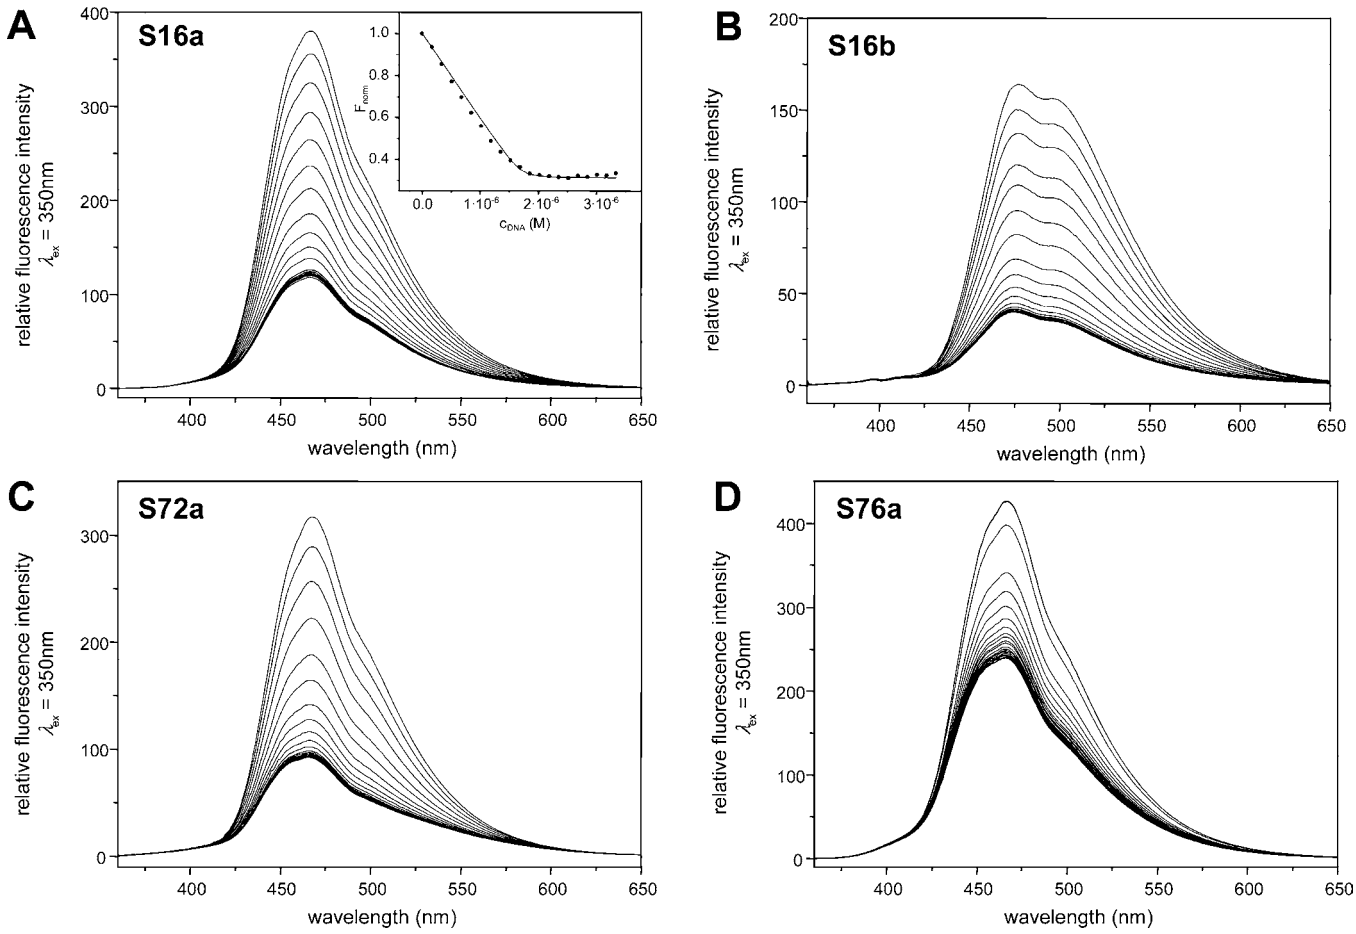

Figure 3. Fluorescence emission spectra of δ-carboline-TFO conjugate **S16a** (A), **S16b** (B), **S72a** (C), and **S76a** (D) titrated with the target duplex at 10 °C; addition of duplex to the conjugate (1.7 μM) results in progressively decreased fluorescence. The inset in (A) shows a linear least-squares fit for the fluorescence intensity at 466 nm. Twenty titration steps up to a 2:1 duplex-to-conjugate molar ratio were performed.

forming oligonucleotide (*27*), the present data show only minor effects on the thermal stabilization from the ligand attachment to either the 5′- or 3′-terminus of the TFO. More significant differences are revealed by looking at hyperchromicities for the triplex-to-duplex transition mainly arising from base stacking interactions also including the ligand chromophore. With the TFO in excess, a relative triplex hyperchromicity was defined with respect to the sum of triplex-to-duplex and duplex-to-single strand hyperchromicities to eliminate any additional influence of concentration (Table 2). Note that in all cases triplex and duplex melting transitions are well-separated, but due to baseline effects a considerable uncertainty has to be taken into account. Nevertheless, the calculated relative triplex hyperchromicities enable the arrangement of the conjugates into three clearly defined groups: **S16a,b** > **S97a,b** > **S93a**, **S72a**, **S76a**. With exclusion of any noticeable effects of the different linker moieties on the hyperchromicity, these data are consistent with enhanced stacking interactions for a 5′-conjugate compared to 3′-conjugates as a result of the structurally different 5′- and 3′-triplex−duplex junctions (*28*) and also with more noticeable structural distortions in the case of a shorter or internal linker. However, persisting stacking of the ligand especially at an internal position with the bases of the dissociated TFO may again contribute to the considerable variation in hyperchromicity upon triplex melting.

Fluorescence Emission. Because a triplex bound benzo-annulated δ-carboline has previously been shown to exhibit a strong fluorescence enhancement upon triplex melting (*16*), changes in fluorescence properties of the PIQ fluorophore were used to monitor DNA−ligand interactions with the conjugates **S16a**, **S16b**, **S72a**, and **S76a**. With an excitation wavelength set to 350 nm for maximum fluorescence emission of all conjugates, fluorescence of free methoxy-substituted PIQb conjugate **S16b** was found to be noticeably weaker compared to the intensities observed with methyl-substituted PIQa conjugates **S16a**, **S72a**, and **S76a** under the same conditions. In contrast, the methyl-substituted ligands in the free conjugate exhibit only small differences in their fluorescence quantum yields as expected (Figure 3).

Addition of the target duplex with concomitant triplex formation induced a modest shift in the emission wavelength but a significant degree of fluorescence quenching for all conjugates. Thus, a small hypsochromic shift in the emission maximum from 467 to 466 nm for PIQa and 477 to 473 nm for PIQb must be attributed to the change in the local environment of the ligand upon triplex formation. Most noticeably, however, **S16a**, **S16b**, **S72a**, and **S76a** conjugates were quenched by 67%, 75%, 71%, and 44% upon saturation with duplex, respectively. The fluorescence emission intensity of the indoloquinolines is expected to be influenced by neighboring bases and their solvent accessibility and may thus be taken as indicator for base−ligand interactions within a formed triple-helical complex. Correspondingly, indoloquinoline fluorophores in conjugates **S16a**, **S16b**, and **S72a** displaying a high degree of quenching (~70%) are likely to be in close contact to DNA bases and efficiently screened from the aqueous solvent in the triple-helical DNA. In contrast, conjugate **S76a** experiencing a considerably smaller degree of quenching (44%) suggests weaker DNA−ligand interactions within the triple helix, possibly resulting from hindered intercalation of the indoloquinoline between base triads

Table 3. Thermodynamic Parameters for the Binding of Conjugate S16a and the Unmodified TFO S0 to the Target Duplex at 10 °C[a]

TFO	method	n	K_a (M^{-1})	$\Delta H°$ (kcal mol^{-1})	$T\Delta S°$ (kcal mol^{-1})	$\Delta G°$ (kcal mol^{-1})

	model-free ITC	---	−	-44.9 ± 0.1	−34.8[c]	
				$\Delta\Delta H°$	$\Delta(T\Delta S°)$	$\Delta\Delta G°$
				−0.7[d]	1.1	−1.8[c]

[a] Average values with standard deviations from three or five (fluorescence titrations) independent experiments at 283 K. [b] Calculated for 283 K with a constant $\Delta H°$ obtained from "model-free" ITC titrations. [c] Calculated with $\Delta G°$ as obtained from ITC or fluorescence titrations. [d] Calculated with $\Delta H°$ obtained from "model-free" ITC titrations.

in line with the UV melting experiments (vide supra). However, without detailed knowledge of the quenching mechanism for these ligands, fluorescence data do not provide further information in support of a particular binding mode.

We also plotted the relative fluorescence intensity for **S16a** at 466 nm taken from the corresponding emission spectra against the duplex concentration (inset Figure 3A). By using a 1:1 binding model for the triplex formation (*18*), a fit of the titration data from five independent experiments yielded an average binding constant of $K_a = 6.2 \times 10^7$ M^{-1} at 10 °C.

Isothermal Titration Calorimetry. Isothermal titration calorimetry (ITC) allows for an almost complete thermodynamic profile for a binding interaction in a single experiment enabling the direct determination of the molar binding enthalpy (*29, 30*). Although ITC has become increasingly popular for the thermodynamic analysis of biomolecular interactions in general and drug−DNA interactions in particular, binding of triplex selective ligands to a duplex target has only rarely been scrutinized by direct calorimetric methods. This is particularly true for ligands covalently attached to the TFO and known to result in more efficient triplex stabilization compared to free ligand apparently due to more favorable entropic contributions on binding. Whereas the formation of a regular triplex of the pyrimidine motif has been thermodynamically characterized by ITC titrations in the past (*31, 32*), no detailed quantitation of enthalpic and entropic effects of bound ligands in a TFO conjugate through direct calorimetric measurements has been reported so far to the best of our knowledge. Clearly, problems with such studies are associated with the significantly varied stability of triplexes under specific conditions and with the rather high accuracy required to reliably quantify the mostly small contribution of the bound ligand on the overall free energy of conjugate binding in particular.

We focused on the ITC thermodynamic analysis of the unmodified reference triplex and of the triplex formation with conjugate **S16a** available in sufficient quantities by its efficient coupling to the 5′-end of the TFO. To ensure an intact duplex target and TFO binding with a free energy of association suitable for accurate ITC measurements, we chose a temperature of 10 °C for all titration experiments based on the UV melting temperatures. All thermodynamic parameters obtained from initial ITC experiments on the triplex formation with unmodified TFO are given in Table 3.

Binding isotherms are constructed by integration of the power output for each injection with respect to time and corrected for the heats of dilution. Through a fit of the observed binding isotherms based on a model with a single set of identical binding sites, the equilibrium binding constant K_a, the binding stoichiometry n, and the molar binding enthalpy $\Delta H°$ were determined to be 2.8×10^6 M^{-1}, 1.02, and −43.3 kcal mol^{-1}, respectively (Figure 4A). Note that triplex formation involves binding of the 9-mer TFO within the major groove of the 15-mer duplex target and should result in a well-defined 1:1 complex in line with the ITC data. In an attempt to further increase its accuracy, the binding enthalpy was directly measured in a model-independent fashion through the excess-site method (*33, 34*). In this protocol, a high concentration of the duplex DNA is placed in the cell and titrated with very low amounts of ligand to ensure complete ligand binding to the target duplex after each injection. Under such excess duplex conditions, the integration of each injection peak yields the heat released per injection and its normalization per mole of added ligand directly results in the molar binding enthalpy without the requirement to resort to specific binding models or fitting procedures (Figure 4B). As shown in Table 3, the determined enthalpy value of −44.2 kcal mol^{-1} for the unmodified triplex is in good agreement with the value determined by the standard ITC titration protocol. Moreover, the high accuracy and good reproducibility of $\Delta H°$ is indicated by its rather small standard deviation calculated for different independent experiments.

The model-free excess-site method was also employed for a direct determination of binding enthalpies for the TFO conjugate **S16a** (Figure 4C). Here, a similar and highly reproducible enthalpy value of −44.9 kcal mol^{-1} is obtained for binding (Table 3). As seen from Figure 4C (**S16a**) and B (**S0**) in the upper panel, the blank titration with the conjugate sample shows larger effects in the endothermic heat of dilution compared to the unmodified TFO at equal concentrations as a consequence of the attached hydrophobic ligand. With an association constant close to 10^8 M^{-1} already determined by fluorescence titrations and the limitations imposed by the ITC method, a standard ITC titration protocol is expected to yield less reliable binding constants in the case of the conjugate, and these were therefore not employed for a subsequent evaluation. In addition, corresponding experiments highlight another potential source of error arising from slow kinetics of triplex formation with the conjugate especially toward the equivalence point under the low-temperature and small concentration conditions required for the experimental setup. Thus, fitting of the isotherms for the conjugate binding consistently underestimated binding enthalpies and association constants. In fact, raw ITC data reveal the influence of slow conjugate association on closer inspection, e.g., through baseline distortions, and it also becomes apparent in corresponding fluorescence titrations requiring delay times between titration steps of up to 30 min in some cases for full equilibration.

In addition to the association constants as determined by fluorescence titrations and ITC titrations, K_a was calculated at 283 K from the UV melting data (Table 2) and is also given in Table 3 for ligand-modified and unmodified triplex. Neglecting any temperature dependence of $\Delta H°$, the van't Hoff equation was solved with the calorimetric binding enthalpy from "model-free" ITC measurements and applied to the association constant given at the melting temperature to

$$K_a(T_m) = \frac{1}{c_{TFO}} \quad (5)$$

$$c_{TFO}(T_m) = c^o_{TFO} - \frac{1}{2} c^o_{duplex} \quad (6)$$

with the concentration of free TFO c_{TFO} and the total TFO and duplex concentration c^o_{TFO} and c^o_{duplex}, respectively. As shown by Table 3, these calculated binding constants K_a deviate by a factor of about 2 and 4 in the case of unmodified and modified TFO and translate to differences in the free energy of association of 0.5 and 0.8 kcal mol^{-1}, respectively. Discrepancies between calorimetric enthalpy changes and thermodynamic analyses based on the van't Hoff relationship have been extensively discussed and may involve coupled processes during association (*31*). In particular, stacking interactions within the unbound single-stranded TFO, especially involving stacking of the polycyclic ligand with the nucleobases, may contribute to a significant temperature dependence of the overall binding enthalpy. Nevertheless, the data as obtained from the different methods are in good agreement given the various approximations and confirm the consistency and reliability of the thermodynamic parameters.

Effect of pH on Triplex Stabilization. In vivo applications of triplex-forming oligonucleotides directed against double-helical target sequences require strong and selective binding at physiological pH and temperature. The effect of pH on the triplex stabilization by the attached ligand has been examined by additional UV melting experiments for the two 5′-conjugates **S16a** and **S16b** and is shown in Figure 5. Clearly, while duplex melting is essentially unaffected triplex melting temperatures increase for the unmodified reference triplex from 12 to 33 °C upon lowering the pH from 6.5 to 5.5 due to a larger extent of third-strand cytosine protonation required for a stable Hoogsteen base pair within the pyrimidine triplex motif (Figure 5A). Again, the PIQ ligands lead to additional stabilization and form stronger triplexes compared to the nonconjugated TFO at all pH values. However, as shown by Figure 5B ligand stabilization strongly depends on the particular pH of the solution ranging from a ΔT_m of about 17 °C at pH 5.75 to only 9 °C at pH 6.5 for conjugate **S16a** and is expected to further decrease above neutral pH.

If protonation equilibria were excluded as major determinants of ligand stabilization, the temperature dependence of ligand binding, i.e., $\Delta H°$, must be responsible for the varying ΔT_m values. Note that changes in melting temperatures reflect triplex stabilizing effects at T_m, and these are strongly dependent on pH (Figure 5A). However, with an experimentally determined $\Delta H°$ of −0.7 kcal mol^{-1} attributed to the DNA interactions with the covalently attached ligand (vide supra) no significant change or even a decrease in ligand binding affinity is expected from the van't Hoff relationship when increasing the overall triplex stability by lowering the pH. Consequently, protonation of the ligand and/or third-strand cytosines must play a major role in the ligand-induced triplex stabilization. With the 5′-attached ligand separated from the nearest cytosine by two thymine bases, any influence of ligand interactions through cytosine protonation is anticipated to only result from long-range effects. This suggests a direct protonation of the ligand as the major contributor to triplex specific binding. In fact, a large increase

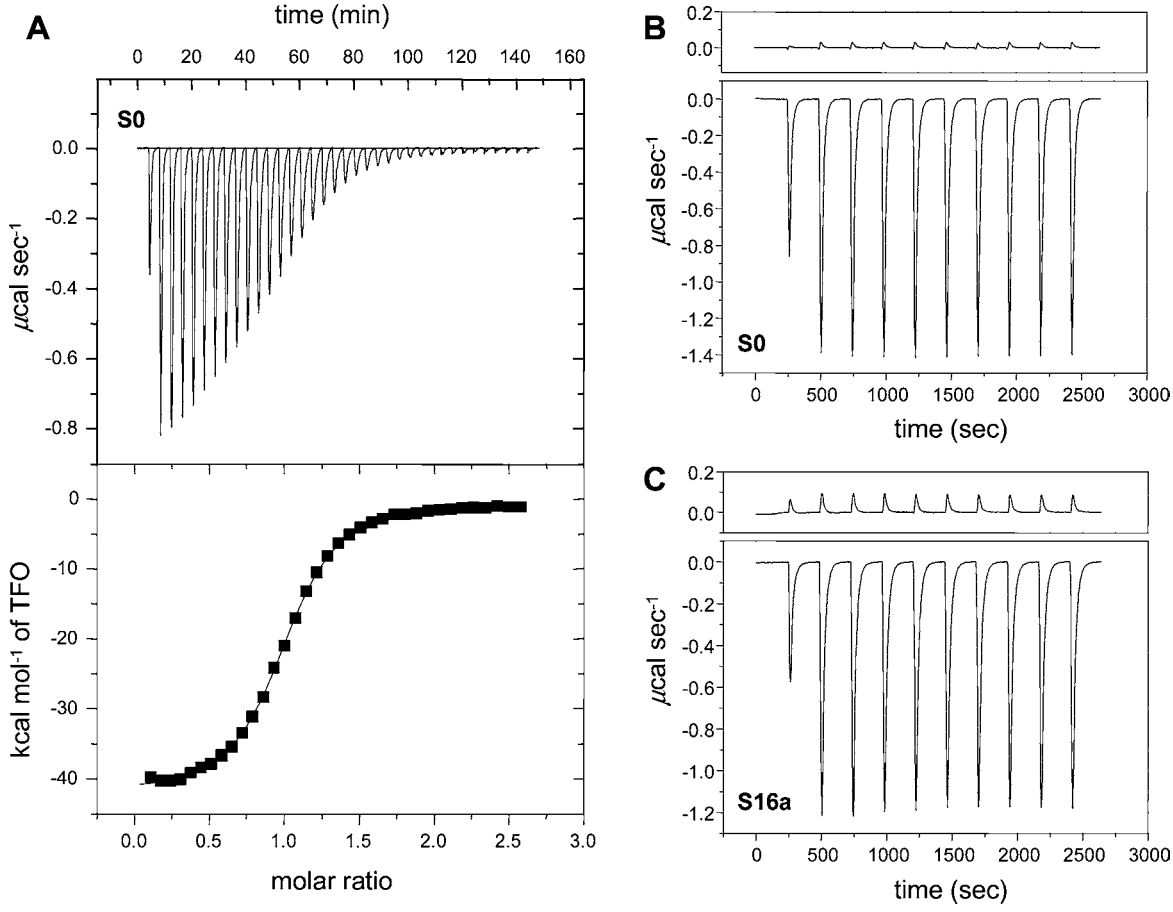

Figure 4. (A) ITC binding isotherm of the triplex formation with unmodified TFO **S0**. The upper panel shows the heat burst for every injection step, and the lower panel represents the corresponding normalized heat signals versus molar ratio. The data points reflect the experimental data, while the solid line represents the calculated fit. (B) The model-independent ITC titration with unmodified TFO **S0** and (C) with conjugate **S16a** representing the blank titration in the upper panel and the blank-corrected ITC data used for the calculation in the lower panel.

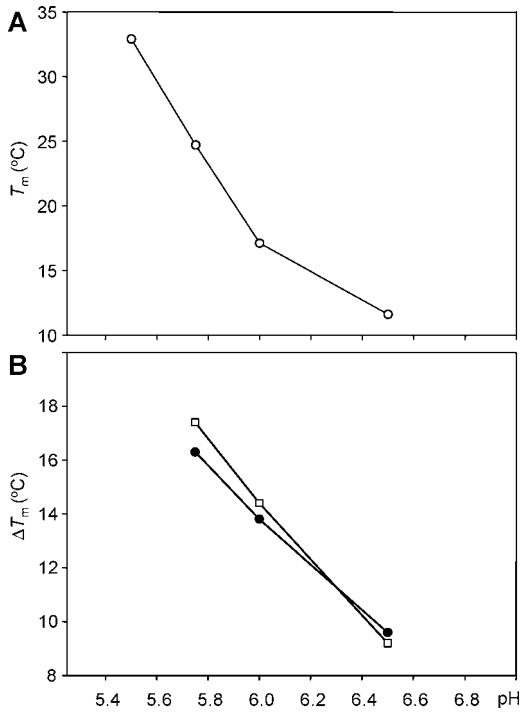

Figure 5. (A) Triplex melting temperatures for the unmodified reference triplex and (B) ΔT_m for the triplex transition with 5′-conjugates **S16a** (open squares) and **S16b** (filled circles) as a function of pH (0.1 M NaCl, 0.02 M cacodylate, 1 mM spermine). Below pH 5.75, no accurate ΔT_m could be obtained due to partially overlapping triplex and duplex melting transitions for the conjugates.

in pK_a values of about two pH units has been observed for two nonconjugated and soluble derivatives of PIQa and PIQb when bound to triplex DNA pointing to enhanced binding energetics for the protonated ligands (see Supporting Information). With apparent pK_a values of 6.2 and 6.7 determined for the methyl- and methoxy-substituted indoloquinolines in the presence of excess triplex DNA, respectively, protonation must be coupled to ligand binding, and a strongly pH dependent but different degree of protonation is expected for the ligand in **S16a** and **S16b** within the experimentally accessed pH range of 6.0 ± 0.5. With its higher pK_a value, the methoxy-substituted ligand of conjugate **S16b** being slightly less stabilizing at pH 5.75 compared to **S16a** becomes more stabilizing at pH 6.5 in line with its significantly higher degree of protonation at this pH. Apparently, triplex binding is only modest under physiological conditions for the present indoloquinolines being mostly deprotonated and uncharged. However, introduction of suitable substituents are expected to considerably increase the pK_a of the indoloquinoline structure beyond 7 when bound to a triplex resulting in compounds with the propensity to strongly bind triplexes even at higher pH.

Thermodynamics of Conjugate Binding. As found previously for different triple helices under various conditions, triplex formation is driven by a large negative enthalpy change and partly balanced by an unfavorable entropy of association for both unmodified and modified TFO. With a molar binding enthalpy for the unmodified third strand of −44.2 kcal mol^{-1}, the calorimetric enthalpy change upon triplex formation amounts to −4.9 kcal mol^{-1} per base being within the range typically observed for a pyrimidine-type triplex (*31, 35*). Thus, a value of −4.9 kcal mol^{-1} per base has also been reported for a similar 15-mer triplex construct of the pyrimidine motif at 15 °C and pH 4.8 (*31*). As a result of their higher apparent pK_a value in a triplex (*36*), cytosine bases as well as the ligand of the TFO are expected to become partly protonated at pH 6 upon

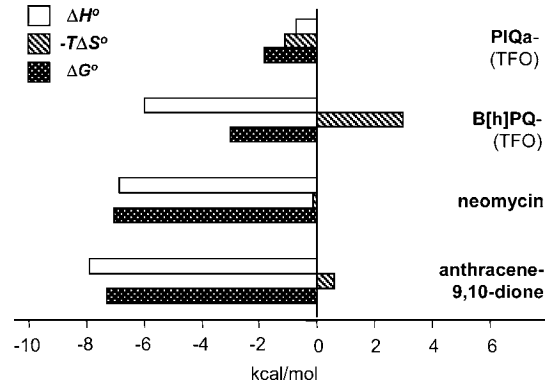

Figure 6. Thermodynamic profiles with enthalpic and entropic contributions $\Delta H°$ and $-T\Delta S°$ to the overall free energy $\Delta G°$ for the triplex interaction of 5′-TFO attached PIQa (see Table 3) and B[*h*]PQ (*24*), as well as of the nonconjugated triplex selective 2,6-bis(ω-aminopropionamido)-substituted anthracene-9,10-dione (*37*) and neomycin (*38*). For comparison, all parameters were calculated for 25 °C if determined at different temperatures assuming temperature-independent binding enthalpies and entropies.

association and the measured $\Delta H°$ involves contributions from the deprotonation of buffer and from the protonation of cytosines, as well as ligand in the conjugate.

Contributions to triplex stability from the tethered indoloquinolines can be evaluated by the differences in enthalpy and entropy changes as determined for the binding of unmodified TFO and ligand-bearing conjugate. These are also given in Table 3. It has to be noted that these values do not exclusively reflect direct ligand−DNA interactions but may also include indirect effects through structural distortions even at distant triple- or double-helical regions caused by the accommodation of the chromophore. Most noticeably, the attached ligand only adds a very small amount of −0.7 kcal mol^{-1} to the overall negative binding enthalpy. This may be partly attributed to the covalent attachment that hampers maximization of interactions within the triplex. On the other hand, tethering the indoloquinolines to the TFO considerably reduces entropic penalties upon binding resulting in a positive entropy change that mostly contributes to the ligand binding affinity. Clearly, even taking into account experimental uncertainties as expressed by the standard deviations, both enthalpy and entropy contributions are small but add to an overall free energy of −1.8 kcal mol^{-1} at 10 °C for the ligand interactions comprising almost 20% of the total standard free energy of triplex formation.

To better assess the triplex affinity of the 5′-attached ligand within the conjugate **S16a**, its thermodynamic profile for triplex binding was compared with corresponding profiles previously reported for a strongly triplex stabilizing and intercalating benzopyridoquinoxaline B[*h*]PQ covalently attached to the 5′-end of a 15-mer TFO (*24*). Note that in contrast to the calorimetric enthalpies for PIQa the thermodynamic parameters for the B[*h*]PQ ligand have been derived from UV melting curves by a van't Hoff analysis. Also included for comparison are thermodynamic parameters on triplex binding that have been reported for two nonconjugated triplex selective ligands through calorimetric measurements, namely, an intercalating 2,6-disubstituted anthracene-9,10-dione (*37*) and the groove binding aminoglycoside neomycin (*38*). After the varied experimental conditions on data collection are disregarded, the profiles as shown in Figure 6 reveal significant differences for the triplex stabilizing contributions at 298 K. Triplex binding for conjugated B[*h*]PQ and the two free anthracene and neomycin ligands is largely enthalpy-driven associated with a significant negative binding enthalpy. In contrast, with only a small change in enthalpy but favorable changes in entropy, binding of the TFO-

attached PIQ is essentially entropy-driven. This suggests rather weak DNA−ligand interactions but significant hydrophobic contributions to the binding free energy for the latter.

The binding affinity toward triple-helical DNA as reflected by the free energy of binding ΔG° is found to be significantly more exergonic for the nonconjugated free ligands compared to the TFO-attached intercalators. It has to be noted, however, that weaker triplex binding is compensated by a much better discrimination of triplex against duplex for the TFO-conjugated ligands making these generally more effective for a triplex thermal stabilization. In fact, they may be considered truly triplex specific in line with spectroscopic data suggesting a one-step dissociation of the TFO conjugate from the triplex upon melting (*16*).

CONCLUSIONS

Novel TFO conjugates with triplex binding indolo[3,2-*b*]-quinoline derivatives attached at the oligonucleotide termini or at an internal thymine position with different linkers were synthesized and tested for their triplex formation. In general, 5′- and 3′-conjugates form triplexes with the highest stability but for maximum thermal stabilization the attachment site, and the type of linker needs to be optimized. The detailed thermodynamic profile and pH dependence of triplex formation points to the importance of ring protonation for the ligands to achieve efficient triplex binding. The present structures still suffer from a relatively low pK_a when employed under neutral solution conditions. However, modified phenyl-indoloquinolines with ring substituents like amino groups should allow for a higher basicity accompanied with apparent pK_a values above 7 and will be promising future candidates for triplex recognition and triplex formation even under physiological conditions.

ACKNOWLEDGMENT

We thank Mrs. R. Schröder for her help in the synthesis of the 5-phenyl-6*H*-indolo[3,2-*b*]quinolines.

Double Displacement: An Improved Bioorthogonal Reaction Strategy for Templated Nucleic Acid Detection

Daniel J. Kleinbaum, Gregory P. Miller, and Eric T. Kool*

Department of Chemistry, Stanford University, Stanford, California 94305-5080. Received April 3, 2010; Revised Manuscript Received April 26, 2010

Quenched autoligation probes have been employed previously in a target-templated nonenzymatic ligation strategy for detecting nucleic acids in cells by fluorescence. A common source of background signal in such probes is the undesired reaction with water and other cellular nucleophiles. Here, we describe a new class of self-ligating probes, double displacement (DD) probes, that rely on two displacement reactions to fully unquench a nearby fluorophore. Three potential double displacement architectures, all possessing two fluorescence quencher/leaving groups (dabsylate groups), were synthesized and evaluated for templated reaction with nucleophile (phosphorothioate) probes both in vitro and in intact bacterial cells. All three DD probe designs provided substantially better initial quenching than a single-Dabsyl control. In isothermal templated reactions in vitro, double displacement probes yielded considerably lower background signal than previous single displacement probes; investigation into the mechanism revealed that one dabsylate acts as a sacrificial leaving group, reacting nonspecifically with water, but yielding little signal because another quencher group remains. Templated reaction with the specific nucleophile probe is required to activate a signal. The double displacement probes provided a ca. 80-fold turn-on signal and yielded a 2−4-fold improvement in signal/background over single Dabsyl probes. The best-performing probe architecture was demonstrated in a two-color, FRET-based two-allele discrimination system in vitro and was shown to be capable of discriminating between two closely related species of bacteria differing by a single nucleotide at an rRNA target site.

INTRODUCTION

Nucleic acid templated chemistry is a versatile approach to a growing number of applications in chemistry, biology, and medicine. These reactions have been used to ligate short oligonucleotides (*1*−*3*), catalyze prodrug release (*4*) or cytotoxic drug generation (*5*), synthesize small molecules (*6*−*9*), and evolve modified nucleic acids (*10*). Templated reactions have also been used to detect nucleic acid sequences both in vitro and in cells (*11*). Unlike more conventional methods for nucleic acid detection such as polymerase chain reaction (PCR) (*12*) and fluorescence in situ hybridization (FISH) (*13, 14*), templated reactive probes can in some cases be employed for cellular RNA/DNA identification without lysing or fixing the cells, and do not require washing steps. This makes probing operationally easier to perform and the results straightforward to interpret. It also allows for the analysis of heterogeneous samples of cells and for sorting cells based on their genetics (*15*). In addition to templated reactive probes, other classes of fluorogenic nucleic acid probes, including molecular beacons and nanoparticle-based systems, are also under investigation for such applications (*16*−*20*).

Several fluorogenic reaction strategies have been investigated for templated nucleic acid detection, including fluorophore uncaging (*21*−*27*), quencher release (*28*), fluorophore synthesis (*29, 30*), fluorophore release (*31*), and quencher transfer (*32, 33*). Our laboratory has described quenched autoligation (QUAL) probes that rely on an S_N2 reaction to displace a fluorescence quencher, unquenching a nearby fluorophore (*34*−*36*). While these probes have been used to discriminate among different strains of bacteria based on small differences in rRNA sequences and to detect high-copy-number mRNAs in mammalian cells, the reported designs can be limited by a significant background signal; a low background would ultimately be needed to detect rarer RNAs. The background signal from the probes arose largely from nontemplated displacement of the quencher by cellular nucleophiles such as water and thiols. Thus, we have pursued new strategies that increase specific signals and decrease such background signals. In this light, we describe here double displacement (DD) probes, which require two displacement events to fully unquench a fluorophore.

Double displacement probes were designed to have two fluorescence quenchers as leaving groups on the terminus of a DNA probe. The nonspecific displacement of only one of these quenchers (by water, for example) should not produce a large increase in fluorescence, since another quencher remains. However, the binding of a DD probe adjacent to a nucleophile probe on a target sequence markedly increases the rate at which the quenchers are displaced, leading to signal generation. Herein, we describe the synthesis and evaluation of three architectures for double displacement. These new probes are shown to provide enhanced initial quenching and also yield considerably lower background signal during in vitro and cellular nucleic acid detection. Two-color DD probes are further shown to discriminate among bacterial cell types in a heterogeneous mixture based on a single-nucleotide polymorphism.

EXPERIMENTAL PROCEDURES

Double Displacement Oligonucleotide Probe Synthesis. Pac-dA, iPr-dG, and Ac-dC phosphoramidites for UltraMild synthesis (Glen Research) were employed in synthesizing oligonucleotides containing the double displacement linker. The fluorescein label was introduced with fluorescein-dT phosphoramidite (Glen Research). The TAMRA label was introduced using a 3′-TAMRA CPG (Glen Research). Deprotection and cleavage from the CPG support was carried out by incubation in 0.05 M K_2CO_3 in CH_3OH (Glen Research) for 4 h at room temperature. The oligonucleotides were purified by reverse-

phase HPLC (Prosphere C18 300 Å 10u 250 mm, eluting with 0.1 M triethylammonium acetate, pH 7.0 and acetonitrile). Probe structure was confirmed by MALDI-TOF mass spectrometry (see Supporting Information).

Preparation of Single-Dabsyl Probes. Single-Dabsyl (butyl linker) probes were prepared and purified as previously described (*36*).

Templated Double Displacement Reactions. Reactions were performed in 70 mM PIPES buffer (pH 7.0) containing 10 mM $MgCl_2$ and 50 μM dithiothreitol in a Flexstation II 384 microplate reader. Reaction mixtures contained 100 nM each of quencher probe and template and 120 nM of nucleophile DNA. Reactions were initiated by addition of the nucleophile DNA to wells containing the quencher probe and template DNA. The emission was measured in 2 min intervals at 525 nm with excitation at 494 nm over 8 h. The control reactions were performed with the template omitted from the reaction mixture.

Monitoring Dabsylate Release by HPLC. Reactions were performed in 70 mM PIPES buffer (pH 7.0) containing 10 mM $MgCl_2$ and 50 μM dithiothreitol at 25 °C. At the specified time points, aliquots of the reaction were taken and injected onto an analytical RP-HPLC column (Alltech Platinum C18 100 Å 5u 250 mm), eluting with 0.1 M triethylammonium acetate, pH 7.0, and acetonitrile. The integration of the dabsylate peak was taken and converted to a measure of the number of equivalents of dabsylate based on a standard curve prepared separately with known concentrations.

Testing Intracellular RNA Detection. *E. coli* K12 and *S. enterica* cells were grown to log phase (OD600 = 0.4−0.6) in Luria−Bertani (LB) media at 37 °C with rapid shaking. Aliquots of media were centrifuged for 5 min. The supernatant was removed and pellets were resuspended in 0.1 mL phosphate-buffered saline solution (pH 7.4). The cells were centrifuged again for 5 min and the supernatant was removed. The pellets were resuspended in 0.1 mL hybridization buffer: 0.9 M sodium chloride and 90 mM sodium citrate (6× SSC) and 0.05% SDS. Aliquots of bacteria suspended in the buffer were treated with quencher probe (200 nM), nucleophile probe (2 μM), and helper probes (3 μM each). The reaction mixtures were incubated in the dark at 37 °C. Aliquots of incubated bacteria were mixed 1:1 with a 1% agarose solution and spotted on a glass slide without washing or fixation steps. Imaging was performed on a Nikon Eclipse E800 epifluorescence microscope equipped with a Nikon Plan AP 100×/1.40 oil immersion objective and a SPOT RT digital camera.

RESULTS

Design and Synthesis of Double Displacement Probes. Three potential double displacement probe scaffolds were designed to improve the signal/background ratio of the original single displacement probe structure (Figure 1). As with the prior design, the leaving group in this approach (called dabsylate in analogy to tosylate) serves both to activate the substrate for electrophilic attack and to quench a nearby fluorophore.

The first two linkers designed are structural isomers based on a 1,3,5-pentanetriol scaffold. The first (1,5-Pentyl) has the quenchers on the two primary positions, which should make both reactive S_N2 substrates. The second (1,3-Pentyl) has the quenchers at a primary and a secondary position. Since S_N2 reactions are approximately 1 order of magnitude slower at secondary carbons than at terminal alkyl positions (*37*), we hypothesized that this scaffold would be less prone to multiple nontemplated reactions. The third new scaffold (Isobutyl) was designed with both quenchers at more hindered positions by using a branched scaffold. Isobutyl electrophiles are expected to react with rates around the same order of magnitude as secondary positions (*37*), which was expected to make this linker the most challenging S_N2 substrate of the three and therefore allow fewer untemplated reactions and an even lower background signal.

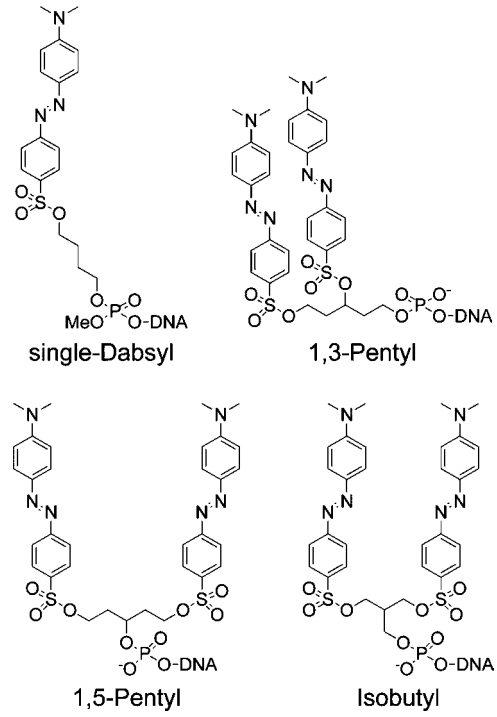

Figure 1. Structures of the reactive parts of double displacement and control (single displacement) probes.

The synthesis of all three new reactive linkers was straightforward, with phosphoramidite analogues prepared on the third alcohol group. The synthesis of the 1,3-Pentyl linker did require extra steps to allow for installation of a quencher at the secondary position instead of one of the primary positions, but it was still synthetically accessible. For the initial studies, we prepared identical 18mer DNA probes having the DD reactive linkers at the 5′ end, along with a fluorescein moiety at the third position. The syntheses of all three DD linker phosphoramidites and their subsequent oligonucleotide conjugation are described in the Supporting Information and Experimental Procedures, respectively.

Initial Quenching Efficiency. The initial quenching efficiencies of the three double displacement probes were measured and compared to the initial degree of quenching of the single-Dabsyl control probe. All three double displacement scaffolds demonstrated superior quenching of the nearby fluorescein moiety, yielding lower initial fluorescence of the unreacted probe (Supporting Information, Figure S1) by a factor of at least four. Such an effect has been demonstrated with molecular beacons, where adding multiple quenchers improved the quenching efficiency (*38*). It is unclear why both the 1,3-Pentyl and Isobutyl probes produce more efficient initial quenching than the 1,5-Pentyl probe, as all three have two quenchers approximately equidistant from the fluorophore. Differences in the structure and flexibility of the linkers may account for these small differences in quenching, by allowing different degrees of contact between quencher and fluorophore.

Templated Unquenching of Double Displacement Probes. We tested the reactivity of the probes in the presence of a DNA template. The fluorescence was monitored over 8 h at 37 °C with 100 nM probes in a pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, and 50 μM dithiothreitol (Figure 2). As a control to evaluate background (off-template) signal levels, the template DNA was omitted in separate reactions for each

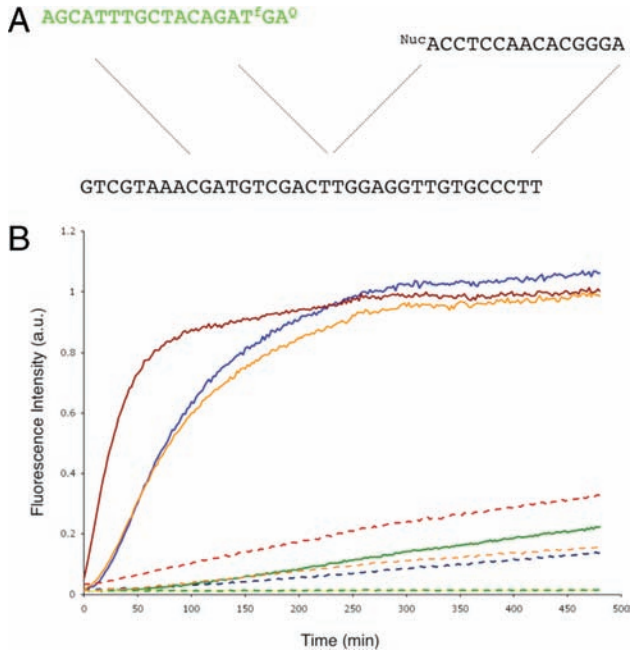

Figure 2. Fluorescence time course of double displacement and single Dabsyl ligation reactions at 37 °C. (A) Sequences of DNA probes and targets (T^f = fluorescein dT; Q = single-Dabsyl or double displacement linker; Nuc = phosphorothioate). (B) 100 nM of 1,3-Pentyl (blue), Isobutyl (green), 1,5-Pentyl (yellow), or single-Dabsyl (red) probe and 120 nM phosphorothioate probe were incubated with or without 100 nM template DNA at 37 °C in pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, 50 μM dithiothreitol. The background (no template) reactions for each probe are shown as broken lines. The fluorescence was measured every 120 s with 494 nm excitation and 525 nm emission. Reactions were repeated in triplicate; representative traces are shown.

probe type. 15mer DNAs with 3′-phosphorothioate groups were used as the nucleophile probe in this and all subsequent experiments. In initial experiments, we also tested 3′-phosphorodithioate nucleophile DNAs; the dithioate moiety is a stronger nucleophile and produces faster displacement reactions (*39*). However, we found that stability issues at 37 °C made them less well suited for these experiments. Reactions and stability of phosphorodithioate nucleophiles in double displacement reactions are described in the Supporting Information.

In templated reactions with the phosphorothioate nucleophile DNA, results showed that two of the three DD probes yielded a substantial fluorescence turn-on signal. The 1,5-Pentyl and 1,3-Pentyl probes showed very similar fluorescence turn-on kinetics, somewhat slower than the rate of the single-Dabsyl control but reaching the same ultimate fluorescence level (Figure 2). The Isobutyl probe, which has both quenchers linked at hindered positions, gave a significantly slower reaction, reaching only ~30% conversion after 8 h. Importantly, background signals for all three DD probes were substantially lower than that of the single-Dabsyl control. Indeed, the background of the slower-reacting Isobutyl probe did not seem to increase at all over the time of the experiment.

From the kinetic data, we plotted the signal/background versus time for each reaction (Figure 3). The 1,3-Pentyl probe showed a higher signal/background at its peak than either the single-Dabsyl or 1,5-Pentyl probe, although the latter had a better ratio over the first hour of reaction. The signal/background ratio for the Isobutyl probe rose more slowly due to its lower reaction rate. However, at long reaction times the value approached that of the best probes. We also evaluated the different probes based on the fold change in fluorescence intensity over time (Figure 4). This metric takes into account the starting fluorescence level

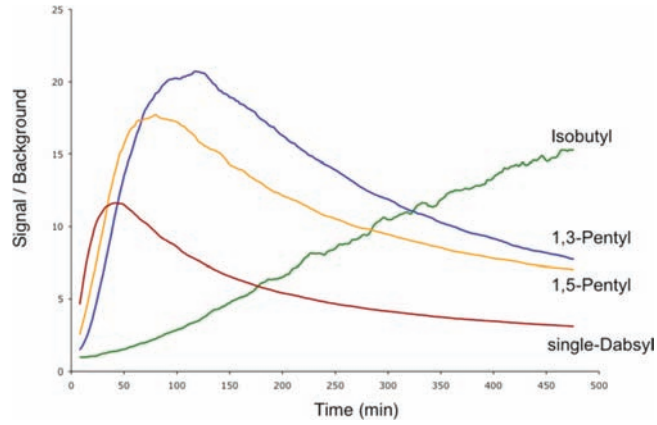

Figure 3. Change in signal/background for double displacement and single Dabsyl probes over time. The signal/background ratios for the 1,3-Pentyl (blue), Isobutyl (green), 1,5-Pentyl (yellow), and single Dabsyl (red) reactions over an 8 h time period. The reactions were run at 37 °C. 100 nM quencher probe and 120 nM phosphorothioate probe were incubated with or without 100 nM template DNA at 25 °C in pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, and 50 μM dithiothreitol. The fluorescence was measured every 120 s with 494 nm excitation and 525 nm emission. The data were smoothed using a 7 point running average.

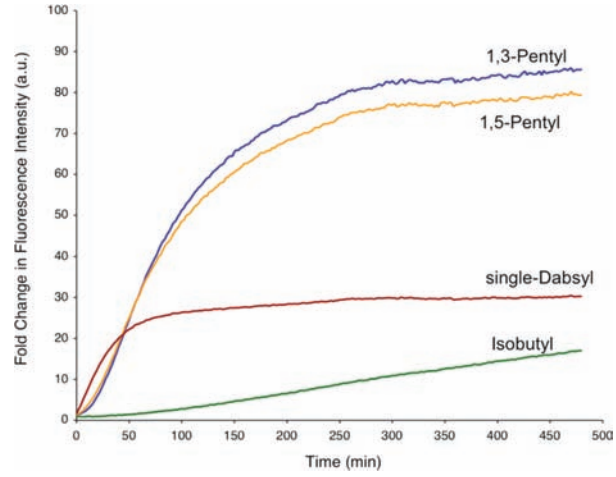

Figure 4. Fold change in fluorescence intensity over time. 100 nM of 1,3-Pentyl (blue), Isobutyl (green), 1,5-Pentyl (yellow), or single Dabsyl (red) probe and 120 nM phosphorothioate probe was incubated with 100 nM template DNA at 37 °C in pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, and 50 μM dithiothreitol. The initial quenching was calculated before the phosphorothioate DNA was added to initiate the reaction. The fluorescence was measured every 120 s with 494 nm excitation and 525 nm emission. Reactions were repeated in triplicate, and the traces shown represent the average fold change in fluorescence at each time point.

of the probes, providing the relative magnitudes of fluorescence turn-on. This is particularly pertinent if the probes will be used for visual evaluations, because the probes with the highest amount of change over time will be the easiest to identify by eye. By this measure, the 1,3-Pentyl and 1,5-Pentyl probes produced similar 75- to 85-fold turn-on, both of which represent a significant improvement over the single-Dabsyl probe (30-fold). These fluorescence enhancements are similar in magnitude to those of the best turn-on values for other templated probes in the literature (*23, 24, 26*−*28*).

Determining Double Displacement Reaction Mechanism. In order to gain insight into the mechanism of reaction of the double displacement probes, the displacement of the quencher leaving group was monitored quantitatively by following the increase in dabsylate concentration in solution over time by RP-

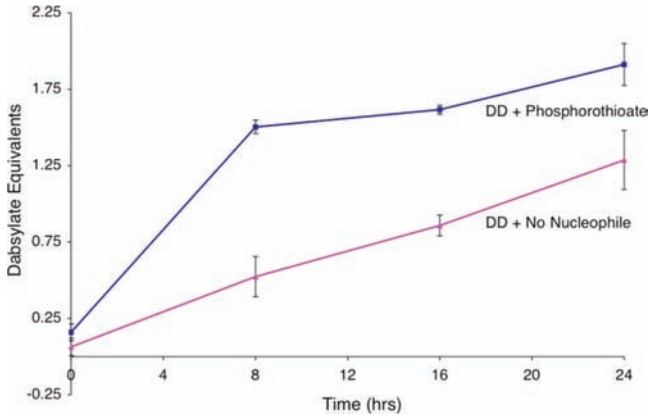

Figure 5. Monitoring dabsylate release in double displacement reaction. The amount of free dabsylate released in solution, as monitored by HPLC from reactions containing 1 μM DD probe, 1 μM template strand, and 1.2 μM phosphorothioate probe (blue) at 25 °C. The DD probe and template with no nucleophile probe present is shown in pink.

HPLC. The 1,5-Pentyl linker was chosen as a representative double displacement scaffold for these experiments. The data show that the rates of dabsylate appearance for reactions with and without a nucleophile probe primarily differ in the first few hours of the reaction (Figure 5). At 8 h, the reaction with the nucleophile had lost 1.5 equiv of dabsylate and the reaction without the nucleophile had lost 0.5 equiv. From then on, the rates of dabsylate appearance are very similar. By the time the reactions with the nucleophile displace 2 equiv of dabsylate, the reaction with no nucleophile present had displaced 1 equiv. This supports the intention of the probe design: while background (water) displacement of one of the quenchers does occur, there is a negligible change in signal until a templated nucleophile can react to displace the second one.

Detection of rRNA in Intact Bacterial Cells. In order to determine if the results we obtained in vitro translated to cellular conditions, all four probes were used to detect a previously targeted rRNA sequence in *Escherichia coli* cells (*39, 40*). Aliquots of bacteria in log phase growth were treated with 0.9 M sodium chloride and 90 mM sodium citrate (6× SSC) + 0.05% SDS, unlabeled helper DNAs, 3′-phosphorothioate probes, and the single Dabsyl or double displacement probes and incubated at 37 °C for 3 h. The purpose of the helper oligonucleotides was to disrupt the secondary structure of the rRNA and increase accessibility for the probes (*41*). The background fluorescence was determined by omitting the 3′-phosphorothioate oligonucleotides from the reaction. No washing or cell preparation steps were taken; the result was simply imaged after 3 h. Figure 6 shows representative images of cells for the foreground and background of each probe. Gratifyingly, the 1,3-Pentyl and 1,5-Pentyl probe give the best contrast between the templated and untemplated reactions in the intact bacteria, fully consistent with the results of the in vitro experiments.

Two-Color Probes for Discrimination Between Bacterial Species. Next, we tested whether double displacement linkers could be adapted to a two-color system of probes that allows one to visually distinguish between different types of cells in a heterogeneous mixture. To this end, we synthesized two new probes, both with a 1,3-Pentyl double displacement linker. Both probes are fluorophore-labeled 10mer oligonucleotides that differ only by a single base pair to render them complementary to a known site in *E. coli* and *Salmonella enterica* rRNA that differs by a single base (G for *E. coli*; U for *S. enterica*). The EC (green) probe has only a fluorescein-labeled dT, while the SE (red) probe was designed to have a FRET pair with a fluorescein-labeled dT as the donor and a 3′-TAMRA fluorophore as the acceptor (Figure 7a). Our laboratory has previously used a similar design for QUAL and Q-STAR probes (*15, 28, 42*).

This set of probes was first tested in vitro to validate the two-color system. Both the EC and SE probes were incubated with the 3′-phosphorothioate strand and either the EC or SE template in pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, and 50 μM dithiothreitol at 37 °C for 1 h. The emission spectra of the individual reactions were measured from 500 to 650 nm with a 494 nm (fluorescein) excitation. When the template containing the complementary sequence for the *E. coli* probe was used, the experiment showed a strong signal at 520 nm, consistent with fluorescein emission. When the *S. enterica* template was used, the probes showed a clear FRET signal, with emission peaks at both 520 and 580 nm (Figure 7b). The kinetics of these reactions were also measured at 37 °C over 8 h with and without the template strands (Supporting Information, Figure S7).

After verifying that these probes performed correctly in vitro, their specificity to the desired cell type was tested. Each probe, along with the 3′-phosphorothioate and the appropriate helper probes, was used to treat *E. coli* and *S. enterica* cells in 6× SSC + 0.05% SDS. The intact cells were imaged under an epifluorescence microscope. The results clearly show that the probes were selectively unquenched with the appropriate cell type, as the images of the probes in the incorrect cells showed fluorescence levels that are equivalent to the fluorescence when

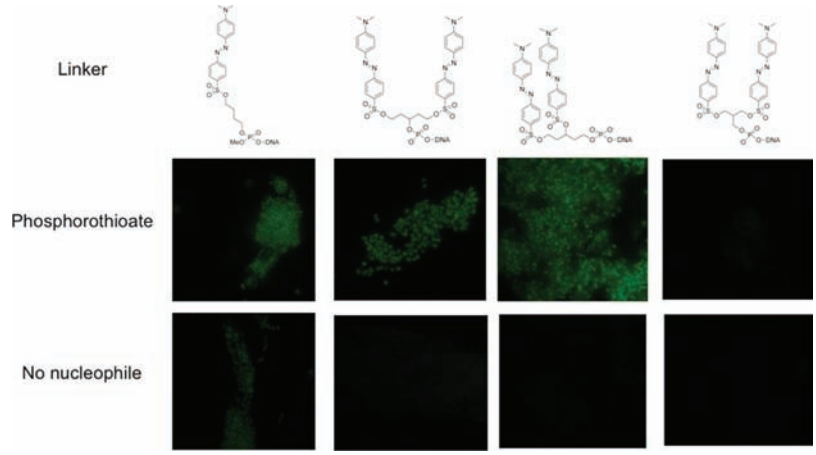

Figure 6. Comparison of double displacement and single Dabsyl probes for detecting cellular 16S rRNA The indicated double displacement or single Dabsyl probe (200 nM), helper DNAs (3 μM), and 3′-phosphorothioate probes (2 μM) were incubated with *E. coli* cells in 6× SSC buffer with 0.05% SDS at 37 °C for 3 h. Images were taken with a black/white camera and false-colored green.

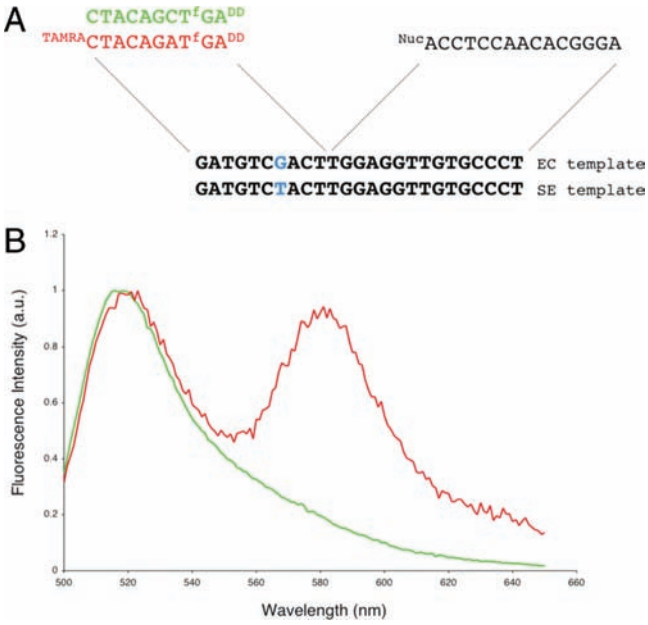

Figure 7. FRET probes for two-color detection scheme. (A) Sequences of DNA probes and targets (T^f = fluorescein dT; DD = 1,3-pentyl linker; Nuc = phosphorothioate). (B) Normalized fluorescence emission spectra of a mixture of EC and SE probes incubated with 3′-phosphorothioate probe and either EC DNA or SE DNA. Conditions: 200 nM EC probe, 200 nM SE probe, 600 nM phosphorothioate DNA, and 200 nM EC (green) or SE DNA (red). The reactions were incubated for 1 h at 37 °C in pH 7.0 buffer containing 70 mM PIPES, 10 mM $MgCl_2$, and 50 μM dithiothreitol. The excitation wavelength was 494 nm.

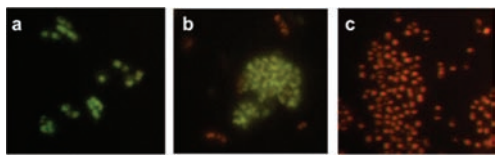

Figure 8. Two-color discrimination of *E. coli* and *S. enterica* based on a single nucleotide polymorphism in the 16S rRNA. EC and SE double displacement probes (200 nM each), helper probes (3 μM), and 3′-phosphorothioate probes (2 μM) in 6× SSC + 0.05% SDS buffer were incubated in the indicated cell type or mixture of cells at 37 °C for 5 h. A B-2A filter was used for imaging. (a) *E. coli* cells. (b) *E. coli* and *S. enterica* cells. (c) *S. enterica* cells.

no nucleophile probe is added (Supporting Information, Figure S8). This study was extended further to show cell-type analysis of a heterogeneous mixture. Both probes were simultaneously added with the same nucleophile and helper strands to a mixture of *E. coli* and *S. enterica* cells. After incubation, the mixture of cells was imaged under a fluorescence microscope, clearly showing two differently colored populations of cells (Figure 8), demonstrating that these probes can be used to distinguish between two cell lines with single nucleotide discrimination.

DISCUSSION

The experiments presented here expand on the previously described quenched autoligation reactions as a viable approach to the detection of nucleic acids. Previous work with this class of reactions showed that nonspecific displacement of the quencher was the primary source of background (*36, 41*). Therefore, in designing the double displacement linkers we sought to use scaffolds that would necessitate two reactions to produce a fully unquenched fluorophore, hoping that this would increase the likelihood that a full unquenching of the probe would include a templated reaction. The results with the three new double displacement probes clearly confirmed this, showing strongly enhanced signal/background as a result of the dual reactive groups. The faster-reacting Pentyl probes also showed improved signal/background in a cellular context. An added benefit of the dual-quencher design was the enhancement of the initial quenching of the probes. For two of the new probes, this produced a much larger increase in fluorescence intensity over time as compared to the previous probes with a single-leaving quencher/leaving group.

The third new probe, based on an isobutyl scaffold, reacted more slowly than expected. Although both leaving groups are at primary positions, the linker appears to be too sterically demanding for the S_N2 reactions necessary for unquenching to occur on a useful time scale. This gives these probes very low background levels, but also a very slow turn-on rate. While these properties may make the Isobutyl probes appropriate for other applications (for example, at higher temperature), they do not lend themselves well to cell-based diagnostics at 37 °C.

Our experiments in single-color detection of rRNA in *E. coli* showed similar trends in signal/background as were observed in vitro. The 1,3-Pentyl and 1,5-Pentyl probes showed a clearer visual difference between the probes with and without the nucleophile strand than did the Isobutyl or single Dabsyl probes. The slow-reacting Isobutyl probes yielded cell images that were hardly fluorescent at all, regardless of whether or not the nucleophile was present. In two-color mixed probe experiments, probes were capable of clearly differentiating between these two cell types based on their genetics in a heterogeneous sample. Thus, the Pentyl probe designs are potentially very applicable in bacterial discrimination in clinical microbiology laboratories, offering clearer signal and less background than previous designs (*42*). Although both the 1,3-Pentyl and 1,5-Pentyl probes performed with similar kinetics and signal/background, from a functional perspective we currently favor the 1,3-Pentyl probes because they appear to give slightly better signal/background in our cellular experiments. However, the 1,5-Pentyl probes do offer a practical advantage, as the synthesis of the phosphoramidite is several steps shorter.

The two-color cellular demonstration of DD probes illustrates one of a number of possible applications of templated chemistry, particularly for single nucleotide discrimination, which is difficult to achieve with classical FISH probes. Continued development of these reactive probes and tests of their application in mammalian cells are underway.
