*3,3,4,4,5,5,6,6-Octafluoro-1,8-diiodohexadecyl Benzoate (**4b**).* Compound **4b** (2.46 g, 29%) was prepared from 1,4-diiodoperfluorobutane, vinyl benzoate, and 1-decene following the same procedure as described for **4a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluoro-1,10-diiodooctadecyl Benzoate (**4c**).* Compound **4c** (1.53 g, 33%) was prepared from 1,6-diiodoperfluorohexane, vinyl benzoate, and 1-decene following the same procedure as described for **4a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorotetradecyl Benzoate (**5a**).* Tributyltin hydride (173 μL, 0.64 mmol) was added to compound **4a** (100 mg, 0.13 mmol) and AIBN (2 mg, 0.01 mmol) in Et_2O (3 mL). The reaction mixture was refluxed under the light of a domestic halogen lamp (I.CEM Züblin AG, type 0201, 500 W) for 15 h. Solvent was removed under reduced pressure and the residue was purified by flash chromatography over silica gel (n-C_6H_{14}/CH_2Cl_2 9:1) to yield benzoate **5a** (61 mg, 90%) as a white waxy solid.

*3,3,4,4,5,5,6,6-Octafluorohexadecyl Benzoate (**5b**).* Compound **5b** (1.38 g, 96%) was prepared from **4b** following the same procedure as described for **5a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorooctadecyl Benzoate (**5c**).* Compound **5c** (1.49 g, 90%) was prepared from **4c** following the same procedure as described for **5a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorotetradecanol (**6a**).* Compound **5a** (3.0 g, 5.61 mmol) was stirred in methanolic 1 M LiOH (20 mL) for 3 h at room temperature. Solvent was removed under vacuum, and the residue was dissolved in CH_2Cl_2, then washed with water and brine. The organic layer was dried over $MgSO_4$ and evaporated, and compound **6a** (2.21 g, 91%) was obtained as a white waxy solid after purification over silica gel (n-C_6H_{13}/CH_2Cl_2 1:1).

*3,3,4,4,5,5,6,6-Octafluorohexadecanol (**6b**).* Compound **6b** (0.60 g, 86%) was prepared from **5b** following the same procedure as described for **6a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorooctadecanol (**6c**).* Compound **6c** (0.47 g, 77%) was prepared from **5c** following the same procedure as described for **6a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorotetradecanoic Acid (**7a**).* Alcohol **6a** (1.0 g, 2.32 mmol) was dissolved in acetone (40 mL) and water (0.5 mL). Jones' reagent was added dropwise at room temperature until a persistent red−brown solution was obtained. The reaction mixture was stirred for 1 h, added with *i*-PrOH (2 mL), and stirred for an additional 15 min period. Solvent was then removed under reduced pressure, water (5 mL) was added, and the resulting mixture was extracted with Et_2O. The organic layer was washed with H_2O, brine, dried over $MgSO_4$, filtered, and reduced under vacuum to yield acid **7a** (0.93 g, 90%) as a white waxy solid.

*3,3,4,4,5,5,6,6-Octafluorohexadecanoic Acid (**7b**).* Compound **7b** (0.37 g, 92%) was prepared from **6b** following the same procedure as described for **7a**.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorooctadecanoic Acid (**7c**).* Compound **7c** (1.64 g, 89%) was prepared from **6c** following the same procedure as described for **7a**.

*N-[1-(2,3-Dihydroxy)propyl]-N,N,N-trimethylammonium Chloride (**8**).* (±)-Glycidol (2 mL, 30.1 mmol), trimethylamine hydrochloride (2.88 g, 30.1 mmol), and *N,N*-diisopropylethylamine (5.25 mL, 30.1 mmol) in methanol (20 mL) were stirred for 12 h at room temperature. Solvent was removed under reduced pressure, and compound **8** (3.65 g, 71%) was purified by recrystallization in EtOH/acetone (1:1 v/v).

*Benzyl 2-Bromoethyl Phosphite (**9**).* *N,N*-Diisopropylethylamine (1.0 mL, 5.73 mmol) was added dropwise to phosphorus trichloride (0.5 mL, 5.73 mmol) in anhydrous THF (10 mL). The reaction mixture was cooled down to −78 °C, and benzyl alcohol (0.6 mL, 5.73 mmol) in THF (20 mL) was added with a syringe driver under vigorous stirring over a 3 h period. The resulting suspension was stirred for 30 min, and a second portion of *N,N*-diisopropylethylamine (1.0 mL, 5.73 mmol) was added. Then, freshly distilled 2-bromoethanol (0.4 mL, 5.73 mmol) in THF (20 mL) was added dropwise over a 3 h period. Stirring was prolonged for 90 min at −78 °C before water (7 mL) was added. The reaction mixture was warmed to room temperature, THF was removed under vacuum, and the residue was washed twice with AcOEt. The organic layer was dried over MgSO4, reduced under vacuum, and purified over silica gel (n-C_6H_{14}/AcOEt 5:5) to yield compounds **9** (1.08 g, 67%) as a slightly yellow oil.

*Benzyl 2-Bromoethyl (2,2-Dimethyl-1,3-dioxolan-4-yl)methyl Phosphate (**10**).* Sulfuryl chloride (4.3 mL, 53.5 mmol) was added dropwise at 0 °C to phosphite **9** (5.0 g, 17.9 mmol) in dry CCl_4 (50 mL). Stirring was prolonged 30 min at 0 °C and 10 min at room temperature. Volatile was removed under vacuum, and the residue was coevaporated twice with anhydrous toluene. Benzyl 2-bromoethyl chlorophosphate was obtained as a colorless oil and was used without purification. (*R*)-(-)-2,2-Dimethyl-1,3-dioxolane-4-methanol (2.37 g, 17.9 mmol) in anhydrous THF (200 mL) was treated with sodium hydride (60% oil suspension, 0.86 g, 21.5 mmol) at 0 °C for 30 min. Then, previously prepared chlorophosphate was added, and the reaction mixture was stirred for 3 h at room temperature. THF was removed under vacuum, saturated aqueous NH_4Cl (100 mL) was added, and the resulting solution was extracted with AcOEt. The organic layer was washed with H_2O, brine, dried over $MgSO_4$, and reduced under vacuum. The residue was purified over silica gel (n-C_6H_{14}/Et_2O 5:5 to 8:2) to yield **10** (4.6 g, 63%, mixture of diastereomers) as a yellow oil.

*2-Azidoethyl Benzyl (2,2-Dimethyl-1,3-dioxolan-4-yl)methyl Phosphate (**11**).* Compound **10** (0.50 g, 1.22 mmol) and sodium azide (0.10 g, 1.54 mmol) were stirred in anhydrous DMF (6 mL) for 2 h at 50 °C. Water (15 mL) was added, and the resulting solution was extracted with Et_2O. The organic layer was dried over $MgSO_4$, reduced under vacuum, and purified by flash chromatography (n-C_6H_{14}/AcOEt 5:5 to 8:2) to yield **11** (0.34 g, 75%, mixture of diastereomers) as a yellow oil.

*2-Azidoethyl Benzyl 2,3-dihydroxypropyl Phosphate (**12**).* Compound **11** (118 mg, 0.32 mmol) was stirred in EtOH (8 mL) with strongly acidic cation exchange resin Dowex 50 × 8 (H^+ form) for 12 h at room temperature. The resin was filtered off, solvent was removed under vacuum, and the residue was purified by flash chromatography (AcOEt/EtOH 10:0 to 8:2) to yield **12** (69 mg, 64%) as a yellow oil.

*(Z)-3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorohexadec-9-enoic Acid (**13**).* Unsaturated acid **13** (0.14 g, 99%, Z/E = 85:15) was obtained as a colorless oil starting from alcohol **17** and following the same procedure as described for **7a**.

*2-Azidoethyl Benzyl 3-{1,2-di[(Z)-3,3,4,4,5,5,6,6,7,7,8,8-dodecafluorohexadec-9-enoyl]-sn-glycero} Phosphate (**14**).* Unsaturated acid **13** (250 mg, 0.53 mmol) in anhydrous CH_2Cl_2 (2 mL) was stirred at room temperature for 4 h with oxalyl chloride (0.25 mL, 2.86 mmol) and DMF in catalytic amount. Volatiles were removed under reduced pressure, and the residue was coevaporated twice with anhydrous toluene and dissolved in CH_2Cl_2 (2 mL). Then, diol **12** (68 mg, 0.21 mmol) and pyridine (45 μL, 0.56 mmol) in anhydrous THF (3 mL) were added, and the reaction mixture was stirred at room temperature for 8 h. Saturated aqueous NH_4Cl was added, and the mixture was extracted with Et_2O. The organic layer was dried over $MgSO_4$,

filtered, and reduced under vacuum. The residue was purified by flash chromatography (*n*-C_6H_{14}/CH_2Cl_2/AcOEt 6:2:2 to 0:0:10) to yield **15** (172 mg, 68%; mixture of isomers, *Z*/*E* = 85:15) as a colorless oil.

*2-Azidoethyl 3-{1,2-di[(Z)-3,3,4,4,5,5,6,6,7,7,8,8-dodecafluorohexadec-9-enoyl]-sn-glycero} Hydrogen Phosphate (**15**).* Bromotrimethylsilane (35 μL, 265 μmol) was added to compound **14** (84 mg, 68 μmol) in anhydrous CH_2Cl_2 (5 mL). The reaction mixture was stirred for 3 h at room temperature and moist THF is added. Solvent was removed under vacuum, and the residue was purified over silica gel ($CHCl_3$/MeOH 10:0 to 6:4) to yield compound **15** (74 mg, 95%; mixture of isomers, *Z*/*E* = 85:15) as a colorless oil.

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluoro-1,10-diiodotetradec-9-enyl Benzoate (**16**).* A degassed mixture of 1,6-diiodoperfluorohexane (200 mg, 0.36 mmol), 1-octyne (80 μL, 0.54 mmol), vinyl benzoate (75 μL, 0.54 mmol), and AIBN (12 mg, 0.07 mmol) was stirred for 15 h at 80 °C in a sealed tube. The resulting mixture was cooled down to room temperature, volatiles were removed under reduced pressure, and the residue was purified by silica gel chromatography (*n*-C_6H_{14}/CH_2Cl_2 9:1 to 0:10) to yield compound **16** (105 mg, 36%, *Z*/*E* = 15:85) as a yellow waxy solid.

*(Z)-3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluorohexadec-9-enyl Alcohol (**17**).* Diiodoester **16** (354 mg, 0.44 mmol) in anhydrous THF (4 mL) was added dropwise to a suspension of $LiAlH_4$ (100 mg, 2.63 mmol) in refluxing THF (8 mL). The resulting mixture was stirred at 66 °C for 30 min and cooled down at room temperature, and excess reagent was slowly decomposed by addition of solid NH_4Cl. Ether (15 mL) was then added, and the organic layer was washed with water and brine, dried over $MgSO_4$, filtered, and reduced under vacuum. The crude residue was purified over silica gel (*n*-C_6H_{14}/CH_2Cl_2 5:5 to 0:10) to yield alcohol **17** (135 mg, 68%, *Z*/*E* = 88:12) as a colorless oil.

Film Formation and Surface Pressure Measurements. Monolayer experiments were performed on a computer-controlled Langmuir film balance KSV 3000 (KSV, Helsinki, Finland). Surface pressure isotherms were recorded on a Teflon trough (570 × 150 mm) with a Wilhelmy plate coupled to a linear transducer. Monolayers were spread from 0.5 mM lipid solutions in hexane/chloroform (1/1: v/v). Volumes ranging from 100 to 300 μL were delivered at several locations across the water surface with a Hamilton microsyringe. At least 15 min were allowed for the spreading solvent to evaporate before monolayer compression. The subphase consisted of purified water (pH 5.35, Millipore filtration system, Barnstead, NANO pure 11) with a resistivity of $18.2 \cdot 10^6$ Ω cm. Compressions were realized using a hydrophilic Delrin barrier (polyacetal). Surface pressure vs molecular area curves were recorded at 21.0 ± 0.5 °C with a compression speed of 2−5 Å^2 per lipid molecule per minute. All measurements were carried out in triplicate. Specific areas A_s, lift-off areas A_{lo}, and collapse pressures π_c were determined as previously described (*26*).

Cell Culture. Human hepatocarcinoma cells (HepG2) were cultured in DMEM supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, 292 mg/L L-glutamine, 4.5 g/L D-glucose, and 10% heat-inactivated FCS. The syrian hamster kidney fibroblast cell line (BHK-21) was cultured in MEM supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, 10 mg/mL L-glutamine, 50 mg/mL tryptose, and 10% FCS. The HeLa cell line was cultured in MEM supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, 292 mg/L L-glutamine, and 10% FCS.

Lipoplex Preparation. For transfection experiments, cationic lipid (30 μL of a 1.8 mM solution in ethanol) and DOPE (6 μL of a 18 mM solution in ethanol) were mixed and added to 10 mM Hepes pH 7.5, 150 mM NaCl (150 μL). After stirring by vortex, the solution was added to the plasmid DNA (6 μg) in 10 mM Hepes pH 7.5, 150 mM NaCl (150 μL). The solution was vortexed again and incubated for 20 min at room temperature before addition to the cells. For gel retardation analysis, the same concentration and procedure were used except that the amount of DNA per sample was 1 μg.

Dynamic Light Scattering Measurements. The average particle size and the polydispersity of the lipoplexes were measured by using photon correlation spectroscopy (Malvern Zetasizer nanoZS, Malvern Instruments Inc., UK) using the multimodal analysis and the automatic mode. Lipoplex solutions (100 μL, vide supra) were diluted 10 times, in DMEM medium unless stated otherwise.

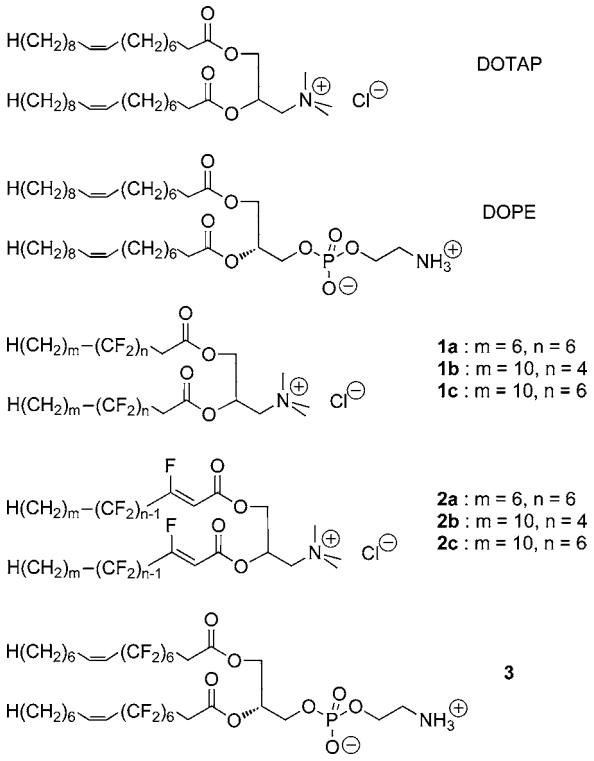
DNA Retardation Assays. After 15 min incubation, complexes were analyzed by electrophoresis through a 1% agarose gel. The gel was run in a 40 mM Tris-acetate-EDTA buffer pH 8.0 (TAE). DNA was then visualized with ethidium bromide solution at 0.5 μg/mL.

Transfection Procedure. Cells were plated in 24-well plates one day before transfection in order to obtain 60−80% confluent cultures at the time of the experiment. Transfection mixture (110 μL containing 2 μg of DNA plasmid, vide supra) was deposited in each well of the triplicate. After a 24 h incubation period, cells were harvested in lysis buffer (250 μL: 8 mM $MgCl_2$, 1 mM DTT, 1 mM EDTA, 1% Triton X-100, 15% glycerol, in 25 mM Tris-phosphate buffer pH 7.8). The cell lysate was centrifuged for 5 min at 10 000 *g* to pellet cell debris. Luciferase light units were measured in a 96-well plate format with a PhL luminometer (Mediators Diagnostika) from an aliquot of the supernatant (50 μL) with 10 s integration after automatic injection of assay buffer (100 μL: lysis buffer without Triton X-100 but supplemented with 2 mM ATP) and 167 μM luciferin (100 μL). The protein content of each cell lysate was measured using the BioRad protein assay. The transfection efficiency was expressed as relative light units/10 s/mg protein (RLU/mg protein) after subtraction of background luciferase value from each sample value. Values of each sample are the means of triplicate determinations.

Lipoplex Cytotoxicity Assessment. Lipoplex cytotoxicity was assessed using a tetrazolium-based assay. Cells were seeded in 24-well culture plates at a density of 5.0×10^4 cells per well and cultured at 37 °C for 24 h. On the next day, culture medium was changed to fresh DMEM medium supplemented with 10% FCS before addition of lipoplexes (100 μL) prepared as previously described. After a 24 h incubation period at 37 °C, culture supernatant was removed, cells were carefully washed with PBS, and 0.5 mg/mL MTT (1 mL) in complete culture medium was added. After a 2 h incubation period at 37 °C, MTT solution was removed and DMSO (1 mL) was added to lyse cells and dissolve reduced MTT. Intensity of MTT reduction was then evaluated by measuring absorbance at 570 nm. Viability of cells treated with lipoplexes was expressed as a percentage of the absorbance measured in untreated cells. Each treatment was assessed in triplicate, and data are presented as means ± sem of $n = 3$ values.

RESULTS AND DISCUSSION

Molecular Design and Chemistry. To investigate the influence of fluoroalkyl moieties located in the vicinity of the headgroup of a cationic lipid on its transfection efficiency, we first need a reference compound and selected the widely used DOTAP (Figure 1). The introduction of fluoroalkyl segments in its structure must fulfill some preliminary requirements in terms of chemical stability. Considering the high reactivity of α,α′-difluoroesters toward water with half-life time for hydrolysis in the range 0.1−5 min (*27*), we decided on structures in which one methylene group lies in between the fluoroalkyl chain



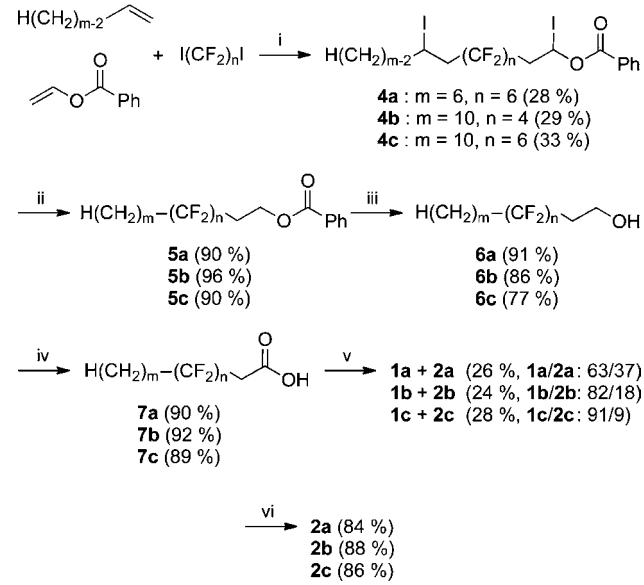


Figure 1. Structures of DOTAP, DOPE, and fluorinated cationic lipids developed.

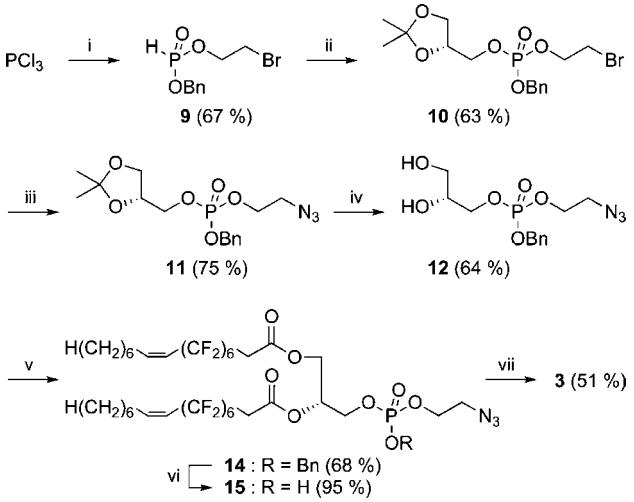
and the carboxyl group. We thus designed compounds **1a**−**c** with modulated lengths for fluoroalkyl and terminal alkyl moieties. In order to target compounds with hydrophobicity tentatively comparable with that of DOTAP, we varied the number of methylene (*m*) and difluoromethylene (*n*) groups in the chains, considering the "1 CF_2 = 1.5 CH_2" rule (*28, 29*) and its variations (1.5 $CH_2 \leq 1$ $CF_2 \leq 4$ CH_2) (*30*). Under mild basic conditions, β,β'-difluoroesters easily eliminate HF, and compounds **2a**−**c** result from a double elimination in **1a**−**c** (vide infra).

A number of transfection protocols with cationic lipids use dioleoylphosphatidylethanolamine (DOPE) as a helper lipid (Figure 1). The role of DOPE in transfection assays has been extensively studied (*31, 32*). The mechanism of action of that lipid has been attributed to its capacity to induce transition of a lipid bilayer from the liquid-crystalline lamellar phase into the inverted hexagonal H_{II} phase. Vierling et al. examined the use of terminal fluorinated glycerophosphoethanolamines analogues of DOPE as helper lipids in nonfluorinated cationic lipid-mediated gene transfer (*18, 19*). A fluorinated segment was introduced at the extremity of the ester at C^1 (or C^1 and C^2) on the glycerol backbone, and the resulting increase in transfection efficiency by cationic lipids was attributed to the pronounced cone-shaped geometry of the molecule, displaying a greater tendency to promote a transition from the lamellar phase into the inverted hexagonal H_{II} phase. Considering the results obtained with lipoplexes prepared from mixtures of **1a**−**c** and DOPE (vide infra), we were especially interested in evaluating a fluorinated analogue of DOPE displaying two fluorous segments close to the lipid polar head. Consequently, we designed HFP compound **3** that displays all structural features of DOPE and displays a fluorous segment in between the double bond and the carboxyl group of the two fatty acid chains. Chain length is less than C_{18} to compensate for enhanced hydrophobicity due to fluorine. Stereochemistry of the double bond is *Z* in order to tentatively preserve the original chain conformation of oleoyl chains. Last, C^2 stereochemistry on glycerol backbone was imposed to fit with that in natural phospholipids.

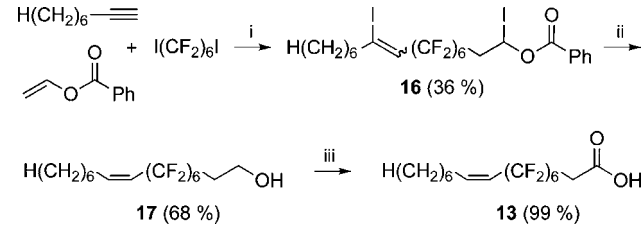


Scheme 1. Synthesis of Compounds 1a−c and 2a−c[a]

[a] Conditions: (i) $NaHCO_3$, $Na_2S_2O_4$; (ii) Bu_3SnH, AIBN; (iii) LiOH; (iv) CrO_3, H_2SO_4; (v) $(COCl)_2$, *N*-[1-(2,3-dihydroxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (**8**), py; (vi) Et_3N.

The synthesis of compounds **1a**−**c** was realized starting from α,ω-diiodoperfluoroalkanes according to Scheme 1. Hemifluorinated fatty acids **7a**−**c** were key intermediates. Their preparation involved the well-described radical addition of a iodoperfluoroalkane to an alkenyl compound (*33*). However, the homobifunctional fluorinated starting material introduced some difficulty, as heterofunctionalization was required. The reaction of a large excess of diiodoperfluoroalkane with 1 equiv of alkene allows high yield but low conversion and is not acceptable due to high cost of the fluorinated reagents. When the reaction was carried out with diiodo and alkenyl compounds in stoichiometric amounts, the proportion of monoalkylated product obtained was close to 50%, which is in agreement with statistics. Nevertheless, the process of the radical reaction remained difficult to monitor and reduction compounds R_F-H rapidly appeared as alkene concentration decreased in the reaction mixture. Consequently, the heterobifunctionalization of the diiodo starting material was carried out using a one-step procedure involving stoichiometric amounts of both alkenyl reagents. Perfluoroalkyl iodide addition to alkene can be promoted in many ways (by photolysis, pyrolysis, electrolysis, free radical initiator, enzymes, metals, and transition metal complexes). In that work, radicals were generated under the conditions described by Rong and Keese, and using sodium dithionite and sodium carbonate in CH_3CN/H_2O (*34*). The yield of the double transformation was close to 30% and was higher than that by any multistep procedure we have experienced. Efforts to run the reaction under anhydrous conditions with triethylborane (*35*) did not give better results either. Radical reduction of compounds **4a**−**c** using Bu_3SnH and AIBN (*36*) proved efficient and **5a**−**c** were obtained in high yield. Benzoate hydrolysis and Jones oxidation of the resulting alcohols **6a**−**c** afforded hemifluorinated fatty acids **7a**−**c** (*37, 38*). Further conversion into acyl chlorides allowed direct coupling with *N*-[1-(2,3-dihydroxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride **8** straightforwardly prepared from glycidol. Fluorinated cationic lipids **1a**−**c** were obtained in 26−28% yield. Important to note is the high sensitivity of compounds **1a**−**c** that very easily eliminate HF even at room temperature. As a consequence, they were obtained as a mixture with eliminated byproducts that were very difficult to separate (**1a**, 37% elimination byproduct; **1b**, 18% elimination byproduct; **1c**, 11% elimination byproduct).

Scheme 2. Synthesis of the Fluorinated Analogue of DOPE 3[a]



[a] Conditions: (i) Et_3N, BrC_2H_4OH, H_2O; (ii) SO_2Cl_2, (*S*)-2,2-dimethyl-1,3-dioxolane-4-methanol, NaH; (iii) NaN_3; (iv) Dowex 50 × 8 (H^+ form); (v) **13**, $(COCl)_2$, py; (vi) TMSBr, H_2O; (vii) PPh_3, H_2O.

In order to tentatively assume better control of the composition and properties of later lipoplexes, compounds **1a**−**c** were quantitatively transformed into the corresponding unsaturated cationic lipids **2a**−**c** upon treatment with Et_3N. The unsaturated double bonds are in the *Z* configuration as was determined from the coupling constant $^3J_{H-F} \approx 29$ Hz, a value which is characteristic of the trans position between fluorine and hydrogen on ethylenic double bonds (*39*, *40*). Lipid **1c**, however, was considered for further biophysical and biological investigations (vide infra), as it was obtained at the lower contamination rate.

Synthesis of the fluorinated analogue of DOPE **3** was achieved according to Scheme 2. Benzyl 2-bromoethyl phosphite **9** was prepared in one step from phosphorus trichloride. Transformation of **9** into corresponding chlorophosphate allowed condensation with (*S*)-2,2-dimethyl-1,3-dioxolane-4-methanol. Resulting phosphotriester **10** was obtained in 53% yield. Bromide nucleophilic displacement with sodium azide provided compound **11**, and the isopropylidene protecting group was removed upon treatment with a strongly acidic cation exchange resin. Resulting diol **12** was then acylated with unsaturated hemifluorinated fatty acid **13** to give **14** in 68% yield. Interestingly, elimination byproducts were not obtained or could not be detected. In the preparation of compounds **2a**−**c**, due to the amphiphilicity of the compounds, the crude reaction mixture was not submitted for aqueous work up but reduced in vacuo and directly purified by silica gel chromatography. This could possibly indicate that HF elimination occurs during concentration of the crude reaction mixture and may be avoided by aqueous workup prior to solvent evaporation. Debenzylation of **14** was achieved with bromotrimethylsilane (*41*, *42*). The final step was reduction of the azide group in **15** via a Staudinger reaction affording **3** in 51% yield.

Unsaturated fluorinated fatty acid **13** was a key compound for the preparation of the fluorinated DOPE analogue. It was prepared in three steps (Scheme 3). The first one involved the reaction of R_FI with an alkynyl compound (*43*−*45*). It was similar to the preparation of **4a**−**c** except that 1-alkene was replaced with 1-octyne. The double radical oxidative addition of 1,6-diiodoperfluorohexane on a stoichiometric mixture of vinylbenzoate and alkyne furnished vinyl iodide **16** as *E*/*Z* mixture (*E*:*Z* = 85:15). Reduction of compound **16** under the conditions employed by Takagi (*n*BuLi, Et_2O, −78 °C) for the synthesis of fluorinated analogues of oleic acid displaying

Scheme 3. Synthesis of Unsaturated Hemifluorinated Fatty Acid 13[a]

[a] Conditions: (i) Na_2CO_3, $Na_2S_2O_4$, AIBN. (ii) $LiAlH_4$. (iii) CrO_3, H_2SO_4.

the fluorous part opposite the carboxyl group proved inadequate (*44*, *45*). Reduction using nBu$_3$SnH-AIBN (*46*) gave a mixture of cis and trans alkenes (*Z*:*E* = 60:40) revealing extended isomerization of the intermediate vinyl radical. More satisfactorily, treatment with lithium aluminum hydride allowed extensive reduction of compound **16** into **17** in better favor of the cis isomer (*47*). Under these conditions, reduction proceeded with full retention of the configuration (*Z*:*E* = 88:12), and concomitant reduction of the benzoate moiety occurred with release of the free primary hydroxyl group. The last step consisted of oxidation of alcohol **17** that was quantitatively transformed into unsaturated hemifluorinated fatty acid **13** upon treatment with CrO_3−H_2SO_4.

Self-Assembly Properties of the Fluorinated Cationic Lipids. Self-assembly properties of fluorinated cationic lipids were investigated at the air/water interface (due to their high content in elimination byproduct, samples **1a** and **1b** were not subjected to monolayer study). Compounds were spread from a hexane/chloroform solution, and the surface pressure π vs area A was recorded. All the compounds analyzed exhibited similar behavior (see Supporting Information). The pressure regularly increased up to collapse pressure at 28−34 mN/m. No surface pressure decrease was recorded at high lateral pressure ($\pi < 30$ mN/m) when the compression barrier was stopped, indicating that the monolayers formed at the air/water interface were stable. The values for specific area A_s, lift-off area A_{lo}, and collapse pressure π_c for compounds **1c** and **2a**−**c** are presented in Supporting Information.

Monolayer spread from saturated lipid **1c** (containing 11% of elimination products) collapsed in a more condensed state than those from unsaturated compounds **2a**−**c**. This indicates that unsaturation to some extent opposes close packing of the compounds. That is further supported by the lower value for the lift-off area recorded for **1c** when compared to those of **2a**−**c**. However, the *Z* configuration of the double bonds in **2a**−**c** seems to be contradictory to these results. Indeed, it is expected that **1c** and the *Z* conformer of **2c** display comparable monolayer properties and more particularly similar specific areas (mean molecular area in the more condensed state of the monolayer). The large difference in specific area between the two compounds could then reflect some unusual conformation of the glycerol backbone in **2c**, and computational modeling would be necessary to get a deeper insight in the packing properties of the compounds. The measured value for specific area of lipid **1c** at the air/water interface was close to twice that of a section of crystalline fluoroalkyl chain (2 × 24.9 Å^2) (*48*). That indicates that compound **1c** collapsed in a highly ordered liquid phase, as no phase transition could be detected through isothermal monolayer compression. The same held for compounds **2a**−**c** though slightly higher A_s values were recorded. For comparison, the A_s value for DOTAP is 50 Å^2, which is larger than twice the section of alkyl chain (16 Å^2) and accounts for a higher free volume within the lipidic phase. That may be correlated to susceptibility to detergents (vide infra).

Table 1. Semiquantitative Evaluation of Lipoplex Stability in the Presence of Surface Active Compounds

	detergent resistance (mM)[b]				
cationic lipid[a]	SDS	NaCh	Tween 80	CHAPS	CTAB
DOTAP	(1)[c]	10	<1	50	1
1c	1 (10)[c]	100	150	150	150
2a	1	10	<1	10 (50)[c]	150
2b	1	10	<1	10	1 (150)[c]
2c	1	50 (150)[c]	1	50	10 (150)[c]
DOTAP/DOPE[d]	1	10	<1	10	1
1c/DOPE[d]	(1)[c]	100	<1	150	1 (150)[c]
2a/DOPE[d]	1	10	<1	50	1 (150)[c]
2b/DOPE[d]	1	10	<1	10	1
2c/DOPE[d]	1	150	<1	50	150

[a] Lipoplexes were prepared as indicated in the experimental section, with N/P = 3. [b] Detergent was added to reach 1, 10, 50, 100, and 150 mM final concentration (concentration of cationic lipid: 0.18 mM). Concentration reported corresponds to the higher one tested at which lipoplexes were 100% preserved. [c] At that detergent concentration, only partial release of plasmid DNA (±10%) is observed. [d] Cationic lipid/DOPE was in the ratio 1/2.

Characterization of Lipid−DNA Complexes. The ability of the fluorinated cationic lipids to interact electrostatically with DNA was studied by conventional electrophoretic DNA retardation assays in which a full retard of plasmid DNA is observed at a lipid/DNA phosphate ratio (N/P) corresponding to electroneutrality. As expected, all the fluorinated lipids led to a full complexation of the plasmid at N/P 1, indicating that the fluorous block does not impact on the ability of the cationic headgroup to interact with the DNA phosphate groups (data not shown).

Cationic lipoplexes destruction may occur essentially through ionic competition or detergence of the lipidic phase (*49*−*52*). Both cause DNA to dissociate from the complex and release nucleic acids then being vulnerable to nuclease attack. We therefore evaluated the resistance of fluorinated lipoplexes in the presence of various surfactants: anionic, cationic, or neutral ones (Table 1). Plasmid DNA was first condensed with fluorinated lipids **1c** and **2a**−**c** at N/P 3 to form overall cationic complexes with putative transfection activity. Complexes were then treated with increasing amounts of surfactant. The resulting mixtures were homogenized and analyzed by gel electrophoresis to allow semiquantitative evaluation of lipoplex destruction by monitoring DNA release. Results indicate that, regardless of the cationic lipid, lipoplexes hardly resisted to anionic surfactant SDS. This is consistent with an effect mediated by electrostatic competition between sulfate and phosphate for the cationic lipid headgroup, coupled to high lipid detergence by the alkyl chain. Sodium cholate (NaCh), the other anionic detergent tested, is a poorer competitor of phosphate for ammonium complexation (due to a higher pk_a value) and lipoplexes resisted better. Integrity of DOTAP, **2a**, and **2b** lipoplexes was respected to up to 10 mM cholate. Remarkably, the higher fluorinated homologues **1c** and **2c** were revealed to form highly stable complexes with DNA that resisted 150 mM sodium cholate, suggesting that these lipids may be impermeable to the hydrophobic cholyl moiety. A similar but less pronounced effect was reported by Vierling's group with FHP lipospermine−DNA complexes that resist a taurocholate concentration twice as high as the corresponding nonfluorinated lipoplex (17.5 mM vs. 10 mM) (*13*, *16*). Next, and to minimize destabilization by anionic contribution, we evaluated the stability of DNA lipoplexes in the presence of neutral (Tween 80), zwitterionic (CHAPS), and cationic (CTAB) detergents. A little surprisingly, neutral surfactant Tween 80 showed drastic effects on lipoplex stability. DOTAP-DNA complexes did not resist much and were fully destroyed even at the lowest detergent concentration investigated (1 mM). The same held for **2a**−DNA and **2b**−DNA complexes. As already observed with SDS and sodium cholate, cationic lipids **1c** and **2c** were revealed to be more potent, likely due to their greater hydrophobic character (longer fatty acid chains, higher fluorine content). The zwitterionic detergent CHAPS, though neutral, exhibited very different behavior and destabilized lipoplexes poorly. Most of them survived to 10−50 mM, and once again, **1c**−DNA and **2c**−DNA were characterized by higher stability. Lastly, cationic CTAB proved highly detrimental to DOTAP-DNA complexes but affected fluorinated lipoplexes only weakly. Thus, even if a superficial positive charge of the lipoplexes may shield the particles from other cations, 1 mM CTAB revealed enough to fully destabilize DOTAP-DNA complexes, whereas fluorinated lipoplexes mostly resisted up to 150 mM. It is interesting to note that the stability of **1c**−DNA complexes was invariably higher than for **2c**−DNA, especially in the presence of Tween 80. The difference in lipoplex stability between **1c**−DNA and **2c**−DNA probably cannot be explained just considering fluorine content (24 vs 22 F atoms). More likely, chain conformation imposed by unsaturation in **2c** thwarts close packing of helical fluorinated chains (vide supra), resulting in higher free volume in the external lipid layer of the lipoplex and consequently higher permeability. Such a permeability increase facilitates access of detergent molecules to the condensed DNA core and favors lipoplex destruction.

As DOPE was used as the lipid helper (vide infra), we characterized the mixed lipoplexes (lipid/DOPE/DNA) and looked at their stability. Considering DOTAP and DOTAP/DOPE lipoplexes, no significant difference was observed in detergent resistance. As DOTAP and DOPE are more likely similarly solubilized by detergents, behavior of a mixed lipoplex was indeed expected to be the same as for the pure DOTAP lipoplex. For mixed fluorinated lipid/DOPE lipoplexes, we could possibly anticipate some differences. Actually, no such deviation was observed, and DNA condensed particles resisted detergents in the same concentration range as with pure fluorinated cationic lipids. Whether DOPE remained associated to the lipoplexes or was depleted via micelle formation was not checked.

From that series of experiments, we conclude that the fluorous segments within the lipid structure indeed increase the stability of the lipoplexes in the presence of surfactants, and the longer the fatty acid chains and the higher the fluorine content, the more stable the lipoplexes are.

It is well-known that the size of transfecting complexes is an important parameter that impacts the cell entry mechanism of the particles. Most cationic particles establish electrostatic interaction with proteoglycans and enter adherent cells entrapped into endosomal vesicles. Escape from these recycling compartments occurs only for complexes incorporating molecules with endosomolytic activity and is the result of the specific activity of such endosomolytic element(s) (*53*, *54*). Efficiency of current and multipurpose lipid or polymeric nucleic acid delivery agents seems to rely on the preparation of "large" complexes with diameter in the 100−1000 nm range for optimal cell anchorage and subsequent intracellular routing activity. Such complexes offer excellent transfection efficiency for adherent cell lines for which multitissular organization does not impede accessibility of large particles to cell surface receptors (*55*−*60*). Even if particles smaller than 100 nm might be more suited for in vivo administration, their efficiency seems to rely on the use of endosomolytic agents with high activity (*61*), and large delivery systems have shown some effectiveness upon regional administration (*62*, *63*).

Classically, optimal gene transfection efficacies are obtained when DNA lipoplexes are prepared in 150 mM NaCl at N/P charge ratio of 3 and above. In these conditions, DNA plasmids assemble with cationic lipids to form cationic aggregates of optimal size. We therefore carried out dynamic light scattering

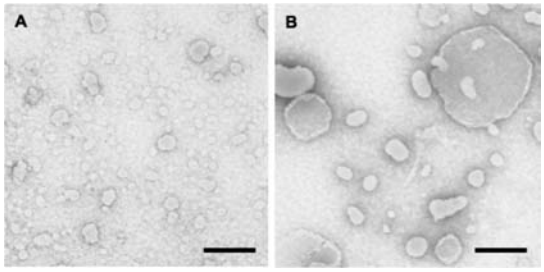


Figure 2. TEM images of **1c**/DOPE (A) and **1c**/DOPE-DNA (B). Figure shows negatively stained samples (uranyle acetate) obtained with fluorinated lipid/DOPE molar ratio 1/2 and total lipid concentration of 1.16 mM (A) and 0.42 mM (B, see Experimental Procedures). Charge ratio N/P is 3. Scale bars correspond to 200 nm.

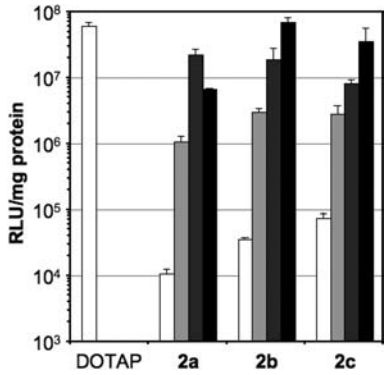

Figure 3. Expression of luciferase in HepG2 cells treated with DNA complexes with DOTAP and fluorinated **2a**−**c** with various compositions. Lipids were mixed with DOPE in different molar ratios (lipid/DOPE molar ratio: white, 1/0; light gray, 1/1; deep gray, 1/2; black, 1/3). Lipoplexes were prepared in 150 mM NaCl, 10 mM Hepes, pH 7.5, at charge ratio N/P 4.

measurements for evaluating the size of lipoplexes DOTAP/DOPE-DNA, **1c**/DOPE-DNA, and **2c**/DOPE-DNA, assembled in 150 mM NaCl (cationic lipid/DOPE 1/2, N/P 3). In these conditions, DOTAP-based lipoplexes show a mean particle size of 140 nm. Lipoplexes prepared from **1c** and **2c** appear as larger particles with mean diameter of 250 and 400 nm, respectively. Lipoplexes were analyzed as well by electron microscopy. No significant difference was observed between DOTAP and fluorinated particles, which presented similar globular morphology, except that negative staining of the latter was more difficult and provided lower contrast (Figure 2). That last point is consistent with some exacerbation of the peripheral hydrophobicity of the particles due to the presence of fluorous segments very close to the surface exposed to the hydrophilic staining material (UO_2^{2+}).

Transfection Biology. The transfection activity of fluorinated lipoplexes was first evaluated on HepG2 cells. The activity of different formulations of lipids **2a**−**c** is shown in Figure 3. Experiments were carried out at a charge ratio commonly used with cationic lipids (N/P 4), and DOTAP was used as a control. Lipoplexes were classically incubated with cells in serum-free conditions for a 4 h period before addition of serum-complemented culture medium. The expression level of luciferase was low for **2a**−**c**/DNA complexes. Transfection efficiency was, however, drastically increased upon addition of the helper lipid DOPE. With **2**/DOPE molar ratio between 1/2 and 1/3, transfection efficacy of most fluorinated lipoplexes was comparable to that of DOTAP. Further optimization of the charge ratio (in the N/P range 1−6) indicated that the transfection efficacy reached a plateau for N/P 3−4, a behavior that was already noticed for classical cationic lipids (*64*).

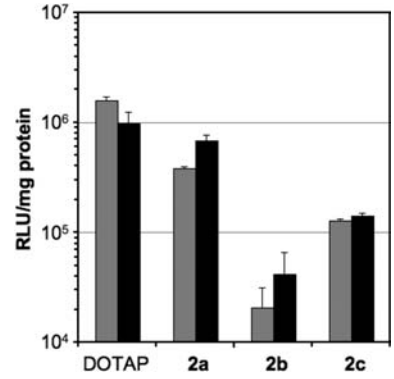

Figure 4. Expression of luciferase in HepG2 cells treated with DNA complexes with cationic lipids DOTAP (N/P 4) and **2a**−**c**/DOPE (1/1 molar ratio, N/P 3) in serum-free conditions (gray) or in the presence of 25% FCS (black).

One serious shortcoming of gene delivery mediated by cationic lipids is that the transfection mostly requires serum-free conditions to be effective. Serum proteins are negatively charged and interact with cationic liposomes, thereby competing with DNA for cationic lipids (*50*). Untimely DNA decomplexation even to a low extent usually results in transfection inhibition. To investigate the effect of serum, we then tested transfection activity of our fluorinated lipoplexes by direct addition of DNA complexes to cells in serum-free conditions and in the presence of 25% fetal calf serum (Figure 4). Lipoplexes were incubated with cells for a 4 h period before the cell culture medium, which contained either too much or too little FCS for optimal cell growth, was replaced with DMEM containing 10% serum. Luciferase expression was monitored 24 h later. Whereas DOTAP transfection efficiency was invariably reduced by 30−40% in the presence of serum, that of fluorinated lipoplexes was preserved or even increased. This might be tentatively interpreted considering that lower adsorption of plasma elements onto fluorinated particles would not significantly provoke their degradation (as is the case with DOTAP particles) but rather would induce or amplify sedimentation, which would result in improved cellular internalization.

Having shown that the transfection activity of fluorinated lipoplexes is not impaired by a high concentration of FCS, we simplified the gene transfection procedure. The following experiments were conducted on the BHK-21 cell line, which is more convenient to culture and to handle than HepG2. DNA lipoplexes were directly added to cells in culture medium containing 10% serum, and transfection/toxicity activities were measured 24 h later without any medium change. The effect of chain unsaturation in fluorinated cationic lipids is presented in Figure 5. At optimal charge ratio N/P 3, DOTAP/DOPE, **1c**/DOPE, and **2c**/DOPE (in a 1/2 molar ratio) roughly displayed similar transfection efficiency in BHK-21 cells. An increase of charge ratio provoked a rapid loss of transfection activity with saturated lipid **1c**, whereas activity remained much better preserved with unsaturated compound **2c** or DOTAP.

The efficiency of DOPE as a helper lipid in fluorinated lipoplexes was somehow uncertain, as DOPE and fluorinated cationic lipids are supposed to segregate. In fact, DOPE was revealed to be even more potent when mixed with compound **1c** than when mixed with DOTAP (Figure 6). DOPE increased DOTAP transfection efficiency by a 40-fold factor, whereas that of **1c** gained up to 4 orders of magnitude. From there, the evaluation of a HFP fluorinated analogue of DOPE appeared inevitable to us. We assumed that the mixture of **1c** and fluorinated DOPE analogue **3** would exhibit different aggregation properties than **1c** and DOPE. Properties of the resulting lipoplexes should thus differ from and, possibly, outdo those

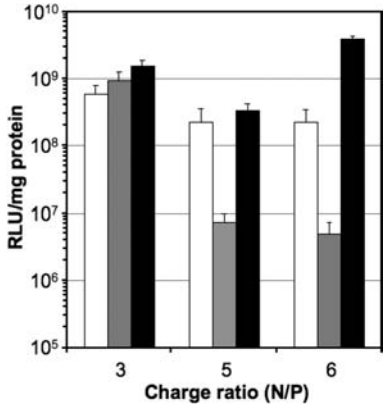

Figure 5. Expression of luciferase in BHK-21 cells treated with DNA complexes with DOTAP (white) and saturated and unsaturated fluorinated lipids **1c** and **2c** (gray and black, respectively). Cationic lipids were mixed in a 1/2 molar ratio with DOPE. Lipoplexes were prepared in 150 mM NaCl, 10 mM Hepes, pH 7.5. Transfection was performed in cell culture medium containing 10% FCS.

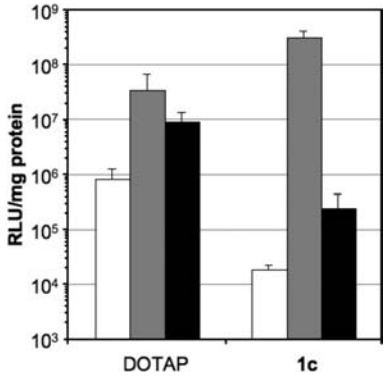

Figure 6. Transfection efficiency of DOTAP and fluorinated cationic lipid **1c**, pure (white) and mixed with DOPE (gray) and its fluorinated analogue **3** (black) in a 1/2 molar ratio. Lipoplexes were prepared at charge ratio N/P 3, in 150 mM NaCl, 10 mM Hepes, pH 7.5. BHK-21 cells were transfected in the presence of 10% FCS.

of **1c**/DOPE-DNA particles. Results did not completely meet our expectations, as **3** only improved transfection efficiency of **1c** by 1 order of magnitude. However, the same quantitative effect was observed with DOTAP and a similar effect was observed with FHP DOPE analogues (*18*, *19*). Although they are surprising at first sight, these results may be rationalized and attributed to the introduction of some lipid heterogeneity in membranes upon fusion/internalization of liposomes/lipoplexes and possibly modifying the internalization pathway and intracellular trafficking. On one hand, mixed lipoplexes, i.e., those containing both fluorinated and nonfluorinated lipids (DOTAP/**3**-DNA and **1c**/DOPE-DNA), most likely exhibit a heterogeneous lipid distribution resulting from partial segregation of the fluorinated and nonfluorinated components. Lipoplexes may thus display discrete nonfluorinated lipid domains at their periphery. These domains are brought into close contact with the negatively charged membrane of cells through electrostatic interactions and may trigger the fusion/internalization process. Incorporation of some fluorinated lipid components into the cell membrane is supposed to introduce additional heterogeneity in the lipid bilayer, possibly resulting in endosome destabilization. On the other hand, fusion of homogeneous fully fluorinated lipoplexes (**1c**/**3**−DNA) with cell membrane is made difficult due to the low miscibility of fluorocarbon−hydrocarbon mixture. Though contact between the fluorinated cationic surface of lipoplexes and the negatively charged cell membrane may be tight, most probably it does not suffice to provoke efficient

Table 2. Mean Size of Lipoplexes in Different Media as Determined by Light Scattering Experiments[a]

	DOTAP/DOPE-DNA (nm)[b]		**1c**/DOPE-DNA (nm)[b]	
incubation medium	− FCS	+ FCS	− FCS	+ FCS
water[c]	100 (0.1)	180 (0.22)	731 (0.25)	1635 (1.00)
150 mM NaCl[c]	140 (0.08)	225 (0.24)	255 (0.38)	400 (0.68)
5% glucose[c]	95 (0.11)	175 (0.22)	1200 (0.55)	1015 (0.47)
MEM	1400 (0.2)	2080 (0.93)	675 (0.35)	680 (0.93)

[a] Complexes were prepared as described for gene transfection assays (cationic lipid/DOPE 1/2, charge ratio N/P 3) and incubated in the absence or presence of 10% FCS. [b] Polydispersity index is indicated into brackets. [c] Solution contains 10 mM Hepes, pH 7.5.

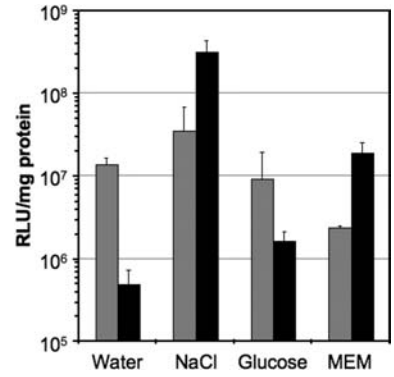

Figure 7. Transfection efficiency of DOTAP/DOPE (gray) and **1c**/DOPE (black) in a 1/2 molar ratio as a function of medium used for lipoplex preparation (for composition, see text). Lipoplexes were prepared at charge ratio N/P 3, and BHK-21 cells were transfected in the presence of 10% FCS.

lipid exchange from lipoplexes to lipid bilayer of the endosomes. Consequent rupture of the endosome and DNA escape are therefore reduced.

Transfection with cationic lipids is known to be significantly affected by the procedure and medium used for the preparation of lipoplexes. Differences probably may be interpreted by considering the size of the resulting complexes, but not exclusively. Therefore, we investigated the influence of the lipoplex preparation medium on the size of the particles (Table 2) and on the level of luciferase expression in BHK-21 cells (Figure 7). Dried lipid mixtures (DOTAP/DOPE and **1c**/DOPE in 1/2 molar ratio) were hydrated in different solutions ((i) 10 mM Hepes buffer, pH 7.5; (ii) 150 mM NaCl, 10 mM Hepes, pH 7.5; (iii) 5% glucose, 10 mM Hepes, pH 7.5; (iv) MEM) before DNA condensation at N/P 3. The size and gene delivery efficacy of these complexes were then evaluated. With the DOTAP-based lipoplex, the mean particle size was in the 100−255 nm range except in MEM (>1 μm). In the presence of 10% FCS, size of the lipoplexes was increased by ca. 50−80%, and the larger particles (obtained in MEM) showed poor transfection efficacy, likely because micrometric size impairs particle endocytosis. The same was observed with fluorinated lipoplexes unless smaller particles were produced in 150 mM NaCl and larger in water or glucose 5%. The fluorinated segment, however, has a significant effect on the assembly process, and **1c**/DOPE-DNA complexes formed in 150 mM NaCl were roughly twice as large as DOTAP/DOPE-DNA complexes. Obtainment of these larger complexes resulted in enhanced transfection activity for reasons discussed earlier. It is important to note, in identical conditions, that the size of **2c**/DOPE-DNA complexes was 690 and 400 nm with and without FCS, respectively, indicating that unsaturation does not significantly alter the assembly process. The larger size of lipoplexes and associated transfection efficacies measured when they were prepared in the medium with higher ionic strength (150 mM NaCl, 10 mM Hepes, pH 7.5) may be explained by considering

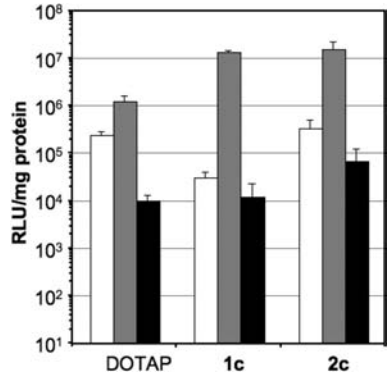

Figure 8. Expression of luciferase in cells treated with pEGFP-Luc complexed by DOTAP/DOPE, **1c**/DOPE, and **2c**/DOPE (1/2 molar ratio) at N/P 3. Three cell lines were investigated: HepG2 (white), BHK-21 (gray), and HeLa (black). Transfection experiments were carried out in the presence of 10% FCS.

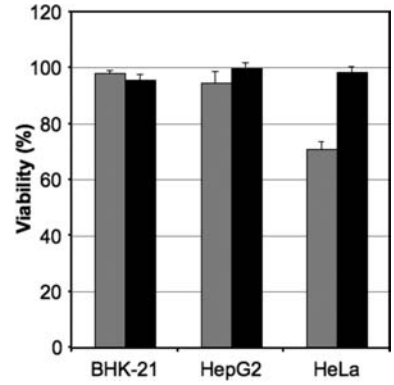

Figure 9. Cytotoxicity of DOTAP/DOPE-DNA (gray) and **1c**/DOPE-DNA (black) on different cell lines. Experiments were conducted at N/P 3 in culture medium supplemented with 10% FCS.

that increasing ionic strength exacerbates hydrophobic interactions and shields electrostatic repulsions. Such conditions allowed kinetically formed and thermodynamically unstable cationic lipoplexes to equilibrate toward lower-energy systems (aggregation). As two fluoroalkyl segments increase hydrophobicity in **1c**, exacerbation of cohesive interactions by ionic strength is stronger than with DOTAP-based particles, provoking a stabilizing effect on the lipid phase and micellar aggregation of higher magnitude. The behavior of **1c**/DOPE-DNA in low ionic strength media is interesting. The absence of salts is supposed to stabilize the colloidal solution to small sizes by favoring electrostatic repulsions (*56*) and large sizes were observed. One possible explanation is that hydration of the fluorinated lipid is much more sensitive to the medium composition than that of classical lipids. When NaCl was substituted for glucose, transfection efficiency was close to that observed when lipoplexes were prepared in 10 mM Hepes buffer pH 7.5, which is consistent with the previous results. The negative influence of MEM on transfection efficiency might be interpreted in terms of both equilibration between phosphate (DNA) and carboxylate (MEM amino acids, 5−6 mM) for ammonium complexation and possible insertion of the side chain of the more hydrophobic amino acids into the lipid phase of the particles. That could account for both destabilization of the DOTAP-based particles and stabilization of **1c**-based ones, the latter being more resistant to both phenomena (vide supra) and taking advantage of ionic strength increase to a greater extent.

Transfection efficiency mediated by nonviral vectors is strongly affected by the cell type. We investigated three different cell lines: HepG2, BHK-21, and HeLa (respectively hepatoma, kidney, and epithelial cells). These cells were treated with mixed **1c**/DOPE, **2c**/DOPE, or DOTAP/DOPE lipoplexes in the presence of FCS. Results are shown in Figure 8. In the BHK-21 cell line, fluorinated lipoplexes appeared more potent than DOTAP-based lipoplex by 1 to 2 orders of magnitude. In HeLa cells, **2c**/DOPE proved superior by almost an order of magnitude to the other formulations. Formulations **2c**/DOPE and DOTAP/DOPE displayed same transfection efficiency in hepatoma cells HepG2, whereas **1c**/DOPE appeared less effective.

To complete our evaluation of fluorinated lipoplexes, we assessed their cytotoxicity as a function of charge ratio and cell type. In a first set of experiments, BHK-21 cells were treated with **1c**/DOPE-DNA or **2c**/DOPE-DNA complexes at various charge ratios (cationic lipid/DOPE 1/2, molar ratio) and using the same amount of DNA plasmid (2 μg) when compared to gene transfection assays (see Supporting Information). Cell viability generally tends to decrease with increasing N/P ratio. That may be explained by considering that positively charged lipoplexes strongly interact with negatively charged cell membranes through electrostatic forces, with potent negative impact on cell membrane integrity and therefore cell homeostasis. In the case of DOTAP lipoplexes, 36% cytotoxicity was observed at N/P 6, and a similar tendency was observed with fluorinated lipoplexes, although these complexes exhibited a limited effect, with cytotoxicity not exceeding 10−20% at N/P 6. In another set of experiments, cytotoxicity of **1c**/DOPE-DNA was evaluated at N/P 3 on three different cell lines, BHK-21, HepG2, and HeLa (Figure 9). No real difference was observed between DOTAP and fluorinated lipoplexes, except for the HeLa cell line. In this cell line, whereas DOTAP lipoplexes provoked 30% cytotoxicity, viability was fully maintained in the presence of **1c**/DOPE-DNA complexes.

CONCLUSIONS

Although a great number of cationic lipids have been designed and evaluated as gene delivery systems, there is still a need for improvement in the design of synthetic lipids for gene transfer. Novel cationic lipids with triblock structure were designed with the purpose of achieving optimal condensation of DNA and enhancing transfection performances. Cationic lipids displaying a fluorous moiety close to their ammonium headgroup were prepared. Self-assembly properties of these cationic lipids were evaluated. They revealed efficient DNA condensing agents, and the resulting lipoplexes displayed enhanced resistance to amphiphilic agents. Transfection data obtained from the fluorinated vectors, alone or as a mixture with different helper lipids, on different cell lines and at various charge ratio revealed in vitro activities that are comparable to that of parent DOTAP, with similar or lower associated toxicity. Due to the fluorous segments within the lipid structure, lipoplexes displayed improved stability, and gene delivery appeared to be regardless of the presence of serum. On the other hand, in vitro transfection efficiency appeared to be very sensitive to the preparation protocol when compared to DOTAP-based lipoplexes. This work highlights the very atypical properties of these fluorinated triblock cationic lipids. Although their in vitro use did not lead to a significant improvement of transfection efficiency, this result does not prejudge their behavior in vivo, as many additional variables, and especially resilience of delivery systems, may induce changes in the behavior of lipoplexes in vivo. Effective impermeabilization of the lipid phase, combined with a preserved ability to deliver genes across endosomal membrane, make these molecules potent building blocks for the preparation of novel gene delivery systems with improved stability and resilience in an in vivo context. In vivo evaluation is currently underway to establish the utility of these new vectors in gene therapy.

Polyamidoamine (PAMAM) Dendrimer Conjugates of "Clickable" Agonists of the A_3 Adenosine Receptor and Coactivation of the $P2Y_{14}$ Receptor by a Tethered Nucleotide

Dilip K. Tosh,[†] Lena S. Yoo,[†] Moshe Chinn,[†] Kunlun Hong,[‡] S. Michael Kilbey II,[‡] Matthew O. Barrett,[§] Ingrid P. Fricks,[§] T. Kendall Harden,[§] Zhan-Guo Gao,[†] and Kenneth A. Jacobson*[,†]

Molecular Recognition Section, Laboratory of Bioorganic Chemistry, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892, Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831, and Department of Pharmacology, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27599. Received October 29, 2009; Revised Manuscript Received December 9, 2009

We previously synthesized a series of potent and selective A_3 adenosine receptor (AR) agonists (North-methanocarba nucleoside 5′-uronamides) containing dialkyne groups on extended adenine C2 substituents. We coupled the distal alkyne of a 2-octadiynyl nucleoside by Cu(I)-catalyzed "click" chemistry to azide-derivatized G4 (fourth-generation) PAMAM dendrimers to form triazoles. A_3AR activation was preserved in these multivalent conjugates, which bound with apparent K_i of 0.1−0.3 nM. They were substituted with nucleoside moieties, solely or in combination with water-solubilizing carboxylic acid groups derived from hexynoic acid. A comparison with various amide-linked dendrimers showed that triazole-linked conjugates displayed selectivity and enhanced A_3AR affinity. We prepared a PAMAM dendrimer containing equiproportioned peripheral azido and amino groups for conjugation of multiple ligands. A bifunctional conjugate activated both A_3 and $P2Y_{14}$ receptors (via amide-linked uridine-5′-diphosphoglucuronic acid), with selectivity in comparison to other ARs and P2Y receptors. This is the first example of targeting two different GPCRs with the same dendrimer conjugate, which is intended for activation of heteromeric GPCR aggregates. Synergistic effects of activating multiple GPCRs with a single dendrimer conjugate might be useful in disease treatment.

INTRODUCTION

Poly(amidoamine) (PAMAM)[1] dendrimers are treelike polymers that have wide application in drug delivery in vivo (*1, 2*). We recently reported the first example of using a PAMAM dendrimeric scaffold for the polyvalent, nanoscale presentation of nucleosides and nucleotides to selectively activate adenosine receptors (ARs) and P2Y receptors to induce intracellular signal transduction (*3*−*5*). Both of these receptor families are cell-surface G protein-coupled receptors (GPCRs). The dendrimer carriers greatly multiply the size of the monomer agonist derivatives, and these multivalent conjugates are intended to bridge multiple binding sites present in GPCR dimers and other higher-order receptor aggregates. In general, we might expect the stability of the ligand in biological systems and its pharmacokinetic and pharmacodynamic properties to be enhanced in the conjugates in comparison to the monomeric ligands.

The A_3AR is found at various levels of expression in neutrophils, eosinophils, cardiac myocytes, skeletal muscle, astrocytes, neurons, and other cell types (*6*) and has distinct effects on cell survival and response to stress. The A_3AR agonist N^6-(3-iodobenzyl)-5′-*N*-methylcarboxamidoadenosine (IB-MECA, CF101) **1** (Chart 1) and its 2-chloro derivative deregulate the NFκB pathway and are currently in clinical trials for the treatment of autoimmune inflammatory diseases and cancer, respectively (*7*−*11*). Anti-ischemic effects of A_3AR agonists also suggest their use in protection of the heart, lung, nervous system, and skeletal muscle (*6, 12, 13*).

We previously synthesized a series of North (N)-methanocarba nucleoside 5′-uronamides as A_3AR agonists of high affinity and selectivity (*14*). These selective agonists, including the anti-ischemic nucleoside MRS3558 **2**, contained a rigid bicyclo[3.1.0]hexane (methanocarba) ring system of the (N) conformation in place of the freely twisting ribose moiety (*9, 11, 12*). These agonists also contained an optimized N^6-(3-chlorobenzyl) group, which enhanced A_3AR selectivity in humans, mice, rats, and other species (*14*). Recently, we extended this series to include dialkyne groups on an extended adenine C2 substituent, e.g., **3a** (*21*). We expected the proximal alkyne to promote receptor recognition and the distal alkyne to serve as a site for coupling to reporter groups while maintaining receptor recognition. Thus, we have selected a region on the nucleoside for attachment that is

Chart 1. Structures of Adenosine A_3AR Agonist Monomers (1−3a) and the Design of Multivalent Dendrimer Conjugates in the (N)-Methanocarba Series, Represented by the Triazole Derivative of General Formula 3b[a]

[a] Compound **3a** was reported in ref *21*.

distal from the pharmacophore and is predicted by modeling to extend into the extracellular region of the A_3AR (*15*).

Here, we coupled the distal alkyne of an A_3AR agonist containing a 2-octadiyne group to azido-derivatized G4 (fourth-generation) PAMAM dendrimer carriers with Cu(I)-catalyzed alkyne-azide cycloaddition, a type of click chemistry (*16*−*18*), to form triazole derivatives, as in conjugate **3b**, and determined the receptor-binding affinity and selectivity. This variation of click chemistry was used previously for coupling biologically active molecules to polymers (*19*). In our previous studies of dendrimer-bound ligands for GPCRs, the small molecular ligands were amide-linked to the carrier (*3*−*5*). For this study, we compared the amide linkages to PAMAM dendrimers with the use of azido groups for conjugation of alkyne derivatives.

We also included PAMAM dendrimers with mixed peripheral azido and amino groups in this study. The incorporation of azides for click chemistry along with the conventional terminal amino/carboxylic groups of the PAMAM dendrimers for amide coupling allowed the facile conjugation of ligands for two different GPCRs (Figure 1). We present the first example of coactivation of two GPCRs by a hybrid PAMAM dendrimer conjugate. The anti-inflammatory A_3AR and the $P2Y_{14}$ receptor, which is activated by endogenous uridine-5′-diphosphoglucose (UDPG) in the neuroimmune system (*20*), serve to illustrate this approach.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. *Materials and Methods.* All reactions were carried out under a nitrogen atmosphere. We purchased *N*-ethyl-*N*′-dimethylaminopropylcarbodiimide hydrochloride (EDC.HCl), UDPG acid trisodium salt (UDPGA), UDPG, G2.5 PAMAM (10 wt % solution in methanol), G3 PAMAM (20 wt % solution in methanol), PAMAM dendrimers (G4, G5.5, and G6, 5 wt % solution in methanol) with an ethylenediamine core from Sigma-Aldrich (St. Louis, MO). All other reagents and solvents, except those indicated, came from Sigma-Aldrich. We purchased dialysis membranes (Spectra/Pore Membrane, MWCO 3500, flat width 18 mm) from Spectrum Laboratories (Rancho Dominguez, CA). Synthesis of compound **3a** is described elsewhere (*21*).

Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker DRX-600 spectrometer with D_2O as a solvent. The chemical shifts are expressed as relative ppm from HOD (4.80). We performed electrospray ionization mass spectrometry (MS) and matrix-assisted laser desorption ionization (MALDI) time-of-flight MS experiments on a Waters LCT Premier mass spectrometer at the Mass Spectrometry Facility, National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), NIH. We analyzed the azido dendrimer precursors on a Varian 500 MHz NMR and on a Bruker Vertex 70 FT-IR. Galbraith Laboratories (Knoxville, TN) performed the elemental analysis.

*G4 PAMAM, Conjugated with 6-Heptynoic acid (**15**).* We added freshly prepared aqueous sodium ascorbate (1 M, 42 μL, 42.1 μmol) to a mixture of G4 PAMAM dendrimer **13** (6.74 mg, 0.42 μmol) and 6-heptynoic acid (1.33 mg, 10.5 μmol) in a mixture of *t*-butanol (0.3 mL) and water (0.3 mL), then added 7.5% aqueous cupric sulfate (70 μL, 20.8 μmol). The reaction mixture was stirred at room temperature overnight, and the product was purified by dialysis in water. The mixture was lyophilized to yield compound **15** (5.45 mg, 68%) as a white, foamy solid. MALDI-MS: calcd 19 029; found 18 928.

*G4 PAMAM, Conjugated with A_3AR Agonist **3a** and 6-Heptynoic Acid (**7**).* We added freshly prepared aqueous sodium ascorbate (1 M, 31 μL, 31 μmol) to a mixture of compound **15** (5.45 mg, 0.28 μmol) and compound **3a** (4.13 mg, 7.74 μmol) in a mixture of *t*-butanol (0.3 mL) and water (0.3 mL), then added 7.5% aqueous cupric sulfate (51 μL, 14.3 μmol). The reaction mixture was stirred at room temperature overnight, and the product was purified by dialysis in water. The mixture was lyophilized to yield compound **7** (5.8 mg, 60%) as a white, foamy solid. ^{1}H NMR (DMSO-d_6, 600 MHz) δ 8.51 (s), 8.14 (s), 7.61 (s), 7.31−7.41 (m), 5.46 (s), 5.68−5.95 (m),

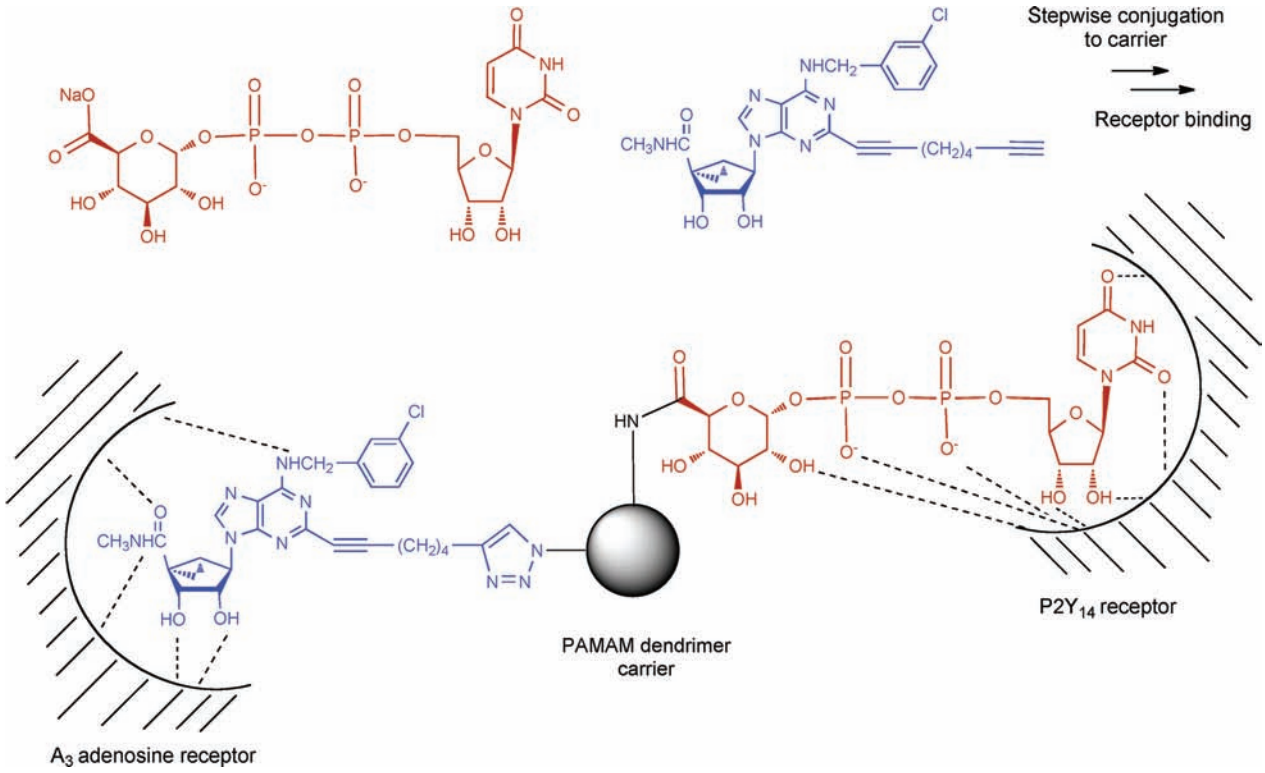

Figure 1. Design of a bifunctional PAMAM dendrimer conjugate for the coactivation of two different GPCRs; shown here are agonists of the A_3AR and the $P2Y_{14}$ receptor. Both receptors are distributed in the immune system and may occur on the same cell (*27*). The stoichiometry of substitution of the dendrimer is not indicated.

3.86 (s), 2.66 (s), 2.21 (s), 1.8 (s), 1.61 (bs), 1.11−1.29 (m). MALDI-MS: calcd 33 852; found 34 088.

*G4 PAMAM, Conjugated with A_3AR Agonist **3a** (**6**).* We followed the procedure used for compound **7** to synthesize compound **6** (69%) from **3a**.^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.50 (bs), 8.15 (bs), 7.60 (s), 7.29−7.59 (m), 5.44 (s), 4.67−5.05 (m), 4.16 (s), 3.86 (s), 2.78 (s), 2.67 (s), 2.08−2.23 (m), 1.82 (s), 1.61 (s), 0.98−1.30 (m). MALDI-MS: calcd 49 991; found 50 844.

*G4 PAMAM, Conjugated with UDPGA (**17**).* We added EDC.HCl (12.5 mg, 65.2 μmol) to a solution of compound **5** (15.3 mg, 1.01 μmol) and UDPGA trisodium salt **16** (22.9 mg, 35.43 μmol) in dimethylsulfoxide (DMSO), then added 0.1 M 2-(*N*-morpholino)ethanesulfonic acid buffer (140 μL). We used 0.1 M HCl to adjust the pH of the reaction mixture to 4.5−5.0. The reaction mixture was stirred at room temperature overnight, and the product was purified by extensive dialysis followed by lyophilization to yield compound **17** (22 mg, 64%). ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.19 (s), 7.86−8.14 (m), 6.55 (m), 5.80 (s), 5.67 (s), 5.38−5.47 (m), 4.07 (s), 3.97 (s), 3.63 (br s), 3.25 (s), 3.12 (s), 2.91 (s), 2.69 (s), 2.24 (s). MALDI-MS: calcd 33 060; found 33 036.

*G4 PAMAM, Conjugated with UDPGA and A_3AR Agonist **3a** (**8**).* We followed the procedure used for compound **7** to synthesize compound **8** (66%) from compound **17**. MALDI-MS: calcd 50 092; found 50 610.

*G2.5 PAMAM, Conjugated with A_3AR Agonist **19** (**9**).* We followed the procedure used for compound **17** to synthesize compound **9** (54%) from dendrimer **18** and compound **19**.^{1}H NMR (D_2O, 600 MHz) δ 7.98 (br s), 6.88 (br s), 4.56 (br s), 3.85 (br s), 3.55 (br s), 3.45 (br s), 3.16−3.36 (m), 3.16 (br s), 3.08 (br s), 2.56−2.98 (m), 2.54 (s), 2.24−2.48 (m), 1.92 (br s), 1.68 (br s). MALDI-MS: calcd. 10 598; found 10 783.

*G2.5 PAMAM, Conjugated with A_3AR Agonist **20** (**10**).* We followed the procedure used for compound **17** to synthesize compound **10** (67%) from dendrimer **18** and compound **20**.^{1}H NMR (DMSO-d_6, 600 MHz) δ 8.11 (s), 7.85−8.01 (m), 7.58 (s), 7.36 (s), 7.18−7.32 (m), 5.06−5.21 (m), 4.88−4.93 (m), 4.65 (s), 4.59 (s), 3.86−3.91 (m), 3.07 (s), 2.65 (s), 2.39 (s), 2.21 (s), 1.85 (s), 1.74 (br s), 1.59 (br s), 1.21−1.33 (m), 1.03 (br s). MALDI-MS: calcd 8370; found 8369.

*G3 PAMAM, Conjugated with A_3AR Agonist **22** (**11**).* We followed the procedure used for compound **17** to synthesize compound **11** (71%) from dendrimer **21** and compound **22**.^{1}H NMR (DMSO-d_6, 600 MHz) δ 8.88 (s), 8.11 (s), 7.73−8.05 (m), 7.58 (s), 7.32 (s), 7.13−7.28 (m), 5.43 (s), 5.03−5.21 (br s), 4.87−4.96 (s), 4.85 (br s), 4.67 (s), 4.61 (s), 3.89 (s), 3.06 (s), 2.82 (s), 2.65 (s), 2.34−2.46 (m), 2.19 (s), 1.83 (s), 1.69−1.78 (m), 1.61 (s), 1.29 (s). MALDI-MS: calcd 13 694; found 13 304.

*G4 PAMAM, Conjugated with A_3AR Agonist **24** (**12**).* We added HATU (4.67 mg, 12.28 μmol) to a mixture of compound **24** (6.72 mg, 12.35 μmol) and dendrimer **23** (2.73 mg, 12.28 μmol) in dry DMF (0.5 mL), then added DIPEA (2.15 μL, 12.22 μmol). The reaction mixture was stirred at room temperature overnight, extensively dialyzed with water, then lyophilized to yield compound **12** (5.5 mg, 61%).^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.46 (br s), 8.10 (s), 7.79−7.93 (m), 7.60 (s), 7.27−7.36 (m), 5.45 (s), 4.67−4.93 (m), 3.87 (s), 3.08 (s), 2.86 (s), 2.66 (s), 2.41 (s), 2.19 (s), 1.78 (s), 1.61 (s), 1.23 (t, J = 24 Hz), 0.80−0.89 (m). MALDI-MS: calcd 47 495; found 47 985.

*Imidazole-1-Sulfonyl Azide Hydrochloride (**26**).* A modification of a published procedure was used (*22*). A suspension of 6.53 g NaN_3 (**25**, 100 mmol, Aldrich, >99.5%) and 100 mL acetonitrile (Aldrich, 99.8% anhydrous) in a 500 mL round-bottom flask was cooled in an ice water bath under a flow of nitrogen. We then added 8.15 mL sulfuryl chloride (100 mmol, TCI American, >98.0%) in 20 mL anhydrous acetonitrile dropwise to the ice-cooled suspension. The mixture was stirred overnight at room temperature, after which we cooled the white suspension to ~0 °C with ice water and added 13.03 g imidazole (191 mmol, TCI America, >98.0%). We warmed the resulting

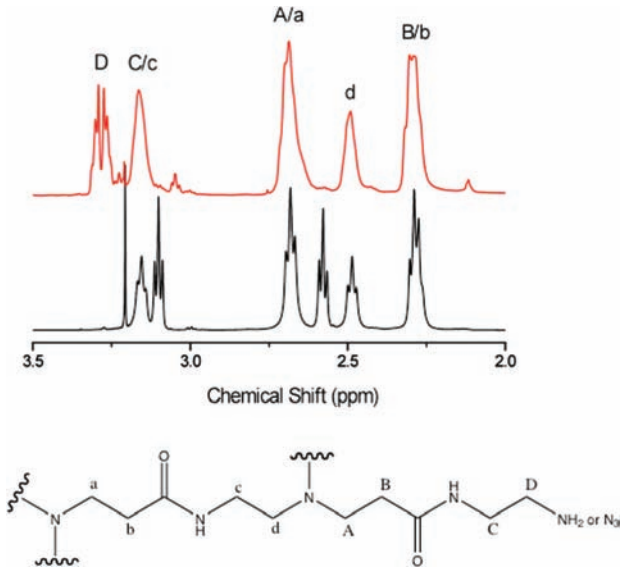

Figure 2. ^{1}H NMR spectra of G4-N_3 (**5**, top), G4-NH_2 from D_2O (**23**, middle). Schematic indication of assignments of the methylene groups (bottom).

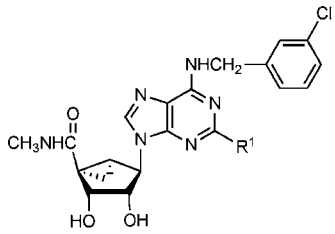
white slurry to room temperature, then stirred it for 3 h. We then diluted it with ethyl acetate (200 mL) and separated and discarded the aqueous layer. We washed the organic layer twice with deionized water (2 × 100 mL), then twice with saturated aqueous $NaHCO_3$ (2 × 100 mL). We then dried it over anhydrous $MgSO_4$ overnight and filtered it. We added an ethanolic HCl solution (196 mmol) dropwise to the filtrate while stirring at ice−water temperature. After we added ∼3 mL, a large amount of white solid appeared. We kept the mixture in an ice bath for 15 min, then at room temperature for 30 min, after which we filtered it. We washed the filter cake with ethyl acetate (3 × 100 mL) to give **26** as a colorless solid (8.65 g, 49.9%), mp 99−101 °C. IR (KBr) 2173, 1383, and 1160 cm^{-1}. ^{1}H NMR (D_2O, 500 MHz) δ 7.61 (dd), 8.02 (dd), 9.39 (dd); ^{13}C NMR (D_2O, 125 MHz) δ = 120.0, 123.5, 137.6. Element Analysis: calcd C, 17.19; H, 1.92; N, 33.41. Found: C, 17.38; H, 1.98; N, 32.97.

*Synthesis of Fully Azido-Derivatized PAMAM (G4) (**13**).* We added anhydrous methanol (10 mL, Aldrich, >99.8%) and 18.15 g G4 PAMAM dendrimer (**23**, Dendritech, Midland, MI, 14.93 w/w % in methanol, [NH_2] = 12.2 mmol) to a 250 mL round-bottom flask. We then added 3.12 g K_2CO_3 (Aldrich, >99.0%, 22.6 mmol) and 31.4 mg $CuSO_4 \cdot 5H_2O$ (Aldrich, 98.0%, 0.126 mmol), causing the solution to take on a pale bluish color. We next added 2.73 g imidazole-1-sulfonyl azide hydrochloride (**26**, 13.1 mmol) to the reaction mixture, and it was stirred at room temperature overnight. The mixture was then dialyzed against deionized water for 7 d, during which we changed the water every 2 h for the first 2 d and thereafter every 4 h. After lyophilization, we collected 2.51 g azide-derivatized G4 dendrimer. The proton NMR is shown in Figure 2. Element analysis: PAMAM-G4: calcd C, 52.81; H, 8.48; N, 24.70, O, 14.01. Fully azide-derivatized G4 PAMAM: calcd C, 47.03; H, 7.15; N, 33.31, O, 12.49; found C, 49.91; H, 7.55; N, 28.07; O, 13.12. The element analyses indicated that 98.0% of primary amines were replaced with azides.

*Synthesis of Partially Azido-Derivatized PAMAM (G4) (**5**).* We added anhydrous methanol (5 mL, Aldrich, >99.8%) and 5.13 g G4 PAMAM dendrimer (**23**, Dendritech, 14.93 w/w % in methanol, [NH_2] = 3.45 mmol) to a 100 mL round-bottom flask. We then added 0.803 g K_2CO_3 (Aldrich, >99.0%, 5.81 mmol) and 17.2 mg $CuSO_4 \cdot 5H_2O$ (Aldrich, 98.0%, 0.069 mmol); the solution took on a pale bluish color. Next, we added 0.43 g imidazole-1-sulfonyl azide hydrochloride (**26**, 2.05 mmol) to the reaction mixture, which was stirred at room temperature overnight. We then dialyzed the mixture against deionized water for 7 d, changing the water every 2 h during the first 2 d and every 4 h thereafter. After lyophilization, we collected 0.45 g partially azide-derivatized G4 dendrimer. Elemental analysis of the partially azide-derivatized G4 PAMAM found C, 49.91; H, 7.55; N, 28.07; O, 13.12. We compared results of the element analysis with the composition of the G4 PAMAM dendrimer and found that 47.2% of the primary amines were replaced with azides, corresponding to ∼31 amines per dendrimer in 64 terminal positions.

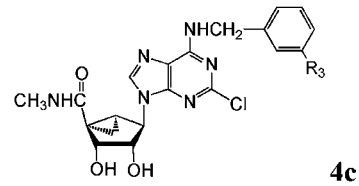
Biological Methods: $P2Y_{14}$ Receptor. *Materials.* We purchased 3-isobutyl-1-methyl-xanthine from Sigma-Aldrich and [^{3}H]adenine from American Radiolabeled Chemicals (St. Louis, MO). We obtained all cell culture medium and serum from Gibco (Invitrogen, Carlsbad, CA).

Cell Culture. We generated C6 glioma cells stably expressing the human $P2Y_{14}$-R ($P2Y_{14}$-C6 cells) as previously described by Fricks et al. (*23*). We cultured $P2Y_{14}$-C6 cells in Dulbecco's modified Eagle's medium (DMEM) supplemented with 5% fetal bovine serum, 1% Geneticin (Gibco), and 1% antibiotic−antimocotic (Gibco) at 37 °C in a 5% CO_2 environment.



Accumulation of Adenosine 3′,5′-Cyclic Phosphate (cAMP). We grew $P2Y_{14}$-C6 cells in 24-well plates and incubated them with 1 μCi [^{3}H]adenine/well in serum-free DMEM for at least 2 h prior to assay. We initiated the assays by adding HEPES-buffered, serum-free DMEM containing 200 μM 3-isobutyl-1-methyl-xanthine and 30 μM forskolin, with or without drugs, and incubation continued for 15 min at 37 °C. We terminated incubations by aspirating the medium and adding 450 μL ice-cold 5% trichloroacetic acid. We isolated [^{3}H]cAMP by sequential Dowex and alumina chromatography and quantified it by liquid scintillation counting as previously described by Harden et al. (*24*).

Data Analysis. We measured the concentrations of the dendrimer−ligand complexes by the concentration of the dendrimer, not the attached ligand. We determined EC_{50} and apparent K_i values with *Prism* software (GraphPad, San Diego, CA); they are presented as mean ± SE. The number of nucleoside moieties on a given dendrimer that are accessible to receptors is uncertain; the data are therefore shown as apparent K_i values. We repeated all experiments at least three times.



Biological Methods: ARs. *Receptor-Binding and Functional Assays.* We obtained [^{3}H]adenosine-5′-*N*-methyluronamide ([^{3}H]-NECA, 42.6 Ci/mmol) from PerkinElmer Life and Analytical Science (Boston, MA). We purchased [^{3}H](2-[*p*-(2-carboxyethyl)phenyl-ethylamino]-5′-*N*-ethylcarboxamido-adenosine) ([^{3}H]-CGS21680, 40.5 Ci/mmol) and [^{125}I]*N*^{6}-(4-amino-3-iodobenzyl)-adenosine-5′-*N*-methyluronamide ([^{125}I]I-AB-MECA, 2200 Ci/mmol) from PerkinElmer. We prepared test compounds as 5 mM stock solutions in DMSO and stored them frozen at −20 °C.

Cell Culture and Membrane Preparation. We cultured Chinese hamster ovary (CHO) cells stably expressing the recombinant hA_1 and hA_3 and human embryonic kidney (HEK) 293 cells stably expressing the $hA_{2A}AR$ in DMEM and F12 (1:1) supplemented with 10% fetal bovine serum, 100 units/mL penicillin, 100 μg/mL streptomycin, and 2 μmol/mL glutamine. In addition, we added 800 μg/mL Geneticin to the A_{2A} media and 500 μg/mL hygromycin to the A_1 and A_3 media. After harvesting the cells, we homogenized them with an electric homogenizer for 10 s, pipetted them into 1 mL vials, and then stored them at −80 °C until we conducted the binding experiments. We measured the protein concentration with a BCA Protein Assay Kit from Pierce Biotechnology (Rockford, IL) (*25*).

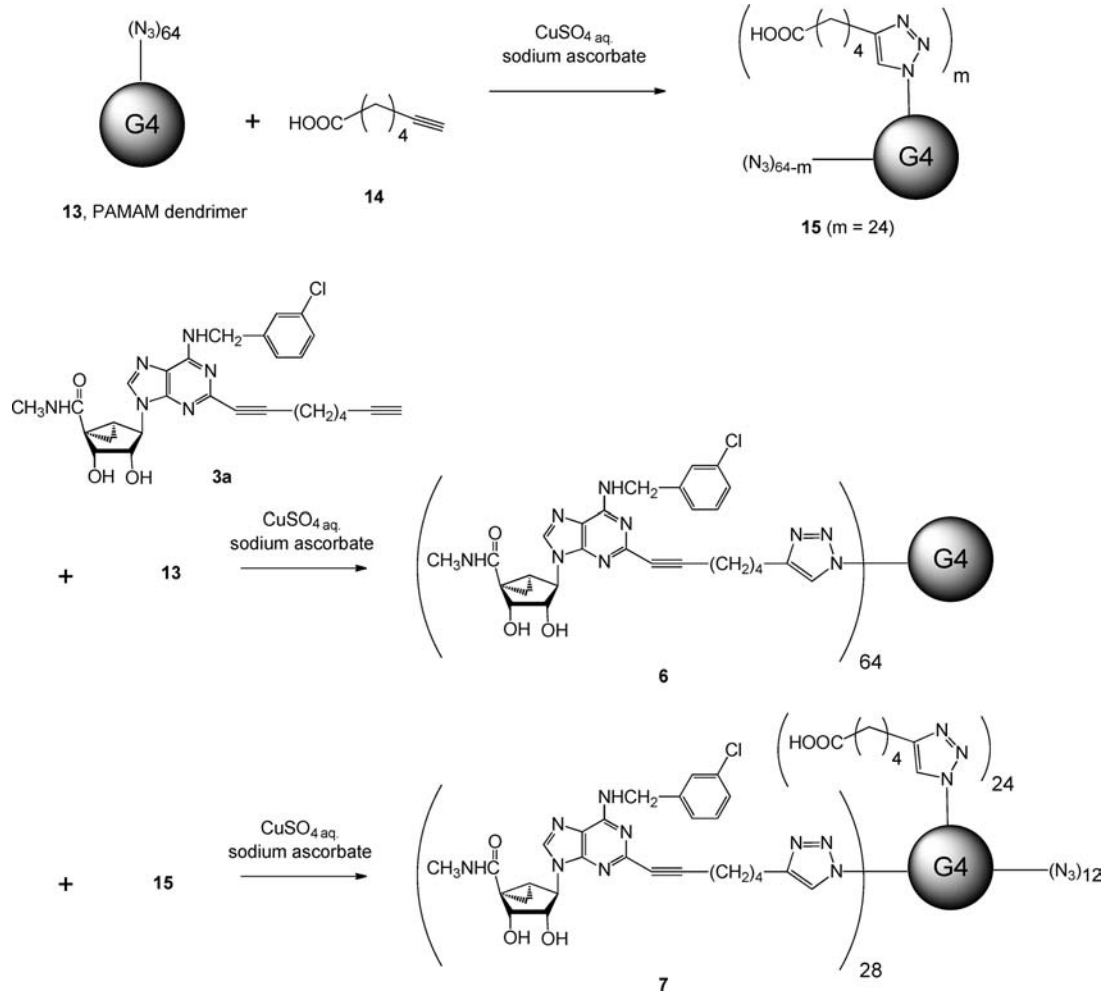
[a] NA: not active in inhibition of radioligand binding (<10%) at 1 μM. All experiments were done on CHO or HEK293 (A_{2A} only) cells stably expressing one of four subtypes of human ARs. The binding affinity for A_1, A_{2A}, and A_3ARs was expressed as K_i values ($n = 3-5$) and was determined by using agonist radioligands ([^{3}H]NECA, [^{3}H]CGS21680, or [^{125}I]I-AB-MECA, respectively), unless noted. A percentage in parentheses refers to inhibition of radioligand binding at the indicated concentration. The concentrations of the dendrimer-ligand complexes were measured by the concentration of the dendrimer, not the ligand. Therefore, all binding K_i values of dendrimers are expressed as apparent K_i values. [b] Affinity values from Tosh et al. (*15, 21*) and Melman et al. (*14*). [c] **2**, MRS3558; **3a**, MRS5221; **4a**, MRS5233; **6**, MRS5246; **7**, MRS5247; **8**, MRS5259; **11**, MRS5216. [d] Coumpound **5** is the dendrimer precursor of **8** and is similar to the dendrimer precursor of **6** and **7**.

Binding Assays. Each tube in the binding assay contained 50 μL of increasing concentrations of the test ligand in Tris-HCl buffer (50 mM, pH 7.5) containing 10 mM $MgCl_2$, 50 μL of the appropriate agonist radioligand, and 100 μL membrane suspension, added sequentially. For the A_1AR (20 μg protein/tube), we used the radioligand [^{3}H]NECA (~3.5 nM, precise final concentration is calculated for each experiment). For the A_{2A}AR (20 μg/tube), we used the radioligand [^{3}H]CGS21680 (~10 nM). For the A_3AR (21 μg/tube), we used the radioligand [^{125}I]I-AB-MECA (~0.3 nM). We determined nonspecific binding with a final concentration of 10 μM unlabeled NECA diluted with the buffer. We incubated the mixtures at 25 °C for 60 min in a shaking water bath. We terminated binding reactions by filtration through Brandel GF/B filters under a reduced pressure with a M-24 cell harvester (Brandel, Gaithersburg, MD). We washed filters three times with 3 mL of 50 mM ice-cold Tris−HCl buffer (pH 7.5). We then placed filters for A_1 and A_{2A}AR binding in scintillation vials containing 5 mL Hydrofluor scintillation buffer and counted with a PerkinElmer Liquid Scintillation Analyzer (Tri-Carb 2810TR). We counted filters for A_3AR binding with a Packard Cobra II γ-counter (PerkinElmer). We determined the K_i values with GraphPad *Prism* for all assays.

Accumulation of cAMP. To determine cAMP production (*26*), we incubated protein kinase A with [^{3}H]cAMP (2 nM) in K_2HPO_4/EDTA buffer (K_2HPO_4, 150 mM; EDTA, 10 mM), 20 μL cell lysate, and 30 μL 0.1 M HCl or 50 μL cAMP solution (0−16 pmol/200 μL for standard curve). We separated bound radioactivity by rapid filtration through Whatman GF/C filters and washed the filters once with cold buffer. We measured bound radioactivity with liquid scintillation spectrometry.

RESULTS



Chemical Synthesis. We prepared various PAMAM dendrimer derivatives of nucleosides and nucleotides (Table 1, **6**−**12**) to act as multivalent ligands of GPCRs. The peripheral groups of the precursor dendrimers contained either all azido groups (Scheme 1), mixtures of azido and amino groups (Scheme 2), or the conventional all amino/carboxylate groups (Scheme 3). The synthetic methods used to partially or fully substitute terminal amino groups of a G4 PAMAM dendrimer with azides are shown in Scheme 4 (*22*). Schemes 1−4 and Table 1 indicate the approximate, average number of attached moieties on each dendrimer, which is actually a statistical distribution of substitution.

We recently introduced terminal alkynyl groups at the C2 position of (N)-methanocarba nucleoside derivatives to serve as sites on the A_3AR agonists for cross-linking by click chemistry (*21*). Thus, a dialkyne was introduced at the C2 position in **2**, and further reaction with azides generally occurred exclusively at the distal alkyne. Prior to coupling the nucleosides to dendrimer carriers, we explored in detail the structure−activity relationship at the distal region of an alkyne-functionalized chain at the 2 position and the resultant click products (*21*).

The synthetic route to the multivalent dendrimer conjugates of nucleosides for activation of the A_3AR that contain 5′-*N*-methyluronamide (N)-methanocarba 2-alkynyl triazoles **6** and **7** is shown in Scheme 1. Click chemistry efficiently coupled the A_3AR agonist **3a** to a PAMAM dendrimer fully substituted with peripheral azido groups. We used two versions of this azido-functionalized dendrimeric scaffold: **15**, containing extra appended carboxylic acid groups for increasing water solubility, and **13**, lacking these groups. We added the carboxylic acid moieties to the azido dendrimer **13** by partial reaction of the peripheral azido groups with hexynoic acid **14**. Thus, we prepared two nucleoside-containing dendrimer derivatives **6** and **7**. Derivative **6** was fully substituted with the adenosine analogue, with 64 nucleoside moieties per dendrimer molecule. Derivative **7** was partially (28 out of 64) substituted with the adenosine analogue and contained 24 carboxylic acid moieties. Twelve azido groups per molecule of **7** remained unreacted.

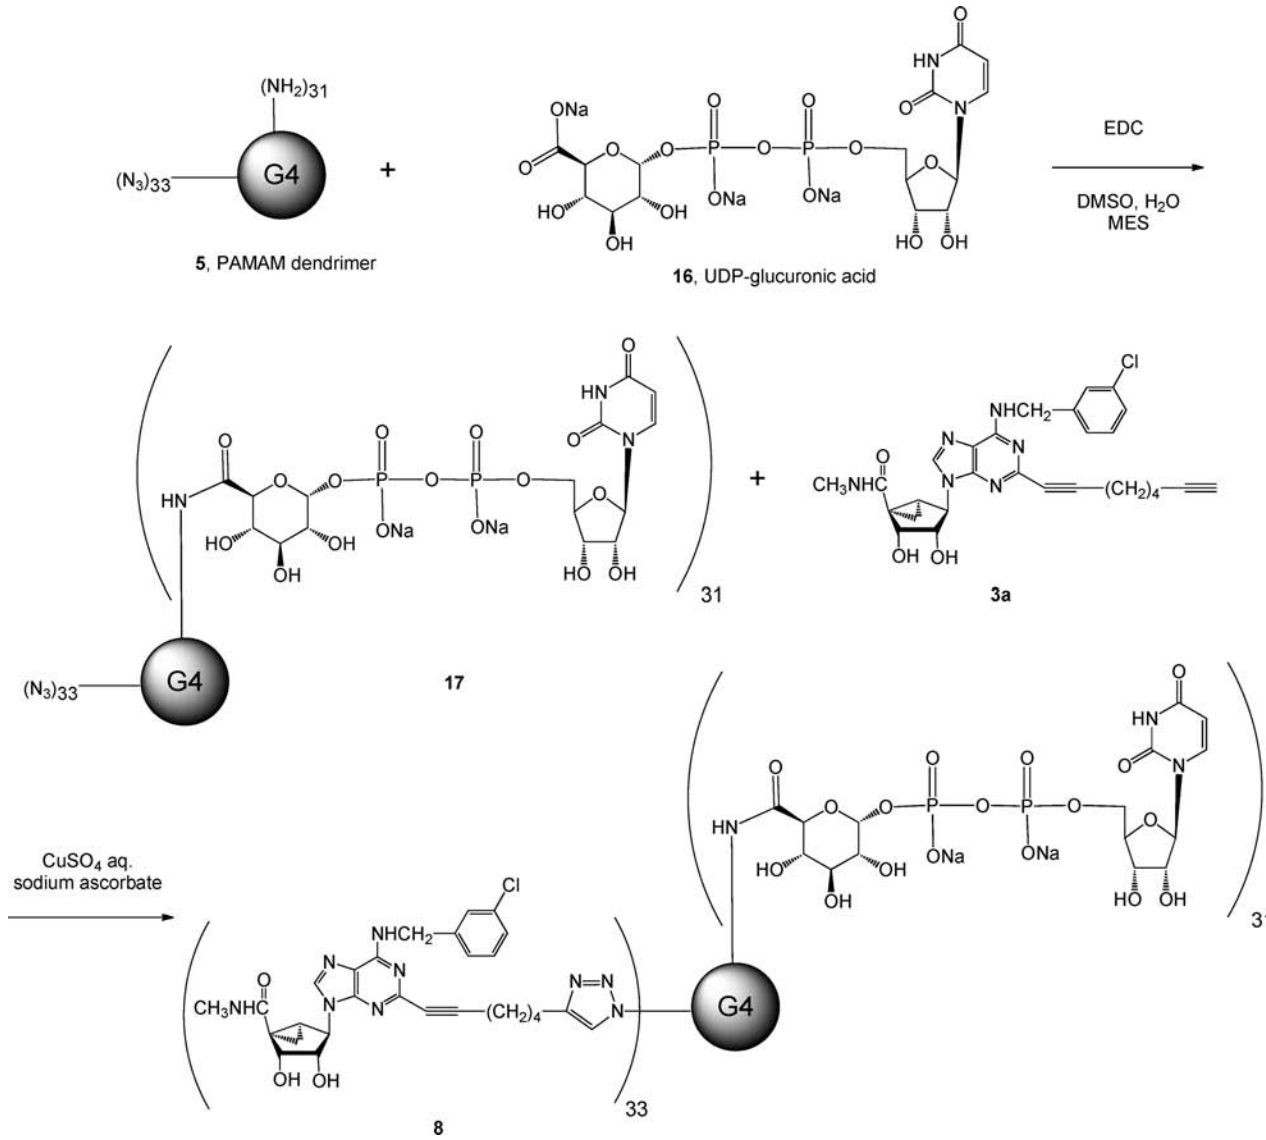
In the next phase of our study, we combined different GPCR ligands, i.e., the A_3AR and another receptor, on the same dendrimer carrier. We selected the $P2Y_{14}$ receptor, which is activated by naturally occurring uridine-5′-diphosphoglucose (UDPG), for this purpose, because, like the A_3AR, it occurs on

Scheme 1. Use of Click Chemisry to Synthesize PAMAM Dendrimer Derivatives 6 and 7, Containing a Functionalized 2-Alkynyl A_3AR Agonist[a]

[a] An optional water-solubilizing group was added in **7**, in the form of an aliphatic carboxylic acid.

immune cells and because we recently introduced high-potency dendrimer conjugates for this subtype (*5*, *27*). Each ligand would provide selectivity for a particular GPCR subtype, and the overall selectivity of the conjugate would be a function of the union of the sets of selectivity of the attached nucleosides. We sequentially coupled alkyne and carboxylic acid derivatized ligands for the two receptors to a novel multifunctional PAMAM dendrimer. Thus, alkynes reacted exclusively with azido terminal groups and carboxylic acids with terminal amino groups on the same dendrimer to randomly (but in a defined ratio) produce a multivalent, binary conjugate.

We proceeded to synthesize a multivalent, binary conjugate of a mixed azido/amino dendrimer **5**, as shown in Scheme 2. In the dendrimer precursor **5**, we determined, through NMR (*28*) (Figure 2) and elemental analysis, that the ratio of amines to azides was ~31:33. Therefore, of the 64 terminal groups on each G4 dendrimer, ~33 would be available for cycloaddition, and the remaining terminal groups would be available for amide formation. We first coupled the amino groups of **5** to the functionalized, $P2Y_{14}$-selective nucleotide UDPGA **16**, which we previously showed to be a suitable functionalized congener for chain attachment without loss of receptor activation (*5*). We then coupled the azido groups of **17** to the functionalized nucleoside **3a**, which is a suitable functionalized congener for chain attachment without loss of binding affinity at the A_3AR (*21*). The product of this second coupling reaction was the mixed dendrimer **8**, in which the average ratio of UDGPA and nucleoside moieties was ~31:33 per G4 dendrimer. Thus, conjugate **8** would be expected to potently activate both A_3 and $P2Y_{14}$ receptors and perhaps maintain selectivity over other ARs and P2Y receptors.



To compare alkyne-azide click chemistry with the more standard amide formation as a means of linking A_3AR-selective agonists to PAMAM dendrimers, we prepared various dendrimer derivatives starting with our previously reported amino and carboxylic-functionalized congeners **19**, **20**, **22**, and **24** (*14*, *15*). The reaction sequences are shown in Scheme 3. We included a variety of dendrimer sizes and sites of conjugation on the nucleoside.

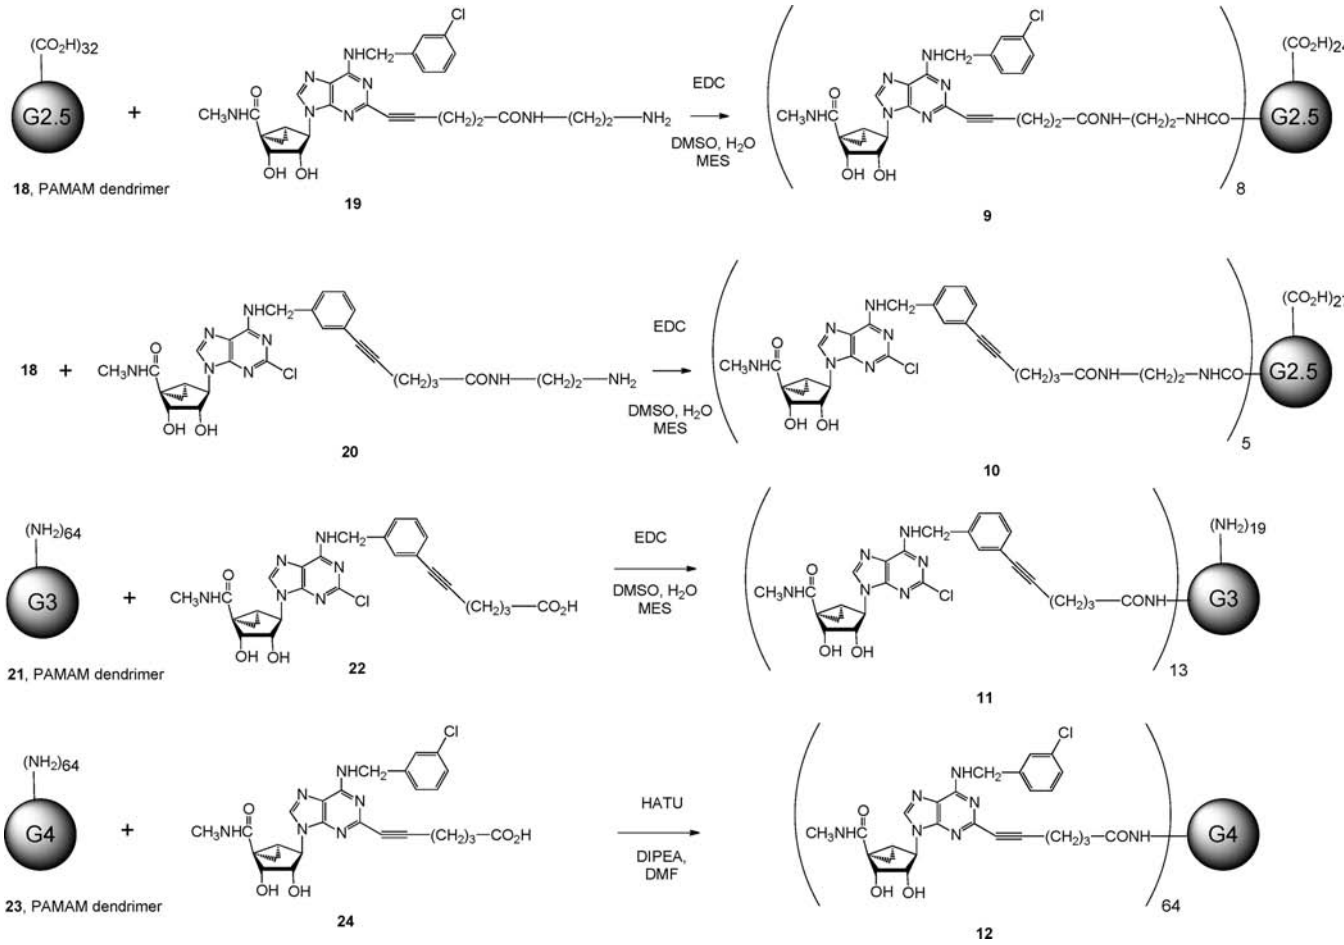
The synthesis of the PAMAM dendrimer intermediate **5** containing equiproportioned peripheral azido and amino groups for conjugation of multiple ligands is shown in Scheme 4. We used the reagent imidazole-1-sulfonyl azide hydrochloride **26** for the conversion of peripheral amino groups to azido groups (*22*). We prepared a fully azido-derivatized G4 dendrimer **13** similarly and used it to synthesize conjugates **6** and **7**.

Quantification of Pharmacological Activity. We tested the dendrimer nucleoside conjugates similarly in binding assays at three hAR subtypes; we used standard radioligands (*29*−*31*) and membrane preparations from CHO cells (A_1 and A_3) or HEK293 cells (A_{2A}) stably expressing a hAR subtype (Table 1) (*32*, *33*). We used the previously reported agonist molecular probes of the A_3AR (**1**, **2**, **3a**, and **4**) for comparison in the biological assays (*15*, *21*).

We included the parent dendrimer **5**, which contained both amino and azido groups, as a control; it was inactive in AR

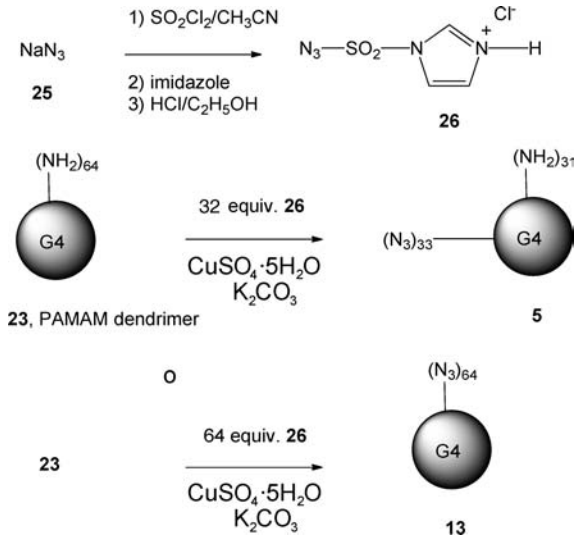
Scheme 2. Synthesis of Two PAMAM Dendrimer Derivatives Containing a Functionalized Agonist of the $P2Y_{14}$ Receptor Derived by Amide Linkage of UDPGA 16[a]

[a] Conjugate **17** contains only the $P2Y_{14}$ receptor agonist; conjugate **8** contains an A_3AR agonist linked through a click reaction of its 2-alkynyl functionalized chain. The dendrimer precursor **5** contained a random distribution of peripheral amino and azido groups in a ratio of ~33:31.



binding at 1 μM. We considered compound **4a** to be a model compound for the attachment of the 2-octadiyne derivative **3a** to azido-bearing PAMAM dendrimers by click chemistry. As reported previously, the triazole-containing monomer **4a** maintained both high potency and selectivity (at least 100-fold) for the A_3AR (*21*).

The multivalent dendrimer derivatives **6** and **7** obtained from **3a** through click conjugation were considerably more potent than **4a** in binding assays at the A_1, A_{2A}, and A_3 ARs. The affinity of **6** and **7** in binding to the A_3AR was particularly high, with K_i values of 0.1−0.3 nM (Figure 3). The fully substituted dendrimer **6** was only 2.3-fold more potent at the A_3AR than the less heavily loaded **7**, which was substituted with nucleosides at 44% of the theoretically available terminal positions. The selectivity of these dendrimer conjugates for the A_3AR in comparison to the A_1AR was still present (161- and 110-fold for **6** and **7**, respectively) but diminished in comparison to the monomer **4a** (>500-fold). However, the A_3AR selectivity of **6** (230-fold) and **7** (180-fold) in comparison to the $A_{2A}AR$ was similar to that of **4a**. Thus, the presence of the carboxylic acid chain in **7** had only minor effects on the observed AR affinity and selectivity, but it increased the observed aqueous solubility. Both **6** and **7** were readily soluble in DMSO at a concentration of 1 mM, but when we diluted the DMSO stock solutions with phosphate-buffered saline for a final calculated concentration of 30 μM, we observed some cloudiness in **6** but not in **7**.



Dendrimer derivative **8** contained an additional covalently bound GPCR ligand, a nucleotide designed to activate the $P2Y_{14}$ receptor. We found that combining strategically functionalized nucleosides and nucleotides on the same dendrimer carrier—for example, to activate both adenosine and P2Y receptors—provided high-affinity recognition at both GPCRs. However, the K_i value of **8** in binding to the A_3AR (39.5 nM) indicated that it was considerably less potent than conjugates **6** and **7**, which contained only the A_3AR agonist ligand. The A_3AR selectivity of **8** was only 2-fold in comparison to the A_1AR and 15-fold in comparison to the $A_{2A}AR$. Thus, it was much less A_3AR selective than were **6** and **7**.

A functional assay of adenylate cyclase inhibition carried out in C6 cells expressing the human $P2Y_{14}$ receptor demonstrated that potency at this receptor was enhanced in the dendrimer conjugate **8** over that of the monomer, with an EC_{50} value of 2.24 ± 0.80 nM (Figure 4). Both UDPG and UDPGA displayed potencies in the same assay of 200−300 nM (*5*). This degree

Scheme 3. Preparation of Amide-Linked Nucleoside Conjugates of PAMAM Dendrimers

Scheme 4. Synthesis of Azido-Derivatized PAMAM Dendrimers, Which Served As Precursors for the GPCR Ligand Conjugates by Reacting with Imidazole-1-Sulfonyl Azide Hydrochloride 26

of potency enhancement at the $P2Y_{14}$ receptor was consistent with previous results of conjugation of UDPGA derivatives to PAMAM carriers (*5*). Dendrimer **17**, which contained only the ligand of the $P2Y_{14}$ receptor (i.e., 31 nucleotides bound per G4 dendrimer) and not the A_3AR-activating moiety, displayed an EC_{50} value at the $P2Y_{14}$ receptor of 2.41 ± 0.77 nM. Curiously, nucleotide-containing dendrimers **8** and **17** also interacted with at least one other subtype of P2Y receptor, but nevertheless with selectivity for the $P2Y_{14}$ receptor. Dendrimers **8** and **17** displayed EC_{50} values in activation of phospholipase C (PLC) by the human $P2Y_2$ receptor of 1.39 ± 0.54 μM and 733 ± 223 nM ($n = 3$), respectively, assayed as described in stably transfected 1321N1 astrocytoma cells (*34*). The native agonist of the $P2Y_{14}$ receptor, UDPG, also activated the human $P2Y_2$ receptor, with an EC_{50} value of 10 μM (*34*).

PAMAM dendrimer conjugates (**9**−**12**) of carboxylic- and amino-functionalized congeners of A_3AR-selective agonists consistently displayed lower affinity in A_3AR binding than did the click-linked dendrimers **6** and **7**. The amide-linked conjugates included derivatives of both terminal carboxylic acid-functionalized dendrimers **9** and **10** and terminal amine-functionalized dendrimers **11** and **12**, ranging from generation 2.5 to 4. The affinities of these dendrimers at the hA_3AR were in the range 12−42 nM, and the nature of the residual terminal groups of the dendrimer carrier had little effect. We did not observe the subnanomolar affinity seen in click-linked nucleoside−dendrimer conjugates. Thus, the high affinity is partially the result of the linkers and the coupling chemistry used, which in **6** and **7** produce a triazole rather than an amide linkage.

The selectivity of the amide-linked dendrimers in comparison to the $A_{2A}AR$ was high (*x*-fold, for compound): >300, **9**; ≫24, **10**; 327, **11**; 62, **12**. However, there was a substantial gain in affinity at the A_1AR over the corresponding monomeric nucleosides. Thus, **10** and **11** lost selectivity for the A_3AR in comparison to the A_1AR. Compound **12** was reversed in its selectivity (6-fold more potent at the A_1AR than at the A_3AR). Conversely, we considered compound **4b** to be a model nucleoside derivative for the amide-linked dendrimer derivatives

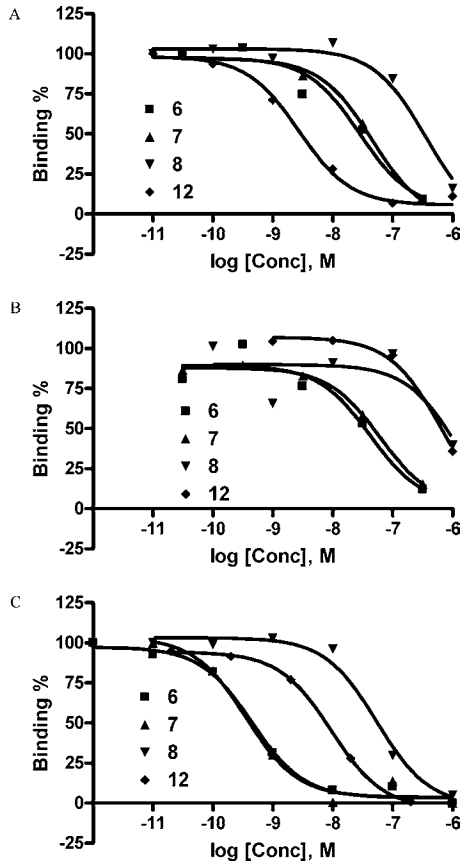


Figure 3. Inhibition of radioligand binding by dendrimer nucleoside conjugates in membranes of CHO cells expressing the human A_1 (A) and A_3 (C) ARs and HEK-293 cells expressing the human A_{2A}AR (B). Inhibition curves at three ARs are shown for the dendrimer−nucleoside conjugates **6** and **7**, in which the linkage to an azide-derivatized dendrimer was formed by click cycloaddition, for the mixed nucleoside/nucleotide conjugate **8** and for the amide-linked nucleoside conjugate **12**. Both **6** and **7** were highly selective for the hA_3AR in comparison to the hA_1 and hA_{2A}ARs.

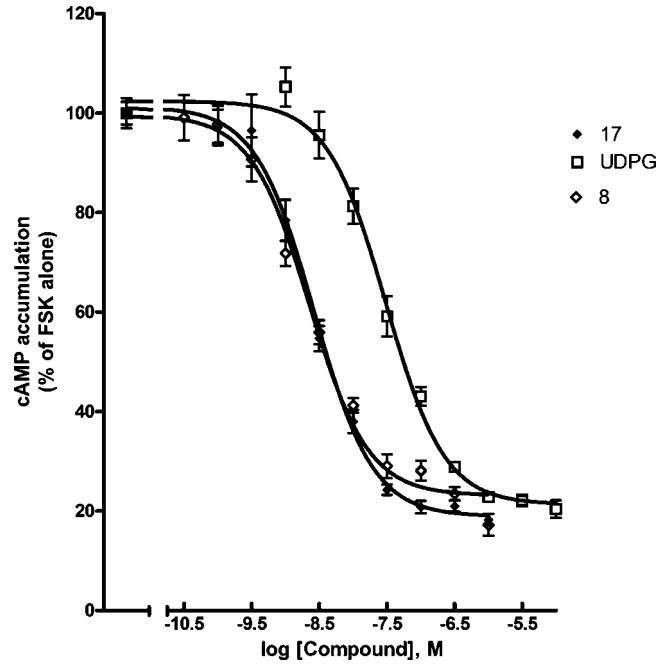

Figure 4. Activation of the G_i-coupled $P2Y_{14}$ receptor stably expressed in C6 cells by the mixed nucleoside/nucleotide G4 dendrimer conjugate **8** (MRS5259) and the nucleotide G4 dendrimer conjugate **17** (MRS2949). Inhibition of forskolin (FSK)-stimulated cAMP is shown in comparison to the effects of UDPG ($n = 3$).

Table 2. Maximal Efficacy of (N)-Methanocarba Adenosine Derivatives in a Functional Assay at the A_3AR

compound	concentration (μM)	% inhibition of cAMP accumulation[a] at the hA_3AR
IB-MECA	1.0	99 ± 6
Cl-IB-MECA	1.0	97
NECA	1.0	100
3a	10	60.2 ± 17.0
4a[b]	10	93.6 ± 17.7
5	1.0	1.7 ± 1.4
6	0.1	98.7 ± 14.3
7	0.1	91.4 ± 20.2
8	0.1	111 ± 20
9[c]	1.0	88.2 ± 15.1
10	1.0	91.3 ± 12.3
11	1.0	101 ± 10
12	0.1	92.1 ± 21.2

[a] The efficacy at the human A_3AR was determined by inhibition of forskolin-stimulated cyclic AMP production in AR-transfected CHO cells, as described in the text. Percent inhibition is shown at the indicated concentration, in comparison to the maximal effect of a full agonist NECA at 1 μM. Data are expressed as mean ± standard error ($n = 3-5$). ND, not determined. [b] Values from Tosh et al. (*21*). [c] EC_{50} values were determined with full curves for compounds **7** (0.12 ± 0.03 nM), **8** (1.36 nM), and **11** (2.93 ± 0.37 nM).

9 and **12**, and it was clearly A_3AR selective. Compound **4c** (63-fold selective for the A_3AR versus the A_1AR) was a model for N^6-functionalized dendrimer conjugates **10** and **11**, although it was a higher homologue with 4 methylenes. Thus, both model compounds **4b** and **4c** were more potent and selective in binding to the A_3AR than were the corresponding amide-linked dendrimers.

We determined binding at the rat A_3AR expressed in CHO cells for selected compounds. The K_i values of the N^6-chain derivatized, amide-linked dendrimers **10** and **11** were 62.0 ± 36.5 and 4.94 ± 1.96 nM ($n = 3$), respectively. The triazole-linked adenosine conjugate **7** with water-solubilizing groups displayed a K_i value of 0.08 ± 0.02 nM in binding to the rat A_3AR. Thus, there was a relatively low degree of species-dependent variation in the observed A_3AR affinity (4-fold greater in rat than human).

We tested the nucleoside conjugates in a functional assay at the A_3AR (inhibition of forskolin-stimulated cAMP production in A_3AR-expressing CHO cells) as shown in Table 2. These multivalent derivatives displayed A_3AR agonist properties with varying degrees of maximal inhibition of forskolin-stimulated cAMP production at 0.1−10 μM (concentration selected to be in >100-fold excess of the K_i value for each). In general, the relative efficacy was similar to that of NECA (1 μM), taken as a reference standard. The dendrimer control was inactive. The EC_{50} value of the amide-linked adenosine conjugate **11** was 2.93 ± 0.37 nM, determined with a full curve in CHO cells stably expressing the human A_3AR (Figure 5). Conjugate **11** was a full agonist in the A_3AR-mediated inhibition of cAMP production. We also determined EC_{50} values for cAMP inhibition with full curves for the triazole-linked adenosine conjugate with water-solubilizing groups **7** (0.12 nM) and **8** (1.36 nM).

DISCUSSION

We used the Cu(I)-catalyzed alkyne-azide click reaction for linking functionalized congeners of AR ligands (*21*, *35*) to other moieties, specifically PAMAM dendrimer derivatives. In this study, we compared different chemical strategies for tethering GPCR ligands to macromolecular carriers. Dendrimer derivatives prepared by click chemistry were particu-

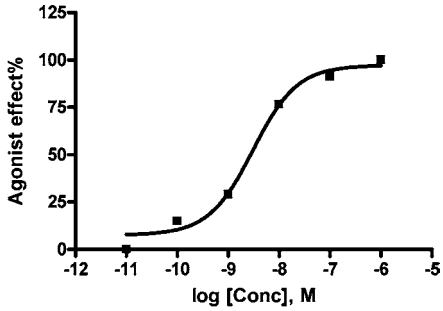

Figure 5. Activation of the G_i-coupled A_3AR stably expressed in CHO cells by **11**. The agonist effect measured is inhibition of forskolin-stimulated cAMP production, in comparison to the maximal effect of a full agonist NECA at 1 μM. Curve is representative of three determinations.

larly potent and selective in binding to the A_3AR. Multivalent nucleoside−dendrimer conjugates **6** and **7** showed much greater A_3AR affinity than the corresponding monomer, the model nucleoside **4a**. Furthermore, amide-linked nucleoside conjugates were considerably weaker than click-linked conjugates in binding to the A_3AR. This illustrates the dramatic effect that both the multivalency and the intermediate structures contained within the functionalized chain can have on interaction with the target receptor (*35*). A comparison with various amide-linked dendrimers showed that the triazole linkage had a general A_3AR affinity−enhancing effect. Click chemistry was previously used to link small molecules to dendrimeric structures, but ours is the first application for studying PAMAM dendrimer derivatives of small-molecular GPCR ligands. Recently, peptide ligands were conjugated to dendrimers by click chemistry for activation of a GPCR (*18*).

Other studies have focused on PAMAM dendrimers as reversible drug carriers, for example, to deliver anticancer drugs that dissociated at the site of action (*36*). Our approach derivatizes a small molecule but allows it to remain active while covalently attached to the carrier (*35*). The binding sites of the receptors are accessible from the extracellular medium. Thus, activation of the desired receptor would not benefit from either drug release or cellular internalization of the dendrimer. The flexible dendrimer conjugate is available to spread over the cell surface and to adopt a conformation that can bridge multiple binding sites (*37*).

The efficiency of the click reaction readily allowed complete substitution in the case of one of the dendrimer derivatives, i.e., **6**. In previous experiences with amide coupling of functionalized nucleosides, we encountered difficulty in the complete substitution of amine-terminated dendrimers (*3, 4*). Click chemistry proved to be a more efficient coupling technique and allowed orthogonal reaction control over the coupling chemistry when two distinct receptor ligands were bound to the same dendrimer carrier (as in **8**). This conjugate was most readily synthesized by amide coupling of the carboxy-functionalized nucleotide followed by click coupling of the alkyne-functionalized adenosine derivative.

This study presents the first example of targeting two different GPCRs with the same dendrimer conjugate, intended for activation of heteromeric aggregates of GPCRs. Each ligand provided selectivity for a particular GPCR subtype, and the overall selectivity of the conjugate was a function of the union of the sets of selectivity of the attached nucleosides. Specifically, the dendrimer conjugate **8** contained ligands for both the A_3AR and the $P2Y_{14}$ receptor. The principle of attachment of UDPG derivatives to PAMAM dendrimers to enhance potency was introduced previously (*5*). This bifunctional dendrimer potently activated both A_3 and $P2Y_{14}$ receptors, although not to the exclusion of other ARs.

The bifunctional dendrimer **8** and its nucleotide−dendrimer precursor **17** both activated one other P2Y receptor examined, the $hP2Y_2$ receptor, with intermediate potency. UDPG itself activates the $hP2Y_2$ receptor with an EC_{50} of 10 μM for stimulation of PLC in stably transfected 1321N1 cells (*34*). Therefore, the potency at both subtypes of P2Y receptors was much greater in the dendrimer conjugates than in the monomer, but the desired selectivity for the $P2Y_{14}$ receptor was maintained. Thus, both covalently tethered GPCR ligands, which were previously shown to be suitable functionalized congeners for coupling to carriers, retained their activity as the mixed dendrimer conjugate **8**. This conjugate had reduced A_3AR affinity in the presence of tethered nucleotide moieties but not reduced $P2Y_{14}$ potency due to the tethered nucleoside moieties. This is the first example of targeting two different GPCRs with the same dendrimer conjugate, which is intended for activation of heteromeric aggregates of GPCRs.

Many examples exist of two small molecules linked with a spacer group to make binary conjugates for activation of two different GPCRs (*35, 38, 39*). Some researchers have systematically varied the length of the spacer to achieve the correct fit to the two adjacent binding sites. This multivalent approach was taken in part because of uncertainty about the geometric orientation of protomer binding sites in a GPCR dimer. Flexible dendritic carriers facilitate empirical testing of a variety of spatial orientations of the same conjugate. This obviates the need to probe the optimal geometry a priori of a single spacer chain to achieve simultaneous binding to two sites.

Both A_3 and $P2Y_{14}$ receptors are distributed in the immune system and appear to occur on the same cell, as was shown for RBL-2H3 mast cells (*27*). Further experiments will be needed to determine whether heteromers composed of A_3 and $P2Y_{14}$ receptors exist and whether this conjugate is capable of bridging the binding sites on both protomers. This approach of mixing receptor ligands on the same dendrimer carrier can be extended to many other combinations of GPCRs.

We know that GPCRs tend not to be evenly or randomly distributed over the surface of a given cell; we demonstrated this for the A_3AR expressed heterologously in CHO cells (*4*). In general, GPCRs may exist as complexes with other receptors and associated proteins. The receptors to which a given GPCR pairs or forms a higher-order aggregate can dramatically affect its pharmacology, and the binding of agonist to both protomers does not have equivalent pharmacological effects (*40*). We lack effective ligand tools for separating the effects of one receptor dimeric combination from another. This approach of mixing ligands for two different receptors (*35, 38, 39, 41*) promises to be a means of achieving selectivity for receptors in a given tissue, based on association or aggregation of GPCRs, in comparison to another tissue in which the same receptor may be alternatively paired. At this early stage, we do not know the topological requirements for selectively targeting these combinations of receptors, because we are just beginning to detect their existence. The multivalent binding to other types of cell surface receptors has been explored through structural modification of the carrier polymer (*42*).

Multivalent conjugates of GPCR ligands provide quantitatively and qualitatively different pharmacological properties than do monomers. Prosthetic groups for targeting or therapeutic purposes or reporter groups for diagnostic purposes might be introduced. Specific combinations of receptor ligands on the same dendrimer carrier might achieve synergistic effects and prove useful for disease treatment, such as inflammatory conditions, to which the current example of adenosine and P2Y receptor ligands apply. Various combinations may be proposed

for targeted therapeutic applications, but the linking strategy to achieve the desired potency and selectivity still requires development. We are working on prototypical examples that could be applied to other combinations of dendrimer-bound GPCR ligands.

Design and Application of Antibody Cysteine Variants

Vladimir Voynov,[†] Naresh Chennamsetty,[†] Veysel Kayser,[†] Hans-Joachim Wallny,[‡] Bernhard Helk,[‡] and Bernhardt L. Trout*,[†]

Massachusetts Institute of Technology, Chemical Engineering, Cambridge, Massachusetts, and Novartis Pharma AG, CH-4057, Basel, Switzerland. Received November 19, 2009; Revised Manuscript Received December 30, 2009

Antibodies are multidomain proteins that are extensively used as a research tool in molecular biology and as therapeutics in medicine. In many cases, antibodies are engineered to contain surface cysteines for the site-specific conjugation of payloads. These antibodies can serve as payload vehicles in targeting a diseased cell to which the conjugated molecules exercise their activity. Here, we design and analyze a set of fourteen new IgG1 cysteine variants, with at least one variant per immunoglobulin fold domain. The cross-linking propensity of these mutants correlates very well with a tool we have developed for measuring aggregation propensity in silico, called spatial aggregation propensity (SAP). Our results indicate the utility of the SAP technology in selecting antibody cysteine variants with desired properties. Moreover, the different oligomerization propensity of the variants suggests a variety of applications in molecular biology and medicine, such as payload delivery, structural analysis, electrophoresis, and chromatography.

INTRODUCTION

Monoclonal antibodies are of significant laboratory and therapeutic use. Antibody derivatives with engineered site-specific fluorescence or binding properties have been developed and used for many years. Antibodies have also been developed as therapeutic agents, currently the fastest growing class of pharmaceuticals (*1*). Antibodies are multidomain proteins of two light and two heavy chains held together by disulfide bonds. The variable regions specify binding to a particular antigen, and part of the constant region is responsible for effector functions via binding to Fc receptors on the surface of immune cells.

Engineering of antibody conjugates has further increased the versatility of antibody applications. In many laboratory techniques, enzymes or fluorescent probes are conjugated to antibodies to carry out an assay function, for example, quantification of antigen abundance. In targeted therapy, conjugation is used to generate new therapeutics with highly specific functions (*2*). For example, toxic small molecules are attached to antibodies that specifically bind biomarkers on diseased cells, and the targeted cells are destroyed by the toxic molecules (*3–6*). Various approaches to antibody conjugation have been pursued, for example, attachment to surface lysines (*7*), to Fc carbohydrates (*8*), or to partially reduced interchain disulfides (*9*).

Antibody conjugation to engineered surface cysteines remains a very attractive option because most antibodies do not have cysteines other than the ones involved in intra- and interchain disulfide bonds. Small molecules can be attached at the specific site of cysteine substitution via thiol-reactive chemistry with molecules such as maleimides (*10–16*). Engineering the C_H1 and C_H3 domains has been favored to avoid interference with antigen binding of the variable regions and effector function of C_H2. Different criteria for successful antibody conjugation via engineered cysteines have been considered. For example, the antibody domain in which to carry out mutations, the exposure of the mutated site, and the amino acid to be substituted are several of the aspects to take into account. A high-throughput screening approach to identifying sites suitable for cysteine engineering and conjugation has been developed (*17*). Yet, there is no universal tool for predicting whether an antibody cysteine variant will be stable and efficiently conjugated, and cysteine variants currently exist only for the C_L, C_H1, and C_H3 domains (*10, 11, 13, 14, 17*).

In this report, we present a new approach to design cysteine variants and the application of that approach to develop a new set of 14 human IgG1 cysteine variants, chosen so that there is at least 1 variant per immunoglobulin fold domain. Most of the variants are stable and efficiently conjugated. In several cases, we observe antibody oligomerization due to intermolecular disulfide bonding and cross-linking of the engineered cysteines. The extent of oligomerization is qualitatively and quantitatively expressed as cross-linking propensity (CLP). We also compare CLP of the variants to a recently developed spatial-aggregation propensity (SAP) parameter (*18–20*). SAP is a measure of the dynamic exposure of hydrophobic patches (see Experimental Procedures). SAP identifies protein aggregation prone regions, which were validated earlier by designing antibodies that were experimentally shown to be significantly more stable than the wild type (*19*). The analysis presented here demonstrates the utility of the SAP technology in designing antibody cysteine variants as well as the various applications of some of the new variants.

EXPERIMENTAL PROCEDURES

Design of Cysteine Variants. Variants 1−13 were designed based on the X-ray structure of antibody-1. Variant 15 was selected from the structure of another IgG1, antibody-2, built by homology modeling based on the structure of antibody-1 (*19*). Variant 14 has the same engineered cysteine as variant 15 but in a modified antibody-2 with mutations W100K and F101K in the heavy chain (*19*). All engineered cysteine sites were exposed on the antibody surface. Polar residues, such as serine, threonine, and asparagine, or charged residues, such as lysine, were substituted with cysteine.

Production of Cysteine Variants. DNA vectors encoding the light and heavy chains of proprietary human IgG1 antibodies

1 and 2 were kindly provided by Dr. Burkhard Wilms from Novartis. The two antibodies have κ-variable light chains and H3 variable heavy chains and are indicated for the treatment of inflammatory and respiratory diseases. The light and heavy chain genes of each antibody were subcloned in vector gWIZ (Genlantis), engineered for protein expression by transient transfection of mammalian cells. Antibody variants were either de novo synthesized (GeneArt) or generated by in-house site-directed mutagenic PCR and confirmed by sequencing. Antibody wild types and variants were expressed by transient transfection of Freestyle HEK 293 cells (Invitrogen) and purified as previously described (*19*) and further specified here. Cell cultures were transfected with filter-sterilized DNA, purified on DNA Maxi Prep columns (Invitrogen) and with linear polyethyleneimine MW 25 000 (PEI) (Polysciences) as the transfection reagent. For each liter of culture, 1 mg of total DNA was incubated with 20 mL of OptiPro (Invitrogen), while 2 mL of 1 mg/mL solution of PEI was incubated with 20 mL of OptiPro. After 15 min incubation at room temperature, the PEI solution was added to the DNA solution, and after another 15 min incubation, the PEI-DNA-OptiPro mix was added to the cell culture. The transfected cell cultures were incubated at 37 °C and 5% carbon dioxide atmosphere. Supernatants were collected 7−10 days post-transfection by centrifugation and filtering through 0.2 μm filters. If transfections were at higher than 1 L volume, the filtered supernatants was concentrated by diafiltration with a 30 kDa molecular weight cutoff membrane before purification. Antibodies were purified on a protein A column (GE Healthcare), eluted with 50 mM citrate buffer, pH 3.5, buffer-exchanged in 50 mM Tris pH 7.0 buffer, and concentrated to 15−50 mg/mL with 30 kDa molecular weight cutoff filters. Typically, antibody-1 wild type was expressed with yield of 25 mg/L and antibody-2 wild type at 24 mg/L. In most cases, the cysteine variants were expressed at comparable levels, with a few exceptions where the mutation affects expression levels.

Thiol Reduction and Labeling. Different methods were attempted for the specific reduction of the engineered surface thiols before labeling. Tris, 2-carboxyethyl, phosphine hydrochloride (TCEP), and a stronger reducing agent, dithiothreitol (DTT), were two of the reagents used, and levels of free thiol were quantified using Ellman's reagent (Invitrogen). We found L-cysteine to work best in our site-specific labeling experiments, so the following two-step protocol was used. First, the variants were incubated with 100−200-fold excess of L-cysteine for 4 h at 37 °C, followed by buffer exchange into TE buffer, pH 7.2. Second, the samples were incubated with 5−10-fold molar excess of Alexa488 maleimide dye (Invitrogen) for 1 h at room temperature or with 10-fold excess of pyrene maleimide dye (Invitrogen) for 12 h at room temperature.

In certain cases, labeling conditions such as time of reaction and dye to protein ratio had to be optimized on an individual basis because not all engineered cysteines were equally amenable to conjugation. Free dye was removed by centrifuging the samples through Sephadex G25 (GE Healthcare) 2−3 times. Then, the labeled protein samples were buffer-exchanged in 50 mM phosphate buffer pH 7.0 and concentrated to 20−50 mg/mL on 30 kDa molecular weight cutoff spin filters. The efficiency of protein labeling was calculated as mole of dye per mole of protein according to manufacturer's protocols (Invitrogen). For carbohydrate labeling, the antibody variant sample was first treated with 10 mM sodium meta-periodate in 100 mM sodium acetate, pH 5.5, (Pierce) to oxidize the carbohydrates. Then, the antibody conjugation was carried out with Alexa350-hydrazide (Invitrogen) at 5−10-fold molar excess of dye at room temperature for 2 h. During labeling, exposure of the fluorophores to light was avoided as much as possible.

Protein Characterization. Antibody samples were analyzed by SDS-PAGE. Gels of 7.5%, 10%, and 12% were used for nonreducing analysis. Gels of 12% were used for reducing analysis of heated samples with DTT. We used a molecular weight marker "Precision Plus Protein Standards" from BioRad, containing proteins of 250, 150, 100, 75, 50, 37, 25, 20, 15, and 10 kDa. Usually, samples of 5−10 μg were loaded per lane. Fluorescent images were taken under UV light before staining with Coomassie Blue. Antibody digestion was carried out by GluC (1:20 wt enzyme per wt antibody, at 25 °C for 12−24 h) and Pronase (1:20 wt enzyme per wt antibody, at 37 °C for 1 h).

We also used size-exclusion high-performance liquid chromatography (SEC-HPLC) to determine monomer levels of labeled antibody variants. Samples were resolved on a TSKgel Super SW3000 column (TOSOH Bioscience), and percent monomer was calculated as the area of the monomeric peak divided by the total area of all peaks.

Reporter Gene Assay. The biological activity of antibody-1 wild type and variants 1−6 was measured in a reporter gene assay, using a genetically modified cell line. This cell line was derived from human embryonic kidney cell and was stably transfected with a reporter construct of a promoter (responsive to signaling via the soluble target that antibody-1 binds) fused upstream of the luciferase gene. In this cell line, exposure to the target stimulated the expression of luciferase in a dose-dependent manner. Addition of graded amounts of antibody-1 to a fixed, submaximal dose of target caused a decrease in the expression of luciferase during an incubation period of 5.5 up to 18 h. At the end of the incubation period, the amount of luciferase was quantified based on its enzymatic activity in the cell lysate. Luciferase catalyzed the conversion of the substrate luciferin to oxyluciferin, a chemiluminescent product. The resultant glow-type chemiluminescence was then determined with an appropriate luminometer. The biological potency of a test sample was determined by comparing its ability to inhibit the target-dependent induction of luciferase activity to that of antibody-1 wild type. The samples were normalized on the basis of protein content. Relative biological activity of the antibody-1 variants was then calculated using a parallel line assay according to European Pharmacopoeia.

SAP Values. Spatial aggregation propensity (SAP) of amino acids in a protein is a tool that was recently developed in our lab based on amino acid surface-accessible area (SAA) and hydrophobicity (*19*), and we already applied to the identification of aggregation prone motifs in IgG antibodies (*18*). The SAP values for radius $R = 5$ Å are calculated from the equation

$$(\mathrm{SAP})_{\mathrm{atom}i} = \sum_{\substack{\text{Simulation}\\ \text{Average}}} \left\{ \sum_{\substack{\text{Residues with at least}\\ \text{one side chain atom}\\ \text{within } R \text{ from atom } i}} \left(\frac{\substack{\text{SAA of side chain atoms}\\ \text{within radius } R}}{\substack{\text{SAA of side chain atoms}\\ \text{of fully exposed residue}}} \times \text{residue hydrophobicity} \right) \right\}$$

RESULTS

Design of a Set of 14 Antibody Variants for Site-Specific Conjugation. We designed a set of 14 IgG1 cysteine variants for site-specific conjugation. Mutations 1−13 were generated in antibody-1. Mutation 14 was generated in wild-type antibody-2 (resulting in variant 15), as well as a modified antibody-2 (resulting in variant 14), leading to a total of 15 variants

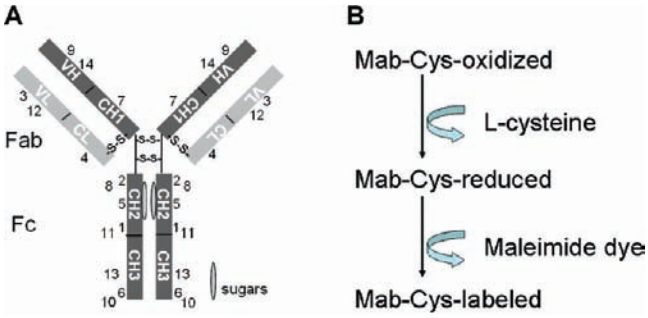

Figure 1. A set of human IgG1 cysteine variants. (A) Relative location of the amino acids substituted with cysteines in the antibody. (B) Outline of a two-step conjugation protocol of antibody cysteine variants.

presented in this report. The idea was to have a distribution of the variants along the antibody surface, with at least one variant per immunoglobulin fold domain (Figure 1A). We substituted polar (ser, thr, asn) or charged (lys) amino acids that are exposed on the antibody surface, so that substitution with the polar amino acid cysteine does not cause a significant change in surface charge distribution and structure of the protein. Different methods for conjugating the engineered surface cysteines were applied, and the one using free cysteine in the first, reducing step worked best for us (Figure 1B).

Certain Cysteine Variants Are More Amenable to Conjugation than Others. Following expression and purification of antibody variants, the engineered surface cysteines are mostly oxidized. For example, both variants 4 and 6 have less than 0.3 free thiol per antibody molecule as opposed to the anticipated 2.0 (1.0 per half antibody) for the antibodies with engineered surface cysteines. We compared the effect of a mild reducing agent, TCEP (Tris, 2-carboxyethyl, phosphine hydrochloride), and a stronger reducing agent, DTT (dithiothreitol), on two of the variants, variant 4 and variant 6. Initially, the non-oligomerizing variant 4 shows 0.13 free thiols per antibody, and the highly oligomerizing variant 6 has 0.25 free thiols per antibody. Aliquots of wild type, variant 4, and variant 6 were treated in four different conditions, 10- and 20-fold molar excess of TCEP, and 5- or 10-fold excess of DTT. After removal of the reducing agent, the samples were resolved on nonreducing PAGE (Supporting Information Figure 1A), and were quantified for free thiol (Supporting Information Figure 1B). A comparison of the results for wild type and variants indicates that the TCEP treatment is sufficient to reduce cysteines in nonoligomerized form (variant 4) with little effect on WT. However, cysteines from oligomers (variant 6) are reduced only after a harsher treatment. Treatment with DTT even at low levels leads to antibody fragmentation. Most non-oligomerizing variants like variant 4 were consequently labeled with ideal efficiency of 2.0; however, oligomerizing variants like variant 6 were underlabeled with efficiencies of 1.0−1.5. Thus, the sites where the surface cysteines are introduced have a profound effect on the ability to decap and conjugate the engineered cysteines.

Distinction of Five Classes of Antibody Cysteine Variants Based on CLP. All variants were expressed by transient transfection and were labeled with Alexa-488 maleimide and Alexa-532 maleimide. Labeled and unlabeled samples were resolved on nonreducing SDS-PAGE for quality control (Figure 2 and Supporting Information Figure 2). Nonreducing gels show monomers as well as the presence of dimers, trimers, and in some cases even higher oligomers. We distinguish five classes of variants. Class I comprises variants that are monomeric and remain stable after labeling (variants 3, 4, 7, 10, 12, 14). Variants of class II contain a small percent of dimers before and after labeling (variants 1, 2, 13). Class III variants have a more pronounced propensity to oligomerize including formation of some trimers (variants 5, 9). Class IV variants have an even higher propensity to oligomerize as evidenced by the presence of aggregates larger than trimer, especially after labeling (variant 6). Class V includes variants of high oligomerization propensity similar to variants of class III and IV with additional structural abnormalities such as fragmentation (variant 8), coloration of purified concentrated sample (variant 11), or extremely poor expression yield (variant 15).

The oligomerization propensity of variants 1−6 was compared on nonreducing SDS-PAGE for unlabeled (Figure 2A) as well as labeled (Figure 2C) samples. The CLP of variants 7−14 was analyzed in a similar fashion (Supporting Information Figure 2A). At least three molecular weight species of unlabeled variants 8 and 11 are resolved by gel filtration and electrophoresis (Figure 2E). The observed coloration in variant 11 most likely occurs because of binding of phenol red from the tissue culture media to erroneously exposed sites of the molecule, indicative of structural abnormalities of this variant. We also note that variant 14 is expressed at a level more than 100 times higher than that of variant 15 (Supporting Information Figure 2B, and Figure 4A). The mutation S7C on the heavy chain is very poorly tolerated in an antibody with a high-SAP patch in the V_H domain (variant 15) resulting in very low expression levels. In contrast, a variant with the same S7C mutation is expressed well when two amino acids in the high-SAP patch, W100 and F101, are substituted with lysines (variant 14). In addition to nonreducing SDS-PAGE, labeled variants were also analyzed by size-exclusion high-performance liquid chromatography (SEC-HPLC). Variants of class I and II are usually more than 95% but at least 80% monomeric, while variants of other classes are less than 70% monomeric, with the rest of the samples forming aggregates of various sizes (Supporting Information Figure 2C).

Engineered Variants Retain Antigen-Binding Activity and Are Specifically Labeled. Labeled and unlabeled variants 1−6 were analyzed for biological activity in a reporter gene bioassay. The variants retain activity within 80% and 130% of wild type, with loss of activity in the range 1−27% of the labeled variants in comparison to their unlabeled counterparts (Figure 2B). Variants 1−14 are labeled exclusively at the light or heavy chain that carries the engineered cysteine, as shown on reducing SDS-PAGE (Figure 2D, Supporting Information Figure 2A). The specificity of labeling is also demonstrated on the differential fluorescence band patterns of variants digested with Pronase and resolved on reducing SDS-PAGE (Supporting Information Figure 2D). Proteolytic treatment of the variants with Pronase yields different fluorescence patterns for most variants but similar patterns for variants with neighboring substitutions, such as variant 3 and 12. Thus, the analyzed engineered variants retain biological activity similar to wild type and are site-specifically labeled.

Correlation between CLP and SAP of the Engineered Variants Suggests a Rational Approach to the Design of Antibody Variants for Site-Specific Conjugation. To determine the correlation between the positions of the cysteine-substituted amino acids and their SAP values, we map the substituted amino acids on the SAP plots for the Fab and Fc parts of antibody-1 (Figure 3A and B). These plots were obtained as shown before (*19*). All substituted residues have neutral or negative SAP. Furthermore, we map the substituted amino acids on the three-dimensional structure of the antibody with SAP (Figure 3c). The overlaid CLP and SAP three-dimensional representation yields another level of information—proximity of the selected sites to hydrophobic patches (high SAP regions) indicated in red. Variants of class I CLP have SAP values between 0 and −0.07 and are not close to hydrophobic patches. Variants of class II are not close to

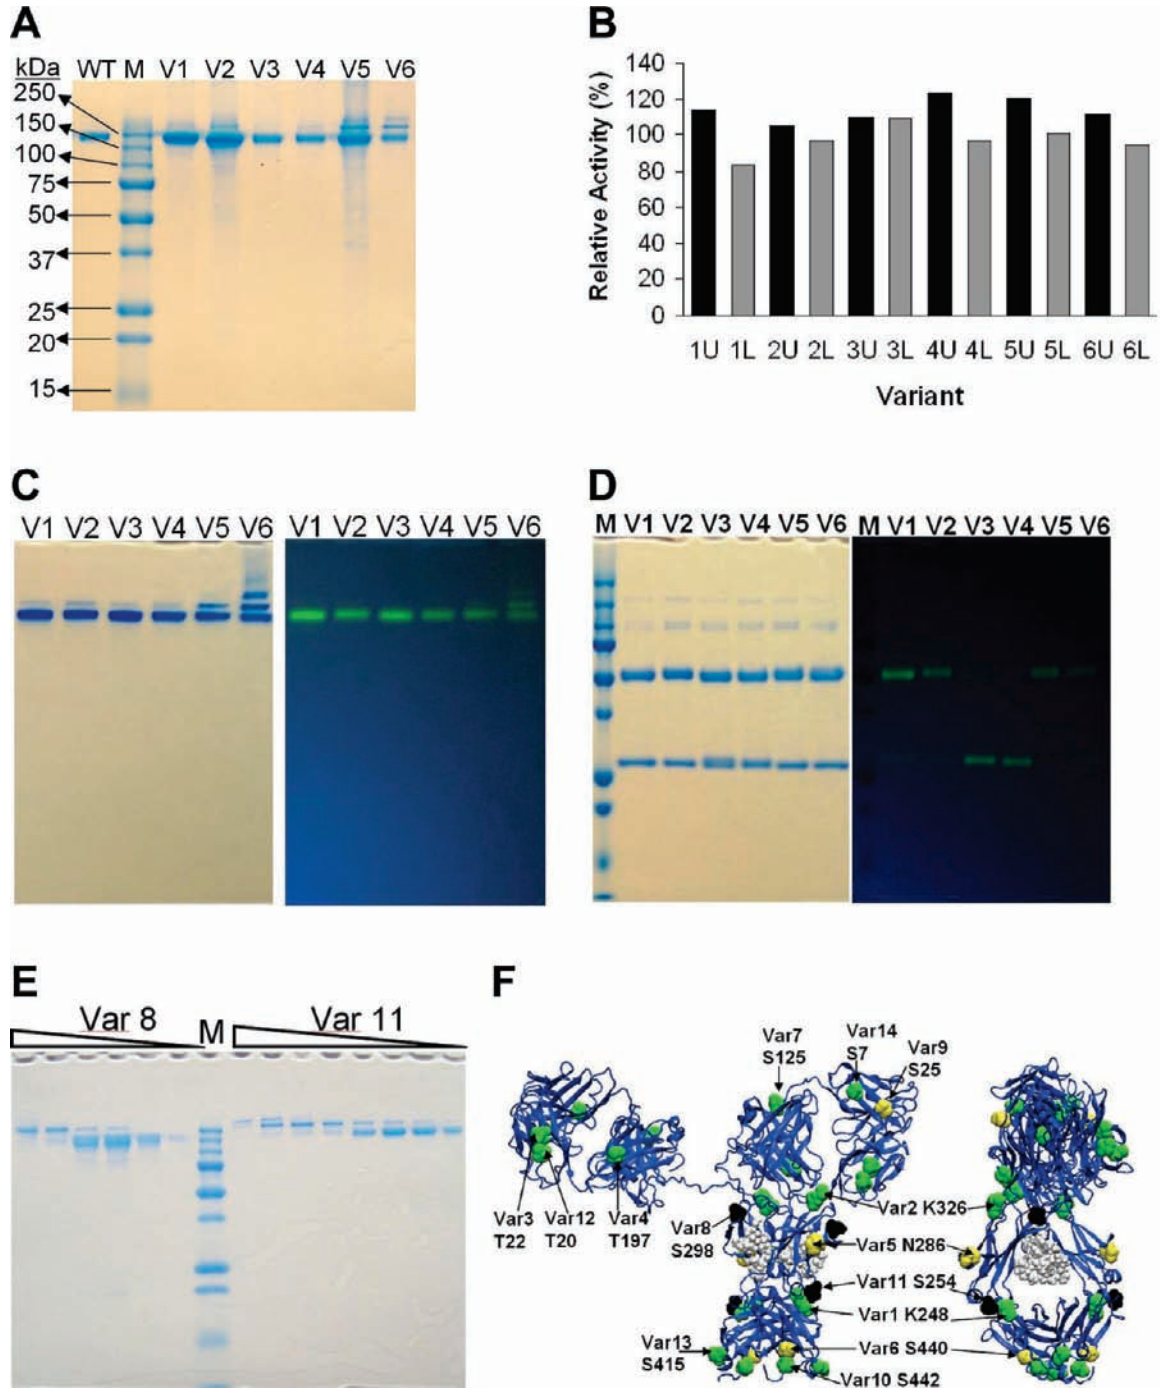

Figure 2. Quality control assessment of the engineered variants. (A) Nonreducing SDS-PAGE protein gel for variants 1−6 before labeling. M is the molecular weight marker (BioRad) used in this, as well as in all other protein gels shown. The molecular weight of each individual band in the ladder is shown in kDa. (B) Biological activity of unlabeled (U) and labeled (L) antibody variants, relative to antibody-1 wild type. (C) Nonreducing SDS-PAGE protein gel for variants 1−6 after labeling: image of the Coomassie stained gel and a fluorescence image of the same gel before staining. (D) Reducing SDS-PAGE protein gel for variants 1−6 after labeling: image of the Coomassie stained gel and a fluorescence image of the same gel before staining. For each antibody variant, the protein band at about 50 kDa corresponds to the antibody heavy chain, and the protein band at about 25 kDa corresponds to the antibody light chain. (E) Gel filtration fractions of variants 9 and 11. (F) Location of each engineered variant on the antibody three-dimensional structure. Green is CLP I and II, yellow is CLP III and IV, and black is CLP V. Variants 1−13 were generated in antibody-1. Variants 14 and 15 were generated in another antibody-2.

hydrophobic patches but have a more negative SAP value, from −0.12 to −0.23. Variants of class III have SAP like those of class I and II but are close (although not immediately adjacent) to hydrophobic sites. Variant 6 of class IV has an SAP value of −0.09 and is not adjacent to high-SAP patches. Yet, this variant is highly oligomerizing, presenting an exception to the SAP/CLP pattern. Variants of class V (variants 8 and 11) have cysteines engineered in immediate proximity to hydrophobic regions with high SAP. These variants show high CLP as well as additional structural abnormalities, regardless of the SAP value of the substituted amino acid. Thus, the comparison of CLP, SAP of the substituted amino acid, and presence or absence of nearby high SAP site (Figure 4A) yield several straightforward and useful criteria for selecting sites for introducing surface cysteines (Figure 4B).

In brief, the correlation between CLP and SAP values of the set of engineered IgG1 variants can be summarized as follows. Cysteine substitution of amino acids of partial exposure (SAP

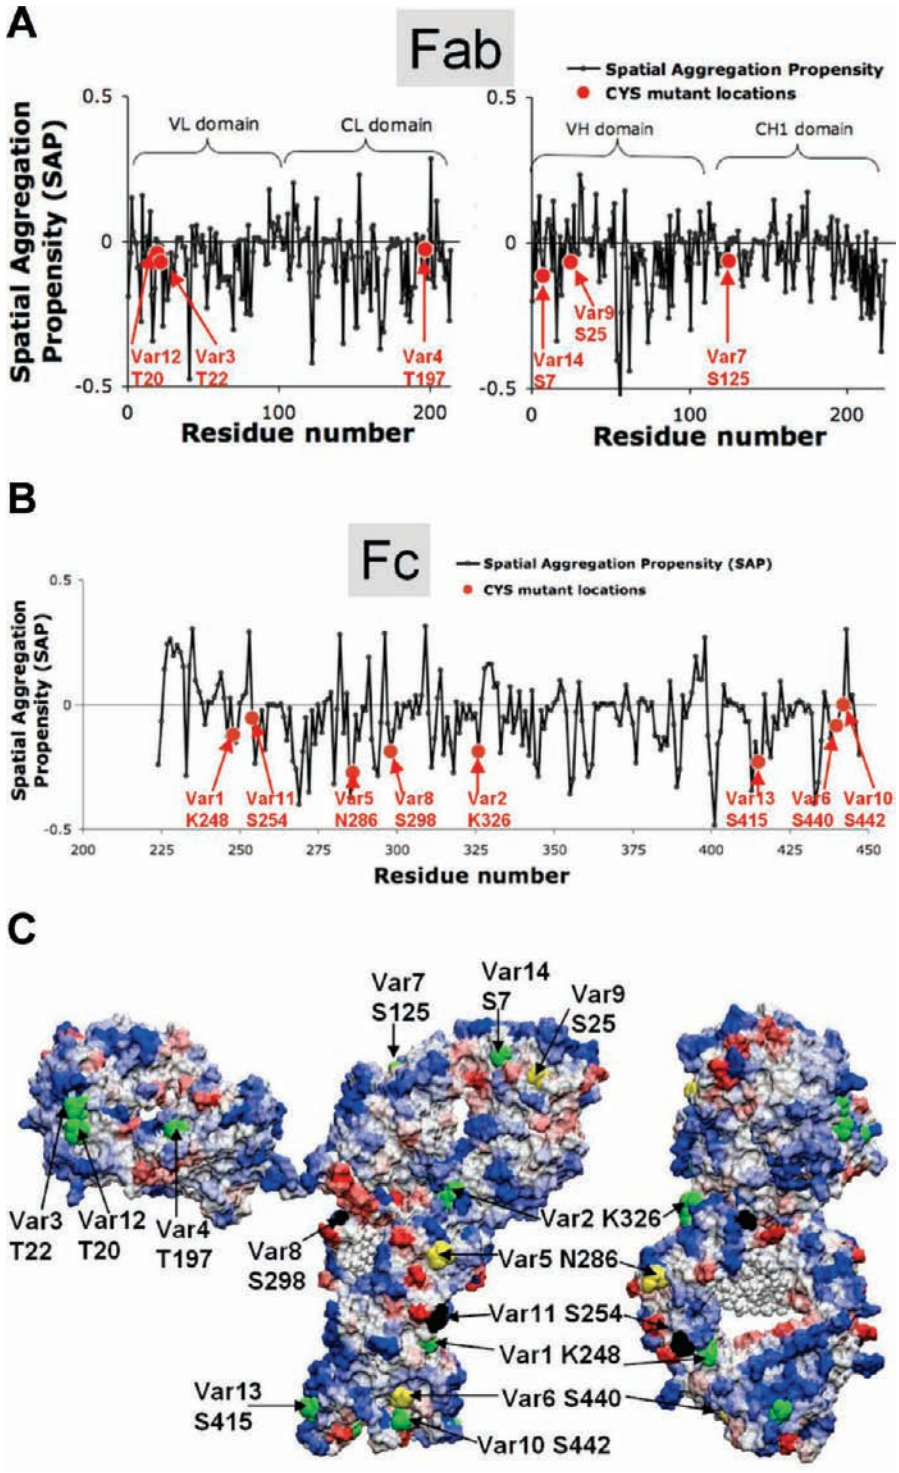

Figure 3. SAP values for the substituted amino acids in variants 1−14 in (A) Fab and (B) Fc. (C) Mutated amino acids on the antibody-1 structure in the SAP context. For comparison, S7 of variant 14 is shown in antibody-1, although it was produced and analyzed in antibody-2. Both front and side views of the antibody molecule are shown. Red is high-SAP, and blue is low-SAP. Green is CLP I and II, yellow is CLP III and IV, and black is CLP V.

from 0.00 to −0.11), and away from high-SAP patches, show low CLP. Cysteine substitutions of amino acids of higher exposure (SAP from −0.12 to −0.23) show some CLP even in the absence of nearby high-SAP patches. The presence of adjacent high-SAP patches leads to high CLP and other structural abnormalities regardless of the SAP value of the particular substituted amino acid.

Most variants were produced by transient transfection with yield between 11 and 37 mg/L with several exceptions (Figure 4A). Variants 9, 12, and 15 were expressed at lower levels. At the same time, variants even with high CLP, such as variants 6, 8, and 11, maintained high levels of expression. For comparison, antibody-1 wild type had an average yield of 25 mg/L, and antibody-2 of 24 mg/L, with our expression methods.

Site-Specifically Labeled Antibody Variants Are Used to Monitor Structural Dynamics of Antibody Domains. We were also interested in applications of the antibody cysteine variants presented here. Successful labeling already indicates potentially efficient conjugation of most variants. In search of additional applications, we noticed a specific emission pattern of one of the variants conjugated with the fluorophore pyrene maleimide. When two pyrene molecules are close together there

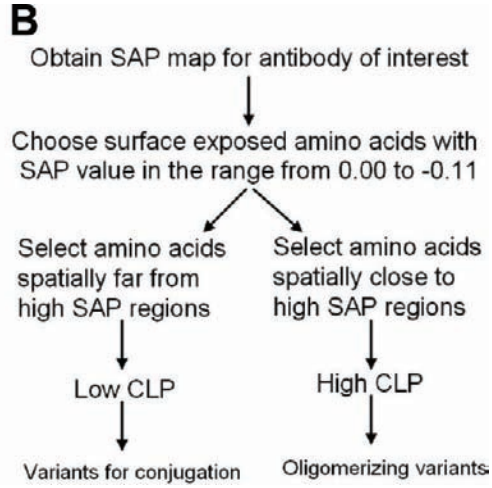

Figure 4. A rational approach to design antibody variants for site-specific conjugation. (A) Correlation between CLP and SAP for the 15 engineered cysteine variants. The domain that contains the mutation, the mutated amino acid, and the expression levels for each variant are shown. For comparison, antibody-1 and antibody-2 wild type were expressed at an average of 25 and 24 mg/L, respectively. Full green cell is CLP I, partial green cell is CLP II, yellow is CLP III and IV, and black is CLP V. Variants 1−13 are generated in antibody-1. Variants 14 and 15 are generated in another antibody-2, and thus, s.c. indicates separate case. Variant 14 is different from variant 15 by two surface amino acid substitutions, W100K and F101K, that is, W and F in variant 15 are replaced with lysines in variant 14. In the column "nearby high SAP", "N" denotes absence, "Y" indicates presence, and "~Y" denotes presence of a less pronounced high-SAP patch. (B) Application of the SAP technology to select surface amino acids for substitution to cysteines that would result in variants with low or high cross-linking propensity.

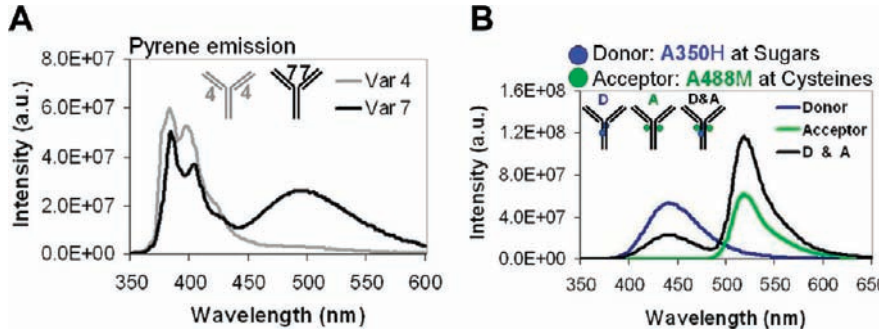

Figure 5. Use of labeled cysteine variants in montoring domain structural dynamics. (A) Fluorescence emission spectra of pyrene-labeled antibody variants 4 and 7. (B) Emission spectra of variant 2 labeled at the carbohydrates, at the engineered cysteines, or at both the carbohydrates and the cysteines.

is a characteristic increase of emission at 465 nm known as excimer fluorescence. We labeled variants 4 and 7 with pyrene maleimide and monitored emission spectra. While variant 4 shows no emission at 465 nm, variant 7 shows strong excimer fluorescence (Figure 5A). Considering the position of the engineered cysteine in C_H1 for variant 7, on the inner side of the Fab domains, the observed result correlates with the known scissoring effect of the Fab's with respect to Fc. Thus, the variant can be used in the analysis of antibody domain dynamics, for example, in examining antibody pluripotence with respect to antigen targets.

As another example of applications to structural dynamics, cysteine variants can be double-labeled, once at the engineered cysteines via maleimide chemistry and once at the carbohydrates via hydrazide chemistry. The engineered cysteines of variant 2 are in Fc and are proximal to the carbohydrate moiety. We observe a significant fluorescence energy transfer between donor and acceptor of double-labeled variant 2 (Figure 5B). Similar fluorescence analysis among different variants and at different conditions permits analysis of protein−carbohydrate interactions (*21*).

An Antibody Variant with High CLP Is a Useful Molecular Weight Control. The strong oligomerization propensity of variant 6 suggested another utility of IgG1 cysteine variants and was explored in greater detail. Labeled variant 6 was subjected to gel filtration chromatography in order to separate monomer from oligomers, and protein-containing fractions were resolved on a 7.5% nonreducing SDS-PAGE, shown after (Figure 6A) and before (Figure 6B) staining with Coomassie Blue. The gel filtration analysis on variant 6 indicates a competition between utilization of the engineered surface cysteines in labeling and in cross-linking: the higher the MW of the species (more cysteines consumed in cross-linking), the lower the labeling efficiency (fewer cysteines available for labeling) (Figure 6B). The highest MW species (five asterisks) has a labeling efficiency of 0.5, while the monomeric species (one asterisk) has a labeling efficiency of 1.0, with the original labeled sample of labeling efficiency 0.8. An antibody variant with multiple oligomers, variant 6, thus presents a suitable standard for high molecular weight proteins, with the additional functionality that it can be site-specifically labeled. Unlike commercially available markers of mixture of proteins, this standard consists of only one protein that can be expressed at very high yield and can be efficiently purified. Moreover, the currently available high molecular weight markers for denaturing gels do not exceed 250 kDa, while variant 6 covers the broad range from 150 kDa (monomer) up to 750 kDa (pentamer).

DISCUSSION

Although the cysteine engineering of proteins and more specifically antibodies has been practiced for many years (*10, 11, 14, 16*), it is still difficult to predict whether an antibody cysteine variant

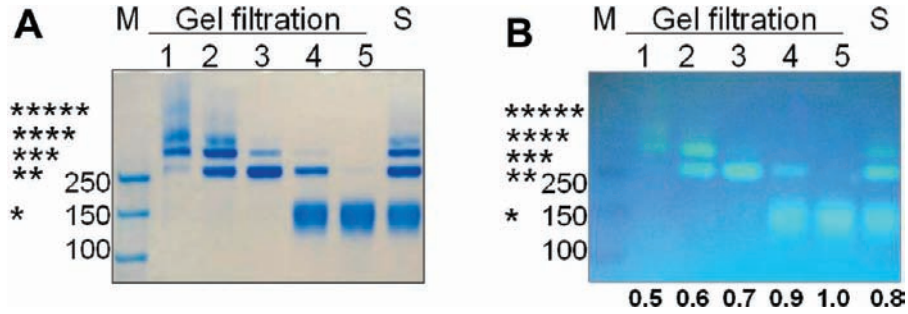

Figure 6. Variant 6 contains at least five species. (A) Gel filtration of Alexa-488 labeled variant 6 species performed on Superdex 200. Aliquots of each protein-containing fraction were analyzed on a 7.5% PAGE under nonreducing conditions. M is molecular weight markers, in kDa, and S is the original labeled sample. The gel is shown after Coomassie staining. Antibody variant 6 monomer (one asterisk) and at least four higher molecular weight species (two, three, four, and five asterisks) are resolved. (B) Fluorescence image of the same protein gel before Coomassie staining. The numbers below the fluorescent image indicate labeling efficiency for each fraction.

will have the desired properties and serve the intended purposes. Two of the most common problems associated with antibody cysteine variants are oligomerization and specificity of labeling. To date, antibody cysteine variants in C_L, C_H1, and C_H3 have been designed (*10, 11, 13, 14, 17*).

We have designed a set of human IgG1 cysteine variants that are broadly distributed on the antibody molecule with at least one variant per immunoglobulin fold domain. Most of these variants are stable and can be conjugated efficiently and specifically without significant loss of biological activity. Thus, the stable antibody variants (for example, variants 1, 3, 4, and 7) add to the repertoire of variants for site-specific conjugation of payload molecules. Engineered surface cysteines on antibodies provide functionality for conjugation of small molecules, for example, cytotoxins. The therapeutic benefit of such immunoconjugates is that, when an antibody to a cell surface antigen binds its target, the toxin or other small molecule is specifically delivered to diseased cells that express that antigen. As another application, if fluorophores are attached to the engineered cysteines, the dynamics of particular domains can be analyzed. Here, we used antibody-1 and antibody-2 as model antibodies. While the mutations in the variable regions of these two antibodies may not apply to antibodies of other allotypes, we expect that our observations on variants with mutations in the constant regions apply to most human IgG1 antibodies.

The observed deviations in biological activity in variants 1−6 compared to wild type may result from variations in post-translational modifications during expression or other minor structural changes. The consistent loss of some activity upon labeling probably reflects structural changes such as partial unfolding or oligomerization in the multiple steps of chemical and mechanical stress during labeling.

Variants 6, 8, and 11 show good expression levels in comparison to wild type even though these variants have high CLP. This suggests that the observed aggregation is a result of specific cross-linking via the surface cysteines and not of a general misfolding and aggregation problem. In contrast, the lower expression levels of variants 9, 12, and 15 in comparison to the corresponding wild-type antibodies suggests that the introduced mutations lead to some folding or secretion problem.

In summary, comparison of the cross-linking propensity of the variants with the SAP values of the substituted sites and the spatial regions around those sites yields a straightforward approach for selecting sites for cysteine substitution and site-specific conjugation. First, less exposed residues (SAP from 0.00 to −0.11) are less likely to lead to oligomerization than more exposed residues (SAP from −0.12 and lower). Second, our results suggest that nearby or immediately adjacent hydrophobic sites exacerbate the cross-linking propensity even of sites with ideal SAP values. Hydrophobic patches are likely to interact and bring adjacent molecules together, thus facilitating intermolecular cross-linking via disulfide bonding of nearby surface cysteines.

The boundaries of the suggested optimal range of 0.00 to −0.11 arise from several criteria developed on the basis of our results. In this report, we considered substitution of polar or charged amino acids with cysteines as opposed to hydrophobic amino acids to avoid significant changes in surface charge; thus, the negative half of the SAP spectrum is represented. The −0.11 limit for variants with low CLP is based on the result for K248 of variant 1. That site has an SAP of −0.12. An exception to the SAP criteria and CLP observations is variant 6, possibly because of fluctuations and exposure at the tip of the C_H3 domain. Our SAP results indicate a higher exposure for S440 (variant 6, SAP = −0.09) than for S442 (variant 10, SAP = 0.00) consistent with the observed lower CLP of variant 10.

CONCLUSION

We propose the implementation of the SAP technology in designing antibody, and by extension any protein, variants for site-specific conjugation. In order to select variants, the following steps should be made: (1) an SAP map for a protein of interest is obtained as previously described (*19*); (2) sites with SAP values between 0.00 and −0.11 are selected; (3) the vicinity of the selected sites are inspected for the presence of high-SAP regions; (4) if such regions are absent, the selected sites are chosen for modification to cysteines. These variants are expected to have low CLP and no structural abnormalities, and thus be suitable for efficient site-specific conjugation. The results presented here demonstrate the better utility of the SAP technology to existing methods in the rational design of protein variants for site-specific conjugation, as well as possible applications of the new variants.

ACKNOWLEDGMENT

We thank a number of colleagues at Novartis: Dr. Burkhard Wilms provided the DNA vectors encoding for the wild-type antibodies, Dr. Holger Heine provided training and advice on transient transfection and antibody purification, Dr. Michael Vetsch suggested using L-cysteine to reduce protein surface cysteines before labeling. We thank Prof. Wittrup from MIT and his students for discussions and for sharing lab equipment. We also thank Dr. Rajaraman Krishnan from MIT/Whitehead Institute for a discussion and suggestions on pyrene labeling, and Anna Levina for technical assistance. This work was supported by Novartis Pharma AG.

Supporting Information Available: Two supplementary figures on cysteine variant reduction with TCEP and DTT,

specificity of labeling by SDS-PAGE, and determination of monomer levels by SEC-HPLC. This material is available free of charge via the Internet at http://pubs.acs.org/.

Received August 19, 2009; Revised Manuscript Received December 3, 2009

A simple bifunctional colorimetric/fluorescent sensing assay is demonstrated for the detection of HIV-1 specific antibodies. This assay makes use of a short peptide sequence coupled to an environmentally sensitive dye that absorbs and emits in the visible portion of the spectrum. The core peptide sequence is derived from the highly antigenic six-residue epitope of the HIV-1 p17 protein and is situated adjacent to a terminal cysteine residue which enables site-specific fluorescent labeling with Cy3 cyanine dye. Interaction of the Cy3-labeled p17 peptide with monoclonal anti-p17 antibody resulted in an up to 4-fold increase in dye absorption and greater than 5-fold increase in fluorescent emission, yielding a limit of detection as low as 73 pM for the target antibody. This initial study demonstrates both proof-of-concept for this approach and suggests that the resulting sensor could potentially be used as a rapid screening method for HIV-1 infection while requiring minimal equipment and reagents. The potential for utilizing this assay in simple field-portable point-of-care and diagnostic devices is discussed.

INTRODUCTION

Halting the spread of human immunodeficiency virus or HIV (along with many other virulent diseases) is a continuing international health priority. In developing countries where healthcare funding, facilities, and treatment are limited, this is of particular concern as infection rates continue to grow. Reducing infection and providing adequate treatment in the third world will be predicated on the development of rapid diagnostics for HIV screening that are sensitive, cheap, robust, and simple to use, have long-term stability, and require minimal equipment and limited-to-no sample preparation. In the most simplistic terms, these diagnostics must be suitable for use in extreme resource-limited environments (UAIDS/WHO report (2007) AIDS epidemic update http://data.unaids.org/pub/EPISlides/2007/2007_epiupdate_en.pdf). Simultaneous developments in two related technologies will help achieve this goal, namely, simple point-of-care (POC) devices combined with robust diagnostic assays. The last two decades have seen tremendous progress in microfabricated POC devices to the point where transition to the field and deployment around the world is now a growing reality (WHO report (2004) Performance evaluations of HIV test kits http://www.who.int/diagnostics_laboratory/publications/evaluations/en/index.html) (*1*−*4*). Although PCR-based detection of conserved HIV-1 DNA sequences has been proposed (*1, 5*), testing for the presence of serological antibodies against HIV is still among the most common initial screening techniques (*1*). These tests often target the viral envelope glycoprotein antigens from HIV type 1 or type 2 (HIV-1, HIV-2), while others screen for the presence of core viral antigen proteins (*1*). Among the latter, the HIV-1 p17 protein has been found to play an active role in viral infection, and antibodies reactivity to a number of the gag-proteins including p17 have also been shown to significantly decrease at the later stages of infection (*6*−*9*). According to a recent UNAIDS/WHO report, 33 million people (∼0.5% of the world population) are living with HIV with the majority of cases being directly attributable to infection with the HIV-1 strain. This establishes the p17 protein as a prime target antigen for HIV detection that can also be more specifically reflective of the initial stages of HIV-1 infection (*5*).

Immunoassay-based techniques such as Western blotting and enzyme-linked immunosorbent assays (ELISAs) are considered the gold standard for the detection of p17 exposure. Various other methods have also been developed that utilize surface-immobilized p17 protein as a capture reagent for detection of HIV-1 p17 specific antibodies (*10, 11*). However, all techniques including PCR commonly require the use of dedicated laboratory equipment for analysis as compared to control samples and standards. Furthermore, the use of the full p17 protein as a capture reagent can be problematic from a field-portable perspective in that functionalized surfaces need to be prepared and will require storage in a buffered environment and/or refrigeration. Clearly, simple and robust immunoassays for HIV detection that can function in complement with POC devices are still needed.

Plaxco's group have been developing peptide-based beacons, which function in a manner somewhat analogous to DNA molecular beacons, and initial attempts to utilize them for detecting HIV-1 specific p17 antibodies have yielded rather promising results (*12, 13*). In their approach, a short peptide sequence comprising a highly antigenic six-residue epitope of the HIV-1 p17 protein was labeled with both a long-lived ruthenium(II) bisbipyridine−phenanthroline fluorophore exhibiting a ∼800 ns lifetime at one terminus and the electron-accepting contact-quencher methyl viologen at the other terminus. Significant quenching of the fluorophore was observed in the unstructured polypeptide while in solution until addition and subsequent binding of the target, anti-p17 antibody forced the peptide into a rigid extended conformation, separating the fluorophore and quencher and generating a 6-fold increase in fluorophore emission (*13*). The resulting optical biosensor

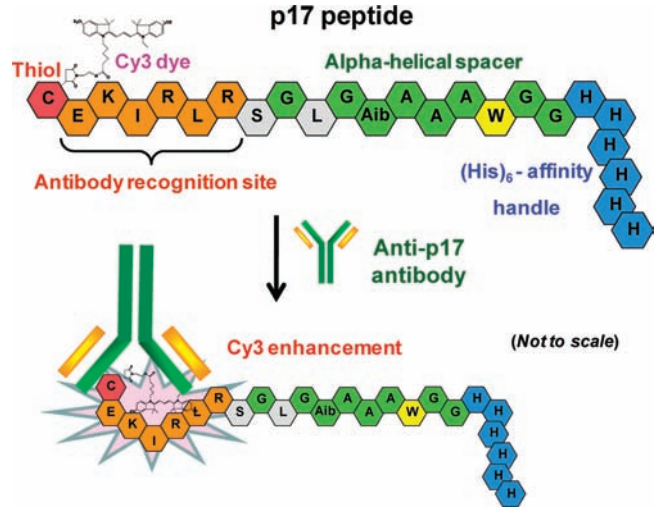
demonstrated a limit of detection (LOD) for p17 HIV-1 antibody of 250 pM and was functional in both serum and saliva samples. Although a sensing configuration utilizing this particular fluorophore combination may not yet be directly transferrable to the simplest field-portable devices, it does highlight several inherent advantages. The use of an extremely short peptidyl sequence as opposed to the full p17-protein is preferred, as it can be readily dried down and stored lyophilized for long periods of time prior to reconstitution in an assay. Additionally, monitoring of antibody binding to labeled peptide simplifies the overall assay procedure significantly. Here, we combine a p17 HIV-1 antibody-specific short peptide sequence with a fluorescent Cy3 dye to create a simplified sensor specific for anti-p17 antibodies that is equally functional in both colorimetric and fluorescent assays. This proof-of-concept study demonstrates a significantly lower LOD than previously described sensors and highlights the simplicity of this approach for generalized screening purposes.



EXPERIMENTAL SECTION

Materials. All chemicals were reagent grade and used as received from the manufacturer. Phosphate buffered saline (10 mM phosphate, 137 mM NaCl, 2.7 mM KCl, pH 7.4, PBS), *N*-[2-hydroxyethyl]piperazine-*N*′[2-ethane sulfonic acid] (HEPES), bovine serum albumin (BSA), imidazole, dimethyl sulfoxide (DMSO), HPLC-grade acetonitrile and Corning 96-well white polystyrene nonbinding surface (NBS) microtiter plates were obtained from Sigma-Aldrich. Chicken immunoglobulin G protein (IgG) was obtained from Jackson ImmunoResearch Laboratories Inc. (West Grove, PA). Murine monoclonal antibody specific for HIV-1 p17 protein (α-p17, Clone 32/1.24.89 IgG1 isotype that reacts to p17 residues 17−22 EKIRLR) was purchased from Zeptometrix Corporation (Buffalo, NY). Cy3-maleimide monoreactive dye (λ_{max} absorption 550 nm, λ_{max} emission 570 nm,) was purchased from GE Healthcare (Piscataway, NJ). Nickel-nitroloacetic acid (Ni-NTA) agarose media was purchased from Qiagen (Valencia, CA). Oligonucleotide purification cartridges (OPC) and triethylamine acetate buffer (TEAA) were obtained from Applied Biosystems (Foster City, CA).

Peptide Synthesis. The antigenic peptide recognized by the monoclonal α-p17 antibody (p17-peptide) was prepared using standard *in situ* neutralization cycles for Boc-solid-phase-peptide synthesis (Boc-SPPS) as described (*14, 15*) and consisted of the sequence CEKIRLRSGLGAibAAAWGGHHHHHH-NH_2 (M_w of 2652, Aib is the non-natural amino acid α-aminoisobutyric acid, and NH_2 is an amide group blocking the C-terminal carboxyl in this sequence). Following synthesis and deprotection, the peptide was purified and isolated by HPLC and both the purity (>99%) and the sequence confirmed by mass-spectral analysis (see Supporting Information for data). The modular design of this peptide (*16*), as highlighted by the different colors in Scheme 1, includes a unique N-terminal cysteine allowing site-specific dye-labeling, the six-residue EKIRLR antigenic epitope recognized by the α-p17, an AibAAA α-helical spacer which is disrupted by flanking G residues, W allowing UV absorption monitoring if needed, and a C-terminal hexahistidine sequence $(His)_6$ which provides an affinity handle for purification via metal-affinity chromatography.

Fluorescent Dye Labeling of p17-Peptide. The peptide was labeled and purified in a manner similar to the method described in detail in ref *17*. Briefly, ∼1 mg of the purified p17-peptide was dissolved in 1 mL 10× PBS pH 7.4 and combined with a large excess of Cy3-maleimide monoreactive dye to ensure complete labeling. The reaction mixture was incubated overnight at 4 °C, and unreacted Cy3 dye was removed using three consecutive 0.5 mL Ni-NTA-agarose columns. The reaction mixture was loaded onto Ni-NTA-agarose media as the C-terminal $(His)_6$ sequence provides a specific affinity handle for this type of purification. Bound peptide was then washed with 10 mL 1× PBS to remove unreacted free dye, and the Cy3-labeled p17-peptide (abbreviated as Cy3-p17-peptide) was eluted using 300 mM imidazole in 1× PBS. A reverse-phase media containing OPC was then used to remove the imidazole and desalt the Cy3-p17-peptide. The OPC cartridge was first equilibrated with 3 mL acetonitrile followed by 3 mL 2 M TEAA before the Cy3-p17-peptide was loaded in. The cartridge was then washed with 50 mL 0.02 M TEAA before the Cy3-p17-peptide was eluted with ∼1 mL 70% acetonitrile in H_2O. The OPC media were regenerated for further rounds of Cy3-p17-peptide purification, as needed, by washing with 3 mL acetonitrile followed by 3 mL 2 M TEAA until the original Ni-NTA-imidazole elutant became clear. Desalted Cy3-p17-peptide was quantitated using UV−vis spectroscopy by measuring the Cy3 absorption (150,000 M^{-1} cm^{-1} at 550 nm) before being aliquoted, dried down, and stored at −20 °C in a desiccator until required.

Scheme 1. Cy3-p17-Peptide Interactions with Monoclonal α-p17 Antibody[a]

[a] (Not to scale). The peptide contains several functional modules including a $(His)_6$ affinity sequence for purification over Ni-NTA media (blue), an Aib-alanine containing helical spacer sequence that is disrupted by flanking glycine residues (green), the antibody recognition element (orange), and a unique terminal cysteine (red) for site-specific fluorophore labeling. α-p17 antibody binding to the Cy3-p17-peptide alters the peptide structure and/or dye environment significantly enhancing both dye absorption and emission and thus transducing signal.

Assays Monitoring Binding of Anti-p17 Antibody to Cy3-p17-Peptide. Interactions of Cy3-p17-peptide with murine α-p17 antibody were monitored by exposing increasing concentrations of antibody to dye-labeled peptide dissolved in buffer. Cy3-p17-peptide was resuspended by first dissolving in DMSO (∼5% of the final volume) followed by 20 mM HEPES buffer pH 8.0. Samples consisted of either 300 or 600 nM (30 or 60 pmol/well in 100 uL final volume) Cy3-p17-peptide exposed to increasing concentrations of the α-p17, control chicken IgG, or BSA ranging from 0 to 10 nM in HEPES buffer. These concentrations were chosen by initially testing the peptide against the antibody for optimal concentrations that allowed sensitive fluorescent and absorption detection prior to the assay (data not shown). The solutions were incubated for 1 h at room temperature before being transferred to 96-well microtiter plates and fluorescence measurements (spectra and intensities) were measured using 530 nm excitation on a Tecan Safire Dual Monochromator Multifunctional Plate Reader (Tecan, Research Triangle Park, NC). Intensities were an average of 9 readings

Figure 1. UV−vis absorbance data. per well. UV−vis spectra of the solutions were recorded using an Agilent Technologies 8453 UV−vis spectrophotometer (Santa Clara, CA). Data from the assays were analyzed and plotted using Microsoft *Excel* (Microsoft, Redmond, WA) and *SigmaPlot* (Systat Software Inc., San Jose, CA), respectively.

RESULTS AND DISCUSSION

A schematic overview of the α-p17 sensing assay discussed here is shown in Scheme 1. The freely diffusing Cy3-p17-peptide in solution has a nominal Cy3-fluorescent emission. Addition of α-p17 to the sensing solution results in specific antibody recognition and binding to the antigenic EKIRLR epitope which is proximal to the dye attachment site. This binding event alters the peptide structure and/or dye environment resulting in a significant enhancement of the Cy3 fluorescent dye photophysical properties which serves as the overall mechanism of signal transduction. We evaluated the α-p17 induced changes in both Cy3 absorbance and emission properties following binding to the labeled peptide.

Figure 1A,B shows representative UV−vis spectra collected from samples consisting of 600 nM Cy3-p17-peptide samples consecutively exposed to increasing concentrations of either α-p17 antibody or a nonspecific chicken IgG control, respectively. The data from this UV−vis analysis is summarized and directly compared in Figure 1C, which plots the signal-over-noise (S/N) ratio at 550 nm (Cy3 absorbance maximum) versus the α-p17 and IgG concentrations. The data clearly show a significant increase in the intensity of the Cy3 absorbance spectra as a function of the α-p17 antibody concentration added. For α-p17 antibody binding, the effect appears to reach an asymptotic plateau at around a 4-fold increase, and this plateau is observed starting at a minimal concentration of ∼1.25 nM. Importantly, almost no significant changes in Cy3 absorption were noted when the Cy3-p17-peptide was exposed to the same concentrations of control chicken IgG; a protein with a similar size and conserved structure as the IgG class of antibody proteins. Using just these changes in Cy3 absorption, an overall LOD (defined as a S/N ratio that is greater than 1 plus 3 times the standard deviation of the blank) of ∼0.156 nM could be derived for α-p17 binding to the Cy3-p17-peptide.

The corresponding fluorescent emission spectra for the same samples prepared in the same manner were also recorded, and representative data are shown in Figure 2. As with the UV−vis data, the fluorescence intensity of 600 nM Cy3-p17-peptide increased as a direct function of the α-p17 antibody concentration added (Figure 2A). The fluorescent enhancement appears to also reach a maximum effect beginning at around 1.25 nM of α-p17 which corresponds to the same concentration noted for the plateau in the absorption data (*vide supra*). Although the data from Cy3-p17-peptide exposed to equivalent concentrations of chicken IgG do show some changes in Cy3 emission, these appear to consist of both increases and decreases in the emission and do not seem to become significant (S/N of 1.1 ± 0.1 for 2.5 nM chicken IgG) until a concentration of 5 nM, which is five times the minimal amount of α-p17 antibody needed for the maximal enhancement effect (Figure 2B). The data from the fluorescence analysis are summarized and compared in Figure 2C, which plots the S/N ratio at 570 nm (Cy3 emission maximum) versus the IgG/α-p17 concentration for sample sets consisting of either 300 nM or 600 nM Cy3-p17-peptide substrate. Exposure of α-p17 antibody to the lower concentration Cy3-p17-peptide was found to generate an up to

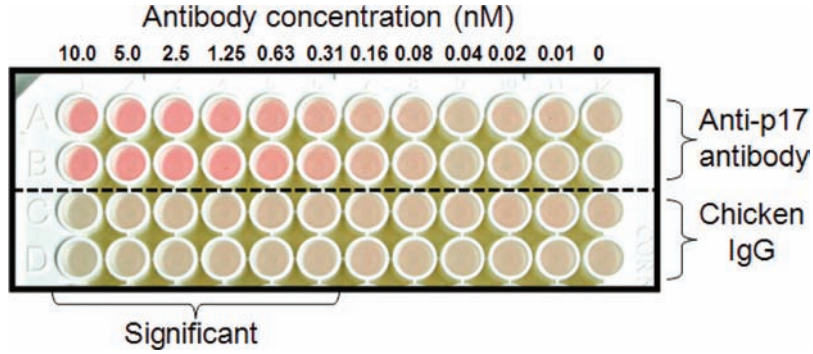

Figure 3. Photographic image of a typical assay performed in a 96-well white microtiter plate where each well contains 600 nM Cy3-p17-peptide. The concentration of the α-p17 antibody in the top two rows (A,B) and the chicken IgG control in the bottom two rows (C,D) is steadily increased (0−10 nM) from right to left.

5-fold increase in the fluorescence emission at 570 nm, with a corresponding LOD of 0.073 nM α-p17 antibody. Overall α-p17 LOD's, determined across multiple studies ($n = 5$), were 0.098 ± 0.012 and 0.073 ± 0.060 nM for the 600 and 300 nM Cy3-p17-peptide samples, respectively. The 73 pM LOD represents a 3.4-fold improvement over that determined by Oh and co-workers using their contact-quenching peptide beacon design (*13*).

We did not note any dye enhancement when α-p17 antibody was exposed to a similarly labeled generic control peptide lacking the antigenic epitope (see Supporting Information Figure 3). Beyond chicken IgG, we also tested 600 nM Cy3-p17-peptide interactions with BSA at a similar concentration range. In this case, BSA represents a nonspecific protein commonly found in serum samples and also often utilized as a blocking agent. The BSA elicits an almost identical response to the nonspecific chicken IgG at the same concentration ranges; see Figure 2C. We also noted that concentrations of BSA ≥ 1000 nM, which is ≥100 times that of the highest α-p17 antibody concentration used, approached a S/N of ∼3 with some sensor configurations (different amounts of Cy3-p17-peptide were tested, data not shown) which is still below the upper S/N limit detected with α-p17 antibody.

The enhancement of Cy3 absorbance and fluorescence properties observed upon α-p17 binding to the labeled-peptide sequence is likely a result of several putative changes in the dye's localized environment. These may include a decrease in polarity or solvation around the dye in the presence of the antibody as well as a reduction in the conformational/rotational mobility of the dye, as suggested by Gruber and co-workers who investigated anomalous fluorescence enhancement of Cy3 upon covalent attachment to IgG and noncovalent binding to avidin (*18*). Similar changes in Cy3 properties have been previously exploited in conjunction with the conformationally coupled bacterial periplasmic maltose binding protein (MBP) to prototype a number of maltose sensing modalities. For these, reduction of Cy3-labeled MBP emission upon maltose addition was either monitored directly (*19*) or in conjunction with semiconductor quantum dot donors in steady-state, excited-state lifetime, single-molecule, and multiphoton fluorescence resonance energy transfer sensing configurations (*20*−*22*). The overall concept based on pairing of fluorogenic dyes with myriad cognate protein or nucleic acid partners such that each has limited fluorescence independently but a strong emission upon binding to each other during biosensing has recently been termed "fluoromodules" (*23*). Indeed, several cyanine dyes structurally analogous to Cy3 have been tested against various single-chain antibodies (scFV) for this type of activity and suggested the exciting possibility of a range of such fluoromodules that can span most of the visible to near-IR spectrum (*23*).

As our overall goal was to evaluate this biosensing approach for the most basic screening purposes, we focused last on demonstrating assay utility with minimal to no electronic instrumentation. Figure 3 shows a digital color image taken of duplicate samples consisting of Cy3-p17-peptide in buffer exposed to increasing concentrations of either α-p17 antibody and the chicken IgG control, top and bottom two rows, respectively. The enhancement in Cy3 dye color intensity upon α-p17 binding, as compared to the IgG control, is most significant for the six antibody concentrations starting at 0.31 nM and higher. This colorimetric approach alone suggests that a rapid assessment of positive binding can easily be made by visual comparison of the samples versus controls against a white background in a microtiter well plate or even a test tube. Should observation of fluorescence also be desired, samples prepared in a similar fashion could be investigated using some form of LED or equivalent light source combined with CCD detection, both powered by batteries in the simplest configuration (*24*, *25*). The enhancement of Cy3 absorption or emission is far more desirable for signal transduction and assay monitoring than observing losses in these properties as the latter can also be caused by a variety of nonspecific or ancillary processes, for example, pH changes, ion presence, or chemical denaturation. We have also found that the Cy3-p17-peptide can be stored lyophilized for long periods of time (6 months to 1 year) and still remain fully functional. This is another desirable property, as it can allow reagents to be prepared beforehand, dried, shipped, and stored until use on an as-needed basis.

CONCLUSIONS

We have shown here a proof-of-concept design for a simple colorimetric and/or fluorescent sensing platform that uses a highly specific peptide coupled with a cyanine dye for the sensitive detection of α-p17 antibodies with a demonstrated LOD of 73 pM. This represents both a first use of a monoclonal antibody with such a fluorescent peptide in this type of sensing strategy and the detection of a clinically relevant and important target with both absorption and fluorescent emission signal transduction modalities. Although encouraging, these initial results also suggest that much research and engineering remains before transitioning to field studies. The overall enhancement mechanism is not yet been fully elucidated, and a greater understanding of the process is still warranted to answer a variety of complex mechanistic questions. For example, the extremely low concentration of antibody utilized to elicit a maximal enhancement effect (1 antibody per ∼4000 Cy3-p17-peptides for the 300 nM peptide sample in Figure 2) strongly suggests that only a very small fraction of the dyes are appropriately responsive perhaps reflecting the antibodies bind-

ing affinity/constant for the epitope in this context. The influence of Cy3 dye spacing/position relative to the epitope sequence on the peptide is clearly important and may be amenable to improvement to allow even more signal enhancement, while placement too far from the epitope may disrupt productive sensing. Iterative testing of such placement along with fluorescent polarization and anisotropy studies may help address this aspect. Testing a variety of other environmentally sensitive dyes in the sensor, including both cyanine-based and other structures, may provide better LODs, larger observed enhancements, and wider sensing ranges with the caveat that signal transduction in the visible portion of the spectrum is preferred for simplicity. Optimization of the dye attachment site in the peptide structure may also contribute similar benefits.

Although similar concentrations of nonspecific antibody or dye-labeled generic peptide lacking the epitope did not trigger any significant sensor changes, we did note that excess concentrations of BSA (>100 times that of the antibody) were able to elicit a sensor response. Therefore, while this platform has demonstrated potential for the sensitive detection of α-p17 antibodies, it is likely that some sample dilution and/or purification may be required before analysis where complex matrices such as blood are used. Significant dilution of serum samples or utilizing an integrated sample cleanup and concentration module are generally accepted sample-pretreatment strategies commonly utilized prior to POC device analysis and can readily help accomplish this (*1*, *2*, *4*, *26*, *27*). Testing of relevant spiked controls and clinical samples will help answer and optimize the LOD and sample dilution/pretreatment issues (using approved BSL III facilities).

These results in combination with other studies (*12*, *13*, *23*) strongly suggest the possibility of developing similar fluoromodule-based assays that are specifically targeted to sensing a variety of other antibodies or antigens. In principle, the method should be applicable to most antibody−epitope interactions regardless of peptide substrate length, as dye-positioning is the determinant. The various fluoromodules could be arrived at by screening combinatorially synthesized peptide libraries against targets of choice in parallel formats. Following on this, it is not hard to envision assays where several different dye-labeled peptides, each expressing different specific epitopes, are utilized in parallel-simultaneous formats to detect the presence of many different antibodies. This could allow the detection of other antibodies associated with different HIV infection stages, secondary infections, or even different strains of HIV. In conclusion, this report adds to the growing body of work which suggests that simplified bioassay formats, such as those exemplified by the fluoromodule-based assays described here, may have much to offer for challenging global health and biosecurity concerns especially in resource-poor environments (*28*).

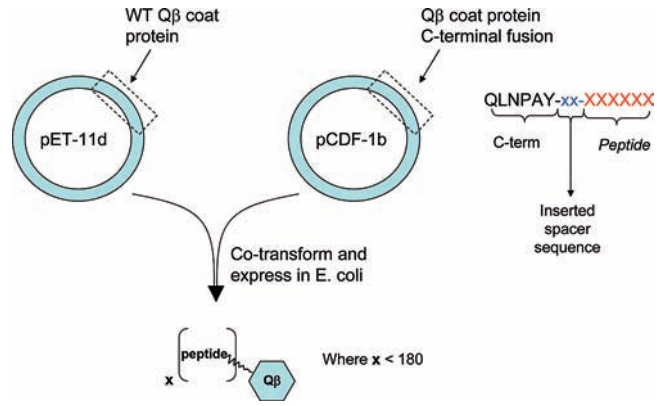
Metal- and Metallocycle-Binding Sites Engineered into Polyvalent Virus-Like Scaffolds

Andrew K. Udit,* William Hollingsworth, and Kang Choi

Department of Chemistry, Occidental College, 1600 Campus Road, Los Angeles, California 90041. Received September 14, 2009; Revised Manuscript Received December 16, 2009



Metal-binding motifs appear on protein scaffolds throughout nature and are critical for a vast array of functions that span structure, electron transfer, and catalysis. In an effort to reproduce and exploit this activity in vitro, described herein are versatile bacteriophage Qβ particles bearing metal-binding motifs polyvalently. The three motifs, His_6, His_6-His_6, and Cys-His_6, were incorporated into the capsid via a coexpression methodology at ratios of 1.1:1, 1.1:1, and 2.3:1 for wild-type to modified coat protein. Size-exclusion chromatography yielded elution profiles identical to wild-type particles, while Ni-NTA affinity chromatography resulted in retention times that increase according to Qβ-His_6 < Qβ-Cys-His_6 < Qβ-His_6-His_6. In addition to interacting with metal-derivatized surfaces, Qβ-Cys-His_6 and Qβ-His_6-His_6 bind heme as evidenced by the appearance of new absorbances at 416 and 418 nm, respectively, upon addition of hemin-Cl. The heme-bearing particles were also found to be electrochemically active as a surface-confined system. While both constructs yield similar $E_{1/2}$ values anaerobically and with carbon monoxide present, and both display similar pH dependences, a standard rate constant $k°$ could only be measured for Qβ-Cys-His_6 (83 s^{-1}), as electron transfer for Qβ-His_6-His_6 was too rapid to estimate. Experiments with rotated-disk electrodes yielded significant activity of the constructs toward dioxygen reduction. The versatility of the particles is further underscored by their multivalent nature, permitting simultaneously a range of activities for applications demanding polyfunctionality.

INTRODUCTION

The critical physiological functions performed by endogenous metal-binding proteins has resulted in decades of research aimed at attempting to recapitulate this activity in vitro in order to both understand and exploit native functions (*1–4*). Harnessing such activity can prove difficult, with key challenges that include design/preservation of catalytically competent centers, activation of these centers (photochemically, electrochemically), immobilization (facilitating stability, separation, etc.), longevity, and optimization of activity (*5*). Hence, there remains great interest in developing alternative (semi)artificial systems that can perform the desired functions (*6–11*). In view of this goal, exploiting reliably self-assembling biological structures is especially attractive; specifically, virus capsids provide convenient polyvalent nanoparticle platforms for building a variety of materials (*12–14*). A handful of groups have demonstrated the potential of these scaffolds with reports that include virus-based batteries (*15*), charge transfer mediators (*16*), catalysts (*17*), and metal nanopatterning (*18*).

The versatile polyhistidine motif has seen primary use in protein purification (*19, 20*), but has also demonstrated utility in areas that include immobilizing redox-active proteins for biosensors (*21*) and cell uptake of antibody−marker conjugates (*22*). More recently, two specific studies describe attempts to engineer metal-binding sites into virus-like particles utilizing this motif. The first appended hexahistidine tags to the hepatitis B virus (HBV[1]) capsid protein (*23*). The added motif was well-tolerated as evidenced by the ability of the particle to assemble while possessing the hexahistidine tag on each of the 80 coat protein subunits. The construct was capable of binding heme moieties via bis-histidine ligation and displayed spectroscopic and electrochemical behavior analogous to that of c-type cytochromes. Interestingly, the chelating tags were apparently not sufficiently accessible to interact with metal-derivatized surfaces, as demonstrated by the inability of the particles to be retained on Ni-NTA substrates. Alternatively, the second notable study incorporated hexahistidine motifs into the capsid of bacteriophage Qβ (Qβ) (*24*). Unlike HBV, displaying hexahistidine tags on Qβ was only achievable using a coexpression methodology (Scheme 1). This yielded particles with variable ratios of wild-type to modified coat proteins where the final ratio is governed by the spontaneous capsid self-assembly process. In contrast to HBV, this clearly indicates that having hexahistidine tags at each of the 180 coat proteins that make up the Qβ capsid is far too disruptive to particle assembly. Similarly divergent and intriguing were the recorded observations: while capable of interacting with a series of metal-derivatized surfaces, the engineered Qβ virions displayed no

propensity to bind metallocycles in solution. As such, in an effort to generate truly versatile platforms, described herein are engineered Qβ capsids that combine all of the aforementioned activities.

EXPERIMENTAL PROCEDURES

Mutagenesis, Protein Expression, Virus Purification, and Characterization. Mutagenesis and cloning protocols proceeded as previously described, using the same forward primer (*24*). Reverse primers were ATA *CTC GAG* TTA GTG GTG GTG GTG GTG GTG GCC ACT GCC ACT GCC ATG ATG ATG ATG ATG ATG TCC TGA and ATA *CTC GAG* TTA GTG GTG GTG GTG GTG GTG GCC ACT GCC ACT GCC ACA TCC TGA TCC TGA TCC ATA CG for Qβ-(His_6-His_6) and Qβ-(Cys-His_6), respectively (restriction sites italicized, priming regions underlined). For Qβ-(His_6-His_6), the previously constructed Qβ-(His_6) was used as the template for PCR.

Protein expression and purification proceeded as previously described (*25*), except instead of ultracentrifugation the particles were purified from sucrose gradients via a second ammonium sulfate precipitation. For expression experiments with Qβ-(Cys-His_6) in the presence of added metals, growth media were supplemented with 0.5 mM of either Hg_2Cl_2, $CoCl_2$, or δ-aminolevulinic acid. Protein was quantified using the Modified Lowry Assay (Pierce).

MALDI-TOF MS. 60 μL of 10 M urea and 10 μL of 1 M DTT were added to 40 μL of ~10 mg of virus. The solution was incubated at 37 °C for 1 h, and then dried down in a vacuum microcentrifuge. The samples were resuspended in 0.2% TFA in H_2O (50 μL) and purified with ZipTips (Millipore) by using the following solutions in the manufacturer-specified protocol: wetting solution 50% MeCN in H_2O, equilibration solution 0.2% TFA in H_2O, wash solution 0.1% TFA/5% MeOH in H_2O, elution solution 5 mL of 0.1% TFA/65% MeCN in H_2O. The resulting solutions of purified peptides (1 μL) were spotted onto the MALDI-MS plate with a saturated solution of α-cyano-4-hydroxycinnamic acid (1 μL, in 1:1 MeCN/H_2O).

Chromatography. FPLC was performed using a Bio-Rad BioLogic Workstation. 400 μL of virus at 1 mg/mL in 100 mM KP_i pH 7 buffer was analyzed per FPLC run. Size-exclusion chromatography (Superose 6) was performed at 0.3 mL/min with isocratic elution using 100 mM KPi buffer pH 7. Affinity chromatography was conducted using prepacked 1 mL Ni-NTA columns (GE Healthcare) with elution using a linear gradient of 0 to 0.5 M imidazole in 100 mM KPi buffer pH 7 at 1 mL/min.

Electronic Absorption Spectroscopy. Samples for spectroscopy consisted of 5 μM hemin-Cl (1/1000 dilution from a 5 mM aqueous stock in 25 mM K_2CO_3) and 0.2 mg/mL virus in 100 mM KP_i pH 7. The resulting spectra were corrected for absorption from free heme in solution. Samples were reduced by adding sodium dithionite to a final concentration of 5 mM.

Cyclic Voltammetry. Voltammograms were recorded using a CH Instruments Electrochemical Workstation and a three-compartment cell with AgCl/Ag reference and platinum wire counter electrodes. Voltammetry was conducted in 100 mM KP_i pH 7 argon-degassed buffer unless otherwise stated. Virus-coated glassy carbon working electrodes (5 mm diameter) were prepared by polishing with a 0.3 μm alumina slurry followed by sonication and then drying in air. An aqueous stock solution of 2 mM hemin-Cl with 5% DMSO was diluted to a final concentration of 100 μM into 100 μL of 10 mg/mL virus solution in 100 mM KP_i pH 7. The polished electrode was submerged into the virus-heme solution and incubated overnight at 12 °C. Before conducting voltammetry, the electrodes were gently washed by repeated dipping in buffer.

Electrolyses and Amplex Red Peroxide Assay. Glassy carbon rotated-disk electrodes were polished exactly as electrodes for voltammetry. Heme-virus solutions were also prepared exactly as for voltammetry, except the final solution was then diluted further to 300 μL with 100 mM KP_i pH 7 buffer. Electrodes were incubated in the heme-virus solution overnight at 12 °C. Experiments were conducted at room temperature (20 °C) in a three-compartment cell using silver and platinum wires as pseudoreference and counter electrodes, respectively. The working chamber was filled with 2 mL of air-saturated 100 mM KP_i buffer pH 7 ($[O_2] = 290$ μM at 20 °C), and electrolyses were conducted for 20 min at −0.5 V at various rotation rates under the control of a Pine Instruments rotator. Electrolyses for assaying the amount of hydrogen peroxide produced were performed at 200 rpm. Cyclic voltammograms were recorded before and after rotation. Hydrogen peroxide content after electrolysis was assessed using the manufacturer-specified protocol for the Amplex Red fluorescence assay (Molecular Probes).

RESULTS AND DISCUSSION

The powerful co-expression technique permitted production of Qβ particles possessing the coat protein sequences listed in Table 1, which include the hexahistidine construct previously described (Qβ-(His_6)) (*24*) and particles bearing either C-terminal double hexahistidine (Qβ-(His_6-His_6)) or cysteine-hexahistidine appendages (Qβ-(Cys-His_6)). Expression and purification using established protocols regularly produced ~20 mg of virus per liter of culture, a good yield, although approximately 3-fold less compared to production of wild-type particles. Denaturing SDS-PAGE showed both wild-type and modified coat proteins with the expected sizes and indicated relatively pure preparations (Figure 1). MALDI-TOF analysis of the coat proteins revealed well-defined peaks at the expected molecular masses; relative coat protein ratios were estimated by integration of the peaks (Table 1). Intact particles were

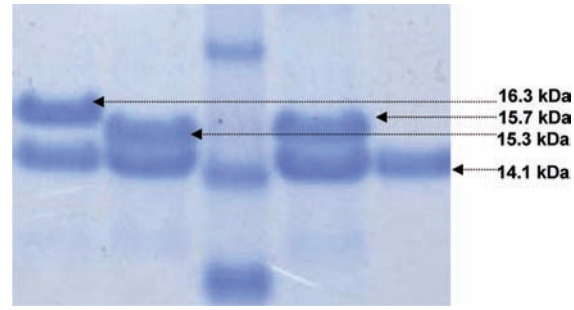

Figure 1. Protein gel (SDS-PAGE) of the purified virus particles showing the coexpressed coat proteins. From left to right: Qβ-(His_6-His_6); Qβ-(His_6); size marker; Qβ-(Cys-His_6); WT.

confirmed by size-exclusion fast-protein liquid chromatography (FPLC), with elution profiles for the mixed particles identical to wild-type (Supporting Information Figure S1). Notably, the ratio of wild-type to fusion coat proteins was not markedly affected by the presence of sucrose, which for some constructs has been shown to alter coat protein ratios (see Udit, Brown, et al. for further discussion).

Virions were found to be stable at 4 °C for months. However, prolonged storage of Qβ-(Cys-His_6) at high concentration (>∼15 mg/mL) resulted in significant aggregation and precipitation, likely via formation of disulfide bonds from the incorporated Cys residues. This is consistent with previous observations for Qβ particles possessing the K16C mutation (most surface-accessible residue (*25*)) in the analogous co-expressed particles, where significant aggregation and precipitation resulted during attempts to purify the virions (data not shown). Indeed, this also suggests a reason for the observed coat protein ratio, as only those particles possessing fewer Cys residues are isolable. To explore the possible stabilizing effects of metals, the Qβ-(Cys-His_6) construct was expressed in the presence of either $CoCl_2$ or Hg_2Cl_2, as well as under conditions typically used for the expression of P450 cytochromes (see Experimental Procedures section for details). No benefits were observed using these protocols, as the purified particles possessed similar coat protein ratios to those expressed under regular conditions (Supporting Information Figure S2). Furthermore, while dilute virus samples were soluble, the addition of 50 μM heme to samples of virus at greater than 2 mg/mL (∼0.8 μM particles) in 0.1 M KP_i pH 7 resulted in aggregation of the particles. The virus-heme aggregates could be partially redispersed by adding DMSO to 20%.

Qβ-(His_6) particles were previously found to interact strongly with metal-derivatized surfaces (*24*). Similar behavior was anticipated and confirmed for the new viruses generated here. The observed retention times during chromatography using Ni-NTA resins are listed in Table 1. Qβ-(His_6-His_6) displayed the longest retention time, consistent with it possessing the greatest number of hexahistidine motifs. Interestingly, Qβ-(Cys-His_6) exhibited the second longest retention time despite it possessing fewer hexahistidine tags compared to Qβ-(His_6). This may indicate that the thiol also participates in binding to the Ni-NTA resin, analogous to prior studies on proteins that display Ni(II)-thiol ligation (*26*). By extension, one can draw comparisons to well-known metal-binding structural motifs in nature (e.g., zinc fingers (*27*)).

As mentioned above, a key motivation for this work was to generate particles that could coordinate heme. While the wild-type and Qβ-(His_6) particles showed no evidence of heme binding (*24*), adding heme to samples of Qβ-(His_6-His_6) and Qβ-(Cys-His_6) immediately gave rise to distinct color changes: the broad absorption maximum at ∼390 nm for free hemin-Cl was replaced by well-defined peaks at 418 and 416 nm for Qβ-(His_6-His_6) and Qβ-(Cys-His_6) (Figure 2), reminiscent of the ferric state of typical heme proteins (e.g., P450, cytochrome c) (note: attempts to resolve the Q-band region were unsuccessful). Consistent with this were the approximate 10 nm red shifts of the absorption maxima upon addition of sodium dithionite, indicative of reduction to ferrous heme (data not shown). Notably, the concentrations used (5 μM hemein-Cl and 0.2 mg/mL virus, 14.2 μM total subunit) did not lead to noticeable aggregation. Although the precise extinction coefficients are not available, values for the analogous cytochrome c and P450 proteins are known to be similar (∼100 mM^{-1} cm^{-1}) (*28–30*). Given this, the relative magnitudes of the absorption maxima are also consistent with the differences in coat protein ratios, as Qβ-(His_6-His_6) displays 1.7 times the absorption intensity

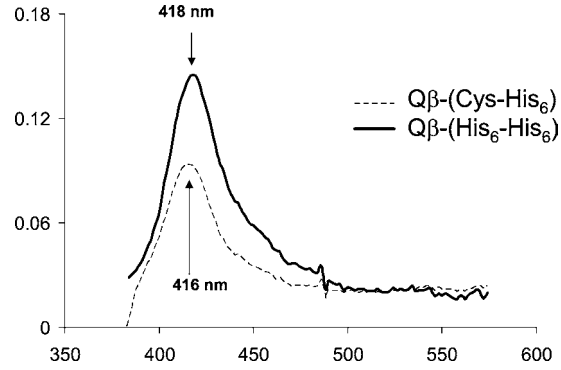

Figure 2. UV−visible absorption spectra of 0.2 mg/mL Qβ particles with 5 μM hemin-Cl recorded in 100 mM KP_i pH 7 buffer with 25 μM K_2CO_3. Spectra are corrected for background absorption from free hemin-Cl.

and possesses 1.3 times as many coat protein fusions compared to Qβ-(Cys-His_6) (note: preparing samples for ICP-MS analysis in order to determine the number of hemes per particle proved intractable due to difficulties in separating free heme from heme-saturated protein solutions via dialysis and size-exclusion chromatography).

Significantly, the Qβ-(His_6-His_6) and Qβ-(Cys-His_6) particles accomplish what the previously reported Qβ-(His_6) and HBV-(His_6) particles could only do uniquely; that is, while Qβ-(His_6) could only interact with metal-derivatized surfaces and HBV-(His_6) could only coordinate heme, the two new particles generated here can perform both functions. Presumably, this is a consequence of placing metal-coordinating ligands (bis-His or Cys-His) in good proximity to each other by having them appear at adequately spaced positions along the same peptide sequence.

The ability to chemically reduce the heme suggested that electrochemical activity may be possible if the heme groups were sufficiently exposed. Thus, samples of 100 μM heme and ∼10 mg/mL virus (700 μM total subunit) were incubated with glassy carbon electrodes at 4 °C overnight. Subsequent voltammetry yielded strong responses for both virus-heme samples: representative voltammograms are shown in Figure 3 and a summary of the electrochemical data is presented in Table 2. Notably, the well-defined voltammogram in Figure 3a is distinct from that of electrodes incubated with only hemin-Cl which yielded a quasi-reversible response (Supporting Information Figure S3). The redox active virus-heme complexes appeared to be surface-confined, as plots of peak current versus scan rate were linear. Given the diameters of the electrode (5 mm) and virus (approximately 30 nm), monolayer coverage would result in 4.6×10^{-14} mol of particles on the surface (9.5×10^{-12} mol of subunits), assuming a close-packed arrangement. By integrating the voltammograms to ascertain the amount of charge passed during each sweep and dividing this number by the value for theoretical monolayer coverage, one obtains average values of 361 and 326 mol of electrons per mole of particle for Qβ-(His_6-His_6) and Qβ-(Cys-His_6). As each particle contains 180 subunits and only a fraction of these per particle have heme binding sites, and since substoichiometric quantities of heme were used to avoid direct cofactor adsorption, this indicates that greater than monolayer coverage has been achieved.

Interestingly, the two constructs display similar electrochemical behavior, as both have comparable half-wave potentials under degassed and CO-saturated conditions (note: while potential shifts were observed in the presence of CO, no changes in the absorption spectra were noted; this may indicate that the virus-heme complexes can more readily participate in ligand exchange when confined to the electrode surface). Also, both

catalytically reduce dioxygen at similar potentials (Figure 3b), although qualitatively, Qβ-(His_6-His_6) displayed greater catalytic currents, consistent with it possessing more heme sites per particle. The comparable behavior observed is not entirely unexpected, as surface effects are known to strongly influence the electrochemical behavior of heme proteins on electrodes (*31–34*); the effect is likely to be magnified in this case, as the heme sites should be displayed on the surface of the viruses and are thus largely influenced by the immediate microenvironment of the solvent and electrode. Conversely, significant differences were observed in the standard rate constants ($k°$). Laviron's theory (*35*) was used to evaluate $k°$, which provides an estimate of this value for surface confined systems when the peak separation exceeds 200 mV. At 30 V/s (note: interpretable voltammograms were not obtained above this scan rate), $k°$ for Qβ-(Cys-His_6) was found to be 84 s^{-1}, while a value was not estimated for Qβ-(His_6-His_6), as the peak separation was only 160 mV. Thus, heme−electrode electron transfer appears to be faster for hemes bound to Qβ-(His_6-His_6) compared to Qβ-(Cys-His_6). This is reminiscent of analogous biological systems where bis-His coordinated heme groups are often associated with rapid electron transfer reactions (e.g., cycotchrome c) while cysteine-ligated hemes serve other purposes, such as catalysis (e.g., P450 cytochromes) (note: Raman spectroscopy was attempted in an effort to further distinguish bis-His vs Cys-His ligation; however, data acquisition proved difficult given the inability to achieve high concentrations and the propensity of the samples to aggregate over time). The ability to mimic such behavior in the virus-heme system alludes to the potential for fine-tuning the observed activity by, for example, mutation to alter the heme electronic environment.

The strong catalytic response of the virus-heme complexes to dioxygen was further explored using rotated-disk electrodes. While prolonged rotation at 400 rpm lead to a gradual decrease in catalytic activity, within the measurable window the catalytic currents for both virus-heme complexes were strong and well above background (Supporting Information Figure S4). Qβ-(His_6-His_6) was found to draw the greater current during electrolysis in air-saturated buffer, consistent with it possessing more heme binding sites per particle compared to Qβ-(Cys-His_6) and in agreement with the qualitative interpretation of the aerobic cyclic voltammograms (discussed above).

Given the different standard rate constants observed, the mechanisms and products of dioxygen reduction for each construct could be markedly different (*36*); indeed, of specific interest is the possibility of dioxygen activation for substrate oxidation (note: heme-mediated dioxygen reduction presents the possibility of dioxygen activation followed by substrate oxidation; preliminary electrolyses using styrene and thioanisole as substrates did not yield any oxidized products). The nature of the dioxygen reduction reaction was examined via electrolysis and the Amplex Red fluorescence assay for peroxide. Electrolyses were conducted with films on rotated-disk electrodes at 200 rpm and −0.5 V (vs AgCl/Ag) for 20 min followed by Amplex Red analysis of an aliquot from the reaction. Using the coulometric data acquired, the total charge passed was used to calculate the moles of peroxide that should have been formed presuming that all of the electrons were used for this purpose; this value was then divided by the moles of peroxide found via Amplex Red. The calculations yield ratios of theoretical peroxide (via coulometry) to measured peroxide (via Amplex Red) for the virus-heme complexes of 0.6 ± 0.2, 12 ± 5, and 11 ± 3 for the negative control (bare electrode), Qβ-(His_6-His_6), and Qβ-(Cys-His_6), respectively. The data therefore indicate that the virus-heme complexes are consuming far more charge than what can be accounted for by the peroxide present in solution. One possible explanation is that the unaccounted charge does indeed yield peroxide, which is then consumed via oxidative damage to the protein; alternatively, the electrons may be used to generate water, analogous to prior studies (*37–39*) (note: ideally, one would use rotated ring-disk electrodes to characterize the dioxygen reduction reaction; however, the instability of the films to prolonged rotation makes this unfeasible). It is presently unclear how this reaction proceeds. Reduction at either the heme periphery or the iron center are possible, although the latter mechanism would require ligand exchange, presuming a coordinatively saturated heme.

In summary, by exploiting a coexpression methodology it was possible to polyvalently display versatile metal-binding motifs on bacteriophage Qβ. The capsid self-assembly process and the resulting stability of the particle resulted in twice as many His_6-His_6 peptides tolerated compared to Cys-His_6, which leads to longer retention on Ni-NTA resins for Qβ-(His_6-His_6). Following heme-binding, it was possible to characterize the particles electrochemically, with both virus-heme complexes exhibiting good catalytic activity toward dioxygen reduction. Although the two particles did not display markedly divergent properties, it is likely possible to fine-tune/alter this activity by selectively mutating the coat protein; for example, incorporating hydrogen bonding residues adjacent to the heme-binding moieties may modulate catalytic activity (*36, 40*). Indeed, this further extends the potential applications: that the particles interact with both metallocycles and immobilized metals, one can easily look toward applications such as immobilizing the particles onto a surface while simultaneously binding a cofactor for catalysis. The potential benefit is further magnified given the polyvalent nature of the scaffold employed.

ACKNOWLEDGMENT

This work was funded by the American Chemical Society Petroleum Research Fund (ACS PRF UNI to AKU), the Dreyfus Foundation (startup grant to AKU), and the HHMI (undergraduate education grant). We are grateful to Mike Hill, Chris Craney, and Aram Nersissian (Occidental College) for use of their facilities; Weidong Wang (Occidental College) for technical support; Mona Shagholi (Caltech) for assistance with MALDI-TOF MS; Don Walker (Caltech), and Hannah Shafaat and Judy Kim (UCSD) for preliminary Raman experiments.

Dendrimers for Vaccine and Immunostimulatory Uses. A Review

Peter M. H. Heegaard,*,† Ulrik Boas,†,‡ and Nanna Skall Sorensen†

Innate Immunology Group, National Veterinary Institute, Technical University of Denmark, Copenhagen, Denmark, and Chemical Institute, University of Copenhagen, Copenhagen, Denmark. Received July 3, 2009; Revised Manuscript Received September 14, 2009

Dendrimers are well-defined (monodisperse) synthetic globular polymers with a range of interesting chemical and biological properties. Chemical properties include the presence of multiple accessible surface functional groups that can be used for coupling biologically relevant molecules and methods that allow for precise heterofunctionalization of surface groups. Biologically, dendrimers are highly biocompatible and have predictable biodistribution and cell membrane interacting characteristics determined by their size and surface charge. Dendrimers have optimal characteristics to fill the need for efficient immunostimulating compounds (adjuvants) that can increase the efficiency of vaccines, as dendrimers can provide molecularly defined multivalent scaffolds to produce highly defined conjugates with small molecule immunostimulators and/or antigens. The review gives an overview on the use of dendrimers as molecularly defined carriers/presenters of small antigens, including constructs that have built-in immunostimulatory (adjuvant) properties, and as stand-alone adjuvants that can be mixed with antigens to provide efficient vaccine formulations. These approaches allow the preparation of molecularly defined vaccines with highly predictable and specific properties and enable knowledge-based vaccine design substituting the traditional empirically based approaches for vaccine development and production.

VACCINES: SOME CHALLENGES AND PROMISES

Infectious diseases continue to pose problems to human and animal populations, although they have been known for a long time, with the associated phenomenon of inflammation being among the earliest described medical symptoms, and although the universal principle of preventive action, vaccination, has been around for more than 300 years. Then known as variolation (*1*), this covers the rather delicate practice of preventing infectious disease by injecting infectious material into an individual. A vaccine traditionally contains pathogens (microbial agents that can cause disease) modified in a way that makes the pathogen lose its disease inducing capacity while at the same time maintaining a sufficient similarity with the unmodified pathogen to provoke the vaccinated host to become immune to disease through the actions of the immune system of the host.

Vaccination has proven to be a very cost-effective way of controlling infectious diseases caused by microbial pathogens and has been known in its modern form since the pioneering work in the late 18th century when Jenner introduced vaccinia (cowpox virus) as the first reliable vaccine (*1*). Subsequently, a range of other successful vaccines have been developed, empirically, on the basis of attenuated or killed microorganisms or their toxins. Nevertheless, efficient vaccines are still lacking against HIV[1] , tuberculosis, malaria, and a range of respiratory and intestinal infectious diseases.

Vaccination has had great successes, for example, resulting in the eradication of smallpox (officially declared extinct in 1980) and the dramatic decrease in formerly widespread diseases like polio, measles, and rinderpest (cattle disease). Even so, a wide range of infectious diseases are still abundantly present around the globe (malaria, tuberculosis, and bacterial and viral diarrhea being the most widespread). Such diseases are generally caused by complex pathogens where a more rational approach in vaccine design is needed (*2*). Some of these "difficult" pathogens attack the immune system itself or are able to change rapidly to avoid the immune system.

There is therefore a growing need for new-generation vaccines to target these infectious diseases. With an increased knowledge of the molecular actions of the immune system, there is now a unique possibility to exploit well-defined chemical methods to create such new vaccines with optimal qualities.

INTERACTIONS BETWEEN THE INNATE AND THE ADAPTIVE IMMUNE SYSTEM

The immune system is a complex of organs, cells, and molecules involved in the difficult task of controlling host defenses against infection. On one hand, it has to react promptly toward different groups of pathogens by mounting different types of protective effector responses. On the other hand, it has to ignore self-antigens and innocuous environmental antigens and microorganisms from food and environment. The decision of whether to react or not is governed by the innate immune system (*3*). This is composed of cellular actors like macrophages and granulocytes, which have the ability to take up and kill ("phagocytose") microbes, and of soluble mediators, such as the complement system and antimicrobial peptides, which function by flagging microbes for phagocytosis or by directly killing them (*4*). The innate immune system, in collaboration with tissue cells, acts as the first line of defense against pathogens (*3*).

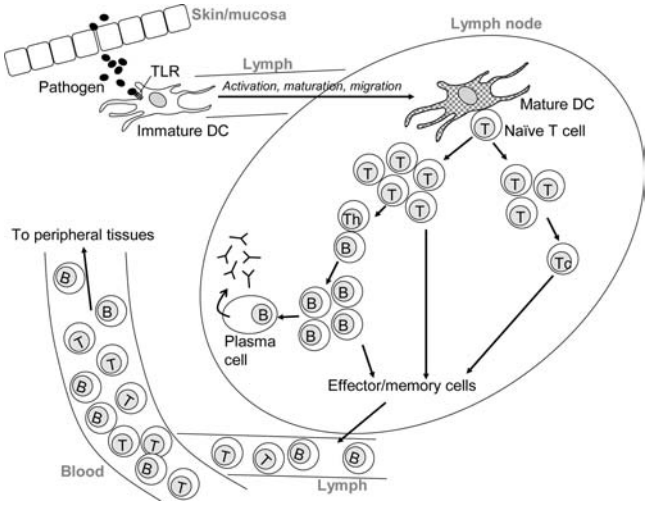

Figure 1. The general "physiology" of an immune response, including the innate response of dendritic cells (DC) at the site of infection through interaction of the pathogen with Toll-like receptors (TLR) and the following adaptive responses located in the lymph nodes resulting in the production of antigen-specific effector cells and molecules transported through the lymphatics and the blood vessels to the infection site.

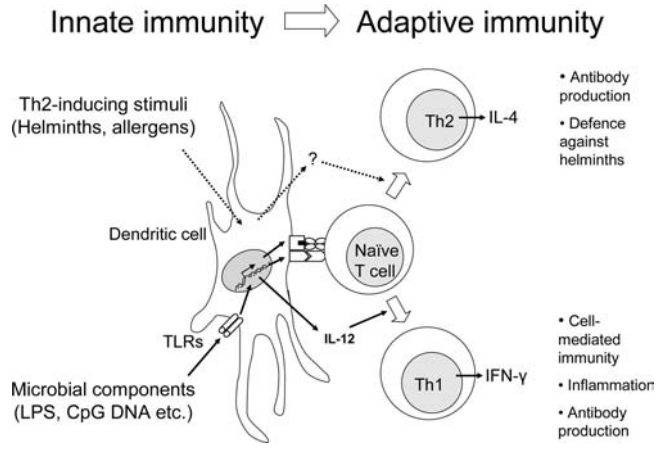

Figure 2. The concept of the polarization or biasing of the adaptive immune responses characterized by the proliferation of different T cell subsets secreting distinct patterns of soluble immune mediators (cytokines) as a result of differences in the nature of the initial microbial stimulus.

Throughout evolution, the innate immune system has developed the ability to become activated by recognizing highly conserved molecular structures specific to microbes (so-called pathogen-associated molecular patterns, or PAMPs) (*5*) by corresponding pattern recognition receptors including the Toll-like receptors (TLR). Binding of PAMPs triggers a fast innate immune response, producing molecular signals that report on the nature of the threat and control the ensuing early defense mechanisms as well as the balance of the subsequent adaptive immune responses (*3*). The adaptive immune system consists of T cells and B cells, which both use receptors with a wide range of specificities. T cell receptors recognize the complex of short peptides (= T cell epitopes) bound to MHC (major histocompatibility complex)-molecules on the surface of APCs (antigen presenting cells). B cell receptors are also secreted as antibodies which are the soluble version of the specific receptor from a given B cell. Antibodies as a protein class are known as the immunoglobulins, and they constitute the active component of humoral (soluble) immunity. In contrast to the T cell receptors, binding of antigens to B cell receptors (and antibodies) is not dependent on their prior binding to MHC molecules, i.e., their binding is not MHC-restricted. A B cell epitope is the site of an antigen molecule that is directly involved in the binding by a particular antibody. An antigen is, however, only an immunogen if it is able to induce an immune response. Functionally, an adaptive immune response comprises the production of antibodies by antigen-specific B cells generally aided by T helper cells in the following way: Upon binding of a protein antigen by the B cell receptor, the B cell will degrade it into peptides and load these onto MHC molecules on its surface, and only if an antigen-experienced (also known as a primed) T helper cell recognizes the peptide-MHC-complex will the B cell be licensed to produce its antibodies (see Figure 1). Such antibody responses are T cell dependent. Thus, although any structure can be recognized as an antigen, only protein-based antigens elicit efficient, full-fledged adaptive immune responses, because only proteins and peptides can engage the T cells required. Therefore, in order for non-protein structures to induce an adaptive immune response and immunological memory, such structures have to be attached to a protein (or peptide) carrier. The priming process is governed by dendritic cells (DCs) (reviewed in ref *6*) and DCs are the only cells that can serve as efficient antigen-presenting cells for this process (*6, 7*). As an example and as shall be seen below, this has formed the basis for a number of carbohydrate−peptide constructs rendering otherwise nonimmunogenic oligosaccharide antigens immunogenic. This is of considerable interest, as carbohydrate antigens are found on, e.g., tumor cells and viruses and have great biological and medical significance.

As a part of the innate immune system, the DCs form networks throughout the body along the skin and mucosal surfaces where they continuously take up antigens from their surroundings serving as sentinels and initiators of the adaptive immune response. Detection of microbes by TLRs on the DCs up-regulates surface expression of MHC molecules presenting pathogen-derived peptides and of co-stimulatory molecules (*3*). During an infection, large numbers of DCs activated in this way will migrate to the nearest draining lymph node, where they interact with and prime only the T cells that are specific for the presented peptides. The general "physiology" of this process is depicted in Figure 1. In addition, the binding of PAMPs to TLRs on DCs induce their release of various soluble mediators (cytokines and chemokines), which will influence the nature of the developing response (*3, 6, 8*). As a result, different effector T helper (Th) cell subsets will develop to promote different types of adaptive responses. A range of pathogens induce DCs to produce IL-12 and other inflammatory cytokines promoting the development of a Th cell subset called Th1 cells. Th1 cells are characterized by their production of interferon- (IFN-) γ. IFN-γ promotes cell-mediated immunity by activating macrophages and by inducing specific subsets of antibodies that enhance macrophage uptake and clearance of pathogens, and by helping to induce cytotoxic T cells. Other types of stimuli (*9*) will not result in the production of inflammatory mediators and will induce Th2 cells producing IL-4, IL-5, and IL-13 promoting another type of immunity characterized by antibody subtypes that can neutralize extracellular pathogens and toxins (*8, 10*) (see Figure 2).

The ability of DCs to take up and present soluble protein antigen in vivo is facilitated by the physical association between the TLR ligand and the protein in question (*11*). In addition, the efficiency of processing and presenting antigens from phagocytosed cargo appears to depend on the presence of TLR ligands within the same cargo (*12*). This means that antigen and TLR ligand have to be associated within the same molecular complex in order for the TLR ligand to efficiently enhance the immunogenicity of the antigen.

Table 1. Different Types of Conventional Adjuvants Classified after Dominant Mode of Action

delivery systems (aggregated/particular)	membrane active adjuvants
Freund's incomplete adjuvant water-in-oil susension aluminum salts liposomes ISCOMs[a] Polymers (PLG[b,c]), etc.)	saponins (quil A, tomatine a.o.) monophosphoryl lipid A[a] DDA[b]
immunomodulatory adjuvants	**mixed mode**
muramyl dipeptide cytokines nonmethylated CpG nucleotides	Freund's complete adjuvant oil-in-water suspensions RIBI, SAF, Titermax, Emulsigen, and others)

[a] Also immunomodulatory. [b] DDA: dimethyldioctadecylammonium bromide. [c] PLG: poly (lactide-*co*-glycolide).

Effector T cells, in contrast to naive T cells, will not enter lymph nodes and instead migrate to relevant nonlymphoid tissues to execute their effector functions (*8, 10*). Importantly, after a microbe has been cleared a subset of effector T cells survives and differentiates into long-lasting memory T cells that are able to respond rapidly to low doses of antigen even in the absence of co-stimulation (*8, 10*). Likewise, memory B cell responses are faster and result in higher-affinity antibodies of subclasses efficiently linking up with cellular immunity (*8*). Thus, immunological memory is a state characterized by enhanced numbers of long-lived and optimally reactive antigen-specific T and B cells and long-lived plasma cells producing high-affinity antibodies (*2, 13*).

VACCINES AND ADJUVANTS

Vaccines are nonpathogenic imitations of pathogens, which, when administered to a host (vaccination), induce immediate as well as long-lasting immunity (host resistance) against the pathogen. This is based on the ability of the immune system of the host to adapt to and thereby *remember* infectious challenges. Modern vaccine design relies on the careful selection of one or a few subunits of the pathogen (antigens). As subunits are often weak immunogens, they normally have to be formulated using adjuvants (latin, adjuvare = to help), i.e., substances enhancing immune responses to antigens mixed with them. Adjuvants can either be delivery systems or immune potentiators (*14*). Delivery systems in general function by aggregating and/or polymerizing antigens, minimizing their spreading from the injection site, increasing their half-life and enhancing their uptake and processing by local antigen-presenting cells (APCs, see below) (*14*−*16*). Immune potentiators may be microbial products or their synthetic versions, or endogenous immunoactive compounds, such as cytokines, chemokines, or costimulatory molecules (*14*). The development of adjuvants has, like that of vaccines, generally been empirically based, and to a large extent, the most efficient adjuvants are complex and somewhat undefined mixtures of surface-active compounds, microbial components, and/or various polymers and lipids (see Table 1), most of which cannot be approved for human use.

An exception is adjuvants based on aluminum salts, broadly referred to as alum, which have good safety profiles with relatively mild side effects and therefore can be applied for human use (*14*). Alum functions as an aggregate delivery system promoting increased uptake by APCs and a Th2 biased antibody production (see below). Next to alum, emulsions of water-in-oil or vice versa stabilized by surfactants are most frequently used (*16*). With a range of important infections, a Th1 response (see below) is needed to obtain protection against disease, but safe and efficient Th1 inducing adjuvants are generally lacking or unsuitable for human use, an example being Freund's complete adjuvant (*16, 17*). Well-known delivery systems include liposomes and microparticles, which are inert carriers of antigen unless immune potentiators have been added to them (*16*). Examples of promising immune potentiators are microbe-derived structures like monophosphoryl lipid A and unmethylated CpG oligonucleotides (*16*). Immune potentiators also may be employed as targeting devices leading the immunogen to optimal antigen presenting cells, e.g., at mucosal surfaces.

Whether a relevant immune response and an ensuing immunological memory directed against the desired antigens will actually provide protection against pathogen-induced disease is dependent on many factors. Early and topically precise responses at the initial site of infection are highly efficient, as the race between the kinetics of a memory-based immune reactivation and pathogen-driven disease development is decisive in the outcome of the infection (*13*). If pre-existing antibodies are present to neutralize a pathogen or its toxins early in the establishment of the infection, vaccine induced immunity boosted at the same time by the infection will cooperate with the pre-existing antibodies to eradicate the pathogen (sterilizing immunity) (*2*). Systemic and mucosal immunity can play together in this, the most efficient immunity achievable to completely prevent establishment of infection.

In order to improve vaccines for the future, there is a need for development of efficient and safe adjuvants for induction of Th1-biased responses, and for inducing immunity at mucosal surfaces. Furthermore, such new adjuvant systems should preferably be molecularly defined. Delivery systems may be combined with immune potentiators to induce Th1-biased immune responses. However, the challenge is to develop adjuvants that are as simple, definable, stable, safe, and generally usable as possible and at the same time in a very efficient way induce the complex responses needed for the creation of optimal immunity. On the basis of relevant scientific and patent literature, the use of highly branched, synthetic polymers known as dendrimers for this purpose is described here.

DENDRIMERS: HISTORY AND STRUCTURES

Dendrimers are a relatively new class of well-defined (i.e., monodisperse) hyperbranched polymers first developed under the name cascade polymers by the group of Vögtle in 1978 (*18*). These initially small hyperbranched molecules constitute the foundation for the later design of polypropylene imine (PPI) dendrimers, developed by the Meijer and Mühlhaupt groups in the early 1990s (*19, 20*). In 1983, Tomalia et al. reported on a new class of dendrimers based on a mixture of amines and amides, the so-called polyamido amine dendrimers, commonly known as PAMAM dendrimers (*21*). A number of other dendrimer designs were reported by various research groups during the 1980s and 1990s, and the development of new dendrimer designs is still ongoing (for an early alternative to PPI and PAMAM dendrimers, see ref *22*).

The dendritic theme was, early in dendrimer history, already taken up by chemists working in the biosciences. In 1988, Tam and co-workers developed the multiple antigen peptide (MAP) system; a dendrimer (or dendron) based on lysine as the monomer (*23a*) and several peptide-based dendrimer designs emerged later (*23b*).

The general structure of dendrimers comprises a well-defined branching pattern from the core and out toward the periphery. The branching defines the dendrimer "generation", with generation 1 being the dendrimer containing only one layer of branching points. The branching principle means that addition of one new branching shell, i.e., an increase in dendrimer generation, will also lead to a doubling of the number of functional groups on the surface of the dendrimer. A fifth-generation PAMAM dendrimer or, more briefly, a G5-PAMAM

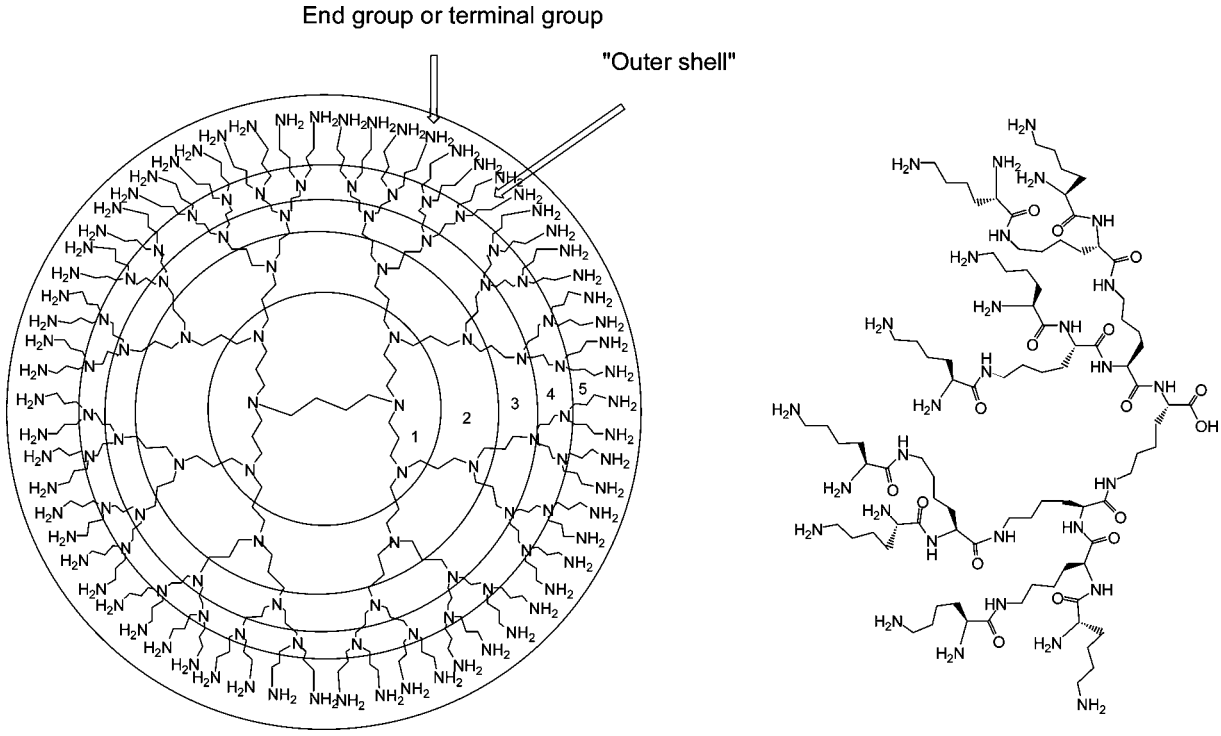

Figure 3. Two examples of dendrimer designs. Left: A G5-PPI (generation 5 poly(propyleneimine)) dendrimer; generations ("shells") are indicated. Right: multiple antigen peptide (MAP) dendron.

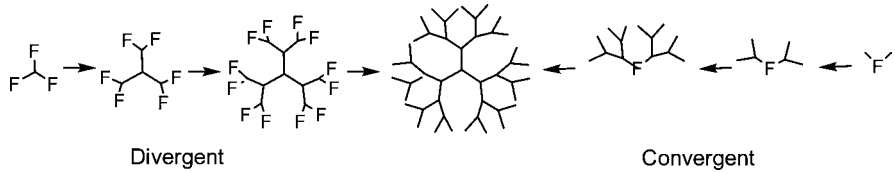

Figure 4. Divergent versus convergent strategy for synthesis of dendrimers. F: "focal points", i.e., starting or branching points where a new shell may be formed either by attaching new "branches" (divergent synthesis) or by coupling entities together to form a bigger dendron (convergent synthesis).

thus contains five branching shells. The inner structure of globular dendrimers is organized into so-called dendrons, which are "tree-shaped" molecular "subgroups" of the dendrimer (see Figure 3). The PAMAM and PPI dendrimer design has a symmetric spherical structure, but other designs as, e.g., the MAP dendrimer are more dendron-like (i.e., tree-shaped) in their design. As a consequence of the intense branching in the dendrimer structure, the higher-generation dendrimers become increasingly globular in structure, with a high number of functional (i.e., terminal) groups displayed at the surface. In the higher-generation dendrimers (G > G3), the dendrimer structure becomes progressively more compartmentalized, with a core region increasingly shielded off from the surrounding solution by the outer shell (the molecular area just beneath the surface), which becomes much more molecularly dense with higher generations.

Dendrimers exhibit a highly multivalent surface conferring a strong potential for interactions with the surroundings. In biology, this property can be rationally exploited, e.g., using dendrimers carrying multiple surface ligand molecules leading to stronger binding per ligand unit compared to the corresponding monomeric ligand. This synergistic increase in binding affinity is due to the preorganization of the ligands at the dendrimer surface, which reduces the loss in entropy upon binding to the dendrimer. This phenomenon is called "the dendritic effect" (also known as the "chelate effect" or "cluster effect"). Dendrimers are flexible molecules varying in hydrodynamic volume depending of solvent type (polarity), salt concentration, and pH, i.e., the dendrimer can show environmentally sensitive extended or contracted conformations. This behavior is intimately connected with the chemical buildup of the dendrimer, with some dendrimers contracting at physiological conditions and others increasing their volume.

Synthesis of Dendrimers. Generally, dendrimers can be synthesized by two approaches. The approach initially applied in the synthesis of PPI and PAMAM dendrimers is called the divergent strategy (Figure 4, left part) in which the dendrimer is synthesized starting from the core and functionalized out toward the periphery. This method has the drawback that the strongly increasing number of reaction points (i.e., surface functionalitites) as a result of the hyperbranching strongly increases the risk of introducing deletions in the structure. Such defective dendrimers are difficult to remove from the final product mixture because of the great molecular similarity with the product. To circumvent this problem, an alternative approach was developed by Hawker and Fréchet relying on the synthesis of the dendrimer from the surface and inward, i.e., the synthetic sequence ends up by joining two or more large dendron segments together at the core to synthesize the final dendrimer (Figure 4, right part). This approach was named the convergent approach (*24*) and has the advantage that intermediate purification is facilitated because of the larger molecular difference (large difference in molecular size and polarity) between the product and the reactants.

Biocompatibility of Dendrimers. For application of dendrimers for biological or biomedical purposes, including therapy,

diagnostic purposes and vaccination, their biocompatibility, i.e., cytotoxicity, immunogenicity, and ability to penetrate various physiological and cellular barriers (including cell membranes), their biodistribution and biological fate (half-life in circulation, excretability, etc.) is of obvious interest.

As a rule, the dendrimer interior structure is to a large extent shielded from the surroundings by the outer shell and the surface, meaning that the biological properties of a dendrimer to a large extent are governed by the characteristics of the surface groups and of the size of the dendrimer. Amino surface groups interact strongly with biological membranes as a result of their highly positive charge and the negative charge of most cell membranes resulting in a high cellular uptake of these molecules by endocytosis. However, with higher-generation (G > G3) amino terminated dendrimers their membrane affinity leads to a more destructive interaction with the membrane resulting in cellular lysis and high cytotoxicity both in vitro and in vivo. The opposite behavior is observed with dendrimers having negatively charged surfaces, e.g., carboxylic acid surfaces. These dendrimers do not interact with most cellular surfaces and hence do not show significant generation dependent cytotoxicity. Noncharged groups may be divided into polar and nonpolar groups, polar membrane noninvasive groups like poly(ethylene glycol) (PEG) chains resulting in a nontoxic behavior of the dendrimer, whereas nonpolar groups as, e.g., lipids interact with the cellular membrane by hydrophobic interactions, in some cases rendering the dendrimer cytotoxic. However, lipids, being an important part of, e.g., bacterial surfaces and molecular targets of the immune system can endow dendrimers with immunostimulating properties (see below). Generally, dendrimers with higher molecular size show a lower biopermeability, regardless of the nature of their surface groups, and in vivo, high-generation dendrimers have high clearance rates from the body via renal excretion, as their size and lack of flexibility result in limited permeability of these dendrimers into the tissues (for a more thorough discussion on this matter, see ref *25*). This results in high levels of dendrimer being deposited in the organs (e.g., liver and kidneys) before excretion. High-generation dendrimers having noncharged PEG chains or negatively charged carboxylate groups on their surfaces show no toxicity. Carboxylate surfaced dendrimers are cleared more rapidly from the bloodstream and deposited into the organs compared to PEG modified dendrimers. The longer blood circulation times of the PEG covered dendrimers are presumably due to the noninvasive character of PEG, which reduces interaction with the vascular walls. High-generation cationic dendrimers (G > G6) may cause problems of toxicity in vivo (*26*). In addition to the tissue toxicity, high-generation amino surfaced dendrimers also result in inflammation and activation of the complement system. As with the membrane interacting, lipid-bearing dendrimers there is a fine balance between cytotoxicity and stimulation of cellular components of the immune system (see below).

DENDRIMER CARRIERS FOR COVALENT ATTACHMENT AND MULTIVALENT DISPLAY OF ANTIGENS

To increase the specificity of vaccines, they should employ highly defined, small parts (subunits) of the pathogen, for example, a peptide representing a part of a microbial protein. There is also a specific need for antibodies directed against small molecules for a wide range of other applications such as diagnostic assays, detection of small molecules (pesticides, peptides, a variety of inorganic molecules) and for research purposes (medical, life sciences, etc.) where exquisite specificity (sub-biomacromolecule) is needed.

Small molecules, however, as a rule, are not immunogenic (*27*). The traditional solution to this has been to couple the antigen of interest to a carrier protein or, in the case of peptides, to polymerize it (*28*−*30*), as increasing the size of the molecule has been empirically known to increase immunogenicity, possibly aided by the presence of multiple copies of the antigen in the molecule and the presence in the carrier protein of T cell epitopes (*30*). Traditional carrier proteins include albumin, ovalbumin, keyhole limpet hemocyanin, and others (*30*). Dendrimers as well-defined, multivalent, derivatizable, and stable molecules are ideal carriers of small antigens, making it possible to prepare multimeric antigenic conjugates with well-defined molecular properties (vide infra) also for human uses. As described above, dendrimers are prepared by highly efficient reactions and therefore, at least for low- and mid-generation dendrimers, are definable at a level normally achievable with much smaller molecules only, leading to molecularly defined antigen-carrier conjugates. To this can be added flexibility in design, ease of handling, and a relatively low price.

It is implicitly assumed for the long list of proposed in vivo uses of dendrimers (imaging, targeting, stabilization (*25*)) that dendrimers do not induce adverse host responses, including immune and/or inflammatory reactions upon administration. With a few exceptions, this generalization seems to hold true for "naked" (i.e., nonderivatized) dendrimers of most types; however, there are very few studies reporting on systematic investigations of this aspect of dendrimer biology. Plank et al. (*31*) reported on complement activation by DNA−dendrimer complexes, and as will be presented below, some dendrimers do seem to exhibit stand-alone adjuvanticity (*32*−*34*). As carriers, dendrimers can be considered immunologically inert scaffolds, and this is the most widespread use of dendrimers for promoting immunogenicity.

Multiple Antigenic Peptide (MAP) System. Interest has focused on one specific class of dendrimers, namely, the peptide dendrons of Tam et al. first described in 1988 (*23a*) (see Figure 3). Historically, these structures were rooted in the peptide world rather than the dendrimer world, peptides being the subject of intense interest as antigens in the 1980s due to the advances in peptide solid-phase synthesis occurring at that time (*35, 36*) and due to the realization that high-affinity immune reactivity demanded efficient methods for presenting peptides to the immune system to be developed and implemented.

Further peptidic dendron designs were described in a number of patents and scientific papers in the 1990s (*23a, 37*−*43*) with some developments described later (*44*), and the MAP carrier is by far the most investigated dendrimer for immunization and vaccination purposes to date (*45*). An excellent review on the structure and synthesis of peptide-based dendrimers in general has been published by Crespo et al. (*23b*).

The basic structure described by Tam (*23a, 37*) is a dendron constructed solely from lysine, taking advantage of the two amino groups (α and ε) being present in each lysine molecule thus constituting branching points for logarithmic growth. A two-layer dendron thus has four free amino groups and a three-layer has eight, equally divided between α- and ε-amino groups (see Figure 5 and Table 2). Tam coined the name "major antigenic peptide" (MAP) for such a structure derivatized with molecules of interest, not limited to peptides but any small molecule that could bind covalently to the terminal amino groups of the MAP "core" dendron.

MAP "cores" are presently available commercially most often bound by a specifically cleavable bond to a solid phase for easy access to stepwise solid-phase peptide synthesis.

The characteristic high-density multimers obtained by this method are claimed to have a favorable immunogenicity, stabilized attached peptide structures, a shielded MAP core not interfering with immune reactions, and an adequate molecular weight (>10 kD) for stimulating immune responses (see

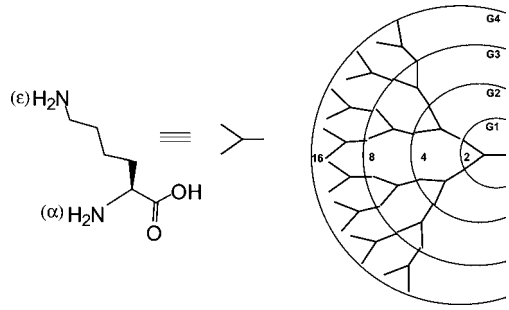

Figure 5. The basic MAP core, based on lysine (left) as the only monomer, indicating core structure and generation dependent increase of amino group numbers, leading to increasing crowding of amino groups in shells of higher generation.

Table 2. PAMAMs and MAPs: Physicochemical Characteristics

reviews (*46*−*50*) and Sadler and Tam (*45*)). Tetra- and octameric MAP cores are preferred, as higher generations are associated with synthesis problems because of increased steric hindrance (incomplete acylations) and increased insolubility due to intra- and intermolecular aggregation phenomena (see discussion below), and increasing the MAP generation often does not improve immunogenicity (*48, 49*).

Molecularly defined immunogen constructs based on the MAP system (*23a, 40, 41, 45*) have been reported to produce peptide-specific antibodies (*45*) and have been applied for vaccine use, for example, a MAP-based malaria vaccine (*42, 51, 52*) which has been tested in phase I clinical trials. This approach seems, however, to have been abandoned for more simple (linear) constructs that seemingly work just as well, provided that a universal T cell epitope was included and mixing with adjuvant was done (*53*). The paper states that "the technical challenges of synthesizing large quantities of homogenous, physical-chemically characterized branched peptides prevented scale-up for production of peptides".

There is also a demand for carriers for efficient presentation of other antigenic moieties than peptides, especially carbohydrates which are found as viral and bacterial surface constituents. When present in their natural membrane environment, these substances are often immunogenic due to noncarbohydrate membrane constituents (lipids and proteins), but on their own, carbohydrates as a rule show low immunogenicity (*27*). Another group of carbohydrate antigens of significant clinical interest is the cancer-specific antigens found on the surface of transformed cells. Such antigens are of diagnostic interest and are evidently also of interest as therapeutic targets or as "address labels" for targeting cytotoxic compounds to transformed cells (*25*). While some types of carbohydrates presented on glycodendrimers (Gal (β1−3) GalNac on G1-G4 PAMAM) are explicitly nonimmunogenic despite their surface-localized, multimeric presentation (*54*), MAPs have been used for presentation of the cancer-specific carbohydrate Tn-antigen (*55*) (αGal-Ser/Thr). In that study, a tetrameric MAP core structure was coupled with the Tn-antigen and with a T cell epitope and was shown to react with monoclonal antibodies against Tn. The same MAP core containing the T cell epitope coupled with trimeric Tn-antigens, i.e., $(\alpha$Gal-Ser/Thr$)_3$ coupled to each of the four "branches" of the MAP was shown to be immunogenic in mice using alum as an adjuvant (*56*). The construct could be used for active immunization against colon carcinomas in BALB/c mice. As both the MAP analogue carrying mono-Tn epitopes and a linear analogue containing two tri-Tn moieties were much less efficient immunogens, it was concluded that the precise spatial arrangement and clustering of the Tn-epitope was very important for the immunogenicity.

Importantly, the MAP core by itself does not seem to be immunogenic and does not confer adjuvanticity to a MAP complex, and accordingly, an adjuvant is needed to boost immune responses against its coupled antigens. Almost all immunizations with MAP constructs reported in the literature have been performed with traditional adjuvants, including aluminum hydroxide, Freund's adjuvant, and saponin adjuvants (*57*). Moreno et al. (*42*) compared the efficiency of a number of such adjuvants with a MAP containing malarial T- and B-epitope peptides in monkeys and mice using subcutaneous administration. A satisfactory response was obtained in both species using the saponin adjuvant QS21 (see Table 3).

As with conventional immunogens, the success of MAPs in vaccination is heavily dependent on choice of adjuvant, dose, and administration route. For example, an octameric FIV (feline immunodeficiency virus) MAP administered with Freund's adjuvant gave rise to high levels of FIV-neutralizing antibodies, while administration with the saponin QS21, although leading to antibodies and cytotoxic cellular responses against the immunizing peptide, did not induce neutralizing activity (*58*). The inclusion of immunopotentiating moieties in MAP structures to ensure adjuvanticity has been demonstrated and is discussed below.

In addition to the lack of adjuvanticity of the MAP core, this structure evidently does not contain T cell epitopes that are needed to achieve a complete adaptive immune response, in contrast to conventional high molecular weight carrier proteins where such epitopes are normally present (*30*). It is thus advantageous to be able to include both B- and T-cell epitopes in a MAP.

The MAP "core" is simple to synthesize by conventional solid-phase peptide synthesis, allowing branching to occur by deprotecting both amino groups in each amino acid residue at the same time (see Figure 6) achieving maximum branching and multimericity in minimal space. Moreover, with peptide antigens, these may be synthesized by solid-phase synthesis, in one synthesis series, on the free amino ends of a solid-phase-coupled MAP core, completing synthesis of the whole immunogen in one peptide synthesis setup accomplishable by automated solid-phase peptide synthesis (*23a*) (Figure 6).

Convergent synthesis strategies have also been reported. Here, coupling of peptides or other molecules is performed in one step to the free amino groups of the MAP core. By using orthogonal protection strategies and/or chemoselective coupling methods, the controlled coupling of different peptides to the same MAP core can be achieved (*48, 59*). Convergent synthesis strategies can be used to overcome problems with stepwise synthesis as, e.g., incomplete acylation steps due to aggregation of the growing peptide chain during synthesis, which is quite often observed, in a sequence-specific manner at high peptide densities during solid phase peptide synthesis (*36*). Also, unprotected peptide segments to be coupled can be purified to homogeneity before coupling, increasing the raw product purity of the MAP, facilitating purification of the MAP. Spacer

Table 3. Peptide Dendrimer Vaccination Results (Serum Titers[b]) with and without Additional Adjuvant (Selected Examples)[a]

	titer, no adjuvant	titer, with adjuvant/type of adjuvant[c]
MAP Carriers		
T cell receptor peptide (*37*)	ND[d]	10^3-10^5/CFA+IFA 10^3-10^4/Alum
malarial peptides (*42*)	ND	10^4/Alum 2×10^5/Alum+QS21
carbohydrate antigen (Tn) (*56*)	ND	5×10^5/Alum
MAP Carriers with Built-in Adjuvanticity		
T cell epitope inclusion: malarial peptides (*76*)	low	6.5×10^4/Titermax 5.3×10^4/CFA+IFA 2.4×10^4/P1004-MPL
lipid core peptide		
streptococcal peptides (i and ii)	1.0×10^5 (i), 6.9×10^3 (ii)	2.2×10^6 (i), 2.6×10^6 (ii)/CFA
peptide alone (*77*)	ND (i), none (ii)	2.0×10^6 (i), 9.0×10^4 (ii)/CFA
chlamydial peptide (chimeric)	ND	5.1×10^5/CFA, 2.6×10^5/NAGO
peptide alone (*39*)	ND	160/CFA
tripalmitate peptide: HIV gp120 peptide, intragastric route (*82*)	1020	ND

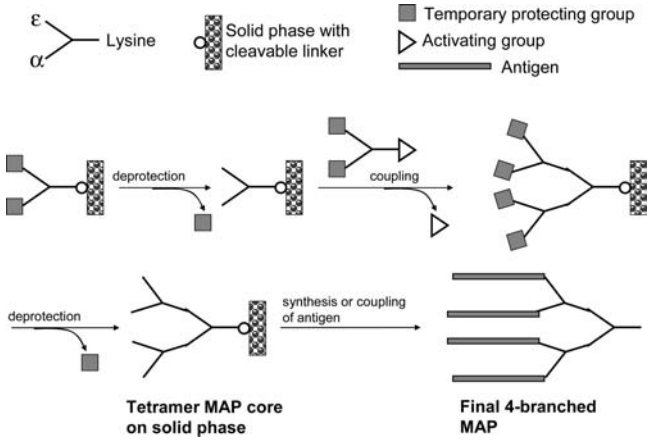

Figure 6. Steps in the solid-phase synthesis of a MAP structure (core and antigens).

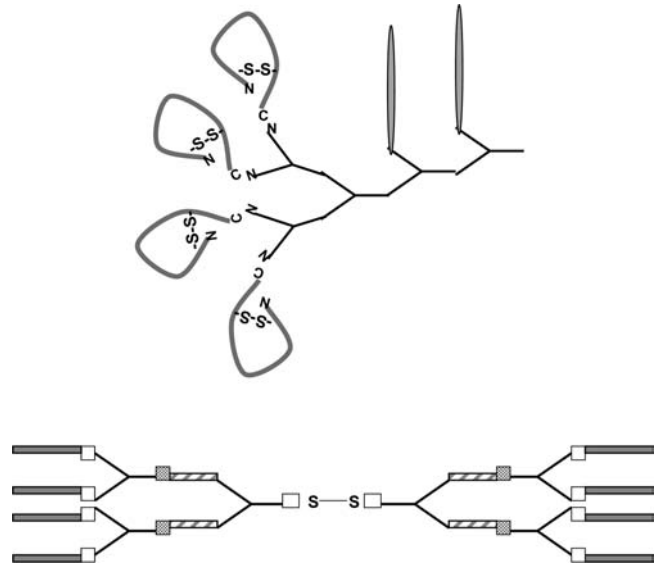

Figure 7. Examples of incorporation of spacers, lipids, and cyclic molecules in MAP structures. Top: Tetrabranched MAP with a dilipidated core and four copies of a cyclic foot-and-mouth disease peptide (*61*). Bottom: Two-dendron 8-branched MAP with two different antigenic peptides (elongated squares) and two different types of peptide spacers (small squares), one type (gray) being cathepsin cleavable (*84*).

segments can be introduced to increase flexibility and accessibility (*46*), and highly structure-stabilized cyclic peptides can also be accommodated in the MAP (*60*), increasing chances of building accurate antigenic peptide mimics for loops and turns in proteins; an example of this is the tetravalent MAP containing cyclic foot-and-mouth disease virus peptides described by Oliveira et al. (*61*) (see Figure 7).

Efficient chemoselective methods for coupling unprotected peptides to MAP cores include creating nonpeptidic bonds between the MAP core and the peptide, e.g., by reacting a thiol nucleophile, which could be the thiol group in the side chain of a cysteine residue, a thiol group introduced by 2-iminothiolane (Traut's reagent), or a thiocarboxylic acid, with a haloacetylated amine, readily obtained by reacting a primary amine with haloacetic anhydride, typically bromoacetic anhydride. In this way, an α,ε-bromoacetylated MAP core can be reacted with thiol-containing peptides forming stable thioether bonds or less stable thioester bonds. Thioester bonds are unstable at pH 7 and above. Chemoselectivity introducing nonpeptidic bonds is also obtained by reacting aldehydes with weak bases, for example, hydroxylamine or substituted hydrazine, forming oxime and substituted hydrazone, respectively (*59*) (see Figure 8). This can be done under acidic conditions inhibiting the competing reaction of nucleophilic groups, which are commonly found in peptide side chains, with the weak base. Aldehydes are not normally present in peptides but can be introduced by mild oxidation of serine, threonine, or cysteine. In this way, an aldehyde containing MAP core can be reacted with aminooxyacetylated peptides forming oxime linkages that are stable at pH 2−7 or with peptide acylhydrazine forming hydrazone-linkages that may be reduced to the more stable hydrazine (Tam (*49*) and Tam and Spetzler (*59*) review these chemistries). Amino-oxyacetic acid is commercially available and can be attached to an amino group of choice, and peptide acylhydrazine can be obtained by reacting a peptide ester with hydrazine.

By using selectively cleavable (orthogonal) protection groups on the α- and ε-amino groups of the MAP core, respectively, the activation, e.g., by bromoacetylation can be confined to one

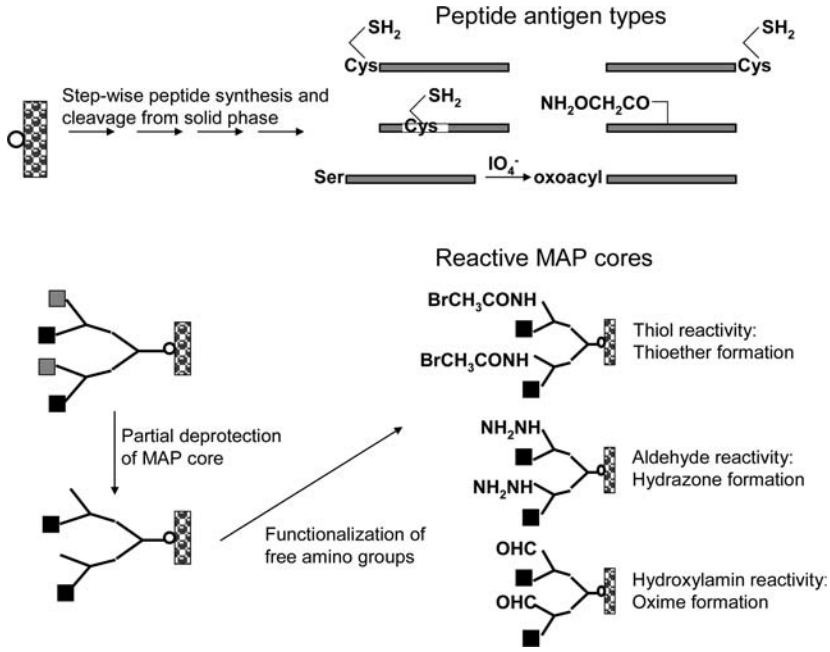

Figure 8. Examples of chemoselective schemes for convergent synthesis of heterofunctionalized MAPs with examples of different types of natural and unnatural peptide functional groups that can be coupled to MAP cores with different reactive groups (after Tam and Spetzler (*59*)). Note that chemistries can be "turned around", i.e., a functional group may be added to either the peptide antigen or the MAP core as desired (as both molecules are peptides).

of these types of amino groups, leaving the other one free for another type of coupling. This allows two different moieties, e.g., T cell peptide epitopes and B cell peptide epitopes, to be coupled to the MAP core in a controlled way. The orientation of the peptide to be coupled can be controlled by the position of the cysteine residue in the peptide (*49, 59*). If the peptide contains a cysteine residue in its natural sequence, this of course limits the possibilities.

Even when using convergent synthesis strategies and low-generation MAPs, which are much less crowded than higher generations, steric hindrance can be present as, for example, described for the preparation of a foot-and-mouth disease virus tetramer MAP by segment coupling: here, a significant proportion of trimer MAP was obtained in the raw product in addition to the desired tetramer (*61*). It has also been reported that even small, commercially available MAP cores may not always show the expected valency (*62*).

The toxicity of MAP structures is generally proportional to the number of free amino groups present. This was investigated for the lipid core peptides (LCP) constructs of Toth (*39*) (see below), and it was demonstrated that cytotoxicity was closely related to the number of cationic groups (amines) on the dendrimer and that toxicity was counteracted by lipid moieties; i.e., molecules with high lipid/amino group ratios were less toxic than molecules with low ratios even at the same number of amino groups (*44*). If amines were substituted, the lipidated dendrimers showed no toxicity. The correlation between cation character and cytotoxicity is a recurring theme with dendrimers (*25*) and can be hypothesized to be caused by the positive charge favouring cell surface interactions facilitating cell membrane perturbation.

Although native peptide structure has been directly shown to be stabilized in a MAP structure (*63*), this is apparently not always the case (*46*). This can be a problem when attempting to raise antibodies that are not only able to react with the immunizing peptide but also with the cognate protein. Limited aqueous solubility has been reported for some MAP constructs (*46*), most probably due to the formation of intermolecular aggregates and/or by intramolecular collapse of peptide conformations in the "branches" of the MAP molecule. In addition to the loss of native peptide structure and the resulting problem with achieving cognate protein immunoreactivity, this leads to problems of handling and dosing such immunogens and, importantly, dramatically decreases the possibility of analyzing the molecule by high-resolution high-precision methods such as mass spectrometry (MS) and HPLC-MS, compromising the possibility of documenting these structures (*42*) or demanding extensive purification to be carried out (*64*), making large-scale production of such vaccine constructs challenging (*53*).

In reality, the propensity of MAP structures to aggregate into difficult-to-analyze complexes may be an important factor in ensuring high immunogenicity of MAP constructs, providing supramolecular structures (aggregates) with very high molecular weights being highly "visible" to the immune system and with high biological stability. This may be promoted by the dense packing of fully substituted lysine residues in the MAP core, which therefore is very hydrophobic and highly amenable to aggregation in aqueous solvents.

Other Peptide-Based Branched Carrier Systems. The concept of using branched peptides for a conformationally controlled display of peptide antigens was also addressed in two different systems of Heegaard et al. (*65*) and Tsikaris et al. (*66*), respectively. Although not strictly dendrimeric in the narrow definition of the term, the main idea here is that the attachment with an optimized spacing to a conformationally stabilized peptide carrier of peptide antigens will restrict the conformational freedom of the peptide antigens, presenting them with better spatial definition than the free peptides, thereby allowing a higher chance of cross-reactivity of the ensuing antibody response with the conformationally defined peptides in their protein of origin. The sequential oligopeptide carriers (SOCs) of Tsikaris et al. (*66, 67*) are thus constrained peptide scaffolds, made up of α-amino isobutyric acids (Aib), e.g., repetition of Lys-Aib-Gly or Aib-Lys-Aib-Gly, in which the ε-amino group of Lys forms attachment points for peptides (Figure 9). Aib was chosen for its pronounced ability to promote α-helix conformation (*68*). Depending on the spacing of the derivatizable lysine residues, antigenic peptides are displayed

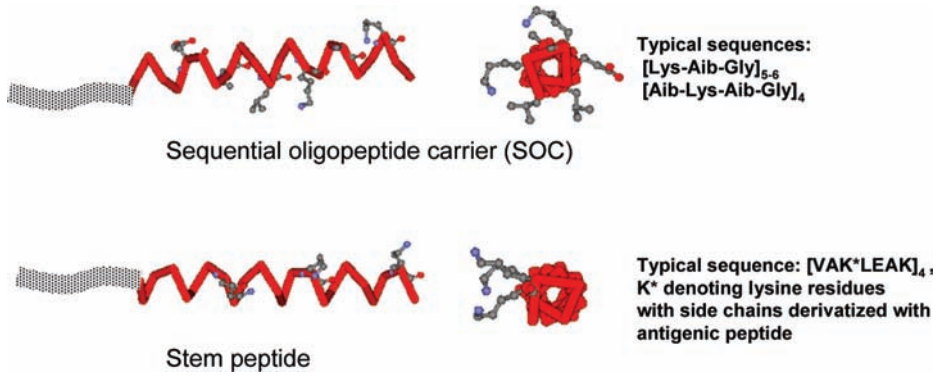

Figure 9. α-Helical model peptide structure (derived from PDB file 1cos.pdb) indicating distribution of attachment points for the sequential oligopeptide carriers of Tsikaris et al. (*66*) and the stem peptide carriers of Heegaard et al. (*65*) as viewed from the side (left) and from the end (right) of the helix. A lipophilic moiety has been included in these structures at the positions indicated (fat dotted line).

at different directions from the carrier helix axis, presumably affecting both antigenic and immunogenic properties (see, e.g., Kargakis et al. (*69*)). The presence of the unnatural amino acid Aib is claimed to cause increased biological stability and hence a prolonged presence of the immunogen, helping to increase efficiency of the immunogen.

These carriers are designed to support the structure (conformation) of the attached peptides, i.e., the peptides will show a more "native" conformation when coupled to the carrier, since peptides coupled to a carrier and being in close contact with the carrier and with each other will experience an environment resembling the crowded peptide-filled space in a folded protein.

The phenomenon of stabilization of inherent conformational structure in small peptides by organizing them on a template has been demonstrated by Tuchscherer et al. in so-called template assisted synthetic peptides (TASP) structures (*70*) in which four identical peptides are coupled to a cyclic template. The increased conformational definition of the coupled peptides compared to the free peptides was shown for a number of different peptides in the TASP system (*70, 71*). None of these systems have reached the popularity of the MAP carriers, maybe due to the simplicity of the MAP carriers.

Non-Peptide-Based Dendrimer Carrier Systems. G5-PAMAM (Starburst) dendrimers have also been used as carriers of the carbohydrate Tn-antigen (see above). These Tn-antigen−dendrimer conjugates were not immunogenic, whereas a Tn-antigen carrying protein (asialo submaxillary mucin) and a dimeric Tn-antigen-conjugated to tripalmitoyl-*S*-glycerylcysteinyl serine lipopeptide gave rise to antibody responses (*72*). In contrast, an octavalent G2-PAMAM with the cancer-related monosaccharide GlcNAc coupled on its surface was immunogenic and resulted in increased cellular immunity leading to reduced tumor growth of previously inoculated melanoma cells in mice, and thus holds promise as a therapeutic agent against this type of cancer (*73*).

Carbohydrate-based (*74*) and polyphenylene-based (*75*) dendrimers have also been reported to be useful as carriers of peptides for immunization purposes; however, no evidence has been presented regarding the immunogenicity obtained with these molecules.

Dendrimer Carriers with Built-In Adjuvanticity. Ideally, a molecularly defined carrier system should not need traditional, molecularly undefined adjuvants to attain sufficient immunogenicity, and should also be able to induce T cell immunity and T cell help.

In the MAP system, different variants of the basic MAP construct containing defined mixtures of B- and T-cell epitopes have been reported (*45, 76*) as have lipid-containing MAPs ("lipid core peptides" (*43, 77*), tripalmitate structures (*78*)), with the lipid serving as a built-in adjuvant (some examples of lipidated constructs are shown in Figure 10, and Table 3 summarizes the immunological properties of some of these carriers).

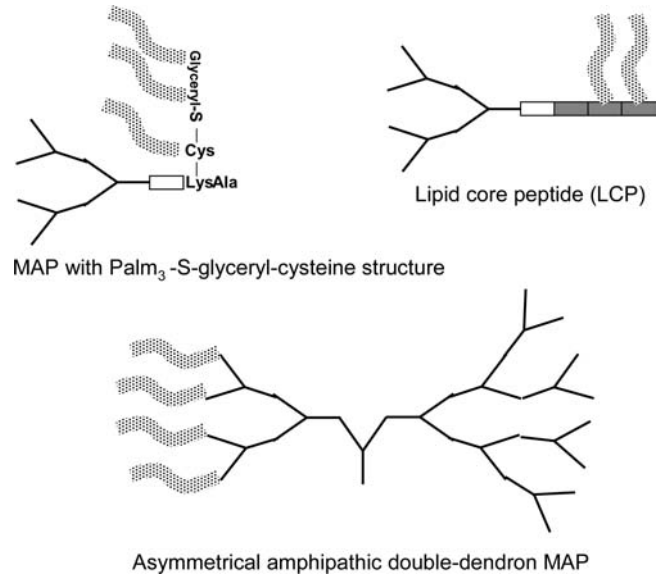

Figure 10. Examples of published self-contained adjuvant MAP structures. Fat dotted lines indicate fatty acid moieties.

Early examples of derivatizable MAP carriers with built-in adjuvanticity (*38*) contained a core region comprising a covalently coupled synthetic adjuvant moiety, viz., the immunostimulating tripalmitoyl-glyceryl structure (see below) coupled via a spacer to the core lysine residue of a MAP structure. This enabled immunization without added adjuvant and represents a molecularly defined complete immunogen that show a reasonable ability to induce antibodies and cellular immunity against HIV-derived peptides in mice. The same idea lies behind the design of the so-called lipid core peptide (LCP) carriers developed and patented by Toth (*39*) wherein MAP structures are attached to a core comprising a number of lipoaminoacids, i.e., amino acids with fatty acid (typically C12−C14) lipophilic side groups. LCP carriers have been used to construct a tetrameric MAP with 2 × 2 peptides corresponding to different regions of a streptococcal membrane protein (*77*). The core of this LCP contained three octyl side chains, and upon subcutaneous immunization without added adjuvant, the construct gave rise to antibody responses and protection levels indistinguishable from those obtained after immunization in the presence of Freund's complete adjuvant (the most powerful adjuvant known). LCPs were also shown to induce cytotoxic T cells using an ovalbumin model peptide and also slowed the development

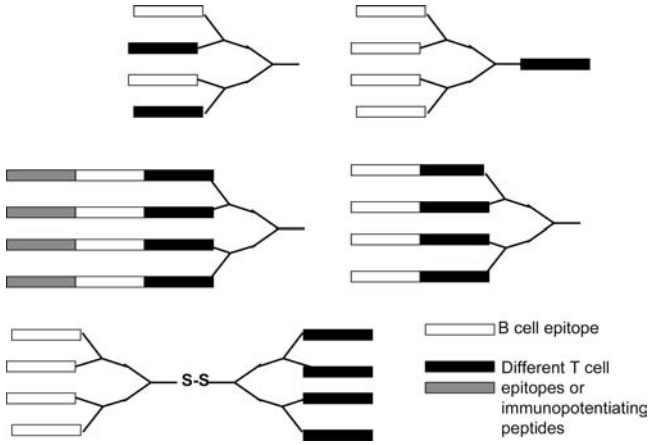

Figure 11. Examples of arrangements of T and B cell epitope peptides in MAP molecules. All of these arrangements have been published.

of tumors in a mouse model, provided an additional alum-type adjuvant was used (*79*). Lipids and MAP structured dendrons are also combined in the carriers described by Florence et al. (*44*); however, in this case the lipid is introduced as fatty acid amides in one-half on the dendron, while the other half is derivatized with relevant antigenic molecules.

The inclusion of lipid PAMPs such as the highly active TLR2-binding tripalmitate-*S*-glyceryl cysteine structure, which is a minimal synthetic analogue of an *E. coli* lipoprotein (*78, 80*) and simple linear saturated fatty acids (e.g., palmitic or myristic acids) (*39, 41, 43*) leads to dramatic increases in immunogenicity of MAPs. This is most probably accomplished by the lipidic moieties promoting contacts with the cell surface membranes of APCs, thereby optimizing exposure of the peptide antigens to these cells and, at the same time, by acting as a TLR agonist activating the cells to secrete immune activating substances (cytokines). In addition to these effects, lipids may enhance the uptake into APCs through pathways leading to MHC I-presentation, which is a prerequisite for induction of cytotoxic T cells that are crucial for the combat of intracellular infections, including viral infections (*81*).

Lipidated MAPs may also have certain advantages as mucosal immunogens, as they are supposed to be able to penetrate mucosal membranes. Thus, a tripalmitate tetravalent MAP containing HIV-peptides was able to induce secretory mucosal immunoglobulin (IgA) as well as serum immunoglobulin (IgG) by oral delivery and also induced cytotoxic, MHC class I dependent T cell responses by intragastric delivery in mice (*82*).

MHC-restriction of T cell activation can be circumvented by using broadly reactive ("universal" or "promiscuous") T cell peptide epitopes, which can be introduced in a MAP structure alongside any antigen of interest, as long as orthogonal chemical strategies (protection groups) can be established that allow the control over this kind of heterofunctionalization (see above and, e.g., ref *49.*). Quite a number of methods and arrangements have been reported for this purpose, some of which are illustrated in Figure 11, and a wide range of orthogonally protected lysine derivatives are commercially available for this purpose. T and B cell epitopic peptides may also be combined by dimerizing two MAPs (see Figure 11), each containing its own type of peptide (the T cell epitope was a promiscuous peptide from tetanus toxoid, B cell epitope was from HIV-1 gp120) (*83*). Dimerization was done by reacting two thiol groups from C-terminal cysteines to form a disulfide bond between the two dendrimer moieties. In this study, it was also investigated whether coupling of such dendrimers to carrier proteins (bovine serum albumin and Hepatitis B surface antigen) affected immunogenicity upon immunization of mice using Freund's adjuvant. The MAP-protein constructs led to broader antigen specificities than the MAP dimer as analyzed by ELISA using peptide antigens corresponding to different HIV gp120 V3 variants, confirming an earlier study (*84*), while the same antibody titers were obtained by the two methods.

MAPs have been shown to be able to directly enhance T cell stimulation as measured by the immune response to fluorescein included as a hapten in a MAP construct also containing a T cell epitope to a level comparable to that obtained after immunization with fluorescein coupled to a carrier protein containing the same T cell stimulatory sequence (*62*). The antibody response was increased several hundredfold to that obtained by immunization with either a monomer fluorescein T cell peptide conjugate or a fluorescein dendrimer not containing the T cell binding peptide. This is direct evidence of the amplifying effect obtained by the MAP-dependent multimerization of the T cell peptide (*62*).

These structures maintain the feature of synthetic simplicity inherent in the MAP concept, and documentation of purity (another important step forward) was possible by mass spectrometry at least in a few cases. Just as with the MAP constructs, SOC constructs with built-in adjuvants (e.g., an interleukin-1 nonapeptide) and also including a promiscuous Th epitope (*85*) and, most recently, constructs containing palmitate have been reported (*69*). These constructs induced antibodies with specificity for the antigenic peptide coupled to the carrier by immunization of rabbits and mice without the addition of adjuvant. Antibody titers were indicated to reach the same level as seen upon immunization in the presence of Freund's incomplete adjuvant (after six immunizations).

A specific subclass of "immunoactive" dendrimers are constituted by dendrimers with targeting moieties in addition to TLR ligands and antigenic moieties, as, e.g., described by Kantchev et al. (*64*) in which a MAP structure is endowed with mannosyl residues in addition to viral peptidic antigens. The rationale behind mannose displaying constructs is to target the MAP to dendritic cells carrying a mannose binding receptor on their surface. Although no vaccination/immunogenicity data are provided, the molecules were obtained by a relatively simple solid-phase strategy and were analyzable by HPLC and mass spectrometry.

Dendrimers as Stand-Alone Adjuvants for Mixing with Antigens. It is clear from the above examples that dendrimers, especially MAP structures, can be endowed with intrinsic adjuvanticity by coupling with various immunopotentiating and/or targeting structures and using them as carriers for delivery of antigens. However, basic MAP structures and other dendrimers may also exhibit stand-alone adjuvanticity in the classical way for mixing with an antigen to increase its immunogenicity.

Contrary to the assumption that dendrimers are immunologically inert structures, which is in some ways a precondition for their use as carriers as described above, a number of examples exist showing that certain underivatised dendrimers may exhibit adjuvant like properties. Thus, there is some evidence that MAP constructs may have an intrinsic ability to overcome MHC-restriction (*49*) and even sometimes can activate T cells without the presence of T cell epitope peptides in the construct (*86*), i.e., a non-lipidated MAP structure in effect working as a stand-alone adjuvant. Olszewska et al. (*86*) found that the immunogenicity obtained was comparable to that of a linear construct containing two copies of a universal T-helper cell epitope from measles virus F protein and a B cell peptide epitope from the same protein. However, the MAP construct achieved this without including T cell epitopes in the construct, implying that T cell help was provided by the MAP construct itself, in some way stimulating APCs to provide the signals necessary to

activate the T cells. In another study (*81*), it was shown that MAPs were processed in APCs by the intracellular antigen processing route, providing a powerful MHC I-restricted cytotoxic T cell response. Again, this was achieved with a nonlipidated MAP. Poupot et al. (*87*) studied a range of phosphorylated dendrimers and found them to activate isolated human monocytes in culture. This process depended on the multimericity of the dendrimer and the surface localization of phosphonic acid and involved TLR2.

While the use of MAP structures as stand-alone adjuvants has not been reported to any great extent, some data are available concerning the potential of other types of dendrimers to act as stand-alone adjuvants, including G3, G5, and other midgeneration PAMAM dendrimers (*32, 33*). A G7 PAMAM administered with influenza antigens was compared to immunization with the antigen in PBS (*32*) in mice, and while the highest concentration of dendrimer was toxic to the mice (the dose corresponded to 290 μg/mouse), 1/10 and 1/100 doses were nontoxic and showed considerable adjuvant activity, increasing antibody titers up to more than 100 times after two immunizations (see Table 4). G1, G4, and G7 PAMAM were tested; G1 did not stimulate antibody production, whereas the other dendrimers showed adjuvant activity linearly correlated with the number of amines. The mechanism is speculated to be through electrostatic adsorption of the virus antigens on the surface of the dendrimer, as the influenza virus hemagglutinin surface antigens have low isoelectric points, i.e., being anionic at neutral pH and binding to the cationic surface groups of PAMAM dendrimers. This classifies the PAMAM dendrimers in these experiments as delivery system type adjuvants.

In another study, Rajananthanan et al. (*33, 34*) looked at G6 PAMAM in comparison with a tomatine ISCOM (*88*)-like adjuvant formulation, tomatine being a saponin glycoalkaloid (quil A-like), and a formulation consisting of glycolipid aggregates. Also, Freund's incomplete adjuvant, Alum, and Provax were used as reference adjuvants for coinjection or 3 h later injection (at a different injection site). Using ovalbumin as a model antigen, mice were immunized s.c. using 50 μg antigen, and the resulting serum antibody reactivity against ovalbumin was analyzed by ELISA. While the tomatine system was shown to induce the highest antibody titers, the simple mixing of antigen and PAMAM also induced "good" antibody responses against ovalbumin, and some effect was also seen when administering PAMAM separately and later than the antigen, suggesting a systemic effect. The dose of PAMAM was 50 μg, and no toxicity (inflammation) was observed. There was no preferential induction of either IgG_1 or IgG_{2a} antibodies indicative of a mixed Th1/Th2 response. Analyzing for cytokine production and proliferation of antigen-restimulated spleen cells from immunized mice, the dendrimer was seen to lead to significant recall proliferation responses compared to antigen alone but lower than the tomatine response, and primarily, Th2-like cytokines (IL-4 and IL-5) were induced by the restimulation. No hypothesis on the method of action of the dendrimer was presented, but systemic effects in addition to antigen adsorption (delivery) effects were indicated to be at play.

DNA vaccination holds great promise for induction of Th1 biased immunity both systemically and at mucosal surfaces (*89*). However, despite initial success in rodents the application of DNA vaccination in humans and in large animals has often proven problematic, as the efficacy is often very low (*90*). The delivery of DNA to host cells upon injection has been identified as one of the main hurdles of DNA immunization in nonrodents (*90, 91*), but although cationic polymers have been investigated for ameliorating this problem (*91*) and although cationic fractured PAMAM-type dendrimers are used on a routine basis for nonviral gene delivery (*92*), there are surprisingly few reports on the use of dendrimers to increase DNA immunization efficacy. Audonnet et al. (*93*) described the use of a number of cationic lipids, lipoamines, and polymers including SuperFect (Qiagen), which is a heat-fractured PAMAM dendrimer, all known as efficient DNA transfection reagents (gene delivery) for their ability to enhance immune responses after immunization with DNA in the form of naked DNA plasmids. An increase in serum titer was demonstrated after two immunizations with plasmid DNA mixed with cationic lipid/neutral lipid from bovine herpes virus-1 in cattle compared to immunization with the plasmid alone. Also, the weight gain of pigs challenged by porcine respiratory virus was increased when pigs were vaccinated with PRV plasmid plus lipids compared to pigs vaccinated with the plasmid only. However, no experimental data using dendrimers were presented in this work (*93*).

CONCLUDING REMARKS

Despite the molecular characteristics of dendrimers (multimericity, definability, derivatizability, and molecular weights above 2 kD), they have at present only to a limited extent been used as carrier molecules to enhance immunogenicity of antigens for vaccine purposes, with the exception being the lysine-based MAP carrier dendrons emerging from the peptide field. Although developed specifically for presenting small peptide antigens to the immune system, the accommodation of nonpeptidic haptens (e.g., carbohydrates (*72*)) and of several different types of peptides simultaneously (B and T cell epitopes) have also been demonstrated. Also, convergent strategies for MAP synthesis have been developed (*49*) as has the synthesis of self-adjuvating (lipid containing) MAPs (*43*). After the first descriptions, further developments/improvements have, however, been few, and in at least one case, the MAP dendrimer approach has been left for the benefit of a linear combination of T and B cell stimulatory peptides (*53*). The use of dendrimers as stand-alone adjuvants is even less well described and investigated.

It is obvious that the application of dendrimers as molecular adjuvants should be further explored and developed especially in the case of DNA vaccination where one of several critical steps is the delivery of DNA to the target cell—a step which is known to be facilitated by administration of certain dendrimer types, at least in vitro. DNA−dendrimer complex formation could even be imagined to help overcome two other pivotal steps in the DNA vaccination method, viz., protecting the DNA against breakdown and targeting the DNA to specific host cells, e.g., in the mucosa (by exploiting the heterofunctionalization potential of the dendrimer to include targeting ligands in the

construct). It is also clear that the potential of dendrimers for other vaccine purposes, both as antigen carriers and as adjuvants, and as combinations of these, is far from fully explored. Being monodisperse polymers, dendrimers offer the possibility of producing molecularly defined adjuvants combining very specific immunomodulating activities with targeting to relevant tissues, e.g., mucosal surfaces, and antigen transportation. The resulting macromolecular constructs are expected to behave as highly immunoactive and specific adjuvant/carrier compounds. Thus, dendrimers are useful generic platforms for developing defined and safe vaccines with new properties and application potentials and will also be useful for basic investigations of the mechanisms behind the induction and control of immunity.

Urocanic Acid Improves Transfection Efficiency of Polyphosphazene with Primary Amino Groups for Gene Delivery

Yongxin Yang, Zhiwen Zhang, Lingli Chen, Wangwen Gu, and Yaping Li*

Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai 201203, China. Received June 17, 2009; Revised Manuscript Received November 17, 2009

The biodegradable cationic poly(2-(2-aminoethoxy)ethoxy)phosphazene (PAEP) bearing primary amino groups and a new PAEP derivative, urocanic acid (UA) modified PAEP (UA-PAEP), were synthesized and investigated for gene delivery. The results indicated that PAEP was able to condense DNA into complex nanoparticles with the size around 120 nm at the polymer/DNA ratio (N/P) of 35, at which PAEP/DNA complex nanoparticles (PACNs) showed efficient transfection activity in complete medium. After conjugating with UA at the substitution degree of 7% (UA-PAEP7), UA-PAEP7/DNA complex nanoparticles (UP7CNs) exhibited higher transfection efficiency than PACNs and UA-PAEP25/DNA complex nanoparticles (UP25CNs) and much lower cytotoxicity compared with PEI/DNA complex nanoparticles (PEICNs). The transfection experiment using a proton pump inhibitor suggested that the gene expression of PACNs and UP-PAEP/DNA complex nanoparticles (UPCNs) was dependent on the endosomal acidification process. The acetate solution (20 mM, pH5.7) improved the transfection activity of UP7CNs in HeLa and COS 7 cell lines, which was almost comparable to PEICNs at the N/P ratio of 35. Therefore, the results suggested that UP7CNs could be a promising carrier for gene delivery.

INTRODUCTION

A number of cationic polymers such as polyethylenimine (PEI) (*1*), chitosan (*2*), poly(L-lysine) (PLL) (*3*), and polyamidoamine dentrimers (*4*), have been widely investigated for gene delivery due to their obvious advantages over viral gene vectors such as low safety risks, preparation in large quantities easily, and low costs. Among these cationic polymers, PEI has become a golden standard of nonviral gene delivery systems (*5*), but the high cytotoxicity and nonbiodegradability limit its usage. So far, great efforts have been made to design and develop novel biodegradable polymers with high transfection activity and low cytotoxicity for gene delivery (*6, 7*). Unfortunately, the ideal cationic polymer has not been found yet.

Polyphosphazenes have been investigated for biomedical and pharmaceutical applications such as drug delivery systems (*8*) and protein matrices (*9*) because of their synthetic flexibility, excellent hydrolytic degradability, and nontoxic degradable products. For gene delivery, the cationic polyphosphazenes have shown good activity in gene transfection recently (*10*−*12*). However, more efforts have to be made before polyphosphazene derivatives with the optimal gene transfer efficiency are found. In our previous work (*13*), poly(imidazole/DMAEA)phosphazene (PIDP) bearing ternary amino groups showed the ability to condense DNA into complex nanoparticles with a size around 100 nm, which could mediate more efficient transfection than PEI/DNA complex nanoparticles (PEICNs) and poly(di-DMAEA)phosphazene/DNA complex nanoparticles at the same polymer/DNA ratio (w/w) in serum-free medium. However, PIDP/DNA complex nanoparticles exhibited much lower gene expression level in medium containing 10% FBS. In order to meet the requisites of in vivo gene delivery, we are looking for a novel cationic polyphosphazene derivative that could achieve efficient transfection in the presence of serum.

On the cellular level, the complex nanoparticles must overcome many obstacles before they release nucleic acid at the target site of action. The first obstacle is traversing the cellular membrane. Complex nanoparticles are able to pass the cellular membrane via endocytosis as long as they have the suitable surface properties such as the appropriate size range and the positive charges (*14, 15*). However, endocytotic uptake may not only expose complex nanoparticles to enzymatic degradation in the lysosome, but also entrap and never release them.

To circumvent above difficulties, we synthesized biodegradable poly(2-(2-aminoethyoxy)ethoxy)phosphazene (PAEP) bearing primary amino groups for efficient gene delivery first. Considering urocanic acid (UA) with an imidazole ring for enhanced endosomal escape, a new PAEP derivative, UA modified PAEP (UA-PAEP), was synthesized in an attempt to improve the transfection activity. In this work, the buffering capacity of polymers, the transfection activity of complex nanoparticles in the presence of serum, and the influence of UA substitution degree on the transfection efficiency were investigated. In addition, the physicochemical property and the cell uptake of the polymer/DNA complex nanoparticles were characterized for further exploration of the mechanism of in vitro gene transfection.

EXPERIMENTAL PROCEDURES

All the reagents (analytical grade) were purchased from Sinopharm Chemical Reagent Co., Ltd. (China), unless otherwise noted. NH_4Cl was dried in a desiccator over P_2O_5 (Panreac). Tetrahydrofuran (THF) was treated with KOH and distilled twice from Na in the presence of benzophenone. Petroleum ether refers to that fraction with a boiling point in the range 60−90 °C. PCl_5 was purified by sublimation. Sulfamic acid (HSO_3NH_2), $CaSO_4 \cdot 2H_2O$, 2-(2-aminoethyoxy)ethanol (Aldrich), sodium hydride (Fluka), and 1,2,4-trichlorobenzene were used as purchased. Trifluoroacetic acid (TFA), *N*,*N*′-dicyclohexylcarbodiimide (DCC), and *N*-hydroxysuccinimide (NHS) were purchased from GL Biochem (Shanghai) Ltd.

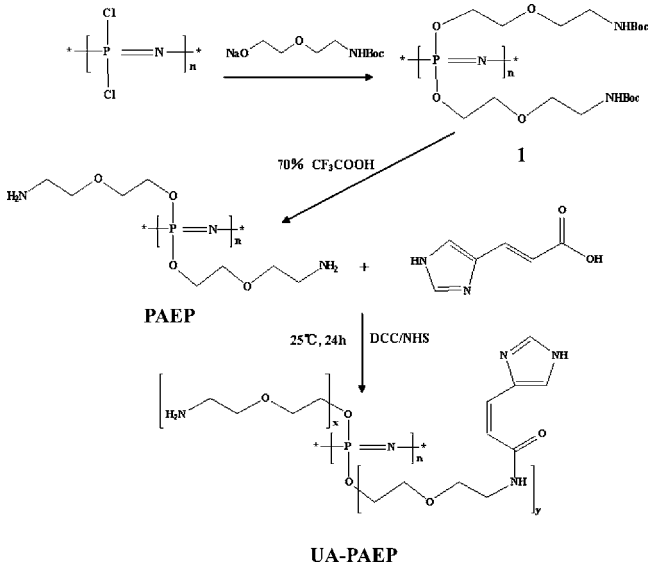

Figure 1. Synthetic scheme of poly(2-(2-aminoethyoxy)ethoxy) phosphazene(PAEP) and UA-PAEP.

Polyethylenimine (PEI 25K), poly(L-lysine) (PLL), and UA were obtained from Aldrich. YOYO-1 was obtained from Invitrogen and Trypan Blue from TianGen. Bafilomycin A1 was purchased from Sigma. pEGFP-N1 (4.7 kb) encoding green fluorescent protein driven by immediate early promoter of CMV was purchased from Clontech Laboratories (Palo Alto, CA, USA). pGL-2Luc was purchased from Promega Corp. (Madison, WI, USA). The plasmid DNA (pDNA) was amplified in DH5α strain of *E. coli* and purified by EndFree Plasmid Mega Kit (Qiagen GmbH, Hilden, Germany).

Cell Lines. Hela cells and COS 7 cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA) and were grown in DMEM containing 10% fetal bovine serum (FBS), streptomycin at 40 μg/mL, and ampicillin at 40 U/mL. Cells were maintained at 37 °C in a humidified and 5% CO_2 incubator.

Synthesis of PAEP and UA-PAEP. Poly(dichloro)phosphazene was prepared directly from PCl_5 and NH_4Cl as described in our previous work (*13*). The synthesis of PAEP (Figure 1) was carried out according to the Allcock's procedure (*16*). To synthesize UA-PAEP, the carboxyl group of UA was activated by the NHS/DCC dissolved in dimethylformamide (5 mL). DCC was 1.2-fold molar excess over UA and NHS/DCC molar ratio was 1:1. The activated UA solution was added to PAEP solution and triethylamine in methanol (10 mL), and the resultant solution was stirred for one day at room temperature. The reaction mixture was dialyzed using cellulose membrane (MW cutoff 6000−8000) against distilled water for 3 days. The resulting solution was lyophilized, and the composition of UA-PAEP was determined by NMR spectra. ^1H NMR and ^{31}P NMR spectra of polymer were obtained from Varian Mercury Plus-400 NMR spectrometer (Varian, USA). The chemical shifts were given relative to tetramethsilane or 85% H_3PO_4 as an external standard. The molecular weight and distribution were determined by gel permeation chromatography (GPC, Waters 600) with acetonitrile/water/trifluoro acetic acid (10/90/0.05, v/v) as the eluent with flow rate (0.5 mL/min). The calibrations were peptide standards.

Buffering Capacity. The buffering capacity of PAEP, UA-PAEP, PLL, and PEI were measured by titration according to the method described by Tseng (*17*). The polymers were diluted to a final concentration of 0.3 mg/mL with 0.1 N NaCl. The solution was adjusted to pH 7.5 before titration proceeded. An aliquot of 0.1 N HCl was successively added into 30 mL of polymer solution (0.3 mg/mL), and the change in pH was monitored by a pH meter (Sartorius, Germany).

Preparation and Characteristics of Polymer/DNA Complex Nanoparticles. The polymer/DNA complex nanoparticles were prepared by adding 100 μL polymer solution with various amounts of polymer to 100 μL of pEGFP (20 μg) in distilled water or 20 mM acetate (pH 5.7) and vortexed for 10 s. The resulting complex nanoparticles were allowed to sit at room temperature for 30 min, then confirmed by electrophoresis on a 1% agarose gel with Tris-acetate-EDTA buffer system (pH 8.0) at 110 V/cm for 45 min. DNA was visualized using ethidium bromide staining. The polymer/DNA charge ratio (N/P) was defined as the ratio between the moles of the amine groups of PAEP or UA-PAEP to those of the phosphate ones of DNA. For plasmid DNA, 330 g/mol corresponds with the average mass of a repeating unit bearing one negative phosphate group.

Size and ζ-potential of complex nanoparticles were measured by laser light scattering following their dilution with water or 20 mM acetate (pH 5.7) using a Nicomp 380/ZLS zeta potential analyzer (Santa California, USA) at 25 °C. For size measurement, scattered light was detected at a 90° angle and the instrument was calibrated with an aqueous poly(styrene) dispersion of particles of 100 nm. ζ-potential measurements of the complexes were carried out in the standard capillary electrophoresis cell at 25 °C.

In Vitro Transfection Experiment. In vitro transfection efficiency was evaluated on Hela and COS 7 cell lines using a plasmid containing a reporter gene encoding enhanced green fluorescence protein (EGFP). Cells were seeded into a 24-well plates at a density of 1×10^5 cells per well in 500 μL of complete medium 24 h prior to transfection. After the polymer/DNA complex nanoparticles containing 2.5 μg of DNA were incubated with cells at 37 °C for 4 h, the medium was replaced with fresh complete medium. After 48 h, the cells were washed twice with PBS and collected. The fluorescence intensity of positive cells was measured with a flow cytofluorometer (Becton Dickinson, USA) equipped with an argon ion laser. PEICNs were used as positive control. The transfection experiment involving bafilomycin A1 was performed as described above except that the cells were preincubated with 200 nM bafilomycin A1 at 37 °C for 30 min.

Cell Viability Assays. The cytotoxicity of complex nanoparticles was determined by MTT assay. The cells were plated on a 96-well culture dish at a density of 2×10^4 cells/well and cultivated in complete medium. After 24 h, the culture medium was replaced with fresh complete medium containing complex nanoparticles at different polymer/DNA (N/P) ratio. After 4 h, the incubation medium was replaced again with fresh medium and incubation for an additional 42 h. The medium was removed and MTT solution (5 mg/mL) was added. Cells were incubated for 4 h at 37 °C in 5% CO_2. Then, the medium containing MTT was removed, and 150 μL of DMSO was added to dissolve the crystals formed by living cells. The absorbance was measured at test wavelengths of 490 nm (Bio-Rad model 550, Hercules, CA, USA).

Cell Uptake of Polymer/DNA Complex Nanoparticles. To evaluate cellular uptake efficiency and subsequent intracellular routing of complex nanoparticles, pGL-2Luc encoding luciferase was used and labeled with YOYO-1. Briefly, 200 μL of pGL-2Luc (0.2 μg/mL) was mixed with 10 μL of 50 μM YOYO-1 and incubated at room temperature for 1 h in the dark. At 24 h prior to uptake experiment, the cells were seeded at a density of 1×10^5 cells/well in 24-well microtiter plates. Then, the complex nanoparticles containing 2.5 μg of YOYO-1-labeled plasmid DNA were added to the cells in fresh complete DMEM medium. After incubation for 1 h at 37 °C, the cells were washed

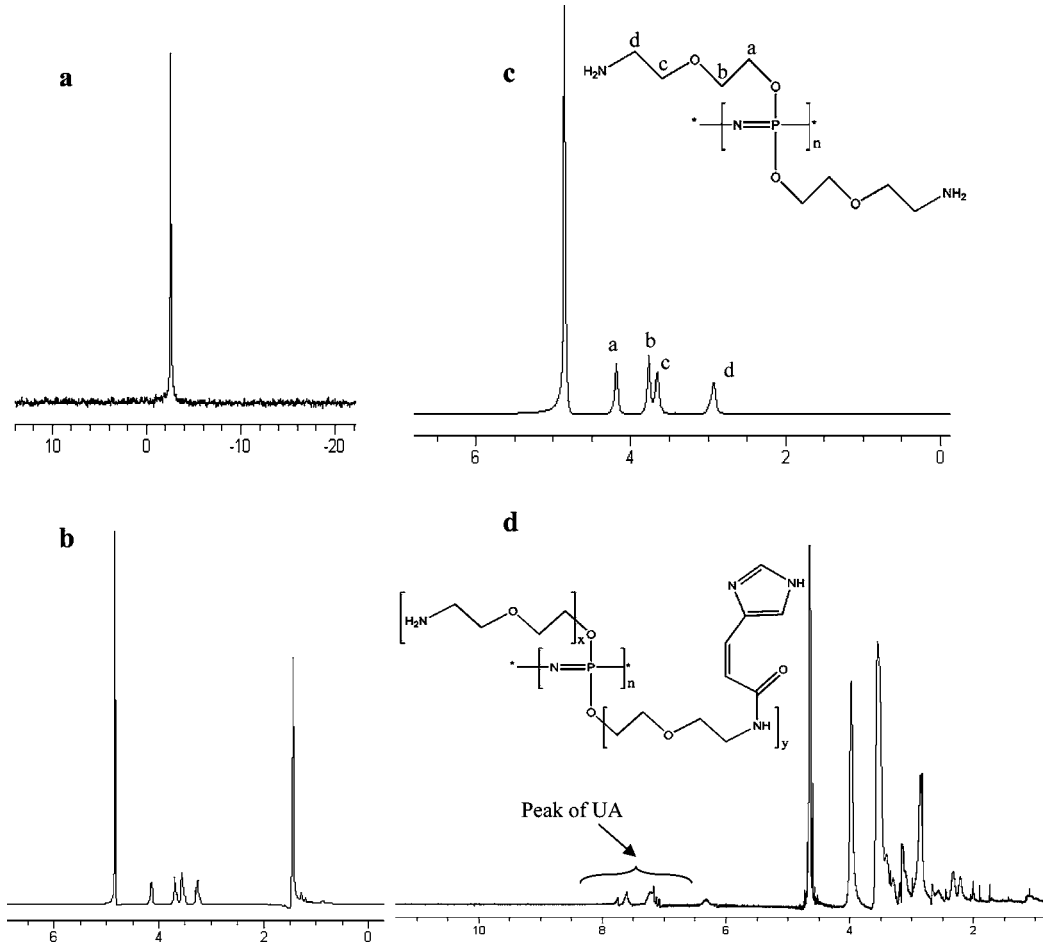

Figure 2. ^{31}P NMR spectra of PAEP (a); ^{1}H NMR spectra of polymer 1 (b), PAEP (c), and UA-PAEP (d).

with cold PBS twice. Fluorescent microscope images of cells were taken simultaneously using an Oliympus Inverted microscope (Japan). Finally, the cells were harvested by trypsinization. To quench the extracellular fluorescence, the cell suspension was mixed with 25 μL of a 0.4% trypan blue (TB) solution in PBS. The mean fluorescence intensity (MFI) of the cells was measured with a flow cytofluorometer. MFI of PEICNs was normalized to 100.

The uptake mechanism of PACNs and UPCNs in Hela cells was examined by means of specific inhibitors of the different endocytic pathways. For inhibition experiments, the cells were first incubated with one of the following inhibitors: 56 μM chlorpromazine (to inhibit clathrin-mediated endocytosis), 10 μM nystatin (to inhibit microtubule-mediated endocytosis), 3 μM cytochalasin D (to inhibit macropinocytosis), or 200 μM genistein (an inhibitor of caveolae-mediated endocytosis) for 30 min in completed medium prior to addition of complex nanoparticles to the cells. Inhibitors were used at concentrations in which they were shown to be active but not cytotoxic in COS 7 cells (*18*).

Statistical Analysis. Statistical analysis was performed using a Student's *t*-test. The differences were considered significant for $p < 0.05$ and $p < 0.01$ indicative of a very significant difference.

RESULTS AND DISCUSSION

Synthesis of PAEP And UA-PAEP. Prior to the substitution reaction, one of the two nucleophilic groups in 2-(aminoethoxy)ethanol had to be protected lest cross-linking of the polymer occurred. In this work, the *tert*-butoxycarbonyl (Boc) group, which decomposes readily by treatment with acid and remains intact under basic conditions, was used to protect amine groups of 2-(aminoethoxy)ethanol. Once polymer 1 was obtained, the deprotection of *tert*-butoxycarbonyl group was carried out by trifluoroacetic acid. Since the deprotection reaction was carried out under acidic condition, chain cleavage was considered to be a possible side reaction. However, no signal that could be attributed to decomposition was observed in ^{31}P NMR of PAEP (Figure 2a). A strong single peak of ^{1}H NMR for Boc group, as shown at 1.36 ppm (Figure 2b), disappeared in ^{1}H NMR spectra of PAEP (Figure 2c). The molecular weight of PAEP was 1.47×10^4 Da. To facilitate the endosome escape, PAEP was coupled with UA using an active ester method to obtain UA-PAEP. PAEP was first dissolved in methanol because it was not soluble in aprotic solvents and diluted with dimethylformamide to react with activated UA. ^{1}H NMR of UA-PAEP in D_2O was shown in Figure 2d. The substitution degrees of UA were 7% (UA-PAEP7) and 25% (UA-PAEP25) of the total amine functions, respectively.

Buffering Capacity of Polymers. The buffering capacity of polymer was tested via titration with 0.1 N HCl. Figure 3 showed that the buffering capacities of UA-PAEP7 and UA-PAEP25 were higher than that of PAEP in the range of pH 4−6.6, which indicated that the involvement of UA improved the buffering capacity of PAEP. The buffering capacity of UA-PAEP slightly increased when the substitution value of UA increased from 7% to 25%. As positive control, PEI showed excellent buffering capacity. PLL exhibited much lower buffering capacity than other polymers as a negative control. It is believed that the correlation of the pH range to the transfection process is between pH 5 and pH 7. In this work, the range of pH 4−6.6 was chosen to compare the buffering capacities of

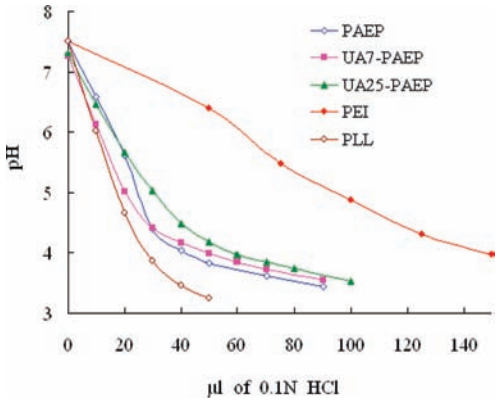

Figure 3. Titration curve of PAEP, UA-PAEP7, UA-PAEP25, and PEI solution (0.3 mg/mL). The polymer solution was titrated with 0.1 N HCl.

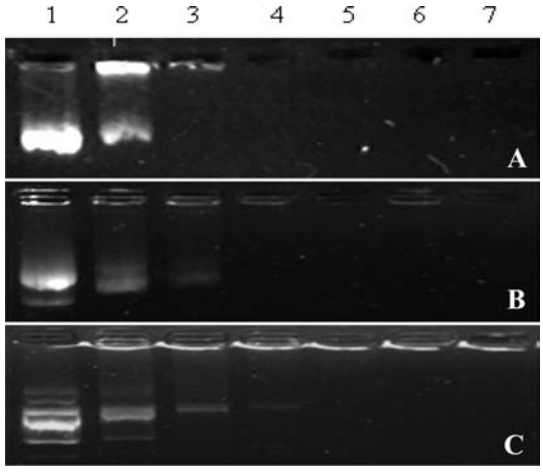

Figure 4. DNA retardation assay by agarose gel electrophoresis using 1% agarose in Tris-acetate running buffer (pH 8.0). (A) Lane 1, DNA control; lanes 2−7, PAEP/DNA (N/P) = 1.2, 2.5, 5, 7.5, 25, and 37, respectively. (B) Lane 1, DNA control; lanes 2−7, UA-PAEP7/DNA (N/P) = 1.2, 2.5, 5, 7.5, 25, and 37, respectively. (C) Lane 1, DNA control; lanes 2−7, UA-PAEP25/DNA (N/P) = 1.2, 2.5, 5, 6.7, 7.5, and 25, respectively.

the polymers according to ref *19*. On the other hands, UP7CNs showed obvious difference in their buffering effects compared with PAEP in the pH range 4−6.6 rather than in the pH range 5−7.

Characterization of Polymer/DNAComplex Nanoparticles. The formation of polymer/DNA complex nanoparticles was confirmed by gel retardation assay. The ratio of polymer/DNA (N/P) at which the electrophoretic mobility of DNA was completely retarded was 2.5:1 for PAEP, 5:1 for UA-PAEP7, and 6.7:1 for UA-PAEP25, respectively (Figure 4). The results indicated that the ability of UA-PAEP condensing DNA was less efficient than PAEP due to the decreased positive charges. It has been reported that the suitable surface property and size range enable the cationic polymer/DNA complex nanoparticles to pass the cellular membrane via endocytosis (*14*). PAEP could condense DNA into nanoparticles with an average diameter around 120 nm at the polymer/DNA (N/P) ratio from 2.5 to 35 in distilled water. According to transfection experiment (see following section), the polymer/DNA complex nanoparticles prepared either in water or in 20 mM acetate (pH 5.7) at the N/P ratio of 35 were used for following experiments. Table 1 showed that the particle sizes of all complex nanoparticles prepared in water were about 120 nm, which were much smaller than those prepared in 20 mM acetate (pH 5.7). Meanwhile, the surface charges of the above complex nanoparticles prepared

Table 1. Average Particle Size and ζ Potential of Polymer/DNA Nanoparticles Prepared in Different Media at the Polymer/DNA Ratio (N/P) of 35

	distilled water		20 mM acetate (pH 5.7)
polymer	particle size (nm)	ζ-potential (mV)	particle size (nm)
PAEP	119.4 ± 5.5	30.5 ± 6.1	161.4 ± 5.2
UA-PAEP7	1230.6 ± 6.2	23.9 ± 4.8	168.8 ± 6.6
UA-PAEP25	115.9 ± 4.3	6.7 ± 3.3	145.7 ± 5.9

in distilled water decreased with increasing degree of UA substitution. The ζ potential of PACNs was the highest (30.5 mV), and that of UA-PAEP25/DNA complex nanoparticles (UP25CNs) was only 6.7 mV. Apparently, the conjugation of UA with the amino groups in PAEP decreased the DNA binding ability of polymer, as well as the charge density of complex nanoparticles.

In VitroTransfection Efficiency. In order to know the transfection activity of PACNs, the experiment was first performed in Hela cells using pEGFP in serum-free medium. As shown in Figure 5A, PACNs yielded the highest transfection efficiency at the N/P ratio of 7.5, which was almost the same order of magnitude as PEICNs at the optimal ratio (N/P = 35). This behavior of PAEP was so different from that of another structurally similar polyphosphazene derivative, poly(di-DMAE-A)phosphazene (*11*), which showed much lower transfection efficiency compared with the PEI polyplexes. PAEP and poly(di-DMAEA)phosphazene are two cationic polyphosphazenes with an identical backbone containing different side chains, which are primary and tertiary amino groups, respectively. It has been reported that the type of charge group is one of the most important parameters for efficient gene transfer (*20*−*22*). Among all carriers with various types of charge groups, polymers with primary amino groups were found to be most efficient in transfecting cell lines (*23, 24*). So, the different types of charge groups might bring about the variance of transfection level between PAPE and poly(di-DMAEA)phosphazene. Then, in vitro transfection efficiency of PACNs prepared in distilled water was evaluated in Hela and COS 7 cell lines to look for the optimal condition of transfection in complete medium. Figure 5B showed that PACNs mediated the highest level of gene expression at the N/P ratio of 35 in both Hela and COS 7 cell lines. The increase of the optimal transfection ratio (N/P) of PACNs from 7.5 in serum-free medium to 35 in complete medium might result from the decreased positive charges of complex nanoparticles after interaction with the components of serum. It was reported that 20 mM acetate (pH 5.7) could ensure a higher positive charge density (*11*). So, the transfection efficiencies of PACNs, UPCNs, and PEICNs prepared either in distilled water or in 20 mM acetate (pH 5.7) at the N/P ratio of 35 were investigated to understand the relationship between preparation medium and transfection activity. The results showed that UP7CNs exhibited higher transfection activity compared with PACNs or UP25CNs in both media (Figure 5C) and the transfection level of UP7CNs was almost comparable to that of PEICNs. Despite the slightly lower buffering effect compared to that of UA-PAEP25, UP7CNs showed higher transfection efficiency than UP25CNs. The superior transfection activity of UP7CNs could result from its suitable positive charges, which are helpful for endocytosis, stability in cytoplasm, and dissociation of pDNA from UP7CNs. Besides, improved buffering capacity of UA-PAEP7 could be another reason accounting for the higher level of gene expression of UP7CNs than that of PACNs. With higher buffering capacity than UA-PAEP7, UP25CNs showed a much lower level of gene expression than UP7CNs. Possibly, fewer positive charges of UP25CNs resulted in weaker electrostatic attractions between pDNA and UA-PAEP25 after UP25CNs escaped from endo-

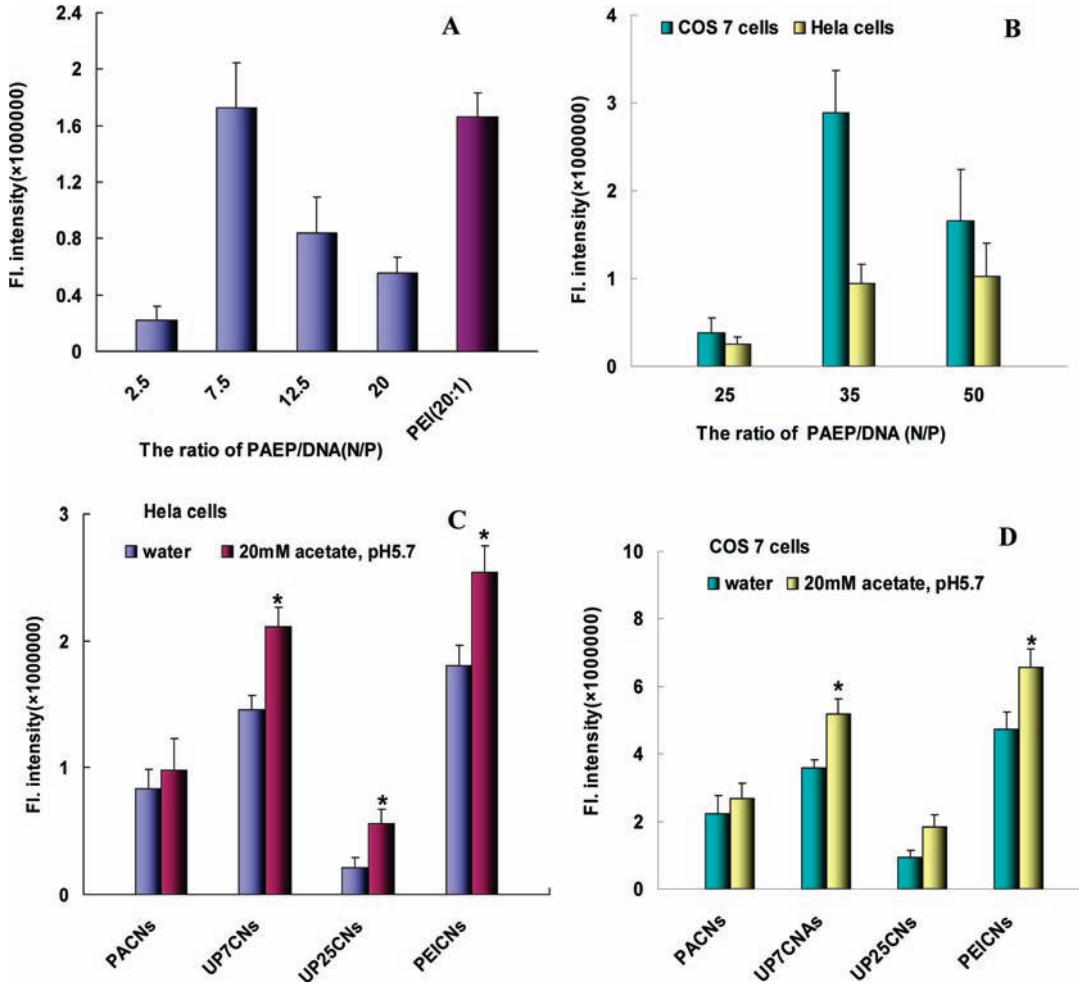

Figure 5. Transfection efficiency of Hela cells mediated by PACNs at various polymer/DNA ratios (N/P) in serum-free DMEM, PEICNs at the N/P ratio of 20 as control group (A). The transfection efficiency of PACNs prepared in water for Hela and COS 7 cells (B). Transfection efficiency of PACNs, UPCNs, and PEICNs prepared in water or acetate pH 5.7 at N/P ratio of 35 for Hela (C) and COS 7 cells (D) ($n = 3$, error bars represent standard deviation). The transfection efficiency was expressed as total fluorescence intensity of 1×10^4 cells. $^*p < 0.05$ compared with the transfection of complex nanoparticles prepared in water.

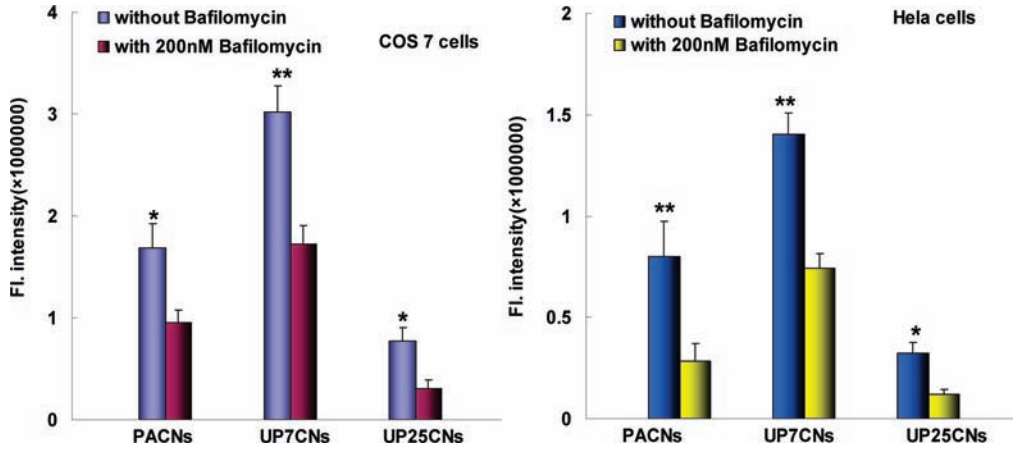

Figure 6. Effect of proton pump inhibitor bafilomycin A1 on transfection mediated by polymer/DNA complex nanoparticles at the polymer/DNA ratio (N/P) of 35. COS 7 cells and Hela cells were transfected in the presence of 200 nM or without Bafilomycin A1, respectively. The transfection efficiency was expressed as total fluorescence intensity of 1×10^4 cells ($n = 3$). $^{**}p < 0.01$ or $^*p < 0.05$ compared with the transfection of complex nanoparticles in the presence of bafilomycin A1.

some into cytosol with higher pH, thus inducing DNA to dissociate with complex nanoparticles and to be hydrolyzed by lysosomal enzyme. Therefore, the poor transfection efficiency of UP25CNs might be attributed to instability resulting from low zeta potential rather than buffering capacity. However, the absence of endosomal escape could be one of reasons accounting for unsatisfactory transfection activity of UP25CNs compared with UP7CNs as well. As for PACNs with the highest zeta potential, inferior buffering capacity might be one of the factors leading to a lower level of gene transfection than UP7CNs.

The acetate solution (20 mM, pH 5.7) improved the transfection activity of UPCNs (especially UP25CNs) in Hela cells

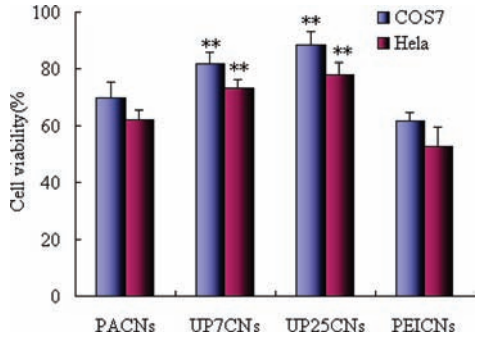

Figure 7. Cytotoxicity of PACNs and UPCNs at polymer/DNA ratio (N/P) on COS 7 cells and HeLa cells measured by MTT assay. PEICNs as control ($n = 3$, error bars represent standard deviation). $^{**}p < 0.01$ compared with the cytotoxicity of PEICNs.

(Figure 9) and COS 7 cells, while this effect was not observed in the case of PACNs. The results suggested that the increased transfection efficiency of UPCNs in 20 mM acetate (pH5.7) could be due to increased positive charges and the enhancement of the protonation from imidazole moieties, especially for UP25CNs with higher UA denstity. However, for PACNs, a permanent positive charge from basic amino groups induced the little alteration of the stability in cytosol as well as the transfection activity without regard to pH of preparation medium. Bafilomycin A1, a proton pump inhibitor, is used to testify whether the buffering-based endosomolytic activity plays an important role on the transfection efficiency. Bafilomycin A1 is an antibiotic that selectively inhibits vacuolar type of H^+-ATPases (*25*). Figure 6 showed that the involvement of Bafilomycin A1 resulted in a significant decrease in the gene expression levels of PACNs and UPCNs in Hela and COS 7 cell lines, which suggested that the transfection efficiencies of all the above complex nanoparticles were dependent on the endosomal acidification process. Because of this, it is very meaningful to conjugate the UA moiety with PAEP to increase the buffering capacity, which benefits the endosomal escape of complex nanoparticles to improve the transfection efficiency. Even if, in the presence of a proton pump inhibitor, the transfection activity of UP7CNs was still higher than that of other complex nanoparticles, which also meant that the marginally increased buffering capacity of UA-PAEP7 was not enough to explain its higher transfection efficiency.

Cytotoxicity of Polymer/DNA Complex Nanoparticles. The cytotoxicity of complex nanoparticles at polymer/DNA ratio (N/P) of 35 in COS 7 and Hela cells was shown in Figure 7. In COS 7 cells, the cell viability of PACNs was 69%, which was slightly higher than that of PEICNs. When PAEP was modified by UA, the cell viability of complexed nanoparticles increased from 81% to 88% with the substitute degree of UA from 7% to 25%. The descending cytotoxicity of polymer modified by UA could be due to the decreased positive charges. The similar results of cytotoxicity also occurred in Hela cells. So, it was obvious that the cytotoxicity of UPCNs was much lower than that of PEICNs in both cell lines.

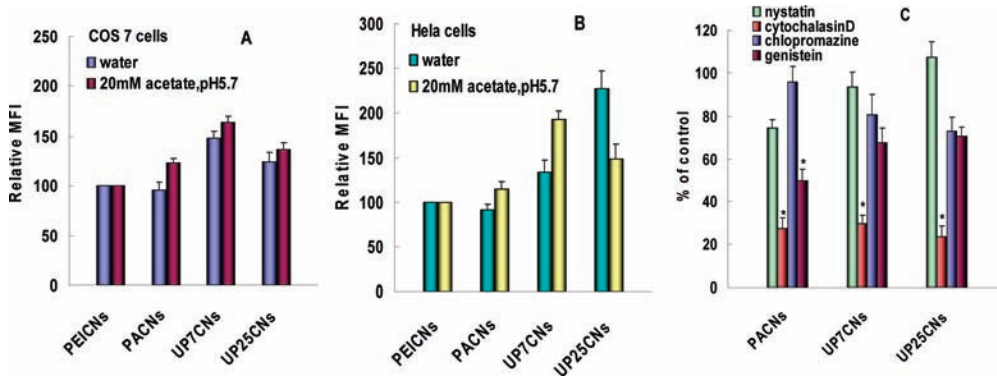

Figure 8. Cellular uptake of nanoparticles prepared in water or acetate (pH 5.7) on COS 7 cells (A) and Hela cells (B). The cells were incubated for 1 h with YOYO-1-labeled nanoparticles. After a subsequent washing and trypsinization, the mean fluorescence intensity (MFI) was analyzed with a flow cytoflurometer. MFI of PEICNs was normalized to 100. Nanoparticles were prepared at the N/P ratio of 35. Cellular uptake of PACNs, UP7CNs, or UP25CNs by Hela cells after incubation with various inhibitors (C). Percentages of cellular uptake expressed as % of control were means ± SD from three independent experiments. *Values significantly different from control ($p < 0.05$).

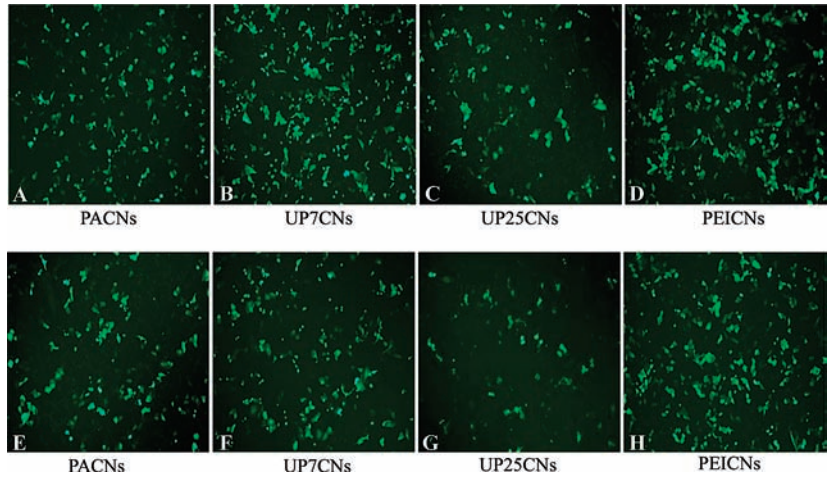

Figure 9. Images of Hela cells transfected with PACNs, UP7CNs, UP25CNs, and PEICNs prepared either in 20 mM acetate (pH 5.7) (A,B,C,D) or in distilled water (E,F,G,H) observed under fluorescent microscope (20× magnification) at the N/P ratio of 35.

Cell Uptake of Polymer/DNA Complex Nanoparticles. Uptake of polymer/DNA complex nanoparticles through endocytosis into the cells is the first step during intracellular gene delivery. It is essential to investigate the cellular uptake of complex nanoparticles for more insight into the diversity of transfection activity among three complex nanoparticles. The amount of pDNA internalized by Hela or COS 7 cells was estimated after quenching the fluorescence of the complex nanoparticles adsorbed on the cell surface by adding trypan blue to the cell suspension in PBS. The PACNs, UPCNs, and PEICNs were prepared at the polymer/DNA ratio (N/P) of 35. As shown in Figure 8A, the DNA uptake efficiency mediated by UP7CNs prepared in either distilled water or 20 mM acetate (pH 5.7) was much higher than that of other complex nanoparticles under same condition in COS 7 cell lines. So, the higher cell uptake level of UP7CNs could be one of the reasons for their superior transfection activity. Although the uptake level of PEICNs was lower than UP7CNs, the strong buffering capacity of PEI 25K, which would benefit intracellular trafficking of nanoparticles, could result in its higher transfection efficiency than UP7CNs. Although UPCNs prepared in 20 mM acetate (pH 5.7) showed enhancement of transfection activities than that prepared in water, no significant difference in terms of DNA uptake of complex nanoparticles between different preparation systems was observed. The results indicated that a weak acid preparation system could improve the compaction of UPCNs rather than their cellular uptake. In Hela cell lines, the uptake of complex nanoparticles prepared in 20 mM acetate (pH 5.7) was similar to that in COS 7 cells, while the DNA uptake level mediated by UP25CNs prepared in distilled water surprisingly was the highest among the three complex nanoparticles.

Current evidence suggests that the positively charged polymer/DNA complex nanoparticles are taken up by means of endocytosis (*26, 27*). Since different endocytic pathways exist, it is important to have a more detailed knowledge of the cellular uptake and routing mechanism of polymer/DNA complex nanoparticles. To know whether the type of endocytosis would bring about the above phenomenon of UP25CNs, quantitative measurement of the uptake of complex nanoparticles in the presence of endocytosis inhibitors was investigated in Hela cell lines. In our experiments, disruption of macropinocytosis by means of cytochalasin D decreased all of PACN, UP7CN, and UP25CN uptake to less than 30%, as a percentage of control (i.e., without preincubation with inhibitor) (Figure 8C). Inhibition of caveolae-mediated uptake by genistein, an inhibitor of tyrosine kinases involved in caveolae-mediated endocytosis, inhibited uptake of UP7CNs and UP25CNs by 67% and 70%, respectively, while the internalization of PACNs was significantly reduced by almost 50%. Inhibition of clathrin-mediated uptake by chlorpromazine and microtubule-mediated by nystatin did not significantly reduce the uptake of PACNs, UP7CNs, and UP25CNs. These results demonstrated that macropinocytosis dominated the uptake routes of three complex nanoparticles. Caveolae-mediated endocytosis was also involved in the uptake of PACNs, while clathrin-mediated and microtubule-mediated pathways were not involved in the uptake of three complex nanoparticles. There was no significant difference in endocytic pathway between UP7CNs and UP25CNs.

It seemed likely that the improvement of transfection mediated by UP7CNs was related to the following parameters including ζ-poptential, pH buffering capacity, and cellular DNA uptake. However, the intracellular trafficking and nuclear uptake are two crucial processes involved in enhanced gene expression of UP7CNs.

CONCLUSION

A biodegradable cationic polyphosphazene with (2-(2-aminoethoxy)ethoxy) as side chains bearing primary amino groups was synthesized and first used for gene delivery. PACNs could mediate efficient transfection in complete medium at the polymer/DNA ratio (N/P) of 35. UP7CNs could enhance the transfection efficiency compared with PACNs and decrease cytotoxicity compared with PEICNs in HeLa and COS 7 cell lines. The transfection experiment using a proton pump inhibitor suggested that the gene expression of PACNs, UPCNs were dependent on the endosomal acidification process. The acetate solution (20 mM, pH 5.7) could further improve the transfection activity of UPCNs, which was almost comparable to PEICNs in HeLa and COS 7 cell lines. So, UP7CNs could be a more potential carrier for gene delivery. Further studies would focus on evaluating in vivo transfection efficiency of UP7CNs.

Increased Sensitivity in Antigen Detection with Fluorescent Latex Nanosphere−IgG Antibody Conjugates

Tao Ji,* M. Catherine Muenker, Rao V. L. Papineni, John W. Harder, Douglas L. Vizard, and William E. Mclaughlin

Carestream Molecular Imaging, Carestream Health, Inc., New Haven, Connecticut 06511. Received July 6, 2009; Revised Manuscript Received January 4, 2010

IgG antibodies were conjugated to Kodak X-Sight nanospheres to develop fluorescent-labeled antibodies using two different synthetic routes: one involving the DTT reduction method, and the other involving Traut's Reagent modification method. These two methods result in different conjugation efficiencies and different performances in antigen detection. Western blotting shows that the nanosphere−IgG antibody conjugates synthesized using the DTT reduction method are more immunospecific than the conjugates synthesized using Traut's Reagent modification method. In addition, the conjugates synthesized using DTT reduction also show higher antigen detection sensitivity than other commercially available fluorescent-IgG antibody conjugates, including Alexa Fluor, Qdot, and CyDye conjugates.

INTRODUCTION

Fluorescent antibodies have been widely used in immunodetection both in life-science research and in clinical applications (*1*−*10*). Most of the fluorescent labels used for the labeling of antibodies are organic molecules that suffer from photobleaching and relatively low fluorescence intensity. Efforts to improve the sensitivity of immunodetection by exploring highly fluorescent and photostable labels have gained considerable momentum over the past decade (*11*−*16*).[1]

We have introduced a class of highly fluorescent organic nanospheres, Kodak X-Sight nanospheres (*17*), for fluorescent labeling of biomolecules. Our nanospheres are approximately 20 nm in diameter and are composed of a cross-linked polymer core coated with a poly(ethylene glycol) derivative that confers over 200 primary amines to the particle periphery. Each nanosphere encapsulates multiple dye molecules in the core, producing bright fluorescence and improved photostability. The primary amine-functionalized poly(ethylene glycol) layer on the surface provides water solubility and allows a variety of biomolecules, such as antibodies, streptavidins, DNA, or enzymes, to be covalently attached through different linking chemistries.

Here, we present the conjugation of IgG antibodies to Kodak X-Sight nanospheres and demonstrate the performance of the conjugates in antigen detection. We also address the challenge of quantitative determination of the number of biomolecules attached to the nanospheres—a problem typical of any nanoparticle-based conjugate system—by the development of a simple and sensitive method based on UV spectroscopy. To the best of our knowledge, this is the first report on utilizing this method to quantify the number of antibodies attached per nanosphere.

A variety of species-specific and highly cross-adsorbed IgG antibodies were successfully conjugated to the nanospheres in four excitation and emission wavelengths ranging from visible to near-infrared (Figure 1). These nanosphere conjugates exhibited increased brightness, high sensitivity, and enhanced signal-to-background ratio in Western blotting assays. We demonstrated up to a 10× improvement in antigen detection over other commercially available, spectrally similar, fluorescent−IgG antibody conjugates. The multiple colors of these nanosphere−antibody conjugates also enable multiplex detection, such as multiplex Western blotting assays, which allows for the detection of several proteins simultaneously on a single blot.

EXPERIMENTAL PROCEDURES

Materials. Kodak X-Sight 549 nanosphere, Kodak X-Sight 650 nanosphere, Kodak X-Sight 691 nanosphere, and Kodak X-Sight 761 nanosphere were manufactured by Carestream Health, Inc. All the reagents used for the X-Sight nanosphere synthesis are reagent grade or better unless otherwise specified. Goat anti-mouse, goat anti-rabbit, and goat anti-rat IgG antibodies were purchased from Jackson Immuno Research Laboratories. *N*-[β-Maleimidopropyloxy]succinimide ester, Traut's Reagent, BupH phosphate buffer saline (0.1 M sodium phosphate, 0.15 M NaCl, pH 7.2), PBS (0.137 M sodium chloride, 0.0027 M potassium chloride, and 0.0119 M phosphates, pH 7.4), Ellman's Reagent, β-mercaptoethanol, diethyl ether, methanol, and nonfat dry milk were obtained from Thermo Fisher Scientific. Dithiothreitol, dimethyl sulfoxide, sodium phosphate monobasic, sodium phosphate dibasic, sodium chloride aqueous solution (5 M), ethylenediaminetetraacetic acid disodium salt solution (0.5 M), conalbumin, trypsin, poly(ethylene glycol) dimethacrylate (Mn, 875), hydrochloric acid (37%), sodium hydroxide, ethyl acetate, hydrogen chloride, ethylene glycol methyl ether methacrylate, divinylbenzene (technical grade), cetylpyridinium chloride, sodium bicarbonate, tetrahydrofuran, and Dowex 50WX4−200 ion-exchange resin were purchased from Sigma-Aldrich. 10× PBS (0.1 M sodium phosphate, 1.5 M NaCl, pH 7.2) was purchased from Bio-Rad Laboratories. NuPAGE 4−12% BT gel, MOPS SDS running buffer (20×),

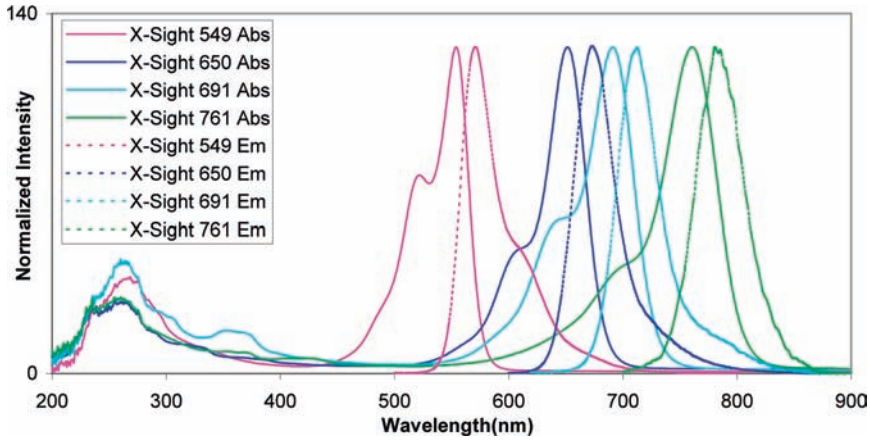

Figure 1. UV absorption and emission spectra of X-Sight nanospheres. Absorption/emission maxima: X-Sight 549, 549 nm/569 nm; X-Sight 650, 650 nm/573 nm; X-Sight 691, 691 nm/715 nm; X-Sight 761, 761 nm/789 nm.

NuPAGE sample reducing agent (10×), NuPAGE antioxidant, NuPAGE transfer buffer (20×), NuPAGE LDS sample buffer (4×), 4−20% tris-glycine gel, Novex native tris-glycine sample buffer (2×), NativeMark protein standard, tris-glycine native running buffer, Alexa Fluor IgG antibody conjugates, and Qdot IgG antibody conjugates were purchased from Invitrogen. ECL Plex Fluorescent Rainbow Marker, illustra NAP-5 columns, Superdex 200 gel media, and Cy3 goat anti-mouse were purchased from GE Healthcare. Cy5 goat anti-mouse, Cy5.5 goat anti-mouse, and NIH/3T3 whole cell lysate were purchased from Rockland Immunochemicals. Immobilon-FL PVDF membrane, Microcon YM-30, and Microcon YM-100 were purchased from Millipore. Primary IgG antibodies (rabbit antibeta tubulin, mouse anti-beta actin, rat anti-HSC 70) were purchased from Abcam. Magnesium sulfate was purchased from Alfa Aesar. Cysteamine was purchased from TCI America. 2,2-Azobis(*N*,*N*-dimethyleneisobutyramidine) dihydrochloride was purchased from Wako Pure Chemical Industries. Spectra/Por dialysis membrane (MWCO 3500) was purchased from VWR.

Instrumentation. SDS PAGE gel was imaged on a KODAK Gel Logic 212 imaging system. Western blot images were taken on a KODAK Image Station 4000MM digital imaging system or on a KODAK In-Vivo Multispectral Imaging System FX. UV spectra were measured on a PerkinElmer Lambda 25 UV/vis spectrometer. Fluorescence spectra were measured on a PerkinElmer luminescence spectrometer LS 50B. Centrifugation was performed on an Eppendorf microcentrifuge 5415R. Chromatography of the conjugates, IgG antibody, and proteins was carried out on a Waters HPLC 2796 equipped with a Superdex 200 column.

Buffer Preparation. PBS (0.1 M sodium phosphate, 0.15 M NaCl, pH 7.5), PBS/5 mM EDTA (0.1 M sodium phosphate, 0.15 M NaCl, 5 mM EDTA, pH 8.0), and phosphate buffer/1 mM EDTA (0.1 M sodium phosphate, 1 mM EDTA, pH 8.0) were prepared from sodium phosphate monobasic, sodium phosphate dibasic, NaCl and EDTA. BupH PBS/10 mM EDTA (0.1 M sodium phosphate, 0.15 M NaCl, 10 mM EDTA, pH 7.2) was constructed from BupH phosphate buffer saline and EDTA. 1× PBS (0.01 M sodium phosphate, 0.15 M NaCl, pH 7.2) was diluted from 10× PBS.

Preparation of Fluorescent Nanospheres. The preparation is described briefly here. For a detailed description of the preparation, see U.S. patent application (*17*)

Preparation of Amine-Terminated Poly(ethylene glycol) Macromonomer. PEG dimethacrylate (335 g) in 100 mL of methanol was treated with cysteamine (5.8 g) and diisopropylethylamine (0.08 g). The mixture was stirred at room temperature for 2 days and then concentrated using a rotary evaporator. The residue was taken up in 1 L of ethyl acetate and extracted with aqueous HCl solution (10%). The aqueous layer was collected, made basic by adding 50% aqueous sodium hydroxide solution, and then extracted with ethyl acetate. The organic layer was dried over magnesium sulfate, filtered, and concentrated. The residue was taken up in anhydrous diethyl ether and treated with gaseous HCl and allowed to stand. The ether was decanted, and the residual dark blue oil was washed with fresh diethyl ether, which was then decanted. The dark blue oil was dried on a rotary evaporator to yield 37 g of the desired product in the form of the hydrochloride salt. ^{1}H NMR (300 MHz, $CDCl_3$): 1.18 (doublet, 3H), 1.93 (broad singlet, 3H), 2.04 (broad singlet, 2H), 2.43−2.77 (broad multiplet, 7H), 3.6−3.7 (broad singlet, $-CH_2CH_2O-$), 3.73 (broad triplet, 2H), 3.29 (broad triplet, 2H), 5.56 (broad singlet, 1H), 6.12 (broad singlet, 1H).

Synthesis of Nanospheres. Typical example: A 500 mL 3-neck round-bottomed flask was modified with Ace #15 glass threads at the bottom and a series of adapters allowing connection of 1/16 in i.d. Teflon tubing. The flask (hereafter referred to as the header flask) was outfitted with a mechanical stirrer and rubber septum with syringe needle nitrogen inlet. The header was charged with methoxyethyl methacrylate (5.63 g), divinylbenzene (0.63 g, mixture of isomers, 80% pure with remainder being ethylstyrene isomers), amine-terminated poly(ethylene glycol) macromonomer (6.25 g), 2,2-azobis(*N*,*N*-dimethyleneisobutyramidine) dihydrochloride (0.06 g), cetylpyridinium chloride (0.31 g), and distilled water (78.38 g). The header contents were brought to pH 5 with 1 N NaOH. A 1 L 3-neck round-bottomed flask outfitted with a mechanical stirrer, reflux condenser, nitrogen inlet, and rubber septum (hereafter referred to as the reactor) was charged with distilled water (159.13 g), 2,2-azobis(*N*,*N*-dimethyleneisobutyramidine) dihydrochloride (0.06 g), sodium bicarbonate (0.06 g), and cetylpyridinium chloride (0.94 g). Both the header and the reactor contents were stirred until homogeneous and were bubble degassed with nitrogen for 20 min. The reactor flask was placed in a thermostatted water bath at 60 °C, and the header contents were added to the reactor over 2 h using a model QG6 lab pump. The reaction was allowed to stir at 60 °C for 16 h. The latex was then dialyzed against distilled water for 48 h using a Spectra/Por dialysis membrane (MWCO 3500) and was stirred over 27.5 g Dowex 50WX4−200 ion-exchange resin (sodium form) overnight to afford 312 g of clear latex of 3.26% solids. The volume average diameter of the nanosphere was found to be 20.89 nm with a coefficient of variation of 0.24 by quasi-elastic light scattering.

Loading the Nanospheres with Dyes. For the synthesis of the dyes loaded inside the nanospheres, see patent application (*17*).

Typical dye loading example: Under dim lighting, 1.4365 g of a dye stock solution of 0.2784% (w/w) in THF was added to a tinted glass vial and was diluted with THF to a final weight of 10.0 g. The amine-functionalized nanosphere (9.996 g) was added to the vial, and the solution was mixed and concentrated to approximately 40−50% volume on a rotary evaporator. Residual THF was further removed by twice adding 3−5 mL of distilled water and stripping ∼1/4−1/3 of the volatiles. 9.4 g of dye-loaded nanospheres of 4.27% (w/w) solids containing 3.94×10^{-3} mol dye per gram of solid nanospheres was obtained.

Fuctionalization of Nanospheres with BMPS. X-Sight 549, 650, 691, and 761 nanospheres, modified with maleimide functional groups, were prepared. In a typical procedure, 549 (40 μL, 32 μM) was added to 60 μL of PBS (0.1 M, 0.15 M NaCl, pH 7.5) and was then added with 6.4 μL (192.2 nmol) of 30 mM BMPS dissolved in anhydrous DMSO. The mixture was stirred at room temperature for 1 h. The maleimide-modified nanospheres were purified on an Illustra NAP-5 column eluted with BupH PBS/10 mM EDTA. ∼500 μL of the purified nanospheres was collected and stored on ice. The concentration of the purified nanospheres, as determined by UV absorbance, was 2.28 μM. The number of maleimide groups attached per nanosphere was quantified by Ellman's Reagent and is ∼80 maleimide groups per nanosphere.

Preparation of SH Groups Containing IgG Antibodies. *DTT Reduction Method.* Typical example: IgG antibody (0.5 mg) was dissolved in BupH PBS/10 mM EDTA (500 μL) at 1 mg/mL. Five microliters of 1 M DTT dissolved in BupH PBS/10 mM EDTA was added to the IgG solution. The mixture was incubated at RT for 1 h on a rotator and transferred to a Microcon YM-30 filter unit. The solution in the Microcon filter unit was concentrated to ∼50 μL by spinning at 13 400 *g* in an Eppendorf microcentrifuge for 11 min. The filtrate was discarded, and the remaining solution in the filter unit was brought up to 500 μL by BupH PBS/10 mM EDTA and spun again at 13 400 *g* for 11 min. This concentration−dilution cycle was repeated three more times. Roughly 50 μL of the modified IgG solution was collected.

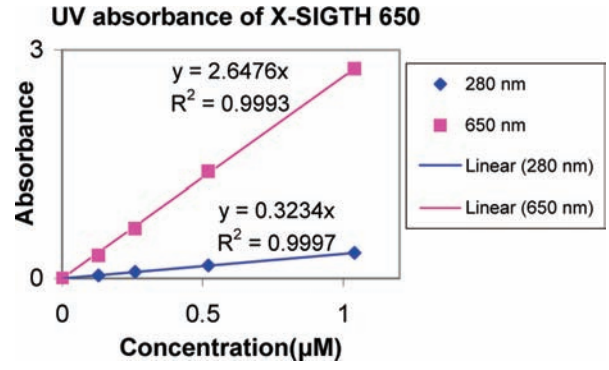
Traut's Reagent Modification Method. Typical example: IgG antibody (0.5 mg) was dissolved in PBS (0.1 M, 0.15 M NaCl, pH 8.0)/5 mM EDTA buffer (500 μL) at 1 mg/mL. 4.76 μL of 7 mM Traut's Reagent dissolved in PBS (0.1 M, 0.15 M NaCl, pH 8.0)/5 mM EDTA buffer was added to the above IgG solution. The mixture was incubated at RT for 1 h on a rotator and transferred to a Microcon YM-30 filter unit. The solution in the Microcon filter unit was concentrated to ∼50 μL by spinning at 13 400 *g* in an Eppendorf microcentrifuge for 11 min. The filtrate was discarded, and the remaining solution in the filter unit was brought up to 500 μL by BupH PBS/10 mM EDTA and spun again at 13 400 *g* for 11 min. This concentration−dilution cycle was repeated one more time. Roughly 50 μL of the modified IgG solution was collected.

Conjugation of IgG Antibodies to Nanospheres. *DTT Reduction Method.* Maleimide-functionalized nanospheres (2.28 μM, 255.7 μL) and BupH PBS/10 mM EDTA (70 μL) were added to the above SH group-containing IgG (50 μL) synthesized by DTT reduction method. The mixture was incubated at RT for 2 h on a rotator. The mixture was then transferred to a Microcon YM-100 filter unit, and the volume was reduced to ∼50 μL on an Eppendorf microcentrifuge. The concentrated solution was fractionated on a self-packed Superdex 200 column eluted with 1× PBS (10 mM sodium phosphate, 0.15 M NaCl, pH 7.2). ∼500 μL of the conjugates was collected. The concentration of the purified nanosphere−IgG antibody conjugates was determined by UV absorbance at λ_{max} to be ∼0.6 μM. The number of IgG antibodies incorporated per nanosphere was quantified by UV absorbance to be 4.4 IgG antibodies per nanosphere.

Traut's Reagent Modification Method. Maleimide-functionalized nanospheres (2.28 μM, 128 μL) and BupH PBS/10 mM EDTA (120 μL) were added to the above SH group-containing IgG (50 μL) synthesized by Traut's Reagent modification method. The mixture was incubated at RT for 2 h on a rotator. The mixture was then transferred to a Microcon YM-100 filter unit, and the volume was reduced to ∼50 μL on an Eppendorf microcentrifuge. The concentrated solution was fractionated on a self-packed Superdex 200 column eluted with 1× PBS (10 mM sodium phosphate, 0.15 M NaCl, pH 7.2). ∼500 μL of the conjugates was collected. The concentration of the purified nanosphere−IgG antibody conjugates was determined by UV absorbance at λ_{max} to be ∼0.4 μM. The number of IgG antibodies incorporated per nanosphere was quantified by UV absorbance to be 3.6 IgG antibodies per nanosphere.

Determination of the Number of Maleimide Groups Attached per Nanosphere. The quantification was done by taking advantage of the high reactivity of BME with the maleimide group. BME reacts with maleimide group in a 1:1 stoichiometry; thus, the number of maleimide groups was determined by the decrease in bulk BME concentration using Ellman's Reagent, which reacts with sulfhydryl group to form a colored compound (molar extinction coefficient of 14 150 cm^{-1} M^{-1} at 412 nm). Briefly, 200 μL of the maleimide functionalized nanosphere (∼0.5 nmol) was incubated with 10 μL of 10 mM BME in BupH PBS/10 mM EDTA for 1 h at RT. Then, 100 μL of the reaction mixture was taken out and mixed with 850 μL of phosphate buffer/1 mM EDTA (0.1 M sodium phosphate, 1 mM EDTA, pH 8.0) and 50 μL of 10 mM Ellman's Reagent predissolved in phosphate buffer/1 mM EDTA. The mixture was incubated for 15 min at RT, and the absorbance at 412 nm was recorded. In the control experiment, 10 μL of 10 mM BME in BupH PBS/10 mM EDTA was incubated with 200 μL of BupH PBS/10 mM EDTA without maleimide functionalized nanospheres for 1 h at RT and was analyzed similarly to estimate the total amount of BME added to the reaction mixture. For the maleimide-modified nanospheres synthesized using the method described in this paper, there are generally about 70−80 maleimide groups attached per nanosphere.

Determination of the Number of Sulfhydryl Groups Generated on the IgG Antibody. The quantification of the sulfhydryl groups on the IgG after DTT reduction and Traut's Reagent modification was done using Ellman's Reagent following the manufacturer's protocol. Briefly, 1 mg of DTT reduced or Traut's Reagent modified goat anti mouse IgG was diluted to 950 μL with phosphate buffer/1 mM EDTA (0.1 M sodium phosphate, 1 mM EDTA, pH 8.0) and was incubated



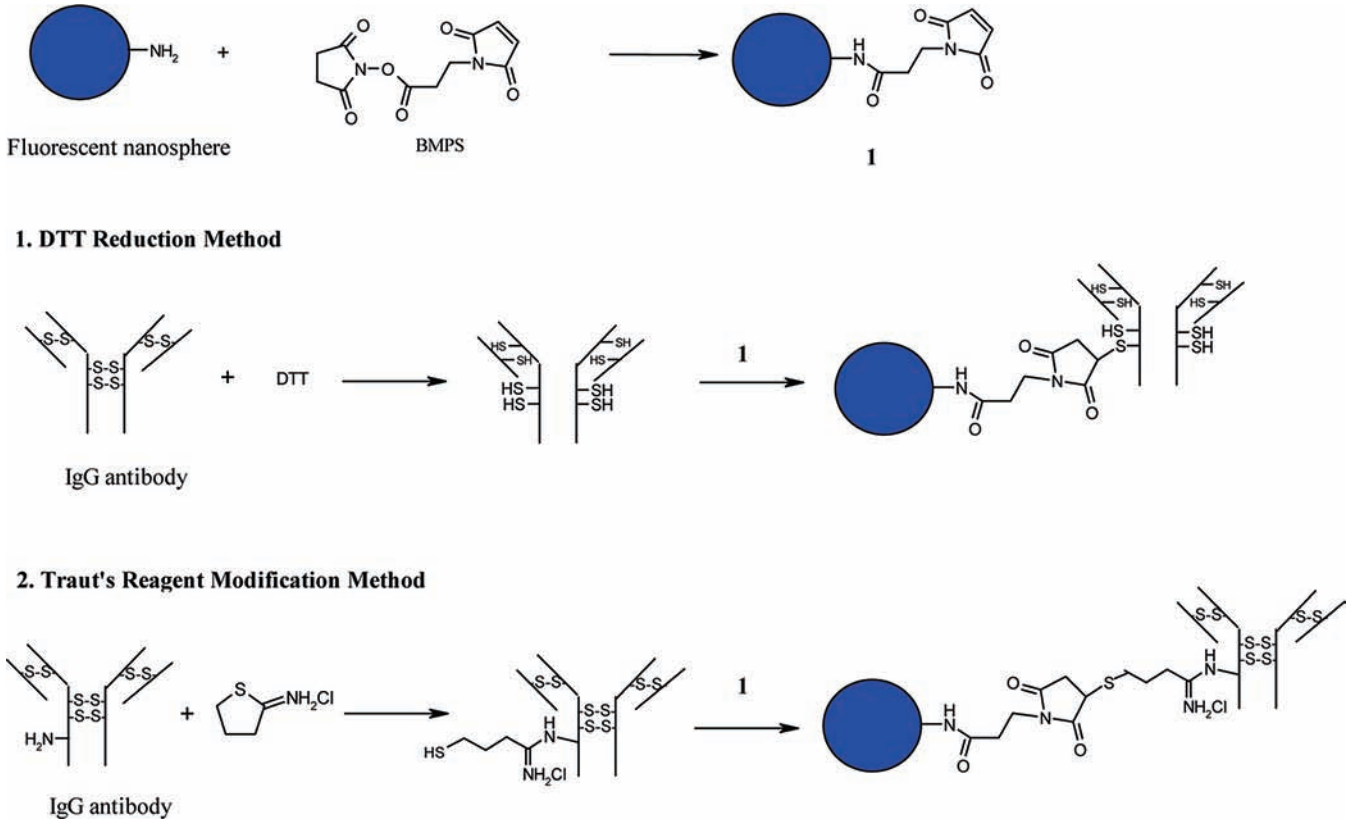


Figure 2. Determination of the ratio (r_f) of the absorbance of nanospheres at 280 nm to the absorbance at 650 nm, $r_f = A_{280}/A_{650} = 0.32/2.65 = 0.12$.

Scheme 1. Synthesis of Nanosphere−IgG Antibody Conjugates

with 50 μL of 10 mM Ellman's Reagent predissolved in phosphate buffer/1 mM EDTA for 15 min at RT. The absorbance of the mixture at 412 nm was recorded. As a blank, 50 μL of 10 mM Ellman's Reagent predissolved in phosphate buffer/1 mM EDTA was incubated with 950 μL of phosphate buffer/1 mM EDTA for 15 min at RT, and the absorbance at 412 nm was recorded. According to the Beer−Lambert law and the extinction coefficient of 14 150 cm^{-1} M^{-1} at 412 nm, the number of sulfhydryl groups per IgG was calculated. Generally, there are about 16 sulfhydryl groups per DTT reduced goat anti mouse IgG and 3−4 sulfhydryl groups per goat anti mouse IgG modified by Traut's Reagent.

Quantification of the Number of IgG Antibodies Attached per Nanosphere. Quantification was done according to eq 1. N is the number of IgG antibodies per nanosphere. C_{ab} is the concentration of IgG attached to the nanospheres. C_p is the concentration of the nanospheres in the conjugates. A_{280} is the absorbance of the conjugates at 280 nm. A_{max} is the absorbance of the conjugates at λ_{max}. 210 000 is the molar extinction coefficient of the IgG antibody at 280 nm in cm^{-1} M^{-1}. r_f is the ratio of the absorbance of the nanospheres at 280 nm to the absorbance at λ_{max}, e.g., the r_f of the 650 nanosphere is 0.12, as shown in Figure 2. k is the slope in M^{-1} of the standard curve of the nanospheres themselves, generated in a series of known concentrations. The light path in the UV absorbance measurement is 1 cm.

The IgG antibody has a typical UV absorbance at 280 nm. According to the Beer−Lambert law, the concentration of IgG antibodies attached to nanospheres could be calculated as $C = A_{280}/\varepsilon$, where the light path is 1 cm. However, the nanospheres also have some absorbance and scattering at 280 nm (Figure 1). In order to get the net absorbance of the IgG antibodies at 280 nm, the contribution of nanospheres at 280 nm is deducted. In the conjugates, the absorbance of the nanospheres at 280 nm was calculated by $A_{max} \times r_f$; A_{max} multiplied by r_f. The concentration of nanospheres in the conjugates was obtained by A_{max}/k. Thus, the number of IgG antibodies attached per nanosphere was determined by the ratio of the concentration of IgG to the concentration of nanospheres in the conjugates.

$$N = \frac{C_{ab}}{C_p} = \frac{(A_{280} - A_{max} \times r_f)/_{210000}}{A_{max}/_k} = \frac{(A_{280} - A_{max} \times r_f) \times k}{210000 \times A_{max}} \quad (1)$$

SDS PAGE. Different amounts of goat anti-mouse IgG antibody with and without DTT treatment were mixed with NuPAGE LDS sample buffer (4×) and loaded into the wells of a 10-well, 4−12% NuPAGE gel. Five microliters of the ECL Plex Rainbow Marker was loaded as a protein ladder. The gel was run at 150 V in MOPS SDS running buffer for about 1.5 h.

Native PAGE. Different amounts of goat anti-mouse IgG antibody with and without DTT treatment were mixed with Novex native tris-glycine sample buffer (2×) and loaded into the wells of a 10-well, 4−20% tris-glycine gel. Five microliters of NativeMark protein standard was loaded as a protein ladder. The gel was run at 150 V in tris-glycine native running buffer for about 5 h.

Western Blotting. *Protein Electrophoresis for Western Blotting.* 3T3 cell lysate was added with a sample reducing agent(10×), boiled at 95 °C for 5 min, and placed immediately on ice. Ten micrograms of the 3T3 cell lysate was loaded per well into a 12-well, 4−12% NuPAGE gel. Five microliters of ECL Plex Rainbow Marker was loaded into the well next to the protein. The gel was run at 100−125 V in MOPS SDS running buffer for about 2 h.

Membrane Transfer. The gel was transferred to an Immobilon-FL PVDF membrane at 30 V at 4 °C on a stirrer overnight.

Blocking and Detection. The membrane was blocked in PBS with 5% nonfat milk for 1 h. Then, it was incubated in primary antibody diluted in PBS with 5% nonfat milk for 1 h at RT

with gentle shaking. The membrane was washed with PBS 3 times for 5 min each at RT. Then, it was incubated in fluorescent IgG antibody diluted in PBS with 5% nonfat milk for 1 h at RT with gentle shaking. The membrane was washed with PBS 3 times for 5 min each at RT. Then, it was imaged on the Image Station 4000MM or the In-Vivo Multispectral Imaging System FX.

Data Analysis of Western Blotting Images. The data were analyzed using KODAK MI Software. The protein band region was selected as a region of interest (ROI). Net intensity is defined as the sum of background-subtracted pixel intensities within the ROI. Background intensity is defined as the median intensity of the perimeter of each ROI. Signal/background is the ratio of net intensity to background intensity.

RESULTS AND DISCUSSION

Synthesis of Fluorescent Nanosphere−IgG Antibody Conjugates. The nanosphere−IgG antibody conjugates were synthesized through three steps: modification of nanospheres by a heterobifunctional linker, such as Sulfo-SMCC, BMPS, AMAS, and so forth; introduction of sulfhydryl groups to the IgG antibodies; and the coupling of the IgG antibodies to the nanospheres. The synthetic routes are shown in Scheme 1. The heterobifunctional linker contains an NHS ester moiety that is reactive toward the amino group and a maleimide group that is reactive toward the sulfhydryl group (*18*). Different starting ratios of linker to nanospheres vs the conjugation efficiency were evaluated. The results show that, if the ratio is too low, the conjugation of the IgG to the nanospheres is not efficient. If the ratio is too high, the solubility of the maleimide-modified nanospheres in aqueous solution decreases tremendously, and some of the nanospheres precipitate out of the solution. It was found that a ratio of linker to nanosphere in the range of ∼100:1 to 150:1 resulted in high conjugation efficiency, little aggregation, and excellent performance of nanosphere−IgG antibody conjugates in Western blotting assays. When the ratio is 150:1, there are generally about 80 maleimide groups attached per nanosphere, and the remaining primary amines on the nanosphere are over 120.

There are several different methods to incorporate sulfhydryl groups into antibodies, such as SATA modification (*19*), Traut's Reagent modification (*20*), and DTT reduction. Here, we report the conjugation using two different methods: DTT reduction and Traut's Reagent modification. DTT was reported to partially reduce the disulfide bonds in the hinge region of the IgG antibody, and the yielded sulfhydryl groups were successfully used as the attachment sites for dyes and other molecules. The advantage of this method is that the attachment sites were in the hinge region—away from the antigen-binding sites—and therefore, the attached molecules did not affect the activity of the IgG antibody (*21*−*25*). However, a recent report indicates that DTT completely dissociates the IgG antibody into heavy and light chains, causing the antibody to lose biological activity (*28*). In the case of SATA and Traut's Reagent modification, the bifunctional linkers randomly react with the primary amino groups on the antibody; therefore, the antigen-binding regions are also subject to modification. Extensive modification of the antigen-binding regions will cause the antibody to lose activity. Therefore, the ratio of the linker to the antibody needs to be carefully controlled.

In this paper, we evaluated both the DTT reduction and Traut's Reagent modification methods and the biological activity of the yielded conjugates. The goat anti-mouse, goat anti-rabbit, and goat anti-rat IgG antibodies used in the experiments are affinity purified and highly cross-adsorbed polyclononal antibodies that are composed of a mixture of IgG1 and IgG2 subclasses. There are quite a few reports in the literature of using DTT to partially reduce the disulfide bonds in the IgG. The experimental conditions varied from mild (10−100-fold molar excess of DTT to IgG, 30 min reaction at RT or at 37 °C) to more harsh conditions (300−7500-fold molar excess of DTT to IgG, 30 min reaction at RT) (*21*−*25*). It was also reported that all the interchain disulfides in IgG were cleaved when 150−1000-fold molar excess of DTT to IgG was used and the reaction was 1−3 h at 37 °C (*26, 27*). Our experimental conditions reported here show that DTT not only reduced the disulfide bonds in the hinge region, but it also reduced the interchain disulfide bonds between the heavy and light chains, which was indicated by the SDS PAGE results in Figure 3a. This finding is consistent with the some of the reports (*26*−*28*). IgG antibodies treated with DTT using the same protocol used in the DTT reduction conjugation were loaded on the gel (Figure 3a, lanes 1−4). Five bands in each lane were detected, of which two major bands were in the lower molecular weight region. These five bands corresponded to a light chain (25 kDa), a heavy chain (50 kDa), a small amount of a half IgG antibody (75 kDa), a whole IgG antibody losing one light chain (125 kDa), and a whole IgG antibody (150 kDa), respectively, while the IgG antibody without DTT treatment showed one main band at 150 kDa (Figure 3a, lanes 5−8). However, SDS PAGE could not deduce whether the antibodies dissociate in the nondenatured condition, because SDS denatures the protein and could dis-

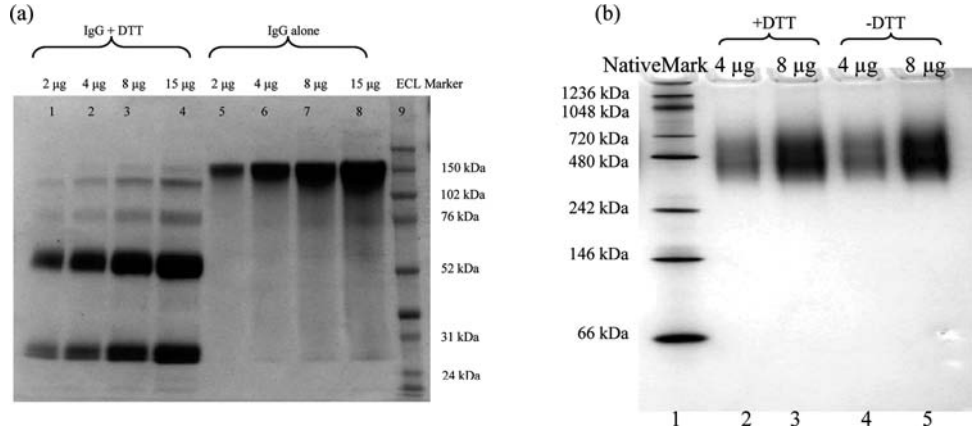

Figure 3. (a) 4−12% SDS PAGE of goat anti-mouse IgG. Lanes 1−4: IgG was treated with 10 mM DTT for 1 h at RT, and then a different amount was loaded on the gel. Lanes 5−8 were loaded with a different amount of IgG without DTT treatment. The gel was run at 150 V for ∼1.5 h. (b) Goat anti-mouse IgG on a 4−20% native PAGE. Lane 1: NativeMark protein standard. Lanes 2−3: IgG was treated with 10 mM DTT for 1 h at RT, and then a different amount was loaded on the gel. Lanes 4−5 were loaded with a different amount of IgG without DTT treatment. The gel was run at 150 V for ∼5 h.

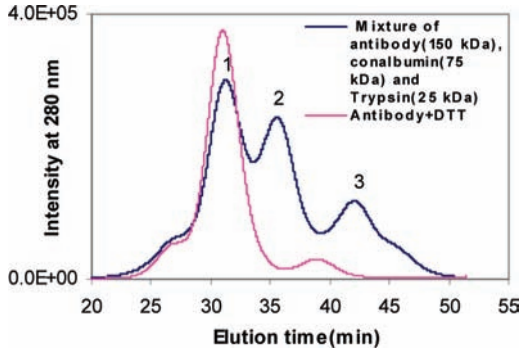

Figure 4. Chromatograms of proteins on HPLC detected at 280 nm. Elution rate: 2 mL/min. Blue curve is the mixture of goat anti-mouse IgG, conalbumin, and trypsin. Pink curve is the goat anti-mouse IgG treated with DTT. 1:1.7 mg/mL of goat anti-mouse IgG, M_w 150 kDa. 2:1.7 mg/mL of conalbumin, M_w 75 kDa. 3:3.0 mg/mL of trypsin, M_w 21 kDa. Mobile phase of blue curve: PBS, pH 7.4. Mobile phase of pink curve: PBS, pH 7.4/10 mM DTT.

sociate heavy and light chains of the antibody treated with DTT. As such, a native PAGE that separates the protein according to the charge, size, and conformation was run, and the result show that DTT reduced antibodies and unreduced antibodies show a similar pattern (Figure 3b), which indicates that the antibody fragments were still held together by noncovalent forces, even though the disulfide linkages were broken. Two bands were detected in both DTT-reduced and unreduced IgG antibodies (Figure 3b), for which the reason is not clear. A similar electrophoresis pattern was observed from more than one IgG antibody preparation. The integrity of the IgG antibodies was also checked by size-exclusion chromatography. In order to establish a running condition that could separate the IgG, half IgG, and the IgG light chain, a mixture of IgG, conalbumin, and Trypsin was used to simulate the mixture of IgG, half IgG, and IgG light chain. Conalbumin is a 75 kDa protein whose size is similar to that of a half IgG, and the molecular weight of trypsin is 21 kDa, similar to an IgG light chain. Three peaks corresponding to IgG, conalbumin, and trypsin, respectively, were detected (Figure 4, blue curve), which indicated that the running condition should be able to separate the IgG antibody, half IgG antibody, and light chain, with the half IgG antibody being eluted out at the similar elution time with that of the conalbumin and the light chain being eluted out at the similar elution time with that of trypsin. In the size-exclusion chromatography of the DTT-reduced IgG antibody, 10 mM DTT was incorporated into the mobile phase to prevent the reformation of the disulfide bridges. One single peak at the same elution time with that of the unreduced antibody corresponding to a molecular weight of 150 kDa was detected (Figure 4, pink curve), indicating that the antibody fragments were still held together by noncovalent interactions under native conditions, even though the interchain disulfide bonds were cleaved. Therefore, with the DTT reduction method, the IgG antibodies attached to the nanospheres were still whole antibodies (Scheme 1).

In the DTT reduction conjugation approach, the feed ratio of IgG antibody to nanosphere was 5.7 to 1, assuming there was no loss of the antibody after DTT reduction and purification. The corresponding conjugation efficiency and yield were determined by UV absorbance measurement according to eq 1. The results showed that the number of IgG antibodies attached was ~4.4 whole antibodies. The conjugation efficiency was also checked on an HPLC equipped with a Superdex 200 column. The chromatogram showed that the peak corresponding to the unconjugated antibody was very small; integration of the peak showed that ~90% of the antibodies were conjugated to the nanospheres (Figure 5a).

Traut's Reagent is very stable in neutral buffers. The hydrolysis is slow compared with the amine reaction rate. Therefore, thiolation with Traut's Reagent does not require a large excess of reagent like SATA. It was reported that, for IgG molecules, a 10-fold molar excess of Traut's Reagent would yield the antibody molecules modified with at least three sulfhydryl groups. Different stoichiometries of Traut's Reagent to IgG antibody (5:1 and 10:1) and IgG antibody to nanosphere (5.7:1 and 11:1) vs the conjugation efficiency and the performance of the conjugates in Western blotting assays was investigated. We found that the overall conjugation efficiency was low relative to the DTT reduction conjugation approach. When 10:1 ratio of Traut's Reagent to IgG antibody was used, a 5.7:1 of antibody-to-nanosphere ratio yielded 2 antibodies attached per nanosphere, and a 11:1 of antibody-to-nanosphere ratio yielded 3.6 antibodies attached per nanosphere, as calculated from eq 1. The low conjugation efficiency was also confirmed by HPLC analysis (Figure 5b). Western blotting results also showed that the 10:1 ratio of Traut's Reagent to antibody did not adversely affect the antibody function compared with 5:1 ratio of Traut's Reagent to antibody.

Western Blotting of the Nanosphere−IgG Antibody Conjugates. The performance of the conjugates synthesized through both the DTT reduction and Traut's Reagent modification method and other commercially available fluorescent−IgG antibody conjugates was investigated by Western blotting assays (Figures 6−9). In order to obtain an accurate comparison, all the Western blotting experimental conditions were kept identical. For example, the blots used for the comparison were transferred from the same gel to avoid the variation in the amount of protein transferred from different gels. The blots were blocked in the same blocker and incubated in the same primary antibody solution, and so forth. After being probed with the fluorescent antibodies, the blots in comparison were placed side by side on

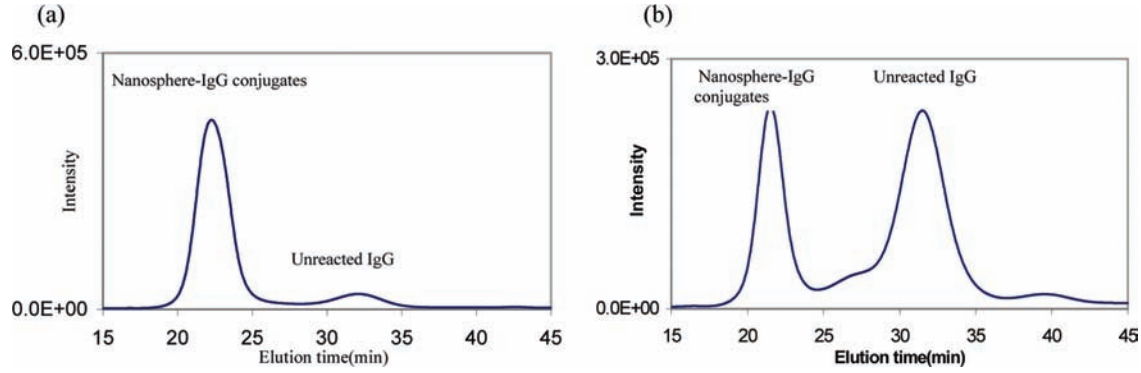

Figure 5. Chromatograms of the X-Sight 650 nanosphere−goat anti-mouse IgG conjugate mixture on HPLC detected at 280 nm. Mobile phase: PBS, pH 7.4. (a) DTT reduction method. (b) Traut's Reagent modification method, Ab: nanosphere = 11:1.

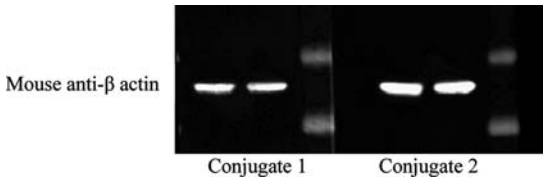

Figure 6. Western blot image of the X-Sight 650 nanosphere−goat anti-mouse IgG conjugates. Each blot contains two duplicated protein bands and a protein ladder on the right-hand side. The concentration of the conjugates in Western blotting assay was 3 nM. Conjugate **1** was synthesized using the Traut's Reagent modification method and has 3.6 antibodies attached per nanosphere. Conjugate **2** was synthesized using DTT reduction method and has 4.4 antibodies attached per nanosphere. Image was scanned for 4 min using excitation/emission filter set 630 nm/700 nm. Data analysis was done using KODAK MI software. The net intensity, background intensity, and signal/background of conjugate **2** was 2.2-fold, 0.8-fold, and 2.8 fold, respectively, of that of conjugate **1**.

the imaging system, and the images were acquired using the optimal excitation/emission filter sets for each fluorescent antibody. In addition, each of the blots was made to contain two duplicate protein bands, and the detected intensity was averaged in the data analysis to minimize the error. The results show that the conjugate synthesized through the DTT reduction method has much better performance than that synthesized through Traut's Reagent modification method, even though they both have about four antibodies attached per nanosphere, and the concentration of both conjugates in the Western blotting assay was the same (Figure 6). The image analysis shows that the net intensity and background intensity of the conjugates synthesized through the DTT reduction method is about 2× and 0.8×, respectively, of the net intensity and background intensity of the conjugates synthesized through Traut's Reagent modification method, and hence the signal-to-background ratio is about 2.8×. It has been demonstrated that nonspecific binding of the nanospheres to the PVDF membrane has contributed substantially to the background intensity in the Western blotting (data not shown). We speculate that the IgG antibody attached to the nanospheres helps to suppress the nanosphere/membrane interaction. The more antibodies that are attached per nanosphere, the lower the background intensity. A smaller difference in the background intensity between conjugates **1** and **2** further indicates that both conjugates have similar amounts of antibody attached per nanosphere. The conjugates synthesized through the DTT reduction method shows higher net intensity, which suggests that the antibodies in the conjugates are more active. The higher activity might be due to the nanospheres' attachment to the hinge region of the antibody, i.e., remote from the antigen binding sites and having less effect on the antibody activity. In the DTT reduction method, the thiol groups in the hinge region cleaved by DTT are more accessible to nanospheres than those in the other regions because the hinge region of the antibody is more flexible, which allows the lateral and rotational movement of the Fab fragments (*29*). With the Traut's Reagent modification method, the nanospheres' attachment sites on the antibodies are not controlled. The nanospheres could be attached to the antigen binding sites, which results in the antibodies losing activity.

The comparison of the performance of the conjugates synthesized through the DTT reduction method with Alexa Fluor IgG antibody conjugates shows that the performance is related to the concentration of the conjugates. Both the signal-to-background ratio and the net intensity increase with increasing concentration from 1.5 nM to 6 nM (Figure 7). For lower wavelength conjugates (Figure 7a,b), the nanosphere conjugates at a concentration of 1.5 nM have comparable

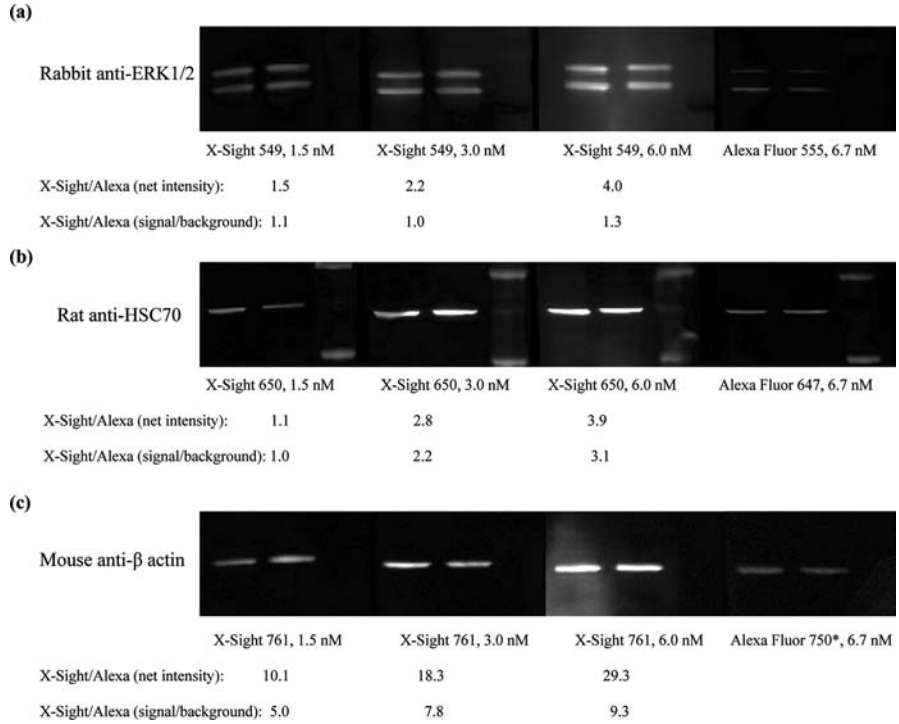

Figure 7. Western blot images of Alexa Fluor IgG antibody conjugates vs the X-Sight nanosphere−IgG antibody conjugates at different concentrations. The images were taken on an Image Station 4000MM. (a) The image was scanned for 25 s using an excitation/emission filter set 515 nm/570 nm. (b) The image was scanned for 30 s using an excitation/emission filter set 610 nm/670 nm. (c) The image was scanned for 3 min using an excitation/emission filter set 730 nm/790 nm. Each blot contains two duplicated protein bands and a protein ladder on the right-hand side. The concentration of the conjugates in the Western blotting assay ranged from 1.5 nM to 6.7 nM. The net intensity and signal/background of X-sight conjugates and Alexa Fluor conjugates were analyzed using MI software. X-Sight/Alexa (net intensity): the ratio of the net intensity of X-Sight nanosphere conjugates to that of Alexa Fluor conjugates. X-Sight/Alexa (signal/background): the ratio of the signal to background of X-Sight nanosphere conjugates to that of Alexa Fluor conjugates.

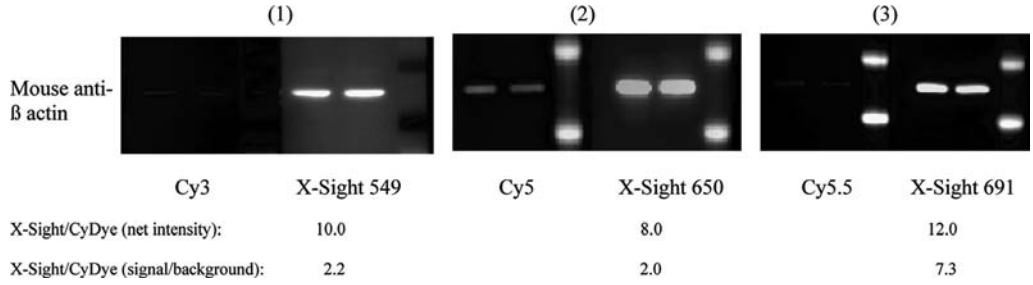

Figure 8. Western blot images of the X-Sight nanosphere−goat anti-mouse IgG conjugates vs CyDye-goat anti-mouse IgG conjugates. The images were taken on an Image Station 4000MM. (1) The image was scanned for 1 min using excitation/emission filter set 515 nm/570 nm. (2) The image was scanned for 1 min using an excitation/emission filter set 635 nm/700 nm. (3) The image was scanned for 1 min using an excitation/emission filter set 635 nm/700 nm. Each blot contains two duplicated protein bands and a protein ladder on the right-hand side. The concentration of the conjugates in Western blotting assay was 3 nM. The net intensity and signal/background of X-sight conjugates and CyDye conjugates were analyzed using MI software. X-Sight/CyDye (net intensity): the ratio of the net intensity of X-Sight nanosphere conjugates to that of CyDye conjugates. X-Sight/CyDye (signal/background): the ratio of the signal to background of X-Sight nanosphere conjugates to that of CyDye conjugates.

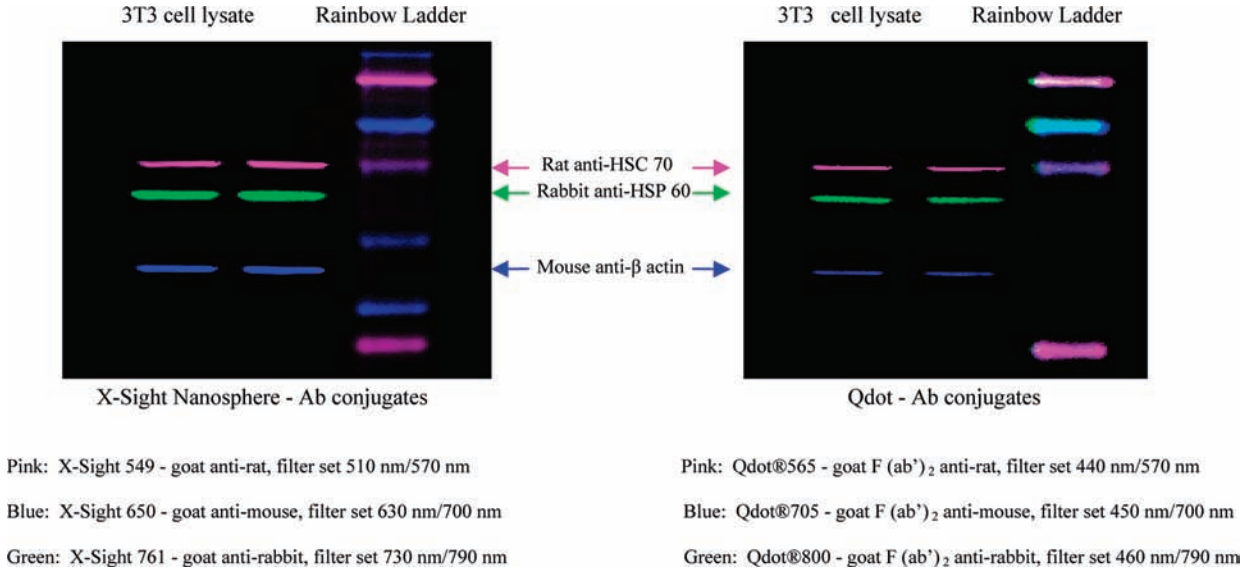

Figure 9. Multiplex Western blot of the X-Sight nanosphere−IgG antibody conjugates vs Qdot IgG antibody conjugates. Blots were probed with the mixture of rabbit anti-HSP60, mouse anti beta actin, and rat anti-HSC 70 primary antibodies followed by the mixture of X-Sight nanosphere-IgG antibody conjugates or the mixture of Qdot−IgG antibody conjugates. Each blot contains two duplicated protein bands and a protein ladder on the right-hand side. Images were captured for 30 s using an optimal excitation/emission filter set for each of the antibody conjugates on the In-Vivo Multispectral Imaging System FX and then overlaid in Photoshop. The concentration of the conjugates in the Western blotting assay was 2 nM. The net intensity and signal/background of X-sight conjugates and Qdot conjugates were analyzed using MI software. X-sight 549/Qdot 565: net intensity, 4.2; signal/background, 4.0. X-sight 650/Qdot 705: net intensity, 2.9; signal/background, 2.1. X-sight 761/Qdot 800: net intensity, 6.3; signal/background, 1.4.

performance with Alexa Fluor conjugates at a concentration of 6.7 nM. At similar concentration of the conjugates, the nanosphere conjugates (6 nM) have much higher signal-to-background ratio and net intensity than Alexa Fluor conjugates (6.7 nM). The X-Sight 761 nanosphere conjugates show higher brighteness and sensitivity than Alexa Fluor 750 conjugates, even at a much lower concentration (1.5 nM) (Figure 7c). Figure 8 shows that our nanosphere conjugates also have higher sensitivity than CyDye conjugates at all comparable wavelengths at matched concentration (3 nM) of the conjugates. It is noteworthy that our nanosphere conjugates not only exhibit higher signal-to-background ratio but also a much higher net intensity. In other words, our nanosphere conjugates were much brighter than Alexa Fluor and CyDye conjugates. Figure 7 shows that the X-Sight 549 and 650 nanosphere conjugates are ~4 times brighter than Alexa Fluor conjugates, and the X-Sight 761 nanosphere conjugates are up to 29 times brighter than Alexa Fluor conjugates. The advantage of relative higher brightness is that the acquisition time for the detection of a certain amount of signal is relatively shortened.

Quantum dots have been widely used in biological applications because of their superior brightness and photostability. The performance of our nanosphere-IgG antibody conjugates and spectrally similar Qdot IgG antibody conjugates in Western blotting assays was also evaluated (Figure 9). Multiplex Western blotting of the X-Sight nanospheres and Qdot conjugates is shown in Figure 9. The images were taken using the optimal filter sets for the X-Sight nanospheres and Qdots conjugates, respectively. The optimal excitation/emission filter sets were evaluated based on the signal-to-background ratio. Figure 9 shows that all of the X-Sight nanosphere conjugates have better performance than the counterparts of Qdot conjugates; they show not only higher signal-to-background ratio, but also much higher net intensity.

CONCLUSIONS

Two different coupling chemistries, BMPS-DTT and BMPS-Traut's Reagent, were evaluated for the synthesis of fluorescent nanosphere−IgG antibody conjugates. Native PAGE and size exclusion chromatography indicate that the DTT reduction

conditions (used herein) minimally disturb the antibody conformation, minimizing the effect upon biological activity of the antibody, even though the disulfide bridges in the antibody were cleaved. Moreover, BMPS-DTT chemistry gives higher conjugation efficiency, and the yielded conjugates show better performance in antigen detection. Side-by-side comparisons with other commercially available fluorescent IgG antibodies, like Alexa Fluor, Qdot, and CyDye antibody conjugates, show that the X-Sight nanosphere conjugates synthesized through BMPS-DTT chemistry provide increased brightness and higher signal-to-background in the detection of antigens.

A Dual-Labeled Knottin Peptide for PET and Near-Infrared Fluorescence Imaging of Integrin Expression in Living Subjects

Richard H. Kimura,[†] Zheng Miao,[†] Zhen Cheng,[†] Sanjiv S. Gambhir,[†,‡] and Jennifer R. Cochran*[,‡]

Department of Radiology, Molecular Imaging Program, and Department of Bioengineering, Cancer Center, Bio-X Program, Stanford University, Stanford, California 94305. Received July 13, 2009; Revised Manuscript Received October 19, 2009

Previously, we used directed evolution to engineer mutants of the *Ecballium elaterium* trypsin inhibitor (EETI-II) knottin that bind to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors with low nanomolar affinity, and showed that Cy5.5- or ^{64}Cu-DOTA-labeled knottin peptides could be used to image integrin expression in mouse tumor models using near-infrared fluorescence (NIRF) imaging or positron emission tomography (PET). Here, we report the development of a dual-labeled knottin peptide conjugated to both NIRF and PET imaging agents for multimodality imaging in living subjects. We created an orthogonally protected peptide-based linker for stoichiometric coupling of ^{64}Cu-DOTA and Cy5.5 onto the knottin N-terminus and confirmed that conjugation did not affect binding to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins. NIRF and PET imaging studies in tumor xenograft models showed that Cy5.5 conjugation significantly increased kidney uptake and retention compared to the knottin peptide labeled with ^{64}Cu-DOTA alone. In the tumor, the dual-labeled ^{64}Cu-DOTA/Cy5.5 knottin peptide showed decreased wash-out leading to significantly better retention ($p < 0.05$) compared to the ^{64}Cu-DOTA-labeled knottin peptide. Tumor uptake was significantly reduced ($p < 0.05$) when the dual-labeled knottin peptide was coinjected with an excess of unlabeled competitor and when tested in a tumor model with lower levels of integrin expression. Finally, plots of tumor-to-background tissue ratios for Cy5.5 versus ^{64}Cu uptake were well-correlated over several time points post injection, demonstrating pharmacokinetic cross validation of imaging labels. This dual-modality NIRF/PET imaging agent is promising for further development in clinical applications where high sensitivity and high resolution are desired, such as detection of tumors located deep within the body and image-guided surgical resection.

INTRODUCTION

The formation of new blood vessels that enable tumor growth is mediated in part by the differential expression or overexpression of various proteins. Among these are the integrin receptors, a family of heterodimeric cell surface receptors that bind extracellular matrix proteins to mediate cell attachment and signaling (*1*). There are currently over twenty different integrin subtypes known. In particular, $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins have been shown to be overexpressed on many different types of tumors and the tumor neovasculature (*2, 3*). These integrins have been proposed to play a role in mediating tumor growth, angiogenesis, and metastasis, making them attractive targets for cancer therapy (*4*−*6*). In addition, diagnostic agents are critically needed to monitor disease progression and to help identify patients who will best respond to integrin-targeted treatments (*7*−*9*).

Multimodal molecular imaging has emerged as a powerful tool in cancer diagnosis, treatment, and management, as well as in drug development (*10, 11*). Many clinical and preclinical imaging applications are based on positron emission tomography (PET), single-photon emission computed tomography (SPECT),[1] near-infrared fluorescence imaging (NIRF), bioluminescence, magnetic resonance imaging (MRI), and ultrasound. Each imaging modality has its own unique strengths and weaknesses; thus, combinations of different imaging modalities are now being used to overcome inherent limitations (*10, 12*). Dual-modality NIRF/PET tracers may find important clinical applications where high-resolution optical imaging is coupled with the sensitivity of nuclear imaging. For example, in tumor detection coupled with surgical procedures, the radionuclide component could initially be used to accurately map lesions that have grown deep within the body. When the radionuclide has sufficiently decayed, the optical mode could aid in image-guided surgery to precisely verify tumor margins during and following resection, using a minimally invasive laparoscopic instrument equipped with a NIRF detection system.

In this study, we developed a dual-modality NIRF/PET imaging agent based on the engineered integrin-binding knottin peptide 2.5D, which binds to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors with high affinity (*13*). Cy5.5 and ^{64}Cu-1,4,7,10-tetra-azacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (^{64}Cu-DOTA), were both chemically conjugated to the knottin N-terminus using a peptide-based linker that contained orthogonal protecting groups for sequential and precise coupling. We measured the integrin binding affinity and specificity of the DOTA/Cy5.5-conjugated knottin peptide compared to unlabeled knottin peptide and peptides conjugated only to DOTA or Cy5.5. Next, we used NIRF and PET imaging to evaluate tumor uptake, pharmaco-

kinetics, and biodistribution of the dual-labeled ^{64}Cu-DOTA/Cy5.5 knottin peptide in human tumor xenograft models and compared these results to imaging studies performed with knottin peptides conjugated only to ^{64}Cu-DOTA or Cy5.5. Compared to ^{64}Cu-DOTA, the hydrophobic Cy5.5 dye had a dramatic effect on probe pharmacokinetics and tissue biodistribution, with robust imaging signals lasting well beyond 24 h. In addition to generating a dual-modality NIRF/PET imaging agent, the cross-linking strategy presented here could be useful in creating other multimodal imaging agents, as well as in creating molecules for theranostic applications that combine imaging diagnostics with therapy.

EXPERIMENTAL PROCEDURES

Materials, Cell Lines, and Reagents. All 9-fluorenylmethyloxycarbonyl (Fmoc) protected amino acids were purchased from Novabiochem/EMD Chemicals Inc. (La Jolla, CA) with the exception of Fmoc-*N*-ε-1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)-3-methylbutyl-L-lysine (Fmoc-Lys(ivDde)-OH) which was purchased from Bachem (Torrance, CA) and Fmoc-L-Tyr(tBu)-Wang Resin which was purchased from CS Bio Company (Menlo Park, CA). The U87MG human glioblastoma cell line was obtained from American Type Culture Collection (Manassas, VA). Detergent-solubilized $\alpha_v\beta_3$, $\alpha_v\beta_5$ integrin receptors (both octyl-β-D-glucopyranoside formulations) and $\alpha_5\beta_1$ integrin (Triton X-100 formulation) were purchased from Millipore (Billerica, MA), and $\alpha_{iib}\beta_3$ (Triton X-100 formulation) was purchased from Enzyme Research Laboratories (South Bend, IN). ^{125}I-labeled echistatin and the backbone cyclized pentapeptide c(RGDyK) were purchased from Amersham/GE Healthcare (Piscataway, NJ) and Peptides International (Louisville, KY), respectively. Phosphate buffered saline (PBS) was from Gibco/Invitrogen (Carlsbad, CA). All other chemicals were purchased from Thermo Fisher Scientific (Pittsburgh, PA) unless otherwise specified. Integrin binding buffer (IBB) was composed of 25 mM Tris pH 7.4, 150 mM NaCl, 2 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mM $MnCl_2$, and 0.1% bovine serum albumin (BSA).

Knottin Peptide Synthesis and Folding. Knottin peptides were synthesized on a CS Bio CS336 instrument using Fmoc-based solid-phase peptide synthesis with Rink amide resin (CS Bio Company). Fmoc groups were removed with 20% piperidine in *N,N*-dimethylformamide (DMF). Amino acid coupling was performed using HOBt/diisopropylcarbodiimide chemistry in DMF. After synthesis, side-chain deprotection and resin cleavage was achieved by addition of a 94:2.5:2.5:1 (v/v) mixture of trifluoroacetic acid (TFA)/triisopropylsilane/ethanedithiol/water for 2 h at room temperature. The crude product was precipitated with cold anhydrous diethyl ether and purified by reversed-phase HPLC using a Varian Prostar instrument and Vydac C_{18} columns. Linear gradients of 90% acetonitrile in water containing 0.1% (v/v) TFA were used for all peptide purifications, which were monitored at an absorbance of 220 nm. Peptide purity was analyzed by analytical-scale reversed-phase HPLC using a Vydac C_{18} column. Molecular masses were determined by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) on a Perseptive Voyager-DE-RP Biospectrometry instrument (Stanford Protein and Nucleic Acid facility). Folding reactions were performed by incubating peptides with 2.5 mM reduced glutathione and 20% dimethlysulfoxide (v/v) in 0.1 M ammonium bicarbonate, pH 9, with gentle rocking overnight. The final oxidized product was purified by reversed-phase HPLC as described above and lyophilized. Purified peptides were dissolved in water, and concentrations were determined by amino acid analysis (AAA Service Laboratory, Damascus, OR). Peptide purity and molecular masses were determined by analytical-scale reversed-phase HPLC and MALDI-TOF MS.

Synthesis of the Chemical Linker, Fmoc-Lys(ivDde)-Gly-Gly-Tyr-N-Hydroxysuccinimide Ester. Fmoc-Lys(ivDde)-Gly-Gly-Tyr was synthesized as described above using a preloaded Fmoc-L-Tyr(tBu)-Wang resin and Fmoc-Lys(ivDde)-OH. This peptide was cleaved from the resin and was purified as described above, leaving the Fmoc and ivDde protecting groups attached. The C-terminal carboxyl group of the peptide was activated as an NHS ester by reaction with *N,N′*-dicyclohexylcarbodiimide (DCC; Pierce Chemical Company, Rockford, IL) and *N*-hydroxysuccinimide (NHS) in DMF and was purified by reversed-phase HPLC to yield Fmoc-Lys(ivDde)-Gly-Gly-Tyr-NHS ester.

Chemical Conjugation of Cy5.5 and DOTA. Knottin peptide 2.5D was reacted with Fmoc-Lys(ivDde)-Gly-Gly-Tyr-NHS ester in DMF containing 2% *N,N*-diisopropylethylamine (DIEA) to yield Fmoc-Lys(ivDde)-Gly-Gly-Tyr-2.5D. The Fmoc group was then removed by incubating this intermediate in DMF with 10% piperidine for 0.5 h to yield NH_2-Lys(ivDde)-Gly-Gly-Tyr-2.5D. This intermediate was reacted with a 5-fold molar excess of an NHS ester-activated DOTA group (DOTA-NHS ester; Macrocyclics, Dallas, TX) in DMF containing 2% DIEA for 0.5 h to yield DOTA-Lys(ivDde)-Gly-Gly-Tyr-2.5D. Next, the ivDde group was removed by incubation in DMF containing 2% hydrazine (Alfa Aesar, Ward Hill, MA) for 0.5 h at room temperature. Finally, DOTA-Lys(NH_2)-Gly-Gly-Tyr-2.5D was reacted with an excess of Cy5.5-NHS ester (Amersham) in DMF containing 2% DIEA for 0.5 h at room temperature to yield DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D. Following each step, the intermediates were purified by reversed-phase HPLC. Molecular masses were determined by MALDI-TOF MS, and peptide products were analyzed by analytical-scale reversed-phase HPLC as described above (Supporting Information Figure S1).

^{64}Cu Radiolabeling. For each radiolabeling reaction, approximately 10−25 μg DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D was incubated with 1−2 mCi $^{64}CuCl_2$ (University of Wisconsin−Madison, Madison, WI) in 0.1 N sodium acetate (pH 6.3) for 1 h at 42 °C. The reaction was terminated with the addition of EDTA. ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D was purified using a PD-10 column (Amersham Biosciences/GE Healthcare) and eluted with PBS (pH 7.4) and passed through a 0.22 μm filter for animal experiments. The radiochemical purity, determined as the ratio of the main product peak to other peaks, was determined by HPLC to be >95%. The radiochemical yield, determined as the ratio of final activity of the product over the starting activity used for the reaction, was usually over 80%. The specific activity of the probe was ∼500 Ci/mmol.

Cell Surface Integrin Receptor Binding and Uptake Assays. Cell surface competition binding assays were performed as previously described (*14, 15*). Briefly, 2×10^5 U87MG cells were incubated with 0.06 nM ^{125}I-labeled echistatin (Amersham) and varying concentrations of peptides in IBB at room temperature for 3 h. The cell-bound radioactivity remaining after washing was measured by scintillation counting. Half-maximal inhibitory competition (IC_{50}) values were determined by nonlinear regression analysis using *Kaleidagraph* (Synergy Software), and are presented as the average of experiments performed on three separate days.

For cell uptake studies, 5×10^5 U87MG or MDA-MB-435 cells were suspended in 50 μL IBB and incubated with ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D (1.5 μCi/tube in 100 μL IBB) with or without 1 μg of c(RGDyK) at 37 °C for 30, 60, and 120 min. Cells were then washed three times with chilled PBS and pelleted by centrifugation. The radioactivity of the cell pellet was measured using a gamma counter (PerkinElmer 1470, Waltham, MA). Cell binding and uptake of the dual-labeled

^{64}Cu-DOTA/Cy5.5 knottin peptide was expressed as the percentage of added radioactivity. Experiments were performed in triplicate.

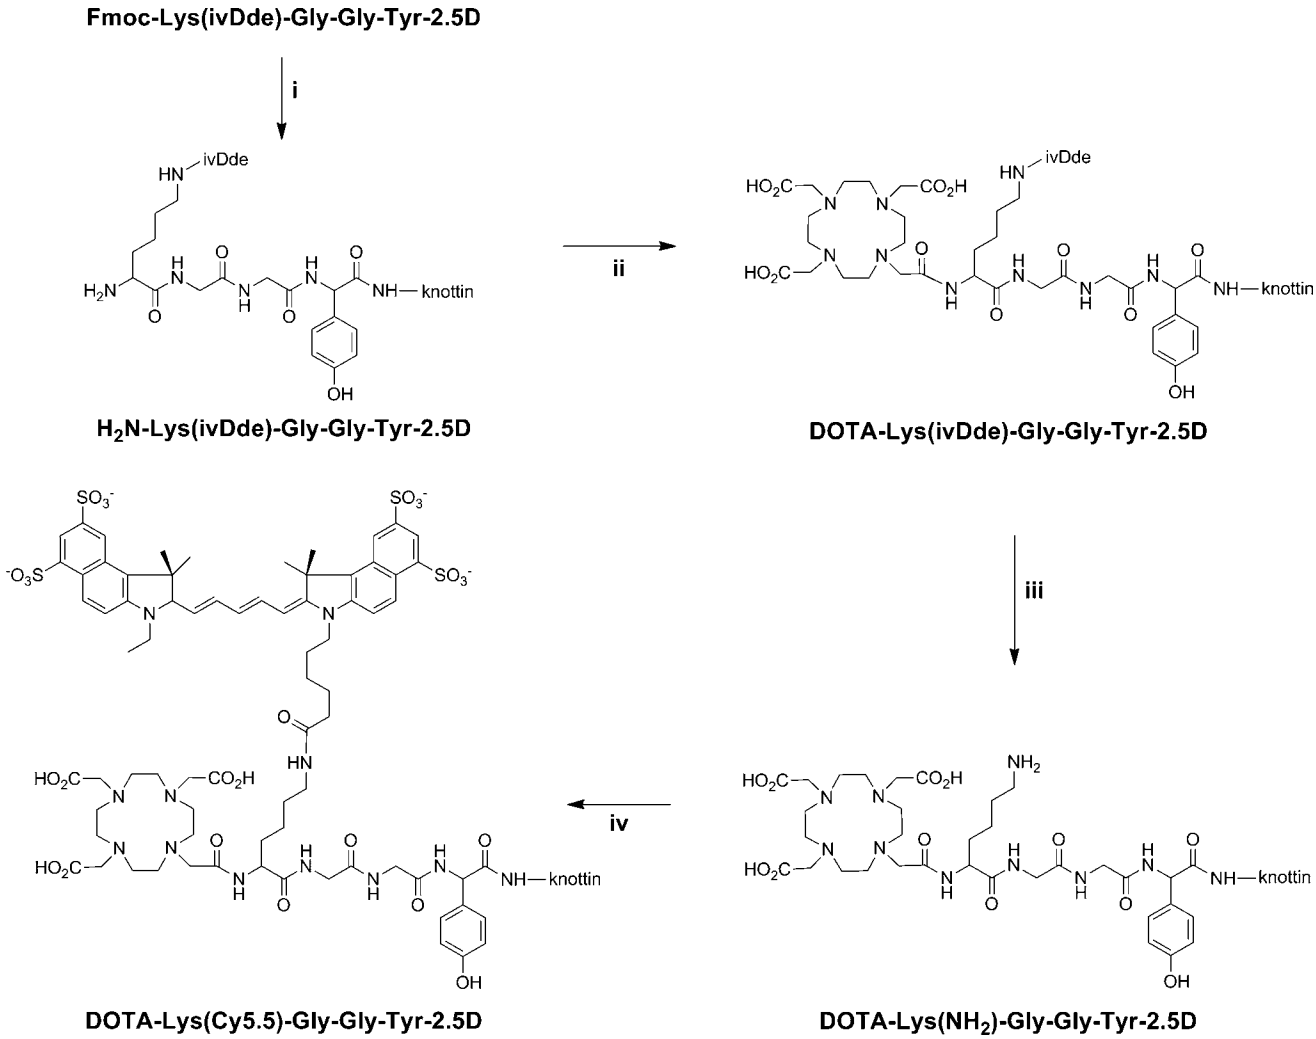
Solid-Phase Integrin Receptor Competition Binding Assay. Integrin receptor competition binding assays were performed as previously described (*15, 16*). Briefly, detergent-solubilized $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$, or $\alpha_{iib}\beta_3$ integrin receptors were diluted to a final concentration of 1 μg/mL in IBB, and 100 μL aliquots were used to coat wells of Maxisorb plates (NalgeNunc, Thermo Fisher Scientific), overnight at 4 °C. The wells were washed and blocked with IBB containing 1% BSA for 2 h at room temperature. ^{125}I-labeled echistatin (0.06 nM) and varying concentrations of unlabeled peptides were incubated in the wells for 3 h at room temperature with gentle rocking and washed 3 times in IBB. Plate-bound radioactivity was solubilized with 200 μL of boiling 2 N NaOH followed by gamma counting. Each data point represents the average value of triplicate wells, and error bars represent the standard deviation.

Tumor Xenograft Models. U87MG glioblastoma cells and MDA-MB-435 melanoma cells were maintained at 37 °C in a humidified atmosphere containing 5% CO_2 in Dulbecco's Modified Eagle Medium or Leibovitz L-15 Medium, respectively, containing 10% heat-inactivated fetal bovine serum and penicillin−streptomycin (all from Invitrogen). Animal procedures were carried out according to a protocol approved by Stanford University Administrative Panels on Laboratory Animal Care. Female athymic nude mice (nu/nu), obtained at 4−6 weeks of age (Charles River Laboratories, Inc., Wilmington, MA), were injected subcutaneously in the right or left shoulder with $\sim 10^7$ U87MG or 5×10^6 MDA-MB-435 cells suspended in 100 μL of PBS. Mice were used for in vivo imaging studies when their tumors reached approximately 8−10 mm in diameter.

Near-Infrared Fluorescence and MicroPET Imaging of Tumor Xenografts. NIRF imaging was performed with an IVIS 200 (Xenogen, Hopkinton, MA) as previously described (*14*). Briefly, a Cy5.5 filter set was used, and fluorescence emission was normalized to photons per second per centimeter squared per steradian (p/s/cm^2/sr). Images were acquired and analyzed using *Living Image 2.50.1* (Xenogen). For all experiments, U87MG tumor-bearing mice ($n = 3$ for each probe) were injected via tail vein with ~1.5 nmol of probe in 100 μL PBS and imaged at various times post injection. Tumor contrast was quantified by drawing identically sized regions of interest (ROI) around the tumor and background tissue located in the mouse's flank (average radiance, p/s/cm^2/sr). Data points represent the average tumor/tissue ratio for a group of three animals.

U87MG or MDA-MB-435 tumor-bearing mice ($n = 3$ or more for each probe) were injected with ~100 μCi (~0.5 nmol) of probe via the tail vein and imaged with a microPET R4 rodent model scanner (Siemens Medical, Knoxville, TN) using 3 or 5 min static scans. Images were reconstructed by a two-dimensional ordered expectation maximum subset algorithm and calibrated as previously described (*17*). ROIs were drawn over the tumor on decay-corrected whole body images using *ASIPro VM* software (Siemens Medical). The mean counts per pixel per minute were obtained from the ROI and converted to counts per milliliter per minute with a calibration constant. ROIs were converted to counts/g/min, and %ID/g values were determined assuming a tissue density of 1 g/mL. No attenuation correction was performed. In NIRF and PET blocking experiments, mice were coinjected with 330 μg (~0.5 μmol) of unlabeled c(RGDyK). For whole animal NIRF/PET correlation plots, the average tumor-to-background tissue ratios were determined using an ROI over tumor tissue and dividing by an ROI over the thigh area for three mice per time point post injection. Linear regression analysis in Microsoft *Excel* was used to determine the R^2 value, and error bars represent the standard deviation.

In Vivo Biodistribution Studies. Anesthetized nude (nu/nu) mice bearing U87MG tumor xenografts were injected with ~100 μCi (~0.5 nmol) of ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D via the tail vein, and were euthanized at 1, 4, and 24 h post injection. Blood, bone, brain, heart, kidney, liver, lung, muscle, pancreas, skin, spleen, and tumor tissue were removed and weighed. The fluorescence flux (photons per second) or gamma emissions (counts per minute) of the tissue were measured by fluorescence imaging or by gamma counting, respectively. For the fluorescence component, the results are expressed as flux/gram of tissue and represent the mean and standard deviation of experiments performed on three mice. Total flux was determined for dissected tissue by drawing a ROI around the entire tissue and subtracting the total background flux from an adjacent equally sized ROI. For studies involving radioactivity, the results were expressed as the percent injected dose per gram (%ID/g) of tissue and represent the mean and standard deviation of experiments performed on three mice. For each mouse, the activity of tissue samples was calibrated against a premeasured aliquot of the radiotracer and normalized to the whole body-weight and to the residual radioactivity present in the tail. For correlation analysis of biodistribution data from three mice, average Cy5.5 tumor-to-tissue ratios were plotted versus average ^{64}Cu tumor-to-tissue ratios for 1, 4, and 24 h time points. Linear regression analysis in Microsoft *Excel* was used to determine the R^2 value, and error bars represent the standard deviation.



In Vivo Metabolite Analysis. For metabolite analysis, anesthetized nude (nu/nu) mice bearing U87MG tumor xenografts were injected with 200−400 μCi of ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D via the tail vein and were euthanized at 1, 4, or 24 h post injection. Blood, liver, kidney, and tumor tissue were removed and suspended in ~500 μL PBS. An additional 500−1000 μL DMF was added, and the tissues were homogenized with a mortar and pestle. The homogenate was filtered using a Costar Spin-X (Corning, Lowell, MA) 0.2 μm nylon microcentrifuge filter to isolate soluble metabolites. The filtrates were analyzed by reversed-phase HPLC. Eluted fractions were collected in 30 s intervals, and a gamma counter was used to determine counts per minute (cpm).

Statistical Analysis. All data are presented as the average value ± SD of n independent measurements. Statistical analysis for animal studies and binding studies were performed by two-factor ANOVA without replication analysis using Microsoft *Excel*. Significance was assigned for p values of <0.05.

RESULTS

Synthesis and Characterization of a Knottin Peptide Conjugated to Both DOTA and Cy5.5. To create a dual-modality NIRF/PET imaging agent, we developed a chemical strategy to couple both ^{64}Cu-DOTA and Cy5.5 to an engineered knottin peptide (knottin 2.5D), which binds to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors with low nanomolar affinity (*13*). A peptide-based linker (Fmoc-Lys(ivDde)-Gly-Gly-Tyr-NHS ester) enabled stochiometric chemical coupling of these two different imaging labels specifically to the knottin N-terminus. The conjugation chemistry is shown in Scheme 1. Fmoc-Lys(ivDde)-Gly-Gly-Tyr was first treated with DCC/NHS to activate the C-terminal carboxylate and generate a reactive succinimide ester group. The tyrosine residue appeared to stabilize the succinimide ester intermediate and afforded a convenient handle for peptide detection and quantification by absorbance at 280 nm. This linker was coupled to the N-terminus of knottin 2.5D through formation of a peptide bond. The Fmoc and the ivDde groups were then selectively and sequentially removed to allow precise coupling of DOTA to the N-terminal amine and Cy5.5 to the ε-amino group of the lysine residue. Each reaction intermediate was purified by reversed-phase HPLC, and the correct mass was

Scheme 1. Chemical Conjugation of DOTA and Cy5.5 to Knottin Peptide 2.5D[a]

[a] The peptide-based cross-linker Fmoc-Lys(ivDde)-Gly-Gly-Tyr was first synthesized and coupled to the N-terminus of the folded knottin peptide 2.5D using succinimide ester activation chemistry. Next, the Fmoc group was removed from the N-terminus of the cross-linker (i: 10% piperidine/DMF, 0.5 h, RT), and the resulting compound was reacted with a 5-fold molar excess of an NHS ester-activated DOTA group (ii: DMF/2% DIEA, 0.5 h, RT) to generate DOTA-Lys(ivDde)-Gly-Gly-Tyr-2.5D. Finally, the ivDde group was removed from the ε-amino group of Lys (iii: 2% hydrazine/DMF, 0.5 h, RT), and the resulting compound was reacted with Cy5.5 NHS ester (iv: DMF/2% DIEA, 0.5 h, RT) to give the final product DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D, which was used for NIRF imaging experiments, or radiolabeled with ^{64}Cu and used for PET imaging experiments.

verified by MALDI-TOF MS (Supporting Information Figure S1). To reduce sample loss associated with purification, we subsequently found that the ivDde deprotection step could be performed in the same reaction vessel used to couple the DOTA group. Next, the resulting integrin-binding knottin bioconjugate DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D (abbreviated DOTA/Cy5.5-2.5D) was radiolabeled with ^{64}Cu through chelation with the DOTA group. We measured the stability of ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D (abbreviated ^{64}Cu-DOTA/Cy5.5-2.5D) upon exposure to mouse serum. Radio-HPLC analysis indicated minimal probe degradation after incubation in a solution of 50% mouse serum for 1 h at 37 °C (Supporting Information Figure S2). Degradation levels increased over time and intact probe was unrecoverable after incubation in serum for 24 h.

Binding of the DOTA/Cy5.5-Conjugated Knottin Peptide to Integrin-Expressing Tumor Cells. To test whether conjugation of Cy5.5 and DOTA to the knottin N-terminus affected binding to integrin receptors, we measured the ability of DOTA/Cy5.5-2.5D to compete with ^{125}I-labeled echistatin for binding to U87MG glioblastoma cells. Echistatin, a polypeptide from snake venom, has a K_D of approximately 0.4 nM for $\alpha_v\beta_3$ integrin (*18*). For comparison, we also measured the relative binding affinities of knottin peptide 2.5D with DOTA or Cy5.5 groups conjugated directly to the N-terminus. All knottin peptides were shown to bind in a dose-dependent matter to U87MG cells. The half-maximal inhibitory concentration (IC_{50}) values of DOTA/Cy5.5-2.5D and unlabeled knottin 2.5D were 30 ± 7 nM and 19 ± 6 nM (*15*), respectively, which were not statistically different ($p < 0.23$) (Table 1). In contrast, the relative binding affinities of DOTA-conjugated knottin 2.5D (IC_{50} = 9 ± 3 nM), and Cy5.5-lableled knottin 2.5D (IC_{50} = 5 ± 1 nM) were statistically significant compared to DOTA/Cy5.5-2.5D ($p < 0.05$). These results indicate that integrin binding affinity is

Table 1. U87MG Cell Binding Data, Reported as IC_{50} Values

ligand	IC_{50}
Echistatin	4 ± 1 nM[a]
Knottin 2.5D	19 ± 6 nM
Cy5.5−2.5D	5 ± 1 nM[a]
DOTA-2.5D	9 ± 3 nM[a]
DOTA/Cy5.5−2.5D	30 ± 7 nM

[a] Difference compared to DOTA/Cy5.5−2.5D is statistically significant ($p < 0.05$).

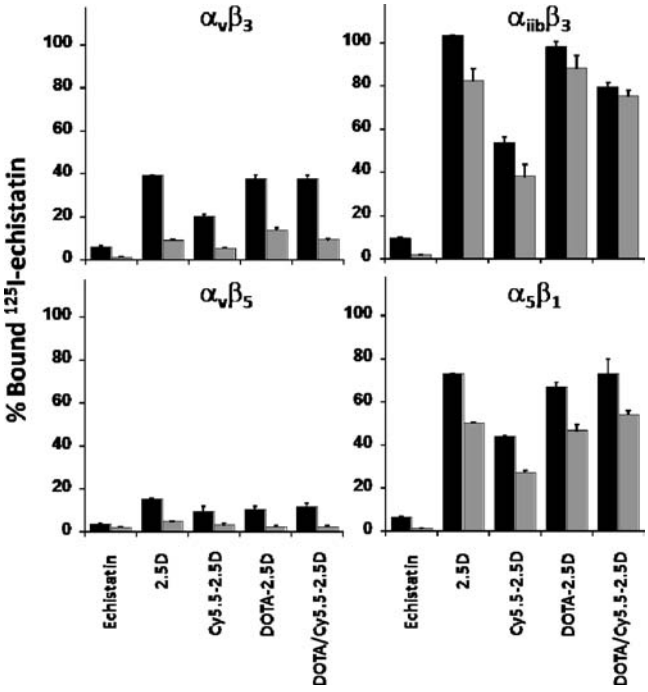


Figure 1. Competition binding of peptides to surface-immobilized integrins. ^{125}I-labeled echistatin was allowed to compete for binding with 5 nM (black bars) or 50 nM (gray bars) unlabeled peptides to detergent-solubilized integrin receptor subtypes $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$, and $\alpha_{iib}\beta_3$. Unlabeled echistatin, which binds to all four integrins with high affinity, was used as a positive control. Error bars represent the standard deviation of measurements performed in triplicate.

relatively unaffected by the addition of both Cy5.5 and DOTA through a flexible peptide linker. The binding isotherms of all of these compounds are shown in Supporting Information Figure S3 to facilitate direct comparison.

Integrin Binding Specificity of the DOTA/Cy5.5-Conjugated Knottin Peptide. We next tested whether conjugation of both Cy5.5 and DOTA to the N-terminus of knottin 2.5D affected its integrin binding specificity. Since U87MG cells have been shown to express $\alpha_v\beta_5$ and $\alpha_5\beta_1$ integrins in addition to $\alpha_v\beta_3$ integrin (*19*), we measured integrin binding specificity by competition of ^{125}I-echistatin to detergent-solubilized $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$, or $\alpha_{iib}\beta_3$ integrin receptors coated onto microtiter plates. Unlabeled echistatin was used as a positive control since it has been previously shown to bind to all four receptors with high affinity (*13, 20*). DOTA/Cy5.5-2.5D exhibited strong binding to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, modest binding to $\alpha_5\beta_1$ integrin, and weak binding to $\alpha_{iib}\beta_3$ integrin (Figure 1). In comparison, similar results were observed with unlabeled knottin 2.5D and DOTA-conjugated knottin 2.5D (*15*). However, knottin peptide 2.5D labeled directly at its N-terminus with Cy5.5 showed increased binding to integrin receptors compared to the other knottin peptides we tested (Table 1 and Figure 1). This increase in binding was statistically significant for all data points compared to unlabeled knottin 2.5D ($p < 0.05$) and could be due to the close proximity of the hydrophobic Cy5.5 dye molecule to the integrin binding epitope. Interestingly, this effect was not observed with the dual-labeled knottin, which has its Cy5.5 and DOTA groups conjugated through the peptide-based linker and not directly at the knottin N-terminus (Figure 1). Cy5.5-labeled peptides, such as the backbone-cyclized pentapeptide c(RGDyK), have also shown increased integrin-binding affinities compared to unmodified compounds (*14*).

In Vivo Near-Infrared Fluorescence Imaging with the DOTA/Cy5.5-Conjugated Knottin Peptide. We tested the ability of the DOTA/Cy5.5-conjugated knottin peptide to target tumors in living subjects to evaluate its potential as an in vivo molecular imaging agent. Figure 2A shows typical NIRF images of athymic nude mice bearing subcutaneous U87MG glioblastoma tumors after tail vein injection of 1.5 nmol of probe. DOTA/Cy5.5-2.5D generated increasing tumor-to-background tissue ratios of 2.96 ± 0.42, 3.11 ± 0.66, 3.60 ± 0.84, and 4.04 ± 0.34 at 1, 2, 4, and 24 h post injection, respectively (Figure 2C). In comparison, knottin peptide 2.5D labeled directly at its N-terminus with Cy5.5 generated similar signals 1, 2, and 4 h post injection (2.09 ± 0.61, 2.57 ± 0.79, and 3.99 ± 0.55, respectively), which persisted at the 24 h time point (4.47 ± 0.39) (*15*). Co-injection of a molar excess of unlabeled c(RGDyK) significantly decreased uptake of DOTA/Cy5.5-2.5D, particularly at later time points ($p < 0.05$) (Figure 2B). At 1 h post injection, the tumor-to-background tissue ratio generated by this mixture was 2.16 ± 0.15 and did not increase to any significant extent at later time points (2.47 ± 0.34 at 24 h) (Figure 2C). This background signal is similar to that observed in other studies with Cy5.5-labeled peptides, including a negative control Cy5.5-labeled knottin peptide we previously tested (*14, 15*).

MicroPET Imaging of U87MG Xenografts with the ^{64}Cu-DOTA/Cy5.5-Conjugated Knottin Peptide. We tested the potential of the ^{64}Cu-DOTA/Cy5.5-conjugated knottin peptide for use as a PET imaging probe in mice bearing U87MG human tumor xenografts. ^{64}Cu-DOTA/Cy5.5-2.5D rapidly accumulated at the tumor site and persisted there throughout the course of the experiment (Figure 2D). We observed tumor uptake values of 4.27 ± 0.46, 4.19 ± 0.36, 4.52 ± 0.31, and 5.02 ± 0.05%ID/g at 1, 2, 4, and 24 h post injection, respectively (Figure 2F). In contrast, knottin peptide 2.5D labeled directly at its N-terminus with ^{64}Cu-DOTA generated similar tumor uptake values at the 1 h time point (4.47 ± 1.21%ID/g) but exhibited significantly faster wash-out (1.48 ± 0.51%ID/g at 24 h). Tumor uptake of ^{64}Cu-DOTA/Cy5.5-2.5D was significantly decreased ($p < 0.05$) by coinjection of ~0.5 μmol of unlabeled c(RGDyK) (Figure 2E), resulting in values of approximately 1−1.5%ID/g from 1 to 24 h post injection (Figure 2F).

A plot of tumor-to-background tissue ratios for NIRF versus PET imaging showed good linear correlation ($R^2 = 0.85$) over 1−24 h, indicating that the two labels are effectively delivered to the tumor, and can be detected by both imaging modalities over the time course of the experiment (Figure 2G). A direct 1:1 correlation is not observed due to inherent differences in the background tissue measured with each noninvasive in vivo imaging technique. More specifically, although the depth of fluorescence light penetration is several millimeters into the muscle, the background signal quantified by NIRF imaging results mainly from high autofluorescence of the skin. In contrast, the background signal obtained in microPET imaging is quantified on the muscle tissue.

Comparative Cell Uptake and MicroPET Imaging in MDA-MB-435 Xenografts. To further confirm integrin specificity, we tested binding and uptake of ^{64}Cu-DOTA/Cy5.5-2.5D in two cell lines: U87MG and MDA-MB-435, a melanoma cell line which expresses 2×10^4 integrin receptors, compared to approximately 1×10^5 integrin receptors expressed on U87MG cells (*21*). As expected, lower levels of probe uptake were observed over time in MDA-MB-435 versus U87MG cells, correlating with their lower levels of integrin receptor expression (Figure 3A). In both cell lines, binding and uptake were blocked by addition of an excess of c(RGDyK). Consistent with these results, tumor uptake of ^{64}Cu-DOTA/Cy5.5-2.5D in MDA-MB-435 xenograft models was much lower compared to uptake in U87MG tumors, exhibiting values of 1.33 ± 0.02%ID/g and 1.01 ± 0.10%ID/g at 1 and 24 h post injection (Figure 3B). Furthermore, MDA-MB-435 tumor uptake was significantly

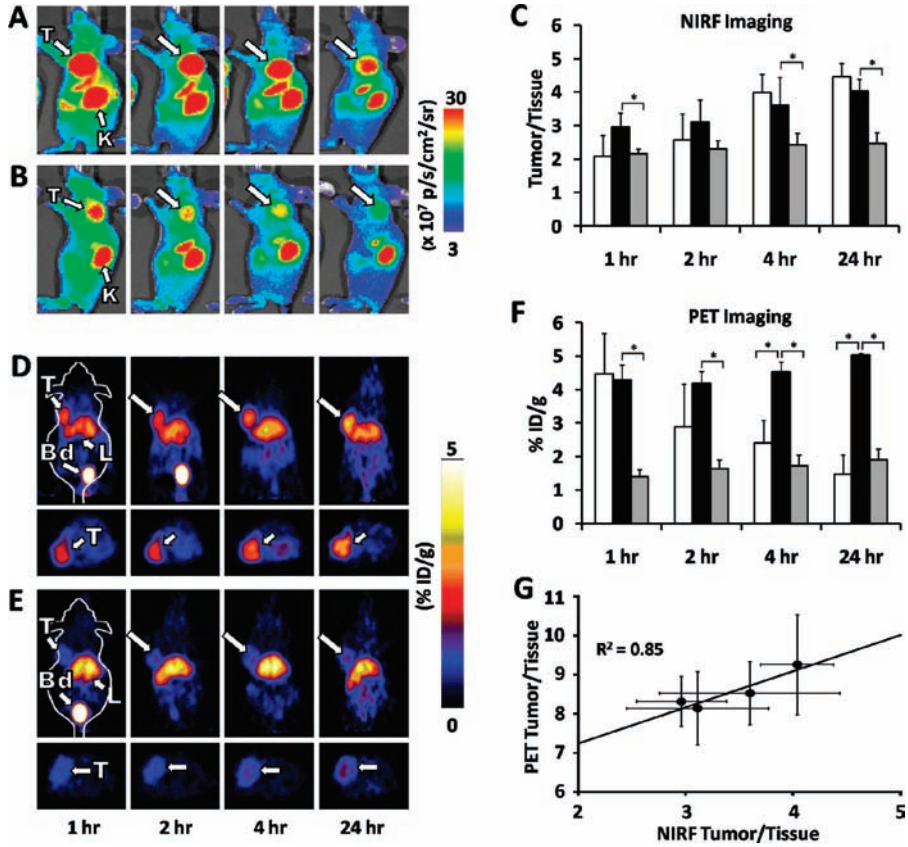

Figure 2. NIRF and microPET imaging of knottin probes in murine human tumor xenograft models. Mice bearing U87MG tumors were injected via tail vein with either (A) 1.5 nmol of DOTA/Cy5.5−2.5D or (D) ∼100 μCi of ^{64}Cu-DOTA/Cy5.5−2.5D. For blocking experiments (B,E), mice were coinjected with an excess (0.5 μmol) of unlabeled c(RGDyK) in addition to labeled knottin peptides. Representative images are shown at 1, 2, 4, and 24 h post injection. T = tumor; K = kidney; Bd = bladder; L = liver. (C) NIRF imaging, represented as the tumor-to-background tissue (tumor/tissue) ratio for Cy5.5−2.5D (white bars), DOTA/Cy5.5−2.5D (black bars), and DOTA/Cy5.5−2.5D plus excess unlabeled c(RGDyK) blocking peptide (gray bars). (F) MicroPET imaging, quantified as the % ID/g of ^{64}Cu-DOTA-2.5D (white bars), ^{64}Cu-DOTA/Cy5.5−2.5D (black bars), and ^{64}Cu-DOTA/Cy5.5−2.5D plus an excess of unlabeled c(RGDyK) blocking peptide (gray bars). (G) Correlation analysis of average tumor-to-background tissue ratios for NIRF and microPET images acquired at 1, 2, 4, and 24 h post injection. Error bars represent the SD of measurements performed on at least three mice. (* $p < 0.05$).

decreased to 0.82 ± 0.05%ID/g and 0.60 ± 0.09%ID/g at 1 and 24 h post injection ($p < 0.05$) upon co-injection of a molar excess of unlabeled c(RGDyK).

Biodistribution Studies of ^{64}Cu-DOTA/Cy5.5- and DOTA/Cy5.5-Conjugated Knottin Peptides. We determined the tissue biodistribution of DOTA/Cy5.5- and ^{64}Cu-DOTA/Cy5.5-conjugated knottin peptides in U87MG tumor-bearing mice using fluorescence and radioactivity measurements. Mice were injected with DOTA/Cy5.5-2.5D and fluorescent images of individual organs were obtained at various time points. In these studies, probe accumulated rapidly at the tumor site at early time points and decreased over time with fluorescence flux/gram values of 373.1 ± 111.3 and 146.1 ± 26.5 for 1 and 24 h post injection, respectively (Figure 4A). Next, mice were injected with ^{64}Cu-DOTA/Cy5.5-2.5D and individual organs were analyzed by gamma counting. For tumor tissue, we observed biodistribution values of 3.24 ± 0.87, 5.64 ± 0.83, and 4.57 ± 0.70%ID/g at 1, 4, and 24 h post injection, respectively (Figure 4B). Higher liver uptake (∼4−7% ID/g at 1 and 4 h) and kidney uptake (∼80%ID/g for 1−4 h) were observed compared to other organs (Figures 4B and 5B). Kidney uptake was reduced at 24 h (∼30%ID/g) in both Cy5.5 and ^{64}Cu biodistribution studies (Figure 5).

To further compare the DOTA/Cy5.5- and ^{64}Cu-DOTA/Cy5.5-knottin biodistribution data, tumor-to-tissue ratios were calculated (Figure 4C−D). In general, the tumor-to-blood and tumor-to-muscle ratios were slightly higher for fluorescence imaging (Cy5.5 uptake) compared to radioactivity measurements (^{64}Cu uptake). This trend was also observed for the tumor-to-tissue ratios for the liver, lung, and spleen. Plots of tumor-to-background tissue ratios for Cy5.5 versus ^{64}Cu uptake in various organs showed good correlation, with an intercept of zero and R^2 values of 0.75, 0.83, and 0.82 for 1, 4, and 24 h post injection, respectively, demonstrating relatively uniform distribution of imaging labels in tumors and off-target tissues (Supporting Information Figure S4). The high tumor-to-blood ratios and high tumor-to-muscle-ratios observed at 1, 4, and 24 h post injection suggest that ^{64}Cu-DOTA/Cy5.5-2.5D may be useful for whole body radiographic imaging where the tumor signal is not obscured by a strongly emitting background signal from nontargeted organs.

Metabolic Stability. Finally, we tested the in vivo stability of ^{64}Cu-DOTA/Cy5.5-2.5D. The metabolic breakdown of probe was examined after recovery from whole mouse blood, tumor, liver, and kidney 1 h post injection. The radioactivity recovered in the soluble tissue extract ranged 50−80% compared to the insoluble cellular debris or pellet fraction. This soluble extract was filtered and separated by reversed-phase HPLC, and fractions were analyzed by gamma counting. The dual-labeled ^{64}Cu-DOTA/Cy5.5 knottin peptide appeared to have similar stability in serum and blood after 1 h incubation (Figure 6 and Supporting Information Figure S2). In contrast, significant breakdown of probe was seen in the tumor, and intact probe was not able to be recovered from the liver and kidney. In these

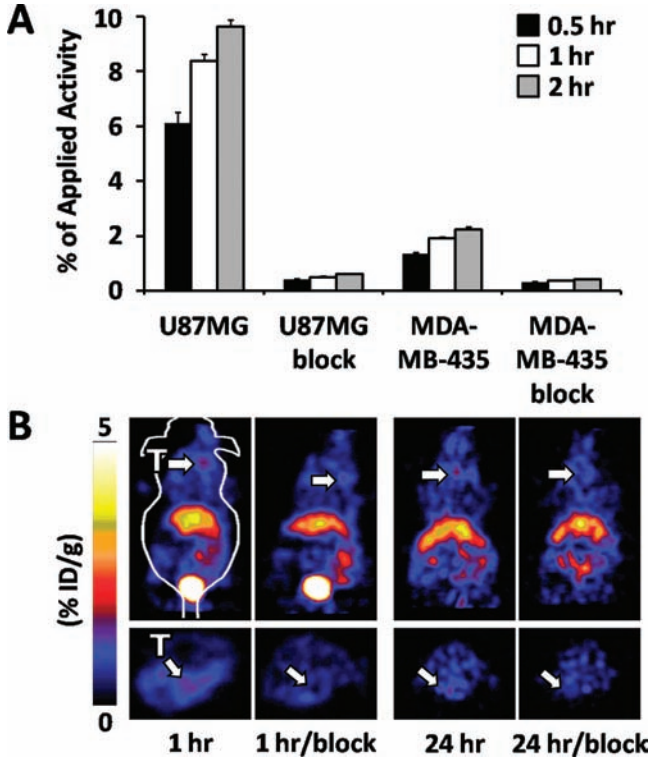

Figure 3. Uptake and imaging in MDA-MB-435 cells and xenograft tumors. (A) Uptake of ^{64}Cu-DOTA/Cy5.5−2.5D in U87MG or MDA-MB-435 cells at 0.5, 1, and 2 h. Blocking studies, indicated by "block", were performed in parallel using a large molar excess of c(RGDyK). (B) MicroPET images of mice bearing subcutaneous MDA-MB-435 tumors at 1 and 24 h post injection. Blocking experiments with unlabeled c(RGDyK) were performed to further demonstrate probe specificity.

samples, metabolites with retention times between 3 and 6 min were present at high levels.

DISCUSSION

A chemical cross-linking strategy was developed to couple two complementary molecular imaging agents onto a disulfide-rich knottin peptide that has been engineered to bind to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins with high affinity. The folding of cystine knot peptides is highly dependent on primary structure (*22*). We observed that simple N-terminal acetylation or biotinylation of EETI-II severely affected its ability to properly fold, consistent with another study on permutants of the cyclotide kalata B1 (*23*). These stringent folding requirements dictated that all conjugation chemistry be performed in solution after the knottin was folded, instead of using on-bead labeling of side-chain protected linear peptides immediately following synthesis. Therefore, we used a cross-linking strategy that selectively and sequentially exposed reactive groups for precise, stoichiometric coupling of both an optical imaging dye and a radiochelator to the knottin N-terminus. The method we developed is flexible and can be used to accommodate a variety of imaging labels, therapeutics, or pharmacokinetic modulators for diverse biomedical applications. Importantly, we demonstrated that attachment of several chemical groups to the N-terminus of the engineered EETI-II knottin peptide did not interfere with its ability to bind to integrin receptors with high affinity.

Stability studies showed that the ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D probe is relatively labile, both in high concentrations of serum and after injection into the body. This breakdown is most likely due to proteolysis of the cross-linking moiety, as we previously showed that knottin peptide ^{64}Cu-DOTA-2.5D exhibited only minimal fragmentation after incubation in serum for 24 h and was recovered intact from the blood, tumor, and kidneys 1 h after injection into mice (*15*). Given that similar maximal tumor uptake levels were observed from ^{64}Cu-DOTA-2.5D and ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D, this proteolysis did not appear to affect its rapid tumor accumulation. However, degradation could have influenced kidney uptake and retention of dye molecules or metals. Cross-linkers composed of non-natural amino acids or peptoids may facilitate a more stable linkage (*24*). In addition, the use of D-amino acids has been shown to stabilize a variety of imaging peptides such as somatostatin (*25*). We are currently using these strategies to create more stable cross-linkers for the development of theranostic agents that will apply molecular imaging to quantify the delivery of cytotoxic drugs to tumors.

The use of a dual-labeled agent has distinct advantages as opposed to coadministering separate single-labeled agents. Having both labels on the same affinity ligand allows pharmacokinetic quantification of a single compound. This is beneficial because, as our study showed, the hydrophobic Cy5.5 dye strongly influenced the pharmacokinetics and tissue biodistribution of the radionuclide imaging agent. In addition, dual labeling allows quantitative cross validation and direct comparison between nuclear and optical imaging using an affinity ligand (*26*). Several groups have developed dual-labeled NIRF/SPECT probes using near-infrared dyes and ^{111}In or ^{99m}Tc radiolabels (*26*−*31*); these probes are specific to a variety of disease targets and have been recently reviewed (*32*). Studies describing chemically defined, dual-labeled NIRF/PET probes have been more limited. NIRF/PET probes have been developed by decorating quantum dots with tumor targeting moieties and radiolabeling the resulting nanoparticles with ^{64}Cu (*33, 34*). Compared to our knottin peptides, these nanoparticles exhibited extremely high uptake in the liver, spleen, lymph nodes, and bone marrow.

Addition of Cy5.5 had both a positive and negative effect on the pharmacokinetics and biodistribution of the probe. In comparison to ^{64}Cu-DOTA-2.5D, which rapidly washed out of the tumor, ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D was significantly retained by the tumor at later time points (Figure 2D). This tumor uptake was specific and mediated by integrin receptors as demonstrated by blocking experiments with c(RGDyK), which interacts with the same integrin binding site as the engineered knottin peptides (Figure 2), as well as the lower levels of tumor uptake in MDA-MB-435 tumors, which express lower levels of integrin receptors compared to U87MG tumors (Figure 3). Moreover, in previous studies we used knottin peptides containing a scrambled sequence to validate the integrin binding specificity of ^{64}Cu-DOTA- and Cy5.5-labeled knottin probes (*13, 15*).

Cy5.5 rapidly accumulated in the kidneys over the course of the imaging experiments (Figures 2A and 5A), consistent with the high levels of kidney uptake and retention we observed with knottin peptide 2.5D labeled only with Cy5.5 (*15*). In our previous studies, the kidney uptake for ^{64}Cu-DOTA-2.5D was 8.08 ± 0.67, 2.69 ± 0.48, and 1.25 ± 0.11%ID/g at 1, 4, and 24 h post injection, respectively (*15*). In contrast, kidney uptake for ^{64}Cu-DOTA-Lys(Cy5.5)-Gly-Gly-Tyr-2.5D was 78.4 ± 13.9 and 80.9 ± 14.9%ID/g for 1 and 4 h post injection; however, after 24 h the radioactivity in the kidneys decreased to 32.2 ± 2.2%ID/g, suggesting that ^{64}Cu metabolites are cleared by the kidneys at later time points. This decrease in kidney signal is not due to the short half-life of ^{64}Cu (12.7 h), as the data have been normalized to account for radioactive decay. Liver uptake (∼4−7%ID/g at 1−24 h post injection) was also higher than previously observed for ^{64}Cu-DOTA-2.5D, in which values of ∼1−2%ID/g were observed 1 to 4 h post injection. Increased liver and kidney uptake may preclude the use of this probe to

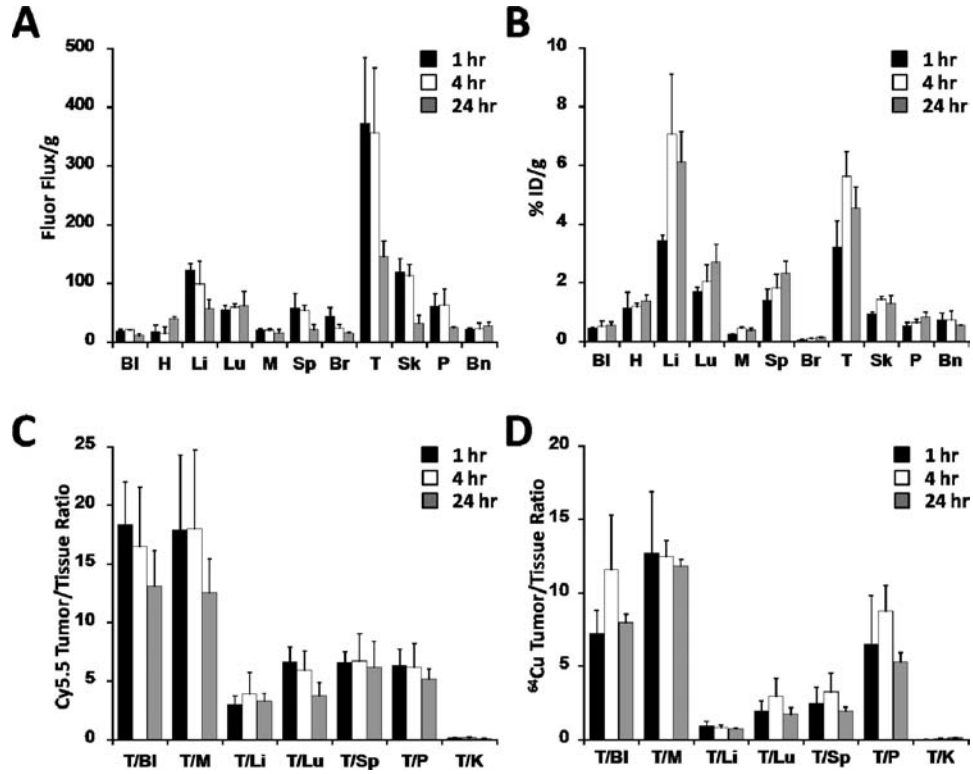

Figure 4. Comparison of Cy5.5 and ^{64}Cu tissue biodistribution. The amount of (A) DOTA/Cy5.5−2.5D or (B) ^{64}Cu-DOTA/Cy5.5−2.5D accumulation was measured in the blood (Bl), heart (H), liver (Li), lung (Lu), muscle (M), spleen (Sp), brain (Br), tumor (T), skin (Sk), pancreas (P), and bone (Bn). (A) Cy5.5 uptake, measured as the fluorescence flux (photons per second) per gram of tissue. (B) ^{64}Cu uptake, quantified as the %ID/g. Comparison of tumor/tissue ratios observed at 1, 4, and 24 h post injection for (C) DOTA/Cy5.5−2.5D or (D) ^{64}Cu-DOTA/Cy5.5−2.5D.

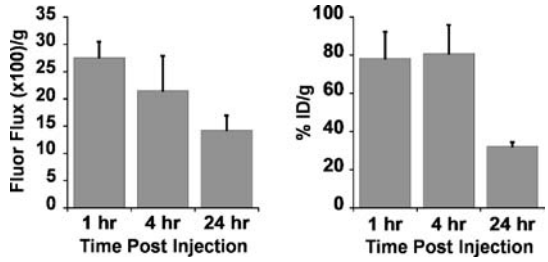

Figure 5. Comparison of Cy5.5 and ^{64}Cu accumulation in the kidney. Uptake of Cy5.5 resulting from injection of DOTA/Cy5.5−2.5D (left panel) was measured as the fluorescence flux (photons per second) per gram of tissue. Uptake of ^{64}Cu-DOTA/Cy5.5−2.5D (right panel) was quantified as the %ID/g.

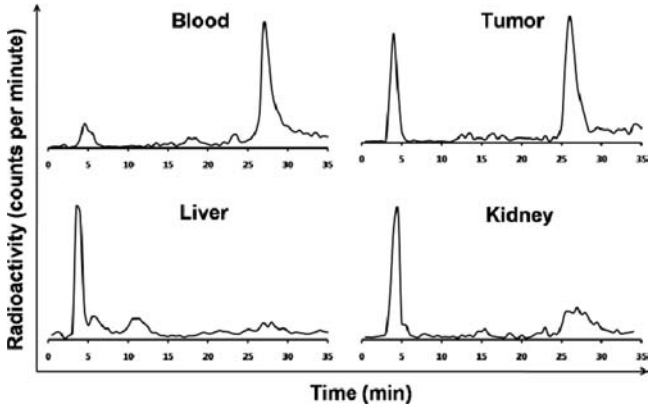

Figure 6. In vivo metabolic stability of ^{64}Cu-DOTA/Cy5.5−2.5D. Homogenized tissues were analyzed by radio-HPLC and gamma counting 1 h post injection. The intact radiotracer elutes at around 27 min.

identify lesions located in the abdomen; however, the spatial resolution of PET imaging, which is in the millimeter range, may allow identification of small lesions in close proximity to these organs. In addition, while kidney uptake and retention were high from Cy5.5-labeled probes, in future studies the use of alternate fluorescent dyes with more favorable biodistribution properties may help address this issue. Small amounts of probe are used for imaging applications; thus, we do not expect this probe to be immunogenic. However, as with any new compound intended for clinical use, this will have to be determined empirically.

In summary, the cross-linking strategy we describe here has broad applicability for site-specific coupling of two different imaging labels, or an imaging label and a therapeutic moiety, to knottin peptides for cancer diagnosis or therapy, or both. Conjugation of a tumor-specific knottin peptide to both a PET imaging agent and a chemotherapeutic agent could allow simultaneous and quantitative measurement of biodistribution and pharmacokinetics, drug delivery to tumors, and tumor response during the course of treatment. Moreover, different combinations of imaging labels may yield additional or unique information during a multimodal scan. The molecular tools developed here will allow research in these areas to be explored.

ACKNOWLEDGMENT

We thank Adam Silverman, Bryan Smith, and Douglas Jones for helpful discussions and critical feedback, Fred Chin and David Dick in the Stanford Cyclotron Facility, and Tim Doyle, Laura Pisani, and Frezghi Habte in the Stanford Small Animal Imaging Facility. Gene delivery biomaterials need to be designed to efficiently achieve nuclear delivery of plasmid DNA. Polycations have been used to package DNA and other nucleic acids within submicrometer-sized particles, offering protection from shear-induced or enzymatic degradation. However, cytotoxicity issues coupled with limited in vivo transfection efficiencies minimize the effectiveness of this approach. In an effort to improve upon existing technologies aimed at delivering nucleic acids, an alternative approach to DNA packaging was explored. Peptide nucleic acids (PNAs) were used to directly functionalize DNA with poly(ethylene glycol) (PEG) chains that provide a steric layer and inhibit multimolecular aggregation during complexation. DNA prePEGylation by this strategy was predicted to enable the formation of more homogeneous and efficiently packaged polyplexes. In this work, DNA-PNA-peptide-PEG (DP3) conjugates were synthesized and self-assembled with 25 kDa poly(ethylenimine) (PEI). Complexes with small standard deviations and average diameters ranging 30−50 nm were created, with minimal dependence of complex size on N/P ratio (PEI amines to DNA phosphates). Furthermore, PEI−DNA interactions were altered by the derivatization strategy, resulting in tighter compaction of the PEI−DP3 complexes in comparison to PEI−DNA complexes. Transfection experiments in Chinese hamster ovary (CHO) cells revealed comparable transfection efficiencies but reduced cytotoxicities of the PEI−DP3 complexes relative to PEI−DNA complexes. The enhanced cellular activities of the PEI−DP3 complexes were maintained following the removal of free PEI from the PEI−DP3 formulations, whereas the cellular activity of the conventional PEI−DNA formulations was reduced by free PEI removal. These findings suggest that DNA prePEGylation by the PNA-based strategy might provide a way to circumvent cytotoxicity and formulation issues related to the use of PEI for in vivo gene delivery.

INTRODUCTION

Nonviral, biomimetic nucleic acid delivery systems have been developed with the aim of designing modular, targeted, and safe constructs for gene therapy. Such an approach has the potential to bring about practical pharmaceutical products with great improvement in combating disease. While viral vectors have achieved efficient delivery of exogenous DNA, their innate immunogenicity and toxicity have raised significant concerns over their clinical development. Despite these limitations, the multiple functionalities and responsiveness of these viral systems provide key insight into how biomimetic vehicles can be more effectively designed.

One widely explored method of nonviral vehicle formulation involves the use of polycations to condense DNA into nano- to submicrometer-scale particles (*1*−*5*). For example, poly(ethylenimine) (PEI) is a cationic polymer that contains a high density of primary, secondary, and tertiary amine groups, and has been used to package DNA and RNA within nanosized complexes (*2, 5*−*7*). Polyplexes made from PEI constitute a highly effective delivery system in vitro, an effect which has been attributed to the capacity of PEI to promote endosomal escape via pH-buffering (*8*−*10*). Unfortunately, concerns about the toxicity of PEI (*11*) and challenges in formulating PEI-based vehicles have limited its applicability in vivo. Cationic polyplexes tend to aggregate and interact with serum proteins after systemic administration, leading to their rapid phagocytic elimination (*12, 13*). They are also nonspecifically internalized by liver cells (*14*−*16*).

One way to overcome the serum instability and nonspecificity of polyplexes is through the steric stabilization of polyplexes with hydrophilic, uncharged polymers. Poly(ethylene glycol) (PEG) has been conjugated to PEI and other DNA-condensing polymers via reaction with primary amine groups along the backbone of the polycation, resulting in enhanced polyplex stability (*6, 17*−*20*). To enhance cell-specific uptake, cell-targeting and other functional peptides have been added directly to the polycation or to the conjugated PEG (*2, 6, 21*−*24*). PEGylation and functionalization of polycationic gene delivery carriers have been explored both pre- and postcomplexation with DNA. Precomplexation PEGylation, involving the complexation of DNA with PEGylated complexation agents, was developed with the intention of minimizing polyplex aggregation during formulation. Polyplexes are inherently heterogeneous due to uncontrolled self-aggregation during the formulation process. Consequently, PEGylated complexation agents have the potential to produce more monodisperse particles (*22, 25, 26*). However, the charge density of the polycation is reduced by PEGylation, making precomplexation PEGylation ineffective for low molecular weight polycations (*3, 27*), and in general, lowering the condensation efficiency (*4, 25, 26, 28*−*30*).

The addition of PEG postcomplexation can be accomplished by PEG grafting onto surface-exposed amine groups on the polyplex and has been shown to effectively stabilize PEI-based polyplexes containing high molecular weight PEI (*6*); in contrast, polyplexes formed from lower molecular weight polycations can be destabilized by this process (*31*). Surface PEGylation has also been shown to alter the intracellular trafficking of particles and to reduce their gene transfer capability (*20*). In an effort to circumvent these limitations, nondisruptive PEGylation strategies have been pursued. For example, cyclodextrin-based polycations have been developed that allow DNA complexation and PEGylation in a single-step reaction. PEGylation occurs by inclusion complex formation between adamantine-PEGs and cyclodextrins, and has no adverse effects on DNA−cation interactions (*22, 31, 32*).

To enable the formulation of polyplexes appropriate for systemic administration and efficient cellular utilization, we have explored a novel formulation strategy that employs peptide nucleic acid (PNA)−peptide conjugates as linkers for the direct and reversible PEGylation of DNA. PNAs are nucleic acid analogues that contain a peptide backbone and can hydrogen bond to cDNA (or RNA) via either conventional Watson−Crick base pairing in the antiparallel direction or Hoogsteen base pairing in the parallel direction. Because PNAs contain a neutral backbone, the PNA−DNA duplex is more stable than the corresponding DNA−DNA duplex, and PNAs can interact with one strand of double-stranded DNA by strand invasion (*33*−*35*). Symmetric PNA oligomers linked by a flexible spacer (PNA "clamps"; Figure 1) form stable PNA−DNA−PNA triplexes (*35*−*38*). PNA clamp binding to plasmid DNA outside of the coding region does not interfere with transcriptional activity and has been previously used to label plasmids with fluorophores and other tags that enable DNA tracking or targeting during gene delivery (*39, 40*).

Our formulation design scheme (Figure 1) employs PNA clamps as linkage points for the direct functionalization of plasmid DNA with protease-sensitive peptides and PEG. The peptide linker serves as a cleavable bridge that will allow cell-triggered dePEGylation (by protease secretion), which we expect should promote improved DNA internalization. Furthermore, because PEG prevents polyplex aggregation, we expect that prePEGylation of the DNA followed by polyplex formation should enable the creation of homogeneous single plasmid complexes, without compromising the efficiency of polycation−DNA compaction. Precise particle size control during formulation can be beneficial in overcoming a variety of physiological barriers such as vascular extravasation (*41*−*45*), interstitial transport (*46, 47*), and cellular internalization (*48*−*53*). For example, studies on the design requirements for effective transcapillary flux of antibody therapies have demonstrated that smaller, positively charged molecules are more efficient at vascular extravasation (*54*−*56*). With respect to interstitial transport, smaller adenoviral particles (∼25 nm) move more efficiently than larger particles (∼100 nm) through multicellular extracellular matrix spheroids (*47*). Furthermore, previous studies have suggested that particles 50 nm or less are optimal for receptor-mediated endocytosis (*57, 58*). Coincidentally, DNA polyplexes containing a single plasmid are believed to be approximately 30 nm in diameter (*59*). Hence, methods to form homogeneous, small particles have clear advantages with respect to in vivo efficacy, as well as from a manufacturing/patient-dosing perspective.

In this work, we demonstrate the development of DNA-PNA-peptide-PEG (DP3) conjugates and observe the corresponding effect of DNA prePEGylation on polyplex formation and in vitro bioactivity. The starting components for these polyplexes (DP3 conjugates and PEI) represent stable compounds, and the methods for polyplex formation are amenable to bedside formulation. Furthermore, with the first demonstration of direct DNA PEGylation for gene therapy, we show that we can form 30−50 nm particles of a homogeneous size distribution that have improved nucleic acid packaging efficiency, low cytotoxicity, and activity that is independent of free PEI in solution. Proof-of-principle of our PNA-based design will lay the foundation for its exploration in vivo.

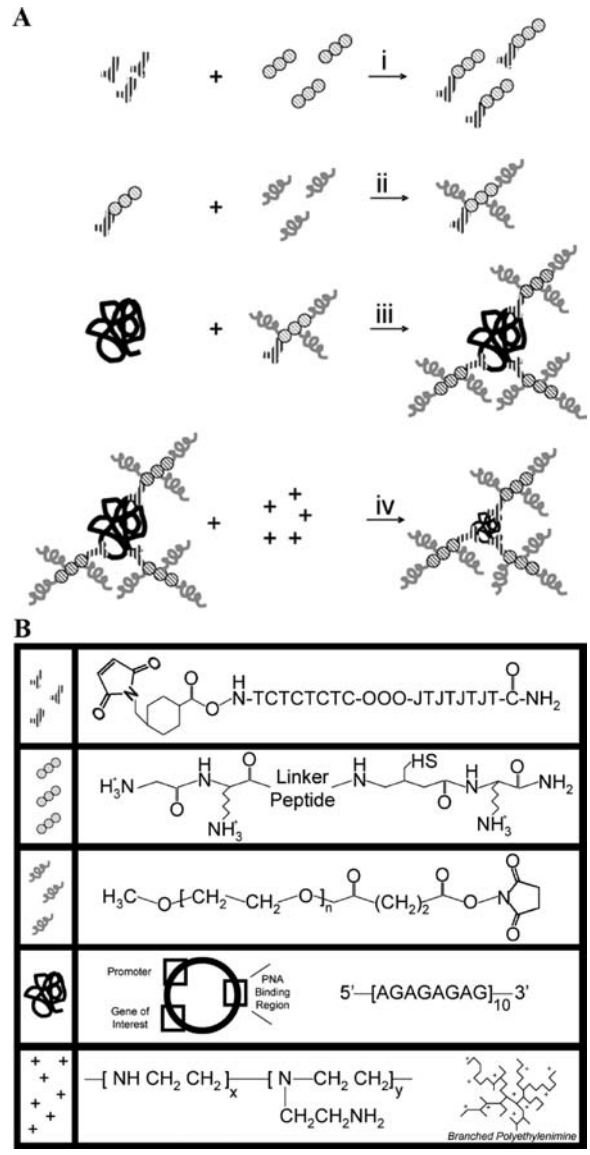

Figure 1. PNA-based vehicle formulation design. (A) The linker peptide (circles; see detailed expansion in [B]) was bound to the PNA ("Y"s) by the reaction of the cysteine thiol with the terminal PNA maleimide (i). Then, succinimidyl-PEG chains (gray squiggles) were bound to the amines on the peptide N-terminus and lysine residues (ii). The PNA-peptide-PEG conjugates were purified and then bound to GWiz plasmid DNA (black scribble) via sequence-specific hydrogen bonding interactions (iii). The final DNA-PNA-peptide-PEG (DP3) conjugate was purified, and 25 kDa branched PEI (+) was added to complex the DNA (iv). (B) Detailed structures of the components of the DP3 conjugates. Figure not to scale.

MATERIALS AND METHODS

Reagents and Materials. PNA clamps (AlexaFluor488/AlexaFluor555/maleimide-TCTCTCTC-OOO-JTJTJTJT-$CONH_2$ (*34*), where O = 8-amino-3,6-dioxaoctanoic acid and J = pseudoisocytosine) with either an AlexaFluor488, AlexaFluor555, or maleimide terminus were synthesized by solid-

phase synthesis and HPLC-purified to >95% purity by Panagene (Daejeon, Korea). The GWiz green fluorescent protein (GFP)-expressing plasmid containing 10 sequential copies of the repeated PNA binding sequence 5′-AGAGAGAG-3′ was purchased from Genlantis (San Diego, CA) (see Supporting Information Figure 1D for the sequence of the PNA binding region), and the non-PNA binding plasmid (SV40-Renilla) was purchased from Promega (Madison, WI). Both plasmids were amplified in *E. coli* and purified with a Qiagen MegaPrep kit. Briefly, competent DH-5α cells were transformed with the appropriate plasmid and cultured overnight in Lysogeny Broth. Cells were lysed and the amplified plasmid was purified and recovered in accordance with the manufacturer's protocols. A 22 amino acid linker peptide (NH_2-*GKG**GPQG/IWGQ**GRGD-SPGDRCK*-$CONH_2$) was synthesized by solid-phase synthesis and HPLC-purified to >95% by Global Peptide Services (Huntsville, AL). This peptide contains an MMP-1-sensitive region (boldfaced with the exact cleavage site indicated by a backslash) (*60*). α-Methoxy, ω-succinimide poly(ethylene glycol) (MW = 5000 g/mol) was synthesized, purified, and analyzed by gel permeation chromatography (GPC) and Fourier transform infrared spectroscopy (FTIR) by Polymer Source, Inc. (Montreal, Canada). 25 kDa branched poly(ethylenimine) (PEI) was purchased from Sigma (St. Louis, MO). Polymer molecular weight was validated by light scattering and GPC by the manufacturer.

Conjugate Development and Particle Formation. *PNA-Peptide-PEG Conjugate Formation.* To form PNA−peptide conjugates, 2 μM of the maleimide-terminated PNA and 0.2 μM of peptide were incubated in 100 μL of 20 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffer (pH 7.4) overnight at 37 °C. A 10-fold excess of PNA was used in this reaction to minimize the presence of unreacted peptide at the end of the reaction. To derivatize the PNA−peptides with succinimide-terminated PEG, 1.25 μL of 4 mM PEG in 20 mM HEPES buffer (pH 7.4) was added to the PNA−peptide reaction mixture (corresponding to a 250-fold molar excess), and the resulting solution was incubated overnight at 37 °C. Following this reaction, unreacted components were removed via centrifugal filtration with a YM-10 centrifugal filtration column (10 000 Da molecular weight cutoff [MWCO], Millipore, Billerica, MA). For this process, the membrane was first primed with a 500 μL distilled water rinse at 12 000 *g* for 30 min in a table-top centrifuge. Following this rinse, sample was added to the column and centrifuged for 30 min at 12 000 *g*. Three separate wash steps followed; in each wash, 500 μL of distilled water was added to the column and subsequently centrifuged for 30 min at 12 000 *g*. To collect the retentate at the end of the washes, the membrane was inverted into a clean tube, and 20 μL of distilled water was added to the membrane. The column was then centrifuged for 2 min at 12 000 *g*. The final recovered volumes were raised to 100 μL by the addition of 20 mM HEPES buffer (pH 7.4).

Estimation of PNA−DNA Hybridization Efficiency. 0.6 pM of the GWiz PNA-binding plasmid or of the SV40-Renilla non-PNA-binding plasmid was incubated with 0−200 pM of AF-PNA in a 10 mM HEPES/50 mM NaCl buffer (pH 7.4) overnight at 37 °C. After incubation, the samples were analyzed by gel electrophoresis on a 1% agarose gel, and the gel was stained with a 1% ethidium bromide solution and visualized on a Bio-Rad Gel Doc XR (Hercules, CA).

DP3 Formation by Hybridization of DNA with PNA-Peptide-PEG Conjugates. 6 pM of DNA was added to the purified PNA-peptide-PEG conjugates in a total volume of 100 μL of 20 mM HEPES buffer (pH 7.4), and the mixture was allowed to incubate overnight at 37 °C (*39*). Unbound PNA-peptide-PEG was removed via centrifugal filtration by a similar procedure as that described for the PNA-peptide-PEG conjugates; a YM-100 column was used (100 000 MWCO, Millipore), and spin times were reduced to 10 min per spin to prevent membrane clogging.

Assessment of DP3 Conjugate Stoichiometry. Tryptophan fluorescence analyses were performed on a Jasco FP-6500 spectrofluorimeter (excitation $\lambda = 280$ nm; emission $\lambda = 350$ nm). An ETC-273T temperature controller and a Julabo AWC-100 water chiller enabled sample analysis to be done at 25 °C. For analysis of peptide standards, peptide was dissolved in a 20 mM HEPES buffer (pH 7.4) at the indicated concentrations and assessed fluorimetrically.

UV/vis spectroscopy measurements were performed on a Nanodrop ND 1000 spectrophotometer (ND-1000) (Thermo Scientific - Nanodrop Products, Wilmington, DE). DNA concentrations were determined as per the manufacturer's protocol. Briefly, 2 μL of sample were placed onto the sample platform. The absorbances at 230 nm, 260 nm, and 280 nm were analyzed, and a corresponding concentration and measure of DNA purity were assessed.

Attenuated total reflectance FTIR (ATR-FTIR) analyses were performed on a Spectrum One FTIR Spectrometer (Perkin-Elmer, Waltham, MA). Ten μL of each sample were dried with air onto a diamond ATR crystal, and 200 runs per sample were subsequently conducted under ambient conditions. Spectra were acquired between 4000 cm^{-1} and 1000 cm^{-1}.

DNA Complexation. 25 kDa PEI solutions were added to DP3 conjugate solutions or free plasmid solutions at varying N/P (PEI nitrogen/DNA phosphate) ratios, following existing protocols (*5*). Briefly, a 500 μL PEI solution was added to a 500 μL DP3 (or free plasmid) solution containing 20 μg of plasmid. The PEI solution was added to the DNA solution in a dropwise fashion while vortexing, and the combined solutions were allowed to form complexes at room temperature for 10 min prior to sample analysis.

DNA Complex Purification. Free PEI was removed from the suspensions of PEI complexes by centrifugal filtration of the complex suspensions with a YM-100 filter. First, the filters were primed with 500 μL of double-distilled water (ddH_2O) for 5 min at 12 000 *g*. Then, 500 μL of complex suspension was added and centrifuged at 100 *g* for 30 min. One 500 μL wash was performed with ddH20. Complex sizes were assessed via dynamic light scattering (DLS) prior to and following purification.

Polyplex Characterization. *Dynamic Light Scattering (DLS) and Zeta Potential Analyses.* DLS and zeta potential analyses were performed at a 90° angle with a Brookhaven (Holtsville, NY) BI9000AT correlator and a Lexel (Fremont, CA) model 95 argon ion laser operating at 488 nm. All measurements were performed at 20 ± 0.2 °C, with sample temperature controlled by an external circulating bath. For DLS, the CONTIN algorithm was used to analyze the autocorrelation functions and estimate the mean diameters and size distributions of the complexes formed. The measured effective hydrodynamic diameters for each sample run were the average values from a total of 5 runs of 2 min each, while the measured zeta potentials for each sample run were the average of 10 runs of 2 min each.

Atomic Force Microscopy. Atomic force microscopy (AFM) was performed on a Nanoscope IIIa atomic force microscope (Digital Instruments, Santa Barbara, CA) used in conjunction with an MLCT cantilever tip (60 nm backside gold coating, 3 μm tip, Veeco, Santa Barbara, CA). Contact-mode AFM images were collected under ambient conditions at approximately 25 °C. Samples were prepared by the complex formulation procedure described above. 50 μL of complex suspension containing 1 μg of DNA was dried for 24 h onto a 77 mm^2 mica substrate. Height and deflection error modes were used for imaging, with scan rates of ∼1 Hz. Image processing was performed using the Nanoscope IIIa software package.

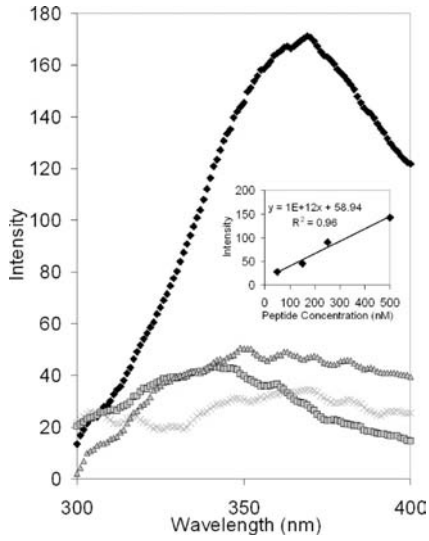

Figure 2. Intrinsic fluorescence of the DNA-PNA-peptide-PEG conjugate. The purified DP3 conjugates and conjugates prepared identically but in the absence of one component were analyzed via intrinsic fluorescence spectroscopy to detect tryptophan residues present in the linker peptide (excitation 280 nm; emission 350 nm). The DP3 conjugate (black diamonds) exhibited significant fluorescence at 350 nm, indicative of the presence of the linker peptide. In contrast, samples prepared in the absence of DNA (gray squares), PNA (gray "X"s), or peptide (gray triangles) had minimal fluorescence at the same wavelength. Inset: the fluorescence emission peak intensities of various linker peptide solutions were analyzed (excitation 280 nm; emission 350 nm).

Scanning Electron Microscopy. Scanning electron microscopy (SEM) was performed on a Hitachi S-4700 field emission scanning electron microscope (Pleasanton, CA). Fifty μL of complex suspension containing 1 μg of DNA was prepared as described and dried overnight onto a 127 mm^2 glass coverslip, fixed with glutaraldehyde, and treated with osmium tetroxide via standard protocols. The complexes were then sputtered with gold, and the sputtered samples were fixed in the sample holder and placed in the vacuum chamber of the microscope under low vacuum (10^{-3} Torr) for imaging.

Ethidium Bromide Exclusion Assays and Nuclease Protection Assays. Ethidium bromide exclusion assays were performed by agarose gel electrophoresis. Complexes were formed as described, over a range of N/P ratios from 0 to 10. Ten μL aliquots of each sample were analyzed on 1% agarose gels formed in the presence of 1% ethidium bromide, and the resulting gels were imaged as described.

Nuclease protection assays were conducted by a modification of existing protocols (*22*). Briefly, 10 μL of 100% mouse serum (Sigma) was added to 10 μL of complex suspension (200 ng of DNA), and the mixture was incubated for 4 h at 37 °C. Subsequently, termination buffer (labeled STOP) containing 38 mM EDTA, 154 mM NaOH, and 38 mM NaCl was added to stop the serum degradation process, and the resulting mixture was incubated for 15 min at 4 °C. DNA was then displaced from the complexes by incubation with 1 mg/mL heparin (stock solution of 10 mg/mL) (Sigma). Samples were then analyzed by agarose gel electrophoresis as described.

In Vitro Transfection and Viability Assays. *Cell Culture.* Chinese hamster ovary (CHO) cells (ATCC, Manassas, VA) were maintained in a humidified, 37 °C atmosphere in Dulbecco's modified eagle medium (DMEM) containing 10% fetal bovine serum (FBS), 100 μg/mL penicillin, and 100 μg/mL streptomycin (Invitrogen).

Transfection. For transfection, 200 000 cells were seeded into each well of a 6 well dish and the cells were grown overnight. Immediately prior to transfection, the growth medium was removed and replaced with 2 mL of serum-free Opti-Mem medium (Invitrogen). 500 μL of complex suspension (containing 10 μg DNA) was formed and added to the cells in a dropwise manner. The complexes were then allowed to incubate with the cells in serum-free medium for 3 h. At that time, the serum-free medium was removed, the cells were washed in PBS, and growth medium was added. The cells were analyzed by flow cytometry and fluorescence microscopy 24 h after transfection. For flow cytometry, the cells were trypsinized, washed in 0.1% BSA, and reconstituted in PBS for analysis with a BD Biosciences FACSCalibur cytometer (San Jose, CA). For fluorescence microscopy, live cells were imaged with a Leica microscope according to established protocols.

Viability. For cell viability assays, an ethidium homodimer dye (Invitrogen) was used to stain for dead cell nuclei. Four microliterse of a 2 mM dye solution was added to the transfected cell cultures, and the cells and dye were incubated for 10 min at room temperature. The cells were subsequently imaged by fluorescence microscopy.

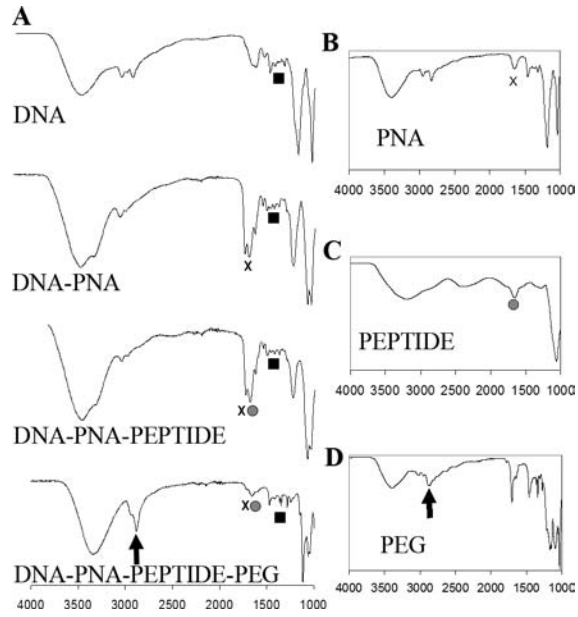

Figure 3. ATR-FTIR characterization of the DP3 conjugates. (A) ATR-FTIR spectra of the GWiz plasmid (top), the DP3 conjugate (bottom), and conjugates lacking one or more conjugate components (middle). The main absorption bands of DNA (black squares) are as follows: 1063 cm^{-1} (symmetric stretching vibration of the phosphate groups), 1222 cm^{-1} (antisymmetric stretching vibration of the phosphate group), 1017 cm^{-1} (vibration of C═N of ribose), and 1693 cm^{-1} (vibrations of C6═O of guanine and C4═O of thymine). Amide bonds, found in both PNA (B) and peptide (C), have an expected peak at approximately 1630 cm^{-1} (black "*x*"s in [A] and [B] and gray circles in [A] and [C]). Peaks attributable to PEG (D) are observed at 2890 cm^{-1} (black arrows in [A] and [D]), indicative of the $-CH_2$-stretching vibrations.

RESULTS

DP3 Conjugate Formation. *PNA-Peptide-PEG Conjugate Formation.* The PNA-peptide-PEG conjugates were formed by the stepwise reaction of the individual components, as summarized in Figure 1. In the first step, PNA−peptide conjugates were formed by the reaction of the N-terminal PNA maleimide groups on the maleimide-terminated PNAs with the cysteine thiol residues near the C-terminus of the peptides. Next, the N-terminus and the two lysine side-chain amine groups on the peptides were reacted with succinimide-terminated PEG. The PNA-peptide-PEG conjugates were purified by centrifugal microconcentration, and the stoichiometry of these conjugates was assessed by fluorescence spectroscopy and ATR-FTIR, as discussed below.

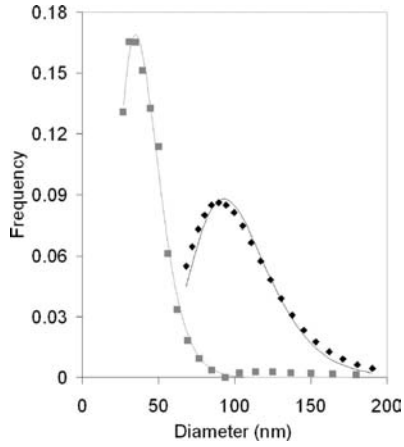

Figure 4. PEI−DP3 and PEI−DNA polyplex size distributions. PEI−DP3 (gray squares) and PEI−DNA (black diamonds) polyplexes were formed at an N/P of 10 and analyzed via DLS. The resulting autocorrelation functions were transformed into the relevant size distributions by the CONTIN algorithm.

PNA-Peptide-PEG Hybridization with Plasmid DNA. To estimate the PNA-peptide-PEG:DNA incubation ratio that would enable saturation of the DNA, the GWiz PNA-binding plasmid and the SV40-Renilla non-PNA-binding plasmid were incubated with AlexaFluor488-labeled PNA (AF-PNA) over a range of ratios to enable PNA strand invasion and PNA−DNA hydrogen bonding. The resulting mixtures were analyzed by gel electrophoresis (Supporting Information Figure 1). An approximate 3-fold molar site excess of AF-PNA:PNA binding sites (equal to a 30-fold molar excess of AF-PNA:GWiz) was effective at achieving saturation of GWiz DNA with PNA, consistent with previous work (*39*), whereas no binding of AF-PNA to the SV40-Renilla DNA was observed.

To form the hybridized DP3 conjugates, the GWiz PNA-binding plasmid was incubated with the PNA-peptide-PEG conjugates, and the DP3 conjugates were purified by centrifugal microconcentration. Intrinsic fluorescence spectroscopy and ATR-FTIR spectroscopy were used to analyze the stoichiometry of the DP3 conjugates. The peptide incorporated into the conjugates included a tryptophan residue whose fluorescence enabled analysis of peptide concentration. Figure 2 illustrates the fluorescence emission spectrum of the DP3 conjugate, as well as the spectra for various control samples that were prepared identically but in the absence of one of the conjugate components. The observed fluorescence of the DP3 conjugate corresponded to a peptide concentration that was a 7-fold molar excess over the concentration of the plasmid (assessed by UV/vis spectroscopy; data not shown), suggesting that PNA-peptide-PEG conjugates were bound to approximately 70% of the available PNA binding sites on the plasmid. Samples prepared identically, but in the absence of peptide, exhibited minimal fluorescence, as expected; samples prepared in the absence of PNA also exhibited minimal fluorescence, suggesting that PNA-peptide-PEG hybridization to the plasmid was mediated by PNA−DNA interactions. Samples prepared in the absence of DNA exhibited minimal fluorescence and provided validation of the efficiency of the purification process.

ATR-FTIR spectroscopy was used as a secondary means of conjugate validation (Figure 3). The DP3 sample spectrum exhibited characteristic peaks indicative of DNA, PNA, peptide, and PEG (Figure 3A, bottom). The DNA spectrum (Figure 3A,

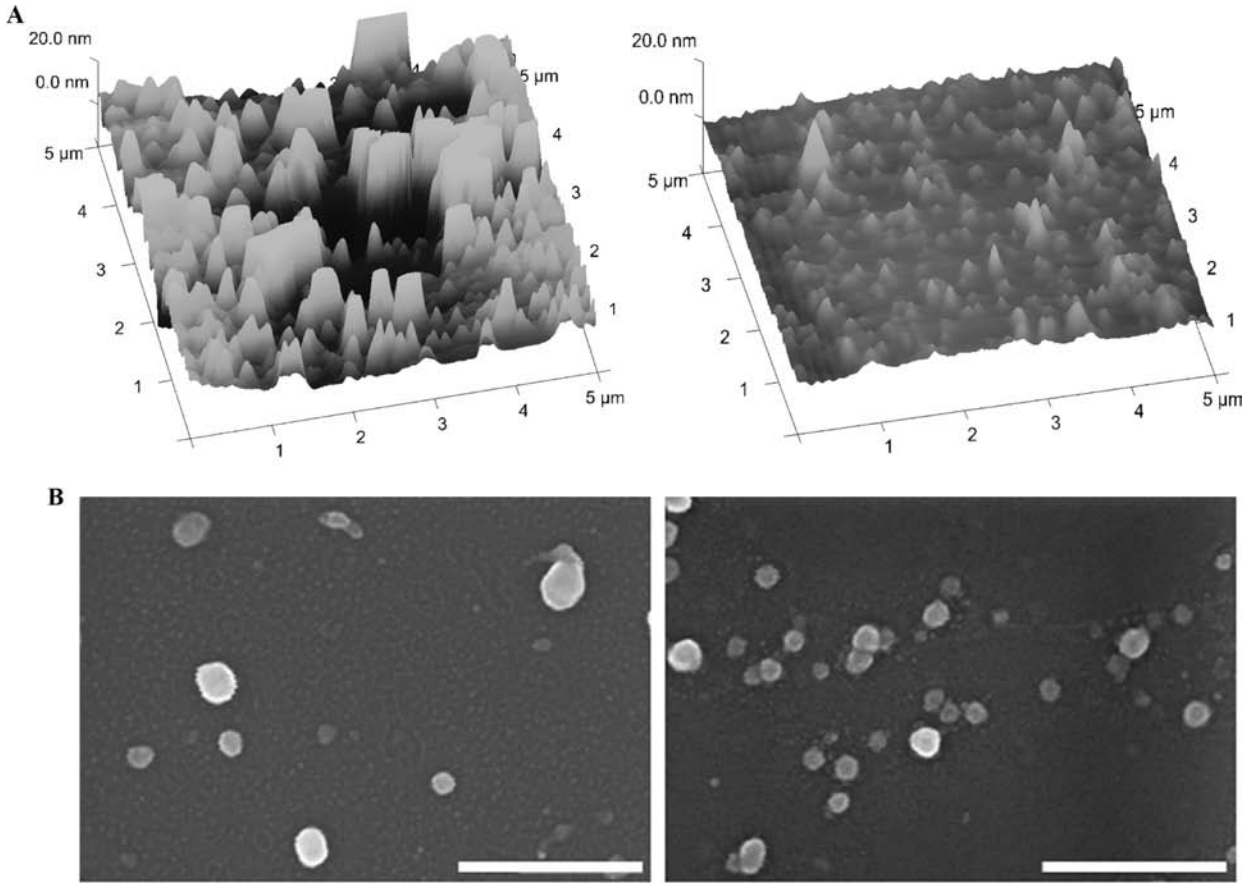

Figure 5. PEI−DP3 and PEI−DNA polyplex shape and size. (A) AFM images of PEI−DNA (left) and PEI−DP3 (right) complexes dried on a mica strip and imaged in contact mode (N/P = 10). (B) SEM images of PEI−DNA (left) and PEI−DP3 (right) complexes dried onto glass substrates (N/P = 10). Scale bar = 500 nm.

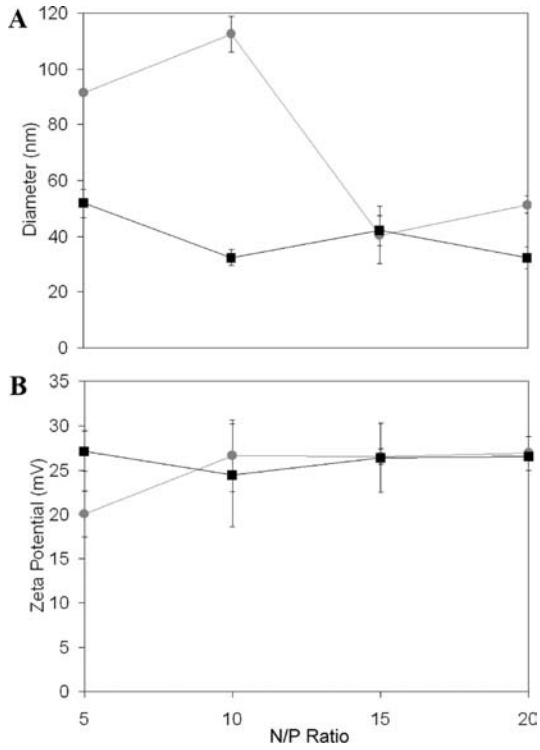

Figure 6. PEI−DP3 and PEI−DNA polyplex characterization by light scattering. (A) DLS was used to assess PEI−DP3 (black squares) and PEI−DNA (open circles) polyplex diameters at N/P = 5−20. Number averaged distributions obtained with the CONTIN algorithm were used to calculate average polyplex diameters. Statistically significant differences are noted at N/P ratios of 5 ($p = 0.006$) and 10 ($p = 0.021$). (B) Phase analysis light scattering was employed to determine the zeta potentials of polyplexes prepared at the same N/P ratios. All data represent the mean values obtained from three separately prepared and analyzed samples per data point. Error bars represent one standard deviation from the mean.

top) had characteristic vibrational signals in the 1000−1500 cm^{-1} region. The PNA and the peptide spectra both exhibited characteristic amide bond signals (1630 cm^{-1}), as expected (Figure 3B and C), whereas the PEG spectrum had a signal at around 2800 cm^{-1}, indicative of the carbon−carbon vibrational stretching along the backbone of the polymer (Figure 3D). In contrast, conjugate samples that were missing one or more of the conjugate components exhibited spectra missing the corresponding signals (Figure 3A, top and middle). Notably, the presence of the characteristic PEG signal only in the DP3 conjugate sample suggested direct DNA prePEGylation.

Physical Characterization of DNA Complexes. *Complex Size and Charge.* The DP3 conjugates and unmodified plasmids were self-assembled with 25 kDa PEI, and the resulting complexes were analyzed by DLS. As shown in Figure 4, the PEI−DP3 complexes were smaller and less heterogeneous than the PEI−DNA complexes at an N/P ratio of 10. By a log-normal statistical fit, the mean of the PEI−DP3 size distribution was reduced in comparison with that of the PEI−DNA size distribution from approximately 100 to 40 nm; the standard deviation of the PEI−DP3 size distribution was reduced by half (from 28 to 14 nm) in comparison with that of the PEI−DNA size distribution. As previously mentioned, the wide standard deviation of PEI−DNA complex diameters is typical for these systems, and is a direct consequence of the multimolecular aggregation that occurs during the formulation process. To further examine this observation, AFM and SEM were utilized to characterize the PEI−DP3 and PEI−DNA complexes (Figure 5A and B). Complex suspensions were dried onto AFM and SEM substrates and the substrates were subsequently analyzed.

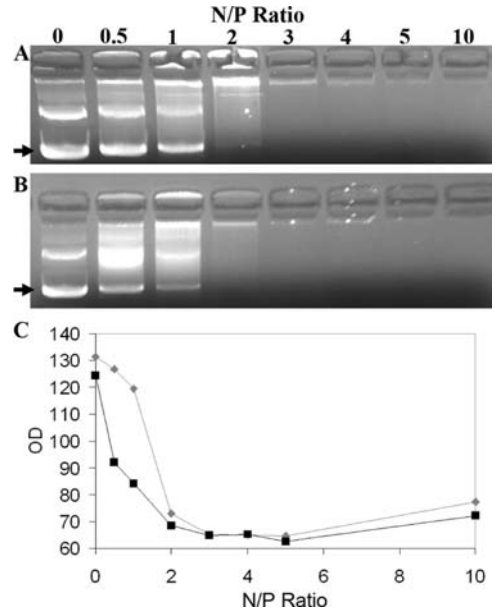

Figure 7. Assessment of complexation efficiency by ethidium bromide exclusion assays. PEI−DNA (A) and PEI−DP3 (B) polyplexes were prepared and analyzed by agarose gel electrophoresis at N/P ratios ranging from 0 to 10. The bands corresponding to supercoiled plasmid DNA are indicated (arrows). (C) Optical density measurements of the supercoiled DNA band for PEI−DP3 (black boxes) and PEI−DNA (white diamonds) polyplexes for the gel shown in A. The trends in optical density were consistent in replicates of the same experiment. Other bands on the gel include open circular and nicked plasmid DNA, as well as DNA aggregates found in the wells of the gel.

AFM and SEM images of the complexes supported the finding that smaller and less heterogeneous complexes formed when the DNA was directly PEGylated prior to complexation.

The size of PEI−DNA complexes depends upon the N/P ratio at which they are formed because of the dependence of colloidal stability on surface charge (*61*). In contrast, it was expected that DNA prePEGylation would reduce this N/P dependence by steric stabilization of the PEI−DP3 complexes. DLS and zeta potential analyses were therefore used to assess the mean complex size and zeta potential as a function of the N/P ratio (Figure 6). As predicted, the PEI−DP3 complexes had similar average diameters, regardless of the amount of polycation introduced, whereas the PEI−DNA complexes were larger at lower N/P ratios (Figure 6A). Zeta potential analyses (Figure 6B) revealed no significant differences between the trends for the PEI−DP3 and PEI−DNA samples.

Complexation Efficiency and Nuclease Protection. Because polymer PEGylation has been shown to destabilize polyplexes (*4, 25, 26, 28−30*), the complexation efficiency and nuclease protection of the PEI−DP3 complexes were explored. Ethidium bromide exclusion assays revealed that complexation efficiency increased as a consequence of the DNA prePEGylation strategy employed with the DP3 conjugate (Figure 7). In this assay, any reduction in DNA band intensity is a consequence of the complexation process excluding ethidium bromide from the nucleic acid, inhibiting its ability to intercalate and fluoresce. At low N/P ratios, the band intensity (as quantified via optical density measurements) for supercoiled DP3 was lower than that for DNA (Figure 7A and B), suggesting that PEI was able to more effectively condense the PEGylated nucleic acid.

Nuclease protection assays were used to examine the resistance of DNA within the PEI−DP3 complexes to serum nucleases. Consistent with the finding that the PEI−DP3 complexes were packaged efficiently at N/P ratios greater than 3, these complexes were also able to protect DNA from

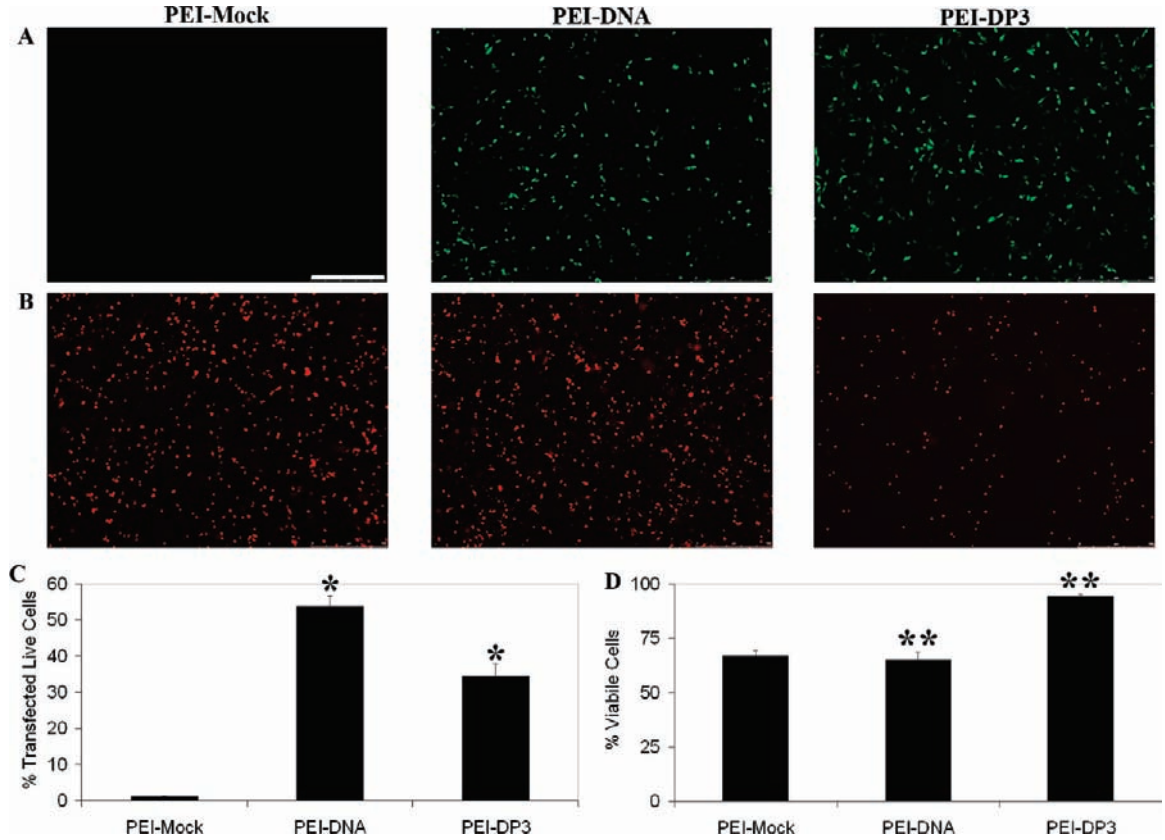

Figure 8. Transfection efficiency and cytotoxicity assays. The transfection efficiencies of PEI-Mock (complexes made with PEI and a non-GFP-expressing plasmid), PEI−DNA, and PEI−DP3 complexes formulated at N/P = 10 were assessed in CHO cells 24 h post-transfection by fluorescence microscopy (A) and flow cytometry (C) to detect GFP fluorescence. The scale bar (shown in [A]) = 500 μm. The data in (C) represent the mean values obtained from three separate transfection experiments, and the error bars represent one standard deviation from the mean. Statistically significant differences were observed between the indicated samples (p [*] = 0.038). (B) The cytotoxicities of the same complexes were evaluated with a ethidium homodimer stain and fluorescence microscopy (B). Quantification was performed by image analysis (D), and [**] indicate a statistically significant difference between the indicated samples (p [**] = 0.0001).

enzymatic degradation (Supporting Information Figure 2). Previous studies have shown the effectiveness of PEI at achieving this goal (*62, 63*).

Complex Bioactivity. *Transfection Efficiency and Cell Viability.* To determine whether DNA prePEGylation and the resulting alterations in complex size influenced cellular transfection, the PEI−DP3 and PEI−DNA complexes were used to transfect CHO cells. After 24 h, a reduction in the transfection efficiency was observed when the PEI−DP3 complexes were used for transfection in comparison with when the PEI−DNA complexes were used (PEI-Mock complexes containing a non-GFP-expressing plasmid were also examined to account for any nonspecific autofluorescence associated with PEI) (Figure 8A and C). Similar trends were observed when transfection was assessed by flow cytometry and image analysis. However, while the transfection efficiency was somewhat lower with PEI−DP3 than with PEI−DNA, the cytotoxicity of the PEI−DP3 complexes was significantly reduced relative to those of both the PEI-Mock and the PEI−DNA complexes (Figure 8B and D).

Complex Purification Effects. Previous work has shown that the in vitro cytotoxicity of PEI−DNA formulations depends largely upon the excess PEI that remains in solution following complexation, and thus can be reduced through complex purification via size exclusion chromatography (*64*). To examine the effects on PEI−DP3 transfection efficiency and cytotoxicity following free PEI removal, centrifugal filtration was used to purify the complexes. As expected, a reduction in cytotoxicity was observed for the PEI-Mock and PEI−DNA complexes following purification (Figure 9). However, the PEI−DP3 complexes retained their low level of cytotoxicity following purification, suggesting that the amount of free PEI in solution following complexation was significantly reduced in these formulations in comparison with conventional PEI−DNA formulations.

While purification of PEI−DNA complexes lowers their cytotoxicity, previous work has shown that the removal of the excess PEI in solution reduces transfection efficiency (*64*). This observation was previously attributed to the role of free PEI in solution in assisting endosomal buffering following cellular internalization (*64*). This particular point is of concern when considering the potential in vivo applicability of PEI−DNA complexes, since the in vitro concentration of free PEI is not an appropriate reflection of the physiological situation. Figure 10 illustrates that the transfection efficiency of the PEI−DP3 complexes increased following purification, whereas that of the PEI−DNA complexes decreased. These changes resulted in transfection levels that were approximately 12% higher when PEI−DP3 was used for transfection as opposed to PEI−DNA (as confirmed by both image analysis [data not shown] and flow cytometry).

DISCUSSION

PEI-based formulations are highly efficient in vitro gene delivery vehicles, in large part because of their capacity to induce endosomal release by pH-buffering (*8*). Unfortunately, the in vivo applicability of these formulations is questionable, given the inherent cytotoxicity of PEI (*64*) and challenges in formulation. In particular, the process of multimolecular aggregation during polyplex formation is a significant issue that results in highly heterogeneous complexes at sizes larger than the optimum for either receptor-mediated internalization or for effective in vivo

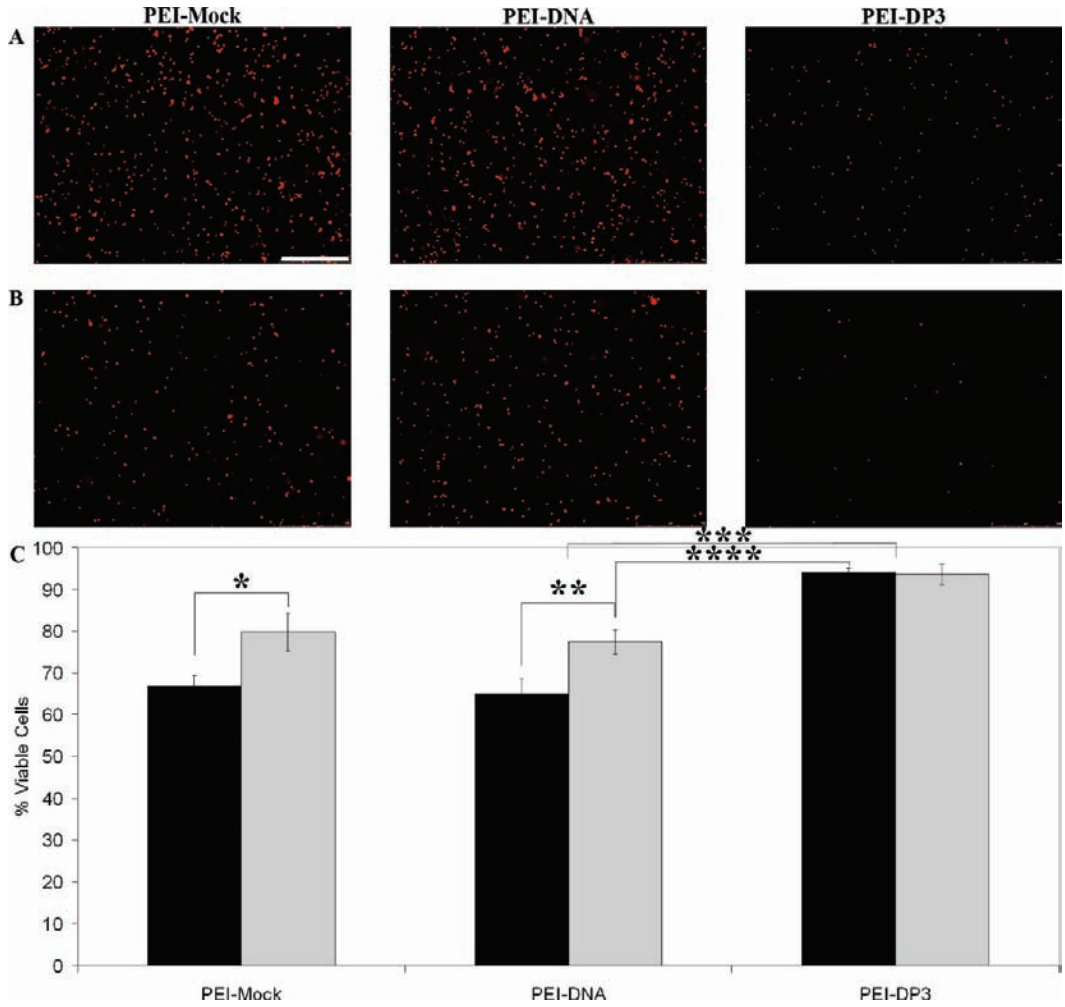

Figure 9. Effect of complex purification on cytotoxicity. unpurified (A) and purified (B) PEI-Mock, PEI−DNA, and PEI−DP3 complexes were used at N/P = 10 to transfect CHO cells, and the cytotoxicity of each formulation was analyzed by ethidium homodimer staining and fluorescence microscopy. Quantification for the unpurified (black bars) and purified (gray bars) formulations was performed by image analysis (C) and indicated statistically significant differences between the indicated samples (p [*] = 0.002; p [**] = 0.02; p [***] = 0.00005; p [****] = 0.00005). All data represent the mean values obtained from three separate transfection experiments, and the error bars represent one standard deviation from the mean. The scale bar (shown in [A] = 500 μm).

administration. Furthermore, the in vitro activity of PEI-based formulations depends upon the presence of free PEI at levels higher than would be feasible in vivo (*64*). To address these issues in PEI polyplex formulation, a novel strategy for DNA prePEGylation has been explored in this work with the goals of reducing aggregation during formulation and producing less heterogeneous and more efficiently packaged polyplexes.

With this aim in mind, PNA-peptide-PEG conjugates were synthesized as the basis for a new class of gene delivery materials. When these PNA-peptide-PEGs were hybridized with DNA, the resulting DP3 conjugates behaved differently than unmodified DNA when they were self-assembled with PEI. The PEI−DP3 complexes were smaller and less heterogeneous than PEI−DNA complexes formulated at the same N/P ratio (Figures 4−6). This observation was confirmed via DLS analysis of particle scattering, as well as by AFM and SEM imaging, which enabled visualization of individual particles. Furthermore, when the N/P ratio was varied, the size of the PEI−DP3 complexes remained constant at ∼30−50 nm, whereas the size of the PEI−DNA complexes was larger at low N/P ratios. Given that DNA polyplexes containing a single plasmid are believed to be approximately 30 nm in diameter (*59*), this result suggested that single plasmid-containing complexes were formed with the DP3 conjugate. This effect was attributed to steric stabilization of the PEI−DP3 complexes by DNA prePEGylation. However, unlike typical surface PEGylation strategies which introduce a brush layer of PEG, the observed shifts in the complex size distribution were the result of a small number of PEG molecules bound to each plasmid through the PNA−peptide linker (∼10−20 PEG molecules, assuming the PNA−peptides were saturated with PEG). As a result, PNA-based DNA prePEGylation did not produce measurable effects on polyplex zeta potential (Figure 6B). Furthermore, the PEI−DP3 complexes did not exhibit significant improvements in salt stability in comparison with PEI−DNA complexes, presumably because a large amount of their surface area was not covered by PEG (data not shown).

Although polymer PEGylation has been shown to destabilize polyplexes (*4, 25, 26, 28−30*), the complexation efficiency and nuclease protection of the PEI−DP3 complexes were not adversely affected by DNA prePEGylation (Figure 7 and Supporting Information Figure 2). To the contrary, ethidium bromide exclusion assays suggested that PEI formed tighter complexes at low charge ratios with the DP3 conjugates than with DNA, suggesting that more polycation was able to bind per DP3-contained plasmid. With more polycation per plasmid, less free PEI would remain in solution. This result would be highly desirable from a cytotoxicity perspective, since the presence of free polycation in solution has been shown to contribute to cell death (*64*). Furthermore, it was consistent with our findings on the cellular activity of the PEI−DP3 complexes (discussed subsequently).

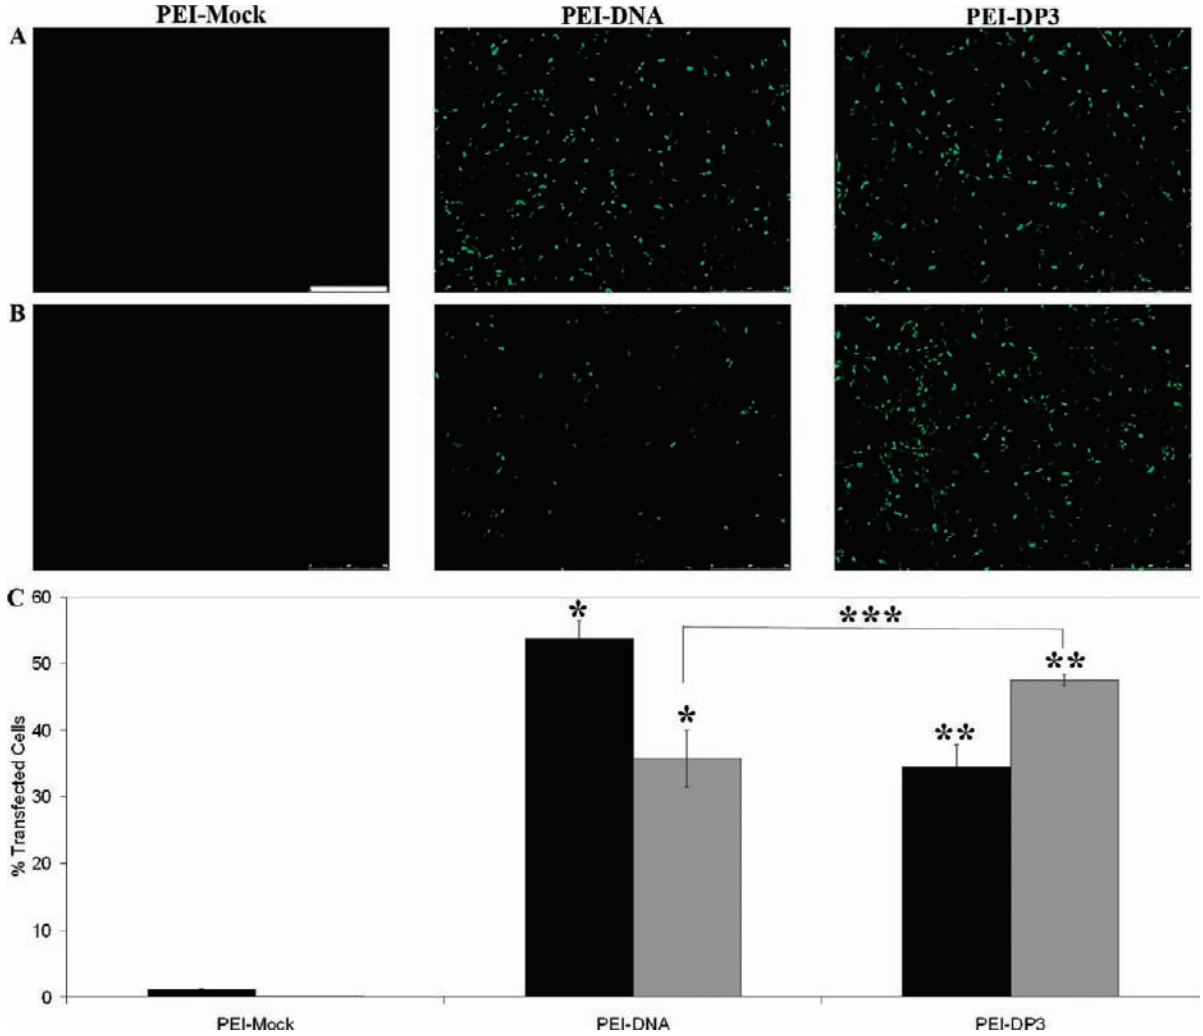

Figure 10. Effect of complex purification on transfection efficiency. Unpurified (A) and purified (B) PEI-Mock, PEI−DNA, and PEI−DP3 complexes were used at N/P = 10 to transfect CHO cells, and the transfection efficiency obtained by each formulation was analyzed by ethidium homodimer staining and fluorescence microscopy. Quantification was performed by flow cytometry for both the unpurified (black bars) and purified (gray bars) formulations (C). All data represent the mean values obtained from three separate transfection experiments, and the error bars represent one standard deviation from the mean. Statistically significant differences were observed between the indicated samples (p [*] = 0.045; p [**] = 0.045; p [***] = 0.046). The scale bar (shown in [A] = 500 μm).

Recognizing the physical differences associated with this proposed formulation, PEI−DP3 complex bioactivity was explored in CHO cells. When transfections were performed with unpurified PEI−DP3 and PEI−DNA complexes (i.e., formulations containing free PEI, as are typically used *7*−*9, 21*), the transfection efficiencies of the PEI−DP3 complexes were slightly lower than those of the PEI−DNA complexes (Figure 8A and C). However, a 30% reduction in cytotoxicity was observed for the PEI−DP3 complexes, most likely as a consequence of the improved complexation brought on by DNA prePEGylation (and the resulting reductions in the levels of free PEI in solution) (Figure 8B and D) (Note: We do not believe that the differences in bioactivity between the two formulations were related to the MMP-1-cleavable peptide incorporated into the PEI-DP3 complexes, given that CHO cells do not express high levels of MMP-1 under the conditions studied.) In an effort to further investigate this effect, free PEI was removed from the formulations and cellular transfections were performed with the purified complexes. The cytotoxicity of the purified PEI−DP3 complexes remained significantly lower than that for the conventional PEI formulations, whereas the transfection efficiency of these complexes increased following purification (Figures 9 and 10). In contrast, the cytotoxicity of the purified PEI−DNA complexes was lower after purification, as expected, and the transfection efficiency of these complexes decreased.

The effects of free PEI removal on the transfection efficiencies achieved by both the PEI−DP3 and PEI−DNA complexes were attributed in part to the known in vitro activity of PEI. The findings with the PEI−DNA complexes were consistent with previous work suggesting that free PEI in solution significantly adds to the activity of PEI formulations by enhancing endosomal buffering (*64*). Thus, the removal of free PEI would be expected to adversely affect transfection efficiency, as was observed. Clearly, a dependence on free polycation to promote efficient gene delivery is not desirable for in vivo applications. The PEI−DP3 complexes appeared to overcome this issue through the inclusion of more PEI per plasmid within the complex, which would enhance the innate endosomal buffering capacity of the complexes. The reasons for the increase in transfection efficiency following the removal of free PEI from the PEI−DP3 formulations were less clear. One possibility is that, with the unpurified PEI−DP3 formulations, the residual PEI in solution blocks polyplex internalization by saturating the available binding sites on the cells.

With a subtle modification of plasmid DNA (the conjugation of ∼10−20 PEG molecules), the complexation and delivery efficiency of a well-known polymer in the gene delivery field has been significantly altered. The effects of DNA prePEGylation on the size distribution, cytotoxicity, and gene delivery efficiency of PEI-based polyplexes are expected to have important impacts

on in vivo activity. As discussed, particles of ~10−100 nm are capable of both avoiding renal clearance (*65*), efficiently exiting the bloodstream, and traveling through interstitial tissues (*46, 47*). Furthermore, the low cytotoxicity and innate activity of the PEI−DP3 complexes in the absence of free PEI should significantly improve in vivo effectiveness. Future work will explore both the dose response of the PEI−DP3 complexes at various N/P ratios in multiple cell lines and the potential benefits of this modified nucleic acid formulation in vivo. The described studies suggest the importance of future efforts focused not only on developing new biomaterials, but also on improving existing systems in the field.

Received July 30, 2009; Revised Manuscript Received February 11, 2010

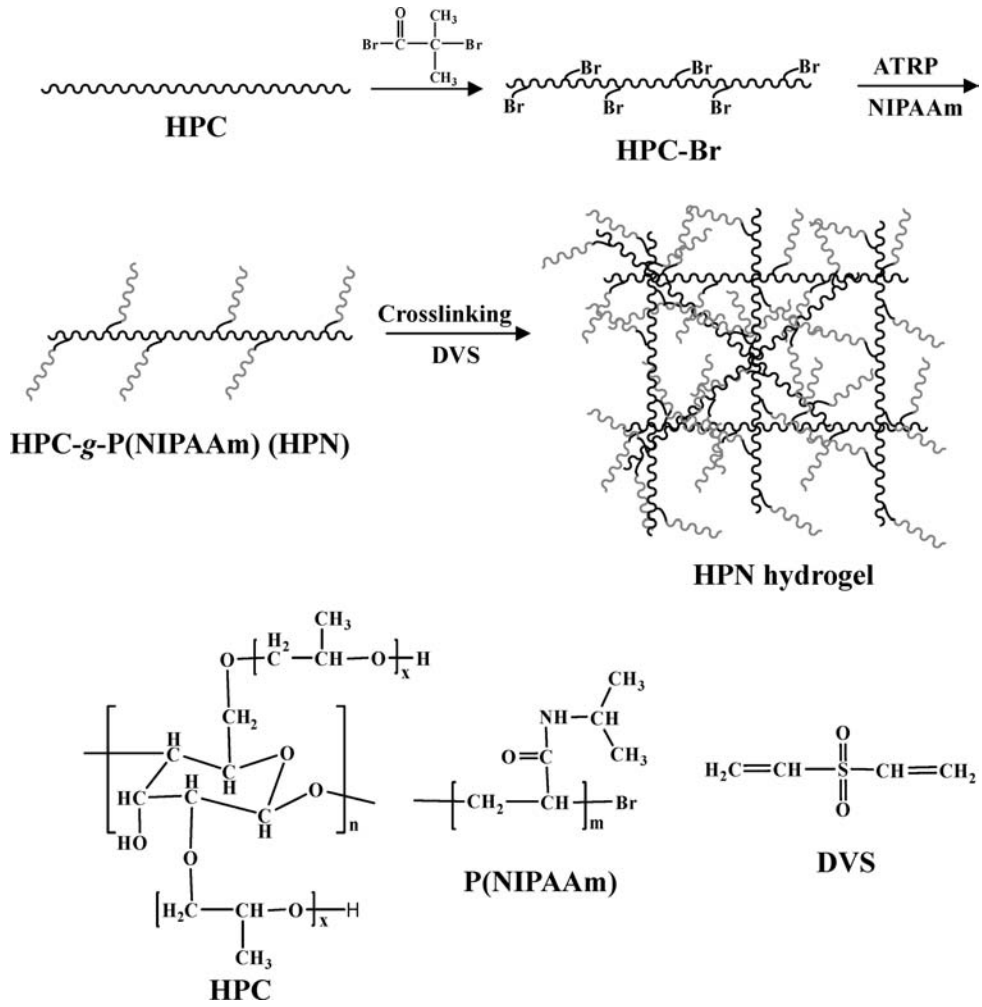
Hydroxypropyl cellulose (HPC) possesses a lower critical solution temperature (LCST) above 40 °C, while the poly(*N*-isopropylacrylamide) (P(NIPAAm)) exhibits a LCST of about 32 °C. Herein, comb-shaped copolymer conjugates of HPC backbones and low-molecular-weight P(NIPAAm) side chains (HPC-*g*-P(NIPAAm) or HPN) were prepared via atom transfer radical polymerization (ATRP) from the bromoisobutyryl-functionalized HPC biopolymers. By changing the composition ratio of HPC and P(NIPAAm), the LCSTs of HPNs can be adjusted to be lower than the body temperature. The MTT assay from the HEK293 cell line indicated that HPNs possess reduced cytotoxicity. Some of the hydroxyl groups of HPNs were used as cross-linking sites for the preparation of stable HPN hydrogels. In comparison with the HPC hydrogels, the cross-linked HPN hydrogels possess interconnected pore structures and higher swelling ratios. The *in vitro* release kinetics of fluorescein isothiocyanate-labeled dextran and BSA (or dextran-FITC and BSA-FITC) as model drugs from the hydrogels showed that the HPN hydrogels are suitable for long-term sustained release of macromolecular drugs at body temperature.

INTRODUCTION

Cross-linked hydrogels are of interest in biomedical applications, because of their tunable chemical and three-dimensional physical network structures, high water content in an aqueous medium without dissolution, and good mechanical properties (*1*−*3*). Intelligent or smart hydrogels, which can undergo volume changes in response to changes in temperature, pH, and antigen, are of great interest in drug delivery, cell encapsulation, and tissue engineering (*4*−*6*). Among the temperature-sensitive hydrogels, poly(*N*-isopropylacrylamide) (P(NIPAAm))-based hydrogels are the most widely studied. P(NIPAAm) is a well-known thermoresponsive polymer and exhibits a lower critical solution temperature (LCST) of about 32 °C in an aqueous medium. P(NIPAAm)-based hydrogels absorb water and exist in swollen states below the LCST. On the other hand, they undergo an abrupt and drastic shrinkage in volume as the medium temperature is raised above the LCST. These characteristics make P(NIPAAm)-based hydrogels specially useful in biomedical applications, such as in controlled release of drugs and in tissue engineering (*7*−*12*).

Natural polysaccharides are very suitable candidates for the design of novel biomaterials, because they are renewable and nontoxic materials. It has been reported that P(NIPAAm) can be grafted to polysaccharide biopolymers, including chitosan (*13, 14*), dextran (*3, 15*), and methylcellulose (*16*), for the preparation of thermosensitive biomaterials. Hydroxypropyl cellulose (HPC) is a derivative of natural polysaccharide cellulose, where some of the hydroxyl groups of cellulose have been hydroxypropylated to form hydrophobic propylene oxide groups (*1, 17*). HPC materials have been approved by the USFDA and widely used in food and drug formulations (*1*). The hydrohphobic and hydrophilic groups impart HPC with a LCST of >40 °C (*1, 17, 18*). However, such LCST is far higher than the body temperature of 37 °C.

In the present work, the body temperature-responsive comb-shaped copolymer conjugates (HPC-*g*-P(NIPAAm) or HPN) composed of HPC backbones and low-molecular-weight P(NIPAAm) side chains are prepared via atom transfer radical polymerization (ATRP) (*19*−*21*) from the bromoisobutyryl-functionalized HPC (HPC-Br) backbones (Scheme 1). Some of the unreacted hydroxyl groups of HPNs are used as cross-linking sites for the preparation of stable HPN hydrogels. The resultant cross-linked HPN hydrogels with controllable LCSTs possess interconnected pore structures. In this work, the in vitro controlled release properties of the smart hydrogels were studied by using fluorescein isothiocyanate-labeled dextran and BSA (or dextran-FITC and BSA-FITC) as model macromolecular hydrophilic drugs. Dextran and BSA labeled or not labeled with FITC have been widely used as models for macromolecular drugs, such as proteins and peptides, in the studies of in vitro release kinetics of drug delivery systems (*22*−*25*). In comparison with HPC hydrogels, the HPN hydrogels can provide the long-term sustained release of macromolecular drugs at body temperature. Such porous HPN hydrogels with body-temperature responsive properties will have potential applications as biomedical materials.



EXPERIMENTAL PROCEDURES

Materials. Hydroxypropyl cellulose powder (HPC, Sigma-Aldrich cat #435007: M_n = 10 000 g/mol and M_w = 80 000 g/mol; from gel permeation chromatography (GPC) with THF as mobile phase: M_n = 28 015 g/mol and M_w = 64 655 g/mol;

molar substitution of propylene oxide groups (MS) of about 3 per glucose unit (*19*), 2-bromoisobutyryl bromide (BIBB, 98%), *N*-isopropylacrylamide (NIPAAm, >99%), poly(*N*-isopropylacrylamide) (P(NIPAAm), $M_n = 20\,000-25\,000$), 1,1,4,7,10,10-hexamethyltriethyenetetramine (HMTETA, 99%), copper(I) bromide (CuBr, 99%), and divinyl sulfone (DVS, >98%), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), penicillin, streptomycin, fluorescein isothiocynate (FITC)-conjugated BSA (BSA-FITC), and FITC-conjugated dextran (dextran-FITC, $M_w \sim 40\,000$) were obtained from Sigma-Aldrich Chemical Co., St. Louis, MO. The HEK293 cell lines were purchased from the American Type Culture Collection (ATCC, Rockville, MD). Dulbecco's phosphate buffered saline (PBS, pH 7.4), used for the drug delivery experiments, was prepared freshly according to the recipes.

Synthesis of HPC-*g*-P(NIPAAm) Comb-Shaped Copolymers (HPNs) via Atom Transfer Radical Polymerization (ATRP). The starting bromoisobutyryl-functionalized HPC (HPC-Br) was synthesized according to the following procedures. About 2.0 g of HPC was dissolved completely in 100 mL of anhydrous methylene chloride with stirring and then kept in an ice bath. About 0.3 mL of BIBB in 5 mL of methylene chloride was added dropwise into the flask through an equalizing funnel over a period of 10 min at 0 °C. After this addition, the flask was sealed. The reaction was allowed to proceed at room temperature for another 5 h to produce the HPC-Br macroinitiator. The final reaction mixture was precipitated with 1000 mL of diethyl ether. The crude polymer was purified by reprecipitation thrice in diethyl ether. Finally, the HPC-Br macroinitiator for the subsequent ATRP was dried under reduced pressure.

The HPC-*g*-P(NIPAAm) comb-like copolymers (HPNs, Scheme 1) were synthesized using a [monomer (2.0 g)]:[CuBr (25.4 mg)]:[HMTETA (77.6 μL)] molar feed ratio of 100:1:1.5 in 15 mL of dioxane containing 0.4 g of HPC-Br at 60 °C. The reaction was performed in a 25 mL flask equipped with a magnetic stirrer and under the typical conditions for ATRP (*20*). NIPAAm, HPC-Br, and HMTETA were introduced into the flask containing 10 mL of dioxane. After HPC-Br and NIPAAm had dissolved completely, the reaction mixture was degassed by bubbling argon for 30 min. Then, CuBr was added into the mixture under an argon atmosphere. The reaction mixture was purged with argon for another 10 min. The flask was then sealed with a rubber stopper under an argon atmosphere. The polymerization was allowed to proceed under continuous stirring at room temperature for 8 to 24 h. The reaction was stopped by exposing to air. The reaction mixture was diluted with about 150 mL of THF. The catalyst complex was removed by passing the blue dilute polymer solution through a short aluminum oxide column where neutral aluminum oxide 90 (Activity I, 0.063−0.200 mm, pH 7.3, Merck & Co., Inc.) was used. A colorless solution was obtained. After removal of THF in a rotary evaporator, the HPNs were precipitated in excess *n*-hexane. The crude polymer was purified by reprecipitation cycles to remove the reactant residues (*21*), prior to being dried under reduced pressure.

Preparation of HPN Hydrogels. The temperature-responsive hydrogels were prepared from the HPN comb-shaped copolymers. Some of the unreacted hydroxyl groups of HPNs were cross-linked using the similar procedures reported earlier (*1, 17*). A homogeneous polymer solution was obtained by adding 1.0 g of the HPN to 10 mL of deionized water. The solution was stirred slowly overnight to ensure uniform mixing while avoiding bubble formation. Then, 40 wt % NaOH was used to adjust the pH of solution to about 13. Subsequently, about 0.1 mL of divinylsulfone (DVS) was added to the copolymer solution. The mixture was stirred for 2 min at room temperature. The mixture was then centrifuged to remove the air bubbles trapped during the stirring process. The air bubble-free sticky solution was kept at 30 °C for 12 h. After the cross-linking reaction, the sample was removed and immersed into distilled water (about 500 mL) at room temperature for 72 h to remove the reactant residues. The water was changed at a 6 h interval. The cross-linked HPN hydrogel was finally freeze−dried.

Polymer Characterization and Cytotoxicity Assay. The temperature-responsive polymers were characterized by gel permeation chromatography (GPC), X-ray photoelectron spectroscopy (XPS), Fourier transform infrared (FTIR) spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, and differential scanning calorimetry (DSC). GPC measurements were performed on a Waters GPC system equipped with Waters Styragel columns, a Waters-2487 dual wavelength (λ) UV detector, and a Waters-2414 refractive index detector. THF with 2 vol % triethylamine was used as the eluent at a low flow rate of 1.0 mL/min. Monodispersed polystyrene standards were used to generate the calibration curve. The XPS measurements were performed on a Kratos AXIS HSi spectrometer equipped with a monochromatized Al K_α X-ray source (1486.6 eV photons), using the same procedures as those described earlier (*20*). After the samples were pressed into KBr pellets, the FTIR spectra were measured on a Bio-Rad FTS 135 FT-IR spectrophotometer. Each spectrum was collected by cumulating 64 scans. ^{1}H NMR spectra were measured on a Bruker ARX 300 MHz spectrometer, using *d*-chloroform (CCl_3D) as the solvent with 1000 scans at a relaxation time of 2 s. The LCST of the HPN samples was determined by DSC (TA 2920 modulated DSC, TA Instruments). All samples were immersed in deionized water at room temperature for 24 h to reach the equilibrium state. These wetted samples were placed in individual hermetic sample pans and then sealed. The thermal analysis of the swollen samples was performed at a heating rate of 3 °C/min in the temperature range 10−60 °C under a nitrogen flow rate of 40 mL/min, using deionized water as the reference.

The cytotoxicity of the HPNs was evaluated using the MTT assay in HEK293 cell lines. Before cell culture, the control commercial P(NIPAAm) was purified by reprecipitation cycles in excess *n*-hexane to remove the potential reactant residues (*21*). The cell lines were cultured in Dulbecco's modified eagle medium (DMEM), supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 units/mL of penicillin and 100 μg/mL of streptomycin at 37 °C, under 5% CO_2, and 95% relative humidity atmosphere. The cells were seeded in a 96-well microtiter plate (Nunc Co., Wiesbaden, Germany) at a density of 10^4 cells/well and incubated in 100 μL of DMEM/well for 24 h. The culture media were replaced with fresh culture media containing serial dilutions of polymers, and the cells were incubated for 24 h. The culture media were replaced with fresh media. Then, 10 μL of sterile-filtered MTT stock solution in PBS (5 mg/mL) was added to each well, reaching a final MTT concentration of 0.5 mg/mL. After 5 h, the unreacted dye was removed by aspiration. The produced formazan crystals were dissolved in DMSO (100 μL/well). The absorbance was measured using a microplate reader (Spectra Plus, Tecan, Zurich, Switzerland) at a wavelength of 570 nm. The cell viability (%) relative to control cells cultured in media without polymers was calculated from $[A]_{test}/[A]_{control} \times 100\%$, where $[A]_{test}$ and $[A]_{control}$ are the absorbance values of the wells (with the polymers) and control wells (without the polymers), respectively. For each sample, the final absorbance was the average value measured from six wells in parallel.

Hydrogel Characterization. The morphology of the HPN hydrogels was imaged using a JEOL scanning electron microscope (SEM, model 5600LV). Prior to the SEM measurements, specimens of the hydrogels were fixed on the metal holders and sputtered with a thin Pt layer. The dry weight (W_d) of each sample was determined after drying the gel to a constant weight under reduced pressure overnight. For the study of temperature-dependent equilibrium swelling ratios, the dry hydrogel samples were equilibrated in deionized water for at least 48 h at a predetermined temperature between 25 and 60 °C. The swelling ratios of the samples were measured gravimetrically. After the excess water on the sample surfaces was wiped off with moist filter papers, the samples were weighed (W_w) (*20*). The weights from three measurements were averaged, and the swelling ratio was calculated from the following formula:

$$\text{swelling ratio} = W_s/W_d$$

where W_s ($= W_w - W_d$) is the weight of water in the swollen sample at a specific temperature.

Drug Loading and in Vitro Release. Dextran-FITC and BSA-FITC were selected as model hydrophilic macromolecular drugs to study the release behaviors of the HPN hydrogels. Drug loadings were achieved by immersing about 60 mg of the freeze−dried hydrogels in about 3 mL of 30 mg/mL PBS solution of dextran-FITC or BSA-FITC at 4 °C for 3 days. The total drug uptake was calculated from weight differences between the freeze−dried hydrogels with and without the drug loading. In vitro protein release analyses of the drug-loaded hydrogels were carried out in 5 mL of PBS buffer at 37 or 20 °C. At a specified sample collection time, 5 mL of the solution was removed and the medium in the test tube was replenished with 5 mL of fresh PBS buffer. The concentrations of the released dextran-FITC and BSA-FITC were determined using a Shimadzu RF 5301PC luminescence spectrophotometer (excitation at 495 nm, emission at 515 nm) with reference to the standard calibration curve. In addition, the circular dichroism (CD) spectra of the released BSA proteins were measured using a CD spectrometer (J-810, JASCO Co., Japan) in the wavelength range 200−250 nm. A JASCO cell of path length of 0.1 cm was used. The α-helix content corresponds to the ellipticity at 208 nm.

Statistical Analysis. All experimental data used for the statistical analysis were obtained from at least three repeated runs. The data were collected in triplicate and expressed as mean ± standard deviations. Error bars represent the standard deviation. The statistical assay was performed using the Student's *t*-test and the differences were considered statistically significant with $p < 0.05$.

RESULTS AND DISCUSSION

Synthesis of Comb-Shaped Copolymers (HPC-*g*-P(NIPAAm) or HPN) Composed of HPC Backbones and P(NIPAAm) Side Chains via ATRP. The preparation of functional polymers is usually carried out in organic solvent. Because of its unique characteristics of both water and organic solubility, HPC is an ideal substrate for developing novel polysaccharide-based biomaterials. The molecular weight (M_n) of the HPC used in this work, as determined from gel permeation chromatography (GPC), is about 2.80×10^4 g/mol, with the

[a] Synthesized using a [monomer (2.0 g)]:[CuBr (25.4 mg)]:[HMTETA (77.6 μL)] molar feed ratio of 100:1:1.5 in 15 mL of dioxane containing 0.4 g of HPC-Br at 60 °C. [b] Determined from XPS N 1s and C 1s core-level spectral area ratios. [c] Determined from the GPC results. PDI = Weight average molecular weight/Number average molecular weight, or M_w/M_n. [d] Determined from the XPS [N]/[C] ratios and the molecular weights of NIPAAm ($M_{[NIPAAm]}$ = 113 g/mol) and HPC unit ($C_{15}H_{27}O_8$; $M_{[HPC]}$ = 335 g/mol), where $[N]/[C] \approx n_{[NIPAAm]}/(6n_{[NIPAAm]} + 15\ m_{[HPC]})$. [e] The temperatures at the minimum points of the endotherms are referred to as the lower critical solution temperatures (LCSTs).

corresponding polydispersity index (PDI) of about 2.3. In order to prepare comb-like copolymers using HPC as a backbone via ATRP, it is essential to introduce alkyl halide initiators onto HPC. In this work, the bromoisobutyryl-functionalized HPC (HPC-Br) (*19*) was prepared via the reaction of hydroxyl groups of HPC with 2-bromoisobutyryl bromide (BIBB) (Scheme 1). Well-defined comb-shaped copolymer conjugates of HPC and P(NIPAAm) (HPC-*g*-P(NIPAAm) or HPN) were subsequently synthesized via ATRP of NIPAAm from HPC-Br. The HPNs with different contents of P(NIPAAm) can be synthesized by varying the ATRP time. Table 1 summarizes the GPC results of HPN1 (from 8 h of ATRP), HPN2 (from 16 h of ATRP), and HPN3 (from 24 h of ATRP). With the increase in reaction time from 8 to 24 h, the M_n of HPN increases from 4.06×10^4 to 7.18×10^4 g/mol, and the P(NIPAAm) content in HPN increases accordingly from 31 to 61 wt %. In addition, the PDIs of HPNs are slightly lower than that of the pristine HPC (Table 1), indicating that the ATRP of NIPAAm is well-controlled.

XPS Analysis. The chemical compositions of the polymers were first determined by XPS. The C 1s core-level spectra of the pristine HPC and HPC-Br samples are shown in Figure 1a,b, respectively. The C 1s core-level spectrum of the pristine HPC can be curve-fitted into three peak components with binding energies (BE's) at about 284.6, 286.2, and 287.6 eV, attributable to the C−H/C−C, C−O, and O−C−O species, respectively (*19*). From the [C−O]/[O−C−O] ratio of 11, the average number of propylene oxide groups ($-OCH_2CH(OH)CH_3$) per anhydroglucose unit of HPC is determined to be about 3, as reported earlier (*19*). When ATRP is carried out from a multifunctional backbone with a high local concentration of initiation sites, the radical−radical coupling of the propagating chains will occur and result in a gel. In order to avoid potential gelation, the starting HPC-Br with moderate concentration of initiation sites was prepared (*19*). The XPS C 1s core-level spectrum of HPC-Br can be curve-fitted into four peak components with BE's at about 284.6, 286.2, 287.6, and 288.4 eV, attributable to the C−H/C−C, C−O/C−Br, O−C−O, and O=C−O species, respectively (*19, 20*). The new O−C=O peak component is associated with the bromide-capped ester groups of HPC-Br. The corresponding Br 3d core-level spectrum is shown in Figure 1b′. From the [Br]/[C] ratio of 0.011 (determined from the sensitivity factor-corrected Br 3d and C 1s core-level spectral area ratio), it can be deduced that about 6 glucose units of HPC-Br possess one ATRP initiation site, or every HPC chain contains about 13 ATRP initiation sites on the average. No gelation was found during subsequent ATRP from such HPC-Br multifunctional initiators.

Figure 1 also shows the C 1s core-level spectra of (c) HPN1 (from 8 h of ATRP), (e) HPN2 (from 16 h of ATRP), and (g) (from 24 h of ATRP). The C 1s core-level spectra of HPNs can be curve-fitted into four peak components with BE's at about 284.6, 285.5, 286.2, and 287.6 eV, attributable to the C−H/C−C, C−N, C−O and O−C−O/O=C−N species, respectively (*22*). The C−N and O=C−N peak components are associated with the P(NIPAAm) side chains. The increase (and decrease)

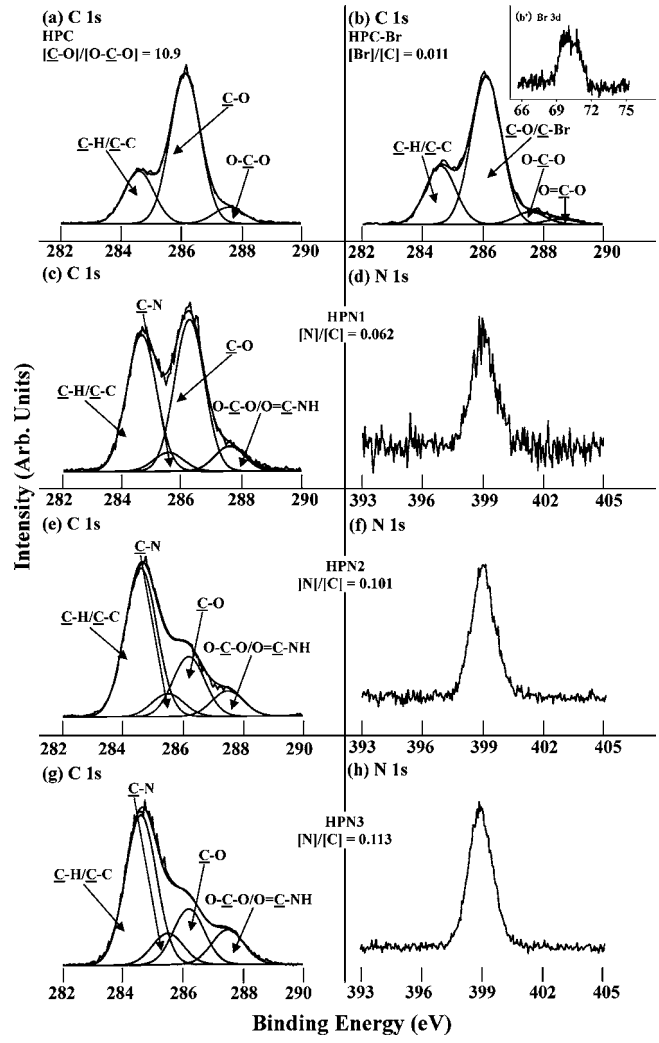

Figure 1. C 1s core-level spectrum of (a) HPC, C 1s, and Br 3d core-level spectra of (b,b′) HPC-Br, and C 1s and N 1s core-level spectra of (c,d) HPN1, (e,f) HPN2, and (g,h) HPN3.

in intensities of the C−N and O=C−N (and C−O) species with ATRP time is consistent with the increase in P(NIPAAm) contents. The corresponding N 1s core-level spectra of HPN1, HPN2, and HPN3 are shown in Figure 1d,f, and h, respectively. From the [N]/[C] ratios determined by XPS, the P(NIPAAm) contents of HPNs can be calculated and are summarized in Table 1. The results are in fairly good agreement with those obtained from the GPC measurements.

FTIR and ^{1}H NMR Studies. Figure 2 shows the FTIR spectra of the (a) pristine HPC, (b) HPC-Br, (c) HPN1, (d) HPN2, and (e) HPN3 polymers. In comparison with that of HPC, the new characteristic band at about 1736 cm^{-1} (peak 1, $\upsilon_{O=C-O}$) is associated with the bromide-capped ester groups of HPC-Br. In all the IR spectra of HPNs, the two strong amide

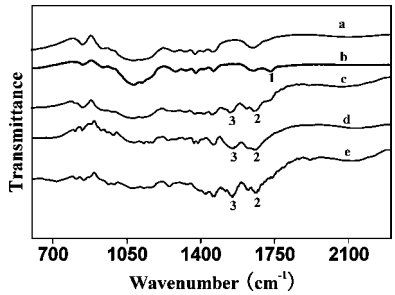

Figure 2. FTIR spectra of (a) HPC, (b) HPC-Br, (c) HPN1, (d) HPN2, and (e) HPN3. (peak 1, 1736 cm^{-1} ($\upsilon_{O=C-O}$); peak 2, 1650 cm^{-1} ($\upsilon_{O=C-NH}$); and peak 3, 1540 cm^{-1} (υ_{N-H}).)

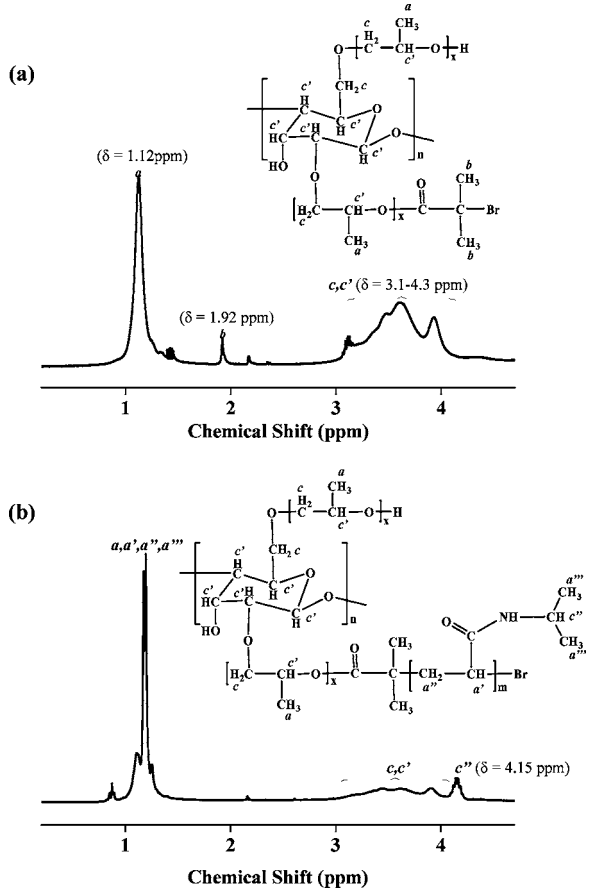

Figure 3. 300 MHz ^{1}H NMR spectra of (a) HPC-Br and (b) HPN3 in CCl_3D.

absorption bands at about 1650 ($\upsilon_{O=C-NH,}$ peak 2) and 1540 cm^{-1} ($\upsilon_{N-H,}$ peak 3) are associated with the P(NIPAAm) side chains (*20*). The relative intensity of peaks 2 and 3 increase significantly with the increases in P(NIPAAm) content. The FTIR results are thus consistent with the XPS results of Figure 1.

The chemical structures of HPC-Br and HPN are also characterized by ^{1}H NMR spectroscopy. Figure 3a shows the ^{1}H NMR spectrum of the HPC-Br macroinitiator. The chemical shift at $\delta = 1.12$ ppm is attributable to the methyl protons of propylene oxide groups (***a***, C−$\underline{CH_3}$). The chemical shift at $\delta = 1.92$ ppm is associated with the methyl protons (***b***, C(Br)−$\underline{CH_3}$) of 2-bromoisobutyryl. The broad chemical shifts in the region 2.9−4.3 ppm are mainly associated with the inner methylidyne and methylene protons (***c***, ***c′***, O−$\underline{CH}$ and O−$\underline{CH_2}$) on the glucose units and propylene oxide groups. From the area ratio of peak ***a*** and peak ***b***, the initiator density of HPC-Br corresponds to one initiator site for every 6.8 glucose units (*19*),

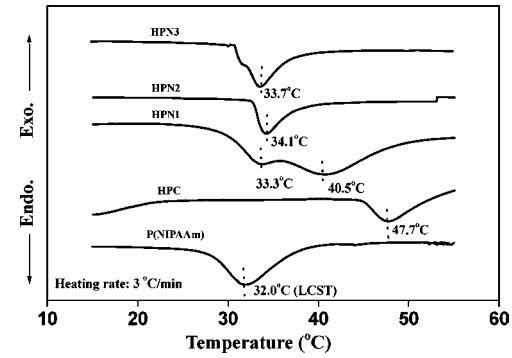

Figure 4. Typical DSC thermograms of HPC, P(NIPAAm), HPN1, HPN2, and HPN3 (the temperatures at the minimum points of the endotherms are referred as LCSTs).

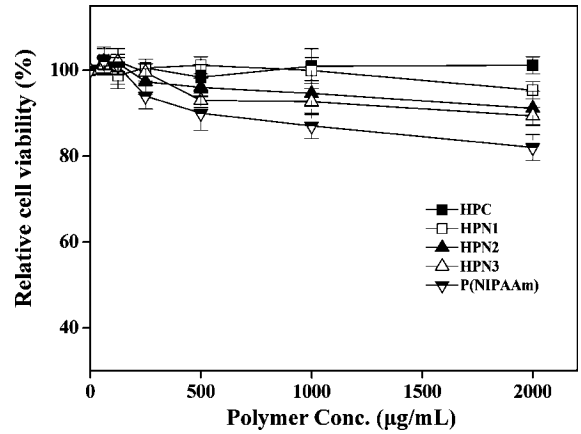

Figure 5. Cell viability assay in HEK293 cell lines with various concentrations of HPC, P(NIPAAm), HPN1, HPN2, and HPN3. Cell viability was determined by the MTT assay and expressed as a percentage of the control cell culture.

fairly consistent with that determined by XPS. Figure 3b shows the ^{1}H NMR spectrum of HPN3. The chemical shifts (***a′***, C−$\underline{CH}$; ***a″***, C−$\underline{CH_2}$; ***a‴***, C−$\underline{CH_3}$) associated with the P(NIPAAm) side chains overlapped completely with the methyl protons of propylene oxide groups (***a***, C−$\underline{CH_3}$) of the HPC backbone. The new chemical shift at $\delta = 4.15$ ppm corresponds to the (***c″***) N−$\underline{CH}Me_2$ methylidyne protons of P(NIPAAm) (*24*). The signal intensities associated with the HPC backbone (***c***, ***c″***) have decreased substantially. Due to the serious overlaps in the characteristic shifts of the components, it is difficult to quantify the P(NIPAAm) segments by ^{1}H NMR.

Lower Critical Solution Temperature (LCST). The LCSTs of HPNs were determined by differential scanning calorimetry (DSC). Figure 4 shows the typical DSC thermograms of the HPC, commercial P(NIPAAm), HPN1, HPN2, and HPN3 polymers. The temperature at the minimum point of the endotherm is referred to as the LCST of the sample. The pristine HPC used in this work exhibits a LCST of about 47.7 °C, similar to that reported earlier (*18*). The LCST of HPC is the consequence of hydrophobic (associated with propylene oxide groups) and hydrophilic (associated with hydroxyl groups) interaction (*17, 18*). HPCs from different batches may have obviously different LCSTs, due to their difference in substituent distribution along the polymer chains (*20*). Nevertheless, their general LCST is significantly higher than body temperature (37 °C). The control commercial P(NIPAAm) with average M_n of 20 000−25 000 has a LCST of about 32 °C, due to the hydrophobic (associated with isopropyl groups) and hydrophilic (associated with amide moiety in the pendant groups) interaction (*20*). As shown in Figure 4, the LCST of HPN decreases with

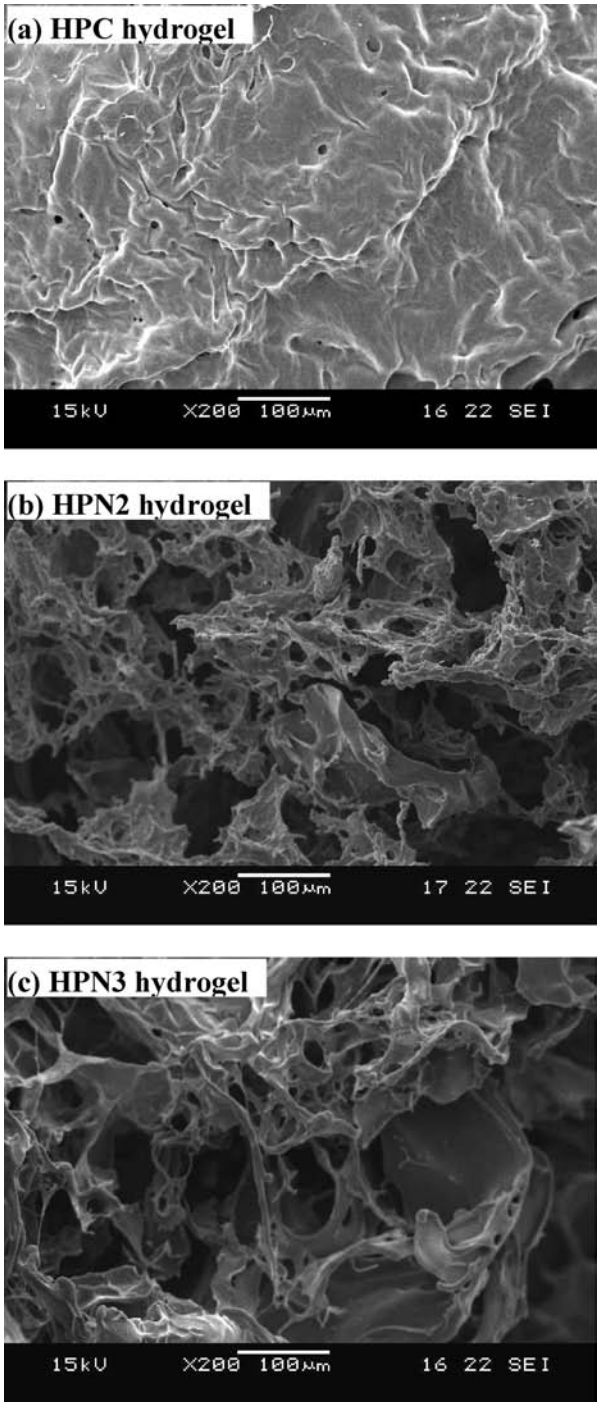

Figure 6. SEM images of (a) HPC, (b) HPN2, and (c) HPN3 hydrogels.

the increase in P(NIPAAm) content (Table 1). The HPN1 with average P(NIPAAm) content of about 33 wt % exhibits a very broad LCST range of 33 to 41 °C. When average the P(NIPAAm) content in HPN2 or HPN3 reaches above 53 wt %, only one minimum point in the DSC endotherm is observed and the corresponding LCST becomes lower than body temperature of 37 °C. The LCST of HPN in this work is the consequence of synergistic hydrophobic and hydrophilic interactions arising from HPC and P(NIPAAm) individual components.

Cytotoxicity Assay. Cytotoxicity is one of the most important factors to be considered in selecting biomaterials. Figure 5 shows the in vitro MTT assay results of cytotoxicity of HPC, commercial P(NIPAAm), HPN1, HPN2, and HPN3 at various concentrations in HEK293 cell lines. HPC does not show any

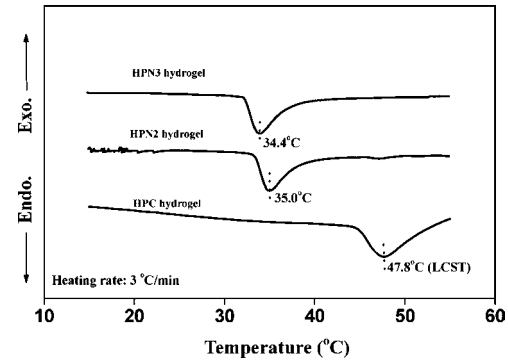

Figure 7. Typical DSC thermograms of HPC, HPN2, and HPN3 hydrogels.

cytotoxicity at polymer concentrations up to 2.0 mg/mL. No acute cytotoxicity associated with the commercial P(NIPAAm) was found, consistent with that reported earlier (*6*). However, the MTT assay suggested that the HPNs at higher polymer concentrations are better tolerated by the cell lines than those of the P(NIPAAm) homopolymer, probably because of the introduction of HPC biopolymer.

Stimuli-Responsive HPN Hydrogels. Because of their lower LCSTs than the body temperature (Figure 4), HPN2 and HPN3 were selected for the preparation of the temperature-responsive HPN hydrogels. Some of the remaining hydroxyl groups of HPN2 and HPN3 can be cross-linked by divinylsulfone (DVS) to produce the corresponding stable HPN2 and HPN3 hydrogels. DVS introduces cross-linking by an addition reaction with the hydroxyl groups on either the HPC backbone or the substituent groups, saturating the DVS carbon−carbon double bond in alkaline solution (*1, 17*). Figure 6 shows the SEM images of the freeze−dried (a) HPC, (b) HPN2, and (c) HPN3 hydrogels. The HPN2 and HPN3 hydrogels possess interconnected pore structures, while no obvious pore structures were observed on the HPC hydrogel under similar conditions. The P(NIPAAm) components may possess some different physical properties (such as solubility) from the HPC counterparts in aqueous medium. The resultant poor incompatibility or phase separation during the hydrogel preparation probably has led the formation of pore structures.

In comparison with those in Figure 4, the DSC thermographs of the hydrogels in Figure 7 suggest that the presence of DVS in the cross-linked matrix do not have a serious effect on the LCSTs (Table 1 and Table 2). The temperature dependence of the swelling ratios of HPC, HPN2, and HPN3 hydrogels was also investigated. Figure 8 shows the typical temperature-dependent swelling ratio of the three hydrogels over the temperature range of 25 to 60 °C in deionized water. The equilibrium swelling ratios of three hydrogels exhibit a similar trend of temperature dependence. As the temperature was increased, the swelling ratio decreases, with the most drastic decrease being observed at around the respective LCSTs of HPC, HPN2, and HPN3 hydrogels (Figure 7). Generally, the main reason for this distinctive characteristic of the hydrogels can be attributed to the unique and rapid transformation between the hydrophilic and hydrophobic states (*20*). At temperatures below the LCST, the hydrophilic groups of the hydrogels form hydrogen bonds with water molecules. These bonds act cooperatively to form a stable shell of hydration around the hydrophobic groups, resulting in greater water uptake and producing a larger swelling ratio. As the external temperature increases, the associative interactions among the hydrophobic groups release the entrapped water molecules from the hydrogel networks. In addition, HPN2 and HPN3 hydrogels possess higher initial swelling ratios than HPC hydrogels at starting

Table 2. Characterization of HPC-*g*-P(NIPAAm) (HPN) Hydrogels

[a] The temperatures at the minimum points of the endotherms are referred to as the lower critical solution temperatures (LCSTs). [b] Prepared in about 10 mL of pH 13 water containing 1.0 g of polymers and 0.1 mL of DVS at 30 °C. [c] Obtained by immersing 60 mg of dry gels in 3 mL of the drug-loaded solution of 30 mg/mL at 4 °C for 3 days. [d] After 10-day in vitro release.

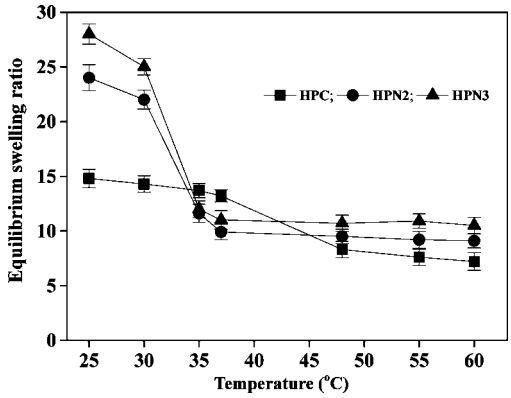

Figure 8. Temperature-dependent equilibrium swelling ratio of HPC, HPN2, and HPN3 hydrogels.

temperature of 25 °C (far lower than their LCSTs), arising probably from the interconnected pore structures of HPN2 and HPN3 hydrogels (Figure 6).

In Vitro Controlled Drug Release. In this work, the in vitro controlled release properties of the smart hydrogels were studied by using fluorescein isothiocyanate-labeled dextran and BSA (or dextran-FITC and BSA-FITC) as model macromolecular hydrophilic drugs. The drug loadings were achieved by immersing the dry HPC, HPN2, and HPN3 gels in 30 mg/mL solution of dextran-FITC (or BSA-FITC) at 4 °C for 3 days. From the data in Table 2, the amount of loaded drug per unit mass of HPN2 and HPN3 gels is higher than that in the corresponding HPC gels, probably due to the interconnected pore structures of HPN2 and HPN3 hydrogels (Figure 6). The release behavior of the loaded drugs was studied at 37 and 20 °C.

Figure 9 shows the release profiles of (a) dextran from the HPC and HPN2 hydrogels and (b) BSA from the HPC and HPN3 hydrogels. The release profile was characterized by an initial burst, followed by a slower and sustained release. This release behavior is a typical biphasic release pattern, similar to those reported (*26, 27*). The initial burst may have been caused by the release of drug molecules located on the outer surfaces, while the sustained release was probably due to the slow macromolecular diffusion from the interior of the hydrogels. There is no obvious difference between the release profiles of HPC hydrogels at 20 and 37 °C (lower than the LCST of HPC of about 48 °C). However, the sustained drug release from the HPN2 and HPN3 hydrogels was slower at 37 °C than at 20 °C. At 37 °C above the LCST of HPN2 and HPN3 (Figure 7), their hydrogel mesh size has decreased upon hydrogel collapse, which in turn decreases the diffusivity of the macromolecules through the hydrogel network and leads to the slower drug release.

The slow and sustained release could provide a continuous drug delivery, prevent the problems of cyclic variations in the

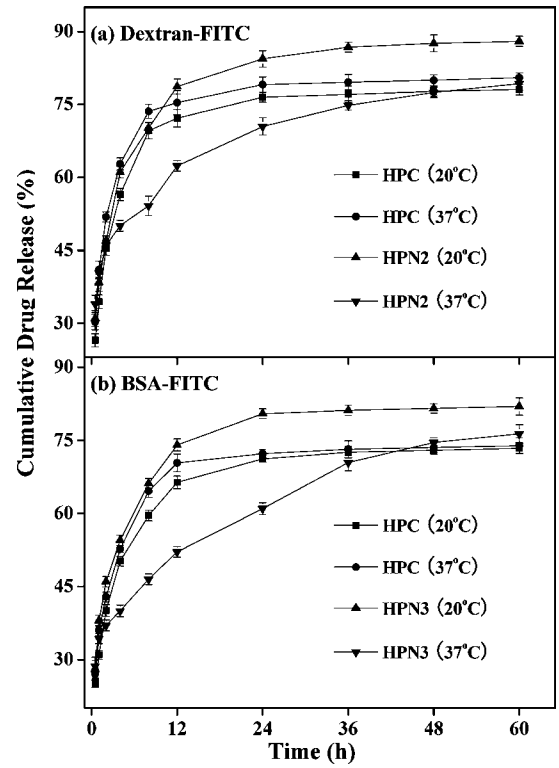

Figure 9. Release profiles of (a) dextran-FITC from HPC and HPN2 hydrogels and (b) BSA-FITC from HPC and HPN3 hydrogels at 20 and 37 °C.

drug concentrations in blood, and produce the maximum pharmacological efficiency (*27, 28*). In addition, the drug release at 20 °C for the HPN2 and HPN3 hydrogels was slightly faster than that of the corresponding HPC hydrogel. The pore structures of the HPN2 and HPN3 hydrogels probably have facilitated the diffusion of drug molecules into the in vitro medium. After 10-day in vitro release (Table 2), the loaded drugs were still not released completely. This phenomenon is very common in drug delivery systems. The presence of physical interactions between the drug and hydrogels probably has hindered the drug diffusion (*28, 29*).

The functions and structures of proteins are inherently correlated. Here, UV-circular dichroism (CD) was used to examine whether the released BSA has retained its native secondary structures. In general, proteins possess three common secondary structures of α-helix, β-sheets, and random coil. The quantitative structural changes of proteins can be evaluated by analyzing the preserved content of α-helix. The α-helix content of proteins can be estimated from the following formula (*29, 30*):

$$\%\ \alpha\text{-helix} = (\theta_{mrd} - 4000)/(33\,000 - 4000)$$

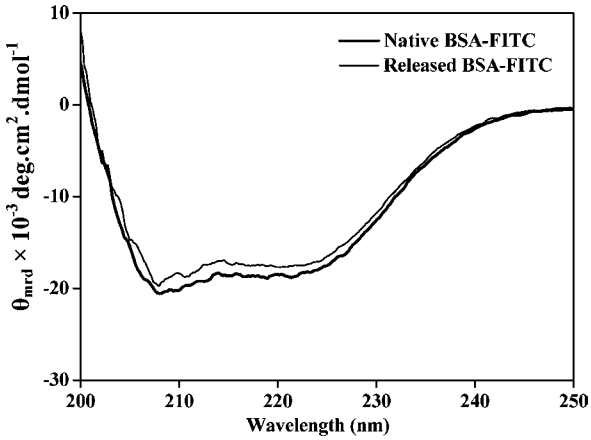

Figure 10. Circular dichroism (CD) spectra of the native BSA-FITC and released BSA-FITC from HPN3 hydrogel.

where θ_{mrd} is the mean molar ellipticity per amino acid residue at 208 nm (deg.cm^2. dmol^{-1}). θ_{mrd} can be calculated using the following formula

$$\theta_{mrd} = (\theta_d M_0)/(10CL)$$

where, θ_d is the measured ellipticity in the unit of mdeg from the CD spectrometer, M_0 is the average molecular weight (Da) per amino acid residue, C is the BSA concentration (mg.mL^{-1}), and L is the sample cell path length (cm). BSA is an ellipsoidal protein with the dimensions of $14 \times 4 \times 4$ nm^3. Its average molecular weight (Da) per amino acid residue is about 118 Da (*31*). Figure 10 shows the typical CD spectra of BSA-FITC released from the HPN3 hydrogel and native BSA-FITC. The CD spectrum of the released BSA is similar to that of the native BSA. The calculated α-helix contents in the released and native BSA are 53% and 57%, respectively, indicating that the conformation of BSA has not been severely or irreversibly altered by adsorption in the hydrogels.

CONCLUSIONS

The comb-shaped copolymer conjugates composed of HPC backbones and short P(NIPAAm) side chains (HPC-*g*-P(NIPAAm) or HPN) have been successfully prepared via ATRP from the bromoisobutyryl-functionalized HPC backbones. The HPN with average P(NIPAAm) content of above 53 wt % exhibited a LCST below the body temperature of 37 °C. The MTT assay from the HEK293 cell line indicated that HPNs possess reduced cytotoxicity. Some of the remaining unreacted hydroxyl groups of HPNs were used as cross-linking sites for the preparation of stable HPN hydrogels. In comparison with the HPC hydrogels, the resultant cross-linked HPN hydrogels possess interconnected pore structures and higher swelling ratios. The HPN hydrogels can also provide the long-term sustained release of macromolecular drugs at body temperature. Such porous smart hydrogels of HPN with controllable LCSTs are potentially useful for biomedical applications. However, it should be noted that such hydrogels may be not suitable as implanted or injected devices due to their poor degradability.

Linker Chemistry Determines Secondary Structure of $p53_{14-29}$ in Peptide Amphiphile Micelles

Dimitris Missirlis,*[,†,‡] Marc Farine,[†] Mark Kastantin,[†] Badriprasad Ananthanarayanan,[†] Thorsten Neumann,[†,‡] and Matthew Tirrell[†,‡]

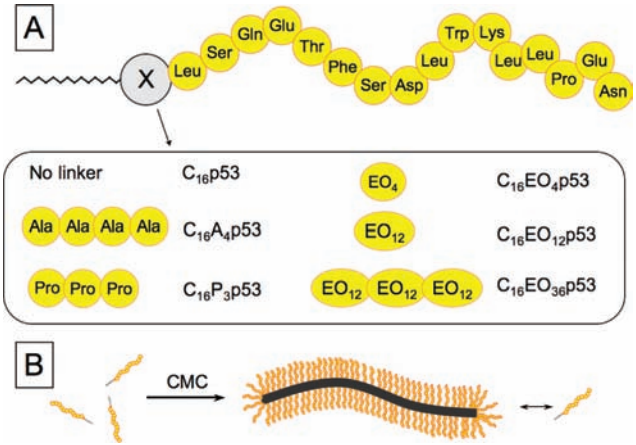
Department of Chemical Engineering and Materials and Materials Research Laboratory, University of California, Santa Barbara, California 93106, and Department of Bioengineering, University of California, Berkeley, California, 94720. Received September 1, 2009; Revised Manuscript Received February 9, 2010

Biofunctional micelles formed via self-assembly of synthetic peptide-lipid conjugates are a class of promising biomaterials with applications in drug delivery and tissue engineering. The micelle building block, termed peptide amphiphile, consists of a lipid-like chain covalently linked through a spacer to a peptide headgroup. Self-assembly results in formation of a hydrophobic core surrounded by a dense shell with multiple, functional peptides. We report here on the effect that different linkers between a palmitic tail and a bioactive peptide ($p53_{14-29}$) have on headgroup secondary structure. Peptide $p53_{14-29}$ may act as an inhibitor of the interaction between tumor suppressor p53 and human double minute-2 (hDM2) proteins by binding hDM2 in a partially helical form, leading to the release of p53 and the induction of apoptosis in certain tumors. Circular dichroism and fluorescence spectroscopy data revealed that the extent and type of secondary structure of $p53_{14-29}$ are controlled through size and hydrogen bond potential of the linker. In addition, the structure of the self-assembled micelles was influenced through linker-dependent altered headgroup interactions. This study provides insight into the mechanisms through which headgroup structuring occurs on peptide amphiphile micelles, with implications on the bioactivity, stability, and morphology of the self-assembled entities.

INTRODUCTION

Self-assembly of peptide amphiphiles (PAs) represents a versatile methodology for preparation of nanostructures with defined shapes and functionalities (*1, 2*). PAs are composed of a hydrophobic segment, generally a single- or double-alkyl tail, linked to a hydrophilic peptide "headgroup". An appealing way to view the supramolecular aggregates formed by PAs in aqueous solutions is as protein analogous micelles held together by hydrophobic interactions in their interior and presenting a high density of functional peptides on their surface. Through appropriate PA design, self-assembly can lead to formation of fibrous scaffolds similar to extracellular matrix proteins for cell attachment and growth (*3, 4*); with different PA molecular architectures, colloidal structures can be prepared to mimic soluble globular protein function (*5*−*7*).

In order to harness the full potential of PAs as building blocks, appropriate functional peptide presentation is required, which can be achieved via control of monomer interactions. The hydrophobic effect is the predominant driving force responsible for self-assembly; however, in contrast to traditional, low molecular weight detergents, the more complex peptide headgroup may provide additional stabilizing interactions such as reversible disulfide formation (*8, 9*), hydrogen bonding (*10*−*12*), and electrostatic bridging between neighboring peptide chains (*3, 13*). A direct consequence and particularly attractive feature of these interactions in the tethered, close-packed surface of the self-assembled structure is their ability to induce peptide folding in distinct secondary structure motifs, thus displaying peptides in a more native manner (*14*).



Conformational sensitivity is key in achieving specificity in biomolecular interactions. The spatial arrangement of amino acids resulting from folding of the polypeptide chain determines the activity of the protein or enzyme. The same sequence folded in a different manner usually has reduced or even altered activity as is most strikingly evidenced in the activity of misfolded proteins. Thus, the ability to mimic naturally occurring secondary structure motifs and present them on supramolecular constructs could lead to development of more potent peptide ligands/inhibitors. A very common protein-folding pattern is the α helix, which possesses diverse functionalities ranging from protein−protein interactions (*15*) and protein−DNA interactions (*16*) to cell membrane pore formation (*17*). Formation of α-helical domains normally occurs upon protein folding into the native protein conformation. Their typical size is 7−14 residues long corresponding to 2−3 helical turns. However, when the same peptide sequence is isolated from the protein it loses its folding ability. The reasons for this loss of secondary structure are primarily the increase in entropy associated with peptide freedom to probe a larger conformational space and the lack of stabilizing forces from neighboring parts of the protein.

To counterbalance the entropic cost of folding, several approaches have been explored (*18*). Adsorption of the peptide on a surface (*19*) or inside a host template (*20*) have both shown to help in helical stabilization. Chemical modification of the peptide with unnatural amino acids and subsequent cross-linking of the side chains has also proven to provide enough stabilizing energy for helix formation (*21*−*26*). Alternatively, the side chains of appropriately inserted natural amino acids (e.g., histidines) can be used for helix stabilization through metal complexation (*21, 27*). Our group as well as others have shown that secondary structure can be induced in a number of different peptides also as a result of their hydrophobic modification with a lipid tail and subsequent self-assembly into micelles (*6, 14, 28, 29*). Crowding effects and conformational

constraints due to dense surface "tethering" of peptide chains on the surface of the micelles are presumed to be the driving forces for assembly (*30, 31*). The type of secondary structure adopted is not solely dictated by the amino acid sequence of the peptide, as has been seen by the folding of the same peptide on a surface into different motifs (*32*). Such observations are reminiscent of peptide misfolding associated with a number of important diseases, e.g., amyloid-β fiber formation (*33*).

Here, we have studied secondary structure conformation of a bioactive peptide in peptide amphiphile micelles and how it is affected by incorporation of different linkers between the peptide and the hydrophobic palmitoyl tail. The peptide we used is derived from the hDM2 binding region of tumor suppressor p53 and has shown potential as an inhibitor of the p53-hDM2 interaction with concomitant reactivation of apoptotic pathways in appropriate cancer cells (*34*). Moreover, peptide activity is linked to its propensity to fold into a short α helix (*23, 35*), and enhanced hDM2 binding of the peptide was reported when helicity was induced through a stapling mechanism (*23*), revealing the importance that secondary structure plays in this protein−protein interaction. Our main goal was to gain understanding of the factors that control peptide folding and supramolecular structure and how these can be manipulated through chemical design of the micelle building block.

EXPERIMENTAL PROCEDURES

Peptide Amphiphile Synthesis. Peptide $p53_{14-29}$ (sequence: LSQETFSDLWKLLPEN) on a Rink amide resin was purchased from Anaspec. Peptide amphiphiles were synthesized from resin-bound peptides using manual Fmoc solid-phase synthesis as previously described (*36*). Following cleavage from the resin, peptide amphiphiles were purified using high-performance liquid chromatography (HPLC; Shimadzu Corporation) on a reverse-phase C_4 column (Vydac), with gradients of acetonitrile in water, containing 0.1% trifluoracetic acid (TFA). A list of the peptide amphiphiles synthesized is presented in Scheme 1 and the chemical structures are shown in Supporting Information Figure S1. Identity of the peptide amphiphiles was verified by electrospray ionization mass spectrometry (Supporting Information Table S1) and purity was determined using analytical HPLC on a reverse-phase C_4 column (Vydac). Peptide amphiphiles with purity greater than 95% were used.

Micelle Preparation. Peptide amphiphiles were dissolved in a 1:1 mixture of chloroform and methanol. The organic solvents were then evaporated under N_2 flow eventually forming a film on a glass vial wall. The film was then dried in vacuum and hydrated in water or buffer at 60 °C for 1 h. Mixed micelles were prepared by hydrating PA films with solutions of Tween 40 (Sigma) at different Tween/PA ratios at 60 °C for 1 h. Following cooling to room temperature, the aqueous micelle solutions were filtered through a 0.45 μm polycarbonate syringe filter (Millipore). All samples were stored at 4 °C and used within 1 week of preparation unless otherwise noted. Fluorescence, circular dichroism, and light scattering measurements were not significantly changed within this time period.

Fluorescence Spectroscopy. Fluorescence was recorded using a Varian Cary Eclipse fluorescence spectrophotometer, equipped with a cuvette holder thermostatted at 25 °C, unless otherwise noted. In steady-state fluorescence emission measurements, tryptophan (Trp) was excited at 280 nm and emission was recorded between 300 and 400 nm. Steady-state anisotropy was measured using manual polarization lenses and calculated using the following equation (*37*):

$$r = \frac{I_{VV} - I_{VH}I_{HV}/I_{HH}}{I_{VV} + 2I_{VH}I_{HV}/I_{HH}} \quad (1)$$

I_{VV}, I_{HH}, I_{VH}, and I_{HV} are fluorescence intensities; the subscripts V and H stand for vertical and horizontal orientations of polarizers, respectively, with the first subscript corresponding to the excitation light and the second to the emitted light. Values of anisotropy presented here are averaged over a range of wavelengths (340−370 nm) after excitation at 290 nm.

Fluorescence quenching measurements were performed after addition of aliquots of a freshly prepared 5 M KI to a solution of p53 or C_{16}p53 (100 uM). Dynamic (collisional) quenching is described by the Stern−Volmer equation (*38*)

$$\frac{I_0}{I} = 1 + K_{SV}[Q] \quad (2)$$

where $[Q]$ is the quencher (KI) concentration, I_0 and I are the fluorescence intensities in the absence and presence of quencher respectively, and K_{SV} is the Stern−Volmer constant. The slope of the plot I_0/I against [KI] gives K_{SV}.

Pyrene Fluorescence Measurements. Dried peptide amphiphile films were dissolved in aqueous pyrene stock solution (6×10^{-7} M) containing traces of tetrahydrofuran (THF) and left to equilibrate at 37 °C for 1 h. Fluorescence emission spectra were recorded at different PA concentrations and the intensity ratio of the third (I_3) to the first (I_1) vibrational band of pyrene was determined. The critical micellar concentration (cmc) was determined as the concentration at the onset of I_3/I_1 ratio increase. The equilibrium constant K_v for partitioning of pyrene between the micellar and aqueous phase was estimated using the equation

$$\frac{F - F_{min}}{F_{max} - F} = \frac{K_v x_{core}(C - \text{cmc})}{\rho_{core}} \quad (3)$$

F_{min}, F_{max}, and F are the minimum, maximum, and intermediate intensity ratio (I_1/I_3), respectively, x_{core} is the micellar core weight fraction and ρ_{core} the density of that core.

Circular Dichroism. CD spectra of PA solutions were acquired using an Olis RSM spectrophotometer in the far UV region (190−250 nm) using quartz cuvettes of 0.5 mm path length. Baseline spectra were subtracted from sample spectra and smoothed using the software supplied by the manufacturer. Mean residual ellipticity, θ, as a function of wavelength, is presented. Temperature scans were performed from 10 to 80 °C to monitor peptide folding stability. It is important to note that using our experimental setup there was a cutoff at approximately 200 nm when PBS 10 mM was used due to buffer component absorption.

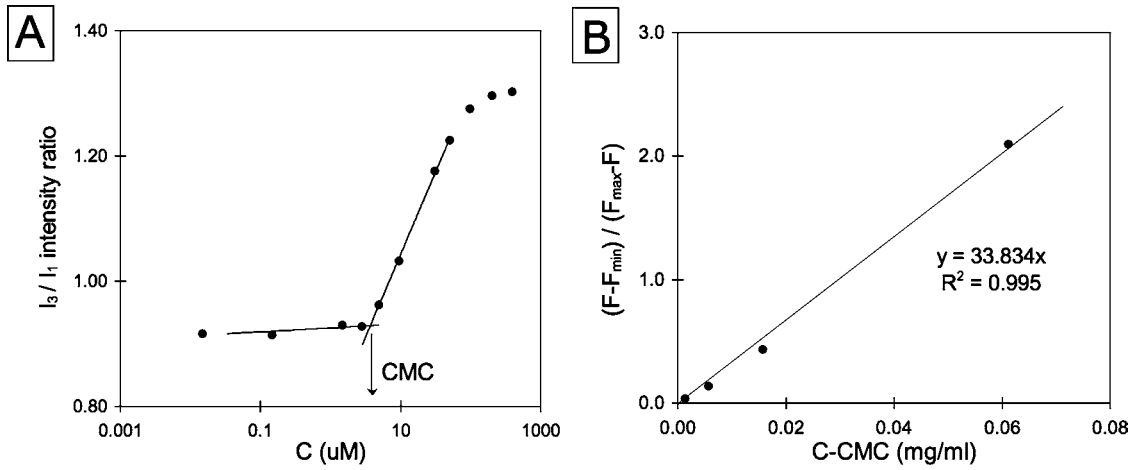

Figure 1. Critical micelle concentration (cmc) determination of C_{16}p53 in PBS 10 mM using the pyrene solubilization method. The onset of increase of the I_3/I_1 intensity ratio of pyrene emission peaks corresponds to the cmc (A). The partition coefficient of pyrene between the hydrophobic core and the aqueous phase is derived from the slope of (B) using eq 3.

Dynamic Light Scattering (DLS). Micelle size was assessed using a DLS system (Brookhaven Instruments) that consisted of an avalanche photodiode detector to measure scattering intensity from a 632.8 nm HeNe laser (Melles Griot) as a function of delay time. Temperature was maintained at 25.0 ± 0.1 °C using a circulating water bath unless otherwise noted. The first-order autocorrelation function was measured at different angles between 40° and 120° to cover a range of scattering wave vector, q, of 0.0090 to 0.0229 nm^{-1}. The autocorrelation function was then fit using a second-order cumulant to extract the average decay rate, Γ_1. The quantity Γ_1/q^2 was then taken as the apparent diffusion coefficient, D_{app}. D_{app} at $q = 0.0132$ nm^{-1} (60°) was used to estimate the translational diffusion coefficient, and the Stokes−Einstein relationship was used to calculate the size of an equivalent hydrodynamic sphere for this particle. This analysis provided a means to compare the relative hydrodynamic size of each micelle but was not taken as an accurate measure of the true hydrodynamic diameter. No extrapolation was performed to $q = 0$ because of the uncertainty in this process for a nonspherical particle.

In order to extract properties of a worm-like micelle from these data, D_{app} was plotted as a function of q. Given the theoretical results of Winkler et al. (*39*), D_{app} will be independent of q for $q < 1/r_g$. As q increases, two regimes may appear: an intermediate scattering vector regime ($1/r_g < q < p$) in which D_{app} increases linearly with q and a large scattering vector regime ($q > p$) in which internal bending modes become important causing D_{app} to increase as $q^{2/3}$. Here, $1/2p$ is the persistence length of the micelle. Thus, the scaling behavior of D_{app} can provide an estimate of the radius of gyration and persistence length.

Atomic Force Microscopy (AFM). AFM analysis was performed using an MFP-3D AFM from Asylum research. The images were recorded in tapping mode using moderate force ratio under ambient conditions equipped with commercial silicon tips (Olympus AC240TS) with resonance frequency $f = 70$ kHz and spring constant of $k = 2$ $^{N}/_{m}$. A typical scan range of 5 μm with a resolution of 512 × 512 pixels was used for each image. Each sample was analyzed in multiple regions. Raw data were leveled by a first and second order of plane fit correction in order to remove the sample tilt.

RESULTS

A series of peptide amphiphiles was synthesized differing only in the linkage between the palmitic tail and the N-terminus of $p53_{14-29}$ peptide in order to investigate the effect of linker length, rigidity, and hydrogen bonding potential on peptide folding and self-assembly (Scheme 1). Linkers and palmitic tail were coupled directly on the resin-bound peptide, providing a simple and efficient methodology of preparing the hybrid molecules (*40*). The A_4 linker was selected since alanines are commonly used to promote the creation of PA fibers through β-sheet formation of peptide headgroups (*3, 11*). Prolines on the other hand have been shown to disrupt H-bonding close to the micelle core and promote assembly into spherical geometries (*41*). Oligo-ethylene oxides of varying lengths were used as flexible spacers between the peptide and the hydrophobic core to investigate the effect of headgroup size without introducing additional chemical interactions between monomers. The chemical structure, along with the measured molecular mass for each peptide amphiphile, is given in the Supporting Information section (Figure S1 and Table S1).

Critical Micellar Concentration. Our hypothesis is that peptide folding occurs as a result of crowding in the micelle corona of peptide amphiphile micelles, and thus, we first aimed at determining the cmc's of the different PA analogues. The cmc's were calculated using the pyrene solubilization method (*42*): the onset of an increase in intensity ratio of the third to the first highest energy emission peaks (I_3/I_1) of pyrene emission spectrum denotes its partitioning into a more hydrophobic microenvironment. For C_{16}p53, this shift corresponds to a cmc of 2.2 μM or 4.7 μg/mL (Figure 1). We estimated the pyrene partition equilibrium constant K_v using eq 3, assuming the density of the micellar core to be that of hexadecane (0.775 g/mL) (*43*). The estimated value of 2.5×10^5 may be compared to a value of 2.0×10^5 extracted from the data of Almgren et al. for sodium hexadecanesulfonate (*43*), suggesting that the hydrophobicity of the core in the two systems is similar and is that of phase-segregated alkane chains.

The cmc values for the other PAs were calculated in the same manner and are given in Table 1. The A_4 linker had no appreciable effect on cmc, whereas an increase was recorded with increasing length of ethylene oxide linker, because of the hydrophilic nature of ethylene oxide oligomers. The unmodified peptide did not cause any appreciable change in pyrene fluorescence emission up to the highest concentration studied (5 mg/mL).

Tryptophan Fluorescence Studies. Tryptophan fluorescence spectroscopy was used to gain insight in peptide folding through steady state, quenching, and anisotropy measurements. Steady-state fluorescence of Trp is sensitive to the polarity of the microenvironment, which is expected to change upon folding

Table 1. Critical Micellar Concentration, Trp_{23} Fluorescence Emission Maximum (λ_{max}), and Trp Anisotropy Values for Unmodified $p53_{14-29}$ and $p53_{14-29}$ Peptide Amphiphiles

	cmc (μM)	λ_{max} (nm)	system anisotropy, r

into an amphipathic helix. A maximum emission wavelength (λ_{max}) at 355 nm for Trp on the unmodified peptide revealed that the fluorophore is fully hydrated (*38*) (Figure 2A). A blue shift of λ_{max} to 347 nm for C_{16}p53 above its cmc indicated a more hydrophobic environment; reduced aqueous solvation of Trp upon self-assembly could result from Trp association (e.g., via stacking (*44*)) with other hydrophobic amino acid side chains in the same or neighboring peptides. The maximum emission wavelength varied among the peptide amphiphiles studied, suggesting different polarity for the tryptophan side chain (Table 1). Compared to C_{16}p53, λ_{max} red-shifted when A_4 or P_3 linkers were incorporated and blue-shifted for the longer EO linkers (EO_{12} and EO_{36}). It is important to note here that λ_{max} for Trp on p53 peptide dissolved in tetraethylene glycol was found to be 339 nm, reflecting the lower polarity of ethylene glycol compared to water.

We used dynamic quenching of tryptophan fluorescence by iodine ions to further probe the polarity of the microenvironment surrounding the chromophores and their accessibility from the aqueous phase. Stern−Volmer plots yielded straight lines confirming dynamic quenching of Trp by I^- (Figure 2B). A decrease of K_{SV} for C_{16}p53 in comparison to the peptide reflects decreased accessibility of the quencher and a more shielded environment of Trp (*44*).

The presence of tryptophan on the self-assembled structure also affected its rotational diffusion as monitored by fluorescence anisotropy (Table 1). In the absence of resonance energy transfer, as is the case for tryptophan, anisotropy provides a measure of the fluorophore's rotational diffusion (*38*), which is related to its microenvironment and is also coupled to the size of the structure onto which it is attached (*37, 45*). The value of Trp anisotropy in $p53_{14-29}$ ($r = 0.030 \pm 0.004$) was the same as that measured for L-tryptophan ($r = 0.031 \pm 0.004$) indicating unhindered rotation of the fluorophore within its excited-state lifetime and a hydrated environment. In contrast, Trp in self-assembled C_{16}p53 exhibited markedly higher anisotropy (Table 1). This increase could arise from Trp confinement due to steric constraints in the molecular level or from its presence on larger structures that have slower rotational diffusion. In order to discern between these two alternatives, we examined peptide anisotropy in a solution of 2,2,2-trifluoroethanol (TFE) at 29 °C. TFE at this temperature has the same viscosity as the aqueous solution used to obtain the values in Table 1 (*46*) and the peptide is in α-helical conformation (see below) but not aggregated. The obtained value of 0.057 ± 0.005 in TFE indicated that anisotropy increases primarily from the reduction in rotational freedom of Trp as a result of peptide folding and the ensuing interactions with the other hydrophobic side chains. Accordingly, disassembly of C_{16}p53 micelles and concomitant loss of peptide folding in a solution of 80% acetonitrile resulted in a decrease of anisotropy to 0.021 ± 0.004. In this case, the lower anisotropy value relative to the peptide arises from the markedly lower viscosity of the solvent.

Anisotropy values for the different PA analogs were higher than that of the unmodified peptide and varied depending on the linker (Table 1). A decrease in anisotropy was observed with increasing length of ethylene oxide linker suggesting higher rotational freedom of Trp and decreased folding. A higher anisotropy of $C_{16}A_4$p53 on the other hand indicated a more constrained microenvironment for Trp in this PA compared to C_{16}p53. Considering the high λ_{max} for $C_{16}A_4$p53, the reason for the higher anisotropy seems to differ qualitatively from the other PAs; a different type of secondary structure that induces tighter peptide packing is responsible for the observed anisotropy, as will be discussed in the following section.

Circular Dichroism Studies. Peptide folding into secondary structure elements was investigated by CD spectroscopy at concentrations of PAs exceeding their cmc. The unmodified peptide exhibited a predominantly random coil conformation with minimal helical content in aqueous solutions at 25 °C as previously reported (*23*) and shown here in Figure 3A. On the contrary, the CD spectrum of C_{16}p53 in water revealed significant folding with a maximum at 195 nm, a deep minimum at 207 nm, a shoulder at 222 nm, and low ellipticity at 230 nm. The spectrum does not resemble that of a typical α-helix, which shows minima at both 207 and 222 nm distinctly, at an intensity ratio close to 1. We suspected that Trp absorption contributes to the unusual CD spectral characteristics (*47−49*). A shift in the ratio between the two minima due to stacking with other aromatic side chains (*50*) and introduction of an additional peak around 230 nm (*48*), which may be positive or negative depending on the orientation of tryptophan relative to the peptide backbone, have both been reported. Oxidation of the tryptophan to an oxindole derivative by NBS resulted in a typical helical CD spectrum exhibiting both minima at 207 and 222 nm at approximately 1:1 ratio (Figure 3C) in accordance with a previous report (*50*). We argue that the absence of the second minimum for C_{16}p53 is indeed related to Trp interference and not the absence of α-helical structure. Oxidation of unmodified peptide did not in itself induce folding as evidenced by the minimal effects on its CD spectrum (Supporting Information Figure S2). However, we cannot exclude the possibility that the polarity change resulting from NBS oxidation did not induce changes in the type of folding. Nevertheless, fitting the NBS-oxidized C_{16}p53 spectrum using a linear combination of basis spectra based on poly(L-lysine) and poly(L-glutamic acid) (*6*) yielded an α-helical content of 63% with the remaining 37% being in random coil conformation (Supporting Information Figure S3).

The similarity of C_{16}p53 spectra in water and 10 mM PBS suggests that there is no effect of ionic strength on folding up to physiological values, and therefore, electrostatic interactions are not the main driving force for folding (Figure 3A). In the presence of 50% TFE, a solvent known to enhance peptide folding (*51*), the amount of α-helicity increased for both peptide and C_{16}p53 as expected (Figure 3B).

Folding stability was studied by monitoring ellipticity of the NBS-oxidized sample at 222 nm with increasing temperature (Figure 3D). A gradual loss of peptide secondary structure was observed; however, even at the highest temperature studied (80 °C), a substantial amount of peptide was folded, indicating a high thermal stability in the aggregate state.

We next analyzed EO-containing PAs in PBS (10 mM; pH 7.4) at 25 °C (Figure 4A). Short ethylene oxide spacers ($C_{16}EO_4$p53 and $C_{16}EO_{12}$p53) resulted in a small shift of the first minimum to 205 nm, which also became deeper, a higher molar ellipticity at 222 nm, and the clear appearance of a negative peak at 230 nm when compared to C_{16}p53. The longer linker ($C_{16}EO_{36}$p53) exhibited a similar spectrum but with higher ellipticity at 205 nm. The spectra indicated a decreasing degree of folding with increasing ethylene oxide length, which becomes more obvious when the NBS-oxidized spectra are compared

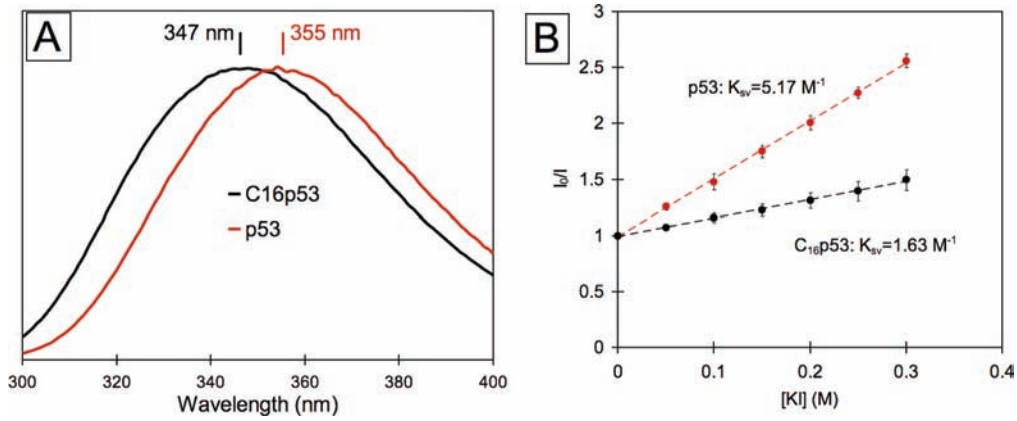

Figure 2. Comparison of Trp fluorescencence spectra of $p53_{14-29}$ and $C_{16}p53$ (A) and Stern−Volmer plots from iodine ion quenching experiments (B).

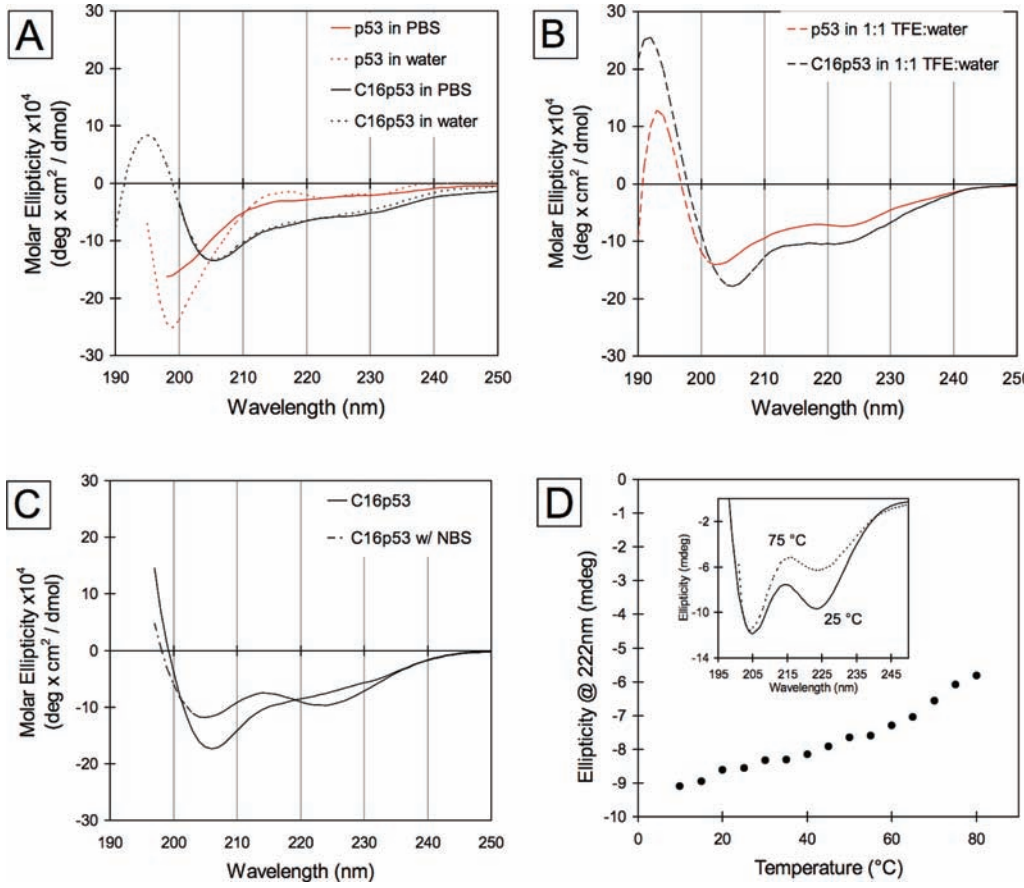

Figure 3. Circular dichroism spectra of $p53_{14-29}$ and $C_{16}p53$ in water and PBS 10 mM (A) and 2,2,2-trifluoroethanol (B). Oxidation of $C_{16}p53$ with 2 equiv. NBS resulted in a 1:1 ratio between ellipticities at 207 and 222 nm consistent with α-helix formation (C). Ellipticity at 222 nm as a function of temperature for NBS-oxidized $C_{16}p53$ (D) and corresponding spectra at 25 °C and 75°(D inset).

(Figure 5A−C). In these oxidized spectra, it is also apparent that the peak at 230 nm is due to tryptophan interference as has previously been predicted (*47*) and experimentally shown (*48, 49, 52−54*) and that the oxidized PAs clearly adopt an α-helical conformation. The peak at 230 nm is not visible in $C_{16}p53$, but this is most likely due to the lower ellipticity for this PA in the vicinity of 222 nm. We calculated α-helical contents of 54%, 45%, and 31% for oxidized $C_{16}EO_4p53$, $C_{16}EO_{12}p53$, and $C_{16}EO_{36}p53$, respectively.

In the PA with the proline linker ($C_{16}P_3p53$), changes were subtle; a slight blue shift of the negative peak at 207 nm and higher ellipticity at 222 nm suggest a slightly lower helical content compared to $C_{16}p53$ (Figure 4B). On the contrary, a dramatic change in the spectrum of $C_{16}A_4p53$ was evidenced (Figure 4B): a negative peak at 214 nm characteristic of β-sheet formation was recorded, in contrast to all previous samples. Oxidation with NBS in this case did not alter the CD spectrum (Figure 5D), which fitted to 91% β-sheet conformation.

Shape and Size of Micelles. The observed differences in peptide folding for the different PA analogues raise the question of how these affect and are in turn affected by micelle geometry. To this end, we performed multiangle dynamic light scattering measurements of PAs above their cmc's. All autocorrelation curves were satisfactorily fit using a cumulant fit to obtain a single average decay rate Γ_1 with moderate values (0.2−0.3) of the parameter Γ_2/Γ_1^2, which defines the width of the

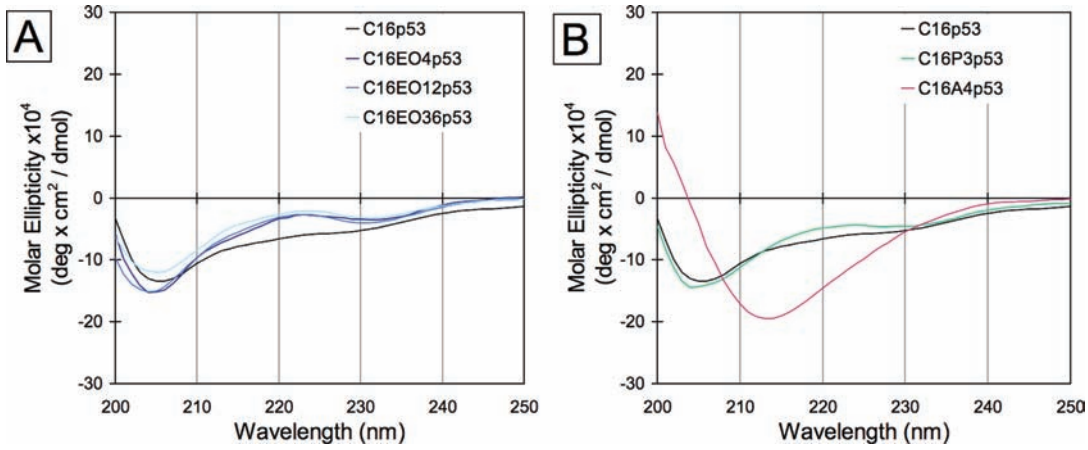

Figure 4. Circular dichroism spectra of ethylene oxide containing analogues (A) and $C_{16}A_4p53$ and $C_{16}P_3p53$ (B) in PBS 10 mM. CD spectrum of $C_{16}p53$ has been added for comparison purposes.

distribution. As an example of the pronounced q-dependence of the apparent diffusion coefficient $D_{app} = \Gamma_1/q^2$, results for $C_{16}p53$ aqueous solutions are presented (Figure 6). The apparent translational diffusion coefficient for the self-assembled structures was estimated at a scattering angle of 60°. Values of 1.91×10^{-8} cm²/s and 1.73×10^{-8} cm²/s were obtained for PBS 10 mM and water, respectively, which correspond to apparent spherical hydrodynamic diameters of 257 and 284 nm. These values exclude the formation of small spherical micelles and along with the observation of angular dependence point to formation of larger anisotropic structures. The insensitivity to ionic strength up to physiological salt concentration (0.15 M) further shows that electrostatic interactions are not the main determining factor in $C_{16}p53$ self-assembly (Figure 6). Hydrodynamic diameters of $C_{16}p53$ at a fixed angle of 90° did not seem to depend largely on concentration showing a small decrease from 0.5 to 2.5 mg/mL (Supporting Information Figure S4). Instead, an influence of temperature on size was noted: larger apparent hydrodynamic diameters were calculated when temperature increased from 5 to 55 °C (Supporting Information Figure S5).

We calculated the apparent hydrodynamic diameters for different batches of the PAs, at a scattering angle of 60° in PBS 10 mM (Figure 7). Interestingly, no major differences between analogues were noted with the exception of $C_{16}EO_{12}p53$. Even though the protocol developed for micelle formation gave far

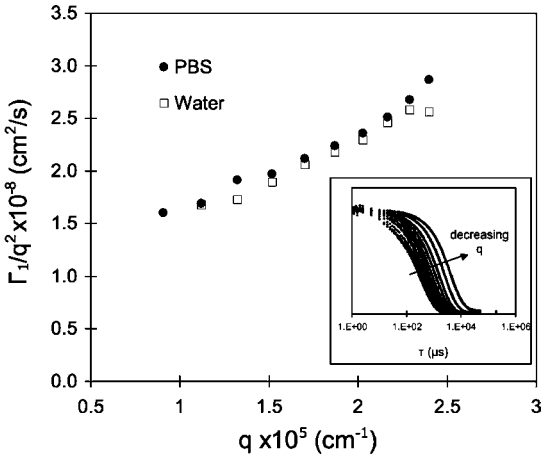

Figure 6. Angular dependence of apparent diffusion coefficient ($D_{app} = \Gamma_1/q^2$) of C_{16}p53 micelles in water and PBS 10 mM, at 25 °C. Normalized autocorrelation curves are shown in the inset for sample in PBS.

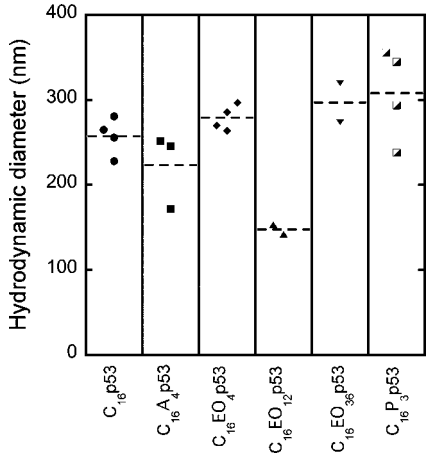

Figure 7. Hydrodynamic diameters of peptide amphiphile micelles in PBS 10 mM at 25 °C. Hydrodynamic diameters were calculated from apparent diffusion coefficients at 60° ($q = 0.0132$ nm^{-1}) and do not represent physical dimensions; they provide values for comparison between the different PA analogues. Each point represents a different batch.

more reproducible DLS results than direct dissolution of the lyophilized PAs and PAs were of high purity, we still observed some batch-to-batch variability indicating that micelle formation was sensitive to sample history and possible impurities. One of our initial hypotheses was that increasing length of the ethylene oxide linker would induce a high degree of curvature on the micelles due to larger headgroups and steric hindrances and thus a decrease in size (*7*). Although sample $C_{16}EO_{12}$p53 showed significantly faster diffusion (smaller size) than C_{16}p53, $C_{16}EO_{36}$p53 did not follow the trend.

The apparent hydrodynamic diameter provides values that are convenient for comparisons but do not correspond to actual physical dimensions. We sought shape information of the supramolecular structures by the use of atomic force microscopy. C_{16}p53 aqueous solutions deposited on freshly cleaved mica and imaged after water evaporation revealed the presence of elongated micelles (Figure 8). These images complement previously reported cryogenic transmission electron micrographs, where elongated structures were observed (*55*). We avoided extracting quantitative values for the size of the self-assembled structures based on AFM, since surface adsorption and the drying process could result in changes of the actual dimensions of the micelles in solution.

Analysis of the scaling behavior of the DLS data revealed no region in which D_{app} was independent of q (Figure 9 and

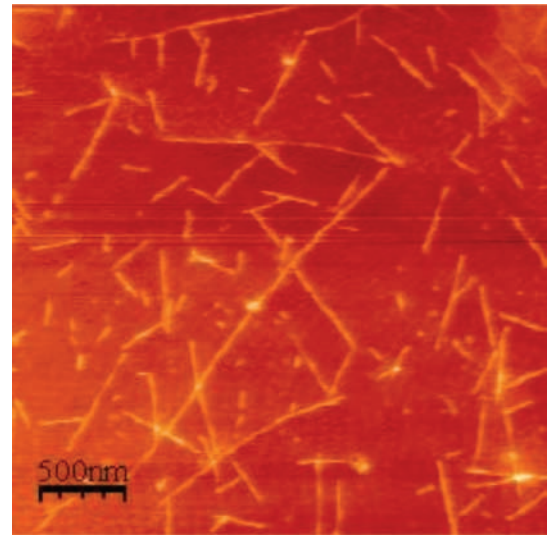

Figure 8. Atomic force micrograph showing formation of elongated micelles of C_{16}p53 deposited on mica following water evaporation.

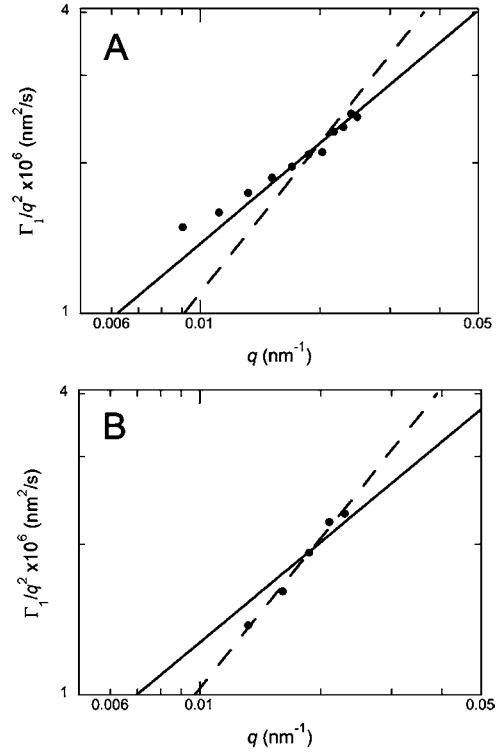

Figure 9. Angular dependence of calculated diffusion coefficient ($D_{app} = \Gamma_1/q^2$) of C_{16}p53 (A) and $C_{16}P_3$p53 (B) micelles in PBS 10 mM, at 25 °C. Solid lines correspond to the relation $D_{app}(q) \sim q^{2/3}$, while dashed lines represent $D_{app}(q) \sim q$.

Supporting Information Figure S6). Thus, the radius of gyration for all micelles is larger than ~100 nm. One exception to this statement is $C_{16}A_4$p53 micelles, for which the low scattering vector regime was found to extend to $q \approx 0.0135$ nm^{-1} corresponding to $r_g \approx 74$ nm (Supporting Information Figure S6). Scaling behavior for C_{16}p53 and $C_{16}EO_x$p53 micelles showed that $D_{app} \sim q^{2/3}$ and had no intermediate scaling region (Supporting Information Figure S6). This observation indicates that the micelles are fairly stiff, as their persistence length may approach $r_g/2$, exceeding 50 nm. In contrast, $C_{16}A_4$p53 and $C_{16}P_3$p53 micelles exhibited only the intermediate scaling region where $D_{app} \sim q$. From this, it can be concluded that $p > 0.022$ nm^{-1} and that the persistence length is less than 20 nm for these

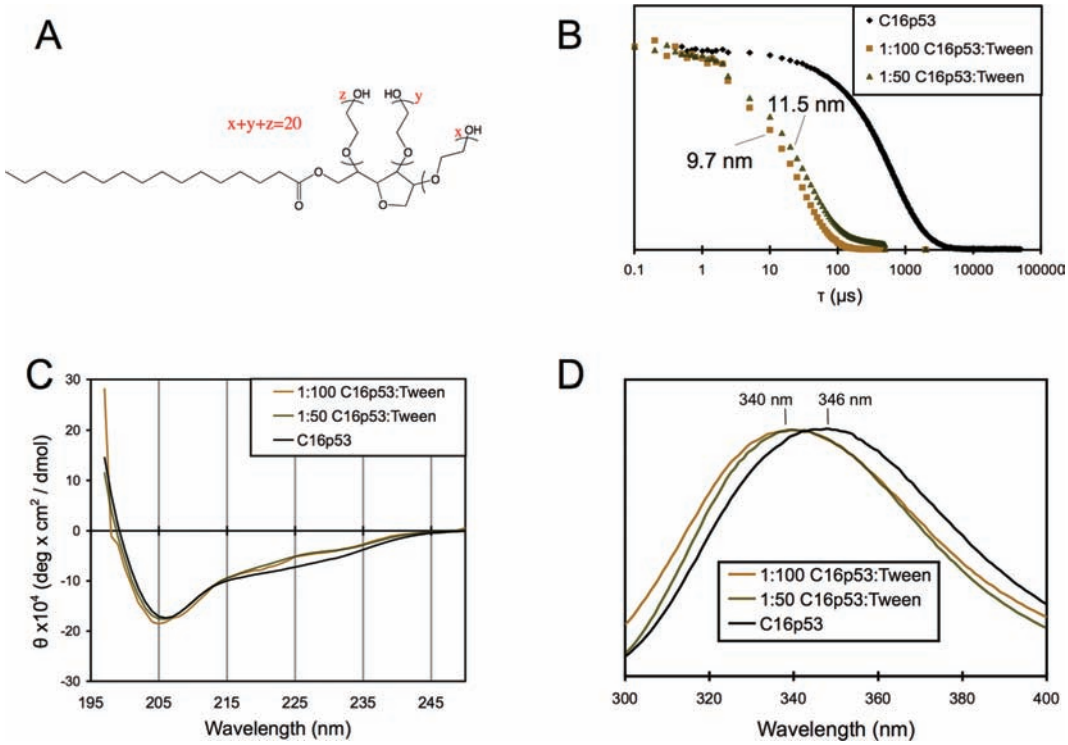

Figure 10. Mixing of C_{16}p53 with Tween 40 (A) at two different molar ratios resulted in formation of small spherical micelles. (B) Normalized autocorrelation curves of mixed micelles compared to single component C_{16}p53 micelles and calculated hydrodynamic diameters. (C) Circular dichroism spectra in PBS 10 mM at 25 °C and (D) Trp fluorescence spectra in PBS 10 mM in mixed micelles.

micelles. Thus, the A_4 and P_3 spacers result in more flexible micelles, although their overall hydrodynamic size is not significantly smaller than that of their C_{16}p53 and $C_{16}EO_x$p53 counterparts.

Formation of Small Spherical Micelles. We hypothesized that peptide folding and headgroup interactions are responsible for the elongated morphology of the self-assembled micelles instead of the highly curved micelles expected from the presence of large peptide headgroups. Indeed, in the absence of these interactions between PAs, formation of small spherical micelles occurred, consistent with monomer geometry. Mixing C_{16}p53 with Tween 40 (Figure 10A) resulted in the formation of small spherical micelles, similar in size to those formed by the surfactant alone (*56*) (Figure 10B). The two different molar ratios examined corresponded to an average of approximately one and two PAs per micelle, based on the reported aggregation number of 95 for pure Tween 40 micelles (*56*). Interestingly, circular dichroism revealed that peptides were folded, albeit to a lesser extent than single component C_{16}p53 micelles (Figure 10C). Examination of Trp fluorescence spectra showed its emission maximum at 340 nm (Figure 10D). The blue shift compared to C_{16}p53-only micelles is most likely a reflection of the ethylene glycol-rich corona formed by the Tween 40.

In contrast to C_{16}p53, the enhanced interactions between monomers of $C_{16}A_4$p53 did not allow the formation of mixed micelles. Mixing of this PA with Tween 40 at a molar ratio of 1:50 was not sufficient to disrupt H-bonding between peptide headgroups and resulted in two micelle populations as evidenced by DLS and β-sheet formation as measured by CD spectroscopy, respectively (Supporting Information Figures S6−S7).

DISCUSSION

Our present findings support conclusions from previous studies to the effect that attachment of a hydrophobic tail to an unfolded peptide and subsequent peptide amphiphile self-assembly induce secondary structure. This study further provides insight on the effect of different incorporated linkers between the palmitic tail and peptide $p53_{14-29}$ on peptide folding and supramolecular structure, demonstrating that secondary structure type and extent can be controlled by appropriate linker selection.

The main driving force for peptide amphiphile self-assembly is the hydrophobic effect of the attached hydrocarbon tails. In their absence, the unmodified peptide does not self-associate at concentrations up to 5 mg/mL, as evidenced by lack of scattering from objects larger than 2 nm or change in pyrene fluorescence spectra. The peptide remains unfolded, present mostly as a random coil, and as a consequence, tryptophan is fully hydrated and easily accessible to quenching ions. Peptide palmitoylation, micelle formation, and minimization of the interfacial area between the oily core and water results in close packing of the peptide headgroups. Loss of conformational freedom due to tethering and confinement leads to folding into defined secondary structure motifs and concomitant Trp fluorescence changes. Such behavior has been predicted using mechanistic models and lattice simulations and has been shown for a number of peptides with differing secondary structure motifs, including α-helices, triple helices, and β-sheets (*6, 14, 28, 29, 57, 58*). Peptide−peptide interactions are not necessary for folding: crowding with oligomeric ethylene oxide headgroups in Tween 40 mixed micelles also induced peptide folding.

However, our results demonstrate the importance of peptide−peptide interactions in determining the peptide secondary structure motifs of different PA analogues. These interactions were altered through the choice of linker and indicate that peptide folding is controlled by a subtle interplay of stabilizing forces. Similar conclusions were recently obtained by a study showing how secondary structure of a leucine-rich peptide was determined from the curvature of the gold particles it was attached onto (*32*). In contrast to that report, curvature in our system is not set a priori but is determined through the self-assembly process. In order to better understand our results, it is important to consider the structure of $p53_{14-29}$ in its physiological

state. There is no crystal structure available for the N-terminus of soluble p53; however, in a complex with hDM2, $p53_{18-26}$ forms an amphipathic α-helix, which inserts into a groove on the surface of hDM2 (*59*). The hydrophobic face of the helix displays the side chains of Phe_{19}, Trp_{23}, and Leu_{26}, which are critical for strong binding, with the aromatic rings of Phe and Trp stacked in close proximity to each other (*59*).

In the simplest PA where palmitic acid is directly attached to the N-terminus of the peptide via an amide bond (C_{16}p53), evidence points to a similar helical structure being formed. The unusual α-helical CD spectrum arises from Trp stacking, consistent with the blue shift that is observed in Trp fluorescence spectroscopy, a reduced accessibility to quenching iodide ions (*44*) and higher fluorescence anisotropy. The CD spectrum could be mistaken for that of a 3−10 helix (*60, 61*), but the demonstration that NBS-oxidized PAs exhibit an α-helical signature, as well as the fact that ellipticity at 195 nm is significantly higher than 0, point to an α-helical conformation. Trp_{23} seems to stack with Phe_{19}, as was found for the hDM2-bound peptide, rather than with another aromatic side chain of a neighboring peptide, since the spectra of C_{16}p53 "diluted" in Tween 40 mixed micelles were identical to those of C_{16}p53 micelles and anisotropy values of isolated peptides folded in the presence of TFE exhibited the same Trp anisotropy as that of folded C_{16}p53. We would like to note that it is not possible to exclude the scenario that NBS oxidation causes a structural change in the folded state of the peptide. Future infrared and/or NMR measurements should be pursued to clarify this point.

When hydrophilic ethylene oxide spacers of increasing length were interposed between peptide and tail, the extent of folding was lower. Again, significant changes in CD spectra upon NBS oxidation helped correlate the negative peak at 230 nm with Trp interference and quantify the decrease of folding in EO-containing analogues. A concomitant decrease in anisotropy was a result of partial unfolding, which increased rotational freedom of the fluorophor, while the blue shift in λ_{max} compared to C_{16}p53 is most likely linked to the presence of ethylene oxide in the micelle corona, which alters the local polarity of Trp. By comparison of the structures of C_{16}p53 and $C_{16}EO_x$p53, it is logical to assume that the observed changes arise from the more flexible nature of the oligo(ethylene oxide) backbone, which positions the peptide further from the core−corona interface, alleviating the molecular frustrations of the peptides, in that region. Moreover, control of α-helical content via ethylene oxide linker length could provide a powerful tool in examining its effect in situations where secondary structure is believed to be important in function.

Inclusion of four alanines linking the peptide with the palmitic tail resulted in formation of β-sheets between peptides. Consequently, Trp is no longer stacked with other side chains and its λ_{max} shows full hydration. The high anisotropy observed is presumably a consequence of the rigidity of the peptide due to the β-sheet structure along the micelle axis. The size of the A_4 linker is comparable to the shortest EO linker (EO_4); the noted difference in secondary structure is therefore a consequence of altered chemistry rather than different positioning of the peptide. Alanine is generally considered an α-helix promoter that favors a condensed state and helix formation is relatively uninhibited due to its small hydrophobic side chain (*62*); here, instead, the alanine side chain from neighboring peptides adjacent to the micelle core come in close proximity with each other, forming the condensed state with hydrogen bonds between them. This allows a tight packing and more parallel orientation of the alkane chains resulting in beneficially smaller interfacial area between the oily core and the aqueous phase. Inclusion of alanines has been shown to promote fiber formation of PAs through β-sheet formation along the fiber axis in a number of previous studies (*4, 10, 11, 13*). It appears that the stabilizing H-bonds from 4 alanines provide enough energy to overcome the tendency of the peptide to fold into an α-helix (*63*). The resulting micelles are stable such that mixing with a nonionic detergent (Tween 40) is not sufficient to disrupt the interactions between monomers, in contrast to what was observed for C_{16}p53 micelles.

Prolines are not able to form H-bonds due to their unique structure (*64*) and therefore disrupt the common secondary structure motifs α-helix and β-sheets. It has also been suggested that Pro may serve as a helix initiator when found at the N-termini of a helix, providing an initial twist and N-capping H-bonds (*65*). In our study, insertion of a rigid short proline linker did not seem to enhance helicity, but on the contrary, a decrease was noted, presumably in an analogous manner as for the EO-containing PAs.

The above findings confirm the importance of amino acid composition and H-bonding availability near the micellar core−corona interface on the folded structure of peptides in the corona. Peptide headgroup structuring and interactions are expected to additionally control the architecture of the self-assembled structure. Indeed, if we assume the peptide as a random coil and calculate the packing parameter (P) (*66*) for C_{16}p53 we obtain $p = 0.10$, predicting the formation of spherical micelles ($P \ll 1/3$): $P = (v)/(Al)$, where $l = 2.2$ nm is the length of the hydrophobic tail, $v = 0.46$ nm^3 its volume, and $A = 2.1$ nm^2 the surface area of the peptide headgroup that we can estimate from a headgroup volume of 2.32 nm^3 (using 0.73 cm^3/g as protein partial specific volume) and its 2-D projection of a peptide "sphere". The observation that elongated structures are formed is therefore consistent with peptide folding and concomitant headgroup area decrease with the peptide extending from the hydrocarbon−peptide interface. Recently, our group described the kinetic process of a simultaneous transition in secondary structure and micelle size to the above effect confirming this link (*67*). Here, no transitions were observed in the period of a week and equilibrium was reached within minutes, presumably due to differences in peptide headgroup as well as in the preparation protocol.

We did not observe major differences in the overall dimensions of the different analogues that we tested. We anticipated that increasing ethylene oxide length would promote spherical micelle formation due to steric effects of the larger headgroup. Nonionic surfactants composed of a 16-carbon tail and oligo(ethylene oxide) (also known as Brij surfactants) have been shown to transform from rod-like micelles (*68*) ($C_{16}EO_6$) to small spherical micelles having a diameter of approximately 11 nm (*69*) ($C_{16}EO_{20}$) with increasing number of ethylene oxide units. Attachment of the peptide at the end of an even longer EO linker did not have the anticipated effect on size presumably due to peptide−peptide interactions that persist even as the peptides are positioned further away from the hydrophobic core. This is consistent with the retention of a degree of peptide folding. Our understanding at this point is that the ethylene oxide segments extend away from the interface more so than would be expected if they adopted a random coil conformation. In contrast, when C_{16}p53 was mixed with an excess of Tween 40, small spherical mixed micelles were formed. This finding implies that peptide−peptide interactions are controlling micelle structure, even though they are not necessary for peptide folding as discussed previously.

Unlike overall size, we observed differences in micelle flexibility. Compared to C_{16}p53, flexibility was not affected by the addition of an EO spacer of any length but rather, by the incorporation of peptide spacers A_4 and P_3. It is possible that the P_3 spacer becomes more disruptive to packing within the micelle corona, causing correlations to decay faster along the micelle length than an extended EO layer. In the case of the A_4

spacer, we believe that β-sheet peptide structure plays a role in micelle flexibility. The coiling of β-sheet tapes may be responsible for cylindrical micelle structure and permit flexibility, as the hydrogen bonding pattern in these coiled tapes runs quasi-radially rather than axially down the micelle. Regardless of the precise mechanism, it is clear that variations in the linker between functional peptide and hydrophobic tail can affect micelle flexibility in addition to peptide secondary structure.

In conclusion, our study demonstrates that we can control the type and extent of peptide folding on self-assembled structures composed of peptide amphiphiles through inclusion of appropriate linkers in the region between the peptide of interest and the hydrophobic domain. Subtle modifications brought about strong effects, which are essential to design efficient PA assemblies. This understanding and control is required in cases where secondary structure is important for function, as in peptide−protein interactions or antibody production (*70*). In particular, the peptide we selected ($p53_{14-29}$) has been shown to exhibit enhanced binding to hDM2 when its α-helical content was increased through chemical modifications (*23*); our next steps are to examine binding of peptide amphiphile micelles to hDM2 and additionally correlate it with peptide folding.

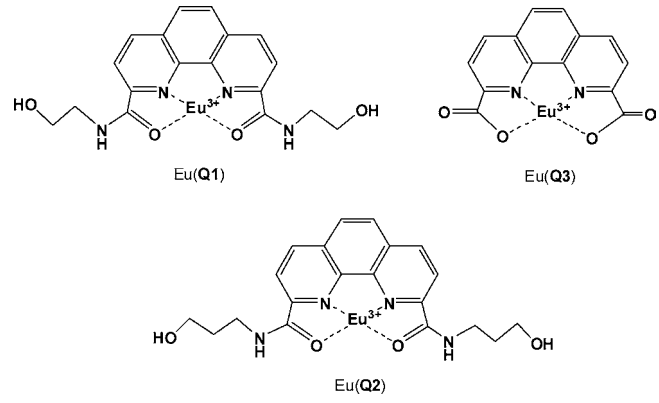
Binding of Europium(III) to a Non-Nucleosidic Phenanthroline Linker in DNA

Ching-Hui Huang,[†] Austin Parish,[†] Florent Samain,[‡] Florian Garo,[‡] Robert Häner,[‡] and Janet R. Morrow*[,†]

Department of Chemistry, 526 Natural Sciences Complex, University at Buffalo, State University of New York, Amherst, New York 14260-3000, and Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, 3012 Bern, Switzerland.
Received September 1, 2009; Revised Manuscript Received January 9, 2010



Eu(III) complexes of DNA containing a non-nucleosidic linker, a derivative of 1,10-phenanthroline-2,6-dicarboxamide (**Q**), are studied with the goal of forming novel lanthanide ion binding sites that are incorporated in the backbone of DNA. One oligonucleotide is short and unstructured (TTTQTTT (**QT6**)) and the other (5′-AGCTCGGTCAQCGAGAGTGCA-3′ (**SQ**)) is studied both in single-stranded form and in the presence of a partially complementary DNA strand. Luminescence spectroscopy studies show that Eu(III) binds to **SQ**, **QT6**, **AQB**, or **QB** 1100-, 56-, 23-, or 27-fold more tightly, respectively, than to a simple 1,10-phenanthroline-2,6-dicarboxamide ligand (**Q1**). Direct excitation and phenanthroline sensitized luminescence spectroscopy supports binding of Eu(III) to the phenanthroline linker in **QT6** and in double-stranded DNA formed from **SQ** and partially complementary sequences that place **Q** in a bulge-like position. Eu(III) hydration numbers range from 3 to 5 when bound to the phenanthroline moiety in modified DNA, consistent with binding to the tetradentate linker and, in some cases, coordination to other groups in the DNA. Thermal melting experiments show that **Q** in a bulge-like structure stabilizes double-stranded DNA and that Eu(III) binding does not markedly affect the stability of the duplex.

INTRODUCTION

There is much interest in the study of DNA that has been functionalized to bind metal ions with useful magnetic, optical, or redox properties. These hybrid materials rely on the self-assembly properties of DNA or DNA analogues to build large organized structures with unique characteristics (*1*−*4*). The incorporation of unnatural ligating groups for metal ions into DNA facilitates the formation of these nucleic acid/metal ion hybrid materials. Such ligands may be incorporated as base modified nucleotides (*2*−*6*) or as non-nucleosidic ligands (*1, 7*−*10*). Ligands may be appended to either the 5′ or 3′-termini of DNA (*11*−*14*) or, alternately, incorporated in midsequence of the DNA (*1, 7, 15, 16*). Ligands appended to the termini of DNA allow for the formation of large supramolecular structures through interaction of metal ions with ligands on distinct DNA strands (*17*). However, ligands incorporated in midsequence sites ultimately are more versatile for control of the metal ion environment within the nucleic acid (*18*). Our interest lies in the formation of metal ion complexes that are incorporated internally within the DNA, but retain open coordination sites at the metal ion center. Such complexes may be useful for the construction of agents for optical and magnetic resonance imaging (*18, 19*).

To date, most reports of ligands incorporated into DNA bind transition metal ions or Zn(II) (*1*−*6*). There are few examples of f-element coordination, despite interest in the rich luminescence, magnetic, and catalytic properties of the lanthanide ions (*12, 20*−*22*). Here, we report, to the best of our knowledge, the first example of a lanthanide(III) complex of a heterocyclic aromatic ligand which is incorporated as a linker into the DNA phosphate diester backbone. The present study incorporates a non-nucleoside building block based on a 1,10-phenanthroline-2,6-dicarboxamide derivative (*23, 24*) into single- and double-stranded DNA. Oligonucleotides are prepared that contain the phenanthroline-containing linker in a sequence containing only thymidines, as an example of a relatively unstructured DNA sequence and in two duplexes in a bulge-like position that lack an opposing nitrogenous base on the complementary strand. The linker was chosen on the basis of the favorable binding and luminescent properties of Ln(III) complexes of analogous 1,10-phenanthroline derivatives that contain either carboxylates (*25, 26*) or alcohols as additional donor groups (Scheme 1) (*27, 28*).

Scheme 1

EXPERIMENTAL PROCEDURES

Materials. $Eu(CF_3SO_3)_3$ was purchased from Aldrich. Unmodified DNAs were purchased from Integrated DNA Technologies (IDT) in desalted form. Oligonucleotides were annealed by heating solutions containing 100 mM NaCl, 20 mM buffer, and oligonucleotide to 90 °C for 10 min and allowed to cool to room temperature overnight. Phenanthroline modified DNA was prepared as reported previously (*18, 19, 26*).

Synthesis. 2,9-Bis(2-hydroxyethylamide)-1,10-phenanthroline (Q1). A mixture of 2,9-bis(methoxycarbonyl)-1,10-phenanthroline (0.094 g, 0.32 mmol) (*29, 30*) and aminoethanol (0.04

mL, 0.66 mmol) was placed under reflux in ethanol (2 mL) for 4 h. The mixture was dried and the resulting solid was added to ethanol with a few drops of chloroform added to promote dissolution. Ether was added until the solution turned cloudy and the solution was placed in the freezer overnight. Yellow needle-shaped crystals were obtained as pure product. Yield: 50%. ESI-MS *m/e*: {**Q1** + H^+}, 355; {**Q1** + Na^+}, 377. ^{1}H NMR (400 MHz, DMSO) δ 9.3 (t, 2H, −NH), 8.8, 8.5 (d, 4H, ring), 8.2 (s, 2H, ring), 4.9 (t, 2H, −OH), 3.7 (t, 4H, $-CH_2OH$), 3.6 (t, 4H, $-CH_2$). ^{13}C NMR (300 MHz, DMSO) δ 164.4, 150.2, 144.2, 138.9, 130.9, 128.5, 121.6, 60.4, 42.4.

2,9-Bis(3-hydroxypropylamide)-1,10-phenanthroline (Q2). A solution containing 2,9-bis(methoxycarbonyl)-1,10-phenanthroline (0.202 g, 0.68 mmol) and 3-amino-1-propanol (0.105 mL, 1.38 mmol) was placed under reflux in ethanol (2 mL) for 4 h. The mixture was dried and the resulting solid was added to ethanol with a few drops of chloroform added to promote dissolution. Ether was added until the solution turned cloudy and the solution was placed in the freezer overnight. Small white crystals were obtained as product. Yield: 50%. ESI-MS *m/e*: {**Q2** + H^+}, 383; {**Q2** + Na^+}, 405. ^{1}H NMR (500 MHz, DMSO) δ 9.5 (t, 2H, −NH), 8.7, 8.4 (d, 4H, ring), 8.2 (s, 2H, ring), 4.8 (t, 2H, −OH), 3.7 (t, 4H, $-CH_2OH$), 3.6 (t, 4H, $-CH_2$), 1.8 (t, 4H, $-CH_2$). ^{13}C NMR (300 MHz, DMSO) δ 164.3, 150.3, 144.3, 138.9, 130.9, 128.5, 121.6, 60.4, 37.9, 32.7.

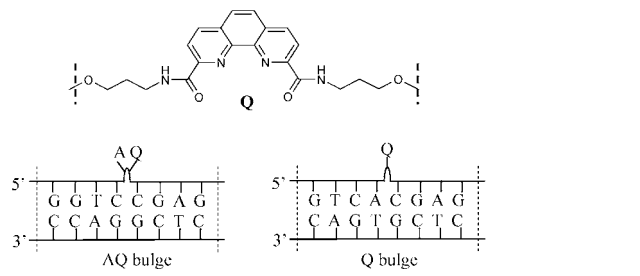
Instrumentation. An Orion research digital ionalyzer, model 510, equipped with a temperature compensation probe was used for all pH measurements. All ^{1}H and ^{13}C NMR were recorded on a Varian Gemini-300, Varian Inova-400 or Inova-500 spectrometer. Modified DNA was synthesized as reported previously (*23*). DNA thermal melting experiments were carried out on a Beckman Coulter DU 800 spectrophotometer equipped with a high performance temperature controller Peltier. The T_m values were calculated by using the MeltWin program and are given in Table 1 (*31*).

Luminescence Spectroscopy (Direct Excitation). Eu(III) excitation spectra and excited-state lifetimes were obtained using a Spectra-Physics Quanta Ray PRO-270−10 Q-switched Nd:YAG pump laser (10 Hz, 60 mJ/pulse) and a MOPO SL for all luminescence measurements (*27*). The $^7F_0 \rightarrow {}^5D_0$ transition of the Eu(III) ion was scanned between 578 and 581 nm while the $^5D_0 \rightarrow {}^7F_2$ emission band was monitored at 628 ± 27 nm using a band-pass filter. Excitation spectra were fit by using the program *Peak Fit 4.12* (Jandel). Time resolved luminescence measurements were collected by using a digital Tektronix TDS 3034B oscilloscope. Five data sets per wavelength were fit to a single exponential decay by using *Graphpad Prism 4* (Graphpad Prism Software, Inc.) and averaged (*28, 29*).

Isotherms from Eu(III) binding to DNA and to phenanthroline modified DNA were fit to eq 1 by using *Sigmaplot 10* (systat). Here, C is the Eu(III) aquo complex, CA is Eu(III) complex bound to DNA, A is the DNA concentration, *X* is mole fraction, and *I* is luminescence intensity at a chosen wavelength. K_d is the dissociation constant. The solution includes 20 μM complex, 20 mM HEPES buffer, 100 mM NaCl.

$$\begin{aligned} F &= [C]_{tot} + [A]_{tot} + K_d \\ [CA] &= \left(F - \sqrt{(F^2 - 4[C]_{tot}[A]_{tot})}\right)/2 \\ X_{CA} &= \frac{[CA]}{[C]_{tot}} \\ X_C &= 1 - X_{CA} \\ I_{obsd} &= X_C I_C + X_{CA} I_{CA} \end{aligned} \quad (1)$$

Luminescence Spectroscopy (Ligand Sensitized). Excitation and emission spectra were obtained using a Cary Eclipse fluorimeter. Excitation spectra were recorded with 0.2 ms delay time and 5 ms gate time in the excitation range 270−320 nm. Emission spectra were recorded for Eu(III) complex in the range 565−720 nm with selective irradiation at 295 nm (λ_{ex} = 295 nm) and for excitation spectra, the wavelength 615 nm (λ_{em} = 615 nm) was monitored.



RESULTS

DNA Sequences. Two different DNA sequences were prepared with a 1,10-phenanthroline-2,9-dicarboxamide incorporated midsequence. The first sequence, 5′-TTTQTTT-3′, was prepared as an example of a simple single-stranded DNA which lacks significant secondary structure (Q represents the 1,10-phenanthroline-2,9-dicarboxamide linker in Table 1). The second sequence, 5′-AGCTCGGTCAQCGAGAGTGCA-3′, was used in combination with partially complementary strands to form two different DNA duplexes that have either Q or an AQ lacking an opposing base on the unmodified DNA strand to give a bulge-like structure (**QB** and **AQB**, see Table 1). For comparison, three DNA duplexes, one fully complementary, one containing a single T-bulge and one containing an AT bulge were studied (Table 1). In addition, the ligands **Q1** and **Q2** were prepared for comparison with the modified DNA sequences (Scheme 1).

The stability of the five DNA duplexes was studied by using optical thermal melting experiments. These experiments showed that **AQB** and **QB** DNA have higher stability in comparison to the natural AT or T bulged DNA (Table 1) with T_m values that increase by 20 °C for the modified duplexes at equal concentrations. This suggests that the phenanthroline linker stabilizes the duplex through stacking interactions with bases in the helix. A more modest increase in stability was previously observed for DNA duplexes that contain Q opposite an abasic site (*23*). The T_m values of all duplexes here were only slightly affected (1−4 °C) by the addition of 1 equiv of Eu(III) (Table 1) at 3, 19, or 25 μM DNA. In addition, Eu(III) has little effect on either the

[a] ΔT_m = Change in T_m upon addition of 3.00 uM $EuCl_3$. ΔT_m of solutions containing 25 uM AQB and 25 μM $EuCl_3$ is −1.0 °C, ΔT_m of 19 uM QB and 19 μM $EuCl_3$ is −1.0 °C. [b] All solutions contain 3.00 uM DNA, 20.0 mM MES buffer, and 100 mM NaCl at pH 6.5.

hyperchromicity or cooperativity of the transition as shown from the similarity of the optimal thermal melting curves in the absence or presence of Eu(III) ion (Supporting Information Figure S1). This shows that binding of Eu(III) under these conditions does not markedly destabilize the DNA duplex.

Luminescence Spectroscopy. Both direct excitation luminescence spectroscopy and phenanthroline linker-sensitized luminescence spectroscopy of Eu(III) bound to modified DNA and **Q1** were used for characterization. For direct excitation luminescence spectroscopy, the Eu(III) $^7F_o \rightarrow {}^5D_o$ transition was excited and the intense luminescence emission band ($^5D_o \rightarrow {}^7F_2$) was monitored. The $^7F_o \rightarrow {}^5D_o$ transition occurs between two electronic states that are nondegenerate and thus not split by ligand fields. This gives rise to a single excitation peak for each Eu(III) complex species, barring overlap of peaks (*32, 33*). In addition, time-resolved luminescence studies give information on the hydration state of the Eu(III) ion by taking into account quenching of the excited state through vibronic coupling with OH and NH groups. The number of bound waters, q, is estimated by using eq 2 (*33, 34*) where A is a constant specific to Eu(III) (1.1 ms), and k_{H2O} and k_{D2O} are the rate constants for luminescence decay in H_2O and D_2O, respectively. The $k_{HNC=O}$ term is to account for quenching by amides (0.075 ms^{-1} for each NH) and α is the total outersphere quenching (0.25 ms^{-1}). Alternately, a simplified form that gives an estimate of q without luminescence lifetime data in D_2O or assumptions about additional ligand quenching contributions, eq 3 (*35*), was used with $A' = 1.05$ ms and $\alpha' = 0.44$. Use of this simplified form is warranted in systems that do not have well-characterized quenching contributions from first and second sphere ligands such as the systems studied here. Amide and second sphere quenching parameters are well-established for macrocyclic complexes (*34*), but not for phenanthroline ligands conjugated to DNA.

$$q = A(k_{H2O} - k_{D2O} - \delta k_{NHC=O} - \alpha) \quad (2)$$

$$q' = A'(k_{H2O} - \alpha') \quad (3)$$

The $^7F_o \rightarrow {}^5D_o$ excitation spectrum of the Eu(III) complex of a simple ligand that is structurally similar to the DNA linker (**Q1** in Scheme 1) has a single peak at 579.32 nm, supportive of a single Eu(III) species in solution (Supporting Information Figure S2). The effective dissociation constant for Eu(**Q1**), determined at pH 6.5, 100 mM NaCl in 20 mM MES buffer, from a plot of the UV−vis absorbance spectrum of **Q1** as a function of Eu(III) (Supporting Information Figure S3) is 46 μM. The complex was further characterized by using time-resolved luminescence spectroscopy. Recovered luminescence lifetimes collected in H_2O and D_2O were used to calculate q values by using either eq 2 or 3 (Table 2). The q values are consistent with tetradentate coordination of the ligand **Q1** to form a Eu(III) complex with five water ligands and an overall coordination number of nine. Nonintegral values of q arise from the inherent uncertainty in the determination of luminescence lifetimes (*32*) as well as the lack of well-established inner- or outer-sphere ligand quenching parameters for Eu(III) phenanthroline derivatives. Nonetheless, a q number of five for Eu(**Q1**) is consistent with tetradentate coordination of **Q1**. This shows that the alcohol groups do not coordinate to Eu(III). Consistent with this postulate that the alcohols are not donor groups, we determined that a related ligand with a longer hydroxyalkyl chain (**Q2**) binds Eu(III) similarly. The effective dissociation constant for Eu(**Q2**), determined at pH 6.5, 100 mM NaCl in 20 mM MES buffer, from a plot of the UV−vis absorbance spectrum of **Q2** as a function of Eu(III) is 41 μM, close to that of Eu(**Q1**) (data not shown). Eu(**Q2**) has a q number of five, also consistent with no coordination of the alcohol groups (Scheme 1, Table 2). Further direct Eu(III) excitation studies were carried out in the presence of up to a 14- or 16-fold excess of **Q1** or **Q2** ligand, respectively (Supporting Information Figure S4). The retention of a single excitation peak and the constancy of the luminescence lifetimes show that the 1:1 complex predominates in solution even under conditions of excess ligand.

Table 2. Luminescence Lifetime Data and the Number of Metal Bound Water Ligands (q) for Eu(III) Complexes of Q1, Q2, and Q-DNA[a]

ligand	λ (nm)[c]	τ_{H2O} (ms)	k_{H2O} (ms^{-1})	τ_{D2O} (ms)	k_{D2O} (ms^{-1})	q[d]	q'[e]

	579.90	0.318	3.14	–	–	–	2.9

[a] Standard deviations in lifetime values are typically ≤7% in H_2O and ≤3% in D_2O (*28*). [b] 25.0 uM DNA, 20.0 mM MES buffer, and 100 mM NaCl with 25.0 uM $EuCl_3$ at pH 6.5. [c] Excitation wavelength is chosen to collect separate lifetime decays for each species. [d] q is the number of bound waters as calculated from eq 2. [e] q' is the number of bound waters as calculated from eq 3.

It is notable that the analogous carboxylate ligand **Q3** (*26*) binds strongly to lanthanide ions and coordinates to the similarly sized Ca(II) ion as a tetradentate ligand through the phenanthroline nitrogens and carbonyl oxygens. However, **Q3** binds Ln(III) many orders of magnitude more strongly than does **Q1** or **Q2** (log $K = 16$ for Gd(**Q3**)), consistent with amides being weaker donor groups than carboxylates (*26, 27*).

The $^7F_o \rightarrow {}^5D_o$ excitation spectrum of Eu(III) in the presence of **QT6** shows two major peaks (579.89 nm, 579.44 nm) and a minor peak (579.05 nm) as shown in Figure 1a. The two major excitation peaks are substantially red-shifted in comparison to Eu(III) aqua ion (*36*) or Eu(III) bound to unmodified DNA (see below). The wavelength of the middle excitation peak is similar to that of the simple ligands **Q1** or **Q2**. Luminescence lifetimes for both major excitation peaks are consistent with a q value of three and are identical within experimental error. This suggests that the two peaks arise from two different species with distinct conformations that both have three bound water molecules. The unexpectedly low q value supports interaction of Eu(III) to DNA groups in addition to the phenanthroline moiety. The identity of the species that gives rise to the minor peak at 579.05 nm is uncertain. One assignment, based on excitation peak wavelength, is Eu(III) bound to unmodified DNA (see below). However, the peak is very small and buried underneath the excitation peaks of the major species, so that it is not possible to obtain luminescence lifetime data to enable making a definitive assignment of the Eu(III) species.

The dissociation binding constant for Eu(III) with **QT6** DNA was determined from a plot of the luminescence intensity of the complex at 579.89 nm as a function of **QT6** DNA and fit to eq 1 to give a K_d of 0.82 μM, 56-fold tighter than for the simple ligand **Q1** (Supporting Information Figures S5, S6). The stronger binding of Eu(III) to **QT6** compared to **Q1** suggests that either the environment of the DNA or other ligating groups on the DNA such as phosphate esters or nucleobases influence the strength of Eu(III) complex formation. However, it is clear that Eu(III) binds primarily to the phenanthroline linker in Q-containing DNA and not solely to the unmodified DNA as shown by comparison to excitation spectra and q numbers of Eu(III) titrated with unmodified DNA (see below). In addition,

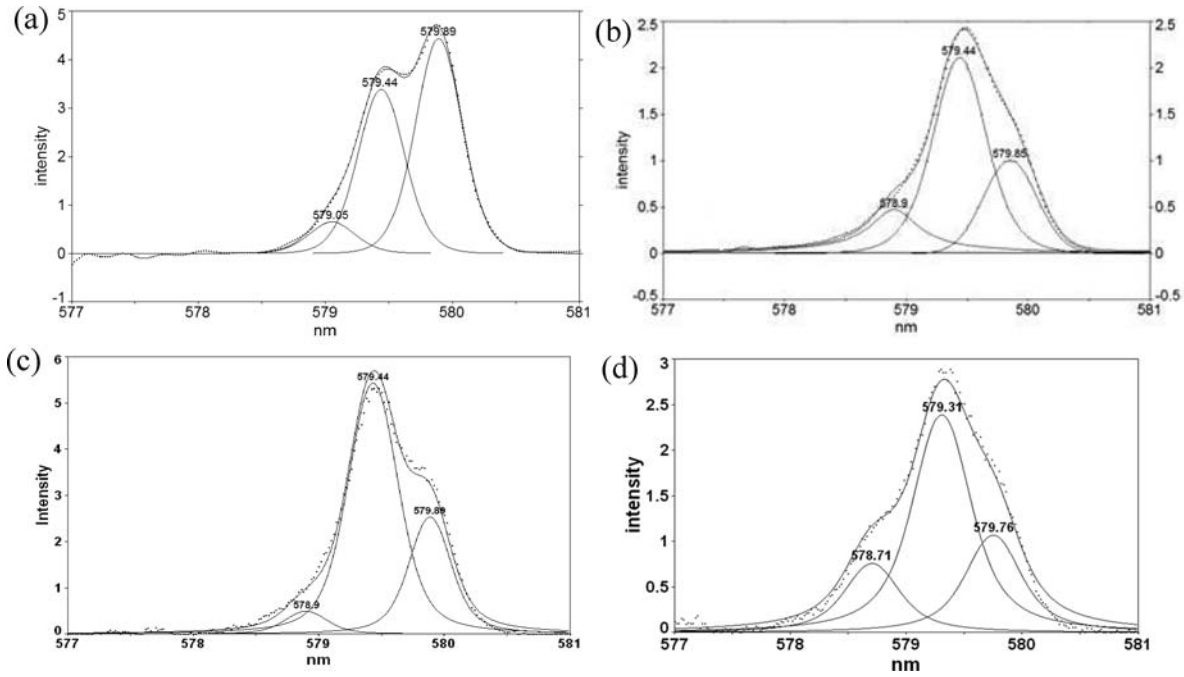

Figure 1. Deconvolution of peaks for the $^7F_0 \rightarrow {}^5D_0$ excitation spectrum with emission monitored at 628 ± 27 nm ($^5D_0 \rightarrow {}^7F_2$) for four phenanthroline DNA Eu(III) complexes. (a) **QT6**, (b) **AQB** (c) **SQ**, (d) **QB**. All samples contain 25.0 uM $EuCl_3$, 25.0 uM DNA, 20.0 mM MES buffer, and 100 mM NaCl at pH 6.5.

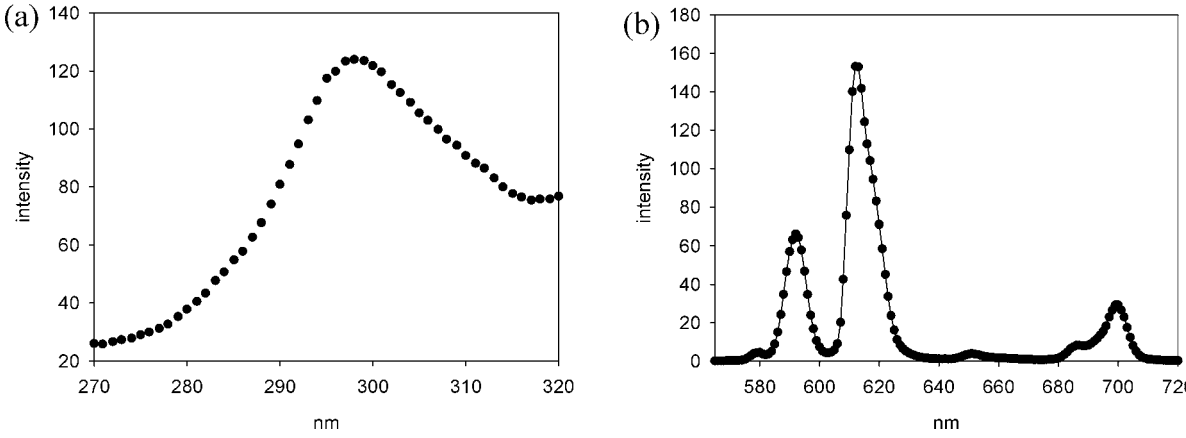

Figure 2. Sensitized luminescence of 50 μM **QT6** and 20 μM $EuCl_3$ at pH 6.5, 100 mM NaCl and 20 mM MES buffer, pH 6.5. (a) Excitation spectrum monitored with luminescence emission at 615 nm. (b) Emission spectrum upon excitation at 296 nm.

studies show that excitation of the phenanthroline linker sensitizes luminescence of Eu(III), supportive of coordination of the Eu(III) to the linker.

Excitation of Eu(**Q1**) at 296 nm gives rise to a typical luminescence emission spectrum of Eu(III) (Supporting Information Figure S7) with the hypersensitive $^5D_o \rightarrow {}^7F_2$ emission at 615 nm as the most intense band. Irradiation of **QT6** in the presence of an equivalent of Eu(III) at 296 nm gives a similar emission spectrum (Figure 2). The excitation spectrum, obtained by monitoring emission at 615 nm for the Eu(**Q1**) or Eu(**QT6**), shows a broad featureless excitation peak that resembles the UV−visible spectrum of the Eu(**Q1**) complex (Figure 2 and Supporting Information Figure S7). This shows that the phenanthroline linker both alone and incorporated into DNA sensitizes luminescence of Eu(III). Under similar conditions, excitation of Eu-bound to unmodified DNA at 296 nm lacks any of the luminescence emission bands of Eu(III) (Supporting Information Figure S8).

Direct Eu(III) excitation spectroscopy of the two double-stranded DNA sequences containing the phenanthroline linker in either bulges **AQB** or **QB** or the single-stranded sequence (**SQ**) is used to monitor binding of Eu(III) to the modified DNA (Table 2 and Figure 1). The dissociation binding constants for Eu(III) with these DNA oligonucleotides were determined from a plot of the excitation luminescence intensity of the complexes at 579.3 nm as a function of DNA and fit to eq 1 to give K_d values of 43 nM, 2.0 μM, and 1.7 μM, for **SQ**, **ABQ**, and **QB**, respectively (Supporting Information Figure S9). For the Eu(III) complex of **SQ**, the concentration of Eu(III) was lowered to 500 nM to attempt to obtain a binding isotherm that was sufficiently gradual to obtain an accurate dissociation constant by fitting to eq 1. However, even at 500 nM Eu(III), our lower limit for obtaining excitation data for binding curves of this complex, our data is indicative of tight binding and can only be used to obtain an upper limit on the dissociation constant ($K_d \leq 43$ nM). Binding of Eu(III) to **SQ**, **AQB**, and **QB** is 1100-, 23-, and 27-fold tighter, respectively, than for the simple ligand **Q1.**

Deconvolution of the steady-state excitation spectra of Eu(III) bound to **AQB**, **QB**, and **SQ** shows three excitation peaks for

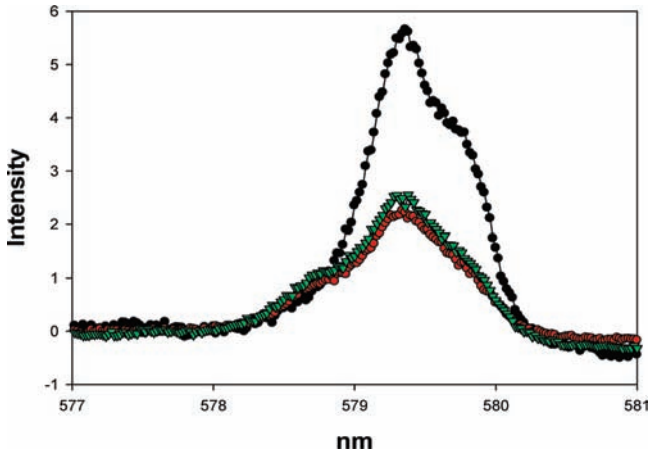

Figure 3. Overlay of the $^7F_0 \rightarrow {}^5D_0$ excitation spectrum with emission monitored at 628 ± 27 nm ($^5D_0 \rightarrow {}^7F_2$) for three phenanthroline DNA Eu(III) complexes. **SQ** (black), **QB** (green), **AQB** (red). All samples contain 2.0 uM $EuCl_3$, 4.0 uM DNA, 20.0 mM MES buffer, and 100 mM NaCl at pH 6.5.

each modified DNA. The middle excitation peaks (579.44, 579.31, and 579.44 nm, respectively) have wavelengths and associated luminescence lifetimes that give *q* numbers of approximately five, similar to that of Eu(**Q1**). The farthest red-shifted peak at 579.89 nm for **SQ** arises from a species with a *q* number that is similar to the middle peak. In contrast, the red-shifted peaks (579.76 and 579.85 nm) for **QB** and **AQB** have associated *q* numbers that are slightly less than their corresponding middle peaks, consistent with additional donor group interactions from DNA and/or fewer quenching contributions from second-sphere interactions. Assignment of the middle and red-shifted excitation peaks in **QB**, **SQ**,and **AQB** to Eu(III) bound to the phenanthroline linker is supported by the fact that the excitation peak wavelengths are too far red-shifted to originate from Eu(III) bound to unmodified DNA and the associated species have *q* numbers which are much lower than those of Eu(III) bound to unmodified DNA (see below). In addition, excitation of the phenanthroline linker leads to Eu(III) luminescence (Supporting Information Figure S8 for Eu(III) bound to **QB**).

The most blue-shifted peaks, which are the lowest intensity in all sequences, are more difficult to assign because they are small and overlap substantially with the middle peak. Interference from luminescence of the other species makes it difficult to obtain accurate *q* numbers to enable making an assignment. The excitation peak wavelengths of the small blue-shifted peaks (578.90, 578.90, and 578.71 nm for **AQB**, **SQ**, and **QB**, respectively) are close to that of Eu(III) bound to unmodified DNA, one possible assignment for this species. The higher *q* number and lower excitation peak wavelength suggests that this site has Eu(III) bound to DNA groups, and not to the phenanthroline linker in **QB** DNA.

In order to compare the luminescence properties of the Eu(III) complex of single-stranded **SQ** to those of bulged duplexes, **QB** and **AQB**, Eu(III) excitation spectra were taken of samples with identical concentrations and laser/MOPO system power (Figure 3). These data show that the major excitation peaks of the Eu(III) complexes of **AQB** and **QB** are less intense in comparison to the Eu(III) complex of the single-stranded **SQ** and that the blue-shifted peak is more prominent in the bulged duplexes.

In comparison, the $^7F_o \rightarrow {}^5D_o$ excitation luminescence spectra of Eu(III) titrated with the unmodified DNAs including stem, AT bulged, and T bulged DNA show a slight red-shift of the excitation peak of the Eu(III) aqua complex from 578.80 to 578.83 nm with a concomitant increase in luminescence intensity (Supporting Information Figure S10). The luminescence lifetimes of solutions containing 20 μM $EuCl_3$ and 4-fold excess DNA at 578.8 nm for stem, AT-, and T-bulged DNA are 105, 120, and 130 μs, respectively, close to the value of 115 μs for fully hydrated Eu(III). These luminescence lifetimes give *q* numbers of 9.6, 8.3, and 7.6, respectively, from eq 2. The moderately increased lifetimes for Eu(III) bound to bulged DNA suggests a displacement of a single water molecule from Eu(III) aqua complex. In contrast, addition of 5 equiv of a pentanucleotide containing thymidine (TTTTT) to $EuCl_3$ under similar conditions shows no apparent change in either the Eu(III) excitation spectrum or luminescence lifetime (*37*).

DISCUSSION

Characterization of lanthanide ion binding sites in DNA and modified DNA is challenging. There are many potential ligand donor groups such as nitrogenous bases and phosphate esters that form binding sites within different DNA secondary structures (*37*−*40*). Direct excitation luminescence spectroscopy facilitates characterization of the Eu(III) environment through comparison of the wavelength and number of the $^7F_o \rightarrow {}^5D_o$ excitation peaks and by determination of hydration (*q*) numbers, yet there are few direct excitation luminescence studies that probe lanthanide ion binding to well-defined DNA (*38, 39*) or RNA (*41*−*43*) structures reported to date. We show here that Eu(III) does not readily lose water molecules upon binding to unmodified double-stranded DNA or bulged DNA. Eu(III) binds with replacement of approximately one water ligand ($q = 7.6$) for T-bulge and binds without losing water ligands to the stem sequence. A hallmark of Eu(III) bound to DNA is that the $^7F_o \rightarrow {}^5D_o$ excitation peak wavelength is very similar to that of the Eu(III) aqua ion with either a small red-shift (<0.1 nm) or no measurable shift at all as shown here and elsewhere (*37*).

Luminescence spectroscopy data support binding of Eu(III) to the phenanthroline linker in modified DNA. This is shown both by the low *q* numbers observed for the two major species (3−5) and by the shift of the excitation peak toward wavelengths that are similar to that observed for phenanthroline derived ligands, such as **Q1**. In addition, sensitized luminescence through excitation of the phenanthroline linker is observed, consistent with binding of Eu(III) to the phenanthroline moiety.

DNA sequence and structure modulates the metal ion environment in the Eu(III)-bound to the phenanthroline linker. **QT6** binds Eu(III) quite strongly with an increased binding strength of 56-fold in comparison to **Q1**. The thymidine sequence produces additional ligating groups around the Eu(III) center that lead to replacement of an additional two water molecules and this may contribute to the tighter binding constant. At this juncture, it is not clear whether the flexibility of the DNA or the type of available nucleobase groups as donors contributes to the reduced *q* value. In contrast, the longer sequence **SQ** binds Eu(III) to give major species with *q* numbers that are close to those in the simple ligand **Q1**. Similarly, the major Eu(III) species of **QB** and **AQB** have *q* numbers that are consistent with a tetradentate phenanthroline ligand. Interestingly, **SQ** binds extremely tightly to Eu(III) with $K_d \leq 43$ nM, or at least 1100-fold tighter-binding than to **Q1**. In comparison, the bulged duplexes **QB** and **AQB** bind Eu(III) with micromolar dissociation constants. Incorporation of Q into the mixed-sequence single-stranded DNA thus increases the strength of Eu(III) binding, most likely through more favorable electrostatic interactions between Eu(III) cation and polyanionic DNA. These Eu(III) interactions are not as favorable if the phenanthroline linker is constrained within a bulged DNA.

There are two major phenanthroline linker-bound Eu(III) complex species for all modified DNA sequences as shown by

direct excitation Eu(III) luminescence spectroscopy. The similarity of the hydration numbers along with the difference in excitation peak frequencies is most consistent with two species that have slightly different Eu(III) coordination environments. In comparison, Eu(**Q1**) has only a single excitation peak. This suggests that DNA gives rise to the two different species in Q-containing DNA strands. The red-shift in the major excitation peak is consistent with coordination of the Eu(III) phenanthroline to an anionic ligand such as a phosphate diester group (*44*).

The third blue-shifted excitation peak is of low intensity in all sequences. This species is associated with a higher than expected *q*-value for a phenanthroline-bound Eu(III) and has an excitation peak maximum that is close to that of Eu(III) bound to unmodified DNA. Thus, it is feasible that this species is Eu(III) bound primarily to DNA and not to the phenanthroline linker moiety. The prominence of this peak in **QB** and **AQB** compared to the single-stranded **SQ** (Figure 3) suggests that there is an additional Eu(III) binding pocket in the bulged region of the DNA.

Further comparison of the luminescence properties of Eu(III) bound to single-stranded **SQ** and bulged duplexes **QB** and **AQB** shows that the Eu(III) complex is quenched in the bulged duplexes in comparison to the single-stranded analogue. These differences are not attributed to water ligand quenching, because the luminescence lifetimes of the two major species in the three Eu(III) bound oligonucleotides are the same within experimental error. Luminescence intensity differences may arise from slight changes in symmetry at the Eu(III) ion or from a different distribution of Eu(III) ion bound to phenanthroline linker versus unmodified DNA. It is noteworthy that previous studies have shown quenching of the Eu(III) excited state by readily oxidized bases such as guanine upon intercalation of Eu(III) complexes with appended aromatic groups into a DNA duplex (*45*). However, this should lead to a decreased Eu(III) luminescence lifetime, which is not observed here.

An important criterion for the construction of metal ion binding sites in defined DNA structures is that metal ion binding should not disrupt DNA structure. Previous studies that had terpyridine linkers incorporated in hairpin loop structures showed that metal ion binding substantially destabilized these structures (*8*). Thermal melting experiments here support stacking of the phenanthroline linker on bases in the DNA helix and show that binding of Eu(III) does not markedly disrupt these structures. The relatively high thermal melting temperatures observed for Eu(III) complexes of bulges **AQB** and **QB** supports stabilization of the bulge-like structure through base stacking or perhaps electrostatic interactions. This bodes well for the preparation of structurally well-defined DNA containing Eu(III) phenanthroline units for sensing and imaging applications.

CONCLUSIONS

This work shows that Eu(III) binds to DNA containing a non-nucleosidic phenanthroline linker, which is incorporated either in single-stranded DNA or in a duplex as part of a bulged loop. Binding of Eu(III) to the modified DNA is 20−1100-fold stronger than to the simple **Q1** or **Q2** ligands, suggesting that other groups on the DNA interact with Eu(III) phenanthroline and/or that electrostatic interactions with the DNA strand increases binding strength. The non-nucleosidic phenanthroline linker has the advantage that it is a planar aromatic group that can stack on the nitrogenous bases of DNA for stabilization of nucleic acid structures as well as act as a luminescence sensitizer for Eu(III) (*25*). As shown here, incorporation of the phenanthroline linker into a site lacking an opposing base gives rise to DNA structures that bind Eu(III) without a marked change in stability. This study shows that it is feasible to incorporate a lanthanide(III) ion complex that retains a large number of water ligands into a site in DNA that contains secondary structure.

Single Molecule Sensitive Multivalent Polyethylene Glycol Probes for RNA Imaging

Aaron W. Lifland, Chiara Zurla, and Philip J. Santangelo*

Georgia Institute of Technology and Emory University, Atlanta, Georgia. Received September 2, 2009; Revised Manuscript Received December 14, 2009

The imaging of RNA in live cells presents a methodological challenge both in the mechanism by which the probes are delivered to the cell and in the sensitivity of the probe. Probes must be delivered to the correct cellular compartment and, once inside the cell, should bind to the target RNA rapidly and with enough sensitivity to detect small numbers of RNA molecules. Here, we report the characterization of a single-molecule sensitive, multivalent RNA imaging probe that utilizes an eight-armed poly(ethylene glycol) core. This probe allowed for the accurate imaging of the human respiratory syncytial virus (hRSV) genomic RNA when delivered into live cells using either reversible membrane permeabilization or TAT-peptide mediated membrane transduction. Neither reversible membrane permeabilization nor TAT mediated delivery proceeded through the endosomal pathway, and both delivery methods demonstrated fast binding kinetics of less than 10 min. Subcellular distributions of RNA were visualized in live cells, as well as RNA-protein colocalization, after fixation and immunostaining of the hRSV RNA binding protein N.

INTRODUCTION

In recent years, the imaging of RNAs in live cells has garnered growing attention with a variety of interesting methods developed for this purpose. This research has been driven by the increased appreciation for the role of post-transcriptional regulation on the function of RNA molecules (*1*), for the role of genomic RNA in viral assembly, and for the stress response of cells in pathogenesis (*2*). From previous research on RNA imaging methods, several design criteria have emerged. Imaging methods must be sensitive enough to detect RNA molecules, which are generally present in low copy numbers, and to enable the tracking of single RNA granules over time in live cells. For probe-based methods, delivery into the correct cellular compartment is critical in order for the probes to bind rapidly to their target. Delivery methods that result in accumulation of probe in the nucleus of cells or utilize endocytic vesicles can lead to nonspecific signal and degradation of the probe.

Single molecule imaging of native and nonengineered RNAs in live cells has recently been achieved by the use of multiply labeled tetravalent RNA imaging probes (MTRIPs) (*3*). These probes consist of four fluorescently labeled linear oligonucleotides bound together by a biotin−streptavidin linkage and recognize their intracellular target RNA through Watson−Crick base pairing. Signal is raised above background by the binding of 2−3 probes per target RNA and through the natural localization of the target RNA. Prior to the introduction of MTRIPs, single molecule studies of specific RNA localization and transport in live cells were limited to plasmid derived RNAs either containing binding site repeats for the MS2-GFP fusion protein (*4*) or containing binding site repeats for a molecular beacon (*5*). Plasmid derived RNAs offer tremendous methodological flexibility, but they preclude the study of native RNA or nonengineered viral RNA and do not allow for imaging native RNAs in vivo.

* Correspondence and requests for materials should be addressed to Philip J. Santangelo (philip.santangelo@bme.gatech.edu), PH: 404-385-2116, FAX: 404-894-4243.

While MTRIPs have proven to be capable of targeting a number of RNAs in various cell types with single RNA sensitivity, the use of a streptavidin core imparts some limitations. Probes with a streptavidin core have a maximum of four noncovalently bound ligands, which limits the number of fluorophores that can be added to a single probe. Streptavidin also contributes significantly to the molecular weight of the probe (∼53 kDa) and might affect the delivery pathway during cell penetrating peptide-mediated delivery (*6*).

Here, we report the synthesis and application of a multivalent RNA imaging probe that utilizes an eight-armed poly(ethylene glycol) (PEG) core. These probes overcome the main limitations imposed by streptavidin by increasing the number of bound ligands while reducing the molecular weight of the core (20 kDa). Moreover, the probes are stabilized by employing a covalent bond between the ligand and the core. PEG was chosen, since it has been shown to reduce toxicity, reduce nonspecific binding, and improve internalization when conjugated to macromolecules and utilized in vivo (*7*−*9*).

In order to demonstrate the efficiency of probe delivery and targeting, we utilized the genomic viral RNA (vRNA) of human respiratory syncytial virus (hRSV) as a model system. The localization of the vRNA of hRSV has been previously characterized by both molecular beacons and MTRIPs and showed high concentrations of viral RNA in cytoplasmic foci termed inclusion bodies (*3, 10, 11*). Delivery of probe into live cells was achieved using reversible membrane permeabilization with streptolysin O (SLO), which has been shown to allow for efficient and homogeneous delivery of macromolecules into the cytoplasm (*3*).The use of SLO results in ∼100% probe delivery efficiency and results in minimal cytotoxicity (*3*). Alternatively, as a delivery strategy, we also used the cell penetrating peptide (CCP) TAT, which, when conjugated to macromolecules, has been shown to transduce them across the plasma membrane (*12*). Indeed, the use of the PEG core permits an increase in the number of bound ligands and allows for the conjugation of delivery and targeting peptides along with RNA targeting oligonucleotides, while maintaining single molecule sensitivity. CPP-conjugated probes are currently of great interest in mo-

10.1021/bc9003876 © 2010 American Chemical Society
Published on Web 02/08/2010

lecular imaging, since they have the advantage of being suitable for use in vivo when labeled with near-infrared fluorophores. As with SLO, CPP based delivery allows for ~100% delivery efficiency and low cytotoxicity at low concentrations and eliminates the need for permeabilization of the membrane, reducing the complexity of the experimental procedure (*13*).

EXPERIMENTAL PROCEDURES

Multivalent PEG Probes. 2′-O-Me RNA/DNA chimeric oligonucleotides were synthesized by Biosearch Technologies, Inc. (Novato, CA) with the following sequence, 5′-**U**XTXT-TX**AAAAAXGGGGCAAAXAA**-3′, where the boldface type is 2′-*O*-Methyl RNA, the X is a dT-C6-NH2 (Supporting Information Figure S3), the 5′-**U** contains a free thiol group (Supporting Information Figure S4), and all others are DNA. The binding region is underlined. Probes were synthesized by first labeling the individual ligands with amine reactive NHS-ester fluorophores Atto 488 (ATTO-TEC GmbH), Cy3B (GE Healthcare), or Atto 647N (ATTO-TEC GmbH) using the manufacturer's protocols. Ligands were subsequently linked to 20 kDa eight-armed maleimide poly(ethylene glycol) (8-Arm PEG) cores (Supporting Information Figure S5) (NOF America) by incubation in a 64:1 molar ratio in PBS (Ambion) and 1 mM EDTA (Ambion) for 12 h at room temperature. 8-Armed PEG probes with TAT were synthesized by adding ligand, Cys-TAT (Anaspec, Cys-TAT 47−57), and 8-Arm-PEG cores in a 64:8:1 molar ratio in 10× PBS, and 1 mM EDTA for 12 h at room temperature. All probes were filtered to remove free ligand and reaction buffer using 30 kDa molecular weight cutoff Nanosep centrifugal devices (Pall Corp.). Purified probes were resuspended in nuclease free PBS and stored at 4 °C.

Cells and Virus. A549 human lung carcinoma cells (ATCC CCL-185) were cultured in DMEM (Lonza) with 10% FBS (Hyclone), 100 U/mL penicillin, and 100 U/mL streptomycin (Invitrogen). Cells were plated on glass coverslips one day prior to experiments. The A2 strain of human respiratory syncytial virus (hRSV) (Crowe laboratory, Vanderbilt University) was used at a MOI = 1 and a titer of 1×10^6 $TCID_{50}$ mL^{-1}.

Probe Delivery. Probes were delivered into A549 cells using reversible membrane permeabilization and peptide mediated delivery. For reversible membrane permeabilization, 2 U/mL Streptolysin O (SLO) (Sigma) were first reduced using 7.5 mM Tris(2-carboxyethyl)phosphine (TCEP) (Peirce) for 1 h at 37 °C. Infected and noninfected cells were rinsed using PBS (-Ca^{2+} -Mg^{2+}) (Thermo) and then incubated with delivery medium containing 0.2 U/mL SLO and 5 nM probe in PBS (-Ca^{2+} -Mg^{2+}) for 10 min at 37 °C. The delivery medium was then removed and replaced with complete growth media for 15 min. For TAT mediated delivery of probes, infected and noninfected cells were incubated in complete medium containing 5 nM TAT conjugated probe for 10 min at 37 °C, after which it was replaced with complete medium for 15 min. For live cell imaging experiments, growth media was replaced with Leibovitz's L15 medium (Invitrogen) immediately prior to image acquisition.

Immunostaining. After probe delivery, cells were rinsed in PBS (Ambion), fixed with 4% paraformaldehyde (Electron Microscopy Science) in PBS, permeabilized using 0.2% Triton-X 100 (Sigma), and blocked with 5% bovine serum albumin (Ambion). Cells were then incubated with a mouse monoclonal primary antibody against the hRSV N Viral Protein (Abcam), CD63 (Developmental Studies Hybridoma Bank), or LAMP-1 (Developmental Studies Hybridoma Bank) for 30 min at 37 °C and with a goat antimouse secondary antibody labeled with Alexa 488 (Invitrogen) for 30 min at 37 °C. After DAPI staining (Invitrogen), cells were mounted on slides using PVA with DABCO (Sigma).

Fluorescence Imaging. Samples were imaged using a Zeiss Axiovert 200 M epifluorescent microscope with a 63×/1.4 NA Plan-Apochromat objective, using Chroma 49002 ET-GFP (FITC/Cy2), 49004 ET Cy3, 49006 ET Cy5 filter sets, an EXFO excite 120 for fluorescence excitation, a Polytek PI objective piezo for taking stacks of images, and a Hamamatsu ORCA-ER AG for capturing digital images. Image *z*-stacks were acquired in 200 nm steps using Volocity (Improvision). Exposure times for probes on glass (Figure 2) were approximately 500 ms. Exposure times for probes in endosomal and lysosomal marker colocalization studies were 400 ms for noninfected cells (Figure 3c,d) and 30 ms for infected cells (Figure 3e,f). Exposure times for RSV vRNA in infected cells and controls, both fixed and live, were approximately 100 ms (Figures 4−5). Identical exposure times in Figures 4 and 5 were used for comparison of intensities.

Image Analysis. All images were deconvolved using the iterative restoration algorithm in *Volocity*. Histograms of mean fluorescence intensity were generated by identifying objects with minimum and maximum intensities set to 4 SD and 100 SD, respectively. Objects smaller than 1 point spread function were removed. Intensity Profiles were generated using *ImageJ* (NIH) Color Profiler plug-in and data tables were imported into *Sigma Plot 11* (Systat Software Inc.) for plotting. Manders overlap coefficient was calculated using *Volocity* software.

RESULTS AND DISCUSSION

hRSV specific ligands were composed of 2′-O-Methyl-RNA and DNA chimeric oligonucleotides with five amine-modified thymidines and a 5′ thiol modification (Supporting Information Figures S3 and S4). The oligonucleotide sequence was designed to be complementary to a gene-end-intergenic-gene-start sequence of hRSV which has three exact repeats in the hRSV genome and is not present in the human genome. The sequence used has previously been shown to be accessible by antisense knockdown experiments, molecular beacon imaging, and MTRIP imaging (*3, 11, 14*). The targeting of three repeats per RNA raises signal significantly above background for even a single RNA per point spread function.

The amine-modified thymidines of the ligands were used to conjugate NHS-ester fluorophores, and the thiol group was used to link the individual ligands to the PEG cores, which were functionalized with eight maleimide active groups (Figure 1a Supporting Information Figure S5). Absorption spectroscopy showed that, on average, 3 dyes were conjugated to each ligand and 6.5 ligands were conjugated to each PEG core (Supporting Information). Probes utilizing the TAT CPP contained an average of 4 oligonucleotides ligands and 1 TAT peptide (Supporting Information). By increasing the brightness of the probes through the use of multiple ligands, rather than increasing the number of fluorophores per ligand, self-quenching was minimized and ligand size was kept to approximately 20 bases. The fluorophores (Atto 488, Cy3B, and Atto 647N) were chosen for their strong absorption in visible wavelengths commonly used for imaging, high quantum efficiency, and low triplet state excitation. The use of ligands with a 2′-O-Methyl backbone conferred increased affinity for the target mRNA, increased signal-to-noise ratio, and nuclease resistance (*15−18*).

In order to test the ligands for nonspecific aggregation, the probes were labeled with Atto 488, Cy3B, or Atto 647N fluorophores and were adsorbed onto a cover glass at 1 nM concentration. Using wide-field fluorescence microscopy, the probes were visible as distinct spots on the glass without apparent aggregation (Figure 2a). Lack of aggregation was confirmed both by fluorescence intensity histograms (Figure 2b−d) and by the lack of colocalization of probes labeled with different fluorophores. When the probes were delivered at 5 nM

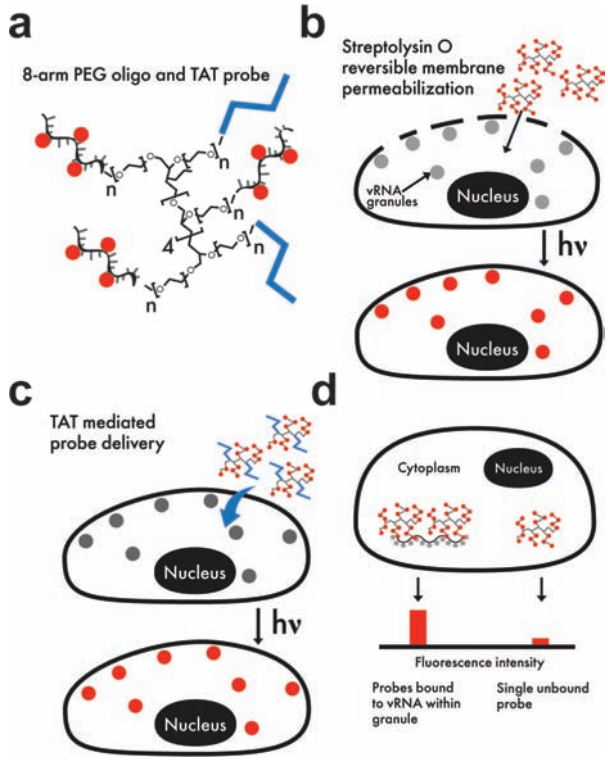

Figure 1. Design, delivery, and imaging of probes. (a) Schematic of the 8-arm PEG conjugated to fluorescently labeled oligonucleotides and TAT peptide (blue). (b) Cells, reversibly permeabilized with streptolysin O, allow for diffusion of probes into the cytoplasm. Probes bound to target RNA are visualized under a fluorescence microscope. (c) Transduction of TAT-PEG probe without streptolysin O permeabilization. (d) Detection of RNA is achieved through the increased signal intensity when multiple probes are bound to a single RNA.

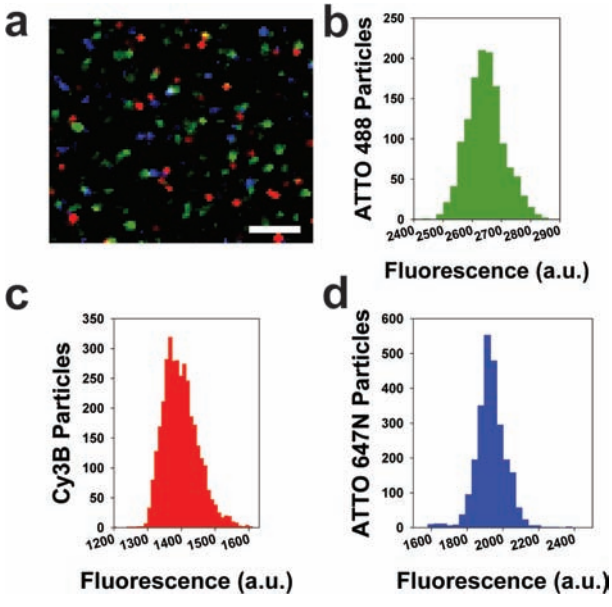

Figure 2. Characterization of single probes on glass. (a) Atto 488 (green), Cy3B (red), and Atto 647N (blue) labeled probes were adsorbed onto glass and analyzed for the colocalization and aggregation. Corresponding intensity histograms (b, c, and d) show a unimodal distribution consistent with single probes. Scale bar is 2 μm.

concentration in A549 cells either by SLO permeabilization (Figure 3a) or by TAT conjugation (Figure 3b), similar spots were visible as seen in the extended focus images. Extended focus images are a projection of all the *z*-planes into a two-dimensional image. The images were presented in this format

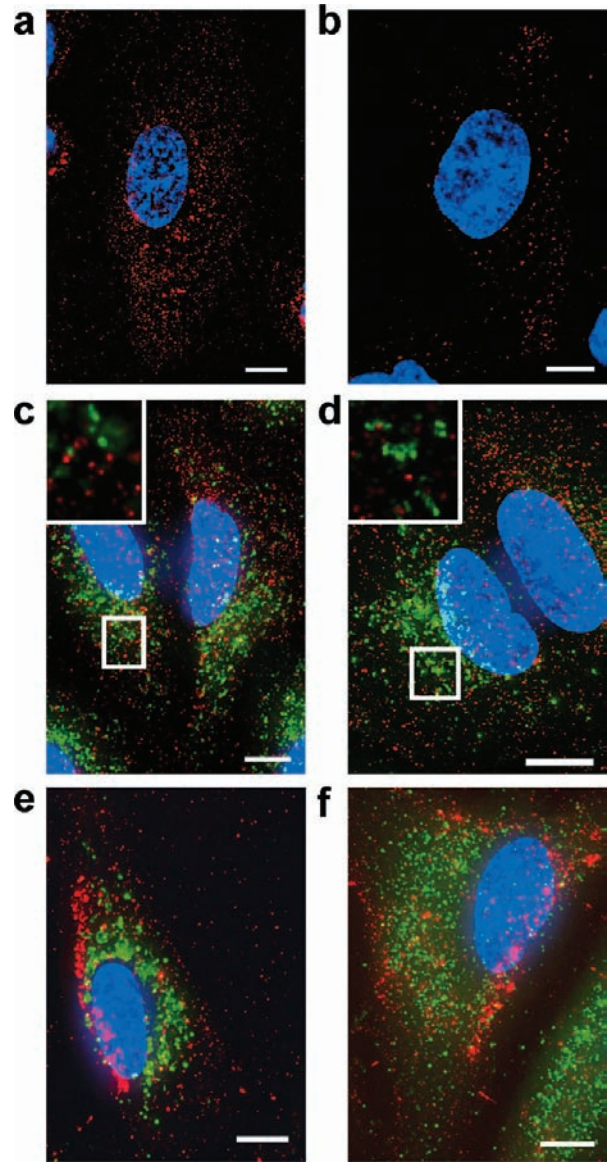

Figure 3. Distribution of PEG probes targeted against hRSV in A549 cells and colocalization with endosomal marker CD63 and lysosomal marker LAMP1. Extended focus of noninfected cells with probe (red) delivered (a) by SLO permeabilization and (b) by TAT conjugation. Extended focus of noninfected cells with probe (red) delivered by TAT conjugation and (c) stained for CD63 (green) and (d) LAMP1 (green). Insets in c and d show single plane from boxed region. Extended focus of hRSV infected cells with probe (red) delivered by TAT conjugation and stained for (e) CD63 (green) and (f) LAMP1 (green). Scale bars are 10 μm.

to include all the relevant signal within the three-dimensional cell. The uniformity of the signal within the cytoplasm indicated that probe was not aggregating due to nonspecific interaction with cellular components.

Recent reports have shown that macromolecule uptake by TAT can proceed through an endocytic pathway, even if this has been suggested to be dependent upon the conjugated macromolecule (*19, 20*). Nonendosomal transduction of the probes is recommended, since it reduces the exposure of the probe to nucleases and eliminates the need for endosomal releasing agents such as poly(propylacrylic acid) to be added to the delivery medium. In order to determine whether or not TAT conjugated probes entered cells through the endosomal pathway, TAT-probes were delivered at 5 nM into uninfected and hRSV infected cells that were subsequently fixed and immunostained for endosomal and lysosomal markers. Cells

were immunostained for cluster of differentiation 63 (CD63) (Figure 3c,e) and lysosomal associated membrane protein 1 (LAMP1) (Figure 3d,f). Multicolor images were obtained by wide-field fluorescence microscopy and deconvolution, and revealed little colocalized signal between the TAT-conjugated probe and protein markers. In these figures, extended views were shown to illustrate the signal within the cell. Some apparent colocalization may be perceived using this presentation due to the merging of signal from different *z*-planes. Inset images from one *z*-plane were included to show the lack of colocalization qualitatively. This was confirmed quantitatively by low Manders overlap coefficients ($R < 0.1$) for the colocalization of the probe with CD63 and with LAMP1 using three-dimensional reconstructions of the images.

In order to demonstrate the applicability of these probes for live cell imaging, the viral genomic RNA of hRSV was imaged in A549 cells both live and after fixation and immunostaining of the hRSV N protein. The hRSV N protein has been shown to reside within inclusion bodies, to colocalize with the hRSV genome in imaging experiments, and to bind to hRSV vRNA (*3, 21*). Co-localization with the N protein served to demonstrate the accurate targeting of the probe to the vRNA. A549 cells were infected with the A2 strain of hRSV and incubated for 24 h. Probes were then delivered at 5 nM via SLO membrane permeabilization and allowed to recover. Subsequently, cells were either fixed with 4% paraformaldehyde for immunostaining or stained with Hoechst 33342 for live cell imaging. Cells fixed and immunostained for the hRSV N protein showed vRNA localization near the plasma membrane and exhibited colocalization with hRSV N protein similar to previously reported data (Figure 4a) (*3*). In order to quantify the degree of colocalization between the vRNA and N protein, Manders overlap coefficients were generated using voxel intensities. Overlap coefficients were generally high, typically $R > 0.8$. Figure 4a shows a representative cell with an overlap coefficient of 0.843. In addition to whole cell automatic colocalization, intensity profiles showed correlation between the hRSV genomic and N protein signal (Figure 4c,d). In the live cell images, similar localization of the vRNA was observed with vRNA predominantly residing in inclusion bodies close to the cell membrane (Figure 4e). Delivery of probe into noninfected cells served as a negative control and resulted in little to no signal when imaged under the same conditions as the infected cells (Figure 4b,f). Interestingly, probes delivered into noninfected cells demonstrated no significant nuclear background.

We subsequently delivered the TAT conjugated probes at 5 nM concentration into hRSV infected and noninfected A549 cells. These probes revealed a similar pattern of RNA localization as the SLO-delivered ones in infected cells both live and upon fixation. In the latter case, colocalization with the viral N protein at the plasma membrane confirmed efficient vRNA targeting (Figure 5a,c,d). In noninfected cells, TAT-conjugated probes exhibited little to no signal (Figure 5b) and appeared to be homogeneously distributed in the cytoplasm (Figure 3b). While the mechanism for TAT-mediated probe delivery is not yet fully understood, our data strongly suggest that it does not involve an endosomal pathway and are consistent with previous reports (*20, 22*). In particular, Vives et al. (*22*) reported that fluorescently labeled TAT peptides were efficiently taken up by cells within 5 min at concentrations as low as 100nM, and the internalization process was shown not to involve an endocytic pathway. The sensitivity of the fluorescein reporter precluded measurements using TAT concentrations below 100nM (*22*). In our case, uptake of probes occurred in less than 10 min at a concentration of 5 nM. Moreover, our probes showed no colocalization with endosomal and lysosomal markers, and colocalized well with the N protein, yielding a

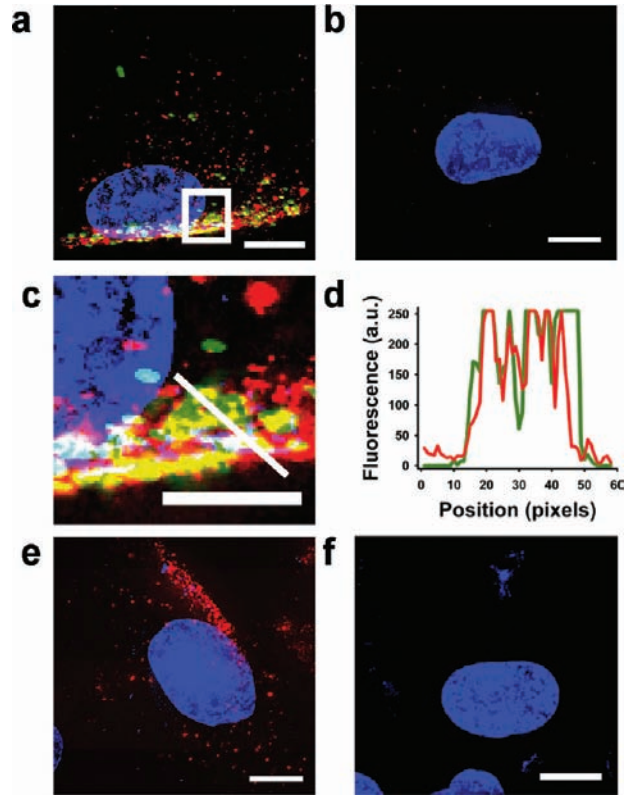

Figure 4. SLO-mediated delivery of PEG probes targeted against hRSV and colocalization with the viral protein N. (d) Intensity profile along line in Figure 4c. Distribution of probes (red) into live hRSV (e) infected and (f) noninfected cells. Nuclei were stained using Hoechst 33342. Scale bars in a,b,e,f are 10 μm. Scale bar in c is 5 μm.

distribution similar to the one observed in SLO membrane permeabilization-based delivery. Additionally, live cell imaging experiments confirmed the results and indicated that cell fixation does not alter probe localization (Figure 5e,f).

CONCLUSION

The importance of trans-acting factors, such as RNA binding proteins and noncoding RNAs, in the regulation of mRNA and viral RNAs has recently garnered increased attention (*23*). These factors are responsible for the post-translational regulation of mRNAs and for the late stages of the viral life cycle such as replication and packaging of viral genomic RNA (*24*). The RNA molecule, along with trans-acting factors, ultimately determines the function of the RNA. In vitro methods for studying these ribonucleoprotein complexes (RNPs) give only an averaged view of the function of these complexes. However, within the cellular context, these RNPs are often heterogeneous, and as such, methods are needed that enable the study of the spatial and temporal dynamics of RNA and interaction with RNA binding proteins within the cell (*25*). These methods must be sensitive because of the low concentration of specific RNAs inside the cell, and must be able to provide accurate subcellular localization of RNA.

Using an eight-arm activated PEG core as a multifunctional platform, we have developed a single molecule sensitive RNA imaging probe. Fluorescently labeled oligonucleotides bound to the PEG core were delivered into live cells using two delivery methods, reversible membrane permeabilization and TAT-mediated transduction. Individual probes were visible both on glass and inside the cells using widefield fluorescence micros-

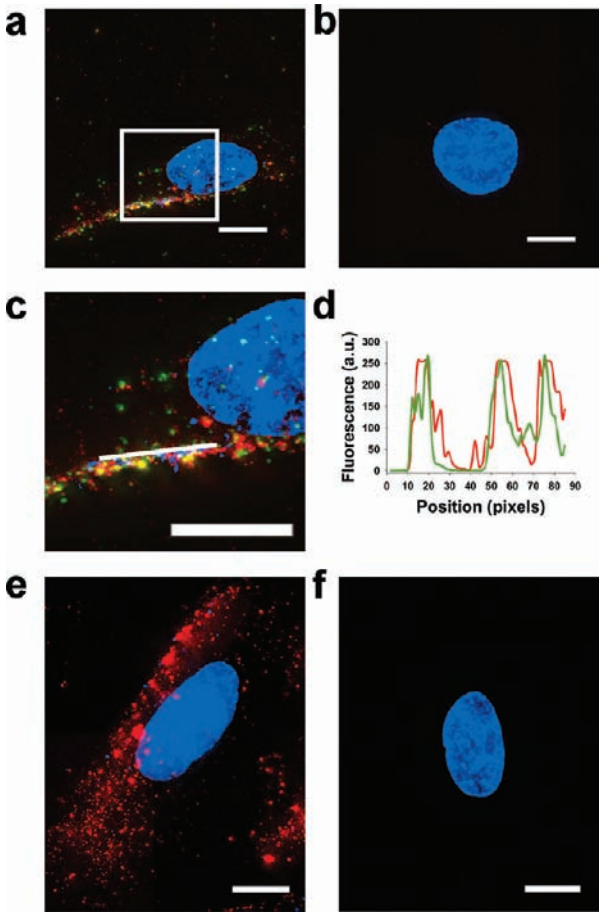

Figure 5. TAT-mediated delivery of PEG probes targeted against hRSV and colocalization with the viral protein N. copy. TAT-mediated delivery did not result in accumulation of probes in endosomes, nor did it result in the nonspecific aggregation of probes inside the cell. To demonstrate the accurate targeting of RNA in the cell, probes targeted against RSV vRNA were delivered into infected cells and demonstrated subcellular localization at the plasma membrane, colocalization with known vRNA binding proteins, and signal substantially higher than in mock infected controls. Signal was observed in less than 10 min regardless of the delivery method and in the presence of probe concentrations of 5 nM. The rapid binding of the probes to their target is an essential feature for the study of RNA dynamics, because it allows for the observation of phenomena that occur on short time scales. In addition to this, the low concentration of the probes contributes to reduce nonspecific binding. Our results suggest that TAT (or other CPPs) conjugated PEG probes may allow for the imaging of specific RNAs in vivo when combined with fluorophores that absorb in the near-infrared wavelengths (*26*).

ACKNOWLEDGMENT

This study was supported by the Georgia Institute of Technology administration (P.J.S.). Strain A2 of hRSV was a kind gift from James E. Crowe Jr. The monoclonal antibodes for CD63 and LAMP1 developed by J. Thomas August and James E. K. Hildreth were obtained from the Developmental Studies Hybridoma Bank developed under the auspices of the NICHD and maintained by The University of Iowa, Department of Biology, Iowa City, IA 52242.

Targeted Dendrimeric Anticancer Prodrug: A Methotrexate-Folic Acid-Poly(amidoamine) Conjugate and a Novel, Rapid, "One Pot" Synthetic Approach

Yuehua Zhang, Thommey P. Thomas, Ankur Desai, Hong Zong, Pascale R. Leroueil, Istvan J. Majoros, and James R. Baker, Jr.*

Michigan Nanotechnology Institute for Medicine and Biological Sciences, Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan 48109. Received September 8, 2009; Revised Manuscript Received December 3, 2009

A targeted dendrimeric anticancer prodrug, a conjugate of generation 5 (G5) polyamidoamine (PAMAM) dendrimer, folic acid (FA), and methotrexate (MTX), has been successfully synthesized by using a novel "one pot" approach which is simple, reproducible, and feasible for large-scale synthesis. All dendrimer products have been characterized by ^{1}H NMR, MALDI-TOF, GPC, and HPLC. With this new method, the ratio of FA versus MTX attached to the dendrimer can be easily tuned to achieve the desired therapeutic effect. A new analytical approach for calculating the numbers of FA and MTX attached to the dendrimer has been established. In vitro studies performed on FA receptor-expressing KB cells show that the new conjugate has a similar affinity and cytotoxic potency to G5-FA-MTX synthesized using the traditional multiple-step approach.

INTRODUCTION

PAMAM dendrimers are highly branched, narrowly dispersed synthetic macromolecules with well-defined chemical structures. PAMAM dendrimers can be easily modified and conjugated with multiple functionalities such as targeting molecules, imaging agents, and drugs (*1*). They are water-soluble, biocompatible, and cleared from the blood through the kidneys (*2*), which eliminates the need for biodegradability. Because of these desirable properties, PAMAM dendrimers have been widely investigated for drug delivery (*3*−*7*), gene therapy (*8*−*10*), and imaging applications (*11*).

Folic acid belongs to the vitamin B family. It is important in cell division because it participates in the biosynthesis of nucleotide bases. There are two membrane-bound folic acid receptors (FR), FR-α and FR-*β*. Both of the 38 kDa FR isoforms bind folic acid with a high affinity (KD < 1 nM) (*12*). The expression of FR in normal tissues is low and restricted to various epithelial cells, such as those of the placenta, choroid plexus, lungs, thyroid, and kidneys (*13, 14*). However, the folate receptors are overexpressed in many epithelial cancer cells, including breast, ovary, endometrium, kidney, lung, head and neck, brain, and myeloid cancers (*14*−*17*), and is internalized into cells after ligand binding (*18*). Although FR is expressed in some normal tissues, as the normal epithelial cells but not the tumor cells are highly polarized and as the FR has been shown to be exclusively localized in the apical side of the cells (e.g., the urine side in kidney), an FR-targeted drug delivery has been shown to cause only minimum nonspecific cytotoxicity when administered systemically (*19, 20*). Tumor-selective targeting has been achieved by an FA-targeted PEG-gemcitabine prodrug (*21*), FA-conjugated multiarm-block copolymer-doxorubicin (*22*), FA-conjugated liposomes encapsulating an antineoplastic drug (*23*) or antisense oligonucleotides (*24*), FA-conjugated protein toxin (*25*), and FA-derivatized antibodies or their Fab/scFv fragments binding to the T-cell receptor (*26*). In vivo studies from our own group showed that the administration of multivalent, folate-targeted dendrimer-methotrexate conjugates resulted in significantly lower toxicity and a 10-fold enhancement in efficacy compared to free methotrexate at an equal cumulative dose (*5, 27*).

* jbakerjr@umich.edu.

In our previous studies, FA and MTX were conjugated to PAMAM dendrimers through amide and ester linkages, respectively, using a multiple-step synthetic route (*5, 6, 28*). The synthetic steps involved partial acetylation of the dendrimer, conjugation of FA using EDC chemistry through amide bonds, glycidation of the remaining amino groups, and finally conjugation of MTX through ester linkage through some of the glycidol moieties. The variability in efficiency of each of these synthetic steps resulted in batch-to-batch reproducibility problems, which limited the application of this technology. In order to address this issue, we have developed a simplified approach for synthesizing multifunctional dendrimers that is amenable to large-scale synthesis. In this approach, the dendrimer is initially fully glycidated and the FA and MTX are simultaneously conjugated to the dendrimer through ester linkages in a "one pot" reaction.

EXPERIMENTAL PROCEDURES

Materials. Amine-terminated G5-PAMAM dendrimer (G5-NH_2) was purchased from Dendritech, Inc. (Midland, MI, USA) and characterized at the Michigan Nanotechnology Institute for Medicine and Biological Sciences, University of Michigan. All chemicals were purchased from Sigma-Aldrich and used as received, unless otherwise specified. Water used in all experiments was purified by a Milli-Q Plus 185 water purification system (Millipore, Bedford, MA) with resistivity higher than 18 MΩ cm. The Spectra/Por dialysis membranes (MWCO 1000 and MWCO 10 000) and phosphate buffer saline were acquired from Fisher.

Nuclear Magnetic Resonance Spectrometry (NMR). ^{1}H NMR spectra were recorded on a 400 MHz Varian Inova 400 nuclear magnetic spectrometer in dimethyl sulfoxide (DMSO-d_6).

Matrix-Assisted Laser Desorption Ionization-Time of Flight (MALDI-TOF) Mass Spectrometry. MALDI-TOF mass spectra were recorded on a Waters TofSpec-2E spectrometer (Beverly, MA, USA), running in linear mode with the high-mass PAD detector, and 2,5-dihydroxybenzoic acid (DHB) in acetonitrile/water (50:50, v/v) was used as the matrix. The instrument was calibrated with bovine serum albumin (BSA, $M_w = 66.43 \times 10^3$) in sinapic acid. The data were acquired and processed by *MassLynx 3.5* software.

High-Performance Liquid Chromatography (HPLC). A reverse-phase HPLC instrument consisting of a System GOLD 126 solvent module, a model 507 auto sampler equipped with a 100 μL loop and a model 166 UV detector (Beckman Coulter, Fullerton, CA USA), and a Phenomenex (Torrance, CA, USA) Jupiter C5 silica-based HPLC column (250 × 4.6 mm, 300 Å) were used for analysis of the products in this work. Two Phenomenex safety guards were installed upstream of the HPLC column. The mobile phase for elution of the PAMAM dendrimer products was a linear gradient beginning with 100:0 water/acetonitrile (ACN) (both containing 0.14 wt % TFA) at a flow rate of 1 mL/min., reaching 20:80 (or 50:50) within 35 min. Trifluoroacetic acid (TFA) (0.14 wt % in both water and ACN) was used as a counterion to make the dendrimer-conjugate surface hydrophobic. All samples were dissolved in the aqueous mobile phase (water containing 0.14% TFA). The injection volume in each case was 35 μL with a sample concentration of 1 mg/mL, and the detection wavelength was 210 or 280 nm. The analysis was performed using Beckman's System GOLD Nouveau software.

Gel Permeation Chromatography (GPC). GPC was used to evaluate the molecular weights and molecular weight distribution of the G5-PAMAM dendrimer, dendrimer derivatives, and conjugates. GPC experiments were performed on an Alliance Waters 2690 separation module (Waters Corp., Milford, MA) equipped with a Waters 2487 dual wavelength UV absorbance detector (Waters Corp.), a Wyatt Dawn HELEOS light scattering detector (Wyatt Technology Corp., Santa Barbara, CA), an Optilab rEX differential refractometer (Wyatt Technology Corp.), and TosoHaas TSK-Gel Guard PHW 06762 (75 × 7.5 mm, 12 μm), G 2000 PW 05761 (300 × 7.5 mm, 10 μm), G 3000 PW 05762 (300 × 7.5 mm, 10 μm), and G 4000 PW (300 × 7.5 mm, 17 μm) columns. Column temperature was maintained at 25 ± 0.2 °C with a Waters temperature control module. Citric acid buffer (0.1 M) with 0.025% sodium azide in water, pH 2.74, was used as a mobile phase at a flow rate of 1 mL/min. The sample concentration was 2 mg/mL, with an injection volume of 100 μL. The number average molecular weight M_n, weight average molecular weight M_w and polydispersity index (PDI) were calculated using *ASTRA 5.34.14* software (Wyatt Technology Corp.)

Synthesis of Hydroxyl-Terminated G5 PAMAM Dendrimer (G5-Gly-OH 2). G5-GLY−OH was synthesized using methods similar to that which has been previously reported (*28*−*30*). G5-NH_2 (500 mg, 0.0174 mmol) was dissolved in methanol (10 mL) in a 50 mL flask. To the solution was added glycidol (442 mg, 4.77 mmol). The mixture was stirred at room temperature under nitrogen overnight. The mixture was dialyzed against water (4 × 4 L) with a cellulose dialysis membrane (MWCO = 1000) for 48 h and was dried by lyophilization (3 days) to yield G5-Gly-OH as a white solid (677 mg, 85%).

Synthesis of a Conjugate of G5 PAMAM Dendrimer, Folic Acid, and Methotrexate (G5-FA-MTX) 3. A solution of G5-Gly-OH **2** (200 mg, 5.06×10^{-3} mmol), MTX (34.1 mg, 0.075 mmol), and FA (17.7 mg, 0.040 mmol) in dimethyl sulfoxide (15 mL) was stirred at room temperature under nitrogen. To the solution was added 2-chloro-1-methylpyridinium iodide (35.3 mg, 0.138 mmol) and 4-(dimethylamino)pyridine (33.7 mg, 0.276 mmol). The mixture was further stirred overnight at room temperature and then poured into water (75 mL). The product was purified by dialysis against isotonic phosphate buffered saline (PBS) buffer (3 × 4 L) and then water (3 × 4 L) with a cellulose dialysis membrane (MWCO = 10 000) over 48 h. The final product was dried by lyophilization (3 days) to yield G5-FA-MTX as a yellow solid (231 mg, 98%).

Measurement of Cellular Binding and Cytotoxicity. KB cells, a subline of the cervical carcinoma HeLa cells (ATCC, Manassas, VA, USA), were grown as a monolayer cell culture at 37 °C and 5% CO_2 in FA-deficient RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS). The 10% FBS provided an FA concentration equivalent to that present in the human serum (~20 nM).

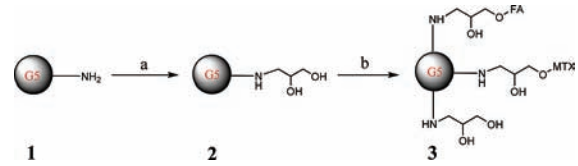

Figure 1. Synthesis of a G5-FA-MTX conjugate using folic acid (FA), methotrexate (MTX), and G5 polyamidoamine (PAMAM) dendrimer. Reagents and conditions: (a) glycidol, methanol, room temperature, 24 h; (b) FA, MTX, 2-chloro-1-methylpyridinium iodide, 4-(dimethylamino)pyridine, dimethyl sulfoxide, room temperature, 24 h.

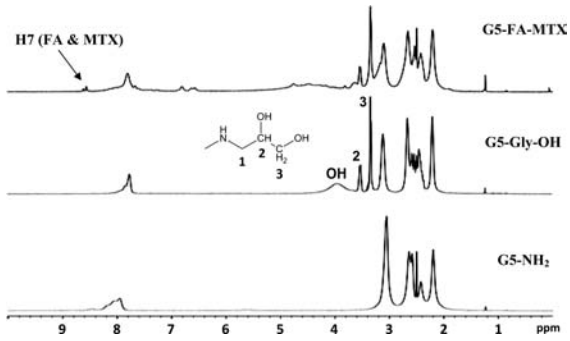
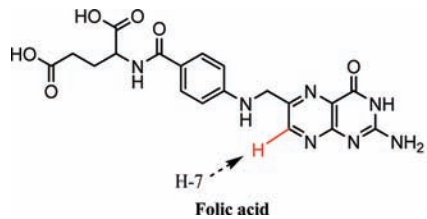
For assessment of the cellular binding of the synthesized conjugate, we have utilized the competition of the conjugate with another previously synthesized dendrimer conjugate ("G5-FI-FA-MTX") that contained 4 molecules of the fluorescent dye fluorescein isothiocyanate (FI), 5 molecules of FA, and 7 molecules of MTX (*7*). The KB cells, plated in 24-well plates, were treated with a mixture of 100 nM of the G5-FI-FA-MTX and varying concentrations of the newly synthesized G5-FA-MTX, added as a mixture at the same time. The cells were incubated at 37 °C for 1 h, and the FL1 fluorescence of 10 000 cells was determined by flow cytometry, as described previously (*7*).

For the cytotoxicity experiments, the cells were seeded in 96-well microtiter plates (3000 cells/well) in medium containing dialyzed serum. Two days after plating, the cells were treated with the dendrimer conjugates in tissue culture medium under the indicated conditions. A colorimetric "XTT" (sodium 3-[1-(phenylaminocarbonyl)-3,4-tetrazolium]-bis(4-methoxy-6-nitro) benzene sulfonic acid hydrate) assay (Roche Molecular Biochemicals, Indianapolis, IN) was performed, following the vendor's protocol. After incubation with the XTT labeling mixture, the microtiter plates were read on an ELISA reader (Synergy HT, BioTek) at 492 nm with the reference wavelength at 690 nm (*7*).

RESULTS AND DISCUSSION

Synthesis. In this study, G5-NH_2 **1** was used as the starting material to synthesize the targeted dendrimeric anticancer drug G5-FA-MTX **3** (Figure 1). The number of available primary amino groups on the surface of G5-NH_2 is 110 (*31*). Starting with G5-NH_2 **1**, the amino groups of G5-NH_2 react with glycidol to yield G5-Gly-OH **2**. In this reaction, excess glycidol was used (glycidol/NH_2 = 3:1) to fully cap the free amino groups on the surface of **1**. Each amino group can theoretically react with two molecules of glycidol to form a tertiary amine. However, calculations based upon the MALDI indicated that the hydroxylation reaction was incomplete, as previous reported by us (*30*). It is hypothesized that steric hindrance prevents some of the terminal amines residing inside the dendrimer from being available for hydroxylation, resulting in an incomplete reaction (*32*). The G5-Gly-OH **2** was purified by dialysis with a cellulose dialysis membrane against water. MTX and FA were attached to the hydroxyl groups of the G5-Gly-OH **2** through ester bonds in a one-pot reaction, using 2-chloro-1-methylpyridinium iodide and 4-(dimethylamino)pyridine as the coupling reagents (Mukaiyama reagent), which is efficient for preparation of esters from equimolar amounts of free carboxylic acid and alcohol. The reaction was conducted in DMSO under nitrogen at room temperature for 24 h. The final product, conjugate **3**, was purified by dialysis with a cellulose dialysis membrane against PBS buffer and then water. The G5-FA-MTX is highly water-soluble, even with 5 FAs and 15 MTXs attached. It was also observed that the numbers of FA and MTX attached on the surface of the PAMAM dendrimer can be easily and reproducibly





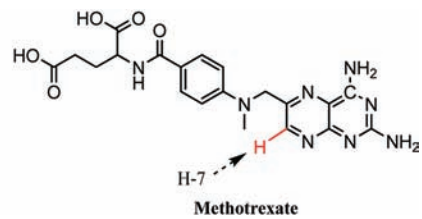


Figure 2. Comparison of the ^{1}HNMR spectra of the G5 PAMAM dendrimer, the hydroxyl-terminated G5 PAMAM dendrimer, and the conjugate of G5 PAMAM dendrimer, FA, and MTX.

adjusted by changing the feeding ratio of FA and MTX in the feed. The numbers of FA and MTX attached on the PAMAM dendrimer were calculated using results from MALDI-TOF, GPC, and ^{1}H NMR. Despite the fact that we have used dialysis as a purification step in these procedures, the application of ultrafiltration would make the synthetic procedure feasible for scale-up synthesis.

^{1}H NMR Spectroscopy. ^{1}H NMR was used to confirm the surface capping of the terminal amines of the dendrimer with glycidol and the attachment of the FA and MTX to the hydroxyl group of the G5-Gly-OH (Figure 2). The ^{1}H NMR of the G5 PAMAM dendrimer shows 6 broad peaks, which correspond to the protons of the amide bond (CONH) at 7.95 ppm, the amino groups (NH_2), the internal methylene groups (CH_2), and those CH_2 next to the amino groups at 3.05, 2.64, 2.58, 2.42, and 2.20 ppm. The ^{1}H NMR spectrum of the G5-Gly-OH clearly shows three new peaks, compared with that of the G5-NH_2. The peak at 3.348 ppm (peak 3) is the resonance of protons of the CH_2 at position 3 of the 2,3-dihydroxylpropyl group. The peak at 3.542 ppm (peak 2) belongs to the CH at position 2 of the 2,3-dihydroxylpropyl group. The broad peak at 3.961 ppm is attributed to two hydroxyl groups of the 2,3-dihydroxylpropyl group. The peak at about 2.47 ppm (*30*) belongs to the protons of the CH_2 at position 1 of the 2,3-dihydroxylpropyl group, which overlaps with peaks associated with the internal protons of the G5-NH_2. Compared with the spectrum of the G5-Gly-OH, the spectrum of the G5-FA-MTX shows additional peaks. Some of the peaks overlap with the peaks of the G5-Gly-OH. The H-7 peaks of the conjugated FA and MTX are present at 8.617 ppm and 8.561 ppm, respectively. They are sharp and well-separated single peaks. The integration ratio of these two peaks represents the molar ratio of MTX and FA, because both MTX and FA contain only one H-7 (Figure 3). Significantly, it is also found that the integration ratio of these two protons is proportional to the feed ratio of MTX and FA in the "one-pot" reaction (Table 1). Therefore, the actual numbers of FA and MTX conjugated to the surface of the dendrimer can be calculated using this integration ratio and molecular weight gain from G5-Gly-OH **2** to G5-FA-MTX **3**, as measured by MALDI-TOF and GPC.

Folic acid

Methotrexate

MALDI-TOF Mass Spectrometry. MALDI-TOF mass spectrometry has been proven to be an important technique for characterization of dendrimers and dendrimer derivatives. It not only provides the average molecular weight, but also gives information about the success of each conjugation reaction and the number of molecules that have been conjugated. Figure 4 shows the MALDI-TOF mass spectra of the G5-NH_2, G5-Gly-OH, and G5-FA-MTX. The molecular weight increase for each species along the synthetic pathway is clearly seen and demonstrates that the hydroxylation (first step) and conjugation (second step: the "one pot" reaction) have occurred. The molecular weight gain of the G5-Gly-OH from the G5-NH_2 is due to the attachment of the 2,3-dihydroxylpropyl group. The average number of 2,3-dihydroxylpropyl groups attached to each amino group may be calculated by the difference divided by the molecular mass of the 2,3-dihydroxylpropyl group and the number of the amino groups on the surface of the dendrimer. The molecular weight increase from the G5-Gly-OH to the G5-FA-MTX is due to the addition of both FA and MTX. The numbers of FAs and MTXs attached to the dendrimer can be calculated using eqs 1 and 2, which are based on the molecular weight gain from the G5-Gly-OH to the G5-FA-MTX, as measured by MALDI-TOF or GPC, and the integration ratio of H-7 of the conjugated FA and MTX. Calculation results have been listed in Table 1.

$$N_{FA} = \frac{\Delta MW \times F_{FA/(MTX+FA)}}{MW_{FA} - 18} \quad (1)$$

$$N_{MTX} = \frac{\Delta MW \times F_{MTX/(FA+MTX)}}{MW_{MTX} - 18} \quad (2)$$

where N_{FA} = molecules of folic acid attached to each PAMAM dendrimer molecule; N_{MTX} = molecules of MTX attached to each PAMAM dendrimer molecule; ΔMW = molecular weight gain of the conjugate from hydroxyl-terminated PAMAM dendrimer; F_{FA} = ^{1}H NMR integration fraction of H-7 (FA over FA and MTX); F_{MTX} = ^{1}H NMR integration fraction of H-7 (MTX over FA and MTX); MW_{FA} = molecular weight of FA; MW_{MTX} = molecular weight of MTX.

High-Performance Liquid Chromatography (HPLC). High-performance liquid chromatography (HPLC) is a widely accepted method for separation and purification of small molecules and macromolecules and is commonly used in chemical, pharmaceutical, and biotechnology laboratories. Recently, HPLC has been used as a vital tool to analyze PAMAM dendrimers of various generations and terminal groups, as well as their conjugates (*33*−*35*). In this study, we used HPLC to evaluate the purity and molecular weight distributions of the conjugates. Small molecule impurities such as unreacted FA, MTX, coupling reagent, and byproduct are very easily differentiated from the dendrimers (G5-NH_2, G5-Gly-OH, and G5-FA-MTX) by HPLC due to the significant difference in retention time. Figure 5 is a representative chromatogram of the conjugate (G5-FA-MTX) under UV 280 nm, which shows a single symmetric peak of the conjugate and a few small impurity peaks attributed to the presence of less than 0.1% free FA, MTX, and other impurities. The result also indicates that the FA and MTX have been successfully attached to the G5-Gly-OH, resulting in a very narrow molecular weight distribution, which is in agreement with the GPC results shown below.

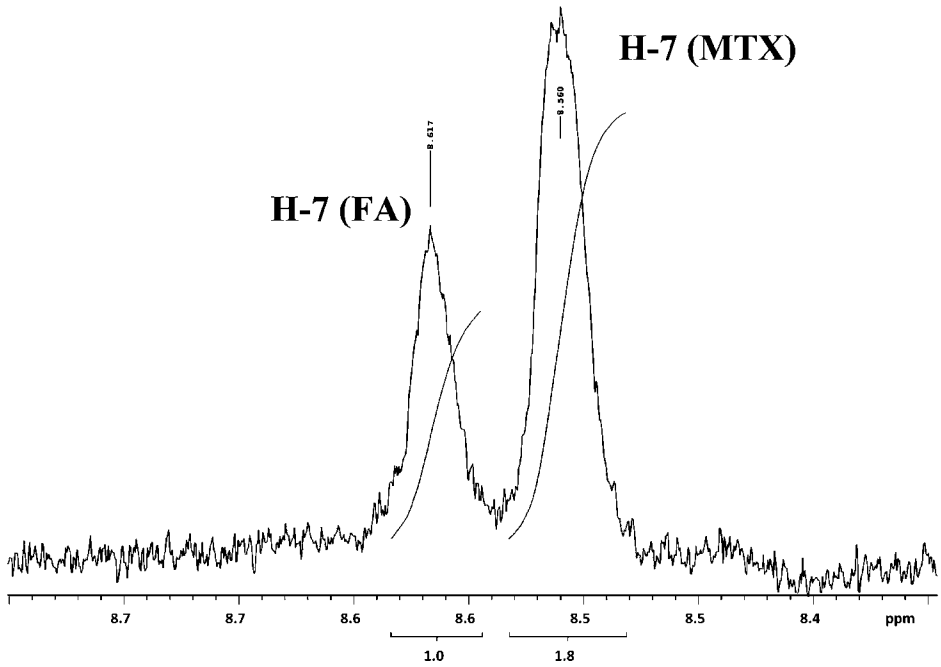

Figure 3. Enlarged scale of the ^{1}H NMR spectrum of proton-7 of conjugated FA and MTX.

Table 1. Reaction Feed Molar Ratio of MTX/FA/G5-Gly-OH, ^{1}H NMR Integration Ratio of H-7 of MTX/FA, and Numbers of MTX and FA on the Conjugate (G5-FA-MTX)

reaction feed molar ratio of MTX/ FA/ G5-Gly-OH	^{1}H NMR integration ratio of H-7s (MTX/FA)	average number of MTX and FA attached on PAMAM
10:7:1	1.38:1.00	6.79 and 5.20
15:8:1	1.86:1.00	9.44 and 5.22
23:8:1	2.83:1.00	14.90 and 5.42
15:10:1[a]	1.33:1.00	9.26 (±0.28[b]) and 7.18 (±0.1[c])

[a] Three batches of parallel synthesis under the same condition: G5-Gly-OH (50 mg), MTX (8.54 mg), FA (5.52 mg), 2-chloro-1-methylpyridinium iodide (8.00 mg), 4-(dimethylamino)pyridine (7.65 mg), DMSO (2.5 mL), N_2, 24 h, cellulose membrane dialysis (6 times 4 L over 48 h), and lyophilization (72 h). Figure 4. MALDI-TOF mass spectra of the G5 PAMAM dendrimer, the hydroxyl-terminated G5 PAMAM dendrimer, and the conjugate of G5 PAMAM dendrimer, folic acid, and methotrexate.

Gel Permeation Chromatography (GPC). A gel permeation chromatography (GPC) instrument equipped with two detectors, a multiangle laser light scattering (MALLS) and a differential refractive index, was used to evaluate the molar mass of the starting PAMAM dendrimer, the hydroxyl-terminated PAMAM dendrimer, and the conjugates. Figure 6 shows the differential mass fraction profile of the G5-NH_2, G5-Gly-OH, and G5-FA-MTX, respectively. All dendrimer samples exhibit a single peak. The number average molecular weights M_n and polydispersity indexes (PDI: M_w/M_n) of the G5-NH_2, G5-Gly-OH, and G5-FA-MTX are 26 060 (1.025), 39 110 (1.042), and 52 800 (1.044), respectively. The ratios of weight- to number-average molecular weights of the G5-NH_2, G5-Gly-OH, and G5-FA-MTX are very close to 1. This indicates that the distribution mass of the individual components is narrow and that the conjugation process at each step is nearly uniform.

The GPC results are somewhat different from those measured by MALDI-TOF, as shown by Figures 4 and 6. This difference is due to the broadening of the MALDI-TOF spectra, as compared to the GPC spectra. Generally, however, GPC is thought to reflect the real average molar mass.

In Vitro Studies. The binding of the newly synthesized G5-FA-MTX onto FA receptor-expressing KB cells was examined. For this, we utilized a previously synthesized G5-FI-FA-MTX conjugate in which the FA and MTX were conjugated to the dendrimer through the classic synthetic pathway (*28*). In addition, a fluorescent dye FITC (FI) was conjugated to the surface of the dendrimer. As shown in Figure 7, at a fixed concentration of G5-FI-FA-MTX (100 nM; concentrations shown are for the intact conjugates), the G5-FA-MTX competed with the former for binding, with a 50% inhibition of binding occurring at ~60 nM. This shows that the G5-FA-MTX binds through the FA receptor with an affinity similar to or slightly better than the G5-FA-MTX synthesized through the classic synthetic pathway (*28*).

The cytotoxicity of the newly synthesized conjugate was determined by the XTT assay, as described in Methods. We have compared the cytotoxicity with another batch of G5-FA-MTX synthesized by Cambrex Inc., using the classic synthetic pathway in which the FA and MTX were conjugated through amide and ester linkages, respectively. Our previous studies have shown that this batch of Cambrex conjugates was cytotoxic in

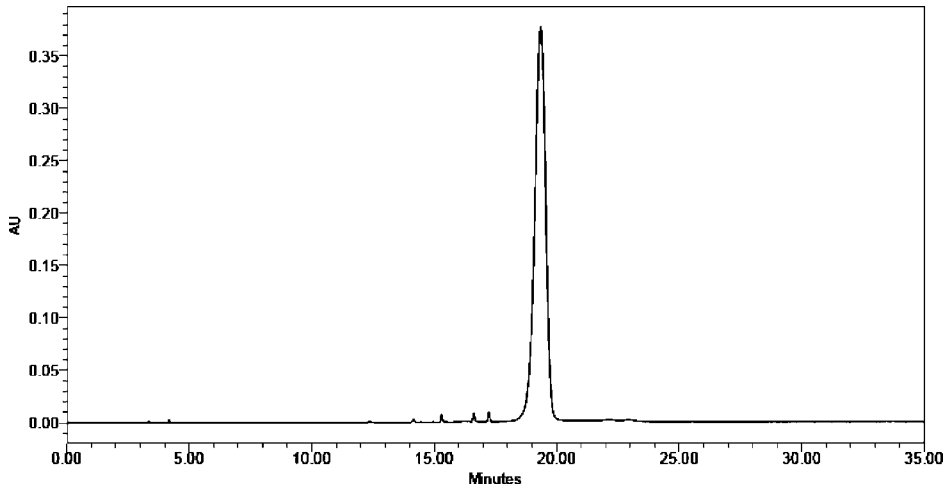

Figure 5. HPLC chromatogram of the conjugate (G5-FA-MTX) under 280 nm.

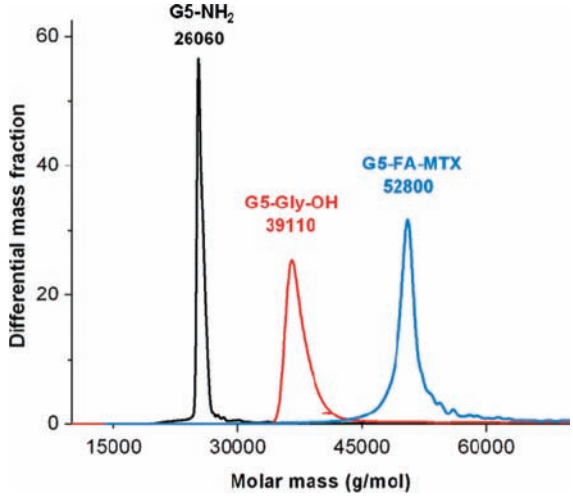

Figure 6. Graph showing the differential molar mass fractions for the G5 PAMAM dendrimer, the hydroxyl-terminated G5 PAMAM dendrimer, and the conjugate of G5 PAMAM dendrimer, FA, and MTX.

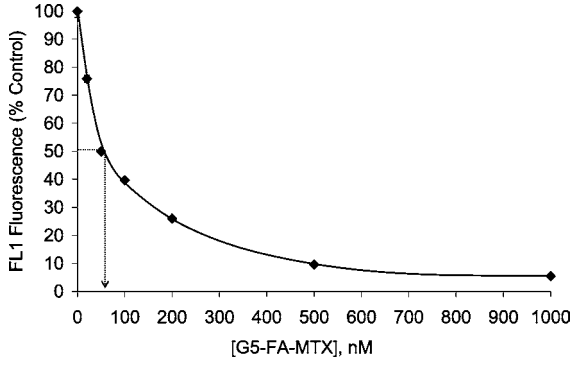

Figure 7. Competition of G5-FA-MTX synthesized using the "one-pot" approach with G5-FI-FA-MTX. The KB cells were treated with the two conjugates simultaneously, as described in Methods, and the mean FL1 fluorescence of 10 000 cells was determined by flow cytometry. The data are expressed as the percent fluorescence obtained for the binding of 100 nM G5-FI-FA-MTX in the absence of G5-FA-MTX. As indicated by the arrow, the concentration of G5-FA-MTX that is required for 50% reduction in binding of the G5-FI-FA-MTX is ~60 nM.

vitro and tumoricidal in vivo, with a potency similar to that of our previously published compound (*5*). As shown in Figure 8,

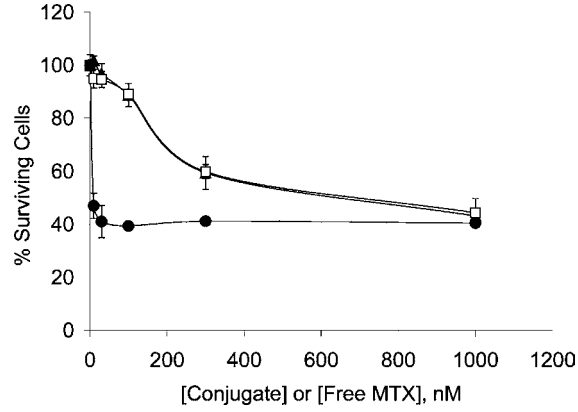

Figure 8. In vitro cytotoxicity of the newly synthesized G5-FA-MTX. The KB cells were treated with different concentrations of the newly synthesized G5-FA-MTX (▲) and free MTX (•). The data also show the cytotoxicity of G5-FA-MTX synthesized through the classic synthetic pathway in which the FA and MTX were conjugated through amide and ester linkages, respectively (□). The cells were treated with the drugs for 5 days, with one change of fresh medium/drug after 3 days, and the live cells were quantified by the XTT assay as described in Methods. The data represent the mean ± SE of 5 replicate cell samples in a representative experiment, with identical data obtained in 3 independent experiments.

the newly synthesized conjugate was as cytotoxic as the Cambrex batch.

CONCLUSION

A targeted dendrimeric anticancer prodrug, a conjugate of PAMAM dendrimer, FA, and MTX, has been successfully synthesized using an improved and simple "one pot" approach. Using this method, FA and MTX can be attached to the dendrimer in any desired ratios in a simple one-step reaction. A new analytical approach for calculating the molecules of FA and MTX attached to each dendrimer molecule has been established. The in vitro studies performed on FA receptor-expressing KB cells show that the new conjugates have similar affinity and cytotoxic potency as the G5-FA-MTX synthesized using the traditional multiple step approach. The results of parallel syntheses have demonstrated that this method is reproducible. The new method will allow easy conjugation of multiple functionalities such as a targeting agent, a drug, and even an imaging agent by utilizing the simple "one-pot" synthetic approach.

Tumor-Targeting, pH-Responsive, and Stable Unimolecular Micelles as Drug Nanocarriers for Targeted Cancer Therapy

Xiaoqiang Yang,[†] Jamison J. Grailer,[‡] Srikanth Pilla,[†] Douglas A. Steeber,[‡] and Shaoqin Gong*[,†,§,||]

Department of Mechanical Engineering, Department of Biological Sciences, and Department of Materials, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53211, and Department of Biomedical Engineering and Wisconsin Institute for Discovery, University of Wisconsin-Madison, Madison, Wisconsin 53706. Received September 23, 2009; Revised Manuscript Received January 31, 2010

A new type of multifunctional unimolecular micelle drug nanocarrier based on amphiphilic hyperbranched block copolymer for targeted cancer therapy was developed. The core of the unimolecular micelle was a hyperbranched aliphatic polyester, Boltorn H40. The inner hydrophobic layer was composed of random copolymer of poly(ε-caprolactone) and poly(malic acid) (PMA-*co*-PCL) segments, while the outer hydrophilic shell was composed of poly(ethylene glycol) (PEG) segments. Active tumor-targeting ligands, i.e., folate (FA), were selectively conjugated to the distal ends of the PEG segments. An anticancer drug, i.e., doxorubicin (DOX) molecules, was conjugated onto the PMA segments with pH-sensitive drug binding linkers for pH-triggered drug release. Transmission electron microscopy (TEM) and dynamic light scattering (DLS) analysis showed that the unimolecular micelles were uniform with a mean hydrodynamic diameter around 25 nm. The drug loading content was determined to be 14.2%. The drug release profile, cell uptake and distribution, and cytotoxicity of the unimolecular micelles were evaluated *in vitro*. The folate-conjugated micelles can be internalized by the cancer cells *via* folate-receptor-mediated endocytosis; thus, they exhibited enhanced cell uptake and cytotoxicity. At pH 7.4, the physiological condition of bloodstream, DOX conjugated onto the unimolecular micelles exhibited excellent stability; however, once the micelles were internalized by the cancer cells, the pH-sensitive hydrazone linkages were cleavable by the intracellular acidic environment, which initially caused a rapid release of DOX. These findings indicate that these unique unimolecular micelles may offer a very promising approach for targeted cancer therapy.

INTRODUCTION

Micelles formed by self-assembly of amphiphilic block copolymers have attracted significant attention in various biomedical fields, including drug and gene delivery (*1–4*). Micelle drug delivery systems can improve the solubility of hydrophobic drugs, stabilize and protect drugs that are sensitive to the surrounding environment, reduce the nonspecific uptake by the reticuloendothelial system (RES), and facilitate targeted drug delivery; however, conventional multimolecuclar micelle drug delivery systems based on the linear amphiphilic block copolymers suffer from instability *in vivo*. Multimolecular micelles are only thermodynamically stable above the critical micelle concentration (cmc) of the amphiphilic copolymers. Above the cmc, micelles are in dynamic equilibrium with the free copolymer molecules in solution, continuously breaking and reforming (*5*). When the concentration of the copolymer is below the cmc, micelles disassemble, thereby releasing the drug prematurely before reaching the tumor target. Furthermore, there are a number of other factors that may affect the *in vivo* stability of the multimolecular micelles including flow stress, interactions between the micelles and the serum components, and variations in temperature, pH, and ionic strength.

The *in vivo* instability problem associated with multimolecular micelles can be overcome by developing unimolecular micelles based on amphiphilic copolymers with a dendritic or hyperbranched structure (*6, 7*). Unimolecular micelles do not disassemble upon dilution and are stable to environmental changes due to their covalent nature, thereby providing excellent *in vivo* stability. Unimolecular micelles also offer other advantages, including high drug loading capacity and narrow nanoparticle size distribution. Furthermore, the highly branched structure of the copolymers can provide many end groups for further functionalization (*8, 9*).

To improve the efficacy of cancer therapy using drug nanocarriers such as unimolecular micelles, the unimolecular micelles must exhibit a number of desirable properties, including *in vivo* stability, high drug loading capacity, and well-controlled nanoparticle sizes, as described previously. In addition, the ability to actively target the tumor cells *via* specific targeting ligands and the ability for controlled drug release *via* stimulus-responsive drug−copolymer linkers are essential.

Drug nanocarriers are desirable for cancer therapy because they can target the tumor tissue through the enhanced permeability and retention (EPR) effect (i.e., passive targeting) (*10*). To further improve the delivery efficiency and cancer specificity, active tumor-targeting ability is also required. Active targeting can be achieved by functionalizing the nanocarriers with targeting ligands such as small molecules (e.g., folate (FA)), peptides (e.g., cRGD) and antibodies, which can recognize and bind to specific receptors/integrins that are unique to or positively expressed on cancer cells (*11*). In terms of controlled drug release, ideally, anticancer drug should not be released during circulation in the bloodstream; however, once the drug nanocarriers are internalized by the cancer cells, a sufficient

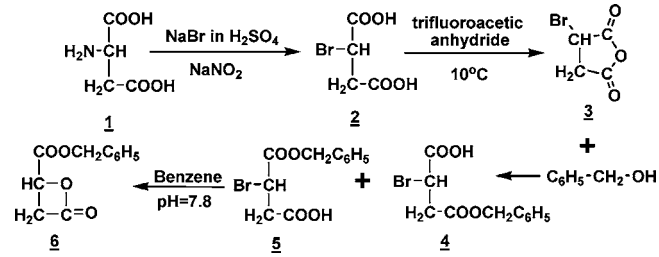
Scheme 1. Schematic Structure of Unimolecular Micelle Based on H40-(poly(β-malic acid)-hydrazone-doxorubicin-*co*-poly(ε-caprolactone))-methoxy-poly(ethylene glycol)-poly(ethylene glycol)-folate (H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA) Polymer

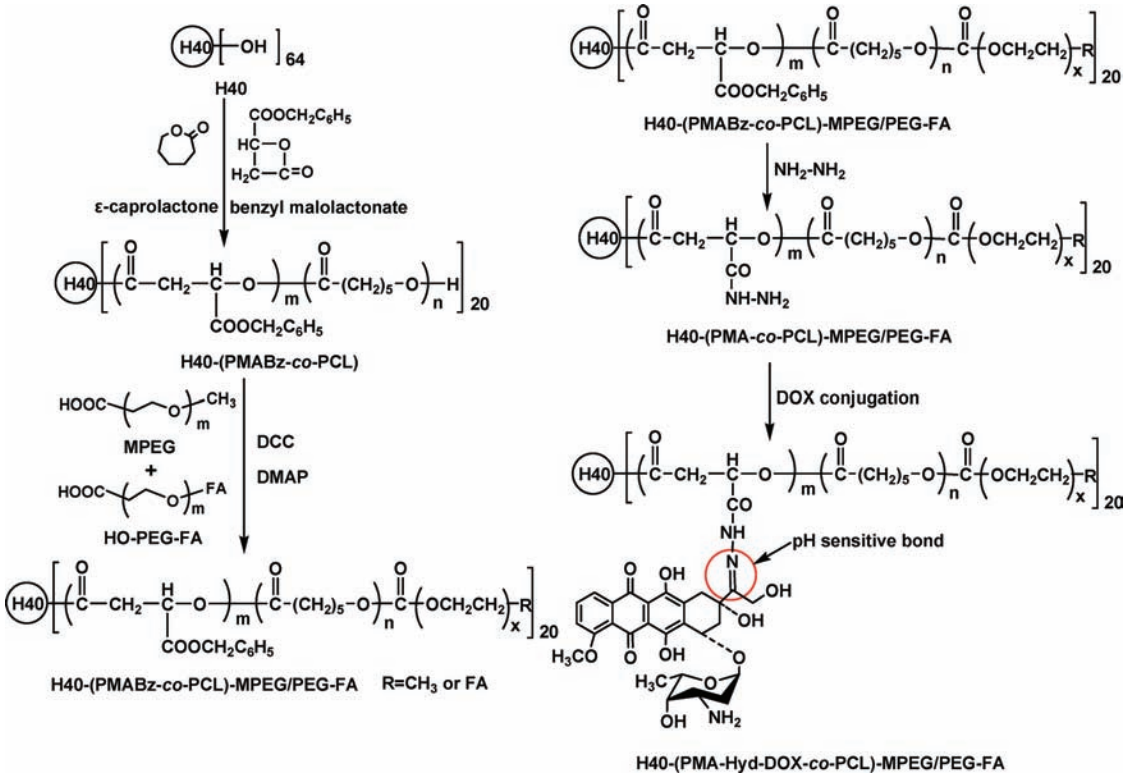


amount of anticancer drug should be released relatively quickly initially in order to effectively kill the cancer cells. The pH value of the bloodstream is approximately 7.4, while that of the endocytic compartments of the cells generally ranges from 4.5 to 6.5. This difference in pH value makes pH-triggered drug release possible (*12*).

Boltorn H40 has received much attention in the design of amphiphilic hyperbranched block copolymers for drug delivery application because of its biodegradability, biocompatibility, globular architecture, and high number of chain end functionalities (*13, 14*). Several excellent reports on drug nanocarriers using the hyperbranched aliphatic polyester, Boltorn H40 as the core are available in the literature. For instance, Prabaharan et al. reported a unimolecular micelle system made of a hyperbranched amphiphilic block copolymer based on Bolton H40 and copolymer of polylactide (PLA) and poly(ethylene glycol) (PEG) using FA as the active tumor-targeting ligands (*15*). Chen et al. reported a drug nanocarrier based on Bolton H40 and copolymer of polycaprolactone (PCL) and PEG, also using FA as the tumor-targeting ligand (*16*); however, in these systems, the anticancer drug, doxrubincin (DOX), was physically encapsulated only in the drug nanocarriers *via* hydrophobic interaction. As such, a significant amount of DOX may be released in the bloodstream during circulation, leading to poor targeting and reduced therapeutic effect.

In this paper, we developed a new type of multifunctional unimolecular micelle based on Boltron H40 as drug nanocarrier for targeted cancer therapy, which exhibited a pH-triggered drug release profile (Scheme 1). These unimolecular micelles were formed by amphiphilic hyperbranched copolymer, H40-((poly(β-malic acid)-hydrazone-doxorubicin)-*co*-poly(ε-caprolactone))-methoxy-poly(ethylene glycol)/poly(ethylene glycol)-folate (H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA) in aqueous solution. As shown in Scheme 1, Bolton H40 was used as the core of the amphiphilic hyperbranched copolymer. The hydrophobic segments of the amphiphilic copolymer arms were formed by random copolymerization of poly(β-malic acid) (PMA) and poly(ε-caprolactone) (PCL). The hydrophilic segments of the amphiphilic copolymer arms were formed by methoxy poly(ethylene glycol) (MPEG) or FA conjugated PEG (MPEG/PEG-FA). FA was used as the active tumor-targeting agent. FA is a vitamin with low molecular weight (M_w = 441.4) and behaves as a ligand because it has high affinity for its receptor, folate-binding protein, which is selectively overexpressed on the surface of many types of human cancer cells (*17, 18*). The PMA and PCL are important biodegradable aliphatic polyesters and of interest for biomedical applications owing to their good

Scheme 2. Synthesis Procedure of Benzyl Malolactonate Monomer



biocompatibility and low immunogenicity (*19*). The anticancer drug, doxorubicin (DOX), is widely used as an antitumor therapeutic agent and was conjugated onto the PMA-*co*-PCL segments through an acid-sensitive hydrazone bond. The random copolymer of PMA and PCL allows the DOX molecules to effectively conjugate onto the PMA segments due to the much reduced steric hindrance from the neighboring MA unit in the random copolymer. The acid-cleavable hydrazone linkages reduce the unwanted DOX release during blood circulation, yet provide quick DOX release initially once inside the tumor cells. This tumor-targeting unimolecular micelle nanosystem with a pH-triggered drug release profile and potentially excellent *in vivo* stability will open many exciting opportunities for targeted cancer therapy.

EXPERIMENTAL PROCEDURES

Materials. L-Aspartic acid, sodium bromide, sodium nitrite, trifluoroacetic anhydride, benzyl alcohol, and stannous octanoate ($Sn(Oct)_2$) were purchased from Fisher Scientific Inc., USA. Boltron H40 (64 hydroxyl groups per molecule theoretically and M_n of 2830 Da) was provided by Perstorp Polyols Inc., USA, and purified with tetrahydrofuran (THF). ε-Caprolactone (ε-CL, from Sigma-Aldrich) was purified by vacuum distillation over calcium hydride (CaH_2). Folic acid, dicyclohexylcarbodiimide (DCC), 4-dimethylamino pyridine (DMAP), and anhydrous hydrazine were purchased from Sigma-Aldrich, USA. MPEG was obtained from Fluka. α-Hydroxy-ω-amino poly(ethylene glycol) (HO-PEG-NH_2) with a M_w of 2000 was purchased from Iris Biotech GmbH and methoxy poly(ethylene glycol) (MPEG, M_w: 2000) was purchased from Fisher Scientific Inc., USA. Doxorubicin hydrochloride (DOX·HCl) was supplied by Tecoland Corporation, USA, and used as supplied. All other chemicals used were of analytical reagent grade. Phosphate and acetate buffered solutions were prepared in our laboratory. RPMI-1640 was purchased from Gibco BRL, USA. The mouse mammary carcinoma, 4T1 (ATCC), was cultured in RPMI medium supplemented with 10% fetal calf serum.

Synthesis of Benzyl Malolactonate Monomer (Scheme 2). Benzyl malolactonate monomer was prepared by a reported simple and reproducible method following Scheme 2 (*20*). First, to an ice-cold clear solution of L-aspartic acid (**1**, 50 g) and NaBr (200 g) in 2 N H_2SO_4 (300 mL), $NaNO_2$ was added progressively over a period of 2 h. The whole mixture was further stirred for 1.5 h at room temperature. After the excess reagents were decomposed by adding urea, the bromosuccinic acid was extracted with ethyl acetate twice. The extracts were combined and washed with slightly acidic water and dried over anhydrous sodium sulfate. The product **2** was recovered after evaporation of ethyl acetate. Second, the product **2** (20 g) was dissolved in anhydrous tetrahydrofuran (THF) (100 mL) containing trifluoroactetic anhydride (23.5 g) in a three-neck flask at 10 °C. The mixture was allowed to stir for 1.5 h at 10 °C and 2 h at room temperature. The THF and trifluoroacetic acid were then distillated under vacuum to yield bromosuccinic anhydride (**3**), a white crystalline compound. Then, benzyl alcohol (13 g) was immediately added to the flask containing **3**.

Scheme 3. Synthesis Procedure of H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA Polymer

The mixture was allowed to react for 4 h at room temperature and 1 h at 60 °C yielding a mixture of bromosuccinic acid monobenzyl ester isomers (**4** and **5**). Finally, the resulting mixture was dissolved in sodium hydroxide water with a pH value of 7.8. Subsequently, 200 mL of benzene was added into the mixture, which was stirred overnight at 50 °C. After cooling, the organic layer was separated from the aqueous phase and crude benzyl malolactonate was recovered after evaporation of the solvent. The product **6** was purified using column chromatography and further vacuum distilled.

Random Copolymerization of Benzyl Malolactonate and ε-Caprolactone Using H40 as Macroinitiator (H40-(PMABz-*co*-PCL)-OH). H40-(PMABz-*co*-PCL)-OH was prepared by the ring-opening polymerization of benzyl malolactonate and ε-caprolactone using H40 as a macroinitiator and $Sn(Oct)_2$ as a catalyst (Scheme 3). H40 (200 mg, 4.5 mmol of hydroxyl groups), benzyl malolactonate (0.5 g 2.43 mmol), ε-caprolactone (3.0 g 26.3 mmol), and catalyst ([catalyst]/[ε-caprolactone] = 1:1000) were added into a 250 mL flame-dried flask under N_2. The reaction was carried out under stirring at 110 °C for 24 h. After the reaction was complete, the mixture was diluted with THF, precipitated into diethyl ether, and washed with diethyl ether to produce a white H40-(PMABz-*co*-PCL)-OH powder.

Synthesis of α-Carboxyl-ω-FA Poly(ethylene glycol) (FA-PEG-COOH). FA-PEG-HO was prepared according to our previous work with a slight modification (*15*). The γ-NHS-FA was dissolved into 5 mL of a mixture of anhydrous DMSO and triethylamine (TEA) with a volume ratio of 10:1. An equimolar amount of HO-PEG-NH_2 was added to the mixture and the reaction was carried out under an anhydrous condition overnight. The product, FA-PEG-HO, was freeze−dried after dialysis against deionized water using cellulose tubing (M_w cutoff: 2000 Da). FA-PEG-COOH was prepared by reacting FA-PEG-OH (2 g, 0.57 mmol) with succinic anhydride (170 mg, 1.7 mmol) in the presence of pyridine. The reaction was carried out in anhydrous toluene under N_2 atmosphere at 70 °C for 24 h. Crude polymer obtained by precipitation into cold diethyl ether was redissolved in dichloromethane (DCM). The resulting DCM solution was washed three times with aqueous hydrochloric acid (10% in v/v) and then four times with a saturated NaCl solution. Then, the organic phase was isolated, dried over magnesium sulfate, and filtered. The final product, FA-PEG-COOH, was recovered by precipitation into cold diethyl ether and dried under vacuum.

MPEG-COOH was prepared from MPEG-OH using a procedure similar to the one described above.

Synthesis of H40-(PMABz-*co*-PCL)-MPEG/PEG-FA. H40-(PMABz-*co*-PCL)-MPEG/PEG-FA copolymer was synthesized by reacting the terminal hydroxyl groups of H40-(PMABz-*co*-PCL)-OH with the terminal carboxyl groups of anhydrous MPEG-COOH and FA-PEG-COOH. The molar ratio of MPEG-COOH and FA-PEG-COOH was 19:1 (the number of PMABz-*co*-PCL arms was 20, which was calculated according to the GPC analysis). For example, H40-(PMABz-*co*-PCL)-OH (5.52 g, 0.044 mmol) was dissolved in 30 mL anhydrous chloroform. Then, a mixture of MPEG-COOH (2.51 g, 1.26 mmol) and FA-PEG-COOH (152 mg, 0.06 mmol), DCC (272 mg, 1.32 mmol) and DMAP (161 mg, 1.32 mmol) in 20 mL anhydrous chloroform was added into the chloroform solution of H40-(PMABz-*co*-PCL)-OH. The reaction was carried out at room temperature for 24 h under stirring. The resulting solution was precipitated with cold diethyl ether twice. The precipitate was dried under vacuum. The impurities and unreacted materials of the product were removed by dialysis against deionized water using cellulose tube (M_w cutoff: 12 000 Da) for 48 h. After dialysis, the H40-(PMABz-*co*-PCL)-MPEG/PEG-FA copolymer was obtained by freeze−drying.

Synthesis of H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA. The benzyl groups of H40-(PMABz-*co*-PCL)-MPEG/PEG-FA were substituted with hydrazide groups for DOX binding by an ester-amide exchange aminolysis reaction (Scheme 3). H40-(PMABz-*co*-PCL)-MPEG/PEG-FA (2 g, 0.012 mmol) was dissolved in 100 mL of anhydrous DMF. Then, anhydrous hydrazine (5 mg, 0.156 mmol) was added to this solution. The reaction was allowed to proceed at 40 °C for 24 h, followed by dialysis against 0.25% ammonia solution using cellulose tube

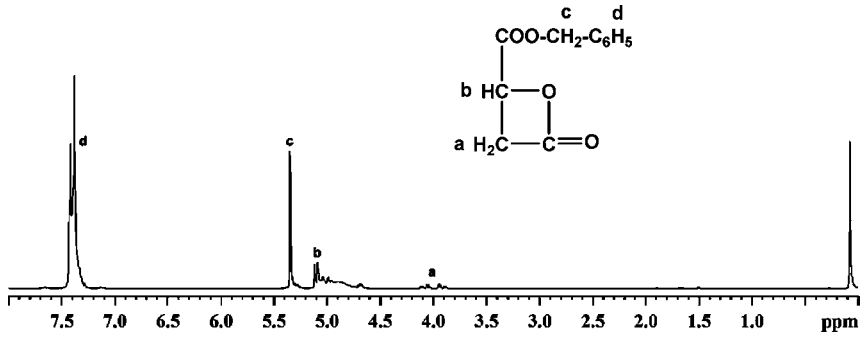


Figure 1. [1]H NMR spectrum of benzyl malolactonate monomer.

(M_w cutoff: 2000 Da) and freeze−drying. To conjugate DOX onto the amphiphilic hyperbranched copolymer, H40-(PMA-Hyd-*co*-PCL)-MPEG/PEG-FA (1.5 g, 0.009 mmol) was dissolved in 50 mL of DMF, and excess amount of DOX·HCl (150 mg, 0.26 mmol) was added. The mixture solution was stirred at room temperature for 24 h while being protected from light. The reaction solution was concentrated to a volume of 10 mL under reduced pressure and dialyzed against deionized water using cellulose tube (M_w cutoff: 2000 Da) for 48 h, followed by gel purification using Sephadex LH-20 to completely remove unbound DOX. For comparison, the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG copolymer without FA targeting ligands was synthesized following the same procedure as described above.

Preparation of H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA Micelles. H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles were prepared using the dialysis method. Briefly, 10 mg of H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA polymer was dissolved in 3 mL of DMF under stirring. Then, 5 mL of deionized water was added dropwise into the above solution. Thereafter, the mixture was dialyzed against deionized water using a dialysis tube (M_w cutoff: 2000 Da) for three days followed by freeze−drying.

Characterization. [1]H NMR spectrum was recorded on a Bruker DPX 300 spectrometer. Gel permeation chromatography (GPC) analysis was carried out at ambient temperature using the 270max Viscotek (Viscotek, USA) GPC system equipped with triple detectors, including a refractive index detector, a viscometer detector, and a light-scattering detector. THF was used as an eluent with a flow rate of 1 mL/min and polystyrene (PS) standards were used for column calibration. The amphiphilic hyperbranched block copolymer solutions in THF (5 mg/mL) were prepared. Absorbance measurements were carried out using a Varian Cary 100 Bio UV−visible spectrophotometer. The size and size distribution of the unimolecular micelles were determined by dynamic light scattering (DLS) (Beckman Coulter PCS submicrometer particle size analyzer, USA) with an angle detection at 90°. Samples for transmission electron microscopy (TEM, Hitachi H-600) analysis were prepared by drying a dispersion of the unimolecular micelles on a copper grid coated with amorphous carbon. Subsequently, a small drop of phosphotungstic acid (PTA) solution (2 wt % in water) was added to the copper grid; after 30 s the grid was blotted with filter paper for TEM observation. The DOX-loading content (DLC), defined as the weight percentage of DOX in unimolecular micelles, was quantified by UV−vis analysis using a Varian Cary model 100 Bio UV−vis spectrophotometer. The DOX was released from the unimolecular micelles in 0.1 N HCl solution to cleave the hydrazone bonds. To determine the drug content in the solution, the absorbance of DOX at 485 nm was measured using a previously established calibration. The DLC measurements were performed in triplicate for each of the samples.

Evaluation of pH Sensitivity. The unimolecular micelle's pH-responsive DOX release behavior was studied using an UV spectrophotometer. First, 50 mg freeze−dried micelle samples were dispersed in 5 mL of medium, placed in a dialysis bag with a molecular weight cutoff of 2000 Da, and then placed into various pH conditions from 7.4 to 4.0 (10 mM phosphate buffer (pH 7.4−6.0), 10 mM acetate buffer (pH 5.8−4.0)). The dialysis bag was then immersed in 100 mL of the release medium and kept in a horizontal laboratory shaker maintaining a constant temperature and stirring. At selected time intervals, the buffered solution (5 mL) outside the dialysis bag was removed for UV−vis analysis and replaced by fresh buffered solution with same volume. The amount of released DOX was analyzed with UV spectrophotometer at 485 nm. Each sample was measured three times.

Cellular Uptake and Cytotoxicity. The cellular uptake and distribution of micelles were performed using flow cytometry and confocal laser scanning microscopy (CLSM). For CLSM studies, 4T1 cells (1×10^6) were seeded onto 22 mm round glass coverslips placed in 6-well plates and grown overnight. Cells were treated with free DOX, DOX-conjugated H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA (i.e., FA-targeted), or H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG (i.e., nontargeted) micelles for 2 h (DOX concentration 20 μg/mL). Then the cells were washed and fixed with 1.5% formaldehyde. Coverslips were placed onto glass microscope slides and DOX uptake was analyzed using a Leica TCS SP2 Confocal System installed on an upright compound microscope (Leica, Wetzler, Germany). Digital monochromatic images were acquired using Leica Confocal Software (v 2.61).

To determine the DOX distribution in the nucleus and cytoplasm of the 4T1 cells, the DOX mean fluorescence intensity (MFI) in the CLSM images was measured in a 4 μm^2 area located in the nucleus or cytoplasm ($n = 10$ cells) for each sample using *ImageJ* software (http://rsb.info.nih.gov/ij). For flow cytometry, 4T1 cells (1×10^6) were seeded in 6-well culture plates and grown overnight. The cells were then treated with free DOX, DOX-conjugated H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA, or H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG micelles for 2 h (DOX concentration 20 μg/mL). Thereafter, the cells were lifted using a cell stripper (Media Tech, Inc.) and washed. The DOX uptake was analyzed using an FACSCalibur flow cytometer (BD bioscience). A minimum of 2×10^4 cells were analyzed from each sample with the fluorescence intensity shown on a four-decade log scale.

The cytotoxicity of the unimolecular micelles against 4T1 cells was studied using the MTT assay. First, 4T1 cells (1×10^4) were seeded in 96-well plates and incubated for 24 h. The media were replaced with fresh media containing free DOX, H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA, H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG micelles with different DOX concentrations or control media and incubated for 48 h. Thereafter, the wells were washed three times with warm phosphate buffer

solution and incubated again for another 3 h with RPMI containing 250 μg/mL of MTT. After discarding the culture medium, 200 μL of DMSO was added to dissolve the precipitates, and the resulting solution was measured for absorbance at 570 nm with a reference wavelength of 690 nm using a microplate reader (Molecular Devices).

RESULTS AND DISCUSSION

Synthesis and Characterization of Benzyl Malolactonate Monomer and H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA. Benzyl malolactonate is a β-substituted β-lactone monomer and was prepared by a reported simple and reproducible method according to Scheme 2 (*20*). This monomer was purified by reverse-phase silica (octadecylsilyl silica (ODS)) and then vacuum-distilled twice (bp = 90 °C, 10^{-3} mm Hg). Figure 1 shows the ^{1}H NMR spectrum of the monomer, confirming the monomer was successfully synthesized (a, 4.0 (d); b, 5.12 (t); c, 5.34 (s); d, 7.35 (s) in $CDCl_3$).

The synthesis of the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymer was carried out according to Scheme 3. First, H40-(PMABz-*co*-PCL)-OH was prepared by the random copolymerization of benzyl malolactonate and ε-caprolactone using H40 as a macroinitiator in the presence of $Sn(Oct)_2$ catalyst. This copolymer was purified by twice precipitating into diethyl ether from chloroform solution followed by filtering and was then dried under vacuum. The structure of the H40-(PMABz-*co*-PCL)-OH copolymer was confirmed by ^{1}H NMR (Figure 2a). The molar ratio of the PMABz and PCL repeat unit was approximately 1:15, which was calculated from the integral ratio of the characteristic peaks at 5.1 (MABz) and 3.9 (CL) ppm). On the basis of the absolute M_w determined by GPC (Table 1), it was estimated that each PMABz-*co*-PCL-OH arm on the hyperbranched H40-(PMABz-*co*-PCL)-OH copolymer had 2 MABz repeat units and 29 CL repeat units. To prepare the nontargeted unimolecular micelles, which can serve as a control for the study of cellular uptake and cytotoxicity of FA-targeted unimolecular micelles, the H40-(PMABz-*co*-PCL)-MPEG amphiphilic copolymer was synthesized by reacting H40-(PMABz-*co*-PCL)-OH with MPEG-COOH in the presence of DCC and DMAP. The number of arms in H40-(PMABz-*co*-PCL)-MPEG was calculated using the following equation: Number of arms = [(M_w of H40-(PMABz-*co*-PCL)-MPEG − M_w of H40-(PMABz-*co*-PCL)-OH)]/M_w of MPEG = [164 540−125 460/2000] ≈ 20. This result is consistent with our previous finding (*15*).

To achieve active tumor-targeting property, the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymer was prepared by reacting H40-(PMABz-*co*-PCL)-OH with a mixture of MPEG-COOH and FA conjugated PEG, i.e., FA-PEG-COOH, in the presence of DCC and DMAP. It is known that folate moieties with pterin heterocycles can self-assemble in an aqueous solution by hydrogen bonds and stacking interactions (*21*). As a result, introducing too many FA moieties to the amphiphilic copolymer decreases the stability of the micelles formed by the amphiphilic copolymer. In addition, the possible formation of dimers, trimers, or self-assembled tubular quarters (*21*) at a higher FA concentration is highly unfavorable for tumor cell targeting because the folate receptor can bind only one FA molecule; thus, the self-assembled FA multimers are incapable of binding to the folate receptors.

During this study, the molar ratio of the FA targeting ligand was controlled through the molar ratio between MPEG-COOH and FA-PEG-COOH, which was kept at 19:1. Thus, the estimated FA molar ratio in H40-(PMABz-*co*-PCL)-MPEG/PEG-FA was 1/20, i.e., 5%. Figure 2b shows the ^{1}H NMR spectrum of the H40-(PMABz-*co*-PCL)-MPEG/PEG-FA copolymer. The typical NMR peaks from the FA moiety appeared

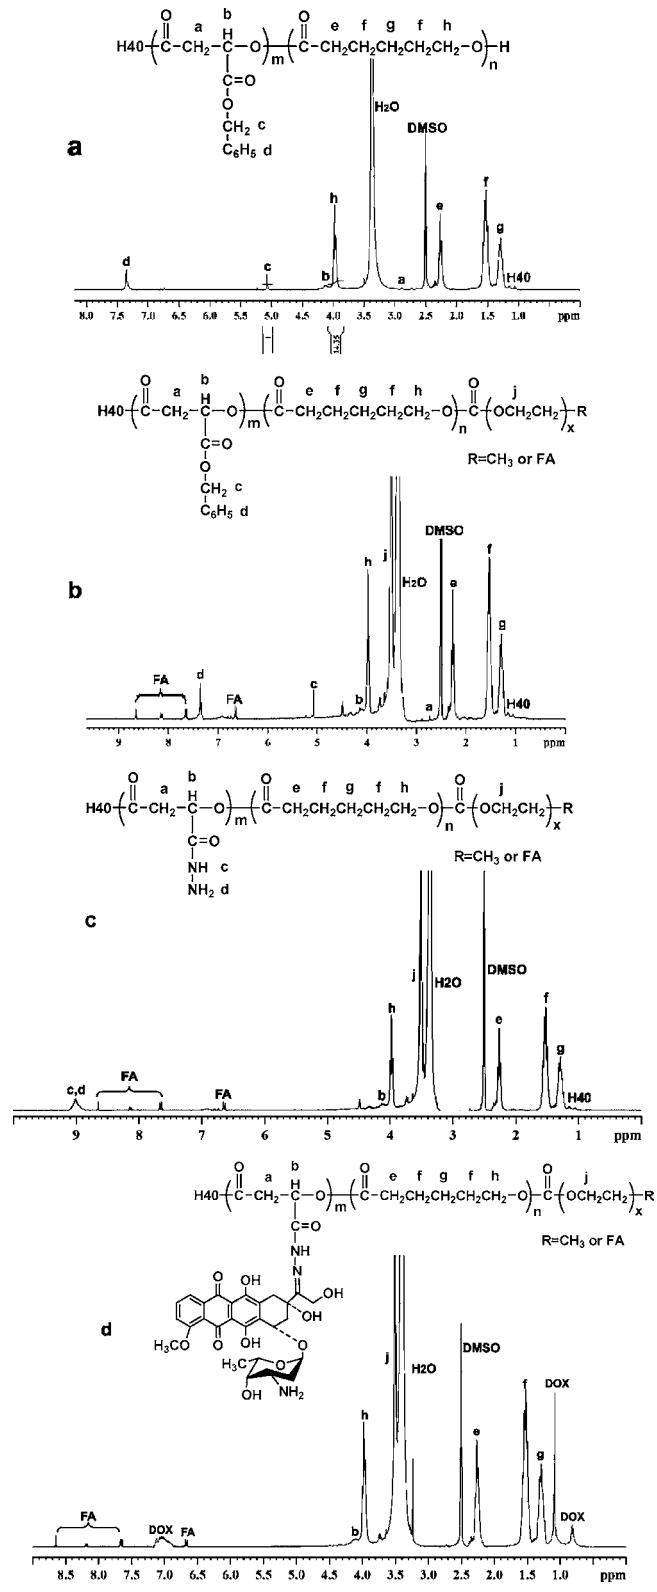

Figure 2. ^{1}H NMR spectra of (a) H40-[(poly(benzyl β-malate)-*co*-poly(ε-caprolactone)] (H40-(PMABz-*co*-PCL)-OH; (b) H40-[(poly-(benzyl β-malate)-*co*-poly(ε-caprolactone)]-methoxy-poly(ethylene glycol)-poly(ethylene glycol)-folate (H40-(PMABz-*co*-PCL)-MPEG/PEG-FA); and (c) H40-[(poly(β-malic acid-hydrazide)-*co*-poly(ε-caprolactone)]-methoxy-poly(ethylene glycol)-poly(ethylene glycol)-folate (H40-(PMA-Hyd-*co*-PCL)-MPEG/PEG-FA); (d) H40-[(poly(β-malic acid-hydrazone-DOX)-*co*-poly(ε-caprolactone)]-methoxy-poly(ethylene glycol)-poly(ethylene glycol)-folate (H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA).

Table 1. GPC Results of H40, H40-(PMABz-*co*-PCL)-OH, and H40-(PMABz-*co*-PCL)-MPEG

samples	M_n	M_w	M_w/M_n
H40	2 830	5 100	1.80
H40-(PMABz-*co*-PCL−OH)	76 500	125 460	1.64
H40-(PMABz-*co*-PCL)-MPEG	115 506	164 540	1.42

at 8.68, 8.17, 7.68, 6.98, and 6.67 ppm. The appearance of these peaks confirms the successful conjugation of FA to the hyperbranched copolymer.

The benzyl groups of the H40-(PMABz-*co*-PCL)-MPEG/PEG-FA copolymer were substituted with hydrazide groups for DOX binding through the ester-amide exchange (EAE) aminolysis reaction (*22*). The reaction was allowed to proceed at 40 °C for 24 h. The structure was confirmed by ^{1}H NMR spectrum as shown in Figure 2c. The NMR peaks originated from the benzyl ester groups (5.1 and 7.4 ppm) presented at the PMABz segments disappeared; meanwhile, the characteristic NMR peak corresponding to the hydrazine groups (9.0 ppm broadening peak) was observed. After the H40-(PMA-Hyd-*co*-PCL)-MPEG/PEG-FA copolymer was purified, it was reacted with an excess amount of DOX to form the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymer. After the reaction was complete, the polymer solution was dialyzed and further purified using Sephadex LH-20 to completely remove any unbound DOX. The structure of the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymer was confirmed by ^{1}H NMR. As shown in Figure 2d, the corresponding peaks of DOX appeared at 0.8, 1.1, and 7.0 ppm, indicating the DOX molecules were successfully conjugated onto the PMA segments by hydrazone bonds. The drug loading content determined by the UV measurement was 14.2 ± 0.3%. Theoretically, if all the hydrazide groups attached on the PMA segments are conjugated with the DOX molecules during the DOX conjugation reaction step, the DOX loading content is close to 15%. Thus, based on the DOX loading content measured by UV (14. 2%) and the theoretical maximum DOX loading content (∼15%), it can be deduced that both PMA repeat units in each arm of the 20-arm hyperbranched copolymer were conjugated with DOX molecules. Namely, there were approximately 40 DOX molecules per H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA molecule.

Micelle Properties of the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA Copolymer. Figure 3A shows the morphology of the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA unimolecular micelles observed by TEM. It can be seen the unimolecular micelles were spherical and most of them had a relatively uniform size, which was about 20 nm. The size and size distribution of the unimolecular micelles were further determined by DLS. The hydrodynamic size of the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA unimolecular micelles was about 25 ± 2 nm, which was somewhat higher than the particle size determined by TEM (i.e., ∼20 nm), as expected. The size distribution, expressed by polydispersity index, was 0.145 ± 0.002. It should be noted that the resulting H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymer micelles were stable over several weeks and displayed no changes in size or size distribution within experimental accuracy during this period.

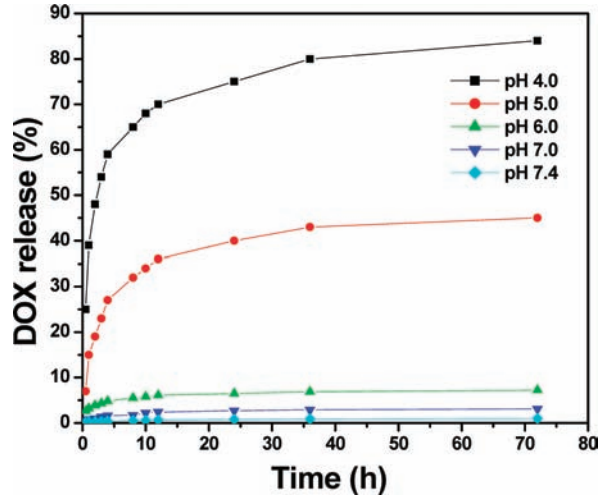

Figure 4. Release profile of DOX from the H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles at different pH values.

Effect of pH on the *in Vitro* DOX Release Rate. The pH-sensitive DOX release behavior of the unimolecular micelles was evaluated at a series of pH values. As shown in Figure 4, the DOX release rate from the unimolecular micelles increased consistently with lower pH values within the pH range of 4.0 to 7.4. A negligible amount of drug release was observed at pH 7.4, the physiological condition of the bloodstream; thus, almost no DOX will be released from the unimolecular micelles during blood circulation, which is a desirable drug delivery characteristic for drug nanocarriers. The pH values of the endocytic compartments in which the FA-conjugated unimolecular micelles are located once internalized by the tumor cells *via* FA-receptor mediated endocytosis generally ranges from 4.5 to 6.5. As shown in Figure 4, the DOX released rate increased significantly within this pH range. In acidic conditions, the acid-sensitive hydrazone bonds are cleaved releasing unmodified DOX from the unimolecular micelles, which are subsequently diffused into the cytoplasm and eventually to the nucleus. At pH 5.0, about 48% DOX was released after 72 h. Thus, once the unimolecular micelles are internalized into the tumor cells, the conjugated DOX can be released effectively to improve the therapeutic outcome of the chemotherapy.

Cellular Uptake of the Unimolecular Micelles. The behaviors of cellular uptake of the FA-conjugated H40-(PMA-Hyd-

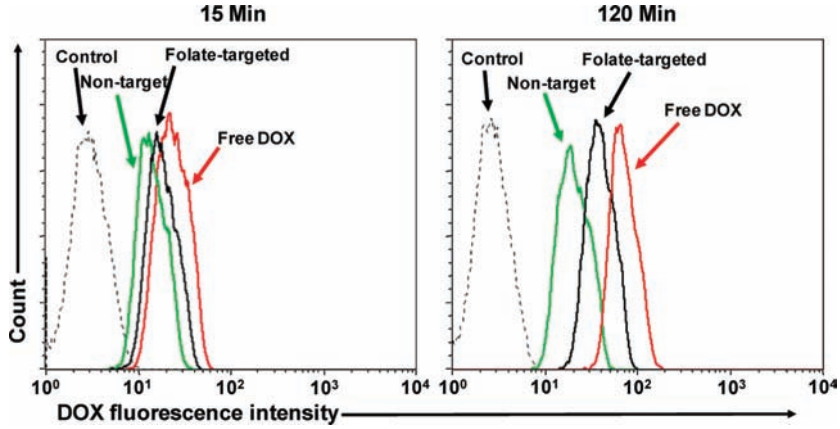

Figure 5. Flow cytometry results of 4T1 cells treated with free DOX, H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG micelles and H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles at 37 °C for 15 and 120 min (DOX concentration 20 μg/mL).

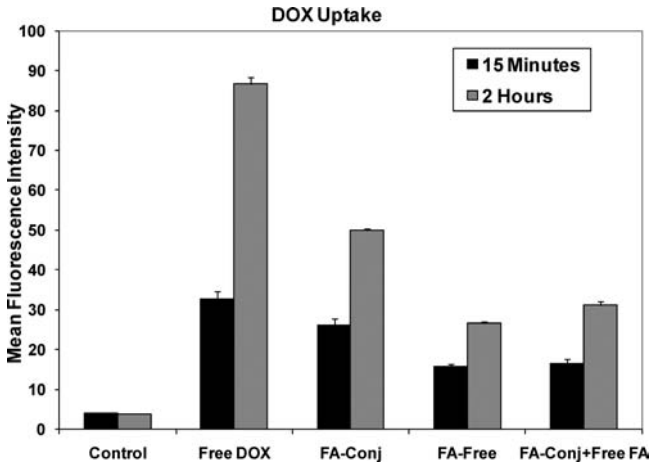

Figure 6. DOX mean fluorescence intensity (MFI) located in the 4T1 cells incubated with free DOX, nontargeted, and FA-conjugated unimolecular micelles for 15 and 120 min.

co-PCL)-MPEG/PEG-FA unimolecular micelles and nontargeted H40-(PMA-Hyd-*co*-PCL)-MPEG unimolecular micelles against folate receptor (FR) positive 4T1 cells were studied using both flow cytometry and CLSM. Figure 5 shows the flow cytometry histograms of the 4T1 cells incubated with free DOX, FA-conjugated micelles, or nontargeted micelles for 15 min and 2 h. As the figure shows, 4T1 cells without any DOX treatment were used as a negative control and showed only the autofluorescence of the cells. The DOX fluorescence intensity (Figure 6) clearly indicated that the cellular uptake of DOX was the highest in 4T1 cells incubated with free DOX, followed by FA-conjugated micelles and then nontargeted micelles. After 15 and 120 min incubation, FA-conjugated micelles showed an increase in cellular uptake, which was approximately 1.7 and 1.9 times (Student's t test; $p < 0.005$ and $p < 0.0001$, respectively) of the cellular uptake of nontargeted micelles, respectively, while the cellular uptake of free DOX was approximately 1.3 and 1.7 times ($p < 0.05$ and $p < 0.00005$, respectively) the cellular uptake of FA-conjugated micelles, respectively. The higher cellular uptake of free DOX compared with DOX conjugated onto unimolecular micelles can be attributed to the different cellular uptake mechanism. Free DOX was transported into cells *via* diffusion (*4*), while unimolecular micelles were taken up *via* an endocytosis process (*23*). However, the higher cellular uptake by the 4T1 cells incubated with FA-conjugated micelles compared with those incubated with nontargeted micelles clearly demonstrated that FA was an effective tumor-targeting ligand for tumor cells with positive FR. Moreover, the FA competition experiment also showed that the cellular uptake level of FA-conjugated micelles in the presence of free FA was dramatically reduced and became essentially equivalent to that of nontargeted micelles indicating the cell uptake of FA-conjugated micelles was FR mediated endocytosis process (Figure 6). These findings were further confirmed by the CLSM images as shown in Figure 7. 4T1 cells incubated with free DOX (Figure 7a) showed the highest DOX fluorescence intensity in both cytoplasm and nuclear after 2 h incubation. This is because free DOX can quickly diffuse into the cytoplasm through the cell membrane and transport into the nucleus, where it can interrupt the DNA replication process (*24*). Consistent with the flow cytometry finding, 4T1 cells incubated with FA-conjugated micelles showed a much higher DOX fluorescence intensity than those incubated with nontargeted micelles due to the FA-receptor mediated endocytosis process.

Cytotoxicity of the Unimolecular Micelles. The cytotoxic effects of free DOX, H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG,

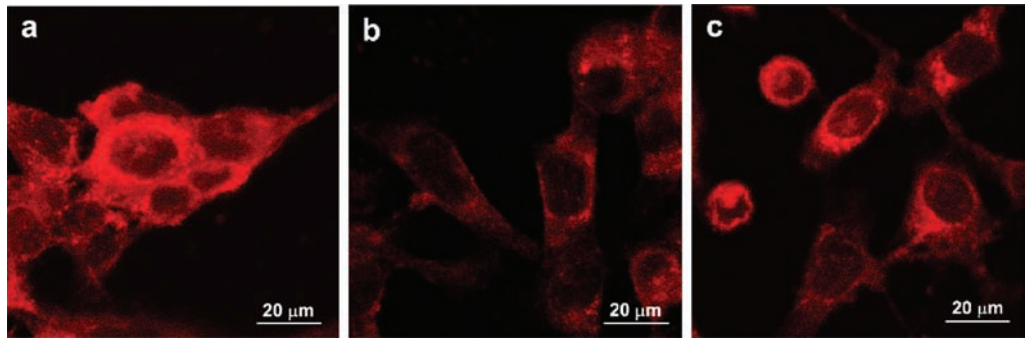

Figure 7. CLSM images of 4T1 cells treated with (a) free DOX; (b) H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG micelles; (c) H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles at 37 °C for 2 h (DOX concentration 20 μg/mL).

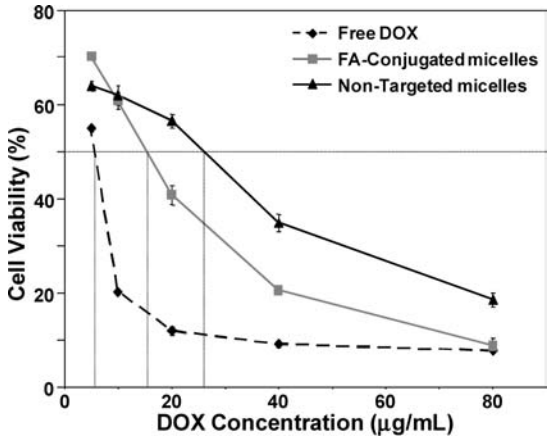

Figure 8. Cytotoxicity of free DOX, H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG micelles, and H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles with different DOX concentrations against 4T1 cells (incubation time 48 h).

and H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA micelles with different DOX concentrations against 4T1 cells after 48 h incubation were studied using the MTT assay. As shown in Figure 8, at the same DOX concentration, free DOX showed the highest cytotoxicity, which is consistent with the fact that 4T1 cells incubated with free DOX had the highest cellular uptake according to the CLSM and flow cytometry analysis. In addition, free DOX can rapidly diffuse into the cell nuclei once inside the 4T1 cells and effectively inhibit the DNA replication in the cancer cells. FA-targeted micelles demonstrated a higher cytotoxicity compared with nontargeted micelles, which is also consistent with its higher cellular uptake observed by CLSM and flow cytometry. Moreover, the concentration yielding half-inhibition to cell growth (IC_{50}) was detected at 5.7, 15.5, and 26.2 μg/mL for free DOX and FA-conjugated and nontargeted micelles, respectively. The enhanced cytotoxicity exhibited by the FA-conjugated micelles again indicates that FA tumor-targeting ligands were effective in enhancing the cellular uptake of the unimolecular micelles.

CONCLUSIONS

Tumor-targeting multifunctional unimolecular micelles that exhibit a pH-triggered drug release profile and potentially excellent *in vivo* stability were developed for targeted cancer chemotherapy. The unimolecular micelles were formed by 20-arm hyperbranched amphiphilic H40-(PMA-Hyd-DOX-*co*-PCL)-MPEG/PEG-FA copolymers. Hyperbranched polyester Boltorn H40 was used as the macroinitiator for the random ring-opening copolymerization of PMABz and PCL, serving as the hydrophobic segments of the amphiphilic copolymers. The anticancer drug DOX was conjugated onto the PMA segments by acid-sensitive hydrazone bonds. Folate, the tumor-targeting ligand, was conjugated selectively (5% molar ratio) to the distal ends of the hydrophilic PEG segments. The hydrodynamic diameter of the unimolecular micelles was 25 $\pm$ 2 nm, determined by DLS. The DOX loading content was found to be 14.2%. There was very little DOX release at pH 7.4 indicating the DOX-conjugated unimolecular micelles will be very stable during blood circulation. On the other hand, DOX was released relatively quickly at lower pH values, indicating a sufficient amount of DOX may be released in the acid endocytic compartments once internalized by the tumor cells. The cellular uptake of the FA-conjugated unimolecular micelles was much higher than that of the nontargeted unimolecular micelles resulting from the FA-receptor mediated endocytosis, thereby leading to a much higher cytotoxicity. Thus, these novel tumor-targeting, pH-responsive, and potentially *in vivo* stable unimolecular micelles may provide a very promising approach for targeted cancer therapy and greatly improve the quality of cancer patient care.

Bioinspired Synthesis and Characterization of Gadolinium-Labeled Magnetite Nanoparticles for Dual Contrast T_1- and T_2-Weighted Magnetic Resonance Imaging

Ki Hyun Bae,[†] Young Beom Kim,[‡] Yuhan Lee,[†] JinYoung Hwang,[‡] HyunWook Park,[‡] and Tae Gwan Park*[,†]

Department of Biological Sciences and Graduate School of Nanoscience and Technology, and Department of Electrical Engineering, Korea Advanced Institute of Science and Technology, Daejeon 305-701, South Korea. Received September 23, 2009; Revised Manuscript Received November 24, 2009

Gadolinium-labeled magnetite nanoparticles (GMNPs) were synthesized via a bioinspired manner to use as dual contrast agents for T_1- and T_2-weighted magnetic resonance imaging. A mussel-derived adhesive moiety, 3,4-dihydroxy-L-phenylalanine (DOPA), was utilized as a robust anchor to form a mixed layer of poly(ethylene glycol) (PEG) chains and dopamine molecules on the surface of iron oxide nanoparticles. Gadolinium ions were subsequently complexed at the distal end of the dopamine molecules that were prefunctionalized with a chelating ligand for gadolinium. The resultant GMNPs exhibited high dispersion stability in aqueous solution. Crystal structure and superparamagnetic properties of magnetite nanocrystals were also maintained after the complexation of gadolinium. The potential of GMNPs as dual contrast agents for T_1 and T_2-weighted magnetic resonance imaging was demonstrated by conducting in vitro and in vivo imaging and relaxivity measurements.

INTRODUCTION

Over the past decade, a variety of inorganic nanomaterials, such as gold nanoparticles, iron oxide nanocrystals, and quantum dots, have drawn significant attention because of their unique and controllable optical, magnetic, and electronic properties (*1*−*3*). Among them, superparamagnetic magnetite nanocrystals have been utilized as useful platform materials for diverse biomedical applications including magnetic drug targeting, biomolecule separation, and hyperthermal cancer therapy (*3*−*5*). Although uniform and highly crystalline magnetite nanoparticles have been recently developed by thermal decomposition processes, they are poorly dispersed in aqueous solution due to their hydrophobic surface coatings (*6, 7*). For biomedical applications, the surface of the magnetite nanoparticles needs to be suitably engineered to acquire improved colloidal stability in physiological media, biocompatibility, drug encapsulation ability, and specific targetability to ensure desirable interactions with cells or tissues. To this end, magnetite nanocrystals have been coated with hydrophilic polymers (e.g., dextran and polyvinylpyrrolidone) or inorganic shells (e.g., gold and silica) (*8, 9*) and encapsulated into polymeric micelles or nanoparticles (*10, 11*).

Magnetic resonance imaging (MRI) has been recognized as a powerful noninvasive diagnostic technique to visualize the fine structure of a human body in a high spatial resolution (*12*). The use of MR contrast agents enables achievement of clear images for accurate diagnosis, by exerting an influence on the longitudinal (T_1) or transverse (T_2) relaxation time of the surrounding tissue. For example, paramagnetic complexes containing gadolinium (Gd^{3+}) or manganese (Mn^{2+}) ions induce the local relaxation change of the nearby water protons and mainly reduce T_1, providing positive contrast (bright signal) on T_1-weighted MR image (*13*). On the other hand, superparamagnetic magnetite nanoparticles have been widely utilized as ultrasensitive negative contrast agents for stem cell tracking and early detection of cancers due to their strong T_2 shortening effect (*14*−*16*). Nevertheless, their clinical applications are quite limited because of the negative contrast effect and magnetic susceptibility artifacts. Since the magnetite nanoparticles represent dark areas in MR images, their negative contrast is often confused with a low-level MR signal arising from adjacent tissues such as bone or vasculature (*17, 18*). Furthermore, susceptibility artifacts can occur as a result of the steep change of local magnetic field around iron oxide nanoparticles, leading to the locally distorted anatomy of surrounding tissue in MR image (*19*).

In the present study, we synthesize and characterize gadolinium-labeled magnetite nanoparticles (GMNPs) using 3,4-dihydroxy-L-phenylalanine (DOPA) as a bioinspired adhesive, and demonstrate their utility as dual contrast agents for T_1- and T_2-weighted MRI. DOPA is a modified amino acid abundantly found within adhesive proteins, which are secreted by marine mussels (*Mytilus edulis*) (*20*). DOPA is known to play an important role in the strong attachment of marine mussels on a wide range of organic and inorganic substrates (*21, 22*). Recently, it was discovered that DOPA and its analogue dopamine can be effectively utilized for anchoring small organic molecules or polymers onto the surface of metal oxides such as TiO_2, Al_2O_3, and Fe_3O_4 (*23*−*25*). Taking advantage of its strong and versatile binding ability, magnetite nanoparticles were surface-coated by a mixed layer of DOPA-terminated poly(ethylene glycol) chains and dopamine molecules, resulting in high water dispersibility and good biocompatibility. The surface of magnetite nanoparticles was further modified with multiple chelating ligands for complexing gadolinium ions. The resultant GMNPs are expected to induce a simultaneous positive and negative contrast enhancement according to the MR imaging protocols employed, making them useful as dual-functional MRI contrast agents (*26*). Depending on the tissue site of interest, GMNPs can be selectively visualized by T_1- or T_2-weighted MRI in order to achieve complementary information that cannot be obtained by the use of only one type of contrast agent, thereby

leading to more precise diagnosis. We examined the stability, morphology, and crystalline structures of GMNPs by using transmission electron microscopy (TEM) and X-ray diffraction (XRD) analysis. The capability of GMNPs to generate dual contrast for T_1- and T_2-weighted MRI was also validated by performing in vitro and in vivo imaging and relaxivity measurements.

EXPERIMENTAL PROCEDURES

Materials. Methoxy-poly(ethylene glycol)-succinic acid (mPEG-SA, M_w = 2000) was obtained from Sunbio Co. (Anyang, Korea). Dopamine hydrochloride (3-hydroxytyramine hydrochloride), 3,4-dihydroxy-L-phenylalanine (DOPA), *N*,*N*′-dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), and gadolinium(III) chloride hexahydrate ($GdCl_3 \cdot 6H_2O$) were purchased from Sigma Chemical Co. (St. Louis, MO). 2-(*p*-Isothiocyanatobenzyl)diethylene triamine pentaacetic acid (*p*-SCN-benzyl-DTPA) was purchased from Macrocyclics (Dallas, TX). Ferumoxides suspension (Feridex) and gadopentetate dimeglumine (Magnevist, Gd-DTPA) were supplied by Berlex Laboratories (Wayne, NJ). Extracel hydrogel kit obtained from Glycosan BioSystems, Inc. (Salt Lake City, UT) was used according to the manufacturer's instruction. All other chemicals were of analytical grade.

Synthesis of DOPA-Conjugated Poly(ethylene glycol) (mPEG-DOPA). mPEG-DOPA was synthesized by conjugating an amino group of DOPA with a carboxylic acid group of mPEG-SA using DCC/NHS succinimidyl carbonate chemistry (*23*). Briefly, mPEG-SA (2116 mg) and DCC (654 mg) were first dissolved in 20 mL of distilled dichloromethane. Then, NHS (183 mg) dissolved in 5 mL of acetone was slowly added to the above solution. After 12 h of reaction under nitrogen atmosphere, the solution was precipitated into excess of cold ethyl ether and then evaporated under vacuum for 2 day. The activated PEG (1120 mg) dissolved in 10 mL of methanol was added to 30 mL of 0.1 M $Na_2B_4O_7$ solution (pH = 9.32) containing 313.5 mg of DOPA. After reaction for 12 h, the solution was dialyzed against acidified deionized water (pH 4) by a Spectra/Por dialysis membrane with a MW cutoff of 1 kDa and then lyophilized. The chemical structure of the product was confirmed by a Bruker DRX 400 ^{1}H NMR spectrometer operating at 400 MHz. The degree of substitution was estimated to be ca. 80% by comparing the relative peak area ratio between two methylene protons from an ethylene oxide group (3.6 ppm) and three protons on a DOPA phenyl ring (6.5−6.9 ppm).

Synthesis of mPEG-DOPA/Dopamine Stabilized Magnetite Nanoparticles. Oleic acid-coated magnetite nanoparticles with an average diameter of 17 nm were produced by thermal decomposition of Fe-oleate complex (*6, 11*). Oleic acid-coated magnetite nanoparticles (5 mg) dispersed in 3 mL of dichloromethane were mixed with 0.5 mL of dimethylformamide containing mPEG-DOPA (13.2 mg) and dopamine hydrochloride (3.3 mg). The solution was added to 10 mL of deionized water, and then sonicated for 2 min by using a Branson sonifier 450 (20 kHz, output control 3, duty cycle 40%). The oil-in-water emulsion was subjected to rotary evaporation at 40 °C for 10 min to remove residual solvent under reduced pressure. The product was purified by dialysis against deionized water for 1 day (MW cutoff of 12 kDa) and then lyophilized.

Synthesis of Gadolinium-Labeled Magnetite Nanoparticles (GMNPs). Five milligrams of the dried mPEG-DOPA/dopamine stabilized magnetite nanoparticles were dispersed in 5 mL of dimethylformamide, and then added in a dropwise manner to a stirred solution of dimethylformamide containing 22.6 mg of *p*-SCN-benzyl-DTPA. After reaction for 16 h, the excess of unreacted DTPA was removed by dialysis against deionized water for 1 day (MW cutoff of 12 kDa). To the colloidal solution of DTPA-grafted magnetite nanoparticles, 25.8 mg of $GdCl_3 \cdot 6H_2O$ was added. After incubation for 24 h, the resultant GMNPs were purified by extensive dialysis against deionized water for 2 days (MW cutoff of 12 kDa), and then stored at 4 °C until use.

Particle Characterization. The core size and dispersion stability of magnetite nanoparticles were investigated by transmission electron microscopy (TEM). The solution of nanoparticles was air-dried on a 300 mesh Formvar/carbon-coated copper grid, and then observed by a Philips F20 transmission electron microscope. The average particle size was determined by measuring the diameters of more than 50 particles in the TEM image. The hydrodynamic diameter of the magnetite nanoparticles was analyzed by using a dynamic light scattering instrument (Zeta-Plus, Brookhaven, NY) equipped with a He−Ne laser at a wavelength of 632 nm. The ζ potential values of the particles dispersed in 0.1 M phosphate-buffered saline solution (PBS, pH 7.4) were also measured in triplicate at a concentration of 0.5 mg/mL at 37 °C. Fourier transform infrared (FT-IR) spectra were recorded in the 500−4000 cm^{-1} region using an EQUINOX55 spectrometer (Bruker, Germany). Lyophilized samples were mixed with dried potassium bromide (KBr) and then compressed to prepare a pellet. For thermogravimetric analysis, dried samples were placed in aluminum sample cells, and a thermogram for each sample was obtained using a TG 209 F3 Tarsus thermo-microbalance (NETZSCH Instruments, Inc., Burlington, MA). Samples were heated at a rate of 10 °C/min up to 700 °C under a flow of nitrogen gas. Elemental analysis data were obtained using a FlashEA 1112 element analyzer (Thermo Finnigan, Italia). The metal concentration of the nanoparticles was quantified using inductively coupled plasma absorption emission spectroscopy (ICP-AES). X-ray powder diffraction profiles were measured using Rigaku D/max-IIIC diffractometer with CuKα radiation (40 kV, 80 mA). The field-dependent magnetization curves of samples were measured at room temperature with a vibrating sample magnetometer (VSM). All the characterizations were performed within 3 months after sample preparation.

***T_1*- and *T_2*-Weighted MRI Experiments.** To verify contrast characteristics of the nanoparticles as MRI contrast agents, longitudinal ($1/T_1$) and transverse ($1/T_2$) relaxation rates were calculated from the magnetic resonance images. The synthesized GMNPs were compared with aqueous $GdCl_3$ solution and Magnevist (Gd-DTPA) at various gadolinium concentration (50, 100, 150, 200, and 250 μM), as well as with mPEG-DOPA/dopamine stabilized magnetite nanoparticles and Feridex at equivalent iron concentration. All samples were diluted in deionized water and compared to pure water as a control. In addition, normal saline (0.9% w/v NaCl, pH 7.4) solution was also used to simulate the relaxation properties of the samples in the physiological environment. All MRI measurements were performed on a whole body scanner (ISOL Technology, South Korea) with a human head coil at a clinically relevant field strength of 3.0 T. Conventional spin−echo pulse sequence was used for both T_1 and T_2 measurements with a single slice of 4 mm thickness, a flip angle of 90°, the number of signal averages of 2, 128 × 128 mm field of view, and 128 × 128 matrices. T_1 relaxation measurements were acquired with repetition time (TR) of 100, 300, 600, 1000, 2000, and 3000 ms with an echo time (TE) of 12 ms, and T_2 relaxation measurements with TE of 12, 30, 60, 100, 200, and 300 ms with a TR of 3000 ms. The longitudinal (T_1) and transverse (T_2) relaxation time were obtained by calculating the mean signal intensity of each sample individually in the respective region of interest of MR images. The specific relaxivities (r_1 and r_1) of the samples were determined by measuring the relaxation rates based on the metal concentration (Supporting Information).

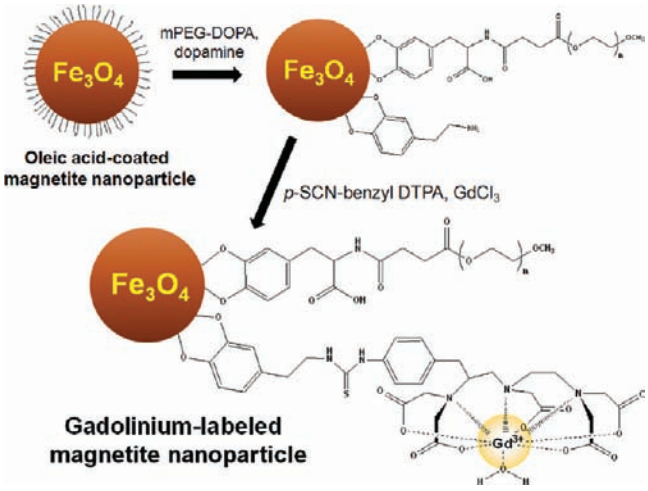

Figure 1. Schematic illustration for the synthesis of gadolinium-labeled magnetite nanoparticles (GMNPs) as dual contrast agents for T_1- and T_2-weighted magnetic resonance imaging.

To evaluate the dual contrast ability of GMNPs in a live animal model, in vivo MRI experiments were performed using BALB/c nude mice. All animal experiments were conducted based on the guidelines provided by Korea Advanced Institute of Science and Technology. GMNPs were suspended in Extracel hydrogel solution with a gadolinium concentration of 0.379 mM in order to prevent leakage from the injection site. A 200 μL aliquot of the suspension was injected subcutaneously into dorsal flanks of nude mice. For comparison, mice were also injected with Magnevist or Feridex at equivalent gadolinium or iron concentration. As a control, only the hydrogel solution was applied for injection. Two mice were included in each group. In vivo MRI was obtained from the same scanner, which was used in in vitro imaging, using a customized quadrature radio frequency (RF) coil with a diameter of 9 cm. T_1-weighted MR images were acquired using a conventional spin−echo sequence using the following parameters: TR/TE = 600/17 ms, 256 × 256 matrices, 100 × 100 mm field of view, a slice thickness of 3 mm, and the number of signal averages of 1. For T_2-weighted MR images, a fast spin−echo sequence was used to reduce acquisition time with the same parameters of T_1-weighted MRI, except for TR/TE = 3500/114 ms and the number of signal averages of 2. Each in vivo scan was completed within an hour.

RESULTS AND DISCUSSION

Figure 1 illustrates a synthetic scheme of gadolinium-labeled magnetite nanoparticles (GMNPs). Oleic acid-coated magnetite nanoparticles with a uniform and highly crystalline structure were first synthesized by the thermal decomposition of iron oleate complexes, as previously reported (*6, 11*). These nanoparticles can only be dispersed in an organic solvent because an oleic acid layer ionically adsorbed on the surface acts as a hydrophobic shell around the iron oxide core (*7*). However, for biomedical applications, it is necessary to make them hydrophilic and well-dispersed in aqueous solution. To prepare water-dispersible magnetite nanoparticles, we utilized DOPA as a bioinspired adhesive to immobilize hydrophilic polymers on the surface of ion oxide structures. Previously, we surface-coated iron oxide nanoparticles with hyaluronic acid (HA) by using dopamine-grafted HA. They showed an excellent water dispersibility while maintaining a superparamagnetic property, useful for HA receptor-specific MRI of cancer cells (*27*). The surface modification process was accomplished by simply incubating oleic acid-coated magnetite nanoparticles with a mixture of DOPA-conjugated poly(ethylene glycol) (mPEG-DOPA) and dopamine in an organic solvent. Since the ortho-

The inset photographs show the dispersion of the magnetite nanoparticles in deionized water. (D) Hydrodynamic diameters of GMNPs dispersed in deionized water and in PBS solution.

dihydroxylphenyl (catechol) group of DOPA and its analogue dopamine forms strong coordination bonds with the surface of iron oxides (e.g., γ-Fe_2O_3, Fe_3O_4) (*25, 28*), it was anticipated that the magnetite nanoparticles was decorated with a mixed layer of mPEG chains and dopamine molecules. The resulting magnetite nanoparticles dispersed in an organic phase could be readily dispersed into an aqueous phase after solvent evaporation. For synthesis of GMNPs, these magnetite nanoparticles were further derivatized with diethylene triamine pentaacetic acid (DTPA), a chelating ligand for binding a paramagnetic gadolinium (Gd^{3+}) ion (*29*). The conjugation reaction of DTPA was carried out through the formation of an isothiourea bond between an isothiocyanate derivative of DTPA (*p*-SCN-benzyl DTPA) and a primary amine group in the dopamine molecule bound on the nanoparticles. Thereafter, DTPA-grafted magnetite nanoparticles were reacted with excess amount of $GdCl_3 \cdot 6H_2O$, resulting in the direct complexation of Gd^{3+} into the particles by chelation. Once nonchelated Gd^{3+} was removed by extensive dialysis against deionized water, GMNPs comprising magnetite nanoparticles carrying numerous gadolinium chelates were successfully produced.

We investigated the size distribution and dispersion stability of GMNPs in aqueous solution by using transmission electron microscopy (TEM) and dynamic light scattering (DLS) analysis. As shown in Figure 2A, oleic acid-coated magnetite nanoparticles were produced with a spherical morphology and an average diameter of 17.2 ± 1.3 nm. The TEM images obviously showed that the core size and shape of magnetite nanoparticles did not significantly change after surface modification with mPEG-DOPA and dopamine, even after the incorporation of paramagnetic gadolinium chelates. It should be noted that the dispersion stability of the oleic acid-coated magnetite nanoparticles was greatly changed after the ligand exchange reaction on the surface from oleic acid to mPEG-DOPA and dopamine (inset photographs). While the oleic acid-coated magnetite nanoparticles were not dispersible in deionized water and finally precipitated out of solution, mPEG-DOPA/dopamine stabilized magnetite nanoparticles and GMNPs exhibited excellent stability

in deionized water, forming a transparent brown solution. This dramatic difference was probably attributed to the hydrophilic nature of PEG chains anchored on the surface of the magnetite nanoparticles. It has been shown previously that the immobilization of PEG on various polymeric and inorganic nanoparticles improves their colloidal stability in aqueous physiological environment due to the steric stabilization effect of surface-exposed PEG chains (*16, 23*). Additionally, it was likely that the surface coating of dopamine molecules might partially contribute to the improved dispersion stability through the charge stabilization of magnetite nanoparticles (*27, 30*). As shown in Figure 2B and C, the magnetite nanoparticles were well-separated from each other without observable aggregation, suggesting that they were effectively stabilized in aqueous solution by the hydrophilic protective shell layer comprising hydrophilic PEG chains and dopamine molecules. Figure 2D presents the hydrodynamic diameters of GMNPs dispersed in deionized water and in PBS solution. The size of GMNPs (73.8 ± 7.6 nm) measured by DLS analysis was larger than the value obtained from TEM, probably due to the swelling of the PEG shell layer on the magnetite nanoparticles in water (*28*). It was also noteworthy that the hydrodynamic diameters and dispersion stability of GMNPs were not greatly changed after the incubation in PBS solution, suggesting that the adhesive properties of DOPA and dopamine molecules bound on the magnetite nanoparticles were significantly maintained in aqueous physiological environment.

Fourier transform infrared (FT-IR) spectroscopy was performed in order to examine the ligand exchange on the surface of magnetite nanoparticles (Figure 3A). The FT-IR spectrum of oleic acid-coated magnetite nanoparticles showed strong absorption bands at 2852 and 2923 cm^{-1}, arising from symmetric and asymmetric C−H stretch in the oleyl chains, respectively. The characteristic bands of oleic acid remarkably decreased after the ligand exchange, whereas new absorption bands centered at 1110 and 1635 cm^{-1} appeared. Since these absorption bands can be assigned to the C−O−C ether stretch of PEG and C═C vibration of catechol rings, respectively, it was evident that the oleic acid on the surface of magnetite nanoparticles was efficiently replaced by PEG chains and dopamine molecules. In the FT-IR spectrum of DTPA-grafted magnetite nanoparticles, an absorption band associated with the O−H stretch in carboxylic acid groups appeared at 3447 cm^{-1}, accounting for the conjugation of DTPA to the dopamine molecule bound on the nanoparticles. The differential thermograms of oleic acid-coated magnetite nanoparticles indicated that the thermal decomposition of oleic acid took place mainly at 282 and 453 °C (Figure 3B). After the ligand exchange, however, the magnetite nanoparticles exhibited a strong mass loss at 405 °C without any signs of the decomposition of oleic acid. This result revealed that the organic layer was completely removed from the particle surface, and mPEG-DOPA chains were anchored onto them concomitantly. It was also found that the weight loss of DTPA-grafted magnetite nanoparticles occurred over a broad range of temperature around 375 °C, presumably due to the desorption of DTPA molecules from the particles. Taken together, these results demonstrated that PEG chains and DTPA molecules were stably immobilized onto the surface of the magnetite nanoparticles via a catechol−metal coordination interaction.

The surface modification processes were further investigated by examining surface charge properties of magnetite nanoparticles. As shown in Figure 4, magnetite nanoparticles coated with only mPEG-DOPA showed a slightly negative ζ potential of −2.9 ± 2.2 mV, which was in agreement with the previous finding (*30*). In contrast, mPEG-DOPA/dopamine stabilized magnetite nanoparticles had a positively charged surface (10.5

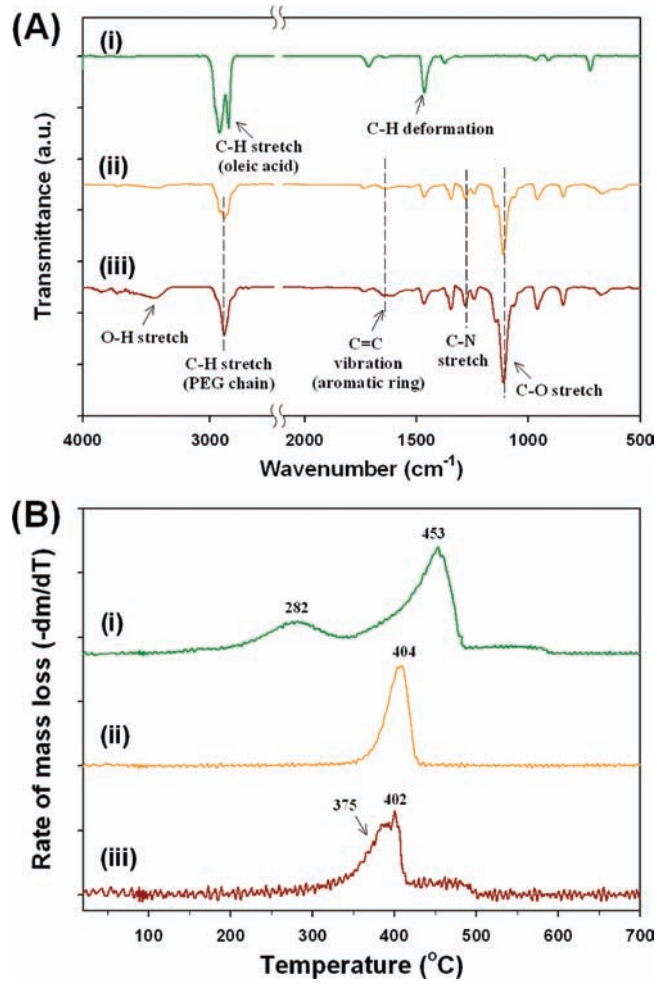

Figure 3. (A) FT-IR spectra and (B) differential thermograms of (i) oleic acid-coated magnetite nanoparticles, (ii) mPEG-DOPA/dopamine stabilized magnetite nanoparticles, and (iii) DTPA-grafted magnetite nanoparticles.

± 2.8 mV) owing to the presence of dopamine molecules bearing free amine groups. It was also found that DTPA-grafted magnetite nanoparticles displayed a negative ζ potential of −21.3 ± 4.9 mV, which can be explained by the surface coverage of the particles with negatively charged DTPA

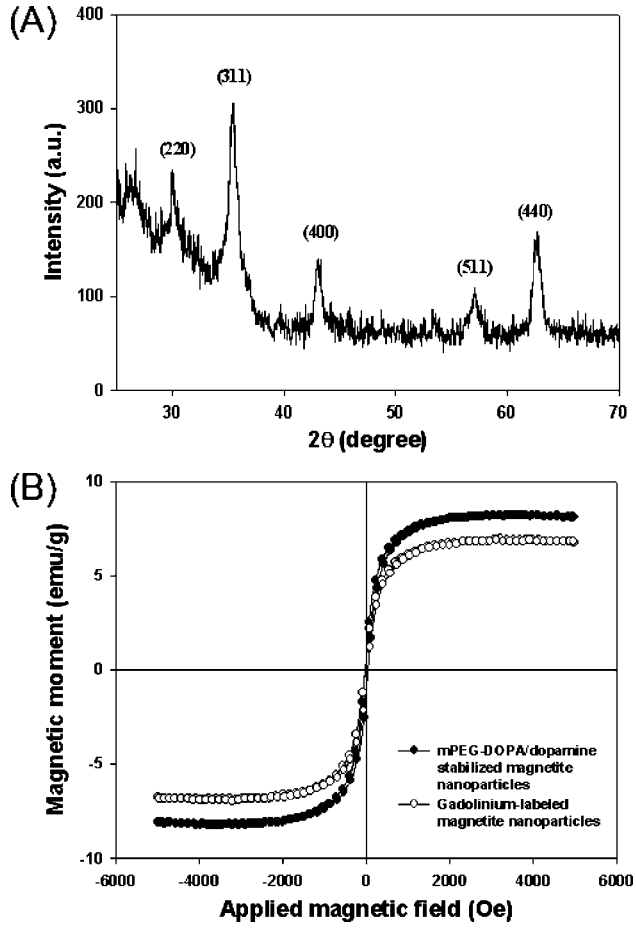

Figure 5. (A) X-ray diffraction pattern of GMNPs. (B) Field-dependent magnetization curve of mPEG-DOPA/dopamine stabilized magnetite nanoparticles (black dots) and GMNPs (hollow dots) at room temperature.

molecules. However, their ζ potential value was dramatically changed to -5.5 ± 3.1 mV upon incubating with an aqueous $GdCl_3$ solution, presumably because cationic Gd^{3+} ions were coordinated to anionic carboxylate groups in DTPA molecules, resulting in the neutralization of the negative surface charge (*31*). ICP-AES analysis of GMNPs indicated that each particle contained 11.5 wt % of Gd atoms, indicating that a single magnetite nanoparticle was covered with ca. 7010 gadolinium chelates. Taking into account the number of the conjugated dopamine molecules determined by elemental analysis, almost 68% of the dopamine molecules immobilized on the surface were estimated to participate in the incorporation of the gadolinium chelates (Supporting Information). It was previously reported that the surface density of Gd^{3+} paramagnetic species might have a profound impact on the positive contrast enhancement of Gd^{3+}-labeled nanoparticles (*32*). In the present study, the surface density of the gadolinium chelates could be controlled by simply changing the ratio of mPEG-DOPA and dopamine, resulting in the formation of GMNPs with tunable compositions and contrast properties. The above results revealed that GMNPs could hold a large number of Gd^{3+} ions within the DTPA-functionalized shell layer around the iron oxide core, and hence they were advantageous for generating gadolinium-enhanced contrast in MRI images.

X-ray diffraction (XRD) pattern was examined to confirm the crystal structure of magnetite nanoparticles (Figure 5A). The XRD pattern of GMNPs displayed characteristic diffraction peaks corresponding to a face-centered cubic (fcc) lattice of magnetite crystals (*9*). This was consistent with the XRD pattern of oleic acid-coated magnetite nanoparticles, suggesting that the surface modification with mPEG-DOPA and gadolinium chelates did not induce any change on the crystallinity of the iron oxide core. Figure 5B shows the field-dependent magnetization curve of the magnetite nanoparticles before and after the functionalization with gadolinium chelates. GMNPs had a lower saturation magnetization value (6.85 emu/g) as compared with that of mPEG-DOPA/dopamine stabilized magnetite nanoparticles (8.12 emu/g), which was probably attributed to the decrease in iron oxide content of the particles (*30, 33*). It was noteworthy that GMNPs exhibited no hysteresis in the magnetization curve, suggesting that the magnetite nanoparticles maintained their superparamagnetic behavior after paramagnetic Gd^{3+} ions were coordinated onto the surface.

To validate the potential of GMNPs as a dual contrast agent, we acquired the T_1- and T_2-weighted MR images and measured the relaxation rates as a function of metal concentration using a 3.0 T MRI scanner. As shown in Figure 6A, GMNPs induced a bright signal enhancement in a concentration-dependent manner on the T_1-weighted images. It should be noted that they exhibited better T_1 positive contrast compared to a clinically available Gd-DTPA-based contrast agent (Magnevist), while there was very little signal enhancement from the magnetite nanoparticles without Gd^{3+} ions. Moreover, the specific relaxivity (r_1) of GMNPs (11.17 mM^{-1} s^{-1}) was markedly higher than r_1 of Magnevist (5.39 mM^{-1} s^{-1}), suggesting that they were much more efficient in enhancing T_1 positive contrast than Magnevist (Figure 6B). It was reported previously that the r_1 values of Gd-based contrast agents were strengthened when bound to large molecules such as proteins and polymers due to the limited molecular motion of Gd^{3+} ions (*29, 34*). Hence, it was conceivable that the remarkably high r_1 value of GMNPs resulted from the reduced mobility of Gd^{3+} ions tightly incorporated into nanometer-scale particles. Despite the high r_1 value (10.15 mM^{-1} s^{-1}), aqueous $GdCl_3$ solution is not approved for clinical use due to toxicity of free Gd^{3+} ions (*13*). Since the covalently immobilized DTPA shell on GMNPs allowed for the strong coordination of Gd^{3+} ions onto the particles, GMNPs were considered to be safer than aqueous $GdCl_3$ solution.

As shown in the T_2-weighted images (Figure 6C), GMNPs also displayed a significant signal reduction with increasing the particle concentration. It was found that the r_2 value of magnetite nanoparticles decreased from 225.81 to 30.32 mM^{-1} s^{-1} after the labeling with Gd^{3+} ions (Figure 6D), suggesting that the paramagnetic gadolinium chelates interfered with the T_2 relaxation processes of the neighboring magnetite nanoparticles (*35, 36*). The observed decrease in the r_2 value was partially attributed to the reduced magnetization of the particles (*7, 37*). Although GMNPs had a lower r_2 compared to that of commercially available Feridex (148.95 mM^{-1} s^{-1}), their T_2 contrast effect was sufficiently strong to generate negative contrast enhancement on the MR images. Since the relaxivities of GMNPs were not diminished in normal saline ($r_1 = 14.45$ mM^{-1} s^{-1}, $r_2 = 36.68$ mM^{-1} s^{-1}), it was anticipated that their relaxation properties were maintained in physiological environment.

We performed in vivo MRI experiments to demonstrate the dual contrast ability of GMNPs in a live animal model. In order to prevent leakage from the injection site, GMNPs suspended in Extracel hydrogel solution were injected subcutaneously into dorsal flanks of nude mice, and then, the hydrogel formed at the injection site was examined by using a 3.0 T MRI scanner. Figure 7A shows that the hydrogel containing Magnevist appears as a bright area in the T_1-weighted MRI. In contrast, a dark signal void can be observed at the injection site of Feridex, indicative of its strong T_2 negative contrast (Figure 7B). As shown in Figure 7C and D, GMNPs displayed a bright signal enhancement

Figure 6. and a marked signal drop at the injection site on the T_1- and T_2-weighted MR image, respectively, while no apparent contrast was detected from the control site containing only the gel matrix. Consequently, the above results demonstrated that GMNPs having high r_1 and r_2 relaxivities exhibited both positive and negative contrast enhancement on the MR images. Due to their dual contrast effect, GMNPs can be utilized to achieve both T_1- and T_2-weighted MR images of the tissue site of interest, and hence increase the accuracy of diagnosis. Furthermore, this dual contrast approach may help to overcome the limitations of traditional iron oxide-based and gadolinium-based contrast agents, thereby expanding opportunities of MRI for diverse therapeutic and diagnostic applications.

CONCLUSIONS

Gadolinium-labeled magnetite nanoparticles were developed as dual contrast agents for T_1- and T_2-weighted magnetic resonance imaging. These nanoparticles were produced through the formation of a mixed layer of poly(ethylene glycol) chains and dopamine molecules via strong coordination bonds of DOPA to iron oxides, and subsequent immobilization of gadolinium chelates onto the nanoparticle surface. The surface modification process did not disturb the crystal structure and

superparamagnetic properties of the magnetite nanoparticles, suggesting that the current strategy would afford stabilization and functionalization of various inorganic nanomaterials, which are poorly soluble and processable in aqueous solution. Moreover, we demonstrated that GMNPs not only had the ability to improve surrounding water proton signals on the T_1-weighted image, but also could induce significant signal reduction on the T_2-weighted image. These novel nanomaterials having both positive and negative contrast could be potentially utilized as molecular imaging probes for a wide range of diagnostic and therapeutic applications.

ACKNOWLEDGMENT

This research was partly supported by the Ministry for Health, Welfare and Family Affairs, the Ministry of Knowledge Economy, and the World Class University project and the National Research Laboratory program from the Ministry of Education, Science and Technology, Republic of Korea. We would like to thank Jaewon Lee and Prof. Jung Hee Lee in Samsung Medical Center for helpful discussion and synthesis of iron oxide nanocrystals, and Myung Wook Song for VSM measurements.

Synthesis and Biophysical Studies of Coronene Functionalized 2′-Amino-LNA: A Novel Class of Fluorescent Nucleic Acids

Pankaj Gupta, Niels Langkjær, and Jesper Wengel*

Nucleic Acid Center, Department of Physics and Chemistry, University of Southern Denmark, 5230 Odense M, Denmark.
Received September 23, 2009; Revised Manuscript Received December 27, 2009

Incorporation of 2′-*N*-(coronen-1-yl)methyl-2′-amino-LNA monomer **X** or 2′-*N*-4-(coronen-1-yl)-4-oxobutanoyl-2′-amino-LNA monomer **Y** into short DNA strands induces high binding affinity toward DNA or RNA and a marked red-shift in steady-state fluorescence emission upon hybridization to cDNA or RNA.

INTRODUCTION

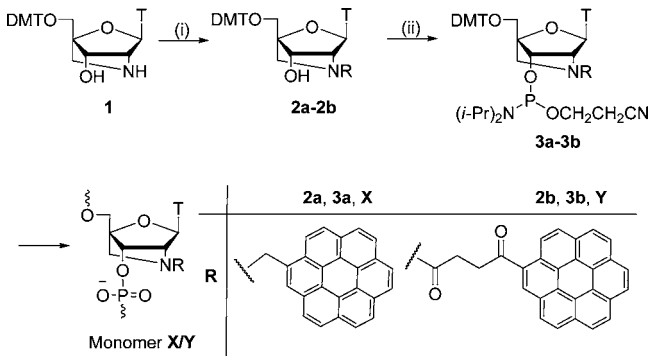
Fluorescent labeling of nucleosides and oligonucleotides is explored for structural studies, nucleic acid sequencing, molecular diagnostics, and other applications relating to genomics (*1*). "Molecular beacons" (*2*−*4*), fluorophore−quencher combination probes (*5*), "scorpion" (*6*), "Pacman" (*7*) or "sunrise primers," (*8*) specific pyrene-conjugated DNA or RNA probes (*9*−*24*), and fluorescence resonance energy transfer (FRET) probes (*5, 25, 26*) are typical example of such probes. Other fluorescent probes have been designed by labeling of oligonucleotides with a single hybridization sensitive moiety (*17, 27*−*37*). These methods have several potential advantages such as sensitivity, flexibility, safety, and relative inexpensiveness compared to the classical radiolabeling method.

The high-affinity hybridization of LNA (locked nucleic acid) (*37*−*42*), 2′-amino-LNA (*43*−*45*), and α-L-LNA (*46*) and the properties of LNA modified oligonucleotides as diagnostic tools and therapeutic agents (*47, 48*) encouraged us to appraise N-functionalized derivatives of 2′-amino-LNA. Recently, LNAs have been functionalized by fluorescent groups such as pyrene (*15, 18, 49, 50*), perylene (*51, 52*), and (phenylethynyl)pyrene (*53*). These pyrene-functionalized LNAs exhibit appealing properties and can be used to sense full complementarity of DNA or RNA counterparts.

Recently, Hrdlicka et al. (*18*) investigated multilabeled pyrene-functionalized 2′-amino-LNA probes which exhibited high-affinity hybridization to DNA/RNA complements, quenched fluorescence of single-stranded probe, and large increase of the quantum yield and fluorescence brightness upon hybridization. More recently, Astakhova et al. (*52, 53*) reported multilabeled perylene- and (phenylethynyl)pyrenecarbonyl-functionalized 2′-amino-LNA probes which exhibited high-affinity hybridization toward cDNA/RNA, considerably quenched fluorescence of single-stranded multilabeled probes, increased fluorescence brightness upon hybridization, high fluorescence quantum yields, and red-shifted emission compared to pyrene-functionalized 2′-amino-LNA probes. However, there is still a need to find optimal fluorochromes which, e.g., display a long-wave emission spectrum relative to pyrene, perylene, and (phenylethynyl)pyrenecarbonyl.

Coronene is a fluorochrome which resembles pyrene in its chemical behavior but differentiates from pyrene with respect to photochemical properties (*54*). Coronene is very stable, showing the properties of a fully benzenoid hydrocarbon. The extra stability of coronene imparted by the sextet ring current has been called "superaromaticity". Unlike pyrene, coronene is not a common fluorescent dye for modification of oligonucleotides, whereas it has been used in the field of lipids (*55*). Nagata et al. (*56*) described coronene as an external binder of DNA, but later, Zinger et al. (*57*) described that the planner coronene molecules partially insert between adjacent DNA bases. Herein, we report the synthesis of monomer **X** (with a methylcoronene moiety attached to 2′-amino-LNA) and monomer **Y** (with a oxobutanoylcoronene moiety attached to 2′-amino-LNA) and oligonucleotides involving them, together with their hybridization and fluorescence properties.

EXPERIMENTAL PROCEDURES



General. Anhydrous reactions were carried out under an atmosphere of nitrogen. Solvents used were of HPLC grade. Acetonitrile and dichloromethane were made anhydrous by storage over molecular sieves (4 Å). TLC was run with Merck silica 60 F_{254} aluminum sheets. ^{1}H NMR spectra were recorded at 300 MHz, ^{13}C NMR spectra at 75.5 MHz, and ^{31}P NMR spectra at 121.5 MHz (δH: $CDCl_3$ 7.26 ppm, DMSO-d_6 2.50; δC: $CDCl_3$ 77.0 ppm, DMSO-d_6 39.4). Chemical shifts are reported in ppm relative to either tetramethylsilane or the deuterated solvent as an internal standard for ^{1}H NMR and ^{13}C NMR, and relative to 85% H_3PO_4 as external standard for ^{31}P NMR. Assignments of NMR spectra, when given, are based on 2D NMR experiments. Coupling constants (*J* values) are given in Hertz. ESI-HRMS were recorded in positive ion mode on an API QSTAR mass spectrometer.

Synthesis of ON2−**ON10.** Nucleoside phosphoramidites **3a** and **3b** were used as building blocks for incorporation of 2′-*N*-(coronen-1-yl)methyl-2′-amino-LNA monomer **X** and 2′-*N*-(coronen-1-yl)-4-oxo-butanoyl-2′-amino-LNA monomer **Y**, respectively, into DNA oligonucleotides (Scheme 1, Table 1) in 0.2 μmol scale synthesis using an automated DNA synthesizer. Standard procedures were used for unmodified monomers (i.e, 3% trichloroacetic acid in CH_2Cl_2 as detritylation reagent; 0.25 M 4,5-dicyanoimidazole (DCI) in CH_3CN as activator; acetic anhydride in THF as cap A solution; *N*-methylimidazole in THF as cap B solution; and 0.02 M iodine in H_2O/pyridine/THF as the oxidizing solution). The stepwise coupling yields were >99% for unmodified phosphoramidites (2 min coupling time) and for **3a** and **3b** 95% and 99% (10 min coupling time, 1*H*-tetrazole as activator), respectively, based on the absorbance of the dimethoxytriyl cation released after each coupling step. After deprotection and cleavage from solid support (32% aq ammonia, 55 °C, 12 h), the modified ONs were precipitated and repeatedly washed with ethanol, and their composition and purity (>80%) verified by MALDI-MS analysis and ion-exchange HPLC, respectively.

[a] Thermal denaturation temperatures [T_m values (°C) (ΔT_m = change in T_m value calculated relative to DNA/DNA or DNA/RNA reference duplex)] measured as the maximum of the first derivative of the melting curve (A_{260} vs temperature) recorded in 10 mM phosphate buffer ([Na^+] = 110 mM, [Cl^-] = 100 mM, [EDTA] = 0.1 mM, pH 7.0) using 1.0 μM concentrations of the two complementary strands. T_m values are averages within ±1 °C of at least two measurements. See Scheme 1 for structure of monomer **X** and monomer **Y**. MALDI-MS *m*/*z* ([M-H]$^-$; found/calc.): **ON3**, 3092/3093; **ON4**, 3020/3022; **ON5**, 3021/3022; **ON6**, 3360/3361; **ON7**, 3161/3163; **ON8**, 3088/3092; **ON9**, 3090/3092; **ON10**, 3500/3501. [b] **ON1** is the cDNA strand to **ON2/ON4/ON5/ON6/ON8/ON9/ON10**; **ON2** is the cDNA strand to **ON3/ON7**. [c] T_m values (°C) toward DNA strands containing a single mismatch in the central position, monomer **X**: G/C/T: 24.0/31.5/28.0; monomer **Y**: G/C/T: 36.5/30.0/35.5. [d] T_m values (°C) toward RNA strands containing a single mismatch in the central position, monomer **X**: G/C/U: 21.0/21.0/18.5; monomer **Y**: G/C/U: 30.0/17.0/22.0.

Thermal Denaturation Studies. Concentrations of oligonucleotides were calculated using the following extinction coefficients (OD/μmol): G, 10.5; A, 13.9; T/U, 7.9; C, 6.6; coronene units, 36.0. The two complementary strands (~1.0 μM) were thoroughly mixed, and the duplex denatured by heating to 80 °C followed by cooling to the starting temperature (5 °C) of the experiment. Quartz optical cells with a path length of 1.0 cm were used. Thermal denaturation curves were obtained on a Perkin-Elmer Lambda 35 UV/vis spectrometer equipped with a PTP-6 peltier temperature programmer. Melting temperatures (T_m values/°C) determined as the maximum of the first derivative of the thermal denaturation curve (A_{260} vs temperature) recorded in 10 mM phosphate buffer ([Na^+] = 110 mM, [Cl^-] = 100 mM, [EDTA] = 0.1 mM, pH 7.0). A temperature range from 5 to 75 °C with a ramp of 1.0 °C/min was used.

UV Absorption Measurements. UV absorption measurements (200−500 nm) were performed on a Shimadzu UV-160A spectrophotometer using quartz optical cells with a path length of 1.0 cm. Measurements were conducted using 1.0 μM of strands in 10 mM phosphate buffer ([Na^+] = 110 mM, [Cl^-] = 100 mM, [EDTA] = 0.1 mM, pH 7.0).

(1*R*,3*R*,4*R*,7*S*)-5-[4-Coronen-1-ylmethyl]-1-(4,4′-dimethoxytrityloxymethyl)-7-hydroxy-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]heptane (2a). Nucleoside **1** (*58*) (0.23 g, 0.40 mmol) was dissolved in anhydrous 1,2-dichloroethane (5 mL). To this stirred solution at rt were added coronene-1-carbaldehyde (0.14 g, 0.42 mmol) and sodium triacetoxyborohydride (0.12 g, 0.60 mmol). After stirring at rt for 6 h, saturated aq $NaHCO_3$ (2 mL) was added and the mixture diluted with ethylacetate (20 mL). The organic phase was washed with saturated aq $NaHCO_3$ (10 mL) and the aq phase was extracted with ethylacetate (2 × 20 mL). The combined organic phase was dried over Na_2SO_4, filtered, and evaporated to dryness under reduced pressure, and the resulting residue was purified by silica gel column chromatography (20−70% EtOAc in petroleum ether, v/v) to afford nucleoside **2a** as a yellowish solid material (210 mg; 60%). R_f = 0.35 (7% MeOH in CH_2Cl_2, v/v); ESI-HRMS *m*/*z* 906.3127 ([M+Na]$^+$, $C_{57}H_{45}N_3O_7$·Na^+ calc. 906.3149); ^{1}H NMR (DMSO-d_6) δ (selected signals) 11.39 (s, NH), 9.16−8.91 (m, Ar), 7.70 (s, H6), 7.48−6.88 (m, Ar), 5.94 (s, 3′−OH), 5.74 (d, J = 6.0 Hz, H1′), 5.21 (d, J = 14.4 Hz, CH_2Ar), 5.03 (d, J = 14.7 Hz, CH_2Ar), 4.35 (d, J = 4.5 Hz, H2′), 3.78−3.72 (m, H3′ and 2 × OCH_3), 3.48 (d, J = 10.8 Hz, H5′a/b), 3.38−3.35 (m, H5′a/b overlapping with H_2O), 3.18 (d, J = 9.6 Hz, H5″a), 2.97 (d, J = 6.0 Hz, H5″b), 1.55 (s, CH_3); ^{13}C NMR (DMSO-d_6) δ 163.8, 158.1, 150.0, 144.7, 135.4, 135.2, 134.7, 134.0, 129.8, 129.7, 128.1, 128.0, 127.9, 127.8, 127.6, 126.9, 126.8, 126.3, 126.1, 126.0, 125.8, 122.6, 121.8, 121.6, 121.5, 121.3, 121.2, 120.8, 113.2, 108.2, 88.5, 86.2, 85.6, 70.7, 66.5, 59.7, 58.1, 56.8, 55.0, 12.4.

(1*R*,3*R*,4*R*,7*S*)-5-[4-Coronen-1-ylmethyl]-7-[2-cyanoethoxy-(diisopropylamino)-phosphinoxy]-1-(4,4′-dimethoxytrityloxymethyl)-3-(thymin-1-yl)-2-oxa-5-azabicyclo [2.2.1]heptane (3a). Nucleoside **2a** (0.13 g, 0.14 mmol) was dissolved in anhydrous acetonitrile (5 mL) under stirring at rt. *N*,*N*-Diisopropylammonium tetrazolide (0.037 g, 0.22 mmol) and bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine (0.14 mL, 0.44 mmol) were added under nitrogen. The reaction mixture was stirred for 3 h at 35 °C and then diluted with EtOAc (40 mL), washed with H_2O (30 mL), 5% aq $NaHCO_3$ (30 mL) and H_2O (30 mL), dried over Na_2SO_4, filtered, and evaporated to dryness under reduced pressure. The residue was purified by silica gel column chromatography (20−60% EtOAc in petroleum ether, v/v) to afford nucleoside **3a** as a yellowish solid material (118 mg; 74%). R_f = 0.60 (60% EtOAc in petroleum ether, v/v); ESI-HRMS *m*/*z* 1106.4259 ([M+Na]$^+$, $C_{66}H_{62}N_5O_8P$·Na^+ calc. 1106.4227); ^{31}P NMR ($CDCl_3$) δ 149.1.

(1*R*,3*R*,4*R*,7*S*)-5-[4-(Coronen-1-yl)-4-oxo-butanoyl]-1-(4,4′-dimethoxytrityloxy methyl)-7-hydroxy-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]heptane (2b). Nucleoside **1** (*58*) (0.40 g, 0.69 mmol) was dissolved in anhydrous dichloromethane (20 mL). To this stirred solution were added *N*-(3-dimethylaminopropyl-*N*′-ethylcarbodiimide hydrochloride (EDC·HCl, 0.14 g, 0.76 mmol) and 3-coronenyl propionic acid (0.30 g, 0.76 mmol) at 0 °C. After warming to rt, the reaction mixture was stirred for 18 h, whereupon it was diluted with dichloromethane (50 mL) and successively washed with brine (40 mL) and H_2O (40 mL). The organic phase was evaporated to dryness under reduced pressure, and the resulting residue was purified by silica gel column chromatography (0−2% MeOH in CH_2Cl_2, v/v) to afford a rotameric mixture (~1:0.43 by ^{1}H NMR) of **2b** as a yellowish solid material (380 mg; 58%). R_f = 0.32 (7% MeOH in CH_2Cl_2, v/v); ESI-HRMS *m*/*z* 976.3291 ([M+Na]$^+$, $C_{60}H_{47}N_3O_9$·Na^+ calc. 976.3210); ^{1}H NMR (DMSO-d_6) δ

(selected signals) 11.50 (br s, NHA), 11.35 (br s, NHB), 9.53−8.92 (m, Ar), 7.79 (s, H6), 7.63−6.82 (m, Ar), 5.68 (s, H-1′A), 5.52 (br s, H-1′B), 4.77 (br s, H-2′B), 4.63 (br s, H-2′A), 4.14 (br s, H-3′A and H-3′B), 1.83 (br s, CH_3-A), 1.16 (br s, CH_3−B); ^{13}C NMR (DMSO-d_6) δ 203.6, 202.1, 170.7, 170.5, 164.0, 157.8, 150.1, 148.3, 140.2, 134.9, 134.9, 133.9, 132.1, 132.0, 129.2, 129.1, 128.9, 128.4, 128.3, 128.0, 127.9, 127.6, 127.4, 127.1, 126.9, 126.8, 126.6, 126.5, 126.4, 126.2, 126.0, 124.8, 124.0, 122.5, 121.9, 121.2, 121.1, 120.9, 120.7, 113.9, 112.7, 109.9, 108.3, 108.2, 89.4, 88.8, 86.4, 79.9, 68.4, 63.3, 56.6, 55.0, 54.9, 50.8, 45.6, 42.0, 36.9, 28.5, 12.4, 10.9.

(1*R*,3*R*,4*R*,7*S*)-5-[4-(Coronen-1-yl)-4-oxo-butanoyl]-7-[2-cyanoethoxy(diisopropylamino)phosphinoxy]-1-(4,4′-dimethoxytrityloxymethyl)-3-(thymin-1-yl)-2-oxa-5-azabicyclo[2.2.1]-heptane (3b). Nucleoside **2b** (0. 32 g, 0.33 mmol) was dissolved in a mixture of anhydrous acetonitrile (7.0 mL) and dichloromethane (2.0 mL) under stirring at rt. *N*,*N*-Diisopropylammonium tetrazolide (0.057 g, 0.50 mmol) and bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine (0.31 mL, 1.00 mmol) were added under nitrogen. The reaction mixture was stirred for 2 h and then diluted with EtOAc (60 mL), washed successively with H_2O (40 mL), 5% aq $NaHCO_3$ (40 mL) and H_2O (40 mL), dried over Na_2SO_4, filtered, and evaporated to dryness under reduced pressure. The residue was purified by silica gel column chromatography (30−90% EtOAc in petroleum ether, v/v) to afford nucleoside **3b** as a yellowish solid material (300 mg; 79%). R_f = 0.60 (80% EtOAc in petroleum ether, v/v); ESI-HRMS *m*/*z* 1176.4282 ([M+Na]$^+$, $C_{69}H_{64}N_5O_{10}P\cdot Na^+$ calc. 1176.4333); ^{31}P NMR ($CDCl_3$) δ 149.0, 150.2.

RESULTS

The bicyclic nucleoside **1** was synthesized according to a published procedure (*58*) and was selectively N-alkylated by reductive amination using coronene-1-carbaldehyde producing *N*-(coronen-1-yl)methyl derivative **2a**. Furthermore, **1** was N-acylated by 4-(coronen-1yl)-4-oxobutanoic acid giving the corresponding nucleoside **2b**. The phosphoramidite building blocks **3a** and **3b** were obtained by standard phoshphitylation of nucleosides **2a** and **2b**, respectively, using bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine as phosphitylating agent (Scheme 1).

Synthesis of oligonucleotides (ONs) containing 2′-amino-LNA monomers **X** and **Y** was performed in 0.2 μmol scale using an automated DNA synthesizer. 1*H*-Tetrazole was used as coupling agent for monomers **X** and **Y** resulting in 95% and 99% stepwise coupling yields, respectively, based on the absorbance of the dimethoxytrityl cation released after each coupling step (see Experimental Procedures section for details). All synthesized ONs were purified by RP-HPLC, and their identity was confirmed by MALDI-TOF mass spectroscopy and ion-exchange HPLC, respectively.

The influence of the functionalized 2′-amino-LNA monomers **X** and **Y** on duplex thermal stabilities was studied toward DNA and RNA complements (Table 1) by UV thermal denaturation experiments using a 10 mM phosphate buffer ([Na^+] = 110 mM, [Cl^-] = 100 mM, [EDTA] = 0.1 mM, pH 7.0). In all cases, the denaturation curves displayed monophasic transitions.

Earlier, it was reported that conjugates containing functionalized 2′-amino-LNA monomers form stable duplexes toward both DNA and RNA complements, and that N2′-acylated 2′-amino-LNA derivatives exhibit higher thermal stabilities than the corresponding N2′-alkylated derivatives (*18, 49*). Our results are in good agreement with these earlier results. Incorporation of a single monomer **X** in mixed 9-mer **ON3** and **ON5** induced an increase in duplex stability toward cDNA (ΔT_m = +2.0 and +3.0 °C compared to the unmodified reference duplex **ON1**:**ON2**) (Table 1). A similar effect was observed for **ON3** and **ON5** with complementary RNA. Surprisingly, **ON4** showed minor destabilization toward cDNA (ΔT_m = −1.5 °C) and complementary RNA (ΔT_m = −0.5 °C). In contrast to the melting temperature results of monomer **X**, a single incorporation of monomer **Y** in mixed DNA 9-mer ONs (**ON7**−**ON9**) induced high-affinity hybridization toward DNA (ΔT_m = +9.0 to +15.0 °C) and RNA (ΔT_m = +9.5 to +12.0 °C). When comparing thermal stabilities of duplexes involving ONs singly functionalized with monomer **Y**, (**ON7**−**ON9**) were higher than those of the corresponding unmodified duplexes and of duplexes involving a perylenemethyl-2′-amino-LNA monomer (*51*), (phenylethynyl)pyrene-functionalized-2′-amino-LNAs (*53*) and N2′-pyrenecarbonyl-functionalized 2′-amino-LNAs (*18*). This indicates that attachment of coronene moieties to 2′-amino-LNA monomers is compatible with duplex formation. To evaluate this further, we performed CD experiments on duplexes formed between **ON8** or **ON9**, each containing one **Y** monomer, and cDNA or RNA (S7, ESI). These spectra indicate similar duplex structures of the modified duplexes and the unmodified reference (**ON2**:DNA and **ON2**:RNA) duplexes, which support that one **Y** modification can be accommodated without significantly disturbing overall duplex structure.

Incorporation of two modifications may, however, have a more profound effect on duplex structure. N2′-Substituents of 2′-amino-LNAs are known to point toward the minor groove (*15, 49*) and may therefore be affected by the narrow minor grooves in A-type duplexes (*59*). Incorporation of two **X** monomers separated by one nucleotide in a 9-mer DNA strand (**ON6**)

Table 2. Thermal Denaturation Studies in Zipper Arrangements[a]

Duplexes	T_m/°C	ΔT_m/°C	Schematic illustration	Constitution
ON1:5′-d(GTG ATA TGC) **ON2**:3′-d(CAC TAT ACG)	28.5	Ref.		
ON3:5′-d(GTG A**X**A TGC) **ON4**:3′-d(CAC **X**AT ACG)	49.0	+20.5		-1 Zipper
ON3:5′-d(GTG A**X**A TGC) **ON5**:3′-d(CAC TA**X** ACG)	33.5	+5.0		+1 Zipper
ON7:5′-d(GTG A**Y**A TGC) **ON8**:3′-d(CAC **Y**AT ACG)	57.0	+28.5		-1 Zipper
ON7:5′-d(GTG A**Y**A TGC) **ON9**:3′-d(CAC TA**Y** ACG)	47.0	+18.5		+1 Zipper

[a] Thermal denaturation temperatures were recorded under the same conditions as described in Table 1. See Scheme 1 for structures of monomer **X** and monomer **Y**. The black droplets illustrate the coronene moieties of **X** and **Y** monomers.

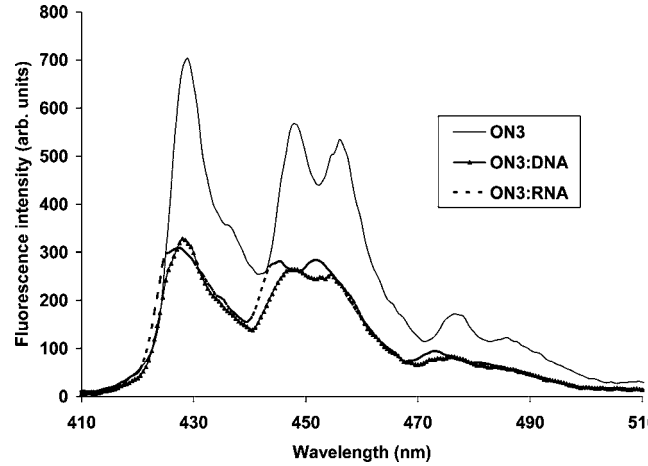

Figure 1. Steady-state fluorescence emission spectra of single-stranded probe **ON3** (with monomer **X**) and of duplexes formed between **ON3** and cDNA (**ON3:DNA**) or RNA (**ON3:RNA**).

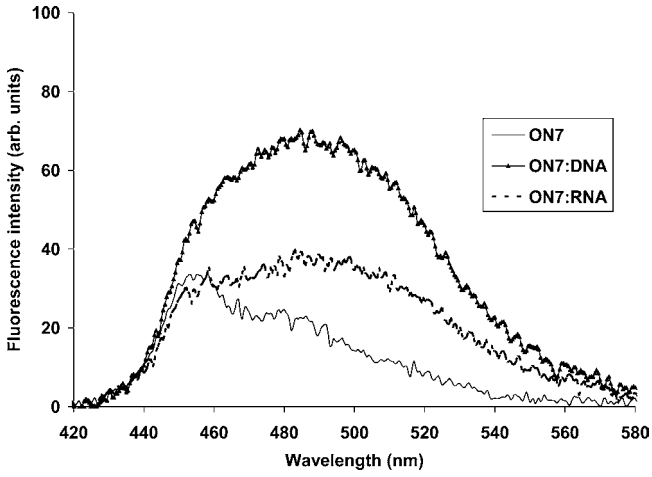

Figure 2. Steady-state fluorescence emission spectra of single-stranded probe **ON7** (with monomer **Y**) and of duplexes formed between **ON7** and cDNA (**ON7:DNA**) and RNA (**ON7:RNA**).

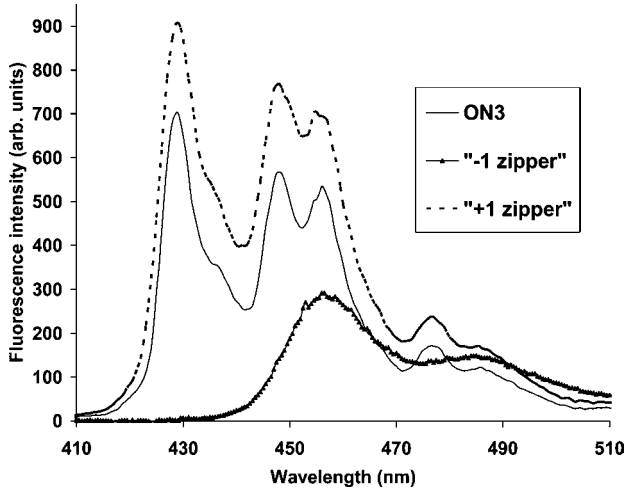

Figure 3. Steady-state fluorescence emission spectra of single-stranded probe **ON3** (with monomer **X**) and of duplexes formed between **ON3** and **ON4** ("−1 zipper" constitution) and **ON3** and **ON5** ("+1 zipper" constitution).

resulted in two melting transitions, which we at present are unable to explain; no transition was observed for **ON6** without a complementary strand. On the contrary, single transitions upon incorporation of two **Y** monomers separated by one nucleotide (**ON10**) were obtained with enhanced thermal stability of the duplex with cDNA (ΔT_m = +1.5 °C per modification) but decreased thermal stability of the duplex with complementary RNA (ΔT_m = −2.7 °C per modification). Relative destabilization toward DNA/RNA complements upon sequential incorporation of two monomers **Y** (relative to incorporation of one **Y** monomer) suggests that the minor groove is too narrow to accommodate the two coronene moieties.

The Watson−Crick base pair selectivity of monomers **X** and **Y** was evaluated by observing thermal denaturation temperatures of duplexes formed between **ON3/ON7** and DNA or RNA strands containing a single mismatched nucleotide opposite monomer **X** or **Y** (see Table 1; footnotes c and d). The base pair selectivity of monomer **X** was satisfactory in the case of T:G DNA and T:U RNA mismatches (−7.5 °C/−9.5 °C, respectively). A relatively weak decrease in thermal stability was observed for the T:T DNA mismatch (−3.5 °C), whereas no mismatch discrimination was observed for the T:C DNA mismatch. Against RNA, **ON3** showed appreciable mismatch discrimination. The base pairing selectivity of monomer **Y** was

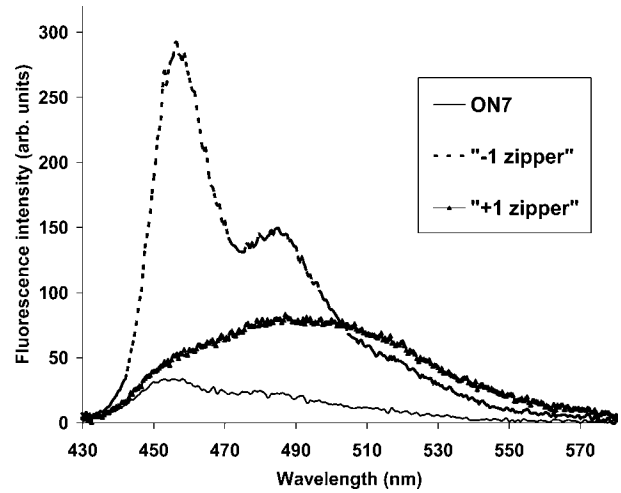

Figure 4. Steady-state fluorescence emission spectra of single-stranded probe **ON7** (with monomer **X**) and of duplexes formed between **ON7** and **ON8** ("−1 zipper" constitution) and **ON7** and **ON9** ("+1 zipper" constitution).

satisfactory in both DNA and RNA contexts: T:T/U (−7.5 °C/−14.0 °C, respectively), T:G (−6.5 °C/−6.0 °C, respectively), and T:C (−13.0 °C/−19.0 °C, respectively).

Studies with **X/Y** monomers positioned in both strands of a duplex were performed in −1 and +1 interstrand zipper (*15*) arrangements of monomer **X** or **Y** (Table 2). Insertion of two **X** monomers in a "−1 zipper" constitution induced extensively increased thermal stability (Table 2, ΔT_m = +20.5 °C), as did insertion of two **Y** monomers (+28.5 °C). On the other hand, insertion of two **X** monomers in a "+1 zipper" constitution induced a limited increase in thermal stability (+5.0 °C), whereas insertion of two **Y** monomers in a "+1 zipper" constitution again induced a significant increase in thermal stability (+18.5 °C). The thermal denaturation temperatures of duplexes involving two modified strands are thus remarkably higher than those of duplexes containing monomers **X** or **Y** in only one strand, indicating that interstrand communication between coronene moieties in the studied "zipper" pattern contributes to overall duplex stability.

The steady-state fluorescence emission spectra of **ON3**−**ON6** containing monomer **X** when excited at its UV absorption maximum λ_{max} 310 nm (10 °C, ±1 °C) showed three emission bands. Insertion of a single **X** monomer in ONs (**ON3**−**ON5**) in general results in quenching of fluorescence intensities (up to half of the intensity of single-stranded ONs) upon hybridization to cDNA or RNA, though a minor increase of fluorescence intensity in the case of **ON4** was observed upon hybridization to cDNA. (Figure 1, and ESI S4.1 to S4.4). However, **ON6** with two **X** monomers separated by one nucleotide upon hybridization with cDNA displayed increased fluorescence intensity (∼2-fold) with unchanged emission wavelength and upon hybridization with complementary RNA slightly increased fluorescence intensity at nearly the same emission wavelength (see ESI S4.5). Incorporation of monomer **X** in ONs (**ON3**−**ON6**) results in fluorescence emission maxima at ∼429 nm, which is 25 nm red-shifted relative to the corresponding pyrenecarbonyl-2′-amino-LNA ONs (*18*), 61 nm blue-shifted relative to the corresponding perylene-3-carbonyl-2′-amino-LNA ONs (*52*) and 1−26 nm blue-shifted relative to the corresponding (phenylethynyl)pyrenecarbonyl-2′-amino-LNA ONs (*53*).

In contrast, insertion of a single **Y** monomer into ONs (**ON7**−**ON9**) in general results in a marked red shift with similar or increased fluorescence intensities upon hybridization to cDNA or RNA (Figure 2 and ESI, S4.6 to S4.9). Surprisingly, **ON10** containing two **Y** monomers upon duplex formation with DNA/

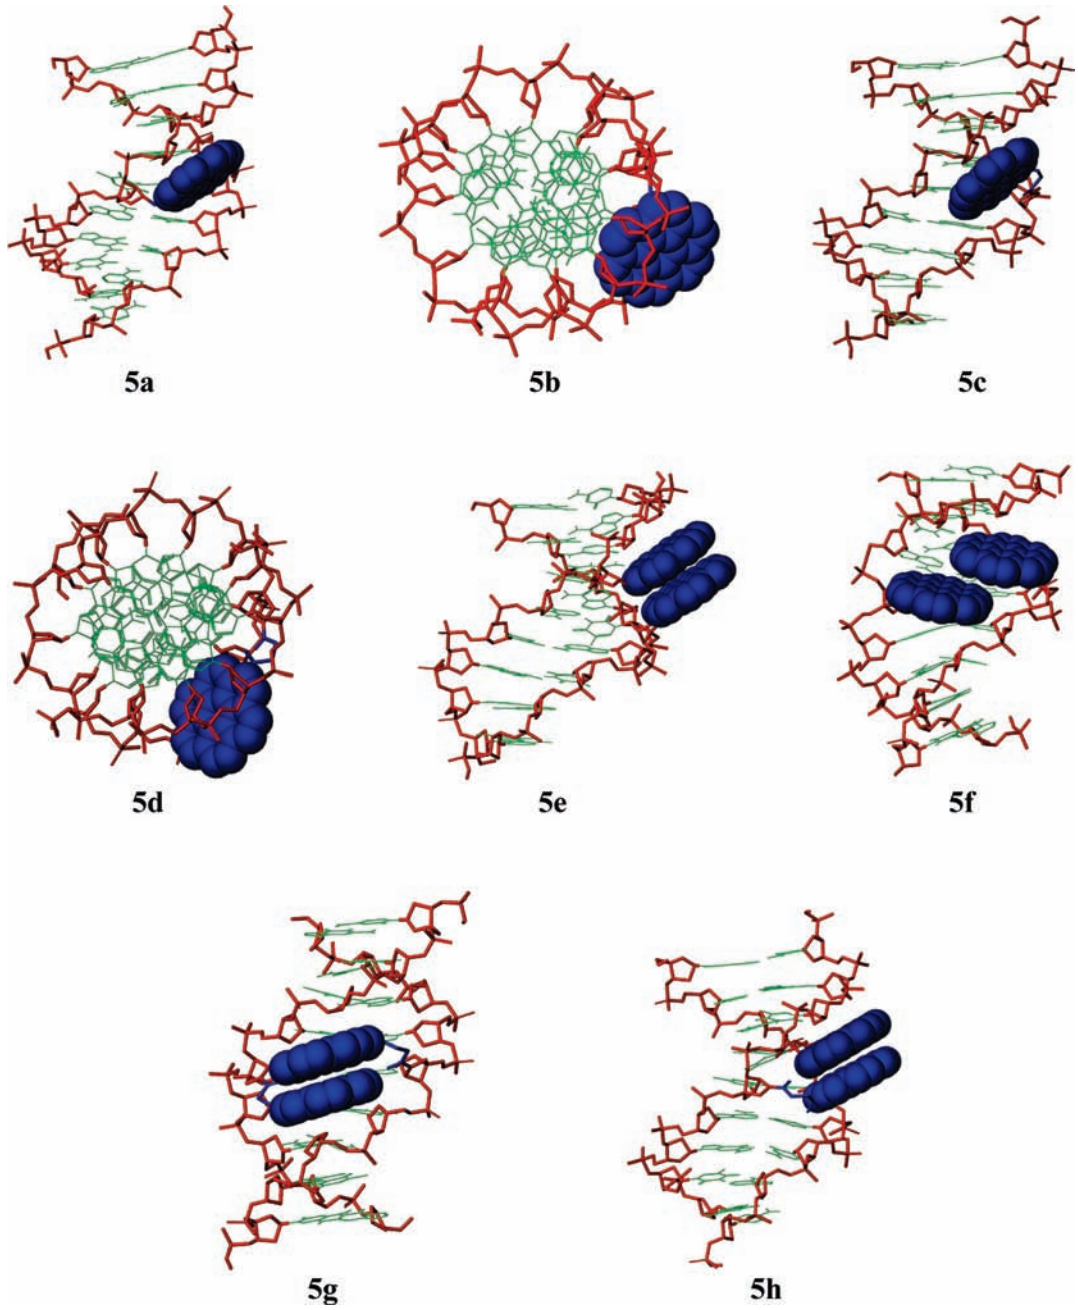

Figure 5. Energy-minimized structures of duplexes. (5a) **ON3**:**DNA** (monomer **X** in side view); (5b) **ON3**:**DNA** (monomer **X** in top view); (5c) **ON7**:**DNA** (monomer **Y** in side view); (5d) **ON7**:**DNA** (monomer **Y** in top view); (5e) **ON3**:**ON4** (monomer **X**, "−1 zipper" arrangement); (5f) **ON3**:**ON5** (monomer **X**, "+1 zipper" arrangement); (5g) **ON7**:**ON8** (monomer **Y**, "−1 zipper" arrangement); and (5h) **ON7**:**ON9** (monomer **Y**, "+1 zipper" arrangement) in side view. Color code: Sugar phosphate backbone (red); coronene (blue); nucleobases (green).

RNA complements showed a slight shift in emission maxima (∼4 nm) to shorter wavelengths with a weakly increased fluorescence intensity (∼1.5-fold) (see ESI S4.10).

Incorporation of a single **Y** monomer in ONs (**ON7**−**ON10**) thus results in a broad, unstructured band with fluorescence emission maxima at ∼453 nm, which is 51 nm red-shifted relative to pyrenecarbonyl-2′-amino-LNA ONs (*18*), 37 nm blue-shifted relative to perylene-3-carbonyl-2′-amino-LNA ONs (*52*), and 7−23 nm blue-shifted relative to (phenylethynyl)pyrene-carbonyl-2′-amino-LNA ONs (*53*). No characteristic changes in the shape of the spectral curves were observed.

Next, fluorescence properties of duplexes formed by **ON3**/**ON7** and singly mismatched DNA/RNA targets were investigated. Noteworthy, as mentioned earlier, the mismatched duplexes display T_m values of more than 19 and 30 °C for **ON3** and **ON7**, respectively. The resulting fluorescence spectra (recorded at 10 °C) are shown in the electronic Supporting Information (Figures S4.1, S4.2, S4.6, and S4.7). Probe **ON3** was seen to be equally sensitive to the presence of mismatched nucleosides in DNA and RNA targets with a ∼2-fold increase in fluorescence intensity for all singly mismatched complexes (Supporting Information Figures S4.1−S4.2). For probe **ON7** containing a single monomer **Y**, the fluorescence effect of mismatches relative to the single-stranded **ON7** and fully matched duplexes did not allow straightforward detection of mismatches (Supporting Information Figures S4.6−S4.7).

All duplexes having monomers **X** in both complementary strands displayed an unstructured emission band at $\lambda_{em} \sim 430$ nm. The fluorescence intensity of the "zippers" was lower in "−1 zipper" constitution and slightly higher in "+1 zipper" constitution than of the previously described duplexes having coronene monomer **X** in only one strand (Figure 3). Duplexes

having monomer **Y** in both complementary strands displayed an unstructured emission band at $\lambda_{em} \sim 484$ nm. In contrast, the fluorescence intensity of the "zippers" was higher in "−1 zipper" constitution and lower in "+1 zipper" constitution than of the previously described duplexes having coronene monomer **Y** in only one strand (Figure 4). Excimer emission was observed neither in single-stranded ONs (**ON3**−**ON10**) nor in their duplexes with DNA/RNA complements, whereas microcrystals of coronene showed both monomer and excimer emission bands (*60*). In contrast, insertion of pyrene-functionalized LNAs in "−1 zipper" motif resulted in strong excimer formation combined with increased thermal stability (*15, 53*).

Molecular modeling of duplexes formed between **ON3** (containing monomer **X**) or **ON7** (containing monomer **Y**) and cDNA (**ON2**) was performed using the AMBER force field (*61, 62*) as implemented in *MacroModel v 8.5* (*63*). Interstrand zipper arrangement modeling were also performed using the same method. All 9-mer duplexes were constructed with the coronene moiety of monomers **X** and **Y** in an extrahelical position. The observed low-energy structures were used for molecular dynamics simulations.

The model structure of the **ON3**:**ON2** hybrid suggests that the attachment of the methylcoronene moiety at the 2′-nitrogen atom of 2′-amino-LNA does not induce significant changes in the duplex geometry and that coronene binds in the minor groove without stacking with the nucleobases (Figure 5a,b). On the other hand, the model structure of hybrid **ON7**:**ON2** revealed many low-energy conformations during dynamics. This can be explained by the more flexible nature of the 4-oxobutanoyl linker of monomer **Y** though the coronene moiety shown still to be positioned in the minor groove (Figure 5c,d). Modeling results of zipper hybrid **ON3**:**ON4** showed the two coronene moieties to be stacking while being positioned in the minor groove (Figure 5e), which could explain the high T_m value measured for this "−1 zipper" duplex. This is substantiated for the **ON3**:**ON5** hybrid in which the two coronene moieties only partially stack (Figure 5f), thus offering an explanation of the lower T_m value observed in this case. The model structure of hybrid **ON7**:**ON8** showed the closest arrangement of the two coronene moieties stacking with each other and with nucleobases (Figure 5g), which correlates with the very high T_m value measured. Hybrid **ON7**:**ON9** showed the two coronene moieties to nicely stack in the minor groove (Figure 5h), but without stacking with the nucleobases.

CONCLUSION

We have studied hybridization and fluorescence properties of coronene moieties attached to the N2-nitrogen atom of 2′-amino-LNA. Incorporation of a single **X** monomer containing a methylcoronene moiety attached to 2′-amino-LNA induced increased T_m values (up to 3 °C) together with quenching of fluorescence intensity when bound to cDNA/RNA. Interestingly, upon incorporation of two **X** monomers separated by one nucleotide in a short **ON**, a 2-fold increase in fluorescence intensity of the resulting duplex with cDNA was observed. Additionally, significant mismatch discrimination was observed by fluorescence changes when a single monomer **X** was incorporated into an ON. Incorporation of monomer **Y** containing an oxobutanoylcoronene moiety attached to 2′-amino-LNA led to remarkably increased thermal affinity toward DNA/RNA complements (up to 15 °C per modification) together with a bathochromic shift in UV absorption upon hybridization with cDNA/RNA. No specific difference in fluorescence intensity was observed by hybridization upon incorporation of two **Y** monomers into a short ON. Interestingly, incorporation of a single monomer **Y** into a short ON allowed better mismatch discrimination toward RNA compared to DNA. The fluorescence properties of the coronene-modified ONs introduced herein, such as fluorescence induced mismatch discrimination and a bathochromic shift in UV absorption upon hybridization with cDNA/RNA, testify to a significant potential for applications in nucleic acid based diagnostics.

Received September 30, 2009; Revised Manuscript Received January 6, 2010

Gold nanoparticles (NPs) functionalized with a mixed shell of well-defined biotinylated glycopolymers and polyethylene glycol (PEG) provide an effective platform for the biomolecular recognition of proteins both in solution and on surfaces. Well-defined biotinylated glycopolymers were first synthesized by the reversible addition−fragmentation chain transfer (RAFT) process. They contain two types of carbohydrate residues either *N*-acetyl *β*-D-glucosaminopyranoside (**GlcNAc**) or α-D-mannopyranoside (**Man**) as pendent groups. The biotinylated glycopolymers and polyethylene glycol were subsequently used in the *in situ* formation of gold glyconanoparticles via an easy photochemical process. The obtained biotinylated glyconanoparticles were characterized by dynamic light scattering (DLS) and transmission electron microscopy (TEM). The bioavailability of the biotin and specific carbohydrate residues at the periphery of the NPs were assessed using the diffraction optic technology (DOT) system. The studies showed the accessibility of the biotin ligands for conjugation to immobilized avidin on the DOTLab biosensor. Furthermore, these avidin conjugated glyconanoparticles were found to selectively immobilize lectins. The specificity of lectin binding was dependent on the type of carbohydrate residues. As such, *N*-acetyl *β*-D-glucosaminoside decorated gold nanoparticles were found to specifically interact with wheat germ agglutinin (WGA) lectin, whereas α-D-mannoside ones were found to specifically interact with Concanavalin A (Con A) lectin.

INTRODUCTION

Gold nanoparticles are receiving enormous attention as they are very promising for biomolecular applications such as labeling, detection, and transfer of genetic materials (*1*).To improve the water stability of synthesized gold cores, different methods were used to prepare water-dispersible and size-tunable gold nanoparticles via the reduction of gold salts in the presence of appropriate stabilizing agents that prevent particle aggregation (*2–6*). Among the preparation methods of gold nanoparticles, the gold salts, chloroaurate ($AuCl_4^-$), were usually reduced with a reducing agent such as sodium tetrahydroborate ($NaBH_4$) in the presence of the desired capping ligands.

Recently, a new photochemical method, reported by Scaiano et al. (*7*), was used to prepare unprotected water-soluble gold nanoparticles via the reduction of $HAuCl_4$ by photochemical decomposition of Irgacure-2959, a water-soluble benzoin, under mild conditions in one step. The preparation process of gold nanoparticles is fast from seconds to minutes, and their sizes could be easily controlled by the intensity of illumination (UV). Following this principle, ligand functionalized water-soluble gold nanoparticles such as biotinylated glyconanoparticles (*8*) and BSA protein-stabilized gold nanoparticles (*9*) have been prepared by our groups via a photochemical process. This method would be a versatile approach for the preparation of surface-coated gold nanoparticles with RAFT prepared polymers.

Focusing on their actual applications in biomedicine and biotechnology, we believe that it is important to consider the surface chemistry for the long-term stability of gold nanoparticles and their biocompatibility. It has been reported that a variety of biocompatible molecules such as proteins (*10, 11*), polyethylene glycol (PEG) (*12*), DNA (*13, 14*), and carbohydrate moieties (*8, 15*) have been utilized to stabilize gold nanoparticles. Following the development of living radical polymerization, various water-soluble polymers with versatile composition and functionality prepared by RAFT polymerization (*16*) were exploited to modify the surface of gold nanoparticles as stabilizers via thiol chemistry after the reduction of the thiocarbonylthio chain-end.

The incorporation of these water-soluble polymers into the shell of gold nanoparticles not only provides a protective shield to prevent their aggregation but also introduces new functions at their periphery. Another important aspect of the surface immobilized polymers bearing reactive functional groups is to provide an opportunity for further surface functionalization. It has been shown that the polymers can tailor the properties of nanoparticles and that the gold cores can also modify the physical properties of polymers (*17–21*).

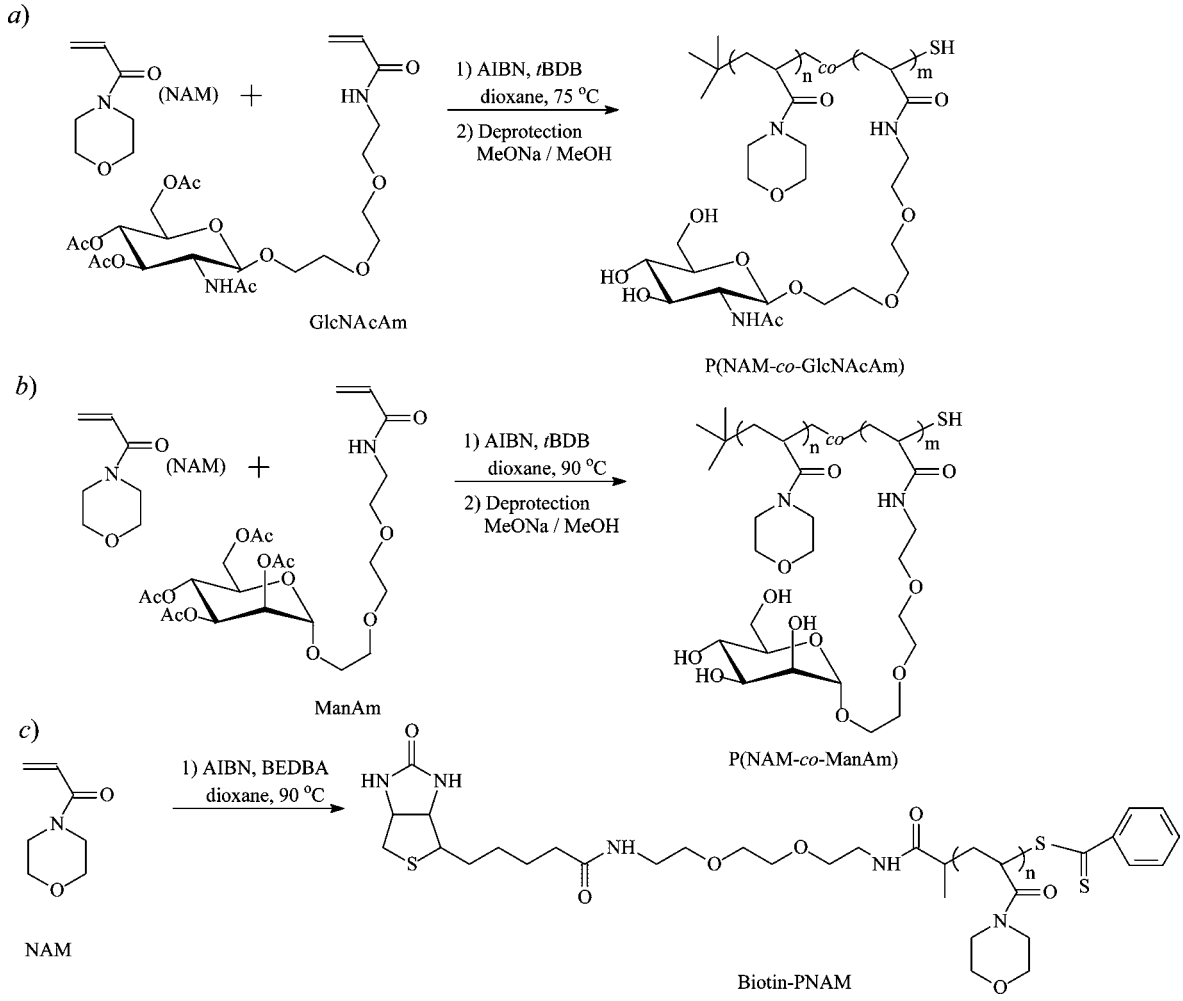
Carbohydrate modified gold nanoparticles have recently attracted much attention since lectin−carbohydrate interactions play crucial roles in a variety of biological processes, including fertilization, cell migration, cancer, and host−pathogen interactions (*22, 23*). Using the gold nanoparticles as a carrier, the outer carbohydrate moieties located on the surface as many antennae increase the ability of carbohydrate−protein interaction as a result of the cluster glycoside effect (*24, 25*). Russell et al. reported the study of gold nanoparticles stabilized with a self-assembled monolayer of a mannose derivative, 2-mercaptoethyl α-D-mannopyranoside, and exploited the α-D-mannoside decorated nanoparticles to examine the binding specificity of the well-known lectin, Concanavalin A (Con A), using UV−visible spectrophotometry (*15*). Lactose-conjugated gold nanoparticles reported by Kataoka et al. (*26*) were prepared from PEG-stabilized gold nanoparticles bearing acetal groups on the outer shell, by reaction with *p*-aminophenyl-*a*-lactosyl. These *a*-lactosyl decorated nanoparticles exhibit specific recognition of *Recinus communis* agglutinin (RCA_{120}) and could be applied in bioassays and biorecognition. Although these nanoparticles were successfully used to study the carbohydrate−lectin interactions, this study was limited to only one kind of lectins and one type of carbohydrate.

In order to investigate the lectin−carbohydrate interaction mechanism, many systems bearing different carbohydrate (or lectin) moieties were developed to study the specific interaction with different lectins (or carbohydrates) by different approaches such as the surface plasmon resonance (SPR), quartz crystal microbalance (QCM), isothermal titration calorimetry (ITC), fluorescence techniques, atomic force microscopy (AFM), and electrochemical impedance spectroscopy (EIS) (*25, 27–32*). Although existing approaches have been partially successful, these reported methods usually require extensive instrumental setup and synthetic complication for the fixation of the targeted group (carbohydrate or lectin) onto the surface of the sensor, which obviously limited the investigation of their interactions. Accordingly, a sensitive, rapid, simple, reliable, and cost-effective method should be found to study these interactions.

Herein, we describe the synthesis of well-defined biotinylated glycopolymers via the RAFT polymerization process. The obtained glycopolymers containing two types of carbohydrate residues, either *N*-acetyl β-D-glucosaminoside (**GlcNAc**) or α-D-mannoside (**Man**) as pendent groups, were subsequently used with PEG for the *in situ* formation of glyconanoparticles via a photochemical process. Combining the photochemical method and RAFT process, different surface-functionalized gold nanoparticles were prepared with or without the biotin and/or the carbohydrate moieties. The obtained nanoparticles were characterized by dynamic light scattering (DLS) and transmission electron microscopy (TEM). To access the availability of the biotin and specific carbohydrate residues located on the nanoparticle surface, a simple instrument, diffraction optics technology (DOT) system, was used to probe the attachment of biotinylated nanoparticles on the surface of the avidin sensor chip, which further provided the possibility of studying specific lectin−carbohydrate interactions between the carbohydrates (GlcNAc or Man) and the lectins (WGA or Con A).

EXPERIMENTAL SECTION

Materials. *N*-Acryloylmorpholine (NAM) (Aldrich, 97%) was distilled under reduced pressure (120 °C, 10 mmHg). 2,2′-Azobis(isobutyronitrile) (AIBN) (Fluka, 98%) was purified by recrystallization from ethanol. 1,4-Dioxane (Acros, 99%) was distilled over $LiAlH_4$ (110 °C). Trioxane (Acros, 99%), EZ-Link Biotin PEO-Amine ((+)-biotinyl-3, 6-dioxaoctanediamine, Pierce), and other materials were used without further purification. Syntheses of *tert*-butyl dithiobenzoate (*t*BDB) (*21*) and *N*-[8-((+)-biotinamido)-3,6-dixoaoctyl]-2-[[2-phenyl-1-thioxoethyl]thio]-propanamide (BEDBA) (*33*) have been described previously. Syntheses of the mannose derivative, 8-acrylamido-3,6-dioxaoctyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (ManAm), and of the *N*-acetyl-glucosamine derivative, 8-acrylamido-3,6-dioxaoctyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (GlcNAcAm), have been described elsewhere (*34*). Synthesis of the biotinylated PNAM homopolymers has been described previously (*33*). Biotin-CTA, *N*-[8-((+)-biotinamido)-3,6-dioxaoctyl]-2-[[2-phenyl-1-thioxo]thio]-4-cyanopentanoate (BCBDBA), was synthesized from succinimido-4-[[2-phenyl-1-thioxo]thio]-4-cyanopentanoate and (+)-biotinyl-3,6-dioxaoctanediamine as shown in Figure S1 in Supporting Information. The photoinitiator, Irgacure-2959, was given by CIBA Specialty Chemicals.



RAFT Polymerization of the Mannose and *N*-Acetylglucosamine Derivatives (ManAm and GlcNAcAm) with Biotin-CTA. RAFT copolymerization of ManAm or GlcNAcAm with *N*-acryloylmorpholine in the presence of biotin-CTA (BCBDBA) has been performed (shown in Schemes 1 and 2) using a procedure similar to that recently reported for a Galactose derivative (*35*) except that the reaction was performed directly inside the NMR spectrometer.

Typical runs for ManAm and for GlcNAcAm are described below. NAM (91 mg, 0.65 mmol), ManAm (85 mg, 0.16 mmol), biotin-CTA (BCBDBA, 7.3 mg, 0.011 mmol), AIBN (0.31 mg, 1.9×10^{-3} mmol), 1,4-d_8-dioxane (423 μL), and trioxane (2.3 mg, internal reference for ^{1}H NMR determination of monomer consumption) (*36*) were introduced in a NMR tube fitted with a Young's valve. The mixture was degassed by five freeze−evacuate−thaw cycles. A first NMR acquisition was carried out at 27 °C. Then, the tube was removed, and the temperature was set at 75 °C. The tube was then reintroduced (time t_0), and acquisitions were regularly performed. The progress of the reaction was monitored by the disappearance of the vinyl proton signals, by comparison of the vinyl protons of NAM (5.7 ppm) and of ManAm (5.6 ppm) with trioxane (5.08 ppm).

NAM (108 mg, 0.765 mmol), GlcNAcAm (102 mg, 0.192 mmol), biotin-CTA (BCBDBA, 1.74 mg, 2.74×10^{-3} mmol), AIBN (0.045 mg, 2.74×10^{-4} mmol), and 1,4-d_8-dioxane (504 μL) were introduced in a NMR tube fitted with a Young's valve. The mixture was degassed by five freeze−evacuate−thaw cycles. A first NMR acquisition was carried out at 27 °C. Then, the tube was removed, and the temperature was set at 90 °C. The tube was then reintroduced (time t_0), and acquisitions were regularly performed. The progress of the reaction was monitored by the disappearance of the vinyl proton signals, by comparison of the vinyl protons of NAM and of GlcNAcAm with nonvinyl protons of GlcNAcAm (3H: H_1, H_3, H_4, 4.76−5.35 ppm) used as the internal reference. Similar experimental conditions were used with *t*BDB instead of biotin-CTA (BCBDBA). Polymer samples were precipitated in a large volume of diethyl ether, recovered by centrifugation, and finally dried under vacuum before SEC analysis.

Deprotection of the Glycopolymer Samples. Typically, for polymer sample biotin-P(NAM-*co*-ManAm), (47 mg, 4.7×10^{-6} mol) was dissolved in a CH_2Cl_2/methanol (1/2 v/v) anhydrous mixture (1.5 mL). A catalytic amount of sodium methylate (sodium methoxide, 25% (w/w) solution in methanol, 0.04 equiv) was added. The mixture was left under stirring at room temperature for 24 h. After evaporation, water was added, and the samples were mixed with some Amberlite IR120PLUS resin (Aldrich), filtrated, neutralized with sodium hydrogenocarbonate ($NaHCO_3$) solution, and purified by dialysis using Slide-A-Lyzer Dialysis Cassettes (Pierce) with a 3,500 molecular weight cutoff (MWCO) for samples with expected molecular weights lower

Scheme 1. Synthetic Route to the Preparation of P(NAM-*co*-GlcNAcAm) and P(NAM-*co*-ManAm) Glycopolymers, and Biotin-PNAM Homopolymer

than 10,000 g·mol^{-1} and a 10,000 MWCO for all other polymers as shown in Table 1.

Formation of Gold Glyconanoparticles (AuNPs). The following protocol is carried out for the synthesis of gold glyconanoparticles, and detailed results are shown in Table 2. Polyethylene glycol having terminal thiol groups (PEG-SH) and the (non) biotinylated glycopolymer were mixed together in an aqueous solution containing $HAuCl_4$ and Irgacure-2959 at a fixed molar ratio of $HAuCl_4 \cdot 3H_2O$, Irgacure-2959, PEG-SH, and glycopolymer of 1:3:0.8:0.2, respectively. This mixture was stirred at room temperature for 10 min. The clear solution was then irradiated for 5 min in a Rayonet photoreactor (Southern N.E. Ultraviolet Co.) using 16 75W UV lamps having a 350 nm wavelength. The color of the final solution changes to purple or pink, indicating the formation of gold nanoparticles. These gold nanoparticle solutions showed very good colloidal stability over several weeks.

Characterization. *NMR.* ^{1}H NMR spectra were recorded on a 200 MHz Bruker AC 200 spectrometer or on a 500 MHz Varian Unity Plus 500 spectrometer, at 25 °C in *d*-chloroform ($CDCl_3$).

Glycopolymer SEC Analysis. Molecular weight distributions of the protected glycopolymers were determined by SEC in THF (SDS, 99%), using a Waters column (Styragel HR4E). The flow rate was maintained at 1 mL·min^{-1} using a Waters 1515 isocratic HPLC pump. Analyses were performed by injection of 20 μL of polymer solution (10 mg·mL^{-1}) in THF. Detection was performed using a Waters 2410 differential refractometer. The molecular weight and polydispersity data were determined using the Waters Breeze software package, according to a PNAM calibration.

Nanoparticle Size Analysis. A model 802 Viscotek DLS instrument operating at a laser wavelength of 825−832 nm was used for particle size measurements in highly dilute aqueous gold dispersions. TEM analyses were also performed to determine the sizes of gold nanoparticles on a Hitachi 800 transmission electron microscope at an acceleration voltage of 200 kV. The samples for TEM were prepared by placing a drop of the nanoparticle solution on carbon coated copper grids.

Diffractive Optics Technology (DOT) Measurements. DotLab data were measured on a Diffractive Optics Technology (DOT) system from Axela Biosensors Inc.; the sensor chip was composed of polystyrene as the substrate and avidin groups have been attached on the surface. PBS buffer was used as the eluent. The nanoparticle samples were loaded into the sensor according to the designed program, the binding events were taking place on the surface of the sensor chip by avidin−biotin interactions, and the height of the diffractive pattern was increased (Scheme 3). The increase in signals was detected synchronously using a laser-based optical system, and the real-time data generated are presented in dotLab software.

its special outstanding features such as the good solubility of PNAM in a wide range of solvents and its virtual lack of toxicity. The synthesized polymers were also used for various biological applications (*37–39*).

With the development of living radical polymerization, reversible addition−fragmentation chain transfer (RAFT) polymerization has proved to be a robust technique for the polymerization of the NAM monomer (*21, 33–35*). Among the studied dithiobenzoates reported by Favier et al. (*21*), *tert*-butyl dithiobenzoate (*t*BDB) has been shown to be a very efficient RAFT agent for NAM polymerization. Well-defined PNAM homopolymers with controlled dimension could be obtained in the presence of *t*BDB using AIBN as the initiator in 1,4-dioxane.

In order to study the specific carbohydrate−lectin interactions, two monomers containing carbohydrate moieties, a mannose derivative, the 8-acrylamido-3,6-dioxaoctyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (ManAm), and a *N*-Acetyl-glucosamine derivative, the 8-acrylamido-3,6-dioxaoctyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (GlcNAcAm), were synthesized and copolymerized with NAM to get the targeted P(NAM-*co*-ManAm) and P(NAM-*co*-GlcNAcAm) copolymers. The conversions of monomers were high (above 80%), and well-controlled polymer chains were obtained as shown in Scheme 1 and Table 1. Their polymerization degrees were calculated to be P(NAM$_{40}$-*co*-ManAm$_4$) and P(NAM$_{234}$-*co*-GlcNAcAm$_{52}$) from the ^{1}H NMR and SEC results.

The RAFT technique is a versatile polymerization process that can be applied to the polymerization of many different monomers both in aqueous and organic solvents. Moreover, it is rather easy to introduce a ligand at the α-chain-end using an appropriate functional RAFT agent. A small biomolecule, biotin, was chosen to be introduced at the terminus of the RAFT agent.

Scheme 3. Schematic Illustration of Surface Bimolecular Recognitions of Biotinylated Surface-Functionalized Gold Glyco-Nanoparticles Interacting with Avidin and Lectin in Sequence on the dotLab Sensor Surface

Using this kind of method, the terminal α-end of each polymer chain contains, in theory, one biotin group. On the basis of this principle, two biotin CTAs, *N*-[8-((+)-biotinamido)-3,6-dioxaoctyl]-2-[[2-phenyl-1-thioxoethyl] thiopropanamide (BEDBA) and *N*-[8-((+)-biotinamido)-3,6-dioxaoctyl]-2-[[2-phenyl-1-thioxo]thio]-4-cyano-pentanoate (BCBDBA), possessing stable bonds between the biotin and the dithioester moieties (amide and ether bonds) were synthesized to perform the homopolymerization of the NAM monomer and statistical copolymerization of NAM with ManAm or GlcNAcAm, respectively.

The synthesis of BEDBA has already been reported in the literature (*33*). BCBDBA, a new biotinylated RAFT agent, was synthesized using an approach similar to that for BEDBA (detailed synthesis and characterization are shown in Supporting Information). After activation of the carboxyl groups using *N*-hydroxysuccinimide (NHS) to form a succinimide-terminated RAFT agent, the biotin moiety (EZ-Link Biotin PEO-Amine) was introduced. These biotin-CTAs proved to be very efficient for the synthesis of the homopolymers of NAM and for the copolymerization of NAM with a protected galactose derivative (*33, 35*). The biotin-PNAM, biotin-P(NAM-*co*-ManAm), and biotin-P(NAM-*co*-GlcNAcAm) copolymers bearing the biotin moiety were synthesized as shown in Scheme 2, and detailed information is collected and presented in Table 1 and Figure 1. After polymerization for 30 min to 2 h, the targeted statistical glycopolymers in protected form were obtained. The global monomer conversion is about 85% and 73% for biotin-P(NAM-*co*-GlcNAcAm) and biotin-P(NAM-*co*-ManAm) copolymers, respectively. From the conversion values, the calculation of the DP was determined and gave biotin-P(NAM_{40}-*co*-$ManAm_7$) and biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$). SEC traces show a monomodal peak with a low polydispersity index for biotin-P(NAM_{40}-*co*-$ManAm_7$) and a monomodal peak with a little broad polydispersity index for biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$) as shown in Figure 1c. The experimental M_n and M_w/M_n values of biotin-P(NAM_{40}-*co*-$ManAm_7$) and biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$) were determined as 12,700 $g \cdot mol^{-1}$ and 1.20 and 53,700 $g \cdot mol^{-1}$ and 1.60, respectively, which is consistent with the theoretical molecular weight calculated from the conversion values using ^1H NMR monitoring of the copolymerization. The end-label biotin functionalization was also calculated to be above 90%, which means that almost each polymer chain has a biotin group at the α terminus.

Using *t*BDB and biotin-CTAs as the RAFT agents, six different kinds of polymer chains were obtained via the RAFT process, and then six telechelic water-soluble glycopolymers (bearing a thiol group at the chain-end), named as biotin-$PNAM_{21}$, biotin-$PNAM_{287}$, P(NAM_{234}-*co*-$GlcNAcAm_{52}$), P(NAM_{40}-*co*-$ManAm_4$), biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$), and biotin-P(NAM_{40}-*co*-$ManAm_7$), were generated after deprotection of the sugar rings by the addition of sodium methylate in methanol. The ^1H NMR spectra before and after deprotection are shown in Figure S2 in Supporting Information. It should be noted that two special samples, the biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$) and biotin-P(NAM_{40}-*co*-$ManAm_7$), are our focused products because they possess both biotin groups and carbohydrate moieties and could be used to investigate biomolecular recognition, especially for the specific (or nonspecific) binding of different lectins. The other samples are used as control samples to evaluate nonspecific binding.

Fabrication of Gold Glyconanoparticles via a Photochemical Process. Gold nanoparticles have received enormous attention because of their unique optical and electronic properties (*1*). To improve their biocompatibility and colloidal stability, the gold nanoparticles were usually surface modified by thiol terminated water-soluble polymers such as PEG chains. Recently, biocompatible gold glyconanoparticles have become the focus of intense interest in biology because surface-functionalized nanoparticles containing bioactive groups such as biotin and carbohydrates could be used as model systems to investigate the biological recognition phenomena involving carbohydrates and proteins.

Gold nanoparticles were usually synthesized by two well-known methods, the Burst and Turkevish methods. Recently, a novel photochemical method reported by Scaiano et al. (*7*) has been used to prepare gold nanoparticles using UV-irradiation. This new method has attracted much attention as the sizes and shapes of gold nanoparticles could be justly controlled by the intensity of UV radiation. They have reported the preparation of highly disperse and stable gold nanoparticles via a photochemical reduction of $HAuCl_4$ with a water-soluble photoinitiator, Irgacure-2959, which decomposes quantitatively in the presence of UV light at a wavelength of 350 nm. Protein-stabilized gold nanoparticles and biotinylated glyconanoparticles have also been reported by our group using this photochemical method (*8, 9*). This new method has proved to be an easy strategy in generating surface-functionalized gold nanoparticles using RAFT-synthesized polymers. However, in the case of those glyconanoparticles, the carbohydrate moieties were introduced to bring hydrophilicity and biocompatibility but were not appropriate to recognize lectins since the sugar ring (galactose) was linked by the C-6 position. Hence, another synthetic strategy was chosen here for the carbohydrate derivatives so that the resulting glycopolymers were bearing the carbohydrate in the C-1 position, then were presenting a structure especially favorable for specific lectin recognition.

In order to study the biomolecular recognition of different proteins and carbohydrates, the functionalized monodisperse gold colloids bearing carbohydrate and biotin moieties on the surface were prepared using photochemical reduction. A mixture of Irgacure-2959, $HAuCl_4$, copolymer, and PEG-SH, at a molar ratio of 3:1:0.2:0.8, was first dissolved in filtered distilled deionized water. The resulting pale yellow solution was then placed in a photochemical reactor for a period of approximately 5−10 min. The clear solution changes from pale yellow to pink, indicating the formation of gold nanoparticles. For purification, the gold colloid solution was then dialyzed against water. It should be noted that the *in situ* reduction minimizes the formation of disulfide bridges between the thiol-terminated polymers.

Particle size measurements of the formed gold nanoparticles were obtained by dynamic light scattering (DLS), and the data were collected after purification. The results are tabulated in

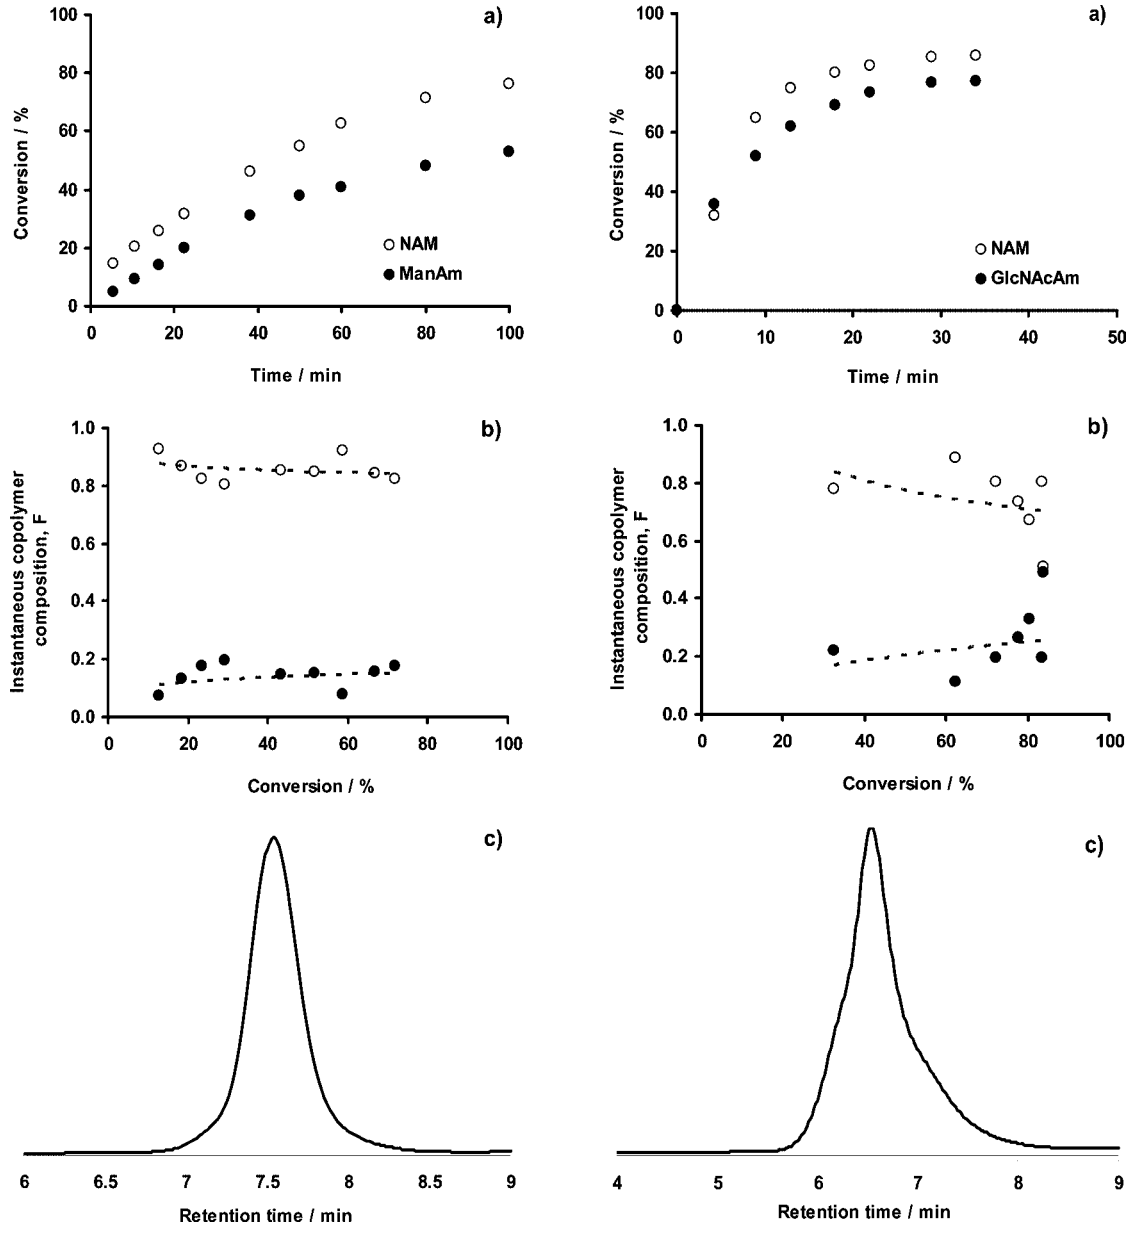

Figure 1. Monomer conversions (a), copolymer compositions (b), and SEC analysis (c) for NAM/ManAm copolymerization (left) and for NAM/GlcNAcAm copolymerization (right) using BCBDBA as the RAFT agent.

Table 2. The sizes of nanoparticles were about 4−6 nm in radius, and the polydispersities were below 0.2. This clearly shows that the mixture of the glycopolymer and -PEG-SH resulted in the formation of relatively monodisperse gold nanoparticles. The obtained gold nanoparticles were very stable, and the sizes of the glyconanoparticles did not change over weeks, which is indicative of the very high stability similar to that of PEGylated gold colloids (*12*). To further characterize the nanoparticles, the P(NAM_{234}-*co*-$GlcNAcAm_{52}$)-functionalized nanoparticles (613ab) were chosen to measure their sizes and shapes using transmission electron microscopy (TEM). Figure 2 shows the spherical and uniform morphology of these gold glyconanoparticles with a size of 4−6 nm in diameter. It should be noted that the smaller size from the TEM image may reveal only the visible gold core compared with that from DLS results. Concerning the stability, the interaction gold-thiol group is generally considered as a strong interaction. A constant diameter (and diameter distribution) was observed over weeks, which indicates a good stability of the gold nanoparticles produced. Glycopolymers, PNAM and PEG, are all biocompatible polymers used in the surface functionalization of the nanoparticles.

Diffraction Optics Technology (DOT). With the development of optical biosensors, a novel diffractive optics technology (DOT) has emerged for the potential applications in the immunoassays fields (*40*). It takes advantage of the inherent properties of diffractive optics to offer label-free real-time measurements and delivers a cost-effective, robust, optical biosensor that detects biomolecular binding even at low concentrations.

The dotLab system used includes precision fluidic control of reagents, buffers, and samples, a proprietary integrated optical assembly designed to function with the dotLab sensor, and software for acquisition, control, and user-interface. The used plastic consumable sensors consist of the polystyrene substrates and avidin-modified surfaces, and the modified surfaces possess nonrandom patterns, which were exposed to coherent light, and then well-defined diffractive images were produced. As the samples bearing biotin groups are loaded in the sensor, the

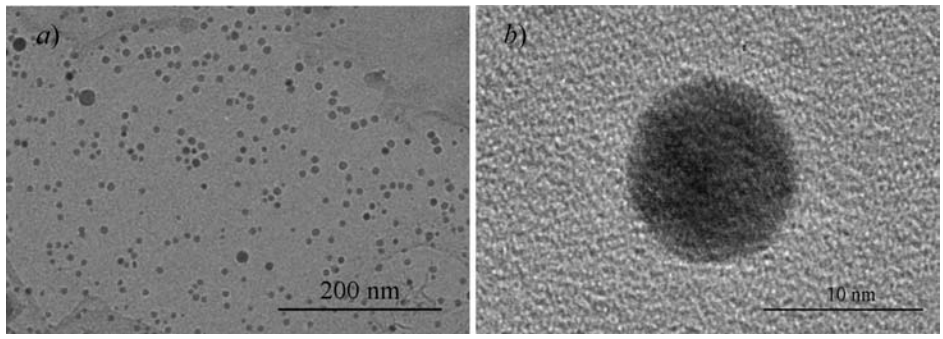

Figure 2. Typical TEM images of glyconanoparticles (613ab) prepared from the P(NAM_{234}-*co*-$GlcNAcAm_{52}$) glycopolymer.

samples are immobilized onto the surface of the sensor via the well-known biotin−avidin interactions that lead to an increase in the height of the diffractive pattern. This in turn increases the diffractive efficiency and diffractive order intensity monitored by a photodiode, and an increased signal of diffractive intensity is shown simultaneously by the software. Owing to the special design of the dotLab sensor with an integrated prism situated below the flow channel, we could monitored biomolecular binding in real time and in complex media because the light source interrogates the diffractive grating without passing through the bulk solution.

Biomolecular Recognition Involving the Carbohydrates and Lectins Detected via DOT. The surface-functionalized gold glyconanoparticles, prepared via the photochemical method, were used to study the availability of the carbohydrates and biotin toward biomolecular recognition processes. Several reference samples were used. The biotinylated nanoparticles (611ab and 612ab) without carbohydrate moieties were prepared from biotin-$PNAM_{21}$ and biotin-$PNAM_{287}$, respectively. The glyconanoparticles (613ab and 614ab) without biotin groups were prepared from P(NAM_{234}-*co*-$GlcNAcAm_{52}$) and P(NAM_{40}-*co*-$ManAm_4$), respectively. It should be noted that the biotinylated glyconanoparticles (615ab and 616ab) elaborated from biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$) and biotin-P(NAM_{40}-*co*-$ManAm_7$) possess both biotin and carbohydrate moieties. However, the carbohydrate moieties are different (α-D-mannoside and *N*-acetyl *β*-D-glucosaminoside) and can be used as models to study the biomolecular specific recognition involving carbohydrates and lectin proteins.

Lectins are carbohydrate-binding proteins which possess a high degree of specificity toward carbohydrates. They play an important role in biological recognition phenomena involving cells and proteins, and some lectins have been widely used as a model system to understand the molecular basis of how the proteins recognize carbohydrates. It has been shown that some lectins were found on the surface of mammalian liver cells which specifically recognize galactose residues. The recognition of lectins and carbohydrates essentially occurs via multiple weak interactions (*25*). In order to further study the specific binding of carbohydrates and lectins, the lectins Concanavalin A (Con A) and wheat germ agglutinin (WGA), were chosen since they are known to specifically interact with α-D-mannoside and *N*-acetyl *β*-D-glucosaminoside moieties, respectively, that are the carbohydrates present on the prepared gold glyconanoparticles to study biomolecular recognition via dotLab measurements.

We first investigated the availability of the biotins incorporated on the surface of the nanoparticles to specifically interact with avidin located on the surface of the sensor using four control samples. The glyconanoparticles (613ab and 614ab) prepared from P(NAM_{234}-*co*-$GlcNAcAm_{52}$) and P(NAM_{40}-*co*-$ManAm_4$) (negative control samples), and two biotinylated nanoparticles (611ab and 612ab) prepared from biotin-$PNAM_{21}$ and Biotin-$PNAM_{287}$ (positive control samples), respectively, were loaded in the dotLab biosensor, and the results are shown in Figure 3. Because of the absence of biotin groups on the surface, the gold nanoparticles (613ab and 614ab) could not be immobilized on the avidin coated sensor chip. The recovery of the initial signal after wash is indicative of the fact that the gold nanoparticles were not attached on the surface of the sensor chip. However, after the biotinylated nanoparticles (611ab and 612ab) were injected into the dotLab instrument containing a preloaded avidin coated sensor chip, a signal could be observed and remained even after the wash with buffer (see Figure 3a and b), which is indicative of the specific interaction of the biotinylated nanoparticles with the avidin-coated sensor chip. These results are consistent with the work of Borisenko and co-workers regarding the aggregation of biotinylated mouse monoclonal antiNT-proBNP onto the streptavidin coated dotLab sensor (*40*) and our groups' recently reported work (*41*).

When the biotinylated glyconanoparticles (615ab and 616ab) elaborated from biotin-P(NAM_{225}-*co*-$GlcNAcAm_{51}$) and biotin-P(NAM_{40}-*co*-$ManAm_7$) were loaded into the dotLab sensor, higher responses were observed as shown in Figures 4 and 5. Because of the presence of biotin on the surface of glyconanoparticles, the nanoparticles remained immobilized on the surface of the avidin-sensor chip even after the wash with buffer.

Two different lectin solutions, Con A and WGA, were loaded following the immobilization of the biotinylated glyconanoparticles on the sensor chip. For *N*-acetyl glucosamine based carbohydrates, after the WGA lectin loading, a high response was observed while, when the same lectin solution was introduced onto PNAM-coated nanoparticles (611ab and 612ab), no increase of signal was observed because of the lack of carbohydrate groups on the surface of the nanoparticles. This indicates that there is no influence of PNAM itself on the carbohydrate/lectin interactions. The fact that the response was still present after the wash clearly showed the specific biomolecular interaction of *N*-Acetyl *β*-D-glucosaminoside residues of (615ab) with WGA. On the contrary, in the cross-experiment, almost no response was observed after the injection of Con A solution, which indicated a low nonspecific interaction and was consistent with the QCM and SPR results reported by Zhang et al. (*28*).

In addition, a strong signal was obtained after the injection of Con A solution to the immobilized glyconanoparticles (616ab) on the sensor chip, showing the specific and expected interactions of Con A with α-D-mannoside, and almost no response was observed when WGA was injected. In both cases, the cross-experiment indicated a low (<10%) nonspecific interaction between lectins and carbohydrates. This clearly demonstrates that the specific interaction of different carbohydrates and lectins such as α-D-mannoside (**Man**) with Con A and *N*-acetyl *β*-D-glucosaminoside (**GlcNAc**) with WGA could be investigated using this biosensing instrument. It further confirmed that the gold nanoparticles are carriers, and the outer carbohydrate moieties seem like many antennae increasing the specific

interaction of lectins and carbohydrates for the cluster glycoside effect. It should be noted that the number of carbohydrate moieties present on the surface of the nanoparticle and how many of those interact with the lectin are important parameters for this study. While this could potentially be calculated, we did not have all the parameters to exactly determine the number of chains per particle and hence the number of carbohydrate groups per particle. For this study, we just wanted to explore the specific recognition of given carbohydrate groups toward specific lectin. Besides, as the carbohydrate−lectin interactions are generally weak, it would be difficult for us to accurately measure the number of carbohydrates that are involved in those interactions.

Conclusions. Carbohydrate-based copolymers containing *N*-acetyl β-D-glucosaminopyranoside (**GlcNAc**) or α-D-mannopyranoside (**Man**) residues were prepared via RAFT polym-

erization using a biotin-CTA or *tert*-butyl dithiobenzoate as the RAFT agents. The obtained copolymers were then conjugated to the surface of gold nanoparticles by thiol chemistry that led to the formation of biotinylated or nonbiotinylated gold glyconanoparticles via a facile photochemical process. The prepared nanoparticles have uniform sizes and narrow polydispersities and are stable in water for weeks. Furthermore, the biotinylated glyconanoparticles were immobilized on the avidin-coated dotLab sensor chip because of the strong affinity between biotin and avidin, and subsequently used as the model to study the specific biomolecular recognition between lectins and carbohydrates. The specific recognitions for different carbohydrates and lectins such as α-D-mannoside with Con A and *N*-acetyl β-D-glucosaminoside with WGA were confirmed by the dotLab biosensing device. Because of the presence of PEG, biotin, and carbohydrate-based copolymer chains on the surface, these gold glyconanoparticles could be applied in biology as highly stable and biocompatible materials.

ACKNOWLEDGMENT

This work is supported jointly by Natural Sciences and Engineering Research Council of Canada and Ontario Centres of Excellence, Emerging Materials and Knowledge (OCE-EMK). We thank Axela Biosensors Inc. (Dr. Jean F. Houle) for providing the DOTLab instrument and sensor chips for this study. We thank Dr Maël Bathfield for the biotin-PNAM samples as well as Professor Stéphane Parola and Dr. Fernand Chassagneux (LMI, University of Lyon) for the TEM micrographs. We thank BioMerieux S.A. company for a Ph.D. grant for Guillaume Gody.

Evaluation of Bifunctional Chelates for the Development of Gallium-Based Radiopharmaceuticals

Cara L. Ferreira,*[,†] Eric Lamsa,[†] Michael Woods,[†] Yin Duan,[‡] Pasan Fernando,[‡] Corinne Bensimon,[‡] Myra Kordos,[‡] Katharina Guenther,[§] Paul Jurek,[||] and Garry E. Kiefer[||]

MDS Nordion, 4004 Wesbrook Mall, Vancouver, British Columbia, Canada V6T 2A3, Ottawa Heart Institute, Ottawa, Ontario, Canada, MDS Nordion, Kanata, Ontario, Canada, and Macrocyclics, Dallas, Texas. Received October 9, 2009; Revised Manuscript Received January 4, 2010

Ga radioisotopes, including the generator-produced positron-emitting isotope ^{68}Ga ($t_{1/2}$ = 68 min), are of increasing interest for the development of new radiopharmaceuticals. Bifunctional chelates (BFCs) that can be efficiently radiolabeled with Ga to yield complexes with good *in vivo* stability are needed. To this end, we undertook a systematic comparison of four BFCs containing different chelating moieties: two novel BFCs, *p*-NO_2-Bn-Oxo (1-oxa-4,7,10-triazacyclododecane-4,7,10-triacetic acid) and *p*-NO_2-Bn-PCTA (3,6,9,15-tetraazabicyclo [9.3.1]pentadeca-1(15),11,13-triene-3,6,9-triacetic acid), and two more commonly used BFCs, *p*-NO_2-Bn-DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) and *p*-NO_2-Bn-NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid). Each BFC was compared with respect to radiolabeling conditions, radiochemical yield, stability, and in vivo clearance properties. *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-NOTA were all more efficiently radiolabeled with Ga compared to *p*-NO_2-Bn-DOTA. *p*-NO_2-Bn-DOTA required longer reaction time, higher concentrations of BFC, or heating to obtain equivalent radiochemical yields. Better stability was observed for *p*-NO_2-Bn-NOTA and *p*-NO_2-Bn-PCTA compared to *p*-NO_2-Bn-DOTA and *p*-NO_2-Bn-Oxo, especially with respect to transmetalation to transferrin. Ga-radiolabled *p*-NO_2-Bn-Oxo was found to be kinetically labile and therefore unstable in vivo. Ga-radiolabeled *p*-NO_2-Bn-NOTA and *p*-NO_2-Bn-PCTA were relatively inert, while Ga-radiolabeled *p*-NO_2-Bn-DOTA had intermediate stability, losing >20% of Ga in less than one hour when incubated with apo-transferrin. Similar stability differences were seen when incubating at pH 2. In vivo PET imaging and biodistribution studies in mice showed that ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-NOTA, and *p*-NO_2-Bn-DOTA all cleared through the kidneys. While there was no statistical difference in the biodistribution results of ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA, ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA cleared more rapidly from blood and muscle tissue but retained at up to 5 times higher activity in the kidneys.

INTRODUCTION

Gallium radioisotopes have long been of interest in nuclear medicine. ^{67}Ga is currently used for infection and tumor imaging (*1, 2*). Another gallium isotope gaining the attention of the nuclear imaging community is ^{68}Ga (*3*−*5*). ^{68}Ga is a generator-produced positron-emitter with a 68 min half-life. There are only a few generator-produced isotopes applicable to positron emission tomography (PET) imaging, and most have short half-lives limiting their applications due to the time requirements for both radiolabeling and target uptake in vivo. The wide use of single photon emission computed tomography (SPECT) imaging can be partially attributed to the convenience of the Tc-99 m generator and the simplicity of the kit chemistry. Despite having higher resolution, PET has had slower adoption because of the need for a nearby cyclotron to produce F-18 and the more complex chemistry needed to incorporate F-18 into the radiopharmaceutical. The availability of a ^{68}Ga generator and kit chemistry to produce ^{68}Ga-based molecular imaging agents could have a significant impact on PET (*4*).

For ^{68}Ga to be effectively used in molecular imaging, agents must be developed with applicable radiochemistry and appropriate biological properties. Due to the short half-life, the radiolabel incorporation needs to be efficient, preferably under mild conditions, and not require subsequent purification. Radiolabeling that yields an injectable radiopharmaceutical with high specific activity after simply adding the ^{68}Ga generator eluant directly to a reagent containing vial would be ideal. The agent also needs to be stable *in vivo* and clear background tissues quickly to allow imaging within the first few hours after injection.

A factor that influences the radiochemistry as well as the biological properties of the agent is the chemical method of incorporating ^{68}Ga. Typically, a bifunctional chelate (BFC) is used to stably chelate the metal and link the metal to a target vector, such as a peptide (*6*). Choosing the right BFC can greatly affect the radiolabeling kinetics and conditions, increase the resulting compound's stability, and influence, to some degree, the pharmacokinetics. The most commonly used BFC for ^{68}Ga is DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), but the radiochemistry typically requires conventional or microwave heating to obtain adequate yields and specific activities quickly (*7*−*11*). More recently, NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid) and derivatives have been radiolabeled efficiently with ^{68}Ga at lower temperatures (*12, 13*) and even at ambient temperature (*14, 15*).

Previously, we have examined two novel bifunctional chelates, *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, for the development of Cu-64 based radiopharmaceuticals (*16*). In this work, we examined the same two BFCs for their potential use in

developing gallium-radiolabeled nuclear imaging agents. These BFCs each contain a 12-membered macrocyclic chelate, *p*-NO_2-Bn-Oxo (1-oxa-4,7,10-triazacyclododecane-4,7,10-triacetic acid), *p*-NO_2-Bn-PCTA (3,6,9,15-tetraazabicyclo [9.3.1]pentadeca-1(15),11,13-triene-3,6,9-triacetic acid), and a *p*-nitrobenzyl substituent, which can be modified for attachment of a targeting vector. To determine whether *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo offered an advantage over the currently used BFCs for Ga-based radiopharmaceutical development, direct comparison of the novel BFCs was made to the analogous BFCs containing the DOTA and NOTA chelating moieties. The BFCs were examined with respect to radiochemistry and stability with both ^{67}Ga and ^{68}Ga. The pharmacokinetics of the Ga-radiolabeled BFCs was also compared through biodistribution and imaging studies in mice.

EXPERIMENTAL SECTION

Materials and Methods. All solvents and reagents were used as received unless otherwise noted. The BFCs, *p*-NO_2-Bn-DOTA, *p*-NO_2-Bn-NOTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-PCTA, were acquired from Macrocyclics Inc. (Texas). ^{67}Ga and ^{68}Ga were obtained as 0.1 N HCl solutions (MDS Nordion Inc.). Water was deionized using a Milli-Q biocel A-10 water purification system. Reaction vials were acid-washed to remove impurities and trace metals.

The HPLC system used for analysis consists of a Waters Alliance HT 2795 separation module equipped with a Raytest Gabbistar NaI detector and a Waters 996 photodiode array (PDA) detector. Analysis of radiolabeled complexes was done on a Phenomenex Hydrosynergy RP C18 4.6 × 150 mm analytical column using a binary solvent system: solvent A = acetonitrile, solvent B = 0.05% trifluoroacetic acid in water. Method 1 was used for *p*-NO_2-Bn-DOTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-PCTA: gradient elution 5% A/95% B to 30% A/70% B over 20 min at 1.5 mL/min. Method 2 was used for *p*-NO_2-Bn-NOTA: gradient elution 5% A/95% B to 50% A/50% B over 30 min at 1.5 mL/min. Positive identification of the ^{67}Ga and ^{68}Ga radiolabeled BFCs was made by comparison of the retention time of the radiodetector peak and the UV detector peak associated with macroscopic scale Ga complex of the respective BFC, whose identity was verified by mass spectroscopy using positive-ion mode electrospray ionization with a Micromass Q-TOF Ultima API time-of-flight mass spectrometer by Mr. Andras Szeitz (University of British Columbia, Department of Pharmaceutical Sciences). Analysis of the stability samples was done by HPLC using the method described above or using a size-exclusion column, Phenomenex BIOSEP SEC2000 7.8 × 300 mm, eluting with 10 mM sodium bicarbonate buffer pH 6.9 at 1.0 mL/min.

^{67}Ga Radiolabeling Study of Reaction Kinetics. The ^{67}Ga solution (50−100 μL, 25 mCi/mL) was added to a reaction vial containing one of the chelates, *p*-NO_2-Bn-DOTA, *p*-NO_2-Bn-NOTA, *p*-NO_2-Bn-Oxo, or *p*-NO_2-Bn-PCTA, in a 10 mM sodium acetate buffer at pH 4−5. The final concentration of chelate ranged 6−300 μM, and the final concentration of Ga^{3+} ranged 3−6 μM. The reactions were done in triplicate and were analyzed by HPLC for radiochemical yield after 5, 10, 30, and 60 min.

^{67}Ga Radiolabeling at Different pH Values. ^{67}Ga (50 μL, 20 mCi/mL) was added to a solution containing one of the BFCs, *p*-NO_2-Bn-DOTA, *p*-NO_2-Bn-NOTA, *p*-NO_2-Bn-Oxo, or *p*-NO_2-Bn-PCTA (50 μL, 60 μM) diluted in 1 mL of buffer (10 mM) at different pH values ranging from 2 to 6. All reactions were done in triplicate. Radiochemical yield was determined by HPLC analysis after 5 and 60 min.

^{68}Ga Radiolabeling Comparison and Optimization. Carrier-free ^{68}Ga (50−400 μL, 1 mCi) was added to BFC (2−2000 nmol) in 1 mL of 200 mM sodium acetate buffer (pH 4). Reactions proceeded at room temperature, 40, or 80 °C and were monitored by HPLC at different time points.

Stability Assessment. Stability assessments were done with both ^{67}Ga and ^{68}Ga radiolabeled BFCs. For ^{67}Ga, carrier-free ^{67}Ga (3−4 mCi) was added to one of the four BFCs (30 μM in 1.0 mL 10 mM sodium acetate buffer pH 4). After 10 min, the radiochemical yield was determined by HPLC. For ^{68}Ga, carrier-free ^{68}Ga (1−2 mCi) was added to one of the four BFCs (20 μM in 1.0 mL 400 mM sodium acetate buffer pH 4), and the resulting solution was heated at 80 °C for 15 min to ensure reaction completion. The radiochemical yield was confirmed by HPLC.

Aliquots of the radiolabeling reactions (200 μL) were added to 800 μL of either a pH 2 buffer (0.1 mM glycine) or an apotransferrin solution (3 mg/mL, pH 6.9 10 mM sodium bicarbonate buffer). The stability solutions were incubated at 37 °C and analyzed by HPLC at different time points to determine the amount of radiolabeled BFC that remained intact.

Biodistribution and Imaging in Mice. A total of 48 male CD1 (25−30 g) mice (Charles River, Canada) were used for the animal study. Each of the four different ^{68}Ga radiolabeled BFCs prepared as described above (10−20 Ci/mmol of BFC) was injected via the lateral tail vein into 12 mice. Animals were injected under light anesthesia with isoflurane; isoflurane levels were maintained at 1.5−2%. Ten of the mice were injected with ∼10 μCi, while two of the mice were injected with ∼50 μCi and used for both imaging and the 4 h biodistribution data. The mice were sacrificed by cervical dislocation while under anesthesia. Tissues were harvested at 15 min, 1 h, and 4 h after injection, with $n = 4$ for each time point and included heart, liver, kidneys, spleen, intestines, skeletal muscle (quadriceps), bone (femur), brain, blood, and urine. Tissues were weighed, and their activity was counted on a gamma counter. The tissue activity was decay-corrected and converted to %ID/g. Student *t* tests were used for analysis, with a $p < 0.05$ considered statistically significant.

PET imaging was carried out on a Siemens Inveon small animal PET scanner (Siemens, Knoxville, Tennessee). The scanner was started 10 s prior to radiotracer injection in order to capture the entire input function. A bolus injection of approximately 50 μCi in 0.15 mL of the ^{68}Ga-radiolabeled BFC was injected intravenously over a 10 s period. List-mode data were acquired for 90 min using a 350−650 keV energy window and a coincidence timing window of 3.4 ns. List-mode PET data were histogrammed two different ways (32 frames of 12 × 10 s, 3 × 60 s, and 17 × 300 s and 2 frames of 1 × 300 s and 1 × 5100 s). The data were reconstructed on a 256 × 256 image matrix with 0.29 × 0.29 × 0.80 mm^3 pixel size using OSEM3D/MAP ($\beta = 0$, OSEM3D iterations = 2, MAP iterations = 18) with corrections for dead-time, isotope decay, detector efficiencies, and randoms.

RESULTS

Radiochemistry. Standards were prepared by adding naturally abundant gallium to each of the BFCs (Figure 1). The parent-ion weight and isotopic distribution observed in the mass spectra confirm the coordination of Ga to the BFCs; Ga-*p*-NO_2-Bn-PCTA $m/z = 581.4, 583.1$; Ga-*p*-NO_2-Bn-Oxo $m/z = 549.2, 551.2$; Ga-*p*-NO_2-Bn-DOTA $m/z = 606.1, 608.1$, Ga-*p*-NO_2-Bn-NOTA $m/z = 505.1, 507.2$. The natural Ga complexes were used as UV/visible detectable standards for HPLC identification of the radiolabeled compounds. Representative HPLC traces for the *p*-NO_2-Bn-PCTA BFC with natural Ga, ^{67}Ga, and ^{68}Ga are shown in Figure 2.

The radiolabeling yield was measured after a fixed reaction time at room temperature at several different pH values. *p*-NO_2-

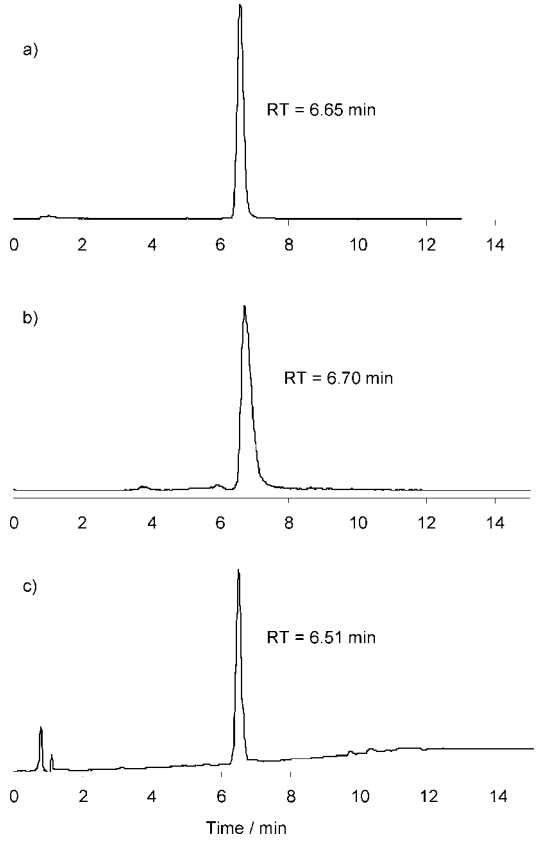

Figure 2. HPLC traces for (a) ^{67}Ga-*p*-NO_2-Bn-PCTA (radiation detector), (b) ^{68}Ga-*p*-NO_2-Bn-PCTA (radiation detector), (c) Ga-*p*-NO_2-Bn-PCTA (UV/visible detector, $\lambda = 280$ nm).

Bn-DOTA was most sensitive to variation in pH, with optimal radiochemical yields at pH 4, 99% after 60 min, and yields dropping to less than 80% at pH 3 and 5. *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-NOTA were radiolabeled efficiently with yields >95% between pH 3 and pH 5. All BFCs showed inferior radiolabeling yields at pH 2 and at pH >6.

The radiolabeling kinetics of each of the BFCs was examined with ^{67}Ga and ^{68}Ga. Table 1 summarizes the optimal reaction conditions, with respect to radiochemical yield and specific activity, determined for each BFC. The BFC concentration had

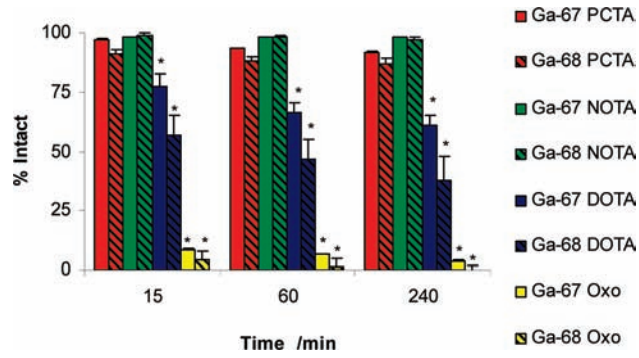

Figure 3. % Ga-BFC intact after incubation in 3 mg/mL apo-transferrin at 37 °C over 4 h. *Values significantly different compared to other Ga-BFC species at the same time point ($p < 0.005$).

the largest impact on reaction time and radiochemical yield. At higher concentrations (>30 μM), all the BFCs achieve >95% radiochemical yield after only 5 min at room temperature. At lower concentrations, slightly longer reaction times (10 min) are required to obtain >95% radiochemical yield for ^{67}Ga-*p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, but *p*-NO_2-Bn-DOTA required significantly longer reaction times (60 min). A similar trend was observed for ^{68}Ga radiolabeling. *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-NOTA were efficiently labeled at room temperature, even when using low concentrations of BFC, while *p*-NO_2-Bn-DOTA had slower reaction kinetics. Heating the reaction at 80 °C was necessary to obtain ^{68}Ga-*p*-NO_2-Bn-DOTA in radiochemical yields and specific activities comparable to those obtained for the other BFCs at room temperature.

Stability. The stability of the Ga-radiolabeled BFCs was assessed in different buffer solutions and in the presence of excess apo-transferrin. No degradation or loss of Ga was observed in the buffered solutions at pH 4 and higher. After 1 h incubating at pH 2, the ^{67}Ga radiolabled BFCs showed negligible degradation or loss of ^{67}Ga, but after 24 h, ^{67}Ga radiolabeled *p*-NO_2-Bn-Oxo and *p*-NO_2-Bn-DOTA showed a 20% and 36% loss, respectively, of ^{67}Ga from the BFC. The kinetic stability in the presence of apo-transferrin for each of the BFCs followed the same trend, whether radiolabeled with ^{67}Ga or ^{68}Ga. *p*-NO_2-Bn-NOTA allowed negligible transfer of the radioisotope to the protein. *p*-NO_2-Bn-DOTA, and to a lesser extent *p*-NO_2-Bn-PCTA, allowed some loss of radioisotope to apo-transferrin over the 4 h time period, while *p*-NO_2-Bn-Oxo was kinetically labile, with almost all of the radioisotope transferred to the protein in less than 15 min.

Biodistribution. The %ID/g for select tissues was determined for each of the ^{68}Ga radiolabeled BFCs in mice at 15 min, 1 h, and 4 h post injection; the results are summarized in Figures 4−8. The majority of activity was found in the kidneys and urine, indicating renal clearance. ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA had significantly more activity in the kidney at all time points, 4−14 times greater than the kidney %ID/g of ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA or *p*-NO_2-Bn-DOTA. The %ID/g of all tissues for ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA were not statistically different. For the liver, intestine, and brain tissue, ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA, *p*-NO_2-Bn-PCTA, and *p*-NO_2-Bn-DOTA were similar, but for blood, heart, muscle, bone, and spleen tissue ^{68}Ga *p*-NO_2-Bn-NOTA cleared more rapidly with statistically ($p < 0.05$) lower activity after 1 h; 80−90% of the activity at 15 min was cleared by 1 h for ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA compared to 45−75% of the activity for ^{68}Ga-radiolableled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA in these tissues. In contrast to the other BFCs, ^{68}Ga-radiolabeled *p*-NO_2-Bn-Oxo did not appreciably clear from

Table 1. Optimized Reaction Conditions for ^{67}Ga and ^{68}Ga Radiolabeling of BFCs[a]

bifunctional chelate	isotope	reaction conditions ([BFC], temperature, time)	radiochemical yield	specific activity (mCi/μmol)
p-NO_2-Bn-PCTA	^{67}Ga	3 μM, RT, 10 min	96.9%	166
	^{67}Ga	15 μM, RT, 5 min	98.4%	35
p-NO_2-Bn-Oxo	^{67}Ga	3 μM, RT, 10 min	98.4%	163

tissue, other than the kidneys, and in some tissues, such as bone, muscle, and intestines, the %ID/g increased over time.

PET imaging experiments were in agreement with the biodistribution studies. The kidney and bladder were clearly visible and contained the highest activity for all of the ^{68}Ga-radiolabeled BFCs. The activity per unit volume measured in the kidney was on average 4.5 times higher for the ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA compared to the other ^{68}Ga-radiolabeled BFCs. While no other tissues could be delineated for ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA, heart and intestine were visible for the other three ^{68}Ga-radiolabeled BFCs at early time points and were most notable in the images of mice injected with ^{68}Ga-radiolabeled *p*-NO_2-Bn-Oxo.

DISCUSSION

To determine if the novel BFCs, *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, offered any advantage for Ga-based radiopharmaceutical development, they were directly compared to the currently used BFCs, *p*-NO_2-Bn-PCTA DOTA and *p*-NO_2-Bn-NOTA. Numerous other reports of radiolabeling and animal studies with DOTA and NOTA containing compounds typically focus on targeted conjugates and not the BFC alone. As well, different isotope suppliers, methods, and reagents can all impact experimental results. So, a direct comparison of the novel BFCs to the analogous DOTA and NOTA containing BFCs was warranted to best evaluate *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo for use with Ga radioisotopes.

Efficient incorporation of the radioisotope in high yields and high specific activity is particularly important for ^{68}Ga, due to the short half-life of radioisotope. If the radiolabeling reaction were to yield product with high radiochemical purity and specific activity, post-radiolabeling purification could be obviated. The need for purification of ^{68}Ga-radiolabeled peptides (*9, 11*−*13, 15*),

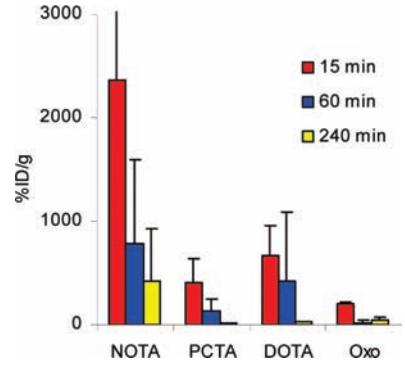

Figure 8. ^{68}Ga-BFC %ID/g in urine in male CD1 mice ($n = 4$) over 4 h.

typically done by HPLC, is not optimal, as it is time-consuming and not necessarily accessible in clinical settings. As some targeting vectors may be sensitive to heat, organic solvents, or extreme pH, radiolabeling reactions that can be done under mild conditions, such as in near neutral aqueous buffers and at room temperature, are preferred.

Comparison of the four BFCs suggested that for labeling with gallium radioisotopes the two novel BFCs, *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, as well as *p*-NO_2-Bn-NOTA, were all superior to *p*-NO_2-Bn-DOTA. The radiolabeling efficiency of *p*-NO_2-Bn-DOTA was greatly impacted by pH, required longer reaction times or heating, and gave lower yields and lower specific activities. Radiolabeling of DOTA conjugates has typically been done at elevated temperatures (*7, 9, 10*), and the slow radioisotope incorporation at room temperature has also been reported (*8*). In contrast, NOTA and NOTA conjugates have recently been reported to radiolabel efficiently under ambient conditions (*14*). The two novel BFCs, *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, also shared this property. Using either ^{67}Ga or ^{68}Ga radiolabeling at room temperature, *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-Oxo, and *p*-NO_2-Bn-NOTA were all efficiently radiolabeled with ^{67}Ga or ^{68}Ga in minutes without the need for heating or purification.

Similar trends were observed whether the radiochemistry was done with ^{67}Ga or ^{68}Ga, as would be expected, but the results were not identical. Differences observed in radiolabeling may be due to differences in the level of trace metal impurities found in the isotope. *p*-NO_2-Bn-DOTA was found to have slower reaction kinetics for ^{68}Ga labeling compared to ^{67}Ga labeling. Trace metals that are coeluted from the ^{68}Ge generator can compete with ^{68}Ga for the BFC (*7, 17*). It has been suggested that heating may improve the selectivity of the BFCs for ^{68}Ga over other trace metals (*17*), which is supported by the high radiochemical yields and specific activities obtained when the ^{68}Ga radiolabeling of *p*-NO_2-Bn-DOTA was performed at 80 °C. The ^{68}Ga radiolabeling efficiency of *p*-NO_2-Bn-NOTA was not impacted by the increased level of metal impurities, possibly due to the smaller macrocycle having a greater preference for the small Ga^{3+} ion.

The greater stability of *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-NOTA was illustrated in the transferrin challenge study. Transferrin is an iron transfer protein found in blood. Due to the similar ionic radius and charge of Fe^{3+} (0.645 Å) and Ga^{3+} (0.620 Å) (*18*), ^{67}Ga or ^{68}Ga are known to bind to transferrin (*1*). In the transferrin challenge experiment, each of the Ga-radiolabeled BFCs was incubated in the presence of excess apo-transferrin, and the amount of Ga lost from the BFC and bound to transferrin was monitored over time. Both Ga-radiolabeled *p*-NO_2-Bn-NOTA and *p*-NO_2-Bn-PCTA proved to be relatively inert over 4 h, which is an appropriate period for imaging with ^{68}Ga. Ga-radiolabeled *p*-NO_2-Bn-DOTA showed some loss of Ga to apo-transferrin over time. The instability of Ga-radiolabeled *p*-NO_2-Bn-DOTA in the presence of serum proteins, such as transferrin, has been previously reported (*8, 9*). Ga-radiolabeled *p*-NO_2-Bn-Oxo was determined to be kinetically labile and was predicted to be unstable in vivo, despite having a thermodynamic stability constant similar to *p*-NO_2-Bn-DOTA (Ga-*p*-NO_2-Bn-Oxo pK = 21.3 (*19*), Ga-*p*-NO_2-Bn-DOTA pK = 21.33 (*20*)). The biodistribution results for Ga-radiolabeled *p*-NO_2-Bn-Oxo supported the *in vivo* instability of this species, as negligible clearance from the blood and other tissues was observed, as well as ^{68}Ga accumulation in bone and muscle tissue.

Mouse biodistribution and imaging studies with the three stable ^{68}Ga-radiolabeled BFCs, *p*-NO_2-Bn-PCTA, *p*-NO_2-Bn-NOTA, and *p*-NO_2-Bn-DOTA, provided information on the effect the BFC has on background uptake and clearance. Because of the short half-life of ^{68}Ga, imaging is done soon after injection leaving minimal time for the radiopharmaceutical to clear from blood and other tissue. All three of the BFCs cleared over time, mainly through the kidneys. For all tissues, the %ID/g values for ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA compared to ^{68}Ga-radiolabeled *p*-NO_2-Bn-DOTA were not statistically different. The biodistributions of these two BFCs were similar despite the structural differences, the slight differences noted in stability, and the difference in charge (at physiological pH, Ga-*p*-NO_2-Bn-PCTA is expected to be neutral, while Ga-*p*-NO_2-Bn-DOTA would be monoanionic) (*21, 22*). While the biodistribution of ^{68}Ga-radiolabeld *p*-NO_2-Bn-NOTA was statistically similar to those of ^{68}Ga-radiolabled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA with respect to uptake and clearance in the intestine, liver, and bone, large differences were observed for all other tissues. ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA cleared much more rapidly from the blood, heart, muscle, and spleen, but had 5 to 20 times more activity retained in the kidney and bladder (urine). The fast clearance from ubiquitous background tissue, such as blood and muscle, appears advantageous for obtaining superior target to background ratios, as long as the imaging target is not in proximity of the kidneys or bladder. Contrastingly, the fast blood clearance may limit the accumulation of the Ga-radiolabeled agent by limiting the circulation time of the agent. By 15 min, ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA in the blood (%ID/g) is already half that of ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA, and by 1 h, ^{68}Ga-radiolabeled *p*-NO_2-Bn-NOTA has almost completely cleared from the blood. ^{68}Ga-radiolabeled *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-DOTA also clear from the blood and related tissues, but at a slower rate. The need for relatively fast blood clearance may need to be balanced with adequate circulation time to ensure target accumulation. The addition of a targeting vector such as a peptide is expected to impact the nontargeted tissue distribution. Dependent on the nature and size of the targeting vector, the blood circulation time of the agent may increase and more activity may be retained in the kidney and/or liver due to metabolic processes. Further studies comparing targeted-peptide-conjugated BFCs for molecular imaging are planned to determine how differences in the clearance rates of blood and other tissues affect target uptake and target to background ratios.

CONCLUSIONS

In this study, we evaluated two novel BFCs, *p*-NO_2-Bn-PCTA and *p*-NO_2-Bn-Oxo, for Ga-based radiopharmaceutical development by direct comparison to the commonly used BFCs, *p*-NO_2-Bn-DOTA and *p*-NO_2-Bn-NOTA. Of the four BFCs, *p*-NO_2-Bn-NOTA and *p*-NO_2-Bn-PCTA were found to be more efficiently radiolabeled under milder conditions and to yield kinetically inert complexes that have appropriate clearance properties in vivo. The biodistribution of ^{68}Ga-radiolabeled

p-NO_2-Bn-PCTA was not statistically different than that of ^{68}Ga-radiolabeled *p*-NO_2-Bn-DOTA. However, *p*-NO_2-Bn-PCTA could be radiolabeled with Ga more efficiently under mild conditions compared to *p*-NO_2-Bn-DOTA. Due to superior Ga-radiolabeling efficiency, *p*-NO_2-Bn-PCTA may be an improved alternative to *p*-NO_2-Bn-DOTA in Ga isotope based radiopharmaceutical development. Radiolabeling with *p*-NO_2-Bn-NOTA gave high radiochemical yields in short reactions times and could be done at room temperature. Fast clearance from most tissue was observed for ^{68}Ga-*p*-NO_2-Bn-NOTA, but considerably higher retention in the kidneys was also noted. While the fast background clearance is advantageous, the fast blood clearance of ^{68}Ga-*p*-NO_2-Bn-NOTA could potentially limit target accumulation and requires further investigation.

Novel Fusogenic Liposomes for Fluorescent Cell Labeling and Membrane Modification

Agnes Csiszár,*,† Nils Hersch,† Sabine Dieluweit,† Ralf Biehl,‡ Rudolf Merkel,† and Bernd Hoffmann†

Institute of Bio- and Nanosystems, IBN-4, Biomechanics, and Institute of Solid State Research, IFF-5, Neutron Scattering, Forschungszentrum Jülich GmbH, 52425 Jülich, Germany. Received October 28, 2009; Revised Manuscript Received January 20, 2010

Efficient delivery of biomolecules into membranes of living cells as well as cell surface modifications are major biotechnological challenges. Here, novel liposome systems based on neutral and cationic lipids in combination with lipids modified by aromatic groups are introduced for such applications. The fusion efficiency of these liposome systems was tested on single cells in culture like HEK293, myofibroblasts, cortical neurons, human macrophages, smooth muscle cells, and even on tissue. Fusogenic liposomes enabled highly efficient incorporation of molecules into mammalian cell membranes within 1 to 30 min at fully unchanged cell growth conditions and did not affect cell behavior. We hypothesize that membrane fusions were induced in all cases by the interaction of the positively charged lipids and the delocalized electron system of the aromatic group generating local dipoles and membrane instabilities. Selected applications ranging from basic research to biotechnology are envisaged here.

INTRODUCTION

Phospholipid vesicles (liposomes) are widely used, e.g., for cell tracking (*1, 2*), for nonviral gene transfer (transfection) (*3–5*), or for drug delivery (*6, 7*). On the basis of their compositions, liposomes are more bioavailable than synthetic polymer capsules (*8*) or quantum dots (QD). Their cellular uptake has been intensely investigated and shows a strong preference of endocytotic cellular uptake over fusion or lipid mediated poration (*9*). Unfortunately, endocytotic pathways go along with limited efficiencies, often below 1%. Increasing efficiencies is therefore of major interest and approached by enhancing the uptake probability of whole liposomes by techniques as, e.g., electroporation (*10*) or microinjection (*11*). The drawback of these techniques is extreme cell stress, and most of them result in high cell death rates. Furthermore, electroporation can hardly be performed on tissues or adherent cells, and protocols as well as reagents still need to be optimized for every cell type.

The more promising alternative for efficiency enhancement is the induction of membrane fusion between liposomes and the plasma membrane of the mammalian cell. Unfortunately, changes in the chemical composition of liposomes like addition of free fatty acids or alcohols (*12*) or increasing of the chain unsaturations in the hydrophobic region of lipids alone seemed not to be sufficient to develop a universally deployable incorporation system for molecules, just to slightly increase fusion efficiency. At the current state, the most effective factors promoting fusion have biological origins. For example, generation of membrane connecting tubuli (*13*) and integration of fusion proteins (*14–17*), as well as viral membrane components (*18, 19*) in the particle surfaces, are effective biochemical techniques to yield high fusion efficiencies. Although effective, these methods are expensive and time-consuming.

Here, a new, simple, and almost universal fusogenic liposome system containing neutral and positively charged lipid molecules, as well as an additional lipid component with an extended conjugated π electron system, variable in the head or chain region of lipid molecules, has been introduced. The fusion efficacy and toxicity of these liposomes was tested on numerous cell types in culture and even on cell tissue. We furthermore present a possible mechanism underlying this constantly high fusion efficiency.

MATERIALS AND METHODS

Materials. 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), 1,2-dioleoyl-3-trimethylammonium-propane, chloride salt (DOTAP), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (ammonium salt) (LR-DOPE), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(1-pyrenesulfonyl) (ammonium salt) (Pyrene-DOPE), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (ammonium salt) (NBD-DOPE), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(cap biotinyl) (sodium salt) (capBio-DOPE), and L-α-lysophosphatidylinositol (sodium salt) (PI) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). All other modified lipids like 1-hexadecanoyl-2-(1-pyrenedecanoyl)-*sn*-glycero-3-phosphocholine (*β*-Pyrene-C10-HPC), DiOC18(3)3,3′-dioctadecyloxacarbocyanine perchlorate (DiO), 2-(4,4-difluoro-5-methyl-4-bora-3*a*,4*a*-diaza-*s*-indacene-3-dodecanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (*β*-BODIPY-C_{12}HPC), *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3*a*,4*a*-diaza-*s*-indacene-3-propionyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (triethylammonium salt) (BODIPY FL-DHPE), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(carboxyfluorescein) (ammonium salt) (Fluorescein-DHPE), *N*-(6-tetramethylrhodaminethiocarbamoyl)-1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (triethylammonium salt) (TMR-DHPE), 2-(4,4-difluoro-5,7-diphenyl-4-bora-3*a*,4*a*-diaza-s-indacene-3-pentanoyl)-1-hexadecanoyl-*sn*-glycero-3-phosphocholine (*β*-BODIPY-C_5-HPC), and Texas Red 1,2-dihexadecanoyl-*sn*-glycero-3-phosphoethanolamine (triethylammonium salt) (TR-DHPE) were ordered from Invitrogen (Eugene, OR).

Liposome Preparation. Lipid components like DOPE, DOTAP, and lipids bonded to aromatic groups were mixed in

chloroform in a weight ratio of DOPE/DOTAP/aromatic lipid of 1/1/0.1. Chloroform was evaporated under vacuum for 0.5−1 h. Then, lipids were dispersed in 20 mM 2-(4-(2-hydroxyethyl)-1-piperazinyl)-ethansulfonic acid (HEPES) buffer (VWR, Darmstadt, Germany) in a total lipid concentration of 2 mg/mL. The solution was vortexed for approximately 1−2 min to produce multilamellar liposomes. After homogenization in an ultrasonic bath for 10−20 min, mainly unilamellar vesicles or liposomes were formed.

Dynamic Light Scattering (DLS). Liposomes made from DOPE/DOTAP (1/1 w/w), DOPE/DOTAP/TR-DHPE (1/1/0.1), and DOPE/DOTAP/β-BODIPY-C_{12}HPC (1/1/0.1) mixtures were studied by dynamic light scattering (*20*) (DLS) in a concentration of 0.02 mg/mL. DLS measurements were performed on a DLS standard setup with an argon ion laser (514 nm) and an Avalanche Photo Diode (APD, ALV, Germany) mounted on an ALV-125 compact goniometer together with an ALV5000E digital correlator (both ALV, Germany). The temperature of the sample was fixed to 20 and 37 °C by a temperature-controlled environment. To account for polydispersity, we evaluated the data according to the CONTIN algorithm (*21*) provided by the ALV-correlator software. The resulting relaxation rate distribution was converted to a hydrodynamic radius distribution according to the Stokes−Einstein relation. A weighting of the relaxation distribution function according to a Rayleigh-Debye theory is not appropriate here because the micelle size is far above the limits of the Rayleigh-Debye theory.

Freeze−Fracture/Transmission Electron Microscopy (TEM). Liposomes made from DOPE/DOTAP (1/1 w/w), DOPE/DOTAP/LR-DOPE (1/1/0.1), and DOPE/DOTAP/β-BODIPY-C_{12}HPC (1/1/0.1) mixtures were studied by freeze−fracture in a concentration of 1 mg/mL. Samples were incubated at 20 °C or at 37 °C for at least 10 min. After incubation, samples were rapidly frozen by plunging into liquid propane cooled by liquid nitrogen. Fracturing was performed at −150 °C in a freeze−fracture apparatus (BAF 400 D, Bal-Tec, Liechtenstein). Etching was achieved by warming the samples to −110 °C for 1 min followed by shadowing with platinum in an electron beam at an angle of 45° and subsequently with carbon at an angle of 90°. The replicas were cleaned with a methanol (VWR, Darmstadt, Germany)/water mixture (9/1 v/v). Replica were captured with copper grids and examined in an EM902 (Carl Zeiss SMT, Oberkochen, Germany) microscope.

Light Microscopy. Samples were imaged at 37 °C using a laser scanning microscope LSM 710 (Carl Zeiss MicroImaging GmbH, Jena, Germany) equipped with an argon ion laser (488 nm) and a helium−neon laser (543 nm). To detect the fluorescent signal of TMR, LR, and TR (excitation 543 nm), a long pass filter LP 650 nm, for BODIPY, DiO, NBD, and fluorescein (excitation 488 nm), a band-pass filter BP 500−520 nm was used. The microscope was equipped with an oil immersion objective EC Plan-Neofluar 40×/1.30 Ph3 (Carl Zeiss). The images were analyzed with the LSM 710 ZEN software (Carl Zeiss).

Fluorescent recovery after photobleaching (FRAP) was used to determine the diffusion constant of lipid components in living cell membranes. For these measurements, an intense, focused laser beam of appropriate wavelength (488 nm for BODIPY FL and 543 nm for LR-DOPE) bleached a small circular spot (ca. 0.5−1 μm^2) on the cell membrane for 50−100 ms. Subsequently, the same beam with a strongly reduced intensity of approximately 3% monitored the reappearance of fluorescence within the circle due to the diffusion of unbleached molecules. The fluorescence recovery curve, $I(t)$ (fluorescence intensity vs time after bleaching) was first corrected as described by Möhl et al. (*22*). Diffusion constants (D) of fluorescent labeled lipids were calculated as follows (*23*):

$$D = 0.224r^2/t_{1/2} \quad (1)$$

where r is radius of the bleached spot and $t_{1/2}$ is half time of fluorescent recovery.

Cell Culture. *Isolation of Rat Embryonic Myofibroblasts.* Fibroblasts were isolated from 18-day old Wistar rat embryos as described earlier (*24*). Cells were seeded on fibronectin coated glass surfaces (2.5 $\mu g/cm^2$ human plasma fibronectin (BD Biosciences, San Jose, CA)). Cells were maintained in F10 Ham's medium (Sigma Aldrich, St. Louis, MO, USA) supplemented with 10% fetal bovine serum and a 1/100 dilution of antibiotics (10 000 units penicillin and 10 mg/mL streptomycin in 0.9% NaCl, (Sigma)). For additional isolation of pericardial tissue, the pericardium was carefully detached from embryonic heart, washed in cold Hanks Balanced Salt Solution (HBSS) (Sigma), and maintained as described above for myofibroblasts.

Isolation of Rat Embryonic Cortical Neurons. Rat embryos were recovered from pregnant rats at day 18 of gestation as described in refs *25* and *26*. Isolated cortical neurons were resuspended in 1 mL Neurobasal Medium (Invitrogen), 1% B27 supplement (Invitrogen), 0.5 mM L-glutamine per hemisphere isolated, and seeded on poly-D-lysine (Sigma) coated glass surfaces (1 $\mu g/cm^2$).

Additional cell types investigated in this study were purchased from different providers and cultivated in the recommended media (Table 1). All cell types listed in Table 1 were cultivated in a humidified incubator at 37 °C and 5% CO_2.

Isolation of Macrophages. Human monocytes were isolated according to the protocol from Noble and Cutts (*27*) using the Leucosep-System (Greiner bio-one, Kremsmünster, Austria). Isolated leucocytes were resuspended in RPMI medium (Sigma) supplemented with 10% fetal bovine serum and a 1/100 dilution of an antibiotic solution (10,000 units penicillin and 10 mg streptomycin in 0.9% NaCl, (Sigma)) and seeded on fibronectin (BD Bioscience, San Jose, CA USA) coated glass surfaces. Nonadherent cells were washed away after four hours. Since monocytes attach to culture surfaces more rapidly than other lymphocytes, this step resulted in an enriched culture. After two days, medium was completely replaced by fresh RPMI containing 0.1 ng/mL granulocyte macrophage colony stimulating factor (G-MCF) (Sigma). After further 3−4 days, monocytes were differentiated to macrophages.

Membrane-Fusion Experiments. For fusion experiments, 5 μL of liposome stock solution was diluted 1/100 with appropriate cell culture medium (Table 1) and gently shaken for 1−2 min at room temperature. Cells in a Petri dish (∅ = 3.5 cm) (20 000−30 000 per dish) were incubated in 500 μL of fusogenic liposomes solution (pH 7.4) for 10−30 min at 37 °C. Subsequently, the fusion mixture was replaced by fresh medium, and cells were imaged by light microscopy.

RESULTS

As lipid base, we used a 1:1 (w/w) ratio of a neutral phospholipid, 1,2-dioleoyl-*sn*-glycero-3-phosphatidylethanolamine (DOPE), and a cationic lipid, 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP). Figure 1 shows the molecular structures of these lipids. This lipid mixture was not able to fuse with cell membranes resulting in low uptake efficiencies (data not shown). The addition of a third lipid component containing large delocalized π electron systems coupled to either the hydrophobic or the hydrophilic lipid parts completely changed the cellular uptake processes. Table 2 summarizes some of the tested aromatic lipid molecules. However, all of them are widely used for fluorescent membrane labeling and none of these molecules can be transferred spontaneously into membranes (*28*) (exception here are lipids of the Di- series, e.g., DiO). Only the synergetic interaction of the three components,

neutral lipid, cationic lipid, and aromatic lipid resulted in an effective fusogenic mixture.

Characterization of the Fusogenic Liposomes. Although DOPE/DOTAP (1/1 w/w) liposomes did not fuse measurably with cell membranes, they were chosen as reference sample to compare their physicochemical behavior with that of the fusogenic liposomes. After preparation, the average radius of the DOPE/DOTAP liposomes was 0.72 ± 0.09 μm (Figure 2a) according to dynamic light scattering analyses. Freeze−fracture and subsequent electron microscopy further specified them as unilamellar vesicles with smooth surfaces at room temperature as well as at 37 °C (Figure 2b).

The addition of aromatic lipid components to a DOPE/DOTAP mixture, e.g., lissamine rhodamine B fluorescent dye coupled to DOPE (Table 2) or β-BODIPY coupled to C_{12}-HPC (Figure 1 and Table 2), just slightly affected the size distributions of liposomes with an average radius of 0.78 ± 0.07 μm and 0.94 ± 0.10 μm, respectively. Smaller vesicles or larger aggregates of vesicles were not observed in the dynamic light scattering analyses (Figure 2a). Vesicles were observed as unilamellar, spherical structures with smooth, nonstructured surfaces at both temperatures similar to the reference sample (Figure 2b).

Administration of Fusogenic Liposomes to Single Cells. In order to prove fusion, HEK293 cells were imaged during incubation with fusogenic liposomes made from DOPE/DOTAP/BODIPY FL-DHPE (1/1/0.1 w/w) lipid mixture (Figure 1a). Immediately after vesicle addition (Figure 3a: 0 s), small green dots, i.e., vesicles, were observed in the BODIPY FL channel. After 100 s, the first fluorescently labeled cell membranes appeared, and 200 s later, most of the plasma membranes could

be imaged in the green fluorescence channel (Figure 3a). Cellular plasma membranes were homogenously labeled by BODIPY FL without liposome clumps on the surface. Unchanged cell behavior and cell growth were detected in the phase contrast channel simultaneously with the appearance of the fluorescent signal in the cell membranes. After successful membrane fusion, excess liposomes were replaced by cell medium, and cell survival and clearance of fluorescent lipids from the plasma membrane were determined. Cell growth of HEK293 was not influenced by liposome fusion, and a healthy cell layer completely covered the glass surface 24 h after fusion. Most dye lipid disappeared from the cell membrane during this time period as shown in Figure 3b.

Several aromatic phospholipid molecules were tested for fusion capacity. Although they all induced membrane fusion with living cells, clear differences were seen in fusion time,

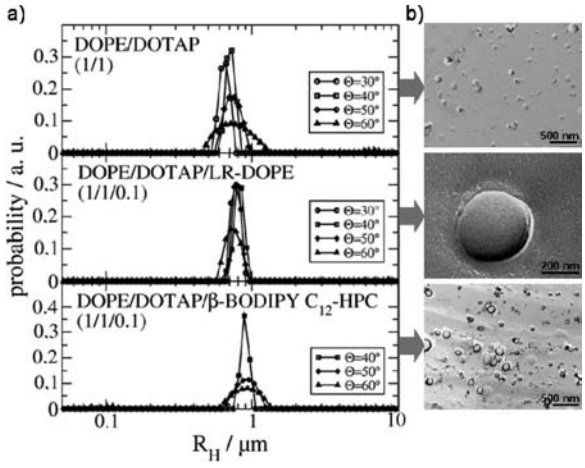

Figure 2. Physico-chemical characterization of fusogenic liposomes. (a) Hydrodynamic radius distribution from dynamic light scattering after CONTIN analysis of DOPE/DOTAP (1/1 w/w), DOPE/DOTAP/LR-DOPE (1/1/0.1 w/w), and DOPE/DOTAP/β-BODIPY-C_{12}HPC (1/1/0.1 w/w) mixtures at 20 μg/mL concentration in 20 mM HEPES buffer. Measurements were carried out at the indicated scattering angles. (b) The same fusogenic vesicles at 2 mg/mL concentration were freeze−fractured and subsequently analyzed by transmission electron microscopy. Note their unilamellar composition and smooth surface.

fusion efficiency, and signal homogeneity in the plasma membrane. These parameters together entered an admittedly subjective efficiency scale (Table 2). The most effective and fast fusion processes with homogeneously distributed fluorescence signals in the cell membrane were induced by large aromatic groups containing hetero atoms with a significantly higher electronegativity, e.g., oxygen, nitrogen, or boron coupled to fluorine (Table 2: ***). Dye molecules as pyrene with a homogenously distributed π electron system without hetero atoms correspondingly were found to be less effective fusion promoters (Table 2: *). Cyclic groups coupled to lipid molecules that were not in compliance with Hückel's rule were also investigated (e.g., capbiotin-DOPE or phosphatidylinositol), and no fusion with cell membranes was detected. Furthermore, the efficiency of pH-sensitive dyes like fluorescein depended on their ionic form. At low pH values where the dye group was deprotonated, they were less effective than at higher pH in the protonated form (Table 2: **).

Table 3. Lateral Diffusion Constant (*D*) and Fluorescence Recovery of Head and Chain-Labeled Lipids Measured in HEK293 Cell Membranes after Liposome Fusion (mean ± sd for *n* measurements)

dye lipid	D (μm^2/s)	recovery (%)	n
LR-DOPE	0.21 ± 0.14	84 ± 5	8
BODIPY FL-DHPE	0.16 ± 0.08	76 ± 6	9
β-BODIPY C_{12}HPC	0.15 ± 0.05	75 ± 7	9

The successful incorporation of aromatic lipid molecules was furthermore controlled by detecting their lateral diffusion constants using fluorescence recovery after photobleaching technique (FRAP) (*29, 30*). Liposome fusion events were induced in HEK293 cells by LR-DOPE and BODIPY FL-DHPE as headgroup-modified lipids and β-BODIPY C_{12}HPC as chain-labeled lipid. Plasma membranes were first localized by confocal imaging. Subsequently, diffusion constants (D) and fluorescence recovery of the dye lipids in the plasma membrane were determined. A typical recovery curve is shown in Figure 3b, and all results are summarized in Table 3. The resulting diffusion constants of all investigated dye lipids were found to be relatively similar with values around 0.18 μm^2/s. Even the location of the aromatic group in the polar head or apolar chain region did not significantly influence the diffusion behavior. Fluorescence recovery, frequently called mobile fraction, was also determined, and the values also appeared statistically similar

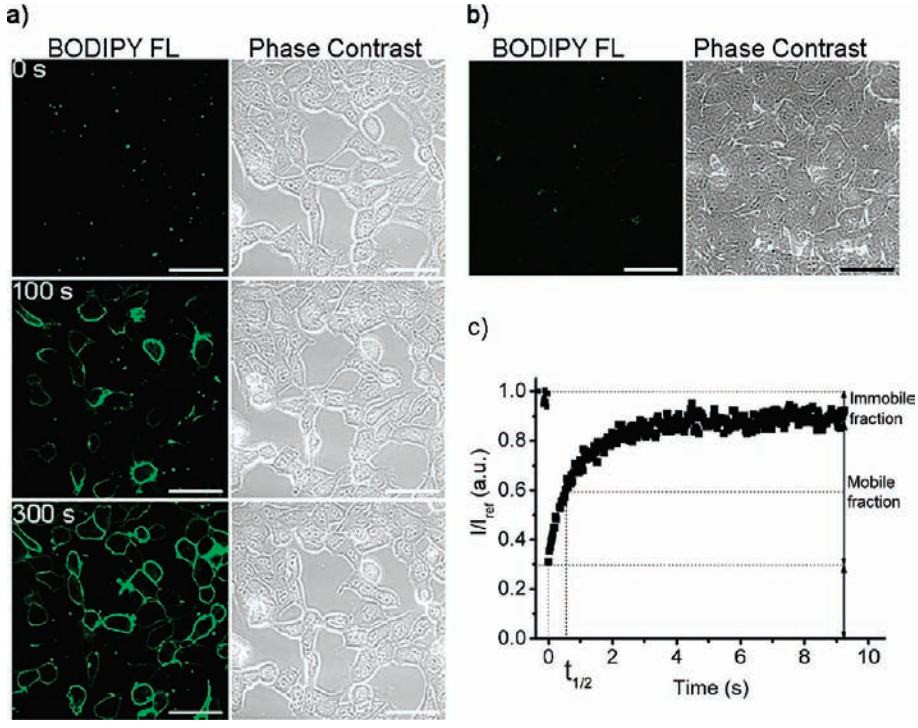

Figure 3. Vesicle fusion with plasma membranes. (a) HEK293 cells were incubated with vesicles made from DOPE/DOTAP/BODIPY FL-DHPE (1/1/0.1 w/w) and analyzed over 300 s in fluorescence (left) and phase contrast (right). Within this time period, efficient membrane fusion was detected with unchanged cell behavior. Scale bars = 50 μm. (b) Uninfluenced cell growth (phase contrast channel) and completely degraded liposomes (BODIPY FL channel) were observed 24 h after membrane fusion. Scale bars = 80 μm (c). Fluorescence recovery curve of LR-DOPE in HEK293 plasma membrane after membrane fusion. The diffusion parameters of LR-DOPE calculated from the FRAP curve confirm the incorporation of fluorescently labeled lipid into the cell membrane.

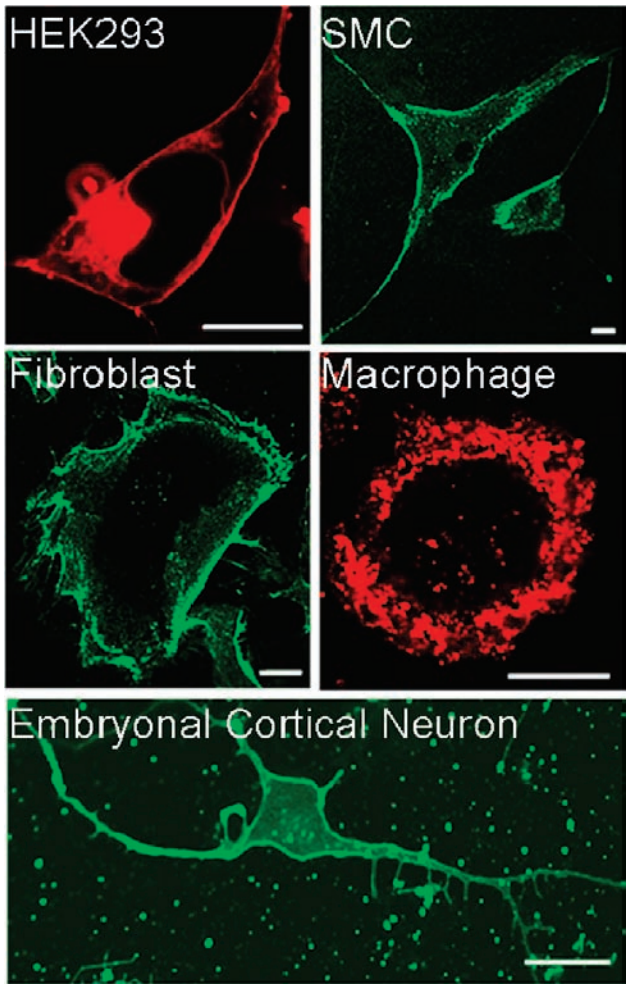

Figure 4. Cell membranes of HEK293, smooth muscle cells (SMC), rat myofibroblasts, human macrophages, and embryonal cortical neurons were fluorescently labeled by vesicle fusion. As aromatic lipids, either LR-DOPE (red) or BODIPY FL-DHPE (green) was used. Scale bars = 10 μm.

to each other (around 78 ± 6%) independent from the dye and its location in the lipid molecule. The measured values were in good agreement with other values given for fluorescent tracer lipid diffusion in cell membranes (*23, 31*).

The ubiquitous ability of our system to induce fusion was successfully proven by labeling many other cell types as human keratinocytes, human macrophages, rat embryonic cortical neurons, bronchial smooth muscle cells, and rat myofibroblasts. For all of these cell types, cell labeling efficiency reached an almost complete labeling of all cells. Only in the case of myocytes was an increased resistance against fusogenic liposomes observed (data not shown). Some labeled cells are presented in Figure 4.

Administration of Fusogenic Liposomes on Cellular Tissue. As an exemplary tissue sample, rat embryonic pericardium, a multicelled layer of defined thickness around the contractile heart apparatus was chosen and incubated with fusogenic liposomes made from DOPE/DOTAP/BODIPY FL-DHPE (1/1/0.1 w/w) lipid mixture for one hour. This prolonged incubation period was necessary due to the increased cell number and the cell stacks on top of each other. Confocal imaging revealed an almost complete staining of all pericardial surface cells. Additionally, almost all cell layers (three to four)

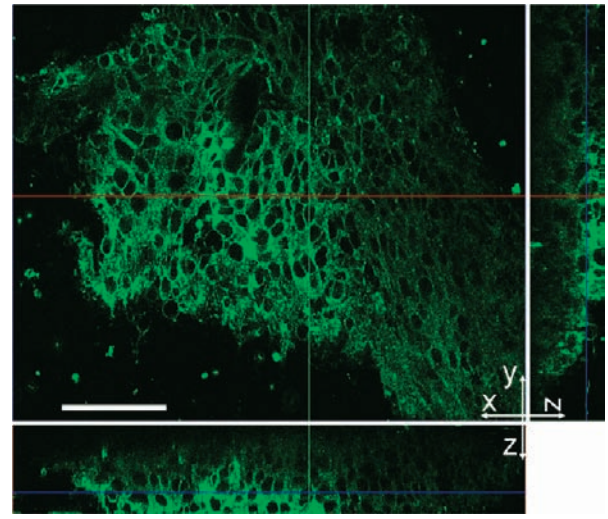

Figure 5. Isolated pericardial tissues were incubated for 1 h using DOPE/DOTAP/BODIPY FL-DHPE (1/1/0.1 w/w) mixture as fusogenic liposomes and subsequently imaged by confocal microscopy. Small micrographs below and on the right of the main image indicate the cross sections parallel to *xz*- and *yz*-planes respectively. Cross section images revealed several fluorescently labeled cell layers below the top layer. Scale bar = 100 μm.

below the top layer were labeled with similar efficiency in spite of the relatively large liposomal size (Figure 5).

DISCUSSION

Classical liposomes used for DNA delivery are based on a composition of neutral and positively charged lipid molecules. The cellular uptake processes of these vesicles have been investigated earlier and have shown a strong preference of endocytotic pathways with a limited efficiency (*32*). Here, the addition of a third lipid component converted these liposomes to a nearly universal fusogenic system. The third lipid component needed to meet the criteria of (a) amphiphilic molecular character to be easily incorporated into biological or biomimetic membranes and (b) a delocalized conjugated π-electron system located in the polar or apolar molecular range. Interestingly, these criteria were fulfilled by almost all fluorescent labels when coupled to phospholipids. Table 2 summarized all successfully tested molecules. Other molecules meeting these criteria should work as well but have not been explicitly tested here since fluorescently labeled lipids had the strong advantage of direct visualization of fusion to unravel the functional mechanism.

The synergistic interaction of the three components, neutral lipid, positively charged lipid, and lipids with an aromatic group resulted in an effective fusogenic mixture. Although the mechanism of action has not yet been elucidated, it is to assume that the neutral molecule DOPE has a cone-like effective shape and supports fusion intermediate states (*33*). The positive charge of DOTAP in the polar headgroup region interacts with the negatively charged glycocalyx of the cell membrane decreasing the distance between liposome and cell membrane and increasing the probability of fusion, respectively (*3*). Additionally, the strong positive charges in the headgroup of liposomes polarize the delocalized π electrons inducing local dipoles. These dipoles presumably yield local instabilities and disorders of molecular arrangements in the bilayer. Cevc and Richardsen reported that such effects could positively influence membrane fusion processes (*12*). Moreover, the presence of an additional heteroatom with high electronegativity, e.g., fluorine (χ = 4 on the Pauling scale) in BODIPY dyes (Figure 1a) or oxygen (χ = 3.5) and nitrogen (χ = 3.0) increased the dipole character in the aromatic group resulting in a higher fusion

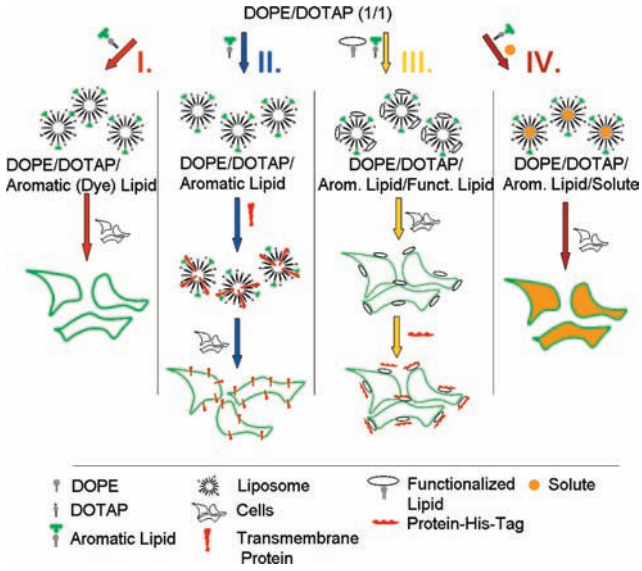

Figure 6. Overview of the potential fields of application for fusogenic liposomes: (I), plasma membrane visualization (II), transmembrane protein incorporation into plasma membranes, (III) cell surface functionalization, and (IV) content delivery.

potential, while molecules with a large but homogenously distributed π electron system like pyrene (Table 2) revealed reduced fusion behavior. Cyclic groups without aromaticity and coupled to phospholipids did not induce fusion processes with membranes of living cells.

Delocalized electron systems could be bound to the head as well as the chain regions of lipids (Table 2, e.g., pyrene or BODIPY) without any influence on the fusion efficiency. The most effective composition ratio between the three components was found from 1/1/0.05 to 1/1/0.2 (w/w) of DOPE/DOTAP/aromatic lipid. A lower amount of aromatic lipids is often not sufficient to promote fusion, while higher concentrations can be toxic to cells. In general, an approximate weight ratio of 1/1/0.1 could be successfully used for the first experimental approaches. The digestion of lipids used in fusogenic liposomes in a weight ratio of 1/1/0.1 of DOPE/DOTAP/aromatic lipid by HEK293 was investigated, and their full degradation was observed in a time period of 24 h accompanied by completely unchanged cell growth. On the basis of these observations, we propose that administration of these novel liposomes yielded highly efficient cell membrane modifications without noticeable toxic side effects.

Liposome fusion events were successfully observed in several cell types like HEK293 cells, human macrophages, rat embryonic cortical neurons, smooth muscle cells, and rat myofibroblasts (Figure 4). After membrane fusion, diffusion constants (D) of aromatic lipids were determined with 0.18 $\pm$ 0.14 $\mu m^2/s$ (Table 3) corresponding to other values given for lipid diffusion in cell membranes (*23, 31*). This value is approximately one magnitude lower in comparison to lipid diffusion in model membranes without hindering proteins where the diffusion constant of NBD-DOPE was found to be 2.5 $\pm$ 0.2 $\mu m^2/s$ (*34, 35*). This fact supports the hypothesis of membrane fusion against liposomal adhesion on cell membrane surfaces. Additionally, the selective fluorescent signal of the cell membrane as well as the short uptake time and the high efficiency suggested a membrane fusion against endocytosis as main uptake mechanism.

These results open a large number of possible pharmaceutical and biotechnological application fields as schematically summarized in Figure 6. Fluorescent membrane labeling is only one of the numerous cell membrane modifications (Figure 6 I). With addition of other functionalized molecules like chelator lipids or biotinylated or antigenic lipids at an optional low concentration, surface functionalization of living cells can be achieved (Figure 6 III). This membrane modification can be completed in an additional step by protein coupling to the cell surface. Furthermore, it is assumed that membrane proteins in addition to functionalized lipids can also be incorporated into fusogenic liposomes and, corresponding to this, into cell membranes as well (Figure 6 II). Nevertheless, if the membrane mixing is accompanied by content mixing, highly efficient delivery of soluble molecules to living cells can be performed (Figure 6 IV). Fusogenic liposomes could easily be modified by tumor specific targeting and used for medical purposes.

In conclusion, we have designed a new, simple and almost universal fusogenic liposome system containing neutral and positively charged lipid molecules as well as additional lipid components with aromatic molecular groups. The liposomes mediate highly effective fusion processes with living cell membranes without toxic side effects. As fusion mechanism, we hypothesize a synergistic interaction of the positively charged lipids and the delocalized electron system of the aromatic group inducing local dipoles and membrane instabilities. However, the exact mechanism has to be investigated in the future. This new type of fusogenic liposomes opens a large number of biotechnological application fields.

ACKNOWLEDGMENT

We thank R. Fricke and K. Michael for isolation of rat cortical neurons. We are also grateful to J. Fleischhauer for technical support.

Synthesis and AFM Characterization of Poly(dG)-poly(dC)-gold Nanoparticle Conjugates

Dragoslav Zikich, Natalia Borovok, Tatiana Molotsky, and Alexander Kotlyar*

Department of Biochemistry, George S. Wise Faculty of Life Sciences, Tel Aviv University, The Center for Nanoscience and Nanotechnology, Tel Aviv University, Ramat Aviv, 69978. Received December 1, 2009; Revised Manuscript Received January 29, 2010

In the present work, we have synthesized conjugates between the 5 nm gold nanoparticles (Au-NP) and 5′ thiol-functionalized, 700 bp poly(dG)-poly(dC). We have completely separated and purified to homogeneity conjugates bearing different number of poly(dG)-poly(dC) molecules per Au-NP by electrophoresis and HPLC. The conjugates were directly visualized by atomic force microscopy. We have demonstrated that Au NP-bound poly(dG)-poly(dC) can be considerably extended by Klenow exo$^-$ polymerase in the presence of dCTP and dGTP.

INTRODUCTION

Since the pioneering works by Alivisatos and Mirkin (*1, 2*), interaction of Au-NP with thiol-modified single-stranded (ss) DNA has become a subject of extensive investigation by chemists, biologists, and physicists. Because of their small size, Au-NP-DNA conjugates exhibit unique physical, chemical, and optical properties and have been used as bases for development of applications in various aspects of nanoassembly (*3, 4*), biodiagnostics (*5*−*7*), and nanoelectronics (*8, 9*). The ability of DNA to form well-defined secondary and tertiary structures offers a variety of possibilities for nanostructure design in a bottom-up approach (*10*). The vast majority of studies in this field were focused on the interaction of ssDNA with metal nanoparticles; much less emphasis has been placed on formation of conjugates between long, functionalized dsDNA and the particles. It has been shown that DNA molecules connected to a particle retain their functional activity and can be processed by restriction enzymes (*10*−*12*), polymerases (*13*), and ligases (*14*). Tsai and co-workers have successfully used a ligase-based approach for the formation of complexes between long (1714 base pairs) random-sequence thiolated dsDNA and gold nanoparticles (*15*). The conjugates bearing a different number of DNA molecules per particle have been efficiently separated from each other by electrophoresis and seen by AFM (*15*). To the best of our knowledge, no nanoparticle conjugates with homogeneous dsDNA polymers have been reported so far. The results of theoretical calculations show that poly(dG)-poly(dC) exhibits better conductance than other homopolymeric DNA form, poly(dA)-poly(dT) (*16*). Therefore, poly(dG)-poly(dC) homopolymer seems to be a promising new candidate for use in DNA-based nanodevices.

We have recently invented a new enzymatic method for the synthesis of homogeneous dsDNA polymers (*17*). This method enables us to synthesize poly(dG)-poly(dC) molecules, ranging from tens to tens of thousands base pairs that are characterized by a narrow length distribution. In addition, these molecules can be functionalized at one or at both 5′-ends with SH-groups or other residues. The ability to introduce SH-groups into the synthesized molecules provides a tool for their covalent attachment to gold surfaces. Attachment of metal particles might provide good electric communication between the electrode and the DNA-NP conjugate via metal/metal contact interactions, thus promoting charge migration though the DNA.

Here, we describe an efficient method for production of poly(dG)-poly(dC) Au-NPs conjugates bearing a different number of DNA molecules per Au-NP. The conjugates were efficiently separated by agarose gel electrophoresis and visualized by AFM. We demonstrate that poly(dG)-poly(dC) molecules connected to a Au-NP can be extended by Klenow exo$^-$ fragment of DNA polymerase.

EXPERIMENTAL PROCEDURES

Synthesis of Au Nanoparticles. Au-NPs of 5 nm in diameter were prepared by the modified citrate reduction method (*18, 19*). 5.9 mg of $HAuCl_4$ was dissolved in 1 mL of double distilled water and added into 47 mL of H_2O to the final concentration of 0.3 mM. The solution was incubated with constant stirring at 25 °C for 10 min. 0.5 mL of 50 mM sodium citrate solution was added to the reaction mixture to a final concentration of 0.5 mM, and the solution was incubated under constant stirring for another 10 min. 0.67 mL of cooled 0.1 M $NaBH_4$ was added into the stirred mixture; the solution developed an orange−red color. The resulting nanoparticles were screened for their size and uniformity by TEM, revealing an average diameter of 5 ± 1.5 nm. The UV−vis spectra showed a characteristic absorption peak at 520 nm. The particles were stabilized with BSPP (bis sulfonatophenylphosphine dehydrate dipotassium salt, Strem Chemicals, USA) as follows. The Au-NPs above were incubated with 0.1 mM BSPP in the dark for 20 h at RT and concentrated using Microcon device YM-50 (Millipore, USA). The excess of BSPP was removed by passing the particles though G-25 Sephadex column (15 × 50 mm, Healthcare, USA) in 20 mM Tris-acetate buffer, pH 7.5. The Au-NPs eluted in the void volume of the column were concentrated using YM-50 Microcon device (Millipore, USA). Concentration of the particles was calculated using an extinction coefficient (ε) of 9.3×10^6 M^{-1} cm^{-1} at 517 nm.

DNA Samples. The $(dC)_{12}$ and SH-$(dG)_{12}$ oligonucleotides were purchased from Alpha DNA (Montreal, Canada). The SH-group in SH-$(dG)_{12}$ was linked to the terminal base at the 5′ end of G-12mer $(dG)_{12}$ oligonucleotides via a six-carbon linker. The oligonucleotides were purified to homogeneity essentially as described (*20*). Purified SH-$(dG)_{12}$ and $(dC)_{12}$ oligomers were incubated in 0.1 M NaOH at an equimolar ratio for 15 min at room temperature and further dialyzed against 20 mM Tris-acetate buffer, pH 7.5, containing 2 mM DTT for 1 h. Figure 1. Electrophoretic separation of Au-NP poly(dG)-poly(dC) conjugates.700 bp 5′-SH-poly(dG)-poly(dC) molecules were incubated with 5 nm Au-NPs at a 4 to 1 molar ratio for 2 h at 60 °C in 20 mM Tris-acetate pH 7.5, containing 0.1 M NaCl. (A) Separation of the sample was conducted on 1.2% agarose gel (7 × 7 cm) at 130 V for 25 min at RT in TEA buffer. The wine-colored bands marked with the numbers correspond to the conjugates bearing one, two, three, and four poly(dG)-poly(dC) molecules, correspondingly. The band in the lower right corner of the gel corresponds to 5 nm Au-NPs. (B) Normalized absorption spectra of samples extracted from gel slices corresponding to bands 2, 3, and 4 (see left panel). Two distinct absorption maxima at 260 and 520 nm correspond to DNA and Au nanoparticle, respectively. The amount of individual conjugates extracted from the gel was quantified by measuring absorption at 520 nm. The relative yield of conjugates was calculated by multiplying the volume by absorption at 520 nm for each individual fraction and dividing the resulting value with that obtained for the initial mixture of conjugates (before electrophoresis). The calculated yields are correspondingly equal to 0.15, 0.37, 0.31, and 0.09 for conjugates bearing one, two, three, and four poly(dG)-poly(dC) molecules.

dialysis was continued against the same buffer not containing DTT for one more hour. Concentrations of G- and C-oligonucleotides were calculated using extinction coefficients at 260 nm of 11.7 and 7.5 mM^{-1} cm^{-1} for G and C bases (*21*), respectively.

DNA Synthesis Reactions. Synthesis of 5′SH-poly(dG)-poly(dC) was performed as described previously (*20*) in a standard reaction assay containing: 60 mM KPi, pH 7.4, 5 mM $MgCl_2$, 5 mM DTT, 1.5 mM dCTP, 1.5 mM dGTP, 0.2 μM Klenow exo$^-$, and 1 μM HPLC purified (see above) template-primer, 5′-SH-$(dG)_{12}$-$(dC)_{12}$. The synthesis was conducted for 2 h at 37 °C. The reaction was terminated by the addition of EDTA to a final concentration of 10 mM.

HPLC Purifications. The separation of synthesized DNA molecules from nucleotides, template-primer, and other reaction components was achieved with a TSK-gel G-DNA-PW HPLC column (7.8 × 300 mm) from TosoHaas (Japan) by isocratic elution with 20 mM Tris-acetate, pH 7.0, for 30 min at a flow rate of 0.5 mL/min. HPLC purification of the oligonucleotides and the synthesized DNA was conducted on an Agilent 1100 HPLC system with a photodiode array detector. Peaks were identified from their retention times obtained from the absorbance at 260 nm for DNA.

Electrophoresis. The poly(dG)-poly(dC) and Au NP-poly(dG)-poly(dC) conjugates were loaded onto 1.2% agarose gel 7 × 7 cm, and then electrophoresed at room temperature at 130 V for 25 min. TAE buffer, in addition to being used to prepare the agarose, also served as the running buffer.

Atomic Force Microscopy. Atomic force microscopy was performed on the molecules adsorbed onto muscovite mica surfaces. A 20 μL aliquot of 1.0−2.0 nM Au NP-DNA sample in 2.0 mM $MgCl_2$ or 2.0 mM $NiCl_2$ was deposited on freshly cleaved mica plates for 2 min, then washed with distilled water and dried by nitrogen blow. AFM imaging was performed on a Solver PRO AFM system (NT-MDT, Russia), in a semicontact (tapping) mode, using 130-μm-long Si-gold-coated cantilevers (NT-MDT, Russia) with resonance frequency of 119−180 kHz. The images were "flattened" (each line of the image was fitted to a second-order polynomial, and the polynomial was then subtracted from the image line) by the Nova image processing software (NT-MDT, Russia). The images were analyzed and visualized using a Nanotec Electronica S.L (Madrid) *WSxM* imaging software (*22*).

RESULTS

To produce the Au-NP-DNA conjugates, 700 bp 5′-thiolated poly(dG)-poly(dC) was mixed with Au-NPs at 4 to 1 molar ratio in 20 mM Tris buffer, pH 7.5, in the presence of 0.1 M NaCl, for 2 h at 60 °C. The incubation resulted in the formation of Au-NP-DNA conjugates bearing a different number of DNA molecules per nanoparticle. The conjugates were separated by electrophoresis in a 1.2% agarose gel, as shown in the Figure 1. The wine-colored bands in the gel (see Figure 1A) correspond to the conjugate products containing distinct number of poly(dG)-poly(dC) molecules per Au-NP. Each band was cut out of the gel with a razor blade. Colored gel slices were placed in dialysis bags containing TAE buffer; each sample was then electroeluted into the bag and collected. Absorption spectra of the eluted Au-NP-DNA conjugates are shown in Figure 1B. The spectra are characterized by absorption maxima at 260 and 520 nm. The absorption at 260 nm is mainly due to DNA, while absorption at 520 nm is due to Au-NPs. Thus, the 260 to 520 nm absorption ratio in the spectrum reflects a relative amount of the DNA molecule per particle (see Figure 1B).

Fractions extracted from the gel slices were further purified and characterized by size-exclusion HPLC. Figure 2A displays the superimposed size-exclusion chromatograms of Au-NP DNA conjugates extracted from the four individual bands in the gel (see Figure 1A). As seen in Figure 2, the conjugates are eluted from the column as single and symmetrical peaks, indicating their high-purity complexes. The HPLC, in addition to confirming their purity, completely separates the conjugates from relatively low molecular weight agarose oligomers, extracted from the gel slices together with the conjugates.

The molecular morphology of HPLC purified Au-NP-poly(dG)-poly(dC) conjugates was elucidated by AFM. The molecules eluted from the HPLC column were deposited onto freshly cleaved, 1 × 1 cm mica and imaged by AFM in a tapping mode. The images of gel-extracted fraction are shown in Figure 3. The vast majority of conjugates seen on A, B, C, and D panels of Figure 3 are composed of 1, 2, 3, or 4 poly(dG)-poly(dC) molecules bound to a single nanoparticle (seen as bright spots

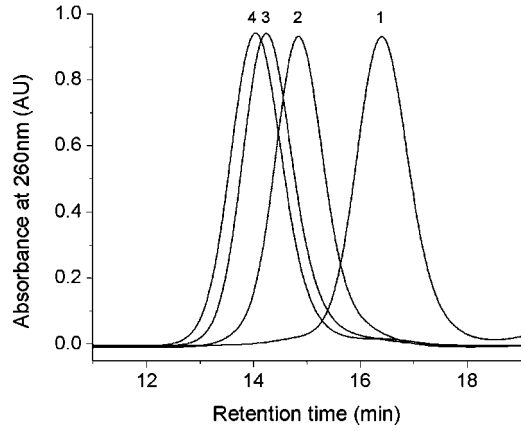

Figure 2. Size-dependent HPLC separation of Au-NP poly(dG)-poly(dC) conjugates. The individual conjugates extracted from the gel (see Figure 1) were loaded onto the size-exclusion column equilibrated with 20 mM Tris-acetate, pH 7.5. Elution profiles of conjugates corresponding to bands 1, 2, 3, and 4 in Figure 1 are indicated with numbers 1 through 4, respectively. The elution was followed at 260 nm.

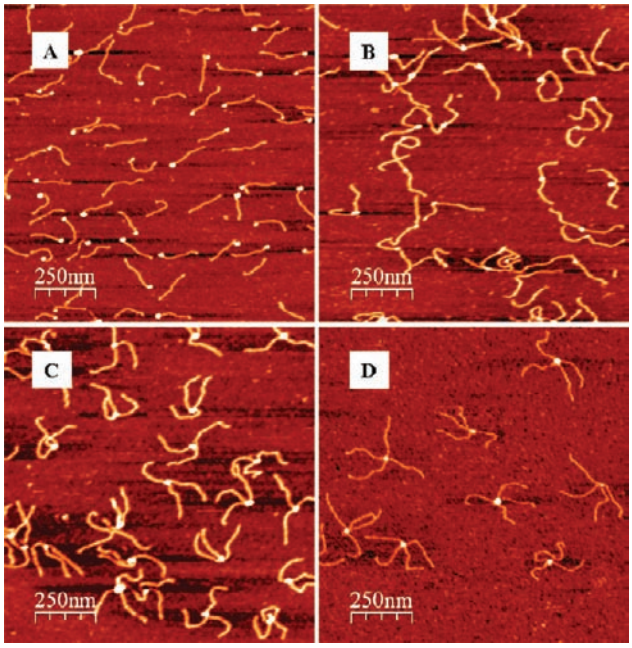

Figure 3. AFM images of Au-NP poly(dG)-poly(dC) conjugates. The conjugates were extracted from the gel (see Figure 1) and purified by size-exclusion HPLC as shown in Figure 2. All conjugates were deposited on a mica surface in 2 mM $NiCl_2$ and scanned in a tapping mode as described in Experimental Procedures. Panels A, B, C, and D present images of conjugates extracted from bands 1, 2, 3, and 4 (see Figure 1) correspondingly.

on the images), respectively. The average estimated contour length of bound DNA molecules is equal to 170 ± 22 nm. This value corresponds well with the contour length of 700 bp poly(dG)-poly(dC) molecules deposited on mica (*23*).

We have investigated the ability of DNA polymerase to extend poly(dG)-poly(dC) molecules attached to a gold nanoparticle. The conjugates comprising two or three poly(dG)-poly(dC) molecules per Au-NP (see Figure 4A,B, respectively) were subjected to the enzymatic reaction with Klenow exo$^-$ DNA polymerase, in the presence of dGTP, dCTP nucleotides, for 20 h at 37 °C. The products of the synthesis were subsequently purified by size-exclusion HPLC and analyzed using AFM. Figure 4 shows that incubation with the enzyme causes considerable increase of the DNA length; the average

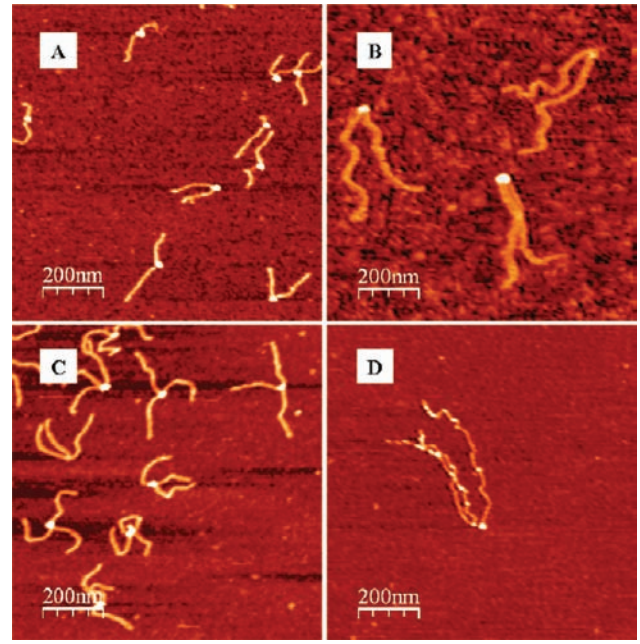

Figure 4. Enzymatic extension of poly(dG)-poly(dC) molecules bound to a Au-NP. The conjugates comprising two (A and B) and three (C and D) poly(dG)-poly(dC) molecules per Au-NP before (A and C) and after (B and D) enzymatic extension. The conjugates were extracted from the gel (Figure 1) and purified by HPLC as shown in Figure 2. The conjugates were incubated in an assay mixture containing 60 mM KPi buffer, pH 7.4, 5 mM $MgCl_2$, 5 mM DTT, 1.5 mM dCTP, 1.5 mM dGTP, and 0.2 μM Klenow exo$^-$, for 20 h at 37 °C, and deposited on a mica surface in 2 mM $NiCl_2$, as described in Experimental Procedures.

contour length of DNA molecules attached to the particle is increased from 170 nm to approximately 450 nm (compare DNA lengths in right and left panels of Figure 4). This clearly demonstrates that Klenow exo$^-$ DNA polymerase is capable of elongating poly(dG)-poly(dC) molecules connected to the Au-NP. The rate of particle-bound poly(dG)-poly(dC) extension is, however, two orders in magnitude lower than that of nonbound DNA (data not shown).

DISCUSSION

The ability to control the number and the length of DNA molecules attached to a single nanoparticle is essential for assembly of DNA-NP conjugates into new functional nanomaterials. Incubation of functionalized oligonucleotides and DNA species with NPs, however, results in a mixture of DNA-NP conjugates bearing different numbers of DNA molecules. Alivisatos and colleagues demonstrated that binding of single-stranded oligonucleotides produces a significant effect on the particle mobility in the electrical field and succeeded to separate conjugates bearing different numbers of oligonucleotides per particle by electrophoresis (*24, 25*). The efficiency of the DNA-NP conjugate separation in gels decreases as the particle size increase and increases as the DNA length increases. Indeed, an excellent separation of the NP conjugates with long random sequence dsDNA was demonstrated by Tsai and co-workers (*15*). In the latter study, random sequence dsDNA molecules were attached to Au-NPs through the SH-group introduced into the DNA, using a ligase-dependent reaction. Here, we employed a polymerase-based method (*17*) to produce the Au-NP conjugates with a homogeneous dsDNA polymer, poly(dG)-poly(dC). This method enables us to synthesize uniform double-stranded poly(dG)-poly(dC) or poly(dA)-poly(dT) wires of desired length (varied from several nanometers to several micrometers), as well as the DNA functionalized with SH groups or/and random oligonucleotide sequences. We have shown that incubation of the

synthesized 700 bp SH-poly(dG)-poly(dC) with Au-NPs yielded a mixture of Au-NP-DNA conjugates bearing different number of DNA molecules per particle that can be easily and completely separated from each other using electrophoresis. The AFM visualization of these products (see Figure 2) confirms that the conjugates extracted from the discrete bands in the gel contain the exact number of poly(dG)-poly(dC) molecules per nanoparticle.

We have demonstrated that Klenow exo$^-$ catalyzes extension of poly(dG)-poly(dC) molecules connected to a Ag-NP, in the presence of dGTP and dCTP. This result corresponds nicely with earlier observations showing that Au-NP-bound DNA molecules can be manipulated with various enzymes, such as ligases (*14, 15, 26*), polymerases (*13*), and restriction enzymes (*10*−*12*).

The formation of conjugates between long (hundreds of base pairs) homogeneous dsDNA polymers and metal NPs has never been shown before. Due to its regular structure, a double-stranded poly(dG)-poly(dC) composed of G- and C-homopolymers provides better conditions for π overlap compared to random sequence DNA. In addition, guanines, which have the lowest ionization potential among DNA bases, promote charge migration through the DNA. This property is especially useful for application of the conjugates in nanoelectronics. Moreover, the polymerase-based method for synthesis used in this work can be effectively employed with the range of functionalities attached to the DNA terminals. In addition to the SH group used for attaching Au-NP, one can functionalize the DNA, for instance, with a random oligonucleotide sequence. The NP-DNA conjugates containing random single-stranded overhang sequences will be recognized by the complementary ones attached to different DNA-NP conjugates, thus connecting DNA wires to one another. These functionalized conjugates may serve a basis for the design and construction of two- and three-dimensional DNA-NP structures. Such NP-DNA structures might possess interesting electrical and plasmonic properties and can be used in the fields of nanoelectronics and nano-optics.

Received December 10, 2009; Revised Manuscript Received February 6, 2010

Integrin $\alpha_v\beta_3$ has been well-documented as one of the key players in the process of tumor angiogenesis. Radiolabeled RGD (Arg-Gly-Asp) peptides that specifically target integrin $\alpha_v\beta_3$ have great potential for tumor early detection and noninvasively monitoring the status of tumor angiogenesis. We developed a cyclic RGD dimeric probe ^{99m}Tc-HYNIC-Gly_3-E[PEG_4-c(RGDfK)]$_2$ (^{99m}Tc-G_3-$2P_4$-RGD2) (using tricine and TPPTS as the coligands, TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate), and investigated whether it could be used to noninvasively visualize and quantify integrin $\alpha_v\beta_3$ expression in vivo. HYNIC-Gly_3-E[PEG_4-c(RGDfK)]$_2$ was synthesized and labeled with ^{99m}Tc. The biodistribution and planar γ-imaging studies of ^{99m}Tc-G_3-$2P_4$-RGD2 were performed in both U87MG (human integrin $\alpha_v\beta_3$ positive/murine integrin $\alpha_v\beta_3$ positive) and HT-29 (human integrin $\alpha_v\beta_3$ negligible /murine integrin $\alpha_v\beta_3$ positive) tumor-bearing nude mouse models. The correlation of ^{99m}Tc-G_3-$2P_4$-RGD2 tumor uptake values (measured by ex vivo biodistribution) with expression levels of human integrin $\alpha_v\beta_3$ or murine integrin $\alpha_v\beta_3$ (measured by Western blot) were determined in U87MG and HT-29 tumor models, respectively. ^{99m}Tc-G_3-$2P_4$-RGD2 exhibited increased receptor binding affinity and in vivo tumor uptake as compared with previously reported RGD dimeric tracer ^{99m}Tc-RGD2 (without Gly_3 and PEG_4 spacers). The tumor uptake of ^{99m}Tc-G_3-$2P_4$-RGD2 was related to the expression levels of both human integrin $\alpha_v\beta_3$ (expressed on tumor cells) and murine integrin $\alpha_v\beta_3$ (expressed on newborn tumor vasculature). Our results demonstrate that ^{99m}Tc-G_3-$2P_4$-RGD2 is a useful agent for integrin $\alpha_v\beta_3$ imaging. The relationship between ^{99m}Tc-G_3-$2P_4$-RGD2 uptake and integrin $\alpha_v\beta_3$ expression level as determined by this study would provide useful information for clinical translation of RGD probes.

INTRODUCTION

Tumor angiogenesis, the formation of new blood vessels from pre-existing vasculature, is one of the key steps for tumor malignancy, invasion, and metastasis (*1*). Angiogenesis depends on specific molecular interactions between vascular cells and components of the extracellular matrix (ECM). Integrins, a family of cell adhesion molecules composed of noncovalently associated α and β subunits, are involved in a wide range of cell−ECM and cell−cell interactions (*2, 3*). Among the integrin family members, integrin $\alpha_v\beta_3$ is highly expressed on activated endothelial cells, but not resting vessels during angiogenesis, and plays an important role in the regulation of tumor growth, local invasiveness, and metastatic potential (*3*). The important role of integrin $\alpha_v\beta_3$ during tumor angiogenesis has stimulated intensive investigation of integrin $\alpha_v\beta_3$-targeted antiangiogenic strategies for cancer treatment and the prevention of cancer recurrence or metastasis (*4, 5*). Noninvasive imaging of integrin $\alpha_v\beta_3$ expression by molecular imaging techniques would also be of great help for early detection of malignancy, evaluation of tumor progress, and monitoring treatment efficacy of anti-angiogenic drugs.

In recent years, a series of Arg-Gly-Asp (RGD) peptide-based multimodality probes were developed for noninvasive imaging of integrin $\alpha_v\beta_3$ expression (*6*−*9*), and several PET (positron emission tomography) probes have been used in clinical investigations (*10*−*14*). To improve the capacity of tumor targeting and in vivo imaging quality, we and others recently designed and synthesized several new RGD dimeric peptides with Gly_3 or PEG_4 (Gly_3 = glycine−glycine−glycine; PEG_4 = 15-amino-4,7,10,13-tetraoxapentadecanoic acid) spacers between the two RGD motifs in homodimeric peptides. The insertion of the spacers significantly increased the tumor uptake and improved the in vivo pharmacokinetics in mouse models (*15*−*18*).

Besides specific expression on the activated tumor vasculature, integrin $\alpha_v\beta_3$ also highly expressed on some tumor cells, such as late-stage glioblastoma, breast and prostate cancers, malignant melanoma, and ovarian carcinoma (*19, 20*). Therefore, in the mouse models bearing human integrin $\alpha_v\beta_3$-positive tumors, RGD peptides would bind to both the murine integrin $\alpha_v\beta_3$ expressed on the activated endothelial cells and the human integrin $\alpha_v\beta_3$ expressed on tumor cells (*21*). However, the relationship between the tumor uptake values of RGD probes and the expression levels of human integrin $\alpha_v\beta_3$ as well as murine integrin $\alpha_v\beta_3$ has not yet been sufficiently illuminated by the literature.

In this study, a new RGD dimeric peptide with two PEG_4 spacers between the two RGD motifs and one Gly_3 spacer on the glutamate α-amino group of the RGD dimer, Gly_3-E[PEG_4-c(RGDfK)]$_2$, was prepared and labeled with ^{99m}Tc by using HYNIC (6-hydrazinonicotinyl) as a chelator (Figure 1). The in vitro and in vivo characteristics of ^{99m}Tc-HYNIC-Gly_3-E[PEG_4-c(RGDfK)]$_2$ (^{99m}Tc-G_3-$2P_4$-RGD2) was compared with the ^{99m}Tc-labeled RGD dimer without Gly_3 and PEG_4 spacers ^{99m}Tc-

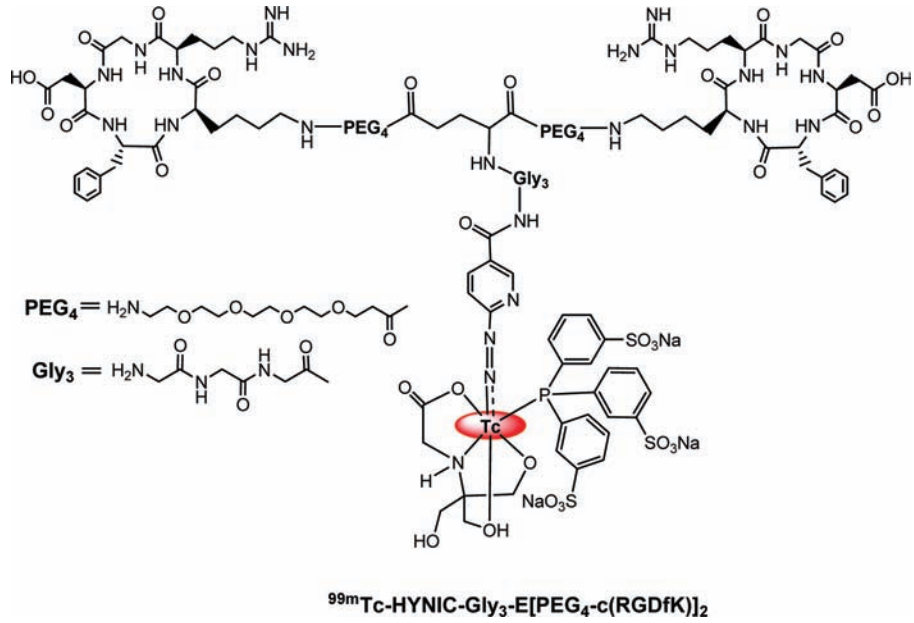

Figure 1. Chemical structure of ^{99m}Tc-HYNIC-Gly$_3$-E[PEG$_4$-c(RGDfK)]$_2$ (^{99m}Tc-G$_3$-2P$_4$-RGD2).

HYNIC-E[-c(RGDfK)]$_2$ (^{99m}Tc-RGD2). The biodistribution properties of ^{99m}Tc-G$_3$-2P$_4$-RGD2 were tested in both human integrin $\alpha_v\beta_3$-positive U87MG human glioma mouse model and human integrin $\alpha_v\beta_3$-negative HT-29 human colon cancer mouse model. The correlation of ^{99m}Tc-G$_3$-2P$_4$-RGD2 tumor uptake values vs the human integrin $\alpha_v\beta_3$ and murine integrin $\alpha_v\beta_3$ expression levels was also investigated.

EXPERIMENTAL PROCEDURES

All chemicals obtained commercially were of analytical grade and used without further purification. Cyclic RGD peptides, c(RGDyK), E[c(RGDfK)]$_2$ (RGD2), and Gly$_3$-E[PEG$_4$-c(RGDfK)]$_2$ (G$_3$-2P$_4$-RGD2) were custom-made by Peptides International (Louisville, KY). Sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinate (HYNIC-NHS) was prepared according to the literature method (*22*). Synthesis of HYNIC-E[c(RGDfK)]$_2$ (HYNIC-RGD2) was described in our previous communication (*23*). Na^{99m}TcO$_4$ was obtained from a commercial ^{99}Mo/^{99m}Tc generator (Beijing Atom High Tech Co., Ltd.). Reversed-phase extraction Sep-Pak C$_{18}$ cartridges were obtained from Waters and were pretreated with ethanol and water immediately prior to use. The syringe filter and poly(ether sulfone) membranes (pore size 0.22 μm; diameter 13 mm) were obtained from Nalge Nuc International. The reversed-phase high-performance liquid chromatography (HPLC) system was the same as that previously reported (*17, 18*). For HYNIC-peptide purification, a Zorbax C$_{18}$ semiprep column (9.4 mm $\times$ 250 mm, 100 Å pore size) was used with a flow rate of 3 mL/min. The gradient mobile phase started with 95% solvent A (0.1% TFA in H$_2$O) and 5% solvent B (0.1% TFA in CH$_3$CN) to 60% solvent A and 40% solvent B at 25 min to 40% solvent A and 60% solvent B at 30 min. The radio-HPLC method used a HP Hewlett-Packard Series 1100 HPLC system equipped with Radioflow Detector LB509 and Agilent Zorbax SB-C$_{18}$ column (4.6 mm $\times$ 250 mm, 5 μm). The flow rate was 1.0 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM NaOAc buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min, then to 10% solvent B at 25 min.

Synthesis of HYNIC-Conjugated G$_3$-2P$_4$-RGD2. HYNIC-G$_3$-2P$_4$-RGD2 conjugate was prepared as previously described (*17, 18*). In brief, a solution of 2 μmol of G$_3$-2P$_4$-RGD2 was mixed with 6 μmol of HYNIC-NHS in 1 mL of a mixture containing DMF and water (1:1 = v:v). The pH was adjusted to 8.5−9.0 using 0.1 N NaOH. After stirring overnight at room temperature, HYNIC-G$_3$-2P$_4$-RGD2 was isolated by semi-preparative HPLC. The collected fractions (Rt = 19.3 min) were combined and lyophilized to yield the final product as a white powder. HYNIC-G$_3$-2P$_4$-RGD2 was obtained in 56% yield with >95% HPLC purity. Matrix-assisted laser desorption/ionization (MALDI) time-of-light (TOF) mass spectrometry (MS): *m*/*z* 2305.92 for [M+NH$_4$]$^+$ (C$_{100}$H$_{147}$N$_{27}$O$_{33}$S, calculated molecular weight 2287.46). HYNIC-RGD2 was prepared as we previously described (*23*).

^{99m}Tc Radiolabeleing. HYNIC-G$_3$-2P$_4$-RGD2 and HYNIC-RGD2 were labeled with ^{99m}Tc using tricine and TPPTS (trisodium triphenylphosphine-3,3′,3″-trisulfonate) as the coligands, and then purified with Sep-Pak C$_{18}$ cartridges as previously described (*23*). After purification, the radiochemical purity of the products ^{99m}Tc-G$_3$-2P$_4$-RGD2 and ^{99m}Tc-RGD2 was both higher than 98% as analyzed by radio-HPLC.

Cell Culture and Animal Models. The U87MG human glioma cell line and HT-29 human colon cancer cell line were purchased from American Type Culture Collection (Manassas, VA). U87MG cells were cultured in low glucose Dulbecco's Modified Eagle's Medium (DMEM) culture medium and HT-29 cells were cultured in high glucose DMEM culture medium. Both cell lines were cultured in medium supplemented with 10% (v/v) fetal bovine serum (FBS) at 37 °C in a humidified atmosphere with 5% CO$_2$. Female BALB/c nude mice (4−5 weeks of age) were purchased from Department of Experimental Animal, Peking University Health Science Center. All animal experiments were performed in accordance with guidelines of Institutional Animal Care and Use Committee (IACUC) at Peking University. U87MG tumor model and HT-29 tumor model were established by subcutaneous injection of 2 $\times$ 10^6 U87MG tumor cells and 2 $\times$ 10^6 HT-29 tumor cells into the right upper flanks of nude mice, respectively. The mice were subjected to γ-imaging and biodistribution studies when the tumor volume reached 200−300 mm^3 (3−4 weeks after inoculation for U87MG tumors, and 2−3 weeks for HT-29 tumors).

Cell Binding Assay. In vitro integrin $\alpha_v\beta_3$-binding affinities and specificities of c(RGDyK), HYNIC-RGD2, and HYNIC-

G_3-$2P_4$-RGD2 were compared via displacement cell-binding assays using ^{125}I-c[RGDyK] as the radioligand. ^{125}I-c(RGDyK) was prepared by labeling c(RGDyK) with Na^{125}I at a high specific activity (~44.4 TBq/mmol) according to the method described in the literature (*24*). Experiments were performed on U87MG cells (human integrin $\alpha_v\beta_3$-positive) as we have previously described (*15, 16, 25*). The best-fit 50% inhibitory concentration (IC_{50}) values were calculated by fitting the data with nonlinear regression using *GraphPad Prism 4.0* (GraphPad Software). Experiments were performed twice with triplicate samples.

Integrin $\alpha_v\beta_3$ Expression on Tumor Cells. The integrin $\alpha_v\beta_3$ expression levels of U87MG and HT-29 cells were determined by saturation binding assay (*26, 27*). Briefly, the antihuman integrin $\alpha_v\beta_3$ antibody Abegrin (*27*−*29*) was labeled with ^{125}I, and then, ^{125}I-Abegrin was used as the integrin $\alpha_v\beta_3$-specific radioligand. U87MG or HT-29 tumor cells were incubated with increasing concentrations of ^{125}I-Abegrin. Nonspecific binding was determined with a 100-fold excess dose of Abegrin. Scatchard plots were derived by plotting bound/free ligand versus bound ligand, and the maximum numbers of binding sites (B_{max}) were calculated by GraphPad Prism software.

Immunofluorescence Staining. The integrin $\alpha_v\beta_3$ expression patterns of U87MG and HT-29 tumor tissues were analyzed by fluorescence staining as previously described (*27, 30*). Frozen tumor tissue sections were incubated with hamster antimouse integrin β_3 antibody (1:100; BD Biosciences, San Jose, CA) and Abegrin (10 μg/mL), and then visualized by Cy3-conjugated donkey antihamster secondary antibody (1:200; Jackson ImmunoResearch Laboratories) and FITC-conjugated donkey antihuman secondary antibody (1:200) under the microscope (Carl Zeiss Axiovert 200M, Carl Zeiss, Thornwood, NY).

Western Blot. The frozen U87MG or HT-29 tumor tissues were homogenized and extracted using T-PER tissue protein extraction buffer. Protein concentration was determined using a microBCA protein assay kit (Pierce Biotechnology, Inc., Rockford, IL, USA) and adjusted to equivalent values using lysis buffer. After SDS-PAGE and transfer, the polyvinylidene fluoride (PVDF) membrane (Invitrogen Corp.; Carlsbad, CA, USA) was blocked with 5% nonfat milk blocking buffer, and then incubated overnight at 4 °C with hamster antimouse CD61 (integrin β_3) primary antibody (BD Biosciences, San Jose, CA) or mouse antihuman CD61 (BD Biosciences, San Jose, CA) primary antibody followed by incubation at room temperature for 1 h with horseradish peroxidase-conjugated secondary antibodies (GE Healthcare). β-actin was used as the loading control, and the bands were detected using enhanced chemiluminescent Western blotting detection system (GE Healthcare). After development, the films were scanned using grayscale mode, and the images were opened in *ImageJ* (http://rsb.info.nih.gov/ij/). A ROI was drawn on the first lane, and the same size/shape ROI was applied to the other lanes and the background to obtain quantitative data of each band intensity. The background signal was subtracted before correlating with the biodistribution data.

Biodistribution and Blocking Studies. Female nude mice bearing U87MG xenografts were injected with 0.37 MBq (10 μCi) of ^{99m}Tc-G_3-$2P_4$-RGD2 or ^{99m}Tc-RGD2 via tail vein to evaluate the biodistribution of the probes in the major organs of mice. At 0.5 and 2 h postinjection (p.i), mice were sacrificed. Blood, tumor, major organs, and tissues were collected, wet-weighed, and measured using a γ counter. The results were presented as percentage of injected dose per gram of tissue (%ID/g). Values are expressed as means ± SD for a group of four animals (n = 4 per group). A blocking study was also performed in a group of four mice bearing U87MG tumors by coinjecting ^{99m}Tc-G_3-$2P_4$-RGD2 with 300 μg unlabeled E[c(RGDfK)]$_2$. At 0.5 h p.i., all four animals were sacrificed for determination of organ biodistribution as described above. As a control study, two groups of HT-29 tumor-bearing nude mice (4 animals per group) were coinjected 0.37 MBq (10 μCi) of ^{99m}Tc-G_3-$2P_4$-RGD2 via tail vein with or without a blocking dose of 300 μg unlabeled E[c(RGDfK)]$_2$. At 0.5 h p.i., all animals were sacrificed for determination of organ biodistribution as described above.

Planar γ Imaging. Each nude mouse bearing U87MG or HT-29 tumor xenografts was injected with ~18.5 MBq (500 μCi) of ^{99m}Tc-G_3-$2P_4$-RGD2 via tail vein (n = 3 per group). Animals were anesthetized with intraperitoneal injection of sodium pentobarbital at a dose of 45.0 mg/kg, then were placed supine on a two-head-camera (GE Infinia Hawkeye) equipped with a parallel-hole, low-energy, and high-resolution collimator. Anterior images were acquired at 0.5 and 2 h p.i. and stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 200 K.

Correlation of ^{99m}Tc-G_3-$2P_4$-RGD2 Tumor Uptake with Integrin $\alpha_v\beta_3$ Expression. To establish tumor models with different integrin $\alpha_v\beta_3$ expression levels, 36 nude mice were randomly divided into 12 groups (3 mice per group), 7 groups of which were used for U87MG (2×10^6 cells/mouse) tumor inoculation and 5 groups of which were used for HT-29 (2×10^6 cells/mouse) tumor inoculation. Groups of nude mice were subcutaneously inoculated with U87MG or HT-29 tumor cells every 3 days to obtain tumors with different sizes. At 5 weeks after initial inoculation of tumor cells, each tumor-bearing nude mouse was injected with 0.37 MBq (10 μCi) of ^{99m}Tc-G_3-$2P_4$-RGD2 via tail vein. At 1 h p.i., all mice were sacrificed, and the tumors were harvested. Half of each tumor tissue was wet-weighed and measured using a γ counter to calculate the tumor uptake (%ID/g), while the other half was used for Western blotting to determine the integrin β_3 level. The relative integrin β_3 expression levels of tumor tissue lysates was correlated with ^{99m}Tc-G_3-$2P_4$-RGD2 tumor uptake using GraphPad software. The %ID/tumor organ value of each tumor (the tumor tissues with obvious necrosis were discarded) was plotted against the quantitative Western blot data. Applying a linear fit, the correlation coefficient (r^2) was calculated to measure the strength of association between the tumor uptake (measured by ex vivo biodistribution) and the integrin β_3 expression level (measured by Western blot). P values less than 0.05 were considered to indicate a statistically significant linear correlation between the two results.

RESULTS

Chemistry and Radiochemistry. HYNIC-G_3-$2P_4$-RGD2 was prepared by direct conjugation of G_3-$2P_4$-RGD2 with HYNIC-NHS in the yield of 56%. The products were purified by HPLC and characterized by MALDI-TOF MS. The HPLC purity of HYNIC-G_3-$2P_4$-RGD2 was >95% before being used for the receptor binding assay and ^{99m}Tc radiolabeling. The labeling procedure was done within 30 min with a yield ranging from 93% to 96%. The radiochemical purity was >98%, and the specific activity of ^{99m}Tc-G_3-$2P_4$-RGD2 was >296 GBq/μmol.

Cell Binding Assay. The receptor-binding affinity of HYNIC-G_3-$2P_4$-RGD2 was determined by performing competitive displacement studies using ^{125}I-c(RGDyK) (integrin $\alpha_v\beta_3$-specific) as the radioligand. For comparison purpose, we also evaluated c(RGDyK) and HYNIC-RGD2 using the same in vitro assay. As shown in Figure 2, all the peptides inhibited the binding of ^{125}I-c(RGDyK) to U87MG cells in a concentration-dependent manner. The IC_{50} values for c(RGDyK), HYNIC-RGD2, and HYNIC-G_3-$2P_4$-RGD2 were 39.41 ± 0.87, 8.13 ± 0.61, and 3.37 ± 0.84 nM, respectively (n = 3, repeated twice). The comparable IC_{50} values of compounds suggest that the

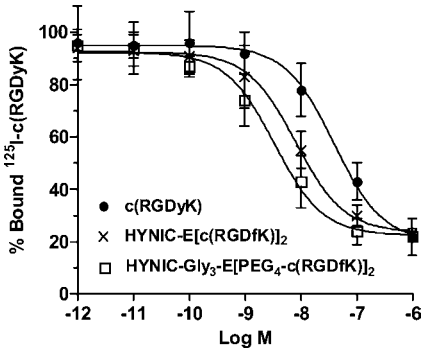

Figure 2. Inhibition of ^{125}I-c(RGDyK) binding to integrin $\alpha_v\beta_3$ on U87MG cells by c(RGDyK) (•, $IC_{50} = 39.41 \pm 0.87$ nM), HYNIC-E[c(RGDfK)]$_2$ (×, $IC_{50} = 8.13 \pm 0.61$ nM), and HYNIC-Gly$_3$-E[PEG$_4$-c(RGDfK)]$_2$ (□, $IC_{50} = 3.37 \pm 0.84$ nM) ($n = 3$, mean ± SD).

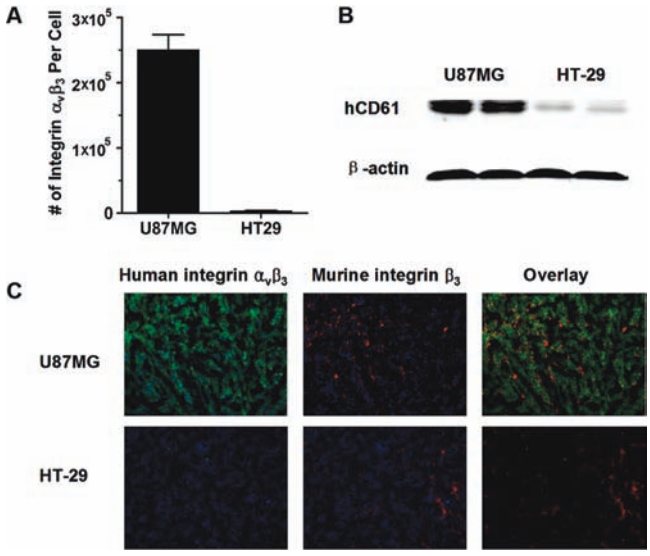

Figure 3. (A) Number of integrin $\alpha_v\beta_3$ per cell for U87MG and HT-29 cells ($n = 3$, mean ± SD). (B) Western blot of human integrin β_3 (hCD61) expression on U87MG and HT-29 cells ($n = 2$). (C) Human integrin $\alpha_v\beta_3$ and mouse integrin β_3 staining of U87MG and HT-29 tumor sections. The antihuman integrin $\alpha_v\beta_3$ and antimurine β_3 antibodies were used as the primary antibodies, respectively.

insertion of the Gly$_3$ and PEG$_4$ linkers increased the receptor-binding affinity of the RGD dimer peptide.

Integrin $\alpha_v\beta_3$ Expression Patterns of U87MG and HT-29 Tumors. We quantified the $\alpha_v\beta_3$ integrin expression levels of U87MG and HT-29 cells through saturation binding assay using ^{125}I-Abegrin as a radioligand. As shown in Figure 3A, U87MG cells expressed a high level of integrin $\alpha_v\beta_3$ ($(2.5 \pm 0.2) \times 10^5$ receptors/cell), while there was a very low integrin $\alpha_v\beta_3$ density on HT-29 cell surface ($<3 \times 10^3$ receptors/cell). After inoculating tumor cells into the nude mice, the human integrin β_3 expression level on U87MG tumor tissues was also significantly higher than that on HT-29 tumor tissues as determined by Western blot (Figure 3B). From fluorescence staining of tumor tissues (Figure 3C), we can clearly see that U87MG tumor expressed a high level of human integrin $\alpha_v\beta_3$, whereas HT-29 tumor did not express human integrin $\alpha_v\beta_3$. Both tumor tissues expressed a moderate level of murine integrin $\alpha_v\beta_3$, which is supposed to be derived from the newly formed tumor vasculature.

Biodistribution. The biodistribution of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was determined in nude mice bearing U87MG tumors. The results are depicted in Figure 4A. The uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG tumors was 7.94 ± 1.74%ID/g at 0.5 h p.i., which was slightly decreased to 6.01 ± 1.30%ID/g at 2 h p.i. (n = 4/group). ^{99m}Tc-G$_3$-2P$_4$-RGD2 cleared predominantly through the renal pathway as evidenced by higher kidney uptake (15.04 ± 0.72%ID/g and 10.55 ± 1.44%ID/g at 0.5 and 2 h p.i., respectively). The other organs such as heart, liver, spleen, lung, muscle, and brain showed very low uptake. The high intestine uptake of the radioprobe was observed, with 18.37 ± 1.54%ID/g and 11.64 ± 1.91%ID/g at 0.5 and 2 h p.i., respectively.

Integrin $\alpha_v\beta_3$ receptor specificity of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was demonstrated by a blocking experiment with coinjection of E[c(RGDfK)]$_2$. The tumor uptake at 0.5 h p.i. was reduced from 7.94 ± 1.74%ID/g to 2.01 ± 1.30%ID/g (Figure 4B), indicating the receptor-mediated targeting of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG tumors. At 0.5 h p.i., the uptake values of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG and HT-29 tumors were compared (Figure 4B). The U87MG (high human integrin $\alpha_v\beta_3$ expression, Figure 3) tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was also significantly higher than the HT-29 (none or low human integrin $\alpha_v\beta_3$ expression, Figure 3) tumor uptake ($n = 4$, $P < 0.01$), which also confirmed the integrin $\alpha_v\beta_3$-specific tumor accumulation of ^{99m}Tc-G$_3$-2P$_4$-RGD2. The HT-29 tumor uptake was also reduced after blocking with an excess dose of unlabeled E[c(RGDfK)]$_2$ (Figure 4B), revealing the specific binding of ^{99m}Tc-G$_3$-2P$_4$-RGD2 to the murine integrin $\alpha_v\beta_3$ receptors that expressed on the tumor vasculature.

The U87MG tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was compared with that of ^{99m}Tc-RGD2. As shown in Figure 4C, the uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG tumors was more than twice that of ^{99m}Tc-RGD2 at any time tested (7.94 ± 1.74 vs 2.50 ± 1.20%ID/g and 6.01 ± 1.30 vs 1.70 ± 0.80%ID/g at 0.5 and 2 h p.i., respectively).

Planar γ Imaging. Representative planar γ-images of U87MG or HT-29 tumor-bearing mice at 0.5 and 2 h p.i. after intravenous injection of ~18.5 MBq (500 μCi) of ^{99m}Tc-G$_3$-2P$_4$-RGD2 are shown in Figure 5. In the U87MG tumor model, the tumors were clearly visible with high contrast to the contralateral background at 0.5 h p.i. With the clearance of the probe, the tumor radioactivity decreased from 0.5 to 2 h. Prominent renal uptake and bladder accumulation of the probe was also observed. The uptake of the probe in other organs such as liver was very low. In the HT-29 tumor model (human integrin $\alpha_v\beta_3$-negligible/murine $\alpha_v\beta_3$-positive), the tumors could also be visualized with moderate tumor-to-background contrast at 0.5 h p.i., which was most likely due to the recognition of the probe to murine $\alpha_v\beta_3$ expressed on the newly formed tumor vasculature; the tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2, however, was significantly lower than that in the U87MG tumors. ^{99m}Tc-G$_3$-2P$_4$-RGD2 also showed high renal uptake and bladder accumulation in the HT-29 tumor-bearing mice, suggesting the renal clearance of the probe. In both tumor models, high activity accumulation in the abdomen, resulting from high kidney and intestine uptake of the probe (Figure 4A), was observed, which may limit the application of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in the detection of abdominal metastases of integrin $\alpha_v\beta_3$-positive tumors.

Correlation of ^{99m}Tc-G$_3$-2P$_4$-RGD2 Tumor Uptake with Integrin $\alpha_v\beta_3$ Expression. Because integrin α_v and β_3 subunites cannot be kept as one entity after protein extraction, we assessed both human and murine integrin β_3 expression in the U87MG and HT-29 tumor tissues using Western blotting. Figure 6A depicts representative Western blots of the murine integrin β_3 in different sizes of HT-29 tumors. Due to the limited expression of human integrin $\alpha_v\beta_3$ on the HT-29 tumor cells, the Western blot of human integrin β_3 was not obtained. U87MG tumors expressed a detectable level of both human and murine integrin β_3. There was a certain variation in the β-actin band intensity

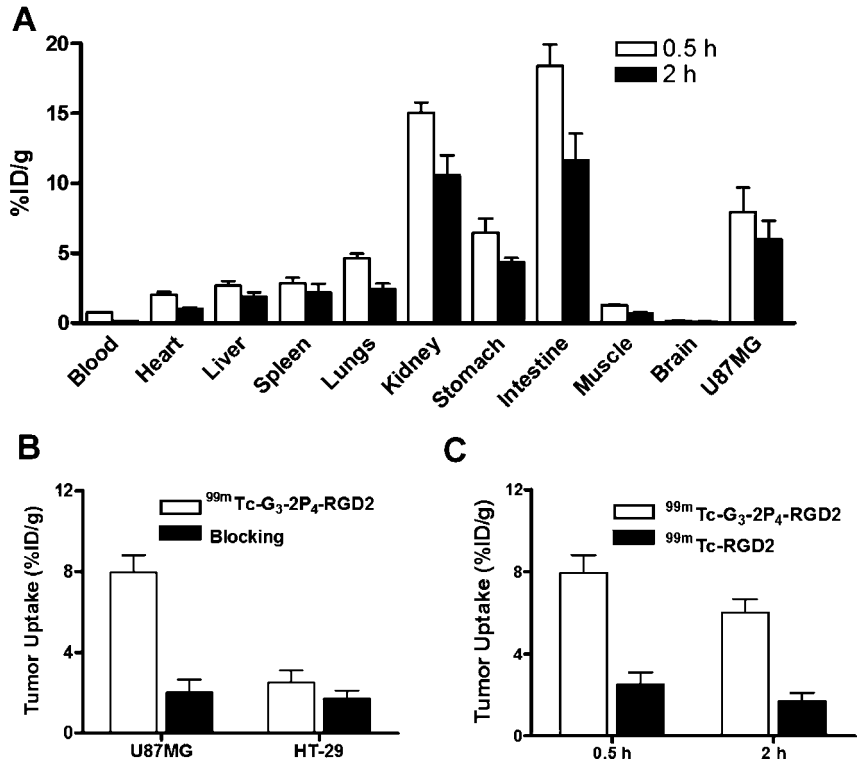

Figure 4. (A) Biodistribution of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG tumor-bearing nude mice at 0.5 and 2 h postinjection. (B) Tumor uptake values of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG and HT-29 tumor-bearing nude mice with and without coinjection of 300 μg unlabeled E[c(RGDfK)]$_2$ as the blocking agent at 0.5 h postinjection. (C) Comparison of tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 and ^{99m}Tc-RGD2 in U87MG tumor-bearing nude mice at 0.5 and 2 h postinjection. Data are expressed as %ID/g ± SD (n = 4 per group).

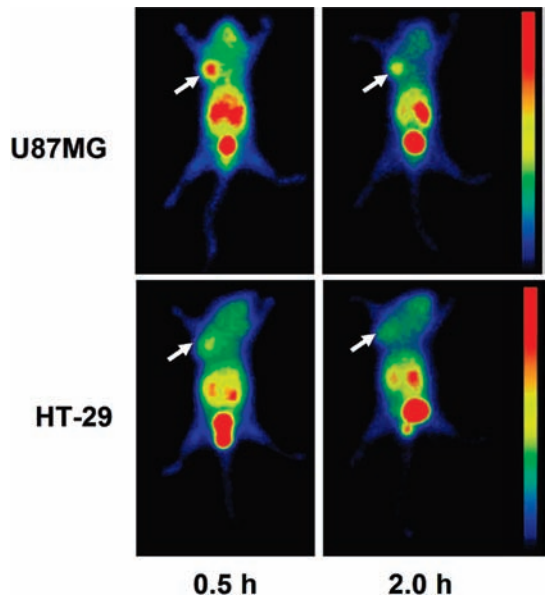

Figure 5. Representative planar γ images of U87MG or HT-29 nude mouse models at 0.5 and 2 h after intravenous injection of ~18.5 MBq (500 μCi) of ^{99m}Tc-G$_3$-2P$_4$-RGD2 (n = 3 per tumor group). Tumors are indicated by white arrows.

among the tumors with different sizes. The Western blot of tumor tissue lysates was analyzed using *ImageJ* to obtain the quantitative data. Relative integrin β_3 expression was calculated for each tumor to correlate with the ^{99m}Tc-G$_3$-2P$_4$-RGD2 tumor uptake measured by the ex vivo biodistribution study. RGD peptide can recognize integrin $\alpha_v\beta_3$ of different origins, therefore, ^{99m}Tc-G$_3$-2P$_4$-RGD2 can bind to both human and murine integrin $\alpha_v\beta_3$ in vivo. In the U87MG tumors, the human integrin $\alpha_v\beta_3$ was expressed in a much higher level than murine integrin $\alpha_v\beta_3$, so it is supposed that most of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was accumulated to the human integrin $\alpha_v\beta_3$ on the U87MG tumor cell surface, leading to a linear correlation between the ^{99m}Tc-G$_3$-2P$_4$-RGD2 tumor uptake and the human integrin β_3 expression (r^2 = 0.51, P = 0.0004, Figure 6B). There is no linear correlation between the ^{99m}Tc-G$_3$-2P$_4$-RGD2 tumor uptake (1 h p.i.) and the relative murine integrin β_3 expression, probably due to the much lower expression of the murine integrin $\alpha_v\beta_3$ compared with human integrin $\alpha_v\beta_3$ in U87MG tumor tissues (Figure 6B). In the HT-29 tumors, the human integin $\alpha_v\beta_3$ was not detectable (Figure 3), so most of ^{99m}Tc-G$_3$-2P$_4$-RGD2 recognized the murine integrin $\alpha_v\beta_3$ that expressed on the tumor newborn vasculature, which resulted in a better linear correlation of the tumor uptake values vs the murine integrin $\alpha_v\beta_3$ expression levels (r^2 = 0.84, P < 0.0001, Figure 6C) in HT-29 tumors.

DISCUSSION

In this study, we have prepared a new RGD dimeric probe ^{99m}Tc-G$_3$-2P$_4$-RGD2 for integin $\alpha_v\beta_3$ targeting. The insertion of two PEG$_4$ spacers between the two RGD motifs and one Gly$_3$ on the glutamate α-amino group of E[c(RGDfK)]$_2$ increased the in vitro integrin $\alpha_v\beta_3$ binding affinity, and the tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 was also significantly higher than that of ^{99m}Tc-RGD2 in integrin $\alpha_v\beta_3$-positive U87MG tumor model. The feasibility of ^{99m}Tc-G$_3$-2P$_4$-RGD2 for the noninvasive detection of integrin $\alpha_v\beta_3$ expression was evaluated in both U87MG and HT-29 tumor models.

We and others recently demonstrated that the insertion of spacers (e.g., Gly$_3$, PEG$_4$) between the two RGD motifs in the RGD dimeric molecule will significantly increase the integrin $\alpha_v\beta_3$ binding affinity, enhance the tumor uptake, and improve the in vivo pharmacokinetics of the new RGD dimeric probes (*31*). In this study, besides the insertion of two PEG$_4$ spacers between the two monomeric RGD motifs, we also inserted a

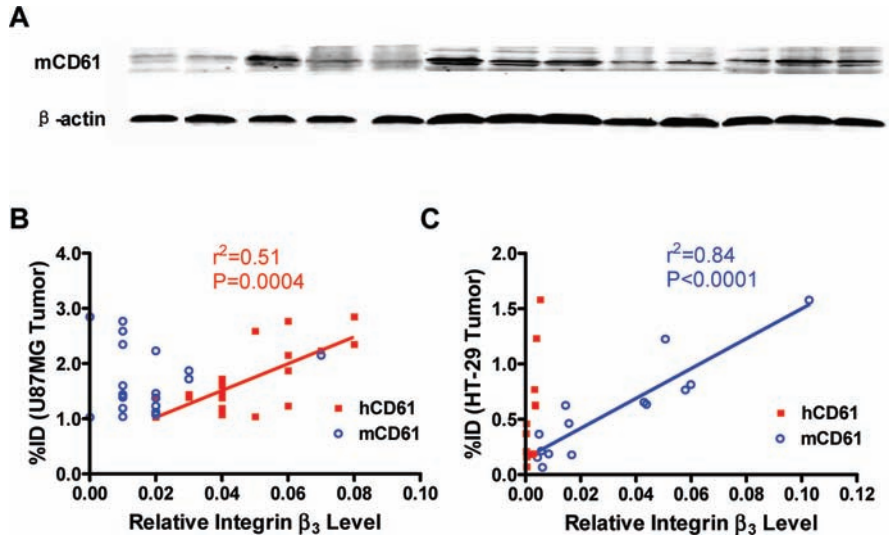

Figure 6. (A) Western blot of murine integrin β_3 (mCD61) expression in HT-29 tumor tissues with different tumor sizes. (B) Correlation of human or murine integrin β_3 (hCD61 and mCD61) expression levels (measured by Western blot) and U87MG tumor uptake values (%ID) at 1 h after intravenous injection of 0.37 MBq (10 μCi) of ^{99m}Tc-G$_3$-2P$_4$-RGD2. (C) Correlation of human or murine integrin β_3 (hCD61 and mCD61) expression levels (measured by Western blot) and HT-29 tumor uptake values (%ID) at 1 h after intravenous injection of 0.37 MBq (10 μCi) of ^{99m}Tc-G$_3$-2P$_4$-RGD2.

Gly$_3$ linker onto the glutamate α-amino group of the RGD dimer, which was suggested to increase the overall hydrophilicity and to alleviate the steric hindrance, thereby increasing the HYNIC conjugation efficiency and ^{99m}Tc labeling yield (*15*). The HYNIC-G$_3$-2P$_4$-RGD2 conjugate showed increased integrin $\alpha_v\beta_3$ binding affinity compared with HYNIC-RGD2 as determined by cell binding assay (Figure 2). Because the Gly$_3$ linker on the glutamate α-amino group of the RGD dimer would not contribute to the enhancement of the receptor-binding affinity, the increased affinity of HYNIC-G$_3$-2P$_4$-RGD2 was therefore most likely due to the insertion of two PEG$_4$ linkers between two RGD motifs. The affinity of HYNIC-G$_3$-2P$_4$-RGD2 was about 2-fold higher than that of the HYNIC-RGD2 (3.37 ± 0.84 nM vs 8.13 ± 0.61 nM) (Figure 2), which is similar to the results of other RGD dimers with Gly$_3$ and PEG$_4$ linkers as we previously reported (*31*). Therefore, although without direct comparison, we can speculate that HYNIC-G$_3$-2P$_4$-RGD2 possesses comparable integrin $\alpha_v\beta_3$ binding affinity with the previously reported new types of RGD dimers. Note that caution should be taken when directly comparing the IC$_{50}$ values of RGD peptides with those reported in the literatures due to the different radioligands (^{125}I-c(RGDyK) or ^{125}I-echistatin) and tumor cells (U87MG or MDA-MB-435) used in different laboratories. The enhanced integrin $\alpha_v\beta_3$ binding affinity of HYNIC-G$_3$-2P$_4$-RGD2 over HYNIC-RGD2 was well evidenced by the significantly increased U87MG tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 compared to that of ^{99m}Tc-RGD2 at any time points examined in the nude mouse model (Figure 4C).

U87MG tumor cells express a very high level of human integrin $\alpha_v\beta_3$, while HT-29 tumor cells express negligible human integrin $\alpha_v\beta_3$ (Figure 3A,B). After inoculating tumor cells into the nude mice, in addition to expressing human integrin $\alpha_v\beta_3$, U87MG tumor tissues also expressed murine integrin $\alpha_v\beta_3$ due to the incorporation of murine endothelial cells during tumor angiogenesis. On the other hand, HT-29 tumor tissues expressed only murine integrin $\alpha_v\beta_3$ due to the negligible expression of human integrin $\alpha_v\beta_3$ on the tumor cells. We tested the in vivo behaviors of the new RGD dimeric probe ^{99m}Tc-G$_3$-2P$_4$-RGD2 in both U87MG and HT-29 tumor models. The tumor uptake of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in U87MG tumors was significantly higher than that in HT-29 tumors, most likely due to the fact that the total integrin $\alpha_v\beta_3$ (both human and murine origins) in U87MG tumors was much higher than that in HT-29 tumors. It should be noted that we have not considered the difference of nonspecific uptake values of ^{99m}Tc-G$_3$-2P$_4$-RGD2 in the two different tumor models here, because the relatively low molecular weight of ^{99m}Tc-G$_3$-2P$_4$-RGD2 would not lead to a high nonspecific tumor accumulation, as evidenced by effective inhibition of tumor uptake in the presence of excess amounts of cold RGD peptide (Figure 4B).

There has been growing interest in the use of noninvasive imaging technology to the drug discovery process and cancer patient management over the past decade (*32, 33*). The ability to noninvasively visualize and quantify integrin $\alpha_v\beta_3$ expression in vivo will certainly provide new opportunities to document tumor angiogenesis, to select patients for antiangiogenic treatment, and to monitor the therapeutic efficacy of antiangiogenic drugs in cancer patients. Although numerous RGD probes have been developed for integrin $\alpha_v\beta_3$ imaging in the past decade, the reports about quantitative correlation between the integrin $\alpha_v\beta_3$ expression levels in vivo and the noninvasive imaging data is rare (*34*−*37*). Haubner et al. (*35*) investigated the relationship between the tumor uptake of RGD probe and the integrin $\alpha_v\beta_3$ expression level for the first time. Several subcutaneous tumor models were produced by inoculating different mixtures of M21 (integrin $\alpha_v\beta_3$ positive) and M21-L (integrin $\alpha_v\beta_3$ negative) cells. The tumor-to-background ratios and the tumor-to-muscle ratios of [^{18}F]Galacto-RGD obtained from PET imaging and direct tissue sampling were compared with relative integrin α_v expression measured by Western blot analysis, and a good correlation was found. In a following clinical study (*36*), a significant correlation of the SUVs of [^{18}F]Galacto-RGD with the integrin $\alpha_v\beta_3$ intensity of immunohisochemical staining as well as with the microvessel density were confirmed. To increase the tumor uptake, Zhang X et al. (*34*) developed a ^{18}F-labeled dimeric RGD probe with enhanced receptor binding affinity and increased tumor uptake compared with monomeric RGD probes, and investigated the relationship of tumor uptake vs the integrin expression level in multiple tumor models. A good correlation was found between the tumor tissue receptor density (number of receptors/milligrams protein measured from SDS-PAGE/autoradiography using ^{125}I-echistatin as radioligand) and the binding potential (BP, calculated from Logan plot transformation of dynamic microPET data). Although the good correlations between the tumor uptake of RGD probes and the integrin $\alpha_v\beta_3$ expression levels were determined in previous reports, the

integrin $\alpha_v\beta_3$ expressed on tumor cells or tumor newborn vasculature has not been well distinguished. In addition, the sensitivity using previously reported RGD probes may be limited due to their relative low tumor uptake and tumor-to-nontumor ratios. For our interests in developing a more sensitive RGD probe that can be used for noninvasively determining the in vivo integrin $\alpha_v\beta_3$ expression, we investigated the integrin $\alpha_v\beta_3$ correlation properties of ^{99m}Tc-G_3-$2P_4$-RGD, which had much higher binding affinity and tumor uptake values compared with ^{99m}Tc-labeled RGD dimer. We determined the correlation between the ^{99m}Tc-G_3-$2P_4$-RGD2 tumor uptake and either murine integrin $\alpha_v\beta_3$ or human integrin $\alpha_v\beta_3$ in both high integrin $\alpha_v\beta_3$ expressing U87MG and low integrin $\alpha_v\beta_3$ expressing HT-29 tumor xenografts.

The significant correlation between the tumor uptake of ^{99m}Tc-labeled RGD probe and integrin $\alpha_v\beta_3$ expression at a fixed time point postinjection is very important for clinical applications, since it would determine the integrin $\alpha_v\beta_3$ expression level by a simple, noninvasive, whole-body SPECT scaning. The U87MG tumor uptake of ^{99m}Tc-G_3-$2P_4$-RGD2 showed linear correlation with human integrin $\alpha_v\beta_3$, yet the r^2 value was relatively low ($r^2 = 0.51$, Figure 6B) because the RGD probe also bound to the murine integrin $\alpha_v\beta_3$ in the U87MG tumors. Note that the total integrin $\alpha_v\beta_3$ expression level (both human and murine origins) cannot be simply obtained by the sum of murine and human integrin $\alpha_v\beta_3$ densities determined by Western blot, due to the difference of the secondary antibodies used in the separated studies. HT-29 tumor tissues expressed negligible human integrin $\alpha_v\beta_3$, so almost all ^{99m}Tc-G_3-$2P_4$-RGD2 would bind to the murine integrin $\alpha_v\beta_3$, which leads to a much better correlation ($r^2 = 0.84$) between the HT-29 tumor uptake and murine integrin $\alpha_v\beta_3$ expression (Figure 6C).

Our results showed that this study cannot be simply translated to clinical situations, because integrin $\alpha_v\beta_3$ expressed on some tumor cells and tumor newborn vasculature in patients are both of human origin. However, our data can validate that, in clinical situations, the RGD probes would target both the integrin $\alpha_v\beta_3$-positive tumor cells and the newborn tumor vasculature. Therefore, caution should be taken when using RGD probes for the noninvasive imaging of tumor angiogenesis in patients, whose tumor itself is integrin $\alpha_v\beta_3$-positive. Biopsy or immunohistochemistry may be needed to confirm the integrin $\alpha_v\beta_3$ expression in tumors after RGD imaging. For patients with integrin $\alpha_v\beta_3$-negative tumors, ^{99m}Tc-G_3-$2P_4$-RGD2 would be a promising probe for characterizing tumor angiogenesis due to the good correlation between the probe uptake and the integrin $\alpha_v\beta_3$ expression on newborn blood vessels.

CONCLUSION

In this study, we prepared a new ^{99m}Tc-labeled RGD dimeric probe ^{99m}Tc-G_3-$2P_4$-RGD2 with increased in vitro receptor binding affinity and in vivo tumor uptake as compared with our previously reported ^{99m}Tc-labeled RGD dimer. The easy availability with high yield and high integrin $\alpha_v\beta_3$ affinity/specificity makes ^{99m}Tc-G_3-$2P_4$-RGD2 promising for noninvasive SPECT imaging of integrin $\alpha_v\beta_3$ expression and allows kit formulation and routine clinical preparation. The tumor uptake of ^{99m}Tc-G_3-$2P_4$-RGD2 was related to both the human integrin $\alpha_v\beta_3$ (expressed on integrin $\alpha_v\beta_3$-positive tumor cells) and murine integrin $\alpha_v\beta_3$ (expressed on newborn tumor vasculature) expression. The data presented in this study would also provide useful information for clinical translation of ^{99m}Tc-labeled RGD probes for tumor imaging, evaluating tumor angiogenesis, and monitoring treatment efficacy of antiangiogenic drugs. Indeed, the preliminary clinical application of the ^{99m}Tc-labeled new RGD dimer for cancer screening is currently in progress.

The transition of a targeted ultrasound contrast agent from animal imaging to testing in clinical studies requires considerable chemical development. The nature of the construct changes from an agent that is chemically attached to microbubbles to one where the targeting group is coupled to a phospholipid, for direct incorporation to the bubble surface. We provide an efficient method to attach a heterodimeric peptide to a pegylated phospholipid and show that the resulting construct retains nanomolar affinity for its target, vascular endothelial growth factor receptor 2 (VEGFR2), for both the human (kinase insert domain-containing receptor - KDR) and the mouse (fetal liver kinase 1 - Flk-1) receptors. The purified phospholipid-PEG-peptide isolated from TFA-based eluents is not stable with respect to hydrolysis of the fatty ester moieties. This leads to the time-dependent formation of the lysophospholipid and the phosphoglycerylamide derived from the degradation of the product. Purification of the product using neutral eluent systems provides a stable product. Methods to prepare the lysophospholipid (hydrolysis product) are also included. Biacore binding data demonstrated the retention of binding of the lipopeptide to the KDR receptor. The phospholipid-PEG2000-peptide is smoothly incorporated into gas-filled microbubbles and provides imaging of angiogenesis in a rat tumor model.

INTRODUCTION

Molecular imaging is unprecedented in its ability to noninvasively provide in vivo information for diagnosis, prognosis, and monitoring of disease. Of the common modalities, ultrasound imaging is noteworthy for its cost effectiveness, portability, and ease of use. The injection of small (2−5 μm diameter) echogenic gas-filled unilamellar vesicles, commonly referred to as microbubbles, allows improved image definition due to the administered microbubble contrast agent. Recently, the use of targeting groups on the surface of these microbubbles has allowed the monitoring of biochemical processes in the body in real time with sensitivity comparable to that of nuclear medicine (*1*).

One of the important biological processes for imaging is angiogenesis. Tumor growth requires the development of new blood vessels, which is correlated with aggressiveness (*2*). Microbubbles targeted to $\alpha_v\beta_3$ (*3*) or via the targeting tripeptide RRL (*4*) have been used to image angiogenesis. However, the receptor tyrosine kinase VEGFR2, or KDR, has been shown to be one of the major mediators of angiogenesis (*5*). Ultrasound bubbles bearing antibodies to VEGFR2 have also shown good imaging of angiogenesis (*6*). For this reason, we focused on developing a peptide-based targeting agent for imaging the KDR receptor with ultrasound bubbles.

We previously described the use of phage display to generate two families of KDR-binding peptides. Each family of peptides was found to bind to a distinct, noncompeting epitope on KDR as evidenced by the finding that members of each family could not displace the KDR-binding of members of the other family. This was exploited by preparation of heterodimer peptides containing one member of each family of peptides. In binding and functional assays, these constructs were superior to individual peptides and homodimer constructs based on each family of peptides. Chemical optimization of a peptide selected from each family and their linkage provided a potent heterodimer peptide ligand for KDR (*7*). A versatile chemical approach for preparation of a range of heterodimeric peptides using disuccinimidyl glutarate (DSG) was also developed (*8*).

Targeted microbubbles for research applications are routinely prepared by the conjugation of biotinylated antibodies, peptides, or small molecules to preformed streptavidin-bound biotinylated bubbles (*9*). Commercial availability of streptavidin-coated bubbles (Target-Ready MicroMarker bubbles, VisualSonics, Toronto, Ontario, Canada) has facilitated adoption of this technique for research studies. The use of streptavidin-coated microbubbles bearing biotinylated targeting vectors in humans is undesirable due to the antigenicity of streptavidin (*10*). Hence, for clinical product applications, covalent attachment of the targeting group to the phospholipid of the bubble surface is optimal. A number of approaches for preparation of targeting microbubbles in this manner have been offered in the literature, including attachment of thiolated targeting groups to maleimide or bromoacetylated bubbles (*11*), carbamate formation by reaction of amines of targeting groups with mixed alkoxy-nitrophenyl carbonates (*12*), amide coupling reactions (*13*), chemical ligation approaches (*14*), and preparation of artificial lipids (*15*).

Success with these strategies has been limited by inconsistent yields, undesired side reactions, deactivation of coupling partners, or concerns about toxicity of unnatural

lipid conjugates. Therefore, the preparation of targeted bubbles still provides challenges. Additional complexity results from the need to incorporate an appropriate spacer group to separate the targeting group from the lipid surface of the bubble. The most commonly used spacers are PEGs (poly(ethylene glycols)) of different chain lengths. Other issues include the incompatibility of the phospholipid ester groups with the conditions of peptide synthesis, particularly the TFA-mediated cleavage/deprotection step. This paper provides a method for the preparation of a viable product for targeted ultrasound clinical imaging.

EXPERIMENTAL PROCEDURES

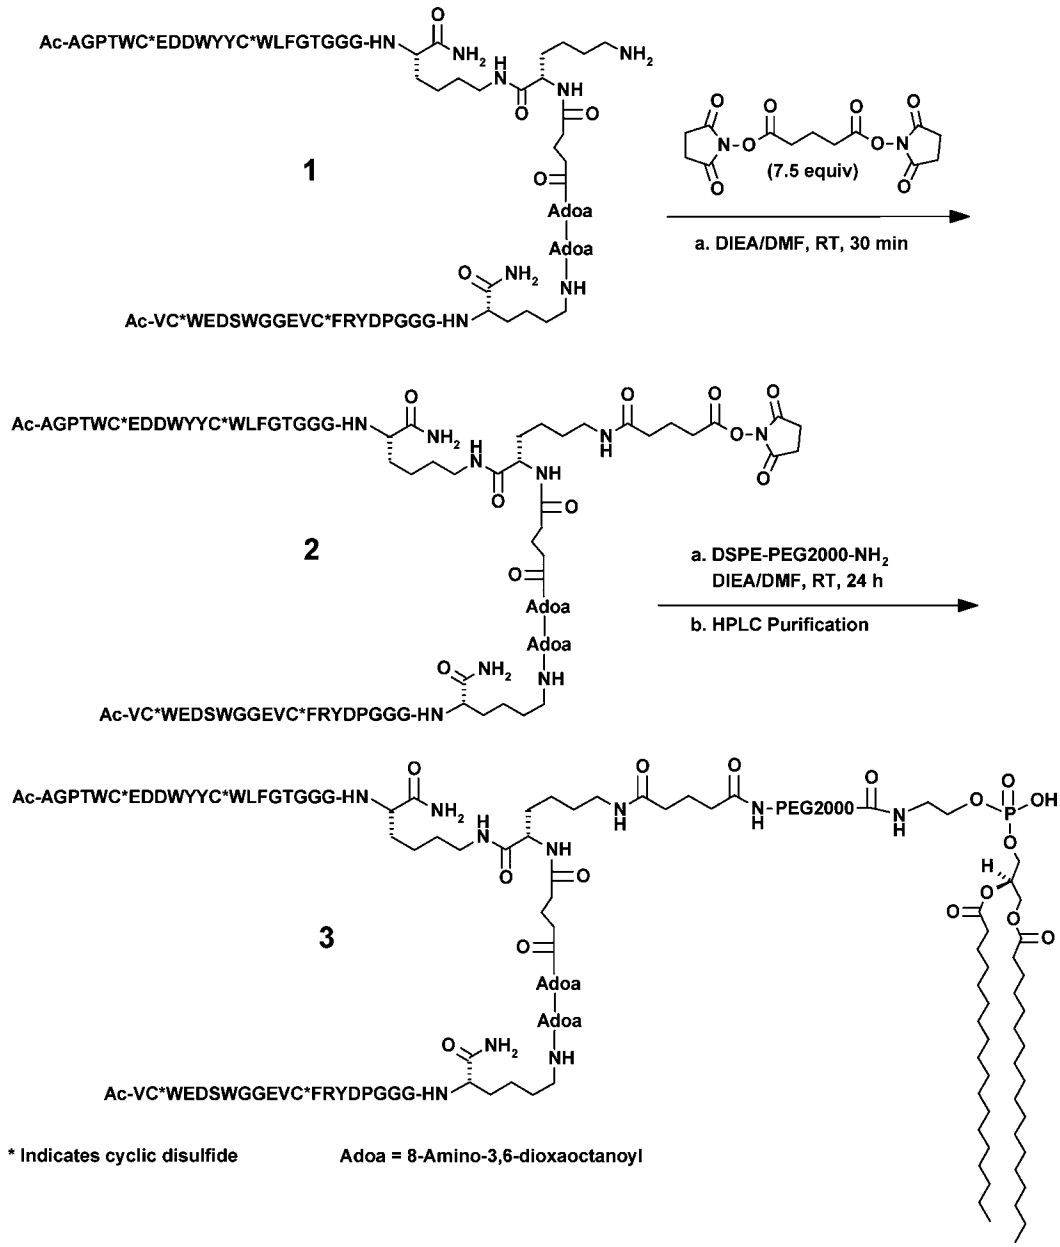
Materials. All common reagents were commercially available and used as received. Disuccinimidyl glutarate (DSG) and 1,2-distearoyl-*sn*-glycero-3-phospho-ethanolamine-*N*-[amino (poly(ethylene glycol))2000] ammonium salt, [DSPE-PEG2000-NH_2] were obtained from Pierce Chemical Co. (Rockford, IL) and Avanti Polar Lipids (Alabaster, AL), respectively. Fmoc-Gly-Gly-Gly-OH was prepared in-house from triglycine by reaction with *N*-hydroxysuccinimidyl-9-fluorenylmethyl carbonate (Fmoc-OSu). AG MP-50 ion-exchange resin was obtained from Bio-Rad (Hercules, CA).

Analytical HPLC. For routine work, analytical HPLC data were obtained using a Shimadzu LC-10AT VP dual-pump gradient system employing a Waters XTerra MS-C18 50 mm × 4.6 mm column, (5 μm particle, 120 Å pore) and gradient or isocratic elution systems using H_2O (0.1% TFA) as eluent A and CH_3CN (0.1% TFA) or CH_3CN-CH_3OH 1:1 (v/v) (0.1% TFA) as eluent B. Detection of compounds was accomplished using a UV detector at 220 and 254 nm. Analytical and purity studies of the phospholipid-PEG2000-peptide derivatives were conducted employing a YMC C4 (250 mm × 4.6 mm, 5 μm particle, 300 Å pore) column or on a Zorbax 300 SB-C3 (150 mm × 3 mm, 3.5 μm particle, 300 Å pore) column and gradient elution using H_2O (10 mM NH_4OAc) as eluent A and CH_3CN-H_2O 9:1 (v/v) (10 mM NH_4OAc) as eluent B. Detection of compounds was accomplished with a SEDEX 55 evaporative light scattering detector (ELSD) and a UV detector.

Preparative HPLC. Preparative HPLC was conducted on a Shimadzu LC-8A dual-pump gradient system equipped with a SPD-10AV UV detector fitted with a preparative flow cell. The solution containing the crude peptide was loaded onto a reversed-phase C18, C4, or C3 column, depending on the compound characteristics, using a third pump attached to the preparative Shimadzu LC-8A dual-pump gradient system. After the solution of the crude product mixture was applied to the preparative HPLC column, the reaction solvents and solvents employed as diluents, such as DMF or DMSO, were eluted from the column at low percentage organic phase composition. Then, the desired product was eluted using a gradient elution of eluent B into eluent A. Product-containing fractions were combined on the basis of their purity, as determined by analytical HPLC and mass spectral analysis. The combined fractions were lyophilized to provide the desired product.

Mass Spectroscopy. Mass spectral data were obtained from MScan Inc. (West Chester, PA) or in-house on an Agilent LC-MSD 1100 mass spectrometer.

Indirect CE-UV for the Simultaneous Analysis of Trifluoroacetate and Acetate Ions. The simultaneous determination of trifluoroacetate and acetate was carried out by capillary electrophoresis (CE) with indirect UV detection at 232 nm. CE data were generated using a PA800 Beckman Coulter system (Fullerton, CA, USA) equipped with an on-column diode-array detector, an autosampler, and a power supply able to deliver up to 30 kV. The separations were performed on a 75 μm (i.d.) × 60 cm (total length)/50 cm (length to the detector) fused silica capillary. A Beckman 32 Karat software package was used for instrument control, data acquisition, and data handling.



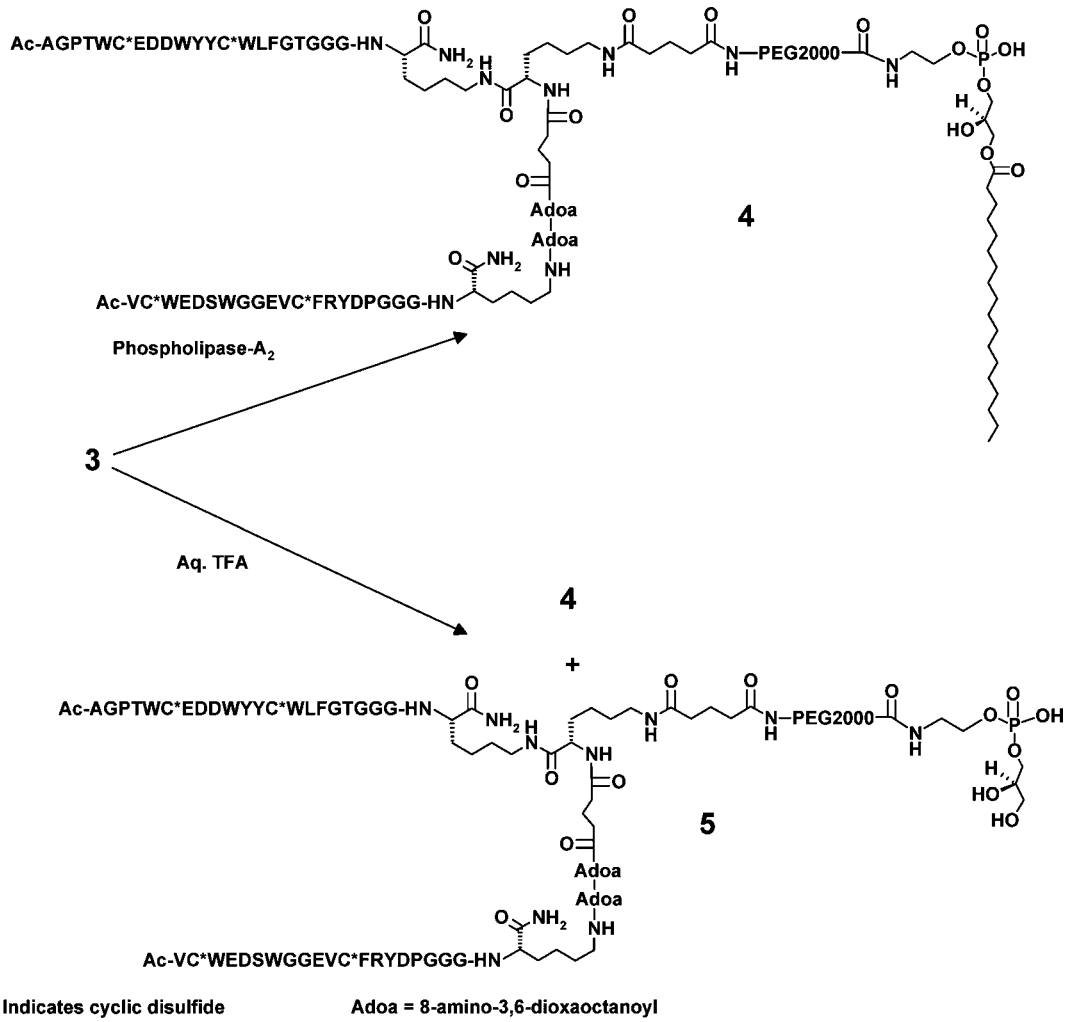
CeofixAnions5 kit (Analis, Namur, Belgium), including a pyridine-dicarboxylic acid buffer at pH 5.6, was used for the quantification of trifluoroacetate and acetate. First, the capillary was rinsed with the initiator buffer, which contains a polycation, to form a positive dynamic coating and invert the electroosmotic flow. Second, the capillary was filled with the accelerator background electrolyte containing a chromophore which absorbs at 232 nm. For quantitative purposes, propionic acid was used as an internal standard. After sample injection by pressure, separation was carried out by applying a high voltage. All experiments were carried out in anionic mode (cathode at the inlet and anode at the outlet). The capillary was thermostatted at 25 °C and a constant voltage of 30 kV (−50 μA) for 6 min, with an initial ramping of 1 min, was applied during analysis. Samples were kept at ambient temperature in the autosampler and injection (~20 nL injection volume) was achieved by low-pressure mode for 15 s at 0.5 psi. Both standard and test solutions were prepared in DMSO−50 mM aqueous NaOH 1:4 (v/v).

Before its first use, the capillary was flushed with 0.1 M NaOH for 1 min, paused for 4 min, then rinsed 0.5 min with 0.1 M NaOH followed by H_2O for 1 min. This initialization procedure was also employed after prolonged storage. Between analyses, the capillary was flushed with 0.1 M NaOH and H_2O (20 psi, 0.5 min each). Before each run, the capillary was pressure-rinsed and filled with the initiator and the accelerator solutions. To achieve reproducible and accurate results, the CEofix buffer solutions were replaced every 20 runs and the first runs of a day were systematically discarded. When not in use, the capillary was washed with 0.1 M NaOH, then H_2O, and stored dry.

Preparation of Heterodimer Peptide Conjugate 1 Having Low TFA Levels. Heterodimer peptide **1** (Scheme 1) was synthesized as a TFA salt following procedures described previously (*8*). Compound **1** as the TFA salt, [120 mg in 80 mL of CH_3CN-H_2O 3:7 (v/v)] was loaded onto an AG MP-50 column and the column was washed with the same eluent until the conductivity was stable at 1 μS/cm. A step gradient elution of the column with NH_4OAc in CH_3CN-H_2O 3:7 (v/v) was conducted using 100 mL aliquots of 200 mM and 400 mM salt followed by 200 mL aliquots of 600 mM and 800 mM salt. The compound eluted at ca. 600 mM salt. The pure product-containing fractions were pooled and lyophilized. The resulting isolate was dissolved in CH_3CN-H_2O 3:7 (v/v) and lyophilized several times to constant weight. This gave 104 mg (86.7% yield) of the pure material **1** as the acetate salt. HPLC: t_R = 5.2 min; assay >99% (area %); column, Waters XTerra MS-C18, 50 mm × 4.6 mm, 5 μm particle, 120 Å pore; eluents: A, H_2O (0.1% TFA); B, CH_3CN (0.1%TFA); elution, initial condition 20% B, linear gradient 20−60% B over 8 min; flow rate, 3 mL/min; detection, UV at 220 nm; MS, API-ES neg. ion; m/z = 1816.3 [M−3H]/3, 1362.0 [M−4H]/4, 1089.2 [M−5H]/5; CE analysis (counter-ion % wt/wt) TFA 0.2%; acetate 0.15%.

Preparation and Purification of the Phospholipid-PEG2000-Peptide Conjugate 3 as Its Acetate Salt from Heterodimer Peptide 1 Acetate Salt (Scheme 1). A solution of the heterodimer peptide (**1**, acetate salt) (0.108 g, 0.02 mmol) in anhydrous DMF (1.0 mL) was added to a solution of disuccinimidyl glutarate (DSG) (50.0 mg, 0.15 mmol) in anhydrous DMF (0.5 mL) containing diisopropylethylamine (DIEA) (0.07 mL, 0.4 mmol, 20 equiv) with vigorous stirring over a period of 2 min and the reaction mixture was stirred for 30 min. HPLC analysis on a Waters XTerra C-18 column and MS showed the disappearance of the starting material

Scheme 1. Preparation of DSPE-PEG2000-Heterodimer Peptide Conjugate 3



and formation of a new product. The solution was concentrated at reduced pressure. The viscous material was stirred with 10 mL of ethyl acetate for 10 min. The precipitated solid, the glutaric acid monoamide mono-NHS ester **2** of the heterodimer peptide **1**, was centrifuged to a pellet. The ethyl acetate was decanted, and this process was repeated three more times and the solid was finally washed with hexane (10 mL) and dried under vacuum (20 mmHg) for 20 min.

A solution of DSPE-PEG2000-NH_2-ammonium salt (0.055 g, 0.02 mmol, 1 equiv) in anhydrous DMF (0.5 mL) was added to a solution of heterodimer intermediate **2** in anhydrous DMF (1.0 mL) containing DIEA (0.07 mL, 0.4 mmol, 20 equiv), and the mixture was stirred at ambient temperature. The reaction was monitored by analytical HPLC and was complete in 24 h. The reaction mixture was then diluted with H_2O (15 mL), and the resulting solution was loaded onto a reversed-phase C4 preparative column (Kromasil Prep C4, 250 × 20 mm, 10 μm particle, 300 Å pore), which had been pre-equilibrated with a buffer containing 20% of CH_3CN-H_2O 9:1 (v/v) containing 10 mM ammonium acetate (NH_4OAc) (eluent B) in 10 mM aqueous NH_4OAc (eluent A) at a flow rate of 25 mL/min. During the application of the sample solution to the column, the flow of the equilibrating eluent from the preparative HPLC system was stopped. After the sample solution was loaded, the flow of the equilibrating eluent was reinitiated and the column was eluted with the equilibrating buffer until the DMF used in the reaction was removed. The column was then eluted with a gradient of 30−100% B over a period of 40 min. Fractions (15 mL) were collected using UV (220 nm) as an indicator of product elution.

Fractions were checked for purity on an analytical HPLC system (YMC C3, 150 mm × 4.6 mm, 5 μm particle, 300 Å pore) using UV at 220 nm and an ELS detector (temp 50 °C, pressure 3.2 psi, sensitivity 10). The latter detector was employed to detect any trace amount of unreacted DSPE-PEG2000-NH_2 which is nearly UV silent at 220 nm. The fractions containing the pure product were pooled and lyophilized. The product was redissolved in H_2O-CH_3CN 4:1 (v/v) and freeze−dried to afford 94 mg (62% yield) of the required compound **3**. HPLC: t_R 9.32 min; assay >99% (area %); column, YMC C4, 50 mm × 4.6 mm, 5 μm particle, 300 Å pore; eluents:

Scheme 2. Hydrolysis of Compound 3 to Compounds 4 and 5

A, H_2O (0.1% TFA); B, $CH_3CN-MeOH$ 1/1 (v/v) (0.1% TFA); elution, initial condition 70% B, linear gradient 70−100% B over 20 min; flow rate, 3.0 mL/min; detection, UV at 220 nm and ELS (temp 50 °C, pressure 3.2 psi, sensitivity 10); CE analysis (counterion % wt/wt): % wt TFA, 0.3%; % wt acetate, 0.4%. MALDI-TOF MS: *m/z* (%) = 8367.7 (100), $[M+NH_4^+ + CH_3CN]^+_{calc} = 8367.6$.

Preparation of Lysophospholipid 4 and Phosphoglyceryl Ester 5 from Phospholipid-PEG2000-Peptide Conjugate 3 by Acid Hydrolysis (Scheme 2). TFA (300 μL) was added to a solution of compound **3** (50 mg) in 30 mL of CH_3CN-H_2O 1:2 (v/v), and the mixture was stirred at room temperature for 7 days. The mixture was purified by preparative HPLC on a YMC C4 (250 mm × 10 mm) column using 10 mm NH_4OAc in H_2O as eluent A and 9:1 CH_3CN-H_2O containing 10 mM NH_4OAc as eluent B. A gradient 10−100% B over a period of 40 min at a flow rate of 10.0 mL/min with UV detection at 220 nm was employed. Fractions were analyzed by HPLC, and those containing pure compound were combined and lyophilized to afford pure products. Compounds **4** (9.8 mg) and **5** (3.2 mg) were isolated. HPLC: t_R Compound **4**, 11.3 min; t_R Compound **5**, 4.09 min; column, Agilent C3, 150 mm × 3 mm, 3.5 μm particle, 300 Å pore; eluents: A, H_2O (10 mM NH_4OAc); B, CH_3CN-H_2O 9:1 (v/v) (10 mM NH_4OAc); elution, linear gradient, 50−100% B over 30 min; flow rate, 1.0 mL/min; detection, ELSD, temp 50 °C, pressure 3.2 psi, sensitivity 10. Under these conditions, t_R of compound **3** was 19.0 min. MALDI-TOF MS: Compound **4**, *m/z* (%) = 8069.0 (100), $[M+Na]^+_{calc} = 8065.1$; Compound **5**, *m/z* (%) = 7801.5 (100), $[M+Na]^+_{calc} = 7798.6$.

Preparation of Lysophospholipid 4 by Enzymatic Hydrolysis of Phospholipid-PEG2000-Peptide Conjugate 3 with Phospholipase-A_2. A solution of compound **3** (40 mg) in 20 mL of $CH_3CN-1.0$ M aqueous HEPES buffer (pH 8.5) 1:2 (v/v) was stirred with a solution of Phospholipase-A_2 (*16*) from honey bee venom (Sigma, 40 units in 25 μL HEPES buffer) at room temperature for 1 h. HPLC analysis indicated the complete conversion of the starting material to the lysophospholipid compound **4**. The crude reaction mixture was treated with 20 mg of hydroxylamine in 2.0 mL of ethanol for 30 min. The resulting solution was purified by preparative HPLC as described above. Fractions were analyzed by HPLC, and those containing the pure product were combined and lyophilized to afford 28 mg (76% yield) of compound **4**, which, in HPLC analysis, coeluted with the material obtained by acid hydrolysis. MALDI-TOF MS: Compound **4**, *m/z* (%) = 8062.0 (100), $[M+Na]^+_{calc} = 8065.1$.

Surface Plasmon Resonance (SPR) Measurements of Binding of Compounds 1 and 3 to Human and Mouse VEGFR2. SPR measurements of the binding kinetics of compound **1** and compound **3** to human and mouse VEGFR2/Fc (R&D Systems, Minneapolis, MN) were carried out on a Biacore X100 instrument (General Electric, Piscataway, NJ). Protein A (Zymed, South San Francisco, CA) was covalently coupled to a CM5 sensor chip (General Electric) using an amine coupling kit (General Electric). For compound **1**, the sample

and running buffer was PBS with 0.005% P20 (General Electric). For compound **3**, the buffer was PBS with the amount of P20 increased to 0.1% to block nonspecific interactions with the sensor chip. For each measurement cycle, human or mouse VEGFR2/Fc was immobilized on the Protein A-conjugated sensor chip at 5 μL/min, then varying concentrations of the compound solution were injected for 3 min at 30 μL/min. Dissociation of the compound from its binding target was measured for 10 min after the end of each injection. The chip was regenerated between cycles with serial injections of 10 mM glycine (pH 2) and 0.025% SDS in H_2O. The sensorgrams obtained for each compound were fit globally to a bivalent binding model using Biacore X100 Evaluation Software v 1.0.

Preparation of VEGFR2-Targeted Microbubbles for Ultrasound Imaging. Compound **3** was incorporated in the phospholipid membrane of microbubbles as previously described (*17*). A 2 mL aliquot of a 5% glucose solution (B. Braun Medical, Sempach, Switzerland) was added to the resulting lyophilized product (BR55). After dissolution of the cake, a suspension of VEGFR2-targeted microbubbles was obtained.

In Vivo Ultrasound Imaging. Ultrasound imaging of VEGFR2-targeted microbubbles (BR55) was performed in an orthotopic breast tumor model in rats as previously described (*17*). Briefly, tumor was induced by injection of 13762 MAT B III rat mammary adenocarcinoma cells (5×10^5 in 100 μL of culture medium) (American Tissue Culture Collection, Manassas, VA) in the mammary fat pad of female Fischer 344 rats (Charles River Laboratories, France). Ultrasound imaging was performed after eight days of tumor growth using a Sequoia 512 scanner (Siemens Medical Systems, Issaquah, WA) equipped with a 15L8 linear transducer (transmit frequency, 7 MHz). BR55 (2.4×10^7 microbubbles) was injected intravenously, and intermittent tumor imaging ($T = 0$ s, $T = 20$ s, $T = 10$ min) was performed using contrast pulse sequencing (CPS) mode at low acoustic power (MI = 0.25) to follow the accumulation of the targeted microbubbles in the tumor. After the 10 min imaging time point, microbubbles present in the tumor were destroyed by increasing the acoustic power (MI = 1.9) and the tumor was imaged immediately thereafter ($T = 11$ min).

RESULTS

Synthesis, Purification, Characterization, and Stability Studies of Phospholipid-PEG2000-Peptide Conjugate 3. We have shown that the affinity of a heterodimer obtained by linking of two phage-derived noncompetitive VEGFR2 (KDR) binding peptides is significantly enhanced vs that of the constituent monomer peptides (*8*). The heterodimer peptide **1** was reacted with DSG (disuccinimidyl glutarate) to provide **2**, the glutaric acid mono-NHS ester monoamide of the heterodimer peptide **1**. The remaining DSG was removed by trituration of compound **2** with ethyl acetate, pelleting and decanting the DSG-rich supernatant. Then, the heterodimer peptide glutaric acid monoamide mono-NHS ester **2** was reacted with DSPE-PEG2000-NH_2 to provide the DSPE-PEG2000-NH-glutaryl heterodimer peptide **3** (Scheme 1).

The crude product was purified by preparative HPLC on a C3 column using an eluent system containing 0.1% TFA. It was observed that the isolated product, bearing TFA, was not stable and, upon standing in solution or as a lyophilizate, undergoes a time-dependent degradation to a lysophospholipid **4** via hydrolysis of one of the stearoyl groups. The formation of compound **4** could be demonstrated by accelerated hydrolysis in the presence of higher concentrations of TFA than that obtained by dissolution of the isolated product **3**. Lysophospholipid **4** was also obtained by enzymatic hydrolysis of compound **3** using Phospholipase A_2 (Scheme 2). Both methods

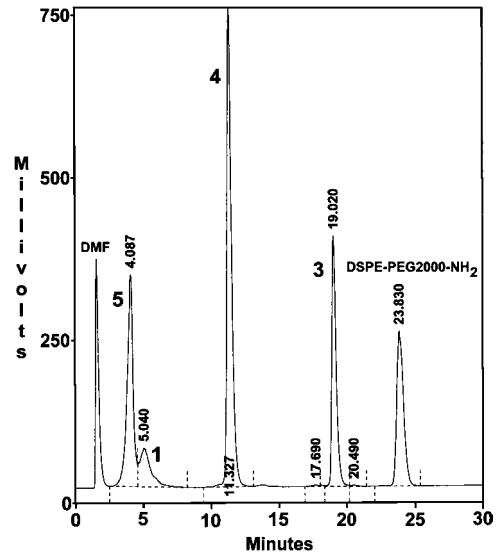


Figure 1. HPLC chromatogram of a mixture containing heterodimer peptide **1**, its DSPE-PEG2000 conjugate **3**, degradation products **4** and **5** and DSPE-PEG2000-NH_2. Conditions: column, Agilent C3, 150 mm $\times$ 3 mm, 3.5 μm particle, 300 Å pore; eluents; A H_2O (10 mM NH_4OAc), B CH_3CN-H_2O 9:1 (v/v) (10 mM NH_4OAc); gradient 50−100% B over 30 min, flow rate 1.0 mL/min; detection, ELSD, temp 50 °C, pressure 3.2 psi, sensitivity 10. **5** = peptide phosphoglyceryl ester, **1** = heterodimer peptide, **3** = DSPE-PEG2000-Glut-heterodimer peptide **1** conjugate, **4** = lysophospholipid.

provided a product which displayed the same HPLC retention time and mass spectrum as the initially detected lysophospholipid **4**.

Lysophospholipid formation could be eliminated by conversion of the trifluoroacetate salt of heterodimer peptide **1** to the stable acetate salt by ion exchange chromatography on AG MP-50 ion-exchange resin and use of this material for the conjugation reaction that provides compound **3**. The decrease in TFA content could be quantified with capillary electrophoresis. The DSPE-PEG2000-NH-glutaryl-heterodimer peptide acetate salt was prepared using DSG followed by preparative HPLC purification using an eluent system buffered with ammonium acetate (Scheme 1) instead of TFA. The HPLC analysis conditions for the separation of the desired product, as well as intermediates and side products, are shown in Figure 1. Studies showed that the material isolated using this procedure is very stable in the solid state and in solution. As an example, aqueous solutions of the isolated material were stable for 21 days at ambient temperature.

After isolation of the acetate salt of **3**, we were surprised to find that this material has a very high affinity for TFA, perhaps due to the PEG linker. Increases in TFA content were obtained from lyophilization with other TFA-containing peptides or during preparative HPLC with ammonium acetate buffer on a column that had previously been used with TFA-containing eluent systems.

Binding Studies of Heterodimer Peptide 1 and Phospholipid-PEG2000-Peptide Conjugate 3. SPR analysis of compound **1** binding to human VEGR-2/Fc indicated that the peptide bound tightly with a K_D of 0.22 nM (Table 1). This is somewhat lower than the K_D of 0.5 nM reported for this compound earlier (*7*), most likely due to the present method of immobilizing VEGFR2/Fc with Protein A, which may better orient the target for binding than did direct amine coupling to the sensor chip. The binding of compound **1** to mouse VEGFR2/Fc was almost 8-fold weaker, with a K_D of 1.6 nM indicating a partial binding preference for the human protein. The phospholipid-PEG2000 conjugate **3** bound human VEGFR2/Fc with a K_D of 4.8 nM (Table 1). The

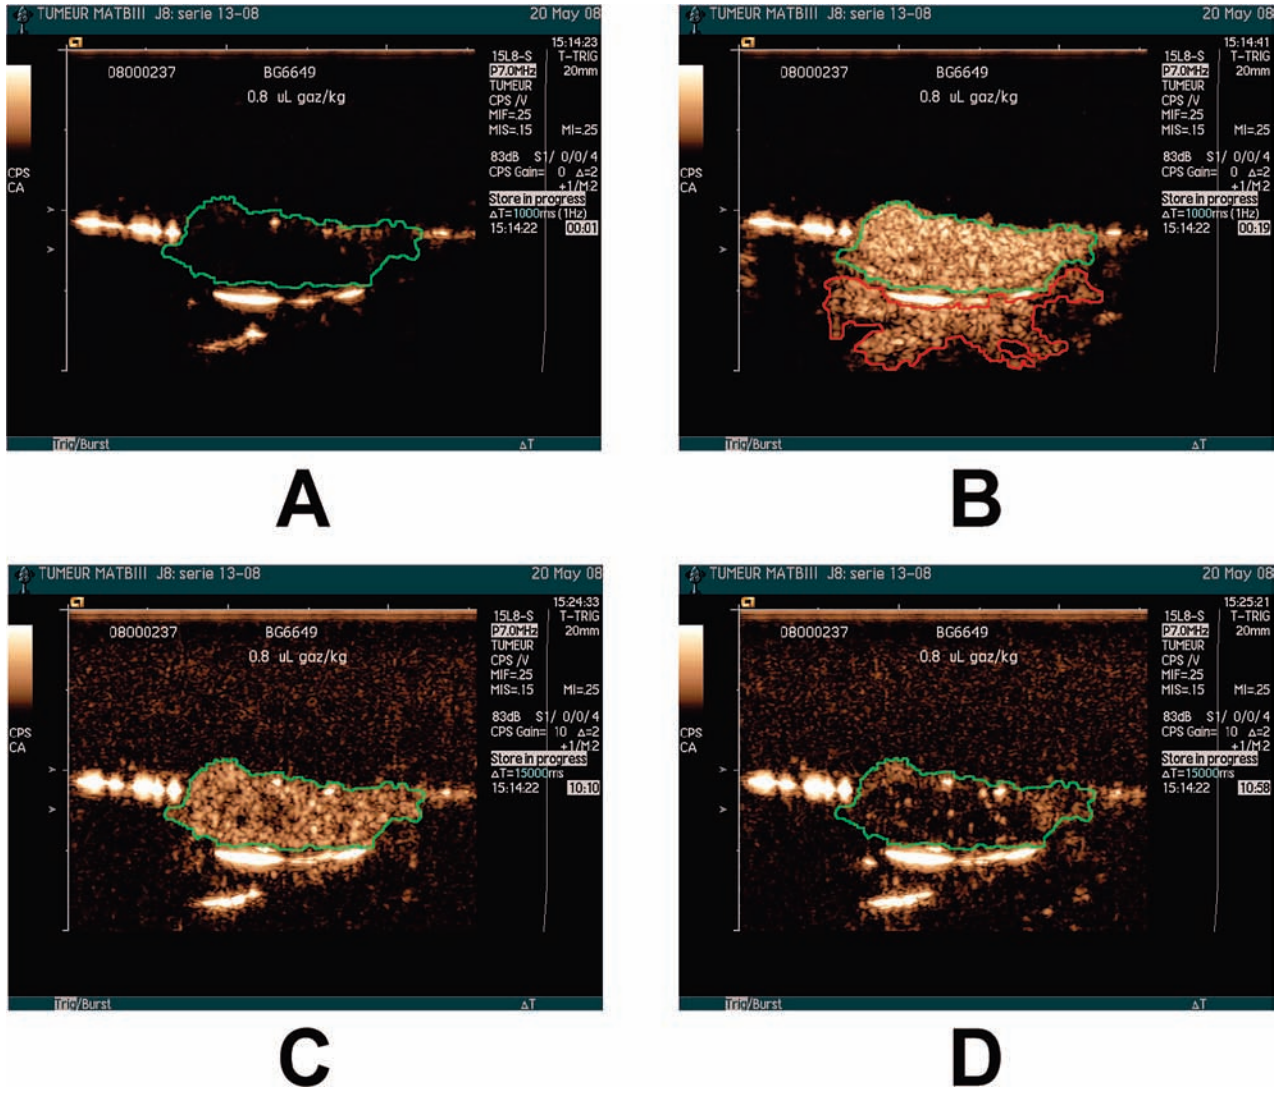

Figure 2. Ultrasound images of MAT B III tumors in CPS mode. Tumor, green outline; nontumoral vasculature, red outline. A: Baseline image before injection of BR55 - the white areas are high intensity reflections of hyperechoic structures. B: At 20 s after injection of BR55 (peak intensity), the circulating microbubbles delineate the vasculature feeding the tumor and the tumor vasculature. C: At 10 min after injection of BR55, freely circulating microbubbles are cleared from the circulation, while the VEGFR2-targeted microbubbles are adherent to the tumor vasculature. D: At 11 min, imaging after destruction of bubbles in the tumor with high acoustic pressure followed by a waiting period for refilling of the tumor with residual circulating bubbles, demonstrated that >95% of the intensity of the image in panel C was due to tumor-bound microbubbles. Depth = 20 mm.

difference in K_D relative to compound **1** was entirely due to a much slower on-rate. Since a higher concentration of P20 detergent had to be used when testing compound **3** to prevent excessive nonspecific binding, it is possible that the kinetic values obtained underestimate the binding to human VEGFR2/Fc. Regardless, it is clear that compound **3** retained potent human VEGFR2 binding capability.

Ultrasound Imaging Results with VEGFR2-Targeted Microbubbles (BR55). BR55 was evaluated in a group of five rats bearing MAT B III mammary tumors of approximately 5−8 mm in diameter (Figure 2). Prior to injection of BR55, ultrasound imaging of the tumor and surrounding area displayed a dark field with small areas of high intensity (panel A); these are artifacts due to highly echogenic anatomical structures (*18*). Following injection of BR55, the strong signal enhancement, due to circulating microbubbles both in the vasculature feeding the tumor and in the intratumoral vasculature, indicated good perfusion of the lesion (panel B). Ten minutes after injection, when microbubbles are largely cleared from the circulation, the signal from the tumor was still enhanced (panel C), indicating that microbubbles were bound to the tumoral endothelium (*19*). Contrast enhancement in the tumor was reduced to background values following the application of a burst of high acoustic pressure and a 1 min waiting period to allow residual circulating

microbubbles to perfuse the tumor (panel D). This confirmed that >95% of the tumoral signal intensity obtained in panel C was due to targeted microbubbles.

DISCUSSION

The preparation of targeted ultrasound bubbles extends the value of contrast enhanced ultrasound. Targeted bubbles are routinely formed in a lab environment by conjugating biotinylated antibodies, peptides or small molecules to streptavidin-coated bubbles (e.g., Target Ready MicroMarker bubbles, VisualSonics). This approach is ideal for a lab environment but not acceptable for human clinical trials, due to the antigenicity of streptavidin (*10*) and the need to conjugate the targeting group to the bubble at the time of use.

For clinical use, there are obvious advantages to direct incorporation of the peptide into the lipid shell of the bubbles. Although a number of different methods for covalent attachment of peptides to lipids have been published, we have found that the coupling of peptides to DSPE-PEG2000 amine with disuccinimidyl glutarate is a mild high-yield process. Although other lengths of PEG spacers were evaluated, the PEG2000 linker was optimal and provided a phospholipid−peptide conjugate with good binding as indicated by surface plasmon resonance studies.

In order to minimize TFA in the product, it proved advantageous to use the acetate salt of the heterodimer peptide **1** in the synthesis of the phospholipid−peptide **3**. Preparative-HPLC employing a dedicated TFA-free system, ammonium acetate buffered eluents, and analysis of collected fractions using an ELS detector was ideal for obtaining a pure and stable product. Adventitious contamination of the isolated fractions with TFA was further prevented by lyophilization of the pooled product-containing fractions on a TFA-free lyophilization unit.

This resulting pure DSPE-PEG2000-heterodimer peptide conjugate **3** could then be incorporated into microbubbles which provided images of active angiogenesis in a rat tumor model. Compound **3** is suitable for further advanced animal studies, as well as clinical studies. The methods for synthesis, purification, and analysis described herein should prove applicable to other phospholipid-PEG linked peptides or antibodies for targeted ultrasound clinical studies.

Supporting Information Available: HPLC chromatogram of purified compound **3**, MALDI-TOF mass spectra of compounds **3** and **4**. This material is available free of charge via the Internet at http://pubs.acs.org.

Transfection Efficiency of Cationic Lipids with Different Hydrophobic Domains in Gene Delivery

DeFu Zhi,[†,‡] ShuBiao Zhang,*[,†] Bing Wang,[†] YiNan Zhao,[†] BaoLing Yang,[†] and ShiJun Yu[‡]

Key Laboratory of Biotechnology and Bioresources Utilization, The State Ethnic Affairs Commission-Ministry of Education, College of Life Science, Dalian Nationalities University, Dalian, Liaoning, China 116600, and School of Chemistry and Chemical Engineering, Liaoning Normal University, Dalian, Liaoning, China 116029. Received September 7, 2009; Revised Manuscript Received January 4, 2010

The structure of cationic lipids is a major factor for their transfection activity. A cationic lipid generally contains four functional domains: a hydrophilic headgroup, a linker, a backbone domain, and a hydrophobic domain. The structure of the hydrophobic domain determines the phase transition temperature and the fluidity of the bilayer and influences the stability of liposomes, the DNA protection from nucleases, the endosomal escape, the DNA release from complex, and the nuclear penetration. Also, toxicity of the lipids is influenced by the hydrophobic domain. The compounds used for gene delivery are classified according to the structure of the hydrophobic domain as follows: aliphatic chains, steroid domain, and fluorinated domain. In this review, we summarized recent research results concerning the structures of the hydrophobic domain, in order to find the effect of the hydrophobic domain on transfection efficiency. Understanding these would be very important for scientists to prepare novel cationic lipids and design novel formulations with high transfection efficiency.

INTRODUCTION

Over the past decades, gene therapy was expected to lead to new, powerful approaches for curing many diseases, which were currently being explored in worldwide clinical trials. Gene therapy offers extraordinary long-term potential for the treatment of human diseases, including inherited and acquired disorders, such as cancer, cystic fibrosis, and AIDS (*1*−*3*). This approach of traditional gene therapy is based on the delivery of genes by transfection vectors and subsequent expression of exogenous DNA into the host genome for long-term expression (*4*−*7*). Broadly speaking, transfection vectors commonly used in gene therapy are mainly classified into two categories: viral and nonviral (*6, 8*). In early clinical trials, although viral vectors such as adenovirus and retrovirus have achieved some success particularly in cancer gene therapy (*9*), they bring about a number of disadvantages, inducing adverse immunogenic responses, high cost, and so forth. Because of these reasons, people try to find a more efficient and flexible security system in the category of nonviral vectors (*6*). Nonviral vectors can be grouped into three main categories—cationic lipids, cationic polymers, and peptides. Compared to their viral counterparts, these vectors are currently considerably less efficient, but their well-defined physical and chemical composition as well as their reduced immunogenicity and toxicity make them promising candidates for gene delivery (*1, 10*−*14*). Cationic lipids have been favored for many potential advantages compared with other nonviral vectors, including significant simplicity and ease of production, good repeatability and biodegradability, potential commercial value, and wide range of clinical application and safety (*15*).

Felgner et al. (*16*) synthesized a glycerol backbone-based cationic transfection lipid−DOTMA[1] (see Figure 1), which was used for introduction of plasmids into cells in 1987. The first in vivo experiments using cationic lipids were conducted in mice

in 1989 (*17, 18*). Since then, a series of efficient cationic transfection lipids have been synthesized (*19*−*23*) and used for delivery of nucleic acids into cells in culture and reported high transgene expression properties (both in vitro and in vivo). Many of these efficient cationic transfection lipids became commercially available as transfection reagents in the late 20th century, and a few liposome formulations have been used in gene therapy clinical trials for treatment of cancer and other genetic disorders (see Table 1).

The basic structure of most of the cationic lipids employed for gene delivery is made up of four chemical functional domains: (i) a hydrophilic headgroup, which is positively charged and allow interactions with negatively charged DNA, usually via the protonation of one (monovalent lipid) or several (multivalent lipid) amino groups; (ii) a hydrophobic domain composed of a steroid or of alkyl chains (saturated or unsaturated); (iii) a linker bond which is between the hydrophobic domain and the backbone, between the cationic headgroup and the backbone or directly and between the hydrophobic domain and the cationic headgroup (often one or more amino acid, or ether, or ester bond); and (iv) a backbone domain which separates the headgroup from the hydrophobic domain, and acts as a scaffold on which the cationic lipid is built (the most common backbone is glycerol-based) (see Figure 2) (*24*). Cationic lipids have become a major research tool for transferring DNA into cells in vitro and are being investigated in a variety of in vivo gene therapy trials on human. As a vector, the geometry of the cationic lipid is an important property regarding its application. The hydrophobic domains represent the nonpolar hydrocarbon moieties of cationic lipids and can be grouped into three categories: aliphatic chains, steroid domain, and fluorinated domain.

Before any discussion of cationic lipids, it should be noted that the separate analysis of each domain is somewhat artificial (*24*−*28*). Transfection efficiency can be affected by structural variations in the hydrophobic domain such as length, the specific type of chemical bonds, and the relative position of the hydrocarbon chains, which can also affect toxicity of cationic lipids. We shall not comment on the relationship of toxicity and structure of cationic lipids in gene delivery here, because we have already published a review about this (*3*). This review is chiefly concerned with the effect of the different hydrophobic domains of cationic lipids on transfection efficiency. The majority of the work studying cationic lipids structure/activity relationship has involved the in vitro delivery of genes.

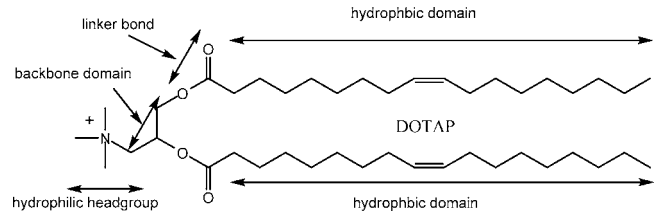

Figure 2. Schematic representation of DOTAP, a commonly used cationic lipid for gene delivery.

ALIPHATIC CHAINS

Cationic lipids with aliphatic chains have been thoroughly researched. The chains are either linear and saturated or linear and monounsaturated and used in liposomal vectors ranging from C_5 to C_{25}, but oleyl, lauryl, myristyl, palmityl, and stearyl have been the most researched ones (*24*). A common variation is the use of branched (*29*), acetylenic (*30, 31*) chains, and *cis*-monounsaturated alkyl chains (*32*) have also been reported.

Number of Aliphatic Chains. It is commonly believed that cationic lipids have one to four hydrocarbon chains. Several studies have also shown that incorporating aliphatic chains with different numbers can improve transfection efficiency potentially by promoting endosomal escape (*16*−*21, 33*−*46*).

Since the pioneering work of Felgner et al. (*16*−*18*) who used the cationic lipid DOTMA with two aliphatic chains, several other related compounds (commercially available transfection reagents with two aliphatic chains, e.g., DOSPA, DOTAP, and DOSPER) have proved moderately successful for gene therapy of pulmonary diseases in animal models (*28*). DOTAP and DOSPER differ from the ether bond-containing reagents DOTMA and DOSPA because DOTAP and DOSPER contain ester bonds, which are endogenous to natural lipids. DOTAP and DOSPER offer higher transfection efficiency and lower cytotoxicity as compared with DOTMA, which may result from the fact that cellular lipases or esterases easily degrade the artificial lipid (*19, 28*).

Most cationic lipids with linear hydrocarbons have two chains in the hydrophobic domain, but cationic lipids with one, three, or four chains are sometimes researched. For aliphatic chains, single-tailed cationic lipids were originally reported to have low transfection efficiency and high toxicity in plasmid delivery (*33, 34*). However, some examples showed that single-tailed cationic lipids may also function in plasmid transfection. Cameron et al. (*34*) described a new class of cationic lipids which offered various numbers of palmitoyl groups in the

hydrophobic domain to prove that the transfection efficiency of the lipid with one chain was inferior to the di- or tri-substituted counterparts (see Figure 3).

In a few examples, single-tailed cationic lipids were successful as transfection reagents. Huang et al. (*33*) compared the transfection properties of several quaternary ammonium detergents on fibroblasts and found that CTAB was most efficient (see Figure 4), but somewhat less than its double-tailed counterparts, such as DOTMA.

Tang et al. (*35*) studied the transfection of liposomes produced from double-tailed 1′,2′-dioleyl-*sn*-glycero-3′-succinyl-1,6-hexanediol ornithine conjugate (DOGSHDO) with an ornithine headgroup, single-tailed OLON with an ornithine headgroup, single-tailed LHON with an ornithine headgroup, double-tailed DOTAP with a quaternary amine group, and single-tailed CTAB with a quaternary amine group. They found that OLON had more transfection activity than its double-tailed analogue, DOGSHDO, whereas double-tailed DOTAP had higher transfection activity than its single-tailed analogue, CTAB. This result shows that neither the headgroup nor the tail group by its own can be the determinant of transfection activity of cationic lipids (*36, 37*). The toxicity of cationic lipid was decreased by introducing a biodegradable ester linkage (LHON) (see Figure 5) and taking the place of the double bond in the middle of the chain without sacrificing the transfection activity.

Then, Patel et al. (*30*) synthesized a cationic lipid, BGDA (see Figure 6), characterized by a bisguanidinium headgroup (actually identical to that in BGTC) and a chain with a diacetylene unit and 25 carbon atoms. It was efficient for in vitro transfection when used in formulations with a similar neutral diacetylene colipid or with DOPE. In the report that inclusion of DOPE may increase the stability of the lipoplexes, BGDA/DOPE liposomes containing high proportions of DOPE were able to completely condense the DNA at lower charge ratios than liposomes with low proportions of DOPE. Within the formulations, cationic lipids can adopt various structural phases, including the micellar, lamellar, cubic, and inverted

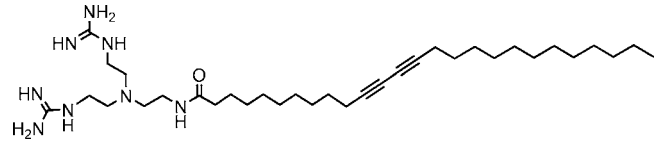

Figure 6. Chemical structures of BGDA.

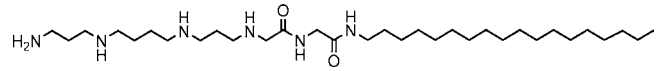

Figure 7. Chemical structures of RPR 228091.

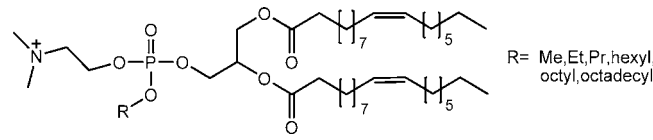

Figure 8. Chemical structures of *O*-alkyl dioleoylphosphatidylcholinium cationic analogues.

hexagonal phase, and arrange back-to-back in bilayers. High transfection activity will be acquired for inverted hexagonal structure when membrane fusion is dominant, but when serum is present, the lamellar structure lipoplexes show great superiority for their inhibition dissociation by serum during lipoplexes transporting. The mechanism by which DOPE exerts its catalytic activity is still poorly defined, but prevailing evidence suggests that its hexagonal-phase-forming propensity likely plays a major role. There are also reports that (*38, 39*) the inclusion of DOPE in the cationic lipid formulation increases transfection activity by enhancing mixing and fusion of liposomes and cell membranes. DOPE forms inverted hexagonal phase structures at ambient temperature (*40*); inclusion of DOPE is presumed to enhance endosomal escape of the lipoplexes into the cytoplasm, as DOPE is thought to have fusogenic properties important for endosomal membrane disruption.

Another example of single-tailed cationic lipid is RPR 228091 (see Figure 7) that was composed of a spermine derived amino acid, coupled to a single C_{18} alkyl chain, and it was suitable for transfection (*41*).

Cationic lipids with three aliphatic chains usually show lower transfection efficiency than lipids with two chains (*34*). However, the transfection can be greatly improved when the third chain is short or could be removed by intracellular reduction of a disulfide bond (*42*−*44*). Rosenzweig et al. (*43*) synthesized a series of *O*-alkyl dioleoylphosphatidylcholinium cationic analogues (see Figure 8) ranging from methyl to octadecyl, and tested them for transfection activity. These compounds could show phase behavior changing with the length of the third chain,

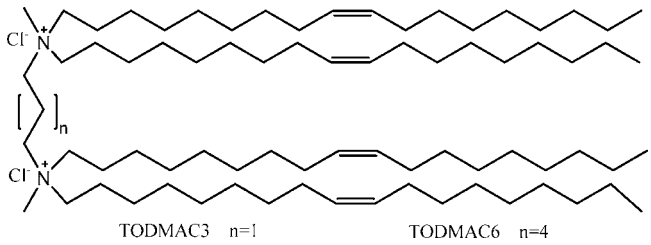

Figure 10. Chemical structures of TODMAC.

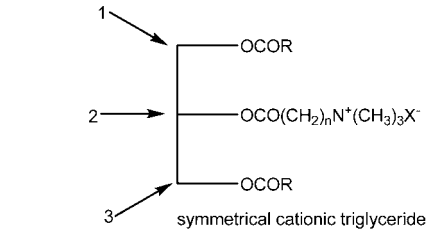

which was an alkyl group linked as phosphate triester. The short-chain (ethyl and propyl) derivatives, which formed a lamellar phase after hydration, were most effective in DNA transfection. The intermediate chain (hexyl) compound, which also formed a lamellar phase in aqueous solution, had approximately the same transfection efficiency as ethyl and propyl. However, hexyl compound assumed a cubic phase in high salt concentrations and became capable of mediating transfection only when vigorously dispersed by sonication. The octyl and octadecyl derivatives formed an inverted hexagonal phase in excess water and exhibited good transfection activity after sonication (*43*).

Byk et al. (*42, 44*) prepared a series of lipopolyamines. They found that the lipid with a dithiol connecting the additional side chain to the vector body showed better transfection activity than the equivalent lipid missing the additional third side chain. Moreover, shorter chains (C_5) showed better transfection activity than longer chain (C_{12}) trilipids (see Figure 9).

A few researchers were interested in novel tetraalkyl cationic lipids (*45*−*47*). Gaucheron et al. (*46*) synthesized a new class of divalent tetraalkyl cationic lipids. These cationic lipids are dimers of DODAC (see Figure 10) joined by a hydrocarbon of three or six carbons in length (TODMAC3 and TODMAC6, respectively). It was concluded that TODMAC6 exhibited potential as a transfection agent as compared to DODAC for in vitro and in vivo use and that the design of cationic lipids according to their ability to induce nonbilayer structure provided a useful guide for synthesis of new cationic lipids. However, TODMAC3 exhibited lower transfection efficiency than that achieved with DODAC.

Generally speaking, for aliphatic chains, single-tailed and three-tailed cationic lipids are better known as surfactants because of their ability to form micelles in solution, but they are more toxic and less efficient than their double-tailed counterparts. Therefore, most of the aliphatic chains in the cationic lipids are double-tailed.

Unsaturation and Branching of Aliphatic Chains. To rationally design and to optimize cationic lipid formulations for efficient gene delivery in therapeutics, many investigations aim at defining a structure−function relationship for cationic lipids. The solid geometry of the unsaturated aliphatic chains is an important variation. A few investigators found that the trans geometry was more favorable to transfection (*48*). However,

Figure 11. Chemical structures of symmetrical cationic triglyceride.

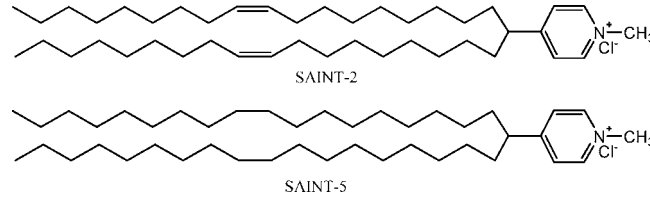

Figure 12. Chemical structures of SAINT-2 and SAINT-5 amphiphiles.

Obika et al. (*49*) obtained an opposite result by synthesizing and evaluating a series of triglycerides **1Aa**−**1Cb** (see Figure 11). They found the cis oleoyl chain (**1Ab**) to be more active in transfection than the trans elaidoyl one (**1Bb**) in quaternary ammonium lipids.

At the same time, they found that the transfection efficiency depends upon both the structure of the acyl chain at the 1- and 3-position of glycerol backbone and the length of the linker connecting the hydrophilic headgroup with the glycerol backbone. The transfection activity was increased when the unsaturated structure was introduced in the middle of a long acyl chain (**1Aa** > **1Bb** > **1Cb**).

The overwhelming majority of the results showed that the unsaturated C18:1 oleyl was the optimal aliphatic chain, which was frequently the best choice for good transfection (*31, 48, 50, 51*). Zuhorn et al. (*52*) synthesized two pyridinium-based lipid analogues with identical headgroups but differing in alkyl chain unsaturation, i.e., SAINT-5 (C18:0) and SAINT-2 (C18:1) (see Figure 12). Their data indicated that at a charge ratio of 2.5/1 the enhancing effect of DOPE on transfection efficiency was highest and the unsaturated C18:1 oleyl SAINT-2/DOPE was more active in transfection than saturated C18:0 SAINT-5/DOPE, which might rely on the relative efficiencies of DNA release from the lipoplexes upon encounter with (intra) cellular membranes.

Koynova et al. (*53*) synthesized two cationic phospholipid derivatives with asymmetric hydrocarbon chains: ethyl esters of oleoyldecanoylethylphosphatidylcholine (C18:1/C10-EPC) and stearoyldecanoylethylphosphatidylcholine (C18:0/C10-EPC). The former was more effective as a DNA transfection agent (human umbilical artery endothelial cells) than the latter, despite their similar chemical structure and virtually identical lipoplex organization. However, an opposite result was obtained by Roosgen and co-workers (*54*), showing that the saturated

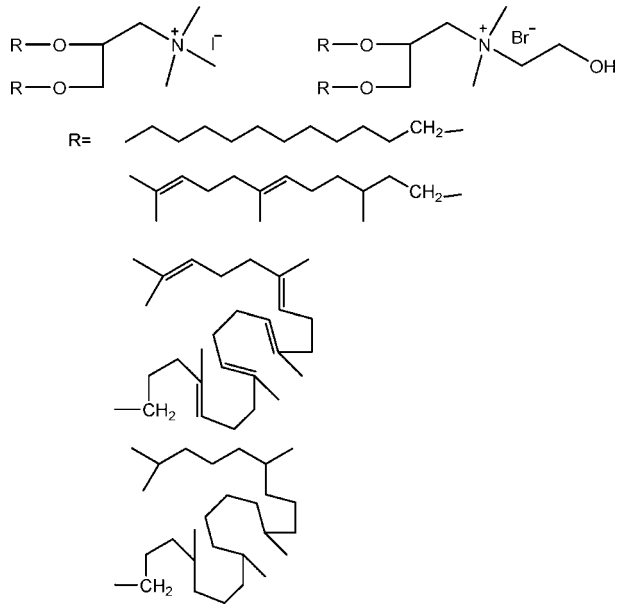

Figure 13. Chemical structures of cationic lipids analogous to DOTMA and DMRIE.

C18:0 performed better than the equivalent C18:1 counterpart; it probably involved other effects like the easier hydrolysis of the headgroup−hydrophobic chain ester linker for saturated than for unsaturated chains.

There are some examples that monoacetylenic or diacetylenic cationic lipids were useful as transfection agents (*30, 31*). Fletcher et al. (*31*) reported the modification of the hydrophobic region of the monovalent cationic lipid DOTAP, by substituting the cis double bonds of the oleate tails with C−C triple bonds in varying positions, in an effort to alter the membrane properties of the lipoplexes with minimal change to the liposome/micelle−DNA interaction. Replacement of the cis double bonds of DOTAP with triple bonds forms more stable liposomes and lipoplex systems near physiological temperatures in comparison to DOTAP by X-ray diffraction studies, perhaps thereby providing enhanced protection to pDNA from extracellular DNA endonucleases. At the same time, the lipid transition is on the cusp of physiologically relevant temperatures, hence preventing overstability and excess rigidity that could otherwise hinder desired cell membrane−lipoplex interactions. It is anticipated that fatty acid tails with triple bonds rather than cis double bonds would exhibit a substantially reduced tangle and consequently afford more rigid liposomal bilayers.

Membrane fluidity may be important for proper assembly of the lipoplexes and is thought to affect endosomal membrane fusion, an essential step required for the DNA to escape from the endosomes; thus, it also has influence on the transfection

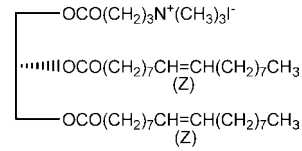

Figure 15. Chemical structures of asymmetrical triglyceride.

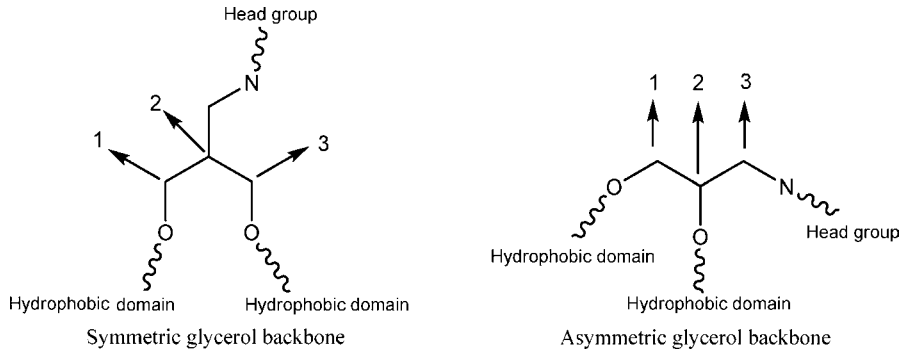
efficiency (*55−61*). It is known that the membrane fluidity increased when an unsaturated structure was introduced into the hydrophobic chain of the lipid, by disrupting membrane packaging and facilitating DNA escape inside the cells. The best chains in terms of benefit to transfection are frequently the unsaturated ones: one reason lies in their effect on the membrane fluidity. A few typical cases have been enumerated in which unsaturated and branched chains help to fluidize the bilayer (*29, 62*). Arpicco et al. (*62*) synthesized a C_{15} dihydro farnesyl derivative (see Figure 13) with an unusual branched structure, which was less active than the C_{12} saturated lipids but, interestingly, more active than commercial lipids, such as DOTMA in almost all cell lines tested.

Similarly, a formulation containing a short unsaturated C14:1 lipid and a branched C_{16} colipid, with very high fluidity, was found to be the best transfectant in vitro from a series of combinations of lipid and co-lipid chains by Ferrari et al. (*29*). These systems should be more fluid than their corresponding fully saturated analogues. A disadvantage of the unsaturation is the reduced stability in storage, because it is susceptible to oxidation (*63*).

Asymmetry of the Hydrophobic Domain. One of the important factors which can affect the efficacy of cationic lipids is the asymmetry of the hydrophobic domain. Some researchers synthesized a series of cationic lipids that were based on glycerol backbone, which was constructed not only in symmetrical structure (see Figure 14) but asymmetrical structure as well (see Figure 14) (*49*).

To compare the transfection ability of a symmetrical cationic triglyceride (**1Ab**) (see Figure 11) with that of an asymmetric triglyceride counterpart (see Figure 15), they were formulated into cationic liposomes with DOPE. It was found that symmetrical cationic triglycerides worked as well as the asymmetrical triglyceride counterpart for transfection efficiency, but showed an obvious advantage over their asymmetric counterparts in the synthesis (*49*).

Several researchers found that the identical alkyl chains are liable to transfect in the lipid structure (*48, 67, 68*). However, most researchers have found that transfection efficiency can be increased either by using the different alkyl chains in the same lipid or by using cationic lipids of asymmetrical backbone (*69*). Cationic lipids which contain different alkyl chains were difficult to synthesize; therefore, only a few examples of cationic lipids with different alkyl chains can be seen in the literature. Heyes



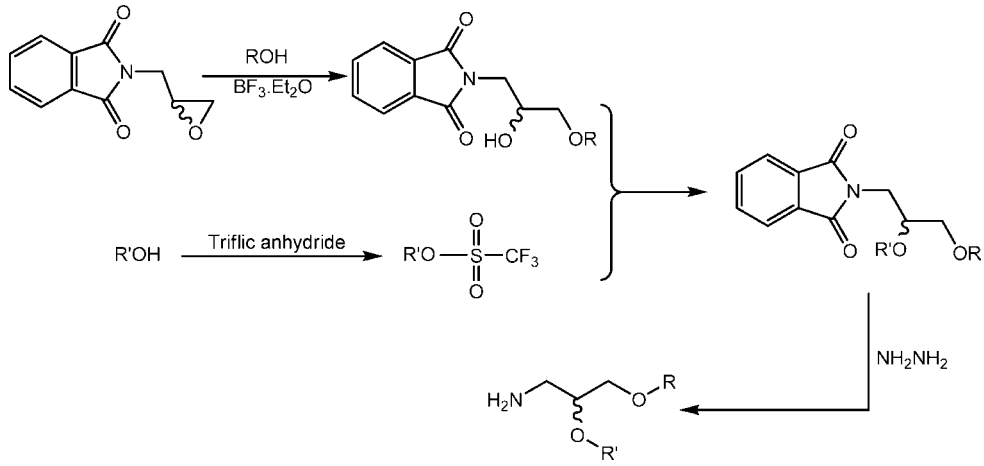


Figure 14. Lipids with glycerol-type backbone.

Scheme 1. Synthesis of Diether Lipids with Symmetric and Asymmetric Hydrophobic Domain

et al. (*69*) synthesized a series of diether lipids of identical or different alkyl chains with primary amino headgroups and showed a convenient route for the synthesis of asymmetric lipids (see Scheme 1). Two of the most effective diether lipids, hydrophobic domain with the shortest identical chains ($R{=}R'{=}C_{12}$) and with particularly different chains ($R{=}C_{12}$, $R'{=}C_{18}$), were chosen.

Ferrari et al. (*29*) found that the hydrocarbon chains of lipid−co-lipid pairs with a high level of asymmetry (C18:1 in lipid−C12:0 in co-lipid) and high symmetry (C16:0 in lipid−C16:0 in co-lipid) had the best transfection efficiency (see Figure 16). Regarding the above explanation, the asymmetry of the hydrophobic domains may afford better intermembrane mixing and the pDNA may be more weakly associated with high symmetry, thus leading to higher transfection levels.

Numerous investigations have also succeeded in developing a highly efficient series of non-glycerol-based novel symmetrical transfection lipids (*64*−*66*). Recently, it was reported that the symmetrical disulfide lipid RPR 128522 (see Figure 17) without glycerol backbone formulated into cationic liposomes with DOPE had obtained significant transfection activity (*62*).

Hyvonen et al. (*64*) synthesized a series of novel symmetrical cationic amphiphilic double-charged 1,4-dihydropyridine derivatives (1,4-DHP) (see Figure 18), which have been shown to condense DNA and efficiently transfect it into cells in vitro, and they were based on dihydropyridine ring backbone.

Although there are many cationic lipids of the symmetrical structure for gene transfection, the in vitro activities of asymmetric lipids are usually superior to the symmetric analogues.

Length of Aliphatic Chains. Much work has been carried out on modifying cationic lipids for use in gene transfection in order to determine if there is a "best" length of chain (*29, 42, 45, 48, 51, 55, 60, 61, 64, 65, 70*−*77*). However, solid conclusions are rarely obtained, for the conclusions of these studies are frequently contradictory. Most of the studies have indicated that cationic lipids with shorter chain length (for saturated chains) were generally important for acquiring high transfection efficiency, since they are responsible for membrane fluidity and good lipid mixing within the bilayer.

For a series of 1,4-dihydropyridine amphiphiles with alkyl chains from C_{10} to C_{16} mentioned above, the C_{10} compound had the highest membrane destabilization activity and achieved the best delivery of DNA in the cytosol, but it did not transfect actively. The equivalent C_{12} compound, although a weaker endosomal disruptor, showed the highest transfection (*64*). In analyzing a series of cationic lipids that differ only by chain length (for saturated chains), most of the studies consider the suitable length to be C_{12} and C_{14}.

Gilot et al. (*77*) synthesized a set of polyvalent cationic lipids (GB compounds) (see Figure 19) derived from natural glycine betaine compounds covalently linked to acyl chains by enzymatically hydrolyzable peptide and ester bonds. Their data indicated that GB compounds allowed high gene transfer efficiency in cultured hepatocytes without cytotoxicity, and

unexpectedly, GB12/GB22 characterized by short acyl chains (C_{12}) was most efficient.

In the absence of serum, all cationic lipids tested with hydrocarbon chains in vicinal configuration esterified to a glycerol backbone (the respective *N*-(1,2-diacyldihydroxypropyl)-*N*,*N*,*N*-trimethylammonium chlorides or *N*-(1,2-diacyldihydroxypropyl)-*N*-(hydroxyethyl)-*N*,*N*-dimethylammonium chlorides, as well as *N*-(1,2-diacyldihydroxypropyl)-*N*-(1,2-dihydroxypropyl)-*N*,*N*-dimethylammonium chlorides with l-auroyl, myristoyl, palmitoyl, stearoyl, and erucoyl chains) were able to transfect cells when combined with DOPE. It was found that the cationic lipid with dimyristoyl chains demonstrated the highest transfection efficiency of plasmid DNA (*78*).

A series of cationic lipids based on lysylaspartate (KD) (see Figure 20), diacyl derivatives with hydrocarbon chains of differing lengths (C_{12}, C_{14}, C_{16}, and C_{18}) exhibited different DNA-binding affinities which were correlated with their in vitro gene transferring capabilities. The KD derivatives with shorter acyl chains (C_{12} and C_{14}) exhibited stronger DNA binding

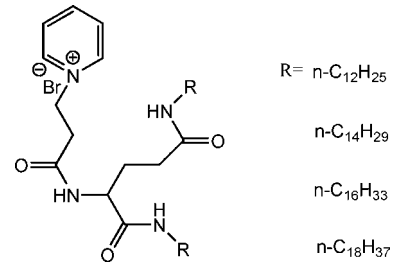

Figure 21. Chemical structures of the glutamide lipids.

affinity and more efficient transfection than those with longer (C_{16} and C_{18}) acyl chains (*79, 80*).

At the same time, the efficiency of cationic lipids with alkyls in the range 12−16 carbons in length was well-documented by Gopal et al. (*81*), and 14-carbon-length lipids were most efficient among several cationic lipids with different chemical structures (see Figure 21).

Felgner et al. (*59*) reported the synthesis and assay results for several series of homologous lipids. They found that, as the length of the saturated aliphatic chain increased from 14 to 18 carbon atoms, the transfection activity of the resulting cationic lipids progressively declined.

In order to understand the relationship between the length of aliphatic chains and transfection activity better, Floch et al. (*82*) synthesized a homologous series of cationic phosphonolipids with different alkyl chain substitutions. The order of transfection efficiency was disteryl (di-C18:0) < dipalmityl (di-C16:0) < dimyristyl (di-C14:0). The transfection efficiency and membrane fluidity of the analogues increased as the length of the aliphatic chains decreased.

However, some degree of rigidity for the membrane is also required, in order to stabilize the liposome (*74, 80*). Long-chain lipids would probably strengthen the stability (*42, 56, 74*). From the interplay of these opposite trends, the optimal chain length depends on the specifics of a given overall cationic lipid structure to achieve the best balance. It should be mentioned that the shorter aliphatic chains allow for better transfection in vitro, whereas the longer aliphatic chains allow for better transfection in vivo (*60, 82*). Whatever the quaternary trimethylonium used for cationic phosphonolipids by using different neutral lipids in the transfection process, in vivo transfection efficiency of compounds involving a C18:1 chain was higher than with the C14:0 analogues and with the reverse in vitro (*60, 82*). It may be that the function of the neutral lipid is different in vitro from that in vivo in the formation of lipoplexes and depends on the nature of the quaternary trimethylonium used.

In general, cationic lipids with the shorter aliphatic chains (C_{12} and C_{14}) were more efficient than the longer (C_{16} and C_{18}) counterparts in transfection efficiency. It is possible that shorter hydrocarbon chains increase the fluidity of the bilayer and favor a higher rate of intermembrane transfer of lipid monomers and lipid membrane mixing, resulting in potential disruption of the endosome and consequent DNA escape from endosomal degradation.

Special Moieties at the Hydrophobic Chains. Some new vectors were designed to covalently connect some special moieties at the end of the hydrophobic chains, in order to get the relationship between hydrophobic chains and transfection efficiency.

Jacopin et al. (*83*) synthesized a glycosylated analogue (see Figure 22) of the dialkylamidoglycylcarboxyspermines, which formed stable particles at low charge ratio and was efficient for gene delivery.

Many groups also reported a few other glycosylated cationic bolaamphiphiles similar to the compound. Brunelle et al. (*84*)

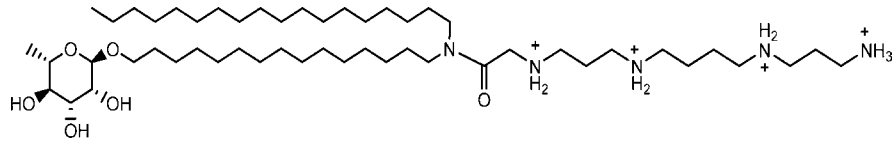

Figure 22. Glycosylated analogue of lipopolyamines.

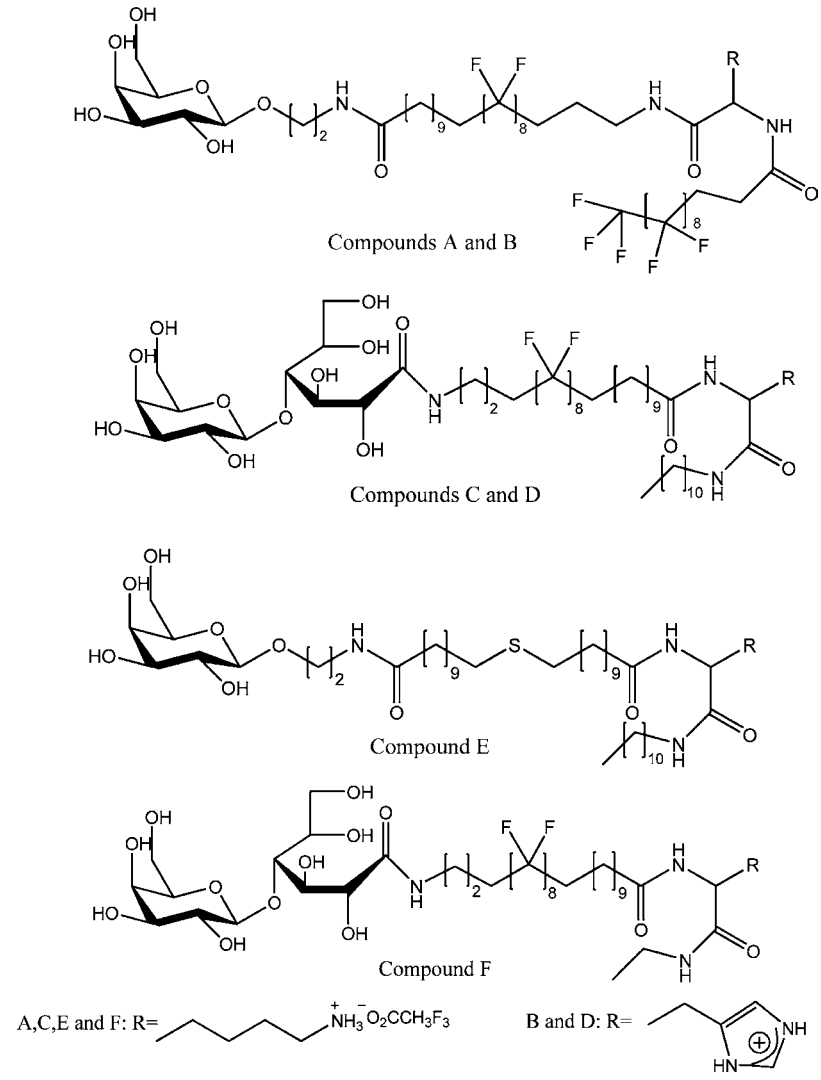

Figure 23. Set of dissymmetric hemifluorocarbon bolaamphiphiles.

synthesized a new series of dissymmetric hemifluorocarbon bolaamphiphiles (see Figure 23), and the dissymmetric functionalization of diiodoperfluorooctane led to bolaamphiphile molecules composed of a partially fluorocarbon core end-capped with a glycoside and an ammonium salt. They found that the incorporation of two fluorinated segments in the molecular structure of the bolaamphiphiles is detrimental for an efficient DNA condensation. In contrast, a partial fluorination of the hydrophobic core of bolas increased not only the DNA complexation abilities, but also the DNA transfection efficiency. Relatively high transfection activity was obtained for the bolaamphiphile possessing a lysine headgroup and one fluorinated segment close to the carbohydrate moiety. This result could be explained by the small size and the positive surface charge of the bolaplex. Vierling's group (*85*) described the synthesis of three new α-galacto-ω-polyamine double-chain bolaamphiphiles (Gal-CL) (see Figure 24), and their design combines a hydrophilic galactosyl residue (which serves as a molecular signal for cell targeting) linked through a long spacer to various hydrophilic linear or branched polyamine polar heads (for the interactions with DNA and its compaction) and to a hydrophobic tail constituted by two long alkyl chains. The three new double-chain bolaamphiphiles, whether used with DOPE or with pcTG90/DOPE, were found to be more efficient nonspecific gene transfer agents than the single-chain head GalSper compound.

A particular example has been found by Abe and co-workers, who reported two hydrophobic chains of a cationic lipid connected two ferrocenes, respectively (*86, 87*). Abbott et al. (*88*) demonstrated that a ferrocene-containing, redox-active cationic lipid (see Figure 25) can be used to offer either high (on) or very low (off) levels of cell transfection depending on a reduced or oxidized state. If successfully developed through future studies, the ability to activate lipoplexes toward transfection and "on demand" could create new opportunities to deliver DNA in vitro and in vivo.

Balakirev et al. (*89*) synthesized a new cationic amphiphilic vector for gene delivery made from the natural provitamin, lipoic

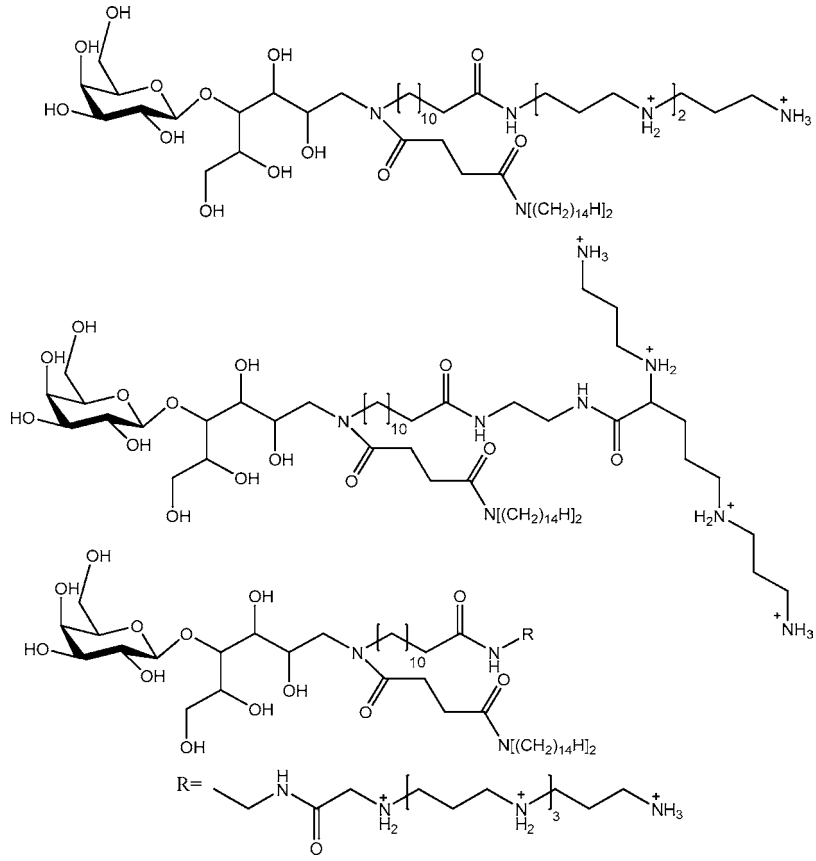

Figure 24. Chemical structures of Gal-CL.

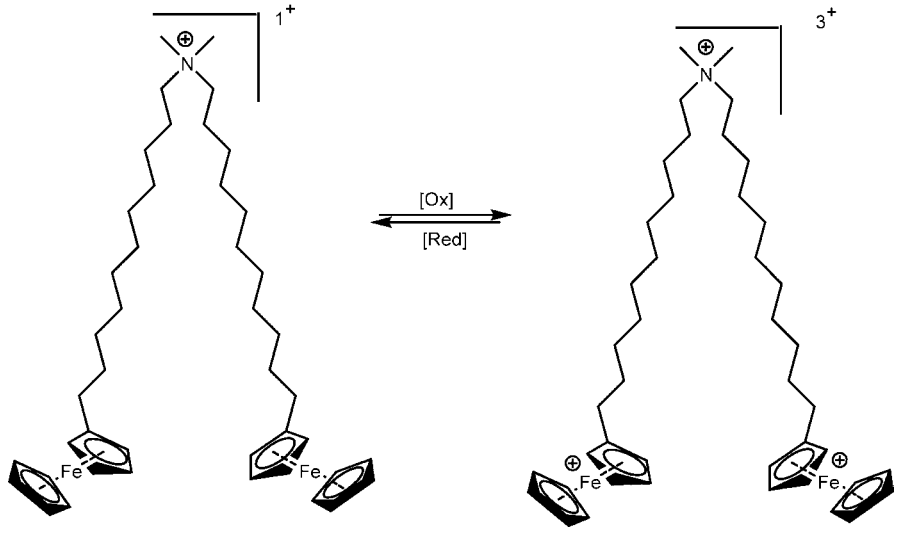

Figure 25. Chemical structures of ferrocene-containing dimethyldioctadecylammonium bromide.

acid. In addition, they demonstrated the principle of a redox-controlled gene delivery system that uses the reversibility of the thiol−disulfide exchange reaction. In the oxidized state, these amphiphiles condensed DNA into stable virus-sized complexes, which efficiently enter cells and released DNA in a reducing intracellular environment by various thiols as well as enzymatically, by thioredoxin reductase. Their data suggested that amphiphile−DNA complexes for gene transfection in vitro showed a several-fold increase of transgene expression compared with DOTAP. Their transfection efficiency can be further augmented by attachment of the nucleus-targeting peptide to the amphiphile. Having been formed from the natural compound lipoic acid, these cationic amphiphiles might be biodegradable and nontoxic.

Grinberg et al. (*90*) introduced the synthesis of a series of amphiphilic derivatives based on vernonia oil (see Figure 26). These compounds with three vernolic acid moieties bound together through a glycerol backbone proved to have good gene transfection properties, their structure is symmetrical, and their chains with some special moieties are branched and unsaturated. It is all these structure in cationic lipid that makes a combination

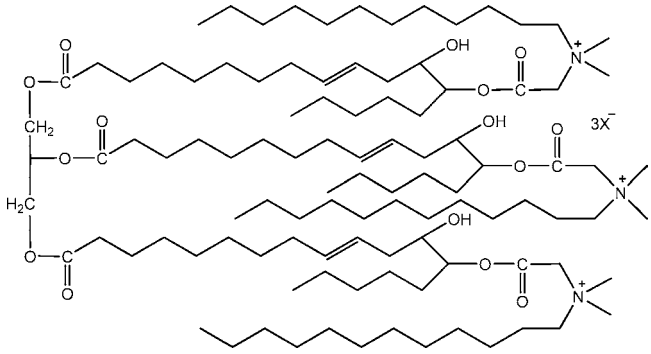

Figure 26. Chemical structures of amphiphilic derivatives based on vernonia oil.

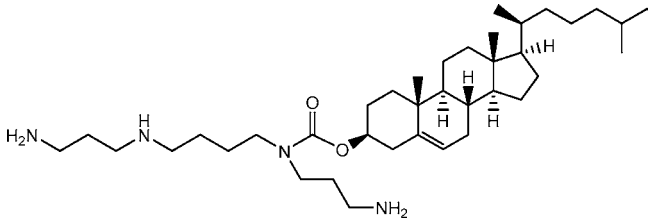

Figure 27. Chemical structure of GL-67.

that facilitated the complexation of DNA and its transport across biological barriers.

STEROID HYDROPHOBIC DOMAIN

In 1991, Gao et al. (*58*) reported the synthesis and application of the cholesterol-based cationic lipid DC-Chol, which was combined with DOPE to tranfect mammalian cells. Since then, considerable effort has been made in the synthesis of steroidal cationic lipids due to their potential applications in gene therapy (*55, 57, 58, 91*−*100*). Among the steroid groups, cholesteryl is by far the most frequently encountered.

For cholesterol-containing cationic lipids, it has been shown that those with the cholesterol hydrophobic domain linked to a multivalent T-shaped headgroup were most efficient when instilled into murine lungs (*91*). An example is cationic lipid GL-67 (see Figure 27), one of the multivalent T-shaped headgroups, which has been found to be particularly efficient for gene transfer to cultured cells and in murine lungs (*91*).

Then, Wu et al. (*101*) reported three cationic cholesterol derivatives differing in their types of amine and bearing a hydroxyethyl group at the amine group, synthesized and formulated into liposomes and nanoparticles as gene delivery vectors, and their formulations were optimized for gene transfection of the human lung adenocarcinoma A549 cell line. They found that the use of cationic lipids with a hydroxyethyl group at the tertiary amine headgroup showed the highest gene expression among cationic cholesterol derivatives lipids.

Otherwise, Philippe Belmont and co-workers (*102*) demonstrated that they synthesized a cationic cholesterol derivative characterized by an aminoglycoside headgroup. The amino-sugar-based cationic lipid was highly efficient for gene transfection into a variety of mammalian cell lines when used either alone or as a liposomal formulation with the neutral phospholipid DOPE. Their results showed the usefulness of cationic lipids composed of an aminoglycoside headgroup and cholesterol tail for gene transfection in vitro and in vivo.

Other steroid compounds used as hydrophobic moieties for cationic lipids include vitamin D (*103*), bile acids (*104*), antibiotic (*105*), cholestane, and litocholic acid (*63*).

Ren et al. (*103*) claimed that a new panel of steroidal cationic lipids (see Figure 26) using commercially available vitamin D_2

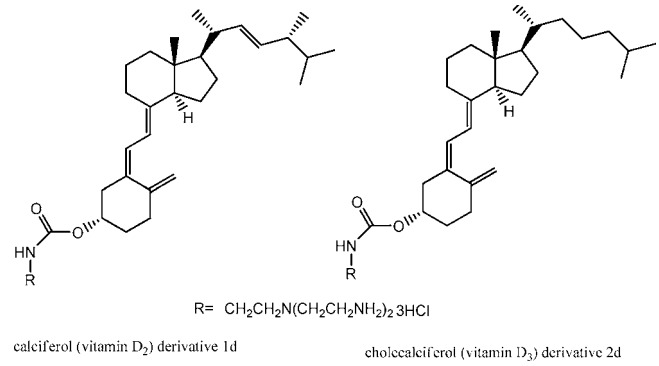

Figure 28. Vitamin D-based cationic lipids.

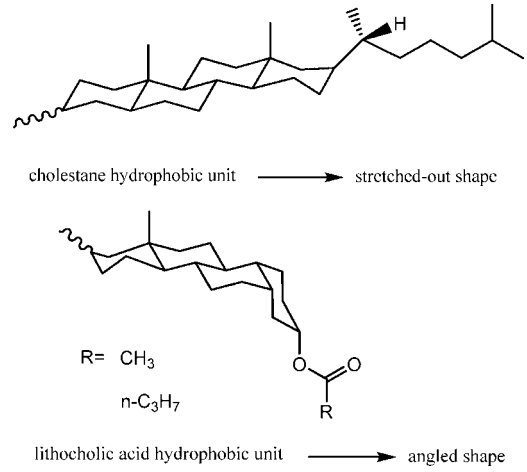

Figure 29. Chlolestane and lithocholic acid-based cationic lipids.

(calciferol) or vitamin D_3 (chole-calciferol) as hydrophobic motifs was synthesized for gene delivery. They found that the synthetic vitamin D-based cationic lipids **1d** and **2d** (see Figure 28) formulated with DOPE as a colipid exhibited superior transfection activity. Transfection results obtained from the experimentation suggested that these new vitamin D-based cationic lipids were useful for transfection reagents in vitro gene transfer studies.

Kichler et al. (*105*) showed that a class of facial amphiphiles, which were made by conjugating different amines to a steroid nucleus, were able to efficiently mediate gene transfer when associated with DOPE and shown to possess significant antibacterial activity even on bacteria strains such as *S. aureus* while being poorly hemolytic. Therefore, they thought that this study could serve as a starting point for the development of new compounds which are able at the same time to deliver a gene medicine and kill bacteria. Fujiwara et al. (*63*) designed a novel potent class of DNA delivery agents based on cholestane and lithocolic acid, of which the former had a *trans*-decaline structure and the latter, a *cis*-decaline structure, different space-filling character. The structure of the former was stretched, and the latter was angled-shaped. The former performed better in transfection efficiency than the latter (see Figure 29).

A few examples showing cationic lipids using a bile acid scaffold had a similar shape to cholesterol but were more hydrophilic due to the presence of polyhydroxyl groups (*104*). A particular example has been found by Randazzo and co-workers (*106*), who reported that incorporation of a double bond in the bile acid moiety enhanced transfection efficiency significantly and produced two compounds with little cytotoxicity and transfection potency comparable to Lipofectamine 2000.

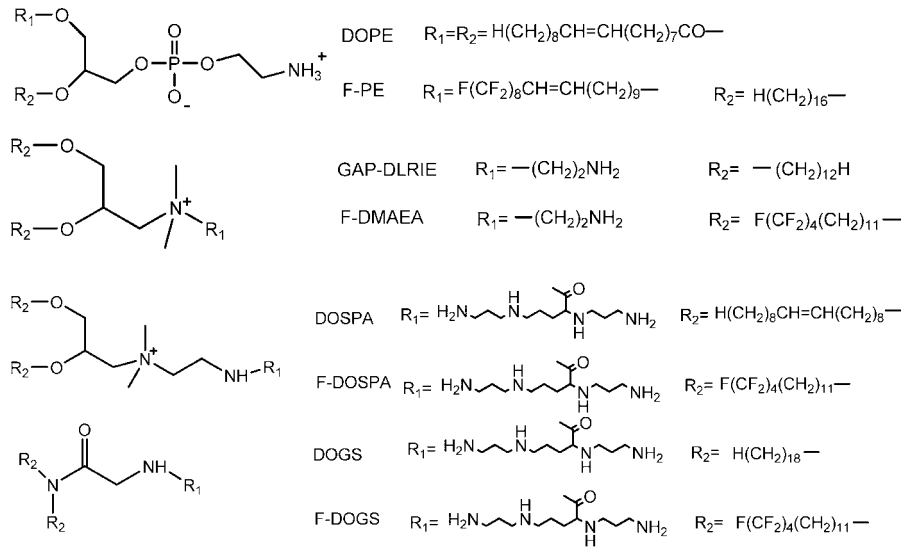

Figure 30. Chemical structure of the fluorinated and conventional cationic and helper lipids used and/or mentioned in this study. F-DOSPA, F-DMAEA, and F-DOGS F-PE are fluorinated lipids.

Lipids with steroid hydrophobic domain tend to rigidify the bilayers and are more stable in the bilayer structure.

FLUORINATED HYDROPHOBIC DOMAIN

The fluorinated part of the hydrophobic chain can also influence the transfection efficiency of cationic lipids in vivo and in vitro. Many varieties of fluorinated cationic lipids have been developed as transfecting agents, which are very efficient in compacting DNA and delivering it to cells in vitro and in vivo cationic lipid-mediated gene delivery (*107*−*111*). Gaucheron et al. (*111*) described the synthesis of fluorinated glycerophosphoethanolamines (F-PEs) helper lipids, which showed a significantly higher transfection helper potential as compared with that of DOPE. Two fluorinated cationic lipids F-DMAEA and F-DOSPA (see Figure 28) were designed by Boulanger et al. (*107*). Their hydrophobic part consisted of two $F(CF_2)_4(CH_2)_{11}$ chains, which led to one of the most efficient gene transfer agents in the fluorinated DOGS series (with either both chains fluorinated to varying degrees or just a single chain fluorinated) (see Figure 30) (*109, 110*). Lipoplexes from the above compounds were very stable to storage and more resistant to detergent in vivo. Their data demonstrated that fluorinated lipids had higher transfection efficiency in vivo and in vitro. It also suggested that their enhanced hydrophobic and lipophobic character prevented them from disintegration and, consequently, from DNA degradation and from interactions with lipophilic and hydrophilic biocompounds. Vierling's group (*112*) also described the synthesis of new perfluorinated dimerizable detergents with a tricationic or tetracationic (linear or branched spermine, respectively) polar head, which exhibited a higher in vitro and in vivo transfection potential than conventional lipoplexes or even than PEI polyplexes. Their production resulted in the development of tiny, monomolecular DNA nanoparticles that were obtained using new perfluorinated dimerizable detergents.

CONCLUSIONS

In recent years, considerable progress has been made in defining conditions that favor or promote lipoplex-mediated transfection, particularly with regard to the structural features of cationic lipids. The extent of gene therapy using synthetic vectors depends on the development of new approaches to improve the features of cationic lipids for the purpose of facilitating their use in vivo. From the chemistry point of view, the structure of cationic lipids is an important factor for their transfection activity and toxicity. Some common conclusions can be achieved by comparing the different structures and their transfection activity in the same family or different families of lipids. The transfection efficiency is not determined solely by one domain of cationic lipids but by the combination of them (*35*). The hydrophobic domain of cationic lipids mainly includes aliphatic chains, steroid domain, and fluorinated domain, which determines the phase transition temperature and the fluidity of the bilayer, and influences the stability of liposomes, the DNA protection from nucleases, amd the DNA release from complex. In the process of DNA transfer, cationic lipids protect DNA against degradation by nucleases and serum components, create a less negative surface charge, can be designed to target delivery to specific cell types through receptor−ligand interactions, and can also facilitate intracellular trafficking, which includes endosomal escape, cytoplasmic transport, and nuclear entry, while also having an important influence on the release of DNA to allow expression (*113, 114*).

Some traditional cationic lipids have been used in gene therapy, many of which have two hydrophobic tails. The chain length, asymmetry, branching, and unsaturation affect transfection activity in vivo and in vitro. Most studies suggest that transfection increases with decrease of chain length or increase of chain asymmetry, branching, or unsaturation. It is possible that shorter, asymmetrical, branched, and unsaturated hydrocarbon chains decrease the phase transition temperature, increase the fluidity of the bilayer, and favor a higher intermembrane transfer rate and lipid mixing, resulting in potential disruption of the endosome and consequent DNA releasing from endosomal degradation (*115*). The introduction of some special groups (such as ferrocene, lipoic acid) in the tail of the lipid can improve the efficiency of transfection and reduce toxicity, and would be worth exploring further as an in vivo delivery system for gene therapy. There is a new strategy which is introducing some special chemical bounds (such as ester linkage) upon traditional hydrophobic tails of cationic lipids that show low toxicity level (*3*) and high transfection efficiency and may provide an optimistic outlook for the development of lipid-based systems that are more applicable for human gene therapy. It might be development trends for cationic lipids that hydrophobic chains with some special moieties are branched and unsaturated.

Cationic lipids using cholesterol as a hydrophobic tail can also improve the efficiency of transfection. This is because the

formation of cholesterol offers rigidity and very stable bilayer structure, as well as its endogenous biodegradability and fusion activity. The hydrophobic domain of cationic lipids can not only directly affect the efficiency of transfection, but also indirectly influence transfection efficiency by the properties of the membrane (membrane fluidity and rigidity) that was formed from them. Further development in structure and properties of membrane will certainly rely on better understanding of vector interaction with plasmid and cellular components. Another trend of cationic lipid development is the substitution of some fluorinated groups for the hydrogens of two hydrophobic tails, which can improve transfection efficiency in vitro and in vivo. Fluorinated liposomes made from highly fluorinated double-chain phospho- or glycolipids, as well as fluorinated lipoplexes made from highly fluorinated polycationic lipospermines and reporter genes, have displayed a number of interesting physicochemical and biological properties (*110*). In general, it seems that, when researchers design cationic lipids for gene delivery, the balances between the opposing factors including fluidity and rigidity, symmetry and asymmetry, saturation and unsaturation, linearity and branching, short chain and long chain, and hydrophilicity and lipophilicity of lipids should be taken into great consideration. It would be very important for scientists to have a good understanding about the effect of the different hydrophobic domains of cationic lipids on transfection efficiency, which would be helpful to prepare novel cationic lipids and design novel formulations with high transfection efficiency.

We report tumor targeting nanoparticles for optical/MR dual imaging based on self-assembled glycol chitosan to be a potential multimodal imaging probe. To develop an optical/MR dual imaging probe, biocompatible and water-soluble glycol chitosan (M_w = 50 kDa) were chemically modified with 5β-cholanic acid (CA), resulting in amphiphilic glycol chitosan-5β-cholanic acid conjugates (GC-CA). For optical imaging near-infrared fluorescence (NIRF) dye, Cy5.5, was conjugated to GC-CA resulting in Cy5-labeled GC-CA conjugates (Cy5.5-GC-CA). Moreover, in order to chelate gadolinium (Gd(III)) in the Cy5.5-GC-CA conjugates, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) was directly conjugated in Cy5.5-GC-CA. Finally, the excess $GdCl_3$ was added to DOTA modified Cy5.5-GC-CA conjugates in distilled water (pH 5.5). The freshly prepared Gd(III) encapsulated Cy5.5-GC-CA conjugates were spontaneously self-assembled into stable Cy5.5 labeled and Gd(III) encapsulated chitosan nanoparticles (Cy5.5-CNP-Gd(III)). The Cy5.5-CNP-Gd(III) was spherical in shape and approximately 350 nm in size. From the cellular experiment, it was demonstrated that Cy5.5-CNP-Gd(III) were efficiently taken up and distributed in cytoplasm (NIRF filter; red). When the Cy5.5-GC-Gd(III) were systemically administrated into the tail vein of tumor-bearing mice, large amounts of nanoparticles were successfully localized within the tumor, which was confirmed by noninvasive near-infrared fluorescence and MR imaging system simultaneously. These results revealed that the dual-modal imaging probe of Cy5.5-CNP-Gd(III) has the potential to be used as an optical/MR dual imaging agent for cancer treatment.

Recently, nanotechnology and molecular imaging have been combined to generate multifunctional nanoparticles that simultaneously facilitate early-stage cancer diagnosis, target drug delivery with minimal toxicity, and monitor cancer treatment (*1*−*3*). In particular, various multimodal nanoparticle imaging probes have been tested to overcome the limitations of either imaging method when used alone (*4, 5*). The combination of magnetic resonance (MR) imaging and near-infrared fluorescence (NIRF) optical imaging for cancer diagnosis have several attractive attributes that have driven the development of molecular imaging strategies for these modalities (*6*−*8*).

The major advantage of NIRF optical imaging is the capability of visualizing target biological molecules (peptides, drugs, DNA, siRNA, proteins, etc.) in vivo with a higher sensitivity (*9*−*15*). However, the spatial resolution of NIRF optical imaging is not enough to show the location of a three-dimensional target molecule with anatomical resolution. MR imaging is one of the imaging techniques used to obtain three-dimensional information. Besides the excellent spatial resolution, one limitation of MRI is its low sensitivity to contrast agents, which are important for the detection of cellular or molecular changes on a nanomolar scale. Therefore, the limited sensitivity of MR imaging can be overcome by combination with NIRF optical imaging methods.

Of note, polymeric nanoparticles are known to accumulate at the solid tumor site by the so-called enhanced permeation and retention (EPR) effect, resulting in efficient accumulation in solid tumor tissues (*16*). Therefore, polymeric nanoparticles have been applied as effective multifunctional nanoparticles capable of enhancing the diagnostic and therapeutic efficacy of imaging probes and therapeutic agents in cancer treatment. This is due to the fact that polymeric nanoparticles exhibited ideal in vivo characteristics, such as biocompatibility and biodegradability, and prolonged circulation time the bloodstream. For example, Doiron et al. recently reported optical/T1 dual imaging agent based on PLGA which encapsulated Gd(III) and rhodamine (*17*). However, it did not describe biodistribution or in vivo tumor targeting. As an optical/T2 dual imaging agent, Yu et al prepared polymer-coated iron oxide nanoparticles with drug loading (*18*). Doxorubicin was used as an anticancer agent that exhibited fluorescence as an optical imaging agent. It efficiently targeted and showed antitumor effects in vivo. However, the imaging probe was still distributed in other major organs such as the liver.

Herein, we introduce tumor targeting chitosan nanoparticles for optical/MR dual imaging that was based on polymeric nanoparticle technology and molecular imaging. Previously, we have developed hydrophobically modified glycol chitosan nanoparticles (HGC) as novel nanosized drug carriers in cancer

treatment that can self-assemble in aqueous solution to form stable nanoparticles (*19*−*21*). Selective accumulation of HGC nanoparticles in the tumor interstitium by the EPR effect was exhibited when systemically administered to deliver various types of therapeutic agents (*19, 21*). To make new optical/MR dual imaging agents, we designed tumor targeting chitosan-based nanoparticles (CNPs) containing dual imaging agents (NIRF dye, Cy5.5 (*20*), and gadolinium (Gd(III)) ions) (*16, 22, 23*) (Scheme 1). The tumor targeting profile and cancer imaging potential of dual imaging probes of chitosan nanoparticles were evaluated in tumor-bearing mice.

To make optical/MR dual imaging nanoparticles biocompatible and water-soluble, glycol chitosan (GC, M_w = 50 kDa) was chemically modified with 5β-cholanic acid (CA) in the presence of EDC and NHS, which promoted amide linkage formation between the amine group of chitosan and carboxyl acid of CA, resulting in GC-CA (*24*−*26*). A colloidal titration method showed that GC-CA had an average molecular weight of 54 kDa, indicating that 11 ± 2 of CA molecules were chemically conjugated to GC (*20*). For the optical/MR dual-modal cancer imaging, 0.5 ± 0.1 of NIRF dye, monohydroxysuccinimide Cy5.5-NHS, was conjugated to GC-CA (Cy5.5-GC-CA). In order to chelate Gd(III) in the conjugates, monoreactive hydroxysuccinimide-DOTA was directly conjugated to the amine groups in the Cy5.5-GC-CA. The degrees of conjugation were in the range from 13 to 45, confirmed by ^{1}H NMR (Table 1). Finally, the excess of $GdCl_3$ was added to DOTA modified Cy5.5-GC-CA in distilled water (pH 5.5). After the reaction, EDTA tetrasodium salt was used to remove the unreacted Gd(III) ions. The weight ratio of Gd(III) in the conjugates was maximized to approximately 6 ± 0.28%, measured by energy dispersive spectroscopy (EDS) and inductively coupled plasma−atomic emission spectrometer (ICP-AES) (Table 1; see Supporting Information). In this study, maximum Gd(III) encapsulated Cy5.5-labled chitosan nanoparticles (Cy5.5-CNP-Gd(III); 6.28 wt %) were used to analyze their characteristics in vitro and in vivo.

Table 1. Characterization of the Weight Ratio of Gd(III) in CNPs

sample	Ds of DOTA[a]	wt (%) of Gd(III)	diameter (nm)
Cy5.5-CNPs	−	−	250 ± 18
Cy5.5-CNPs-[Gd(III)-2%]	13	2.39	260 ± 28
Cy5.5-CNPs-[Gd(III)-4%]	34	4.22	320 ± 35
Cy5.5-CNPs-[Gd(III)-6%]	45	6.28	350 ± 42

The dried Gd(III) encapsulated chitosan conjugates, when dissolved in aqueous solutions, spontaneously self-assembled into stable Cy5.5 labeled and Gd(III) encapsulated chitosan nanoparticles (Cy5.5-CNP-Gd(III)). Dynamic light scattering and transmission electron microscopy (TEM) analyses revealed that Cy5.5-CNP-Gd(III) were spherical and approximately 350 nm in size (Figure 1a). In phosphate buffered saline (PBS) at 37 °C, the Cy5.5-CNP-Gd(III) remained dispersed and maintained their original nanoparticle size for up to 40 days, indicating the excellent stability of nanoparticle probes in aqueous conditions (Figure 1b). Also, Cy5.5-CNP-Gd(III) were rapidly taken up within one hour by HeLa cells expressing a green fluorescence protein-tagged histone 2B (HeLa H2B-GFP), but free Cy5.5 molecules were not taken up by the cells within same time. Of note, most of the internalized particles were found in the cytoplasm (NIRF filter; red), not in the GFP-labeled nuclear compartment (FITC filter; green) (Figure 1c). This rapid cellular uptake characteristic of Cy5.5-CNP-Gd(III) facilitated delivery of anticancer drugs and imaging agents into the cytoplasmic compartment of target tumor cells. Moreover, Cy5.5-CNP-Gd(III) exhibited almost 100% of cell viability (Figure 1d), even at the relative high concentration up to 250 μg/mL.

To demonstrate the ability of Cy5.5-CNP-Gd(III) as an optical/MR dual-modal imaging probe, we obtained the NIRF

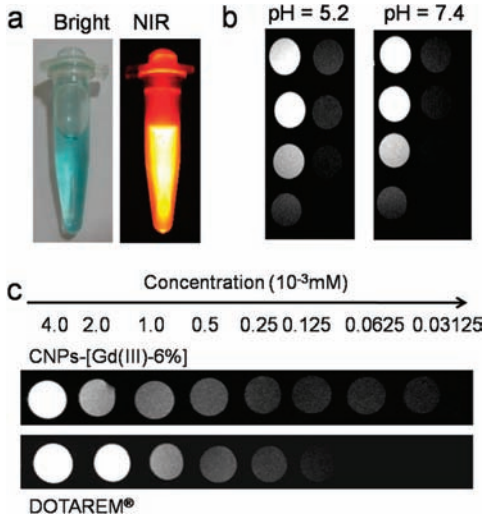

Figure 2. (a) Bright and NIRF images of the Cy5.5-CNP-Gd(III) in PBS. (b) T1-weighted spin−echo images of Cy5.5-CNP-Gd(III) in acidic (pH 5.2) and physiological condition (pH7.4). (c) T1-weighted spin−echo MR image (1.5T) showing bright MR signals of DOTEM and Cy5.5-CNP-Gd(III) in PBS.

optical and MR images from the optical or MR phantom test, respectively. Cy5.5-CNP-Gd(III) solution (1 mg/mL in PBS) produced a strong NIRF signal when we used a Cy5.5 filter set (Figure 2a), facilitating noninvasive imaging of the nanoparticles in live animals. The bright signal enhancement in the T1-weighted MR images revealed a progressive increase as the concentration of Cy5.5-CNP-Gd(III) increased. In particular, they showed the same T-1 weight MR image at the different pH conditions, indicating the stability of chelated Gd(III) ions in the nanoparticles (Figure 2b). As a comparison, we obtained MR images of commercialized MR contrast agent DOTAREM. The contrast efficiency of Cy5.5-CNP-Gd(III) was less than that of DOTAREM, at the higher Gd(III) concentration (>2.0 × 10^{-3} mM) (Figure 2c). It is deduced that the encapsulated Gd(III) in the hydrophobic inner part of nanoparticles decreased the

relaxivity of Gd(III), resulted in the reduction of accessibility in aqueous condition. Interestingly, it retained higher contrast signal at the lower concentration. This phantom study demonstrated the potential value of Cy5.5-CNP-Gd(III) as a contrast agent for optical and MR imaging, simultaneously.

We subsequently monitored the time-dependent in vivo biodistribution of Cy5.5-CNP-Gd(III) after intravenous injection into nude mice bearing pectoral subcutaneous murine squamous carcinoma cells (SCC7) tumors of about 8−10 mm in diameter by using Kodak Image Station; with a special C-mount lens and Cy5.5 bandpass emission filter (Figure 3a). Cy5.5-CNP-Gd(III)-treated mice (5 mg/kg) presented a strong NIRF signal throughout the whole body within 6 h of injection, indicating that the nanoparticles rapidly circulated in the bloodstream. From the NIRF optical images, we could delineate subcutaneous tumors from the surrounding background tissue at 6 h postinjection, and they exhibited a maximum NIRF signal beginning at 12 h postinjection. It should be noted that the tumors maintained this maximal NIRF intensity for 3 days, but the NIRF signal persisted for up to 5 days postinjection, with a gradual decrease in signal in the tumor. Of note, ex vivo NIRF images of excised tissues (liver, lung, kidney, heart, and the tumors) provided substantial evidence for the EPR effect-based tumor targeting ability of Cy5.5-CNP-Gd(III) in SCC7 tumor-bearing mice (Figure 3b) at 1 day postinjection of Cy5.5-CNP-Gd(III). The image revealed that Cy5.5-CNP-Gd(III) were mainly taken up by the tumor tissues, whereas their uptake in normal tissues was not significant. Furthermore, the NIRF total photon counts per gram of each organ from the tumor tissues were 3- to 7-fold higher than those from other organs, providing decisive evidence that Cy5.5-CNP-Gd(III) specifically targeted tumor tissues (Figure 3c). Via microscale images, Cy5.5-CNP-Gd(III) initially localized in the peripheral region of tumors after 6 h postinjection in mice, and the

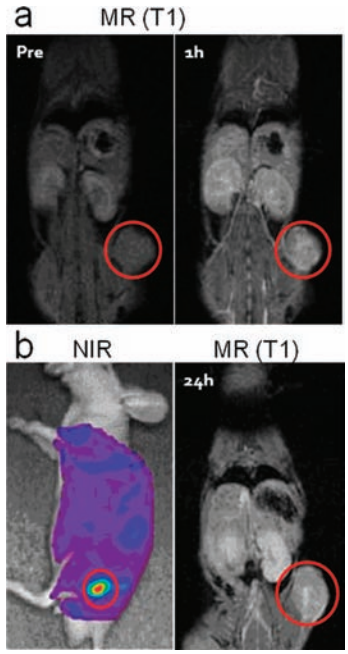

Figure 4. Tumor target specificity of Cy5.5-CNP-Gd(III) in SCC7 tumor-bearing mice (diameter = 8−10 mm). (a) Coronal slices of T1-weighted MR images of Cy5.5-CNP-Gd(III) in SCC7 tumor-bearing mice at 0 and 1 h postinjection. Red circles indicate that SCC-7 tumor tissue. (b) Both NIRF and T1-weighted MR images were simultaneously observed after 1 day postinjection of Cy5.5-CNP-Gd(III) (5 mg/kg).

maximum NIRF intensity was observed throughout the entire tumor after 12 h postinjection (Figure 3d). All images were reproducible and revealed the feasibility as a targeted optimal imaging probe for in vivo cases. On the basis of this imaging data, our glycol chitosan nanoparticles showed higher tumor homing ability in tumor-bearing mice. Until the exact mechanism of the higher tumor homing ability is completely evaluated, the unique characteristics of the glycol chitosan nanoparticles that we observed in vitro (i.e., stability in blood, deformability, and rapid cellular uptake) may have contributed significantly to their tumor targeting by the EPR effect in vivo (*19, 24*−*26*). Furthermore, when the Cy5.5-CNP-Gd(III) was injected into the tumor-bearing mice, it presented a prolonged blood lifetime, in which 50% glycol chitosan nanoparticles could circulate for 23 h, compared to free Cy5.5 (Supporting Information Figure SI1).

Next, we investigated whether optical/MR dual imaging could be used to detect tumor tissues in live animals. In SCC7 tumor-bearing mice (8−10 mm in diameter), both NIRF optical and MR imaging readily detected the inoculated tumor tissues after 1 day postinjection of Cy5.5-CNP-Gd(III) (5 mg/kg). First of all, MR imaging showed tumor tissues. In particular, coronal T1-weight MR images showed a high spatial resolution of tumor tissues after 1 day postinjection (Figure 4a). The clear margin of tumor tissue in soft tissue could be completely delineated by the bright T1-weight MR image, indicating the excellent nanoparticle accumulation at the tumor site. The relative signal enhancement (RSE, %) was calculated in the region of interests (ROIs) of the T1-weighted images. After 1 day postinjection of Cy5.5-CNP-Gd(III), the ROI value at tumor strongly increased from 70 to 162, compared to that of muscle (65 to 95). Noticeable brightening appeared at tumor with the RSE value of 231%, indicating the higher tumor targeting ability of glycol chitosan nanoparticles. However, the sensitivity was not higher compared to that of optical imaging. As we expected, NIRF imaging showed a strong and sensitive fluorescence image under explore Optix system, indicating high sensitivity of NIRF imaging, but the high-resolution histological and spatial image was not enough to clearly delineate the exact tumor site (Figure 4b). As NIRF optical imaging offers high sensitivity and the prospect of real-time intraoperative monitoring of tumor biopsy, on the other hand, MR imaging offers excellent spatial resolution and intrinsic soft-tissue contract. Thus, the combination of NIRF optical imaging and MR imaging for cancer imaging may overcome the limitations of either imaging method when used alone.

In conclusion, we prepared tumor targeting nanoparticles for optical/MR dual imaging that was based on self-assembled glycol chitosan nanoparticles. For the optical/MR dual imaging, Cy5.5 as NIRF and DOTA to chelate Gd(III) were directly conjugated in the chitosan conjugates. In tumor-bearing mice, Cy5.5-labeled and Gd(III) ion-chelated chitosan nanoparticles showed long and stable blood circulation characteristics, and they demonstrated excellent tumor targeting ability based on the EPR effects. More importantly, the combination of NIRF optical imaging and MR imaging for cancer imaging not only offered high sensitivity, but also presented excellent spatial resolution of target tumor tissue. Therefore, Cy5.5-CNP-Gd(III) has the potential to be used as optical/MR dual imaging agents for cancer imaging.

Received December 18, 2009; Revised Manuscript Received February 9, 2010

Quantum dots (QD) are inorganic nanocrystals with outstanding optical properties, specially suited for biological imaging applications. Their attachment to biomolecules in mild aqueous conditions for the design of bioconjugates is therefore highly desirable. 1,3-dipolar [3 + 2] cycloaddition between azides and terminal alkynes ("click chemistry") could represent an attractive QD functionalization method. Unfortunately, the use of the popular Cu(I)-catalyzed version of this reaction is not applicable for achieving this goal, since the presence of copper dramatically alters the luminescence properties of QD dispersions. We demonstrate here that copper-free click chemistry, between strained cyclooctyne functionalized QD and azido-biomolecules, leads to highly luminescent conjugates. In addition, we show that QD-cyclooctyne can be used at previously unreported low concentration (250 nM) for imaging the incorporation of azido-modified sialic acid in cell membrane glycoproteins.

Fluorescence imaging, from the cellular to the macroscopic range, is an invaluable tool to improve our knowledge of complex biological pathways, in particular, those not ruled by genomics, such as post-transcriptional modifications (e.g., phosphorylation, glycosylation). In the last ten years, inorganic semiconductor nanocrystals known as quantum dots (QD) have drawn attention as a potential alternative to classical organic fluorophores for imaging purposes (*1*−*3*). Their tunable, narrow, and symmetric emission band, long luminescence lifetime, and good photostability make them attractive objects for fluorescence in vitro diagnostics and in vivo imaging (*4*−*9*). Conjugation of QD with biomolecules such as antibodies, proteins, enzymes, DNA, and oligosaccharides is a prerequisite to their use as biological probes for fluorescence imaging. Therefore, the presence on QD surfaces of reactive moieties allowing further mild, selective, bioorthogonal, and water-compatible ligation with biomolecules, while keeping the outstanding optical properties of the nanoparticle, is of crucial importance. In this regard, Cu(I)-catalyzed 1,3-dipolar [3 + 2] cycloadditions between azides and terminal alkynes, considered by Sharpless "the cream of the crop" among "click" reactions that can be carried out in water (*10*−*13*), seems to be an attractive method for QD bioderivatization. Indeed, Cu(I) promoted click chemistry has been extensively used for the modification of numerous bio- or synthetic polymers (*14*−*18*) and capsules (*18*−*20*), as well as the functionalization of gold (*21*−*23*), silica (*24*), and iron oxide (*18, 25*−*27*) nanoparticles, as well as carbon nanotubes (*18, 24*). The selective and orthogonal reactivity of the azido and terminal alkyne groups has been used for the conjugation of a number of these materials with a wide range of synthetic molecules and biomolecules (peptides, proteins, enzymes, drugs, saccharides, dyes, organometallic compounds, and so forth) while keeping their functionalities (*22, 23, 25, 27, 28*). Moreover, the reaction leads to the formation of a very stable triazole linker, quantitatively, with a limited number of byproduct, and in mild conditions.

Quite surprisingly, however, the use of Cu(I) promoted click chemistry for QD functionalization has only been sparingly reported (*29*). This may be accounted for by the fact that a strong inhibition of the QD luminescence has been observed for bare CdS nanocrystals in the presence of copper ions (*29*−*31*). It has been proposed that isolated Cu^+ or ultrasmall Cu_xS (x = 1−2) aggregates form on the QD surface, inhibiting their emission properties (*30, 31*). Despite their poly(ethylene glycol) (PEG) organic coating and their protective inorganic ZnS shell, commercial CdSe/ZnS/PEG_{2000}-NH_2 QD (Invitrogen ITK 545 aminoPEG, noted as QD-amine **1**) used in this study also suffer a dramatic irreversible luminescence inhibition whenever incubated in the presence of $CuSO_4$/sodium ascorbate (NaAsc), the Cu(I) catalyst classically described for Huisgen cycloadditions in water (Figure 1). Two main mechanisms can account for the QD luminescence inhibition in the presence of copper, either (i) luminescence quenching due to nondestructive energy transfer or photoinduced electron transfer between the semiconductor nanomaterial and the Cu cations, which could actually be chelated by the PEG chains coating the nanoparticles; or (ii) chemical reaction between copper and the CdSe/ZnS particles themselves, leading to a partial or complete destruction of the core−shell structure responsible for the luminescence properties (reduction of the number of luminescent dots and/or their intrinsic luminescence intensity). In addition to the formation of Cu_xS aggregates on the surface of CdS nanocrystals (*30, 31*), rapidly occurring cation exchange altering the inner core structure of CdS and CdSe quantum dots has been reported (*32, 33*). In this latter case, the modification of the crystalline structure and shape of the small particles, accompanied by the modification of their optical properties, has been observed (*32, 33*). More thorough studies on the copper-induced luminescence inhibition mechanism of QD-amine **1** are in progress and will be detailed elsewhere. However, evidence supporting hypothesis (ii) has already appeared: (1) Energy and

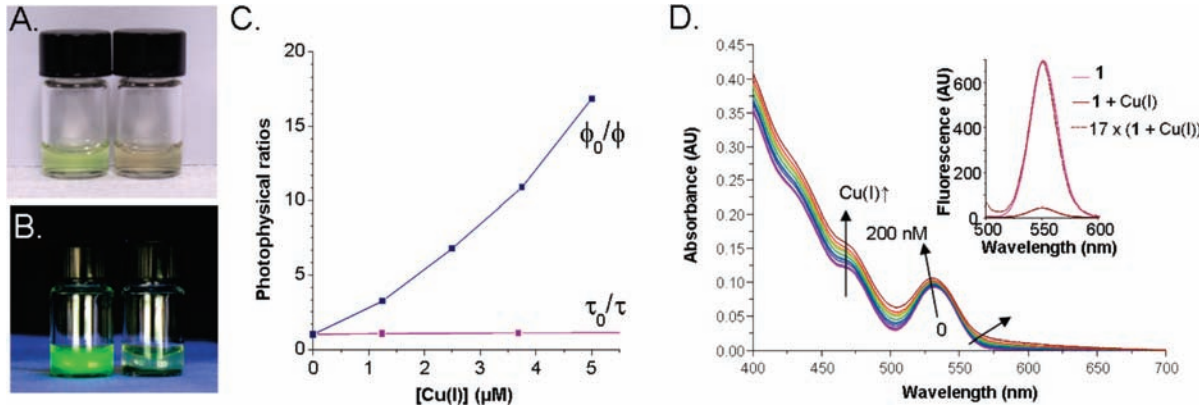

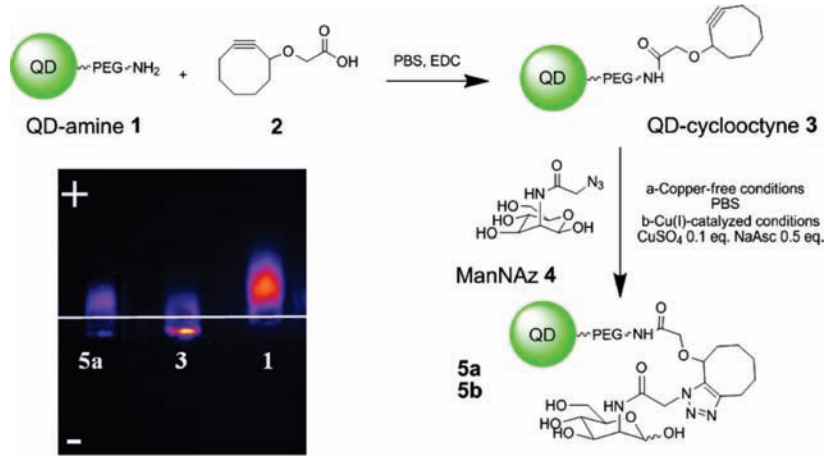

Figure 1. Cu-induced luminescence inhibition of QD-amine **1** (17 nM) in 1× PBS. (A,B) Photographs of the suspensions under white (A) and UV (B) light before (left) and after (right) NaAsc/$CuSO_4$ addition (25 μM). (C) Stern−Volmer plots depicting the luminescence inhibition of QD-amine **1**. Φ (respectively τ) is QD luminescence quantum yield (respectively luminescence lifetime). 0-subscript stands for values in the absence of Cu (I). (D) Absorption spectra of QD-amine **1** (17 nM) in the presence of increasing concentrations of Cu(I). Inset: luminescence spectra of QD-amine **1** (17 nM) in the absence and in the presence of 5 μM Cu(I).

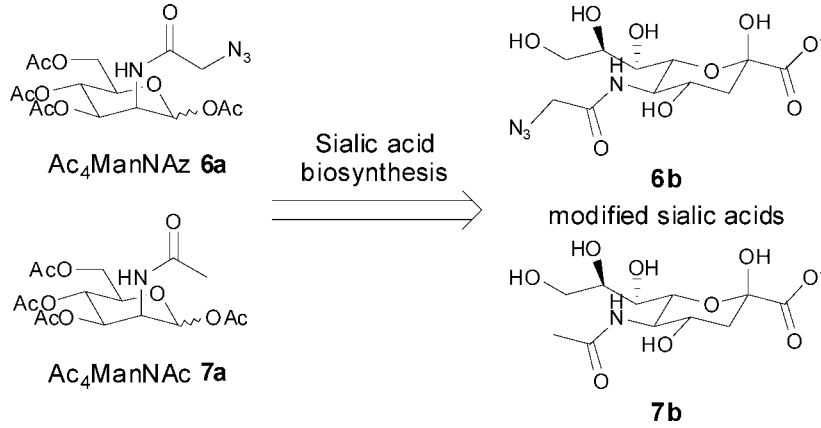
electron transfer has always been reported to affect both nanoparticle luminescence quantum yield (Φ) and lifetime (τ) (*34*−*36*). The Stern−Volmer plot Φ_0/Φ depicting the ratio of the luminescence quantum yield of QD-amine **1** before (Φ_0) and after (Φ) addition of Cu(I) solution (Figure 1) evidence strong luminescence inhibition (decrease by 50% for usual click conditions: 0.1 equiv Cu(I) per functional group). Moreover, even after five washes with PBS, which should have eliminated residual copper in solution or copper tied by weak interaction to the QD surface, Φ is not restored. The nature of the copper-related QD luminescence inhibition is further investigated by performing luminescence lifetime measurement. As already accounted for in the literature, CdSe dispersions observed as a macroscopic sample display multiexponential luminescence decays (*37, 38*). However, biexponential fit of the data most often provides a satisfactory description in order to account for QD luminescence quenching by electron or energy transfer (*34*−*36*). The luminescence decays in 1× PBS buffer of the core−shell CdSe/ZnS QD-amine **1** used in this study can indeed be satisfactorily fitted by biexponential decays, with a major "long" component $\tau \approx 20$ ns and a minor short-lived component (2.7 ns), both insensitive to copper concentration (see details in Supporting Information). Since only modifications of Φ and not τ are observed, it suggests that it is the number of emitting nanocrystals that is affected by copper addition, rather than the involvement of QD exciton interactions. (2) Cu(I) or Cu(II) solutions do not display absorption bands in the 500−600 nm range that would overlap with the absorption and emission spectra of the particles and induce energy transfer, and the redox potentials of the species involved should not lead to electron transfer according to the study reported by Mattoussi et al. (*36*). (3) Only slight spectral modifications are observed upon copper addition in quantum dot dispersion: 2 nm blue shift for the plasmon absorption band, in addition to a global increase of the solution absorbance (Figure 1). These spectral modifications are similar to those observed by Isarov et al. (*31*), who accounted them for by the formation of small Cu_xS aggregates on the nanocrystal surface. (4) The possible exchange of shell Zn^{2+} by Cu^{2+} cations is highly thermodynamically favorable due to the lower solubility of CuS ($K_s = 8 \times 10^{-37}$) in comparison to ZnS ($K_s = 2 \times 10^{-25}$ (wurtzite) to 3×10^{-23} (zinc blende)) (*39*), whereas the number of copper ions added in the solution is in the same range as those of zinc cations constituting the QD shell (calculated using 4 nm as the CdSe/ZnS diameter according to the supplier, and 2.7 nm diameter CdSe core according to the emission wavelength (*40*)). Moreover, the ionic diameter of Cu^{2+} (0.72 Å) is identical to that of Zn^{2+} (0.72 Å), and both ZnS and CuS can crystallize with a hexagonal structure, which should facilitate the exchange in the QD shell (*33, 39, 41*). The small size of the nanocrystals (4 nm total diameter, 2.7 nm core) means that only 5 to 6 atomic layers constitute the core−shell QD, which moreover display a high surface to volume ratio, which could account for an important solid reactivity (*33*).

If the presence of copper induces the irreversible formation of nonemissive nanocrystals with a different composition and structure than the starting QD particles, Cu(I) click chemistry cannot be used for the functionalization of these objects while preserving their inner structure integrity. Copper-free click reactions are therefore highly desirable for QD derivatization in biological media. The possibility to use the Bertozzi's modification of the 1,3-dipolar [3 + 2] cycloaddition between azides and alkynes, known as "copper-free click chemistry", has been investigated to achieve this goal (*42*−*47*). The principle of copper-free click chemistry relies on the use of cycle's strain, such as in the cyclooctyne moiety present in compounds **2** and **3** (Scheme 1), to replace the Cu(I) catalysis as the reaction's driving force. Moreover, copper-free click chemistry avoids the presence of the metallic cation, potentially toxic for living cells, the presence of which can therefore be restrictive for in vivo reactions (*43*). In order to investigate the impact of the functionalizing conditions (classical and copper-free click chemistry) on QD luminescence, QD-amine **1** are derivatized with cycloot-1-yn-3-glycolic acid **2** by EDC coupling to afford QD-cyclooctyne **3** after size exclusion chromatography (Scheme 1). QD-cyclooctyne **3** are then reacted with a DMSO solution of azido-tagged mannosamine (ManNAz **4**), a good model for further in vivo imaging studies, in the absence (leading to **5a**) or in the presence (leading to **5b**) of a "Cu-click buffer". After purification by size-exclusion chromatography, the success of the coupling reactions is qualitatively assessed by agarose gel electrophoresis (Scheme 1), since the migration pattern of the nanoparticles are dependent on the QD size, charge, and coating (*48*). QD functionalization is further evidenced by modification of the particle hydrodynamic diameter and zeta potential measured using dynamic light scattering in PBS buffer (Table 1). QD-amine **1** has an inner negative polymer coating, which is partly counterbalanced by the terminal protonated amino groups at the end of the PEG chains. Overall, the zeta potential of QD-amine **1** is slightly negative (−3.5 ± 5.6 mV), and particles migrate toward the positive pole in the gel (Scheme 1). Alkyne derivatization induces a negative shift of the zeta potential of QD-cyclooctyne **3** (−25.6 ± 7.6 mV), as surface positive ammonium groups of QD-amine **1** are replaced by

Scheme 1. Functionalization of QD Surface by Copper-Free (a) and Cu(I)-Catalyzed (b) Click Chemistries[a]



[a] Modifications of the QD surface are qualitatively assessed by electrophoretic migration of the particles on agarose gel.

nanoparticles	hydrodynamic diameter (nm)[a,b]	zeta potential (mV)[a,c]	absorption maximum (nm)[b]	emission maximum (nm)[b,d]	luminescence quantum yield[a,b,d]
QD-amine **1**	14.7 ± 0.4	−3.5 ± 5.6	530	552	100
QD-cyclooctyne **3**	9.6 ± 0.7	−25.6 ± 7.6	531	552	137 ± 14
5a	16.3 ± 2.0	−41.4 ± 2.1	530	551	127 ± 13
5b	16.9 ± 1.2	−39.5 ± 3.7	530	550	47 ± 5

[a] Standard deviation for three different measures. [b] Measures are performed in 1× PBS buffer (10 mM phosphate, 137 mM NaCl, pH 7.3). [c] Measures are carried out in 0.1× PBS buffer (1 mM phosphate, 13.7 mM NaCl, pH 7.3) in order to limit the buffer conductivity. Several peaks are observed in zeta potential analysis, even with commercial QD-amine **1**. The values indicated refer to the main peak (>65%). [d] Excitation at 488 nm.

Scheme 2. Cell Machinery Modification of Mannosamines Ac_4ManNAz 6a and Ac_4ManNAc 7a to Biosynthesize Sialic Acids 6b and 7b, Respectively

neutral alkyne groups. Interestingly, the hydrodynamic diameter of particles **3** (9.6 ± 0.7 nm) is reduced in comparison to that of QD-amine **1** (14.7 ± 0.4 nm), probably because the rather hydrophobic ending groups prefer to retract in the PEG chains of the QD-coating polymer than remain in aqueous solution. Moreover, QD-cyclooctyne **3** migrate in the agarose gel toward the negative pole. Such a migration pattern has already been reported for gold (*49*) and CdSeTe/ZnS (*50*) nanoparticles coated by poly(ethylene glycol) chains. It has been accounted for by the association of positively charged cations, such as sodium and potassium cations present in PBS or TBE buffer, with the ethyleneoxide motif (*51*). Therefore, PEG chains associated with positive charges would be the entities that appear on the particle surface for QD-cyclooctyne **3**, accounting for their electrophoretic migration toward the negative pole. As previously suggested for other quantum dot conjugates, gel migration orientation would be mainly governed by the charges on the external surface of the particles, whereas zeta potential might rather reflect the overall charges of the QDs (taking into account their inner negative charges) (*50*). ManNAz **4** grafting onto the QD **5a** and **5b** is evidenced by an important increase of the particle hydrodynamic diameter (∼16−17 nm) and a shift of the zeta potential (∼ −40 mV) (Table 1), along with an electrophoretic migration toward the positive pole. The presence of negative charges on the QD-ManNAz particles **5a** and **5b** might be due to the long-known reaction between carbohydrate diols and the borate ions of the electrophoresis buffer. Indeed, neutral carbohydrates are known to migrate toward the positive pole in such electrophoretic conditions (*52*). The two QD-ManNAz conjugates **5a** and **5b** display similar structural properties (size and zeta potential), regardless of the functionalization method used. In particular, the increase of the hydrodynamic diameter of the particles can certainly be attributed to the stretching of the highly hydrophilic PEG-saccharide chains in the aqueous phase. However, if alkyne derivatization does not alter the QD luminescence and integrity

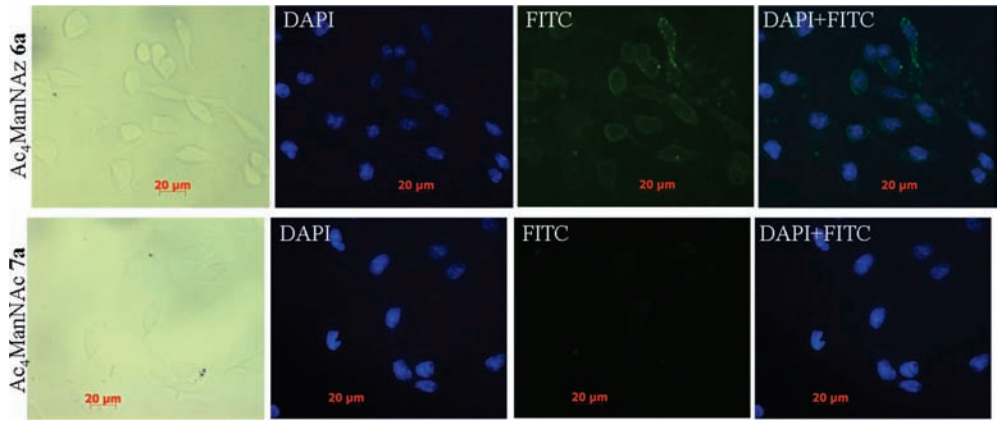

Figure 2. Fluorescence microscopy images of CHO cells treated with Ac_4ManNAz **6a** or Ac_4ManNAc **7a** (negative control) at 200 μM for 3 days, incubated with QD-cyclooctyne **3** (green) at 250 nM for 4 h at 4 °C, and fixed with paraformaldehyde 4%. Nuclei have been stained with DAPI (blue).

(QD-cyclooctyne **3** display even ~30% improved Φ in comparison to QD-amine **1**), the presence of copper for QD modified by classical click chemistry (conditions **b**) induces a loss of about half of the luminescence for the QD suspension (Table 1). Interestingly, copper-free click chemistry (conditions **a**) allows the modification of the QD surface with a high remaining luminescent quantum yield (Table 1). Strain-promoted Huisgens cycloaddition thus appears as a method of choice for the functionalization of QD using such a bioorthogonal and biocompatible "click" reaction.

To outline the interest of QD modified by cyclooctynes for biological applications, the possibility to use QD-cyclooctyne **3** for the in vivo imaging of the metabolic incorporation of sialic acids on cell membrane glycoconjugates is investigated. The development of new fluorescent tools for the in vivo imaging of the biosynthesis of glycoconjugates is of tremendous interest. The modification of cell surface glycosylation is a common phenotypic change that occurs in a number of pathologies, including carcinogenesis (*53*−*55*). It mainly affects the outer part of the carbohydrate moiety of glycoproteins and glycolipids, leading to the expression of tumor associated carbohydrate antigens (TACA). Most of TACA are sialylated and the expression of TACA such as sialyl-Lewis^x or sialyl-Tn is usually linked to tumor aggressiveness (*56, 57*). Acetylated azidomannosamine Ac_4ManNAz **6a** (or peracetylated mannosamine Ac_4ManNAc **7a** used as a negative control) is incubated with CHO (Chinese Hamster Ovary) cells for incorporation in membrane glycoconjugates via a metabolic savage pathway (*58*). Acetylated Ac_4ManNAz **6a** is used instead of ManNAz **4**, since acetylation allows for a better cellular internalization and incorporation in glycoconjugates (*59*). Briefly, cells treated with Ac_4ManNAz **6a** (200 μM) or with Ac_4ManNAc **7a** (200 μM) for 3 days metabolize the mannosamine moiety into sialic acids **6b** and **7b**, which can subsequently be used by the cell machinery and be incorporated in the newly synthesized glycoproteins exposed on the cell membrane (Scheme 2) (*60*). The incorporation of the azido-modified metabolite **6b** transferred to the cell's membrane epitope is revealed using copper-free click chemistry with QD-cyclooctyne **3** as labeling agent (incubation at 250 nM for 4 h at 4 °C, to avoid particle endocytosis). Epi-fluorescence microscopy images are recorded and are displayed in Figure 2. Cell membranes are clearly labeled by the QD conjugate **3** when CHO cells have been incubated with Ac_4ManNAz **6a**, contrary to the negative control Ac_4ManNAc **7a** for which no background signal is detected, indicating the absence of QD agglomeration or precipitation at the cell surface. The low photobleaching rate of QD under microscopic illumination, as well as the multimeric presentation of cyclooctyne moieties on their surface, could account for the improved detection sensitivity (250 nM of QD-cyclooctyne **3**) in comparison to other organic dye based probes, used at >50 μM concentrations (*43*). The copper-free click reaction is therefore successfully performed in biological media and allows labeling with QD at submicromolar concentrations with a good signal/noise ratio.

We have demonstrated that copper-free click chemistry offers a great opportunity for QD facile bioorthogonal derivatization, while bypassing the luminescence inhibition of the particles observed in the presence of Cu(I), the catalyst classically used for alcyne-azide conjugation. Because of their excellent optical properties in general, and their reduced photobleaching rate during microscopic observations in particular, QD modified by cyclooctyne groups prove to be an interesting alternative to organic fluorescent probes usually used for in vivo metabolic imaging (*43*). Numerous other applications, especially in the field of biology, can be envisioned using this new functionalization process of QD, taking benefit of both the outstanding optical properties of the nanocrystals as labeling agents and the versatile chemistry of copper-free azido/constraint alkyne cycloaddition that circumvent the impossibility of using the popular Cu(I)-catalyzed version of this reaction.

ACKNOWLEDGMENT

We acknowledge Peter Reiss (CEA, INAC) for fruitful discussion of the results. This work is supported by the Commissariat à l'Energie Atomique, France, through the "Technologies pour la santé'" program (TIMOMA2).

Received June 24, 2009; Revised Manuscript Received December 15, 2009

Neogalactosylated and neolactosylated albumins are currently used as radiopharmaceutical agents for imaging the liver asialoglycoprotein receptors, which allows the quantification of hepatic liver function in various diseases and also in healthy liver transplant donors. We developed an original process for synthesizing a chelating neolactosylated human albumin using maleimidopropyl-lactose and maleimidopropyl-diethylene triamine pentaacetic acid (DTPA) derivatives. The lactosylated protein (LACTAL) conjugate showed excellent liver uptake compared to nonlactosylated protein and a very high signal-to-noise ratio, based on functional assessment of biodistribution in mice using ^{99m}Tc-scintigraphy.

INTRODUCTION

The evaluation of hepatic function is required to determine the physiological status of the liver, particularly for patients with liver disease whose treatment of choice is hepatectomy or liver transplantation (*1*). Therefore, determination of the hepatic function is crucial to predict patient outcome before and after hepatectomy or liver transplantation (*2*), as well as for healthy liver donor assessment. Asialoglycoproteins are internalized into hepatocytes via the asialoglycoprotein receptors which recognize galactose and *N*-acetyl-galactosamine moieties bound to proteins. The number of asialoglycoprotein receptors on the hepatocytes of patients with liver disease is reduced and is thus considered a good indicator for the evaluation of liver function (*3, 4*). In addition, noninvasive quantification of the liver uptake of radiolabeled asialoglycoproteins also provides useful information, especially in terms of spatial distribution of hepatic function. The asialoglycoprotein receptors are localized mainly on liver parenchymal cells (*5*) and play a major role in the hepatic clearance of serum proteins (*6*). Most of the receptors (90%) are located on sinusoidal faces of hepatocytes with only 10% on lateral faces (*7*). Non-hepatic cells such as endothelial and Kupffer cells have no or few asialoglycoprotein receptors (*8*), and hepatocytes are the most represented cells in the liver. Therefore, targeting the asialoglycoprotein receptors results in targeting mainly hepatocytes.

The measurement of the hepatic functional reserve by kinetic studies of liver binding and blood clearance of galactosylated ligands to the asialoglycoprotein receptors is validated and directly reflects the number of functional hepatocytes (*9, 10*). Quite a few reports of procedures for the preparation of a modified human serum albumin (HSA) have been described for use as a liver radiopharmaceutical agent (*11*−*14*). For instance, de Graaf et al. (*11*) recently showed that ^{99m}Tc-DTPA-galactosylalbumin (^{99m}Tc-GSA) scintigraphy combined with SPECT (single photon emission computed tomography) is a feasible noninvasive method to assess hepatic functional volume in normal rat liver, as well as during liver regeneration in a rat model with partial hepatectomy. However, these procedures have a number of limitations: long reaction times, reduction of structural disulfide bonds, alterations of the neat charge of the protein, or reactions involving toxic reagents such as sodium cyanoborohydride for reductive amination. Therefore, the aim of our study was to develop an alternate process to prepare a DTPA-lactosyl albumin (LACTAL), using a quick single-step reaction involving maleimido-derivatized reagents, and perform preclinical studies to validate its use as a radiopharmaceutical for liver function imaging (*15*).

MATERIAL AND METHODS

Material. Chemical reagents were obtained from Sigma-Aldrich company, and solvents from SDS (France). 4-Nitrophenylcarbonate Wang resin was obtained from Novabiochem. 3-(Maleimido) propionic acid *N*-hydroxysuccinimide ester and lactosylamine were obtained using described procedures (*16, 17*). Human serum albumin compliant with European safety regulations was purchased from LFB (France) as a 40 mg/mL solution in normal saline (Vialebex). Vasculocis (i.e., ^{99m}Tc human albumin) was obtained from Cisbio IBA (France). Disposable aseptic 0.22 μm filters were purchased from Millipore Company. The ^{99}Mo/^{99m}Tc-generators were purchased from Mallinckrodt Company. The ITLC SG plates were purchased from PALL Corporation (France). Tin salts were purchased from Sigma-Aldrich Company (99.995% purity). Bicinchonic acid assay for protein quantitation was purchased from Pierce by Perbio Scientific. Quantichrom Calcium Assay Kit for DTPA determination was from Gentaur (Belgium). Grafting on HSA, preparation of the ready to use mixture with $SnCl_2$, and lyophilization were performed under sterile conditions. Analyti-

cal HPLC was performed on a Merck-Hitachi gradient pump equipped with a L-6200A intelligent pump and a UV−visible detector L-4000 Merck. Electrophoresis of proteins was performed on NuPage 10% Bis-Tris Gel from InVitrogen.

1-(β-D-Lactosyl)-3-maleimidopropionamide or Maleimidopropyl-Lactose (1). β-D-lactosylamine (100 mg; 0.25 mmol, ref *16*) was dissolved in DMF (2 mL), 3-(maleimido)propionic acid *N*-hydroxysuccinimide ester (73 mg; 0.28 mmol) was added and the mixture was stirred overnight at room temperature. The reaction medium was evaporated and the residue precipitated in acetone. The white solid obtained by centrifugation was washed several times with acetone and dried to give **1** (73 mg; 60%). This product is hygroscopic and should be stored accordingly. Anal. Calcd for $C_{19}H_{28}N_2O_{13}$; H_2O: C 44.70, H 5.88, N 5.49. Found: C 44.24, H 6.08, N 4.88.

{Carboxymethyl-[2-(carboxymethyl-{2-[carboxymethyl-({2-[3-(2,5-dioxo-2,5-dihydro-pyrrol-1-yl)-propionylamino]-ethylcarbamoyl}-methyl)-amino]-ethyl}-amino)-ethyl]-amino}-acetic acid or Maleimidopropyl-DTPA (3). 4-Nitrophenyl carbonate Wang resin (1 g; 0.54 mmol/g) was swollen in *N*-methylpyrrolidone (NMP) and ethylenediamine was added in excess (0.36 mL; 10 equiv). It was left under gentle shaking overnight. It was then thoroughly rinsed with NMP and a solution of diethylene triamine pentacetic dianhydride (1.9 g; 5.4 mmol; 10 equiv) in NMP (20 mL) was added, followed by triethylamine (0.8 mL; 10 equiv). The suspension was shaken overnight. The resin was washed with NMP (3 × 10 mL), H_2O (1 × 10 mL; contact 30 min), absolute ethanol (3 × 10 mL), and ether (2 × 10 mL), and dried in air.

A solution of trifluoroacetic acid (TFA) (9 mL), H_2O (1 mL), and triisopropyl silane (200 μL) was added to the dry resin and allowed to react 3 h at 30 °C. The eluate was concentrated and the residue washed with ether to give (**2**) as a white powder (0.268 g; 84% crude).

The powder was dissolved in DMSO (1 mL), then 3-(maleimido)propionic acid *N*-hydroxysuccinimide ester (0.14 g; 1.1 equiv) and triethylamine (0.14 mL; 2 equiv) were added. The mixture was left at room temperature overnight then diluted with ethyl acetate to induce precipitation. The precipitate was centrifuged, rinsed with ethyl acetate and ether, and dried to give **3** (0.16 g; 51% overall yield; hygroscopic). MS: *m/z* 587. ^{1}H NMR (400 MHz, DMSO, δ ppm): 7.28 (s, 2H), 4.55 (m, 2H), 4.40−4.10 (m, 7H), 3.86−3.57 (m, 9H), 3.15 (m, 2H), 2.92 (m, 2H). ^{13}C NMR (100 MHz, D_2O, δ ppm MeOH): 176.72; 174.00; 172.77; 170.6; 134.65; 57.59; 57.36; 57.29; 57.11; 52.10; 51.35; 38.88; 38.67; 34.87; 34.60. Anal. Calcd for $C_{23}H_{34}N_6O_{12}$; H_2O: C 45.69, H 5.96, N 13.90. Found C 45.59, H 5.74, N 13.30.

LACTAL Synthesis. Instruments and solutions were sterilized using a Getinge Vertical Sterilizer AVOR 130. Buffer was degassed by sonication in a US cleaning bath (Branson 1510). Iminothiolane (6 mg, 64 μmol in 200 μL PBS/EDTA 5 mM pH 7.8), maleimido-propyl-lactose (3.3 mg, 6.8 μmol in 100 μL PBS/EDTA 5 mM), and buffered maleimido-propyl-DTPA (2 mg, 3.4 μmol in 100 μL PBS/EDTA 5 mM) were added to the solution of HSA (100 μL, 4 mg, 59 nmol, 3.2 μmol NH_2). All components were gently mixed during 1 h at room temperature. Then, the mixture was diluted to 4 mL with NaCl 0.9% (degassed with N_2 and filtered under 0.22 μm) and transferred to a centrifuge ultrafiltration system with a molecular weight cutoff of 30 kDa. The mixture was centrifuged at 4000 rpm (3000 *g*) during 10 min, until the filtrate did not contain any DTPA. The absence of residual DTPA reagent was controlled by taking a sample of the filtrate (180 μL) and adding an excess of $EuCl_3$, $6H_2O$ (20 μL, 1 g/L). Measurement of the europium signal by time-resolved fluorescence at 616 nm with a spectrofluorimeter (Victor2, Perkin-Elmer) indicated the diminution of the DTPA content as washes proceeded.

The total protein amount recovered from the experiment was quantified by the BCA reagent. The modified HSA (10 μL of a solution estimated to be at 1 mg/mL) was mixed with 200 μL of the BCA reagent and incubated for 30 min at 37 °C. The concentration was obtained from a standard concentration range of unmodified HSA taken at 562 nm. 98 ± 1% of protein was recovered from the process.

The amount of lactose coupled to the protein was determined by the method of Dubois (*18*). The modified HSA (10 μL, 1 mg/mL) was introduced in a glass vial, then phenol (5% in water, 190 μL) and concentrated sulfuric acid (200 μL) were added. The vial was heated at 90 °C during 5 min then left to cool down at room temperature. Measurements were done at 490 nm; the concentration was calculated from a standard concentration range of lactose and indicated 30 ± 3 lactose/HSA (mol/mol).

The amount of DTPA coupled to the protein was determined by the Quantichrom Calcium Assay Kit (Gentaur). The modified HSA (100 μL, 1 mg/mL) was introduced in a 1 mL cuvette, then $CaCl_2$ (20 μL, 1 M) was added, and the volume was completed with 500 μL of the calcium working solution provided by the kit. After 3 min, the optical density was measured at 612 nm giving the free calcium concentration from which the amount of DTPA could be deduced. 5 ± 1 DTPA/HSA (mol/mol) was found.

The modified and unmodified albumin were analyzed by HPLC using a Vydac column C4−214TP5415 (4.6 mm × 150 mm) (Interchim, Montluçon, France), eluted with a gradient from 90/10 A/B to 10/90 A/B during 20 min with a flow rate of 1 mL/min (solvent A: H_2O + 0.1% TFA, solvent B: acetonitrile) and detection at 220 nm. HSA elution time: 12.1 ± 0.1 min. LACTAL elution time: 11.8 ± 0.1 min. (Despite the small difference in elution time, a shoulder was clearly observed when a mixture of the two compounds were injected.) Electrophoresis (MOPS buffer, 150 V) was performed with LACTAL and HSA and compared with the SeeBlue Plus2 Pre-Stained Standard (Invitrogen, 4−250 kDa). The modified protein appeared as a single band. The estimated mass for LACTAL was 93 kDa, which corresponded to 29 lactose units and 5 DTPA (Figure 1).

Preparation of LACTAL Lyophilisate and Labeling. The pH of a modified protein solution (500 μL, 15 mg/mL) was carefully adjusted to 1.5 with HCl 1 N, then a solution of stannous chloride in HCl 1 N (10 mg/mL, 20 μL, 28 μg/mg protein) was added and the mixture was left 20 min protected from light at room temperature. The volume was adjusted to 1 mL and aliquoted in 5 × 2 mL serum vials (200 μL, 1.44 mg/vial), frozen in liquid nitrogen, and lyophilized. The system was then equilibrated to atmospheric pressure by nitrogen. The vials were sealed under nitrogen using a glovebox.

The lyophilized product was redissolved in NaCl solution (0.9%; 1 mL). A saline solution of ^{99m}Tc (pertechnetate) freshly eluted from a ^{99}Mb generator was added (5−7 × 10^6 Bq/200 μg prot), and the mixture was incubated for 30 min at 50 °C. Radio-TLC chromatograms were obtained using a BIOSCAN Miniscan system. The radiochemical purity was checked using ITLC methods to determine the amounts of unbound and hydrolyzed ^{99m}Tc. ITLC/Umezawa (ethanol/10% ammonium

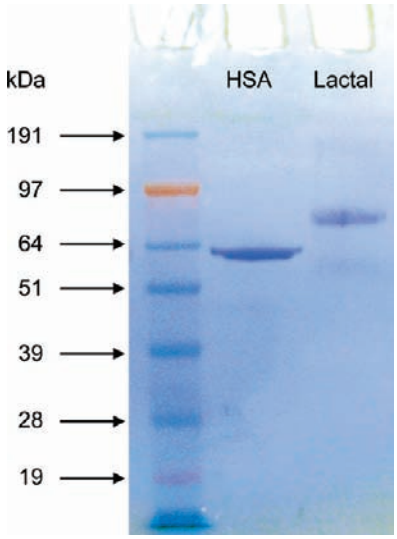

Figure 1. Gel electrophoresis of HSA and LACTAL with the Invitrogen NuPAGE Novex kit (MOPS buffer, 150 V).

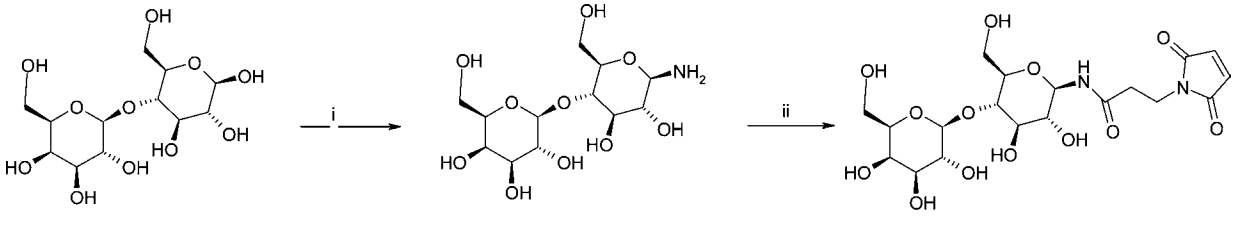
acetate = 1:1) was used to check the labeling efficiencies. Unbound ^{99m}Tc moved to the solvent front, and LACTAL-bound ^{99m}Tc stayed at the origin on ITLC/Umezawa. The solution of ^{99m}Tc-LACTAL was stable at room temperature for 20 h.

Biodistribution Studies. A gamma scintillation counter Wizard 1480 automatic model from Perkin-Elmer Company was used for counting radioactivity of mouse organs in biodistribution studies. Male mice (26−28 g) were injected via the tail vein with 0.55 MBq of ^{99m}Tc-labeled ligand. Animals were anesthetized and sacrificed at planned time-points (three per time point; 10, 30, and 90 min). Blood and organ samples (heart, blood, kidney, spleen, lung, and liver) were collected, weighed with an electronic balance, and counted in a gamma scintillation counter.

In Vivo Imaging Studies. A small-animal dedicated gamma camera from BIOSPACE Lab (France) equipped with a low-energy high-resolution parallel collimator was used for imaging rats (field of view: 8 cm). Following anesthesia with pentobarbital, male Wistar rats (n = 9, 220−240 g) were injected intravenously through the penis vein with 200 μL of tracer (5−10 MBq). The rats were then placed on their back on the gamma camera where posterior planar acquisitions were recorded.

RESULTS

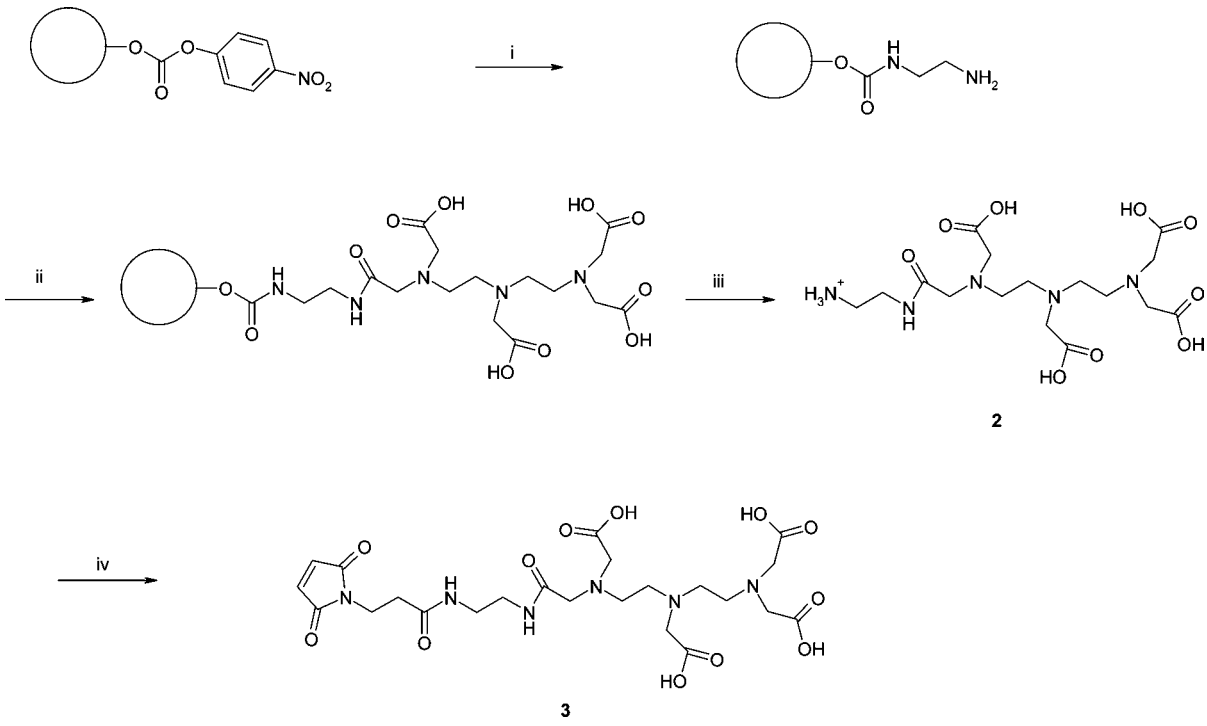
Synthesis of the Maleimidopropyl-Lactose. D-Lactose was first reacted with ammonium carbamate in methanol/water to give the carbamate salt of the amino-lactoside which was treated just before use with triethylamine to give the 1-aminosugar as described in the literature (*16*). This product was reacted with 3-(maleimido)-propionic acid *N*-hydroxysuccinimide ester (*17*) to give the final maleimidopropyl-lactose **1** (Scheme 1). This product could be stored for months at 4 °C in dry atmosphere.



Synthesis of the Maleimidopropyl-DTPA. For a better regioselective reaction of the multifunctional DTPA, we developed a solid-phase synthesis (Scheme 2). 4-Nitrophenylcarbonate Wang resin was reacted with excess ethylene diamine in NMP. The reaction progress could be monitored in UV by the release of 4-nitrophenol (410 nm). After thorough washings, DTPA anhydride was added in excess and the mixture swirled for 1 h. End of reaction was monitored by negative Kaiser and TNBS tests. Successive washings with NMP, water, methanol, and diethyl ether were performed to eliminate the excess of DTPA, hydrolyze the remaining anhydride function, and dry the resin. The resin was dried in air, and a mixture of trifluoroacetic acid/water/triisopropylsilane was added as a degrafting reagent. The solution was thoroughly evaporated to give pure ethylenediamine-DTPA (**2**) which was condensed without further purification with 3-(maleimido)-propionic acid *N*-hydroxysuccinimide ester to give maleimidopropyl-DTPA (**3**).

Synthesis of the Modified Albumin (LACTAL). In preliminary studies, the modified protein was prepared in two separated steps: first, introduction of the thiol functions with iminothiolane (*19*), then addition of the maleimido-lactose (**1**) and maleimido-DTPA (**3**). This allowed quantitation of the intermediate thiol groups with the Ellman reagent. However, this first step was unreliable, leading to unreproducible amounts of thiol groups which was probably due to rearrangement of the iminothiolane moiety with time (*20*) or oxidation. The protocol was then modified to a single-step process (Scheme 3). The successive addition of iminothiolane, lactose, and DTPA derived maleimide compounds allowed achieving the reproducible HSA modification. The lactose and DTPA derivatives (**1** and **3**) were introduced on the ε-amino groups of the protein lysines without significant changes in the ionic balance of the protein (*21*); the presence of EDTA avoided thiol oxidation. There was no evidence in favor of the formation of aggregates which could induce changes in surface properties of the protein molecule.

Stability of the Solution and of the Lyophilisate. Stability of the solution of LACTAL was checked after a one-year storage at 4 °C and 32 months for the lyophilized kit. There were no differences from freshly prepared material, no aggregates were observed, and the imaging properties were identical.



In Vivo Imaging in Rats. The biodistribution of the tracer was studied through the completion of an acquisition in list mode over an extended period up to 2 h in some rats. Figure 2 shows a sequence of 15 dynamic images of 2 min each, corresponding to the first 30 min post iv administration. Just after injection, the distribution of LACTAL resembled an intravascular tracer and the anatomical regions showing high activity at this stage corresponded to highly vascularized organs. Then, the images highlighted an early and predominantly hepatic uptake with a plateau that was reached between 2−6 min and continued for

Scheme 3. One-Step Preparation of LACTAL: Human Serum Albumin Modified by Simultaneous Introduction of Maleimidopropyl-Lactose and -DTPA Derivatives

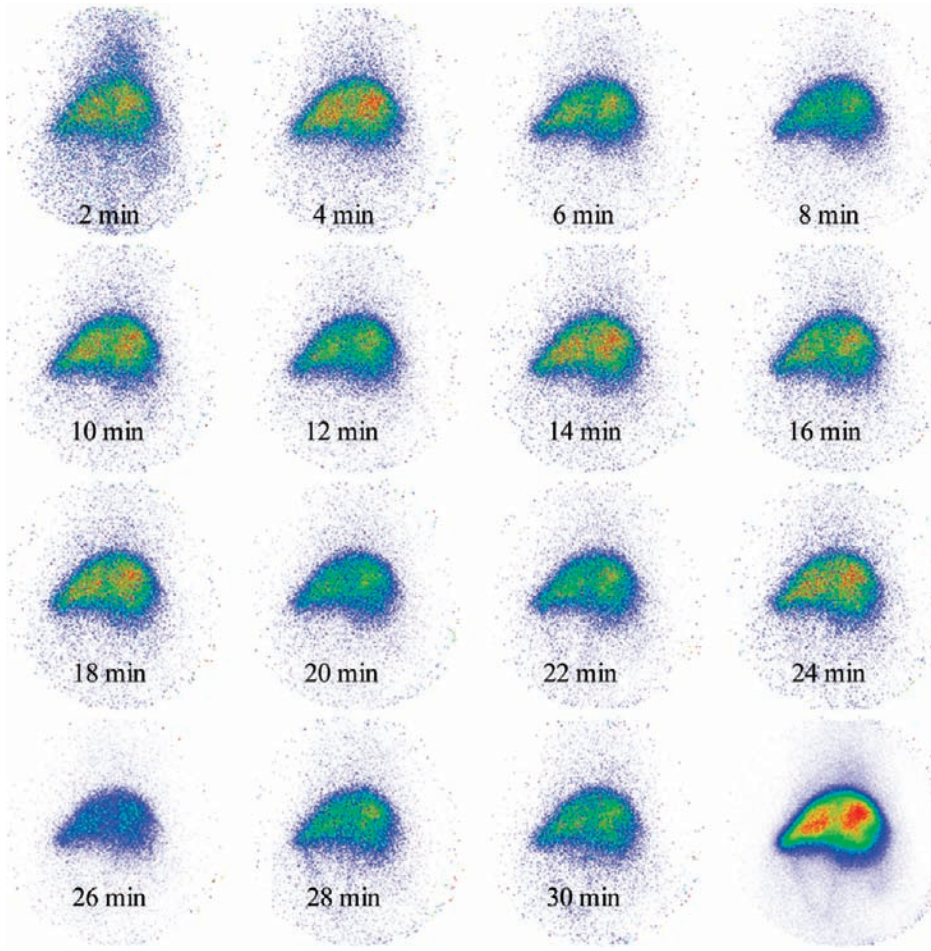

Figure 2. Posterior planar scintigraphic acquisition was started immediately after intravenous injection of 200 μL of ^{99m}Tc labeled LACTAL (5−10 MBq). List-mode data were acquired for at least 30 min for all animals. Using Biospace software, the list-mode data were reformated into fifteen 2 min frames. The last image on the bottom right is a summed image (0−30 min).

at least 20 min in this animal species. After 30 min, the liver uptake began to decrease, and analysis of dynamic images such as those in Figure 3 (12 images of 5 min each between 30 and 90 min after iv injection) referred to a disposal of the product by the bile ducts. An important passage in the gastrointestinal tract most likely in the form of degradation products was also visible. The last picture showed predominant radioactivity in the digestive tube and some traces in the bladder indicating the modes of degradation and elimination of the tracer.

Biodistribution in Mice. The biodistribution of LACTAL in mice is illustrated in Table 1. The activities were measured in different organs and expressed as the percentage of the injected dose per gram of organ. Non-lactosylated ^{99m}Tc human serum albumin (Vascolucis) was used as a control. The biodistribution data confirmed the results of the visual analysis of scintigraphic acquisitions. The liver uptake was very early and intense. Splenic fixation was much lower, confirming the specificity of the radiolabeled molecule for ASGP hepatic receptors. Blood levels were very low after 10 min reflecting the very high plasma clearance; a slight rise to late time is likely to reflect intrahepatic degradation of the tracer leading to release of ^{99m}Tc labeled catabolites in the bloodstream. Contrary to what was observed with LACTAL, the activity in hepatic tissue of the control (Vascolucis) one hour after the injection was much lower than the blood activity. These results are consistent with the fact that this tracer remains mainly in the intravascular compartment (Table 1).

DISCUSSION

Although the indocyanine green clearance test is widely used to assess the hepatic functional reserve before hepatectomy, discrepancies between indocyanine green clearance values and histological observations in the liver are noted in given instances. Volumetric measurements may not be relevant in patients with advanced chronic liver disease requiring major liver resection (*22*). In a similar way, iminodiacetic acid ^{99m}Tc labeled derivatives are good tracers of the hepatic biliary clearance and are mostly dedicated to the diagnosis of gall bladder dysfunctions by cholescintigraphy (*23*). These tracers are not specifically targeted to the asialoglycoprotein receptors.

Previously reported work indicated that the measurement of the hepatic functional reserve could be very useful before hepatectomy as well as for the evaluation of the post-transplantation residual hepatic functional reserve in donors. It could also be useful for the follow-up and functional prognosis of the hepatic graft, staging, and preoperative evaluation. Furthermore, a precise assessment of functional hepatic reserve would also be useful for the follow-up and prognosis of hepatic function in cirrhotic patients, the evaluation of surgical resection extension in patients with hepatocellular carcinoma, and prognosis in acute hepatitis. The preoperative estimation of the maximal removal rate of ^{99m}Tc GSA radioligand in the predicted liver remnant has proved useful for determining the hepatectomy procedure (*24*).

There are at least 5 different glycosylated tracers identified, based on a literature search. ^{99m}Tc-Galactosyl-neoglycoalbumin

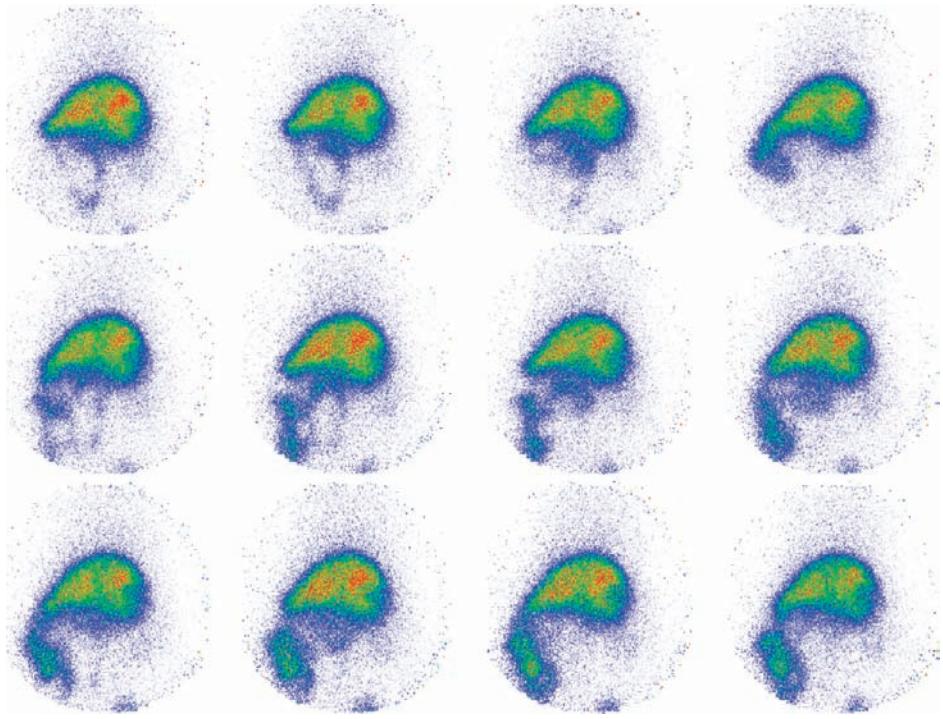

Figure 3. Posterior planar scintigraphic acquisition was performed between 30 and 90 min after intravenous injection of 200 μL of ^{99m}Tc labeled LACTAL (5−10 MBq). Using Biospace software, the list-mode data were reformated into twelve 5 min dynamic frames.

[a] Results were expressed as the percentage of injected dose per gram of organ (% of ID/g of organ) at the different times.

(^{99m}Tc-NGA) was prepared by the covalent coupling of 2-imino-2-ethyloxymethyl-1-thiogalactose to human serum albumin (*13*) (about 24 galactose units per albumin molecule). Labeling of this compound with ^{99m}Tc was achieved by an electrolytic method. Biodistribution studies in rabbits demonstrated that the liver is the only site with ^{99m}Tc-NGA uptake (*25*). As for ^{99m}Tc-GSA (*11*), preclinical studies demonstrated its diagnostic efficiency, the safety and the stability of ^{99m}Tc-NGA, but the labeling method is difficult to implement in most clinical departments. This is why a diethylenetriaminepentaacetic acid conjugated neogalactosylated albumin was developed later on (*26*). The reaction is very quick and yields HSA derivatives containing 4.5 to 7 DTPA per mole of protein. The combination of galactosylated albumin to DTPA enabled the production of an instant kit (*27*). Numerous publications are available concerning the use of this radiopharmaceutical, which is distributed only in Japan and not commercially available in European countries. Besides, the chemical process for synthesis is a derivatization with cyanomethyl-thiogalactose which may lead to toxic byproduct.

^{67}Ga-desferoxamine-galactosyl-neoglycoalbumin (^{67}Ga-DF-NGA) is a galactosylated human serum albumin molecule. It is similar to NGA, as described above except for a covalent coupling of a desferoxamin molecule. Thus, DF-NGA indirectly binds to ^{67}Ga. This radiomarker has demonstrated high liver uptake in rabbits, but it has never been administered to humans (*14*). ^{99m}Tc-Neolactosylated-albumin (^{99m}Tc-LSA) is the only glycosylated human albumin synthesized by conjugating lactose to HSA using a reductive amination process (*12*). However, the use of sodium cyanoborohydride in this reaction is questionable for human use. Direct labeling with ^{99m}Tc was possible due to the adjunction of medronate and stannous chloride to the reduced LSA.

We have developed a new synthetic process for a lactosylated albumin which involves a simultaneous set of reactions with the protein. Thiol functions were generated by reaction of iminothiolane with the ε-amines of lysines, in the presence of the maleimides derivatives (lactose and DTPA). This avoided the formation of byproduct induced by the rearrangement of the iminothiol moiety (*20*) or by oxidation. The same conjugation chemistry was used for the introduction of both the ligand (lactose) and the cryptant (DTPA), leading to reliable and reproducible results and the control of the two entity ratio.

This new process involved five simple steps: (1) synthesis of a maleimide derivative of the targeting ligand (in the example, lactose) and of a technetium chelate (diethylene triamine pentaacetic acid, DTPA); (2) introduction of thiol functions by reaction of iminothiolane on the ε-amino groups of the protein lysines and simultaneous covalent grafting of the ligand and chelate moieties on the protein carrier (this smoothly provided functionalization without significant changes in the ionic balance of the protein (*21*)); (3) purification of the modified protein by ultrafiltration; (4) lyophilization after addition of the correct amount of stannous chloride (for technetium reduction); (5) prior to injection, association with technetium or another radioligand or contrast agent by chelation. This chemistry can easily be

adapted to the conjugation of many other ligands, including sugars, peptides or vitamins, and other markers can be introduced into the DTPA cryptants for other modes of detection (i.e., magnetic resonance imaging or fluorescence). Furthermore, the reaction times are considerably shorter than the above-mentioned protocols thus avoiding bacteria growth.

Asialoglycoproteins are internalized into hepatocytes via a receptor that recognizes the terminal galactose and *N*-acetyl-galactosamine residues of carbohydrate chains. The uptake and the intracellular processing of ^{125}I and ^{99m} Tc NGA were studied in an isolated perfused rat liver model (*28*). After a 1 min pulse administration of iodine NGA, 40% of the radioactivity was taken up at first pass by the liver, and after 15−20 min, 82% of the ^{125}I was released at the sinusoidal pole of the hepatocyte, predominantly as small catabolites. In contrast, only 4% of ^{99m}Tc galactosylated albumin taken up by the liver reappeared in the perfusate, and 40% of the radioactivity was found in the bile one hour after injection. Our results confirmed that liver captation was very high after first pass (80% of injected dose) and that the majority of the injected activity was eliminated by the biliary track. The residual activity in the liver was 34% ID after 90 min. Unlike colloidal tracers, the liver uptake was not accompanied by a splenic uptake suggesting a specific hepatocyte captation as also shown by Kim et al. (*29*). No or very little activity was visible in the urinary tract.

CONCLUSION

A receptor-specific ligand for the asialoglycoprotein hepatic receptor was developed using a straightforward, cyanide-free conjugation with human serum albumin. The pharmaceutical validation of the process will need complementary studies. Imaging and biodistribution studies demonstrated hepatic targeting and rapid blood clearance for this tracer. ^{99m}Tc-LACTAL accumulated mainly in the liver, and there was negligible uptake in the spleen. Kinetic parameters provided by these experiments will be useful for the design and the implementation of supplementary non clinical studies and phase I trials in healthy volunteers. In addition, this process could enable efficient and fast modification of protein templates with other ligands and chelated nuclei for use in nuclear medicine or magnetic resonance imaging of different targets.

ACKNOWLEDGMENT

We thank the CNRS for a one-year support for a valorisation engineer (M. A-L.). We would like to thank Mr. Abdelhakand Jallane for his technical assistance in biodistribution studies and Dr. Anne Gruaz-Guyon for her scientific advice.

We developed highly luminescent and cost-effective quantum dot (QD)-neutravidin (NTV) bioconjugates to detect the tyrosine kinase B (TrkB) receptors distributed in the cultured hippocampus neurons. Hippocampal neurons were incubated with biotinylated anti-TrkB antibody, followed by further incubation with QD-NTV bioconjugates. QD-NTV biomarkers on the extracellular domain of TrkB receptors were imaged by the combined atomic force microscope and confocal laser scanning microscope (AFM-CLSM) providing resolved (nanometer-scale) structural and fluorescent images. We found that TrkB receptors were distributed over the neuronal cell bodies (soma) and neurites. TrkB receptors in the somata looked more concentrated, but those in the neurites appeared punctate. Thus, our QD-based immunocytochemistry technique combined with an AFM-CLSM can be used for three-dimensional morphology of neurons on nanometer-scale structural resolution and their fluorescence images with QDs. Furthermore, this technique can be applied for real-time fluorescence imaging or long-term study of live neurons.

INTRODUCTION

Currently, researches in neuroscience have been focused on the fundamental understanding of ligand (or neurotrophins)−receptor interaction mechanism, the localization of receptors on the surface of neurons, and receptor-bound signal trafficking. Neurotrophins are a family of growth factors regulating differentiation, maturity, and survival of neurons. The diverse functions of neurotrophins are mediated by their specific interaction with tyrosine kinase receptors (*1*). The tyrosine kinase receptors (Trks) include TrkA (a receptor for nerve growth factor (NGF)), TrkB (a receptor for brain-derived neurotrophic factor (BDNF) and neurotrophin-4/5 (NT-4/5)), and TrkC (a receptor for neurotrophin-3 (NT3)). Specially, TrkB (Tyrosine Kinase B), expressed in the developing nervous system including the forebrain, caudal midbrain, hindbrain, spinal cord, the trigeminal ganglion, and differentiating neural crest cells, possesses high binding affinity to brain-derived neurotrophic factor (BDNF) and neurotrophin-4(NT-4) (*2*). The binding of BDNF to TrkB receptor activates downstream intracellular cascades, regulating neuronal development and plasticity, long-term potentiation, and apoptosis (*3*). It was also reported that short-term physical exercise stimulates BDNF and TrkB gene expression in the brain (*4*). It was recently revealed that signaling through TrkB receptors appears to be related to Alzheimer's disease (*5*). Genetic ablation of TrkB gene in the forebrain changes hippocampal spine density and length in an age- and region-specific manner, which in turn may affect synaptic transmission and plasticity. The hippocampus is best recognized for its role in declarative memory and spatial learning (*6*). To understand the pathogenic mechanism related to the TrkB receptors as well as the development and regulation of the nervous system, it is important to monitor the localization of TrkB receptors in hippocampal neurons.

For several decades, an immunocytochemical method has been developed to detect antigens (e.g., extracellular surface of membrane receptors) using antigen−antibody reaction. To visualize antigens with an optical microscope, antibodies have to be labeled with various and multiple fluorescent dyes simultaneously (*7*). Optical microscopy provides selective and specific visualization of labeled species in the sample, and renders it possible to monitor the process and dynamics of living cells with high temporal resolution. The lateral resolution of optical microscopy is usually limited by the diffraction to about half the wavelength of the light used, thus restricting to achieve a detailed structural image. Great advances in optical microscopy such as near field scanning optical microscopy (NSOM), stimulated emission depletion microscopy (STED), photoactivated localization microscopy (PALM), and stochastic optical reconstruction microscopy (STORM) have been achieved to overcome the optical diffraction limit, but there still are constraints for realizing time-resolved dynamics or three-dimensional imaging (*8*).

Electron microscopy (EM) is a well-established technique identifying highly resolved structural features of targets in the sample on subnanometer-scale resolution. However, EM can be applied to only fixed cells (*9*). Our integrated AFM and CLSM (AFM-CLSM) has advantages over EM or OM in that nanometer-scale spatial resolution, frame/second temporal resolution, and chemical identification through fluorescence detection can be done simultaneously for live cells. Using AFM-CLSM, we can easily get optical and spatial images of targets on the cells. We can also take the depth-resolved (*z*-stack) fluorescent images of antigens by CLSM together with their nanometer-

scale cellular structural images by AFM. AFM is a subnanometer resolution scanning-probe device in which a sharp tip at the end of a flexible cantilever is scanned over the samples' surface (*10*). AFM has been used to take three-dimensional images of live biological samples, because it can provides structural details at subnanometer resolution in an ambient air or under liquid environment (*11*). Over the past few years, various efforts have been made to combine optical microscopy and AFM in order to study a range of biological processes in terms of a 3D structural and fluorescent image (*12*−*17*). CLSM offers high-quality three-dimensional fluorescent images over conventional wide-field optical microscopy, due to its ability to control the depth of a focal plane to eliminate out-of-focus light or glares in specimens and its capability to collect serial (i.e., *z*-stack) optical images for thick specimens.

In order to investigate the localization of TrkB receptors, we labeled them with highly luminescent, no-photobleaching, and photostable fluorescent QDs. Semiconductor quantum dots with broad absorption, high extinction coefficient, high luminance, narrow, and tunable emission wavelength through the adjustment of their size are ideal fluorophores as biological tagging materials (*18*−*20*). In addition, compared with conventional organic dyes or GFPs, QDs have high photostability and can resist to photobleaching for a prolonged time of AFM-CLSM measurement (*21*−*23*). QDs have been used for protein and DNA immunoassays, fluorescence resonance energy transfer (FRET), diagnostics, live cell imaging through bioconjugation, and high-throughput screening. At present, bioconjugates of QDs bound to ligands such as streptavidins, neutravidins, and biotinylated proteins are excellent tools for the study of neuroscience. In our study, we report the synthesis of highly luminescent water-soluble QD-neutravidin (NTV) bioconjugates and the spatial and optical characterization of TrkB receptors in cultured hippocampal neurons using combined atomic force and confocal microscopy. We synthesized semiconductor QDs with a high photoluminescence quantum yield (∼80% PL QY at room temperature) and a narrow size distribution and a chemical composition gradient in a radial direction of a spherically shaped QD (*25*). Our QDs with a chemical composition gradient have better structural stability and quantum efficiency. Water-soluble quantum dots were prepared by replacing the oleic acid (OA) attached to the surface of QDs with mercaptopropionic acid (MPA). Even after the surface modification with MPA, our QDs still maintain high quantum efficiency due to our original QD structure of chemical composition gradients in a radial direction. Water-soluble QDs kept at 4 °C have been stable for up to one year. We conjugated QDs in phosphate buffered saline (PBS) of pH 7.4 with NTVs which bound with biotinylated anti-TrkB antibody. NTV has more advantages over commonly used streptavidin (STV) in that NTV is more cost-effective and reduces nonspecific binding because of more neutral pI (pH at isoelectric point) (*24*). Water-soluble QD-NTV bioconjugates interact with TrkB receptors, pretreated with biotinylated anti-TrkB receptor antibody and located in cultured hippocampal neurons, via a high affinity between avidin and biotin. The distribution of TrkB receptors in cultured hippocampal neurons was observed three-dimensionally by AFM-CLSM at nanometer-scale spatial resolution combined with optical fluorescence images.

MATERIALS AND METHODS

Reagents. Cadmium oxide (CdO, 99.99%), zinc acetate (99.9%, powder), selenium (99.9%, powder), sulfur (99.9%, powder), trioctylphosphine (TOP, 90%), oleic acid (OA, 90%), 1-octadecene (ODE, 90%), mercaptopropionic acid (MPA, 99.8%), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), *N*-hydroxysuccinimide (NHS), sephadex G-25 (beads for gel-filtration), agarose for gel electrophoresis, sodium phosphate dibasic heptahydrate (for PBS buffer solutions, ACS reagent grade), sodium dihydrogen phosphate dehydrate (for PBS buffer solutions), Trizma base (minimum 99.9% titration) and acetic acid (glacial) for Tris-Acetate EDTA (TAE) buffer solutions, brilliant blue R and bromophenol blue sodium salt for electrophoresis and biological analysis, ethylene diamine tetra acetic acid sodium salt (EDTA sodium salt), paraformaldehyde were purchased from Sigma Aldrich. Neutravidin (NTV) was purchased from Pierce.

Biotinylated antibody against mouse TrkB extracellular domain (BAF1494), which is polyclonal full length goat IgG, was purchased from R&D system. Hexane, methanol, ethanol, acetone, and chloroform were purchased from Daejung chemicals. All chemicals were used as purchased without further purification. Buffer solutions are homemade.

Single-Step Synthesis of Quantum Dots with Chemical Composition Gradients. The highly luminescent green-emitting (the emission wavelength is 520 nm with a fwhm of less than 30 nm) CdSe/ZnS quantum dots with chemical composition gradients were produced by our previously reported single-step synthetic method (*25*). The size of green-emitting CdSe/ZnS QDs with chemical composition gradients were measured to be 6 nm (with a size distribution of less than 5%) by transmission electron microscopy (TEM).

Preparation of Water-Soluble Quantum Dots. We prepared water-soluble quantum dots by replacing the oleic acid (OA, originally coordinated ligand to QDs as they were produced) with mercaptopropionic acid (MPA) (*25, 26*).

Measurement of Quantum Yield (QY) of QDs. The photoluminescence quantum yield (PL QY) of CdSe/ZnS QDs with chemical composition gradients dispersed in 0.2 M PBS buffer of pH 7.4 was measured and estimated by comparing their photoluminescence intensities with those of primary standard dye solutions (emission close to the QDs, Coumarin 545 with the QY of 0.95 in ethanol) at the same optical density (0.05) at the same excitation wavelength of 465 nm. The room temperature PL QY of the green-emitting QDs is typically ∼80%.

Measurement of the Concentration of QDs. In this study, the concentration of green-emitting CdSe/ZnS QDs was measured using an Agilent 8454 UV−vis spectrometer and was calculated based upon a previously reported method (*27*).

Water-Soluble Quantum Dot-Bound Neutravidin (QD-NTV). The conjugation was carried out through a coupling reaction between the carboxyl group of MPA and an amino group of NTV using EDC as the coupling activator (*28*). The concentration ratio of QDs to NTV is 1:40 in moles. The conjugation of QDs dispersed in PBS buffer with NTV was done as follows. The 100 μL of 2 mM EDC dissolved in 0.2 M of 2-(morpholino) ethanesulfonic acid (MES) of pH 6.0 was added to the QD solution, and then the resulting solution was stirred mildly for 5 min. The 50 μL of 5 mM NHS dissolved in 0.2 M of MES of pH 6.0 was added to the e-tube mixture with a 30 min mild stirring at room temperature. After 30 min stirring, the mixture was purified by size exclusion chromatography using sephadex G-25. Only QDs reacted with EDC and NHS were collected. Then, 5 μL of NTV taken from the stock solution (stock solution: 10 mg dissolved in 1 mL of 0.2 M borate of pH 9.5) was diluted with 95 μL of 0.2 M borate of pH 9.5, and then this solution was added to the solution containing QDs reacted with EDC and NHS. The solution was stirred at room temperature for 2 h, and QD-NTV was purified by a Sephacryl S-400 HR size exclusion spin column (GE healthcare, Sweden).

Cell Culture. Primary hippocampal neurons were cultured from mice embryo E18 (ICR strain) by modified protocol from Baker et al. (*29*). Briefly, pregnant ICR mice were euthanized

to decapitate fetus and dissect out the fetal brains. Hippocampi were removed under a dissecting microscope and trypsinized with 2.5% trypsin solution in distilled water. Then, neurons were dissociated and plated on the poly(L-lysine)-coated glass bottom culture dishes in a concentration of 50,000/cm^2. Neurons were grown for two weeks in maintenance medium (neurobasal medium containing 2% B-27, 1 mM glutamine, and penicillin/streptomycin) before fixation.

Cell Fixation. For the detection of TrkB receptors, mouse hippocampal neurons were fixed with 4% paraformaldehyde on ice for 10 min. Then, we washed the cells with PBS more than 3 times. In order to reduce the nonspecific binding, the cells were blocked with 2% (wt/vol) of BSA dissolved in PBS for overnight at 4 °C. Next day, we washed the cells with PBS more than 3 times.

Detection of TrkB Receptors on a Mouse Hippocampus Neuron Cell Surface. Biotinylated anti-TrkB antibodies and QD-NTV were diluted in PBS. Fixed and BSA-blocked primary neurons were incubated with 5 μg/mL of a mouse anti-TrkB antibody that recognized the external domain of a TrkB receptor (catalog no. BAF 1494; R&D systems) for 2 h at room temperature. Then, the neurons were washed with PBS several times to eliminate the nonspecific binding of biotinylated anti-TrkB antibody. Next, we sequentially incubated the neurons with 160 nM of QD-NTV for 2 h at room temperature. During this incubation, final bioconjugation of biotinylated anti-TrkB antibody with QD-NTV via avidin−biotin coupling was made at the cell surface where TrkB receptors were located. For an optical microscope measurement, neuron cells were examined just right after a QD-labeling step. For combined atomic force and confocal microscopy measurements, neuron cells were dehydrated with 75%, 90%, and 100% of ethanol in series, and then they were air-dried.

MEASUREMENTS AND ANALYSIS

Optical Characterization. Room-temperature optical absorption spectra of CdSe/ZnS core/shell QDs with chemical composition gradient were measured with an Agilent 8454 UV−vis diode array spectrometer. QDs were diluted in hexane or PBS. Photoluminescence spectra were collected on an ACTON spectrometer connected with a photomultiplier tube (Acton Research).

Gel Electrophoresis. The conjugation of water-soluble QDs with NTVs was confirmed by gel electrophoresis (Mupid-2 plus model). Gels were 1% agarose in Tris-Acetate EDTA (TAE) buffer. Gels were run at 100 V for 80 min with TAE buffer as the running buffer. Gel images were taken on an Olympus EX 140 with a UV lamp (VL-4LC, made in EEC).

Fourier Transform Infrared (FT-IR) Spectroscopy. To confirm an amide bonding of QDs with NTVs, we carried out the analysis of FT-IR vibration spectra of samples of QD-NTV (JASCO FT/IR-660 plus, made by JASCO).

Confocal Laser Scanning Microscopy. The confocal fluorescent images and differential interference contrast (DIC) images of QD-labeled hippocampus neurons were obtained using Fluoview FV1000 confocal laser scanning microscope (CLSM; Olympus, Tokyo, Japan) connected to an IX 81 inverted microscope (Olympus, Tokyo, Japan) with a UPLAPO 60X waterproof objective (its numerical aperture (NA) was 1.20). QDs were excited with a 488 nm Ar^+ ion laser line and detected in the wavelength range 510−530 nm. The confocal fluorescence images were overlaid with DIC images in order to locate the components of neuron cells in more informative way.

Combined Atomic Force Microscopy and Confocal Laser Scanning Microscopy (AFM-CLSM). Fluorescent and nanometer-scale spatially resolved structural images of QD-labeled cells were obtained with a combined AFM-CLSM. A MFP-3D (atomic force microscope, Asylum Research) was placed on an IX 81 inverted microscope (Olympus) coupled to a Fluoview FV 1000 confocal laser scanning microscope (CLSM; Olympus). The combined AFM-CLSM setup was placed on a TS-140 antivibration optical table, and then the whole thing was enclosed in an acoustically isolated chamber. In order to get a three-dimensional fluorescence image of neurons by CLSM, we collected the depth-resolved (i.e., z-stack) fluorescence images of neurons in every 0.3 μm. The whole image of neurons was reconstructed from all the z-stack fluorescence images. Neurons were imaged at a scan rate of 1.0 Hz in the contact mode with an Asylum Research AFM. A 200-μm-long PNP-TR cantilever (NanoWorld, Switzerland) with a spring constant of 0.08 N/m and a resonant frequency of 17 kHz was used. The tip radius of curvature is smaller than 10 nm. The force of 1.0 nN was maintained during imaging. We positioned the cantilever tip in the AFM head over the optical axis of the CLSM by manually adjusting the AFM stage in the combined AFM and CLSM instrument.

RESULTS AND DISCUSSION

We produced highly luminescent semiconductor quantum dots (QY ~80%) by our single-step synthesis of QDs with chemical composition gradients (*25*). In the bioconjugation study, we used green CdSe/ZnS core/shell QDs with chemical composition gradients emitting at 520 nm with a fwhm less than 30 nm. The size distribution of the QDs is within 5%. The average size of the QDs is 6 nm in diameter. The unique structure of our QDs (QDs with gradual chemical composition gradient outward) has good merits: the relaxation of the strain caused by the lattice mismatch between the CdSe core and the ZnS shell even though the thickness of the outer part of the QDs is more than two atomic layers, funneling the excitons toward the cores of QDs due to chemical composition gradients (i.e., energy-gradient structure) and thus enhancing the photoluminescence (PL QY ~80%). In order to use QDs for biological applications, we need to have water-soluble QDs. The QDs as produced by our single-step synthetic method were originally surface-passivated with oleic acid that functioned as a solvent and coordinating ligand. Water-soluble QDs were prepared by replacing the oleic acid coordinated to their surfaces with mercaptopropionic acid (MPA) via a conventional ligand exchange reaction (*25, 26*). The MPA-capped QD precipitates are collected out from the turbid mixture by several centrifugal purifications. We disperse MPA-capped QDs in PBS. Figure 1a shows the photoluminescence spectra of green-emitting CdSe/ZnS core/shell QDs with chemical composition gradient (high quantum yield ~80%) capped with oleic acids (OA) and dispersed in hexane (denoted with solid line) and those capped with MPAs and dispersed in PBS (denoted with dotted line). As shown in Figure 1a, water-soluble QDs capped with MPAs still maintain high quantum efficiency. Figure 1b shows high luminance of both QD-OAs dispersed in hexane and QD-MPAs dispersed in PBS under an indoor common fluorescent lamp. Figure 1c shows the photoimages of the same QDs irradiated with a UV lamp under the indoor common fluorescent lamp off. Our green-emitting CdSe/ZnS core/shell QDs with chemical composition gradients either capped with oleic acids (OA) or capped with MPAs are highly luminescent (measured to be ~80% QY, using a reference dye of coumarin 545 with 95% of QY in ethanol). Water-soluble QD-MPAs dispersed in PBS have been stable for more than a year at 4 °C. Eventually, in order to detect TrkB receptors on the neuron cells through the interaction between QD-neutravidin (QD-NTV) and biotinylated anti-TrkB antibody, we need to generate QD-NTV. A solution of NTV powder dissolved in 0.2 M borate of pH 9.5 is mixed with QD-MPAs dispersed in PBS. The concentration of QD-MPAs turns out 0.42 μM and 10 mg

Figure 1. of NTV is dissolved in 1 mL of 0.2 M borate of pH 9.5, and thus that of NTV turns out to be 167 μM. The conjugation is made through a coupling reaction between the carboxyl group of MPA and an amino group of NTV using EDC as the coupling activator (*28*). After the coupling reaction, the mixture of QD-MPA, NTV, and QD-NTV was purified through gel filtration. QD-NTV conjugates are confirmed by the two following methods. In one way, samples were analyzed by electrophoresis on a 1% agarose gel in Tris acetate EDTA (TAE) buffer. Gels are run at 100 V for 80 min with TAE buffer as the running buffer. Figure 2a shows the green fluorescent images of a gel plate with well-resolved separation of QD-NTVs from QDs. The top band is QD-NTVs and the bottom band is QDs only. In the other way, as shown in the Figure 2b, the left well in the gel plate is loaded only water-soluble QDs, the right well is loaded with water-soluble QD-NTV. The interaction between SO_3^- functional group of brilliant blue R (or called Coomassie blue) and NH_3^+ amino functional group of amino acids such as tyrosine, histidine, and phenyl alanine causes the blue stain in the protein moiety under the solution of pH 4.3. In the destaining solution (pH < 2), gel becomes transparent except for the bands containing protein moieties. The blue stain confirms there is a protein moiety. The right well in the gel plate is indeed QD-NTVs. Using a Fourier transform infrared (FT-IR) spectrometer, we obtained vibration spectra of functional groups of QD-MPA, NTV, and QD-NTV. The FT-IR spectra were shown in Figure 3. The IR bands at 1554 and 1440 cm^{-1}, at 3405 and 3350 cm^{-1}, and at 3413 cm^{-1} are characteristic bands of asymmetric and symmetric stretching bands of $-COO^-$ functional group in QD-MPA, primary amine N−H stretching bands of free NTV, and N−H stretching bands of conjugated QD-NTV, respectively (*30, 31*). The amide bands I and II of NTV itself are shown at 1644 cm^{-1} and at 1526 cm^{-1}. The conjugated amide bands of −CONH− functional group in QD-NTV are located 1366 cm^{-1} and 1154 cm^{-1} (red-shifted from those of QD-MPA). Next, the avidin−biotin interaction was used for the detection of TrkB receptors through ligand−receptor binding. In our study, neutravidin [MW 60kD, pI 6.3] instead of streptavidin [MW 53kD, pI 6.8−7.5] or avidin [MW 67kD, pI 10] was used because neutravidin with lysine-rich residues available to amide bondings with carboxylic groups of QD-MPA does not have an Arg-Tyr-Asp (RYD) sequence, which may cause nonspecific bindings, and because deglycosylated neutravidin reduces oligosaccharide-based lectin binding with biotin-binding affinity retained (*26*). We used biotinylated anti-TrkB antibody (R&D systems) as a binding moiety to QD-NTV. The scheme we took for fluorescence imaging was the binding via avidin−biotin coupling between TrkB receptors attached with biotinylated anti-TrkB antibodies on the neuron cells through antigen−antibody interaction and QD-NTV (a fluorescent tag).

We prepared biotinylated anti-TrkB antibody dissolved in PBS (5 μg/mL). The two-week-grown hippocampal neurons were plated at a density of 50,000 cells/cm^2 onto poly(L-lysine)-coated glass-bottomed culture dish. Cultured hippocampal neurons were fixed with 4% paraformaldehyde on ice for 10 min, and the cells were washed with PBS more than 3 times. In order to reduce the nonspecific binding, the cells were blocked with 2% (wt/vol) of BSA dissolved in PBS for overnight at 4 °C, and then, we washed the cells with PBS more than 3 times. There are some reports that the conjugates of QDs with antibodies bind specifically to membrane receptors in both fixed and live cells (*32*−*34*). In the first step, we checked nonspecific binding of QD-NTV to cultured primary mouse hippocampal neurons. The conjugation of QD-NTV to cultured hippocampal neurons was carried out in PBS. Mouse hippocampal neurons

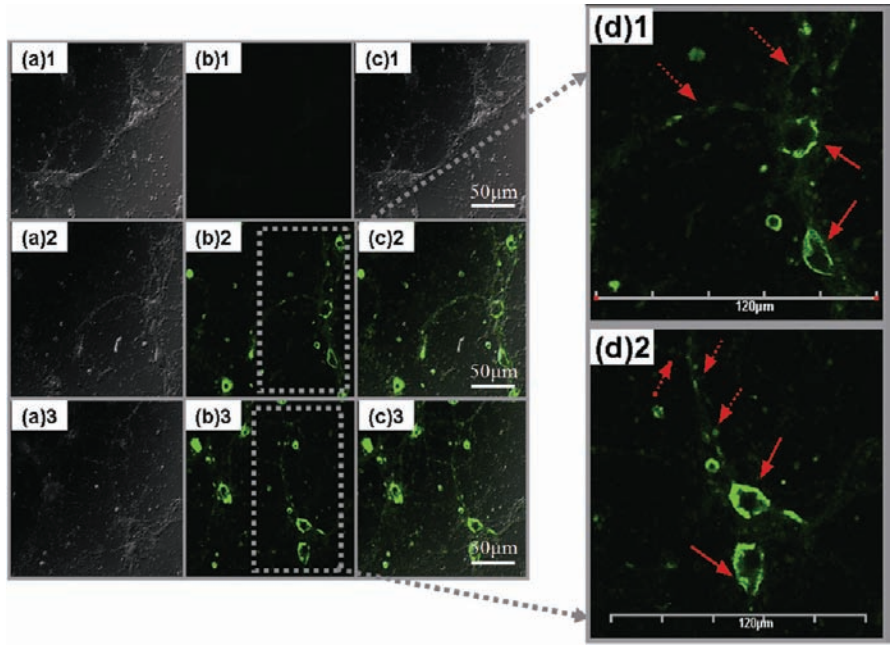

Figure 4. DIC and confocal fluorescence microscopic images of mouse hippocampal neuron. (a) 1−2: DIC images of the neuron cell with biotinylated anti-TrkB antibody unattached and that with biotinylated anti-TrkB antibody attached, respectively. (a) 3: DIC image of other region of the neuron cell with biotinylated anti-TrkB antibody attached. (b) 1: fluorescent image of the neuron cell without any biotinylated anti-TrkB antibody treated with QD-NTV and shows no fluorescence. (b) 2−3: fluorescent images of two different regions of the cultured hippocampal neurons with biotinylated anti-TrkB antibody treated with QD-NTV. (c) 1−3: the overlapped images of (a) 1−3 and (b) 1−3, respectively. (d) 1−2: enlarged images of some part of (b) 2−3, the neuron cell bodies and neurites are marked with solid and dashed arrows, respectively.

were incubated with 160 nM of QD-NTV for 2 h, and then we washed the cells with PBS more than 3 times. After washing the cell many times, QD fluorescence signal does not appear on the surface of the cells (Figure 4(b)1). Thus, we confirm that QD-NTV rarely binds nonspecifically to the cell membrane in fixed hippocampal neurons. In the second step, in order to detect endogenous TrkB receptors on cultured hippocampal neurons, we treated the cells with biotinylated anti-TrkB antibody (5 μg/mL) dissolved in PBS buffer for 2 h. To eliminate nonspecific binding of biotinylated anti-TrkB antibody, the cells were washed with PBS several times. Biotinylated anti-TrkB antibodies were specifically located at the TrkB receptors on the neuron cells through antigen−antibody interaction. Then, we incubated cultured hippocampus neurons attached with biotinylated anti-TrkB antibody with 160 nM of QD-NTV for 2 h. QD-NTV specifically bound to biotinylated anti-TrkB antibody of the neuron cells via avidin−biotin coupling. Finally, the bioconjugation via avidin−biotin coupling between biotinylated anti-TrkB antibody located at the TrkB receptors on the neurons and QD-NTV were made for fluorescence imaging.

In Figure 4, (a)1−3 are DIC (differential interference contrast) images of the neuron cells, (b)1−3 are fluorescent images of the neuron cells, (c)1−3 are overlapped images of DIC images (a)1−3 with fluorescent images (b)1−3. Figure 4(a)1 shows a DIC image of the neuron cell without any biotinylated anti-TrkB antibody treated with QD-NTV; the (b)1 panel is a fluorescent image of the neuron cell without any biotinylated anti-TrkB antibody treated with QD-NTV and shows no fluorescence, and thus confirms no nonspecific binding between the neuron cell and QD-NTV. Nonspecifically bound QD-NTV to the cells has been eliminated through washing with PBS buffer. Figure 4(a)2−3 and (b)2−3 are DIC images and fluorescent images of two different regions of the cultured hippocampus neuron cells with biotinylated anti-TrkB antibody treated with QD-NTV, respectively. QD-NTV specifically binds to biotinylated anti-TrkB antibody of the neuron cells via avidin−biotin coupling. From the overlapped images of Figure 4(a)1−3 and (b)1−3 shown in (c)1−3 panels, we clearly see QD green fluorescence present on the neuron cell bodies and neurites. Figure 4(c)2 and (c)3 shows QD green fluorescence signals from the neuron cell bodies and neurites. More green fluorescence signal came from the neuron cell bodies. Thus, more TrkB receptors were distributed over the cell bodies (soma) than the neurites within neurons. Enlarged images of some part of Figure 4(b)2−3 are shown in part (d)1−2. The neuron cell bodies and neurites are marked with solid and dashed arrows, respectively. TrkB receptors in the cell bodies (soma) were distributed in a highly concentrated manner, whereas those in the neurites were distributed in a punctuate manner, as shown enlarged images (Figure 4(d)1−2). The location of TrkB receptors has been previously studied by Swanwick et al. (*35*). However, the fluorescence images were not enough to show three-dimensional structures. Drake et al. reported the localization of TrkB receptors in hippocampal neurons with EM (*36*), but due to the limitation to prepare samples, their results did not properly reflect the distribution of TrkB receptors over the whole neuronal structure. Our homemade combined atomic force microscope and confocal laser scanning microscope (AFM-CLSM) instrument enables the three-dimensional imaging of neurons on nanometer-scale structural resolution and fluorescent chemical identification. With the homemade AFM-CLSM, we obtained 3-D images of QD-labeled TrkB receptors in hippocampal neurons, and these were shown in Figure 5. We obtained AFM-CLSM images after dehydration and air-drying of QD-labeled neuron cells. The three-dimensional cell surface topography (Figure 5b) is obtained by the three-dimensional surface-plotting of the height-contrast image (Figure 5a). The topographical image of the cell surface was shown on nanometer scale, and the cell's maximal height was ~1.5 μm. The 3-D cellular structures, such as somata and neurites, were clearly visualized. We obtained the depth-resolved (i.e., z-stack) fluorescence images of neurons in every 0.3 μm and reconstructed them (x, y, z = every 0.3 μm) to get a three-dimensional fluorescence image of neurons. The merged 3-D neuron image of the structural image by AFM and the fluorescent image by CLSM is shown in Figure 5d. Thus, the whole fluorescent TrkB signals

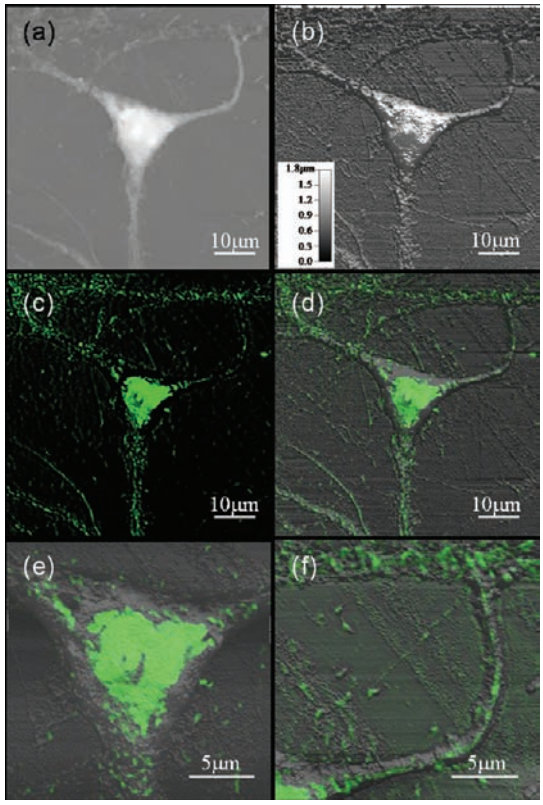

Figure 5. Image of cultured hippocampal neurons acquired with combined AFM-CLSM. (a) Height contrast image. (b) 3-D surface plot of height image. (c) CLSM fluorescence image. This is two-dimensional projection fluorescence image. (d) 3-D surface plot of height image combined with a CLSM projection image given in (c). (e) Magnified image of soma region shown in (d). over the cell surface can be correlated to the cellular ultrastructure resolved by AFM. Magnified AFM-CLSM image shows that TrkB receptors are distributed in a highly concentrated manner in the central soma but punctately at the edge of soma (Figure 5e). Furthermore, TrkB receptors appeared to be punctate in the neurites, consistent with the report from Swanwick et al. (*35*). Additionally, most punctate TrkB receptors in the neurites were located on the high ridges of neurites. Thus, our AFM-CLSM analysis using QD enabled us to discover precise correlation between immunocytochemically fluorescent signals and cellular structures, which could not be done with a conventional fluorescent image analysis system.

CONCLUSION

We have demonstrated that the highly luminescent bioconjugates of QD-neutravidin and biotinylated anti-TrkB antibody are available to acquire the distribution of TrkB receptors by depth-resolved fluorescent signals, which are highly correlated with nanoscale cellular structural images. We synthesized nearly monodispersed water-soluble CdSe/ZnS core/shell QDs (QY ~80% at room temperature) with chemical composition gradients emitting at 520 nm with a fwhm less than 30 nm. QD-NTV is made through a coupling reaction between the carboxyl group of water-soluble QD-MPA and the amino group of NTV using EDC as the coupling activator. In order to study the neurons through AFM-CLSM, we generated the bioconjugates of biotinylated anti-TrkB antibody, which detect the TrkB receptors on the surface of neurons with QD-NTV via avidin−biotin coupling. We compared the conjugated QD-NTV fluorescent signals between neurons treated with biotinylated anti-TrkB antibody and QD-NTV and neurons treated with only QD-NTV. QD fluorescence is present only on the cells treated with biotinylated anti-TrkB antibody. This result confirms the successful bioconjugation between QD-NTV and biotinylated anti-TrkB antibody. From the fluorescence study, we find that TrkB receptors are distributed widely over the neuron cell bodies (soma), whereas they are distributed as a punctate structure on the neurites. We further discover the precise localization of TrkB receptors by correlating the fluorescent image with nanoscale cellular structures resolved by AFM. AFM-CLSM images show that TrkB receptors are located broadly in the central soma but showing punctate structures at the edge of soma. Interestingly, punctate signals of TrkB receptors on the neurites are located on the high ridges of neurites. Over the repeated scans by AFM-CLSM imaging, the bioconjugates show no photobleaching. Thus, we suggest that our QD-based immunocytochemistry technique can be utilized for stable structural and fluorescent imaging in neurons by AFM-CLSM. Furthermore, our bioconjugate, QD-NTV-biotin-TrkB, can be applied for real-time fluorescence signal trafficking or long-term imaging in live neurons.

In Vivo Tumor-Targeted Fluorescence Imaging Using Near-Infrared Non-Cadmium Quantum Dots

Jinhao Gao,*,† Kai Chen,† Renguo Xie,‡ Jin Xie,† Yongjun Yan,† Zhen Cheng,† Xiaogang Peng,‡ and Xiaoyuan Chen*,†,§

Molecular Imaging Program at Stanford, Department of Radiology and Bio-X Program, School of Medicine, Stanford University, 1201 Welch Road, Stanford, California 94305-5484, Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville, Arkansas 72701, and Laboratory for Molecular Imaging and Nanomedicine, National Institute of Biomedical Imaging and Bioengineering, National Institutes of Health, Bethesda, Maryland 20892. Received July 21, 2009; Revised Manuscript Received February 10, 2010

This article reported the high tumor targeting efficacy of RGD peptide labeled near-infrared (NIR) non-cadmium quantum dots (QDs). After using poly(ethylene glycol) to encapsulate InAs/InP/ZnSe QDs (emission maximum at about 800 nm), QD800-PEG dispersed well in PBS buffer with the hydrodynamic diameter (HD) of 15.9 nm and the circulation half-life of ~29 min. After coupling QD800-PEG with arginine−glycine−aspartic acid (RGD) or arginine−alanine−aspartic acid (RAD) peptides, we used nude mice bearing subcutaneous U87MG tumor as models to test tumor-targeted fluorescence imaging. The results indicated that the tumor uptake of QD800-RGD is much higher than those of QD800-PEG and QD800-RAD. The semiquantitative analysis of the region of interest (ROI) showed a high tumor uptake of 10.7 ± 1.5%ID/g in mice injected with QD800-RGD, while the tumor uptakes of QD800-PEG and QD800-RAD were 2.9 ± 0.3%ID/g and 4.0 ± 0.5%ID/g, respectively, indicating the specific tumor targeting of QD800-RGD. The high reproducibility of bioconjunction between QDs and the RGD peptide and the feasibility of QD-RGD bioconjugates as tumor-targeted fluorescence probes warrant the successful application of QDs for in vivo molecular imaging.

INTRODUCTION

The integration of nanotechnology with molecular biology and medicine has resulted in active developments of a new emerging research area-nanobiotechnology (*1*). This technological innovation, referred to as nanomedicine by the National Institutes of Health (NIH), has great potential to offer exciting and abundant opportunities for discovering new materials, processes, and phenomena in biomedicine. Nanoscale materials have now been widely exploited in many biomedical applications, such as biosensor, disease detection, molecular imaging, and disease treatment (*2*−*7*). The basic rationale is that the metal, metal oxide, semiconductor, or self-assembled molecular nanostrucuters have novel properties and functions that are not available from bulk counterparts or individual molecules. One of the most advanced and exciting forefronts of nanobiotechnology is the application of quantum dots (QDs) in biology and medicine (*8*). After surface functionalization using peptides, proteins, and antibodies, QDs indeed showed great ability to target and detect specific tissues in living subjects by the rapid readout of fluorescence imaging (*9*−*16*). Compared with the organic dyes and fluorescent proteins, QDs show many unique optical properties, such as narrow and tunable emission spectra, superior photostability, high quantum yields, and the capacity of simultaneous excitation of multiple fluorescence colors. Moreover, there are many more alternatives in QDs with NIR emission for in vivo imaging than organic dyes, such as CdTe/CdSe (*17*), $InAs_xP_{1-x}$/InP/ZnSe (*18*), CuInSe (*19*), and Cu-doped InP/ZnSe (*20*) QDs. The QDs emitting at above 700 nm in the NIR region minimize the problems of indigenous fluorescence of tissues and meet the requirements of in vivo biological imaging applications. However, it is reported that Cd-containing QDs indeed showed cytotoxicity under extreme conditions (*21, 22*). Several studies have shown that QDs may be systemically distributed in organs and tissues. The absorption, distribution, metabolism, and excretion characteristics are highly variable for QDs because of the wide variation in QD physicochemical properties (*23*−*25*). For in vivo applications, metabolic clearance of the nanoparticles remains an issue, that is, it is hard to know about how these nanoparticles would be completely cleared out of the body. To avoid such a dilemma, one strategy is to replace the Cd metal by other more benign elements. For example, $CuInS_2$/ZnS core/shell QDs do not contain any Class A elements (Cd, Pb, and Hg) or Class B elements (Se and As) (*26*), which may show great potential as biocompatible probes for biomedical applications. Recently, carbon dots (C-dots) as new emerging optical probes have aroused research interest because of their nontoxicity compared with semiconductor QDs (*27*). Another important strategy is the surface coating and modification of QDs, which improve water solubility, stability, and biocompatibility, and assign a desired bioactivity (*24*). For example, QDs can be coated with hydrophilic poly(ethylene glycol) (PEG) groups or a cross-linked silica shell (*8, 28*) to render QDs biocompatible and can be further conjugated with bioactive moieties to target specific biologic tissues or cells.

Cancer is a class of diseases in which a number of cells display uncontrolled growth, invasion, and sometimes metastasis. Cell adhesion molecule integrin $\alpha_v\beta_3$ is a key player in tumor angiogenesis, progression, and spread. Integrin $\alpha_v\beta_3$ specifically binds the arginine−glycine−aspartic acid (RGD)-containing components in the interstitial matrix (*29*). Integrins expressed on endothelial cells modulate cell migration and survival during angiogenesis, while integrins expressed on carcinoma cells

potentiate metastasis by facilitating the invasion and movement across blood vessels (*30*). Tumor expression of integrin $\alpha_v\beta_3$ correlates well with the tumor progression in several malignancies, such as melanoma, glioma, and breast cancer (*31*−*33*). In this work, we chose non-cadmium and NIR QDs as the low-toxic and efficient fluorescence probe to image the integrin $\alpha_v\beta_3$-positive tumor vasculature in vivo after the surface modification of RGD peptide.

EXPERIMENTAL SECTION

Preparation of QD800-PEG. The synthesis of InAs/InP/ZnSe core/shell/shell QDs (emission maximum at about 800 nm) is similar to that described in the previous publication (*34*). We used the conjugate of phospholipid and poly(ethylene glycol) (DSPE-PEG2000 amine: 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)-2000], Avanti Polar Lipids, Inc.) to encapsulate QD800 and make the nanoparticles water-dispersible (*28, 35*). Typically, we mixed as-synthesized QD800 (10 nmol) and DSPE-PEG2000 amine (∼1.8 μmol) in 200 μL of chloroform and left the container open in a fume hood to evaporate the chloroform solvent slowly at room temperature. The dry sample was pumped under vacuum for about 4 h to remove chloroform completely and then redispersed in water by gentle sonication. The as-prepared QD800-PEG was purified by centrifugation using Millipore (Centrifugal filter devices, 100 K) at 4000 rpm for 20 min to remove the excess amount of DSPE-PEG2000 amine. The final concentration of QD800-PEG in PBS buffer (1×) was about 10 μM ready for further bioconjugation.

Synthesis of QD800-RGD and QD800-RAD. The procedure for surface functionalization of QD800-PEG with amine terminal groups is similar to that used in our previous report with a minor modification (*36*). We mixed QD800-PEG (1 nmol) and 4-maleimidobutyric acid *N*-succinimidyl ester (1 μmol) in borate buffer (pH ∼8.5) and incubated the mixture at room temperature for about 2 h with gentle shaking. After purification by a NAP-10 column (GE Healthcare Life Sciences), we added thiolated RGD peptide (c(RGDy(ε-acetylthiol)K), denoted as RGD-SH, 1 μmol) (*36*) into the activated QD800 sample and kept shaking for about 2 h at room temperature. After further purification by the NAP-10 column, we stored the QD800-RGD conjugate in PBS buffer with a concentration of 1 μM ready for animal use. For comparison, we added thiolated RAD peptide (c(RADy(ε-acetylthiol)K), denoted as RAD-SH, 1 μmol) instead to synthesize the QD800-RAD conjugate as a control.

Animal Model. Animal experiments were performed according to a protocol approved by the Stanford University Institutional Animal Care and Use Committee. The U87MG human glioblastoma tumor model was established by subcutaneous injection of U87MG cells (∼5×10^6 in 50 μL of PBS) into the front flank of female athymic nude mice (Harlan). The mice were subjected to imaging studies when the tumor volume reached 200−500 mm^3 (about 3 weeks after inoculation).

Half-Life Measurement. After the tail vein injection of QD800-PEG (200 pmol) in normal nude mice, we collected blood samples (∼15 mg each) at intervals of about 10 min and repeated them about 5 times. The blood samples were mixed with 20 μL of heparin (Sigma-Aldrich) solution (4 units/mL) and subjected to fluorescence imaging immediately using IVIS Imaging System (IVIS 100 Series; Cy5.5 excitation filter, 605−665 nm; ICG emission filter, 800−875 nm). Under the assistance of Living Image software, we recorded the information of the region of interest (ROI) for each blood sample.

In Vivo and Ex Vivo Fluorescence Imaging. After the tail vein injection of QD800-RGD, QD800-PEG, and QD800-RAD (∼200 pmol in each mouse), the mice were monitored at multiple time points (e.g., 0.5, 1, 4, 5, 6, 18, and 24 h) using IVIS Imaging System (IVIS 100 Series; Cy5.5 excitation filter, 605−665 nm; ICG emission filter, 800−875 nm). For ex vivo imaging, after the tumors and major organs were harvested, we immediately subjected the tissues to fluorescence imaging using IVIS Imaging System.

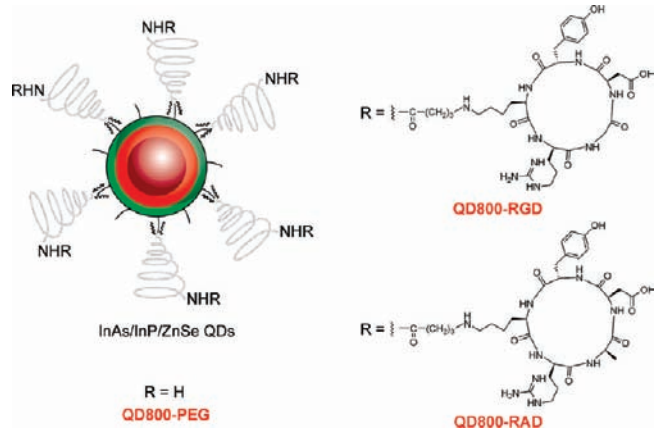

Figure 1. Structure of QD800-PEG, QD800-RGD, and QD800-RAD.

Immunofluorescence Staining. After 4 h p.i. of QD800-RGD, QD800-PEG, and QD800-RAD, the mice were sacrificed, and the tumors were harvested and frozen in OCT medium (Sakura Finetek) immediately. The tissues were cut into 5-μm-thick slices using microtome for fluorescence microscopy studies. U87MG tumor frozen tissue slices were fixed in cold acetone for about 10 min and dried in air for about 30 min. The sections were blocked with 10% donkey serum for about 10 min and then incubated with a rat antimouse CD31 monoclonal antibody (1:50; BD BioSciences) for 30 min at room temperature. After incubation with a Cy3-conjugated donkey antirat secondary antibody (1:100; Jackson ImmunoResearch Laboratories, Inc.) for another 30 min, we examined the tumor sections under fluorescence microscopes.

RESULTS AND DISCUSSION

Peptide-Labeled QDs. The as-synthesized InAs/InP/ZnSe core/shell/shell QDs (emission maximum at about 800 nm) with TOPO as surfactant only dispersed in nonpolar organic solvents, such as hexane and chloroform (Figure 2A,B). Poly(ethylene glycol) phosphatidylethanolamine (e.g., DSPE-PEG2000 amine) is one kind of micelle-forming hydrophilic polymer-grafted lipids (*28*). Therefore, the TOPO capped QDs could be encapsulated in the hydrophobic core of this micelle. We used DSPE-PEG2000 amine to coat QDs to make the QDs become water-dispersible and improve their biocompability. The procedure of coating is very facile and highly repeatable. The water-dispersible QD800-PEG (∼19% in QY) with an amine terminal group allows further modification and bioconjugation on the surface of nanoparticles. In order to maintain the binding activity of the circle (RGDyK), we used 4-maleimidobutyric acid *N*-succinimidyl ester as the heterodimeric cross-linker to conjugate QD800-PEG with the thiolated RGD peptide c(RGDy(ε-acethylthiol)K) to yield QD800-RGD (Figure 1). We also conjugated QD800-PEG with the thiolated RAD peptide c(RADy(ε-acethylthiol)K) to produce QD800-RAD as the negative control.

Analysis of Hydrodynamic Diameter (HD) and Circulation Half-Life. After surface coating and modification, all three samples (QD800-PEG, QD800-RGD, and QD800-RAD) could disperse well in PBS buffer. The absorbance and fluorescence emission spectra indicated that these water-dispersible QD samples maintain the optical properties with an emission

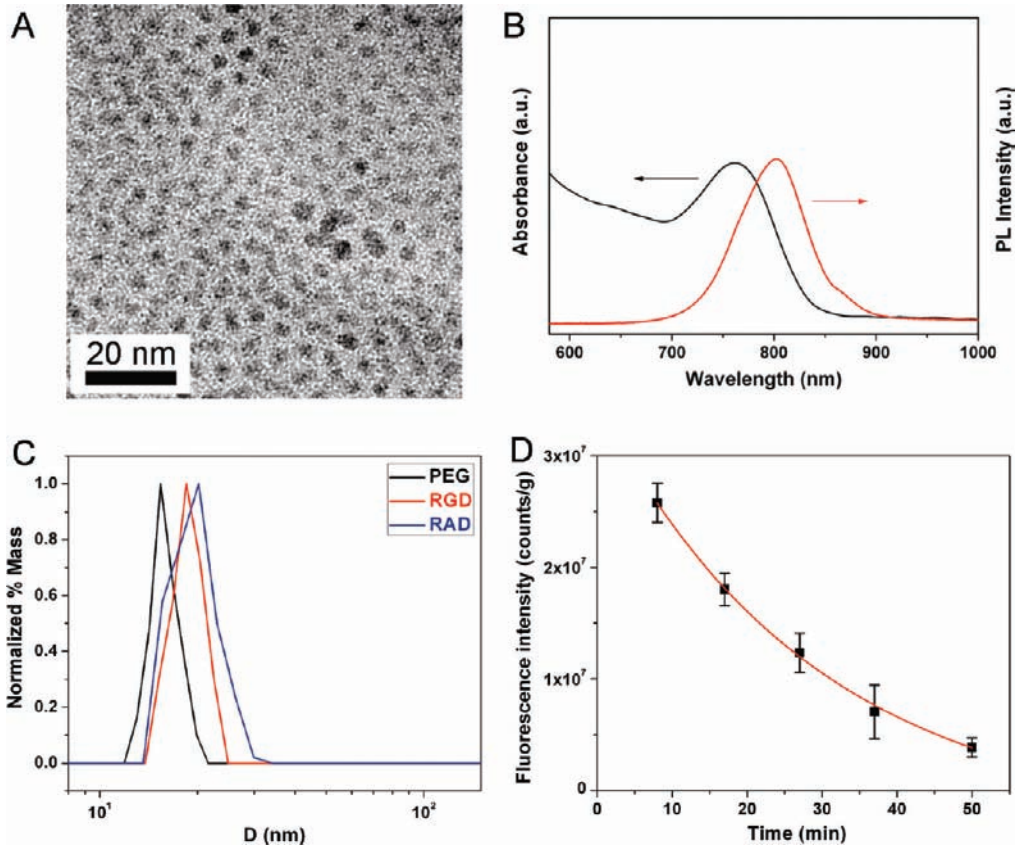

Figure 2. (A) TEM image and (B) absorbance and fluorescence emission spectra of InAs/InP/ZnSe core/shell/shell nanoparticles dispersed in chloroform, showing that the size of QDs is about 5 nm in diameter with the maximum emission peak at about 800 nm. (C) DLS analysis of QD800-PEG, QD800-RGD, and QD800-RAD with the HDs in PBS buffer of 16.5 nm, 19.6 nm, and 20.1 nm, respectively. (D) Circulation half-life analysis of QD800-PEG in nude mice, showing that the half-life of QD800-PEG is 29.0 ± 9.1 min.

maximum at ~800 nm in PBS buffer or 90% mouse serum (Figures S1 and S2, Supporting Information). After incubation of QD samples in mouse serum under typical body temperature (37 °C) for 24 h, over 80% of the emission intensity of QD800-RGD and QD800-RAD remained (Figure S3, Supporting Information), suggesting the good physiological stability of these peptide-labeled QDs. Dynamic light scattering (DLS) analysis showed that the HDs of QD800-PEG, QD800-RGD, and QD800-RAD are about 16.5 nm, 19.6 nm, and 20.1 nm, respectively (Figure 2C). On the basis of the size of these QD samples, the number of amine groups on the surface of each QD800-PEG (60−70 free amine groups) and the maximum ligand conjugation efficiency (40%−50%) (*37*), we estimated that there are 20−35 RGD peptides or RAD peptides on each peptide-labeled QD. In comparison with the small molecule mercaptopropionic acid (MPA) capped QD800-MPA (about 10 nm in HD) (*34*), QD800-PEG has a larger size in HD because of polymer coating. After the bioconjugation of RGD or RAD peptides on the surface of nanoparticles, the HDs of nanoparticles were slightly increased. In order to test the circulation half-life of QD800-PEG, we collected the blood samples within 1 h after the tail vein injection of QD particles in nude mice. Following the one-phase exponential decay, the analysis of the decrease in fluorescence intensity (i.e., ROI measurement) per gram of blood sample during blood circulation indicated that the half-life of QD800-PEG is about 29 min (Figure 2D). With the increase of HDs after peptide coupling, we estimated that the half-lives of QD800-RGD and QD800-RAD might be slightly shorter than that of QD800-PEG.

In Vivo Tumor-Targeted Imaging. After the preparation of these three samples (QD800-PEG, QD800-RGD, and QD800-RAD) with the final concentration of 1 μM in PBS buffer, we

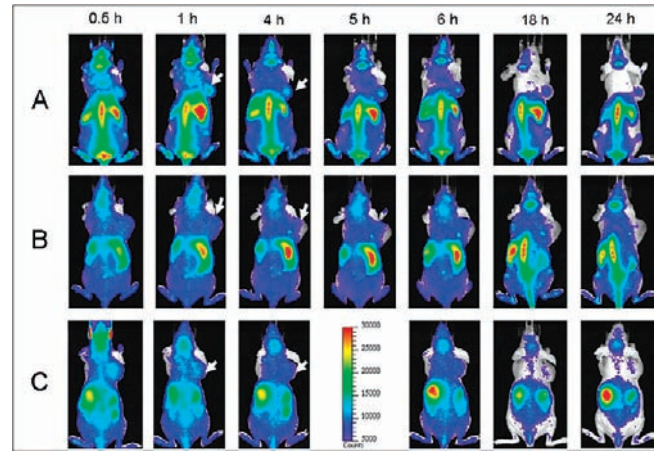

Figure 3. In vivo fluorescence imaging of U87MG tumor-bearing mice (arrows) injected with (A) QD800-RGD, (B) QD800-PEG, and (C) QD800-RAD.

administered intravenous injections (200 μL per mouse) into the athymic nude mice bearing subcutaneous U87MG human glioblastoma tumors. We used an IVIS 100 series to take the fluorescence images at multiple time points (0.5, 1, 4, 5, 6, 18, and 24 h). We set the Cy5.5 excitation filter (615−665 nm) and the ICG emission filter (800−875 nm) to take the fluorescence images with a strong fluorescent signal and low background signal. As shown in Figure 3, as early as 0.5 h postinjection (p.i.), the fluorescence signal derived from QD800-RGD and QD800-RAD both appeared in the tumors. After about 1 h, the tumors were very distinguishable from other tissues with good fluorescence contrast (arrows) in the mice injected

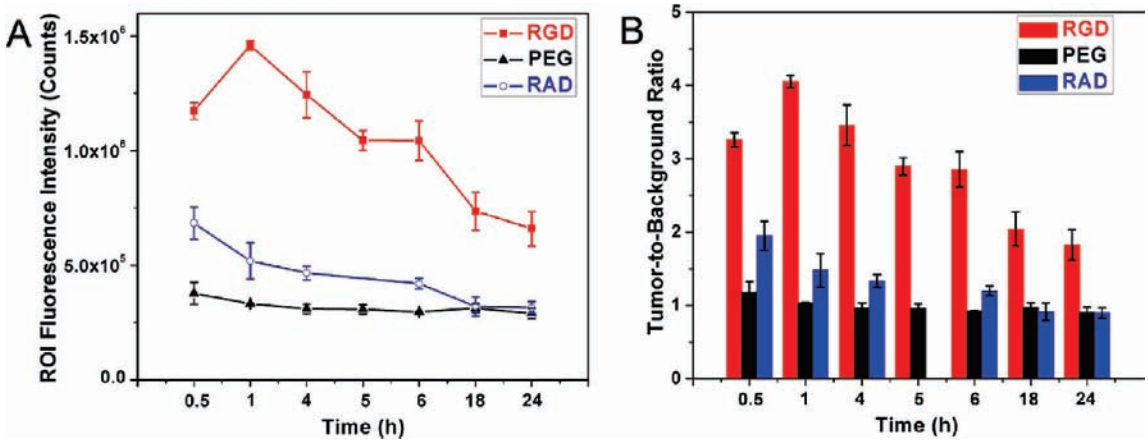

Figure 4. (A) Tumor fluorescence intensity-time and (B) tumor-to-background ratios of mice injected with QD800-RGD, QD800-PEG, and QD800-RAD. The data are represented as mean ± standard deviation (SD), $n = 3$/group.

with QD800-RGD (Figure 3A), indicating highly specific tumor targeting of QD800-RGD. However, the tumor fluorescence intensity decreased over the time in the mice injected with QD800-RAD (arrows, Figure 3C). We did not observe the tumor contrast in the mice injected with QD800-PEG (Figure 3B). The particularly bright fluorescence from the liver, spleen, and bone marrow reflected the reticuloendothelial system (RES)'s accumulation of QDs at these sites, which accounts for the relatively short half-lives of these QDs. The rapid uptake of QDs by the RES may significantly reduce their half-lives. It is noticed that the tumor contrast was still obvious even after 24 h in the mice injected with QD800-RGD, indicating that the tumor targeting of QD800-RGD induces high retention of QDs in the tumor site, which was further confirmed by the analysis of ROI. Under the assistance of Living Image software, we recorded the information of ROI and computed the statistical data for the ROI measurements. As shown in Figure 4A, after about 1 h p.i. of QD800-RGD, the fluorescence signal of the tumor reached the maximum and then slightly decreased over time (tumor-to-background ratios were 3.26 ± 0.10, 4.26 ± 0.08, 3.46 ± 0.27, 2.90 ± 0.12, 2.85 ± 0.24, 2.04 ± 0.23, and 1.83 ± 0.21 at 0.5, 1, 4, 5, 6, 18, and 24 h p.i., respectively, $n = 3$/group; Figure 4B), while there was little to no tumor contrast in the mice injected with QD800-PEG or QD800-RAD (Figure 4B).

Ex Vivo Fluorescence Imaging and Semiquantitative Analysis. At 4 h p.i., the mice injected with QD800-RGD, QD800-PEG, or QD800-RAD were sacrificed. We collected the tumors and major organs to acquire fluorescence images under the same conditions as those in immediate in vivo imaging. As shown in Figure 5, ex vivo imaging further confirmed the obvious fluorescence signal in the U87MG tumor of mice injected with QD800-RGD (Figure 5A), whereas there was virtually no fluorescence signal in the tumors of mice injected with QD800-PEG or QD800-RAD (Figure 5B,C). Although the fluorescence intensity of the liver was highest among all of the organs, the difference between tumor fluorescence signals indicated that only QD800-RGD has the capability to specifically target and detect the U87MG tumor.

The fluorescence signal intensity of ex vivo imaging is close to a true reflection of the QDs retained inside the organs because of deep penetration in the NIR region and no antofluorescence in ex vivo images. Then, we performed the ROI analysis on the ex vivo fluorescence images to semiquantitatively study the uptake ratio of QDs in each organ. As shown in Figure 5D, the ROI analysis showed high tumor uptake of 10.7 ± 1.5%ID/g in the mice injected with QD800-RGD, while the tumor uptakes of QD800-PEG and QD800-RAD under the same conditions

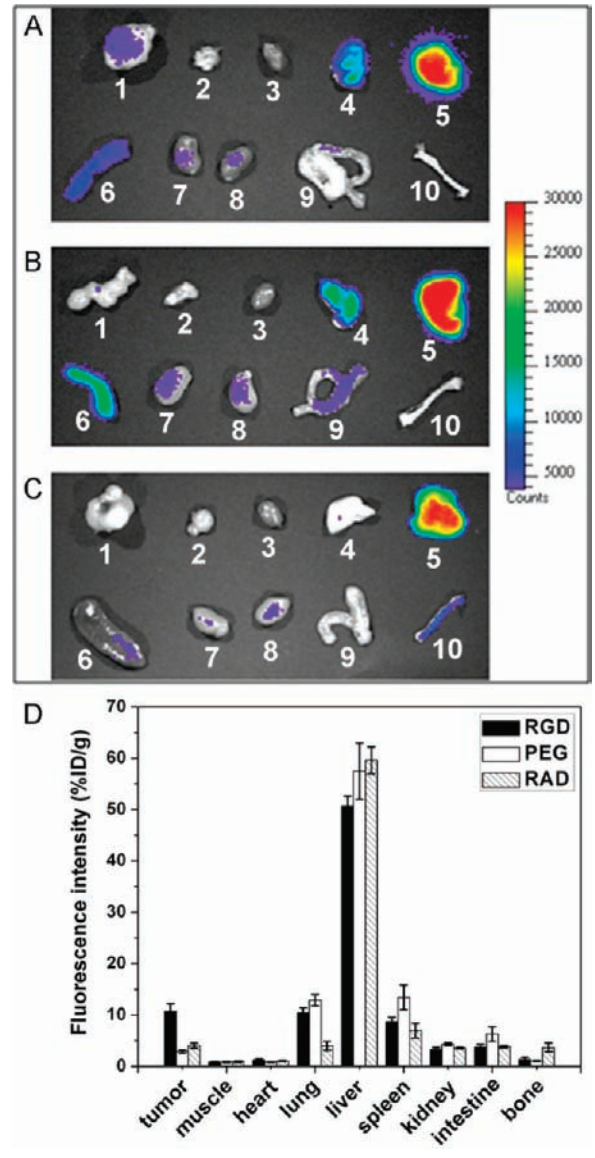

Figure 5. Ex vivo NIR fluorescence imaging after 4 h p.i. of (A) QD800-RGD, (B) QD800-PEG, and (C) QD800-RAD. In each image 1, U87MG tumor; 2, muscle; 3, heart; 4, lung; 5, liver; 6, spleen; 7, kidney (left); 8, kidney (right); 9, intestine; and 10, bone. (D) ROI analysis of major organs in ex vivo fluorescence imaging after 4 h p.i. of QD800-RGD, QD800-PEG, and QD800-RAD. The data are represented as mean ± standard deviation (SD), $n = 3$/group.

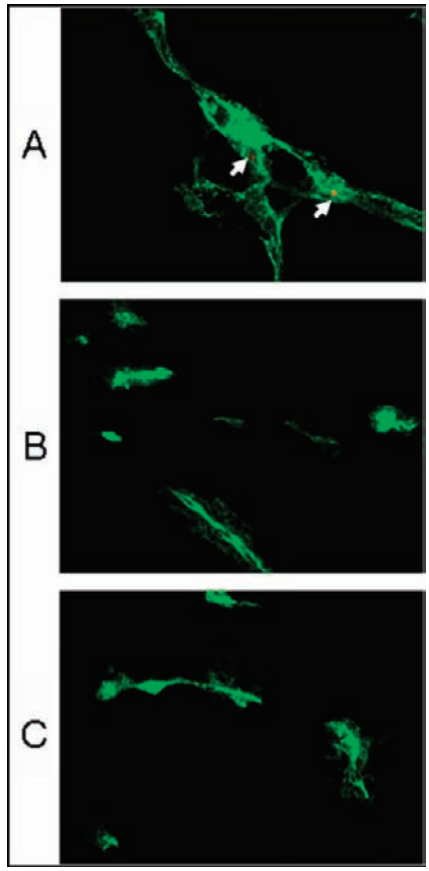

Figure 6. Immunofluorescence staining (CD31, green) of frozen U87MG tumor tissue slices from mice after 4 h p.i. of (A) QD800-RGD, (B) QD800-PEG, or (C) QD800-RAD. Arrows point to QD800-RGD nanoparticles staying within the tumor angiogenic vessel. Magnification: 400×.

were 2.9 ± 0.3%ID/g and 4.0 ± 0.5%ID/g, respectively. The semiquantitative ROI analysis further confirmed that QD800-RGD could be an excellent candidate as a probe for tumor-targeted fluorescence imaging. In order to verify the highly specific targeting of QD800-RGD to the integrin $\alpha_v\beta_3$-positive tumor, we used the LS174T tumor model with very low $\alpha_v\beta_3$ overexpression (*38*) as the negative control to do the fluorescence imaging (Figure S4, Supporting Information). The low LS174T tumor uptake of QD800-RGD (~2.8%ID/g at 4 h p.i.) indicated that QD800-RGD specifically targets integrin $\alpha_v\beta_3$ in living mice.

Histology Study. In order to investigate the microscopic localization of QDs in the tumors, CD31 immunostaining of tumor tissue slides would allow the visualization of tumor vasculature. From the fluorescence overlay images (Figure 6), we indeed found the presence of QD800-RGD in the tumor vessels (arrows, Figure 6A) but no QD fluorescence signal in the tumor vessels of mice injected with QD800-PEG or QD800-RAD (Figure 6B,C). The excellent overlay between QD fluorescence and CD31 staining of tumor vessels confirmed that QD800-RGD did not extravasate the tumor vessels, suggesting that these QDs with big size (about 20 nm in HD) could only target vascular integrin but not tumor cell integrin (*9, 10, 39*). However, the QDs with smaller size (<10 nm in HD) may facilitate extravasation due to the enhanced permeability and retention (EPR) effect, enhance the specific targeting to tumor cells, and minimize the RES uptake (*40*−*43*). Indeed, the coating, size, and surface charge of NIR QDs are three key features to influence the in vivo behavior of QDs and should be considered for future designs of QDs as imaging probes for clinical uses (*43*−*45*).

CONCLUSIONS

In this work, we have investigated in vivo tumor-targeted fluorescence imaging using QD800-RGD. The QD800-RGD nanoparticles are NIR fluorescent (emission wavelength higher than 750 nm), non-cadmium containing (lower toxic than Cd-based QDs (*34*)), and specific to target integrin $\alpha_v\beta_3$. In comparison with QD800-PEG and QD800-RAD, the tumor uptake of QD800-RGD is much higher with good contrast from the surrounding tissues, indicating specific tumor targeting of QD800-RGD. The results shown here, together with our previous work (*9, 10, 36*), fully demonstrated the reproducibility of bioconjugation between QDs and RGD peptide, the feasibility of QD-RGD bioconjugates as tumor-targeted fluorescence probes, and the possibility of QDs in the applications of molecular imaging and diagnosis.

High Relaxivity Trimetallic Nitride (Gd_3N) Metallofullerene MRI Contrast Agents with Optimized Functionality

Jianfei Zhang,[†] Panos P. Fatouros,[‡] Chunying Shu,[†] Jonathan Reid,[†] Lesley Shantell Owens,[†] Ting Cai,[†] Harry W. Gibson,[†] Gary L. Long,[†] Frank D. Corwin,[‡] Zhi-Jian Chen,[§] and Harry C. Dorn*,[†]

Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24060, and Department of Radiology and Department of Neurosurgery, Virginia Commonwealth University, Richmond, Virginia 23298. Received August 23, 2009; Revised Manuscript Received November 20, 2009

Water-soluble poly(ethylene glycol) (PEG) functionalized and hydroxylated endohedral trimetallic nitride metallofullerene derivatives, $Gd_3N@C_{80}[DiPEG(OH)_x]$, have been synthesized and characterized. The ^1H MRI relaxivities in aqueous solution were measured for the derivatives with four different molecular weights of PEG (350−5000 Da) at 0.35, 2.4, and 9.4 T. The 350/750 Da PEG derivatives have the highest relaxivities among the derivatives, 237/232 mM^{-1} s^{-1} for r_1 and 460/398 mM^{-1} s^{-1} for r_2 (79/77 mM^{-1} s^{-1} and 153/133 mM^{-1} s^{-1} based on Gd^{3+} ion), respectively, at a clinical-range magnetic field of 2.4 T. These represent some of the highest relaxivities reported for commercial or investigational MRI contrast agents. Dynamic light scattering results confirm a larger average size for 350/750 Da PEGs derivatives (95/96 nm) relative to longer chain length derivatives, 5000 Da PEG derivatives (37 nm). Direct infusion of the optimized 350 Da PEG derivatives into live tumor-bearing rat brains demonstrated an initial uniform distribution, and hence, the potential for effective brachytherapy applications when the encapsulated Gd^{3+} ions are replaced with radioactive ^{177}Lu.

INTRODUCTION

Magnetic resonance imaging (MRI) is widely used in the clinical diagnosis of cancer and other diseases. Improved contrast can be obtained by the use of intravenously injected paramagnetic contrast agents due to their extravasation across leaking vasculature and subsequent accumulation in lesions. Since contrast agents are widely employed in clinical MRI studies, these agents must be biologically safe and have a high relaxivity in order to minimize the amount delivered. Currently, the most widely used MRI contrast agents are gadolinium chelates: the large number of unpaired electrons (seven) per Gd^{3+} ion and favorably long electron spin−lattice relaxation time significantly increase the relaxation rate of water hydrogens (*1, 2*). However, it has been recently reported that nephrogenic systemic fibrosis (NSF), a painful and debilitating disorder of the skin and systemic tissues in patients with renal insufficiency, is associated with exposure to Gd^{3+} ions from contrast agents (*3, 4*). New contrast agents with higher relaxivity and lower toxicity are an important target of current investigations.

Because of their shape, capacity for multiple *endo* encapsulants and isolation of the Gd^{3+} ions from the bioenvironment, endohedral metallofullerenes (EMFs) represent ideal next generation nanoparticles as diagnostic biomedical nanoprobes. Several new classes of MRI contrast agents, water-soluble endohedral metallofullerenes, have been reported (*5*−*17*). EMFs have been functionalized with hydrophilic groups, e.g., −OH or −COOH (*8*−*12*). These water-soluble EMF derivatives show significantly greater relaxivities than the chelated Gd^{3+} compounds in current clinical use.

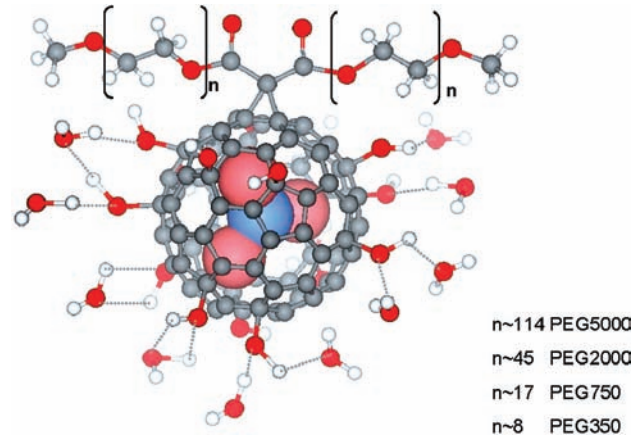

Figure 1. The $Gd_3N@C_{80}[DiPEG(OH)_x]$ nanoparticle with several hydrogen-bonded water molecules shown.

We have previously reported the synthesis of trimetallic nitride templated (TNT) EMFs, $A_xB_{3-x}N@C_{80}$ (A,B = metal, x = 0−3) (*18*). The TNT EMFs have an additional advantage: they can encapsulate up to three Gd^{3+} ions inside the cage, resulting in higher relaxivity. If different metal atoms/ions are encapsulated, e.g., Lu, Tb, Ho, and so forth, TNT EMFs can also act as multimodal (MRI and radiotherapy) platforms with the same biodistribution. We previously reported the synthesis of $Gd_3N@C_{80}[DiPEG5000(OH)_x]$ (PEG = poly(ethylene glycol)) (*7*), which is water-soluble and exhibits high relaxivity. *In vitro* and *in vivo* studies demonstrated the potential applicability of this MRI contrast agent. More recent studies have also demonstrated high relaxivity for related TNT EMFs with different functionalities (*13, 15, 16*). The high relaxivity of the TNT EMFs derivative arises from the following factors: (1) the large number of exchangeable water molecules coordinated to the hydroxyl groups which are attached to the carbon cage (Figure 1) and are simultaneously relaxed by the $(Gd_3N)^{6+}$

endohedral cluster, (2) the slow rotational correlation time caused by the long PEG chain and aggregation effects.

In the current study, we synthesized pegylated and hydroxylated $Gd_3N@C_{80}$ with different PEG chain lengths (350−5000 MW), and the relaxivities of these derivatives were measured at three different magnetic field strengths. The optimum PEG chain of these pegylated and hydroxylated $Gd_3N@C_{80}$ derivatives is an important structural property for potential MRI studies at different magnetic field strengths. To demonstrate the *in vivo* applicability of these high-relaxivity contrast agents, a convection-enhanced delivery (CED) method was used to infuse $Gd_3N@C_{80}$[DiPEG(OH)$_x$] directly into a brain-tumor-bearing rat.

MATERIALS AND METHODS

Synthesis of $Gd_3N@C_{80}$[DiPEG(OH)$_x$]. $Gd_3N@C_{80}$ was produced by the standard Krätschmer-Huffman (K−H) method with the introduction of nitrogen gas into the K−H generator (*18*). The product was purified by HPLC as previously reported (*19*). 1,8-Diazabicyclo(5.4.0)undec-7-ene (DBU, FW 152.24), 98%, was purchased from Sigma-Aldrich; 99% CBr_4, 99% 18-crown-6, 50% sodium hydroxide solution, and 30 wt % hydrogen peroxide were used as obtained from Aldrich Chemical Co. Di{ω-methyl-poly(ethylene glycol)} malonate (DiPEG) 350, 750, 2000, and 5000 (MW. 768, 1568, 4068, 10 068, respectively) were prepared from ω-methyl-poly(ethylene glycol)s (PEGs) as follows: To a solution of PEG and triethylamine (TEA) in CH_2Cl_2, a solution of malonyl dichloride in CH_2Cl_2 was added dropwise. The molar ratio of PEG/TEA/malonyl dichloride was 2:2:1. The solution was stirred at room temperature under N_2 protection for 3 h, concentrated and dropped into a large amount of ethyl ether, and then fractionated by a silica gel column.

$Gd_3N@C_{80}$, DiPEG, DBU, and CBr_4 were dissolved in chlorobenzene in molar ratio 1:20:20:67. After deaeration with bubbling argon for 30 min, the solution was stirred overnight at room temperature. The resultant mixture was evaporated, and the residue was dissolved in toluene. To this solution, 18-crown-6 and 50% sodium hydroxide solution were added, and the resultant solution was stirred for 4 h. 1.5 mL hydrogen peroxide was added drop by drop, and more water was added. The mixture was stirred overnight at room temperature. The resultant solution was concentrated and separated on a Sephadex G25 (Pharmacia) size-exclusion gel column with distilled water as eluent to afford a narrow golden band (first fraction, pH ≤ 7). (See Supporting Information Figure 1.)The yield was up to 95%.

Relaxivity Measurements. The concentrations of Gd^{3+} ions were determined by inductively coupled plasma optical emission spectroscopy (ICP-OES, Perkin-Elmer Optima 5300DV) at 342.247 nm. The instrument was calibrated by a 10 ppm ICP standard solution. Each molecule was assumed to encapsulate three Gd^{3+} ions, so the concentration of $Gd_3N@C_{80}$[DiPEG(OH)$_x$] was assumed to be one-third of the Gd^{3+} ion concentration.

The proton relaxation times were measured at three different magnetic field strengths: 0.35 T (TEACH SPIN PS1-B), 2.4 T (Bruker/Biospec), and 9.4 T (Varian Inova 400). The inversion−recovery method was used to measure T_1 and the Carr-Pucell-Meiboom-Gill method was used for measurement of T_2. The relaxivities were extracted from linear fits of plots of relaxation rates ($1/T_1$ and $1/T_2$) vs the concentrations of the paramagnetic species.

Dynamic Light Scattering. Dynamic light scattering (DLS) measurements were carried out with an ALV/CGS-3 compact goniometer system and ALV/LSE-5003 multi-τ digital correlator at 25 °C. He−Ne laser producing vertically polarized light of λ_0 = 632.8 nm was used as a light source. Each sample was filtered with a 0.5 μm cellulose acetate membrane filter.

Animal Studies. We used a convection-enhanced delivery method (*7*) to infuse 0.0235 mM $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] into a live rat brain tumor and followed the functionalized EMF redistribution over the course of several days. Infusion was applied for 180 min at a rate of 0.2 μL/min with a total infusion volume of 36 μL.

RESULTS AND DISCUSSION

^{1}H NMR. ^{1}H NMR spectra of $Gd_3N@C_{80}$[DiPEG(OH)$_x$] was performed on an Inova 400. Figure 2a displays the ^{1}H NMR spectra of $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] and malonyl DiPEG350 in D_2O. In $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] the $-OCH_3$ and $-OCH_2CH_2-$ signals appeared at δ3.35 ppm (s, 6H) and 3.67 ppm (m, 52H), respectively; the signals for $-COOCH_2-$ and $COOCH_2CH_2-$ centered at 4.32 ppm (t, 4H) and 3.78 ppm (t, 4H) in the malonate disappeared in the TNT EMFs derivative apparently due to the strong paramagnetic effect of the Gd^{3+} ions. The NMR spectra of other PEG derivatives gave similar results.

UV−Vis. The UV−Vis spectra of $Gd_3N@C_{80}$ and $Gd_3N@C_{80}$[DiPEG2000(OH)$_x$] are shown in Figure 2b. For $Gd_3N@C_{80}$, there is an absorption peak at about 710 nm and a second absorption occurs at 410 nm (*20*). These absorptions are attributed to the $\Pi\rightarrow\Pi^*$ transitions (*21*). For the functionalized metallofullerenes, however, these characteristic features are significantly reduced. This indicates that the conjugated π structure of the carbon cage has been significantly altered. Similar results were obtained with other samples with different molecular weights ($Gd_3N@C_{80}$[DiPEG5000, 750, 350(OH)$_x$]).

Mass Spectra. To confirm the functionalization, MALDI-TOF mass spectra were obtained for DiPEG750, $Gd_3N@C_{80}$[DiPEG750], and $Gd_3N@C_{80}$[DiPEG750(OH)$_x$] (see Supporting Information Figure 2). The spectrum for DiPEG 750 was a series of peaks centered at about *m*/*z* 1388. The peaks were separated by *m*/*z* 44, which is the mass of the (CH_2CH_2O) unit. The spectrum of $Gd_3N@C_{80}$[DiPEG750] was a series of peaks centered at about *m*/*z* 2907. The separation of *m*/*z* 1 is attributed to the isotope effect of $Gd_3N@C_{80}$. We can clearly see that $Gd_3N@C_{80}$ was successfully functionalized with DiPEG750. However, in the mass spectrum of $Gd_3N@C_{80}$[DiPEG750(OH)$_x$] we only observed peaks for metallofullerene (*m*/*z* 1447) and PEG fragments (centered at *m*/*z* 759 and separated by 44). Even though the molecular ion peak was not observed, the metallofullerene and PEG fragments indicate successful functionalization.

MRI Relaxivity. The ability of paramagnetic compounds to enhance the relaxation rate can be described by the following equation (*1, 2*):

$$\frac{1}{T_{i,\mathrm{obs}}} = \frac{1}{T_{i,\mathrm{H_2O}}} + \frac{1}{T_{i,\mathrm{para}}} = \frac{1}{T_{i,\mathrm{H_2O}}} + r_i[\mathrm{M}] \quad i = 1,2 \quad (1)$$

$1/T_1$ and $1/T_2$ are the longitudinal and transverse relaxation rates. $1/T_{i,\mathrm{obs}}$ is the observed value of the solution and $1/T_{i,\mathrm{para}}$ is the contribution of the paramagnetic compound. [M] is the concentration of the paramagnetic species. r_1 and r_2 are defined as longitudinal and transverse relaxivities, respectively, which are expressed in $(\mathrm{mM}\cdot\mathrm{s})^{-1}$.

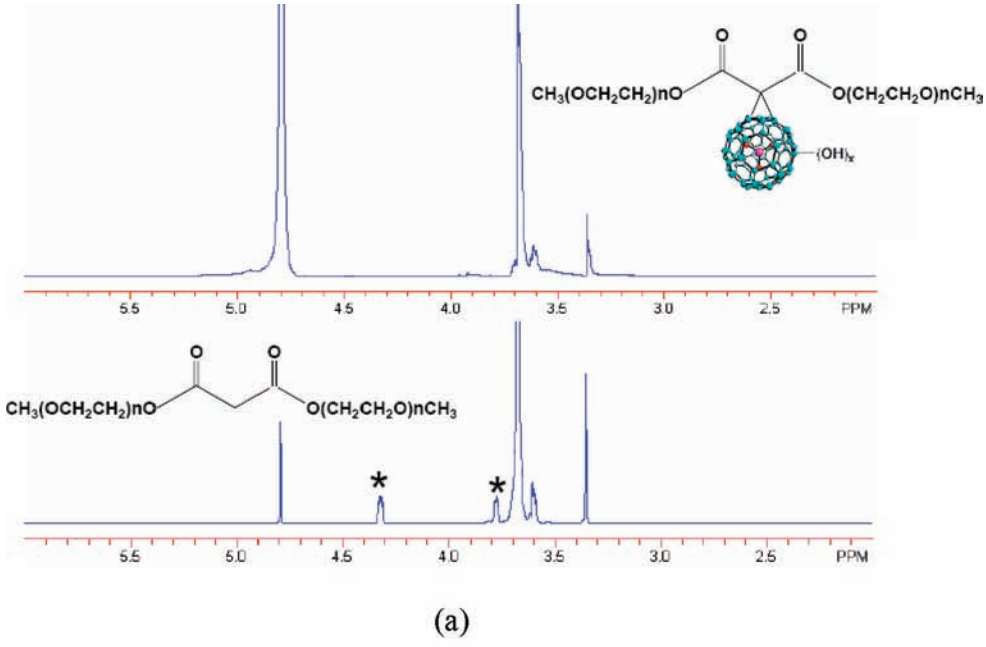
A major contribution to $1/T_{i,\mathrm{para}}$ arises from the simultaneous relaxation of multiple water molecules. This is the result of the dipolar electron−nuclear spin interaction between the large fluctuating Gd^{3+} electron magnetic moment and the water hydrogen nucleus. These relaxed water molecules undergo subsequent rapid exchange with bulk water. Dipole−dipole interactions are described by the Solomon-Bloembergen-Morgan

(SBM) equations. In the high-field region (above 10 MHz), these equations reduce to (*1, 2*)

$$\frac{1}{T_{1M}} = \frac{6}{15}\frac{\gamma_I^2 g^2 \mu_B^2 S(S+1)}{r_H^6}\left(\frac{\tau_C}{1+\omega_H^2\tau_c^2}\right) \quad (2)$$

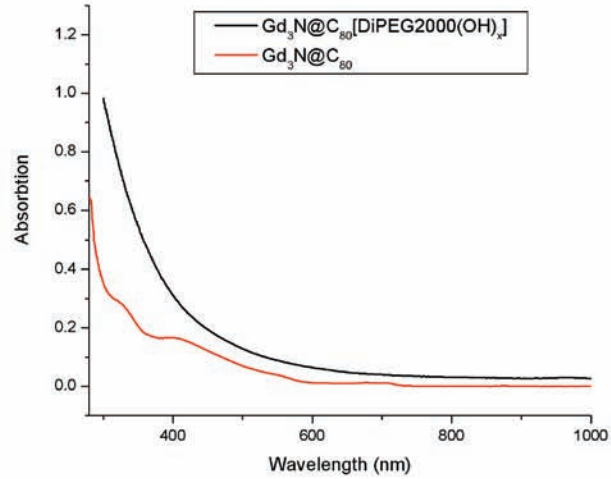
$$\frac{1}{T_{2M}} = \frac{1}{15}\frac{\gamma_I^2 g^2 \mu_B^2 S(S+1)}{r_H^6}\left(4\tau_c + \frac{3\tau_C}{1+\omega_H^2\tau_c^2}\right) \quad (3)$$

$$\tau_C^{-1} = \tau_M^{-1} + \tau_R^{-1} + \tau_{1e}^{-1} \quad (4)$$



If a water exchange process exists, then the relaxation rates are (*1, 2*):

$$\frac{1}{T_{1,para}} = \frac{q[M]/55600}{T_{1M}+\tau_M} \quad (5)$$



$$\frac{1}{T_{2,para}} = \frac{q[M]/55600}{T_{2M}+\tau_M} \quad (6)$$

[M] is in units of mM, τ_R is the rotational correlation time, τ_M is the residence time of the coordinated water molecules, ω_H is the Larmor frequency of proton, τ_{1e} is the longitudinal relaxation time of electron, and q is the number of the water molecules that coordinate to the paramagnetic molecules. τ_C is dominated by the shortest correlation time among τ_R, τ_M, and τ_{1e}. If τ_R is the dominant time, the relaxivity as a function of frequency shows a broad maximum peak that increases with increasing τ_R (*1*).

In the present investigation, the relaxivities of all the $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples were measured. The results are summarized in Table 1. Our previously reported relaxivities for $Gd_3N@C_{80}$[DiPEG5000(OH)$_x$] (*7*) are also listed, and they agree with the current data. All the $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples have high r_1 and r_2 values at all three magnetic field strengths. The r_1 values range from

	237 (79.0 Gd^{3+} based)	2.4
	68.2 (22.7 Gd^{3+} based)	9.4

[a] The relaxivities were measured at room temperature in water.

139 mM^{-1} s^{-1} (Gd^{3+} based relaxivity 46.3 mM^{-1} s^{-1}) to 237 mM^{-1} s^{-1} (Gd^{3+}-based relaxivity 79.0 mM^{-1} s^{-1}) for the different PEG chains at 2.4 T compared to the value of about 4 mM^{-1} s^{-1} for commercially available Gd^{3+} ion chelated contrast agents. Several other groups have also reported r_1 values of mono gadofullerene derivatives, that is, one Gd^{3+} ion per fullerene cage. These r_1 values are typically higher than those of commercial MRI contrast agents. In our work, the relaxivities of all the $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples are significantly higher on a per molecule basis. A summary of these other studies and the relaxivities of $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] in the current study are presented in Table 2 (*6, 8, 9, 11, 12, 22*).

As previously indicated, a primary reason for the high molar relaxivity of the $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples in comparison with other endohedral metallofullerenes derivatives originates from the presence of three Gd^{3+} ions within the cage: the charge transfer between the $(Gd_3N)^{6+}$ cluster and the $(C_{80})^{6-}$ cage leads to a very stable nanoparticle. Previous studies have confirmed that ferromagnetic coupling in this cluster gives rise to a large magnetic moment, 21 μB (*23*). The dipolar electron−nuclear spin interaction between the fluctuating Gd^{3+} electron magnetic moment and the large number of exchangeable water hydrogen atoms induces efficient proton relaxation. This is in contrast with the conventional Gd-DTPA complex, which has a single water molecule bound in the first coordination sphere of the metal ion, exchanges rather slowly with the bulk water, and the entire complex tumbles very rapidly.

Further factors contributing to the relaxation process relate to the unique property of the fullerenes to aggregate and form large nanoclusters. Aggregation occurs frequently for water-soluble metallofullerenes and affects the relaxivity significantly as previous studies have shown (*5, 9*). For the low molar mass $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples, the aggregates are formed by hydrogen bonding between −OH groups; however, the hydrophobic fullerene−fullerene interactions are also strong. Hence, fullerene aggregates can be formed. According to the Debye-Stokes equation for rigid spherical particles

$$\tau_R = 4\pi\eta r_{eff}^3/3k_BT$$

the rotational correlation time τ_R increases as the particle radius increases, which is an important parameter influencing relaxivity as a function of magnetic field strength. It has also been postulated that the presence of these aggregates might lead to a "confined" pool of water molecules in the interstitial spaces between individual gadofullerenes, which exchanges rapidly with the bulk water increasing again the relaxivity (*24*). Depending on the PEG length and aggregate size, different restricted pools of water would be created as mentioned above influencing the measured overall relaxivities.

Table 3. r_2/r_1 Ratios of the Pegylated/Hydroxylated Samples

sample	r_2/r_1 (0.35 T)	r_2/r_1 (2.4 T)	r_2/r_1 (9.4 T)
5000	1.19	1.59	3.54
2000	1.14	1.58	5.20
750	1.11	1.72	4.33
350	1.18	1.94	6.42

In the limit of $\tau_M \ll T_{1M}$, T_{2M} for eqs 2 and 3, we obtain

$$r_2/r_1 = [3 + 4(1 + \omega_H^2\tau_C^2)]/6 \quad (7)$$

At low field, $\omega_H^2\tau_C^2 \ll 1$ and the ratio approaches the value $7/6 = 1.17$. Our measured ratios of r_2/r_1 are listed in Table 3. On the basis of eq 7, the ratios at 0.35 T are consistent with the predicted value. Another result of the SBM equations is $\omega_H\tau_C \approx 1$ at maximum r_1. According to eq 7, this leads to $r_2/r_1 \approx 11/6 = 1.83$ for the peak. The ratios for the 750 and 350 PEGs at 2.4 T are close to $11/6 = 1.83$ and hence the maximum r_1 values should occur near 100 MHz (2.4 T). We can also see that at 2.4 T the 750/350 Da species has the maximum r_1 of all the samples. Hence, at 2.4 T for the 750/350 samples we obtain $\tau_C = 1/\omega_H = 1.59$ ns, which is significantly longer than the commercial contrast agent, e.g., $\tau_R = 66$ ps for the [Gd(DTPA-BMA)] (*1*). This assumes that τ_C is dominated by a rotational component.

The aggregation behavior was studied by DLS experiments. The DLS results for all $Gd_3N@C_{80}$[DiPEG(OH)$_x$] samples are shown in Figure 3. The mean peak positions are 75 nm, 76 nm, 58 nm, and 37 nm for $Gd_3N@C_{80}$[DiPEG350(OH)$_x$], $Gd_3N@C_{80}$[DiPEG750(OH)$_x$], $Gd_3N@C_{80}$[DiPEG2000(OH)$_x$], and $Gd_3N@C_{80}$[DiPEG5000(OH)$_x$], respectively. The 350PEG and 750PEG samples have the largest average aggregation size (∼75 nm), while the 5000PEG sample is much smaller (∼37 nm). The trend of decreasing aggregation size with increasing molecular weight is consistent with the relaxivity trend. It should

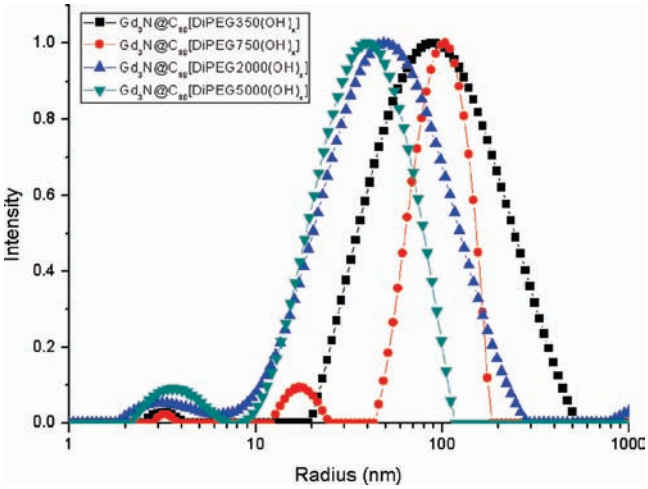

Figure 3. Size distribution of $Gd_3N@C_{80}$[DiPEG(OH)$_x$] from DLS experiments. The mean peak positions are 75 nm, 76 nm, 58 nm, and 37 nm for $Gd_3N@C_{80}$[DiPEG350(OH)$_x$], $Gd_3N@C_{80}$[DiPEG750(OH)$_x$], $Gd_3N@C_{80}$[DiPEG2000(OH)$_x$] and $Gd_3N@C_{80}$[DiPEG5000(OH)$_x$], respectively.

also be noted that these pegylated particles clearly deviate from spherical shape and the ones with longer PEG chains might exhibit internal flexibility. This could be an important additional factor for the observed reduced relaxivities for these larger molecules due to increased anisotropic rotation described by a fast local motion component that controls relaxivity and a slow global motional component (*25*).

Animal Infusion Study. Pure T_1 computed images of three consecutive brain slices of a live rat brain following infusion of 0.0235 mM $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] into the brain tumor are shown in Figure 4. The middle column indicates the slice with the tumor, while the left and the right columns are slices without tumor used as controls. Immediately after the infusion is terminated ("3.5 h"), the $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] nanoparticles have been distributed throughout the tumor, reducing the tissue T_1 values. The tumor appears as a dark area, as the white circle indicates. As time progresses, the brain tumor grows and the $Gd_3N@C_{80}$[DiPEG350(OH)$_x$] nanoparticles appear to be pushed out into the tumor periphery. This is illustrated at day 7 in the T_1 map, which shows aggregates on the surface, and the T_1-weighted image shows an enhancement ring around the tumor. These results illustrate the enhanced *in vivo* relaxivity of this optimized $Gd_3N@C_{80}$-[DiPEG350(OH)$_x$] system at low molar concentrations. It should also be noted that after 7 days the nanoparticles can still enhance the MRI contrast, which indicates that these metallofullerene agents can be used for long-term imaging diagnostic applications. In addition, these metallofullerene agents provide a platform for effective brachytherapy applications when Gd is replaced and/or combined with other radioactive agents (^{177}Lu).

CONCLUSIONS

We synthesized hydroxylated and pegylated Gd-containing TNT EMFs, $Gd_3N@C_{80}$[DiPEG(OH)$_x$], with different chain lengths of PEG. The relaxivities were measured at three magnetic field strengths. All the samples show significantly higher r_1 and r_2 compared to commercially available Gd-chelates and show considerable promise as a new class of contrast agents. They represent some of the highest relaxivities reported in the literature for commercial and investigational MRI contrast agents. Analyzing the field dependence of r_1, r_2, and r_2/r_1 indicates reasonable agreement with the predictions of the SBM theory under the assumption that the rotational correlation time τ_R dominates the relaxation process. Direct infusion of these particles into the live tumor-bearing rat brain demonstrates an initial uniform distribution and hence the potential for effective brachytherapy applications when Gd is replaced with radioactive ^{177}Lu.

DNA Photocleavage by DNA and DNA−LNA Amino Acid−Dye Conjugates

Adva Biton, Aviva Ezra, Jana Kasparkova, Viktor Brabec, and Eylon Yavin*

Department of Medicinal Chemistry, The Institute for Drug Research, The School of Pharmacy, The Hebrew University of Jerusalem, Hadassah Ein-Karem, Jerusalem 91120, Israel, and Institute of Biophysics, Academy of Sciences of the Czech Republic, v.v.i., 61265 Brno, Czech Republic. Received August 26, 2009; Revised Manuscript Received December 28, 2009

DNA photocleavage by triplex forming oligonucleotides (TFO) has potential implications in both biotechnology and medicine. We have synthesized a series of homopurine DNA and DNA/LNA 14-mers to which an amino acid (glycine or L-tryptophan) and a cyanine dye are covalently linked. Two cyanine dyes were examined that include a quinolinium ring linked to a benzothiazolium ring through a monomethine (TO1) or trimethine (TO2) linker. The 14-mer sequence was chosen to target mdm2, a ubiquitin ligase (E3) that regulates p53 by promoting its ubiquitylation and proteosomal degradation. Such inhibition has been previously proposed as a therapeutic approach to target wild-type p53-expressing cancers. To examine whether our TFO conjugates photocleave the mdm2 target, we incubated the various conjugates with the mdm2 plasmid and irradiated the samples with visible light. We show that only the TFO with the complementary sequence and with an intervening L-tryptophan leads to the linearization of the plasmid after a short irradiation time (10 min) exciting the dye (λ_{max}(TO1) = 500 nm and λ_{max}(TO2) = 630 nm) with visible light. Furthermore, the photoreactivity is more pronounced for the LNA/DNA conjugate, an observation that is consistent with improved hybridization to the DNA target. Sequence specificity of the photoreaction is further corroborated on a synthetic 44-mer duplex containing the TFO site. Evidence for a ROS-dependent mechanism is also given and discussed.

INTRODUCTION

The selective photocleavage of DNA holds great therapeutic potential as means of down-regulating gene expression in a controlled and persistent manner (*1*−*4*). A common and attractive approach depends on light activation of a DNA−dye conjugate, leading to the formation of reactive oxygen species (ROS) that are localized at the target site (*2, 3, 5*). Such an approach merits from the control in localizing the damage at a given area (e.g., tissue) and at a timely fashion.

Several studies have shown that such site-specific selectivity is achievable. Notable are extensive studies with psoralen-conjugates, that upon UV irradiation lead to stable cross-links on the target duplex DNA (*6*−*24*). Some ODN-conjugates have shown site-specific photoreactivity upon irradiation in the visible region (*25*−*32*), and only very few reports have applied dyes that have relevant wavelengths for in vivo applications (i.e. over 600 nm) (*33*−*35*).

For example, a lutetium (III) texaphyrin complex tethered to a 2′-OMe RNA analogue was shown to selectively photocleave a complementary DNA strand after sample irradiation (λ = 732 nm) followed by piperidine treatment, resulting in DNA strand breaks primarily at guanine residues (*34*). Such reactivity is a consequence of singlet oxygen generation that preferably oxidizes guanine, the base with the lowest oxidation potential of all four natural DNA bases. Piperidine is then required in order to promote DNA scission at oxidized sites.

The use of visible light to achieve direct DNA strand breaks would be advantageous, since (1) there would be no toxicity due to irradiation (as opposed to UV) and (2) DNA damage would be more deleterious (strand break as opposed to nucleobase oxidation). Thiazole orange (TO) is a highly fluorescent intercalating dye and an efficient singlet oxygen sensitizer (*36*). TO has negligible fluorescence in solution, and obtains intense fluorescence when bound to nucleic acids. Kelley and co-workers have shown that, upon tethering TO to a dipeptide having either L-tryptophan (W) or L-tyrosine (Y), photoactivation of the dye (at 500 nm) resulted in the generation of a stable peroxide on the aromatic ring promoting nonselective DNA cleavage (*37, 38*). It was also shown that Y and W were required for the observed DNA cleavage (as determined by supercoiled plasmid nicking) and that replacing these amino acids with glycine or L-phenylalanine resulted in a peptide−dye conjugate that had no apparent photoinduced activity toward plasmid DNA.

Inspired by the photoreactivity of TO-peptides discovered by the Kelley group, we decided to explore the possibility of tethering TO-tryptophan to a TFO in order to achieve frank DNA strand breaks after visible light irradiation of the conjugate in the presence of the target plasmid DNA. In addition to monomethine TO-conjugates, we synthesized a series of DNA conjugates that include a cyanine dye with a trimethine linker (TO2) (*39*), as this dye is photoexcited at a wavelength (630 nm) that is relevant for tissue penetration (i.e., photodynamic therapy) in an in vivo setting.

Furthermore, we explored the outcome of introducing LNA bases in the TFO in order to improve the hybridization of such TFOs to the targeted DNA (*40*−*46*). We chose a TFO consisting of the homopurine sequence 5′-AAAGGAAAGGGAAA to target the Mdm2 oncogene. Mdm2 acts as an inhibitor of p53 by accelerating its intracellular degradation. As Mdm2 is overexpressed in many cancer cells, it is an attractive anticancer target (*47*−*49*).

Herein, we report on the synthesis of the TFO conjugates and their photoreactivity toward the mdm2 gene in its DNA plasmid form and in a synthetic DNA duplex containing the TFO binding site.

EXPERIMENTAL PROCEDURES

Irradiation with Plasmid PCMV-MDM2. Photoinduced DNA cleavage experiments were done using the MDM2 plasmid

(8427 bp's) containing the target sequence that was incubated with the various DNA conjugates overnight at 37 °C. For DNA conjugates, the following buffer was used for incubation: 2 mM EDTA, 20 mM Tris, and 200 mM NaCl (pH = 7.4). For DNA/LNA conjugates, the following buffer was used for incubation: 10 mM NaH_2PO_4 and 50 mM NaCl (pH = 7.4).

Each of the conjugates were irradiated (in a dark room) for the indicated time with visible light. The light source used was a 150 W halogen lamp. This lamp (mrc) has a fiber optic that allows us to aim the light source onto the sample. Samples were placed in an eppendorf tube and the light source (from the filament) was about 1 cm away from the sample. Visible light was filtered with a cutoff filter (passing light between 400 to 600 nm for TO1 and 500 to 750 nm for TO2).

Irradiation with Synthetic 44-mer Duplex. The 44-mer duplex DNA as well as ssDNA markers were purchased from Synthezza (Jerusalem, Israel) and used as received. These sequences are as follows: 44-mers (with TFO target underlined), 3′ TCGGTCCGAAAGTAGTTTCCTTTCCCTT-TATGATAGTCTAAACA-5′; and its complementary sequence, 5′-AGCCAGGCTTTCATCAAAGGAAAGGGAAA-TACTATCAGATTTGT-3′. 23-mers: 3′-TTCCCTTTATGAT-AGTCTAAACA-5′ and 5′-AAGGGAAATACTATCAGA-TTTGT-3′. 20-mers: 3′-CCTTTATGATAGTCTAAACA-5′ and 5′-GGAAATACTATCAGATTTGT-3′. 17-mer: 3′-CCTTTAT-GATAGTCTAAACA-5′. 14-mer: 3′-TTATGATAGTCTAAA-CA-5′.

The 44-mer duplex containing the 14 base targeting sequence at its center was incubated (37 °C, 16 h) with an equimolar concentration (100 μM) of conjugate **3a**. The following buffer was used for incubation: 10 mM Tris, 100 mM NaCl, and 1 mM EDTA. All the samples were irradiated (in a dark room) for the indicated time (30 min) with visible light as described for plasmid irradiation.

Gel Electrophoresis. Agarose (1%) gel electrophoresis was carried out using Tris-acetate-EDTA (TAE) buffer. Running conditions: 60 min at 100 V. Denaturing (15% Urea) PAGE (19:1 acrylamide/bis-acrylamide) was carried out in Tris-borate-EDTA (TBE) buffer. Running conditions: 120 min at 100 V. The gels were stained with EB for 15 min and washed with DDW.

T_m Measurements. All thermal denaturation studies were carried out using quartz cuvettes with an optical path length of 1 cm on a Cary 300 UV/vis spectrophotometer interfaced with a computer for data collection and analysis. The temperature was increased and decreased from 20 to 80 °C at the rate of 1 °C/min. Samples were heated at 90 °C for 5 min and cooled down to room temperature for several hours prior measuring the melting profile of the dsDNA (44-mer). For triplex formation, the LNA-TFO (conjugate **3a**) was incubated with the dsDNA at 37 °C for 16 h.

Thermal denaturation experiments were carried out on a sample containing 1 μM duplex and same concentration of TFO for the triplex study. All samples were prepared in 10 mM Tris, 100 mM NaCl, and 1 mM EDTA. The melting temperature was determined by plotting the first derivative of the absorbance versus temperature profile and is accurate to ±1 °C.

Solid-Phase Synthesis of DNA and DNA/LNA Conjugates. The DNA (or DNA/LNA) oligomers were synthesized on an automated DNA synthesizer (ABI 3400) using standard phosphoramidite chemistry removing the DMT group at the 5′ end. All subsequent coupling reactions were performed on the solid phase (CPG resin (Glen Research), 2 μmol scale). The 5′-OH end of the oligos were extended with an ethylenediamine spacer by reacting the 5′-OH group with carbonyldiimidazole (CDI) (50 μmol CDI in 1 mL CH_3CN) for 1 h. After washing resin with CH_3CN (3 × 1 mL), ethylenediamine (10 μmol) and diisopropylethylamine (DIEA, 12 μmol) were added, and the reaction vessel was shacked overnight at RT. After washing the resin with dioxane (3 × 1 mL), CH_3CN (2 × 1 mL), and DCM (2 × 1 mL), coupling reactions with NPS (*O*-nitrophenylsulphenyl)-protected amino acids (L-tryptophan and glycine) were carried out using 4 equiv NPS-a.a. (8 μmol), 4.8 equiv HOBT (9.6 μmol), 4.8 equiv (9.6 μmol) HATU, and 8 equiv (16 μmol) DIEA in dry *N*,*N*-dimethylformamide (DMF, 1 mL) for 3 h. The NPS protecting group was removed with 2% dichloroacetic acid (DCA) in thioacetamide (TAA) (dissolved in 1 mL *N*-methylpyrrolidone ((NMP)) for 15 min. The free amine was finally coupled to the carboxy functionalized thiazole orange (TO1 or TO2, 4 equiv (8 μmol) under conditions as described for amino acid coupling.

DNA and DNA/LNA conjugates were removed from the resin by treating solid support with a 33% solution of NH_4OH for 1−2 h at room temperature. The supernatant was removed and incubated at 37 °C for 24 h to ensure the removal of all protecting groups from DNA and LNA bases. The NH_4OH solution was dried under vacuum and the resulting solid was purified by RP-HPLC (Shimatzu LC2010) using a semipreparative C18 reverse-phase column (Phenomenex, Jupiter 300 A) at a flow rate of 3.5 mL/min. Conditions for HPLC separation of DNA and DNA/LNA conjugates are described in detail in Supporting Information. Mobile phase A was either 50 mM NH_4OAc (pH 5.5) or 50 mM TEAA (pH = 7) with 5% CH_3CN; mobile phase B was either CH_3CN or MeOH. HPLC purified DNA and DNA/LNA conjugates were characterized by MALDI-TOF MS (see Table 1).

Table 1

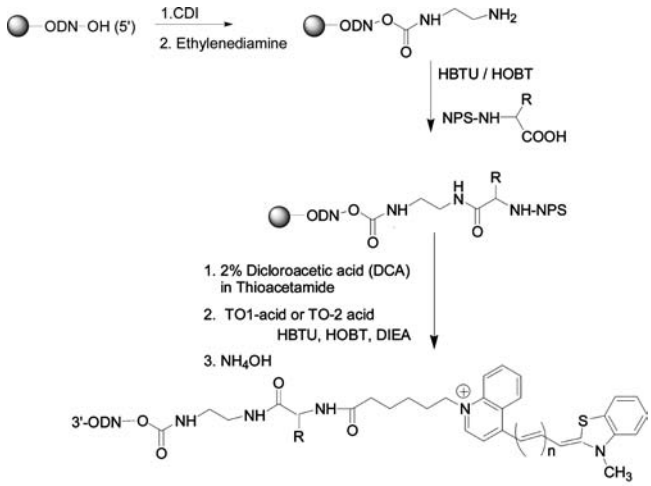
RESULTS



Synthesis of DNA and DNA/LNA-Amino Acid-Dye Conjugates. Scheme 1 shows the synthetic strategy for the synthesis of DNA and DNA/LNA-amino acid-dye conjugates with two cyanine dyes having either a monomethine linker (TO1) or a trimethine linker (TO2). Upon photoexcitation of such dye conjugates, the following processes are expected: (1) generation of singlet oxygen and/or peroxide upon photoactivation according to the choice of the intervening amino acid and (2) selective cleavage of the target DNA by conjugating a complementary TFO strand to the amino acid−dye moiety.

The possible photochemically induced reactions are depicted in Scheme 2.

Synthesis of cyanine dyes (TO1 and TO2) with pendant carboxylic acid moieties was accomplished according to the literature (*39*). Initially, the oligomer (14-mer homopurine, vide post) was synthesized on an automated DNA/RNA synthesizer on a standard CPG solid support. All subsequent reactions were carried out on the solid support including linker extension, as well as amino acid and dye conjugations.

NPS protected amino acids (glycine and L-tryptophan) were used for all conjugates. As the removal of NPS is achievable at mild reducing acidolysis conditions (*50*), this type of chemistry should be suitable for peptide-ODN synthesis. Indeed, we have

Scheme 2. Possible Photochemical Pathways of DNA and DNA/LNA-Amino Acid-Dye Conjugates

found that using NPS-protected amino acids is superior to that of Fmoc protected amino acids (based on HPLC analysis; data not shown). Finally, DNA and DNA/LNA conjugates were removed from the solid support by treating resins with a 33% solution of NH_4OH for 1−2 h. Subsequently, base protecting groups were removed by incubating the ammonia solution at 37 °C for 24 h. All DNA conjugates were then HPLC purified on a reverse phase C18 column and analyzed by Maldi-TOF MS (see Supporting Information for HPLC chromatograms).

Choice of Amino Acid and DNA Sequence. The introduction of L-tryptophan in close proximity to the dye is expected to lead to its oxidation via singlet oxygen sensitization yielding a peroxide on the indole ring (*37, 38*). Such an ROS is anticipated to cause direct DNA strand breaks. Of all the aromatic amino acids that exert such reactivity (Trp, Tyr, and His), L-tryptophan has been shown to yield the highest peroxide levels (*51*). A 14-mer homopurine sequence (5′-AAAGGAAAGGGAAA-3′) was chosen as a triplex-forming oligonucleotide (TFO) that has the propensity of forming a triplex with the sense strand of the mdm2 gene in an antiparallel fashion (*4*). A plasmid of this gene (P-CMV-mdm2) was used as the DNA target; this plasmid includes the 14-mer TFO target.

Thus, the "wild-type" TFO includes an intervening L-tryptophan between the ODN and the dye (conjugate **1a**, Scheme 1). As a comparison, we chose to introduce glycine at this position, as it is not expected to react with singlet oxygen, and in turn, such a conjugate should exclusively yield singlet oxygen upon photoactivation (conjugate **1b**, Scheme 1). In addition, we synthesized a scrambled TFO sequence with an intervening L-tryptophan as a control conjugate that potentially may form a peroxide on the indole ring but is not expected to form a triplex with the target DNA (conjugate **1c**, Scheme 1).

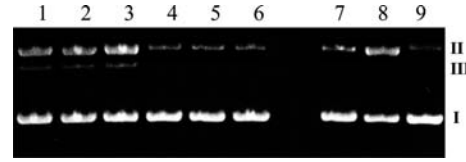

Figure 1. Photocleavage activity of conjugates **1a**−**1c** on the PCMV-MDM2 (8427 bp) plasmid in a buffer consisting of 2 mM EDTA, 20 mM Tris, and 200 mM NaCl (pH = 7.4) as determined by agarose gel electrophoresis. Solutions contained 2 μg plasmid and 10 μM TFO. Lanes 1−4: plasmid + conjugate **1a** (with L-tryptophan) after 15, 20, and 30 min of irradiation and in the dark, respectively. Lanes 5−6: plasmid + conjugate **1b** (scrambled) after 30 min of irradiation and in the dark. Lanes 7−8: plasmid + conjugate **1c** (with glycine) in the dark and after 30 min of irradiation. Lane 9: plasmid after 30 min irradiation.

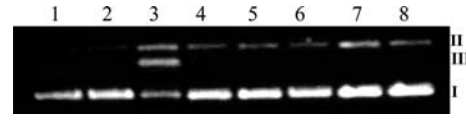

Figure 2. Oxygen dependence of photocleavage reaction of conjugates **1a** and **1b** with PCMV-MDM2 plasmid as determined by agarose gel electrophoresis. Solutions contained 2 μg plasmid and 10 μM TFO. Lanes 1 and 2, plasmid in the dark and after 30 min of irradiation; lanes 3−5, plasmid + conjugate **1a** without inhibitor, with NaN_3 (1 mM), and with Trolox (0.1 mM), respectively; lanes 6−8, plasmid + conjugate **1b** with NaN_3 (1 mM), without inhibitor and with Trolox (0.1 mM), respectively. The same buffer was used as in Figure 1.

Conjugates **1a**−**1c** all contain TO1 that is photoexcited at 500 nm. As a comparison, the analogous conjugates (conjugates **2a**−**2c**) were synthesized that include TO2; a dye that is excited at a longer wavelength, namely, 630 nm.

Finally a set of conjugates were synthesized with TO1 that included several LNA's as means to improve triplex formation (conjugates **3a**−**3c**).

Photocleavage of Plasmid DNA by DNA Conjugates. Prior to irradiation, DNA conjugates were incubated for 16 h with the plasmid DNA at 37 °C. In the case of the all-DNA TFO conjugates (**1a**−**c**, **2a**−**c**) a 100-fold molar excess of TFO was used to ensure triplex formation (*24*). As shown on the agarose gel (Figure 1), visible light irradiation of DNA conjugate **1a** with TO1 leads to some DNA relaxation of the supercoiled form (I) to the relaxed form (II) with a faint band corresponding to the linearized form (III) (lanes 1−3). Photoirradiation of the DNA conjugate with glycine (**1b**) results in some DNA relaxation of the plasmid with no indication of linearization (lane 8). Finally, the conjugate with the scrambled sequence (conjugate **1c**) has no apparent effect on the target plasmid DNA (lanes 5−6). Clearly, the photoreaction is sequence-specific, as the conjugate with the scrambled sequence (conjugate **1c**) does not lead to any detectable DNA photocleavage.

The DNA conjugates (**2a**−**2c**) with the TO2 dye were next examined for their photoactivity toward the mdm2 plasmid. As shown in Figure 3, a similar behavior was seen with these conjugates (**2a**−**2c**) as for the previous set (conjugates **1a**−**1c**). Thus, conjugate **2a** (with L-tryptophan) leads to extensive nicking of the supercoiled plasmid (lanes 6 and 7) with some indication for linearized plasmid (form III). Conjugate **2c** (scrambled) shows no photoactivity (lanes 2−4), similar to the behavior observed for conjugate **1c**. Finally, conjugate **2b** (with glycine) leads to some DNA relaxation (form II) (lanes 9−10) with no sign of the linear form (III).

Photocleavage of Plasmid DNA by DNA/LNA Conjugates. Prior to irradiation, DNA/LNA conjugates (**3a**−**3c**) were incubated for 16 h with the plasmid DNA at 37 °C. With

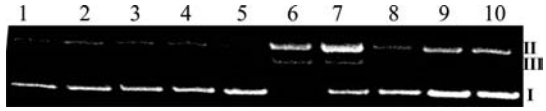

Figure 3. Photocleavage of PCMV-MDM2 plasmid by DNA conjugates with an appended cyanine dye TO2 as determined by agarose gel electrophoresis. Solutions contained 2 μg plasmid and 10 μM TFO. Lane 1, plasmid irradiated for 1 h (DNA only); lanes 2−4, plasmid + conjugate **2c** (scrambled) in the dark and after 1 h and 30 min irradiation, respectively; lanes 5−7, plasmid + conjugate **2a** (with L-tryptophan) in the dark and after 1 h and 30 min of irradiation, respectively; lanes 8−10, plasmid + conjugate **2b** (with glycine) in the dark and after 1 h and 30 min of irradiation, respectively. The same buffer was used as in Figure 1.

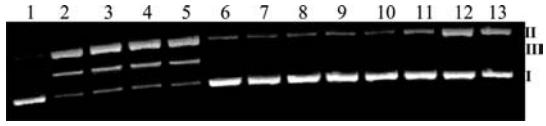

Figure 4. Photocleavage of PCMV-MDM2 plasmid by TFO containing LNA conjugates **3a**−**3c** (with TO1) in phosphate buffer (10 mM NaH_2PO_4, 50 mM NaCl, pH = 7.4), as determined by agarose gel electrophoresis. Lane 1, plasmid irradiated for 30 min (DNA only); lanes 2−6, plasmid + conjugate **3a** (with L-tryptophan) after 10, 15, 20, and 30 min irradiation and in the dark, respectively; lanes 7−9, plasmid + conjugate **3c** after 15 and 30 min irradiation and in dark, respectively; lanes 10−3, plasmid + TFO conjugate **3b** in the dark and after 10, 15, and 30 min irradiation, respectively.

the LNA/DNA hybrid (conjugates **3a**−**3c**), only a 2-fold access was used as such TFOs have been shown to readily from a triplex at such molar ratios. In order to verify triplex formation by the LNA conjugates, a synthetic 44-mer duplex containing the 14 base targeting sequence at its center was incubated (37 °C, 16 h) with an equimolar concentration (100 μM) of conjugate **3a**. Thermal denaturation profiles of the duplex and the triplex were carried out (see Supporting Information for thermal denaturation curves). A T_m value of 52 °C was determined by subtracting the triplex profile from that of the duplex profile. This value is similar (T_m = 50 °C) to that reported for a homopyrimidine 15-mer TFO containing 6 LNA's (*52*). The photoactivity of these set of conjugates is shown in Figure 4. Conjugate **3a** is shown to cause substantial linearization of the mdm2 plasmid after a short irradiation period of 10 min (lane 2). No significant change in the amount of nicked and linearized plasmid is observed at longer periods of irradiation (lanes 3−5). The scrambled LNA/DNA conjugate (**3c**) has no apparent photoactivity, whereas the conjugate with glycine (**3b**) leads only to plasmid DNA relaxation (form II).

Photocleavage of a Synthetic 44-mer Duplex DNA by DNA/LNA Conjugate 3a. To gain insight into the selectivity of DNA photocleavage by the LNA TFO (conjugate **3a**), a synthetic 44-mer duplex containing the 14-mer target site of conjugate **3a** was utilized as the DNA target. The 44-mer strands were chosen from the mdm2 plasmid with 15-mers flanking both sides of the central 14-mer target (underlined) as follows: 3′-TCGGTCCGAAAGTAGTTTCCTTTCCCTT-TATGATAGTCTAAACA-5′,5′-AGCCAGGCTTTCATCAAAG-GAAAGGGAAATACTATCAGATTTGT-3′.

A denaturing polyacrylamide gel (subsequently stained with EtBr) was used to follow the photoreaction (Figure 5). In lanes 1−6, various lengths of ssDNA were added as DNA markers in order to estimate the length of the DNA photoproduct formation. As shown in lane 9, a new migrating band is seen above the faster migrating TFO (**3a**) after sample irradiation (30 min); a product that is not observed in the dark control (lane 10: TFO + 44-mer duplex DNA without irradiation). This band migrates similarly to the 17-mer (lane 5). Thus, this gel is indicative of a site-specific photoreaction leading to a distinct

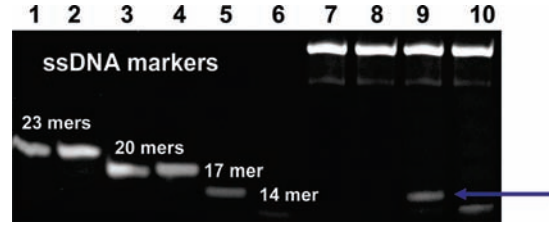

Figure 5. Photocleavage of a synthetic duplex DNA (a 44-mer containing the TFO targeting site at its center) by the TFO containing LNA conjugate **3a** (with TO1) in phosphate buffer (10 mM NaH_2PO_4, 50 mM NaCl, pH = 7.4), as determined by 15% denaturing polyacrylamide gel electrophoresis. Lanes 1−6: ssDNA markers with the same sequence composition as the 44-mer. 20- and 23-mers are from the 5′-end of the TC-rich 44-mer and from the 3′-end of the AG-rich 44-mer, respectively. 14- and 17-mers are from the 5′-end of the TC-rich 44-mer. Lanes 7 and 8: 44-mer duplex DNA in the dark and after irradiation (30′), respectively. Lanes 9 and 10: 44-mer duplex DNA and the LNA conjugate **3a** after 30′ irradiation and in the dark, respectively. Blue arrow indicates the formation of a new photoinduced DNA product. The gel was run in Tris-borate-EDTA (TBE) buffer for 120 min at 100 V and stained with ethidium bromide.

band that is in the range of 16−18 bases. It is not clear as to the fate of the remaining duplex (ca. 29 base pairs). We assume that this duplex is not well resolved and remains with the original 44-mer duplex at the upper part of the gel.

Photocleavage Activity Is Oxygen Dependent. In order to verify the involvement of reactive oxygen species (ROS) in the DNA photocleavage reaction, two ROS scavengers were used. Inhibition of cleavage in the presence of singlet oxygen quencher NaN_3 indicates the involvement of singlet oxygen as the reactive species (*53*) whereas a radical scavenger such as Trolox (*37, 54*) indicates the involvement of a peroxide.

As shown in Figure 2, there is a clear indication that the photoactivity depends on reactive oxygen species (ROS). Both NaN_3 and Trolox almost completely shut down photoreactivity of conjugate **1a** (Figure 2, lanes 4 and 5, respectively). These data are in agreement with both singlet oxygen and peroxide as the ROS involved in the observed photoactivity. In the case of conjugate **1b**, some attenuation in photoinduced DNA nicking is observed in the presence of NaN_3 (Figure 2, compare lanes 6 and 7). In the presence of Trolox (Figure 2, lane 8), DNA nicking is attenuated but to a lesser extent. As the photoactivity of this conjugate (**1b**) is generally not substantial, it is difficult to conclude on the inhibitory effect of Trolox on the photoactivity of conjugate **1b**.

DISCUSSION

Photocleavage of a specific gene at a PDT-relevant wavelength may be a powerful tool for genetic modifications both in biotechnology and in gene therapy. Toward this goal, we have studied a series of TFO conjugates that differ in several characteristics: (1) the choice of sequence (i.e., wild type vs scrambled), (2) the intervening amino acid (i.e., Gly vs Trp), (3) the dye molecule (i.e., TO1 vs TO2), and (4) the ODN type (i.e., DNA vs DNA/LNA). Table 1 summarizes the photoactivity of the various conjugates.

It is important to stress the contribution of the intervening amino acid. When glycine is placed between TFO and dye (conjugates **1b**, **2b**, and **3b**), the only photoinduced DNA damage to the mdm2-plasmid is nicking of supercoiled DNA (form I) to its relaxed form (form II), an observation that is consistent with singlet oxygen reactivity. However, when L-tryptophan is introduced, photoactivation of the conjugates (**1a**, **2a**, and **3a**) in the presence of the mdm2 plasmid leads to its linearization; particularly for the LNA/DNA conjugate (conjugate **3a**, Figure 4, lanes 2−5, and Table 1). This

observation is highly relevant in the context of the cell as such DNA damage (i.e., double strand breaks) is less manageable by the cellular DNA repair mechanism (*55*).

As Trolox inhibits this photoreaction (Figure 2, lanes 6) and in accordance with studies on the photoactivity of peptide-TO1 (*37, 38*), we conclude that a peroxide is formed on the indole ring of L-tryptophan leading to a radical reaction (most likely by 5′-hydrogen abstraction (*51*)). It is this mechanism that distinguishes the photoactivity of L-tryptophan containing conjugates (**1a**, **2a**, and **3a**) from their glycine counterparts (**1b**, **2b**, and **3b**).

The fact that linearization is more pronounced in the LNA/DNA TFO could be related to the superior hybridization that is expected from such a TFO in comparison to DNA-only TFO's. All conjugates with a scrambled TFO sequence (**1c**, **2c**, and **3c**) did not produce any detectable DNA damage upon photoactivation. This is indicative of a photoinduced reaction that is sequence-dependent. This is further supported by the photocleaved DNA product (lane 9, Figure 5) formed after irradiation of a synthetic 44-mer DNA duplex with the LNA TFO (conjugate **3a**).

Finally, when comparing both cyanine dyes (TO1 and TO2) we observe a similar photoactivity for all DNA conjugates (see Table 1). This is encouraging since, as opposed to TO1, TO2 has not been studied in the context of DNA damage. Thus, we have established the potential of utilizing cyanine dyes with longer absorption wavelengths for site-specific DNA photocleavage by TFO-Trp-Dye conjugates.

ACKNOWLEDGMENT

We thank the Alex Grass Center for Drug Design and Synthesis of Novel Therapeutics for financial support. The PCMV-MDM2 plasmid was generously provided by Prof. Matthias Dobbelstein. We thank Shimon Steingart for technical assistance. J.K. and V.B. were supported by the Grant Agency of the Academy of Sciences of the Czech Republic (IAA400040803).

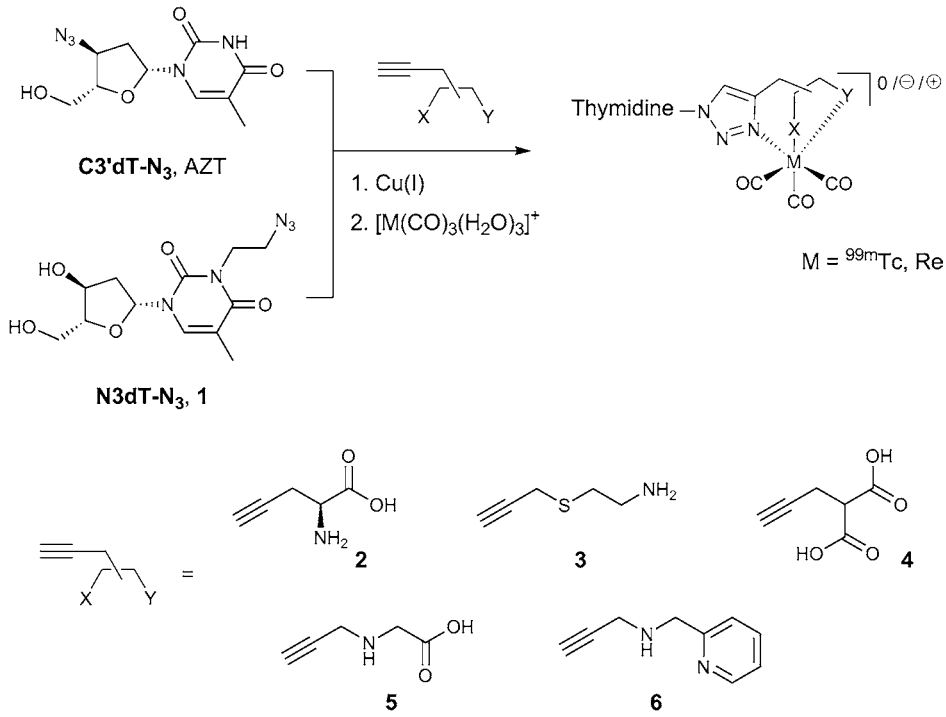
Received August 27, 2009; Revised Manuscript Received March 9, 2010

Human cytosolic thymidine kinase (hTK1) has proven to be a suitable target for the noninvasive imaging of cancer cell proliferation using radiolabeled thymidine analogues such as [^{18}F]3′-fluoro-3′-deoxythymidine ([^{18}F]FLT). A thymidine analogue for single photon emission computed tomography (SPECT), which incorporates the readily available and inexpensive nuclide technetium-99m, would be of considerable practical interest. hTK1 is known to accommodate modification of the structure of the natural substrate thymidine at the positions N3 and C3′ and, to a lesser extent, C5. In this work, we used the copper-catalyzed azide−alkyne cycloaddition to synthesize two series of derivatives in which thymidine is functionalized at either the C3′ or N3 position with chelating systems suitable for the $M(CO)_3$ core (M = ^{99m}Tc, Re). The click chemistry approach enabled complexes with different structures and overall charges to be synthesized from a common precursor. Using this strategy, the first organometallic hTK1 substrates in which thymidine is modified at the C3′ position were identified. Phosphorylation of the organometallic derivatives was measured relative to thymidine. We have shown that the influence of the overall charge of the derivatives is dependent on the position of functionalization. In the case of the C3′-functionalized derivatives, neutral and anionic substrates were most readily phosphorylated (20−28% of the value for the parent ligand thymidine), whereas for the N3-functionalized derivatives, cationic and neutral complexes were apparently better substrates for the enzyme (14−18%) than anionic derivatives (9%).

INTRODUCTION

Human thymidine kinase 1 (hTK1[1]) is a cytosolic enzyme which catalyzes the γ-phosphate transfer from ATP to the 5′-hydroxyl groups of thymidine (dT) and 2′-deoxyuridine (dUrd). Other hTK1 substrates include 3′-azido-3′-deoxythymdine, AZT, and 3′-fluoro-3′-deoxythymidine, FLT, where thymidine has been modified at the C3′-position, and the phosphorylation of which is the first step in their activation as anti-HIV prodrugs (*1, 2*). It is well documented, however, that hTK1 is among the most selective of the nucleoside kinases and is particularly sensitive to changes in the structure of the natural substrates dT and dUrd (*3*). Eriksson et al. have shown that minor modification of the structure at the 5-position is possible, for example, 5-halo and 5-ethyl substitutions are tolerated, but substitution with bulkier groups such as 5-propenyl or 5-(2-chloroethyl) are not (*1, 4*). More recently, Tjarks and co-workers have shown that hTK1 is also amenable to modification of thymidine at the N3-position (*5, 6*). Functionalization with a series of bulky carborane derivatives, tethered from N3 of the pyrimidine base with varying spacer length, does not prevent phosphorylation of the nucleoside analogue. The experimental results of substrate activity investigations have all since been rationalized by the determination of the 3-D structure of hTK1, which confirms that hTK1 has a much smaller binding site than other nucleoside kinases (*7*).

Unlike the activity of other mammalian deoxyribonucleoside kinases, hTK1 activity is stringently cell cycle regulated (*3*). Active enzyme is not found in resting cells, but activity increases dramatically by the time cells reach the S-phase, to coincide with DNA synthesis. A number of thymidine analogues, which aim to target the high hTK1 activity in proliferating cells, have been developed. As potential agents for boron neutron capture therapy, thymidine derivatives incorporating *closo-o-* and *nido-m*-carboranes have been extensively investigated (*5, 6, 8, 9*). Similarly, thymidine derivatives labeled with radionuclides suitable for positron emission tomography (PET) have been developed with the goal of monitoring tumor growth and response to therapy (*10−12*). However, PET nuclides typically have very short half-lives and their production is expensive, usually requiring an onsite cyclotron. A thymidine analogue labeled with technetium for in vivo single photon emission computed tomography (SPECT) would be of considerable interest. Technetium has nearly perfect decay characteristics for diagnostic applications ($T_{1/2}$ = 6 h, 140 keV γ-radiation); moreover, it is readily available at low cost from a ^{99}Mo/^{99m}Tc generator system.



Given the promising reports of the retained substrate activity of N3-functionalized carborane thymidine derivatives (*5, 6, 9*), the N3 position is appealing for functionalization with a technetium complex. We recently reported the synthesis and in vitro evaluation of two series of technetium-labeled thymidine

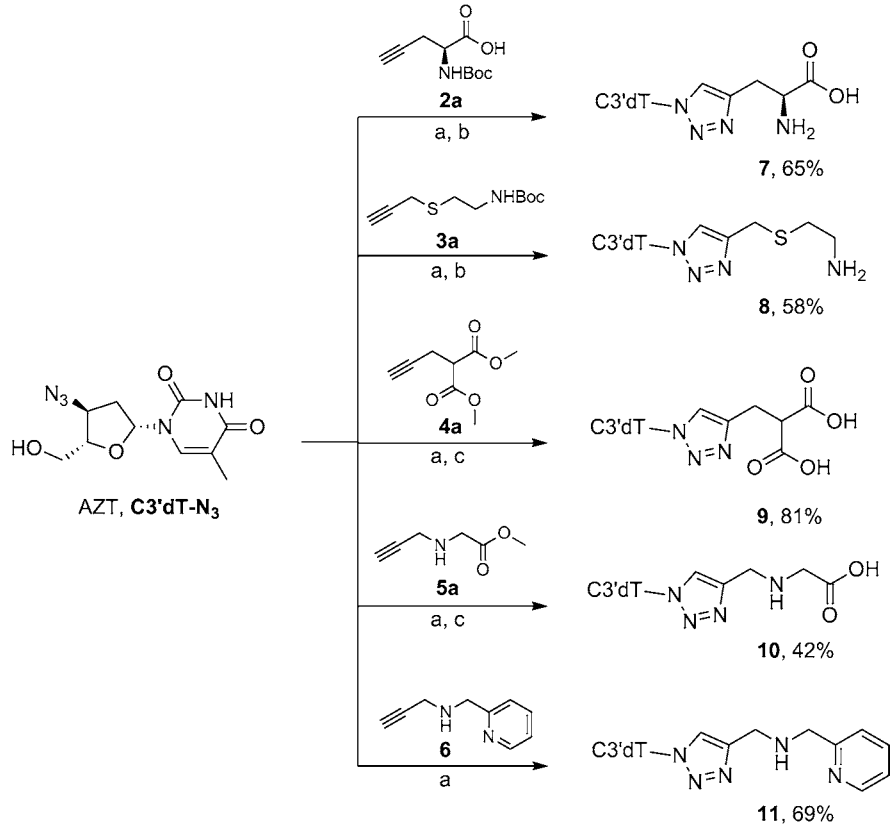
derivatives in which the nucleoside was functionalized at the N3 position and could qualitatively show that all of the compounds retained activity toward hTK1 (*13, 14*). It has also been reported that minor structural modifications at the C3′ position do not dramatically lower affinity toward hTK1 (*4*). From the elucidation of the structure of hTK1, Welin et al. suggest that tolerance of C3′ modification could be a result of the open nature of the C3′/C4′ environment and the proximity of the C3′ substituent to the surface of the enzyme (*7*). However, to our knowledge there have not been any systematic investigations into the steric tolerance of hTK1 at this position. Tjarks' group report a small series of compounds in which thymidine has been functionalized at the 3′ position with a carborane (*15*). Unfortunately, the poor stability of these compounds prevented their thorough characterization with respect to their activity toward hTK1.



The aim of the current investigation was the synthesis of technetium-labeled thymidine analogues, which have the potential to be used in radiopharmacy as proliferation markers. We chose to investigate the substrate activity of C3′-functionalized thymidine analogues, and to compare these with N3-functionalized derivatives, particularly with regard to their overall charge. We used the "click-to-chelate" approach (*14, 16*) for the parallel synthesis of two series of derivatives which could be labeled with technetium and rhenium (Scheme 1). This strategy exploits the remarkable features of the copper catalyzed azide−alkyne cycloaddition (*17, 18*) and enables simultaneous formation of the chelating system and conjugation to a biologically relevant molecule in a single, high-yielding step. In the present study, a series of bidentate alkynes (Scheme 1, **2**−**6**) were reacted with either the commercial C3′-azido thymidine derivative AZT (C3′dT-N_3) or an N3 azido-thymidine derivative (N3dT-N_3, **1**) to yield two sets of conjugates with efficient tridentate triazole-containing chelators for the $M(CO)_3$ core (M = ^{99m}Tc, Re). This enabled us to identify novel organometallic substrates for hTK1 and qualitatively analyze structure−activity relationships. Preliminary investigations were also carried out into the cell-internalizing ability of representative complexes in two human glioblastoma cell lines.

RESULTS AND DISCUSSION

Chemistry. Thymidine can be readily functionalized at the C3′ position using the "click-to-chelate" approach starting from the commercially available azide 3′-azido-3′-deoxythymidine, AZT. Tridentate chelators for the $M(CO)_3$ core were incorporated by reaction of AZT with a suitable alkyne (Scheme 2). Suitable alkynes (Scheme 1) were prepared by alkylation of propargylamine with bromoacetate (**5**), alkylation of commercial amines with propargyl bromide (**3** and **6**), or are commercially available (**2** and **4**). Full details of the synthesis of the alkyne components used were recently reported (*14*). The copper catalyzed azide−alkyne cycloaddition was performed using standard Sharpless conditions: 1 equiv of alkyne and 1 equiv of azide were stirred at room temperature for 12 h in a mixture of *t*BuOH and water with catalytic amounts of copper acetate (0.1 equiv) and sodium ascorbate (0.2 equiv) (*19*). For ease of purification of the products, alkynes **2**−**5** were substituted with compounds **2a**−**5a**, in which carboxylic acids were protected as methyl esters and primary amines were Boc-protected. However, in previous studies we have shown that for radiolabeling purposes it is not necessary to use protected substrates or indeed to purify the ligands prior to radiolabeling (*14, 16*).

Thymidine derivatives **7** and **8** were prepared from the reactions of AZT with alkynes **2a** and **3a**, respectively. In both cases, the Boc-protected triazole products were purified by silica gel chromatography using mixtures of CH_2Cl_2 and MeOH before the Boc protecting groups were removed in a mixture of trifluoroacetic acid (10%) and CH_2Cl_2. Compounds **7** and **8** were purified by solid-phase extraction using Sep-Pak columns. Thymidine derivatives **9** and **10** were prepared from the reactions of AZT with alkynes **4a** and **5a**, respectively. The intermediates were purified by silica gel chromatography before the methyl esters were removed with aqueous NaOH. Compounds **9** and **10** were purified by solid-phase extraction using Sep-Pak columns. Compound **11** was purified by silica gel

chromatography after the reaction of AZT and *N*-propargyl-pyridine-2-methylamine, **6**.

The N3-functionalized thymidine derivatives **12**, **13**, **15**, and **16** have been reported previously, however, they were only characterized via mass spectrometry (*14*). For their synthesis, thymidine was functionalized at the N3 position with an azido-ethyl group following the recently reported procedure (*14*) (Note: In an evaluation of the "click-to-chelate" approach, the compounds were synthesized using stock solutions (10^{-2} M) of the deprotected analogues of alkynes **2**, **3**, **5**, and **6**, compound **1**, copper(II) acetate, and sodium ascorbate (*14*)). In analogous procedures to the synthesis of the C3′-functionalized derivatives described above, tridentate chelators for the $M(CO)_3$ core (M = ^{99m}Tc, Re) were installed at the N3 position by reacting the N3-functionalized azido-thymidine derivative **1** or the *O*-TBDMS protected precursor **1a** with alkynes **2**−**6** using standard conditions for the click reaction and as outlined in Scheme 3. Thymidine derivatives **12** and **13** were prepared from the reactions of the *O*-TBDMS protected N3-functionalized thymidine precursor, **1a**, and alkynes **2a** and **3a**, respectively. The protected triazole intermediates were purified by silica gel chromatography using mixtures of CH_2Cl_2 and MeOH. In both cases, the Boc and TBDMS protecting groups of the products were removed in a single step with HCl in MeOH. Compounds **12** and **13** were purified by solid-phase extraction, although compound **12** could also be recrystallized from MeOH. Similarly, derivative **14** was prepared from the reaction of **1a** with alkyne **4a**. The protected intermediate was stirred in HCl/MeOH to remove the TBDMS protecting groups, followed by aqueous NaOH to remove the methyl esters. Thymidine derivative **15** was prepared from the reaction of **1** and alkyne **5a**. The intermediate was purified by silica gel chromatography before the methyl ester was removed with aqueous NaOH. In this case, removal of the TBDMS protecting groups from the azido-thymidine derivative **1a** with NBu_4F proved more efficient before the click reaction, as **1** could more easily be separated from excess NBu_4^+ salts than the more hydrophilic triazole product **15**. Both compounds **14** and **15** were purified by solid-phase extraction using Sep-Pak columns. Compound **16** was purified by silica gel chromatography after the reaction of **1** and *N*-propargyl-pyridine-2-methylamine, **6**.

The $Re(CO)_3$ complexes of all of the functionalized thymidine derivatives were prepared from the precursor $[ReBr_3(CO)_3][NEt_4]_2$ and a stoichiometric amount of the corresponding ligand in a mixture of MeOH and water at 50 °C. In each case, the quantitative formation of the product was observed by HPLC. The crude products were purified by solid-phase extraction using Sep-Pak columns and a water−MeOH gradient. The IR spectra of all of the rhenium complexes revealed the typical *fac*-$Re(CO)_3$ pattern with significantly blue-shifted, intense CO stretching frequencies (around 2020 cm^{-1} and 1880 cm^{-1}) compared with the starting material $[ReBr_3(CO)_3]^{2-}$ (2000 cm^{-1} and 1868 cm^{-1}). NMR analyses provided evidence that in each case the metal core is site specifically coordinated to the tridentate metal chelating system introduced at either the C3′ or N3 position, and showed similar features to model complexes which were synthesized with benzyl azide and characterized previously (*14*). Typically, the proton NMR spectra showed low field shifts of the protons in the chelating system after metal chelation. Independent resonances are observed for each proton in the CH_2 groups of the chelating system; they become distinguishable due to a lack of symmetry in the metal chelate. As was the case with the model complexes, signals for the protons of coordinated primary and secondary amines were also observed in the NMR spectra of the thymidine complexes as a result of the decrease in rate of H/D exchange. A key difference between the thymidine chelates and the analogous model complexes is the appearance of diastereoisomers, which can be distinguished in some cases by NMR and/or HPLC. For the C3′ complexes, HPLC analyses revealed two isomeric products for both

Scheme 3[a]

$[Re(CO)_3\mathbf{8}]Br$ and $[Re(CO)_3\mathbf{10}]$, but only in the case of $[Re(CO)_3\mathbf{11}]Br$ were two isomers apparent in the ^1H NMR spectrum. For the N3-functionalized complexes $[Re(CO)_3\mathbf{13/16}]Br$ and $[Re(CO)_3\mathbf{15}]$, two diastereoisomers can be distinguished by NMR. The differences in chemical shifts of the two isomers are most pronounced for the complex $[Re(CO)_3\mathbf{13}]Br$, and HPLC analysis also revealed two product peaks in this case. In analogous model complexes, where a benzyl group substitutes the thymidine residue, isomers were not distinguishable by either HPLC or NMR (*14*). All of the complexes were readily water-soluble, which is a prerequisite for in vitro assessment.

Crystals of the complex $[Re(CO)_3\mathbf{11}][CF_3CO_2]$ suitable for X-ray crystallography were prepared by exchange of the bromide anion with the more bulky $CF_3CO_2^-$ anion using the corresponding silver salt. The final crystals were grown by diffusion of diethyl ether into a solution of the complex in methanol. Structural analysis revealed that the counterion was a mixture of Br^- and $CF_3CO_2^-$ as a result of incomplete precipitation of AgBr. The structure of the complex cation confirmed the expected tridentate, facial coordination of the κN,κN,κN chelator, which has not previously been structurally characterized (Figure 1). The Re−N3 bond length (2.146 (3) Å) is in agreement with the Re−N (triazole) bond length in other $Re(CO)_3$ complexes with triazole-containing ligands (*14*). Similarly, the Re−N4 (2.218(4) Å) and Re−N5 (2.181(3) Å) bond lengths are consistent with those found in $Re(CO)_3$ complexes with amine and pyridine containing chelators (*20*−*22*). For example, Banerjee et al. report the crystallographic characterization of a series of tridentate chelating systems for the $M(CO)_3$ core (M = ^{99m}Tc, Re) which incorporate an aliphatic amine with pyridyl and/or imidazoyl donor groups and are structurally similar to the chelator in compound **11** (*20*). The Re−N bond lengths in the novel triazole-containing chelating system were consistent with the values reported for the coordinated aliphatic amines (2.23−2.29 Å), pyridyl (2.16−2.18 Å), and imidazoyl (2.14−2.16 Å) groups. Crystallographic data are reported in the Supporting Information.

Selected bond lengths [Å] and angles [°]: Re(1)−N(3) 2.146(3), Re(1)−N(4) 2.218(4), Re(1)−C(31) 1.915(4), Re(1)−C(32) 1.929(5), Re(1)−N(5) 2.181(3), Re(1)−C(33) 1.900(5), C(33)−Re(1)−C(31) 91.46(18), C(33)−Re(1)−C(32) 88.3(2), C(31)−Re(1)−C(32) 87.17(19), C(32)−Re(1)−N(3) 172.83(16), C(31)−Re(1)−N(5) 171.65(19), C(33)−Re(1)−N(4) 170.51(16).

Radioactive technetium-99 m complexes were prepared with the ligands **7**, **8**, **10**, **11**, **12**, **13**, **15**, and **16**. The complexes were prepared quantitatively by adding the organometallic precursor $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (*24*) to a solution of the ligand in physiological phosphate buffer (PBS; pH 7.4) and heating for 45 min at 95 °C. In each case, a single product was observed. Characterization of the radioactive complexes was accomplished by comparison of the retention times observed in the γ-HPLC

Scheme 4

trace with those in the UV-trace of the corresponding rhenium complexes. Given the experimental limitations, the retention times matched for all pairs of complexes. For in vitro and enzymatic studies, ^{99m}Tc complexes were separated from unreacted thymidine derivatives by HPLC.

In Vitro Evaluation of the Organometallic Thymidine Derivatives. *Substrate Activity toward Human Thymidine Kinase.* By incubating solutions of the complexes with ATP in the presence of hTK1, we have shown previously that the ^{99m}Tc-labeled complexes [^{99m}Tc(CO)$_3$**12**] and [^{99m}Tc(CO)$_3$**15**] are substrates for the enzyme (*14*). Under the same conditions, substrate activity was not observed with the complexes [^{99m}Tc(CO)$_3$**13**]$^+$ and [^{99m}Tc(CO)$_3$**16**]$^+$ (*14*). In the current investigation, the hTK1 substrate activities of all target rhenium complexes were assessed using a coupled thymidine kinase-pyruvate kinase-lactate dehydrogenase UV assay ($\lambda = 340$ nm) as previously described (*6, 25*). We were able to show that all of the C3′-functionalized and N3-functionalized rhenium complexes were substrates for hTK1 (Scheme 4). The results with both series of compounds are presented in Table 1. The phosphorylation of thymidine was arbitrarily set to 100%.

In the first series of complexes, the ribose of thymidine is functionalized directly at the C3′ position and there is no spacer between the thymidine and metal chelate. The metal-labeled compounds have varying overall charges depending on the functional groups of the chelating system. The relative rates of phosphorylation ranged from 13−28%. The neutral complex [Re(CO)$_3$**10**] had the highest relative phosphorylation of 27.6 ± 1.9%. There is a clear trend in phosphorylation rate as a function of overall charge. The anionic C3′-functionalized compound (23.1 ± 1.8%) has a comparable rate of phosphorylation to the neutral C3′-functionalized compounds (27.6 ± 1.9% and 20.3 ± 0.8%), whereas the cationic complexes appear to be much less readily phosphorylated (12.5 ± 0.5% and 14.2 ± 0.2% for [Re(CO)$_3$**8**]Br and [Re(CO)$_3$**11**]Br, respectively). This is perhaps surprising given that the structure of hTK1 co-crystallized with the feedback inhibitor thymidine triphosphate (dTTP) shows the proximity and suspected interaction of the C3′ substituent (in the case of dTTP, a hydroxyl group) with a glycine residue and an aspartic acid residue (*7*). There is, however, an arginine residue in the same region of the active site. Interaction between the C3′ substituent and the cationic side chain of arginine may compensate for the loss of interaction with the C3′ hydroxyl group of thymidine, and thus be an explanation for the greater substrate efficiency of the anionic complex compared to the cationic complexes. However, at the moment this remains purely speculative, and only co-crystallization of the complex with the enzyme would provide further insight into the observed trend.

In the second series of compounds, thymidine was functionalized at the N3 position. As for the C3′-functionalized complexes, the overall charges of the derivatives vary, but in all cases, there is an ethyl spacer between thymidine and the metal complex. The phosphorylation data show that in general the C3′-functionalized compounds are better substrates for hTK1 than the N3-functionalized compounds. The phosphorylation is relatively low compared to thymidine for all of the complexes (9−18%), although interestingly, in this series of compounds the neutral and cationic complexes appear to be better substrates than the anionic complex. This is consistent with results from Tjarks et al., which show that zwitterionic NH_3^+-*nido-m*-carborane-substituted thymidine analogues (with a propyl spacer) have high substrate activity (*26*). However, the variation in the phosphorylation of the two cationic complexes (10.9 ± 0.4% and 16.8 ± 0.2% for [Re(CO)$_3$**13**]Br and [Re(CO)$_3$**16**]Br, respectively) suggests that, in addition to overall charge,

Table 2. Internalization into the Human Glioblastoma Cell Lines U251 and LN229, with and without Pretreatment with 5-Fluorodeoxyuridine, as a Percentage of the Initial Activity Added

structural differences in the metal chelate also affect the substrate affinity for hTK1. It is not possible, therefore, to rule out structural differences in addition to overall charge as the reason for the lower substrate affinity of the complex [Re(CO)$_3$**14**]NEt$_4$, which in contrast to the anionic C3′-functionalized compound had the lowest phosphorylation rate in the series (9.0 ± 0.4%).

In a second, direct assay, the radioactive and nonradioactive complexes [^{99m}Tc/Re(CO)$_3$**X**] (**X** = **7**, **10**, **11**, **15**) were incubated with ATP and recombinant hTK1 only. The enzymatic reactions were analyzed by HPLC (UV-trace at λ = 254 nm for the rhenium complexes, γ-trace in the case of the radioactive Tc-99m complexes). For both the ^{99m}Tc and the Re compounds, phosphorylation resulted in a measurable shift in retention time on a C_{18} reversed phase column and the monophosphorylated products [^{99m}Tc/Re(CO)$_3$**X**]-**P** (**X** = **7**, **10**, **11**, **15**) were distinguished clearly from the starting material. In the case of the complex [Re(CO)$_3$**7**], the reaction mixture was purified by HPLC, and the fractions collected were analyzed by mass spectroscopy. The fraction corresponding to the starting material showed a mass peak at m/z = 651.09, $[C_{18}H_{19}N_6O_9Re]H^+$. The more hydrophilic phosphorylated complex, [Re(CO)$_3$**7**]-**P**, revealed a mass peak at m/z = 731.03 $[C_{18}H_{20}N_6O_{12}PRe]H^+$. In time dependent HPLC experiments monitoring the phosphorylation of complex [Re(CO)$_3$**7**], an increase in the concentration of the monophosphorylated species, [Re(CO)$_3$**7**]-**P**, and corresponding decrease in the concentration of the starting complex was observed.

Cell Internalization Experiments. hTK1 is located in the cytosol, and therefore, a potential substrate has to pass through the cell membrane before it can be phosphorylated. If this transport is not achieved actively via nucleoside transporters, then it must occur by passive diffusion (*27*). This has been suggested as the major cell internalization route for the carborane-thymidine derivatives reported by Tjarks et al. (*26*) Similarly, AZT is not recognized by the ubiquitously expressed human equilibrative nucleoside transporter type 1 (hENT1) and is transported primarily by passive diffusion (*28*). By analogy to the N3-functionalized carborane derivatives and AZT, we suspected passive diffusion would be the most likely cell internalization route of our C3′/N3-functionalized complexes.

In a preliminary study of the cell internalizing ability of the organometallic thymidine derivatives, we investigated the internalization of one ^{99m}Tc(CO)$_3$-labeled complex from each series of compounds. We expected the neutral complexes to be the most likely to be internalized based on our previous experience (*13*). We therefore chose to investigate the neutral complex [^{99m}Tc(CO)$_3$**7**] from the series of C3′-functionalized compounds. To complete a previous series of N3-functionalized thymidine analogues, we chose to investigate the cationic complex [^{99m}Tc(CO)$_3$**16**]$^+$, (internalization of anionic and neutral N3-functionalized thymidine analogues has been observed previously) (*13*). The incorporation of both complexes into two human glioblastoma cell lines was measured and compared with the incorporation of ^{125}I-iododeoxyuridine (^{125}IdUrd), using cell lines and conditions established for the incorporation of ^{125}IdUrd (*29, 30*). Internalization was measured with and without pretreatment with 5-fluorodeoxyuridine (FdUrd), which is known to increase uptake of 5-iododeoxyuridine by inhibiting endogenous thymidine synthesis and inducing upregulation of nucleoside transporters (*29, 31*−*33*). The results for both cell lines, U251 and LN229, and with and without 5-fluorodeoxyuridine pretreatment are presented in Table 2.

The data show that there was only minor cell-associated radioactivity after incubation of both cell lines with [^{99m}Tc(CO)$_3$**7**] and [^{99m}Tc(CO)$_3$**16**]$^+$. This can be rationalized either as a lack of uptake or as a lack of intracellular retention of the radioactive probes. Assuming that the complexes are stable in vitro and are intracellularly phosphorylated, the data suggest that neither of the ^{99m}Tc-labeled derivatives are able to enter the cells. The fact that pretreatment with 5-fluorodeoxyuridine (FdUrd), which should stimulate nucleoside transport, had no effect on the amount of radioactivity associated with the cells, provides further evidence that uptake is not mediated by nucleoside transporters. It is likely that the structural modification at either the C3′ or the N3 position is significant enough to prohibit active incorporation mediated by nucleoside transporters. This is in agreement with our previous experience of organometallic thymidine derivates. Although we reported moderate cell uptake of N3-functionalized thymidine derivatives (0.6−4.8%) into SKNMC tumor cells, uptake increased with increasing lipophilicity (*13*). We assume, therefore, that factors such as hydrophilicity, charge, and/or size prevent [^{99m}Tc(CO)$_3$**7**] or [^{99m}Tc(CO)$_3$**16**]$^+$ exhibiting any significant internalization via passive diffusion. An alternative explanation for the negligible accumulation of radioactivity is that either the compounds are not sufficiently phosphorylated or they are susceptible to intracellular degradation. It has been shown for a number of N3-functionalized carboranyl thymidine analogues that the compounds cannot compete intracellularly with endogenous thymidine (*34*).

CONCLUSIONS

Starting from two azido-functionalized thymidine derivatives, we were able to investigate the influence of the position of the metal complex on the substrate affinity, as well as the influence of charge on the relative phosporylation of two series of novel M(CO)$_3$-labeled thymidine derivatives. The "click-to-chelate" approach was used to synthesize thymidine derivatives functionalized with a tridentate chelator for the M(CO)$_3$ core at either the C3′ or N3 position of thymidine. All of the conjugates could be readily labeled with the M(CO)$_3$ precursors to form well-defined organometallic complexes, with differing structures and overall charges. Incubation of the Re(CO)$_3$ derivatives with ATP in the presence of hTK1 led to the formation of monophosphorylated organometallic thymidine derivatives, which were observed by HPLC and unambiguously identified by mass spectroscopy. In this way, we were able to show that all of the compounds tested, which vary in the position of the metal chelate and overall charge, were substrates for hTK1. For each of the complexes, the rate of phosphorylation was measured quantitatively relative to thymidine, the natural substrate for hTK1. We could show that for the two sets of compounds investigated the C3′-functionalized thymidine derivatives were on average more readily phosphorylated by hTK1 than the N3-

functionalized derivatives. Furthermore, we have shown that the effect of the overall charge of the substrate is dependent on the position of the metal complex. For the C3′-functionalized complexes, the rates of phosphorylation followed the trend neutral ≈ anionic > cationic. In the case of the N3-functionalized derivatives, the trend neutral ≈ cationic > anionic was observed for the relative phosphorylation rates of the complexes.

The first cell internalization experiments did not give promising results. Neither of the C3′ or N3 functionalized derivatives tested were either actively or passively transported into cells. It seems unlikely that any of the current set of compounds will be useful as a proliferation marker. The incorporation of, for example, a cell penetrating peptide sequence may improve uptake, however, introduction of an additional targeting group would induce further structural changes that in turn would decrease the substrate activity of compounds which already show significantly lower activity than the natural substrate. As we have shown and noted before in a similar study of technetium-labeled glucose analogues, it is possible to develop ^{99m}Tc-based, small molecular substrates for a given enzyme (such as hexokinase, or in the present case hTK1). However, a critical point during the development of such compounds is their active transport by transporters with further substrate specificity (such as Glut1 or a nucleoside transporter) to their intracellular targets. Although there have been recent reports of organometallic pseudoamino acids which target the LAT transporter (*35*), in general it would appear that ^{99m}Tc and metal-based radiopharmaceuticals which target receptors which themselves facilitate internalization show much more promise for the future.

EXPERIMENTAL DETAILS

Chemistry. All chemicals were purchased from Sigma-Aldrich or Fluka, Buchs, Switzerland. All chemicals and solvents were of reagent grade and were used without further purification unless otherwise stated. The precursor *fac*-$[Re(CO)_3Br_3][NEt_4]_2$ (*36*) was prepared according to the published procedure. $[Na][^{99m}TcO_4]$ was eluted from a ^{99}Mo/^{99m}Tc-generator (Covidien, Petten) with a 0.9% saline solution. Reactions were monitored by HPLC or by thin-layer chromatography (TLC) using precoated silica gel 60 F_{254} aluminum sheets (Merck), and visualized by UV absorption or stained with a solution of ninhydrin in EtOH. Column chromatography was performed using silica gel 60 (Fluka; particle size 0.04−0.063 mm). Analytical HPLC was performed using a Merck-Hitachi L-7000 system equipped with an L-7400 tunable absorption detector and an XBridge C-18 reverse phase column (5 μM, 4.6 × 150 mm, Waters). HPLC solvents were either water with 0.1% TFA (solvent A) and MeCN (solvent B) or water (solvent A) and MeOH (solvent B) (for purification of ^{99m}Tc complexes) with a flow rate of 1 mL/min. The gradient was as follows: 0−15 min, gradient from 95% A to 20% A; 15−20 min, gradient from 20% A to 95% A; 20−25 min, 95% A. Sep-Pak columns (Waters) were washed with methanol and water prior to use. Products were eluted using water or a water−methanol gradient. Nuclear magnetic resonance spectra were recorded on a 400 MHz Bruker spectrometer. ^{1}H and ^{13}C chemical shifts are reported relative to residual solvent peaks or water as a reference. Values of the coupling constant, *J*, are given in hertz (Hz). The following abbreviations are used for the description of ^{1}H NMR spectra: singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), doublet of doublets (dd), broad singlet (bs). The chemical shifts of complex multiplets are given as the range of their occurrence. Infrared spectra were recorded on a Perkin-Elmer Spectrum 100 FT-IR, with a universal ATR sampling accessory. Low resolution mass spectra were recorded with a Micromass Quattro micro API LC-ESI using either the negative or positive ionization mode. High-resolution mass spectra were recorded with a Bruker FTMS 4.7T BioAPEXII.

^{125}I-IdUrd of high radiochemical purity was prepared from the precursor 5-tri-*n*-butyl-stannyl-2′-deoxyuridine and purified by SepPak RP-18 cartridges using a modified version of a method originally described by Foulon et al. (*37, 38*) Radiochemical purity was repeatedly verified by TLC using polyethyleneimine cellulose F strips (Merck, Darmstadt, Germany) with a mobile phase of 0.2 M ammonium bicarbonate and radioactivity reading on a Tracemaster 20 (Berthold, Bad Wildbad, Germany). In all experiments, ^{125}I-IdUrd represented >98% of overall ^{125}I activity. Contamination with unlabeled IdUrd was avoided in the production of ^{125}I-IdUrd. It was calculated that the standard activity of 5 kBq ^{125}I-IdUrd in 0.5 mL used in the incorporation experiments represented a concentration of 0.2 nM, though this is only an indicative value, as it has not been experimentally verified.

3′,5′-Di-*O*-(*tert*-butyl-dimethyl-silanyl)thymidine and 3-(2-bromoethyl)-3′,5′-di-*O*-(*tert*-butyl-dimethyl-silanyl)thymidine were synthesized according to previously published procedures (*13*). All analytical data were in accordance with those already published (*13*).

3-(2-Azidoethyl)-3′,5′-di-O-(tert-butyl-dimethyl-silanyl)thymidine, **1a.** 3-(2-Bromoethyl)-3′,5′-di-*O*-(*tert*-butyl-dimethyl-silanyl)thymidine (1.03 g, 1.78 mmol) was dissolved in MeCN (20 mL) and 10 equiv of NaN_3 (1.16 g 17.8 mmol) were added. The reaction mixture was stirred at 80 °C for 16 h and followed by TLC. After cooling to room temperature, the solvent was removed under reduced pressure and the product extracted into EtOAc and washed twice with water and once with saturated NaCl. The aqueous phases were re-extracted with EtOAc. The organic phases were combined, dried over Na_2SO_4, and evaporated under reduced pressure to give the pure product as a colorless liquid (750 mg, 80%). ^{1}H NMR ($CDCl_3$) δ 7.48 (d, J = 0.9, 1H); 6.36 (m, J = 7.9, 5.8, 1H); 4.40 (m, 1H); 4.19 (m, J = 6.3, 1.9, 2H); 3.94 (m, J = 2.4, 1H); 3.87 (dd, J = 11.4, 2.6, 1H); 3.76 (dd, J = 11.4, 2.3, 1H); 3.54 (t, J = 6.3, 2H); 2.30−2.23 (m, 1H); 2.02−1.95 (m, 1H); 1.93 (s, 3H); 0.92 (s, 9H); 0.89 (s, 9H); 0.19 (s, 6H); 0.08 (s, 3H); 0.07 (s, 3H) ppm. ^{13}C NMR ($CDCl_3$) δ 163.5, 151.0, 134.0, 110.1, 88.0, 85.7, 72.4, 63.1, 48.6, 41.6, 40.0, 26.1, 25.9, 18.5, 18.1, 13.2, −4.5, −4.7, −5.2, −5.3 ppm. High res. MS (ESI) *m/z* 562.2851 $[C_{24}H_{45}N_5O_5Si_2]Na^+$ (calc. 562.2851).

3-(2-Azidoethyl)thymidine (N3dT-N$_3$), **1.** 3-(2-Azidoethyl)-3′,5′-di-*O*-(*tert*-butyl-dimethyl-silanyl)thymidine (900 mg, 1.67 mmol) was dissolved in THF (20 mL). NBu_4F (1.16 g, 3.68 mmol) was added and the reaction was stirred at room temperature and followed by TLC. After two hours, the solvent was removed under reduced pressure and a 1:1 mixture of water and EtOAc (40 mL) was added. The solvent was evaporated from the aqueous phase under reduced pressure and the crude product was purified by column chromatography with a mixture of CH_2Cl_2 and methanol (9%) to give the product as a colorless liquid (500 mg, 96%). ^{1}H NMR (D_2O) δ 7.69 (d, J = 1.1, 1H); 6.30 (m, J = 6.7, 1H); 4.47 (m, J = 6.4, 4.2, 1H); 4.18 (m, J = 7.0, 5.4, 2H); 4.04 (m, J = 8.7, 3.8, 1H); 3.85 (dd, J = 12.5, 5.0, 1H); 3.77 (dd, J = 12.5, 3.6, 1H); 3.56 (t, J = 5.8, 2H); 2.44−2.32 (m, 2H); 1.92 (d, J = 0.98, 3H). ^{13}C NMR ($CDCl_3$) δ 166.03, 152.21, 136.44, 111.16, 87.24, 86.61, 71.01, 61.76, 49.50 (MeOH), 48.90, 40.94, 39.41, 12.88 ppm. High res. MS (ESI) *m/z* 312.1299 $[C_{12}H_{17}N_5O_5]H^+$ (calc. 312.1302).

Alkynes, **2−6.** 2-propargyl glycine, **2**, *N*-Boc-2-propargyl glycine, **2a**, and 2-propargyl dimethyl malonate, **4a**, are commercially available. Alkynes **3** and **5** were prepared according to published procedures (*14*), alkyne **6** was prepared from the reaction of pyridine-2-methylamine (0.53 g, 4.89 mmol), and propargyl bromide (0.58 g, 4.89 mmol) in a solution of triethylamine (1.02 mL, 7.34 mmol) in MeCN (50 mL). The reaction mixture was stirred at 50 °C and followed by TLC.

After 4 h, the solvent was removed and the reaction mixture purified by column chromatography with CH_2Cl_2 and MeOH (5%). The product was isolated as a yellow liquid (178 mg, 25%). Full analytical data for compounds **2**−**6** and **2a**−**5a** can be found in the Supporting Information. Data were in agreement with those already published (*14*).

Copper Catalyzed Azide−*Alkyne Cyclycloaddition. General Procedure A.* The alkyne (1−2 equiv) and azide (1 equiv) were added to a 1:1 mixture of *t*BuOH and water to form a 0.1 mM solution. 0.1 equiv of $Cu(OAc)_2 \cdot H_2O$ and 0.2 equiv of sodium ascorbate were added and the mixture stirred at room temperature for 12 h.

Compound **7.** As per general procedure A, with AZT (130 mg, 0.49 mmol) and **2a** (137 mg, 0.64 mmol). The solvent was removed and the residue redissolved in a mixture of CH_2Cl_2 and MeOH (10%). The crude product was purified by column chromatography with a mixture of CH_2Cl_2 and MeOH (10%) to give the Boc protected triazole product (183 mg, 77%). ^{1}H NMR (CD_3OD) δ 7.91 (s, 1H), 7.89 (s, 1H), 6.49 (t, J = 6.5, 1H), 5.39 (m, 1H), 4.33 (m, 1H), 4.25 (t, J = 5.4, 1H), 3.89 (dd, J = 12.2, 2.9, 1H), 3.77 (dd, J = 12.2, 3.1, 1H), 3.24 (dd, J = 14.6, 5.1, 1H), 3.13 (dd, J = 14.6, 6.6, 1H), 2.93−2.83 (m, 1H), 2.77−2.64 (m, 1H), 1.91 (s, 3H), 1.41 (s, 9H) ppm. ^{13}C NMR (CD_3OD) δ 166.29, 152.10, 137.98, 124.35, 111.50, 86.66, 86.40, 80.54, 62.14, 61.07, 38.88, 28.82, 12.51 ppm. High res. MS (ESI) *m*/*z* 481.2039 $[C_{20}H_{28}N_6O_8]H^+$ (calc. 481.2041). The intermediate (120 mg, 0.25 mmol) was dissolved in a mixture of CH_2Cl_2 (12.5 mL) and TFA (1.25 mL) and stirred overnight at rt. The solvent was removed under reduced pressure, and the residue redissolved in water (1 mL) and neutralized with 5 M NaOH. The crude product was purified by solid phase extraction using a Sep-Pak column. The fractions containing the product were evaporated under reduced pressure to give **12** as a colorless oil (81 mg, 85%).^{1}H NMR ($CDCl_3$) δ ^{1}H NMR (400 MHz, MeOD) δ 8.01 (s, 1H), 7.91 (s, 1H), 6.49 (t, J = 6.6, 1H), 5.42 (m, 1H), 4.36 (m, 2H), 3.91 (dd, J = 12.1, 3.0, 1H), 3.78 (dd, J = 12.1, 3.2, 1H), 3.43 (dd, J = 15.7, 5.0, 1H), 3.35 (d, J = 15.7, 7.3, 1H), 2.94−2.82 (m, 1H), 2.79−2.65 (m, 1H), 1.91 (s, 3H) ppm. ^{13}C NMR (CD_3OD) δ 170.88, 166.50, 152.48, 142.79, 138.29, 124.79, 111.94, 86.90, 86.55, 62.44, 61.49, 53.79, 39.18, 27.32, 12.61 ppm. Rhenium Complexes. Tricarbonyl rhenium complexes were synthesized according to the following general procedure: 1 equiv of thymidine containing ligand and 1 equiv of $[ReBr_3(CO)_3][NEt_4]_2$ were dissolved in a 1:1 mixture of MeOH and water to form a 0.1 M solution. In the reactions with ligands **9** and **14**, the pH of the reaction mixture was adjusted to 7 with aqueous NEt_4OH. The reaction was stirred at 50 °C for 2 h and followed by HPLC. The solvents were removed under vacuum and the residue was purified by solid phase extraction using a Sep-Pak column and a water-MeOH gradient to give the $Re(CO)_3$ complex as a white or off-white powder.

Technetium-99m Complexes. The 99 m-technetium tricarbonyl complexes of ligands **7**, **8**, **10**, **11**, **12**, **13**, **15**, and **16**, were synthesized according to the following general procedure: A solution of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ (50 μL; ~500 MBq mL^{-1}) was added to a 10^{-3} M solution of the relevant ligand (50 μL) diluted with PBS (400 μL; pH 7.4) to give a final ligand concentration of 10^{-4} M. The reaction mixtures were heated for 45 min at 95 °C. The radioactive product was separated from unlabeled ligand by HPLC. The complexes were characterized by comparison of their HPLC retention times (γ-trace) with those of their rhenium analogues (UV-trace).

X-ray Crystallography. Crystallographic data were collected at 183(2) K on an Oxford Diffraction Xcalibur system with a Ruby detector (Mo K_α radiation, $\lambda = 0.7107$ Å) using graphite-monochromated radiation. A suitable crystal was covered with oil (Infineum V8512, formerly known as Paratone N), mounted on top of a glass fiber and immediately transferred to the diffractometer. The program suite CrysAlis^{Pro} (*CrysAlis*^{Pro} software system (2007), Oxford Diffraction Ltd., Oxford, UK) was used for data collection, semiempirical absorption correction and data reduction. The structure was solved with direct methods using SIR97 (*39*) and refined by full-matrix least-squares methods on F^2 with SHELXL-97 (*40*). The final model was checked with the help of the program Platon (*41*). CCDC-743723 contains the supplementary crystallographic data for this paper. This data are presented in the Supporting Information or can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

In Vitro Analysis. *Phosphorylation Transfer Assays.* Thymidine and thymidine analogues $[Re(CO)_3$**7**$-$**16**$]^{0/+/-}$ were assayed at 25 °C for 15 min in 200 μL of a mixture containing 155.38 μL water, 10 μL 1 M HEPES buffer (pH 7.5), 0.2 μL 1 M DTT, 0.42 μL 100 mM PEP, 0.5 μL 1 M $MgCl_2$, 7.2 μL 5 mM NADH, 2 μL 100 mM ATP, 0.6 μL pyruvate kinase (1350 U/mL), 0.7 μL lactate dehydrogenase (1420 U/mL), 5 μL hTK1 (~0.5 mg/mL), and 20 μL of a 10 mM solution of thymidine or the thymidine analogue $[Re(CO)_3$**7**$-$**16**$]^{0/+/-}$.

For each substrate, the linear decrease in UV absorption at 340 nm was measured from 0 to 15 min. The gradients of the regression lines between 6 and 12 min were compared to thymidine, the phosphorylation of which was assumed to be 100%.

Thymidine analogues $[Re(CO)_3$**X**$]^{0/+}$ (**X** = **7**, **10**, **11**, **15**) were also assayed at 37 °C for 1 h in 200 μL of a mixture containing 112.3 μL water, 10 μL 1 M HEPES buffer (pH 7.5), 0.2 μL 1 M DTT, 0.5 μL 1 M $MgCl_2$, 2 μL 100 mM ATP, 5 μL hTK1 (~0.5 mg/mL), 20 μL of a 10 mM solution of $[Re(CO)_3$**X**$]^{0/+}$ (**X** = **7**, **10**, **11**, **15**), and 50 μL of an aqueous solution of $[^{99m}Tc(CO)_3$**X**$]^{0/+}$ (**X** = **7**, **10**, **11**, **15**) (~100 kBq). The reaction mixtures were quenched by addition of 800 μL 5 mM EDTA solution and analyzed by HPLC.

Cell Lines and Culture. Two human glioblastoma cell lines were used: U251 (American Type Culture Collection, ATCC) and LN229 (a gift from Prof. N. de Tribolet, Service of Neurosurgery, University Hospital, Geneva, Switzerland). Cells were cultured at 37 °C and 5% CO_2 in RPMI 1640 with glutamax I (Invitrogen AG, Basel Switzerland), supplemented with 10% heat-inactivated fetal bovine serum (Chemie Brunschwig AG, Basel, Switzerland), penicillin (50 units/mL), and streptomycin (0.05 mg/mL; Life Technologies Inc., Grand Island, NY, USA), which was changed twice a week. Because mycoplasma contamination is a potential source of increased nucleoside turnover and could therefore modulate FdUrd efficacy, the cell lines were regularly tested for four major potential mycoplasma contaminations (Mycoplasma Detection Kit, F. Hoffmann-La Roche Ltd., Basel, Switzerland).

Radioactive dT Analogue Incorporation Assay. 24-well culture dishes were plated with 20 000 cells for LN229 and with 15 000 cells for U251. After 3 days, the exponentially growing cells were incubated for 2 h at 37 °C and 5% CO_2 with either 5 kBq ^{125}I-IdUrd, 10 kBq $[^{99m}Tc(CO)_3$**7**$]$, or 10 kBq $[^{99m}Tc(CO)_3$**16**$]^+$ in 0.5 mL medium. After this time, the supernatant was removed and the cells were washed three times with PBS. The cells were detached with 300 μL of 1 M NaOH. Radioactivity was measured in a gamma counter (Wizard 3" 1480 automatic gamma counter, Wallac Oy, Turku, Finland) and the results expressed as a percentage of the initial activity added. In the FdUrd pretreatment assay, cells were pretreated with 1 μM FdUrd and incubated for 1 h at 37 °C and 5% CO_2. After this time, the supernatant was removed and the cells were washed twice with PBS before either 5 kBq ^{125}I-IdUrd, 10 kBq $[^{99m}Tc(CO)_3$**7**$]$, or 10 kBq $[^{99m}Tc(CO)_3$**16**$]^+$ was added in 0.5 mL fresh medium.

Supporting Information Available: NMR and HPLC analysis of target complexes, crystal data and structure refinement for $[Re(CO)_3$**11**$][CF_3CO_2]_{0.8}[Br]_{0.2}$, and further details of the phosphorylation assay. This material is available free of charge via the Internet at http://pubs.acs.org.

"Zero-Length" Dimers of Ribonuclease A: Further Characterization and No Evidence of Cytotoxicity

Francesca Vottariello, Chiara Costanzo, Giovanni Gotte, and Massimo Libonati*

Dipartimento di Scienze Morfologico-Biomediche, Sezione di Chimica Biologica, Facoltà di Medicina e Chirurgia, Università di Verona, Strada Le Grazie 8, I-37134 Verona, Italy. Received September 15, 2009; Revised Manuscript Received February 10, 2010

"Zero-length" dimers of ribonuclease A, a novel type of dimers formed by two RNase A molecules bound to each other through a zero-length amide bond [Simons, B. L., et al. (2007) *Proteins 66*, 183−195], were further characterized and tested for their possible in vitro cytotoxic activity. Results obtained are the following. Besides dimers, also trimers and higher oligomers could be identified among the products of the covalently linking reaction, and the "zero-length" dimers prepared by us appear not to be a unique species. The product was indeed heterogeneous, and results obtained with two RNase A mutants, E9A and K66A, indicated that amino and carboxyl groups others than those belonging to Lys66 and Glu9 are involved in the amide bond. As for their functional properties, the "zero-length" dimers degrade poly(A)·poly(U) (dsRNA) with an activity that increases with the increase of the oligomer's basicity and yeast RNA (ssRNA) with an activity that instead decreases with the increase of oligomer's basicity, which is in agreement with previous data. No cytotoxicity of the RNase A "zero-length" dimers could be evidenced in assays performed with various tumor cells lines; the dimers, instead, become cytotoxic if cationized by conjugation with polyethylenimine (PEI) [Futami et al. (2005) *J. Biosci. Bioengin. 99*, 95−103]. However, PEI derivatives of RNase A "zero-length" dimers and PEI derivatives of native RNase A resulted to be equally cytotoxic. In other words, protein "dimericity" does not play any role in this case. Moreover, the acquired cytotoxicity does not seem to be specific for tumor cells: PEI-cationized native RNase A was also cytotoxic toward human monocytes.

INTRODUCTION

Many ribonucleases were found to be endowed with remarkable biological activities, among which an interesting in vitro and in vivo cytotoxic action against tumor cells (*1*−*5*). This finding aroused new interest in this class of enzymes and opened a new chapter in the field of potential anticancer therapy. Among cytotoxic monomeric ribonucleases, a well-known example is onconase, an enzyme found in the oocytes and early embryos of *Rana pipiens* (*2*). Among mammalian pancreatic-type ribonucleases, well-known is the ribonuclease from bovine semen, BS-RNase[1]. Bovine seminal RNase is a unique natural dimer, with its two subunits sharing 83% identity with bovine pancreatic ribonuclease (*6, 7*). This dimeric RNase is endowed with various biological activities, among which is a strong antitumor action (*7, 8*).

Artificial dimers of RNase A were casually obtained for the first time in 1962 by Crestfield, Stein, and Moore (*9*). These authors envisaged the way in which an RNase A dimer could form and proposed a model consisting in the exchange between two ribonuclease molecules of their N-terminal ends (*9, 10*). This mechanism was later identified and confirmed by Eisenberg and colleagues in studying the structure of the diphtheria toxin (*11, 12*), and named "three-dimensional (3D) domain swapping". In 1998, Eisenberg et al. (*13*) found it to determine the structure of one (the N-dimer, as it was called later) of the two dimeric conformers of RNase A that had been identified by Crestfield and colleagues (*10*). Dimerization of RNase A had also been obtained by cross-linking two enzyme molecules with the bifunctional reagent dimethyl suberimidate, which reacts with the ε-amino group of one lysine residue of each protein molecule (*14*). These cross-linked RNase A dimers exhibited antitumor action similar to that of BS-RNase (*15, 16*). All ribonuclease dimers, natural or artificial, degrade double-stranded RNA (*14, 17*), DNA/RNA hybrids (*18*), and poly(A) (*19*) under conditions where native, monomeric RNase A does not. On this basis, the idea grew that "dimericity" could be a determinant factor in conferring novel and functionally important side properties to a ribonuclease (*14*−*19*). Evidence further supporting this idea also came from dimeric mutants of human pancreatic RNase (*20*) or bovine pancreatic RNase A (*21*), which were shown to be selectively cytotoxic toward tumor cells, while the corresponding native, monomeric proteins are devoid of any biological activity.

With the procedure described by Crestfield et al. (*9*), i.e., by lyophilizing RNase A from 40−50% acetic acid solutions, trimers, tetramers, and higher-order oligomers also form besides dimers, each species comprising, like dimeric RNase A (*10*), at least two conformers, one more basic, one less basic, one more abundant, and one less (*22*−*27*). The structure of the second, more abundant and more basic RNase A dimer (C-dimer), formed through the exchange of the C-termini between two protein molecules (*28*), and the structure of the

C-terminal domain-swapped cyclic trimer (C-trimer) (*25, 26, 28*) have been solved, and plausible models were proposed for another trimer and several other RNase A oligomers (*23*−*29*). The 3D domain-swapped RNase A oligomers larger than dimers are also able to degrade dsRNA (*22, 24, 27*). Dimers and higher oligomers of RNase A are cytotoxic (*30*) like BS-RNase (*7, 8*) and the RNase A cross-linked dimers (*15, 16*) and trimers (*31*), the extent of these activities increasing as a function of the oligomers' complexity (*24, 30, 32*). Therefore, not only the "dimericity", but in general the "oligomericity" of a ribonuclease, characterized by the increase of the basicity of the complex, was thought to be an important structural determinant for the acquisition by the enzyme of novel functional properties (*24, 32*). In 2006, Leich et al. designed a fusion protein consisting of two RNase A molecules bound to each other by a peptide linker of varying length and composition between the C-terminus of one and the N-terminus of a second ribonuclease molecule by gene duplication (*33*). This tandem RNase A dimer is a potent cytotoxic agent against human erytroleukemia cells (further evidence of the importance of ribonuclease dimericity), although its ribonucleolytic activity is severely reduced. More recently, Simons et al. prepared a novel type of covalently linked RNase A dimer, which consists of two enzyme molecules bound to each other through a zero-length amide bond (*34*). This dimer also is able to degrade double-stranded poly(A)·poly(U) besides ssRNA (*34*).

We do not know whether the cytotoxic tandem dimer of Leich et al. is also able to attack double-helical polyribonucleotides. On the other hand, Simons et al. did not show whether their "zero-length" RNase A dimers might acquire cytotoxic activity in parallel with their ability to degrade double-stranded RNA. Theoretically, both an additional enzymatic activity for the tandem dimer of Leich et al. and a biological action for the "zero-length" dimer of Simons et al. could reasonably be expected. Here, we have examined the latter possibility, i.e., whether RNase A dimerized through the zero-length amide bond, according to the procedure of Simons et al. (*34*), could show a cytotoxic action. The results we obtained were negative, i.e., the "zero-length" dimers do not show, at least under the experimental conditions and with the cell lines used by us, any significant cytotoxicity. They acquire a high cytotoxic activity against tumor cells cultures if cationized with polyethylenimine (PEI) according to the procedure outlined by Futami et al. (*35*). The extent of this cytotoxicity is, however, not higher than that, already evidenced by Futami et al. (*35*), exerted by PEI-cationized monomeric RNase A. Moreover, the latter appears to be cytotoxic also against human monocytes, i.e., normal cells.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were of the highest purity available. Their origin is specified in text and legends to figures and tables. Bovine seminal ribonuclease was a kind gift of Dr. J. Matousek (Institute of Animal Physiology and Genetics, The Academy of Sciences of the Czech Republic, Libechov 27721, Czech Republic). Isolation and purification of the enzyme were performed as described elsewhere (*30*).

In Vacuo Cross Linking of RNase A. According to the procedure outlined by Simons et al. (*34, 36*), bovine pancreatic RNase A (Type XII-A, purchased from Sigma Chem. Co., lot no. 124K7680, R5500) was dissolved in ddH_2O at a concentration of 5−40 mg/mL (when necessary, the pH of the solution was adjusted to 7.0 with 1 N NaOH) and lyophilized. The glass tube was sealed under vacuum (∼0.5 mBar) and incubated in an oven at 85 °C for 96−144 h. After releasing the vacuum, the protein sample was reconstituted with 40 mM sodium phosphate buffer, pH 6.7, to obtain a final protein concentration of 10 mg/mL. Then, the sample was incubated at 50 °C for 24 h to dissociate RNase A noncovalent oligomers formed.

Conjugation of Bovine RNase A and Its "Zero-Length" Dimers to Polyethylenimine. We followed the procedure described by Futami et al. (*35*). Native RNase A was dissolved in a 60 mg/mL solution of polyethylenimine (PEI, M_n 1200, M.W. 1300 Da, Sigma #482595, lot no. 05329KH), pH 5.0; protein final concentration, 1 mg/mL. EDC (Sigma #E7750, lot no. 107K0664) was added, final concentration, 0.1 mg/mL. The mixture was incubated for 16−24 h at room temperature. The same procedure was followed for the conjugation of the zero-length dimers. Then, the mixture was dyalized against water, and concentrated with Amicon Ultra filters (Millipore), cutoff 3000 Da. At the end, the material was lyophilized. Otherwise, it was partially purified performing two-step cation-exchange chromatography (see next paragraph).

Purification and Analysis of the Covalent RNase A Oligomers. *Size-Exclusion Chromatography.* Purification of the covalent RNase A oligomers was accomplished by two size-exclusion chromatography steps performed with a Superdex 75 26/60 column (GE-Healthcare) attached to an äKTA FPLC system, at room temperature. The column was equilibrated with 0.2 or 0.4 M NaP (pH 6.7)/0.15 M NaCl. The flow rate was 1 mL/min. To determine the yield of the reaction and the purity of the products the mixture of oligomers was analyzed with two size-exclusion chromatography steps using a Superdex 75 HR 10/300 column (GE-Healthcare) attached to an äKTA FPLC system, at room temperature. The column was equilibrated with 0.2 and 0.4 NaP, pH 6.7, in the first and second purification step, respectively. Elution was performed at a flow rate of 0.15 mL/min in the first and 0.07 mL/min in the second purification step.

Ion-Exchange Chromatography. Analyses of the covalent RNase A "zero-length" oligomers were also performed with cation-exchange chromatography using either Source 15S HR 10/10 or Mono S strong cationic columns (GE-Healthcare) and the same äKTA FPLC system mentioned above, at room temperature. Three different gradients were applied to the columns. The first was a preliminary stepwise gradient of NaP (70−90 mM, pH 6.7), followed by a linear (90−200 mM, pH 6.7) gradient at a flow rate of 1 mL/min (total, 44 min). The second was a linear 40−200 mM NaP (pH 6.7) gradient at a flow rate of 1 mL/min (total, 60 min). The third was a stepwise 40−200 mM NaP (pH 6.7) gradient.

To separate the RNase A-PEI conjugate(s) from nonconjugated RNase A and purify the products, two different elution schemes of cation-exchange chromatography were used: (i) a stepwise procedure, increasing by 30 mM, from 70 to 400 mM, the NaP (pH 6.7) concentration, and (ii) a two-step cation-exchange chromatography, each step under isocratic conditions (first step: 70 mM NaP, pH 6.7, to elute the nonconjugated protein; second step: 400 mM NaP, pH 6.7).

Quantification of the "Zero-Length" Oligomers. Each oligomeric species produced was quantified by measuring the area of its peak appearing in the gel filtration pattern of the first size-exclusion purification step and calculating its percentage relative to the sum of the areas of all peaks eluted. The purity of the "zero-length" species was also determined by measuring the intensity of the corresponding gel band with the use of the *ImageJ* program and calculating its percentage relative to the sum of the intensities of all bands.

Gel Electrophoresis. Cathodic gel electrophoresis under nondenaturing conditions was performed according to Goldenberg (*37*), with slight modifications (*22*), using β-alanine/acetic acid buffer, pH 4.0. 12.5−15% polyacrylamide gels were run at 20 mA for 100−140 min at 4 °C. Fixing and staining were performed with 12% trichloroacetic acid and 0.1% Coomassie Blue R-250.

SDS PAGE was performed according to Laemmli (*38*) using Tris/glycine buffer, pH 8.3. 12.5−15% polyacrylamide gels and 18% acrylamide gels were used to analyze the "zero-length" species or the products conjugated to PEI. Gels were run at 20−22 mA for 100−120 min at room temperature. Staining was made with a solution containing 0.025% Coomassie Blue R-250, 40% methanol, and 7% acetic acid.

DNA gel electrophoresis was performed with a 1% agarose gel, using 0.04 M Tris-acetate buffer, pH 8, containing 1 mM EDTA (TAE buffer). Gels were run at 100 V for 60 min, and a 500 bp Molecular Ruler (Bio-Rad #170−8203) was used as a molecular weight standard.

Production of RNase A mutants. *Construction of the Mutants.* The gene coding for wild-type RNase A, cloned into the expression vector pT7−7 (containing also the gene that codes for ampicillin resistance) between the *NdeI* and *Hin*dIII restriction enzyme sites, was kindly provided by Professor A. Di Donato (Faculty of Sciences, the University of Naples). Two mutants of the RNase A gene (E9A and K66A) were obtained using the QuikChange II Site-Directed Mutagenesis Kit (Stratagene, #200523, lot no. 1260135). pT7−7 template (with the RNase A wt gene) was added to the reaction buffer containing dNTPs and mutagenic primers.

The sequences of the primers were as follows:

Mutant E9A	FW 5′-GCAGCAGCCAAGTTTG*CC*GCGGCAGCACATGGAC-3′
	RV 5′- GTCCATGTGCTGCCGC*G*CAAACTTGGCTGCTGC-3′
Mutant K66A	FW 5′-CCCAGAAAAATGTTGCCTGC*GC*GAATGGGCAGACC-3′
	RV 5′-GGTCTGCCCATTC*GC*GCAGGCAACATTTTTCTGGG-3′

DNA polymerase was added and PCR performed. After denaturation of the double-stranded DNA template at 95 °C for 30 s, the first cycle was started: 95 °C for 30 s, annealing at 57 °C for 1 min, and polymerization at 68 °C for 12 min. These steps were repeated 16 times. Finally, the sample was cooled to 4 °C.

The DNA template was digested with *DpnI*, and the mutated and amplified plasmid was used to transform the XL1-Blue supercompetent cells. A colony of these cells was isolated and inoculated in 5 mL of LB containing Ampicillin (100 μg/mL). This overnight culture was used for plasmid DNA miniprep purification, using the Wizard Plus SV Minipreps DNA Purification System (Promega, #A1330, lot no. 182970). A DNA gel electrophoresis was performed to verify the presence of the amplified pT7−7 plasmid after PCR and DNA miniprep purification. Furthermore, the plasmidic DNA was sequenced and the presence of the desired mutation confirmed.

Production and Purification of RNase A from E. coli Inclusion Bodies. The PT7−7 plasmid containing the RNase A mutated gene was added to *E. coli* strain BL21-Gold (DE3) cells and incubated on an ice bath for 30 min. Cells were then transformed by thermal shock at 42 °C for 20 s. After 1 min on ice, the transformed *E. coli* was regenerated in 1 mL of LB (without ampicillin) and incubated at 37 °C for 1 h with shaking. After centrifugation of the culture, the pellet was resuspended in 100 μL of LB broth. Cells were seeded on LB Agar plates containing 100 μg/mL ampicillin, and incubated at 37 °C overnight. A colony was then isolated and inoculated in 5 mL of LB with 50 μg/mL ampicillin. This culture was incubated at 37 °C with shaking for at least 6 h, then inoculated in 150 mL of LB with 50 μg/mL ampicillin and incubated overnight at 37 °C with shaking. Fifteen milliters of this culture was used to inoculate 500 mL of LB containing 50 μg/mL ampicillin. The inoculated culture was shaken at 37 °C until the early log phase (A_{600} = 0.6 O.D.) was reached. It was then induced to express the cDNA coding for RNase A by adding IPTG (0.5 mM, final concentration). Induction of protein expression was performed overnight under the same conditions of the incubation.

The culture was centrifuged at 5500 rpm for 10 min and bacteria were resuspended in 0.1 M Tris-acetate buffer, pH 8.4 (10 mL/1000 OD_{600} units), containing PMSF as inhibitor of serine proteases and cysteine protease (4 μL of 0.1 M PMSF/g *E. coli*).

To verify the presence of RNase A in the cell culture before starting protein extraction, an analysis with SDS PAGE was performed (18% polyacrylamide gel, Tris/glycine buffer, pH 8.3). Amounts corresponding to 0.126 OD_{600} of *E. coli* collected before and after induction with IPTG were run at 20−22 mA at room temperature.

Cell lysis and inclusion bodies extraction were performed by incubation with lysozyme (0.8 mg/g *E. coli*) at room temperature for 20 min, and by freezing (in liquid nitrogen) and thawing (at 37 °C). After these last steps, the extract was treated as described elsewhere (*39*) to perform RNase A renaturation. To verify the presence of RNase A in the fractions eluted during these two purification steps, a Kunitz assay (*40*) was performed (purified yeast RNA as substrate), using native RNase A (Sigma Aldrich, type XII-A, R5500) as a control.

Determination of Free Amino Groups. 150 μg of protein were dissolved in 1 mL of 0.15 M sodium tetraborate ($Na_2B_4O_7$), pH 9.5. 0.2 mL of 0.015 M TNBS was added to the solution ("blank" consisted in 1 mL of 0.15 M sodium tetraborate, pH 9.5, and 0.2 mL of TNBS (*14*)). The reaction mixtures were maintained in the dark at 37 °C for 45 min. Reaction was stopped by adding 2 mL of 85−90% formic acid. Spectrophotometric measurements were performed at 340 nm, and the native, monomeric RNase A value was taken as a standard corresponding to 11 free amino groups (*14*).

Enzymatic Assays.

A. Ribonucleolytic activity on ssRNA (purified yeast RNA) as substrate was determined spectrophotometrically at 300 nm, according to Kunitz (*40*). One unit is the amount of enzyme that is capable of causing a decrease of the RNA absorbance at 300 nm (measured in the initial linear tract) per minute at 25 °C. The substrate is a 0.05% solution of purified yeast RNA in 0.05 M sodium acetate, pH 5.0.

B. The activity of the various RNase A species on the double-helical poly(A)·poly(U) complex (Sigma-Aldrich, P1537) as substrate (40 μg/mL) was determined spectrophotometrically at room temperature by measuring, as described elsewhere (*17*), the increase of the absorbance at 260 nm after addition of the various RNase species to the assay mixtures. One enzyme unit is the amount of enzyme that catalyzes the cleavage of one μmol of phosphodiester linkages of the double helical substrate per minute at 25 °C (*22, 45*).

Specific activities are expressed as units per milligram protein.

Cell Lines and Proliferation Assays. PSN1 (human pancreas adenocarcinoma), K562 (human chronic myelogenous leukemia), and U937 (human leukemic monocyte lymphoma) cell lines were grown in RPMI 1640 medium supplemented with 2 mM L-glutamine, 10% FBS, and 50 mg/mL gentamicin sulfate (BioWhittaker, Cambrex). Human cervix carcinoma HeLa cells were cultured in DMEM supplemented with 2 mM glutamine, 10% FBS, and 50 mg/mL gentamicin sulfate. All mentioned cell lines were incubated at 37 °C with 5% CO_2. Human monocytes were separated by centrifugation on Ficoll-Paque Plus under endotoxin-free conditions from buffy coats of healthy donors. Monocytes (99.8% pure), obtained as described in ref *41* and with the MACS Human Monocyte Isolation Kit II (Miltenyi Biotec), were resuspended in RPMI 1640 supplemented with 10% low endotoxin FBS and 2 mM L-glutamine (BioWhittaker).

At the beginning of each experiment, PSN1 cells were plated at 4×10^3 cells/well, K562 cells at 8×10^3 cells/well, and monocytes at 2×10^4 cells/well. All cell lines were plated in

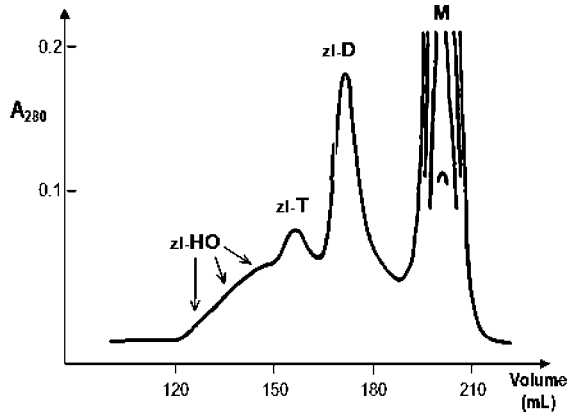

Figure 1. Purification and analysis of RNase A "zero-length" oligomers by size-exclusion chromatography. Twenty milligrams of the oligomers' mixture prepared by the procedure outlined by Simons et al. (*34, 36*) were applied onto a Superdex 75 26/60 (GE-Healthcare) column. Buffer: 0.2 M NaP, pH 6.7/0.15 M NaCl (*34*). Flow rate: 1 mL/min, room temperature. M: monomeric RNase A. zl-D, zl-T, zl-HO: "zero-length" dimer, trimer, and higher oligomers of RNase A.

96-well plates and after 24 h treated as described in the figure legends. At the end of the treatments, cell viability was determined by a metabolic assay using the CellTiter 96 AQ_{ueous} One Solution reagent (Promega) following the manufacturer instructions. Cultures were incubated for 2 h at 37 °C with 5% CO_2, and conversion of MTS into formazan was read at 490 nm.

RESULTS AND DISCUSSION

Preparation of "Zero-Length" Dimers of RNase A. RNase A "zero-length" dimers were obtained with the procedure described by Simons et al. (*34*). The products of the reaction were heated at 50 °C for 24 h to dissociate the noncovalent aggregates possibly formed, purified, and analyzed by gel filtration and SDS PAGE. The gel filtration profile (Figure 1) shows the elution of a great amount of monomeric protein (M), preceded by a clear peak of dimer (zl-D), a smaller peak of trimer (zl-T), and a region of unidentified higher oligomers (zl-HO). By measuring the areas of the peaks and/or the intensity of the bands, the following amounts could be calculated: 15.2 ± 1.9% for the dimer, 5.3 ± 2.0% for the trimer, and 3.7 ± 2.6% for the higher oligomers. The SDS PAGE analysis (Figure 2A) shows several clearly visible bands, of which the densest one is the residual monomeric RNase A. After gel filtration, the purity of the various oligomeric species was determined by electrophoretic analyses. Their purity values decreased as a function of the oligomers' sizes (Figure 2B): the dimer was 76.8 ± 6.9% pure, the trimer 46.9 ± 6.7%, and the higher oligomers 44.8 ± 14.8%. The dimeric species, isolated from the gel filtration pattern, was subjected to an ion-exchange chromatographic purification (*22, 24, 34*), the results of which indicated that the product was actually very heterogeneous (data not shown). All species collected from the gel filtration were also analyzed by cathodic gel electrophoresis (Figure 2C). It is clearly visible that they display an electrophoretic mobility similar to that of the corresponding domain-swapped oligomers, but their spreading bands suggest that the material is heterogeneous. Focusing on zl-D, its heterogeneity could be due to the presence of not only a single dimer (*34*), but to more than one product of the reaction. In other words, this could mean the possible involvement of amino and carboxyl groups other than only those belonging to Lys66 and Glu9.

Are Lys66 and Glu9 the Only Reactive Residues? An Answer from Two RNase A Mutants. To test this hypothesis, we prepared two mutants of RNase A, E9A and K66A, through site-directed mutagenesis (see Experimental Procedures). On the basis of the work of Simons et al. (*34*), these two protein species should not react in the cross-linking reaction developed by these authors, that is, no "zero-length" dimers of RNase A should form. Before testing this possibility, we verified the nature of the two mutants by sequencing their plasmidic DNA. In addition, the elution profiles of the two mutants obtained with a cation-exchange chromatography performed under isocratic conditions (Supporting Information Figure 1) confirmed that the site-directed mutagenesis had been successful. Indeed, the K66A variant is more acid than the wild type lacking one basic amino acid residue and elutes before native RNase A, whereas the E9A mutant, lacking an acid residue, becomes more basic and elutes definitely later. The two mutants were now subjected to the identical experimental conditions used with native RNase A to produce "zero-length" dimers, and the results obtained are shown in Figure 3 and Table 1. It clearly appears that the two variants (Figure 3A,B) are capable of forming dimers, trimers, and higher oligomers in amounts and relative proportions (Table 1) similar to those obtained with native RNase A (Figure 3C). Therefore, differently from what observed by Simons et al. (*34*), Lys66 and Glu9 are not the only residues of RNase A reacting in the procedure.

Determination of Free Amino Groups. To improve the understanding of the results presented above, we determined (by the reaction with TNBS; see Experimental Procedures, and ref *14*) the number of free amino groups present in the protein species deriving from the two variants. They were analyzed before (monomers) and after (monomers M, and dimers, zl-D) subjecting them to the in vacuo heating reaction outlined by Simons et al. (*34*). Table 2 shows the results obtained. On the basis of the eleven NH_2 groups present in native, monomeric RNase A (*14*), it clearly appears that between two and four lysine residues are involved in the amide bond(s) forming in the procedure (*34*) in all types of dimers examined. The analysis was also performed on the monomers (M) of the three RNase A species. In the case of the monomeric K66A variant, both the unheated and heated (H, i.e., subjected to the in vacuo heating reaction) mutant have one NH_2 group less than native RNase A. The missing amino group is obviously that of the Lys66 residue which was mutated in to alanine. Notably, no intramolecular bonds form in the K66A variant. On the contrary, in the E9A variant one amino group is missing only after the in vacuo heating reaction (H E9A M), as it occurs in native RNase A (H-wt M). This might suggest that an intramolecular amide bond could form in these species, involving the Lys66 ε-NH_2 (*34*). The acid partner to react should be the carboxyl group of Asp121 (*42*), whose distance from Lys66 (*42, 43*) is suitable for the reaction to occur.

Enzymatic Assays. All RNase A oligomers obtained so far, either by cross-linking reactions or by one of the other ways by which the enzyme protein can aggregate (*24, 44*), acquire the ability to degrade double-stranded polyribonucleotides. The extent of the degrading activity increases with the size of the oligomer, i.e., with the number or density of positive charges present on the molecule (*24, 45*). The ability of a ribonuclease to digest dsRNA was in fact ascribed to the occurrence of a high protein basicity (*17, 45, 46*). Along with this novel catalytic action, basic ribonucleases and the RNase A oligomers maintain their activity against ss-RNA, the extent of which, however, decreases as the size and/or the basicity of the protein molecule increase (*24, 45, 47*), this being just the opposite of what happens with double-helical RNA substrates. On this basis, we tested the "zero-length" dimers and trimers, and the higher, indistinct oligomers for their action on dsRNA. Table 3 shows the activities of the "zero-length" oligomers of native RNase A (wt zl-D, wt zl-T, wt zl-HO) and of the "zero-length" dimers

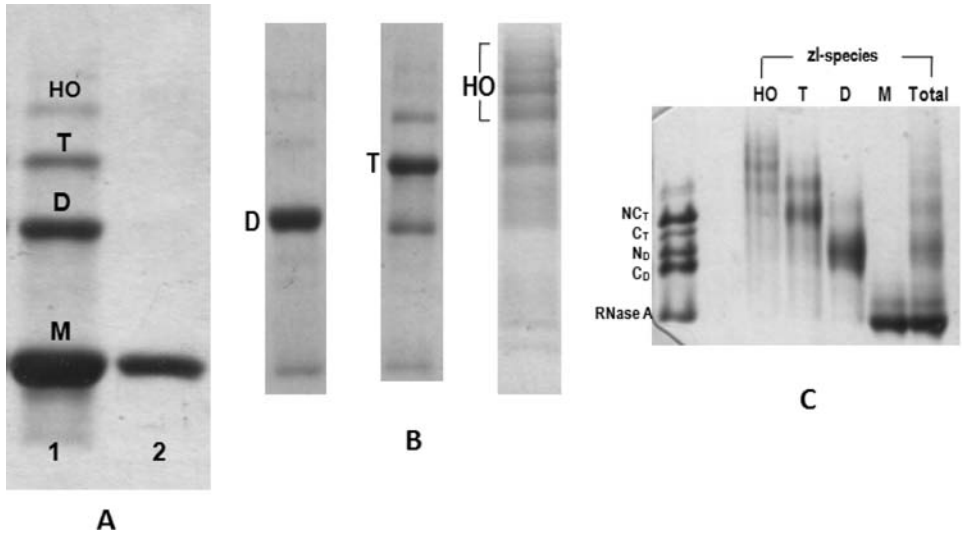

Figure 2. Denaturing and nondenaturing PAGE analysis of the RNase A "zero-length" oligomers. (A) 12.5% polyacrylamide SDS PAGE. Lane 1, 12 μg of the total mixture obtained by the procedure outlined by Simons et al. (*34*); see also Experimental Procedures; lane 2, 2 μg of native RNase A (Sigma Type XII-A) as a standard. (B) 12.5% polyacrylamide SDS PAGE purity assay of the various oligomeric species. Oligomers were purified by two successive gel filtrations. Densities of bands were determined by the *ImageJ* (1.36−6 MB) program. (C) 12.5% polyacrylamide cathodic PAGE of the RNase A "zero-length" species collected from gel filtration and compared with the domain swapped RNase A oligomers (*22, 23*). "Zero-length" RNase A oligomers: M = monomer; D = dimer; T = trimer; HO = higher-order oligomers. In cathodic PAGE: RNase A, native monomer (2 μg); N_D, C_D, N- or C-terminus swapped RNase A dimers (3 μg each); NC_T, N+C-termini swapped trimer (3 μg); C_T, cyclic C-terminus swapped trimer (2 μg).

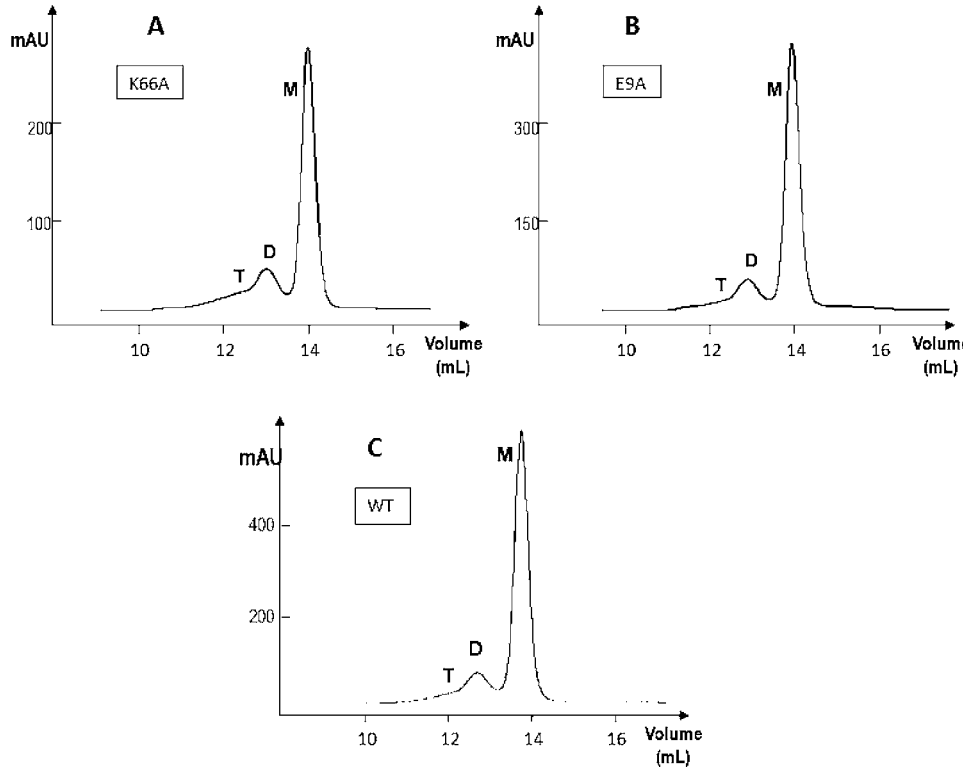

Figure 3. Size-exclusion chromatography of "zero-length" oligomers formed by the two RNase A mutants. The reaction mixture, after heating at 50 °C and cooling, was applied on to a Superdex 75 10/300 (GE-Healthcare) column; buffer, 0.2 M NaP, pH 6.7, containing 0.15 M NaCl; flow rate, 0.15 mL/min, at room temperature. (A) K66A, 1 mg applied; (B) E9A, 1.5 mg applied. (C) WT (wt RNase A), 2 mg applied.

obtained from its two variants (E9A zl-D, K66A zl-D) on dsRNA (poly(A)·poly(U)) or ssRNA (yeast RNA), compared to the action of the corresponding monomeric species. The activities of BS-RNase and of the 3D domain-swapped RNase A oligomers are also included for comparison. The activity values determined with both the ds- and ssRNAs as substrates are in agreement with previous results (*23, 24, 42, 45, 47*); however, it is worth pointing out the lower capacity of degrading dsRNA shown by the K66A variant and its oligomers, compared with native RNase A, which can be ascribed to the one positive charge missing in the mutant. While the activity values of the "zero-length" dimers against poly(A)·poly(U) determined by Simons et al. (*34*) and by us here are similar, we could not confirm the activity values on ssRNA as reported in ref *34*: in our hands, the zl-D, zl-T, and zl-HO are progressively less active as a function of the increase of their size (or positive charges

Table 1. Yields (%) of the "Zero-Length" Oligomers formed by the RNase A Species[a]

oligomers[b]	WT	K66A	E9A
zl-D	15.2 ± 1.9	17.0 ± 0.2	14.7 ± 0.9
zl-T + zl-HO	9.0 ± 2.9	10.6 ± 0.8	5.9 ± 0.1

[a] Yields were determined by measuring the area of each peak and calculating its percentage relative to the sum of the areas of all peaks eluted. The values reported for the two mutants are means of the measured areas from three different gel filtration experiments ± s.d., while the values relative to the wt are means of 11 gel filtration experiments (see Experimental Procedures) ± s.d. [b] WT, native RNase A; zl-D, "zero-length" dimer; zl-T, "zero-length" trimer; zl-HO, "zero-length" higher oligomers.

Table 2. Free Amino Groups Present in Each RNase A Species

RNase A species	free NH_2 groups[a]
RNase A	11.0[a]
H-wt M[b]	10.3 ± 1.2
wt zl-D	7.5 ± 0.9
E9A M	11.4 ± 0.9
H-E9A M	10.0 ± 1.0
E9A zl-D	7.9 ± 0.9
K66A M	9.3 ± 0.8
H−K66A M	10.0 ± 0.8
K66A zl-D	7.9 ± 0.7

[a] In each experiment, the absorbance value determined for native, monomeric RNase A was made equal to 11 amino groups, based on 11 free amino groups present in the native protein (*14*). The values reported are means of four experimental values ± s.d. [b] H, "heated", i.e., RNase A monomeric species recovered after being subjected to the in vacuo heating procedure reported (*34*) and used to prepare the cross-linked, "zero-length" oligomers. wt, native RNase A; M, monomeric species; zl-D, "zero-length" dimers.

Table 3. Enzymatic Activities of the Various RNase A Monomeric and "Zero-Length" or Domain-Swapped Oligomeric Species on Single-Stranded (Yeast) or Double-Stranded (poly(A)·poly(U)) RNA

RNase species	specific activity,[a] poly(A)·poly(U) as substrate	specific activity,[a] Yeast RNA as substrate
BS-RNase	7.8 ± 1.3	15.5 ± 3.4
RNase A	2.4 ± 0.5	70.3 ± 8.8
H-wt M	1.3 ± 0.5	62.9 ± 8.6
wt zl-D	4.6 ± 1.1	44.7 ± 6.3
wt zl-T	6.3 ± 2.1	29.0 ± 4.4
wt zl-HO	11.3 ± 2.7	5.1 ± 0.6
E9A M	1.1 ± 0.2	73.6 ± 7.0
H-E9A M	n.d.[b]	66.4 ± 8.3
E9A zl-D	2.0 ± 0.2	36.0 ± 8.4
K66A M	0.5 ± 0.1	66.8 ± 6.2
H−K66A M	n.d.[b]	68.5 ± 4.1
K66A zl-D	0.6 ± 0.2	40.4 ± 5.6
N_D	2.8 ± 0.1	40.7 ± 18.1
C_D	8.6 ± 0.7	16.0 ± 3.5
NC_T	16.1 ± 3.6	33.2 ± 7.7
C_T	20.5 ± 2.2	25.7 ± 2.2
HO	24.2 ± 2.1	15.5 ± 2.7

[a] Specific activity values were calculated as described in refs *17*, *45* (see also Experimental Procedures). Each value is the mean of results obtained in several different assays ± s.d. Amounts of enzyme used with poly(A)·poly(U) as substrate: monomer, 10 μg; dimer, 5 μg; trimer, 2.5 μg; higher oligomers, 1 μg. Amounts of enzyme used with yeast RNA as substrate: monomer or dimers, 0.5 μg; trimer, 1.0 μg; higher oligomers (HO), 1.5 μg. N_D, C_D, N- or C-terminus swapped RNase A dimers; NC_T, N+C-termini swapped trimer; C_T, cyclic C-terminus swapped trimer; HO, mixture of N+C-swapped higher-order RNase A oligomers. [b] Not determined. H (heated) wt M: see legend to Table 2.

density), which agrees with all previous results (*24, 42, 45, 47*). The enzymatic activity values of the three RNase A monomeric variants determined with yeast RNA as substrate before and after the in vacuo heating reaction show that the activities of the wt enzyme and E9A monomeric variant slightly decrease after the reaction, while the activity of the K66A variant does not. Although modest, that lowering in activity might be ascribed to the modification of D121, whose catalytic role in RNase A is well-known (*48*). The activity of monomeric K66A, on the contrary, does not substantially change, remaining slightly lower than that of the wt enzyme and E9A mutant either before or after the reaction. This is in line with the known catalytic role of K66 P0 subsite (*49*). Although the differences of the enzymatic activities (see Table 3) are modest and lower than what could be expected for species that potentially lose D121 (*48*), it has to be taken into account that possibly yeast RNA is not the most appropriate ssRNA substrate to highlight them (*48*). Nevertheless, the trend shown by the enzymatic activity of the three RNase A monomeric variants agrees with the hypothesis that the K66-D121 intramolecular bond could form in the in vacuo heating of wt RNase A.

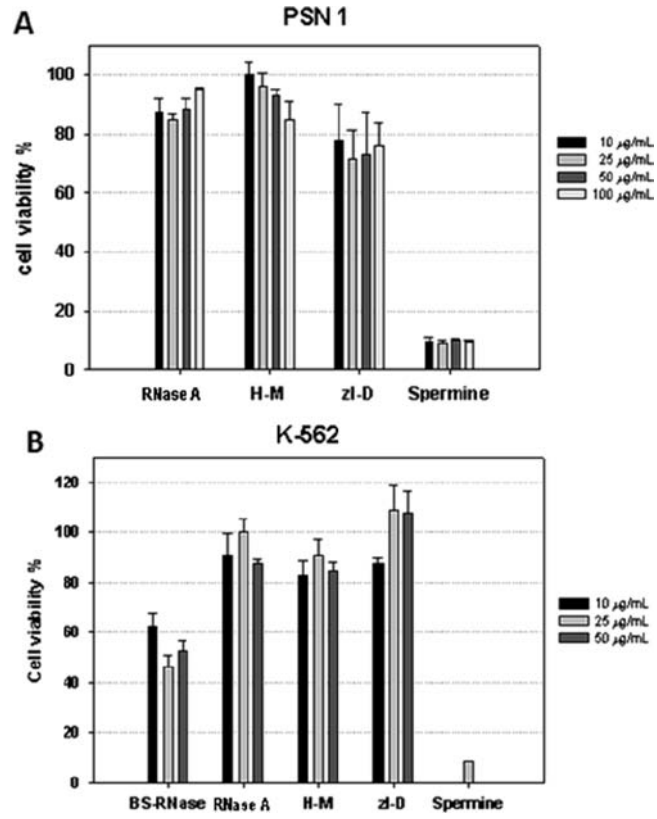

Figure 4. Cytotoxic activity of the various RNase A "zero-length" species on two different tumor cell lines. The various "zero length" oligomers were purified, lyophilized, and dissolved in sterile, twice-distilled water just before their addition to the cell cultures for 48 h (see Experimental Procedures). H-M indicates native, monomeric RNase A subjected to, and recovered after, the in vacuo heating (H) procedure of Simons et al. (*34*); zl-D, "zero-length" dimers of RNase A. (A) PSN1 cell cultures. The various "zero length" oligomers and spermine were used at 10 μg/mL, 25 μg/mL, 50 μg/mL, and 100 μg/mL. (B) K562 cell cultures. The various RNase A "zero-length" species were used at 10 μg/mL, 25 μg/mL, 50 μg/mL, and spermine at 20 μg/mL. Cell viability was calculated as a percentage of treated versus untreated cells. Each value shown is the mean of three measures from three independent experiments ± s.d.

Are the RNase A "Zero-Length" Dimers Cytotoxic? This novel type of dimers was tested on PSN1 human adenocarcinoma cell line grown in culture. The results are shown in Figure 4A. We tested various concentrations of (i) native RNase A (NH-M), (ii) the RNase A that was recovered from the in vacuo heating reaction, indicated as H-M, (iii) the "zero-length" dimers (zl-D), and in addition (iv) spermine as a positive control. After 48 h incubation, no significantly higher cytotoxic action of the "zero-length" dimers, compared to that of the two monomeric

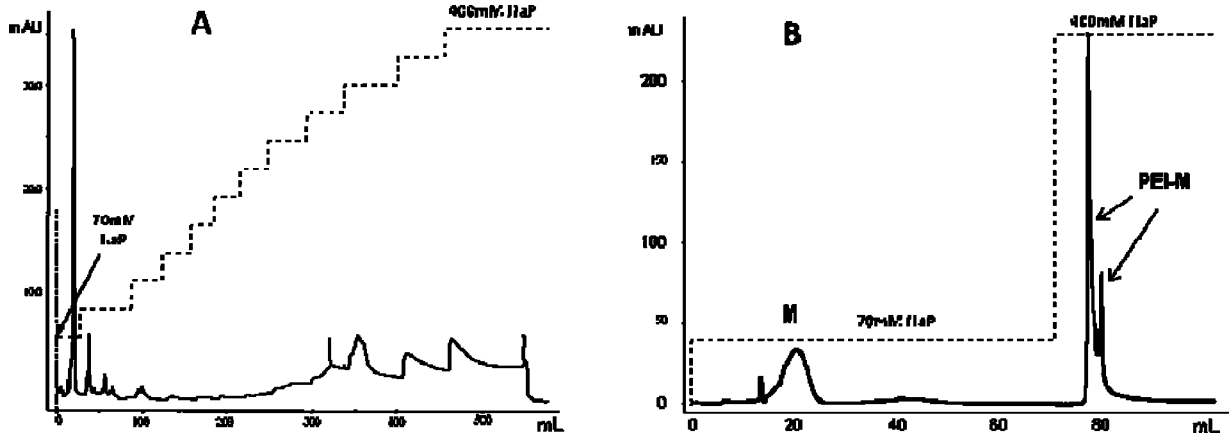

Figure 5. Purification and analysis of monomeric RNase A conjugated with polyethylenimine. (A) Stepwise cation-exchange chromatography of the PEI-RNase A complex. The reaction mixture was dialyzed against Milli-Q water and concentrated by Amicon filters (cut off 3000 Da). 750 μg of material were applied on to a Source 15S HR 10/10 (Ge-Healthcare) column. Eluting buffer, NaP, pH 6.7. Starting NaP concentration, 70 mM; at each step, it was raised by 30 mM. Final NaP concentration, 400 mM. Before the end of chromatography, 1 M NaCl was also added to ensure a complete elution of all conjugated species. (B) Partial purification of the PEI-RNase A complex (1 mg): cation-exchange chromatography with a Source 15S HR 10/10 (GE-Healthcare) column. Buffer: NaP, pH 6.7. Two-step chromatography under isocratic conditions: first step, 70 mM NaP buffer, with elution of nonconjugated monomeric RNase A; second step, 400 mM NaP buffer, with elution of the PEI-conjugated species. Percentage values were calculated by measuring the areas of single peaks (see Experimental Procedures). M, RNase A monomer; D, dimer; T, trimer; HO, higher oligomers of RNase A; PEI-M, polyethylenimine-conjugated monomeric RNase A.

species, could be evidenced, while the unspecific cytotoxicity of spermine was remarkably high.

A second experiment was carried out with K562 cells, which previously were shown to be susceptible to the action of BS-RNase (*50*). The cells were subjected for 48 h to the action of all RNase A species at the concentrations indicated (see Figure 4B), but the zl-D were inactive, while BS-RNase and spermine were considerably cytotoxic. By extending this experiment up to 72 h, the results did not change (data not shown).

Further experiments were performed with HeLa and U937 cells using the same protein concentrations and times of incubation tested with PSN1 cells. In these cases also, the various RNase A species resulted to be totally inactive (data not shown), while spermine was cytotoxic like in the previous experiment. In conclusion, therefore, the "zero-length" oligomers of RNase A appear to be devoid, at least under the experimental conditions and with the cell lines used by us, of any significant cytotoxic activity.

Cationization of Native RNase A and Its "Zero-Length" Dimers with Polyethylenimine and Analysis of the Products of the Conjugation Reaction. The cytotoxicity of RNase A cationized with polyethylenimine (PEI) has been shown by Futami et al. (*35*). Could the PEI-cationized RNase A "zero-length" dimer(s) acquire a cytotoxic action higher than that of the PEI-cationized monomer, which could be ascribable to the dimericity of the RNase A molecule? To answer this question, we used the procedure outlined by Futami et al. (ref *35*; see also Experimental Procedures) to cationize with PEI the zl-D prepared by us. The reaction was first carried out with native, monomeric RNase A, to obtain the species called PEI-M. The products of the reaction were purified and analyzed by cation-exchange chromatography and SDS PAGE. Figure 5A shows the profile of a cation-exchange chromatogram in which a stepwise increase of NaP concentration was applied (see Experimental Procedures). A sharp peak appeared at a NaP concentration of 70 mM (pH 6.7). From its position, it can be deduced that it corresponds to unreacted RNase A contained in the reaction mixture. At higher salt concentration, several irregular peaks emerged successively. This in turn suggests that the product of the PEI-RNase A conjugation is a heterogeneous mixture of PEI-M species deriving from the reaction of the various carboxyl groups available on the protein. To make the isolation of the PEI-RNase A products easier, a different chromatographic approach was followed (Figure 5B): after the elution of monomeric unreacted RNase A at 70 mM NaP, pH 6.7 (*22*−*24*), the NaP concentration was brought to 400 mM. Two sharp, but not completely resolved, peaks of conjugated species eluted immediately. They were collected, dialyzed against water, concentrated with Amicon ultrafilters, and electrophoresed or kept at 4 °C until use. The SDS-PAGE analysis carried out on these PEI-M products (Supporting Information Figure 2) confirmed that they were heterogeneous. Now, we carried out the conjugation reaction of the RNase A "zero-length" dimers with polyethylenimine. The results (data not shown) were qualitatively similar to those obtained with native RNase A. Considering that the starting dimeric protein species to be PEI-conjugated was actually a mixture of "zero-length" dimers and not the only E9-K66 zl-D as described in ref *34*, the product of the conjugation reaction could have obviously been even more heterogeneous than the one obtained with monomeric RNase A. We decided therefore to use the entire, unpurified mixture of PEI-RNase A "zero-length" dimer(s) (PEI-zl-D) to determine its enzymatic and biological activity.

Table 4. Enzymatic Activity of PEI-Conjugated or Not Conjugated RNase A on Double-Stranded (poly(A)·poly(U)) or Single-Stranded (yeast) RNA

RNase species	Specific activity[a], poly(A)·poly(U) as substrate	Specific activity[a], yeast RNA as substrate
BS-RNase	6.9 ± 0.8	14.0 ± 1.6
RNase A	1.9 ± 0.1	75.3 ± 8.4
PEI-M (NP[b])	2.6 ± 0.5	41.3 ± 5.3
zl-D	4.3 ± 0.3	59.7 ± 2.5
PEI-zl-D (NP[b])	8.4 ± 1.1	38.0 ± 8.2

[a] Specific activity values calculated as described (refs *17*, *45*; see also Experimental Procedures). Each value is the mean of three different assays ± s.d. Concentrations of the various enzyme species in the assay: 10 μg monomer, and 5 μg dimer with poly(A)·poly(U) as substrate; 0.5 μg monomer or dimer with yeast RNA as substrate. [b] NP: not purified, total reaction mixture (*35*) dialyzed against water, concentrated, and then dissolved (1 mg/mL) in Milli-Q water.

Enzymatic Assay of the "Zero-Length" RNase A Dimers Conjugated to Polyethylenimine. Table 4 shows the enzymatic activities of the PEI-zl-D on dsRNA and ssRNA. The assay comprised the action of (i) native RNase A, (ii) the PEI-native RNase A complex (PEI-M), (iii) the unconjugated

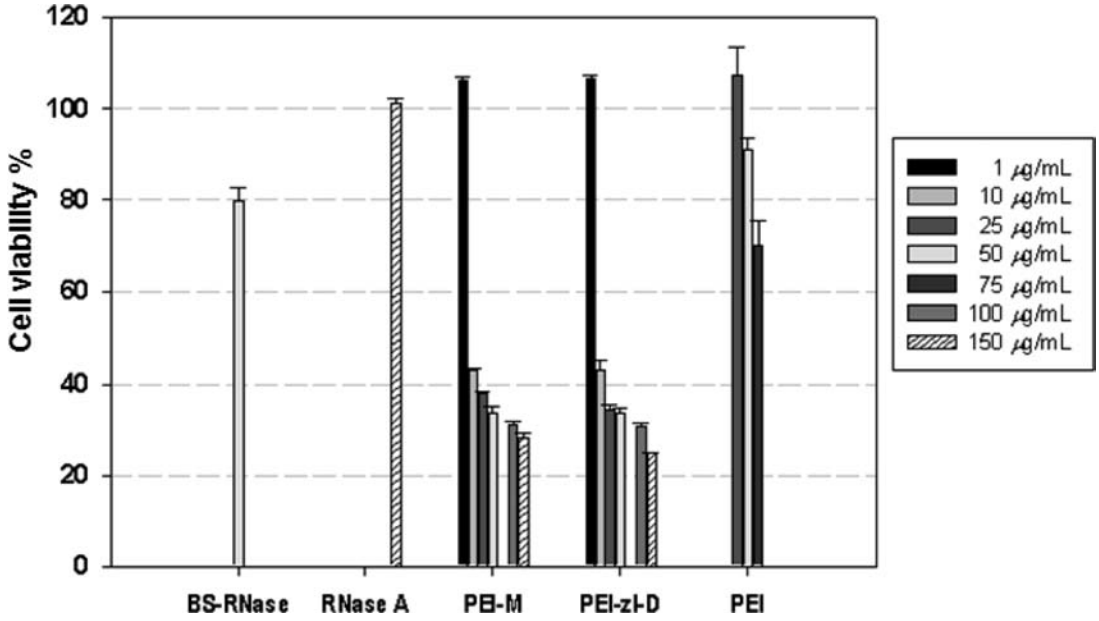

Figure 6. Cytotoxic action of the PEI-RNase A monomeric and dimeric complexes on K562 cell line, as a function of protein concentration. Interaction of the various RNase species with cells lasted 24 h. The two RNase A species (PEI-M and PEI-zl-D) were not purified samples. M, monomeric RNase A; zl-D, RNase A "zero-length" dimers. BS-RNase, bovine seminal RNase, PEI-M, PEI-conjugated monomeric RNase A; PEI-zl-D, PEI-conjugated RNase A "zero-length" dimers; PEI, polyethylenimine. PEI alone was used at 50% concentration that of the RNase A species, as it had been estimated to represent about half of the mass of the PEI-RNase A complexes (see text for details). Cell viability was calculated as a percentage of treated versus untreated cells. Each value shown is the mean of three measures from three independent experiments ± s.d.

"zero-length" RNase A dimers (zl-D), (iv) the PEI-RNase A "zero-length" dimers (PEI-zl-D) complex(es), and (v) BS-RNase for comparison. As for the dsRNase activity, while that of PEI-M was only about 30% higher than the activity of native RNase A, the degrading actions of the "zero-length" dimers as such (220% higher), BS-RNase (360% higher), and PEI-zl-D (440% higher) were remarkable, and in line with results presented in this work or elsewhere (*22*−*24, 27, 45, 47*). The same is true for the results obtained with yeast RNA as a substrate, i.e., all RNase A derivatives and BS-RNase showed lower activity values in comparison with the activity of native RNase A. This result is also in agreement with all previous available data, and with the interpretations advanced elsewhere (*24, 42, 47*). PEI alone (not shown) was absolutely inactive.

In conclusion, the relationship between the RNase basicity and the increased activity on dsRNA or the decreased activity on ssRNA was once again confirmed here. Indeed, the RNase A derivatives are more basic than native RNase A, as demonstrated by the chromatographic pattern of Figure 5, although their pI values are missing. Instead, the pI of BS-RNase is known to be at pH 10.3 (versus the RNase A pI at pH 9.6) as shown in 1972 by D'Alessio et al. (*6*), who demonstrated the higher basicity of BS-RNase compard to RNase A.

Cytotoxicity on K562 Cells of RNase A Monomers and "Zero-Length" Dimers Cationized by Conjugation with Polyethylenimine. The cell line used in the following experiments was K562, which, as mentioned above, is sensitive to BS-RNase. Figure 6 shows the results obtained in a 24 h test by comparing the cytotoxic actions of various concentrations of the PEI-M and the PEI-zl-D complexes with the cytotoxic actions of native RNase A, BS-RNase (both tested in single doses), and three concentrations of PEI alone. We have chosen the amount of PEI (MW 1300 Da) to be tested alone as the one theoretically corresponding to the amount of the substance (five molecules) bound to 50% of the side-chain carboxyl groups present in RNase A. It clearly appears that PEI-M and PEI-zl-D showed strong but quite similar cytotoxicity values, whereas PEI alone was inactive at 25 μg/mL and slightly cytotoxic at 50 or 75 μg/mL. RNase A (150 μg/mL) was inactive and BS-RNase slightly active at 50 μg/mL. Additional experiments as a function of time were performed using two different doses of all agents tested above, i.e., 10 μg/mL (Supporting Information Figure 3A) and 25 μg/mL (Supporting Information Figure 3B). Only PEI-M and PEI-zl-D showed a significant but quite similar cytotoxic action at a concentration of 10 μg/mL, while very modest, if any, was the cytotoxic activity of BS-RNase under identical conditions. At the concentration of 25 μg/mL, stronger but again quite similar to each other were the actions of both PEI-M and PEI-zl-D, whereas the cytotoxic activity of BS-RNase was now evident but still rather modest. In conclusion, the RNase A "zero-length" dimers cationized with polyethylenimine did not acquire a cytotoxic action higher than that of the PEI-cationized monomeric RNase A.

Moreover, we also tested the latter complex on human monocytes, and Figure 7 shows the results obtained. It is quite clear that both the unpurified and purified PEI-RNase A complexes, at the concentration of 25 μg/mL, showed a remarkable cytotoxicity toward monocytes under conditions where BS-RNase (50 μg/mL), native RNase A (100 μg/mL) or PEI alone (12.5 μg/mL) were substantially inactive. Therefore, the cytotoxic action of monomeric RNase A (and presumably that of its "zero-length" dimers) conjugated to PEI appears not to be specific for tumor cells, which drastically decreases the significance of a potential therapeutic use of ribonucleases cationized with polyethylenimine.

Why are the Non-Cationized "Zero-Length" Dimers of RNase A Not Cytotoxic? While native, monomeric RNase A is not cytotoxic (*24, 30*−*32*), other members of the pancreatic-type ribonuclease superfamily display, often along with other biological actions, remarkable activity against malignant tumor cells (*1, 7, 8, 51*−*55*). Cytotoxic RNases usually present a high basic charge density and the ability to evade the cytosolic ribonuclease inhibitor (cRI). The former is a feature also linked to the ability of a ribonuclease to attack dsRNA: the higher the number of positive charges present in the proximity of the

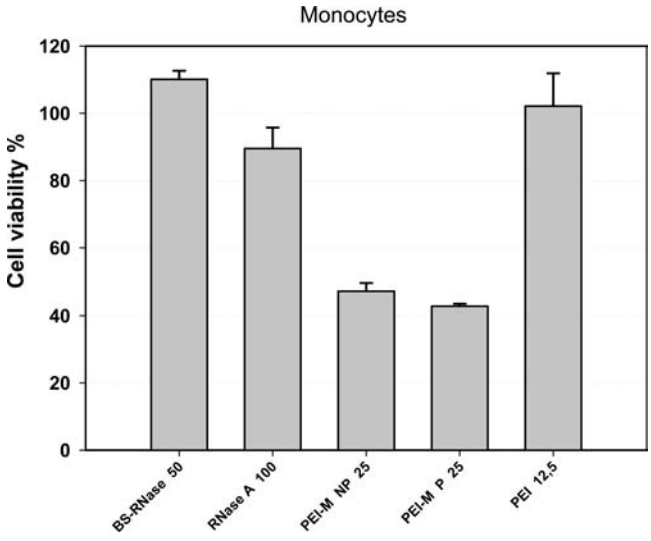

Figure 7. Action of polyethylenimine-cationized RNase A on human monocytes. Monocytes were plated in 96-well plates at 2×10^4/well and incubated overnight. Then, the following substances were added: BS-RNase, 50 μg/mL; native RNase A, 100 μg/mL; purified or unpurified native PEI-RNase A complex(es), 25 μg/mL; PEI, 12.5 μg/mL. The cells were treated for 24 h at 37 °C. Cell viability was calculated as a percentage of treated versus untreated cells. Each value shown is the mean of three measures from three independent experiments ± s.d.

enzyme active site, the higher the ability of the RNase to degrade dsRNA (*17, 22, 24, 27, 32, 45*). It has to be recalled here that the preservation of enzymatic activity also seems to be mandatory for a ribonuclease to be cytotoxic or, generally, biologically active (*24, 30, 33, 56*). It is also worth mentioning that enzymatic activity and cytotoxicity cannot be proportionally related to each other (*57, 58*). This evidence suggests that ribonuclease cytotoxicity could actually be ruled by several factors, among which is the possibility for the enzyme protein to evade interaction with the cytosolic ribonuclease inhibitor. However, several exceptions to the "rule" that only RNases able to evade interaction with cRI are cytotoxic were recently found (*33, 59, 60*). Therefore, it could not be surprising that the "zero-length" dimers of RNase A are ineffective against tumor cells notwithstanding they are not trapped by cRI (*34*) and are enzymatically active toward ss- and dsRNA (ref *34*, and present work). The conformational stability (*61*) and, above all, the location of the positive charges on an RNase molecule (*62*) can be determinant for it to be biologically active (*61, 62*) considering either the efficacy of the RNase−RNA interaction (*32, 45, 61, 62*) or the productive interactions that the protein can build with the cell membrane in order to be internalized (*62−64*). As far as the RNase A zl-D (*34, 36*) are concerned, it must be recalled that their molecular structure is unknown. On the basis of the study of Simons et al., it appears improbable for their structure to be similar to any of the well-known dimeric structures of RNase A (*9−11, 13, 23−28*) or even to that of the cross-linked dimers constructed by Wang, Wilson, and Moore in 1976 (*14*). Indeed, in this last case the diimidoester linker leaves remarkable freedom to the two protein molecules linked to each other. Instead, the amide bond of the RNase A zl-D makes the vicinity of the two protein subunits quite tight. In other words, these novel dimers should be characterized by a relatively strong immobility, high rigidity, and lower symmetry compared to other known dimeric ribonuclease structures (*13, 28, 29*). The structural characteristics of the RNase A zl-D might be a key in understanding why this novel type of RNase A dimer is not cytotoxic. On the other hand, the evident accessibility of its active site to substrates, and the positive charge density of the protein, which could maintain its enzymatic activity against both ss- and dsRNA, are facts that point out the substantial complexity of the matter (*65*). Moreover, since from the present work it appears that the amide bond induced by the procedure outlined by Simons et al. (*34, 36*) may intervene not only between Lys66 and Glu9 (*34*), but also between amino and carboxyl groups of other amino acid residues, the reciprocal location of the protein subunits in the dimer can vary remarkably.

Therefore and in conclusion, the compactness and the possibly variable features of the structure of the RNase A "zero-length" dimers may be their most characteristic structural aspect, responsible, at least partly, for the absence of cytotoxicity in them, making these dimers different in this respect from other natural or artificial ribonuclease dimers.

ACKNOWLEDGMENT

This work was supported by the Italian Ministero per l'Istruzione e la Ricerca Scientifica and the University of Verona, Verona, Italy (Grant: ex60%-Gotte07). We deeply thank Dr. Monica Vincenzi, the Medical Faculty of the University of Verona, for the DNA sequencing experiments.

Synthesis and Characterization of Alkylated Poly(1-vinylimidazole) to Control the Stability of its DNA Polyion Complexes for Gene Delivery

Shoichiro Asayama,* Tomoe Hakamatani, and Hiroyoshi Kawakami

Department of Applied Chemistry, Tokyo Metropolitan University, 1-1 Minami-Osawa, Hachioji, Tokyo 192-0397, Japan.
Received September 17, 2009; Revised Manuscript Received March 25, 2010

Poly(1-vinylimidazole) (PVIm) with alkylated imidazole groups has been synthesized as a pH-sensitive polycation to control the stability of its DNA polyion complexes for gene delivery. The resulting alkylated PVIm (PVIm-R) was water-soluble despite deprotonation of the imidazole groups at physiological pH, as determined by acid−base titration and solution turbidity measurements. Agarose gel retardation assay proved that the alkylated imidazole groups worked as anchor groups to retain DNA. Pyrene fluorescence measurement showed that the hydrophobic domain of the DNA complex with butylated PVIm (PVIm-Bu) increased after the protonation of imidazole groups of the PVIm-Bu to enhance the membrane disruptive activity. The PVIm-Bu exhibited no significant cytotoxicity in spite of the existence of cationic groups. The resulting PVIm-Bu/DNA complexes easily released DNA, as compared with the octylated PVIm, which was examined by competitive exchange with dextran sulfate. As a result, the PVIm-R/DNA complexes mediated efficient gene delivery, and the gene expression depended on the length and density of the alkyl chains. These results suggest that pH-sensitive PVIm-R's control of the stability of DNA polyion complexes enhanced noncytotoxic gene delivery by the optimized alkylated imidazole groups.

INTRODUCTION

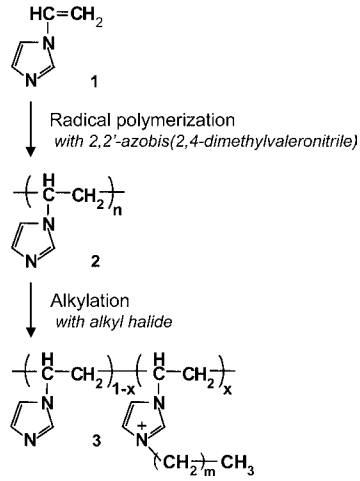
In gene delivery systems, the formation of polycation/DNA polyion complexes is a key factor for the new design of efficient delivery (*1*−*3*). The polyion complexes on the cell plasma membrane are internalized into acidic endosomal vesicles where they are subjected to a significant pH change from pH 7 to 5 (*4*). Endosomal escape is one of the critical factors for efficient gene delivery. pH-sensitive polymers such as poly(ethylenimine) (PEI[1]), which is able to capture protons entering an endosome, have been used to achieve efficient release of the delivered material from endosomes (*5*−*7*). PEI induces swelling of the endosomes that leads to membrane disruption, that is, the proton sponge effect.

Recently, polymers modified with histidine or other moieties containing an imidazole group have shown significant enhancement of gene expression without increasing cytotoxicity compared with that of nonmodified polymers (*8*−*12*). In this case, histidine or other moieties containing an imidazole group have made polycation/DNA complexes escape from an endosome by a proton sponge mechanism. The imidazole heterocycles displaying a pK_a around 6 possess buffering capacity in endosomal pH, inducing membrane destabilization after their protonation. The resulting imidazole groups facilitate the release of polycation/DNA complexes to cytosol.

However, we have already reported a poly(1-vinylimidazole) (PVIm) with several aminoethyl groups, that is, aminated PVIm (PVIm-NH_2), for a pH-sensitive polycation to enhance cell-specific gene delivery (*13*). By using PVIm-NH_2 as a pH-sensitive DNA carrier, as well as a lactosylated poly(L-lysine) as a cell-targeting DNA carrier, the resulting ternary complexes specifically mediate gene expression. Gene expression depends on our new concept that DNA ternary complexes dissociate ligand polycations in response to endosomal pH (*13, 14*). However, PVIm-NH_2/DNA binary complexes mediate no significant gene expression.

In this study, to develop PVIm-NH_2 for the realization of efficient gene expression, we have synthesized PVIm with several alkylated imidazole groups, that is, alkylated PVIm (PVIm-R). PVIm is a water-soluble homopolymer possessing many imidazole groups. In spite of a large capacity for H^+ buffering at endosomal pH, PVIm has difficulty in forming complexes with DNA at physiological pH because its imidazole groups are negligibly charged at physiological pH. The introduced alkylated imidazole groups with a quaternary nitrogen atom are expected to work as new anchor groups to retain DNA and to control the stability of polyion complexes. The control of the stability of the polyion complexes by the length and density of the alkylated imidazole groups has no precedent, to the best of our knowledge. Consequently, pH-sensitive PVIm-R's control of the stability of DNA polyion complexes is expected to mediate efficient gene expression by optimizing the length and density of the alkylated imidazole groups.

EXPERIMENTAL PROCEDURES



Materials. 1-Vinylimidazole (VIm), 1-bromobutane, 1-bromooctane, and pyrene were purchased from Aldrich Chemical Co. (Milwaukee, WI). VIm was distilled under reduced pressure. 2,2′-Azobis(2,4-dimethylvaleronitrile) (V-65) and bromoethane were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), and V-65 was recrystallized from ethanol. Iodomethane was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). PEI solution (M_n = ∼60,000) and salmon testis deoxyribonucleic acid (DNA) sodium salt were from Sigma Chemical Co. (St. Louis, MO). All other chemicals of a special grade were used without further purification.

Scheme 1. Synthesis of Alkylated Poly(1-vinylimidazole)

Synthesis of PVIm-R. The synthetic route of PVIm-R is shown in Scheme 1. VIm (**1**) (300 μL) and V-65 (15.8 mg) as an initiator were dissolved in 2.7 mL of *N*,*N*-dimethylformamide (DMF). The radical polymerization reaction was carried out at 45 °C for 1 day. After the reaction, the content was poured into a large excess of acetone, and the precipitate was dried *in vacuo*. The resulting polymer (**2**) (25 mg) and various amounts of alkyl halide (iodomethane, bromoethane, 1-bromobutane, or 1-bromooctane) (3−100 μL) were dissolved in 2 mL of DMF. The reaction was carried out at 40 °C for 1−6 days according to each case. The reaction mixture was poured into a large excess of diethyl ether. The precipitate was dried *in vacuo* and dissolved in water. After dialysis against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10^3), the resulting polymer (**3**) was obtained by freeze-drying.

Gel Filtration Chromatography (GFC). GFC was carried out using a JASCO PU-980 pumping system (Tokyo, Japan) at the flow rate of 1.0 mL/min with a Shodex OHpak SB-804 HQ column (Showa Denko K. K., Tokyo, Japan). The aqueous solution containing 0.5 M CH_3COOH and 0.2 M $NaNO_3$ was used as a mobile phase. One hundred microliters of 1 mg/mL samples were injected into the column. Eluate was detected by a refractive index detector (RI-1530, JASCO). Calibration was made with polyethylene glycol standards.

^{1}H NMR Spectroscopy. Each polymer (3 mg) was dissolved in 700 μL of D_2O (99.8 atom % deuterium; Acros, NJ). The ^{1}H NMR spectra (400 MHz) were obtained by a JEOL JNM-AL400 spectrometer (Tokyo, Japan).

Acid−Base Titration and Turbidity Measurement of PVIm-R. To 1.5 mL of an aqueous solution of the polymer (3.3 mg/mL) was added a 1 M HCl solution, and the acidic polymer solution (pH 4) was titrated with a 0.2 M NaOH solution. The pH value was checked with a pH meter (model F-52T, Horiba, Kyoto, Japan). The titration was carried out by the stepwise addition of 0.2 M NaOH and stopped at pH 10. The turbidity of the solution during the titration was measured by monitoring the absorbance at 500 nm with a spectrophotometer (model Ubest-55, JASCO, Tokyo, Japan).

Agarose Gel Retardation Assay. Salmon testis DNA was dissolved in PBS (−) at 1.1 mg/mL. The resulting DNA stock solution was added to the polymer solutions in 50 mM sodium phosphate buffer (pH 7.5 or pH 6.0) at various polymer/DNA ratios. The final diluted concentration of DNA was adjusted to 66.7 μg/mL. After 30 min of incubation at room temperature, each sample (corresponding to 1 μg of DNA) was mixed with a loading buffer and loaded onto a 1% agarose gel containing 1 μg/mL of ethidium bromide (EtBr). Gel electrophoresis was run at room temperature in 50 mM sodium phosphate buffer (pH 7.5 or pH 6.0) at 50 V for 15 min. The DNA bands were visualized under UV irradiation. In the case of the assay for the stability of the PVIm-R/DNA complexes, gel electrophoresis was run in the presence of dextran sulfate (1−20 mM as sulfate group) incubated with each sample at room temperature for 10 min.

Pyrene Fluorescence. A known amount of pyrene in acetone solution was added to PBS (−), resulting in the solution at a final concentration of 6.0×10^{-7} M. The pyrene solution (1 mL) was mixed with the PVIm-R/DNA complexes in 1 mL of PBS (−) where 29 μg/mL DNA was used at a +/− ratio of 1, 4, or 12. The sample solution was incubated overnight at room temperature, and emission spectra with excitation at 337 nm were recorded. The fluorescence intensity ratio of the first band at 373 nm to the third band at 384 nm (I_1/I_3) was analyzed at pH 7.4 or pH 6.0.

Hemolysis Assay. The PVIm-R/DNA complexes were prepared at a +/− ratio of 12 with 10 mM sodium phosphate buffer (pH 7.4 or pH 6.0) containing 130 mM NaCl. Then, 150 μL of the resulting sample containing 186 μg of PVIm-R was incubated with 20 μL of preserved sheep blood (Cosmo Bio Co., Ltd., Tokyo, Japan) for 120 mim at 37 °C. After centrifugation (13000 rpm, 1 min, 4 °C), the released hemoglobin was determined by measuring the absorbance at 570 nm with a Model-550 microplate reader (Bio-Rad Laboratories, Inc., Tokyo, Japan).

Cell Viability Assay. HepG2 cells (a gift from the Japan Health Sciences Foundation), human hepatoma cell line, were cultured in tissue culture flasks containing Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated FBS. The cells were seeded at 1×10^4 cells/well in a 96-well plate and incubated overnight at 37 °C in a 5% CO_2 incubator. The cells were treated with each polymer (0−400 μg/mL) and incubated for 24 h at 37 °C. By further incubation for 4 h, the cell viability was measured using the Alamar Blue assay (*15*) in triplicate.

Transfection Procedure. In a typical 96-well plate experiment, 1×10^4 cells/well HepG2 cells were transfected in Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated FBS by the addition of 15 μL of PBS (−) containing 200 ng of plasmid DNA encoding the modified firefly luciferase (pGL3-Control Vector; from Promega Co.) and complexed with polycations. After 1 day of incubation, the medium was removed, and the cells were further incubated for 2 days in Dulbecco's modified Eagle's medium supplemented with 10% FBS. Then, the cells were subjected to the luciferase assay (Promega kit) according to the manufacturer's instructions. Luciferase activities were normalized by protein concentrations and are presented as relative light units (RLU). Protein concentrations were determined by the BCA protein assay kit (Pierce) according to the manufacturer's instructions.

RESULTS AND DISCUSSION

Synthesis of PVIm-R. As shown in Scheme 1, PVIm (**2**) was reacted with an alkyl halide such as 1-bromobutane for alkylation to obtain quaternary imidazole groups. The number-average molecular weight of each resulting polymer (**3**) determined by GFC was about 8.8×10^3. The ^{1}H NMR spectrum of the resulting polymers showed the characteristic signals of both PVIm (*16*) [δ 1.8−2.2 (methylene), 2.3−3.7 (methine), and 6.4−7.2 (imidazole) ppm] and alkyl [δ 0.7−0.8 (terminal-methyl), 1.0−1.2 (3-methylene of butyl or 3,4,5,6,7-methylene of octyl), and 1.4−1.7 (2-methylene) ppm] moieties. From the signal ratio, the content (density) of alkylated imidazole groups was calculated. Thus, we have synthesized PVIm with quaternary imidazole groups, that is, PVIm-R.

pH-Dependent Behavior of PVIm-R in Water. To examine the ionic properties of the remaining imidazole groups, we

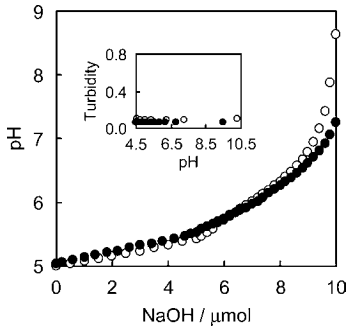

Figure 1. Acid−base titration curves of PVIm-R: (●) 18 mol % butylated PVIm; (○) 40 mol % butylated PVIm. Acidic polymer solutions (3.3 mg/mL) were titrated with the stepwise addition of 0.2 M NaOH. (Inset) Effect of pH on the solubility of the PVIm-R in water (3.3 mg/mL): (●) 18 mol % butylated PVIm; (○) 40 mol % butylated PVIm. The turbidity was measured by monitoring the absorbance at 500 nm of the polymer aqueous solution during acid−base titration.

carried out the acid−base titration of the resulting PVIm-R solution, as shown in Figure 1. Butylated PVIm, that is, PVIm-Bu, was chosen for representative PVIm-R. The imidazole protons of the PVIm-Bu were gently dissociated around pH 6 so that the pK_a of the PVIm-Bu was considered to be around 6. The proton dissociation profile approximately depended on the content of butylated imidazole groups. Namely, the 18 mol % butylated PVIm exhibited larger capacity of proton buffering around pH 6 because PVIm-Bu had more unmodified imidazole groups with a pK_a around 6. However, proton buffering of the 40 mol % butylated PVIm occurred in a little lower region of pH, suggesting that proton dissociation occurred easily because of the more hydrophobic environment near the imidazole groups. It should be noted that the aqueous solution of PVIm-Bu exhibited no significant turbidity above pH 6 in spite of the deprotonation of imidazole groups (Figure 1, inset). These results suggest that PVIm-R such as PVIm-Bu possessed a large capacity of proton buffering at endosomal pH and that the PVIm-R was water-soluble despite the deprotonation of the imidazole groups.

pH-dependent Complex Formation between DNA and PVIm-R. We examined whether the PVIm-Bu, as representative PVIm-R, formed the polyion complexes with DNA by agarose gel electrophoresis (Figure 2A). At pH 7.4, no band was observed when the DNA was mixed with an excess of PVIm-Bu (lanes 4−6). The band disappearance is considered to be attributed to the induction of the coil−globule transition of DNA and the resulting inhibition of the intercalation of EtBr (*17, 18*). In particular, almost no free DNA was observed at the [butylated imidazole]$_{PVIm\text{-}Bu}$/[phosphate]$_{DNA}$ ratio of 1 (lane 3), where the amount of the cationic butylated imidazole groups of PVIm-Bu was equal to the anionic phosphate groups of DNA. The excess PVIm-Bu polymers are considered to remain in the free state (Figure S-1, Supporting Information). Even in the presence of an excess amount of the unmodified PVIm at pH 7.4, it is reported that most of the DNA migrated into the plus pole of the gel owing to the complete deprotonation of the imidazole groups (*13, 19*). These results suggest that the PVIm-Bu formed the DNA complexes at the stoichiometric charge ratio of DNA to butylated imidazole groups; that is, the butylated imidazole groups worked as unique anchor groups to retain DNA. Furthermore, the free DNA observed at the [butylated imidazole]$_{PVIm\text{-}Bu}$/[phosphate]$_{DNA}$ ratio of 0.5 at pH 7.4 (lane 2) completely disappeared at pH 6.0 (lane 2′). This is due to the protonation of the unmodified imidazole groups of the PVIm backbone.

To examine further the pH-dependent behavior of the DNA complexes with PVIm-Bu, we investigated the hydrophobicity

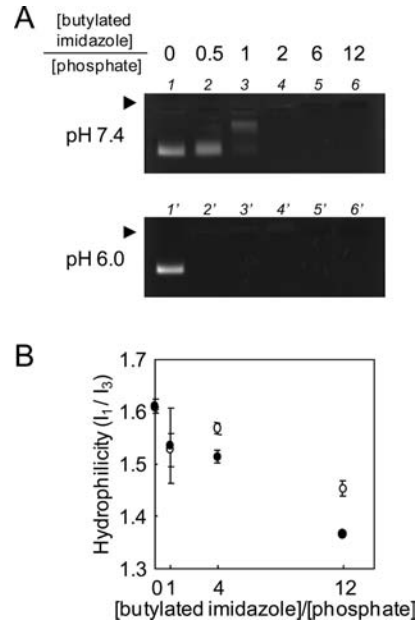

Figure 2. (A) Analysis of the pH-dependent formation of the complexes between DNA and PVIm-R by agarose gel electrophoresis. Interaction of 18 mol % butylated PVIm with DNA at pH 7.4 (lanes 1−6) or pH 6.0 (lanes 1′−6′): lanes 1 and 1′, DNA alone; lanes 2−6 and 2′−6′, PVIm-Bu/DNA mixtures at different unit ratios relative to butylated imidazole groups of PVIm-Bu per phosphate group of DNA ([butylated imidazole]/[phosphate] = *0.5*, *1*, *2*, *6*, or *12*), lanes 2 and 2′, *0.5*; lanes 3 and 3′, *1*; lanes 4 and 4′, *2*; lanes 5 and 5′, *6*; lanes 6 and 6′, *12*. The solid arrowhead indicates the well where each sample was loaded. (B) I_1/I_3 of pyrene fluorescence in PBS(−) with PVIm-Bu/DNA complexes at pH 7.4 (○) or pH 6.0 (●). The complexes were formed at +/− ratio of 1, 4, or 12 where the final concentration of DNA was 14.5 μg/mL. I_1/I_3 was defined as the fluorescence intensity ratio of the first band at 373 nm to the third band at 384 nm where the final concentration of pyrene was 0.3 μM.

of the complexes by using the fluorescence of pyrene. An emission intensity ratio of the first (373 nm) to the third (384 nm) peaks of pyrene, I_1/I_3, is known to be sensitive to the microenvironmental polarity surrounding the pyrene molecule (*20*). Consequently, this ratio has been widely used to estimate the hydrophobic nature (*21−23*). Namely, since this parameter decreases with an increase of hydrophobicity, it represents hydrophilicity. Figure 2B depicts the I_1/I_3 ratio of pyrene fluorescence in the buffer containing various PVIm-Bu/DNA complexes at pH 7.4 or pH 6.0. In buffers dissolving DNA, the I_1/I_3 ratios of pyrene were approximately 1.6 at pH 7.4 and pH 6.0. The presence of PVIm-Bu affected hydrophilicity (I_1/I_3 ratio), which tended to decrease as the [butylated imidazole]$_{PVIm\text{-}Bu}$/[phosphate]$_{DNA}$ ratio increased. These results suggest that the PVIm-Bu/DNA complexes formed the domain with a hydrophobic nature. Furthermore, it should be noted that hydrophilicity (I_1/I_3 ratio) in the presence of the excess amount of PVIm-Bu ([butylated imidazole]$_{PVIm\text{-}Bu}$/[phosphate]$_{DNA}$ = 4 or 12) at pH 6.0 was lower than that at pH 7.4. The resulting hydrophobic nature is therefore considered to increase even after the protonation of imidazole groups of the PVIm-Bu. These results suggest that the protonated PVIm-Bu enhanced the micelle formation which consisted of the shell of the protonated imidazole groups and the core of the butylated imidazole groups. It can be said that the PVIm-Bu/DNA complexes were capable of varying their hydrophobic−hydrophilic balance in response to endosomal pH.

Biochemical Properties of the PVIm-R/DNA Complexes. To examine the effect of the resulting pH-dependent change of the hydrophobic−hydrophilic balance on the interaction with the real cell membranes, we measured the hemolytic activity

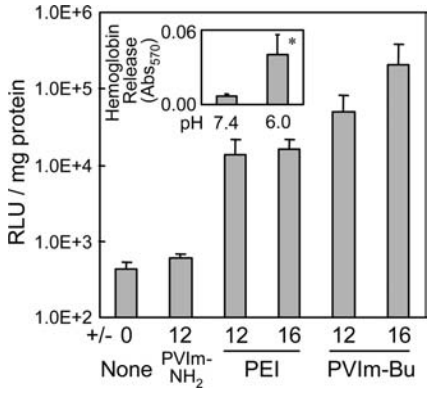

Figure 3. Transfection of luciferase gene to HepG2 cells by the DNA complexes with PVIm-R. As PVIm-R, 18 mol % butylated PVIm was used at the +/− ratio of 12 or 16. The PVIm-NH_2/DNA complexes at +/− ratio of 12 and the PEI/DNA complexes at +/− ratio of 12 or 16 were used as the control. The cells (1×10^4 cells/well) were transfected by adding 200 ng of plasmid DNA complexed with polycations for 1 day in the presence of 10% FBS. Gene expression was determined 2 days later as RLU normalized by protein concentrations. Symbols and error bars represent the mean and standard deviation of the measurements made in paired samples ($n = 3$). (Inset) Effect of pH on the hemolytic activity of PVIm-R/DNA complexes. Erythrocytes were incubated with the PVIm-Bu/DNA complexes at the +/− ratio of 12 for 120 min at 37 °C in 10 mM sodium phosphate buffer (pH 7.4 or pH 6.0) containing 130 mM NaCl. The released hemoglobin was determined by measuring the absorbance at 570 nm (Abs_{570}), where the Abs_{570} in the absence of the PVIm-Bu/DNA complexes (pH 7.4 or pH 6.0) was used as a baseline. Symbols and error bars represent the mean and standard deviation of the measurements made in paired samples ($n = 3$). * indicates statistical significance ($p < 0.02$) when compared to the pH 7.4 value.

of the PVIm-Bu/DNA complexes as representative PVIm-R/DNA complexes (Figure 3, inset). The complexes caused negligible hemolysis at pH 7.4, whereas the hemolytic activity significantly increased at pH 6.0. These results suggest that the membrane disruptive activity of the PVIm-Bu/DNA complexes increased at endosomal pH. The hydrophobic−hydrophilic balance of the PVIm-Bu/DNA complexes at endosomal pH is considered to enhance membrane disruptive activity. It is therefore expected that PVIm-Bu enhances the ability to escape from acidic endosomal vesicles.

As a result of the membrane disruptive activity at endosomal pH, we first examined the gene expression mediated by the PVIm-Bu/DNA complexes. As shown in Figure 3, the PVIm-Bu/DNA complexes mediated remarkable gene expression, which was higher than that mediated by the control PEI. It should be noted that the PVIm-Bu/DNA complexes showed gene expression values approximately 100 times higher than that of the PVIm-NH_2/DNA complexes. These results suggest that not PVIm-NH_2 but PVIm-Bu possessed the required properties as a gene carrier. A main property is considered to be the stabilization of the DNA complexes, not the proton buffering, by the introduced alkyl groups such as butyl groups.

Stability of PVIm-R/DNA Complexes. To confirm the stability of the PVIm-R/DNA complexes, we attempted to release DNA from the polyion complexes by competitive exchange with other polyanions (*24*). For effective transfection, the release of DNA should not happen outside the target cell, whereas that must occur somewhere inside to allow the binding of the transcription machinery. In biological fluids, the proteins borne by various anionic polysaccharides circulate. As an extreme case, dextran sulfate was used as a polyanion; namely, the agarose gel electrophoresis was carried out after the PVIm-R/DNA complexes were incubated with dextran sulfates. The results are shown in Figure 4. As the concentration of the dextran sulfate increased, the DNA increasingly migrated (lanes 4−6)

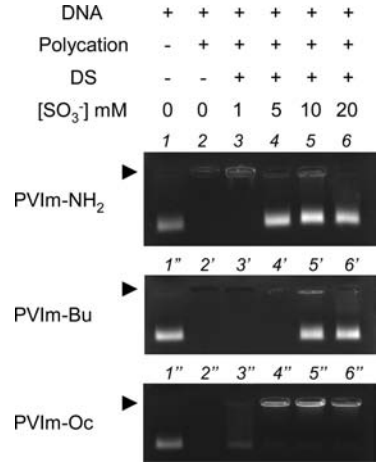

Figure 4. Release of DNA from PVIm-R/DNA complexes by dextran sulfates (DS) as assessed by agarose gel electrophoresis: lanes 1, 1′, and 1″, DNA alone; lanes 2, 2′, and 2″, 0 mM; lanes 3, 3′, and 3″, 1 mM; lanes 4, 4′, and 4″, 5 mM; lanes 5, 5′, and 5″, 10 mM; lanes 6, 6′, and 6″, 20 mM. The DNA mixtures with 18 mol % butylated PVIm (PVIm-Bu) or 18 mol % octylated PVIm (PVIm-Oc) at the +/− ratio of 12 were incubated for 10 min at room temperature in the presence (lanes 3′−6′ and 3″−6″) or absence (lanes 2′ and 2″) of DS (1−20 mM as sulfate group), followed by loading to the gel. As the control, the DNA mixture with PVIm-NH_2 at the +/− ratio of 12 was used in the presence (lanes 3−6) or absence (lane 2) of DS. The solid arrowhead indicates the well where each sample was loaded.

in the case of PVIm-NH_2/DNA complexes. However, in case of DNA complexes with octylated PVIm, that is, PVIm-Oc, almost no DNA migrated even in the presence of a higher concentration of dextran sulfate (lane 6″). These results suggest that PVIm-NH_2/DNA complexes easily released DNA by exposure to polyanions and that PVIm-Oc/DNA complexes stably retained DNA. It is worth noting that it was hard to migrate the DNA in the case of the PVIm-Bu/DNA complexes, as compared with the PVIm-NH_2/DNA complexes (lane 4′). This is probably caused by an adequate length of alkyl chains to stabilize the electrostatic interaction between PVIm-R and DNA. It is reported that the stability of polycation/DNA complexes depends on the chain length of a whole polymer; namely, the longer polycation is found to interact with DNA more strongly than the shorter one (*25*−*27*). In this study, the stability of polycation/DNA complexes has depended on the chain length of introduced alkyl chains in the polycation, which promises a unique design of polycation/DNA complexes. We have therefore considered that PVIm-Bu/DNA complexes have the ability to retain DNA stably outside the target cell and to release DNA adequately inside the cell for transcription.

Cytotoxicity of PVIm-R/DNA Complexes. Cytotoxicity of a gene carrier is an important factor for clinical applications. Free polycations exist solely when DNA is released from the polyion complexes (*28*). Furthermore, the overall cytotoxicity of free polycations is higher than that of the corresponding complexes. Accordingly, we chose the cytotoxicity assay of the free polycations to give a worst case estimating the interaction of the polycations with cells rather than that of the polyion complexes with DNA. As shown in Figure 5, we therefore examine the effect of PVIm-R on cell viability. The viability of HepG2 hepatoma cells did not significantly decrease when PVIm-Bu was added up to the concentration of 400 μg/mL, which was higher than the transfection conditions. Consequently, it is worth noting that PVIm-Bu exhibited no apparent cytotoxicity. The control methylated and ethylated PVIm, that is, PVIm-Me and PVIm-Et, respectively, exhibited the same tendency as PVIm-Bu. However, little viability was observed when PVIm-Oc, as well as the control PEI, was added up to 50

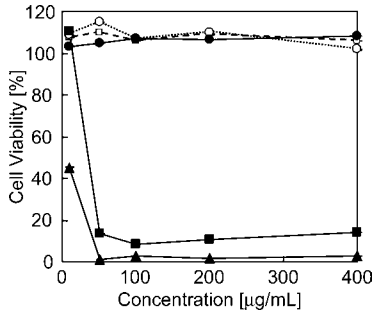

Figure 5. Effect of PVIm-R on the viability of HepG2 cells after 1 day of incubation: (●) 20 mol % butylated PVIm (PVIm-Bu); (■) 20 mol % octylated PVIm (PVIm-Oc); (○) 20 mol % ethylated PVIm (PVIm-Et); (□) 20 mol % methylated PVIm (PVIm-Me); (▲) PEI. Symbols and error bars represent the mean and standard deviation of the measurements made in triplicate wells.

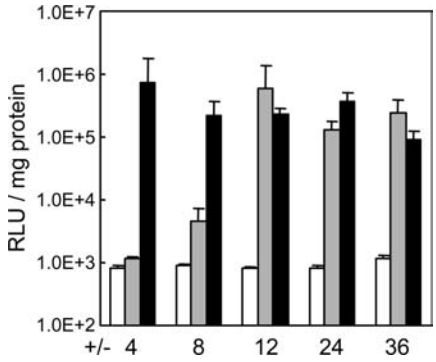

Figure 6. Effect of the density of the alkylated imidazole groups on the transfection activity mediated by PVIm-R/DNA complexes. As PVIm-R, 7 mol % butylated PVIm (white bars), 23 mol % butylated PVIm (gray bars), or 38 mol % butylated PVIm (black bars) was used for the transfection. The PVIm-Bu/DNA complexes were prepared at the +/− ratio of 4, 8, 12, 24, or 36. Other experimental conditions are the same as those described in Figure 3.

μg/mL. These results suggest that PVIm-R with a relatively short length of alkyl groups such as butyl, ethyl, or methyl groups promises to be a noncytotoxic gene carrier. The noncytotoxic property may be attributed to the partial shielding of surface charge, as poly(ethylene glycol) (*29*), by unmodified imidazole groups. However, PVIm-R with a relatively long length of alkyl groups such as octyl groups is considered to cause significant cytotoxicity by the presence of the more amphiphilic property for cell membrane damage. Actually, a little significant cytotoxicity was observed when PVIm-Bu was added up to the concentration of 1000 μg/mL, where PVIm-Me and PVIm-Et exhibited no significant cytotoxicity (Figure S-2, Supporting Information).

Gene Delivery by PVIm-R/DNA Complexes. As a result of no apparent cytotoxicity, we further examined the gene expression mediated by PVIm-R/DNA complexes in view of the density of alkylated imidazole groups. As shown in Figure 6, the PVIm-Bu polycations with different densities of butylated imidazole groups were used as representative PVIm-R for DNA complex formation. Little gene expression was observed at any +/− ratio when we used the DNA complexes with PVIm-Bu with a lower density (7 mol %) of butylated imidazole groups. In case of the PVIm-Bu with a higher density (38 mol %) of butylated imidazole groups, however, the DNA complexes mediated remarkable gene expression even if the complexes at the +/− ratio of 4 was used. Although the DNA complexes with PVIm-Bu with a middle density (23 mol %) of butylated imidazole groups mediated little gene expression at the +/− ratio of 4, the DNA complexes at higher +/− ratios succeeded

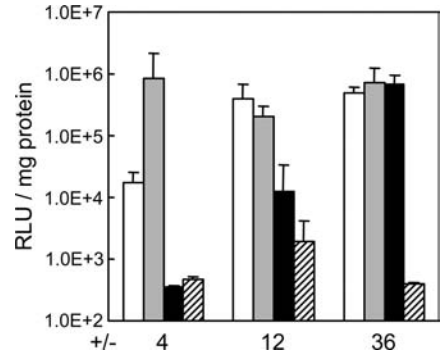

Figure 7. Effect of the length of the alkylated imidazole groups on the transfection activity mediated by PVIm-R/DNA complexes. As PVIm-R, 20 mol % methylated PVIm (PVIm-Me) (white bars), 20 mol % ethylated PVIm (PVIm-Et) (gray bars), 20 mol % butylated PVIm (PVIm-Bu) (black bars), or 20 mol % octylated PVIm (PVIm-Oc) (hatched bars) were used for the transfection. The PVIm-R/DNA complexes were prepared at the +/− ratio of 4, 12, or 36. Other experimental conditions are the same those described in Figure 3.

in remarkable gene expression. These results suggest that the density of the butylated imidazole groups in PVIm-Bu was an important factor for gene delivery.

As a result of the dependency of the density of the butylated imidazole groups, we finally examined the gene expression mediated by the PVIm-R/DNA complexes in view of the alkyl chain length of alkylated imidazole groups. Figure 7 shows the effect of the alkyl chain length of PVIm-R with a middle density (20 mol %) of alkylated imidazole groups on gene expression. As expected, PVIm-Oc mediated little gene expression because of too stable retention of DNA (Figure 4) and significant cytotoxicity (Figure 5). As a result of PVIm-Bu with a middle density (18 mol %, Figure 3; 23 mol %, Figure 6) of alkylated imidazole groups, the gene expression mediated by the PVIm-Bu/DNA complexes depended on the +/− ratio. It should be noted that PVIm-Me and PVIm-Et mediated higher gene expression than PVIm-Bu at lower +/− ratios. Especially, the gene expression mediated by the PVIm-Et/DNA complexes did not depend on the +/− ratio. These results suggest that the alkyl chain length of the alkylated imidazole groups was also an important factor for gene delivery.

Gene expression decreased with a decrease in the density of the alkylated (butylated) imidazole groups (Figure 6). The higher gene expression mediated by PVIm-Me and PVIm-Et is therefore unexpected (Figure 7) because the shorter length of the alkyl chain decreased the apparent density of the alkylated imidazole groups. However, it is surprising that the PVIm-Bu/DNA complex with a middle density of butylated imidazole groups was more stable than that with higher density (Figure S-3, Supporting Information). The excess butylated imidazole groups are therefore considered to enhance the membrane disruptive activity to escape from acidic endosomal vesicles. Furthermore, it is also surprising that the DNA complex with PVIm-Me or PVIm-Et was more stable than that with PVIm-Bu (Figure S-4, Supporting Information). At present, the stability mechanism is unclear; analysis is now in progress for more detailed investigations. Nevertheless, it can be said that the PVIm-Et/DNA complex as well as the PVIm-Me complex has more adequate retention of DNA for gene delivery, as compared with the PVIm-Bu/DNA complex. Although amphiphilic imidazolinium compounds for gene delivery were previously reported, the compounds form liposomes whose stability depends on the length of the dialkyl groups of imidazolinium (*30*). In this study, many alkyl groups in PVIm-R are considered to be intertwined with DNA grooves and the degree of intertwining may affect the transcription of the delivered gene.

Taking these results into account, alkylated imidazole groups are essential and unique functional groups in PVIm-R for efficient gene delivery.

Conclusions. We have synthesized a unique pH-sensitive polycation PVIm-R and evaluated the physicochemical and biochemical properties of the pH-sensitive gene carrier. The resulting PVIm-R was water-soluble in spite of the deprotonation of the imidazole groups at physiological pH. PVIm-R/DNA complex formation was mediated by alkylated imidazole groups working as anchor groups to retain DNA. The DNA complex with butylated PVIm (PVIm-Bu) formed the domain with a hydrophobic nature, which increased after the protonation of imidazole groups of PVIm-Bu. The increased hydrophobic−hydrophilic incline of the PVIm-R/DNA complexes at endosomal pH enhanced membrane disruptive activity. PVIm-Bu exhibited no significant cytotoxicity in spite of the existence of cationic groups and easily released DNA, as compared with PVIm-Oc. By using PVIm-R as a pH-sensitive DNA carrier, PVIm-R/DNA complexes mediated efficient gene delivery attributed to the alkylated imidazole groups, and gene expression depended on the length and density of the alkyl chains. Consequently, PVIm-R's control of the stability of DNA polyion complexes enhanced noncytotoxic gene delivery by optimized alkylated imidazole groups. The control of the polycation/DNA complex properties by varying the length and density of the alkyl chains grafted onto PVIm is expected to offer unique designs for gene delivery systems.

Supporting Information Available: Analysis of the formation of the complex between DNA and PVIm-Bu by agarose gel electrophoresis in the absence of EtBr; effect of PVIm-R on the viability of HepG2 cells after 1 day incubation; release of DNA from PVIm-Bu/DNA complexes by dextran sulfates (DS) as assessed by agarose gel electrophoresis; and release of DNA from PVIm-R/DNA complexes by dextran sulfates (DS) as assessed by agarose gel electrophoresis. Synthesis of Pyridyl Disulfide-Functionalized Nanoparticles for Conjugating Thiol-Containing Small Molecules, Peptides, and Proteins

André J. van der Vlies,[†] Conlin P. O'Neil,[†] Urara Hasegawa,[†] Nathan Hammond,[†] and Jeffrey A. Hubbell*[,†,‡]

Institute of Bioengineering (IBI) and Institute of Chemical Sciences and Engineering (ISIC), Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne CH-1015, Switzerland. Received October 10, 2009; Revised Manuscript Received March 25, 2010

Previously we reported emulsion polymerization of propylene sulfide with Pluronic F127 as an emulsifier, yielding nanoparticles (NPs) in the 25 nm size range. Immunologically functional NPs were prepared by adding an antigen−Pluronic conjugate to the polymerization mixture (Reddy, S. T., et al. (2007) *Nat. Biotechnol. 25*, 1159). We sought a more flexible scheme for conjugation of antigens and other biomolecules to the NP surfaces that would allow for milder reaction conditions than achievable during the polymerization step. Here, we present the synthesis of such functionalizable NPs in the form of NPs that carry thiol-reactive groups, to which thiol-containing antigens (peptide or protein) or other biomolecules can be conjugated under mild conditions to yield immunofunctional NPs. The Pluronic-stabilized poly(propylene sulfide) (PPS) NPs with thiol-reactive pyridyl disulfide groups are prepared in two steps by (1) emulsion polymerization of propylene sulfide in the presence of a carboxylate-Pluronic and (2) reaction of the carboxylic acid groups on the NP surface with cysteamine pyridyl disulfide and a water-soluble carbodiimide reagent. We choose pyridyl disulfide groups to have a reduction-sensitive disulfide bond linking the antigen to the NP surface, allowing efficient release of antigen inside the cell in response to the reductive conditions within the endosome. The functionalizable NPs are characterized by proton NMR, dynamic light scattering (DLS), UV/vis spectroscopy, and transmission electron microscopy (TEM). Conjugation of small molecules and protein to the NP surface is presented.

INTRODUCTION

In the field of immunotherapy, one aims to either elicit or repress an immune response by directly affecting the immune system. Antigen-presenting cells (APCs[§]) patrol the body for antigens, the most powerful APCs being dendritic cells (DCs) (*1, 2*). After taking up the antigen, the DCs move to the draining lymph node to present peptides processed from the antigen and stimulate naive CD4 and CD8 T cells for induction of humoral and cell-mediated immunity (*3*). In order to induce an adaptive immune response, the DC should mature before presenting antigen to T cells. Maturation of DCs is induced by the presence of a danger signal, also referred to as an adjuvant, often selected as a ligand of Toll-like receptors (*4*).

On the basis of the above-mentioned needs, there has been growing interest in the use of biomaterials in both antigen and adjuvant delivery (*5*). Immobilizing an antigen onto or encapsulating it within the polymeric vehicle can protect the antigen from enzymatic degradation, and the carrier itself can be delivered intracellularly, enabling antigen processing and presentation to take place. Most work has focused on targeting peripheral immature DCs using polymeric poly(lactide-*co*-glycolide) (PLGA) microparticles (*6*−*12*) and polyelectrolyte microcapsules (*13*). However, these cells must travel to the draining lymph nodes to present the antigen to T cells. We previously showed that immature DCs in the lymph node can be targeted efficiently using ultrasmall nanoparticles (NPs) of about 25 nm in diameter exploiting the interstitial flow from the blood capillaries to the lymphatic capillaries and then draining lymph nodes (*14*). In this way the most potent APCs in the lymph node are targeted directly and very efficiently.

Poly(propylene sulfide) (PPS) NPs are synthesized by emulsion polymerization of propylene sulfide using Pluronic F127 an emulsifier surfactant (*15, 16*). The NPs consist of a hydrophobic rubbery cross-linked PPS core with a Pluronic-coated surface. The hydrophobic PPS core allows for encapsulation of hydrophobic drugs, should it be desired, and is stimulus-responsive toward oxidation (*16, 17*). We showed that exposure to hydrogen peroxide as a model intracellular oxidant leads to oxidation of the thioether groups leading to sulfoxide and sulfone structures, making the initial hydrophobic PPS core hydrophilic and thus soluble (*16*). This allows the incorporated drug to be released and offers a mechanism for particle clearance from the body (*17*). To show that these NPs are not only taken up by lymph-node-resident DCs but also induce adaptive immunity, we used ovalbumin (OVA) as a model antigen. OVA-NPs, prepared by incorporating an OVA−Pluronic conjugate into the NP polymerization mixture, induced both a humoral and cell-mediated immune response when injected into mice (*18*), the terminal Pluronic hydroxyl groups on the surface of the NPs activating complement to serve as an adjuvant (*18*).

A limitation of the scheme described above is the need for synthesizing a Pluronic−antigen conjugate for each antigen to be bound to the NP surface. Furthermore, the antigen is linked to the NP with a bond that is not cleavable under biological conditions, which could be problematic for antigen release, especially of peptides, within DCs. We therefore sought a scheme by which to provide NPs with a reactive group that would allow straightforward conjugation of antigens and further allow release upon endocytosis by DCs. We choose thiol-reactive pyridyl disulfide groups at the surface of the NP, as antigens such as peptides and proteins can be easily engineered to contain free cysteine groups. The formed disulfide bond between the antigen and NP would allow efficient release of antigen within the cell in response to the reductive conditions within the endosome. This report describes the concept, synthesis, and characterization of thiol-reactive, reductively sensitive NPs and the conjugation with low molecular weight compounds and proteins.

EXPERIMENTAL PROCEDURES

Materials and Methods. Pluronic F127, hydroxyethylpiperazineethanesulfonic acid (HEPES) (Sigma), streptavidin-Alexa488 (Invitrogen), (+)-D-biotin (Applichem), aldrithiol, fluorescamine, trifluoracetic acid (TFA), triisopropylsilane (TIS), phenol, 0.5 M $NaOCH_3$ in methanol, propylene sulfide, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), *N*-hydroxysuccinimide (NHS), Tris(2-carboxyethyl)phosphine hydrochloride (TCEP·HCl), iodoacetamide, potassium hydroxide, CaH_2 (Aldrich), dithiothreitol (DTT) (Biorad), Sephadex G50, Sepharose 6B, Sepharose CL-6B (Sigma), Ellman reagent (Pierce), cysteamine hydrochloride, potassium carbonate, mercaptopropionic acid methyl ester, triphenylphosphine, acetic acid, methanesulfonyl chloride, sodium hydroxide, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC), *N*-hydroxysulfosuccinimide sodium salt (sulfo-NHS), triphenylmethanol, $BF_3 \cdot Et_2O$ (Fluka), and morpholineethanesulfonic acid (MES) (Calbiochem) were used as received. All chemicals relating to peptide synthesis were from Novabiochem. Molecular sieves (3 Å, Fluka) were heated at 180 °C under reduced pressure for at least 16 h. Diethyl ether, methanol, and toluene were used as received. Dimethylformamide (DMF) was distilled over CaH_2 under reduced pressure at 40 °C and kept over molecular sieves. Dichloromethane was dried over molecular sieves. Water was distilled twice or freed from salt using the Milli-Q water system. All reactions were done under argon (Messer) atmosphere.

^1H NMR. Spectra were measured on a Bruker 400 Ultrashield spectrometer. NMR was performed in deuterated chloroform ($CDCl_3$), deuterated methanol (CD_3OD), or deuterated dimethyl sulfoxide (DMSO-d_6). Peaks are referenced against residual solvent at 7.26 ppm ($CDCl_3$), 3.35 ppm (CH_3OD), or 2.50 ppm (DMSO-d_6). For each sample 32 scans were collected and the D1 was set at 10 s.

UV/Visible Spectroscopy. Spectra were obtained on a Shimadzu UV mini 1240 UV/visible spectrophotometer using 1.0 cm quartz cuvettes or a Tecan Safire^2 well plate reader using polystyrene well plates.

Dynamic Light Scattering. Data were obtained on a Malvern Nanoseries Zetasizer instrument with 632 nm laser using PMMA cuvettes by diluting NP solutions with PBS (10 mM, pH 7.4) to a final NP concentration of 2 mg/mL. Sizes are given in nm and are obtained as the *Z*-average by fitting the correlation function using the cumulant method.

High Resolution Mass Spectrometry. Spectra were collected by the Institute of Chemical Sciences and Engineering (ISIC) at the Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland. ESI-TOF-MS data were acquired on a Q-Tof Ultima mass spectrometer (Waters) fitted with a LockSpray dual electrospay ion source and operating in the positive ionization mode. The samples were diluted in methanol acidified with 0.1% HCOOH and introduced into the mass spectrometer by infusion at a flow rate of 20 mL/min. External calibration was carried out with a solution of phosphoric acid at 0.01%. Data were processed using the MassLynx 4.1 software.

Transmission Electron Microscopy. Carbon coated 400 mesh copper grids (Agar Scientific, Stansted, U.K.) were prepared under glow discharge, and 5 μL of NP solution was placed onto the grid. After 60 s, the grid was washed with H_2O and then dried by blotting the side of the grid with filter paper. To stain, 5 μL of 2% uranyl acetate solution was added to the grid. After 30 s, the stain was blotted off the same as above and was allowed to dry for 5 min at room temperature before analysis. Microscope images were acquired on a Philips CM-12 TEM (Koninklijke Philips Electronics, Eindhoven, The Netherlands). Images were captured using a Gatan MSC CCD camera (Gatan Inc., Grandchamp, France) and processed using Adobe Photoshop software (Adobe Systems, San Jose, CA). TEM images were analyzed with Scion image analysis software, and size results are given as the mean diameter ± SD and number of particles measured in parentheses.

Preparative HPLC. Purification by HPLC was done by reverse phase HPLC chromatography using a C18 column. Separation and collection were performed by UV and mass directed software (Waters, Baden-Daettwil, Switzerland).

SDS−PAGE. The 10% gels were run at 300 V for 2 h. Protein bands were visualized by UV.

Ellman Assay (19). Ellman solution was prepared by dissolving 4.0 mg of Ellman reagent in 1.0 mL of Ellman buffer (1 mM EDTA, 100 mM phosphate, pH 8.0). Thiol concentrations were measured by reacting 20 μL of Ellman solution with 20 μL of sample. After 15 min the mixture was diluted by the addition of 960 μL of Ellman buffer and the absorbance at 412 nm read. Thiol concentrations were calculated from a standard curve using thiomaleic acid. In the range 1−4 mM measurements were done in a well plate using 200 μL of sample. For thiol concentrations in the range 50−1000 μM, measurements were done using a quartz cuvette.

Fluorescamine Assay (20). Fractions from the Sepharose 6B and Sepharose CL-6B column (50 μL) were mixed with 100 μL of 100 mM HEPES, pH 8, and 20 μL of a solution of fluorescamine (5 mg/mL) in acetone. The sample was reacted at room temperature for 15 min and the fluorescence (λ_{ex} = 390 nm, λ_{em} = 475 nm) read using black polystyrene Nunc plates.

Pyridyl Disulfide Loading NPs. Pyridyl-NP solutions were mixed 1:1 by volume with a 5 mM TCEP·HCl solution in 100 mM HEPES, pH 8, and reacted for 15 min. The absorbance at 340 nm was read, and after correction for the absorbance of pyridyl-NP and TCEP·HCl the concentration of pyridyl disulfide calculated from a standard curve of pyridine thione (**8**) in HEPES, pH 8. If the concentration was too high, NP solutions were diluted with H_2O.

Compound Synthesis. *Pluronic Bromide (1).* **1** was prepared as reported before (*21*).

Pluronic Mesylate (2). An amount of 23.6 g (1.86 mmol) of Pluronic F127 was dissolved in 500 mL of toluene, and 100 mL of toluene was removed by azeotropic distillation using a Dean−Stark trap. The solution was cooled to room temperature, and 2.6 mL (18.6 mmol, 10 equiv) of triethylamine and 1.4 mL (18.6 mmol) of methanesulfonyl chloride was added. After 18 h the yellow suspension was filtered and the clear yellow filtrate concentrated under reduced pressure. The residue was dissolved in 100 mL of CH_2Cl_2, filtered over a SiO_2 bed (1.0 cm (diameter) × 5.0 cm (height)), and the SiO_2 was washed with CH_2Cl_2 (3 × 50 mL). The filtrate was concentrated to a

volume of about 50 mL and precipitated in 1000 mL of Et_2O. The white precipitate was filtered off, washed with 100 mL of Et_2O, and dried under reduced pressure to yield 21.0 g (89%) of white powder. The degree of functionalization was 100% according to ^{1}H NMR. ^{1}H NMR ($CDCl_3$): $\delta = 4.35-4.38$ (m, CH_2-O-SO_2-), 3.60−3.67 (m, CH_2, PEG), 3.47−3.58 (m, CH_2, PPO), 3.34−3.42 (m, CH, PPO), 3.07 (*s*, -SO_2-C$\underline{H}_3$), 1.11−1.15 (CH_3, PPO).

*Pluronic Thioether Propionic Acid Methyl Ester (**3**).* An amount of 21.0 g (**2**) was dissolved in 100 mL of DMF, and to the clear solution was added 2.29 g (16.5 mmol) of potassium carbonate followed by 2 mL (16.5 mmol) of mercaptopropionic acid methyl ester. The mixture was stirred for 20 h and concentrated under reduced pressure. The residue was dissolved in 100 mL of CH_2Cl_2 and mixed with 11 g of activated carbon. The mixture was filtered over a filter cell and the residue washed with CH_2Cl_2 (3 × 100 mL). The clear colorless filtrate was reduced to about 50 mL by evaporation and precipitated in 1000 mL of Et_2O. The white solid was filtered, washed with 100 mL of Et_2O, and dried under reduced pressure to yield 18.2 g (87%). The degree of functionalization was 92% according to ^{1}H NMR. ^{1}H NMR ($CDCl_3$): $\delta = 3.70$ (s, OCH_3), 3.59−3.63 (m, CH_2, PEG), 3.46−3.58 (m, CH_2, PPO), 3.36−3.44 (m, CH, PPO), 2.83 (*t*, $J = 7.6$ Hz, -O-CH_2-C$\underline{H}_2$-S-), 2.73 (*t*, $J = 7.2$ Hz, −S-C$\underline{H}_2$-CH_2-CO-), 2.63 (t, $J = 7.2$ Hz, -CH_2-CO-), 1.12−1.16 (CH_3, PPO).

*Pluronic Thioether Propionic Acid Sodium Salt (**4**).* An amount of 18.0 g (**3**) (2.83 mmol) was dissolved in 200 mL of Milli-Q water, and to the clear solution added a solution of 0.57 g (14.1 mmol) of sodium hydroxide in 5 mL of Milli-Q water. After 21 h the solution was transferred into a regenerated cellulose dialysis tube, molecular weight cut-off (MWCO) of 3.5 kDa, and dialyzed against 5 L of Milli-Q for 29 h with replacement of the water three times. The solution was lyophilized to yield 12.2 g (68%) of white solid. The degree of functionalization according to ^{1}H NMR was 95%. NMR ($CDCl_3$): $\delta = 3.59-3.63$ (m, CH_2, PEG), 3.46−3.58 (m, CH_2, PPO), 3.35−3.44 (m, CH, PPO), 2.83 (t, $J = 6.4$ Hz, -O-CH_2-C$\underline{H}_2$-S-), 2.73 (t, $J = 6.8$ Hz, -S-C$\underline{H}_2$-CH_2-CO-), 2.50, (t, $J = 6.8$ Hz, -CH_2-CO-), 1.13−1.16 (CH_3, PPO).

*Pyridyl Disulfide Cysteamine HCl Salt (**5**).* An amount of 0.57 g (0.5 mmol) of cysteamine·HCl was added to a solution of 3.3 g (15.0 mmol) of aldrithiol in 10 mL of methanol. The yellow solution was stirred overnight and the product obtained by precipitation in 500 mL of Et_2O. After filtration, the residue was dissolved in 15 mL of MeOH and again precipitated in 500 mL of Et_2O. The white solid was dried under reduced pressure to yield 0.94 g (84%). ^{1}H NMR (DMSO-d_6): $\delta = 8.51-8.50$ (m, 1H), 8.30 (bs, 3H), 7.86−7.82 (m, 1H), 7.75 (d, 1H), 7.31−7.28 (m, 1H), 3.13−3.05 (m, 4H). HRMS $[M + H]^+$ calculated for $C_7H_{10}N_2S_2$ 187.0364, found 187.0358.

*Pluronic Pyridyl Disulfide (**6**).* Amounts of 0.25 g (0.02 mmol) of **4** and 22.8 mg (0.2 mmol) of NHS were dissolved in 5 mL of CH_2Cl_2. To the clear solution were added 38 mg (0.2 mmol) of EDC, 44 mg (0.2 mmol) of **5**, and 38 μL (0.2 mmol) of triethylamine, and the turbid mixture was stirred for 18 h at room temperature. The yellow solution was concentrated in a flow of N_2 and the residue dissolved in 5 mL of H_2O. The milky solution was transferred to a dialysis bag (MWCO = 3.5 kDa) and dialyzed against 2 L of H_2O for 1 day. The polymer was recovered by lyophilization to yield 0.19 g (76%). The degree of functionalization according to ^{1}H NMR was 95%. ^{1}H NMR ($CDCl_3$): $\delta = 8.51$ (m, CH_{aromat}), 7.64 (m, CH_{aromat}), 7.55 (m, CH_{aromat}), 7.33 (bs, NH), 7.13 (m, CH_{aromat}), 3.69−3.59 (m, CH_2, PEG), 3.58−3.44 (m, CH_2, PPO), 3.42−3.33 (m, CH, PPO), 2.94 (t, CH_2, $J = 5.6$ and 6.0 Hz), 2.88 (t, CH_2, $J = 7.2$ Hz), 2.74 (t, CH_2, $J = 6.8$ and 6.4 Hz), 2.51 (t, CH_2, $J = 7.2$ and 7.6 Hz), 1.14 (m, CH_3, PPO).

Table 1. Dynamic Light Scattering Results for the Different NP Formulations[a]

	carboxylate-NP		pyridyl disulfide-NP	
wt % COOH	*Z*-avg[b] (SD)	PDI[c] (SD)	*Z*-Avg[b] (SD)	PDI[c] (SD)
0	31.8 (0.80)	0.260 (0.003)		
10	33.0 (0.31)	0.142 (0.006)	35.7 (0.13)	0.207 (0.005)

50	32.6 (0.08)	0.147 (0.004)	42.5 (0.30)	0.225 (0.009)
75	32.9 (0.18)	0.145 (0.006)	42.0 (0.15)	0.219 (0.002)
100	31.3 (0.22)	0.113 (0.001)	42.4 (0.17)	0.209 (0.004)

[a] Values are the average of three measurements of the same sample. [b] Size in nm as measured by the *Z*-average obtained by fitting the correlation function using the cumulant method. [c] Polydispersity index (PDI) calculated from fitting the correlation function using the cumulant method.

*Thioacetic Acid S-[3-[3-(3-Acetylsulfanylpropoxy)-2,2-bis-(3-acetylsulfanylpropoxymethyl)propoxy]propyl] Ester (**7**).* The four-arm initiator was synthesized as reported (*16*).

NP Synthesis. This was adapted from that reported (*16*). An amount of 10 mL of Milli-Q H_2O was freed from oxygen by three evacuation/purge (Ar) cycles, and under Ar flow the hydroxyl- and carboxylate Pluronic (500 mg total) were added. After all the Pluronic was dissolved the resulting solution was again evacuated and purged with Ar three times, and under Ar flow 400 μL (5.0 mmol) of propylene sulfide was added. The emulsion was stirred for 30 min after which 24.3 mg (0.04 mmol) of the four-arm initiator **7**, previously reacted for 15 min with 322 μL of 0.5 M $NaOCH_3$ (0.16 mmol) solution in MeOH, was added under Ar. The mixture was stirred for another 15 min, and then an amount of 60 μL of DBU (0.4 mmol) was added. The mixture was stirred for 24 h and exposed to air for 2 h to cross-link, and the remaining thiolates were quenched by the addition of 47.5 mg (0.26 mmol) of iodoacetamide and stirred for 2 h. Ellman assay of the NP solution confirmed the absence of thiolate anions, and the mixture was dialyzed (MWCO = 100 kDa) against 5 L of Milli-Q water for at least 2 days with regular replacement of the water. After filtration (0.22 μm filter) the size of the NPs was measured by dynamic light scattering and a small volume was lyophilized to obtain the NP concentration in mg/mL. NMR of the solid was used to calculate the weight % of Pluronic in the NPs.

*Pyridinethione (**8**).* The ether fractions of **5** were combined and concentrated under reduced pressure, and the residue was dissolved in 10 mL of MeOH and reacted with 1.74 g (15.0 mmol) of cysteamine·HCl overnight. The turbid mixture was diluted with 100 mL of EtOAc and washed with 100 mL of H_2O. After the organic phase was dried over Na_2SO_4 the mixture was filtered and the clear solution concentrated under reduced pressure. The residue was purified by SiO_2 column chromatography, $R_f = 0.46$ (EtOAc). ^{1}H NMR ($CDCl_3$): $\delta = 7.61-7.56$ (m, 1H), 7.43−7.39 (m, 1H), 6.81−6.78 (m, 1H), 1.79 (bs, 1H). HRMS $[M + H]^+$ calculated for C_5H_5NS 112.0221, found 112.0297.

Synthesis of Pyridyl Disulfide-NPs, General Procedure. To the carboxylate-NP solution is added solid MES to a final concentration of 100 mM and the pH adjusted to 4.0−4.5 with a pH meter. To the clear solution are added pyridyl disulfide cysteamine·HCl, sulfo-NHS, and EDC all at an excess of 20 equiv relative to the amount of Pluronic as calculated from NMR. After reaction for 2−24 h the solution is dialyzed for at least 2 days to remove unreacted reagents using MWCO = 3.5−10 kDa. The pyridyl disulfide-NPs in Table 1 and Figures 2−4 were made by reacting for 24 h and then purified using MWCO = 3.5 kDa dialysis tubing. Below follows the detailed reaction for functionalization of 100 wt % carboxylate-NPs. To

3.0 mL of 100 wt % carboxylate-NP solution (50.4 mg/mL), corresponding to 28.7 mg/mL of Pluronic according to NMR, was added 60 mg of MES (final concentration 102 mM), and the pH was adjusted to 4.4. To the NP solution containing 86.1 mg of carboxylate-Pluronic (0.014 mmol of carboxylate groups) were added 30.1 mg (0.14 mmol, 10 equiv) pyridyl disulfide cysteamine·HCl salt, 30.1 mg of sulfo-NHS (0.14 mmol, 10 equiv), and 33.1 mg (0.17 mmol, 12 equiv) of EDC. After 22 h the NP solutions were dialyzed against 5 L of Milli-Q water (MWCO = 3.5 kDa) for 2 days. After filtration through 0.22 μm filter, the size was measured by dynamic light scattering. The concentration of the pyridyl disulfide groups was determined by measuring the absorbance at 340 nm after reducing the NPs with TCEP·HCl. Lyophilization of a small sample yields the concentration of the NP solution.

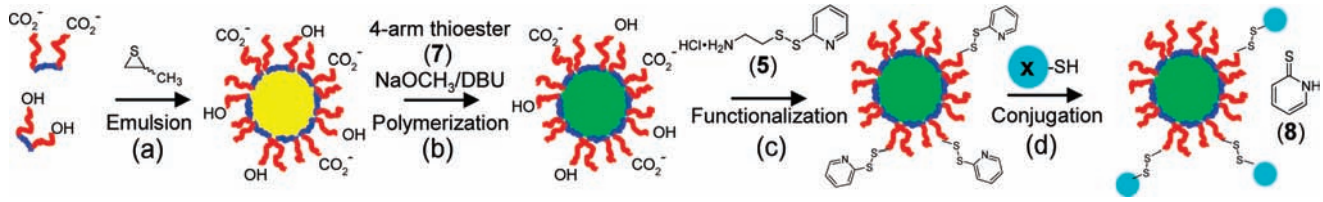
*Trityl Cysteamine (**9**).* An amount of 11.4 g (100 mmol) of cysteamine·HCl and 27.3 g (105 mmol) of triphenylmethanol was added to 100 mL of DMF, and the mixture was heated at 60 °C for 15 min to obtain a clear-yellow solution. The solution was cooled, 14 mL of BF_3·Et_2O (110 mmol) was added, and the mixture was heated at 80 °C. After 14 h the mixture was concentrated under reduced pressure and the oil was dissolved in 500 mL of EtOAc. Upon standing a white solid precipitated that was filtered off. The remaining clear EtOAc solution was washed with saturated NaCl (aq) solution, causing more solid to precipitate that was filtered off. Both solids were combined and dried under reduced pressure, yielding 33.1 g (93 mmol, 93%) of tritylcysteamine·HCl salt. The free base was prepared by treating 2.9 g (8.1 mmol) of the HCl salt with 150 mL of saturated KOH (aq) solution and 500 mL of Et_2O. The clear layers were separated, and the organic phase was dried over Na_2SO_4 and concentrated under reduced pressure. This yielded after drying under reduced pressure 2.0 g (8.3 mmol, 78%) of the free salt. NMR ($CDCl_3$): δ = 7.44 (m, 6H, CH_{aromat}), 7.27 (m, 9H, CH_{aromat}), 2.60 (t, 2H, CH_2−N, J = 6.4 and 6.6 Hz), 2.34 (t, 2H, CH_2-S, J = 6.4 and 6.6 Hz), 1.48 (br, 2H, NH_2). HRMS $[M + H]^+$ calculated for $C_{21}H_{21}NS$ 320.1473, found 320.1466.

*Biotin Cysteamine (**10**).* Amounts of 0.49 g (2.0 mmol) of D-(+)-biotin, 0.47 g (2.0 mmol) of EDC, and 0.96 g (5.0 mmol) of *N*-hydroxysuccinimide were suspended in 10 mL of DMF. After the addition of 0.58 g (5.0 mmol) of **9** and 278 μL (2.0 mmol) of triethylamine the mixture was stirred for 2 days at room temperature. The mixture was concentrated under reduced pressure and taken up in 50 mL of EtOAc and washed with H_2O (3 × 50 mL). After drying over Na_2SO_4 and solvent removal the residue was dissolved in a mixture of 10 mL of CF_3COOH and 10 mL of CH_2Cl_2, and 431 μL (2.1 mmol) triisopropylsilane was added. After 4 h the volatiles were removed in a flow of N_2 and the residue was dissolved in 25 mL of EtOAc and extracted with H_2O (3 × 10 mL). The aqueous extracts were combined and lyophilized. The compound was purified by HPLC to yield 0.091 g of white solid (15% overall yield). ^{1}H NMR (CD_3OD): δ = 4.53 (m, 1H), 4.34 (m, 1H), 3.37 (t, 2H, J = 6.8 Hz), 3.25 (m, 1H), 2.97 (dd, 1H, J = 4.8 and 12.81 Hz), 2.74 (d, 1H, J = 12.8 Hz), 2.64 (t, 2H, J = 7.2 Hz), 2.25 (t, 2H, J = 7.2 Hz), 1.82−1.58 (m, 4H), 1.54−1.42 (m, 2H). HRMS $[M + H]^+$ calculated for $C_{12}H_{21}N_3O_2S_2$ 304.1154, found 304.1157.

Biotin-NPs. Pyridyl disulfide-NPs (500 μL, 35.2 mg/mL, 75% NP) with a pyridyl disulfide loading of 1.9 mM were diluted with 500 μL of HEPES solution (200 mM, pH 8.0) and added to 1.1 mg (3.6 μmol, 1.8 equiv) of biotin cysteamine. The reaction was followed by measuring the absorbance at 340 nm in a quartz cuvette. After 1 h the absorbance was stable and the NPs were purified by dialysis (MWCO = 10 kDa) against 5 L of H_2O for 24 h with regular replacement of water. The presence of biotin on the NPs was confirmed by the HABA/avidin displacement assay (*22*). The number of biotin molecules per NP was estimated to be approximately 800 (see Supporting Information).

*Ac-SDKDSLKCG-OH Peptide (**11**).* Fmoc-Gly (0.65 mmol, 194.0 mg, 3 equiv) was coupled to NovaPEG Wang resin (250 mg, loading 0.87 mmol/g) with 134.6 mg (0.65 mmol, 3 equiv) of DCC and 13.2 mg (0.11 mmol, 0.5 equiv) of DMAP in 10 mL of DMF. After the resin was washed with DMF (5 × 10 mL) the Fmoc group was removed with 20% piperidine in DMF (10 mL) and after washing with DMF (5 × 10 mL) used to couple the other amino acids using standard Fmoc-amino acid/HBTU/HOBt/DIPEA (0.5 M/0.5 M/0.5 M/1.0 M, 5 equiv solutions in DMF) double coupling Fmoc chemistry on a Chemspeed peptide synthesizer. After Fmoc removal of the last amino acid serine the N-terminus was acetylated by reaction with acetic acid/HBTU/HOBt/DIPEA. The peptide was cleaved from the resin using 4 mL of TFA/TIS/phenol/H_2O, 35:2:2:1, for 4 h and precipitated in diethyl ether to yield the crude peptide that was purified by reverse phase HPLC to yield 71 mg (0.064 mmol, 29%) of white solid. HRMS $[M + H]^+$ calculated for $C_{43}H_{12}N_2O_{20}S$ 1109.4785, found 1109.4803.

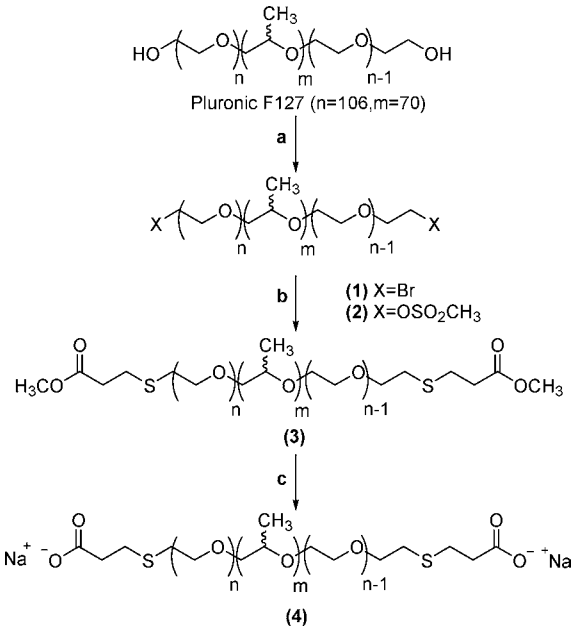
Peptide-NPs. A solution of the peptide was prepared at a thiol concentration of 2.1 mM, and 100 μL of this solution was diluted with 100 μL of 100 mM acetate buffer, pH 4, and added to 200 μL of pyridyl-NP solution (58.8 mg/mL, 25% NP) with a pyridyl disulfide loading of 0.93 mM. The excess of thiol to pyridyl disulfide was 10%. The reaction was followed by measuring the absorbance at 340 nm in a well plate reader. After 2 h the absorbance was stable and the peptide-NPs were purified by gel filtration over Sepharose 6B beads eluting in water (200 μL sample and 10 mL bed volume). Presence of the peptide on the NPs was measured with fluorescamine. The number of Ac-SDKDSLKCG-OH peptide molecules per NP was estimated to be approximately 160 (see Supporting Information).



Reduction of Peptide-NPs. An amount of 200 μL of purified peptide-NPs was mixed with 10 μL of a solution of 57.2 mg/mL TCEP·HCl, resulting in a final concentration of 9.5 mM reducing agent. The mixture was incubated for 2 h, and the NPs were purified by gel filtration over Sepharose 6B beads eluting in water (200 μL sample and 10 mL bed volume). As a control, 200 μL of purified peptide-NPs mixed with 10 μL of H_2O was purified as well.

OVA-Functionalized NPs. OVA (12.5 mg/mL) in 10 mM PBS was reduced with DTT at a final concentration of 32 mM for 4 h. Excess reducing agent was removed by gel filtration over Sephadex G50 eluting with H_2O. The fractions were analyzed by Ellman assay prior to lyophilization to quantify the amount of OVA; it was assumed that all cysteines were present in the thiol form. Pyridyl disulfide-NPs with a pyridyl disulfide loading of 547 μM (41 mg/mL, 25% NP) were added to 750 μL of lyophilized 100 mM HEPES, pH 8.0, solution, and the clear solution was added to 7.85 mg of lyophilized OVA resulting in a final OVA concentration of 10.4 mg/mL (236 μM). The reaction mixture was incubated overnight at 4 °C and purified by gel filtration over Sepharose CL-6B beads eluting in water (180 μL sample and 12 mL bed volume). As a control, nonreduced OVA was reacted in the same way. Presence of the OVA protein was measured with fluorescamine. The number of OVA protein molecules per NP was estimated to be approximately 75 (see Supporting Information).

RESULTS



In Scheme 1, the design concept of the functionalizable NPs is shown. When a carboxylate-Pluronic is mixed with the hydroxyl-Pluronic into the propylene sulfide emulsion, NPs can be prepared with surface carboxylate groups. These carboxylate

Scheme 1. Synthesis of Funtionalizable Nanoparticles[a]

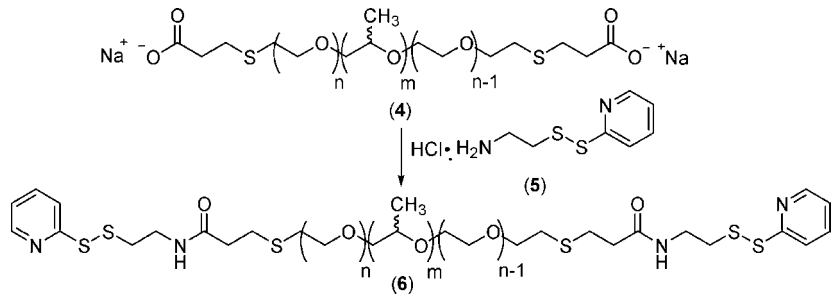
[a] (a) Hydroxyl-Pluronic and carboxylate-Pluronic are used to make an emulsion with propylene sulfide. (b) To the emulsion is added four-arm thiol initiator, and polymerization is started by addition of base. After polymerization, particles are exposed to air to cross-link, and the remaining thiolates are end-capped with iodoacetamide. (c) The carboxylate-nanoparticles are reacted with pyridyl disulfide cysteamine (**5**) to yield thiol-reactive functionalizable nanoparticles. (d) Conjugation of thiol-containing biotin (**10**), AcSDKDSLKCGOH peptide (**11**), and OVA protein gives biological-functional nanoparticles.

Scheme 2. Synthesis of Carboxyl-Functionalized Pluronic[a]

[a] (a) $SOBr_2$, toluene, reflux 4 h (**1**) or CH_3SO_2Cl, Et_3N, toluene, overnight (**2**); (b) thiopropionic acid methyl ester, K_2CO_3, DMF, overnight; (c) NaOH (aq), overnight.

groups on the NP surface can then be converted into pyridyl disulfide groups. The thiol-reactive pyridyl disulfide group allows for conjugation with thiol-containing small molecules, peptides, and proteins. The first step is synthesis of carboxylate group-carrying NPs. To accomplish this, a Pluronic-carboxylate was synthesized as shown in Scheme 2.

As the first step of Pluronic carboxylation, both hydroxyl groups were converted into either the bromide by reaction with thionyl bromide or the mesylate with methanesulfonyl chloride in toluene. The degree of functionalization was 100% for both the bromide and mesylate according to NMR, as no OH groups were visible in deuterated DMSO. Harris et al. showed that the OH group of PEG occurs as a triplet at $\delta = 4.58$ ppm in this aprotic solvent and can be used to determine the degree of functionalization reliably (*23*). Nucleophilic substitution of the bromide or mesylate with mercaptomethyl propionate in the presence of potassium carbonate in DMF afforded the corresponding methyl ester in high yield. Hydrolysis of the ester in aqueous NaOH yielded the carboxylate-Pluronic, as was shown by the disappearance of the CH_3 group at 3.7 ppm. The presence of the carboxylate groups was furthermore confirmed by reaction with pyridyl disulfide cysteamine·HCl in the presence of EDC and NHS (Scheme 3) to yield the corresponding pyridyl disulfide-Pluronic. In addition, the degree of functionalization was calculated by reducing the pyridyl disulfide groups with TCEP·HCl in aqueous HEPES, pH 8, and reading the absorbance at 340 due to pyridinethione release. The degree of functionalization was 100% on a mass basis.



The synthesized carboxylate-Pluronic was used for NP synthesis. To gain information on how it would affect NP synthesis, the weight ratio of carboxylate-Pluronic to hydroxyl-Pluronic in the polymerization mixture was varied between 0% and 100%. (For some applications, retention of surface hydroxyl groups on the NPs is important (*18*).) DLS and TEM show that the addition of carboxylate-Pluronic does not significantly affect the size of NPs compared to the NPs with hydroxyl-Pluronic alone, as can be seen from Table 1 and Figure 1, panels A and B. However, the polydispersity index (PDI) was lower than for NPs with hydroxyl-Pluronic alone, which is reflected by the absence of the larger particles in 100% carboxylate-NPs (Figure 1B) and their presence in the hydroxyl-NPs (Figure 1A).

From NMR, the degree of polymerization of propylene sulfide can be calculated by comparing the integral ratio after normalizing of the propylene sulfide CH_3 group at 1.3 ppm and that of the four-arm initiator methylene group -CH_2- at 1.8 ppm. Figure 2 shows the degree of polymerization as a function of weight percentage carboxylate-Pluronic present in the polymerization mixture. The average degree of polymerization for the different carboxylate-NPs is 63 ± 3 propylene sulfide monomer units, which corresponds to 16 ± 1 units per initiator arm in average. These values are quite similar to those (58 and 14 units, respectively) calculated for hydroxyl-NPs. NMR also allows calculation of the weight contributions of Pluronic, PPS, and initiator to the total NP mass (see Supporting Information). From Figure 3 it can be seen that the different carboxylate-NPs all have a similar composition. The average values are $57 \pm 2.1\%$ for Pluronic, $39 \pm 2.0\%$ for PPS, and $3.6 \pm 0.2\%$ for the initiator. These values agree well with those found for hydroxyl-Pluronic alone NPs (55%, 41%, and 4.1%, respectively).

Having established that NPs can be made using the carboxylate-Pluronic, the next step was reacting them with pyridyl disulfide cysteamine·HCl, obtained in a single step from cysteamine·HCl and aldrithiol in methanol, using standard EDC/sulfo-NHS coupling chemistry at pH 4.0−4.5. The amount of Pluronic was calculated from NMR data of lyophilized carboxylate-NPs. Since it was not clear what the amount of carboxylate-Pluronic in the 10−75% carboxylate-NPs was, calculations of coupling reagents were based on the total amount Pluronic in the NP solutions (as measured by NMR), which was similar for all carboxylate-NPs solutions. The number of equivalents of EDC (24 equiv), sulfo-NHS (20 equiv), and pyridyl disulfide cysteamine·HCl (20 equiv) relative to Pluronic was fixed, and the reactions were carried out at the same time.

After functionalization, the NPs were dialyzed and characterized by DLS (Table 1) and TEM (Figure 1C). The PDI slightly increased, and TEM supports the DLS data, as larger particles are present as well. NMR of the different NPs revealed the presence of the pyridyl disulfide group by the four characteristic signals of the pyridyl disulfide group as observed for the pyridyl

Scheme 3. Synthesis of Pyridyl Disulfide-Functionalized Pluronic[a]

disulfide-Pluronic (**6**). More importantly, the presence of a broad signal at 7.3 ppm assigned to the NH of the amide bond, and also present in the above-mentioned pyridyl disulfide-Pluronic, confirmed successful conjugation (see Supporting Information). In Figure 4 the number of pyridyl disulfide groups relative to the number of propylene glycol repeating units on the Pluronic

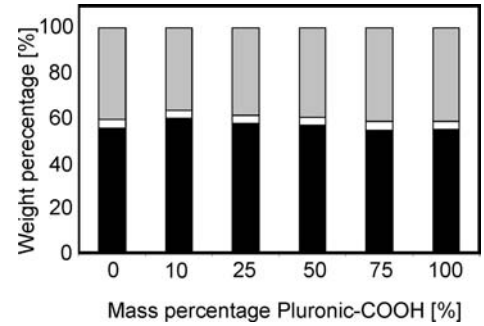

Figure 3. Mass percentage of Pluronic (black), poly(propylene sulfide) (gray), and initiator (white) of total NP weight as a function of weight percentage carboxylate-Pluronic in the polymerization mixture as calculated from NMR.

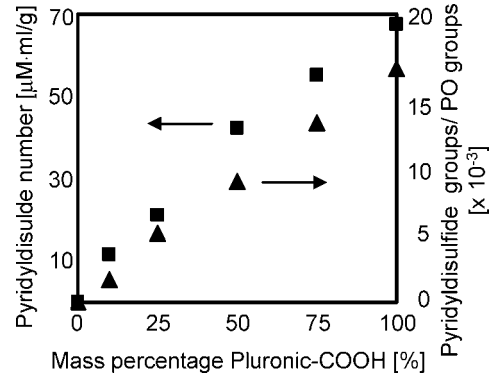

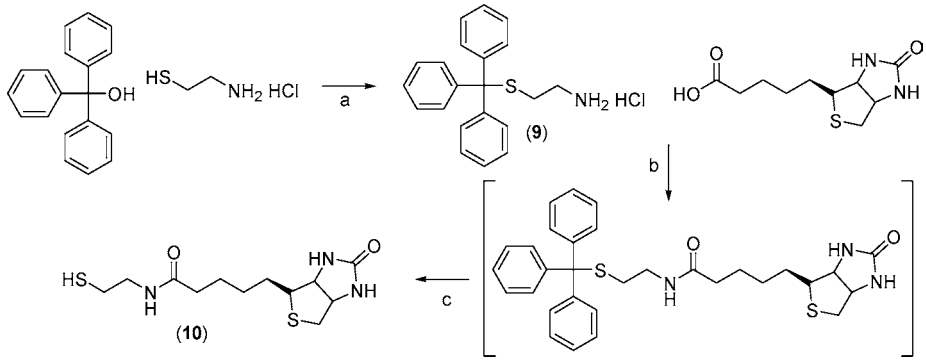

Figure 4. Number of pyridyl disulfide groups divided by the number of repeating propylene oxide (PO) units (triangles) as calculated from NMR from the ratio of pyridyl disulfide groups in μM (as measured by release of pyridine thione after reduction with TCEP·HCl) and NP concentration in mg/mL. The pyridyl disulfide number (squares) is a linear function of weight percentage carboxylate-Pluronic in the polymerization mixture.

as measured with NMR shows that there is a linear relationship between the feed ratio of carboxylate-Pluronic and the amount of pyridyl disulfide-Pluronic present on the NP. However, the reaction does not lead to full conversion of all carboxylate into pyridyl disulfide groups, as can be calculated from the carboxylate-Pluronic feed ratio at 100%. By comparison of the experimentally determined ratio of pyridyl disulfide groups to propylene glycol groups with that theoretically calculated, about 57% of carboxylate groups were determined to have reacted. A similar value of 61% is obtained by measuring the release of pyridine thione after reduction with TCEP·HCl and comparing this concentration with that calculated from the NP concentration and weight percentage of Pluronic in the NP solution. This low functionalization degree is not due to loss and/or modification of carboxylic acid groups during NP synthesis. Control experiments with the carboxylate-Pluronic under conditions used for

Table 2. Dynamic Light Scattering Results for the Different Conjugated NPs[a]

compd	*Z*-Avg[b] (SD)	PDI[c] (SD)
biotin	36.4 (0.26)	0.201 (0.003)
peptide	36.7 (0.21)	0.209 (0.003)
OVA	56.0 (0.32)	0.267 (0.006)

[a] Values are the average of three measurements of the same sample. [b] Size in nm as measured by the *Z*-average obtained by fitting the correlation function using the cumulant method. [c] Polydispersity index (PDI) calculated from fitting the correlation function using the cumulant method.

polymerization but without the addition of propylene sulfide did not lead to changes in the NMR spectrum (data not shown). The same linear trend is observed if the total pyridyl disulfide loading in μM is normalized by the NP concentration in mg/mL, the pyridyl disulfide number (Figure 4). Both DLS and TEM confirmed that the NPs kept their small size but that some aggregation occurred as shown by the increase in PDI (Table 1) and the presence of bigger particles in TEM (Figure 1C).

With the pyridyl disulfide-NPs at hand, we wanted to show that we could easily conjugate small molecules, peptides, and proteins. We first considered conjugation of a thiol-containing biotin to the NPs. In Scheme 4, the synthesis of this compound is outlined. After purification by HPLC, the biotin cysteamine was conjugated to pyridyl disulfide-NPs and purified by dialysis. DLS (Table 2) and TEM (Figure 1D) both show that the NPs kept their size. Successful conjugation was shown by adding the biotin-NPs to streptavidin Alexa488 and loading the NP solutions on a SDS−PAGE gel. From Figure 5 (lanes 4−6) it can be seen that above a certain biotin/streptavidin molar ratio, all streptavidin was bound to the NP surface and was no longer able to move into the gel. The reductive sensitivity of the biotin-NP disulfide linkage is clearly illustrated by running the gel (lanes 8−10) in the presence of mercaptoethanol, a reducing agent that leads to cleavage of the disulfide bond between biotin and the NP.

To see the effect of molecular size on conjugation, a model peptide was synthesized with a cysteine added at the C-terminus. Conjugation of the peptide was done at pH 4, and excess peptide was removed by gel filtration on Sepharose 6B beads. Figure 6A shows the elution profile for pyridyl disulfide-NP after reducing the fractions with TCEP·HCl and measuring the absorbance at 340 nm due to pyridinethione release. As can be seen from Figure 6A, the NPs elute as a sharp peak and DLS confirmed the presence of NPs in the fractions. Figure 6B shows the elution profile of peptide-NP after gel filtration as measured after reaction of the lysine residues on the peptide with fluorescamine and measuring the fluorescence intensity. As can be seen, the peptide is bound to the NPs, as the elution profile is practically the same as that measured for the pyridyl disulfide-

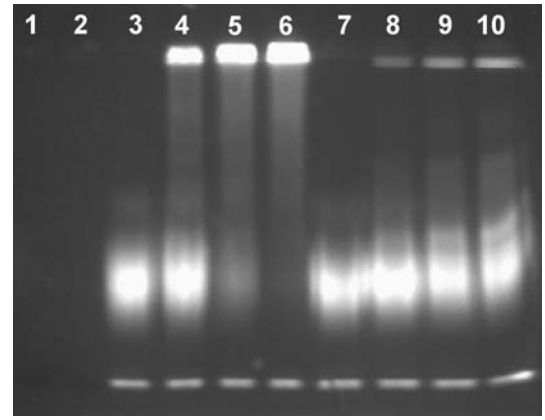

Figure 5. SDS−PAGE gel showing the interaction between biotin-NPs and streptavidin-Alexa488: (lane 1) ladder; (lane 2) biotin-NPs (15 μL); (lane 3) streptavidin-Alexa488 (10 μg); (lanes 4−6) streptavidin-Alexa488 (10 μg) with increasing volumes (5, 10, and 15 μL) of biotin-NPs; (lanes 7−10) same as for lanes 3−6 but in the presence of β-mercaptoethanol.

NP. DLS (Table 2) shows that the NPs still have similar size relative to the pyridyl disulfide-NP. To show that this peptide is linked by a disulfide bond, the peptide-NPs were reduced with TCEP·HCl prior to gel filtration. In Figure 6C it can be seen that the peak in Figure 5B is completely gone and that a new peak can be observed at higher elution volume, which is due to free peptide.

Having shown that a small molecule and a larger peptide can be conjugated to the pyridyl disulfide-NPs, we were also interested in conjugating proteins. We choose OVA, a 44 000 Da protein that after full reduction has six cysteine residues, and we conjugated it to the NPs. From the elution profile shown in Figure 7A, it can be seen that all OVA has been conjugated. Reduction of OVA is necessary, as shown for the elution profile of the reaction mixture of OVA that had not been reduced prior to conjugation (Figure 7B). Clearly OVA elutes much later than when bound to the NPs.

DISCUSSION

We previously reported the emulsion polymerization of propylene sulfide/Pluronic F127 by anionic ring-opening polymerization (*16*). The presence of the two hydroxyl groups of the Pluronic F127 on the surface of the cross-linked polypropylene sulfide core opens the possibility of introducing biological functionality onto the NPs by modifying the α,ω hydroxyl groups. However, this should be done prior to making the NPs, as commonly used hydroxyl activation chemistries are not compatible with the aqueous solution of the NPs. For this reason, Pluronic F127 has been modified with reactive groups and

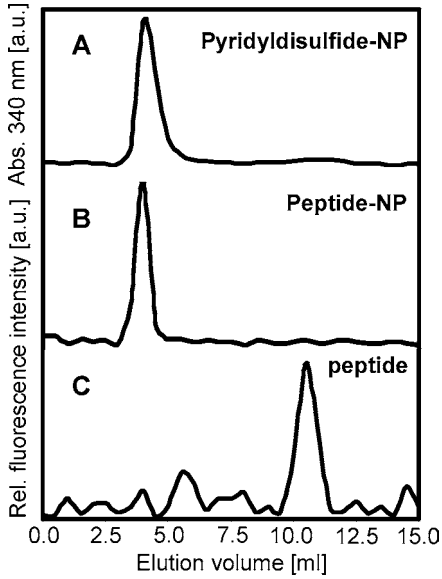

Figure 6. (A) Elution profile of pyridyl disulfide-NPs. Fractions were reduced with TCEP·HCl, and the absorbance at 340 nm due to pyridine thione was measured. (B) Elution profile of peptide-NPs after purification. (C) Elution profile peptide-NPs after reduction with TCEP·HCl. Fractions were reacted with fluorescamine, and the fluorescence intensity was measured.

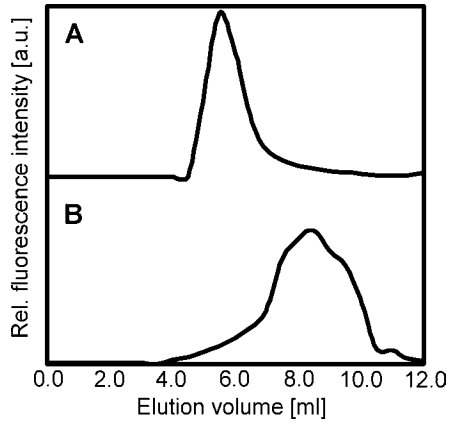

Figure 7. Elution profile after reacting pyridyl disulfide-NPs at pH 8 with (A) reduced and (B) nonreduced ovalbumin. Fractions were analyzed by addition of fluorescamine and measurement of the fluorescence intensity.

reacted with molecules prior to nanoparticle synthesis to obtain biologically functional nanoparticles. Previously we have modified Pluronic F127 with *p*-nitrophenol (*17*) and vinylsulfone (*18*) groups that allow conjugation of peptides (*24*) and proteins (*16, 18*) using amines and thiols.

Despite the successful applications described above, there remains a disadvantage in our previous scheme, in that for making biological-functional NPs each time the corresponding functionalized Pluronic has to be synthesized, which may limit the scope of use of the biological-functional NPs. Furthermore, the polymerization conditions during NP synthesis might be deleterious for the bioactivity of, for example, proteins for which the conservation of sensitive native three-dimensional structure is highly important. Indeed, in the case of the GOx-NPs, despite careful optimization of the synthesis, more than 30% loss of enzyme activity after NP synthesis was observed.

For these reasons, we sought to develop a more flexible system that would allow for mild reaction conditions and broad pH range to conjugate small molecules, peptides, and proteins to the NP surface. We reasoned that a thiol-reactive group on the surface of the NP for binding to the NPs might be most advantageous, as peptides and proteins can be easily engineered to have a free thiol group. In this way with only one NP batch, functionalizable NPs, one would have access to a number of biological-functional NPs.

Chart 1. Commonly Available Thiol-Reactive Groups (A) Vinylsulfone, (B) Acrylate, (C) Maleimide, (D) Alkyl Bromide or Iodide, (E) Pyridyl Disulfide

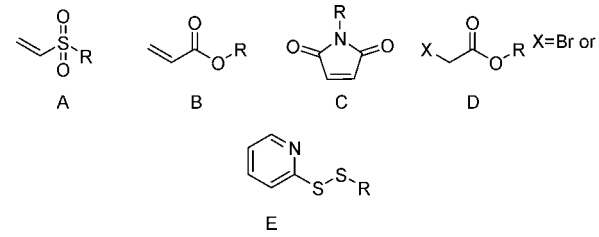

Chart 2. Reaction between Pyridyl Disulfide and a Thiol To Give a Mixed Disulfide with Release of Pyridine Thione

For the thiol-reactive group on the NP surface, there are several options, as shown in Chart 1. First are the Michael acceptors vinylsulfone (**A**), acrylate (**B**), and maleimide (**C**). These groups react with thiols in a conjugate Michael addition to form a thioether bond between the thiol and double bond. A thioether bond is also formed when the thiol reacts in a nucleophilic substitution reaction with bromo and iodo derivatives (**D**). The disadvantage of these thiol-reactive groups is that a physiologically irreversible thioether bond is formed. In the case of antigen delivery, this might be problematic, as the antigen is not released from the NP after being taken up by the cell unless first proteolytically processed. Despite the fact that the acrylate-based conjugate is cleavable by ester hydrolysis, this group is problematic for long-term storage of the aqueous antigen-NPs solution.

Another thiol-reactive group is the pyridyl disulfide group (**E**) that reacts with thiols to give a disulfide bond and releases pyridine thione as shown in Chart 2. This disulfide exchange reaction is practically irreversible because of the formation of the very stable pyridine thione which has a anomalously low pK_a value (*25*). This is also the reason why this reaction takes place over a broad pH range between 4 and 8 (data not shown). In addition to the broad pH range, conjugation using the pyridyl disulfide group has two other advantages: the amount of protein or peptide conjugated can be quantified by measuring the release of pyridine thione, and the peptide or protein is linked to the NP surface via a reduction-sensitive disulfide bond, which allows a cellular mechanism for antigen release after endocytosis due to the reductive potential early during endolysosomal processing. This increase in reducing environment will result in cleavage of the peptide/protein-NP disulfide bond and allow for release of the peptide or protein from the NP to affect its biological activity. This antigen release mechanism was not possible in the original scheme using the vinylsulfone coupling; rather, proteolytic release was required. For this reason we functionalized the NPs with this pyridyl disulfide group. The most straightforward approach is synthesis of a pyridyl disulfide-Pluronic and adding this to the polymerization mixture to make pyridyl disulfide-NPs. However, a problem is that the thiolate species that are responsible for the polymerization of propylene sulfide could also react with the pyridyl disulfide groups on the Pluronic. Indeed, after synthesizing pyridyl disulfide-Pluronic (*21*) and addition to the polymerization mixture, NMR showed that the pyridyl disulfide group was not present after NP

synthesis (data not shown). To circumvent this problem, i.e., introducing the thiol-reactive pyridyl disulfide group in the presence of thiolate species, we came to the following approach as outlined in Scheme 1. As the first step, carboxylate-functionalized NPs are synthesized and, in the second step, functionalized with a pyridyl disulfide containing a free amine to introduce the thiol reactive groups. Note that we choose the NPs to have a negative charge instead of positive (amines) to avoid the potential toxic effects of cationic charges that could arise from unreacted amine groups. The carboxylate-Pluronic was therefore synthesized in three steps from Pluronic F127 as outlined in Scheme 1. The use of the methyl ester was necessary, as reaction of mercaptopropionic acid also led to substitution at the carboxylic acid leading to an ester bond as was visible from ^{1}H NMR by the occurrence of a triplet around 4.2 ppm. After alkaline hydrolysis, the carboxylate-Pluronic was kept as its sodium salt so as to not interfere during NPs synthesis by lowering the pH. As the final step in characterizing the carboxylate-Pluronic, the polymer was reacted with pyridyl disulfide·HCl to give pyridyl disulfide-Pluronic. This polymer would serve as a reference for characterization of the pyridyl disulfide NPs.

With the carboxylate-Pluronic at hand, NPs were synthesized by emulsion polymerization with different COOH-to-OH Pluronic mass ratios. After exposure to air for 2 h to form disulfides, the remaining free thiolate anions that were spatially too far apart to form disulfides were blocked by the addition of iodoacetamide. Previous work had shown that this is effective in blocking thiolates (*15*) and capping was quantitative as measured by Ellman assay. This blocking is important to avoid a disulfide exchange reaction when the pyridyl disulfide groups are introduced onto the NPs. From the DLS and TEM data, it can be seen that the addition of carboxylate-Pluronic did not significantly affect the size of the final NPs. The PDI, however, dropped significantly (Table 1), suggesting that the negatively charged NP surface stabilizes the particles, which can be explained by DLVO theory, which states that like charge stabilizes colloid particles (*26*). In addition, the carboxylate-Pluronic did not influence the ring-opening polymerization of propylene sulfide to a significant extent as shown by the degree of polymerization and weight composition of the NPs. This shows that the NP synthesis is not affected significantly by the presence of the carboxylate-Pluronic in the polymerization mixture. Because of overlap of the characteristic signals of the carboxylate-Pluronic at 2.5, 2.7, and 2.8 ppm with the broad CH and CH_2 signals at 2.5−2.7 and 2.8−3.0 ppm of the PPS, it was not possible to determine the percentage of carboxylate-Pluronic present in the 10−75% carboxylate-NPs by NMR. For this reason we used the conjugation with pyridyl disulfide cysteamine·HCl as an indirect measurement to obtain insight into how the carboxylate-Pluronic was incorporated into NP surface as a function of the feed ratio in the polymerization mixture. From the 100% carboxylate-NPs, it was calculated that only about 60% functionalization was achieved, even though the carboxylate-Pluronic alone could be functionalized almost quantitatively. This lower degree of functionalization is not due to loss of carboxylate groups as was shown in control experiments. An explanation could be that some carboxylate groups remain inaccessible during functionalization, though how that would happen is unclear: interaction of the negatively charged carboxylate group with the hydrophobic PPS is unlikely. It is therefore more likely that the EDC/sulfo-NHS coupling chemistry itself limits the degree of functionalization because of its inherent water sensitivity. Indeed model experiments in which pyridyl disulfide cysteamine·HCl was coupled (using NHS) to the carboxylate-Pluronic that had been used in NP synthesis led to almost quantitative conversions in CH_2Cl_2 but only 45% in MES (aq) buffer (data not shown). The linear trend in Figure 4 suggests that the percentage of carboxylate-Pluronic on the NP surface is the same as that in the polymerizing mixture but that only about 60% can be functionalized. This finding enables the control of surface density of pyridyl disulfide groups on the NP surface by adjusting the feed ratio in the polymerization mixture of carboxylate- to hydroxyl-Pluronic.

Having shown that pyridyl disulfide groups could be introduced onto the NPs, it was important to show that these are actually in contact with the aqueous phase and available for conjugating with peptides and proteins. To explore this, we synthesized a thiol-containing biotin molecule and reacted it with the pyridyl disulfide-NPs. With this biotin molecule at both ends of the Pluronic, it would also be possible to see whether after conjugating biotin on the Pluronic ends the NP surface would be still accessible for interaction with large proteins. Biotin interacts with streptavidin, a 66 000 Da protein, to form the strongest noncovalent bond known in nature. Indeed biotin on the NPs is able to interact with the binding pockets of streptavidin, as shown in Figure 5. This result shows that the pyridyl disulfide groups on the NP surface are accessible in the aqueous phase for conjugation and that streptavidin is able to interact with the conjugated biotin on the NP surface. The biotin-NPs are furthermore interesting from a staining point of view. Having biotin bound to the NPs enables us the ability to probe the presence of the NPs in tissues by cryosectioning and staining with fluorescently labeled streptavidin.

For immunotherapy applications normally whole immunogenic proteins are used; however, they typically lead to release of a limited number of antigenic peptides when processed within DCs. For example the OVA protein yields two (SIINFEKL and ISQAVHAAHAEINE) antigenic peptide sequences upon processing by DCs (*27*). Since peptides are easily accessible by solid phase peptide synthesis, they can be made to have a free cysteine residue, enabling conjugation to NPs. As a model, we synthesized a nine amino acid peptide containing a cysteine and conjugated it to the NP. For purification of the peptide-NP, gel filtration was used because it is time saving and a better purification method compared to dialysis, especially with increasing size of the molecule to be conjugated. The presence of the peptide on the NPs was confirmed with DLS and fluorescamine (*20*). Important in our concept of antigen-bearing NPs is the reductive sensitivity of the antigen-NP disulfide bond. For this reason, we exposed both the biotin-NPs and peptide-NPs to a reducing agent to demonstrate sensitivity to reduction. In the case of biotin, mercaptoethanol led to a cleavage of the disulfide bond at room temperature as shown by SDS−PAGE gel where the streptavidin was no longer bound to the NP surface and freely moved into the gel. For the peptide-NP, addition of TCEP·HCl also led to disulfide cleavage as could be shown after gel filtration.

Finally we wanted to show that it is also possible to conjugate a larger protein. We choose OVA because it is a model antigen that is used frequently in immunotherapy studies. OVA has four free cysteine residues and one disulfide bond that would allow easy conjugation using our functionalization scheme. The problem is that these four cysteine residues are buried in the native state and are not reactive toward iodoacetic acid at pH 8.2, an alkylation agent (*28*). For this reason we reduced OVA to expose all six cysteine residues (four free and two in a disulfide). This, however, leads to a potential problem of cross-linking, as the NP surface is decorated with several pyridyl disulfide groups. With careful optimization, we managed to conjugate OVA to pyridyl disulfide-NPs. From Figure 6A it can be seen that all OVA eluted in one peak and that free OVA was not detected. DLS indicated an increase in size but the OVA nanoparticles still remained small (Table 2). That practically

no free OVA was present is clearly illustrated in Figure 6B by elution nonreduced OVA, which elutes at a much higher elution volume and shows the need for reducing OVA prior to conjugation. Indeed, if conjugation of reduced OVA is not quantitative, the elution profile shows both peaks (data not shown).

To conclude, we have presented a scheme by which to make thiol-reactive Pluronic-stabilized poly(propylene sulfide) NPs by incorporating a carboxylate-Pluronic into the hydroxyl-Pluronic/propylene sulfide mixture that was subsequently reacted with pyridyl disulfide cysteamine to yield pyridyl disulfide-NPs. The polymerization and NP composition were not affected by the presence of the carboxylate-Pluronic, and the number of pyridyl disulfide groups on the NP surface could be controlled by changing the weight ratio of carboxylate-Pluronic to hydroxyl-Pluronic in the mixture. We further showed that we could conjugate biotin, a nine amino acid peptide, as well as the larger protein OVA. Currently we are exploring the functionalizable NPs scheme for immunological application by conjugating antigenic peptides, proteins, and protein structures with adjuvant activity.

ACKNOWLEDGMENT

We thank the Competence Centre for Materials Science and Technology (CCMX) of the ETH-Board Switzerland for partial funding of this research.

Radiolabeled cholecystokinin-8 (CCK8) peptide analogues can be used for peptide receptor radionuclide imaging and therapy for tumors expressing CCK2/gastrin receptors. Earlier findings indicated that sulfated CCK8 (sCCK8, Asp-Tyr(OSO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2) may have better characteristics for peptide receptor radionuclide therapy (PRRT) than gastrin analogues. However, sCCK8 contains an easily hydrolyzable sulfated tyrosine residue and two methionine residues which are prone to oxidation. Here, we describe the synthesis of stabilized sCCK8 analogues, resistant to hydrolysis and oxidation. Hydrolytic stability was achieved by replacement of the Tyr(OSO_3H) moiety by a robust isosteric sulfonate, Phe(p-CH_2SO_3H). Replacement of methionine by norleucine (Nle) or homopropargylglycine (HPG) avoided undesired oxidation side-reactions. The phenylalanine analogue Phe(p-CH_2SO_3H) of L-tyrosine, synthesized by a modification of known synthetic routes, was incorporated in three peptides: sCCK8[Phe^2(p-CH_2SO_3H),Met^{3,6}], sCCK8[Phe^2(p-CH_2SO_3H),Nle^{3,6}], and sCCK8[Phe^2(p-CH_2SO_3H),HPG^{3,6}]. All peptides were *N*-terminally conjugated with the macrocyclic chelator DOTA (1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) and radiolabeled with In-111. In vitro binding assays on CCK2R-expressing HEK293 cells revealed that all three peptides showed specific binding and receptor-mediated internalization, with binding affinity values (IC_{50}) in the nanomolar range. In vitro oxidation studies demonstrated that peptides with Nle or HPG indeed were resistant to oxidation. In vivo targeting studies in mice with AR42J tumors showed that tumor uptake was highest for ^{111}In-DOTA-sCCK8 and ^{111}In-DOTA-sCCK8[Phe^2(p-CH_2SO_3H),Nle^{3,6}] (4.78 ± 0.64 and 4.54 ± 1.15%ID/g, respectively, 2 h p.i.). The peptide with the methionine residues replaced by norleucine (^{111}In-DOTA-sCCK8[Phe^2(p-CH_2SO_3H), Nle^{3,6}]) showed promising in vivo characteristics and will be further investigated for radionuclide imaging and therapy of CCK2R-expressing tumors.

INTRODUCTION

Cholecystokinin (CCK), a functional peptide hormone in the gastrointestinal tract and the brain, mediates a variety of hormonal and neuromodulatory functions mediated by two receptors, CCK1R and CCK2R (*1*). In addition, a splice variant of the CCK2R was identified, CCK2i4svR, which is expressed at relatively low levels in human colorectal cancer and in pancreatic cancer, but not in normal tissue (*2*). All three receptors belong to the superfamily of G-protein coupled receptors. Several tumor types, such as small cell lung cancers (SCLC) and medullary thyroid carcinomas (MTC), abundantly express CCK2/gastrin receptors (CCK2R) (*3*).

Since both gastrin and CCK8 display a high affinity for these receptors (*3*), radiolabeled analogues of these peptides may be considered for peptide receptor imaging and peptide receptor radionuclide therapy (PRRT). We have previously shown that sCCK8 (Asp-Tyr(OSO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2) has good characteristics for PRRT compared to gastrin analogues (*4*). Sulfated CCK8 has affinity for both the CCK1 and CCK2 receptor, and shows better CCK2R targeting characteristics as compared to nonsulfated CCK8 (nsCCK8). Behr et al. found that minigastrin analogues showed extremely high kidney uptake, whereas CCK8 exhibited low kidney uptake (*5*). The high kidney uptake was shown to be related to the pentaglutamate sequence of minigastrin, and was found to be reduced by coinjection of poly-Glu-containing peptides (*6, 7*). Unlike gastrin, sCCK8 includes a sulfated tyrosine (Tyr) residue that is easily hydrolyzable. Moreover, an Fmoc-Tyr(SO_3H)-OH building block is difficult to use in solid-phase peptide synthesis (SPPS), as it is acid labile (*8*). Another pitfall of sCCK8 is the presence of two methionines (Met) that are prone to oxidation to sulfoxides during radiolabeling and potentially also in vivo, leading to loss of receptor binding (*9, 10*). Therefore, we aimed to develop new and stabilized sCCK8 analogues, resistant to both hydrolysis and oxidation. To this end, we envisaged replacement of the Tyr sulfate moiety by a robust isosteric sulfonate. Since sulfonate isosteres of tyrosine sulfate are not commercially available, synthetic preparation of the phenylalanine analogue Phe(p-CH_2SO_3H) from L-tyrosine was required, to afford a Phe(p-CH_2SO_3H) building block that can be incorporated in peptide sequences under normal coupling conditions in SPPS without additional side chain protection (*11*). Second, to prevent oxidation, two sCCK8 analogues were designed with the Met residues replaced by norleucine (Nle) or homopropargylglycine (HPG) (*12, 13*). All peptides were *N*-terminally conjugated with the macrocyclic chelator DOTA (1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) to allow radiola-

beling. Finally, the three sCCK8 analogues were characterized both in vitro and in vivo and compared to DOTA-sCCK8.

EXPERIMENTAL PROCEDURES

Synthesis of Fmoc-Phe(p-CH_2SO_3Na)-OH. *General Methods.* Solvents were distilled from appropriate drying agents prior to use and stored under nitrogen. Chemicals were purchased from Sigma-Aldrich and used as received, unless stated otherwise. Reactions were carried out under inert atmosphere of dry nitrogen or argon. Standard syringe techniques were applied for the transfer of dry solvents and air- or moisture-sensitive reagents. Reactions were followed, and R_F values were obtained using thin-layer chromatography (TLC) on silica gel-coated plates (Merck 60 F254) with the indicated solvent mixture. Detection was performed with UV-light. NMR spectra were recorded on a Bruker DMX 300 (300 MHz) spectrometer in $CDCl_3$ solutions (unless otherwise reported). Chemical shifts are given in ppm with respect to tetramethylsilane (TMS) as internal standard. Coupling constants are reported as *J*-values in Hz. Mass was determined by LCQ measurement. Column or flash chromatography was carried out using ACROS silica gel (0.035−0.070 mm, and ca. 6 nm pore diameter).

*N-tert-Butyloxycarbonyl-L-tyrosine Methyl Ester (**1**).* 30.0 g (165.55 mmol) L-tyrosine was dissolved in 1.1 L MeOH and cooled on an ice bath. 15.65 mL (215.24 mmol, 1.3 equiv) $SOCl_2$ was added dropwise and the reaction mixture was refluxed at 75 °C overnight. The solvent was evaporated, and the crude product (38.2 g white solid) was used in the next step. ^{1}H NMR (D_2O) δ 3.25 (dq, 2H, Ar-CH_2-CH), 3.86 (s, 3H, -OCH_3), 4.39 (t, 1H, α-C*H*), 6.91−7.21 (dd, 4H, Ar-*H*).

Next, 38.2 g crude product was dissolved in 500 mL dioxane/H_2O (1/1). 34.65 g (412.5 mmol, 3 equiv) $NaHCO_3$ and 43.21 g (198 mmol, 1.2 equiv) Boc_2O were added and the mixture was stirred at RT for 2 h. Dioxane was removed in vacuo and EtOAc was added. The organic layer was washed with water and brine, dried on $MgSO_4$, filtered, and concentrated to yield an orange oil, that crystallized overnight, yielding 44.52 g (150.7 mmol, 91% over 2 steps) of white crystals. R_F (EtOAc/heptane 1/1) 0.49; mp 95 °C; ^{1}H NMR ($CDCl_3$) δ 1.42 (s, 9H, −C(CH_3)$_3$), 3.02 (dq, 2H, Ar-CH_2-CH), 3.71 (s, 3H, -OCH_3), 4.53 (m, 1H, α-C*H*), 4.98 (m, 1H, -N*H*), 5.50 (bs, 1H, -O*H*), 6.72−6.99 (dd, 4H, Ar-*H*).

*N-tert-Butyloxycarbonyl-O-trifluoromethylsulfonyl-L-tyrosine Methyl Ester (**2**).* (*14, 15*) 1.0 g (3.39 mmol) of compound **1** was dissolved in 40 mL CH_2Cl_2 and cooled on an ice bath. Then, 720 μL (4.23 mmol, 1.25 equiv) DIPEA and 1.45 g (4.23 mmol, 1.25 equiv) phenyltriflimide were added, before stirring the mixture at RT overnight. Solvent was removed in vacuo, and the remaining colorless oil was dissolved in 40 mL EtOAc. The solution was washed with H_2O, 0.1 M HCl, and brine, dried on $MgSO_4$, and concentrated. The crude product was purified by flash column chromatography (EtOAc/heptane 15/85). Yield: 1.095 g (2.56 mmol, 79%) white crystals (after drying in vacuo). R_F (EtOAc/heptane 1/1) 0.65; mp 48 °C (lit.48−49 °C); ^{1}H NMR ($CDCl_3$) δ 1.41 (s, 9H, -C(CH_3)$_3$), 3.00−3.20 (dq, 2H, Ar-CH_2-CH), 3.71 (s, 3H, -OCH_3), 4.61 (m, 1H, α-C*H*), 5.00 (m, 1H, -N*H*), 7.22 (s, 4H, Ar-*H*). MS(ESI-TOF): 392.0 ($M+H^+$), calcd 392 ($M+H^+$).

*N-tert-Butyloxycarbonyl-p-vinyl-L-phenylalanine Methyl Ester (**3**).* 1.43 g (30.4 mmol, 1.2 equiv) of LiCl in a 250 mL flask was flame-dried in vacuo. 100 mL of dry DMF, 10.95 g (25.6 mmol) of compound **2**, and 8.23 mL (28.2 mmol, 1.1 equiv) tri-*n*-butyl vinyl tin were added. The mixture was stirred at RT for 10 min. $(PPh_3)_2PdCl_2$ (0.91 g, 3 mol %) was added, and the mixture was heated up to 90 °C and stirred overnight in sealed flask. Water was added and the product was extracted with EtOAc/heptane (1/1, 3 × 20 mL). Organic layers were dried on $MgSO_4$ and concentrated in vacuo. The crude product was purified by flash column chromatography (CH_2Cl_2, EtOAc/heptane 1/1). Yield: 6.12 g (19.8 mmol, 68%) colorless oil. R_F (EtOAc/heptane 1/3) 0.42; ^{1}H NMR ($CDCl_3$) δ 1.42 (s, 9H, −C(CH_3)$_3$), 3.05−3.14 (m, 2H, Ar-CH_2-CH), 3.71 (s, 3H, -OCH_3), 4.58 (m, 1H, α-C*H*), 4.97 (m, 1H, -N*H*), 5.22 (d, J = 10.88, 1H, CH=CH*H*), 5.71 (d, J = 17.61, 1H, CH=C*H*H), 6.68 (dd, J = 17.61, 1H, C*H*=CH_2), 7.07 (d, J = 9.17, 2H, Ar-*H*), 7.33 (d, J = 8.06, 2H, Ar-*H*).

*N-tert-Butyloxycarbonyl-(p-hydroxymethyl)-L-phenylalanine Methyl Ester (**4**).* (*11*) Ozone was bubbled through a solution of the vinyl compound **3** (4.26 g, 13.96 mmol) in 60 mL MeOH at −60 °C until the solution turned blue. The mixture was stirred under N_2 for 10 min at −60 °C and 10.3 mL (139.6 mmol, 10 equiv) of Me_2S was added. The mixture was stirred for 1 h at −60 °C. Then, $NaBH_4$ (2.64 g, 69.8 mmol, 5 equiv) was added. The mixture was stirred at −60 °C for 10 min, then allowed to warm to 0 °C and stirred for an additional 45 min. Saturated NH_4Cl (60 mL) was added, and the product was extracted with EtOAc (2 × 100 mL). The organic layers were dried on $MgSO_4$, filtered, and concentrated to give a yellow−brown oil. The crude product was purified by flash column chromatography (EtOAc/heptane 2/3 → EtOAc 100%). Yield: 8.18 g (26.5 mmol, 50.4% over 2 steps, 74%) of white/yellow crystals. R_F (EtOAc/heptane 1/1) 0.31; mp 81 °C; ^{1}H NMR ($CDCl_3$) δ 1.42 (s, 9H, −C(CH_3)$_3$), 3.08 (dd, J = 10.36, 2H, Ar-CH_2-CH), 3.72 (s, 3H, -OCH_3), 4.57 (m, 1H, α-C*H*), 4.67 (d, J = 5.85, 2H, -CH_2OH), 4.97 (m, 1H, -N*H*), 7.11 (d, J = 8.02, 2H, Ar-*H*), 7.29 (d, J = 8.02, 2H, Ar-*H*). MS(ESI-TOF): 332.2 ($M+Na^+$), calcd 332.16 ($M+H^+$).

*(p-Chloromethyl)-L-phenylalanine Methyl Ester (**5**).* (*16*) Compound **4** (10.03 g) was dissolved in 350 mL of CH_2Cl_2 and $SOCl_2$ (25−30 equiv) was added dropwise, before refluxing overnight. After evaporation to dryness, the remaining solid was rinsed twice with Et_2O and dried. The product was used in the next step without further purification. Yield: 4.59 g (62%) of an off-white solid. R_F (CH_2Cl_2/MeOH/AcOH 9/1/0.1) 0.34; mp 178 °C (lit. 180 °C); ^{1}H NMR (MeOD) δ 3.15−3.32 (dq, 2H, Ar-CH_2-CH), 3.81 (s, 3H, -OCH_3), 4.33 (m, 1H, α-C*H*), 4.65 (s, 2H, -CH_2Cl), 7.28 (d, 2H, Ar-*H*), 7.43 (d, 2H, Ar-*H*); MS(ESI-TOF): 228.0 ($M+H^+$), calcd 228.07 ($M+H^+$).

*(p-Sulfomethyl)-L-phenylalanine (**6**).* (*11, 16*) Compound **5** (4.59 g, 20.2 mmol) was dissolved in 200 mL H_2O and 20.3 g (161.6 mmol, 8 equiv) Na_2SO_3 was added. The mixture was refluxed at 100 °C for 3 h. The solvent was removed in vacuo and the crude product was washed with EtOH, yielding 32.25 g of a white solid after drying in vacuo. The crude product was used in the next step. ^{1}H NMR (D_2O) δ 3.08−3.12 (dq, 2H, Ar-CH_2-CH), 3.97 (m, 1H, α-C*H*), 4.20 (s, 2H, -CH_2SO_3Na), 7.33 (d, 2H, Ar-*H*), 7.43 (d, 2H, *H*). MS(ESI-TOF): 280.3 ($M+H^+$), calcd 280.3 ($M+H^+$).

*N-Fluorenyl-9-methoxycarbonyl-(p-sulfomethyl)-L-phenylalanine (**7**).* (*16*) The sulfonate product **6** (5 mmol) was dissolved in 40 mL H_2O, cooled on an ice-bath and pH was set to 9.0 with 0.1 M NaOH. Next, 2.11 g (6.25 mmol, 1.25 equiv) Fmoc-OSu was dissolved in 50 mL dioxane and added to the mixture. The mixture was stirred on an ice-bath for 30 min, then at RT for 6 h while maintaining the pH between 8.5 and 9.0 with an automatic titrator filled with 0.1 M NaOH. Dioxane was evaporated and the excess Fmoc-OSu was extracted with diethyl ether. The aqueous solution was acidified to pH 5 with 1 M HCl and concentrated to dryness. The crude product was dissolved in methanol, the insoluble material was removed by filtration, and the methanol was evaporated. The residue was dissolved in water and was washed with ethyl acetate before concentration. This product was purified by column chroma-

tography (MeCN/H_2O 9/1), yielding 1.04 g of white solid (2.07 mmol, 41.4% over 2 steps). R_F (ACN/H_2O 9/1) 0.24; mp 185 °C (lit. 184 °C); ^{1}H NMR (MeOD) δ 2.93−3.18 (dq, 2H, Ar-CH_2-CH), 3.99 (m, 1H, α-C*H*), 4.20 (s, 2H, -CH_2SO_3Na), 7.15−7.41 (m, 8H, Ar-*H* (Fmoc)), 7.61 (d, 2H, Ar-*H*), 7.78 (d, 2H, Ar-*H*); MS(ESI-TOF): 480.1 (M−H$^+$), calcd 480.11 (M−H$^+$).

Synthesis of DOTA−Peptides. Peptides were synthesized on a peptide synthesizer (Peptide Synthesizer SP 4000-LAB, Labortec AG) by applying the Fmoc-strategy. In all coupling steps, DIPCDI and HOBt were used, except for coupling of Fmoc-Phe(*p*-CH_2SO_3H) and DOTA(*t*-Bu)$_3$, which was performed in the presence of HBTU and DIPEA. After completion of the synthesis of the peptide on the resin, the peptide was cleaved off by stirring in TFA/ethanedithiol (EDT)/triisopropyl silane (TIS)/H_2O (92.5/2.5/2.5/2.5) for 3−5 h. The mixture was filtered, the filtrate centrifuged with Et_2O. The precipitated peptide was washed with Et_2O and centrifuged several times. Formation of the correct product was corroborated with mass spectrometry (ESI-TOF).

The remaining *t*-Bu protecting groups of the chelator were removed by stirring the product in TFA in the presence of a few drops of concentrated HCl, leading to complete removal of all protecting groups within 1 h. Three peptides were synthesized: DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H)] (DOTA-D-Asp-Phe(CH_2SO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2), DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] (DOTA-D-Asp-Phe(CH_2SO_3H)-Nle-Gly-Trp-Nle-Asp-Phe-NH_2), and DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), HPG^{3,6}] (DOTA-D-Asp-Phe(CH_2SO_3H)-HPG-Gly-Trp-HPG-Asp-Phe-NH_2).

Peptides were analyzed by analytical HPLC (Alltima C18 5 μm, 3.2 × 150 mm, Alltech, USA) with 5−75% ACN 0.1% TFA in H_2O 0.1% TFA as an eluent. DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H)] and DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] were further purified by SP RP-HPLC (ReproSil 100 C18 250 mm × 10 mm, Dr. A. Maisch HPLC-GmbH, Germany), using ACN 0.1% TFA (5−75% over 30 min) in H_2O 0.1% TFA as an eluent. Peptide-containing fractions (detected by UV-light) were lyophilized and analyzed by HPLC and mass spectrometry. DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H)] = 1525.7 (M−H$^+$), calcd = 1526.55. DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] = 1489.8 (M−H$^+$) calcd = 1490.64. DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), HPG^{3,6}] = 1481.8 (M−H$^+$) calcd = 1482.58.

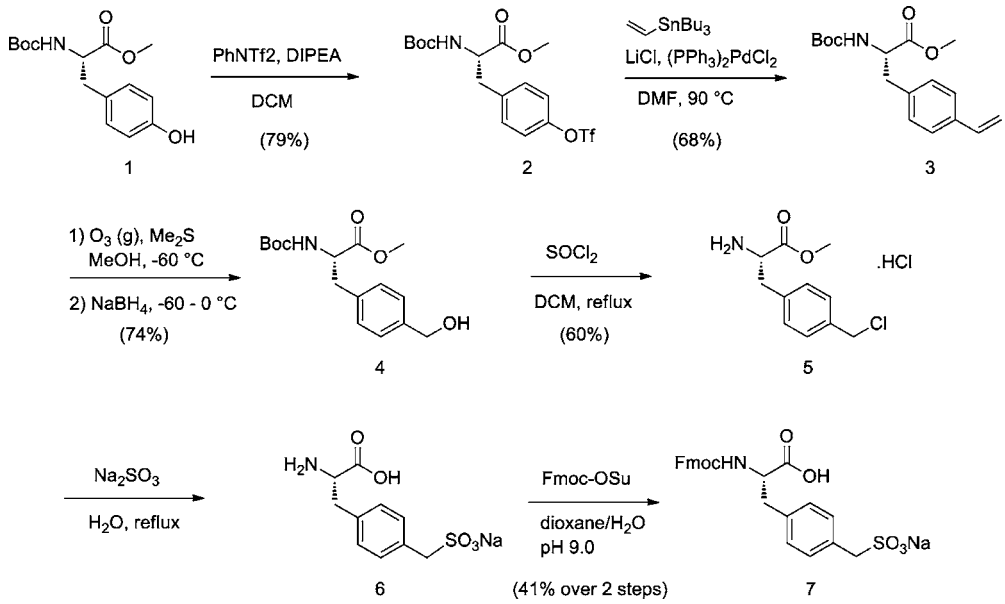
DOTA-sCCK8 was prepared as described before (*17*).

Radiolabeling. The DOTA-conjugated peptides were radiolabeled with $^{111}InCl_3$ (Covidien, Petten, The Netherlands) in 0.25 M ammonium acetate buffer, pH 5.0, for 30 min at 95 °C. Labeling efficiency and radiochemical purity were checked by HPLC (1100 series LC system, Agilent Technologies, Palo Alto, CA, USA, RP-C18 column 5 μm, 4.6 × 250 mm) with a gradient of H_2O containing 0.1% TFA and ACN containing 0.1% TFA, and ITLC on ITLC-SG strips (Pall Life Sciences, Milford, MA, USA) with 0.1 M NH_4OAc/0.1 M EDTA (1/1 v/v) (R_F labeled peptide = 0, R_F unbound ^{111}In = 1), as well as MeOH/3.5% NH_3 (1/1 v/v) (R_F colloid = 0, R_F unbound ^{111}In or labeled peptide >0.8) as eluents. The radiochemical purities of peptides used in the studies described here were always above 95%. Maximum specific activity was 5.5 GBq/μmol.

Determination of Partition Coefficient (log P). To determine the lipophilicity of the radiolabeled peptides, approximately 60 000 dpm ^{111}In-DOTA-peptide was diluted in 3 mL PBS. An equal volume of 1-octanol was added to obtain a binary system. The system was vortexed for 10 s and mixed more gently for another 4 min. The two layers were separated by centrifugation (3000 *g*, 5 min). Three samples of 250 μL were taken of both layers and the radioactivity was determined in a 3″ well-type gamma-counter (Wallac 1480-Wizard 3, Perkin-Elmer, Boston, MA, USA). The log P value was calculated with the following formula:

$$\text{Log P}_{\text{octanol/water}} = \log(\text{cpm}_{\text{octanol}}/\text{cpm}_{\text{water}})$$

Oxidation Experiments. To study the susceptibility of the peptide analogues to oxidation, the ^{111}In-labeled peptides were incubated with oxidation buffer (H_2O_2/acetic acid/NH_4OAc 1/3/36) for 10 min at RT. Before and after incubation, the peptides were analyzed using RP-HPLC.



Stability Experiments. To study the stability of the peptide analogues, the ^{111}In-labeled peptides were incubated in human serum for 4 h at 37 °C. The samples were centrifuged at 3000 *g* for 5 min. The plasma was removed and mixed with acetonitrile. Before and after incubation, the peptides were analyzed using RP-HPLC.

Internalization Experiments. The internalization of the radiolabeled DOTA−peptides was investigated using HEK293-CCK2R cells (obtained from M. Hellmich, Univ. of Texas Medical Branch, Galveston, USA). Cells were cultured in Dulbecco's Modified Eagle's medium (DMEM) and supplemented with 10% fetal calf serum (FCS) and G418 (400 μg/mL). Cells were grown in a humidified atmosphere with 5% CO_2 at 37 °C. Cells were grown to confluency in 6-well plates. Radiolabeled peptide was added at a concentration of 4.4 × 10^{-2} nM (12 000 dpm/well). Cells were incubated for 0.5−2 h at either 0 or 37 °C, medium was removed, and cells were washed with ice-cold binding buffer (DMEM supplemented with 0.5% w/v bovine serum albumin (BSA)). To remove receptor-bound radiolabeled peptide, cells were incubated with acid buffer (0.1 M acetic acid, 154 mM NaCl, pH 2.0) for 10 min at 0 °C. After washing the cells twice with ice-cold PBS, the internalized fraction was determined by counting the cells in a gamma counter. The receptor-bound activity was also determined by counting the acid wash fractions.

Determination of IC_{50} Values. The 50% inhibitory concentration (IC_{50}) of the peptides for binding the CCK2R was determined on HEK293-CCK2R cells in a competitive binding assay. Cells were grown to confluency in 6-well plates. Cells were washed with binding buffer and incubated at RT for 10 min in binding buffer. Subsequently, unlabeled peptide was added in the range 0.1−100 nM together with a trace amount of ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), HPG^{3,6}] (12 000 dpm). After incubation at RT for 1 h, binding buffer was removed and cells were washed twice with binding buffer. Cell-associated radioactivity was determined. The IC_{50} was defined as the peptide concentration at which 50% of binding without competitor was reached. IC_{50} values (including standard deviations) were calculated using *GraphPad Prism* software (version 4.00 for Windows, GraphPad Software, San Diego, CA, USA).

Biodistribution Studies. The in vivo tumor targeting potential of the ^{111}In-DOTA-peptides was investigated in female athymic BALB/c mice. Subcutaneous tumors were induced by inoculation with CCK2R expressing AR42J cells (rat tumor of the exocrine pancreas). Cells were cultured in DMEM with 4500 mg/L D-glucose (Gibco, Invitrogen, Breda, The Netherlands), supplemented with 10% FCS and 1% penicillin/streptomycin. Mice were inoculated s.c. with 4 × 10^6 AR42J cells (200 μL) in the left flank. When tumors had reached a weight of 0.2 g, mice were divided in groups of 5 mice each and 370 kBq ^{111}In-DOTA-peptide (0.1 μg) was injected intravenously. Specificity was studied in groups (n = 5) which received a 1000-fold molar excess of unlabeled sCCK8. Mice were killed 2 h postinjection (p.i.), a blood sample was drawn, and tissues of interest were dissected, weighed, and counted in a gamma-counter along with a standard of the injected activity to allow calculation of the injected dose per gram tissue (% ID/g). Animal experiments

Scheme 1. Synthesis Route of Fmoc-Phe(p-CH_2SO_3H)-OH

were approved by the local animal welfare committee and carried out according to national regulations.

Statistical Analysis. All mean values are expressed as mean ± standard deviation (SD). Statistical analysis was performed using one-way analysis of variance using *GraphPad InStat* software (version 3.10, Graphpad software). The level of significance was set at $p < 0.05$.

RESULTS

Synthesis of Phe(p-CH_2SO_3H) and Peptides. Since sulfonate building blocks are not commercially available, Fmoc-Phe(*p*-CH_2SO_3H)-OH was synthesized starting from L-tyrosine, by modification of known routes (Scheme 1). First, the amino group and the acid functionality were protected by a Boc- and a methyl group, respectively. The hydroxy group of **1** was activated by triflation using phenyltriflimide and DIPEA, giving the triflate **2** in 79% yield (*14*). The next step, a Stille vinylation (*14, 18*), was performed under strictly dry conditions and required careful workup and rapid purification to obtain the vinylated product **3**. Ozonolysis and reduction of the vinyl compound was performed immediately to obtain the hydroxymethylated compound **4** (*15, 18*). The chloromethyl derivative **5**, obtained from alcohol **4** by treatment with thionyl chloride, was converted into the sulfonate **6** by refluxing in water in the presence of a large excess of Na_2SO_3 (*9*). NMR spectra showed that the methyl group was concomitantly removed in this reaction, thereby obviating a separate deprotection step. The final step in the synthesis of the sulfonate building block was Fmoc-protection of the amine under basic conditions (*16*). The overall yield of the synthesis starting from L-tyrosine was 9% (*19*).

Having the phenylalanine sulfonate building block **7** at hand, we investigated the synthesis of sCCK8 analogues by solid-phase peptide synthesis. Initial application of standard coupling conditions (HOBt, DIPCDI) to Fmoc-Phe(*p*-CH_2SO_3H)-OH failed to afford incorporation of Phe(*p*-CH_2SO_3H)-OH in the peptide. Fortunately, switching of reagents to HBTU and DIPEA led to the desired octapeptide uneventfully. To obtain other more stable sCCK8 peptide analogues not susceptible to oxidation, methionine residues were replaced by either norleucine (Nle) or homopropargylglycine (HPG) residues. After incorporation of the final amino acid, the macrocyclic chelator DOTA was coupled on the resin as tri-*tert*-butyl protected derivative. The latter coupling reaction was found to proceed optimally under the action of HBTU and DIPEA. After cleavage from the resin with TFA/H_2O (92.5/2.5, v/v) in the presence of ethanedithiol (EDT) and triisopropyl silane (TIS), with simultaneous protective group removal, the peptides were purified by RP-HPLC. Molecular structures of the peptides are depicted in Figure 1.

Partition Coefficient. For ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H] and ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,Nle^{3,6}], the log P values were -2.97 ± 0.02 and -2.93 ± 0.13, respectively. The log P value for ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,HPG^{3,6}] was -2.86 ± 0.14. These values were comparable to that of the lead compound, ^{111}In-DOTA-sCCK8: -2.91 ± 0.20. All compounds were relatively hydrophilic, and the molecular changes did not affect the hydrophilicity of the peptide significantly.

Oxidation Experiments. After 10 min incubation in oxidation buffer (containing hydrogen peroxide and acetic acid), about 66% of the ^{111}In-labeled DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Met^{3,6}] was oxidized, as judged by RP-HPLC. Both ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H),Nle^{3,6}] and ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,HPG^{3,6}] did not show any oxidation.

Stability Experiments. In vivo, the peptide analogues should remain intact long enough to target the gastrin/CCK2 receptors. After 4 h incubation in human serum at 37 °C, peptides remained intact. Of the ^{111}In-labeled DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Met^{3,6}] 2.3% was oxidized after incubation in the serum.

Internalization Experiments. Internalization of the peptides by HEK293-CCK2R cells was investigated in vitro. After 2 h incubation at 37 °C, 35.2 ± 2.1% of the added ^{111}In-DOTA-sCCK8 was internalized by the cells, most of it during the first 30 min (Figure 2). Receptor bound fraction after 2 h was 11.6 ± 0.7%. Of both ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H)] and ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,HPG^{3,6}], about 13% of the added radiolabeled compound was internalized by the CCK2R after 2 h at 37 °C, while 10−12% was still receptor-bound. The internalized fraction of ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,Nle^{3,6}] after 2 h was 26.8 ± 1.4% with a receptor-bound fraction of 9.4 ± 0.6% (Figure 2). Internalization kinetics of ^{111}In-DOTA-sCCK8 and ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,Nle^{3,6}] showed to be similar, although the percentage of internalized fraction was about 7% lower for the synthetic peptide ($P < 0.05$). Similar data were found using AR42J cells (data not shown).

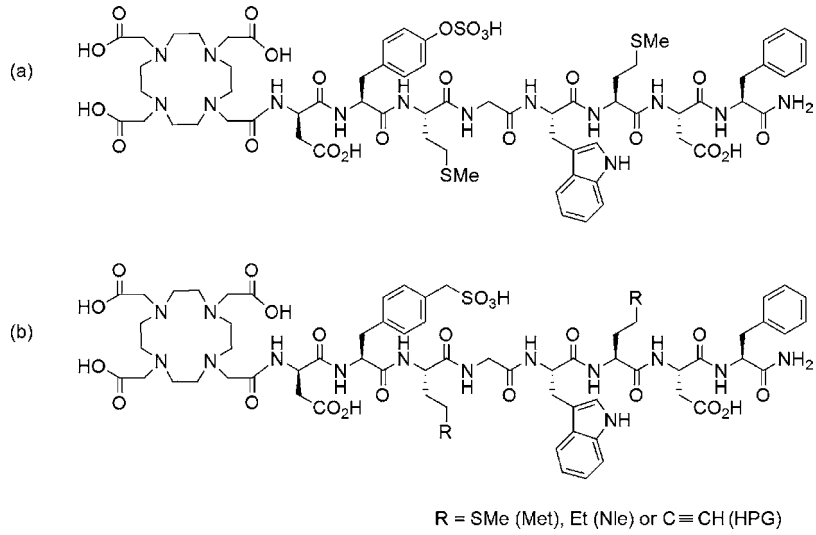


Figure 1. Molecular structures of (a) DOTA-sCCK8 and (b) synthetic DOTA-peptides.

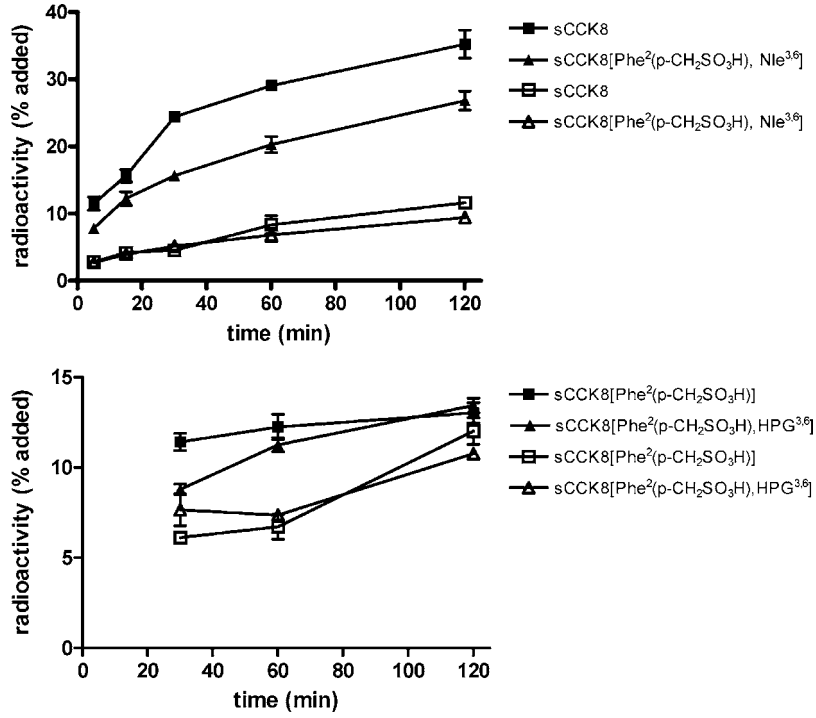

Figure 2. Internalization and receptor bound fractions in HEK293-CCK2R cells. Closed symbols indicate internalized fraction and open symbols indicate receptor-bound fraction. Values are expressed as percentage of the total amount added.

Determination of IC_{50} Values. The apparent IC_{50} values for binding CCK2R were determined for all peptides, using HEK293-CCK2R cells in a solid-phase competitive binding assay (Figure 3). All peptides showed an IC_{50} in the low nanomolar range, although the apparent IC_{50} values of the three synthesized peptides were approximately 10-fold higher than that of the lead compound. The apparent IC_{50} value for sCCK8 was 1.16 ± 0.06 nM, for DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H)] 27.2 ± 1.44 nM, for DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] 11.6 ± 1.06 nM, and for DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), HPG^{3,6}] 13.2 ± 1.12 nM.

Biodistribution. The potential of the radiolabeled DOTA-peptides for in vivo targeting of CCK2R expressing tumors was investigated in athymic mice with AR42J tumors. The biodistribution 2 h p.i. for each of the four ^{111}In-labeled peptides is summarized in Figure 4.

Tumor uptake of ^{111}In-DOTA-sCCK8 and ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,Nle^{3,6}] were comparable (4.78 ± 0.64 and 4.54 ± 1.15% ID/g, respectively). The radioactivity concentration of these peptides in the tumor was the highest of all tissues studied ($P < 0.001$). For both other compounds, the tumor uptake was significantly lower (2.18 ± 0.18% ID/g for ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H], $P < 0.001$) and 1.92 ± 0.31% ID/g for ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H,HPG^{3,6}], $P < 0.001$), and pancreatic concentration for these peptides was at the same level as the concentration in the tumor. Tumor uptake of all compounds could be blocked by coinjection of an excess of unlabeled sCCK8, indicating receptor-mediated uptake. For all compounds tested, the uptake in the normal tissues, such as the blood, lungs, muscle, spleen, and small intestine was low. Specific uptake was also found in the pancreas and, to a lesser extent, in the stomach. Most likely, this is due to relatively high CCK2R

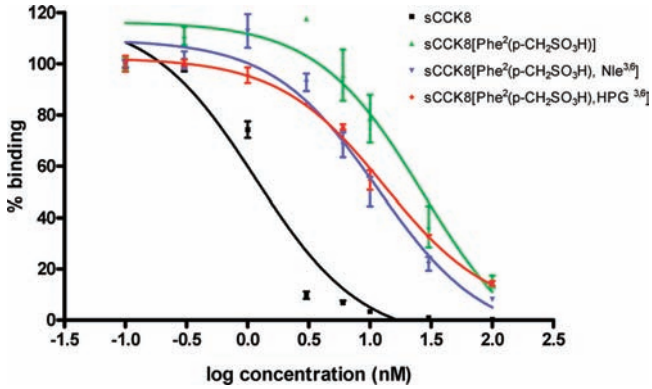

Figure 3. Competition binding analyses (IC_{50}) of four peptides using HEK293-CCK2R cells.

expression in murine pancreatic tissue en stomach. Kidney uptake of all peptides was low (<1.5% ID/g).

DISCUSSION

In earlier studies, we as well as others have shown that radiolabeled CCK8 peptide analogues show promise for peptide receptor radionuclide targeting of small cell lung cancers and medullary thyroid carcinomas (*4, 5, 8, 12*). In particular, sCCK8 was found to possess better CCK-receptor targeting behavior (*4*). An important drawback of the peptides used to date, however, is the intrinsic hydrolytic instability of the tyrosine sulfate ester. Moreover, since CCK8 contains two methionine residues, radiolabeling inevitably leads to varying amounts of thioether oxidation, which negates the binding affinity of the peptide to CCKR. Having these drawbacks in mind, we aimed for sCCK8 peptide analogues with improved stability as compared to the lead compound sCCK8. This study describes the characterization of three DOTA-conjugated analogues of the sCCK8 peptide.

A promising method to avoid the instability of the sulfate ester is the replacement of the sulfated tyrosine by a phenylalanine sulfonate isostere, featuring a covalent C−S bond that is fully resistant to water. However, lack of commercial availability of such an unnatural amino acid necessitated a suitable synthetic preparation.

Synthesis started with a tyrosine triflate derivative (**2**), which is readily available from the corresponding protected tyrosine **1** by reaction with phenyl triflimide. For the synthesis of the hydroxymethylphenylalanines, we investigated different routes: the palladium-catalyzed coupling of the tyrosine triflate with *tert*-butyl acrylate (Heck reaction) and the coupling of the tyrosine triflate to vinyltributylstannane in the presence of metallic palladium and lithium chloride (Stille reaction), leading to styrene derivative **3**. The latter reaction was found to give the best results, which is similar to the published data (*14, 18*). Both Tilley et al. and the group of Larsen described this reaction with slightly different tyrosine derivatives and they could obtain the allylated compounds in good yields (65−82%) after purification (*14, 18*). We found that careful workup and immediate ozonolysis and reduction were essential to obtain the hydroxymethylated product **4** in acceptable yields. We also attempted to follow the four-step synthesis route described by Miranda et al. (*16*), but the chloromethylation of phenylalanine, the first step in this route, also failed to succeed in our hands, as reported earlier (*19*). In addition, a third attempt involved synthesis of the hydroxymethylphenylalanine directly by a Stille reaction with (tributylstannyl)methanol (*20*). Several palladium complexes and solvents were investigated, but the desired compound could not be produced.

The chloromethyl derivative **5** was obtained from the alcohol **4** by treatment with thionyl chloride. We found that during this

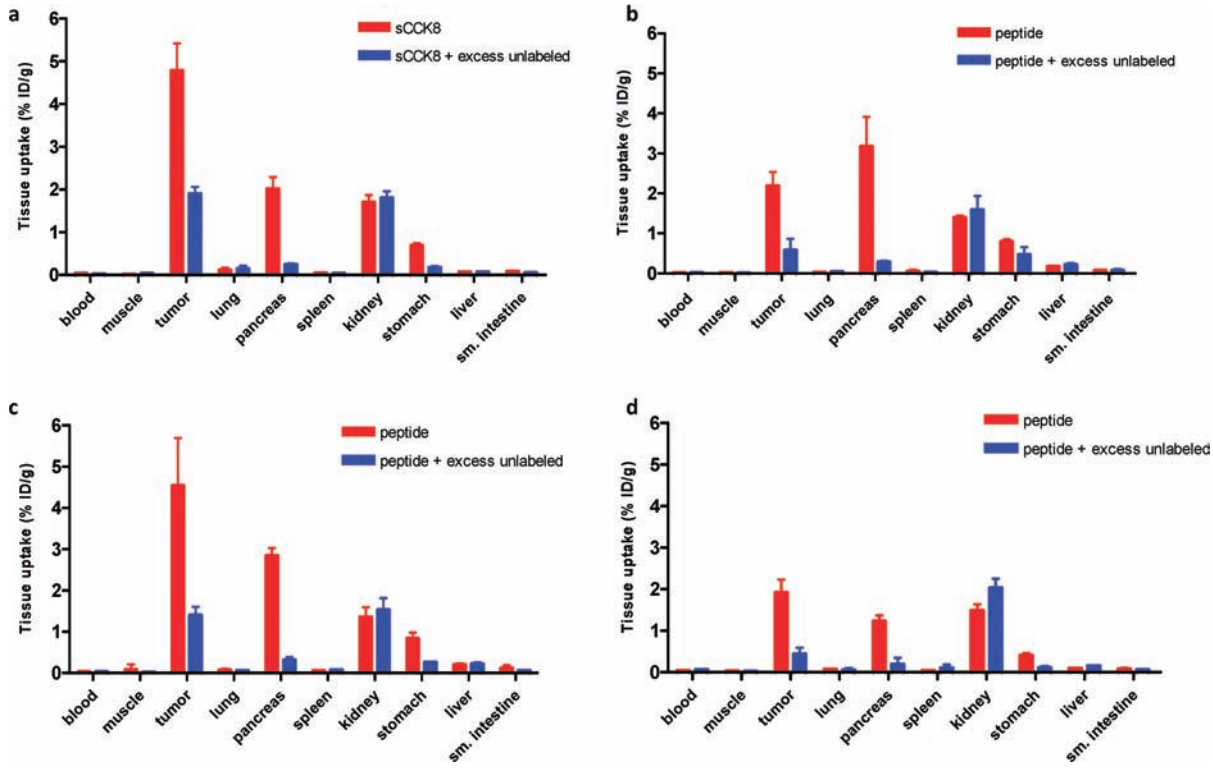

Figure 4. Biodistribution of (a) DOTA-sCCK8, (b) DOTA-sCCK8[Phe^2(p-CH_2SO_3H)], (c) DOTA-sCCK8[Phe^2(p-CH_2SO_3H), $Nle^{3,6}$], and (d) DOTA-sCCK8[Phe^2(p-CH_2SO_3H), $HPG^{3,6}$] in athymic mice bearing CCK2R expressing tumors in the left flank. Values are expressed as percentage of the injected dose per gram tissue ($n = 5$ mice/group). Blocking was performed by coinjection of a 1000-fold molar excess of unlabeled sCCK8. Mice were dissected at 2 h p.i.

reaction the Boc-protective group was conveniently removed as well, probably due to the formation of HCl in this reaction. The next step, conversion to the sulfonate **6**, was also accompanied by an unintended but useful side reaction, i.e., hydrolysis of the methyl ester, thereby saving another deprotection step. On the basis of the whole sequence, it can be concluded that a practical, multigram-scale procedure has been developed in only 8 steps starting from L-tyrosine, leading to the final Fmoc-protected sulfonate building block **7** in an acceptable yield (9%).

The Fmoc-Phe(*p*-CH_2SO_3H)-OH building block was smoothly incorporated in the peptide sequence on solid phase, but required replacement of the typical DIPCDI/HOBt mixture with HBTU and DIPEA as coupling reagents. Three peptides were synthesized with the sulfonate building block, differing in the presence of Met, Nle, or HPG residues on both positions 3 and 6. Finally, all peptides were N-terminally conjugated with the macrocyclic chelator DOTA, also requiring HBTU/DIPEA for activation.

Receptor binding studies and internalization studies were performed on HEK293 cells stably expressing the CCK2 receptor. Substituting the tyrosine sulfate by its phenylalanine isostere resulted in sCCK8 analogues with apparent affinities for the CCK2 receptor in the low nanomolar range. When the Met residues were replaced by Nle residues, a more stable peptide was obtained with comparable tumor uptake in CCK2R positive tumors. Reubi et al. also found that replacement of methionine by norleucine in a DTPA-conjugated nonsulfated CCK8-peptide does not affect the binding affinity for the CCK2 receptor, but increases the plasma stability of the compound (*12*). In contrast, Mather et al. found that substitution of the methionine residue with norleucine in gastrin peptide analogues lowered both in vitro binding affinity and tumor uptake in vivo. As Mather synthesized gastrin analogues and not CCK8 analogues, these peptides may be affected differently by substitution of methionine by norleucine. This difference may also be due to the two additional histidines on the N-terminus (*9*). The group of Aloj synthesized and evaluated a series of cyclic sCCK8 peptide analogues, in which the tyrosine sulfate and both methionines were preserved. They found that cyclization of the peptides caused a 1000-fold decrease in affinity for both the CCK1 and CCK2 receptor (*21, 22*).

Homopropargylglycine has not earlier been applied in tumor-targeting peptides, but has been generally shown to be a suitable and stable substitute for methionine (*13*). We found that replacement of methionine by homopropargylglycine caused reduction of CCK2R affinity resulting in reduced uptake of the radiolabeled peptide in the AR42J tumor.

The CCK2 receptor belongs to the family of G-protein-coupled receptors. When gastrin or CCK8 binds to the receptor, the complex is internalized, after which the receptor can be recycled or metabolized. After binding and internalization of ^{111}In-labeled peptides, the radiometal is retained intracellularly in the lysozomes. The peptides in this study all showed time-dependent internalization. About 27% of ^{111}In-DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] was internalized after 2 h, where ^{111}In-DOTA-sCCK8 showed 35% internalization ($P < 0.05$).

The peptides in this study showed very low kidney retention (1.5% ID/g, 2 h p.i.) and display also low uptake in the main peripheral tissue. This is in contrast with ^{111}In-labeled minigastrin analogues, which display a very high kidney uptake, 40−60% ID/g (*5*). Derivatives of minigastrin, lacking the pentaglutamate sequence, showed a comparably low kidney uptake compared to CCK8 analogues (*23*). Low kidney and peripheral tissue retention are prerequisites for receptor-targeted imaging and therapeutic agents. The observed specific uptake in the pancreas can be explained by the fact that in rodents the pancreas expresses the CCK-receptor, whereas in human pancreatic tissue, the CCK2 receptor is not expressed. Therefore, in a clinical setting, pancreatic uptake of radiolabeled sCCK8 analogues is not expected.

In summary, DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}] is a peptide with receptor affinity and tumor uptake comparable to sCCK8, but with an increased stability and therefore is a promising peptide for use in PRRT.

CONCLUSION

A successful synthetic route was developed to a tyrosine isostere that is not susceptible to hydrolysis of the sulfate ester linkage and therefore is a valuable building block for the preparation of medicinally relevant peptides. A series of radiolabeled sCCK8 analogues with increased stability over the natural peptide was successfully synthesized by solid-phase peptide synthesis. The peptide with methionine residues replaced by norleucine (DOTA-sCCK8[Phe^2(*p*-CH_2SO_3H), Nle^{3,6}]) showed promising characteristics for CCK2R targeting and will be further investigated for its potency in imaging and therapy.

In Situ Growth of Side-Chain PEG Polymers from Functionalized Human Growth Hormone—A New Technique for Preparation of Enhanced Protein−Polymer Conjugates

Johannes Pall Magnusson,[†] Sara Bersani,[‡] Stefano Salmaso,[‡] Cameron Alexander,[†] and Paolo Caliceti*,[‡]

School of Pharmacy, University of Nottingham, University Park, Nottingham NG7 2RD, United Kingdom, and Department of Pharmaceutical Sciences, University of Padua - Via F. Marzolo 5, 35131, Padova, Italy. Received October 29, 2009; Revised Manuscript Received February 12, 2010

The application of atom transfer radical polymerization (ATRP) for preparation of a novel class of protein−polymer bioconjugates is described, exemplified by the synthesis of a recombinant human growth hormone (rh-GH) poly(ethylene glycol) methyl ether methacrylate (PEGMA) hybrid. The rh-GH protein was activated via a bromoester functionalized linker and used as a macroinitiator to polymerize the hydrophilic monomer PEGMA under solely aqueous conditions at 4 °C. ATRP conditions resulted in controlled polymer growth from rh-GH with low-polydispersity polyPEGMA chains. The rh-GH PEGMA product exhibited properties consistent with the presence of attached hydrophilic polymer chains, namely, high stability to denaturation and proteolysis. The polymerization conditions and conjugation proceeded with retention of the biological activity of the hormone. The rh-GH PEGMA was administered subcutaneously to rats and the activity compared to native rh-GH. The rh-GH PEGMA exhibited similar activity as the native rh-GH in vivo when a daily dose of 40 μg was administered. However, when a higher dose of 120 μg was administered with 3 days between injections the bioavailability of the rh-GH PEGMA was significantly better than that of the native. The results therefore demonstrate that ATRP can be successfully used as a general alternative approach to direct polymer conjugation, namely, PEGylation, to produce PEG-like protein conjugates. This technique can be exploited to design and synthesize protein−polymer derivatives with tailored therapeutic properties.

INTRODUCTION

Proteins are of increasing interest in medicine (*1–3*) and the emerging field of bionanotechnology (*4, 5*). Advances in recombinant DNA techniques have made possible the production of therapeutic proteins in large quantities (*6*). However, the potential for applying proteins in clinical and technological settings has been limited since they are prone to denaturation and aggregation in vitro (*7*), while in vivo, proteins administered by standard routes exhibit poor pharmacokinetic properties (*8*). In efforts to circumvent these problems, proteins have been selectively modified by tailoring their amino acid sequences (*9, 10*) and/or by attachment of polymer chains (*11–13*). Of the latter, the attachment of poly(ethylene glycol) (PEG) polymers (PEGylation) has been most extensively studied (*14*) and has already created numerous successful products for the clinic (*15*). Attached PEG enhances the stability of the protein, increases the hydrodynamic volume, and makes the surface less accessible to proteases and the immune system (*16*). This leads to better retention times in the body and improved bioavailability (*17*). However, PEGylation is not without certain limitations. PEG is difficult to modify after conjugation to a protein—for example, when a cell-targeting ligand or a fluorophore is needed—and the purification of unreacted PEG from a protein polymer mixture can be highly problematic. The alternative option to attaching a preformed polymer to a protein is to grow a polymer from a protein such that no free polymer in solution is formed. The benefits of the "growing from" approach are not limited to ease of purification and addition of targeting ligands or other chemical moieties, physicochemical or biological modifiers, after growth of polymer from the protein. If the polymerization can be controlled, a wide variety of bioconjugates with potentially "tunable" activity can be prepared from a single protein precursor: these might include block copolymers wherein different segments of the polymer chain confer specific properties such as response to pH or other microenvironmental stimuli, tightly defined hydrophilic/hydrophobic character, membrane insertion, cell recognition properties, or resistance to proteases. However, the chemical strategies needed to grow PEG and related substituted oxiranes from a protein in a controllable manner, such as living anionic polymerization, are not compatible with retaining protein structure and activity.

In recent years, controlled radical polymerization techniques (*18–21*) have enabled the growth of polymers with highly defined molar masses and functional group content from a wide variety of commercially available monomers. Methacrylate monomers with oligo(ethylene glycol) side chains can be prepared using these routes to form comb polymer analogues of PEG. As a consequence, there is now considerable interest in evaluating whether these polymers might replace PEG in biomedical settings. One such possibility is to generate polymer−protein conjugates by growing PEG-analogue polymers such as PEGmethacrylate (PEGMA) from proteins functionalized with a polymerization-initiating site. A number of recent papers have demonstrated the feasibility of using proteins as macroinitiators from which to grow polymers (*22, 23*). To date, while there have been recent reports of postpolymerization attachment of poly(PEGmethacrylates) [polyPEGMA)] to peptides and proteins (*24–28*), reports of growing these polymers directly from proteins have been quite scarce (*23, 29*).

Here, we describe the synthesis of a poly(PEGMA) conjugate of recombinant human growth hormone (rh-GH) by controlled radical polymerization from an initiator-functionalized rh-GH

precursor. We chose rh-GH as the protein model because the native protein is the drug of choice for treatment of growth deficiency and PEGylated GH forms have been developed either by nonspecific or, recently, by selective polymer conjugation (*30–32*). We activated rh-GH by a lysine reactive linker, and then, poly(PEGMA) was grown from the protein under solely aqueous conditions at low temperature. The rh-GH polymer hybrid was characterized and tested in an in vivo model and was found to exhibit increased activity in comparison to the native protein. The combination of mild conditions for bioconjugation and polymer synthesis makes this technique favorable as a generic approach for the modification of biomacromolecules. In addition, the good biocompatibility profile of poly(PEGMA) (*33*), the enhanced stability of the rh-GH bioconjugate, and the desire to reduce the daily injection profile currently adopted for rh-GH in the clinic suggest that the conjugate is promising for therapeutic applications.

MATERIALS AND METHODS

Materials. The recombinant human growth hormone (rh-GH) was a kind gift of Bio-Ker srl (Pula, Italy). α-Br-isobutyryl bromide (98%), copper(II) bromide ($CuBr_2$, 99%), L-ascorbic acid (99%), and triethylamine (Et_3N, 99.5%) were used as received from Sigma Aldrich (St. Louis, MO, USA). Poly(ethylene glycol) methyl ether methacrylate (PEGMA, M_n 475) was purchased from Sigma Aldrich and purified before use by passing through a column filled with neutral alumina. Water used for the polymerizations was of ELGA grade. Tris(2-pyridyl) methylamine (TPMA) was prepared as described elsewhere (*34*). Dialysis membrane (MWCO 6−8000, regenerated cellulose) was used as received from Spectrapor (Tempe, AZ, USA). All solvents and reagents were of analytical or HPLC grade and purchased from Sigma or Fisher Scientific (Loughborough, UK) unless otherwise stated. Deuterated solvents were obtained from Sigma. Tetra(ethylene glycol) (TEG, 99%) was dried via three cycles of distillation with anhydrous toluene.

Animals. Four-week-old hypophysectomized female Sprague−Dawley rats, weighing 70−80 g, were obtained from Charles River (Como, Italy). Animal care and handling were performed in accordance with the provisions of the European Economic Community Council Directive 86/209 (recognized and adopted by the Italian Government with the approval decree D.M. No. 230/95-B) and the NIH publication no. 85−23, revised in 1985.

Initiator Synthesis. *Compound* **1***: 2-[2-[2-(2-Hydroxyethoxy-)ethoxy]ethoxy]-ethyl-α-bromo-2-isobutyrate (HO-TEG-Br).* Anhydrous tetra(ethylene glycol) (TEG, 100 g, 0.51 mol) and triethylamine (Et_3N, 5.7 g, 0.05 mol) were dissolved in 100 mL of tetrahydrofuran (THF), and the mixture was placed in an ice bath. α-Br-isobutyryl bromide (11.9 g, 0.05 mol) was added dropwise to the mixture under vigorous stirring. The reaction was left for 1 h in the ice bath and at room temperature for 16 h. The mixture was filtered and the THF was removed under vacuum; the remaining oily residue was dissolved in 150 mL of water and extracted twice with 150 mL of dichloromethane. The organic solution was dried by addition of anhydrous Na_2SO_4 and filtered. The solvent was removed under vacuum and the resultant oily residue was purified by silica chromatography using 10:90 methanol:diethyl ether as eluent to give HO-TEG-Br (compound **1**, Figure 1). The synthesis resulted in HO-TEG-Br as a pale yellow oil in 80% yield. The purity and the product identity were verified by high-resolution mass spectrometry (HRMS) and NMR spectroscopy. HRMS spectra were recorded on an ESI-TOF Waters 2795 separation module/micromass LCT platform.^{1}H and ^{13}C NMR spectra (Supporting Information, Figures S1 and S2) were recorded on a Bruker 400 spectrometer at 399.8 MHz (^{1}H) and 100.5 MHz (^{13}C) in chloroform-*d*. Chemical shifts are reported in ppm relative to TMS.

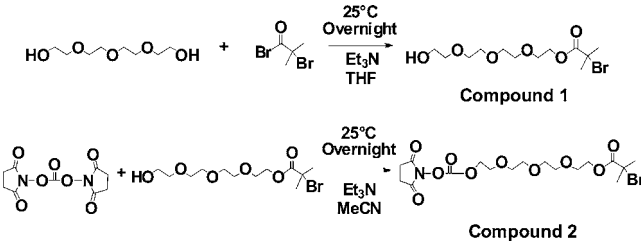

Figure 1. Synthesis of a TEG-based amine-reactive ATRP initiator.

HRMS: calcd for (M^+) 342.0678 and (M+Na) 365.0576; found (M+Na^+) 364.8483. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 4.32 (m, 2H), 3.76−3.51 (m, 14H), 2.66 (s, 1H), 1.92 (m, 6H). ^{13}C NMR ($CDCl_3$): δ 171.57, 72.49, 70.63, 70.56, 70.33, 68.73, 65.09, 61.67, 55.72, 30.53. The NMR spectra are reported in the Supporting Information.

Compound **2***: 1-(2,5-Dioxopyrrolidin-1-yloxy)-1-oxo-2,5,8,11-tetraoxatridecan-13-yl-α-bromo-2-isobutyrrate (succinimidyl-TEG-Br).* Anhydrous HO-TEG-Br (2.45 g, 7.1 mmol) was dissolved in 5 mL of acetonitrile (MeCN). *N*,*N*′-Disuccinimidyl carbonate (DSC, 2.16 g, 8.5 mmol) and Et_3N (0.87 g, 8.5 mmol) were added. The reaction mixture was left at room temperature for 16 h. The MeCN was evaporated and the oily residue dissolved in chloroform and washed 3 times with an equivalent amount of water. The final organic solution was dried by addition of anhydrous Na_2SO_4 and filtered. The chloroform was evaporated and the oily residue purified by silica chromatography as reported above to give succinimidyl-TEG-Br (compound **2,** Figure 1) as a yellow oil in 70% yield. The purity and the product identity were verified by high-resolution mass spectrometry (HRMS) and nuclear magnetic resonance. The ^{1}H and ^{13}C NMR spectra (Supporting Information, Figure S3 and S4) were recorded as reported above.

HRMS: calcd for (M^+): 483.0740 and (M+Na^+) 506.0638; found (M+Na^+) 506.0536. (Note, presence of (M+H_2O) peak at 503.1014 indicated NHS-hydroxylation under MS conditions.) ^{1}H NMR ($CDCl_3$, 400 MHz): δ 4.48−4.46 (m, 2H), 4.36−4.33 (m, 2H), 3.85−3.67 (m, 12H), 2.85 (s, 4H), 1.96 (m, 6H). ^{13}C NMR ($CDCl_3$): δ 171.60, 168.59, 151.62, 70.87, 70.69, 70.62, 70.59, 70.21, 68.71, 68.32, 65.15, 55.81, 30.74, 25.54.

Conjugation of Initiator to rh-GH. Recombinant human growth hormone (rh-GH, 90 mg, 0.004 mmol) was dissolved in 40 mL of 1 mM phosphate buffer, 0.15 M NaCl, pH 7.5. Succinimidyl-TEG-Br (100 mg, 0.20 mmol) was dissolved in 1 mL of DMSO and added dropwise; the reaction was left for 90 min at room temperature. The mixture was dialyzed for 3 days at 4 °C, and then lyophilized to yield the rh-GH-TEG-Br conjugate (macroinitiator) (90 mg) as a powdery solid.

MALDI-TOF. MALDI-TOF (Matrix-assisted laser desorption/ionization (time-of-flight)) analysis was carried out on a Bruker MALDI TOF Ultraflex II machine. Briefly, an aqueous solution of the conjugate (1.0 mg/mL) was mixed with an equal volume of matrix material (8 mg sinapic acid, 0.5 mL water and 0.5 mL MeCN). An aliquot (2 μL) of the resulting mixture was spotted onto a plate target and allowed to dry. The level of conjugation was determined by comparing the molar mass of the conjugate to the native protein.

Polymer Growth from rh-GH. The macroiniator rh-GH-TEG-Br (30 mg, 0.0014 mmol) was dissolved in 4.5 mL of 1 mM phosphate buffer, 0.15 M NaCl, pH 8.0. PEGMA 475 (475 mg, 1 mmol), $CuBr_2$ (11.2 mg, 0.05 mmol), and TPMA (14.5 mg, 0.05 mmol) were added to the protein solution. The mixture was placed in an ice bath at 4 °C and bubbled through with argon. After 15 min, ascorbic acid (1.32 mg, 0.0075 mmol) was added to initiate polymerization. The reaction was stopped after 16 h, and the free monomers, copper, and ligand were removed

by dialysis, which was carried out for 3 days at 4 °C in 4 mM EDTA. The protein solution was then dialyzed against water, frozen with liquid nitrogen, and lyophilized. Two hundred milligrams of product (rh-GH-PEGMA) was collected.

SDS PAGE. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was carried out at 100 mV using 8% acrylamide gel prepared by the standard method and visualized by Coomassie staining (*35*). The gels were additionally stained for PEG by Iodine (*36*).

Circular Dichroism Analysis. Circular dichroism (CD) spectra were recorded in the far UV region (195−250 nm) using rh-GH solutions (0.1 mg/mL, 4.5 μM) or an equimolar quantity of rh-GH-PEGMA in 20 mM phosphate buffer, 0.15 M NaCl, pH 7.2. A J-810 Jasco spectrodichrograph (Tokyo, Japan) instrument was used.

Protein and PEG Content in the rh-GH-PEGMA Conjugate. Protein concentrations of the native and the rh-GH-PEGMA were evaluated spectrophotometrically using the calculated molar coefficient extinction at 280 nm of rh-GH ($\varepsilon = 16\,170\ M^{-1}\ cm^{-1}$). The concentration was also confirmed by BCA Protein Assay (Pierce, Rockford IL, USA) (*32*) using native rh-GH solutions as standard for the calibration curve [Abs = 0.7926 (Protein conc, mg/mL) + 0.0317, $R^2 = 0.9997$]. PEG [poly(ethylene glycol)] content in the rh-PEGMA solution was determined by an iodine assay (*33*) using a calibration curve obtained by plotting the absorbance at 535 nm against PEG concentration in the range 2−5 μg/mL, [Abs = 0.0664 (PEG conc, μg/mL) + 0.001, $R^2 = 0.99$].

The polymer/protein molar ratio in the rh-GH-PEGMA derivative was spectrophotometrically evaluated by a trinitrobenzensulfonic acid (TNBS) colorimetric method (*37*).

Molar Mass Analysis. Polymers were cleaved from protein specifically by adopting a method from Jaquemard et al. (*38*). The protein−polymer hybrid (10 mg), anhydrous THF (10 mL), and tetra-*n*-butylammonium fluoride (TBAF, 100 μL) were placed in a round-bottom flask with a condenser, and the mixture was refluxed for 6 h. The THF was evaporated and the polymer extracted into DMF and analyzed by gel permeation chromatography (GPC).

Molar masses and molar mass distributions of the polymer species were determined using a Varian Laboratories GPC-50 instrument with triple detection (RI, viscometry and MALLS). Chromatograms were run at 50 °C using dimethylformamide (DMF) as eluent with a flow rate of 1 mL/min. The columns used were Polargel L; detection was performed by a Refractive Index detector (RI). The GPC was calibrated with linear PMMA (poly(methyl methacrylate)) standards.

High-Performance Liquid Chromatography Analysis. Size-exclusion analyses (SEC-HPLC) were run on a Shimadzu LC-10AS pump with the SPD-10A detector set at 214 nm. The system was equipped with a Bio-Gel SEC 40-XL column (5 μm, 300 × 7.8 mm; BioRad, Milan, Italy) and isocratically eluted with 63 mM phosphate buffer, 3% isopropanol, pH 7.0, at a flow rate of 0.6 mL/min.

Stability Studies. Stability studies were performed by incubation of rh-GH (1 mg/mL) or equimolar rh-GH-PEGMA solutions in 20 mM phosphate buffer, 0.15 M NaCl, pH 7.4, at 37 °C. Parallel samples were incubated at 37 °C under magnetic stirring in order to simulate stress conditions. At scheduled times, aliquots (50 μL) were taken and diluted with buffer (50 μL), centrifuged at 5000 rpm for 5 min, and analyzed by SEC-HPLC as reported above. The area under the curve corresponding to native or rh-GH-PEGMA bioconjugate was compared with standard titration curves obtained with the rh-GH and rh-GH-PEGMA, to evaluate the remaining protein content in the PBS solution.

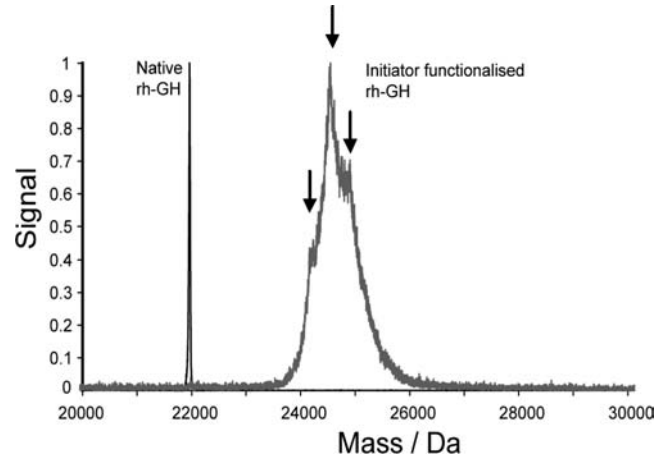

Figure 2. MALDI-TOF analysis: native rh-GH and α-Br isobutyryl-tetra(ethylene glycol)-functionalized rh-GH conjugate (initiator functionalized rh-GH). The arrows indicate the rh-GH forms functionalized with 6, 7, and 8 α-Br isobutyryl-tetra(ethylene glycol) moieties.

Pepsin Proteolysis. Native rh-GH (400 μg) or equimolar amounts of rh-GH-PEGMA were dissolved in 2 mL of 0.01 M HCl and added to 1 mL of 25 μg/mL pepsin solution in 0.01 M HCl (25:1 rh-GH/pepsin molar ratio). The solutions were maintained at 25 °C. At scheduled times (0, 15, 30, 60, 90, 120 min), samples (250 μL) were removed and analyzed by the TNBS assay to determine the protein amino groups released by protein hydrolysis. The degradation degree was calculated on the basis of the optical density values obtained at the experimental time points, which were referred to the maximal optical density obtained with the native protein (100%) achieved as a plateau after 9 h incubation with the proteolytic enzyme.

In Vivo Activity. Forty hypophysectomized female Sprague Dowley rats weighing 70−80 g were randomly divided into five groups of eight animals. Animals of Group A were treated on days 0, 1, 2, 3, 4, and 5 by subcutaneous injection of a physiological solution (200 μL); animals of Groups B and C were treated on days 0, 1, 2, 3, 4, and 5 by subcutaneous injection of native rh-GH (40 μg) or equimolar of rh-GH-PEGMA in physiological solutions (200 μL), respectively; animals of Groups D and E were subcutaneously injected at days 0 and 3 with native rh-GH (120 μg) or equimolar of rh-GH-PEGMA in physiological solutions (200 μL), respectively. The animals were weighed daily, and the weight increase was recorded. The activity of the hormone was estimated by changes in the body mass of the animals as described previously by Clark et al. (*32*).

RESULTS

rh-GH-PEGMA Preparation. The synthetic strategy adopted to prepare compound **1** (Figure 1) employed a large excess of tetraethylene glycol to favor its monoacylation. Silica chromatography yielded compound **1** in high purity and good yield (80%). Compound **1** was reacted subsequently at the free hydroxyl terminus to generate compound **2** as a heterobifunctional spacer with an amine-reactive component at one end and an ATRP initiating site at the opposite end. The yield of product **2** following purification was 70%.

The ATRP initiator linker (compound **2**) was reacted with rh-GH at pH 7.5 in order to ensure conjugation at the terminal amine and lysine residues (*39*). Modification of the all accessible amino groups was achieved by using a large excess of compound **2** compared to rh-GH.

MALDI-TOF spectra of the native rh-GH and the conjugated protein reported in Figure 2 revealed that the linker conjugation yielded three main species corresponding to conjugates bearing

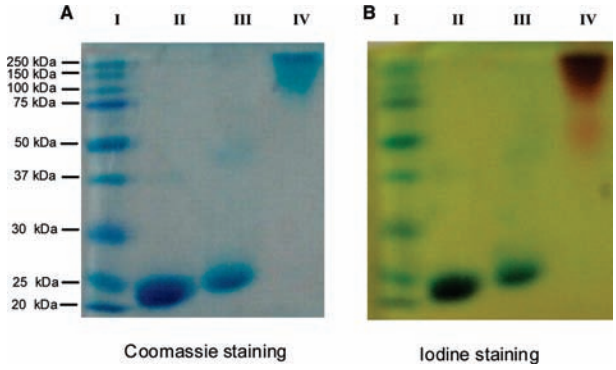

Figure 3. SDS PAGE stained with Coomassie blue (A) and iodine (B): Lane I, protein marker; Lane II, native rh-GH; Lane III, initiator functionalized rh-GH; Lane IV, rh-GH-PEGMA.

6, 7, and 8 tetra(ethylene glycol)-α-Br-isobutyryl functions (mol wt 24 130, 24 485, and 24 840 Da, respectively). This result indicates that the majority of the 10 protein amino groups (9 Lys and 1 amino terminal Phe) were modified. The species with 7 initiator-modified moieties was predominant. After PEGMA polymerization, the TNBS analysis gave a mean of 9 modified amino residues per protein, corresponding to 90% of available amino groups. The higher value for the colorimetric assay was most likely due to the fact that the assay is dependent on the accessibility of TNBS to the amines, which results in an overestimation of the number of modified amines in the conjugate compared to the native protein (*40*). Therefore, it is more likely that the MALDI TOF results gave a better indication of the degree of conjugation of the initiator and the polymer to rh-GH.

SDS PAGE analysis of the native rh-GH (Lane II), initiator-functionalized rh-GH (Lane III), and the rh-GH-PEGMA conjugate (Lane IV) illustrated that after the polymerization neither native nor macroinitiator (rh-GH-TEG-Br) were present (Figure 3). The polymerization resulted in the protein-containing fractions of the polymer-conjugate migrating less through the gel and remaining at the top (higher molar mass regions) of the gel (Figure 3A). Iodine staining confirmed the presence of PEG in the same regions (Figure 3B), providing further support for the formation of the PEGMA-rh-GH conjugate.

Structural Characterization of rh-GH-PEGMA. The protein−polymer hybrid composition was evaluated by UV absorbance at 280 nm and BCA assay for protein determination and by an iodine assay for PEG quantification. The spectroscopic analysis of rh-GH-PEGMA solutions showed that the conjugate consisted of 15% protein and 85% polymer by mass. This was equivalent to a total molar mass of 147 kDa for the protein polymer hybrid. Therefore, the molar mass of the polymer chains calculated by combining the number of modified amino groups obtained by the MALDI-TOF analysis, and the molar mass obtained by the spectroscopic assays was 19.5 kDa. Additionally, the molar mass of polymer species liberated from the conjugate by acidic hydrolysis of the conjugate was measured by gel permeation chromatography (GPC profiles reported in the Supporting Information, Figure S5). A molar mass peak (M_p) of 22 kDa with a polydispersity index of 1.2 was obtained, which is in reasonable agreement with results obtained by the other methods. The slight variation in the molar mass determined by GPC and the spectrometric assays was most probably a function of the GPC calibration with poly(methyl methacrylate) standards which have different hydrodynamic properties from the comb-type PEGMA polymers. More importantly, the GPC analysis demonstrated that all the polymer species on the protein were narrowly and equally distributed around the M_p. Therefore, it can be assumed that all of the activated amines had similar accessibility and efficiency to propagate the polymerization. According to the number of polymer chains and their molar mass, the monomer conversion after 16 h reaction was 38%.

Size-exclusion HPLC chromatography (HPLC profiles reported in the Supporting Information, Figure S6) confirmed the higher molar mass of rh-GH-PEGMA compared to native protein. Dynamic light scattering indicated the presence of species of R_H 10−12 nm in buffer, which is consistent with the modified protein size, but no larger aggregates or precipitates were observed under the concentrations and conditions employed for DLS.

Both CD and UV−vis spectra obtained with rh-GH-PEGMA conjugate overlaid the spectra recorded with the native protein indicating that no significant alterations in the protein conformation were induced by polymer conjugation. The CD profiles reported in Figure 4 show that conjugation did not induce alteration in the secondary structure of rh-GH. The α-helix content calculated according to the k2D method was 57% in the conjugate and 58% in the native protein, which is in agreement with the data reported in the literature.

Stability of rh-GH-PEGMA. The stability profiles obtained for rh-GH and rh-GH-PEGMA at 37 °C in solution are shown in Figure 5. The concentration of rh-GH in the solution slightly decreased throughout the experiment time indicating that the protein slowly denatured, leading to aggregation and precipitation. The concentration of rh-GH-PEGMA on the other hand did not change during the experiment, demonstrating that the attached polymer chains enhanced the physical stability of the protein thus preventing aggregation and precipitation phenomena.

The stability of rh-GH and rh-GH-PEGMA was also investigated under stress conditions produced by high solution agitation. The stability profiles depicted in Figure 6 demonstrated that the PEGMA conjugation prevented protein aggregation and

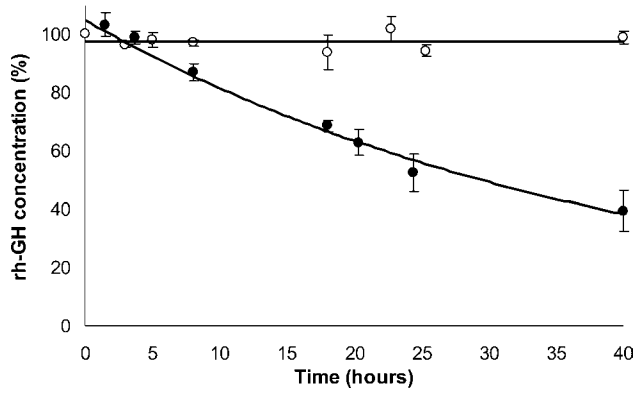

Figure 6. Stability profile of native rh-GH (●) and rh-GH-PEGMA (○) at 37 °C under stress conditions.

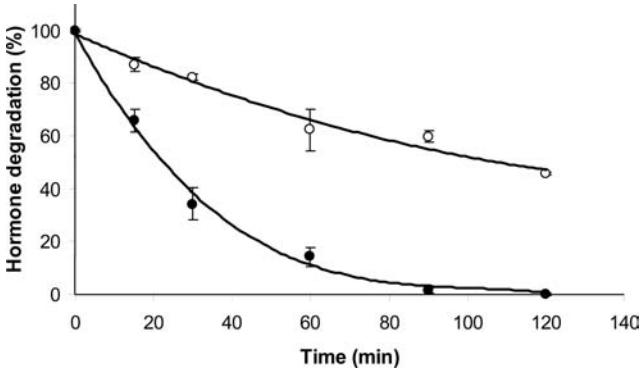

Figure 7. Degradation profiles of native rh-GH (●) and rh-GH-PEGMA (○) incubated with pepsin.

precipitation in an even more pronounced fashion under agitation than in solution. Indeed, under stress the native protein rapidly aggregated and precipitated when stirred, which was reflected by a first-order concentration decrease of the native protein. The rh-GH-PEGMA concentration by contrast was not significantly affected by the agitation.

Under proteolytic conditions, the native rh-GH was rapidly degraded. Figure 7 shows that the concentration of native rh-GH was reduced by 50% in 20 min and complete degradation of protein occurred by 120 min. In contrast, 50% degradation of rh-GH PEGMA required at least 120 min in the presence of pepsin. We attribute this to the PEGMA chains on the surface of the rh-GH polymer conjugate preventing access for the protease, which in turn led to improved stability.

Biological Investigations. The biological activity of native and rh-GH-PEGMA were examined in vivo by subcutaneous administration of equimolar doses of the two protein forms to hypophysectomized rats. Two different dosage protocols were used: daily administration of 40 μg rh-GH equivalent dose for 6 days and 120 μg rh-GH equivalent dose twice a week. The daily weight increase of the animals was monitored for 9 days as shown in Figure 8.

Figure 8a shows that daily administration of 40 μg hormone equivalent dose of rh-GH-PEGMA elicited similar body weight profiles to those obtained with the same dosage regimen of native hormone. A few days after the final injection of the protein, the weight of the animals in both groups started to decline.

Higher doses of 120 μg were administered to other groups of animals in a dosing regime involving 3 days between the injections (Figure 8b). The native rh-GH elicited a single day dose response. The weight of the animals increased the day following an injection of the native rh-GH but afterward the

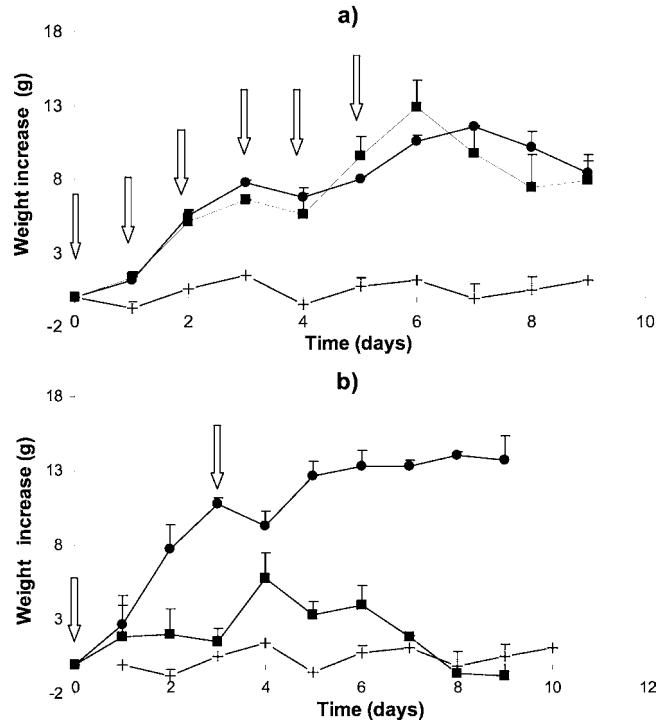

Figure 8. Rat weight increase (%) after administration of rh-GH and rh-GH-PEGMA. In (a), 40 μg daily treatment (arrows) of native rh-GH (■), rh-GH-PEGMA (●), and buffer (+) (Control); in (b), rat weight increase (%) after administration 120 μg twice a week treatment (arrows) of native rh-GH (■), rh-GH-PEGMA (●), and buffer (+) (Control).

weight of the animals remained constant or declined. The rh-GH PEGMA injections, on the other hand, exhibited a sustained response for a few days following the injections. At that point in time, the weights of the animals that had received the native rh-GH injections were not significantly different from the control group. The weights gained by the animals following injections of the rh-GH PEGMA were maintained for the remainder of the study.

DISCUSSION

The aim of this work was to evaluate whether the "growing from" polymerization could be used as an alternative approach to conventional direct PEGylation for production of pharmaceutically active polymer−protein conjugates. Controlled radical polymerization related protocols possess a number of potential advantages compared to "grafting to" polymer conjugation. These include high versatility and tunability, control of polymer molar mass and polydispersity, as well as reduced purification drawbacks. These advantages, together with the easier and versatile site-selective conjugation of low molecular weight anchoring functions (initiators), as compared to site-selective large bulky polymer conjugation, potentially allow a much greater diversity of polymer−protein conjugates to be prepared. However, it is important to consider carefully the method by which the polymer can be grown from a protein and the means by which an initiating group can best be attached.

Our primary aim was to demonstrate proof of concept of the "growing from" approach to obtain active protein−polymer bioconjugates in a controlled way. We thus prepared an α,ω-heterobifunctional ATRP initiator linked via a tetra(ethylene glycol) spacer to an active ester (Compound **2**), so that polymer growth sites could be generated from derivatized accessible amino groups on rh-GH. MALDI-TOF and SDS-PAGE confirmed reaction of the linker with rh-GH and the modified

protein was found to be an active macroinitiator for polymer growth. The derivatization degree of rh-GH with the linker was in fair agreement with data reported for prior modifications with other polymers in the literature (*31*), which have indicated that Lys-115 is unreactive and four other lysines of the ten present on rh-GH are poorly reactive. We chose an ATRP route for polymer growth, as this method is advantageous for generating a very wide range of molar masses with good control. Also, ATRP can operate under mild conditions, which is important to prevent protein denaturation and inactivation. Finally, we wanted to establish an all-aqueous protocol, as the flexibility inherent to the ATRP approach allows for the introduction of many different monomers, each of which might contribute to a desired property or activity. Surprisingly, there have been relatively few reports to date of ATRP polymerizations from proteins, and none have reported "grafting from" proteins at low temperature in water. The success of the grafting-from procedure we adopted here was shown by the narrow molar mass range of the polymers grown from the protein and the complete conversion of macroinitiator to polymer−protein conjugate as shown by SDS-PAGE, iodine staining, gel permeation chromatography, and titrations. Importantly, all the initiator domains on the protein structure were involved in the polymerization process. This was a relevant finding, as it indicated the robustness of the polymer-growth methodology. Although all the lysines derivatized were close to the surface of rh-GH, they were in subtly different environments; the fact that the polymers grew to a molar mass of about 20 kDa with narrow polydispersity ($M_w/M_n = 1.2$) is indicative that the initiator termini were free to react equally and that chain growth occurred smoothly from all the sites. The low polydispersity and the homogeneous product features are important requisites from a regulatory viewpoint, as the resulting conjugates are less heterogeneous than polymer−protein conjugates generated with polymers obtained through conventional free-radical routes.

The improved stability of the rh-GH to aggregation and precipitation from solutions as a consequence of bioconjugation is attributable to the presence of the PEGMA comb polymer shell. PEGMA chains, with their dense hydrophilic surface layer, have in fact been reported to reduce aggregation compared to conventional PEG (*41*). The presence of about 7 polyPEGMA chains on the rh-GH conjugate was most likely to have been responsible for the enhanced protein stability. Although the PEG side chains on the PEGMA systems we used were smaller (8−9 ethylene glycol repeat units, $M_n \sim 475$) compared to those used by Ryan et al. (*24*) for direct salmon calcitonin conjugation ($M_n \sim 1100$), the hydrated polymer shell around the protein is still likely to present a strong entropic barrier to aggregation processes.

Increased resistance to pepsin degradation also occurred after polymer conjugation. This resistance to pepsin activity is due to reduced access of the protease to the rh-GH target confirming the steric shielding of the conjugated polymer chains. There is of course a trade-off between steric shielding to protect against proteases while not shielding the active site of the prepared bioconjugate to the extent that functionality is lost (*42*).

The in vivo data on the effect of rh-GH and rh-GH-PEGMA indicated that the functional activity of the hormone was not affected significantly by polymer conjugation. Administration daily of 40 μg equivalent doses of rh-GH and rh-GH-PEGMA over 6 days resulted in similar weight growth profiles. However, for a higher equivalent dose (120 μg), introduced at day 0 and day 3 only, there was a significant enhancement in the weight gain of the animals, indicative of enhanced and sustained bioactivity.

The enhanced bioactivity obtained with rh-GH-PEGMA was similar to that reported for rh-GH analogues obtained by site-specific 20 kDa PEG monoconjugation (*30*) and multiple 5 kDa PEG attachment (*32*). Intriguingly, our data with the PEGMA-modified rh-GH showed enhanced activity compared to the native rh-GH over the same dosing regime as the previously reported mono-PEGylated analogue, despite the more extensive derivatization on multiple amino group residues for the rh-GH-PEGMA. Clark et al. (*32*) demonstrated that all the rh-GH derivatives obtained by random modification with several PEG chains displayed higher pharmacological activity than the parent molecule. Nevertheless, it was shown that the in vivo activity of PEGylated rh-GH was affected by the number of the attached polymer molecules, PEG size, and shape (*43*). This result is probably due to a balance of effects bestowed by the polymer conjugation. Indeed, the rh-GH in vitro activity was found to significantly decrease as the polymer size or number of polymer chains increase, while the protein stability and the pharmacokinetic behavior are known to improve as the polymer content in the conjugate increases (*44*). In vivo, the activity decrease may be counterbalanced by the increased stability and enhanced pharmacokinetic profile of the conjugate that, depending on its structural composition of the conjugate, may display improved therapeutic efficacy compared to the native counterpart as observed with other proteins (*44, 45*). Therefore, it is possible that a derivative containing several high molecular weight polymer chains displays a better pharmacological performance than derivatives obtained with higher numbers of polymers each of lower molar mass. Additionally, it should be considered that polyPEGMA has a different structure than linear PEG. The polyPEGMA in this study contains short PEG side chains attached to a polymethacrylate backbone via an ester bond. This structural difference may be an important factor in maintaining the high biological activity. Indeed, polyPEGMA chains are less flexible than linear PEG owing to their "bottle brush" structure and, therefore, may have a lower masking effect. Furthermore, PEG can be slowly released in vivo from the PEGMA side chains by ester bond cleavage. In both cases, the accessibility of the protein for receptor recognition would be enhanced compared to the conformationally highly mobile linear PEGs of similar molar mass.

Overall, the obtained data reported in the present paper are supportive of a novel GH bioconjugate with enhanced stability and pharmacodynamic properties compared to the native protein. Similarly to other protein drugs, the clinical need for daily injections of GH has already led to the development of new PEGylated derivatives, but the ATRP−polymer conjugates we have prepared here have a number of potential advantages over the PEGylated counterparts. The combination of synthetic polymers with natural biomolecules has been shown to be beneficial in many areas (*46*) due to the ability to tailor the properties of the synthetic component while exploiting, for example, the specificity of the natural polymer. However, the synthetic part of a bioconjugate produced via ATRP might also contain blocks that further enhance activity compared to conventional linear or branched PEG conjugates. PEGMA analogues are more easily modified via copolymerization with components that can change conformation in response to pH, temperature, redox, or other stimuli, enabling the activity of the protein to be controlled by the attached polymer. Responsive polymer−protein conjugates have been prepared previously (*47–49*), but the detailed study of such systems in vivo is still unexplored. In addition, PEGMA polymers created via this route can be end-functionalized or reacted at side-chains (*50*) in a way not possible for conventional PEG reagents, and thus, addition of targeting agents, cell penetrating peptides, and so forth would be more simple to accomplish than for conventional PEGylated

proteins. ATRP routes to these new "smart" bioconjugates are under active investigation in our laboratories.

CONCLUSIONS

We have demonstrated that "grafting from" polymerization methodologies can be successfully exploited to produce new protein−polymer bioconjugates with tunable properties. This approach opens new perspectives in optimization of protein bioconjugates for pharmaceutical applications. The synthesis and characterization of a novel rh-GH PEGMA polymer conjugate using a living polymerization technique was carried out under wholly aqueous conditions that ensure protein stability during the conjugate polymer growth process. The aqueous ATRP polymerization method offers great versatility for controlling the polymer topology and creates materials with well-defined properties and customizable functionalities. The latter is especially important for biomedical applications. The growth of the polymers from the protein generated a conjugate material with improved stability of the proteinaceous component in solution and more importantly enhanced the pharmacokinetics of the protein. The data indicate that proteins modified with ATRP-grown polymer might be administered less frequently than native proteins, thus offering the possibility of increased patient compliance and more cost-effective treatment.

Folic acid can be covalently conjugated to chitosan molecules via its γ-carboxyl moiety and thus retain a high affinity for colorectal cancer cells bearing folate receptor overexpression. Colorectal cancer is one of the leading causes of malignant death and often goes undetected with current colonoscopy practices. Improved methods of detecting dysplasia and tumors during colonoscopy will improve mortality. A folic acid conjugated chitosan nanoparticle as a suitable vehicle for carrying 5-aminolaevulinic acid (5-ALA) is developed to enhance the detection of colorectal cancer cells in vivo after a short-term uptake period. Chitosan can be successfully conjugated with folic acid to produce folic acid−chitosan conjugate, which is then loaded with 5-ALA to create nanoparticles (fCNA). The loading efficiency of 5-ALA in fCNA particles and the *z*-average diameter were in the range 35−40% and 100 nm, respectively. The zeta-potential for fCNA was 20 mV, enough to keep the nanoparticle stable without aggregation. The fCNA is then incubated with HT29 and Caco-2 colorectal cancer cell lines overexpressing folate receptor on the surface of the cell membrane to determine the rate of accumulation of protoporphyrin IX (PpIX). The results show that fCNA can be taken up more easily by HT29 and Caco-2 cell lines after short-term uptake period, most likely via receptor-mediated endocytosis, and the PpIX accumulates in cancer cells as a function of the folate receptor expression and the folic acid modification. Therefore, the folic acid−chitosan conjugate appears to be an ideal vector for colorectal-specific delivery of 5-ALA for fluorescent endoscopic detection.

INTRODUCTION

Folic acid is a ligand that is useful for targeting cell membrane and enhancing nanoparticle endocytosis via the folate receptor. It is a stable, inexpensive, and generally poorly immunogenic chemical with a high affinity for the folate receptor (*1, 2*). Because the folate receptor overexpresses on many human epithelial cancer cell surfaces, including cancers of the ovary, kidney, uterus, colon, and lung, conjugation of drugs and macromolecules with folic acid can enhance their uptake and targeting ability (*3*−*9*). Folic acid conjugates, which are covalently derivative via folate's γ-carboxyl moiety, can maintain a high affinity to the folate receptor, and the mechanism of cellular uptake of folic acid conjugates by folate receptors is as effective as that of folic acid chemical (*2*). They can enter cells by folate receptor-mediated endocytosis and move through many organelles by vesicular trafficking, which can supply materials to release into cell cytoplasm. Later, the unligated folate receptor may recycle to the cell surface to transport more folic acid conjugates (*2, 3*). This process has more advantages for the efficient intracellular delivery of anticancer agents or macromolecules than the one that relies on cell membrane markers.

The incidence of colorectal cancer is increasing worldwide and its prognosis remains poor (*10*). In general, survival is inversely related to extent of tumor spread at time of detection. Relative rates of survival of 50% at three years and 40% at five years have remained unchanged since the 1960s (*11*). Prognosis is excellent with detection at an early stage. Unfortunately, small colorectal neoplasia and early cancer are frequently overlooked during endoscopy. Therefore, a powerful and highly sensitive tool for the detection of precancerous lesions would be of great value.

Photodiagnosis is one of the most promising and noninvasive methods for detecting malignant or premalignant tissue (*12*). Currently, detection of abnormal tissue usually involves the use of an exogenous chromophore, such as protoporphyrin IX (PpIX), excited by optima light to generate fluorescence in cancer lesions (*13*). The 5-aminolevulinic acid (5-ALA) used in the study, a precursor in heme group synthesis, is totally degraded intracellularly and converted to PpIX. Because the decomposition rate of PpIX in cancer cells differs from that in normal cells, the photosensitive fluorophore, PpIX, can be used to detect cancer lesions (*14, 15*). Protoporphyrin IX in normal cells is usually maintained at a constant level and quickly degraded if it exceeds the equilibrium level. However, this feedback mechanism does not function well in cancer cells, where PpIX degrades at a slow pace and accumulates at very high concentrations. In addition, ferrochelatase, one of the major enzymes involved in converting PpIX into heme, remains at low activity in cancer cells and results in the limited availability of iron that partially contributes to the high concentration of PpIX in those abnormal cells (*16*). Generally, PpIX can be totally degraded within 2 to 4 h in normal cells and 12−24 h in cancer cells (*17*).

Because unprotected 5-ALA is easily engulfed by bacteria in the gastrointestinal tract (GI tract), its presence is open to misinterpretation and it has not been suitable as a marker during endoscopy (*18*). We have developed a chitosan nanoparticle vehicle for carrying 5-ALA that prevents bacterial uptake (*19*). Chitosan is the polymer of 2-amino-2-deoxy-β-D-glucan by

glycosidic linkages. The primary amino groups on the molecular chain of chitosan have special properties that make chitosan more useful in pharmaceutical applications. Compared with other biological polymers, chitosan is more cationic, which allows it to approach cell membranes more easily. In addition, it has muco-adhesive properties that prolong its retention to targeted substrates (*20*−*24*). Additionally, chitosan induces no allergic reactions or immuno-rejections. Also, its bacteriostatic properties discourage bacterial uptake in the GI tract (*25*). Furthermore, chitosan is a linear polyamine with an abundance of free amino groups that promote cross-linkage. Its cationic nature also promotes ionic cross-linkage with multivalent anions, such as sodium tripolyphosphate (STPP) (*26*).

Our previous study using chitosan as a vehicle for 5-ALA has shown that the accumulation of PpIX in colorectal cancer cells could be detected after 24 h incubation (*19*). In order to enhance the uptake and targeting ability of nanoparticles into targeted cells, target-specific ligands are usually used to conjugate to the surface of the polymer carrier. The main aim of this study was to determine the suitability of the synthesized folic acid−chitosan conjugates for carrying 5-ALA and to determine its targeting and uptake efficiency in different human colorectal cancer cell lines (HT29 and Caco-2) by folate receptor-mediated endocytosis after a short-term uptake period for the clinical practice.

EXPERIMENTAL PROCEDURES

Materials. Chitosan (99% deacetylation and 150 kDa M.W.) and 5-aminolevulinic acid (5-ALA) were purchased from Fluka (Germany). Sodium tripolyphosphate (STPP) was purchased from Wako Pure Chemical Industries (Osaka, Japan). Folic acid was purchased from TCI (Tokyo, Japan). 1-(3-Dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) was purchased from Acros Organics (New Jersey, USA); anhydrous dimethyl sulfoxide (DMSO) was purchased from Riedel-de Haën (Germany). They were all reagent grade and used without further purification.

Conjugation of Folic Acid with Chitosan. The process of conjugation of folic acid to chitosan molecules is described as follows: A solution of folic acid and EDC in 20 mL anhydrous DMSO (molar ratio was 1:1) was prepared and stirred at room temperature until EDC and folic acid were well-dissolved and mixed. The mixture was then added slowly to 0.5% (w/v) chitosan in acetic acid aqueous solution (0.1 M, pH 4.7) and stirred at room temperature in the dark for 16 h to let folic acid conjugate onto chitosan molecules. The solution was brought to pH 9.0 by dripping with NaOH aqueous solution (1.0 M) and centrifuged at 2500 rpm to spin down the folic acid−chitosan conjugate. The precipitate was dialyzed first against phosphate buffered saline (PBS, pH 7.4) for 3 days and then against water for 4 days. Finally, the folic acid conjugated chitosan was isolated as a sponge by lyophilization and kept for follow-up study (*6, 7*). Folic acid−chitosan conjugates were formed at selected amino groups of chitosan to folic acid molar ratios from 1:0.02 to 1:0.2. Abbreviations for different folic acid−chitosan conjugates are shown in Table 1.

Characterization of the Folic Acid−Chitosan Conjugates. The chemical compositions of chitosan, folic acid−chitosan conjugates, and folic acid were characterized with an ATR-FT-IR spectrometer (VARIAN UMA600; Palo Alto, CA) to determine the characteristics of the folic acid−chitosan conjugates. The ^{1}H NMR spectra of folic acid−chitosan conjugates were recorded on a Bruker Avance-400 MHz NMR spectrometer (Bruker BioSpin, MA, USA) using deuterium acetic acid-d_4/deuterium oxide solution (1/4 v/v) as a solvent.

The folic acid to amino groups molar ratios in folic acid−chitosan conjugates were estimated by determining the intensity of absorption maximum (285 nm) of folate derivative in 0.02% folic acid−chitosan conjugate solution with an ultraviolet−visible (UV−vis) spectrophotometry (Cary 50 Conc, Varian; Australia). In this study, folic acid powder was dissolved in 0.1 M NaOH solution and diluted to a series of gradient folic acid standard solutions that were used to prepare the calibration curve in the range 0.0025−0.05 mg/mL for further analysis.

Table 1. Molar Ratio of Folic Acid/Amino Groups in Folic Acid−Chitosan Conjugates and Yield of the Synthesis Conjugates[a]

[a] ($n = 5$).

Synthesis of Nanoparticles. The preparation of chitosan nanoparticles loaded with 5-ALA was based on the ionic gelation interaction between positively charged chitosan and negatively charged STPP at room temperature (*27*). The negative charge of ionized 5-ALA also partially contributed to the gelation interactions in this study. The preparation process is briefly described as follows: 0.05% chitosan and folic acid−chitosan conjugate solutions were prepared by dissolving 0.5 mg chitosan powder and folic acid−chitosan conjugate sponge in 1 mL 0.01 M acetic acid solution at pH 4.0, respectively. 0.15% 5-ALA solution was prepared by dissolving 1.5 mg 5-ALA powder in 1 mL 0.05% STPP solution, where STPP were dissolved in PBS beforehand. Either 2 mL of STPP solution or 2 mL of 5-ALA solution was added to 5 mL of chitosan or folic acid−chitosan conjugate solution with a peristaltic pump at a flow rate of 0.5 mL/min to prepare the CN, CNA, fCN, and fCNA nanoparticle suspended solutions, where CN and fCN were represented as chitosan and folic acid conjugated chitosan nanoparticles without 5-ALA loading, and chitosan and folic acid conjugated chitosan nanoparticles loaded with 5-ALA were termed CNA and fCNA. The preparation of fCNA was schematically illustrated in Figure 1. The prepared nanoparticle suspended solutions were later used directly without further treatment.

Particle Size and the Zeta-Potential of CN, CNA, fCN, and fCNA. Measurements of particle size and zeta-potential of various nanoparticles were performed on the Zetasizer-3000 (Malvern Instruments; Westborough, MA) by dynamic light scattering measurements and laser Doppler electrophoresis, respectively. Particle size was measured at 25 °C with a 90° scattering angle based on the Zetasizer-3000 internal setting. The cumulative curve was used to present the mean hydrodynamic diameter. Measurements of zeta-potential were made using the aqueous flow cell in the automatic mode at 25 °C (*28*).

Loading Efficiency of 5-ALA in CNA and fCNA. Loading efficiency of 5-ALA in nanoparticles was assessed by centrifuging the particle solution at a 20 000 *g* force to spin down the particles. The suspension was collected and then reacted with 2,4,6-trinitrobenzene sulfonic acid (TNBS) as an assay reagent to detect 5-ALA in the suspension. Assay was performed by using a TNBS kit (Pierce Chemical Company; Rockford, IL) according to the manufacturer's instructions. In the study, 5-ALA powder was dissolved in reaction buffer (0.1 M sodium bicarbonate, pH 8.5) and diluted to a serial of gradient 5-ALA standard solutions that were used to prepare the calibration curve in the range of 2−20 μg/mL for further analysis. The loading

efficiency of 5-ALA in the nanoparticles was calculated with the following equation:

$$\text{loading efficiency (\%)} = \frac{C_t - C_f}{C_t} \times 100\%$$

where C_t and C_f were total amount of 5-ALA and free amount of 5-ALA in the suspension, respectively.

Transmission Electron Microscope Examination. Carbon-coated 200 mesh copper grids were immersed in CN, CNA, fCN, and fCNA solutions. Grids were placed on delicate-task-wipers to absorb excess liquid and then dried in a desiccator overnight. The dried copper grids with CN, CNA, fCN, and fCNA were examined under the Hitachi TEM H-7500 (Tokyo, Japan).

Determining Expression of Folate Receptor among Colorectal Cancer Cell Lines. Expression content of folate receptor on cell membrane was determined by Western blot method. Two colorectal cancer cell lines (HT29 and Caco-2) were pretreated by scraping the cell cultures into cold lysis buffer (RIPA buffer) containing protease inhibitors. Whole cell lysate was assayed for the protein concentration by using the DC protein assay (Bio-Rad; Hercules, CA) with bovine serum albumin as standard. Total protein (30 μg) was separated on 10% SDS−polyacrylamide gel electrophoresis (SDS-PAGE) gels, and then transferred to polyvinylidene fluoride (PVDF) membranes (Amersham Biosciences; Sweden). The PVDF membranes were incubated in blocking buffer (5% nonfat dry milk, 0.1% Tween20 in TBS) at room temperature for 60 min, and subsequently treated with primary antibody, rabbit antihuman folate receptor (1:1000 dilution, Santa Cruz Biotechnology; CA, USA), in blocking buffer overnight at 4 °C. Membranes were washed with Tris-buffered saline (TBS) containing 0.1% Tween20 (USB Corporation; Cleveland, OH), and further incubated with the horseradish peroxidase-conjugated antirabbit IgG (1:5000 dilution, Sigma) as secondary antibody at room temperature for 60 min. Finally, membranes were incubated in blocking buffer at room temperature for 60 min, and then washed with PBS containing 0.1% Tween20. The bands of proteins were visualized by using chemiluminescence enhancing (Amersham Parmacia Biotech; Piscataway, NJ) and exposed to Hyperfilm MP. The signals of antihuman folate receptor in the Western blotting were quantified with the software *ImageQuant 5.1*, and the data were normalized to β-actin expression.

Measurement of Accumulated PpIX. Cell lines HT29 and Caco-2 were cultured in Dulbecco's Modified Eagle's Medium (GIBCO; Grand Island, NY) supplement with 10% (v/v) fetal bovine serum, 2 mM glutamine, 10 mM nonessential amino acids, 50 IU/mL penicillin, and 50 Ag/mL streptomycin, at 37 °C and in an atmosphere of 5% CO_2, respectively. Cultured medium was changed on alternate days until confluent.

The following quantities of cells were seeded onto 24-well culture plates: 1.2×10^5/well HT29 and 3×10^4/well Caco-2. After cell lines were cultured for 24 h, the medium was replaced with fresh medium containing CNA and fCNA. The CNA and fCNA solutions were concentrated to 10× by Amicon Ultra (Centrifugal Filter Devices, Millipore) to remove the unloaded 5-ALA beforehand. Moreover, because of no blood supplement in the GI tract, the fresh medium without serum supplement was used. Cells were further cultured for 3, 6, and 12 h to allow uptake of nanoparticles and to convert 5-ALA to PpIX. In order to determine the effect of folic acid−folate receptor mediated

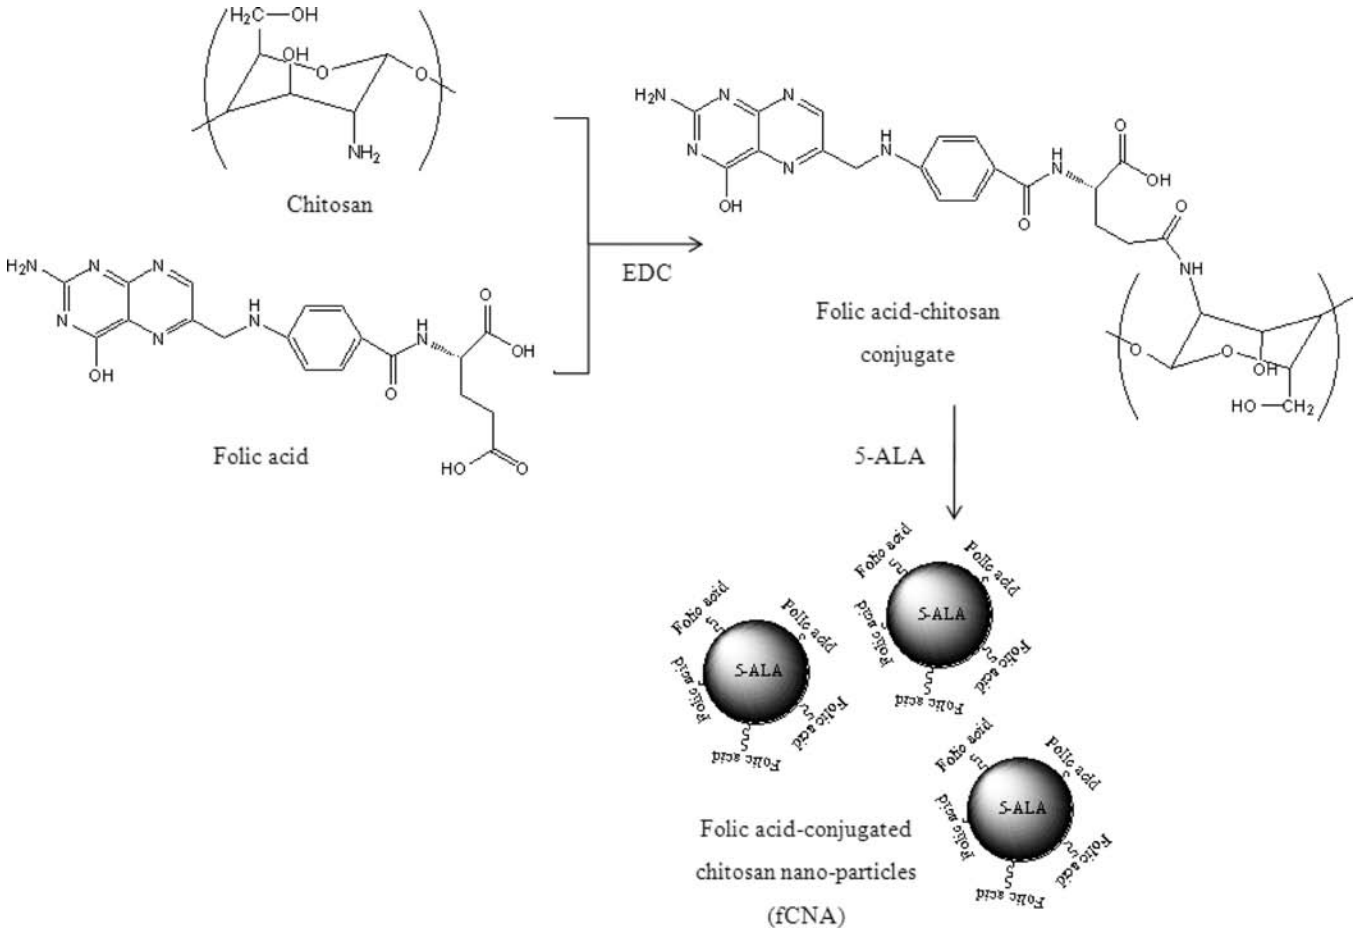

Figure 1. Schematic illustration of the preparation folic acid-conjugated chitosan nanoparticles for PpIX accumulation in colorectal cancer cells.

endocytosis on the endogenously synthesized PpIX, fresh culture media, both with or without free folic acid, were tested at the same time. The concentration of free folic acid (5 mM) used was expected to result in complete saturation of folate receptors (*5*). After removal of the cultured medium, plates were washed with PBS three times. The PpIX were extracted with DMSO, and the fluorescent intensity of PpIX was determined by the spectrofluorometer (Molecular Device Spectra Max Gemine XS; Sunnyvale, CA) with the excitation wavelength of 405 nm and the emission wavelength at 635 nm. The fluorescent intensity was expressed as accumulative percentage.

In order to evaluate the feasibility of the prepared fCNA on colorectal cancer cells detection after short-term uptake period, the glass plate was placed in a Petri dish and seeded with HT29, Caco-2, or a normal cell line (human colon fibroblast (CCD112)). After cells were cultured for 24 h, medium was replaced with fresh medium containing CAN, fCNA, and 5-ALA. To confirm the nanoparticle uptake content as a function of the folate receptor expression and the folic acid modification, a fluorescent compound, calcein, was incorporated simultaneously into CNA and fCNA as a fluorescent marker. Cells were further cultured for 12 h to allow for uptake of nanoparticles and conversion of 5-ALA to PpIX. After the cultured medium was removed, the glass plate was washed three times with PBS and the cells were fixed with 10% formalin and then examined under a spectral confocal and multiphoton system (Leica TCS SP5, Wetzlar, Germany). The average fluorescent intensity of calcein in cells was quantified with the *MetaMorph* imaging software (v 7.5, Molecular Devices, USA) to demonstrate the content of nanoparticle uptake. The data represented an average of five regions obtained from randomly chosen areas of each sample, and the brightness of the green emission light of the CNA group was designated as 100% for the individual colorectal cancer cell lines.

Statistical Analysis. Mean plus/minus standard deviation (SD) and graphs were used to describe the data. One-way analysis of variance (ANOVA) with post hoc muti-comparison methods, such as Fisher's LSD test and Tamhane's T2 test, was used to assess the differences in the fluorescent intensity of PpIX and calcein in colorectal cancer cells fed with CNA and fCNA. All p values were two-sided, and their significance level was 0.05. The software of statistic package for social science 11.0 (SPSS 11.0) was used to conduct all statistical analysis.

RESULTS

Characterization of Folic Acid−Chitosan Conjugates. Folate acid−chitosan conjugates could be synthesized by chemically linking folic acid to chitosan via EDC as a carboxyl activating agent. They were formed at the selected amino groups of chitosan to folic acid molar ratios from 1:0.02 to 1:0.2. Abbreviations for different folic acid−chitosan conjugates are shown in Table 1. The FT-IR spectra of the chitosan, folic acid−chitosan conjugates (f06Chi, f20Chi), and pure folic acid were shown in Figure 2. Because the folic acid modification in the folic acid-chitosan conjugate, f02Chi, was too low to easily determine the difference between chitosan and folic acid−chitosan conjugate in FT-IR spectra, it was not shown in Figure 2. Characteristic FT-IR absorption peaks of folic acid at 1450, 1520, and 1605 cm^{-1} were observed in the spectrum of folic acid−chitosan conjugates. In the pure folic acid and folic acid−chitosan conjugates, the absorption bands at 1450 and 1605 cm^{-1} were assigned to the stretching vibrations of C═C in the backbone of the aromatic ring (*29*). Furthermore, chitosan and folic acid−chitosan conjugates all contained the −CONH− group. The carbonyl absorption band, C═O, is known as the amide I band, and N−H is termed the amide II band. Their position depends on the degree of hydrogen bonding and, thus, the physical state of the compound. The most significant IR frequencies of the chitosan and folic acid−chitosan conjugates are the amide I band (carbonyl stretching) and the amide II band

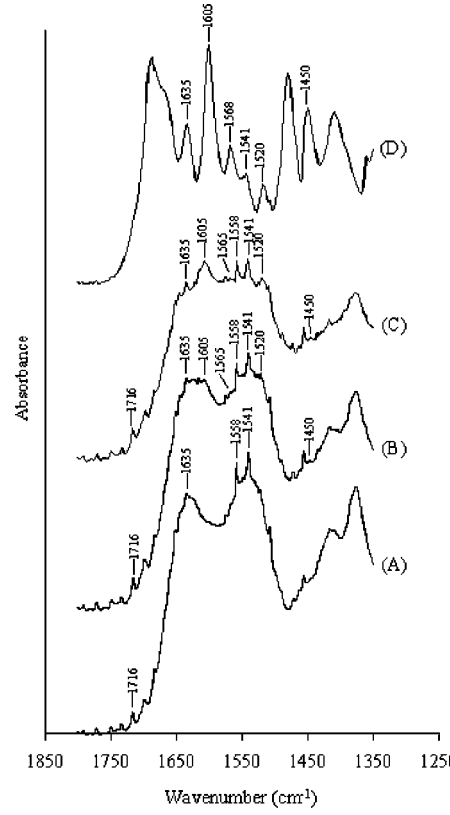

Figure 2. FT-IR spectra of folic acid−chitosan conjugates (A) chitosan, (B) f06Chi, (C) f20Chi, and (D) pure folic acid.

Table 2. Relative Intensity Ratio of the N−H Bending over C═O Stretching in Chitosan and Folic Acid−Chitosan Conjugates

sample	band		wavenumber (cm^{-1})	intensity ratio (Amide II/ Amide I)
chitosan	Amide II	free N−H	1541	1.813
			1558

			1558	
		bonded N−H	1565	
	Amide I	bonded C═O	1635	1
		free C═O	1716	

Table 3. z-Average Diameter, Zeta-Potential, and Loading Efficiency of Chitosan Nanoparticles Prepared in Different Conditions

sample	z-average diameter[a] mean ± SD (nm)	PDI[b]	zeta-potential (mV)	loading efficiency mean ± SD (%)
CN	102.4 ± 7.74	0.252	25.0 ± 1.84	−
CNA	96.0 ± 4.82	0.392	24.4 ± 1.78	43.1 ± 5.71
f02CN	100.1 ± 10.75	0.434	22.6 ± 1.54	−
f02CNA	93.6 ± 5.80	0.381	21.9 ± 2.09	38.9 ± 3.52
f06CN	99.0 ± 7.00	0.444	21.1 ± 2.19	−
f06CNA	112.8 ± 13.19	0.457	20.1 ± 1.76	35.5 ± 1.40

[a] z-average diameter is the mean diameter based on the intensity of scattered light. [b] PDI = polydispersity index (ratio of weight- to number-average particle diameter).

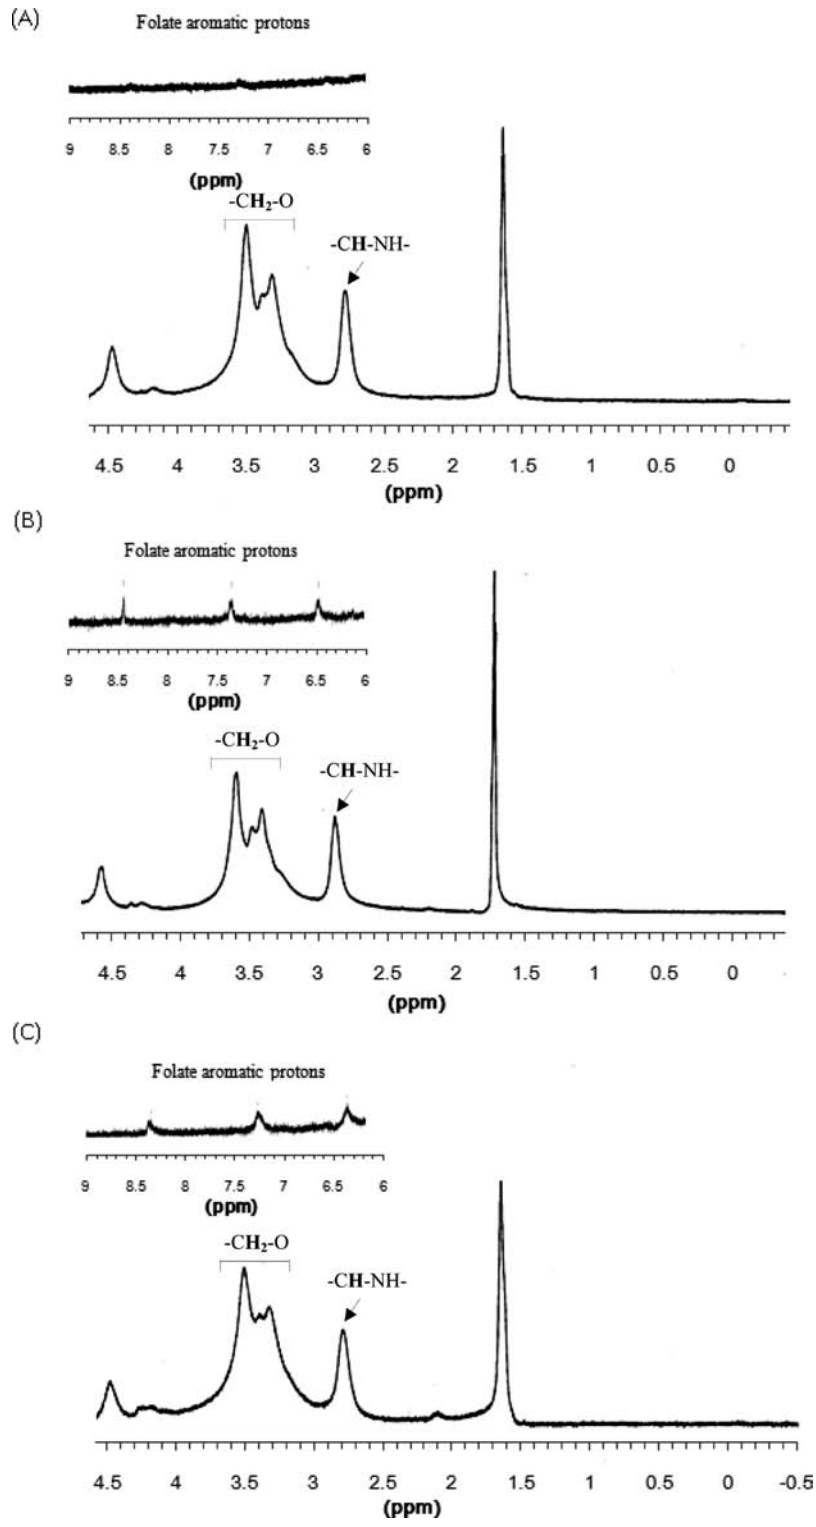

Figure 3. ^{1}H NMR spectrum of f02Chi (A), f06Chi (B), and f20Chi (C) folic acid−chitosan conjugates in an acetic acid-d_4/D_2O solution (1/4 v/v).

(N−H deformation mode) vibration. The former is typically around 1720−1740 cm^{-1} and is shifted to lower frequencies by hydrogen bonding (weakening of the force constant due to partial single-bond character). The latter is typically between 1500 and 1550 cm^{-1} and is believed to shift to the higher frequencies upon hydrogen-bond formation (strengthening of the force constant for deformation vibrations) (*30*). Figure 2 shows that there were two absorption peaks for the C═O group. The peak at about 1635 cm^{-1} represented the bonded C═O stretching and the peak at about 1716 cm^{-1} represented the free C═O stretching (*31*). The amide II band was observed at a relatively high frequency (1565 cm^{-1}), most probably due to the hydrogen-bond formation. The peaks at about 1541 and 1558 cm^{-1} were related to free N−H bending. In Table 2, it can be seen that the amide II/I intensity ratio increased with increasing folic acid conjugation in folic acid−chitosan conjugates.

Successful synthesis of folic acid−chitosan conjugates was also confirmed by a ^{1}H NMR spectroscopy, and the ^{1}H NMR spectra of folic acid−chitosan conjugates are shown in Figure 3. The signals at δ 1.65, 2.88, and 3.08−3.64 ppm were assigned

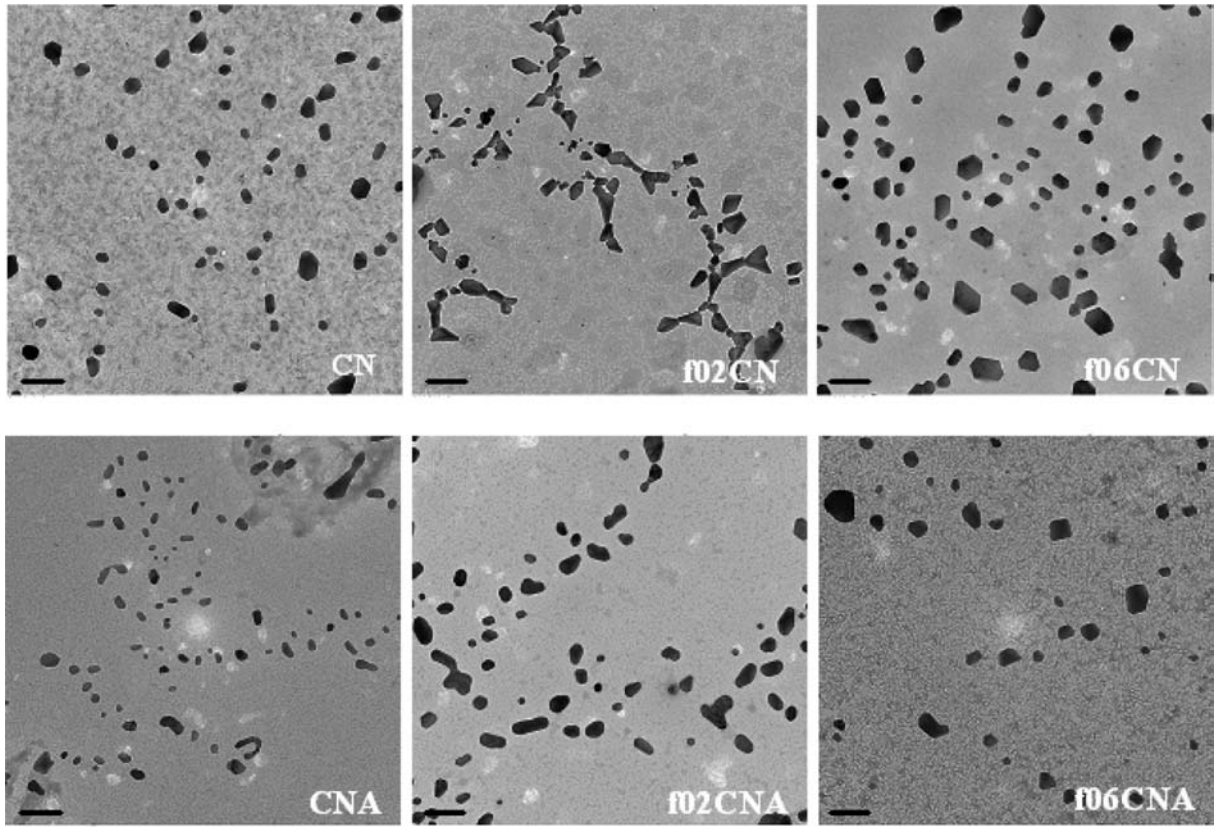

Figure 4. Photos from TEM for CN and CNA modified with folic acid or without. The scale bar in the picture is 1 μm.

to the resonance of the monosaccharide residue protons, $-COCH_3$, $-CH-NH-$, and $-CH_2-O-$, respectively (*2, 7*). The signals appearing at δ 6.3−8.5 ppm in the ^1H NMR spectra of folic acid−chitosan conjugates attributed to the resonance of the folate aromatic protons, and they revealed that the couple of the folate residue to the chitosan could be achieved via EDC-mediated reaction (*7, 32*).

Table 1 shows the molar ratio of folic acid to amino groups in folic acid−chitosan conjugates evaluated by an absorbance at $\lambda = 285$ nm in the UV−vis spectra of the conjugates. The lowest molar ratio was 0.008 in f02Chi, which was two-fifths of the formulated molar ratio; however, the highest molar ratio was up to 0.059 (f20Chi), three-tenths of the formulated molar ratio only. The incremental trend of the folic acid conjugation in the folic acid−chitosan conjugates matched that of folic acid addition, but it was still lower than the formulated molar ratio. Moreover, the yield of f02Chi was 81.6%, and decreased to 53.2% as the folic acid addition in the reaction increased (f20Chi) (Table 1).

Particle Size, Zeta-Potential, and Loading Efficiency of 5-ALA in Nanoparticles. Table 3 shows the *z*-average diameter, zeta-potential, and loading efficiency of chitosan nanoparticles, which were prepared in different conditions. When chitosan was conjugated with an abundance of folic acid molecules (f08Chi, f10Chi, and f20Chi), it was difficult to dissolve it into 0.01 M acetic acid solution completely, most likely due to the unsolvable property of folic acid in acetic acid (*33*). Accordingly, folic acid−chitosan conjugates with large folic acid modification were not suitable for use as a carrier for 5-ALA in the present prepared nanoparticle condition. As shown in Table 3, the *z*-average diameter of the prepared nanoparticles did not vary significantly with change of folic acid on chitosan polymer (CN and fCN) or 5-ALA loading (CNA and fCNA). Also, the *z*-average diameter of prepared nanoparticles was about 100 nm. The zeta-potential analysis revealed that the nanoparticles prepared in different conditions all bore a positive charge (in the range 20−25 mV). However, when the CN was modified with folic acid, as was so-called fCN, the zeta-potential of particles decreased with increase in the percentage with folic acid conjugation. If the CN and fCN were loaded with 5-ALA, the zeta-potential of the CNA and fCNA decreased slightly as compared with CN and fCN, respectively. The loading efficiency of 5-ALA in CNA was 43% and decreased to 35% with increasing percentage of folic acid conjugation.

Figure 4 shows the particle sizes of CN, CNA, fCN, and fCNA as determined by transmission electron microscopic examination (TEM). The particle size distribution of CN and CNA was major in the range 60−200 nm, but fell into the range 100−600 nm for f06CN and f06CNA. Therefore, the particle size distribution strongly depended on and increased with the increase of percentage of conjugated folic acid. These results are in agreement with the polydispersity index (PDI) values of the prepared nanoparticles measured by dynamic light scattering measurements using the Zetasizer-3000.

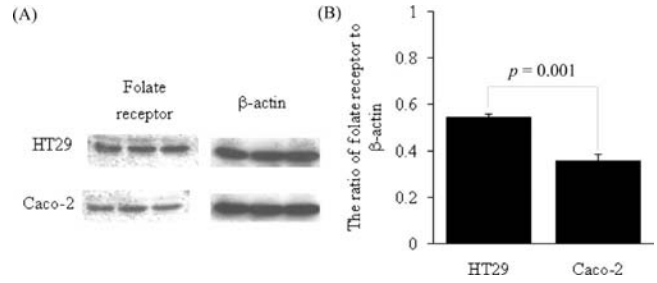

Figure 5. (A) Western blot analysis of folate receptor expression and (B) the ratio of folate receptor to β-actin quantified with the software *ImageQuant 5.1* on HT29 and Caco-2 colorectal cancer cell membrane ($n = 3$).

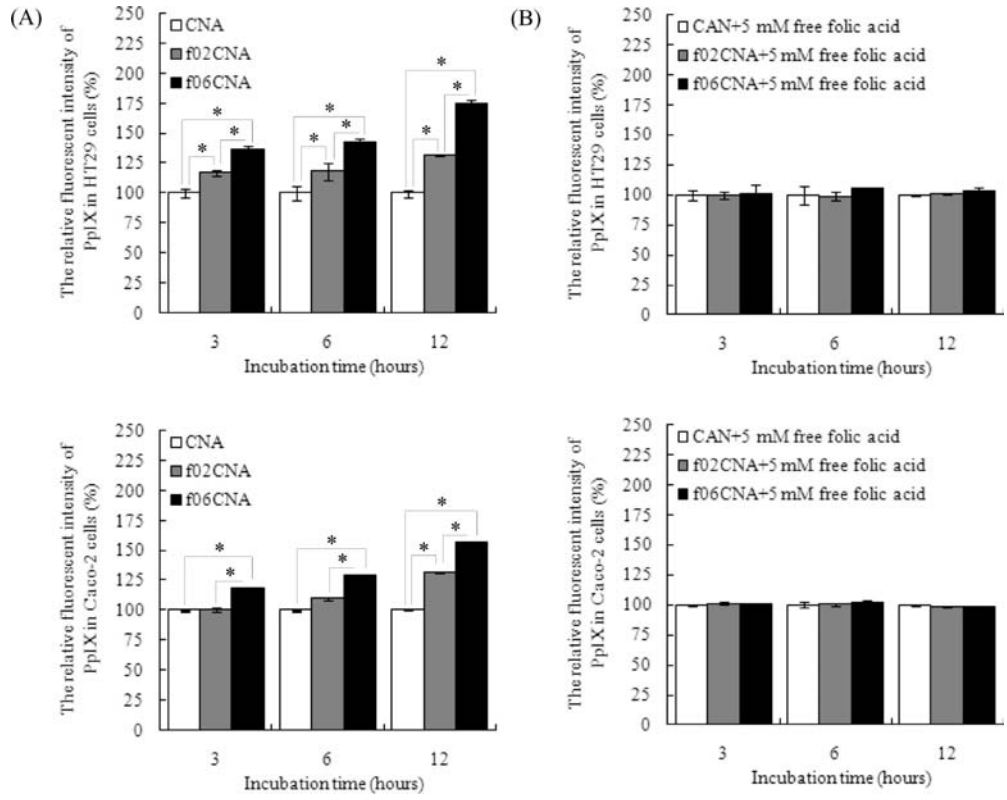

Figure 6. (A) Relative fluorescent intensity of PpIX in HT29 and Caco-2 cells when fed with the prepared CNA, f02CNA, and f06CNA for 3, 6, and 12 h. (B) In order to determine the effect of folic acid−folate receptor mediated endocytosis on the endogenously synthesized PpIX, the relative fluorescent intensity of PpIX in HT29 and Caco-2 cells was also be estimated when cultured in a fresh medium with the nanoparticle suspension and 5 mM free folic acid addition for 3, 6, and 12 h. *: $p < 0.05$.

Expression of Folate Receptor among Colorectal Cancer Cell Lines. Because folate receptors are known to be overexpressed and actively internalized through folate receptor-mediated endocytosis in various types of colorectal cancer cells, folic acid has been considered to be a suitable ligand for improving the cellular uptake of drugs and macromolecules into cells (*3*). Therefore, the expression of folate receptor on HT29 and Caco-2 colorectal cancer cells was examined by the Western blot method and shown in Figure 5. It was apparent that expression of folate receptor depended on the cell line: expression of folate receptor was of a low level for Caco-2 cells, whereas HT29 cells exhibited 1.5-fold higher expression of folate receptors than did Caco-2 cells.

Measurement of PpIX in Colorectal Cancer Cells. Figure 6 shows the relative fluorescent intensity of PpIX in HT29 and Caco-2 cells cultured in a medium with or without free folic acid addition. The brightness of the emission light of the CNA group was designated as 100% for the individual colorectal cancer cell lines. Figure 6A shows that increase of bright red emission light of PpIX in HT29 and Caco-2 cells was only 31.3% and 31.2%, respectively, when the cells were cultured with f02CNA for 12 h. However, when f06CNA was fed to HT29 and Caco-2 cells, increases in intensity of brightness were 42.5% and 28.8% after 6 h of incubation and significantly up to 74.8% and 57.2% after incubating for 12 h, respectively.

In order to evaluate the role of folic acid in the cellular uptake of folic acid-conjugated chitosan nanoparticles, CNA, f02CNA, and f06CNA coincubated with free folic acid were fed to the HT29 and Caco-2 cells. Figure 6B shows that there were no significant brightness intensity differences among CNA, f02CNA, and f06CNA groups and that free folic acid molecules could compete with f02CNA and f06CNA for folate receptors and suppress the receptor-mediated endocytosis of the prepared particles. These results showed that folic acid−chitosan conjugates could significantly enhance the cell uptake of 5-ALA and the accumulation of PpIX in HT29 and Caco-2 cells via the folate receptor-mediated endocytosis.

Figure 7 shows the red fluorescence of PpIX excited by a green laser and observed under a spectral confocal and multiphoton system in HT29, Caco-2, and CCD112 cells, which were fed with CNA, f02CNA, f06CNA, or 5-ALA for 12 h. Pure 5-ALA or 5-ALA in the prepared nanoparticles has been released in colorectal cancer cell lysosomes and then converted into PpIX, which accumulated in cells and then was excited by a green laser and emitted red light. Figure 7 shows CNA, fCNA, and 5-ALA taken up by CCD112 cells. Because of the quick degradation rate of PpIX in the normal cell, no red light was emitted and interference with malignant cell identification was unlikely.

A compound, calcein, is a membrane-impermeant fluorescent dye and can be incorporated into the prepared CNA and fCNA simultaneously by the electrostatic interaction between negatively charged calcein and positively charged chitosan. When HT29 and Caco-2 cells were fed with the calcein-incorporated CNA and fCNA nanoparticles for 12 h, the green brightness of calcein excited by a UV light increased with the increasing folic acid modification in the prepared nanoparticles (Figure 8A). As presented in Figure 8B, HT29 cells fed with the highest folic acid conjugated nanoparticles (f06CNA) exhibited a substantial calcein fluorescent intensity, suggesting the high activity for folate receptor-mediated endocytosis in HT29 cells with higher folate receptor expression. These results also demonstrated that enhancement of cellular association and uptake was induced by the specific interaction of folic acid conjugated nanoparticle with its receptor on the cellular surface and by

subsequent internalization through the receptor-mediated endocytosis.

DISCUSSION

Folic acid is a stable, inexpensive, and generally poorly immunogenic chemical. It can be covalently conjugated to chitosan molecules via its γ-carboxyl moiety and thus retain a high affinity for folate receptors. Moreover, the ability of cellular uptake of folic acid−chitosan conjugate via folate receptor-mediated endocytosis is still as good as that of folic acid (*6*). In this study, the folic acid−chitosan conjugates bearing different content of folate derivatives could be fabricated by varying the folic acid to amino groups of chitosan molar ratios in the synthesis procedure (Table 1). The FT-IR and ^{1}H NMR spectra of the folic acid−chitosan conjugates confirmed that folic acid could be conjugated onto chitosan molecules successfully, but the relevant signals in ^{1}H NMR spectra, which were recommended by Wang et al. (*32*) and could be used to ascertain the regiochemistry of the linkage of folate derivatives and chitosan, were masked by the strong and broad signals owing to the resonances of the protons associated to chitosan monosaccharide residues (Figures 2 and 3). Thus, we were unable to determine the regiochemistry of the folate linkage in folic acid−chitosan conjugates from ^{1}H NMR spectra, but it could be inferred that folic acid was conjugated to an amino group via its γ-carboxyl moiety mostly due to the reaction conditions chosen and the steric constraints.

Chitosan was chosen as the cationic polymer because it provides many free amino groups that can be quickly gelled to form micro/nanoparticles once it contacts polyanions (*34*). In this study, we found a weak association between the particle size of the prepared nanoparticles and the folic acid conjugation or 5-ALA load. However, the zeta-potential and loading efficiency of 5-ALA depended on the folic acid conjugation. Zeta-potential can greatly influence particle stability through electrostatic repulsion between particles. Greater zeta-potential resulted in improved stability of nanoparticles in the solution and a narrower size distribution, presumably because the charged particles repelled one another and therefore overcame the natural tendency to aggregate (*35*).

As shown in Table 3, the zeta-potential of the CN and CNA was about 25 mV. This provided enough surface charge to stabilize the particles from aggregation, which was decreased when CN and CNA were conjugated with folic acid. When the more electroneutral folate derivatives displaced the protoned amino groups (f06CN and f06CNA), the zeta-potential was even down to 20 mV, and therefore it might not provide enough repulsive force to stabilize the particles from aggregation for long-term storage. These results are consistent with the Zeta-sizer-3000 measurements and TEM observations. When the prepared particles conjugated with folic acid, they got a large PDI value (Table 3) and a wide particle size distribution in the range 100−600 nm (Figure 4).

When CNA was conjugated with folic acid (fCNA), the loading efficiency of 5-ALA decreased to 38% and 35% for f02CNA and f06CNA particles, respectively (Table 3). In f02CNA and f06CNA particles, a number of amino groups were replaced by folic acid and reduced the positive charges on chitosan molecules to attract 5-ALA molecules. Moreover, the spatial hinder of folate derivatives on chitosan backbone might

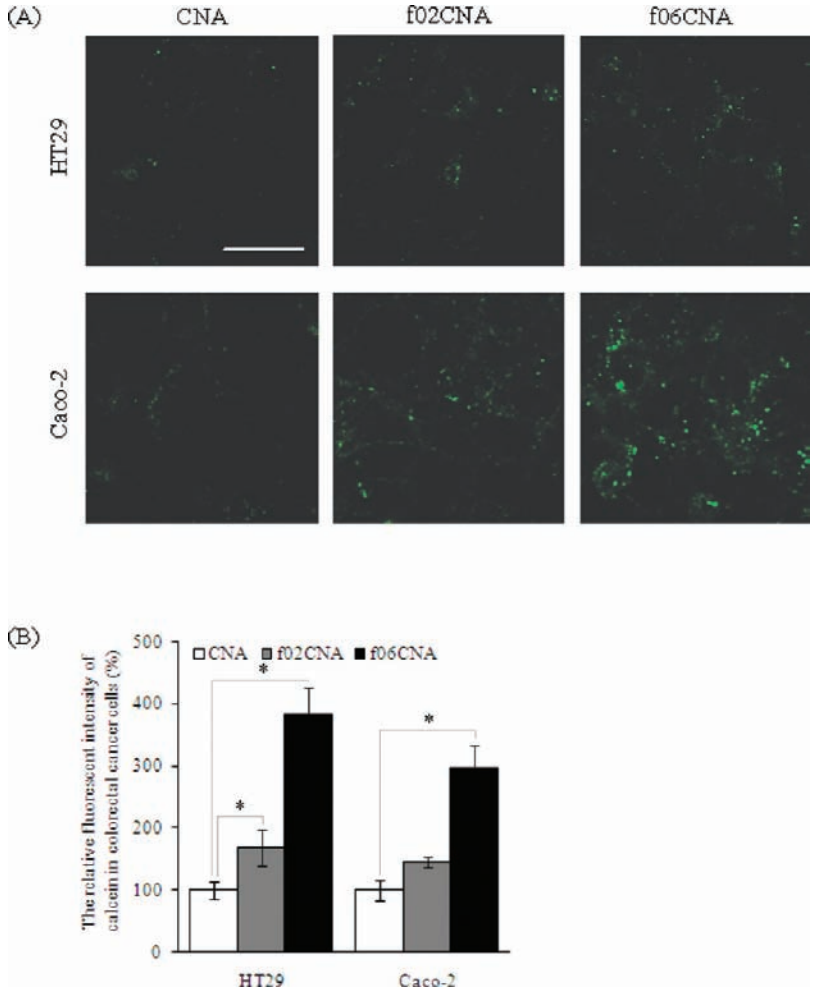

Figure 8. (A) Green fluorescent images of calcein in HT29 and Caco-2 cells when fed with the calcein-incorporated CNA, f02CNA, and f06CNA nanoparticles for 12 h. The scale bar in the image is 25 μm. (B) The relative fluorescent intensity of calcein in HT29 and Caco-2 cells. *: $p < 0.05$.

resist the interaction between chitosan and 5-ALA molecules. On the basis of these reasons, the loading efficiency appeared strongly dependent on the content of folic acid conjugation. In the previous studies (*19*), no red fluorescence of PpIX could be observed in *E. coli* when fed with the prepared CNA nanoparticles, and it pointed out that the uptake of 5-ALA in *E. coli* could be precluded by encapsulating 5-ALA in an antibacterial material, such as chitosan. Furthermore, the incorporation of 5-ALA in the CNA would be stable because of the lack of 5-ALA release from the particle and uptake by *E. coli*. Therefore, it was feasible to load 5-ALA in the CNA and fCNA nanoparticles and then deliver them into colorectal cancer cells via folate receptor-mediated endocytosis.

Folate receptor is frequently overexpressed on the surface of many human cancer cell types, such as carcinomas of the kidney, ovary, uterus, testis, and adenocarcinomas of the colon (*4*). For this reason, many studies have used folic acid as a ligand with cationic liposomes and other polymers to target cells with folate receptor expression and promote its entry into malignant cells via folate receptor-mediated endocytosis. Figure 6A shows that, for f06CNA group, much more PpIX accumulated in HT29 and Caco-2 cells than that for CNA group. This enhancement of PpIX accumulation might be due to the high folic acid conjugation on f06CNA, which could result in stronger affinity to the folate receptor on HT29 and Caco-2 cell membrane and higher efficacy of internalization via folate receptor-mediated endocytosis. Moreover, variation in the degree of folate receptor among various colorectal cancer cell lines will result in variation in degree of target uptake efficiency. The folate receptor expression on HT29 cell membrane was remarkable higher than that on Caco-2 cell membrane (Figure 5), and this resulted in a lower f06CNA engulfment and a lower difference in the enhanced PpIX accumulation in Caco-2 cells than in HT29 cells (Figure 6A). In addition, the improvement of cell uptake via electrostatic attraction between particles and cell membrane was not conspicuous for HT29 and Caco-2 cells due to no difference of PpIX accumulation in HT29 and Caco-2 cells when cultured in a fresh medium suspending with the prepared nanoparticles bearing different surface charge and free folic acid (Figure 6B).

In previous studies, 5-ALA was encapsulated in chitosan nanoparticles and taken up by cells but not bacteria, which could interfere with the efficacy of detection of cancer cells. However, culturing the 5-ALA loading chitosan nanoparticle with cancer cells for 24 h would result in an observable fluorescent intensity (*19*). The conjugation of folic acid onto a chitosan molecular backbone via amide bond could promote the uptake of particles into a cell after only 12 h of incubation time. The HT29 and Caco-2 cells showed a stronger uptake of f06CNA nanoparticles than those of pure 5-ALA alone (Figure 7). When HT29 and Caco-2 cells were fed with f06CNA, the f06CNA was easily engulfed via folate receptor-mediated endocytosis, and then 5-ALA could be converted into to PpIX intracellularly to reach the visual fluorescent intensity noted after 12 h of incubation. Since PpIX in normal cells is always maintained at a constant level (*16*), no red fluorescence suggesting interference with the diagnostic results could be observed inside CCD112 cells

(Figure 7). The results shown in Figure 8 confirmed that the f06CNA was easily taken up either in HT29 cells or in Caco-2 cells as against the CNA. However, the difference in the enhanced particle uptake evaluated from the calcein fluorescence intensity was much higher than that determined by PpIX accumulation, suggesting that the release of 5-ALA from f02CNA and f06CNA was slow and sustained and resulted in a lower improvement of PpIX accumulation. These findings suggest that 5-ALA would be a perfect precursor exogenous chromophore for detecting cancer lesions and that chitosan conjugated with folic acid could be a suitable vehicle for carrying 5-ALA.

In clinical applications, because employing folic acid conjugated with chitosan nanoparticles only in oral form might result in dissolution in the stomach at a pH that is lower than that of the pK_a of chitosan (*34*), coating the conjugate with a pH-sensitive polymer, such as poly(acrylic acid) (*35*), would be necessary. Furthermore, the usage of STPP and acetic acid solution in the particle preparation process will not cause any distress to the blood circulation or other part of human systems when the folic acid-conjugated chitosan nanoparticles are applied as an oral form for the colon-specific drug delivery system.

CONCLUSIONS

In this study, a chitosan nanoparticle that was successfully conjugated with folic acid and loaded with 5-ALA was taken up by HT29 and Caco-2 cell lines, most likely via receptor-mediated endocytosis. Chitosan conjugated with folic acid appears to be an ideal vector for colorectal-specific drug delivery of 5-ALA for fluorescent endoscopic detection of colorectal cancer.

Considerations of Solid-Phase DNA Amplification

Ramkumar Palanisamy,† Ashley R. Connolly,† and Matt Trau*

Centre for Biomarker Research and Development, Australian Institute for Bioengineering and Nanotechnology (AIBN), The University of Queensland, Brisbane Qld-4072, Australia. Received November 10, 2009; Revised Manuscript Received February 3, 2010

Solid-phase (SP) polymerase chain reaction (PCR) is an increasingly popular tool used to produce immobilized DNA for a variety of applications, including high-throughput DNA sequencing and SNP analysis. Despite its usefulness, the mechanism of DNA amplification using immobilized primers has not been thoroughly explored. Herein, we describe a SP-PCR process that was designed to explore and better understand some limitations of SP-DNA amplification. The rate of SP-DNA amplification was measured, and the ability to exponentially amplify DNA on a surface was demonstrated. Approximately 50 amol of DNA was amplified to detectable levels using SP-PCR. The mechanism and some limitations of the reaction were investigated by measuring the density of the primer on the surface prior to amplification and the amount of immobilized amplicon produced after SP-PCR. This enabled some of the practical limitations of the reaction to be addressed within a logical theoretical framework.

INTRODUCTION

The polymerase chain reaction (PCR) has revolutionized the field of molecular biology by enabling a specific fragment of DNA in a heterogeneous mixture to be amplified in excess of one million fold. This very sensitive technique enables DNA to be amplified to levels that are detectable and useful in a wide range of biological applications (*1, 2*).

Conventionally, PCR is performed in solution using two primers that are each designed to hybridize to the 3′ ends of a denatured DNA duplex. A thermostable DNA polymerase is used to extend the 3′ end of each primer to replicate the duplex, which accumulates exponentially with repetitive rounds of thermal cycling. PCR can also be used to generate an immobilized amplicon in a process called solid-phase (SP) PCR. There are two common forms of SP-PCR. In one form, DNA amplification is initiated with both primers in solution to enable the amplicon to be produced in an amount sufficient to extend an immobilized primer (*3*−*6*). The second form involves generating an immobilized amplicon by grafting both primers on a surface (*6, 7*). The primer(s) can be immobilized on a microtiter plate (*8, 9*), a flat surface (*10*−*12*), or a microbead encased in a micelle. In each case, enzymatic extension of the primer produces a tethered amplicon that can be easily detected, quantified, and manipulated for subsequent applications including cloning, high-throughput DNA sequencing and SNP detection (*13, 14*).

Despite its potential, the amount of immobilized amplicon produced using SP-PCR is limited. Although the surface itself reduces the yield of amplicon, numerous nonfouling surfaces and strategies to project the primer away from the surface have had only limited success (*15, 16*). To better understand the factors that reduce the yield of amplified DNA, a SP-PCR assay on silica microbeads was developed. This enabled the mechanism of SP-DNA amplification to be thoroughly investigated. The detection limit of the SP-PCR system was determined, and the kinetics of DNA amplification on the surface of a microbead were investigated. The amount of immobilized primer extended during the amplification reaction was also quantified and the accuracy of the assay was assessed. These data provide an insight into the mechanism and some of the fundamental limitations of SP-DNA amplification.

MATERIALS AND METHODS

Fluorescently Encoded Microbeads. Preparation of 6 μm diameter silica microbeads has been previously described (*17*). The microbeads were coated with aminopropylsilane, and the surface was derivatized with adipic acid (*18*).

Coupling of Oligonucleotides to Microbeads. The 5′ end of the forward primer was coupled to 6 μm adipic acid coated microbeads using standard 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) chemistry (*18*). The DNA coupled microbeads were pelleted by centrifugation at 10 000 G for 30 s and washed three times with 1 mL of 0.1 M 2-morpholinoethane sulfonic acid (MES buffer supplemented with 0.01% SDS) and stored at 4 °C.

Oligonucleotides. Unlabeled oligonucleotides were purchased from GeneWorks (GeneWorks Pty. Ltd., Adelaide, Australia), and fluorescently labeled oligonucleotides were purchased from Invitrogen (Invitrogen Corporation, California, USA). The oligonucleotides used in this study are listed in Table 1.

Solid-Phase Polymerase Chain Reaction. 50 pg of single-stranded (ss) DNA template was amplified in a 30 μL reaction containing 1.25 U of Taq DNA polymerase (GoTaq Flexi DNA polymerase, Promega Corporation, Wisconsin, USA), 0.2 mM

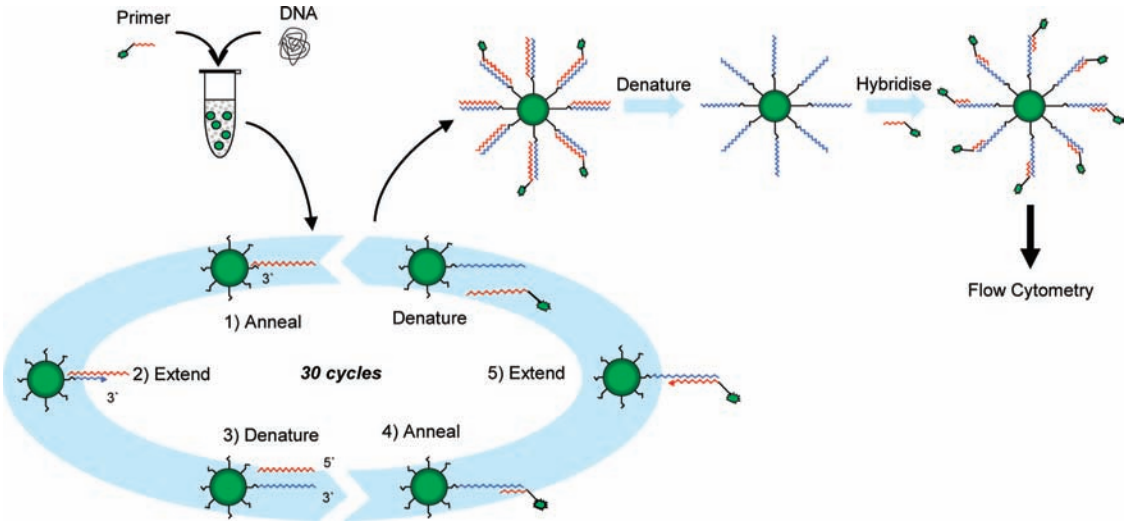

Figure 1. SP-PCR. Microbeads containing the immobilized forward primer were suspended in a solution containing the reverse primer and the DNA template. The template annealed to the immobilized forward primer (1) enabling the 3′ end of the primer to be extended by Taq polymerase (2) to generate dsDNA. The DNA duplex was thermally denatured (3) to allow the reverse primer to anneal to the newly synthesized immobilized amplicon. (4). Extension of the reverse primer regenerated dsDNA duplex (5) which was subjected to repetitive cycles of denaturation, annealing, and extension to produce many immobilized amplicons. The extent of SP-PCR was determined by denaturing the amplicon and probing the surface immobilized ssDNA with a fluorescent reverse primer. The level of fluorescence was quantified using a flow cytometer.

of each dNTPs, 2.5 mM $MgCl_2$, 1× PCR buffer (GoTaq PCR buffer, Promega), 0.1% Tween 20, 0.5 μM of A488 reverse primer, and approximately 4×10^4 microbeads containing the immobilized forward primer. Cycling was carried out in a Corbett Research thermocycler using the following conditions: denaturation at 94 °C for 1 min, followed by 30 cycles of 94 °C for 1 min, 55 °C for 2 min, and 72 °C for 1 min.

DNA Hybridization. Following PCR, the immobilized amplicon was denatured at 100 °C for 90 s in 400 μL of 4× SSC buffer (0.6 M NaCl, 0.06 M sodium citrate). The microbeads were pelleted and denaturation was repeated twice. 50 ng of A488 reverse primer was hybridized to the immobilized ssDNA in 10 μL milli Q and 4 μL hybridization buffer (50 mM $NaHPO_3$, 0.5 M NaCl, and 0.5% SDS). Hybridization was performed at 55 °C for 60 min in a vessel shaking at 1400 rpm. The microbeads were then washed and suspended in 100 μL of 0.01% SDS in preparation for analysis using flow cytometry.

Flow Cytometry. Fluorescence on the surface of the microbeads was measured using a DakoCytomation Moflo flow cytometer. The Alexa 488 (A488) fluorophore (Invitrogen Corporation, CA, USA) was excited with a 488 nm laser and emission monitored at 530 nm. The Cy5 fluorophore (GE Healthcare Bio-Sciences, Uppsala, Sweden) was excited with a 635 nm laser and emission monitored at 670 nm. Data were collected on a logarithmic scale and analyzed using *Summit* v 4.0 software.

RESULTS

Assay Design. The mechanism of SP-PCR was investigated using a PCR assay designed to exclusively amplify surface immobilized DNA. The assay was initiated by hybridization of a ssDNA template to an immobilized forward primer. Enzymatic extension of the immobilized primer generated an immobilized amplicon. A reverse primer could then hybridize to the immobilized amplicon and undergo extension to produce a copy of the ssDNA template (Figure 1). Therefore, SP-PCR will only progress after enzymatic extension of the immobilized forward primer. This enabled the mechanism of SP-PCR to be analyzed in the absence of any amplification of DNA in solution, which will inevitably occur if amplification is initiated with a dsDNA template.

Following amplification, the amount of PCR product on the surface was measured by denaturing the amplicon and hybridizing a fluorescently labeled DNA probe to the immobilized ssDNA. The intensity of the fluorescent signal on surface of the microbead was measured using a flow cytometer to reveal the amount of SP-DNA synthesis.

Assay Optimisation. Several parameters likely to affect SP-PCR were optimized to ensure efficient DNA amplification. Washing the microbeads with PCR buffer prior to amplification was essential for successful SP-PCR. The concentration of magnesium was varied between 2 and 3 mM and amplification was optimal at 2.5 mM. To ensure amplification was not limited by the amount of the reverse primer in the reaction, its concentration was the doubled from 0.5 μM which produced only 15% increase in the amount of immobilized amplicon. Subsequent increases in concentration had no effect on the yield of SP-DNA amplification. 4×10^4 microbeads were used in the SP-PCR. The amount of forward primer in the PCR was changed by varying the number of microbeads added to the reaction. Halving the number had no significant effect on the yield of the immobilized amplicon, while an excess number of microbeads reduced the yield of immobilized amplicon, which was attributed to sedimentation of the microbeads.

The rate of hybridization of a complementary strand of DNA to the immobilized primer will dictate the duration of the annealing step during PCR. This was determined by directly hybridizing a complementary fluorescent probe to the immobilized forward primer at 55 °C in PCR buffer. The extent of hybridization to the immobilized primer was determined by measuring the fluorescence using flow cytometry. After hybridization for 1.5 min, the fluorescence on the surface of the microbead reached 70% of the maximum level measured after 10 min. This indicated an annealing time of approximately 2 min during SP-PCR cycling was sufficient for the DNA template to hybridize to the immobilized primer.

Detection Limit. Fluorescently encoded microbeads have been used for sensitive detection of PCR products (*19*−*22*). However, amplification of DNA directly on a surface is considerably less sensitive (*6, 7*). Therefore, we investigated some factors that were likely to influence SP-DNA amplification

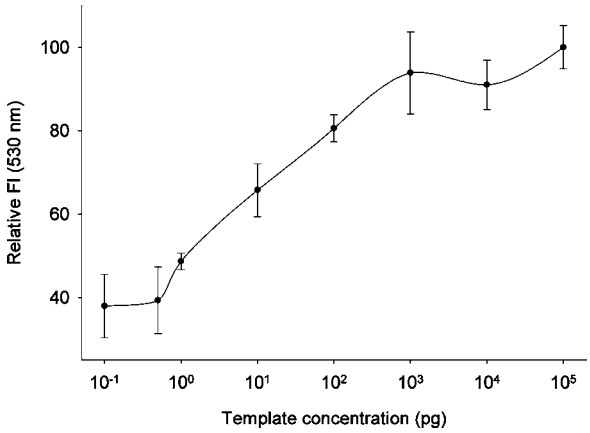

Figure 2. Replicate SP-PCR were prepared each containing approximately 4×10^4 microbeads with the forward primer immobilized on their surface, the reverse primer in solution, and the specified amount of DNA template. Following amplification, the immobilized dsDNA was denatured and the extent of SP-PCR was determined by hybridizing a fluorescent probe to the immobilized ssDNA amplicon. Values represent the mean fluorescence ± standard deviation of triplicate reactions (*y*-axis) for each template concentration (*x* axis) which was determined by flow cytometric analysis of the microbeads.

in an attempt to characterize and better understand the limitations of the reaction.

The detection limit and analytical range of this SP-PCR was assessed by amplifying serial dilutions of the DNA template (from 100 ng to 100 fg) in triplicate reactions containing the immobilized forward primer and the reverse primer in solution. The extent of SP-DNA amplification was determined by hybridizing a fluorescent probe to the ssDNA immobilized on the surface after denaturation of the amplicon. The fluorescence increased with template concentration (Figure 2), indicating that more DNA amplification occurred on the surface at higher template concentration. When the DNA template was present in excess of 1 ng, there was no significant increase in the amount of immobilized amplicon produced, suggesting the surface became saturated with the with PCR products. The coefficient of variation of the replicate reactions varied from 4% to 20% and was, on average, 10% throughout the analytical range of template concentrations.

Amplification Mode. The amount of SP-PCR product increased as more DNA template was added to the reaction (Figure 2). However, it is unclear if this increase was the result of linear amplification or inefficient exponential amplification of the template. When a single primer is used in a PCR, the amount of template will only double after each cycle resulting in linear amplification of DNA. In the presence of both primers, DNA amplification progresses exponentially and the amount of amplicon produced is maximized. Therefore, the mode of SP-DNA amplification was investigated by omitting the reverse primer to ensure linear amplification of the template. The reverse primer was then added to a replicate reaction to enable it to proceed exponentially. The extent of DNA amplification was determined by hybridizing a fluorescent probe to the ssDNA remaining on the surface after denaturation of the amplicon. After 25 cycles of linear amplification, there was a 2.3-fold increase in the amount of PCR product on the surface. After 25 cycles of exponential PCR, there was a 7.8-fold increase in the amount of PCR product, which was 3.4-fold more than linear amplification (Figure 3). This demonstrates that the reverse primer is utilized during SP-PCR to increase the amount of SP-DNA produced during amplification.

The change in fluorescence on the surface of the bead at different cycle numbers was used to determine the efficiency of SP-DNA amplification. In a PCR, the initial amount of DNA template (T_o) amplifies with an efficiency (E_t) over (j) cycles to produce an amount of product (T_j) according to eq 1 (*23*).

$$T_j = T_o(1 + E_t)^j \quad (1)$$

Equation 1 was solved for different values of E_t to produce a curve that approximated the experimentally acquired data (Figure 3). This revealed that exponential SP-PCR progressed with an amplification efficiency (E_t) of approximately 9%, before the reaction reached a plateau after 17 cycles.

Quantification. The amplification efficiency of SP-PCR is approximately 91% lower than PCR performed in solution. This inefficiency may be attributed to a low primer concentration, its inability to diffuse through solution, or inefficient enzymatic extension. However, attempts to overcome these inefficiencies by projecting primers away from the surface or modifying surface have had only limited success (*15, 16*). In an attempt to better understand the factors that limit SP-PCR, the amount of DNA amplification on the surface was accurately measured.

Initially, the amount of forward primer immobilized on the surface of each microbead was quantified. Different amounts of a fluorescently labeled DNA strand complementary to the immobilized primer were prepared and incubated with replicate samples containing 4×10^4 microbeads. The fluorescence on the surface of each bead was plotted as a function of DNA concentration to produce a curve indicative of a Langmuir isotherm (*24*) (Figure 4). The amount of immobilized primer was determined by calculating the amount of fluorescent DNA that saturated the surface of 4×10^4 microbeads. A 6.0 ± 0.5 μm diameter microbead was found to contain $(2.6 \pm 0.2) \times 10^6$ primers or $(2.3 \pm 0.3) \times 10^{10}$ primers per mm^2. Therefore, approximately 0.17 pmol of forward primer was added to each PCR with the addition of 4×10^4 microbeads.

The amount of immobilized amplicon produced after 30 cycles of SP-PCR was also measured. Following amplification, the immobilized amplicon was denatured to generate immobilized ssDNA. Different amounts of the fluorescently labeled

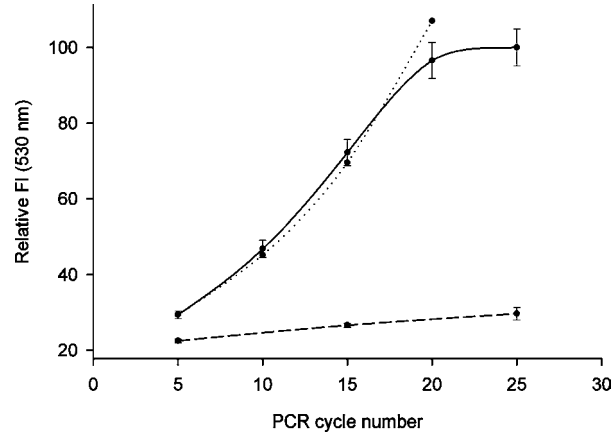

Figure 3. Replicate SP-PCRs were prepared each containing approximately 4×10^4 microbeads with the forward primer immobilized on their surface and 1 ng of DNA template. The reverse primer was either omitted from the SP-PCR (dashed line) or added to the reaction (solid line). Amplification progressed for the indicated number of cycles. Following amplification, the immobilized dsDNA was denatured, and the extent of SP-PCR was determined by hybridizing a fluorescent probe to the immobilized ssDNA amplicon. Values represent the mean fluorescence ± standard deviation of triplicate reactions (*y*-axis) for each template concentration (*x* axis), which was determined by flow cytometric analysis of the microbeads. The efficiency of exponential SP-PCR was calculated by solving eq 1 for different values of E_t. An amplification efficiency of 9% ($E_t = 0.09$) and an arbitrary T_o value of 72.17 were substituted into eq 1 to calculate T_j at different cycle numbers to obtain a line (dotted) that best fits the experimental data.

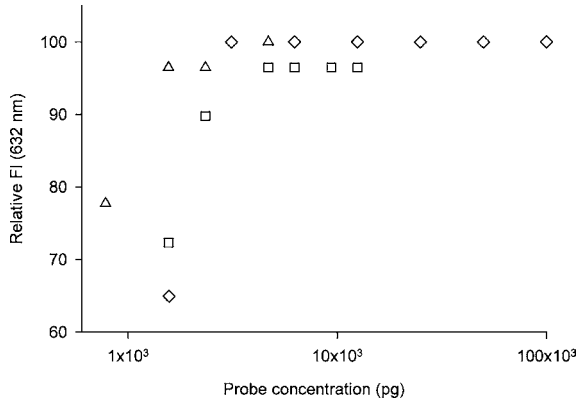

Figure 4. Replicate samples containing 4×10^4 microbeads with the forward primer immobilized on the surface were prepared. Each sample was hybridized with the specified concentration of fluorescently labeled oligonucleotide probe (◇), complementary to the immobilized primer. The experiment was repeated (□) and performed with fewer microbeads (2×10^4 (Δ)). The fluorescence on the surface of each bead was measured using flow cytometry. The values represent the average fluorescence on the surface of each microbead (*y*-axis) for each concentration of the complementary fluorescent probe (*x*-axis) measured by flow cytometry. The amount of immobilized primer was determined by calculating the amount of fluorescent DNA that saturated the surface of the microbeads.

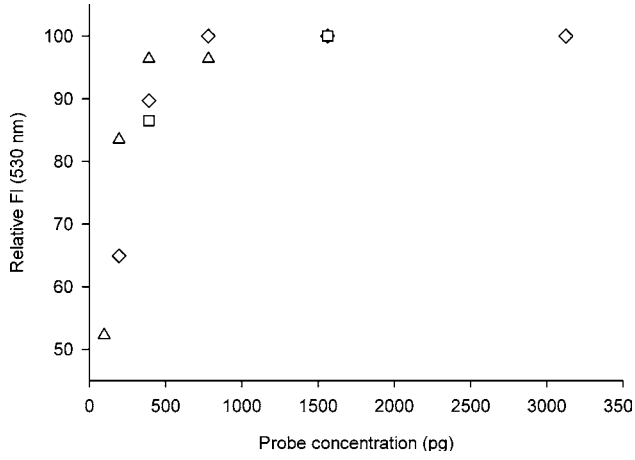

Figure 5. SP-PCR amplification of 1 μg of DNA template was performed in replicate reactions containing 2×10^4 microbeads, then the immobilized amplicons were denatured. Each sample was hybridized with the specified concentration of fluorescently labeled oligonucleotide probe (◇), complementary to the immobilized amplicon. The experiment was repeated (Δ) and performed with fewer microbeads (1×10^4 (□)). The fluorescence on the surface of each microbead was measured using flow cytometry. The values represent the average fluorescence on the surface of each microbead (*y*-axis) for each concentration of the complementary fluorescent probe (*x*-axis). The amount of immobilized amplicon produced by SP-PCR was determined by calculating the amount of fluorescent DNA that saturated the surface of the microbeads.

reverse primer were prepared and incubated with replicate samples containing 2×10^4 microbeads. The fluorescence on the surface of each microbead after hybridization is depicted in Figure 5. The amount of immobilized PCR product was measured and it was calculated that each microbead contained $(9.5 \pm 0.7) \times 10^5$ amplicons, or $(8.4 \pm 1.1) \times 10^9$ amplicons per mm^2. Therefore, only (36 ± 7)% of the primers immobilized on the surface were extended after 30 cycles of SP-PCR.

The molecular geometry of ssDNA in solution has been modeled. The theoretical radius of gyration of a 96 base ssDNA amplicon was calculated to be approximately 3.0 nm with a cross section area of 28.8 nm^2. Therefore, each 6.0 ± 0.5 μm bead can ideally contain $(3.5 \pm 0.4) \times 10^{10}$ amplicons per mm^2. Therefore, only (24 ± 4)% of the available surface was covered with the amplicon after 30 cycles of SP-PCR.

DISCUSSION

We have devised a SP-PCR assay on a microbead that enabled the mechanism of SP-DNA amplification to be explored. The assay described herein was performed using only the reverse primer in solution to generate an immobilized amplicon. This enabled the mechanism of SP-PCR to be analyzed in the absence of any amplification of DNA in solution. DNA was amplified exponentially on the surface and the amount of amplicon produced was quantified.

Reaction conditions for optimal SP-DNA amplification were elucidated and found to be similar to those of conventional PCR, despite the reported use of lengthy cycling parameters (*5*). Conditioning the DNA-coated surface with the PCR reaction buffer was essential for successful amplification and hybridization of the template to the immobilized primer occurred rapidly during thermal cycling. The forward primer was found to be securely immobilized on the surface despite reports of primer detachment during thermal cycling (*6*). The stability was attributed to the covalent attachment of the forward primer and the molecular stability of the silica microbeads. As a result, the coefficient of variation was on average 10% between replicate amplification reactions. This level of reproducibility was obtained without agitating the microbeads during thermal cycling, which has been reported to retard SP-DNA amplification (*25*). It is unclear if the microbeads remain in suspension during the reaction, but it is clear that they all contain a consistent amount of surface immobilized amplicon. Therefore, the template was not locally sequestered on the surface but diffused freely in solution initiating DNA polymerization on different microbeads in the reaction.

The amount of PCR product generated on the surface of each microbead increased when more template was added to the reaction (Figure 2). However, when the template concentration was in excess of 1 ng there was no appreciable increase in the amount of amplicon produced. This may be due to the DNA template saturating the surface or other factors may be acting to retard amplification. It is generally accepted that lack of diffusion, proximity to the surface, and low concentration of the immobilized primer most likely inhibit SP-DNA amplification (*15, 16, 25, 26*). However, *Taq* polymerase was enzymatically active while in close proximity to the surface and was able to perform both forward and reverse priming reactions effectively. Moreover, the DNA template was shown to undergo exponential amplification during the reaction. The efficiency of exponential SP-PCR was approximately 9% (i.e., $E_t = 0.09$) indicating that only 9 of 100 primers were extended during each cycle of PCR. This is substantially lower than solution PCR where the efficiency approaches 90−100% (i.e., $E_t = 0.9-1.0$) (*27*). Attempts to increase the overall yield of the immobilized amplicon by increasing PCR cycle number and reducing the number of microbeads had no measurable impact on the detection limit. Approximately 3×10^7 copies of DNA could be amplified to detectable levels by SP-PCR.

Only a fraction (36%) of the immobilized primers were extended during SP-PCR. This suggests amplification was not limited by the amount of the immobilized primer, but more likely by the generation of the amplicon itself. The immobilized amplicon (96 bases) was 2.4-fold longer than the primer (40 bases) and could conceivably "mask" adjacent primers after amplification. More specifically, primers within approximately one gyration radius of the amplicon would experience this masking effect. This will predominate when the primers are immobilized at high density, while at low density, amplification will be limited by insufficient primers.

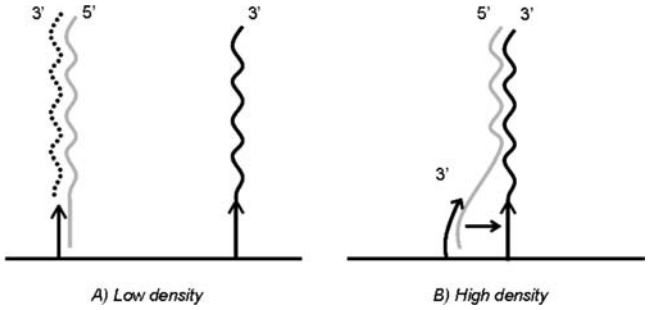

Figure 6. Neighboring DNA interactions during SP-PCR. (A) When the DNA amplicons (black line) are at low density, the 3′ end of the immobilized primer (arrow) will undergo extension by Taq polymerase to produce a new immobilized amplicon. (B) As SP-PCR progresses, the amplicon density increases and it is proposed that extension of the immobilized primer is retarded because the DNA template (gray line) will hybridize to an adjacent amplicon in preference to the primer.

A 96-base amplicon has a theoretical gyration radius of 3.0 nm and a cross-sectional area of approximately 28.8 nm^2. This would enable approximately 3.5×10^{10} amplicons to be produced per mm^2, on the surface of each 6 μm bead. However, only 8.4×10^9 amplicons were generated per mm^2, which is substantially lower than expected. The amount of product produced during SP-PCR may not be limited exclusively by primer "masking", other factors may also retard amplification.

SP PCR progressed exponentially, but amplification was retarded during the later cycles (Figure 3) which suggests the progress of the reaction was inhibiting amplification. As the amount of immobilized PCR product increased, the DNA template may be likely to hybridize to the immobilized amplicon in preference to the primer. This will prevent primer extension and limit the amount of SP-DNA amplification. This inhibitory effect is more likely to occur when the immobilized primer and amplicon are in close proximity. More specifically, when separated by the approximate gyration diameter of the template, the PCR template is more likely to hybridize to the immobilized amplicon in preference to the immobilized primer (Figure 6). Under these conditions, it is predicted that SP-DNA amplification will reach a "plateau" when the immobilized amplicon density is 75% lower than that predicted theoretically. This is equivalent to $(8.7 \pm 1.0) \times 10^9$ amplicons per mm^2, which is similar ($97 \pm 17\%$) to the experimentally determined value of $(8.4 \pm 1.1) \times 10^9$ amplicons per mm^2. The inhibitory effect of SP-PCR is likely to be enhanced by factors that increase the gyration radius of the amplicon. Larger amplicons have an increased gyration radius and are predicted to have a lower yield during SP-PCR, which is consistent with experimental findings (*28*). "Spacers" designed to project the primers from the surface will make the primers more accessible to the polymerase, but will also increase the gyration radius of the amplicon and may limit the yield of SP-PCR.

In summary, we have characterized some factors that influence SP-DNA amplification and have identified other factors that are likely to limit the yield of DNA during amplification. It has been demonstrated that DNA polymerase retained catalytic activity in close proximity to a surface. SP-PCR was used to exponentially amplify ssDNA to generate a unique homogeneous amplicon on a surface. However, the amplification efficiency was substantially lower than that of solution-phase PCR. The amount of amplicon produced was not exclusively limited by a lack of diffusion and concentration of the immobilized primer, but more likely by the production of the immobilized amplicon during the reaction. The data presented here provide insight into the mechanism of SP-DNA amplification and highlight some factors that may need to be addressed in order to achieve efficient DNA amplification on a surface.

Novel Cationic Lipids Based on Malonic Acid Amides Backbone: Transfection Efficacy and Cell Toxicity Properties

Martin Heinze,[†] Gerald Brezesinski,[‡] Bodo Dobner,[†] and Andreas Langner*[,†]

Institute of Pharmacy, Department of Biochemical Pharmacy, Martin-Luther-University, Wolfgang-Langenbeck-Strasse 4, 06120 Halle (Saale), Germany, and Max Planck Institute of Colloids and Interfaces, Am Muehlenberg 1, 14476 Potsdam, Germany. Received November 11, 2009; Revised Manuscript Received December 23, 2009

Gene delivery using nonviral approaches has been extensively studied as a basic tool for intracellular gene transfer. Despite intensive research activity, the aim of creating a vector which meets all necessary demands has still not been reached. One possibility to solve the nonviral vector associated problem of low transfection efficacy is the development of new cationic amphiphiles. Therefore, the non-glycerol-based cationic lipids **1**−**9** have been synthesized and tested for in vitro gene delivery experiments. The backbone structure of the lipids consists of a malonic acid diamide with two long hydrophobic chains. The degree of saturation of the hydrophobic chains and the structure of the polar cationic headgroup were varied. The preparation follows an easy process and facilitates the trouble-free insertion of different alkyl chains. By studying in vitro gene delivery an increase of transfection efficacy was observed when using at least one unsaturated alkyl chain in the hydrophobic part and lysine or bis(2-aminoethyl)aminoethylamid as hydrophilic headgroup. This leads to cationic lipids exhibiting comparable or even higher transfection efficacies compared to the commercially available LipofectAmine and SuperFect.

INTRODUCTION

Without doubt, gene therapy is a very promising method for the treatment of cancer and genetic diseases which are still insufficiently treatable (*1–3*). Although a lot of work has been done creating efficient gene shuttles and progress has been made over the past years, there exists no satisfying gene transfer system. In addition to the application of viral vectors, the design and synthesis of new cationic lipids is a very promising tool for gene therapy. While the transduction with modified viruses is very efficient especially for in vivo gene transfer, viruses have eminent disadvantages due to their immunogenic potential and their possibility to induce cancer (*4–7*). Nonviral gene delivery systems have, on one hand, been demonstrated as standard tools for in vitro transfection with currently more than 60 commercially available kits (*8*). On the other hand, they are regarded as a promising approach for the treatment of genetic diseases (*9, 10*) and cancer (*11–13*). However, nonviral gene delivery suffers from low transfection efficiency. Surely this is the main reason that these gene delivery systems have just a marginal stake in clinical trials (*14*). For this reason, it is of great importance to advance nonviral gene transfer systems. One possibility is the development of new, efficient, and nontoxic cationic lipids.

There are mainly three structures of cationic amphiphiles used for gene delivery: glycerol derived lipids and cholesterol-based and non-glycerol-based compounds. The group of glycerol derived lipids includes in addition to *N*-[1-(2,3-dioleyloxy)propyl]-*N,N,N*-trimethylammoniumchloride (DOTMA)[1] , first described by Felgner in his pioneering work (*15*), 1,2-dioleoyloxy-3-(trimethylammonio)propane (DOTAP), 1,2-dimyristyloxypropyl-3-dimethyl(hydroxyethyl)ammoniumbromide (DMRIE), and 2,3-dioleyloxy-*N*-[2-(spermincarboxamido)ethyl]-*N,N*-dimethyl-1-propane-ammoniumtrifluoracetate (DOSPA) (*16–18*). Substances that exhibit no glycerol backbone are also capable of transfering genes into cells, especially by the usage of *N*-methyl-4-(dioleyl)methylpyridiniumchloride (SAINT-2) or 1-[2-(oleoyloxy)ethyl]-2-oeyl-3-(2-hydroxyethyl)imidazoliniumchloride (DOTIM) (*19, 20*).

For a number of these and other cationic amphiphiles, it was shown that hydrophobic chains as well as the polar head and even the connecting backbone have a great influence on the transfection efficiency (*16, 19, 21–23*). Several groups have been working on establishment of a structure−function relationship to define the requirements for safe and efficient gene transfer with cationic lipids (*16, 19–26*).

We have now designed a new class of cationic lipids consisting of the diamide structure of malonic acid as anchor group for the hydrocarbon chains as well as the cationic headgroup inclusive spacer molecules. The idea for the preparation of these new substances is mainly based on three characteristics: First, the new compounds are easy to produce starting from cost-effective materials, and the syntheses facilitate the trouble-free insertion of different alkyl chains. Second, it may be accepted that the compounds should have biocompatibility due to the amide bond as a connection between polar headgroup, linker moiety, and partially the hydrophobic chains. Third, a positive effect may result from the ability of the malonic diamide structure to build an H-bonded network, which could stabilize the complex formation especially under neutral conditions.

The characteristic of the compounds is the specific feature of hydrophobic chain bound to malonic acid amides backbone. One alkyl chain is bound to C2 of the malonic acid, whereas the second hydrophobic chain was linked via an amide bond to one of the carboxylic groups of the diacid. The two alkyl chains that are necessary for satisfying gene delivery vary in the degree of saturation. Starting from two C16 chains, we replaced them by successive substitution with the oleyl residue whereby the chain was elongated. According to the generally accepted finding that spacer molecules enhance the efficacy of transfection (*27*), at first we used only ethylene diamine and tris(aminoethyl)amine as spacer molecules. These compounds were connected with the malonic acid backbone by a second amide bond. Lipids **1**−**3** with the ethylene amine spacer itself were capable of transfering DNA into cells in culture, admittedly to a minor degree. However, this molecule residue was introduced for binding a proper cationic headgroup. The primary amino group was then transformed into a further amide function with boc-lysine resulting in two protonable amine residues after elimination of the protective groups. On the other hand, the tris(aminoethyl)-amine comprises both the spacer and the headgroup resulting from the two aminoethyl residues at the tertiary amine. This branched structure is suitable for the creation of dendrimer-like headgroups (*28*).

The main focus of attention for the new lipids was concentrated on transfection efficacy and toxicity properties compared with LipofectAmine and SuperFect, as they are the frequently used nonviral gene delivery systems. In first tests with these new transfection reagents, we have observed enhanced gene transfection activity with regard to commercially available vectors.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. All materials and reagents were purchased from SigmaAldrich Co. Ltd. unless otherwise stated. All solvents were analytically pure and dried before use. The reactions were performed under argon. TLC was carried out on aluminum sheets precoated with silica gel 60 F254 (Merck) and developed with bromothymol blue dip. Column chromatography was performed using silica gel 60 (0.04−0.063 mm) for middle-pressure liquid chromatography (MPLC, Büchi, Germany) or silica gel 60 (0.063−0.200 mm) for normal-pressure procedure. The ESI−mass spectra were recorded with a Finnigan MAT 710 C (Thermo Separation Products, San Jose, USA) with electron spray ionization energy of 4.5 kV in negative and positive modus. EI−mass spectra were prepared with an AMD 402 (70 eV, AMD Intecta GmbH, Harpstedt, Germany). The ^{1}H NMR and the ^{13}C NMR spectra were recorded on a Varian Gemini 2000. For performing the elemental analysis, a Leco apparatus was used. The final products were fully characterized by ^{1}H NMR, ^{13}C NMR, mass spectrometry, and elemental analysis. p-CMV-SPORT-β-Gal plasmid and LipofectAmine reagent were purchased from Invitrogene Life technologies (Germany). SuperFect and plasmid isolation kit were purchased from QIAGEN (QIAGEN, Hilden, Germany). LLC PK1 cells (ATCC CL−101) were purchased from the American Type Culture Collection (ATCC USA) and A549 cells from German Collection of Microorganisms and Cell Cultures (DSMZ GmbH). Cell culture media, fetal bovine serum, and phosphate buffered saline were supplied from PAA Laboratories (PAA Laboratories GmbH Germany). Antibiotics and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma (Sigma Aldrich, Germany). DOPE was purchased from Fluka (Switzerland), and cholesterol was supplied from Roth (Carl Roth GmbH Germany).

Alkyl Malonic Acid Monoethyl Ester IIa,b. The alkyl malonic acid diethyl ester **I** (0.045 mol) was dissolved in ethanol (30 mL). Then, potassium hydroxide (2.92 g, in 30 mL ethanol) was added dropwise during 1 h into the solution with stirring. The mixture was stirred for further 3 h and was then allowed to stand overnight at room temperature. The mixture was heated for a short time to reflux, and the hot solution was filtered to remove bis-potassium salt. From the cooled mixture, the monopotassium salt of hexadecyl malonic acid monoethyl ester was separated by filtration. The salt was dissolved in water and acidified with equimolar amount of 0.1 M hydrochloric acid. The crude monoester was then extracted three times with 30 mL ether. The combined etheral solutions were washed with water and brine, dried over sodium sulfate, and evaporated to dryness. The compound was purified by crystallization from heptane or by column chromatography using silica gel 60.

In the case of **IIb**, no salt precipitates. Therefore, the mixture was concentrated under vacuum to the half of the volume and acidified after cooling. Compound **IIb** was then extracted 3 times with ether, and the combined etheral phase was washed and dried as described above. **IIb** was purified by column chromatography.

Hexadecyl Malonic Acid Monoethyl Ester (IIa). The experimental data were in agreement with the literature (*29*).

(9*Z*)-Octadec-9-enyl Malonic Acid Monoethyl Ester (IIb). Yield: 68%, colorless oil, $C_{23}H_{42}O_4$, 382.57 g/mol, EI−MS: 382 (M^+).^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.85 (t, 3H, [−C*H*$_3$]), 1.20−1.90 (m, 29H, [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_7$−], [−OCH_2CH_3]), 1.95−2.05 (m, 4H, [−CH_2CH═$CHCH_2$−]), 3.38−3.40 (t, 1H, [−C*H*−]), 4.22 (q, 2H, [−OCH_2CH_3]), 5.30−5.39 (m, 2H, [−C*H*═C*H*−]). Anal. Calcd.: C, 72.20; H, 11.06. Found: C, 71.92; H, 11.17.

2-[(Alkylamino)carbonyl]octadecanoic Acid Ethyl Ester IIIa,b. *Procedure 1.* Compound **IIa** (0.014 mol) and 10 mL thionyl chloride were given into a flask, and the mixture was allowed to stand overnight at room temperature until a clear solution appears. Then, the excess thionyl chloride was removed under vacuo. The residue was dried under vacuum over potassium hydroxide. After that, the crude malonic ester chloride was dissolved in 50 mL dry $CHCl_3$ and cooled down to 0 °C. Hexadecylamine or oleylamine (0.013 mol) and triethyl amine (1.3 g, 0.013 mol), dissolved in 10 mL dry $CHCl_3$, were dropped into the solution with stirring at the same temperature. After 2 h stirring at room temperature, the $CHCl_3$ solution was washed three times with ice water and dried over sodium sulfate. The crude product was crystallized from acetone.

Procedure 2. A suspension of compound **II** (0.014 mol), hexadecylamine or oleylamine (0.014 mol), and 3.5 g (0.014 mol) EEDQ in 100 mL ethanol was heated for 24 h at 50 °C. The solvent was then reduced to half of the volume, diluted with 100 mL $CHCl_3$, and washed with water. After drying the organic layer over sodium sulfate, the solvent was evaporated and the residue recrystallized from acetone.

2-[(Hexadecylamino)carbonyl]octandecanoic Acid Ethyl Ester (IIIa). Yield: 91% (procedure 1), 86% (procedure 2), $C_{37}H_{73}NO_3$, 580.0 g/mol, mp: 72−73 °C. ESI−MS: (M^++Na).^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.85 (t, 6H, 2[−C*H*$_3$]), 1.23−1.86 (m, 61H, [−OCH_2CH_3], [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_{14}CH_2NH$−]), 3.14−3.18 (m, 2H, [−CH_2NHCO−]), 3.22−3.28 (m, 1H, [−C*H*−]), 4.16 (q, 2H, [−OCH_2CH_3]), 6.52−6,55 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 76.62; H, 12.69; N, 2.41. Found: C, 76.58; H, 12.70; N, 12.37.

2-{[(9*Z*)-Octadec-9-enylamino]carbonyl}octadecanoic Acid Ethyl Ester (IIIb). Yield: 83% (procedure 1), 83% (procedure 2), $C_{39}H_{75}NO_3$, 606.03 g/mol, mp: 45−47 °C. ESI−MS: (M^++H). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.85 (t, 6H, 2[−C*H*$_3$]), 1.18−1.86 (m, 57H, [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_6CH_2NH$−], [−OCH_2CH_3]), 1.90−2.04 (m, 4H, [−CH_2CH═$CHCH_2$−]), 3.14−3.27 (m, 3H, [−CH_2NHCO−], [−C*H*−]), 4.17 (q, 2H, [−OCH_2CH_3]),

5.30−5.35 (m, 2H, [−C*H*═C*H*−]), 6.53−6.56 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 77.29; H, 12.47; N, 2.31. Found: C, 76.96; H, 12.43; N, 2.37.

2-{[(9*Z*)-Octadec-9-enylamino]carbonyl}-(11*Z*)-icos-11-enoic Acid Ethyl Ester (IIIc). Yield: 83% (procedure 2), $C_{41}H_{77}NO_3$, 632.04 g/mol, EI−MS: 632 (M^+, 100), mp: 32−35 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.87 (2t, 6H, 2[−CH_3]), 1.17−1.88 (m, 51 H, [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_7$−], [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_6CH_2NH$−], [−OCH_2CH_3]), 1.90−2.05 (m, 8H, 2[−CH_2CH═$CHCH_2$−]), 3.15−3.19 (m, 2H, [−CH_2NHCO−]), 3.20−3.27 (m, 1H, [−C*H*−]), 4.19 (q, 2H, [−OCH_2CH_3]), 5.30−5.40 (m, 4H, 2[−C*H*═C*H*−]), 6.50−6.54 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 77.91; H, 12.28; N, 2.21. Found: C, 77.83; H, 12.38; N, 2.30.

Saponification of IIIa−c. *General Procedure.* Potassium hydroxide (0.56 g, 0.01 mol) was added to a suspension of compound **III** (2.9 g, 0.005 mol) in ethanol (50 mL), and the mixture was heated under reflux for 5 h. After cooling to room temperature, the precipitated potassium salt was filtered by suction, washed with ether, and dried in vacuum. The salt (3.0 g, 0.0049 mol) was then suspended in 50 mL water containing 1.25 mL conc. HCl under cooling with ice and stirring. After 1 h, the acid **IV** was thrice extracted with $CHCl_3$. The combined $CHCl_3$ layers were dried and evaporated and the residue was crystallized from heptane.

2-[(Hexadecylamino)carbonyl]octadecanoic Acid (IVa). Yield: 85%, white crystals, $C_{35}H_{69}NO_3$, 577.96 g/mol, mp: 74−76 °C. ESI−MS: (M-H).^{1}H NMR (400 MHz, $CDCl_3$/CD_3OD) δ: 0.86 (t, 6H, 2[−CH_3]), 1.23−1.95 (m, 58 H, [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_{14}CH_2NH$−]), 3.09−3.18 (m, 2H, [−CH_2NHCO−]), 3.26−3.35 (m, 1H, [−C*H*−]), 5.89−5.94 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 76.16; H, 12.60; N, 2.54. Found: C, 76.16; H, 12.67, N, 2.54.

2-{[(9*Z*)-Octadec-9-enylamino]carbonyl}octadecanoic Acid (IVb). Yield: 82%, white crystals, $C_{37}H_{71}NO_3$, 577.96 g/mol, mp: 74−76 °C. ESI−MS: (M-H).^{1}H NMR (400 MHz, $CDCl_3$/CD_3OD) δ: 0.86 (t, 6H, 2[−CH_3], 1.18−1.89 (m, 54H, [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_6CH_2NH$−]), 1.92−2.05 (m, 4H, [−CH_2CH═$CHCH_2$−]), 3.14−3.30 (m, 3H, [−CH_2NHCO−], [−C*H*−]), 5.30−5.36 (m, 2H, −C*H*═C*H*−]), 6.45−6.50 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 76.89; H, 12.38; N, 2.42. Found: C, 76.91; H, 12.36; N, 2.42.

2-{[(9*Z*)-Octadec-9-enylamino]carbonyl}-(11*Z*)-icos-11-enoic Acid (IVc). Yield: 85%, white waxy substance, $C_{39}H_{73}NO_3$, 604.00 g/mol, mp: 70−72 °C. ESI−MS: (M-H).^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.80−0.89 (t, 6H, 2 [−CH_3]), 1.20−1.90 (m, 50H, [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_7$−], [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_6CH_2NH$−]), 1.92−2.08 (m, 8H, 2[−CH_2CH═$CHCH_2$−]), 3.08−3.30 (m, 3H, [−CH_2NHCO−], [−C*H*−]), 5.34−5.40 (m, 4H, 2[−C*H*═C*H*−]), 6.05−6.15 (m, 1H, [−N*H*−]). Anal. Calcd.: C, 77.54; H, 12.18; N, 2.32. Found: C, 77.44; H, 12.36; N, 2.30.

Reaction of IVa−c with the Spacer Molecules to Va−f. *Procedure 1.* Compound **IV** (1 mmol) was dissolved in 50 mL CH_2Cl_2 and 140 mg (1.2 mmol) *N*-hydroxysuccinimide were added. Then, 288 mg (1.4 mmol) DCC was added to the slurry, and the mixture was allowed to stir for 12 h at room temperature. After that time, the precipitate of dicyclohexyl urea was filtered off and ethylene diamine or tris(aminoethyl)amine (20 mmol) was added to the solution. The mixture was stirred for 4 h at room temperature. The organic layer was then filtered, washed with water and brine, and dried over sodium sulfate. After evaporation of the solvent, the crude product was purified by column chromatography on silica gel 60 and $CHCl_3$/methanol using gradient technique.

Procedure 2. Triethylamine (0.152 g, 1.5 mmol) was added to a solution of compound **IV** (1 mmol), ethylene diamine or tris(aminoethyl)amine (20 mmol), and BOP (0.442 g, 1 mmol) in CH_2Cl_2 (20 mL). The mixture was stirred at room temperature overnight. The solution was filtered, washed with water, dried over sodium sulfate, and evaporated. The residue was purified by crystallization from heptane.

***N*-(2-Aminoethyl)-*N*′,2-dihexadecyl Propane Diamide (Va).** Yield: 65% (procedure 1), 83% (procedure 2), white substance, 594.01 g/mol, mp: 74−76 °C. ESI−MS: (M^++H), ^{1}H NMR (400 MHz, $CDCl_3$/CD_3OD) δ: 0.87 (t, 6H, 2[−CH_3]), 1.00−1.57 (m, 58H, [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_{14}CH_2NH$−]), 2.72 (m, 2H, [H_2NCH_2−]), 2.90−3.10 (m, 4H, [−CH_2NHCO−], [$H_2NCH_2CH_2NHCO$−]), 3.25−3.31 (m, 1H, [−C*H*−]), 4.15−4.20 (m, 2H, 2[−N*H*−]). Anal. Calcd.: C, 74.81; H, 12.73; N, 7.07. Found: C, 74.75; H, 12.69; N, 7.05.

***N*-(2-Aminoethyl)-2-hexadecyl-*N*′-[(9*Z*)-octadec-9-enyl]-propane Diamide (Vb).** Yield: 68% (procedure 1), 80% (procedure 2), white substance, $C_{39}H_{77}N_3O_2$, 620.05 g/mol, mp: 68−71 °C. ESI−MS: (M^++H).^{1}H NMR (400 MHz, $CDCl_3$/CD_3OD) δ: 0.85 (t, 6H, 2[−CH_3]), 1.20−1.88 (m, 54H, [$H_3C(CH_2)_{15}$−], [$H_3C(CH_2)_6CH_2CH$═$CHCH_2(CH_2)_6CH_2NH$−]), 1.92−2.03 (m, 4H, [−CH_2CH═$CHCH_2$−]), 2.79−2.81 (m, 2H, [H_2NCH_2−]), 2.94−3.23 (m, 4H, [−CH_2NHCO−], [$H_2NCH_2CH_2NHCO$−]), 3.26−3.30 (m, 1H, [−C*H*−]), 5.29−5.35 (m, 2H, [−C*H*═C*H*−]), 5.77−5.80 (m, 2H, 2[−CON*H*−]). Anal. Calcd.: C, 75.55; H, 12.52; N, 6.78. Found: C, 75.43; H, 12.37; N, 6.69.

Reaction Va−c to Compounds VIa−c. *General Procedure.* 0.84 mmol of compound **V** was dissolved in 30 mL CH_2Cl_2. 0.9 mmol (0.4 g) diboc-lysin-*N*-hydroxysuccinimid ester was given to this solution. The mixture was stirred for 1 h at room temperature and then for another 10 h under reflux. After that time, the solvent was evaporated, the residue was chromatographed using a short column and dry silicagel with $CHCl_3$/methanol (98:2, v/v) as eluent. The so-purified product was dissolved in 15 mL CH_2Cl_2, and 1 mL trifluoro acetic acid was added. The mixture was allowed to stir for 4 h, then mixture was diluted with 60 mL $CHCl_3$. 100 mL diluted ammonia was poured into the mixture, which was shaken until two clear phases evolved. The organic layer was separated, dried over sodium sulfate, and evaporated. The crude products **VI** were then purified by column chromatography using silicagel 60 and $CHCl_3$/methanol/NH_3 with gradient technique.

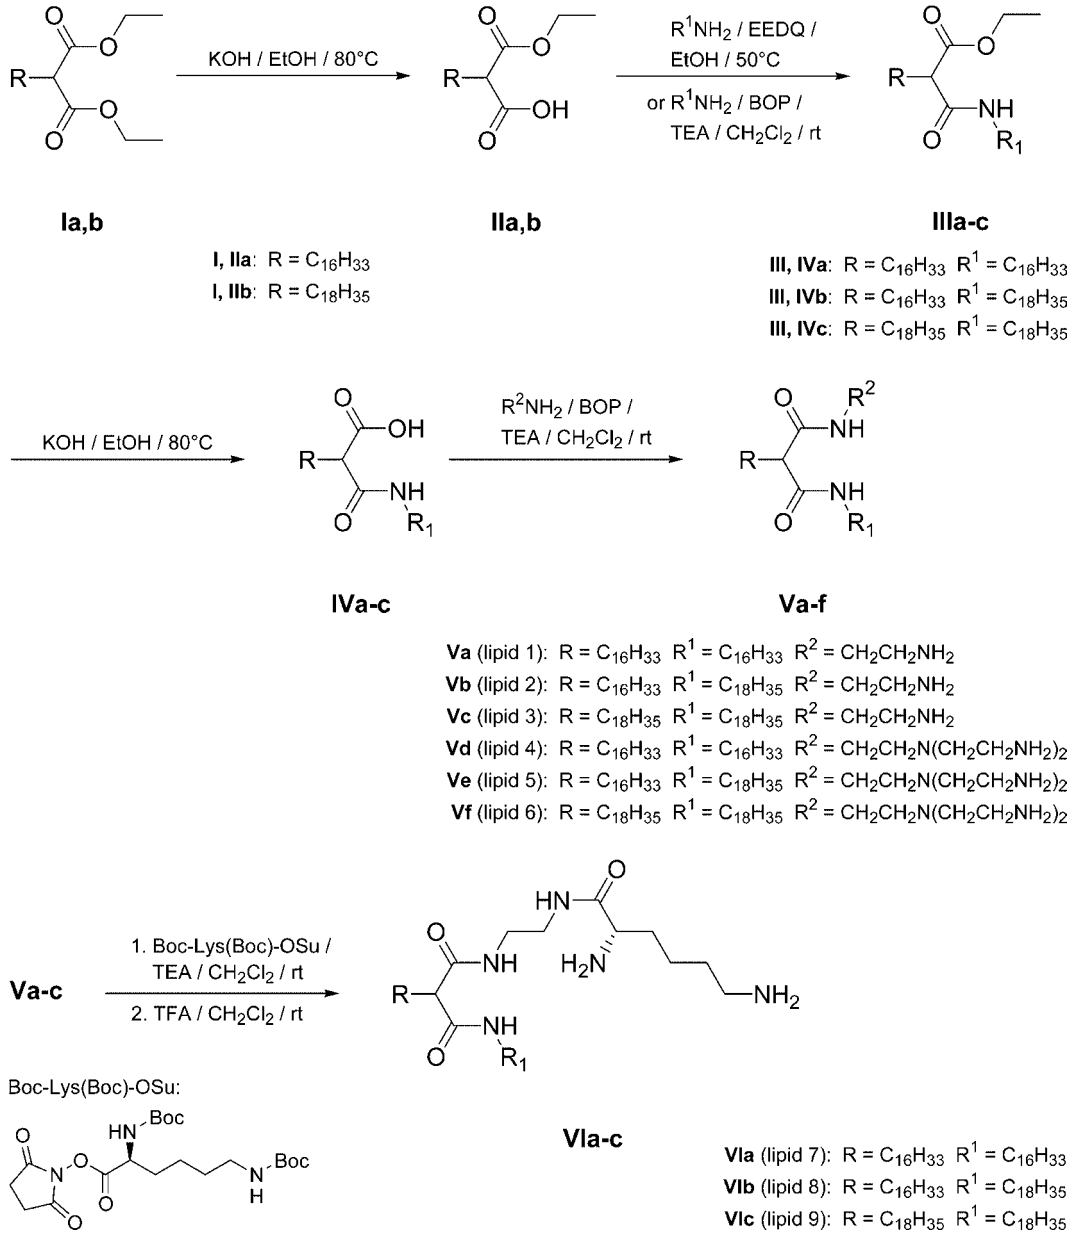
Anal. Calcd. for $C_{47}H_{91}N_5O_3 \times H_2O$: C, 71.25; H, 11.83; N, 8.84. Found: C, 71.37; H, 11.57; N, 8.86.

Preparation of Liposomes. A $CHCl_3$/methanol solution (9/1, v/v) of the pure cationic lipid was combined with a $CHCl_3$ solution of DOPE or cholesterol. The mixtures were dried under reduced pressure to remove the organic solvent, and the dried film was vacuum-desiccated for 3 h. The lipid film was dissolved in distilled water at room temperature to a final concentration of 2 mg lipid/mL. The film was allowed to swell in a water bath at 40 °C for at least 15 min. Subsequently, the lipid formulations were vortexed and sonicated to clarity in a bath sonicator. The samples were stored in the refrigerator at 4 °C before experiments.



Preparation of Plasmid DNA. pCMV Sport β-Gal was isolated from *Escherichia coli* DH5α (Invitrogene life technologies) using a Quiagen plasmid mega kit (Quiagen) following the manufacturer's instructions (*30*). DNA with an $OD_{260}/OD_{280} = 1.94$ was used for experiments.

Cell Culture. LLC PK1 cells (porcine kidney epithelial cells) were cultured in 75 cm^2 tissue culture flasks in Medium 199 adjusted to contain 2.2 g/L sodium bicarbonate, 10% fetal bovine serum (FBS), and 0.05 mg/mL gentamycin at 37 °C and 5% CO_2. The cells were grown confluently and were regularly split twice a week. Only cells that had undergone fewer than 30 passages were used for transfection and MTT experiments.

A549 cells (human lung carcinoma cells) were cultured in 75 cm^2 tissue culture flasks in Dulbecos's modified eagle medium (DMEM) adjusted to contain 4.5 g/L glucose, 10% FBS, and 0.05 mg/mL gentamycin at 37 °C and 5% CO_2. The cells were grown confluently and were regularly split twice a week. For experiments, only cells in the range of passages 20−60 were used.

Transfection Biology. 16−24 h before transfection, cells were seeded into a 96 well plate at a density of 8000−10 000 cells/well by usage of LLC PK1 and 18 000−20 000 in the case of A549 cells. Lipoplex mixtures were prepared by combining plasmid DNA (0.1 μg per well = 2.5 μg/mL) with varying amounts of cationic liposome suspension in the absence or presence of 10% serum in Medium 199 or DMEM. The samples were incubated for 15 min at room temperature (total volume 40 μL/well). The N/P ratios were varied from 1:1 to 4:1 or even higher in cases when the results of experiments foreshadow increasing transfection efficacies at higher charge ratios. During this time, cells were washed once with phosphate buffered saline (PBS). Then the complexes were added to the cells. After 4 h of incubation, 160 μL of Medium 199 or DMEM was added to the cells in a way that the final concentration of FBS reached 10%. The medium was refreshed after 24 h, and the reporter gene activity was estimated after 48 h. Therefore, the cells were washed with PBS lysed for 15 min in lysis buffer (5 mM Chaps in 50 mM Hepes buffer). The solution was taken out of the wells, reunited in safe-lock tubes (Eppendorf), centrifuged, and stored on ice. It was pipeted again in a 96 well plate and substrate solution [1.33 mg/mL of *O*-nitrophenyl-β-galactopyranoside (ONPG), $MgCl_2$ 2 mM, β-mercaptoethanol 100 mM in 0.2 M sodium phosphate pH 7.3] was added and incubated for 30 min at 37 °C. The reaction was stopped with 1 M sodium carbonate. Absorption at 405 nm was converted to β-galactosi-

Scheme 1. Synthesis of Lipids 1−9 Starting from Alkyl Malonic Acid Diethyl Ester

dase units using a calibration curve constructed with pure commercial β-galactosidase enzyme. Protein concentration was detected with bichinonic acid reaction (*31*). Absorption at 570 nm was converted by using a calibration curve made of bovine serum albumin. All experiments were carried out sixfold. Every experiment was repeated three to five times on different days.

Toxicity Assay. Cytotoxicity of the lipoplexes was assessed by the MTT reduction assay (*32*). The cytotoxicity assays were performed in 96 well plates by maintaining the same ratio and number of cells and lipoplexes as used in the transfection experiments. MTT was added after refreshing the medium (24 h after addition of lipoplexes to the cells) and incubated for 3 h at 37 °C. Afterward, the cells were lysed with a mixture of 10% sodium dodecyl sulfate in acetic acid/dimethyl sulfoxide. Absorption was measured at 570 nm. The results were expressed as percent viability = [A_{570} (treated cells) − background]/[A_{570} (untreated cells) − background] × 100.

Size Measurements. The sizes of liposomes and lipoplexes were measured in distilled water by photon correlation spectroscopy on a HPPS−ET (Malvern, U.K.) with sample refractive index of 1.25 and a viscosity of 0.8872 at 25 °C. Lipoplexes were prepared by following the instructions used for transfection experiments and measured with 2.5 μg DNA/mL sample. The *z*-average and PDI were calculated by using the automatic mode. Every sample was measured by three spectroscopic runs consisting of ten consecutive scans, each of 10 s in duration. Results shown are the average of these three values.

X-Gal Staining. To estimate a successful transfection, cells were histochemically stained with 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal). β-Galactosidase expressing cells can be indicated by blue color. The experiments were carried out in 24 well plates with a density of 40 000−50 000 cells per well and DNA concentration of 2.5 μg/mL (1.25 μg/well in 24 well plate). 48 h after transfection, cells were washed two times with PBS (2 × 500 μL) and fixed with 0.2% glutaraldehyde and 2.0% formaldehyde in PBS for 10 min at room temperature. Afterward, the cells were washed with PBS again (2 × 500 μL) and were stained subsequently with 1 mg/mL X-gal in PBS containing 2 mM $MgSO_4$ and 4 mM $K_3[Fe(CN)_6]$ and 4 mM $K_4[Fe(CN)_6]$ for 3 h at 37 °C.

Statistical Analysis. All measurements were collected (n = 3−9) and expressed as means ± standard deviation. One-way

ANOVA was used in conjunction with Bonferoni's multiple comparison test to assess the statistical significance.

RESULTS

Synthesis of Malonic Acid Amides Cationic Lipids. The synthesis of the compounds is shown in Scheme 1. Starting from long-chain monoalkylated malonic acid esters, which are easy to prepare by alkylation reaction of malonic acid diesters (*33*) with the corresponding alkyl halides or methansulfonates, one of the ester groups was saponified according to published methods (*34*). We have also studied the preparation of the monoester starting from malonic esters with different alcoholic residues followed by a selective saponification. Because of the simplicity of the first reaction, this procedure was used. Compounds **IIa**,**b** were then transformed into the 2-alkylmalonic acid ester amides **IIIa**−**c** by reaction with hexadecyl or oleyl amine using condensing reagents. The most effective reagents were 2-ethoxy-1-ethoxycarbonyl-1,2-dihydrochinoline (EEDQ) and the benzotriazole derived compounds known from peptide synthesis, like (benzotriazol-1-yloxy)-tris-(dimethylamino)-phosphoniumhexaflourophospahte (BOP), leading to the products in high yield.

For the synthesis of **IIIa**,**b**, the activation via the corresponding acid chloride was also a high-yield procedure, but in the case of the unsaturated chain of **IIb**, we used only the modern condensation agents. The saponification of the ester with potassium hydroxide yields the acids. For the second coupling reaction with ethylene diamine or tris(aminoethyl)amine to **Va**−**f**, *N*-hydroxysuccinimide/*N,N*′-dicyclohexylcarbondiimid (DCC) or better BOP was used as condensing reagent. We found that a 20-fold excess of the di- or triamine is necessary. This ensures yields of more than 70%. On the other hand, the reaction with only a 5- to 10-fold excess leads only to a yield of 20%, also in the case of BOP as the most effective condensing reagent. The introduction of a lysine residue into compounds **Va**−**c** was realized in good yields using the commercially available diboc-lysine-*N*-hydroxysuccinimide ester. The crude products were purified to some extent by filtration using silica gel. For the removal of the protective groups, trifluoroacetic acid in methylene chloride was used. The yields after the two steps were more than 50%.

In Vitro Transfection and Cell Toxicity of Malonic Acid Amides Cationic Liposomes. To form liposomes for gene transfer experiments, cationic amphiphiles are usually mixed with colipids. Most frequently, 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) and cholesterol are used (*26, 35–37*). Their influence on transfection is ascribed to their tendency to adopt the inverted hexagonal H_{II} phase that seems to be necessary for the DNA release from the endosomal compartment (*36, 38–42*). For that reason, all of the lipids **1**−**9** were mixed in different molar ratios with DOPE or cholesterol to determine the most auspicious combination. To identify the kind of structure/activity relationship for the malonic acid amides, nearly 60 samples were prepared and tested for their ability to transfect cells in culture.

Figure 1 summarizes the relative in vitro gene delivery efficiencies of lipid **8** mixed with colipids. Lipoplex (cationic liposome/DNA complex) mixtures were prepared by combining plasmid DNA (0.1 μg per well = 2.5 μg/mL) with varying amounts of cationic liposome suspension in plain Medium 199. The N/P ratios were varied from 1:1 to 4:1. Lipid **8** has been proven to be successful for gene transfer into cells in culture. The majority of the analyzed samples exhibit high transfection efficacies. All tested combinations of this lipid with cholesterol show equal or higher transfection efficacy than LipofectAmine and SuperFect. Merely the maximum values were found at different N/P ratios. The use of DOPE as colipid decreases the transfection efficiencies. Only lipid **8**/DOPE 1:1 (*n*/*n*) is comparable to commercially available gene transfer kits.

Table 1 summarizes the results of all lipids **1**−**9** in combination with the used helper lipids. It shows the most auspicious combination of any lipid with any colipid in gene transfer experiments. Furthermore, the N/P ratio, the MTT based percent cell viability, and the results of size measurements are listed. Apart from four samples, for all new lipids transfection was detected, but only lipid **6**, lipid **8**, and lipid **9** exhibit transfection efficacies that make them comparable to commercially available vectors. Liposomes that consist of lipid **6** or lipid **8** and cholesterol as colipid lead to increasing transfection efficacies. As shown in Figure 2, this effect is statistically significant compared to LipofectAmine (*) or SuperFect (^), whereas the effects on cell survival are similar.

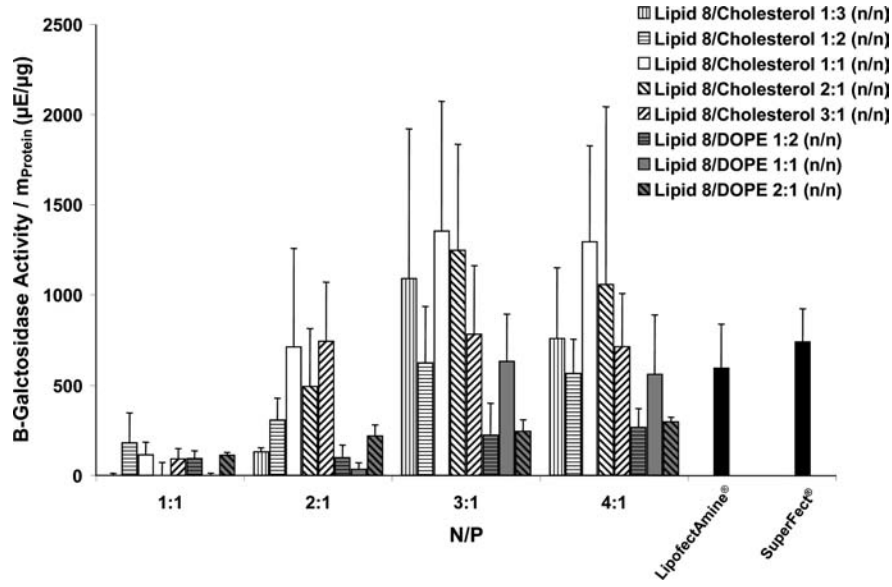


Figure 1. In vitro transfection efficacies of lipid **8** in LLC PK1 cells using cholesterol and DOPE as colipid (at different lipid/cholesterol or lipid/DOPE molar ratios). Micro units of β-galactosidase related to cell protein concentration were plotted against the varying N/P ratios. The transfection efficiencies of the liposome samples were compared to those of the commercially available LipofectAmine and SuperFect. The experiments were performed as described in the text. The transfection values shown are the average of at least three experiments carried out on three different days.

[a] The transfection and viability values listed are the average of at least three experiments carried out on different days.

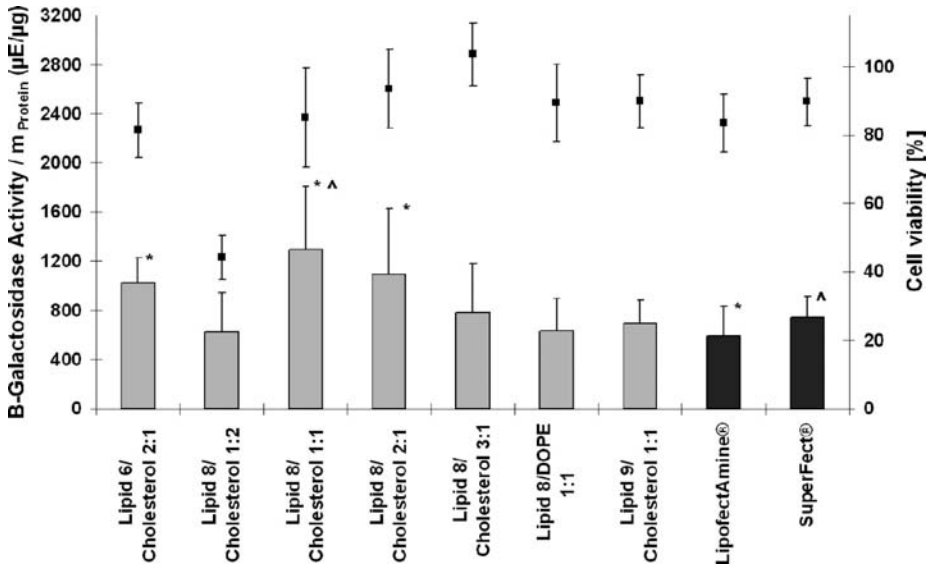

Figure 2. In vitro transfection efficacies and cell viability values of lipids **6**, **8**, and **9** in LLC PK1 cells using cholesterol or DOPE as colipid (at different lipid/cholesterol or lipid/DOPE molar ratios). Micro units of β-galactosidase related to cell protein concentration and cell viability in % were plotted against different samples. The transfection efficiencies of the liposomes were compared to that of commercially available LipofectAmine and SuperFect. Percent cell viability is plotted on secondary *y*-axis via scatter diagram. The transfection and cytotoxicity values shown are the average of at least three experiments carried out on three different days. Statistical analyses were carried out with $p < 0.05$, one-way ANOVA, and Bonferoni's multiple comparison tests (*^).

Figure 3 summarizes the results of gene transfer experiments in LLC PK1 cells with LipofectAmine (A), lipid **1** (B), and lipid **6** (C) visualized by histochemical staining (X-Gal assay). Whereas LipofectAmine and lipid **6**/cholesterol 2:1 (*n*/*n*) lead to considerable staining of wells, no colored cells were found when using lipoplexes consisting of lipid **1** as gene transfer reagent.

In the majority of cases, the cell viability fluctuates between 80% and 90% (cf. Table 1). These results suggest that the applied liposomes have an influence on the cell survival but that the efficacy of the gene transfer is not directly coupled with the toxicity. For instance, lipid **1** and lipid **7** with no or low transfection efficacy have similar or even stronger influence on the cell viability than lipid **6**, lipid **8**, or lipid **9**, although those are proven to be successful for the transfection process.

Figure 4 shows the results of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) measurements of lipid **1**, lipid **7**, and lipid **8** and lipid **9** lipoplexes. The addition of lipoplexes decreases the cell viability. This effect was observed for all lipids and all N/P ratios. Furthermore, there is no statistically significant difference between the charge ratios of one sample, which suggests that the cell viability is already decreased at low lipid concentrations. An increase of cationic lipid concentration shows little effect on the toxicity at least in applied N/P ratios. Interestingly, the influence on cell viability of lipid **1** in combination with cholesterol is more distinct than that of lipid **8** or lipid **9**. Liposomes, which are not qualified for in vitro gene delivery, influence cell survival to the same degree or even more than efficiently transfecting samples. By comparing lipoplexes that consist of lipid **9** with those of lipid **1** and lipid **7**, the differences in cell viability are statistically significant just like the comparison of lipid **1** and lipid **8**. The results suggest that the chemical structure of the cationic lipid and the composition of liposomes play a major role in cell damaging characteristics, as well as in the ability to transfer nucleic acids. It was observed that the addition of lipoplexes leads to derogation of LLC PK1 cell survival independent of successful or unsuccessful gene transfer. Transfection of cells in culture is to a certain level connected with toxicity, but the reverse is not compulsory. To look for other parameters, which

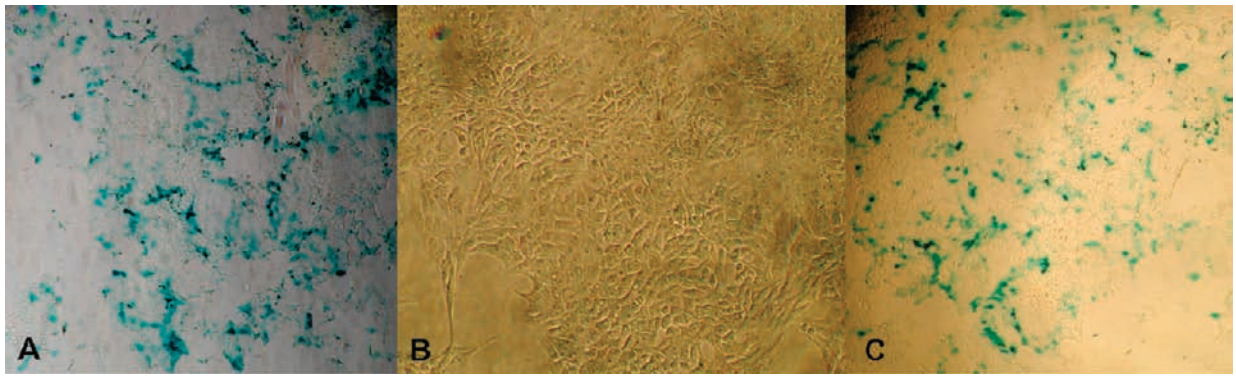

Figure 3. Pictures of X-Gal assay in LLC PK1 cells using lipid **1**, lipid **6**, and LipofectAmine. Cells were incubated with 2.5 μg/mL of DNA and stained 48 h after starting transfection. Figure 4. MTT-based cellular cytotoxicities of lipids **1**, **7**, **8**, and **9** in LLC PK1 cells using DOPE or cholesterol as colipid (at a lipid/colipid molar ratio of 1:1). The percent cell viability was plotted against the varying N/P ratios. The experiments were performed as described in the text. The cytotoxicity values shown are the average of at least three experiments carried out on different days.

are important for cell damaging characteristics of cationic liposomes, MTT measurements of lipoplexes consisting of lipid **8** were specified.

Figure 5 summarizes these results in LLC PK1 cells. As shown, the N/P ratios are varied from 1:1 to 4:1 for all applied lipoplexes. The concentration of lipid **8** is the same in all samples and increases merely with increasing N/P ratios (in the range 4.05−16.2 μmol/L). It is shown that lipoplexes consisting of a larger percentage of colipids exhibit more cytotoxic potential as lipoplexes consisting of larger percentage of lipid **8**. With increasing concentration of the helper-lipid, cell survival decreases. This effect is highly pronounced using cholesterol, but also visible using DOPE as colipid. The concentration of the colipid also seems to play a decisive role in cell damaging characteristics of cationic liposomes. As the mixed liposomes influence the shape and structure of lipoplexes, variances in the ratio between the cationic and the helper lipids has an impact not only on transfection efficacy, but also on compatibility and consequently the cell viability.

Figure 6 summarizes the results of PCS measurements for selected malonic acid amides. Since particle size seems to be crucial for transfection efficiencies compared with lipoplex charge or zeta potential (*41*), the size measurements of all lipoplexes were used to find a correlation of transfection efficacy and particle size. For DOTAP lipoplexes, it was shown that particles with 500 nm sizes were more effective in cell culture experiments than 100 nm lipoplexes (*41, 43*). For successful in vivo gene transfer, particles should have a size less than 150 nm, because larger ones are quickly cleared from blood (*44, 45*).

The results of size measurements of six liposomes and lipoplexes consisting of lipid **1**, lipid **2**, lipid **7**, lipid **8**, and lipid **9** are plotted. They were chosen to distinguish between well-transfecting and nontransfecting lipoplexes. All of them disclose some similarities. The increasing particle size in connection with increasing cationic lipid concentrations has a maximum value at charge equalization (*17*). The displaced maximum values are presumably due to varied capability to condense DNA. By comparing lipoplexes consisting of lipid **7**, lipid **8**, and lipid **9**, it is conspicuous that not only the number of amine residues and the cationic lipid concentration but also the fluidity of liposome membranes is important for charge equalization. Unfortunately, the differences in particle size between transfecting and nontransfecting liposomes are marginal, so that differentiations between the samples are hardly assessable. Certainly, it should be noted that lipoplexes, which exhibit appreciable transfection features, have *z*-average values which are only slightly larger than those of the pure liposomes. The particle size of the majority of lipoplexes is less than 500 nm (cf. Table 1).

As a matter of course, lipid **6**, lipid **8**, and lipid **9** were analyzed for their ability to transfer genes in another cell strain. Figure 7 summarizes the results of in vitro gene delivery and

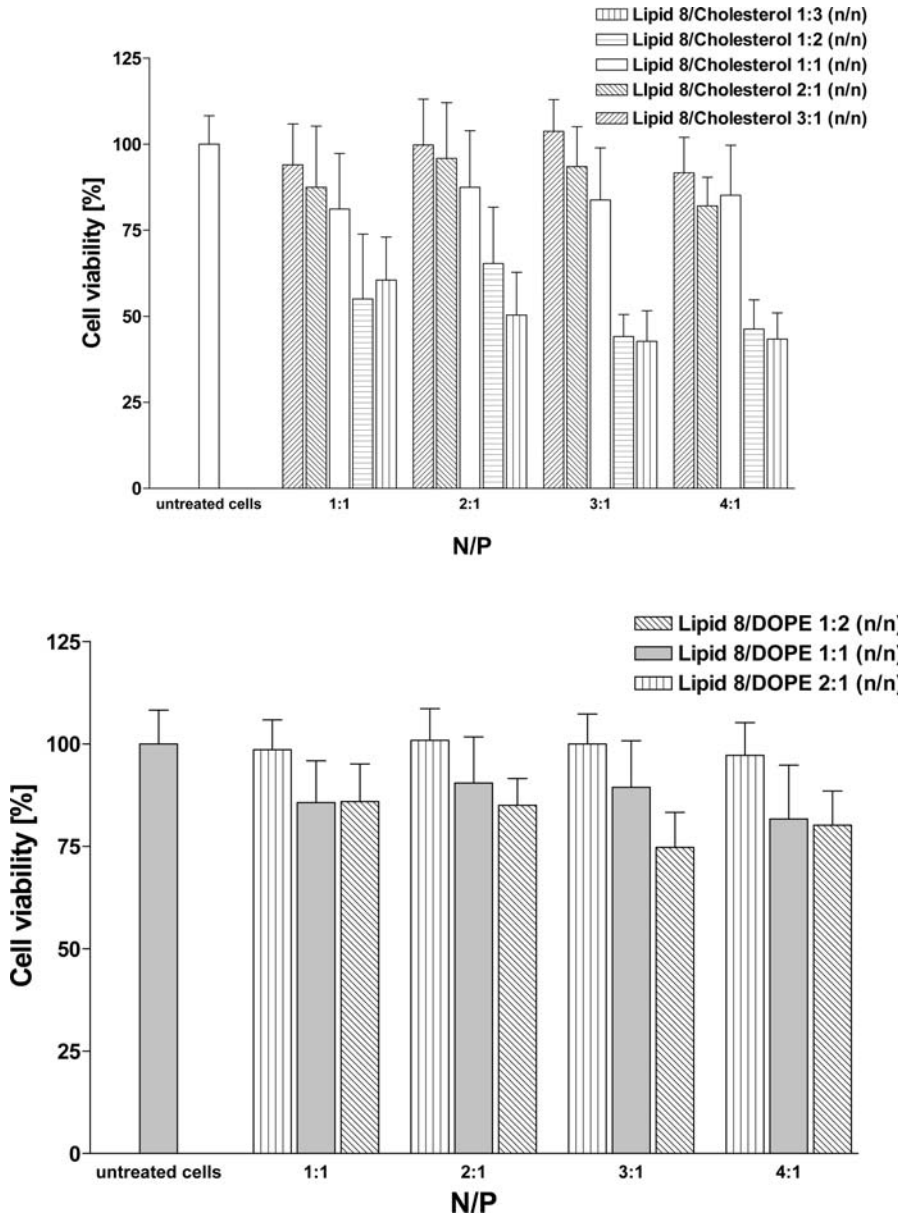

Figure 5. MTT-based cellular cytotoxicities of lipid **8** in LLC PK1 cells using cholesterol and DOPE as colipid (at different lipid/colipid molar ratios). The percent cell viability was plotted against the varying N/P ratios.

MTT based cell viability assays in A549 cells. Even if transfection efficacy of lipid **8** is not as appreciable as in LLC PK1 cells, it is still comparable to LipofectAmine and SuperFect. In human lung carcinoma cells, the multivalent cationic lipids **6** and **9** with two unsaturated alkyl chains were found to transfer DNA statistically significantly better than commercially available vectors at similar cell viability values (*).

Figure 8 summarizes the experiments of gene transfer in the presence of FBS in LLC PK1 cells. Lipoplexes were incubated with the cells as described in the Experimental Procedures section, certainly the concentration of serum was adjusted to 10% from the outset of experiments and kept for 48 h. Admittedly, total protein concentration of human serum that is between 66 and 83 g/L (*46*) is just reached with a level of 60%, but information about serum compatibility of applied lipoplexes is still possible. A slight influence of serum was observed for SuperFect and lipid **8**/cholesterol 2:1 (*n*/*n*), whereas lipid **8**/cholesterol 2:1 (*n*/*n*) offers nearly twice the amount of transfection efficacy. Notably, for LipofectAmine, which contains DOPE, a decrease of gene transfer was observed. Lipoplexes consisting of lipid **6** and lipid **9** deteriorate in transfection efficacy in regard to gene transfer without serum over a period of 4 h. Nevertheless, these samples exhibit gene transfer rates in excess of LipofectAmine that are partially statistically significant (*).

DISCUSSION

Since their introduction as gene carriers in 1987 (*15*), cationic liposomes have become well-studied nonviral vectors (*47*). Lipoplex mediated gene delivery systems are currently the most favorable means to achieve transgene expression in cells in culture. In the meantime, about 1300 clinical trials in gene therapy research have been carried out (*14*). Although hundreds of cationic lipids have been studied (*48*), there is still a need to develop new gene transfer systems.

By engineering new lipids for nonviral gene delivery, it is important to investigate structure/activity relationships to expedite the reasonable development of these substances. In the case of malonic acid amides, several effects of structure−function relationships were demonstrated. Independent of the chemical structure of the hydrophilic molecule part or the colipid, it was observed that the insertion of at

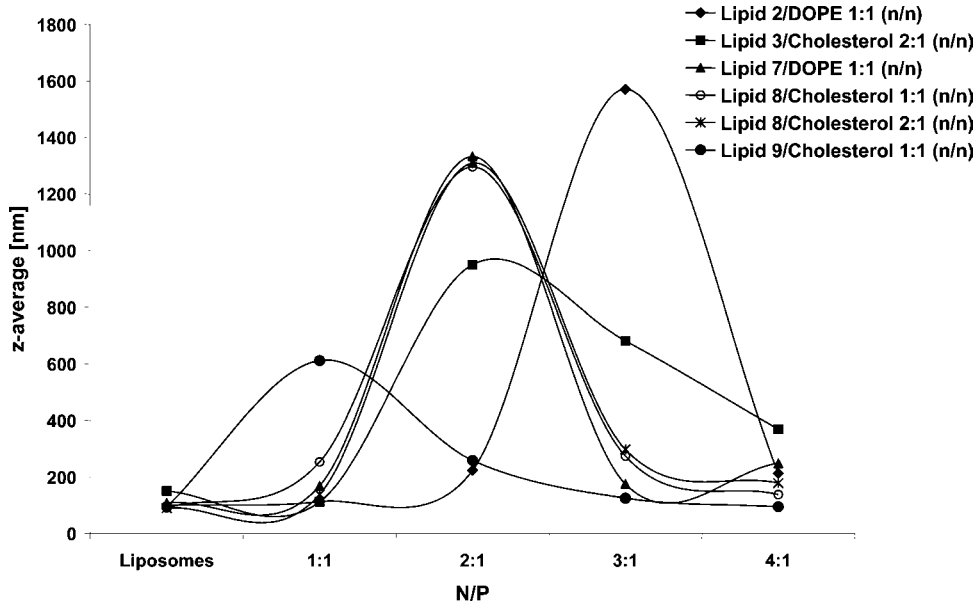

Figure 6. Photon correlation spectroscopy analyses of liposomes and lipoplex mixtures: Changes of particle size as a function of increasing lipid concentration (concentration of DNA = 2.5 μg/mL). The average diameters of lipoplex particles in each set of lipoplex mixtures were determined by three spectroscopic runs comprising ten consecutive scans, each of 10 s in duration.

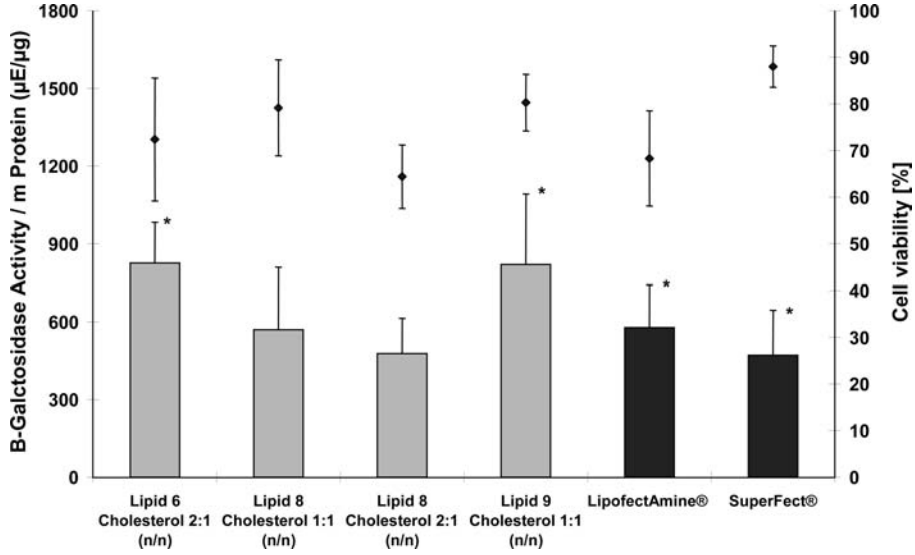

Figure 7. In vitro transfection efficacies and MTT based cell viability values of lipids **6**, **8**, and **9** in A549 cells using cholesterol as colipid. The transfection efficacies and percent cell viability values were compared with LipofectAmine and SuperFect. Percent cell viability is plotted on a secondary *y*-axis via scatter diagram. The transfection and cell viability values shown are the averages of at least three experiments carried out on different days. Statistical analyses were carried out with $p < 0.05$, one-way ANOVA, and Bonferoni's multiple comparison tests (*).

least one unsaturated alkyl chain leads to higher transfection efficacies. Already, Felgner et al. could demonstrate that increasing membrane fluidity often leads to increasing transfection efficacies (*16*). This effect has been attributed to an enhanced capability of fluid amphiphiles to condense DNA (*16, 49*). Besides the electrostatic interaction of cationic lipids and DNA, packing properties of the lipids seem to be important for the condensation of DNA (*40*). It was shown that the insertion of tris(aminoethyl)amine and lysine as hydrophilic headgroup increase transfection efficacy. Although lipids **1**−**3** are able to adsorb DNA in monolayer experiments and protect partially nucleic acids in ethidium bromide exclusion assay (data not shown), multivalent headgroups seem to be more suitable for lipoplex-mediated gene transfer. Except for monovalent substances, all lipids exhibit higher transfection efficacies in combination with cholesterol as colipid. Helper lipids mainly affect the tertiary structure of the plasmid DNA in lipoplexes (*8*). Although this does not affect the transfection effiency (*39, 50*), the influence of colipids for gene transfection is indisputable. As mentioned above, colipids influence the transfection because of their tendency to adopt the inverted hexagonal H_{II} phase that seems to be necessary for the DNA release from the endosomal compartment. Furthermore, DOPE promotes the lipid exchange between liposome and the endosome membrane, which is also crucial for the endosome releasing process (*51, 52*).

The fact that cholesterol was found to be a more efficacious colipid than DOPE is an encouraging result in regard to in vivo gene transfer experiments. Although the application of cationic liposomes as gene delivery systems in cells in culture is popular, the in vivo application still has serious drawbacks (*53*). Due to the chemical structure of the lipids used, liposomes interact with different components of the human

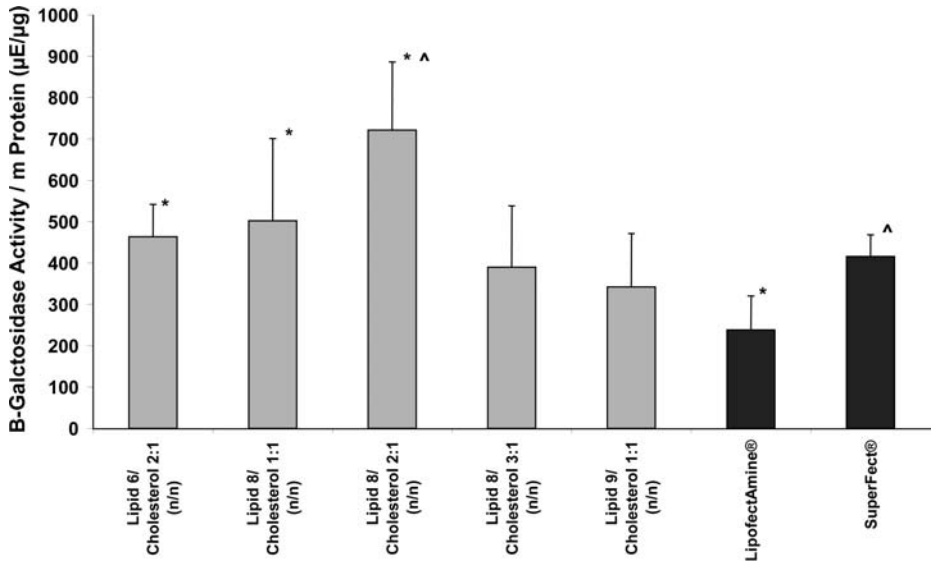

Figure 8. In vitro transfection efficacies of lipids **6**, **8**, and **9** in LLC PK1 cells in the presence of serum compared with LipofectAmine and SuperFect. Concentration of FBS was adjusted to 10% from the outset of experiment and kept up for 48 h. N/P ratios: lipid **6**, 6:1; lipid **8**, 4:1 and 4:1; lipid **9**, 3:1. The transfection values shown are the average of leastwise three experiments carried out on three different days. Statistical analyses were carried out with $p < 0.05$, one-way ANOVA, and Bonferoni's multiple comparison tests (*^).

organism, especially negatively charged amphipathic proteins and polysaccharides that are present in blood, mucus, or tissue matrix (*47*). Plasma proteins like albumin adsorb on the liposome surface and make them recognizable for cells of the reticuloendothelial system (*54*). For liposomes consisting of phospholipids, it is well-known that lipoproteins lead to membrane disintegrations as a consequence of lipid exchange. Mainly liposomes containing lipids with unsaturated fatty acids interact notably with lipoproteins (*55*). For that reason, DOPE is unsuitable for in vivo gene transfer (*56*). On the contrary, cholesterol was found to stabilize the lipoplex structure in blood (*57, 58*). To minimize disadvantageous effects of nonviral vectors in systemic gene delivery, PEG−lipid conjugates were successfully incorporated in lipoplexes (*59*). On the other hand, lipoplexes exhibiting certain serum stability without modification could advance in vivo gene delivery. As shown, cationic liposomes that consist of malonic acid amides have the ability to transfer nucleic acids even in the presence of FBS.

Malonic acid amides describe an interesting novel group of cationic amphiphiles. Nine substances were synthesized and mixed with DOPE or cholesterol, and liposomes were tested for their ability to transfect cells in culture. It was shown that three of them transfect cells at comparable or even higher levels than commercially available LipofectAmine and SuperFect. Thereby, it was observed that lipids containing at least one unsaturated alkyl chain in the hydrophobic molecule part and multivalent headgroups are very successful in gene transfer experiments. Along with this, the cell damaging characteristics of lipoplexes were analyzed. Although the addition of lipoplexes is connected with decreasing cell survival, in the majority of cases the applied lipoplexes show remarkably high cell viability (>80%).

Furthermore, some lipids proved to be successful in gene transfer experiments notwithstanding the presence of serum. Certainly, despite these promising results, further research is clearly needed to clarify the complex mechanism of cationic lipid mediated gene transfer. The presented malonic acid amides are qualified for these requirements. The preparation facilitates the trouble-free variation of alkyl chain length. In addition, multivalent hydrophilic molecule parts are suited to link other cationic residues or molecules for functionalization. Thereby, we expect further developments from this kind of cationic lipids toward successful in vivo gene transfer.

Received November 16, 2009; Revised Manuscript Received February 28, 2010

A synthetic antigen targeting membrane-fusion mechanism of HIV-1 has a newly designed template with C3-symmetric linkers mimicking N36 trimeric form. The antiserum produced by immunization of the N36 trimeric form antigen showed structural preference in binding to N36 trimer and stronger inhibitory activity against HIV-1 infection than the N36 monomer. Our results suggest an effective strategy of HIV vaccine design based on a relationship to the native structure of proteins involved in HIV fusion mechanisms.
