EDITORIAL: Thanks to Our Editorial Advisory Board and Reviewers

We welcome the following distinguished scientists as *new members* of the Editorial Advisory Board, and we look forward to working with them to take the journal in new directions.

Christine Allen, University of Toronto
David Andreu, Pompeu Fabra University
You Han Bae, University of Utah
Santanu Bhattacharya, Indian Institute of Science
Marcel P. Bruchez, Carnegie Mellon University
Jari Hovinen, PerkinElmer
Lee Josephson, Harvard University
Rudy Juliano, University of North Carolina
Hisataka Kobayashi, National Institutes of Health
Felix Kratz, University of Freiburg
Igor L. Medintz, U.S. Naval Research Laboratory
Dario Neri, ETH Zurich
Ravindra K. Pandey, Roswell Park Cancer Institute
William M. Pardridge, University of California Los Angeles
Theresa M. Reineke, Virginia Tech
Molly S. Shoichet, University of Toronto
Arne Skerra, Technische Universitat Muenchen
Gang Zheng, University of Toronto

We are thankful to the following *outgoing members* of the Editorial Advisory Board for their service during the past years, and we wish them well in their future endeavors.

Carolyn J. Anderson, Mallinckrodt Institute of Radiology
Darryl Bornhop, Vanderbilt University
Sylvia Daunert, University of Kentucky
Ruth Duncan, Cardiff University
Philip R. Hamann, Wyeth Research
Allan S. Hoffman, University of Washington
Michael R. Lewis, University of Missouri—Columbia
Helmut R. Mäcke, University Hospital Basel
Sheri L. Morrison, University of California Los Angeles
Glenn D. Prestwich, University of Utah
Keith Rose, University of Geneva
John E. Shively, City of Hope
Caroline J. Springer, CRC Centre for Cancer Therapeutics
Suresh Srivastava, Brookhaven National Laboratory
M. Graca H. Vicente, Louisiana State University
Eric Wickstrom, Thomas Jefferson University
John R. Yates III, The Scripps Research Institute

These scientists have played a significant role in advising, reviewing, and guiding the journal, and the effects of their contributions will persist.

The *continuing members* of the Editorial Advisory Board, whose service to the journal is gratefully acknowledged, are as follows:

Jacqueline K. Barton, California Institute of Technology
Jean-Paul Behr, University of Strasbourg
Cynthia J. Burrows, University of Utah
Chien-Hsing Ken Chang, Immunomedics, Inc.
Xiaoyuan (Shawn) Chen, National Institutes of Health
Patrick Couvreur, Université de Paris-Sud
Mark E. Davis, California Institute of Technology
Peter B. Dervan, California Institute of Technology
Gene M. Dubowchik, Bristol-Myers Squibb
David Filpula, Enzon Pharmaceuticals, Inc.
M. G. Finn, The Scripps Research Institute
Shiroh Futaki, Kyoto University
David A. Goodwin, Stanford University (Emeritus)
Anna Grandas, Universitat de Barcelona
Anne Gruaz-Guyon, Inserm
M. Frederick Hawthorne, University of Missouri Columbia
John E. Hearst, University of California Berkeley (Emeritus)
Ned D. Heindel, Lehigh University
W. E. Hennink, Utrecht University
Greg T. Hermanson, Thermo Fisher Scientific
Donald J. Hnatowich, University of Massachusetts
Dr. Kenneth A. Jacobson, National Institutes of Health
Alexander V. Kabanov, University of Nebraska Medical Center
Kazunori Kataoka, University of Tokyo
John A. Katzenellenbogen, University of Illinois
Sung Wan Kim, University of Utah
Thomas Kissel, Philipps University Marburg
Kenji Kono, Osaka Prefecture University
Jindrich Kopecek, University of Utah
Robert Langer, Massachusetts Institute of Technology
Christopher P. Leamon, Endocyte Pharmaceuticals, Inc.
Shuang Liu, Purdue University
Hiroshi Maeda, Sojo University
Thomas J. Meade, Northwestern University
Oleg Melnyk, CNRS/Universite de Lille
Peter E. Nielsen, University of Copenhagen
Jong-sang Park, Seoul National University
Tae Gwan Park, KAIST
Tariq Rana, Burnham Institute for Medical Research
Steven L. Regen, Lehigh University
Ralph Reisfeld, Scripps Clinic and Research Foundation
Steve Roffler, Academia Sinica
P. August Schubiger, ETH - Zurich
Peter G. Schultz, The Scripps Research Institute
Francis C. Szoka, Jr., University of California San Francisco
David H. Thompson, Purdue University
David A. Tirrell, California Institute of Technology
Donald A. Tomalia, Dendritic Nanotechnologies, Inc.
Vladimir P. Torchilin, Northeastern University
Eishun Tsuchida, Waseda University
Pierre Vierling, Universite de Nice Sophia-Antipolis
Ernst Wagner, Ludwig-Maximilians-University
Ralph Weissleder, Massachusetts General Hospital

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2009 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the twentieth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are as follows:

Samuel Achilefu	Dennis Benjamin	Hak Soo Choi	Kazuhisa Fujimoto
Catalina Achim	Steven Benner	Francisco Ciruela	Toshiaki Furuta
William E. Acree	Paul D. Benny	Gary Cline	Shiroh Futaki
Hidetaka Akita	David Eric Benson	Chris E. Cooper	Detlef Gabel

Antibody−Drug Conjugates: Linking Cytotoxic Payloads to Monoclonal Antibodies

Laurent Ducry* and Bernhard Stump

Lonza Ltd, CH-3930 Visp, Switzerland. Received May 4, 2009; Revised Manuscript Received July 7, 2009

Antibody−drug conjugates (ADCs) combine the specificity of monoclonal antibodies (mAbs) with the potency of cytotoxic molecules, thereby taking advantage of the best characteristics of both components. Along with the development of the mAbs and cytotoxins, the design of chemical linkers to covalently bind these building blocks is making rapid progress but remains challenging. Recent advances have resulted in linkers having increased stability in the bloodstream while allowing efficient payload release within the tumor cell.

INTRODUCTION

After cardiovascular diseases, cancer represents the second most common cause of death in the Western world and is a major area of focus for the pharmaceutical industry. Surgery and radiotherapy are generally used when a tumor is localized to a certain tissue, but chemotherapy is needed when metastasis has occurred. Despite extensive research, most anticancer drugs have nonspecific toxicity. By targeting the cell cycle and thereby killing rapidly proliferating cells, they do not explicitly discriminate between healthy and tumor tissues and only gain a limited selectivity for malignant cells. Such cytotoxic drugs have a narrow therapeutic window, which limits their efficacy and results in severe side effects. Due to a lack of selectivity, drug concentrations that would eradicate the tumor can often not be used. In addition, tumors can develop resistance against anticancer drugs after prolonged treatment. Therefore, achieving improved tumor selectivity through targeting of cytotoxic drugs to the cancer cells is needed.

A promising approach to achieving a more selective treatment is targeted prodrug therapy (*1*). Antibody−drug conjugates (ADCs) are ideal candidates for such prodrugs. ADCs are monoclonal antibodies (mAbs) linked to cell-killing drugs. Thanks to their high binding specificity for tumor-specific antigens, mAbs can be used as vehicles to target cell-killing payloads to tumor cells. Unique or overexpressed, tumor-specific antigens can be found in a wide range of human tumor cells (*2*). Some mAbs have the ability to recognize and specifically bind to these tumor-associated antigens. They can be used as single agents for the treatment of cancer through binding to cancer-cell-specific antigens and induction of an immunological response against the target cancer cell (*3*). However, therapeutic efficacy is often limited by the extent to which the antibody leads to cell death. Monoclonal antibodies are extremely discriminating for their targets but sometimes therapeutically ineffective on their own. The insufficient efficiency of most naked mAbs in cancer therapy has been circumvented by arming the immunoglobulin with radioactive isotopes (*4*) or cytotoxic drugs (*5*−*7*) (Figure 1), yielding highly specific ADCs.

ADCs can be viewed as sophisticated delivery systems for antitumor cytotoxic drugs. The mAb guides the toxin precursor to the target cancer cell, where the prodrug can be converted chemically and/or enzymatically to the parent drug and unfold its cytotoxic activity. The ADC is exposed to different conditions on its journey from the blood vessels to the molecular target in the tumor tissue. The mode of action at cellular or molecular level is complex, with each step bringing its own challenges:

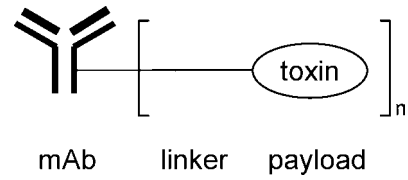

Figure 1. Schematic representation of an antibody−drug conjugate.

a. Circulation. The ADC must behave like a naked antibody when circulating in the plasma. In particular, the linker must be stable in the bloodstream to limit the damage to healthy tissue. Decomposition or decay would release the cytotoxin before being delivered to the target site.

b. Antigen Binding. It is necessary that the conjugated mAb retains high immunoaffinity. Attaching the cytotoxic compound to the mAb must thus not disturb its binding specificity.

c. Internalization. A sufficient intracellular concentration of the drug must be achieved. This is challenging because antigen targets on cell surfaces are often present in limited numbers and the internalization process for antigen−antibody complexes is frequently inefficient.

d. Drug Release. Once internalized, the ADC has to efficiently release the original cytotoxic drug in its active form inside the tumor cell.

e. Drug Action. The inherent potency of the released drug must be sufficient to kill the tumor cell, even at low concentration. To achieve significant cytotoxicity, use of very potent drugs with subnanomolar IC_{50} (as free drug) becomes necessary. It has been shown that compounds found to be too toxic when tested as a stand-alone chemotherapy agent are suitable candidates for ADC payloads. These toxins can be 100 to 1000 times more cytotoxic than traditional anticancer agents.

The molar loading of the drug on the mAb can be tuned to achieve the desired potency. Because of points (c) and (d), linkage of several drugs is generally necessary to achieve significant cytotoxicity. However, if too many cytotoxic molecules are attached

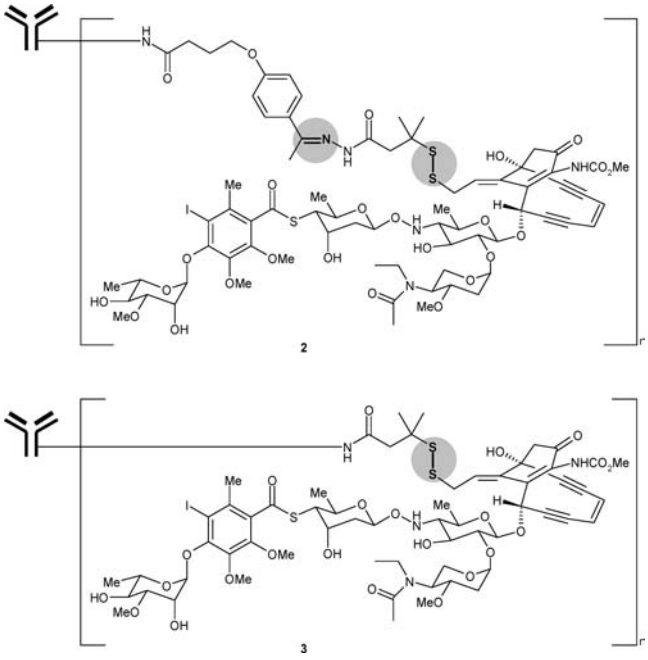

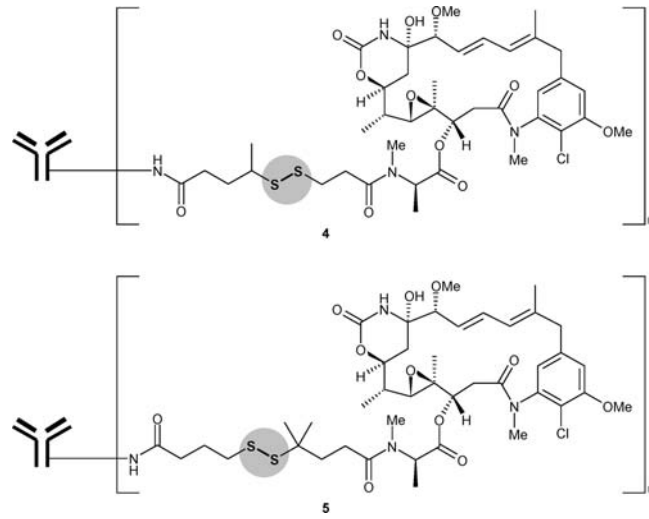

Chart 3

to the antibody, the body may recognize the conjugate as a damaged form of the protein and quickly clears it from the system, proving points (a) and/or (b) to be problematic. The extent of drug substitution may also affect pharmacokinetics, so that most of the time 2−4 drugs per antibody give the best therapeutic window (*8, 9*). To avoid the interference with the antigen recognition, the drugs are ideally linked at the Fc or constant region of the mAb that does not participate in binding to the antigen (point (b)). To regain the full cytotoxic potential of the drugs, cleavable linkers releasing the drug molecule at the target site in unmodified form were developed to address point (d), although these also affect the stability of the construct. Therefore, the right balance between plasma stability and efficient drug release at the target cell has to be found.

The insights gained during ADC development within the past decade have resulted in a number of new strategies and drugs (*4*−*7*). This review focuses on linker technologies used to attach low molecular weight cytotoxic drugs to mAbs. The linker is a small but central part of ADCs and as such accounts for stability in circulation, favorable pharmacokinetic properties, and efficient release of toxic agent at the tumor site.

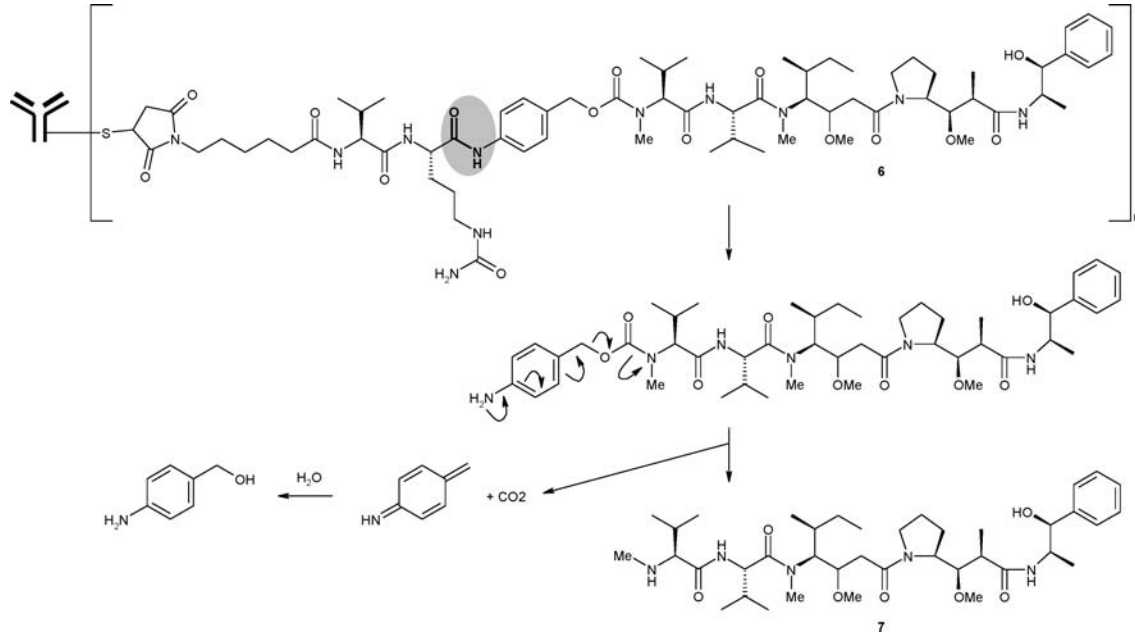
CHEMICALLY LABILE LINKERS

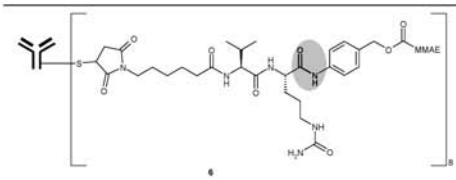
Selective linker cleavage and payload release is based upon the differential properties between the plasma and some cytoplasmic compartments. Linkers were chosen that were stable in the blood's neutral pH environment but were getting cleaved once the ADC entered the lower pH environment found inside a cell. The focus in the early days of ADC development was on acid-cleavable hydrazone linkers that were relatively stable at neutral pH (bloodstream pH 7.3−7.5), but were undergoing hydrolysis once internalized into the mildly acidic endosomes (pH 5.0−6.5) and lysosomes (pH 4.5−5.0).

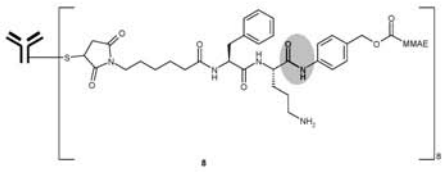
In the 1990s, Bristol-Myers Squibb scientists covalently linked doxorubicin, an intercalating agent that blocks DNA replication and is used as chemotherapeutic agent, to the humanized mAb BR96 (*10*). Doxorubicin was connected over a (6-maleimidocaproyl)hydrazone linker to cysteine residues of the Lewis-Y specific mAb. The preclinical activities of BR96-doxorubicin (**1**, Chart 1) were remarkable, but despite the use of eight drugs per mAb molecule, the amount of conjugate needed to achieve these effects *in vivo* were high (>100 mg/kg). This was presumably due to the relatively low potency of doxorubicin (IC_{50} of 0.1−0.2 μM for human carcinoma lines (*11*), whereas subnanomolar activities are now typically seen for ADC payloads). Moreover, the half-life of the drug in the blood was approximately 43 h, which is short compared to the half-lives of several days to weeks of the naked BR96 mAb in humans. The compound later failed to show sufficient clinical efficacy.

The first and so far sole mAb linked to a cytotoxic payload that has been given regulatory approval is Wyeth's gemtuzumab ozogamicin (**2**, Mylotarg; Chart 2) (*12*−*14*). The drug was approved by the US Food and Drug Administration (FDA) in 2000 for use in patients over 60 suffering from relapsed acute myelocytic leukemia (AML), the most common form of leukemia in adults. Gemtuzumab ozogamicin (**2**) consists of *N*-acetyl-γ-calicheamicin (an enediyne antibiotic that binds to the minor groove of DNA and causes double-strand breaks leading to apoptosis) covalently attached to humanized anti-CD33 IgG4 κ antibody (hP67.6) via a bifunctional linker. The 4-(4-acetylphenoxy)butanoic acid moiety allows for attachment to surface-exposed lysines of the antibody over an amide bond and forms an acyl hydrazone linkage with *N*-acetyl-γ-calicheamicin dimethyl hydrazide. Upon internalization of the ADC, the calicheamicin prodrug is released by hydrolysis of the hydrazone in lysosomes of the CD33-positive target cells. The hydrolyzability of an unconjugated intermediate at 37 °C over 24 h increased from 6% at pH 7.4 to 97% at pH 4.5 (*15*). The enediyne drug then gets activated by reductive cleavage of the disulfide bond. This disulfide linkage has been stabilized by two methyl groups to prevent premature release of calicheamicin by circulating reduced thiols, such as glutathione. In most preclinical models, the hydrazone linkage produced ADCs with higher potency than the corresponding amide-bearing conjugate **3**, providing evidence that with this mAb the disulfide alone is insufficient for

Scheme 1. Presumed Release Mechanism of MMAE (7) from ADC 6 Incorporating a Valine-Citrulline Peptidic Linker







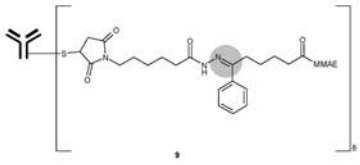


Table 1. Compared Stabilities of Enzyme-Labile and Chemically Labile Linkers in ADCs with MMAE Conjugated to cBR96 mAb

ADC	Linker	Half-live mouse plasma	Half-live human plasma	Maximum tolerated dose

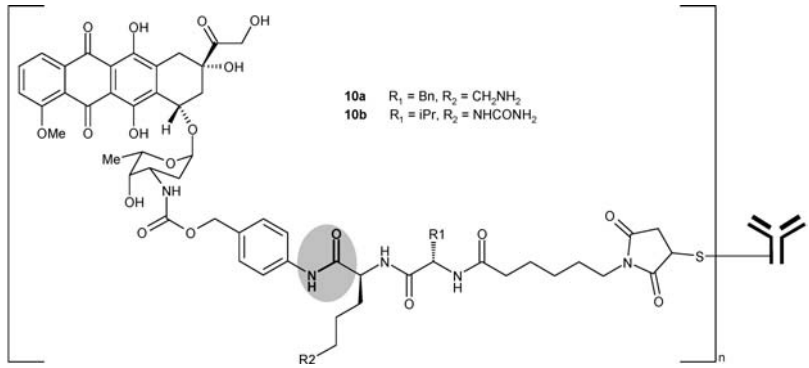
	Phenylalanine-lysine	12.5 days*	80 days*	n/a
	Hydrazone	2.1 days	2.6 days	15 mg/kg



* projected half-life

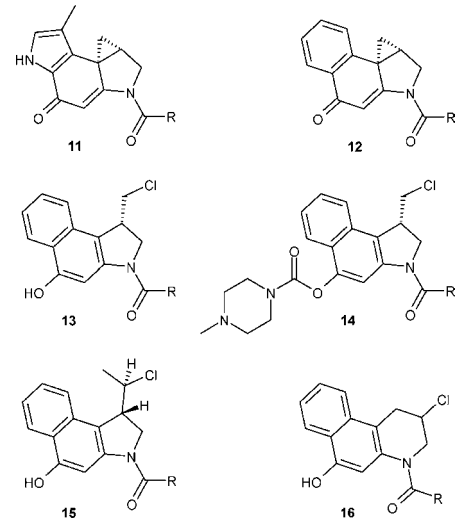
efficient release of the drug in the target cell. Interestingly, with the murine mAb CTM01, ADC **3** showed activities equal to or even greater than that of the corresponding hydrazone conjugate **2** in several *in vitro* and *in vivo* tumor models, revealing that this conclusion is not general (*16*). In clinical trials, however, compound **3** had only limited evidence of activity.

Mylotarg has met limited successes due to a narrow therapeutic window. The linker technology based on pH-dependent release mechanism is possibly not sufficiently stable and too much of the drug is being released in the bloodstream, as pharmacokinetic data have shown that the mean half-life of Mylotarg is 72 h (*15*). Nonetheless, the development of CMC-544 (inotuzumab ozogamicin), which is a humanized anti-CD22 mAb identically attached to *N*-acetyl-γ-calicheamicin dimethyl hydrazide via the acid-labile 4-(4′-acetylphenoxy)butanoic acid linker is ongoing at Wyeth. Although this ADC is closely related to Mylotarg, good stability was shown in both human plasma and serum (rate of hydrolysis of 1.5−2%/day over 4 days) (*17, 18*).

Disulfide bonds can be an alternative to acid-labile hydrazone linkers. In this case, the release is attributed to the high intracellular concentration of glutathione. This thiol-containing tripeptide is present in micromolar concentrations in the blood, whereas its concentration in the cytoplasma is in the millimolar range (up to 1000-fold higher). This is especially true for tumor cells, where irregular blood flow leads to hypoxic state (decreased oxygen level), resulting in enhanced activity of reductive enzymes and therefore even higher glutathione concentrations. In the absence of sulfhydryl groups, disulfide

Chart 4

bonds are thermodynamically stable and provide reasonably good stability in the bloodstream.



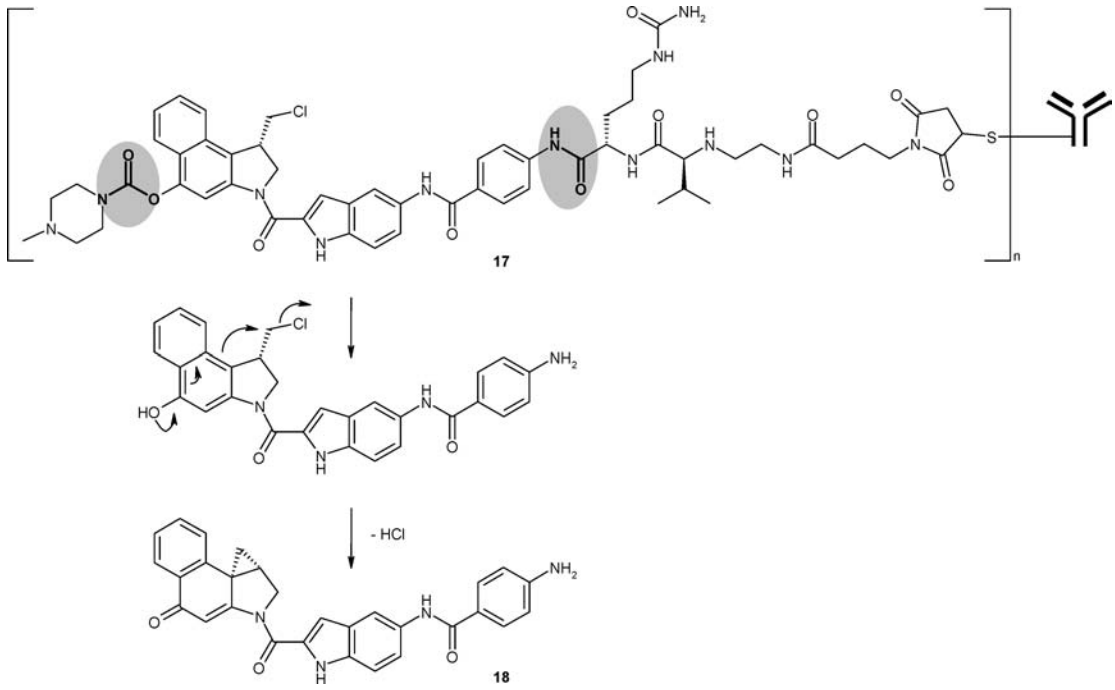
An example of an intracellularly cleavable disulfide-based linker was already discussed above (see "amide" conjugate **3**). Other examples are taxoid ADC payloads, conjugated via a disulfide-bearing 4-mercaptopentanoate linker to mAbs directed against the epidermal growth factor receptor (*19*). However, the most significant examples are ADCs where the immunoglobulin is connected over the same type of linker to ImmunoGen's drugs DM1 or DM4 (*20*−*22*). These potent thiol-containing maytansine analogues are antimitotic agents that bind to tubulin and inhibit microtubule assembly. After internalization of the ADC via antigen-mediated endocytosis and delivery to lysosomes by vesicular trafficking, the mAb is believed to be degraded, affording lysine derivatives linked to the toxin (*22*). Further intracellular modifications like cleavage of the disulfide linker through a disulfide exchange, and finally thiol methylation presumably catalyzed by intracellular methyltransferases, generate potent derivatives of DM1 or DM4 (*22*). These methylated drugs are uncharged, enabling them to pass back out through cell membranes to broaden their attack; the drug not only kills from inside the cell, but also knocks out adjacent cells within the tumor that are not targeted by the antibody (*23*). The linker of compound **4** (Chart 3) nevertheless proved to be relatively unstable *in vivo* (half-life of 47 h in mice) (*24*). Replacement of DM1 by DM4 structurally leads to the introduction of two methyl substituents on the carbon atom geminal to the disulfide bond, thereby limiting the accessibility for reducing agents. Consistent with these considerations, ADC **5** exhibits an increased half-life of 102 h in mice.

ENZYME-LABILE LINKERS

Chemically labile linkers often suffer from limited plasma stability. An alternative approach to achieve better control of the drug release involves linking a drug to an antibody via a peptide linkage. The free drug can be specifically cleaved from the carrier by the action of lysosomal proteases (e.g., cathepsin or plasmin) present at elevated levels in certain tumor tissues (*25*). Peptidic bonds are expected to have good serum stability, as proteases are normally not active outside cells because of unfavorable pH conditions and inhibition by serum protease inhibitors.

Seattle Genetics is using a maleimido-containing dipeptide linker to conjugate cysteine residues of mAbs with monomethyl auristatin E (MMAE, **7**) and F (MMAF), two auristatin derivatives that bind to tubulin and inhibit microtubule assembly. A valine-citrulline linker was designed to provide high plasma stability (half-lives in mice and monkey of 6.0 and 9.6 days, respectively) as well as a cleavage site for proteases (*26*). Efficient hydrolysis of the dipeptide linker by cathepsin B has been established *in vitro*. After enzymatic cleavage, 1,6-elimination of the strongly electron-donating 4-aminobenzyl group will occur, releasing MMAE in its active form (Scheme 1). This self-eliminating spacer is needed to spatially separate the drug from the site of enzymatic cleavage (*27*). Otherwise, the bulky payload has a negative influence on the kinetics of the peptide hydrolysis, as the access to the enzyme's active site can be affected.

Chart 5



Comparison of plasma stabilities of ADCs bearing enzyme-labile valine-citrulline or phenylalanine-lysine linkers (**6** and **8**, respectively) with ADC **9** equipped with a chemically labile hydrazone linker connecting MMAE with the cBR96 mAb showed impressively the advantage of the peptide linkage (Table 1): in human plasma, the ADC **6**, featuring a peptidic valine-citrulline-derived linker, exhibits an almost 100-fold increased stability compared to its hydrazone relative **9** and the *in vitro* specificity was increased (*26*). The peptidic linker has a half-life of 6 days in mice compared to 2 days for the hydrazone linker (3-fold improvement), resulting in a lower *in vivo* toxicity (*28*). Several ADCs incorporating a peptidic linker are in clinical development, with the most advanced being cAC10-vcMMAE (SGN-35) for CD30-positive hematologic malignancies (*26, 29, 30*).

In addition to *N*-terminus linked MMAE and MMAF, attachment of dipeptide linkers at the *C*-terminus was studied as a way to vary the rate of drug release and thus ADC potency and tolerability (*26, 31*). For MMAF, it could be shown that linking the mAb over a dipeptide linker to the C-terminus of the drug can lead to further improvement of the therapeutic window.

The superiority of enzyme-labile linkers was also shown for doxorubicin derivatives conjugated to mAbs (*11, 32*). With this

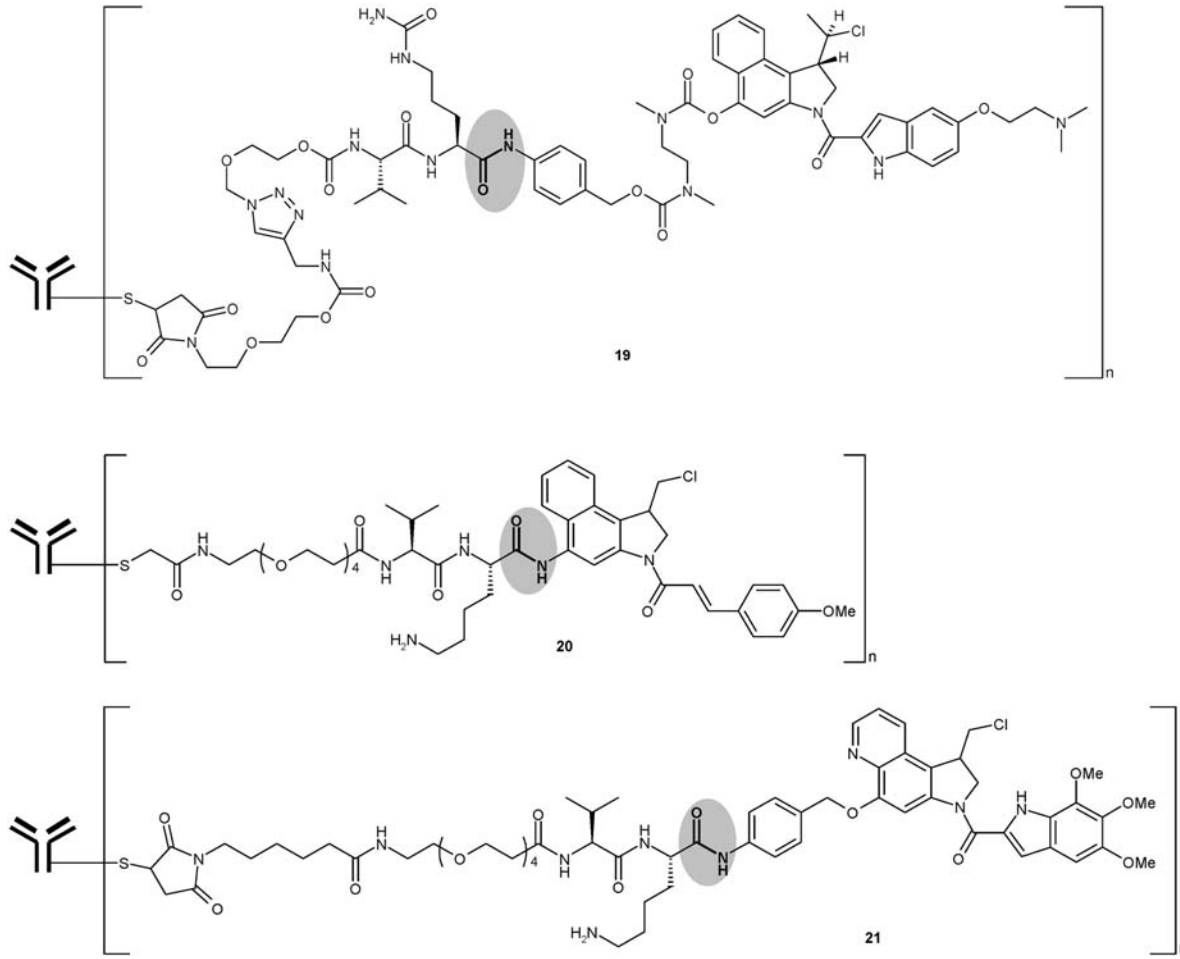
Scheme 2. Presumed Release Mechanism of CBI-Containing Drug 18 from ADC 17

strategy, the immunological specificity of BR96 mAb−peptide−doxorubicin conjugates **10a** and **10b** (Chart 4) was significantly improved compared to that of the corresponding hydrazone-based conjugate **1** (*11*), demonstrating again the importance of the linker structure for the ADC properties.

Peptide-containing linkers have been successfully used with CC-1065-derived toxins. CC-1065, duocarmycins, and other cyclopropapyrroloind-4-one (CPI, **11**; Chart 5) derivatives are potent minor-groove binding DNA alkylating agents. According to Boger et al., cyclopropabenzindol-4-one analogues (CBI, **12**) are chemically more stable, biologically more potent, and synthetically more accessible than their parent compounds incorporating the natural CPI alkylation subunit (*33*). In analogy to a duocarmycin prodrug (*34*), the seco-CBI precursor **13** was developed. This compound, which was postulated to show improved pharmacokinetics, will provide the CBI analogue **12** via Winstein cyclization (*35*). A further improvement was achieved by protecting the phenolic hydroxyl group with an enzyme-labile carbamate, as in derivative **14**, decreasing the toxicity of the prodrug while increasing its water solubility by introduction of an additional basic nitrogen (*36*).

Using their UltiMAb technology, Medarex conjugated compound **14** to a mAb via a peptidic linker (*37*). Conceptually, this approach is a double prodrug strategy. It does not only improve the drug's therapeutic efficacy by conjugating it to a tumor-specific mAb, but additionally employs a prodrug of the cytotoxic agent that has reduced potency and thus minimizes side effects before being released intracellularly by carboxyesterases. The two activating steps needed to trigger the release of the active drug (Scheme 2) may lead to an enlarged therapeutic window.

Tietze et al. have reported that the CBI prodrugs **15** and **16** exhibit lower toxicities due to the reduced reactivity of the secondary chloride compared to the primary chloride present in **13** and **14** (*39*−*41*). Such derivatives with secondary chlorides (see, for example, ADC **19**; Chart 6) are used in Syntarga's SpaceLink conjugation technology (*42*). To our knowledge, no data are yet published on the linker stability.



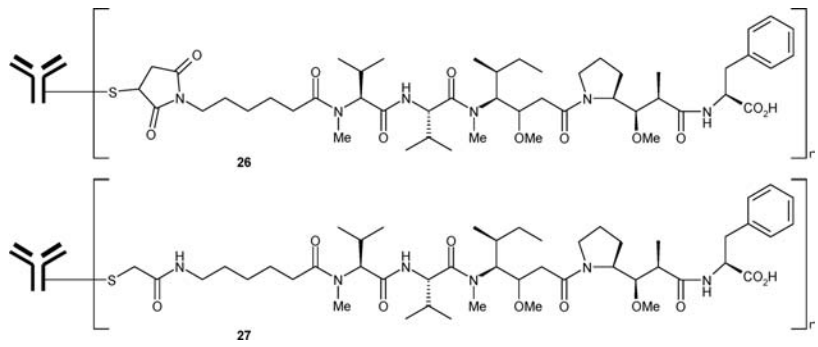
To extend its ADC technology to drugs with a complementary mode of action, Seattle Genetics has developed ADCs **20** and **21** (Chart 6) containing an amino-CBI and a hydroxy aza-CBI payload, respectively (*43*). Because of the hydrophobicity of this class of molecules, attention was focused on developing hydrophilic peptide-linker derivatives that prevented aggregation. This was achieved by use of a more hydrophilic valine-lysine sequence (compared to valine-citrulline as in ADC **6**) and incorporating a tetra(ethylene glycol) unit between the mAb and the peptide linker. The direct attachment of the linker to the amine of the CBI building block (as in **20**) or over a self-immolative *p*-aminobenzyl spacer to the corresponding hydroxyl group of the aza-CBI toxin (as in **21**) prohibits the spontaneous formation of the active toxin in the plasma. Only the enzymatic cleavage of the linker after internalization of the ADC into the cancer cell triggers the release of the prodrug that can now be transformed into the DNA-alkylating cyclopropyl derivative via a Winstein cyclization.

Another type of enzyme-labile linker was recently reported by Seattle Genetics (*44*). In this case, a carbohydrate moiety serves as the cleavage site. Its hydrophilic nature should limit aggregation. Interestingly, the β-glucoronide moiety in ADC **22** is not directly linking the ADC with the payload. Nevertheless, cleavage by β-glucuronidase triggers the 1,6-elimination of the spacer liberating the free drug **23** (Scheme 3). This carbohydrate motif was also used in ADCs bearing Camptothecin analogues (*45*).

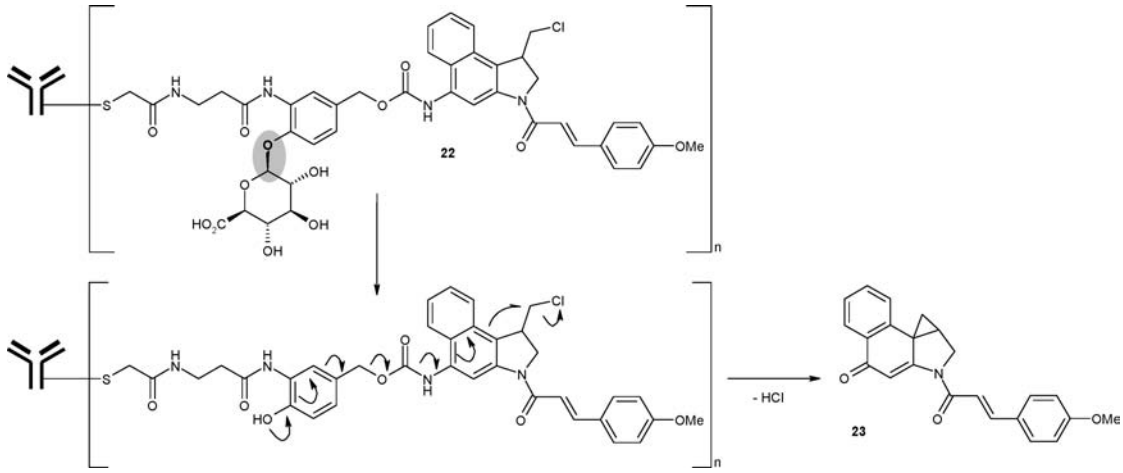
NONCLEAVABLE LINKERS

ImmunoGen has reported the fortuitous discovery of a noncleavable thioether bond to link DM1 to mAbs (*22, 46*). Derivative **24** was actually prepared as a control experiment, but surprisingly, this noncleavable thioether linked ADC also proved very potent. The release mechanism is believed to occur via internalization of the ADC followed by degradation of the mAb component in the lysosome, resulting in the release of the maytansinoid drug **25** still attached via the linker to a lysine residue. This chemical modification of the drug did not diminish its cytotoxic potential. This form of the drug is, however, charged and presumably not able to diffuse into neighboring cells. Hence, it cannot kill adjacent tumor cells

Chart 6



that do not express the target antigen (antigen-negative cells). Besides this by-stander effect (*23*), there is an additional reason why cleavable linkers may have a broader efficacy. Although internalization is often the common initial activation process for both cleavable and noncleavable linkers (*22*), ADCs with cleavable linkers may also be active even when they are poorly internalized (*47*). One possible explanation is that, when the linker is cleaved in extracellular space, the free drug subsequently permeates the cell to reach its target. This mechanism is not operating for ADCs incorporating noncleavable linkers, which must be internalized and degraded within the cell to become active. They are thus dependent on the biology of the target cell.



The *in vivo* stability of the thioether-linked ADC **24** proved, with a half-life of 134 h in mice, superior to that of compounds **4** and **5** (47 and 102 h, respectively). ADCs with noncleavable linkers were found to be better tolerated (*47*), presumably resulting in an improved therapeutic index. The use of noncleavable linkers has thus become an important feature of ImmunoGen TAP (tumor-activated prodrug) conjugation technology. This is best exemplified by the promising clinical results obtained by Genentech's trastuzumab-DM1 (T-DM1) for HER2-positive metastatic breast cancer (*48*).

Seattle Genetics made the same finding with MMAF, namely, that the cleavable dipeptide linker (as in **6**) could be replaced by a noncleavable thioether bond (as in ADC **26**; Chart 7) while retaining the *in vivo* activity (*49*). Mass spectrometry showed that the released drug was a cysteine-adduct of MMAF, presumably resulting from mAb degradation within lysosomes as proposed for maytansinoid conjugate **24**. MMAE, although closely related structurally, was not

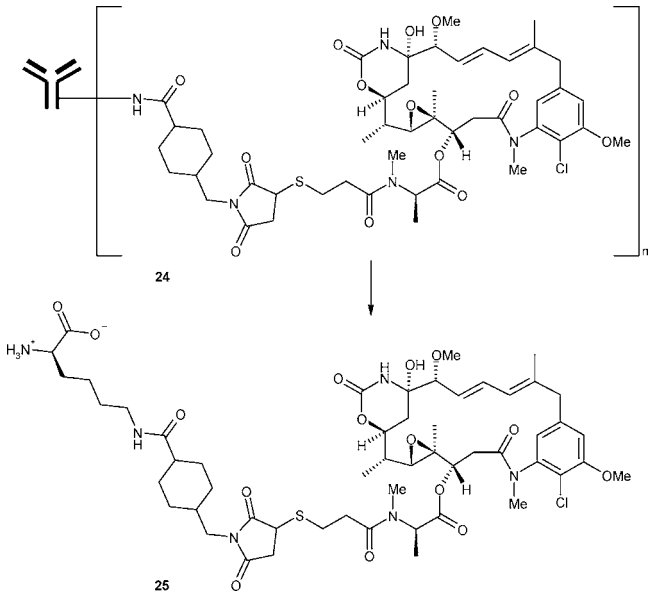


Chart 7

Scheme 3. Postulated Release Mechanism of CBI-Containing Drug 23 from ADC 22

Scheme 4. Release of Maytansine Drug-Derivative 25 through Lysosomal Degradation of ADC 24

active when attached in this manner. Only MMAF can sustain significant modification to the *N*-terminal position and still retain its potency. Recently, it was shown that a slow transfer of the drug from the ADC to albumin cysteines in the plasma occurs with alkyl-maleimide ADCs (*50*). To counteract this effect, the linker stability was enhanced by replacing the maleimide (as in ADC **26**) with an acetamide functionality (as in ADC **27**). This type of ADC led to no apparent degradation in the bloodstream for up to 14 days.

CONCLUSION

A promising approach to improve the potency of antibody-based cancer therapies is to conjugate the mAb with cytotoxic chemotherapeutic drugs. In the foreseeable future, ADCs will eventually fulfill the promise of specific delivery of cytotoxic drugs to tumor cells (targeted therapy), thus avoiding the dose-limiting toxicity of chemotherapy that occurs as a result of its effects on normal cells. The linker technology profoundly impacts ADC potency, specificity, and safety. Early ADC linkers were commonly derived from acid-labile hydrazones, which were designed to be cleaved inside target cancer cells, but inevitably underwent cleavage at nontarget sites. Newer linkers feature hindered disulfides and peptidic moieties that have achieved greater *in vivo* stability. To spare nontarget tissues from chemotherapeutic damage, noncleavable linkers were recently developed. They are thus far the most stable linkers used in ADCs. This recent development may shift some of the future challenge in ADC development from the linker technology toward finding cytotoxic drugs that retain their potency when bearing a covalently attached linker. The improved linker stability and reduced toxicity, however, come together with greater target dependence than in the case of cleavable linkers. ADCs with noncleavable linkers must be internalized and degraded within the cell, whereas compounds with cleavable linkers may be active against targets that are poorly internalized through extracellular drug release and drug entry into tumor cells. Similarly, killing of bystander antigen-negative cells through targeting of antigen-positive cells (collateral toxicity) is presumably only possible with cleavable linkers. The Lonza ADC-team thus believes that no general linker design exists for all ADCs or cancer types. Despite significant progress, each mAb must be examined separately in order to optimize a specific delivery system.

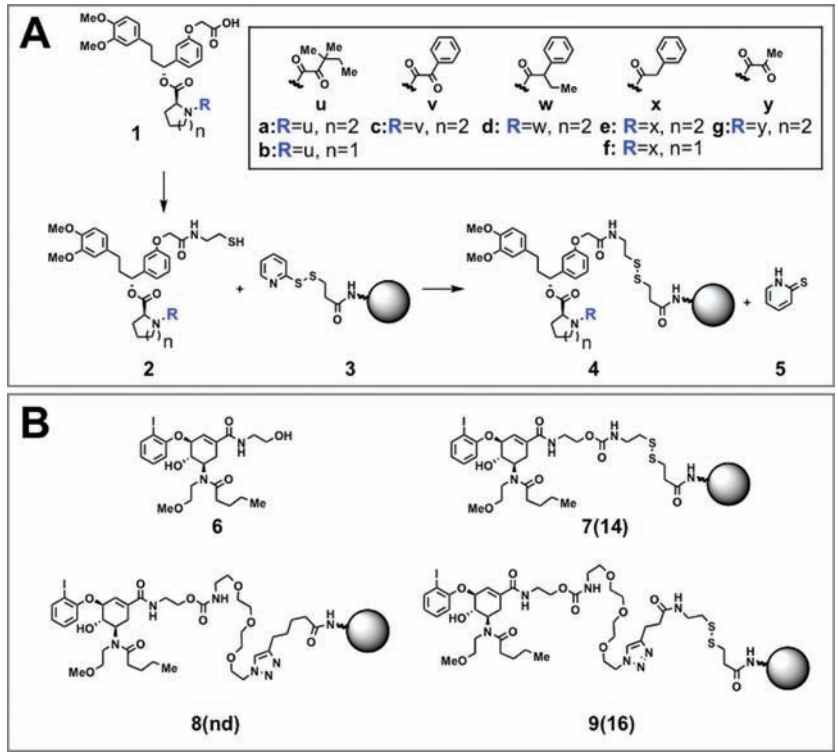
Center for Systems Biology Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, and Howard Hughes Medical Institute Department of Chemistry and Chemical Biology, Harvard University, Cambridge, Massachusetts. Received October 7, 2009; Revised Manuscript Received November 9, 2009

Nanoparticles bearing surface-conjugated targeting ligands are increasingly being explored for a variety of biomedical applications. The multivalent conjugation of targeting ligands on the surface of nanoparticles is presumed to enhance binding to the desired target. However, given the complexities inherent in the interactions of nanoparticle surfaces with proteins, and the structural diversity of nanoparticle scaffolds and targeting ligands, our understanding of how conjugation of targeting ligands affects nanoparticle binding remains incomplete. Here, we use surface plasmon resonance (SPR) to directly and quantitatively study the affinity and binding kinetics of nanoparticles that display small molecules conjugated to their surface. We studied the interaction between a single protein target and a structurally related series of targeting ligands whose intrinsic affinity varies over a 4500-fold range and performed SPR at protein densities that reflect endogenous receptor densities. We report that even weak small molecule targeting ligands can significantly enhance target-specific avidity (by up to 4 orders of magnitude) through multivalent interactions and also observe a much broader range of kinetic effects than has been previously reported. Quantitative measurement of how the affinity and kinetics of nanoparticle binding vary as a function of different surface conjugations is a rapid, generalizable approach to nanoparticle characterization that can inform the design of nanoparticles for biomedical applications.

Targeted nanoparticles are an exciting class of materials that are undergoing clinical development as diagnostics, molecular imaging probes, and therapeutic delivery vehicles (*1*). Targeting is typically achieved through the surface display of multiple high affinity ligands, such as antibodies, peptides, or natural products. Multivalent interactions between the nanoparticles and their targets can increase the affinity of target binding (avidity) (*2*), much as multivalency in Nature facilitates the attachment of pathogens to host cells, or circulating cells to vascular endothelium (*3, 4*). More recently, investigators have used synthetic, non-natural product small molecules as targeting ligands on the surface of nanoparticles (*5, 6*). This approach allows a much more diverse range of chemical matter to be used for targeting and enables libraries of small molecule modified nanoparticles to be rapidly screened for the desired binding properties. Non-natural product small molecules generally have much weaker affinity for their targets (e.g., micromolar K_D), so their use as targeting ligands assumes that multivalent avidity effects will enhance the binding affinity. This notion is supported by the observation that multivalency enhances the avidity as well as recognition specificity of weak interactions between carbohydrates and their protein partners (*7–9*) and increases the biologic activity of a weakly binding therapeutic (*10*). However, given the complexities inherent in interactions of nanoparticle surfaces with proteins (*11, 12*), we sought to develop an approach that could quantitatively describe the binding of a surface-conjugated nanoparticle to its target, and that was sufficiently rapid and generalizable to be widely applicable to the development and characterization of targeted nanoparticles.



Here, we use surface plasmon resonance (SPR) to directly and systematically study the affinity and binding kinetics (*13*) of nanoparticles that display targeting small molecules conjugated to their surface. To enable direct comparisons, we study a series of structurally related ligands to the same protein, whose intrinsic K_D varies over a 4500-fold range. Importantly, we perform SPR measurements at target protein densities that are comparable to those reported for known cellular targets. These studies demonstrate that even weak small molecule ligands can increase the avidity of nanoparticle target interactions, but also reveal unanticipated effects on binding kinetics. As targeted nanomaterials move toward clinical application, a quantitative understanding of the structure−activity relationships underlying their avidity and kinetics would inform the future design of targeted nanoparticles.

We chose the well-studied interaction between synthetic derivatives of the natural product FK506 and its target protein, FK506-binding protein 12 (FKBP12). A series of structurally related synthetic FK506 analogues possessing K_Ds that range from 24 nM to 110 μM (*14*) (Scheme 1A) were individually conjugated to a dextranated magnetic nanoparticle (cross-linked iron oxide, or CLIO) originally developed for MR imaging (*15*)

Scheme 1. Conjugation of Small Molecules to Nanoparticles[a]

[a] A. Conjugation of a series of synthetic derivatives of FK506 (**1**) by sulfhydryl exchange. B. Small molecule that binds aurora A kinase (**6**) and nanoparticle conjugates obtained by sulfhydryl exchange and Huisgen 1,3-dipolar cycloaddition.

and biosensor applications (*16*). This nanoparticle has a diameter of approximately 38 nm in aqueous solutions. We conjugated small molecule ligands to sulfhydryl reactive groups on the nanoparticle using sulfhydryl exchange, and ultraviolet quantitation of the amount of released pyridine-2-thione (**5**) allowed calculation of the average number of small molecules conjugated to each nanoparticle (*17*) (Scheme 1A). (For ligands of class **1**, our conjugation linkers utilized the same carboxylic acid moiety that has been previously used to modify this class of compounds while preserving their affinity for FKBP12 (*18–21*).) Nanoparticles with low and high small molecule valency (approximately 3−5 vs 13−18 small molecules per nanoparticle, respectively) were selected for further study; the number of small molecules conjugated per nanoparticle is depicted in parentheses (e.g., **4a(17)** corresponds to particle **4a** with 17 conjugated small molecules).

Binding of small molecule conjugated nanoparticles to their target protein is specific and exquisitely sensitive to the density of protein immobilized onto the SPR sensor chip. Since our target protein is immobilized to the sensor chip as an FKBP12-GST (glutathione S-transferase) fusion protein, we tested nanoparticles for nonspecific binding to GST and saw no binding to either unmodified or small molecule conjugated nanoparticles (Figure 1A,B). In contrast, at protein densities commonly used for SPR experiments, targeted nanoparticles remain bound to an FKBP12-GST surface (hereafter called an FKBP12 surface) with no appreciable dissociation even after more than 12 min (Figure 1C). At lower protein densities (e.g., 100 response units, corresponding to approximately 1 protein per 648 nm^2), we observe a measurable (but still slow) off-rate that allows calculation of dissociation kinetics (Figure 1C). Of note, this low protein density is still the same order of magnitude at which physiologically relevant receptors are expressed on cell surfaces. For instance, the HER2 receptor is expressed in SKBR-3 breast cancer cells at a density of $\sim 1 \times 10^6$ receptors per cell (*22*); assuming a single-sided disk 15 μm in diameter, this corresponds to a HER2 receptor every 707 nm^2. An analogous calculation for folate receptors on KB cells ($\sim 2.5 \times 10^6$ receptors per cell (*23*)) corresponds to a receptor every 283 nm^2.

We measured the association rate k_a, dissociation rate k_d, and dissociation constant K_D (k_d/k_a) for the interaction of FKBP12 with each small molecule (**1a**−**1g**), as well as with those same small molecules conjugated to CLIO nanoparticles (**4a**−**4g**) (Scheme 1A). For each experiment, small molecules or nanoparticles were flowed in parallel over a reference sensor bearing GST (see Supporting Information); the minimal signal arising from GST interaction is then subtracted out to yield SPR tracings that reflect specific interactions with FKBP12 (Figure 1D,E). Small molecule and nanoparticle sensorgrams were analyzed with a Langmuir 1:1 binding kinetic analysis, using software provided by the instrument manufacturer (Biacore). $K_{D(free)}$ for all free ligands are in excellent agreement with previously published values, ranging from 24 nM to 110 μM (Table 1). By comparison, the conjugated nanoparticles show profound changes in both association and dissociation kinetics, with only the weakest free ligand, compound **1g**, failing to bind FKBP12 when conjugated to a nanoparticle. As expected, k_d for the multivalent nanoparticles are all markedly decreased relative to the corresponding free ligand (up to 3400-fold slower for **4a(17)** vs **1a**). (Dissociation of FKBP12-GST from the surface is negligible during the time course of these experiments; see Supporting Information.) In contrast, k_a for different nanoparticles show widely divergent effects. For instance, nanoparticle **4a(17)** has a 400-fold slower k_a compared to the free ligand **1a**, while nanoparticle **4f(20)** has a 39-fold faster k_a compared to the free ligand **1f**.

$K_{D(multivalent)}$ (calculated from k_d and k_a) for all of the nanoparticles is in the single digit nanomolar range. To relate $K_{D(multivalent)}$ to $K_{D(free)}$ in cases where the precise number of ligand−target interactions is not known, Whitesides and colleagues defined an enhancement factor β, which increases as the relative affinity of a multivalent interaction increases: $\beta =$

[a] Corresponding groups of free ligand and conjugated nanoparticles are listed in alphabetical order (**a**−**g**). Nanoparticle names have the measured number of small molecules conjugated per nanoparticle (valency) in parentheses. $\beta = K_{D(free)}/K_{D(multivalent)}$. Valency was not determined for nanoparticle **8(nd)**.

$K_{D(free)}/K_{D(multivalent)}$ (*3*). For the multivalent nanoparticles tested here, β ranges from approximately 4 to 9500; the largest β is for ligand **1f**, with a K_D of 39 μM as a free ligand and a $K_{D(multivalent)}$ of 4.15 nM as nanoparticle **4f(20)**. Thus, nanoparticles bearing ligands with weak intrinsic affinity demonstrate greater β and increased affinity (avidity).

The rate map in Figure 2 graphically summarizes several features of the data: (i) A series of multivalent nanoparticles, all binding to the same protein target with approximately the same $K_{D(multivalent)}$, can nonetheless display markedly different kinetics. (ii) Conjugating free ligands (open symbols) to form the corresponding multivalent nanoparticles (closed symbols) has dramati-

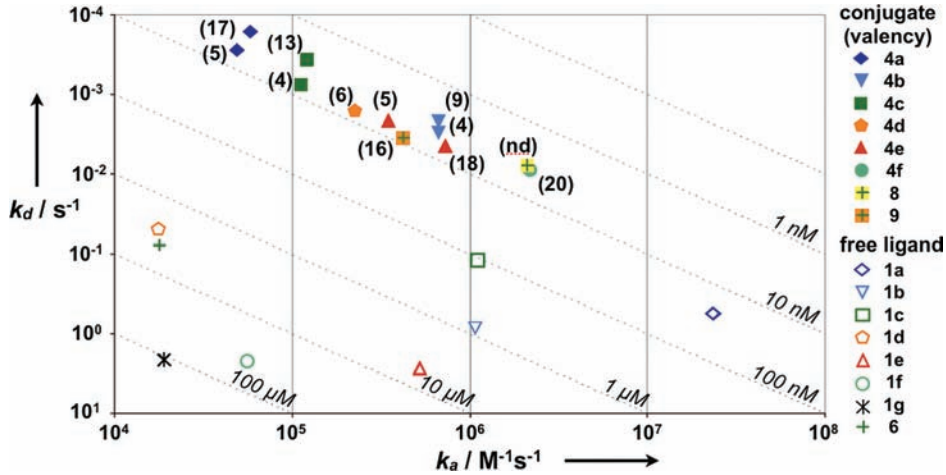

Figure 2. Rate maps summarizing binding affinity and kinetics. Different combinations of k_a and k_d that result in the same K_D are indicated by dashed lines. Data for free ligands are depicted by open symbols; for each ligand, the corresponding nanoparticles are depicted by a solid symbol of the same shape, with conjugation valency listed in parentheses next to the solid symbol. Valency of **8(nd)** was not determined.

9(16)	1.89×10^4	2.57×10^{-3}	1.91×10^3	1.30×10^{-5}	1.36×10^{-7}	6.84×10^{-9}	1.99×10^1	0.34

[a] Bivalent interactions between A (analyte) and B (immobilized ligand) are described by the following equations: (1) A + B $\leftrightarrows$ AB (with rate constants k_{a1} and k_{d1}, and $K_{D1} = k_{d1}/k_{a1}$), (2) AB + B $\leftrightarrows$ AB_2 (with rate constants k_{a2} and k_{d2}, and $K_{D2} = k_{d2}/k_{a2}$). [b] k_{a2} (RU^{-1} s^{-1}) was converted approximately to k_{a2} (M^{-1} s^{-1}) as follows: k_{a2} (M^{-1} s^{-1}) = k_{a2} ($RU^{-1}s^{-1}$) × MW × 100.

cally diverse effects on interaction kinetics; $k_{d(multivalent)}$ decreases to a variable extent, and $k_{a(multivalent)}$ can increase, decrease, or remain largely unchanged. (iii) Under the tested protein densities, adding more small molecule ligands to each nanoparticle has a modest effect on both kinetics and affinity.

We also extended our analysis to a relatively uncharacterized synthetic small molecule screening "hit". Compound **6** (Scheme 1B), discovered through a biochemical affinity screen, binds aurora A kinase with $K_{D(free)} = 4\ \mu M$ (*24*). We conjugated **6** to CLIO using sulfhydryl exchange (conjugates **7(14)** and **9(16)**) or Cu(I)-catalyzed Huisgen 1,3-dipolar cycloaddition ("click" chemistry, conjugate **8**) (Scheme 1B). (Conjugation of **6** to CLIO utilized the same primary alcohol that was used to immobilize **6** in the affinity screen that led to its discovery (*19, 24*).) Nanoparticle **7(14)** does not bind to immobilized aurora A kinase (data not shown). In contrast, nanoparticles **9(16)** (with a similar but longer linker than the inactive **7(14)**) and **8** both show significantly increased avidity, with $K_{D(multivalent)} = 9$ and 4 nM, and $\beta = 480$ and 1100, respectively (Table 1 and Figure 2). Thus, in this second model system, multivalent attachment of a weakly binding screening "hit" results in large β factors and enhanced avidity toward the compound's target. The rate map in Figure 2 illustrates how different methods of conjugating the same molecule (e.g., in nanoparticles **9(16)** and **8**) can result in significantly divergent effects on binding kinetics (especially with regard to k_a) (Figure 2).

Because it is not possible to precisely determine the number of interactions each nanoparticle makes with immobilized ligands, all of the above sensorgrams used a simple binary interaction model (similar to one used for other nanoparticle studies (*23*); full details in Supporting Information). In fact, a binary model fits the data quite well with very small residual differences (between experimental and fitted curves; residual curves are shown in Supporting Information) and small χ^2 values (minimized sum of the squared residual difference). This is consistent with our choice of relatively sparse protein densities to mimic physiologic receptor densities. To estimate the contribution of higher-order interactions, we reanalyzed the data using a tertiary interaction model (i.e., corresponding to a bivalent interaction between the nanoparticle and protein) as follows (the full binding model is described in Supporting Information):

(1) A + B $\leftrightarrows$ AB (with rate constants k_{a1} and k_{d1}, and $K_{D1} = k_{d1}/k_{a1}$)

(2) AB + B $\leftrightarrows$ AB_2 (with rate constants k_{a2} and k_{d2}, and $K_{D2} = k_{d2}/k_{a2}$).

For the conjugated nanoparticles **4a**−**4f** and **9**, the ratio of K_{D1}/K_{D2} correlates with $K_{D(ligand)}$, the dissociation constant for the free ligand ($R^2 = 0.57$; Table 2 and Figure 3A). That is, the bivalent mode of binding contributes more to the overall nanoparticle interaction (greater K_{D1}/K_{D2} ratio) for nanoparticles bearing ligands of weaker intrinsic affinity (larger $K_{D(ligand)}$). This is consistent with our finding that nanoparticles bearing weaker ligands also exhibit the greatest β and enhancement of avidity. Interestingly, the avidity effect for weaker ligands appears to be mediated primarily by the dissociation rate of the bivalent interaction. The dissociation constant for the free ligand ($K_{D(ligand)}$) shows a strong correlation with k_{d1}/k_{d2} ($R^2 = 0.76$; for weaker free ligands, $k_{d1} \gg k_{d2}$) but no correlation with k_{a1}/k_{a2} ($R^2 = 0.01$) (Table 2 and Figure 3B,C). While it is uncertain

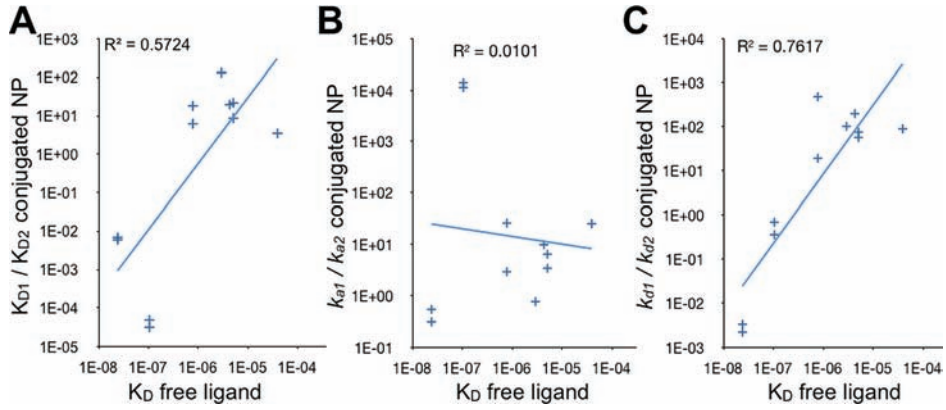

Figure 3. Relative contribution of monovalent vs bivalent reaction terms to nanoparticle binding as a function of the intrinsic K_D of the free ligand. A. As the intrinsic affinity of the free ligand becomes weaker, K_{D1}/K_{D2} increases ($R^2 = 0.57$). B. No correlation between k_{a1}/k_{a2} and intrinsic affinity of the free ligand. C. As the intrinsic affinity of the free ligand becomes weaker, k_{d1}/k_{d2} increases ($R^2 = 0.76$).

whether the nanoparticles interact through bivalent or higher-order interactions, this analysis confirms that multivalent interactions make important contributions to nanoparticle avidity.

Predicting the structure−activity relationships (SAR) for multivalent ligands has not been straightforward, even for relatively small systems such as dimers of the antibiotic vancomycin (*25*). This problem is exacerbated as functionalized nanoparticles increasingly utilize chemically and structurally diverse scaffolds (e.g., dextranated nanoparticles, dendrimers, albumin, liposomes) and targeting ligands (e.g., antibodies, peptides, aptamers, or low-affinity small molecules). Here, we have performed SPR on relatively sparse but physiologic protein surfaces (*22, 23*) to very sensitively detect how subtle variations in targeting ligands can affect binding kinetics and affinity. Our target protein densities are approximately 100-fold sparser than those used to document very large avidity effects for folate-targeted dendrimers (*23*), and our findings provide a complementary view of avidity at a distinct, physiologically relevant regime of protein concentrations. Using even slightly denser (e.g., 4-fold) protein surfaces, we observed essentially no dissociation of nanoparticles (Figure 1C), which suggests that our results may underestimate the maximal avidity obtainable with these particles, as well as the contribution of higher ligand valencies. Other factors, such as deformable and fluid membranes that could facilitate close apposition of cellular receptors, could further increase avidity.

We demonstrate strong avidity effects (β of up to 4 orders of magnitude) for nanoparticles conjugated to relatively weak (micromolar K_D) small molecule ligands, including "hits" from a high-throughput screen. We observed a dramatic decrease in k_d for the nanoparticles relative to the free ligand, consistent with other reports (*23*); however, we observed a much wider variety of effects on k_a than has been reported previously, including markedly increased, markedly decreased, or unchanged k_a relative to the free ligands. These unanticipated effects on binding kinetics were revealed because of the deliberate constraints of our experiment (a common protein target, shared nanoparticle scaffold, similar valency, and identical conjugation chemistry), which were imposed to allow detailed comparisons of multivalent binding. The kinetic differences displayed by our series of related functionalized nanoparticles could translate into functional differences. For instance, nanoparticle affinity and association and dissociation rates can all affect how deeply an intravascular circulating agent penetrates into tissue before its target sites become effectively saturated (*26*); the relative contribution of these variables depends on several in vivo factors, including capillary permeability, particle size, and target density.

Overall, this approach can be generalized rapidly to a variety of ligand−target combinations, as it does not require de novo development of a cell-based assay for each target. Systematic application of this approach could reveal principles that guide nanoparticle design. For instance, our studies suggest that a view in which nanoparticles are largely modular assemblies of scaffold, linker, and targeting ligand may be too simplistic; instead, SPR studies could clarify how different structural components collaborate to determine binding kinetics and affinities. Our data also suggest testable hypotheses about how nanoparticles with distinct binding and kinetic properties will behave in complex in vitro and in vivo systems. This in turn has broad implications for the design and synthesis of functionalized nanoparticles for the imaging, diagnosis, and treatment of disease.

Targeted delivery of therapeutic drugs promises to become the norm to treat cancer. Here, we conjugated the cytotoxic agent 6-hydroxypropylacylfulvene (HPAF) to anginex, a peptide that targets galectin-1, which is highly expressed in endothelial cells of tumor vessels. In a human ovarian cancer model in mice, the conjugate inhibited tumor growth better than equivalent doses of either compound alone. Immunofluorescence on tumor tissue demonstrated that the conjugate, like parent anginex, selectively targeted tumor vasculature and inhibited tumor angiogenesis. Increased activity from the conjugate further suggests that HPAF retains at least some of its normal cytotoxic activity when linked to anginex. More importantly perhaps is the observation that the conjugate abrogates apparent systemic toxicity from treatment with HPAF. This work contributes to the development of tumor vascular targeting agents against cancer in the clinic.

INTRODUCTION

When used at optimal doses, chemotherapeutic agents can result in considerable systemic toxicity. Recently, it was demonstrated in the clinic that chemotherapy at doses below maximally tolerated doses can be very effective when used in combination with the antiangiogenic agent, Avastin (Genentech) (*1*). In fact, a number of antiangiogenic agents have been developed and used in a similar fashion in various preclinical animal models (*2*−*4*). The most promising of these appear to be those that act directly on endothelial cells (EC) (*5*), because they are effective against a broad spectrum of tumors and less prone to induce drug resistance (*5*). Moreover, such EC-specific agents are also being used as tumor targeting moieties to increase specificity of chemotherapeutics (*6*) and to deliver contrast agents for magnetic resonance imaging (MRI) (*7*). For example, the α_v integrin-binding RGD tripeptide has been coupled to the chemotherapeutic drug doxorubicin, and shown in tumor-bearing mice to prolong survival, decrease the optimal effective dose, and reduce toxicity (*6*).

Another EC specific antiangiogenic agent, anginex (*8, 9*), targets galectin-1 (gal-1) (*10*), a cell surface glycan binding protein that is highly upregulated in tumor-activated EC (*10*−*12*). Differential stromal elevation of gal-1 over the tumor parenchyma has been reported in several cancers, including cancer of the breast (*13*), colon (*14*), prostate (*15*), and ovary (*16*). By weakly binding to "carrier protein" plasma fibronectin (*17*), anginex is transported through the cardiovascular system to the tumor vasculature where the peptide binds gal-1 (*10*). Anginex binding to gal-1 disrupts tumor EC adhesion and migration, thereby inducing EC apoptosis and resulting in the inhibition of tumor angiogenesis (*10, 18*). Because gal-1 is likely expressed in most tumor types at relatively high levels, using anginex as a tumor vasculature homing device should be widely applicable.

The acylfulvenes are a semisynthetic class of compounds derived from illudin S, a toxin from the *Omphalotus illudens* mushroom, that demonstrate broad spectrum antitumor activity in studies conducted in vitro and in vivo. Irofulven (MGI-114; 6-hydroxymethylacylfulvene) is a leading member of the acylfulvene analogues and has shown clinical activity against a variety of cancers, either as a monotherapy or in combination with other chemotherapeutic agents (*19*). Similar to other alkylating agents, dose-limiting toxicities, such as myelosuppression, neutropenia, thrombocytopenia, nausea, vomiting, and fatigue, are observed when therapeutic concentrations of irofulven are used in patients (*20, 21*). At higher doses, ocular disturbances and symptoms of renal tubular acidosis have been observed (*20, 21*). Conjugating acylfulvenes to a vascular targeting agent, like anginex, has the potential not only to reduce the chemotherapeutic's toxicity profile and maintain, or even improve, efficacy in the clinic, but also to be employed against a broader spectrum of tumors. In this report, we conjugated an irofulven analogue, 6-hydroxypropylacylfulvene (HPAF) to anginex and investigated the ability of anginex to act as a tumor vasculature homing device. In human tumor xenograft studies, we found that the conjugate indeed targeted the tumor vascu-

(B) The chemical structure of irofulven is shown. (C) Schematic representation of the leucylester derivative of hydoxypropylacylfulvene synthesis, starting with HPAF, is shown.

lature and was more efficacious than either agent alone, without systemic toxicity.

EXPERIMENTAL PROCEDURES

Synthesis of 6-Hydroxypropylacylfulvene Conjugated to Anginex. The irofulven analogue, 6-hydroxypropylacylfulvene, was conjugated to amino acid side-chain carboxylate groups on the peptide anginex (MW = 3941 Da) via a leucyl ester linkage as shown schematically in Figure 1. For convenience, we refer to the leucyl ester derivative of HPAF as HPAF-LE (MW = 380 Da) throughout this paper. Chemical linkage was performed manually using Fmoc chemistry. Coupling was performed by dissolving an excess (1.2 mol equiv) of HPAF in Activator 1 (HATU in DMF). This solution was cooled on ice, and then Activator 2 (DIPEA in DMF) was added. The reaction mixture remained on ice for 5 min before it was added to a solution of anginex and DMF and allowed to react overnight. The next morning, a mixture of acetonitrile and water was added to the reaction mixture, which was then lyophilized.

Because the C-terminal carboxylate of anginex is amidated, there are three possible sites for coupling of HPAF-LE to the anginex side-chain carboxylates: D26, E29, and D33 (Figure 1). To favor coupling to one site per anginex molecule, the molar ratio of HPAF-LE/anginex was adjusted to 1.2:1 during the coupling reaction. Mass spectrometry (MS) analysis on the crude conjugate indicated that the desired products were obtained, with 3941 Da for unreacted anginex and 4353 Da for the 1:1 conjugate. No 2:1 conjugate (4688 Da) was detected.

The crude conjugate was purified by HPLC (CH semiprep column) using a water/ACN gradient running from 25% to 100% ACN. For this procedure, 10 mg of crude material was dissolved in 1 mL ACN/9 mL water, sonicated for 10 min, and centrifuged. Five mL was injected per HPLC run. Although unreacted anginex (about 10% by analytical HPLC) could be separated from the reaction products by HPLC, the three 1:1 (HPAF/anginex) conjugates could not be separated, and biological studies were performed on this mixture of single adduct conjugates.

To prevent possible compound instability, we prepared fresh working solutions on the day of administration. For in vitro studies, the conjugate, e.g., was dissolved in a stock solution of 100% ethanol (30 mg/mL), aliquoted out, and kept frozen at −80 °C. On the day of use, a work solution was prepared by diluting the stock solution in media, such that the ethanol content was reduced to 3% at the highest concentration tested in vitro (20 μM). No decline in activity was observed in repeated experiments, suggesting that the compound was stable when prepared in this fashion. Similarly, in animal studies, the conjugate was made fresh on the initial day of treatment, first dissolved in pure ethanol and then diluted in PBS to reduce ethanol content (3% in the 50 mg/kg and 0.6% in the 10 mg/kg treatment group). To check for degradation, samples were routinely submitted for MS analysis, including following in vitro studies for material remaining in solution.

Antibodies. Antianginex antibody was made and used in our lab as previously described (*10*). Antigal-1 antibodies were purchased from Santa Cruz Biotechnologies, and react with both human and murine galectin-1. Galectin-1 is highly conserved intra- and interspecies, being 90% identical between human and murine amino acid sequences (*26*).

Cell Culture. Human umbilical vein derived EC (HUVEC)[1] were harvested and cultured as described earlier (*22*). Human epithelial ovarian carcinoma MA148, murine melanoma B16F10, and human alveolar epithelial carcinoma A549 cells were cultured, as described previously (*22*−*24*).

Proliferation Assay. HUVEC were seeded in a 96-well culture plate coated with 0.2% gelatin (2 h at 20 °C). MA148

[1]Abbreviations: EC, endothelial cell; HUVEC, human umbilical vein EC; PBS, phosphate buffered saline; BSA, bovine serum albumin; VTA, vascular targeting agent.

cells were seeded in noncoated 96-well plates. Both cell types were seeded at a concentration of 3000 cells per well and allowed to adhere overnight at 37 °C in 5% CO_2/95% air before treatments were initiated. Cells were then exposed to complete medium supplemented with 10 ng/mL bFGF, 0.4% Endo-Gro (VEC technologies Rensselaer, NY), 10 ng/mL VEGF, or 20% FBS, with or without various concentrations of anginex, HPAF, anginex−HPAF conjugate, or gal-1 antibody (1/1000; Santa Cruz Biotechnologies, CA) for 72 h. Cell Counting Kit (CCK-8; Dojindo, Japan) was used to assess cell proliferation rates relative to untreated cells, as described previously (*23, 25*). All measurements were done in triplicate, and each experiment was performed at least three times.

Cell Adhesion Assay. HUVEC suspended in complete medium, with or without anginex-HPAF conjugate or anginex (both 10 μM), were seeded at a concentration of 10 000 cells in a 96-well culture plate as described above and allowed to adhere for 2 h on gelatin (0.2% w/v; 50 μL) or gal-1 (1 mg/mL; 50 μL). Subsequently, the wells were aspirated and washed with PBS carefully to discard the nonadherent cells, and complete media were added to the cells. Cell Counting Kit (CCK-8) was used to calculate the number of adherent cells (*23, 25*). All measurements were done in triplicate, and each experiment was performed at least three times.

MA148 Ovarian Carcinoma Mouse Model. Female athymic nude mice (nu/nu, 5−6 weeks old) were purchased from the National Cancer Institute and allowed to acclimate to local conditions for at least 1 week. Animals were given water and standard chow ad libitum and were kept on a 12 h light/dark cycle. Experiments were approved by the University of Minnesota Research Animal Resources ethical committee. Exponentially growing human ovarian MA148 epithelial carcinoma cells were cultured, harvested, suspended in serum free RPMI (2.0×10^6 cells/mouse), and inoculated subcutaneously (s.c.) into the right flank of the mouse, as described previously (*3, 25*). Studies were carried out in a therapeutic intervention model with established tumors to test the capacity of the conjugate to inhibit or reduce tumor growth. Tumors were allowed to grow to the size of approximately 75 mm^3 prior to randomization and initiation of treatment (all treatments were administered q3d×4 IP in 3% v/v ethanol/PBS). When tumors reached the size of about 1500 mm^3, animals were euthanized as per the approved protocol. As an indirect measurement of general toxicity, body weights of mice were monitored twice weekly, using a digital balance (Ohaus Florham, NJ).

Tumor volume was determined by measuring the size of the tumors on the flanks of the mice. The diameters of tumors were measured using calipers (Scienceware, Pequannock, NJ), and the volume was calculated using the equation to determine the volume of a spheroid: $(a^2 \times b \times \pi)/6$, where a is the width of the tumor and b is the length of the tumor. A complete response was defined as tumor regression to less than 15 mm^3 (3 mm in diameter), and a partial response was defined as a smaller tumor than at the start of treatment. Stable disease was defined as tumor volume less than 100 mm^3.

Immunohistochemistry. We used immunohistochemistry on MA148 tumor tissue from mice to demonstrate that the conjugate, like parent anginex, targets gal-1. For this work, similarly sized tumors were embedded in tissue freezing medium (Miles Inc.; Elkart, IN), snap-frozen in liquid nitrogen, and subsequently cut into 5 μm sections. Preparation and procedures for the frozen tumor sections were performed as described previously, with slight modifications (*23*). Briefly, sections of tissue were fixed for 10 min in acetone, and then incubated for 30 min in PBS/5%BSA/3%FBS to saturate aspecific binding sites. After washing with PBS, the slide was incubated with 10 μg of conjugate per slide, and followed by a washing step, tissue was incubated with antianginex and antigalectin antibodies (1:50) (*10*). Following overnight incubation, slides were washed with PBS and respective secondary antibodies were added: fluorescein isothiocyanate (FITC)-conjugated for conjugate detection and phycoerythrin (PE) for gal-1 detection (Sigma Chemical; St. Louis, MO) (*10*).

Microvessel density was detected using a 1:50 dilution with phycoerythrin (PE)-conjugated antibody to mouse CD-31 (PECAM-1; Pharmingen; San Diego, CA) or FITC conjugated antibody to mouse αSMA (alpha smooth muscle actin; Pharmingen; San Diego, CA) (*24*). A minimum of 10 randomly chosen images per treatment group were acquired using an Olympus BX-60 microscope at 200× magnification and digitally analyzed and differentially quantified by morphometric analysis (*24*).

Statistical Analyses. Tumor volume was analyzed using general linear mixed models (*27*). During the process of model selection, the likelihood ratio test was used to determine random effects and variance−covariance structures. The final general linear mixed model of tumor volume on the original scale contained interaction terms of treatment with both time and time^2, while that of tumor volume on a natural log scale, i.e., ln(tumor volume +1), contained the interaction of treatment with time only. The variance−covariance structure of random effects was unstructured, whereas that of random errors was first-order autoregression. Using derived parameters, model-based tumor growth curves for raw data were drawn, and the integral from day 1 to day 26 for each curve was estimated from the area under the curve. This area-under-the-curve integral provided estimates of percentage inhibition in tumor growth for treatment versus control groups over the time course of the study, rather than just on a single day. We also performed nonparametric and postcomparison tests, i.e., Kruskal−Wallis and Wilcoxon Rank-Sum, as well as Student's t test to validate differences between control and treatment data sets.

RESULTS AND DISCUSSION

Initially, we assessed the ability of conjugate to inhibit proliferation of various cells in culture. Anginex inhibited endothelial cell (EC) proliferation (Figure 2A) with an IC_{50} value of 5 μM, consistent with previous results (*8, 18, 22, 23*). In comparison, both the conjugate and HPAF-LE at 5 μM exhibited greater than 90% inhibition of EC proliferation, with IC_{50} values of 1.4 μM and 0.6 μM, respectively. Results were the same whether medium was supplemented with 10 ng/mL bFGF, 10 ng/mL VEGF, 0.4% Endo-Gro, or 20% FBS. Although anginex was essentially inactive against human ovarian carcinoma MA148, murine melanoma B16F10, and human alveolar epithelial carcinoma A549 cells, HPAF-LE and conjugate were quite effective, with respective IC_{50} values of 11 μM and 14 μM against MA148 (Figure 2B), 7 μM and 23 μM against B16F10 (Figure 2C), and 0.1 μM and 0.6 μM against A549 (Figure 2D).

These results suggest that conjugation to the peptide anginex does not substantially modify the effectiveness of HPAF-LE as a chemotherapeutic agent. This is interesting because acylfulvenes are known to function intracellularly by forming DNA adducts (*28*), and for this to occur, the conjugate should be internalized by these cells. At least with EC, anginex is known to be rapidly internalized upon binding to the cell surface (*10*). Nevertheless, demonstration that the acylfulvene-based anginex conjugate can still promote formation of acylfulvene−DNA adducts requires further investigation.

To demonstrate that the conjugate still targets gal-1 like parent anginex (*10*), we employed cell adhesion and competition assays, as well as ex vivo double immunostaining (Figure 3). As illustrated in Figure 3A, conjugate and anginex significantly ($p < 0.05$) block EC adhesion on gal-1-coated surfaces, whereas

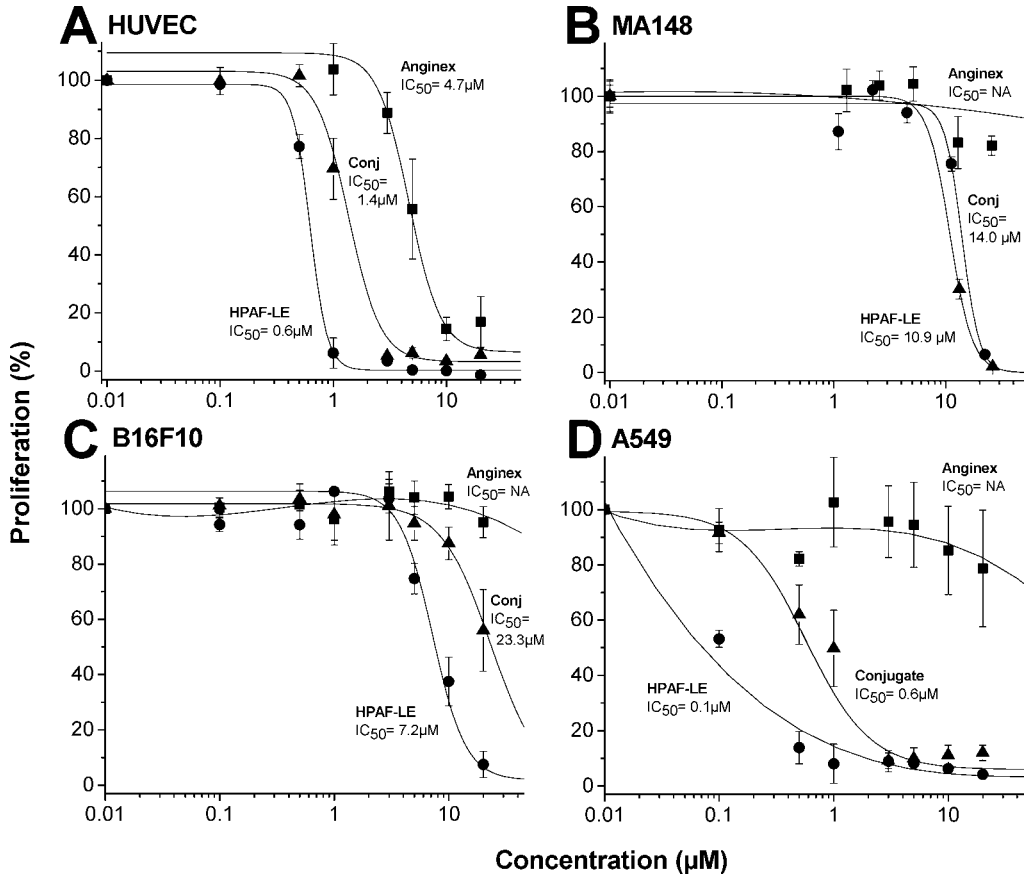

Figure 2. Differential inhibition of EC and MA148 cell proliferation by HPAF-LE, anginex, and conjugate. Concentration response curves of HPAF-LE, anginex, and conjugate on HUVEC (A), MA148 proliferation (B), B16F10 (C), and A549 (D). Average values for quantification of at least three separate experiments are shown ± SEM.

both conjugate and anginex could not block adhesion of EC to gelatin-coated surfaces. In addition, the inhibitory proliferation by both compounds was diminished by the presence of anti-gal-1 antibody (Figure 3B).

Using double immunostaining of cross sections from untreated MA148 xenograft tumors, we first showed that the antianginex antibody cross-reacted with the conjugate, indicating that the epitopes on anginex peptide were not blocked by the presence of the conjugated irofulven analogue (Figure 3D, middle panel). Then, we showed that gal-1 is present in the stroma of MA148 tumor tissue (Figure 3C,D upper panel), confirming earlier reports (*27*), and that gal-1 and conjugate could be identified by immunofluorescence (Figure 3D). The merged images, which illustrate the morphology of tumor blood vessels, demonstrate colocalization of gal-1 and conjugate (Figure 3D, lower panel). This in turn allows us to conclude that the conjugate indeed targets gal-1, and that conjugation of HPAF-LE to the peptide does not interfere with its ability to target gal-1.

Next, we compared the in vivo activity of HPAF-LE (5 and 10 mg/kg) to that of irofulven (1.5 and 3 mg/kg) and carboplatin (32.5 mg/kg) in the MA148 human ovarian carcinoma model (IP administration on a q3d×4 schedule, Figure 4A). Carboplatin was used as the standard comparator in this model because platinum agents are the most widely used drugs in first-line defense against ovarian cancer (*3, 29*). Our study demonstrated a dose response in both irofulven and HPAF-LE treated mice. Although HPAF-LE at 5 mg/kg or 10 mg/kg inhibited MA148 tumor growth to a similar degree to irofulven at 1.5 mg/kg or 3 mg/kg, respectively, irofulven was about 3-fold more effective than HPAF-LE at the same dose (Figure 4B). On the other hand, HPAF-LE at 10 mg/kg had essentially the same effect as carboplatin at 32 mg/kg, which amounts to a 3-fold improvement in dose over this platinum agent. The toxicity profiles of all compounds tested appeared to be very similar, with body weight gains being somewhat suppressed compared to those in vehicle-treated mice (Figure 4C).

To assess the effect of the conjugate on tumor growth, we treated MA148 tumor-bearing mice with the conjugate (10 mg/kg and 50 mg/kg), along with several control groups (vehicle treatment, and stand-alone treatments with anginex (10 mg/kg and 50 mg/kg) and HPAF-LE (5 mg/kg)). Figure 5A shows tumor growth curves for all groups. Even though the time course for the study is shown out to day 28, mice received treatment only during the first 10 days and were euthanized when tumors reached the size of about 1500 mm^3. Overall, tumor growth was inhibited in all treated groups compared to that in the vehicle-treated control group, and both anginex and the conjugate showed a dose response. On the day when control mice had to be sacrificed (day 23), Student's *t*-test indicated that the conjugate at 50 mg/kg inhibited tumor growth by 94% ± 1.6% compared to vehicle-treated control mice ($p = 0.02$), whereas equimolar doses of anginex (50 mg/kg) and HPAF-LE (5 mg/kg) inhibited tumor growth by 76% ± 7.3% ($p = 0.03$) and 82% ± 5.0% ($p = 0.03$), respectively (Figure 5B). Analysis of data on day 23 using Kruskal−Wallis and Wilcoxon Rank-Sum nonparametric and post-comparison tests showed that, while there were no significant differences between anginex (10 and 50 mg/kg), HPAF-LE (5 mg/kg), and conjugate (10 mg/kg) groups, there was a significant ($p = 0.003$) difference between conjugate (50 mg/kg) and HPAF-LE treated groups. This was supported by statistical analysis over the time course of the study using general linear mixed models, which showed significant differences between the control group and all other groups (anginex 10 mg/kg, $p < 0.01$; anginex 50 mg/kg and conjugate

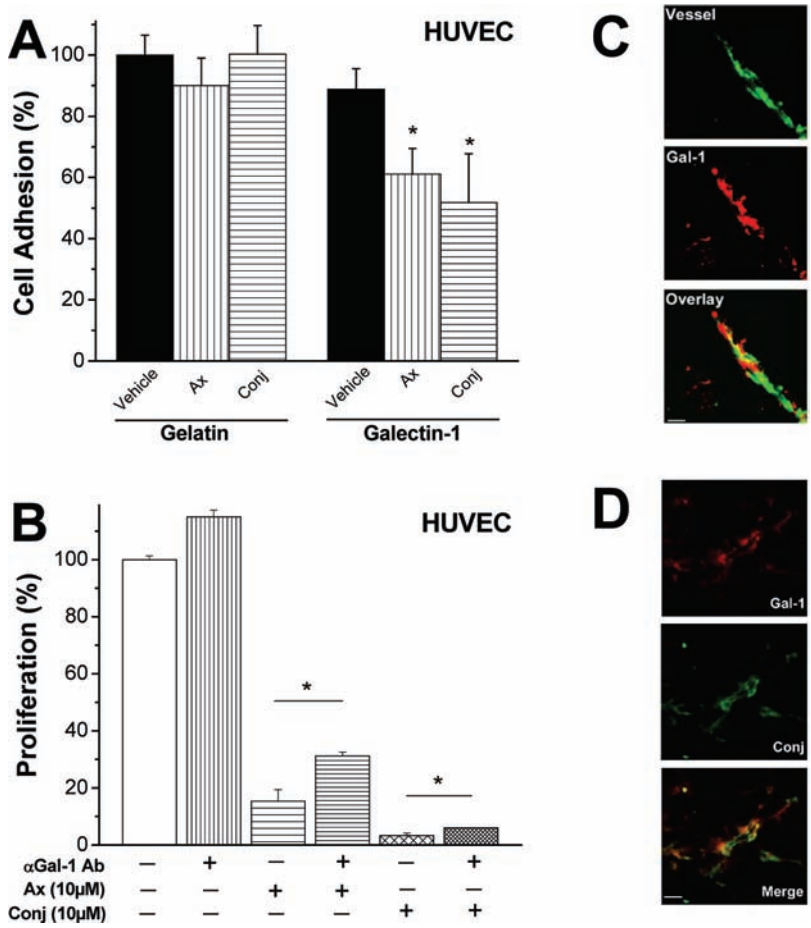

Figure 3. (A) EC adhesion to gal-1 coated surface, but not to gelatin-coated surface, is inhibited by conjugate (10 μM) or anginex (10 μM). (B) Conjugate (10 μM) or anginex (10 μM) EC proliferation inhibition is significantly reduced by anti-gal-1 antibody (1/1000). (C) Immunohistochemistry staining of mouse vessels, pericytes (green; αSMA), gal-1 expression (red); co-localization of gal-1 and mouse vessels (yellow; CD31). (D) Immunohistochemistry staining of mouse vessels, showing that HPAF-LE anginex conjugate targets gal-1 in MA148 tumors: gal-1 expression (red); conjugate binding (green); co-localization of gal-1 and conjugate (yellow). Original magnification 200×; scale bar = 50 μm.

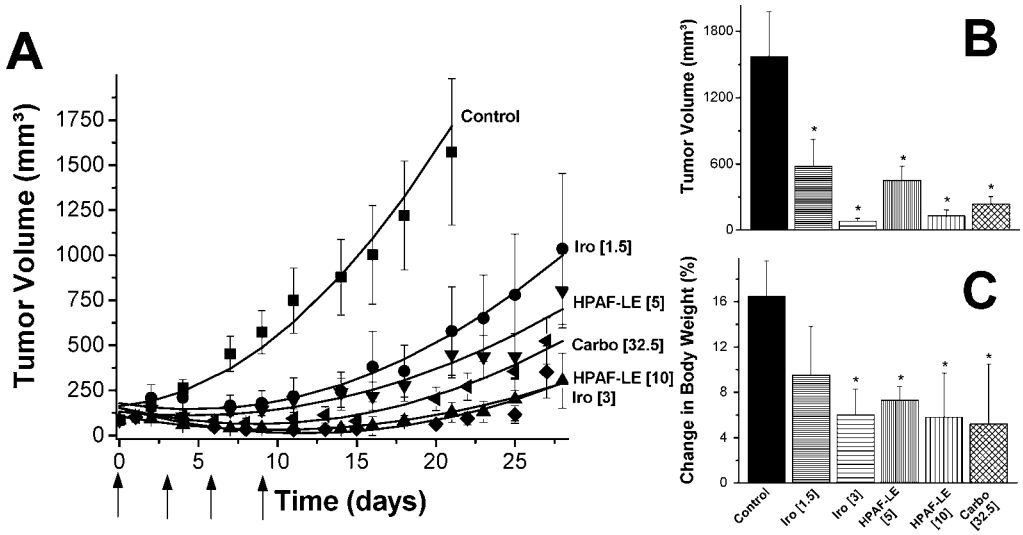

Figure 4. MA148 tumor growth inhibition by HPAF-LE, irofulven, and carboplatin. (A) Six groups of mice were studied (treatments were all administered IP q3d×4): two HPAFLE groups (5 mg/kg, $n = 7$, and 10 mg/kg, $n = 7$), two irofulven groups (1.5 mg/kg and 3 mg/kg, each $n = 8$), one carboplatin group (32.5 mg/kg, $n = 8$), and one control group (vehicle, $n = 7$), as indicated. Tumors were allowed to grow to the size of approximately 75 mm^3 prior to initiation of treatment. Tumor volumes are plotted as mm^3 (± SEM). (B) MA148 tumor growth inhibition by the individual treatments derived from the growth curves in panel A. Data represent means ± SEM on day 21 after the initiation of treatment. (C) The average gain in body weight (in %) for the experimental groups indicated. Data represent means ± SEM on day 21 after the initiation of treatment.

10 mg/kg, $p = 0.001$; HPAF-LE and conjugate 50 mg/kg, $p < 0.001$), as well as, e.g., between conjugate (50 mg/kg) and HPAF-LE treated groups ($p = 0.04$). Furthermore, at the end of the study on day 37 (absent control group due to sacrifice),

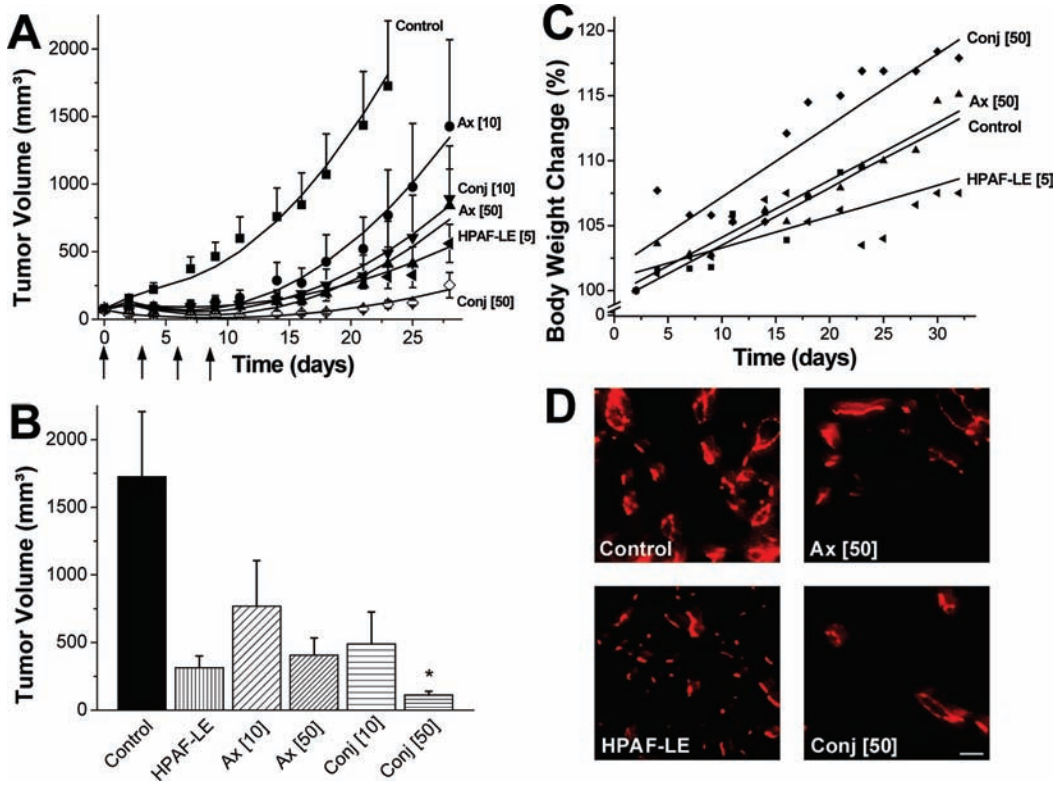

Figure 5. MA148 tumor growth inhibition by HPAF-LE-anginex conjugate. (A) Six groups of mice were studied (treatments were all administered IP q3d×4): two conjugate groups (10 mg/kg and 50 mg/kg), two anginex groups (10 mg/kg and 50 mg/kg), one HPAF-LE group (5 mg/kg), and one control group (vehicle), as indicated. Tumors were allowed to grow to the size of approximately 75 mm^3 prior to initiation of treatment (n = 10−12 animals per treatment). (B) MA148 tumor growth inhibition by the individual treatments derived from the growth curves in panel A. Data represent means ± SEM on day 23 after the initiation of treatment. *$p < 0.003$ for conjugate compared to other treatment groups. (C) The average change in body weight, normalized to individual weights at the start of treatment (in %) for the experimental groups indicated, are plotted over time with linear line fitting (no significant differences $p < 0.9$). (D) Representative images illustrate the average amount of vessel density staining on tumor tissue from control, anginex (50 mg/kg), HPAF (5 mg/kg), and conjugate (50 mg/kg) treated groups. Original magnification 200×; scale bar = 50 μm.

conjugate treated mice had an average tumor size of 600 mm^3, whereas the average tumor size of HPAF-LE treated mice reached this value on day 32, amounting to a tumor growth delay time of about 5 days in mice treated with conjugate compared to HPAF-LE.

This improvement in efficacy from the conjugate was also reflected in the level of individual tumor responses (Table 1). On day 11, analysis of individual mice showed that administration of conjugate at 50 mg/kg resulted in 20% complete remissions, 60% partial responders, and 20% stable diseases, whereas the HPAF-LE treated group (5 mg/kg) had 8% complete and partial responders and 17% stable diseases. At the lower dose of conjugate (10 mg/kg), 17% of the mice had either a complete or partial remission, or stable disease. In the anginex-treated groups, administration of 50 mg/kg caused 17% partial responders and 67% stable diseases, whereas at 10 mg/kg, there was 50% stable diseases. At the end of the study, more than 2 weeks after the last treatment, tumors relapsed in conjugate-

Table 1. Tumor Responses after Different Treatment Regimens[a]

[a] Following binarization of images (magnification 200×), microvessel density was estimated by scoring the total number of white pixels per field. Results show the mean white pixel count per image ± standard error. At least 3 different tumors per treatment group were analyzed with a total of 10 or more images. [b] Mean number of vessel end points ± standard error as determined after skeletonization of the images. [c] Mean number of vessel branch points/nodes per image in pixels ± standard error as determined after skeletonization of the images. [d] Mean total vessel length per image in pixels ± standard error as determined after skeletonization of the images. [e] $p < 0.001$. Experimental group compared to vehicle (Kruskal−Wallis Test). [f] $p < 0.01$. Conjugate group (50 mg/kg) compared to molar equivalent Anginex (50 mg/kg) Wilcoxon Rank-Sum Test. [g] $p < 0.03$. Conjugate group (50 mg/kg) compared to molar equivalent HPAF-LE group (5 mg/kg) Wilcoxon Rank-Sum Test.

treated animals. The control group showed no responders and no stable diseases.

Although we found that the effective concentration of conjugate in vitro is lower than its effective dose in vivo, we realize that such differences are not always readily explainable, since in vivo exposure is multifaceted and would require complete pharmacokinetic and dynamic studies. Nevertheless, a dose of 50 mg/kg is not that unusual for a protein/peptide-based therapeutic in mouse studies (*30*), and we did observe the absence of apparent toxicity from the conjugate or anginex at either dose (10 mg/kg or 50 mg/kg) in any of the mice. Apparent lack of toxicity is based on normal weight gain (Figure 5C) and normal behavior in mice during the study. Trend line fitting ($R^2 > 0.8$) revealed that the rate of weight gain in the HPAF-LE (5 mg/kg) treated animals was reduced 3-fold as compared to the conjugate (50 mg/kg) treated animals, i.e., 0.19% vs 0.58% weight gain per day (Figure 5C). This is consistent with dose limiting toxicities usually observed from agents of this class of alkylating chemotherapeutics (*20*).

To demonstrate changes in microvessel density, we used immunohistochemistry (CD31 staining) on cryosections of MA148 tumor tissue from treated and untreated mice (Table 2 and Figure 5D). Morphometric analysis of viable tissue showed that microvessel density in treated groups was reduced in comparison to that in control tumor tissue. General morphology of tumor tissue showed that mice treated with higher doses of anginex or conjugate had regional antivascular effects, resulting in necrotic centers and surviving rims. At either dose, effects from conjugate and anginex are comparable, whereas there is a significantly ($p < 0.03$) smaller effect from HPAF-LE at a molar equivalent dose. These data indicate that conjugation of HPAF-LE to anginex does not affect the ability of anginex to function as an antiangiogenic agent. On the other hand, MA148 tumor growth inhibition (Figure 5A) is significantly ($p = 0.01$) greater from treatment of mice with the conjugate (50 mg/kg) compared to that from anginex (50 mg/kg), and this enhancement should result from the presence of HPAF-LE on targeting peptide anginex.

Although the precise mechanism by which anginex-conjugated HPAF-LE functions in situ remains unknown, it may be that improved efficacy is attributable to increased in vivo exposure of the acylfulvene moiety at the target site, i.e., targeting and sequestering within the tumor, and/or greater serum half-life. Moreover, although it is indirect evidence, it appears that conjugation of HPAF-LE to anginex reduces the inherent toxicity from the acylfulvene moiety. Body weight gain was normal during the course of the treatment with the conjugate (5.5% weight gain compared to 5.6% weight gain for control animals, Figure 5C), whereas it was significantly ($p = 0.03$) lower (3.2%) in HPAF-LE treated mice. Taken together, this study suggests that HPAF-LE can be made more effective when conjugated to anginex as a tumor targeting agent.

Thiol-Modified Chitosan Sulfate Nanoparticles for Protection and Release of Basic Fibroblast Growth Factor

Yi-Cheng Ho,[‡] Shao-Jung Wu,[§] Fwu-Long Mi,*[,†,‡,⊥] Ya-Lin Chiu,[||] Shu-Huei Yu,[#] Nilendu Panda,[||] and Hsing-Wen Sung*[,†,||]

Department of Biotechnology, Nano Materials R&D Center, and Department of Polymer Materials, Vanung University, Chung-Li, Taiwan, ROC, Department of Chemical Engineering, MingChi University of Technology, Taipei, Taiwan, ROC, and Department of Chemical Engineering, National Tsing Hua University, Hsinchu, Taiwan, ROC. Received May 8, 2009; Revised Manuscript Received November 20, 2009

A series of chitosan (CS) derivatives, the 6-*O*-carboxymethylchitosan (6-O-CC), 2-*N* sulfated 6-*O*-carboxymethylchitosan (N-SOCC) and the 2-*N* and 3,6-*O* sulfated 6-*O*-carboxymethyl chitosan (N,O-SOCC) were synthesized in this study. The chemical structures and the degrees of substituted carboxymethyl and sulfate groups of the synthesized compounds were respectively determined by FT-IR spectra and elemental analysis. N,O-SOCC displayed the highest protective efficiency for basic fibroblast growth factor (bFGF) as examined by the L929 fibroblast culture test and docking simulation. N,O-SOCC-4-thio-butylamidine (TBA) conjugates prepared by modification of N,O-SOCC with 2-iminothiolane were in situ cross-linkable. The degrees of thiol substitution of the 2-iminothiolane modified N,O-SOCC polymers were determined to be in the ranges of 45.9 ± 3.7 and 415.6 ± 12.5 μmol SH/g SOCC by quantifying the amount of thiol groups on the thiolated polymers with Ellman's reagent. The 2-iminothiolane modified N,O-SOCC and CS complex could be used for preparing nanoparticles by a polyelectrolyte self-assembly method, and the release of bFGF from the nanoparticles was successfully controlled. L929 fibroblast culture tests showed that the thiol modified N,O-SOCC/CS nanoparticles could effectively protect bFGF from inactivation over a 120 h period. The results of this study suggest that the thiol modified N,O-SOCC/CS nanoparticles may be useful as novel materials for specific delivery of bFGF with mitogenic activity.

INTRODUCTION

Heparin and heparan sulfate (HS) are members of the glycosaminoglycan family possessing higher negative charge density than other known biological macromolecules. Heparin/HS is able to establish ionic interactions with a variety of proteins including enzymes, extracellular-matrix proteins, various cytokines, and members of the family of fibroblast growth factors (FGFs), epidermal growth factor (EGF), and the transforming growth factor (TGF) (*1, 2*). Such interactions especially control specified polysaccharide−protein interactions and possess biological potential in relation to cell growth, wound healing, and tissue regeneration, as well as thrombin inhibition (*3*).

Basic fibroblast growth factor (bFGF) is a heparin/HS-binding growth factor and has shown therapeutic potential to enhance angiogenesis, soft tissue formation, re-epithelialization, and collagen maturation, as well as to accelerate bone fracture healing (*4, 5*). Heparin/HS can stabilize an active conformation of bFGF and enhance interaction with specific cellular receptors (*6, 7*). On the basis of these reasons, many studies have reported the development of heparin-functionalized materials for the purpose of delivering bFGF to enhance tissue regeneration (*8*−*10*). Besides, preparations of conjugates of bFGF and polymer-based gene delivery vectors became potential targets for cancer gene therapy because fibroblast growth factor receptors (FGFRs) are highly expressed on a variety of human cancer cells (*11, 12*).

In recent years, significant advances in the modification of polysacchsarides with specific structures or synthesis of polymers with pendent saccharides offer one biomimetic strategy to obtain heparin-like materials. For example, acrylamide with alkene-derivatized mono- and disaccharides can be polymerized to yield glycopolymers with biologically active, sulfated *N*-acetyl-D-glucosamines on the side chains (*13*). Chemical modifications of biological macromolecules such as dextran, colominic acid, poly(γ-glutamic acid), and alginate with sulfate or sulfonate groups have been shown to bind various growth factors and protect them from inactivation (*14, 15*).

Chitosan (CS) and its derivatives have been used for the purpose of biomedical applications, such as gene delivery (*16*). A series of chitosan derivatives, the 6-*O*-carboxymethylchitosan (6-O-CC), 2-*N* sulfated 6-*O*-carboxymethylchitosan (N-SOCC) and the 2-*N* and 3,6-*O* sulfated 6-*O*-carboxymethylchitosan (N,O-SOCC) were synthesized in this work. The structures of 6-O-CC, N-SOCC, and N,O-SOCC were characterized by FT-IR spectra analysis. The studies of L929 cell proliferation and docking simulation were used to investigate the growth factor protective effects of these chitosan derivatives with carboxymethyl and sulfate groups substituted in different position. 2-Iminothiolane as a prethiomer was reacted with N,O-SOCC to prepare the thiol-modified N,O-SOCC polymers, and the degrees of thiolation were determined by a colorimetric assay using Ellman's reagent. The 2-iminothiolane modified N,O-SOCC polymers displayed in situ cross-linking properties due to the oxidation of substituted thiol groups. Basic fibroblast

growth factor (bFGF) were readily immobilized in the 2-iminothiolane modified N,O-SOCC/chitosan (CS) nanoparticles, and the immobilized bFGF could be released in a sustained manner with mitogenic activities. The novel materials prepared from the thiol-modified N,O-SOCC polymer may be useful to deliver bFGF for biomedical applications.

EXPERIMENTAL PROCEDURES

Materials. Monochloroacetic acid, isopropyl alcohol, and sodium carbonate were purchased from ACROS Chemical Co. (USA). Chitin powder was acquired from Tokyo Chemical Industry Co., Ltd. Oleum ($H_2SO_4 \cdot SO_3$), dithiothreitol (DTT), and trimethylamine sulfur trioxide were purchased from Sigma-Aldrich Chemical Co., Ltd. (USA). 2-Iminothiolane was from Aldrich Chemical Co. (Milwaukee, WI). CS (MW 60 kDa) with a degree of deacetylation of approximately 85% was acquired from Koyo Chemical Co. Ltd. (Japan). Recombinant human bFGF and enzyme-linked immunosorption assay (ELISA) kit were obtained from R&D Systems (Minneapolis, MN, USA).

Synthesis of 6-O-CChitin and 6-O-CC. 6-O-CChitin was prepared according to the method described in the previous literature with some modification (*17*). 8.16 g of chitin powder was suspended in 40 mL sodium hydroxide solution (0.4 g/mL) including 0.2% sodium dodecyl sulfate (SDS) at 4 °C, and the slurry was kept in a freezer at −20 °C overnight. The frozen alkali-chitin was suspended in 200 mL isopropyl alcohol at room temperature, and 11.34 g of monochloroacetic acid was added in portions with mechanical stirring until the reaction mixture was neutralized. The product was filtered and washed with ethanol. The residue was extracted with water, and the water extract was slowly added to acetone to precipitate the crude product. The crude product was extensively dialyzed against deionized water and finally freeze−dried to obtain 6-O-CChitin. 9.65 g of 6-O-CChitin was placed in 40 mL NaOH/isopropyl alcohol aqueous solution (0.4 g/mL) and refluxed for 3 h under purging with nitrogen. The gel-like product was dissolved in water and precipitated by slowly adding acetone to the aqueous solution. The precipitation was dissolved in water and lyophilized after thorough dialysis against deionized water to remove the salt. The final product was 6-O-carboxymethylchitosan (6-O-CC).

Synthesis of N-Sulfated 6-O-CC. 6-O-CC was N-sulfated according to the method developed by Holme and Perlin (*18*). 6-O-CC (0.23 g) was suspended in 60 mL of an aqueous solution of sodium carbonate (0.33 g), stirred at 65 °C, and trimethylamine sulfur trioxide complex (0.62 g) was added. The reaction was carried out for 20 h. The media became clear and homogeneous at the end of the reaction. At the determined reaction time, the mixture was cooled to room temperature, extensively dialyzed against deionized water, and finally freeze−dried to obtain N-sulfated 6-O-CC (N-SOCC).

Synthesis of N,O-Sulfated 6-O-CC. N-SOCC was further sulfated for the preparation of N,O-Sulfated 6-O-CC (N,O-SOCC), according to the method developed by Vikhoreva et al. (*19*). Sulfation of N-SOCC was conducted in a reaction vessel by adding of small portions of oleum to a dimethylformamide (DMF) excess (0.53 g oleum and 2.12 g DMF per 0.29 g N-SOCC). The mixture was stirred vigorously at 5 °C, and then N-SOCC was added to the mixture for sulfation reaction. By stirring for 2 h, the reaction mixture was cooled to 20 °C, and a solid fraction was separated by filtration through a glass filter. Crude N,O-SOCC was precipitated from solution in 5-fold acetone volume and washed with acetone twice, then dissolved in distilled water with simultaneous neutralization with a 20% NaOH solution. Sodium salts of N,O-SOCC were extensively dialyzed against deionized water, and finally freeze−dried to obtain purified N,O-SOCC. Degrees of carboxymethylation and sulfation of the chitosan derivatives were determined by elemental analysis. The schematic procedure for the synthesis of 6-O-CChitin, 6-OCC, N-SOCC, and N,O-SOCC were shown in Figure 1.

Characterization of the Synthesized Compounds. The synthesized 6-O-CChitin, 6-OCC, N-SOCC, and N,O-SOCC products were characterized by FT-IR (Perkin-Elmer Spectrum RX1 FT-IR System, Buckinghamshire, England). The substitutions of carboxymethyl groups and sulfated groups were determined by elemental analysis (Elementar vario EL □) of the content ratios of C, H, O, N, and S in the synthesized 6-O-CChitin, 6-OCC, N-SOCC, and N,O-SOCC polymers. Molecular weights of chitin and its derivatives were measured by gel permeation chromatography (GPC), which incorporated a TSK G3000-PW column and a RI 150 refractive index detector with 0.1 M aq NaCl eluent flowing at 1.0 mL/min at 30 °C (*20*).

Protection of Mitogenic Activity of bFGF Using 6-OCC, N-SOCC, and N,O-SOCC Polymers. The mitogenic activity of the bFGF protected by the synthesized polymers, under acidic condition, was assessed in vitro by determining its ability to stimulate the proliferation of L929 fibroblast cells cultured in serum-free Eagle's MEM medium, according to the method reported by Akashi et al. (*21*). The bFGF solution (5 μg/mL) was dissolved in phosphate buffered saline (PBS) containing the synthesized 6-OCC, N-SOCC, and N,O-SOCC polymers. The mixture was adjusted to pH 4.0 with HCl. After 30−120 min of incubation, the solutions were diluted with Eagle's MEM containing 10% FCS, and then these solutions added to chlorate-treated L929 fibroblasts which had been preincubated 24-well multiplates at 1×10^4 cells/well for 24 h at 37 °C. The final concentration of bFGF in the medium was 250 ng/mL, whereas the concentration of all synthesized polymers was 10 μg/mL. Cell viability is determined in percent by comparison to control cell cultures uisg a MTT cell viability assay kit (Biotium, Inc. USA). The bFGF protective activity was evaluated as relative cell proliferation respectively in polymer treated groups, at pH 4.0, as compared with the control group (in PBS, pH 7.4). Percent cell number = (cell number in treated bFGF and polymer treated groups)/(cell number in the control). The control (100%) consists of cells incubated with bFGF and polymers under normal conditions (37 °C, 5% CO2, pH =7.4).

Docking Simulation. Molecular modeling was performed with the program AutoDock using parameters adapted from the AMBER force field. The dimer units of 6-OCC, N-SOCC, and N,O-SOCC polymers and heparin were used for molecular docking in Sybyl mol2 format. A heparin-binding site of bFGF was obtained from X-ray crystallography as reported in the literature (*22*). The structural data of bFGF were obtained from the Protein Data Bank (entry code 1BFC). The flexible torsions of ligands were calculated with AutoTors, which docked a flexible ligand into a rigid receptor. To carry out docking simulations, a grid box was defined to enclose the heparin binding site with dimensions of $60 \times 60 \times 60$ Å^3 and a grid spacing of 0.375 Å. Docking was performed using the Lamarckian genetic algorithm (LGA) and Solis and Wets algorithm, where the number of GA is 10, the population size is 50, the maximum number of energy evaluations is 250 000, and the size of local search space to sample is 1.0 will perform at most 300 interactions. The simulation results were shown by figures displaying atomistic pictures of the molecules generated using the molecular graphic program UCSF Chimera.

Thiolation of N,O-SOCC. Thiolated N,O-SOCC was prepared by reacting 2-iminothiolane with amino groups bestows SH groups to N,O-SOCC (*23*). Initially, 500 mg of N,O-SOCC was dissolved in 50 mL of DI water and different amounts of 2-iminothiolane (200−600 mg) was added with 1 mL of 2% DTT. The pH value was adjusted, respectively, with 0.1 M

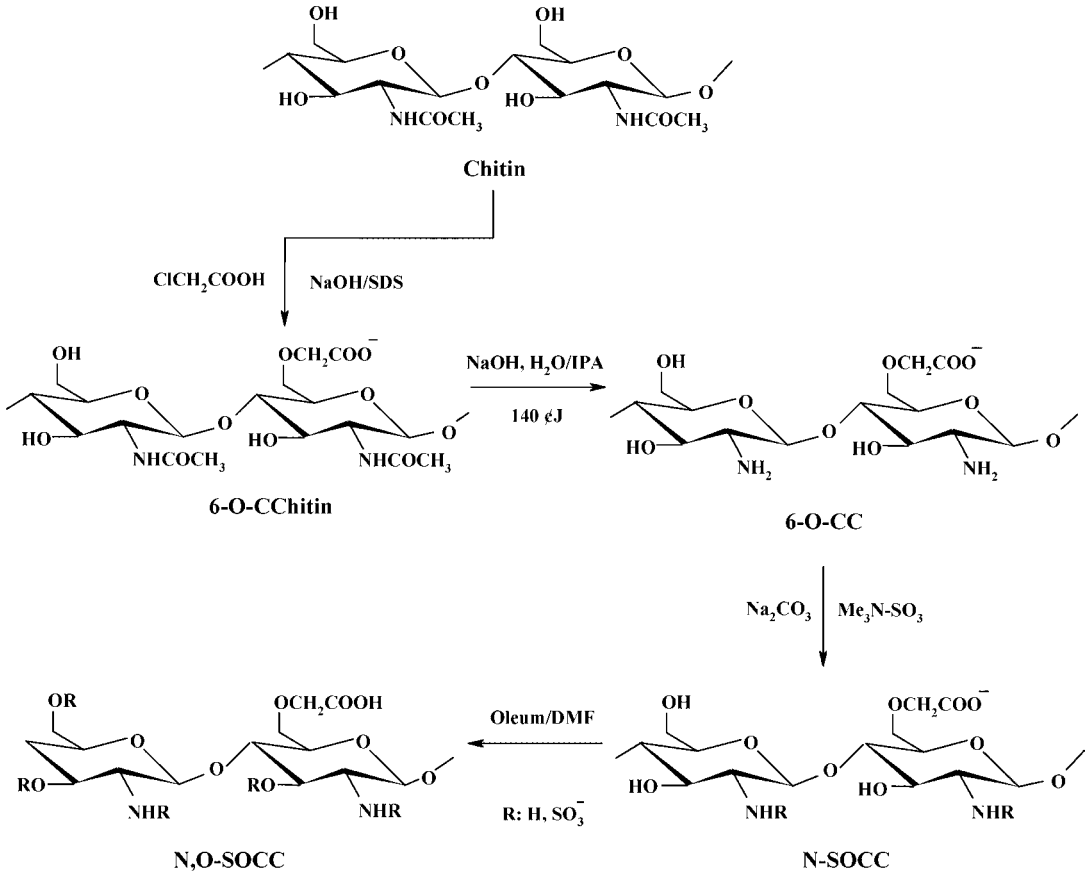

Figure 1. Schematic illustration of the procedures for synthesis of 6-O-CC, N-SOCC, and N,O-SOCC. SDS, sodium dodecyl sulfate; IPA, isopropanol; Oleum, fuming sulfuric acid; DMF, dimethylformamide.

NaOH and HCl to pH 5.0 or 7.0. The coupling reaction was allowed to proceed for 24 h at room temperature under continuous stirring. For purification, the resulting polymer conjugate was dialyzed against 5 mM HCl containing 1% NaCl, against 5 mM HCl and finally against 1 mM HCl to obtain a final pH of 3. Thereafter, the reaction mixtures were dialyzed to remove unreacted 2-iminothiolane at 10 °C and obtain the new kind of thiolated polymer, the 2-iminothiolane modified N,O-SOCC.

Determination of the Thiol Group Content. The degree of modification was determined by quantifying the thiolated N,O-SOCC polymers with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB, Ellman's reagent) (*24, 25*). DTNB working reagent was prepared by add 50 μL of the DTNB solution and 100 μL Tris solution into 840 μL deionized water. First, 5 mg of thiolated N,O-SOCC polymers was dissolved in 2.5 mL of deionized water. Afterward, 10 μL sample solution was mixed with 990 μL of DTNB reagent and incubated 5 min at 37 °C. The absorbance values of the samples were immediately measured at 415 nm using PowerWave X340 (Bio-TEK Instrument, Inc., Winooski, VT, USA) plate reader. The amount of thiol moieties was calculated from an standard curve obtained by the 2-iminothiolane modified N,O-SOCC solutions with increasing amount of cysteine.

Thiol Oxidation. The 2-iminothiolane modified N,O-SOCC was then dissolved in 100 mM acetate buffer pH 5.0, 100 mM phosphate buffer pH 6.0, or PBS (phosphate buffered saline) buffer pH 7.4, in a final concentration of 0.5% (w/v) at 4 °C. After dissolution, the samples were incubated at 37 °C under permanent shaking. At predetermined time points, aliquots of 500 μL were withdrawn and 50 μL of 1 M HCl was added in order to quench any further reaction. The amount of remaining thiol groups was determined with Ellman's reagent as described above.

Preparation of Polyelectrolyte Complex Nanoparticles. The 2-iminothiolane modified N,O-SOCC/CS nanoparticles were prepared using a polyelectrolyte complex method under magnetic stirring at room temperature. In brief, an aqueous 2-iminothiolane modified N,O-SOCC (1.0 mg/mL, 2 mL, pH 7.4) was added by flush mixing with a pipet tip into aqueous CS at various known concentrations (0.15, 0.30, 0.60, 0.90, or 1.20 mg/mL, 8 mL, pH 6.0). The polyelectrolyte complex nanoparticles were collected by centrifugation at 12 000 rpm for 20 min. Supernatants were discarded, and nanoparticles were resuspended in DI water for further studies. The mean particle sizes and zeta potential values of nanoparticles were measured using a Zetasizer (3000HS, Malvern Instruments Ltd., Worcestershire, UK).

bFGF Entrapment. For preparing the bFGF-loaded nanoparticles, 1 mL of bFGF stock solution (1 μg/mL) was added to the dissolved N,O-SOCC or 2-iminothiolane modified N,O-SOCC solutions (2.0 mg/mL, 1 mL) with continuous stirring at 4 °C. After dissolution of bFGF, the mixed N,O-SOCC or 2-iminothiolane modified N,O-SOCC solution was respectively added into an aqueous CS (1.2 mg/mL, 8 mL) as described before. Afterward, the bFGF-loaded nanoparticles were collected by centrifugation and the amounts of bFGF in the supernatants were analyzed to determine the free bFGF content. The bFGF loading efficiency was calculated by dividing the weight of the loaded bFGF (subtract free bFGF from total amount of bFGF) by the total amount of bFGF (*26*).

The amounts of bFGF were measured by enzyme-linked immunosorption assay (ELISA) kit (Human bFGF Duoset; R&D Systems, Minneapolis, MN, USA). ELISA plates (NUNC; Polylabo, Strasbourg, France) were coated with capture monoclonal antibodies and blocked with 1% BSA (w/v) for 1 h. After adding the appropriately diluted samples to the ELISA plates,

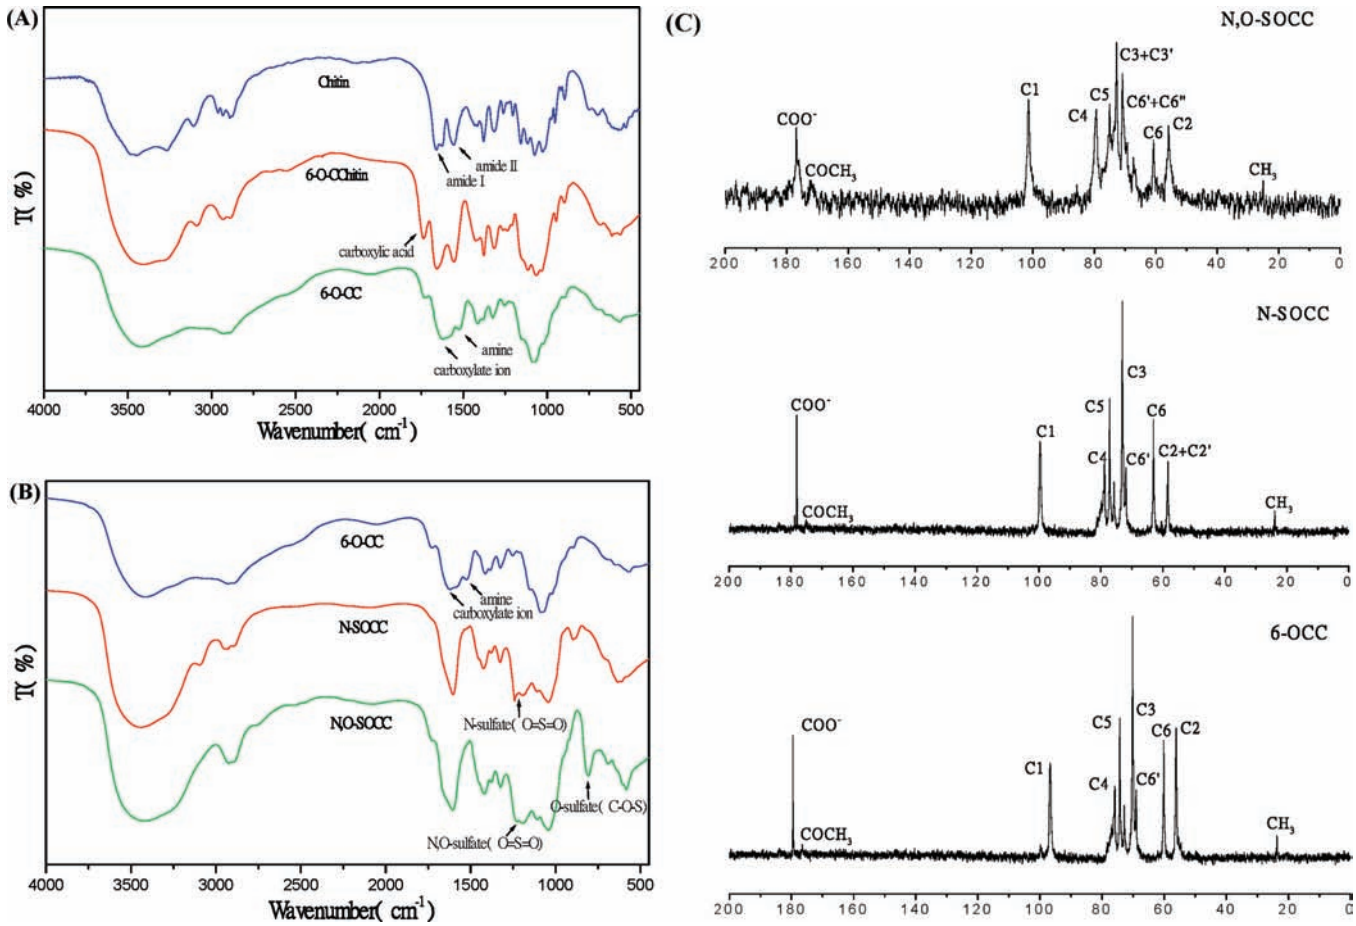

Figure 2. FT-IR spectra of (A) chitin, 6-O-CChitin, and 6-O-CC; (B) 6-O-CC, N-SOCC, and N,O-SOCC; and (C) ^{13}NMR spectra of 6-O-CC, N-SOCC, and N,O-SOCC.

released bFGF was detected using antihuman bFGF polyclonal antibodies. Then, streptavidin-conjugated horseradish peroxidase was added to the plates. The enzyme substrate (tetramethylbenzidine and peroxide) was added and incubated for color development for 20 min. The enzyme reaction was stopped by adding an acidic solution. The absorbance of the samples was read at 450 nm using PowerWave X340 (Bio-TEK Instrument, Inc., Winooski, VT, USA) plate reader. All of the experiments were repeated six times.

Long-Term Release of Protected bFGF for Cell Proliferation. The release profiles of bFGF from the 2-iminothiolane modified N,O-SOCC/CS nanoparticles were determined to study the effects of the in situ cross-linkable thiolated N,O-SOCC on long-term release of protected bFGF. The samples were incubated at 37 °C under continuous agitation, in 5 mL of PBS (pH 7.4) or PBS containing 5.0 mM glutathione (GSH) (*27*). At various time points, the release medium was collected and centrifuged at 12 000 rpm for 20 min, and the supernatant was withdrawn and fresh buffer was replenished. The amounts of bFGF in the supernatants were determined with the above-mentioned method of ELISA assay. All of the experiments were repeated four times.

Long-term protection of the mitogenic activity of the growth factor was assessed by proliferation of L929 fibroblasts cultured in serum-free Eagle's MEM medium with 250 ng/mL of bFGF either in solution or equivalent weight bFGF in nanoparticles. Cell cultured in serum-free Eagle's MEM medium without adding bFGF was used as a control. The cell proliferation was measured using a hemocytometer at different time points over a period of 5 days post-treatment.

Statistical Analysis. Statistical analysis for the determination of differences in the measured properties between groups was accomplished using one-way analysis of variance and determination of confidence intervals, performed with a computer statistical program (*Statistical Analysis System*, v 6.08, SAS Institute Inc., Cary, NC). All data are presented as a mean value with its standard deviation indicated (mean ± SD). Differences were considered to be statistically significant when the p values were less than 0.05.

RESULTS AND DISCUSSION

Synthesis and Characterization of 6-O-CC, N-SOCC, and N,O-SOCC. 6-O-CC was synthesized from its original compound—chitin. Figure 2A showed the FT-IR spectrum of chitin, 6-O-CChitin and 6-O-CC polymers. The characteristic absorption at 1580 cm^{-1} and 1620−1660 cm^{-1} was respectively assigned to the amide I (N—H) and amide II (C═O) stretch of chitin (*18*), while the characteristic absorption at 1710−1715 cm^{-1} was assigned to the carboxylic acid groups on 6-OCChitin. After deacetylation of 6-OCChitin in alkali solution, the carboxylic acid groups were converted into carboxylate ions (∼1650 cm^{-1}), which were partially overlapped with the amine groups (∼1560 cm^{-1}) on 6-O-CC.

Figure 2B showed the FT-IR spectrum of 6-O-CC, N-SOCC, and N,O-SOCC polymers. N-SOCC demonstrated a significant decrease of N—H absorption bands around 1560 cm^{-1} as compared with 6-O-CC. The characteristic absorption bands in the area of 1160−1260 cm^{-1} (O═S═O asymmetric stretch) indicated the presence of sulfamate groups (N-sulfation) (*18*). N-SOCC was further sulfated with oleum, leading to the final

Table 1. Substitution Degrees of 6-O-CChitin, 6-O-CC, N-SOCC, and N,O-SOCC

	DDA[a]	DC[b]	DS[c]	M_w[d]
Chitin	—	—	—	—
6-O-CChitin	—	0.46	—	1.54×10^5
6-O-CC	0.92	0.46	—	1.38×10^5
N-SOCC	0.92	0.46	0.51	8.75×10^4
N,O-SOCC	0.92	0.46	1.13	5.73×10^4

[a] DDA means the degree of deacetylation. [b] DC means the degree of carboxymethylation. [c] DS means the degree of sulfation. [d] M_w means the weight-average molecular weights determined by GPC.

product, N,O-sulfated 6-O-CC (N,O-SOCC) with nonselective sulfate groups at the 2-N, 3-O, and 6-O positions (*19*). The additional characteristic band of N,O-SOCC observed at 800 cm^{-1} representing the C—O—S stretch, suggesting the formation of sulfate ester linkage via the O-sulfation reactions with hydroxyl groups (*20*).

Figure 2C showed the ^{13}C NMR spectra of 6-O-CC, N-SOCC, and N,O-SOCC polymers of chitosan and carboxymethylchitosan. In the spectrum of 6-O-CC, the signals observed at 176.5 and at 23.6 ppm were assigned to the carbonyl carbon of $COCH_3$ and the methyl carbon (CH_3), respectively. The signal at 96.7 ppm was assigned to carbon C-1 of 6-O-CC, and those signals at 56.3, 70.1, 75.9, 74.3, and 60.2 ppm were assigned to carbons C-2, C-3, C-4, C-5, and C-6, respectively. The signal observed at 179.5 ppm is assigned to the carbonyl carbons of carboxymethyl groups (*28*). The spectrum of N-SOCC showed split signals at 58.1 ppm corresponding to N-sulfation, though it was not completely sulfated because the unsulfated signal of C-2 could still be observed (C2+C2′) (*18*). The ^{13}C NMR spectrum of N,O-SOCC indicated that in additional to the N-sulfation, the C-6 and C-3 hydroxyl groups were both partly sulfated (O-sulfation) because of the existence of sulfated and unsulfated signals (C6+C6′+C6″ and C3+C3′) (*19, 20*). The degrees of carboxymethylation and sulfation estimated from elemental analysis, and the molecular weights determined by GPC were shown in Table 1.

bFGF Protective Efficiency and Docuking Simulation. Figure 3A shows the effect of the substituted carboxymethyl and sulfate groups of the synthesized 6-O-CC, N-SOCC, and N,O-SOCC on the retention of bFGF activity. At pH 4.0, the L929 cells proliferated well in serum-free medium containing bFGF and N-SOCC or N,O-SOCC. Dextran sulfate and (1→6)-α-D-mannopyranan sulfate having sulfate groups have been reported to interact with FGFs and mimic heparin effects on the biological activities of FGFs (*29, 30*). Interestingly, N,O-SOCC showed higher bFGF-protective effect compared with its N-SOCC counterpart under the tested pH condition ($p < 0.05$), suggested that the interaction between the sulfated polymer and bFGF requires not only N-sulfate groups, but also the O-sulfate groups. In contrast, 6-O-CC without the sulfate groups could not significantly protect bFGF, and the bFGF-induced cell growth in serum-free Eagle's MEM medium was not observed.

It is noted that binding of bFGF and heparin is mediated by ionic interaction between both N- and O-sulfate groups of heparin molecules and certain lysine (R) and arginine (K) cations in bFGF (*31*). In the study of docking simulation, four docking ligand molecules, respectively, correlating with the dimer units of 6-O-CC, N-SOCC, N,O-SOCC, and heparin were designed (Figure 4A), and their docking energies were computed (Table 2). The N,O-SOCC ligand with the lowest docked energy structure showed sulfate-mediated interactions between bFGF and the ligand involving 2-*N*-sulfate, 3-*O*-sulfate, and 6-*O*-sulfate groups of the ligand and R121, K126, and K136 residues of bFGF (Figure 4B). The interactions between K120, K126 residues and the N,O-SOCC ligand are also mediated via 6-*O*-carboxymethyl groups (Figure 4B). The sulfate groups appeared to predominantly bind to basic amino acid residues, while the carboxymethyl groups complement sulfate groups to contribute in stabilizing the binding structure (*14*). N,O-SOCC substituted with 6-*O*-carboxymethyl groups and 2-N, 3-O, and 6-O sulfate groups may have well-balanced steric and electrostatic structures that can stably interact with bFGF to protect the growth factor against acidic inactivation.

The results of docking simulation and cell proliferation reveal that N,O-SOCC shows the lowest computed docking energy and is the most effective ligand in the retention of bFGF activity (Table 2). Although the N,O-SOCC ligand might have higher affinity to bFGF than heparin, N,O-SOCC is still less effective in the retention of bFGF activity for cell proliferation, as

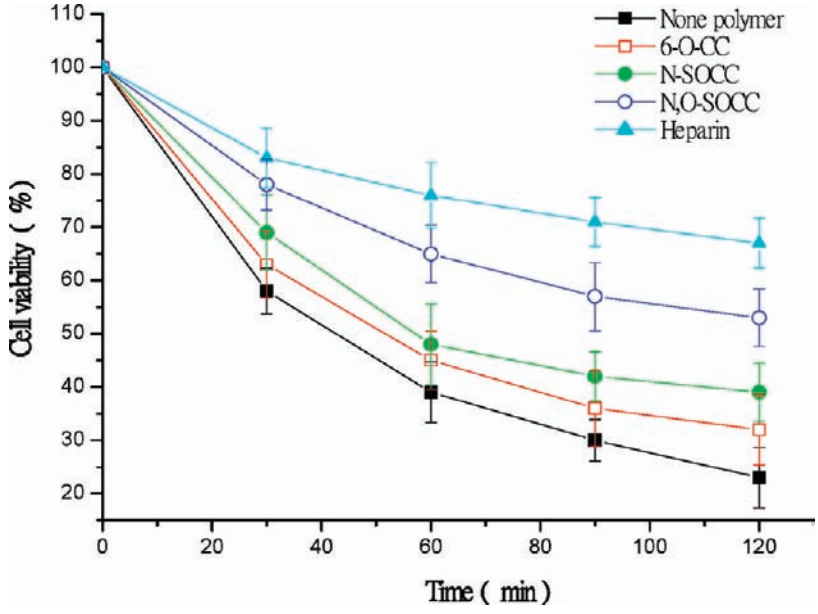

Figure 3. Comparison of the bFGF-protective effect of 6-O-CC, N-SOCC, N,O-SOCC, and heparin polymers under acidic condition (bFGF in pH 4.0 medium, 30−120 min of incubation). Chlorate-treated L929 fibroblasts proliferated in serum-free culture medium with bFGF (250 ng/mL) and polymers (10 μg/mL) for 96 h.

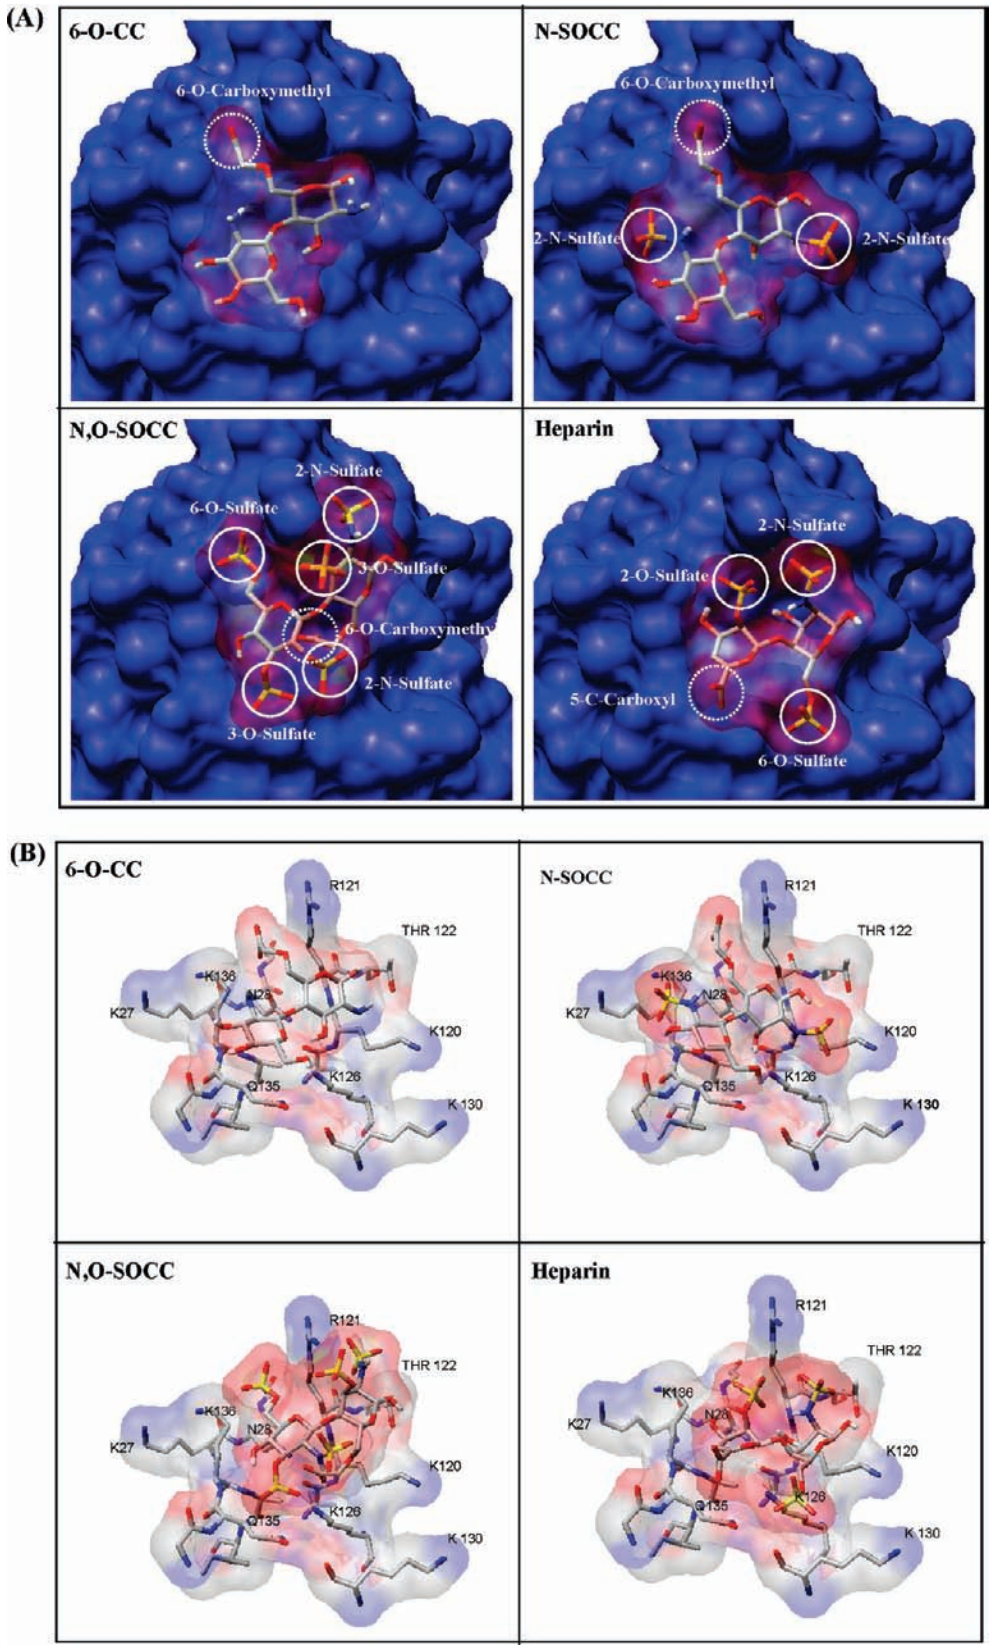

Figure 4. Molecular modeling of docking simulation. (A) Docking conformations of 6-O-CC, N-SOCC, N,O-SOCC, and heparin docking ligands after binding to the heparin-binding site of bFGF. (B) Interaction of 6-O-CC, N-SOCC, N,O-SOCC, and heparin with the amino acids residues at the heparin-binding site of bFGF.

compared with its heparin counterpart (Figure 4A). This will be attributed to heparin not only demonstrating high affinity to FGF family growth factors but also binding to its receptor that facilitates FGF-receptor dimerization and activation (*32*).

Synthesis and Characterization of Thiolated N,O-SOCC. In situ gelling systems based on chitosan derivatives have been developed for glucose-sensitive, pulsatile delivery of insulin (*33*). Thiol-functionalized polymeric micelles or nanoparticles

Table 2. Docked Energy of 6-O-CC, N-SOCC, N,O-SOCC, Thiolated N,O-SOCC, and Heparin

	F[a]	INTM[b]	INTN[c]	Dk[d]

[a] F means the free energy (kcal/mol). [b] INTM means the intermolecular energy (kcal/mol). [c] INTN means the internal energy (kcal/mol). [d] DK means the docked energy (kcal/mol). [e] Thiolated N,O-SOCC means the 2-iminothiolane modified N,O-SOCC.

have also been investigated for molecular recognition, tumor immunotargeting, or intracellular DNA delivery in response to glutathione (*28, 34, 35*). In this work, N,O-SOCC was selected for thiolation because the correlated ligand has the lowest docking energy. The thiolated N,O-SOCC polymer prepared by modification of N,O-SOCC with 2-iminothiolane was in situ cross-linkable. Apart from a sulfhydryl group, a cationic moiety is also introduced in the form of an amidine substructure resulting in a N,O-SOCC-4-thio-butylamidine (TBA) conjugate (*23*). The schematic procedure for the synthesis of 2-iminothiolane modified N-SOCC and the formation of its disulfide compound is shown in Figure 5. The modification of N,O-SOCC with 2-iminothiolane can be performed under inert condition to avoid the oxidation of thiol groups. The low reactivity of 2-iminothiolane in acid has also been reported (*23*). Therefore, we synthesized the thiolated N,O-SOCC in acidic (pH 5) and neutral (pH 7) conditions, and the reactants were purged with nitrogen. The amount of covalently attached thiol groups on the thiolated polymers was shown in Table 3.

The docking ligand molecule correlates with the 2-iminothiolane modified N,O-SOCC displayed a higher docking energy as compared with its original N,O-SOCC counterpart, revealing a lower thiolated N,O-SOCC affinity of bFGF (Table 2). The steric hindrance of the conjugated thiomer (TBA) resulted in the shift of 2-N, 3-O, and 6-O sulfate groups to the region far from the heparin-binding residues, such as R121, K126, and

Table 3. Substituted Thiol Moieties on the 2-Iminothiolane Modified N,O-SOCC Polymers

polymer N,O-SOCC	2-iminothiolane (g)	pH	conjugated thiol groups (μmol/g polymer)
500 mg	200 mg	5.0	45.2 ± 3.7
500 mg	400 mg	5.0	67.5 ± 7.9
500 mg	600 mg	5.0	298.4 ± 9.8
500 mg	200 mg	7.0	97.3 ± 7.1
500 mg	400 mg	7.0	258.4 ± 8.6
500 mg	600 mg	7.0	415.6 ± 12.5

K136 (Figure 6A). This simulated result suggested that bFGF protective efficiency of the thiolated N,O-SOCC might be decreased with the increase of the substituted thiomer degree. Therefore, we selected a 2-iminothiolane modified N-SOCC product with mediate thiol substitution [258.4 ± 8.6 (μmol/g polymer)] for the following studies.

Thiol Oxidation of 2-Iminothiolane Modified N,O-SOCC. At pH 7.4, in the presence of oxygen, the thiol groups on the 2-iminothiolane modified N,O-SOCC can be easily oxided to disulfide bonds (Figure 6B), forming an in situ cross-linked network structure. Depending on the pH value, the thiol groups of 2-iminothiolane modified N,O-SOCC were oxidized, thereby forming inter- as well as intramolecular disulfide bonds. At pH 5.0, the thiol groups of 2-iminothiolane modified N,O-SOCC remained stable toward oxidation, whereas at pH 6.0, a decrease of 56% in the thiol moieties was observed, within 6 h of oxidation in air. Raising the pH value from 6.0 to 7.4 led to a higher concentration of negative thiolate anions, representing the reactive form for oxidation, finally resulting in a significant decrease of thiol moieties due to the formation of disulfide bonds (*23, 25*). These results revealed that thiolated N,O-SOCC could be used as an in situ cross-linkable polymer to entrap peptide or protein drugs for specific drug delivery purpose.

Characterization of 2-Iminothiolane Modified N,O-SOCC/CS Nanoparticles. 2-Iminothiolane modified N,O-SOCC and CS complex could be used for preparing nanoparticles by a polyelectrolyte self-assembly method. The particle sizes and the zeta potential values of the thiol-modified N,O-SOCC/CS

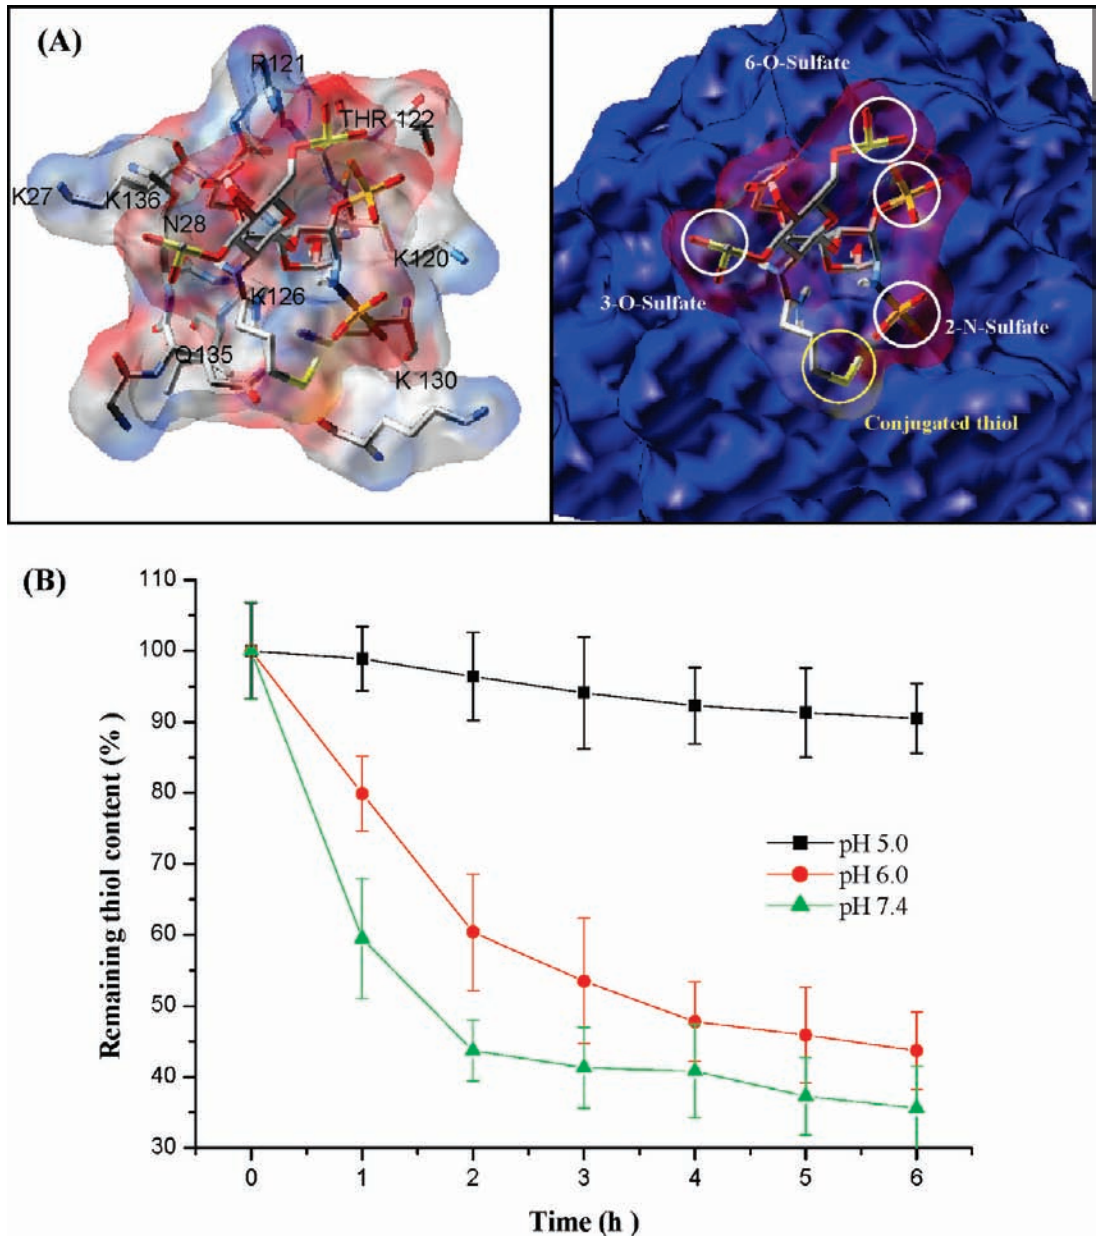

Figure 6. (A) Docking conformation of the 2-iminothiolane modified N,O-SOCC ligand after binding to the heparin binding site of bFGF and the interaction of the 2-iminothiolane modified N,O-SOCC with the amino acid residues of bFGF. (B) Decrease in thiol groups of 1.0% (w/v) 2-iminothiolane modified N,O-SOCC at pH values 5.0, 6.0, and 7.4. The thiol content of the 2-iminothiolane modified N,O-SOCC was 258.4 ± 8.6 μmol/g polymer.

nanoparticles, prepared at varying concentrations of the thiolated N,O-SOCC and CS, were determined, and the results are shown in Table 4. It was found that the particle size values of the prepared nanoparticles were mainly determined by the relative amount of the local concentration of the 2-iminothiolane modified N,O-SOCC in the added solution to the surrounding concentration of CS in the sink solution. At a fixed concentration of CS, an increase in the CS concentration allowed the thiolated N,O-SOCC molecules interacting with more CS molecules and thus formed a larger-sized nanoparticle. The formed nanoparticles had CS exposed on the surfaces and thus had a positively charged zeta potential.

In contrast, as the amount of local 2-iminothiolane modified N,O-SOCC molecules sufficiently exceeded that of surrounding CS molecules, the formed nanoparticles had the thiolated N,O-SOCC exposed on the surfaces and thus had a high negative charge of zeta potential. Therefore, the particle size and the zeta potential value of the prepared thiolated N,O-SOCC/CS nanoparticles can be controlled by their constituted compositions. The nanoparticles shelled with 2-iminothiolane modified N,O-SOCC were unstable, while those shelled with CS remained

Table 4. Effects of Various Weight Ratios (or charge ratios) of Chitosan to 2-Iminothiolane Modified N,O-SOCC on Mean Particle Size and Zeta Potential of Nanoparticles

2-iminothiolane N,O-SOCC/CS (w/w)	2-iminothiolane N,O-SOCC/CS charge ratio	mean particle size (nm)	zeta potential (mV)
1/0.6	1.00/0.48	218.4 ± 8.6	−21.8
1/1.2	1.00/0.95	[c]	[c]
1/2.4	1.00/1.90	242.6 ± 6.9	20.3
1/3.6	1.00/2.86	262.8 ± 3.4	28.1

[a] Prepared in deionized water (pH 6.0, $n = 5$). [b] Ratio of positively charged $-NH_3^+$ groups on CS to negatively charged $-COO^-$ and $-SO_3^-$ groups on 2-iminothiolane modified N,O-SOCC. [c] Precipitation of aggregates was observed after 1 h.

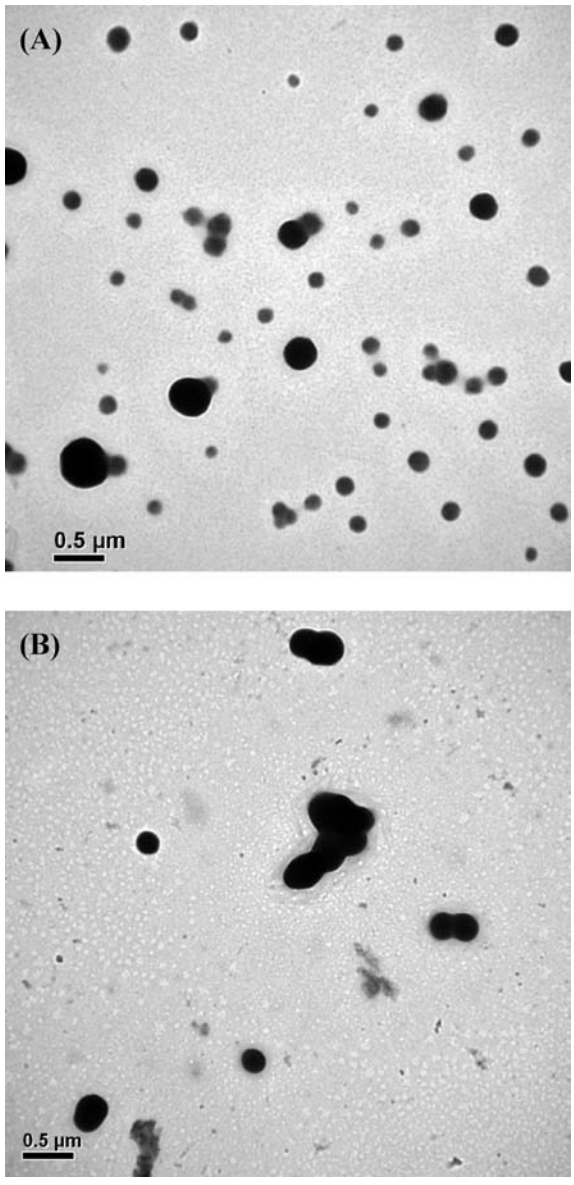

Figure 7. TEM micrographies of the 2-iminothiolane modified N,O-SOCC/CS nanoparticles shelled with (A) CS (1.0 mg/mL thiolated N,O-SOCC: 1.2 mg/mL CS) and (B) 2-iminothiolane modified N,O-SOCC (1.0 mg/mL thiolated N,O-SOCC: 0.30 mg/mL CS).

intact in PBS buffer. Even a minute amount of free thiolated N,O-SOCC in the medium could react with the thiol groups shelled on nanoparticles to form disulfides and finally resulted in the aggregation of nanoparticles. The results obtained by the TEM examination showed that the morphology of the prepared nanoparticles shelled with CS (1.0 mg/mL thiolated N,O-SOCC: 1.2 mg/mL CS) was spherical in shape with a smooth surface, while the nanoparticles shelled with 2-iminothiolane modified N,O-SOCC (1.0 mg/mL thiolated N,O-SOCC: 0.30 mg/mL CS) were aggregated due to the oxidation of surface thiol groups to disulfide bonds between the nanoparticles (Figure 7). Therefore, the CS shelled nanoparticles (1.0 mg/mL thiolated N,O-SOCC: 1.2 mg/mL CS) was selected for the following studies of bFGF entrapment and release.

In body fluids and extracellular matrixes, a relatively low concentration of GSH (approximately 2−20 μM) could be found. In contrast, inside cells the concentration of GSH is 0.5−10 mM. The variation of particle size in simulated physiological condition (pH 7.4 with 10 mM glutathione) was determined to study the stability of nanoparticles. As shown in Table 5, the mean particle size of GSH-treated nanoparticles gradually increased, reaching about 480 nm within 120 h. However, without GSH treatment, the nanoparticles in PBS solution showed negligible size variation within the same period of time. This result suggested that the cleavage of disulfide linkage in the presence of GSH led to swelling of the nanoparticles.

Table 5. Variation of Mean Particle Size of Thiolated N,O-SOCC/CS Nanoparticles in GSH-Containing PBS Solution

time (h)	pH 6.0 (in DI water)	pH 7.4 (in PBS)	pH 7.4 (in PBS/GSH medium)
0	289.9 ± 4.5	289.9 ± 4.5	289.9 ± 4.5
24	293.7 ± 7.8	307.4 ± 7.3	425.4 ± 7.3
48	298.2 ± 5.9	309.5 ± 5.8	447.8 ± 8.6
72	301.6 ± 6.7	307.6 ± 7.1	462.1 ± 6.8
96	299.1 ± 8.5	308.4 ± 6.5	471.5 ± 7.9
120	298.9 ± 6.9	309.1 ± 7.7	480.6 ± 8.4[a]

[a] The concentration of GSH is 10 mM.

bFGF Entrapment and Release. Chitosan and its derivative-based nanoparticles have been previously investigated for delivery of bioactive reagents, including proteins and genes (*36*−*38*). In this study, the thiolated N,O-SOCC, as an in situ cross-linkable polymer, has the advantage of entrapping bFGF without leading to the decrease in bioactivity of the peptide drug. The encapsulation of bFGF does not seem to significantly change the size and zeta potential of the nanoparticles. We have found that nanoparticles prepared only by CS and N,O-SOCC (the N,O-SOCC/CS nanoparticles), without modification with thiol groups, were very unstable and disintegrated rapidly in PBS buffer due to the balance of electrostatic charges by phosphate salts. Owing to the formation of covalently disulfide bonds, the 2-iminothiolane modified N,O-SOCC/CS nanoparticles with a positive surface charge (1.0 mg/mL thiolated N,O-SOCC: 1.2 mg/mL CS) could be used for bFGF entrapment and were kept stable in PBS buffer. The bFGF loading efficiency for N,O-SOCC/CS and 2-iminothiolane modified N,O-SOCC/CS nanoparticles were 61.4% ± 5.8% and 54.9% ± 3.6%, respectively.

Figure 8A shows the release profile of bFGF from the nanoparticles of N,O-SOCC/CS and 2-iminothiolane modified N,O-SOCC/CS nanoparticles in PBS buffer and the buffer containing glutathione. The N,O-SOCC/CS nanoparticles were unstable in PBS and could disintegrate rapidly to release the growth factor quickly. In contrast, the 2-iminothiolane modified N,O-SOCC introduced the disulfide bonds could assembled with CS into stable nanoparticles, coinciding with a slower release rate. The thiolated N,O-SOCC/CS nanoparticles shelled with CS suggested that bFGF-binding N,O-SOCC could be incoporated in the core of nanoparticles. Glutathione can reduce the covalent disulfide bonds to thiols leading to a quicker release of the growth factor from the nanoparticles.

Cell Proliferation. The mitogenic activity of bFGF released from the 2-iminothiolane modified N,O-SOCC/CS nanoparticles after 5 days of incubation was evaluated by L929 cell culture in serum-free Eagle's MEM medium (Figure 8B). The cell number of L929 fibroblasts does not seem to increase in the serum-free basal medium (control), indicating no additional cell growth in the medium without bFGF. The addition of bFGF in a free form to the basal medium stimulated the growth of L929 fibroblasts at day 2, and the growth increase of cells is significant as compared with that of the control group. The cells in the medium added with the bFGF-loaded, N,O-SOCC/CS nanoparticles showed increased cell proliferation comparable to the group of cells cultured with a free-form bFGF, because the nanoparticles disintegrate rapidly to release the growth factor quickly. Conversely, cells treated with bFGF-loaded, thiol modified N,O-SOCC/CS nanoparticles demonstrated a sustained significant increase in the cell proliferation activity ($p < 0.05$).

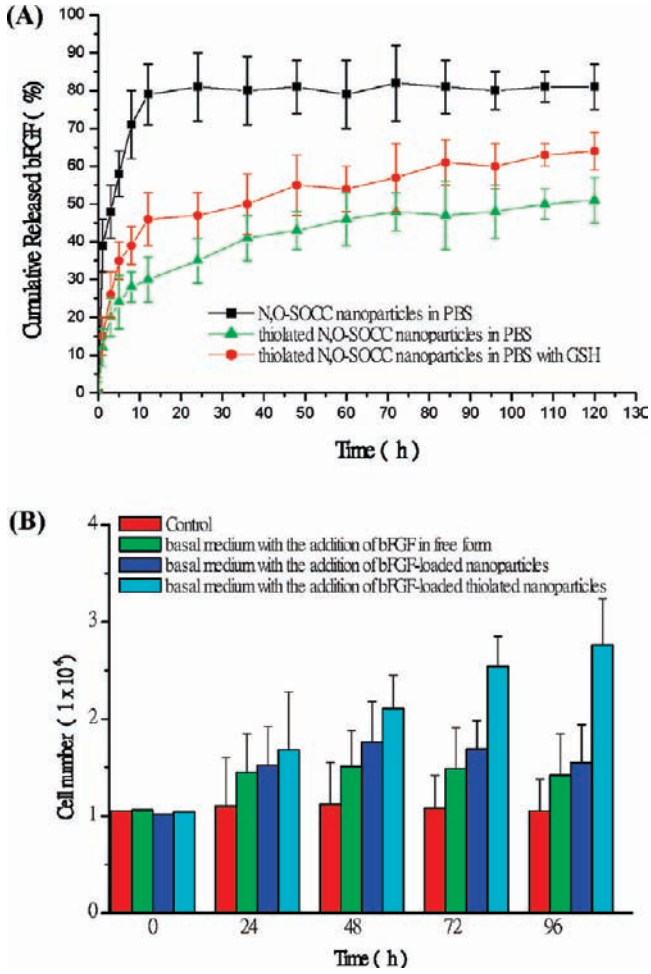

Figure 8. (A) Release profiles of bFGF from N,O-SOCC/CS and 2-iminothiolane modified (thiolated) N,O-SOCC/CS nanoparticles at 37 °C in 10 mL of PBS (pH 7.4) or PBS containing 5.0 mM glutathione (GSH). The thiol content of the 2-iminothiolane modified N,O-SOCC was 258.4 ± 8.6 μmol/g polymer. (B) The growth kinetics of L929 fibroblasts cultured in serum-free culture medium (basal medium), basal medium with the addition of bFGF in free form, and the N,O-SOCC/CS and 2-iminothiolane modified (thiolated) N,O-SOCC/CS nanoparticles loaded with bFGF.

This result indicates that only the thiol modified N,O-SOCC/CS nanoparticle is able to protect bFGF from inactivation over the long term.

Due to the protective effect of the nanoparticles, mitogenic activity of bFGF could be retained for a long time, without evident denaturation. The released growth factor could effectively bind to the cellular bFGF receptor for cell growth. It was encouraging to find that the nanoparticles could be easily mixed with several biological components such as alginate, chitosan, collagen, gelatin, and hyaluronic acid to be reshaped into nanoparticle-containing hydrogels or 3-D scaffolds. As reported in the literature, the therapy of ischemic disease and "in advance angiogenesis" for cell transplantation are two important objectives of angiogenesis in tissue engineering. In tissue repairing applications, therapeutic strategies of injecting bFGF-containing nanoparticles to stimulate arteriogenesis in animal models suffering from occlusive vascular disease received significant benefit from improved targeting, less invasiveness, better growth-factor stability, and more sustained growth-factor release (*39*).

Other studies reported that prolonged retention of activity of the growth factors and controlled release of the signal proteins at the site of action with reduced burst effect became possible by encapsulating the factors in micro- or nanoparticles before being incorporated with hydrogels or 3-D scaffolds (*40*). The results of this study suggest that the thiol modified N,O-SOCC/CS nanoparticles may be useful as novel materials for tissue engineering and might yield interesting future work.

CONCLUSIONS

In conclusion, we have synthesized a heparin-like chitosan derivative, N,O-sulfated, 6-O-carboxymethylchitosan (N,O-SOCC). N,O-SOCC demonstrated high affinity to bFGF and could protect mitogenic activity of bFGF as investigated by cell proliferation and docking simulation. Thiol modified N,O-SOCC was assembled with CS to form thiolated N,O-SOCC/CS nanoparticles. The thiolated N,O-SOCC/CS nanoparticles enhance the bFGF-stimulated cell growth through protecting the released growth factor from inactivation. It may be useful as a new biomaterial for the controlled release of bFGF for tissue-engineering applications.

Idera Pharmaceuticals, Inc., 167 Sidney Street, Cambridge, Massachusetts 02139. Received June 4, 2009; Revised Manuscript Received November 30, 2009

Bacterial and synthetic DNA containing unmethylated CpG motifs act as ligands of Toll-like receptor 9 (TLR9). Our earlier studies showed that 5′-accessibility of synthetic oligodeoxynucleotides containing CpG motif (ODN) is required for TLR9-mediated immune stimulatory activity. Blocking the 5′-end of ODN through conjugation to a variety of moieties reduces immune stimulatory activity (*Bioconjugate Chem.* **2002**, *13*, 966−974). In the present study, we conjugated a model peptide, a 28-amino-acid-long β-amyloid peptide, to either the 5′- or the 3′-end of an ODN via C3 and C6 alkyl linkers. We compared the immune stimulatory activity of the resulting conjugates with that of a parent ODN without conjugation in TLR9-transfected cells, mouse spleen cell cultures, and in vivo in mice. ODN with the peptide conjugated at the 3′-end via C3 and C6 linkers had immune stimulatory activity similar to that of the parent ODN in both in vitro and in vivo in mice. On the contrary, conjugation of peptide at the 5′-end of the ODN significantly abrogated immune stimulatory activity. In conclusion, the results presented here demonstrate that peptide/protein conjugation to ODN is optimal at the 3′-end with either C3 or C6 linker and conjugation at the 5′-end leads to significant loss of TLR9-mediated immune stimulation.

INTRODUCTION

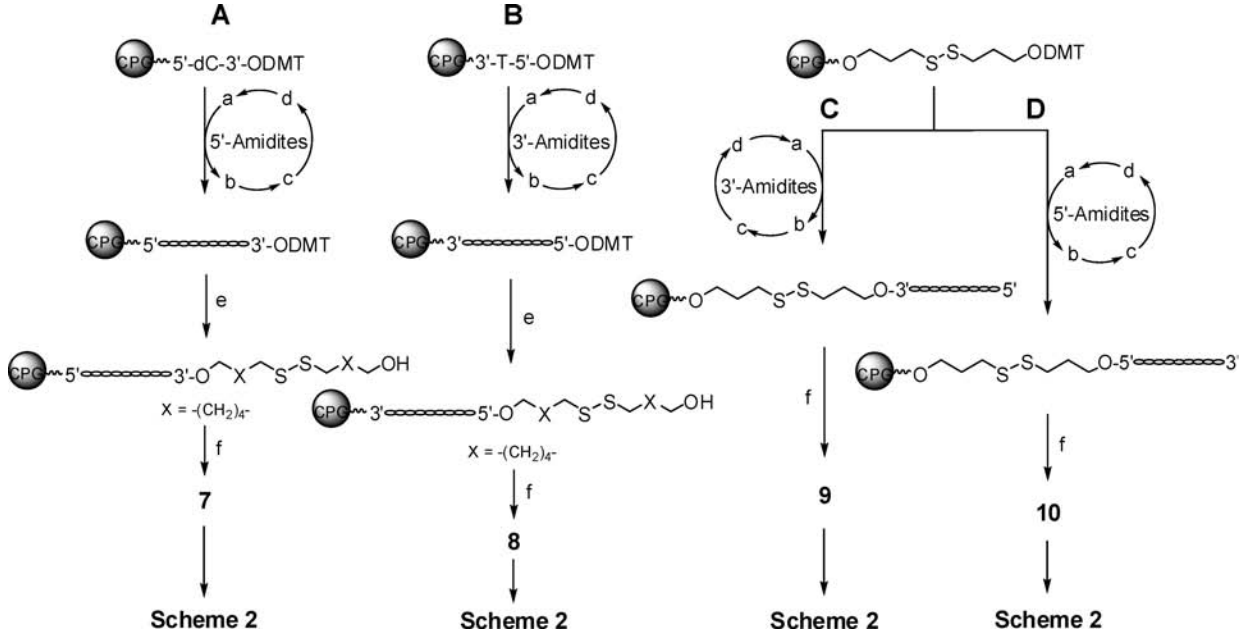
Toll-like receptor 9 (TLR9) belongs to a family of conserved pathogen-associated molecular pattern recognition receptors and is predominantly expressed in the endosomal membranes of human B cells and plasmacytoid dendritic cells (pDCs). Synthetic oligodeoxynucleotides containing unmethylated CpG motifs (ODNs) act as ligands of TLR9 (*1*). Stimulation of TLR9 with ODN leads to the activation of MyD88-dependent NF-κB and MAPK pathways, resulting in Th1-type immune responses (*2, 3*). Agonists of TLR9 are currently at various stages of clinical evaluation for the treatment of cancers, allergies, and infectious diseases and as adjuvants with vaccines (*1–4*).

Agonists of TLR9 (ODNs) induce potent Th1-type immune responses and show encouraging results as adjuvants when coadministered with DNA/protein/peptide vaccines (*5–12*). In addition to coadministration of ODN with vaccines/antigens (proteins), studies have been carried out to deliver both protein and ODN to the same antigen-presenting cell (APC) either by coformulation of both agents in liposomes or by conjugating proteins to ODN to increase immune responses (*13*). Some of the peptides/proteins conjugated to ODNs include Amb a 1, OVA, β-galactosidase, and HIV gp120 (*14–17*). Proteins and peptides are commonly conjugated to the 5′-end of ODN, because the chemical modifications required for conjugation reactions at the 5′-end are easily accomplished during the solid-phase synthesis (*18*). Recently, a conjugate of Amb a 1-ODN failed to meet the end points in a clinical study, prompting us to perform the present study to further elucidate the impact of 5′-conjugation of peptide to ODN on immune stimulatory activity.

Our extensive structure−activity relationship studies of ODNs have identified critical structural features in the pentose sugar (*19–22*), phosphate backbone (*23*), nucleobases (*24, 25*), and nucleosides (*26*) required for TLR9 stimulation. Our previous studies showed that the 5′-end of an ODN must be accessible for TLR9-mediated immune stimulatory activity. Modifications such as conjugation of di-, tetra-, or longer oligonucleotide, a fluorescein molecule or hairpin structures at the 5′-end block 5′-accessibility, resulting in significant abrogation of TLR9-mediated immune stimulatory activity (*27, 28*).

In the present study, we synthesized 5′- and 3′-conjugates of ODN and a model 28-mer β-amyloid peptide using C3 and C6 linkers and compared their immune stimulatory activity with that of the parent ODN in TLR9 transfected HEK293 and J774 cell lines, mouse spleen cell cultures, and in vivo in mice.

EXPERIMENTAL PROCEDURES



Reagents. Bromoacetyl-β-amyloid peptide (BrAc-DAEFRHDSGYEVHHQKLVFFAEDVGSNK-OH) was purchased from AnaSpec (San Jose, CA). Disulfide functionalized ODNs 5′-CTATCTGACGTTCTCTGT-3′-$(CH_2)_6$S-S$(CH_2)_6$OH (**7**), HO-$(CH_2)_6$S-S$(CH_2)_6$-5′-CTATCTGACGTTCTCTGT-3′ (**8**), 5′-CTATCTGACGTTCTCTGT-3′-$(CH_2)_3$S-S$(CH_2)_3$OH (**9**), and HO$(CH_2)_3$S-S$(CH_2)_3$-5′-CTATCTGACGTTCTCTGT-3′ (**10**) and unmodified ODNs **1** and **6** were synthesized as described below. DTT was obtained from Sigma-Aldrich (St. Louis, MO). Illustra NAP-25 columns were purchased from GE Healthcare (Piscataway, NJ). Thiol-modifier C6 S-S phosphoramidite and C3 S-S controlled-pore glass solid support were obtained from ChemGenes (Wilmington, MA) and Glen Research (Sterling, VA), respectively. Regular 5′-O−DMT-3′-phosphoramidites and reverse 3′-O-DMT-5′-phosphoramidites of dA, dC, dG, and T were obtained from Applied Biosystems (Foster City, CA) and ChemGenes (Wilmington, MA), respectively.

Synthesis and Purification of Disulfide-Functionalized ODNs. Both 3′- and 5′-disulfide functionalized ODNs **7**−**10** (Scheme 1) as well as unmodified ODNs **1** and **6** (Table 1) with phosphorothioate (PS) backbone were synthesized on a MerMade 6 DNA synthesizer (Bioautomation, Inc., Plano, TX) using β-cyanoethylphosphoramidite chemistry. Synthesis was carried out on a 10-μmol scale as DMT-off in either 3′ → 5′ or

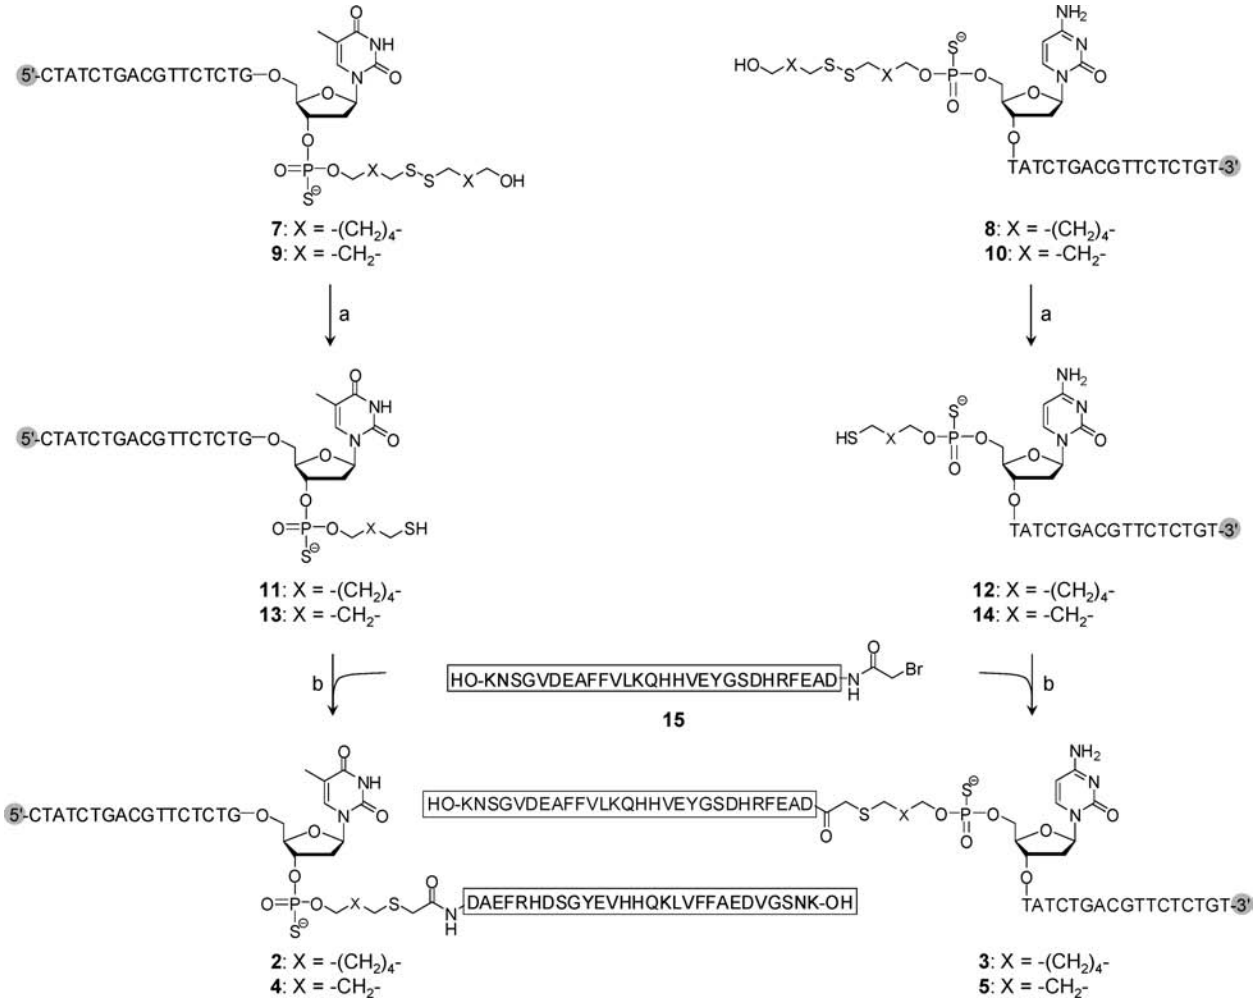
[a] All are oligodeoxynucleotides with phosphorothioate backbone; **P** = β-amyloid (1−28) peptide. [b] Molecular weights as determined by MALDI-ToF mass spectrophotometer; calcd and obsd indicate calculated and experimental values, respectively. [c] FLP = full length product; CGE = capillary gel electrophoresis.



5′ → 3′ direction as needed. Beaucage sulfurizing agent was used as an oxidizing agent to obtain the PS backbone modification (*29*). ODN **7** with C6 linker disulfide modification at 3′-end was achieved using 5′-dC solid support and 5′-phosphoramidites followed by final coupling with C6 S-S linker phosphoramidite (Sheme 1A). On the other hand, ODN **8** with C6 linker disulfide modification at the 5′-end was achieved using 3′-dT solid support and 3′-phosphoramidites followed by final coupling with C6 S-S linker phosphoramidite (Scheme 1B). Conversely, ODNs **9** and **10** with C3 linker disulfide modification at 3′- and 5′-ends were achieved using 3′- and 5′-phosphoramidites, respectively, on C3 S-S thiol-modifier solid support (Scheme 1C,D). After the synthesis, ODNs were cleaved from the solid support and deprotected using 28−30% ammonium hydroxide solution at 56 °C for 16 h. Solid support was removed by filtration; excess ammonia was removed under vacuum.

The remaining solution was diluted with 5 vol equiv of distilled water, and crude ODNs were purified on a Waters (Milford, MA) 600 HPLC system using a Source 15Q resin (GE Healthcare Biosciences, Piscataway, NJ) column (20 cm × 250 mm) at 85 °C. A 25 mM Tris−HCl, pH 7.5 buffer containing 20% acetonitrile was used as buffer A and 2.5 M NaCl in buffer A was used as buffer B. HPLC purification was performed at a flow rate of 10 mL/min running100% buffer A for 2 min, and then increasing buffer B from 0% to 30% in 10 min then 30% to 70% in 40 min. The major absorbance peak detected at 260 nm was collected, solvent was evaporated by rotoevaporation, and the residue was redissolved in RNAase-free water and desalted as following.

Then ODNs were desalted on a C18 reverse-phase HPLC column and dialyzed against United States Pharmacopea-quality sterile water for irrigation (Braun). All ODNs synthesized were lyophilized and reconstituted in distilled water, and the concentrations were determined by measuring UV absorbance at 260 nm. The purity of all ODNs was determined by analytical anion-exchange HPLC (DNA Pack100 column) and capillary gel electrophoresis (P/ACE MDQ, Beckman Coulter, Fullerton, CA). The sequence integrity was characterized by matrix-assisted laser desorption/ionization-time-of-flight (MALDI-ToF) mass spectrometry (Micro MX, Waters, USA).

Preparation of Free Thiol-Functionalized ODNs 11−14 (Scheme 2). About 2.5 mg of each of the 3′- or 5′-disulfide functionalized ODNs **7**−**10** were dissolved separately in 2.25 mL of 100 mM sodium phosphate, pH 7.2 buffer and treated with 0.25 mL of 1 M DTT solution in 100 mM sodium phosphate, pH 7.2 buffer at room temperature. The mixture was vortexed, centrifuged, and the reaction progress monitored by MALDI/ToF mass spectral analysis. The reaction was completed in about 3.5 h, and the mixture was purified on Illustra NAP-

Scheme 2. Schematic Showing the Synthesis of 3′- and 5′- ODN-β-Amyloid Peptide Conjugates[a]

[a] Reagents and conditions: (a) 100 mM DTT in 100 mM sodium phosphate buffer pH 7.2, rt, 3.5 h; (b) DMSO/100-mM sodium phosphate buffer pH 7.2, rt, 24 h. Free 3′- and 5′-ends are highlighted.

25 column using water by following the supplier's protocol. Thiol-functionalized ODNs **11**−**14** obtained from ODNs **7**−**10**, respectively, were stored frozen immediately after elution and lyophilized to avoid dimerization. The purity and sequence integrity of ODNs were determined by analytical anion-exchange HPLC (DNA Pack100 column), capillary gel electrophoresis, and MALDI-ToF mass spectrometry.

Synthesis and Purification of ODN−Peptide Conjugates (2−5) (Scheme 2). About 2 mg of bromoacetyl-β-amyloid peptide **15** in 0.1 mL of DMSO was treated with 2.5 mg of 3′- or 5′-thiol functionalized ODN (**11**−**14**) in 0.9 mL of 100 mM sodium phosphate, pH 7.2 buffer, vortexed and centrifuged, and the mixture was allowed to react at room temperature. The reaction progress was monitored by analytical anion-exchange-HPLC and MALDI/ToF mass spectral analysis. After 24 h, ODN−peptide conjugates (**2**−**5**) were purified on an anion exchange HPLC equipped with Source 15Q column at 85 °C using a gradient of solvent B (25 mM Tris−HCl, pH 7.5 buffer containing 20% acetonitrile and 2.5 M NaCl) over solvent A (25 mM Tris−HCl, pH 7.5 buffer containing 20% acetonitrile). Pure fractions were desalted on a C18 cartridge, dialyzed, and lyophilized to get conjugate as a white fluffy solid. Conjugates were reconstituted in distilled water, and concentrations were determined by measuring UV absorbance at 260 nm. The purity of ODNs **2**−**5** was determined by analytical anion-exchange HPLC (DNA Pack100 column), capillary gel electrophoresis, and denaturing PAGE. The sequence integrity of ODNs was characterized by MALDI-ToF mass spectrometry.

HEK293 Cell Assays. HEK293 cells stably expressing mouse TLR9 (Invivogen, San Diego, CA) were cultured and transiently transfected with secreted form of human embryonic alkaline phosphatase (SEAP) reporter plasmid (pNifty2-Seap) (Invivogen) as described previously (*30*). After transfection, medium was replaced with fresh culture medium, ODNs were added to the cultures, and the cultures were continued for 18 h. At the end of ODN treatment, culture supernatants were harvested and used for measuring SEAP activity by the QuantiBlue method following the manufacturer's protocol (Invivogen). The data are shown as fold increase in NF-κB activity over PBS control.

J774 Cell Cultures, Preparation of Nuclear Extracts, and EMSA. For NF-κB activation studies, murine J774 macrophage cells (ATCC) were plated at a density of 5×10^6 cells/well in 6-well plates and cultured as described previously (*31*). Cells were treated with ODNs at 1 μg/mL concentration for 1 h. Nuclear extracts were prepared using the nuclear extraction kit (Sigma) according to the manufacturer's instructions, and protein concentrations were determined by Bradford assay. Samples were either used immediately or stored frozen at −70 °C. NF-κB activation in the nuclear extracts was monitored by electrophoretic mobility shift assay (EMSA) as described previously (*31*).

Mouse Spleen Cell Cultures. Spleen cells from C57BL/6 mice were prepared and cultured in RPMI complete medium consisting of RPMI 1640 with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine. Mouse spleen cells were plated in 96-well plates at

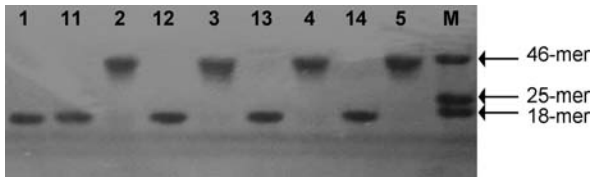


Figure 1. Denaturing PAGE analysis of purified ODNs **1**−**5** and **11**−**14** (lane numbers correspond to ODN numbers used in the text). Lane M is marker ODNs of defined length.

5×10^6 cells/mL and incubated with different concentrations of ODNs. Culture supernatants were collected after 24 h. The levels of cytokines and chemokines in the culture supernatants were measured using a mouse multiplex kit on an Applied Cytometry Systems Luminex 100 or 200 instrument, and the data were analyzed using *StarStation* software version 2.0. The required reagents were purchased from Invitrogen (Carlsbad, CA).

In Vivo Studies in Mice. Four-to-six-week-old female C57BL/6 mice were obtained from Taconic Farms, Germantown, NY. The animal studies reported in the paper were carried out following Idera's IACUC guidelines and approved protocols. Mice ($n = 3$) were injected subcutaneously (s.c.) with 20 μg of ODN (1 mg/kg). Blood was collected by retro-orbital bleeding 2 h after ODN administration, and serum IL-12 levels were determined by sandwich ELISA.

RESULTS

Synthesis of ODN-β-Amyloid Peptide Conjugates. We have synthesized ODN−peptide conjugates by covalently attaching N_α-(bromoacetyl)peptide (amino acids 1−28 fragment of the β-amyloid protein) to 5′- or 3′-thiol modified 18-mer phosphorothioate ODNs with C6 or C3 linkers. In this approach, first we synthesized ODNs functionalized with C6- and C3-linker disulfide moieties at 3′- and 5′-ends as shown in Scheme 1 (ODNs **7**−**10**). ODNs **7**−**10** were converted to activated-thiol-functionalized ODNs **11**−**14** by cleaving the disulfide bridge with DTT (Scheme 2). Then, ODN−peptide conjugates **2**−**5** (with thioether linkages) with C6 and C3 linkers were obtained by adding the bromoacetyl peptide **15** to ODNs **11**−**14** with an activated thiol function at either the 3′- or 5′-end (Scheme 2). ODN **1** served as a parent immune stimulatory agent without peptide conjugation. ODN **6** was a control that had the same length and structure as that of ODN **1** but lacked an immune stimulatory motif.

All ODNs were characterized by MALDI/ToF mass spectral analysis for their sequence integrity, and the purities were checked by HPLC and capillary gel electrophoresis (Table 1). All ODNs were also analyzed by denaturing slab gel polyacrylamide gel electrophoresis (PAGE). Figure 1 shows PAGE profiles of ODNs **1**−**5** and **11**−**14**. ODNs **11**−**14** (with a thiol functional group at the 3′- or 5′-end) had mobility similar to that of ODN **1**, which is an 18-mer. ODN-β-amyloid peptide conjugates **2**−**5** moved slower as that of a 46-mer ODN marker, suggesting the formation of peptide conjugates (Figure 1).

Activity of ODNs in TLR9-Expressing HEK293 Cells. TLR9 agonists activate immune signaling pathways, including the NF-κB pathway (*32*). To determine the effects of 3′- and 5′-conjugation of peptide to ODN, as well as the linker length between ODN and peptide, HEK293 cells transfected with mouse TLR9 and SEAP reporter gene were stimulated with ODNs **1**−**6** and examined for NF-κB activation. The results of dose-dependent NF-κB activation over PBS control are shown in Figure 2. The control ODN **6** (lacking a stimulatory motif) exhibited no activity. ODNs **1**−**5** showed activation of NF-κB to different levels for 3′- and 5′-conjugates (Figure 2). ODNs **2** and **4** (with peptide conjugated at the 3′-end) induced levels of NF-κB activation similar to that of parent ODN **1**, suggesting that conjugation of peptide at the 3′-end has minimal effect on TLR9-mediated immune stimulatory activity of ODN (Figure 2). Additionally, spacer length between ODN and peptide (**2** with C6-linker vs **4** with C3 linker) has insignificant effect on immune stimulation. In contrast, ODNs **3** and **5** (with peptide conjugated at the 5′-end) induced lower levels of NF-κB than ODNs **1**, **2**, and **4** (Figure 2). These results support our previous observations that an accessible 5′-end is required for TLR9 recognition and stimulation and that blocking of the 5′-end of an ODN by conjugation of a bulkier ligand abrogates immune stimulation (*27, 28*).

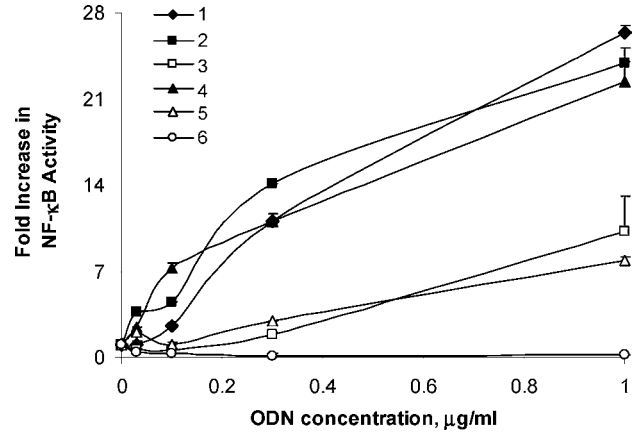

Figure 2. Dose-dependent activation of NF-κB in HEK293 cells expressing mouse TLR9 by ODNs **1**−**6**. Data shown are representative of three independent experiments.

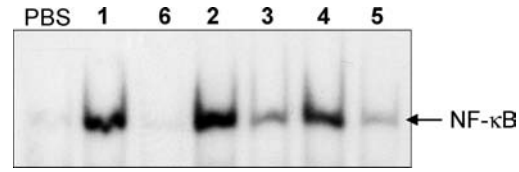

Figure 3. Activation of NF-κB in J774 murine macrophages upon treatment with ODNs. Autoradiogram showing NF-κB activation at 1 μg/mL concentration of indicated ODNs. Lane numbers correspond to ODN numbers used in the text. Experiments were carried out as described in the Experimental Section. Data shown are of one representative experiment of three independent experiments.

Activity of ODNs in J774 Cells. To further study the effects of 3′- and 5′-conjugation of peptide to ODN and the role of linker length on NF-κB activation, J774 mouse macrophage cells, which express TLR9 (*32*), were stimulated with 1 μg/mL ODNs **1**−**6** and the nuclear extracts were examined for NF-κB activation by EMSA. The results are presented in Figure 3. The presence of bands corresponding to NF-κB with ODNs **1**, **2**, and **4** suggest that the transcription factor NF-κB was activated (Figure 3). In contrast, the band intensity with ODNs **3** and **5** was minimal, suggesting that conjugation of peptide at the 5′-end of ODN results in the loss of TLR9-mediated immune activation (Figure 3).

Activity of ODNs in Mouse Spleen Cell Cultures. To study the impact of peptide conjugation with different linker lengths at the 3′- or 5′-end of ODN in primary cells, we evaluated ODN-induced production of cytokines in C57BL/6 mouse spleen cell cultures. The induction of IL-12, IL-6, MIP-1α, and TNF-α at 10 μg/mL concentration of ODN in spleen cell cultures is shown in Figure 4. The response was dependent on the dose of ODN (Supporting Information Figure 1). Control ODN **6** (lacking a stimulatory motif) induced no or insignificant levels of IL-12, IL-6, MIP-1α, and TNF-α in mouse spleen cell cultures. ODNs

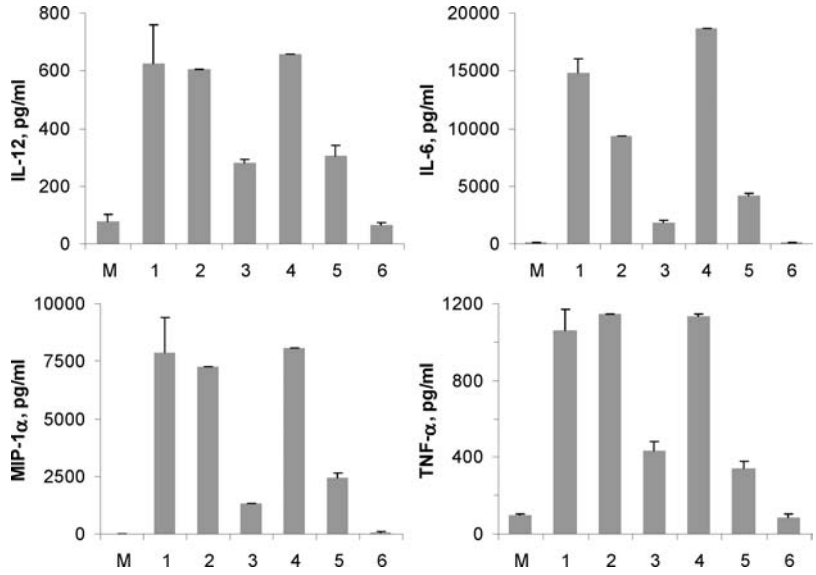

Figure 4. IL-12, IL-6, MIP-1α, and TNF-α induction profiles of ODNs **1**−**6** (10 μg/mL concentration) in C57BL/6 mouse spleen cell cultures. Spleen cells were cultured in the presence of ODNs for 24 h, and the levels of secreted cytokines in culture supernatants were measured by multiplex luminex assay as described in the Experimental Section. Each value is an average of three replicate wells, and the results are of one representative experiment of three independent experiments.

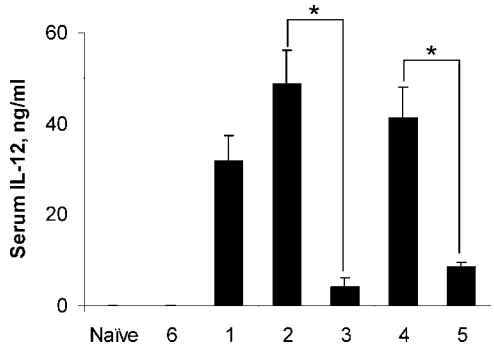

Figure 5. In vivo IL-12 induction by ODNs **1**−**6** administered s.c. to C57BL/6 mice at 1 mg/kg dose. Blood was collected 2 h post-ODN administration, and serum IL-12 levels were determined by ELISA as described in the Experimental Section. Data shown are representative of three independent experiments. * $p < 0.001$.

2 and **4** (peptide conjugated with C6 and C3 linkers at the 3′-end) induced similar levels of IL-12, IL-6, MIP-1α, and TNF-α to that of parent ODN **1** (Figure 4). In contrast, ODNs **3** and **5** (peptide conjugated with C6 and C3 linkers at the 5′-end) induced lower levels of IL-12, IL-6, MIP-1α, and TNF-α than did ODNs **1**, **2**, and **4** (Figure 4). These results are consistent with HEK293 and J774 cell culture results and further confirm that blocking the 5′-end of ODN results in decreased TLR9-mediated immune stimulatory activity.

Activity of ODNs In Vivo in Mice. We then examined the in vivo IL-12 induction profiles of ODNs **1**−**6** in mice to further understand the effects of site of peptide conjugation. ODNs were administered subcutaneously to C57BL/6 mice at a dose of 1 mg/kg, and serum IL-12 levels were determined by sandwich ELISA 2 h post-ODN administration. As shown in Figure 5, control ODN **6** induced no IL-12, whereas ODN **1** induced higher levels of IL-12 compared with ODN **6** suggesting that the stimulatory motif is required for immune responses. ODNs **2** and **4** (peptide conjugated with C6 and C3 linkers at the 3′-end) induced slightly higher levels of IL-12 than did ODN **1** (Figure 5). In contrast, ODNs **3** and **5** (peptide conjugated with C6 and C3 linkers at the 5′-end) induced significantly lower levels of serum IL-12 than did ODNs **1**, **2**, and **4** (Figure 5). These in vivo data are in agreement with the results observed in cell-based assays.

DISCUSSION

While coadministration of ODN and vaccine candidates has yielded promising results (*11, 12*), attempts are being made to deliver both antigen (protein/peptide) and ODN to the same APC to enhance cross-presentation and cross-priming (*17*). Liposomal formulations and conjugation of protein/peptide antigen to ODN are commonly employed to deliver both of the components to the same APC (*17*).

Our previous studies showed that an accessible 5′-end of an ODN is required for TLR9-mediated immune responses and blocking the 5′-end results in loss of immune stimulatory activity (*27, 28*). In the present study, we have conjugated a 28-mer β-amyloid peptide that is not immunogenic to distinguish ODN-mediated TLR9 activation from peptide/protein-induced immune responses and study the role of 5′-accessibility of ODN for TLR9-mediated immune responses. In vitro studies carried out in TLR9 transfected cell line, mouse macrophage J774 cell line, and mouse primary splenocytes showed that conjugation of peptide at the 5′-end of ODN significantly reduces TLR9-mediated immune responses. Conjugation of peptide at the 3′-end of ODN resulted in similar activity to that of parent ODN.

Moreover, we have also examined whether the proximity of peptide to the 3′- or 5′-end of the ODN would have an effect on TLR9-mediated immune stimulation of 3′- and 5′-conjugates by synthesizing and studying peptide−ODN conjugates using C3- and C6-linkers. ODN conjugated with peptide at the 3′-end through C3- and C6-linkers showed similar TLR9-mediated immune responses to that of the parent ODN, suggesting that the effects observed in these studies are not dependent on the proximity of peptide to the 3′- or 5′-end of ODN, but because an accessible 5′-end of ODN is required for TLR9-mediated immune stimulation. These results were further confirmed in acute administration studies in vivo in mice, in which the parent compound without peptide conjugation and the two conjugates that have peptide attached at the 3′-end of ODN either via C6- or C3-

linker (**2** and **4**) are significantly more immune stimulatory than those with peptide conjugated at the 5′-end (**3** and **5**).

Our previous studies have demonstrated that differences in immune stimulatory activity of 3′- and 5′-conjugates is due to the requirement of 5′-end accessibility for TLR9-mediated immune responses, but not as a result of their differences in cellular uptake, as both types of conjugates are taken up by cells to the same extent (*28*). Further, these studies have shown that conjugation of a mono, di, tetra, or oligonucleotide through 5′−5′ linkage or a fluorescein moiety, but not a phosphorothioate group, at the 5′-end significantly reduces TLR9-mediated immune responses (*28*). These results together with the present studies with a peptide conjugated at the 5′- and 3′-end of ODN suggest that an accessible 5′-end of ODN is required for TLR9-mediated immune responses and conjugation of bulkier moieties like peptides/proteins at the 5′-end of ODN results in loss of TLR9-mediated immune responses.

Several peptide/protein−ODN conjugates are currently at various stages of preclinical and clinical evaluation for the treatment of various disease indications (*13–17, 33–37*). These studies have utilized conjugation of peptides at the 5′-end of ODN due to ease of incorporation of chemical modifications required for conjugation. The present studies described above suggest that conjugation of peptides or proteins at the 5′-end of ODN does not benefit the TLR9 agonist-mediated immune responses to the full extent. A ragweed allergen, Amb a 1, conjugated at the 5′-end of an ODN has been the most extensively studied and evaluated in human clinical trials (*15, 33, 34*). However, the clinical trial results have failed to achieve the end points.

We have also conjugated other peptides of 23 and 28 amino acids to ODN and observed a loss of TLR9-mediated activity with 5′-, but not 3′-, conjugates (data not shown). Taken together, the present results clearly demonstrate that conjugation of large molecules such as peptides/proteins at the 5′-end of an ODN could lead to significant loss of TLR9-mediated immune stimulatory activity, thereby compromising the advantage provided by TLR9-mediated adjuvant activity. Therefore, conjugation of peptides/proteins at the 3′-end of ODN would be beneficial.

Fluorescence-Based Liver Microsomal Assay for Screening of Pharmaceutical Reactive Metabolites Using a Glutathione Conjugated 96-Well Plate

Xiang Ma[†,‡] and Eric Chun Yong Chan*[,†]

Department of Pharmacy, Faculty of Science, National University of Singapore, 18 Science Drive 4, Singapore 117543, and Department of Chemical and Biomolecular Engineering, Faculty of Engineering, National University of Singapore, 4 Engineering Drive 3, Singapore 117576. Received July 3, 2009; Revised Manuscript Received November 16, 2009

The purpose of our paper is to develop and validate a fluorescence-based mouse liver microsomal (MLM) assay in screening pharmaceutical reactive metabolites (RMs) using a glutathione (GSH)-conjugated 96-well plate. Poly(2-hydroxyethylmethacrylate) (pHEMA) polymeric membrane was coated on 96-well plates to provide a functional support for GSH conjugation. Oxidized GSH (GSSG) was conjugated on a cyanogen bromide (CNBr)-activated pHEMA surface. The conjugated GSH was regenerated after the reduction of GSSG using D,L-dithiothreitol (DTT). X-ray photoelectron spectroscopy, Ellman's, and fluorescence assays were applied to validate the chemistry and optimize the processes of GSH conjugation. The performance of the 96-well assay was further cross-validated using *N*-acetyl-*p*-benzo-quinone imine (NAPQI), a RM of acetaminophen (APAP), and the *in vitro* MLM assay of APAP. Finally, the developed method was applied to screen a batch of marketed drugs and chemicals on the formation of RMs. Our results indicated that optimum conditions were obtained for pHEMA loading, CNBr activation of pHEMA, and GSSG coupling and reduction. The detection limit of the assay for NAPQI was 500 nM with good specificity. *In vitro* MLM assay of APAP demonstrated a positive trapping index (TI) of 19.3%. The subsequent RM screening of a series of marketed drugs and chemical compounds resulted in a range of TI values (1.0−25.7%) that corroborated with their capacity in generating RMs. The differences of TI values are statistically significant between the compounds which are known to produce RMs and those that do not generate reactive intermediates. In conclusion, we successfully developed a fluorescence-based GSH-conjugated 96-well plate platform for the screening of RMs using MLM.

INTRODUCTION

Drug discovery and development is a time-consuming and expensive enterprise (*1*). It has been estimated that only 1 in 5000 compounds makes it to the market from drug discovery (*2*). Major contributors to the high attrition rate in drug development, other than poor clinical efficacy, are serious adverse drug reactions, undesired side effects, and unfavorable drug metabolism and pharmacokinetics (DMPK) properties (*3*). Because of the inherent high failure rates related to drug development, a recent trend in the pharmaceutical industry is to front-load drug absorption, distribution, metabolism, elimination, and toxicity (ADMET)[1]screening to an early stage in parallel with the optimization of pharmacological efficacy (*4*). Among the ADMET properties, the metabolic profile of a new chemical entity (NCE) is a pertinent characteristic to be elucidated during its development (*5*).

Metabolism is a biotransformation process that occurs in liver and other organs by which endogenous compounds and xenobiotics are converted into water-soluble derivatives that are more readily excreted via the kidney (*6*). Cytochrome P450 enzymes play a primary role in the metabolism of a diverse range of xenobiotics, including therapeutic agents. Although the major roles of drug metabolism are elimination and detoxication, metabolism may also result in toxicological outcomes. Some therapeutic agents can undergo biotransformation to electrophilic reactive metabolites (RMs) that have intrinsic chemical reactivity to bind covalently to cellular macromolecules, such as lipids, nucleic acids, and proteins. There is a substantial amount of evidence that RMs are critical cellular mediators of liver toxicity (*6*−*8*). Acetaminophen (APAP) was among the first set of drugs to be extensively studied on its relationship of hepatotoxicity to the covalent binding of cellular proteins by *N*-acetyl-*p*-benzoquinone imine (NAPQI), a RM of APAP (*9, 10*). Presently, there is an emerging consensus in drug discovery and development that formation of RMs is not a desirable characteristic of a drug candidate because of the potential safety concern, especially hepatotoxicity. Therefore, in order to reduce the attrition rate in drug development, both screening and structural characterization of RMs have been integrated into the ADMET-guided lead optimization process of some pharmaceutical companies (*11, 12*).

Direct measurement of the levels of covalent binding of RMs to liver microsomal proteins *in vitro* was often adopted as an early screening tool several years ago (*11*−*13*). This experiment requires the use of radio-labeled drug candidate and such a low-throughput method is currently reserved during the late stage of drug discovery. A more common approach for the identifica-

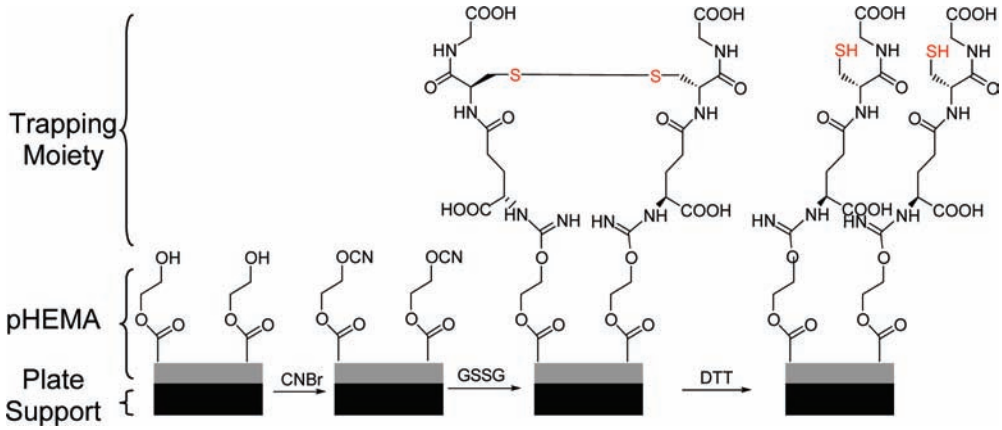
tion of RMs nowadays is to trap them with an established nucleophile that is structurally smaller and easier to work with compared to proteins. One of the techniques includes the conjugation of pharmaceutical RMs with glutathione (GSH) via reaction with the latter's nucleophilic thiol group. GSH is an endogenous tripeptide that contains cysteine glutamate glycine amino acids (Figure 1a). It is used commonly to evaluate the potential of drug candidates in generating thiol-reactive species upon oxidative metabolic activation in incubations with liver microsomes. Endogenously, GSH is an antioxidant and protects cells from toxins such as free radicals and RMs. In the RM-trapping assay by GSH, the stable RM−GSH adducts are typically characterized by liquid chromatography/tandem mass spectrometry (LC/MS/MS). Traditionally, a constant neutral loss (CNL) scanning experiment in the electrospray ionization positive mode (ESI+) has been employed to screen and characterize the RM−GSH adducts (*14*). Since some GSH adducts such as thioester-linked GSH adducts may not afford the neutral loss of 129 Da (*15, 16*), a precursor ion (PI) scanning experiment in the electrospray ionization negative mode (ESI-) was developed as an alternative for the screening of RM−GSH conjugates (*17*). While the RM-trapping assay using GSH and LC/MS/MS has proven to be an effective and reliable approach, the application of both CNL and PI scanning experiments in the screening of RMs is not suitable for high-throughput screening (HTS) of hit compounds. Hence, in the early stage of the drug discovery especially after HTS of drug candidates on the biological activity, the availability of a relatively high-throughput and low-cost screening method for the profiling of RMs would be desirable (*18, 19*).

The pharmaceutical industry has adopted 96- and 384-well microtiter plates with liquid-dispensing and plate-handling robotics as the standard platform for HTS. The vast majority of HTS techniques are focused on bioactivity testing of compounds using biochemical or cellular screens (*20*). However, HTS is comparatively less commonly applied in toxicity testing especially in the profiling of RMs (*21*). The goal of our work was to develop and optimize a novel HTS platform for RM profiling using the liver microsomal system. In this paper, we investigated the immobilization of oxidized GSH (GSSG, Figure 1b) on a 96-well plate after poly(2-hydroxyethylmethacrylate) (pHEMA) (Figure 1c) polymeric membrane coating and functional group activation of pHEMA for GSSG conjugation. We also investigated the GSSG reduction to GSH for the subsequent trapping reaction with RMs. With the use of an optimized fluorometric assay, the performances of our RM profiling strategy were evaluated using the NAPQI standard, *in vitro* mouse liver microsomal (MLM) assay of APAP and *in vitro* MLM assay of a series of marketed drugs and chemical compounds.



EXPERIMENTAL PROCEDURES

Materials. Glutathione oxidized (GSSG), glutathione reduced (GSH), cyanogen bromide (CNBr), poly(2-hydroxyethylmethacrylate) (pHEMA), DL-dithiothreitol (DTT), acetaminophen (APAP), *N*-acetyl-*p*-benzoquinone imine (NAPQI), *N*-(iodoacetylaminoethyl)-1-naphthylamine-5-sulfonic acid (1,5-I-AEDANS), 5,5′-dithio-bis-(2-nitrobenzoic acid) (DTNB; Ellman's reagent), mitomycin C, 3-acetamidophenol, sulfanilamide, procainamide hydrochloride, amodiaquine, deiquat monohydrate, zomepirac sodium salt, tolmetin sodium salt dehydrate, diclofenac sodium salt, acetaminophen, verapamil donepezil, galantamine, memantine, cimetidine, pilocarpine, and streptomycin were purchased from Sigma-Aldrich (Singapore). NADPH regenerating system solutions A and B and pooled mouse liver microsomes (MLM) were purchased from BD Gentest (Woburn, MA). All solutions were prepared with Milli-Q water obtained from a Millipore Direct-Q3 UV water purification system (Millipore S.A.S, Molsheim, France). The 96-well plates were Corning 96-well black flat bottom polystyrene nontreated microplates (Corning, NY). All other reagents used were of analytical grade.

Instrumentation. The 96-well plates were washed on a Tecan HydroFlex Platform (Tecan, Austria) while fluorescence intensity was measured using a TECAN Infinite M200 plate reader (Tecan, Austria). The X-ray photoelectron spectroscopy (XPS) measurements were performed using an AXIS His spectrometer (Kratos Analytical Ltd., England) equipped with a monochromatized A1 Kα X-ray source (1486.6 eV photons). A constant dwell time of 100 ms and a pass energy of 40 eV were used throughout the experiments. NAPQI-GSH conjugate generated using MLM incubation was analyzed using an ACQUITY UPLC system (Waters, Milford, MA) interfaced with a quadrupole, orthogonal acceleration time-of-flight tandem mass spectrometer (QTOFMS) equipped with an ESI source (Q-Tof Premier, Waters, Manchester, U.K.). The UPLC/QTOFMS system was controlled by MassLynx 4.1 software (Waters).

Conjugation of GSH on pHEMA Coated Surfaces. During early method development, pHEMA was coated on glass Petri dishes using the appropriate proportion of the reagents to investigate the immobilization of GSH (Scheme 1). pHEMA (5 mg/mL, 5 mL) was casted on each glass Petri dish at 23 ±

Scheme 1. Schematic of the Immobilization of the GSH via the Activation of Hydroxyl Functional Groups on pHEMA Support (Activated by CNBr)

1 °C overnight to allow evaporation of the alcoholic casting solvent. CNBr (2 mg/mL, pH 11.5) was then freshly prepared in aqueous solution and added in 5 mL of solution to the pHEMA precoated dish. To allow for sufficient activation, a 1 h incubation time was applied. After the reaction time, the dish was washed with 10 mL of sodium bicarbonate solution (0.1 M) for one time and subsequently water for two times. GSSG solution (2 mM) was then prepared in sodium carbonate buffer (0.1 M, pH 9.5) and added in 5 mL of solution to the CNBr-activated dish. Coupling of GSSG to CNBr-activated supports preceded quite efficiently between pH 8.0 and 9.5. Amine containing buffers such as Tris and other nucleophiles were avoided due to potential competition for coupling sites. An overnight incubation at 23 ± 1 °C was used to ensure a high extent of GSSG immobilization on pHEMA. The elemental contents of carbon, oxygen, nitrogen, and sulfur of the pHEMA-coated, CNBr-activated and GSSG-conjugated glass chips were measured using XPS.

GSH was formed by subsequent reduction of conjugated GSSG using DTT. In our study, DTT solution (2 mM, 10 mL) was freshly prepared in phosphate buffer (0.1 M, pH 8) and incubated with the GSSG-conjugated pHEMA dish for 1 h at 23 ± 1 °C. The dish was tested using Ellman's assay for free thiol group determination (*22*) after washing with copious amount of water. The procedure is based on the reaction of the thiol group with Ellman's reagent 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB) to generate the 2-nitro-5-thiobenzoic acid (TNB) which is quantified subsequently by measuring the absorbance of the anion (TNB^{2-}) at 412 nm.

Conjugation of GSH to pHEMA on 96-Well Plates. To determine the optimal thickness of pHEMA layer on the surface of the 96-well plates, serial dilutions of the alcoholic pHEMA solution were introduced into each well of the 96-well plates at a constant volume of 100 μL, resulting in decreasing thickness of the polymeric membrane (3, 1, 0.5, and 0.25 mg/well). Considering that different evaporation rate of casting solvent might also have an effect on the morphology of the polymer on the surface, casting temperature was also evaluated from 23 to 70 °C. Immobilization and subsequent reduction of GSSG were performed on each well of the plates, and the conjugated GSH density was measured fluorometrically using 1,5-I-AEDANS as the probe molecule. 1,5-I-AEDANS (0.1 mM, 100 μL) was added into DTT pretreated and nontreated wells that were regarded as test and blank, respectively. The optimized conditions (concentration of pHEMA and casting temperature) were adopted to prepare pHEMA-coated plates for the next stage of our optimization experiments.

After determination of the optimal thickness and casting temperature of pHEMA, the activation of pHEMA, and conjugation and reduction of GSSG were also optimized. As shown in Scheme 1, three steps of the chemical reaction were used to immobilize GSH onto the polymer support, namely, CNBr activation, GSSG conjugation, and DTT reduction. In each step of the reaction, optimization of the reaction time and reagent concentration were explored while maintaining other variables unchanged. The CNBr activation time and concentration were varied between 0 and 60 min and 0−10 mg/mL, respectively. GSSG conjugation time and concentration were experimented between 0−6 h and 0−4 mM, respectively. Finally, DTT reduction time and concentration were investigated between 0 and 150 min and 0 and 4 mM, respectively.

For the determination of the quantity of conjugated GSH in all optimization experiments, a solution (100 μL) of 1,5-I-AEDANS (0.1 mM) in phosphate buffer was transferred to each well and incubated at 23 ± 1 °C for 1 h. The plate was then washed three times with Milli-Q water and subjected to fluorescence measurement using the Tecan plate reader. Conjugated GSH−1,5-AEDANS was excited at 360 nm (9 nm bandwidth), and fluorescence emission was recorded simultaneously at 490 nm (20 nm bandwidth).

Determination of Nucleophilic Potential of Conjugated-GSH. NAPQI, a commercially available RM of APAP, was employed as a standard to determine the nucleophilic potential of the conjugated GSH. The GSSG-conjugated plate was charged with 100 μL of freshly prepared DTT (2 mM) solution per well and incubated at 25 °C for 1 h. NAPQI solution was prepared in a series of concentrations at 100, 10, 5, 1, 0.5, 0.1, and 0.05 μM using Milli-Q water. The DTT pretreated plate was then incubated with NAPQI solutions (100 μL per well) at 23 ± 1 °C. After a 1 h incubation, the plate was washed with Milli-Q water three times and subsequently incubated with 1,5-I-AEDANS (100 μL, 0.1 mM) in phosphate buffer at 23 ± 1 °C for 1 h. The plate was washed three times with Milli-Q water and subjected to fluorescence measurement as described earlier.

Ultra Performance Liquid Chromatography−Quadrupole Time-of-Flight Tandem Mass Spectrometry (UPLC/QTOF/MS/MS) Analysis of NAPQI−GSH. For the confirmation of the *in vitro* generation of NAPQI, a sample consisting of 800 μM APAP incubated in MLM with GSH for 60 min at 37 °C was analyzed. Chromatographic separations were performed on an AQUITY UPLC BEH C_{18} 1.7 μm, 50 mm × 2.1 mm i.d. column (Waters). The column heater and autosampler were kept at 60 and 4 °C, respectively. The mobile phases consisted of solvent A (0.1% formic acid in water) and solvent B (0.1% formic acid in acetonitrile). The optimized elution conditions were gradient of 0.1−10.0% solvent B (0−1.80 min), 10.0−95.0% solvent B (1.80−1.81 min), isocratic at 95.0% solvent B (1.81−2.14 min), and isocratic at 0.1% solvent B (2.15−2.50

min). The flow rate was 0.7 mL/min. The eluent was split postcolumn (ratio of 2:1 between waste and MS) into the ESI source using a T-splitter so as to enhance the MS sensitivity.

The QTOFMS system was tuned for optimum sensitivity and resolution in electrospray positive ionization mode (ESI+) mode using leucine enkephalin (50 pg/uL infused at 5 μL/min). The QTOF/MS/MS analysis was operated in "V" mode, and the optimized conditions were as follows: capillary voltage 3400 V, sampling cone 24 V, source temperature 100 °C, desolvation temperature 350 °C, cone gas flow 0 L/h, desolvation gas flow 500 L/h, collision energy 15 eV, MCP detector voltage 1800 V, pusher voltage 915 V, pusher voltage offset −0.70 V, and puller voltage 640 V. The precursor mass was set at 457.1 Da, and continuum data were acquired for each sample from 50 to 600 Da with a 0.2 s scan time and a 0.02 s interscan delay. Prior to analysis, the system was calibrated in ESI+ mode using 0.5 M sodium formate solution infused at a flow rate of 4 μL/min. All analyses were acquired using an independent reference spray via the LockSpray interface to ensure high mass accuracy and reproducibility; the $[M + H]^+$ ion of leucine enkephalin (2 ng/μL infused at 3 μL/min) was used as the reference lock mass (*m*/*z* 556.2771). The LockSpray was operated at a reference scan frequency, reference cone voltage, and collision energy of 10 s, 30, and 18 V, respectively.

MLM Assay of APAP Using a GSH-Conjugated 96-Well Plate. The test compound APAP solution (50 mM) mixed with MLM proteins in potassium phosphate buffer (50 mM, pH 7.4) was prewarmed at 37 °C for 5 min. The reaction was then initiated by the addition of a NADPH A and B regenerating system to give a final volume of 1 mL in eppendorf tubes. The final reaction mixtures contained 1 mM APAP and 1 mg/mL microsomal protein, respectively. The solution (100 μL) was added subsequently into each well of a DTT pretreated plate and incubated at 37 °C for 1 h. After the incubation, the reaction was terminated by washing the plate with Milli-Q water three times. Immediately after washing, 100 μL of 1,5-I-AEDANS (0.1 mM) solution in phosphate buffer (0.1 M, pH 8) was added and the plate was incubated for 1 h. After the reaction period, the plate was then washed again and subjected to fluorescence measurement. Positive controls consisted of incubations with only NAPQI solution (100 μM) while negative controls were incubations that lacked in APAP substrate. Blank wells were not subjected to DTT treatment. The performance of the plate was quantified as the trapping index, TI%, which was calculated using the following equation where F_t, F_{pc}, and F_{nc} are the fluorescence intensities of test wells, positive control wells, and negative control wells, respectively.

$$\mathrm{TI\%} = \frac{(F_t - F_{pc})}{(F_{nc} - F_{pc})} \times 100\%$$

RM Screening of Marketed Drugs and Chemical Compounds Using a GSH-Conjugated 96-Well Plate. The marketed drugs used to evaluate the RM profiling strategy were verapamil, donepezil, galantamine, memantine, cimetidine, pilocarpine, streptomycin, zomepirac, procainamide, amodiaquine, tolmetin, sulfanilamide, diclofenac, and mitomycin C. The two chemical compounds are 3-acetomidopgenol and deiquat. These substrates (including APAP) in stock aqueous solution (50 mM) were loaded on DTT pretreated 96-well plates. A solution of NADPH A and B mixed with MLM proteins in potassium phosphate buffer was prewarmed at 37 °C for 5 min. A total of 98 μL of the solution was then transferred to each well of the drug loaded 96-well plate. Each final reaction mixture contained 1 mM of the test drug substrate and 1 mg/mL of microsomal protein with a total volume of 100 μL. The plate was incubated at 37 °C for 1 h. After the incubation, the reaction was terminated by washing the plate with Milli-Q water three times. Immediately after washing, 100 μL of 1,5-I-AEDANS (0.1 mM) solution in phosphate buffer (0.1M, pH 8) was added and the plate was further incubated for 1 h. After the reaction period, the plate was then washed again and subjected to fluorescence measurement. The TI % was determined based on the method above.

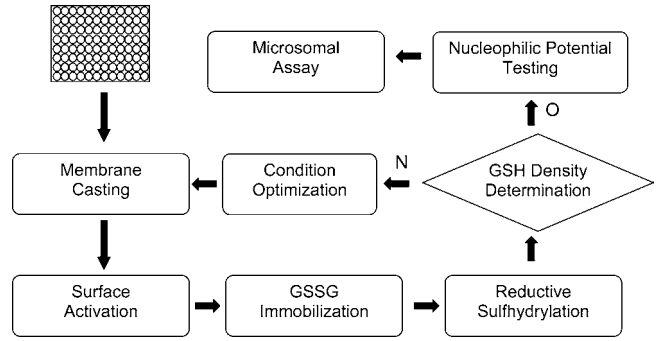


Figure 2. Workflow of the immobilization of GSH on a 96-well plate (O and N refer to optimum and nonoptimum, respectively).

Table 1. Surface Element Analysis by XPS for GSSG-Conjugated pHEMA

	percentage (%)		
elements	pHEMA	CNBr-activated pHEMA	GSSG-conjugated pHEMA
O	36.43	33.55	30.74
C	63.57	66.44	68.91
N		0.01	0.26
S			0.09

Data Analysis. A one-way analysis of variance (ANOVA) was conducted to determine statistical significance between the TI values of compounds which are known to produce RMs and those that do not generate reactive intermediates using the MLM system. The statistical test was performed using GraphPad Prism 4 software (GraphPad Software, San Diego, CA), and a *P*-value of <0.05 was considered statistically significant.

RESULTS

Conjugation of GSH on pHEMA Coated Surfaces. Before performing the development work using 96-well plates as shown in the summary flowchart (Figure 2), it was essential to confirm the feasibility of the various reactions leading up to the conjugation of GSH on pHEMA-coated surfaces. For this purpose, elemental analysis of the polymeric surfaces was conducted by XPS and the results are shown in Table 1. pHEMA consists of oxygen and carbon elements (Figure 1c) which were analyzed by XPS yielding the respective percentages of 36.43 and 63.57%. After CNBr activation, the percentage of carbon content was found to be increased with an associated decline in the percentage of oxygen, indicating cyanogen attachment on the surface of pHEMA. The untraceable nitrogen content in XPS was possibly due to the relatively lower contribution of nitrogen in the polymer. After GSSG was conjugated on the surface of pHEMA, the percentage of nitrogen atoms was found to increase to 0.26% due to its higher nitrogen content in the GSSG molecule (Figure 1b). XPS further confirmed the coupling of GSSG based on the 0.09% of sulfur atom detected. In addition, the percentage of oxygen atoms also dropped substantially due to the lower content of oxygen in the GSSG molecule. Our results further indicated that the ratios of the respective elements were not significantly different when the incubation time was increased. This was possibly due to the fact that the surface modification reaction was already saturated using the reaction conditions mentioned above.

Table 2. Fluorescence Intensity and Signal-to-Noise (S/N) Ratio of Each Well Using Different Casting Conditions

			fluorescence intensity[a] (SD)		
no.	pHEMA (mg per well)	casting temperature (°C)	DTT-treated	nontreated	S/N ratio
1	3	25	12200 (1010)	2247 (450)	5.4
2	3	70	OL[b]	2175 (520)	
3	1	25	1301 (121)	876 (232)	1.5
4	1	30	2937 (533)	821 (225)	3.6
5	1	40	4557 (344)	336 (18)	13.6
6	1	50	5706 (309)	409 (61)	14.0
7	1	60	5918 (403)	432 (46)	13.7
8	1	70	6181 (393)	360 (45)	17.1
9	0.5	70	3474 (312)	323 (19)	10.8
10	0.25	70	1377 (78)	167 (20)	8.2

[a] Values were average of intensity ± SD of 6 replicates. [b] The reading was over limit (OL) based on the instrument settings.

On the basis of the results of the Ellman's assay (*22*) for free thiol group determination, we confirmed the presence of free thiol groups in the DTT-treated GSSG-conjugated pHEMA-coated Petri dish. The positive color change from light yellow to brown confirmed the presence of free thiol groups. Our XPS and Ellman's assay data demonstrated collectively that GSSG was successfully conjugated on pHEMA, and the free thiol groups were regenerated in the DTT-treated dish. Using these conditions, we proceeded to apply the methodology to the 96-well plate system and further optimized the conditions for the screening of RMs *in vitro* (Figure 2).

Conjugation of GSH to pHEMA on 96-Well Plates. Sensitivity was a key consideration for the detection of trace levels of RMs. Therefore, a sensitive detection method for free thiol group of GSH using fluorometric assay was necessary. 1,5-I-AEDANS has been extensively used in labeling cysteine in protein analysis because it has an advantage that it reacts rather specifically with the thiol group and spares other nucleophilic functional groups of proteins. This specificity renders 1,5-I-AEDANS particularly useful in our study where the level of emission from the fluorescence probe was inversely proportional to the amount of trapped RMs. In this study, 5-I-AEDANS was used in all our optimization experiments to determine the density of the conjugated GSH on pHEMA-coated 96-well plates.

Regarding the optimization of the casting temperature and concentration of pHEMA, the testing conditions and results are summarized in Table 2. Our results suggest that both the concentration of pHEMA and casting temperature played an important role in determining the fluorescence signal. When the loaded pHEMA amount was reduced, the density of the conjugated GSH was also decreased as expected. Similarly, it was found that higher temperature gave higher fluorescence emission which represented a higher density of conjugated GSH. The best signal/noise ratio (S/N = 17.1) was obtained when 1 mg of pHEMA was casted on each well of the plate at 70 °C. However, the density of the conjugated GSH based on the fluorescence emission under this condition was found to be too high for obtaining sufficient sensitivity to detect trace levels of RM. Thus, the optimum density of GSH was achieved by further reducing the loading amount of pHEMA to 0.25 mg per well at 70 °C where the approximate S/N ratio and absolute fluorescence emission value were 8.2 and 1377 ± 78, respectively. Further decreasing the loading amount of pHEMA only resulted in a lower S/N ratio of less than 6 (Table 2). For the next phase of optimization, pHEMA (125 mg) was dissolved in ethanol (95%, 50 mL) to make up a 2.5 mg/mL solution. The pHEMA solution was casted onto each 96-well plate by pipetting 100 μL of the above solution into each well of the plate using a multichannel pipettor. The solution in the plate was allowed to dry in an incubator at 70 °C overnight. A thin, hard film of optically clear polymer was tightly bound to the plastic surface after the alcohol evaporated.

The results of the optimization of CNBr activation, GSSG conjugation, and DTT reduction are presented in Figure 3. In each step of the reaction, optimization of the reaction time and reagent concentration were investigated while maintaining other variables unchanged. As shown in Figure 3a, the activation of the hydroxyl group by CNBr was fast, and the maximal fluorescence value was attained at 20 min of reaction duration. Another important parameter was the concentration of CNBr. As reported in Figure 3b, the use of 1 mg/mL of CNBr was determined to be optimum to obtain a high activation level of the pHEMA polymer. In the second step, both the increases in the duration of the GSSG immobilization (Figure 3c) and GSSG concentration (Figure 3d) were found to strongly improve the immobilization efficiency. The optimum reaction time and GSSG concentration were 2 h and 2 mM, respectively. In the DTT reduction step (Figure 3f), 2 mM of reductive DTT reagent was optimum in reducing the conjugated GSSG into GSH to expose the free thiol group. The reaction time for achieving the target fluorescence intensity of approximately 1400 was achieved at 1 h (Figure 3e).

For the subsequent validation assay, the pHEMA-coated plates were rehydrated using 100 μL per well of Milli-Q water during which the polymer swelled without dissolving. An aqueous solution of CNBr (1 mg/mL) was freshly prepared in Milli-Q water, and the solution was adjusted to pH 11.5 with 0.2 M NaOH. The CNBr solution (100 μL) was then transferred into each well of the plates and reacted on pHEMA for 20 min at 25 °C. After the reaction period, the CNBr-activated plates were washed once with 0.1 M $NaHCO_3$ and then three times with Milli-Q water using a Tecan plate washer. Subsequently, an aqueous solution of GSSG (100 μL, 2 mM) in carbonate buffer (0.1 M, pH 9.5) was added and allowed to react for 2 h at 25 °C. After the coupling reaction, the GSSG-conjugated plates were washed again as described above and stored dry at 4 °C before the reduction reaction.

GSH was formed by reduction of conjugated GSSG using DTT as described (Scheme 1). Phosphate buffer (0.1 M) was prepared, and the pH was adjusted to 8.0 using 1 M NaOH. DTT (2 mM) was freshly prepared in phosphate buffer and was added (100 μL) into each well of the plate. The reduction was carried out for 1 h, and the plate was washed with Milli-Q water three times. These plates were used for the subsequent *in vitro* assays.

Determination of Nucleophilic Potential of Conjugated-GSH. NAPQI, a RM of APAP, was used to determine the nucleophilic potential of conjugated GSH. The GSH-conjugated plate was prepared based on the optimized conditions as discussed above. Different concentrations of NAPQI were added into the wells and incubated at 23 ± 1 °C for 1 h. The plate was then subjected to fluorometric assay based on 1,5-I-AEDANS to determine the amount of free unbound GSH. Wells without treatment by DTT were included in the assay as blanks. The negative controls were the DTT-treated wells where only vehicle solution was incubated. The nucleophilic activity of conjugated GSH toward NAPQI was significant and concentration-dependent as shown in Figure 4. At the concentration of 10 μM or more of NAPQI, about 90% of the conjugated GSH bound to NAPQI while the remaining 10% bound to the fluorescence probe. The detection limit for NAPQI was approximately 500 nM where the TI% was 11.2%. However, when the concentration was further reduced to 100 nM or lower, the trapping of NAPQI was not reproducibly detected. Nonetheless, the detection limit of 500 nM of NAPQI was potentially

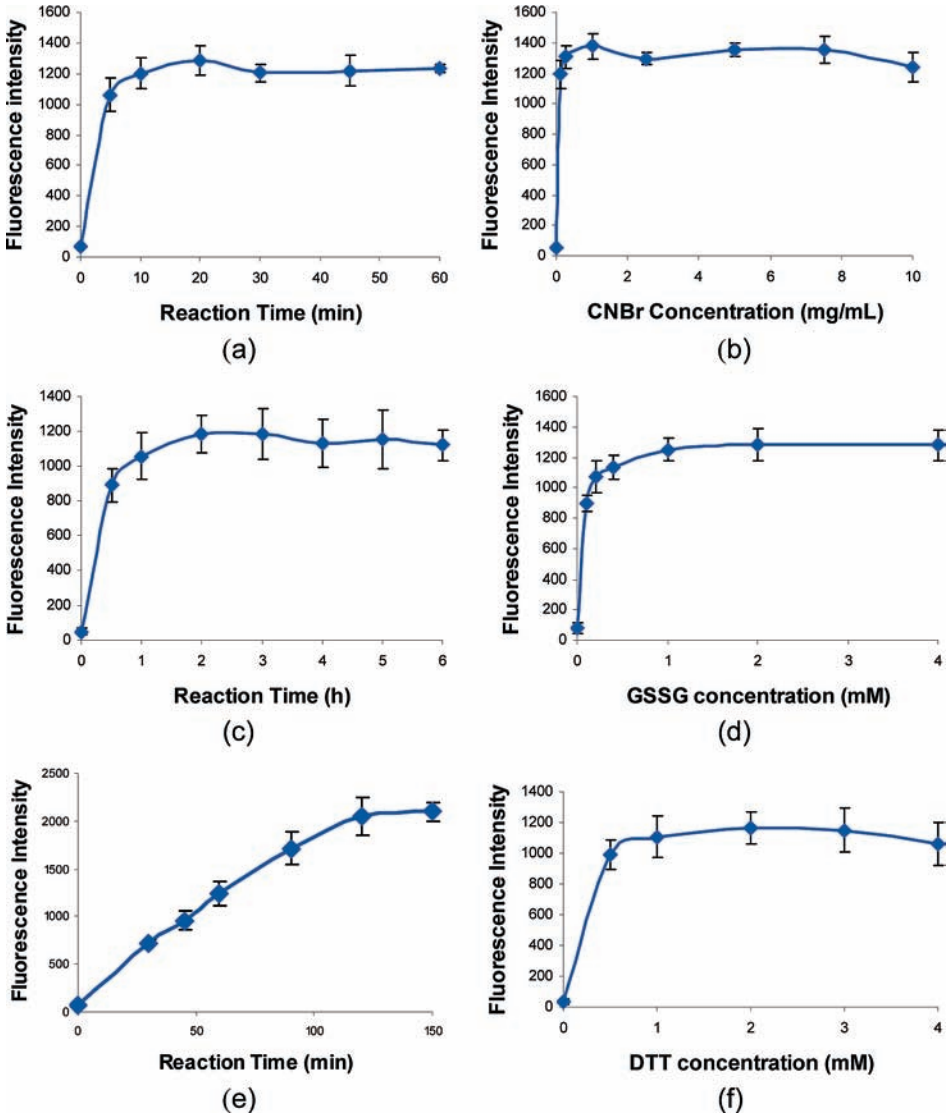

Figure 3. Reaction optimization of CNBr activation (a) time and (b) concentration; GSSG immobilization (c) time and (d) concentration; DTT reduction (e) time and (f) concentration.

sensitive to be explored for the *in vitro* profiling of RM using the MLM assay of 1 mM APAP.

UPLC/QTOF/MS/MS Analysis of NAPQI−GSH. With the use of MassLynx, the theoretical calculated masses, mass accuracy (millidaltons (mDa) and parts per million (ppm)), i-FIT (the likelihood that the isotopic pattern of the elemental composition matches a cluster of peaks in the spectrum) values, and elemental compositions associated with NAPQI−GSH and its fragments were generated and studied. With the use of a mass tolerance of 10 ppm, the experimentally determined masses/mDa/ppm/i-FIT/elemental composition of NAPQI−GSH ($[M + H]^+$) was 457.1383/−1.0/−2.2/ 0.0/$C_{18}H_{25}N_4O_8S$ and its fragments were (i) $[M - 75]^+$: 382.1070/−0.3/−0.8/5.7/$C_{16}H_{20}N_3O_6S$; (ii) $[M - 129]^+$: 328.0961/−0.6/−1.8/0.2/$C_{13}H_{18}N_3O_5S$; (iii) $[M - 146]^+$: 311.0707/0.5/1.6/3.6/$C_{13}H_{15}N_2O_5S$; (iv) $[M - 188]^+$: 269.0606/1.0/3.7/7.9/$C_{11}H_{13}N_2O_4S$; (v) $[M - 232]^+$: 225.0704/0.6/2.7/0.7/$C_{10}H_{13}N_2O_2S$; (vi) $[M - 249]^+$: 208.0428/−0.4/−1.9/0.9/$C_{10}H_{10}NO_2S$; and (vii) $[M - 275]^+$: 182.0279/0.3/1.6/0.2/$C_8H_8NO_2S$, respectively (Figure 5). On the basis of the accurate mass measurement of the parent and product ions and the fragmentation pattern of the NAPQI−GSH adduct, we confirmed the formation of NAPQI *in vitro* using the MLM assay of APAP.

MLM Assay of APAP Using a GSH-Conjugated 96-Well Plate. In order to validate that NAPQI produced *in situ* could be trapped by our GSH-conjugated 96-well plates, a standard *in vitro* MLM assay with APAP as a substrate was

trapping index (TI%)			19.3%

adopted. The results are shown in Table 3. The TI% of the APAP was determined to be 19.3%. Assuming NAPQI was the main reactive species, our data suggested that approximately 19% of conjugated GSH reacted with NAPQI, while the remaining unbound GSH was detected using the fluorescence probe.

RM Screening of Marketed Drugs and Chemical Compounds Using MLM. Zomepinac, procainamide, 3-acetomidophenol, amodiaquine, tolmetin, deiquat, sulfanilamide, diclofenac, mitomycin C, and APAP were selected for the RM screening experiment. These drugs and chemicals were selected as they had been reported to generate reactive metabolite in previous microsomal study (*23*−*27*). Verapamil, donepezil, galantamine, memantine, cimetidine, pilocarpine, and streptomycin were tested as negative controls as they are known not to produce any electrophilic species metabolically. On the other hand, NAPQI at 100 μM was used as a positive control as it was believed to block all the trapping GSH moieties and set the TI at 100%. As shown in Figure 6, after incubation with MLM, these substrates exhibited different degrees of trapping

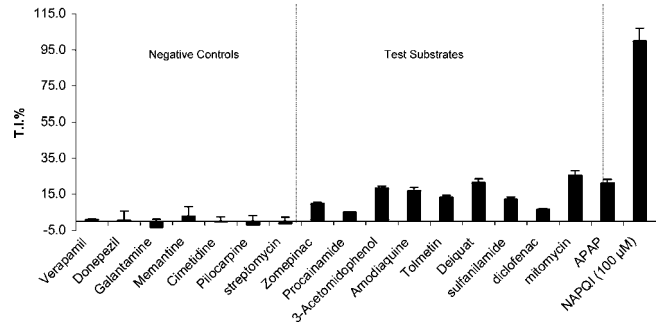

Figure 6. Plot of TI% values of selected marketed drugs and chemical compounds screened by the mouse liver microsomal assay using the fluorescence-based GSH-conjugated 96-well.

index (−3.2 to 25.7%). The highest TI% was attributed to mytomycin C, a chemotherapeutic agent, with a TI of 25.7%. Accordingly, the TI values of negative control substrates were marginally low at −3.2 to 2.8%. The differences in TI values between the negative control substrates (verapamil, donepezil, galantamine, memantine, cimetidine, pilocarpine, and streptomycin) and test substrates (zomepinac, procainamide, 3-acetomidophenol, amodiaquine, tolmetin, deiquat, sulfanilamide, diclofenac, mitomycin C, and APAP) were found to be statistically significant for the MLM system ($P < 0.05$). The data also indicated that the background signal related to the reoxidation of free GSH was minimal during the microsomal incubation.

DISCUSSION

In this study, we aimed to develop a HTS 96-well plate platform with conjugated GSH for the screening of pharma-

ceutical RMs. The most challenging part of our study was the conjugation of GSH trapping molecule on 96-well plates. Most commercially available 96-well plates are made of polystyrene (Figure 1d). Unmodified polystyrene normally has no active sites or functional groups available for the direct immobilization of ligands. For this reason, the hydrophobic character of a polystyrene surface was often exploited to noncovalently immobilize ligands through passive adsorption (*28*−*30*). However, for coupling of small molecules, such as the tripeptide GSH, the technique of simple adsorption may not work. In many instances, hydrophilic substances do not adhere very well to the hydrophobic polystyrene surface. Direct aryl functionalities may be useful for covalent ligand attachment via an electrophilic aromatic substitution (*31, 32*). However, the conditions of such a reaction are normally harsh and somewhat difficult to execute on polystyrene microtiter plates because the latter would be clouded, colored, or deformed. Another direct covalent linking method was also available using chemical attachment by a UV-catalyzed free radical reaction (*33*−*35*). This approach might result in a covalent linkage and maintain the critical optical clarity necessary for enzyme-linked immunosorbent assays (ELISA). However, the photoreactive cross-linking agents are generally costly and the resulting yield of conjugated ligand is also low.

In this paper, we developed a novel approach to provide a covalent link between the plate surface and GSH ligand where the intermediate noncovalent coating of a polymer that contains functional group was exploited. The polymeric membrane coating would provide a reactive site for chemical modification. The preferable functional group for subsequent activation and attachment of an affinity ligand was the primary hydroxyl group. Primary hydroxyls are amenable to a wide assortment of activation procedures but do not contribute to nonspecific binding of nontargeted molecules. Although many classical organic reactions may be used to modify the hydroxyl group, care was taken in choosing our method, since some required solvents may also dissolve the polymeric membrane. pHEMA (Figure 1c) attracted our interest because it has been traditionally used as an agent to coat a 96-well plate so as to reduce cell adhesivity in cell culture. pHEMA is also a hydrophilic hydrogel of neutral charge with the preferable hydroxyl functional group. After conversion of the hydroxyl group into an amine active functional group, it could be used to immobilize the GSSG on the plate surface. Another important property of this support material is that it has a hydrolyzable ester group. After trapping of RM, pHEMA offers the potential to cleave away the RM−GSH conjugate for LC/MS/MS analysis.

GSH (Figure 1a) contains two nucleophilic groups, namely, the amino and thiol groups. The thiol group was targeted for trapping pharmaceutical RMs during the *in vitro* liver microsomal assay. However, the thiol group is highly reactive and prone to auto-oxidation to GSSG (Figure 1b) by oxygen in the atmosphere during the workup process (*36*). In our study, we exploited the unique redox property of the GSH−GSSG pair as a strategy for thiol protection during the conjugation process. The linked disulfide group of GSSG would not compete with its amino group for the CNBr-activated electrophiles during the conjugation process (*37*). The use of GSSG would also circumvent challenges related to auto-oxidation of GSH. After the immobilization, the free thiol group of GSH was regenerated via a reductive thiolation reaction (*38*) (Scheme 1). On th basis of the results of XPS and Ellman's assay, we confirmed the feasibility of this chemical strategy and applied it for coupling GSH to pHEMA-coated surfaces.

During of coupling of excess GSH to precoated functional pHEMA polymeric membrane, it was pertinent to ensure that the thiol trapping group of GSH was intact and active for subsequent conjugation with RMs. As the density of conjugated GSH influenced the sensitivity of the assay in detecting trace levels of RMs produced by the *in vitro* liver microsomal system, it became important to optimize the immobilization conditions so as to achieve the best S/N ratio and sensitivity for the assay. A density determination step was also essential to control the quality of the plate. The structure of polymeric pHEMA as a coating material is dominated by the presence of primary hydroxyl groups sticking out from a polyvinyl backbone (Figure 1c). The chains are held together and stabilized by periodic cross-links formed by the ethylene dimethacrylate monomer. The chemical structure of pHEMA forms numerous tertiary α-carbonyl esters of pivalic acid, one of the most stable and least hydrolyzable esters known (*39*). Once dissolved in ethanol and casted onto a 96-well plate surface, it formed a thin, hard, and optically clear membrane which remained tightly bonded to the polystyrene surface after the alcohol was evaporated. The film was stable in aqueous solution within the pH range of 2−12 but was dissolvable in organic solvent. This latter physicochemical property posed great challenge in selection of suitable reagents and conditions for membrane activation and GSSG immobilization. In our study, the projected hydroxyl groups in pHEMA were preferentially activated to be reactive toward the amino group of GSSG in an aqueous environment (Scheme 1). Among amine reactive chemistries, CNBr has grown to be the most prevalent method for the activation of hydroxyl groups of polysaccharide matrixes (*40*). The CNBr-activated support could subsequently be used to couple to small ligands as well as to high molecular weight biopolymers containing primary amine moiety. In this study, we successfully optimized the conditions in the activation of pHEMA surfaces using CNBr, coupling of GSSG to CNBr-activated surfaces, and subsequent reduction of GSSG to GSH to obtain optimal GSH density for the trapping of RMs.

As the objective of this paper was to develop a 96-well plate platform for the profiling of RM, we further validated our optimized assay using commercially available NAPQI to determine the detection limit and optimum density of GSH. Our data demonstrated the detection limit of the trapped NAPQI was 500 nM, which was near the estimated trace levels of RM produced by 1 mM of APAP *in vitro* using the liver microsomal system. Before validating our RM profiling strategy using the MLM assay of APAP, it was essential to confirm the biotransformation of APAP to NAPQI electrophilic species *in vitro* using the standard microsomal assay. This was important to ensure that the subsequent binding to the conjugated-GSH was related to NAPQI and not other forms of nonspecific binding. With the use of UPLC/QTOF/MS/MS with GSH trapping, the high mass accuracies of the parent and product ion and the characteristic fragmentation pattern of the NAPQI−GSH conjugate supported strongly that NAPQI was generated *in vitro* using our MLM assay. Our results obtained for the RM profiling assay of APAP (TI of 19.3%) confirmed that the GSH-conjugated 96-well plates could be applied for the profiling of NAPQI generated from APAP *in vitro* in addition to standard NAPQI. Finally, we subjected our RM profiling strategy to the screening of a series of marketed drugs and chemical compounds. Importantly, for the compounds that are known to generate electrophilic metabolites (*21*−*25*), our assay identified them positively with a range of TI ranging from 5.1 to 26.0% in MLM. As expected, the TI value of verapamil was close to 0% since this compound did not generate electrophilic metabolites *in vitro*. This confirmed that our experiment was selective toward reactive species and nonspecific binding was maintained at a minimal. Similar observations were made with regards to the other negative control substrates.

Currently, there is a growing demand in the pharmaceutical industry for an efficient method that can be used to screen a large volume of compounds for the formation of pharmaceutical RMs. Hit and lead compounds that show the propensity in forming RMs may be eliminated at an early stage of drug development. This "fail early, fail cheap" approach renders the drug discovery process more cost-effective. Furthermore, the information gleaned from the structural elucidation of RMs is important for the drug development team. Medicinal chemists will become more mindful of specific functional groups that are liable for the generation of RMs and should be avoided in the design of the next generation of drug candidates. Direct detection and characterization of RMs have been proven to be extremely difficult. A widely utilized strategy is to trap reactive metabolites generated by cytochrome P450 enzymes with a capture molecule such as GSH, and resulting stable GSH adducts can be subsequently characterized by tandem mass spectrometry (LC/MS/MS). This method is sensitive and reliable but is time-consuming and unsuitable for high-throughput screenings. While there has been a recent report that challenged the use of *in vitro* covalent binding data to prospectively predict toxicity (*41*), it was determined in a separate study (*42*) that there is a general trend between the extent of thiol adduct formation and the potential for drug-induced toxicity. The latter study suggested that screening of thiol adduct formation is a pertinent part of an overall discovery optimization paradigm. The present study describes a novel approach that demonstrates good sensitivity and reliability, as well as suitability for the high-throughput screening of RMs. High sensitivity is critical for the current method to detect less abundant RMs. In a quantitative term, sensitivity of a given analytical method is normally assessed by the S/N ratio of a designated benchmark compound. For the present method, trapping of RMs was not measured directly, However, identification of GSH adducts by the our method was largely based on unbound GSH which was covalently bound to a fluorescence moiety that was subsequently measured. Therefore, the density of the GSH immobilized on the plate was a pertinent factor to ensure sufficiently high sensitivity of our assay. We optimized the amount of GSH conjugated on the 96-well plate extensively and achieved an optimal balance to ensure high S/N ratio and sensitivity as well as low assay variability. The amenability of our method for high-throughput screening of RMs is another important attribute. Although only 18 compounds were involved in our validation study, the throughput of our assay was clearly improved because of its high efficiency using a 96 well plate and suitability for screening RMs at an unprecedented speed. Therefore, fully automated identification of RMs can be accomplished in a high-throughput fashion if large libraries of compounds are screened.

In conclusion, we presented a novel and feasible conjugation method of GSH for the fast profiling of pharmaceutical RM. The detection of a fluorescence signal with 1,5-I-AEDANS enables semiquantitative and reciprocal measurement of RM−GSH formation and renders it possible for the broad screening of drugs described in our study without the use of radio-labeled materials. In this study, we have not completely optimized the sensitivity of the assay and investigated sufficiently the TI% for compound rejection. Future research should further improve the sensitivity of our assay so that RM may be detected at micromolar level of drug incubation. At the same time, more marketed drugs should be screened using our platform so that the correlation of TI values with established toxicities may be established.

ACKNOWLEDGMENT

This work was supported by the National University of Singapore grant (Grant R-279-000-249-646) for the initiative on advanced membranes for pharmaceutical and biomedical applications. The authors are grateful to Professor Neal Chung and Associate Professor Chan Sui Yung for facilitating the grant support. The assistance by Ms. New Lee Sun in the UPLC/MS/MS analysis of reactive metabolite is also acknowledged.

Nanotubes Functionalized with Lipids and Natural Amino Acid Dendrimers: A New Strategy to Create Nanomaterials for Delivering Systemic RNAi

Joshua McCarroll,[§,†,||] Huricha Baigude,[§,†,‡] Chao-Shun Yang,[§,†,‡] and Tariq M. Rana*[,†,‡]

Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, Massachusetts 01605, and Program for RNA Biology, Sanford Children's Health Research Center, Burnham Institute for Medical Research, 10901 North Torrey Pines Road, La Jolla, California 92037. Received July 7, 2009; Revised Manuscript Received November 13, 2009

Single-walled carbon nanotubes (SWNT) have unique electronic, mechanical, and structural properties as well as chemical stability that make them ideal nanomaterials for applications in materials science and medicine. Here, we report the design and creation of a novel strategy for functionalizing SWNT to systemically silence a target gene in mice by delivering siRNA at doses of <1 mg/kg. SWNT were functionalized with lipids and natural amino acid-based dendrimers (TOT) and complexed to siRNA. Our model study of the silencing efficiency of the TOT-siRNA complex showed that, in mice injected at 0.96 mg/kg, an endogenous gene for apoliproprotein B (ApoB) was silenced in liver, plasma levels of ApoB decreased, and total plasma cholesterol decreased. TOT-siRNA treatment was nontoxic and did not induce an immune response. Most (80%) of the RNA trigger molecules assembled with TOT were cleared from the body 48 h after injection, suggesting that the nanotubes did not cause siRNA aggregation or inhibit biodegradation and drug clearance *in vivo*. These results provide the first evidence that nanotubes can be functionalized with lipids and amino acids to systemically deliver siRNA. This new technology not only can be used for systemic RNAi, but may also be used to deliver other drugs *in vivo*.

INTRODUCTION

Single-walled carbon nanotubes (SWNT) have unique electronic, mechanical, and structural properties as well as chemical stability that make them ideal nanomaterials for applications in materials science and medicine. However, native SWNT have poor solubility and biocompatibility, which has stimulated approaches to functionalize them by conjugating molecules such as peptides, nucleic acids, and polymers (*1, 2*). The potential of SWNT has recently been investigated in the cellular delivery of DNA plasmids and of small interfering RNAs (siRNAs) for gene silencing (*2, 3*). To date, however, the potential of designing, creating, and applying SWNT for systemic delivery of nucleic acids or drugs has not been investigated.

RNA interference (RNAi), a gene-silencing mechanism whereby double-stranded RNA (dsRNA) induces the sequence-specific degradation of homologous mRNA (*4*), has been widely used to identify gene functions and holds great potential to provide a new class of therapeutic agents (*5*). During RNAi, long dsRNA is processed by Dicer into short-interfering RNAs (siRNAs) and incorporated into the RNA-induced silencing complex (RISC) (*6*), a multiturnover enzyme complex that cleaves the target mRNA. The RNAi machinery can also be programmed in cells by introducing duplexes of siRNAs (*7, 8*) that are assembled into siRISC containing Dicer, Argonautes and other proteins (reviewed in ref *9*). Therefore, new siRNA-based therapeutic agents could be designed to lower concentrations of disease-causing gene products.

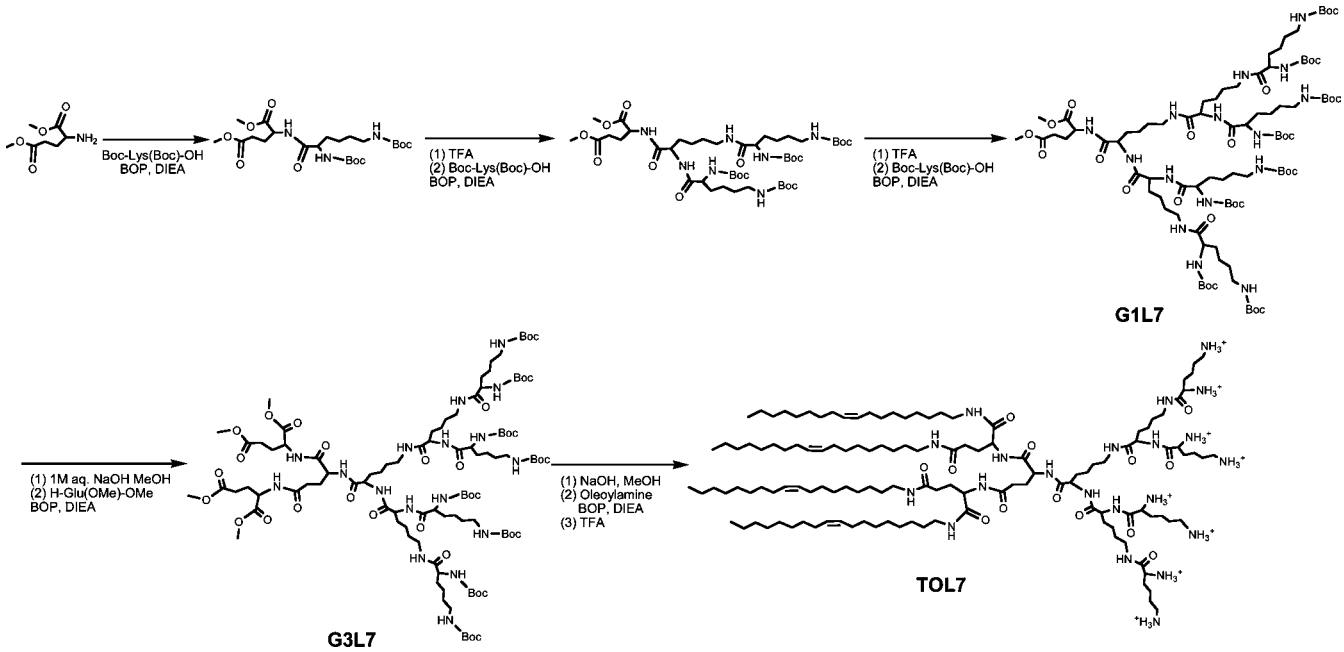
However, the development of such siRNA-based therapies faces two barriers: (1) identification of chemically stable and effective siRNA sequences, and (2) efficient delivery of these sequences to *in vivo* targets using siRNA amounts that can be translated to clinically feasible doses for humans. Recent advances in understanding the rules for chemically modifying siRNA sequences without compromising their gene-silencing efficiency (*10*−*12*) have allowed the design and synthesis of therapeutically effective siRNA molecules that can silence target genes *in vivo* (*13, 14*). Furthermore, siRNAs have recently been delivered *in vivo* to successfully inhibit various gene functions. This delivery has been facilitated by conjugating cholesterol to siRNA (*14*) or to oligonucleotide inhibitors of miRNA (*15*), by forming stable nucleic acid−lipid particles (SNALP) of siRNA (*13, 16*), and by assembling lipid−siRNA complexes (*17, 18*). In addition, a protamine−antibody fusion protein has been used to deliver siRNAs to HIV-infected cells (*19*). Recently, application of nanotubes to successfully deliver siRNA in cells has been reported (*3, 20*−*22*).



Despite this progress, new chemistry and delivery approaches are greatly needed to systematically silence disease-causing genes in a tissue-specific manner with high efficiencies and at clinically achievable doses. Here, we report the design and creation of novel nanotubes (TOT) functionalized with lipids and natural amino acid-based dendrimers. We used these TOT to systemically silence a target gene in mice at siRNA doses of <1 mg/kg. Moreover, this treatment did not induce an immune response and showed favorable pharmacokinetics.

EXPERIMENTAL PROCEDURES

Synthesis of Nanotubes Functionalized with Lipids and Lysine Dendrimers (TOT). To create functionalized new nanomaterial, single-walled carbon nanotubes (SWNT) were oxidized and cut by suspending 20 mg of SWNT in 40 mL of

a mixture of concentrated H_2SO_4/HNO_3 (3:1) and sonicating at 40 to 50 °C for 3 h (*23*). The resulting suspension was poured into 350 mL water and filtered through a 100 nm pore membrane. The resulting solid was washed repeatedly with water, resuspended in water, and centrifuged (5000 rpm, 10 min) to remove large particles.

Synthesis of Glutamic Acid−Lysine Dendrimer Generation 1 (G1L1). A mixture of H-Glu(OMe)-OMe hydrochloride (0.50 g, 2.4 mmol), Boc-lysine(Boc)-OH dicyclohexylamine salt (1.24 g, 2.4 mmol), and DIEA (0.80 mL, 4.72 mmol) was suspended in 30 mL DMF under nitrogen atmosphere (*24, 25*). After the suspension was cooled to 0 °C in an ice bath, BOP reagent (1.1 g, 2.4 mmol) was added. The reaction was performed at 0 °C for 30 min and then at room temperature for 24 h. Then, the solvent was removed by evaporation, and the resulting syrup was dissolved in ethyl acetate, followed by washing with 5% citric acid, 5% sodium bicarbonate, and water. After the solution was dried over anhydrous sodium sulfate, the target compound was purified by silica gel chromatography using ethyl acetate and hexane (4:1) as eluent. The purity of the compound was confirmed by TLC, and G1L1 was obtained as a white powder (1.01 g) in 91% yield.

^{1}H NMR (DMSO-d_6, ppm): 1.17−1.57 (m, 24H, −C(CH_3)$_3$, −CH_2−), 2.23−2.31 (m, 4H, −CH_2−), 3.01 (m, 2H, −CH_2−), 3.84 (m, 2H, −C(NH−)HCH_2−), 3.68 (s, 6H, −CH_3), 6.61−6.65 (m, 2H, −CONH−), 7.65 (t, 1H, −CONH−). MS (ESI) *m*/*z* 526.48 (M + Na)$^+$.

Synthesis of Glutamic Acid−Lysine Dendrimer Generation 2 (G1L3). *Deprotection of G1L1.* G1L1 was dissolved in a mixture of dichloromethane and trifluoroacetic acid. After vigorously stirring at room temperature for 30 min, the solvents were evaporated, and the syrup was washed with anhydrous ethyl ether.

Synthesis of G1L3. Deprotected G1L1 was reacted with Boc-lysine(Boc)-OH in a similar method described above to give G1L3 in 88% yield. ^{1}H NMR (DMSO-d_6, ppm): 1.17−1.57 (m, 54H, −C(CH_3)$_3$, −CH_2−), 2.23−2.31 (m, 4H, −CH_2−), 3.01 (m, 6H, −CH_2−), 3.84 (m, 2H, −C(NH−)HCH_2−), 4.14 (m, 2H, −C(NH−)HCH_2−), 3.68 (s, 6H, −CH_3), 6.61−7.65 (m, 7H, −CONH−). MS (ESI) *m*/*z* 982.95 (M + Na)$^+$.

Synthesis of Glutamic Acid−Lysine Dendrimer Generation 3 (G1L7). G1L3 was deprotected and reacted with Boc-lysine(Boc)−OH in a similar method described above to give G1L7 in 82% yield.

^{1}H NMR (DMSO-d_6, ppm): 1.17−1.57 (m, 118H, −C(CH_3)$_3$, −CH_2−), 2.23−2.31 (m, 4H, −CH_2−), 3.01 (m, 14H, −CH_2−), 3.84 (m, 4H, −C(NH−)HCH_2−), 4.14 (m, 4H, −C(NH−)-HCH_2−), 3.68 (s, 6H, −CH_3), 6.61−7.65 (m, 15H, −CONH−). MS (ESI) *m*/*z* 1896.84 (M + Na)$^+$.

Synthesis of Glutamic Acid−Lysine Dendrimer Generation 4 (G2L7). G1L7 (0.36 g, 0.19 mmol) was stirred in a mixture of methanol (15 mL) and 1 M NaOH solution (15 mL) at room temperature. The demethylation process was monitored by TCL (DCM/methanol, 10: 1). After the reaction was complete, the suspension was neutralized by adding dilute hydrochloric acid, followed by evaporation, extraction with chloroform, and washing with dilute HCl solution. Then, the solution was dried and the solvent was removed to give demethylated G1L7 as oil.

The oil was dissolved in 5 mL DMF. To this solution was added H-Glu(OMe)-OMe hydrochloride (0.163 g, 0.77 mmol), DIEA (0.164 mL), and BOP reagent (0.34 g, 0.77 mmol). The reaction was performed at 0 °C for 30 min and at room temperature for 24 h. Then, a mixture of ethyl acetate and hexane (4:1, 100 mL) was poured into the reaction flask, and the resulting precipitate was collected by filtration. The solid was suspended in 10 mL methanol and reprecipitated by adding ethyl acetate and hexane to give a white powder (0.31 g) in 75% yield. ^{1}H NMR (DMSO-d_6, ppm): 1.17−1.57 (m, 118H, −C(CH_3)$_3$, −CH_2−), 2.23−2.31 (m, 12H, −CH_2−), 3.01 (m, 14H, −CH_2−), 3.84 (m, 6H, −C(NH−)HCH_2−), 4.14 (m, 4H, −C(NH−)HCH_2−), 3.68 (s, 12H, CH_3), 6.61−7.65 (m, 17H, −CONH−). MS (ESI) *m*/*z* 2183.06 (M + Na)$^+$.

Synthesis of Tetra-Oleoyl Lysine Dendrimer Generation 3 (TOL7) (Scheme 1). Demethylated G2L7 (0.09 g, 0.05 mmol), oleoylamine (0.14 g, 0.54 mmol), and DIEA (0.15 mL) were dissolved in DMF. BOP (0.24 g, 0.54 mmol) was added, and the solution was stirred at r.t. for 24 h. After workup, a white powdery TOL7 (0.12 g) was obtained in 80% yield.

^{1}H NMR (DMSO-d_6, ppm): 0.81 (t, 12H, −CH_3), 1.21−1.62 (m, 154H, −CH_2−), 1.93−1.99 (m, 16H, −CH_2CH═CHCH_2−),

2.73, 2.96−3.03 (m, 22H, $-CH_2NH-$, $-CH_2NH_2$), 3.59, 4.18 (m, 10H, $-OCCH(NH-)CH_2-$), 5.28 (m, 8H, $-CH{=}CH-$), 7.75−8.48 (m, 25H, $-CONH-$, $-NH_2$). MS (MALDI-TOF) *m*/*z* 2322.91 $(M + Na)^+$.

Conjugation of TOL7 to Oxidized SWNT (TOT). To a solution of TOL7 (0.5 mL, 24 mg/mL) in water was added SWNT stock solution (2 mL). EDC (80 mg) was added, and the suspension was stirred at r.t. After 2 h, the mixture was filtered through a polycarbonate filter, rinsed, and resuspended in water, followed by dialysis against pure water for 3 days. The larger particles were removed by centrifuge at 7000 rpm for 5 min. The final concentration of TOT was 0.2 mg/mL. The concentration of TOL7 on SWNT was determined by quantitative Kaiser assay (*26*). The structure of TOT was characterized by transmission electron microscopy (Core Electron Microscopy Facility, UMASS Medical School) and dynamic light scattering (Department of Food Science, Umass Amherst).

Preparation of TOT-siRNA Complexes. All siRNAs used in these studies were chemically synthesized using silyl ethers to protect 5′-hydroxyls and acid-labile orthoesters to protect 2′-hydroxyls (2′-ACE) (Dharmacon, Lafayette, CO, USA). After deprotection and purification, siRNA strands were annealed as described (*11*): ApoB siRNA (ORF position 10049−10071): Unmodified (UM) sense 5′-GUCAUCACACUGAAUACCAAU-3′, antisense 5′-AUUGGUAUUCAGUGUGAUGACAC-3′; chemically modified (CM) sense 5′-$G^SU^FC^FAU^FC^FACACU$-$GAAUAC^{FS}C^FAA^SU^F$-propylamine-3′, antisense 5′-PAU^FU^FG-$GUAUUCAGUGUGAU^FGAC^{FS}A^SC$; UM mismatch (mm) siRNA sense 5′-GUGAUCAGACUCAAUACGAAU propylamine-3′, antisense 5′-AUUCGUAUUGAGUCUGAUCACAC-3′; CM mm sense 5′-$G^SU^FGAU^FC^FAGACUCAAUAC^FGAA^SU^F$ propylamine-3′, antisense 5′-$AU^FU^FCGUAUUGAGUCUG$-$AU^FCAC^{FS}A^SC$. The superscript letters F and S represent 2′-O-F and HS-backbone modifications, respectively. TOT-siRNA complexes were prepared by mixing siRNA and TOT in Hepes saline or Opti-MEM culture medium (Invitrogen) and incubating at room temperature for 20 min (see below).

***In Vitro* Assay for RNAi Activity of TOT-siRNA.** FL83B (mouse hepatocyte) cells were maintained at 37 °C with 5% CO_2 in F12 Khangians modified culture medium (ATCC, USA) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin and 100 μg/mL streptomycin. Cells were regularly passaged and plated in 96-well and 6-well culture plates 16 h before transfection at 70% confluency. Cells were transfected with 1 mL/well of complex (siRNA-TOT) for 2.5 h at 37 °C. Medium was removed and replaced with complete medium without antibiotics and incubated for an additional 24 h. Cell viability was assessed using a CellTiter 96 AQ_{ueous} One Solution cell proliferation assay by colorimetric analysis of the MTS tetrazolium compound according to the manufacturer's instructions (Promega, USA). Total RNA was extracted using RNeasy minispin columns and treated with DNase I (Qiagen, USA) before quantitation. To assess levels of ApoB mRNA, real-time quantitative PCR (qPCR) was performed using SYBR Green (Qiagen USA) with forward (5′-TTCCAGCCATGGGCAACTT-TACCT-3′) and reverse (5′-TACTGCAGGGCGTCAGTGA-CAAAT-3′) ApoB primers. ApoB mRNA levels were normalized against the housekeeping gene GAPDH using forward (5′-ATCAAGAAGGTGGTGAAGCAGGCA-3′) and reverse (5′-TGGAAGAGTGGGAGTTGCTGTTGA-3′) GAPDH primers.

***In Vivo* Assay for RNAi Activity of TOT-siRNA.** Six- to eight-week-old male C57BL/6 mice (Charles River laboratories, USA) were maintained under a 12 h light/dark cycle in a pathogen-free animal facility. Mice were injected via the lateral tail vein with phosphate buffered saline pH 7.4 (PBS) or TOT-siRNA complexes of chemically modified (CM) ApoB siRNA or its mismatched (mm) siRNA. At 48 h after injection, liver tissue levels of ApoB mRNA, plasma levels of ApoB protein, and total plasma cholesterol were measured. For pharmacokinetic studies, liver tissue levels of ApoB mRNA were analyzed at various time intervals (48−144 h) after the injection.

Measurement of *in Vivo* ApoB mRNA and Protein Levels. To determine ApoB mRNA levels in liver tissue after siRNA treatment, small uniform tissue samples were collected from three regions of the liver. Total RNA was extracted with Trizol and treated with DNase I before quantification. ApoB mRNA levels were determined by qPCR as described above. ApoB protein levels were determined by Western blot using a polyclonal goat anti-ApoB100/48 antibody (Santa Cruz, USA). ApoB protein levels were then detected by enhanced chemiluminescence (PerkinElmer Life Sciences, USA). As a control, fibronectin was visualized by immunoblot using a polyclonal rabbit antifibronectin antibody (Sigma, USA).

Measurement of Total Cholesterol Levels. Plasma cholesterol was measured by a commercial enzyme assay according to the manufacturer's instructions (Biodesign International, USA).

***In Vivo* Interferon Induction.** To assess for any nonspecific immune response to injected TOT-containing siRNA, mouse liver tissue was assessed for expression of two interferon (IFN)-inducible genes, IFN-induced protein with tetratricopeptide repeats 1 (IFIT1), and signal transducer and activator of transcription 1 (STAT 1). Liver tissue was obtained from mice treated with PBS (control) and TOT-ApoB siRNA. Expression of IFIT1 and STAT1 were measured by qPCR as described above using the following primers: IFIT1 forward, 5′-AAAC-CCTGAGTACAACGCTGGCTA-3′; IFIT1 reverse, 5′-AAAC-CCTGAGTACAACGCTGGCTA-3′; STAT 1, forward: 5′-CAGCTGCAAAGCTGGTTCACCATT-3′; STAT 1 reverse, 5′-AGGTTCGATCTGACAACACCTGCT-3′. IFIT1 and STAT 1 mRNA levels were normalized against the housekeeping gene GAPDH. In addition, plasma IFN-α levels were quantified 24 h after the final injection using sandwich ELISA according to the manufacturer's instructions (PBL Biomedical Laboratories, USA). As a positive control for both assays, C57BL/6 mice were injected via the lateral tail vein with 250 μg polyinosinic−polycytidylic acid (Poly IC, total volume 0.125 mL). Six hours after the injection, liver and plasma samples were collected.

RESULTS AND DISCUSSION

To create a novel SWNT-based nanomaterial for efficient systemic siRNA delivery, we hypothesized that SWNT should be functionalized with at least two moieties: (1) a positive charge for siRNA binding, and (2) lipid chains to modify the hydrophilic properties of siRNA-SWNT and make contacts with cellular membranes (Figure 1a,b). Thus, we constructed TOL7, a lysine-based dendrimer with covalently attached oleoyl lipid chains. The MALDI-TOF mass spectrum (Figure 1a) shows a major peak at 2322.91, which matches the calculated molecular mass of TOL7 ($2300.47 + Na^+$). Although the spectrum also shows some other minor peaks due to the lower purity of starting material (oleoylamine contains 60% C18 chain), nonetheless, the MS and ^1H NMR confirms the successful synthesis of the target molecule. The lipid moieties on TOL7 bind to the hydrophobic wall of the nanotube upon mixing a solution of TOL7 and oxidized SWNT. However, we found that adding EDC to the mixture during the coupling increases the loading of TOL7 to the nanotube, suggesting that a covalent attachment occurred through amide bonds between carboxyl groups of SWNT and amines on the surface of TOL7, which facilitated the TOL7-SWNT interaction. Quantitative analysis by performing Kaiser assay showed that in the presence of EDC the loading was 1.35 mg TOL7 to 1.0 mg SWNT, higher than in the absence of EDC (1.0 mg TOL7 to 1.0 mg SWNT). SWNT modified

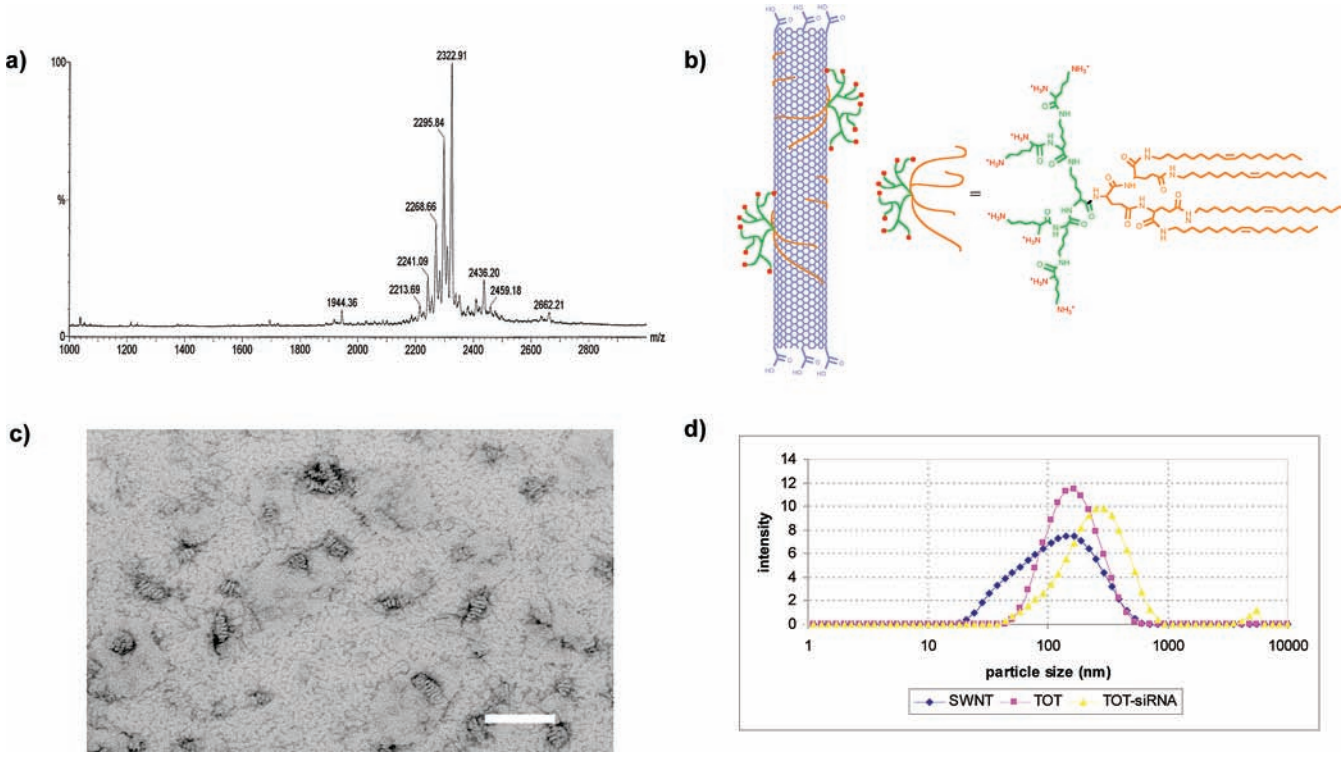

Figure 1. Structural analysis of lysine dendrimers TOL7 and functionalized nanotube TOT. (a) MALDI-TOF MS spectrum of TOL7. (b) Chemical structure of TOL7 and schematic illustration of TOT. (c) Electron micrograph of TOT complex and (d) particle size distribution of oxidized single-walled nanotube (blue), TOT (pink), and TOT-siRNA (yellow) complex by dynamic light scattering. Scale bar = 200 nm.

with TOL7 (see Experimental Procedures for details) is denoted here as TOT (Figure 1). Electron microscopic images of TOL7 assembled on the surface of SWNT reveal regular lateral striations on the surface of 80- to 150-nm nanotubes (Figure 1c). These striations suggest that TOL7 molecules are coupled to SWNT by forming half-cylinders on the nanotube surface, consistent with a previous report (*27*) showing supramolecular self-assembly of lipid derivatives on carbon nanotubes.

To test the efficacy of TOT for systemic RNAi, we chose as model system the endogenous mouse gene, apolipoprotein B (ApoB). ApoB, a large protein that exists in two forms, ApoB100 and ApoB48 (*28*), is a ligand for the low-density lipoprotein (LDL) receptor and is involved in cholesterol metabolism. Mouse ApoB contains 4515 amino acids and is predominantly expressed in the liver and intestine. In mice, both ApoB100 and ApoB48 are expressed in the liver, whereas ApoB48 is predominantly expressed in the intestine. Heterozygous knockout mouse models for ApoB show a 20% decrease in serum cholesterol levels and resist diet-induced hypercholesterolemia (*29*).

In humans, serum levels of ApoB have been strongly correlated with increased risk of coronary artery disease (*28, 30*). Because ApoB is a large protein for which no three-dimensional structural data are available, it is not a suitable target for small molecule development to treat hypercholesterolemia. An alternative therapy that has recently been explored in a mouse model is to silence ApoB with siRNA chemically modified by conjugation to cholesterol (*14, 31*). These studies were very encouraging in providing proof of the concept for developing RNAi-based therapeutics (*14*), but the amounts of siRNA used (50 mg/kg) would translate to unfeasible doses for clinical application in humans (*31*). Furthermore, the delivery of siRNA required cholesterol conjugation, which might increase risk factors in patients who cannot tolerate higher levels of cholesterol. Lower doses of siRNAs have recently been used by encapsulating them in SNALP to efficiently silence ApoB in nonhuman primates (*16*), but this approach requires a sophisticated SNAPL assembly. Therefore, we planned to develop a new nanomaterial that can be used to easily assemble siRNA for systemic delivery. To test our approach for systemic siRNA delivery and to achieve ApoB silencing with siRNA doses in animals that are clinically relevant for RNAi-based therapy in humans, we chose ApoB silencing in mice as an animal model system.

To determine whether TOT could deliver active siRNA to its target and silence ApoB mRNA levels *in vitro*, we treated FL83B (mouse hepatocyte) cells with TOT-siRNA complexes and analyzed ApoB mRNA levels by quantitative PCR (qPCR). TOT-siRNA containing ApoB siRNA almost completely silenced ApoB mRNA expression (>80%) in FL83B cells relative to that in controls or cells treated with TOT containing mismatched siRNA (Figure 2a). Notably, the efficiency of ApoB mRNA silencing using TOT to transport siRNA was similar to that of cells transfected with Lipofectamine 2000 complexed to siRNA (Figure 2a), although we observed slightly lower RNAi with TOT as compared with L2K. Similar to unmodified siRNA, TOT containing our chemically modified siRNA directed against ApoB efficiently silenced ApoB mRNA (Figure 2a). These results therefore show that our modifications to siRNA did not negatively influence its RNAi activity (Figure 2a). Furthermore, these reduced levels of ApoB mRNA levels in FL83B cells were not due to TOT-siRNA induced cell toxicity, as confirmed by cell viability assays (Figure 2b). Taken together, these results demonstrate that TOT-siRNA is nontoxic and efficiently transports siRNA into cells.

To determine the effect of TOT on the uptake and localization of siRNA in FL83B cells, we used Lipofectamine 2000 (L2K) or TOT as described above to deliver Cy3-labeled siRNA to cells. The localization of Cy3-SS/AS-3′N3 siRNA was first established by transfecting it into cells using L2K. In both live and 4′,6-diamidino-2-phenylindole (DAPI)-stained transfected cells (*32*), Cy3-labeled siRNA delivered by L2K was localized

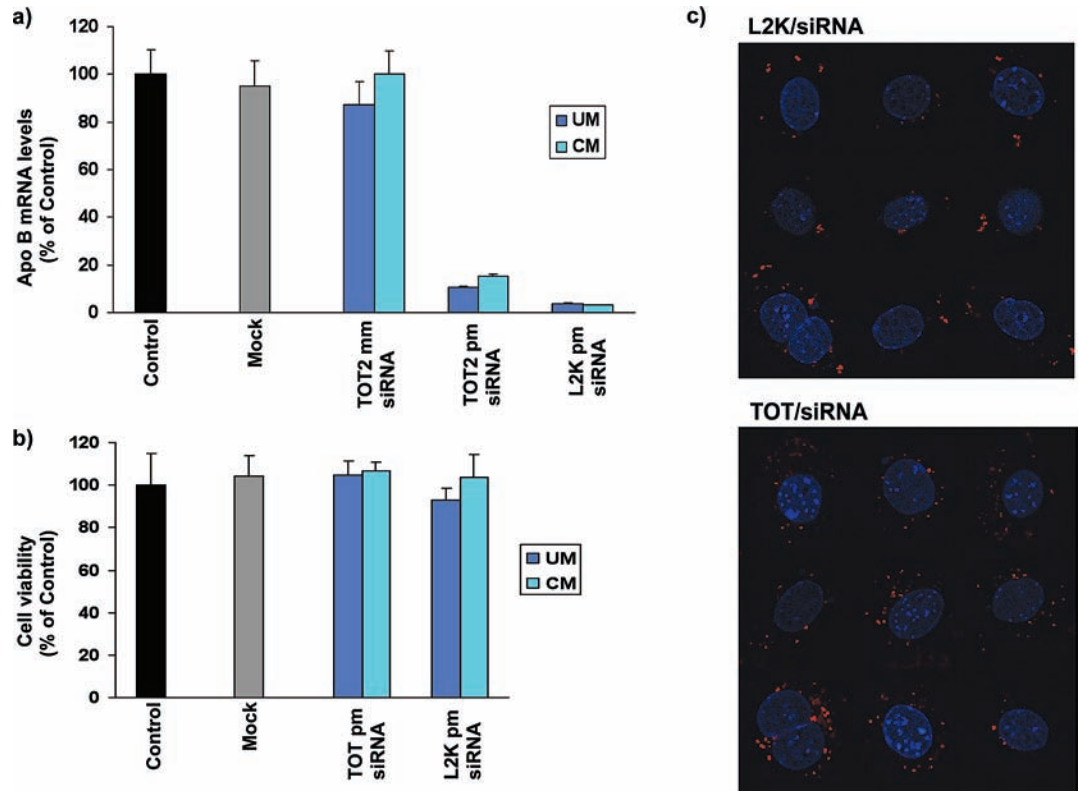

Figure 2. *In vitro* silencing of ApoB by TOT-siRNA. (a) TOT-siRNA complex specifically silences ApoB in mouse hepatocyte cells. FL83B cells were treated for 24 h with TOT without siRNA (Mock) or with TOT-siRNA complex containing unmodified (UM) siRNA, chemically modified (CM) siRNA, or their respective mismatches (mm). As a control, Lipofectamine 2000 (L2K) was used to transfect chemically modified or unmodified siRNA. ApoB mRNA levels are expressed as percent of control (no transfection). Each value represents the mean ± SD of duplicate cultures from two representative experiments. (b) FL83B cells remain viable after 24 h treatment with TOT-siRNA complex. Cells were treated with TOT without siRNA (Mock) or with TOT-siRNA complex containing unmodified (UM) or chemically modified (CM) siRNA. Cell toxicity levels are expressed as percent of control (no transfection). Each value represents the mean ± SD of duplicate cultures from two representative experiments. (c) Localization of siRNA. Cells were transfected with Cy3-labeled siRNA using Lipofectamine 2000 (L2K) or with siRNA-TOT complex. Localization of the duplex siRNA after 24 h was monitored by confocal microscopy. Overlay images of siRNA and nuclear DNA (4′,6-diamidino-2-phenylindole [DAPI] stained) are shown.

to the cytoplasm around the periphery of the nucleus (Figure 2c). To determine the effect of TOT on localization of Cy3-SS/AS-3′N3 siRNA, cells were transfected with the Cy3-labeled siRNA-TOT complex. Similar to the siRNA delivered into cells by L2K, siRNA delivered by TOT localized to perinuclear regions of the cytoplasm (Figure 2c). This localization pattern is typical for siRNA transfection because siRNA duplexes are first localized to cytoplasm, which are not P bodies, and then released to form RISC assembly for RNAi functions and localization to P bodies together with argonaute proteins (*9, 32, 33*). Due to low fluorescence intensity and higher backgrounds, it is quite difficult to quantify the amount of RNA released and subsequent assembly into RISC in cells. Nonetheless, this result indicates that siRNA delivery by TOT did not affect cellular localization of the RNA and did not cause any aggregate formation or nuclear translocation of siRNA.

We next determined the ability of TOT to deliver siRNA to its target and to silence ApoB expression *in vivo*. To determine if chemical modifications in the siRNA sequence are necessary for *in vivo* RNAi, we verified that injecting mice with cholesterol-conjugated unmodified siRNA did not significantly knock down ApoB expression (data not shown), consistent with a previous report (*14*). Therefore, our *in vivo* experiments focused on TOT containing chemically modified siRNA. After mice were injected via tail vein with TOT complexed to either chemically modified ApoB-targeted siRNA or its mismatch, samples of liver and plasma were analyzed (see Experimental Procedures for details). To quantify ApoB mRNA silencing throughout the liver, separate regions were analyzed for ApoB mRNA levels. ApoB mRNA decreased in a dose-dependent manner in liver tissue from mice treated with TOT-siRNA relative to that in liver tissue from control mice and mice treated with TOT containing mismatched siRNA (Figure 3a).

The maximum silencing effect of TOT-siRNA was reached at 0.96 mg/kg, resulting in 56 ± 4% reduction in ApoB mRNA ($n = 5$ animals). Increasing the siRNA dose did not enhance the *in vivo* RNAi efficiency (data not shown).). We reasoned that applying multiple doses would not enhance the silencing efficiency of TOT-siRNA, since our previous work showed that a nanoparticle created from similar dendrimer (iNOP) did not increase the RNAi efficiency when injected multiple times in animals (*34*). To quantify the amount of ApoB siRNA in livers of mice injected with varying doses of TOT-siRNA, total RNA was isolated from liver 48 h after treatment and guide strand ApoB siRNA was identified by Northern blot analysis. Interestingly, the amount of guide strand in mouse liver decreased with decreasing doses of injected siRNA (Figure 3b). It was not clear why higher concentrations of TOT-siRNA did not increase RNAi efficiency. Nonetheless, these observations show a clear correlation between *in vivo* RNAi efficiency and amount of guide strand delivered.

To determine if silencing of ApoB mRNA correlated with reduced plasma levels of ApoB protein, we used immunoblot analysis to measure levels of ApoB100 and ApoB48. Both ApoB100 and ApoB48 serum levels decreased to >60% of control (Figures 3c,d) in mice injected with 0.96 mg/kg TOT-siRNA, while fibronectin levels were unaffected. These results show that TOT-siRNA complex efficiently silenced ApoB

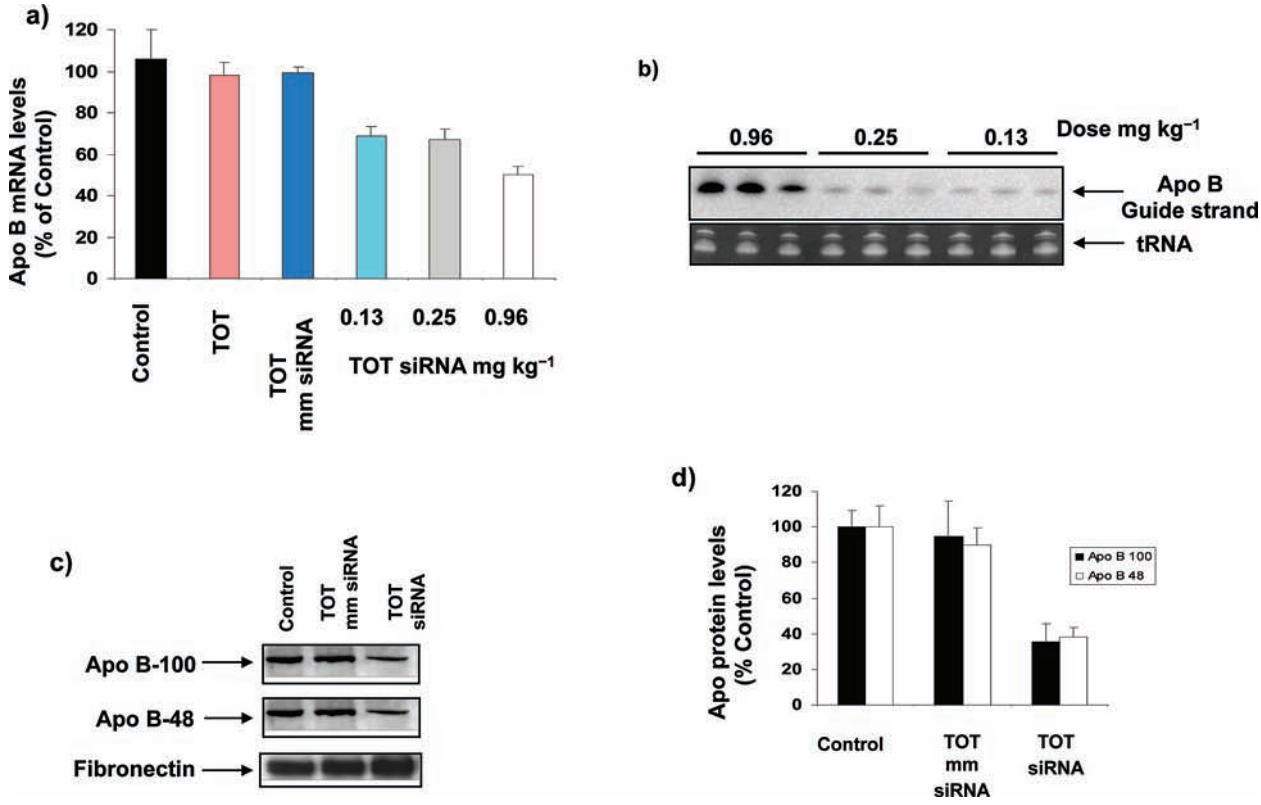

Figure 3. *In vivo* silencing of ApoB by TOT-siRNA. (a) ApoB is specifically silenced in livers of mice injected with TOT-siRNA complex. ApoB mRNA levels were reduced in livers of mice treated 48 h earlier with varying doses of TOT complexed to chemically modified (CM) siRNA or its mismatch (mm). Values represent the mean ± SD of tissue samples from three liver regions ($n = 3-5$ animals). Data are expressed as percent of control. (b) ApoB siRNA content in mouse liver varies with TOT-siRNA dose. Total RNA was isolated from livers of mice treated with varying doses (a) of TOT complexed to unmodified (UM) or chemically modified (CM) siRNA, and was identified by Northern blot analysis. A representative Northern blot shows the presence of the ApoB guide strand siRNA in mouse liver 48 h after the treatment. tRNA was identified as a positive control. (c) ApoB protein plasma levels are reduced in mice injected with TOT-siRNA. Mice were injected with TOT-siRNA containing chemically modified (CM) siRNA or its mismatch (mm), and 48 h later, plasma was analyzed for ApoB100 and ApoB48 protein levels by Western blot analysis with anti-ApoB100 or anti-ApoB48. Total protein loading was confirmed by assessing plasma fibronectin levels. (d) Quantification of reduced ApoB plasma levels after TOT-siRNA treatment. Western blots for mouse plasma levels of ApoB100 and ApoB48 (d) were analyzed by densitometry. Data are expressed as percent of control ($n = 3-5$ animals).

expression *in vivo*. Remarkably, this TOT-mediated silencing required only 0.96 mg/kg siRNA, a clinically feasible dose for RNAi therapeutic applications.

To investigate the physiological effects of ApoB mRNA silencing on cholesterol metabolism, we measured total plasma cholesterol levels in mice 48 h after a single injection of 0.96 mg/kg TOT-siRNA. As shown in Figure 4a, TOT-siRNA-mediated silencing of ApoB expression in liver and plasma samples was correlated with a reduction of total cholesterol (33 ± 10%). However, cholesterol levels were unchanged in mice treated with PBS TOT (control) or with TOT containing mismatched siRNA (Figure 4a). Together, these findings demonstrate that TOT-siRNA-mediated targeting of ApoB could provide a clinically significant new approach to reducing cholesterol levels in patients with hypercholesterolemia.

siRNA-based therapies could have at least two major side effects: (1) activation of an immune response (*35, 36*) and (2) toxic effects. To address the concern that a nonspecific immune response could be elicited by injecting mice with TOT-CM siRNA, their liver tissue RNA was assessed by qPCR for induction of the interferon (IFN)-inducible genes, IFN-induced protein with tetratricopeptide repeats 1 (IFIT1) and signal transducer and activator of transcription 1 (STAT 1), and plasma IFN-α levels were measured by ELISA. Our results show that injecting mice with TOT-siRNA did not alter the expression of IFLT1 and STAT 1 genes in the liver (data not shown), nor did it induce the release of IFN-α in plasma relative to controls (Figure 4b). To address concerns about TOT-siRNA toxicity, all mice were monitored daily for overall health, food intake, and weight changes. At the end of TOT-siRNA treatment, mice were sacrificed and necropsied. Histological sections of liver, our target tissue for ApoB silencing, were prepared and independently examined for toxic effects by a board-certified animal pathologist. No histological differences were noted between tissues from control (no treatment or TOT only) mice and from those treated with TOT-siRNA complex (data not shown). These results demonstrate that TOT-siRNA treatment may not induce an immune response in animals and caused no apparent toxic effects.

One concern about applying nanotechnology in medicine is its safety. Nanomaterials used to deliver a drug could cause undesired effects by inhibiting the drug's biodegradation and clearance, thus prolonging its half-life *in vivo*. To address this question, we determined the *in vivo* pharmacokinetics of TOT-siRNA by injecting mice with 0.96 mg/kg of TOT-siRNA via tail vein, isolating liver tissues at various times after injection, and analyzing different regions for ApoB mRNA levels. The maximum knockdown of ApoB mRNA was observed 48 h after injecting TOT-siRNA, and the ApoB mRNA levels increased to ~80% after 72 h and remained at that level until 144 h (Figure 5a). To determine the amount of ApoB siRNA in mouse liver, total RNA was isolated from livers at various times after injecting mice with TOT-siRNA, and guide strand ApoB siRNA was identified by Northern blot analysis. The amount of guide strand found in mouse liver was greatest at 48 h after TOT-siRNA injection and decreased with time (up to 144 h) (Figure

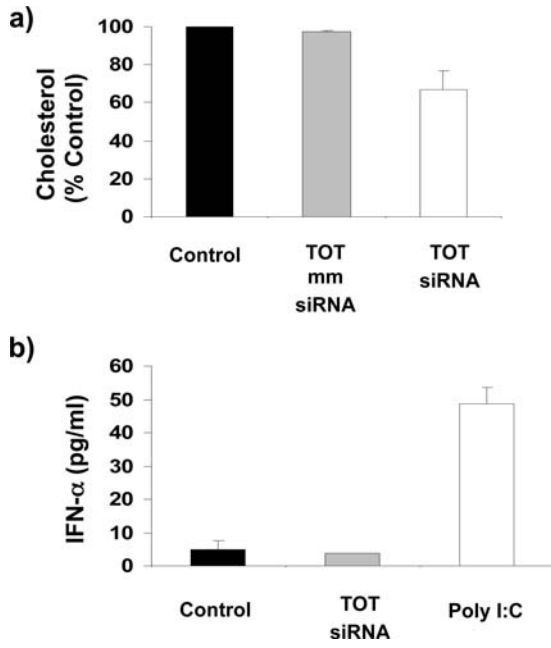

Figure 4. (a) TOT-siRNA therapeutically reduces cholesterol levels. Plasma cholesterol levels were measured 48 h after injecting mice with 0.96 mg/kg TOT-siRNA complex. (b) TOT-siRNA treatment does not induce interferon response in mice. IFN-α plasma levels were measured 48 h after injecting mice with 0.96 mg/kg TOT without siRNA (Mock) or with 0.96 mg/kg TOT-CM siRNA. As a positive control, IFN-α plasma levels were measured after injecting mice with 250 μg Poly IC. Each value represents the mean ± SD of 5 plasma samples from each treatment group.

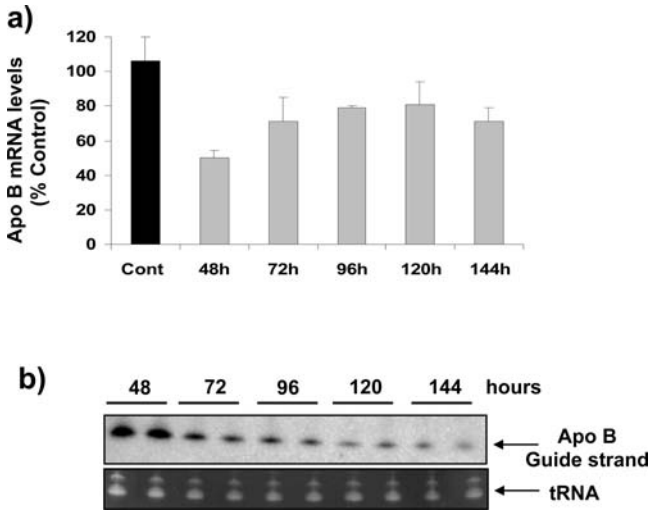

Figure 5. Pharmacokinetics of TOT-siRNA. (a) Mice were injected with 0.96 mg/kg of TOT-siRNA, and ApoB mRNA levels were measured in liver at various times after injection. Values represent the mean ± SD of tissue samples from 3−5 animals. (b) ApoB siRNA decreases with time in livers of mice injected with TOT-siRNA. Mice were injected with TOT-siRNA (a), total RNA was isolated from their livers at various times after injection, and ApoB siRNA guide strand was identified by Northern blot analysis. A representative Northern blot shows that the amount of ApoB guide strand siRNA decreased over the time range shown. tRNA was identified as a positive control.

5b). Taken together, these results show a correlation between *in vivo* RNAi efficiency at various times after TOT-siRNA treatment and amount of guide strand present in mouse liver. Although these findings do not directly demonstrate the half-life of nanomaterial *in vivo*, however, these results suggest that the RNA trigger molecules in the siRNA-TOT complexes were not trapped in liver and were cleared quite rapidly from the body.

Nanomedicine has recently emerged as a new branch of science that explores applications of nanotechnology for diagnosing, monitoring, treating, and controlling biological functions (*37*). However, the questions of physiological toxicity and favorable pharmacology of nanomaterials remains unanswered. Here, we present evidence that a new approach to designing nanotubes can be used to create nanomaterials for *in vivo* delivery of siRNA to silence endogenous disease-related genes at clinically acceptable and therapeutically affordable doses. Injecting mice with only 0.96 mg/kg siRNA in complex with TOT (SWNT functionalized with lipids and natural amino acid-based dendrimers) silenced ApoB mRNA and reduced protein levels in liver, decreased plasma levels of ApoB, and lowered total plasma cholesterol. Moreover, TOT treatment was nontoxic and did not induce an immune response. Most of the RNA molecules (80%) assembled with TOT were cleared from the body 48 h after treatment, indicating that the nanotubes did not inhibit siRNA biodegradation and clearance, ensuring a short half-life for siRNA *in vivo*. These results provide the first evidence that nanotubes can be safely and effectively used to systemically deliver siRNA, thus offering a new technology for systemic RNAi and potentially for delivering other drugs *in vivo*.

ACKNOWLEDGMENT

We thank Michael Czech, Craig Mello and members of the Rana lab for helpful discussions, and Dr. David Garlick for histological examination of slides. We also thank Dr. Gregory Hendricks and his group at the Core Electron Microscopy Facility, UMASS Medical School for their advice and help with the electron microscopy experiments. This work was supported in part by a grant from the NIH to T.M.R.

A Doubly Labeled Penetratin Analogue as a Ratiometric Sensor for Intracellular Proteolytic Stability

Rainer Fischer,*[,†,‡,||] Hansjörg Hufnagel,[†,‡,⊥] and Roland Brock[‡,§]

Interfaculty Institute for Cell Biology, University of Tübingen, Auf der Morgenstelle 15, 72076 Tübingen, Germany, and Department of Biochemistry, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, P.O. Box 9101, 6500 HB Nijmegen, The Netherlands. Received July 8, 2009; Revised Manuscript Received November 12, 2009

Endocytosis has been shown to play a major role in the cellular import of cationic cell-penetrating peptides (CPPs) and CPP conjugates. Considering the presence of proteolytic activities inside the endolysosomal compartment, it is necessary to assess the consequences of the import mechanism on the intracellular integrity of the vector and the cargo. In this work, a penetratin analogue terminally labeled with two different fluorophores was synthesized and used as a sensor to quantitatively dissect the contribution of intracellular proteolytic activities on the breakdown of this specific CPP. Using a panel of lysosomal protease inhibitors, the endocytic compartment was identified as the major site of degradation. In contrast, an inhibitor of the proteasome had little effect on intracellular peptide integrity. Very remarkably, inhibitors of endolysosomal proteolysis also affected the intracellular distribution of fluorescence, leading to a reduction of fluorescein fluorescence in the cytoplasm. This change in fluorescence distribution was very similar to the one observed after incubation of cells with inhibitors of endosomal acidification. These results indicate that cytoplasmic fluorescence, typically interpreted as CPP entering the cytosol, may originate from proteolytic breakdown products.

INTRODUCTION

The lipid bilayer of the plasma membrane protects the intracellular content from entry of pathogens and molecules that may interfere with cellular functions. Only molecules within a narrow range of molecular size, net charge, and polarity are able to directly cross the plasma membrane (*1*). On the other hand, the introduction of membrane-impermeable molecules into mammalian cells has important applications in biomedical (*2*) as well as in fundamental research (*3, 4*). Applications include the import of siRNAs interfering with gene expression (*5*) or peptides that disrupt molecular interactions in cellular signal transduction (*6*).

Peptide-mediated import has attracted growing attention as a delivery technology during the past decade (for reviews, see *refs* 7−9). Cell-penetrating peptides (CPPs) represent a group of functional peptides with little cell-type specificity. These peptides mediate the noninvasive import of cargo molecules into cells *ex vivo* as well as in animals (*10, 11*). Peptides (*6, 12*), proteins as large as 120 kDa (*11, 13*), oligonucleotides (*14*), plasmids (*15*), siRNA (*16*), peptide nucleic acids (PNAs) (*17*), and even nanoparticles (*18*) have been used as cargo for intracellular delivery. The majority of these types of cargo exert their biological activity inside the cytoplasm or the nucleus of the treated cells.

The amphiphatic and basic penetratin peptide, derived from the third helix of the homeodomain of the *Drosophila* Antennapedia[1]transcription factor, has been widely used as a CPP (*19*). Despite its broad acceptance as a molecular carrier, the mechanism of internalization and intracellular trafficking of the penetratin peptide is still not fully understood. Earlier data demonstrated transfer of penetratin across a pure lipid bilayer (*20*) without forming pores (*20, 21*) independent of endocytosis, but more recently published data have indicated endocytosis as an uptake mechanism for the internalization of the penetratin peptide (*22, 23*).

However, for cationic CPPs taken up by endocytosis, the mechanism by which these molecules are actually released into the cytoplasm still needs to be addressed, as well as the question to which degree proteolytic breakdown occurs during endocytic uptake. So far, only evidence was presented that endosomal acidification is involved in the release into the cytosol (*23, 24*).

The investigation of cellular trafficking and cellular distribution of CPPs has greatly benefited from the incorporation of fluorophores as reporter moieties providing the possibility to follow the fluorescently labeled CPPs in living cells (*25, 26*). Problems associated with the fixation and labeling of CPP-

loaded cells (*25*) can be avoided and loading efficiencies can be compared quantitatively by live cell flow cytometry (*23, 25*).

In order to further address molecular details of intracellular trafficking and breakdown, we synthesized a penetratin analogue that was amino- and carboxy-terminally labeled with 5,6-carboxy-fluorescein (Fluo) and carboxytetramethylrhodamine (Tamra), respectively. Peptides incorporating two different fluorescent dyes have served as sensors for conformational changes (*27, 28*) and proteolytic breakdown (*29, 30*). Förster (Fluorescence) resonance energy transfer (FRET) (*31*) provides a sensitive readout for molecular events affecting the proximity of the reporter groups.

In a former contribution, we applied a doubly labeled cell-penetrating cathepsin substrate to determine proteolytic selectivity (*23*). In this contribution, we have extended this approach to a doubly labeled penetratin. On the basis of a ratiometric protocol, we developed a protocol for flow cytometry to monitor peptide breakdown within living mammalian cells.

By incubating mammalian cells with the doubly labeled peptide in the presence of a variety of protease inhibitors, we were able to assess the contribution of different post-endocytic proteolytic activities from different cellular compartments after endocytic uptake for the penetratin CPP.

EXPERIMENTAL PROCEDURES

Materials. Standard chemicals for peptide chemistry were obtained from Fluka (Deisenhofen, Germany) and Merck (Darmstadt, Germany); solvents were p.a. grade. Fluorenylmethoxycarbonyl (Fmoc)-amino acids were purchased from Novabiochem (Heidelberg, Germany), Senn Chemicals (Dielsdorf, Switzerland), and Orpegen Pharma (Heidelberg, Germany). Fmoc-Lys(Dde)-OH was purchased from Novabiochem (Läufelfingen, Schweiz). Rink amide resin was purchased from Rapp Polymere (Tübingen, Germany). The isomeric mixtures of 5(6)-carboxyfluorescein (Fluo) and 5(6)-carboxytetramethylrhodamine (Tamra)-*N*-succinimidyl ester were supplied by Fluka. Bafilomycin A1 was from Tocris Biotrend (Bristol, UK), chloroquine diphosphate from Fluka, the furin inhibitor (Dec-RVKR-CMK) from Calbiochem (Bad Soden, Germany), lactacystin from Professor Corey (Harvard, University), E-64d from Serva (Heidelberg, Germany), and leupeptin from Bachem (Bubendorf, Switzerland).

Peptide Synthesis. Automated peptide synthesis was performed on an automated peptide synthesizer (RSP5032, Tecan, Hombrechtlikon, Switzerland) using solid-phase Fmoc/tBu-chemistry in 2 mL syringes according to the following protocol: Fmoc-amino acids (12-fold excess) were coupled by *in situ* activation using *N*,*N*′-diisopropylcarbodiimide (DIC)/HOBt in dimethylformamide (DMF) for 90 min followed by removal of the Fmoc-protecting group by treatment with piperidine/DMF (1:4, v/v) twice for 8 min. The resin was washed with DMF (6×) after each coupling and deprotection step. Side chains of Asn and Gln were Trityl (Trt)-protected, the side chains of Lys and Trp were *tert*-butyloxycarbonyl (Boc)-protected, and the side chain of Arg was 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (Pbf)-protected. Peptides were cleaved off the resin by treatment with trifluoro acetic acid (TFA)/triisopropylsilane (TIS)/ethanedithiole/H_2O (92.5:2.5:2.5:2.5, v/v/v/v) for 4 h. Crude peptides were precipitated by adding cold diethyl ether (−20 °C). The precipitated peptides were collected by centrifugation and resuspended in cold diethyl ether. This procedure was repeated twice. Finally, peptides were dissolved in *tert*-butyl alcohol/H_2O (4:1, v/v) and lyophilized 3 times.

Reverse-Phase High-Performance Liquid Chromatography (RP-HPLC). Peptides and conjugates were analyzed by analytical RP-HPLC using a water (0.1% TFA) (solvent A)/ACN (0.1% TFA) (solvent B) gradient on a Waters 600 System (Eschborn, Germany) with detection at 214 nm. The samples were analyzed on an analytical column (Nucleosil 100, 250 × 2 mm, C18 column, 5 μm particle diameter; Grom, Herrenberg, Germany), using a linear gradient from 10% B to 100% B within 30 min (flow rate: 0.3 mL/min). All peptides were purified by preparative RP-HPLC (Nucleosil 300, 250 × 20 mm, C18 column, 10 μm particle diameter; Grom, Herrenberg, Germany) on a Gilson preparative HPLC system (Bad Camberg, Germany), equipped with a 321 Pump and a 156 UV/vis detector, flow rate: 10 mL/min. Gradients were adjusted according to the elution profiles and peak profiles obtained from the analytical HPLC chromatograms. Purities of peptides used in this study were >98% (214 nm, HPLC).

Matrix-Assisted-Laser-Desorption/Ionization−Time-of-Flight-Mass-Spectrometry (MALDI-TOF MS) of Synthetic Peptides. One microliter of 2,5-dihydroxyacetophenone (DHAP) matrix (20 mg of DHAP, 5 mg of ammonium citrate in 1 mL of isopropyl alcohol/H_2O (4:1, v/v)) was mixed with 1 μL of each sample (dissolved in ACN/water (1:1) at a concentration of 1 mg/mL) on a gold target. Measurements were performed using a MALDI-TOF system (G2025A, Hewlett-Packard, Waldbronn, Germany). For signal generation, 20−50 laser shots were added up in the single-shot mode.

Solid-Phase Synthesis of Tamra-Penetratin-Fluo. The doubly labeled peptide Tamra-Penetratin-Fluo was synthesized according to our previously described protocol (*29*) using Fluo(Trt)-Lys-Rink amide resin. The peptide RQIKIWFQNRRMKWKK was assembled on this resin in a 15 μmol scale as described above (*32*). A small fraction of this peptide was cleaved off and analyzed (H-RQIKIWFQNRRMKWKK-εLys-(Fluo)-NH_2 (purity 80% (HPLC, 214 nm), calcd $[M+H]^+$ = 2733.3 Da, found $[M+H]^+$ = 2733.3 Da, determined by MALDI-TOF MS)). Five micromoles of the resin-bound and side chain protected peptide was then reacted with 5(6)-carboxytetramethylrhodamine-*N*-succinimidyl ester (10 μmol, 5.3 mg) in DMF (200 μL) containing DIPEA (25 μmol, 4.3 μL). After 16 h, the resin was thoroughly washed with DMF to remove excess of Tamra. Cleavage and deprotection of the doubly labeled peptide amide were performed as described above. The peptide was dissolved in ACN/water (1:1), lyophilized, and analyzed using RP-HPLC and MALDI-TOF MS. Methionine sulfoxide reduction was performed as described (*33*). The peptide was then purified as described by preparative RP-HPLC (Figure 1).

Peptide Stock Solutions. Peptides were dissolved in DMSO to concentrations of 10 mM. These stock solutions were further diluted 1:20 in ddH_2O. Peptide concentrations were determined on the basis of absorption of the rhodamine label by UV/vis spectroscopy of a further 1:100 dilution in methanol. Absorptions of these solutions were measured at 540 nm (ε = 95 000 L/ (mol·cm)).

Cell Culture. The adherent MC57 fibrosarcoma cell line was grown in a 5% CO_2 humidified atmosphere at 37 °C in RPMI 1640 medium with stabilized glutamine and 2.0 g/L $NaHCO_3$ (PAN Biotech, Aidenbach, Germany) supplemented with 10% fetal calf serum (PAN Biotech), 100 U/mL penicillin, and 100 μg/mL streptomycin (Biochrom, Berlin, Germany). Cells were passaged by trypsinization with trypsin/ethylenediaminetetraacetic acid (EDTA) (0.05/0.02% (w/v)) (Biochrom) in PBS every third to fourth day.

Confocal Laser Scanning Microscopy (CLSM). Confocal laser scanning microscopy was performed on an inverted LSM510 laser scanning microscope (Carl Zeiss, Göttingen, Germany) fitted with a Plan-Apochromat 63× 1.4 N.A. lens. All measurements were performed with living, nonfixed cells.

MC57 cells were seeded at a density of 10 000/well in 8-well chambered cover glasses (Nunc, Wiesbaden, Germany). Two

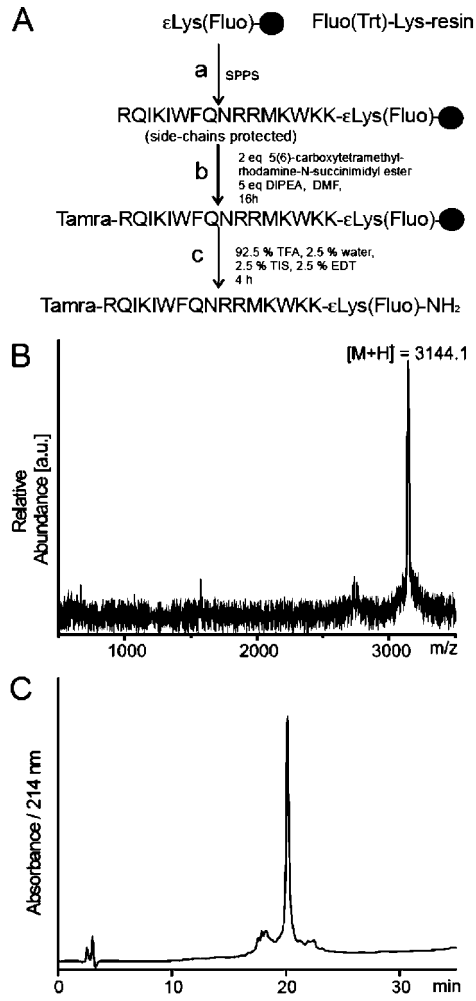

Figure 1. Scheme for the synthesis and analytical data for Tamra-Penetratin-Fluo. (A) Scheme for the synthesis of the doubly labeled penetratin peptide amide Tamra-RQIKIWFQNRRMKWKK-εLys(Fluo)-NH_2 (=Tamra-Penetratin-Fluo). The penetratin peptide is assembled by automated solid-phase peptide synthesis (a) on the free ε-amino group of the N^{α}-carboxyfluorescein-labeled lysyl-Rink amide resin followed by (b) introduction of the second fluorophore at the N-terminus of the solid-phase bound peptide, and (c) cleavage of the peptide amide off the resin and side-chain deprotection. In order to further increase the purity of the raw product, the methionine sulfoxide was subsequently reduced as described previously. (B) MALDI-TOF mass spectrum (theor. $[M+H]^+ = 3145.7$ Da). (C) HPLC elution profile of the crudeTamra-RQIKIWFQNRRMKWKK-εLys(Fluo)-N_2 peptide.

days later, before addition of inhibitors and peptides, cells were washed once with serum-free RPMI 1640. The indicated inhibitor was added in 200 μL serum-free RPMI 1640 30 min before addition of peptides. After 2 h incubation with peptides, images were acquired immediately at RT with excess peptide in the medium.

For double detection of fluorescein and Tamra, the 488 nm line of an argon-ion laser and the light of a 543 nm helium−neon laser were directed over an HFT 488/543 beam splitter, and fluorescence was detected using an NFT 545 beam splitter in combination with a BP 505−530 band-pass filter for fluorescein detection and an LP 560 long-pass filter for Tamra detection.

Fluorescence Emission Spectra. Fluorescence emission spectra were recorded at RT using an LS50B spectrofluorometer (Perkin-Elmer, Norwalk, CT, USA). The excitation and emission bandwidths were set to 10 nm.

Fluorescence Emission Measurements in Cell Lysates and Ratiometric Measurements. MC57 cells were seeded in 6-well plates (Sarstedt, Nümbrecht, Germany) in serum-containing RPMI 1640. Two days later, the confluent cell layer was washed with serum-free RPMI 1640 and incubated with 500 μL serum-free RPMI 1640 (with/without the indicated inhibitor) for 30 min. Then, Tamra-Penetratin-Fluo was added, and after 2 h incubation, cells were washed twice with PBS, detached using EDTA (5 mM)/PBS (10 min at 37 °C), transferred into a fresh tube, and washed twice with 1 mL ice-cold PBS. A small fraction of the cells were used for analysis by flow cytometry. Cell suspensions were then resuspended in 1 mL PBS and split into half. Both suspensions were then transferred into a fresh tube and spun down (14 000 rpm).

Supernatants were removed, and one-half of the cells was lysed in 200 μL NP-40 lysis buffer (0.5% (v/v) NP-40, 150 mM NaCl, 5 mM EDTA, 50 mM TRIS, pH 7.0, containing protease inhibitor cocktail (Roche Diagnostics, Mannheim, Germany)). The lysates were then sonicated and centrifuged for 30 min at 4 °C and 14 000 rpm. Fluorescence emission spectra of the supernatants were recorded immediately (excitation at 492 nm). These lysates were always stored on ice.

The second half of the cells was lysed in 180 μL NP-40 lysis buffer (0.5% (v/v) NP-40, 150 mM NaCl, 5 mM EDTA, 50 mM TRIS, pH 7.0). The lysates were then also sonicated and centrifuged for 30 min at 4 °C and 14 000 rpm. Twenty microliters of proteinase K-solution (10 mg/mL, Sigma, Taufkirchen) were then added to the supernatants. After 16 h digestion, fluorescence emission spectra of the supernatants were recorded (excitation 492 nm) (see Figure 4A).

In order to quantify the absolute amounts of digested Tamra-Penetratin-Fluo in cell lysates, we performed fluorescence emission measurements in lysis buffer as described above based on a standard solution containing different amounts of intact and digested peptide. The ratios (520 nm/575 nm) obtained by this procedure were used to calculate relative amounts of intact and digested substrate.

To prepare standard solutions, Tamra-Penetratin-Fluo (100 nM) was digested at 37 °C with proteinase K (20 μg/mL) in NP-40 lysis buffer (containing 0.5% (v/v) NP-40, 150 mM NaCl, 5 mM EDTA, 50 mM TRIS, pH 7.0). After 5 h, the reaction was stopped by adding PMSF (final concentration 500 μM). Different amounts of this solution and fresh undigested Tamra-Penetratin-Fluo (100 nM in NP-40 lysis buffer, including 500 μM PMSF) were mixed, and fluorescence emission spectra of the solutions were recorded (excitation at 492 nm).

To account for the influence of other constituents of the cell lysates and postlysis proteolysis, we lysed cells that had not been incubated with any peptide or inhibitor in lysis buffer containing various ratios of intact and digested substrate. Different amounts of solutions containing fresh, undigested Tamra-Penetratin-Fluo (100 nM, in NP40 lysis buffer containing 500 μM PMSF) and completely digested Tamra-Penetratin-Fluo according to above-mentioned procedure were mixed (ratios 0/100, 25/75, 50/50, 75/25, 100/0). Protease inhibitor cocktail was then added to all five solutions. Then, these solutions were used for the preparation of cell lysates essentially as described above, and fluorescence emission spectra of the solutions were recorded (excitation at 492 nm). All measurements were performed in duplicate and ratios (520 nm/575 nm) were calculated and plotted. These data were fitted using a linear function. Complete inactivation of proteinase K using PMSF at the indicated concentration was verified in a different experiment (data not shown).

Flow Cytometry. Flow cytometry was performed on a FACS-Calibur (Becton Dickinson, Franklin Lakes, USA). Vital cells were gated on the basis of sideward scatter and forward

scatter. For calculating the fluorescence emission ratios, the median fluorescence intensities of 5000 vital cells were taken.

RESULTS

***In Vitro* Proteolytic Digestion of Tamra-Penetratin-Fluo.** In order to address the intracellular proteolytic breakdown of penetratin (Table 1 A), the peptide was N- and C-terminally labeled with Tamra and fluorescein, respectively (Figure 1A). In previous studies, both fluorophores were demonstrated to be compatible with the uptake of penetratin by mammalian cells (*29, 34*). Assembly of the peptide on a carboxyfluorescein-preloaded resin, followed by N-terminal labeling of the peptide with Tamra-*N*-hydroxy-succinimidyl ester yielded the final product in high purity (85%, Figure 1B,C). The fluorescence of both dyes within the Tamra-Penetratin-Fluo peptide was almost completely quenched (Figure 2A,B). This loss of fluorescence in both channels is most likely attributed to a mechanism involving dimer formation (*28*). As expected, digestion of the peptide by proteinase K enhanced the fluorescence emission of both fluorophores significantly (Figure 2A,B). In order to rule out that the differences in fluorescence emission were caused by the adhesion of the intact peptide to plastic and glass (*35*), the ratio of fluorescein (520 nm) versus rhodamine emission (575 nm) upon excitation at 492 nm was calculated (Figure 2C). This experimental approach renders the detection of changes in the fluorescence spectra robust toward changes in concentration (*36*). The ratio was almost doubled upon proteinase K digestion in HBS buffer from about 1.7 to 3.0. The ratiometric difference between intact and digested peptide was even more pronounced when using NP 40 buffer. Here, the ratio was about 0.3 for the intact peptide and 2.8 for the completely digested peptide and might be due to secondary structure induced by NP 40. Both results validate that, next to a dequenching of both fluorophores, digestion of the peptide also led to a more pronounced increase of fluorescein fluorescence due to a loss of FRET.

Confocal Fluorescence Microscopy of Tamra-Penetratin-Fluo-Incubated Cells. The *in vitro* spectral characteristics demonstrate that Tamra-Penetratin-Fluo can serve as a sensitive sensor for probing the proteolytic integrity of this peptide inside mammalian cells. We therefore performed live cell confocal fluorescence microscopy of murine MC57 cells pulsed with Tamra-Penetratin-Fluo. In these cells, our data indicated that penetratin accesses the cytoplasm in an endocytosis- and acidification-dependent way (*23*). The Tamra-Penetratin-Fluo peptide was taken up efficiently in MC57 cells (Figure 3). A high degree of colocalization for the fluorescence of both fluorophores could be observed in vesicular structures. Little Tamra fluorescence was detectable within the cytoplasm and the nucleus. In contrast, pronounced fluorescein fluorescence was present in these compartments. Furthermore, some vesicular structures contained either Fluo fluorescence or Tamra fluorescence. Similar to the cell-penetrating Cathepsin D substrate, this differential localization indicates proteolytic breakdown within the endocytic compartment and preferential release of fluorescein-labeled fragments into the cytoplasm (*29*).

Endolysosomal Acidification Plays a Major Role in Intracellular Peptide Integrity. The results indicated that penetratin is subject to proteolytic degradation. We therefore intended to determine in more detail the extent of breakdown and the proteases involved in the intracellular degradation of the peptide. For this purpose, we followed our previously developed protocol for the incubation of cells with inhibitors of cellular proteases and quantification of intact peptides in cell lysates (*29*). Generally, there is a concern that, in intact cells, the reduction of fluorescein fluorescence by the acidic conditions in the endosomes (*37*) and concentration quenching set a limit to the quantitative assessment of the proteolytic breakdown using a microscopy approach (*38*).

First, a set of four different inhibitors was selected that affect proteolytic activity in different cellular compartments (Table 1B). Bafilomyin A1 (*39*) and chloroquine (*40*) are widely used inhibitors of endosomal acidification (for review, see *41*). Endolysosomal proteases have an acidic pH optimum. For this reason, these inhibitors also efficiently inhibit endolysosomal proteolysis (*42, 43*). The bacterial metabolite lactacystin was chosen as an inhibitor of peptide degradation within the cytosol by blocking the 20S proteasome (*44*). Furthermore, an inhibitor of the protease furin was included. Furin is ubiquitously expressed and mainly localized in the trans-Golgi network, although some portion of the protease cycles between this compartment and the cell surface. Furin cleaves proteins and peptides within cationic stretches (*45*), and more importantly, furin was demonstrated to cleave the HIV-1 Tat protein, which contains the cationic CPP Tat in its sequence, inside cells (*46*).

MC 57 cells were pulsed with the Tamra-Penetratin-Fluo peptide in the absence and presence of these different inhibitors. After incubation, the cell suspensions were split in half (Figure 4A). One-half of the cell population was lysed in the presence of protease inhibitors to prevent postlysis proteolysis, and fluorescence emission spectra of the cell lysates with excitation of fluorescein were recorded immediately (Figure 4B, left panel). The second half of the cell suspensions were lysed in lysis buffer. Aliquots of the lysates were then digested with proteinase K in order to cleave all peptides present in the lysates before recording emission spectra (Figure 4B, right panel).

For all samples, digestion with proteinase K led to fluorescence emission ratios (520 nm/575 nm) very similar to the value of 2.8 observed for completely digested Tamra-Penetratin-Fluo in NP-40 lysis buffer (Figure 2C). For cells pulsed with peptide in the absence of inhibitor, the ratio was 2.3 indicating degradation of the major part of the peptides inside the cells. Bafilomycin A1 and chloroquine showed the strongest inhibitory effects on peptide degradation. The emission ratios decreased in both cases to about 0.9. Lactacystin and the furin inhibitor showed little, albeit significant, effect on the emission ratios (Figure 4C). These results indicate that the endosomal passage has a major impact on the integrity of the peptide inside the cell, while the proteasome seems to degrade only a rather small fraction of the intracellular peptide.

The Endolysosomal Compartment Is the Major Site of Degradation of Penetratin. Even though bafilomycin A1 and chloroquine are expected to reduce the activity of endolysosomal proteases, at this stage it could not be concluded whether the increased integrity of the peptides caused by both drugs was due to the inhibition of endolysosomal proteases or due to the inhibition of an acidification-dependent entry of intact peptide into the cytoplasm, followed by degradation inside the cytosol (*23*). In the latter case, lactacystin-insensitive cytoplasmic proteases would contribute significantly to the breakdown of the peptide. In order to resolve this issue, peptide-pulsed cells

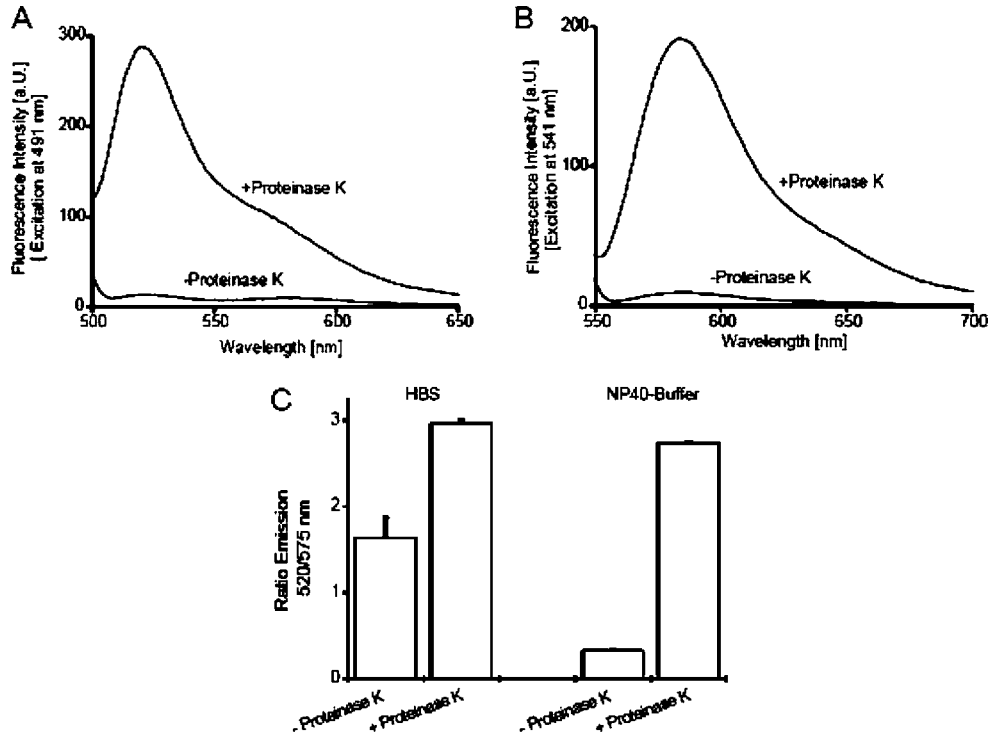

Figure 2. Tamra-Penetratin-Fluo as a proteolytic sensor. Fluorescence emission spectra of Tamra-Penetratin-Fluo (100 nM) in HBS with excitation at (A) 492 nm and (B) 541 nm with (upper curves) and without (lower curves) digestion with proteinase K (100 μg/mL, 1 h). (C) Fluorescence ratios were calculated for the data shown in A (digest in HBS, first two columns) and for an identical digest in NP-40 lysis buffer. Each condition was tested in duplicate; error bars represent the absolute deviations from the mean value.

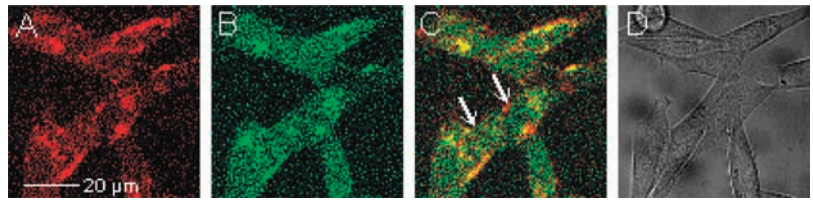

Figure 3. Endocytic uptake and intracellular localization of Tamra-Penetratin-Fluo in MC57 cells. MC57 cells were incubated with serum-free medium containing Tamra-Penetratin-Fluo (3 μM) for 30 min and were then analyzed by multichannel CLSM. Panel A shows the Tamra fluorescence and Panel B the fluorescein fluorescence of the substrate. Panel C shows the overlay of these two channels. Panel D shows the transmission channel.

were incubated with the broadband cysteine protease inhibitors leupeptin (*47*) and E-64d (*48*). Inside the endolysosomal compartment, members of the aspartic and cysteine proteases comprise the major part of protease activity. Most mammalian lysosomal cysteine proteases are cathepsins, although not all cathepsins are cysteine proteases (*49*). Both leupeptin and E-64d reduced the proteolytic degradation of Tamra-Penetratin-Fluo significantly, albeit not as significantly as bafilomycin A1 (Figure 5A).

Finally, we intended to confirm the relevance of these results for intact cells. For this purpose, flow cytometry was employed. Fluorescein was excited with the 488 nm line of the argon ion laser, and the fluorescence of fluorescein and rhodamine was detected in two channels. Especially for the testing of a large number of different conditions, flow cytometry is superior to microscopy-based measurements of intact cells. In this case, different concentrations of E-64d and leupeptin were tested. In cell lysates, for both compounds an increase in inhibitor concentration increased the fraction of intact peptide (Figure 5B). We compared these results to data obtained from flow cytometry using intact cells instead of lysates (Figure 5C). Differences in the ratios determined by both techniques are due to different sizes of the spectral windows and, second, to concentration- and pH-dependent quenching effects of the fluorophores inside the cells. Still, both sets of values exhibited a strong linear correlation (Figure 5D), when the ratios of the FL1 and FL2 emission (corresponding to the intensity of the fluorescein and tamra channel) obtained from flow cytometry were plotted against the corresponding ratios of fluorescence of emissions at 520 and 575 from cell lysates, confirming the applicability of both experimental approaches.

Live Cell Microscopy to Determine the Impact of Inhibitors on the Intracellular Localization of Fluorescence. To further confirm that E-64d and leupeptin exerted their activity on lysosomal proteases, live cell confocal microscopy was performed in the absence and presence of different inhibitors. If the degradation was mediated primarily by endolysosomal cysteine proteases, the colocalization of both fluorophores should increase inside endosomal compartments. Incubation of cells with E-64d increased the degree of colocalization within endocytic vesicles and reduced the cytoplasmic fluorescein fluorescence (Figure 6B). Since bafilomycin A1 had a profound effect on breakdown, we included this inhibitor in this experiment, as well. Bafilomycin A1 also led to a strong reduction in cytoplasmic fluorescence (Figure 6C). Still, the E-64d-induced phenotype was different from the one induced by bafilomycin A1. Instead of being localized in the cell periphery, for

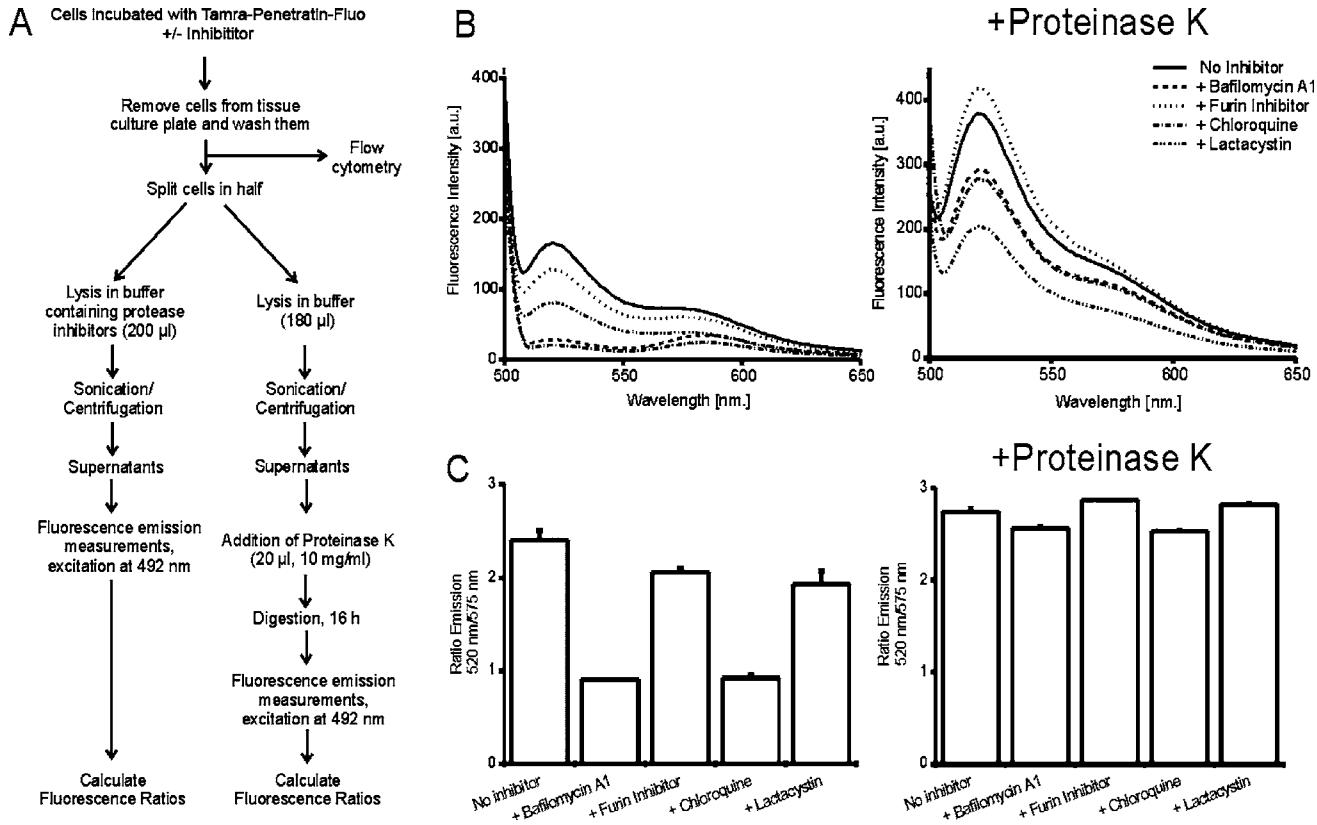

Figure 4. Ratiometric fluorescence emission spectroscopy in cell lysates. (A) Experimental workflow for the measurement of fluorescence emission ratios in cell lysates including the detection of fluorescence by flow cytometry (Figure 5). (B) MC57 cells were incubated with Tamra-Penetratin-Fluo (3 μM) for 2 h in serum-free medium in the absence or presence of different inhibitors (300 nM bafilomycin A1, 50 μM furin inhibitor, and 100 μM chloroquine or 50 μM lactacystin). The inhibitors were added 30 min prior to the peptide. Cells were then washed and removed from the tissue culture plate using EDTA/PBS. Cell lysates were then prepared as described in the Experimental Section. In brief, one-half were lysed in NP-40-lysis buffer containing protease inhibitors. After sonication and centrifugation, fluorescence emission spectra were recorded immediately with excitation at 492 nm (left panel). The other half of the peptide-pulsed cells were lysed in NP-40-lysis buffer. After sonication and centrifugation, proteinase K was added. Lysates were digested for 16 h at 37 °C. Fluorescence emission spectra were then recorded with excitation at 492 nm (right panel). (C) Fluorescence ratios were calculated from the data shown in A. Each condition was tested in duplicate; error bars represent the absolute deviations from the mean value.

bafilomycin A1 peptide-loaded vesicles were concentrated in a region next to the nucleus.

Quantification of Intracellular Breakdown. Our analyses demonstrate that the endocytic uptake has a major impact on peptide integrity. In order to convert the emission ratios into absolute concentrations, we employed solutions containing known fractions of intact and degraded peptide for calibration. By a combination of results obtained for the effects of bafilomycin A1, chloroquine, leupeptin, and E-64d, the amount of peptide in an intact form can be estimated to be around 40% of the total peptide entering the cell (Figure 7).

DISCUSSION

The results presented in this paper provide a quantitative account of the intracellular fate of the cell-penetrating peptide penetratin by a combination of fluorescence microscopy, fluorescence emission spectroscopy, and flow cytometry. The investigation of intracellular proteolysis of proteins and peptides is of high general interest for the cellular import of bioactive molecules. The endolysosomal pathway is the major route of entry and processing of antigens to be presented by antigen-presenting cells. Analysis of the processing of peptides and proteins in the endolysosomal compartment is therefore of major significance, both for understanding the basis of antigen-presentation and for the development of new biologicals as drugs such as immunotherapeutics (*49*).

For CPP, analysis of the intracellular proteolytic fate is of great relevance for understanding the molecular mechanisms by which these peptides mediate uptake and to which extent the uptake mechanism may compromise the activity of these peptides. In the original contribution on penetratin, it was found that this peptide is mainly found in its intact form inside the cell (*19*), but the assay was based on a detection of biotinylated peptides using Western Blot analysis and did not address distribution in different cellular compartments. We cannot exclude that conjugation with two fluorophores affected the trafficking pathway (*50*). However, for their application as mediators of cellular uptake, an analysis of CPP-conjugates may be more relevant than analysis of a CPP alone.

A major advantage of the doubly labeled peptide is that the same molecule can be applied to different fluorescence-based techniques. Therefore, the results can then be cross-validated. We demonstrate that the measurements in the cell lysates strongly correlate with live cell techniques, i.e., flow cytometry and live cell fluorescence microscopy. The strong positive correlation of the flow cytometry measurements with the measurements in cell lysates indicates that, at least for relative comparisons of different conditions, concentration quenching and acidification is less of a concern than initially assumed.

Our results confirm the rather small impact of cytoplasmatic peptide degradation in comparison to endosomal peptidases on the fate of the Tamra-Penetratin-Fluo construct. The amount of intact peptide (Figure 7A) was calculated on the basis of fluorescence ratios (data not shown) and a calibration curve (Figure 7B). Nevertheless, the impact of furin inhibitor that increased the amount of intact peptide by 20% and the 5%

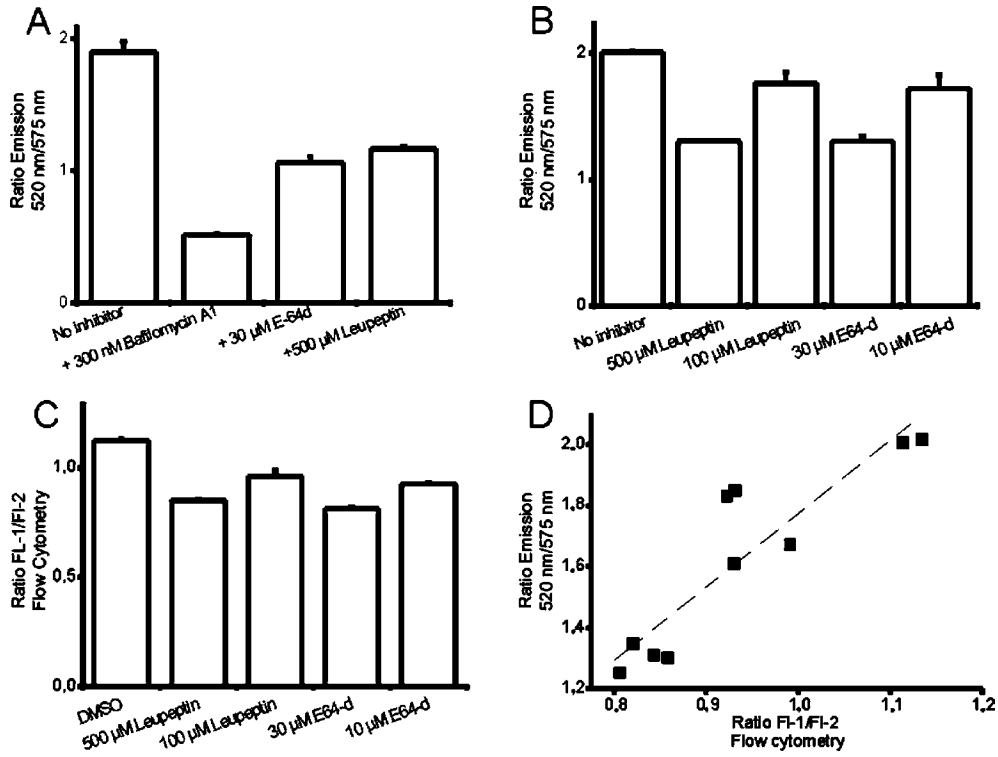

Figure 5. Involvement of cysteine proteases in the cellular degradation of Tamra-Penetratin-Fluo. (A) MC57 cells were incubated with Tamra-Penetratin-Fluo (4 μM) for 2 h in serum-free medium in the absence or presence of different inhibitors, as indicated. The inhibitors were added 30 min prior to the peptide. Cells were then washed, removed from the tissue culture plate using EDTA/PBS. Cells were then washed once more and lysed in NP-40-lysis buffer containing protease inhibitors. After sonication and centrifugation, fluorescence emission spectra were recorded immediately with excitation at 492 nm, and fluorescence ratios were calculated from the data. (B) The same experiment as in (A) was performed applying different concentrations of cysteine proteases inhibitors. Shown are fluorescence ratios in cell lysates; each condition was tested in duplicate; error bars represent the absolute deviations from the mean value. (C) A small fraction of the cells from experiment 5B were subjected to analysis by flow cytometry before lysis and ratios of FL-1 channel vs FL-2 channel were calculated. Each condition was tested in duplicate; error bars represent the absolute deviations from the mean. (D) For each condition, the different ratios obtained in B (measurements in cell lysates) and C (flow cytometric data) were plotted. Here, the individual data points instead of the means of the duplicates are shown.

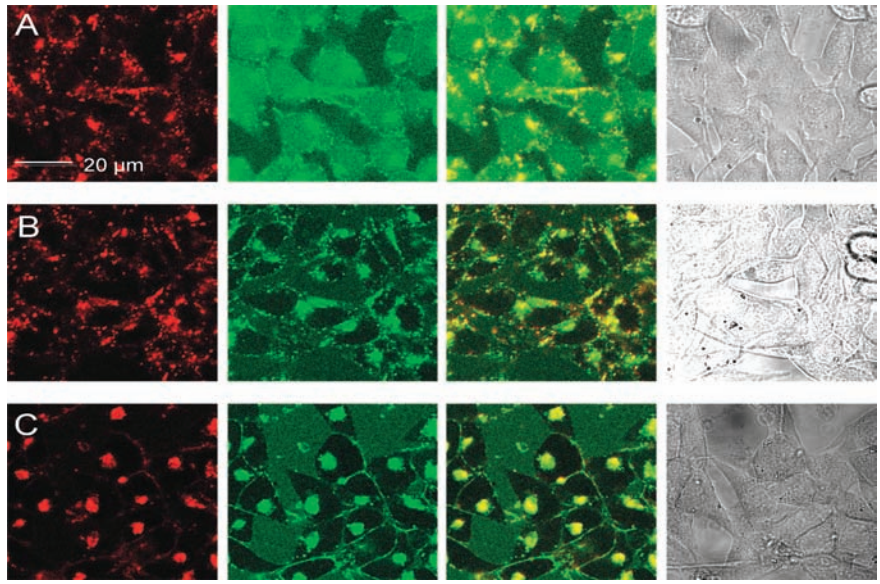

Figure 6. Impact of bafilomycin A1 and a cysteine protease inhibitor on the subcellular distribution of Tamra-Penetratin-Fluo. MC57 cells were incubated with Tamra-Penetratin-Fluo (4 μM) for 2 h in serum-free medium in the absence or presence of different inhibitors (panels A, no inhibitor; panels B, 30 μM E-64d; panels C, 300 nM bafilomycin A1). The inhibitors were added 30 min prior to the peptide. Left panels show the Tamra fluorescence, followed by the fluorescein channel, and the superposition of both fluorescence channels. Right panels show the transmission images.

increase yielded by lactacystin indicate that at least 20−25% of the penetratin analogue leave the endosomal compartment and reach the cytosol and/or the Golgi network where furin is mainly located. The impact of an inhibitor of the furin protease supports an involvement of retrograde transport in the intracellular fate of cationic CPPs such as penetratin (*23*). For the 40% of intact peptide found in the absence of any inhibitor, the origin cannot be resolved. It will be interesting to further investigate

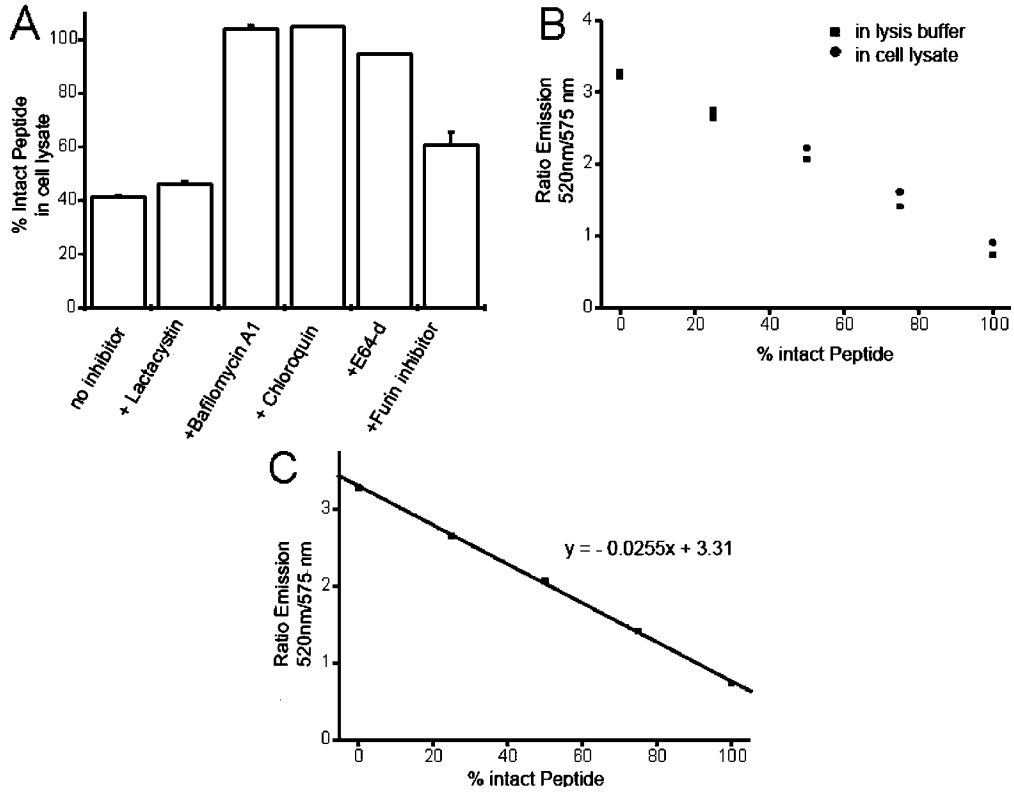

Figure 7. Absolute quantification of intracellular breakdown. For quantification, all experiments were performed in 12-well plates (previous ones were performed in 6-well plates). Ratiometric values obtained in an inhibitor experiment (data not shown) were transformed into percentage of intact peptides (A) using the parameters shown in the equation in (C). (B) A solution containing 100 nM of Tamra-Antp-Fluo was digested with proteinase K in lysis buffer. After blocking protease activity by addition of PMSF, different amounts of this solution and a 100 nM Tamra-Penetratin-Fluo solution were mixed to yield the indicated fractions of digested peptide and fluorescence emission spectra were recorded upon excitation at 492 nm. These solutions were also used to lyse cells in 12-well plates, and emission spectra were recorded and ratios calculated again to show the value of measurements in cell lysates. (C) Linear regression for the ratiometric values obtained for the internal standard solutions in lysis buffer.

whether this material was located in endosomes, still associated with the plasma membrane, or released into the cytoplasm and nucleus.

The results obtained for the doubly labeled penetratin analogue also demonstrate that one needs to be cautious about interpreting results obtained for peptides carrying only one label. Unless, inside the cytoplasm selective dequenching of fluorescein but not rhodamine occurred, the distribution of fluorescein did not reproduce the localization of the intact peptide. Instead, elimination of cytoplasmic fluorescein fluorescence upon incubation with leupeptin and E-64d indicates that this fluorescence rather originated from fluorescein-labeled peptide fragments released into the cytoplasm.

The similarity of effects observed for bafilomycin A1 and the inhibitors of endosomal proteases warrants further investigation into the role of endosomal acidification in endosomal peptide release. In the absence of inhibitors, cytoplasmic fluorescence may originate from fluorescein-labeled fragments released into the cytoplasm and from intact peptide that was released in an acidification-dependent manner. However, in this case, more cytoplasmic rhodamine signal had been expected. Bafilomycin A1 should inhibit both release and degradation, while E-64d and leupeptin should only interfere with degradation. Nevertheless, the role of endosomal acidification has been validated for proteolytically stable (*51*) cell-penetrating β-peptides (*24*) and in a functional assay for the cell-penetrating HIV-Tat protein (*52, 53*).

The calibration of ratiometric measurements by flow cytometry with measurements in cell lysates is a specific strength of the approach described here for defining the intracellular fate of CPPs. It will therefore be highly interesting to extend this approach to further CPPs and their analogues. By using the same pair of fluorophores, differences in proteolytic profiles will allow valuable conclusions about differences in trafficking routes.

ACKNOWLEDGMENT

We gratefully acknowledge the technical assistance of Nicole Sessler in peptide synthesis and thank Günther Jung for providing excellent facilities in peptide chemistry and instrumental analytics. Synthesis and In Vitro Testing of New Potent Polyacridine−Melittin Gene Delivery Peptides

Nicholas J. Baumhover, Kevin Anderson, Christian A. Fernandez, and Kevin G. Rice*

Divisions of Medicinal and Natural Products Chemistry and Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242. Received July 14, 2009; Revised Manuscript Received October 28, 2009

The combination of a polyacridine peptide modified with a melittin fusogenic peptide results in a potent gene transfer agent. Polyacridine peptides of the general formula $(Acr\text{-}X)_n$-Cys were prepared by solid-phase peptide synthesis, where Acr is Lys modified on its ε-amine with acridine, X is Arg, Leu, or Lys and n is 2, 3, or 4 repeats. The Cys residue was modified by either a maleimide−melittin or a thiolpyridine-Cys-melittin fusogenic peptide resulting in reducible or non-reducible polyacridine−melittin peptides. Hemolysis assays established that polyacridine−melittin peptides retained their membrane lytic potency relative to melittin at pH 7.4 and 5. When combined with plasmid DNA, the membrane lytic potency of polyacridine−melittin peptides was neutralized. Gene transfer experiments in multiple cell lines established that polyacridine−melittin peptides mediate expression as efficiently as PEI. The expression was very dependent upon a disulfide bond linking polyacridine to melittin. The gene transfer was most efficient when X is Arg and n is 3 or 4 repeats. These studies establish polyacridine peptides as a novel DNA binding anchor peptide.

INTRODUCTION

An important element of many polyplex nonviral gene delivery systems is a releasable fusogenic peptide that can effect endosomal lysis (*1*). The endosomal escape of DNA is especially essential for receptor-targeted gene delivery systems to avoid polyplex degradation by the lysosome (*2*−*4*).

To improve the endosomal escape of DNA, several prior studies have incorporated fusogenic peptides, including GALA, KALA, HA2, JTS-1, and melittin, into a nonviral gene delivery system (*5*−*11*). Most applications in gene delivery have utilized melittin because of its relative ease of chemical synthesis and because its mechanism of membrane lysis has been extensively studied (*12*−*14*). Melittin has been covalently attached to polylysine, PEI, and cationic lipids and even self-polymerized by terminal disulfide bonds and demonstrated to increase in vitro gene transfer efficiency (*4, 10, 11, 15, 16*).

While DNA anchoring polymers such as PEI, polylysine, dendrimers, and chitosan are known to bind ionically to the phosphate backbone of plasmid DNA, this strategy leads to the formation of cationic polyplexes that favor in vitro gene transfer, but to a much lesser degree in vivo gene transfer (*17*). This is partly because positively charged polyplexes bind non-specifically to proteins and cells (*18*). Attempts at masking the charge with PEG still results in a residual positive charge as measured by zeta potential (*19, 20*). The non-specific binding of PEGylated cation polyplexes in vivo complicates strategies that attempt to combine a receptor ligand and releasable fusogenic peptide into a non-viral delivery system (*21, 22*). Consequently, it would be beneficial to reversibly bind fusogenic peptides, receptor ligand, and PEG to DNA while simultaneously controlling the charge of polyplexes. Likewise, it would be advantageous if the DNA binding anchor were sufficiently small in size to allow for its chemical manipulation and specific functionalization with PEG, targeting ligand, and fusogenic peptide (*22*).

Polyacridine peptides have been shown to reversibly bind with high affinity by intercalating into double-stranded DNA (*23*). An early study by Szoka demonstrated the synthesis of a divalent acridine neoglycopeptide for delivery of DNA to the cells expressing the asialoglycoprotein receptor (*24*). More recently, polyacridine-nuclear localization sequences (NLS) possessing up to three acridines were shown to improve in vitro gene transfer (*25, 26*).

However, to date, a polyacridine DNA binding peptide has not been substituted with a fusogenic peptide. The new strategy described herein demonstrates the synthesis of polyacridine−melittin as a DNA binding peptide and establishes its efficacy as a potent in vitro gene transfer agent. The results demonstrate that short polyacridine anchor peptides bind to plasmid DNA with sufficient affinity to deliver melittin in vitro and have the potential to control DNA polyplex charge to allow improved in vivo gene delivery.

MATERIALS AND METHODS

Unsubstituted Wang resin for peptide synthesis, 9-hydroxybenzotriazole, Fmoc-protected amino acids, *O*-(benzotriazole)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU), 1,3-diisopropylcarbodiimide (DIC), Fmoc-Lysine-OH, and *N*-methyl-2-pyrrolidinone (NMP) were obtained from Advanced ChemTech (Lexington, KY). *N*,*N*-Dimethylformamide (DMF), trifluoroacetic acid (TFA), and acetonitrile were purchased from Fisher Scientific (Pittsburgh, PA). Diisopropylethylamine, piperdine, acetic anhydride, tris(2-carboxyethyl)-phosphine hydrochloride (TCEP), 9-chloroacridine, maleic anhydride, 2,2′-dithiodipyridine (DTDP), and thiazole orange were obtained from Sigma Chemical Co. (St. Louis, MO). Polyethylene amine (PEI 25 KDa) was purchased from Aldrich (Milwaukee, WI). D-Luciferin and luciferase from *Photinus pyralis* were obtained from Roche Applied Science (Indianapolis, IN). HepG2, CHO, and 3T3 cells were acquired from the American Type Culture Collection (Manassas, VA). Inactivated qualified fetal bovine serum (FBS) was from Life Technologies, Inc. (Carlsbad, CA). BCA reagent was purchased from Pierce (Rockford, IL). pGL3 control vector, a 5.3 kb luciferase plasmid containing a SV40 promoter and enhancer, was obtained from Promega (Madison,

WI). pGL3 was amplified in a DH5α strain of *Escherichia coli* and purified according to manufacturer's instructions.

Synthesis of 9-Phenoxyacridine and Fmoc Lysine (Acridine). 9-Phenoxyacridine was synthesized with modification from the methods of Tung et al. (*27*). Briefly, 12 g of phenol (127.5 mmol) and 0.72 g of sodium hydroxide (18 mmol) were heated to 100 °C. To the liquefied phenol, 2.8 g of 9-chloroacridine (13.105 mmol) was added and stirred vigorously for 1.5 h. The reaction was quenched by the addition of 100 mL of 2 M sodium hydroxide, then allowed to sit at RT overnight. A yellow precipitate was filtered, washed with water, and dried in vacuo (3.4822 g, 12.835 mmol, 97.9%, m.p. 123−124 °C, TLC 15:5:1:0.5 ethyl acetate/methanol/hexane/acetic acid, $R_f = 0.18$). ^{1}H NMR (DMSO-d_6) δ 8.23 (d, 2H), 8.04 (d, 2H), 7.88 (t, 2H), 7.59 (t, 2H), 7.32 (t, 2H), 7.08 (t, 1H), 6.88 (d 2H).

Fmoc-Lysine(Acridine)-OH was prepared by adding 2.18 g of Fmoc-Lys-OH (5.91 mmol) in liquid phenol (6.781 g, 73.01 mmol) to 9-phenoxyacridine (3 g, 11.06 mmol), then heated at 60 °C for 4 h under an argon atmosphere. Diethyl ether (80 mL) was then added while stirring vigorously until a yellow precipitate formed that was immediately recovered by filtration and washed repeatedly with diethyl ether. The product was allowed to dry overnight under vacuum (2.90 g, 5.32 mmol, 90%), m.p. 135−140 °C, TLC 1:1, 0.1 v/v % TFA/acetonitrile, $R_f = 0.75$). MS: $(M + H^+)^{1+} = 545.5$ *m/z*. ^{1}H NMR (DMSO-d_6) δ 6.7−7.8 (m, 17H), 3.6−3.95 (m, 2H), 3.25−3.53 (br, 3H), 2,06 (m, 1H), 0.8−1.5 (m, 6H).

Synthesis of Maleimide Glycine (Mal-Gly-OH). Glycine (5 g, 66.6 mmol) and maleic anhydride (6.6 g, 66.6 mmol) were suspended in 80 mL of acetic acid and allowed to react for 3 h at RT. The resulting white precipitate was collected by filtration, washed with cold water, and dried (10.95 g, 63.3 mmol, 95%, m.p. 187−189 °C, TLC 2:1:1:1 isopropyl alcohol/acetic acid/ethyl acetate/water, $R_f = 0.5$). The glycine maleic acid intermediate was characterized by proton NMR (300 MHz, DMSO-d_6): $\delta = 9.2$ (s, 1H), 6.397 (d, 1H, $j = 8.57$ Hz), 6.310 (d, 2H, $j = 12.86$ Hz), 2.0 (d, 2H, $j = 6.86$ Hz).

Glycine maleamic acid (5.2 g, 30.04 mmol) and 2.1 equiv of triethylamine (6.37 g, 63 mmol) were refluxed for 3 h in 500 mL toluene with removal of water with a Dean−Stark apparatus. Upon reaction completion, the toluene solution was decanted and dried. The resulting solid was acidified with 2 M HCl, extracted with ethyl acetate, dried with $MgSO_4$, and evaporated to yield Mal-Gly-OH (1.7 g, 11 mmol, 36.5%, m.p. 99−110 °C, TLC 2:1:1:1 isopropyl alcohol/acetic acid/ethyl acetate/water, $R_f = 0.72$). The product was characterized by proton NMR (300 MHz, DMSO-d_6): $\delta = 7.108$ (s, 2H), 4.105 (s, 2H) (*28*).

Synthesis and Characterization of Polyacridine−Melittin Analogues. Melittin analogues, polyacridine peptides, and control peptides were prepared by solid-phase peptide synthesis using standard Fmoc procedures with 9-hydroxybenzotriazole and HBTU double couplings on a 30 μmol scale on an Advanced ChemTech APEX 396 synthesizer. Mal-melittin was prepared by coupling Mal-Gly-OH to the N-terminus of sidechain protected full-length melittin on resin utilizing a 6-fold excess of Mal-Gly-OH, DIC, and HOBt, reacted for 4 h while stirring. The resin was filtered; washed with DMF, DCM, and methanol; then dried. Peptides were removed from resin and sidechain deprotected using a cleavage cocktail of TFA/triisoproylsilane/water (95:2.5:2.5 v/v/v) for 3 h followed by precipitation in cold ether. Precipitates were centrifuged for 10 min at 4000 rpm at 4 °C and the supernatant decanted. Peptides were then reconstituted with 0.1 v/v % TFA and purified to homogeneity on RP-HPLC by injecting 0.5−2 μmol onto a Vydac C18 semipreparative column (2 × 25 cm) eluted at 10 mL/min with 0.1 v/v % TFA with an acetonitrile gradient of 20−45 v/v % over 30 min while monitoring tryptophan (Abs 280 nm) or acridine (Abs 409 nm). The major peak was collected and pooled from multiple runs, concentrated by rotary evaporation, lyophilized, and stored at −20 °C. Purified peptides were reconstituted in 0.1% v/v TFA and quantified by absorbance (tryptophan $\varepsilon_{280nm} = 5600$ M^{-1} cm^{-1}, thiolpyridine, and tryptophan $\varepsilon_{280nm} = 10\,915$ M^{-1} cm^{-1}, or acridine $\varepsilon_{409nm} = 9266$ M^{-1} cm^{-1}) to determine isolated yield. Purified peptides were characterized by LC-MS by injecting 2 nmol onto a Vydac C18 analytical column (0.47 × 25 cm) eluted at 0.7 mL/min with 0.1 v/v % TFA and an acetonitrile gradient of 10−55 v/v% over 30 min while acquiring ESI-MS in the positive ion mode.

Cys-melittin was reacted with 10 equiv of DTDP in 2-propanol/2 N acetic acid (10:3) for 8 h at RT to generate the thiolpyridine protected peptide. The reaction mixture was concentrated by rotary evaporation and applied to a Sephadex G-10 column eluted (2.5 × 50 cm) with 0.1 v/v % TFA while monitoring absorbance at 280 nm to remove excess DTDP. The peptide peak fractions were pooled, concentrated, lyophilized, and purified to homogeneity by RP-HPLC as described previously.

Poly(Acr-X)$_n$-SS-melittin and poly(Acr-X)$_n$-Mal-melittin peptides were synthesized on a 2 μmol scale based on melittin, using 1.7 equiv (3.4 μmol) of the reduced poly(Acr-X)$_n$-Cys, where X equals Arg, Lys, or Leu. Mal-melittin (2 μmol) was prepared in 8 mL of 10 mM ammonium acetate pH 5 and added to poly(Acr-X)$_n$-Cys and 2 mL of methanol to facilitate solubility. The reaction occurred over 12 h at RT as determined by analyzing aliquots by LC-MS. At completion, the reaction mixture was concentrated by rotary evaporation and lyophilized prior to purification of poly(Acr-X)$_n$-Mal-melittin by RP-HPLC eluted with 0.1 v/v % TFA and acetonitrile gradient (35−45% over 30 min) while detecting at 409 nm.

Alternatively, thiolpyridine-Cys-melittin (2 μmol) was prepared in 8 mL of 10 mM ammonium acetate pH 6 and added to 3.4 μmol poly(Acr-X)$_n$-Cys in 2 mL of methanol. After 24 h, poly(Acr-X)$_n$-SS-melittin was purified and characterized by LC-MS as described above.

Polyacridine−Melittin Hemolysis Assay. Whole blood was obtained from male ICR mice by heart puncture with heparinized 22G needles and collected in conical tubes containing 10 mL of 0.15 M PBS (pH 7.4) prewarmed to 37 °C. Erythrocytes were immediately separated from plasma by centrifugation at 2000 rpm for 2 min, washed three times with 10 mL of PBS, and then diluted to 1.5 × 10^8 cells/mL. Peptides were prepared at 15 μM and serially diluted to 10−0.01 μM, after which 100 μL was pipetted in triplicate into a MultiScreenHTS BV 96-well plate. Erythrocytes (50 μL, 7.5 × 10^6 cells) were added to the peptides and incubated at 37 °C for 1 h followed by filtration on a Multiscreen vacuum manifold (Millipore Corporation, Billerica, MA). The filtrate was measured for abs$_{410nm}$ on a Biotech plate reader (Biotech Instruments Incorporated., Winooski, VT) and compared to the 100% hemolysis caused by replacing PBS with water. Peptide DNA polyplexes (1.5 nmols and 7.5 μg pGL3) were also assayed for hemolysis as described above.

Formulation and Characterization of Polyacridine−Melittin Polyplexes. The relative binding affinity of peptides for DNA was determined by a fluorophore exclusion assay (*29*). pGL3 (200 μL of 4 μg/mL in 5 mM Hepes pH 7.5 containing 0.1 μM thiazole orange) was combined with 0, 0.05, 0.1, 0.25, 0.35, 0.5, 1, and 2 nmols of peptide in 300 μL of Hepes and allowed to bind at RT for 30 min. Thiazole orange fluorescence was measured using an LS50B fluorometer (Perkin-Elmer, U.K.) by exciting at 498 nm while monitoring emission at 546 nm with the slit widths set at 10 nm. A fluorescence blank of thiazole

orange in the absence of DNA was subtracted from all values before data analysis. The data are presented as nmol of peptide per μg of DNA versus the percent fluorescence intensity plus/minus the standard deviation determined by three independent measurements.

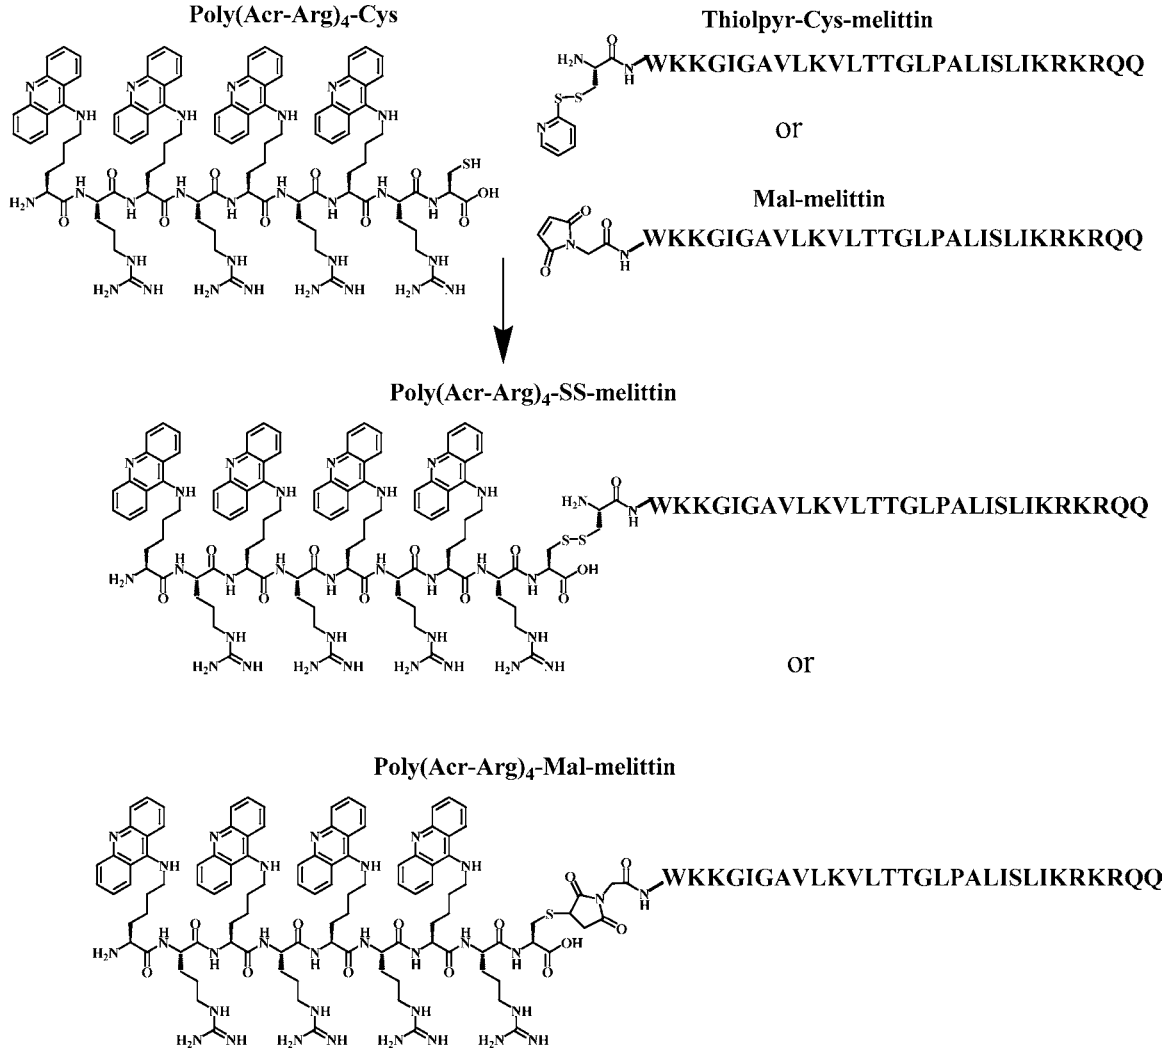
Particle size and zeta potential were determined by preparing 2 mL of polyplex in 5 mM Hepes pH 7.5 at a DNA concentration of 30 μg/mL with 15 nmols/mL of peptide (0.5 nmol of peptide per μg of DNA). Particle size was measured by quasi-elastic light scattering (QELS) at a scatter angle of 90° on a Brookhaven ZetaPlus particle sizer (Brookhaven Instruments Corporation, NY). The zeta potential was determined as the mean of ten measurements immediately following acquisition of the particle size.

Polyacridine−melittin DNA polyplexes were prepared at 0.5 nmol of peptide per μg of DNA at a concentration of 100 μg per mL of DNA and directly deposited on a freshly cleaved mica surface and allowed to bind for 10 min prior to washing with deionized water (*30*). Alternatively, naked DNA (100 μg pGL3 per mL) was prepared in 10 mM Tris, 1 mM EDTA pH 8, then diluted to 1 μg per mL in 40 mM Hepes 5 mM nickel chloride pH 6.7, and deposited on a fresh cleaved mica surface for 10 min followed by washing with deionized water. An Asylum atomic force microscope (AFM) MFP3D (Santa Barbara, CA) was operated in the AC-mode in order to image either naked DNA or DNA polyplexes using a silicon cantilever (Ultrasharp NSC15/AIBS, Mikro Masch).

Polyacridine−Melittin Polyplex Toxicity. The in vitro toxicity of polyacridine−melittin polyplexes was evaluated by MTT assay (*31*). CHO, HepG2, and 3T3 cells were plated on 6 × 35 mm wells at 5 × 10^5 cells/well and grown to 40−70% confluency. The media was replaced with 2 mL of fresh MEM supplemented with 2% FBS and the cells treated with 10 μg of DNA polyplex (0.5 nmol peptide/μg DNA) in HBM (HBM; 5 mM Hepes, 0.27 M mannitol, pH 7.5). After 6 h, the media was replaced with fresh culture media and grown an additional 18 h. Alternatively, cells were treated with DNA polyplexes for 24 h. The media was replaced with 2 mL of fresh media and 500 μL of 0.5% (w/v) 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) in PBS solution and allowed to incubate at 37 °C for 1 h to let formazan crystals form. The media containing MTT was removed, and the crystals dissolved by the addition of 2 mL of dimethyl sulfoxide (DMSO) and 250 μL Sorenson's Glycine Buffer, then measured by absorbance 595 nm on a microplate reader. The percent viability was determined relative to untreated cells.

In Vitro Gene Transfer of Polyacridine−Melittin DNA Polyplexes. HepG2 cells (5 × 10^5) were plated on 6 × 35 mm wells and grown to approximately 50% confluency. Transfections were performed in MEM supplemented with either 2% or 10% FBS, sodium pyruvate (1 mM), and penicillin and streptomycin (100 U and 100 μg/mL). Polyplexes were prepared at a DNA concentration of 30 μg/mL and a stoichiometry of 0.5 nmol peptide per μg of DNA in HBM (HBM; 5 mM Hepes, 0.27 M mannitol, pH 7.5). Polyplexes (10 μg of DNA in 0.3 mL of HBM) were added dropwise to wells in triplicate and incubated 24 h. After 24 h, the cells were washed twice with 2 mL of ice-cold phosphate-buffered saline (Ca^{2+}- and Mg^{2+}-free) and then treated with 0.5 mL of lysis buffer (25 mM Tris chloride, pH 7.8, 1 mM EDTA, 8 mM magnesium chloride, and 1% Triton X-100) for 10 min at 4 °C. Cell lysates were scraped, transferred to 1.5 mL microcentrifuge tubes, and centrifuged for 10 min at 13,000 *g* at 4 °C to pellet cell debris. Lysis buffer (300 μL) and sodium-ATP (4.3 μL of a 165 mM solution at pH 7, 4 °C) were combined in a test tube, mixed briefly, and immediately placed in the luminometer. Luciferase relative light units were measured by a Lumat LB 9501 (Berthold Systems, Germany) with 10 s integration after automatic injection of 100 μL of 0.5 mM D-luciferin. The relative light units were converted to fmol using a standard curve generated by adding a known amount of luciferase to 35 mm wells containing 50% confluent HepG2 cells. The resulting standard curve had an average slope of 2.6 × 10^4 RLU/fmol enzyme. Protein concentrations were measured by a BCA assay using bovine serum albumin as a standard (*32*). The amount of luciferase recovered in each sample was normalized to mg of protein and reported as the mean and standard deviation obtained from triplicate transfections. PEI pGL3 polyplexes were prepared by mixing 35 μg of DNA in 525 μL of HBM with 43.8 μg PEI in 525 μL of HBM while vortexing to create DNA complexes possessing a charge ratio (NH_4^+/PO_4^-) of 9:1. Cells were transfected with 10 μg PEI−DNA polyplexes as previously described. CHO and 3T3 (5 × 10^5) cells were plated on 6 × 35 mm wells and grown to ca. 50% confluency and then transfected as described above.

RESULTS



Synthetic Strategy for Polyacridine−Melittin. Naturally occurring melittin isolated from bee venom is a 26 amino acid peptide amide composed of two α-helices conjoined through an interrupting proline (*12*−*14*). Numerous studies have been conducted to investigate the mechanism and sequence specificity of melittin's membrane lytic activity.

Natural melittin contains a single aromatic Trp at residue 8 and does not contain a Cys residue. To improve the synthesis of polyacridine−melittin, we replaced Trp 8 with Leu, and reinstalled a single Trp near the N-terminus in Cys-Trp-Lys-Lys. The reactivity of the Cys residue was increased by flanking Lys residues. This also allowed selective chromatographic detection of full-length melittin at 280 nm. These modifications resulted in a Cys-melittin analogue, CWKKGIGAVLKVLTTGLPALISLIKRKRQQ, that SOPMA analysis (*33*) predicted to maintain α-helical character. A similar Mal-melittin analogue (Mal-GWKKGIGAVLKVLTTGLPALISLIKRKRQQ), possessing an N-terminal maleimide-glycine (Mal-G) in place of Cys, was also prepared.

Polyacridine and melittin peptides were synthesized using HBTU/HOBt with increased coupling efficiency compared to DIC. Early attempts to synthesize polyacridine peptides using DIC resulted in heterogeneous mixtures of truncated peptides with minimal recovery of full-length peptide. The identity of the spacing amino acid between Lys-acridine residue significantly influenced the synthetic yield. Bulky amino acid side chains and protecting groups such as Lys-Boc, Phe-Trt, Leu, Glu-OBut, and Arg-Pbf were well-tolerated, whereas Gly surprisingly was not. Polyacridine peptides possess a C-terminal Cys to accommodate bioconjugation to Cys-melittin or Mal-melittin. Polyacridine peptides possessing an alternating Lys-Acr (Acr) spaced by Arg, Lys, or Leu were designed to influence the charge character of the anchor peptide (Scheme 1 and Table 1). The lengths of polyacridine peptides were systematically varied to possess 2−4 Acr-Arg repeats to examine the influence of affinity. Polyacridine nona-peptides were routinely obtained in 30−35% purified yield with >95% purity.

Polyacridine−melittin peptides were designed to possess either a reducible dithiol or a nonreducible maleimide linkage (Scheme 1 and Table 1). The most expedient synthetic route proved to be cleavage of Cys-melittin from the resin, followed by modification with dithiol dipyridine to produce a thiolpyr-melittin. The RP-HPLC monitoring of the reaction of thiolpyr-melittin with poly(Acr-Arg)$_4$-Cys is illustrated in Figure 1A and B. The desired poly(Acr-Arg)$_4$-SS-melittin product is formed with complete consumption of thiolpyr-melittin, along with formation of a poly(Acr-Arg)$_4$-Cys$_2$ byproduct (Figure 1B). This

Scheme 1. Synthesis of Polyacridine−Melittin Peptides

Thiolpyr-melittin is reacted with the DNA binding anchor peptide poly(Acr-Arg)$_4$-Cys at pH 6 to yield poly(Acr-Arg)$_4$-SS-melittin as a reducible gene transfer polyacridine melittin peptide. Alternatively, Mal-melittin is reacted with poly(Acr-Arg)$_4$-Cys at pH 5 to yield a non-reducible poly(Acr-Arg)$_4$-Mal-melittin gene transfer peptide. In each case, Acr refers to a Lys substituted on its ε-amine with acridine. The Arg was substituted with Lys and Leu to produce DNA binding anchor peptides with different affinity. The poly(Acr-Arg)$_n$ was also varied from $n = 2-4$ repeats.

synthetic route resulted in poly(Acr-X)$_n$-SS-melittin in 35−50% purified yield at >95% purity as illustrated by LC-MS analysis of purified poly(Acr-Arg)$_4$-SS-melittin (Figure 1C). ESI-MS was used to establish structure based on the triple and quadruple charged positive ions corresponding to the calculated mass of the desired polyacridine−melittin peptide (Figure 1C, inset). The release of melittin from poly(Acr-Arg)$_4$-SS-melittin was established by reaction with TCEP to regenerate poly(Acr-Arg)$_4$-Cys and Cys-melittin peptide peaks (Figure 1D).

Poly(Acr-X)$_4$-Mal-melittin peptides, where X is Arg, Lys, or Leu, were synthesized to compare their gene transfer properties with poly(Acr-Arg)$_4$-SS-melittin (Scheme 1 and Table 1). The synthetic strategy utilized Gly-maleimide that was coupled to the N-terminus of the fully protected melittin peptide on resin (Scheme 1). Upon workup, this yielded Mal-melittin that was then directly conjugated to poly(Acr-X)$_n$-Cys peptides. The conjugation of Mal-melittin with poly(Acr-Arg)$_4$-Cys was monitored by RP-HPLC resulting in the complete consumption of Mal-melittin and the formation of poly(Acr-Arg)$_4$-Mal-melittin. Purification of poly(Acr-Arg)$_4$-Mal-melittin was achieved with a final yield of 35% and >95% purity. Reducible and nonreducible polyacridine−melittin peptides with Acr-Arg repeat of 2 and 3 were synthesized with similar yield and purity, and characterized by LC-MS (Table 1).

Physical Properties of Polyacridine−Melittin DNA Polyplexes. The binding of polyacridine−melittin peptides to pGL3 was investigated using a thiazole orange exclusion assay (*29*). Polyacridine−melittin peptides were found to compete for intercalation and displace thiazole orange resulting in a decrease in fluorescence intensity. When titrated at increasing concentration, the fluorescence decreased until an asymptote was reached at an equivalence point (Figure 2A). Analysis of the DNA binding affinity of poly(Acr-Arg)$_4$-Cys established an equivalence point at approximately 0.4 nmol peptide per μg of DNA. By comparison, Cys-melittin demonstrated weaker binding and was not able to fully exclude thiazole orange, only approaching an equivalence point at approximately 0.5 nmol of peptide per μg of DNA (Figure 2A). Alternatively, poly(Acr-Arg)$_4$-SS-melittin demonstrated higher affinity resulting in an equivalence point at approximately 0.25 nmol of peptide per μg of DNA. This affinity is comparable to that afforded by a Cys-Trp-Lys$_{18}$ peptide using the same assay (*29*).

Comparison of poly(Acr-Arg)$_{2-4}$-SS-melittin demonstrated nearly equivalent affinity for Acr-Arg repeats of 3 and 4, but

[a] Calculated and observed mass as determined by ESI LC-MS. [b] RBC hemolysis at pH 7.4 and 5.0. [c] N.D. = not determined.

less affinity afforded for a repeat of 2 (Figure 2B). Direct comparison of the DNA binding affinity of poly(Acr-Arg)$_4$-SS-melittin with poly(Acr-Lys)$_4$-SS-melittin and poly(Acr-Leu)$_4$-SS-melittin established that there was a negligible difference, with each producing fully complexed polyplexes at 0.3 nmol per μg of pGL3 (Figure 2C).

The particle size and zeta potential of polyacridine−melittin polyplexes were determined by QELS analysis (Table 2). Poly(Acr-Arg)$_4$-SS-melittin and poly(Acr-Arg)$_4$-Mal-melittin produced polyplexes of 79−84 nm average diameter, respectively. Comparison of the size of polyplexes prepared with poly(Acr-Arg)$_3$-SS-melittin (126 nm) and poly(Acr-Arg)$_2$-SS-melittin (737 nm) established that shorter repeats produced larger particle size (Table 2). This result is consistent with earlier findings that indicated that shorter, low-affinity polylysine peptides (<13 residues) produced larger polyplexes, whereas polylysine of 18 repeats or longer produced polyplexes of approximately 80 nm in diameter.

Substitution of the spacing Arg for Lys or Leu in Acr-Arg repeats resulted in a minimal change in particle size (Table 2). This supports the hypothesis that polyintercalation, and not ionic binding, is primarily responsible for the binding affinity to DNA. To test this hypothesis, an analogue was prepared that replaced the acridine modified Lys with an acetyl on the ε-amine of lysine resulting in poly(Lys(Ac)-Arg)$_4$-SS-melittin. This analogue produced polyplexes of average diameter of 177 nm, suggesting a significantly lower affinity (Table 2).

To further validate the change in particle size determined by QELS, polyplexes were analyzed by atomic force microscopy (AFM) (*30*). Analysis of pGL3 by AFM demonstrated an open structure occupying 0.5−1 μm with no single morphology (Figure 3A). Polyplexes prepared with poly(Acr-Arg)$_2$-SS-melittin appeared to form clusters composed of several individual particles that account for the larger size determined by QELS (Figure 3B). In contrast, the AFM images for polyplexes prepared with poly(Acr-Arg)$_4$-SS-melttin (Figure 3C), poly(Acr-Leu)$_4$-SS-melittin (Figure 3D), and poly(Acr-Lys)$_4$-SS-melittin (Figure 3E) all appeared to be less aggregated resulting in overall smaller particle size. It is interesting to note that the zeta potentials of polyacridine−melittin polyplexes containing a spacing Arg, Lys, or Leu were approximately +25 mV (Table 2). This result indicated that the charge on melittin strongly influenced the overall charge of polyplexes prepared with different anchoring peptides.

Biological Activity of Polyacridine−Melittin DNA Polyplexes. The membrane lytic potency of polyacridine−melittin peptides were investigated using a RBC hemolysis assay (*9*). As anticipated, poly(Acr-X)$_4$-Cys anchor peptides alone were inactive in membrane lysis. Alternatively, modification of the N-terminus of natural melittin with Cys-Trp-Lys-Lys and substitution of Leu for Trp 8 to generate Cys-melittin, resulted in retention of RBC hemolytic (HL_{50}) potency at pH 7.4 relative to natural melittin (Figure 4A). Likewise, the hemolytic potency of poly(Acr-Arg)$_4$-SS-melittin was comparable to Cys-melittin, indicating the attachment of the polyacridine anchor had a negligible influence on the membrane lytic activity of Cys-melittin. The results for polyacridine−melittin peptides possessing either a reducible or non-reducible linkage are summarized in Table 1, establishing their nearly equivalent hemolytic potency at pH 7.4.

The hemolytic potency of polyacridine melittin peptides was also determined at pH 5 to simulate the pH of the endosome. In contrast to an earlier finding that C and N-terminal modification of natural melittin with Cys-(Lys)$_4$ resulted in the complete loss of hemolytic activity at pH 5 (*9*), Cys-melittin possessed an improved pH 5 RBC lytic potency relative to that of natural melittin (Figure 4B). Consequently, poly(Acr-Arg)$_4$-SS-melittin and poly(Acr-Arg)$_4$-Mal-melittin both possess potent hemolytic activity at pH 7.4 and 5 (Table 1). When combined with pGL3, Cys-melittin and Mal-melittin maintained their hemolytic activity at pH 7.4, demonstrating their weak association with DNA (Figure 4C). In contrast, the hemolytic activity of poly(Acr-Arg)$_4$-SS-melittin DNA polyplexes was completely neutralized due to the strong binding of the polyacridine peptide with DNA (Figure 4C). Reduction of the disulfide bond would decrease the binding affinity to DNA and thereby release hemolytic Cys-melittin.

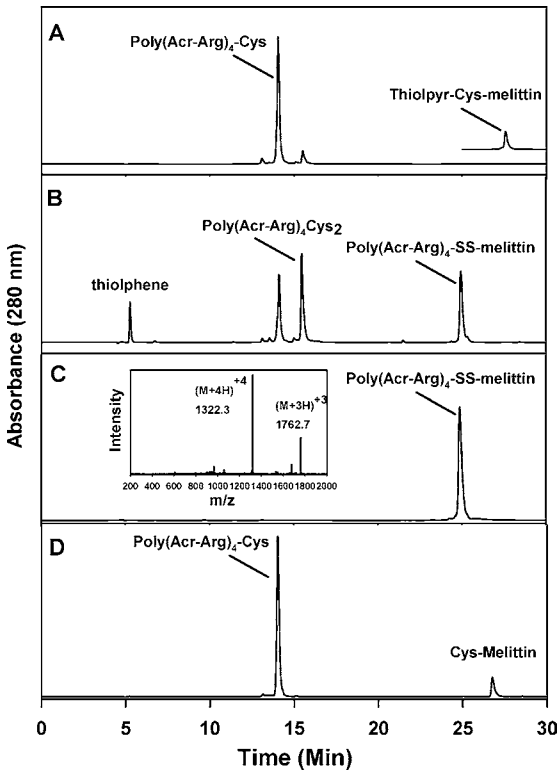

Figure 1. RP-HPLC analysis of polyacridine-melittin peptide synthesis. The reaction monitoring of poly(Acr-Arg)$_4$-Cys with thiolpyr-Cys-melittin at time 0 at 1.7:1 mol ratio is illustrated in panel A. The RP-HPLC chromatograms were produced by injecting 2 nmol then eluting with 0.1% TFA (v/v) and an acetonitrile gradient of 10−55% over 30 min while monitoring absorbance at 280 nm. The reaction monitoring at 12 h established the complete consumption of thiolpyr-Cys-melittin with formation of the product poly(Acr-Arg)$_4$-SS-melittin and by-products of dimeric poly(Acr-Arg)$_4$-Cys$_2$ and thiolphene (panel B). LC-ESI-MS of purified poly(Acr-Arg)$_4$-SS-melittin produced ions of 1762.7 *m*/*z* and 1322.3 *m*/*z*, respectively (inset), corresponding to a mass of 5285.2 amu (panel C). Reduction of poly(Acr-Arg)$_4$-SS-melittin with TCEP resulted in formation of equimolar amounts of poly(Acr-Arg)$_4$-Cys and Cys-melittin (panel D).

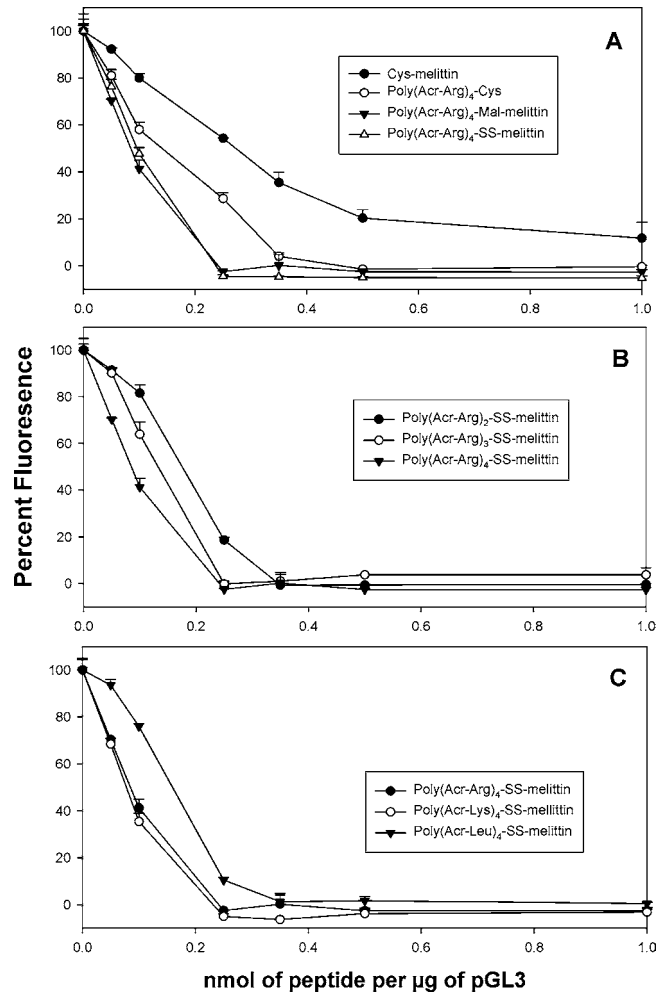

Figure 2. Relative binding affinity of polyacridine-melittin peptides to DNA. The concentration-dependent displacement of the thiazole orange from DNA by polyacridine−melittin peptides was used to establish relative affinity. Cys-melittin bound weakly to DNA resulting in an asymptote in the fluorescence intensity at approximately 0.5 nmol of peptide per μg of DNA, compared to 0.35 for (Acr-Arg)$_4$-Cys and 0.25 for poly(Acr-Arg)$_4$-SS-melittin (panel A). Comparison of poly(Acr-Arg)$_{2-4}$-SS-melittin established that poly(Acr-Arg)$_2$-SS-melittin was the weakest binding resulting in an asymptote at 0.35 nmols of peptide per μg of DNA, whereas poly(Acr-Arg)$_{3and4}$-SS-melittin were nearly equivalent in displacing thiazole orange (panel B). An equal DNA binding affinity was demonstrated for poly(Acr-Arg)$_4$-SS-melittin, poly(Acr-Leu)$_4$-SS-melittin, and poly(Acr-Lys)$_4$-SS-melittin, each resulting in polyplex formation at 0.25 nmol of peptide per μg of DNA (panel C).

To establish a relationship among peptide anchor length, reducibility, and peptide DNA stoichiometry, CHO cells were transfected with polyplexes formed with poly(Acr-Arg)$_2$-SS-melittin, poly(Acr-Arg)$_3$-SS-melittin, poly(Acr-Arg)$_4$-SS-melittin, and poly(Acr-Arg)$_4$-Mal-melittin while varying the peptide to DNA ratio from 0.1, 0.3, 0.5, and 0.75 nmols of peptide per μg of DNA (Figure 5). Luciferase reporter gene expression for polyplexes formed with 0.1 nmol of peptide per μg DNA resulted in expression comparable to a WK$_{18}$/DNA control polyplex. Increasing the stoichiometry to 0.35 nmols of peptide per μg of DNA or higher increased the gene expression approximately 100-fold relative to 0.1 nmol of peptide per μg of DNA. Within this series, poly(Acr-Arg)$_4$-SS-melittin produced the highest expression at a stoichiometry of 0.3 and 0.5. The expression mediated by poly(Acr-Arg)$_4$-SS-melittin was approximately 1000-fold greater than that of poly(Acr-Arg)$_4$-Mal-melittin, which differed only by the reducibility of the linkage between the anchor and melittin (Figure 5).

A broader panel of polyacridine−melittin peptides were combined with pGL3 at a fixed stoichiometry of 0.5 nmol per μg of pGL3 and used to mediate gene expression in HepG2, 3T3, and CHO cells. As illustrated in Figure 6, polyacridine−melittin peptides of the poly(Acr-Arg)$_{2-4}$-SS-melittin series produced the highest gene transfection in all three cell lines, with levels similar to that of PEI (9:1 N:P) when performed with either 2% or 10% FBS. By comparison, poly(Acr-Lys)$_4$-SS-melittin and poly(Acr-Leu)$_4$-SS-melittin were approximately 10−100-fold less active in gene transfer than poly(Acr-Arg)$_4$-SS-melittin in all three cell lines. Reducible poly(Acr-Arg)$_{2-4}$-SS-melittin peptides were 100−1000-fold more active in gene transfer compared to poly(Acr-Arg)$_4$-Mal-melittin in all three cell lines. The importance of the reductive release of melittin was also determined for poly(Acr-Lys)$_4$-SS-melittin and poly-(Acr-Leu)$_4$-SS-melittin in all three cell lines.

To establish the contribution of poly-acridine to DNA binding affinity and gene transfer, the ε-amine of lysine was modified with an acetyl group to prepare poly(Lys(Ac)-Arg)$_4$-SS-melittin. Gene transfer mediated by poly(Lys(Ac)-Arg)$_4$-SS-melittin was approximately 100−1000-fold less relative to poly(Acr-Arg)$_4$-SS-melittin in all three cell lines (Figure 6). To further establish the importance of the anchor peptides, Cys-melittin and dimeric-melittin were used to mediate gene transfer (Figure 6). Both mediated gene transfer that was 10−100-fold lower than poly(Acr-Arg)$_{2-4}$-SS-melittin, demonstrating the importance of the polyacridine anchor in this gene transfer system. Alterna-

[a] Mean particle size of peptide-DNA polyplex (0.5 nmol of peptide per μg of DNA) as determined by QELS. [b] Mean zeta potential determined in 5 mM Hepes, pH 7.4. [c] Percent viability of peptide-DNA polyplexes determined by MTT assay in CHO, HepG2, and 3T3 cells at 10 μg DNA dose (0.5 nmol of peptide per μg DNA) applied to 5×10^5 cells for 6 h.

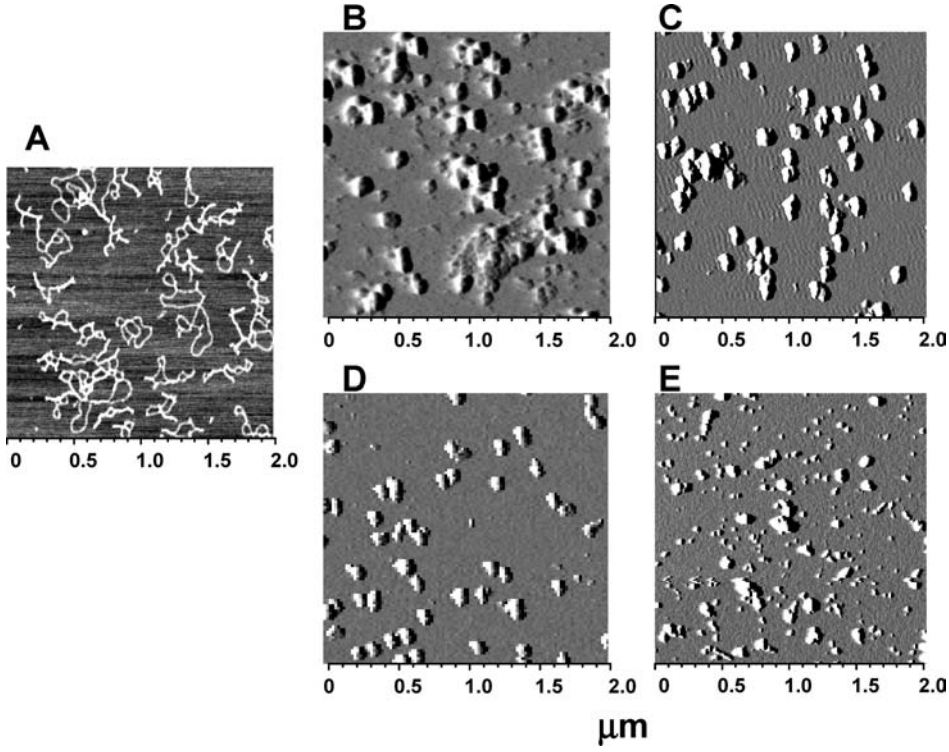

Figure 3. Atomic force microscopy of polyacridine−melittin polyplexes. The size and shape of pGL3 (A) or polyacridine−melittin DNA polyplexes (B−E) were determined by atomic force microscope. Poly(Acr-Arg)$_2$-SS-melittin (B), poly(Acr-Leu)$_4$-SS-melittin (C), poly(Acr-Arg)$_4$-SS-melittin (D), and poly(Acr-Lys)$_4$-Mal-melittin (E) pGL3 polyplexes are compared. The results establish that the weaker DNA binding of poly(Acr-Arg)$_2$-SS-melittin results in aggregated polyplexes.

tively, poly(Acr-Arg)$_n$Cys peptides produced negligible gene transfer on their own, establishing the importance of both the anchor peptide and melittin.

The toxicity of polyacridine DNA polyplexes was assessed by MTT assay on CHO, HepG2, and 3T3 cells (Table 2). Poly(Acr-Arg)$_{2-3}$-SS-melittin DNA polyplexes display very little toxicity in all three cell lines. However, poly(Acr-Arg)$_4$-SS-melittin and poly(Acr-Arg)$_4$-Mal-melittin polyplexes resulted in approximately 70% cell viability whereas control peptide poly(Lys(Ac)-Arg)$_4$-SS-melittin polyplexes were more toxic, resulting in 55% viability. Treatment of CHO, 3T3, and HepG2 cells with 10 μg of poly(Acr-Lys)$_4$-SS-melittin and poly(Acr-Lys)$_4$-Mal-melittin polyplexes for either 6 or 24 h resulted in the same degree of toxicity, whereas lowering the DNA polyplex dose to either 1 or 5 μg resulted in 100% viability. Despite its lower gene transfer efficiency, poly(Acr-Leu)$_4$-Mal-melittin polyplexes were less toxic compared to poly(Acr-Leu)$_4$-SS-melittin polyplexes, which produced approximately 50% viability (Table 2).

DISCUSSION

The endosome has been proposed as one of the major barriers that limits the gene transfer efficiency of nonviral gene delivery systems (*34*). To increase the endosomal escape of plasmid DNA, many prior studies have incorporated fusogenic peptides into experimental delivery systems (*4, 8, 16, 35−40*). Most often, a fusogenic peptide is linked to a PEI or polylysine to allow for multivalent reversible ionic binding with the phosphate backbone of DNA (*4, 10, 11*). While this approach often leads to significant increases in gene transfer efficiency in vitro, ionic interactions are relatively weak leading to premature dissociation of the carrier in vivo and degradation of the DNA (*41*). To overcome weak binding, higher molecular weight polycations are used. These can be prepared with reducible linkages that revert to low molecular weight, lower affinity polycations and

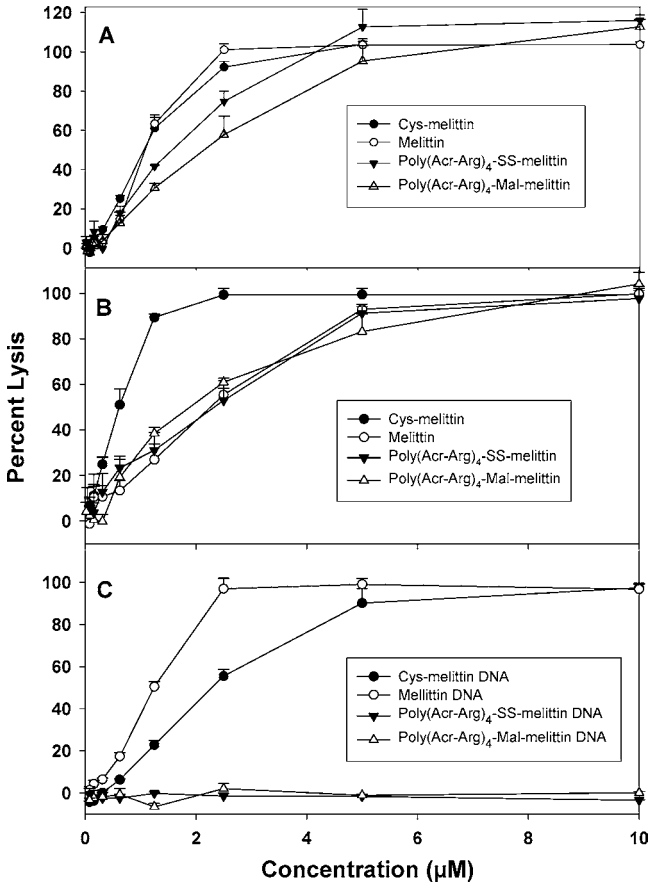

Figure 4. Membrane lytic potency of polyacridine−melittin peptides. The hemolytic activity of melittin and polyacridine−melittin peptides were compared at pH 7.4 and 5 using a RBC hemolysis assay. The results establish Cys-melittin is equally potent as natural melittin at pH 7.4 (panel A), but more potent at pH 5 (panel B). In comparison, poly(Acr-Arg)$_4$-SS-melittin retains nearly full hemolytic potency at pH 7.4 (panel A) but is less potent at pH 5. However, when combined with pGL3, the pH 7.4 hemolytic activity of both Cys-melittin and melittin is nearly unchanged, whereas poly(Acr-Arg)$_4$-SS-melittin is non hemolytic (panel C). These results establish the masking of poly(Acr-Arg)$_4$-SS-melittin membrane lytic activity while bound to DNA.

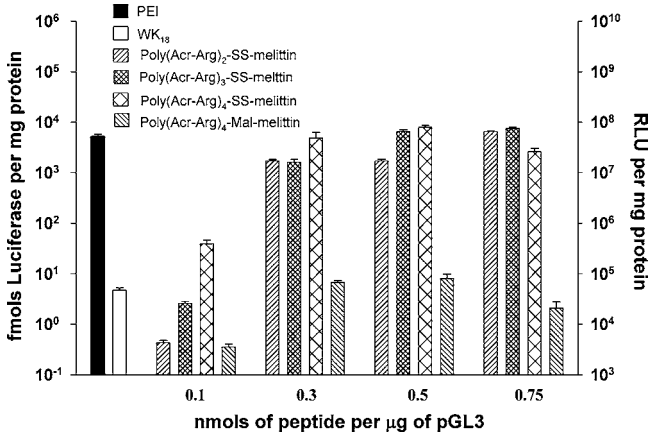

Figure 5. Comparative in vitro gene transfer potency of polyacridine−melittin polyplexes. CHO cells were transfected with increasing amounts of peptide (0.1, 0.35, 0.5, and 0.75 nmol peptide per microgram DNA) combined with 10 μg pGL3. The luciferase expression determined at 24 h represents the mean and standard deviation for three independent transfections.

trigger the release of DNA inside the cell (*21, 22, 42*−*45*). However, despite numerous attempts, i.v. dosed polycationic

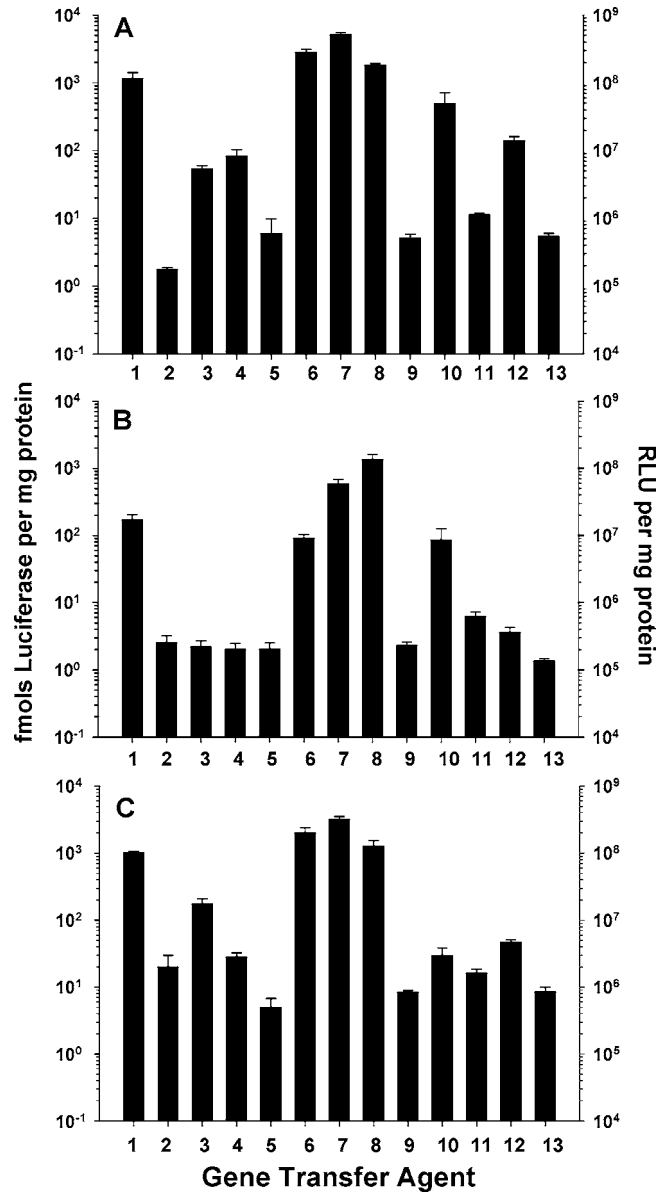

Figure 6. Cell-dependent in vitro gene transfer potency of polyacridine−melittin polyplexes. The relative gene transfer efficiency of DNA polyplexes was determined in CHO (A), 3T3 (B), and HepG2 (C) cells. Transfections were performed with 10 μg of pGL3 polyplex prepared with 0.5 nmol of peptide per μg of DNA. The gene transfer efficiency mediated by polyacridine−melittin peptides was compared to PEI (N/P 9:1) DNA polyplexes and WK$_{18}$ DNA polyplexes. The bars indicate transfection pGL3 combined with (1) PEI, (2)WK$_{18}$, (3) dimeric-melittin, (4) Cys-melittin, (5) poly(Lys(Ac)-Arg)$_4$-SS-melittin, (6) poly(Acr-Arg)$_2$-SS-melittin, (7) poly(Acr-Arg)$_3$-SS-melittin, (8) poly-(Acr-Arg)$_4$-SS-melittin, (9) poly(Acr-Arg)$_4$-Mal-melittin, (10) poly(Acr-Lys)$_4$-SS-melittin, (11) poly(Acr-Lys)$_4$-Mal-melittin, (12) poly(Acr-Leu)$_4$-SS-melittin, and (13) poly(Acr-Leu)$_4$-Mal-melittin. The luciferase expression was determined at 24 h. The results represent the mean and standard deviation for three independent transfections.

DNA polyplexes are unable to produce therapeutic levels of gene expression (*22*).

We have therefore explored an alternative method of binding fusogenic peptides to plasmid DNA by reversible intercalation. Preliminary studies suggested that a single acridine binds to DNA through intercalation but with relatively weak affinity. Consequently, we sought to increase the binding affinity by preparing polyacridines. Considering the pioneering studies of Szoka who developed a synthetic scheme to prepare a diacridine glycopeptide (*24*), Vierling with a single acridine modified nuclear localizing peptide (*26*), and Nielsen who prepared and

tested di and triacridine nuclear localization peptides (*25*), we sought a simplified approach that would allow us to extend the valency of polyacridine to four or more acridine units and control the charge of polyacridine DNA polyplexes. We therefore adopted a strategy reported by Ueyama et al. (*23*), who demonstrated that polyacridine peptides could be prepared from Fmoc-Lys(Acr) using solid-phase synthesis. Several early attempts at synthesis established that polyacridine peptides could be prepared in good yield (>30%) provided that coupling was conducted with HBTU and that a spacing amino acid was used that had a bulky side chain or protecting group. Using Gly as a spacing amino acid resulted in poor yields.

The synthetic design of polyacridine peptides took into account the relative DNA binding affinity by varying polyacridine repeat, the influence of the spacing amino acid on gene transfer and linkage between polyacridine and a melittin fusogenic peptide. As indicated in Figures 5 and 6, there is a strong dependency on the nature of the linkage between polyacridine and melittin in relationship to the gene transfer efficiency. A reducible disulfide bond provided a means for the triggered release of melittin either at or inside the cell. The reduction of the disulfide bond greatly diminishes the affinity of melittin for DNA, releasing it and unmasking its membrane lytic activity (Figure 2C). The released melittin apparently enhances gene transfer by lysis of endosomal membranes that then allows the DNA to more efficiently reach the cytosol and the nucleus, resulting in gene expression that equals or surpasses that of PEI in multiple cell lines (Figure 6). In support of this mechanism, polyacridine linked to melittin by a non-reducible maleimide is 1000-fold less active in gene transfer, despite its equivalent membrane lysis potency against RBCs (Table 1). These results agree with previously observed improved gene transfer mediated by a reductively triggered release of a fusogenic peptide from a gene delivery system (*10, 46*).

The length of the polyacridine repeat appears to be less important for in vitro gene transfer, since repeats of 2, 3, and 4 poly(Acr-Arg)-SS-melittin all produced nearly equivalent gene transfer in three cell lines (Figure 6). However, it is clear that poly(Acr-Arg)$_2$-SS-melittin has lower affinity for DNA as indicated by its ability to displace an intercalator dye (Figure 2B). The lower affinity results in larger DNA polyplexes as determined by QELS (Table 2) and AFM (Figure 3B). However, larger polyplexes also sediment more efficiently, facilitating in vitro gene transfer.

The spacing amino acid of Arg, Lys, or Leu within a poly(Acr-X)$_4$-SS-melittin only slightly influences their affinity for binding DNA (Figure 2C). Each of the resulting polyplexes possessed comparable size, charge, and shape as determined by QELS, zeta potential, and AFM (Table 2, Figure 3). However, the gene transfer efficiency was influenced significantly by the identity of the spacing amino acid in the order Arg > Lys > Leu (Figure 6). In each case, and in each cell line, the reducible polyacridine−melittin peptide mediated greater expression than the nonreducible analogue. The mechanism by which the spacing amino acid influences gene transfer efficiency is unclear. We speculate that the polyacridine and spacing amino acid collaborate to provide DNA binding affinity. It is likely that, following disulfide bond reduction to release the melittin, the anchoring peptide binds to DNA with less affinity, and the charge character of the polyplex changes significantly.

Nonetheless, it is clear that polyacridine is necessary to mediate significant gene transfer. This is further established with a control peptide, poly(Lys(Ac)-Arg)$_4$-SS-melittin, that was fully active in membrane lysis but proved to be approximately 1000-fold less active than poly(Acr-Arg)$_4$-melittin in mediating gene transfer (Figure 6).

The lytic potency of melittin on cells in culture has been well documented (*12, 14*). However, this toxicity can be overcome by polymerization of melittin through disulfide bonds resulting in its neutralization due to high-affinity binding to DNA (*9*). It is apparent that even dimeric-melittin can bind to DNA and mediate moderate gene transfer (Figure 6). The MTT assay did establish that polyacridine−melittin peptides are moderately toxic (approx 50−70% viable) when added to DNA at 0.5 nmol of peptide per microgram of DNA or higher (Table 2). However, this toxicity is the result of saturation of the DNA with polyacridine peptide resulting in unbound peptide that can lyse cells. Lower stoichiometries of 0.3 nmol of peptide per microgram of DNA or lower DNA doses of 5 and 1 μg result in negligible toxicity on all three cell types.

In conclusion, we have described a new polyacridine DNA binding anchor that, when linked with melittin through disulfide bond, produces potent in vitro gene transfer. The polyacridine anchor is designed to be optimized for either in vitro or in vivo gene transfer by controlling the binding affinity to DNA and charge of resulting DNA polyplexes. Furthermore, the Cys residue allows coupling of fusogenic peptides, ligands, and PEG. These attributes should allow polyacridine several unique advantages compared to other polycationic DNA binding peptides and polymers.

Tumor Delivery and In Vivo Processing of Disulfide-Linked and Thioether-Linked Antibody−Maytansinoid Conjugates

Hans K. Erickson,* Wayne C. Widdison, Michele F. Mayo, Kathleen Whiteman, Charlene Audette, Sharon D. Wilhelm, and Rajeeva Singh

ImmunoGen, Inc., 830 Winter Street, Waltham, Massachusetts 02451. Received July 15, 2009; Revised Manuscript Received October 5, 2009

Antibody−drug conjugates (ADCs) are designed to eradicate cancer cells that express the target antigen on their cell surface. A key component of an ADC is the linker that covalently connects the cytotoxic agent to the antibody. Several antibody−maytansinoid conjugates prepared with disulfide-based linkers such as those targeting the CanAg antigen have been shown to display more activity in preclinical mouse xenograft models than corresponding conjugates prepared with uncleavable thioether-based linkers. To investigate how the linker influences delivery and activation of antibody−maytansinoid conjugates, we isolated and characterized the [^{3}H]maytansinoids from CanAg-positive tumor tissues following a single intravenous administration of 300 μg/kg (based on maytansinoid dose) of anti-CanAg antibody (huC242)-^{3}H-maytansinoid conjugates prepared with cleavable disulfide linkers and an uncleavable thioether linker. We identified three target-dependent tumor metabolites of the disulfide-linked huC242-SPDB-DM4, namely, lysine-N^{ε}-SPDB-DM4, DM4, and *S*-methyl-DM4. We found similar metabolites for the less hindered disulfide-linked huC242-SPP-DM1 conjugate with the exception that no *S*-methyl-DM1 was detected. The sole metabolite of the uncleavable thioether-linked huC242-SMCC-DM1 was lysine-N^{ε}-SMCC-DM1. The AUC for the metabolites of huC242-SMCC-DM1 at the tumor over 7 d was about 2-fold greater than the corresponding AUC for the metabolites of the disulfide-linked conjugates. The lipophilic metabolites of the disulfide-linked conjugates were found to be nearly 1000 times more cytotoxic than the more hydrophilic lysine-N^{ε}-linker-maytansinoids in cell-based viability assays when added extracellularly. The cell killing properties associated with the lipophilic metabolites of the disulfide-linked conjugates (DM4 and *S*-methyl-DM4, and DM1) provide an explanation for the superior in vivo efficacy that is often observed with antibody−maytansinoid conjugates prepared with disulfide-based linkers in xenograft mouse models.

INTRODUCTION

Antibody−drug conjugates (ADC[1]) are targeted anticancer agents that utilize the specificity of a monoclonal antibody (mAb) to deliver potent cytotoxic agents to cancer cells that express the target antigen. Several ADCs are currently showing promise in clinical trials, and one, gemtuzumab ozogamicin, has been approved for the treatment of acute myeloid leukemia (*1*). It employs a derivative of the potent DNA-damaging agent calicheamicin γ^1 linked to an anti-CD33 antibody. Other ADCs under clinical evaluation utilize derivatives of the potent antimitotic agents, auristatin and maytansine (*2, 3*), linked to antibodies targeting different cancer-antigens such as the anti-HER2 mAb-maytansinoid conjugate, trastuzumab-DM1, that recently advanced to phase III evaluation for the treatment of metastatic breast cancer (*4*), and the anti-CD30 mAb-auristatin conjugate, SGN-35, that has demonstrated significant activity in patients with relapsed or refractory CD30-positive lymphomas (*5*).

A key design feature of ADCs is the chemical nature of the linker that connects the cytotoxic agent to the antibody (*4, 6*−*12*). Several ADCs utilize "uncleavable" linkers that contain no sites for chemical or enzymatic cleavage in biological systems (*8, 10*). Since the release of the free cytotoxic agent from these ADCs requires complete hydrolysis of the polypeptide backbone of the antibody component in the lysosomes of cells (*10, 11*), these conjugates have the advantage of minimizing the release of the cytotoxic agent during circulation in plasma. Indeed, the clearance of these conjugates from plasma following administration to mice is similar to the clearance of the unmodified antibody used to prepare the ADC (*13*). Other ADCs that utilize "cleavable" linkers with disulfide, hydrazone, or peptide moieties, which are cleaved by chemical or enzymatic processes in the tumor, may have somewhat lower stability during circulation in plasma than their uncleavable counterparts, depending on the specific chemical structure of the linker (*7*).

During the preclinical development of IMGN242 (huC242-SPDB-DM4), several disulfide linkers with varying susceptibility toward cleavage by thiol−disulfide exchange reactions were prepared by changing the steric hindrance adjacent to the disulfide bond (*12*). For example, IMGN242 has a sterically hindered disulfide linkage with two methyl groups on the carbon adjacent to the maytansinoid side of the disulfide bond, while the huC242-SPP-DM1 conjugate has a relatively less hindered disulfide linkage with one methyl group on the carbon adjacent to the antibody side of the

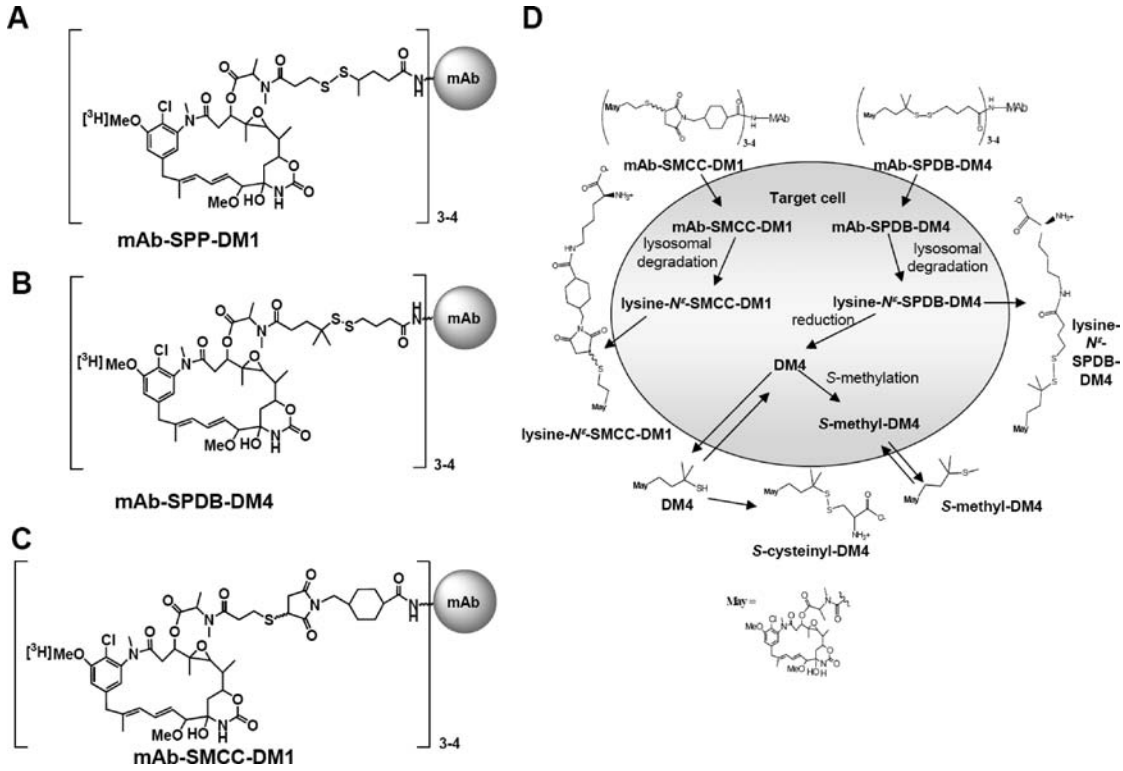

Figure 1. (A,B,C) Structures for the three antibody−maytansinoid conjugates used in this study. (D) Model for the activation of huC242-maytansinoid in targeted cancer cells (*10*). The activation of the disulfide-linked huC242-SPP-DM1 conjugate (not shown) is similar to the activation of huC242-SPDB-DM4 with the exception that the DM1 metabolite is not S-methylated.

disulfide bond (Figure 1A,B). Other disulfide-linked conjugates with varying degrees of steric hindrance and an uncleavable thioether-linked version were evaluated in mouse xenograft models (*12, 14*). The disulfide-linked conjugate, IMGN242, was found to have the most antitumor activity and the widest therapeutic window in vivo as defined by the difference between the maximum tolerated dose and the minimally effective dose in mouse xenograft models. Similar preclinical observations have led to the selection of other disulfide-linked antibody−maytansinoid conjugates (AMC's) for further clinical development (*15*−*17*). In addition, several disulfide-linked AMCs targeting B-cell antigens were recently shown to display significantly more activity in mouse xenograft models than the corresponding uncleavable versions (*18*). However, an uncleavable linker was found to yield more antitumor activity in preclinical models for a trastuzumab−maytansinoid conjugate targeting the HER2 antigen when compared with disulfide-based linkers (*4*), suggesting that there are properties unique to the target antigen (or cancer cell) that influence the observed antitumor activity of AMCs.

We previously identified the major target-cell metabolites of the disulfide-linked huC242-SPDB-DM4 and the uncleavable huC242-SMCC-DM1 conjugate and found that both conjugates were processed to lysine-linker-maytansinoids following antigen-mediated internalization and lysosomal processing. However, only the disulfide-linked lysine-linker-maytansinoid underwent further intracellular processing to yield the liphophilic metabolites, DM4 and *S*-methyl-DM4 (Figure 1) (*10*). We proposed that "bystander" effects associated with these metabolites could enhance the potency of disulfide-linked conjugates in vivo if the processing of the conjugates within tumors was the same as those observed in vitro. This would explain why disulfide-linked AMCs for certain targets such as CanAg display more activity than uncleavable versions in preclinical models. However, the relationship between the in vitro and in vivo target-cell processing of the conjugates is unclear and other possibilities such as better processing and tumor delivery for disulfide-linked conjugates in vivo could also explain the observed efficacy results. In the current study, we examined the in vivo processing and delivery by isolating the ^{3}H-maytansinoid metabolites from tumor tissue following the treatment of mice bearing CanAg positive COLO 205 tumors with the thioether-linked huC242-SMCC-[^{3}H]DM1, and the two hindered disulfide-linked conjugates huC242-SPDB-[^{3}H]DM4 and huC242-SPP-[^{3}H]DM1. Our findings support our previous proposal that the superior activity of the disulfide-linked huC242-maytansinoid conjugates over the uncleavable huC242-SMCC-DM1 conjugate is likely due to the unique cell-killing properties associated with the metabolites derived from the disulfide-linked conjugates.

EXPERIMENTAL PROCEDURES

Cell Lines and Reagents. All cells were obtained from the American Type Culture Collection and grown in the recommended culture medium. Ultima Flo M scintillation fluid and solvable were from PerkinElmer life and analytical sciences. All chemicals were obtained from Sigma-Aldrich. The HPLC 10 μm C-18 column (0.46 × 25 cm, Vydac) was obtained from the Nest Group. The ULTRA-TURRAX T8 dispersing instrument was obtained from IKA Works Inc.

Preparation of Conjugates. Both tritium-labeled DM1 and DM4 were prepared from tritium-labeled ansamitocins P-3 by methods that were previously described for the synthesis of unlabeled DM1 and DM4 (*12*). The tritium-labeled ansamitocin P-3 was prepared as follows. First, the C20-OMe methyl group of ansamitocins P-3 was removed by incubation with the bacterial strain *Streptomyces platensis* to give ansamitocins PDM-3 (*19*). The C-20-OH moiety of ansamitocins PDM-3 was then methylated using tritium-labeled methyl iodide by a method described by Iwaskai (*20*). AMCs were prepared as described elsewhere (*12*) using the tritium-labeled DM1 and DM4. The humanized anti-CanAg monoclonal antibody, huC242, and

isotype-matched nonbinding human IgG_1 antibodies, mAb with similar pharmacokinetic properties as huC242, were isolated at ImmunoGen. Neither huC242 or any of the nonbinding control antibodies bind to any antigen in mice. In this report, conjugates are described by including the abbreviation for the linkers used in conjugation. The average ratio of maytansinoid molecules-DM1 or DM4-linked per antibody molecule (D/A) for each conjugate was as follows: huC242-SPP-DM1 (3.9 D/A), huC242-SMCC-DM1 (3.3 D/A), huC242-SPDB-DM4 (3.4 D/A), huC242-SPP-[^{3}H]DM1 (4.0 D/A), huC242-SMCC-[^{3}H]DM1 (4.1 D/A), huC242-SPDB-[^{3}H]DM4 (3.9 D/A), nontargeting mAb-SMCC-[^{3}H]DM1 (4.3 D/A), nontargeting mAb-SPDB-[^{3}H]DM4 (3.7 D/A).

Mouse Xenograft Models. Female CB-17 severe combined immunodeficient mice (SCID mice; Taconic Laboratories, Germantown, NY) bearing COLO 205 tumor xenografts were used for both the in vivo efficacy and metabolism studies. Mice were inoculated with 3×10^6 COLO 205 cells in 100 μL serum-free medium by subcutaneous injection in the area under the right shoulder. CB-17 SCID mice were randomized into four groups ($n = 6$ for efficacy, $n = 2$ for metabolism studies) by tumor volume, 12 days post inoculation of COLO 205 cells. The tumor volumes ranged from 165.6 to 413.4 (296.5 ± 80.5, mean $\pm$ SD) mm^3. Treatments began on the same day. The tumor volumes were measured as described previously (*12*). Log_{10} cell kill was calculated as described elsewhere (*21*). For the metabolism studies, the systemic circulation of mice was flushed by injecting 5 mL PBS into the left ventricle and draining through an incision in the inferior vena cava immediately following sacrifice. Whole tumor tissues were collected, frozen in liquid nitrogen, and stored at -80 °C.

In Vitro Cell Proliferation Assays. The cytotoxic potencies of the maytansinoids toward human cancer cell lines were assessed using a WST-8 cell viability assay as described previously (*12*). For controls to assess the antigen dependence on the activity of the huC242-maytansinioid conjugates, 1 μM unconjugated huC242 was added to the cells 30 min prior to the addition of the conjugate.

Extraction of [^{3}H]maytansinoid Metabolites from Tumor Tissue. Tumor tissue was thawed on ice and immediately cut into small pieces. Five volumes (v/w) of ice-cold 10 mM Tris−HCl, pH 7.5, containing 5 mM NEM was added, and the tissue was homogenized with a Ultra-Turrax T8 dispersing instrument with a S8N dispersing tool (IKA Works Inc.). The homogenate was then placed on ice for 2 h to allow complete alkylation of any free thiols with *N*-ethyl-maleimide (NEM), trapping any intratumoral DM1 or DM4 thiol metabolites as the respective NEM adducts. The alkylation also eliminates the possibility of DM1 or DM4 release from intact conjugate during the workup through thiol disulfide interchange. A portion of the homogenate (0.4 mL) was extracted three times with a solution (3.4 volumes) of ethyl acetate/methanol (7.5:1, v/v), and the extracts were evaporated to dryness in an evacuated centrifuge. The samples were then dissolved in 0.12 mL 20% aqueous acetonitrile containing 0.025% TFA and analyzed by HPLC.

Determination of Total Radiolabeled Maytansinoid Associated with Tumor Tissue. Homogenate of the entire tumor tissue was prepared as described above. The homogenates were solubilized using solvable (PerkinElmer) as described by the manufacturer, and radioactivity was determined by liquid scintillation counting (LSC).

Analytical Methods. Maytansinoids were separated on an analytical C-18 column (Vydac, 0.46 × 25 cm) (*10*). The effluent was collected in 0.5 or 1 mL fractions, and the radioactivity associated with each fraction was determined by mixing each vial with 4 mL Ultima Gold liquid scintillation cocktail before counting for 5 min in a Tri-Carb 2900T liquid scintillation counter. LCMS analysis was performed as described previously (*10*).

RESULTS

The Uncleavable huC242 Antibody−Maytansinoid Conjugate Displays Similar Cytotoxic Activity to Disulfide-Linked Conjugates in Vitro but Lower Antitumor Activity in Vivo. The two disulfide-linked conjugates—huC242-SPDB-DM4 and huC242-SPP-DM1—and the uncleavable conjugate huC242-SMCC-DM1 were assayed for their cytotoxic potency against antigen-positive COLO 205 cells using a cell viability assay. All three conjugates displayed similar cytotoxic potencies (IC_{50} 50−90 pM) upon a 4-day exposure of the cells to the conjugates (Figure 2A). These observed cytotoxicities were reduced over 100-fold ($IC_{50} > 5$ nM) when the assay was repeated in the presence of excess unconjugated huC242 antibody demonstrating that cell killing by the conjugates was antigen-specific.

We then investigated the antitumor activities of the conjugates against established COLO 205 xenografts in SCID mice. A single intravenous administration of 300 μg/kg based on DM1 or DM4 (equivalent to ~15 mg/kg based on antibody dose) of the three conjugates was administered once the tumors had reached a relatively large size of 300 mm^3. The same treatment conditions were selected for the metabolism studies described in the following sections. The antitumor responses are displayed in Figure 2B. A single administration of huC242-SPDB-DM4 was found to be more active than huC242-SPP-DM1 (log cell kill 0.9 vs 0.5, respectively), while huC242-SMCC-DM1 was inactive under these conditions. Although treatment with huC242-SMCC-DM1 elicited no measurable tumor regression for the 300 mm^3 established tumors in this study, previous studies have demonstrated significant antitumor activity when smaller established COLO 205 xenografts (100 mm^3) were treated with a greater total dose (750 μg/kg of conjugated DM1, ~38 mg/kg based on antibody dose administered as five daily injections of 150 μg/kg/d) (*14*).

Accumulation of ^{3}H-maytansinoid in Tumor Tissue. DM1 and DM4 were tritium-labeled at the C-20 methoxy group (Figure 1A,B) and conjugated to the huC242 antibody as described previously (*10, 14*). The [^{3}H]AMCs were found to exhibit in vitro cytotoxicities similar to non-radiolabeled AMCs (data not shown). SCID mice bearing COLO 205 tumors were treated with single intravenous injections of 300 μg/kg based on DM1 or DM4 (~15 mg/kg antibody dose) of the three [^{3}H]AMCs and tumor tissues were analyzed for total radioactivity to determine the percentage of the administered conjugate (based on DM1 or DM4) that had accumulated per gram of tumor tissue (%ID/g). Figure 2C shows the %ID/g over time following the administration of the conjugate. The AUC for the %ID/g associated with the huC242-SMCC-[^{3}H]DM1 was nearly 2-fold greater than the AUC associated with the two disulfide-linked conjugates, huC242-SPP-[^{3}H]DM1 and huC242-SPDB-[^{3}H]DM4. Next, we investigated the relationship between the administered dose of the conjugate and tumor localization. SCID mice bearing COLO 205 xenografts (2 animals per dose group) were treated with single bolus injections of 100 μg/kg, 200 μg/kg, and 300 μg/kg (based on maytansinoid) of huC242-SMCC-[^{3}H]DM1 or huC242-SPDB-[^{3}H]DM4 and the tumor localization after 2 days was calculated as described above (Figure 2D). The %ID/g associated with both conjugates changed little in the dose range of 100−300 μg/kg based on DM1 or DM4 (~5−15 mg/kg antibody dose). In addtion, at all doses, the %ID/g localized with the uncleavable huC242-SMCC-DM1 conjugate (10−12%ID/g) was 1.5- to 2-fold greater than the %ID/g associated with the cleavable huC242-SPDB-[^{3}H]DM4 conjugate (6−8%ID/g).

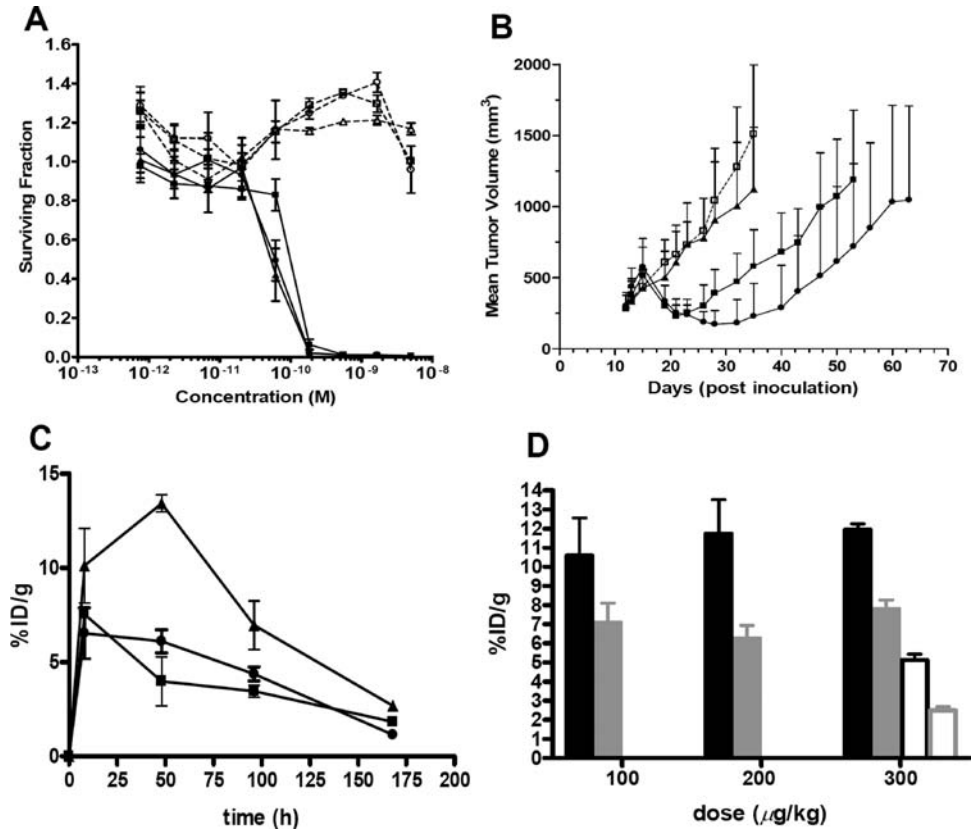

Figure 2. Targeted activity and tumor localization of huC242-maytansinoid conjugates. (A) In vitro activities of huC242-SMCC-DM1, huC242-SPDB-DM4, and huC242-SPP-DM1. COLO 205 cells were exposed to different concentrations of huC242-SMCC-DM1 (▲), huC242-SPDB-DM4 (●), and huC242-SPP-DM1 (■) in the presence (△,○,□) or absence (▲,●,■) of 1 μM huC242 for 4 d. Surviving fraction is plotted vs concentration (based on mAb). (B) Antitumor activities in SCID mice bearing subcutaneous COLO 205 xenografts. A single bolus injection of a vehicle control (□), huC242-SMCC-DM1 (▲), huC242-SPDB-DM4 (●), and huC242-SPP-DM1 (■) were each administered at a dose of 300 μg/kg once tumors reached sizes of 300 mm^3. Dosage is based on the amount of conjugated DM1 or DM4 and is approximately equivalent to 15 mg/kg of antibody. (C) Tumor localization of huC242-SMCC-[^{3}H]DM1, huC242-SPDB-[^{3}H]DM4, and huC242-SPP-[^{3}H]DM1conjugates. The percentage of the injected dose of [^{3}H]DM1 or [^{3}H]DM4 accumulated per gram of tissue (%ID/g) at 8 h, 2 d, 4 d, and 7 d from mice treated with single bolus injections of huC242-SMCC-[^{3}H]DM1 (▲), huC242-SPDB-[^{3}H]DM4 (●) and huC242-SPP-[^{3}H]DM1 (■). Conjugates were administered at a dose of 300 μg/kg (based on DM1 or DM4 concentration) once tumors reached sizes of 300 mm^3. The radioactivity accumulated in tumor tissues was determined by LSC of solubilized tumor homogenates and divided by the total CPM of tritium administered. (D) The effect of dose and antigen targeting on accumulation. Tumor accumulation (%ID/g) at 2 d following single bolus injections of 100 μg/kg, 200 μg/kg, and 300 μg/kg (based on DM1 or DM4 concentration) of huC242-SMCC-[^{3}H]DM1 (black), huC242-SPDB-[^{3}H]DM4 (gray) once tumors reached sizes of 300 mm^3. Tumor localization for the nontargeting mAb_1 SMCC-[^{3}H]DM1 (open black bars) and mAb_2-SPDB-[^{3}H]DM4 (open gray bars) was also determined at the 300 μg/kg dose.

To investigate the antigen specificity of maytansinoid localization at the tumor, two nontargeting conjugates were prepared, mAb-SPDB-[^{3}H]DM4 and mAb-SMCC-[^{3}H]DM1, each using antibodies that do not bind to COLO 205 cells (data not shown). The %ID/g of these nontargeting conjugates was determined at the 300 μg/kg dose in mice bearing COLO 205 tumors (Figure 2D) two days following administration of the conjugates. The %ID/g for the nontargeting conjugates was approximately 3-fold lower than the respective targeting huC242 conjugates at the same dose (Figure 2D). As was observed for the targeting conjugates, the tumor accumulation of the uncleavable nontargeting conjugate was greater than the tumor accumulation of nontargeting disulfide-linked mAb-SPDB-[^{3}H]DM4 conjugate.

Extraction of ^{3}H-maytansinoid Metabolites from Tumors. To determine the amount and nature of the released maytansinoids, the conditions for the extraction of protein-free ^{3}H-maytansioids from tissue homogenates were first optimized by spiking tissue homogenates with synthetically prepared ^{3}H-maytansinoids and measuring the recovery by HPLC. We found the highest (80%) recoveries for all of the metabolites using a mixture of ethyl acetate and methanol (data not shown). To ensure that maytansinoids were not released from the intact conjugate during the ex vivo homogenization and extraction steps, radiolabeled conjugates were added to freshly prepared COLO 205-tumor homogenates and extracted following the optimized procedure. The extracts were analyzed for ^{3}H-metabolites by reverse-phase HPLC and found to contain no metabolites (data not shown).

Once the conditions for the extraction of protein-free maytansinoids were optimized, portions of the tumor homogenates collected 2 d after treatment with 300 μg/kg of the conjugates in Figure 2B were extracted and analyzed for ^{3}H-maytansinoid metabolites by reverse-phase HPLC and LSC (Figure 3A,B). Three major tumor metabolites were observed with retention times identical to those of the synthetic standards lysine-N^{ε}-SPDB-DM4, *S*-(*N*-ethylsuccinimid-2-yl)DM4 (DM4-NEM), and *S*-methyl-DM4 for both the targeting huC242-SPDB-[^{3}H]DM4 and the nontargeting mAb-SPDB-[^{3}H]DM4 conjugates (Figure 3A). DM4-NEM is the protected form of the DM4 metabolite that arises from alkylation of DM4 in the tissue homogenates with NEM. In separate experiments, mass spectral analysis of the isolated [^{3}H]maytansinoid metabolites showed the expected masses (DM4-NEM, M + Na^+ = 927; lysine-N^{ε}-SPDB-DM4, M + Na^+ = 1048.4; *S*-methyl-DM4, M + Na^+ = 816.4, M + K^+ = 832.5). The sole tumor metabolite from mice treated with huC242-SMCC-[^{3}H]DM1 and the nontargeting mAb-SMCC-

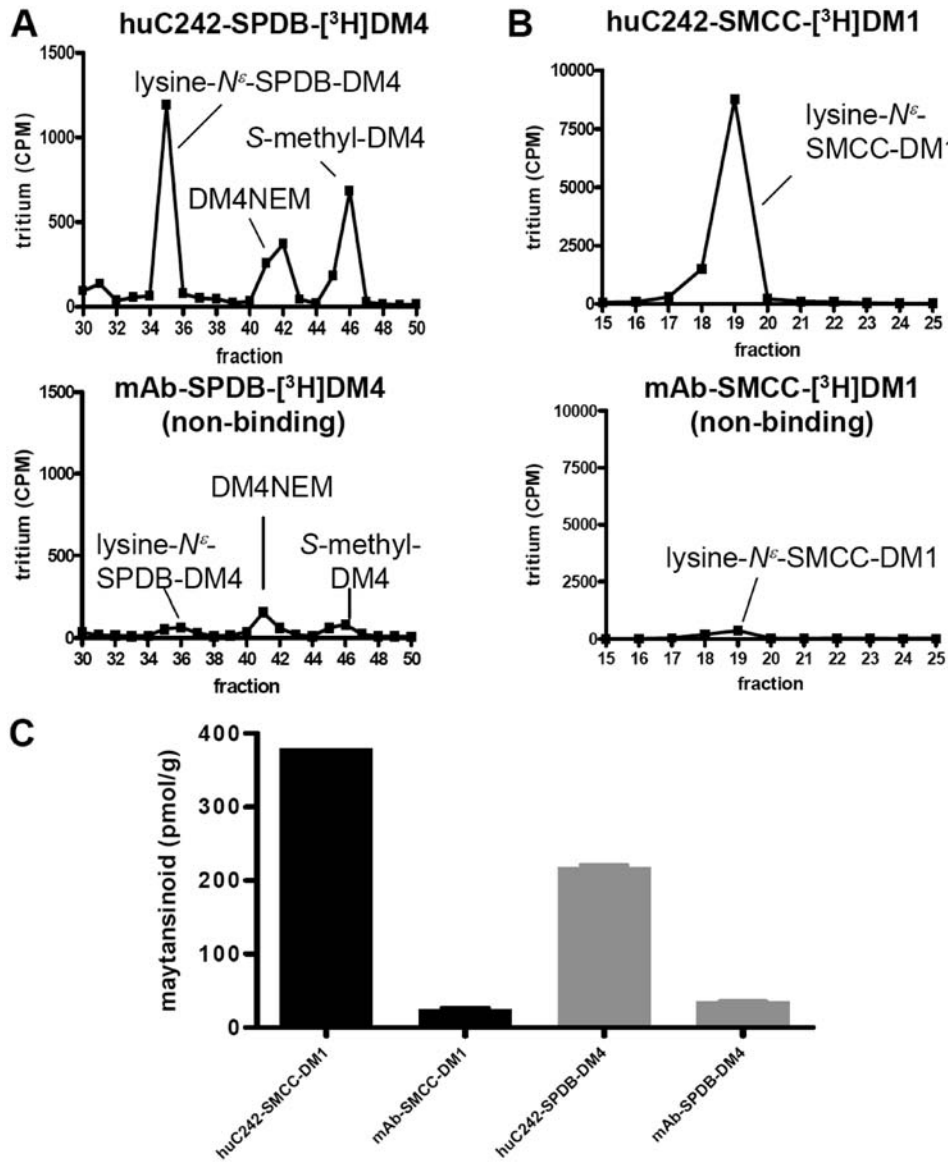

Figure 3. [^{3}H]Maytansinoid metabolites in tumor tissues 2 d following treatment of COLO 205-bearing SCID mice with antibody-[^{3}H]maytansinoid conjugates. (A) Chromatograms associated with tumor metabolites of huC242-SPDB-[^{3}H]DM4 and nontargeting control mAb-SPDB-[^{3}H]DM4, and (B) huC242-SMCC-[^{3}H]DM1 and nontargeting mAb-SMCC-[^{3}H]DM1. Portions of the tumor homogenates analyzed in Figure 2B were extracted, and the extracts were analyzed for metabolites by HPLC. The effluent from the samples associated with the uncleavable conjugate, and the disulfide-linked conjugates were collected in 1 and 0.5 mL fractions, respectively. The radioactivity in each effluent fraction was determined by LSC. The chromatograms show the fraction number on the abscissa and counts per minute of tritium on the ordinate. (C) Total metabolites. The peaks of radioactivity from the chromatograms in A and B were converted to pmol of maytansinoid metabolites, and the sum of the metabolites from each chromatogram was divided by the weight of tumor tissue analyzed to calculate the pmol/g.

[^{3}H]DM1 was lysine-N^{ε}-SMCC-DM1 (Figure 3B). In separate experiments, the lysine-N^{ε}-SMCC-DM1 metabolite was found to have the expected mass ($M + Na^+ = 1125.5$). The radioactivity associated with each of the metabolites in Figure 3A,B were converted to picomole of maytansinoid per gram of tumor tissue (pmol/g) using the specific radioactivities associated with the [^{3}H]AMCs and the weight of the corresponding tumors (Figure 3C). The data revealed a specific effect of antigen binding on accumulation of maytansinoid metabolite(s). The tumor accumulation for the targeting huC242-SPDB-DM4 conjugate was 6-fold higher than the corresponding accumulation from the nontargeting mAb-SPDB-DM4, while the accumulation of maytansinoid metabolites from the targeting huC242-SMCC-DM1 was 16-fold greater than the accumulation from nontargeting mAb_1-SMCC-DM1.

The time course for the accumulation of maytansinoid metabolites was assessed in tumor tissues collected at 8 h, 2 d, 4 d, and 7 d following administration of the huC242-[^{3}H]maytansinoid conjugates for which the tumor localization data was described in Figure 2. The HPLC chromatograms in Figure 4 display the peaks of radioactivity associated with the tumor metabolites isolated from each sample. The sole metabolite of huC242-SMCC-[^{3}H]DM1 at all time points was lysine-N^{ε}-SMCC-[^{3}H]DM1 (Figure 4A). The major metabolite of huC242-SPDB-[^{3}H]DM4 observed at the first time point (8 h) was lysine-N^{ε}-SPDB-[^{3}H]DM4 (72% of total metabolites) (Figure 4B). However, DM4-NEM (24% of total metabolites), representing intratumoral release of DM4, and a small amount of *S*-methyl-DM4 (4% of total metabolites) were also evident by 8 h.

Figure 4C displays the signals for the amount of radioactivity associated with the tumor metabolites from mice treated with huC242-SPP-[^{3}H]DM1. Peaks of radioactivity with retention times identical to the synthetic standards, lysine-N^{ε}-SPP-DM1 and *S*-(*N*-ethyl succinimid-2-yl)DM1 (DM1-NEM), were ob-

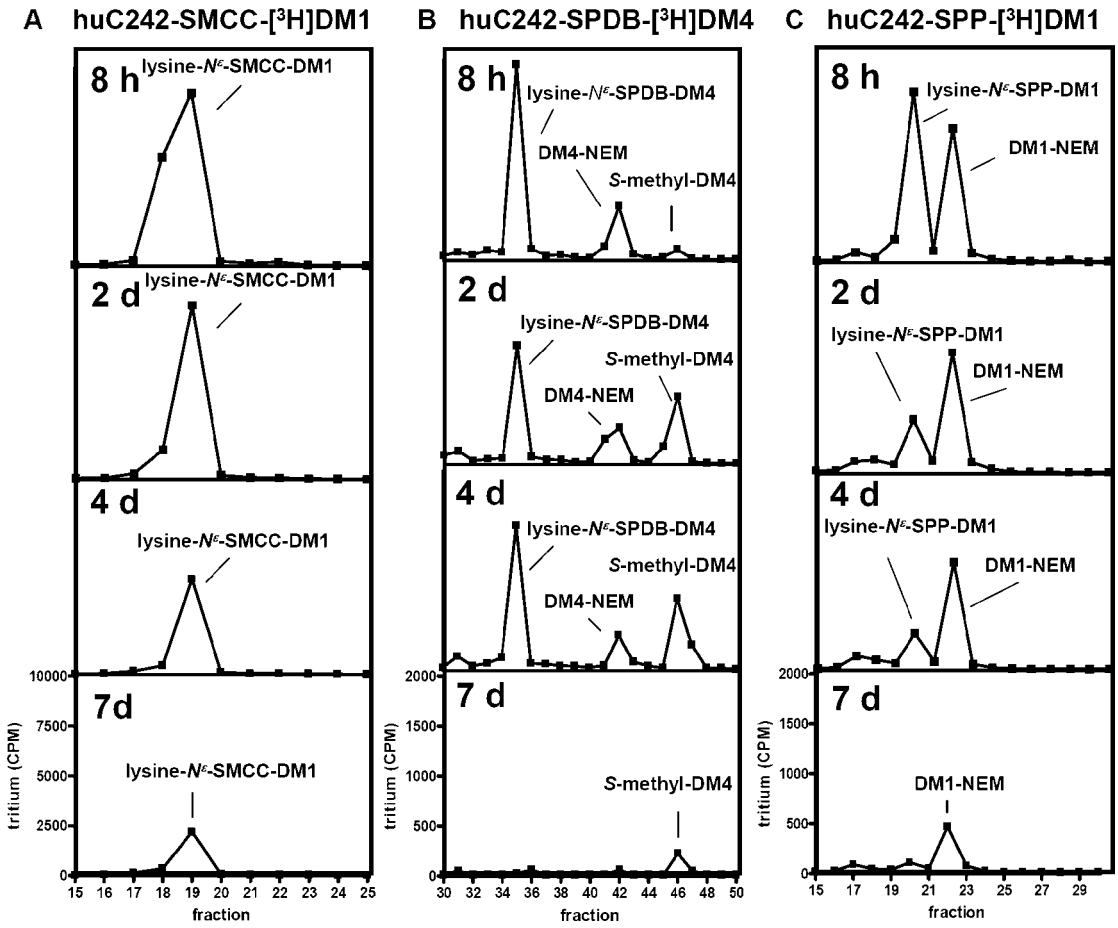

Figure 4. Maytansinoid metabolites formed in tumor tissues over time. Chromatograms associated with tumors collected from mice 8 h, 2 d, 4 d, and 7 d following administration of huC242-SMCC-[^{3}H]DM1 (A), huC242-SPDB-[^{3}H]DM4 (B), and huC242-SPP-[^{3}H]DM1 (C). Portions of the tumor homogenates from the COLO205 bearing SCID mice treated with a single dose of 300 μg/kg (DM1 or DM4 dose/ ~15 mg/kg antibody dose) described in Figure 2C were analyzed for metabolites described in Figure 3. The chromatograms show the fraction number on the abscissa and counts per minute of tritium on the ordinate.

served in the tumor tissues from the first three time points. The identities of the two metabolites were confirmed in separate experiments by LC-MS (DM1-NEM, M + Na^+ = 885.3; lysine-N^ε-SPP-DM1, M + Na^+ = 1020.3 and M + K^+ = 1036.4). The major difference between metabolites of huC242-SPP-[^{3}H]DM1 and huC242-SPDB-[^{3}H]DM4 was the absence of *S*-methyl-[^{3}H]DM1 in the tumor tissues from the mice treated with huC242-SPP-[^{3}H]DM1, suggesting that the DM1 thiol is a poor substrate for the *S*-methyltransferase in tumor cells. Nearly 45% of the total metabolite at 8 h was associated with DM1−2-fold higher than the percentage of DM4 and *S*-methyl-DM4 in the corresponding 8 h tumors treated with huC242-SPDB-[^{3}H]DM4, consistent with its less hindered and more readily reducible disulfide linker.

The radioactivity associated with the metabolites generated from the three ^{3}H-conjugates in tumor tissues from Figure 4 was converted to picomoles per gram of tumor tissue (pmol/g). Figure 5 shows the accumulation of the maytansinoid metabolites per gram of tumor tissue over time following administration of each conjugate to the mice. The AUC over seven days associated with the lysine-N^ε-SMCC-[^{3}H]DM1 metabolite was about 2-fold greater than the corresponding AUCs of the total extractable metabolites from either of the two disulfide-linked conjugates. We further demonstrate that the observed metabolites account for the majority of the radioactivity at the tumors (Supporting Information Figure S1).

Cytotoxic Potency of Maytansinoid Metabolites Identified in Vivo. Maytansinoids bind to the same vinca alkaloid binding domain of tubulin as the antimitototic drug vinblastine. Maytansine was found to be about 3- to 10-fold more cytototoxic than vinblastine toward several cell lines (*22*). The major maytansinoid metabolites identified in vivo were prepared synthetically, and their cytotoxic potencies were assayed against several human carcinoma cell lines using a cell viability assay. The IC_{50} values for each of the maytansinoids are displayed in Table 1. The *S*-methyl-DM4 and *S*-methyl-DM1 (the latter not identified in significant quantities in vivo) display the highest potency with IC_{50} values of between 0.01 and 0.03 nM, 2- to 3-fold higher than the potency of maytansine. All of the lysine derivatives are 100- to 1000-fold less potent than *S*-methyl-DM1 and *S*-methyl-DM4, likely due to the inability of these charged maytansinoids to diffuse into cells (*10*). The two thiol-bearing metabolites, DM1 and DM4, were not tested in the assay because their potencies measured in vitro assays are variable, and less than that of the reference compound, maytansine, likely due to the formation of mixed disulfides via thiol/disulfide exchange reactions with cystine and protein disulfides in the cell culture medium.

Efflux of Maytansinoid Metabolites from Cells. Previously, we speculated that the more lipophilic maytansinoid metabolites (DM1, DM4, and *S*-methyl-DM4) generated within the target cells could diffuse out of the cells and into and kill neighboring cells (bystander effect), providing additional activity for disulfide-linked conjugates (*14*). To estimate whether the concentrations of the metabolites were high enough within the tumor cells to reach levels where efflux would be expected, we first determined those levels in vitro. Cultures of COLO 205 cells (2×10^6 cells/mL) were treated with varying concentrations of

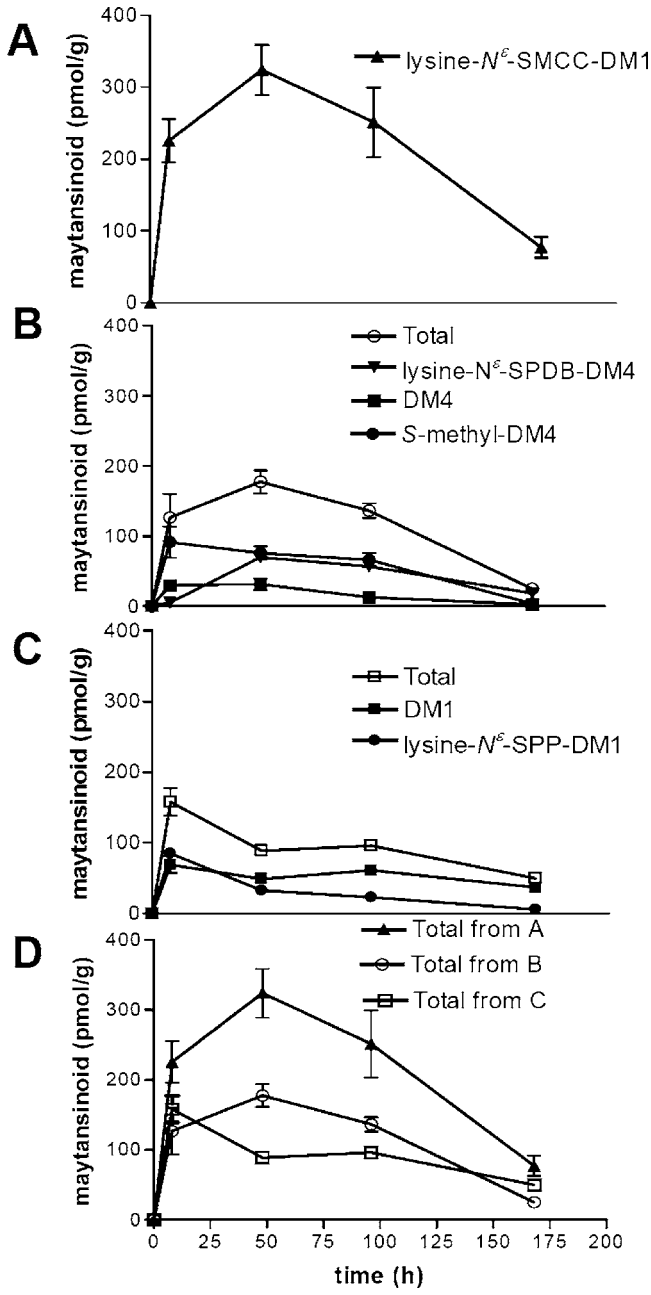

Figure 5. Kinetics of tumor processing. The amounts of maytansinoid metabolites in tumor tissue at 8 h, 2 d, 4 d, and 7 d following a single intravenous administration of 300 μg/kg (DM1 or DM4 dose/ ~15 mg/kg antibody dose) of (A) huC242-SMCC-[^{3}H]DM1; lysine-N^{ε}-SMCC-DM1(▲), (B) huC242-SPDB-[^{3}H]DM4; lysine-N^{ε}-SPDB-DM4 (▼), DM4 (■), *S*-methyl-DM4 (●), total metabolites (○), (C) huC242-SPP-[^{3}H]DM1; lysine-N^{ε}-SPP-DM1 (●), DM1 (■), total metabolites (□), (D) total metabolites from A−C. The radioactivities associated with each of the metabolites (Figure 4) were divided by the amount of tumor tissue analyzed to calculate the pmol/g. The relative pmol/g data differs slightly from the relative peak areas in Figure 4 due to differences in tumor weights.

huC242-SPDB-[^{3}H]DM4 (50 nM, 5 nM, or 0.5 nM) for 24 h, and the cells and medium were analyzed for metabolites as described previously (*10*). The amount of metabolites, as quantified by radioactive measurements, was used to calculate the number of maytansinoid molecules per cell. Exposure of cells to 5 nM and 50 nM huC242-SPDB-[^{3}H]DM4 resulted in an intracellular accumulation of 590 000 and 5 100 000 maytansinoid molecules per cell, respectively, and significant accumulation of maytansinoids in the medium via efflux from the cell (an amount corresponding to about 60% of the intracellular accumulation). Exposure of cells to 0.5 nM conjugate for 24 h resulted in accumulation of 39 000 molecules per cell and no detectable efflux (Supporting Information Figure S2 and Supporting Information Table 1).

We next estimated the average number of maytansinoid molecules per cell localized in the tumors from the current study. The C_{max} for the total maytansinoid metabolites of huC242-SPDB-[^{3}H]DM4 in tumor tissue in the current study was 180 pmol/g (Figure 5A). Assuming the cell density in COLO 205 tumor xenografts is in the range $(2-4) \times 10^8$ cells/mL (*23*), an average value of 300 000−600 000 molecules/cell of maytansinoid metabolites was observed in the tumor tissue. Since we observe significant efflux from COLO 205 cells that have accumulated this level of metabolite in vitro, the results displayed in Figure 5 suggest that it is very likely that cellular efflux of the metabolites also occurred within the tumors of the current study.

DISCUSSION

The major maytansinoid metabolites of the disulfide-linked and uncleavable thioether-linked huC242-maytansinoid conjugates isolated from tumor tissue imply an in vivo activation pathway similar to the one described previously from our in vitro studies (Figure 1) (*10*). A major metabolite observed in the tumor tissue from mice treated with all three conjugates is the lysine-linker-maytansinoid metabolite, presumably formed by the degradation of each conjugate in the lysosomes of the targeted cancer cells (*10*). The lysine-N^{ε}-SMCC-DM1 metabolite is the only maytansinoid metabolite observed in the tumor tissue of mice treated with the uncleavable huC242-SMCC-DM1 conjugate, reflecting the stability of the thioether linker. By contrast, analysis of tumor tissues from the mice treated with the cleavable disulfide-linked huC242-SPDB-DM4 and huC242-SPP-DM1 conjugates reveal the additional lipophilic metabolites, DM4 and *S*-methyl-DM4, and DM1, respectively. In vitro, we found that the DM4 and *S*-methyl-DM4 metabolites of huC242-SPDB-DM4 were formed within target cells from lysine-N^{ε}-SPDB-DM4 following reduction and *S*-methylation steps. The observed tumor metabolites suggest similar tumor cellular processing steps in vivo. Similarly, the lysine-N^{ε}-SPP-DM1 metabolite of huC242-SPP-DM1 appears to be reduced in vivo to yield DM1; however, the released DM1 does not appear to be further *S*-methylated. In separate experiments, we found that DM1 was less readily *S*-methylated than DM4 by the endogenous *S*-methyl-transferase(s) of COLO 205 cells, as well as several other human carcinoma cells in vitro (data not shown).

In vitro, the maytansinoid metabolites were all found to be released from the target cells into the medium where the readily diffusible DM1, DM4, and *S*-methyl-DM4 metabolites retain their cell killing potency, while the lysyl derivatives lose their cell killing potency, presumably because the charged lysyl moiety hinders diffusion across the plasma membrane of cells and thus inhibits re-entry into neighboring cells (*10*). We have speculated previously that the potential for bystander killing of neighboring cells by diffusible metabolites may partially explain why the disulfide-linked huC242-SPP-DM1 was found to eradicate mixed tumor xenografts consisting of antigen-positive and antigen-negative cells as previously reported and why—as observed in this study—the cleavable disulfide-linked huC242-maytansinoid conjugates have more antitumor activity than the uncleavable thioether-linked conjugate toward COLO 205 cells that express the target antigen homogeneously (*10, 14*). In the study described herein, we estimate that the levels of the tumor metabolites accumulated in vivo are high enough to allow for the metabolites to diffuse from the target cells

Table 1. Cytotoxic Potencies of Maytansine and Metabolites of Antibody−Maytansinoid Conjugates Towards Human Carcinoma Cell Lines in Vitro (4 d Exposure).

	in vitro IC_{50} (nM)				
maytansinoid	A375 (melanoma)	BJAB (B-cell)	COLO205 (colon)	KB (cervix)	MOLT-4 (T-cell)
maytansine	0.05	0.03	0.08	0.05	0.09
lysine-N^{ε}-SPP-DM1	10	50	60	10	>100
lysine-N^{ε}-SPDB-DM4	2	7	20	3	16
lysine-N^{ε}-SMCC-DM1	8	8	17	10	16
S-methyl-DM1	0.02	0.01	0.03	0.02	0.03
S-methyl-DM4	0.02	0.01	0.03	0.03	0.03

within the solid tumors, providing support for the hypothesis that bystander killing contributes significantly to tumor eradication in vivo upon treatment with cleavable disulfide-linked conjugates. Such bystander killing may explain why the disulfide-linked conjugates are more active than the uncleavable conjugate despite the fact that the levels for the tumor metabolites of the disulfide-linked conjugates were about 2-fold lower than the corresponding levels for the uncleavable conjugates. The relative tumor accumulation does not appear to correlate with the serum half-lives of the conjugates determined in separate experiments (unpublished data). One explanation for this may be that the lipophilic metabolites of the disulfide-linked conjugates—implicated in the bystander effect—may diffuse out of the tumor tissue more readily than the lysine-N^{ε}-SMCC-DM1 metabolite of the huC242-SMCC-DM1 conjugate. Previously, we have shown that the rates of processing of both disulfide-linked conjugates and uncleavable conjugates are similar in vitro (*10*), and the in vivo results from this study suggest that the mechanism of processing is the same as that determined in the in vitro experiments (Figure 1). Thus, it appears that the very property that allows penetration of the small-molecular-weight lipophilic cytotoxic agent throughout the tumor, resulting in higher antitumor activity, may also result in the maytansinoid metabolites being more readily cleared from the tumor. Despite yielding the highest concentration of tumor metabolites, the huC242-SMCC-DM1 conjugate displayed no detectable antitumor activity at the dose tested in the current study, yet in vitro, the huC242-SMCC-DM1 conjugate and the disulfide-linked conjugates all displayed similarly high cytotoxic potencies. This suggests an uneven uptake and metabolism of the conjugates within COLO 205 tumor xenografts. In another preclinical study, the uncleavable trastuzumab-SMCC-DM1 conjugate was found to have more antitumor activity than the disulfide-linked trastuzumab-SPP-DM1 conjugate in mice bearing HER2-positive tumor xenografts (*4*), suggesting that distribution and delivery of maytansinoid metabolites is sufficient in the trastuzumab-DM1/HER2 system without the need for bystander killing. Thus, the selection of the optimal linker for a given tumor-specific antibody−maytansinoid conjugate requires preclinical experimentation and may depend upon many factors including the biology of the antigen and the biology of the tumor.

Treatment of mice with nontargeting mAb-SMCC-[^{3}H]DM1 and mAb-SPDB-[^{3}H]DM4 resulted in levels of metabolites that were 6-fold and 16-fold lower than the levels observed in mice treated with the targeting huC242-SMCC-[^{3}H]DM1 and huC242-SPDB-[^{3}H]DM4 conjugates, respectively. These results indicate that the tumor metabolites of the targeting huC242−maytansinoid conjugates were formed primarily through a CanAg antigen-mediated mechanism. We were intrigued by the fact that low levels of metabolites are formed from nontargeting conjugates, because it may explain why, in some xenograft mouse models, the nontargeting conjugates at high doses have been found to display significant antitumor activity, albeit significantly lower than that of the corresponding targeting conjugates. The concentration of the nontargeting conjugates in the tumor tissue at the dose used in this study (15 mg/kg) reached 40 nM for mAb-SPDB-[^{3}H]DM4 and 80 nM for mAb-SMCC-[^{3}H]DM1 at 2 d (approximated from the data shown in Figure 2D). At these concentrations, some antigen-independent uptake, for example, by pinocytosis, is likely. The nontargeted processing was more efficient for the disulfide-linked conjugate than for the uncleavable conjugate as shown in Figure 3 suggesting that the release of maytansinoids by thiol/disulfide exchange mechanisms in a nonlysosomal compartment (or extracellularly) may be relatively more significant for antigen-independent metabolism.

Our data are consistent with the proposal (*10, 14*) that disulfide-linked huC242-maytansinoid conjugates are more active than the uncleavable huC242-SMCC-DM1 conjugate in mouse xenograft models due to "bystander" killing. We identified and characterized the major maytansinoid metabolites of the conjugates and estimate that they are produced at levels that would allow for their efflux from targeted cancer cells. Diffusion of the lipophilic metabolites of the disulfide-linked conjugates within the tumor may possibly overcome the numerous barriers that serve to limit access of antibody-based therapeutics to solid tumor targets (*24−26*). We are currently applying the methods developed here to investigate how the target antigen and tumor type influence the delivery and metabolism of AMCs.

ACKNOWLEDGMENT

We thank John Lambert and Ravi Chari for their many helpful suggestions and their careful reading of the manuscript, and Rabih Gabriel and Barbara Leece for the reagents and assistance.

Supporting Information Available: An assessment of the radioactivity associated with tumor tissues (mass balance) is provided. In addition, an analysis of the dose-dependent efflux of metabolites following treatment of target COLO 205 cells in vitro with huC242-SPDB-[^{3}H]DM4 is also provided. This material is available free of charge via the Internet at http://pubs.acs.org.

Fluorescent Nanoprobes as a Biomarker for Increased Vascular Permeability: Implications in Diagnosis and Treatment of Cancer and Inflammation

Britto S. Sandanaraj,*,† Hans-Ulrich Gremlich,† Rainer Kneuer,*,† Janet Dawson,‡ and Stefan Wacha†

Global Imaging Group and Department of Autoimmunity, Transplantation and Inflammation, Novartis Institutes for Biomedical Research, Basel, Switzerland. Received July 15, 2009; Revised Manuscript Received September 27, 2009

This article describes the use of a fluorescent nanoprobe as a functional biomarker for the identification of increased vascular permeability in cancer/arthritis disease models. Synthesis of the fluorescent nanoprobe was achieved by passive loading of a fluorophore inside the nanoparticle using thin film hydration method. The outer layer of the nanoprobe was decorated with poly(ethylene glycol) arms to increase the bioavailability of the fluorophore. Stability studies of the nanoprobe showed that the particles were stable up to 70 days. The uptake and internalization of the fluorescent nanoprobe inside target cells was confirmed by fluorescence microscopy studies. Co-localization of the probe with the target tissue *in vivo* was unambiguously identified using intravital microscopy. Results from *in vivo* imaging studies showed that the particles had a long half-life in the circulation and passively targeted tumor or arthritic tissue. The increased and specific uptake of the fluorescent nanoprobe in tumor/arthritic tissue is attributed to an enhanced permeation and retention (EPR) effect. Use of an optical method to validate anti-inflammatory drugs in an arthritis disease model is demonstrated in this study. In general, this methodology could be used for detection of leaky vasculature in different pathological states.

INTRODUCTION

Biomarkers play a crucial role in both preclinical and clinical evaluation of drugs (*1–7*). In particular, imaging-based biomarkers can speed up drug discovery by supplementing or replacing preclinical and clinical pharmacokinetic and pharmacodynamic assessment, including target selection and modulation. In addition, imaging-based biomarkers could be used for diagnosis, staging, prognosis, and treatment selection (*8–10*).

Presence of leaky vasculature is a classical biomarker for some diseases which include cancer (*11*), inflammation (*12, 13*), and diabetes (*14, 15*). The intrinsic biological processes that drive the formation of leaky blood vessels can vary depending on various disease conditions. However, leaky blood vessels present in different disease conditions share some unique properties that could be used as biomarkers for the identification of pathological states. Dynamic contrast-enhanced MRI (DCE-MRI) (*16, 17*), positron-emission tomography (PET) (*18*), dynamic contrast-enhanced CT (DCE-CT) (*19–21*), and contrast enhanced ultrasound (CEUS) (*22*) have been routinely used as functional biomarkers for measuring the vascular leakiness in various disease conditions. Although these techniques have clearly paved the way for the use of imaging based biomarkers as a routine tool in both preclinical and clinical settings, they are not optimum in their performance: for example, DCE-MRI suffers from quantification and reproducibility, use of DCE-CT might be a problem because of the high exposure to X-ray radiation, and requirement for in-house cyclotron is a limitation in the case of PET. Therefore, there is a need for new functional biomarkers to overcome these issues.

Fluorescence microscopy and near-infrared fluorescence (NIRF) imaging are important research tools in the area of *in vivo* imaging applications (*10, 23–28*) These techniques provide information at a molecular level, thus offering a distinct advantage over other imaging modalities such as magnetic resonance imaging and computer tomography. The use of light in the near-infrared range (NIR; 650−950 nm) is well suited for *in vivo* studies due to the reduced absorbance and scattering of endogenous substances (especially water, oxyhemoglobin, and melanin). The low cost and high sensitivity of this imaging modality has increased the widespread use of this technique in diagnostics (*29*), preclinical drug discovery (*30, 31*), and, to some extent, clinical settings (*32, 33*).

The use of optical methods to assess vascular leakiness is an attractive imaging based biomarker to speed up drug discovery in preclinical settings. As a "proof of concept", we have shown that "optical imaging combined with fluorescent nanoprobes" can be used effectively as a functional biomarker for the identification of increased vascular leakiness. The versatility of this method is demonstrated by using this technique for diagnosis and monitoring of two different disease conditions where vascular leakiness exists. In general, this methodology can be extended to any disease model where leaky blood vessels exist. This technology can be translated easily to clinical settings since all the components used for formulation of fluorescent nanoprobes are clinically approved for different applications (*34*). By encapsulating a clinically approved fluorescent dye (e.g., indocyanine green (*35, 36*) (ICG)) inside a nanoprobe, this nanoparticle can be used as a biomarker for functional imaging in clinical settings. The preclinical studies described here were carried out with a nanoparticle-ICG formulation for one such application in a mouse model (*vide infra*). We have used sterically shielded liposome (SSL) (*37*) based nanoparticulates as a delivery vehicle to carry our fluorescent probes to their target location. The reason for using a delivery vehicle is twofold; first, it increases the bioavailability of the probe in *in vivo* conditions, second, it increases the targeting efficiency of this nanoparticle toward leaky vasculature (*11, 38*), thus reducing the signal/noise ratio. Since all the components of the formula-

tion are already used in clinics, we do not anticipate any toxicity from the delivery vehicle. Apart from *in vivo* validation of the probe, we have also validated the performance of the probe at the cellular level.

EXPERIMENTAL PROCEDURES

Reagents. Egg phosphaditylcholine, cholesterol, 1,2-disteroyl-*sn*-glycero-3-phosphoethanolamine-*N*-methoxy(poly(ethylene glycol))-2000) were purchased from Avanti Polar Lipids, Inc. Cyanine 5.5 and indocyanine green (ICG) were purchased from Fluka. Hoechst, Phalloidin, and CM-DiI were purchased from Molecular Probes. RPMI medium and fetal bovine serum were purchased from Invitrogen.

Synthesis and Characterization of Fluorescent Nanoprobes. Liposomes were prepared at defined molar ratio of individual lipids to give a predetermined total lipid concentration of 7.6 mg/mL. Egg phosphaditylcholine, cholesterol, 1,2-disteroyl-*sn*-glycero-3-phosphoethanolamine-*N*-methoxy-(poly(ethylene glycol))-2000) (2:1:0.2 molar ratio) and fluorescent probe (Cy5.5 or ICG) were dissolved in 5 mL chloroform, and the resulting mixture was evaporated on a rotary evaporator under room temperature. The resulting lipid film was again subjected to high vacuum to remove residual solvent. Finally, the lipid film was hydrated at 50 °C with 5 mL 10 mM PBS buffer (pH 7.4) to give liposome solution. The hydrated mixture was frozen at liquid nitrogen temperature and heated to 50 °C. This treatment was repeated 3 times for the preferential encapsulation of Cy5.5 or ICG inside the nanoprobe. After this, the solution was passed through a 0.2 μM filter (3 times) to get rid of larger particles. The unbound probe molecules present in the bulk solution were separated by passing solution through a Sephadex G-25 M column. Percentage encapsulation efficiency of Cy5.5 and ICG was 5% and 50%, respectively. Liposomes were lysed by the addition of methanol, and the encapsulation efficiency was calculated from the amount of released dye, which is determined from the UV−vis calibration curve. Size of nanoprobes was characterized by dynamic light scattering using a Zetasizer Nano ZS over a time period of 70 days at 4 °C.

Spectroscopic Measurements. The UV−vis absorption spectra were recorded on a PerkinElmer spectrophotometer using plastic cells. Fluorescence spectra were recorded on a Varian fluorimeter. The spectra were recoded using a 1 mL disposable plastic cell. Excitation and emission bandwidth was kept at 2.5 and 5 nm, respectively, for Cy5.5 nanoprobe and for ICG nanoprobe bandwidth was kept at 10 and 20 nm, respectively. Cy5.5 nanoprobe was excited at 660 nm and the emission was recorded from 670 to 900 nm. For ICG-nanoprobe, the excitation wavelength was 770 nm and emission was recorded from 770 to 900 nm.

Cell Studies and Imaging with IN Cell Analyzer 3000. Prostate cancer cells (PC3, passage number 12) were cultured at 37 °C under 5% CO_2 in RPMI supplemented with 10% heat-inactivated fetal bovine serum, 2% glutamine, and 0.1% penicillin−streptomycin solution. For passaging, cells were detached with 0.25% trypsin/1 mM EDTA, counted with nucleocounter (ChemoMetec, Allerød, Denmark), and the required number of cells were seeded in T75 cell culture flasks. For imaging plates, Cells were seeded on black Corning 384-well plates using multidrop, 10 000 cells/well in 100 μL, and incubated for 24 h. After 24 h, 16.6 μL nanoprobes (PEGylated nanoprobe 1: size = 73 nm, Cy5.5 concentration = 50 μg/mL. PEGylated nanoprobe 2: size = 120 nm, Cy5.5 concentration = 43 μg/mL. Naked nanoprobe: size = 106 nm, Cy5.5 concentration = 24 μg/mL. Control nanoprobe: size = 106 nm, Cy5.5) were added and incubated for required time. The cells were fixed by adding 100 μL 8% PFA which contained 50 ng/well Hoechst (a nuclear stain). Thus, the end concentration of PFA was 4% and that of Hoechst was 25 ng/well. Cells were incubated with PFA and Hoechst for 15 min at RT. Then, the PFA-Hoechst solution was aspirated. The cells were washed once with PBS. The cells were washed twice with 20 μL PBS, which was aspirated, and the wells were filled with 20 μL PBS. The plates were sealed with silverseal aluminum tape and kept at 4 °C in the dark until imaging with the IN Cell Analyzer 3000. Images were acquired using the IN Cell Analyzer 3000 (GE Biosciences, Piscataway, NJ) automated cell imager. Flat field correction was done using a plate with various mixtures of Oregon Green (Molecular Probes, Carlsbad, CA), Cy5 calibration reagent (GE Biosciences), and Alexa Fluor 350 carboxylic acid (Molecular Probes). Images for the nuclear stain Hoechst and Cy5.5 were taken on 2 different channels with 2 CCD cameras simultaneously. Cy5.5 was excited with the 647 nm krypton laser, and a 695/BP55 emission filter was used to collect the emitted light. Hoechst was excited with 350 nm line of the argon laser, and a 450/BP50 emission filter was used to collect the emitted light. Exposure time for both the channels was 1.7 ms.

Intravital Imaging and Preparation of DiI mice. Two weeks before the experiment, 2×10^6 PC3 prostate cancer cells were labeled *in vitro* with DiI and implanted subcutaneously into nude mice. Twenty-four hours before imaging, the Cy5.5-labeled nanoprobe (size = 120 nm, Cy5.5 concentration = 43 μg/mL) was injected via tail vein injection 5 min before imaging, FITC-dextran (M_W = 500 000; 5 μL of 1 mg/mL stock diluted into 95 μL NaCl 0.9%) was applied via tail vein injection as well, and then mice were anesthetized with Ketamin/Xylasol and a skin-flap was performed in order to get access to the subcutaneously implanted tumor. Images were taken using the IV100 intravital microscope from Olympus using 4× and 20× objectives as well as a 27× stick lense for highest resolution. A stock solution of 1 mg/mL CM-DiI (Molecular Probes) was prepared in dimethyl sulfoxide (DMSO) and stored at −20 °C. For labeling of cells, the stock solution was diluted in cell culture medium to achieve a concentration of 10 μg/mL. One million cells were suspended per milliliter and incubated for 30 min at 37 °C. Cells were gently resuspended every 5 min. Afterwards, cells were washed twice in PBS (centrifugation for 10 min at 400 *g* at room temperature) and resuspended in cell culture medium at 750 000 cells per 100 μL.

Mouse Tumor Model and NIRF Imaging. 3×10^6 PC-3 human prostate adenocarcinoma (ATCC: CRL-1435) cells in 100 μL HBSS (1 mg/mL Matrigel) were injected under Forene inhalation narcosis on the right flank of 6−8 week old female athymic nude mice for generation of subcutaneous tumors.

The Siemens BonSAI Imager was used (Siemens AG, Medical Solutions, and Erlangen, Germany). NIRF imaging started at day 14 after inoculation of the tumor cells, and NIRF images were recorded 6, 24, 48, 72, and 96 h after i.v. administration of the 100 μL Cy5.5 nanoprobe (size = 73 nm, Cy5.5 concentration = 50 μg/mL). For NIRF measurements, the animals were anaesthetized using 1.5% Isoflurane (Abbott, Cham) in nitrous oxide/oxygen 2:1 administered via a face mask. The duration of the anesthesia was 3 min. All experiments have been carried out in adherence to the Swiss laws of animal protection. For fluorescence excitation, three laser diodes at 660 nm with a power of 10 mW/cm^2 were used. The fluorescent light emitted from the sample (mouse) was detected by a charge-coupled device (CCD) camera (Hamamatsu) equipped with a focusing lens system (macro lens 60 mm, 1:2.8, Nikon). The CCD features low noise and

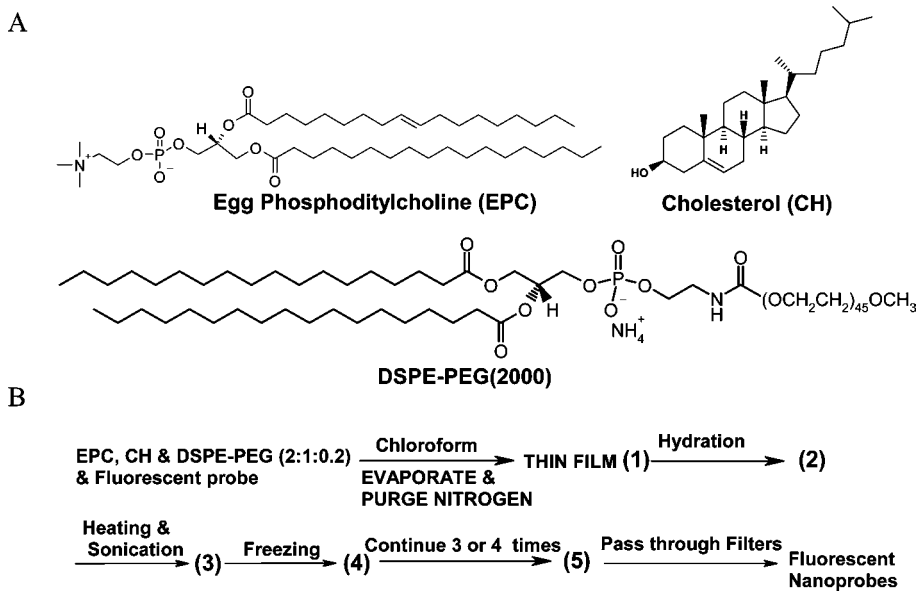

Figure 1. (A) Chemical constituents of fluorescent nanoprobe. (B) Schematic representation of formulation procedure.

low dark signal enabling low light level detection as well as long integration times. The matrix size of the images is 532 × 256 pixels. A hard filter was used for detection wavelength selection (700 nm). Data acquisition (i.e., integration) times ranged from 0.5 to 2.0 s depending on the intensity of fluorescence. The experiment was controlled by a PC using the Siemens SYNGO software. NIRF images have been analyzed quantitatively on a ROI basis using the same SYNGO software.

Mouse Antigen Induced Arthritis Model and NIRF Imaging. Ten female OF-1 mice, 12−14 weeks of age, were used. They were housed under standard conditions with a 12 h light/dark cycle, and water was provided *ad libitum*. During the 14 days before imaging experiments, the animals were fed a low-pheophorbide diet to reduce autofluorescence. Arthritis was induced in all 10 mice. The phase of systemic immunization proceeded as follows. Mice were sensitised intradermally on the back at two sites to methylated bovine serum albumin (mBSA) homogenised 1:1 with complete Freund's adjuvant on days −21 and −14 (0.1 ml containing 1 mg/ml mBSA). On day 0, the mice were anaesthetised using a 5% isoflurane/air mixture and maintained using isoflurane in a face mask for the intra-articular injections. The right knee received 10 μl of 10 mg/ml mBSA in 5% glucose solution (antigen injected knee), while the left knee received 10 μl of 5% glucose solution alone (vehicle injected knee). From day 0 to 7, the animals were treated with dexamethasone (NVP-AFC572-AB-2; 1 mg/kg, p.o.) or vehicle (A. dist). Arthritis development was monitored by measuring the lateral joint diameter with an Oditest vernier caliper on days 0, 2, and 4.

Using a GE eXplore Optix small animal imager (GE Healthcare, London, England), NIRF images for arthritis studies were recorded 6 h after i.v. injection of the ICG nanoprobe (size= 120 nm, ICG concentration = 151 μg/mL). For NIRF measurements, the animals were anaesthetized using 1.5% Isoflurane (Abbott, Cham) in nitrous oxide/oxygen 2:1 administered via a face mask. The duration of the anesthesia was 3 min, the time needed to scan 1 animal. All experiments have been carried out in adherence to the Swiss laws of animal protection. A pulsed laser at 670 nm with a power of 4.4 mW at 80 MHz repetitive rate and pulse durations of 60 ps was used for fluorescence excitation. The fluorescent light emitted from the sample (mouse) was detected by a photomultiplier tube (TD-

RESULTS AND DISCUSSION

Formulation and Characterization of Fluorescent Nanoprobes. Formulation of sterically shielded liposomes (SSL) was achieved by thin film hydration method. Egg phosphatidylcholine, cholesterol, 1,2-disteroyl-*sn*-glycero-3-phosphoethanolamine-*N*-methoxy(poly(ethylene glycol))-2000) (2:1:0.2 molar ratio) and Cy5.5 or ICG were mixed together and subjected to repeated freeze−thaw cycles and filtration through polycarbonate membranes and finally passed through a Sephadex column (Figure 1A). The size and polydispersity index (PDI) of the synthesized nanoprobes were estimated using dynamic light scattering (DLS) technique. Scanning electron microscopy studies showed that the particles are spherical and about the size of 100−150 nm, which is consistent with the results from DLS studies (data not shown). The liposome particles are decorated with poly(ethylene glycol) (PEG) arms in order to improve the pharmacokinetics/pharmacodynamics *in vivo* and avoid particle phagocytosis by macrophages (*39*).

As the probe molecules can be hydrophilic or hydrophobic depending on the nature of chemical functionality, it is crucial that delivery vehicles can encapsulate all types of compounds irrespective of their hydrophilic/hydrophobic index. The advantage of using liposomes is twofold: (i) they have an aqueous interior where hydrophilic compounds can be dissolved in the nanoscale dimension; (ii) second, they also have lipid bilayers made up of phosphatidylcholine and cholesterol that can be exploited to encapsulate hydrophobic probe molecules. Therefore, we consider that liposome-based nanoparticulates are ideal delivery vehicles for *in vivo* and cell-based applications. In order to demonstrate that our delivery vehicles can indeed encapsulate all types of probe molecules, we have tested the encapsulation ability of these particles with both hydrophobic (indocyanine green, ICG) and hydrophilic (Cy5.5) fluorescent probes. As expected, the liposomes can dissolve both hydrophilic and hydrophobic probe molecules (Figure 2). We also carried out

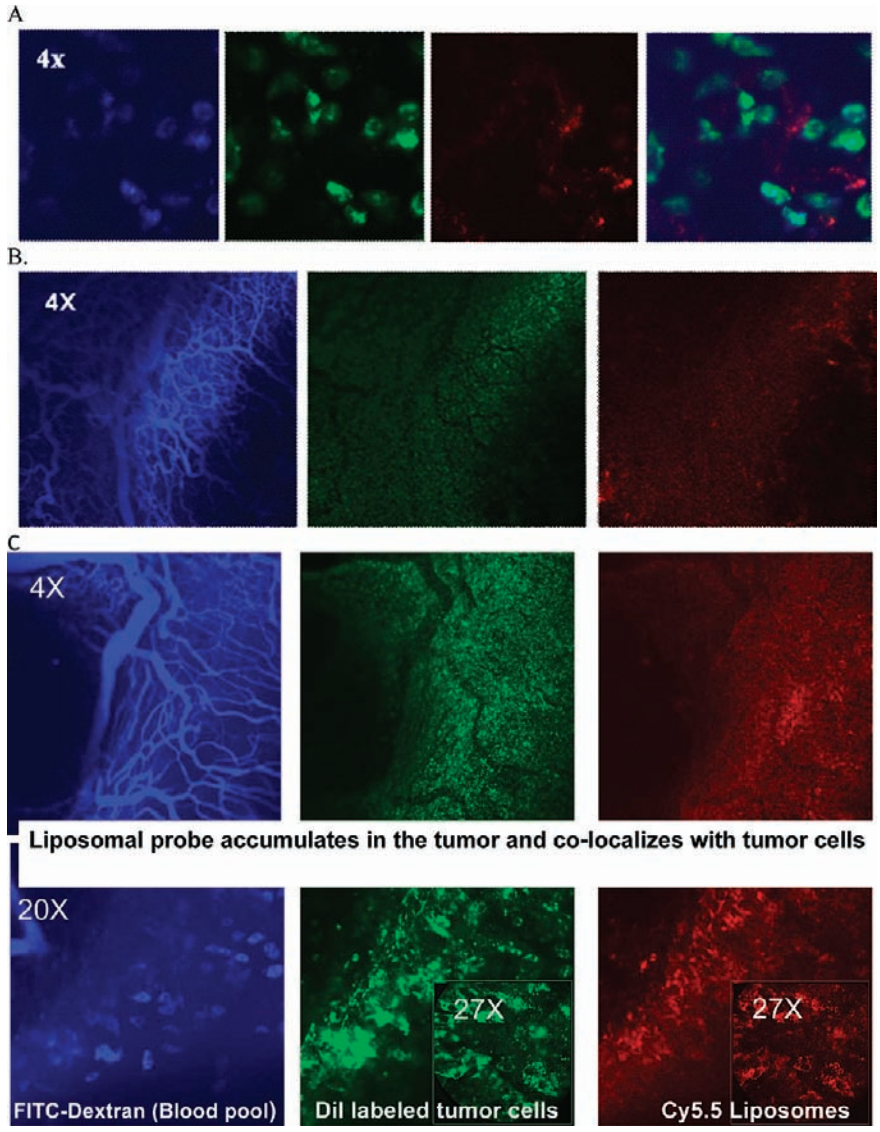

Figure 4. Cy5.5-labeled nanoprobe (size = 120 nm, Cy5.5 concentration = 43 μg/mL) was injected via tail vein injection 5 min before imaging, FITC-dextran (M_W = 500 000; 5 μL of 1 mg/mL stock diluted into 95 μL NaCl 0.9%) was applied via tail vein injection. (A) 30 min; (B) 6 h; (C) 24 h.

fluorescence measurements to determine that the dye inside the nanoscale compartment of liposomes resembles a dye in bulk solution. This is important because it has been shown that increased local concentration of a fluorophore inside the aqueous interior of the liposome might result in fluorescence quenching, thus complicating any analysis of the results. We have also performed stability studies of liposome formulation for 70 days and found that the particles were exceptionally stable. There was no problem of particle aggregation with long-term storage (Figure 2C).

***In Vivo* Studies of Fluorescent Nanoprobes in Tumor Model.** In order to test the passive targeting efficiency of these particles toward leaky vasculature, we chose tumor and arthritis disease models in mice. These two diseases share a common feature, which is the leaky vasculature nature of tumor/arthritic tissue (*11*) where the fluorescent liposome particles can be trapped and retained for longer time periods through the process called enhanced permeation and retention (EPR) effect (*11, 38*). The first *in vivo* studies of fluorescent nanoprobes were carried out in mice bearing PC3 tumors. PC3 tumor cells were subcutaneously implanted in nude mice and allowed to grow for 2 weeks until tumors achieved size of 150 mm^3. The nanoprobe containing Cy5.5 dye was injected i.v. via the tail vein of the mice and the particles tracked at different times. The 6 h time point revealed that the particles were circulating uniformly throughout the body. There was no preferential accumulation of particles in the tumor tissue/region at this time point, and the nanoprobe was distributed uniformly throughout the body. However, at 24 h, we could differentiate between tumor area and other parts of the body because of the enhanced fluorescence signal from the tumor region. We continued the studies to the next day, and the third reading was taken at the 48 h time point. The fluorescence signal intensity from the tumor area further increased, but the fluorescence signals from other parts of the body remained the same as previous time points. The studies were continued for another two days; the fluorescence signal at the 72 h time point started to decrease gradually and attained the base level at the 96 h time point (Figure 3a). Another interesting feature is that the fluorescence signal from a nontumor area remained the same during the entire study period (Figure 3b). In addition to that, we did not observe any adverse side effects in the animals due to nanoparticle toxicity and they were healthy throughout the study period. The above studies reiterate the point that these nanoprobes have good bioavailability and there are no toxicity issues associated with these delivery vehicles.

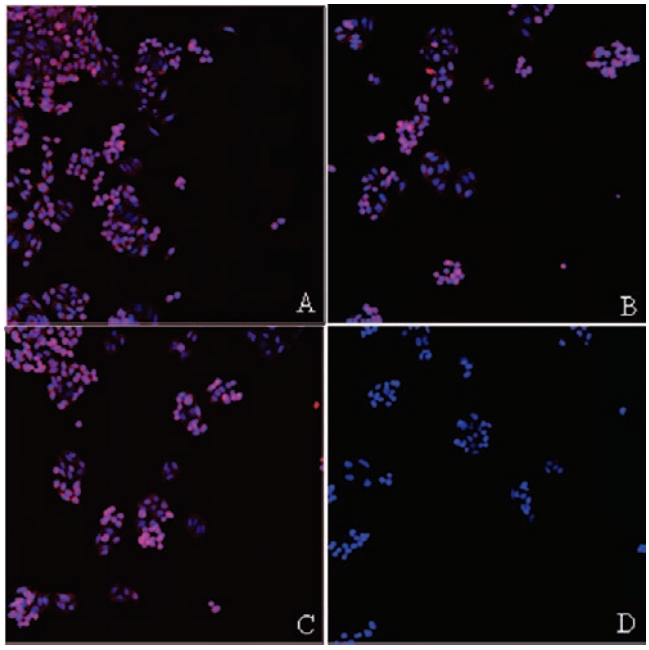

Figure 5. Intracellular uptake studies of nanoprobes in PC3 cell line: (A) PEGylated nanoprobe 1, size ~120 nm; (B) PEGylated nanoprobe 2, size ~73 nm; (C) naked nanoprobe (without PEG coating), size ~106 nm; (D) control nanoprobe (empty liposomes), size ~106 nm.

Intravital Microscopy Studies. The results from *in vivo* studies gave us only the macroscopic picture of the targeting nature of our nanoprobe toward tumor tissue but did not reveal information about the localization of our probe inside tumor cells. In order to look more closely at the cellular level, we have used intravital microscopy (IVM) for our studies. IVM has the ability to provide insight into various molecular and cellular processes *in vivo* with high spatial and temporal resolution down to the subcellular level (*40*). More recently, IVM was used to study the architecture and physiology of tumor neovasculature (*41*). For our studies, nude mice were implanted with DiI-labeled (green channel) PC-3 cells 2 weeks before nanoprobe infusion. The study involved 6 mice total, 2 mice/group, 3 time points (20 min, 6 h, and 24 h). The blood vessels were stained with FITC-labeled dextran (blue channel). Cy5.5-labeled nanoprobe (red channel) was injected in the tail vein and measurements were taken at time points similar to tumor studies in order to compare the results. At the 20 min time point, the fluorescent nanoprobe did not extravasate from intact blood vessels to the tumor tissue. After 6 h, Cy5.5-labeled nanoprobes were taken up by some of the tumor cells, which is in contrast to the *in vivo* imaging study results where fluorescence signal from the tumor area remained the same as the background signal (Figure 4). The inherent difference between fluorescence signal intensities from these two methods is attributed to the high sensitivity of IVM. However, the IVM results at the 24 h time point resembled *in vivo* studies in which fluorescent particles are retained in the tumor region for extended period. The colocalization of the nanoprobes and tumor cells at the 24 h time point suggests that the nanoprobe might be internalized by the tumor cells. In summary, the biodistribution and pharmacokinetics trends of liposome particles in *in vivo* studies are supported by the intravital microscopy results.

Intracellular Uptake of Nanoprobes in Tumor Cells. The results from intravital microscopy results suggest that nanoprobes might be internalized by tumor cells, but it is not definitive evidence. Therefore, we have focused our attention on *in vitro* cellular characterization of the nanoprobes through fluorescence microscopy. The uptake of custom-designed nanoparticles or microparticles inside a living cell depend on size, shape, and the particle surface potential (*42, 43*). In a classical example, DeSimone et al. showed that positively charged microparticles were taken up by the live cells more readily compared to negatively charged particles. In our studies, we

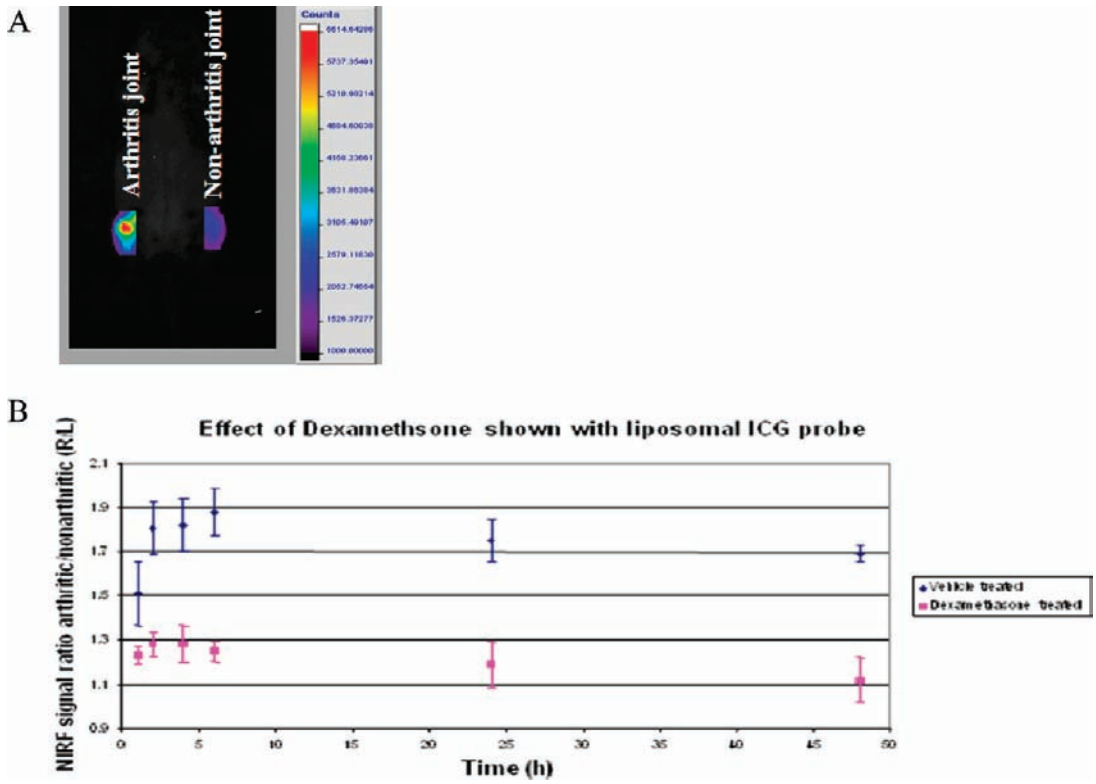

Figure 6. (A) NIRF images for arthritis studies were recorded 6 h after i.v. injection of the ICG nanoprobe (size ~120 nm, ICG concentration = 151 μg/mL). (B) Effect of drug treatment. Each data point represents the mean ± SEM of 10 animals.

have used PEG-coated nanoprobes to increase the circulation time and bioavailability of the fluorescent cargo. In order to demonstrate that PEG-coated nanoprobes have the same ability to get into the cells as nanoprobes without PEG coating, we incubated PEG-coated nanoprobes and naked nanoprobes with PC3 cells, and the particle internalization was analyzed. Results from fluorescence microscopy show that both particles were indeed internalized by the PC3 cells irrespective of their surface charge. We also studied the effect of particle size on the internalization process; however, it does not have any effect. The reason for the above phenomenon may be the small difference in the nanoparticle size (73 nm vs 120 nm) that we tested in this study (Figure 5).

Inflammation Imaging. Encouraged by the results in the tumor model, we wanted to extend this methodology to another disease model. We have chosen an arthritis model, antigen-induced arthritis (AIA), because of the presence of leaky vasculature in arthritic tissue (*44, 45*). We encapsulated indocyanine green (ICG), a clinically approved fluorescent dye (*36*), inside the nanoprobe. Arthritis was induced in the right knee of mice by the injection of mBSA into the joint in mice previously sensitized to mBSA systemically. The nanoprobes were injected i.v. via the tail vein and the NIRF measurements taken at different time points (Figure 6). There was no preferential accumulation of particles in the arthritis joints at initial time points. However, at the 24 h time point, we saw 2-fold increases in fluorescence signal from arthritic joint compared to the nonarthritic joint. These studies indicate that the nanoparticles can passively target leaky vasculature and can be trapped in arthritic joints for a longer time. The extension of this methodology in an arthritic disease model has shown the versatile nature of this methodology. The effects of drugs on vascular leakiness were subsequently investigated using fluorescent nanoparticles. Animals were treated orally with vehicle or dexamethasone at a dose of 0.3 mg/kg. Dexamethasone is an anti-inflammatory steroid from a class of drugs frequently used to treat human rheumatoid arthritis (RA) (*46–48*). Nanoprobes were injected i.v. after the administration of dexamethasone or vehicle, and the fluorescence signal was measured for these two groups of animals. The fluorescence signal from arthritic joint of the dexamethasone-treated animals was similar to the signal from nonarthritic joints. In contrast, the signals from the arthritic joints of vehicle-treated animals were 2-fold higher than the nonarthritic joints. This result indicates that treatment with dexamethasone can inhibit the vascular leakiness associated with the inflammation in the arthritic joints. The above results indicate that this method could be used as a tool to screen the efficacy of anti-inflammatory compounds in preclinical settings.

Preclinical and Clinical Implications of the Present Findings. The immediate question that one might ask is, how is this biomarker different from existing optical biomarkers for the detection of vascular leakiness? How could it be used to identify different stages of cancer or arthritis? Is it possible to translate this biomarker from preclinical to clinical use?

Use of near-infrared fluorescent probes for the detection of arthritis has previously been reported in the literature (*29, 49*). However, these small molecule fluorescent probes suffer from severe limitations that arise due to poor pharmacokinetics and biodistribution properties (*50*). In addition, these probes nonspecifically bind to various blood proteins (*51*). Fluorophore-labeled antibodies were also explored for these kinds of applications (*49*). However, no specific biomarker for arthritis is known. The significance of our finding is the elegant combination of delivery vehicle (*34*) (PEGylated liposomes) and the fluorescent probe (ICG), as both are clinically approved for use in humans for different applications. By encapsulating ICG inside liposomes, the half-life time of this probe is increased from minutes (*50*) to several hours. Second, the size range of liposome particles (100−200 nm) favors the targeting efficiency of these particles toward leaky vasculature. Out of all, the most important finding of this report is the use of an optical method to screen anti-inflammatory drugs in *in vivo* conditions in preclinical settings. The utility of this method goes beyond the present findings. This tool also could be used to detect at least two stages of antigen-induced arthritis in mouse model, since the vascular leakiness drastically differs between acute and chronic phase of inflammation (*52*). The extravasation of fluorescent liposomes during acute-phase inflammation is expected to be higher compared to chronic phase, and therefore, the NIRF signal during acute phase should be higher compared to chronic phase. With respect to tumor imaging, the limitation of this probe is the detection of tumors with sizes less than 1−2 mm^3, as neovascularization starts only after tumor reaches size of about ∼2 mm^3, which results in leaky vasculature of tumor tissue (*53–56*). On the positive side, this method could be used as a tool to screen the efficacy of various antiangiogenic agents in various tumor models based on the notion that the treatment with antiangiogenic compounds should result in normalization of abnormal blood vessels that should result in decreased extravasation of fluorescent liposomes to tumor tissue (*57*).

CONCLUSION

We have shown the design, synthesis, and characterization of fluorescent nanoprobes. Stability studies of nanoprobe solutions show that these particles are stable for long periods of time. These nanoparticles are decorated with poly(ethylene glycol) for the enhanced circulation and passive targeting of tumor/arthritis tissue. Apart from the validation of probes with near-infrared fluorescence imaging studies, the probes have also been validated in intravital and fluorescence microscopy studies. Results from our studies show that optical imaging combined with appropriate nanoparticles could be used as functional biomarkers for the presence of increased vascular leakiness in pathological conditions. The concept behind the application of this new technology is demonstrated in two different disease models.

ACKNOWLEDGMENT

We thank Mr. Fritz Wenger and Ms. Alexandra Suter for preparing the animals for the *in vivo* imaging studies. We also thank members of Gabriel Lab for their support and assistance. This work was funded by Novartis Institutes for Biomedical Research, Education Office, and Global Imaging Group.

Strategies and Limitations in Dendrimeric Immunogen Synthesis. The Influenza Virus M2e Epitope as a Case Study

Wioleta Kowalczyk, Beatriz G. de la Torre, and David Andreu*

Department of Experimental and Health Sciences, Pompeu Fabra University, Barcelona Biomedical Research Park, Dr. Aiguader 88, 08003 Barcelona, Spain. Received July 27, 2009; Revised Manuscript Received December 3, 2009

Dendrimeric platforms such as multiple antigen peptides (MAPs) are regarded as one of the most efficacious approaches for antigenic presentation. Originally described as available by stepwise solid-phase peptide synthesis (SPPS), MAPs have also been prepared by chemical (thioether, oxime, hydrazone) ligation of appropriately functionalized tetra- or octavalent polylysine scaffolds with the peptide antigen to be multiply displayed. In this work, the advantages and limitations of two of the most frequent methods of MAP preparation, namely, chemoselective thioether ligation in solution, and all-solid-phase synthesis, have been tested in the case of a particularly troublesome epitope model, the ectodomain of protein M2 from influenza virus (M2e). The strong tendency of M2e to self-associate is a serious inconvenient for conjugation in solution, which as a result fails to produce the target MAPs with the specified number of M2e copies. In contrast, the fully stepwise SPPS approach is shown to be quite practical, especially when 6-aminohexanoic acid spacer units providing increased internal flexibility are inserted at each branching point.

INTRODUCTION

The usually low immunogenicity of short peptide epitopes, which precludes their use in free form for purposes such as raising antisera or candidate vaccine trials, has been addressed by various strategies, chiefly conjugation to carrier proteins (for an exhaustive treatment, see ref *1*), but also lipidation (*2, 3*) or association to particulate systems such as liposomes (*4, 5*) or immunostimulating complexes (*6*). One particularly successful approach has been multimerization, either by simple polymerization (*7*) or by chemically better defined strategies such as conjugation to sequential oligopeptide carriers (*8, 9*), display on lysine scaffolds (*10, 11*), or, last but not least, incorporation into dendrimeric systems such as the multiple antigenic peptides (MAPs) pioneered by Tam in the 1980s (*12*). MAPs are based on a small immunologically inert core of radially branching lysine dendrites onto which a number of peptide epitopes are attached. The result is a large macromolecule with a high molar ratio of peptide antigen to core molecule that usually does not require further conjugation to a carrier protein (though it may benefit from it; see, e.g., *refs* 13, 14). MAPs were originally described as available by standard stepwise solid-phase peptide synthesis (SPPS) (*12*), but have later also been produced in solution through various forms of chemical ligation (*15*−*17*). As the ligation reactions usually involve the combination of prepurified peptide modules, they can purportedly produce chemically more unambiguous materials (*16*) than SPPS methods, where minute but cumulative synthetic errors (deletions, truncations, etc.) become amplified by multimerization and may predictably lead to relatively heterogeneous immunogens. While the fairly extensive literature on, e.g., the immunological and microbiological applications of MAP and similarly dendrimeric platforms, highlights their value as candidate vaccines (*18*) or antimicrobial agents (*19, 20*), it is not always informative enough on the chemical specifications of the constructs at hand. In particular, and to the best of our knowledge, the literature on immunopeptides, MAPs, and similar bioconjugates lacks comparative studies where the potential merits and flaws of each synthetic (solution or stepwise SPPS) approach are evaluated in adequate chemical detail. In this work, we have investigated these aspects as they apply to a synthetically demanding peptide epitope (see below), then selected and improved the synthetic route leading to MAP platforms with optimal specifications.

The epitope chosen for this study is based on the N-terminal ectodomain (M2e) of influenza type A virus matrix protein 2 (M2). The M2 protein forms a pH-activated proton channel on the surface of the virion that mediates the uncoating of the viral particles in endosomes of the infected cell (*21*). The importance of the M2 protein in viral replication has been demonstrated by the ability of the antiviral drug amantadine and M2 specific antibodies to reduce viral propagation *in vitro* and *in vivo* (*22*−*24*).

M2 is made up of three main regions: the N-terminal, 24-residue ectodomain (M2e), the ensuing 19-amino acid transmembrane region that tetramerizes to form the pore of the proton channel (*25*), and the 54-residue cytoplasmic tail. While M2 is expressed abundantly on infected cell surfaces, in virus particles only a few M2 copies are displayed (*24*), in contrast to the other two major viral surface proteins hemagglutinin (HA) and neuraminidase (NA) (*26*−*29*). M2 is also weakly immunogenic relative to HA and NA (*30*) and highly conserved among human influenza virus strains (*31*). Table 1 lists (nonexhaustively) the M2e sequences from different influenza strains. It can be seen that, despite a high number of outbreaks up to the present 2009 pandemic, M2e has experienced minimal sequence alterations since 1933 (*32*), when the first human influenza strain was isolated. This remarkable lack of genetic variability, plus its relatively small size and the fact that antibodies to M2e protect mice from influenza A mortality, have made M2e a very popular epitope, not only for general immunogenicity studies but also as a potential vaccine candidate (*26, 31, 33*−*37*). M2e-based vaccines have been mostly obtained by either chemical conjugation to carrier proteins such as keyhole limpet hemocyanin, bovine serum albumin, or outer membrane protein complex or

Figure 1. General structures of the different MAPs in this study. For type 1, the tioether linkage between the peptide epitope and the tetra-acetylated Lys core is shown. For type 2, the line between the epitope and the Lys core indicates a peptide bond. For type 3, the wavy lines around every Ahx residue emphasize the flexibility provided by this residue.

by genetic insertion into hepatitis B virus core antigen or papaya mosaic virus (PapMV) vaccine platforms (*26, 31, 38*−*40*).

As mentioned above, the goal of this study was to evaluate the advantages and limitations of chemical (thioether) ligation vs SPPS approaches for producing MAP dendrimeric peptides, and M2e was judged to be an interesting epitope not only for its above-mentioned biological relevance but also for the fact that despite its apparent (24 amino acid) simplicity it turns out to be synthetically nontrivial. Thus, three different types of MAP constructs (Figure 1) have been designed and prepared by either chemical ligation or SPPS methods, and the product composition of each synthetic trial has been analyzed in considerable detail. The study reveals how some structural peculiarities of the chosen M2e epitope, mainly its tendency to self-associate, entail considerable difficulties for the chemical ligation approach. In such an unfavorable context for conjugation in solution, the SPPS-based MAP synthetic strategy, especially fine-tuned in the present case to prevent sequence aggregation, emerges as the preferred route to MAP platforms displaying the M2e epitope.

EXPERIMENTAL PROCEDURES

Chemicals and Biologicals. Fmoc-protected amino acids were obtained from Senn Chemicals (Dielsdorf, Switzerland). Fmoc-Ser(tBu)-Ser($\Psi^{Me,Me}$pro)OH and Fmoc-Rink-amide (MBHA) resin were from Novabiochem (Läufelfingen, Switzerland). ChemMatrix resin, 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), and *N*-hydroxybenzotriazole (HOBt) were from Matrix Innovation (Montreal, Canada). HPLC-grade acetonitrile, and peptide synthesis grade *N*,*N*-dimethylformamide (DMF), dichloromethane (DCM), *N*,*N*-diisopropylethylamine (DIEA), and trifluoroacetic acid (TFA) were from SDS (Peypin, France). Anti-influenza A virus M2 protein monoclonal antibody 14C2 and rabbit polyclonal antibody to mouse IgG were from Abcam plc (Cambridge, UK). SIGMA*FAST p*-nitrophenyl phosphate tablets were from Sigma (Saint Louis, MO, USA). 96 well microplates were from Corning Inc. (Corning, NY, USA). All other reagents were of the highest quality available commercially.

General SPPS Protocols. Automated syntheses were performed in an ABI433 peptide synthesizer (Applied Biosystems, Foster City, CA) running standard Fmoc (FastMoc) protocols (*41*) at 0.1 mmol scale on Fmoc-Rink-amide ChemMatrix resin. Eight-to-10-fold excesses of Fmoc-L-amino acids and HBTU/HOBt, in the presence of double the molar amount of DIEA, were used for the coupling steps, with DMF as solvent. All side-chain functions were protected with TFA labile groups. In the longer M2e epitope, the two pairs of consecutive Ser residues were introduced as the pseudoproline dipeptide Fmoc-Ser(tBu)-Ser($\Psi^{Me,Me}$pro)-OH using a manual coupling with 4-fold excess

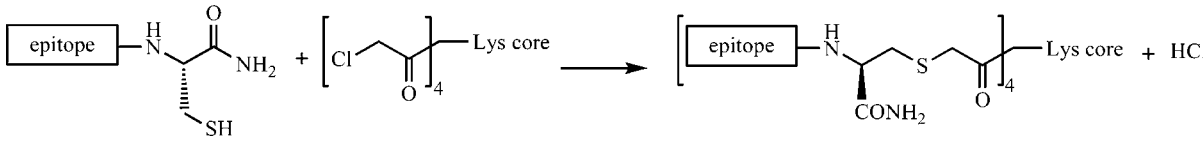
[a] As described in Figure 1. [b] MAPs with flexible spacers.

of dipeptide and HATU in the presence of DIEA (8-fold excess) in DMF. For manual synthesis operations, the peptide resin was placed in a syringe reactor fitted with a porous polyethylene disk. After synthesis completion, peptide resins were N-deblocked with piperidine/DMF (20% v/v) prior to full deprotection and cleavage with TFA/H_2O/EDT/TIS (94:2.5:2.5:1 v/v, 90 min, RT). Peptides were precipitated by addition of chilled methyl *tert*-butyl ether, taken up in aqueous AcOH (10% v/v), and lyophilized.

Analysis and Purification. Analytical reversed-phase HPLC was performed on C_{18} or C_8 columns (4.6 × 50 mm, 3 μm, Phenomenex, Torrance, CA) in a model LC-2010A system (Shimadzu, Kyoto, Japan). Solvent A was 0.045% (v/v) TFA in water, solvent B was 0.036% (v/v) TFA in acetonitrile. Elution was done with linear gradients of solvent B into A over 15 min (see chromatograms for further details) at 1 mL/min flow rate, with UV detection at 220 nm. Preparative HPLC was performed on C_{18} (21.2 × 250 mm, 10 μm, Phenomenex) or on C_8 column (10 × 250 mm, 10 μm, Phenomenex) in a Shimadzu LC-8A instrument. Solvents A and B were 0.1% TFA (v/v) in water and acetonitrile, respectively, and elution was again with linear gradients of solvent B into A over 35 min, at 25 or 5 mL/min flow rate for C_{18} or C_8 separations, respectively, with UV detection at 220 nm. Preparative fractions of satisfactory purity (>95%) by analytical HPLC were pooled and lyophilized. The purified peptides and MAPs were characterized for identity by MALDI-TOF MS in a Voyager DE-STR instrument (Applied Biosystems), using either sinapinic or α-hydroxycinnamic acid matrixes. MS spectra were in the reflector mode for the two linear peptide epitopes and the tetravalent Lys core; for larger-sized analytes, the linear mode was used. For even larger sized MAPs (e.g., the last two entries in Table 2), spectra were acquired in an LTQ-Orbitrap XL instrument (Thermo Fisher, San José, CA).



Type-1 MAPs by Thioether Ligation. The peptide epitopes M2e and sM2e to be conjugated to the tetravalent branched Lys core (see Figure 1) were prepared by the above SPPS protocols and, after significant optimization, particularly for M2e (see Results below), were characterized by analytical HPLC and MALDI-TOF MS (see Table S1, Supporting Information). In all cases, the purified peptides were obtained in free thiol form, with no disulfide detected by MS. The tetravalent [$(Lys)_2$LysLysLysCys(S-*t*Bu)] core was also assembled by SPPS in the ABI433 instrument at 0.1 mmol scale. For the first two Lys residues (from the C-terminus), the conventional Fmoc-Lys(tBu) derivative was used; branching was then achieved by introducing Fmoc-Lys(Fmoc) at the following two synthetic cycles. After this, the synthesis was switched to the manual mode (see above) for deprotection with piperidine/DMF (20% v/v) for 5 and 15 min and chloroacetylation with 4 mmol of chloroacetic acid in the presence of an equivalent amount of diisopropylcarbodiimide in dichloromethane. Cleavage with TFA/H_2O/TIS (95:2.5:2.5 v/v/v, 1 h, RT) and preparative RP-HPLC purification led to the target branched peptide in analytical HPLC-homogeneous form and with the expected mass by MALDI-TOF MS (see Figure S1 and Table S1, Supporting Information).

For the thioether ligation reaction, 1.16 mg (1 μmol) of the tetra-chloroacetylated Lys core was dissolved in 5 mL of 20 mM Tris, 2 M guanidinium chloride buffer, pH 7.6, at 50 °C, then 12 μmol (12-fold molar excess) of either M2e or sM2e peptide epitope were added portionwise to the solution, adjusting the pH as required. Aliquots of the mixture were taken for analytical HPLC and MALDI-TOF MS, and when no further changes in the HPLC profile were observed (usually after 15−20 h), the reaction product was separated by preparative RP-HPLC. Fractions representative of different degrees of epitope incorporation (Table 2, first entry) were characterized by analytical HPLC and MALDI-TOF MS. For further details, see the Results section below.

Full Stepwise SPPS of Type-2 and Type-3 MAPs. The different MAP constructs (see Figure 1 for details) were assembled mostly by automated procedures in an ABI433 synthesizer running the FastMoc protocols discussed above on Fmoc-Rink-amide ChemMatrix resin at 0.02 mmol scale. 10-fold excesses of Fmoc-protected L-amino acids and HBTU/HOBt in the presence of DIEA (20-fold excess) were routinely used throughout. Branching was achieved at the appropriate points by incorporation of the Fmoc-Lys(Fmoc) derivative. As above, the two Ser-Ser dipeptides of the full-length M2e epitope were introduced in the manual mode as the pseudoproline dipeptide Fmoc-Ser(tBu)-Ser($\Psi^{Me,Me}$pro)-OH. Deprotection and cleavage were as described in the general SPPS protocols above. The synthetic crudes were purified by preparative HPLC and characterized by analytical HPLC and MALDI-TOF MS. Analytical data on the different MAPs are given in Table 2.

ELISA. Peptide stock solutions (either the single M2e sequence or tetravalent type-3 MAP) were initially made up at 25 μM concentration in PBS (pH 7.4), then serially diluted so that 0.8, 0.6, 0.4, and 0.2 nmol peptide aliquots in 50 μL PBS were placed in triplicate in the wells of a microtiter plate for overnight coating at 4 °C. Wells were then washed three times with PBS containing 0.05% Tween-20, and the remaining sites on the wells were blocked by 3% BSA in PBS/Tween-20 at 37 °C for 2 h. After another three washes, 200 μL of a 1:10 000 dilution of mouse monoclonal 14C2 was added to wells and incubated for 2 h at 37 °C. The wells were washed three times

Scheme 1. Thioether Ligation Route to Type-1 MAPs

with PBS/Tween-20 to remove unbound antibody, then incubated with a 1:5000 dilution of the alkaline phosphatase conjugate of rabbit polyclonal antimouse IgG in 1%BSA/PBS/Tween-20 for 2 h at 37 °C. Wells were next washed three times with PBS/Tween-20, and 50 μL of a 1.0 mg/mL solution of *p*-nitrophenyl phosphate in 0.2 M Tris, 5 mM $MgCl_2$ was added to each well. After 30 min incubation, the plate was read at 405 nm in an ELx808 microplate reader (Bio-Tek Instruments Inc., Winooski, VT).

RESULTS

Ligation Approach to M2e Dendrimers. The different types of MAP structures produced and examined in this study are shown in Figure 1, along with the sequences of full-length (M2e) and shortened (sM2e) versions of the M2 ectodomain epitope. An influenza H5N1 M2e peptide sequence was used in this study in which the two internal Cys residues were changed to Ser to prevent disulfide bond formation which would complicate the synthetic work (see Table 1). Table 2 provides detailed molecular structures and analytical data to help the reader through the following description and discussion.

The M2e peptide initially used in the ligation approach to type-1 MAP contained a Cys residue in free thiol form required for the thioether ligation reaction with the tetra-chloroacetylated branched lysine core (Scheme 1), which in turn was made with a C-terminal Cys orthogonally protected with a temporary *tert*-butylthio group ensuring temporary protection during the ligation step and eventually enabling, after deprotection, either dimerization of the MAP or further conjugation onto a higher-order carrier. Another feature of this type-1 MAP (see Figure 1) was the two Lys residues adjacent to the first Lys branching point. The purpose of this Lys-Lys motif was to define a cathepsin-like cleavage site (*7*) which might favor the in vivo processing of the dendrimeric moiety.

An unforeseen problem of the ligation approach was that the 25-residue-long M2e peptide turned out to be a relatively challenging synthetic target, requiring considerable optimization. A first synthesis on standard Rink-amide by the typical Fmoc methodology resulted in a complex, unpromising product vis-à-vis its subsequently expected use (Figure 2A). Use of the demonstrably superior Rink-amide ChemMatrix resin (*42*) and double coupling at some positions (Glu residues 16 and 14, plus the entire Glu8-Ser2 stretch, based on MS analysis of the crude from the initial trial, and on prediction of difficult sequences with the Peptide Companion program) ameliorated only partially the situation (Figure 2B). In a third, successful trial, the above improvements plus replacement of the two pairs of consecutive Ser residues in the M2e sequence with the pseudoproline dipeptide Ser(tBu)-Ser($\Psi^{Me,Me}$pro)-OH (*43*−*45*) led to a more acceptable product that could be purified and characterized as the desired M2e peptide in free thiol form (Figure 2C; see also Figure S1 and Table S1, Supporting Information). The chemoselective ligation of this purified, sparingly soluble peptide to the $ClAc_4$-Lys core was carried out in Tris-Cl buffer at pH 7.6 and 50 °C, using a 10−12-fold molar excess of M2e peptide in order to drive the reaction into completion. Addition of chaotropic agents (e.g., guanidinium chloride) to multimer-building reactions of this type has been predicated as preventing aggregation and favoring maximal substitution (*46, 47*), but in our case, it did not have any positive effect. Analytical RP-HPLC of the ligation process revealed quite a complex reaction mixture (Figure 3), which by MALDI-TOF MS analysis (Figure S3,

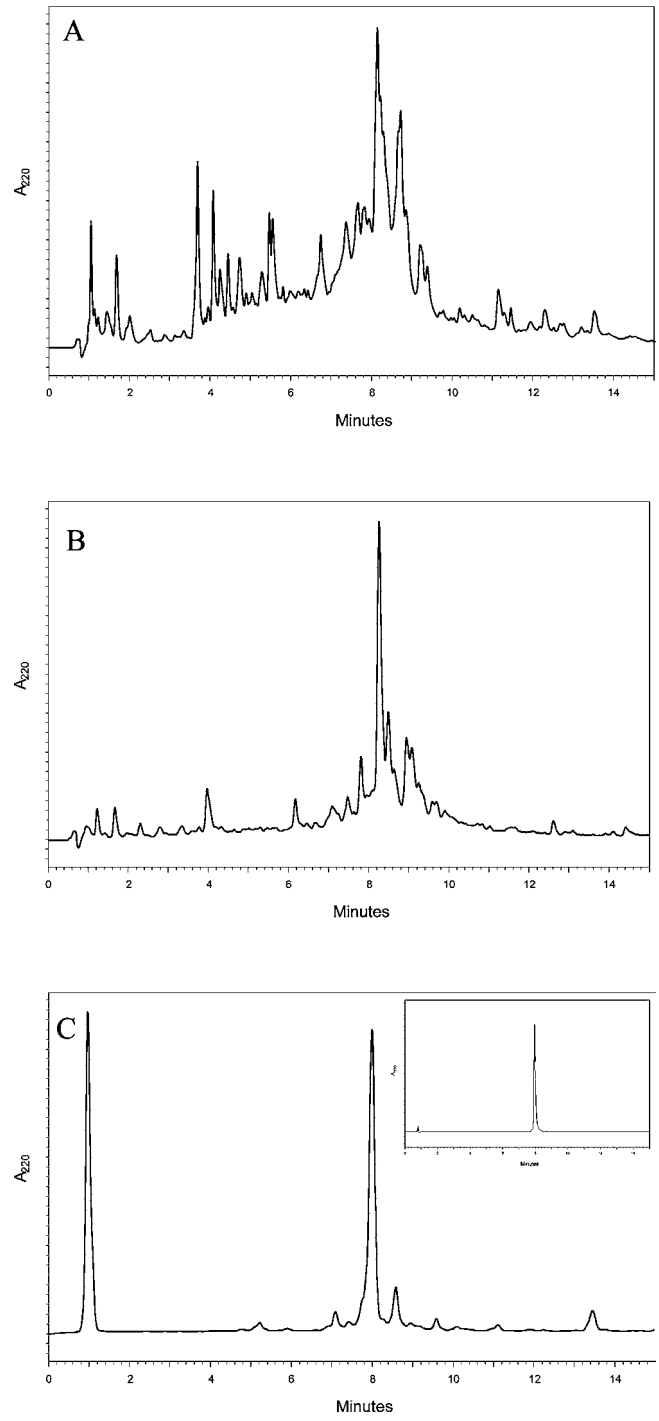


Figure 2. HPLC of crude M2e peptide made by different Fmoc synthesis strategies. A: Rink amide MBHA resin. B: Rink-amide ChemMatrix resin, double couplings at selected positions. C: as in B, with pseudo-Pro dipeptide replacements. 5−50% linear gradient of eluent B into A over 15 min. Analytical C_{18} column. Inset: HPLC of purified M2e, same elution conditions. See Experimental Procedures (Analysis and Purification section) in the main text for further details.

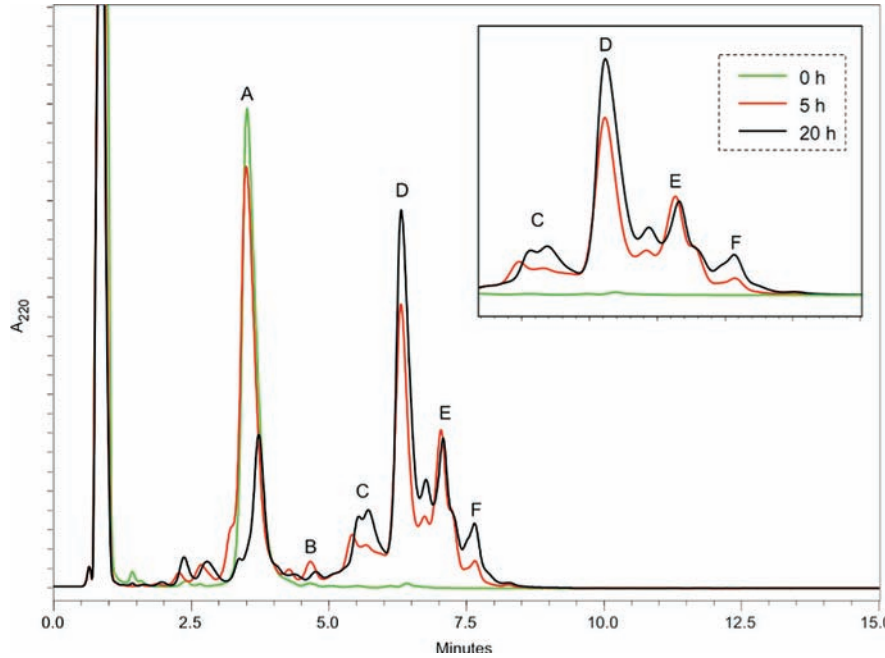

Figure 3. Progress of the chemical ligation of M2e to $ClAc_4$-Lys core monitored by HPLC at 0, 5, and 20 h reaction time (green, red, and black traces, respectively). 20−35% linear gradient of eluent B into A over 15 min. Analytical C_{18} column. Peaks labeled A−F correspond to M2e peptide, 1-copy MAP, mixture of 1- and 2-copy MAP, M2e dimer and tetramer, 3-copy MAP, mixture of 3- and 4-copy MAP, respectively.

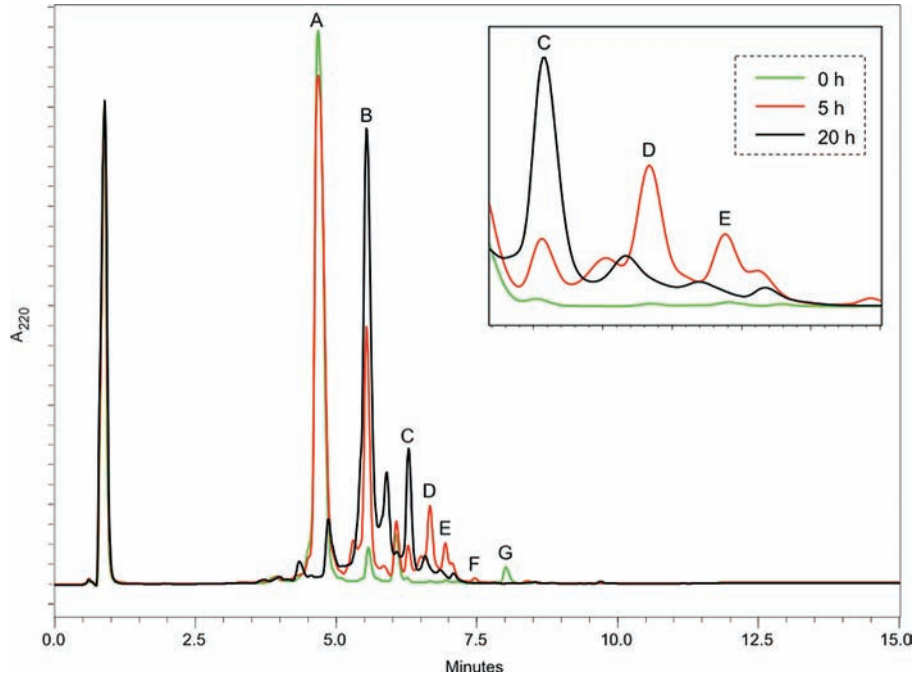

Figure 4. Progress of the chemical ligation of sM2e to $ClAc_4$-Lys core monitored by HPLC at 0, 5, and 20 h reaction time (green, red, and black traces, respectively). 10−40% linear gradient of eluent B into A over 15 min. Analytical C_{18} column. Peaks labeled A−G correspond to sM2e peptide, sM2e dimer, 4-copy MAP, 3-copy MAP, 2-copy MAP, 1-copy MAP, and unreacted $ClAc_4$-Lys core, respectively.

Supporting Information) was shown to include type-1 MAPs containing different numbers of copies of the M2e epitope (Table 2, first entry). HPLC resolution of these MAP products was poor (Figure 3), even using rather shallow gradients. Coeluting with the MAP products, substantial levels of the disulfide dimer of M2e were found (Figure 3), and quite unexpectedly, sizable amounts as well of a species that by MALDI-TOF and MS/MS analysis was identified as a tetramer of M2e (Figures S3A and S4, Supporting Information), i.e., the aggregate of two M2e (disulfide) dimers.

Since the aggregation tendency of the 25-residue M2e epitope posed unanticipated complications in the ligation approach, a shorter version of M2e (sM2e) was prepared (Figure S2 and Table S1, Supporting Information). This peptide was much simpler to make and gave no evidence of multimerization. Using the above reaction conditions, the ligation of the $ClAc_4$-Lys core and sM2e proceeded smoothly, as monitored by analytical RP-HPLC (Figure 4). MALDI-TOF MS analysis (Figure S5, Supporting Information) showed the target dendrimer (four copies of the sM2e peptide) as the main outcome, although byproducts with two or three copies of sM2e were also present in the reaction mixture. Results are summarized in Table 2.

Solid-Phase Approach to M2e Dendrimers. Since the chemoselective ligation described above fell short of expecta-

tions as an efficient route to M2e dendrimeric constructs, we turned our attention to the originally reported SPPS method of MAP synthesis. The two MAP varieties made by this approach, types 2 and 3 (Figure 1), similarly to type 1 contained a Cys residue at the C-terminus, to be used for dimerization, attachment of an additional peptide epitope (e.g., a T-cell epitope), or conjugation to carrier proteins (KLH or BSA), all with a view to further increasing the immunogenicity of the constructs.

Given the difficulties observed during the synthesis of the M2e peptide (see above), the shortened sM2e sequence was initially chosen to optimize the synthetic methodology. As shown in Figure 1, the first MAP attempted by SPPS was of the classical, type 2 variety, displaying four copies of sM2e (Table 2, third entry). This dendrimer was obtained rather straightforwardly by stepwise SPPS on a Rink amide ChemMatrix resin using standard Fmoc chemistry (Figure S6, Supporting Information) with double couplings throughout the sequence of the epitope. Next, and in anticipation of the difficulties that a full-length M2e epitope might pose to MAP synthesis, it was decided to enhance the overall flexibility of the MAP skeleton by introducing 6-aminohexanoic acid (Ahx)[1] spacer units at each branching point. This modification defined a novel architecture, type-3 MAP (Figure 1), first tested in tetravalent fashion with the uncomplicated sM2e epitope (Table 2, fourth entry). Again, this dendrimer was readily accessible, basically trouble-free, through stepwise SPPS (Figure S7, Supporting Information). With such favorable results in hand, it seemed appropriate to take on the potentially challenging synthesis of the MAP with four copies of the full-length M2e epitope (Table 2, fifth entry). The same tactics that had significantly improved the synthesis of the single-chain M2e, namely, replacement of the two Ser-Ser pairs by pseudoproline dipeptides (Fmoc-Ser(tBu)-Ser($\Psi^{Me,Me}$pro)OH), were again applied in a stepwise Fmoc SPPS on Rink amide ChemMatrix resin, again using double couplings throughout the entire M2e epitope sequence. Once more, the SPPS approach turned out a rather clean, easily purifiable and satisfactorily characterized end product (Figures S8 and S9, Supporting Information). Encouraged by this positive result, the strategy was pushed one step further in the synthesis of a type-3 octavalent sM2e MAP (Table 2, sixth entry). Remarkably, the end product was again readily accessible and characterized (Figure S10, Supporting Information). The logical extension of the all-SPPS approach was the octavalent version of the M2e MAP (Table 2, last entry). Unfortunately, application of the so-far successful combination of improvements (i.e., Ahx spacers, ChemMatrix resin, double couplings, pseudoproline dipeptide mimics) completely failed this time to provide any discernible trace of the desired MAP product.

Immunological Evaluation of M2e Presentations. After having proven the feasibility of obtaining a multimeric version of M2e in a relatively trouble-free way, it remained to be ascertained whether the enhanced epitope display provided by the tetravalent MAP platform translated into an equivalent increase in antigenic recognition (*48, 49*). This point was investigated by means of an ELISA where the monovalent M2e peptide and its tetravalent version (Table 2, fifth entry) were tested against the M2e-specific monoclonal 14C2. Lack of specific antibodies prevented a similar evaluation with sM2e-displaying MAPs. Figure 5 shows that the antigenic response obtained with the single M2e peptide was indeed amplified with the MAP, with a 3-to-4-fold increased response that was in good agreement with the multimerization level provided by the MAP.

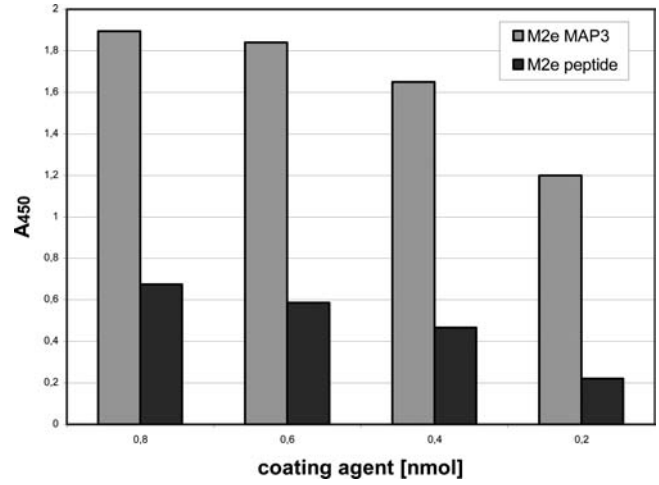

Figure 5. ELISA of M2e peptide in monomer (black columns) and type-3 MAP (gray columns) presentations against 14C2 monoclonal antibody.

DISCUSSION

The goal of this study was to examine the relative advantages and limitations of the two main approaches to MAP constructs, namely, chemical ligation in solution (*16, 50, 51*) or fully stepwise SPPS (*12*). As a backdrop for such an endeavor, there was an intuition, partially grounded on our own previous experience in the field, that a nontrivial fraction of the synthetic attempts on MAPs by either of the above approaches had met with problems such as insolubility of the final product, sluggish progress of chemical ligation, and so forth, all leading to unsatisfactory results that either went unreported or were published with minimal, if any, chemical documentation.

In principle, the former (ligation) method would appear to be conducive to superior results, since purification of the intermediates (peptide epitope and branched Lys core) would yield an end product devoid of the minute but inevitable impurities (truncations, deletions) accumulated over a stepwise process, where the simultaneous growth of four—or even eight—peptide chains on a single molecular platform may, in some cases, promote aggregation, and in general have an amplifying effect on side reactions and thus the heterogeneity of the final product. These theoretical benefits of the ligation approach, however, can be severely challenged by experimental facts, as the above results on the incomplete conjugation of both M2e and sM2e epitopes on type-1 MAP scaffolds show. The most likely cause for our failure to obtain type-1 MAPs with the maximum number of epitope copies as a major final product is that, as successive epitope units are incorporated onto the $ClAc_4$-Lys scaffold, they generate a certain steric hindrance that may seriously hamper the access of (the Cys nucleophilic sulfur atom of) any incoming peptide epitope to the remaining unreacted ClAc groups. In the particular case of the present study, the nature of one of the peptide epitopes chosen, i.e., the full-length M2e, posed even additional difficulties for the chemoselective ligation approach (see below), exceeding in complexity any other similar reaction within our own expertise (*18*). It is indeed known from structural studies that the ion channel-forming transmembrane domain of M2 protein exists as a homotetramer (*21, 25, 52*−*57*). The present results would appear to suggest that, beyond the transmembrane region, an

aggregation propensity is also inherent (or somehow relayed) to the ectodomain as well.

Yet, even when this latter inconvenient was dealt with appropriately (i.e., by switching to a shorter sM2e epitope), solution ligation remained a less rewarding approach to MAP constructs than originally anticipated. In assessing the evidently complex outcome of this synthetic route (see especially Figure 3, also Figure 4), it is worth noting that, of all the possible products (final and intermediate) of such a ligation reaction, only the 4-copy MAP has a univocal chemical constitution; other intermediates (i.e., those with 1−3 epitope copies) may exist as slightly similar but constitutionally nonequivalent (though isobaric) isomers, depending on which positions in the branched Lys scaffold are occupied by the epitopes. Therefore, and despite very careful collection, HPLC fractions representative of a given M2e epitope multiplicity (n= 2, 3, 4) were not strictly homogeneous.

The alternative approach to MAPs, namely, fully stepwise SPPS, was for its part not devoid of difficulties either. While the relatively simple type-2 MAP with four copies of the sM2e epitope was viable, the known propensity to aggregate of the biologically more relevant M2e epitope (see Ligation approach to M2e dendrimers, Results section) might pose synthetic trouble for the corresponding MAP. As a safeguard against interchain association, it seemed to us that augmenting the global flexibility of the growing MAP construct by insertion of Ahx spacing units might be beneficial. This was indeed proven so in the syntheses of the tetravalent type-3 MAPs of both sM2e and M2e, as well as for the octavalent MAP of sM2e. However, extension of the approach to an octavalent M2e MAP did not meet with success, and its synthetic viability remains an open question.

In sum, depending on the targeted level of multiplicity and on the size and aggregation potential of the epitope to be displayed, MAP synthesis can range from facile to outright impracticable. The theoretical advantage that chemoselective ligation of prepurified components offers is seriously offset by slow reaction rates (possibly due to steric hindrance) and, in aggregation-prone peptide epitopes such as M2e, by additional adverse effects. This appears to give an edge to the original SPPS approach, which can be even further improved—especially in the case of potentially problematical epitopes such as M2e—by an enhancement of the internal flexibility of the construct such as that provided by the insertion of Ahx spacing units at the different branching points of the MAP dendrimer. While this appears to have a positive effect on synthetic viability and general quality (e.g., yield, solubility) of the end product, it cannot be regarded as a failsafe solution, as our results on the octavalent M2e show. All in all, our data suggest that, as for other similarly complex biomolecules, careful fine-tuning of synthetic conditions is essential if chemically well-defined MAPs, e.g., suitable for drug registry, are desired. In studies currently underway, we continue to explore the validity of the above and other approaches for other MAP platforms where sequence-specific features of the peptide epitope may again translate into synthetic complications.

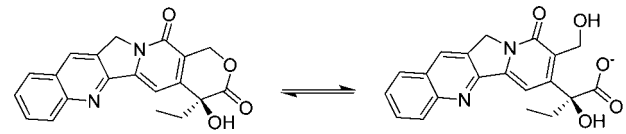
Controlled Synthesis of Camptothecin−Polylactide Conjugates and Nanoconjugates

Rong Tong and Jianjun Cheng*

Department of Materials Science and Engineering, University of Illinois at Urbana−Champaign, Urbana, Illinois 61821.
Received August 11, 2009; Revised Manuscript Received November 4, 2009



We report here a unique method of formulating camptothecin−polylactide (CPT-PLA) conjugate nanoparticles, termed nanoconjugates (NCs), through CPT/(BDI)ZnN(TMS)$_2$ [(BDI) = 2-((2,6-diisopropylphenyl)amido)-4-((2,6-bisalkyl)-imino)-2-pentene] mediated polymerization of lactide (LA) followed by nanoprecipitation. When CPT was used as the initiator to polymerize LA in the presence of (BDI)ZnN(TMS)$_2$, the polymerization was completed within hours with nearly 100% CPT loading efficiency and 100% LA conversion. CPT loading as high as 19.5% can be achieved for the CPT-polylactide (CPT-PLA) conjugate prepared at a LA/CPT ratio of 10. The steric bulk of the chelating ligands and the type of metals used had a dramatic effect on the initiation of the LA polymerization and the tendency of the ring-opening of the CPT lactone. The CPT/(BDI)ZnN(TMS)$_2$-mediated LA polymerization yielded CPT-PLA conjugates with well-controlled molecular weights and narrow molecular weight distributions (1.02−1.18). The nanoprecipitation of CPT-PLA led to the formation of NCs around 100 nm in size with narrow particle size distributions. Sustained release of CPT from CPT-PLA NCs was achieved without burst release. CPT-PLA NCs were toxic to PC-3 cells with tunable IC_{50} possible by adjusting the drug loading of the CPT-PLA NCs.

INTRODUCTION

20(S)-Camptothecin (CPT), a topoisomerase II inhibitor isolated from the Chinese tree *Camptotheca acuminate* in the 1960s, exhibits a broad range of anticancer activity in various animal models (*1, 2*). CPT has low aqueous solubility in its therapeutically active lactone form. Once placed in an aqueous solution at physiological pH, the lactone form of CPT is quickly transformed to its carboxylate form, which is highly toxic and therapeutically inactive (*3*−*5*). Serum albumin preferentially binds to the carboxylate form of CPT and serves as the driving force of shifting the lactone−carboxylate equilibrium (shown in Scheme 1) toward the formation of the carboxylate (*3*−*5*). These pharmacological properties of CPT result in rapid deactivation and fast clearance of CPT from the circulation after it is intravenously administered. To overcome these drawbacks, CPT has been conjugated to various polymeric carriers for improved solubility, enhanced stability of its lactone form and reduced renal clearance (*6*−*14*).

Polymer−CPT conjugates prepared with conventional coupling chemistry have various heterogeneities that may impact their pharmacological and pharmacokinetic properties *in vivo*. For instance, various polymers used for the conjugation of CPT were prepared via condensation reaction with molecular weight distributions (MWDs) over the range 1.5−2.5 (*6, 8*). It is also difficult to control the site of CPT conjugation to polymers with pendant functional groups. Furthermore, the direct conjugation of CPT through its C20-hydroxyl groups involves complex, multi-step reaction; the CPT must first be converted to a CPT-amino ester and then conjugated to a polymer that contains carboxylate groups via the amine end group of the CPT-amino ester (*12, 15*).

Scheme 1. Equilibrium of CPT Lactone and Carboxylate Forms

Here, we report a simple, unique chemistry that allows for one-step conjugation of CPT to the terminal carboxylate group of polylactide (PLA). Instead of using coupling chemistry, we developed a ring-opening polymerization method to facilitate the incorporation of CPT to PLA. Through a living polymerization, both the initiation (drug incorporation) and the chain propagation proceed in a well-controlled manner and result in materials with predefined drug loadings and MWDs in the range 1.02−1.18. The resulting CPT−PLA conjugate was nanoprecipitated to form CPT−PLA conjugate nanoparticles, termed nanoconjugates (NCs), around 100 nm in size with narrow polydispersities and controlled antitumor toxicities.

EXPERIMENTAL PROCEDURES

General. D,L-Lactide (LA) was purchased from TCI America (Portland, OR), recrystallized three times in toluene, and stored at −30 °C in a glovebox prior to use. All of the anhydrous solvents were purified by alumina columns and kept anhydrous by using molecular sieves. CPT was purchased from LC Laboratories (Woburn, MA), dried, and stored at −30 °C in a glovebox. Triethylamine (TEA) was dried with 4 Å molecular sieves overnight, transferred by a cannula under nitrogen to a dry flask that contained CaH_2, refluxed overnight, distilled and collected under nitrogen, and stored in a glovebox over activated 4 Å molecular sieves. All other chemicals were purchased from Sigma-Aldrich (St Louis, MO) and used as received unless otherwise noted. The molecular weights (MWs) of PLA were determined by gel permeation chromatography (GPC also

known as size exclusion chromatography (SEC)) equipped with an isocratic pump (model 1100, Agilent Technology, Santa Clara, CA), a Dawn Heleos 18-angle laser light scattering detector and an Optilab rEX refractive index detector (Wyatt Technology, Santa Barbara, CA). The wavelength of the Heleos detector was set at 658 nm. The size exclusion columns (Phenogel columns 100 Å, 500 Å, 10^3 Å and 10^4 Å, 5 μm, 300 $\times$ 7.8 mm, Phenomenex, Torrance, CA) used for the analysis of polymers or polymer−drug conjugates were serially connected on the GPC. The GPC columns were eluted with THF (HPLC grade) at 40 °C at 1 mL/min. HPLC analyses were performed on a System Gold system equipped with a 126P solvent module and a System Gold 128 UV detector (Beckman Coulter, Fullerton, CA). An analytical reverse-phase (RP) column was utilized to separate CPT, CPT-succinic acid (CPT-SA), and other CPT derivatives. The NMR studies were conducted on a Varian UI500NB system (500 MHz). The sizes and the polydispersities of the PLA-CPT NCs were determined on a ZetaPALS dynamic light scattering (DLS) instrument (15 mW laser, incident beam = 676 nm, Brookhaven Instruments, Holtsville, NY). The lyophilization of the NCs was carried out on a benchtop lyophilizer (FreeZone 2.5, Fisher Scientific, PA). The BDI ligands (BDI-1 (*16*), BDI-2 (*16*), BDI-3 (*16*), and BDI-4 (*17*)) were synthesized by following the procedures previously reported. Synthesis and characterization of the corresponding metal complexes of these ligands were also previously reported (*16*−*19*). The low-resolution electrospray ionization mass spectrometry (LR-ESI MS) experiments were performed on a Waters Quattro II mass spectrometer. The high-resolution electrospray ionization mass spectrometry (HR-ESI MS) experiments were performed on a Micromass Q-TOF Ultima system. The PC-3 cells (ATCC, Manassas, VA) used in the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay (*20*) were cultured in Ham's F12K medium containing 10% fetal bovine serum, 1000 units/mL aqueous penicillin G, and 100 μg/mL streptomycin. The SEM analysis of NCs was conducted on a Hitachi-S4700 high-resolution scanning electron microscope.

General Procedures for the Preparation of CPT−PLA Conjugate via CPT-Mediated Ring-Opening Polymerization of LA. (BDI-3)ZnN(TMS)$_2$ (5.5 mg, 8.9 μmol) was dissolved in anhydrous THF (300 μL). The solution was added to a vial containing CPT (3.0 mg, 8.6 mmol), and the mixture was stirred for 15 min until the CPT was completely dissolved in THF. LA (124 mg, 0.86 mmol) was dissolved in a vial containing THF (940 μL), and the resulting solution was added to the mixture of CPT/(BDI-3)ZnN(TMS)$_2$ ([LA]$_0$ = 0.69 M). FT-IR was used to follow the conversion of the LA in the polymerization solution by monitoring the intensity of the lactone band at 1772 cm^{-1}. After the LA was completely consumed, the polymerization was quenched with ice-cold methanol (10 mL). The precipitate (CPT−PLA) was collected by centrifugation and then dried under vacuum. The resulting CPT−PLA conjugate was denoted as CPT-LA$_n$ where n is the monomer/initiator (LA/CPT) molar ratio.

Reaction of CPT with Succinic Anhydride (SA) Mediated by Zn or Mg Catalysts. In a glovebox, (BDI-3)ZnN(TMS)$_2$ (6.2 mg, 0.01 mmol) was dissolved in anhydrous THF (200 μL). The solution was added to a clean vial containing CPT (3.5 mg, 0.01 mmol) and THF (300 μL) and stirred for 15 min until the CPT was completely dissolved. SA (1.1 mg, 0.011 mmol) in THF (600 μL) was added and the vial was tightly sealed. It was then immediately taken out of the glovebox and stirred for 4 h at 40 °C. The reaction was quenched with ice-cold methanol (1 mL). An aliquot of this solution was analyzed by HPLC equipped with an analytical C18 column (Luna C18(2), 250 $\times$ 4.6 mm, 5 μ, Phenomenex, Torrance, CA). The mobile phase for the HPLC analysis was a solvent mixture containing equal volumes of acetonitrile and water (0.1% TFA). All HPLC spectra were recorded and analyzed by a UV detector at 370 nm. The areas of the HPLC peaks of CPT and the CPT-SA were integrated and used for the quantification of their concentrations as compared to corresponding standard curves. An aliquot of the reaction mixture was also used for the MS analysis.

The CPT-SA used for NMR analysis was collected by preparative thin-layer chromatography (prep-TLC, silica gel with a fluorescent indicator (254 nm), 1.5 mm thickness, Aldrich), and developed by ethyl acetate/methanol (v/v = 10/1). The R_f values of CPT and CPT-SA were 0.7 and 0.1, respectively. The silica gel was removed from the glass plate and the CPT-SA was extracted with methanol (2 $\times$ 30 mL). The methanol solution was then removed under vacuum; the resulting CPT-SA was analyzed by ^{1}H NMR. ^{1}H NMR (CD_3OD, 500 MHz): δ 8.63 (s, 1H, 7-H), 8.21 (d, J = 8.5 Hz, 1H, 12-H), 8.07 (d, J = 8.0 Hz, 1H, 9-H), 7.87 (td, J_t = 8.5 Hz, J_d = 1.5 Hz, 1H, 11-H), 7.71 (td, J_t = 8.0 Hz, J_d = 1.0 Hz, 1H, 10-H), 7.43 (s, 1H, 14-H), 5.57, 5.44 (AB, J_{AB} = 17.0 Hz, 2H, 17-H), 5.35 (s, 1H, 5-H), 2.81 (t, J = 7.5 Hz, 2H, $-CH_2-$COOH), 2.55 (t, J = 7.5 Hz, 2H, $-CH_2-CH_2-$COOH), 2.24 (m, 2H, 18-H), 0.99 (t, J = 8.0 Hz, 19-H). MS (LR-ESI, positive mode): calculated for $C_{24}H_{20}N_2O_7$ $[M + H]^+$ m/z 449.1; found m/z 449.1. MS (HR-ESI, positive mode): calculated for $C_{24}H_{20}N_2O_7$ $[M + H]^+$ m/z 449.1349; found m/z 449.1355.

General Procedure for the Formation and Characterization CPT−PLA Nanoconjugates (NCs). A DMF solution containing the CPT-LA$_{10}$ conjugate (100 μL, 5 mg/mL) was added dropwise to nanopure water (4 mL). The resulting CPT-LA$_{10}$ NCs were collected by ultrafiltration (15 min, 3000 $\times$ g, Ultracel membrane with 10 000 NMWL, Millipore, Billerica, MA) and were characterized by DLS and SEM for particle sizes and by HPLC for drug loading and release kinetics.

Hydrolysis of CPT-LA$_{10}$ NCs. The CPT-LA$_{10}$ NC in water (1 mL, 1 mg/mL) was treated with a NaOH solution (1 M, 1 mL) for 12 h. The solution was then tuned to pH 2 by phosphoric acid addition, which resulted in a yellow solution. The solvent was removed by rotary evaporation. The resulting residue was then dissolved in acetonitrile/water (0.1% TFA) (v/v = 1/1) and injected into a semiprep HPLC column (Jupitor Proteo 90 A, 250 $\times$ 21.20 mm, 10 μ, Phenomenex, Torrance, CA). The fraction that had the identical elution time to the authentic CPT was collected. After the solvent was removed by vacuum, the resulting yellow, oily residue was dissolved in phosphoric acid/methanol at a volume ratio of 1:1. The solution was tuned to pH 3−4 by 0.1 M NaOH and then extracted with chloroform (5 $\times$ 100 mL). The organic phase was combined and dried with $MgSO_4$. After the $MgSO_4$ was removed by filtration and the solvent was removed under vacuum, the resulting pale yellow solid was analyzed by ^{1}H NMR. The ^{1}H NMR spectrum of the CPT released from CPT−PLA NCs was identical to that of the authentic CPT (see Figure 6B) (*21*).

Release Kinetics of the CPT-LA$_n$ NCs and the CPT/PLA Nanoparticle (NP). CPT/PLA NPs were prepared through nanoprecipitation of CPT and PLA (MW = 1.5 $\times$ 10^4 g/mol) by following the procedures reported in literature (*22*). The CPT-LA$_{10}$ NCs were prepared with CPT-LA$_{10}$ conjugate by following the standard nanoprecipitation procedure described above. The NCs (or NPs) were collected and washed three times with nanopure water by ultrafiltration (Ultracel membrane 10 000 NMWL, Millipore, Billerica, MA). The NCs (or NPs) collected from the ultrafiltration device were dispersed in 1$\times$ PBS solution (pH = 7.4) (1 mg/mL) and incubated at 37 °C. At selected time intervals, an aliquot of NCs (or NPs) ($\sim$1 mL) was taken out of the incubator and centrifuged at 10 000 rpm for 10 min. The

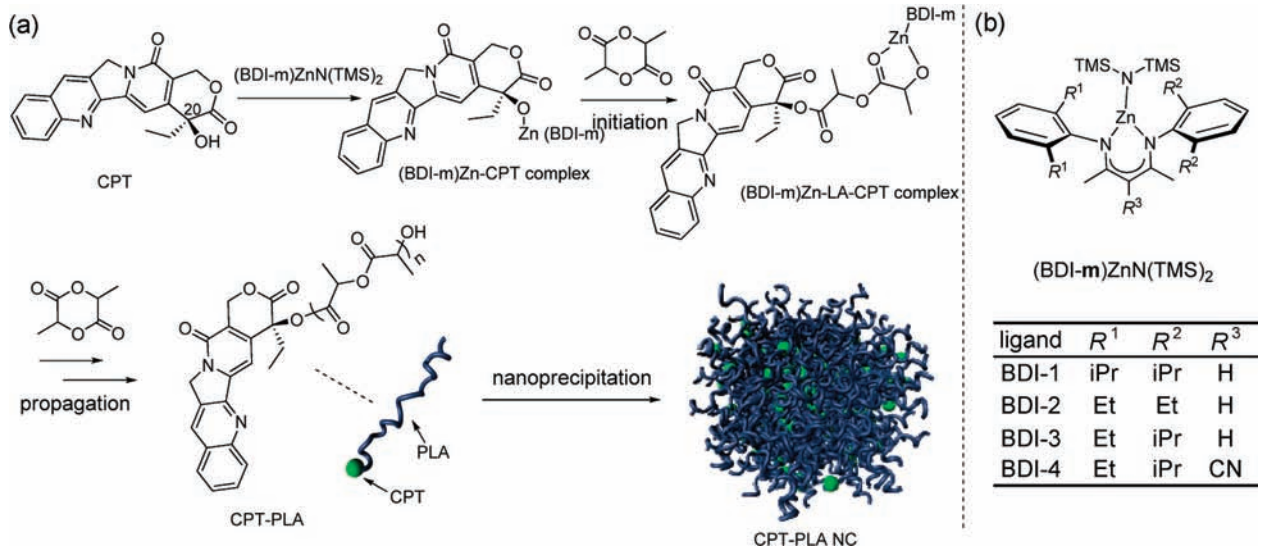

Figure 1. (a) Schematic illustration of (BDI-m)ZnN(TMS)$_2$/CPT mediated ring-opening polymerization of LA to make CPT−PLA conjugates followed by nanoprecipitation of the resulting CPT−PLA conjugates for the preparation of CPT−PLA nanoconjugates; (b) The structure of (BDI-m)ZnN(TMS)$_2$ (m = 1−4).

supernatant (500 μL) was carefully transferred to an Eppendorf tube using a micropipet without disturbing the precipitates (NCs or NPs). The solution was tuned to pH 2 with phosphoric acid (85%), and the resulting solution was directly injected into HPLC equipped with an analytical pentafluorophenyl RP-column (Curosil-PFP, 250 × 4.6 mm, 5 μ, Phenomenex, Torrance, CA). A mixture of acetonitrile and water (containing 0.1% TFA) at a volume ratio of 1:1 was used as the mobile phase. The flow rate was set at 1 mL/min. The area of the HPLC peak of the released CPT was intergraded for the quantification of CPT as compared to the standard curve for this drug.

Determination of the Cytotoxicity of CPT-LA$_n$ NCs. PC-3 cells were placed in a 96-well plate for 24 h (10 000 cells per well). Cells were washed with 100 μL of prewarmed PBS. Freshly prepared CPT-LA$_{10}$, CPT-LA$_{25}$, and CPT-LA$_{50}$ NCs (prepared in 1× PBS, 100 μL) were added to the cells. CPT was used as a positive control. Untreated cells were used as a negative control. PLA NPs without CPT being conjugated or encapsulated were prepared via the nanoprecipitation of the PLA with a MW of 14 kDa (*22, 23*) and were subsequently used as a negative control in the MTT study. The PLA-NPs were applied to PC-3 cells at a concentration up to 0.5 μg/mL. The cells were incubated for 72 h in a 5% CO_2 incubator at 37 °C. The standard MTT assay protocols were followed thereafter (*20*).

RESULTS AND DISCUSSION

(BDI)MN(TMS)$_2$/CPT (M = Zn, Mg)-Mediated Polymerization of Lactide. By mixing a hydroxyl-containing compound (ROH) with a metal-amido complex, M-OR, a highly active metal alkoxide can be generated *in situ* and can be subsequently used to initiate a controlled polymerization of LA (*24−26*). Many well-designed M-ORs can quantitatively incorporate OR to the PLA termini with 100% monomer conversions (*18, 19, 27−31*). Recently, we demonstrated that hydroxyl-containing therapeutic agents with complex structures, such as paclitaxel and doxorubicin, can form coordination complexes with metal catalysts and subsequently initiate controlled LA polymerizations with the drug molecules being covalently attached to the PLA through ester linkers (*32, 33*). Both paclitaxel and doxorubicin have complex molecular structures that contain multiple hydroxyl groups. By using rationally designed metal catalysts, we were able to control the polymerization to be initiated at one of the specific hydroxyl groups of these complex therapeutic molecules (*32, 33*). In the context of expanding this drug-initiated ring-opening polymerization technique to other therapeutic molecules, we studied CPT-initiated LA polymerization.

We first tested the feasibility of forming CPT-metal complex. (BDI-1)MgN(TMS)$_2$ (Figure 1), a catalyst that we previously used in paclitaxel- and doxorubicin-mediated ROP of LA (*32, 33*), was dissolved in THF. A colorless solution was obtained. We then added this solution to a vial containing CPT powder (1 equiv relative to (BDI-1)MgN(TMS)$_2$). After the mixture was stirred for 20 min, it was noted that CPT was completely dissolved and the solution color gradually became orange. In the absence of (BDI-1)MgN(TMS)$_2$, however, CPT remained insoluble in THF and the solution stayed colorless. The sharp contrast of the solubility of CPT in the presence versus in the absence of (BDI-1)MgN(TMS)$_2$ as well as the color change after CPT was mixed with (BDI-1)MgN(TMS)$_2$ suggest possibly a coordination reaction between CPT and the (BDI-1)MgN(TMS)$_2$. (BDI-1)Mg-CPT alkoxide through the C20-OH of CPT is presumably the complex formed *in situ* via the coordination of (BDI-1)MgN(TMS)$_2$ and CPT (Figure 1).

We next examined whether the mixture of (BDI-1)MgN(TMS)$_2$/CPT could initiate LA polymerization. After LA (100 equiv) in THF was added dropwise to the (BDI-1)MgN(TMS)$_2$/CPT mixture, the polymerization proceeded rapidly and was completed within 10 h with 100% LA conversion; the monomer conversion was followed by monitoring the intensity of the lactone band of LA at 1772 cm^{-1} on a FT-IR. One interesting observation was that the orange color of the polymerization solution gradually faded away during the course of polymerization, which indicated the segregation of the (BDI-1)Mg from CPT. This observation was in good agreement with the proposed reaction mechanism as shown in Figure 1a. After 100% LA conversion was achieved, the polymerization solution was analyzed by HPLC, which showed that CPT was completely incorporated to PLA with no detectable free CPT in the polymerization solution (data not shown). This observation was similar to what we observed in paclitaxel- and doxorubicin-initiated LA polymerization, both of which gave 100% drug incorporation efficiency in corresponding drug-initiated polymerization (*32, 33*). The incorporation efficiency is also the initiation efficiency, which is the percent of therapeutic agent utilized in the initiation of LA polymerization and is equivalent to the encapsulation efficiency utilized in making NPs via

Table 1. CPT/(BDI)MN(TMS)$_2$ Mediated LA Polymerization (M = Zn or Mg)[a]

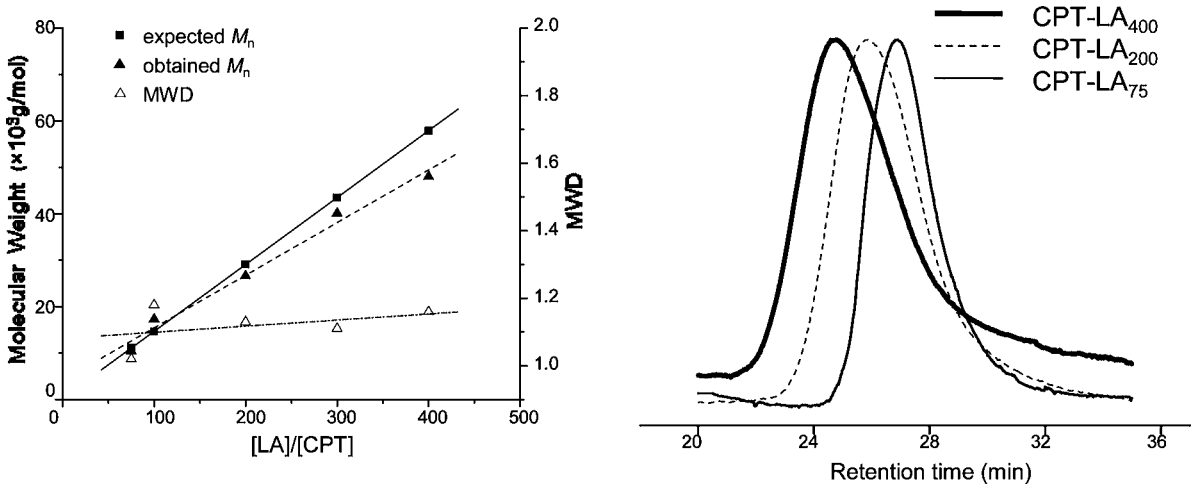
noncovalent, encapsulation strategy. The M_n of the resulting CPT−PLA conjugate was 1.13 × 10^4 g/mol, which was in good agreement with the expected M_n (1.47 × 10^4 g/mol) (entry 1, Table 1). The molecular weight distribution (MWD) of the CPT−PLA conjugate, however, was relatively broad (M_w/M_n = 1.31) due in part to the chain transfer during polymerization (*18*). In our previous studies of paclitaxel- and doxorubicin-initiated LA polymerization, only the primary or the secondary hydroxyl groups of these drugs could efficiently initiate the polymerizations of LA (*32, 33*). The present study demonstrated for the first time that the C20-OH of CPT, a tertiary hydroxyl group, could also be activated by (BDI-1)MgN(TMS)$_2$ to initiate LA polymerization.

In order to achieve better controlled polymerization, we next tested (BDI-1)ZnN(TMS)$_2$, a Zn analogue of (BDI-1)MgN(TMS)$_2$. As reported by Coates and co-workers, Zn catalysts in general out-perform Mg catalysts for LA polymerization (*18*). After (BDI-1)ZnN(TMS)$_2$ and CPT were mixed and stirred for 20 min, a light yellow solution was obtained. This (BDI-1)ZnN(TMS)$_2$/CPT complex mediated LA polymerization at an M/I ratio of 100 and gave CPT−PLA conjugate with a very narrow MWD (M_w/M_n = 1.07, entry 2, Table 1). However, the CPT incorporation efficiency was only 61% based on the HPLC analysis, indicating the poor efficiency of forming Zn-CPT complex during the initiation step. The actual M/I ratio in this reaction was 163 (calculated based on the LA/CPT ratio of 100:0.61). It was therefore not surprising that the obtained M_n (2.83 × 10^4 g/mol) was substantially higher than the M_n calculated based on the LA/CPT ratio of 100:1 (expected M_n = 1.47 × 10^4 g/mol, entry 2, Table 1,). The poor efficiency of the coordination of CPT with (BDI-1)ZnN(TMS)$_2$ was due in part to the relatively low activity of Zn as compared to Mg as well as the steric bulk of BDI-1 ligand surrounding the coordination site (Figure 1b). We next studied whether enhanced incorporation efficiency of CPT could be achieved by using a Zn catalyst with a BDI ligand with reduced steric bulk and/or altered electronic property.

It has been reported that subtle change of BDI ligands can significantly affect the activity of (BDI)ZnN(TMS)$_2$ and its capability of controlling the polymerizations of cyclic esters or carbonates (*16, 34*−*38*). Specifically, the 2,6-substituents of the aryl groups (at the R^1 and R^2 positions) and the substitute at the R^3 position were found to have profound effects on the activity of the catalysts (Figure 1b) (*17*). We synthesized a series of zinc catalysts containing BDI ligands with variable 2,6-aryl substituents and R^3 group (Figure 1b) and then used these catalysts in CPT-initiated LA polymerizations. We first checked the effect of the steric bulk of BDI on the LA polymerization. BDI-2 is an analogue of BDI-1 whose isopropyl (iPr) groups at both R^1 and R^2 position were replaced by ethyl (Et) groups, while BDI-3 is an analogue of BDI-1 whose iPr groups were replaced by Et groups only at both R^1 position. Both ligands were synthesized and used to prepare the corresponding (BDI)ZnN(TMS)$_2$ catalysts. As expected, the steric bulk of the BDI at its R^1 and R^2 positions had a profound effect on the capability of the Zn catalysts to form coordination complexes with CPT during the initiation step. As compared to the 61% of incorporation efficiency observed with the use of (BDI-1)ZnN(TMS)$_2$, 100% incorporation efficiencies were observed in both (BDI-2)ZnN(TMS)$_2$/CPT and (BDI-3)ZnN(TMS)$_2$/CPT mediated polymerizations. The corresponding M_n values (2.01 × 10^4 g/mol and 1.73 × 10^4 g/mol, entries 3 and 4, Table 1) were much closer to the expected M_n than that of the PLA−CPT obtained from the (BDI-1)ZnN(TMS)$_2$/CPT mediated LA polymerization (entry 2, Table 1). Narrow MWDs (M_w/M_n < 1.2) were obtained for the CPT−PLA conjugates derived from (BDI-2)ZnN(TMS)$_2$/CPT and (BDI-3)ZnN(TMS)$_2$/CPT mediated polymerizations (entries 3 and 4, Table 1). BDI-4, an analogue of BDI-3 with a cyano group at the R^3 position (Figure 1b), was also prepared and studied. However, CPT remained insoluble in THF containing 1 equiv (BDI-4)ZnN(TMS)$_2$, indicating the poor efficiency of forming (BDI-4)ZnN(TMS)$_2$/CPT coordination complex at room temperature. Thus, it was not surprising that the mixture of CPT and (BDI-4)ZnN(TMS)$_2$ could not initiate LA polymerization at room temperature (entry 5, Table 1). When this mixture of CPT and (BDI-4)ZnN(TMS)$_2$ was incubated at 40 °C for 20−30 min, CPT was completely dissolved, suggesting that the formation of (BDI-4)ZnN(TMS)$_2$/CPT coordination complex requires higher temperature. The CPT−PLA conjugate derived from (BDI-4)ZnN(TMS)$_2$/CPT-mediated LA polymerization had a high loading efficiency (98%) and a M_n very close to the expected molecular weight (entry 6, Table 1), but its MWD (M_w/M_n = 1.32, Table 1) was broader than that of the CPT−PLA conjugate derived from the (BDI-3)ZnN(TMS)$_2$/



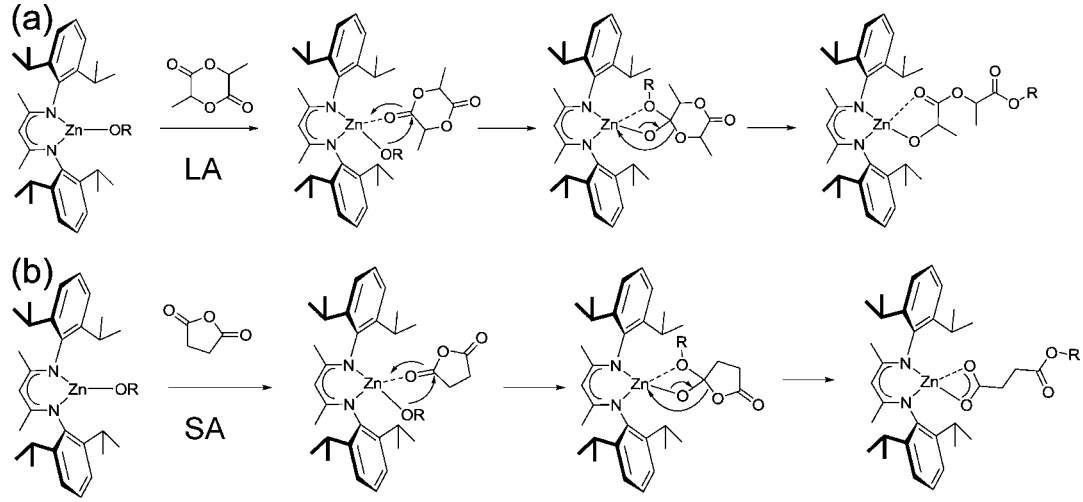


Figure 2. (a) (BDI-3)ZnN(TMS)$_2$/CPT mediated ring-opening polymerization of LA at various LA/CPT ratios. (b) Overlay of the GPC trace of CPT-LA$_{75}$, CPT-LA$_{200}$, and CPT-LA$_{400}$ prepared by (BDI-3)ZnN(TMS)$_2$/CPT mediated LA polymerizations.

Scheme 2. Suggested Insertion-Coordination Mechanism of (BDI)Zn-OR Mediated Ring-Opening of (a) LA and (b) SA

CPT-mediated polymerizations. On the basis of these preliminary studies, (BDI-3)ZnN(TMS)$_2$ was found to be the overall best catalyst with respect to control over CPT incorporation and polymerization. (BDI-3)ZnN(TMS)$_2$ was therefore selected for further investigation for its capability to control polymerization of LA at various LA/CPT ratios.

Excellently controlled polymerizations were observed over a broad range of LA/CPT ratios from 75 to 400 when the LA polymerizations were mediated by (BDI-3)ZnN(TMS)$_2$/CPT (Table 2). Quantitative CPT incorporation efficiencies and very narrow MWDs (M_w/M_n = 1.02−1.18) were observed in all experiments performed. The obtained MWs of the CPT−PLA conjugates were in excellent agreement with the expected MWs (Table 2), which followed a linear correlation with the LA/CPT ratios (Figure 2a). Monomodal GPC MW distribution curves were observed in all CPT−PLA conjugates prepared with various LA/CPT ratios (Figure 2b). The well-controlled polymerization mediated by (BDI-3)ZnN(TMS)$_2$ likely proceeded through the widely accepted insertion-coordination mechanism (Scheme 2a).

Control of Initiation by (BDI)ZnN(TMS)$_2$ Catalysts. As mentioned earlier, the lactone ring of CPT should be preserved in order to maintain the antitumor activity of CPT. However, it is known that the lactone ring of CPT is unstable and subject to ring-opening in the presence of a nucleophile. We next studied how the initiation could be specifically controlled at the C20-OH of CPT with negligible CPT lactone ring-opening during (BDI)ZnN(TMS)$_2$/CPT initiated LA polymerizations.

In the initiation step, LA first reacts with (BDI)Zn-CPT alkoxide and then is inserted between the CPT and Zn to generate (BDI)Zn-lactide-CPT alkoxide, the new chain-propagating end group (Scheme 2a). CPT does not involve the subsequent chain propagation. Apparently, the most critical step determining whether the lactone ring of CPT is opened or remains closed is the initiation step. As LA is subject to rapid polymerization and the resulting CPT−PLA conjugate is difficult to be precisely characterized, we used succinic anhydride (SA) as the model monomer to study (BDI)ZnN(TMS)$_2$/CPT mediated initiation. Such a reaction led to the formation of CPT-succinic acid (CPT-SA), a small molecule instead of a polymer, whose structure can be easily determined by routine characterization methods.

When just CPT and SA were mixed without addition of other reagents, no reaction occurred (entry 1, Table 3). Triethylamine (TEA), a non-nucleophilic base, has been used previously to facilitate the ring-opening of SA by an alcohol (*39*). When TEA was added to the mixture of CPT and SA, the reaction was very slow and generated CPT-SA with a yield of 10.6% after the reaction mixture was incubated at 40 °C for 12 h (peak z, Figure 3a−i; entry 2, Table 3). A substantial amount of CPT in its carboxylate form was also detected (peak x, Figure 3a−i), indicating that the lactone ring of CPT was unstable in the

Table 3. Ring Opening of Succinic Anhydride (SA) by CPT in the Presence of TEA, EDC/DMAP, or (BDI)MN(TMS)$_2$ (M = Mg or Zn)[a]

entry	temp (°C)	catalyst	solvent	time (h)	yield (%)[c]

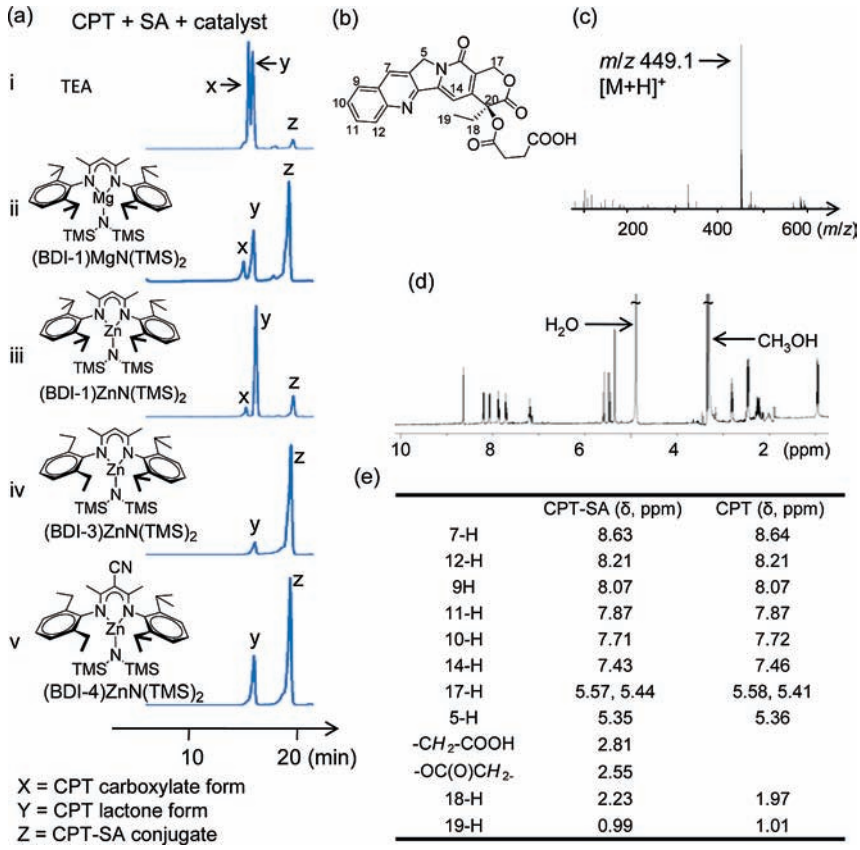
7	40	(BDI-4)ZnN(TMS)$_2$	THF	4	71.7

[a] All reactions were performed at a SA/CPT/catalyst ratio of 1.1:1:1 ([SA]$_0$ = 0.01 M). Abbreviations: SA = succinic anhydride; CPT = camptothecin; TEA = triethylamine; temp = temperature; EDC = *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide; DMAP = dimethylaminopyridine. [b] [EDC]/[DMAP] = 4/1. [c] Determined by the HPLC measurement of the CPT-succinic ester (CPT-SA) generated in the reaction solution.

presence of TEA. In a control study, when naphthalene ethanol, an alcohol with a primary −OH group that is supposed be more reactive for nucleophilic reaction than the tertiary C20-OH of CPT, was used for the conjugation with SA in the presence of TEA, the yield of naphthalene-SA was 86.8% (data not shown).

N-(3-Dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC), in conjunction with 4-(dimethylamino)-pyridine (DMAP), has been used previously for the conjugation of CPT with SA (*40*). When the reaction of CPT and SA was performed in the presence of EDC and DMAP at 40 °C for 12 h, the yield of CPT-SA was only 12.8% (entry 3, Table 3), which was in good agreement with the previously reported result (*40*) and further confirmed the low activity of the tertiary C20-OH group of CPT.

We next studied the ring-opening of SA by CPT in the presence of Mg or Zn catalysts. (BDI-1)MgN(TMS)$_2$ mediated conjugation of CPT and SA resulted in CPT-SA conjugates (Scheme 2b) with 59.5% yield when the reaction was carried out at 40 °C for 4 h (entry 4, Table 3). CPT in carboxylate form was also detected (peak x, Figure 3a−ii), indicating that the CPT lactone ring was opened in the presence of (BDI-1)MgN(TMS)$_2$ and that it may function not only as a ROP catalyst, but also as a strong base. The mechanism of ring opening remains elusive. When such a reaction was mediated by (BDI-1)ZnN(TMS)$_2$, a weaker base and a less reactive ROP catalyst compared to its Mg analogue, CPT-SA in 18.8% yield was obtained (entry 5, Table 3). Formation of small amount of CPT in its carboxylate form was also detected (peak x, Figure 3a−iii).



As shown in the polymerization study mentioned above (Table 1), the chelating BDI ligands have a significant impact on the activity of the BDI-metal complexes for LA polymerization. We tested (BDI-3)ZnN(TMS)$_2$, which was previously identified to be the best catalyst for CPT-initiated LA polymerization, in this CPT/SA conjugation reaction. CPT-SA in 89.1% yield was obtained when the reaction of CPT and SA was carried out at 40 °C for 4 h in the presence of (BDI-3)ZnN(TMS)$_2$ (entry 6, Table 3). The substantially increased yield of CPT-SA in this experiment indicated that (BDI-3)ZnN(TMS)$_2$ activated the tertiary C20-OH group of CPT very effectively to allow for facile nucleophilic ring opening of SA. Very interestingly, CPT-SA was the only product formed; no carboxylate form of CPT was detected (Figure 4a−iv). Excellently controlled ring opening of SA by CPT with no detectable CPT carboxylate was also observed with the use of (BDI-4)ZnN(TMS)$_2$ (Figure 3a−v), although the yield of the CPT-SA (71.7%, entry 7, Table 3) was not as high as that derived from the (BDI-3)ZnN(TMS)$_2$-mediated reaction (entry 6, Table 3).

The CPT-SA (peak z, Figure 3a−iv) was collected by preparative thin-layer chromatography and analyzed by MS (Figure 3c) and ^{1}H NMR (Figure 3d,e). The high-resolution MS analysis showed that the CPT-SA has a $[M + H]^+$ m/z= 449.1355, which was in excellent agreement with the expected $[M + H]^+$ m/z= 449.1349. To determine whether the SA ring was opened by the C17-OH (formed after the opening of the lactone ring of CPT) or by the C20-OH (Figure 3b), we compared the ^{1}H NMR spectra of CPT-SA and CPT (Figure 3e). If C17-OH mediated the ring opening of SA, the chemical shift of the C17-H of CPT-SA should change to some extent. However, as shown in Figure 3e, the chemical shift of the C17-H of CPT-SA was nearly identical to that of the authentic CPT (with a change of less than 0.03 ppm, Figure 3e), indicating that the lactone ring of CPT is well-preserved in CPT-SA. In fact, the only major change of the chemical shifts among all the protons of CPT was the C18-H, which was shifted downfield from 1.97 ppm for CPT to 2.23 ppm for CPT-SA (Figure 3e). The only possible explanation is that the SA ring was opened by the C20-OH by CPT (Figure 3b). The high yield of CPT-SA obtained in this experiment indicated that (BDI-3)ZnN(TMS)$_2$ was capable of efficiently activating the C20-OH of CPT to facilitate the ring-opening reaction with SA. The CPT/SA ring-opening conjugation mediated by BDI-Zn catalyst appeared to be a versatile method for converting the C20-hydroxyl group of CPT to a carboxylic acid end group with a degradable ester linker, which can be further used for conjugation to various drug delivery vehicles through the conventional carboxylate−amine coupling chemistry.

Controlled Formation of CPT−PLA Nanoconjugates and Their *in Vitro* Evaluation. CPT−PLA conjugated nanoparticles, termed nanoconjugates (NCs) in this study to differentiate them from the NPs prepared by coprecipitating drugs and polymers, were readily prepared through the nanoprecipitation of CPT−PLA conjugates (Figure 1a) after the metal and the BDI ligand were removed by solvent extraction. NCs of less than 100 nm in size with narrow, monomodal particle distributions were readily obtained (Table 4 and Figure 4). The narrow size distributions and monomodal size distribution of NCs were in sharp contrast to the multimodal particle distributions frequently observed in the NPs prepared by the coprecipitation of polymers and drugs (*22, 23*). It is not clear why NCs derived from the nanoprecipitation of PLA−CPT conjugates have such narrow size distributions (Figure 4a). As the multimodal particle distributions in conventional NPs were attributed in part to the self-aggregation of the nonencapsulated drugs (*22*), the unimolecular structure of polymer−drug conjugates with reduced heterogeneities (low polymer polydispersities, controlled site of conjugation on CPT and PLA, absence of free CPT) may contribute to the formation of NCs with low particle polydispersity.

DLS can give quick assessment of the NP size and size distribution; however, the data should be treated with caution and compared with data collected by other techniques. When the same CPT−PLA NC was dried and analyzed by SEM (Figure 4b), the NC size distribution was found to be not as narrow as that observed in DLS (Figure 4a). As the particle sizes were assessed under different conditions using these two different techniques, the impact of the drying process for the SEM sample preparation on the particle size distribution is unclear. It should be noted, however, that both SEM and DLS analyses showed that there were no large aggregates (over 300−500 nm) as observed frequently in NPs prepared through the coprecipitation of polymers and drugs (*22, 23*).

Because both monomer conversion and drug incorporation were quantitative (Table 4), the drug loadings of CPT−PLA NCs can be predetermined by adjusting LA/CPT feeding ratios. At a low M/I ratio of 10, the drug loading of CPT−PLA NC can be as high as 19.5% (CPT-LA$_{10}$, Table 4). To our

knowledge, this CPT−PLA NC has by far one of the highest loadings of CPT ever reported (*2, 8*).

We then studied the release kinetics of CPT from CPT−PLA NCs in PBS solution (pH = 7.4) at 37 °C. Even at drug loading as high as 20%, sustained release of CPT from CPT-LA_{10} NC was observed through the hydrolysis of the ester linker that connects the CPT and the PLA (Figure 5a); roughly 40% of CPT was released from CPT-LA_{10} NC in 7 days with no burst release of CPT being observed (Figure 5a). This observation was in sharp contrast to the burst release of PLA/CPT NP that was prepared by the coprecipitation of CPT and PLA. In the latter system, the release of CPT depends entirely on diffusion of the drug from polymer matrices; as much as 97.1% of the encapsulated CPT was released from CPT/PLA NP when the NP was incubated in PBS for 24 h at 37 °C (Figure 5a). The released CPT (in PBS, pH = 7.4, 37 °C) has an HPLC elution time identical to that of authentic CPT (Figure 6a) and was confirmed to have identical molecular structure to that of authentic CPT after it was isolated and characterized by ^1H NMR (Figure 6b).

Cheng and co-workers have previously reported the synthesis and development of IT-101 (*10−13*), a CPT−cyclodextrin polymer conjugate with the drug molecule being conjugated to the polymeric carrier via a triglycinyl ester linker. IT-101 has been evaluated in numerous preclinical studies and a phase-I human clinical study (*41−43*). Roughly 25% of the CPT in IT-101 was released in 24 h when the release kinetics study was performed in PBS (pH = 7.4) at 37 °C (*12*), whereas 15% of CPT was released from CPT-LA_{10} NC under similar condition (Figure 5). In CPT-LA_{10} NC, CPT is connected to PLA through a lactic ester bond, a linker with similar hydrophobicity and size to the glycinyl ester linker of IT-101. Because PLA is hydrophobic, the water and ions (H^+, OH^-) may not have easy access to the lactic ester linker in CPT−PLA NC as to the glycinyl ester of IT-101 in which CPT is conjugated to hydrophilic cyclodextrin polymers. It is therefore not surprising to observe decreased CPT release rate in CPT-LA_{10} NC compared to that of IT-101. It is anticipated that the release rate of CPT may further decrease when the pH value surrounding CPT−PLA NCs decreases from 7.4 to 5. This pH range is

Table 4. Preparation and Characterization of CPT−PLA NCs[a]

of particular importance and interest because it is well-known that the cancerous tissues and the endosomes, where the NPs will be located following endocytosis, show pH changes in this range. The decreased hydrolysis rate of ester linkers may contribute to the antitumor efficacy *in vivo*. For instance, we found that a trace amount of CPT in conjugated form in the harvested tumor tissues of mice could be detected by HPLC 109 days after the administration of IT-101 (data not reported). Very surprisingly, the amount of CPT detected in tumor tissue was inversely proportional to the tumor size at day 109. It is yet to be confirmed for the correlation of long-term tumor inhibition with the reduced release rates of CPT drug delivery system in slightly acidic environment.

The *in vitro* toxicities of CPT−PLA NCs were determined by MTT assays in PC-3 cells (Figure 5b). The IC_{50} values of CPT-LA_{10}, CPT-LA_{25}, and CPT-LA_{50} NCs with similar sizes (50−100 nm) were 389, 730, and 908 nM, respectively. The MTT studies revealed that the toxicity of the CPT-PLA NC, which was directly related to the release kinetics of CPT, could be tuned by the CPT loading in the NCs (Figure 5b). In general, NCs with higher drug loadings released drug more rapidly (*32, 33*) and therefore showed higher toxicities (Figure 5b). This observation was presumably due to the fact that the NCs derived from the nanoprecipitation of the higher-loading (lower MW) CPT−PLA conjugates have more loosely packed structures, as compared to the NCs derived from the lower-loading (higher MW) CPT−PLA conjugates. Therefore, the ester linkers between CPT and PLA in the NCs with higher drug loadings were more accessible to the aqueous phase and were subject to faster hydrolysis. PLA NPs without CPT were used as a negative control and were found to show negligible toxicity to the PC-3 cells. The cell viability was 0.956 ± 0.003 when the PC-3 cells were incubated with the PLA NPs at a concentration of 0.5 μg/mL for 72 h at 37 °C.

Conventional polymeric NPs prepared via coprecipitation of polymers and drugs have several formulation challenges that remain to be addressed (*44−47*). NPs typically exhibit a "burst" drug release in aqueous solution; as much as 80−90% of the encapsulated drugs are rapidly released during the first few to tens of hours (*48*). The rapid dose dumping may cause severe systemic toxicities (*49*). In addition, drug loadings in conventional NPs can be very low, typically in the range 1−5% in most NPs studied (*48, 50, 51*). Drug loading of a delivery vehicle has been a critical measure of its utility in clinical settings (*52, 53*). At lower drug loadings, a larger amount of delivery vehicles is needed. Due to the limited body weight and blood volume of animals, the administered volumes are usually fixed. For instance, the volume of a solution intravenously administered to mice with 20 to 30 g body weights should be controlled to below 100 μL (*11*). Intravenous administration of NPs with 1 wt % drug loading in a 100 μL

solution at a dose of 50 mg/kg to a nude mouse with 20 g body weight requires the formulation of a concentrated, 1 g/mL NP solution, which is too viscous to formulate and inject intravenously. The third major challenge presented by NPs prepared via the encapsulation approach is the lack of a general strategy to achieve quantitative drug encapsulation. Depending on the amount of drug used, the hydrophobicity and hydrophilicity of the drug and the compatibility of the drug and polymer, the encapsulation efficiencies vary drastically over the range 10−90% (*48, 54*). Non-encapsulated drugs may self-aggregate (*48*) and can be very difficult to remove from the NPs. These formulation challenges significantly impact the processability and clinical translation of NP delivery vehicles prepared by drug/polymer coprecipitations.

PLA/CPT NPs prepared by the coprecipitation method have been previously reported to give low drug loading (0.1−1.5%), low loading efficiency (2.8−38.3%), and poorly controlled release kinetics (*55*). Depending on the formulation method, 20−90% of the encapsulated CPT was released within 1 h after the NP was exposed to the PBS solution. The ring-opening polymerization method that we developed allows for the incorporation of CPT to PLA with a tunable drug loading as high as 20% and 100% loading efficiency (Table 4), which is in line with the high drug loading reported in polyglutamate−CPT conjugates (*2, 8*). The unique conjugation technique allows for formation of CPT-containing PLA NCs with superbly controlled formulation parameters, which makes PLA−CPT NCs potentially useful agents for sustained treatment of cancer *in vivo*.

CONCLUSION

Preparation of PLA−drug conjugates with controlled drug loading and release profiles has been previously reported using conventional coupling chemistry (*56−60*). In this study, we report a unique conjugation method that allows for CPT conjugation to PLA via CPT-initiated ROP of LA. This method allows for facile incorporation of CPT to PLA and forms PLA−CPT conjugates with low polydispersities, predetermined drug loadings (as high as 20%), and 100% loading efficiencies. By controlling the metal and the chelating ligands of the catalysts, the initiation of LA polymerization can be specifically controlled at the C20-OH of CPT with negligible lactone ring opening in CPT. CPT conjugated to PLA should maintain its lactone form (the therapeutically active form). The BDI-metal chelating complexes do not have deleterious effects on CPT and can be easily removed by solvent extraction. Because both Zn and Mg ions are biocompatible (as key elements in our dietary mineral supplements), there should not be significant safety concerns regarding the use of these two metal catalysts for the ROP and formulation of NCs for potential clinical applications. Multigram scale of PLA−CPT conjugates can be readily prepared within hours using this one-pot polymerization approach. Because CPT molecules are covalently conjugated to PLA, the postreaction formulation process (nanoprecipitation, purification, sterilization, lyophilization, shipping and handling, transportation, etc.) can be much more readily handled with a minimum change of sample property, in contrast to drug/polymer NPs prepared via encapsulation methods that struggle to prevent drug release during the formulation process. Given that the lack of a controlled formulation for nanoparticulate drug delivery vehicles presents bottlenecks to their clinical translation, this unique, ROP-mediated conjugation methodology may contribute to the development of clinically applicable CPT and CPT-analogue based nanomedicines.

ACKNOWLEDGMENT

This work is supported by the National Science Foundation (Career Program DMR-0748834), the National Institute of Health (R21 grant 1R21CA139329-01), and the Siteman Center for Cancer Nanotechnology Excellence (SCCNE, Washington University)-the Center for Nanoscale Science and Technology (CNST, University of Illinois at Urbana−Champaign). R.T. acknowledges a student fellowship from SCCNE. We would like to thank Professors Martin Burke and Jeffrey Moore for providing the anhydrous solvents.

Note Added after ASAP Publication: This manuscript was released ASAP on December 10, 2009 with errors in the structures of Scheme 2. The revised version was released on December 15, 2009.

New Nucleotide Analogues with Enhanced Signal Properties

Dmitry Cherkasov,*,† Thorsten Biet,‡ Englbert Bäuml,‡ Walther Traut,§ and Michael Lohoff†

Institute for Medical Microbiology, BMFZ, Philipps University of Marburg, Hans-Meerweinstrasse 2, 35043 Marburg, Germany, and Institute of Chemistry and Institut für Biologie, Zentrum für Medizinische Strukturbiologie, Universität Lübeck, Ratzeburger Allee 160, 23538 Lübeck, Germany. Received August 16, 2009; Revised Manuscript Received October 31, 2009

We describe synthesis and testing of a novel type of dye-modified nucleotides which we call macromolecular nucleotides (m-Nucs). Macromolecular nucleotides comprise a nucleotide moiety, a macromolecular linear linker, and a large macromolecular ligand carrying multiple fluorescent dyes. With incorporation of the nucleotide moiety into the growing nucleic acid strand during enzymatic synthesis, the macromolecular ligand together with the coupled dyes is bound to the nucleic acid. By the use of this new class of modified nucleotides, signals from multiple dye molecules can be obtained after a single enzymatic incorporation event. The modified nucleotides are considered especially useful in the fields of nanobiotechnology, where signal stability and intensity is a limiting factor.

INTRODUCTION

Nucleotides conjugated with fluorescent dyes have been widely used to label nucleic acids for different techniques in molecular biology, e.g., FISH, microarray, or Sanger sequencing, for over 20 years. The state of the art structure of these nucleotides comprises a nucleotide moiety, a short linker arm, and a low molecular weight fluorescent dye moiety, e.g., fluorescein or a cyanine dye. Regarding signal strength, this structure has been sufficient for most analytical purposes. The presence of a large population of identically labeled nucleic acid molecules used for signal generation not only contributed to the required strength of the signal, but also compensated for photophysical phenomena of individual molecules like blinking and spectral drift. Recent developments in analytical science opened new frontiers down to the level of nanoscale and single molecules (*1–6*). Here, the detection of fluorescent signals is increasingly influenced by peculiarities in the photophysical behavior of individual fluorophores, e.g., blinking (*7, 8*), which result in uncertainties and instability of signal detection. Thus, the development of new technologies may benefit from the redesign of dye-labeled nucleotides.

In particular, single molecule sequencing technologies hold great promise regarding cost and time reduction, compared to methods which require bulk populations of DNA molecules for sequencing (*9–13*). Since the late 1990s, several techniques for single molecule sequencing have been under development by academic groups (*14–16*) and commercial vendors (e.g., www.helicosbio.com, www.genovoxx.com, www.visigenbio.com, www.pacificbiosciences.com, www.nanoporetech.com); two newly published approaches (*17, 18*) use differently labeled nucleotides during the primer extension reaction to translate the sequence content into specific light signals that can be detected. The raw data accuracy in both procedures ranges from 80% to 95% in a single run. In comparison, sequencing methods based on the analysis of bulk populations achieve about 99% (www.illumina.com). One of the reasons for the relatively high error rate in those novel approaches is the use of a single fluorophore molecule as the source of the light signal. During sequencing, each fluorophore is excited only for a short period of time (tens to hundreds of milliseconds). During this period of time, several photophysical phenomena, e.g., blinking, quenching, spectral shift, and photobleaching (*3, 6, 8*), can lead to a hindrance of signal detection, resulting in a loss of sequence information. Further augmentation of sequencing speed during single molecule sequencing will most likely require even shorter illumination periods, resulting in a further increase of the error rate. Taken together, single molecule sequencing technologies should address signal stability issues in order to overcome such limitations.

In this paper, we present a new type of nucleotide analogues—collectively called m-Nucs (macromolecular nucleotides) here—that may solve the problem of signal instability. We assumed that ideally each nucleotide should carry several dye molecules. By using such nucleotides during sequencing, incoporation of only one nucleotide molecule into the growing strand will result in an accumulated signal produced from a bunch of molecules instead of only one fluorophore. Such nucleotides could have several advantages compared to conventionally labeled nucleotides. First, because each dye molecule is functioning as an individual light generator independent from others, the probability of nonemitting states in one particular nucleotide decreases with the number of dye molecules in this nucleotide. Second, the strength of the fluorescent signal from multiple dye molecules is greatly increased compared to that of only one dye molecule. Thus, the crucial parameters signal stability and signal strength could be dramatically improved by multiple labeling of nucleotides with fluorescent dyes. In the present study, we report on the development of such nucleotides and their labeling technology.

In the following, we describe the new nucleotide analogues, their synthesis, and their suitability as substrates in solid-phase primer extension assays. The synthesis was conducted by coupling of a long PEG (poly(ethylene glycol)) linker carrying a biotin moiety to nucleotide analogues, the 5-allylamine-dUTP and the 5-propargylamine-dCTP. Subsequently, streptavidin or its derivatives were coupled to the biotin moiety of the PEG linker. The resulting compounds contain the nucleotide moiety, a long PEG linker, and streptavidin, which can be modified with multiple dye molecules. The incorporation of such new nucle-

otides into the growing strand by several DNA polymerases was shown using a solid-phase primer extension assay.

MATERIAL AND METHODS

Materials. Chemical reagents and solvents were purchased from Sigma-Aldrich (Seelze, Germany), oligonucleotides from MWG Biotech (now Eurofins MWG Operon, Ebersberg, Germany). All DNA polymerases were from New England Biolabs (Frankfurt a. Main, Germany). Silica gel 60 F254 TLC (thin layer chromatography) plates were purchased from VWR International (Darmstadt, Germany), SA (streptavidin) and paramagnetic beads from Promega (Mannheim, Germany), and premixed 30% acrylamide−bisacrylamide solution from Bio-Rad Laboratories (Munich, Germany). Ultrafiltration vials (Microcon MWCO 50 kD and 100 kD) were purchased from Millipore (Schwalbach, Germany). We used dUTP-16-Biotin and Fluorescein-12-dUTP from Roche Applied Science (Mannheim, Germany); Fluorescein-12-dCTP from Perkin-Elmer (Offenbach a. Main, Germany); dUTP-AA (5-aminoallyl-dUTP) and dCTP-PA (5-propargylamino-dCTP) from Jenabiosciences (Jena, Germany); and NHS-PEG-Fluorescein (*N*-hydroxysuccinimidyl ester−poly(ethylene glycol)−fluorescein, M_w 5000) and NHS-PEG-5000-biotin (*N*-hydroxysuccinimidyl ester−poly(ethylene glycol)−biotin, M_w 5000) from Nektar Therapeutics (San Carlos, CA, USA). SA-PE (streptavidin-R-phycoerythrin) was from Invitrogen (Karlsruhe, Germany). HPLC was conducted on TSKgel DEAE-2SW columns from Sigma-Aldrich.

Synthesis of Compounds. *General Considerations.* The components of the m-Nucs synthesized in this study are a nucleotide moiety, a water-soluble linker (PEG-linker), and streptavidin or its derivatives, e.g., dye-labeled streptavidin. An overview of the composition of nucleotide conjugates is given in Table 2. Synthetic schemes are shown in the Supporting Information Supplement 1 and Figure 1.

First, we coupled PEG-biotin to the nucleotides to generate precursors of the m-Nucs (compounds **1** and **2**). Next, dNTP-PEG-biotin (abbreviated as dNTP-PEG-B) was coupled to streptavidin (SA) or its phycoerythrin (PE)-modified derivative (compounds **3** to **5** and **7**). To produce dye-labeled streptavidin derivatives, NHS-PEG-fluorescein was coupled to SA (compound **6**). In all protocols, separation of the resulting m-Nucs from unbound dNTP-PEG-biotin or other compounds with a molecular weight of less than 50 kDa was performed via ultrafiltration and repetitive washes.

Synthesis of Compounds **1** *and* **2.** To generate compound **1**, dUTP-PEG-B, NHS-PEG-5000-biotin (20 mg) was added to a solution of dUTP-AA (500 μL, 20 mM, in 50 mM borate buffer, pH 8.5) and the reaction was allowed to proceed for 1 h at room temperature. After that, compound **1** was isolated by DEAE-HPLC in a salt gradient (0.0 to 0.5 M NaCl in Tris−HCl buffer, 50 mM, pH 8.0). Compound **1** was eluted from the DEAE-HPLC column at around 0.3 M NaCl. Fractions were collected and analyzed by UV−vis and TLC (silica gel 60 F254) in an ethanol−water mixture (70:30, v/v) for the presence of dUTP-AA (retention factor $R_f = 0.4$) and dUTP-PEG-B ($R_f = 0.05$). The fractions of dUTP-PEG-B with no detectable contaminations of dUTP-AA were combined and stored at −20 °C.

Compound **2**, dCTP-PEG-B, was synthesized in a similar way, but exchanging dCTP-PA for dUTP-AA.

Synthesis of Compounds **3** *and* **4.** To produce compound **3**, (dUTP-PEG-B)$_1$-SA, 1 mg of streptavidin was dissolved in 1 mL of 50 mM Tris−HCl buffer, pH 8.0, and an equimolar amount of compound **1** (as a 0.17 mM solution in 0.1 mL of 50 mM Tris−HCl buffer, pH 8.0) was added to the streptavidin-containing solution. The resulting solution was kept at room temperature for 1 h. After that, compound **3** was separated from compounds with lower molecular weight by repetitive ultrafiltration using Microcon MWCO 50 kDa filters according to manufacturer's instructions, using 50 mM Tris−HCl buffer, pH 8.0.

Compound **4**, (dCTP-PEG-B)$_1$-SA, was synthesized in a similar manner, using dCTP-PEG-B, however, instead of dUTP-PEG-B.

Synthesis of Compounds **5***,* **7***, and* **8.** For the synthesis of compound **5**, (dUTP-PEG-B)$_4$-SA, 0.5 mg streptavidin was dissolved in 0.5 mL of 50 mM Tris−HCl, pH 8.0, and a 5-fold excess of dUTP-PEG-B (as 0.1 mM solution in 0.5 mL of 50 mM Tris-HCl buffer, pH 8.0) was added. The resulting solution was kept at room temperature for 1 h. After that, compound **5** was separated from compounds with lower molecular weight as described for compound **3**.

Compound **8**, (dUTP-16-B)$_4$-SA, was synthesized in a similar way to compound **5**, but using dUTP-16-biotin instead of dUTP-PEG-B.

Compound **7**, (dUTP-PEG-B)$_n$-SA-PE, was synthesized in a similar way as described for compound **5**: a solution of 0.2 mg SA-PE conjugate (streptavidin-R-phycoerythrin) was added to an excess of dUTP-PEG-B (as 0.1 mM solution in 0.2 mL of 50 mM Tris−HCl buffer, pH 8.0). The resulting mixture was kept at room temperature for 1 h. Thereafter, compound **7** was separated from compounds with lower molecular weight by repetitive ultrafiltration via Microcon MWCO 100 kDa filters according to the manufacturer's instructions, using 50 mM Tris−HCl buffer, pH 8.0. R-phycoerythrin is a naturally occurring large fluorescent protein with a molecular weight of about 240 kDa. Therefore, the streptavidin-R-phycoerythrin conjugate has a size of more than 240 kDa. In this conjugate, some biotin binding sites may have been inactivated during coupling of PE to SA, or the access to the binding site may be hindered by PE. Therefore, (dNTP-PEG)$_n$-SA-PE represents a mixture of compounds, where the number of dNTP-PEG-molecules per SA-PE can be in the range 1−4.

Synthesis of Compound **6***, (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein).* To obtain compounds with a ratio of 5 dye molecules to 1 nuc-macomolecule, compound **5** was subjected to additional labeling of SA by NHS-PEG-fluorescein according to the manufacturer's recommendations. NHS-PEG-fluorescein was dissolved in DMSO (100 mg/mL), while 0.1 mg of compound **5** was dissolved in 100 μL of 50 mM phosphate buffer, pH 7.5. Labeling was conducted at room temperature by stepwise addition of the NHS-PEG-fluorescein solution to the compound **5** containing solution until a final NHS-PEG-fluorescein concentration of 0.5 mM was reached. After labeling, compound **6** was separated from byproduct of the reaction by ultrafiltration with MWCO 50 kDa and repeated washes with 50 mM phosphate buffer, pH 7.5, until no more dye was detected in the waste wash. The colored substance with >50 kDa was collected. Calculation of the average number of fluorescent dye molecules per one molecule of streptavidin in compound **6** was conducted using the known starting amount of compound **5** and molar extinction coefficient for PEG-fluorescein ($\varepsilon_{490} = 80.000$ M^{-1} cm^{-1} in a buffer solution, pH 9). It was concluded that, on average, compound **6** was labeled by five fluorescein molecules per molecule of compound **6**. The labeled compound **6** was dissolved in 50 mM Tris−HCl buffer, pH 8.0, and stored at 4 °C until needed. Measurements of excitation and emission spectra were conducted in 50 mM Tris−HCl buffer pH 8.5 at RT.

Solid-Phase Primer Extension Assay. To test m-Nucs in an enzymatic reaction, a solid-phase primer extension assay was chosen. Modified nucleotides were incorporated into the primer in a template-dependent reaction and, being attached to the solid phase, could be easily separated from the reaction mixture after

Table 1. Oligonucleotides Used in the Study

no.	laboratory name	3′ modification	5′ modification	sequence (from 5′to 3′)[a]
1	Primer T7−19			TAATACGACTCACTATAGG
2	Primer T7−19-Cy3		Cy3	TAATACGACTCACTATAGG

the incorporation reaction. After that, extended primers were separated by gel electrophoresis and visualized by detection of signals from the fluorescent labels coupled to the nucleic acid strands (fluorescently labeled primers or incorporated fluorescently labeled nucleotides).

All DNA polymerases were tested in an incorporation buffer consisting of 50 mM Tris−HCl pH 8.0, 50 mM NaCl, 5 mM $MgCl_2$, 10% glycerol, and 0.2 mM EDTA. The washing buffer for the magnetic beads was 50 mM Tris−HCl pH 8.0, 50 mM NaCl, 10% glycerol, and 0.2 mM EDTA. The stop-buffer used to terminate the enzymatic reaction consisted of 50 mM Tris−HCl pH 8.0, 50 mM NaCl, 10% glycerol, and 20 mM EDTA.

Primer and template (Table 1) were annealed by incubation in incorporation buffer (0.2 mL, 1 μM each) at 80 °C for 2 min followed by cooling to RT for 10 min. The combinations of primer and template for each experiment are described in the Results section; the sequences are listed in Table 1.

To prepare the solid phase with bound template−primer complex, an oligo dT_{48}-3′-biotin-anchor was bound to streptavidin which was immobilized on paramagnetic beads, and the template−primer complex was bound to this anchor. The following protocol was used: Streptavidin beads (600 μL) were washed twice with washing buffer, then 5 μL of 100 μM oligo dT_{48}-3′-biotin was added and incubated for 5 min at RT. After that, the beads were washed twice with washing buffer to remove unbound oligo dT_{48}-3′-biotin. The anchor-containing magnetic beads were used immediately or stored at 4 °C for several weeks until use.

The solution with annealed template primer was added to the anchor-containing beads and incubated for 5 min at 37 °C. Then, beads loaded with the template−primer pairs were rinsed with washing buffer, suspended in 100 μL of this buffer, and used immediately or stored in washing buffer at 4 °C for maximally one week. Immediately prior to use in the primer-extension reaction, loaded beads were briefly rinsed with washing buffer containing 1 μM biotin to saturate all free biotin binding sites on the beads and twice with washing buffer to remove unbound biotin. For each primer extension reaction, 10 μL of the bead suspension was used.

To conduct the primer extension reaction, beads with attached template−primer complexes were combined at room temperature with m-Nucs and other components of the reaction to yield a final volume of 19 μL per reaction. For the enzymatic reactions, dNTPs, commercially available modified nucleotides, or m-Nucs were used at final concentrations of 1 μM or higher as indicated. Each reaction was initiated by the addition of 1 μL of a particular polymerase (i.e., 5 units of Klenow Fragment (exo -) DNA polymerase, or 5 units of *Taq* DNA polymerase, or 2 units of *Vent* (exo-) DNA polymerase) and incubated at 37 °C for 15 min. The incorporation reaction was limited to the first two to five bases starting from the 3′-OH of the primer, because at least one dNTP necessary for further extension was omitted from the reaction. The reaction was stopped by addition of 200 μL of stop buffer. After that, the nucleic acid strands bound to the beads were washed several times to remove the unincorporated nucleotides. In the last step, the suspension of beads with bound nucleic acid strands was concentrated to a volume of 10 μL and loaded directly onto the vertical slab gel (10% polyacrylamide) or stored at 4 °C until analysis.

Electrophoretic Analysis. The primer extension products were analyzed on 10% polyacrylamide−bisacrylamide gels, prepared from 30% of the Bio-Rad stock solution (acrylamide/bisacrylamide, 19.5:0.5% w/w). Gel electrophoresis was conducted at 120 V on a BioRad Miniprotean in 50 mM Tris−HCl Buffer pH 8.0 at 60 °C for 3 min and after that for 10 to 25 min at 40 °C. The 60 °C step served to dissociate the extended nucleic acid strands from the template and, hence, disconnect them from the magnetic beads. After the run, the gel was exposed to UV illumination, and fluorescence images were taken with a CCD camera. Signal intensities were compared using the software Bio-Profile Bio 1D (Vilber Lourmat GmbH). The signal from the extension product obtained from compound **6** was taken as a standard for comparison to other signals. Its relative fluorescent intensity was arbitrarily set to 5 fluorescence units according to the number of the fluorescein molecules bound to the single streptavidin molecule of compound **6**.

RESULTS

Synthesis. To evaluate substrate properties of m-Nucs, several different compounds were synthesized (synthetic schemes are shown in the Supporting Information Supplement 1, Figure 1). These nucleotide conjugates comprise differences in nucleotide moieties (dUTP or dCTP), composition and size of the macromolecular ligands (streptavidin, streptavidin-(PEG-fluorescein)$_5$, streptavidin-phycoerythrin), and linker size. Since there was a potential for binding of more than one nucleotide moiety to one macromolecular ligand, compounds comprising one or several nucleotide moieties were synthesized.

To synthesize the nucleotides modified with NHS-PEG-biotin (compounds **1** or **2**, Table 2), the strategy of Giller et al. 2003 (*19*) for modification of dUTP-AA and dCTP-PA by Dye-NHS was adopted. We replaced Dye-NHS with a NHS-PEG-biotin derivative. The nucleotide analogues, dUTP-AA and dCTP-PA, contain a side chain at the 5 position of the pyrimidine base, allylamine in dUTP-AA, and propargylamine in dCTP-PA. Each side chain includes a primary amino group, which can be further modified. The coupling of NHS-PEG-biotin to the dUTP-AA and dCTP-PA was performed in an aqueous solution. The course of the reaction was followed by TLC analysis, and the products were subsequently purified by HPLC. TLC and UV-analysis indicated a successful modification of nucleotides (altered R_f and nonaltered UV absorption spectrum). As described for the nucleotide analogues dUTP-AA and dCTP-PA (*19*), the covalent binding of a given NHS-conjugated ligand (e.g., a dye) to the nucleotide occurs only at the primary amino group of the allylamine or propargylamine side chain. Accordingly, we assumed the structure depicted in Figure 1 for the new nucleotide analogues. To the best of our knowledge, this is the first time that coupling of such a long linker to a nucleotide moiety is described.

Streptavidin has four binding sites for biotin and a potential to bind up to four dNTP-PEG-B molecules. To synthesize further derivatives carrying streptavidin or its modifications, compound **1** or **2** or commercially available dUTP-16-biotin was added to solutions containing streptavidin or its modifications, so that a range of compounds could be formed (Table 2).

To account for the possible effects of multiple binding of dNTP-PEG-B or the presence of free biotin binding sites within

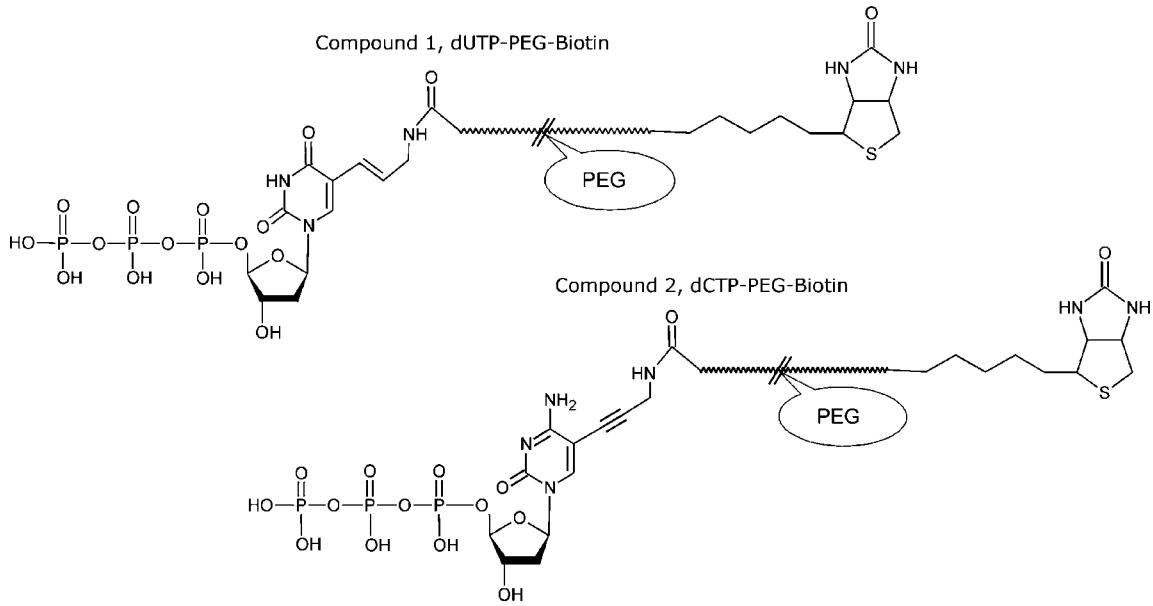

Figure 1. Structure of compounds **1** and **2**.

Table 2. Composition of Synthesized Compounds and Abbreviations[a]

compound no.	name	dNTP/SA ratio	nucleotide moiety	PEG-linker	macromolecular moiety
1	dUTP-PEG-B	-	dUTP	PEG5000	PEG

[a] $n = 1, 2, 3$ or 4. Abbreviations: Biotin is indicated as "B", e.g., dUTP-PEG-B is dUTP-PEG-biotin; PEG-fluorescein is indicated as "PEG-Fluor", streptavidin as "SA", poly(ethylene glycol) as "PEG", R-Phycoerythrin as "PE".

one m-Nuc, we synthesized m-Nucs with ratios of 1:1 and 4:1 between dNTP-PEG-B and streptavidin. By setting up the reaction with equimolar amounts of compound **1** (or **2**) and streptavidin, compounds **3** and **4** were synthesized. Approximately 25% of the available biotin binding sites were occupied by dUTP-PEG-B in compound **3** or by dCTP-PEG-B in compound **4**, corresponding to a 1:1 ratio. The 4:1 ratio corresponds to the occupation of all four binding sites of streptavidin by dNTP-PEG-B moieties. To obtain the 4:1 ratio between dNTP-PEG-B and streptavidin (compound **5**), we used saturating amounts of dUTP-PEG-B in the binding reaction.

M-Nucs with and without fluorescent labels were synthesized. Compounds **3**−**5** and compound **8** contained no additional fluorescent dyes and therefore had no fluorescent signal properties in the visible spectrum. They were used in further steps to synthesize fluorescently labeled compound **6**, and in enzymatic reactions to monitor the electrophoretic mobility of the extended nucleic acids or for testing different DNA polymerases. The fluorescently labeled compounds were synthesized in two ways. (1) The low molecular weight dye fluorescein was coupled to the streptavidin moiety of compound **5**, resulting in compound **6**. (2) A streptavidin-R-phycoerythrin conjugate was used in the coupling reaction, resulting in compound **7**. The two ways represent general cases of the synthetic procedures to obtain m-Nucs: first, nonfluorescent m-Nucs are synthesized and thereafter modified by fluorescent dyes or, on the contrary, a large fluorescent structure is first assembled and then coupled to the dNTP moiety.

When we generated the fluorescently labeled m-Nuc compound **6**, we found that direct coupling of fluorescein to streptavidin resulted in a decrease of fluorescence from fluorescein dyes (data not shown). This phenomen can be partially explained by self-quenching effects of fluorescein molecules if placed in close proximity to each other and by the influence of the streptavidin itself (*20*–*22*). Gruber et al. (*20*) circumvented the last phenomenon by introduction of a PEG spacer between fluorescein and streptavidin. Similar to their procedure, we used a commercially available fluorescein derivative containing a PEG spacer, NHS-PEG-fluorescein, to covalently bind fluorescein to compound **5**. After chemical coupling and purification, a quantification of the number of coupled fluorescein molecules per one molecule of compound **6** was conducted using UV−vis spectroscopy. Knowing the amount of compound **5** in the reaction and measuring the absorption at 490 nm of compound **6**, we calculated an average number of about 5 fluorescein molecules per molecule of compound **6**. Excitation and emission spectra of compound **6** are shown in the Supporting Information Supplement 2, Figure 2.

Substrate Properties of dUTP-PEG-B and $(dUTP\text{-}PEG\text{-}B)_1$-SA. DNA polymerase Klenow Fragment (exo-) was tested for its capacity to use the nucleotide analogues. For this purpose, we performed primer extension assays using natural dNTPs (dATP, dCTP), synthesized nucleotide analogues, Klenow fragment (exo-), and fluorescently labeled primer annealed to a template which was immobilized on magnetic beads. Incorporation of the nucleotides occurred in a single round of reactions. According to the template sequence, the order of the incorporation was A, C, T, A, A, and then stopped since dGTP was omitted from the reaction mix. In this series of experiments, dUTP-PEG-B or $(dUTP\text{-}PEG\text{-}B)_1$-SA (compounds **1** and **3**) replaced dTTP. A reaction mix containing $(dUTP\text{-}PEG\text{-}B)_1$-SA but omitting the Klenow fragment (exo-) served as a negative

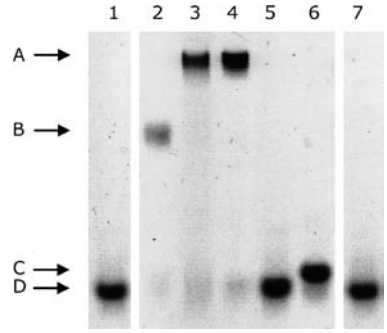

Figure 2. Fluorescent gel image of electrophoretically separated Cy3 labeled primer and extension products. Standard primer extension assays were performed using the Cy3-labeled primer T7−19-Cy3, the template oligo 87, dATP, dCTP, Klenow Fragment (exo-), adding or omitting the following components. Lane 1: with $(dUTP\text{-}PEG\text{-}B)_1$-SA but without Klenow Fragment (exo-). Lane 2: with dUTP-PEG-B. Lane 3: as in lane 2 but strepavidin was added after the reaction and before electrophoresis. Lane 4: with $(dUTP\text{-}PEG\text{-}B)_1$-SA. Lane 5: with $(dUTP\text{-}PEG\text{-}B)_1$-SA but EDTA added to suppress incorporation by the polymerase. Lane 6: with $(dUTP\text{-}PEG\text{-}B)_1$-SA and 50 μM dTTP as a competitor. Lane 7: with $(dUTP\text{-}PEG\text{-}B)_1$-SA but without dCTP, to test misincorporation. A: Extended primer after incorporation of dUTP-PEG-biotin and subsequent binding of exogenous streptavidin (lane 3) or after incorporation of $(dUTP\text{-}PEG\text{-}B)_1$-SA (lane 4). B: Extended primer after incorporation of dUTP-PEG-B in the absence of SA (lane 2). C: Extended primer after incorporation of five unmodified nucleotides ACTAA (lane 6). D: primer T7−19-Cy3 only (lane 1). Abbreviations for nucleotide conjugate structures: Streptavidin (SA), poly(ethylene glycol) (PEG), biotin (B).

control (Figure 2, lane 1). In the presence of polymerase, the primer was extended and dUTP-PEG-B incorporated, seen as a drastic shift in mobility (Figure 2, lane 2). The incorporation of dUTP-PEG-B was verified by incubation of the extended primer with saturating amounts of streptavidin before electrophoresis. This led to a further increase in molecular weight and electrophoretic retardation (Figure 2, lane 3). When $(dUTP\text{-}PEG\text{-}B)_1$-SA (which already contains streptavidin) was used instead of dUTP-PEG-B in the extension assay, the extended primer showed the same mobility in electrophoresis (Figure 2, lane 4). The result demonstrates that $(dUTP\text{-}PEG\text{-}B)_1$-SA was indeed incorporated during the extension assay by Klenow fragment (exo-) DNA polymerase. Three more controls tested the correct enzymatic incorporation of $(dUTP\text{-}PEG\text{-}B)_1$-SA into the growing DNA strand. When EDTA was added to suppress the Mg^{2+}-dependent polymerase activity, no incorporation was detected (Figure 2, lane 5). Incorporation of $(dUTP\text{-}PEG\text{-}B)_1$-SA was outcompeted when dTTP (50 μM final concentration) was added to the extension reaction (Figure 2, lane 6). To test the ability of polymerase to discriminate complementary and noncomplementary base pairing of $(dUTP\text{-}PEG\text{-}B)_1$-SA, the extension reaction was performed with dATP and $(dUTP\text{-}PEG\text{-}B)_1$-SA, but without dCTP and dGTP. In this reaction, for $(dUTP\text{-}PEG\text{-}B)_1$-SA to be incorporated, the polymerase would have to incorporate it opposite the guanosine base, i.e., noncomplementary base, but no incorporation was seen (Figure 2, lane 7).

Two other DNA polymerases, *Taq* and *Vent* (exo -), were also able to use compound **3** in the incorporation reaction (results not shown). In similar assays, compounds dCTP-PEG-B, $(dCTP\text{-}PEG\text{-}B)_1$-SA, and $(dUTP\text{-}PEG\text{-}B)_4$-SA (compounds **2**, **4**, and **5**) were tested and also found to be incorporated into the primer (results not shown). In contrast, $(dUTP\text{-}16\text{-}B)_4$-SA (compound **8**) was not incorporated at all. It contained a short linker between the nucleotide and streptavidin and, therefore, probably was not a suitable substrate for the Klenow fragment (exo-) DNA polymerase in the primer extension assay (Supporting Information Supplement 3, Figure 3, lanes 1 to 3). Two other DNA polymerases, *Taq* and *Vent* (exo-), were also unable to use $(dUTP\text{-}16\text{-}B)_4$-SA in the incorporation reaction (Supporting Information Supplement 3, Figure 3, lanes 4 to 9).

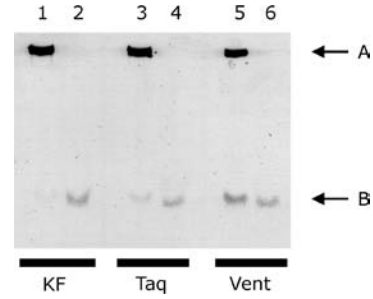

Figure 3. Fluorescent gel image of electrophoretically separated Cy3 labeled primer and extension products with $(dUTP\text{-}PEG\text{-}B)_n$-SA-PE. Standard primer extension assays were performed with Klenow fragment (exo-), "KF", lanes 1 and 2; *Taq* Polymerase "Taq", lanes 3 and 4; and *Vent* (exo-) Polymerase "Vent", lanes 5 and 6. Controls contained EDTA to suppress the incorporation (lanes 2, 4, 6). A: extended primer after incorporation of $(dUTP\text{-}PEG\text{-}B)_n$-SA-PE (lanes 1, 3, and 5). B: primer T7−19-Cy3 (lanes 2, 4, 6). Abbreviations for nucleotide conjugate structures: Streptavidin (SA), poly(ethylene glycol) (PEG), biotin (B), R-Phycoerythrin (PE).

The shift of electrophoretic mobility of strands extended by a single m-Nuc was considerable, compared to those extended by natural nucleotides (Figure 2). Upon incorporation of compound **1**, the mobility of the extended oligonucleotide with the length of only 22 nucleotides corresponded to that of nucleic acid fragments with 100 to 150 nucleotides in length (Supporting Information Supplement 4, Figure 4, lane 2). After incorporation of the even larger compound **3**, the mobility of the extended oligonucleotide corresponded to that of fragments with 500 to 700 nucleotides (Supporting Information Supplement 4, Figure 4, lane 3). The relative mobility of the molecules in the gel is influenced by charge, shape, and size of a molecule. All of them may have caused the mobility shift seen in m-Nuc extended oligonucleotides. Similar changes in mobility are known from the electophoretic mobility shift assays (EMSA) often used in the characterization of protein−nucleic acid interactions (*23*).

Acceptance of m-Nucs with a Size of over 200 kDa. To test the influence of a ligand with an even larger size than that of streptavidin, a commercially available streptavidin-R-phycoerythrin conjugate (SA-PE) was used in the synthesis of a m-Nuc ($(dUTP\text{-}PEG\text{-}B)_n$-SA-PE, compound **7**). Standard primer extension assays were set up with $(dUTP\text{-}PEG\text{-}B)_n$-SA-PE and Klenow fragment (exo-). The control reaction contained EDTA to suppress the Mg^{2+}-dependent polymerase primer extension under exposure to UV illumination, fluorescent signals from Cy3 labeled primer as well as fluorescent signal from PE were used to detect the position of the reaction products. As shown in Figure 3, lane 1, $(dUTP\text{-}PEG\text{-}B)_n$-SA-PE was successfully used as a substrate by Klenow Fragment (exo-) but not incorporated in the presence of EDTA (Figure 3, lane 2). Because $(dUTP\text{-}PEG\text{-}B)_n$-SA-PE has its own strong fluorescence due to PE, the success of its incorporation by the Klenow fragment (exo-) was established by the appearance of a strong fluorescent signal in the top of the gel (lane 1, band A) and disappearance of the signal from the fluorescently labeled primer at the bottom of the gel (compare with lane 2, band B). This means the primer was consumed during the extension reaction.

Acceptance of m-Nucs by Polymerases from Different Families. Because size, shape, and geometry of the polymerase itself, as well as differences in the nucleotide binding sites and enzymatic coupling rate may play a critical role in the acceptance of m-Nucs, two further polymerases, *Taq* polymerase (a member of the DNA polymerase family A), and *Vent* (exo-) polymerase (belonging to DNA polymerase family B) were

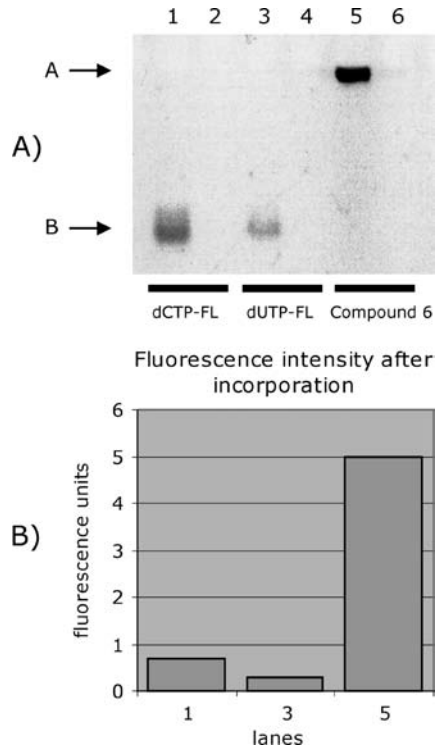

Figure 4. Signal intensities after primer extension with Fluorescein-12-dUTP, Fluorescein-12-dCTP and (dUTP-PEG-B)$_4$-SA-(PEG-Fluor)$_5$. (A) Gel image of electrophoretically separated primers extended by fluorescently labeled nucleotides. Lane 1: Fluorescein-12-dCTP (dCTP-FL). Lane 2: Fluorescein-12-dCTP and EDTA. Lane 3: Fluorescein-12-dUTP (dUTP-FL). Lane 4: Fluorescein-12-dUTP and EDTA. Lane 5: (dUTP-PEG-B)$_4$-SA-(PEG-Fluor)$_5$. Lane 6: (dUTP-PEG-B)$_4$-SA-(PEG-Fluor)$_5$ and EDTA. A: Extended primer after incorporation of (dUTP-PEG-B)$_4$-SA-(PEG-Fluor)$_5$. B: Extended primer after incorporation of Fluorescein-12-dCTP or Fluorescein-12-dUTP. (B) Relative fluorescence intensities of primer extension products from lanes 1, 3, and 5 in (A). tested for their ability to use (dUTP-PEG-B)$_n$-SA-PE (compound **7**), the largest of all m-Nucs synthesized in this study.

Standard primer extension assays were set up as described above. While most protocols recommend a temperature regime around 60−70 °C for optimal extension reaction by thermostable polymerases, it is known that *Taq* polymerase is active also at 37 °C (*24*). (dUTP-PEG-B)$_n$-SA-PE contained protein (SA and PE). To avoid possible denaturation effects at elevated temperatures around 70 °C, the reactions were performed at 37 °C as for Klenow fragment (exo-). As a control for enzymatic incorporation, parallel reactions were set up with EDTA as described above. Both types of polymerases accepted (dUTP-PEG-B)$_n$-SA-PE as a substrate, as shown by the bright fluorescent bands at the top of the gel (Figure 3, lanes 3 and 5). The incorporation of (dUTP-PEG-B)$_n$-SA-PE was suppressed by EDTA (Figure 3, lanes 4 and 6). The extent of primer consumption, however, differed between *Taq* and *Vent* (exo-) polymerases. While almost all primer was used up in the reaction with *Taq*, a fraction of the primer had not been extended in the reaction with *Vent* (exo-). The difference may by explained by a lower activity of *Vent* (exo-) polymerase at lower temperatures. We have not yet investigated this effect further.

Comparison of Signal Intensities. To compare signal intensities of the new nucleotides with conventional fluorescein modified nucleotides, primer extension reactions were conducted with m-Nuc (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein)$_5$ (compound **6**), which had been labeled with fluorescein, and compared to extension reactions with commercially available Fluorescein-12-dUTP or Fluorescein-12-dCTP. The primer extension reactions were set up similarly to those described before with the exceptions that the primer used in these experiments was not labeled and specific combinations of nucleotides were used. The reaction mixes contained dATP and Fluorescein-12-dCTP (Figure 4A, lanes 1 and 2), dATP, dCTP, and Fluorescein-12-dUTP (Figure 4A, lanes 3 and 4), or dATP, dCTP, and (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein)$_5$ (Figure 4A, lanes 5 and 6). No fluorescent signal was observed in lanes with reactions containing EDTA (Figure 4A, lanes 2, 4, and 6), used as control to suppress enzymatic reaction. This means that wash steps were effective and no unspecific co-isolation of the fluorescently labeled nucleotides with magnetic beads occurred. As can be seen in Figure 4A, (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein)$_5$, as well as the commercially available fluorescently labeled nucleotides, was incorporated into the growing strand of DNA by the Klenow fragment (exo-). Due to the large size of the (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein)$_5$, the position of the fluorescent band was shifted toward the top of the gel (Figure 4A, lane 5) compared to the position of bands with the low molecular weight nucleotide analogues (Figure 4A, lanes 1 and 3).

Since, according to the template sequence, only one fluorescently labeled nucleotide was incorporated in each growing DNA strand in the three primer extension reactions, the fluorescent signals were comparable. The signal intensity generated by incorporation of (dUTP-PEG-B)$_4$-SA-(PEG-Fluorescein)$_5$ (Figure 4B, lane 5) was about 7-fold stronger than the signal from Fluorescein-12-dCTP (Figure 4B, lane 1) and 15-fold stronger compared to the Fluorescein-12-dUTP signal (Figure 4B, lane 3). Besides this, we detected a difference in signal intensity between the two conventionally labeled nucleotides (Fluorescein-12-dCTP, lane 1, and Fluorescein-12-dUTP, lane 3) in this particular setting. Although we did not investigate this difference in detail, the signal heterogeneity between commercial dCTP and dUTP analogues may be explained by the remarkable sensitivity of fluorescein to the DNA microenvironment, particulary to the DNA sequence content (*25, 26*).

DISCUSSION

The aim of this study was the synthesis and applicability testing of a novel kind of modified nucleotide which were labeled with several fluorescent dyes molecules per nucleotide. We describe here the design of such nucleotides and call them m-Nucs (for macromolecular nucleotides). The general structure comprises one or several nucleotide moieties, a large, macromolecular ligand labeled with dyes, and a macromolecular linear linker, which connects each nucleotide moiety with the macromolecular ligand. Using this new class of modified nucleotides in enzymatic incorporation reactions, signals from multiple dye molecules are obtained when only one nucleotide molecule is incorporated, thus considerably enhancing the signal strength of this nucleotide.

For the construction of such nucleotides, several general aspects have to be taken into consideration. First, the individual dye molecules have to have sufficient distance from each other in order to achieve a strong fluorescent signal from each of them. To this end, dyes should be coupled to a larger structure, e.g., a polymer. In this study, streptavidin (SA) was used as a polymer and the dyes were coupled to its reactive surface groups via a PEG-linker. A second aspect refers to the fact that the large structure may impede the incorporation of nucleotides coupled to such macromolecular ligands. The solution found to overcome this limitation was a long hydrophilic linker, in this study, PEG, to separate the nucleotide moiety from the bulky streptavidin molecule. As a third aspect, the positioning of the linker on the

nucleotide itself is an important factor affecting the function of the nucleotide. Here, we used the 5-position of pyrimidines as acceptor sites for the linker, because its modifications are known to be tolerated by DNA polymerases (*27, 28*). Therefore, the pyrimidines 5-Allylamino-dUTP and 5-Propargylamino-dCTP were used by us as starting compounds to couple the PEG-linker to the nucleotide moiety.

Once the m-Nucs were generated, their functionality had to be tested. Specifically, it had to be proven that coupling to a large molecule did not interfere with the substrate properties of the nucleotides during an incorporation reaction. Using dUTP-PEG-B for a test, we showed that the modified nucleotides preserved their ability to be incorporated into the growing strand by the polymerases. This finding encouraged us to test whether a further modification, namely, coupling of either streptavidin modified by dyes or another even larger ligand like PE, would still result in conservation of substrate properties. In this paper, we demonstrate that this is indeed the case: the nucleotide moiety coupled to a macromolecular ligand via a long hydrophilic linker preserves its substrate properties. It can be incorporated into the growing nucleic acid chain by a number of DNA polymerases in a template-dependent manner. Therefore, such m-Nucs can be used in primer extension reactions.

The ability to be incorporated proves that the nucleotide moiety preserves its accessibility to the nucleotide binding center of the polymerase. Usually, PEG-linkers influence the interaction of two compounds, providing a shielding effect that decreases the binding strength of a potential partner. Apparently, in the situation discussed here, PEG does not shield the nucleotide moiety, at least not completely, and allows an interaction between nucleotide and polymerase. Further, PEG apparently leaves sufficient mobility for the nucleotide moiety in the solution, thus preserving the substrate properties of a low molecular weight ligand. In contrast, a simple combination of a nucleotide carrying a convential short linker, dUTP-16-Biotin, with streptavidin led to an inhibition of incorporation of the nucleotide into the growing strand (Supporting Information, Supplement 3, Figure 3). We attribute this effect to steric hindrance by the large streptavidin molecule, brought about by the close proximity to the nucleotide moiety (linker length of only 16 atoms). This apparently repelled the polymerase and inhibited the polymerase−nucleotide interaction.

The use of m-Nucs with a long linker and an increased number of dye molecules instead of conventionally labeled nucleotides with only short linker and one dye molecule offers several advantages. First, according to theoretical assumptions, the cumulative strength of fluorescent signal from m-Nuc should increase. This is supported by our findings that m-Nucs carrying multiple dye molecules indeed created increased fluorescent signal when compared to those from conventional fluorescently labeled nucleotides (see Figure 4). Second, because each fluorophore bound to m-Nuc can emit light independently from the others bound to the same m-Nuc, the effect of disturbing events such as blinking and bleaching, which lead to reduced visibility of a given dye molecule, should be minimized. Third, the long linker itself plays an important role by separating the fluorophores from the DNA strand. This feature is interesting because not only the pecularities of a single fluorophore introduce uncertanties in signal detection as discussed in the introduction, but also local DNA sequence content may have a strong influence on signal intensity of fluorophores. Several studies have analyzed those effects on commonly used fluorescent dyes like fluorescein, Cy3, and rhodamines, conjugated to the oligonucleotides via short linkers (*25, 26, 29–34*). Particularly, fluorescein is known to be sensitive to the local DNA sequence content (*25, 26*). We chose fluoresein as a fluorophore to label m-Nucs, in order to challenge the structure of m-Nucs for such potentially detrimental effects. Indeed, there was a difference in fluorescent signal intensity even between incorporated commercial nucleotide analogues. The difference may be explained by quenching of fluorescence caused by DNA (see Figure 4). On the other hand, the fluorescence intensity of compound **6** exceeded the fluorescence of fluorescein modified dCTP and dUTP by more than five times, i.e., by a factor larger than a simple addition of fluorescence intensities of individual dyes would have predicted. We attribute this effect to the structure of m-Nucs. Apart from the number of dye molecules (e.g., in compound **6**), the larger distance between the fluorophores in an incorporated m-Nuc and the nucleic acid strand may have contributed to the increase of fluorescence intensity. When placed in close proximity of a fluorochrome, guanosine bases are supposed to have a quenching effect on some commonly used fluorochromes (*25, 33*). Altogether, effects of the nucleic acid bases on the dye molecules of a particular incorporated m-Nuc may be minimized due to introduction of a long linker between the nucleotide moiety and the dyes, thus leading to a more uniform fluorescence and its independence from the sequence content.

As pointed out in the Introduction, limitations in signal detection are one of the obstacles in the field of nanobiotechnology, especially in the field of DNA analysis on the single molecule level. We believe that m-Nucs may reveal a new perspective in this field. Until now, only a limited numbers of fluorophores, such as Rhodamine 6G, TAMRA, Cy3, Cy5, and several Alexa-dyes or Atto-dyes had sufficiently high quantum yields and stability for analyzing single fluorescent molecules in biological applications (*2, 3, 6–8, 35*). Because, within a m-Nuc, a large number of dyes can be coupled to the nucleotide, one can now use a larger variety of dyes of different nature and spectral properties.

One particular application which may be considerably influenced by our novel m-Nucs, is single molecule nucleic acid sequencing. Here, the current technology deals with considerable limitations in part due to the use of conventionally labeled nucleotide structures including sequencing errors in the range 5−20% (*17, 18*). We anticipate that this error rate can be considerably decreased by the use of m-Nucs. Different additional requirements need to be met to use the m-Nucs for the sequencing at the single molecule level. In particular, it is desirable to have m-Nucs capable of supporting reversible termination for the sequencing by synthesis scheme and m-Nucs labeled with different fluorophores, e.g., with four different dyes corresponding to each nucleic base. To meet these requirements, we are presently adopting m-Nucs for reversible termination and sequencing reaction of nucleic acid strands (Cherkasov et al. manuscript in preparation).

Genetically Engineered Clostridial C2 Toxin as a Novel Delivery System for Living Mammalian Cells

Jörg Fahrer,[†] Rainer Plunien,[†] Ulrike Binder,[†] Torben Langer,[†] Hartmut Seliger,[‡] and Holger Barth*[,†]

Institute of Pharmacology and Toxicology, University of Ulm Medical Center, Albert-Einstein-Allee 11, and Research Group on Chemical Functions in Biosystems, University of Ulm, Albert-Einstein-Allee 47, D-89081 Ulm, Germany. Received August 17, 2009; Revised Manuscript Received November 30, 2009

The C2 toxin of *Clostridium botulinum* is a binary bacterial protein toxin, comprising the enzyme component C2I and the separate binding/translocation component C2IIa. C2IIa mediates the transport of C2I into the host cell cytosol. The N-terminal domain of C2I (C2IN) is enzymatically inactive but essential for C2IIa-mediated internalization of C2I. Here, we exploit the C2IIa/C2IN system to generate a recombinant C2IN−streptavidin fusion protein allowing for the delivery of biotinylated molecules into the cytosol of mammalian cells. C2IN−streptavidin overproduced in *E. coli was* affinity-purified and capable of binding biotinylated proteins in a concentration-dependent manner. Real-time surface plasmon resonance confirmed the biotin-mediated interaction yielding a K_D-value of ~0.75 μM. Internalization of C2IN−streptavidin into the cytosol of epithelial cells and macrophages was demonstrated by immunoblot analysis and confirmed by confocal microscopy. Cell viability studies showed no cytotoxic effects of the novel transporter. Furthermore, Vero cells treated with biotin−fluorescein or biocytin−Alexa488 as model cargo displayed a specific C2IN−streptavidin/C2IIa-dependent uptake, providing proof-of-principle for the functionality of this novel delivery system.

INTRODUCTION

C2 toxin produced by *C. botulinum* is the archetype of binary actin-ADP-ribosylating toxins, comprising the two nonlinked proteins C2I and C2II (*1*). The enzyme component C2I harbors ADP−ribosyltransferase activity, whereas C2II represents the binding/translocation moiety. C2II is converted by proteolytic cleavage into its biologically active form C2IIa (*2*), which directs the uptake of C2I into the host cell cytosol. C2IIa forms ring-shaped heptamers, also referred to as prepores, and binds to complex carbohydrate receptors on the cell surface of eukaryotic cells (*3, 4*). Subsequently, cell-surface bound C2IIa serves as a docking platform for C2I, allowing toxin assembly on the cell surface, which in turn triggers receptor-mediated endocytosis (*5*). Acidification of early endosomes results in a structural change of C2IIa heptamers to the so-called pore conformation, triggering their insertion into the endosomal membrane and subsequent pore formation (*6*). Translocation of C2I through this pore is driven by a pH gradient between the cytosol and the endosomal lumen. This process is facilitated by the host cell factors Hsp90 and cyclophilin A, as recently demonstrated (*7, 8*). In the cytosol, C2I catalyzes the covalent modification of actin with ADP-ribose, inducing the depolymerization of the actin cytoskeleton (*9*).

The N-terminal domain of C2I (C2IN) is enzymatically inactive but essential for C2IIa-mediated internalization of C2I (*10*). The adaptor domain C2IN has been successfully used for the cellular import of various proteins, such as the virulence factor SpvB from *S. enterica* (*11*) or dihydrofolate reductase (*12*). Furthermore, C2IN has been genetically fused to bacterial C3 ADP-ribosyltransferases, which are selective inhibitors of Rho GTPases. This allowed the delivery of C3 proteins into numerous eukaryotic cell lines to study Rho-mediated signaling and turned out to be a powerful pharmacological tool (*10, 13*).

Streptavidin, produced by *Streptomyces avidinii*, is a tetrameric protein which exhibits an extraordinary affinity for biotin ($K_D = 10^{-15}$ M) (*14*). In addition, streptavidin is an exceptionally stable protein, showing a high resistance against heat, denaturants, or extreme pH values. Owing to these properties, it has been used in a wide range of applications including life sciences, (nano-) medicine, and drug delivery (*15*−*17*). Streptavidin and its chicken homologue avidin have recently been used as cellular delivery systems in conjunction with molecular Trojan horses. These systems comprise monoclonal antibodies directed against cell-surface receptors, such as the transferrin receptor, that induce receptor-mediated endocytosis, thus enabling the passage through biological membranes (*18, 19*). In this approach, avidin or streptavidin are either genetically fused to the respective monoclonal antibody or covalently linked by chemical means. Previously, a bioconjugate consisting of streptavidin and an antibody to the human insulin receptor was applied for the intracellular delivery of radiopharmaceuticals in vivo (*20*). Streptavidin was also fused to the cell-penetrating peptide TAT and demonstrated to promote the internalization of a biotinylated cargo into mammalian cells (*21, 22*). Moreover, an antitransferrin receptor−avidin fusion protein was used to deliver biotinylated molecules in myeloma and T cell lymphoma cells (*23*). Recently, streptavidin mutants have been generated allowing for a reversible biotin binding due to a decreased affinity. Sano and co-workers described the construction of a dimeric streptavidin, which is capable of biotin binding, however, with reduced affinity ($K_D = 1.5 \times 10^{-7}$ M) (*24*).

In the present study, we exploit the transport mechanism of the clostridial C2 toxin in conjunction with dimeric streptavidin allowing for the delivery of exogenous biotinylated molecules into mammalian cells. We report the generation, functional characterization, and application of a chimeric C2IN−streptavidin fusion protein. Notably, C2IN−streptavidin applied in combina-

tion with the binding/translocation component C2IIa was detected in the cytosol of various tested mammalian cell types, emphasizing its versatility as a delivery system. We provide proof-of-principle for this novel transport system using biotin−fluorescein or biocytin−Alexa488 as cargo.

EXPERIMENTAL PROCEDURES

Cloning of C2IN−Streptavidin. Plasmid pGEX2T-C2I (*10*), harboring a GST-tagged version of C2I, was digested with *Bam*HI to remove the C-terminal part of C2I and religated yielding pGEX2T-C2IN. Streptavidin cDNA was amplified by PCR from plasmid TSA43 (*24*) using the primers StrepI (5′-GAATTCAGATCTGGCATCACCGGCACC-3′) and StrepII (5′-GAATTCGGATCC CTACACCTTGGTGAA-3′) to introduce a *Bgl*II and a *Bam*HI site, respectively. The PCR product was ligated in the pCR-Blunt vector using the Zero Blunt PCR cloning kit (Invitrogen, Karlsruhe, Germany) and transformed in competent *E. coli* DH5α cells. Isolated pCR−streptavidin was then digested with *Bgl*II and *Bam*HI, ligated with *Bam*HI-digested pGEX2T-C2IN, and transformed in competent *E. coli* cells. Subsequently, the C2IN−streptavidin construct was sequenced with the pGEX2T 5′- and 3′-sequencing primers. In addition, the C2IN−streptavidin boundary was analyzed with the sequencing primers 5′-SeqI (5′-TTAGATAGGGATGC-TATAGGC-3′) corresponding to position 280−300 and 3′-SeqII (5′-GTCACGATGAAGGTCGAGCC-3′) mapping to position 709−728 of the C2IN−streptavidin construct.

Expression and Purification of Recombinant Fusion Protein. C2IN was overproduced in *E. coli* BL21 and purified as described previously (*10*). C2IN−streptavidin was overexpressed as GST-tagged fusion protein in *E. coli* BL21 and isolated by affinity chromatography. Briefly, *E. coli* BL21 transformed with pGEX2T-C2IN-streptavidin was grown at 37 °C in Luria−Bertani (LB) medium supplemented with 100 μg/mL ampicillin to an optical density of 0.6−0.8. To induce protein expression, isopropyl-β-D-thiogalactopyranoside (IPTG) was added to a final concentration of 0.2 mM, and cultures were incubated at 29 °C for 6 h. Bacteria were harvested by centrifugation for 10 min at 4 °C at 4400 *g*, resuspended in buffer containing 0.1% Triton X-100, and disrupted by sonication. Cellular debris was sedimented for 15 min at 4 °C at 20 000 *g*, and the clear supernatant was incubated with glutathione−agarose beads (Macherey-Nagel, Düren, Germany) for 2 h at room temperature. After centrifugation for 5 min at 1000 *g*, the beads were washed 2 times with lysis buffer and 2 times with PBS pH 7.4. To remove the GST-tag, the immobilized protein was incubated with thrombin (15 NIH units/L culture) for 1 h at room temperature, and supernatant containing C2IN−streptavidin was obtained by centrifugation at 10 000 *g* for 1 min. To eliminate thrombin, the supernatant was further incubated with benzamidine beads (GE Healthcare, München, Germany) for 10 min and collected. Isolated C2IN−streptavidin was analyzed for homogeneity by SDS-PAGE followed by Coomassie staining. Protein identity was confirmed by Western blot analysis with an anti-streptavidin antibody (Abcam, Cambridge, UK) and an anti-C2IN antibody raised in rabbits (*25*), respectively.

To monitor the time-dependent expression of C2IN−streptavidin, 300 μL aliquots of the suspension culture were collected and analyzed by SDS-PAGE and Coomassie staining. In addition, the GST-tagged protein was detected on a nitrocellulose membrane using an anti-GST antibody (BD Biosciences, Heidelberg, Germany).

SDS-PAGE and Immunoblot Analysis. Proteins were separated by SDS-PAGE on 12.5% gels according to the method of Laemmli (*26*). For immunoblot analysis, the proteins were transferred onto a nitrocellulose membrane (Whatman, Dassel, Germany) by electroblotting using a semidry system (PeqLab, Erlangen, Germany) or alternatively with a wet-blot chamber (GE Healthcare, München, Germany). The membranes were blocked for 1 h at room temperature with 5% nonfat dry milk in PBS containing 0.1% Tween 20 (PBS-T) followed by 1 h incubation with the respective antibodies in blocking solution. After washing the membranes with PBS-T, the blots were probed with the appropriate secondary antibodies coupled to horseradish peroxidase (1:2000), and proteins were detected by enhanced chemiluminescence.

Overlay Blot Assay. Biotinylation of proteins was carried out using the EZ-Link Micro Sulfo-NHS-Biotinylation Kit (Pierce, Bonn, Germany). To assess the biotin-binding properties of the generated fusion protein, increasing amounts of C2IN−streptavidin as well as the negative control C2IN (each protein 1−50 pmol) were subjected to SDS-PAGE. After separation, the proteins were transferred on a nitrocellulose membrane by wet blotting and the membrane was blocked. Subsequently, the membrane was incubated with biotinylated BSA in PBS-T (5 μg/mL) or biotinylated C3bot (1 μg/mL). To disrupt unspecific binding, the membrane was washed with PBS-T containing 500 mM NaCl followed by three washing steps in PBS-T. Bound biotin-labeled BSA or C3bot were detected with streptavidin-POD (Roche, Mannheim, Germany) diluted 1:2000 in PBS-T.

Surface Plasmon Resonance. All SPR experiments were performed with a Biacore 2000 system equipped with a CM5 sensor chip (GE Healthcare). C2IN−streptavidin in sodium acetate buffer (pH 4.5) was immobilized onto a CM5 sensor chip using the amine coupling procedure to obtain a final response level about 2500 RU. An activated reference cell without immobilized ligand was used to subtract buffer refractive effects and as a control for unspecific binding. The following concentrations of biotin-labeled C3bot protein from *Clostridium botulinum* were injected at room temperature: 750 nM, 1 μM, 2.5 μM, 5 μM, 7.5 μM, 10 μM. Flow rate was set to 30 μL/min with the following parameters: 130 s contact time, 1800 s dissociation time. Dissociation was carried out in HBS buffer pH 7.4 without a regeneration step. Baseline levels were stable throughout all cycles. Data evaluation was carried out using *BIAevaluation* software v 3.2.

Cell Culture and Cytotoxicity Assays. HeLa and Vero cells were cultured at 37 °C and 5% CO_2 in Minimum essential medium (MEM), and CHO cells were maintained in a 1:1 mixture of Ham's F12/ Dulbecco's modified Eagle medium (DMEM), containing 10% heat-inactivated fetal calf serum (FCS), L-glutamate (2 mM), 100 U/mL penicillin, and 100 μg/mL streptomycin. Cells were routinely trypsinized and reseeded three times per week. J774A.1 cells (a kind gift of Dr. Singh Chhatwal, Braunschweig, Germany) were cultured at 37 °C and 5% CO_2 in DMEM, containing 10% heat-inactivated FCS, L-glutamate (4 mM), penicillin (100 U/mL), and streptomycin (100 μg/mL). Cells were routinely scraped off and reseeded three times per week.

Cell viability was determined by trypan blue exclusion. Briefly, Vero cells were seeded in a 12 well plate (4×10^4 cells/well) and grown overnight. Subsequently, varying concentrations of C2IN−streptavidin and C2IIa were added in serum-free medium. As a positive control, cells were exposed to 1 μM staurosporine. After 2 h, the medium was removed and the cells were incubated for another 3 h with MEM supplemented with FCS. Thereafter, cells were collected by trypsination and mixed 1:1 with 0.4% trypan blue solution. Viable and nonviable (i.e., blue) cells were counted with a hemocytometer permitting the calculation of the cell viability. In addition, cell proliferation was assessed over a period of 48 h using the Cell Titer 96 Aqueous nonradioactive cell proliferation

assay (Promega, Mannheim, Germany). Briefly, Vero cells were seeded in 96 well plates at a density of 5×10^3 cells per well. The next day, cells were incubated with different combinations of C2IN−streptavidin and C2IIa, as well as 0.5 μM staurosporine as a positive control. Cell viability was determined after 5, 24, and 48 h, respectively, by measuring absorbance at 490 nm in an ELISA reader.

Cell Fractionation by Digitonin Treatment. To obtain the cytosolic fraction of cultured Vero cells, digitonin-based cell fractionation was performed according to the method described by Sørensen and co-workers (*27*).Vero cells grown in 12 well plates were preincubated at 37 °C in serum-free medium for 30 min. Subsequently, a combination of C2IN−streptavidin (2 μg/mL) and C2IIa (4 μg/mL) was added to the medium and cells were incubated for up to 4 h with the complex. As a control, cells were left untreated or incubated without the binding/translocation component C2IIa. Cells were then washed twice with PBS to remove unbound toxin from the surface. Thereafter, cells were incubated in the presence of digitonin (20 μg/mL in PBS) for 5 min at 25 °C to permeabilize the cell membrane and for additional 25 min at 4 °C to allow the cytosol to diffuse into the buffer. The supernatant was carefully collected and adherent extracted cells were scraped off in Laemmli loading buffer. The samples were then subjected to SDS-PAGE and transferred to a nitrocellulose membrane by wet blotting, and C2IN−streptavidin was detected with a polyclonal anti-C2IN antibody as described before. Thereafter, the blot membrane was stripped, and the identity of the cytosolic fraction was confirmed by immunoblot analysis of cytosolic marker protein Hsp90, using a monoclonal anti-Hsp90 antibody (Santa Cruz Biotechnology, Heidelberg, Germany). Importantly, the absence of early endosomes in this fraction was verified in immunoblot with an antibody directed against rab5 (BD Biosciences, Heidelberg, Germany), a marker protein for early endosomes.

Immunofluorescence Microscopy of C2IN−Streptavidin-Treated Cells. For immunocytochemical analysis of C2IN−streptavidin uptake, cells were seeded on sterile coverslips at a density of 3.5×10^4 per well and incubated in 12-well culture dishes overnight. Cells were then treated with a combination of 1 μg C2IN−streptavidin and 2 μg C2IIa in serum-free medium for 2 h. Medium was exchanged and cells were incubated for another 2 h. As controls, cells were left untreated or incubated with the single components, i.e., C2IN−strepavidin or C2IIa. Subsequently, cells were fixed with 4% paraformaldehyde, permeabilized with 0.4% Triton X-100, and blocked with 5% dry milk powder in PBS-T. C2IN−streptavidin was then visualized with an α-streptavidin antibody (1:1000 in PBS) in conjunction with a secondary antibody−Alexa488 conjugate (1:400 in PBS). Finally, nuclei were counterstained with Hoechst 33342 (1:20 000 in PBS), and coverslips were mounted with ProLong Gold antifade reagent (Invitrogen, Karlsruhe, Germany). Confocal microscopy was performed with a Zeiss Axiovert 200 M microscope equipped with a LSM510 Meta laser scanning device (Zeiss, Oberkochen, Germany). 1-μm-thick sections were recorded with LSM Image Examiner and processed with *ImageJ* software (NIH, USA).

Confocal Microscopy to Monitor Biotin−Fluorophor Uptake into Vero Cells. To analyze the uptake of biotin−fluorescein (Sigma, Deisenhofen, Germany) or biocytin−Alexa488 (Invitrogen, Karlsruhe, Germany), Vero cells were grown overnight on sterile coverslips. After preincubation of 2 μg C2IN−streptavidin and an excess of fluorescein−biotin or biocytin−Alexa488 for 30 min, the mixture was supplemented with 4 μg C2IIa, and complex formation was allowed to occur for 30 min at 4 °C. Subsequently, the complex was added to the cells and incubated for 2 h. Untreated cells, cells incubated with biotinylated fluorophor alone or with the complex omitting C2IIa, served as controls. After 2 h, the medium was replaced by serum-containing MEM, and cells were further incubated for 2 h. Cells were then processed for immunofluorescence as described above. After fixation and permeabilization, cells were blocked and early endosomes were stained with a primary antibody directed against EEA1 (Novus Biologicals, Littleton, USA) in conjunction with an Alexa 647-labeled secondary antibody. Cells embedded in ProLong Gold antifade reagent were visualized using a LSM510 Meta confocal system connected to a Zeiss Axiovert 200 M microscope (Zeiss, Oberkochen, Germany). *z*-Stack images were recorded in 1 μm confocal sections using LSM Image Examiner and processed with *ImageJ* software.

Reproducibility of the Experiments and Statistics. All experiments were performed independently at least twice. Results from representative experiments are shown in the figures. Values ($n \geq 3$) are calculated as mean ± standard deviation (S.D.) using the GraphPad *Prism4* software.

RESULTS

Cloning, Expression and Purification of C2IN−Streptavidin. To generate a recombinant C2IN−streptavidin fusion protein, dimeric streptavidin was cloned in frame to C2IN, yielding the expression vector pGEX-2TGL-C2IN-streptavidin. The fusion construct features the N-terminal domain of C2I, which mediates the interaction with C2IIa to trigger cellular uptake, and a dimeric streptavidin, thus providing a versatile adaptor for biotinylated molecules (Figure 1A). The GST-tagged fusion protein was overproduced in *E. coli* BL21, and time-dependent expression was monitored. Western blot analysis with a monoclonal α-GST antibody revealed maximum expression 6 h post induction (p.i.), whereas longer expression times resulted in degradation of the fusion protein (Figure 1B). Thus, bacterial cultures were harvested after an expression period of 6 h. Then, C2IN−streptavidin was purified using glutathione−agarose affinity chromatography and analyzed by an immunoblot with a polyclonal α-streptavidin antibody (Figure 1C). After immobilization on the beads, the GST-tag was removed by thrombin cleavage releasing C2IN−streptavidin into the supernatant (Figure 1C, elution). C2IN−streptavidin was not completely soluble, as it could still be detected in the bacterial pellet. However, genetic fusion to C2IN markedly enhanced the solubility compared to the expression of dimeric streptavidin, which has to be purified under denaturing conditions (*24*). The purified protein was then checked for homogeneity by SDS-PAGE and Coomassie staining and revealed about 85% purity as calculated by *ImageJ* (Figure 1D, left panel). In addition, protein identity was confirmed by Western blot analysis with a polyclonal α-C2IN antibody (Figure 1D, right panel).

Biotin Binding Properties of the Novel C2IN−Streptavidin Fusion Protein. In order to characterize the binding of biotin-labeled macromolecules to C2IN−streptavidin, an overlay blot technique was employed. To this end, we have selected three biotinylated proteins differing in size and origin: bovine serum albumine (BSA), the ADP-ribosyltransferase C3bot from *Clostridium botulinum*, and calf alkaline phosphatase, Increasing amounts of the fusion protein and C2IN as negative control were subjected to SDS-PAGE and transferred onto a nitrocellulose membrane. Following incubation with 5 μg/mL biotinylated BSA, unspecifically interacting biotinylated protein was removed by high-salt washes, and bound BSA was detected using streptavidin−POD. Biotinylated BSA specifically interacted with C2IN−streptavidin in a concentration-dependent manner, whereas the negative control C2IN did not show any signal (Figure 2A). In addition, C2IN−streptavidin was incubated with streptavidin−POD omitting biotinylated BSA. Here, no signal was

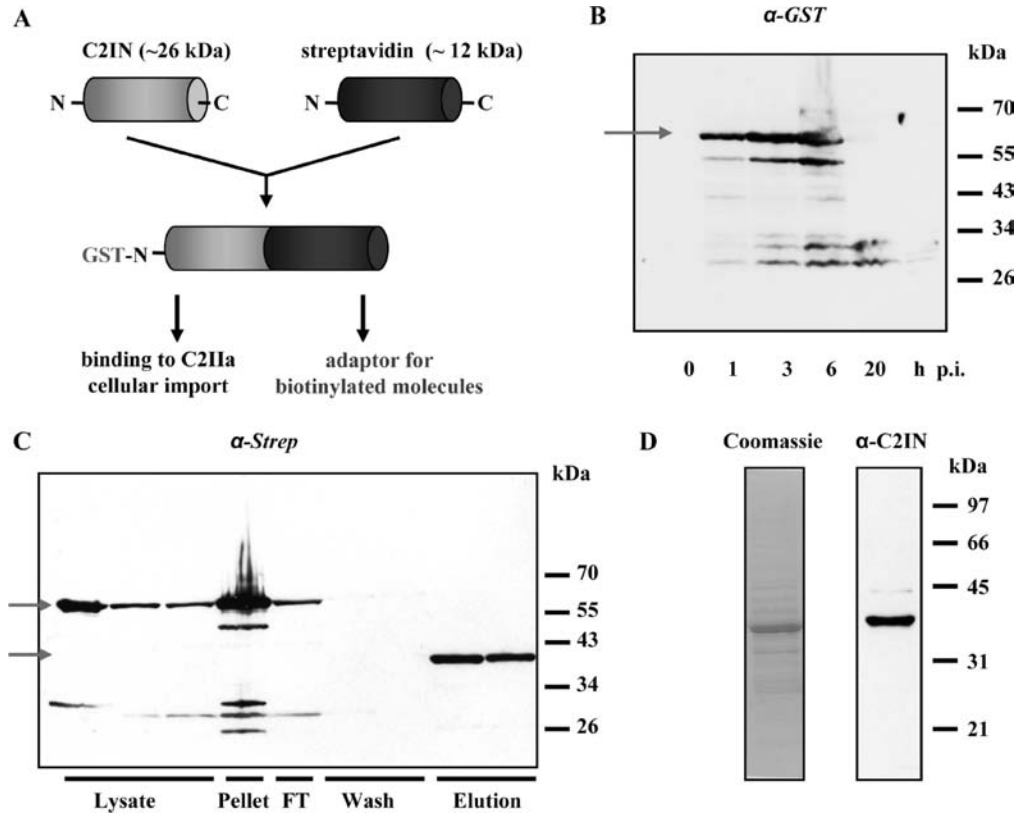

Figure 1. Cloning, expression, and purification of C2IN−streptavidin. (A) Cloning strategy to generate the novel fusion protein C2IN−streptavdin. (B) Time-course of C2IN−streptavidin expression in *E. coli* BL21. Aliquots of the suspension culture were removed after the time points post induction (p.i.) as indicated and analyzed by Western blotting with a monoclonal α-GST antibody. The arrow highlights the GST-C2IN-streptavidin fusion protein (C) Purification of GST-C2IN-streptavidin by affinity chromatography. Fractions obtained during the purification process were collected and C2IN−streptavidin was detected using a polyclonal α-streptavidin antibody. The upper arrow indicates the GST-tagged C2IN−streptavidin. The GST tag was removed by specific thrombin cleavage, yielding the 37 kDa fusion protein (designated by the lower arrow). (D) Characterization of isolated C2IN−streptavidin. 2.5 μg of the fusion protein was subjected to SDS-PAGE and visualized by Coomassie staining (left panel). Moreover, protein identity was confirmed by Western blot analysis with a polyclonal α-C2IN antibody (right panel).

observed, thus excluding a direct interaction of both streptavidin conjugates (data not shown). Next, biotinylated C3bot was shown to bind to immobilized C2IN−streptavidin with an affinity comparable to biotinylated BSA (Figure 2B), which was also demonstrated for biotin-coupled alkaline phosphatase (data not shown). To obtain more quantitative information on the biotin−streptavidin mediated interaction, binding kinetics were assessed by real-time surface plasmon resonance (*28, 29*). C2IN−streptavidin was covalently immobilized on a Biacore CM5 sensor chip, and biotinylated C3 was injected in HBS buffer pH 7.4 at various concentrations ranging from 750 nM to 10 μM. Concentration-dependent binding was monitored and allowed the determination of binding kinetics resulting in a K_D value of 7.57×10^{-7} M (Figure 2C and Table 1). Signal was corrected for unspecific binding and buffer changes using an activated reference cell. Taken together, the fusion protein C2IN−streptavidin is functionally active with regard to biotin binding. As expected, the binding affinity was clearly reduced in comparison to wild-type streptavidin, but is in the range reported for dimeric streptavidin (*24*).

Specific Internalization of C2IN−Streptavidin into the Cytosol of Epithelial Cells and Macrophages. As a next step, the time-dependent uptake of C2IN−streptavidin in living Vero cells was monitored after cell fractionation by digitonin. C2IN−streptavidin and the translocation/binding component C2IIa were preincubated on ice and then added to the culture medium. At the time points indicated, cells were permeabilized with digitonin to extract the cytosolic proteins. The cytosolic fraction as well as the remaining extracted cells were then subjected to SDS-PAGE and analyzed by Western blotting using a polyclonal α-C2IN-antibody (Figure 3A). Increasing amounts of C2IN−streptavidin were observed in the cytosolic fraction in a time-dependent manner, reaching a maximum after 4 h, which was confirmed by time course experiments over a period of 8 h (data not shown). However, the majority of the fusion protein was detected in the extracted cells representing cell-bound or vesicular-internalized C2IN−streptavidin. Treatment of cells with C2IN−streptavidin in the absence of C2IIa resulted in weak nonspecific binding or uptake, which could only be observed after long exposure times. The identity of the cytosolic fraction was attested by immunoblot analysis of cytosolic marker protein Hsp90 (Figure 3B), showing approximately 50% of Hsp90 in the extracted cytosolic fraction, which is in line with previous studies applying digitonin extraction (*30*). Importantly, Rab5 as endosomal marker protein was found exclusively in extracted cells, ruling out a contamination of the cytosolic fraction by early endosomes (Figure 3C). Consistent with this observation, EEA1 as another marker for endosomes was only detected in extracted cells (data not shown). Furthermore, the specific internalization of C2IN−streptavidin into the cytosol of other mammalian cells was demonstrated for human epithelial HeLa cells, hamster epithelial CHO cells, and murine macrophage-like J774A.1 cells (Figure 3D). The uptake kinetic of C2IN−streptavidin into the cytosol of HeLa cells was similar to Vero cells, culminating 4 h after treatment (Figure 3D, upper panel). CHO cells exhibited the most efficient internalization of C2IN−streptavidin into the cytosol, whereas incubation of cells without the transport component C2IIa resulted in a weak background signal of C2IN−streptavidin (Figure 3, middle panel). Compared to the epithelial cell lines,

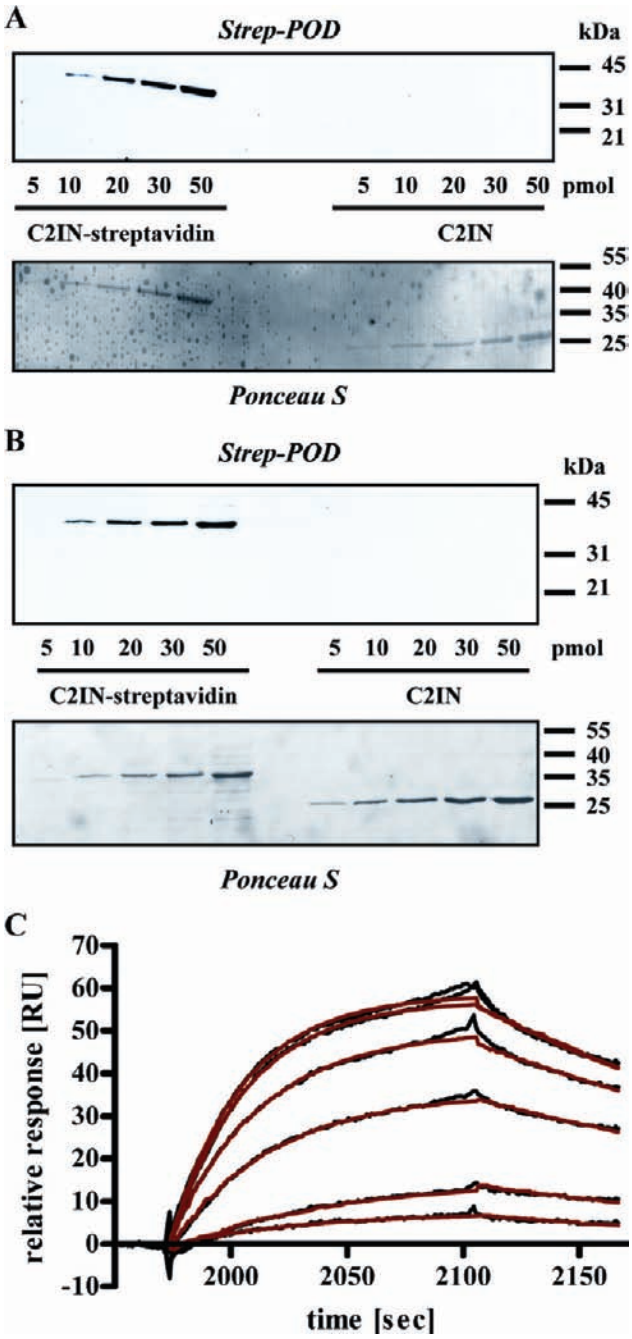

Figure 2. Characterization of C2IN−streptavidin with regard to biotin binding. (A) Overlay blot using biotinylated BSA. Increasing amounts of C2IN−streptavidin and C2IN as negative control were separated by SDS-PAGE and transferred onto a nitrocellulose membrane stained with Ponceau S. Following incubation with 5 μg/mL biotinylated BSA, unspecifically interacting biotinylated protein was removed by high-salt washes and bound BSA was detected using streptavidin−POD. (B) Overlay blot using biotinylated C3bot protein. This experiment was performed as describe above, except that 1 μg/mL C3bot protein was applied. (C) Real-time SPR analysis. C2IN−streptavidin was immobilized on a Biacore CM5 sensor chip and increasing concentrations of biotinylated C3bot protein were injected (750 nM up to 10 μM). Black lines show experimentally obtained data, whereas red lines indicate the calculated curve fit according to a Langmuir 1:1 model.

Table 1. Binding Kinetics of C2IN-Streptavidin and Biotinylated C3bot Obtained from Real-Time SPR Analysis

k_a (M^{-1} s^{-1})	k_d (s^{-1})	K_D (M)	χ^2
6.75×10^3	5.11×10^{-3}	7.57×10^{-7}	0.174

J774A.1 macrophages displayed a pronounced nonspecific binding/internalization of the fusion protein in the absence of C2IIa, most likely due to pinocytosis (Figure 3D, lower panel). Unlike the other cell types tested, lower amounts of C2IN−streptavidin were detected in the cytosol of J774A.1 cells.

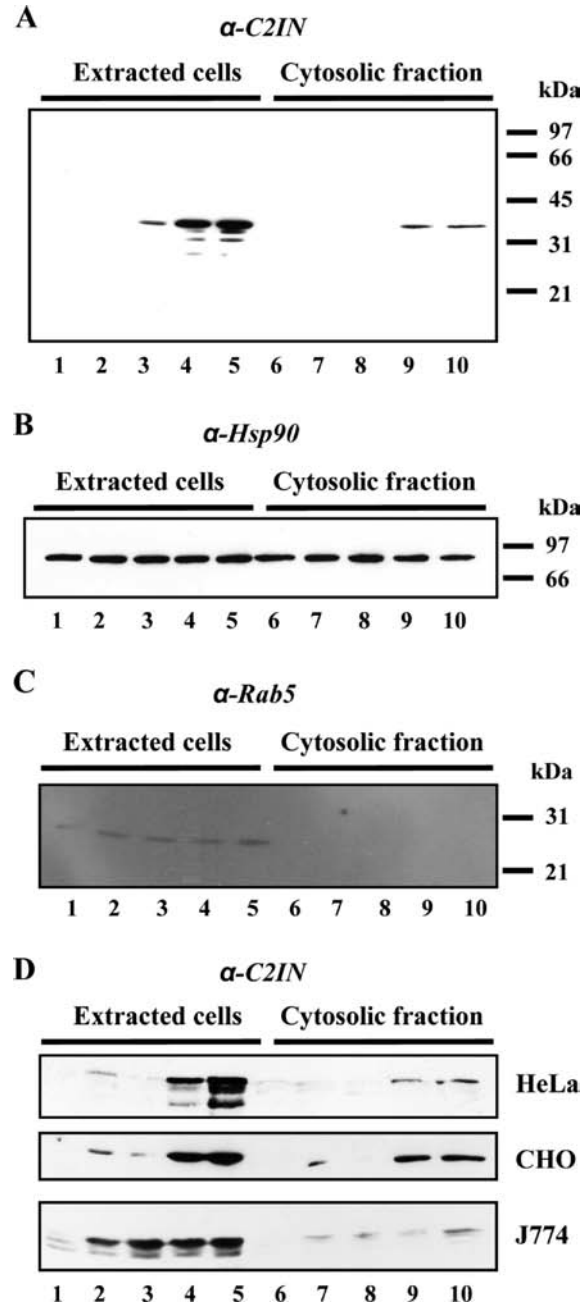

Figure 3. Uptake of C2IN−streptavidin into the cytosol of Vero cells. (A) Vero cells were treated with a combination of C2IN−streptavidin and C2IIa. As control, cells were left untreated or exposed to C2IN−streptavdin alone. After 0.5, 2, or 4 h, respectively, the cells were permeabilized by digitonin treatment to extract cytosolic proteins. The cytosolic supernatant was collected, and the remaining extracted cells were lysed. Both fractions were subjected to SDS-PAGE and analyzed by immunoblotting with a polyclonal α-C2IN-antibody. Lanes 1 and 6: control cells, 4 h. Lanes 2 and 7: cells treated with C2IN−streptavidin alone, 4 h. Lanes 3−5 and 8−10: cells treated with C2IN−streptavidin and C2IIa, 0.5, 2, and 4 h. Equal protein loading was confirmed by Ponceau S staining (data not shown). (B) Immunodetection of Hsp90, a cytosolic marker protein, on the same blot. (C) Visualization of Rab5, a marker protein for early endosomes, by Western blotting to exclude a possible contamination of the cytosolic fraction with early endosomes during digitonin treatment. (D) Treatment of HeLa, CHO, and J774 cells with a combination of C2IN−streptavidin and C2IIa as described under (A).

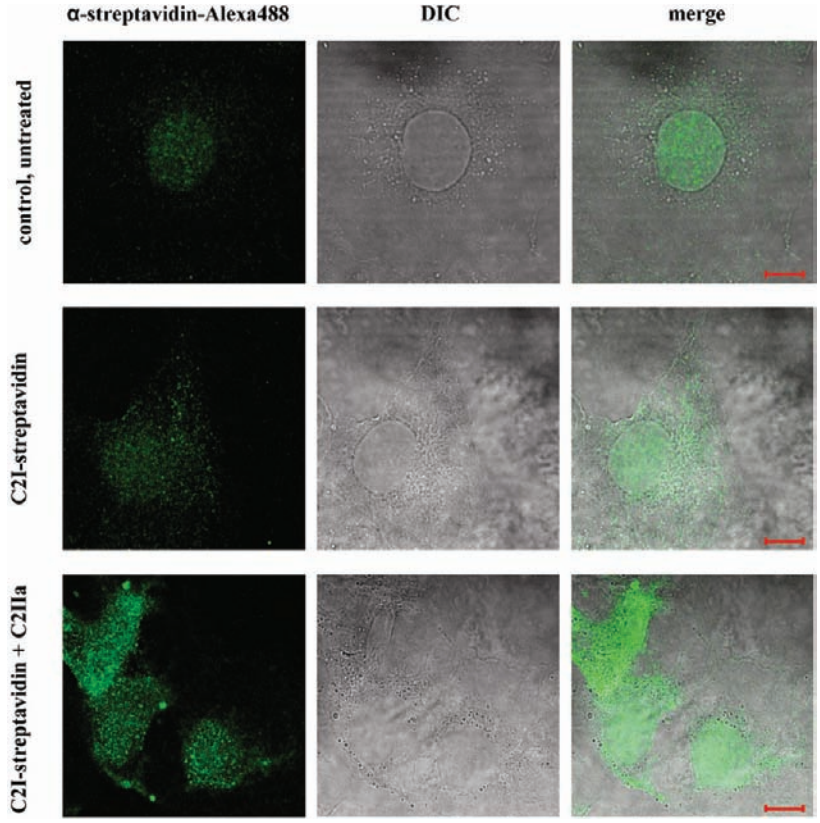

Figure 4. Confocal microscopy of internalized C2IN−streptavidin. Vero cells grown on coverslips were incubated with C2IN−streptavidin and C2IIa (1 + 2 μg). After 4 h, cells were fixed and C2IN−streptavidin was visualized by an α-streptavidin antibody and a secondary antibody coupled to Alexa488. Cells embedded in ProLong Gold antifade reagent were then analyzed by confocal microscopy and optical thin layer sections obtained were processed with *ImageJ*. Representative pictures thereof are shown. Scale bars correspond to 10 μm.

In addition, confocal laser-scanning microscopy was performed to analyze the intracellular localization of C2IN−streptavidin in more detail. Vero cells grown on coverslips were incubated with C2IN−streptavidin and C2IIa. After 4 h, cells were fixed and C2IN−streptavidin was visualized by an α-streptavidin antibody together with a secondary antibody coupled with Alexa488. Strikingly, confocal microscopy showed the uptake of the novel fusion protein as revealed by bright intracellular foci and diffuse staining (Figure 4). In contrast, untreated cells and cells treated with C2IN−streptavidin alone displayed weak diffuse background staining. In conclusion, we demonstrated the specific, i.e., C2IIa-dependent, uptake of C2IN−streptavidin into the cytosol of different mammalian cell types, which underscores the versatility of this novel delivery system.

Absence of Cytotoxic Effects of the Novel Transporter C2IN−Streptavidin/C2IIa. To reveal any possible cytotoxic effect of the fusion protein generated, Vero cells grown overnight were incubated with different combinations of C2IN−streptavidin and C2IIa for 5 h. Staurosporine, a well-known inducer of apoptosis, was used as positive control. Cell viability was determined by trypan blue assay, which is based on the selective uptake of trypan blue dye in dead cells, whereas living cells exclude the dye (Figure 5A). No effect was observed even at high concentrations (1 μg/mL C2IN−streptavidin + 2 μg/mL C2IIa), whereas the positive control staurosporine markedly decreased the cell viability to 60%. To monitor long-term effects on cell proliferation, cells were seeded in 96 well plates and treated with increasing concentrations of C2IN−streptavidin and C2IIa ranging from 100 ng/mL + 200 ng/mL up to 2.5 μg/mL + 5 μg/mL. After 5, 24, and 48 h, respectively, cell viability was assessed using the MTS proliferation assay. No cytotoxicity of the novel transporter could be recorded (Figure 5B). It should be noted that full-length C2I induces delayed caspase-dependent apoptosis after 24 h due to its intrinsic and persistent ADP-ribosyl-transferase activity (*31*), which has been removed in the novel fusion protein. In contrast to C2IN−streptavidin, staurosporine dramatically reduced the cell viability to about 25% after 48 h of incubation. Moreover, putative adverse effects of C2IN−streptavidin on the actin cytoskeleton were analyzed by immunofluorescence microscopy using the actin-specific probe phalloidin-Alexa 594, but no alterations were observed compared to control cells (data not shown).

C2IN−Streptavidin/C2IIa-Mediated Uptake of Biotin−Fluorescein in Vero Cells. Finally, biotin−fluorescein was used as model cargo to test the functionality of the novel transport system. Vero cells grown on coverslips were treated with a complex of biotin−fluorescein and the transporter C2IN−streptavidin/C2IIa. After 4 h, cells were fixed and permeabilized with Triton X-100. To visualize the endosomal marker protein EEA1, cells were stained with a polyclonal α-EEA1 antibody in conjunction with an Alexa647-coupled secondary antibody. Confocal laser scanning microscopy showed several bright foci in cells treated with the transporter together with fluorescein-labeled biotin (Figure 6A). These spots were obviously localized in the cytosol and did not overlap with early endosomes as evidenced by the vesicular EEA1 staining. In contrast, cells exposed to biotin−fluorescein alone or with the transporter omitting C2IIa revealed no signal, demonstrating the specific uptake mediated by the transport system. Since the acidification of early endosomes may diminish the fluorescence signal of fluorescein, we used the polar tracer biocytin−Alexa488, which is cell-impermeant and shows enhanced pH stability. As observed for biotin−fluorescein, the C2IN−streptavidin/C2IIa delivery system mediated the uptake of biocytin−Alexa488 in

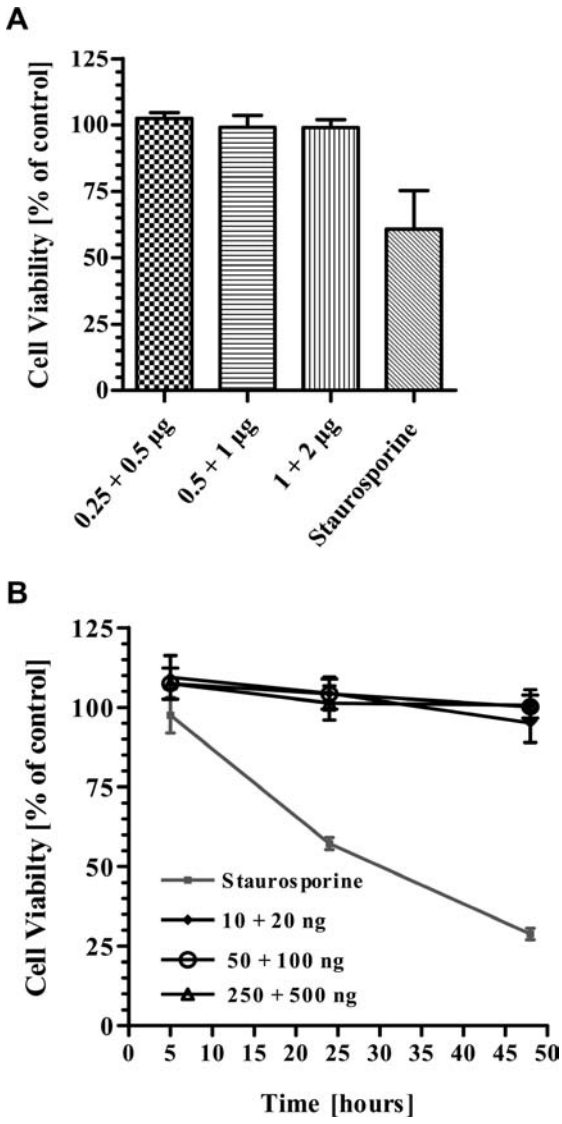

Figure 5. Determination of putative cytotoxic effects caused by C2IN−streptavidin. (A) Trypan blue exclusion. To reveal putative adverse effects on cell viability, Vero cells grown overnight were incubated with different combinations of C2IN−streptavidin and C2IIa for 5 h at 37 °C. Staurosporine, a well-known inhibitor of protein kinases and inducer of apoptosis, was used as a positive control. Subsequently, cell viability was determined by trypan blue assay using phase contrast microscopy. (B) To monitor long-term effects, cells were seeded in 96 well plates and treated with increasing concentrations of C2IN−streptavidin and C2IIa. After 5, 24, and 48 h, respectively, cell viability was assessed using the MTS proliferation assay. As above, staurosporine treatment was included as positive control. Data in (A) and (B) are expressed as mean ± SD, $n = 2$ (each experiment performed as quadruplicate).

Vero cells (Figure 6B). Confocal microscopy showed bright green foci and partial colocalization with early endosomes (Figure 6B), which is attested by the yellow staining in the merged channel. Control experiments were performed as described for biotin-labeled fluorescein and displayed no signal in the green channel (data not shown). In summary, our data clearly demonstrate the successful application of the novel transporter as delivery system for biotinylated molecules.

DISCUSSION

In the present study, we describe the successful generation of a novel molecular Trojan horse based on genetic engineering of the clostridial C2 toxin and a dimeric streptavidin, which is superior to biochemical conjugation with regard to homogeneity and its site-directed character. The novel fusion protein C2IN−streptavidin was overexpressed in *E. coli* and purified to homogeneity followed by removal of the GST tag. This native isolation procedure resulted in moderate yields, but led to soluble and functionally active protein. Alternative purification under denaturing conditions provides higher yields, but the protein precipitated on a biotin−agarose column, most likely due to improper refolding (data not shown). The purified fusion protein displayed a moderate affinity for biotinylated proteins as shown by an overlay blot technique and real-time SPR measurements. Compared to the dimeric streptavidin mutant ($K_D = 1.5 \times 10^{-7}$ M) (*24*), the affinity is slightly reduced probably due to steric constraints of the fusion protein affecting the biotin binding. This decreased affinity should allow for the reversible binding of internalized biotinylated molecules. In particular, endogenous free biotin generated by biotinidase (*32*) could displace biotinylated cargo by competition on the binding sites after internalization into the cytosol. On the other hand, this feature may be unfavorable with regard to the stability of the C2IN−streptavidin−biotin complex in vivo, which may be disrupted by serum proteins. Molecular Trojan horses employing wild-type avidin or streptavidin exhibit a very tight (strept) avidin−biotin binding, which is stable in the bloodstream in vivo (*33, 34*).

Moreover, we demonstrated the successful delivery of C2IN−streptavidin into the cytosol of diverse eukaryotic cell lines of human, rodent, and monkey origin. The observed slight variations in the internalization efficiency of the protein among the different cell types might be due to different expression levels of the C2 toxin receptor and/or for different velocities of endocytosis and intracellular protein translocation processes. Importantly, all hitherto tested vertebrate cell lines and primary cultured cells express the C2 toxin receptor on their cell surface, thus rendering these cells sensitive for C2 intoxication (*13*). Therefore, our novel delivery system comprising C2IN−streptavidin and C2IIa is suitable for a plethora of eukaryotic cell types. In contrast, conventional molecular Trojan horses encompassing receptor-specific antibodies are species-specific and limited to the expression pattern of the receptor. In addition, the novel C2-derived transporter did not affect cell viability over a time period of 48 h, nor did it induce any morphological changes, thus permitting its unrestricted application in cell cultures studies. Finally, we provided proof-of-principle for our novel delivery system using biotin−fluorescein as cargo, which was specifically internalized into Vero cells. Interestingly, biotin−fluorescein was detected in the cytosol of Vero cells and showed no colocalization with early endosomes. However, fluorescein exhibits no fluorogenic properties below pH 6, which may result in loss of signal during the acidification of endosomes. Therefore, biotin−fluorescein localized to early/late endosomes may not be detectable by confocal microscopy. To overcome this limitation, the fluorescent tracer biocytin−Alexa488 was applied. This conjugate is cell-impermeable due to its polarity and offers superior pH stability, allowing for the fluorescence detection even in acidic cellular compartments. Intriguingly, biocytin−Alexa488 was specifically delivered into Vero cells in a C2IN−streptavidin/C2IIa-dependent manner and showed partial colocalization with early endosomes.

The uptake mechanism of the binary C2 toxin of *C. botulinum* has been extensively characterized and is well-understood in most aspects, which also holds true for the novel fusion protein C2IN−streptavidin. Unlike the C2 toxin, the entry pathways of other delivery vectors such as cell penetrating peptides are still unclear and seem to involve different mechanisms (*35, 36*). With regard to the binary C2 system, C2IIa has two major functions. First, C2IIa mediates the binding of C2I via its N-terminal domain to the cell surface, and second, it facilitates

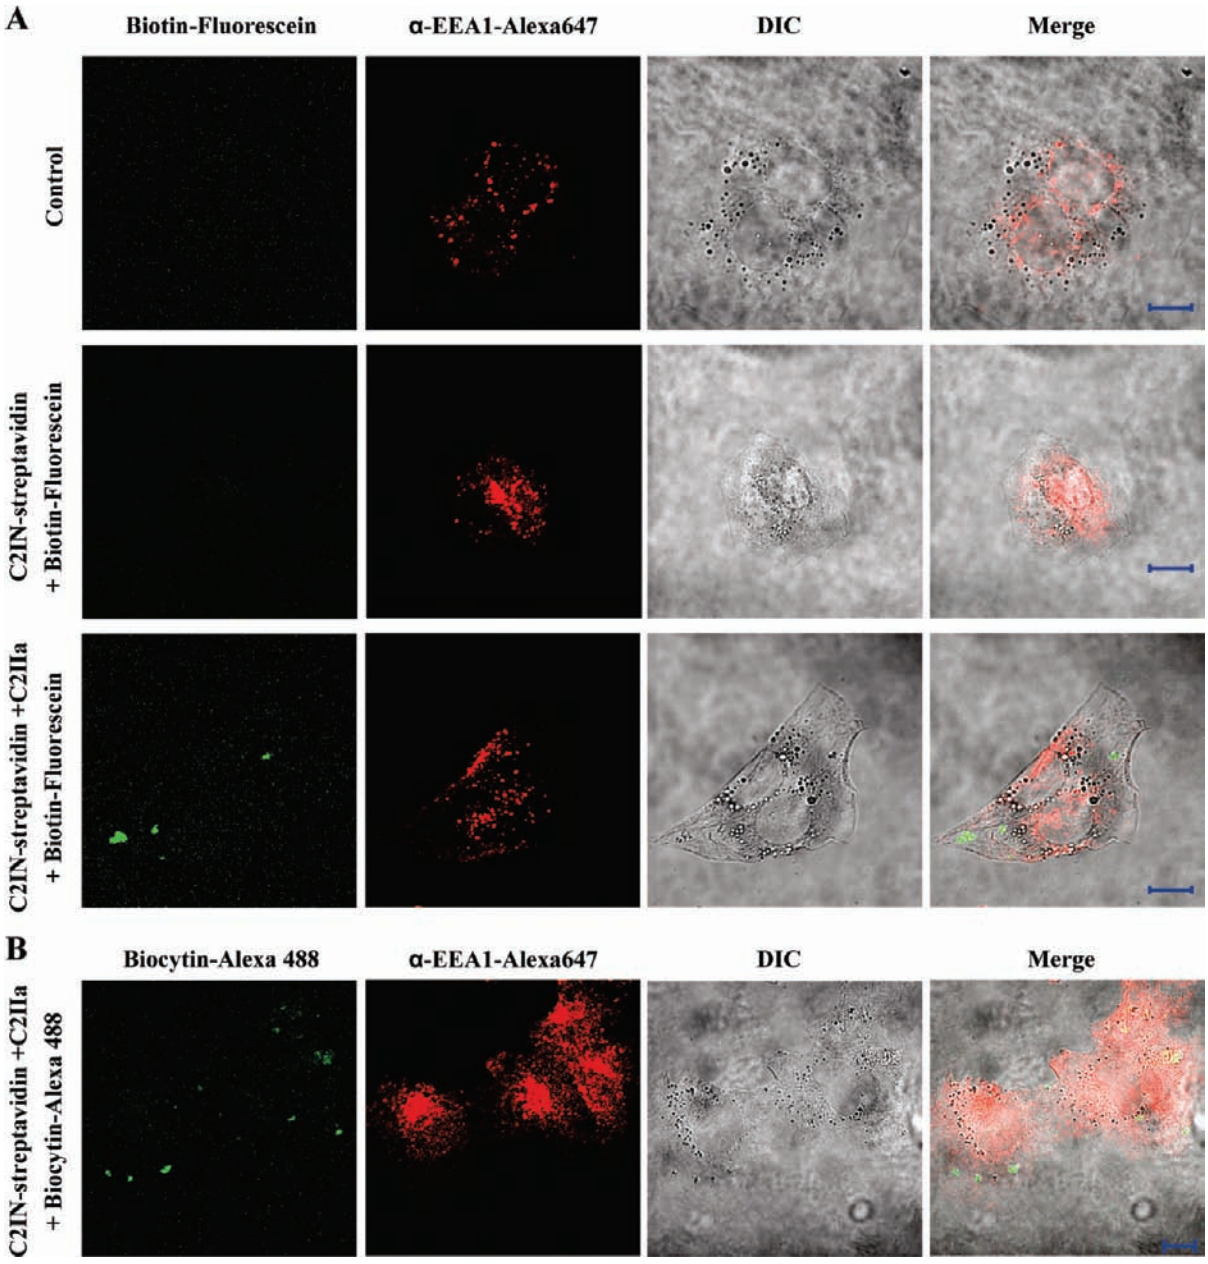

Figure 6. C2IN−streptavidin/C2IIa-mediated uptake of biotin-labeled fluorescent tracers into Vero cells. (A) Vero cells grown on coverslips were treated with a complex consisting of biotin−fluorescein in combination with the transporter C2IN−streptavidin/C2IIa. After 4 h, cells were fixed and permeabilized with Triton X-100. To visualize the endosomal marker protein EEA1, cells were stained with a polyclonal α-EEA1 antibody in conjunction with an Alexa647-coupled secondary antibody. Cells embedded in ProLong Gold antifade reagent were then analyzed by confocal microscopy and recorded thin layer *z*-stack images were processed and merged with *ImageJ*. Representative images thereof are displayed. Scale bars correspond to 10 μm. (B) Vero cells were treated and analyzed by confocal microscopy as describe above, except that biocytin−Alexa488 was used instead of biotin−fluorescein.

the membrane translocation of C2I from endosomes into the host cell cytosol by pore formation. The translocation channel formed by the C2IIa pore was shown to be 25−32 Å in width (*37*), which allows the passage of small molecules as attested by the transport of biotin−fluorescein into the cytosol of Vero cells in the present study. However, the narrow inner diameter of the translocation pore may limit the transport of larger molecules such as biotinylated proteins into the cytosol, thus trapping them in endosomes. To solve this problem, pH-responsive polymers such as poly(propylacrylic acid) (PPAA) could be used, which trigger endosomal membrane disruption upon luminal acidification (*38*). Biotinylated PPAA was reported to promote the internalization and endosomal release of an antibody complex containing streptavidin (*39*). It has also been successfully applied together with TAT−streptavidin to direct the uptake of a biotinylated protein to the cytosol, representing a useful tool for delivery systems (*21*).

With regard to immunogenicity, humans are only slightly responsive to the chicken homologue avidin, which may result from consumption of egg white causing oral tolerance (*40*). In contrast, streptavidin was shown to be immunogenic in humans, which might be a drawback for long-term or repetitive treatments, e.g., during cancer radioimmunotherapy (RIT) (*41*). Nevertheless, the use of streptavidin in cancer RIT led to promising clinical results, increasing the tumor/background ratio and the delivery of higher therapeutic doses (*15*). Lack of glycosylation is another advantage of streptavidin compared to chicken avidin, which shows unspecific binding due its carbohydrate modification, impairing its use in several applications (*42*).

The use of bacterial toxins as delivery systems is well-known and protein toxins such as diphtheria toxin (DT) have been employed as so-called immunotoxins to selectively kill cancer cells (*43*). For that purpose, the binding domain of DT has to be replaced by ligands that interact with surface antigens abundant on cancer cells, e.g., epidermal growth factor, allowing for a concentration of the toxin on the target cell. After translocation into the cytosol, DT catalyzes the ADP-ribosylation of elongation factor 2, thereby blocking protein synthesis, which results in cell death (*44*). As pointed out above, the binary C2 toxin represents a universal transport system due to the ubiquitous expression of its corresponding receptor on many eukaryotic cells. Previously, several chimeric fusion proteins based on the adaptor domain C2IN were created by genetic engineering (*10, 11*), allowing the cellular uptake and cell-biological characterization of proteins, which do not enter cells. However, the construction and expression of recombinant fusion proteins is time-consuming and cumbersome, whereas the use of the chimeric C2IN−streptavidin as versatile binding platform for a variety of biotinylated molecules is convenient and applicable to nearly all systems. Therefore, the novel cellular transporter C2IN−streptavidin/C2IIa should be a valuable tool for the uptake of biotinylated siRNA, peptides, and even proteins. A promising approach would be the targeted silencing of genes, e.g., involved in inflammation or carcinogenesis by siRNA. Very recently, Xia and co-workers reported the successful delivery of siRNA into the cytosol of human endothelial cells mediated by a molecular Trojan horse, showing efficient RNA interference similar to cationic polyplexes (*45*).

In summary, we have successfully established C2IN−streptavidin as a novel delivery system, which can be used as molecular Trojan horse in a variety of eukaryotic cells. Furthermore, we demonstrated C2IN−streptavidin/C2IIa-mediated internalization of fluorescent biotinylated tracers as cargo in Vero cells, providing proof-of-principle for this universal transporter.

ACKNOWLEDGMENT

We are grateful to Dr. Takeshi Sano, Boston, USA, for the generous gift of dimeric streptavidin cDNA and Bernd Betzler, University of Ulm, Germany, for the expression vector harboring streptavidin cDNA. We would like to thank Dr. Angelika Rück, ILM, University of Ulm, Germany, for kindly providing the confocal microscope facility and Dr. Alexander Bürkle, University of Konstanz, Germany, for critically reading the manuscript.

Synthesis and Characterization of Biodegradable HPMA-Oligolysine Copolymers for Improved Gene Delivery

Rob S. Burke and Suzie H. Pun*

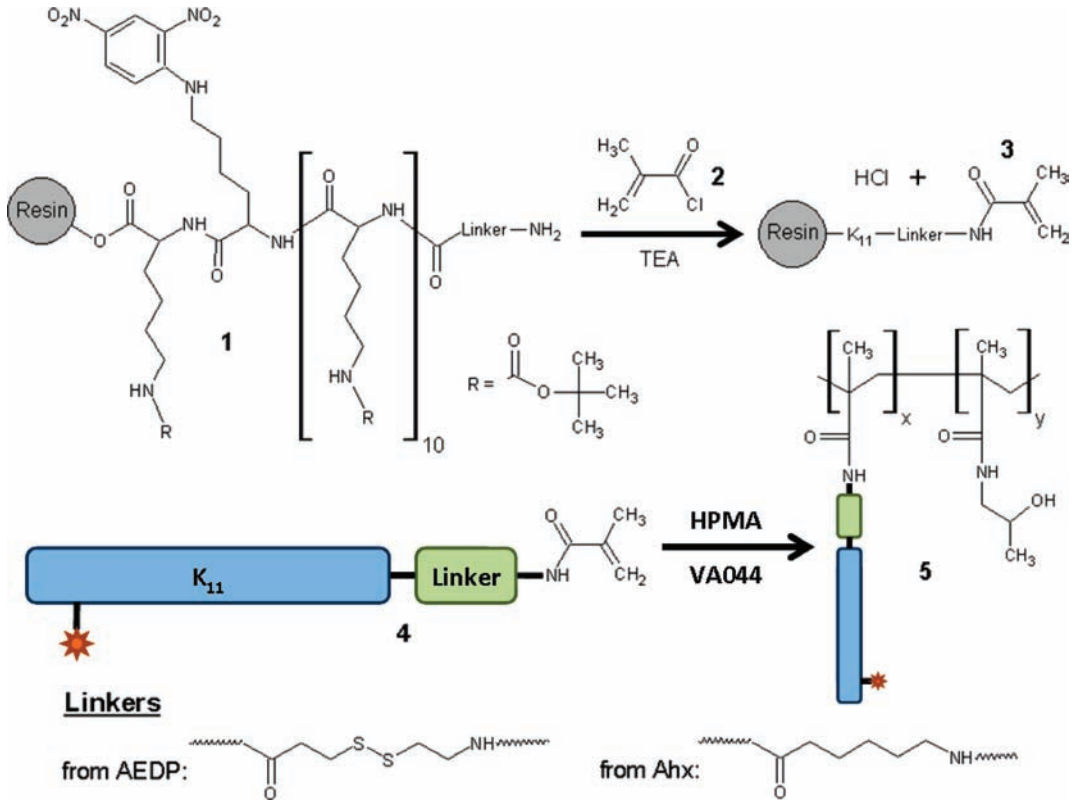
Department of Bioengineering, University of Washington, Seattle, Washington 98195. Received August 18, 2009; Revised Manuscript Received October 21, 2009

Bioactive peptides, including DNA-binding, endosomal release, and cell targeting peptides, have been integrated into synthetic gene carriers to improve delivery efficiency by enabling the vectors to overcome barriers to gene delivery. Our overall goal is to develop multifunctional, peptide-based polymers that incorporate motifs to condense DNA and facilitate sequential trafficking steps. One approach is to polymerize vinyl-terminated peptides by radical polymerization. In this work, cationic oligolysine peptides were designed to contain vinyl termini with internal reducible linkers. These peptides were copolymerized with HPMA to form biodegradable, DNA-condensing copolymers for gene delivery. The polymerization conditions were optimized by varying the initiator to monomer ratios, macromonomer to comonomer ratios, and reactant concentrations. The synthesized copolymers were shown to possess several important properties required for *in vivo* gene delivery applications, including (i) efficient DNA binding and condensation, (ii) the ability to stabilize particles against salt-induced aggregation, (iii) the ability to resist extracellular polyplex unpackaging, (iv) biocompatibility and the potential to be degraded into nontoxic components after cellular uptake, and (v) efficient delivery of plasmid to cultured cells.

INTRODUCTION

Polymeric gene delivery vectors have been widely studied over the past two decades as alternatives to viral vectors. Though there have been significant advances in the field of polymer-based delivery during this time, the limited efficiency of these vectors remains a weakness. Bioactive peptides can be incorporated into the delivery vehicles to aid in overcoming different barriers to delivery, and the functionalities of the peptides that have been used include DNA binding, targeting, and endosomal escape (*1*−*3*). Though many investigators have generated peptide-functionalized polymers by conjugating peptides to polymers, several groups have recently demonstrated polymerization of peptide monomers with an acrylamide comonomer (*4*−*8*). In this work, we apply this polymerization technique to synthesize peptide-based copolymers for use as gene delivery agents. These unique polymers possess integrated properties of DNA packaging, stability, and biodegradability in a single material without the need for further modification.

Cationic polymers used to deliver DNA can be highly toxic, so it is important to consider the interplay between the potential toxicity and transfection efficiency of the polymer when designing a new polycation. It has been shown that both the efficacy and toxicity of nonviral gene delivery vehicles are directly correlated to their molecular weight, leading to a situation where it is difficult to develop a system with both high delivery efficiency and low toxicity (*9*). To engineer a solution to this problem, investigators have cross-linked low-molecular-weight components using reducible cross-linkers to increase effective molecular weight for DNA condensation while ensuring that the cationic components can degrade into less toxic low molecular weight peptides or polymers (*9*−*15*). Reducible linkers are also attractive for gene delivery applications because such linkers enable the design of copolymers that maintain stability extracellularly, when a high molecular weight is needed to retain the DNA in a packaged state, and degrade intracellularly, when a low molecular weight is desired to facilitate unpackaging of the DNA for transcription.



The peptide-based polymers presented here contain a linker between the polymerizable vinyl group and the peptide. A stable linker and a reducible linker were both used in order to evaluate the effect of polymer degradation on transfection efficiency and cell toxicity. A cationic oligolysine peptide was selected for polymerization due to its ability to package DNA through electrostatic interactions. Wadhwa et al. first studied the dependence of DNA condensation and transfection efficiency on the length of the oligolysine peptide used to condense the DNA (*16*). The authors found that peptides with 13 or more lysine residues bound tightly to DNA, condensed the DNA into small polyplexes around 100 nm in diameter, and mediated transfection. However, peptides possessing 8 lysine residues or fewer were drastically weakened in their ability to bind DNA and mediate effective transfection (*16*). The materials presented here contain oligolysines with 11 lysine residues. This length was selected so that the polymerized material could potentially mediate strong DNA binding, while the free peptides could easily be displaced after cleavage from the HPMA backbone, thus facilitating DNA unpackaging.

In summary, we report here the synthesis and evaluation of HPMA-peptide copolymers for gene delivery applications. First, a series of copolymers was synthesized in order to determine the effect of the polymerization conditions on the polymer properties. The copolymers were characterized for their molecular weight, composition, and ability to condense DNA. The most promising copolymers were studied further, and polyplexes of these copolymers and DNA were assessed for their size, ability to resist unpackaging, salt stability, transfection efficiency, and cellular toxicity in a series of *in vitro* experiments. Several copolymers were identified with transfection efficiencies similar to that of PLL but with much lower cellular toxicities. This copolymer system is modular, and this model system can be expanded to include other peptide monomers that further increase the gene delivery efficiency of the copolymers.

Scheme 1. Methacryloylation of Linker-Conjugated Peptides (1) and Synthesis of Copolymers (5) by Radical Polymerization of Peptide Monomers (4) and HPMA

EXPERIMENTAL SECTION

Materials. gWiz-Luciferase plasmid (gWiz-Luc, Endotoxin-free) was purchased from Aldevron. All other materials were purchased from Sigma-Aldrich and used without further purification unless otherwise stated.

Synthesis of Fmoc-AEDP. *N*-(9-Fluorenylmethoxycarbonyl)-protected 3-[(2-aminoethyl)dithio] propionic acid (Fmoc-AEDP) was synthesized by a modified protocol based on published methods of Fields and co-workers (*17*). Briefly, 3 mmol of 9-fluorenylmethyl *N*-succinimidyl carbonate (Fmoc-OSu) was dissolved in 15 mL of dimethoxyethane (DME). Two millimoles of 3-[(2-aminoethyl)dithio] propionic acid (AEDP, from Pierce) and 4.4 mmol of sodium bicarbonate were dissolved in 5 mL of dH_2O and then added dropwise to the 15 mL of Fmoc-OSu in DME while stirring. The reaction was allowed to proceed overnight at RT with stirring in the dark. Reaction completion was checked by TLC using a running buffer of 97% chloroform/3% glacial acetic acid (v/v) with the following spots: AEDP ($R_f = 0$), Fmoc ($R_f = 1$), Fmoc-AEDP ($R_f = 0.95$). The reaction was filtered through a 0.2 μm pore size PVDF filter, and the DME was removed by rotary evaporation. Forty milliliters of 0.1 N HCl was added to the remaining solution and stirred for 1 h. Forty milliliters of chloroform was added and the solution was stirred for 4 h. The reaction mixture was extracted with two washes of 0.1 N HCl and two washes of dH_2O. The organic phase was isolated and filtered, the chloroform was removed by rotary evaporation, and a slightly yellow, oily substance was recovered.

Synthesis of DNP-Labeled K_{11} and Unlabeled K_{11} Peptides. One gram of Fmoc-Lys(Boc)-NovaSyn TGT resin (0.2 mmol lysine, from Novabiochem) was swelled in dimethylformamide (DMF), and the N-terminal amine groups of the Lys preloaded onto the resin were deprotected by two incubations for 10 min in 20% (v/v) piperidine in DMF. Four equivalents each of lysine-dinitrophenyl (Lys-DNP, from Novabiochem) and *O*-(7-azabenzotriazole-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HATU, from GenScript Corp) were dissolved in 5 mL of 0.4 M *N*-methylmorpholine (NMM) in DMF. The activator and amino acid solution was then added to the resin, and the coupling reaction was allowed to proceed for 1 h at RT. The resin was washed with DMF, and the remainder of the peptide was synthesized using standard Fmoc-based solid-phase peptide synthesis (SPPS) conditions with 4 equiv of lysine amino acid (Fmoc-Lys(Boc), from Protein Technologies) and 4 equiv of HATU on a PS3 peptide synthesizer (Protein Technologies). Ten additional Lys residues were added for a total of eleven Lys residues with one Lys-DNP residue on the K_{11}-DNP peptide. The purity of the peptide was assessed by HPLC, and the mass was measured using an Esquire electrospray ion trap mass spectrometer (ESI-MS) from Bruker Daltonics (Supporting Information). The unlabeled K_{11} peptide was synthesized in exactly the same way, except without adding the Lys-DNP residue.

Synthesis of DNP-Labeled K_{11}-AEDP-MC and K_{11}-Ahx-MC Modified Peptides. Four equivalents each of Fmoc-AEDP and HATU dissolved in 5 mL of 0.4 M NMM in DMF were added to N-terminally deprotected K_{11}-DNP-resin containing 0.1 mmol peptide. The coupling reaction was allowed to proceed for 1 h at RT. The resin was washed with DMF and then deprotected by twice incubating the resin with 20% piperidine in DMF for 5 min at RT, yielding K_{11}-AEDP **1** (with the linker coming from AEDP). The peptide was then methacryloylated as shown in Scheme 1, following a protocol similar to that of O'Brien-Simpson et al. (*4*). The minimum amount of anhydrous DMF required to fluidize the resin was added and the resin was transferred to a reaction flask kept on ice under nitrogen. Triethylamine (TEA, 20 equiv) was injected into the flask, followed by dropwise addition of 10 equiv of methacryloyl chloride **2** (MC). The reaction was stirred for 1 h on ice and then 1 h at RT in O_2-free conditions, yielding compound **3**. The

[a] The initiator wt % was calculated as a weight percent of HPMA monomer. [b] The percent yield is presented as the weight of polymer recovered divided by the total weight of the monomers added to the reaction.

resin was washed and the peptide cleaved by incubation with a cleavage cocktail of 95% trifluoroacetic acid (TFA), 2.5% triisopropylsilane (TIPS), and 2.5% dH_2O for 3 h at RT. The cleaved peptide K_{11}-AEDP-MC **4** was precipitated in diethyl ether three times, and the pellet was dried, yielding a chalky yellow solid, and stored at −20 °C. The synthesis of K_{11}-Ahx-MC **4** was performed in the same way, except that 4 equiv of Fmoc-6-aminohexanoic acid (Fmoc-Ahx, from Novabiochem) was used instead of Fmoc-AEDP to generate a peptide monomer that does not contain a cleavable disulfide linkage. The purity of the peptides was assessed by HPLC and found to be >90% (Supporting Information). Desired products were confirmed by mass spectrometry using an Esquire ESI-MS from Bruker Daltonics (Supporting Information).

Copolymerization of HPMA with Peptide Monomer. For each copolymer, 10 mg peptide monomer **4** was used in the feed at the mole percent shown in Table 1 with the required amount of HPMA monomer (Polysciences, Inc.). The weight of the initiator 2,2′-azobis[2-(2-imidazolin-2-yl)propane]dihydrochloride (VA044, from Wako Specialty Chemicals) used for each polymerization was calculated as a weight percent of HPMA monomer, as indicated in Table 1. For a given copolymerization, the appropriate amounts of peptide monomer, HPMA monomer, and VA044 initiator were dissolved in the amount of degassed reaction buffer (6 M guanidine hydrochloride, 2 mM EDTA, 0.5 M Tris base, buffered to pH 8.3 with HCl) to give the final total monomer concentration indicated in Table 1. The reaction solutions were transferred to glass reaction vials, bubbled with N_2 gas for 15 min, and then sealed and heated at 44 °C for 48 h to generate copolymers **5**. Four separate copolymer series were investigated, as shown in Table 1, where series A, B, and C used the noncleavable K_{11}-Ahx-MC **4** in the copolymers while series D used the disulfide-linked K_{11}-AEDP-MC **4**. Series A varied the weight percent of initiator, while series B and C varied the mole percent of peptide monomer and total monomer concentration.

Purification and Characterization of Copolymers. The copolymers were dialyzed against dH_2O using a 7 kDa MWCO membrane and purified by HPLC to remove any unreacted monomers. After organic solvent removal *in vacuo* and lyophilization to recover a fluffy yellow solid, the copolymers were dissolved at 5 mg/mL in running buffer (0.3 M sodium acetate buffered to pH 4.4 with acetic acid) for analysis by gel permeation chromatography (GPC) as described by Hennink and co-workers (*18*). A Viscotek GPCmax, which was controlled by Viscotek OmniSEC software, was used with an OHpak SB-G guard column (Shodex) in line with an OHpak SB-804 HQ column (Shodex) and a refractive index (RI) detector (Viscotek). The molecular weights of the copolymers were determined by using the OmniSEC software to compare the elution time of the copolymer to a standard curve generated from the elution times of narrow-polydispersity poly(ethylene oxide) TSK standards (Tosoh) of different molecular weights. The percent incorporation of peptide into the copolymer was determined by comparing to a standard curve of DNP absorbance at 360 nm (A_{360}).

Polymer Degradation Studies. Copolymers A4 and D1 were diluted to 5 mg/mL in HEPES buffered glucose (HBG; 20 mM HEPES and 5% glucose (w/v) buffered to pH 7.4 with NaOH) and analyzed by HPLC. HPLC was performed using a Jupiter 4 μm Proteo 90 Å (250 × 4.6 mm) reversed-phase analytical column (Phenomenex) and a gradient from 98% Buffer A (H_2O + 0.01% TFA) to 30% Buffer B (acetonitrile + 0.01% TFA) developed over 25 min. The same copolymers were then diluted to 5 mg/mL in HBG containing the reducing agent dithiothreitol (DTT, final concentration of 10 mM) and incubated for 5, 30, or 60 min before being analyzed by HPLC with detection at 215 nm.

Polyplex Formulation and Characterization. The gWiz-Luc plasmid was diluted in HBG to a concentration of 0.1 mg/mL and mixed with an equal volume of polymer (also diluted in HBG) at the desired lysine to DNA phosphate (N/P) ratio. For particle sizing measurements, all polyplexes were formed at N/P = 5. After mixing, the polyplexes were allowed to form for 5 min at room temperature. Twenty microliters of each polyplex sample (containing 1 μg DNA) was mixed with either 80 μL HBG or PBS and the 100 μL sample was assayed for particle size by dynamic light scattering (DLS) measured on a Brookhaven Instruments Corp ZetaPALS instrument. Particle sizing measurements were performed at a wavelength of 659.0 nm with a detection angle of 90° at RT.

DNA Condensation. The gWiz-Luc plasmid was mixed with the bis-intercalating dye YOYO-1 iodide (Invitrogen/Molecular Probes) at a dye/base pair (D/BP) ratio of 1:25 and incubated at 50 °C for 2 h to equilibrate the dye complexes with DNA (*19*). Polyplexes were formed at various N/P ratios from 0 to 5 by complexing YOYO-labeled DNA with the polymers or peptides in HBG as described above. Twenty microliters of the polyplex solution and 80 μL of HBG were added to each well of a 96-well plate, and the fluorescence from each well was measured on a Tecan Safire^2 plate reader with excitation at 491 nm and emission at 513 nm. Fluorescence signal from polyplexes with N/P > 0 was normalized to N/P = 0 (DNA only) signal.

Polyplex Unpackaging Studies. The gWiz-Luc plasmid was labeled with YOYO and poly(L-lysine) (PLL, 12−24 kDa, from Sigma), K_{11}-DNP peptide, and copolymers B1, C1, and D1 were used to form polyplexes at N/P = 5 in HBG as described above. Twenty microliters of polyplex solution were mixed with 80 μL of HBG, HBG containing 0.1 mg/mL heparan sulfate (HS, from Sigma), or HBG containing 0.5 mg/mL HS in each well of a 96-well plate. Additionally, 20 μL of polyplexes formed with copolymer B1 or D1 were mixed with 80 μL of HBG containing DTT and/or HS at specific concentrations in each well of a 96-well plate. The polyplexes mixed with 10 mM DTT were allowed to incubate for 30 min at RT, and the polyplexes

mixed with 25 mM DTT were allowed to incubate for 1 h at RT. The fluorescence from each well was measured on a Tecan Safire^2 plate reader with excitation at 491 nm and emission at 513 nm. Fluorescence signal from polyplexes with N/P > 0 was normalized to N/P = 0 (DNA only) signal.

***In Vitro* Transfection Efficiency.** Human cervix epithelial adenocarcinoma cells (HeLa, passage 25, ATCC # CCL-2) were seeded in complete cell culture medium (MEM + 10% FBS + 1% antibiotic/antimicrobial) at a density of 5×10^4 cells/well in each well of a 24-well plate. The 24-well plates were placed in a 37 °C incubator with 5% CO_2 for 24 h to allow the HeLa cells to attach. Polyplexes were formed at N/P = 5 using 1 μg of gWiz-Luc plasmid DNA in 20 μL total volume. Each sample was brought up to 200 μL with OptiMEM I (Invitrogen). The cells were washed twice with PBS, and the transfection solutions were added. The 24-well plates were returned to the incubator for 4 h, at which time the polyplex solution was replaced with complete cell culture media after washing the cells with PBS. The cells were returned to the incubator for a further 44 h. After a total incubation of 48 h, the luciferase expression was quantified with a luciferase assay kit (Promega Corp.) according to the manufacturer's instructions, except that a freeze−thaw cycle at −20 °C was included after the addition of the lysis buffer to ensure complete cell lysis. Luminescence intensity was measured on a Tecan Safire^2 plate reader with integration for 1 s. The total protein content in each well was measured by a BCA Protein Assay Kit (Pierce) according to the manufacturer's instructions so that the luciferase activity measured in each well could be normalized by the total protein content in each well. Each sample was tested in replicates with $n = 8$, but one outlier was identified in the copolymer D1 data set (using the interquartile method of identifying outliers). The statistical significance of differences in the samples was determined using Student's *t*-test, where a *p*-value of less than 0.05 was considered significant.

Cellular Toxicity. HeLa cells were seeded in complete cell culture medium at a density of 1×10^4 cells/well in each well of a 96-well plate. The 96-well plates were placed in a 37 °C incubator with 5% CO_2 for 24 h to allow the HeLa cells to attach. The cells were washed with PBS, the polymer and peptide samples were diluted to the indicated concentrations with OptiMEM, and 100 μL of polymer or peptide sample was added to the cells. The 96-well plates were returned to the incubator for 4 h, at which time the polymer or peptide solution was replaced with complete cell culture media after washing the cells with PBS. The cells were returned to the incubator for a further 40 h. Finally, 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS reagent, from Promega Corp.) was added to the cells, the cells were returned to the incubator for 4 h (for a total incubation of 48 h), and the number of viable cells in each well was quantified by measuring the absorbance at 490 nm on a Tecan Safire^2 plate reader.

RESULTS AND DISCUSSION

Synthesis of Fmoc-AEDP and Peptide Monomers. Oligolysine peptides containing 11 lysine residues and a lysine-DNP residue (K_{11}-DNP) were synthesized by SPPS. DNP was included as a label for the peptide; antibodies to DNP can be used in future studies to track the polymer. An Fmoc-protected, nonreducible or reducible linker (Ahx or AEDP, respectively) was then conjugated to the N-terminus of the peptides using the same SPPS chemistry. Finally, the deprotected N-termini of the linker-modified peptides **1** were reacted with MC **2** in order to introduce a reactive vinyl group for radical polymerization (Scheme 1). The masses of K_{11}-DNP, linker-modified, and MC-modified peptides agreed very well with the calculated masses, as shown in Table 2, and the purity of each peptide was found to be greater than 90% by HPLC (Supporting Information).

Table 2. Calculated Weights of the Various Peptide Monomers and Peptide Monomer Precursors Compared to the Weights Determined by ESI-MS

peptide	calculated (g/mol)	found (g/mol)[a]
K_{11}	1722.3	1722.6
K_{11}-Ahx	1835.3	1835.7
K_{11}-Ahx-MC	1903.3	1903.8
K_{11}-AEDP	1885.3	1885.7
K_{11}-AEDP-MC	1953.3	1953.7

[a] All weights found by mass spectrometry correlate within 0.03% of the actual mass.

Copolymerization of HPMA with Peptide Monomer. The vinyl-functionalized peptides **4** were copolymerized with HPMA by radical polymerization to generate copolymers **5** (Scheme 1). Poly(*N*-(2-hydroxypropyl)methacrylamide) (HPMA), originally synthesized by Kopeček and co-workers (*20, 21*), has been incorporated in polymer−drug conjugates that have entered phase I/II clinical trials (*22*−*26*). In a landmark clinical study, it was found that cumulative doses of HPMA copolymer in excess of 20 g/m^2 could be administered to patients without any polymer-related toxicity or immunogenicity (*22*). In addition, HPMA has been grafted onto quaternary amine-containing polymers and used to sterically stabilize polyplexes formed with these graft copolymers (*27*−*29*). HPMA was therefore chosen for copolymerization with peptide monomers due to its ease of incorporation into copolymers, ability to sterically stabilize colloids, and lack of toxicity when injected into human patients.

Three series of nonreducible poly(HPMA-*stat*-K_{11}) copolymers were synthesized in order to determine the effect of polymerization conditions on polymer properties and composition (Table 1). In series A, the amount of VA044 initiator used during polymerization was varied while keeping the total monomer concentration and ratios of comonomers (5 mol % peptide, 95 mol % HPMA) fixed. For uncontrolled radical polymerizations, increasing the radical to monomer ratio increases the number of chains initiated, thereby reducing the molecular weight of the resulting polymers. As expected, the copolymers synthesized in series A follow the trend of decreasing molecular weight with increasing amount of initiator (Table 1). HPLC analysis revealed that increasing the amount of initiator increased the incorporation of peptide into the copolymer but also increased the amount of HPMA homopolymer without any peptide. Thus, 5 wt % VA044 initiator was used for the subsequent polymerizations.

In series B and C, the amount of peptide monomer added in the feed was changed to 1 and 10 mol %, respectively. Among copolymers A3, B1, and C1, the weight percent initiator and total monomer concentration are constant, and the only difference is the mole percent of peptide monomer in the feed. A comparison of these copolymers shows that increasing the amount of peptide monomer in the feed leads to increased weight percent of peptide in the final copolymer, as well as a reduced overall molecular weight (Table 1). It is very likely that this reduction in overall molecular weight is caused by a lower reactivity of the peptide macromonomer, as it has been shown that macromonomers often have lower reactivities than smaller monomers (*30, 31*). Radke and Müller investigated copolymerization of macromonomers with methyl methacrylate and showed that increasing the macromonomer concentration leads to an increase in viscosity of the polymerization solution and a lower reactivity of the macromonomer due to decreased mobility of the larger macromonomer compared to the smaller comonomer (*30*). The authors also demonstrated that the average segment densities surrounding the propagating radical site

decrease with increasing distance between the reactive center and the nearest macromonomer (*30*). The macromonomer is therefore most reactive when it is at its lowest mole percent in the feed, resulting in long stretches of comonomer that extend the distance between macromonomers and reduce the steric hindrance of high segment densities that prevents the addition of the next macromonomer.

The incorporation efficiency of the peptide macromonomer decreases with increasing mole percent of peptide macromonomer in the feed (63% of feed for B1, 60% of feed for A3, and 44% of feed for C1), which is consistent with lower reactivity of the peptide monomer at higher mole percents in the feed. Furthermore, as the mole percent of peptide macromonomer is increased, the formation of long polymers becomes more dependent on the incorporation of the macromonomer to continue the polymerization. Thus, the decreased reactivity of the peptide macromonomer most likely plays a significant role in the reduction in total copolymer size seen with increasing mole percent of peptide monomer in the feed. Similar behavior was reported in another system where increasing the feed mole percent of a comonomer with lower reactivity decreased the overall molecular weight of the resulting copolymer (*32*). The decrease in molecular weight with increasing mole percent of peptide may also be attributed to the DNP label on the peptide, because it is known that DNP can act as a chain transfer agent during radical polymerization (*33, 34*). The ability of DNP to accept radicals retards the polymerization, extending the time required for polymerization in the presence of DNP compared to a polymerization in the same conditions except without DNP (*33*). Thus, the copolymers synthesized at the higher mole percent of peptide will be retarded the most due to the presence of the highest concentration of DNP, and 48 h may not be long enough to extend the chains fully, resulting in lower molecular weights.

Copolymers B2 and C2 were synthesized to determine the effect of changing the total monomer concentration in the polymerization solution. First, it should be noted that changing total monomer concentration had only a minor effect on the weight percent of peptide in the final copolymers. Also, the inverse relationship between peptide mole percent in the feed and resulting copolymer MW still held. Comparisons of B1 vs B2 and C1 vs C2 show that polymerizations at lower monomer concentrations led to copolymers with lower total molecular weights. It has been shown that the degree of polymerization (DP) of a polymer generated from macromonomers during uncontrolled radical polymerization increases with increasing macromonomer concentration, mainly due to the increase in viscosity at higher macromonomer concentrations (*35*). Higher viscosity reduces the rate of termination, thus extending the lifetime of the polymerization and increasing the DP, due to a diffusion-controlled limit on bimolecular termination (*35*). Thus, the viscosity of the reaction solution is an important factor for optimization: not only does a high viscosity decrease the reactivity of the macromonomers, which tends to lead to smaller copolymers, but a higher viscosity also decreases the rate of termination, which tends to allow for larger copolymers. Comparison within series B or series C in Table 1 shows that, for a given composition, increasing the monomer concentration leads to higher percent incorporation of the peptide in the final copolymer (44% for C1 compared to 39% for C2 and 63% for B1 compared to 40% for B2). Furthermore, when comparing between series, these studies demonstrate that the peptide monomer concentration has less of an effect on the percent peptide incorporation than does the mole percent of peptide monomer in the feed. Thus, the maximum concentration of 85 mg/mL (above which gelation of the reaction mixture would occur during polymerization) was employed for all further polymerizations.

Copolymer D1 was synthesized to investigate the effect of a reducible AEDP linker incorporated in the peptide monomer. The polymerization conditions for D1 were the same as for A3. Copolymer D1 has a lower MW and a slightly higher peptide mole percent incorporation in the final copolymer compared with A3. The difference in polymer properties might be due to the change in the hydrophobicity of the Ahx versus AEDP linkers in the peptide monomers, especially since the linker group is close to the propagating radical site. It is known that radical attack on an alkene can lead to radical transfer to a nearby sulfur atom and the opening of a ring during polymerization (*36*). However, the increased distance of the disulfide bond in the AEDP to the alkene group in the MC, compared to the single carbon spacer in the ring-opening polymerization (*36*), will greatly reduce the ability of the sulfur atom to accept radicals. Thus, only very minimal reversible chain transfer or chain extension through the sulfur atom is expected to occur in this system.

In summary, a library of p(HPMA-*stat*-K_{11}) copolymers was synthesized so that materials with a range of properties could be tested to determine the optimal formulation for gene delivery. The successful synthesis of copolymers with different amounts of peptide, different molecular weights, and reducible versus nonreducible linkages between the peptides and the copolymer backbone has been demonstrated.

Demonstration of Degradability of Copolymer D1. To test the degradation of copolymers synthesized with reducible (D1, with AEDP linker) and nonreducible (A4, with Ahx linker) peptides, D1 and A4 were incubated with the reducing agent DTT, and polymer degradation was monitored by HPLC (Figure 1). D1 copolymer elutes between 15 and 17 min. Treatment with 10 mM DTT results in free peptide release by 5 min (~14.7 min elution time). The resulting HPMA homopolymer elutes at 17.4 min. Taken together, these results show that, under reducing conditions, copolymer D1 is efficiently degraded into free peptide and the HPMA polymer backbone. Conversely, the DTT had no effect on the HPLC traces when incubated with nonreducible copolymer A4, indicating that the reducing agent was not able to cleave the peptide attached with a nonreducible linker (data not shown).

Polyplex Formulation and Characterization. Polyplexes were first formed by mixing copolymers with plasmid DNA in HBG. HBG was selected because it has previously been shown to be an ideal buffer for polyplex formulation with minimal aggregation (*37*). The cationic polymers poly(L-lysine) (PLL) and polyethylenimine (PEI) formed small polyplexes with sizes on the order of 200 nm when complexed with DNA at N/P = 5 in HBG (Figure 2). Similarly, all of the copolymers tested (A4, B1, C1, and D1) also formed small polyplexes with sizes around 200 nm when complexed with DNA at N/P = 5 in HBG. The size of polyplexes formed with unlabeled K_{11} peptide was very large (over 1 μm at N/P = 5 in HBG), consistent with the decreased ability of short cationic peptides to bind and condense DNA. Unexpectedly, the size of polyplexes formed with DNP-labeled K_{11} peptide at N/P = 5 in HBG was similar to the sizes of the polyplexes formed with the copolymers, PEI, and PLL. We hypothesize that the hydrophobic DNP label may increase the peptide's affinity for DNA, thus increasing its ability to condense DNA into small particles.

The salt stability of the polyplexes formed with the copolymers is an important characteristic, because polyplexes prepared for *in vivo* use will need to be salt stable when administered intravenously in order to avoid aggregation that can lead to embolism. The polyplexes are able to maintain small sizes in the low-salt HBG buffer because of intermolecular repulsion due to their positive surface charge at N/P = 5. However, when PBS is added, the higher amount of salt reduces the electrical

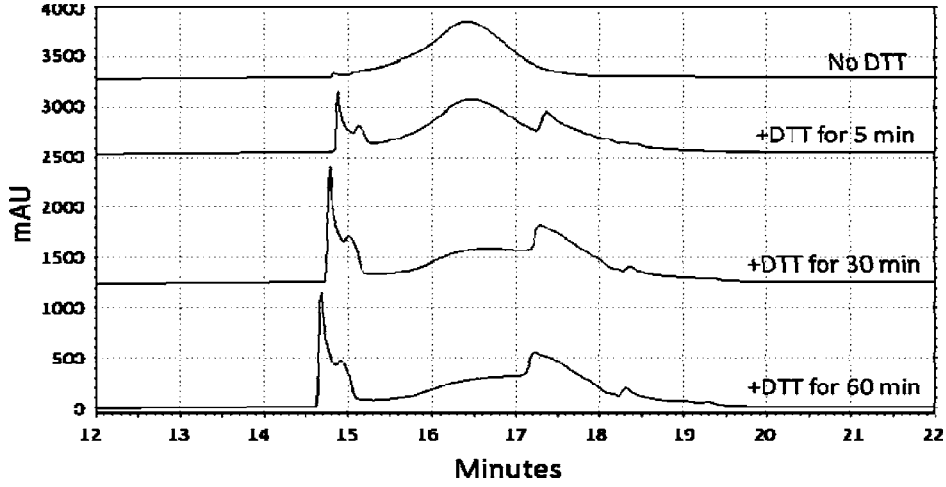

Figure 1. Evaluation of copolymer D1 degradation under reducing conditions. HPLC elution traces of copolymer D1 with no DTT and after being treated with DTT for various times. DTT treatment results in liberation of K_{11}-DNP peptide (14.7 min) and HPMA homopolymer (17.4 min).

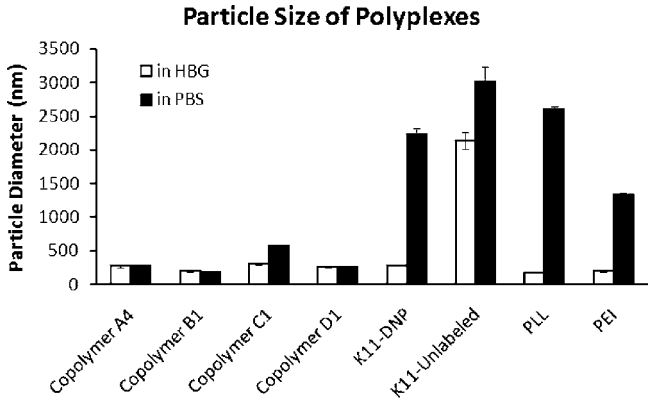

Figure 2. Polyplex size in HBG (20 mM salt) and 150 mM PBS. All peptides and polymers efficiently condensed plasmid in HBG to nanoparticles of <200 nm in diameter except unlabeled K_{11}. HPMA copolymers formed stabilized nanoparticles even in PBS.

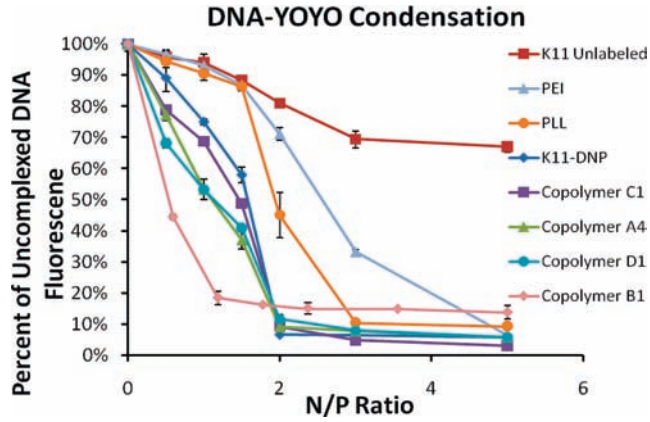

Figure 3. Extent of DNA condensation vs N/P ratio for HPMA copolymers, control polymers, and unpolymerized peptides. The fluorescence signal from DNA-YOYO was normalized to the fluorescence signal of DNA only (N/P = 0). Fluorescence signal decreases with increasing N/P ratio due to quenching of YOYO fluorescence resulting from DNA condensation.

double-layer thickness, rendering the particles susceptible to aggregation. As seen in Figure 2, PLL- and PEI-based polyplexes aggregate to sizes over 1 μm when diluted in PBS. Similar aggregation behavior is observed for the polyplexes formed with either unlabeled or DNP-labeled peptide. In contrast, polyplexes formed with all of the copolymers remain stable with a small size, even when diluted into PBS. It has been shown that cationic polymers modified with HPMA can be used to condense DNA and remain stable at high salt concentrations (*27*), where the HPMA is believed to take on a brush-like conformation on the surface and prevent aggregation by acting as a steric barrier. In a similar manner, a portion of the hydrophilic HPMA segments of the copolymer will be present on the surface of the polyplexes, and we hypothesize that they also adopt a brush-like conformation on the polyplex surface to resist aggregation. In support of this theory is the fact that copolymer C1, which has the lowest percentage of HPMA, almost doubles in size upon addition of PBS.

Determination of Plasmid Packaging Efficiency. The efficiency of plasmid condensation by polycations can be monitored by a YOYO-1 quenching assay (*19*). The fluorescence of the YOYO-1 DNA intercalator is quenched when YOYO-labeled plasmid is packaged into a condensed state. Addition of PLL or PEI to YOYO-labeled plasmid results in decreasing fluorescence with increasing N/P ratio, with full condensation occurring at N/P = 3 for PLL and N/P = 5 for PEI (Figure 3). The unlabeled K_{11} peptide is unable to efficiently condense plasmid at the N/P ratios investigated. These results are consistent with the particle sizing results, where at N/P = 5 the unlabeled peptide was not able to form small particles. In contrast, the DNP-labeled K_{11} peptide fully condensed DNA at N/P = 2. Again, these results are fully consistent with the particle sizing results, which indicated that the K_{11}-DNP peptide was able to condense DNA into small particles. The copolymers condensed DNA more efficiently than K_{11}-DNP likely due to the higher cationic valency of the copolymers. However, this effect is minor compared to the benefit derived from having HPMA in the copolymer. As can be seen in Figure 3, the copolymer able to most effectively condense DNA is B1, which has the lowest mole percent of peptide, and the copolymer to least effectively condense DNA is C1, which has the highest mole percent of peptide. Copolymers A4 and D1, which contain an intermediate amount of peptide between that of B1 and C1, possess an intermediate ability to condense DNA. These data suggest that the presence of HPMA drastically increases the affinity of the copolymer for the DNA. A YOYO condensation assay was performed with HPMA homopolymer, and YOYO fluorescence was partially quenched, lending support to the hypothesis that HPMA itself is able to interact with the DNA.

Determination of Plasmid Unpackaging. For systemic delivery applications, vector stability in the bloodstream and tissue is an important consideration. We and others have

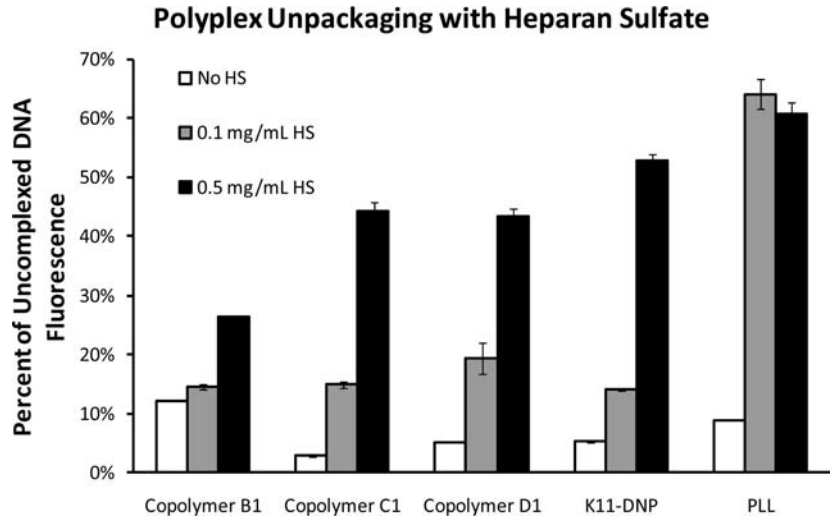

Figure 4. HS-mediated unpackaging of YOYO-labeled polyplexes. HS was diluted in HBG at various concentrations, and 80 μL of the indicated solution was added to 20 μL of polyplex (N/P = 5) containing 1 μg of DNA. Fluorescence signal increases after incubation with HS due to polyplex unpackaging and dequenching of YOYO fluorescence.

previously demonstrated that extracellular polyanions cause premature PEI polyplex unpackaging *in vivo* likely due to a polyelectrolyte exchange reaction (*19, 38, 39*). Polyplex stability in the presence of destabilizing agents can also be evaluated using a YOYO-based fluorescence assay. As can be seen in Figure 4, polyplexes formed at N/P = 5 and diluted with HBG containing no HS are fully packaged, indicated by low YOYO fluorescence. Polyplexes formed with PLL or PEI are fully unpackaged after dilution into HBG containing HS at a concentration of 0.1 mg/mL (PEI data not shown). In contrast, polyplexes formed with copolymer B1 maintained DNA in a fully condensed state after incubation with 0.1 mg/mL HS. Polyplexes formed with copolymer C1 or D1 and polyplexes formed with K_{11}-DNP were found to unpackage only slightly when incubated with 0.1 mg/mL HS. When the concentration of HS was increased to 0.5 mg/mL, polyplexes formed with K_{11}-DNP peptide fully unpackaged, while polyplexes formed with copolymers B1, C1, and D1 remained partially packaged. These results are consistent with the affinities of the copolymers for DNA determined in the DNA-YOYO condensation assay. We hypothesize that both the DNP label and the HPMA can interact with the DNA, thus increasing the affinity of the binding of the copolymers and peptides to DNA and decreasing the susceptibility of the polyplexes to unpackaging.

The optimal design of the polymeric *in vivo* gene delivery vehicle will need to allow for intracellular unpackaging, which is required for transcription (*40*). If the vectors are simply designed for maximum extracellular stability, they will be unable to unpackage intracellularly, and the delivered cargo will be rendered useless. To overcome this challenge, copolymers were synthesized containing the DNA-condensing peptides linked to the polymer backbone through a reducible disulfide linkage. When the peptides are cleaved from the copolymer backbone, the affinity for DNA should be decreased and unpackaging should be more likely. The extracellular milieu is known to be an oxidizing environment; in contrast, the cytosol is a highly reducing environment due to the excess of reduced glutathione (GSH), thioredoxin, glutaredoxin, peroxiredoxins, and nicotinamide adenine dinucleotides (NADH and NADPH) over the oxidized analogues of these molecules (*41*−*43*).

The extent of polyplex unpackaging due to competitive displacement of the polycation by HS was evaluated under reducing and nonreducing conditions for polyplexes formed with copolymer D1 (Figure 5). The polyplexes were first formed and then diluted in a buffer containing DTT, HS, or both. Reducing the linkage on copolymer D1 between peptide and polymer backbone without adding HS did not lead to any destabilization. Adding HS without DTT decreased the condensation state of the DNA-YOYO from 5% of uncomplexed DNA fluorescence to 19% of uncomplexed DNA fluorescence. Including 10 mM DTT or 25 mM DTT in the incubation with HS decreased the condensation state of the DNA-YOYO further, to 31% and 35% of uncomplexed DNA fluorescence, respectively. Reducing agents are present intracellularly at low millimolar concentrations (*41*), so these conditions were chosen to mimic the intracellular environment most closely. As can be seen from Figure 4, the maximum fluorescence recovery achieved with even 0.5 mg/mL HS was 60% of uncomplexed DNA fluorescence. There is a slight further increase in unpackaging when the DTT concentration and incubation time are increased. Thus, the polyplexes formed from copolymer D1 are more easily unpackaged under the reducing conditions of the cell cytosol. Polymers synthesized with peptides that do not contain the DNP label are expected to exhibit even more efficient DNA release under reducing conditions. In contrast, polyplexes formed from the nonreducible copolymer B1 were unaffected by any of the treatments.

***In Vitro* Transfection Efficiency.** gWiz-Luc plasmid was delivered to HeLa cells using various delivery vehicles, and the efficiency of delivery was determined by the quantitative luciferase reporter system (Figure 6). Unlabeled K_{11} peptide did not mediate increased gene delivery over plasmid DNA only (data not shown) most likely due to its inability to form stable polyplexes; however, the DNP-labeled K_{11} peptide, which was able to form stable polyplexes, did mediate an increased gene delivery efficiency compared to DNA only, though this difference was not statistically significant due to high variability. All of the copolymers were found to mediate statistically significant ($p < 0.01$) increases in transgene expression compared to plasmid only. In addition, copolymers A3, C1, and D1 mediated statistically significantly ($p < 0.01$) increased transfection efficiency compared to unpolymerized K_{11}-DNP peptide.

Since the delivery efficiency of oligolysine and PLL is known to depend on the molecular weight of the cationic delivery agent, it was expected that the copolymers that have more than one peptide incorporated and thus a higher effective molecular weight of lysine segments would have higher delivery efficiency than peptide alone. Due to the same effect, it was also expected that the copolymers based on the nonreducible Ahx linker would show increasing efficiency with increasing amounts of peptide

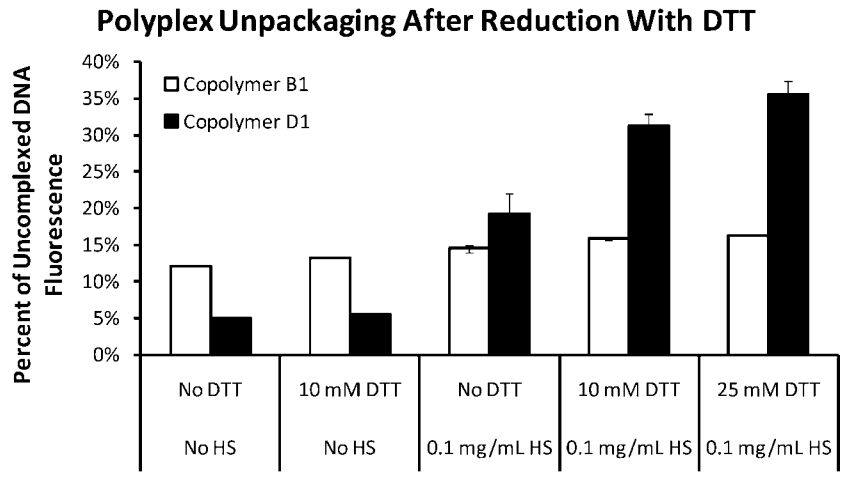

Figure 5. HS-mediated unpackaging of YOYO-labeled polyplexes formed with reducible (D1) and nonreducible (B1) copolymers before and after incubation with the reducing agent DTT. HS and DTT were diluted in HBG at various concentrations, and 80 μL of the indicated solution was added to 20 μL of polyplex (N/P = 5) containing 1 μg of DNA. The samples containing 10 mM DTT were incubated for 30 min and the samples containing 25 mM DTT were incubated for 1 h to ensure complete reduction of the disulfide linker.

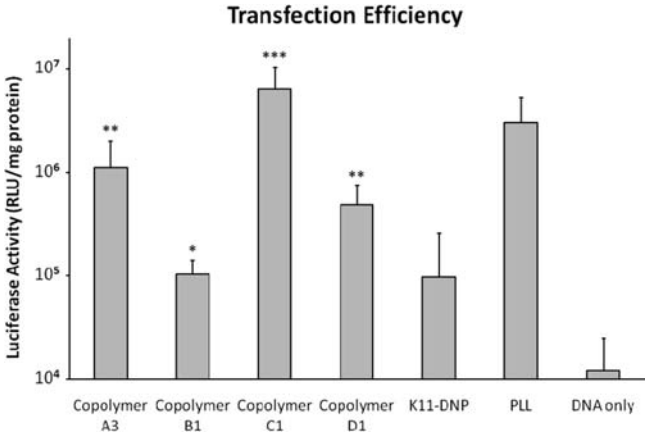

Figure 6. Gene delivery efficiency of selected carriers (formulated at N/P = 5) to HeLa cells as measured by luciferase activity 48 h after transfection. Results are reported as the mean RLU/mg protein ± SD for replicate samples, with all samples having $n > 7$. The asterisk (*) denotes that copolymer B1 was statistically significantly different from DNA only ($p < 0.01$). The double asterisk (**) denotes that copolymer A3 and copolymer D1 were both statistically significantly different from copolymer B1 ($p < 0.01$), K_{11}-DNP peptide ($p < 0.01$), and DNA only ($p < 0.01$). The triple asterisk (***) denotes that copolymer C1 was statistically significantly different from copolymer A3 ($p < 0.01$), copolymer B1 ($p < 0.01$), copolymer D1 ($p < 0.01$), K_{11}-DNP peptide ($p < 0.01$), PLL ($p < 0.05$), and DNA only ($p < 0.01$).

in the copolymer. This trend was observed, with C1 having 37.8 wt % peptide and the highest delivery efficiency, A3 having 30 wt % peptide and an intermediate delivery efficiency, and B1 having 7.7 wt % peptide and the lowest delivery efficiency. However, the average number of peptides per copolymer was inversely proportional to the copolymer transfection efficiency. These data indicate that the weight percent of peptide in the copolymer, not the absolute number of peptide monomers in the copolymer, is correlated with transfection efficiency.

One possible explanation is that the density of peptides in the copolymer could determine the cooperativity of the increase in effective polycation molecular weight. For example, copolymer B1 has an average of approximately 158 HPMA monomers per peptide monomer. In contrast, copolymer A3 has ~32 HPMA monomers per peptide monomer on average, and copolymer C1 has ~22 HPMA monomers per peptide monomer. Assuming even distribution of peptides in the polymer chain, copolymers with peptides that are more closely spaced could possess a higher effective polycation molecular weight and mediate more effective gene delivery, while the copolymers with peptides spaced further apart could have a lower effective polycation molecular weight and lower transfection efficiency.

Another possible explanation is that vector unpackaging affects transfection efficiency. Schaffer et al. have shown that the vectors with high intracellular stability mediated the lowest amounts of gene expression, while expression was greatly enhanced by using vehicles that easily dissociated from the DNA because the DNA could more easily be transcribed (*40*). From Figure 3, it can be seen that copolymer B1 condenses DNA most efficiently, while copolymer C1 condenses DNA least efficiently (among the Ahx-based copolymers). Analogously, from Figure 4, it can be seen that copolymer B1 is more resistant to unpackaging than copolymer C1.

A third possible explanation for the differences in transfection efficiencies is that polyplexes formed with the different copolymers may have unequal abilities to mediate cellular internalization. Polyplexes generated from covalently linked PLL-HPMA were found to have reduced cellular association and internalization compared to polyplexes formed with unmodified PLL (*29*). Conjugation of poly(ethylene glycol), another polar nonionic polymer, to PEI polyplexes causes a reduction in the amount of polyplex internalization that leads to a decreased transfection efficiency (*44, 45*). It has been noted that increasing the amount of shielding polymer PEG in PEI-based polyplexes reduces transfection efficiency (*45*), which is similar to the observed trends of decreasing transfection efficiency for poly(HPMA-*stat*-K_{11}) copolymers with increasing amounts of HPMA.

The AEDP-based, reducible copolymer D1 has a similar weight percent of peptide and resistance to unpackaging under nonreducing conditions when compared to copolymer C1 (Figure 4). However, from Figure 6, it can be seen that the transfection efficiency of copolymer D1 is statistically significantly lower ($p < 0.01$) than that of copolymer C1. If copolymer D1 degradation and plasmid release occurs much more rapidly than nuclear delivery of plasmid, the DNA may be degraded by nucleases before transcription can occur. Thus, the data suggest that there is an optimal intracellular stability of polyplexes for efficient gene expression.

It should be noted that copolymer C1 was found to mediate a higher transfection efficiency than PLL ($p < 0.05$). Copolymer C1 was able to more efficiently deliver DNA even though it only has about 8 kDa of mass from oligolysine in each copolymer. Copolymer C1 may have nearly optimal oligolysine

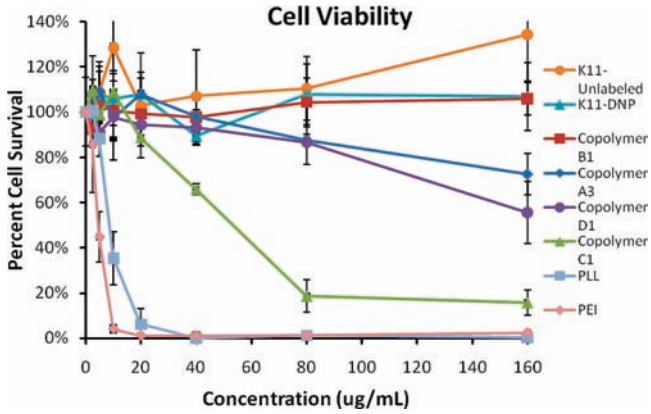

Figure 7. Cell viability of HeLa cells after incubation with free polymers, copolymers, and peptides at the indicated concentrations, as measured by an MTS assay.

content for DNA packaging without limiting intracellular DNA release. In this study, the copolymers were compared to PLL because, like PLL, they contain only primary amines on the lysine side chains to serve as cationic groups for DNA condensation. PEI, in contrast, has secondary and tertiary (in the case of branched PEI) amines that have lower pK_a values. It is currently believed that PEI mediates endosomal escape through a proton sponge effect due to this buffering capacity (*46*−*48*), which leads to typically higher transfection efficiencies than those achieved by PLL. This modular copolymer system has the ability to incorporate other peptides that may include endosomal escape functionality to further increase the transfection efficiency to rival that of PEI.

Cellular Toxicity. Both the efficacy and the toxicity of cationic polymer gene delivery vehicles are directly related to their molecular weight (*9*). The toxicity of the synthesized polymers, PLL, and PEI was tested in HeLa cells. Cheng et al. recently demonstrated that the toxicity profiles of polycations against HEK293, HeLa, and HepG2 are very similar (*49*); therefore, HeLa cell lines were used as a representative cell line. All of the synthesized copolymers were found to be much less toxic than PLL (Figure 7). One factor very likely contributing to the lower toxicity is that the copolymers contain HPMA, and HPMA has been shown to be nontoxic up to very high concentrations (*22*). Even still, copolymer A3 has, on average, 15.7 kDa of oligolysine for each polymer strand, which is comparable to the 12−24 kDa PLL that was used. Copolymer A3 is found to have good biocompatibility, with greater than 70% cell viability at the highest concentration tested. The lower toxicity may be due to the spacing of HPMA between peptides that reduces the toxicity associated with the cationic lysines. Copolymer C1 contains, on average, 8 kDa of oligolysine per polymer strand, but has a high peptide weight percent (and thus the fewest HPMA monomers spaced between its peptides) and was the most toxic of all the copolymers tested. It has been suggested that one mechanism for cationic polymer-induced cellular toxicity is for the polymers to form channels in the outer mitochondrial membrane, which allows the caspase-3 translocation and cytochrome *c* release that are hallmarks of apoptosis (*50*). We speculate that the HPMA between the peptides hinders the formation of these channels in the outer mitochondrial membrane, thus reducing the toxicity of the copolymers with large amounts of HPMA spaced between the peptides.

Several investigators have cross-linked low-molecular-weight polycations using reducible disulfide bonds to generate high-molecular-weight conjugates that efficiently condense and deliver DNA, but which become less cytotoxic fragments upon intracellular reduction (*9*−*15*). Copolymer D1 was synthesized to allow reduction of the peptide linkers and release of peptides from the polymer backbone. In composition, reducible copolymer D1 is very comparable to the nonreducible copolymer C1, with 10 kDa and 8 kDa from oligolysine in the copolymer, 35.5 and 37.8 wt % peptide, and 25 and 22 HPMA monomers between each peptide, respectively. Despite the similarities in composition, copolymer D1 is much less toxic than copolymer C1 (Figure 7).

CONCLUSIONS

We have demonstrated the synthesis of novel copolymers for gene delivery by radical copolymerization of a modified peptide monomer with an HPMA comonomer. These copolymers can condense DNA into small polyplexes that are stable at physiological salt concentrations and also resistant to unpackaging. The copolymers were also shown to deliver DNA into HeLa cells with an efficiency comparable to PLL while mediating much less cytotoxicity than PLL. This modular system has the capacity to incorporate other types of peptides into the polymer backbone, and these peptides may perform functions that increase transfection efficiency (such as endosomal escape) or specificity (such as targeting). Furthermore, the polymerization conditions could be further optimized to produce better copolymers. In contrast to traditional free radical polymerization that leads to suboptimal incorporation of macromonomers, it has been shown that controlled polymerization schemes greatly improve the incorporation of macromonomers into copolymers by reducing the disparity in reactivities between macromonomers and the smaller comonomers (*31*). Moving to a controlled radical polymerization technique also has the added benefit of producing more well-defined copolymers of more consistent composition and with lower PDIs. The development of nearly monodisperse, targeted copolymers that mediate high levels of gene delivery can be possible in the near future using this system as a basis for further improvements.

ACKNOWLEDGMENT

The authors would like to thank Dr. Anthony Convertine for helpful discussions regarding the polymerization strategy. Mass spectrometry was performed in the Department of Chemistry Mass Spectrometry Facility, with special thanks to Dr. Martin Sadilek for his training and support on the ESI-MS instrument. GPC was performed with equipment in the laboratory of Dr. Patrick Stayton and Dr. Allan Hoffman, with special thanks to Dr. Scott Henry for his assistance. This work was supported by an NSF CAREER Award (CBET-0448547) to S.H.P., and NIH/NINDS grants 5R21NS052030 and 1R01NS064404. R.S.B. is grateful to the National Science Foundation for a graduate research fellowship.

Genetic Engineering of a Bifunctional IgG Fusion Protein with Iduronate-2-Sulfatase

Jeff Zhiqiang Lu,[†] Eric Ka-Wai Hui,[†] Ruben J. Boado,[†,‡] and William M. Pardridge*[,‡]

ArmaGen Technologies, Inc., Santa Monica, California 90401, and Department of Medicine, University of California Los Angeles, Los Angeles, California 90024. Received August 31, 2009; Revised Manuscript Received October 5, 2009

Iduronate-2-sulfatase (IDS) is a lysosomal sulfatase that prevents the accumulation within the brain of glycosoaminoglycans. However, IDS does not cross the blood−brain barrier (BBB). To enable BBB transport, human IDS, minus its signal peptide, was fused to the carboxyl terminus of the heavy chain of a chimeric monoclonal antibody (mAb) to the human insulin receptor (HIR). The HIRMAb crosses the BBB on the endogenous insulin receptor and acts as a molecular Trojan horse to ferry the IDS into brain. The HIRMAb-IDS fusion protein was expressed in COS cells and purified with protein A affinity chromatography. The size of the fusion heavy chain, as measured with Western blotting and antibodies to either human IDS or human IgG, was increased about 80 kDa, relative to the size of the heavy chain of the parent HIRMAb. The HIRMAb-IDS fusion protein retained high-affinity binding for the HIR. The IDS enzyme specific activity of the fusion protein was 51 ± 7 nmol/h per microgram of protein, which is comparable to the enzyme activity of recombinant IDS. The fusion protein was taken up by human fibroblasts, and the accumulation of glycosoaminoglycans in fibroblasts null for the sulfatase was decreased 84% by treatment with the fusion protein. The HIRMAb-IDS fusion protein is a bifunctional IgG-sulfatase fusion protein, which has been specifically engineered for targeted drug delivery across the human BBB.

INTRODUCTION

Mucopolysaccharidosis (MPS) type II (MPS-II), or Hunter's syndrome, is a lysosomal storage disorder caused by defects in the gene encoding the lysosomal enzyme, iduronate-2-sulfatase (IDS) (*1*). MPS-II is treated with recombinant human IDS in enzyme replacement therapy (*2*). However, many cases of MPS-II affect the central nervous system (*3, 4*), and enzyme replacement therapy is not effective for the brain, because the IDS does not cross the blood−brain barrier (BBB) (*4, 5*). In MPS-II cases that do affect the brain, the use of ERT is considered optional (*5*).

IDS, and other lysosomal enzymes, can be made to cross the human BBB following the re-engineering of the enzyme as a fusion protein with a BBB molecular Trojan horse (*6*). The latter is an endogenous peptide, or peptidomimetic monoclonal antibody (mAb), that crosses the BBB via an endogenous receptor-mediated transport system. The molecular Trojan horse with the highest BBB permeation rate is a mAb against the α-subunit of the human insulin receptor (HIR) (*7*). Genetically engineered forms of the chimeric or humanized HIRMAb have been produced (*8*), and these cross the BBB in the adult Rhesus monkey in vivo at rates comparable to small molecule penetration of the brain. Previously, the lysosomal enzyme, iduronidase (IDUA), the enzyme mutated in MPS-I (*9*), was re-engineered as a fusion protein with the HIRMAb (*10*). The HIRMAb-IDUA fusion protein retained high binding affinity for the HIR and high IDUA enzyme activity. The fusion protein normalized intracellular IDUA enzyme activity and glycosoaminoglycan (GAG) accumulation in MPS-I fibroblasts, and confocal microscopy demonstrated that the HIRMAb-IDUA fusion protein was targeted to the lysosomal compartment of MPS-I fibroblasts (*10*). The HIRMAb-IDUA fusion protein was rapidly transported across the Rhesus monkey BBB in vivo, at a level that would normalize the brain IDUA enzyme activity at a therapeutic dose of 0.6 mg/kg intravenously (*10*). The re-engineering of lysosomal enzymes as fusion proteins with BBB molecular Trojan horses represents a new approach to the treatment of the brain in lysosomal storage disorders.

The HIRMAb-IDUA described previously (*10*) is specific for MPS-I. Patients with MPS-II have mutations in IDS, which also adversely affects the brain. Therefore, the purpose of the present investigation was to engineer a new treatment of the brain in MPS-II, wherein the amino terminus of the mature human IDS is fused to the carboxyl terminus of the heavy chain of the HIRMAb. The structure of the HIRMAb-IDS fusion protein is shown in Figure 1. The HIRMAb-IDS fusion protein is a heterotetrameric protein comprising two heavy chains and two light chains. These studies examined the bifunctional properties of this IgG-enzyme fusion protein to determine if the new fusion protein both bound the HIR with high affinity and retained high IDS enzyme activity. The extent to which intracellular IDS enzyme activity and GAG accumulation were normalized in MPS-II fibroblasts was also investigated.

MATERIALS AND METHODS

Engineering of HIRMAb Heavy Chain-IDS Fusion Protein Expression Vector. The human IDS cDNA, encoding Ser^{26}-Pro^{550} (*1*), minus the 25 amino acid signal peptide (Genbank NP_000193), was produced by reverse transcription and PCR, starting with human liver polyA+ RNA (Clontech). Human liver cDNA was prepared using the SuperScript first-strand synthesis kit (Invitrogen, San Diego, CA) and oligodeoxythymidine priming. The IDS cDNA was cloned using 2 μL liver cDNA reverse transcription reaction, 0.2 μM IDS forward and reverse ODN primers, 0.2 mM deoxynucleotidetriphos-

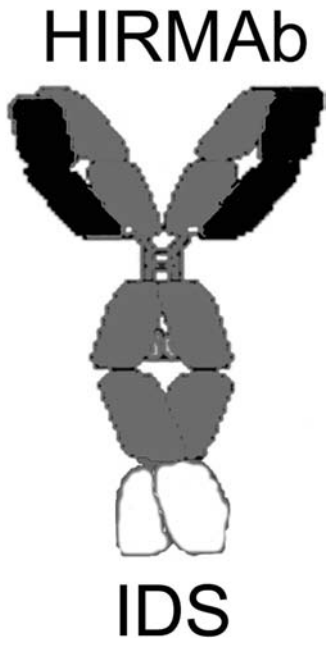

Figure 1. The HIRMAb-IDS fusion protein is formed by fusion of the amino terminus of the mature IDS to the carboxyl terminus of the CH_3 region of the heavy chain of the chimeric HIRMAb. The fusion protein is a bifunctional molecule: the fusion protein binds the HIR, at the BBB, to mediate transport into the brain, and expresses IDS enzyme activity, which is deficient in MPS type II (Hunter's syndrome).

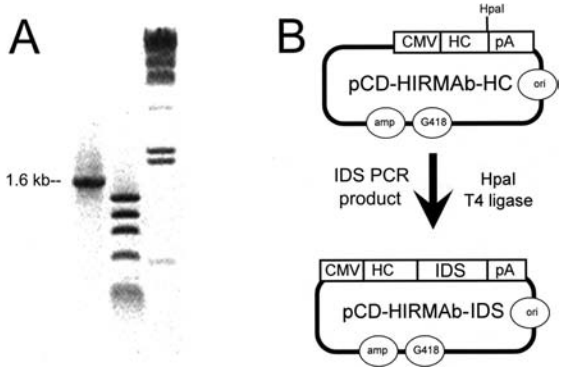

Figure 2. (A) Ethidium bromide stain of agarose gel of human IDS cDNA (lane 1), which was produced by PCR from human liver cDNA, and IDS-specific primers (Methods). Lanes 2 and 3: PhiX174 *Hae*III digested DNA standard, and Lambda *Hin*dIII digested DNA standard. (B) The heavy chain of the HIRMAb-IDS fusion protein is expressed by the pCD-HIRMAb-IDS plasmid, which is generated by subcloning the IDS cDNA into the *Hpa*I site of the pCD-HIRMAb-HC plasmid.

phates, and 2.5 U PfuUltra DNA polymerase (Stratagene, San Diego, CA) in a 50 μL Pfu buffer (Stratagene). The amplification was performed in a Mastercycler temperature cycler (Eppendorf, Hamburg, Germany) with an initial denaturing step of 95 °C for 2 min followed by 30 cycles of denaturing at 95 °C for 30 s, annealing at 55 °C for 30 s and amplification at 72 °C for 1 min. PCR products were resolved in 1% agarose gel electrophoresis, and the expected major single band of ~1.6 kb corresponding to the human IDS cDNA was isolated (Figure 2A). The cloned human IDS was inserted into the pCD-HIRMAb HC eukaryotic expression plasmid at the *Hpa*I site, and this expression plasmid was designated pCD-HIRMAb-IDS, as outlined in Figure 2B; the pCD-HIRMAb-HC expression plasmid encodes the heavy chain (HC) of the chimeric HIRMAb. The entire expression cassette of the plasmid was confirmed by bidirectional DNA sequencing. The IDS forward PCR primer was a 23-mer coding for the 7 amino acids at the beginning of the mature IDS protein. This primer introduces "CC" nucleotides to maintain the open reading frame and to introduce a Ser-Ser linker between the carboxyl terminus of the CH_3 region of the HIRMAb HC and the amino terminus of the IDS minus the 25 amino acid signal peptide of the enzyme. The IDS reverse PCR primer was a 27-mer complementary to the end of the IDS cDNA including the stop codon, "TGA", immediately after the terminal Pro of the mature human IDS protein. The fusion of the IDS monomer to the carboxyl terminus of each HC is depicted in Figure 1.

Transient Expression of HIRMAb-IDS Fusion Protein in COS Cells. COS cells were plated in 6-well cluster dishes and were dual-transfected with pHIRMAb-LC and pCD-HIRMAb-IDS plasmids using Lipofectamine 2000, with a ratio of 1:2.5 μg DNA:μL Lipofectamine, and conditioned serum free medium was collected at 3 and 7 days. The pHIRMAb-LC encodes for the light chain (LC) of the chimeric HIRMAb. Expression was confirmed by measurement of human IgG secreted to the medium by ELISA, as described previously (*10*). For production of larger amounts of fusion protein, COS cells were transfected in 10 × T500 flasks. The 3 day and 7 day media were pooled, and the 2 L of serum free conditioned medium was concentrated with tangential flow filtration (Millipore) followed by purification with protein A affinity chromatography.

SDS-PAGE and Western Blotting. The purity of protein A purified fusion protein produced by COS cells was evaluated with 12% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) with 5% β-mercaptoethanol. Immunoreactivity was tested with a primary goat antibody to human IDS (R&D Systems, Minneapolis, MN) or a primary goat antiserum against human IgG heavy and light chains (Vector Laboratories, Burlingame, CA). Immunoreactivity of the HIRMAb-IDS fusion protein was compared to human recombinant IDS expressed in myeloma cells from R&D Systems.

HIR Receptor Assay. The affinity of the fusion protein for the HIR extracellular domain (ECD) was determined with ELISA. Chinese hamster ovary cells permanently transfected with the HIR ECD were grown in serum-free media, and the HIR ECD was purified with a wheat germ agglutinin affinity column, as previously described (*11*). The HIR ECD was plated on Nunc-Maxisorb 96 well dishes and the binding of the HIRMAb or the HIRMAb-IDS fusion protein to the HIR ECD was detected with a biotinylated goat antihuman IgG (H+L) secondary antibody, followed by avidin and biotinylated peroxidase (Vector Laboratories, Burlingame, CA). The concentration of either HIRMAb or HIRMAb-IDS fusion protein that gave 50% maximal binding was determined with a nonlinear regression analysis.

IDS Enzyme Assay. The IDS enzyme activity was determined with a fluorometric assay using 4-methylumbelliferyl α-L-iduronide-2-sulfate (4-MUS) (*12*), which was purchased from Moscerdam Substrates (Rotterdam, The Netherlands). This substrate is hydrolyzed by IDS to 4-methylumbelliferyl α-L-iduronide (MUBI), and the MUBI is hydrolyzed by iduronidase (IDUA, Aldurazyme, Genzyme, Boston, MA) to 4-methylumbelliferone (4-MU), which is detected fluorometrically with a Farrand filter fluorometer using an emission wavelength of 450 nm and an excitation wavelength of 365 nm. A standard curve was constructed with known amounts of 4-MU (Sigma-Aldrich, St. Louis, MO). The assay was performed by incubation at 37 °C at pH = 4.5 for 4 h in McIlvaine's buffer, followed by the addition of 12 ug of IDUA and an additional 24 incubation at 37 °C. The incubation was terminated by the addition of 0.2 mL of 0.5 M sodium carbonate (pH = 10.3). One unit = 1 nmol/h.

Fusion Protein Uptake and Biological Activity in MPS Type II Fibroblasts. Fibroblasts were chosen as a model system, since type II MPS Hunter fibroblasts (GM000298), as well as healthy human fibroblasts (GM000497), are available from the Coriell Institute for Medical Research (Camden, NJ). The cells were grown in 6-well cluster dishes to confluency. The medium was aspirated, wells washed with phosphate buffered saline (PBS), and incubated with 1 mL of Dulbecco's modified Eagle medium without serum, along with a range of concentrations of the HIRMAb-IDS fusion protein, for 2 h at 37 °C. The medium was aspirated, and the wells were washed extensively (1 mL/well, 5 washes) with PBS, and the monolayer was extracted in 0.3 mL/well of lysis buffer (5 mM sodium formate, 0.2% Triton X-100, pH = 4.0), followed by four freeze/thaw cycles, and microfuged 10 min 4 °C. The supernatant was removed for IDS enzyme activity and bicinchoninic acid protein (BCA) assay. The uptake of the fusion protein was expressed as nanomoles per hour of IDS enzyme activity per milligram of cell protein.

Sulfate incorporation into cellular glycosoaminoglycans (GAG) is increased in the absence of cellular IDS (*13*). Therefore, ^{35}S incorporation into the healthy and Hunter fibroblasts was measured with or without treatment of the cells with the HIRMAb-IDS fusion protein. Type II MPS or healthy human fibroblasts were plated in 6-well cluster dishes at 250 000 cells/well and grown for 4 days in DMEM with 10% fetal bovine serum. The medium was discarded, the wells were washed with PBS, and 1 mL/well of low-sulfate F12 medium with 10% dialyzed fetal bovine serum was added, along with 5 mM $CaCl_2$, the HIRMAb-IDS fusion protein (0.3 ug/mL), and 10 uCi/mL of ^{35}S-sodium sulfate (Perkin-Elmer, Boston, MA). Following a 24 h incubation at 37 °C, the medium was aspirated, the wells were washed with cold PBS (1 mL, 5 washes), and the cells were lysed with 0.4 mL/well of 1 N NaOH. The lysate was heated 60 °C for 60 min to solubilize protein, an aliquot was removed for BCA protein assay, and the sample was counted for radioactivity with a Perkin-Elmer Tri-Carb 2100 liquid scintillation counter. The data were expressed as ^{35}S counts per minute (CPM) per microgram of protein, as described previously (*10*). The percent normalization of GAG accumulation was computed from $[(A - B/(A - C)] \times 100$, where A = the ^{35}S radioactivity incorporated in untreated Hunter fibroblasts, B = the ^{35}S radioactivity incorporated in Hunter fibroblasts treated with the HIRMAb-IDS fusion protein, and C = the ^{35}S radioactivity incorporated in healthy human fibroblasts.

RESULTS

DNA sequencing of the expression cassette of the pCD-HIRMAb-IDS plasmid encompassed 4063 nucleotides (nt), including a 714 nt cytomegalovirus promoter, a 9 nt full Kozak site (GCCGCCACC), a 2970 nt HIRMAb HC-IDS fusion protein open reading frame, and a 370 nt bovine growth hormone polyA sequence. The plasmid encoded for a 989 amino acid protein, comprising a 19 amino acid IgG signal peptide, the 443 amino acid HIRMAb HC, a 2 amino acid linker (Ser-Ser), and the 525 amino acid human IDS minus the enzyme signal peptide. The predicted molecular weight of the heavy-chain fusion protein, minus glycosylation, is 108 029 Da, with a predicted isoelectric point (pI) of 6.03.

Dual transfection of COS cells with the pCD-HIRMAb-IDS and the pHIRMAb-LC produced 2.3 L of serum-free conditioned medium over a 7 day incubation. The HIRMAb-IDS fusion protein was purified by protein A affinity chromatography to homogeneity as demonstrated by SDS-PAGE (Figure 3). The size of the heavy chain of the HIRMAb-IDS fusion protein, 135 kDa, is about 80 kDa larger than the heavy chain of the HIRMAb, whereas both proteins have light chains of equal size

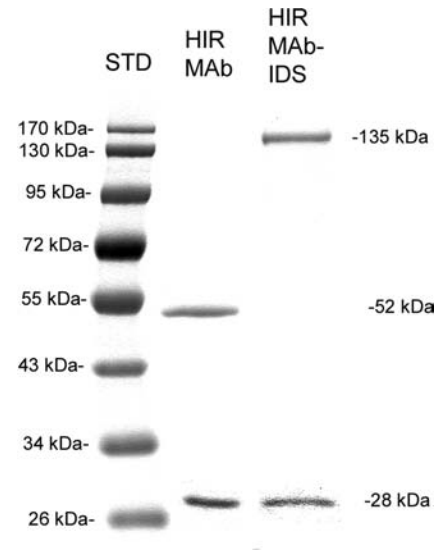

Figure 3. Reducing SDS-PAGE of molecular weight standards (STD), the purified HIRMAb, and the purified HIRMAb-IDS fusion protein.

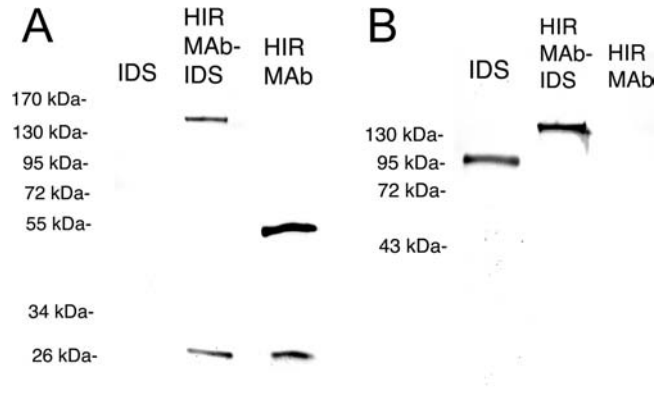

Figure 4. Western blot with either antihuman (h) IgG primary antibody (A) or antihuman IDS primary antiserum (B). The immunoreactivity of the HIRMAb-IDS fusion protein is compared to the chimeric HIRMAb and recombinant human IDS. Both the HIRMAb-IDS fusion protein and the HIRMAb have identical light chains on the anti-hIgG Western. The HIRMAb-IDS fusion heavy chain reacts with both the anti-hIgG and the antihuman IDS antibody, whereas the HIRMAb heavy chain only reacts with the anti-hIgG antibody. The size of the HIRMAb-IDS fusion heavy chain, 130 kDa, is about 80 kDa larger than the size of the heavy chain of the HIRMAb, owing to the fusion of the 80 kDa IDS to the 50 kDa HIRMAb heavy chain.

(Figure 3). On Western blotting of the purified HIRMAb and the HIRMAb-IDS fusion protein, the antihuman IgG antibody reacts with a 135 kDa heavy chain for the fusion protein, and a 52 kDa heavy chain for the HIRMAb, and the difference in size, 80 kDa, is due to the fusion of IDS (Figure 4A). The antihuman IgG antibody reacts equally with the light chain of either the HIRMAb-IDS fusion protein or the HIRMAb, since both proteins comprise the same light chain, but the antihuman IgG antibody does not react with recombinant human IDS (Figure 4A). The anti-IDS antibody reacts with the 135 kDa heavy chain of the fusion protein and with the recombinant IDS, but not with the heavy chain of the HIRMAb (Figure 4B).

The affinity of the fusion protein for the HIR extracellular domain (ECD) was determined with a ligand binding assay using lectin affinity purified HIR ECD (Materials and Methods section). There is comparable binding of either the chimeric HIRMAb or the HIRMAb-IDS fusion protein for the HIR ECD with ED_{50} of 0.32 ± 0.15 nM and 0.40 ± 0.04 nM, respectively (Figure 5). The IDS enzyme activity was determined with a

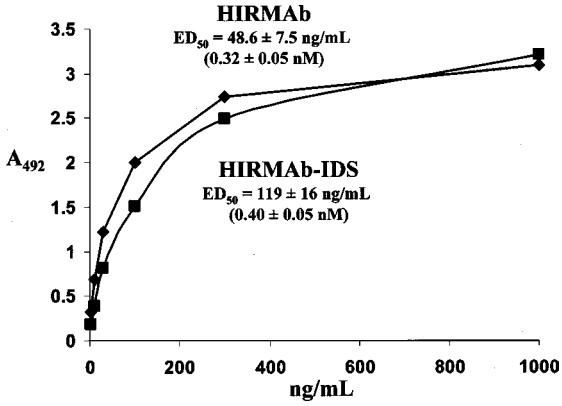

Figure 5. Binding of either the chimeric HIRMAb or the HIRMAb-IDS fusion protein to the HIR extracellular domain (ECD) is saturable. The ED_{50} of HIRMAb-IDS binding to the HIR ECD is comparable to the ED_{50} of the binding of the chimeric HIRMAb.

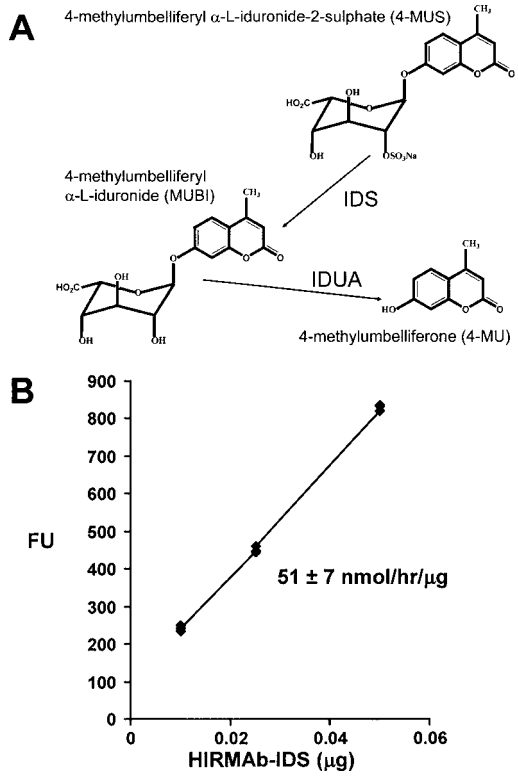

Figure 6. (A) Substrate (4-MUS), intermediate (MUBI), and product (4-MU) of the two-step enzymatic fluorometric assay of IDS enzyme activity. (B) The fluorometric units (FU) are proportional to the mass of purified HIRMAb-IDS fusion protein, and the average enzyme specific activity of the fusion protein is 51 ± 7 nmol/h/μg protein.

two-step enzymatic fluorometric assay outlined in Figure 6A. The fluorometric units were proportional to the mass of purified HIRMAb-IDS fusion protein, and the enzymatic activity of the fusion protein was 51 ± 7 nmol/h/μg protein (Figure 6B).

The HIRMAb-IDS fusion protein was taken up by MPS type II fibroblasts (Figure 7A). The basal IDS activity in these cells without treatment is very low, 10 ± 3 nmol/h/mg_p. The intracellular IDS enzyme activity increases in proportion to the concentration of medium HIRMAb-IDS (Figure 7). The normal IDS enzymatic activity in healthy human fibroblasts is shown by the horizontal bar in Figure 7. A medium concentration of the HIRMAb-IDS fusion protein of ~500 ng/mL causes a 100% normalization of intracellular IDS enzyme activity (Figure 7). The Hunter fibroblasts, with or without treatment with 0.3 ug/mL HIRMAb-IDS fusion protein in the medium, and the healthy

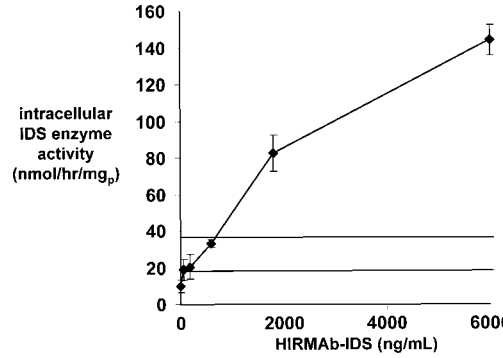

Figure 7. Intracellular IDS enzyme activity is increased in Hunter fibroblasts in proportion to the concentration of medium HIRMAb-IDS fusion protein. Data are means ± SE (n = 3 dishes/point). The horizontal bar is the IDS enzyme activity in healthy human fibroblasts (mean ± SD).

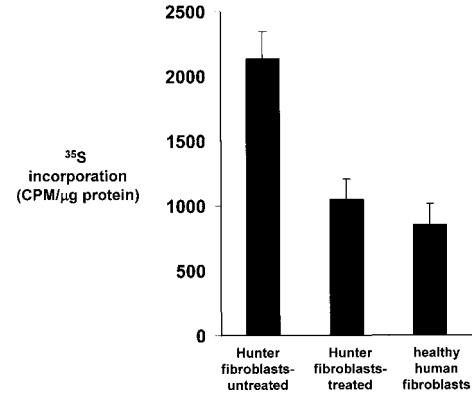

Figure 8. Reversal of glycosaminoglycan (GAG) accumulation in Hunter fibroblasts with a single treatment of 0.3 ug/mL of HIRMAb-IDS fusion protein in the medium. There is an 84% reduction in GAG accumulation, as compared to the ^{35}S incorporation in healthy human fibroblasts ($p < 0.0005$). Data are means ± SE (n = 4 dishes/point).

human fibroblasts, were incubated 24 h in the presence of ^{35}S-sodium sulfate, which is incorporated into intracellular GAGs. Treatment with the HIRMAb-IDS fusion protein reduces GAG accumulation in Hunter fibroblasts by 84% as compared to healthy fibroblasts ($p < 0.0005$) (Figure 8).

DISCUSSION

The results of this study are consistent with the following conclusions. First, a fusion gene has been genetically engineered that encodes the HIRMAb-IDS fusion protein depicted in Figure 1, and following expression in COS cells, the heavy chain of the fusion protein is about 80 kDa larger than the heavy chain of the chimeric HIRMAb (Figure 3), and the fusion protein heavy chain reacts with antibodies to both human IgG and human IDS (Figure 4). Second, the fusion protein is a bifunctional molecule and binds both the HIR ECD with comparable affinity to the chimeric HIRMAb (Figure 5) and has high IDS enzyme activity (Figure 6). Third, the HIRMAb-IDS fusion protein is taken up by Hunter fibroblasts (Figure 7) and causes an 84% decline in GAG accumulation with 24 h of treatment (Figure 8).

There are multiple approaches possible for the engineering of an IgG-enzyme fusion protein, as the enzyme could be fused to either the amino terminus or the carboxyl terminus of either the IgG heavy chain or light chain. If the enzyme is fused to the amino terminus of the IgG chain, then the enzyme is translated and folded before the IgG chain in the host cell, and this might ensure retention of enzyme activity in the fusion

protein. However, the antigen binding site of the IgG chain is near the amino terminus and fusion of the enzyme at the amino terminus could impair IgG binding to the target receptor. These considerations were confirmed in the engineering of a fusion protein of the HIRMAb and human β-glucuronidase (GUSB). Fusion of the GUSB to the amino terminus of the HIRMAb heavy chain resulted in a retention in GUSB enzyme activity, but greatly impaired binding of the fusion protein to the HIR (*14*). With regard to another lysosomal enzyme, IDUA, a HIRMAb-IDUA fusion protein retained high HIR binding and high IDUA enzyme activity following fusion of the IDUA to the carboxyl terminus of the CH_3 region of the HIRMAb heavy chain (*10*). A similar result is demonstrated in the present study on the engineering of the HIRMAb-IDS fusion protein shown in Figure 1. The fusion protein binds the HIR with the same high affinity as the HIRMAb (Figure 5). The IDS enzyme activity of the HIRMAb-IDS fusion protein is also retained, as the IDS enzyme specific activity, 51 $\pm$ 7 nmol/h/μg protein (Figure 6B), is comparable to the enzyme activity of human recombinant IDS (*15*). The engineering of the IgG-IDS fusion protein variant shown in Figure 1 places the IDS in a dimeric configuration. IDS is a member of a family of sulfatases, which includes arylsulfatase A (ASA) (*16*), and the natural configuration of ASA at neutral pH is a dimeric structure (*17*).

The retention of IDS enzyme activity in the HIRMAb-IDS fusion protein indicates this fusion protein is correctly processed in the host cell. The SDS-PAGE (Figure 3) and the IgG and IDS Western blotting (Figure 4) show that the fusion protein secreted to the medium is of the correct size. IDS is a member of a family of sulfatases (*16*), wherein the activity of the enzyme is activated following the conversion of Cys-59 to a formylglycine residue by a sulfatase modifying factor in the endoplasmic reticulum (*18*). The retention of IDS enzyme activity in the HIRMAb-IDS fusion protein indicates the IDS is activated within the host cell despite fusion to the HIRMAb heavy chain.

The HIRMAb-IDS heavy chain is triaged to the lysosome within the target cell following uptake via the cell membrane HIR, as evidenced by the 84% reduction in GAG accumulation within the Hunter fibroblast (Figure 8). Prior studies with the HIRMAb-IDUA fuson protein used confocal microscopy to confirm localization of the fusion protein within the lysosomal compartment of the human fibroblast (*10*). The reduction in GAG accumulation shown in Figure 8 was observed following exposure of the Hunter fibroblasts to a 0.3 ug/mL concentration of the HIRMAb-IDS fusion protein (Figure 8). A concentration of 0.3 ug/mL of the HIRMAb-IDS fusion protein is a subtherapeutic dose (Figure 7). This result corroborates prior studies, which suggest that partial restoration of intracellular lysosomal enzyme activity causes therapeutic effects within the cell (*19*).

The HIRMAb is specific for the human insulin receptor and cross-reacts with the Old World primate insulin receptor in Rhesus monkeys, but does not react with the insulin receptor in other species (*7*). Consequently, the HIRMAb-IDS fusion protein cannot be administered to mouse models of MPS-II, as the fusion protein would not be recognized by the murine insulin receptor. There is no known mAb against the mouse insulin receptor that can be used as a BBB Trojan horse. Furthur drug development of the HIRMAb-IDS fusion protein as a new therapy for treatment of the brain in MPS-II will require evaluations of the potential toxicity and immunogenicity of this fusion protein. With respect to immunogenicity of fusion proteins, recent studies report on the administration of high doses to Rhesus monkeys of a fusion protein of the HIRMAb and either glial derived neurotrophic factor (GDNF) (*20*) or IDUA (*21*). The administration of large doses of the HIRMAb fusion proteins, 10−20 mg/kg, caused no tissue toxicity and had no effect on glycemic control in plasma or cerebrospinal fluid (*20, 21*). A 20 mg/kg dose of fusion protein is large compared to the projected therapeutic dose of HIRMAb-enzyme fusion proteins, 0.6 mg/kg (*10*). There was minimal immune response to the HIRMAb fusion proteins (*20, 21*). The re-engineering of recombinant proteins as IgG fusion proteins may reduce the potential immunogenicity of the recombinant protein, which can be a side effect of enzyme replacement therapy (*22*). Recent work shows that the constant region of human IgG contains amino acid sequences, called Tregitopes, which induce immune tolerance (*23*). Therefore, the re-engineering of human IDS as the HIRMAb fusion protein shown in Figure 1 may reduce the immunogenicity of the lysosomal enzyme in MPS-II patients, as well as enable enzyme penetration of the BBB.

The present work aimed at the development and application of transferrin receptor (TrfR)-targeted sterically stabilized liposomes encapsulating anti-*BCR-ABL* siRNA or asODN. Transferrin was coupled to the surface of liposomes encapsulating siRNA or asODN through the postinsertion method. Cell association and internalization were assessed by flow cytometry and confocal microscopy, respectively. *BCR-ABL* mRNA and Bcr-Abl protein levels were evaluated by qRT-PCR and Western blot, respectively. Cell viability was assessed using the resazurin reduction method. The amount of coupled transferrin and the size and stability over time of the liposomes were very satisfactory and reproducible. The siRNA encapsulation yield was dependent on the concentration of the encapsulation buffer used (20 or 300 mM), as opposed to asODN encapsulation yield which was high for both concentrations tested. Cell association and internalization studies were performed in leukemia cell lines treated with liposomes coupled to Trf (Trf-liposomes) or albumin (BSA-liposomes) or with nontargeted liposomes (NT-liposomes) encapsulating fluorescently labeled siRNA (Cy3-siRNA). These experiments clearly indicated that BSA- and NT-liposomes have no ability to promote the delivery of the encapsulated nucleic acids and that the Trf-liposomes deliver the nucleic acids by a Trf receptor-dependent mechanism. The Trf-liposomes encapsulating siRNA or asODN promote sequence-specific down-regulation of the *BCR-ABL* mRNA, although a certain extent of nonspecific sequence effects at the protein and cell viability level were observed. Overall, our results indicate that Trf-liposomes encapsulating gene silencing tools allow combining molecular and cellular targeting, which is a valuable approach for cancer treatment.

INTRODUCTION

Chronic myeloid leukemia (CML) is a hematopoietic stem cell disease caused by a t(9;22)(q34;q11) reciprocal translocation between chromosomes 9 and 22, leading to the *BCR-ABL* oncogene, that encodes a constitutively active tyrosine kinase, the Bcr-Abl protein, which is responsible for the malignant transformation in the disease (*1–3*).

Antisense oligonucleotides (asODN) are short, single-stranded molecules of DNA or RNA (typically 18−25 nucleotides in length) promoting targeted mRNA cleavage or blocking its translation (*4, 5*). Small interfering RNA (siRNA) are short, double-stranded RNA molecules normally with 21−23 nucleotides in each strand that promote the cleavage of complementary mRNA by activation of the RNA interference mechanism (*6–9*).

AsODN and siRNA are powerful gene silencing tools, although there are many obstacles to their *in vitro* and *in vivo* use, namely, enzymatic degradation mediated by nucleases present in the serum (*6, 10, 11*), low cellular uptake caused by the high molecular weight and the net negative charge (*10–12*), as well as renal excretion (*6, 10*). All these features contribute to poor *in vivo* pharmacokinetic properties of asODN and siRNA molecules. To overcome these limitations, different approaches have been tried in the past years, like chemical modifications of siRNA (*8, 10*) and asODN (*13, 14*), in an attempt to generate molecules more resistant to nuclease degradation and in some cases less prone to off-target effects (*8, 10*).

The use of liposomes to deliver siRNA or asODN allows protection of nucleic acids from nuclease degradation and can be engineered in order to confer sustained plasma concentration and targeted delivery, thus leading to more specific nucleic acid accumulation in tumor cells.

The transferrin receptor (TrfR) is a cell membrane-associated glycoprotein (*15–17*) that has been explored as a target to deliver liposomes into cancer cells (*18, 19*), due to its overexpression on tumor cells (*15, 16, 20*), accessibility on the cell surface, and constitutive endocytosis (*20*). Transferrin (Trf), an 80 kDa glycoprotein, is the natural ligand for TrfR and undergoes internalization mediated by this receptor (*17, 20*).

When considering intravenous administration, which is relevant for implementing a therapeutic approach against CML, it is important to confer long circulating times to the liposomes. This feature can be achieved by "insertion" of hydrophilic polymers in the liposome surface, with poly(ethylene glycol) (PEG) being one of the most extensively studied for this purpose. The main aim is to obtain an aqueous shield around the liposomes that prevents their aggregation during preparation and opsonization by serum components, which can further lead to blood elimination by macrophages of the mononuclear phagocytic system, thus improving biodistribution and consequently pharmacokinetics (*21–23*).

This work aimed at efficiently encapsulating asODN or siRNA (designed to specifically silence the *BCR-ABL* oncogene) in TrfR-targeted sterically stabilized liposomes. These liposomes were characterized in terms of their size, siRNA or asODN encapsulation yield, the amount of coupled Trf protein, and size stability over time. Our results clearly indicate that cellular

internalization of the targeted liposomes occurs through TrfR-mediated endocytosis. In addition, it was demonstrated that the developed TrfR-targeted formulation allowed to achieve the desired gene silencing effect mediated by either siRNA or asODN. A correlation between the reduction of the levels of *BCR-ABL* mRNA and decrease of the corresponding Bcr-Abl protein and cytotoxicity was observed.

EXPERIMENTAL PROCEDURES

Chemicals. Cholesterol (Chol) was obtained from Sigma (St Louis, MO, USA); all the other lipids, *N*-palmitoyl-sphingosine-1-[succinyl(methoxypolyethylene glycol) 2000] (C16 mPEG 2000 Ceramide), 1,2-distearoyl-*sn*-glycero-3-phosphatidylcholine (DSPC), 1,2-dioleoyl-3-dimethylammonium-propane (DODAP); 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-[maleimide (polyethylene glycol)2000] ammonium salt (DSPE-PEG-MAL), were obtained from Avanti Polar Lipids (Alabaster, AL, USA). Human holo-transferrin (Trf) and bovine serum albumin (BSA) were purchased from Sigma.

Small interfering RNA molecules were purchased from Dharmacon RNA Technologies (Lafayette, CO, USA). The Cy3-labeled anti-*BCR-ABL* siRNA (Cy3-siRNA) (custom synthesis) and asODN molecules were purchased from Ambion (Austin, TX, USA) and Microsynth AG (Switzerland), respectively. The sequences of the used nucleic acids are presented in Table 1. All the other chemicals were obtained from Sigma unless stated otherwise.

Preparation of Trf or BSA-Coupled PEG2000-DSPE Micelles. Trf and BSA proteins were modified with the addition of thiol groups through reaction with 2-iminothiolane hydrochloride (2-IT). For this purpose, Trf or BSA and 2-IT freshly dissolved in HEPES buffer (20 mM HEPES, 145 mM NaCl, pH 8) were mixed in a protein/2-IT molar ratio of 1:10 and gently stirred for 1 h, in the dark at room temperature.

A lipid film of DSPE-PEG-MAL was prepared by solvent evaporation under a mild stream of N_2 and further dried under vacuum for 2 h. This dried lipid film was then hydrated with MES buffer (20 mM HEPES, 20 mM MES, pH 6.5), at a concentration above 2.3 μM, the critical micellar concentration of the lipid (*24*). Micelles were formed by strong vortex followed by 15 s heating in a water bath at 38 °C and a second vortex shaking. Then, the freshly thiolated proteins were coupled to the freshly prepared DSPE-PEG-MAL micelles by a thioester linkage (protein to micelles molar ratio of 1:1). The coupling reaction was performed overnight, in the dark at room temperature with gentle stirring. Micelles without conjugated ligand were prepared, as controls for Trf-micelles, by adding HEPES buffer to the micelles.

The remaining free MAL groups in the micelles were quenched by the addition of β mercaptoethanol at a maleimide/β mercaptoethanol molar ratio of 1:5, under stirring for 30 min at room temperature.

Encapsulation of asODN or siRNA into Liposomes and Subsequent Postinsertion of Trf-conjugates. A solution containing 13 μmol of total lipid composed of Chol/DSPC/DODAP/C16 mPEG 2000 Ceramide (45:22:25:8, mol %) in 200 μL of absolute ethanol, and a solution of 0.041 μmol of siRNA or 0.096 μmol of asODN in 300 μL of 20 mM or 300 mM citrate buffer, pH 4, were heated at 60 °C. The lipids were then slowly added under strong vortex to the siRNA or asODN solution. Upon their formation, the liposomes were extruded, 21 times, in a LipoFast mini extruder (Lipofast, Avestin, Toronto, Canada) through 100-nm-diameter polycarbonate filters (Avestin, Toronto, Canada). Then, dialysis was performed in HBS, pH 7.4, through a regenerated cellulose tubular membrane with MWCO 6000−8000 (Cellu Sep T2, Membrane Filtration Products, Inc., Seguin, TX, USA) for 3 h at room temperature to remove ethanol and raise the external pH. Subsequently, the total lipid concentration was assessed by cholesterol quantification. For this purpose, samples were added to absolute ethanol (1:6, v:v) and Infinity Cholesterol Liquid Stable Reagent (Thermo Electron; Melbourne, Australia). Absorbance was measured at 500 nm in a spectrophotometer and the concentration assessed against a cholesterol standard curve. The cholesterol quantification allowed the determination of the total lipid that remained at this stage and consequently the determination of the amount of micelles to be added.

Finally, 2 or 4 mol % (relative to the total lipid concentration) of Trf/BSA-coupled PEG-DSPE micelles or PEG-DSPE micelles without ligand was added to the liposomes. The insertion of protein−conjugates onto the liposomes was performed upon incubation in a water bath at 38 °C for 17 or 24 h, in the dark.

Purification of Liposomes. After incubation with micelles, Trf/BSA-liposomes or NT-liposomes (nontargeted liposomes) were purified by size exclusion chromatography on a Sepharose CL-4B column, using HBS, pH 7.4, as running buffer to remove external siRNA or asODN, as well as nonconjugated micelles and chemical reagents used during the liposomal preparation.

Liposome Characterization. Particle size distribution was assessed by photon correlation spectroscopy (N5 submicrometer particle size analyzer, Beckman Coulter, Miami, FL, USA). For this purpose, liposomes were diluted in filtered HBS, pH 7.4, at room temperature, so that the required signal ($(1-10) \times 10^5$ counts/s) was achieved. Measurements were made at a 90° angle and at 20 °C. The quantification of Trf or BSA associated with the liposomes was made with the BCA Protein Assay Kit (Pierce, Rochford, IL, USA) against a BSA standard curve at 570 nm in a microplate reader, Multiskan Ex (Thermo Labsystems, Vantaa, Finland).

The amount of siRNA and asODN entrapped inside liposomes was assessed by the Quant-iT RiboGreen RNA assay (Molecular Probes, Invitrogen, Karlsruhe, Germany) against a siRNA/asODN standard curve. Liposomes were dissolved upon addition of 0.6 mM of octaethylene glycol monododecyl ether ($C_{12}E_8$) and the RiboGreen fluorescence (λ_{ex} 485 nm, λ_{em} 530 nm, cutoff 515 nm) was measured using a Spectra Max Gemini EM plate reader fluorimeter (Molecular Devices, Sunnyvale, CA).

Cell Lines. K562 and LAMA-84 cells purchased from DSMZ (Braunschweig, Germany) and BJ cells, human fibroblasts, kindly provided by Paulo J. Oliveira (Center for Neurocience and Cell Biology, University of Coimbra, Coimbra, Portugal) were maintained in culture at 37 °C, 5% CO_2, under humidified atmosphere, in RPMI-1640 medium supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) (Gibco, invitrogen, California, USA), penicillin (100 U/mL), and streptomycin (100 μg/mL) (Cambrex, NJ, USA).

Cell Transfection. K562 and LAMA-84 cells (20 000 cells/well) in RPMI-1640 culture medium supplemented with 10% FBS and antibiotics were seeded in 96 round well plates. BJ cells (8000 cells/well) also in RPMI-1640 culture medium supplemented with 10% FBS and antibiotics were seeded in 96 flat well plates. Cells were transfected with Trf- or BSA-

associated liposomes or with nontargeted liposomes at 37 °C for 4 h. After incubation with liposomes, the medium was replaced with fresh medium and cells further incubated for 44 h. Following this first transfection, cell culture medium was replaced with fresh medium, and a second transfection protocol was initiated (similar formulations and same concentrations of asODN or siRNA as used in the first transfection protocol). Concerning K562 and LAMA-84 cells, immediately after adding liposomes to cells, the resulting suspension was transferred to 48-well plates. After 4 h of incubation, 800 μL of culture medium were added to each well and cells were kept in culture.

Cell Viability. Cell viability was evaluated 48 h after the second transfection, by the resazurin reduction assay (*25*). The assay measures the chemical reduction of the resazurin dye resulting from cellular metabolic activity and allows the determination of viability over the culture period without harming the cells. Briefly, 200 μL of cell suspension, double transfected as described in the previous section, was transferred to 96-well plates, and the culture medium was replaced with 10% (v/v) resazurin dye in RPMI-1640 medium without serum and antibiotics. After 2.5 h of incubation at 37 °C, the absorbance at 540 nm (reduced form) and 630 nm (oxidized form) was measured in a microplate reader Multiskan Ex (Thermo Labsystems, Vantaa, Finland). Cell viability was calculated as percentage of control cells using the equation

$$[(A_{540} - A_{630})\text{treated cells} \times 100)/(A_{540} - A_{630})\text{control cells}]$$

Western Blot. Forty-eight hours after the second transfection, cells were collected, washed twice with cold PBS, and lysed with lysis buffer [25 mM HEPES, 1 mM EGTA, 1 mM EDTA·Na_2, 2 mM $MgCl_2$, 50 mM NaF, pH 7.5, containing freshly added 200 mM PMSF, 2 mM DTT, 1 mM $NaVO_4$, 0.1% (v/v) Triton X-100 and protease inhibitors (Chymostatin, Pepstatin A, Leupeptin L, Antipain Hydrochloride) (Sigma Chemical Co., St. Louis, MO, USA)]. Concentration of protein lysates was estimated through the Bradford method (Bio-Rad Protein Assay, Bio-Rad), and equal amounts (30 μg) of protein were loaded in a 4.5% stacking, 6% resolving SDS-polyacrylamide gel. Electrophoresis was carried out at 80 V for 15 min and 110 V for approximately 30 min. Proteins were transferred to polyvinylidene difluoride (PVDF) membranes (Amersham Biosciences, UK) and incubated under stirring for 1 h at room temperature in blocking solution (TBS containing 0.1% Tween 20 and 5% dry milk). Bcr-Abl protein and actin were detected with anti c-Abl monoclonal antibody (Santa Cruz, CA, USA) and mouse antiactin monoclonal antibody (Immuno, MP Biomedicals, Ohio, USA), respectively.

Proteins were detected by chemifluorescence using an alkaline phosphatase labeled secondary antibody, antimouse IgG + IgM alkaline phosphatase linked antibody (Amersham Biosciences, UK), and the enzyme substrate ECF (Amersham Biosciences, UK) to yield a highly fluorescent product detected in a VersaDoc imaging system (Bio-Rad). The analysis of band intensity was performed using the *Quantity One* software (Bio-Rad).

qRT-PCR. Cells (20 000 cells/well) were doubled-transfected as described above. Twenty-four hours after the second transfection (72 h after beginning the treatment), cells were collected and kept at −80 °C until RNA extraction.

Frozen cellular pellets were slightly thawed at room temperature and RNA extraction performed with RNeasy Mini Kit (Quiagen, Hilden, Germany), according to the manufacture's recommendations. RNA concentration was determined by the Quant-iT RiboGreen Assay Kit (Molecular Probes, Invitrogen, Karlsruhe, Germany) using a rRNA standard curve.

cDNA synthesis was performed with SuperScript III First-Strand Synthesis SuperMix Kit for qRT-PCR (Invitrogen, Karlsruhe, Germany). For each sample, cDNA was produced from 1 μg of total RNA and the reaction was performed according to the manufacturer's instructions and the following protocol: first step, 10 min at 25 °C; second step, 30 min at 50 °C; third step, 5 min at 85 °C. Then, samples were chilled on ice and incubated with RNase H at 37 °C for 20 min in order to remove any RNA contamination.

Table 2. Sequences of Primers Used in qRT-PCR

BCR-ABL	forward primer	5′TCCGCTGACCATCAATAAGGA3′
	reverse primer	5′CACTCAGACCCTGAGGCTCAA3′
B2M	forward primer	5′GAGTATGCCTGCCGTGTG3′
	reverse primer	5′AATCCAAATGCGGCATCT3′

Polymerase chain reaction was performed in real time (qPCR) with the iQ SYBR Green Supermix Kit (Bio-Rad). The endogenous gene (housekeeping gene, hk) β-2-microglobulin (*B2M*) was used as endogenous control. The housekeeping gene and respective primers used in this work were tested and selected by the Europe Against Cancer program (*26, 27*).The sequences are presented in Table 2, and the concentrations were optimized to 150 nM for *BCR-ABL* and *B2M*.

Briefly, 5 μL of the cDNA (2.5× diluted with DNase free deionized water) obtained in the reverse transcription reaction was used to evaluate *BCR-ABL* and housekeeping genes levels. Analysis was done in 96-well PCR plates (iCycler iQ, Bio-Rad), and qPCR was performed as follows: one single cycle at 95 °C for 1.30 min, followed by 40 cycles of two steps, first step of 15 s at 95 °C, second step of 30 s at 60 °C. A melting curve was always built to demonstrate a single amplification product reaction per well. The melting curve protocol started immediately after the qPCR and consisted of 10 s heating at 55 °C, followed by 80 steps of 10 s, with a 0.5 °C increase in temperature at each step. Nontemplate controls (cDNA was replaced with water to evaluate whether qPCR reagents were contaminated with the cDNA) were always evaluated. In addition, a negative control with a *BCR-ABL* negative cell line, HL-60, was performed. The threshold cycle (C_t) values were generated automatically by the iQ5 Optical System Software. To each gene, and in each experiment, a standard curve was performed. The reaction efficiencies of all genes were between 90% and 110%, and $r^2 > 0.99$, thus allowing the use of the comparative method for mRNA level quantification, according to the following formula: $2^{-\Delta\Delta Ct \times 100}$ (where *C*t is the threshold cycle and $\Delta\Delta C$t stands for ΔCt sample − ΔCt control ⇔ (*C*t *BCR-ABL* − *C*t hk) sample − (*C*t *BCR-ABL* − *C*t hk) control).

Flow Cytometry Studies. To evaluate the extent of cell association of Trf- or BSA-associated liposomes or NT-liposomes, cells were transfected with fluorescently labeled siRNA (Cy3-siRNA) encapsulated in each one of the mentioned liposomes. Cells were seeded in RPMI-1640 culture medium (200 000 cells/well) in 48-well plates. To demonstrate that the receptor-mediated internalization is temperature-dependent, cells were incubated 1 h at 4 °C or at 37 °C, prior to liposome addition. To demonstrate that the internalization of Trf-liposomes is mediated by TrfR, this receptor was saturated by incubating the cells for 30 min with 125 μM of free holo-transferrin (dissolved in HBS, pH 7.4), as performed by others (*19, 28*). After these pretreatments, cells were incubated with the formulations under study for 4 h at 37 or 4 °C. Subsequently, cells were collected in conic tubes (BD, Biosciences), washed twice with cold PBS, and resuspended in 500 μL of cold PBS. All samples were immediately analyzed in a FACS Calibur flow cytometer (BD, Biosciences). Cy3 fluorescence was evaluated in the FL-2 channel. The data were then analyzed by *Cell Quest* software (BD). Cell association was only assessed in viable cells, these being gated based on the morphological features and on Trypan Blue staining (FL-3 channel). The cell association efficiency of each formulation was assessed by comparing the relative fluorescence units (RFU)

increase relative to nontreated cells (RFU of cells treated with the formulation under study/RFU of nontreated cells).

Confocal Microscopy Studies. In order to assess the extent of cellular internalization of the developed liposomes, confocal microscopy studies on transfected cells were performed. Cells were transfected with the formulations under study as described in the previous section. Then, cells were collected in conic tubes (BD, Biosciences), washed with cold PBS, fixed with 4% paraformaldehyde for 20 min in the dark, at room temperature, washed with cold PBS, stained with the fluorescent DNA-binding dye Hoechst 33342 (Molecular Probes, Oregon, USA) (1 μg/mL) for 5 min, in the dark, washed with cold PBS, and mounted in Mowiol mounting medium (Fluka, Sigma). Confocal images were acquired in a point scanning confocal microscope Zeiss LSM 510 Meta (Zeiss, Germany), with a 40× EC Plan-Neofluar or with a 63× Plan-Apochromat oil immersion objectives, and argon (488 nm), DPSS (561 nm), diode (405 nm), and helium−neon (633 nm) lasers. Preparations were excited at 561 nm for the Cy3 (em: >560 nm) and at 405 nm for Hoechst 33342 (em: 420−480 nm). Differential interference contrast (DIC) images were obtained using the helium−neon (633 nm) laser. Digital images were acquired using the LSM 510 Meta software. All instrumental parameters pertaining to fluorescence detection and image analyses were held constant to allow sample comparison.

Statistical Analysis. All data are presented as mean ± standard deviation (SD), and are the result of at least three independent experiments. One-way ANOVA analysis of variance combined with Tukey post-test or regular two-way ANOVA analysis of variance combined with Bonferroni post-test were used for multiple comparisons. Statistical differences are presented at probability levels of $p > 0.05$, $p < 0.05$, $p < 0.01$, and $p < 0.001$.

RESULTS

Development of Trf-Liposomes Encapsulating siRNA or asODN. Stabilized nucleic acids lipid particles (SNALP) were prepared on the basis of previous work developed by Semple et al. (*29*). SNALP is the adopted designation for siRNA encapsulation mediated by electrostatic interaction with stabilized lipid particles, whereas the ODN-containing counterpart is designated by stabilized antisense lipid particles (SALP). However, in this paper the SNALP designation was adopted for liposomes encapsulating either siRNA or asODN.

In this study, liposomes composed of Chol/DSPC/DODAP/C16 mPEG 2000 Ceramide (45:22:25:8, mol %) were used. The inclusion of 25% of the ionizable aminolipid DODAP, which has a positive net charge at pH 4, and becomes neutral at physiological pH, allows to achieve high nucleic acid encapsulation efficiencies and simultaneous obtainment of liposomes with neutral net charge (*30*). Thus, the encapsulation step is performed at pH 4, under which conditions the majority of the DODAP lipid is positively charged, forming complexes with the negatively charged asODN or siRNA at a 2/1 (±) charge ratio, resulting in high encapsulation yields. The liposome external pH is then raised to 7.4, leading to neutralization of the DODAP and consequent release of the nucleic acids bound to the liposomal external membrane surface.

The encapsulation yields obtained for both asODN and siRNA were very high (Figure 1A). Remarkably, our results demonstrated that the buffer concentration is extremely important for siRNA encapsulation, since at 20 mM of citrate buffer a 92.17 ± 1.39% encapsulation yield was achieved, whereas at 300 mM a drastic reduction of the encapsulation yield to 7.72 ± 5.29% was observed. In contrast, asODN encapsulation was independent of the buffer concentration, reaching values of approximately 100% for both 20 and 300 mM citrate buffer.

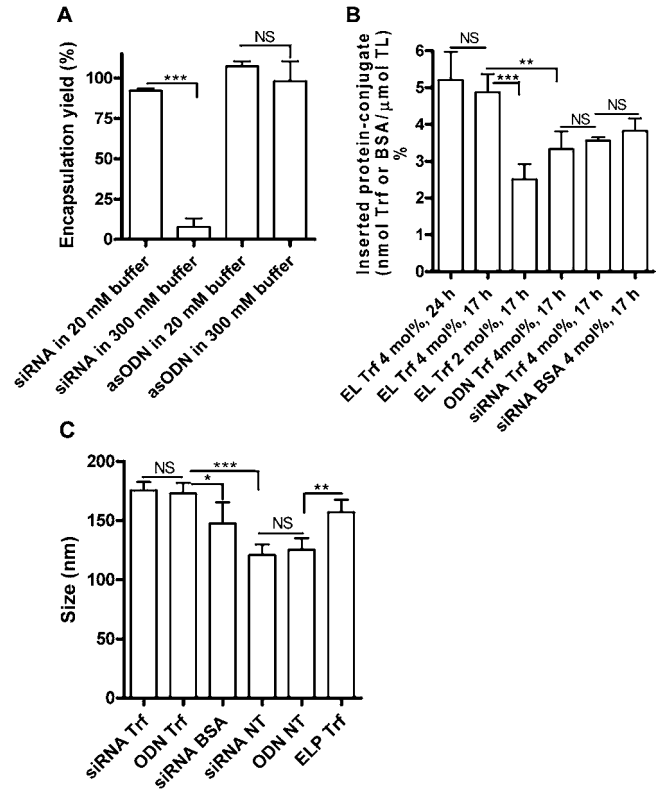

Figure 1. Physicochemical characterization of the developed liposomes. (A) Encapsulation yields: siRNA or asODN dissolved in 20 mM or 300 mM citrate buffer, pH 4, were encapsulated, as described in Experimental Procedures. The encapsulation yield was assessed by the RiboGreen assay. (B) Inserted protein−conjugate: the amount of protein−conjugate (Trf- or BSA-PEG-DSPE) inserted onto the liposomes was assessed by the BCA assay. The influence of using either 2 or 4 mol % of micelles and 17 or 24 h of incubation time, in the presence or absence of nucleic acids, on the extent of insertion of protein−conjugates onto preformed liposomes was evaluated. The tested conditions were as follows: empty liposomes incubated with 4 mol % Trf-micelles for 24 h (EL Trf 4 mol %, 24 h) or 17 h (EL Trf 4 mol %, 17 h); empty liposomes incubated with 2 mol % of Trf-micelles for 17 h (EL Trf 2 mol %, 17 h); liposomes encapsulating siRNA incubated for 17 h with 4 mol % BSA-micelles (siRNA BSA 4 mol %, 17 h) or with 4 mol % Trf-micelles (siRNA Trf 4 mol %, 17 h); and liposomes entrapping asODN incubated for 17 h with 4 mol % of Trf-micelles (ODN Trf 4 mol %, 17 h). (C) Liposome particle size: Particle size distribution of the Trf- or BSA-coupled liposomes encapsulating siRNA (siRNA Trf and siRNA BSA, respectively), Trf-coupled liposomes encapsulating asODN (ODN Trf), nontargeted liposomes encapsulating siRNA or asODN (siRNA NT and ODN NT, respectively), or Trf-coupled liposomes without nucleic acids (ELP Trf) were analyzed by photon correlation spectroscopy. One-way ANOVA analysis of variance combined with Tukey post-test was performed. NS $p > 0.05$, *$p < 0.05$, **$p < 0.01$, and *** $p < 0.001$.

The attachment of Trf or BSA to the liposomal surface was performed by postinsertion of Trf/BSA-coupled PEG_{2000}-DSPE conjugates (in a micellar form) into preformed liposomes, as described in Experimental Procedures. The influence of the incubation time and the percentage of micelles added to the liposomes on the amount of inserted protein−conjugate onto the liposomes was evaluated. As can be observed in Figure 1B, there is no advantage to prolonging the incubation time beyond 17 h, as no enhancement on the amount of inserted protein−conjugate is achieved (for 4 mol % of micelles). In contrast, the percentage of micelles incubated with the liposomes significantly affects the amount of inserted protein−conjugate. In fact, when preformed liposomes were incubated with 4 mol % of micelles, a value of 4.88 ± 0.49 nmol Trf/μmol total lipid (TL) was obtained, whereas incubation of preformed liposomes

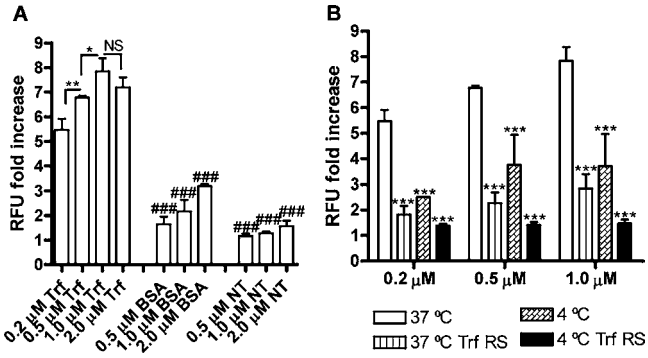

Figure 2. Extent of association of Trf-coupled liposomes loaded with Cy3-siRNA to LAMA-84 cells. (A) Cells were incubated at 37 °C for 4 h with different concentrations of Trf-coupled liposomes encapsulating 0.2−2.0 μM Cy3-siRNA (0.2−2.0 μM Trf), BSA-coupled liposomes encapsulating 0.5−2.0 μM Cy3-siRNA (0.5−2.0 μM BSA), or nontargeted liposomes encapsulating 0.5−2.0 μM Cy3-siRNA (0.5−2.0 μM NT). (B) Cells were incubated with different concentrations of Trf-liposomes loading Cy3-siRNA at 37 °C in the presence (37 °C Trf RS) or absence (37 °C) of an excess of free Trf or incubated at 4 °C in the presence (4 °C Trf RS) or absence (4 °C) of free Trf. The fluorescence of the Cy3-siRNA associated to LAMA-84 cells was assessed by flow cytometry. (A) One-way ANOVA analysis of variance combined with Tukey post-test and (B) regular two-way ANOVA analysis of variance combined with Bonferroni post-test for multiple comparisons were used. ***$p < 0.001$, **$p < 0.01$, *$p < 0.05$, and NS $p > 0.05$ when the comparison was established between the conditions indicated by the lines (A) or when comparison was established with cells treated at 37 °C in the absence of free Trf (B). ###$p < 0.001$ when the comparison was established with the corresponding concentration of siRNA encapsulated in Trf-liposomes (A).

with 2 mol % resulted only in 2.51 ± 0.41 nmol Trf/μmol TL. It was also observed that the postinsertion of Trf or BSA micelles is more efficient in empty liposomes (4.88 ± 0.49 nmol Trf/μmol TL) than in liposomes containing nucleic acids (3.55 ± 0.10 nmol Trf/μmol TL) and that Trf- and BSA-PEG-DSPE conjugates are transferred with the same efficiency by postinsertion.

Results obtained from photon correlation spectroscopy revealed that the size of all developed formulations is under 200 nm (Figure 1C) with a polydispersion index below 0.3 (data not shown), which indicates that liposomes exhibit a narrow particle size distribution. We also observed that, six months after liposome preparation, the size and polydispersion index did not change (data not shown), indicating a good stability of the formulations over time. As expected, the insertion of protein−conjugates onto the liposome surface slightly enhances liposomal size: Trf- (siRNA Trf) or BSA- (siRNA BSA) coupled liposomes encapsulating siRNA exhibit 175.5 ± 7.28 nm and 147.65 ± 17.81 nm, respectively, and NT-liposomes containing siRNA (siRNA NT) present 121.03 ± 8.83 nm. No differences in the particle size of liposome encapsulating siRNA or asODN were observed. The extent of protection conferred by the liposomal formulations to the encapsulated nucleic acids against the nuclease degradation was assessed. For this purpose, liposomes encapsulating siRNA or asODN were incubated with Quant-iT RiboGreen RNA reagent in the presence or absence of the surfactant $C_{12}E_8$. In the absence of the surfactant, the extent of the interaction between the probe and the nucleic acids is reduced to approximately 90%, indicating that these formulations confer a high degree of protection against nuclease degradation (data not shown).

Cell Association of Trf-Liposomes Is Specifically Mediated by Trf Receptor. The extent of association of liposomes bearing Trf or BSA attached at the end of PEG chains or of NT-liposomes, encapsulating Cy3-labeled siRNA, to LAMA-84 cells was assessed by flow cytometry. As can be observed in Figure 2A, the presence of Trf attached to the end of PEG-grafted lipids is the main thing responsible for the observed extent of liposome−cell association. Cells incubated with BSA-liposomes or NT-liposomes revealed no significant cell association, illustrated by the low increase of the fluorescence intensity of the transfected cells as compared to nontreated cells. As can be observed, the RFU fold increase for cells treated with 2.0 μM siRNA encapsulated in Trf-liposomes (2.0 μM siRNA Trf) was 7.20 ± 0.40, in contrast to 3.20 ± 0.07 and 1.57 ± 0.22 fold increase observed upon treatment of the cells with BSA-liposomes and NT-liposomes, respectively. Our results also indicate that the extent of cell association of Trf-coupled liposomes containing Cy3-siRNA is dependent on the lipid concentration incubated with the cells up to 0.34 mM of total lipid, which corresponds to 1.0 μM siRNA, since no significant difference on the RFU of cells treated with 1.0 μM or 2.0 μM siRNA encapsulated in Trf-liposomes was observed.

To clearly demonstrate that the ligand Trf coupled at the surface of the liposomes triggers their cell internalization through theTrfR, competitive inhibition studies were performed. Cells were incubated with 125 μM of free human holo-Trf to block the TrfR. As illustrated in Figure 2B, a drastic decrease of cell association of Trf-liposomes for all tested concentrations was observed. At 1.0 μM siRNA and incubation at 37 °C, the observed RFU was 7.84 ± 0.54, whereas with presaturation of the Trf receptor, the RFU decreased to 2.85 ± 0.54. The effect of the temperature on the extent of liposome−cell association was examined through the incubation of tumor cells with Trf-liposomes at 4 and 37 °C. As expected, incubation at 4 °C resulted in a significant reduction of the extent of liposome−cell association as compared to the incubation at 37 °C (at 1.0 μM siRNA, the RFU was reduced from 7.84 ± 0.54 to 3.72 ± 1.25). It was also observed that Trf receptor saturation performed at 4 °C resulted in the highest reduction observed for the extent of cellular association, with a RFU of 1.48 ± 0.15, indicating that binding of the liposomes to the cell surface is also affected by the saturation of TrfR.

The results of liposome−cell association obtained with Trf-, BSA-, or NT-liposomes encapsulating FAM-asODN were very similar to those obtained with correspondent counterparts containing Cy3-siRNA, suggesting that the association process is not dependent on the nature of the encapsulated nucleic acid (data not shown).

Cell Internalization of Trf-Liposomes Is Specifically Mediated by Trf Receptor. In order to gain further insights into the pathway of cell internalization of the developed formulations, confocal microscopy studies were performed (Figure 3). Upon incubation of the cells with liposomes, at 37 °C, cell internalization of Cy3-siRNA was only detected for the cells incubated with Trf-liposomes (Figure 3A,F). For BSA-(Figure 3B) or NT-liposomes (Figure 3C), no Cy3-siRNA inside the cells was observed. This same observation was registered upon saturation of the Trf receptor at 37 °C (Figure 3D) or upon treatment of the cells at 4 °C (Figure 3E).

The results obtained for cell internalization of liposomes encapsulating FAM-asODN were very similar to those obtained for Cy3-siRNA encapsulated into liposomes (data not shown). Therefore, altogether our results indicate that cell association and internalization of the developed formulations occur via temperature- and Trf receptor-dependent mechanisms.

Cytotoxicity Mediated by TrfR-Targeted Liposomes Encapsulating anti-*BCR-ABL* siRNA or asODN. In order to assess the biological activity of the developed formulations, toxicity in two leukemia cells lines, LAMA-84 and K562 cells, and in a nonmalignant cell line, BJ cells (human fibroblasts), was evaluated by the resazurin reduction method (Figure 4). As can be observed in Figure 4A, for LAMA-84 cells the nontargeted liposomes and the BSA-coupled liposomes do not

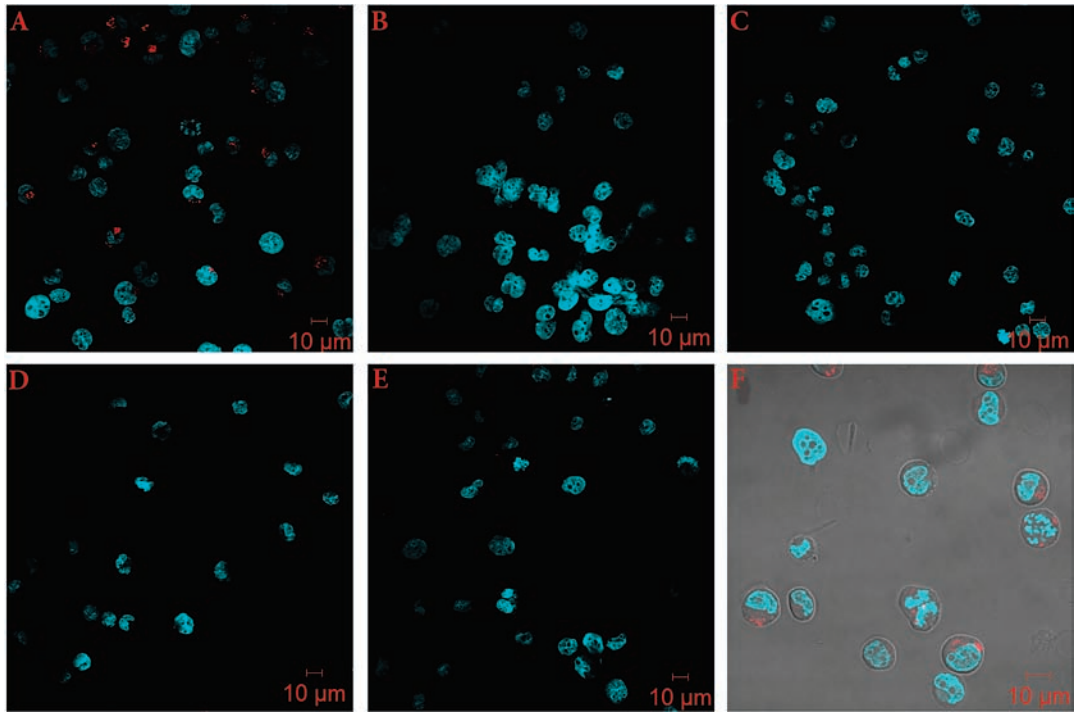

Figure 3. Confocal microscopy images from studies performed in LAMA-84 cells incubated with Trf-coupled liposomes loaded with Cy3-siRNA. Cells were incubated for 4 h, at 37 °C, with 1 μM of Cy3-siRNA encapsulated in (A,F) Trf-coupled liposomes, (B) BSA-coupled liposomes, (C) NT-liposomes, or (D) Trf-coupled liposomes in the presence of an excess of free Trf. (E) LAMA-84 cells incubated with Trf-coupled liposomes at 4 °C. Confocal images were acquired in a point scanning confocal microscope Zeiss LSM 510 Meta (Zeiss, Germany), (A−E) with a 40× EC Plan-Neofluar. (F) Differential interference contrast (DIC) images were taken with a 63× Plan-Apochromat oil immersion objectives.

cause significant effects on the cell viability. In contrast, Trf-liposomes encapsulating specific siRNA anti-*BCR-ABL* led to dose-dependent cytotoxicity, reaching, for example, a cell viability of 46.97 ± 2.73%, upon incubation with 2 μM siRNA. Sequence specificity was not proven for the entire range of concentrations tested, since the scrambled one also significantly decreased cell viability (57.93 ± 9.73% at 2 μM).

In order to validate the results obtained with LAMA-84 cells, Trf-liposomes and BSA-liposomes were tested in K562 cells, whose *BCR-ABL* mRNA levels are 1.72-fold higher than LAMA-84 cells, as assessed by qRT-PCR (data not shown). In addition, TrfR levels of LAMA-84 cells are 15.68-fold higher than K562 cells, as assessed by CD71 measurement using flow cytometry (data not shown). As observed for LAMA-84 cells, the BSA-liposomes promote much lower toxicity than Trf-liposomes on K562 cells (Figure 4B). Treatment of K562 cells with Trf-liposomes resulted in higher extent of cytotoxicity as compared to LAMA-84 cells. For K562 cells, the off-target effects, evaluated by the cytotoxicity promoted by the scrambled siRNA, are lower than those observed for LAMA-84 cells. Concerning the nonmalignant BJ cells, which have no *BCR-ABL* oncogene, Trf- or BSA-liposomes encapsulating anti-*BCR-ABL* siRNA at the tested concentrations led to very low cytotoxicity.

As illustrated in Figure 4C, the observed toxicity effect of liposomes loaded with asODN against LAMA-84 cells reinforced the results obtained with siRNA-loaded liposomes. As can be observed, the cytotoxicity promoted by Trf-liposomes is dependent on the asODN dose. However, off-target cytotoxic effects mediated by the scrambled asODN were observed at a certain extent (70.38 ± 3.077 of cell viability for 2.0 μM). In addition, nontargeted liposomes (2.0 μM specific NT) or empty TrfR-targeted liposomes (2.0 μM ELP Trf) at the same lipid concentration as the one used to treat cells with 2.0 μM asODN-containing Trf-liposomes do not induce cytotoxicity.

***BCR-ABL* mRNA Knockdown Mediated by TrfR-Targeted Liposomes Encapsulating anti-*BCR-ABL* siRNA or asODN.** To evaluate the *BCR-ABL* knockdown efficiency of the liposomes encapsulating anti-*BCR-ABL* siRNA or anti-*BCR-ABL* asODN, *BCR-ABL* mRNA levels were analyzed in LAMA-84 cells double-transfected with the formulations under study. It was observed that only the liposomes encapsulating asODN or siRNA targeted to the TrfR were able to reduce the *BCR-ABL* mRNA levels. Regarding the Trf-liposomes encapsulating siRNA (Figure 5A), the observed silencing effect is dependent on the siRNA concentration up to 1 μM (59.81 ± 2.90%) without significant differences between 1 and 2 μM. For the Trf-liposomes loading asODN (Figure 5B), a higher dose was required (double) to obtain the same *BCR-ABL* knockdown achieved by Trf-liposomes loading siRNA molecules, where a significant reduction on the *BCR-ABL* mRNA levels (64.32 ± 9.0%) was only observed at 2.0 μM asODN. The observed *BCR-ABL* mRNA knockdown can be considered sequence-specific for both gene silencing molecules, since no significant reduction in the mRNA levels was observed with the scrambled sequences at the tested concentrations.

Bcr-Abl Protein Levels upon Treatment with TrfR-Targeted Liposomes Encapsulating anti-*BCR-ABL* siRNA or asODN. To evaluate the impact of *BCR-ABL* mRNA knockdown mediated by anti-*BCR-ABL* siRNA and by anti-*BCR-ABL* asODN on the oncoprotein levels, Western blot of LAMA-84 cells double-transfected with liposomes encapsulating siRNA (Figure 6A) or asODN (Figure 6B,C) was performed. As expected, no effect on the oncoprotein levels was observed upon treatment of the cells with nontargeted liposomes. On the other hand, Trf-liposomes encapsulating specific siRNA promoted a reduction in the oncoprotein levels. This effect was dose-dependent up to 1 μM (60.54 ± 12.35), since no further reduction was observed when 2 μM siRNA encapsulated in Trf-liposomes was added to the cells (Figure 6A). Our results also indicate that the protein knockdown

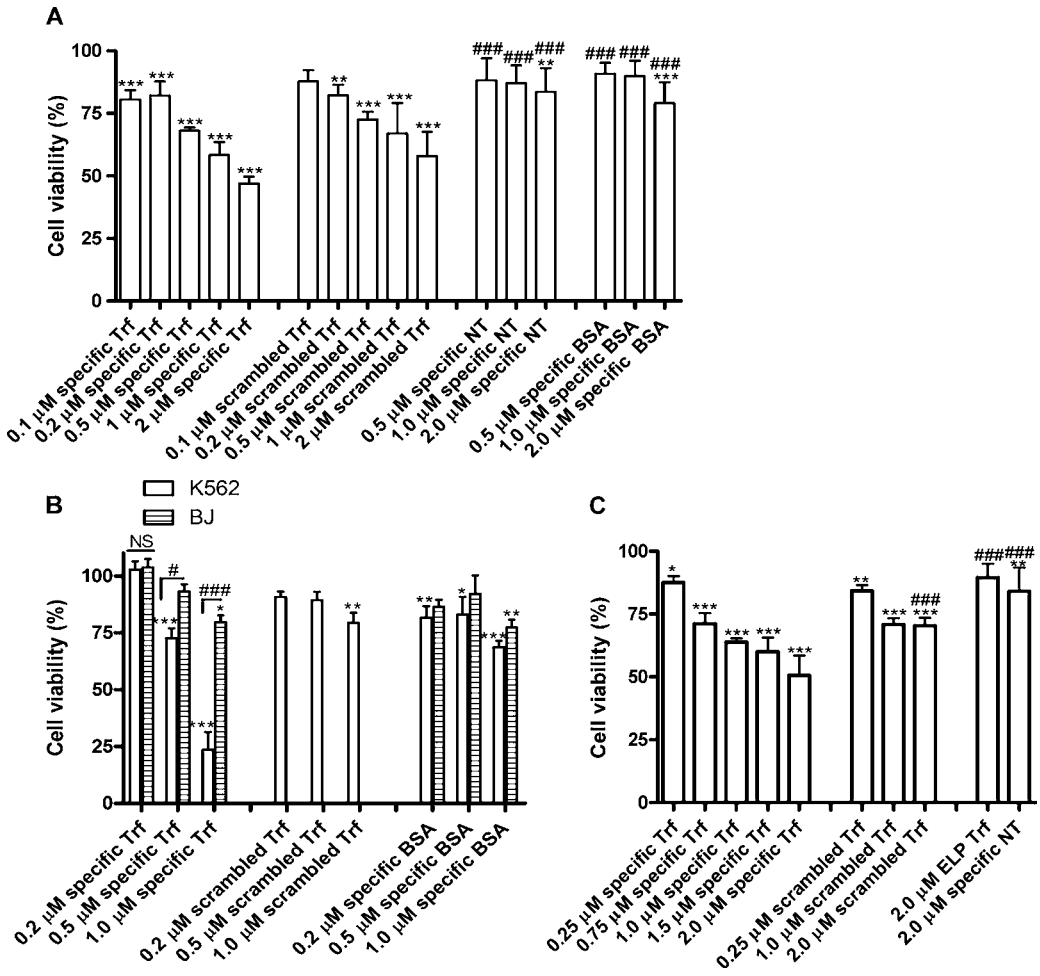

Figure 4. Cell viability upon two transfections with Trf-coupled liposomes loading anti-*BCR-ABL* siRNA or anti-*BCR-ABL* asODN. (A) LAMA-84, (B) K562, and BJ cells were incubated with different concentrations of specific or scrambled anti-*BCR-ABL* siRNA encapsulated in Trf-liposomes, BSA-liposomes, or NT-liposomes. (C) LAMA-84 cells were double-treated with specific or scrambled anti-*BCR-ABL* asODN encapsulated in Trf-liposomes or in NT-liposomes, as well as with empty Trf-liposomes (ELP Trf). Cell viability was assessed 48 h after the second transfection by the resazurin reduction method. (A,C) One-way ANOVA analysis of variance combined with Tukey post-test and (B) regular two-way ANOVA analysis of variance combined with Bonferroni post-test were used for multiple comparisons. ***$p < 0.001$; **$p < 0.01$; *$p < 0.05$, and no symbol $p > 0.05$ when comparison was established with nontreated cells; ###$p < 0.001$; #$p < 0.05$, and NS $p > 0.05$ comparison established with the corresponding concentration of specific siRNA/asODN encapsulated in Trf-liposomes (A,C) or comparison established between the conditions indicated by the lines (B).

is sequence-specific up to 1 μM, since the scrambled sequence did not promote any effect up to that concentration. However, for the highest concentration tested (2 μM), a significant reduction in the oncoprotein levels was observed (66.78 $\pm$ 13.13%) when cells were tested with scrambled sequence encapsulated in TrfR-targeted liposomes. Thus, at this concentration the protein knockdown cannot be considered sequence-specific. Concerning Trf-liposomes loaded with asODN (Figure 6B,C), the promoted effect by the specific asODN is dose-dependent for all tested concentrations. However, similarly to what was observed for siRNA, also off-target effects were observed upon treatment of the cells with 2 μM scrambled asODN loaded in TrfR-targeted liposomes.

Nevertheless, it should be emphasized that, independently of the sequence specificity of the siRNA/asODN molecules, reduction in the levels of Bcr-Abl protein is dependent on the cellular targeting specificity. As a matter of fact, in contrast to what was observed to the TrfR-targeted liposomes, no effect on the levels of protein was observed when cells were treated with 2 μM of specific siRNA or asODN encapsulated in BSA-coupled liposomes or nontargeted liposomes.

DISCUSSION

Gene silencing tools, such as siRNA and asODN, play an important role in therapeutic and fundamental research. However, these molecules have important limitations related to stability and pharmacokinetics. To circumvent these limitations, many approaches such as the use of delivery systems and chemical modifications of the nucleic acids have been tested. In fact, several strategies have been described referencing the design of chemically modified siRNA or asODN molecules less susceptible to nuclease degradation and less prone to immune system activation (*8, 10, 13, 31*). However, some of the major problems of these molecules are not overcome with these modifications, such as the poor pharmacokinetics, the unfavorable biodistribution throughout the body, and the inability to target specific diseased tissues or cells, like cancer cells. Therefore, the successful clinical application of gene silencing approaches is dependent on the development of effective delivery systems such as liposomes, capable of solving these issues by protecting the encapsulated molecules from nuclease degradation, conferring long circulation times in the bloodstream and with the ability to deliver the carried molecules to target cells through interaction with cell surface receptors.

The aim of this work was to encapsulate siRNA or asODN molecules, designed to specifically silence *BCR-ABL* mRNA, in liposomes targeted to the Trf receptor of leukemia cells. The encapsulation of anionic siRNA and asODN in the aqueous space of lipid vesicles by a passive encapsulation method leads

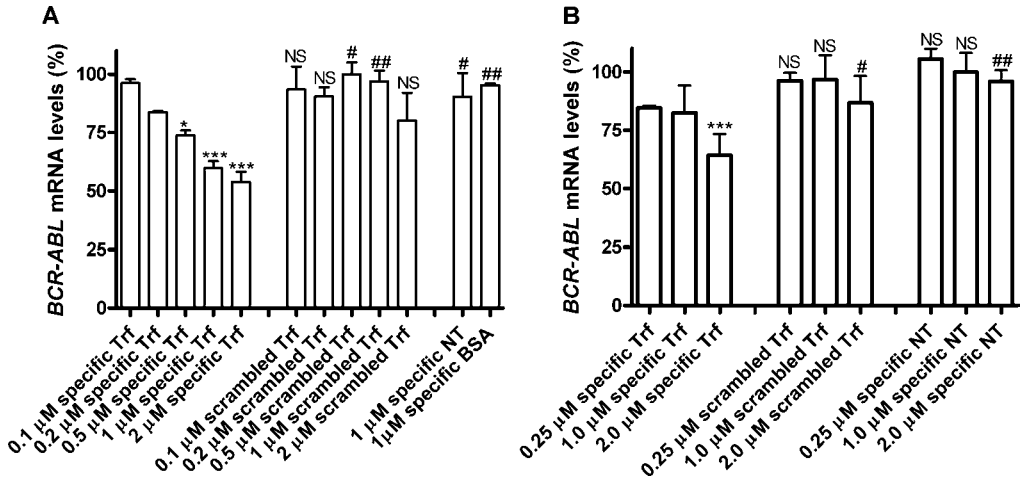

Figure 5. *BCR-ABL* mRNA levels in LAMA-84 cells upon treatment with anti-*BCR-ABL* siRNA or anti-*BCR-ABL* asODN. (A) LAMA-84 cells were double-transfected with different concentrations of specific or scrambled anti-*BCR-ABL* siRNA or (B) anti-*BCR-ABL* asODN, encapsulated in Trf-liposomes (Trf), BSA-liposomes (BSA), or NT-liposomes (NT). *BCR-ABL* mRNA levels of treated samples were evaluated as compared to those of nontreated cells, and were normalized against *B2M* housekeeping gene. Detection was performed by qRT-PCR, as described in Experimental Procedures. One-way ANOVA analysis of variance combined with Tukey post-test was used for multiple comparisons. ***$p < 0.001$, *$p < 0.05$, and no symbol $p > 0.05$ when comparison was established with nontreated cells; #$p < 0.05$, ##$p < 0.01$, and NS $p > 0.05$ when comparison was established with the corresponding concentration of specific siRNA/asODN encapsulated in Trf-liposomes.

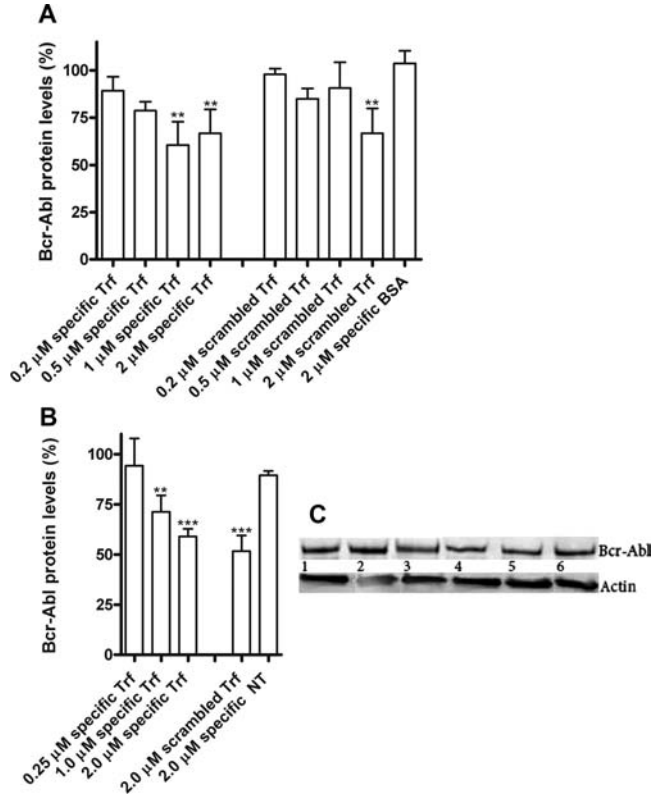

Figure 6. Bcr-Abl protein levels in LAMA-84 cells double-transfected with anti-*BCR-ABL* siRNA or anti-*BCR-ABL* asODN encapsulated in TrfR-targeted liposomes. (A) LAMA-84 cells were double-transfected with different concentrations of specific or scrambled anti-*BCR-ABL* siRNA or (B,C) different concentrations of specific or scrambled anti-*BCR-ABL* asODN encapsulated in Trf-liposomes, BSA-liposomes, or NT-liposomes. Cells were collected 48 h after the second transfection for evaluation of Bcr-Abl protein levels by Western blot. One-way ANOVA analysis of variance combined with Tukey post-test was used for multiple comparisons. ***$p < 0.001$, **$p < 0.01$, and no symbol $p > 0.05$ when comparison was established with nontreated cells. (C) is a representative Western blot result of LAMA-84 cells treated with anti-*BCR-ABL* asODN; lane 1, sample of nontreated cells; lane 2, cells treated with 2.0 μM of specific asODN encapsulated in NT-liposomes; lane 3, cells treated with 2.0 μM scrambled asODN encapsulated in Trf-liposomes; lanes 4, 5, and 6, cells treated with 2.0, 1.0, and 0.25 μM specifc asODN encapsulated in Trf-liposomes, respectively.

to very low encapsulation efficiencies and consequently to a tremendous waste of nucleic acids. Cationic liposomes, which form lipoplexes with the nucleic acids, can mediate reasonable levels of transfection *in vitro* without wasting nucleic acids during lipoplex preparation. However, their *in vivo* application is limited by their large size and net positive charge, which triggers rapid clearance from the blood circulation. In addition, lipoplexes are not tissue-specific, being mainly distributed into lung, liver, and spleen, and very often exhibit toxicity (*32–34*). Moreover, from the formulation point of view, lipoplexes are

thermodynamically unstable and display a tendency to form larger aggregates over time (*14, 35, 36*).

Semple et al. developed a new method to encapsulate asODN, leading to the so-called stabilized antisense lipid particles (SALP) (*29*). These authors demonstrated that the addition of lipids dissolved in ethanol to an aqueous solution of asODN resulted in the formation of small multilamellar liposomes encapsulating the asODN with a very good encapsulation yield. Thus, in this work we have explored this method to carry out asODN encapsulation and assessed whether by performing some modifications it could be applied as well to siRNA encapsulation. This nucleic acid entrapment process is based on the spontaneous electrostatic interaction with cationic liposomes together with the membrane destabilizing effect of ethanol and with the inclusion of PEG-derivatized lipids, which allows control of liposome size to avoid aggregation.

Thus, the high encapsulation yields achieved in this work, for both asODN and siRNA, are mainly attributed to the inclusion of the ionizable cationic lipid DODAP, which is positively charged at pH 4 and consequently able to complex anionic nucleic acids through electrostatic interactions. In our hands, yields of encapsulations of close to 100% were obtained. These high encapsulation yields were also reported by others using SALP for asODN encapsulation in a liposomal formulation similar to that used in this work (*29*) or for siRNA encapsulation in a different liposomal formulation (*37*).

Concerning the encapsulation process, our results clearly demonstrate that the major difference between siRNA and asODN encapsulation efficiency is in the significant impact of the citrate buffer concentration. As previously described, very low encapsulation yields of siRNA were observed when using 300 mM citrate buffer as opposed to 20 mM. In contrast, for asODN molecules both 300 mM and 20 mM allowed high encapsulation yields. These encapsulation yields can be explained by the different role of salt and buffer concentrations in the encapsulation of nucleic acid molecules, depending on their chemical characteristics. Indeed, as reported previously, concerning the phosphodiesters, as the siRNA molecules used in this work, the use of citrate buffers at 20 mM will be required to facilitate efficient charge interactions between DODAP and the nucleic acid, since at higher buffer concentration, these charge interactions are shielded, resulting in very low encapsulation yields (*38–40*). On the other hand, phosphorothioate nucleic acids, as the asODN molecules used in this work, bind strongly to cationic molecules, and therefore, the encapsulation efficiency is much less sensitive to the differences in the buffer and salt concentrations.

The covalent attachment of a protein to the liposome surface can be performed by active or passive coupling methods (*41*). However, as the maleimide group of derivatized lipids used for coupling the protein to the lipid is susceptible to hydrolysis, forming ring-opened maleamic acids which are unreactive (*41*), the implementation of coupling methods that allow a fast reaction of the maleimide function with the thiol functionalized protein is mandatory. Indeed, it has been demonstrated that the postinsertion method (passive coupling method) allows higher levels of protein coupling as compared to the active method (*41*). Thus, in this work, the postinsertion coupling method was selected. Trf and BSA coupled at the terminus of MAL-PEG-derivatized lipids, organized in a micellar form, were transferred into preformed liposomes encapsulating nucleic acids. It has been reported that postinsertion occurs in a temperature- and time-dependent manner (*24, 42, 43*) and frequently is performed close to the phase transition temperature (T_c) of the membrane-forming lipids. However, in this work, the postinsertion was performed for 17 or 24 h at 38 °C, which is below the T_c of the membrane forming lipid DSPC (55 °C), in an attempt to prevent transferrin denaturation observed at temperatures close to 55 °C. As a consequence of the low temperature used for the postinsertion, the obtained yields of protein−conjugate inserted onto the liposomal surface were very low (12.18 ± 1.23% for empty liposomes and 8.9 ± 0.24% for siRNA-encapsulating liposomes; data not shown). Another possible explanation for the low transfer yield is the high amount of PEG-Cer lipid existing in the preformed liposomes (8 mol %), which was reported to decrease the postinsertion efficacy (*41, 43*). Under these circumstances, prolonging the transfer time beyond 17 h did not improve the postinsertion yield. In addition, the incubation of 4 mol % instead of 2 mol % of protein-containing micelles led to a higher amount of protein coupled to liposomes, although the postinsertion yield was not enhanced. To the best of our knowledge, this is the first work establishing a correlation between the effect of transfer time (17 and 24 h) and content of Trf-micelles (2 and 4 mol %) added to the liposomes, and the amount of protein−conjugate transferred onto the liposome surface. Our results also indicate that the amount of protein transferred onto the liposomes is similar for both BSA and Trf, and therefore, BSA-liposomes are good control formulations for targeting specificity studies. The yield and the amount of protein−conjugate transferred are significantly higher for empty liposomes as compared to nucleic acid-loaded liposomes. A possible explanation is that loaded liposomes have more rigid lipid membranes and therefore are less prone to the insertion of protein−conjugates into the preformed liposomes, through replacement of pre-existing PEG-lipids (*41*).

Concerning the size of the liposomes, and similarly to what was previously reported (*19*), insertion of Trf or BSA protein−conjugates onto liposomes leads to a significant increase of particle size. A higher size enhancement was observed following Trf coupling as compared to BSA, which can be explained by the different molecular weight of these proteins (Trf ∼ 80 kDa and BSA ∼ 66 kDa). Nevertheless, it should be emphasized that all developed formulations exhibit sizes below 200 nm, with homogeneous particle size distribution (PI smaller than 0.3) and without aggregation during the six month period of observation upon storage at 4 °C. Thus, this liposome preparation method allowed the production of liposomes with reproducible protein/lipid ratio, high levels of nucleic acid encapsulation, and interesting shelf life properties. Therefore, it can be concluded that, from a production point of view, this technology allowed us to produce sophisticated formulations in a quite simple and reproducible way with a very good accuracy.

Results from targeting specificity and competitive inhibition studies clearly indicate that BSA- and NT-liposomes have no ability to promote the delivery of the encapsulated nucleic acids. Additionally, when TrfR was saturated and the temperature was decreased to 4 °C, the extent of cell association and internalization of Trf-liposomes was drastically reduced, clearly demonstrating that internalization of Trf-liposomes is mainly mediated by the TrfR at the cell surface.

The molecular and cellular effects promoted by the developed formulations on leukemia cells (LAMA-84 and K562) and on a nonmalignant cell line (BJ) were assessed. As expected, only Trf-liposomes encapsulating anti-*BCR-ABL* siRNA or asODN were able to promote modifications on *BCR-ABL* mRNA and oncoprotein Bcr-Abl levels, as well as on cell viability. Indeed, the advantage of targeted liposomes as compared to nontargeted liposomes concerning the intracellular delivery and consequently the biological activity of the delivered nucleic acids has been reported (*19, 44*). A dose-dependent cytotoxicity for both anti-*BCR-ABL* siRNA and asODN when delivered by Trf-liposomes was observed. Nevertheless, off-target effects mediated by scrambled sequences were also observed to a certain extent,

namely, for the highest concentration tested. The Trf-liposomes encapsulating anti-*BCR-ABL* siRNA or asODN were effective in decreasing viability in both leukemia cell lines tested, without significant effect on the nonmalignant cell line BJ that does not present the *BCR-ABL* translocation.

Our results from qRT-PCR indicated that the *BCR-ABL* mRNA downregulation was only possible when siRNA or asODN were delivered by Trf-liposomes. The anti-*BCR-ABL* siRNA led to more efficient reduction of mRNA levels as compared to the anti-*BCR-ABL* asODN, since siRNA promoted the same extent of gene silencing with lower concentrations. Both siRNA- and asODN-mediated *BCR-ABL* mRNA knockdown were sequence-specific at the tested concentrations.

At the protein level, Trf-liposomes encapsulating siRNA led to dose-dependent reduction of Bcr-Abl levels up to 1 μM, beyond which (at 2 μM siRNA) significant off-target effects were observed. Therefore, 2 μM of siRNA had no advantage since the slight enhancement in cytotoxicity, as compared to that observed for 1 μM concentration, is in part attributed to the enhancement of the off-target effects at the protein level. Thus, as previously reported by others (*45–47*), siRNA molecules mediate dose-dependent off-target effects. Therefore, it is possible that above a certain concentration (1 μM) siRNA molecules can knockdown proteins (including Bcr-Abl) by nonspecific mechanisms. This off-target effect observed at the 2 μM concentration was also observed for asODN molecules. Similarly to what was observed for *BCR-ABL* mRNA, at the Bcr-Abl protein level siRNA are more potent gene silencing tools than asODN, since 2 μM asODN was required to achieve the same extent of protein knockdown as 1 μM siRNA. This higher potency of siRNA as compared to asODN has been reported by other authors (*44, 48*) and is in agreement with our previous results (unpublished data). In contrast to the specificity observed at the mRNA level, off-target effects at 2 μM were observed for both siRNA and asODN molecules regarding protein knockdown. These findings suggest that the siRNA and asODN molecules are capable of interacting nonspecifically with the Bcr-Abl protein. In fact, it has been previously reported that both siRNA and asODN molecules can promote off-target effects even when the sequences are designed to have no physiological target (*49–51*). In addition, it was demonstrated that these molecules can act at the protein level without affecting the mRNA levels (*45, 51*), acting as aptamers (nucleic acids with the ability of interfering directly with protein, further leading to its degradation). Therefore, the cytotoxicity caused by off-target effects mediated by Trf-liposomes encapsulating scrambled siRNA or scrambled asODN, at the 2 μM concentration, is not caused by interference at the *BCR-ABL* mRNA level, but rather by unspecific interaction with Bcr-Abl protein and probably also with other proteins. Moreover, the possibility of siRNA scrambled sequences acting as a microRNA should not be excluded (*52*), and consequently, some of the off-target effects observed for the scrambled sequences at 2 μM concentration may result from off-target mRNA translation inhibition mediated by siRNA through mechanisms similar to those described for microRNA. Therefore, the assessment of the extent of off-target effects triggered by siRNA and asODN molecules is a very difficult task. In fact, it has been reported that some of the observed effects mediated by siRNA are siRNA sequence-specific rather than target-specific (*53*). Moreover, it has been demonstrated that some of the sequences most widely used as controls for siRNA off-target effects, such as the siRNA against GFP, deregulates endogenous genes (*49*). Therefore, it seems that off-target effects constitute a well-established limitation of this gene silencing approach, and consequently, caution should be employed in the interpretation of the results.

In conclusion, the developed liposomes exhibited excellent features in terms of asODN and siRNA encapsulating efficiency, particle size, stability over time, and reproducibility of manufacturing. Results from studies in LAMA-84 and K562 cells clearly demonstrated that cell association and internalization of Trf-liposomes are mediated by the TrfR and a notorious *BCR-ABL* mRNA and Bcr-Abl protein down-regulation leading to significant toxicity in leukemia cells. These results illustrate the importance of combining molecular and cellular targeting as a valuable approach for cancer treatment. Further *in vivo* studies are required to assess the clinical potential of the developed formulations for the treatment of CML.

Received September 11, 2009; Revised Manuscript Received November 12, 2009

Aptamers are known for their short *in vivo* circulating half-life and rapid renal clearance. Their conjugation to poly(ethylene glycol) (PEG) is a way to improve their residence in the body. Two aptamers (AptD and AptF), having a disulfide protected thiol modification on the 3′ end, have been conjugated to maleimide activated PEGs of various molecular weights and structures (linear PEG20; branched PEG20 and 40; PolyPEG17, 40, and 60 kDa). The high yield coupling (70−80% in most of the cases) could be achieved using immobilized *tris*[2-carboxyethyl]phosphine hydrochloride (TCEP) as reducing agent at pH 4. The affinity of PEGylated AptD for its target was reduced by conjugation to linear PEG20 and branched PEG40, but not to branched PEG20 and PolyPEGs. This work demonstrates an alternative approach to PEGylation of aptamers, and that the effect of PEG on the affinity for the target varies according to the structure and conformation of the synthetic polymer.

INTRODUCTION

Aptamers are nucleic acid-based molecules (usually 8−15 kDa) that can selectively bind to almost any target such as extracellular proteins, peptides, enzymes, and small molecules. Aptamers can be selected using the systematic evolution of ligands by exponential enrichment (SELEX) method from libraries of oligonucleotides having random sequences. Moreover, they have shown low toxicity and immunogenicity. These characteristics make aptamers interesting and potentially powerful molecules for targeted therapy (*1*−*4*). Since aptamers are small and highly charged molecules, they are subject to rapid renal elimination, resulting in a short *in vivo* half-life. Conjugation to synthetic polymers such as poly(ethylene glycol) (PEG) is frequently used in order to improve the performance of biomolecules as therapeutics (*5*−*11*). The increase of the hydrodynamic volume/molecular weight of aptamers above the renal filtration cutoff, achievable by PEGylation, can overcome this potential limitation (*12, 13*). PEG shows low toxicity, nonimmunogenicity, and high solubility in water and is commercially available in various configurations (linear, branched, or comb-shaped) and molecular weights and with a large variety of terminal functional groups suitable for conjugation (*14*−*17*). A few examples of PEGylated aptamers can be found in the literature, and they have been prepared by coupling the activated polymer to amino-modified aptamers (*18*−*21*). In addition, comb polymers of PEG acrylate containing a pyridyl disulfide terminus have been reversibly conjugated to siRNA (*22*).

In this present work, a 3′-thiol-modified (disulfide protected) 25 base DNA aptamer, previously selected against the protein core of MUC1 glycoprotein (AptD) (*23*), has been successfully conjugated via a maleimide functional group to a range of PEG-based polymers of varying topology and molecular weight. This includes conventional linear PEG (LinPEG20 kDa) and branched PEGs (BrPEG20 and 40 kDa) and three novel PolyPEG structures (PolyPEG17, 40, and 60 kDa). PolyPEGs were selected as novel PEGylating agents due to their "comb-like" architecture based on a polymethacrylate backbone with PEG "teeth" attached to it by ester bonds. These α-functional polymers are prepared by transition-metal-mediated living radical polymerization (TMM-LRP) and have previously been shown to conjugate proteins and peptides via a range of functionalities (*24*−*26*). Recent studies have demonstrated that PolyPEG is particularly effective for conjugation to peptides such as salmon calcitonin, retaining bioactivity and conferring an increased half-life *in vivo* (*27*). The comb-shaped polymer has been shown to have interesting additional properties to linear PEGs such as reduced viscosity (*16*). Moreover, because the PEG "teeth" in PolyPEG are attached by ester bonds to the backbone, its structure could degrade to small units that are readily excreted over time from the body, avoiding the potential toxicological problems due to renal epithelial vacuolization on administration to animals shown by linear PEG (*28, 29*).

The affinity of the various PEGylated aptamer D for their target has been studied using a convenient fluorescent intercalator displacement (FID) assay to detect any influence of the polymers on the binding.

The optimized conjugation conditions were used to PEGylate a second 25 base thiol-modified DNA aptamer (AptF) previously selected for the tumor glycosylated MUC1 glycoprotein (*30*) in order to demonstrate that the high-yield conjugation reaction is not dependent on the aptamer sequence.

EXPERIMENTAL PROCEDURES

Materials and Methods. All polymerizations were carried out using standard Schlenk techniques under an inert atmosphere of nitrogen. Poly(ethylene glycol) methyl ether methacrylate (MeOPEGMA M_n = 1100 g·mol^{-1}) was purchased from Aldrich (Gillingham, UK). *N*-(Ethyl)-2-pyridylmethanimine and 2-bromo-2-methyl propionic acid 2-(3,5-dioxo-10-oxa-4-aza-tricyclo[5.2.1.02,6]dec-8-en-4-yl) (**1**) were synthesized as previously reported (*26, 31*). Copper(I) bromide (Aldrich, 98%) was

Scheme 1. Synthesis of α-Maleimide Functional PolyPEGs and Subsequent Conjugation to an Aptamer[a]

[a] Reagents and conditions: (a) $Cu^{I}Br$/*N*-(ethyl)-2-pyridylmethanimine/(methoxyPEG1100)methacrylate, toluene, 50°C; (b) toluene reflux, 6 h; (c) immobilized TCEP, ammonium formate buffer pH 4, 37 °C.

purified as described elsewhere (*32*). Hydrosart, stabilized cellulose, MWCO 10 kDa, filtration area 0.1 m^2, was purchased from Sartorius AG (Goettingen, Germany).

The sequences of AptD and AptF are, respectively, 5′-GCA GTT GAT CCT TTG GAT ACC CTG G-3′ and 5′-GGC GTA CGG TAG GCG GGG TCA ACT G-3′. Both aptamers have a 3′-thiol-modification protected as disulfide (−S-S-C_3H_6-OH) (IDT Integrated DNA Technologies, Leuven, Belgium). The control aptamer (AptX) is a 25 base oligo of random composition (12% A, 20% C, 32% G, and 36% T).

Linear PEG20 kDa and branched PEG20 and 40 kDa were acquired from Nektar Therapeutics (Huntsville, AL, USA). PolyPEG17, 40, and 60 kDa were provided by Warwick Effect Polymers Limited (Coventry, UK). Immobilized *tris*[2-carboxyethyl]phosphine hydrochloride (TCEP) disulfide reducing gel was purchased from Pierce (Illinois, USA). Agarose and PAGE gels were stained with ethidium bromide and imaged on Kodak Image Station 440.

$[Ru(phen)_2DPPZ](PF_6)_2$ was synthesized according to literature (*33*). The MUC1 core peptide (APDTRPAPG) was prepared by the Oligonucleotide and Peptide Synthesis Unit, University of Nottingham. The emission measurements were recorded in the range 450−700 nm on a FluoroMax-P Fluorometer (Jobin Yvon Horiba).

Synthesis of Maleimide Functional PolyPEGs (*3*). In a typical polymerization, a mixture of **1** (0.535 g, 1.49 mmol), poly(ethylene glycol) methyl ether methacrylate (50 g, 46.3 mmol), and copper(I) bromide (0.214 g, 1.49 mmol) in toluene (100 mL) was deoxygenated by a series of five freeze−pump−thaw cycles. Degassed *N*-(ethyl)-2-pyridylmethanimine (0.9 mL, 6.57 mmol) was added, and the resultant solution was stirred at 50 °C. Samples were removed periodically for molecular weight and conversion analysis. At the end of the polymerization, the solution was diluted with toluene (200 mL) and bubbled with air for 7 h. The solution was then filtered through a column containing basic alumina and the solvent removed under reduced pressure to yield an off-white solid, which was dissolved in water and purified by dialysis using Hydrosart membrane (MWCO 10 kDa). The solution was freeze−dried and the product **2** obtained as a white powder.

A solution of polymer **2** (3 g, 0.079 mmol) in toluene (30 mL) was warmed to reflux for 6 h. The solvent was then removed under reduced pressure and the off-white solid dissolved in water and purified by dialysis as above. The solution was freeze−dried and the product **3** obtained as a white powder.

Synthesis of the PEGylated Conjugates. In a typical PEGylation reaction, the 3′-disulfide protected aptamer (3 nmol) in 20 μL of 18 mM ammonium formate pH 4 was added to 30 nmol of each PEG (1:5 reduced aptamer to PEG molar ratio), followed by 3 μL of immobilized *tris*[2-carboxyethyl]phosphine hydrochloride (TCEP) disulfide reducing gel. The mixture was mixed for 1 h at 37 °C, centrifuged, and the supernatant lyophilized.

High-Performance Liquid Chromatography (HPLC) Analysis and Isolation of PEGylated Aptamer D. The HPLC analyses and isolation of the various PEGylated conjugates of AptD are described in the Supporting Information section and Figures S3 and S4. A 0.02 mM aqueous solution of AptD was used as the standard.

Fluorescent Intercalator Displacement (FID) Assay. A 50 nM solution of AptD, PEGylated AptD, or the control AptX in 5 mM $MgCl_2 \cdot 6H_2O$, 100 mM NaCl (pH 7.2), was titrated with a 0.1 mM solution of $[Ru(phen)_2DPPZ](PF6)_2$ in 5 mM $MgCl_2 \cdot 6H_2O$, 100 mM NaCl (pH 7.2), until saturation. The displacement of the aptamer-bound ruthenium complex was studied at the excitation wavelength of 434 nm by adding aliquots of a 20 mM solution of target peptide (MUC1 core peptide) in 5 mM $MgCl_2 \cdot 6H_2O$, 100 mM NaCl (pH 7.2).

RESULTS

Synthesis of Maleimide Functionalized PolyPEGs. The maleimide functionalized PolyPEGs used in this study were prepared via copper catalyzed living radical polymerization. The protected maleimide initiator (**1**) was used for the polymerization of (methoxyPEG_{1100}) methacrylate in the presence of $Cu^{I}Br$ and an iminopyridine ligand (*31*), followed by the reintroduction of the maleimide functionality by a retro-Diels−Alder reaction (*26*) (Scheme 1). Supporting Information Figures S1 and S2 show the ^1H NMR analyses of products **2** and **3**.

Separation of Unconjugated and PEGylated Aptamer D by Anion-Exchange HPLC. Conjugation reactions were monitored by anion-exchange chromatography and quantified from the peak areas using a 0.02 mM aqueous solution of AptD as standard. The unconjugated aptamer had a R_t of *ca.* 18.0 min, while the PEGylated products eluted earlier at *ca.* 12, 13, or 14 min, depending on the size and structure of the PEG (Supporting Information Figures S3 and S4). The conjugation yields were determined by absorbance at 260 nm, after confirming that the PEG moieties did not contribute to the absorption of the conjugates by comparing UV−vis calibration lines of the aptamer and the PEGs at this wavelength (data not shown). AptD-PolyPEG40 and AptD-PolyPEG60 did not elute consistently from the column under standard conditions, which was most probably due to their structure. Therefore, their conjugation yields were quantified by imaging of the agarose gel. Different

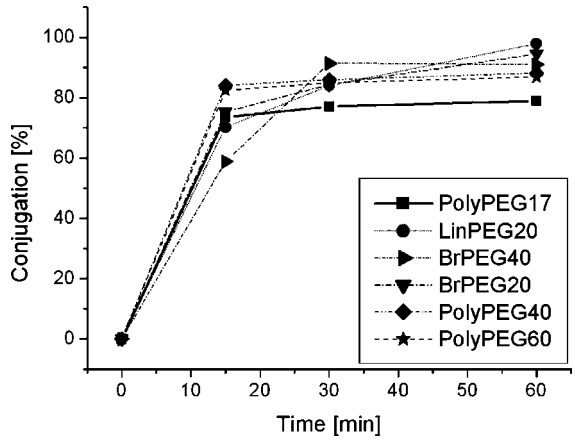

Figure 2. Kinetic study of the conjugation of AptD to various PEGs at 37 °C and 1:5 molar ratio (reduced aptamer/PEG).

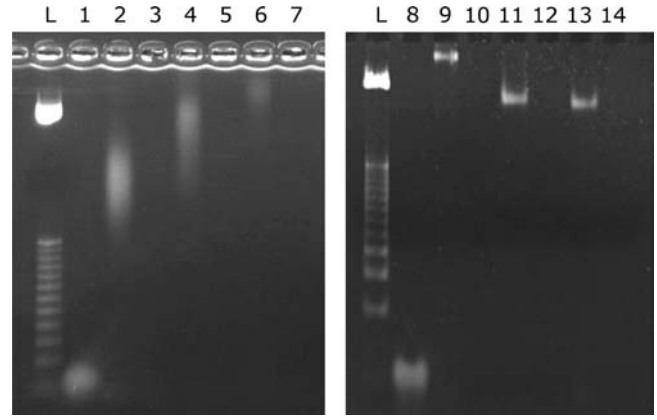

Figure 3. Agarose (2%) (left) and native PAGE (7%) gel (right) of the AptD−PEG conjugates. Lines: L, 25 base pair ladder; 1 and 8, AptD; 2, AptD-PolyPEG17; 3, free PolyPEG17; 4, AptD-PolyPEG40; 5, free PolyPEG40; 6, AptD-PolyPEG60; 7, free PolyPEG60; 9, AptD-BrPEG40; 10, free BrPEG40; 11, AptD-LinPEG20; 12, free LinPEG20; 13, AptD-BrPEG20; 14, free BrPEG20. The running buffer was 1 × TBE (Tris-Borate-EDTA).

HPLC conditions (eluents and gradient) for these conjugates need to be further investigated.

Optimizing the Reaction Conditions for High-Yield PEGylation. All PEGylations were performed using immobilized TCEP gel as reducing agent at pH 4. Very low conjugation was achieved using other reagents such as dithiotreitol (DTT) and non-immobilized TCEP. Preliminary aptamer−PEG conjugation reactions were performed at two different temperatures (25 and 37 °C). Anion-exchange HPLC analyses showed that an increase of the conjugation yield was achieved at 37 °C (Figure 1). Subsequently, the effect of the molar ratio of aptamer to PEG on conjugation was studied at 37 °C (Figure 1).

Optimal conjugation yields were achieved when the reaction was performed at 37 °C for 1 h using an aptamer/PEG molar ratio of 1:5 (reduced aptamer/PEG). A kinetic study of the conjugation of the thiol-modified aptamer to other polymers (branched PEG20 and 40 kDa; PolyPEG17, 40, and 60 kDa) using these optimized conditions also produced the highest yields of conjugate (>78%) after 1 h (Figure 2). The extension of the reaction time to 2 h did not improve the PEGylation yield further.

Identification of Conjugates by Gel Electrophoresis. The PEGylated aptamers (AptD-LinPEG20, AptD-PolyPEG17, AptD-BrPEG20, AptD-PolyPEG40, AptD-BrPEG40, and AptD-PolyPEG60) were isolated by preparative anionic-exchange HPLC and analyzed by agarose gel electrophoresis for the PolyPEG derivatives and native polyacrylamide gel electrophoresis (PAGE) for the linear and branched PEGs. The use of different gel matrices was due to the poor migration of the branched PEG 40 kDa conjugate in agarose gel. Unconjugated aptamer and PEGs were used as controls. The shift of the aptamer to higher molecular weights confirmed its successful conjugation (Figure 3).

Effect of Conjugation on AptD Affinity for Its Target Peptide. $[Ru(phen)_2DPPZ]^{2+}$ shows a strong photoluminescence only when in contact with DNA (double- or single-stranded) (*34, 35*). The FID assay studies the decrease in fluorescence due to the displacement of the ruthenium complex bound to the aptamer by adding the target peptide. The percent decrease in fluorescence and the extent of binding of the target to the aptamer are directly related. A control 25 base DNA aptamer (AptX), having unspecific binding affinity for the same peptide, and the unmodified aptamer D were used as controls. All compounds were dissolved in the same solution previously used for the selection of the aptamer (*23*). The data show that the displacement of the ruthenium complex from AptD, either unmodified or PEGylated, by the target peptide is cooperative (Figure 4). The midpoints and cooperativity values are summarized in Table 1. The data show that the various conjugates have different influences on binding, depending on the molecular weight and structure of the PEG component.

The midpoint values of AptD-LinPEG20 and AptD-BrPEG40 are higher compared to that of the unconjugated aptamer, whereas those for AptD-BrPEG20 and all of the AptD-PolyPEGs are similar to that of the unconjugated aptamer. In addition, the cooperativity of the PEG20 and BrPEG40 conjugated aptamer were increased, whereas those

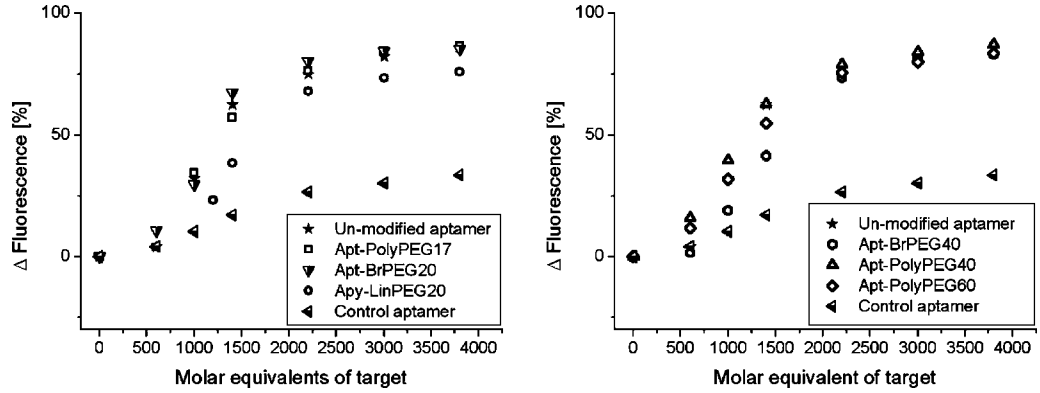

Figure 4. FID binding curves of the target peptide against AptD-PEG conjugates, AptD, and control aptamer (AptX). Displacement of the aptamer-bound ruthenium complex was studied at an excitation wavelength of 434 nm.

Table 1. Midpoints and Cooperativity Values of AptD and PEGylated AptD Obtained from the FID Studies[a]

conjugate	midpoint [mol equiv of target]	cooperativity [*n*]
Unmodified AptD	1140.50	3.92
AptD-LinPEG20	1420.07	4.80
AptD-BrPEG20	1100.80	4.62
AptD-BrPEG40	1375.76	4.22
AptD-PolyPEG17	1185.02	3.57
AptD-PolyPEG40	1051.30	3.01
AptD-PolyPEG60	1150.00	3.20

[a] The calculations were done using the Hill equation: $y = y_\infty + (y_0 - y_\infty)/[1 + (x/K)^n]$ (*42*), where y is the spectroscopic response, x is the concentration of the added reagent, y_0 is the response when $x = 0$, y_∞ is the maximal response when $x = \infty$, K is the concentration of x at the midpoint, and n is the degree of cooperativity.

for BrPEG20 and all PolyPEGs were similar to that for the unmodified aptamer.

DISCUSSION

The conjugation of high molecular weight polymers, such as PEG, to small biomolecules has been shown to prolong their circulating half-life *in vivo* by preventing rapid renal clearance. So far, the only examples of PEGylated aptamers in the literature have been prepared by coupling the activated polymer to an amino modification on the aptamer. Therefore, the aim of our work is to propose an alternative way to PEGylate aptamers *via* a maleimide−thiol reaction. Additionally, new comb-shaped PEGs (PolyPEGs) were synthesized and then conjugated to the aptamer as for the conventional and commercially available PEGs.

PolyPEG is a comb-shaped molecule with a polymethacrylate backbone and pendant PEG teeth formed by polymerization of commercially available PEG methacrylate monomers. This is prepared by living radical polymerization (*36*−*38*) which allows the incorporation of specific functionality on the chain end, which can be subsequently used for conjugation reactions (*26, 39, 40*). As expected for living polymerizations, the reaction exhibited linear kinetics with respect to monomer concentration and the polymers had narrow molecular weight distributions. Monomer conversions were calculated via ^{1}H NMR spectroscopy by monitoring the decrease of the integrals of the monomer vinyl signals (6.2 and 5.6 ppm) using the sharp peak at *ca*. 3.4 ppm (MeO end group) as the internal standard. The molecular weight of the polymer was calculated by comparing the relative integrals of the vinyl signal at 6.5 ppm and the MeO groups of the PEG branches (3.35 ppm) (Figure 5).

The optimized conjugation conditions (reduced aptamer/PEG ratio of 1:5, for 1 h at 37 °C) were used to PEGylate a second thiol-modified DNA aptamer (AptF). The resulting conjugates

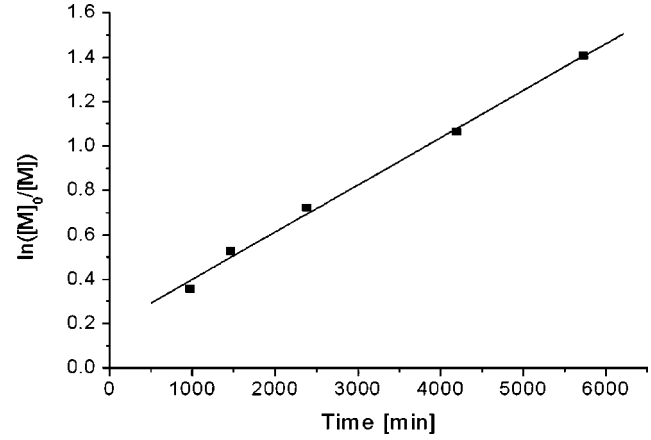

Figure 5. Typical first-order kinetics plot for the polymerization of a protected maleimide functional PolyPEG (PolyPEG40) (**2**).

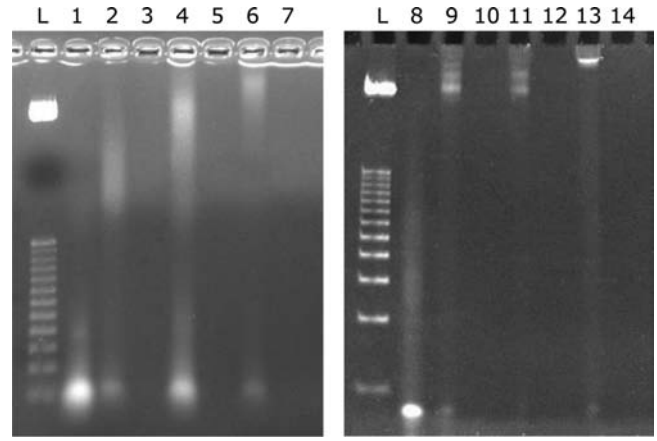

Figure 6. Agarose (left) and native PAGE (right) gels of the AptF-PEG conjugates. Lines: L, 25 base pair ladder; 1 and 8, AptF; 2, AptF-PolyPEG17; 3, free PolyPEG17; 4, AptF-PolyPEG40; 5, free PolyPEG40; 6, AptF-PolyPEG60; 7, free PolyPEG60; 9, AptF-LinPEG20; 10, free LinPEG20free; 11, AptF-BrPEG20; 12, free BrPEG20; 13, AptF-BrPEG40; 14, free BrPEG40.

were analyzed by gel electrophoresis (Figure 6). The conjugation yields, quantified by anion exchange HPLC using a 0.02 mM aqueous solution of AptF as standard and confirmed by band intensity on the gels, were >75%.

Post-selection modifications on an aptamer can alter its original structure and overall charge and thus its binding affinity for the target. A convenient fluorescent intercalator displacement (FID) assay using $[Ru(phen)_2DPPZ]^{2+}$ was performed to test

the retention of affinity for its target of the isolated AptD-PEG conjugates (*33*−*35, 41*).

Two parameters have been considered for the evaluation of the aptamer−peptide binding affinity: the concentration of peptide needed to displace 50% of the metal (midpoint), and the alteration in binding of a peptide molecule to the aptamer due to the prior binding of another peptide molecule to the same aptamer. The binding can be enhanced (positive cooperativity) or decreased (negative cooperativity). All FID plots in Figure 4 are sigmoid, showing a positive cooperative displacement of the Ru^{2+} moiety from the aptamer (either unmodified or PEGylated) by the addition of the target. Branched PEG40 kDa and linear PEG20 kDa clearly interfere with the binding of the aptamer to its target, decreasing the affinity. Compared to the unmodified aptamer, higher quantities of peptide are needed to displace 50% of the bound Ru^{2+} (higher midpoints) despite the greater effect on the displacement shown by the increase of the target concentration (higher cooperativities). The binding is, however, not completely compromised for the BrPEG40 conjugate, as the maximum effect is not reduced. In contrast, AptD-BrPEG20 shows a lower midpoint value, most possibly due to the higher cooperativity. The three aptamer−PolyPEG conjugates display similar binding affinities for the target, which were like that of the unmodified aptamer. In each case, although the PolyPEG products show a slight decrease in cooperativity, the midpoints are reached at very similar molar equivalents of target peptide to that required for the unmodified AptD used as a positive control. As expected, the 25 base aptamer having unspecific binding affinity (control AptX) showed only a 33.5% decrease in fluorescence after the addition of more than 3 times the molar equivalent of peptide necessary to reach the midpoint for the unmodified AptD.

In summary, we report an efficient, high-yielding method for the PEGylation of two thiol-modified aptamers using a range of PEG-based polymers of differing structures and molecular weights. This procedure can be considered as an alternative to the most common approach of using PEG active esters and amino modified aptamers. We have shown that PEGylation has a distinct influence (exemplified by a variation of midpoints and cooperativity values) upon the binding affinity of AptD for its target. Reduced binding affinity was only apparent for the AptD-LinPEG20 and AptD-BrPEG40 conjugates. This suggests that it is the physical size and conformation of the 20 kDa PEG (random coil) and 40 kDa (2 × 20 kDa) branched PEG that causes the reduction in affinity, since it is not observed with either branched 20 kDa (2 × 10 kDa) PEG and even larger molecular mass PolyPEG polymers, which are "brush-shaped". Further *in vivo* studies of the pharmacokinetic and biodistribution properties of the aptamer−PEG conjugates will be undertaken.

Poly(amidoamine) (PAMAM) dendrimers are highly branched spherical polymers that have a unique surface of primary amine groups and provide a versatile design for targeted delivery of pharmaceuticals and imaging agents. Acetylation or succinylation of surface amine groups of PAMAM dendrimer derivatives is frequently performed to reduce nonspecific uptake. However, since targeting molecules, drugs/imaging agents, and acylating reagents react with the amine groups on dendrimer, such modification may limit the number of targeting molecules and/or drugs or may result in insufficient charge reduction. In this study, a γ-glutamyl PAMAM dendrimer was designed and synthesized as a new precursor for targeting device. The relationship between surface electrical properties of the PAMAM dendrimer derivatives and pharmacokinetics was also determined. A PAMAM dendrimer (generation 4.0) was modified with a small number of Bolton-Hunter reagent to prepare **Phe-P** (pI 9.2). The amine residues of **Phe-P** were γ-glutamylated to prepare **Glu-P** (pI 7.1). The α-amine residues of **Glu-P** were then acetylated or succinylated to prepare **Ac-Glu-P** (pI 5.3) or **Suc-Glu-P** (pI 3.6). For comparison, **Phe-P** was acetylated or succinylated to prepare **Ac-P** (pI 6.0) or **Suc-P** (pI 5.1). All the PAMAM dendrimer derivatives exhibited similar molecular size (7.2 to 7.8 nm) except for **Ac-P** (5.1 nm). The biodistribution studies were performed after radioiodination of each PAMAM dendrimer derivative with Na[^{125}I]I. When injected intravenously to mice, both **[^{125}I]Ac-P** and **[^{125}I]Suc-P** exhibited prolonged radioactivity levels in the blood and significantly lower hepatic and renal radioactivity levels than those of **[^{125}I]Phe-P**. Both **[^{125}I]Glu-P** and **[^{125}I]Ac-Glu-P** showed residence times in the blood similar to those of **[^{125}I]Ac-P** and **[^{125}I]Suc-P**. However, **[^{125}I]Glu-P** also registered higher radioactivity levels in the kidney. High hepatic and renal radioactivity levels were observed with highly anionic **[^{125}I]Suc-Glu-P**. These results indicate that, while the manipulation of pI between 5 to 6 would be appropriate to enhance blood retention and reduce renal and hepatic uptake, the amount of primary amine residues on dendrimer surface may also play a crucial role in their renal uptake. The findings in this study show that γ-glutamyl PAMAM dendrimers would constitute versatile precursors to prepare PAMAM dendrimer-based targeting devices due to their neutral molecular charge (pI 7.1) and the presence of a large number of α-amine residues available for conjugation of targeting molecules and drugs/imaging agents.

INTRODUCTION

Dendrimers are highly branched macromolecules with well-defined architecture. A large number of dendrimer derivatives of different constituent atoms and sizes have been synthesized so far (*1*). The unique characteristics of dendrimers such as uniform and controlled size, monodispersity, and modifiable surface group functionality make these molecules appealing for biomedical applications (*2*). The ability to functionalize their terminal groups with targeting molecules and drugs/imaging agents in a specific and controllable manner renders the molecules potential carriers for targeted drug delivery (*3*−*7*). In addition, their interior can encapsulate various molecules (*8*). Among the dendrimer derivatives, the starburst polyamidoamine (PAMAM) dendrimers, highly branched spherical polymers, are soluble in aqueous solution and have a unique surface of primary amine groups (*1*). PAMAM dendrimers have been investigated as carriers in gene transfection (*9*), MRI contrast agents, boron-neutron capture therapy (*10*) (*11*), and drug delivery applications (*8, 12, 13*).

When PAMAM dendrimers with surface amine groups were injected into mice, however, they were eliminated rapidly from circulation and accumulated in the liver, kidney, lung, and spleen (*14*−*16*). This would be attributable to the electrostatic interaction between positively charged dendrimer molecules and negative charged residues on cell surface at physiological pH (*17, 18*). Indeed, carboxylic acid-terminated dendrimers exhibit longer residence time in the blood and lower accumulations in the liver and kidney when compared with amine-terminated counterparts (*15, 19*). The acetylation or succinylation of free terminal amine groups of drug-conjugated PAMAM dendrimers also improved pharmacokinetics (*4, 20, 21*). However, since the acylation reagents, targeting molecules, and drugs/imaging agents react with amine groups on PAMAM dendrimer surface, such chemical modification may cause insufficient charge reduction and/or may limit the number of targeting molecules or drugs/imaging agents especially when the targeting molecules and/or drugs possess positive charges. The lack of knowledge concerning the relationship between molecular charges and pharmacokinetics of PAMAM dendrimer makes the modification cut-and-try, and further understanding of the relationship would provide insight for rationale design of PAMAM dendrimer-based targeting devices.

In the present study, γ-glutamylation of a PAMAM dendrimer was estimated as a new approach to manipulate the molecular charges of an amine-terminated PAMAM dendrimer (generation 4.0) without impairing the number of targeting molecules and drugs/imaging agents. The relationship between the molecular charges and pharmacokinetics a PAMAM dendrimer was also investigated.

EXPERIMENTAL PROCEDURES

Materials. Na[^{125}I]I was purchased from MP biomedicals Inc. (Irvine, CA). PAMAM dendrimer (polyamidoamine dendrimer, generation 4.0) was purchased from Aldrich (St. Louis, MO). TLC analyses were performed with silica plates (Silica gel 60 F_{254}, Merck, Tokyo) developed with 80% methanol. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a JEOL JNM-ALPHA 400 spectrometer (JEOL Ltd., Tokyo) with tetramethylsilane as an internal standard. Fast atom bombardment mass spectra (FAB-MS) were taken on a JEOL JMS-HX-110A mass spectrometer (JEOL Ltd.). The diameter of PAMAM dendrimer derivatives was determined by dynamic light scattering using DLS-700 (Photal Otsuka Electronics, Osaka, Japan). Zeta potentials were measured using an electrophoretic light scattering spectrophotometer (ELS-6000, Photal Otsuka Electronics). *N*-Succimidyl-3-(4-hydroxyphenyl)propionate (compound **1**) was synthesized according to the procedure of Bolton et al. (*22*). Other reagents were of reagent grade and used as received.

Synthesis of *N*-α-*tert*-Butoxycarbonyl-L-glutamic Acid γ-*N*-Succinimidyl Ester α-*tert*-Butyl Ester (*2*). *N*-α-*tert*-Butoxycarbonyl-L-glutamic acid α-*tert*-butyl ester (Boc-Glu-OtBu; 3 g, 9.89 mmol) and *N*-hydroxysuccinimide (NHS; 1.25 g, 10.8 mmol) were dissolved in tetrahydrofuran (THF, 20 mL). The reaction mixture was cooled in an ice bath, and a solution of *N,N*′-dicyclohexylcarbodiimide (DCC, 2.2 g, 10.8 mmol) in THF (8 mL) was added dropwise while keeping the reaction temperature below 5 °C. The reaction mixture was then stirred at room temperature overnight. After removing precipitated DCC urea by filtration, the filtrate was purified by column chromatography on silica gel using a mixture of ethyl acetate/hexane (1:2) as an eluent to produce compound **2** (3.1 g, 79.3%) as a white solid. ^{1}H NMR ($CDCl_3$): δ 1.44−1.51 (18H, overlapped, Boc, *tert*-butyl), 2.02 (1H, m, CH), 2.26 (1H, m, CH), 2.70 (2H, m, CH_2), 2.83 (4H, s, CH_2), 4.25 (1H, s, CH), 5.14 (1H, d, CONH); FAB-MS $(M+H)^+$: *m*/*z* 401. Found: 401.

3-(4-Hydroxyphenyl)propionate-Conjugated PAMAM Dendrimer (Phe-P). Since the PAMAM dendrimer is supplied as a methanol solution, the solvent was replaced with a mixture of 8 mL *N*,*N*-dimethylformamide (DMF) and 1 mL water to prepare the PAMAM dendrimer at a concentration of 200 mg (1.4×10^{-5} mol)/9 mL. A solution of compound **1** (37.0 mg) in DMF (1 mL) was then added dropwise to the PAMAM solution, and the reaction mixture was stirred for 2 h at room temperature. The resulting **Phe-P** was purified by diafiltration using an Amicon Ultra-4 (NMWL 5 kDa, Millipore Japan, Tokyo). After removing the solvent in vacuo, **Phe-P** was obtained as a yellow oil (140 mg, 63.4%). ^{1}H NMR (D_2O): δ 2.26−2.54 (m, PAMAM methylene), 2.66 (s, PAMAM methylene), 2.75−3.00 (overlapped, PAMAM methylene, propionate methylene), 3.02−3.18 (overlapped, PAMAM methylene, propionate methylene), 3.18−3.38 (m, PAMAM methylene), 3.43 (t, PAMAM methylene), 6.73 (d, CH), 7.02 (d, CH).

Acetyl-PAMAM (Ac-P). To a solution of **Phe-P** (50 mg) in dimethyl sulfoxide (DMSO, 2 mL) was added a mixture of acetic anhydride (48.8 μL) and diisopropylethylamine (89.9 μL). After stirring for 2 days at room temperature, the solution was evaporated in vacuo. The residue was dissolved in 1 N NaOH solution (5 mL) and heated at 50 °C for 1 h. The resulting **Ac-P** was purified by diafiltration using the Amicon Ultra-4. After removing the solvent in vacuo, **Ac-P** was obtained as a yellow oil (33 mg, 55.8%).^{1}H NMR (D_2O): δ 1.95 (s, CH_3), 2.26−2.51 (m, PAMAM methylene), 2.62 (s, PAMAM methylene), 2.81 (overlapped, PAMAM methylene, propionate methylene), 3.04−3.38 (overlapped, PAMAM methylene, propionate methylene), 6.77 (d, CH), 7.06 (d, CH).

Succinyl-PAMAM (Suc-P). A solution of succinic anhydride (330 mg) in THF (5 mL) was added dropwise to a solution of **Phe-P** (150 mg) dissolved in a mixture of THF (3.3 mL) and 1 N NaOH (7.7 mL) while maintaining the reaction solution at pH 9 by an addition of 1 N NaOH. The reaction mixture was then stirred for 2 h at room temperature. The solvent was removed in vacuo, and the crude **Suc-P** dissolved in 0.5 M ammonium acetate buffer (pH 7.4) was purified by diafiltration using the Amicon Ultra-4. After removing the solvent in vacuo, **Suc-P** was obtained as a yellow oil (130 mg, 61.8%). ^{1}H NMR (D_2O): δ 2.38−2.58 (m, PAMAM methylene), 2.78 (s, PAMAM methylene), 2.95 (overlapped, PAMAM methylene, propionate methylene), 3.12−3.42 (overlapped, PAMAM methylene, propionate methylene), 6.77 (d, CH), 7.07 (d, CH).

γ-Glutamyl-PAMAM (Glu-P). To a solution of **Phe-P** (135 mg) in DMSO (1.5 mL) was added a mixed solution of compound **2** (380 mg) and diisopropylethylamine (248 μL) in DMSO (2 mL), and the reaction mixture was stirred for 2 h at room temperature. After removing the solvent in vacuo, the residue was purified by gel permeation chromatography (TOYOPEARL HW-40S, 1 cm × 25 cm) using methanol as an eluent to produce Boc-Glu(OtBu)-Phe-P. Boc-Glu(OtBu)-Phe-P was then dissolved in a mixture of trifluoroacetic acid (TFA, 4.5 mL) and anisole (0.5 mL), and the reaction mixture was stirred for 2 h at room temperature. The solution was neutralized with 1 N NaOH under cooling in an ice bath, and the conjugate (**Glu-P**) was purified by diafiltration using the Amicon Ultra-4. After removing the solvent in vacuo, **Glu-P** was obtained as a yellow oil (81 mg, 43.5%). ^{1}H NMR (D_2O): δ 2.08 (d, CH_2), 2.21−2.46 (m, PAMAM methylene, glutamic acid), 2.59 (s, PAMAM methylene), 2.78 (overlapped, PAMAM methylene, propionate methylene), 3.04−3.35 (m, PAMAM methylene), 6.73 (d, CH), 7.02 (d, CH).

Succinyl γ-Glutamyl PAMAM (Suc-Glu-P). To a solution of **Glu-P** (54 mg) in DMSO (2 mL) was added a mixed solution of diisopropylethylamine (123 μL) and succinic anhydride (42 mg) in DMSO (1 mL). The reaction mixture was stirred overnight at room temperature, and the resulting **Suc-Glu-P** was purified by diafiltration using the Amicon Ultra-4. After removing the solvent in vacuo, **Suc-Glu-P** was obtained as a yellow oil (26 mg, 39.3%). ^{1}H NMR (D_2O): δ 1.85 (d, CH_2), 2.10 (d, glutamic acid), 2.27 (d, glutamic acid), 2.32−2.57 (m, PAMAM methylene, glutamic acid), 2.65 (s, PAMAM methylene), 2.83 (m, PAMAM methylene), 2.95 (overlapped, PAMAM methylene, propionate methylene), 3.05−3.41 (m, PAMAM methylene), 3.48 (s, PAMAM methylene), 3.73 (t, glutamic acid), 4.11 (t, glutamic acid), 7.06 (d, CH), 7.64 (d, CH).

Acetyl γ-Glutamyl PAMAM (Ac-Glu-P). A mixed solution of diisopropylethylamine (190 μL) and acetic anhydride (51 μL) in DMSO (1 mL) was added to a solution of **Glu-P** (40 mg) in DMSO (1 mL). The reaction mixture was stirred overnight at room temperature. The resulting **Ac-Glu-P** was purified by diafiltration using the Amicon Ultra-4. After removing the solvent in vacuo, **Ac-Glu-P** was obtained as a yellow oil (32 mg, 72.7%). ^{1}H NMR (D_2O): δ 1.84 (d, CH_2), 1.97−2.15 (m, glutamic acid), 2.27 (t, glutamic acid), 2.35−2.66 (m, PAMAM methylene, glutamic acid), 2.69−3.19 (m, PAMAM methylene, propionate methylene), 3.23−3.53 (m, PAMAM methylene),

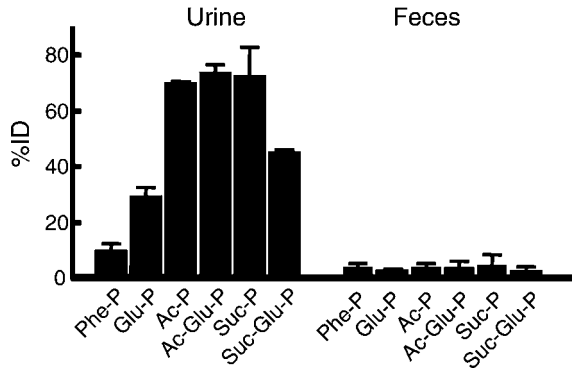

Figure 1. Cumulative radioactivity levels in urine and feces for 48 h postinjection of [^{125}I]PAMAM derivatives in normal mice.

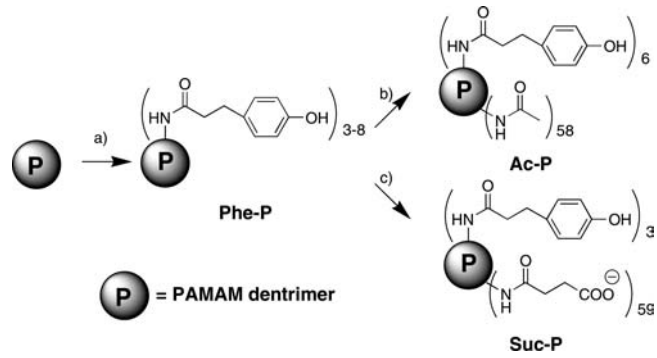
3.61 (t, glutamic acid), 4.11 (t, glutamic acid), 6.78 (d, CH), 7.25 (2d, CH).

^{125}I-Labeled PAMAM Derivatives ([^{125}I]PAMAM Derivatives). A solution of 169 μg of freshly prepared chloramine-T in 10 μL of 0.1 M phosphate buffer (pH 7.4) was added to a mixture of Na[^{125}I]I (5 μL) in 0.01 M NaOH and a PAMAM derivative (0.22 mg/100 μL) in 0.1 M phosphate buffer (pH 7.4). The reaction mixture was incubated for 15 min before quenching the reaction with aqueous sodium bisulfite (73 μg, 10 μL). All the PAMAM derivatives were radioiodinated under similar conditions. [^{125}I]PAMAM derivatives were then purified by diafiltration using the Microcon YM-3 (NMWL 3 kDa, Millipore Japan). The radiochemical purity was determined by TLC.

Zeta Potential and Particle Size of PAMAM Derivatives. Each PAMAM derivatives were dissolved in 0.05 M phosphate buffer (pH 7.4) at a concentration of 5 mg/3−5 mL. The zeta potentials and the sizes of the PAMAM derivatives were determined by an electrophoretic light scattering spectrophotometer and by a dynamic light scattering.

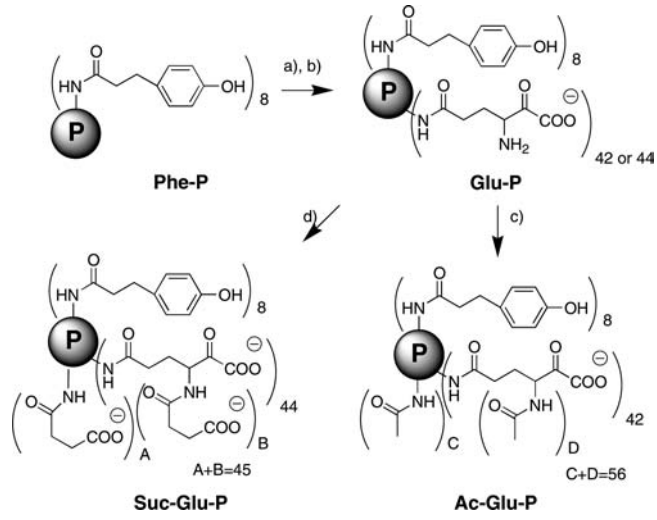
Isoelectric Points (pIs) of [^{125}I]PAMAM Derivatives. Polyacrylamide isoelectric focusing (IEF) was performed to determine the pI values of each [^{125}I[PAMAM derivative. Aliquots of each [^{125}I]PAMAM derivative (3 μL) along with standard solution were applied onto the gel (TEFCO, Tokyo). IEF was performed at 100 V for 1 h, 200 V for 1 h, and 500 V for 30 min. The IEF gel was autoradiographed to reveal radioactive bands using a bioimaging analyzer, FUJIX BASS-2000 II (Fujifilm, Tokyo). The molecular markers were stained with Coomassie Brilliant.



Biodistribution of [^{125}I]PAMAM Derivatives. Animal studies were conducted in accordance with our institutional guidelines and were approved by the Chiba University Animal Care Committee. The biodistribution of radioactivity after intravenous administration of [^{125}I]PAMAM derivatives (70.4 fmol, 100 μL) to 6-week-old mice was determined at 10 min, 1 h, 3 h, 24 h, and 48 h postinjection. Groups of 4−5 mice were used for the experiments. Organs of interest were removed and weighed, and the radioactivity counts were determined with an auto well gamma counter. Urine and feces were collected for 48 h postinjection, and the radioactivity counts were also determined (Figure 1).

Statistical Analysis. Data are expressed as the means ± SD where appropriate. Results were statistically analyzed using the unpaired Student's *t*-test. Differences were considered statistically significant when p was <0.05.

RESULTS



Preparation of [^{125}I]PAMAM Derivatives. PAMAM derivatives were synthesized according to the procedure outlined in Schemes 1 and 2. The reaction of the PAMAM dendrimer with *N*-succinimidyl-3-(4-hydroxyphenyl)propionate introduced 3 to 8 molecules of 3-(4-hydroxypenyl)propyl groups per molecule of the PAMAM dendrimer to prepare **Phe-P**. The treatment of **Phe-P** with acetic anhydride or succinic anhydride introduced 58 molecules of acetyl groups (**Ac-P**) or 59 molecules of succinyl groups (**Suc-P**). Similarly, the reaction of **Phe-P** with compound **2**, followed by deprotection of the Boc and *tert*-butyl groups provided **Glu-P** with 44 glutamyl groups per molecule of **Phe-P**. The acylation of **Glu-P** with acetic anhydride or succinic anhydride introduced 56 acetyl (**Ac-Glu-P**) or 45 succinyl groups (**Suc-Glu-P**) per molecule of **Glu-P**.

Scheme 1[a]

[a] (a) Compound **1**, (b) acetic anhydride, (c) succinic anhydride.

Scheme 2[a]

[a] (a) Compound **2**, diisopropylethylamine, (b) TFA, anisole, (c) acetic anhydride, (d) succinic anhydride.

Radioiodinatoin of each PAMAM derivative was performed by the chloramine-T method, and the [^{125}I]PAMAM derivatives were obtained with radiochemical yields and purities of over 35% and over 92.5%, respectively.

Zeta Potential, pI, and Size Measurements of the PAMAM Derivatives. Zeta potential, pI, and size of the PAMAM derivatives are summarized in Table 1. The mean particle sizes of the PAMAM derivatives were almost similar (7.2 to 7.8 nm) except for **Ac-P** (5.1 nm). **Phe-P** exhibited the highest pI of 9.2, while **Suc-Glu-P** reached the lowest pI of 3.6. The pIs for the PAMAM dendrimers ranged from 3.6 to 9.2, which correlated well with their zeta potentials ($R^2 = 0.85$), as shown in Figure 2.

Biodistribution of [^{125}I]PAMAM Derivatives in Mice. The biodistribution of radioactivity after injection of [^{125}I]PAMAM

Table 1. Properties of PAMAM Dendrimer Derivatives

Compound	pI	zeta potential (mV)	Diameter (nm)
Phe-P	9.2	3.0 ± 3.0	7.5
Glu-P	7.1	−12.4 ± 3.0	7.2
Ac-P	6.0	−11.3 ± 1.3	5.1
Ac-Glu-P	5.3	−23.2 ± 0.9	7.3
Suc-P	5.1	−27.6 ± 2.9	7.4
Suc-Glu-P	3.6	−25.0 ± 2.1	7.8

derivatives to mice is summarized in Tables 2 and 3. **[^{125}I]Phe-P** showed rapid elimination rate from the blood with high and persistent radioactivity levels in the liver, kidney, spleen, and lung. At 48 h postinjection, 10% and 3.7% injected dose was excreted in the urine and feces, respectively.

Both **[^{125}I]Ac-P** and **[^{125}I]Suc-P** showed similar biodistribution profiles. They showed longer residence time of the radioactivity in the blood and significantly lower radioactivity levels in the liver, lung, kidney, and spleen when compared with **[^{125}I]Phe-P**. At 48 h postinjection of **[^{125}I]Suc-P** and **[^{125}I]Ac−P**, over 70% of the injected radioactivity was excreted in the urine.

All the glutamyl-PAMAM derivatives exhibited prolonged residence time of the radioactivity in the blood. However, a large difference was observed in their tissue distribution profiles. **[^{125}I]Glu-P** showed low radioactivity levels in the liver, spleen, and lung but exhibited high and persistent radioactivity levels in the kidney. At 48 h postinjection, approximately 30% of the injected radioactivity was excreted in the urine. Contrary to **[^{125}I]Glu-P**, **[^{125}I]Ac-Glu-P** significantly reduced renal radioactivity levels with approximately 74% of the injected radioactivity excreted in the urine by 48 h. **[^{125}I]Suc-Glu-P**, on the other hand, exhibited moderate radioactivity levels in the kidney and the liver with 45% injected radioactivity being excreted by 48 h.

DISCUSSION

The pharmacokinetics of PAMAM dendrimer is predominantly determined by their molecular sizes and surface electrical properties (*14, 15*). The PAMAM dendrimer derivatives synthesized in this study possess similar molecular sizes at pH 7.4 except for **Ac-P** where all the amine residues were capped with acetyl or 3-(4-hydroxyphenyl)propyl groups (Table 1). The slightly smaller molecular size of **Ac-P** would be attributable to a lower amount of ionizable terminal groups on its surface, since ionization of terminal groups on dendrimers leads to a more expanded overall conformation (*23*−*25*). In addition, all the PAMAM derivatives possess molecular sizes much smaller than those recognized by the reticuloendothelial system of the body (*26*). In light of these findings, the pharmacokinetics of the PAMAM derivatives would predominantly be governed by their surface electrical properties. The good correlation between the zeta potentials and the pIs of the PAMAM derivatives shows that the surface electrical properties of the six PAMAM dendrimer derivatives can be characterized and expressed as their pIs.

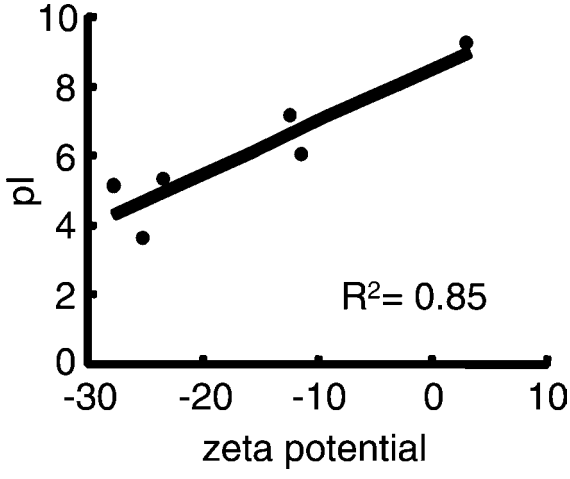


Figure 2. Correlation between pIs and zeta potentials of PAMAM denderimer derivatives.

Acetylation or succinylation of surface amine groups constitutes the most widely applied procedure to reduce surface charges of PAMAM dendrimers. The acetylation or succinylation of **Phe-P** (pI 9.2) decreased pIs of the resulting **Ac-P** (pI 6.0) or **Suc-P** (pI 5.1). The comparative biodistribution of **[^{125}I]Ac-P**, **[^{125}I]Suc-P**, and **[^{125}I]Phe-P** reinforced the previous finding that pI reduction is effective at prolonging the residence time in the blood and reducing accumulation in the liver, spleen, lung, and kidney. This is supported by higher amounts of radioactivity excreted in the urine for 48 h postinjection of **[^{125}I]Suc-P** and **[^{125}I]Ac-P**.

To further lower the pI of a PAMAM dendrimer, glutamylation of a PAMAM dendrimer was performed. Each modification converts an amine group to an amine and a carboxylic acid, and the resulting **Glu-P** showed pI 7.1. The acetylation or succinylation of the residual α-amine groups of **Glu-P** provided **Ac-Glu-P** or **Suc-Glu-P** with pI values of 5.3 and 3.6, respectively. In biodistribution studies, **[^{125}I]Glu-P** exhibited radioactivity levels in the blood significantly higher than and similar to those of **[^{125}I]Phe-P** and **[^{125}I]Ac-P**, respectively. However, **[^{125}I]Glu-P** registered high and persistent localization of radioactivity in the kidney. The renal accumulation of radioactivity observed with **[^{125}I]Glu-P** was significantly decreased by acetylation of the α-amine groups of **Glu-P**. These results suggest that, while blood clearance would predominantly be governed by their net charges, surface electrical properties (e.g., the amount of primary amine resides on the surface) would affect renal accumulation. This is supported by similar renal radioactivity levels and urinary excretion rates of the two acetylated PAMAM derivatives, **[^{125}I]Ac-P** and **[^{125}I]Ac-Glu-P**. The pI reduction is also found effective in reducing renal radioactivity levels of polypeptides and peptides (*27*−*31*). The findings in this study also suggest that the surface properties of polypeptides and peptides may be responsible for their renal reabsorption after glomerular filtration.

The extensive succinylation of **Glu-P** produced **Suc-Glu-P** with the lowest pI of 3.6. **[^{125}I]Suc-Glu-P** showed higher radioactivity levels in the kidney and the liver after injection when compared with **[^{125}I]Ac-P**, **[^{125}I]Suc-P**, and **[^{125}I]Ac-Glu-P**. Since scavenger receptors on Kupffer cells of liver can bind a variety of polyanionic ligands (*32, 33*), the hepatic accumulation of **[^{125}I]Suc-Glu-P** would be caused by the binding of the highly anionic PAMAM derivative to scavenger receptors. Similarly, renal accumulation of succinylated proteins (*32, 34*) (*35*) and ^{111}In-labeled minigastrin suggests that high carboxylate modification of PAMAM also facilitates renal accumulation.

In this study, Bolton-Hunter reagent was conjugated directly to the amine residues of PAMAM dendrimer (Scheme 1) for radioiodination. It is well-known that radioiodinated proteins using the reagent undergo rapid deiodination and the radioactivity levels decrease from tissues of accumulation. However, **[^{125}I]Phe-P**, **[^{125}I]Glu-P**, and **[^{125}I]Suc-Glu-P** showed persistent localization of radioactivity at tissues of accumulation (Tables 2 and 3). Similar results were reported by another group using a PAMAM derivative radioiodinated with *N*-succinimidyl 3-iodobenzoate (*21*). These results showed that the amide bond between the radioiodinated reagent and surface amine groups of PAMAM dendrimers is hardly cleaved in the lysosomes. These findings also reinforced the previous study that the

liberation of cytotoxic drugs was scarcely observed from dendrimers conjugated via amide bonds (*38*).

CONCLUSION

The findings in this study suggest that the reduction of pI to 5 to 6 would be appropriate to reduce nonspecific accumulation and prolong circulation time of PAMAM dendrimers. This study also indicates that γ-glutamyl PAMAM dendrimers would constitute versatile precursors to prepare PAMAM-based targeting devices even when targeting molecules and/or drugs of positive charges are used. This modification may also be useful to facilitate the release of drugs that are covalently conjugated with the primary amine residues of α-glutamic acids via amino acids (*39*) or a lysomotropic linkage (*36, 37*) (*40*−*42*) in lysosomal compartment of target tissues. In addition, γ-glutamyl PAMAM dendrimers may prevent toxicity by converting the primary amine groups to amphoteric ones (*4*).

ACKNOWLEDGMENT

TECHNICAL NOTES

Cleavable Linker for Photo-Cross-Linked Small-Molecule Affinity Matrix

The introduction of a cleavable site in a photoactivatable linker, which is used to immobilize small molecules on an affinity matrix via a site-nonselective carbene addition/insertion reaction, makes it possible to verify the presence of the immobilized small molecule on the affinity matrix. It also permits the efficient detection of proteins covalently bound to the immobilized small molecule.

INTRODUCTION

The affinity purification of protein targets for biologically active small molecules (BASMs) has traditionally been used for forward chemical genetic studies (*1*). Such experiments have provided not only key information on the mode of action of BASMs, but also insights of relevance to other biological processes. The traditional target discovery/identification process consists of the following three steps: (1) the search for a position on a BASM of interest that does not significantly abrogate the intrinsic biological activity; (2) preparation of the BASM conjugate with a biotin or an affinity matrix that is covalently attached via a linker; and (3) biochemical pull-down experiments using the synthesized conjugate. Although this traditional approach has yielded many promising results in the past two decades, it remains both time-consuming and challenging in many cases.

In the course of our efforts to develop a rapid and widely applicable approach to enhance the target discovery/identification process, we recently reported a photo-cross-linked small-molecule affinity matrix in which the BASM of interest is immobilized on photoactivatable linker-coated (PALC) agarose beads **1a** via a site-nonselective carbene addition/insertion reaction when treated with UV irradiation (Figure 1) (*2*). This platform is very effective when the BASM of interest tolerates UV irradiation (365 nm), and has been used to pull down cellular targets for BASMs in our laboratory. Using this technology, we recently identified a detoxification enzyme, namely, glyoxalase I, as a molecular target of methyl gerfelin, a fungus-derived osteoclastogenesis inhibitor (*3*).

Despite these successes, we identified serious problems with the technology. First, there is a possible difference in the cross-linking efficiency between BASMs. We have already shown with LC/MS/MS that a variety of small molecules may be photo-cross-linked with the photoactivatable linker **1a** (*4, 5*). However, molecules having different functionalities and/or molecular sizes are thought to react differently with the photogenerated carbenes, resulting in different numbers of immobilized molecules. It was even difficult to verify the presence of the immobilized small molecule on the affinity matrix.

The second problem is the nature of covalent bond formation between the BASM and the PALC affinity matrix. A growing number of BASMs are known to bind covalently with their protein targets (*6*), but such ligand-reacting proteins are sometimes difficult to detach from the affinity matrix if the ligands are immobilized covalently on the affinity matrix.

These problems led us to consider the introduction of a cleavable site in the photoactivatable linker. Among the various

options, we selected a disulfide bond because it was reported to be stable in many biological applications and it can be cleaved selectively using mild reducing agents such as glutathione or dithiothreitol (DTT) (*7*). A cleavable photoactivatable heterobifunctional reagent utilizing disulfide linkage was reported as early as 1981 (*8*), but the utility in forward chemical genetic study has not yet been fully assessed.

We therefore designed and prepared the cleavable photoactivatable linker-coated (CPALC) affinity matrix **2a** (Figure 2) and compared it with **1a** in terms of its ability to immobilize BASM. We also demonstrate here that **2a** could be used for efficient detection of the BASM binding protein, especially in the context of the protein-reacting ligand.

EXPERIMENTAL PROCEDURES

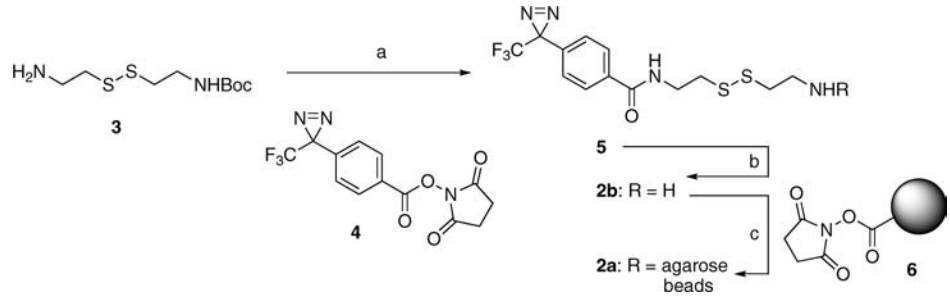
Materials and Instrumentation. All chemical reactions were carried out under argon atmosphere with dehydrated solvents under anhydrous conditions, unless otherwise noted. Dehydrated THF and CH_2Cl_2 were purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). Other solvents were dehydrated and/or distilled according to standard protocols. Reagents were obtained from commercial suppliers and used without further purification, unless otherwise noted. Reactions were monitored by thin-layer chromatography (TLC) carried out on Kieselgel 60 F_{254} silica gel plates (Merck KGaA) or NH-silica gel plates (Fuji Silysia Chemical Ltd., Aichi, Japan). Column chromatography was performed on silica gel 60N (spherical, neutral, 63-210 μm; Kanto Chemical Co., Inc., Osaka, Japan) or Chromatorex NHDM 1020 (amine-coated silica gel, 100−200 mesh; Fuji Silysia Chemical Ltd., Kasugai, Japan). IR spectra were recorded on a JASCO FT/IR-410 Fourier transform infrared spectrometer. ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra were recorded on a JEOL JMN AL400 spectrometer. Mass spectra were recorded on JEOL JMS-DX303, JEOL JMS-700, and Waters Micromass ZQ2000 LC mass spectrometers.

Synthesis of Cleavable Photoactivatable Linker-Coated Agarose Beads

Disulfide 5. A solution of NHS ester **4** (72.2 mg, 0.221 mmol), *N*-(*tert*-butoxycarbonyl)cystamine (**3**) (87.5 mg, 0.347 mmol, 1.6 equiv), and Et_3N (310 μL, 2.21 mmol, 10 equiv) in CH_3CN (3 mL) was stirred at rt for 5.5 h. After an addition of water (10 mL), the mixture was extracted with ethyl acetate (2 × 70 mL). The combined organic layers were dried over $MgSO_4$, filtered, and concentrated in vacuo. The residue was purified via silica gel column chromatography (ethyl acetate/hexane = 1:2) to afford **5** (96.6 mg, 0.208 mmol, 94%) as a pale yellow oil. **5**: IR (neat) 3323, 2978, 2928, 1694, 1644, 940 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.90 (d, J = 8.2 Hz, 2H), 7.24 (d, J = 8.3 Hz, 2H), 4.95 (s, 1H), 3.78 (q, J = 6.1 Hz, 2H), 3.47 (q, J = 6.1 Hz, 2H), 2.99 (t, J = 5.5 Hz, 2H), 2.80 (t, J = 6.7 Hz, 2H), 1.41 (s, 9H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 166.5, 156.0, 135.4, 132.2, 127.7, 126.5, 121.9 (q, $^1J_{CF}$ = 274.4 Hz), 79.8, 39.6, 39.0, 38.8, 37.7, 28.3, 28.3 (q, $^2J_{CF}$ = 40.9 Hz); HRMS (EI) m/z 464.1178 (M^+), calcd. for $C_{18}H_{23}O_3N_4F_3S_2$ 464.1164.

Cleavable Photoactivatable Linker 2b. To a solution of **5** (69.7 mg, 0.15 mmol) in CH_2Cl_2 (3 mL) was added trifluoroacetic acid (330 μL, 4.5 mmol, 30 equiv) at rt. After stirring for 3 h, the mixture was concentrated in vacuo, and the residue was purified via amine-coated silica gel column chromatography ($MeOH-CHCl_3$ 0:100 → 1:10 → 1:4) to afford **2b** (47.6 mg, 0.131 mmol, 87%) as a pale yellow oil. **2b** IR (neat) 3323, 1638, 1154 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.81 (d, J = 9.1 Hz, 2H), 7.25 (d, J = 8.4 Hz, 1H), 6.71 (1H, brs), 3.82 (t, J = 6.1 Hz, 2H), 3.03 (t, J = 6.1 Hz, 2H), 2.93 (d, J = 6.1 Hz, 2H), 2.80 (t, J = 6.1 Hz, 2H); ^{13}C NMR (400 MHz, $CDCl_3$) δ 166.3, 135.4, 132.4, 127.4, 126.6, 121.9 (q, $^1J_{CF}$ = 275.3 Hz), 42.3, 40.6, 38.8, 37.5, 28.3 (q, $^2J_{CF}$ = 40.1 Hz); HRMS (EI) m/z 364.0641 [$(M+H)^+$], calcd. for $C_{13}H_{15}ON_4F_3S_2$ 364.0639.

Cleavable Photoactivatable Linker-Coated (CPALC) Agarose Beads 2a. Commercially available NHS-activated Sepharose 4 fast flow beads (**6**) (GE Healthcare Bioscience, Uppsala, Sweden; 160−230 nmol NHS/10 μL of swelled beads, 150 μL) were washed successively with 1 mM aq HCl (5 × 1 mL) and coupling solution (1:1 dioxane−0.1 M aq $NaHCO_3$) (2 × 1 mL) at rt. To swelled beads (150 μL) was added a solution of **2b** (6.3 mg, 17.3 mmol) in coupling solution (100 μL) and methanol (50 μL) at rt. The mixture was shaken by using a CM-1000 mixer (EYELA, Tokyo, Japan) for 2 h. The resultant beads were washed with the coupling solution (5 × 1 mL). To the beads was added a 1 mM solution of ethanolamine in Tris−HCl buffer (0.1 M Tris−HCl, pH 8.0, 1 mL), and the mixture was shaken for an another 1 h. The beads were washed with Milli-Q (5 × 1 mL), then transferred into a spin column using 1 mL of Milli-Q. The beads were washed with methanol (3 × 400 μL), centrifuged, and dried in vacuo.



Immobilization of Small Molecules on the PALC- and CPALC-Agarose Beads. PALC- or CPALC-agarose beads (100 μL) were washed with Milli-Q (3 × 400 μL) using a spin column and transferred to a glass sample vial. Solution of a small molecule (10 mM in MeOH, 150 μL) was added to the vial, and the mixture was concentrated using a rotary evaporator and dried in vacuo. The beads were suspended in 2-propanol (200 μL), residual water absorbed on the beads was removed azeotropically using a rotary evaporator, and the beads were dried again in vacuo. The beads were irradiated at 365 nm (4 J/cm^2) by a CL-1000 L ultraviolet cross-linker (UVP Inc., San Gabriel, CA), then washed with 50% aq MeOH, MeOH, DMSO, and MeOH (3 × 400 μL each) to give small-molecule-immobilized beads. The beads were suspended in PBS (8 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 137 mM NaCl, 3 mM KCl, pH 7.4) containing 1 mM sodium azide, and stored at 4 °C. The beads were washed with PBS before use.

Cleavage of Immobilized Small Molecules from the CPALC Small Molecule Beads and MS Analysis. CPALC small molecule beads (10 μL) were treated with a 100 mM DTT solution in ethanol (100 μL) at 50 °C for 10 min. The supernatant was analyzed by a Waters Micromass ZQ 2000 LC mass spectrometer.

Preparation of Phoslactomycin D-Immobilized Beads (PLM-D Beads). To NHS-activated Sepharose 4 fast flow beads (50 μL), which were washed and swelled as described for the synthesis of CPALC agarose beads (**2a**), was added phoslactomycin D (1.1 mg, 1.7 μmol) in coupling solution (100 μL) and MeOH (50 μL). The mixture was shaken for 2 h. The resultant beads were washed with Milli-Q (2 × 1 mL) and MeOH (5 × 1 mL). To the beads was added a 1 mM solution of ethanolamine in Tris−HCl buffer (0.1 M Tris−HCl, pH 8.0, 1 mL), and the mixture was shaken for 1 h. The beads were washed with Milli-Q (5 × 1 mL), then transferred into a spin column using 1 mL of Milli-Q. The beads were washed successively with 50% aq MeOH, MeOH, DMSO, and MeOH (3 × 400 μL each) to give PLM-D beads. The beads were suspended in PBS (8 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 137 mM NaCl, 3 mM KCl, pH 7.4) containing 1 mM sodium azide, and stored at 4 °C. The beads were washed with PBS before use.

Detection of PP2A Subunits Using Phoslactomycin D-Immobilized Beads. HL-60 cells (RIKEN Cell Bank, Ibaraki, Japan) were washed twice with PBS, then suspended in binding buffer (50 mM Tris−HCl, 150 mM NaCl, 1 mM EDTA, and 2.5 mM EGTA, pH 7.5) containing 1 mM DTT, 0.1 mM $MgCl_2$, and Complete protease inhibitor cocktail (Roche Diagnostics GmbH). Suspended cells were lysed by sonication, and the resulting mixture was incubated at 4 °C

Scheme 1. Synthesis of Cleavable Photoactivatable Table Linker-Coated (CPALC) Agarose Beads[a]

[a] Reagents and conditions: (a) **4**, Et_3N, CH_3CN, 5.5 h, 94%; (b) trifluoroacetic acid, CH_2Cl_2, r.t., 3 h, 87%; (c) **6**, 0.1 M aq $NaHCO_3$−dioxane (1:1), r.t., 2 h, then ethanolamine, r.t., 1 h.

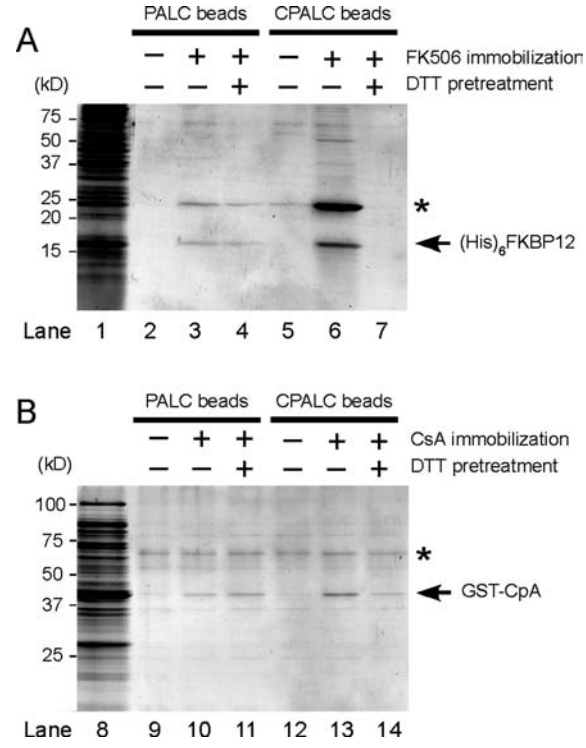

Figure 4. Detection of CsA- and FK506-binding proteins using PALC- and CPALC-agarose beads. (A) Detection of FKBP12 using FK506-immobilized beads: PALC- (lanes 2−4) or CPALC- (lanes 5−7) agarose beads were irradiated in the presence (lanes 3, 4, 6, and 7) or absence (lanes 2 and 5) of FK506. The beads were incubated with cell lysates of *E. coli* overexpressing $(His)_6$-FKBP12 overnight. Beads in lanes 4 and 7 were pretreated with DTT before being incubated with cell lysate. The beads were washed and analyzed by 15% SDS-PAGE followed by CBB staining. *protein unidentified. (B) Detection of cyclophilin A (CpA) using cyclosporin A (CsA)-immobilized beads.

for 2 h. After the insoluble material was removed by centrifugation (13 000 × *g*, 4 °C, 30 min), the supernatant was collected as cell lysate. The total protein concentration of the cell lysate was determined by the Bradford method to be 5.7 mg/mL. The lysate was diluted with binding buffer containing 0.1 mM DTT and 0.1 mM $MgCl_2$, and the diluted cell lysate (800 μL, 2 mg protein) was incubated with 10 μL of PLM-D beads or 20 μL of CPALC PLM-D beads at 4 °C for 1 h. The reacted beads were washed with binding buffer containing 0.2% NP-40 (5 × 700 μL). The bound proteins were eluted from the beads by boiling with 20 μL of SDS sample buffer (140 mM Tris−HCl, 22.4% glycerol, 6% SDS, 10% 2-mercaptoethanol, 0.02% bromophenol blue, pH 6.8) at 110 °C for 10 min. The total volume of sample eluted from CPALC PLM-D beads and 1/10 of the sample eluted from PLM-D beads were subjected to SDS-PAGE.

Western Blot Analysis. Eluted proteins from beads were separated on SDS−polyacrylamide gel (10%), and then transferred to PVDF membrane (Millipore, Bedford, MA). After blocking with TBS-T (10 mM Tris-HCl, 150 mM NaCl, 0.05% Tween 20, pH 8.0) containing 6% CS (#SH30072.03; Hyclone Laboratories Inc., Logan, UT) at rt for 1 h, the membrane was incubated with rabbit anti-PP2A/a antibody (#07−250; Millipore) in the same buffer at a dilution of 1:1000 at 4 °C overnight. After washing with TBS-T, the membrane was incubated with peroxidase-labeled antirabbit IgG antibody (#NA934 V; GE Healthcare) at a dilution of 1:1000 at rt for 1 h. PP2A/a protein was detected with SuperSignal West Pico chemiluminescent substrate (Pierce, Rockford, IL) according to the manufacturer's instructions. After the detection, the membrane was treated with stripping buffer (25 mM glycine−HCl, 1% SDS, pH 2) at rt for 45 min. The stripped membrane was incubated with anti-PP2A/cα antibody (#610555; BD Biosciences, San Jose, CA) in TBS-T containing 5% skim milk at a dilution of 1:1000 at 4

°C overnight. PP2A/cα protein was detected with SuperSignal West Pico chemiluminescent substrate.

RESULTS AND DISCUSSION

The cleavable photoactivatable linker **2b** was synthesized in two steps using known *N*-(*tert*-butoxycarbonyl)cystamine and 4-[3-(trifluoromethyl)-3*H*-diazirin-3-yl]-benzoic acid *N*-hydroxysuccinimidyl ester (Scheme 1). Conjugation of **2b** on agarose beads was also quite straightforward, yielding the CPALC affinity matrix **2a**. The amount of the cleavable linker **2b** introduced on the matrix **2a** was estimated to be 269 ± 41 nmol in 1 mL of swollen beads using a spectroscopic method (*9*). This result is similar to the amount of **1a** introduced on the PALC agarose matrix (241 ± 5 nmol mL^{-1}).

First, we immobilized cyclosporin A (CsA) and FK506 onto **2a** by using the same procedure that was used for the immobilization of these compounds onto **1a** (*2*). Specifically, a solution of the respective small molecules was independently mixed with the CPALC beads **2a**, and the mixtures were concentrated and dried in vacuo. The dried beads covered with the respective small molecules were exposed to UV light (365 nm, 4 J/cm^2) and then washed thoroughly with methanol, DMSO, and PBS. Control beads were prepared by the photolysis of the CPALC beads **2a** in the absence of small molecules.

To verify the extent of compound immobilization, both the resulting CPALC CsA and FK506 beads were treated independently under the cleavage conditions (100 mM DTT in ethanol, 50 °C, 10 min). The MS analysis of the supernatant solution clearly confirmed the presence of cleaved photo-cross-linked products, as shown in Figure 3. No ion peaks from residual compounds (*m*/*z* 1202 and 803 for CsA and FK506, respectively) were observed. The MS analyses also confirmed that the above condition almost completely (>95%) cleaved the disulfide linkage, which was not affected in the absence of reducing agent (data not shown).

To validate the ability of the cleavable beads to capture and purify the binding protein in the context of the immobilized ligand, cleavable affinity beads were treated with a protein mixture containing their target proteins. The CsA molecule is known to bind to cyclophilin A (CpA) (*10*), a peptidyl prolyl cis−trans isomerase, with a K_D of 36.8 nM (*11*), whereas FK506 binds to another peptidyl cis−trans isomerase FKBP12 with a K_D of 0.4 nM (*12*). Cleavable CsA and FK506 beads were mixed with the cell lysates of an *E. coli* BL21(DE3)pLysS strain overexpressing GST-cyclophilin A conjugate (GST-CpA) and $(His)_6$-tagged FKBP12, respectively. Proteins that coprecipitated with the respective beads were then subjected to SDS gel electrophoresis.

As can be seen in Figure 4, CPALC CsA and FK506 beads can be used to purify their binding proteins (lanes 6 and 13 in Figure 4A and B, respectively), although we identified some difference between the cleavable and noncleavable versions, especially in the amount of nonspecific binding protein (denoted by the asterisks). However, when the cleavable beads were pretreated with DTT (100 mM in ethanol, 50 °C, 10 min) before being incubated with cell lysates, the beads largely lost their ability to isolate binding proteins because of the absence of the ligand.

This platform was then applied to detect a protein that forms a covalent bond with its ligand. We recently reported that the antifungal antibiotics known as phoslactomycins (*13*) inhibit protein phosphatase 2A (PP2A) through the covalent modification of cysteine-269 of the catalytic subunit of PP2A (PP2A/c) (*14*). However, when we prepared affinity beads on which phoslactomycin D (PLM-D: **3**, Figure 5A) was immobilized covalently through an amide linkage (Figure 5C, left) and used them for a pull-down experiment, only a very small amount of PP2A/c was detected by Western blot analysis (Figure 5B, lane 3, upper section) as compared to the amount of PP2Aa, a scaffolding subunit of PP2A that is known to bind to PP2A/c

through hydrogen bonding networks (*15, 16*) (lane 3, lower section). Although there are examples in which ligand-binding proteins were detected by using similar protocols (*17*), this was an obvious example in which the primary target molecule for a protein-reacting ligand was not detected sufficiently using an affinity matrix on which a small molecule was covalently immobilized. PALC PLM-D beads also gave similar results (data not shown). On the other hand, using the CPALC affinity matrix developed in the present study, the same analysis successfully detected both PP2A/c and PP2A/a (lane 5).

In summary, we have shown here that the cleavable small-molecule affinity matrix enables confirmation of small-molecule immobilization. We also confirmed its use in the detection of target proteins in the context of a protein-reacting ligand.

The combined use of this platform with LC/MS/MS may make it possible to quantitatively determine the amount of immobilized small molecule and/or small molecule−protein conjugate by comparison with an internal standard. Furthermore, it may be possible to determine what and how many conjugates are formed on the photo-cross-linked affinity matrix by combining this method with LC/MS/MS analysis. Efforts toward this goal are ongoing in our laboratory.

ACKNOWLEDGMENT

This work was supported by a Grant-in-Aid for Young Scientists (A) (No. 19681023; to NK) from the MEXT, Japan, and by the RIKEN Chemical Biology Project. We thank Dr. Takemichi Nakamura (RIKEN) for his helpful input. We also thank Prof. Takayuki Doi and Dr. Masahito Yoshida for assistance with the LC/MS analysis.

Chemical Strategies for the Synthesis of Peptide−Oligonucleotide Conjugates

Kui Lu,*[,†,‡] Qun-Peng Duan,[†] Li Ma,[†] and Dong-Xin Zhao[†]

School of Chemistry and Chemical Engineering, Henan University of Technology, Zhengzhou 450001, China, and Henan Institute of Engineering, Zhengzhou 451191, China. Received April 8, 2009; Revised Manuscript Received September 16, 2009

The use of synthetic oligonucleotides and their mimics to inhibit gene expression by hybridizing with their target sequences has been hindered by their poor cellular uptake and inability to reach the nucleus. Covalent postsynthesis or solid-phase conjugation of peptides to oligonucleotides offers a possible solution to these problems. As feasible chemistry is a prerequisite for biological studies, development of efficient and reproducible approaches for convenient preparation of peptide−oligonucleotide conjugates has become a subject of considerable importance. The present review gives an account of the main synthetic methods available to prepare covalent conjugation of peptides to oligonucleotides.

INTRODUCTION

Synthetic oligonucleotides (ONs[1]) constitute a class of potential therapeutic agents for the treatment of viral infections and genetic diseases by therapeutic regulation of gene expression (*1*, *2*). However, their systemic therapeutic use is hindered by their poor cellular uptake and inability to reach the nucleus. In order to meet the requirements for therapeutic applications, chemically modified ONs have attracted great interest (*1*). Desired improvement of certain properties, such as cell-specific delivery, cellular uptake efficiency, intracellular distribution, and target specificity, can be achieved by covalent association to peptides (*3*). These covalently associated conjugates of peptides with antisense or siRNA ONs can bind to mRNA, double-stranded DNA, protein, or catalysts in antisense, triplex, aptamer, or ribozymes application, respectively. In addition, this covalent incorporation leads to a more consistent product in which the desired properties can be controlled and changed by structural variations. Thus, development of efficient and reproducible methods for convenient preparation of covalently linked peptide−oligonucleotide conjugates (POCs) has become a subject of considerable importance.

These covalently attached POCs can be synthesized either by postsynthetic coupling of prepurified peptides and ONs or by stepwise solid-phase synthesis without intermediate purification. The progress of this field has been reviewed every few years (*3*−*9*). This short review attempts to provide an overview of vast repertoire of chemical protocols developed so far for the chemical synthesis of POCs. In addition, the advantages and areas of concern associated with the use of postsynthetic and stepwise solid-phase approach are also discussed.

CHEMISTRY OF PEPTIDE−OLIGONUCLEOTIDE CONJUGATES

Conjugation of peptide to oligonucleotide (ON) mostly occurs at 5′- or 3′-ends of the ON. The 2′-position of ribose sugar and nucleobases has also been used for appending the peptides. The synthetic approaches employed for POCs synthesis fall into two general categories: the postsynthetic conjugation approach (or fragment coupling strategy) and the stepwise solid-phase synthesis (or online solid-phase synthesis) approach. On applying the postsynthetic conjugation approach, the ON and the peptide are built in a separate support utilizing standard protocols but are conveniently functionalized to be linked after synthesis. When using the stepwise solid-phase approach, the peptide−oligonucleotide conjugate is prepared in a single support using special protecting groups and modified protocols which minimize subreactions. These approaches are further categorized into two different categories depending on the type of covalent bond generated between the ON and the peptide. The different synthetic approaches are described in following sections.

Post-Synthetic Conjugation. One of the simplest solutions to the problem of chemical incompatibility between peptides and ONs is to avoid the issue by preparing both components separately utilizing peptide and ON standard synthetic methodologies followed by linking both compounds together. Prior to the conjugation, it is required to ensure a unique and specific linkage between peptides and ONs when attaching certain reactive functionalities to both molecules. There are a variety of chemical linkages that have been used to link the peptide and ON fragments. The following section reviews in detail the synthesis of POCs with these linkages.

Conjugation through Thioether or Disulfide Linkage. Several methods for preparation of POCs have been described, most of which are based on the specific reactivity of the thiol group. Thiols afford specific and rapid conjugation and react with a wide variety of substrates (*10*). In the past few years, there have been a couple of papers in which methods to synthesize the peptide conjugates of ONs or siRNA via thioether or disulfide linkage have been reviewed (*6*, *7*, *9*, *11*−*13*).

Thioether linkage is one of the most commonly used linkages for peptide conjugates of ONs due to its higher stability. There

are two main types of thioether linkage formation: nucleophilic substitution of haloacetamides (Figure 1a) and Michael-type addition of thiols to maleimides (Figure 1b). Halogenoacetyl group introduced into peptides using haloacetic anhydrides was reacted with 5′-deprotected thiol-containing oligonucleotide (*14*−*17*). Maleimide−thiol protocol provides the required selectivity in order to obtain unambiguous oligonucleotide−peptide conjugates from unprotected precursors in most cases (*18*). Coupling of thiolated ONs with maleimido-peptides has thus been used successfully for the synthesis of thioether-linked POCs (*10*, *14*, *19*). Furthermore, conjugation to maleimido-peptides gives rise to better results, as there are fewer side products (*19*). Tregear et al. have described that thiolated oligodeoxynucleotides can react selectively and efficiently with maleimide-derivatized 18mer TAT and 22mer C-terminal gp41 vector peptides (*10*). Alternatively, coupling of Cys-containing peptides (*20*−*23*) or thiolated peptides (*24*) obtained from SPPS using a disulfide bond-based linker (*25*) with 5′-maleimide-functionalized ONs has also been used successfully for the synthesis of thioether-linked POCs. Maeda et al. established a new, efficient method to synthesize the peptide conjugates of ONs via thioether linkage (*26*). In this method, ONs incorporating a vinyl purine in their sequences were synthesized and conjugated with glutathione or Cys-containing peptide through thioether bond formation.

The coupling of thiol-containing ON with thiol-containing peptide via a disulfide linkage has been used to prepare various ON 5′- or 3′-peptide conjugates. Three straightforward routes to generate disulfide cross-linked POCs are summarized in Figure 2. The disulfide linkage can be formed either by direct oxidation of two thiols (route A) (*27*) or by preliminary activation of one thiol with pyridylsulfenyl (Pys) or 3-nitropyridylsulfenyl (Npys) group followed by nucleophilic substitution (route B and C) (*24*, *28*−*34*). However, direct oxidation may produce mixtures of undesired homodimers as well as the desired asymmetric disulfide. By preactivation of one of the thiols, the possibility to produce undesired homodimers of ON or the peptide can be circumvented. Since Pys or Npys group protecting thiol acts as a very good leaving group in the presence of free thiol and thus leads to an efficient conjugation reaction. The yield of isolated conjugates depends on the route of coupling and the peptide's structure. A comparison of the yields revealed that route C appears to be the procedure of choice for preparation of the disulfide cross-linked POCs (*29*). An advantage of route C is that the preparation of ON in the smaller scale requires less manipulation prior to conjugation. In addition, these pyridyl groups are base-sensitive and hence cannot be used during the automated ON synthesis due to the harsh final basic treatment for nucleobase deprotection. Hence, ONs with free thiol are mostly used for conjugation, and the peptide is modified by thiol group masked with 2-thiopyridyl derivatives.

Gait et al. (*35*, *36*) and Corey (*37*) described full protocols for the conjugation of peptides to ONs or siRNA via a disulfide linkage. The reaction between two thiol-containing components, one of which is first activated with a Pys or Npys group before addition of the second thiol component, is very rapid and complete. However, in the case of hightly cationic peptide, there are severe problems in maintaining solubility of the components and the resultant conjugate in aqueous solution due to aggregation and precipitation. These factors reduce the yield considerably. This can be avoided by using a high concentration of denaturing agent in both conjugation and HPLC purification steps, which allows such disulfide conjugates to be readily isolated in the pure form (*29*, *31*, *35*, *37*). Another method to overcome the problem of precipitation is to load a preactivated thiol-containing ON on the anion exchange column and add the thiol-containing peptide, followed by thorough washing to remove the excess peptide, elution with a highly concentrated salt solution (*38*, *39*). Defrancq et al. developed a novel heterobifunctional linker molecule containing a thiol-reactive nitropyridyl disulfide group and an aldehyde-reactive aminooxy group (*40*). The disulfide linkage could be formed first, followed by the formation of the oxime linkage and vice versa. By utilizing the linker molecule, a peptide−oligonucleotide conjugate was prepared.

Conjugation through Amide Linkage. Conjugation of peptides to ONs through amide bond formation involves reaction of an amino group with an activated carboxylic group. There are considerable reports wherein the fragments of POCs are linked via amide linkages. The amide linkage formation between peptides and ONs is discussed below.

Bruick et al. have utilized an ON template to direct the ligation of unprotected peptides to ONs via a stable amide linkage in aqueous solution (*41*). In this template-directed ligation procedure, a C-terminal thioester peptide was converted to a thioester-linked oligonucleotide−peptide intermediate. The ON portion of the intermediate bound to a complementary oligonucleotide template, placing the peptide in close proximity to an adjacent template-bound ON that terminated in a 3′-amine. The ensuing reaction results in an amide-linked oligonucleotide−peptide conjugate. In this procedure, however, amino acid cyclization can be a problem; thus for certain small peptides that tend to adopt a cyclic conformation, the amine terminus of the peptide may compete with the amine-terminated ON, resulting in cyclization of the peptide rather than ligation of the peptide to the ON.

Similarly, the C-terminus of peptides was efficiently coupled to 3′-terminal alkyl-amines of protected ONs in a convergent manner to yield the corresponding POCs (*42*). This conjugation reaction requires extremely mild conditions and does not require a large excess of conjugate substrate. Furthermore, the conjugates were obtained in high isolated yields (83−99%).

Another method of chemoselective conjugation, which can form a stable amide linkage between the peptides and ONs, is called "native chemical ligation" (*43*). This native chemical ligation approach, originally devised for the coupling of

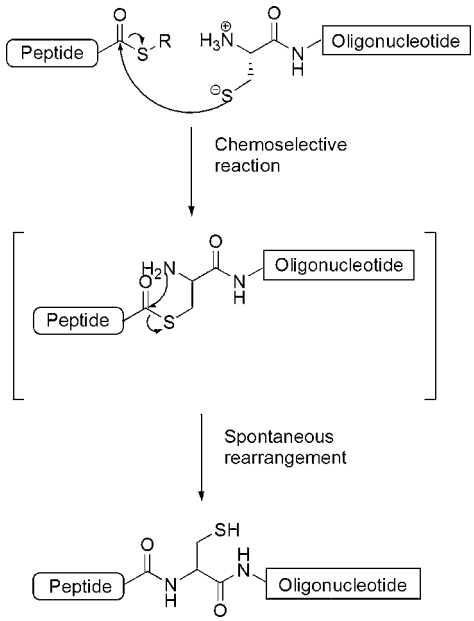

Figure 3. Chemical reaction involved in"native chemical ligation" conjugation of a peptide thioester and an oligonucleotide functionalized with a 5′-cysteine to form a stable amide linkage.

unprotected peptide segments in the chemical synthesis of proteins, has also been adapted to the conjugation of peptides to ONs. Stetsenko and co-workers have synthesized a range of POCs using this powerful approach (*44*−*46*). In this method, an N-terminal thioester peptide and a 5′-cysteinyl ON are first synthesized separately on solid supports. The unpurified, deprotected, functionalized peptide and ON can then be used in a native chemical ligation conjugation in aqueous solution (Figure 3). The advantage of this approach is that efficient coupling is achieved in the presence of denaturing agents and organic cosolvents. Thus, in principle, this method is suitable for both hydrophobic and hydrophilic peptides. Being similar to the template-directed ligation procedure, amino acid cyclization can also be a problem. Successful peptide−oligonucleotide conjugation occurred when amino acid cyclization side reactions could not take place, as was the case for peptides with an N-terminal proline, sarcosine, or alanine. In contrast, a peptide with an N-terminal glycine was prone to cyclization, and thus, no conjugation product was formed.

Gait and co-workers have reported several efficient methods for the synthesis of POCs by means of amide bond formation on a solid support (*47, 48*). They have successfully used substituted ON carrying a 5′-carboxylic acid function (**1**; Figure 4), while still attached to the solid support, to conjugate to a range of amines or to the N-termini of short peptides using normal peptide-coupling conditions to yield the highly pure conjugates (*47*). Similarly, they have also described an efficient method for the synthesis of ON 2′-peptide conjugates via amide bond formation on the solid phase. In this procedure, protected ONs bearing a 2′-*O*-carboxymethyl group were obtained by using a novel uridine 3′-phosphoramidite building block **2**, where the carboxylic acid moiety was introduced as its allyl ester. This protecting group is stable to the conditions used in solid-phase oligonucleotide assembly, but easily removed by treatment with palladium(0) and morpholine. The resulting ONs were then efficiently conjugated on a solid support under normal peptide coupling conditions to various amines or to the N-termini of small peptides to give pure products in good yield. Another procedure for the synthesis of POCs containing an amide linkage between the 2′-carboxy group of a modified ON and the amino terminus of a peptide has also been described by the same

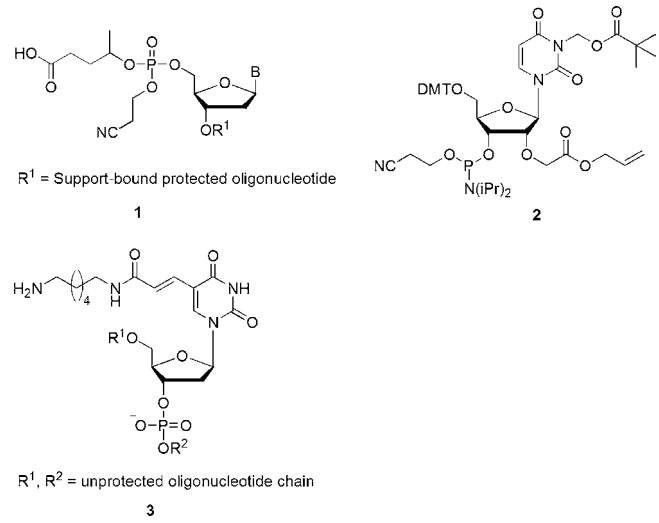

Figure 4. Building blocks for the synthesis of amide-linked POCs.

research group (*49*). In this procedure, fully deprotected ONs containing a carboxymethyl group at the 2′-position of the sugar residue were first obtained by a two-step oxidation of the 1,2-diol side chain of a 2′-modified ON by sodium periodate followed by sodium chlorite. The resulting 2′-*O*-carboxymethyl ONs were then reacted to a number of amino acid derivatives or short peptides containing N-terminal amine in the presence of a water-soluble carbodiimide to afford ON 2′-peptide conjugates in good yield (*49*). Thereby, using this method, ON 2′-peptide conjugates can be prepared via amide linkage.

In some POCs, the amino groups of the modified nucleobase have been linked to peptides through different functional groups. For example, Viladkar has used various amino acids and dipeptides to conjugate to ONs having the modified thymidine nucleoside **3**, which bears a reactive amino group on the C-5 position of pyrimidine (*50*). ONs containing the modified thymidine nucleotide were prepared, purified, and then coupled to fully or partially protected amino acids or dipeptides through their C-terminal carboxylic acids, in 50% DMF at pH 7.0. It may be noted that the ON and peptide fragments of the conjugates are separated by a spacer arm of 10 atoms. It is reported that the use of relatively highly concentrated EDC could improve the conjugation yield remarkably that depends on the presence of bulky amino acid chain, and complete conjugation can be achieved within a few hours.

Conjugation through Oxime, Thiazolidine, or Hydrazone Linkage. Covalent conjugates of ONs with peptides, which are linked by oxime, thiazolidine, or hydrazone groups, can be obtained by the reaction of carbonyl groups with aminooxy group, 1,2-aminothiol and hydrazino, or hydrazido group, respectively. There are numbers of review articles recently published in which conjugation of peptides to ONs through these founctional groups has been described (*7, 9, 51*). The present article therefore does not include an exhaustive account on the use of oxime, thiazolidine, and hydrazone reactions for oligonucleotide conjugation with peptides. Only some recent and representative examples are described below.

The aminooxy group reacts readily with a variety of electrophiles. The high nucleophilicity of this group is determined by an alpha-effect, or the presence of a lone electron pair on the adjacent heteroatom (*52*). The high reactivity of the aminooxy group toward aldehydes has been utilized for chemoselective ligation of aminooxy-modified peptides to aldehyde-modified ONs or vice versa, resulting in formation of a highly stable oxime linkage. Moreover, oxime bond formation has been successfully employed to prepare the POCs bearing

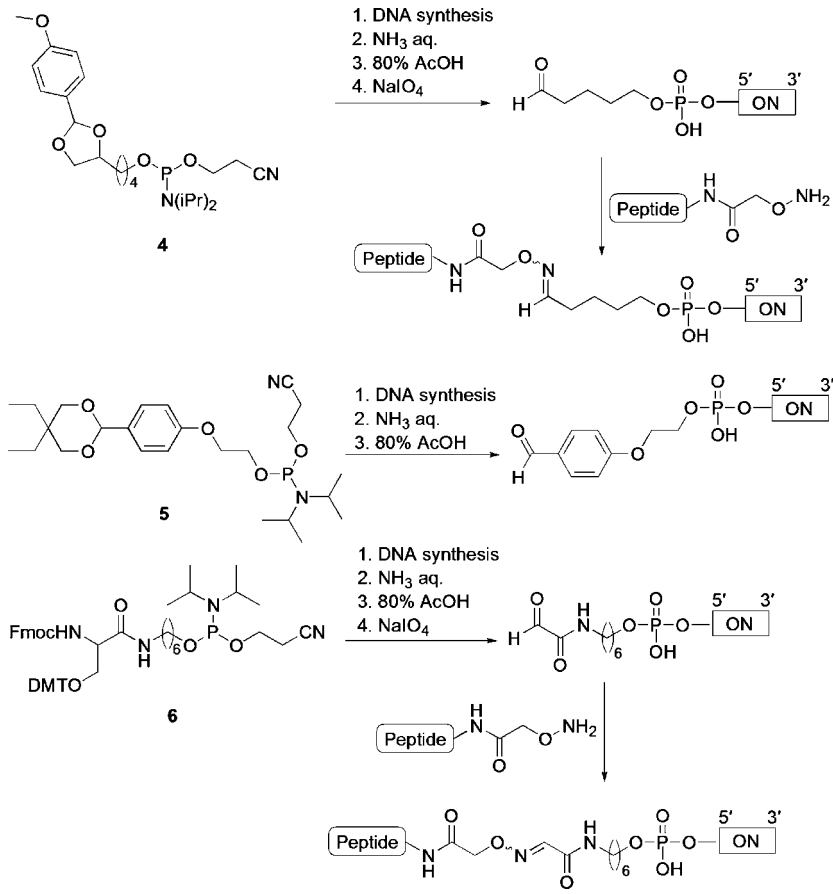

Figure 5. Synthesis of 5′-aldehyde and 5′-glyoxylyl oligonucleotides and conjugation with aminooxy peptides.

peptides at either 5′- or 3′-ends of the ON. Recently, two brief overviews of various synthetic approaches for the preparation of POCs through oxime bond formation have been described by Defrancq et al. (*53*, *54*).

There are three phosphoramidite derivatives (**4**−**6**; Figure 5) that are capable of introducing the aldehyde and glyoxylic aldehyde precursors at 5′-end of the ON (*55*−*57*). The phosphoramidite derivative **4** was prepared in two straight steps starting from 1,2,6-hexane triol and incorporated at the 5′-end of the ON during the solid-phase ON synthesis using the routine coupling procedure (*55*). Acetic acid treatment generated the ON carrying the 5′-diol moiety. The aldehyde-containing ON was prepared by periodate oxidation of 5′-diol. Subsequent conjugation with aminooxy modified peptide leads to the formation of 5′-conjugates with aldo-oxime bonds (Figure 5). The above phosphoramidite derivative was also employed to prepare glycopeptide−oligonucleotide conjugates bearing a glycocluster at the 5′-terminus of ONs (*58*). In this procedure, a cyclodecapeptide scaffold was used as a key intermediate to anchor the carbohydrate cluster and the ON through sequential oxime bond formation. Another phosphoramidite derivative **5** was also prepared in two straight steps starting from 4-(2-hydroxyethoxy)benzaldehyde and introduced at the 5′-end of the ON by the solid-phase ON synthesis (*56*). Acetic acid treatment generated the oligonucleotide carrying the 5′-benzaldehyde moiety (Figure 5). ON modified with this benzaldehyde moiety has been used for immobilization on semicarbazide-modified glass surfaces. The third phosphoramidite derivative **6** was prepared from serine (*57*). An O,N-blocked serine residue was introduced into ONs by use of this phosphoramidite during standard DNA synthesis, followed by ammonolysis and periodate oxidation to generate ONs with 5′-glyoxylic aldehyde. The resulting 5′-glyoxylic aldehyde ON is further reacted with aminooxy-containing peptide to obtain 5′-conjugates with glyoxylic oxime bond (Figure 5).

By using the above-mentioned strategies, conjugation of aldehyde or glyoxylic aldehyde modified ONs to RGD or NLS peptides was successfully achieved by Dumy′s research group (*55*, *57*). Similarly, conjugates of 5′-aminooxy modified ON with N-terminal glyoxylic aldehyde RGD and NLS peptide were also obtained by the same research group (*55*). However, the coupling of an aminooxy ON to an aldehyde peptide is less convenient to work up because free aminooxy ONs are very often prone to react with traces of carbonyl compounds, which are present in HPLC solvents or in the atmosphere. Therefore, this approach is not recommended for the synthesis of oxime conjugates. By comparing the relative stability of POCs linked by glyoxylic oxime linkage and aldo-oxime linkage, it was found that POCs linked by glyoxylic oxime linkage show higher stability at acidic to neutral pH but lower stability at alkaline pH (*55*, *57*).

Similar to the 5′-terminus, a postsynthetic oxidation strategy was used by Defrancq and co-workers for the production of aldehyde (*59*−*61*) and glyoxylic aldehyde (*62*) moiety at the 3′-position. The strategy utilized three commercially available modified long-chain alkyl amino-CPG (*7*−*9*) (Figure 6) supports to prepare aldehyde or glyoxylic aldehyde modified ONs. After the automated DNA synthesis, the ONs were cleaved from each support and deprotected by the conventional ammonia treatment to afford ONs **10**, **11**, and **12**. Subsequent periodate oxidation afford ONs with 3′-aldehyde or 3′-glyoxylic aldehyde. It must be mentioned that the solid support **8** gives irreproducible results, and the efficiency of the support for the introduction of 1,2-amino alcohol was found to decrease over a period of time even when stored at low temperature. Consequently, the other two commercially available solid supports were preferred for the

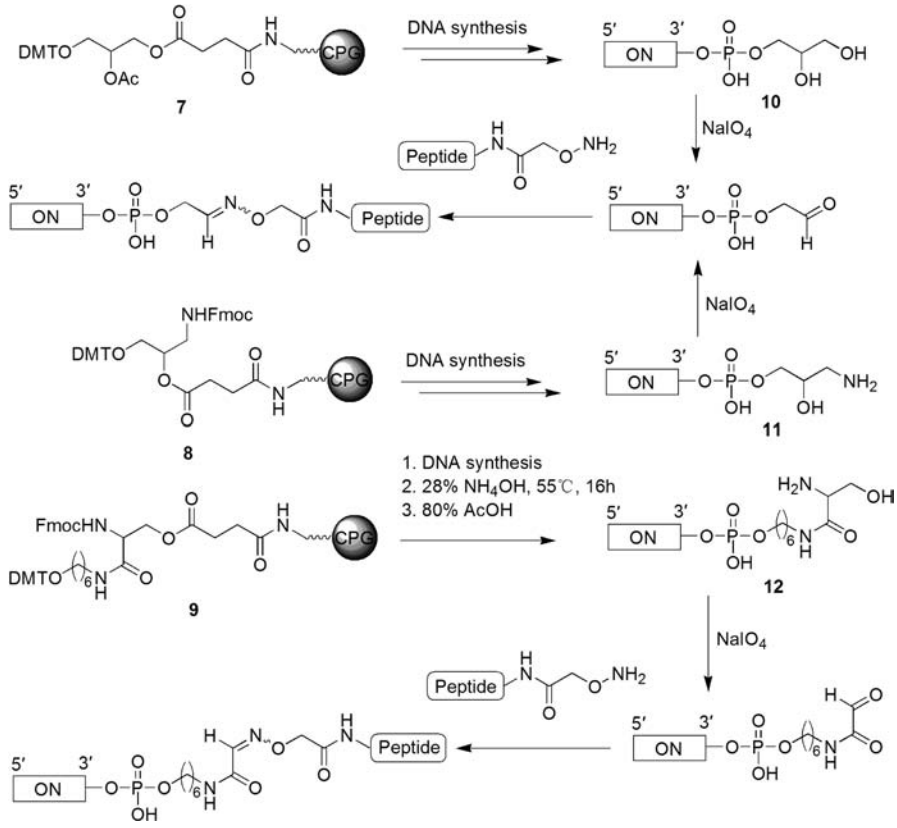

Figure 6. Synthesis of 3′-POCs through oxime bond formation.

introduction of the 3′-aldehyde or 3′-glyoxylic aldehyde into ONs. The 3′-aldehyde- or 3′-glyoxylic aldehyde-containing ON was used to prepare the ON conjugates with RGD or NLS peptides similar to the one discussed for 5′-conjugation (*59*−*62*) (Figure 6).

The aforementioned protocol described for the preparation of 3′- or 5′-conjugates can also be applied in sequential fashion for the preparation of 3′,5′-bis-conjugates. The preparation of ONs sustaining two aldehyde moieties at each terminus, followed by reaction with aminooxy-containing RGD or NLS peptides to afford 3′,5′-conjugates through oxime bond formation, has been reported by Defrancq and co-workers (*63*). This method employed bifunctionalised ONs in single step without the need of a protection strategy, under mildly acidic conditions. The conjugates were obtained in high yields. The major advantage of this ligation technique is that it requires neither a coupling reagent nor chemical manipulations. It just requires mixing the two fragments, namely, the aminooxy- and the aldehyde-containing oligomers. However, the above approach was limited to conjugation with similar peptides. Another method was later reported by the same research group in which bis-functionalized ON conjugates bearing different groups at the two extremities based on sequential formation of the oxime bonds were prepared (*64*). This strategy was utilized to prepare conjugates bearing two different peptides or a peptide and a fluorescent reporter group (*64*).

In addition to all of the above, the high reactivity of the aminooxy group toward ketones has also been utilized for chemoselective conjugation of peptides to ONs, resulting in formation of a highly stable oxime linkage (*65, 66*). Sheppard et al. have described the synthesis of DNA molecules bearing ketone functional groups (*ketone*-DNA) and the efficient postsynthetic modification of single-stranded *ketone*-DNA with an aminooxy RGD-peptide through oxime formation (Figure 7). In this approach, the methyl ketone-containing phosphoramidite derivative **13** (Figure 7) was first synthesized by modifying the C-5 position of uridine. Employing standard phosphoramidite coupling procedures, phosphoramidite **13** was used to synthesize *ketone*-DNAs. Reaction of single-stranded *ketone*-DNAs with the aminooxy RGD-peptide forms an oxime linkage (Figure 7) (*65*). Being in some ways analogous to this reported procedure, another alternative approach has been developed by Miller et al. in which the aminooxy group of AOQ-modified oligonucleotides can be conjugated to the ketone functionality introduced into the peptide via bromoacetone treatment forming a highly stable oxime linkage (Figure 8) (*32, 66*). This procedure was successfully used to prepare AOQ-modified 2′-*O*-methylribonucleoside conjugates of a tetrapeptide, RGDC, and a derivative of HIV tat peptide having a C-terminus cysteine.

Another useful fragment ligation approach in solution involves thiazolidine formation. In this approach, reaction of an aldehyde-containing ON with a cysteine-containing peptide forms a thiazolidine linkage (*55, 61, 67*) (Figure 9). For peptides containing free thiol groups, the reaction is sensitive to oxidizers so that the reaction must be carried out in the absence of oxygen.

Conjugation of aldehyde or glyoxylic aldehyde modified ONs to hydrazino peptides has been described by a number of publications. Melnyk et al. (*68*) used 5′-glyoxylyl ONs for conjugation with a hydrazino peptide (Figure 10). In this procedure, a 5′-amino ON was acylated via *O,O*′-diacetyl tartaric anhydride on a solid phase. At the end of the reaction, a glyoxylyl group was generated by a mild periodate oxidation after ON deprotection. It was found that almost 50% conjugation reaction occurs in a few seconds and the reaction was completed in 15 min (*68*). A new strategy to prepare ON modified by 5′-glyoxylic aldehyde group was also developed by the same research group (Figure 11) (*69*). This strategy utilized a novel phosphoramidite **14** derivatized by a bis[2-(*tert*-butyldisulfanyl)ethoxycarbonylamino]acetyl moiety for the synthesis of ONs modified at the 5′-end by an α-oxo aldehyde functionality. Incorporation of the phosphoramidite reagent onto the 5′-end

of ONs was performed after the automated solid-phase oligonucleotide synthesis. Simultaneous cleavage/deprotection of the ONs and unmasking of the α-oxo aldehyde group could be achieved using NaOH in aqueous methanol in the presence of excess dithiothreitol (100 equiv) (*69*).

Ligation of an aldehyde group onto the 5′- or 3′-end of an ON limits the number and position of conjugated moieties. There are a few papers describing the synthesis of POCs wherein a peptide is incorporated to the 2′-position via a 2′-aminonucleoside (*70*−*72*), but this scheme can suffer from low yield (*71*, *72*). In addition, the ligation of 2′-aminonucleosides and their acyl derivatives strongly decreases duplex stability (*73*). In contrast, synthesis of POCs with single and multiple peptides attached to 2′-aldehydes through thiazolidine, oxime, and hydrazone linkages has been shown by Zatsepin and co-workers (*74*). These POCs incorporating single or multiple peptides were obtained by synthesizing 2′-deoxyoligonucleotides and 2′-*O*-methyloligonucleotides carrying one or more 2′-aldehyde groups and then coupling it to peptides containing an N-terminal cysteine, aminooxy, or hydrazide group in good yield (Figure 12) (*74*). The same group also used a novel uridine phosphoramidite **15** (Figure 13) to generate aldehyde at the 2′-position and have successfully used it to prepare POCs through oxime or thiazolidine bond formation (*75*) (Figure 13). This facile conjugation approach allows specific coupling in aqueous solution of unprotected ONs containing aldehyde groups to unprotected N-terminally modified peptides. The advantages of this method were described as threefold: first, the reaction did not require use of a large excess of peptide (1.2−1.8 equiv); second, there is an ability to attach more than one peptide to ONs at defined sites and the freedom to attach additional moieties (i.e., fluorescent groups) at both the 3′- and 5′-ends of the ON; third, linkage by this process did not interfere with oligonucleotide-to-target hybridization. However, the hydrazones formed were liable to hydrolysis in the neutral and basic pH ranges. Thus, borohydride reduction was required (Figure 12). In addition, another method involving the conversion of the 2′-aldehyde group into a 2′-hydrazine and an efficient conjugation of the 2′-hydrazine ONs to *N*-glyoxylylpeptides has been reported by the same group (*76*). In this method, ONs containing a novel nucleoside, 2′-*O*-(2-hydrazinoethyl)uridine, were synthesized by reduction of hydrazones formed from 2′-*O*-(2-oxoethyl)oligonucleotides with 9-fluorenylmethyl carbazate with sodium cyanoborohydride, followed by concentrated aqueous ammonia deprotection. The resulting 2′-hydrazine ONs were used to synthesize POCs with *N*-glyoxylylpeptides via hydrazone formation (Figure 14).

Conjugation through the N-Acylphosphoramidate Linkage. The preparation of POCs with an N-acylphosphoramidate linkage has been described by Grandas and co-workers (*77*) wherein the N-acylphosphoramidate diesters can be obtained by either (i) phosphitylation of carbamoyl groups with chloroalkoxy(dialky1amino)phosphines and a tertiary base and

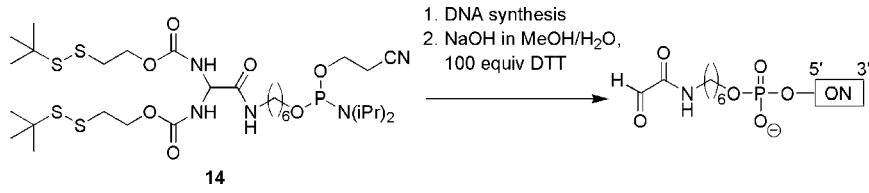

Figure 11. Synthesis of 5′-glyoxylyl oligonucleotides.

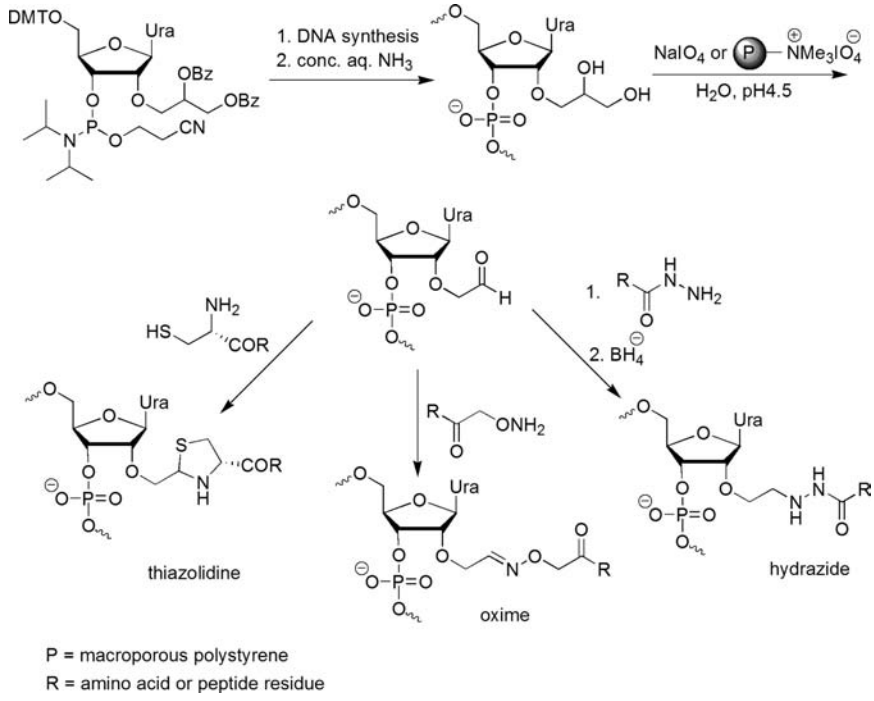

Figure 12. Preparation of 2′-O-carboxymethyl POCs through thiazolidine, oxime, and hydrazide linkages.

reaction of the resulting phosphorodiamidite with an alcohol and tetrazole followed by oxidation, or (ii) tetrazole-mediated reaction of a phosphoramidite and a primary carboxamide and subsequent oxidation. Using the former, they have synthesized a POC with an N-acylphosphoramidate union for the first time. Furthermore, the resultant POC has been shown to be stable under a variety of basic conditions and labile to treatment with an acidic reagent, but the presence of the nitrogen-linked acyl group increases the acid stability compared with unmodified phosphoramidate groups (*77*).

Conjugation through Urea or Carbonyl Linkage. Fujii and co-workers have reported a universal method to prepare a series

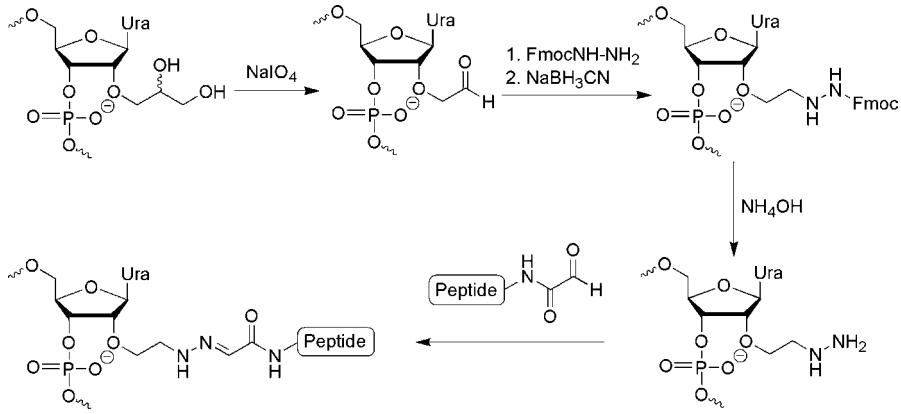

Figure 14. Synthesis of 2′-hydrazine oligonucleotides and conjugation with N-glyoxylylpeptides via hydrazone linkage.

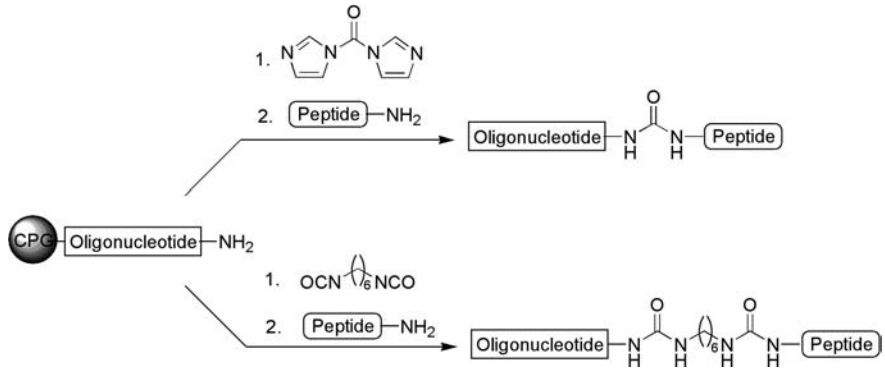

Figure 15. Postsynthetic conjugation of oligonucleotides to peptides through urea or carbonyl linkage.

types of POCs containing a urea (*78*, *79*) or a carbonyl (*80*) linkage as the linking functionality (Figure 15). The strategy of this protocol was that an ON fragment, carrying a free amino group prepared on a CPG support, was reacted with α,ω-diisocyanatoalkane or carbonyl diimidazole and then with a peptide fragment bearing a single reactive amino group. The resulting oligonucleotide−peptide conjugate covalently linked to a solid support was cleaved from the CPG and deprotected by treatment with ammonia (Figure 7). By this approach, a series of NLS peptides were covalently coupled to the 5′-end, to the 3′-end, and to the middle of the ON sequence. It is notable that all amino acids except for lysine and cysteine, whose ε-amino group and thiol group were protected by trifluoroacetyl group and acetyl group, respectively, could be used with their side chain unprotected during the coupling procedure. However, it is required that all the peptides, except peptides with a lysine at their C-termini, be coupled to β-alanine residue at their N-terminus as the reactive nucleophilic moiety for effective coupling in these methods. Conjugation of ONs to peptides with any component of amino acids can be obtained in good yield using this strategy.

Conjugation through Phosphate Linkage. Hayakawa et al. has reported a novel approach for the preparation of POCs with a base-labile phosphate linker between the peptide and ON via the allyl-protected phosphoramidite strategy (*81*). In this procedure, the phosphoramidite method was used with allyl protecting for the internucleosidic phosphate linkages and the C-terminal of the peptide and allyloxycarbonyl protecting for the nucleoside bases and the N-terminal of the peptide. The coupling proceeded between the terminal hydroxyl of an oligonucleotide still coupling to a solid phase and the phosphoramiditylated hydroxyl of a serine or threonine residue of a peptide followed by oxidized by *t*BuOOH to generate a phosphodiester bond. Finally, the removal of the allylic protecting groups and the detachment of the products were achieved under nonbasic or mild basic conditions. This method generally provides the target compounds in high yields and in good purity without conspicuous degradation of the base-labile phosphate linkage between the oligonucleotide and the peptide (*81*).

Conjugation through Diels−Alder Reaction. The Diels−Alder reaction is another strategy which offers the prospect of quickly and reliably linkage creating between a peptide and an oligonucleotide. This reaction is a cycloaddition between a conjugated diene and a dienophile to form a cyclohexene structure. Being fast and efficient in aqueous solution besides being chemoselective, the Diels−Alder reaction has been applied successfully to the bioconjugation of nucleic acids (*82*−*84*). Synthesis of POCs using the Diels−Alder reaction between a diene and a dienophile has been reported by Picken (*85*) and Grandas et al. (*86*). In this approach, the peptide was linked to a dienophile and the ON was linked to a diene. According to Picken's description, 2-furfuryl-NHCO$(CH_2)_4$CONH-oligonucleotide was reacted with a peptide−maleimide derivative to generate the Diels−Alder adduct (Figure 16a). Similarly, Grandas et al. obtained the POCs by the reaction between an acyclic diene linked to the ON chain and a maleimide-derivatized peptide (Figure 16b). Very recently, a nucleotide carrying a peptide via a Diels−Alder cyclohexene linkage was prepared and sequence-specifically incorporated into DNA (*87*). This cyclohexene-derivatized nucleotide carrying a peptide allows for the functional labeling of DNA strands under mild conditions without additional catalysts.

The cycloaddition reactions in water are clean, fast, and chemoselective, and they allow the straightforward synthesis of large peptide−oligonucleotide conjugates, containing any nucleoside or trifunctional amino acid, which are otherwise difficult to obtain (*86*). However, maleimide dienophile used in this reaction is susceptible for Michael addition reactions with other nucleophilic centers on peptides or oligonucleotides and may give rise to side reactions.

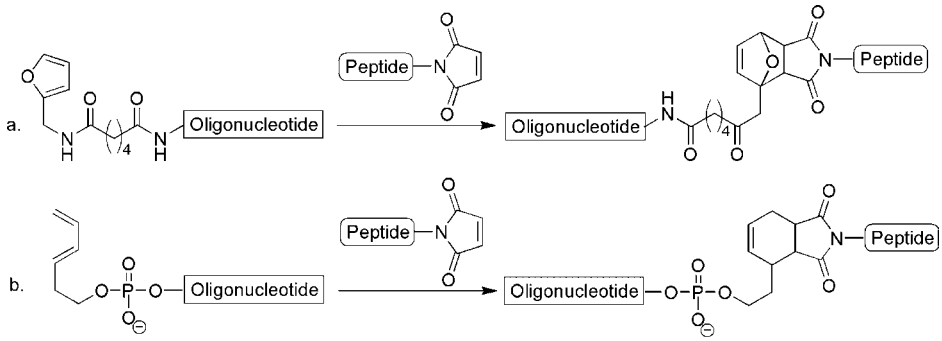

Figure 16. Schemes for the preparation of POCs by Diels−Alder reaction.

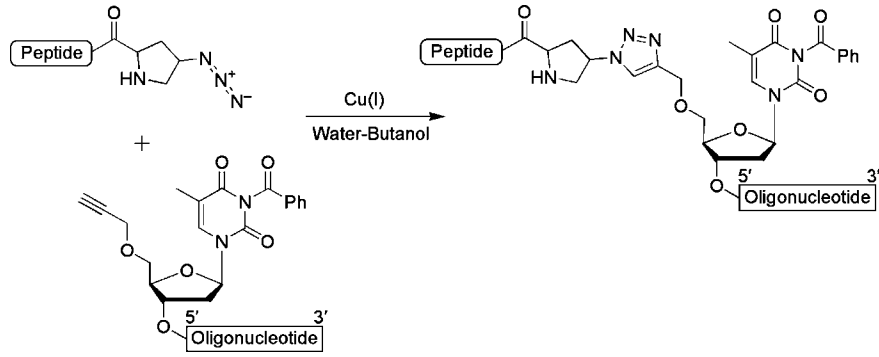

Figure 17. DNA-alkyne conjugation with 4-azidoprolyl-peptide using click reaction in solution.

Conjugation through Triazole Formation using 1,3-Dipolar Cycloaddition Reaction. The Huisgen 1,3-dipolar cycloaddition reaction involving reaction between alkyne and azide to form 1,2,3-triazoles, the so-called "click" reaction (*88, 89*), has been added to the repertoire of ONs modifying methods. The use of this click reaction for postsynthetic modification of ONs has been the subject of a recently published minireview article (*90*). Recently, this 1,3-dipolar cycloaddition reaction has been employed to synthesize POC using ligation of peptide-azide to DNA-alkyne through triazole formation (*91*). In this procedure, an ON labeled by an alkynyl group at the 5′-end and a peptide modified with an azido group at the N-terminus were synthesized. The corresponding 5′-alkynyl ON was used for "click-"conjugation with peptide-azide to produce a 1,2,3-triazole linkage between these two reactants in high purity and yield (Figure 17). This reaction can be carried out in either water or organic medium and be employed postsynthetically on purified units modified with alkynyl and azido functionalities, without additional functional group protecting strategies. This 1,3-dipolar cycloaddition chemistry is very chemoselective, only occurring between alkynyl and azido functional groups with high yield. In addition, the resulting 1,2,3-triazoles are stable under aqueous conditions and high temperature (*92*).

Total Stepwise Solid-Phase Synthesis Approach. The total stepwise solid-phase synthesis strategies suggested to date fall into two major categories: either a branched linker bearing an amino group for peptide synthesis and a hydroxyl function for subsequent assembly of the ON sequence is utilized, or a linker carrying a hydroxyl function is attached to the amino terminus of the support-bound peptide and used as a starting point for the ON chain assembly. Both approaches meet with the same difficulty, namely, incompatibility of the protecting group strategies usually applied to ON and peptide synthesis. The incompatibility of the protecting group strategies leads these approaches to be limited to incorporation of peptides with amino acids whose side chains are compatible with base-labile protecting groups or those amino acids that do not require protection. For this reason, special protecting groups that have been summarized by Kim et al. (*7*) and Grandas et al. (*93*) and modified deprotection protocols should be used. The chemistries used need to be mild enough to support the consecutive synthesis of ON and peptide, and the deprotection conditions must not affect the ON. Very recently, the methods described for the stepwise solid-phase synthesis of POCs have been reviewed as a part of a review article on the solid-supported synthesis of oligonucleotide conjugates (*94*).

Preparation of Oligonucleotide 3′-Peptide Conjugates. Most of the stepwise synthesis reported in the references generated POCs containing the peptide moiety at the 3′-end of ON (*38, 95−111, 117*). In this strategy, the peptide is first synthesized using two kinds of N-termini protected amino acids. One is the Boc-amino acids containing base labile protecting groups (Fmoc, Fm, Tfa, Tos, Dnp) for the protection of trifunctional amino acid side chains (*95, 97, 103, 106, 107, 117*). These base-labile protecting groups can be removed concomitantly with the nucleotide protecting groups. The other is the Fmoc-amino acids containing acid-labile (BOC) protecting groups for the protection of trifunctional amino acid side chains. These acid-labile protecting groups were removed by treatment with TFA-1,2-ethanedithiol (9:1) (*96, 98−102, 104, 105*). In the case of Boc-amino acids, the repetitive acid treatments used for the removal of the BOC group were performed without the presence of the oligonucleotide. Truffert et al. have reported a general automated procedure for the synthesis of oligonucleotide 3′-peptide conjugates (*104*). In order to avoid the use of strong acids, they used the Dde group for amino side-chain protection of lysine. Subsequent deprotection can be achieved by treatment with ethanolamine or hydrazine. Antopolsky and colleagues (*112*) have proposed a process using Fmoc-ornithine-methyltrityl (Mtt) as a precursor for arginine. Conversion of ornithine to arginine required additional steps, which involved treatment of the peptide containing Fmoc-Orn(Mtt) with TFA/dichloromethane, triethylamine/dichloromethane, and finally incubation in THF/triethylamine. Stromberg et al. have reported a uniform protection strategy (i.e., Bpoc group and Ddz group) for the N^{α} protection of the amino acids. Both groups could be

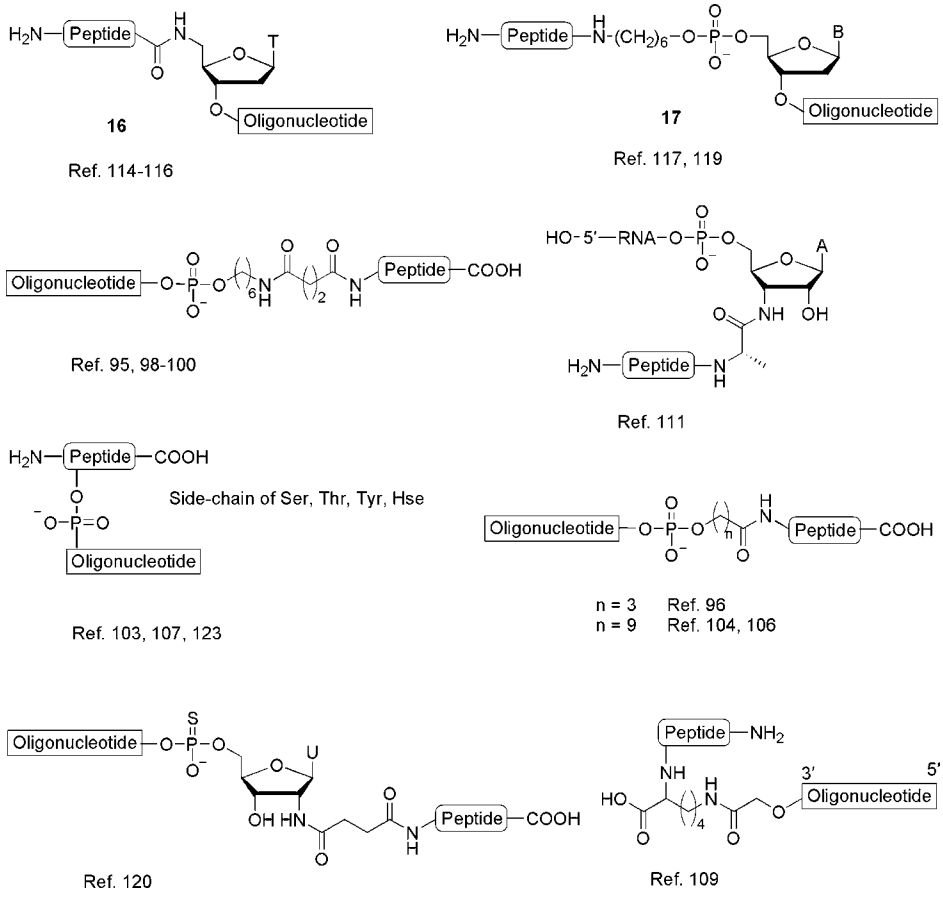

Figure 18. Linker molecules described for connecting the oligonucleotide and the peptide part in the stepwise solid-phase approach.

removed easily by treatment with TFA solution (0.2−3%) in a few minutes (*113*).

Preparation of Oligonucleotide 5′-Peptide Conjugates. In addition to oligonucleotide 3′-peptide conjugates, there are also some POCs which have been prepared carrying small peptides at the 5′-end of the ONs (*114*−*117*). For instance, 5′-amino-2′,5′-dideoxythymidine was coupled at the 5′-termini of the ON, generating an amino group from which peptide synthesis begins (*114*−*116*) (**16**; Figure 18). Further, Kool et al. have developed a simple and rapid one-pot approach to conversion of naturally substituted 5′-OH ONs (on the solid support) to 5′-amino-oligonucleotides (*118*). Compared to the typical multistep synthesis of modified phosphoramidites, this approach represents a great improvement in terms of cost and time. Thus, this approach to 5′-amine offers a substantial savings in time and effort for the total stepwise solid-phase synthesis of POCs. Recently, another straightforward approach for the synthesis of 5′-peptide oligonucleotide conjugates has been developed by Eritja and colleagues (*119*). In this approach, the ON was first assembled using standard phosphoramidite protocols. Subsequent introduction of *N*-6-MMT-aminohexyl phosphoramidite afforded 5′-amino-oligonucleotide. Then, the peptide was synthesized on support-bound oligonucleotide containing the free amino group by standard Fmoc chemistry. The POCs (**17**) were obtained after standard ammonia treatment. A similar approach has been attempted by Grandas et al. to synthesize methionine-containing peptide−oligonucleotide hybrids (*117*). However, great difficulties were encountered in coupling Fmoc-methionine to the H_2N-linker-oligonucleotide-resin. Only the use of the strongest carboxyl activating agents was found to allow quantitative coupling of the methionine derivatives.

Peptide−Oligonucleotide-Connected Linkers Used in Consecutive Synthesis of POCs. To connect via chemical bonds the peptide and ON fragment, different linker molecules have been described (Figure 18). These molecules carry a carboxyl group or an amino group for peptide synthesis and a hydroxyl function for assembly of the ON. The simplest case of the coupling linkers is the side chain of the amino acids containing hydroxyl functions. These amino acids include Ser, Thr, Tyr, and Hse.

Solid Support Used in Consecutive Synthesis of POCs. For the total stepwise solid-phase synthesis, it is necessary to choose a suitable solid support for conjugate synthesis and avoid unwanted side reactions. Polystyrene supports and CPG supports are used in peptide and ON synthesis, respectively. Most reports have described the successful use of CPG for the synthesis of POCs (*96*, *98*, *99*, *104*, *114*, *116*). However, CPG is not suitable in some cases. The yield can be improved when Teflon (*101*), polystyrene (PS) (*97*, *103*, *107*), poly(ethylene glycol) (PEG) (*121*), and poly(ethylene glycol)-polystyrene (PEG-PS) grafts (*95*, *122*) were used instead. Some of the low coupling yields reported on CPG are related to the method of activation for the amino acid or to an inherent property of a given CPG batch (*114*). Coupling reactions mediated by HBTU/HOBT are more efficient than coupling reactions with symmetrical anhydrides and some active esters (*114*). On the other hand, coupling reactions on Teflon, PS, and PEG-PS are less dependent on the activation manner during peptide synthesis but are less efficient in ON synthesis. The low coupling yields when using these supports for the synthesis of ON can be compensated by increasing the coupling time and changing the solvent to dissolve the phosphoramidites (*95*, *97*, *103*, *107*).

Solid-Phase-Anchored Linkers Used in Consecutive Synthesis of POCs. After choosing a suitable solid support, it is required to prepare an *ad hoc*-derivatized support linking a suitable spacer, which can be selectively cleaved at the end of the conjugate synthesis. The linkage between the peptide−oligonucleotide

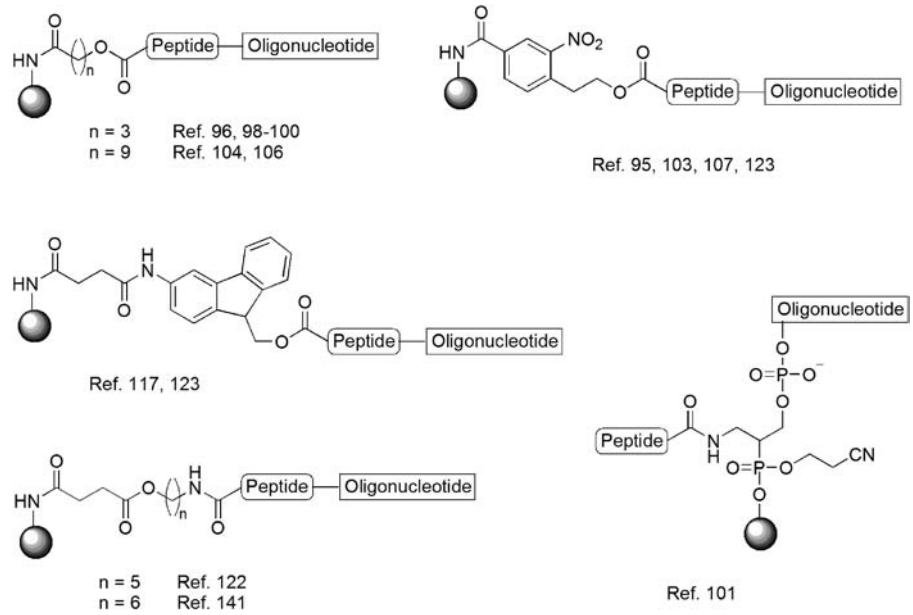

Figure 19. Linkers starting with the synthesis of the peptide between the POCs and the solid support.

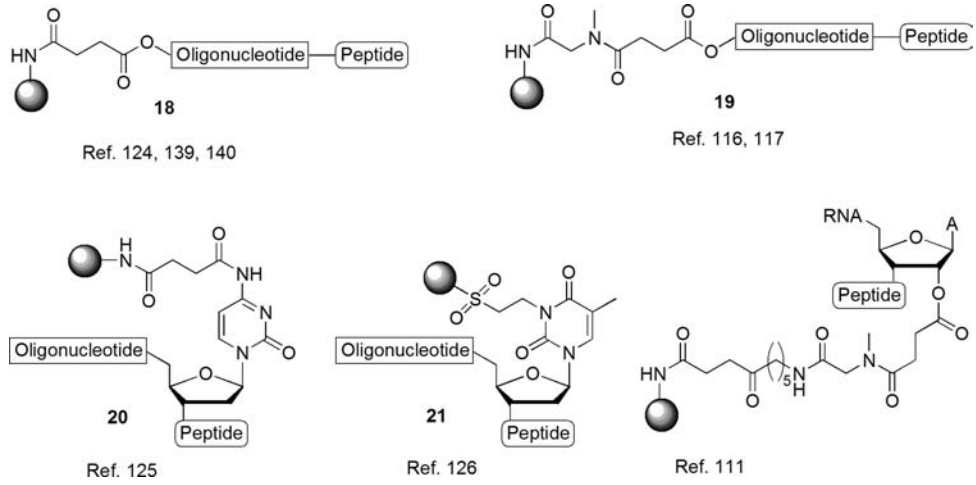

Figure 20. Linkers starting with the synthesis of the oligonucleotide between the POCs and the solid support.

conjugate and the solid support is usually a base-labile linker that starts with the synthesis of the peptide (Figure 19). Linkers from the peptide field are acid-labile and incompatible with the ON moiety. Thus, most of the linkers used to immobilize the peptide moiety have an ester function that can be cleaved with concentrated ammonia (*95, 100−104, 108*), ethylenediamine (*101*), ethanolamine (*104*), sodium hydroxide (*106*), or tetrabutylammonium fluoride (TBAF) (*103, 107, 123*). In most cases, treatment of traditional peptide handles with ammonia and primary amines generates a mixture of the C-terminal amide and carboxylate. The use of sodium hydroxide or TBAF gives the pure carboxylate peptides, but the complete deprotection of the nucleobases requires an additional ammonia treatment (*4*). Some linkages starting with the synthesis of the ON between the POCs and the solid support have also been reported (Figure 20). For instance, Grandas's research group (*124*) has used PS supports modified with a nucleotide building block to obtain nucleopeptide Boc-Ser(pTCT)-NHcHex (**18**; Figure 20). Bannwarth et al. (*116*) have used a sarcosine modified CPG support (**19**) to obtain the directly linked chimeric DNA-peptide-DNA conjugates wherein both the C- and N-termini of the peptides are conjugated to ONs. Piccialli and co-workers (*125, 126*) have designed and synthesized a cytidine-based support (**20**, **21**) for preparation of 3′- as well as 5′-peptide conjugates of ON. The conjugates were obtained in good isolated yields.

Other Methods. Besides the aforementioned chemical methods, the POCs have also been synthesized by enzymatic and mixed chemical and enzymatic methods. For example, Waldmann and colleagues have reported a method to prepare the small nucleopeptides by mixed chemical and enzymatic methods (*127, 128*). In this procedure, a combination of enzyme-labile and chemical protecting groups was used as C-terminal protecting groups. Advantages of this method are that the biocatalysts used are chemo- and stereoselective and the reaction can be carried out under mild conditions. Consequently, the peptide or phosphate bonds and other protecting groups are not cleaved under the reaction conditions. Silverman and co-workers have recently described the formation of nucleopeptide linkages catalyzed by deoxyribozymes (DNA enzymes) (*129*). They have demonstrated that deoxyribozymes have the ability to catalyze efficient formation of a Tyr-RNA nucleopeptide linkage between the side chain of tyrosine and a 5′-triphosphate-RNA. The reaction occurs when these functional groups are placed in an appropriate structural context, such as three-helix-junction architecture.

However, the analogous reactions of serine and lysine side chains are very inefficient and undetected, respectively.

CONCLUSIONS

During the past two decades, quite a number of POCs have been prepared and evaluated for various applications. It has been shown that linking peptides to oligonucleotides improves some of the desired properties of oligonucleotides such as cellular delivery (cell-penetrating properties) (*130*−*133*), increased stability to exonucleases (*97, 134*), improved binding to complementary sequences (*3, 4*), and greater rate of hybridization (*135*). Furthermore, peptide sequences have been used for the introduction of multiple nonradioactive labels in oligonucleotides (*98*−*100, 102, 105*), for the preparation of sequence-specific artificial nucleases (*104, 106, 107, 136, 137*), and as molecular bar codes in oligonucleotide combinatorial libraries (*114, 138, 139*).

In addition, several approaches for preparing POCs have been developed and evaluated over the past two decades. However, in the published procedures so far, both postsynthetic conjugation and stepwise approaches are methodologies that are far from routine. The reason for this is that there are advantages and defects for each route. For the postsynthetic approach, a major advantage is that peptides do not need to be stable under conditions of oligonucleotide assembly or vice versa. Thus, unlike the total stepwise approach, there is no issue of incompatibility of deprotection and assembly chemistries; all peptide side chains and nucleobases are deprotected before conjugation. However, the typically modest conjugation yield strongly depends on the varying solubilities of the peptides. In particular, highly basic peptides form nonspecific interactions with oligonucleotides, which may lead to poor coupling efficiency and low yield. Furthermore, this approach always requires several purification steps for both peptides and oligonucleotides, and finally the target conjugates as well. Conversely, the total stepwise method is typically characterized by a very high conjugation yield and a single purification step, and compatible with automation. Nevertheless, the stepwise solid-phase approach becomes tedious for synthesis of long conjugates. Moreover, there is still room for improvement in standard peptide synthesis technologies. For example, the limited choices of suitable protecting groups, which are compatible with peptide and oligonucleotide synthesis, is an important consideration.

Thereby, currently, the best choice for the preparation of small amounts of POCs wherein the peptide fragment is a protein or a large peptide is the postsynthetic conjugation approach, while the stepwise solid-phase protocol is suitable for the construction of large amounts of conjugates containing short peptide sequences. In addition, most of the studies on POCs focused only on synthesis, which may be related to the low yield. Therefore, the future development of a simple and straightforward procedure for generating highly pure POCs in high yield will be needed to inspire an increasing number of laboratories to prepare more conjugates, and thus enlarge their fields of application.

ACKNOWLEDGMENT

The authors would like to thank Xiu-Ling Cui for carefully revising the manuscript. This work was supported by National Natural Science Foundation of China (Grants 20572016 and 20772033) and Foundation of He'nan Educational Committee (G 2006KYCX017).

Delivery of NADPH-Cytochrome P450 Reductase Antisense Oligos Using Avidin−Biotin Approach

Venkateswaran C. Pillai,[†] Rekha Yesudas,[‡] Imam H. Shaik,[†] Thomas J. Thekkumkara,[‡] Ulrich Bickel,[†] Kalkunte S. Srivenugopal,[‡] and Reza Mehvar*,[†]

Department of Pharmaceutical Sciences and Department of Biomedical Sciences, School of Pharmacy, Texas Tech University Health Sciences Center, 1300 Coulter, Amarillo, Texas 79106. Received October 14, 2009; Revised Manuscript Received December 21, 2009

Although avidin-mediated intracellular delivery of oligonucleotides or proteins has been shown before, the efficacy studies are lacking. Here, we tested the effectiveness of avidin for delivery of a cytochrome P450 reductase (CPR) antisense oligo in rat liver epithelial cells. A phosphorodiamidate morpholino oligo (PMO) against CPR was biotinylated using four reagents with short, cleavable, or long linkers, followed by conjugation with avidin. The dose-inhibitory response of the unmodified PMO in the presence of a transfection reagent (Endoporter, EP) and the effectiveness of the EP-assisted and avidin-assisted delivery of biotinylated PMOs were tested by Western blot analysis. Additionally, in a preliminary study, the avidin−biotin PMO with a long linker was also tested in vivo in rats. The biotinylated oligos were at least as effective as the unmodified oligo. Whereas the avidin conjugate of biotinylated PMO with the short linker was ineffective, those with the long linkers showed significant reductions in CPR protein expression. Finally, the in vivo study showed modest, but significant, reductions in CPR activity. In conclusion, these studies show for the first time that avidin-mediated intracellular delivery of biotinylated oligos can effectively knock down target genes in vitro, depending on the length of the linker. Additionally, the avidin−biotin approach may be of potential value for in vivo gene knockdown.

NADPH-cytochrome P450 reductase (CPR) is a flavoprotein first identified in the liver by Horecker in 1950 (*1*) as a cytochrome c reductase. The key function of CPR is to donate electrons mainly to cytochrome P450 enzymes. It has been reported (*2*−*5*) that CPR can generate reactive oxygen species (ROS) by direct and indirect mechanisms. The direct mechanisms include the generation of superoxide (*3*) and redox cycling of cellular Fe^{3+} (*2, 3*) and quinones/quinoid compounds (*5*) to generate hydroxyl radicals and free semiquinone radicals, respectively. Additionally, CPR contributes to generation of superoxide and hydrogen peroxide indirectly via uncoupling mechanism of the cytochrome P450 monoxygenases system (*6, 7*). Indeed, CPR has been suggested as a potential source of endogenous oxidative stress and DNA damage (*8*). Hence, CPR inhibition may reduce ROS generation and oxidative stress in different diseases of the liver.

In mammals, the expression of liver CPR is regulated by thyroid hormone (*9*−*11*). It has been reported that depletion of thyroid hormone by hypophysectomy (*9*) or treatment with the antithyroid drugs methimazole (*9*) or propylthiouracil (*11*) significantly reduces CPR activity and protein in the liver, an effect that is reversed by thyroxine therapy. However, manipulation of thyroid hormone levels is considered a nonspecific method of CPR inhibition because it affects a number of other physiological processes. Additionally, chemical inhibitors of CPR, such as diphenyleneiodonium (*12*) and α-lipoic acid (*13*), usually exert other nonspecific effects. On the other hand, inhibition of protein expression using antisense oligos or by RNA interference could potentially be relatively specific (*14*). Therefore, we chose to use the latter approach in our studies by applying a phosphorodiamidate morpholino oligo (PMO) (*15*) against CPR. PMOs are among the modified DNA analogues that block the translation initiation through an RNase-H independent process (*15, 16*). The modification of DNA in PMOs include replacement of deoxyribose sugars by morpholine and the charged phosphodiester linkages by nonionic phosphorodiamidate linkages (*15*). Consequently, PMOs are neutral and resistant to degradation by nucleases. Additionally, in contrast to phosphorothioates, which are known to bind nonspecifically to extracellular, cell surface, and intracellular proteins, PMOs exhibit little or no nonspecific protein binding (*15, 16*).

Because of their large size and physicochemical properties, unassisted delivery of antisense oligos into the cells is usually very limited after both in vitro and in vivo applications (*17*−*20*). Consequently, different methods, such as viral and nonviral vectors, have been used to improve their cellular delivery and effects. One of these methods is the use of avidin as a cationic carrier for delivery of biotinylated oligos (*21*−*24*). This method is based on the high-affinity binding of avidin to biotin (*25*) and entry of the avidin-bound cargo to the cell by endocytosis (*21*). Indeed, previous studies showed that the avidin−biotin approach can deliver antisense oligos or peptides to the isolated bovine capillaries in vitro (*21*) or antisense oligos to the liver of rodents in vivo (*23, 24*). However, we are not aware of any studies demonstrating that such an approach can indeed result in gene knockdown. Therefore, our main aim for the current study was to investigate the effectiveness of the avidin−biotin approach for delivery of a PMO antisense against CPR to a rat liver cell model. Because the binding of the avidin−biotinylated antisense to the target mRNA may be affected by the linker between biotin and antisense, we also tested the effects of linker length and cleavability on the effectiveness of the conjugates. Finally, the effectiveness of such an approach was tested in a

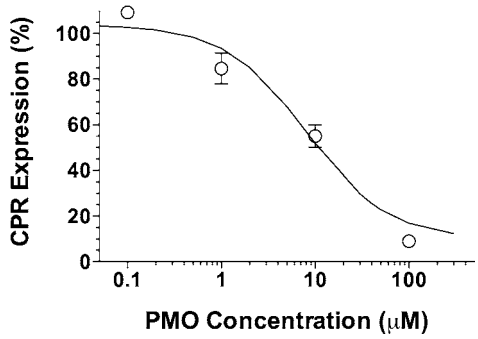

Figure 1. Relationship between the concentrations of unmodified PMO and CPR protein expression in rat liver epithelial cells. Cells were incubated with different concentrations of PMO in the presence of a 2 μM concentration of the transfection reagent Endoporter for 48 h. CPR expression was determined in the cell lysate by Western blot analysis. Symbols and bars represent experimental mean and SD (n = 3), respectively, and the line represents the model fitted relationship.

preliminary in vivo study in rats. Details of the experimental procedures are available in the Supporting Information.

Rat liver epithelial (WB-F344) cells (*26*, *27*) were incubated for 48 h in the presence of 0.0, 0.1, 1, 10, and 100 μM concentrations of a 25-mer phosphorodiamidate morpholino oligo (PMO) against CPR and 2 μM of an in vitro transfection reagent (Endoporter, EP). Afterward, cells were lysed, and the lysate was used for CPR protein analysis using Western blotting method. Unmodified PMO showed dose-dependent decreases in CPR protein expression (Figure 1). Whereas a 0.1 μM concentration of PMO showed no inhibition of CPR, a 100 μM concentration inhibited CPR protein expression by ~90%. The nonlinear regression fit to the data revealed an IC_{50} value of 8.05 μM and a maximum inhibition of 94.0% for the unmodified PMO in the presence of EP transfection reagent.

Next, four different linkers (L1, L2, L3, and L4; Figure 2) were used to biotinylate the PMO against CPR. The biotinylated PMOs were characterized before and after retention of the biotinylated moiety on an avidin affinity column. The pre- and post-avidin column samples were then subjected to size exclusion HPLC to quantitate the degree of biotinylation. Figure 3 shows the chromatograms of the biotinylated PMO with the L1 linker before (Figure 3A) and after (Figure 3B) passage through the avidin column. The difference between the post-column and precolumn peak areas reflects the biotinylated fraction retained on the avidin column. The percentages of biotinylation, estimated from the postcolumn and precolumn samples, analyzed in triplicate, were 80.8, 74.9, 86.6, and 87.9 for the samples with L1, L2, L3, and L4 linkers, respectively.

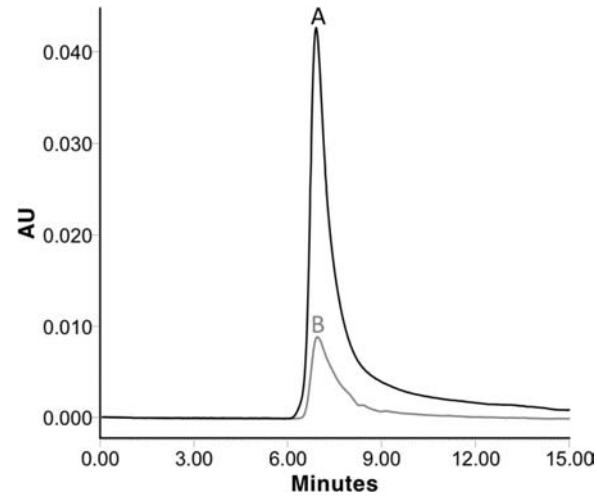

Figure 3. Representative chromatograms of a biotinylated PMO with linker 1 before (A) and after (B) passage through an avidin column that retains the biotinylated PMO. Chromatograms A and B represent the total (biotinylated plus free PMO) and free PMO, respectively.

These data indicate a relatively high degree of biotinylation with relatively small differences among biotinylation reagents with different linkers.

To determine the effect of biotinylation of PMO on its antisense effect, a 5 μM concentration of PMO biotinylated with L1 (PMO-L1-Biotin), L2 (PMO-L2-Biotin), L3 (PMO-L3-Biotin), or L4 (PMO-L4-Biotin) was incubated with WB cells for 48 h in the presence of EP. Additionally, unmodified PMO and invert PMO were used for comparison. As demonstrated in Figure 4, all four biotinylated PMOs inhibited CPR protein expression at least as effectively as the unmodified PMO (Figure 4). Interestingly, the biotinylated PMOs with the L1 (PMO-L1-Biotin) and L4 (PMO-L4-Biotin) linkers showed significantly (P <0.01 and <0.05, respectively) higher inhibition of CPR expression, compared with the unmodified PMO (Figure 4). As expected, the invert PMO did not significantly affect the CPR protein expression.

To determine the effectiveness of avidin for delivery of the biotinylated PMO, biotinylated PMOs were conjugated with avidin at a 1:1 molar ratio. The avidin conjugated biotinylated PMOs (5 μM) with L1 (PMO-L1-Biotin:Avidin), L2 (PMO-L2-Biotin:Avidin), L3 (PMO-L3-Biotin:Avidin), or L4 (PMO-L4-Biotin:Avidin) linkers were then incubated with WB cells for 48 h in the absence of the transfection reagent EP. Whereas avidin-conjugated biotinylated PMO with the short linker (L1) did not show any inhibitory effect, the two conjugates with the

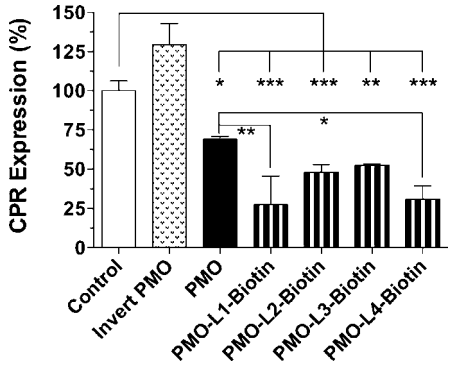

Figure 4. Effects of biotinylation with reagents containing linkers 1−4 on the inhibition of CPR protein expression by PMO in rat liver epithelial cells. Cells were incubated with a 5 μM concentration of PMO in the presence of a 2 μM concentration of the transfection reagent Endoporter for 48 h. CPR expression was determined in the cell lysate by Western blot analysis. Columns and bars represent mean and SD (n = 3), respectively. *P < 0.05, **P < 0.01, and ***P < 0.001 (one-way ANOVA, followed by Tukey's post hoc analysis).

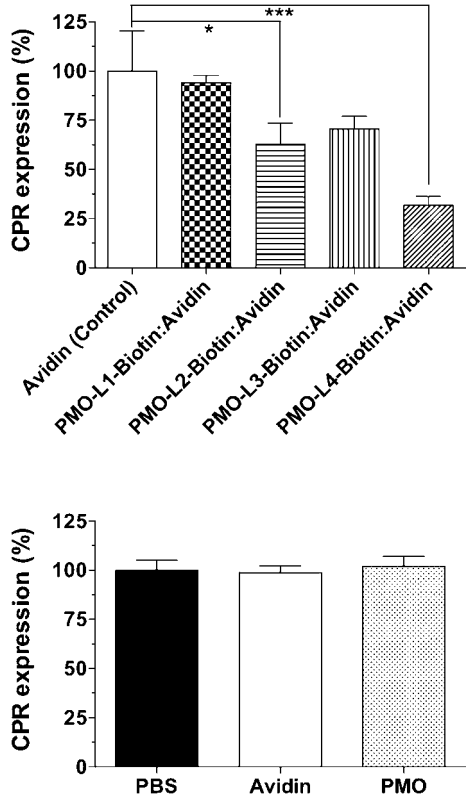

Figure 5. Effects of avidin-mediated delivery of PMO biotinylated with reagents containing linkers 1−4 on the inhibition of CPR protein expression in rat liver epithelial cells. Cells were incubated with a 5 μM concentration of avidin alone (control) or avidin−biotin PMOs (top) or with phosphate buffered saline (PBS) or a 5 μM concentration of avidin alone or PMO alone (bottom) in the absence of the transfection reagent Endoporter for 48 h. CPR expression was determined in the cell lysate by Western blot analysis. Columns and bars represent mean and SD (n = 3), respectively. *P < 0.05 and ***P < 0.001 (one-way ANOVA, followed by Tukey's post hoc analysis).

long linkers (L2 and L4) showed significant reductions in CPR protein expression (P < 0.05 and P < 0.001, respectively) (Figure 5, top). As for the conjugate with the cleavable linker (L3), the reduction in the CPR protein expression did not reach statistical significance. Overall, among all the tested conjugates, the avidin-conjugated biotinylated PMO with L4 showed the highest degree of CPR protein inhibition (∼70%). Control experiments with

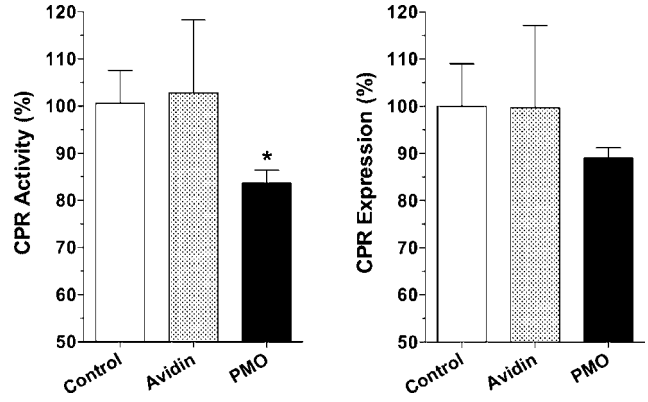

Figure 6. Microsomal CPR activity (left) and expression (right) in rat livers after intravenous administration of vehicle (control), 40 mg/kg/day of avidin (Avidin), or 5 mg/kg/day of PMO-L4-Biotin:Avidin (PMO) for 3 days. Microsomal CPR expression and activity were determined 24 h after the last dose. Columns and bars represent mean and S.D., respectively (n = 8 for the control group and 4 for the avidin and PMO groups). * Significant difference (P < 0.05, one-way ANOVA, followed by Tukey's post hoc analysis) between PMO and control and between PMO and avidin.

phosphate-buffered saline (PBS), avidin alone, and PMO alone demonstrated that neither PMO alone in the absence of any transfection reagent nor avidin alone had any suppressive effects on CPR expression (Figure 5, bottom).

Finally, in a preliminary study, male Sprague−Dawley rats (75−100 g) were treated intravenously with vehicle, avidin (40 mg/kg), or 5 mg/kg/day doses of PMO-L4-Biotin:Avidin for 3 days and the microsomal CPR activity (*28*) and protein expression were determined. The avidin-conjugated PMO showed (Figure 6) modest, but significant, reductions in the rat liver microsomal CPR activity, relative to the control (17% decline) and Avidin (19% decline) groups. As for the CPR protein contents, an 11% reduction in the PMO group, compared with the control or Avidin group, did not reach statistical significance using multiple comparisons.

One of the main hurdles in the CPR research is that there are no specific chemical inhibitors for this protein to be used for delineation of its role in oxidative injury. Hence, we sought to use the antisense approach in this study to specifically inhibit the translation of CPR at its mRNA level. Our dose−response data (Figure 1) using the PMO against CPR showed a dose-dependent inhibition of CPR in WB cells with an IC_{50} of 8 μM and 90% inhibition of CPR at a concentration of 100 μM (Figure 1). However, the reported (*29*) turnover half-life of CPR in rat liver microsomes is 29−35 h, which suggests that a complete inhibition of protein expression is expected to result in a maximum of 70% decline in the protein levels after 48 h of incubation. Therefore, a higher degree of inhibition observed after the PMO concentration of 100 μM (∼90%, Figure 1) suggests that the PMO antisense used in our study may exert some nonspecific effects at this high concentration.

To use avidin as a carrier, the antisense oligos are first biotinylated to take advantage of the high-affinity binding of avidin to biotin, which has a dissociation half-life of 89 days (*25*). Because biotinylation of antisense oligos may alter their physicochemical properties and binding to the target mRNA, we studied the effects of biotinylation with different linkers on the CPR inhibitory effect of our PMO antisense. Biotinylation of PMO not only did not adversely affect the inhibition of CPR expression, but also caused an improvement of their effects in the case of PMO-L1-Biotin and PMO-L4-Biotin (Figure 4). The reasons for this improvement are not clear from our studies. However, possible explanations could be an improvement in

the EP-mediated delivery of the PMO antisense to the cytosol and/or improved binding of the PMO to the target mRNA as a result of biotinylation. These results are in agreement with those reported by Boado and Pardridge (*22*) who showed that RNase H caused degradation of *tat* sense RNA in the presence of a biotinylated phosphodiester antisense oligo against *tat*. However, they did not compare the efficacy of the biotinylated oligo with that of nonbiotinylated oligo. Nevertheless, our studies appear to be the first examination of the effects of biotinylation on the inhibitory activity of PMO oligos.

An in vitro study using isolated bovine capillaries (*21*) showed that avidin acts as a carrier for cellular uptake of a biotinylated antisense oligonucleotide or a model peptide. It was suggested that the avidin-mediated uptake is associated with endocytosis and is based on the cationic nature of the avidin protein. Additionally, a more recent study (*24*) showed that a radiolabeled biotinylated oligo conjugated to avidin was internalized into the mouse hepatocytes without the assistance of transfection reagents. However, neither of these studies reported the effects of the antisense or peptide. When we first tested the inhibitory effects of an avidin conjugate of the commercially available biotinylated PMO against CPR (PMO-L1-Biotin:Avidin) in our WB cells, we were disappointed by the lack of inhibitory effect of this conjugate (Figure 5). Because the linker between biotin and PMO was short (L1, Figure 2), we hypothesized that this lack of effect is due to the steric hindrance of avidin, impeding the interaction of the oligo with its target mRNA. Therefore, in a subsequent study, we biotinylated our PMO with reagents that contained long (L2 and L4) or cleavable (−S−S−) linkers (Figure 2). In agreement with our hypothesis, all these linkers inhibited the CPR expression, although the reduction did not reach statistical significance with the cleavable linker (L3; Figure 5). Interestingly, CPR inhibition with the avidin-mediated delivery of PMO with L2 or L4 linkers (Figure 5) was as effective as or more effective than the inhibitory effect observed with the EP-mediated delivery of the unmodified PMO (Figure 4). These results suggest that avidin-mediated delivery using appropriate linkers may be an alternative approach to transfection reagents in the intracellular delivery of PMOs in vitro.

Although the in vivo distribution of avidin conjugates of biotinylated oligos has been reported previously in rodents (*23, 24*), we are not aware of any in vivo studies testing the inhibitory effects of these conjugates. The previously reported distribution studies (*23, 24*) suggested high accumulation of the conjugates in the liver. Therefore, we tested the efficacy of PMO-L4-Biotin:Avidin, which had shown the strongest in vitro effect (Figure 5), in a preliminary study in rats. The in vivo study (Figure 6) showed for the first time that an avidin-mediated in vivo gene knockdown is feasible. However, the relatively low level of inhibitory response suggests that such an approach may be limited by the potency of the gene knockdown agent. This is because, to deliver a 5 mg/kg dose of CPR PMO (M_w of 8476), we had to administer a 40 mg/kg dose of avidin (M_w of 68000) in a 1:1 molar ratio used in our studies. This is a relatively high dose for in vivo administration of avidin, limiting the dose of oligo that may be delivered by this approach. Thus, the avidin-mediated in vivo gene knockdown approach may be more suitable for delivery of more potent oligos or other gene knockdown agents, such as siRNAs, that inhibit CPR expression at nanomolar concentrations (*30*).

In conclusion, our studies show for the first time that avidin-mediated intracellular delivery of biotinylated oligos can effectively knock down target genes in vitro. Further, it was shown that the efficacy of an avidin-conjugate of biotinylated PMO antisense against rat liver epithelial cell CPR depends on the length of the linker between the biotin and PMO, with longer linkers being more effective than a short linker. Although preliminary studies indicated feasibility of in vivo gene knockdown by the avidin−biotin approach, the method may be limited by the requirement for relatively large amounts of avidin. Further studies are needed to test this approach for in vivo delivery of more potent agents, which require smaller amounts of avidin administration.

Herein, we prepared tumor-targeting peptide (AP peptide; CRKRLDRN) conjugated pH-responsive polymeric micelles (pH-PMs) in cancer therapy by active and pH-responsive tumor targeting delivery systems, simultaneously. The active tumor targeting and tumoral pH-responsive polymeric micelles were prepared by mixing AP peptide conjugated PEG-poly(D,L-lactic acid) block copolymer (AP-PEG-PLA) into the pH-responsive micelles of methyl ether poly(ethylene glycol) (MPEG)-poly(β-amino ester) (PAE) block copolymer (MPEG-PAE). These mixed amphiphilic block copolymers were self-assembled to form stable AP peptide-conjugated and pH-responsive AP-PEG-PLA/MPEG-PAE micelles (AP-pH-PMs) with an average size of 150 nm. The AP-pH-PMs containing 10 wt % of AP-PEG-PLA showed a sharp pH-dependent micellization/demicellization transition at the tumoral acid pH. Also, they presented the pH-dependent drug release profile at the acidic pH of 6.4. The fluorescence dye, TRITC, encapsulated AP-pH-PMs (TRITC-AP-pH-PMs) presented the higher tumor-specific targeting ability in vitro cancer cell culture system and in vivo tumor-bearing mice, compared to control pH-responsive micelles of MPEG-PAE. For the cancer therapy, the anticancer drug, doxorubicin (DOX), was efficiently encapsulated into the AP-pH-PMs (DOX-AP-pH-PMs) with a higher loading efficiency. DOX-AP-pH-PMs efficiently deliver anticancer drugs in MDA-MB231 human breast tumor-bearing mice, resulted in excellent anticancer therapeutic efficacy, compared to free DOX and DOX encapsulated MEG-PAE micelles, indicating the excellent tumor targeting ability of AP-pH-PMs. Therefore, these tumor-targeting peptide-conjugated and pH-responsive polymeric micelles have great potential application in cancer therapy.

INTRODUCTION

Polymeric micelles formed by amphiphilic block copolymers in aqueous conditions have been investigated as a tumor-targeting drug delivery system in cancer therapy, because they can form a stable nanosized micellar structure, resulting in accumulation and extravasation into the target tumor tissue, which is called an enhanced permeation and retention effect (EPR effect) (*1, 2*). Importantly, pH-responsive polymeric micelles (pH-PMs) are more attractive for their sharp pH-dependent structural disruption in tumoral acidic pH, which results in rapid drug release at target tumor tissue (*3*−*5*). This is because tumor tissues have a more acidic environment, due to the lactic acid produced by acidic intracellular organelles and hypoxia. Due to the tumoral acidic pH microenvironments, various amphiphilic copolymers containing pH-responsive histidine and sulfonamide moieties have been designed to present a sharp pH-dependent micellization/demicellization transition, resulting in the demicellization leading to rapid drug release at target tumor tissues (*3, 6*). Therefore, pH-PMs not only successfully targeted at tumor tissue, but also enabled rapid drug release into the target tumor tissue (*7*−*9*).

We also developed pH-PMs composed of poly(ethylene glycol) methyl ether−poly(β-amino ester) (MPEG-PAE) (*10*), which presented a sharp pH-responsive micellization/demicellization transition at the tumoral acidic pH condition (pH 6.4−6.8), due to its tertiary amine with a pK_b of about 6.5 (*11, 12*). However, the pH-responsive MPEG-PAE micelles at the acidic pH buffer might take a few hours to present the sharp pH-dependent responsiveness at the tumoral weakly acidic pH microenvironment. It is also reported that most pH-responsive polymeric micelles at the acidic buffer condition required a prolonged reaction time to present a pH-responsiveness. On the basis of the time-delayed pH-responsiveness of polymeric micelles, the in vivo pH responsiveness of various polymeric micelles at the target tumor tissue might be less effective than that in the in vitro pH buffer condition, due to the very small tumor volume and the lower tumor targeting ability. Therefore, the pH-responsive polymeric micelles should be specifically targeted and remained for a long time at the target tumors, wherein the pH-responsive polymeric micelles might present a sharp pH-dependent micellization/demicellization transition.

Herein, to enhance the specificity and retention time of pH-PMs at the target tumor, we prepared tumor-specific peptide (AP peptide; CRKRLDRN)-conjugated pH-responsive MPEG-PAE micelles (AP-pH-PMs). It was reported that AP peptide had very specific binding affinity to IL-4 receptors of atherosclerotic plaques and breast tumor tissues (*13*−*15*). Therefore, we anticipated that AP-pH-PMs may increase the pH-responsiveness at the target tumors, due to the enhanced tumor

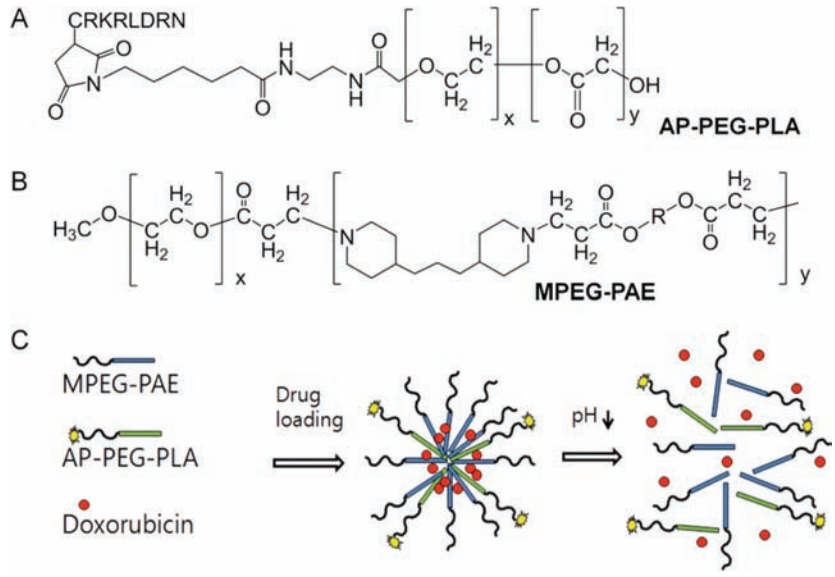

Figure 1. Design strategy of peptide-conjugated pH-responsive micelle: (A) Chemical structure of tumor-targeting AP peptide (CRKRLDRN) coupled PEG-PLA block copolymer (AP-PEG-PLA) and (B) pH-responsive MPEG-PAE block copolymer (MPEG-PAE). (C) Schematic diagram depicting tumor-targeting and pH-responsive polymeric micelles of AP-PEG-PLA/MPEG-PAE (AP-pH-PM), which triggered doxorubicin (DOX) release by the sharp pH-dependent micellization/demicellizaton transition at the tumoral acidic pH.

targeting ability in vivo. In order to prepare AP peptide-modified polymeric micelles, AP peptide grafted PEG-poly(D,L-lactic acid) block copolymer (AP-PEG-PLA) was prepared and mixed with pH-responsive MPEG-PAE block copolymer in aqueous condition. These mixed amphiphilic block copolymers were self-assembled to form stable AP-pH-PMs (Figure 1). The AP-pH-PMs containing 10 wt % of AP-PEG-PLA showed a sharp pH-dependent micellization/demicellization transition at the tumoral acid pH (pH 6.8−6.9). To assay the tumor targeting ability of AP-pH-PMs in MDA-MB231 human breast tumor-bearing mice, fluorescence dye, TRITC, encapsulated AP-pH-PMs were noninvasively monitored using optical fluorescence imaging technology. Finally, doxorubicin (DOX) was encapsulated into the AP-pH-PMs (DOX-AP-pH-PMs), and its enhanced therapeutic efficacy was studied in MDA-MB231 human breast tumor-bearing mice, compared to control free DOX and DOX encapsulated pH-responsive MEPG-PAE micelles (DOX-pH-PMs), respetively (*16*).

RESULTS AND DISCUSSION

In order to enhance the targeting specificity and retention time of pH-PMs at the target tumor, first, human breast tumor-specific AP peptide (CRKRLDRN) chemically conjugated to the PEG-PLA block copolymer (AP-PEG-PLA) was prepared by chemical coupling thiolated AP peptide to maleimide-terminated PEG-PLA block copolymer in acetonitrile/water (Figure 1A). After the reaction, the solution was lyophililized and reprecipitated in cold diethyl ether for twice the time, followed by drying in a vacuum oven for 12 h (yield: 85%), resulting in AP-PEG-PLA (M_w = 19.6 kDa). Second, pH-responsive block copolymer was prepared by a Michael-type step polymerization between hydrophilic methyl ether poly(ethylene glycol) (MPEG) and pH-responsive/biodegradable poly(β-amino ester) (PAE) (Figure 1B), wherein the MPEG-PAE (M_w = 17.4 kDa) has 2.6 mol equiv of PAE per 1 M of PEG (see the Supporting Information), as previously reported (*10*). The AP peptide-modified pH-responsive micelles (AP-pH-PMs) were simply prepared by a solvent evaporation method (Figure 1C). The polymer mixture containing 10 wt % of AP-PEG-PLA and 90 wt % of MPEG-PAE in organic solvent was evaporated to give the polymer thin film, and the film was incubated in distilled water or PBS at 37 °C for 30 min. After the incubation, the dried polymer film was dispersed by signification for 2 min. This amphiphilic AP-PEG-PLA/MPEG-PAE mixture was spontaneously self-assembled to form stable polymeric micelles with an average diameter of 156 nm at normal pH of 7.4. Also, the AP-pH-PMs showed a sharp micellization/demicellization transition at tumoral acidic pH values (pH 6.8−6.9). It is deduced that amphiphilic MEPEG-PAEs are ionized and completely dissolved at the weakly acidic condition.

For the assay, the tumor targeting ability and anticancer therapeutic efficacy of AP-pH-PMs, 10 wt % of fluorescence dye, TRITC, or 10 wt % of anticancer drug, doxorubicin (DOX), was encapsulated into the AP-pH-PMs by the solvent evaporation method, respectively (see Supporting Information) (*17*). Hydrophobic TRITC or DOX was well-encapsulated into the hydrophobic inner cores of the polymeric micelles with a higher loading efficiency of about 90%. The TRITC or DOX encapsulated polymeric micelles (TRITC-AP-pH-PMs or DOX-AP-pH-PMs) showed a slightly increased average size of about 180 nm, measured by dynamic light scattering (Figure 2A), wherein the polydisersity of each polymeric micelle was fairly low (0.021 mg/mL), indicating narrow size distribution of each polymeric micelle. The TEM images also showed the spherical particle morphologies of DOX-AP-pH-PMs. As control, TRITC or DOX was also encapsulated into the pH-PMs without AP peptide (TRITC-pH-PMs and DOX-pH-PMs) using the same solvent casting method. The overall characteristics of each polymeric micelle, including loading efficiency, average size, and pH transition, are summarized in Table 1.

As expected, DOX-AP-pH-PMs began to be rapidly demicellized with decreasing pH values because the tertiary amines of PEA polymer were completely ionized at the lower pH value (6.8−6.9) (Figure 2B). This pH-dependent micellization/demicellization transition of DOX-AP-pH-PMs was very similar to that of MPEG-PEA micelles at the pH of 6.4−6.8, which may specifically respond to the tumoral weakly acidic extracellular pH (*5*). DOX release profile from the AP-pH-PMs was examined using a dialysis method. It was obvious from Figure 2C that DOX release was highly influenced by pH value, indicating a pH-dependent drug release profile. At pH 7.4, the release rate of DOX was very low with less than 20% of the DOX released

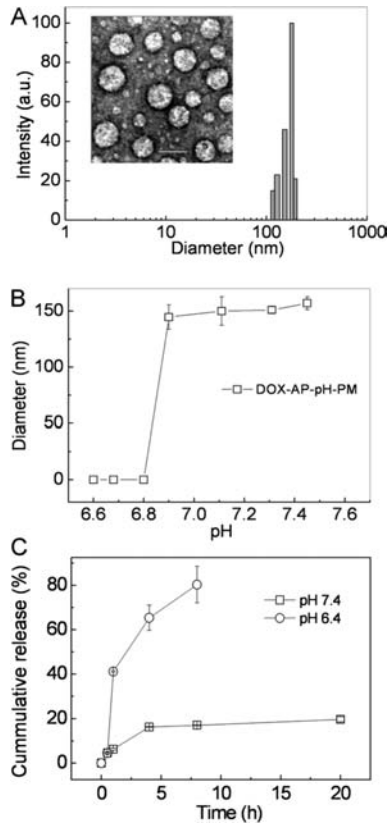

Figure 2. Characteristics of DOX-encapsulated AP-pH-PMs (DOX-AP-pH-PMs): (A) Size distribution of DOX-AP-pH-PMs (1 mg/mL in PBS at pH 7.4). The inset image presents TEM image of DOX-AP-pH-PMs (1 mg/mL in distilled water). (B) Average size change of DOX-AP-pH-PMs as a function of pH. (C) In vitro release profiles of DOX from DOX-AP-pH-PMs at different pH values (6.4 and 7.4) at 37 °C measured by UV−vis spectroscopy.

Table 1. Characterization of pH-Responsive Polymeric Micelles

sample	feed amount (wt %)	loading efficiency (%)	size (nm)[a]	μ^2/Γ^{2b}
pH-PM	−	−	62	0.014
AP-pH-PM	−	−	150	0.018
TRITC-pH-PM	10	86 ± 2.5	132	0.021
TRITC-AP-pH-PM	10	90 ± 2.8	182	0.019
DOX-pH-PM	10	82 ± 2.8	183	0.023
DOX-AP-pH-PM	10	86 ± 2.8	181	0.024

[a] The average size was measured with dynamic light scattering. [b] Polydispersity factor for polymeric micelles.

in 20 h, while a noticeably increased release rate of DOX was observed at pH 6.4 with more than 65% of the DOX released within 4 h. It is deduced that, at pH 7.4, most AP-pH-PMs maintained their micellar structure and kept DOX in the micellar core, while they were rapidly demicellized in a short time at pH 6.4, followed by releasing DOX. This drug release profile of AP-pH-PMs indicated that AP peptides on the micelle's surface did not have any effect on the pH-dependent drug release profile of pH-responsive MPEG-PEA micelles (*18*).

The tumor-specific targeting ability of fluorescence dye, TRITC, encapsulated polymeric micelles (TRITC-AP-pH-PMs) in the MDA-MB-231 human breast cancer cell culture system was evaluated using confocal laser microscopy, whereas, as control, TRITC-pH-PMs without AP peptide moieties at the micelle's surface were used. Figure 3 shows the enhancement of cellular uptake with AP-pH-PMs over pH-PMs, suggesting that AP peptide modified micelles were more rapidly taken into the cells by the specific binding affinity to IL-4 receptors of breast cancer cells (*15*). The TRITC's fluorescence intensity of

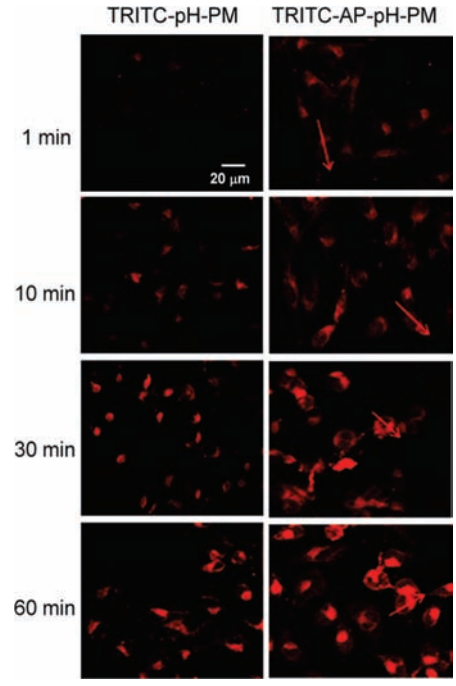

Figure 3. Confocal laser scanning microscopy of TRITC encapsulated pH-PMs (TRITC-pH-PMs) and AP-pH-PMs (TRITC-AP-pH-PMs) in MDA-MB-231 cancer cell culture system. The scale bar is 20 μm in the image.

the TRITC-AP-pH-PM treated cells was always higher than that of TRITC-pH-PM treated cells at any moment. In particular, only after 1 min postincubation, TRITC-AP-pH-PMs-treated cells presented substantial fluorescence intensity at the cytoplasm part, indicating rapid receptor-medicated endocytosis (red arrows; see NIR fluorescence histogram in Supporting Information Figure S1) (*19*). As incubation time increased, the fluorescence intensity increased up to 1 h and most cells presented strong fluorescence in the cytoplasm and perinuclear compartments. However, TRITC-pH-PMs did not present rapid cellular uptake in the cell culture system, due to the bioinert PEG surface of polymeric micelles. It suggested that the surface modification of pH-PMs with tumor-targeting AP peptides greatly enhanced the cellular uptake profile of pH-responsive polymeric micelles by rapid receptor-medicated cellular adherence and uptake.

The tumor targeting ability of the TRITC-AP-pH-PMs was also measured using noninvasive and live optical imaging system. When the tumor volume grew to 150−200 mm^3, TRITC-pH-PMs and TRITC-AP-pH-PMs containing 1 mg/kg of TRITC were administrated intravenously into the MDA-MB231 human breast tumor-bearing mice. After the scheduled time points, the fluorescence signals of TRITC-pH-PMs and TRITC-AP-pH-PMs were noninvasively quantified by measuring total photon counts at the target tumor tissues (Figure 4A) (*20*). At 1 h postinjection of TRITC-AP-pH-PMs, the inoculated tumor was clearly delineated from the body, indicating rapid tumor accumulation of TRITC-AP-pH-PMs. Moreover, the fluorescence signals gradually increased up to 24 h postinjection. However, TRITC-pH-PM-treated mice showed minimum fluorescence intensity at the target tumors up to 12 h. It means that pH-PMs without AP peptides might be less effective in targeting at the tumor tissues, due to the bioinert PEG surface of pH-PMs, compared to AP-pH-PMs. After 24 h postinjection, the delayed tumor targeting ability of pH-PMs was observed, indicating that the pH-responsiveness of MPEG-PAE micelles is not very effective in the real tumor model in vivo. The fluorescent total photon counts per gram of TRITC-AP-pH-PM-treated tumors were 2-fold higher than those of the TRITC-

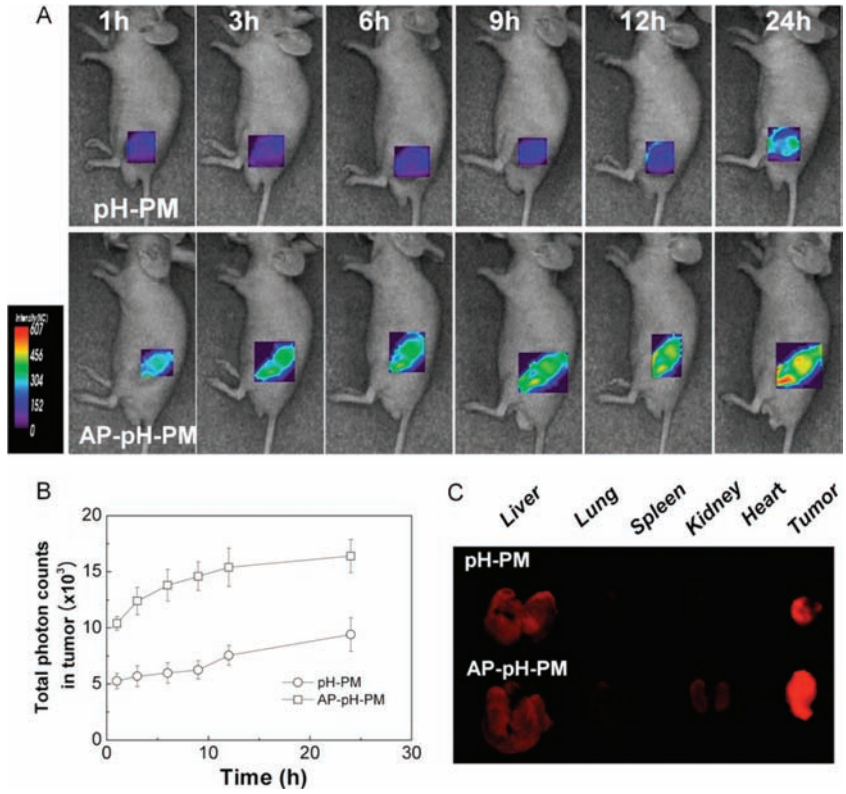

Figure 4. In vivo and ex vivo biodistribution of peptide conjugated pH-responsive micelles: (A) In vivo fluorescence images of MDA-MB-231 tumor xenografted athymic nude mice injected with TRITC-pH-PM and TRITC-AP-pH-PM, respectively. (B) Quantification of in vivo tumor targeting ability of TRITC-pH-PMs and TRITC-AP-pH-PMs were recorded as total photon counts per centimeter squared per steradian (p/s/cm^2/sr) per each tumor at 1 day postinjection ($n = 3$). The data represent mean ± s.e. (C) Ex vivo fluorescence image of dissected organs after 24 h postinjection of TRITC-pH-PMs and TRITC-AP-pH-PMs.

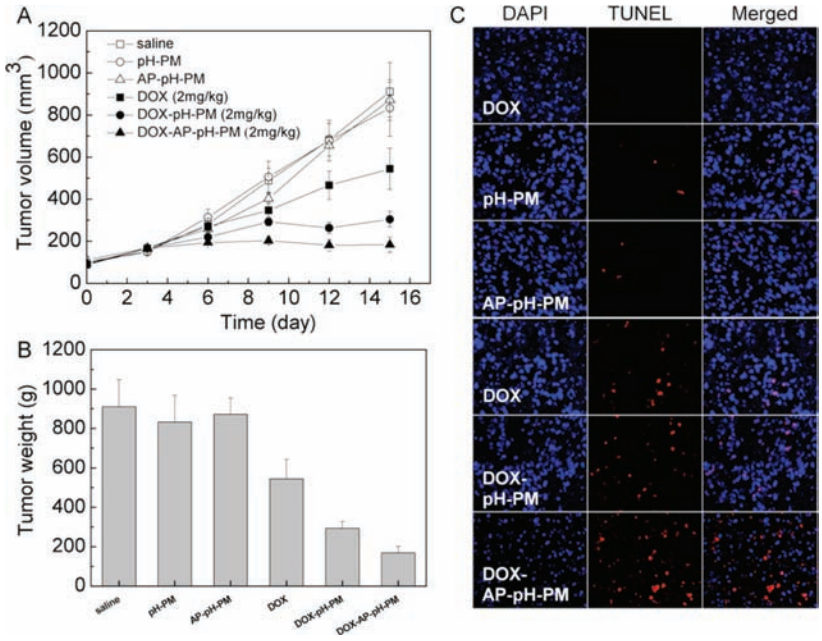

Figure 5. In vivo anti-tumor therapy of doxorubicin encapsulated micelles: (A) In vivo anti-tumor therapeutic efficacy of saline (□), pH-PM (○), AP-pH-PM (△), free DOX (2 mg/kg) (■), DOX- pH-PM with 2 mg/kg of DOX (•), and DOX-AP-pH-PM 2 mg/kg of DOX (Δ) ($n = 5$). Values represent the mean ± SD. (B) Tumor weights of MDA-MB-231 tumor-bearing mice 15 days post-treatment. (C) Immunohistological detection of apoptotic cells (TUNNEL assay) in MDA-MB-231 tumor-bearing mice 15 days post-treatment.

pH-PM-treated tumors over any time period (Figure 4B). These results indicated that the AP-pH-PMs could be specifically targeted in a short time period and localized for a long time at the target tumors. Interestingly, ex vivo fluorescence images of excised organs showed substantial evidence of the tumor-targeting ability of TRITC-AP-pH-PMs (Figure 4C). After 24 h postinjection, mice were sacrificed, and major organs such as liver, lung, spleen, kidney, and heart, as well as the tumors, were isolated to evaluate the in vivo biodistribution of TRITC-AP-pH-PMs and TRITC-pH-PMs. Strong fluorescence signals were observed in the tumor tissues, indicating the tumor targeting ability of both pH-PMs and AP-pH-PMs, while other

tissues showed negligible NIRF signals, except for the liver, in which biodegradable polymers were metabolized. Interestingly, TRITC-AP-pH-PMs presented the stronger fluorescence signal in the target tumor, compared to TRITC-pH-PM. The tumor targeting ability of AP peptide-modified polymeric micelles could increase the tumor targeting specificity and retention time at the target tumor.

The in vivo anti-tumor efficacy of the DOX-encapsulated AP-pH-PMs (DOX-AP-pH-PMs) was also evaluated in MDA-MB-231 human breast tumor-bearing mice (*21*). Figure 5A shows the growth curves of the tumors after intravenous injection of saline, polymeric micelles alone (pH-PMs, AP-pH-PMs), free DOX (2 mg/kg), or DOX-loaded polymeric micelles (DOX-pH-PMs, DOX-AP-pH-PMs) with 2 mg/kg of free DOX. The tumor growth rate of pH-PMs and AP-PMs-treated mice were similar to that of mice treated with saline, indicating that polymeric micelles had no therapeutic effect on the tumor growth. However, free DOX, DOX-pH-PMs, and DOX-AP-pH-PMs-treated mice showed significant anti-tumor therapeutic efficacy, respectively. At 15 day postinjection, the average tumor volume in free DOX-treated mice was suppressed and reached only 544 ± 98 mm^3, compared with 911 ± 137 mm^3 attained in saline-treated mice. DOX-pH-PM-treated mice also showed more efficient anti-tumor efficacy than free DOX, with the average tumor volume of 304 ± 37 mm^3. In particular, DOX-AP-pH-PM-treated mice decreased substantially the tumor volumes by 183 ± 37 mm^3, indicating that AP-pH-PMs could successfully deliver the encapsulated DOX at the target tumor. It suggested that AP peptide-modified polymeric micelles could specifically deliver encapsulated drugs to the target tumor by the tumor-targeting ability of AP peptides on their micelle's surface, as previously confirmed by in cell culture system and in vivo imaging data. At 15 day postinjection, DOX-AP-pH-PMs greatly suppressed the tumor weight to 18.6%, compared to the saline-treated mice, whereas free DOX and DOX-pH-PMs suppressed the tumor weight to 60% and 32%, respectively. The anti-tumor efficacy of pH-PM-DOX was also evaluated by the TUNEL assay, which detects apoptosis at the tumor tissues (Figure 4C) (*22*). No significant apoptotic cells were seen in tumors from saline and polymeric micelle-treated micelles. However, tumor tissues treated with DOX-AP-pH-PMs showed the highest TUNEL signals compared to tumors treated with free DOX and DOX-pH-PMs, indicating the excellent anticancer therapeutic efficacy of DOX-AP-pH-PMs.

Collective results from both in vitro and in vivo studies strongly supported the anticancer therapeutic efficacy of AP-pH-PMs as a new nanosized drug carrier with higher tumor-targeting ability. DOX molecules were efficiently loaded into the AP-pH-PMs and rapidly released under acidic conditions with higher tumor-targeting ability. The increased tumor-targeting characteristics of AP peptide-modified and pH-responsive polymeric micelles were evaluated in a cell culture system and tumor-bearing mice using a fluorescence imaging technique, which showed that AP-pH-PMs efficiently deliver anticancer drugs, resulting in excellent anticancer therapeutic efficacy. Taken together, the tumor-homing and pH-responsive AP-pH-PMs have great potential application in cancer therapy.

Synthesis and Bioconjugation of 2 and 3 nm-Diameter Gold Nanoparticles

Christopher J. Ackerson,[†] Pablo D. Jadzinsky,[‡] Jonathan Z. Sexton,[§] David A. Bushnell, and Roger D. Kornberg*

Department of Structural Biology, Stanford School of Medicine, 299 Campus Drive West, Stanford, California 94305. Received March 28, 2009; Revised Manuscript Received November 9, 2009

By adjustment of solvent conditions for synthesis, virtually monodisperse 4-mercaptobenzoic acid (*p*-MBA) monolayer-protected gold nanoparticles, 2 and 3 nm in diameter, were obtained. Large single crystals of the 2 nm particles could be grown from the reaction mixture. Uniformity was also demonstrated by the formation of two-dimensional arrays and by quantitative high-angle annular dark-field scanning transmission electron microscopy. The 2 and 3 nm particles were spontaneously reactive for conjugation with proteins and DNA, and further reaction could be prevented by repassivation with glutathione. Conjugates with antibody Fc fragment could be used to identify TAP-tagged proteins of interest in electron micrographs, through the binding of a pair of particles to the pair of protein A domains in the TAP tag.

INTRODUCTION

Thiolate-monolayer protected gold nanoparticles (AuNPs) are stable, nanometer-scale metal nanoparticles, passivated by organothiolate monolayers. They have attracted attention for their ease of synthesis, and for their remarkable chemical and electronic properties (*1*). Synthesis by the method of Brust (*2*) results in polydisperse products (*3*), whose size range may be narrowed by purification (*4–8*), etching (*9*), annealing (*10*), or ripening (*11*). Homogenous thiolate AuNPs coupled to biomolecules, such as DNA or proteins (*12, 13*), hold great promise for electron microscopy (*14*), nanoscale construction (*15*), enzyme enhancement (*16*), and other applications.

We previously reported the formation of a linker-free bond between a thiolate AuNP and a protein (*17*). The method entailed a chemical oxidation step to activate the AuNP (*18*), followed by protein conjugation, and reduction to quench AuNP reactivity. As conjugation was incomplete, gel filtration was performed to remove unreacted protein and AuNP. The limitations of this work were a residual size heterogeneity of the purified AuNPs, the requirement for multiple steps of activation and deactivation, and incomplete conjugation.

We have now overcome these limitations, through the direct synthesis of essentially homogeneous thiolate AuNPs, a high intrinsic reactivity of the AuNPs, and efficient protein conjugation. The choice of thiolate and the conditions for AuNP synthesis were important for these advances. The implications extend beyond the particular examples and applications described for the formation and structure of thiolate AuNPs in general.

EXPERIMENTAL SECTION

Nanoparticle Synthesis. Screening of reaction conditions was performed in 96 well plates with 1 mL total volume per well. Following a reaction time of about 16 h, product was precipitated by the addition of 2 mL of methanol, product was collected by centrifugation, the supernatant was removed, and the product was redissolved in 50% aqueous glycerol. Product was analyzed by 15T/5C Tris-borate EDTA buffered polyacrylamide gel electrophoresis (TBE−PAGE), at no more than 150 V, until a satisfactory separation was observed in the gel. Reaction conditions explored in this manner included pH (2−13), *p*-MBA:Au(III) ratio (0.5:1−10:1), $NaBH_4$:Au(III) ratio (0.5:1−10:1), and concentration of aqueous methanol (5% to 95%). Synthesis of 3 nm AuNPs was identical to that of 2 nm AuNPs except that it was accomplished in 87% aqueous methanol. Further details of nanoparticle synthesis may be found in Section S1 of the Supporting Information.

Protein Conjugation. For analytical purposes, a mixture containing 0.8 μg of candidate protein, 300 μM Tris-carboxy ethyl phosphine (TCEP), and 200 μM Au_{144} AuNP was incubated in a total volume of 15 μL at 37 °C for 1 h. Control reactions contained water instead of Au_{144} AuNP. The reaction mixture was combined with an equal volume of 50% glycerol and fractionated by sodium dodecyl sulfate (SDS)−PAGE (12%/3.3C) for 1 h at 150 V.

Preparative Gel Electrophoresis. In order to drive the reaction to completion, a large excess of AuNP:scFv was used. Excess AuNP was removed by native gel electrophoresis. Up to 5 mL of sample may be loaded and separated in a 5T/5C TBE buffered acrylamide gel, in a Bio-Rad Mini-Protean III gel electrophoresis apparatus, with 1.5 mm plate spacing and a single well preparative comb, run at 80 V constant voltage. The bands are visible in the gel without enhancement by stain, because of the visible absorption of the AuNP. The bands may be excised with a razor blade, crushed by passing through a syringe, and eluted into a desired buffer.

Repassivation. In a typical repassivation experiment, a series of 15 2-fold dilutions of glutathione (GSH), varying from 650 mM to 20 μM, was prepared. Equal volumes (3 μL) of glutathione solution and gold/protein (500 μg/mL) or gold/DNA conjugate were mixed and incubated for 1 h at 37 °C, followed by analysis by 12T/3.3C or 10T/5C PAGE for gold/protein and gold/DNA conjugates, respectively.

Electron Microscopy. Particles shown in Figures 2, S1, S2, and S3 (Supporting Information) were drop cast on 400 mesh glow discharged carbon-coated copper electron microscope (EM) grids (EM Sciences) and examined in an FEI CM12 EM, operated at 100 kV accelerating voltage.

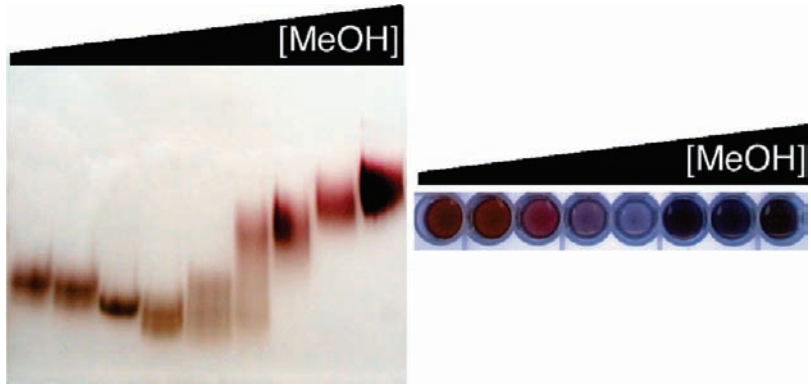

Figure 1. PAGE (15T/5C) revealing changes in product size and dispersity as a function of methanol concentration (from left to right, 7, 17, 27, 37, 47, 57, 67, 77, and 87% methanol) (left panel). The deep red color of the leftmost reactions indicates soluble product and the black color of the rightmost reactions indicates insoluble product. A reaction performed in 27% methanol, which produced 2 nm particles, is in the third well from the left.

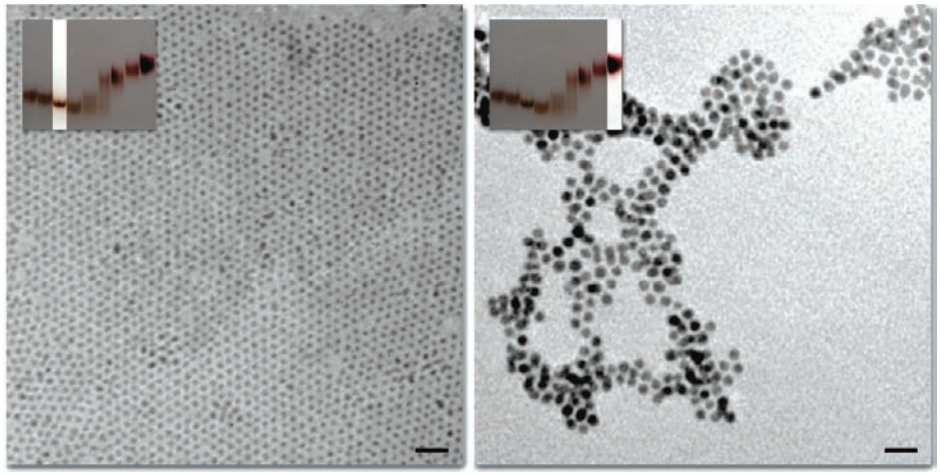

Figure 2. Transmission EM images of MPCs produced in 27% methanol (left panel) and 87% methanol (right panel). Scale bar represents 10 nm.

Cryo-EM. Samples (3 μL, approximately 0.2 mg protein/mL) were deposited on copper quantifoil grids (R2/4 spacing), blotted, and plunge-frozen in liquid ethane with an automated vitrification apparatus. Samples were imaged in a liquid-nitrogen cooled FEI Tecnai G2 Polara with an acceleration voltage of 300 kV. Images were recorded on a 2k X 2k Peltier-cooled CCD camera (Tietz TemCam-F224HD). Images were recorded at 2 μm underfocus to enhance the visibility of the nanoparticles. Contrast transfer function correction was not performed; therefore, protein density was not visible at this underfocus.

RESULTS

Nanoparticle Synthesis. Brust synthesis is accomplished in a two-step reaction, by mixing a 3-fold molar excess of organic thiol and a trivalent gold salt, with a phase transfer catalyst if necessary, to produce a gold-thiol polymer, which is then reduced with borohydride. The effects of varying the thiol:gold ratio and borohydride concentration have been widely reported. When a water-soluble product is synthesized, the reaction is typically performed in aqueous methanol. We undertook a systematic exploration of conditions for the synthesis of *p*-MBA-protected gold AuNPs (*19, 20*), varying the pH, reactant concentration, reduction time, and aqueous methanol concentration.

Reaction products were analyzed by polyacrylamide gel electrophoresis (PAGE) (*7*), and those with narrow size distributions were further analyzed by EM. Optimal yields of AuNPs were obtained with a pH of 13, a *p*-MBA: Au(III) mole ratio of 3.4:1, and an Au(III) concentration of 10 μM. Longer reduction (16−18 h) with less borohydride produced more uniform product than shorter reactions with more borohydride.

The percentage of methanol in the reaction affected both the size and uniformity of the product. Reactions performed in 27% and 87% aqueous methanol gave nearly uniform AuNPs, as shown by the sharp bands in PAGE (Figure 1) and the formation of two-dimensional ordered arrays on EM grids (Figure 2 and Supporting Information Figure S2). Approximate diameters of 2.0 and 3.0 nm were measured for the AuNPs. At other methanol concentrations, heterogeneous particles were obtained (Supporting Information, Figure S3).

The exceptional uniformity of the 2 nm AuNPs prompted an attempt at crystallization. In the presence of various salts, including sodium chloride and sodium borate (at least 0.15 M), and ammonium acetate (at least 0.2 M), single crystals were obtained. The largest crystals, approximately 300 μm in the longest dimension, were produced by slow evaporation from sodium chloride solution, and gave diffraction to 5.5 Å resolution (Supporting Information, Figure S4.) A similar synthesis, differing only in the pH prior to borohydride reduction, led to crystals of a 1.5 nm particle diffracting to 1.1 Å resolution (*21*).

The 2 nm AuNPs were further characterized by quantitative high-angle annular dark-field scanning transmission EM (HAADF-STM). A value of 144 ± 22 atoms for the gold core was obtained (Supporting Information, Figure S5.) For comparison, HAADF-STM gives a value of 13.6 ± 3.4 atoms for the gold core of an Au_{13} particle (*22*). The 15% standard deviation in the measurement of the 2 nm particles compares favorably with the 25% standard deviation in the measurement of the Au_{13} particle. Much of the measurement error may be attributed to unevenness in the carbon support film. The ^{1}H NMR spectrum of the 2 nm AuNP displayed a broad band centered on the

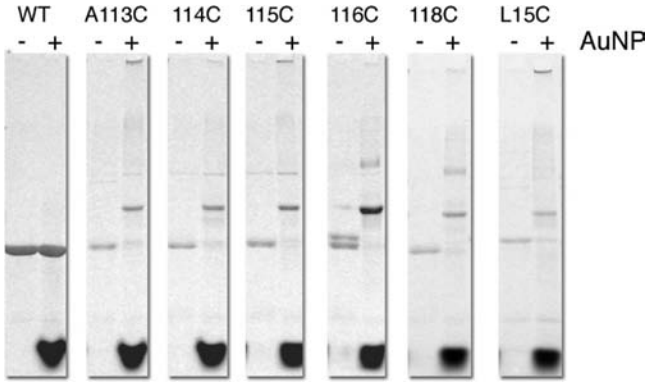

Figure 3. scFv reactivity. The leftmost gel shows the wild-type (WT) NC10 scFv in the presence (+) and absence (−) of gold. To the right is the A113C nested mutant in which a gel-shifted band appears in the presence of the 2 nm AuNP. The shifted band was observed in the presence of AuNP for all mutants of the NC10 scFv tested.

positions of the peaks from *p*-MBA, confirming the surface immobilization of the *p*-MBA and the absence of any chemical alteration by exposure to high pH or borohydride (Supporting Information, Figure S6). The UV/visible spectrum of the 2 nm AuNPs (Supporting Information, Figure S11) included peaks at ~300 and ~510 nm and was similar to the spectrum of the well studied 29 kDa compound (*23–26*). There are at least 4 previous reports of UV/vis spectra for the 29 kDa or Au_{144} compound, found in *refs* 23–25 and *26*. Each of these spectra differs in fine detail, but a hallmark of this compound is a very small surface-plasmon resonance-like inflection or peak at 510 nm or 2.4 eV. Differences between the three spectra and the spectrum accompanying our report may be accounted for by differences in the ligand comprising the monolayer and by differences in instrument sensitivity. This compound has recently been analyzed by high resolution mass spectroscopy and reported to have a core of Au_{144} (*25*, *26*).

Reaction of *p*-MBA AuNPs with Cysteine Mutant Proteins and Thiolated DNA. In our previous work, glutathione AuNPs were activated by oxidation with permanganate for conjugation with the NC10 scFv antibody fragment (*17*). Single cysteine residues were introduced at or near the C-terminus of NC10 for the purpose. Substitution mutants S112C and A113C contained cysteines in place of the last two structured residues of NC10 revealed by X-ray diffraction. C-terminal extension mutants 114C−118C contained cysteines one to five positions beyond the last structured residue. In addition, in mutants L15C, Q80C, G15C, and P14C, cysteines were substituted for surface residues elsewhere in the framework region of NC10. Glutathione AuNP conjugates were only obtained with C-terminal extension mutants 116C−118C, showing a requirement for exposure of the cysteine residue for reactivity (*17*). In contrast, the 2 nm *p*-MBA AuNP reacted with all NC10 mutants, resulting in a characteristic gel shift upon SDS−PAGE (Figure 3). Conjugate formation was essentially quantitative, except in the case of S112C, L15C, Q80C, and G15C mutants, whose reactivity was slightly diminished. A surface cysteine mutant of catalase, K560C, showed no reactivity at all (Supporting Information, Figure S7). The 2 nm *p*-MBA AuNP reacted rapidly and quantitatively with synthetic oligonucleotides bearing terminal thiol groups (*27*) (Supporting Information, Figure S8.)

Reaction of *p*-MBA AuNPs with native cysteine residues in proteins, and detection by EM. Reaction of *p*-MBA AuNPs was tested with two proteins bearing native cysteine residues, muscle actin and antibody Fc fragment. The 2 nm *p*-MBA AuNP formed conjugates with three of the seven cysteines in muscle actin, as shown by SDS−PAGE (Supporting Information, Figure S9). The antibody Fc fragment contains two polypeptide chains with a disulfide bond between them. Following the reduction of the disufide bond with TCEP, reaction with both 2 and 3 nm *p*-MBA AuNPs was observed. Detection in this case took advantage of the strong binding of Fc fragments to protein A, in particular to the two protein A domains in the widely used tandem affinity purification (TAP) tag (*28*). EM of AuNP-Fc bound to TAP-tagged protein showed pairs of closely apposed gold particles. These pairs of particles were clearly attributable to conjugates, and distinguishable from unreacted AuNP-Fc, scattered across the micrographs, on the basis of their characteristic spacing (Figure 4).

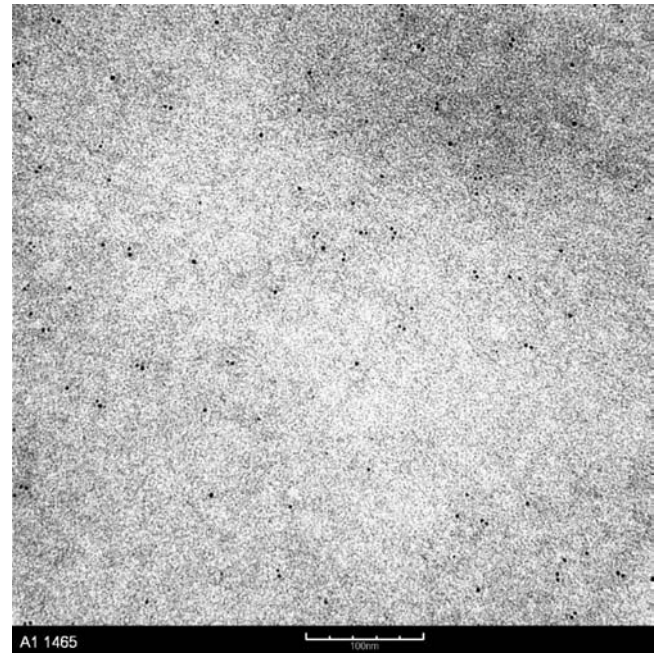

Figure 4. TAP-tagged RNA polymerase was incubated with Fc/2 nm particle conjugates and drop cast onto a carbon coated EM grid.

Quenching *p*-MBA AuNP Reactivity. In order to quench the reactivity of *p*-MBA AuNP−protein conjugates toward further protein sulfhydryls, we took advantage of the unreactivity of glutathione AuNPs noted previously. Treatment of the 2 nm *p*-MBA AuNP with 1 mM glutathione for 1 h at room temperature proved effective for the purpose. We presume that the product was repassivated (most or all *p*-MBA replaced by glutathione) because the AuNP remained intact (Supporting Information, Figure S10), while reactivity was lost. Following conjugation and repassivation, NC10 scFv retained affinity for its antigen, the tetrameric N9 neuraminidase, as shown by mixing with neuraminidase and cryo-EM. Characteristic sets of four gold particles were observed (Figure 5). The DNA in repassivated AuNP conjugates also remained capable of interaction, as shown by hybridization with the complementary strand and gel electrophoresis.

DISCUSSION

The notable results of this work include the following: the effect of solvent on the products of *p*-MBA AuNP synthesis; the formation of virtually monodisperse 2 and 3 nm particles; the growth of large single crystals of the 2 nm particle amenable to X-ray diffraction analysis; the spontaneous reactivity of *p*-MBA particles toward protein and DNA sulfhydryls; the quenching of reactivity by repassivation with glutathione; and a method for distinguishing particles bound to proteins of interest from free particles by EM.

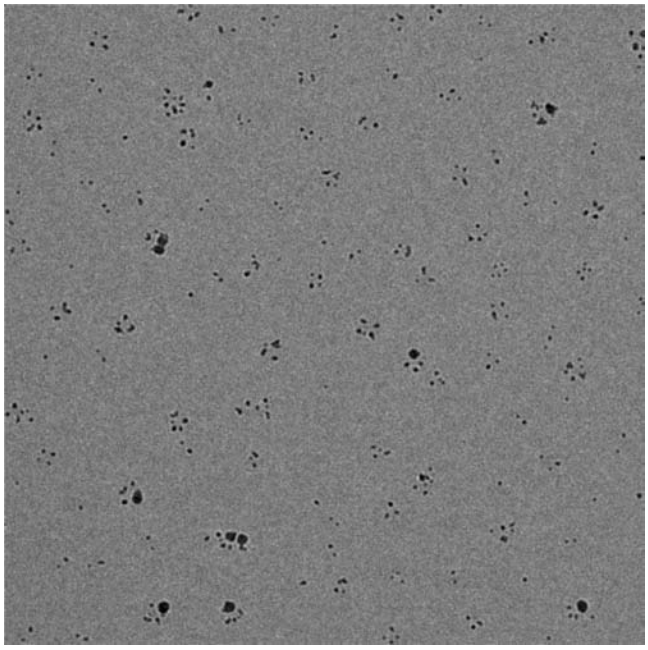

Figure 5. Cryo-EM of NC10/2 nm AuNP mixed with N9 neuraminidase. The tetrameric structure of N9 neuraminidase results in the binding of four scFv fragments. The larger particles observed are 10 nm AuNP, included as markers in this cryo-EM preparation.

On the basis of transmission EM, HAADF-STEM, and UV−vis spectroscopy, we identify the 2 nm particle as having an Au_{144} core, consistent with other recent assignments for an AuNP often referred to as a 29 kDa compound. An important contribution of our work is the direct synthesis, with no requirement for purification, annealing, ripening, or etching to obtain an essentially monodisperse product, as judged from the formation of single crystals, from an exceptionally narrow band in PAGE, from HAADF-STEM, and from TEM.

The 2 nm particles were insoluble at methanol concentrations above 27% (Figure 1, right panel). The uniformity of the particles may therefore be due, in part, from growth in solution to a critical size, at which precipitation occurs. The 3 nm particles appeared less uniform than the 2 nm particles and did not precipitate at the methanol concentration used. Their size distribution may be narrowed by a reduced reaction rate under the high pH conditions used. Others have suggested that reducing the rate of reduction may allow the creation of more uniform particles (*29*). We have observed that the color change indicative of particle formation requires hours for reactions performed at high pH, as opposed to seconds for reactions at low pH.

Metal nanoparticles are believed to be stabilized by electronic shell filling for smaller particles and geometric shell filling for larger particles. The concept of shell filling leads naturally to the idea of a magic number series. In the case of gold AuNPs, nominal inorganic masses of 5, 8, 15, 20, 29, 45, and 93 kDa have been derived (*6*, *30*, *31*). Recent X-ray structure determination of the 5 kDa (Au_{25}) (*32*) and 20 kDa (Au_{102}) (*21*) compounds led to the conclusion that even particles as large as Au_{102} are stabilized as electronic shell filling (*33*).

The structure and exact formulation of the 29 kDa compound, which we identify here as an Au_{144} 2 nm particle, remains a matter of conjecture. For 144 gold atoms, closure of a 90e- or 92e-electronic shell would require 52 or 54 ligands (on the assumption that each gold atom donates one electron and each *p*-MBA group withdraws one electron from the electronic shell) (*33*). This argument has been called into question, however, by recent mass spectroscopy, which led to a formulation of the 29 kDa compound as $Au_{144}(SR)_{59}$ (*24*), and a DFT calculation, which argued for an assignment of $Au_{144}(SR)_{60}$ (*34*).

Our previous work (*15*) established a method for the formation of rigid, specific, and discrete gold nanoparticle/protein conjugates. The method yields a direct bond between gold atoms of the gold nanoparticle core and the sulfhydryl moiety of a cysteine residue, whereas the commercial product, Nanogold (Nanoprobes, Yaphank, NY), relies on a flexible organic linker and a maleimide group to accomplish binding to cysteine residues. The elimination of the linker facilitates applications requiring rigid immobilization of AuNPs on proteins. Conjugates formed by electrostatic interaction with traditional colloidal gold may also be rigid, but will not necessarily have a precise number of AuNPs bound at the same location on every protein.

In contrast to our previous work with glutathione AuNPs, the formation of protein and DNA conjugates with *p*-MBA AuNPs was more facile and more promiscuous. Whereas the reaction of activated glutathione AuNPs with scFvs bearing reduced, exposed cysteine residues never surpassed 50%, the *p*-MBA AuNPs reacted quantitatively with exposed cysteine residues. Moreover, while glutathione AuNPs showed only slight reactivity toward the 116C extension mutant of the NC10 scFv and no reactivity toward the shorter 115C, 114C, A113C, and S112C extension mutants, *p*-MBA AuNPs reacts almost quantitatively with mutants 114C and longer.

The high reactivity of *p*-MBA AuNPs may in some cases capture nonnative conformations of the scFv or other protein target. While most conjugates formed with the NC10 scFv retained affinity for the N9 neuraminidase antigen, conjugates with the Q80C framework mutant of NC10 showed diminished affinity. The failure of conjugate formation with the K560C mutant of catalase is important in this regard. The cysteine residue in the K560C mutant is located in a depression on the protein surface, rendering it inaccessible to an AuNP of the diameter used (Supporting Information, Figure S7). The AuNP evidently did not induce protein denaturation sufficient for reactivity.

ACKNOWLEDGMENT

We thank Laurent Menard and Ralph Nuzzo for HAADF-STM analysis, Peter Loewen for catalase and catalase mutants, and Corey Liu and the SMRL for NMR. We also thank Pamela Bjorkman and Grant Jensen for their interest in large gold AuNPs, which stimulated our work. Portions of this research were carried out at the Stanford Synchrotron Radiation Laboratory, a national user facility operated by Stanford University on behalf of the U.S. Department of Energy, Office of Basic Energy Sciences. The SSRL Structural Molecular Biology Program is supported by the Department of Energy, Office of Biological and Environmental Research, and by the National Institutes of Health, National Center for Research Resources, Biomedical Technology Program, and the National Institute of General Medical Sciences. This research was supported by NSF grant CHE-0617050 and NIH grant AI21144.

Note Added in Proof: An additional mass spectrum of the extensively studied "29 kDa Compound," assigning a molecular formula of $Au_{144}(SR)_{60}$ was reported in December of 2009. Synthesis of Peptide−Protein Conjugates Using *N*-Succinimidyl Carbamate Chemistry

Peptide−protein conjugates are useful tools in different fields of research as, for instance, the development of vaccines and drugs or for studying biological mechanisms, to cite only few applications. *N*-Succinimidyl carbamate (NSC) chemistry has been scarcely used in this area. We show that unprotected peptides, featuring one lysine residue within their sequences, can be converted in good yield into NSC derivatives by reaction with disuccinimidylcarbonate (DSC). No hydrolysis of the NSC group was observed during RP-HPLC purification, lyophilization, or storage. NSC peptides reacted efficiently within minutes with lysozyme used as model protein. To illustrate usefulness of the method consisting of the synthesis of a peptide−protein conjugate of biological interest, a NSC peptide derived from a peptide substrate for tyrosylprotein sulfotransferase (TS) was synthesized and ligated to receptor-binding nontoxic B-subunit of Shiga toxin (STxB). Immunofluorescence studies showed the intracellular delivery of the TS-STxB conjugate and its ability to circulate to the Golgi as the native STxB protein. Moreover, we demonstrate that the TS label could be sulfated by tyrosylprotein sulfotransferases present in the Golgi. Thus, NSC chemistry permitted rapid synthesis of a peptide−protein conjugate worthwhile for studying the transport of proteins from the plasma membrane to the Golgi. The second part of this article describes a more general method for synthesizing peptide−protein conjugates without any limitation of the peptide sequence. The conjugates were assembled by combining NSC chemistry and α-oxo semicarbazone ligation. To this end, a glyoxylyl NSC peptide was synthesized and reacted with lysozyme. The glyoxylyl groups on the protein were then reacted with a semicarbazide peptide to produce the target peptide−protein conjugate. Both reactions, namely, urea bond formation and α-oxo semicarbazone ligation, were carried at pH 8.0 using a one-pot procedure.

INTRODUCTION

Nowadays, various methods are available for the synthesis of peptide−protein conjugates. Site-specific ligation methods, by exploiting a unique functional group present within the protein, lead to well-characterized conjugates. Reaction of a cysteine residue with haloacetyl (*1*) or maleimidyl (*2*) peptides is often used in this field. Alternatively, unnatural functional groups helpful for site-specific ligation such as keto or aldehyde groups can be introduced into protein-specific sites by using chemical methods (*3*, *4*), enzymatic techniques (*5*), or living organisms (*6*).

Random peptide−protein conjugates are also useful tools in different fields of research as, for example, the development of vaccines (*7*) or drugs (*8*, *9*) or for studying biological mechanisms (*1*). Their preparation is often carried out using *N*-succinimidyl carboxylic ester (NSCE)-based bifunctional reagents (*10*). Usually, the bifunctional reagent is reacted first with the protein leading to formation of amide bonds between surface-exposed ε-amino groups and NSCE moiety. Then, the second functional group is used to attach peptide molecules (*7*). The synthesis of peptide−protein conjugates by direct reaction of NSCE peptides with proteins is less common. For instance, Kida et al. have recently described the synthesis of a Tat-Cys-NSCE peptide by reacting Tat-Cys with 6-maleimidohexanoic acid *N*-succinimidyl ester (*11*). However, the sensitivity of Tat-Cys-NHSE peptide toward hydrolysis precluded its purification by RP-HPLC. Consequently, the crude Tat-Cys-NSCE peptide was stored at −80 °C and directly used in the conjugation experiments. A similar approach was reported by Inglese et al. for the attachment of a protein kinase A substrate to proteins (*12*).

N-Succinimidyl carbamate derivatives (NSC), whose chemistry is related to NSCE, have been scarcely used for the synthesis of conjugates. Morpurgo et al. reported the synthesis of an NSC derivative of biotin for protein labeling (*13*). Later on, Clavé et al. described the synthesis of a fully protected NSC dipeptide scaffold (*14*). This reagent was coupled to the N-terminal amino group of substance P. Pasut et al. described the synthesis of a PEG-β-alanine NSC derivative for protein pegylation (*15*). In these studies, besides the NSC group, no other functional moiety was present on the molecules. To the best of our knowledge, the synthesis of NSC peptides incorporating functional side chains, their purification, and coupling to proteins was not reported in the literature.

We describe here the synthesis of NSC peptides incorporating functional side chains (phenol group of tyrosine, hydroxyl group of serine, imidazole group of histidine, carboxylic acid group of glutamic acid, and/or indole group of tryptophan). These peptide derivatives were successfully purified by RP-HPLC and coupled to proteins. Lysozyme was used as a model protein to optimize preparation of conjugates. Obviously, the partial conversion of NSC group into an isocyanate group during the conjugation experiment is a fact. To illustrate the value of the method consisting of the synthesis of a peptide−protein

conjugate of biological interest, a NSC peptide derived from a peptide substrate for tyrosylprotein sulfotransferase (TS) (*10*) was synthesized and ligated to receptor-binding nontoxic B-subunit of Shiga toxin (STxB). STxB binds to glycosphingolipid Gb3 in the plasma membrane of target cells. After binding, STxB is transported to the endoplasmic reticulum, via endosomes and the Golgi. Due to this property, STxB can potentially be used for vectorization of drugs (*16*). The colocalization of TS-STxB conjugate with a Golgi marker was studied by confocal immunofluorescence microscopy. The ability of the TS label within the TS-STxB conjugate to be sulfated by Golgi tyrosylprotein sulfotransferase was also examined.

In the second part of this article, we describe a more general method for synthesizing peptide−protein conjugates, which is not limited by the peptide sequence. The conjugates are assembled using a one-pot procedure combining NSC chemistry and α-oxo semicarbazone ligation. To this end, a glyoxylyl NSC peptide was synthesized and reacted with lysozyme at pH 8.0 to produce glyoxylyl lysozyme. The crude reaction mixture was then reacted with a semicarbazide peptide. Ligation between the glyoxylyl groups on the protein and the semicarbazide group on the peptide resulted in one-pot formation of the target peptide−protein conjugate.

EXPERIMENTAL PROCEDURES

Solid-Phase Peptide Synthesis of Peptides 1−4a. Solid-phase synthesis was performed using the Fmoc/*tert*-butyl strategy on a Novasyn TGR resin (0.1 mmol scale) in a microwave peptide synthesizer (CEM μ WAVES, Saclay, France). Couplings were performed using 5-fold molar excess of each Fmoc L- or D-amino acid, 4.5-fold molar excess of HBTU, and 10-fold molar excess of DIEA. Final deprotection and cleavage from the resin was carried out with TFA/thioanisol/TIS/H_2O 92.5/2.5/2.5/2.5 by vol. The resin beads were filtered, and the filtrate was precipitated in diethyl ether/heptane 1/1 by vol, dissolved in water, and lyophilized. The crude peptide was purified by RP-HPLC on a 100 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05%TFA by vol (6 mL/min, detection 215 nm, 0−40% B in 60 min). Fractions were collected and lyophilized to produce **1−4a** (yields are indicated in Table 1). The purity of peptides **1−4a** was >95% as determined by analytical RP-HPLC and CZE. MS data are in accordance with the proposed structures (see Table 1 and Supporting Information).

Synthesis of NSC Peptides 1−4b. DSC (16.6 mg, 65 μmol) was dissolved in dry DMF (340 μL) at rt under N_2. Peptide **1−4a** (6.5 μmol) and triethylamine (0.45 μL, 3.2 μmol) were solubilized in dry DMF (85 μL) and then added in one portion to DSC solution. The mixture was stirred at rt for 1 h. The crude mixture was diluted with 20 mL of 1% by vol aqueous TFA and purified by RP-HPLC on a 100 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05% TFA by vol (6 mL/min, detection 215 nm, 0−40% B in 60 min). Fractions were collected and lyophilized to produce **1−4b** (yields are indicated in Table 1).

The purity of peptides **1−4b** was >95% as determined by analytical RP-HPLC and CZE. MS data are in accordance with the proposed structures (see Table 1 and Supporting Information).

Synthesis of NSCE Peptide 1c. A solution of suberic acid bis(*N*-succinimidyl ester) DSS (64 mg, 175 μmol) in dry DMF (700 μL) at rt under nitrogen was added to a stirred solution of peptide **1a** (30 mg, 17.5 μmol) and triethylamine (2.4 μL, 17.5 μmol) in dry DMF (340 μL). The mixture was stirred at rt for 1 h. The crude mixture was then diluted with 20 mL of 1% by vol aqueous TFA and purified by RP-HPLC on a 100 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05%TFA by vol (6 mL/min, detection 215 nm, 0−40% B in 60 min). Fractions were collected and lyophilized to produce 15 mg of pure peptide **1c** (46%). The purity of peptide **1c** was >95% as determined by analytical RP-HPLC. MS data are in accordance with the proposed structure (see Supporting Information).

Labeling of Lysozyme, General Procedure. Lysozyme (Appligene ref 130172, 0.41 mg, 0.028 μmol, 0.2 mM final concentration) in 10 mM pH = 7.4 PBS buffer (140 μL) was added to NSC peptide **1−4b** (0.2 μmol). The mixture was stirred at 4 °C for 1 h. Analysis of the reaction mixtures by RP-HPLC and CZE showed that ∼50% of lysozyme molecules were modified. MALDI-TOF analysis of the mixtures revealed the presence of up to 4 peptide chains on lysozyme.

Labeling of STxB. STxB was produced and purified as described elsewhere (*17*). STxB (1.11 mg, 0.14 μmol, 0.32 mM final concentration) in pH = 8.0 sodium phosphate buffer (450 μL) was added to NSC peptide **1b** (2.24 μmol). The mixture was stirred at rt for 1 h. The conversion was ∼70% as determined by LC-MS. MALDI-TOF analysis of the mixture revealed grafting of up to 3 peptide chains on STxB. The conjugate was purified by filtration to produce TS-STxB-a or purified by RP-HPLC to produce TS-STxB-b.

Purification by Filtration, TS-STxB-a. 300 μL of the above reaction mixture was filtered and washed with PBS (3 × 20 mL) on a 3 kD membrane (3000 MWCO PES Vivascience, UK). The total volume after this step was 750 μL. The solution concentration (0.92 μg/μL) was determined using the bicinchoninic BCA assay (*18*).

RP-HPLC Purification, TS-STxB-b. 100 μL of the above reaction mixture was purified by RP-HPLC on a 300 Å 5 μm C18 XBridge column (4.6 × 250 mm) using a linear water/acetonitrile gradient (1 mL/min, eluent A is 0.05% TFA in water, eluent B is 0.05% TFA in CH_3CN/water 4/1 by vol, 0−100% B in 30 min, detection at 215 nm). Fractions were collected and lyophilized to produce TS-STxB-b. The conjugate was dissolved in 100 μL of PBS. The solution concentration (0.5 μg/μL) was determined using the bicinchoninic BCA assay (*18*).

Synthesis of Peptide 5 and Glyoxylyl Peptide 6. Solid-phase synthesis of peptide **5** H-SAAFGGK-NH_2 was performed using the Fmoc/*tert*-butyl strategy on a Novasyn TGR resin (0.1 mmol scale) in a microwave peptide synthesizer (CEM μ WAVES, Saclay, France). Couplings were performed using 5-fold molar excess of each Fmoc L-amino acid, 4.5-fold molar excess of HBTU, and 10-fold molar excess of DIEA. Final deprotection and cleavage from the resin was carried out with TFA/TIS/H_2O 95/2.5/2.5 by vol. The resin beads were filtered and the filtrate was precipitated in diethylether/heptane 1/1 by vol, dissolved in water, and lyophilized to produce 71 mg of peptide **5** (82%). The purity of peptide **5** was >90% as determined by

analytical RP-HPLC and CZE. MS data are in accordance with the proposed structure (see Supporting Information).

A solution of peptide **5** (21.3 mg, 0.024 mmol) in 0.1 M pH 7.0 sodium phosphate buffer (6.4 mL) was reacted for 10 min with sodium periodate (10.5 mg, 0.049 mmol) at rt. The reaction mixture was quenched with ethanolamine (3.5 μL, 0.037 mmol) and purified immediately by RP-HPLC on a 100 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05% TFA by vol (6 mL/min, detection 215 nm, 0−40% B in 60 min). Fractions were collected and lyophilized to produce peptide **6** (11 mg, 64%).

The purity of peptide **6** was 90% by analytical RP-HPLC and 92% by CZE. MS data are in accordance with the proposed structure (see Supporting Information).

Synthesis of Glyoxylyl NSC Peptide 7. A solution of glyoxylyl peptide **6** (11 mg, 0.015 mmol) and triethylamine (1.07 μL, 0.007 mmol) in dry DMF (153 μL) was reacted with DSC (58.7 mg, 0.229 mmol). The mixture was stirred at rt for 1 h. The crude mixture was diluted with 10 mL of 0.3% by vol aqueous TFA and purified immediately by RP-HPLC on a 100 Å 5 μm C18 Nucleosil column using a linear water/acetonitrile gradient containing 0.05% TFA by vol (6 mL/min, detection 215 nm, 0−40% B in 60 min). Fractions were collected and lyophilized to produce glyoxylyl NSC peptide **7** (6 mg, 53%).

The purity of peptide was 87% by analytical RP-HPLC. MS data are in accordance with the proposed structure (see Supporting Information).

Preparation of Peptide−Protein Conjugates. Reaction of Lysozyme with Peptide 7 and then α-Oxo Semicarbazone Ligation with Peptide 8. The synthesis of semicarbazide peptide **8** was described in detail elsewhere (*19*). This peptide sequence is derived from HIV1 POL 476−484 protein.

Labeling with Peptide 7. A solution of lysozyme (0.85 mg, 0.06 μmol, 0.2 mM) in 0.1 M pH 8.0 sodium phosphate buffer (300 μL) was added to peptide **7** (0.30 mg, 0.42 μmol). The mixture was stirred at rt. The reaction was monitored by MALDI-TOF analysis. The reaction was complete after 1 h as visualized by MALDI-TOF mass spectrometry. The MS spectra showed grafting of up to three peptide **7** molecules to lysozyme.

Ligation between Glyoxylyl Lysozyme and Semicarbazide Peptide 8. The above mixture was then added to semicarbazide peptide **8** (1.00 mg, 0.84 μmol). The mixture was stirred at 37 °C for 2 h and then at rt for 72 h. MALDI-TOF analysis showed ligation of up to two semicarbazide peptide **8** molecules to lysozyme.

Retrograde Transport of TS-STxB-a,b Conjugates from the Plasma Membrane to the Trans Golgi Network. *Immunofluorescence Analysis.* 200 000 HeLa cells were placed on coverslip in 24-well test plate (TPP, Switzerland) and incubated with 2 μM TS-STxB-a,b conjugate or STxB for 40 min at 4 °C in PBS++ (PBS containing 0.9 mM $CaCl_2$, 0.52 mM $MgCl_2$ and 0.16 mM $MgSO_4$) and then shifted to 37 °C for 1 h (water-jacketed incubator, Forma Scientific). Cells were fixed with paraformaldehyde (300 μL of a 4% w/v solution in PBS), washed with PBS++, and then permeabilized with saponin solution (300 μL, 0.2% w/v saponin, 2% w/v BSA in PBS buffer). Each coverslip was incubated with 30 μL saponin solution containing 0.2% by vol of 13C4 murine anti-STxB antibody (hybridoma from ATCC #CRL 1794; see ref *20*) and 0.5% by vol of goat antibody against GM130 (C-19, Santa Cruz). Cells were washed with saponin solution and then incubated with 30 μL saponin solution containing 0.5% by vol antimurine Cy3-labeled secondary antibody (Beckman Coulter) and 0.5% by vol antigoat Alexa 488-labeled secondary antibody (Molecular Probes). Coverslips were mounted using 10% aqueous polyvinyl alcohol (Mowiol 4−88 from Fluka), 25% glycerol, and 59% Tris-HCl 0.2 M pH 8.5). Cells were analyzed by confocal microscopy (Leica Microsystems, Mannheim, Germany).

Sulfation Assay. Sulfation assay was performed as described elsewhere (*21*) using STxB, TS-STxB-a (conjugate purified by filtration), TS-STxB-b (conjugate purified by RP-HPLC), and TS-STxB-c. TS-STxB-c is a recombinant STxB protein modified at the C-terminus by two tandem sulfation sites. It is used as a positive control; see ref *22*. Proteins were incubated with 300 000 HeLa cells at 4 °C in sulfate-free Dulbecco's Modified Eagle Medium (DMEM, Invitrogen) for 30 min. Cells were washed with sulfate-free DMEM. 250 μL of radioactive sulfate ($^{35}SO_4^{2-}$, Perkin-Elmer) in sulfate-free DMEM (final activity 480 μCi/mL) were added to cells (120 μCi/300 000 cells). Cells were incubated for 2 h at 37 °C and then lysed in 900 μL of RIPA buffer (150 mM NaCl, 1% NP-40, 0.5% deoxycholic acid, 0.1% SDS, 50 mM Tris pH 8.0) and 9 μL of protease−inhibitor cocktail (1 mg/mL aprotinin, 1 mg/mL leupeptin, 1 mg/mL antipain, 1 mg/mL pepstatin, 1 M benzamidine, 40 mg/mL phenylmethanesulfonyl fluoride in DMSO). The cell lysate was precipitated with protein G-sepharose (GE Healthcare) loaded with anti-STxB antibody 13C4. Precipitated proteins were analyzed by tris-tricine gel (5 mL gel contains 1.7 mL 30% acrylamide,1.9% bis-acrylamide; 1.7 mL 3 M Tris-HCl with 0.3%SDS pH 8.45; 1.1 mL water; 0.7 mL glycerol; 50 μL 10% ammonium persulfate; 5 μL *N,N,N′,N′*-tetramethylethylenediamine) electrophoresis. Sulfated proteins were detected by autoradiography (STORM860, Molecular Dynamics).

RESULTS AND DISCUSSION

Molecules exposed at the plasma membrane can be circulated to early endosomes for recycling or targeted to lysosomes for degradation. Some molecules are directed to other cell compartments such as the Golgi apparatus or the endoplasmic reticulum (ER). This pathway, termed the retrograde route (*21*), plays a key role in important cellular functions such as antigen presentation (*16*) and cell signaling (*23*).

One strategy used to prove that a protein is transported from the plasma membrane to the Golgi is to modify it with a peptide sequence (TS) which can be enzymatically modified in the Golgi. Peptides presented in Table 1 are derived from the tyrosine sulfation site of rat chromogranin B (*24*). The tyrosine residue within the EEPEYGE motif is sulfated by tyrosylprotein sulfotransferase, an enzyme which is exclusively located in the trans Golgi network. Previous studies have shown TS−protein conjugates utility for studying the retrograde transport of proteins. Sulfation of the TS label was detected by incubating cells with radioactive sulfate followed by immunoprecipitation of the conjugate (*1*).

The work described in the first part of this article was motivated by the need to have an easy access to various TS−protein conjugates. TS peptides were modified at the C-terminus by a Lys(biotin) residue, thereby allowing capture of the TS−protein conjugates using streptavidin-coated beads. TS peptide sequence features four glutamic acid residues, with a negative charge at physiological pH. Thus, the labeling of proteins with TS peptide may significantly lower the isoelectric point (pI) of proteins. The solubility, binding, and biological properties of proteins heavily depend on their pI (*25*−*29*). The interactions of proteins with cell membranes (*28, 30*) are also often dictated by charge effects. Finally, pI control of labeled proteins by varying the label charge has been demonstrated to facilitate purification of labeled proteins by isoelectric focusing techniques (*31*). In this context, synthesis of a series of TS peptides with a range of pI was worth considering. To this end, 2 to 5 arg residues were incorporated at the N-terminus of peptides 1−4. D-Arg residues were chosen to minimize degradation of the peptide label in biological media.

Figure 1. TS-peptides **1**−**4** synthesized in this study. Two to five D-Arg residues were incorporated at the N-terminus of the TS substrate to modulate the pI of peptides.

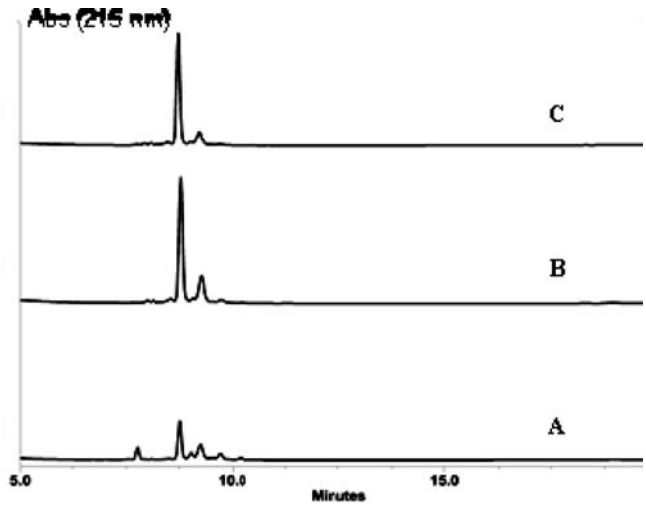

Figure 2. Effect of the DSC mode of addition and stoichiometry on the RP-HPLC yield. Peptide **1a** was reacted at rt in anhydrous DMF with DSC in the presence of triethylamine (2 equiv). (A) Peptide and base were mixed and added over 1 h period to DSC (2 equiv). (B) Peptide and base were mixed and added in one portion to DSC (2 equiv). (C) Same as B using 10 equiv of DSC.

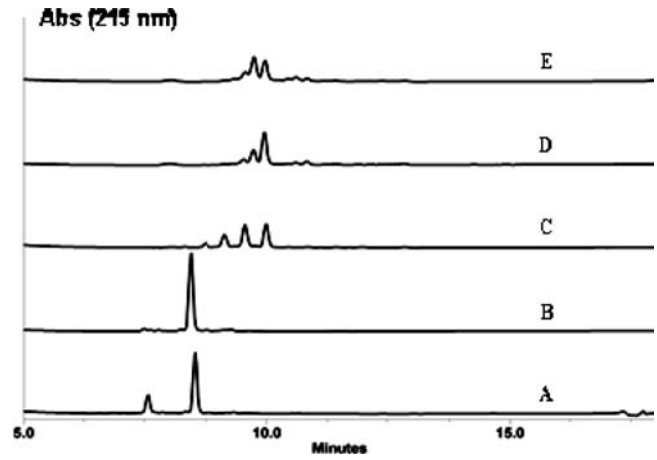

Figure 3. Effect of base stoichiometry on the RP-HPLC yield. Peptide **3a** was reacted at rt in anhydrous DMF with DSC (10 equiv) in the presence of triethylamine. Peptide and base were mixed and added in one portion to DSC. (A) TEA 0.5 equiv, 5 min; (B) TEA 0.5 equiv, 30 min; (C) TEA 10 equiv, 5 min; (D) TEA 10 equiv, 30 min; (E) TEA 10 equiv, 2 h.

NSC Peptide Synthesis and Stability. Peptides **1**−**4b** were obtained by reacting the corresponding precursors **1**−**4a** with DSC in anhydrous DMF. In a first approach, formation of the *N*-succimidylcarbamate moiety was examined using peptide **1a** and 2 equiv of both base and DSC. Slow addition of peptide **1a** to DSC led to a complex mixture (Figure 2A) in which target peptide **1b** represented only 37% of the total detected area. Alternately, addition of peptide **1a** in one portion (Figure 2B) led to a 67% RP-HPLC yield. The use of 10 equiv of DSC slightly improved the yield up to 73% (Figure 2C).

Next, the amount of DSC was fixed to 10 equiv, and we examined the influence of the base amount on the reaction yield using peptide **3a** (Figure 3). The use of an excess of base (Figure 3C−E) produced complex mixtures in which target peptide **3b** was not detected. Alternately, the use of 0.5 equiv of base (Figure 3A,B) permitted the clean conversion of peptide **3a** into NSC peptide **3b**. After 30 min, **3b** was formed nearly quantitatively (Figure 3B). The use of an excess of DSC minimized the formation of urea side-products by reaction of the formed NSC peptide **1**−**4b** with starting peptide **1**−**4a**. The critical role played by base stoichiometry can be explained by the potential conversion of NSC group into the highly reactive isocyanate moiety in basic conditions. Evidence for this degradation is introduced later on. Isocyanate groups react efficiently with amino groups as well as with the phenol group of tyrosine, and thus can be responsible for the multiple side-products observed when two or more equivalents of triethylamine were used. DSC high reactivity allows formation of NSC groups using substoichiometric amounts of base. In these experimental conditions, NSC group is stable and TS-peptides **1**−**4b** could be isolated

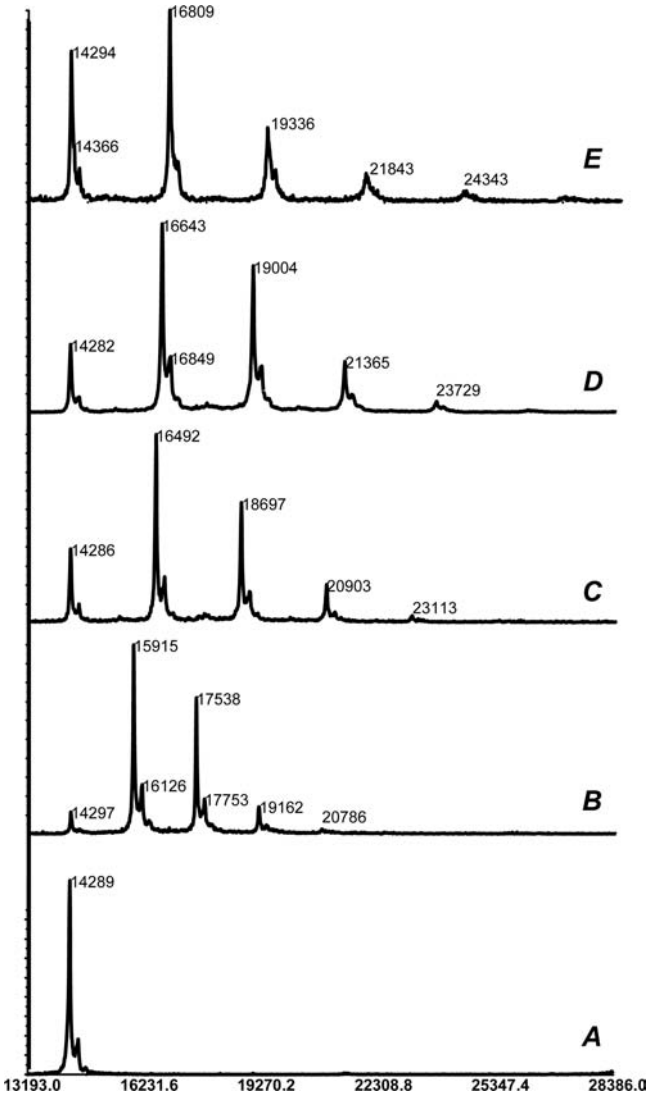

Figure 4. Reaction of lysozyme with peptides **1**−**4b**. MALDI-TOF analysis of the reaction mixtures after 1 h (pH 7.4, 4 °C). (A) without peptide, (B) peptide **1b**, (C) peptide **2b**, (D) peptide **3b**, (E) peptide **4b**.

successfully with a 59−61% yield after RP-HPLC purification. Lyophilized peptides **1**−**4b** were homogeneous by LC-MS and CZE; they displayed the expected molecular ions and were stable for months at −20 °C. ^{1}H and ^{13}C NMR analysis of peptide **1b** confirmed the NSC group presence on the ε-amino group of the C-terminal Lys residue. This procedure was successfully used for converting Ac-YLFSVHWPPLNKA-OH into corresponding NSC derivative Ac-YLFSVHWPPLNK(COOSu)A-OH, showing its compatibility with histidine, serine, tryptophan, and asparagine residues also (see Supporting Information).

For comparison, the same experimental conditions were used to convert peptide **1a** into **1c** in the presence of DSS (Figure 1). The RP-HPLC yield reached only 50% after 90 min of reaction. Peptide **1a** could efficiently be converted into peptide **1c** by using 1 equiv of base (46% isolated yield). Thus, synthesis of NSC peptides requires lower amounts of base compared to NSCE peptides, probably due to the higher reactivity of DSC compared to DSS.

Afterward, we examined the stability of peptides **1b**,**c** in water. Peptides **1b**,**c** were stable enough at room temperature in water containing TFA (pH 2) allowing their purification by RP-HPLC. Typically, hydrolysis of **1b** amounted to 3% after 3 h and only 19% after 18 h. The stability of peptides **1b**,**c** was also studied at pH 6.0. The half-life of NSCE peptide **1c** was 2 h. Peptide **1d** (Figure 1) was the sole species detected by RP-HPLC. The half-life of peptide **1b** was around 10 min. In this case, LC-MS analysis of the mixture revealed, besides peptide **1a**, formation of a novel compound corresponding to isocyanate **1e** (Figure 1). Reaction of this intermediate with benzylamine led to formation of urea **1f**, which displayed the expected fragment ions by matrix-assisted laser desorption ionization-time-of-flight postsource decay analysis.

In situ conversion of NSC peptide **1b** into isocyanate **1e** is probably at the origin of this peptide short half-life. Indeed, carbamates, which cannot be converted into isocyanates such as those derived from secondary amines, are known to be less reactive toward nucleophilic attack than parent carboxylic esters. For example, Gassman et al. have shown that a *p*-nitrophenyl-carbamate derived from a secondary amine is less reactive with nucleophiles than *p*-nitrophenyl acetate (*32*). As demonstrated later on, in situ formation of isocyanate moiety during the conjugation step might also explain the rapid formation of conjugates relative to NSCE derivatives.

Conjugation of Peptides 1−4b to Lysozyme. Lysozyme contains seven Lys residues within its sequence. Thus, 7 equiv of NSC peptide was used in the conjugation experiment. Lysozyme (0.2 mM final concentration) was reacted with NSC peptides **1**−**4b** at pH 7.4 in PBS buffer at 4 °C. A combination of RP-HPLC and CZE analyses showed a conversion of 50% for all tested NSC peptides. Lysozyme labeled with peptide **1b** coeluted by RP-HPLC with the native protein, whereas CZE permitted separation of the labeled protein from the native one due to the low pI of peptide **1b**. Alternately, lysozyme labeled with peptide **4b** could be separated from lysozyme by RP-HPLC, with the labeled material eluting earlier than the unlabeled one, whereas no separation was observed by CZE. The pI of peptide **4b** is close to the pI of lysozyme, explaining why the conjugate between peptide **4b** and lysozyme was not separated from the native protein by CZE. These experiments highlight the interest of varying the NSC peptide pI to match the physicochemical properties.

Figure 4 shows the MALDI-TOF spectra of the reaction mixtures. Up to four peptide chains were linked to lysozyme showing the efficiency of the conjugation reaction. Several studies have proven that NSCE derivatives react with ε-amino groups of proteins and sometimes with hydroxyl-containing amino acids too (*33*). Likewise, reaction of isocyanates with amino, thiol, hydroxyl, and/or imidazole groups within proteins is also possible (*34*). Thus, it cannot be excluded that such reactions might also occur with NSC peptides, which are at least partially converted in situ into isocyanate peptides.

RP-HPLC analysis of the crude reaction mixtures showed also, after 1 h, the absence of NSC peptides **1**−**4b** and two novel peaks in the TS peptide region. The latest eluting peak corresponded to peptides **1**−**4a**, formed by the NSC group hydrolysis. The other peak was attributed to cyclic peptide **1**−**4g** (Figure 5), resulting from the intramolecular reaction between the phenol group of tyrosine and the *N*-succinimidyl carbamate or isocyanate. Indeed, peptide **4g** showed a band at 263.5 nm, typical of an *O*-acetyl tyrosine, whereas the tyrosine residue within peptide **4a** displayed a band at 275.3 nm as expected. Peptide **4g** was isolated by RP-HPLC and treated with 0.1 M NaOH. These experimental conditions led to conversion of **4g** into a compound that coeluted with peptide **4a**. MALDI-TOF and UV spectra of **4a** and of the compound obtained from **4g** were also identical. Overall, these data support the structure proposed for cyclic peptides **1**−**4g**.

Finally, we have compared the reaction rate of peptides **1b**,**c** with lysozyme. LC-MS analysis of the reaction mixtures revealed that reaction of NSC peptide **1b** with lysozyme occurred in less than 5 min (50% conversion). Alternately, the

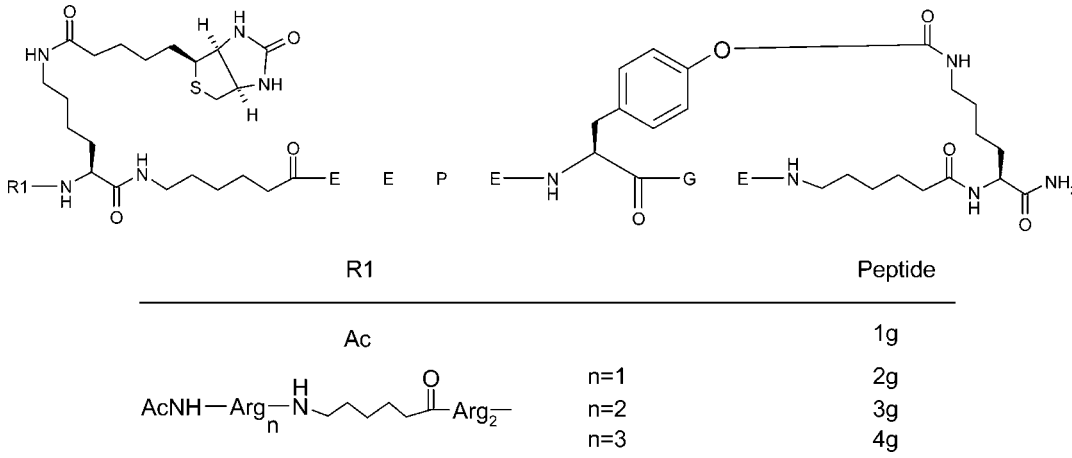

Figure 5. Cyclic peptides **1**−**4c** formed during the labeling reaction by reaction between the phenol group of tyrosine and the NSC group on C-terminal Lys residue.

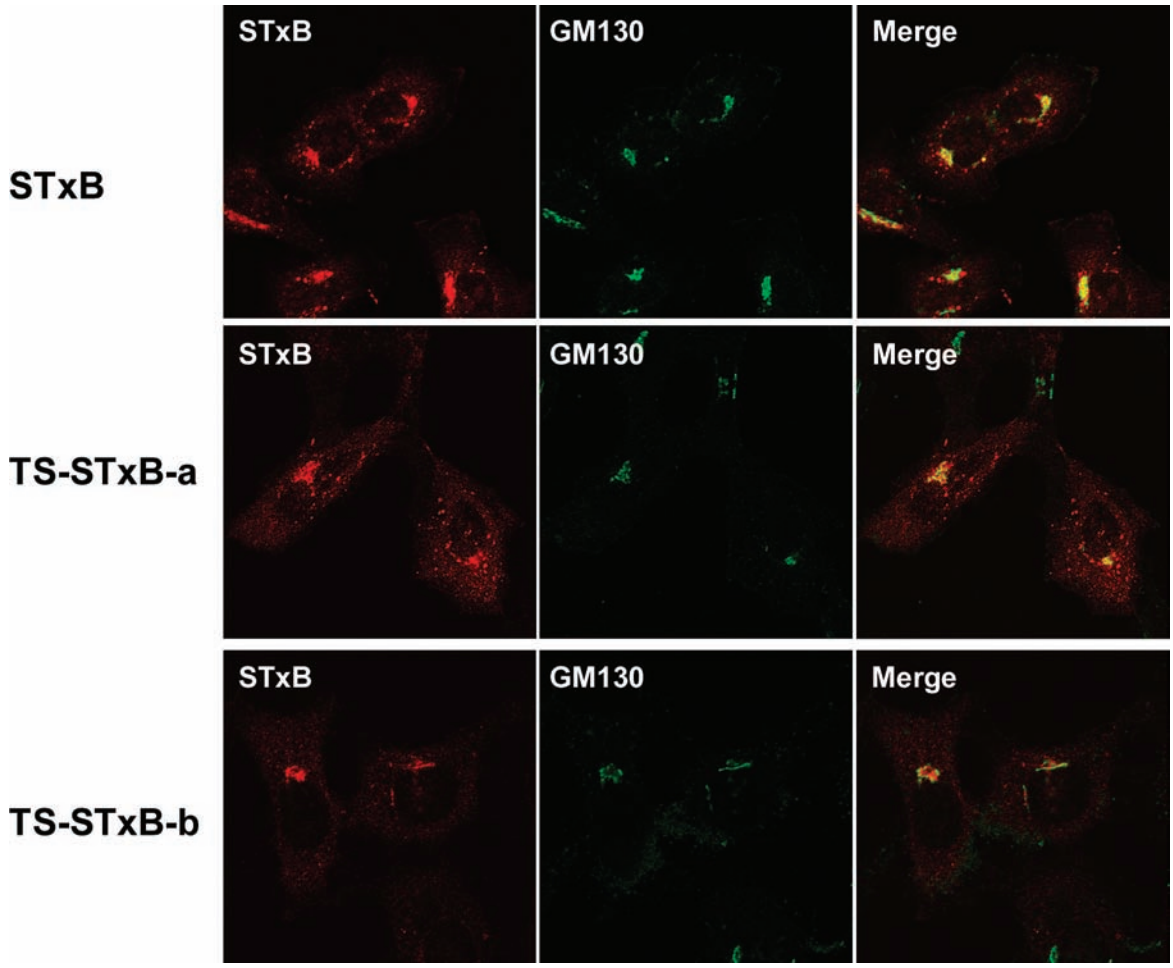

Figure 6. Immunofluorescence study of the retrograde transport of STxB and TS-STxB-a,b conjugates from the plasma membrane to the trans Golgi network. HeLa cells were incubated with 2 μM STxB or TS-STxB-a,b conjugates. Cells were fixed with paraformaldehyde, permeabilized with saponin, and then incubated with 13C4 murine anti-STxB antibody (hybridoma from ATCC #CRL 1794, see ref *20*) and C-19 goat antibody against GM130, a marker of the Golgi. Cells were washed with saponin solution and then incubated with secondary antibodies (Cy3-labeled antimurine, Alexa 488-labeled antigoat). Cells were analyzed by confocal microscopy (Leica Microsystems, Mannheim, Germany).

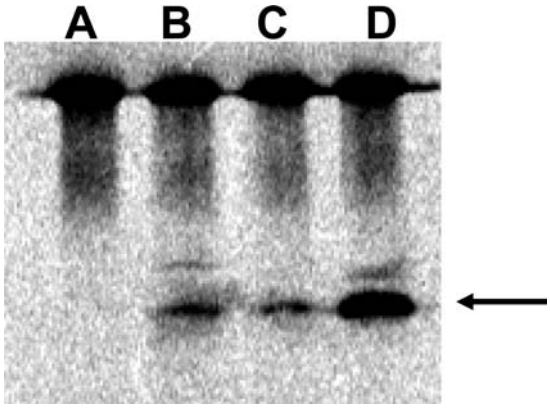
reaction of lysozyme with peptide **1c** led to only 20% conversion after 5 min and required about 1 h to go to completion (80% conversion). Thus, NSC peptides allow rapid conversion of proteins into peptide−protein conjugates, a property that can be an advantage for the labeling of unstable proteins.

Synthesis of TS-STxB Conjugates and Biological Studies. The retrograde route is used by Shiga toxin (*35*) to exert its toxic effects. This toxin has an AB5 structure. The A domain is responsible for the toxic effects of Shiga toxin. The B-subunit STxB (7.7 kD) forms a pentamer which preferentially binds the eukaryotic receptor globotriaosylceramide (Gb3). The B pentamer has the capacity of targeting the toxin to the retrograde route, allowing transfer of the A-subunit to the cytosol by retro-translocation from the endoplasmic reticulum. STxB is a



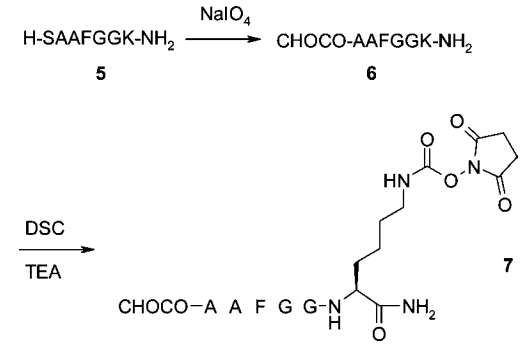


Figure 7. Sulfation assay using STxB (lane A), TS-STxB-a (lane B), TS-STxB-b (lane C), and TS-STxB-c (lane D). Proteins were incubated with HeLa cells at 4 °C in sulfate-free DMEM, and then incubated with $^{35}SO_4^{2-}$ in sulfate free DMEM at 37 °C for 2 h. Cells were lysed and STxB proteins were captured using protein G-sepharose loaded with anti-STxB antibody 13C4. Precipitated proteins were separated by tris-tricine gel electrophoresis, and gels were analyzed by autoradiography. The arrow points to the different STxB proteins.

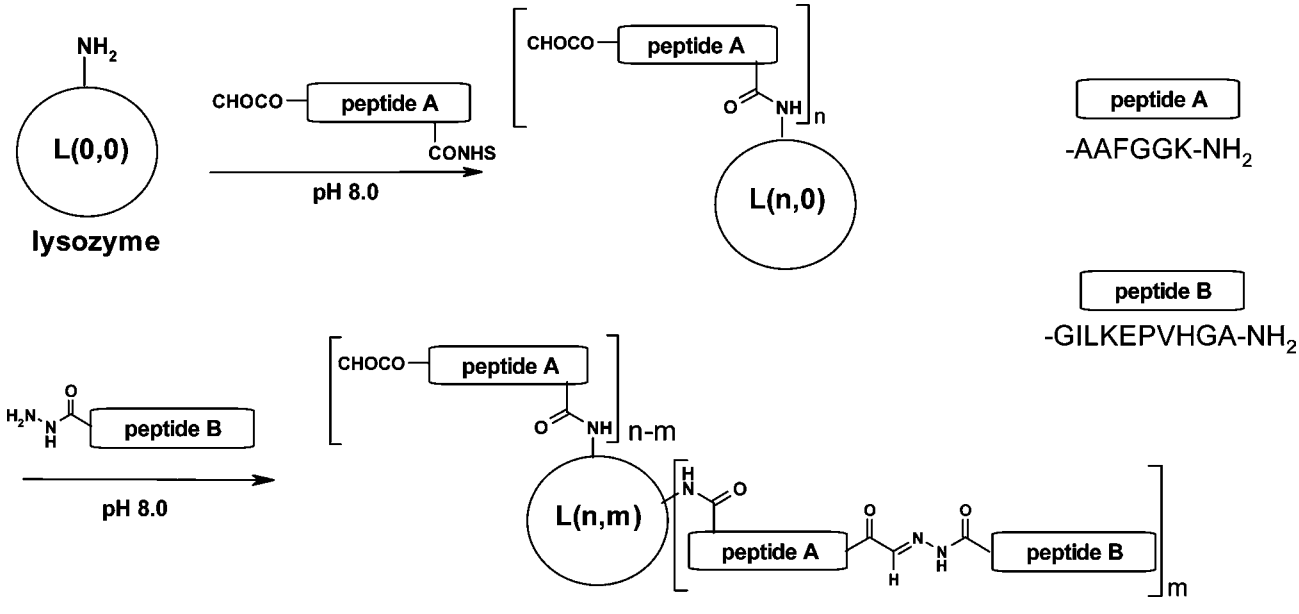
valuable marker for the retrograde route and was used here to prove the usefulness of TS conjugates prepared using NSC chemistry.

STxB labeling was performed using peptide **1b** as described above. LC-MS analysis of the product revealed that 80% of STxB was modified. MALDI-TOF analysis of the product showed the presence of up to three TS peptides per STxB monomer. The conjugate was purified either by ultrafiltration on a 3 kD membrane (TS-STxB-a) or by RP-HPLC (TS-STxB-b). TS-STxB-a,b were identical by LC-MS. Both conjugates were tested to evaluate the impact of RP-HPLC and lyophilization steps on the TS-STxB-b biological activity.

The retrograde transport of STxB and of TS-STxB-a,b from the plasma membrane to the trans Golgi network was first studied by immunofluorescence confocal microscopy using HeLa cells (Figure 6). The three proteins colocalized with GM130, a protein which is bound to Golgi membranes (*36*). This experiment shows that modification of STxB by NSC



Scheme 2. Synthesis of Glyoxylyl NSC Peptide 7

peptide **1b** did not alter the capacity of the protein to target the retrograde route. We next studied the TS label capacity within the conjugates to be sulfated by tyrosylprotein sulfotransferase, an enzyme which is associated with the Golgi membrane (Figure 7) (*37*, *38*). STxB was used as a negative control (lane A, Figure 7), whereas TS-STxB-c, a recombinant STxB protein modified at the C-terminus by two tandem sulfation sites, was used as a positive control (*21*). Cells were first incubated with the different STxB proteins and then in the presence of $^{35}SO_4^{2-}$ in sulfate-free DMEM to allow incorporation of radioactive sulfate within the TS labels. Cells were lysed and STxB proteins were immunoprecipitated using anti-STxB monoclonal antibody. Radioactive bands were detected by autoradiography. The arrow in Figure 7 points to STxB proteins. This experiment shows a radioactive band for the positive control (TS-STxB-c, lane D) but not for the negative control (STxB, lane A). A band is also seen for TS-STxB a or b, showing that the TS label introduced using NSC chemistry is sulfated by tyrosylprotein sulfotransferase present in the Golgi. Overall, these data show that NSC chemistry allows the synthesis of conjugates that preserve the capacity of STxB protein to target the retrograde route and the ability of TS peptide to be sulfated in the cell.

One-Pot Synthesis of Peptide−Protein Conjugates. The method described above can only be used with peptides lacking Lys residues within their sequences such as the TS peptide described above. The two-step strategy depicted in Scheme 1 allows overcoming this limitation. The first step involves reaction of bifunctionnal peptide A with the protein using NSC

Scheme 1. One-Pot Synthesis of Peptide Protein Conjugates Can Be Performed by Combining NSC Chemistry and α-Oxo Semicarbazone Ligation

Scheme 3. Synthesis of Semicarbazide Peptide 8

[a] MALDI MS spectra were acquired in the linear mode by using a PerSeptive Biosystems Voyager DE-STR instrument fitted with a 337 nm nitrogen laser (25 kV, grid 92%, delay time 750 ns). Matrix: 3,5-Dimethoxy-4-hydroxycinnamic acid (20 mg/mL). Entry 1: lysozyme. Entries 2−4: reaction with peptide **7**. Entries 5−7: reaction with peptide **7** and peptide **8**.

chemistry. This allows introducing an α-oxo aldehyde group on the surface of the protein, which can be subsequently ligated chemoselectively with peptide B featuring a semicarbazide group at the N-terminus (Scheme 1). To date, semicarbazone chemistry has been mainly used for linking peptides to surfaces (*39*−*42*). To the best of our knowledge, however, ligation between semicarbazide and glyoxylyl peptides was not reported before. This may be due to the difficulty synthesizing peptides featuring a semicarbazide group at the N-terminus, because this moiety is rapidly hydrolyzed in the acid eluents (pH 2) often used for peptide RP-HPLC analysis or purification. A solution to this problem has recently been described by the use of a nearly neutral buffer instead for the purification step (*19*).

Peptide A synthesized in this work is used as spacer. A Phe residue was inserted into the sequence to facilitate UV detection. However, peptide A can potentially be used for introducing a bioactive sequence or a label depending on the final application.

The strategy described in Scheme 1 requires glyoxylyl NSC peptide **7** and semicarbazide peptide **8** synthesis. Peptide **7** was prepared starting from peptide **5** H-SAAFGGK-NH_2 (Scheme 2). Oxidation of peptide **5** into peptide **6** COCHO-AAFGG-NH_2 by sodium periodate was performed using standard experimental conditions (*4*). Glyoxylyl NSC peptide **7** was then synthesized by treating peptide **6** with 0.5 equiv of triethylamine and an excess of DSC, as described above for NSC TS peptides **1**−**4b**. Attempts to convert peptide **6** into the corresponding NSCE ester with DSS, as described above, failed probably due to imine formation between α-oxo aldehyde and ε-amino moieties in basic conditions.

Model peptide **8** synthesis was performed by coupling Boc-NHNHCO-imidazole to peptidyl resin assembled using Fmoc/*t*-Bu strategy (Scheme 3) (*19*). Semicarbazide peptide **8** was stable during TFA deprotection and cleavage and was purified by RP-HPLC in a pH 6.5 triethylamonium acetate buffer.

Lysozyme was used again as a model protein. Reaction between lysozyme and glyoxylyl NSC peptide **7** was performed in a pH 8.0 sodium phosphate buffer. MALDI-TOF analysis of the reaction mixture revealed grafting of up to three glyoxylyl NSC peptide **7** molecules (L1−3,0 see entries 2−4, Table 2; see also Figure 8). After 1 h, the reaction mixture was reacted with semicarbazide peptide **8** at same pH. Up to two semicarbazide peptide **8** molecules were linked to lysozyme (entries

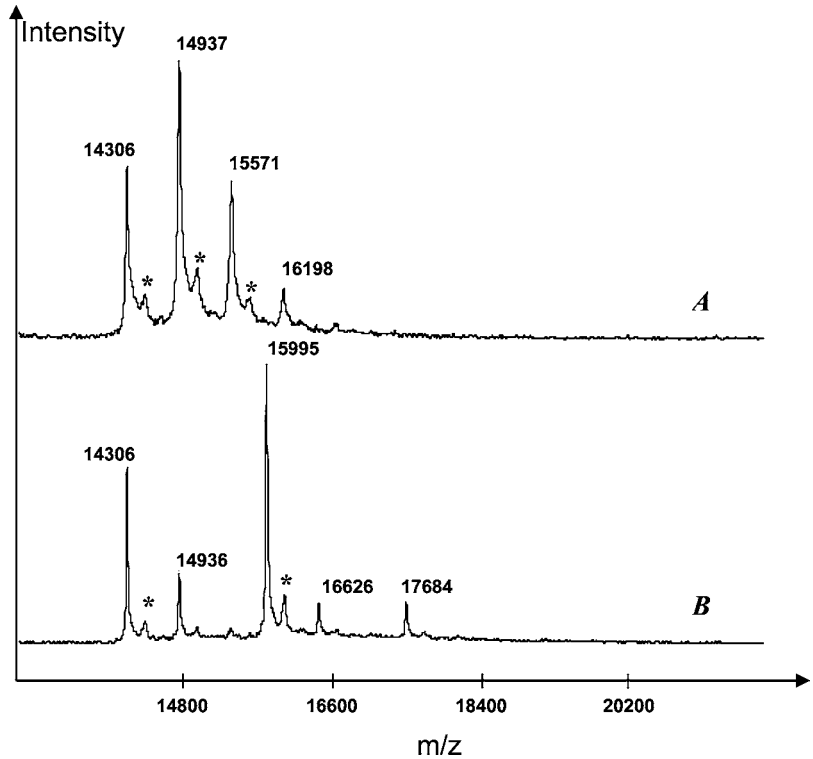

Figure 8. MALDI-TOF analysis of the one-pot conversion of lysozyme L into L(*n*,*m*) peptide-lysozyme conjugates. (A) after reaction with glyoxylyl NSC peptide **7**, (B) after reaction with peptide **7** and semicarbazide peptide **8**. See Table 2 for experimental conditions. The asterisk corresponds to protein−matrix adducts.

5−7, Table 2). Usually, Schiff-base formation between glyoxylyl peptides and peptide hydrazides is carried out at pH 5.5. In this study, successful formation of the α-oxo semicarbazone bond at pH 8.0 permitted the one-pot synthesis of peptide−protein conjugates in a straightforward manner.

In conclusion, we have shown that NSC peptides can easily be synthesized in high yield by reacting unprotected peptide precursors with DSC. The method requires the presence of only one reactive ε-amino group within the peptide sequence. Importantly, NSC peptides were stable during standard RP-HPLC purification at pH 2 and in the lyophilized form for months. Their reaction with ε-amino groups of proteins occurred efficiently and rapidly (<5 min), probably due to in situ partial conversion of NSC group into isocyanate moiety. The method was used for grafting a peptide substrate for tyrosylprotein sulfotransferase to lysozyme, a model protein, or STxB the receptor-binding nontoxic B-subunit of Shiga toxin, a valuable marker for the retrograde route. The biological activity of the STxB conjugate was verified by immunofluorescence confocal microscopy or using a sulfation assay. We have also described a novel method for synthesizing peptide−protein conjugates, which is compatible with all proteinogenic amino acids. The conjugates were assembled by combining NSC chemistry and α-oxo semicarbazone ligation. To this end, a glyoxylyl NSC peptide was synthesized and reacted with lysozyme to produce glyoxylyl lysozyme. The crude reaction mixture was then reacted with a semicarbazide peptide. Ligation between the glyoxylyl groups on the protein and the semicarbazide group on the peptide resulted in formation of the target peptide−protein conjugate. Both reactions were carried out at pH 8.0, thus allowing the one-pot synthesis of the conjugate without the need to adjust pH in between.

Overall, NSC chemistry described here is an interesting tool for preparation of conjugates of biological interest and complements the chemical toolbox of the peptide chemist.

ACKNOWLEDGMENT

We are grateful to the French Ministry of Research for its financial support, to the EEC, CNRS, Région Nord Pas-de-Calais and Cancéropôle Nord-Ouest for their grants. The work was performed in Chemistry Systems Biology platform facility of the Institute of Biology (Lille, France, http://csb.ibl.fr). GS was supported by a PhD fellowship from *Fondation pour la Recherche Médicale* (FRM).

Synthesis of Specific SPECT-Radiopharmaceutical for Tumor Imaging Based on Methionine: ^{99m}Tc-DTPA-bis(methionine)

Puja Panwar Hazari, Gauri Shukla, Vijay Goel, Krishna Chuttani, Nitin Kumar, Rajnish Sharma, and Anil Kumar Mishra*

Division Cyclotron and Radiopharmaceutical Sciences, Institute of Nuclear Medicine and Allied Sciences, Brig SK Mazumdar Road, Delhi-110054, India. Received May 2, 2009; Revised Manuscript Received January 6, 2010

Methionine-diethylenetriaminepentaaceticacid-methionine [DTPA-bis(Met)] was synthesized by covalently conjugating two molecules of methionine (Met) to DTPA and was labeled with ^{99m}Tc in high radiochemical purity and specific activity (166−296 MBq/μmol). Kinetic analysis showed K_m of 12.95 ± 3.8 nM and a maximal transport rate velocity (V_{max}) of 80.35 ± 0.42 pmol μg protein^{-1} min^{-1} of ^{99m}Tc-DTPA-bis(Met) in U-87MG cells. DTPA-bis(Met) had dissociation constants (K_d) of 0.067 and 0.077 nM in U-87MG and BMG, respectively. ^{35}S-methionine efflux was trans-stimulated by ^{99m}Tc-labeled DTPA conjugate demonstrating concentrative transport. The blood kinetic studies showed fast clearance with $t_{1/2}$ (F) = 36 ± 0.5 min and $t_{1/2}$ (S) = 5 h 55 min ± 0.85 min. U-87MG and BMG tumors saturated at ∼2000 ± 280 nmol/kg of ^{99m}Tc-DTPA-bis(Met). Initial rate of transport of ^{99m}Tc-DTPA-bis(Met) in U-87MG tumor was found to be 4.68 × 10^{-4} μmol/kg/min. The tumor (BMG cell line, malignant glioma) grafted in athymic mice were readily identifiable in the gamma images. Semiquantitative analysis from region of interest (ROI) placed over areas counting average counts per pixel with maximum radiotracer uptake on the tumor was found to be 11.05 ± 3.99 and compared ROI with muscle (0.55 ± 0.13). The tumor-to-contralateral muscle tissue ratio of ^{99m}Tc-DTPA-bis(Met) was found to be 23 ± 3.3. Biodistribution revealed significant tumor uptake and good contrast in the U-87MG, BMG, and EAT tumor-bearing mice. In clinical trials, the sensitivity, specificity, and positive predictive values were found to be 87.8%, 92.8%, and 96.6%, respectively. ^{99m}Tc-DTPA-bis(Met) showed excellent tumor targeting and has promising utility as a SPECT-radiopharmaceutical for imaging methionine-dependent human tumors and to quantify the ratio of MET^+/HCY^-.

INTRODUCTION

Development of a highly specific and sensitive noninvasive imaging modality that can enhance the ability to closely correlate diagnosis with pathology, distinguish inflammation from tumors, differentiate tumor grades, accurately delineate tumor volume, monitor treatment responses, and identify residual tumor/recurrence remains a desirable goal to improve the current clinical management of cancers.

The natural amino acids are transported inside the cells by specific carrier-mediated transport systems and get incorporated into proteins and intermediary metabolites to different extents. Several transporters are based on system L such as LAT1, LAT2, LAT3, and LAT4, which have been identified at the molecular level (*1*−*5*). Among the identified transporters, LAT1 is consistently expressed at high levels in cancer cells as LAT1 transporter, and therefore is a candidate substrate for transport into cancer cells (*6*). Many synthetic derivatives, such as methyl-aminoisobutyric acid (MeAIB), and various halogenated derivatives of phenylalanine and tyrosine have also been shown to enter the cells using similar transport systems but are not metabolized. The role of overexpression of transporter systems of neutral amino acid has been reported in literature (*7*). Therefore, many natural amino acids (such as methionine, glycine, tyrosine, phenylalanine, and leucine) and their synthetic analogues have been labeled with radioactive isotopes and are being explored as tumor imaging agents for PET/SPECT (*8*−*13*).

The major metabolic functions of methionine are in protein synthesis and conversion to *S*-adenosylmethionine (Adomet), which is required in multiple metabolic pathways. Methionine (Met) dependence has been shown in vitro in a number of human cell lines of different cellular origin, and the dependence may reflect the overall imbalance in the transmethylation (*14*−*17*). Metabolic defects in cancer cells often manifest in the inability to grow in media where Met has been replaced by its precursor HCY (*18*, *19*). Increase in amino acid uptake is one of the earliest events associated with in vitro transformation (*20*) thus inducing upregulation of the amino acid transporter expression to enhance the facilitated transport (*21*). Because the uptake of amino acids (AA) in normal tissue is low and increases across glioma capillaries and tumors, the contrast between tumor and normal tissue is generally better with amino acid scanning as compared to FDG-PET or any other imaging modality (*22*−*25*). Currently, PET using L-[methyl-^{11}C]-methionine (MET) is the most popular AA-imaging modality for tumors, although its use is restricted to PET centers with an in-house cyclotron facility for successful use of isotope in amino acid labeling.

Polydentate ligands are of particular interest because of their capability to adopt an organized conformation in the complexed form. Entrapment of metal ion into a framework of multidentate poly(aminocarboxylates) such as DTPA covalently attached to mAbs with some metallic radionuclides, especially ^{111}In, and various other lanthanides has been proven to provide thermodynamically stable compounds suitable for clinical trials (*26*). The anhydride derivatives of DTPA are generally easier to synthesize because of the commercial availability of DTPA. In particular, complexation of DTPA moiety with ^{99m}Tc showed excellent results as a metallopharmaceutical for medical imaging.

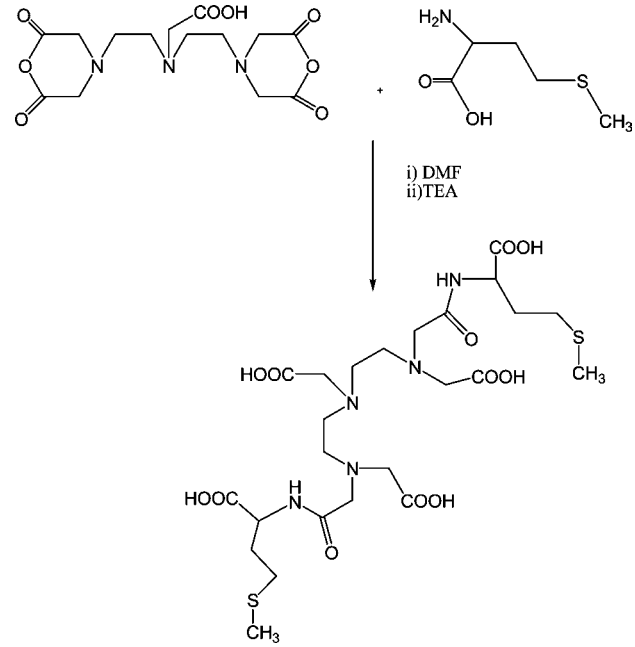
The work reported in the literature has shown that the conjugated DTPA [DTPA-B-(SLex)A] forms stable complexes with lanthanides and transition metals (*27*). The main objective of our study was to design and synthesize a novel amino acid derivative based on DTPA, which forms stable complexes with most lanthanides and transition metals in the periodic table. Second, to introduce a chelating group without compromising the biological integrity of the amino acid for diagnosis of cancer using nuclear medicine and MR techniques.

As a part of our efforts to explore the application of targeted radiopharmaceuticals for site-directed diagnosis and cancer therapy, (*28*−*31*) we hereby report the synthesis, characterization, and radiochemistry of ^{99m}Tc labeled DTPA-bis(Met) conjugate and its evaluation in nude mice bearing human malignant glioma cell lines (U-87MG and BMG). Covalent attachment of a strong chelating agent, DTPA, with methionine provides binding sites to which reduced ^{99m}Tc is strongly bound. Radiolabeling of the purified methionine DTPA−conjugate with ^{99m}Tc, stability studies in human serum under physiological conditions, and blood kinetics in rabbits are reported. Cytotoxicity was determined by MTT and clonogenic assays. The efficiency of DTPA-bis(Met) in vitro was assessed by cell uptake assays in tumor cell lines (U-87MG and BMG) and human embryonic kidney cell line and in vivo by biodistribution studies with athymic mice bearing subcutaneous U-87MG and BMG cell line. Clinical studies in patients were carried out to establish the specificity and sensitivity of the new SPECT radiopharmaceutical in patients for better detection and delineation of metabolic tumors of different histological grades.



MATERIALS AND METHODS

Chemicals. Acetonitrile, methanol, and water (HPLC grade) were obtained from Merck Germany Ltd. L-Methionine, diethylenetriaminepentaacetic acid, DTPA bisanhydride, triethylamine, dimethylformamide, methanol, ethanol, stannous chloride dihydrated ($SnCl_2 \cdot 2H_2O$), trifluoroacetic acid, MTT, 2-methylaminoisobutyric acid (MeAIB), 2-amino-bicyclo-(2,2,1)-heptane-2-carboxylic acid (BCH), L-arginine, L-valine, L-alanine, L-leucine, and L-glutamine were purchased from Sigma-Aldrich Co. ^{99m}Tc and ^{35}S-L-methionine were procured from Regional Center for Radiopharmaceuticals (Northern Region), Board of Radiation and Isotope Technology (BRIT), Department of Atomic Energy, India.

Cell Culture. Monolayer cultures of human malignant glioma cells, U-87MG (obtained from NIMHANS, Bangalore), normal embryonic kidney cells, HEK, and BMG were maintained at 37 °C in a humidified CO_2 incubator (5% CO_2, 95% air) in DMEM (Sigma, USA) supplemented with 10% fetal bovine serum (GIBCO), 50 U/mL penicillin, 50 μg/mL streptomycin sulfate, and 2 μg/mL nystatin. Cells were routinely subcultured twice a week using 0.05% Trypsin (Sigma, USA) in 0.02% EDTA.

Instrumentation. ^{1}H NMR spectra were determined by using Bruker Avance II 400. Mass spectrum (ES^+MS) was recorded on a Aligent 6310 ion trap. HPLC analyses were performed on a Waters Chromatograph efficient with 600s coupled to a Waters 2487 photodiode array UV detector. The C-18 RP Beckman column (5 μ, 1 mm × 125 cm) column was used applying the elution system described in the text. C-18 Cartridges were purchased from Waters. Radioactive samples were counted using Capintech automated well-type counter. Beta scintillation counts were obtained by mixing samples in optiphase scintillation cocktail using Wallac Micro beta Trilux 1450 LSC, Perkin-Elmer (ACBR, Delhi University). Radioimaging and biodistribution studies were done using a planner gamma camera HAWKEYE. The clinical scintigraphs were obtained using a rectangular large field of view gamma camera (HAWKEYE dual head, GE medical systems, Milwaukee, Wisconsin, USA) with a low-energy all-purpose collimator.

Scheme 1. Synthesis of Diethylenetriaminepentaacetic Acid bis(methionine)[a]

[a] (i) DTPA-bis anhydride, (ii) L-methionine, (iii) DMF, (iv) triethylamine.

Animal Models. All animal experiments were performed in accordance with guidelines of INMAS animal ethics committee. New Zealand rabbits, athymic mice, and albino balb/c mice were used for blood clearance, imaging, and biodistribution. Mice and rabbits were housed under conditions of controlled temperature of 22 ± 2 °C and normal diet. Athymic mice were inoculated subcutaneous with 0.1 mL of cell suspension (5 × 10^6 BMG/U-87MG cells) just above the right hind leg under sterilized conditions. Balb/c mice were inoculated subcutaneously EAT (15 × 10^6 cells) in the right hind leg.

PATIENTS AND METHODS

Patients. Human protocols have been approved by Institutional human ethics committee.

Scintigraphy. Whole body images were obtained using dual head gamma camera. ^{99m}Tc-DTPA-bis(Met) imaging was performed after i.v. administration of 15 mCi (555 MBq) radiotracer. Whole body scan was done after 1 h, 3 h, 6 h, and 24 h injection of radiotracer as a standard protocol and 5 patients were also imaged at 5, 10, 30, 45, 60, and 180 min. Semiquantitative analysis was generated from region of interest (ROI) placed over areas counting average counts per pixels with maximum radiotracer uptake on the lesions and compared to symmetric counterparts with ROI in soft tissues. Thirty-three breast cancer patients underwent in-house FDG scan. Brain cancer patients also underwent MDP scan.

Statistical Methods. Data is reported as mean ± standard deviation (S.D.). Data were analyzed by the two-tailed Student's *t* test for comparison with the control. Value of $P < 0.05$ was considered statistically significant.

EXPERIMENTAL SECTION

Synthesis of Diethylenetriaminepentaacetic Acid Bis(methionine) Scheme 1. DTPA anhydride (500 mg; 1.4 mmol) and L-methionine (522 mg; 3.50 mmol) were dissolved in 5 mL of

DMF (anhyd.), and 15 mol equiv of triethylamine (2.35 mL) was then added. The reaction was allowed to proceed for 48 h at 55 °C.

Completion of the reaction was checked by running TLC plates in water (0.01% TFA) and methanol (7:3; v/v) [R_f for Met: 0.89; R_f for DTPA-bis(Met): 0.75]. Triethylamine and DMF were evaporated under reduced pressure using a rotaevaporator. The chemical purity of DTPA-bis(Met) conjugate was examined by analytical HPLC on Beckman C-18 reverse-phase column (4.6 mm × 250 mm). The mobile phase was 0.05% TFA in water (solvent A) and methanol (solvent B) with a flow rate of 0.5 mL/min. Gradient 0−14 min A/B 90/10−50/50, 14−23 min A/B 50/50−0/100, 23−28 min A/B 0/100−90/10.

Yield: 758 mg,1.16 mmol, 82.66%. IR (ν, cm^{-1}) 3437, 2817, 1610. ^{1}H NMR (400 MHz, D_2O): δ = 4.42−4.19 (m, NH−CH_2, 2H), 3.685 (br, s, CH_2, 4H), 3.7−2.37 (m, CH_2−CH_2, 22H), 2.026, 2.005 (br, s, 2H) ppm. ^{13}C NMR (400 MHz, D_2O): δ = 178.70, 178.35 (C═O), 173.18, 174.48 (COOH), 58.40, 58.09, 57.09, 56.16, 54.01, 53.89, 52.45, 49.77, 49.37 (CH_2−CH_2, 11C), 30.86, 29.87, 29.76, 28.79 (CH_2−S, 4C), 14.20, 13.87 (S-CH_3, 2C) ppm. Calculated mass $[M+H]^+$ 656.2 found *m/z* = 656.6 $[M+H]^+$, 678.2 $[M+Na]^+$ (see Supporting Information). Elemental analysis calcd for $C_{24}H_{41}N_5O_{12}S_2$: C, 43.96; H, 6.30; N, 10.68; O, 29.28; S, 9.78. Found C, 43.95; H, 6.31; N, 10.67; O, 29.29; S, 9.78.

Radiolabeling of DTPA-bis(Met) with ^{99m}Technetium. DTPA-bis(Met) (2 mg) was dissolved in a shielded vial and stannous chloride (300 μL; 1 mg dissolved in N_2 purged 1 mL of 10% acetic acid) was added followed by addition of freshly eluted (<1 h) ^{99m}Technetium pertechnetate (82 MBq; 200 μL). The pH of the reaction mixture was adjusted to 7 with 0.1 M Na_2CO_3 and purged with N_2, and shaken to mix. The vial was allowed to stand for 15 min at room temperature (25 °C).

Radiochemical Purity. The number of ligand molecules involved in complexation with ^{99m}Tc was determined by ascending thin layer chromatography on ITLC-SG (Paul Gelman, USA) strips using 100% acetone as developing solvent and simultaneously in pyridine/acetic acid/water (PAW) (3:5:1.5) and saline. Each TLC was cut in 0.5 cm segments and counts of each segment were taken. By using this method percentage of free $Na^{99m}TcO_4^-$, reduced/hydrolysed ^{99m}Tc, and the complex formed between ^{99m}Tc and DTPA-bis(Met) conjugate could be calculated. ^{99m}Tc-DTPA-bis(Met) conjugate remained at the origin, and free technetium traveled with the solvent front in acetone.

The radiolabeled conjugate was then purified using a C-18 reversed-phase extraction cartridge, which was preconditioned with 10 mL methanol and subsequently activated with 30% methanol. The cartridge was successively rinsed with 5 mL distilled water, and radiolabeled conjugate was eluted in 5 mL of 5% ethanol.

Human Serum Stability Evaluation. Human serum was prepared by allowing blood collected from healthy volunteers to clot for 1 h at 37 °C in a humidified incubator maintained at 5% carbon dioxide/95% air. Then, the samples were centrifuged at 400 *g*, and the serum was filtered through 0.22 μm syringe filter into sterile plastic culture tubes. The radiolabeled DTPA-bis(Met) was immediately placed in a CO_2 chamber incubated at 37 °C and then analyzed to check for any dissociation of the complex. Percentage of free pertechnetate at a particular time point that was estimated using acetone and pyridine, acetic acid, and water (PAW) (3:5:1.5) as mobile phase represented percentage dissociation of the complex at that particular time point in serum.

Cytotoxicity Studies of DTPA-bis(Met). Cytotoxicity was determined using the MTT [3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide] assay. Exponentially growing cells were plated in a 96-well microtiter plate at a uniform cell density of 4000 cells/well, 24 h before treatment. Cells were treated with varying concentrations of drug (nM−mM range) for 2 h, and MTT assays were performed. At the end of treatment, negative control and treated cells were incubated with MTT at a final concentration of 0.05 mg/mL for 2 h at 37 °C, and the medium was removed. The cells were lysed, and the formazan crystals were dissolved using 150 μL of DMSO. Optical density is measured on 150 μL of extracts at 570 nm (reference filter: 690 nm). Mitochondrial activity was expressed as percentage of viability compared to negative control (mean ± SD of triplicate cultures). % of viability = [OD (570 nm − 630 nm) test product/OD (570 nm − 630 nm) negative control] × 100%.

Macrocolony Assay of DTPA-bis(Met). Monolayer cultures of U-87MG and BMG cell lines were trypsinized and 100 to1000 cells were plated depending upon the concentrations of the drug in 60 mm petridishes and incubated at 37 °C in 5% CO_2 humidified atmosphere for 8 days. Colonies were fixed in methanol and stained with 1% crystal violet. Colonies containing more than 50 cells were counted (Figure 2).

Cell Uptake and Efflux Studies of ^{99m}Tc-DTPA-bis(Met). *Measurement of ^{99m}Tc-DTPA-bis(Met) Transport.* U-87MG cells were plated at a density of 10^5 cells per well in a 96-well microtiter plates and allowed to adhere overnight prior to transport studies, which were carried out as described previously. Briefly, adherent cells were rinsed twice with a modified Hepes-buffered Krebs solution, and uptake was initiated by adding Hepes-buffered Krebs (50 μL per well; 37 °C) containing 10 μM of ^{99m}Tc-DTPA-bis(Met) to the monolayers. Incubations were terminated by placing the plates on melting ice and rinsing cells three times with 200 μL ice-cold Krebs buffer. 100 μL of the protein lysis buffer was then added to wells causing rapid lysis of cells. Bradfort protein reagent was added to the wells for total protein estimation. Absorbance values were determined at 595 nm on an ELISA plate reader after 20 min of incubation at room temperature. Values obtained were converted to total protein per well using a protein standard curve generated from bovine serum albumin. The amount of radioactivity (CPM) in cell lysates was determined by gamma scintillation counting. Uptake was then calculated and expressed in units of pmoles μg protein^{-1}·min^{-1}.

Time Course and Kinetics of Transport ^{99m}Tc-DTPA-bis-(Met) Transport. The time course of uptake of was monitored by incubating cells with (100 μM) in Hepes-buffered Krebs solution (50 μL; 37 °C) for varying time periods ranging from 30 s to 60 min. Transport was then terminated and total accumulated in cells determined as described above. In kinetic experiments, cells were incubated for 10 min in either normal Hepes-buffered Krebs solution (50 μL; 37 °C) or Na^+-free Krebs solution described above containing increasing concentrations (0.005−0.1 μM) of ^{99m}Tc-DTPA-bis(Met). The data obtained were fitted using the Michaelis−Menten equation.

Cell Binding Studies. The specificity of ^{99m}Tc-DTPA-bis(Met) to bind externally on tumor cells were examined by receptor binding assays on three human cell lines. U-87MG and BMG were grown in normal DMEM, 10% and 5% FBS, respectively. HEK was cultured in high-glucose DMEM with 10% FBS. Monolayer cultures of the cell lines were washed with HBSS and were then incubated for 2 h in HBSS at 37 °C prior to the experiment. Binding experiments was conducted at 37 °C. Cells were incubated for 30 min with increasing concentrations (0.01 nM−10 μM) of ^{99m}Tc-DTPA-bis(Met) in the absence and presence of the 100-fold excess unlabeled methionine to estimate the total binding and nonspecific binding respectively. Specific binding was obtained by subtracting nonspecific binding from total binding. At the end of each experiment, the cells were

washed with cold PBS four times. The cell-associated radioactivity was determined by gamma scintillation counting.

Selective and Na^+-Dependency of Transport. Inhibition of ^{99m}Tc-DTPA-bis(Met) transport by competitor amino acids was investigated by incubating cells with Krebs solution containing 10 μM ^{99m}Tc-DTPA-bis(Met) in the absence or presence of a 100-fold excess (1 mM) or increasing concentrations of a BCH inhibitor substrate. Parallel inhibition studies were carried out by replacing normal Krebs solution with Na^+-free Krebs. In sodium-free experiments, the buffer was modified by replacing NaCl, $NaHCO_3$, and NaH_2PO_4 with choline chloride, choline bicarbonate, and KH_2PO_4, respectively.

Cells were incubated with ^{99m}Tc-DTPA-bis(Met) for 30 min at 37 °C in standard Krebs buffer. After this period, cells were washed and incubated in fresh buffer containing 1 mM of either BCH, L-leucine, L-glutamine, or 2-methylaminoisobutyric acid (MeAIB), L-valine, and L-alanine. Radioactivity in the medium and in cell lysates was determined at 5, 10, and 15 min, and the efflux values expressed as percent of radioactivity released from the cells: radioactivity in medium/(radioactivity in medium + radioactivity in lysates) × 100%.

Trans-Stimulation of ^{35}S-L-Methionine Efflux in U-87MG Cells. To measure efflux of ^{35}S-methionine, U-87MG cells were preloaded with 10 μM (10 μCi) ^{35}S-methionine for 2 h at 25 °C. The loaded methionine was then allowed to efflux in HBSS solution in the presence and absence of 1 mM (10 mCi) of labeled DTPA-bis(Met). At end of the experiment, cells were washed with ice-cold buffer. The amount of methionine left was measured after the cells were digested. The accumulative amount effluxed plus the remaining ^{35}S-L-methionine in the cell monolayers were used to calculate the intracellular concentration of methionine at time zero. The efflux was calculated in micrograms per milliliter, and the efflux was compared with the control.

Blood Kinetics. In normal rabbit, 300 μL of the complex (11.1 MBq activity) was injected intravenously through the dorsal ear vein. Blood was withdrawn from the other ear vein at different time intervals starting from 5 min to 24 h. Persistence of activity in the circulation was calculated, assuming total blood volume as 7% of the body weight (Figure 3).

Dose Escalation and Biodistribution. Human malignant glioma U-87MG and BMG cells were injected subcutaneously just above the hind leg of nude mice. When the tumors were easily palpable and approximately 0.17 g, mice were used for dose escalation and biodistribution study. Dose escalation study was performed using increasing concentrations 10, 100, 1000, 1500, 2000, 2500, 3000, and 4000 nmol/kg of ^{99m}Tc-DTPA-bis(Met), which was injected into tumor-bearing nude mice and the mice were sacrificed after 4 h. In biodistribution study, intravenous injection of ^{99m}Tc-DTPA-bis(Met) conjugate in a volume of 100 μL (2.72 μmol/kg, 3.7 MBq activity) was injected through the tail vein of each mice. Mice were dissected at 1, 4, and 24 h post injection; different tissues were taken out, weighed, and counted in a gamma counter calibrated for ^{99m}Tc energy. A group of 5 mice were coinjected with a blocking dose of 618 μmol/kg of unlabeled methionine. Uptake of the radiotracer in each tissue was calculated and expressed as percentage injected dose per gram of the tissue (%ID/g) (Table 1). Animal protocols have been approved by Institutional Animal Ethics Committee.

In Vivo Tumor Pharmacokinetics and Scintigraphy in Tumor Bearing Nude Mice. The change in tumor concentration of ^{99m}Tc-DTPA-bis(Met) as a function of time was studied by administering 2.50 μmol/kg (2.96 MBq activity). Noninvasively dynamic study was performed at a time interval of 1 min up to 30 min and then at 60, 120, 150, 180, 210, 240, and 270 min. Semiquantitative analysis was carried out by generating ROI on tumor and soft tissue. Tumor imaging was performed in BMG cell line implanted tumor bearing nude mice administering 100 μL of the labeled conjugate (2.18 μmol/kg, 2.96 MBq activity). Images were taken using planar gamma camera. Images were obtained at different time intervals starting from 15 min to 24 h after post injection (Figure 4).

[a] Athymic mice and BALB/c mice, body weight = 22−30 g. Data from groups of five mice are expressed as mean %ID/g ± S.D. Based on estimates assuming blood volume = 7% of the body weight.

Clinical Studies. In the study, 55 patients were included to perform DTPA-bis(Met) SPECT imaging in tumors of different origin. Out of them, 47 female patients (median age 44 years, range 28−68 years) had palpable breast masses (*32*), and all of them underwent ultrasound, mammography, and fine needle aspiration cytology. Two patients having brain tumor, one with primary cancer, and another previously treated and now suspected as having recurrence were also included. Three patients had regional lymph node cancer and three had osteosarcoma. Twenty-four breast cancer and nine benign breast lump cases also underwent in-house FDG scan.

RESULTS

Synthesis of DTPA-bis(Met). The synthesis of DTPA-bis(Met) conjugate was performed by reacting DTPA bisanhydride with L-methionine (Scheme 1). The final product was obtained in 82.66% yield and purified using reversed-phase HPLC, and HPLC retention time was found to be 8.6 min for methionine and 5.8 min for DTPA-bis(Met). Mass spectroscopy confirmed the integrity of the product. MS, *m*/*z* calculated for $C_{24}H_{41}N_5O_{12}S_2$ $[M+H]^+$ 656.22, found $[M+H]^+$ and $[M+Na]^+$ at 656.3 and 678.2, respectively, in ESI positive mode (Figure 1).

Quality Control of Labeled DTPA-bis(Met) Conjugate. The labeled complex remained at the point of spotting and $^{99m}TcO_4^-$ moved toward the solvent front in acetone. The yield

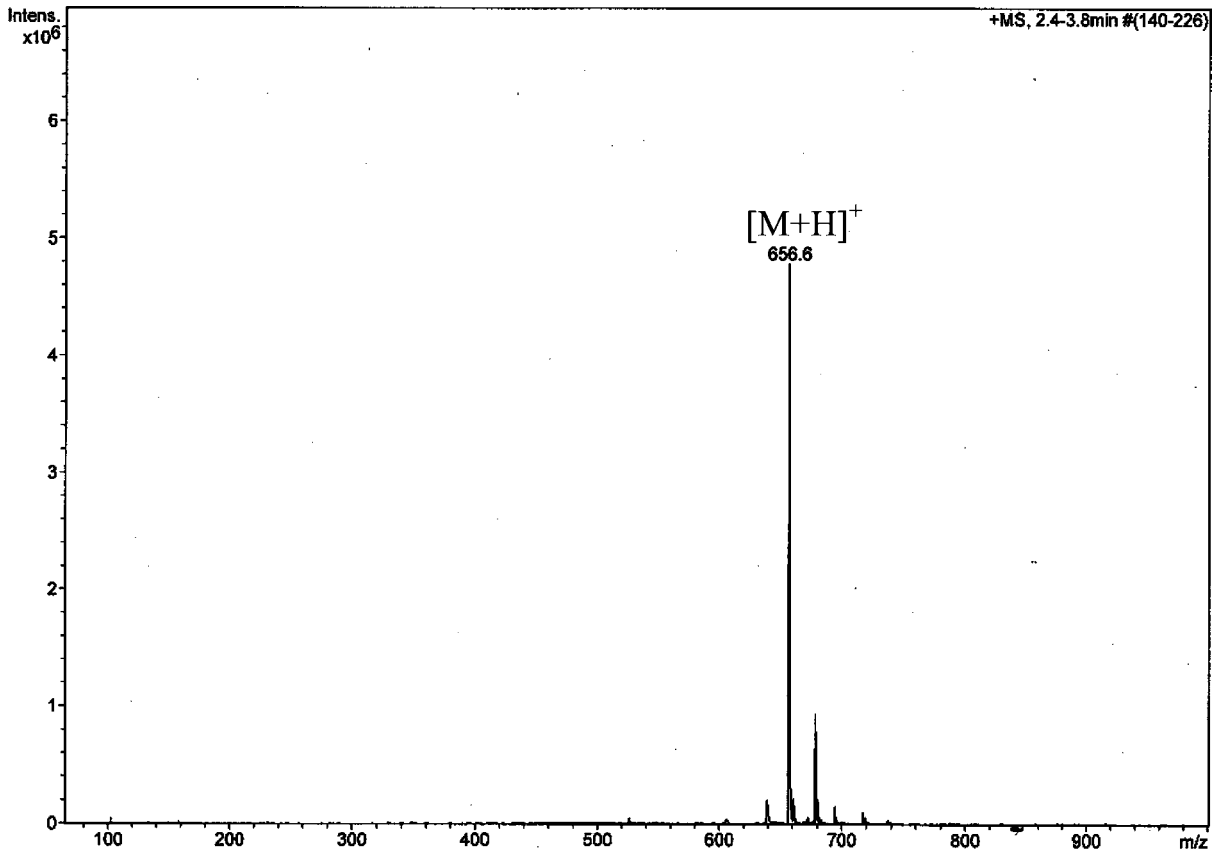

Figure 1. Mass spectrum of diethylenetriaminepentaacetic acid bis(methionine).

of free and complexed ligand, thus, could be estimated. The labeling yield was found to be greater than 96%, as determined by different solvent systems chromatographically. The reaction mixture was kept in saline for various time intervals carried out in in vitro stability studies. Percentage radiolabeling was calculated for 0, 2, 4, 6, and 24 h. Even up to 24 h, labeling efficiency was found to be 96.27%, implying that the labeled DTPA-bis(Met) conjugate was quite stable. The resulting solution was then eluted through a C-18 reverse-phase extraction cartridge. The metal binding assay confirmed the radiochemical purity to be >99%. Phosphor imaging showed a single spot indicating formation of only one species. Radiolabeled DTPA-bis(Met) conjugate was eluted in ≥99% radiochemical purity with specific activity of 4500−8000 μCi/μmol (166−296 MBq/μmol) through C-18 extraction cartridge. Radiochromatogram showed a single peak eluting at 6.4 min by C-18 reverse-phase column and came through flow using solvent system of 10 mM ammonium acetate and acetonitrile.

Human Serum Stability Evaluation. The purified ^{99m}Tc-DTPA-bis(Met) was incubated in freshly extracted human serum under physiological conditions. Radiolabeled conjugates were challenged with the proteins (albumin and transferrin) present in the serum to test the stability of the radiolabeled DTPA-bis(Met). Major transcomplexation of ^{99m}Tc was observed for unmodified Met to be 66% after 1 h. DTPA-bis(Met) showed 2.9% transcomplexation of ^{99m}Tc in serum. Approximately more than 94% of the radioactivity remains associated with the conjugate after 2 h challenge at 37 °C. It was sufficiently stable up to 24 h, as only 4% of the radiolabeled drug dissociated in serum at 24 h.

Cytotoxicity Studies of DTPA-bis(Met). By analysis of the MTT assay data at different concentrations (nM to mM range), it was found that, at a concentration of 1 mM, 2 h exposure resulted in lyses of 60% of U-87MG cells. It was observed that, when 10 μM of DTPA-bis(Met) was incubated with BMG cell line for 2 h, only 5% of the cells were killed. The two cell lines U-87MG and BMG showed concentration-dependent cytotoxicity. U-87MG showed survival value of 0.47 ± 0.028 at 1 mM for unlabeled DTPA-bis(Met). A surviving fraction of 0.54 ± 0.015 at 1 mM for the BMG cell line was observed in the clonogenic assay (Figure 2). The time-dependent curve showed a regain of the metabolic viability of the BMG cell line at 72 h post-treatment.

Cell Uptake Studies. *Time Course and Kinetics.* Time course experiments revealed that transport of ^{99m}Tc-DTPA-bis(Met) into cells was rapid and linear for up to 10 min, saturating thereafter, and reaching a plateau after 30 min of incubation. Kinetic analysis revealed that transport of ^{99m}Tc-DTPA-bis(Met) occurs via a saturable high-affinity carrier with a Michaelis constant (K_m) of 12.95 ± 3.8 nM and a maximal transport rate velocity (V_{max}) of 80.35 ± 0.42 pmol. μg protein^{-1} min^{-1} (Figure 3). A single linear regression line was obtained in the Eadie-Hofstee transformation (inset Figure 3B) indicative of the function of a saturable system or systems with comparable functional characteristics. When repeated in the absence of Na^+, transport of ^{99m}Tc-DTPA-bis(Met) was indistinguishable from that observed in normal Krebs buffer, since rates measured in Na^+-free Krebs solution were only marginally lower than those determined in the presence of Na^+.

Cell Binding Studies. The ability of DTPA-bis(Met) conjugate to bind LAT1 transporters on the surface of tumor cell lines U-87MG, BMG, and HEK was examined by binding assay using ^{99m}Tc- DTPA-bis(Met) as the labeled ligand. Nonspecific binding was determined using 100-fold excess of unlabeled methionine. Examination of binding curves showed significant external binding of the labeled DTPA-bis(Met) conjugate. Scatchard plot analysis revealed affinity of the labeled DTPA-bis(Met) on tumor cell lines. K_d was

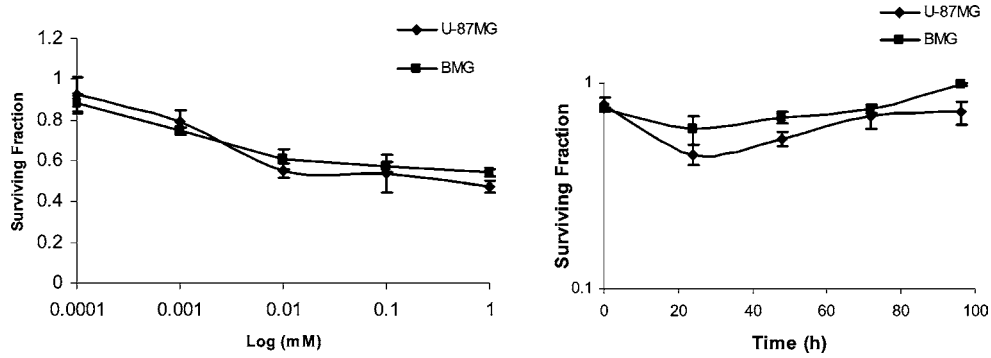

Figure 2. Cytotoxicity of DTPA-bis(Met) conjugate in U-87MG and BMG cell line: (a) concentration-dependent and (b) time-dependent curve as determined by clonogenic survival assay.

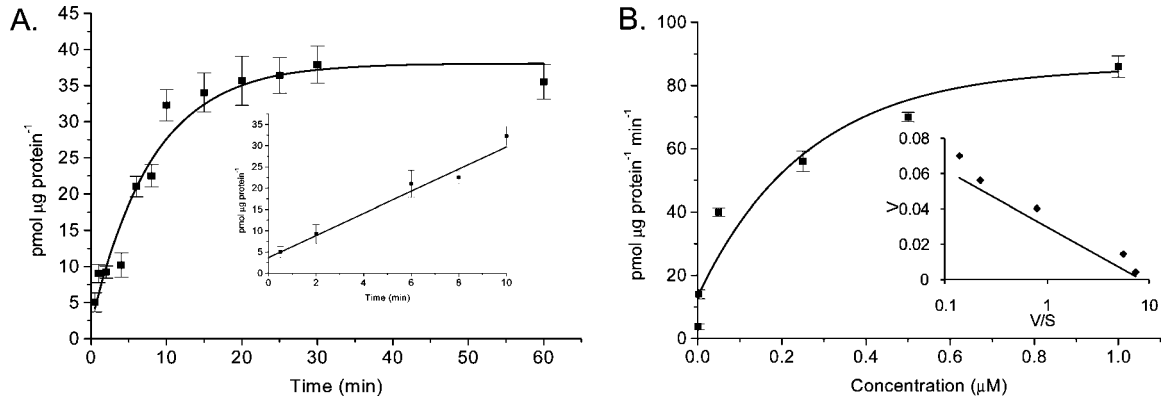

Figure 3. Time course and kinetics of ^{99m}Tc-DTPA-bis(Met). (A) Uptake was monitored from 30 s to 60 min. (B) Transport of ^{99m}Tc-DTPA-bis(Met) was monitored over 10 min period in U-87MG Cells. The inset shows an Eadie-Hofstee plot of saturable transport. Values are the mean ± SD of 3 replicate measurements in 3 separate experiments.

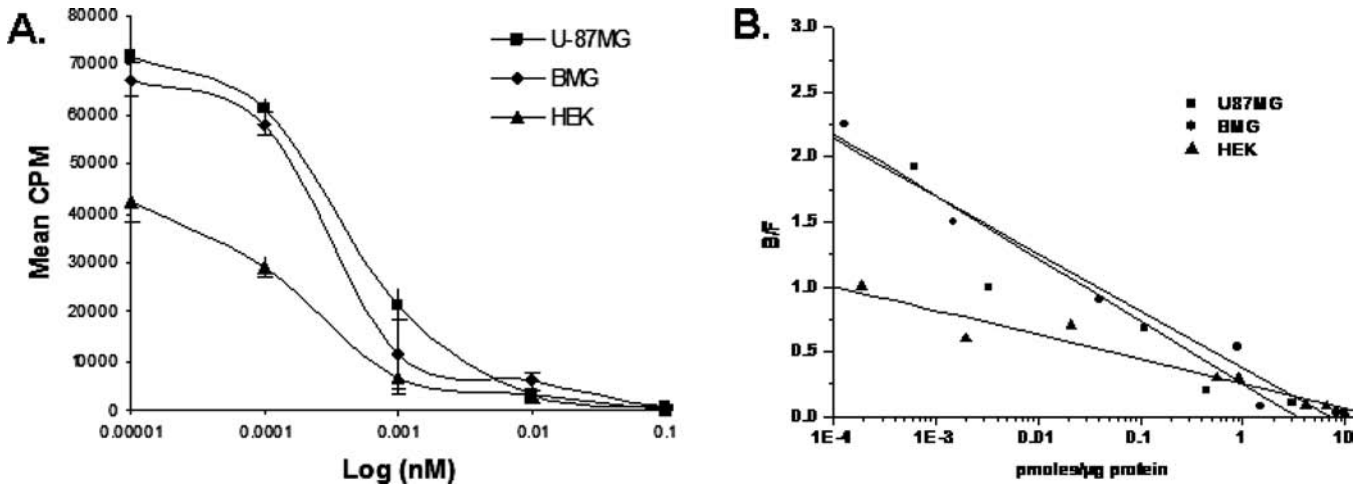

Figure 4. (A) Displacement using increasing concentrations of unlabeled methionine and labeled ^{99m}Tc-DTPA-bis(Met) was conducted in binding buffer The plot is representative of three independent experiments. (B) Scatchard plot of the specific binding data to the ratio of hound to free (B/F) for U-87MG, BMG, and HEK cell lines.

found to be 0.067 and 0.077 nM in U-87MG and BMG, respectively. In human embryonic kidney cell line, K_d was found to be 0.10 nM (Figure 4B).

Selectivity of ^{99m}Tc-DTPA-bis(Met) Transport. Cross inhibition studies were carried out in the presence and absence of Na^+ to evaluate the substrate specificity of the transporter associated with ^{99m}Tc-DTPA-bis(Met) uptake by U-87MG cells. Under these conditions, transport of ^{99m}Tc-DTPA-bis(Met) was not affected by a 100-fold excess of either 2-methylaminoisobutyric acid (MeAIB), a model substrate for system A, or L-valine and L-alanine, which are known substrates for the ASC system but was inhibited by 68 ± 1.9%, 52 ± 1.2%, and 36 ± 2.1% in the presence of 2-amino-bicyclo-(2,2,1)-heptane-2-carboxylic acid (BCH), L-phenylalanine, and L-leucine, respectively.

Trans-Stimulation of ^{35}S-L-methionine Efflux in U-87MG Cells. The efflux of ^{35}S-methionine was measured in the presence and absence of 1 mM (10 mCi) of ^{99m}Tc-labeled DTPA-bis(methionine). The amount of ^{35}S-L-methionine incorporated during the loading and subsequent washing protocol was less than 10 μM. It was evident from the experiment that ^{35}S-L-methionine efflux was trans-stimulated by extracellular 1 mM of DTPA-bis(Met). The magnitude of effect was observed to be higher at 30 min (0.32 ± 0.04 μg/mL). It was evident from the experiment that the presence of ^{99m}Tc-labeled DTPA-

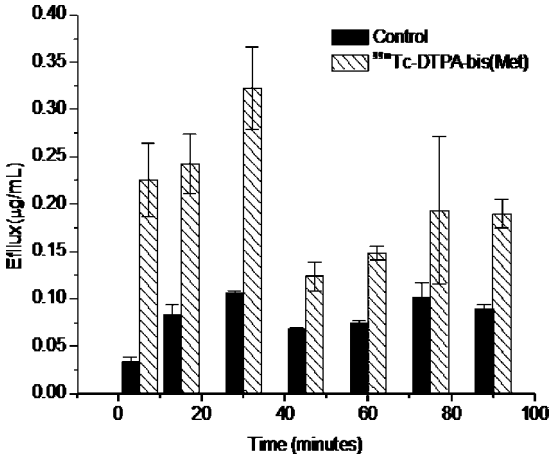

Figure 5. Trans-stimulation of ^{35}S-methionine efflux by extracellular ^{99m}Tc-labeled DTPA-bis(methionine). Efflux was measured for 90 min at 25 °C. Values mean ± SD, $n = 3$, each performed in duplicate $P < 0.05(0.0016)$ compared with control.

bis(Met) in the culture medium significantly ($P < 0.05$) trans-stimulated efflux of ^{35}S-methionine (Figure 5).

Blood Kinetics. In vivo clearance in rabbits revealed that there was a rapid clearance of DTPA-bis(Met) from the circulation, as only 17.6% of injected activity remained in the circulation at 30 min. After 30 min, the clearance followed a slow pattern, and at 24 h, approximately 0.76% activity persisted in the blood (Figure 6). The biological half-life was found to be $t_{1/2}$ (F) = 36 ± 0.5 min and $t_{1/2}$ (S) = 5 h 55 min ± 0.85 min.

Biodistribution. Dose escalation studies were performed to determine the concentration of ^{99m}Tc-DTPA-bis(Met) that would saturate U-87MG and BMG tumors. U-87MG tumor grafted nude mice were injected with increasing concentrations in the range 10−4000 nmol/kg, and after allowing 4 h for clearance of unbound conjugates from the tissues, tumor and normal tissue were dissected. U-87MG and BMG tumors were saturated at ∼2000 ± 280 nmol/kg of ^{99m}Tc-DTPA-bis(Met). In contrast, soft tissue (muscles) accumulated negligible quantities of the conjugate. Biodistribution studies in mice conducted to quantify localization of the radiolabeled DTPA conjugate on U-87MG, BMG, and EAT tumors are shown in Table 1. Athymic mice implanted with U-87MG and BMG cell line exhibited accumulation in kidneys (2.21 ± 0.08% ID/g) and 3.24 ± 0.52% ID/g, respectively, at 1 h showing that the complex is excreted by renal routes. Biodistribution revealed high tumor uptake in the U-87MG tumor bearing nude mice; tumor to muscle ratio reached 52.5 at 4 h postinjection. Biodistribution studies in nude mice xenographed with U-87MG and BMG human malignant glioma cell lines have shown that tumor uptake of ^{99m}Tc was found to be 2.14 ± 0.9% ID/ g and 1.08 ± 0.11% ID/ g at 1 h.

Comparative biodistribution was carried out for ^{99m}Tc-labeled methionine and ^{99m}Tc-DTPA-bis(Met) in EAT tumor. It was evident from the study that directly labeled methionine accumulated in liver and a major part of the radiolabeled methionine cleared through the hepatobiliary route (Figure 7). Localization of the radioactivity in the liver, stomach, and small intestine was low, less than 2% ID/g at 1 h for ^{99m}Tc-DTPA-bis(Met). Good clearance of the radiolabeled conjugate was also observed from these organs. EAT tumor uptake at 1 h was 2.8 ± 0.12% ID/g for ^{99m}Tc-DTPA-bis(Met) at 4 h.

^{99m}Tc-DTPA-bis(Met) was administered through the ear vein in U-87MG grafted athymic mice with and without coadministration of a 250 μg blocking dose of methionine, which showed significant blocking of the receptors at the tumor site with uptake of 0.36 ± 0.06% ID/g as compared to 2.14 ± 0.9% ID/ g for ^{99m}Tc-DTPA-bis(Met) at 1 h (Figure 8).

In Vivo Tumor Kinetics and Scintigraphy. In vivo tumor kinetics was studied in U-87MG cells over a time period ranging from 1 to 270 min. Initial rate of transport of ^{99m}Tc-DTPA-bis(Met) was found to be 4.68×10^{-4} μmol/kg/min (Figure 9).

Further, the rate was decreased to 6.77×10^{-5} μmol/kg/min over 30 min and found to saturate at 1.02×10^{-5} μmol/kg/min. However, the initial rate of soft tissue uptake was 3.23×10^{-5} μmol/kg/min. After 30 min, the rate of transport further increases 100-fold as compared to the accumulation in the soft tissue.

Imaging of animals was carried out at different time intervals after administering labeled compound intravenously. The mice depicted the beginning of accumulation of activity in tumor at 30 min, which reached a maximum at 4 h and remained almost stable for 6 h. The tumors (BMG cell line) grafted in athymic mice were readily identifiable in the γ images (Figure 10).

Semiquantitative analysis generated from region of interest (ROI) placed over areas counting average counts per pixel with maximum radiotracer uptake on the tumor was found to be 11.05 ± 3.99 and compared to ROI with muscle (0.55 ± 0.13). The tumor-to-contralateral muscle tissue ratio of ^{99m}Tc-DTPA-bis(Met) was found to be 23 ± 3.3. In the mice that received coadministration of 250 μg blocking dose of

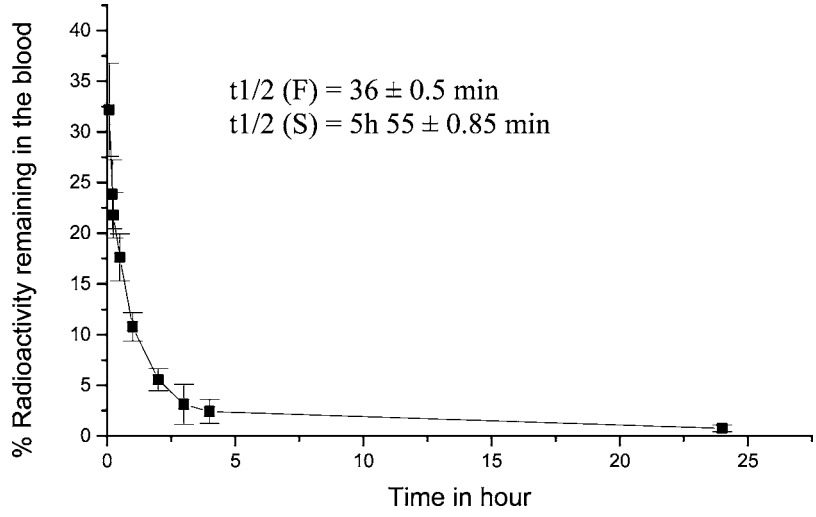

Figure 6. Blood clearance of ^{99m}Tc-DTPA-bis(Met) (11.1 MBq activity) administered through ear vein in normal rabbit.

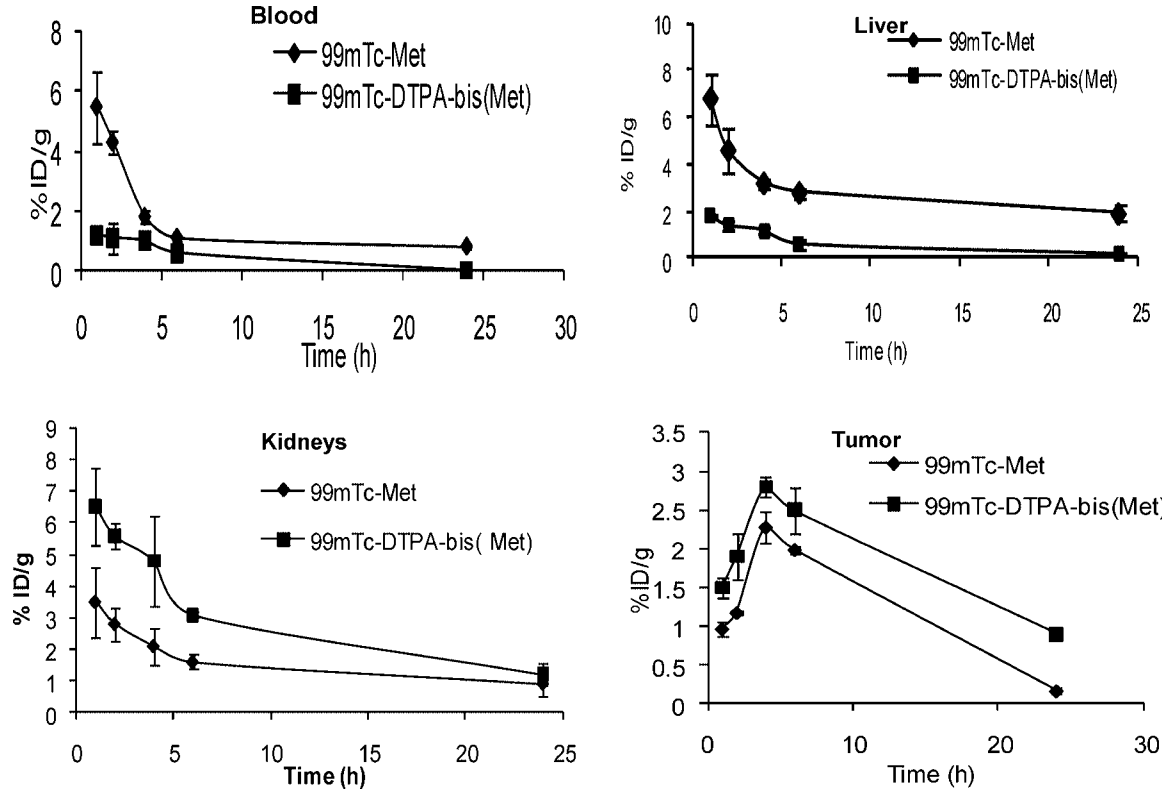

Figure 7. Comparative biodistribution of ^{99m}Tc-Met and ^{99m}Tc-DTPA-bis(Met) (11.1 MBq activity) administered through ear vein in EAT tumor-grafted Balb/c mice.

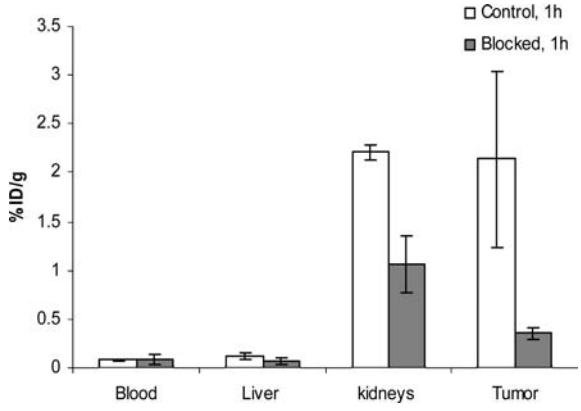

Figure 8. Tumor, blood, liver, and kidney activity of ^{99m}Tc-DTPA-bis(Met) administered through the ear vein in U-87MG grafted athymic mice with and without a coadministration of a blocking dose.

methionine, the uptake in the tumor was 0.46 ± 0.06% ID/g, significantly lower at 1 h postinjection (Figure 9). Comparative evaluation of biodistribution of ^{99m}Tc-labeled methionine and ^{99m}Tc-DTPA-bis(Met) in normal rabbits was also conducted (see Supporting Information). It was found that directly labeled methionine accumulated in the liver, whereas negligible uptake was seen for ^{99m}Tc-DTPA-bis-(Met).

Clinical Studies. Clinical studies in normal volunteers showed fast renal clearance in patients. Two hours after administration of ^{99m}Tc-DTPA-bis(Met), a good percentage of the injected activity was cleared through the kidneys. Insignificant tracer accumulation was observed in the hepatic region. Semiquantitative analysis was generated from region of interest (ROI) placed over areas counting average counts per pixel with maximum radiotracer uptake at the tumor site and compared to symmetric counterparts with ROI in soft tissues (target to nontarget ratios are shown in Table 2).

DISCUSSION

The polyaminopolycarboxylate ligand having two reactive sites (bisanhydride of DTPA) for the conjugation of amino acid favors the formation of complex with only one ligand per metal atom, which is required for in vivo stability and biological activity. The conjugate was labeled with ^{99m}Tc and evaluated in vitro and in vivo for its competence in clinical diagnosis of metabolic tumors. Radiochemical analysis showed that the drug is specifically coordinated with ^{99m}Tc radionuclide. In vitro human serum stability studies under physiological conditions suggested that there was least transcomplexation of the labeled drug.

This targeted agent was tested for the ability to induce cytotoxicity in the cancer cell lines using both an assay of mitochondrial activity (in a MTT assay) and a clonogenic assay. The unlabeled conjugate showed concentration-dependent cytotoxicity. A direct correlation was observed between MTT assay and clonogenic assay. Receptor binding experiments were performed to verify the biological integrity upon modification of methionine. Scatchard analysis confirmed good binding affinity to its target, as K_d values on malignant cancer cell lines were found to be in sub-picomolar range.

The expression and function of L-type amino acid transporter 1 (LAT1), a major catalytic subunit of system L, in human glioma cells have been reported in the literature (*33*). Several of the amino acid transport systems can be distinguished by their dependence on Na^+, response to other competitive AA, and response to specific nonmetabolizable AA analogues. System A, for example, is inhibited by α-(methylamino)isobutyric acid (MeAIB), whereas system L is inhibited by BCH. A combination of treatments was applied to incubated skin strips to define the AA transport systems operating for L-Ala, L-Leu,

Table 2. Semiquantative ROI Analysis Showing Lesion Target to Nontarget Ratios (T/NT) in Patients Expressed as Mean ± S.D.

no. of patients	patients	ROI (T/NT)	results
47	palpable breast masses, median age 44 (range 28−68 years), 33 breast carcinoma, 14 benign masses	3.7 ± 0.29 (range 2.73−6.06)	true positive DTPA-bis(Met) uptake in 29/33 patients, negative in 4 patients. 13 benign masses came out to be negative and 1 positive. Sensitivity = 87.8%; Specificity = 92.8%
3	brain cancer, median age 65 (range 45−82) 2 brain malignancy, 1 suspected recurrence	4.72 ± 0.48 (range 4.38−5.06)	positive in brain malignancies, recurrence not observed for 1 patient in both DTPA-bis(Met) and FDG scan
2	regional lymph node cancer	3.47 ± 2.05 (range 2.01−4.92)	DTPA-bis(Met) scan positive in all cases
3	osteosarcoma	5.31 ± 0.93 (range 4.64−6.38)	DTPA-bis(Met) scan positive in all cases

L-Cys, and L-Lys. The L system for which there is strong evidence of its involvement in the uptake process of ^{99m}Tc-DTPA-bis(Met) is the Na^+-insensitive system L, which shows high specificity for branched-chain and aromatic amino acids and utilizes the nonmetabolizable bicyclic BCH analogue as a system-specific substrate. Thus, since BCH was found to block the transport of ^{99m}Tc-DTPA-bis(Met) in competitive binding studies, it is reasonable to conclude that this pathway does contribute to the uptake of ^{99m}Tc-DTPA-bis(Met) to a significant extent. Moreover, the system L substrates such as L-leucine and L-phenylalanine caused marked inhibition of ^{99m}Tc-DTPA-bis(Met) transport. The inhibition was found to be independent of the presence of Na^+, which is a characteristic of the L transporter. Thus, the marked inhibition caused by L-leucine and BCH strongly supports the idea that system L is being utilized by ^{99m}Tc-DTPA-bis(Met) for entry into cells. Moreover, ^{99m}Tc-DTPA-bis(Met) demonstrated trans-stimulation of ^{35}S-L-methionine indicated for an exchange mechanism of transport. The data provide direct evidence for transport against a concentration gradient and not just via passive diffusion only.

The pharmacokinetic profile of ^{99m}Tc-DTPA-bis(Met) showed its high target uptake with the diagnostically useful target-to-nontarget ratio over a short period of time. The labeled drug

showed fast clearance that resulted in a decrease in the background activity.

The high specificity of results in selective uptake and distribution of the radiolabeled receptor ligand at the tissues, which are known to contain a substantial concentration of the target receptor that can be visualized in the high-quality images, obtained 1 h after administration of ^{99m}Tc-DTPA-bis(Met) in animal models with and without coadministration of blocking dose, which allows the advantage of comparing in vitro receptor binding studies and tumor-bearing animal studies. Dynamic study as a function of time revealed the rate of transport of ^{99m}Tc-DTPA-bis(Met) at the tumor site and soft tissue. The biodistribution studies showed that ^{99m}Tc-labeled methionine persisted in the liver up to 4 h, which indicates its hepatobiliary clearance, and the radiolabeled DTPA-conjugate cleared through renal routes.

Accurate interpretation of SPECT scans in suspected tumors relies on comparison of the amount of methionine taken up by the lesion with the normal value for that region of soft tissue. A normal value is typically determined by measuring uptake in the corresponding region of the contralateral tissue.^{99m}Tc-DTPA-bis(Met) accumulated in nearly all cancers with varying histology and histological grades. ^{99m}Tc-DTPA-bis(Met) imaging with SPECT is an effective method for evaluating head and neck cancer and, apparently, other types of human cancer. Furthermore, SPECT images of the tumors appeared to correlate well with the extent of cancers determined by other methods. It can provide useful information with reasonably high sensitivity and specificity in prognostic value for determining tumor masses. Normal tissues such as the salivary glands, however, accumulate ^{99m}Tc-DTPA-bis(Met), which may impair the detection of small tumors with a low uptake.

In summary, we have synthesized a new imaging agent ^{99m}Tc-DTPA-bis(Met) showing substantial promise for tumor scintigraphy, as significant accumulation is observed in athymic mice bearing the subcutaneous BMG cell line (malignant glioma). Breast, head, and neck cancers of varying histology can be imaged with ^{99m}Tc-DTPA-bis(Met). Although accumulation of the tracer in the salivary and lachrymal glands may occasionally interfere with image interpretation, ^{99m}Tc-DTPA-bis(Met) SPECT is a cost-effective method for imaging breast, head, and neck cancer. It can detect malignancy with reasonably high sensitivity and specificity. It may also be useful in the assessment of tumor extent when management of cancer is planned. This system has an added advantage over ^{11}C-methionine, as there are logistical hindrances in its use at centers that do not have an on-site cyclotron. Therefore, considering the apparent usefulness of new SPECT radiopharmaceutical ^{99m}Tc DTPA-bis(Met), future clinical study is warranted with attractive radionuclides and metal ions used in diagnosis and therapy.

ACKNOWLEDGMENT

We thank Dr. R. P. Tripathi, Director INMAS, for providing necessary facilities. The work was supported by Defence Research and Development Organization, Ministry of Defence, under R&D project INM −311.

Received June 15, 2009; Revised Manuscript Received December 6, 2009

A novel, biocompatible, and nontoxic dermal filler using hyaluronic acid (HA) hydrogels was successfully developed for tissue augmentation applications. Instead of using highly reactive cross-linkers such as divinyl sulfone (DVS) for Hylaform, 1,4-butanediol diglycidyl ether (BDDE) for Restylane, and 1,2,7,8-diepoxyoctane (DEO) for Puragen, HA hydrogels were prepared by direct amide bond formation between the carboxyl groups of HA and hexamethylenediamine (HMDA) with an optimized carboxyl group modification for effective tissue augmentation. The HA-HMDA hydrogels could be prepared within 5 min by the addition of HMDA to HA solution activated with 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC) and 1-hydroxybenzotriazole monohydrate (HOBt). Five kinds of samples, a normal control, a negative control, a positive control of Restylane, adipic acid dihydrazide grafted HA (HA-ADH) hydrogels, and HA-HMDA hydrogels, were subcutaneously injected to wrinkled model mice. According to the image analysis on dorsal skin augmentation, the HA-HMDA hydrogels exhibited the best tissue augmentation effect being stable longer than 3 months. Furthermore, histological analyses after hematoxylin-eosin (H&E) and Masson's trichrome staining revealed the excellent biocompatibility and safety of HA-HMDA hydrogels. The dermal thickness and the dermal collagen density in wrinkled mice after treatment with HA-HMDA hydrogels for 12 weeks were comparable to those of normal mice. Compared with HA-DVS hydrogels and Restylane, the excellent tissue augmentation by HA-HMDA hydrogels might be ascribed to the biocompatible residues of amine groups in the cross-linker of HMDA. The HA-HMDA hydrogels will be investigated further as a novel dermal filler for clinical applications.

INTRODUCTION

Recently, tissue augmentation has been studied extensively for cosmetic applications such as antiaging treatment and plastic surgery (*1, 2*). Various dermal fillers were developed for long-lasting soft tissue augmentation with reduced allergic reaction in clinical applications. Bovine collagen, which is an FDA approved dermal filler, has been used for longer than 20 years (*3, 4*). However, the bovine collagen has been reported to cause an allergic reaction by nonhuman origin materials such as scarring, urticaria, redness, and so forth (*5*). Accordingly, human-origin collagen was developed to reduce the side effects with a duration of less than 6 months in the body. In order to reduce side effects and prolong the tissue augmentation effect, hyaluronic acid (HA) hydrogels were developed as a novel dermal filler (*6*). Hylaform was synthesized with divinyl sulfone (DVS), Restylane and Juvederm with 1,4-butanediol diglycidyl ether (BDDE) (*6*), and Puragen with 1,2,7,8-diepoxyoctane (DEO). The softness and tissue augmentation effect of dermal fillers were controlled by changing the cross-linking density with various cross-linkers. The tissue augmentation by Restylane, which is widely used all over the world, lasts for 6 months with significantly reduced side effects. All dermal fillers were prepared by the cross-linking of hydroxyl groups of HA with various cross-linkers. However, we have previously reported a protocol to control the molecular degradation of HA hydrogels for tissue augmentation by the cross-linking of carboxyl groups of HA with bis(sulfosuccinimidyl)suberate (BS^3) (*7*). Adipic acid dihydrazide modified HA (HA-ADH) hydrogels with ADH content higher than 70 mol % degraded slowly, being stable longer than 6 months, whereas HA-DVS hydrogels degraded almost completely within 6 months after subcutaneous injections to ICR mice (*7, 8*).

HA is a biodegradable, biocompatible, nonimmunogenic, and natural linear polysaccharide. HA is the only nonsulfated glycosaminoglycan (GAG) that is abundant in synovial fluid and extracellular matrix (ECM) (*9*). The molecular weight (MW) of HA ranges from several thousands to more than millions. High MW HA in the tissues degrades by HA receptor mediated degradation in the lymph node, liver, and kidney (*10*). In particular, when HA degrades to specific sizes of 3−10 repeating units, the resulting oligomeric HA promotes differentiation, vascularization, and migration of stem cells (*11, 12*). Due to the excellent biological and physicochemical properties, HA and chemically modified HA have been widely used for various medical applications such as arthritis treatment, ocular surgery, drug delivery, and tissue engineering (*13–17*). However, HA is known to have a very short half-life of several hours in the body, which should be overcome for tissue augmentation applications. The residence time of HA can be prolonged by the chemical modification of carboxyl groups of HA (*7, 18*) on the basis of the fact that carboxyl groups are the recognition site of hyaluronidase (*11*) and HA receptors (*19–22*).

In this work, we developed a novel, biocompatible, and nontoxic dermal filler using HA hydrogels for tissue augmentation applications. Instead of using highly reactive cross-linkers such as DVS, BDDE, and DEO, HA hydrogels were prepared by direct amide bond formation between the carboxyl groups of HA and hexamethylenediamine (HMDA) with an optimized carboxyl group modification for effective tissue augmentation. HMDA used as a cross-linker for the preparation of collagen hydrogels was reported to be nontoxic and promote the attachment and proliferation of keratinocytes and fibroblasts (*23*). Wrinkled model mice were prepared for tissue augmentation tests by daily treatment of the dorsal skins with 0.2 μg of 1α-25-dihydroxyvitamin D_3 in ethanol for 4 weeks (*24*). Five different samples of a normal control, a negative control, a positive control of Restylane, HA-ADH hydrogels, and HA-HMDA hydrogels were injected into the dorsal subcutaneous tissues of wrinkled model mice. The tissue augmentation effect was assessed using a surface image analyzer with histological analyses after hematoxylin−eosin (H&E) and Masson's trichrome staining. The novel HA-HMDA hydrogels were discussed for further clinical applications.

MATERIALS AND METHODS

Materials. Sodium hyaluronate, sodium salt of hyaluronic acid (HA), with a molecular weight (MW) of 234 kDa was purchased from Lifecore Co. (Chaska, MN) and HA with a MW of 1.0 MDa was kindly provided by Shinpoong Pharmaceutical Co. (Ansan, Korea). Bis(sulfosuccinimidyl) suberate (BS^3) was purchased from Pierce Chemical Co. (Rockford, IL). 1-Ethyl-3-[3-(dimethyl amino)propyl]carbodiimide (EDC), phosphate buffered saline (PBS) tablet, hexamethylenediamine (HMDA), potassium cyanide, hematoxylin−eosin (H&E), Masson's trichrome, and hyaluronidase from *Streptomyces hyalurolyticus* were purchased from Sigma-Aldrich (St. Louis, MO). Adipic acid dihydrazide (ADH) and divinyl sulfone (DVS) were purchased from Tokyo Chemical Industry Co. (Tokyo, Japan) and 3-(4-carboxybenzoyl)quinoline-2-carboxaldehyde (CBQCA) from Invitrogen Co. (Carlsbad, CA). Hydrochloric acid (HCl), sodium hydroxide (NaOH), methanol, and 1-hydroxybenzotriazole monohydrate (HOBt) were obtained from Wako Pure Chemical Industries (Osaka, Japan). Restylane was purchased from Q-Med AB (Uppsala, Sweden). All reagents were used without further purification.

Synthesis of HA-ADH Hydrogels. HA-ADH (MW = 234 kDa) with ca. 70 mol % ADH content was prepared as described elsewhere (*7*, *8*). Then, HA-ADH was dissolved in PBS (0.01 M, pH 7.4) for 2 h. As a specific cross-linker to hydrazide, BS^3 was also dissolved in PBS, which was added to the HA-ADH solution. The amount of BS^3 was 20 mol % of hydrazide groups in HA-ADH. The final precursor solution was mixed and incubated at 37 °C for 1 h to complete the cross-linking reaction for HA-ADH hydrogel preparation.

Synthesis of HA-DVS Hydrogels. HA (MW = 234 kDa) was dissolved at a concentration of 4.0 wt % in 0.2 N NaOH (pH = 13). After complete dissolution, DVS was added to the HA solution for the cross-linking reaction with hydroxyl groups of HA (*7*, *8*). The molar ratio of DVS to HA repeating units was 1:1. The final precursor solution was mixed and incubated at 37 °C for 1 h to complete the cross-linking reaction for HA-DVS hydrogel preparation. Then, the hydrogels were sealed within a prewashed dialysis membrane tube (MWCO of 7 kDa) and dialyzed against PBS for 24 h. The ions (Na^+ and OH^-) diffused out though the dialysis membrane neutralizing the pH inside the HA-DVS hydrogels.

Synthesis of HA-HMDA Hydrogels. HA (MW = 234 kDa) was dissolved at a concentration of 4.0 wt % in double distilled water. After complete dissolution, HMDA was added to the HA solution for cross-linking reaction with carboxyl groups of HA. The molar ratio of HMDA to the carboxyl group of HA was 1:1. EDC and HOBt, activating the carboxyl groups of HA, were dissolved in water and added to the mixed solution of HA and HMDA for HA-HMDA hydrogel preparation. The final precursor solution was incubated at 37 °C for 1 h to complete the cross-linking reaction. Then, prepared HA-HMDA hydrogels were sealed within prewashed dialysis membrane tube (MWCO of 7 kDa) and dialyzed against PBS for 3 days to remove the remaining EDC, HOBt, and HMDA completely. HPLC analysis of HA-HMDA hydrogels degraded by the treatment with hyaluronidase (100 U/mL) was carried out to confirm that there was no remaining reactant within the HA-HMDA hydrogels. In order for in vivo tissue augmentation tests, HA-HMDA hydrogels were prepared by the cross-linking of HA (MW = 1.0 MDa) solution at a concentration of 1.0 wt % with 25 mol % HMDA of HA repeating units.

Characterization of HA Hydrogels. After preparation of three kinds of HA hydrogels, the resulting characteristics of HA hydrogels were investigated by ^{1}H NMR analysis of degraded HA hydrogels after treatment with hyaluronidase (100 U/mL). The residual contents of BS^3, DVS, and HMDA were quantified in comparison with the methyl resonance (δ = 1.85−1.95 ppm) of acetamido moiety of the *N*-acetyl-D-glucosamine. In addition, the amine content of pendant HMDA in HA-HMDA hydrogels was quantified by CBQCA analysis (*25*, *26*).

In Vitro Degradation Tests of HA Hydrogels. Each HA hydrogel for in vitro degradation tests was prepared in a syringe as described in our previous work (*7*, *8*). Three kinds of HA hydrogel samples, HA-ADH hydrogels, HA-DVS hydrogels, and HA-HMDA hydrogels, were put into vials, respectively. PBS (0.2 M, pH 6.2) containing 50 U of hyaluronate lyase was added to each vial, which was incubated at 37 °C for predetermined time intervals (0−48 h). After that, the supernatant was completely removed and the remaining weight of HA hydrogels was measured with a balance. The degree of HA hydrogel degradation was represented by a weight ratio (%) of the remaining HA hydrogel to the original HA hydrogel.

In Vivo Tissue Augmentation Tests of HA Hydrogels. Wrinkled model mice were prepared by daily treatment of dorsal skins of female ICR hairless mice at an age of 6 weeks with 0.2 μg of 1α-25-dihydroxyvitamin D_3 in ethanol for 4 weeks as described elsewhere (*24*). In order to measure the wrinkled surface area, a square (1.5 × 1.5 cm^2) was tattooed on the dorsal skin of ICR mouse (n = 5 for each sample). Two HA hydrogels of HA-ADH hydrogels and HA-HMDA hydrogels were mixed with equal volume of PBS and completely micronized with a homogenizer (T-18 basic, IKA, Tokyo, Japan) at 8000 rpm for 5 min, respectively. Each 400 μL of the prepared HA microhydrogels was injected to fill evenly the wrinkled area within the dorsal tattooed rectangle. For comparison, three kinds of control groups were also tested, normal mice as a normal control, wrinkled mice without tissue augmentation as a negative control, and those treated with Restylane as a positive control. Tissue augmentation was assessed by measuring the area of square on the dorsal skin with an image analyzer once a week for 11 weeks. The mice were sacrificed in 12 weeks for histological analyses (n = 3 for each sample). The dissected tissue around the tattooed square was fixed in 10% (v/v) buffered formaldehyde, dehydrated with a graded ethanol series, and embedded in paraffin. The specimen was sliced into 4-μm-thickness sections and stained with hematoxylin and eosin (H&E) to investigate the inflammation and soft tissue regeneration. The sliced specimens were also stained with Masson's trichrome to investigate a collagen density in the dermis. More than 50 random sites of Masson's trichrome-positive area in blue color in the dermis were analyzed for quantification with *Adobe*

RESULTS AND DISCUSSION

Preparation, Characterization, and in Vitro Degradation Tests of HA Hydrogels. Many kinds of dermal fillers using HA hydrogels were commercialized under the trade names of Hylaform, Restylane, Juvederm, Puragen, and so on. All dermal fillers were prepared by the cross-linking of hydroxyl groups of HA with various cross-linkers such as DVS, BDDE, and DEO. We have previously reported the sustained degradation of HA-ADH hydrogels with carboxyl group modifications in comparison with HA-DVS hydrogels cross-linked by Michael addition between DVS and hydroxyl groups of HA. HA-ADH hydrogels with ADH content higher than 70 mol % appeared to be stable longer than 6 months, whereas HA-DVS hydrogels degraded almost completely within 6 months after subcutaneous injections to ICR mice (*7*). The results could be explained by the fact that the carboxyl group of HA is known to be the recognition site of hyaluronidase and HA receptors (*19–22*).

However, with increasing chemical modification of carboxyl groups, HA-ADH hydrogel became brittle and its swelling ratio decreased drastically. HA is hygroscopic due to carboxyl groups on the backbone. The swelling property is influenced by negative charge repulsion of HA-COOH, which may have a significant effect on tissue augmentation (*9, 27*). In addition, considering that all functional groups in the reactive cross-linkers (Figure 1a) are not reacted for the preparation of HA hydrogels, we tried to synthesize HA hydrogels with a relatively nonreactive HMDA after direct activation of HA-COOH with EDC and HOBt. Figure 1b shows a schematic representation for the preparation of HA-HMDA hydrogels with sustained degradation and good swelling characteristics in the body. HA hydrogels were prepared by the amide bond formation between carboxyl groups of HA and HMDA with an optimized amount of intact carboxyl groups for effective tissue augmentation. After exhaustive dialysis, the HPLC analysis of HA-HMDA hydrogels degraded by the treatment with hyaluronidase confirmed that there was no remaining EDC, HOBt, and HMDA within the HA-HMDA hydrogels. According to ^{1}H NMR analysis of degraded HA hydrogels, the amount of cross-linkers within the HA-HMDA hydrogels was ca. 8 mol % of HA repeating units. In addition, CBQCA analysis revealed that the pendant amine content in HA-HMDA hydrogels was ca. 3.7 mol % of HA repeating units, reflecting the incomplete reaction of both amine groups in HMDA.

In vitro degradation tests of HA hydrogels were carried out to investigate their degradation and swelling characteristics by measuring the remaining weight of HA hydrogels after treatment with hyaluronidase. As shown in Figure 2, HA-DVS hydrogels degraded completely in 26 h, whereas HA-ADH hydrogels

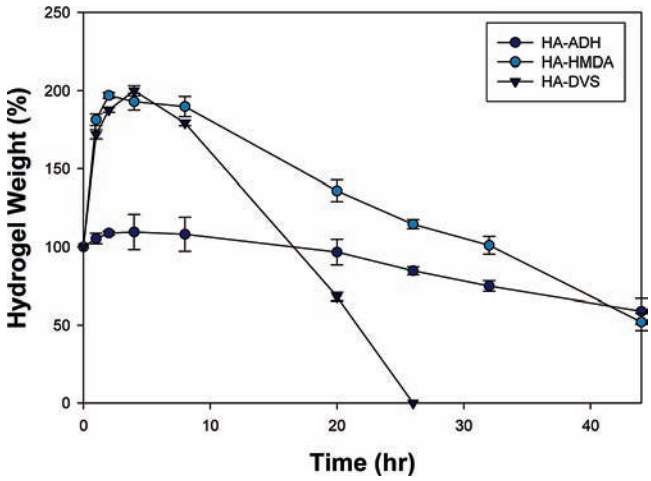

Figure 2. In vitro degradation of adipic acid dihydrazide modified hyaluronic acid (HA-ADH, black ●) hydrogels, HA hydrogels cross-linked with hexamethylenediamine (HA-HMDA, blue ●) after activation with 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide and 1-hydroxybenzotriazole monohydrate (HOBt), and HA hydrogels cross-linked with divinyl sulfone (HA-DVS, ▼) by the treatment with hyaluronidase from *Streptomyces hyalurolyticus*.

degraded only partially in 44 h. Interestingly, the degradation rate of HA-HMDA hydrogels was in the middle with comparable swelling characteristics to HA-DVS hydrogels. The swelling ratio of HA-HMDA hydrogels and HA-DVS hydrogels was twice that of HA-ADH hydrogels. The more rapid degradation of HA-HMDA hydrogels with 8 mol % HMDA of HA repeating units than HA-ADH hydrogels with 70 mol % ADH and ca. 10 mol % BS[3] might be ascribed to the lower degree of carboxyl group modification. From the results, we supposed that the novel HA-HMDA hydrogels would be successfully applied for tissue augmentation.

In Vivo Tissue Augmentation Tests of HA Hydrogels. The newly developed HA-HMDA hydrogels were assessed in wrinkled model mice for tissue augmentation applications in comparison with Restylane. HA-HMDA hydrogels were synthesized and completely micronized with a homogenizer for the preparation of injectable microhydrogels. ^{1}H NMR analysis of Restylane after treatment with hyaluronidase revealed that the amount of cross-linkers within the hydrogel network was ca. 3−5 mol %. Wrinkled model mice were prepared by daily treatment of the dorsal skins with 0.2 μg of 1α-25-dihydroxyvitamin D_3 in ethanol for 4 weeks as described elsewhere (*24*). Five different samples of a normal control, a negative control, a positive control of Restylane, HA-ADH hydrogels, and HA-HMDA hydrogels were subcutaneously injected to eight tattooed sites on the back of wrinkled model mice. Due to the soft and viscoelastic properties, HA-HMDA microhydrogels could be injected through 30-gauge needle, whereas HA-ADH hydrogels were done through 24-gauge needle. The HA-ADH hydrogels with highly modified carboxyl groups appeared to be brittle and were not easily distributed evenly in the wrinkled tissue.

Figure 3 shows the tissue augmentation effect of HA hydrogels in 7 weeks. The wrinkled dorsal skin in the negative control group remained without tissue augmentation. As shown in Figure 3c, HA-ADH hydrogels appeared to have a tendency to conglomerate in the wrinkled tissue with increasing postin-

Figure 3. Figure 4. Effect of hyaluronic acid (HA) hydrogels on tissue augmentation determined by measuring the dorsal tattooed surface area in ICR hairless mouse once per a week for 11 weeks: (○) normal mice without treatment as a normal control, (●) wrinkled mice without tissue augmentation as a negative control, those treated with (▼) Restylane as a positive control, and (■) HA hydrogels cross-linked with hexamethylenediamine (HMDA) after activation with 1-ethyl-3-[3-(dimethylamino)propyl] carbodiimide and 1-hydroxybenzotriazole monohydrate (HOBt). Statistical analyses using *t*-test clearly revealed the difference in tissue augmentation effect between Restylane and HA-HMDA hydrogels (* $P < 0.05$).

jection time. We could recover the conglomerated HA hydrogels from the subcutaneous of wrinkled mice. Accordingly, HA-ADH hydrogels prepared with a reactive cross-linker of BS^3 were not considered for further development. However, HA-HMDA hydrogels resulted in comparable tissue augmentation to Restylane on the photoimages in 7 weeks (Figure 3b,d). The results might be ascribed to the good swelling characteristics of HA-HMDA hydrogels as well as sustained degradation. There was no outward inflammation or adverse effects during in vivo tests. Figure 4 shows the change of tattooed surface area on the back of an ICR mouse after injection of various dermal filler samples. The tattooed surface areas of the normal control group and the negative control group without tissue augmentation were not changed significantly until the end of in vivo tests (Figure 4). The tissue augmentation effect of HA-HMDA hydrogels was maintained continuously up to 11 weeks, which was statistically better than that of Restylane ($P < 0.05$ in Figure 4). The results were thought to reflect the higher stability of HA-HMDA hydrogels with carboxyl group modifications than Restylane with hydroxyl group modifications in the subcutaneous tissue of ICR mouse.

Histological Analysis after Tissue Augmentation Tests. Histological analysis was carried out with H&E staining at 12 weeks after treatments with HA hydrogels. The daily treatment of dorsal skins of mice with 0.2 μg of 1α-25-dihydroxyvitamin D_3 in ethanol caused the induction of wrinkling in the mice. In comparison to normal mice (Figure 5a), epidermis was flattened and dermis became coarse, reflecting the skin damage in wrinkled mice (Figure 5b). Treatments with Restylane and HA-HMDA hydrogels (Figure 5c,d) caused significant changes in the epidermis, dermis, and hypodermis of wrinkle-induced mice. The epidermis was meandered and became similar to that of normal mice. Moreover, the subcutaneous injection of Restylane and HA-HMDA hydrogels (Figure 5c,d) induced significant dermis regeneration compared to the negative control (Figure 5b). In particular, the thickness of regenerated dermis by HA-HMDA hydrogel was comparable to that of normal mouse (Figure 5a,d). Compared to other groups, the most distinguished advantage of HA-HMDA hydrogels was found in the regenerated hypodermis. The treatment with HA-HMDA hydrogels (Figure 5d) resulted in a mild infiltration with comparable numbers of macrophages and lymphocytes to those of normal mice (Figure 5a), whereas infiltration numbers significantly increased in other groups (Figure 5b,c). Figure 5e−g shows the representative images of macrophage and lymphocyte infiltration in the negative control, positive control of Resylane, and HA-HMDA hydrogels. The relatively high biocompatibility of HA-HMDA hydrogels might be ascribed to the nontoxic amine residues in contrast to the possible toxic remaining groups of BDDE in Restylane and DVS in HA-DVS hydrogels (Hylaform). The amine pendant groups within HA-HMDA hydrogels might be advantageous for cellular attachment and proliferation (*23*). Figure 6 shows a quantification of the thickness of regenerated dermis after treatment with various HA hydrogel samples. The regeneration of dermis by HA-HMDA hydrogel was the most effective contributing to tissue augmentation. According to a statistical analysis using *t*-test, the thickness of regenerated dermis by HA-HMDA hydrogel was significantly thicker than those of the positive control (* $P < 0.05$) and the negative control (** $P < 0.01$), but not so much different from that of the normal control (*** $P = 0.41$).

Histological sections of skin samples were also subjected to Masson's trichrome staining to visualize the extracellular matrix (ECM) components, especially the collagen in dermis. The collagenous component of dermal extracellular matrix is responsible for the strength and resiliency of skin (*28*). The blue color region in dermis corresponds to the collagen layer (Figure 7). Compared to the negative control, a remarkable increase of collagen bundles was observed after treatment with Restylane and HA-HMDA hydrogels. In particular, the regenerated collagen density by HA-HMDA hydrogel was comparable to that of normal mice (Figure 7d). The induction of wrinkling in the dorsal skin resulted in significantly reduced collagen density (Figure 7b), which might be ascribed to the reduced collagen biosynthesis by 1α-25-dihydroxyvitamin D_3 treatment and the following damage in the dermis. Figure 8 shows a quantification of the collagen density of regenerated dermis after treatment with various HA hydrogel samples. HA-HMDA hydrogel showed the most effective regeneration of collagen bundles. According to a statistical analysis using *t*-test, the regenerated collagen density by HA-HMDA hydrogel was significantly higher than those of the positive control (* $P < 0.05$) and the negative control (** $P < 0.01$), but not much different from that of the normal control (*** $P = 0.27$). Considering all these results, HA-HMDA hydrogels were thought to be a novel dermal filler with excellent biocompatibility as well as statistically significant tissue augmentation.

CONCLUSIONS

HA-HMDA hydrogels were successfully developed as a novel dermal filler with excellent biocompatibility and tissue augmentation effect. Instead of using reactive cross-linkers such as DVS, BDDE, and DEO, HA-HMDA hydrogels were prepared by direct amide bond formation between HMDA and the carboxyl groups of HA activated with EDC and HOBt. According to in vitro degradation tests with hyaluronidase, the degradation rate of HA-HMDA hydrogels with an optimized carboxyl group modification for effective tissue augmentation could be controlled between those of HA-ADH hydrogels and HA-DVS hydrogels. The image analysis on dorsal skin augmentation in wrinkled model mice showed that HA-HMDA hydrogels resulted in the best tissue augmentation being stable longer than 3 months. Furthermore, histological analyses with H&E and Masson's trichrome staining revealed the excellent biocompatibility of HA-HMDA hydrogels possibly due to the nontoxic residues of amine groups in the cross-linker of HMDA. The thickness of regenerated dermis and the regenerated

Versatile route for "click chemistry" compatible heterobifunctional PEGs was established through preparation of α-tetrahydropyranyloxy-ω-hydroxyl poly(ethylene glycol) (THP-PEG-OH) via ring-opening polymerization of ethylene oxide using 2-(tetrahydro-2*H*-pyran-2-yloxy)ethanol as an initiator, followed by the functionalization of ω-OH group to either the azido or alkyne group. Quantitative azidation of THP-PEG-OH was confirmed from the analysis of molecular functionality of the derivatives. While the conversion efficiency of ω-alkynation was appropriately 70%, the unreacted THP-PEG-OH fraction was successfully removed by ion-exchange chromatography after the carboxylation of the hydroxyl group with succinic anhydride. Then, the protecting group of the α-end, THP, was removed in mild acidic media, followed by two- or three-step modification of the resulting α-hydroxyl group to primary amino or thiol groups. Consequently, "click chemistry" compatible heterobifunctional PEG derivatives (X-PEG-Y; X = NH_2 and SH, Y =Azide and Alkyne) were synthesized with high efficiency and controlled molecular weight.

INTRODUCTION

Conjugation and immobilization of biomolecules (e.g., proteins, peptides, and carbohydrates) with functional small molecules and synthetic polymers have widely been used as a useful research tool in chemical, biological, and pharmaceutical fields. The former group mainly consists of fluorescence reagents such as organic dyes, which were exploited for target detection and quantification (*1, 2*). The latter has been aimed at alteration or improvement of the physicochemical properties of biomacromolecules. The most successful strategy employs poly(ethylene glycol) (PEG) as the conjugating polymer, termed "PEGylation" (*3*−*5*). In general, PEGylation improves water solubility, reduces toxicity, and increases the tolerance against enzymatic degradation and the in vivo half-lives of bioactive macromolecules (*3*−*6*). Indeed, several PEGylated therapeutic proteins have clinically been investigated (*7, 8*).

The Cu(I)-catalyzed 1,3-dipolar cycloaddition of azides and terminal alkynes to form a triazole ring, "click chemistry" coined by Sharpless, has recently received considerable attention (*9*−*11*) and been utilized as a versatile ligation reaction in the field of bioconjugation including PEGylation (*12, 13*). This "click" reaction is highly chemoselective and can be performed under mild conditions in aqueous buffers with a wide range of pH, indicating high applicability for site-specific conjugation. Therefore, the PEGylation technique integrated with "click chemistry" is a promising approach for site-specific modification of bioactive macromolecules (*14, 15*). Indeed, there are several reports including the "click"-based PEGylation procedure for the preparation of well-defined polymers and functional nanostructures, demonstrating the efficient reaction with high conversion in aqueous condition as well as in organic solvents (*16*−*18*). Additionally, to construct PEGylated biopharmaceutics with multifunctionality, development of α,ω-heterobifunctional PEGs with both well-controlled molecular weight and high derivatizability is inevitable. Although preparation of heterobifunctional PEG having an azido or alkyne group at one end may be feasible using of homobifunctional PEGs as the starting materials, the synthetic methods contain some drawbacks such as repeated column purification in each reaction step and, consequently, low yield. Thus, exploiting of versatile synthetic design of α,ω-heterobifunctional PEGs with high productivity and compatibility to "click"-based conjugation is essential.

In a previous paper, we reported the preparation of azido-terminated heterobifunctional PEGs using a radical addition of thiol compounds to the allyl terminus of PEG derivative (*19*). This radical addition method, however, is inadaptable to the utilization of the alkyne moiety. Herein, we wish to communicate the facile synthetic route applicable to heterobifunctional PEGs possessing azido or alkyne function at one chain end with controlled molecular weight via the ring-opening polymerization of ethylene oxide. Monoprotected ethylene glycol derivative, which was obtained by tetrahydropyranylation of one hydroxyl group, was prepared and applied to an initiator of polymerization as the first step. The tetrahydropyranyl (THP) group is one of the useful protecting species of hydroxyl group, and shows both easy installation and general stability under nonacidic condition (*20*). Moreover, after the acid-catalyzed hydrolysis of THP, the deprotected hydroxyl group can then be devoted to further derivatization (Scheme 1).

Scheme 1. Synthetic Route to Heterobifunctional PEG Derivatives Possessing Azido and Alkyne Functional Groups

EXPERIMENTAL PROCEDURES

Materials. 2-(Tetrahydro-2*H*-pyran-2-yloxy)ethanol (Fluka, US) and ethylene oxide (EO; Sumitomo Seika Chemical, Japan) were dried over calcium hydride and distilled under an argon atmosphere. Potassium naphthalene was prepared as a tetrahydrofuran (THF) solution according to a previous paper (*21*), whose concentration was determined by titration. *N*,*N*-Dimethylformamide (DMF), THF, triethylamine (TEA), and methanesulfonyl chloride (Ms-Cl) were purchased from Wako Pure Chemical Industries, Ltd., (Osaka, Japan) and purified by conventional methods. Ammonia solution (ca. 25% (NH_3)), propargyl bromide in toluene solution (80 wt %), sodium azide, potassium ethyl xanthogenate, and other reagents were used as received.

Synthesis of THP-PEG-OH (1). General procedure: monoprotected ethylene glycol, 2-(tetrahydro-2*H*-pyran-2-yloxy)ethanol (1.43 mmol, 195 μL), and potassium naphthalene (1.23 mmol) in 4.1 mL of THF were added to dry THF (90 mL) in a 200 mL flask equipped with a three-way stopcock under argon atmosphere to form potassium alcoholate as an initiator. After stirring for 10−15 min, liquid EO (381 mmol, 16.8 g) was added to the solution via a cooled syringe. The mixture was allowed to react for 48 h at 25 °C and followed by a pouring into diethyl ether to precipitate the polymer. The recovered polymeric sample was dried in vacuo and then freeze−dried from benzene. The yield of obtained polymer was 97% (16.2 g). GPC: number-average molecular weight (M_n) = 11 500, M_w/M_n = 1.03. ^{1}H NMR (500 MHz, $CDCl_3$, δ in ppm): 1.46−1.83 (m, CH-(C$\underline{H}_2$)$_3$-CH_2 of THP), 3.85 (t, CH-$(CH_2)_3$-C$\underline{H}_2$-O of THP), 4.59 (t, O−C$\underline{H}$-O of THP).

Synthesis of THP-PEG-Azide (2). The azide end group was introduced by the mesylation of the hydroxyl terminus and subsequent substitution with sodium azide, according to the previous method (*19*).

Freeze−dried polymer **1** (THP-PEG-OH) (1.13 g, 0.20 mmol) from benzene (30 mL) was dissolved in anhydrous THF (15 mL) followed by the addition of TEA (102 mg, 1.01 mmol). The mixture was then added to a solution of Ms-Cl (102 mg, 0.89 mmol) in THF (3 mL) under Ar stream, and stirred overnight at room temperature. After the reaction, the polymer was recovered by precipitation into ether and dried in vacuo, yielding a white solid.

This mesylated polymer (1.00 g, 0.15 mmol) was dissolved in DMF (12 mL), followed by sodium azide (400 mg, 6.15 mmol) addition, and was stirred at 45 °C for 3 days. After the reaction, DMF was partially evaporated and diluted with water (40 mL), then extracted by dichloromethane (6 × 120 mL). The combined organic layer was dried over $MgSO_4$, filtered, concentrated, and then reprecipitated into ether. The recovered polymer was freeze−dried from benzene. (0.83 g, 83%). ^{1}H NMR (500 MHz, $CDCl_3$, δ in ppm): 1.46−1.85 (m, CH-(C$\underline{H}_2$)$_3$-CH_2 of THP), 3.46 (t, CH_2-C$\underline{H}_2$-N_3), 3.85 (t, CH-$(CH_2)_3$-C$\underline{H}_2$-O of THP), 4.59 (t, O-C$\underline{H}$-O of THP).

Synthesis of THP-PEG-Alkyne (3). To prepare THP-PEG-Alkyne (**3**), modification of hydroxyl group of polymer **1** and the removal of unalkynated PEG was performed. Polymer **1** (THP-PEG-OH, 1.50 g, 0.25 mmol) was freeze−dried from benzene and dissolved in anhydrous THF (15 mL). Subsequently, potassium naphthalene solution was added until the solution turned pale green to reactivate the chain end and stirred for 15 min. To the solution was added propargyl bromide (299 mg, 2.51 mmol) as toluene solution, and the reaction mixture was stirred at room temperature for 48 h. Then, the polymer was recovered by precipitation into ether twice and dried by freeze−drying with benzene. 1.35 g (0.23 mmol) of the resulting polymer was dissolved in dichloromethane (3 mL), followed by the addition of pyridine (1 mL). After the stirring for 1.5 h, 2 mL of solution of succinic anhydride (40 mg, 0.40 mmol) in dichloromethane was introduced and reacted at 30 °C for 24 h. To quench the remaining succinic anhydride, ethanol (about 1 mL) was added and stirred for another 24 h. The resulting polymer was recovered by precipitation into ether and dried in

vacuo. To isolate THP-PEG-Alkyne (**3**), this polymer mixture was dissolved in the mixed-solvent (H_2O/acetonitrile = 4/1 v/v) and separated through an ion exchange column (DEAE-Sephadex). Further purification was carried out by dialyzing against distilled, deionized water using a Spectrapro dialysis membrane (MW cutoff 3500) and then freeze−drying to obtain THP-PEG-Alkyne (**3**) (535 mg, 40%). ^{1}H NMR (300 MHz, $CDCl_3$, δ in ppm): 1.46−1.85 (m, CH-(C$\underline{H}_2$)$_3$-CH_2 of THP), 2.43 (t, C$\underline{H}$ of Alkyne), 4.20 (s, O-C$\underline{H}_2$-C of Alkyne), 4.59 (t, O-C$\underline{H}$-O of THP).

Deprotection of THP Group. A 1.0 g sample of the THP-ended PEG (**2** or **3**) was dissolved into methanol (ca. 15 mL), and 4−5 drops of 1 mol/L hydrochloric acid (HCl) aqueous solution was added. After stirring around 4 h at ambient temperature, the reaction mixture was poured into ether to precipitate the PEG sample. The recovered polymer was washed with ether carefully and dried in vacuo. The removal of the THP group was confirmed by ^{1}H NMR spectroscopy.

Amination Reaction of HO-PEG-Y (Y = N_3 and OCH_2−C≡CH). To prepare amino-terminated heterobifunctional PEG, NH_2-PEG-Azide, or NH_2-PEG-Alkyne, two-step modification was performed: activation of hydroxyl group by methanesulfonyl ester formation and substitution with ammonia. In the first step, the mesylation reaction of the resultant polymer, HO-PEG-Y (Y = N_3 and OCH_2−C≡CH), was carried out according to the same procedure as described above. After precipitation into ether, filtration, and freeze−drying from benzene, the mesylated polymer was mixed with 25 wt % ammonia aqueous solution and stirred at room temperature for about 4 days. After the reaction, to remove excess ammonia, the mixture was partially evaporated and dialyzed first against diluted ammonia solution (ca. 0.125 N in H_2O) and then against distilled water using a Spectrapro dialysis membrane (MW cutoff 3500). Lyophilization of the dialyzed solution gave the amine-functionalized polymer, NH_2-PEG-Y (Y = N_3 (**4**) and OCH_2−C≡CH (**5**)).

Synthesis of Dithiocarbonate Introduced HO-PEG-Y (Y = N_3 (6) and OCH_2−C≡CH (7)). To derivatize HO-PEG-Y (Y = N_3 and OCH_2−C≡CH) with dithiocarbonate moiety, preparation of the methanesulfonyl ester of the polymer and subsequent substitution with potassium ethyl xanthogenate was carried out according to a previous report (*22*). The mesylation reaction of the resultant polymer, HO-PEG-Y (Y = N_3 and OCH_2−C≡CH), was carried out according to the same procedure as described above. After the precipitation into ether, filtration, and freeze−drying from benzene, the mesylated HO-PEG-OCH_2-C≡CH (207 mg) was dissolved in THF (20 mL). After the stirring for 20 min, 4 mL of cosolvent (THF/DMF = 5/5 vol %) containing potassium xanthogenate (111 mg, 0.69 mmol) was added and stirred at room temperature for 10 h. The reaction mixture was then mixed with dichloromethane (100 mL) and washed with a saturated NaCl aqueous solution several times. The organic layer was dried over $MgSO_4$, filtered, concentrated, and then reprecipitated into ether. The recovered polymer, CH_3CH_2-O-(C═S)-S-PEG-OCH_2-C≡CH was freeze−dried from benzene (176 mg, 85%). To introduce the *O*-ethyldithiocarbonate group at the hydroxyl terminus of HO-PEG-N_3, the same procedure was performed. After freeze−drying, the yield of the recovered sample was determined to be 83%.

Synthesis of HS-PEG-Y (Y = N_3 (8) and OCH_2-C≡CH (9)). To prepare the thiol-terminated PEG derivatives, HS-PEG-Y (Y = N_3 and OCH_2−C≡CH), simple reaction with propylamine (*22*) or sodium hydroxide solution was conducted. The azido-terminated PEG containing dithiocarbonate moiety (polymer **6**) (100 mg) was dissolved in methanol (2 mL), and sodium hydroxide (66 mg) aqueous solution (500 μL) was slowly added. The mixture was stirred for 12 h at room temperature and then dialyzed against distilled water. After the lyophilization of the dialyzed solution, the thiolated sample, HS-PEG-N_3 (**8**) was obtained as white powder (86 mg, yield = 86%). ^{1}H NMR (500 MHz, $CDC1_3$, δ in ppm): 2.88 (t, CH_2-C$\underline{H}_2$-SH and C$\underline{H}_2$-SS-C$\underline{H}_2$), 3.49 (t, CH_2-C$\underline{H}_2$-N_3).

Thiolation reaction of alkyne-terminated sample (polymer **7**) was performed by reference to the previous method (*22*). Polymer **7** (40 mg) was dissolved in THF (1 mL) and reacted with propylamine (100 μL) at room temperature. After the reaction for 3 h, the polymer solution was dialyzed against MeOH followed by the complete evaporation of the solvent under vacuum. The polymer was purified by reprecipitation into cold ether and dried in vacuo (33 mg, yield = 80%). ^{1}H NMR (500 MHz, $CDCl_3$, δ in ppm): 2.44 (t, C$\underline{H}$ of Alkyne), 2.88 (t, CH_2-C$\underline{H}_2$-SH and C$\underline{H}_2$-SS-C$\underline{H}_2$), 4.20 (s, O-C$\underline{H}_2$-C of Alkyne).

Table 1. Results of Ring-Opening Polymerization of EO[a]

[a] Polymerization was conducted in THF at 25 °C for 48 h. [b] After reprecipitation into ether. [c] Determined by GPC (DMF eluent) calibrated with commercial PEO standards. [d] Determined by MALDI-TOF MS spectra.

Polymer Analysis. ^{1}H NMR spectra were recorded on JEOL JNM-AL (300 MHz) or JEOL Alpha series (500 MHz) spectrometer (JEOL, Tokyo, Japan). ^{13}C NMR spectra were recorded on JNM-AL model at 75.45 MHz. Chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane. Number-average molecular weight (M_n) and molecular weight distribution (M_w/M_n) were determined using a GPC (TOSOH HLC-8220) system equipped with two TSK gel columns (G4000HHR and G3000HHR) and an internal refractive index (RI) detector. Columns were eluted with DMF containing lithium chloride (10 mM) with a flow rate of 0.8 mL/min and at a temperature of 40 °C. Molecular weights were calibrated with poly(ethylene glycol) standards (Polymer Laboratories, Ltd., UK). MALDI-TOF-MS spectra were recorded using Bruker REFLEX III. α-Cyano-4-hydroxycinnamic acid was used as the matrix for the ionization operated in the reflection mode.

RESULTS AND DISCUSSION

Although the hydroxyl group does not show high reactivity in itself comparing with other functional groups, the hydroxyl group can be converted to useful reactive groups through the activation and subsequent nucleophilic substitution. Hence, the availability of the hydroxyl group is potentially high. If homotelechelic HO-PEG-OH is used as a starting material for the preparation of heterobifunctional PEG derivatives, however, undesired yield of homobifunctional product and multiple column purification process are inevitable. Here, we designed a simple synthetic procedure containing preparation of hydroxyl-terminated PEG as the intermediate, of which one hydroxyl group is protected quantitatively, and alternating functionalization of both terminal ends.

Preparation of Monoprotected PEG via Polymerization of EO. In this study, monotetrahydropyranylated ethylene glycol derivative, 2-(tetrahydro-2*H*-pyran-2-yloxy)ethanol, was selected as an initiator for anionic polymerization of EO, because the tetrahydropyranyl (THP) group is one of the useful protecting species of hydroxyl group (*20*), and shows both easy installation and general stability under nonacidic conditions. In other words, it is expected that the THP protecting group is stable under

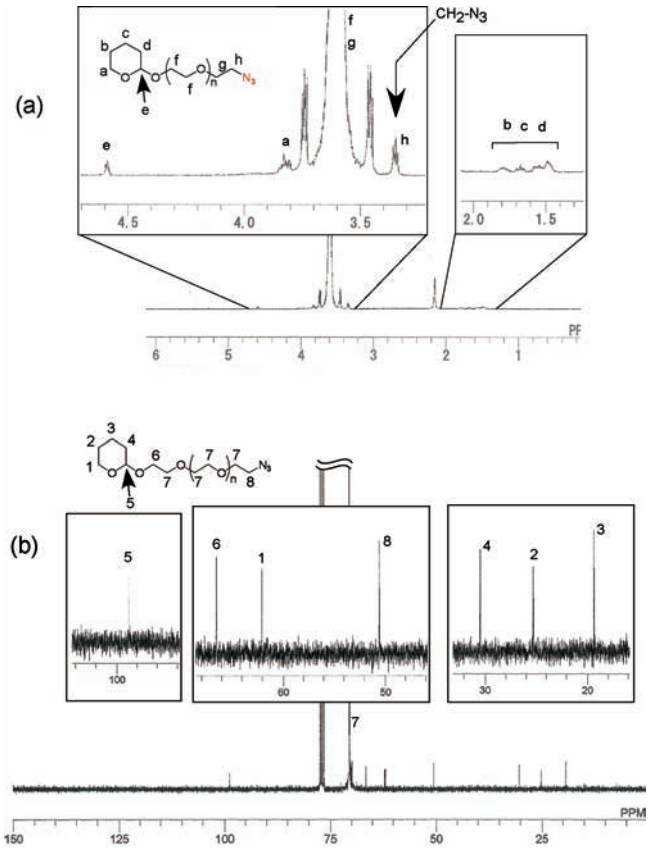

Figure 1. (a) 500 MHz ^{1}H NMR spectrum of THP-PEG-Azide (in $CDCl_3$ at 20 °C). (b) ^{13}C NMR spectrum of THP-PEG-Azide (in $CDCl_3$).

polymerization condition of EO and subsequent functionalization step with azide/alkyne. Table 1 shows the results of the polymerization of EO in the presence of monotetrahydropyranylated ethylene glycol as an initiator. All polymerization proceeded with excellent isolated yields of the polymeric samples (>96%), and the M_n values determined by GPC and MALDI-TOF MS showed good agreement with calculated values, indicating the controlled molecular weight of THP-PEG-OH (**1**) without any side reaction.

Azidation Reaction of THP-PEG-OH. To demonstrate the versatility of THP-PEG-OH (**1**), selective and quantitative modification of the ω-hydroxyl end was examined. First, the azidation reaction was conducted through the two-step modification, the mesylation and the substitution by sodium azide, of hydroxyl function as described in the Experimental Section.

In the ^{1}H NMR spectrum of the product after azidation (run 2 in Table 1), the proton signals of THP group are detected at δ 4.63 ppm (e), 3.86 ppm (a), and 1.46−1.85 ppm (b, c, d), respectively. In addition to these signals, the methylene unit adjacent to the azido group ($CH_2\underline{CH_2}N_3$ (h)) was observed at 3.39 ppm (Figure 1a). With comparison of the integral ratio of proton signals at α- (δ 4.63 ppm (e)) and ω-ends (δ 3.39 ppm (h)), the quantitative conversion from the hydroxyl to the azido group was indicated. Additionally, the ^{13}C NMR spectrum shows that the methylene and methyne signals of the THP structure are detected around δ 99.4 ppm (C5), 65.3, ppm (C6), 62.0 ppm (C1), 30.3 ppm (C4), 25.4 ppm (C2), and 19.7 ppm (C3), respectively (Figure 1b). Moreover, no signal of the methylene carbon adjacent to the hydroxyl terminus ($CH_2\underline{C}H_2OH$: δ = 61.5 ppm) (*23*) was detected. These results strongly support the quantitative introduction of azido functionality at the ω-end of THP-PEG-OH.

Preparation of THP-PEG-Alkyne (3). To represent the selective derivatization of THP-PEG-OH (**1**) applicable to "click chemistry", the introduction of alkyne moiety, the counterpart of azide/alkyne cycloaddition reaction, was studied. For alkynation of the hydroxyl group of THP-PEG-OH, Williamson's ether synthetic method with propargyl bromide was performed after the formation of alcolate by the addition of potassium naphthalene. From ^{1}H NMR analysis of the resulting product, the proton signals of the

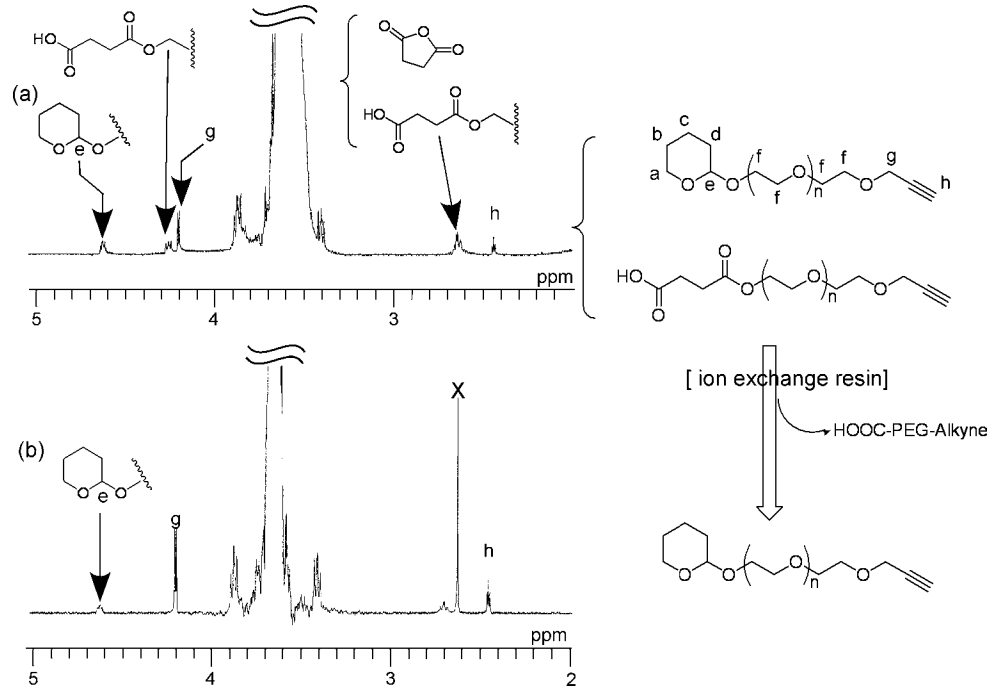

Figure 2. ^{1}H NMR spectra of alkyne-terminated PEGs; sample after the carboxylation reaction (a) and sample through DEAE-Sephadex resin column (b) (300 MHz in $CDCl_3$).

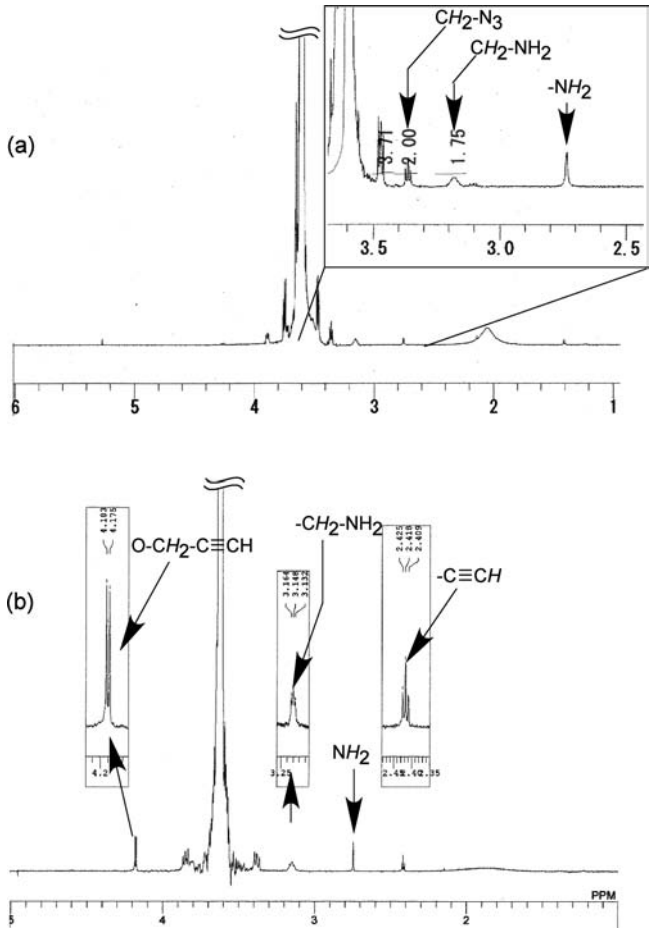

Figure 3. (a) 500 MHz ^{1}H NMR spectrum of NH_2-PEG-Azide (in $CDCl_3$). (b) ^{1}H NMR spectrum of NH_2-PEG-Alkyne (in $CDCl_3$).

alkyne moiety are detected at δ 2.43 ppm (h) and 4.20 ppm (g), respectively, with the signals assigned to the THP group, indicating the efficient alkynation (Figure 2a). However, the conversion rate of alkynation estimated by ^{1}H NMR analysis was relatively low (around 70%). The polymer sample with remaining THP-PEG-OH will yield the undesired byproduct, homobifunctional HO-PEG-OH, after the deprotection of the THP group. Then, separation of the unalkynated THP-PEG-OH from the sample was examined with simple column purification. After the carboxylation of the remaining hydroxyl group with succinic anhydride in dichloromethane, the polymer mixture was passed through the ion exchange column. The carboxylated PEG was separated from the mixture by ionic absorption with DEAE-Sephadex resin in a column, whereas the alkynated sample, THP-PEG-Alkyne, was eluted without retention. In the ^{1}H NMR spectrum of the sample after the dialysis and lyophilization, no signal based on the carboxylated PEG was observed, suggesting the effective removal of unalkynated fraction and isolation of the quantitative alkyne-functionalized THP-PEG.

Preparation of NH_2-PEG-Y (Y = N_3 (4) and OCH_2−C≡CH (5)). Removal of protective group, THP, will allow further derivatization of the α-terminal end of azido- or alkyne-terminated PEG. Deprotection of THP was carried out under acidic condition with diluted HCl, and ^{1}H NMR spectrum of the resulting sample indicated absence of the proton signals corresponding to the THP group (data not shown). To convert a hydroxyl group of the deprotected samples, HO-PEG-Azide and HO-PEG-Alkyne, to primary amino group, mesylation and subsequent nucleophilic substitution by ammonia was performed. In the ^{1}H NMR spectrum of aminated sample (Figure 3a), the characteristic methylene signals adjacent to both the azido group (-$C\underline{H}_2N_3$: δ = 3.36 ppm) and the primary amino group (-$C\underline{H}_2NH_2$: δ = 3.18 ppm) were clearly observed. Additionally, the amination degree estimated from the integral ratio of these proton signals was 85% and above, indicating successful preparation of NH_2-PEG-N_3. Likewise, the ^{1}H NMR spectrum of aminated HO-PEG-Alkyne exhibits the distinguishing signals assigned to both the alkyne moiety (C$\underline{H}$ of Alkyne: δ = 2.41 ppm and O-C$\underline{H}_2$-C of Alkyne: 4.18 ppm) and the primary amino group (-C$\underline{H}_2NH_2$: δ = 3.14 ppm) in Figure 3b. Moreover, to confirm the quantitative terminal functionalization of this alkyne-terminated PEG sample, the analysis by MALDI-TOF MS spectroscopy was also conducted. Figure 4 shows the MS spectrum of NH_2-PEG-Alkyne (**5**). The major series of the molecular masses of the product is expressed in the following equation

$$MW_{MS} = 44.053n(EO) + 39.05(\text{Alkyne moiety; } CH_2C \equiv CH) + 16.02(NH_2) + 22.99(\text{sodium})$$

In this analysis, only parent ions of each polymer molecule as expected are observed, without the signal assigned to the byproduct NH_2-PEG-NH_2. These data strongly support the successful preparation of NH_2-PEG-Alkyne (**5**).

Preparation of HS-PEG-Y (Y = N_3 (8) and OCH_2−C≡CH (9)). To demonstrate the versatility of this synthetic route based on THP-PEG-Y (Y = Azide and

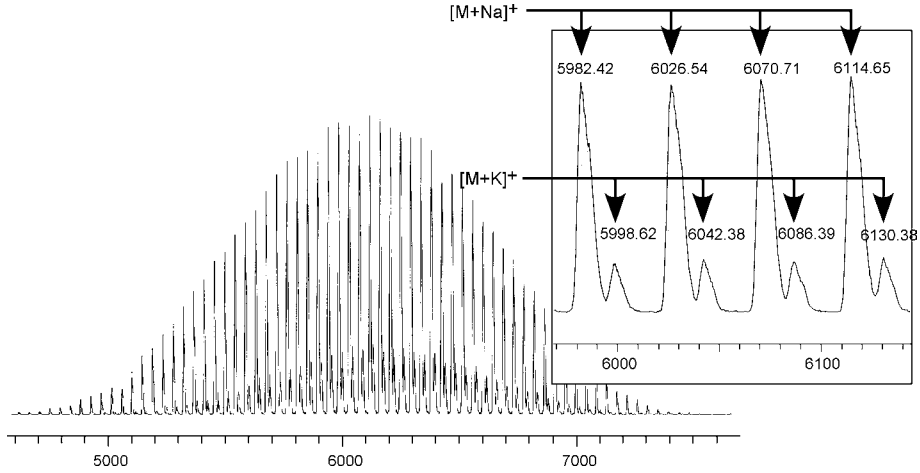

Figure 4. MALDI-TOF MS spectrum of NH_2-PEG-Alkyne.

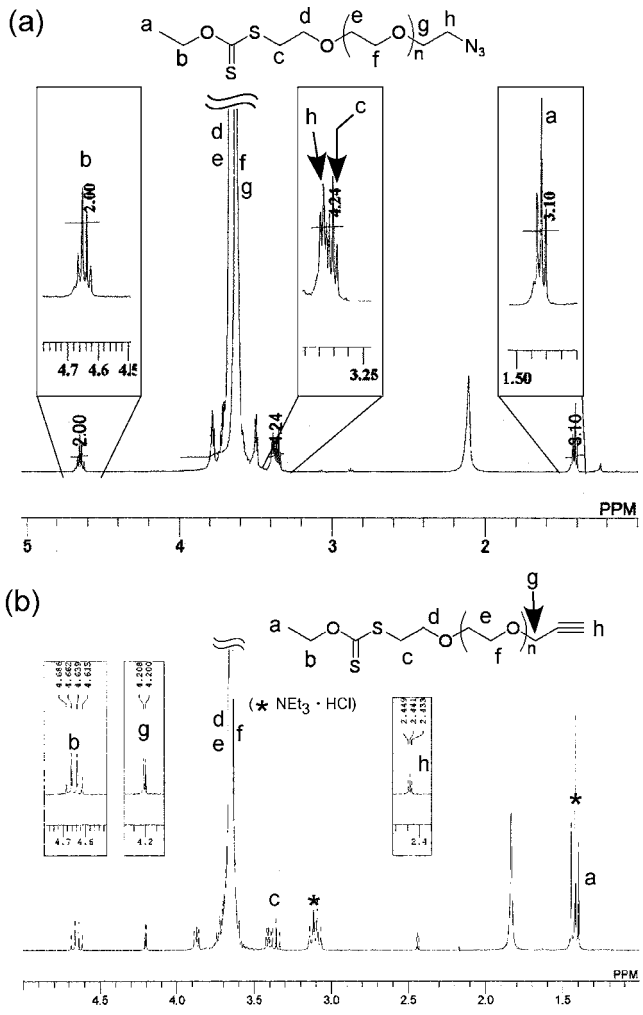

Figure 5. ^{1}H NMR spectra of derivatized samples with dithiocarbonate moiety: Azide-PEG (a) (500 MHz in $CDCl_3$) and Alkyne-PEG (b) (300 MHz in $CDCl_3$).

Alkyne), the derivatization of the α-terminal end to the thiol functional group was examined after the removal of the THP protective group. PEG derivatives introduced with the dithiocarbonate moiety at the α-position were prepared as the first step to HS-PEG-Y (Y = Azide and Alkyne) through the two-step modification, the mesylation and the substitution by potassium xanthogenate, of hydroxyl function as described in the Experimental Section. In the ^{1}H NMR spectrum (Figure 5a), the characteristic methyl and methylene signals of the dithiocarbonate unit were clearly observed at 1.85 ($S(C{=}S)-OCH_2C\underline{H}_3$), and 4.65 ppm ($S(C{=}S)O-C\underline{H}_2CH_3$), respectively, and the proton signal assigned to the azido group ($-C\underline{H}_2N_3$: δ = 3.37 ppm) was also detected. In addition, comparison between the integral ratios of these signals indicated the quantitative conversion of the hydroxyl group to the dithiocarbonate structure without any damage on the azido functionality. For derivatization of HO-PEG-Alkyne, the reaction similar to the azido-terminated PEG sample was conducted. From the ^{1}H NMR analysis of the resultant polymer, both signals assigned to the alkyne moiety (C$\underline{H}$ of Alkyne: δ = 2.41 ppm and O-C$\underline{H}_2$-C of Alkyne: 4.18 ppm) and the dithiocarbobnate structure ($S(C{=}S)-OCH_2C\underline{H}_3$): δ = 1.85 and $S(C{=}S)O-C\underline{H}_2CH_3$): δ = 4.65 ppm) were clearly detected (Figure 5b). These results indicate the successful derivatization of heterobifunctional THP-PEG-Y (Y = Azide and Alkyne) with dithiocarbonate moiety under the mild reaction condition. Figure 6 shows the ^{1}H NMR spectrum of the obtained HS-PEG-Azide. The proton signals corresponding to the ethyldithiocarbonate moiety completely disappeared, while the characteristic signals of both azide and methylene proton adjacent to thiol group were detected ($CH_2C\underline{H}_2N_3$: δ 3.39, and $CH_2C\underline{H}_2S$: δ 2.89 ppm, respectively). In addition, no decomposition of the azido group during the alkali reaction was detected in the ^{1}H NMR spectrum, suggesting the end-functionalization with the high reaction conversion. After the thiolation reaction of alkyne-terminated PEG, the characteristic signals were observed without any side reaction (see the Experimental Section). These investigations indicated that the thiolation reaction of PEGs possessing azido or alkyne function proceeded under the mild conditions.

In conclusion, the facile synthesis of the azido- or alkyne-possessing heterobifunctional PEGs via EO polymerization was demonstrated in this study. Controlling the MW and the selective functionalization of the α- and ω-termini of heterobifunctional PEGs was successfully presented. These functional PEG derivatives can be used in Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction (click chemistry) to introduce versatile biofunctional moieties into the azido or alkyne terminus, and are thus relevant to a wide range of applications in the field of bioconjugate chemistry.

Site-Specific Incorporation of *p*-Propargyloxyphenylalanine in a Cell-Free Environment for Direct Protein−Protein Click Conjugation

Bradley C. Bundy[†,§] and James R. Swartz*[,†,‡]

Department of Chemical Engineering, Stanford University, Stanford, California 94305-5025, and Department of Bioengineering, Stanford University, Stanford, California, 94305-5444. Received June 30, 2009; Revised Manuscript Received November 20, 2009

The tyrosine analog *p*-propargyloxyphenylalanine (pPa), like tyrosine, has limited water solubility. It has been postulated that this limited solubility has contributed to reduced cellular uptake of pPa and thus reduced *in vivo* incorporation of pPa into proteins. Using a cell-free protein synthesis system (CFPS) to circumvent cellular uptake, pPa has been incorporated site-specifically into proteins with high specificity at yields up to 27 times greater than the highest previously reported yield. The alkyne group present on proteins incorporated with pPa provides a reactive residue for site-specific bioconjugation with the copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC). Previously, incorporation of another CuAAC-compatible unnatural amino acid *p*-azido-L-phenylalanine (pAz) was demonstrated with CFPS. However, incorporation of pPa may be preferred over pAz due to the instability of the pAz's aryl-azido moiety upon UV or near-UV light exposure. Also, the ability to incorporate site-specifically both reactants of the CuAAC (the alkyne group of pPa and the azido group of pAz) into proteins enables direct site-specific conjugation of heterologous proteins. We have demonstrated (for the first time to our knowledge) a one-step, linker-less, site-specific, direct protein-to-protein conjugation using CuAAC and unnatural amino acids.

INTRODUCTION

With the advent of recombinant protein production and an ever increasing tool kit for protein optimization, proteins have become some of the most valuable molecules on earth (estimated $90+ billion U.S. market share in 2009) (*1*). A powerful tool for both optimizing protein function and creating new protein-based materials is the covalent modification of proteins. This is especially important to improve pharmaceutical protein pharmacokinetics, study protein function and trafficking, perform artificial post-translational modification, and construct new biomolecule-based materials (*2*, *3*). Although a number of methods have been developed for post-translational protein modification, only a few methods enable site-specific protein conjugation. By employing a cell-free approach, we seek to improve the yields of a particularly attractive method for site-specific conjugation. We also seek to demonstrate for the first time to our knowledge a direct, one-step, linker-less, site-specific protein-to-protein conjugation using the well-accepted copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC)[1] reaction.

A wide variety of methods targeting natural amino acid residues have been developed to facilitate covalent conjugation to proteins. However, only a few are widely used, and these typically target nucleophilic moieties present on lysine, cysteine, aspartic acid, and glutamic acid residues. In fact, over 70% of the protein conjugating reagents available from Molecular Probes and Pierce Biotechnology target lysine and cysteine (*4*). Unfortunately, these methods do not conjugate site-specifically when more than one residue of the targeted amino acid is surface-accessible. To obtain site-specific attachment, the protein must be mutated to remove the conjugation-targeted amino acid from undesirable attachment locations, and additional mutagenesis is often required to present the conjugation-targeted amino acid at the desired site. However, protein modification of this scale often negatively affects protein folding, function and/or stability.

Targeting the C- and N-terminus of proteins for post-translational conjugation has also been considered (*5*). However, this is complicated by similar chemical functionality found on the side chains of lysine and arginine or aspartic and glutamic acid (*5*). Although some progress has been made toward specifically conjugating at the protein termini, there are many cases when the terminus is inaccessible for attachment or, more importantly, when attachment to a different location is necessary for the desired function (*6*).

A particularly attractive method of circumventing issues related to natural amino acid mediated protein bioconjugation is the use of unnatural amino acids. Tirrell and co-workers have demonstrated the ability to substitute methionine with unnatural amino acids that display uniquely reactive residues (such as azido homoalanine) using methionine auxotrophic strains. Although protein can be produced at reasonable yields of around 20−50 μg/mL (*7*), this technique only offers a global replacement of methionine and would require the same protein modifications discussed previously if multiple methionines in the wild-type protein are surface-accessible. Further, global replacement of methionine could significantly alter the protein structure and compromise protein function.

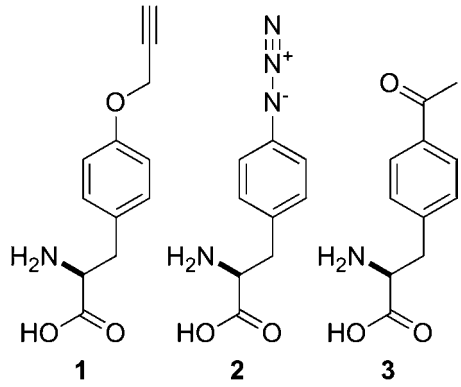

Figure 1. Structure of *p*-propargyloxyphenylalanine (**1**), *p*-azido-L-phenylalanine (**2**), and *p*-acetyl-L-phenylalanine (**3**).

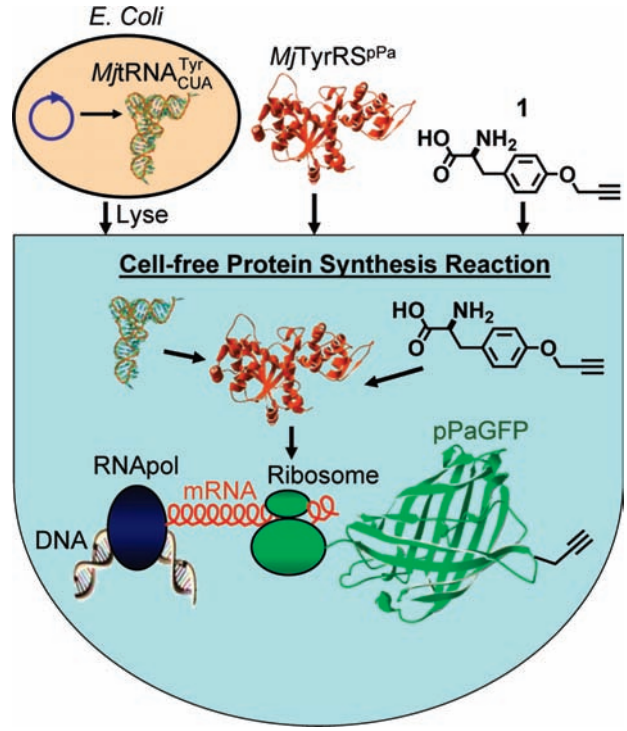
Schultz and co-workers have developed a technology for truly site-specific incorporation of functionally unique unnatural amino acids by expressing othogonal tRNAs and aminoacyl-tRNA synthetases (*8*). Their *Escherichia coli*-based system uses (1) a *Methanococcus jannaschii* tyrosyl-aminoacyl-tRNA synthase (*Mj*TyrRS) evolved to exclusively charge a given unnatural amino acid and (2) a *Methanococcus jannaschii* tyrosyl-tRNA with an amber stop anticodon (MjtRNA$^{Tyr}_{CUA}$). By expressing the above pair and including the unnatural amino acid in the *E. coli* fermentation media, the unnatural amino acid is incorporated into proteins only in the location encoded by the amber stop codon UAG on the corresponding mRNA (*8, 9*). Similar technology has also been transferred to yeast and mammalian cells (*10, 11*). Site-specific conjugation using proteins expressed with this system requires minimal protein modification, as the unnatural amino acid is only incorporated at the desired location. The gene needs only to be modified by installing the amber stop codon at the desired location. Over 30 unnatural amino acid have been incorporated in this way with, for the most part, high selectivity for the unnatural amino acid, although at typically lower product yields (1 to 20 μg/mL) (*12, 13*). Further optimization work with one unnatural amino acid (*p*-benzoyl-L-phenylalanine) did increase protein yields to 40 μg/mL (*14*). Although the yield and incorporation efficiency varies depending on the unnatural amino acid, one unnatural amino acid in particular, *p*-propargyloxyphenylalanine, **1** (Figure 1), was found to be expressed only at lower yields (0.05 μg/mL and 2.0 μg/mL in *E. coli*) and at lower incorporation efficiencies (80% to 91% versus >93%) relative to other unnatural amino acids (*15*−*17*). It has been postulated that the cause was limited transport of **1** into the cell which could be due to the low aqueous solubility of **1** (*11*). **1** is an analogue of tyrosine, the least soluble of the natural amino acids (*18*), and like tyrosine, has poor solubility. The incorporation of **1** is of particular interest, as it contains a stable alkyne group that can be used for bioconjugation.

To overcome the putative transport limitation to incorporation of **1**, we expanded a cell-free protein synthesis (CFPS) approach. Recently, our *E. coli* based cell-free system was modified to include the *Mj*TyrRS/MjtRNA$^{Tyr}_{CUA}$ pair for the site-specific incorporation of *p*-azido-L-phenylalanine, **2**, and *p*-acetyl-L-phenylalanine, **3** (Figure 1). Protein yields up to 660 μg/mL and 110 μg/mL, respectively, were reported (*12*); however, both **2** and **3** have reasonably good water solubility, as they are analogues of phenylalanine, which is 60 times more water-soluble than tyrosine. Additionally, both **2** and **3** have been incorporated *in vivo* with high selectivity (>95%) and at relatively high yields suggesting that cellular uptake of these unnatural amino acids is not limiting (*17, 19, 20*).

Although the cell-free incorporation of both **2** and **3** is attractive, the open translation environment of the cell-free protein synthesis system (CFPS) is potentially even better suited for incorporation of unnatural amino acids with poor cellular uptake and with low water solubility. We seek to further demonstrate the utility of CFPS by site-specifically incorporating the potentially cell-transport-limited and poorly water soluble **1** into the model proteins dihydrofolate reductase (DHFR) and superfolder green fluorescent protein (sfGFP) (Figure 2). The unnatural amino acid **1** is of particular importance, as it contains an alkyne group that can be conjugated to azido containing entities with the highly selective copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC). Unlike **2**, which can also be used with CuAAC, **1** is not UV sensitive. Also, as will be described, efficient production of pairs of proteins, one with **1** and the other with **2**, enable the site-specific conjugation of two proteins in a one-step reaction without requiring an additional chemical linker (Scheme 1).



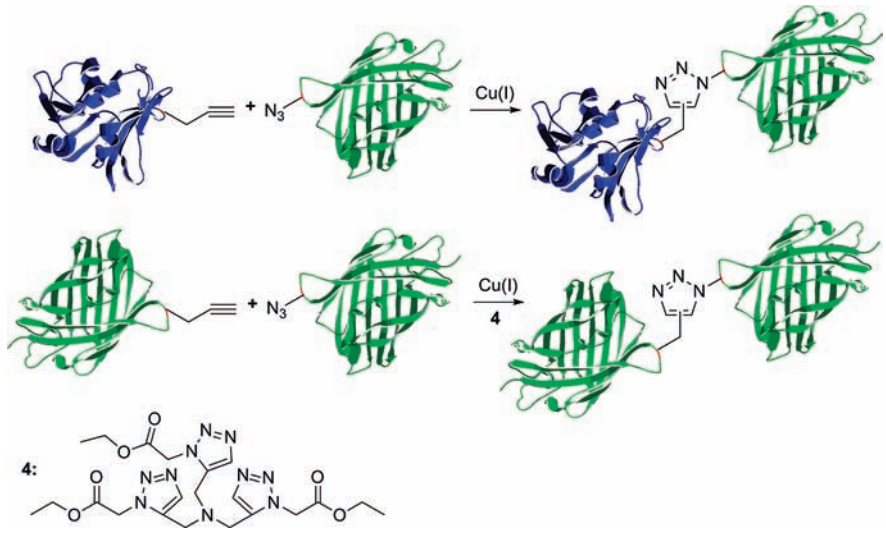


Figure 2. Cell-free protein synthesis reaction incorporating *p*-propargyloxyphenylalanine. The transcription and translation machinery and the MjtRNA$^{Tyr}_{CUA}$ were added as part of the *E. coli* lysate. *Mj*TyrRS^{pPa}, **1**, T7 RNA polymerase (RNApol), DNA plasmid template encoding pPaGFP, and other necessary cofactors were added directly to the CFPS environment.

EXPERIMENTAL PROCEDURES

Plasmid Construction. The sequence encoding the streptag (WSHPQFEK) was added directly before the stop codon on the 3′ end of the DHFR10 gene by PCR using the plasmid pK7eDHFR10−6H (*12*) as the DHFR10 gene source. The resulting gene was ligated into plasmid pY71 at the *Nde*I and *Sal*I restriction sites generating plasmid pY71eDHFR-V10unAA. The pY71 plasmid is a simplified version of the pK7 plasmid previously reported for use in CFPS (Supporting Information) (*21*). The plasmid pET15bsfGFP was a kind gift from Kevin P. Kent and Steven G. Boxer and contains a superfolder GFP variant with the sequence codon optimized for expression in *E. coli* (Supporting Information) (*22*). The codon encoding threonine 216 was replaced by the amber stop codon, and the streptag encoding sequence was added to the 3′ end by PCR. The resulting gene was ligated into pY71 at the *Nde*I and *Sal*I restriction sites creating plasmid pY71sfGFP-T216unAA. A

Scheme 1. Copper(I)-Catalyzed Azide−Alkyne [3 + 2] Cycloadditions (CuAAC) of pPaDHFR + pAzGFP (top) and pPaGFP + pAzGFP (bottom)

plasmid expressing *Mj*TyrRS^{pPa} (*Mj*TyrRS specific for *p*-propargyloxyphenylalanine, **1**) was generated to contain the *Mj*TyrRS^{pPa} sequence previously reported on plasmid pPR-MjRS-1 (*16*). The *Mj*TyrRS^{pPa} gene with a 3′-hexahistidine tag sequence was constructed using plasmid pK7pAzRS-6H (*12*) as a template and making the necessary mutations by overlap PCR. The resulting gene was ligated into pY71 at the *Nde*I and *Sal*I restriction sites resulting in the plasmid pY71pPaRS-6H.

***p*-Propargyloxyphenylalanine Synthesis and Solubility Analysis.** *p*-Propargyloxyphenylalanine, **1**, was synthesized as reported previously (*23*), and the product was characterized by electrospray mass spectrometry (Supporting Information Figure S1). The solubility of **1** at 25 °C was determined by first incubating 5 mM of **1** in Milli-Q water for three days with continuous end-over-end agitation. The solution was subjected to 21 000 × *g* for 1 h, and the soluble **1** solution was aspirated, after which the precipitated **1** was dried overnight under vacuum. The solubility of **1** was calculated on the basis of the weight of the dried insoluble **1** compared to the initial quantity of **1** added.

Cell-Free Protein Synthesis. *Extract and MjTyrRS Preparation. E. coli* extract used for CFPS was prepared from an *E. coli* KC6 strain harboring the pDule-tRNA plasmid with the *Mj*TyrRS^{pAz} (*Mj*TyrRS specific for **2**) gene removed (*12*). The strain was fermented in 1 L of defined media (*24*) using a 2.5 L Tunair fully baffled shake flask (Shelton Scientific, Shelton, CT, USA) at 37 °C and constant shaking at 280 rpm. The culture was harvested at OD 4.0 (3.5 h after inoculation), and the cells were pelleted and washed 3 times with S30 buffer (*24*). After the final wash, the cells were resuspended in 1 mL S30 buffer per gram cells and lysed by single pass homogenization (700 Rotary Homogenizer, Fisher Scientific, Pittsburgh, PA) at pressures of 17 000 to 25 000 psi. The homogenate was clarified by discarding the pellet after each of two rounds of centrifugation for 30 min at 30 000 × *g*. The clarified extract was activated by incubating at 37 °C for 80 min while shaking at 280 rpm; after which, the extract was flash-frozen and stored at −80 °C until use. *Mj*TyrRS^{pPa} and *Mj*TyrRS^{pAz} were affinity purified from BL21pLys cells harboring the plasmid pY71pPaRS-6H or pK7pAzRS-6H using a previously described protocol (*12*).

Cell-Free Protein Synthesis Reaction. Cell-free protein synthesis (CFPS) reactions for incorporating **1** or **2** were performed with a few modifications to the standard PANOxSP system (*25*). The reactions were preformed in 1.5 mL Eppendorf tubes or 6-well plates (Fisher Scientific, Waltham, MA) at 15 μL to 1 mL volumes and incubated for 8 h at 30 °C unless noted otherwise. The reactions contain the following components obtained from Sigma-Aldrich (St. Louis, MO) unless otherwise specified: 1.2 mM ATP, 0.85 mM GTP, 0.85 mM UTP, 0.85 mM CTP, 34 μg/mL folinic acid, 0.33 mM nicotinamide adenine dinucleotide (NAD), 0.27 mM coenzyme A (CoA), 1.5 mM spermidine, 1 mM putrescine, 175 mM potassium glutamate, 10 mM ammonium glutamate, 13 mM magnesium glutamate, 2.7 mM sodium oxalate, 2 mM each of the 20 standard proteinogenic amino acids, 2 mM of **1** (synthesized) or **2** (Chem-Impex Int., Wood Dale, IL), 30 mM phosphoenolpyruvate (Roche Molecular Biochemicals, Indianapolis, IN), 85 μg/mL *E. coli* tRNA mixture (Roche Molecular Biochemicals), 100 μg/mL T7 RNA polymerase (prepared as described previously (*21*), 5 to 25 μM l-[U-14C] Leucine (GE Healthcare, Piscataway, NJ), 0.8 to 5 mg/mL *Mj*TyRS^{pPa} or *Mj*TyrRS^{pAz} prepared as described above, 28% v/v of extract prepared from *E. coli* lysate as described above, and 12 nM plasmid (either pY71eDHFR-V10unAA or pY71sfGFP-T216unAA purified with Qiagen Plasmid Maxi Kit, Valencia, CA).

Cell-Free Protein Synthesis Yield Analysis. Total synthesized protein yields were determined from the percent of radioactive ^{14}C-leucine incorporated into protein. Radioactivity measurements were made using Beckman ReadySafe Scintillation Cocktail and a Beckman LS3801 Liquid Scintillation Counter (Beckman Coulter, Fullerton, CA). ^{14}C-leucine labeled proteins were precipitated and washed three times with 0.5% trichloroacetic acid, TCA, before measuring radioactivity levels. Soluble yields were determined by centrifuging the CFPS reaction product at 4 °C and 21 000 *g* for 15 min before TCA-precipitation and scintillation counting of the supernatant. The detailed procedure has been described previously (*21*). Soluble full-length yields were determined by subjecting the supernatant after the above-mentioned centrifugation to SDS-PAGE gel electrophoresis followed by autoradiography and densitometry. Specfically, NuPAGE 10% Bis-Tris and 4−12% Bis-Tris Gels (Invitrogen, Carlsbad, CA), Mark12 Unstained Standard MW Marker (Invitrogen), SimplyBlue SafeStain (Invitrogen), and Kodak BioMax MR Autoradiography Films (Rochester, NY) were used following manufacture's instructions. *ImageJ* 1.36b software (National Institutes of Health, USA) was used to estimate the relative intensity of the protein bands for densitometry (*26*).

Activity Assays. *DHFR.* The specific activity of DHFR (and DHFR variants containing unnatural amino acids) was measured with the Dihydrofolate Reductase Assay Kit (Sigma-Aldrich)

by following the conversion of NADPH to $NADP^+$ as determined by absorbance at 340 nm. Prior to the activity assay, DHFR was purified using the C-terminal streptag and 0.2 mL gravity-flow *Strep*-Tactin Sepharose mini-columns per manufacture's instructions (IBA GmbH, Gottingen, Germany).

sfGFP. An *in vivo* produced and affinity purified sfGFP (courtesy of Kevin P. Kent and Steven G. Boxer, Stanford University) was used as a reference for sfGFP activity (*22*); with 100% activity being equivalent to the specific activity of *in vivo* produced sfGFP. The specific activity of sfGFP (and variants containing unnatural amino acids) was measured using either (1) a NanoDrop 3300 Fluorimeter (Thermo Scientific, Waltham, MA) with blue excitation source setting and emission measurement at 511 nm or (2) a Mithras Multimode Microplate Reader LB 940 (Berthold Technologies, Wildbad, Germany) with a F485 excitation filter and a F535 emission filter.

***p*-Propargyloxyphenylalanine Incorporation Selectivity Analysis.** To verify the previously reported high selectivity of *Mj*TyrRS^{pPa} for **1** (*16*), CFPS reactions were performed with and without **1**. The product was subjected to electrophoresis using NuPAGE 10% Bis-Tris SDS-PAGE gels. Autoradiography of the dried SDS-PAGE gel was performed to determine the amount (if detectable) of full-length product produced in the absence of **1** compared to the amount of full-length product produced in the presence of **1**.

Extraction and Characterization of tRNA from CFPS Extract. The tRNA from 100 μL of cell extract (prepared from KC6 with *Mj*tRNA$^{Tyr}_{CUA}$ expression) was extracted with an equivalent volume of phenol/chloroform/isoamyl alcohol 25:24:1 followed by vortexing, phase separation by a 2 min spin at 21 000 $\times$ *g*, and aspiration of the aqueous phase. Both a 0.1 equiv of 3 M sodium acetate, pH 5, and a 2.5 equiv of 200 proof ethanol were added to the aspirated aqueous phase. After an overnight incubation at 4 °C, the solution was subjected to centrifugation at 21 000 $\times$ *g* for 20 min. The resulting pellet was washed with 70% ethanol and repelleted by centrifugation at 21 000 $\times$ *g* for 20 min. After air-drying, the pellet was resuspended in 25 μL of 10 mM phosphate buffer pH 8.0. The Nanodrop 2000 Spectrophotometer and the Qubit-iT 5−100 ng RNA Assay (Invitrogen) were used to determine the relative amount of DNA and RNA purified. The concentration of ethanol-extracted tRNA was compared to the concentration of tRNA in the CFPS extract using 15% TBE-urea SDS-PAGE gel electrophoresis with ethidium bromide staining and densitometry with *ImageJ* 1.36b software (*26*).

CuAAC Reactions. CuAAC reactions were performed anaerobically with equimolar concentrations of the **1**-containing and **2**-containing proteins. The Cu(I) complex tetrakis(acetonitrile)copper(I) hexafluorophosphate ($[(CH_3CN)_4Cu]PF_6$) (Sigma-Aldrich) was used as a catalyst at final concentrations ranging from 0.1 to 1 mM. In GFP dimerization CuAAC reactions, a tris-triazole ligand **4** (Scheme 1), which helps facilitate the CuAAC reaction (*27*), was added at 2 equiv of the Cu(I) complex concentration. The reaction was buffered with 10 mM potassium phosphate, pH 8.0. The final concentration of each reactant was 1.6 μM in the pPaDHFR and AzGFP CuAAC reaction. The pPaGFP and pAzGFP CuAAC conjugation reactions contained 4.7 to 5.8 μM of each reactant. All reactions were performed anaerobically for 8 h or overnight. Post-CuAAC activity assays were performed as described above. The extent of completion of the CuAAC reactions was evaluated by NuPAGE 10% or 4−12% Bis-Tris SDS-PAGE gel electrophoresis followed by autoradiography and densitometry (*ImageJ* software). Desalting of CuAAC reaction product to remove Cu(I) was performed using Illustra Microspin G-25 Columns (GE Healthcare) per the manufacture's specifications.

Size-Exclusion Separation of the Click Reaction Product. A 2.5 mm $\times$ 250 mm column was fabricated from a 1 mL Serological polystyrene pipet (Fisher Scientific, Waltham, MA) and the membrane from a Pharmacia Biotech XK 16 column. The column was packed with Superdex75 resin (GE Healthcare) at a 0.3 mL/min flow rate using 10 mM potassium phosphate buffer at pH 8.0 and a peristaltic pump. Prior to size exclusion separation, the column was transported to an anaerobic environment and flushed with deoxygenated 10 mM phosphate buffer at pH 8.0. The click reaction product (20 μL) was added directly to the column followed by deoxygenated phosphate buffer pH 8.0 at 0.3 mL/min. Fractions of 0.1 mL were collected, and the specific activity of sfGFP in each fraction was determined by (1) scintillation counting to determine sfGFP concentration and (2) measuring fluorescence with the Mithras Multimode Microplate Reader. The distribution of dimerized sfGFP and monomeric sfGFP in each fraction was visualized by NuPAGE 10% Bis-Tris SDS-PAGE electrophoresis with Novex Sharp Prestained Standard (Invitrogen) and SimplyBlue SafeStain.

RESULTS AND DISCUSSION

Cell-Free Incorporation of *p*-Propargyloxyphenylalanine. Although *p*-propargyloxyphenylalanine, **1**, (Figure 1) has been reported to have lower solubility than other unnatural amino acids (*11*), the solubility limit of this amino acid has not been previously reported. After synthesis of **1** using methods described previously (*23*) and characterization by mass spectroscopy (Supporting Information Figure S1), we found the equilibrium solubility of **1** in water at 25 °C to be 1.9 mM (standard deviation = $\pm$0.9 mM, $n = 3$). The limited solubility of **1** is not surprising, as it is a hydrophobic analogue of tyrosine, the least water-soluble natural amino acid (2.5 mM water solubility at 25 °C) (*18*). Incorporation of **1** into proteins provides a unique terminal alkyne residue which can be exploited for protein conjugation using the copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC) "click" reaction. However, the incorporation of **1** into proteins using *in vivo* techniques has resulted in lower yields (0.05 to 2.0 μg/mL in *E. coli*) and low incorporation efficiencies (*15*−*17*). It has been postulated that limited cellular uptake of **1**, potentially due to low solubility of **1**, is the cause (*11*). To overcome the potential cellular uptake barrier to producing proteins containing **1** at higher yields, we evaluated the open transcription/translation environment of cell-free protein synthesis (CFPS).

Previously, by incorporating the *Mj*TyrRS/*Mj*tRNA$^{Tyr}_{CUA}$ pair developed by the Schultz lab into our *E. coli* based CFPS reactions, the unnatural amino acids *p*-azido-L-phenylalalnine, **2**, and *p*-acetyl-L-phenylalanine, **3**, were site-specifically incorporated into proteins (Figure 1) (*12*). **2** contains a terminal azide moiety which, like terminal-alkyne moiety of **1**, can be used with the CuAAC reaction for protein modification. However, unlike **1**, care must be taken to prevent UV and near-UV exposure to **2** before and after incorporation, as the terminal azide is destabilized by its neighboring aromatic ring and rapidly degrades upon exposure to UV or near-UV light (*28*). In cases where UV and near-UV light exposure is difficult to avoid, incorporation of the UV-insensitive **1** may be a better choice as it also facilitates site-specific bioconjugation by CuAAC. Also, the ability to incorporate site-specifically both the alkyne moiety by **1** and the azide moiety by **2** at significant yields provides a way to site-specifically conjugate two different proteins to each other in a one-step, linker-less manner as will be described in detail later.

In demonstrating site-specific incorporation of **1** with our CFPS reaction, superfolder green fluorescent protein (sfGFP) and *E. coli* dihydrofolate reductase (DHFR) were chosen as model proteins. Incorporation of **1** at surface-accessible locations

Table 1. CFPS Reaction Yields of Total Protein, Soluble Protein, Soluble Full-Length Protein, and Active Soluble Full-Length Protein

protein	total protein (μg/mL)[a]	soluble protein (μg/mL)[a]	full-length soluble protein (μg/mL)[b]	percent active full-length soluble protein (%)[c]
pPaGFP	1188 ± 50	978 ± 71	175 ± 16	109 ± 4.1
pPaDHFR	111 ± 9.4	86 ± 0.6	86 ± 0.6	116 ± 25
pAzGFP	1047 ± 71	801 ± 29	141 ± 5.3	99 ± 3.2
pAzDHFR	155 ± 10	129 ± 1.9	129 ± 1.9	90 ± 15

[a] The total and soluble protein yields were determined based on scintillation counting of TCA precipitated ^{14}C-labeled proteins as detailed in the Experimental Procedures. [b] The yield of full-length soluble protein was determined by densitometry using the autoradiogram of the SDS-PAGE gel loaded with the soluble fraction of the CFPS product. [c] The percent of active full-length soluble protein was determined from specific activity of soluble affinity purified protein compared to the reported specific activity of 45 units/mg for *E. coli* DHFR (*12*) and the specific activity of *in vivo* produced sfGFP. The number following ± symbol represents 1 standard deviation and $n \geq 3$ except for the soluble protein yield where $n = 2$.

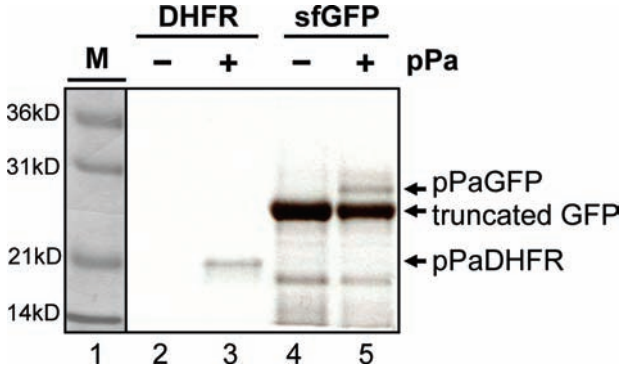

Figure 3. Verifying selectivity of *Mj*TyrRS^{pPa} for *p*-propargyloxyphenylalanine. Autoradiogram of SDS-PAGE gel of CFPS products when attempting to express pPaDHFR without **1** (lane 2), pPaDHFR with **1** (lane 3), pPaGFP without **1** (lane 4), and pPaGFP with **1** (lane 5). Lane 1 is the Coomassie stained SDS-PAGE image of the Mark 12 protein standard (Invitrogen) aligned with the autoradiogram. The molecular weight (MW) is 19kD for pPaDHFR, 27kD for pPaGFP, and 24kD for GFP truncated at the incorporation site of **1**.

(T216 for sfGFP and V10 for DHFR) was encoded by substituting in the amber stop codon. To facilitate incorporation of **1**, *Mj*TyrRS^{pPa} (*Mj*TyrRS specific for **1**), **1**, *E. coli*-extract containing *Mj*tRNA$^{Tyr}_{CUA}$ and other cofactors were combined in a cell-free protein synthesis reaction as detailed in the Experimental Procedures (Figure 2). Using this modified CFPS reaction, both pPaGFP (sfGFP with **1** incorporated at the T216 site) and pPaDHFR (DHFR with **1** incorporated at the V10 site) were produced. As shown in Table 1, the volumetric yield of full-length, soluble pPaGFP and pPaDHFR was over 8 times the highest reported yield for *in vivo* produced protein containing **1** (2 μg/mL in *E. coli* and 10 μg/mL in *S. cerevisiae*) (*16, 17*). The full-length soluble pPaGFP and pPaDHFR produced with CFPS were affinity purified and assayed for activity. The emission spectra of pPaGFP was identical to *in vivo* produced and affinity purified sfGFP (courtesy Boxer Lab, Stanford University), and both pPaGFP and pPaDHFR were found to be completely active (Table 1, Supporting Information Figure S2). The selectivity of the CFPS reaction for incorporation of **1** over other natural amino acids at the amber stop codon was also evaluated by excluding **1** from the CFPS reaction. High selectivity for **1** was verified, as full-length product of both pPaGFP and pPaDHFR was undetectable when **1** was excluded from the CFPS reactions; however, significant product was observed after **1** was added (Figure 3). Tryptic digestion of pPaDHFR and LC-MS further confirmed the incorporation of **1** at the location encoded by the amber stop codon (Supporting Information Figure S3). The volumetric yields listed in Table 1 were obtained from 0.5 mL reactions (43 μg pPaDHFR and 87.5 μg pPaGFP per 0.5 mL reaction), and similar yields were observed with 30 μL and 0.75 mL CFPS reactions. Also, the scalability of our base *E. coli* based CFPS reactions from 15 μL to 1 L without a decrease in protein production yield has previously been demonstrated (*29*).

As a comparison and to enable the direct protein-to-protein attachment that will be discussed later, **2** was also incorporated into sfGFP (pAzGFP) and DHFR (pAzDHFR) at the same location as **1** using CFPS. The same reagents were used to incorporate **2** as used with **1** with the exception of replacing *Mj*TyrRS^{pPa} with a *Mj*TyrRS specific for **2** (*Mj*TyrRS^{pAz}) and replacing **1** with **2**. Similar yields and activities of pAzGFP and pAzDHFR were obtained compared to pPaGFP and pPaDHFR (Table 1, Supporting Information Figure S2).

Optimization for Incorporation of *p*-Propargyloxyphenylalanine. As shown in Table 1, only 15% of the 1.2 mg/mL of protein produced in the pPaGFP cell-free reaction is full-length pPaGFP, 27 kD. The majority of protein (~1 mg/mL) produced is a truncated product that matches the molecular weight of sfGFP truncated at the amber stop codon (24 kD) (Figure 3). This suggests that the CFPS reaction has the potential to produce ~1 mg/mL of active pPaGFP; however, the ability to incorporate **1** at the amber stop codon is limiting. pAzGFP gave similar results with only 13% of the 1.0 mg/mL of protein produced corresponding to full-length soluble protein (Table 1). The production of pPaDHFR and pAzDHFR is also likely limited by the incorporation of the unnatural amino acid, as active DHFR production has been reported at yields of 930 μg/mL using a similar CFPS system (*12*). In the case of pPaDHFR and pAzDHFR, the relatively small difference in total and full-length yields is likely due to the short, truncated DHFR (9 amino acids long) being rapidly degraded by peptidases in the cell extract.

To optimize for incorporation of **1**, we first assessed temperature effects. The CFPS reactions are typically performed at the optimal *E. coli* fermentation growth temperature of 37 °C (*30*). Since translation is slower at lower temperatures, this might provide more time for the *Mj*tRNA$^{Tyr}_{CUA}$ to be charged or for the charged *Mj*tRNA$^{Tyr}_{CUA}$ to be accepted by the ribosome. Although *Mj*tRNA$^{Tyr}_{CUA}$ has been shown to be accepted by the *E. coli* ribosome, the *Methanococcus jannaschii* tRNA has a smaller variable loop (5 nucleotides) compared to the *E. coli* tRNA's larger variable loop (13 nucleotides), and this could decrease the affinity of the *E. coli* translational complex for *Mj*tRNA$^{Tyr}_{CUA}$ (*31*). Also, previous work incorporating **2** using a similar CFPS system demonstrated that reactions conducted at 30 °C provided higher yields by prolonging the duration of protein synthesis (*12*). The expression of pPaGFP responded similarly with double the amount of active pPaGFP produced at 30 °C (156 μg/mL, SD = 20 μg/mL) compared to 37 °C (75 μg/mL, SD = 17 μg/mL) (Figure 4AB). While the production rate of total protein and incorporation of **1** drops off rapidly after the first hour at 37 °C, the prolonged translation between hours 1 and 8 at 30 °C appears to be responsible for higher incorporation yields at 30 °C (over 80% of the active pPaGFP was produced during this period). Dropping the temperature further to 25 °C decreased total protein production by 68%, but did not significantly reduce the rate of **1** incorporation or reduce the total amount of protein containing **1** produced. At

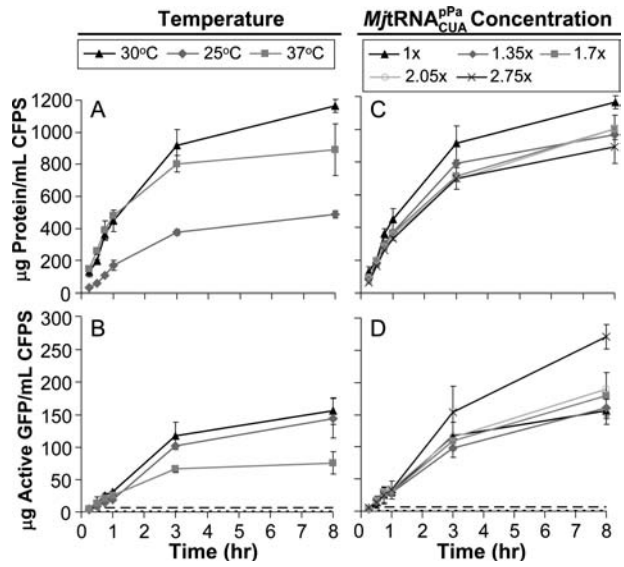

Figure 4. Effect of temperature and *Mj*tRNA$^{Tyr}_{CUA}$ concentration on cell-free protein synthesis yields of pPaGFP. The total protein production yields (full-length and truncated pPaGFP) (A,C) and active pPaGFP production yields (B,D) are shown over the course of an 8 h CFPS reaction at temperatures 25 to 37 °C (A,B) and tRNA concentrations 1 to 2.75 times the tRNA concentration in a standard 30 °C CFPS reaction incorporating **1** (C, D). Background fluorescence from the CFPS reaction (without expressing sfGFP) was insignificant (black, dotted line). Fluorescence due to 1 mg/mL of GFP truncated at the **1** incorporation site (black, dashed line) is also shown.

25 °C, incorporation of **1** is still limiting, as only 30% of the protein is produced as full-length active pPaGFP (Figure 4AB).

Another potential factor limiting **1** incorporation is the concentration of charged-*Mj*tRNA$^{Tyr}_{CUA}$ available to the ribosome. As *Methanococcus jannaschii* is a hyperthermophile that optimally grows at 85 °C (*32*), the activity of the *Mj*TyrRS^{pPa} may be significantly lower at the optimal CFPS temperature of 30−37 °C. Increasing the concentration of the enzyme *Mj*-TyrRS^{pPa} and/or the reactants *Mj*tRNA$^{Tyr}_{CUA}$ and **1** should increase the overall concentration of charged-*Mj*tRNA$^{Tyr}_{CUA}$, assuming the concentration of ATP is not limiting. We first assessed increasing the concentration of *Mj*TyrRS^{pPa} above the typical concentration of 1.6 mg/mL used in this study and found that 2- and 3-fold increases in *Mj*TyrRS^{pPa} concentration did not increase incorporation of **1** (results not shown). This result is not surprising, as the concentration of *Mj*TyrRS^{pPa} used in this study was five times greater than the concentration of TyrRS previously reported for incorporation of unnatural amino acids in a CFPS reaction (*12*).

We did not assess increasing the concentration of **1** in the CFPS reaction, as (1) the current 2 mM concentration of **1** in CFPS is close to its water solubility limit at 25 °C (1.9 mM) and (2) increasing **2** concentrations above 2 mM did not increase the yield of protein containing **2** (*12*). However, with an increase in the concentration of *Mj*tRNA$^{Tyr}_{CUA}$, the other reactant involved in charging *Mj*tRNA$^{Tyr}_{CUA}$ with **1** was assessed. The concentration of *Mj*tRNA$^{Tyr}_{CUA}$ is likely limiting, as (1) the CFPS environment is 20 times more dilute than the *E. coli* cytoplasm (*33*), and thus the concentration of *Mj*tRNA$^{Tyr}_{CUA}$ is also diluted 20 times relative to the *in vivo* system, and (2) in the *in vivo* system, the concentration of *Mj*tRNA$^{Tyr}_{CUA}$ was found to be limiting, as 30−40% higher yields of proteins containing unnatural amino acids were recently reported when the *Mj*tRNA$^{Tyr}_{CUA}$ was expressed at higher concentrations (*14*). To increase the *Mj*tRNA$^{Tyr}_{CUA}$ concentration in the CFPS reaction, the nucleic acid (including the *Mj*tRNA$^{Tyr}_{CUA}$) was extracted by ethanol precipitation from our *E. coli* lysate and added directly to the CFPS reaction. The amount of extra *Mj*tRNA$^{Tyr}_{CUA}$ added to the CFPS reaction was estimated on the basis of the relative concentrations of extracted tRNA compared to tRNA in the *E. coli* lysate (Supporting Information Figure S4). The addition of the extracted RNA increased the yield of active product containing **1**, although a modest drop in total protein production of ∼20% was observed (Figure 4CD). The most significant increase in **1** incorporation occurred at the highest *Mj*tRNA$^{Tyr}_{CUA}$ concentration estimated to be 2.75 times the original concentration. At this *Mj*tRNA$^{Tyr}_{CUA}$ concentration, the yield of active pPaGFP increased 75% to 271 μg/mL (SD = 19 μg/mL), which is 27 times greater than the highest published yield for protein containing **1** (Figure 4D) (*17*).

Although a substantial gain in the yield of pPaGFP was observed by increasing the *Mj*tRNA$^{Tyr}_{CUA}$ concentration, room for improvement remains, as only 30% of the total protein produced was active full-length pPaGFP. As the CFPS provides a unique environment with direct access to biochemical reactions (including translation and tRNA-charging), the CFPS is well-suited for continued work to study and increase the efficiency of unnatural amino acid incorporation. For example, the impact of the competition for the amber stop codon between **1**-charged-*Mj*tRNA$^{Tyr}_{CUA}$ and release factor 1 (an essential protein) could be assessed by removing the release factor 1 from the CFPS extract before the CFPS reaction. Also, CFPS provides the opportunity to simplify the system to assess different steps along a biochemical pathway. As an example, the *Mj*tRNA$^{Tyr}_{CUA}$ could potentially be charged with **1** at a higher temperature before being added to the CFPS reaction to directly assess the effect of **1**-charged-*Mj*tRNA$^{Tyr}_{CUA}$ concentration on the incorporation of pPa into proteins. Improvements made to the CFPS system could also be applied in further optimizing the incorporation of unnatural amino acids.

Direct Site-Specific Protein−Protein Conjugation. Proteins with **1** incorporated have a unique terminal alkyne moiety, which can be covalently conjugated to azido moieties with the copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC). The CuAAC reaction is considered the "cream of the crop" of click chemistries and has been widely used since its discovery (*34, 35*). The ability to perform the CuAAC at biologically friendly conditions (physiological temperature and pH) and achieve high conjugation efficiencies with relatively low reactant concentrations is particularly attractive for protein conjugation applications (*36*). The CuAAC reaction has been successfully used to bioconjugate proteins, enzymes, viruses, oligonucleotides, and cell surfaces for a number of applications including drug and gene delivery, bioseparation, and cell-surface display (*37, 38*).

With the ability to site-specifically incorporate either an alkyne (**1**) or azido (**2**) moiety, the CuAAC reaction could also be used to site-specifically conjugate proteins in a one-step reaction without using a chemical linker. Potential applications include (1) creating fusion proteins when a single polypeptide of the fusion partners does not express and/or fold correctly, (2) linking protein complexes together to form protein-based materials, and (3) decorating protein complexes such as virus-like particles for vaccine and drug delivery applications.

As proof of concept, pPaDHFR and pAzGFP were directly bioconjugated using the CuAAC reaction (Scheme 1). Both pPaDHFR and pAzGFP were anaerobically incubated overnight at room temperature with 1 mM of the Cu(I) complex tetrakis(acetonitrile)copper(I) hexafluorophosphate ([$(CH_3CN)_4$Cu]-PF_6) resulting in a conjugation yield of about 43% based on densitometry (Figure 5). However, after the CuAAC reaction, the activity of pPaDHFR was undetectable and the activity of pAzGFP dropped to only 8.7% (SD = 0.5%, n = 3) of the original activity. The control reactions mimicking the CuAAC

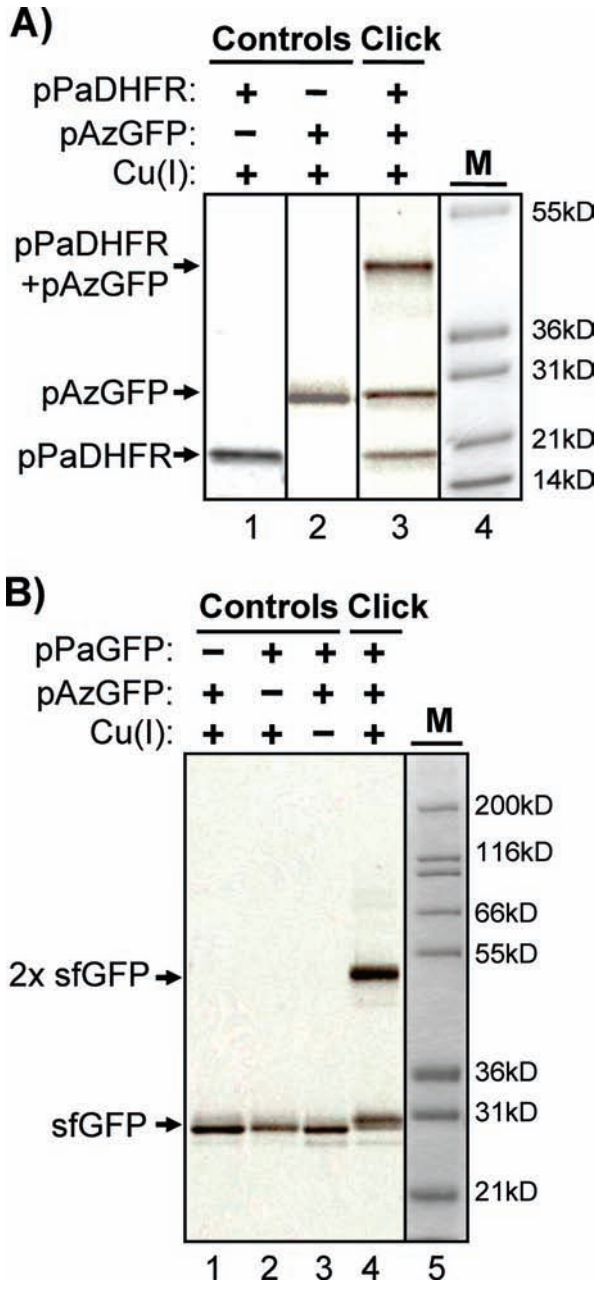

Figure 5. Copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition results. (A) Autoradiogram of the SDS-PAGE gel containing the CuAAC reaction product of pPaDHFR and pAzGFP (lane 3) and controls of pPaDHFR alone (lane 1) and pAzGFP alone (lane 2). In all cases, the Cu(I) complex concentration was 1 mM and the samples were incubated overnight anarobically. (B) Autoradogram of the SDS-PAGE gel containing the pPaGFP and pAzGFP CuAAC reaction product (lane 4). Controls were the combined pPaGFP and pAzGFP but without the Cu(I) complex (lane 1) and the pAzGFP (lane 2) or pPaGFP (lane 3) separately exposed to the Cu(I) complex. The concentration of the Cu(I) complex was 0.25 mM in all cases where the Cu(I) complex was added and samples were incubated for 8 h anaerobically. Lane 4 of A and lane 5 of B represent the Coomassie-stained Mark 12 protein standard aligned to the autoradiogram. The light band below sfGFP is likely truncated sfGFP (Figure 3).

reaction conditions but with pPaDHFR and pAzGFP in separate tubes also resulted in undetectable pPaDHFR activity and a drop in pAzGFP activity to only 14% (SD = 4%, $n = 3$) of the original activity. When pPaDHFR and pAzGFP were incubated anaerobically overnight without the Cu(I) complex, no loss in activity was observed, suggesting that the Cu(I) complex is the cause of the loss in protein activity. The inhibition of activity due to copper is not completely unexpected, as the addition of a few millimoles of copper ion has been reported to completely quench GFP fluorescence (*39*). In addition, the presence of the Cu(I) has been reported as a problem in a few other cases causing disassembly of some viruses, degradation of oligonucleotides, and cellular toxicity (*36, 37, 40*).

As sfGFP appears more resistant to the Cu(I) complex exposure than DHFR, direct pPaGFP-pAzGFP bioconjugation was used to evalutate the impact of lowering Cu(I) concentration on activity (Scheme 1). In addition to lowering the Cu(I) concentration, a tris-triazole ligand **4** (*27*) (Scheme 1) was added at 2 equiv of the Cu(I) concentration to increase the CuAAC reaction rate. The reaction time was also decreased to 8 h. A 75% reduction in the Cu(I) compound concentration to 0.25 mM increased post-Cu(I) compound exposure activity from 9% to 57% of the original activity, and pPaGFP-pAzGFP was directly conjugated at 62% reaction efficiency as determined by densitomitry (Figure 5).

As the CuAAC has been reported as less efficient at lower Cu(I) concentrations (*38*), we next sought to assess the impact of removing the Cu(I) compound before measuring activity to determine the reversibility of the inhibition. Similar to the results above, the pPaGFP and pAzGFP specific activity dropped by 30% after a CuAAC reaction with 0.25 mM Cu(I) complex and the tris-triazole ligand **4** when compared to a control where the Cu(I) complex was not added. However, post CuAAC reaction removal of the Cu(I) complex using a G-25 desalting column restored the specific activity of the sfGFP mixture (conjugated pPaGFP-pAzGFP, unreacted pPaGFP, and unreacted pAzGFP) to pre-Cu(I) complex exposure levels (Figure 6CD).

To further confirm that direct conjugation of pPaGFP to pAzGFP without a chemical spacer did not inhibit activity, conjugated pPaGFP-pAzGFP was separated from the unconjugated monomers using a 2.5 mm × 250 mm Superdex75 size exclusion column (Figure 6B,D). The specific activity of covalently conjugated pPaGFP-pAzGFP (lane 5 of Figure 6D) was similar to the specific activity of monomeric pPaGFP and pAzGFP (Figure 6C and lane 8 of Figure 6D), with the measurements within 1 standard deviation of each other. A similar specific activity was also measured from size exclusion fractions 6 and 7 which contained a mixture of conjugated and unconjugated pPaGFP and pAzGFP. On the basis of these results, it appears that the effect of the Cu(I) complex on the activity of pPaGFP and pAzGFP is reversible upon removal of the Cu(I) complex after the CuAAC reaction. In addition, direct protein−protein conjugation without a chemical linker as a spacer did not inhibit sfGFP specific activity. This is the first time to our knowledge that proteins have been site-specifically conjugated without a chemical linker using a single CuAAC reaction.

Although the CuAAC worked effectively in the above protein−protein conjugation and for the majority of applications previously attempted, there are a few cases where the Cu(I) catalyst has been reported to be problematic in causing disassembly of some macromolecular structures, degradation of oligonucleotides, and cellular toxicity (*34, 36−38, 40*). To minimize or eliminate the negative effect of Cu(I) in these instances, our laboratory and others are working to increase the reaction efficiency while reducing the reaction time and the concentration of Cu(I) catalyst needed. It has recently been demonstrated that, by applying an electrochemical potential, a CuAAC reaction was performed with 98% conjugation efficiency in 15 min with 0.1 mM Cu(I) (*36*). Also, chemical additives, such as the tris-triazole ligand **4** used in this work, can stabilize the less stable Cu(I) from oxidizing to the Cu(II) oxidation state. Another alternative being developed is the use of a copper-free CuAAC reaction that uses a strained cycloalkyne which conjugates with high chemoselectivly to azido

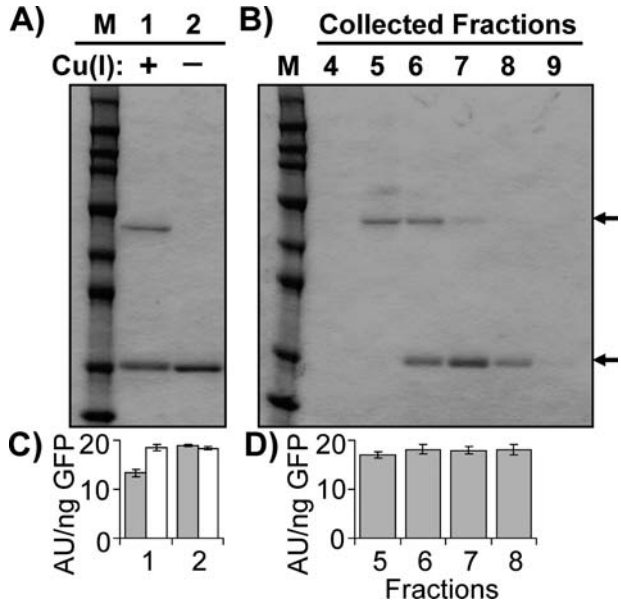

Figure 6. Restoration of the specific activity of sfGFP. (A) Coomassie-stained SDS-PAGE gel containing the pPaGFP and pAzGFP CuAAC reaction product with 0.25 mM Cu(I) complex (lane 1) and a control reaction product performed identically to the CuAAC but without the Cu(I) complex (lane 2). Lane M was loaded with Novex Sharp Prestained Standard (Invitrogen, bottom to top band kDs: 20, 30, 40, 50, 60, 80, 110, 160, 260). (B) Coomassie-stained SDS-PAGE gel containing the 0.1 mL fractions collected off the 2.5 mm × 250 mm Superdex75 size exclusion column. Lanes 4−9 represent fractions 4−9, as the radiolabeled protein was detected predominantly in only fractions 5−8, although fractions 1−28 were collected and tested for the presence of sfGFP. Lane M was loaded with the same protein standard and has the same band distribution as A. Arrows represent the expected location of sfGFP (lower) and covalently dimerized sfGFP (upper). (C) Specific activity of sfGFP in emission AU (arbitrary units) per nanogram of sfGFP following the CuAAC reaction (1, same as lane 1 of A) and the reactants without the Cu(I) complex (2, same as lane 2 of A). Gray bars represent specific activity after CuAAC reaction, and white bars represent specific activity after CuAAC and G-25 desalting (GE Healthcare) to remove the Cu(I) complex. (D) sfGFP specific activity of the 0.1 mL fractions 5−8 collected from the Superdex75 size exclusion column. Note that the size exclusion column should separate the sfGFP from the Cu(I) complex. The error bars in C and D represent 1 standard deviation of $n \geq 3$ measurements. Note: the lower conjugation efficiency of 37% (measured by densitometry) is attributed to a longer exposure time to UV light experienced by this pAzGFP reactant compared to the pAzGFP used in the previous reactions (Figure 5).

moieties in the absence of Cu(I) (*41*). By synthesizing an unnatural amino acid containing the strained cycloalkyne group and evolving a *Mj*TyrRS specific for this unnatural amino acid, the copper-free CuAAC could also be employed for site-specific, linker-less protein−protein conjugation.

CONCLUSIONS

We have demonstrated for the first time to our knowledge a linker-less one-step protein−protein bioconjugation that is site-specific and requires minimal protein mutagenesis (only an insertion or substitution of *p*-propargyloxyphenylalanine, **1**, and *p*-azido-L-phenylalanine, **2**). The conjugation uses the copper(I)-catalyzed azide−alkyne [3 + 2] cycloaddition (CuAAC), which is considered biocompatible, as it is performed at physiological conditions with high conjugation efficiencies at low reactant concentrations (*36, 37*). Initial work verified that pPaDHFR and pAzGFP were conjugated at 43% efficiency and the addition of a tris-triazole ligand **4** resulted in a 62% conjugation efficiency for pPaGFP+pAzGFP. Although a reduction in protein activity due to exposure to Cu(I) did occur, post-CuAAC removal of Cu(I) restored protein activity. Also, the direct protein−protein conjugation without a chemical spacer did not appear to inhibit protein activity. Current work to increase conjugation efficiency while seeking to minimize the duration and concentration of Cu(I) exposure during CuAAC for Cu(I) sensitive applications is underway. A copper-less CuAAC could provide an effective solution for Cu(I) sensitive applications. By increasing the conjugation efficiency and expanding the technology to copper sensitive applications, the one-step linker-less conjugation provides an attractive technology to overcome the current conjugation limitations requiring (1) significant mutagensis to enable site-specific conjugation, (2) a chemical linker, and/or (3) multiple reactions with intermediate purifications.

The **1**- and **2**-incorporated proteins used for direct conjugation were produced using cell-free protein synthesis (CFPS) reactions. The CFPS environment was shown to be particularly useful when cellular uptake of an unnatural amino acid such as **1** might limit incorporation. This has led to a 27-fold improvement of protein incorporated with **1** compared to the highest reported yields for *in vivo* incorporation of **1** (*17*). Also, as demonstrated, direct access to the tRNA-charging and translation environment in the CFPS reaction allows the researcher to rapidly evaluate potential limitations to unnatural amino acid incorporation for optimization of product synthesis. Finally, insights gained from the CFPS system could potentially be used in developing a better *in vivo* system for incorporating unnatural amino acids.

ACKNOWLEDGMENT

We would like to thank the Zhenan Bao Lab at Stanford University, specifically Ying Jiang, for help with the synthesis of *p*-propargyloxyphenylalanine. The Christopher E. D. Chidsey Lab of Stanford University kindly supplied the tris-triazole ligand used to accelerate the CuAAC reaction. Kevin P. Kent and Steven G. Boxer of Stanford University kindly provided the gene encoding for sfGFP and *in vivo* produced sfGFP. Chris Adams and Theresa McLaughlin of the Vincent Coates Foundation Mass Spectrometry Laboratory, Stanford University (http://mass-spec.stanford.edu) performed the mass spectroscopy assays and analysis in this work.

Supporting Information Available: Plasmid and sfGFP sequences. Emission profile of sfGFP, pPaGFP, and pAzGFP. Mass spectra of **1** and digested pPaDHFR. *Mj*tRNA$^{Tyr}_{CUA}$ concentration estimate. This material is available free of charge via the Internet at http://pubs.acs.org.

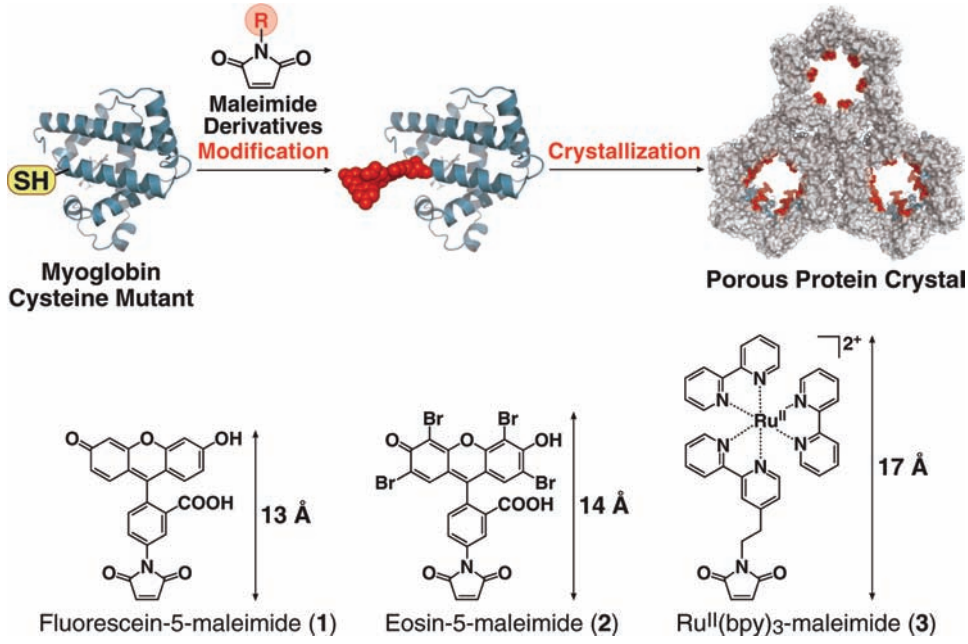
Protein assemblies have attracted increasing attention for construction of biohybrid materials. Protein crystals can also be regarded as solid protein assemblies. The present work demonstrates that protein crystals can be employed as porous biomaterials by site-specific modifications of the crystals of recombinant sperm whale myoglobin mutants. The myoglobin crystals of space group *P*6 provide hexagonal pores consisting of the building blocks of six Mb molecules, which form a pore with a diameter of 40 Å. On the basis of the lattice structure of the Mb crystals, we have selected appropriate residues located on the surface of the pores for replacement with cysteine. This enables modification of the pore surface via coupling with maleimide derivatives. We have succeeded in crystallizing the modified Mb mutants, retaining the *P*6 lattice, and consistently aligning nanosized functional molecules such as fluorescein, eosin, and $Ru(bpy)_3$ into the hexagonal pores of the Mb crystals. Our strategy for site-specific modification of protein crystal pores is applicable to various protein crystals with porous structures. We believe that modified porous protein crystals will provide attractive candidates for novel solid materials in nanotechnology applications.

INTRODUCTION



It has been recently recognized that the design of protein assemblies holds promise for construction of biohybrid materials which have the potential to play crucial roles in the field of biotechnology (*1–8*). Efforts to modify nanosized space of caged, tubular, and two-dimensional protein assemblies have recently attracted increasing attention because nanospaces are expected to provide sufficient space to accommodate large and complex functional molecules for biotechnological applications (*3, 6, 8–13*). Protein crystals can also be regarded as solid protein assemblies. Malgolin et al. have indicated that protein crystals consist of highly ordered protein assemblies with unique nanosized porous structures (*14, 15*). The protein crystals comprise solvent-filled pores ranging from 30% to 65% of the total crystal volume with the advantageous properties of high porosity (0.5−0.8), large surface area (800−2000 m^2/g), and a wide range of pore sizes (20−100 Å). These properties comparable to typical porous materials suggest that pores of protein crystals are able to provide enough spaces to promote various reactions (*15–17*).

Protein crystals are able to serve as heterogeneous catalysts even under extreme conditions including high temperature, organic solvents, and extreme acidity or basicity when stabilized by cross-linkages (*14*). A recent report has described that soaking of cross-linked virus crystals in a buffer solution containing metal ions causes the metal ions to be deposited within the porous spaces of the crystals and converted into metallic materials in the presence of reducing reagents (*18*). It has been recognized that transport of water, ions, and organic molecules in protein channels are crucial processes in various biological reactions. Experimental and theoretical studies of diffusion and absorption of small molecules in porous protein crystals have been reported (*19, 20*). These reports suggest that porous protein crystals may be useful as biohybrid materials if the pore surfaces could be selectively modified by a combination of site-directed mutagenesis and bioconjugation techniques. However, there have been no reports of modification of the pore surfaces of porous protein crystals because the consensus has been that even small a amount of modified proteins (<10 mol %) would have serious effects on the nucleation process and the quality of the crystals (*21*). In order to overcome these problems, we demonstrate site-specific modifications of the porous protein crystals of recombinant sperm whale myoglobin (Mb) mutants by a cysteine−maleimide coupling reaction as shown in Scheme 1 (*22, 23*). The Mb crystals belong to space group *P*6 and provide hexagonal pores consisting of six Mb molecules, which provide a pore with a diameter of 40 Å (Figure 1) (*22*). On the basis of the lattice structure of the Mb crystal, we selected appropriate residues on the surface of the pores for replacement with cysteine to modify the pore surface by the coupling reaction with maleimide derivatives. This is necessary because Mb does not have any natural cysteine residues (*22*). We have succeeded in crystallizing the modified Mb mutants which retain the *P*6 lattice and have reproducibly aligned functional molecules into the hexagonal channels of the Mb crystals. We have characterized the structures and the properties

EXPERIMENTAL PROCEDURES

Materials. Reagents were purchased from Molecular Probes, Nacalai Tesque, Wako, TCI, Sigma-Aldrich, and Hampton Research and used without further purification. Synthesis of Ru^{II}(bpy)$_3$-maleimide (**3**) is described in Supporting Information.

Modification of Mb Cysteine Mutants with Maleimide Derivatives. Myoglobin cysteine mutant genes were prepared using a Stratagene Quikchange Multi Site kit. The expression and purification of proteins were performed as reported previously (*24*). DMF solution of 5 equiv maleimide derivative was added to a solution of Mb cysteine mutant in 10 mM Tris−HCl pH 7.0. The reaction mixture was stirred at 18 °C for 2 h in the dark. The mixture was centrifuged and passed through Sephadex G-25 equilibrated with 15 mM potassium phosphate pH 6.0. The resulting solution was loaded onto a CM52 column on an ÄKTA explorer 10S FPLC system (GE Healthcare). The protein was eluted with a linear gradient of 15 mM potassium phosphate buffer (pH 6.0) and 30 mM potassium phosphate buffer (pH 9.0). The protein concentration of samples was determined by the pyridine hemochromogen method (*25*). The concentration of **1** was estimated by measuring the absorbance at 493 nm (extinction coefficient 83 000 cm^{-1} M^{-1}) (Supporting Information Figure S1).

Crystallization of Mbs Modified with Maleimide Derivatives. Crystallization of Mbs modified with maleimide derivatives was carried out as described previously (*22*). The purified protein in 10 mM potassium phosphate buffer (pH 7.5) was concentrated to 30 mg/mL. Crystals were obtained using the sitting-drop vapor diffusion method. A 2 μL protein solution was added to a 4 μL reservoir solution (2.5−2.7 M ammonium sulfate in 20 mM Tris/HCl pH 9.0) and equilibrated against a 1000 μL reservoir solution. The hexagonal crystals grew within one week (0.15 × 0.15 × 0.05 mm^3). The X-ray data collection and crystallographic refinement are described in the Supporting Information. The coordinate of **1**·K102CMb has been deposited in the Protein Data Bank under accession codes of 3A2G.

Soaking of WTMb Crystals in the Mother Liquid Buffer Containing Uranine and Eosin Y. WTMb crystals were placed in mother liquor of crystallization (2.5 M ammonium sulfate in 20 mM Tris/HCl pH 9.0) containing dye molecules for 16 h at 4 °C. Then, the crystals were soaked in solution of 2.5 M

ammonium sulfate in 20 mM Tris/HCl pH 9.0 for 3 days at 4 °C. The soaking solution was changed two times during this process.

Time-Resolved Luminescence Spectroscopy in Single Protein Crystal of 3•K102CMb. A specialized microspectrophotometer was constructed to measure time-resolved spectra in single protein crystals. A crystal was briefly immersed in a cryoprotectant solution that consisted of 20% (v/v) glycerol and 2.6 M ammonium sulfate in 20 mM Tris/HCl pH 9.0. Then, the crystal was mounted to a Mounted CryoLoop and set in a helium chamber at 100 K. The crystal was excited with 355 nm (0.15 mJ/cm^2, 4 ns laser pulse) generated from a Q-switched Nd:YAG laser (Quantel Brilliant). The emission decay of excited state of **3** in **3**•K102CMb crystals was monitored at 580 nm.

Physical Measurements. UV−vis spectra were recorded on a Shimadzu UV-3101PC UV/vis spectrophotometer. ESI-TOF mass spectra were measured on a LCT-Premier XE (Waters, UK) and CsI (1 mg/mL) in 50% H_2O/CH_3CN was used for mass scale calibration. All samples were dialyzed against 5 mM ammonium acetate buffer at 4 °C. Fluorescence measurements were obtained on a F-7000 fluorescence spectrophotometer (Hitachi) at 12 °C in 20 mM Tris-HCl pH 9.0. A specialized microspectrophotometer was constructed to measure UV−vis and fluorescence spectra in single crystals (Bunkoh-keiki Co., LTD). Thin protein crystals (0.15 × 0.15 × 0.01 mm^3) were used for the measurements.

RESULTS AND DISCUSSION

We replaced Lys102 and Gly153 with cysteine residues because these residues (i) do not participate in intermolecular interactions in the crystal and (ii) are exposed to the internal surface of the hexagonal pores in spite of size and hydrophobicity of the residues (Figure 1). Thus, two cysteine mutants, K102CMb and G153CMb, were prepared for conjugation with functional molecules on the interior surface of the hexagonal pores in the Mb crystal lattice. To elucidate the effects of hydrophobicity, charge, and size of functional molecules on the crystal formation of the Mb mutants, fluorescein-5-maleimide (**1**) and eosin-5-maleimide (**2**) were selected (Scheme 1). These compounds have different hydrophobicity. Since fluorescent molecules are known to be very sensitive to the surrounding environment, marked changes in their absorption and fluorescence spectra would be expected if the molecules interact with each other (*26*). Furthermore, $Ru^{II}(bpy)_3$-maleimide (**3**), which has a positive charge, was chosen to estimate the effects of charge and larger size (17 Å) on the modification of the pores (Scheme 1).

In order to modify K102CMb with **1**, a DMF solution of **1** was added to a buffer solution of K102CMb at pH 7.0 as previously reported (*23*). After stirring for 2 h at 18 °C, the mixture was purified by column chromatography (G-25 and CM-52). **1**•K102CMb was obtained with an isolated yield of 33%. The UV/vis spectrum of **1**•K102CMb has two peaks at 409 and 493 nm, which originate from the Soret band of Fe(III)-heme and the fluorescein molecule, respectively, in a 1:1 ratio, as estimated from their extinction coefficients (see Supporting Information Figure S1). The ESI-TOF mass spectrum of purified **1**•K102CMb has a peak assignable to **1**•K102CMb (measured: 18 348 Da, calcd: 18 348 Da) (see Supporting Information Figure S2). The modification site of **1**•K102CMb was confirmed by the MALDI-TOF-MS spectra of the **1**•K102CMb fragments digested with Lys-C *Achromobacter* and chymotrypsin after purification with a reverse-phase HPLC (see Supporting Information). These results indicate that K102CMb is conjugated with **1**. The other conjugates, **2**• and **3**•K102CMb and **1**•G153CMb, were prepared under the same conditions. The ESI-TOF mass spectra of **2**•K102CMb, **3**•K102CMb, and **1**•G153CMb indicate molecular weights of 18 664 Da (calcd: 18 663 Da), 18 612 Da (calcd: 18 613 Da), and 18 419 Da (calcd: 18 419 Da), respectively.

Crystallization of the purified **1**•, **2**•, and **3**•K102CMbs and **1**•G153CMb was carried out according to a previously reported method for recombinant sperm-whale myoglobin (*22*). The crystal structures of **1**•, **2**•, and **3**•K102CMb and **1**•G153CMb were refined to resolutions of 1.75, 1.79, 1.35, and 1.40 Å, respectively, with the space group *P*6 (Table 1). The root-mean-square deviations (rmsds) for C_αs from WTMb were 0.34, 0.26, 0.34, and 0.52 for **1**, **2**, and **3**•K102CMb and **1**•G153CMb, respectively (*22*). The results indicate that perfect modification of the pore surfaces of the *P*6 lattice Mb crystals has been achieved by crystallization of the modified Mb mutants.

The electron density map of **1**•K102CMb indicates a clear $2|F_o| - |F_c|$ electron density at the K102C residue. This is consistent with the presence of two conformations of the maleimide moiety of **1** (Figure 2a). The electron density maps of **2**• and **3**•K102CMb showed that $2|F_o| - |F_c|$ electron densities appear immediately above the sulfur atoms of the cysteine residues at position 102 as observed in **1**•K102CMb, while these densities were too low to fit the models of **2** and **3** (Figure 2b,c). We could not determine the exact location of the G153C residue modified with **1** because the electron density of residues 151−153 is disordered as shown in Figure 2d. In addition, relative to WTMb, conformational changes of the residues surrounding the fluorescent moieties were not observed. These results suggest that the functional moieties can be oriented in

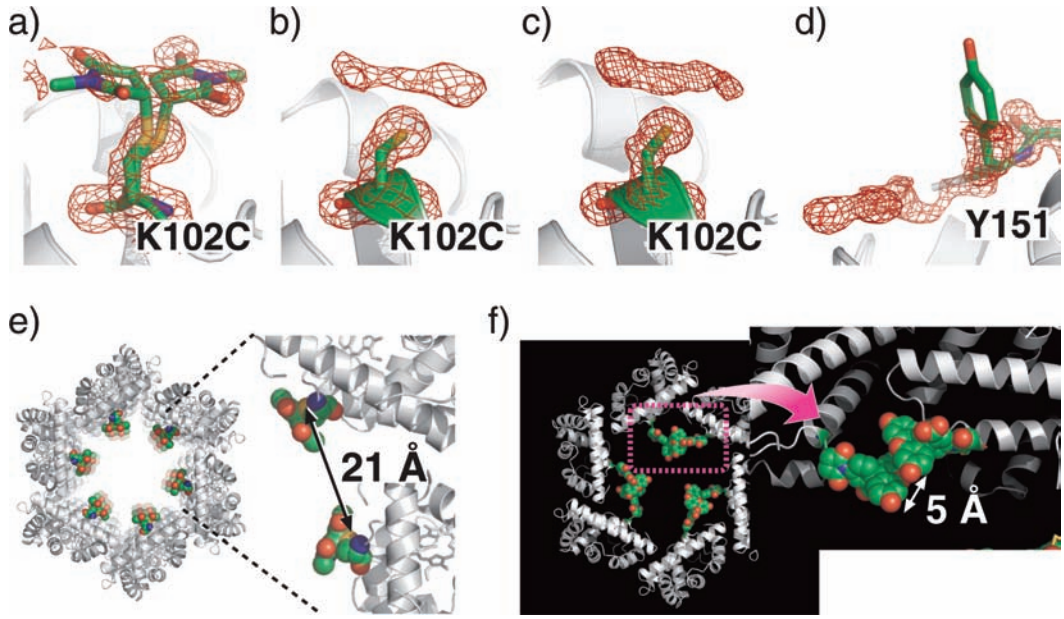

Figure 2. Crystal structures of (a) **1**•K102CMb, (b) **2**•K102CMb, (c) **3**•K102CMb, and (d) **1**•G153CMb. Close-up views of the K102C and the G153C residues with the $2|F_o| - |F_c|$ electron density at the modified cysteine residues at the 1 σ level are shown in red. (e) Crystal packing diagram of **1**•K102CMb. The distance between two cysteinyl sulfur atoms at position 102 of two adjacent Mb molecules is indicated by the arrow. (f) Proposed structure of fluorescein dimers fixed in the hexagonal pores of **1**•K102CMb.

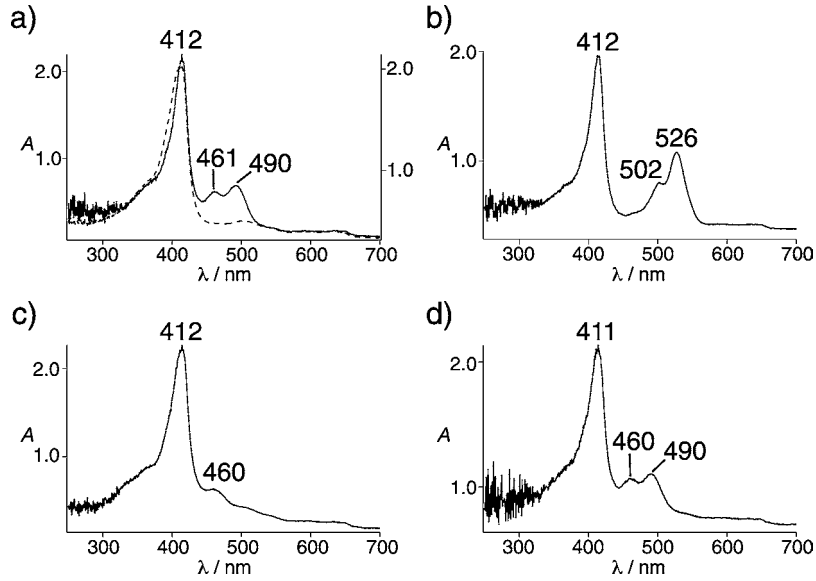

Figure 3. UV/vis spectra of the crystals of (a) **1**•K102CMb (solid line) and WTMb (dashed line), (b) **2**•K102CMb, (c) **3**•K102CMb, and (d) **1**•G153CMb.

several directions at the conjugation sites, regardless of their hydrophobicity, charge, and size, because they are not involved in any specific interactions with nearby residues.

In order to evaluate the environment in the proximity of **1**, the absorption spectra of **1**•K102CMb and **1**•G153CMb were measured in the crystal state (Figure 3). The absorption spectrum of the crystal of **1**•K102CMb has three absorption maxima at 412, 461, and 490 nm (Figure 3a), while **1**•K102CMb in solution has two absorption maxima at 409 and 493 nm derived from heme and the **1** moiety, respectively (Supporting Information Figure S1). The Soret bands at 412 nm in the crystal state and 409 nm in solution indicate that the coordination structure of the five-coordinate high-spin Fe(III)-heme in solution is retained in the crystals (*27*). The new peaks at ca. 460 nm of **1**•K102CMb and **1**•G153CMb were exclusively observed in the crystal state due to the formation of a ground-state complex (H-type dimer) of the fluorescein moieties (Figure 3a,d) (*28*). In the **1**•K102CMb crystal pore, the fluorescein moieties, which are conjugated to cysteine residues, appear to form an H-type dimer in parallel planes placed at a distance of ca. 5 Å as shown in Figure 2f (*28*), even though the distance between the two sulfur atoms of cysteine 102 residues on adjacent Mb molecules is 21 Å (Figure 2e). This is a somewhat unexpected result in light of a previous report of an undecapeptide with two fluorescein molecules conjugated to two amines whose nitrogen atoms are separated by a distance of 13.6 Å (*29, 30*). In this molecule, the fluorescein moieties are unable to form a dimer in solution due to the small dimerization constant of fluorescein and the relative flexibility of the undecapeptide (*29, 30*). Our observations of **1**•K102CMb indicate that even the small dimerization constant of fluorescein is enough to facilitate the formation of the dimer within the Mb crystal pore. Moreover, upon soaking the K102CMb crystals in the mother liquid buffer containing 10 mM fluorescein sodium salt for 16 h, only 0.01 free-fluorescein molecule/Mb was

observed to remain inside the pore space without dimer formation after several instances of equilibration with the mother liquid buffer without the fluorescein salt. These results indicate that the covalent conjugation of **1** into the Mb crystal pores restricts the orientation of the fluorescein moieties. Thus, the double conformation of **1** in **1**•K102CMb (Figure 2a) appears to be caused by the dimer formation with the **1** moiety of the other Mb molecule, which is in parallel orientation in the Mb crystal pores as shown in Figure 2f (*28*, *31*). The dimer formation of **1** in **1**•G153CMb crystals appears to be due to the restricted mobility of the peptide fragment (151−153) conjugated with the **1** moiety in the pore space despite the disorder of the fragment (Figure 2d).

It is also concluded that the eosin moiety (**2**) in the **2**•K102CMb crystal forms the H-type dimer structure which is similar to **1** in the **1**•K102CMb crystal (Figure 2f). Evidence for this assignment is provided by the characteristic absorption peaks at 502 and 526 nm (Figure 3b) (*30*). These results suggest that, when the fluorescent moieties are conjugated at the appropriate positions of the Mb crystal pores, they are able to accumulate and form dimers regardless of the hydrophobicity of the fluorescent molecules. The absorption peak at 460 nm of **3**•K102Mb shows that the coordination structure of $Ru^{II}(bpy)_3$ is retained within the pore (Figure 3c) (*26*). The $Ru^{II}(bpy)_3$ complex in the **3**•K102CMb crystal exhibits an emission peak at 580 nm with excitation at 355 nm. The emission decay of the excited state of **3** (^{3}MLCT) in the **3**•K102CMb crystal exhibits two components with short (1.6 μs, 66%) and long (10.4 μs, 33%) emission lifetimes at 100 K. These components are assignable to the bimolecular (triplet−triplet annihilation) and monomolecular reactions of ^{3}MLCT of **3**, respectively, as observed in the $[Ru^{II}(bpy)_3]^{2+}$ in micelles or the crystal state (*32*, *33*). The predominant bimolecular reaction suggests that $[Ru^{II}(bpy)_3]^{2+}$ complexes are closely packed with each other in the **3**•K102CMb crystal, although we expect that **3** cannot form a dimer structure in the pores of the Mb crystals because the dimer of $[Ru(bpy)_3]^{2+}$ molecules is not observed even if they are densely packed in the crystal state of $[Ru(bpy)_3](PF_6)_2$ (*34*).

In conclusion, we have succeeded in accumulating nanosized functional molecules into the hexagonal pores of Mb crystals with high efficiency by crystallization of Mb mutants covalently conjugated to extrinsic functional molecules. The results demonstrate that the process of crystallization of the modified Mb mutants is not affected by hydrophobicity or charge state of the functional molecules when conjugated to the specifically designed Mb sites. Moreover, this method provides for fixation of molecules which cannot be absorbed by soaking techniques, into the Mb crystal pores. Our strategy for site-specific modification of protein crystal pores is applicable to various protein crystals with porous structures. We believe that modified porous protein crystals will provide attractive candidates for novel solid materials in nanotechnology applications.

ACKNOWLEDGMENT

Received July 14, 2009; Revised Manuscript Received December 22, 2009

Computer modeling approaches to identify new inhibitors are essentially a very sophisticated and efficient way to design drugs. In this study, a bivalent nonpeptide intergrin $\alpha_v\beta_3$ antagonist (bivalent IA) has been synthesized on the basis of an in silico rational design approach. A near-infrared (NIR) fluorescent imaging probe has been developed from this bivalent compound. *In vitro* binding assays have shown that the bivalent IA ($IC_{50} = 0.40 \pm 0.11$ nM) exhibited improved integrin $\alpha_v\beta_3$ affinity in comparison with the monovalent IA ($IC_{50} = 22.33 \pm 4.51$ nM), resulting in an over 50-fold improvement in receptor affinity. NIR imaging probe, bivalent-IA-Cy5.5 conjugate, also demonstrated significantly increased binding affinity ($IC_{50} = 0.13 \pm 0.02$ nM). Fluorescence microscopy studies showed integrin-mediated endocytosis of bivalent-IA-Cy5.5 in U87 cells which was effectively blocked by nonfluorescent bivalent IA. We also demonstrated tumor accumulation of this NIR imaging probe in U87 mouse xenografts.

INTRODUCTION

Integrins, a family of cell adhesion molecules, are involved in a wide range of cell−extracellular matrix (ECM) and cell−cell interactions (*1*, *2*). Up to now, 18 α and 8 β subunits have been described, which assemble into 24 different receptors (*3*). Among them, integrin $\alpha_v\beta_3$ has been intensively studied due to its important role in tumor angiogenesis and tumor metastasis. It is highly expressed on activated tumor endothelial cells and fast-growing tumor cells but not resting endothelial cells and normal organs; the receptor is therefore suggested as a molecular target for tumor therapy and imaging. Targeting $\alpha_v\beta_3$ by directly inhibiting its function is potentially an effective strategy for cancer treatment. Cyclic arginine-glycine-aspartic acid (RGD) peptide, Vitaxin (MedImmune), and cilengitide (EMD Serono) are currently undergoing clinical trials with melanoma and glioblastoma multiforme patients (*4*, *5*). Although a series of monomeric and multivalent RGD peptides have been reported as an anchor for targeting $\alpha_v\beta_3$ in molecular imaging, nonpeptide antagonists were rarely used and few of them have used rational design to construct the optimal multivalent integrin $\alpha_v\beta_3$ ligands (*6*, *7*). In this report, we describe the synthesis and evaluation of a bivalent nonpeptide small molecule intergrin $\alpha_v\beta_3$ antagonist based on an in silico rational design approach. A near-infrared (NIR) fluorescent imaging probe has been developed for tumor angiogenesis imaging from this bivalent compound. We demonstrated the improved receptor binding affinity, receptor binding specificity of the bivalent IA, and a promising tumor accumulation of the NIR bivalent IA imaging probe in mouse xenografts.

Previously, we have developed an integrin $\alpha_v\beta_3$ targeting small molecular fluorescent probe derived from a small molecule $\alpha_v\beta_3$ antagonist, 4-[2-(3,4,5,6-tetrahydropyrimidine-2-lamino)-ethyloxy]benzoyl-2-(*S*)-aminoethylsulfonyl-amino-*h*-alanine (Figure 1, IA) (*8*). We have also developed a polymerized liposome-based vascular targeted nanoparticle delivery system using IA as tumor targeting ligand while carrying a payload for simultaneous imaging and therapy (*9*). In this study, we used IA as parent compound and constructed a bivalent ligand with a computer modeling designed linker to enable multivalent ligands to mimic, compete with, or inhibit natural interactions. Linker length and rigidity can affect the multivalent ligand−receptor interaction. In addition, the linkers used should have good physicochemical properties such as high stability and low toxicity. Hence, we chose carbon chain as the backbone of linkers and studied linkers with different lengths by computer simulation to predict the optimal structure for bivalent ligands followed by chemical synthesis and *in vitro* and *in vivo* validation (Figure 1).

Considering more avid binding could improve the tumor targeting properties, we further developed a NIR optical imaging probe based on the bivalent IA for tumor $\alpha_v\beta_3$ integrin imaging. The utilization of NIR probes in cancer imaging strategies has attracted wide attention, because light scattering in tissue decreases with the reciprocal of the fourth power of wavelength and hemoglobin has minimal absorbance and autofluorescence in the NIR window (*10*, *11*). NIR imaging technology is relatively inexpensive and absent the biological effects of radioactive probes. In this investigation, our plan was to develop a cyanine dye (Cy5.5) conjugated NIR fluorescent $\alpha_v\beta_3$ bivalent imaging probe (bivalent-IA-Cy5.5) with strong and specific binding. If successful, this imaging probe has great potential for early detection of tumors and micrometastatic lesions.

EXPERIMENTAL PROCEDURES

General. All solvents and reagents were purchased from commercial sources and used without further purification. ^{1}H NMR and ^{13}C NMR were obtained on a Bruker Ultrashield at 300 and 75 MHz, respectively. Chemical shifts were reported in ppm (δ) downfield of tetramethylsilane and coupling constants were given in hertz. The purification of the crude product was carried out on a semipreparative reversed-phase high-perfor-

mance liquid chromatography (HPLC) system equipped with a diode array UV−vis absorbance detector (Agilent 1200 HPLC system). Mass spectral data were recorded on a ThermoFinnigan LCQ Fleet using electrospray as the ionization method. U-87 glioblastoma cells were obtained from American Type Culture Collection and were grown in Dulbecco's Modified Eagle's Medium DMEM (DMEM) supplemented with 10% fetal bovine serum (FBS) at 37 °C in humidified atmosphere.

Computer Modeling. The *AutoDock* program (version 3.0.5) was used for docking calculations (*12*). The graphical program *SYBYL* (version 16.91, Tripos, Inc.) was used for model building of the ligand structures, to generate missing hydrogen atoms and assign partial charges for protein targets used in AutoDock runs, and for energy minimization of initial ligand structures. Structural figures were generated using *WebLab Pro*.

Protein Coordinates. The structure of extracellular segment of integrin $\alpha_v\beta_3$ (PDB entry 1jv2) was used for the docking simulations of integrin $\alpha_v\beta_3$. The extracellular segment of the human integrin structure contains two subunits α (957 residues) and β (692 residues). The $\alpha_v\beta_3$ when complexed with Arg-Gly-Asp (RGD) reveals that the pentagonal peptide inserts into a crevice between the propeller and βA domains on the integrin head (*4*). The RGD sequence makes the main contact area with the integrin, and each residue participates extensively in the interaction, which is completely buried in the protein interior. For our simulations, we selected subunit β, and used Glu^{220}, Asn^{215}, Asp^{217}, and Pro^{219} as the target coordinate for binding, as they are in close contact with RGD. No water molecules were included. Sybyl was used to add essential hydrogens and assign partial charges from the Kollman united-atom force field to the target protein.

Ligand Coordinates. The structures of bivalent-IA-Cy5.5 were built in SYBYL Biopolymer package and energy minimized with MMFF94 force field by 100 steps. The orientations of ligands were overlaid on the integrin $\alpha_v\beta_3$ in the crystal structure to allow similar starting coordinates to be used. Prior to docking runs, all ligand structures were translated arbitrarily 30 Å from the surface of the $\alpha_v\beta_3$. Because the ligands are highly flexible, with multiple rotatable dihedrals present even in the monvalent system, we adopted a two-stage strategy for protein/ligand complex structure modeling, involving simulated annealing (SA) and rigid docking, that partially takes into account ligand flexibility. In the SA step, a 1 ns MD trajectory was generated for each ligand at a temperature of 1500 K. Structures saved every 1 ps underwent energy minimization, and the optimized structures were sorted by energy. Our long-term goal is to use 5−10 lowest-energy structures of the ligand, thus identified, in rigid docking to the integrin. In our preliminary studies, we only employed a single conformer for each ligand—the lowest-energy structure from the SA run. At this stage, the conformational analysis was approximate, as a crude solvation model was employed, with interactions with solvent described by introducing a distance-dependent dielectric constant.

Simulation of Substrate Binding Using AutoDock. The auxiliary program AutoGrid was used for generation of affinity grid fields. The program assigned the center of the grids automatically. The dimensions of the grid were 60.0 Å × 60.0 Å × 60.0 Å with grid points separated by 0.375 Å. The ligands were then docked using the Lamarckian Genetic Algorithm (LGA). The parameters for the LGA configurational search were identical for all docking jobs. Ligand flexibility was taken into account by including rotations around bivalent-IA-Cy5.5 single bonds in the conformational search. The maximum translation step was kept constant at 0.2 Å for every cycle, but the maximum quaternion rotation step and dihedral rotation step had a reduction factor of 0.99 per cycle starting from a maximum rotation of 5.0°. For the search to be extensive, the program uses a multiple starting approach in combination with a time-dependent random number generator. The number of runs was set to 10. For each run, a population of 50 individuals was used, with at most 250 000 function evaluations used and run for at most 27 000 generations. The first top individual was preserved each generation. The mutation rate was 0.02 and the crossover rate 0.80. The GA's selection window was 10 generations; the α parameter was set to 0. After docking simulations had been carried out, the 10 solutions produced were grouped into clusters such that the ligand rms deviations within each cluster were below 0.5 Å. The clusters were also ranked by the value of the lowest-energy solution within each cluster. The lowest-energy solution and the solutions with energies within 5 kcal/mol of this value were considered as possible binding models.

Bivalent Ligands Synthesis. Bivalent ligand 3 was synthesized in three steps (Figure 1). To a solution of the 2-(((9*H*-fluoren-9-yl)methoxy) carbonylamino) octanedioic acid (100 mg, 0.24 mmol) in EtOAc (20 mL), dicyclohexylcarbodiimide (110 mg, 0.53 mmol), and *N*-hydroxysuccinimide (60 mg, 0.52 mmol) were added at 0 °C. The mixture was stirred at 0 °C for 8 h (detected by TLC). Solvent was evaporated under reduced pressure to get the crude intermediate **2**. Compound **2** was dissolved in DMSO (9 mL) for next step reaction without further purification. To this DMSO solution, IA (250 mg, 0.50 mmol) and diisopropylethylamine (0.2 mL, 1 mmol) were added and the mixture was stirred at ambient temperature for 24 h. After

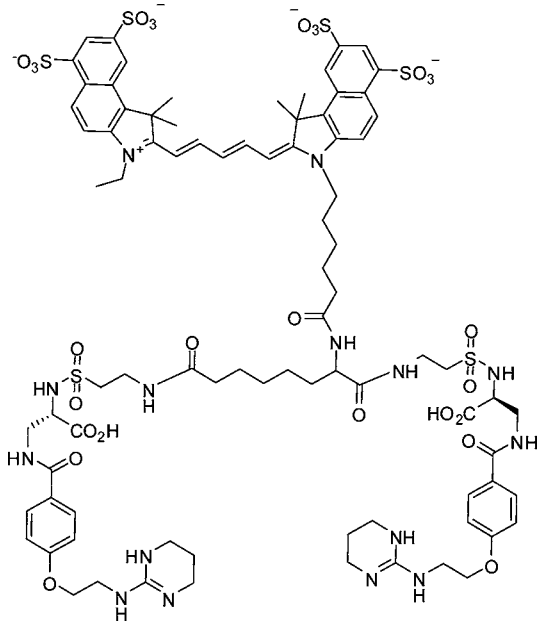

Figure 2. Schematic structure of bivalent-IA-Cy5.5 conjugate.

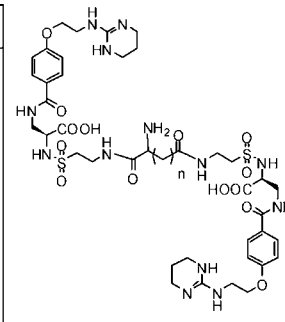
removing solvent at reduced pressure, 10 mL of water was added, and the white solid was removed by filtration. The aq solution was lyophilized, and the residue was recrystallized in methanol and acetone (1:3) to give pure bivalent IA **3** with 50% yield as white solid. ^{1}H NMR (300 MHz, D_2O): 7.65 (m, 4H), 6.93 (m, 4H), 4.16 (m, 7H), 3.84 (m, 4H), 3.30 (m, 10H), 3.21 (m, 10H), 2.05 (t, 2H, J = 7.0 Hz), 1.80 (m, 6H), 1.43 (m, 2H), 1.18 (m, 4H). MS (electrospray): *m*/*z* 1066.3 (100, $[M+H]^+$, calculated 1065.4); 533.8 ($[M+2H]^{2+}$. calculated 533.7).

Bivalent-IA-Cy5.5 Conjugate Synthesis. (Figure 2) Bivalent IA **3** (1.5 mg, 1.4 μmol) and 1.2 equiv of Cy5.5-NHS (2.0 mg, 1.7 μmol) were dissolved in 1 mL DMSO, and then 0.1 mL triethylamine was added. The reaction mixture was stirred in the dark at ambient temperature overnight and then quenched by adding 200 μL of 5% acetic acid (HOAc). The crude product was purified by a semipreparative reversed-phase HPLC employing a PhenomenexLuna C-18 column (250 mm × 10 mm) with the mobile phase starting from 95% solvent A (0.05% ammonia acetate in water) and 5% solvent B (acetonitrile) to 40% solvent A and 60% solvent B at 30 min, and the flow rate is 4 mL/min. Fractions containing bivalent-IA-Cy5.5 conjugates were collected, lyophilized, redissolved in saline at a concentration of 1 mg/mL, and stored in the dark at −20 °C until use. The analytical HPLC method was performed with the same gradient system, but with a Phenomenex C-18 column (250 mm × 4.6 mm) and flow rate of 1 mL/min. The purity of Cy5.5-labeled bivalent IA was over 98% from analytical HPLC analysis. The yield of bivalent-IA-Cy5.5 conjugate was over 70%. The purified bivalent-IA-Cy5.5 conjugate was characterized by mass spectroscopy (MS). MS (electrospray): *m*/*z* 1965.7 ($[M+H]^+$, calculated 1965.2); 983.1 (100, $[M+2H]^{2+}$, calculated 983.6). The absorption and fluorescence emission characteristics of bivalent IA-Cy5.5 conjugates were identical to those of free Cy5.5, as apparent from the spectra measured in H_2O (data not shown).

U-87 MG Xenograft Model. Animal procedures were performed according to a protocol approved by The Methodist Hospital Research Institute Animal Care and Use Committee (IACUC). Female athymic nude mice (nu/nu), obtained from Charles River Laboratories, Inc. (Cambridge, MA) at 4−6 weeks of age, were injected subcutaneously in the right rear thigh with 1×10^7 U-87 MG cells (see general procedures) suspended in 100 μL of phosphate-buffered saline (PBS). The cancer cells were harvested from subconfluent cultures with 0.25% trypsin. Trypsinization was stopped with DMEM containing 10% FBS, after which the cells were washed once in serum-free medium and resuspended in PBS. Trypan blue exclusion was performed to ensure >90% cell viability. The tumor bearing mice were subjected to *in vivo* imaging studies when the tumors reached 0.4−0.6 cm in diameter.



***In Vitro* Binding Assay.** To determine the receptor-binding ability, the bivalent ligands were tested for their ability to competitively inhibit the attachment of the natural ligand vitronectin to purified human $\alpha_v\beta_3$ by enzyme-linked immunosorbent assay (ELISA). Purified integrin $\alpha_v\beta_3$ protein (Chemicon International, Temecula, CA) was applied to 96-well polystyrene microtiter plates at 0.1 μg/well. After overnight incubation at 4 °C, the plates were washed and then blocked with milk solution (KPL, Inc., Gaithersburg, MD) at room temperature for 2 h. The blocking buffer was removed, and the plates were inoculated in quadruplicate with bivalent IAs with a typical starting concentration of 125 nM. Serial dilutions were prepared in the 96-well plates using multichannel pipettes. Biotinylated vitronectin solution (0.1 μg/well) was added to each well as a standard competitor. The plates were incubated at room temperature for 3 h, washed, and the bound vitronectin detected using NeutrAvidin-HRP conjugate at 0.01 μg/well (Pierce, Rockford, IL) and LumiGlo chemiluminescent substrate system (KPL, Inc., Gaithersburg, MD). The luminescence was read using a FLUOstar OPTIMA Microplate Reader (Durham, NC). The concentration of inhibitor producing 50% inhibition (IC_{50}) of vitronectin binding to $\alpha_v\beta_3$ was calculated on the basis of a curve fitting model using *KaleidaGraph 3.5* (Synergy Software, Reading, PA). c-[RGDfV] (Peptides International, Inc.) was also tested using the same method described above.

Fluorescence Microscopic Studies. To demonstrate that the bivalent-IA-Cy5.5 imaging probe can act as a specific ligand for $\alpha_v\beta_3$ integrin receptor in living cells, and to demonstrate the binding and subcellular localization of the bivalent probe, U-87 MG (ATCC HTB-14), a human glioblastoma cell line known to overexpress integrin $\alpha_v\beta_3$, was used in a probe binding assay (*4*). For fluorescence microscopy studies, 1×10^4 U87 cells were cultured on 35 mm MatTek glass-bottomed culture dishes. After 24 h, cells were washed with PBS and then incubated with bivalent-IA-Cy5.5 (200 nM) at 37 °C for 45 min. Integrin specificity of the probe binding was verified by incubating U87 cells with and without a blocking dose of the nonfluorescent bivalent IA (20 μmol/L). After the incubation period, the cells were washed three times with ice-cold PBS. The fluorescence signal of the cells was recorded using FluoView 1000 laser scanning confocal microscope (Olympus) under a 40× oil immersion objective, with laser excition at 675 nm (Cy5.5). A differential interference contrast image was also taken so that the origin of fluorescent signals could be confirmed.

***In Vivo* Fluorescence Imaging of Tumors.** ~3×10^6 U-87 cells were implanted bilaterally in the posterior flanks of immunocompromised (nu/nu) mice and grown to ~4−6 mm in diameter. Imaging was carried out with a group of 5 mice. After palpable masses were detected, animals were manually restrained and imaging probes were intravenously administered (lateral tail vein) using a 30 G needle via aseptic technique. Free Cy5.5 was prepared by dissolving the same Cy5.5NHS ester used for labeling the bivalent IA (GE Healthcare) in phosphate buffered saline (PBS), pH 7.4, overnight at 4 °C. Stock concentration of free Cy5.5 was measured optically using the molar exctinction coefficient of 250 000 M^{-1} cm^{-1} using a UV−visible spectrophotometer using the maximum absorbance wavelength (675 nm) as recommended by the supplier (GE Healthcare). The bivalent-IA-Cy5.5 was weighed and confirmed

Table 1. Conformational Energy of Bivalent IA and NIR Imaging Probe

Form of IA	Linker composition	Linker Length	Conformational Energy (kcal/mol)

by spectrophotometer measurements. Appropriate dilutions of each probe were made in PBS, pH 7.4, and filter sterilized (0.2 μm) immediately prior to use. All animals weighing between 18 and 20 g received 10 nmol of imaging probe (total volume of 100 uL). Fluorescence imaging was performed with a small animal dedicated optical imaging system (Xenogen/Caliper IVIS-200, Mountain View, CA) under continuous 1.5−2.0% isoflurane delivered through the integrated anesthesia system. At 2, 4, 7, 24, and 48 h postinjection, images were acquired with the surface of the tissue of interest (tumor) approximating a perpendicular viewing angle relative to the camera line of sight; this viewing angle was also used for normal tissue selection. For determining tumor contrast, mean fluorescence intensities of the tumor area (*T*) defined as radiance (photons/s/cm^2/sr) at the right rear leg of the animal and of the area (*N*) at the right flank (normal tissue) were calculated by region-of-interest (ROI) analysis using the corresponding photograph of each image acquisition data set to identify the tumor region. Preinjection imaging was also performed to determine baseline autofluorescence. For competitive inhibition studies, mice (n = 3) were coinjected with 500 nmol bivalent IA and 10 nmol of imaging probe (bivalent-IA-Cy5.5) following the same procedure described above. Free Cy5.5 studies were performed in the same manner following the intravenous injection of 10 nmol. For ex vivo biodistribution imaging, two tumor-bearing mice were imaged 24 h post injection of bivalent-IA-Cy5.5 and thereafter euthanized per IACUC protocol (CO_2 and cervical dislocation). Tumor and major internal organs (heart, lung, liver, spleen, gastrointestinal tract, and kidneys) were harvested, weighed, and imaged against a black paper background. All image acquisition parameters were as follows: epi-illumination; Cy5.5 Em/Ex; Bin: (HR)4, FOV: 12.9; f2; 0.2 s.

Data Processing and Statistics. All data are given as means ± SD of n independent measurements. Statistical significance was assigned for P values less than the boundaries of tumors. Quantitative data were acquired with the software provided from the instrument's manufacturer (*Living Image*, v 3.1). Statistics software from R Development Core Team (2009). (R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. ISBN 3-900051-07-0, URL http://www.R-project.org).

RESULTS

Computer Modeling. From calculations of binding energies and ligand spatial distributions, the prediction of favored protein−ligand binding modes, interaction strengths, and binding specificity can be obtained with AutoDock simulations. Ten (10) LGA (Lamarckian genetic algorithm) docking runs were performed for each protein−ligand pair, with each run producing one possible binding mode or solution. The solutions were first sorted in terms of the binding mode, i.e., the position and orientation of the ligand relative to the protein target. The solutions were clustered on the basis of rms (root-mean-square) deviations in ligand atomic positions, with structures with rmsd of less than 0.5 Å grouped into a cluster. The total number of generated low-energy clusters measures the specificity of binding (*12–15*). A small number of clusters indicates that the ligand has only a few possible binding modes and interacts with a specific site (or sites) on the target protein. On the other hand, a large number of clusters implies existence of a wide range of binding modes and lack of specific ligand−target interactions. The second step in sorting solutions involves identification of the solution of lowest binding energy within each cluster and ranking the different clusters according to this energy value. The solution with the lowest energy in the top-ranked cluster and all solutions with energies higher by up to 5.0 kcal/mol were considered as possible binding modes for ligand to target.

Docking of Bivalent-IA-Cy5.5 to the Integrin $\alpha_v\beta_3$. A summary of the AutoDock results is presented in Table 1; the docked structures of the first and second clusters are shown in Figure 3. The docking of bivalent-IA-Cy5.5 to the integrin $\alpha_v\beta_3$ produced 3 clusters out of 10 runs. There were 5 solutions in the first cluster with an average docking energy of −34.04 kcal/mol. The binding site defined by this cluster is in the cleft between the RGD binding domain in integrin $\alpha_v\beta_3$. It is observed that bivalent-IA-Cy5.5 stays at that site in the presence of the whole protein. This cluster presents the best model for a possible bivalent-IA-Cy5.5 interaction to the integrin $\alpha_v\beta_3$. A comparison of the AutoDock results suggests that this binding conformation corresponding to the linker length of the bivalent-IA-Cy5.5 is a better substrate of integrin $\alpha_v\beta_3$. The binding of bivalent-IA-

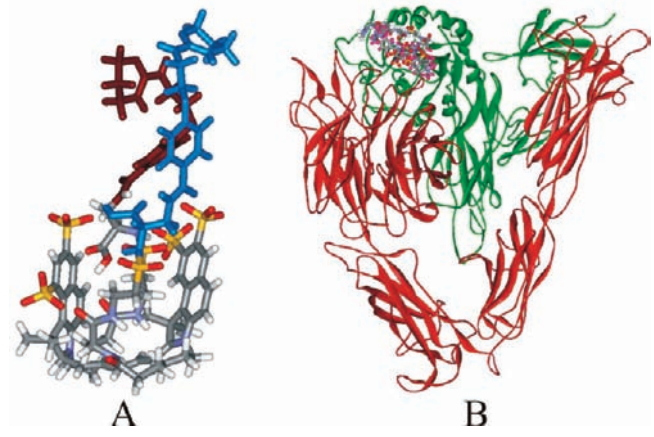

Figure 3. The lowest-energy conformation of bivalent-IA-Cy5.5 conjugate (A). Interaction of bivalent-IA-Cy5.5 with the Integrin (B). The lowest energy conformation is obtained from the analysis of molecular dynamics trajectories. Integrin structure is obtained from the open form of integrin crystal structure (1JV2).

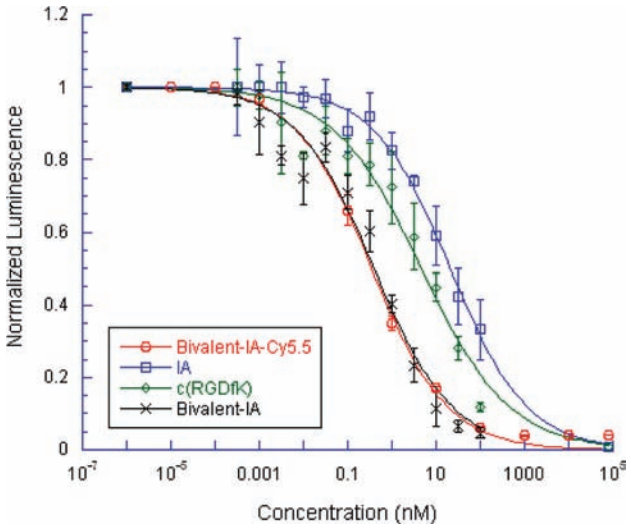

Figure 4. Enzyme-linked immunosorbent assay (ELISA) of IA (IC_{50}: 22.33 ± 4.51 nM), bivalent IA (IC_{50}: 0.40 ± 0.11 nM), bivalent-IA-Cy5.5 conjugate (IC_{50}: 0.13 ± 0.02 nM), and c-[RGDfV] (IC_{50}: 4.80 ± 3.01 nM). All of the points were done in triplicate.

Cy5.5 to the protein is stronger (lower energy) and more specific (small number of clusters) compared to other conformations with different linker length. The microscopic reason for these effects appears to be a lack of fit between different Cy5.5 conformation and the inhibitor/substrate binding site. The docking results are approximate. The scoring is based on an empirical energy function, solvation effects treated with a highly simplified model, and only ligand flexibility taken into account, with the protein structure kept fixed (*12–15*). Thus, the AutoDock results should only be considered as qualitative. The calculated binding energy results are in qualitative agreement with the observed inhibitory effects. Additionally, the simulations suggest that bivalent-IA-Cy5.5 with this conformation has a higher specificity and better fit into the known active site than other conformations.

***In Vitro* Binding Affinity.** Enzyme-linked immunosorbent assay (ELISA) was used to measure the competitive binding of antagonists and biotinylated human vitronectin for the immobilized integrin $\alpha_v\beta_3$. The IC_{50} value for parent compound IA, bivalent IA, bivalent-IA-Cy5.5 conjugate, and c-[RGDfV] were 22.33 ± 4.51, 0.40 ± 0.11, 0.13 ± 0.02, and 4.80 ± 3.01 nM, respectively (Figure 4). Cy5.5 conjugation did not decrease the receptor binding affinity of the resulting NIR fluorescent bivalent IA.

Fluorescence Microscopy. Bivalent-IA-Cy5.5 conjugate was incubated with U87 cells known to overexpress integrin $\alpha_v\beta_3$. Images were taken with a confocal fluorescent microscope. Receptor-mediated endocytosis was observed in the cells. The binding of bivalent-IA-Cy5.5 to U87 cells was effectively blocked by coincubation with nonfluorescent bivalent IA (Figure 5).

***In Vivo* Imaging of Integrin Overexpression in Xenograft U-87 Tumors.** Whole animal fluorescence imaging of subcutaneously implanted U-87 xenograft tumors demonstrated increased signal in tumor sites at 7, 24, and 48 h postconstrast injection (Figure 6). Imaging at earlier time points (2 and 4 h) showed intense systemic fluorescence signal due to relatively slow clearance of the compound. However, at 7 h, there is sufficiently high tumor-to-normal tissue (*T*/*N*) contrast to clearly discern the lesion; and by 24 and 48 h, the most intense signal is evident at the tumor site. Region of interest (ROI) analysis was performed by determining the boundaries of superficial tumors based on photographic images; this region was then measured for fluorescence signal (radiance units, photons/s/cm^2/steradian). Normal tissue was selected by copying the ROI of each sample to a site in the anterior flank. As plotted in Figure 7, *T*/*N* ratios reach a plateau at 24 h with an average maximum of ∼1.84. For the 7, 24, and 48 h time points, the fluorescence signals of the tumor and normal tissues were statistically significantly different (two sample, one side *t* test, *p*-value 0.006, 0.015, and 0.007, respectively, $n = 5$).

To ascertain the specificity of this tumor tissue signal localization, competitive inhibition studies were carried out using the nonfluorescent (without Cy5.5) bivalent IA. Using the same tumor model, a 10-fold excess of bivalent IA was coadministered with 10 nmol of bivalent-IA-Cy5.5 and were imaged at

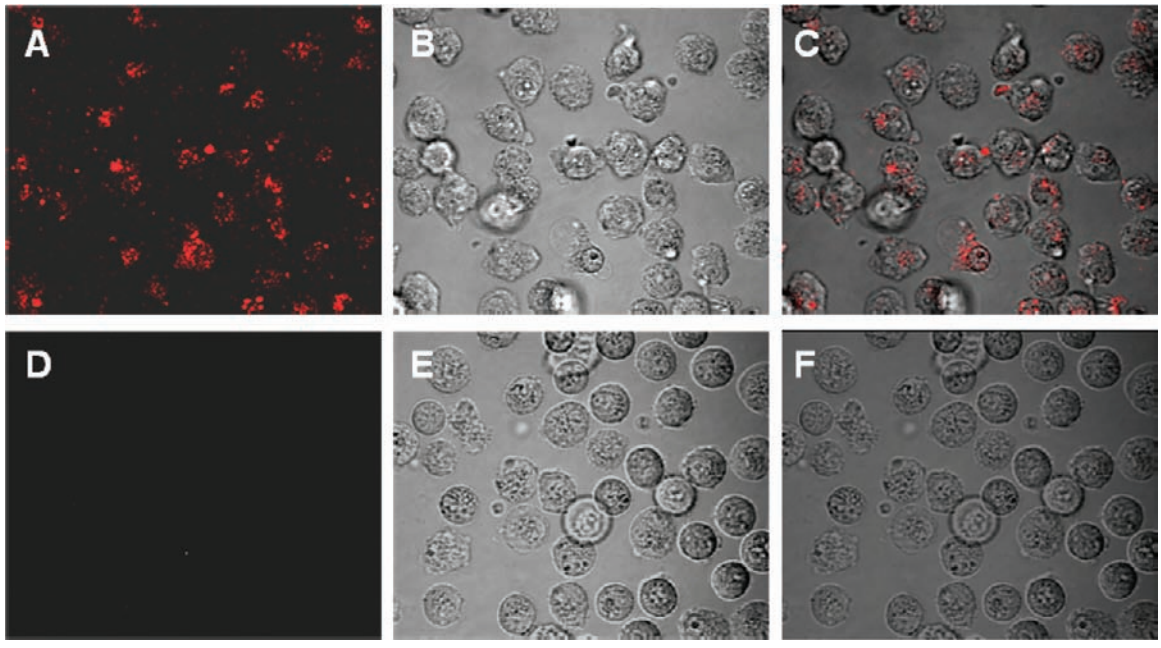

Figure 5. Specific binding of the bivalent-IA-Cy5.5 with U-87 cells. The left (A,D), middle (B,E), and right panels (C,F) represent fluorescence, brighten, and fusion images, respectively, taken from the same field of view. Confocal laser-scanning microscopy images of U-87 glioblastoma incubated with bivalent-IA-Cy5.5 demonstrated endocytosis of the imaging probes (A−C). U-87 cells blocking experiment with nonfluorescent bivalent IA demonstrated a complete blockage of endocytosis of the imaging probes (D−F).

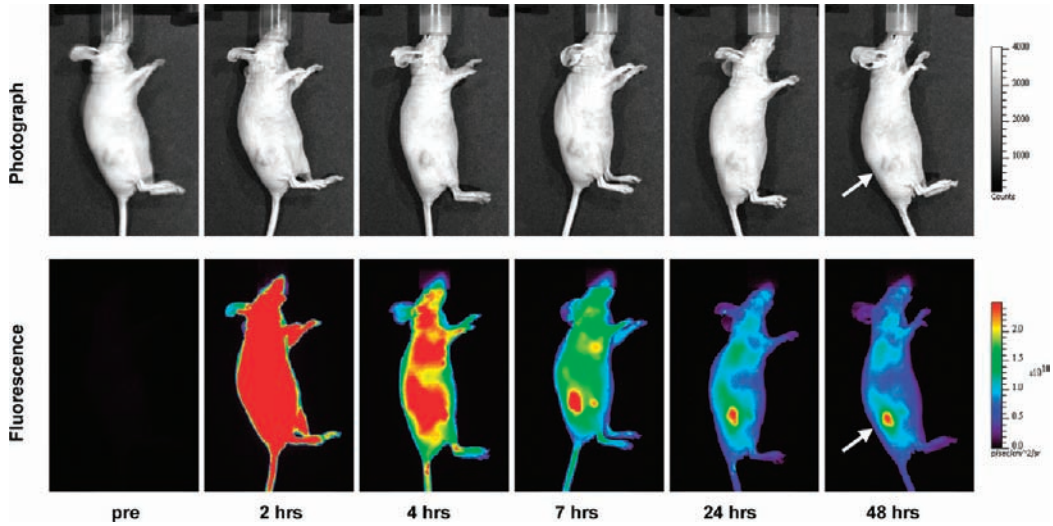

Figure 6. In vivo fluorescence imaging of live U-87 xenograft tumor-bearing mice. Photograph images (top panel) of representative mouse subject at selected time points. Photon scale is shown in the right; corresponding near-infrared fluorescence imaging (bottom panel). Radiance scale is shown in the color bar to the right (p/s/cm^2/sr). Subject was anesthetized with 1.5−2.0% isoflurane through a nose-cone. Arrow indicates tumor.

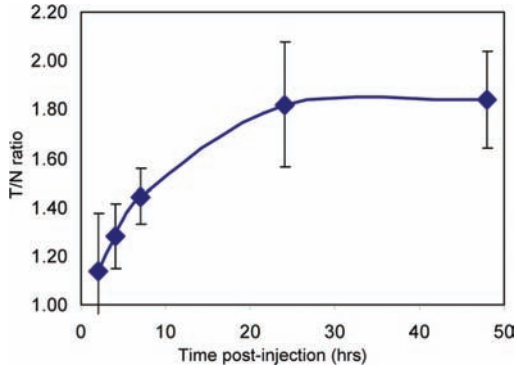

Figure 7. Region of interest (ROI) analysis of fluorescence signal (radiance) from tumor relative to normal tissue (*T*/*N*) vs time course following bivalent-IA-Cy5.5 administration (in hours). Error bars at each time point represents standard deviation from $n = 5$ subjects.

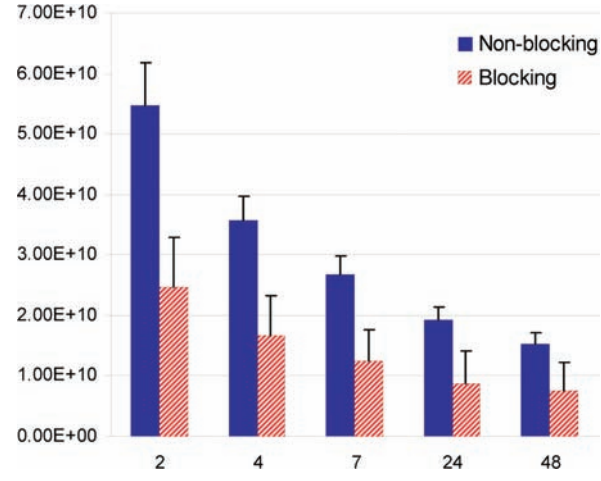

Figure 8. Competitive inhibition of bivalent-IA-Cy5.5 conjugate with nonfluorescent bivalent IA. Significant blocking of tumor fluorescence signal (*y*-axis) was observed at all time points (*x*-axis). Units of radiance (p/s/cm^2/sr). Error bars indicate SD from SD ($n = 6$ blocked, $n = 4$ nonblocked).

2, 4, 7, 24, and 48 h. ROI analysis was again performed as described above. When compared between blocking and nonblocking controls, fluorescence signals within tumors were reduced at all time points measured but were most pronounced in the earlier time points (2, 4, and 7 h), perhaps due to differing clearance rates of the two compounds (Figure 8). Nonetheless, the observed blocking effect was significant at all time points (two samples, one side *t* test, $p = 0.001$ (2 h); 0.002 (4 h); 0.003 (7 h); 0.012 (24 h); and 0.019 (48 h); $n = 6$ (blocking); $n = 4$ (nonblocking control). As a negative control, two tumor-bearing animals were intravenously injected with 10 nmol of the free Cy5.5 and imaged at 24 h post-injection. As shown in Figure 9, there is an overall reduction in systemic fluorescence signal from the entire animal. The relative amount of fluorescence signal from the tumor appears to be slightly higher than the background but is lower than that achieved with the bivalent-IA-Cy5.5 (Figure 9, compare left and right panels). This result is best explained by a higher clearance rate of the free fluorophore and a certain degree of nonspecific binding to tumors as observed by other investigators (*16*). Collectively, these data support the specificity of the bivalent-IA-Cy5.5 for integrin $\alpha_v\beta_3$ associated with U-87 tumors.

Given the intrinsic limitation in tissue penetration of excitation and emission photons from fluorophores, ex vivo imaging was performed to assess the fluorescence signal of the tumor relative to internal organs. Following the intravenous administration of the bivalent-IA-Cy5.5, two tumor-bearing animals were imaged as described above, imaged at 24 h postinjection and immediately thereafter euthanized for harvest of internal organs. Tumors and the major organs—heart/lung (en bloc), liver, spleen, gastrointestinal tract, and bilateral kidneys—were resected and placed on a black background and imaged under the same imaging acquisition protocol (Figure 10). Quantitative analysis was performed by measuring the total photon flux of each selected tissue and divided by the mass (Figure 11). The highest signal per mass of tissue was observed for the tumor, followed next by the heart and lung (en bloc), and kidneys. These data indicate that the bivalent-IA-Cy5.5 is specific for the tumor tissue, likely through binding to its cognate integrin receptor. Given the moderate level of fluorescence signal in the heart and lung, this compound is likely to have a relatively slow blood pool clearance rate. Fluorescence signal from the kidneys suggests mainly renal clearance of the agent, and minimal liver signal suggest low hepatic metabolism. Detailed bio-

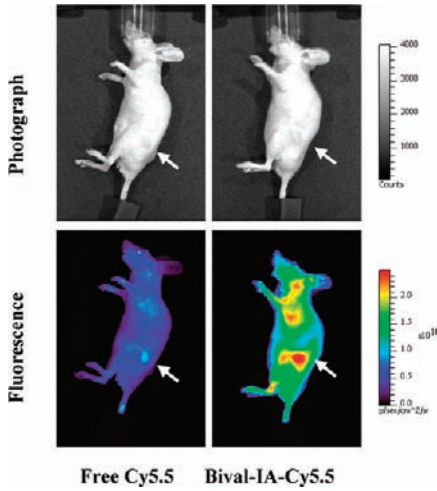

Figure 9. *In vivo* fluorescence imaging of live U-87 xenograft tumor-bearing mice at 24 h postintravenously administered unconjugated Cy5.5 (left panel) vs bivalent IA-Cy5.5 (right panel). distribution, pharmacokinetic, and toxicity studies will be reported separately.

DISCUSSION

Glioblastoma multiforme (GBM) is the most common primary brain tumor, as well as the deadliest (*17*). Malignant gliomas present some of the greatest challenges in the management of cancer patients worldwide, despite notable recent achievements in oncology. Even with aggressive surgical resections using state-of-the-art preoperative and intraoperative neuroimaging, along with recent advances in radiotherapy and chemotherapy, the prognosis for GBM patients remains dismal. Mean survival after diagnosis is about 1 year (*18*). Preclinical data indicate that angiogenesis is essential for the proliferation and survival of malignant glioma cells, which suggests that inhibition of angiogenesis might be an effective therapeutic strategy.

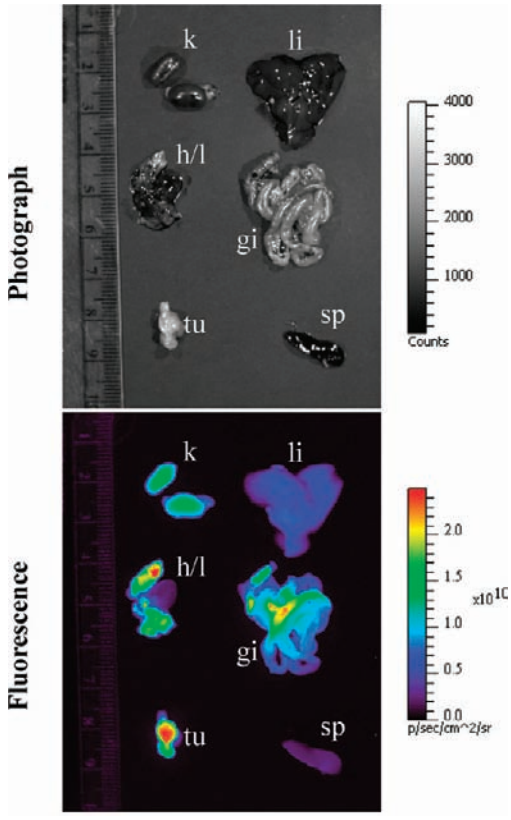

Figure 10. Representative *ex vivo* NIR imaging of major internal organs harvested from a xenograft tumor-bearing mice at 24 h post i.v. injection of bivalent IA-Cy5.5. Top panel: photograph (photon scale is shown to the right). Bottom: fluorescence image (p/s/cm^2/sr). Harvested organs are as follows: (k) kidneys; (li) liver; (h/l) heart and lungs; (gi) small and large intestines; (t) U-87 tumor; (sp) spleen.

NIRF imaging has been proven to be a very powerful tool for noninvasive imaging of various diseases in preclinical models especially in rodents (*10*). In an effort to leverage this robust modality, we sought to apply NIRF imaging techniques for studying an important molecular target, integrin $\alpha_v\beta_3$, expressed by glioblastoma cells. Our ultimate goal was to develop imaging and therapeutic agents targeted to integrin $\alpha_v\beta_3$ for early detection, treatment, and monitoring of glioblastoma as well as other malignancies. To achieve this goal, we set out to design and develop a highly specific and sensitive NIRF agent for this clinically important target.

Computer-assisted approaches to identify new inhibitors via pharmacophore, molecular modeling, docking, and structural interaction fingerprints is rapidly becoming an integral part of rational approaches to drug design. In silico assessment of the free energy and the binding affinity of receptor-inhibitors prior to synthesis permits sophisticated and efficient methods to design drugs. Hood et al. demonstrated that the integrin antagonist, 4-[2-(3,4,5,6-tetrahydropyrimidine-2-lamino)ethyloxy]benzoyl-2-(*S*)-aminoethylsulfonyl-amino-*h*-alanine (IA) can be used as a targeting agent for gene delivery to tumor neovasculature (*2*). A rationally designed bivalent IA by computer modeling could theoretically have better binding affinity and thus greater avidly to target cells expressing this receptor. In an effort to develop the bivalent IA probe for tumor angiogenesis imaging, an extensive simulation with varying linker lengths and composition was carried out. Our results (shown in Table 1) demonstrated that bivalent IAs with linkers containing 5 to 8 carbons (n = 2−5) exhibited descending conformational energy, while the linker shorter than 5 carbons (n < 2) had a significantly higher energy. On the basis of these simulation results, we chose the 8-carbon linker (n = 5), which has the lowest conformational energy to construct the first bivalent IA. Among various commercially available linkers, 2-aminododecanedioic acid, which carries two carboxylic acid groups at each end with a total of eight carbons (n = 5), was chosen as the best linker for the prototype construct. This analysis predicted that the bivalent IA with an 8-carbon linker (n = 5) containing the NIR fluorophore, Cy5.5 dye, would not sterically impact the binding to the integrin protein.

In vitro binding assays have shown that the bivalent IA ($IC_{50} = 0.40 \pm 0.11$ nM) exhibited significantly improved integrin $\alpha_v\beta_3$ affinity when compared to the parent compound IA ($IC_{50} = 22.33 \pm 4.51$ nM), resulting in a 50-fold improvement in receptor affinity (IC_{50}) over that of the parent compound IA and a 10-fold improvement over c-[RGDfV] ($IC_{50} = 4.80 \pm 3.01$ nM). NIR imaging probe, bivalent-IA-Cy5.5 conjugate, also demonstrated significantly increased binding affinity ($IC_{50} = 0.13 \pm 0.02$ nM). Fluorescence microscopy studies demonstrated integrin-mediated endocytosis of the bivalent-IA-Cy5.5 conjugate in U-87 cells, which was effectively blocked by nonfluorescent bivalent IA. This result provides strong supporting evidence that bivalent-IA-Cy5.5 binds specifically to the $\alpha_v\beta_3$ integrin receptor expressed on the tumor cell surface.

Systemically administered bivalent-IA-Cy5.5 in tumor-bearing mice resulted in modest accumulation at the tumor site with improved tumor/normal tissue signal over time (up to 48 h). This effect is best explained by the relatively slow clearance of the probe from the circulation as evident from the high fluorescence observed throughout the test animals at earlier time points (up to 24 h). Consistent with prior studies using a monomeric integrin peptidomimetic conjugated to a chelate for radioisotope imaging, tumor accumulation was time-dependent and required washout from normal tissue for optimal contrast (*8*). Although the tissue penetration of excitation and emission photons of near-infrared light is superior to wavelengths of the visible spectrum, a substantial percentage of light is attenuated as a function of tissue depth. Hence, fluorescence measurements likely underestimate the true accumulation of integrin-specific probes at the target tissue.

The experimental results presented here demonstrate the ability to noninvasively image integrin $\alpha_v\beta_3$ overexpression in live whole animals using a bivalent small molecule with improved receptor binding properties generated by in silico design. A major impetus for our experimental design was to demonstrate proof of concept in generating a new class of targeted imaging agents by leveraging known structure activity relationships and in silico modeling to further improve receptor binding properties of existing molecules. Prior multivalency studies have clearly shown the utility of expanding the repertoire of drugs by reconfiguring molecules as multimers (*19*, *20*). We propose that such approaches will have significant impact in the drug discovery process by providing a mechanism to alter the pharmacologic properties of existing as well as novel drugs.

CONCLUSION

We have successfully synthesized and evaluated a novel near-infrared fluorescent nonpeptidic bivalent integrin $\alpha_v\beta_3$ antagonist for tumor imaging with improved binding avidity relative to the monovalent ligand. The design of this bivalent compound was facilitated by in silico modeling which guided synthetic strategy in a practical application of optimizing a biologically relevant imaging probe. We suggest that this approach represents a general paradigm to improve receptor binding affinities of extant compounds through rationally designed multivalent configurations. More research will be carried out to rationally design bivalent ligands with different types of linkers using computer modeling followed by *in vitro* and *in vivo* evaluation.

Received July 15, 2009; Revised Manuscript Received December 7, 2009

The synthesis of affinity matrices for 6-aminophenanthridine (6AP) and 2,6-dichlorobenzylidenaminoguanidine (Guanabenz, GA), two unrelated prion inhibitors, is described. In both cases, the same simple spacer, ε-aminocaproylaminopentanol, was introduced by a Mitsunobu reaction and the choice of the anchoring position of the linker was determined by the study of the residual antiprion activity of the corresponding 6AP or GA conjugates. Very recently, these two affinity matrices were used for chromatography assays leading to the identification of ribosome (via the rRNA) as a common target of these two antiprion drugs. Here, we show, using competition experiments with Quinacrine (QC) and Chlorpromazine (CPZ), two other antiprion drugs, that QC, but not CPZ, may also directly target the rRNA.

INTRODUCTION

Prion-based diseases are transmissible and yet incurable fatal neurodegenerative disorders (*1*). Among these diseases are Creutzfeldt-Jakob disease (CJD) in humans, bovine spongiform encephalopathies in cattle, and Scrapie in sheep and goats. These diseases are associated with neuronal cell death, which leads to characteristic "spongiform" vacuolation of the brain, and are therefore termed spongiform encephalopathies. According to the "protein-only" hypothesis, prions are mostly if not solely composed of an abnormally folded form (PrP^{Sc}) of the PrP protein (PrP^{C}), a glycosyl-phosphatidyl inositol (GPI) anchored protein normally expressed at the surface of a number of cell types including in particular neurons. Transmissibility necessitates the conversion of host PrP^{C} by exogenous PrP^{Sc}. PrP^{Sc} isoform displays a pronounced protease resistance, shows an increase in β-sheet structures, and forms amyloid fibers. Despite intensive works devoted to the study of prions and their mechanisms of propagation, many fundamental questions related to the mechanism of the infection and subsequently to the mechanisms of action of known antiprion compounds remain unanswered. On the basis of the assumption that PrP^{Sc} corresponds to (or at least is part of) the pathogenic entity, various approaches aimed at reducing PrP^{Sc} or PrP^{C} levels for the development of prion disease therapies are currently being explored (comprehensively reviewed in ref *2*). A proof of concept for these approaches has been made recently by showing that depleting PrP^{C} from neurons of prion-infected mice in which the *Prnp* gene can be turned off, not only prevented progression of disease, but also reversed spongiosis and early cognitive and neurophysiological dysfunctions (*3, 4*). Therefore, approaches leading to reduction of endogenous PrP^{C} and/or PrP^{Sc} levels may well be effective after the appearance of the neurological symptoms. Among these approaches are identifications of pharmacological compounds promoting PrP^{Sc} clearance. Some of these identifications are based on the use of cell-free systems (*5–8*), whereas others are based on the use of mammalian cells chronically infected with prions (*9–12*) and reviewed in ref *13*. All these assays are time- and money-consuming, in particular, because experiments have to be carried out in highly secured laboratories. For these reasons, we recently developed a rapid and economical budding yeast (*Saccharomyces cerevisiae*) based two-step assay to screen for antiprion molecules (*14, 15*). This assay allows easy detection of compounds active against two yeast prions and has led, among others, to the isolation of 6-aminophenanthridine (6AP) **1a** and 2,6-dichlorobenzylidenaminoguanidine (Guanabenz, GA) **1b** (Figure 1). This yeast-based assay was validated for the isolation of drugs active against mammalian prions, since most of the active compounds isolated, including 6AP and GA, turned out to also be active against mammalian prions in mammalian cell-based assays mentioned above (*16*). In addition, both 6AP and GA exhibited significant activity in a mouse model for scrapie (*17*).

Although direct interaction with the prion protein PrP^{C} has been established by NMR spectroscopy (*18*) or by surface plasmon resonance (*19*) for some drugs, this has not been evaluated with most of the known antiprion agents. Recently, using immobilized 9-aminoacridine, Prusiner's group was able to discriminate PrP^{C} and PrP^{Sc} in an affinity chromatography assay (*20*). Moreover, even if some of the compounds are known to bind PrP, it is not established whether their antiprion activities exclusively rely on this binding ability. Therefore, the mechanism of action of most antiprions remains unclear, and at least two different mechanisms can be envisioned: drugs can either act in *cis* directly on prion aggregates or in *trans* on cellular elements required for prion propagation. In addition, identification of these unknown biological mechanisms may provide new

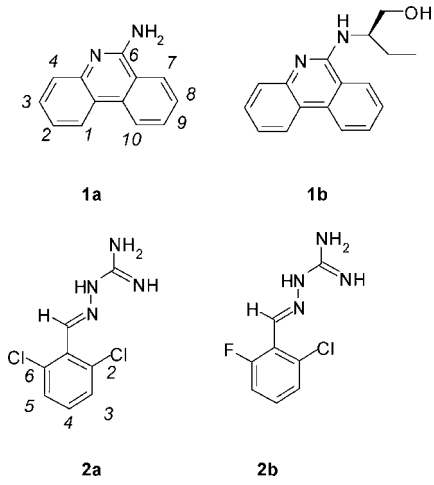

Figure 1. 1a, 6-aminophenanthridine (6AP) and **2a**, 2,6-dichlorobenzylidenaminoguanidine: Guanabenz (GA), two antiprion drugs active against both yeast and mammalian prions and their respective inactive controls, **1b** (6APi) and **2b** (GAi).

insights for other neurodegenerative disorders characterized by the occurrence of protein misfolding as observed in prion diseases (*21*).

For these reasons, identification of these mechanisms using reverse screening approaches is of particular interest. Several comprehensive methods exist to decipher cellular mechanisms targeted by small chemical compounds, including affinity chromatography on immobilized drugs.

Affinity chromatography has been used in the determination of the molecular targets of several compounds. Most of them are kinase inhibitors such as flavopiridol (*22*), purvalanol (*23*), (*R*)-roscovitine (*24*), gefitinib (*25*), and SU6668 (*26*). Affinity chromatography has also been performed with the immunosuppressor FK506 (*27*) and geldanamycin, which was therefore shown to be a specific inhibitor of HSP 90 (*28*).

As a typical example, the determination of the molecular targets of (*R*)-roscovitine led, apart from the expected cyclin-dependent kinases, to the identification of pyridoxal kinase, an unexpected target. This was confirmed by X-ray crystallography, and surprisingly, roscovitine appeared to bind the pyridoxal pocket rather than the ATP binding site (*29*).

In affinity chromatography experiments, a spacer arm is introduced between the compound of interest and the solid supports with the aim of avoiding steric hindrance. The structure of the spacer arm matters considerably. Polyoxyethylenic linkages are generally used. A carboxylic acid group is often introduced on the active molecules. Therefore, the introduction of the spacer on the bioactive compound is frequently achieved by a multiple-step procedure. The position of the linkage is critical, as the conjugate should, at least partially, retain biological activity. Linkage should be introduced at several positions of the molecule under study and the biological activity of the resulting conjugates tested. If available, structure−activity relationships provide useful information on the positions of linkage which are more likely to allow molecular recognition by the biological targets (for a review, see ref *30*).

In this paper, we report the synthesis of affinity matrices for the two unrelated antiprion drugs cited above: 6-aminophenanthridine (6AP) and 2,6-dichlorobenzylidenaminoguanidine (guanabenz, GA) by immobilization of the conjugates on preactivated Sepharose beads. The 6AP and GA affinity beads were very recently used and allowed to determine that protein folding activity of the rRNA (Ribosome-borne Protein Folding Activity, RPFA) is a selective target of both 6AP and GA (*31*). Here, using competition experiments on 6AP and GA affinity matrices with free quinacrine (QC) and chlorpromazine (CPZ), two other active antiprion compounds, we found that QC, but not CPZ, may also target the ribosome directly.

EXPERIMENTAL PROCEDURES

Chemical Methods. Reactions were monitored by TLC using Merk silica gel 60F-254 thin layer plates. Column chromatography experiments were carried out on SDS Chromagel 60 ACC, 40−63 μm. Column chromatography (CC) was performed using silica gel (70−200 μm). Melting points were determined on a Kofler hot-stage (Reichert) and are uncorrected. NMR spectra were recorded on Bruker Avance 400 MHz. Chemical shifts are given in parts per million (ppm) downfield of tetramethylsilane (TMS) used as an internal standard. Infrared spectra were recorded on a FTIR Schimadzu 8300. The HPLC analyses were carried out on a system consisting of a Waters 600 system controller, a Jones chromatography heater−chiller oven, and a Waters 994 photodiode array detector. Mass spectra (electrospray ionization (ESI) were measured on a TSQ Quantum (Thermo Electron Corporation) instrument. Elemental analyses for C, H, and N were performed on a Thermoquest EA-110 apparatus. 6AP was prepared as described previously (*32, 33*). Commercially available GA was used or obtained upon condensation of aminoguanidine with 2,6-dichlorobenzaldehyde.

(*R*)-6-(1-Hydroxybut-2-ylamino)phenanthridine, 6APi (1b). A mixture of 6-chlorophenanthridine (2.14 g, 10 mmol), (*R*)-2-aminobutanol (3 mL, 35 mmol), and NEt_3 (3 mL, 40 mmol) was heated at 110 °C for 2 h. After cooling to rt, 30 mL H_2O was added, and the mixture was extracted with CH_2Cl_2 (2 × 10 mL). The solvent was evaporated and **1b** crystallized from EtOAc. Mp 176−178 °C. Anal. ($C_{17}H_{18}N_2O$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 1.19 (t, J = 7 Hz, 3H, C*H*$_3$); 1.78 (p, 2H, C*H*$_2$CH$_3$); 3.76 (t, 1H, J = 9 Hz, 1H, C*H*$_2$OH); 3.98 (d, J = 10.9 Hz, 1H, C*H*$_2$OH); 4.26 (m, 1H, C*H*CH$_2$OH); 5.57 (br s, 1H, O*H*); 6.75 (br s, 1H, N*H*); 7.34 (t, $J_{1-2} = J_{2-3}$ = 7.5 Hz, 1H, 2-H); 7.54 (t, $J_{7-8} = J_{8-9}$ = 7.5 Hz, 1H, 8-H); 7.59 (t, 1H, 3-H); 7.70 (d, J_{3-4} = 8 Hz, 1H, 4-H); 7.77 (t, 1H, J_{9-10} = 7.5 Hz, 9-H); 7.86 (d, 1H, 7-H); 8.31 (d, 1H, 1-H); 8.51 (d, 1H, 10-H). ^{13}C NMR ($CDCl_3$) δ 10.8; 24.7; 56.8; 68.2; 118.5; 120.3; 121.5; 121.8; 122.5; 122.6; 125.7; 126.7; 128.7; 130.2; 133.6; 142.9; 153.7.

2-Chloro-6-fluoro-benzylideneaminoguanidine, GAi (2b). Aminoguanidine hydrochloride (2.20 g, 20 mmol) was added to a solution of 2-chloro-2-fluorobenzaldehyde (3.16 g, 20 mmol) in 50 mL EtOH followed by the addition of AcONa, 5H_2O (2.72 g, 20 mmol). After 2 h reflux, the hot mixture was filtered, and **2b** precipitated upon cooling to rt. Yield 87%. Mp 164−167 °C. Anal. ($C_8H_8ClFN_4$) C, H, N. ^{1}H NMR (DMSO) δ 5.50 (br s, 4H, 2 N*H* + N*H*$_2$); 7.15 (t, $J_{3-4} = J_{4-5}$ = 8 Hz, 1H, 4-H); 7.50 (d, 1H, 3-H); 7.65 (dd, J_{F-5} = 10 Hz, 1H, 5-H); 8.20 (s, 1H, NC*H*).

Benzyloxy-6-aminophenanthridines 1c−e (reaction in liquid ammonia). Ammonia (200 mL) was introduced into a flask connected with an efficient condenser followed by $Fe(NO_3)_3$ (0.02 g) and piece by piece Na (0.23 g, 10 mmol) additions. The solution was stirred for 0.5 h during this period; the initial blue color of the solution of Na gradually turned to gray indicating the complete conversion into $NaNH_2$. To this suspension, benzyloxyanilines (1.99, 10 mmol) dissolved in the minimum amount of anhydrous Et_2O were added. The mixture was stirred for 0.5 h followed by the addition of 2-chlorobenzonitrile (1.37 g, 10 mmol) in anhydrous Et_2O. The mixture was stirred for 2 h, and lithium (0.14 g, 20 mmol) was then added. After 2 h stirring, NH_4Cl (10 g) was gradually introduced under vigorous stirring. Ammonia was evaporated overnight. After addition of H_2O (50 mL), the mixture was extracted with CH_2Cl_2 (3 × 30 mL), and the organic layer was first washed with brine (40 mL), then dried with Na_2SO_4 and evaporated.

The residue was applied to a silica gel column and eluted first with CH_2Cl_2 and then with CH_2Cl_2−MeOH (99:1 to 95:5).

1-Benzyloxy-6-aminophenanthridine (1c) and 3-benzyloxy-6-aminophenanthridine (1e). 3-Benzyloxyaniline led to a mixture of compounds **1c** and **1e**. The two isomers could not be separated by column chromatography. They were isolated in 23% yield as a (1:1) mixture.

2-Benzyloxy-6-aminophenanthridine (1d). Prepared from 4-benzyloxyaniline. Yield 45%. Mp 138−141 °C. Anal. ($C_{20}H_{16}N_2O$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 5.22 (s, 2H, CH_2); 5.47 (brs, 2H, NH_2); 7.31 (dd, $J_{3-4} = 9$ Hz, $J_{1-3} = 2.4$ Hz, 1H, 3-H); 7.32 (t, $J = 7.2$ Hz, 1H, C_6H_5); 7.37 (t, 2H, $J = 7.2$ Hz, C_6H_5); 7.41 (m, 3H, C_6H_5 + 8-H); 7.52 (d, $J_{3-4} = 8$ Hz, 1H, 4-H); 7.69 (t, 1H, 9-H); 7.86 (s, 1H, 1-H); 8.09 (d, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 7-H); 8.42 (d, $J_{9-10} = 8.2$ Hz, 10-H).

3-Benzyloxy-6-aminophenanthridine (1e) (by Suzuki-Miyaura cross coupling). A solution of 5-benzyloxy-2-bromoaniline (1 g, 3.6 mmol) in 20 mL dioxane and 6 mL 1 M Na_2CO_3 was stirred under N_2 for 5 min. Pd[P(C_6H_5)$_3$]$_4$ (0.2 g, 0.17 mmol) was then introduced followed by 2-(4,4,5,5-tetramethyl-[1,3,2]-dioxaborolan-2-yl)-benzonitrile (3.6 mmol, 0.825 g). The mixture was refluxed for 12 h and then concentrated. The residue was extracted with CH_2Cl_2 (3 × 10 mL). The organic solution was washed with H_2O and dried with Na_2SO_4 and evaporated. The final compound was purified by column chromatography (CH_2Cl_2−EtOH, 98:2) and crystallized from EtOAc. Yield: 63%. Mp 121−123 °C. Anal. ($C_{20}H_{16}N_2O$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 5.20 (s, 2H, CH_2); 5.32 (br s, 2H, NH_2); 7.11 (dd, $J_{1-2} = 9.2$ Hz, $J_{2-4} = 2.4$ Hz, 1H, 2-H); 7.26 (d, 1H, 4-H); 7.34 (t, $J_{3'-4'} = J_{4'-5'} = 7.2$ Hz, 1H, 4′-H); 7.41 (t, 2H, $J_{2'-3'} = J_{5'-6'} = 7.2$ Hz, 3′-H and 5′-H); 7.50 (d, 2H, 2′-H, and 6′-H); 7.55 (td, $J_{8-10} = 1$ Hz, $J_{8-9} = 8$ Hz, 1H, 8-H); 7.76 (td, $J_{9-10} = 0.8$ Hz, 1H, 9-H); 7.86 (d, $J_{7-8} = 8$ Hz, 1H, 7-H); 8.34 (d, 1H, 1-H); 8.44 (d, $J_{9-10} = 8.4$ Hz, 1H, 10-H). ^{13}C NMR ($CDCl_3$) δ 70.5; 108.7; 114.6; 115.9; 117.9; 122.7; 123.4; 123.7; 126.4; 128.0; 128.4; 129.0; 131.2; 134.8; 137.3; 146.2; 155.5; 160.1. IR (KBr) γ 517; 621; 681; 718; 757; 811; 856; 890; 994; 1020; 1085; 1135; 1178; 1220; 1253; 1300; 1357; 1402; 1460; 1514; 1547; 1600; 1657; 1755; 1824; 1958; 2368; 2848; 2851; 3114; 3314; 3742.

Phthalylation of Benzyloxy-6-Aminophenanthridines. The amines **1c**−**e** (0.7 g, 2.3 mmol) were dissolved in THF (30 mL) containing 1 mL NEt_3. Phthalic anhydride (0.34 g, 2.3 mmol) was then added, and the mixture was refluxed for 6 h. THF was removed under reduced pressure. Water (20 mL) was added and the mixture extracted with CH_2Cl_2 (3 × 10 mL). The organic layer was dried (Na_2SO_4) and evaporated. The residue was subjected to chromatography (CH_2Cl_2 100%) and crystallization from *i*-PrOH.

2-(1-Benzyloxyphenanthridin-6-yl)-isoindole-1,3-dione (3c). Yield: 80%. Mp 189−193 °C. Anal. ($C_{28}H_{18}N_2O_3$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 5.45 (s, 2H, CH_2); 7.33 (d, $J_{2-3} = 8$ Hz, 1H, 2-H); 7.42 (t, $J_{3'-4'} = J_{4'-5'} = 7.2$ Hz, 1H, 4′-H); 7.47 (t, $J_{2'-3'} = J_{5'-6'} = 7.2$ Hz, 2H, 3′-H and 5′-H); 7.60 (d, 2H, 2′-H and 6′-H); 7.65 (t, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 8-H); 7.70 (t, $J_{3-4} = 8$ Hz, 1H, 3-H); 7.80 (t, 1H, 9-H); 7.88 (m, 3H, phthalyl and 4-H); 7.93 (d, 1H, 7-H); 8.05 (dd, $J = 5.6$ Hz, $J = 3.2$ Hz, 2H, phthalyl); 9.72 (d, $J_{9-10} = 8.8$ Hz, 1H, 10-H). MS (E^+) *m*/*z*: 431 $[M + H]^+$; 453 $[M + Na]^+$.

2-(2-Benzyloxy-phenanthridin-6-yl)-isoindole-1,3-dione (3d). Yield: 81%. Mp 138−141 °C. Anal. ($C_{28}H_{18}N_2O_3$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 5.30 (s, 2H, CH_2); 7.40 (t, $J_{3'-4'} = J_{4'-5'} = 7.2$ Hz, 1H, 4′-H); 7.45 (t, $J_{2'-3'} = J_{5'-6'} = 7.2$ Hz, 2H, 3′-H + 5′-H); 7.50 (dd, $J_{3-4} = 9.4$ Hz, $J_{1-3} = 2.4$ Hz, 1H, 3-H); 7.57 (d, 2H, 2′-H and 6′-H); 7.69 (t, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 8-H); 7.90 (m, 4H, phthalyl, 9-H and 4-H); 8.05 (m, 3H, phthalyl and 1-H); 8.15 (d, 1H, 7-H); 8.62 (d, $J_{9-10} = 8.8$ Hz, 1H, 10-H).

2-(3-Benzyloxyphenanthridin-6-yl)-isoindole-1,3-dione (3e). Yield: 83%. Mp 121−123 °C. Anal. ($C_{28}H_{18}N_2O_3$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 5.24 (s, 2H, CH_2); 7.35 (t, $J_{3'-4'} = J_{4'-5'} = 7.2$ Hz, 1H, 4′-H); 7.41 (t, $J_{2'-3'} = J_{5'-6'} = 7.2$ Hz, 2-H, 3′-H + 5′-H); 7.48 (dd, $J_{1-2} = 9.4$ Hz, $J_{2-4} = 2.4$ Hz; 1H, 2-H); 7.50 (d, 2H, 2′-H and 6′-H); 7.61 (t, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 8-H); 7.70 (d, 1H, 4-H); 7.87 (dd, $J = 3.2$ Hz, $J = 5.6$ Hz, 2H, phthalyl); 7.88 (m, 2H, 7-H and 9-H); 8.04 (dd, 2H, phthalyl); 8.55 (d, 1H, 1-H); 8.61 (d, $J_{9-10} = 8.8$ Hz, 10-H). ^{13}C NMR ($CDCl_3$) δ 70.7; 111.4; 119.6; 120.4; 122.5; 123.3; 123.9; 124.5; 126.1; 127.4; 128.1; 128.6; 129.1; 132.1; 132.6; 135.1; 135.5; 136.7; 145.3; 146.4; 159.9; 167.7. Debenzylation of 2-(Benzyloxyphenanthridin-6-yl)-isoindole-1,3-diones. Preparation of Phenols 4c−e. 0.1 g of 10% Pd/C and 0.5 mL of AcOH were added to a solution of 2-(benzyloxyphenanthridin-6-yl)-isoindole-1,3-dione (1.9 mmol, 0.65 g) in 50 mL EtOH and 50 mL CH_2Cl_2. The mixture was stirred under H_2 atmosphere (AP) for 12 h. The catalyst was removed by filtration through a Whatman filter. The filter was washed once with 5 mL EtOH. The phenols crystallized upon concentration of the ethanolic solution.

2-(1-Hydroxyphenanthridin-6-yl)-isoindole-1,3-dione (4c). Yield: 97%. Mp 189−193 °C. Anal. ($C_{21}H_{12}N_2O_3$) C, H, N.^{1}H NMR ($CDCl_3$) δ 7.23 (d, $J_{2-3} = J_{3-4} = 8$ Hz, 1H, 2-H); 7.52 (t, 1H, 3-H); 7.59 (t, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 8-H); 7.68 (d, 1H, 4-H); 7.82 (m, 4H, phthalyl and 7-H and 9-H); 7.97 (dd, $J = 3.2$ Hz, $J = 5.6$ Hz, phthalyl); 9.80 (d, $J_{9-10} = 8.4$ Hz, 1H, 10-H); 10.9 (br s, 1H, OH).

2-(2-Hydroxyphenanthridin-6-yl)-isoindole-1,3-dione (4d). Yield: 82%, Mp 201−203 °C. Anal. ($C_{21}H_{12}N_2O_3$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 7.35 (t, 1H); 7.63 (dd, 1H, $J_{3-4} = 8.5$ Hz, $J_{1-3} = 3$ Hz, 3-H); 7.71 (t, 1H); 7.95 (m, 5H, phthalyl + 1H); 8.10 (m, 4H, phthalyl); 8.18 (d, 1H, 7-H); 8.60 (d, 1H, 10-H); 8.75 (brs, OH).

2-(3-Hydroxyphenanthridin-6-yl)-isoindole-1,3-dione (4e). Yield: 98%. Mp 169−172 °C. Anal. ($C_{21}H_{12}N_2O_3$) C, H, N.^{1}H NMR ($CDCl_3$) δ 7.30 (dd, $J_{1-2} = 8.8$ Hz, $J_{2-4} = 2.4$ Hz, 1H, 2-H); 7.49 (t, $J_{7-8} = J_{8-9} = 8$ Hz, 1H, 8-H); 7.52 (d, 1H, 4-H); 7.80 (m, 4H, phthalyl + 7-H + 9-H); 7.97 (dd, $J = 5.6$ Hz, $J = 3.2$ Hz, phthalyl); 8.41 (d, 1H, 1-H); 8.52 (d, $J_{9-10} = 8.2$ Hz, 1H, 10-H); 9.50 (brs, 1H, OH).

Preparation of Spacers (5a,b). *N*-Hydroxybenzotriazole (2.83 g, 21 mmol) and dicyclohexylcarbodiimide (4.14 g, 20 mmol) were added to a cooled (5 °C) solution of *ε*-*Z*-aminocaproic acid (6.62 g, 25 mmol) in 50 mL EtOAc. The mixture was left under stirring for 2 h at rt. The precipitated dicyclohexylurea was filtrated and washed once with 10 mL EtOAc. 5-Aminopentan-1-ol (2.16 g, 21 mmol) and NEt_3 (5 mL) were added to the combined filtrates. After 3 h stirring, the mixture was diluted in 150 mL EtOAc and washed with 20 mL 1 N HCl followed by 50 mL saturated $NaHCO_3$ and then with 20 mL H_2O. Derivatives **5** crystallized upon concentration of the solvent. Further purification could be achieved by crystallization from EtOAc.

5-(6-Benzyloxycarbonylaminohexanoylamino)pentan-1-ol (5a). Yield: 85%. Mp: 108−110 °C. Anal. ($C_{19}H_{30}N_2O_4$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 1.25−1.85 (m, 12H, 6 × CH_2); 2.15 (t, $J = 7.4$ Hz, 2H, CH_2CO); 3.19 (q, $J = 6.4$ Hz, 2H, CH_2NH); 3.26 (q, $J = 6.4$ Hz, 2H, CH_2NH); 3.64 (t, $J = 6.4$ Hz, CH_2OH); 4.88 (br s, 1H, NH); 5.08 (s, 2H, CH_2C$_6$H$_5$); 5.56 (br s, 1H, N*H*); 7.28−7.38 (m, 5H, C_6H_5). ^{13}C NMR ($CDCl_3$) δ 23.4; 25.3; 25.6; 25.9; 29.7; 30.0; 32.5; 36.9; 39.6; 41.2; 62.9; 67.0; 128.5; 128.9; 137.0; 156.9; 173.3. General Procedure for the Mitsunobu Reaction. Synthesis of Conjugates (6c−e). *Z*-Aminocaproylaminopentanol (**5a**) (1.8 mmol, 0.63 g) and triphenylphosphine (1.8 mmol, 0.47 g) were added to a solution of 2-(hydroxyphenanthridin-6-yl)-isoindole-1,3-dione (**4c−e**) (1.8 mmol, 0.61 g) in THF (30 mL). The mixture was cooled to 0 °C, and *iso*-propyl diazodicarboxylate (1.8 mol, 0.378 g) was introduced under vigorous stirring. After 2 h at rt, the reaction mixture was concentrated and H_2O (20 mL) was added. The aqueous suspension was extracted with CH_2Cl_2 (3 × 15 mL), the organic layer was dried with Na_2SO_4, and the solvent was evaporated. The final compound was obtained after column chromatography (EtOAc−CH_2Cl_2−toluene: 50−25−25).

(5-{5-[6-(1,3-Dioxo-1,3-dihydroisoindol-2-yl)-phenanthridin-1-yloxy]-pentylcarbamoyl}-pentyl)-carbamic Acid Benzyl Ester 6c. Yield 92%. Mp 134−137 °C. Anal. 6-Amino-2-(benzyloxycarbonylaminohexanoylaminopentyloxy)phenanthridine (7d). Yield 62%, Mp 118−122 °C. Anal. ($C_{32}H_{38}N_4O_4$) C, H, N. ^1H NMR ($CDCl_3$) δ 1.47 to 1.62 (m, 12H, 6 × CH_2); 2.23 (t, $J = 6.5$ Hz, 2H, CH_2CO); 3.20 (q, $J = 6.5$ Hz, 2H, CH_2NH); 3.35 (q, $J = 6.5$ Hz, 2H, CH_2NH); 4.22 (t, $J = 6.4$ Hz, 2H, CH_2O); 4.85 (brs, 1H, NH); 5.12 (s, 2H, $CH_2C_6H_5$); 5.85 (br s, 2H, NH_2); 7.32 (m, 5H, C_6H_5); 7.52 (d, $J_{3-4} = 7.5$ Hz, 1H, 3-H); 7.65 (m, 2H, 4-H + 8-H); 7.85 (m, 1H, 9-H); 7.96 (s, 1H, 1-H); 8.10 (d, $J_{7-8} = 8$ Hz, 1H, 7-H); 8.54 (d, $J_{9-10} = 8.2$ Hz, 1H, 10-H).

6-Amino-3-(benzyloxycarbonylaminohexanoylaminopentyloxy)phenanthridine (7e). Yield 48%. Mp: 123−125 °C. Anal. ($C_{32}H_{38}N_4O_4$) C, H, N. ^1H NMR ($CDCl_3$) δ 1.42−1.69 (m, 12H, 6 CH_2); 2.15 (t, $J = 7.3$ Hz, 2H, CH_2CO); 3.13 (q, $J = 6.4$ Hz, 2H, CH_2NH); 3.22 (q, $J = 6.4$ Hz, 2H, CH_2NH); 4.06 (t, $J = 6.6$ Hz, 2H, CH_2OAr); 5.01 (s, 2H, $CH_2C_6H_5$); 5.71 (br s, 2H, NH_2); 7.24 (m, 5H, C_6H_5); 7.39 (dd, $J_{1-2} = 8$ Hz, $J_{2-3} = 2.4$ Hz, 2-H); 7.52 (m, 2H, 4-H and 8-H); 7.81 (m, 2H, 7-H + 9-H); 8.38 (d, 1H, 1-H); 8.50 (d, $J_{9-10} = 8.2$ Hz, 10-H). MS (E^+) *m/z*: 543 $[M + H]^+$; 565 $[M + Na]^+$.

Removal of the Z-group. Preparation of 3-(6-Aminocaproylaminopentyloxy)-6-phtalimidophenanthridine (8e). Pd/C 10% (0.1 g) and 35% hydrochloric acid (0.2 mL) were added to a solution of **6e** (0.336 g, 0.5 mmoL) in 10 mL EtOH and 10 mL CH_2Cl_2. The mixture was stirred under H_2 atmosphere (AP) for 12 h. The catalyst was removed by filtration through a Whatman filter. The filter was rinsed once with 1 mL EtOH. The hydrochloride was isolated upon concentration under vacuum and used in the immobilization step without further purification.

{5-[5-(3,5-Dichloro-4-formylphenyloxy)-pentylcarbamoyl]-pentyl}-carbamic Acid *tert*-Butyl Ester (11). Boc-aminocaproylaminopentanol (3 mmol, 0.906 g) and triphenylphosphine (3 mmol, 0.786 g) were added to a solution of 2,6-dichloro-4-hydroxybenzaldehyde **10** (*35*) (3 mmol, 0.525 g) dissolved in 30 mL of THF. The mixture was cooled to 0 °C, and *iso*-propyl diazodicarboxylate (3 mmol, 0.590 g) was introduced under vigorous stirring. After 2 h at rt, the reaction mixture was concentrated and H_2O (20 mL) was added. The aqueous suspension was extracted with CH_2Cl_2 (3 × 10 mL), and the organic layer was dried with Na_2SO_4 and the solvent evaporated. The final compound was obtained after column chromatography (EtOAc−toluene: 50−50). Yield: 83%. Mp: 68−70 °C. Anal. ($C_{23}H_{34}Cl_2N_2O_5$) C, H, N. ^1H NMR ($CDCl_3$) δ 1.52 (s, 9H, $C(CH_3)_3$); 1.36−1.71 (m, 10H, CH_2); 1.86 (q, 2H, CH_2); 2.20 (t, 2H, $J = 7.5$ Hz, CH_2CO); 3.12 (dd, 2H, $J = 6.3$ Hz, CH_2NH); 3.29 (dd, 2H, $J = 6.3$ Hz, CH_2NH); 4.04 (t, 2H, $J = 6.1$ Hz,

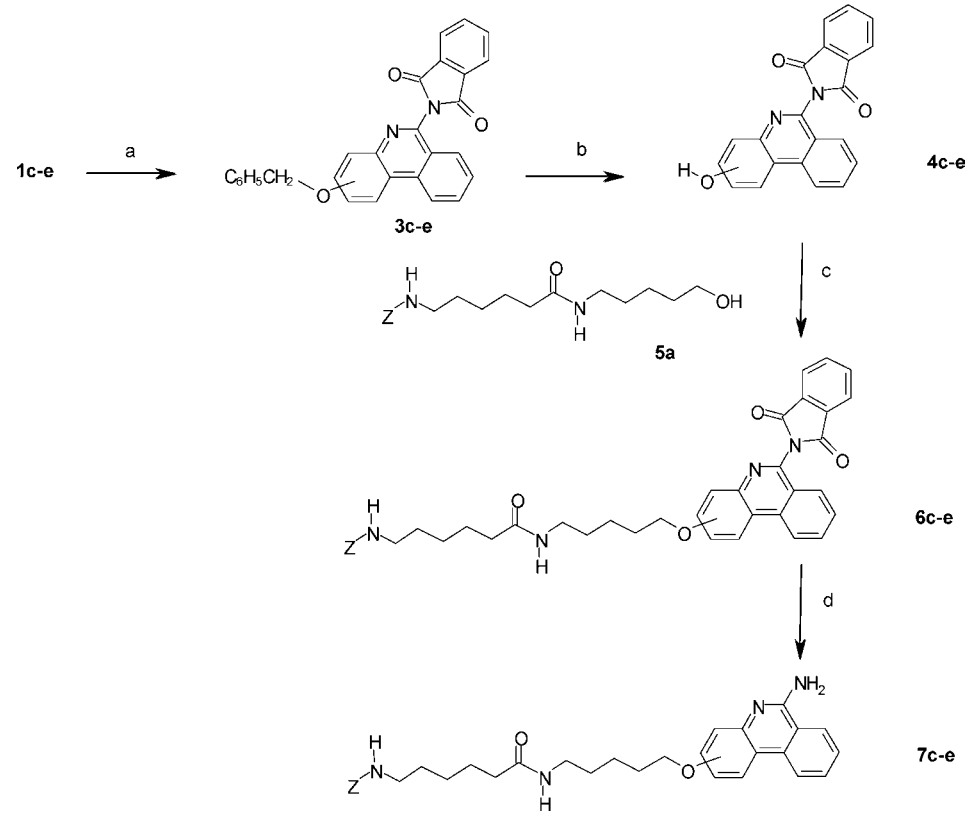
{5-[5-(3,5-Dichloro-4-benzylidenaminoguanidine)-pentylcarbamoyl]-pentyl}-carbamic Acid *tert*-Butyl Ester (12). Aminoguanidine hydrochloride (0.22 g, 2 mmol) was added to a solution of conjugate **11** (0.98 g, 2 mmol) in 10 mL EtOH followed by the addition of AcONa, $5H_2O$ (0.27 g, 2 mmol). After 2 h refluxing, the hot mixture was filtered, and **12** precipitated upon cooling to rt. Yield: 54%. Anal. ($C_{24}H_{38}Cl_2N_6O_4$) C, H, N. ^{1}H NMR ($CDCl_3$) δ 1.24−1.63 (m, 10H, 5 × CH_2); 1.43 (s, 9H, $C(CH_3)_3$); 1.74 (q, 2H, CH_2); 2.17 (t, J = 7 Hz, 2H, CH_2CO); 3.08 (q, J = 6.03 Hz, 2H, CH_2NH); 3.25 (q, 2H, CH_2NH); 3.95 (t, J = 6 Hz, 2H, CH_2−O); 5.79 (br s, 2H, NH_2); 6.35 (br s, 1H, NH); 6.88 (s, 2H, 3-H and 5-H); 8.36 (s, 1H, NCH). ^{13}C NMR ($CDCl_3$) δ 23.0; 25.1; 26.1; 28.2; 28.3; 29.0; 29.4; 36.1; 39.0; 68.0; 78.6; 115.2; 123.9; 134.8; 141.4; 155.9; 157.9; 160.6; 172.9.

2,6-Dichloro-4-(ε-aminocaproylaminopentyloxy)-benzylidenaminoguanidine) Trifluoroacetate (13). CF_3COOH (1 mL) was added to a solution of **12** (0.27 g, 0.5 mmol) in CH_2Cl_2 (10 mL). The solution was stirred for 2 h at rt and then concentrated until dryness. The viscous oil crystallized upon trituration with 2 mL cyclohexane followed by trituration with 2 mL Et_2O. Yield 76%, mp 75−78 °C. ^{1}H NMR (DMSO-d_6) δ 1.21−1.88 (m, 12 H, 6 × CH_2); 2.21 (t, J = 7 Hz, 2H, CH_2CO); 3.03 (m, 4H, 2CH_2NH); 4.02 (t, J = 6 Hz, 2H, CH_2−O); 6.23 (m, 4H, NH); 6.84 (s, 2H, 3-H and 5-H); 8.25 (s, 1H, NCH).

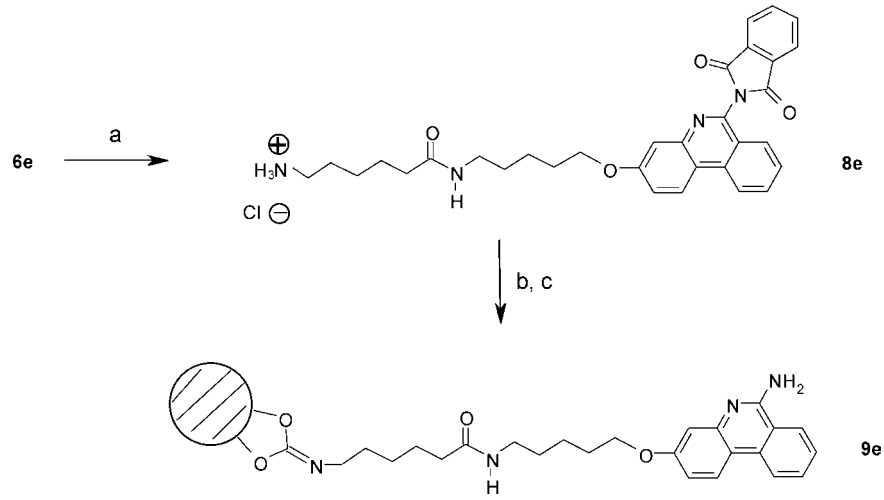
Immobilization of Ligands on Activated Sepharose Beads. Ligands were attached to CNBr-activated Sepharose 4 fast flow from Amersham Pharmacia according to the manufacturer's directions. A solution of 0.1 mmol ligands **8e** or **13** in 2 mL DMSO was added to 38 mL pH 8.3 solution (0.02 M $NaHCO_3$ + 0.1 M NaCl). This solution (0, 1, 2, 5 mL) was added to approximately 1 mL of beads suspended in pH 8.3 solution (final volume in each cartridge 10 mL). The cartridges were allowed to shake for 12 h at rt. The solutions were then drained from the beads, and 10 mL ethanolamine buffered solution (pH 8.5) was added to each cartridge, which was allowed to shake for 3 h at rt. This quenching step was repeated once. The phthalyl protecting group of 6AP-beads was then removed. A 3 mL solution of H_2O, DMF, and hydrazine hydrate (1:1:1) was added to the cartridges. After 15 min shaking, the solution was drained and the beads washed 3 times with 10 mL buffer. Finally, 10 mL buffer containing 1 g·L^{-1} NaN_3 was added to each cartridge, which was stored at 4 °C.



Affinity Chromatography Experiments on Immobilized 6AP and GA. These experiments were performed as previously described (*31*). Briefly, yeast (*Saccharomyces cerevisiae*) cell extracts were prepared using homogenization buffer (25 mM Tris-HCl (pH 7.4), 100 mM NaCl, 0.2% Triton X-100, and 1 mM PMSF). Yeast protein extracts were obtained from a culture growing at 30 °C ($OD_{600\ nm}$ = 0.8). Cell pellets were resuspended in homogenization buffer (300 μL/100 mL of culture) and lysed using acid-washed glass beads (purchased from Sigma, 300 μL/100 mL of culture). Homogenates were vortexed for 30 s followed by 30 s ice-cooling (six times) and then centrifuged for 3 min at 3000 rpm at 4 °C. Supernatants were recovered, assayed for protein content (using Bio-Rad protein assay), and immediately loaded batchwise on the affinity matrices. Just before use, 6AP and GA beads were washed with 1 mL of bead buffer (50 mM Tris−HCl (pH 7.4), 5 mM NaF, 250 mM NaCl, 5 mM EDTA, 5 mM EGTA, 0.1% Nonidet P-40, 10 μg/mL of leupeptin, aprotinin, and soybean trypsin inhibitor, and 100 μM benzamidine) and diluted 4 times in this buffer. 200 μg of yeast protein extract were added to 40 μL of diluted beads (10 μL of packed beads). The volume was adjusted to 600 μL by adding bead buffer, and the tubes were rotated at 4 °C for 30 min. Competitions with active or inactive drugs were performed with free compounds (or the corresponding volume of DMSO) at a final concentration of 1 mM incubated with cell extracts for 3 min before the mixture was added to the affinity matrix. Then, bead buffer containing the same quantity (1 mM) of the corresponding free compound was added immediately (as described previously) to reach a final volume of 600 μL. After incubation, a brief spin at 10 000 *g* at 4 °C, and removal of the supernatant, the beads were washed 4 times with bead buffer before addition of 35 μL of 2× Laemmli sample buffer. Following heat denaturation for 3 min at 95 °C, bound proteins were analyzed by 10% SDS-PAGE as described below.

Electrophoresis and Silver Staining. The proteins bound to 6AP or GA matrices were separated by 10% SDS-PAGE (precast NuPAGE−InVitrogen−1 mm thick gel) followed by silver staining using a GE Healthcare Life Sciences SDS-PAGE silver staining kit.

RESULTS



Preparation of 6-Aminophenanthridine Beads. The synthesis of the conjugates of 6AP is depicted in Schemes 1 and 2. Condensation of 2- or 3-benzyloxyaniline with 2-chlorobenzonitrile in liquid ammonia using metal amides (*32*) led to benzyloxy-6-aminophenanthridine **1c−e**. The mixture of **1c** and **1e** could not be separated on column chromatography. Alternatively, 3-benzyloxy-6-aminophenanthridine **1e** was obtained in a Suzuki−Myaura coupling procedure (*33*). Phthalylation of 6-aminophenanthridines **1c−e** afforded derivatives **3c−e**. The benzyl group was removed by catalytic hydrogenation to afford phenols **4c−e**. The spacer arms **5** were obtained by acylation of 5-aminopentanol with Boc or *Z*-ε-aminocaproic acid. Condensation of phenols **4c−e** with spacer **5a** under Mitsunobu reaction conditions led to conjugates **6c−e**. Finally, the phtalimido protecting group was eliminated to afford **8c−e**. Following the evaluation of **8c−e** in the antiprion test, the removal of

the Z-group was performed only on **6e**, which bears the spacer arm in position 3.

Elimination of the Z protecting group of **6e** led to the conjugate **8e**. The immobilization of conjugate **8e** was performed on commercially available preactivated beads (CNBr). Several ratios of ligand conjugated to the Sepharose beads were tested. In the following affinity chromatography experiments, optimal results were obtained with the matrices made using the bigger volume of ligand solution (5 mL). Residual activated groups were quenched by aminoethanol. Finally, the phthalyl protective group was removed by hydrazinolysis. Optimization of reaction conditions led to the selection of a DMF, H_2O, hydrazine hydrate (1:1:1) mixture (Scheme 3).

Preparation of Guanabenz Beads. The conjugate was easily obtained from 2,6-dichloro-4-hydroxybenzaldehyde **10** (*35*). Coupling of the Boc-protected spacer arm **5b** was achieved under Mitsunobu conditions leading to conjugate **11**. This aldehyde gave the protected GA conjugate **12** upon refluxing with aminoguanidine in EtOH. Acidic cleavage of the Boc protecting group led to the trifluoroacetate **13**, which was eventually coupled to Sepharose preactivated beads to obtain GA-beads **14** (Scheme 4).

Affinity Chromatography Assays. The ability of CPZ and QC to compete for ribosomal components binding on 6AP and GA beads is depicted in Figure 2. As can be seen, QC (lanes

6), but not CPZ (lanes 5), was able to compete for the binding of ribosomal components to both 6AP and GA beads.

DISCUSSION

We have previously described two single-step routes for the synthesis of 6APs (*32, 33*). In the present work, these two approaches were used. In preliminary structure−activity studies, we noticed that derivatives substituted on the amino group were devoid of any antiprion activity. Therefore, **1b** was selected as an inactive control useful for the affinity chromatography assays. This also indicates that the spacer arm should not be linked to the 6-amino group. Further, this amino group of 6AP appeared to be rather nucleophilic and then, if unprotected, would likely react in the coupling procedure on the activated Sepharose beads. In order to circumvent this major problem, a protective group which could be eliminated after grafting the conjugate to the beads was required. It implies that the deprotection of the 6-amino group of 6AP derivatives should be achieved under mild conditions. The phthalyl protective group fulfilled this requirement. The antiprion activity of conjugates **7c**−**e** has been evaluated in the yeast prion-based assay. Only the **7e** derivative substituted in position 3 retained some antiprion activity of **1a**, whereas conjugates **7c** and **7d**, substituted in position 1 or 2 respectively, were totally inactive (*31*). Therefore, **8e** was selected for the affinity chromatography study. Concerning GA beads, we noticed that arginine-containing peptides have been previously grafted on Sepharose beads. In these assays, the unprotected amidine group did not interfere in the coupling process (*34*). Therefore, in contrast to the preparation of 6AP beads, it was estimated that the amidine group of Guanabenz conjugate did not need to be protected.

Affinity chromatography experiments were performed with both 6AP and GA beads. Interestingly, although the two compounds are chemically unrelated, they were both found to interact with the ribosome in an RNA-dependent manner (*31*). First, both 6AP and GA showed specific interactions with ribosomal components: most of the proteins specifically bound to 6AP or GA beads turned out to be ribosomal proteins. The binding of these ribosomal proteins was specific, as they were absent from control beads (Figure 2, panel B, lane 1 in both gels), present on 6AP or GA beads (lane 2) and respectively competed away by free 6AP (left gel, lane 3) or by free GA (right gel, lane 3) but not by free 6APi (left gel, lane 4) or by free GAi (right gel, lane 4). The interaction of both 6AP and GA with ribosomal components was then shown to be RNA-dependent, as a treatment of the cellular extracts with RNase A before affinity chromatography purification completely abolished the binding of all ribosomal proteins. 6AP and GA were further shown to selectively interact with the domain V of the large rRNA (rRNA) of the large subunit of the ribosome. Therefore, the binding of ribosomal components to 6AP or GA beads is best explained by postulating that, in affinity chromatography experiments, immobilized 6AP or GA retains the entire ribosome due to the ability to specifically interact with domain V of the large rRNA. Interestingly, in parallel to their ability to specifically interact with domain V of the large rRNA, both 6AP and GA were shown to specifically inhibit its protein folding activity. Indeed, in addition, to bear the peptidyl transferase activity involved in translation, domain V of the large rRNA of the large subunit of the ribosome has also been shown to be able to assist protein folding, at least *in vitro* (*36*). We thus found that both 6AP and GA inhibit this ribosome-borne protein folding activity (RPFA) without any effect on the peptidyl transferase activity of the ribosome. Both 6APi (**1b**) and GAi (**2b**), which are inactive as antiprion chemical derivatives of, respectively, 6AP and GA, were unable to compete for the binding of ribosomal components to both 6AP and GA beads and also to inhibit RPFA (*30*). We thus proposed that the antiprion effect of both 6AP and GA could be due to their ability to inhibit the RPFA, and thus, RPFA could be involved in prion propagation. Therefore,

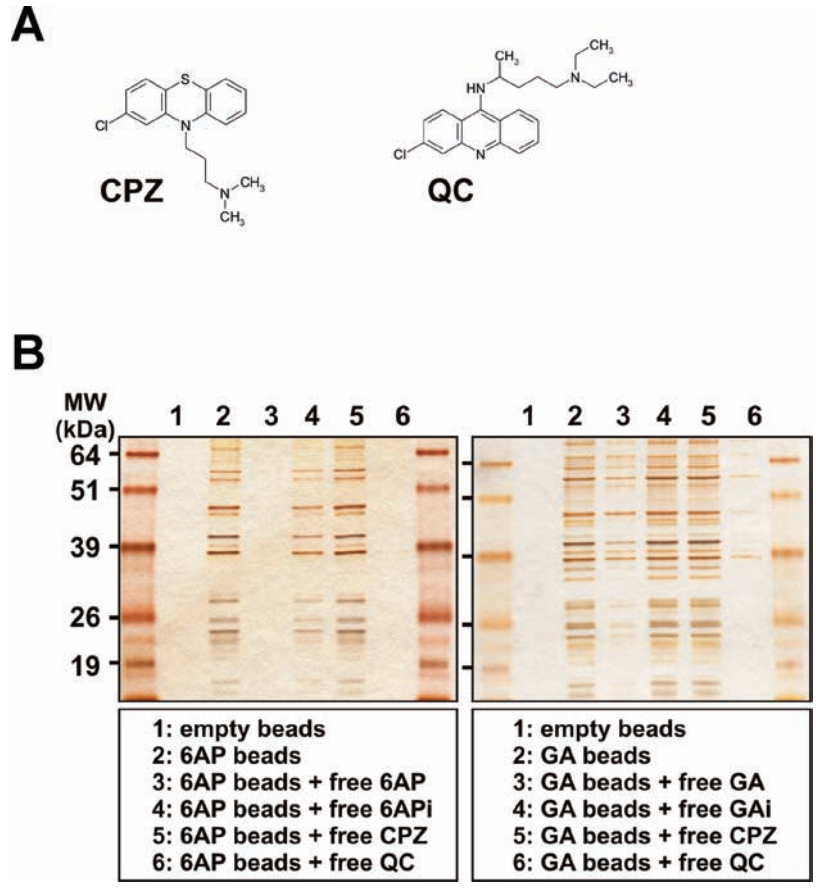

Figure 2. Competition experiments with Chlorpromazine (CPZ) and Quinacrine (QC). A. Molecular structures of CPZ and QC were depicted. B. Extracts from yeast were incubated with 6AP beads (left panel) or GA beads (right panel). The beads were then washed extensively and the bound proteins analyzed by SDS-PAGE. Proteins were then silver-stained. Most of the bands were previously identified as ribosomal proteins from both the small and large subunits of the ribosome. In both gels, lane 1 corresponds to chromatography using control beads without 6AP (left gel) or GA (right gel), and lane 2 to chromatography using 6AP (left gel) or GA (right gel) beads. Note that, in both cases, the patterns of eluted ribosomal proteins were rather similar. In both gels, lanes 3 to 6 correspond to competition experiments with the indicated free compounds. Note that QC, but not CPZ, was able to compete for the binding of ribosomal components to both 6AP and GA beads.

we were interested in determining if other known antiprion drugs could compete for the binding of ribosomal components on 6AP and GA beads when added to a mix of 6AP or GA beads and cellular extracts. This possibility is particularly appealing, as free 6AP was shown to efficiently compete for the binding of ribosomal components to GA beads, and vice versa (*31*), clearly indicating that they share overlapping binding sites on rRNA, which was indeed recently shown to be the case (*37*). Therefore, the ability of other unrelated antiprion drugs to compete for the binding of the ribosome to 6AP and GA beads would be an indication that these compounds share at least some common binding sites on domain V of the large rRNA of the large ribosomal subunit with 6AP or GA. Hence, all these molecules could share the same biological target accounting for their antiprion effect. Quinacrine (QC) and Chlorpromazine (CPZ) are two drugs already in use in humans for the treatment of malaria and psychosis, respectively. They were recently isolated as active *ex vivo* against mammalian prion in a N2a cell-based model (*8*) and the latter against yeast prions (*13*). The ability of CPZ and QC to compete for ribosomal components binding on 6AP and GA beads was determined (Figure 2). Interestingly, whereas QC was clearly able to efficiently compete for the binding of ribosomal components to both 6AP and GA beads (at least as efficiently as 6AP and GA themselves), CPZ was not, as observed for 6APi and GAi, derivatives of 6AP and GA that are inactive as antiprion drugs. These results suggest that QC, but not CPZ, could share at least some binding sites with 6AP and GA on the large rRNA. The fact that CPZ was unable to compete for the binding of rRNA on 6AP and GA beads suggests that either it has other biological target(s) or it also targets the ribosome and possibly also the large rRNA but on different and nonoverlapping binding sites than 6AP and GA.

CONCLUSION

In the present study, we have used a simple chemical spacer arm easy to introduce by Mitsunobu reaction. Therefore, the introduction of the linker requires the synthesis of phenols obtained from their benzyl ether precursors compatible themselves with the various reaction conditions used in the synthesis of the tricyclic phenanthridine moitie. This spacer arm can be considered less hydrophilic than classical polyoxyethylenic linkers, thus greatly facilitating the purification of the conjugates by column chromatography. The two hydrophobic parts of the spacer should not be able to establish interactions either with the bioactive molecule or with the hydrophilic Sepharose beads. The amide bond in the middle of the linker reduces the flexibility of the spacer. To the best of our knowledge, the deprotection of functional groups after grafting on the beads has not been previously reported. Using this procedure, we synthesized affinity chromatography matrices for both 6AP and GA, two antiprion drugs active from yeast to mammals. The identification of the protein folding activity of the ribosome as a common target of both compounds suggests the intriguing possibility that this largely unknown function borne by the large rRNA could be involved in prion propagation. Finally, it has been recently found that PrP^C is an amyloid-β oligomers receptor (*38*).

Because amyloids β-fibers are found in the brains of people suffering from Alzheimer's disease, this finding enhances the interest of studies aiming at deciphering the cellular mechanisms involved in the appearance and/or propagation of prion-based diseases.

ACKNOWLEDGMENT

We thank Sophie Mairesse-Lebrun for the microanalyses determinations of compounds and the ANR "blanche" from the French Ministère de la Recherche for financial support. DTT was supported by a PhD program from the French "Ministère de la Recherche" and CV by a Junior Contract from INSERM.

Intracellular Trafficking and Unpacking of siRNA/Quantum Dot-PEI Complexes Modified with and without Cell Penetrating Peptide: Confocal and Flow Cytometric FRET Analysis

Hyukjin Lee, In-Kyoung Kim, and Tae Gwan Park*

Department of Biological Sciences and Graduate School of Nanoscience and Technology, Korea Advanced Institute of Science and Technology, Daejeon 305-701, Korea. Received August 3, 2009; Revised Manuscript Received November 16, 2009

Cationic quantum dots (QDs) were utilized to complex small interfering RNA (siRNA) for studying intracellular trafficking, unpacking, and gene silencing. Positively charged polyethylenimine (PEI) was covalently conjugated on the surface of QDs to complex with cyanine dye labeled vascular endothelial growth factor siRNA (cy5-VEGF siRNA) for the formation of nanosized polyelectrolyte complexes (PEC). Fluorescence resonance energy transfer (FRET) was achieved between cy5-VEGF siRNA and PEI conjugated QDs (QD625) in the complex. From confocal microscopic analysis, intracellular uptake and release of siRNA from the PEC were visualized as a function of incubation time. The extent of cy5-siRNA release from the PEC was quantitatively evaluated by flow cytometric analysis. In addition, PEI conjugated QDs were further modified with a protein transduction domain (PTD) from human transcriptional factor, Hph-1. The two siRNA/QD-PEI complexes with and without Hph-1 have shown markedly different intracellular uptake behaviors and unpacking kinetics of cy5-siRNA. However, they exhibited similar extent of VEGF gene knockout regardless of Hph-1, but showed much higher gene silencing efficiency than siRNA/PEI complexes. The present study demonstrates that PEI conjugated QDs can be utilized as a useful siRNA carrier to analyze intracellular trafficking and unpacking pathway as well as to effectively silence a target gene.

INTRODUCTION

In recent years, small interfering RNA (siRNA) attracted much attention as a potent therapeutic nucleic acid drug for treatment of various diseases (*1–3*). Intracellularly delivered siRNA triggers RNA interference (RNAi), resulting in the specific down-regulation of target gene expression (*4–7*). Contrary to antisense oligonucleotides (ODN), siRNA requires a much lower dosage to achieve a sequence-specific gene inhibition effect. Although siRNA is a powerful gene regulation agent, therapeutic applications are limited mainly due to poor cellular uptake and accelerated degradation in biological fluids (*8, 9*). To overcome various intra- and extracellular delivery problems, cationic polymers and lipids have been popularly utilized as gene condensing agents to form positively charged, nanosized polyelectrolyte complexes (PEC) (*10, 11*). Among the cationic polymers, polyethylenimine (PEI) has been widely used for its superior buffering capacity, which allows excellent cargo translocation from endosomes to the cytoplasm by the "proton sponge" effect (*12, 13*). It was also previously reported that chemically modified PEI derivatives such as poly(ethylenimine)-*g*-poly(ethylene glycol) (PEI-g-PEG) and PEI-g-PEG-folate exhibited prolonged circulation in bloodstream and allowed target-specific cellular uptake via receptor-mediated endocytosis (*14–16*).

However, cellular uptake, cytosol specific release, and subcellular trafficking events of siRNA using cationic gene carriers are still unclear (*17*). Many studies have been pursued to discover different cellular uptake mechanisms and complicated intracellular fates (*18–20*). In particular, initial uptake and subcellular trafficking pathways of nucleic acid drugs need to be addressed in detail, when specific cellular uptake mechanisms, such as receptor-mediated endocytosis and cell membrane penetrating transcytosis, are employed. Fluorescently labeled nucleic acids and/or cationic carriers were widely used to investigate intracellular trafficking of PEC (*21, 22*). While these studies provide some valuable information about the localization of therapeutic nucleic acids and carriers within the cell, they mostly fail to show the decomplexation kinetics of the intracellular PEC. Recently, fluorescence resonance energy transfer (FRET) employing a pair of donor/acceptor organic fluorescent dyes has been utilized for dynamic monitoring of intracellular PEC fates (*23*). However, due to inherent instability of organic fluorescent dyes, semiconductor quantum dots (QDs) have emerged as an alternative FRET donor for proximal organic acceptor dyes (*24*). Since QDs have unique properties that surpass the conventional organic fluorescence dyes, such as tunable fluorescence emission, narrow photoemission, broad absorption spectrum, high extinction coefficients, and photostability, a wide range of surface-engineered QDs are extensively used as versatile molecular and cellular imaging agents (*25–27*). More recently, it was shown that QDs can be utilized to monitor the intracellular delivery and decomplexation of plasmid DNA (pDNA) (*28*). However, this approach required complex image analysis and data collection procedures from a particle-specific voxel-based method to evaluate the intracellular release of pDNA from QD-labeled polyplexes.

In this study, we report an alternative method for rapid analysis of intracellular siRNA uptake as well as the quantitative evaluation of siRNA unpacking from the cationic QD carriers. Instead of using a particle-specific voxel-based imaging analysis, we have used flow cytometric analysis to study the FRET interactions between cyanine dye labeled siRNA (cy5-siRNA) and cationic QD carriers. To prepare cationic QD carriers, PEI conjugated QD625 (QD-PEI) was synthesized for nanocomplexing with cy5-siRNA. The siRNA/QD-PEI complexes were utilized to investigate the time course for endocytic cellular uptake, subcellular trafficking, and unpacking of cy5-siRNA.

Protein transduction domain (Hph-1) peptide conjugated QD-PEI was also prepared to monitor nonendocytic cellular uptake and to study its effect on the trafficking and unpacking behavior of cy5-siRNA. Hph-1 was chosen as a cell penetrating domain to test its ability to cross the cell membrane and deliver the complexes without the assistance of the ATP-dependent endocytic pathway (*29, 30*). The analysis was performed at various time points to support the results obtained from confocal image analysis. Gene-silencing efficiencies of QD-based cationic carriers were comparatively evaluated in the serum containing condition.

EXPERIMENTAL PROCEDURES

Materials. Carboxylic acid modified quantum dots (Qdot625 ITK) were purchased from Invitrogen (Eugene, OR). 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (EDC) and succinimidyl 4-(*p*-maleimidophenyl) butyrate (SMPB) were obtained from TCI (Tokyo, Japan) and Pierce (Rockford, IL), respectively. Branched polyethylenimine (PEI, M_w 25 000) was provided from Sigma-Aldrich (St. Louis, MO). Vascular endothelial growth factor (VEGF) siRNA and cyanine 5 conjugated VEGF siRNA (sense, 5′-GGAGUACCCUGAUGAGAUCdTdT-3′; antisense, 5′-GAUCUCAUCAGGGUACUCCdTdT-3′) were purchased from Dharmacon (Lafayette, CO). Protein transduction domain (PTD) peptide from human transcriptional factor, Hph-1 (YARVRRRGPRRGGC), was obtained from Forhuman Tech (Seoul, Korea). Penicillin/streptomycin, fetal bovine serum (FBS), and Rosewell Park Memorial Institute 1640 medium (RPMI 1640) were supplied from Gibco BRL (Grand Island, NY). All other chemicals and reagents were of analytical grade.

Synthesis of PEI-Modified QDs (QD-PEI). To prepare PEI-conjugated QDs, EDC was used as a coupling agent to form an amide bond between primary amine group of PEI and carboxylic acid group of QD625. One hundred microliters of EDC (50 mg/mL) diluted in 400 μL of pH 7.4 phosphate buffered saline (PBS) solution was added into 200 μL of PEI solution (10 mg/mL in PBS) in a vial. Ten microliters of QD625 stock solution (8 μM) was added in 290 μL of PBS solution. The QD solution was slowly added into the activated PEI solution and stirred for 2 h in dark condition at room temperature. The unconjugated PEI fraction was removed by centrifugation at 10 000 rpm for 10 min using an ultrafiltration filter tube (Vivaspin, MWCO: 50 000 Da). The remaining solution was washed 2 times with PBS solution. The resultant PEI conjugated QD625 was referred to as QD-PEI. The volume of QD-PEI solution was adjust to 100 μL with PBS solution and stocked at 4 °C for further use.

Synthesis of QD-PEI-Hph-1 Conjugate. QD-PEI conjugated with Hph-1 was produced using a bifunctional cross-linker, SMPB. One milligram of SMPB was dissolved in 500 μL of DMSO before adding 400 μL of PBS solution. The solution was added into 500 μL of Hph-1 (2 mg/mL) and stirred for 1 h to activate a sulfhydryl group of Hph-1. The resultant solution was dialyzed (MWCO: 1000) for 2 h to remove unreacted SMPB. After dialysis, the solution in a dialysis membrane was collected and transferred into a vial to react with QD-PEI. Two microliters of QD-PEI was added to the vial, stirred for 1 h, and dialyzed (MWCO: 25 000) overnight at 4 °C. The QD-PEI conjugated Hph-1 was referred to as QD-PEI-Hph-1. The prepared QD-PEI-Hph-1 conjugate was stored at 4 °C.

Preparation and Characterization of QD-PEI/cy-siRNA Complexes. VEGF siRNA modified with a cyanine-5 dye at the 5′ end of its sense strand was utilized. QD-PEI was incubated with cy5-siRNA at 100, 200, 400, 800, 1000, 1600, and 3200 molar ratio of siRNA to QD-PEI at room temperature for 15 min in deionized water. The formation of siRNA/QD-PEI complexes were characterized by gel retardation and decomplexation assay, transmission electron microscopy (TEM) image analysis, and FRET-based assay. The morphology of QD-PEI was obtained using TEM. Twenty microliters of cy5-siRNA/QD-PEI complex solution at a molar ratio of 400:1 was deposited onto a 300 mesh copper grid. The grid was air-dried at room temperature and analyzed by Zeiss Omega 912 TEM (Carl Zeiss, Oberkochen, Germany). For decomplexation of cy5-siRNA/QD-PEI, 1 μg of heparin solution (100 mg/mL) was added to the complex solution prepared with a 3200:1 molar ratio of cy5-siRNA to QD-PEI and incubated for 15 min at room temperature. Decomplexation was analyzed by gel electrophoresis (2% agarose gel). FRET between QD and cyanine dye conjugated to siRNA was examined for various complexes prepared at different molar ratios of QD-PEI to cy5-siRNA (1:100, 1:200, 1:400, 1:800, and 1:1000). The emission spectra of the QD-PEI/cy5-siRNA complexes were measured by spectrofluorophotometer (SLM-AMINCO 8100, SLM Instrunments Inc., Rochester, NY) at an excitation of 350 nm.

Cell Cultures. Human prostate carcinoma cell line (PC-3) expressing VEGF was provided from the Korean Cell Line Bank (Seoul, Korea). The cells were maintained in RPMI1640 with 10% FBS, 100 IU/mL penicillin, and 100 μL streptomycin at 37 °C in a 5% CO_2 humidified atmosphere.

Confocal Image Analysis. For conical images, PC-3 cells were seeded in a 35 mm Petri dish (Ibidi, Germany) at a density of 5×10^4 and maintained for 48 h. Two kinds of complexes, QD-PEI/cy5-siRNA and QD-PEI-Hph-1/cy5-siRNA, at 1:400 molar ratio were prepared in serum-free media and incubated for 15 min at room temperature. After serum-containing media were added into the solution, cells were transfected with the complexes and incubated for 30 min, 2 h, and 6 h. After the transfection, the media were discarded and the cells were washed 3 times with PBS solution. After the cells were fixed with 3.7% paraformaldehyde solution, confocal images were obtained at each time point using LSM510 confocal laser scanning microscope (Carl Zeiss Inc., USA). To acquire a fluorescence signal of QD-PEI (emission: 625 nm), each sample was excited at 488 nm. A fluorescence signal of cy5-siRNA was detected at 670 nm with an excitation at 643 nm. A FRET signal was obtained at 670 nm with an excitation at 488 nm.

Fluorescence Activated Cell Sorter (FACS) Analysis. To quantitatively examine intracellular uptake and unpacking of QD-PEI/cy5-siRNA and QD-PEI-Hph-1/cy5-siRNA complexes, flow cytometric analysis was conducted. PC-3 cells were seeded into a 6-well-plate at a density of 3×10^5 and maintained for 24 h. One microgram of cy5-siRNA was complexed with QD-PEI, and then cells were transfected for 1 h at 37 °C. After the transfection, the cells were washed three times with PBS solution and incubated with fresh media for 0 to 5 h. For flow cytometry analysis, the resultant cells were trypsinized and collected in an Eppendorf tube. The cells were sieved with a cell strainer (BD Bioscience, USA), and the volume of samples was adjusted to 2 mL with cold PBS solution. Fifteen thousand cells were monitored and evaluated by FACSAria (BD Bioscience, USA) to determine the cellular uptake and unpacking of cy5-siRNA/QD-PEI complexes. To calculate overall uptake and unpacking of PEC in the cells, fluorescence intensity of cy5-siRNA was first obtained (F_{cy5}). Fluorescence intensity of QD-PEI and FRET mediated cy5 emission was abbreviated as F_Q and $F_{f,cy5}$, respectively. The percent release of cy5-siRNA from PEC (F_r) at each time point was calculated from eq 1.

$$F_r = (1 - F_{f,cy5}/F_{cy5}) \times 100 \quad (1)$$

Gene Silencing Efficiency. PC-3 cells were seeded on a 12-well plate at a density of 1×10^5 and maintained for 24 h. Five micrograms of siRNA was used to formulate PEC with QD-PEI, QD-PEI-Hph-1, LipofectAmine, and PEI. After 15 min

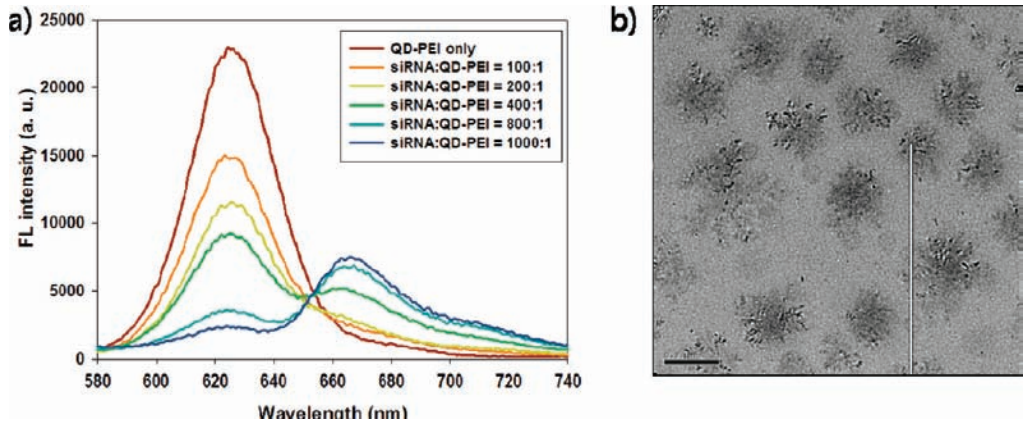

Figure 2. (a) Fluorescence spectra of QD-PEI/cy5-siRNA complexes excited at 350 nm with increasing molar ratio of cy5-siRNA. (b) TEM image of QD-PEI/cy5-siRNA complexes (scale bar is 200 nm).

incubation with different gene carriers, PC-3 cells were transfected for 2 h. After the transfection, the media were replaced with fresh serum-containing media and incubated for 6 h. The media were discarded in order to remove endogenously secreted VEGF, and fresh media were added to the cells. After 16 h, the incubating media were collected to measure the amount of released VEGF by using Quantikine human VEGF immunoassay kit (R&D System, Minneapolis, MN).

RESULTS AND DISCUSSION

Figure 1 shows the schematic illustration of QD-PEI and QD-PEI-Hph-1 conjugates. Carboxylic acid groups of QDs were activated using EDC to generate *O*-acylisourea active intermediates, and reacted with primary amine groups of PEI. A thiol group of Hph-1 peptide was additionally conjugated on the QD-PEI using a heterobifunctional coupling reagent (SMPB). By forming nanosized polyelectrolyte complexes (PEC) by electrostatic interactions between cationic QD carriers and anionic cy5-siRNA, it was expected that FRET occurred by emitting a fluorescence signal at 670 nm when QDs were excited at 350 nm. On the contrary, upon unpacking and releasing of cy5-siRNA from the PEC, emission fluorescence signals of free QD-PEI and cy5-siRNAs would be separately observed along with the gradual decrease of the FRET emission signal over time. To test our hypothesis, intensity of QD fluorescence signal emitting at 625 nm was monitored with increasing amount of cy5-siRNA for PEC formation (Figure 2a). Since QD had a broad excitation wavelength range, QD-PEI was excited at a wavelength of 350 nm to avoid the excitation of cy5-siRNA. From the fluorescence spectra, it was observed that emission spectra of QD were well-overlapped with absorption spectra of cy5-siRNA to allow sufficient energy transfer to generate FRET signal. It was also noticeable that the formation of PEC between QD-PEI and cy5-siRNA induced reduced fluorescence intensity of QD signal at 625 nm. At a molar ratio over 400:1 (siRNA/QD), the emission fluorescence signal of cy5-siRNA via energy transfer was clearly identified. The particle size and morphology of QD-PEI/cy5-siRNA complexes were studied by TEM (Figure 2b). About 200 nm sized spherical PEC were observed in a well-dispersed state, and several dark objects were identified within the complex structure due to the presence of electron-dense QDs. The QD-PEI/cy5-siRNA complexes were further characterized by gel electrophoresis. Surface charge of complexes and the number of cy5-siRNA loaded onto QD-PEI were estimated by gel retardation assay. Negatively charged carboxylic acid group modified QDs migrated downward, while QD-PEI disappeared from the gel due to the highly positive surface charge (see Supporting Information Figure S1). To mimic the intracellular unpacking of cy5-siRNA from QD-PEI, negatively charged heparin was incubated with QD-PEI/cy5-siRNA com-

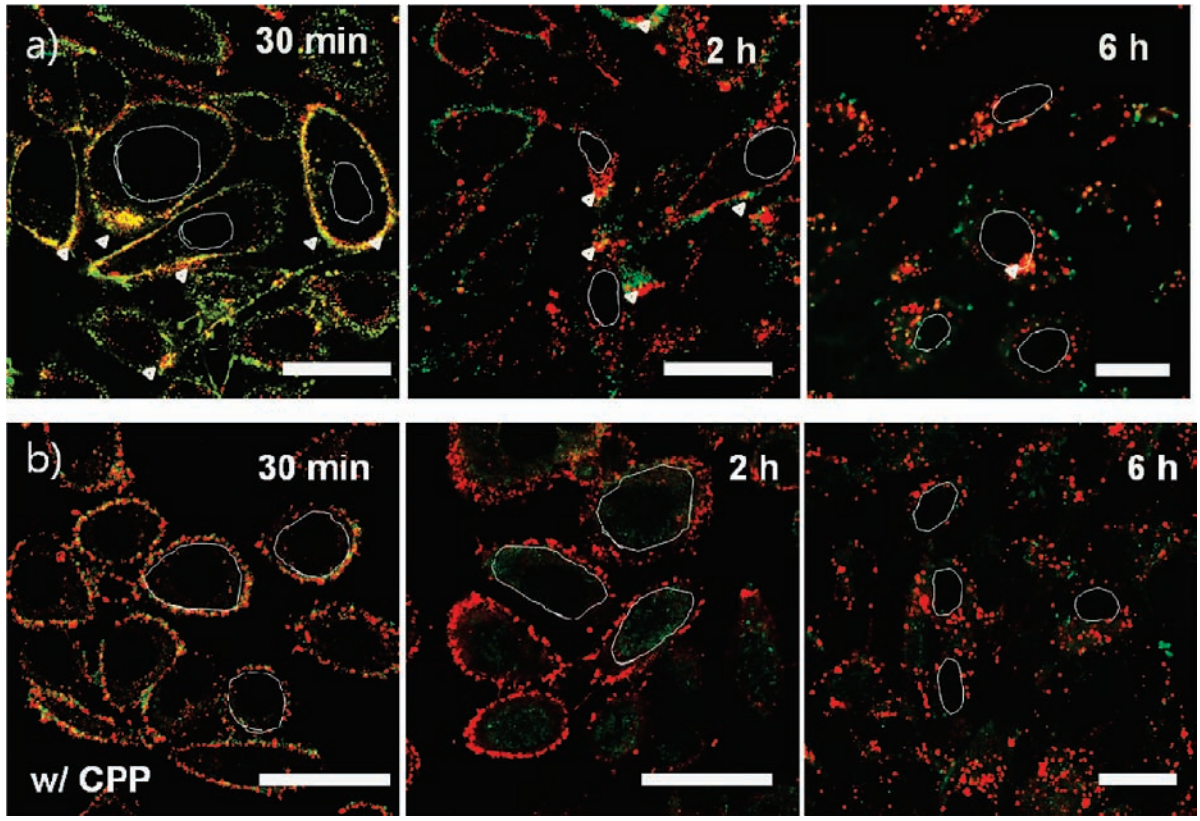

Figure 3. Intracellular uptake of cationic QD-PEI/cy5-siRNA complexes: (a) QD-PEI/cy5-siRNA and (b) QD-PEI-Hph-1/cy5-siRNA after 30 min, 2 h, and 6 h. Nucleus membranes are marked in white (scale bar is 10 μm).

plexes. It was observed that QD-PEI/cy5-siRNA complexes were fully decomplexed by releasing cy5-siRNA from the PEC (see Supporting Information Figure S1).

To investigate two different intracellular delivery mechanisms of QD-PEI and QD-PEI-Hph-1 complexed with cy5-siRNA, confocal images after transfection were obtained in a time-dependent manner. Ten picomoles of cy5-siRNA was utilized to prepare PEC with QD-PEI and QD-PEI-Hph-1 at the molar ratio of 400:1. QD-PEI and cy5-siRNA could be visualized in green and red color, respectively. As shown in Figure 3a, most QD-PEI/cy5-siRNA complexes were bound onto the cell membrane at 30 min and appeared in yellow color (merged image of green and red color). The cell surface bound complexes were probably due to the initial electrostatic interactions between positively charged PEC and negatively charged cell membrane (*21*). The yellow color in the image indicated that QD-PEI and cy5-siRNA were colocalized as a result of intact nanocomplex structure. After 2 h incubation, the subcellular uptake of QD-PEI/cy5-siRNA complexes could be seen along with the partial dissociation of cy5-siRNA from the PEC. Unpacked QD-PEI and cy5-siRNA could be visualized predominantly in the endosomal compartment near the inner cell membrane. In addition, unpacked cy5-siRNA in red color could be visualized as scattered dots in the cytoplasmic region. At 6 h incubation, it could be observed that siRNA was fully unpacked and released from the PEC and mostly sequestered in the cytoplasm, possibly interacting with some subcellular organelles. When an endosomal marker was used to label early endosomes, it was clearly visualized that most QD-PEI/cy5-siRNA complexes were located within endosomes until 2 h incubation (see Supporting Information Figure 2S). The time-dependent trafficking observation also suggested that QD-PEI/cy5-siRNA complexes started to escape from the early endosomes and cy5-siRNA was released from the PEC as early as 2 h incubation, in accordance with a typical endocytic and subsequent subcellular trafficking process (*28*).

On the other hand, the intracellular uptake manner of Hph-1 modified PEC was substantially different from that of QD-PEI/cy5-siRNA. After 30 min incubation, the QD-PEI-Hph-1/cy5-siRNA complexes were already located within the cells, and they were accumulated in the perinuclear region (Figure 3b). In addition, the intensity of the yellow image near the nuclear membrane was greatly reduced compared to that of QD-PEI/cy5-siRNA, indicating that the unpacking process of cy5-siRNA from the PEC was initiated within the cells as early as 30 min incubation. This reveals that the surface-conjugated cell-penetrating Hph-1 could facilitate intracellular uptake of QD gene carrier directly via a transcytosis process, and the PEC near the nucleus in the cytoplasm was readily decomplexed to release unpacked siRNA. At 2 h incubation, more cy5-siRNA was unpacked and released from the PEC, but still bound onto the nuclear membrane, while some part of the QD-PEI-Hph-1 entered into the nucleus. Endosome staining results revealed that cy5-siRNA was not located within endosomes, supporting direct transcytosis of Hph-1 conjugated QD complexes (see Supporting Information Figure 2S). After 6 h incubation, free cy5-siRNA was clearly visualized throughout the cytoplasm as punctuated dots. It is likely that Hph-1 originally derived from a human transcription factor played a key role not only in transporting the PEC within cells via a nonendocytic pathway, but also in targeting to the nucleus (*29, 30*). In fact, the nuclear migration behavior of Hph-1 has been previously identified, and many cell-penetrating peptides exhibit a strong tendency to migrate into the nucleus and accumulate in the perinuclear region (*31*).

Intracellular unpacking kinetics of siRNA from each complex was quantitatively evaluated by flow cytometry analysis. Compared to the conventional pixel-counting method using the

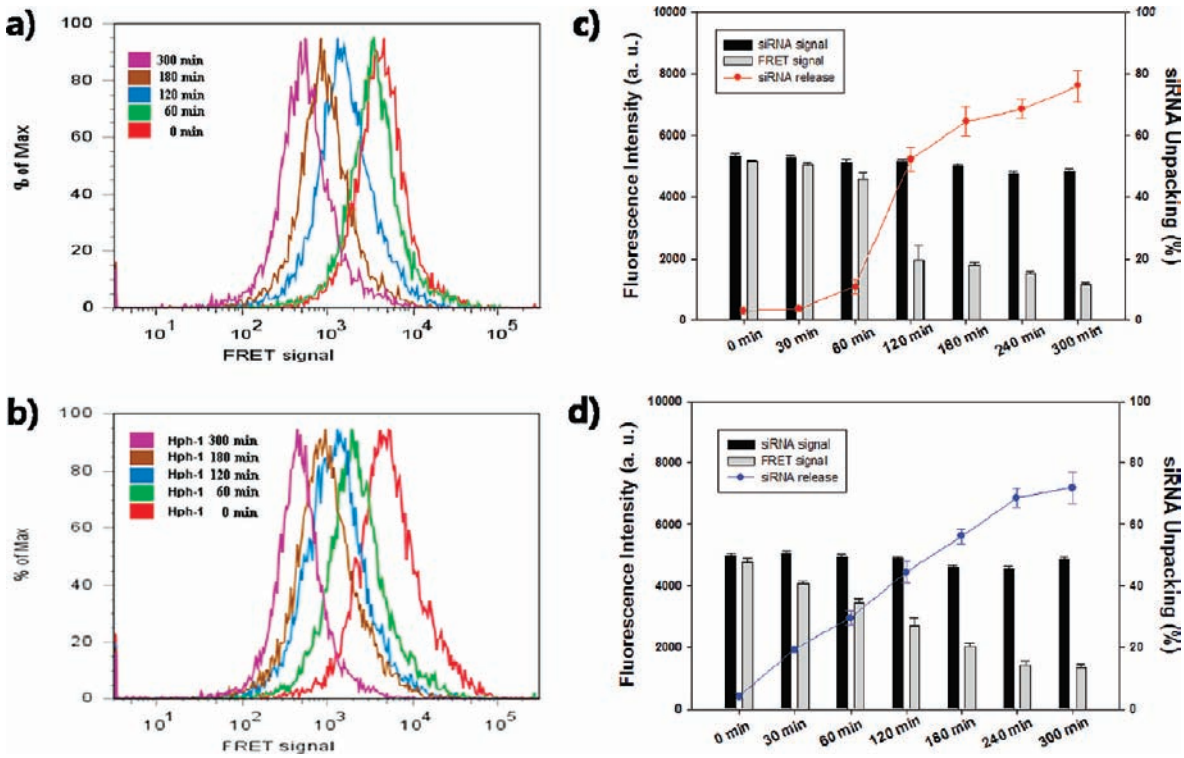

Figure 4. Intensity change of FRET-mediated signals during the incubation time. (a) QD-PEI and (b) QD-PEI-Hph-1. The comparison of cy5-siRNA signals versus FRET-mediated signals and the release of cy5-siRNAs during the incubation time ($n = 5$). (c) QD-PEI and (d) QD-PEI-Hph-1.

confocal images, the flow cytometry based FRET analysis offers more precise data for quantitative evaluation of time-dependent siRNA unpacking within live cells (*32–34*). For cytometry analysis, two different laser sources and detectors were utilized to measure the separate fluorescence signals from cy5-siRNA and QD-PEI, simultaneously. As shown in Figure 4, the intensity of cy5-siRNA signals within the cells was monitored as a function of time as compared to that of FRET-induced fluorescence signals. Since the transfection time was fixed to 1 h for all samples, the total amount of siRNA within the cells remained similar in all time points. Unlike the cy5-siRNA signal, FRET-induced fluorescence signal emitted from the PEC was decreased dramatically with the incubation period. It was assumed that, at zero incubation time, most of the cy5-siRNA within the cells formed compact PEC. The intensity changes in FRET-induced fluorescence signal at each time point are shown in Figure 4a,b. The higher FRET intensity value indicates the compact structure of QD-PEI/cy5-siRNA complexes within the cells. On the other hand, decreasing FRET-induced fluorescence signal indicates the unpacking of cy5-siRNA from the PEC. In Figure 4a, it is shown that FRET-induced fluorescence signals minimally decreased until 1 h postincubation using QD-PEI as a gene carrier. The FRET intensity value only decreased about $5.4 \pm 0.3\%$ at 1 h, but started to reduce dramatically thereafter resulting in $53.7 \pm 3.2\%$ reduction of FRET intensity value at 2 h. Further decrease in FRET intensity value was observed in a time-dependent manner until 5 h postincubation. In the case of QD-PEI-Hph-1, the initial uptake amount of cy5-siRNA was similar to that of QD-PEI (Figure 4b). However, unpacking the kinetic rate of cy5-siRNA from QD-PEI-Hph-1 was much faster than that of QD-PEI, showing $29.7 \pm 2.6\%$ reduction of FRET-induced fluorescence signal at 1 h. Furthermore, QD-PEI-Hph-1 complexes exhibited an almost constant release of cy5-siRNA for an entire 5 h incubation period. It was likely that the delayed release of cy5-siRNA from the QD-PEI complexes was due to their ATP-dependent endocytic cellular uptake, followed by endosomal escape of cy5-siRNA into the cytoplasm (*35*). From the comparative unpacking kinetics of siRNA, it was clear that Hph-1 conjugated QD complexes were directly taken up by cells in a non-endocytic manner with accelerating decomplexation of cy5-siRNA in the cytosol, which was also supported by facile intracellular uptake of Hph-1 conjugated QD complexes in ATP-deficient conditions (see Supporting Information Figure 3S). The flow cytometry results of siRNA unpacking were well-correlated with the confocal images shown in Figure 3.

To evaluate the gene silencing efficiency of QD-PEI/siRNA and QD-PEI-Hph-1/siRNA, VEGF overexpressing PC-3 cells were used. Cationic QD-based gene carriers were applied to the cells in 10% serum-containing media as well as conventional cationic carriers such as PEI and LipofectAmine to compare the relative gene inhibition efficiency of each carrier. As shown in Figure 5, QD-PEI/siRNA and QD525-PEI-Hph-1/siRNA exhibited VEGF expression of 228.0 ± 20.0 pg/mL and 193.2 ± 16.4 pg/mL, respectively. These gene inhibition efficiencies were comparable to that of LipofectAmine (209.3 ± 46.6 pg/mL). On the other hand, PEI exhibited much lower gene inhibition efficiency of 548.8 ± 91.9 pg/mL. It is known that, in the presence of serum proteins, cationic polymers such as PEI often show reduced gene silencing effects due to nonspecific protein adsorption on the positively charged surface of the complexes (*35*). From our results, it is still not clear why the PEI conjugated QDs show superior gene silencing efficiency compared to PEI. It seems that PEI with embedded multiple QDs could facilitate the endocytic cellular uptake of the complexes more than naked PEI. This was based on the assumption that QD-PEI/siRNA complexes were hard nanospheres, whereas PEI/siRNA complexes were soft and elastic ones. It is likely that not only the size, but also the morphology and hardness of QD-PEI/siRNA complexes may affect intracellular uptake of siRNA (*36*). As a result, enhanced cellular uptake of QD-based PEC along with maintaining the "proton sponge" effect might lead to the observed superior gene silencing effect. It is also interesting to observe similar gene silencing extents between QD-PEI and QD-PEI-Hph-1, although QD-PEI-

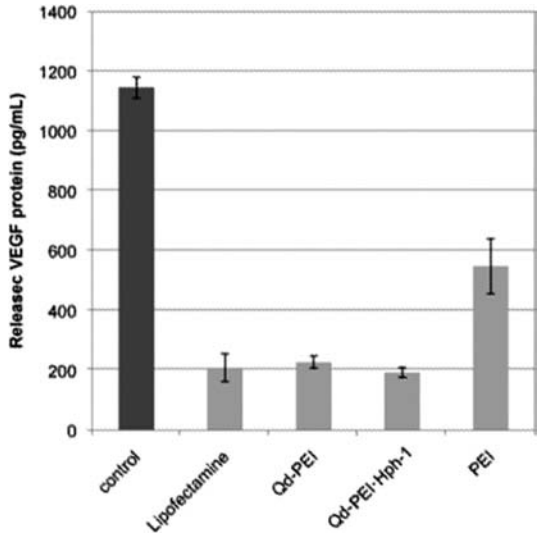

Figure 5. Inhibition of VEGF gene expression by QD-PEI/siRNA and QD-PEI-Hph-1/siRNA complexes compared to that of Lipofectamine and PEI ($n = 5$).

Hph-1 showed much faster cytosolic delivery of PEC than that of QD-PEI. This discrepancy was likely due to the fact that the amount of VEGF in the transfected cells was analyzed after 24 h post-transfection, which was sufficiently long for QD-PEI/siRNA complexes to completely release free siRNA in the cytosol (*37*). This could result in no difference in apparent gene silencing efficiency. Lastly, it should be noted that PEI-modified QD carriers showed markedly reduced cytotoxicity as compared to PEI (see Supporting Information Figure 4S), which makes them an ideal carrier for siRNA delivery as well as for intracellular FRET analysis.

CONCLUSION

We have synthesized two different QD based gene carriers, QD-PEI and QD-PEI-Hph-1, which could form PEC with cy5-siRNA by electrostatic interactions. Using the QD-based nanocarriers, intracellular trafficking of cy5-siRNA was successfully monitored by confocal analysis as a function of incubation time. Furthermore, flow cytometry analysis enabled the quantitative evaluation of cy5-siRNA unpacking from the QD-PEI and QD-PEI-Hph-1 complexes. To the best of our knowledge, this is the first report on the quantitative flow cytometry analysis of siRNA release from the gene carrier within live cells. This study also demonstrates that QD-PEI and QD-PEI-Hph-1 carriers could be employed as excellent siRNA delivery carriers.

Reducible Poly(amido ethylenimine)-Based Gene Delivery System for Improved Nucleus Trafficking of Plasmid DNA

Ji Hoon Jeong,*[,†,‡] Sun Hwa Kim,[§] Lane V. Christensen,[‡] Jan Feijen,[||] and Sung Wan Kim[‡]

In a nonviral gene delivery system, localization of a plasmid DNA in the nucleus is a prerequisite for expression of a desired therapeutic protein encoded in the plasmid DNA. In this study, a reducible polymer-based gene delivery system for improved intracellular trafficking and nuclear translocation of plasmid DNA is introduced. The system is consisted of two components, a plasmid DNA having repeated binding sequence for a karyophilic protein, NFκB, and a reducible polymer. A reducible poly(amido ethylenimine), poly(TETA-CBA), was synthesized by a Michael-type addition polymerization between cystamine bisacrylamide and triethyl tetramine. The polymer forming tight complexes with plasmid DNA could be degraded in the reductive cytosol to release the plasmid DNA. The triggered release mechanism in the cytosol could facilitate the interaction between cytosolic NFκB and the plasmid DNA having repeated NFκB biding motif. Upon activation of NFκB by interleukin-1β (IL-1β), most of the plasmid distributed in the cytoplasm was localized within the nucleus, resulting in significantly higher gene transfection efficiency than controls with nondegradable PEI. The current study suggests an alternative way of improving transfection efficiency by taking advantage of endogenous transport machinery for intracellular trafficking and nuclear translocation of a plasmid DNA.

INTRODUCTION

Over the last decades, a lot of nonviral gene delivery systems based on synthetic materials have been developed to replace virus-originated gene carriers that are often questioned for safety issues (*1, 2*). However, there is still room to improve transfection efficiency of nonviral methods. Synthetic carriers should overcome a number of extracellular and intracellular barriers to deliver plasmid DNA to the cell nucleus where gene transcription occurs. Among the challenging barriers, the dissociation of plasmid DNA from a carrier complex, the transport of plasmid DNA to the peri-nuclear space in the cytoplasm, and the passage of plasmid DNA across the nuclear membrane are considered rate-limiting steps in a polymer-based gene delivery carrier (*3, 4*). Although efficient intracellular trafficking and nuclear translocation of plasmid DNA is essential to achieve desirable transfection efficiency, the delivery mechanism by a nonviral gene carrier has not been clearly understood. One possible mechanism is the nucleus localization of plasmid DNA by disruption of the nuclear envelope during mitotic cell division (*5*). Active nuclear transport of plasmid DNA by employing a nuclear localization signal (NLS) was previously suggested (*6*), but the effectiveness of NLS in transfection still seems to be controversial (*7*). Recent studies showed that plasmids containing a specific sequence recognized by a nuclear protein (nuclear factor κB, NFκB) could improve transfection possibly due to nuclear-protein guided intracellular trafficking and active nuclear translocation of the plasmid DNA (*8*−*10*). However, in this case, the release of plasmid DNA from carrier/DNA complexes is a prerequisite for the interaction of the nuclear protein to plasmid DNA that may lead to the guided trafficking and nuclear transport of plasmid DNA.

We previously demonstrated that reducible poly(amido ethylenimine)s successfully carry out unpacking of complexes owing to a reductive degradation of the polymer backbone in the cytoplasm, leading to enhanced transfection efficiency (*11, 12*). In this study, we used a plasmid DNA containing repeated NFκB binding sites in conjunction with the reducible poly(amido ethylenimine) to improve cytosolic release of plasmid DNA. It was hypothesized that the triggered release of the plasmid DNA with the NFκB binding sites in the reductive cytoplasm would facilitate the access of NFκB to the plasmid DNA to improve nuclear translocation, which may consequently lead to enhancement of transfection efficiency.

MATERIALS AND METHODS

Materials. For polymer synthesis, triethylenetetramine (TETA) and cystamine bisacrylamide (CBA) were purchased from Sigma-Aldrich (St. Louis, MO) and Polysciences (Warrington, PA), respectively, and were used without further purification. Branched polyethylenimine (bPEI, M_w 25 000), ethidium bromide, buthionine sulfoxamine (BSO), dithiothreitol (DTT), and (3-(4,5-dimethylthyazolyl-2)-2,5-diphenyl tetrazolium bromide) (MTT) was obtained from Sigma-Aldrich (St. Louis, MO). All cell culture products including fetal bovine serum (FBS) and Dulbecco's Modified Eagle's Medium (DMEM) were purchased from Invitrogen (Carlsbad, CA). Mouse interleukin-1β (IL-1β) and a protease inhibitor cocktail containing aprotinin, bestatin, leupeptin, E-64, and pepstatin A were obtained from Sigma-Aldrich (St. Louis, MO).

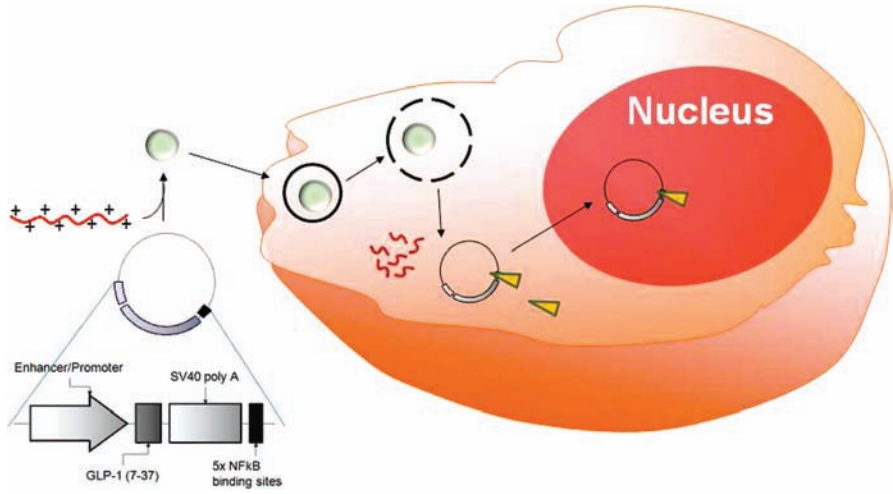

Figure 1. Schematic illustration of a gene delivery system based on a reducible polymer and a plasmid that can interact with cytosolic karyophilic protein, NFκB.

Synthesis of a Reducible TETA-CBA Copolymer. Reducible TETA-CBA copolymer was synthesized by Michael-type addition polymerization as described previously (*11*). Briefly, addition polymerization between TETA (449 mg, 3.1 mmol) and CBA (800 mg, 3.1 mmol) was performed in 10% aqueous methanol at 50 °C for 16 h. The reaction was terminated by adding an excess amount of the amine donor (TETA). The product was purified by ultrafiltration (MWCO 1000) and lyophilized. The chemical composition of the synthesized polymer was estimated by using ^{1}H NMR. The polymer molecular weight (M_w) was 3350, as determined by gel permeation chromatography (GPC).

Plasmid DNA. A plasmid DNA (pSIGLP1NFκB) containing an expression cassette of GLP-1 and five direct repeats of NFκB binding motif (5′-GGGGACTTTCC-3′) was constructed as described in a previous report (*9*). The repeated NFκB binding sites was inserted after SV40 polyadenylation site (Figure 1). Plasmid DNA was purified from *E. coli* by an alkaline lysis method using a silica-based anion exchange column (Qiagen, Valencia, CA).

Electrophoretic Mobility Shift Assays. Varying amounts of poly(TETA/CBA) and a fixed amount of plasmid DNA (300 ng) were separately diluted in PBS. The diluted polymer and DNA solutions were combined at varying weight ratios and mixed with gentle vortexing to form complexes. Dithiothreitol (DTT, 2.5 mM) was added to one of the test groups to observe the release of plasmid DNA by a reductive degradation of the polymer. The complexes were allowed to be stabilized for 30 min at ambient temperature and loaded onto 0.8% agarose gel. Electrophoresis was performed with a current of 120 V for 20 min in TAE buffer solution (40 mM Tris/HCl, 1% (v/v) acetic acid, 1 mM EDTA). Retardation of the complexes was visualized by using an image analyzer equipped with UV transilluminator (GelDoc, BioRad, Hercules, CA) after ethidium bromide staining.

Cell Culture and Transfection. Mouse fibroblast cells (NIH3T3) was cultured in DMEM supplemented with 10% FBS and maintained at 37 °C in a humidified 5% CO_2 atmosphere. Before transfection, the cells were trypsinized and 10^5 cells per well were plated in a six-well plate (35 mm diameter). The cells were then incubated at 37 °C in a humidified 5% CO_2 atmosphere for 24 h.

Before transfection, the plasmid DNA (2 μg) and the desired amount of either TETA-CBA (DNA/polymer = 10:1 w/w) or bPEI 25 kDa (DNA/polymer = 0.75:1 w/w) were separately diluted in PBS and mixed. The mixture was incubated to form complexes for 15 min at room temperature and added to the cells. The cell culture medium was replaced with serum-free medium prior to the addition of the complexes. After 3 h incubation at 37 °C, the medium was removed and supplemented with a fresh cell culture medium containing 10% FBS and a protease inhibitor cocktail. For the activation and nuclear translocation of cytoplasmic NFκB, IL-1β (20 ng/mL) was added to the medium. The concentration of GLP-1 was determined by ELISA (Linco Research, St. Charles, MO), as previously described (*13*).

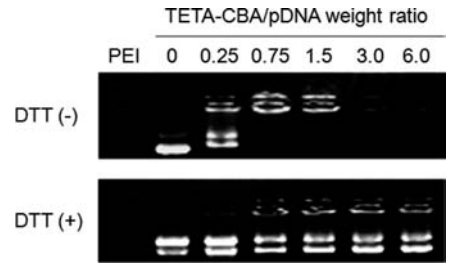

Figure 2. Electrophoretic mobility shift assays of poly(TETA/CBA)/plasmid DNA complexes at various polymer/siRNA weight ratios. Dithiothreitol (DTT, 2.5 mM) was added to generate a reductive environment to trigger the release of plasmid DNA from the complexes.

Flow Cytometry. To determine cellular association of the transfection complexes formed from a desired polymer (either TETA-CBA or PEI), the transfected cells were trypsinized and washed three times with cold PBS, and fixed by 1% paraformaldehyde at 4 °C before flow cytometric analysis (FACS Caliber, Becton-Dickinson, Mount View, CA). At least 1×10^4 events were analyzed to generate each diagram.

Confocal Microscopy. The cells were grown in glass-bottomed dishes (Glass Bottom Microwells; MatTek Corp., Ashland, MA). The plasmid DNA was fluorescently labeled with Cy3 by using Label-IT kit (Mirus Bio, Madison, WI). The transfection and NFκB activation were carried out as described above. The transfected cells were incubated for additional 2 h in the absence and presence of 20 ng/mL of IL-1β, prior to the observation. The cells were then washed five times with cold PBS, fixed by submerging the cells in 1% paraformaldehyde at 4 °C for 30 min, and washed three times with cold PBS. The subcellular localization of the complexes was visualized by a laser scanning confocal fluorescence microscopy using Olympus Fluoview FV300 microscope (Melville, NY). An oil immersion objective lens was used for the epidetection configuration.

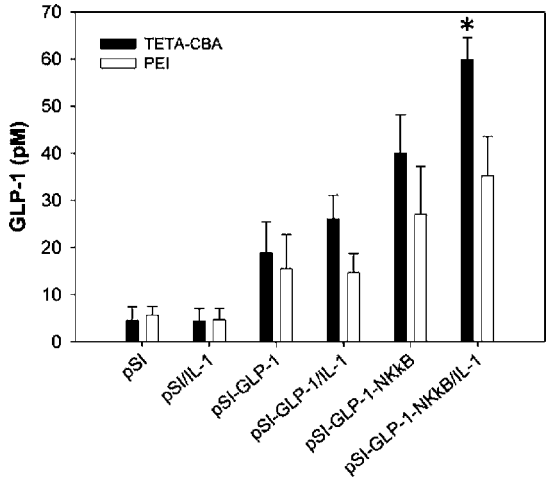

Figure 3. Transfection efficiencies of various formulations based on either TETA-CBA or PEI. IL-1β was added to activate nuclear translocation of NFκB. The expression level of secreted GLP-1 was determined by ELISA and given as the mean $\pm$ SD ($n = 3$). *$p < 0.01$ compared to the PEI-based control.

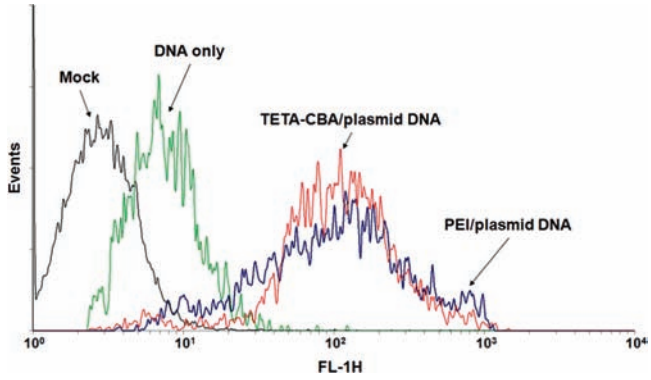

Figure 4. Cellular association of pSIGLP1NFκB/TETA-CBA and pSIGLP1NFκB/PEI complexes, analyzed by flow cytometry.

Nuclear localization of plasmid DNA was quantified by relating fluorescence intensities from two arbitrarily defined regions of interest (ROIs): the whole cell (FL_{cell}) and the nucleus ($FL_{nucleus}$). Fluorescence intensity from each ROI was separately analyzed by using *ImageJ* v 1.42 software (http://rsb.info.nih.gov/ij). Percent fluorescence in the selected nucleus region ($FL_{nucleus}/FL_{cell} \times 100$) was calculated and presented as mean percent nuclear localization $\pm$ SEM ($n = 50$).

RESULTS AND DISCUSSION

Viruses have evolved to transfer their genetic information to host cells for the production of progeny. For the efficient delivery of its genome to the host nucleus, a virus contains multiple functional components that facilitate cellular entry, endosomal escape, the dissociation of genetic material from capsid protein complex, and nuclear transfer by the aid of host nuclear localization mechanism. It has long been a challenging problem to develop a synthetic carrier that mimics the viral infection machinery (*14*). Gene therapy based on a plasmid DNA encoding a desired therapeutic gene depends largely on successful entry of plasmid DNA into the nucleus, independent of the type of gene delivery method. After cellular entry and endosomal escape, a carrier/plasmid DNA complex or a plasmid DNA released from the complex should move toward the perinuclear space where nuclear translocation of a plasmid DNA occurs. However, the nanoparticular complex or plasmid DNA with several millions of molecular weight can hardly pass through a highly viscous medium of the cytoplasm filled with an extensive network of cytoskeletons, proteins, mRNAs, and various subcellular organelles (*15, 16*). In addition, the passage of macromolecules through the nuclear envelope is also restricted. The nuclear pore complex only allows passage of biological macromolecules with molecular weight of less than 60 kDa unless they have a signal peptide for nuclear localization (NLS), which can be recognized by nuclear importins, carrier proteins for nuclear localization of various karyophilic proteins. Therefore, we designed a virus-mimicking gene delivery system that can use an endogenous nuclear transport mechanism by using a reducible polymer that is degradable in the cytoplasm and a plasmid DNA containing a repeated binding motif for NFκB, an endogenous transcription factor. The plasmid DNA was designed to use the transcription factor as an intracellular carrier for active nuclear translocation of a plasmid DNA. A ubiquitously expressed transcription factor, NFκB, mainly exists as an inactive heterodimer with IκB protein in the cytoplasm (*17*). When the cell is stimulated by a specific signal, IκB is phosphorylated and rapidly degraded. This results in the exposure of NLS motif, leading to rapid nuclear translocation of NFκB (*18*). It was previously reported that a plasmid containing NFκB binding sequence demonstrated enhanced cytoplasmic mobility and nuclear translocation of the plasmid DNA (*8*), leading to enhanced transfection efficiency (*9, 19*). Since the interaction between the plasmid DNA and NFκB is a prerequisite to achieve efficient karyophilic protein-guided cytosolic trafficking and nuclear translocation, unpackaging of the plasmid DNA/polymer complexes should be occurring soon after the endosomal escape of the complexes. An endosomal escape and the cytosolic unpacking of the complexes could be facilitated by using a reducible polymer, TETA-CBA.

A reducible TETA-CBA copolymer was synthesized by Michael addition polymerization between amine donor (TETA) and bisacrylate (CBA), as described previously (*11*). The disulfide linkages in TETA-CBA are expected to be cleaved into amidoamine monomers in the reductive cytoplasm. The proton buffering and reductive degradation properties of the copolymer were studied in a previously published result (*11, 12*). The cationic copolymer interacts with plasmid DNA to form tight complexes for efficient gene delivery to cells (*11, 20*). Once localized inside the cells, the backbone of TETA-CBA may be degraded by the action of intracellular reduced glutathione, resulting in the cytosolic release of the plasmid DNA. The released plasmid DNA containing the repeated NFκB motif could then bind to the DNA binding domain of cytosolic NFκB without interference of the cationic carrier. The NFκB bound to the plasmid could act as an intracellular vehicle for the plasmid DNA. Stimulation of the cells with a cytokine such as IL-1β causes the degradation of the IκB unit and the exposure of an NLS moiety of NFκB, leading to intracellular trafficking of the NFκB-plasmid DNA to the perinuclear space and concurrent transfer of the NFκB-plasmid DNA into the nucleus. The hypothetical intracellular delivery mechanism based on a reducible polycation and a plasmid DNA with a karyophilic protein binding site is illustrated in Figure 1.

A plasmid DNA (pSIGLP1NFκB) encoding glucagon-like peptide-1 (GLP-1) was previously constructed (*9*) and used to evaluate gene transfection efficiency. The electrostatic interaction between the plasmid DNA and TETA-CBA polymer could form tight complexes, which could be readily degraded to release the plasmid DNA in the presence of a reducing force (Figure 2). The degradation of the polymer in a reductive environment agrees well with previous results (*11*). The pSIGLP1NFκB/TETA-CBA formulation demonstrated only a slightly higher production of GLP-1 in mouse fibroblast cells (NIH3T3) than a formulation with a nondegradable control polymer, PEI 25

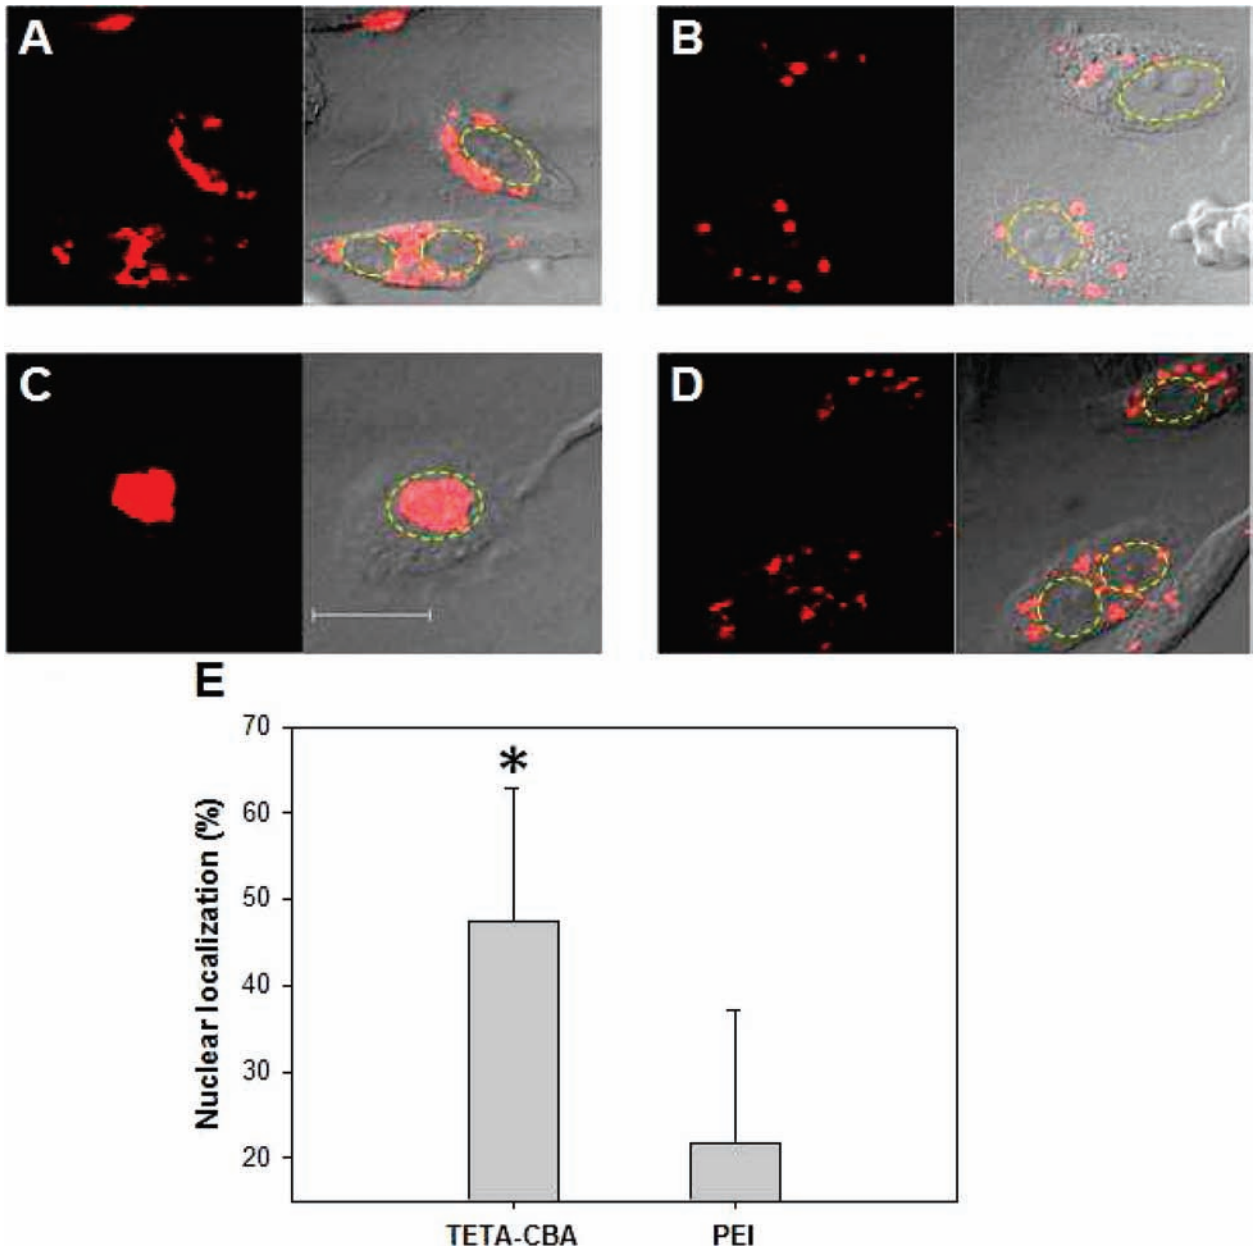

Figure 5. Subcellular localization of Cy3-labeled pSIGLP1NFκB formulated with either TETA-CBA (A,C) or PEI (B,D) after transfection in NIH3T3 cells. Prior to observation, the cells were incubated for additional 2 h in the absence (A,B) and presence (C,D) of IL-1β stimulation. Dashed line indicates the nucleus. (E) Nuclear association of plasmid DNA after IL-1β stimulation was determined by relating two arbitrarily defined regions of interest (ROIs: ROI_1 = the whole cell, ROI_2 = the nucleus) and given as percent nuclear localization ± SD ($n = 50$). *$p < 0.05$ compared to the PEI-based control.

kDa (Figure 3). The addition of IL-1β, which can initiate the dissociation of IκB from NFκB heterodimer and the nuclear translocation of NFκB (*18*), to the cells treated with the pSIGLP1NFκB/TETA-CBA formulation resulted in a significant increase in GLP-1 expression. However, the control formulation (pSIGLP1NFκB/PEI) failed to show a significant increase in GLP-1 expression after the IL-1β stimulation. A cellular association profile of the transfection complexes from either TETA-CBA or PEI-based formulation was not significantly different from that of the other (Figure 4). The results suggest that the improved transfection efficiency may be due to the NFκB-guided intracellular trafficking and active nuclear translocation of the plasmid DNA. To test the hypothetical suggestion, the subcellular localization of plasmid DNA after transfection was observed using confocal laser scanning microscopy. The Cy-3 labeled plasmid DNA formulated with TETA-CBA was distributed over the cytoplasm 5 h after transfection (Figure 5A). However, most of the fluorescently labeled plasmid DNA was localized in the cytoplasmic space, rather than in the nucleus, suggesting that the DNA dissociated from the polymer/DNA complex could not penetrate the nuclear membrane via passive diffusion. The uneven distribution of the plasmid DNA in the cytoplasm may be due to restricted movement of high molecular weight plasmid DNA in the highly viscous mesh-like network of the cytoplasm. The cytosolic reductive release of genetic materials such as plasmid DNA and siRNA could also be observed in previous observations with reducible polymeric carriers (*21*, *22*). In contrast to the TETA-CBA formulation, PEI formulations seemed to exist as complexes or larger aggregates in a specific location, suggesting that complexes formed from PEI and plasmid DNA may not be readily dissociated in the cytoplasm (Figure 5B). When stimulated by IL-1β, nuclear accumulation of the fluorescently labeled plasmid DNA (pSIGLP1NFκB) could be observed in the cells treated

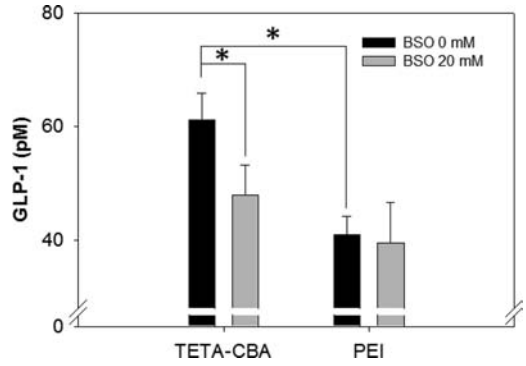

Figure 6. Effect of DL-buthionine sulfoxamine (BSO) on transfection efficiencies of formulations based on either TETA-CBA or PEI. Activation and nuclear translocation of NFκB was initiated by the addition of IL-1β. The expression level of secreted GLP-1 was determined by ELISA and given as the mean $\pm$ SD ($n = 3$). *$p < 0.01$ compared to the PEI-based control.

with the pSIGLP1NFκB/TETA-CBA formulation (Figure 5C). However, no significant movement of the plasmid DNA to the nuclear region was detected in the cells transfected with the pSIGLP1NFκB/PEI formulation, even after IL-1β treatment (Figure 5D). The improved nuclear localization was quantitatively measured by using image analysis software (*ImageJ*). Nuclear localization of the fluorescently labeled plasmid DNA was obtained by relating fluorescence intensities from two arbitrarily defined regions of interest (ROIs): the whole cell (FL_{cell}) and the nucleus ($FL_{nucleus}$). After stimulation with IL-1β, the pSIGLP1NFκB/TETA-CBA formulation showed a significantly higher accumulation of the plasmid DNA in the nuclear region compared to PEI formulation. In conjunction with the qualitative observation with confocal microscopy, the data suggest that the reductive degradation of the reducible polymer and release of the plasmid DNA in the cytoplasm would play an important role in the NFκB-mediated cytosolic trafficking and the nuclear import of the plasmid DNA by facilitating the interaction between NFκB and the binding motif in the plasmid DNA.

The role of cytosolic reductive degradation of the TETA-CBA in NFκB-mediated nuclear translocation of pSIGLP1NFκB was further studied by using DL-buthionine sulfoxamine (BSO), which effectively reduces the level of intracellular reduced glutathione (*23*). Pretreatment of the cells with BSO caused a reduction in transfection efficiency of TETA-CBA. In addition, the extent of reduction in GLP-1 expression was much higher in the cells treated with the TETA-CBA formulation when IL-1β stimulation was given (Figure 6). However, PEI-mediated transfections were not affected by the BSO treatment. This result strongly supports our initial hypothesis in which the triggered release of the plasmid DNA in the cytoplasm could promote the chance of interaction between NFκB and the plasmid DNA. The interaction would lead to the improved nuclear translocation, resulting in enhanced expression of GLP-1.

Mimicking the viral infection mechanism for improved transfection requires the elaborate integration of functional elements, including targeting moieties, endosomal escape, intracellular trafficking, and nuclear translocation functionalities into a nanoscale container, i.e., a nanoparticle. In this study, we introduced a gene delivery system that can take advantage of endogenous nuclear transport mechanisms by combining a reducible polymeric gene carrier and a plasmid DNA containing repeated binding motif for a karyophilic protein, NFκB. The delivery system could successfully achieve enhanced transfection by efficient coordination of cytosolic triggered release and NFκB-mediated nuclear translocation mechanisms. This demonstrates an alternative strategy for integrating several functionalities in a polyelectrolyte-based nanoparticular container. Besides the intracellular delivery, additional functionalities, including improved extracellular stability and tissue specificity, are to be incorporated to produce a gene delivery system that eventually mimics virus infection machinery.

Synthesis of three new cationic thiol-reactive maleimide−porphyrin derivatives and their use in site-specific conjugation to monoclonal antibodies is reported. The selective reactivity toward thiols is demonstrated using competition experiments, where both thiols and amines are present. This selectivity was used to successfully achieve specific conjugation of two porphyrins to cysteine residues present in the antiangiogenic antibody L19, expressed in small immunoprotein (SIP) format. The effect of length and hydrophilicity of the linkage between porphyrin and maleimide was also investigated, and maximum photocytotoxicity was achieved with the longest and most hydrophilic chain. Immunoreactivity and in vitro photocytotoxicity for these well-characterized porphyrin−antibody conjugates are described.

INTRODUCTION

Photodynamic therapy (PDT) is now an established clinical cancer treatment (*1*). PDT combines a photosensitizing compound, light, and oxygen to promote the destruction of localized neoplastic lesions (*2, 3*). Although PDT is employed in most of the developed countries of the world with good effect, the selectivity of commercial PDT agents for tumor tissue remains an area where there is considerable room for improvement. Typically, tumor to peritumoral tissue ratios are significantly below 10:1 at the time of treatment (*4*). Lack of selectivity requires the administration of increased doses of photosensitizer to achieve the desired clinical effect, which in turn causes generalized photosensitivity for the patient and leads to small safety margins when treating tumors in sensitive areas, such as the brain.

In order to improve targeting of photodynamic sensitizers to tumor tissue, a number of strategies have been devised (*5*−*8*). One of the most promising of these targeting methods is the use of antibodies or antibody fragments, often termed photoimmunotherapy (PIT). PIT combines the photosensitizing properties of a photosensitizer and the targeting capabilities of an antibody, usually by conjugating one to the other in such a way that neither photophysical nor immunogenic properties are compromised (*9*).

Many different monoclonal antibodies (mAb) (*9*−*21, 33*) and antibody fragments of different formats, including scFv (single chain Fv antibody fragment) (*21*−*24*), F(ab′)$_2$ (*13, 25*−*28*), and SIP (small immunoprotein, or mini-antibody) (*21*), have been used to obtain photoimunoconjugates for targeted photodynamic therapy. From all the different available formats, small immunoproteins (SIP) appear to offer the best compromise among stability, blood clearance, and tumor accumulation (*29*−*31*).

The majority of these antibodies and antibody fragments are specific to antigens overexpressed on tumor cells; however, normal cells can also express these antigens, leading to nonspecific uptake (*9, 32*). Several research groups have avoided this problem by using immunoconjugates that target markers in the tumor vasculature (*18, 19, 21, 23, 24, 33, 34*).

The most common method used for conjugation of photosensitizers to antibodies involves coupling the terminal amino group of lysine residues on the antibody to a reactive group on the porphyrinic photosensitizer. These reactive groups are often some form of active ester, generated from carboxy-bearing photosensitizers, or isothiocyanates. Only a few reports describe the conjugation of photosensitizers to the thiol groups of cysteine residues (*14, 15, 25*−*28, 40*). Cysteine residues represent an attractive bioconjugation target because, unlike lysine residues, cysteines on antibodies are remote from the binding site.

Clearly, in order to effectively target cysteine residues, reactive groups which are selective for thiols must be incorporated into the photosensitizer structure. Recently, several porphyrins bearing thiol-reactive functionalities have been reported in the literature (*12, 35*−*41*); however, to our knowledge, none of these molecules has been used to generate a functional photoimmunotherapy conjugate.

In the present work, we report the synthesis and utility of novel water-soluble porphyrin derivatives bearing maleimide moieties for the site-specific and stoichiometrically controlled labeling of a reduced small immunoprotein of the antiangiogenic L19 antibody [SIP(L19)]. The full water solubility promoted by the presence of three quaternized pyridyl groups avoids the noncovalent binding often found with more hydrophobic photosensitizers. Contamination with noncovalently bound photosensitizers is a significant problem in the developed photoimmunoconjugates, as this material can transfer to other serum components upon systemic administration. The combination of full water solubility with the highly thiol selective maleimide moiety renders the conjugation procedure simple, reproducible, and fast, generating well-characterized functional photoimmunoconjugates.

Finally, the effect of length and hydrophilicity of the linker between porphyrin and maleimide was examined, due to the

close proximity of the two available cysteines on SIP(L19) and the possibility that this may lead to self-quenching of photosensitizer excited states and consequent lowering of photodynamic activity.

EXPERIMENTAL PROCEDURES

General. ^{1}H and ^{13}C NMR spectra were recorded on JEOL Eclipse 400 and JEOL lambda 400 spectrometers (operating at 400 MHz for ^{1}H and 100 MHz for ^{13}C). $CDCl_3$ was used as solvent and TMS as internal reference for all the non-water-soluble porphyrin derivatives, DMSO-d_6 was used as solvent and as internal reference for all the water-soluble porphyrin derivatives (in this case, chemical shifts are reported in δ (ppm) from the central reference peak of the solvent: DMSO-d_6 2.50 ppm and 39.5 ppm for ^{1}H and ^{13}C NMR, respectively). All the chemical shifts are expressed in δ (ppm) and the coupling constants (J) in Hertz (Hz). Unequivocal ^{1}H assignments were made using 2D COSY; ^{13}C assignments were made on the basis of 2D HSQC and HMBC experiments (delay for long-range J C/H couplings were optimized for 7 Hz). Mass spectra (low and high resolution) were performed by the EPSRC Mass Spectrometry Service, Swansea. UV−vis spectra were recorded on an Agilent 8453 spectrophotometer using dichloromethane, dichloromethane/methanol mixtures, or water as solvent. Preparative thin-layer chromatography was carried out on 20 × 20 cm^2 glass plates precoated with silica gel 60 (0.5 mm thick, Uniplate, Analthech). Flash chromatography was carried in silica gel 60 (MP Biomedicals, 32−63 μm). Analytical TLC was carried out on precoated sheets with silica gel 60 (Fluka, 0.2 mm thick). Commercial solvents and reagents were used without further purification unless stated otherwise. The starting porphyrins 5-(4-aminophenyl)-10,15,20-tri-(4-pyridyl)porphyrin **1** (*45*) and 5-(4-carboxyphenyl)-10,15,20-tri-(4-pyridyl)porphyrin **5** (*46*) were prepared according to literature procedures.

Synthesis. *5-[4-(N-Phenylmaleamic acid)]-10,15,20-tri-(4-pyridyl)porphyrin,* ***2.*** To a stirred solution of 5-(4-aminophenyl)-10,15,20-tri-(4-pyridyl)porphyrin (100.0 mg, 0.159 mmol) **1** in nitrobenzene (15 mL) was added maleic anhydride (37.0 mg, 0.381 mmol, 2.4 equiv). The reaction mixture was protected from moisture and kept under constant stirring at 100 °C for 22 h. After allowing the reaction to cool to room temperature, *n*-hexane was added in order to promote the precipitation of the product and to remove the nitrobenzene. Upon filtration, the obtained solid was taken up in dichloromethane and purified by flash chromatography using as first eluent a mixture of dichloromethane/methanol (85:15) and as second eluent dichloromethane/methanol (70:30). After precipitation with *n*-hexane, the product was obtained as a brown solid in 96% yield (112.6 mg). ^{1}H NMR ($CDCl_3$, 400 MHz), δ: −2.99 (br s, 2H, N*H*), 6.12 (d, J = 13.2 Hz, 1H, -NHCOCHC*H*CO$_2$H), 6.40 (d, J = 13.2 Hz, 1H, -NHCOC*H*CHCO$_2$H), 8.02 and 8.07 (AB, J = 8.2 Hz, 4H, 5-Ar-*o*,*m*-H), 8.11 and 8.14 (2d, J = 4.9 Hz, 4 + 2H, 10,15,20-Ar-*o*-H), 8.56−8.86 (m, 8H, H-β), 8.88 and 8.91 (2d, J = 4.9 Hz, 4 + 2H, 10,15,20-Ar-*m*-H), 13.2 (s, 1H,-CO$_2$*H*). ^{13}C NMR ($CDCl_3$, 100 MHz), δ: 116.4, 116.9, 118.2 (5-Ar-*m*-C), 121.6, 129.4, and 129.5 (10,15,20-Ar-*o*-C), 130.1 (−COCH=*C*HCO$_2$H), 134.9 (5-Ar-*o*-C), 136.3 (−CO*C*H=CHCO$_2$H), 136.7, 138.6, 147.5, and 147.6 (10,15,20-Ar-*o*-C), 150.52, 150.54, 164.6 (−NH*C*O−), 172.4 (-*C*O$_2$H). Reaction of 5-(4-Maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin with N-Acetyl-L-cysteine Methyl Ester, ***16.*** To a stirred solution of 5-(4-maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin **3** (15.0 mg, 0.0210 mmol) in dry DMF (2 mL) was added *N*-acetyl-L-cysteine methyl ester (9.3 mg, 0.0526 mmol, 2.5 equiv). The reaction was kept under constant stirring and protected from moisture until all the starting porphyrin was consumed (6 min, according to TLC). After this period, the product was precipitated with diethyl ether (50 mL) and hexane (5 mL), filtered, and redissolved in a mixture of dichloromethane/methanol. After purification by preparative TLC, using a mixture of dichloromethane/methanol (95:5) as eluent, and precipitation with methanol over dichloromethane, the product (isolated as a mixture of two diasteriomers not separable by TLC, designated as **D1** and **D2**) was obtained as a purple solid in 94% yield (17.8 mg). ^{1}H NMR ($CDCl_3$, 400 MHz), δ: −2.90 (s, 2H, N$\underline{H}$), 2.15 and 2.16 (2s, 6H, **D1**+**D2**-NHCOC$\underline{H}_3$), 2.81 (dd, J = 3.9 Hz, J = 18.8 Hz, 1H, **D1**-H″), 2.88 (dd, J = 3.9 Hz, J = 18.8 Hz, 1H, **D2**-H″), 3.12 (dd, J = 7.8 Hz, J = 14.1 Hz, 1H, **D1**-SC$\underline{H}_2$CH(NHCOCH$_3$)CO$_2$CH$_3$), 3.37 (dd, J = 5.0 Hz, J = 14.4 Hz, 1H, **D2**-SC$\underline{H}_2$CH(NHCOCH$_3$)CO$_2$CH$_3$), 3.51 (dd, J = 9.2 Hz, J = 18.8 Hz, 1H, **D1**-H‴), 3.53 (dd, J = 9.2 Hz, J = 18.8 Hz, 1H, **D2**-H‴), 3.66 (dd, J = 5.0 Hz, J = 14.4 Hz, 1H, **D2**-SC$\underline{H}_2$CH(NHCOCH$_3$)CO$_2$CH$_3$), 3.77 (dd, J = 4.0 Hz, J = 14.1 Hz, 1H, **D1**-SC$\underline{H}_2$CH(NHCOCH$_3$)CO$_2$CH$_3$), 3.86 and 3.87 (2s, 6H, **D1**+**D2**-CO$_2$C$\underline{H}_3$), 4.14 (dd, J = 3.9 Hz, J = 9.2 Hz, 1H, **D2**-H′), 4.34 (dd, J = 3.9 Hz, J = 9.2 Hz, 1H, **D1**-H′), 5.02−5.08 (m, 1H, **D2**-SCH$_2$C$\underline{H}$(NHCOCH$_3$)-CO$_2$CH$_3$), 5.07−5.14 (m, 1H, **D1**-SCH$_2$C$\underline{H}$(NHCOCH$_3$)-CO$_2$CH$_3$), 6.53 (d, J = 8.1 Hz, 1H, **D1**-SCH$_2$CH(N$\underline{H}$COCH$_3$)-CO$_2$CH$_3$), 6.92 (d, J = 7.8 Hz, 1H, **D2**-SCH$_2$CH-(N$\underline{H}$COCH$_3$)CO$_2$CH$_3$), 7.77 (dd, J = 1.9 Hz, J = 8.4 Hz, 4H, **D1**+**D2** 5-Ar-*m*-H), 8.16 (d, J = 5.8 Hz, 12H, **D1**+**D2** 10,15,20-Ar-*o*-H), 8.33 (dd, J = 1.9 Hz, J = 8.4 Hz, 4H, **D1**+**D2** 5-Ar-*o*-H), 8.84 (d, J = 4.7 Hz, 4H, **D1**+**D2** H-β), 8.86−8.89 (m, 8H, **D1**+**D2** H-β), 8.95 (d, J = 4.7 Hz, 4H, **D1**+**D2** H-β), 9.06 (d, J = 5.8 Hz, 12H, **D1**+**D2** 10,15,20-Ar-*m*-H). ^{13}C NMR ($CDCl_3$, 100 MHz), δ: 23.3 (**D1**+**D2**-NHCO$\underline{C}$H$_3$), 34.7 (**D1**-S$\underline{C}$H$_2$CH(NHCOCH$_3$)CO$_2$CH$_3$), 35.0 (**D2**-S$\underline{C}$H$_2$CH(NHCOCH$_3$)-CO$_2$CH$_3$), 36.0 and 36.6 (**D1**+**D2**-CO$\underline{C}$H$_2$CHSCH$_2$CH-(NHCOCH$_3$)CO$_2$CH$_3$), 38.8 (**D1**-COCH$_2$$\underline{C}$HSCH$_2$CH(NHCOCH$_3$)-CO$_2CH_3$), 40.2 (**D2**-COCH$_2$$\underline{C}$HSCH$_2$CH(NHCOCH$_3$)CO$_2CH_3$), 51.3 (**D1**-COCH$_2$CHSCH$_2$$\underline{C}$H(NHCOCH$_3$)CO$_2CH_3$), 52.4 (**D2**-COCH$_2$CHSCH$_2$$\underline{C}$H(NHCOCH$_3$)CO$_2CH_3$), 53.1 and 53.2 (**D1**+**D2**-CO$_2$$\underline{C}H_3$); 117.4, 117.7, 120.07, 120.10, 124.76, and 124.79 (**D1**+**D2** 5-Ar-*m*-C); 129.5 (10,15,20-Ar-*o*-C), 131.6 and 131.7 (C-β), 135.2 (5-Ar-*o*-C), 142.08, 142.14, 148.4 (10,15,20-Ar-*m*-C), 150.0, 170.2 (**D1**-NH$\underline{C}$OCH$_3$), 170.4 (**D2**-NH$\underline{C}$OCH$_3$), 171.2 (**D2**-$\underline{C}$O$_2$CH$_3$), 171.3 (**D1**-$\underline{C}$O$_2$CH$_3$); 173.4 and 173.6 (**D1**+**D2**-CH$\underline{C}$O), 176.0 and 176.1 (**D1**+**D2**-$\underline{C}$OCH$_2$). UV/vis (CH_2Cl_2/MeOH- 3%), λ_{max} (log ε): 417 (6.04), 513 (4.67), 547 (4.16), 588 (4.16), 643 (3.71). HRMS (ESI) calcd for $C_{52}H_{39}N_9O_5S$ $(M + H)^+$ 890.2868, found: 890.2862.

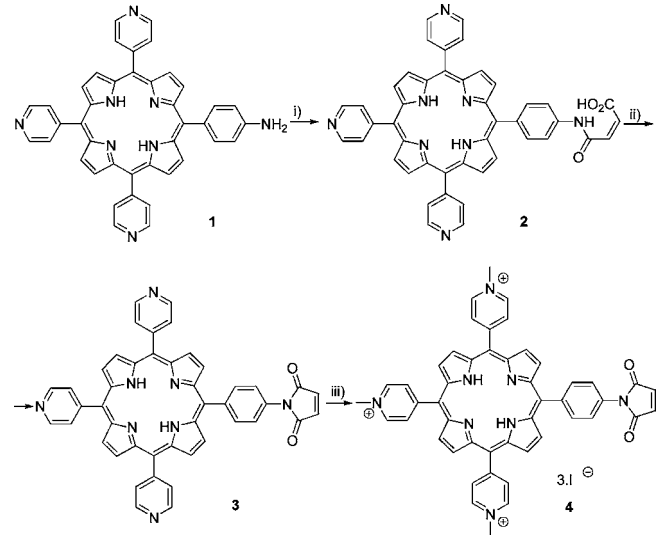
Competition Experiments. *Reaction of 5-(4-Maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin* ***3*** *with 1-Propylamine and 1-Propanethiol.* To a stirred solution of 5-(4-maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin **3** (13.2 mg, 0.0185 mmol) in dry DMF (2 mL) was added a mixture of 1-propylamine (76 μL, 0.924 mmol, 50 equiv) and 1-propanethiol (84 μL, 0.928 mmol, 50 equiv). The reaction was kept under constant stirring and protected from moisture for 10 min. After this period, the product was precipitated with diethyl ether (50 mL) and *n*-hexane (5 mL), filtered, and redissolved in dichloromethane.

Reaction of 5-(4-Maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin ***3*** *with N-Acetyl-L-cysteine Methyl Ester and N_α-Acetyl-L-lysine Methyl Ester Hydrochloride.* To a stirred solution of N_α-acetyl-L-lysine methyl ester hydrochloride (16.3 mg, 0.070 mmol, 2.6 equiv) in dry DMF (3 mL) was added anhydrous potassium carbonate (11.6 mg, 0.084 mmol, 1.2 equiv relative to lysine). After allowing the mixture to stir at room temperature for 10 min, in order to promote the amino acid neutralization, *N*-acetyl-L-cysteine methyl ester (12.4 mg, 0.070 mmol, 2.6 equiv) was added. Once the amino acid was completely dissolved, 5-(4-maleimidophenyl)-10,15,20-tri-(4-pyridyl)porphyrin **3** (18.9 mg, 0.0265 mmol) was added and the reaction mixture was allowed to stir at room temperature and protected

from moisture. After 10 min, diethyl ether (50 mL) and *n*-hexane (5 mL) were added to the reaction mixture to promote precipitation of the porphyrinic material.

BIOLOGICAL DATA



Preparation of SIP(L19). The cloning, expression, and purification of SIP(L19) antibody have been described elsewhere (*29, 42*). Briefly, SIP(L19) cDNA had been cloned into the pCDNA3.1 vector (Invitrogen). The derived construct was transfected in CHO-S cells (Gibco - Invitrogen), and selected stable clones were grown in PowerCHO-CD 2 media (Lonza) and used to express the protein, which was purified from the supernatant by protein A affinity chromatography.

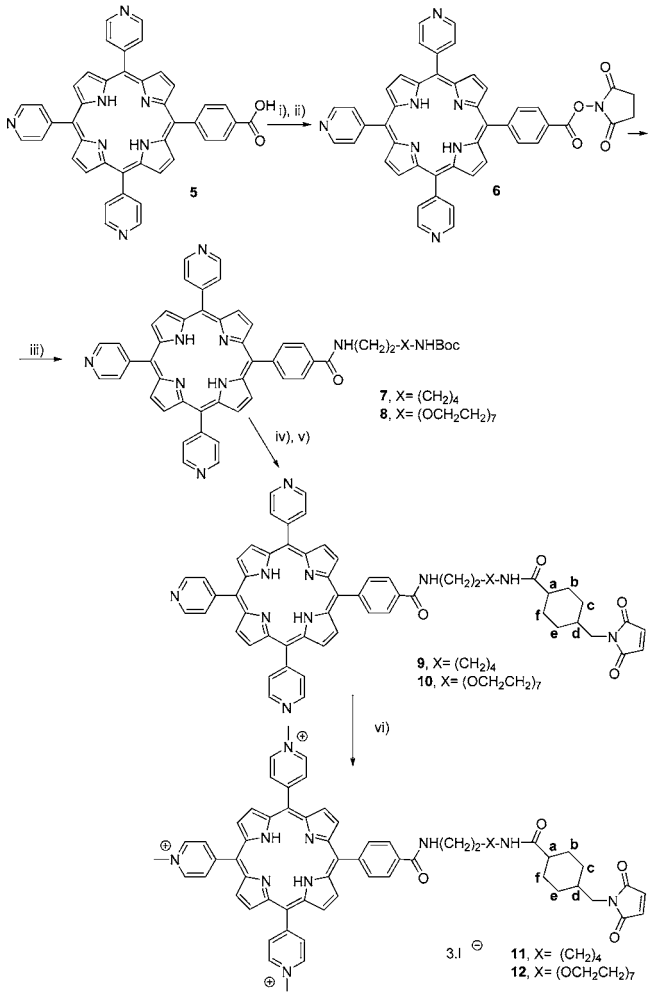
Preparation of Photoimmunoconjugates. SIP(L19)-PS conjugates were prepared as follows: ~30-fold molar excess of TCEP (tris-(2-carboxyethyl)phosphine hydrochloride, Pierce) was added to purified SIP antibody (0.5 mg/mL, PBS pH 7.4) and incubated for 12 h at 4 °C. Then, a 40-fold excess of maleimide-porphyrin (**4**, **11**, or **12**) (1 mg/mL in DMSO) was added to the mixture and incubated for 3 h at room temperature, gently shaking. The antibody−photosensitizer conjugates were then purified from free photosensitizer over a PD-10 column (GE Healthcare) and dialyzed overnight against PBS pH 7.4 at 4 °C.

Quality of the Photoimmunoconjugates. SIP−photosensitizer (SIP-PS) conjugates were analyzed by SDS-PAGE under non-reducing conditions using the Invitrogen PAGE system following manufacturer instructions. The gels were first analyzed under Cy5 filter lamp and then stained with Coomassie blue. The labeling ratio was estimated spectroscopically by measuring the absorbance at 280 nm for the SIP (assuming that a 1 mg/mL of SIP solution gives absorption of 1.4 units at 280 nm) and at 422 nm for porphyrin **4** ($\varepsilon = 255\,390\ M^{-1}\ cm^{-1}$), 424 nm for porphyrin **11** ($\varepsilon = 248\,208\ M^{-1}\ cm^{-1}$), and 425 nm for porphyrin **12** ($\varepsilon = 188\,489\ M^{-1}\ cm^{-1}$). Furthermore, mass spectrometric analysis was also used to assess the labeling ratio. For MALDI-TOF analysis, the SIP(L19) and the conjugates were mixed with a sinapinic matrix (10 mg/mL in 50% CAN and 0.05% TFA) at a 1:4 dilution and spotted onto the MALDI target plate. The analysis of samples was performed on a freshly tuned AB4800 MALDI-TOF/TOF mass spectrometer. For data analysis, the *Data Explorer* software (version 4.8) from Applied Biosystem was used. The immunoreactivity of the SIP-PS conjugates was measured by BIAcore (*43*) and by ELISA assay over 7B89 (*44*), an EDB-containing protein (data not shown).

Photocytotoxicity Assay. L-M fibroblasts (ATCC number: CCL-1.2, L-M) were grown in DMEM (Gigbo-Invitrogen) media supplemented with 10% FCS and antibiotics and maintained at 37 °C in 5% CO_2. For the in vitro phototoxicity assay, 30 000 cells/well in a 96 well plate were seeded and incubated overnight at 37 °C in 5% CO_2. The next day, media were removed and cells were incubated with 50 μL of SIP or SIP−porphyrin conjugate in the appropriate dilutions (in PBS) for 1 h at 37 °C. Cells were subsequently washed with PBS twice in order to remove unbounded antibodies, and cells were then covered with 50 μL of PBS. The cells were then irradiated using as light source the KL 1500 electronic (Zeiss) tungsten halogen lamp equipped with a 620/60 filter (Chroma) for a total light dose of 60 J/cm^2 (*21*). After light treatment, PBS was removed and 100 μL of fresh medium were added. The cells were then incubated at 37 °C, 5% CO_2 atmosphere overnight. Controls include SIP−porphyrin conjugate without light, PBS only plus light, unconjugated SIP plus light, and no PBS or medium only without light. The following day, cell viability was measured using the Cell Titer 96Aqueous One Solution Cell Proliferation Assay (Promega), performed according to the manufacturer's instruction. The percentage of cell growth inhibition was calculated as a ratio of the counts between treated cell over the relative control (cells treated with SIP−porphyrin conjugate without light exposure).

Scheme 1. Synthesis of Maleimide−Porphyrin 4

Reagents and conditions: (i) maleic anhydride, nitrobenzene, 100°C, 22 h, 96%; (ii) sodium acetate, acetic anhydride, 80 °C, 4 h, 84%; (iii) methyl iodide, DMF, 40 °C, 4 h, 95%.



RESULTS AND DISCUSSION

Chemistry. *Synthesis of the Water-Soluble Porphyrin Photosensitizers.* Three different synthetic strategies were used in order to obtain maleimide−porphyrin derivatives **4**, **11**, and **12**. In the first one, the maleimide moiety is directly connected to the *para* position of a phenyl ring present on the macrocycle (Scheme 1); in the second, a hydrocarbon spacer was built-in and the maleimide moiety was introduced using the heterofunctional linker SMCC (succinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate) (Scheme 2). The final synthetic procedure involved the simultaneous extension of the linker between porphyrin and maleimide, and introduction of increased hydrophilicity by using a poly(ethylene glycol) chain (Scheme 2), as opposed to the hydrocarbon linker used in the synthesis of **11**. The three maleimide−porphyrins were synthesized in order to first allow site-specific conjugation to cysteine residues on the antibody, but also to probe the effect of enforced proximity of the porphyrins, caused by the close location of cysteine residues used for conjugation on the SIP. SIP(L19) exists as a homodimer in aqueous solution (*21*), even after reduction of the disulfide bridge, due to hydrophobic interactions of the two monomers; thus, the two thiols used for conjugation are always found in close proximity.

The starting porphyrins (**1** and **5**) required for these syntheses were obtained by established methods using, respectively, Adler (*45*) and modified Rothemund (*46*) conditions.

5-(4-Aminophenyl)-10,15,20-tri-(4-pyridyl)porphyrin **1** was used as starting material for the preparation of the water-soluble maleimide−porphyrin **4**. The pyridyl groups provide the water-solubilizing units, upon quaternization, and the amino group represents the chemical moiety needed for the introduction of the maleimide (Scheme 1). Upon reaction of porphyrin **1** with maleic anhydride in nitrobenzene, derivative **2** was obtained in 96% yield after purification by flash chromatography and precipitation from methanol over dichloromethane. Subsequent treatment with sodium acetate and acetic anhydride afforded the required maleimide−porphyrin **3** in 84% yield. The last step of this synthetic procedure involved quaternization of the pyridyl

Scheme 2. Synthesis of Maleimide−Porphyrins 11 and 12[a]

[a] Reaction conditions: (i) $SOCl_2$, pyridine, 50 °C, 30 min; (ii) *N*-hydroxysuccinimide, 50 °C, 3 h, 90%; (iii) $NH_2(CH_2)_6NHBoc$, K_2CO_3, DMSO, 40 °C, 40 min, 82% or $NH_2(CH_2)_2(OCH_2CH_2)_7NHBoc$, K_2CO_3, DMSO, 40 °C, 5 d, 53%; (iv) TFA/CH_2Cl_2 (1:1), rt, 50 min; (v) SMCC, DIEA, DMF, rt, 1 h, 85% for **9** or SMCC, DIEA, DMF, rt, overnight, 55% for **10**; (vi) CH_3I, DMF, 40 °C, 4 h, 80% for **11** or CH_3I, DMF, 40 °C, 4 h, 75% for **12**.

nitrogens with methyl iodide; the reaction was carried out at 40 °C for 4 h and afforded the water-soluble maleimide−porphyrin **4** in 95% yield after precipitation with diethyl ether/dichloromethane.

During the implementation of our synthetic procedure, two reports appear in the literature with similar strategies for preparing maleimide−porphyrin derivatives (*35, 36*). The differences in these procedures rely mainly in the starting porphyrin derivatives, solvents, and temperatures used. In both cases, non-water-soluble tetraphenylporphyrin (*35*) or the corresponding water-soluble anionic trisulfonated derivatives were obtained (*35, 36*). As mentioned before, hydrophobic porphyrins cannot be used for bioconjugation to proteins due to unacceptable amounts of noncovalently bound material (*45*). Sulfonated maleimide−porphyrins may be of use for bioconjugation; however, cationic water-soluble porphyrins resist aggregation to much higher concentrations, thus facilitating conjugation procedures.

The synthesis of maleimide−porphyrins **11** and **12** (Scheme 2) involved the use of 5-(4-carboxyphenyl)-10,15,20-tri-(4-pyridyl)porphyrin **5** as starting material and 1,6-diaminohexane or *O,O′*-di-(2-aminoethyl)hexaethylene glycol as spacers between the porphyrin macrocycle and the maleimide group.

After converting the carboxylic acid into the respective *N*-hydroxysuccinimidyl ester **6** via the acyl chloride, *N*-Boc-1,6-diaminohexane was coupled in dry DMSO using potassium carbonate as base. Derivative **7** was obtained in 82% after purification by flash chromatography and precipitation in *n*-hexane over dichloromethane.

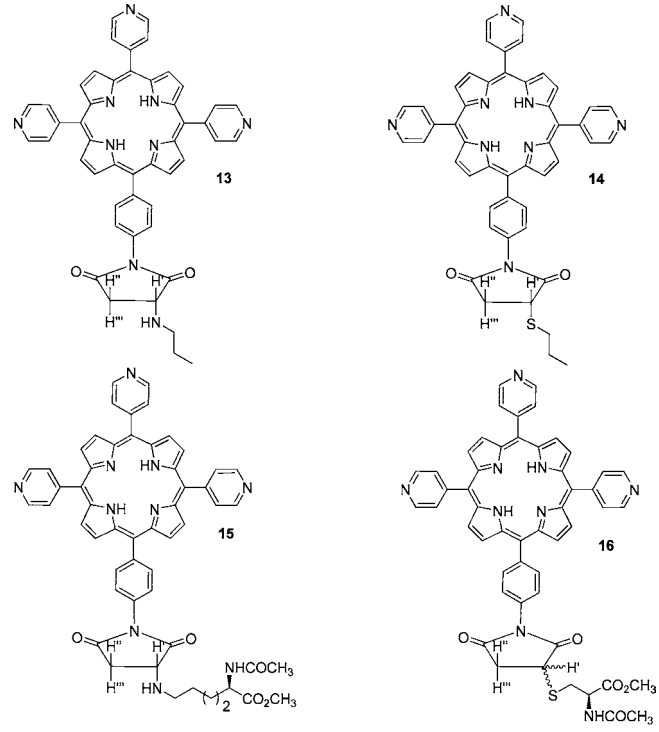


Figure 1. Conjugates obtained from the reaction of maleimide-porphyrin **3** with 1-propylamine (*13*), 1-propanethiol (*14*), N_α-acetyl-L-lysine methyl ester hydrochloride (*15*), and *N*-acetyl-L-cysteine methyl ester (*16*).

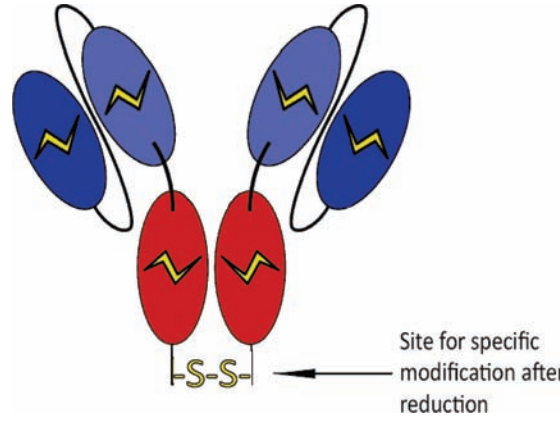

Figure 2. Schematic representation of SIP(L19) showing the conjugation site.

The maleimide−porphyrin **9** was obtained in 85% yield after removal of the Boc-protecting group in TFA/CH_2Cl_2 and subsequent coupling with SMCC in dry DMF in the presence of DIEA. The free amine turned out to be very unstable and hence was not isolated or characterized. The crude mixture obtained after TFA treatment was neutralized with aqueous sodium carbonate, extracted with dichloromethane, dried over sodium sulfate, concentrated under reduced pressure, and promptly used in the reaction with SMCC.

For the PEG-linked derivative **10**, a similar strategy was used, but the 1,6-diaminohexane was replaced by or *O,O′*-di-(2-aminoethyl)hexaethylene glycol. In this instance, the PEG-porphyrin **10** was obtained in 55% yield.

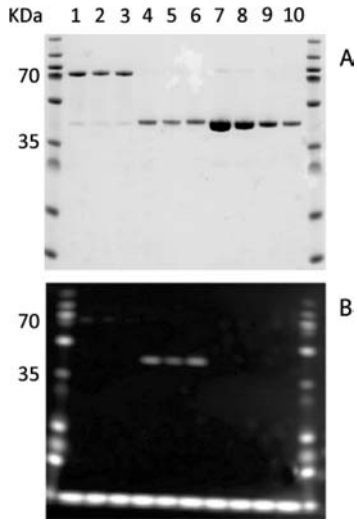

Figure 3. SDS-PAGE of SIP(L19) and SIP(L19) conjugates (Lanes 1−3: control reaction of SIP(L19) conjugated with porphyrins **4**, **11**, and **12** without reducing procedure. Lanes 4−6: SIP(L19) conjugated with porphyrins **4**, **11**, and **12**. Lanes 7−10: SIP(L19) reference standards (0.8 mg/mL, 0.4 mg/mL, 0.2 mg/mL, and 0.1 mg/mL). A: Coomassie blue staining. B: Cy5 fluorescence imaging. The signal at the bottom of the gel is due to the bromophenol blue contained in the SDS sample loading buffer.

Finally, in both cases water solubility was introduced, similarly to derivative **4**, by quaternization of the pyridine rings with methyl iodide affording porphyrins **11** and **12** in 80% and 75% yields, respectively.

Reactivity of the Maleimide Moiety toward Thiols Vs Amines. Porphyrin derivative **3** was chosen to probe the reactivity of the maleimide moiety toward thiols and amines. In order to achieve this, a set of experiments were planned using as amines 1-propylamine and N_α-acetyl-L-lysine methyl ester hydrochloride and as thiols 1-propanethiol and *N*-acetyl-L-cysteine methyl ester.

Under the test conditions (dry DMF at room temperature), both 1-propylamine and 1-propanethiol were found to react with the maleimide−porphyrin **3** over 10 min (Figure 1, compounds **13** and **14**).

The reactions carried out with N_α-acetyl-L-lysine methyl ester hydrochloride and *N*-acetyl-L-cysteine methyl ester also afforded the expected conjugates with both amino acid derivatives (Figure 1, compounds **15** and **16**). Since the N_α-acetyl-L-lysine methyl ester was in its hydrochloride form, the experimental procedure had to be adjusted and carried out in the presence of potassium carbonate. The resulting conjugates **15** and **16** were obtained, after purification by TLC, in respective yields of 75% and 94%. Concerned that the addition of potassium carbonate was responsible for the lower yield obtained with conjugate **15**, we tested the stability of maleimide−porphyrin **3** in DMF and in the presence of the inorganic base. It was found that potassium carbonate provoked some decomposition of the starting material, with ∼50% decomposition after 60 min. Notwithstanding this fact, the coupling reaction, under the tested conditions, is extremely fast (6 min according to TLC), so the decomposition rate promoted by potassium carbonate is believed not to interfere significantly with the coupling reaction.

These experiments demonstrate that there is no inherent specificity of the maleimide moiety when challenged with amines and thiols separately, both behaving as nucleophiles in an identical manner. Although as the next experiments would show, the scenario changes when both amines and thiols are present in the reaction mixture.

Two independent experiments were set up: one using the aliphatic thiol and amine and the other one the amino acid derivatives. In both cases, the same number of equivalents of amine and thiol were used, and the reactions were protected from atmospheric moisture and allowed to stir for 10 min. After this period, diethyl ether and hexane were added to the mixture in order to precipitate all the porphyrinic material. After dissolution and reprecipitation from methanol over dichloromethane, the ^{1}H NMR spectra from the obtained products revealed that in both cases, i.e., 1-propylamine/1-propanethiol and N_α-acetyl-L-lysine/*N*-acetyl-L-cysteine methyl esters, only the thioethers were obtained.

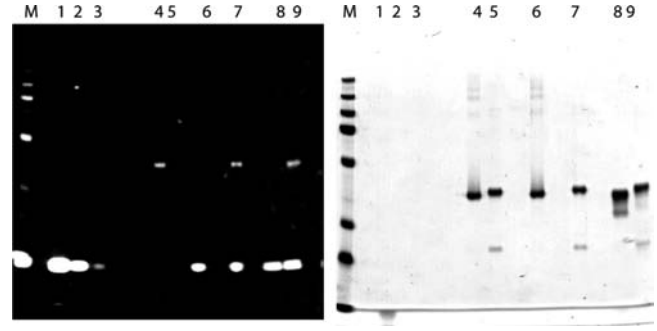

Figure 4. SDS-PAGE analysis (left panel, Cy5 fluorescence imaging; right panel, blue Coomassie staining). Lanes 1−3: Dilution series of porphyrin **4** (250 μg/mL; 25 μg/mL; 0.25 μg/mL). Lanes 4 and 5: SIP(L19) and SIP(L19)-PS**4** using transparent loading buffer. Lanes 6 and 7: SIP(L19) and SIP(L19)-PS**4** using transparent loading buffer spiked in with ∼25 ng of porphyrin **4**. Lanes 8 and 9: SIP(L19) and SIP(L19)-PS**4** using standard (containing bromophenol blue) loading buffer.

These results confirm that, despite the fact that the maleimide moiety is able to react with both amines and thiols separately, when both are present in the reaction mixture and compete for reaction with the maleimide, the thioether conjugate is isolated exclusively, probably due to significant differences in kinetics of nucleophilic attack. These results are supported by the data collected from the bioconjugation experiments with the reduced SIP(L19) as we will demonstrate later.

Biology. *Preparation and Characterization of Photoimmunoconjugates.* SIP(L19) is a third-generation (*47*), clinical-stage, recombinant antibody specific against the tumor neoangiongenesis marker EDB of fibronectin (*48*). The antibody consists of a homodimer covalently linked through a c-terminal disulfide bridge with a molecular weight of ∼80 kDa (Figure 2) and was expressed in mammalian cells and purified to homogeneity on a protein A sepharose column.

In order to achieve site-specific labeling of the cysteine residues at the protein c-term, without affecting the intradomain disulfide bridges, optimal reducing conditions for the SIP were achieved using TCEP (tris-(2-carboxyethyl)phosphine hydrochloride) and a longer time exposure to the reducing agent, compared to standard reducing conditions using DTT. TCEP has the advantage, compared to other common reducing agents (i.e., DTT), to be stable over time at physiological pH and does not need to be removed from the reaction mixture prior to coupling with maleimide derivatives (*49*, *50*).

The quality of the SIP−photosensitizer (SIP-PS) conjugates was assessed after the reaction cleanup steps (gel filtration and dialysis) by SDS-PAGE (Figure 3 and Figure 4).

Imaging of the gel by fluorescence revealed no free, noncovalently bound photosensitizer (*24*) in the conjugate solution (Figure 3B, lower panel). As expected, the antibody bands of the control reactions (SIP plus maleimide−porphyrin without reduction) did not show a significant fluorescence signal. The gel was then stained with Coomassie blue to confirm the purity and concentration of the conjugates (Figure 3A, upper panel).

Reduction and coupling does not affect the dimeric nature of the SIP in aqueous solution (Figure 5) or its immunoreactivity

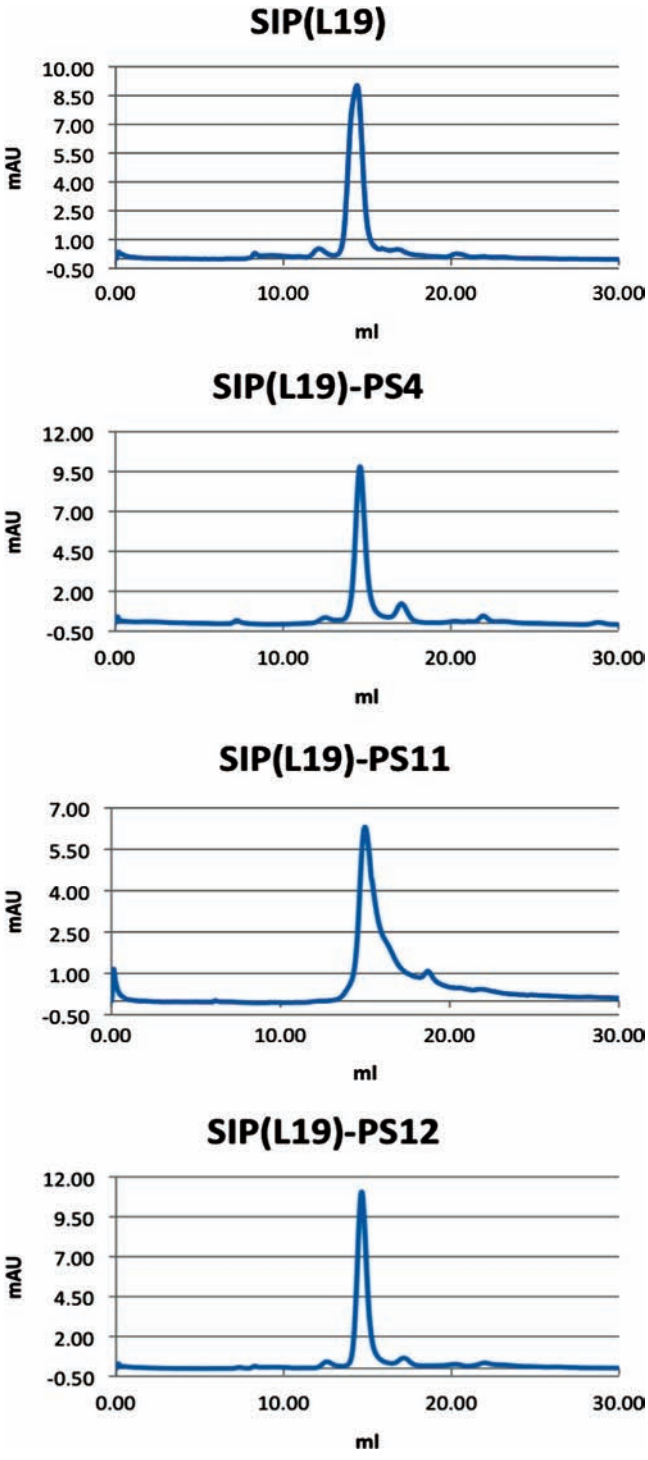

Figure 5. Size-exclusion chromatography profile of SIP(L19) and SIP(L19)−PS conjugates.

(*21*). Furthermore, no precipitation of the conjugates was observed, even after freeze/thawing procedure. The immunoreactivity, analyzed by ELISA and BIAcore, was above 90% when compared to the unmodified SIP(L19) (data not shown).

The theoretical photosensitizer (PS) loading ratio of the SIP is two photosensitizers per antibody molecule, based on available cysteine residues, and this is in perfect agreement with mass spectrometry data (Figure 6 and Figure 7), showing that after reduction and labeling reactions one PS moiety is covalently coupled per antibody monomer (as with SDS-PAGE, the conditions used for MALDI-MS lead to detection of the SIP in its monomeric form), without detection of the unmodified SIP.

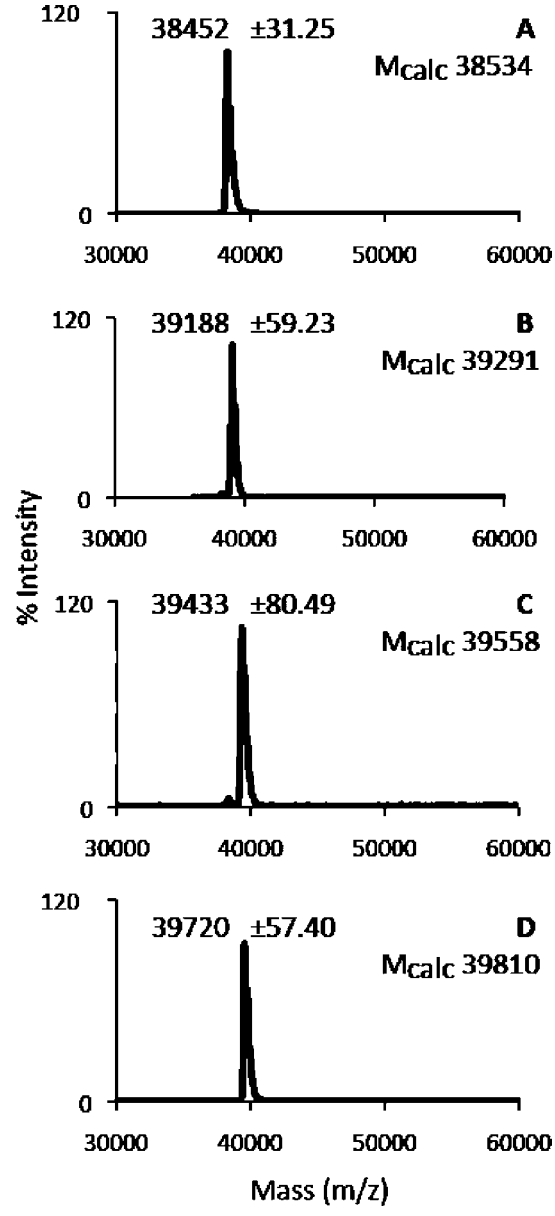

Figure 6. MALDI TOF/TOF spectra for (A) SIP(L19), (B) SIP(L19)-PS**4**, (C) SIP(L19)-PS**11**, and (D) SIP(L19)-PS**12**.

Although the chemical competition experiments described above indicated that the maleimide−porphyrin **3** was capable of reacting with the amino groups of lysine residues, these experiments were performed in a nonaqueous environment without pH control. The fact that using a large excess of maleimide−porphyrin results in two porphyrins per antibody, and the negligible reactivity with nonreduced antibody, strongly suggests that these have conjugated preferentially to the two available cysteine residues generated by reduction. The selectivity of conjugation is in agreement with the reported specificity of maleimides for thiols in the pH range 6.5−7.5 (*51*−*53*).

The number of porphyrins per antibody was also determined spectrophotometrically and gave estimated loading ratios (Porphyrin/SIP) of 0.76 for derivative **4**, 0.9 for **11**, and 1.75 for **12**. The fact that the apparent ratio of porphyrin/SIP determined by UV−visible spectroscopy increases as the length of spacer chain between porphyrin and maleimide increases suggests again that both porphyrins are attached to positions in close proximity on the antibody.

LM-fibroblasts were chosen to evaluate photocytotoxicity of the conjugates (Figure 8) because they naturally produce the

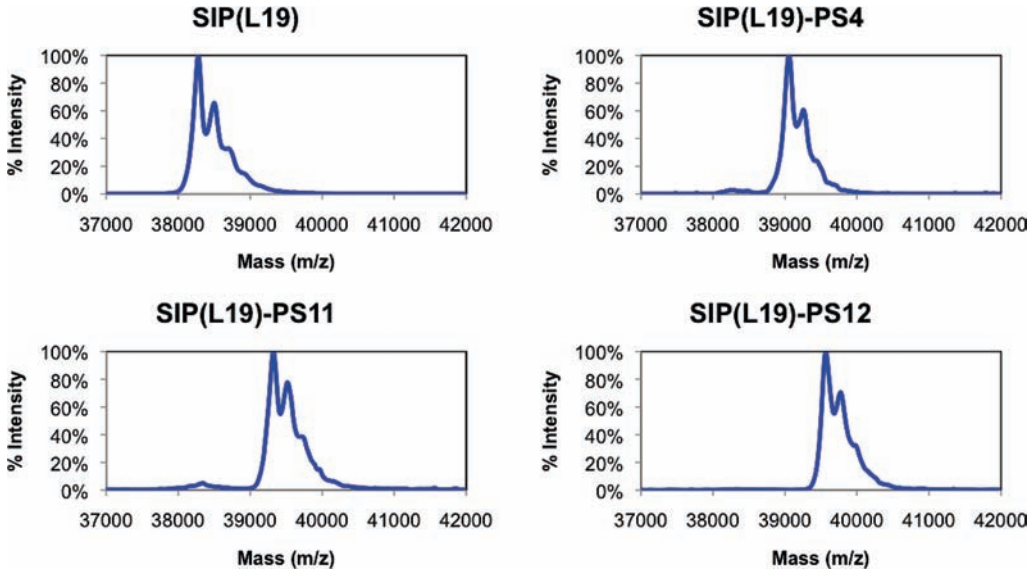

Figure 7. Magnified mass spectra, from Figure 4, of SIP(L19) and SIP(L19)-PS conjugates.

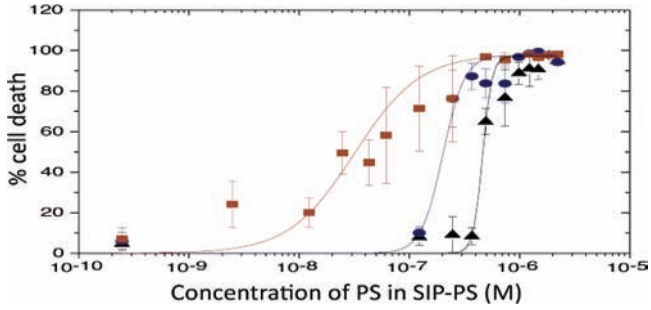

Figure 8. Photocytotoxicity for SIP(L19)-PS**4** (black ▲), SIP(L19)-PS**11** (blue •), SIP(L19)-PS**12** (red ■) carried out in L-M fibroblasts using the MTS assay (the obtained values are the means of at least three independent experiments ± SD). The solid line represents the fit of the data using the Hill equation.

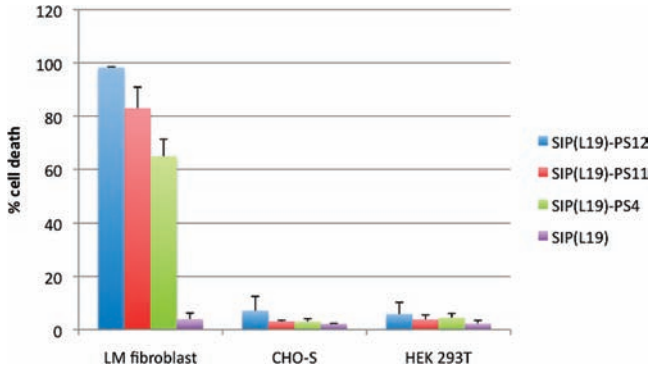

Figure 9. Activity of SIP(L19) and SIP(L19)-PS conjugates (5×10^{-7} M with respect to PS for conjugates and 20 mg/mL protein in all cases) on antigen-positive (LM fibroblast) and antigen-negative (CHO-S, HEK 293T) cells.

antigen for the L19 antibody (EDB + Fibronectin), thus avoiding either chemical coupling of the antigen or genetic manipulation on cells. Furthermore, LM-fibroblasts are stable over multiple passages, thus representing a good model system for the in vitro testing of L19 photoimmunoconjugates. This experiment showed the crucial importance of the length and nature of the linker between the SIP and the photosensitizer, as porphyrin **12** proved to be approximately 1 log more effective when compared to the conjugate **4**. As the porphyrin macrocycle is the same in each case, this could be caused by excited-state quenching between photosensitizers when coupled to the SIP, again suggesting the possibility of two porphyrin moieties in close proximity with each other. The increasing trend in activity observed in going from **4** to **11** and then **12** is consistent with increased freedom of movement associated with longer linkers.

Importantly, immuno-photocytotoxicity is antigen-specific, as evidenced by the lack of L19-photosensitizer killing in cells (CHO-S, HEK 293T) which do not express EDB(+)-fibronectin (Figure 9).

CONCLUSIONS

The data presented here clearly show that it is possible to perform site-specific conjugation of porphyrin-based photosensitizers to cysteine residues present on a monoclonal antibody with relevance to the photodynamic therapy of cancer. The well-characterized conjugates retain both the immunoreactivity of the antibody and the photodynamic activity of the photosensitizer. Enhancement of approximately 1 order of magnitude in photocytotoxicity using antigen-positive cells is possible by optimization of the linkage between porphyrin and the maleimide group used for conjugation with the cysteines. We believe the ability to generate well-characterized and photodynamically active antibody-photosensitizer conjugates with a clinically relevant antibody is a significant step toward the translation of this technology into a realistic treatment for solid tumors.

ACKNOWLEDGMENT

The authors thank the European commission for a FP6 grant to fund the Immuno-PDT consortium (FP6 LSHC-CT-2006-037489-ImmunoPDT). Financial contributions from the Swiss National Science Foundation, the ETH Zürich, the European Union (ADAMANT project), the Swiss Cancer League, the SwissBridge Foundation and the Stammbach Foundation are also gratefully acknowledged. We thank the EPSRC mass spectrometry centre, Swansea, for analyses.

Radioimmunotherapy of Human Colon Cancer Xenografts with ^{131}I-Labeled Anti-CEA Monoclonal Antibody

Zhaofei Liu,[#] Cunjing Jin,[#] Zilin Yu, Jing Zhang, Yan Liu, Huiyun Zhao, Bing Jia,* and Fan Wang*

Medical Isotopes Research Center, Peking University, Beijing 100191, China. Received August 12, 2009; Revised Manuscript Received December 15, 2009

Radioimmunotherapy (RIT) is a promising approach for the treatment of a wide variety of malignancies. The aim of this study was to investigate the therapeutic efficacy of ^{131}I-labeled anticarcinoembryonic antigen (CEA) monoclonal antibody CL58 in a human colon cancer mouse model. In vitro and in vivo characteristics of ^{125}I-CL58 were evaluated in LS180 human colon cancer cells and the nude mouse model. ^{131}I-CL58 was prepared and its in vivo therapeutic efficacy was tested. ^{125}I-CL58 showed high affinity to LS180 cells, as well as high tumor uptake and long tumor retention in LS180 tumor xenografts. ^{131}I-CL58 exhibited dose-dependent inhibition of LS180 tumor growth. With the excellent in vitro and in vivo characteristics, and the effective therapy for colon cancer in animal model, ^{131}I-CL58 is a promising agent for RIT of CEA-positive tumors including colon cancer.

INTRODUCTION

Colorectal cancer, accounting for higher morbidity and mortality, is the second most lethal and third most common malignancy in western developed countries (*1*) and the third common gastrointestinal tumor in China (*2, 3*). Although multiple kinds of managements in prevention, screening, treatment, and surveillance of this disease have been developed systematically in the last decades, the major cause of cancer mortality is most likely due to dissemination and distant metastasis.

In the exploration of methods to manage colorectal cancer, chemotherapy is the principal adjuvant therapy, and the addition of radiotherapy to chemotherapy has not been shown to improve outcomes (*4*). To reduce the systemic toxicity elicited from the chemotherapy, tactics involving biomarkers on cancer cells recognized by exogenous targeted molecules (e.g., peptides, oligonucleotides, aptamers, and antibodies) were conducted. Among these investigations, radioimmunitherapy (RIT), which typically consists of radionuclide and antibody, has been investigated extensively as a useful strategy for the treatment of a variety of neoplasms (*5*−*7*). For the agents of RIT, the antibody acts as a vehicle for selective delivery of cytotoxic radionuclides to destroy the tumor while sparing the normal organs and tissues. FDA approval of two radiolabeled antibody-based products for the treatment of non-Hodgkin's lymphoma (NHL) was an initial success of hardworking investigation of the subject of RIT in the past decades (*8, 9*). Although the efficacy of RIT for solid tumors was less encouraging than that of hematologic tumors (*10*), it indeed gives hope for this subject; moreover, some lessons and experiences have already been acquired for further investigation.

Many colorectal cancer markers, such as carcinoembryonic antigen (CEA), TAG-72, A33, Ep-CAM (17−1A), and CSA-p, have been studied as the therapeutic targets in preclinical or clinical settings (*11*). Among all the colon cancer markers, CEA was first described as a gastrointestinal onco-fetal antigen, although it is now well-known to be overexpressed in a majority of carcinomas, including gastrointestinal cancers, respiratory and genitourinary cancers, and also breast cancers (*12, 13*). ^{131}I-labeled anti-CEA antibodies for RIT of colon cancer have shown encouraging results in preclinical and clinical trials (*14, 15*). Moreover, an adjuvant regimen of RIT showed exciting results in patients with colorectal cancer and liver metastases (*16*).

CL58 is a murine anti-CEA monoclonal antibody (IgG1 subtype). Previous studies have shown the successful application of radiolabeled CL58 for CEA-positive tumor imaging and radioimmunoguided surgery (*17, 18*). In this study, in vitro and in vivo characteristics of iodinated CL58 were evaluated, and the RIT efficacy of ^{131}I-labeled CL58 in nude mice bearing human colon cancer xenografts was investigated.

EXPERIMENTAL PROCEDURES

Radiolabeling of mAb. The murine anti-CEA monoclonal antibody CL58 was generated as previously reported (*17, 18*). An isotype-matched control murine IgG1 (mIgG) was purchased from Sigma. Iodination of mAb CL58 or mIgG was performed using Iodogen method as previously described (*19, 20*). Briefly, 2 mCi (74 MBq) of ^{125}I or ^{131}I (Beijing Atom High Tech, Beijing, China), 50 μg of mAb CL58 or mIgG, and 100 μL of 0.2 M phosphate buffer (pH 7.4) were added in the vial coated with 50 μg Iodogen (Sigma-Aldrich, St. Loius, MO). After reacting for 7−10 min at room temperature, the mixture was purified with PD-10 column (Amersham, Piscataway, NJ). Labeling yield and radiochemical purity of the products were measured by ITLC (85% methanol as the mobile phase) on a radio-thin layer scanner (Bioscan AR2000, Washington, DC).

Cell Culture and Animal Model. The human colon carcinoma cell line LS180, with a cell surface CEA expression rate of 81% (*17*), was maintained in Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum (FBS) at 37 °C under a humidified atmosphere containing 5% CO_2. All animal experiments were performed in accordance with Guidelines of Peking University Health Science Center Animal Care and Use Committee. Five-week-old female BALB/c nude mice were purchased from the Department of Experimental

Animal, Peking University Health Science Center (Beijing, China). The LS180 tumor model was generated by subcutaneous injection of 1×10^7 LS180 cells into the left flanks of the nude mice.

Affinity of ^{125}I-CL58. The equilibrium dissociation constant (K_d) of ^{125}I-CL58 was determined by saturation binding study using the previously described method with some modifications (*20*). Briefly, LS180 cells seeded in 48-well plates were incubated in triplicate with increasing concentration of ^{125}I-CL58 (from 20 ng/mL to 1.2 μg/mL, in 1% BSA binding buffer). The total volume of each well was adjusted to 200 μL. Nonspecific binding at each concentration was determined by adding an excess dose of unlabeled CL58 (~100-fold). After 2 h of incubation at 4 °C, the reaction medium was removed and cells were washed with ice-cold PBS. The cells were lysed with 2 M NaOH, and the cell-associated radioactivity was measured in a gamma counter (Wallac 1470-002, Perkin-Elmer, Finland). Results were analyzed by nonlinear regression (one-site binding) using GraphPad *Prism 4.0* (GraphPad Software, San Diego, CA) to obtain the best-fit K_d and B_{max} values, and a Scatchard transformation was subsequently performed. Data were expressed as the average of triplicate samples.

Biodistribution. LS180 tumor-bearing nude mice were randomly divided into groups ($n = 4$/group) when the tumor size reached 0.5−0.8 cm in diameter (~10 days after inoculation). Each mouse was injected intravenously with 100 μL of ^{125}I-CL58 (5 μCi, 5 μg). At selected time points (4 h; 1, 3, 5, and 7 d), mice were euthanized, and samples or organs of interest were removed, weighed, and counted in a gamma counter. The results were calculated as a percentage of the injected dose per gram tissue (%ID/g). To determine the specific accumulation of ^{125}I-CL58 in LS180 tumors, ^{125}I-mIgG (5 μCi, 5 μg) was injected intravenously into a group of 4 tumor-bearing mice, and the biodistribution (3 d postinjection) was determined as depicted above.

γ-Imaging. For planar gamma imaging studies, two LS180 tumor-bearing mice were injected intravenously with 200 μCi of ^{125}I-CL58 via tail vein after anesthetization. Mice were placed prone on a two-head γ-camera (Siemens, E.Cam) equipped with a parallel-hole, low-energy, and high-resolution collimator. Imaging was performed at 1, 2, and 6 d postinjection. After completion of imaging, mice were euthanized.

Radioimmunotherapy of ^{131}I-CL58. Therapy studies of ^{131}I-CL58 were investigated in LS180 tumor-bearing mice (the original tumor volume was 135 ± 58 mm^3). Animals were randomly divided into six groups, each of which had 6 mice. The tumor-bearing mice in therapeutic groups were administrated intravenously with escalating doses (150 μCi, 300 μCi, and 450 μCi) of ^{131}I-CL58 via tail vein. The mice in the control groups were administrated with normal saline, cold mAb CL58, and 150 μCi of ^{131}I-mIgG via tail vein, respectively. The tumor volume was estimated, assuming the tumors were ellipsoid, using the formula/volume = $4\pi/3$ (1/2 length × 1/2 width × 1/2 height). Tumor size and animal weight were measured every 2−3 days, and the mouse was culled and euthanatized once the tumor volume reached >1500 mm^3 or the body weight lost >20% of its original weight. Normal tissues including liver and kidney were isolated, fixed in 5% buffered formalin, embedded in paraffin, and sections were stained with hematoxylin and eosin (H&E) for histopathological analyses.

Statistical Analysis. Quantitative data were expressed as mean ± SD. Statistical analysis was done using a one-way ANOVA for multiple groups and an unpaired Student's *t* test.

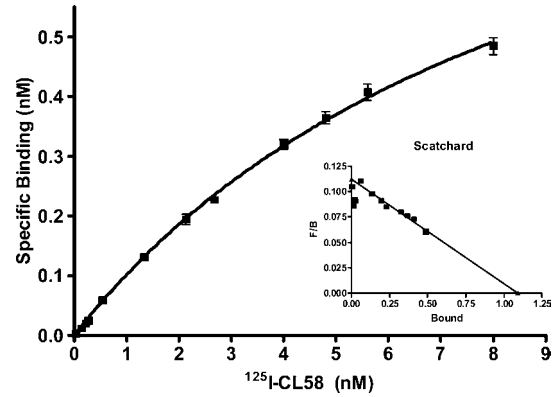

Figure 1. Saturation binding of ^{125}I-CL58 to EGFR on LS180 human colon cancer cells. Results were analyzed by nonlinear regression using GraphPad *Prism 4.0* software, and a Scatchard transformation was subsequently performed. Data are expressed as the means ± standard deviation (SD) ($n = 3$).

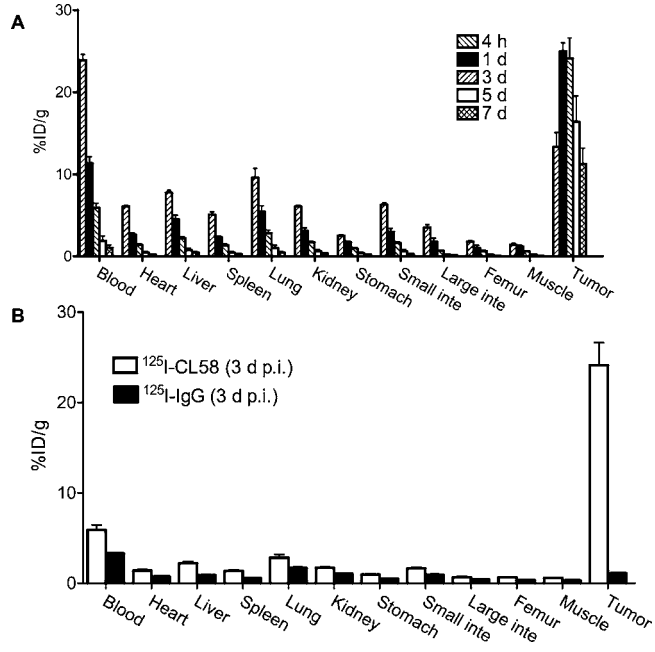

Figure 2. (A) Biodistribution of ^{125}I-CL58 (5 μCi per mouse) in LS180 tumor-bearing nude mice at 4 h, and 1, 3, 5, and 7 d postinjection. (B) Biodistribution comparison of ^{125}I-CL58 and ^{125}I-mIgG (isotype-matched control) (5 μCi per mouse) in LS180 tumor-bearing nude mice on 3 d postinjection. Data are expressed as %ID/g ± SD ($n = 4$ per group).

P values of <0.05 were considered statistically significant (GraphPad *Prism 4.0*).

RESULTS

Saturation Binding Assay. Anti-CEA monoclonal antibody CL58 was labeled with ^{125}I or ^{131}I using the Iodogen method. The labeling yield was >70% and the radiochemistry purity was >99% after purification with PD-10 column. The binding affinity of ^{125}I-CL58 to LS180 cells was determined by a saturation binding assay. As shown in Figure 1, the equilibrium dissociation constant (K_d) was determined to be 9.73 ± 0.84 nM, and B_{max} was calculated to be approximate 8.20×10^6 sites/cell. (means ± SD, $n = 3$).

Biodistribution Studies of ^{125}I-CL58. Biodistribution studies of ^{125}I-CL58 were performed in BALB/c nude mice bearing LS180 human colon carcinoma xenografts. As shown in Figure 2A, the tumor uptake of ^{125}I-CL58 at 4 h, and 1, 3, 5, and 7 d

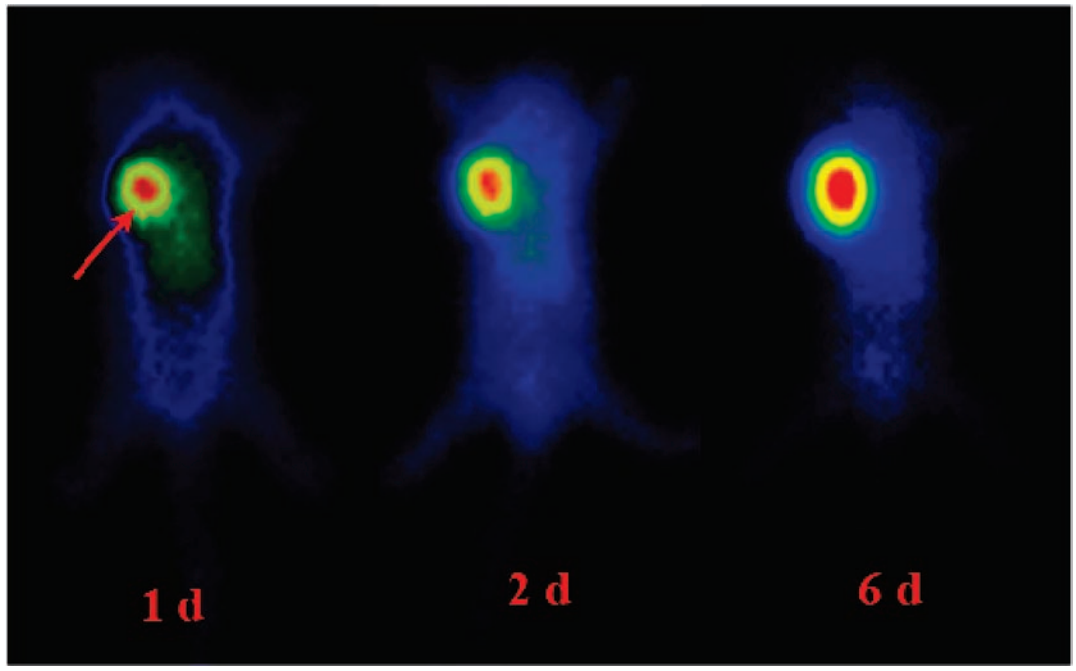

Figure 3. Representative planar γ images of ^{125}I-CL58 (200 μCi per mouse) in LS180 tumor-bearing nude mice on 1, 2, and 6 d postinjection. Arrow indicates the location of tumor.

postinjection were 13.34 ± 3.43%ID/g, 24.99 ± 2.00%ID/g, 24.11 ± 4.99%ID/g, 16.41 ± 5.40%ID/g, and 11.25 ± 3.82%ID/g, respectively, which were significantly higher than that of other organs after 1 d postinjection ($p < 0.001$). The blood radioactivity eliminated from 23.91 ± 1.35%ID/g to 1.05 ± 0.66%ID/g from 4 h to 7 d postinjection. For most normal organs, there was a progressive washout of radioactivity with the time, which was concomitant with the clearance of radioactivity from blood. The uptake of ^{125}I-CL58 in all normal organs was <0.5%ID/g on 7 d postinjection. The tumor-to-nontumor (T/NT) ratio of ^{125}I-CL58 showed an increasing trend for all organs during the entire period of this study, indicating the pretty good tumor targeting property of ^{125}I-CL58 in CEA-positive tumor model.

The in vivo CEA binding specificity of ^{125}I-CL58 was confirmed by performing the biodistribution of ^{125}I-mIgG in LS180 tumor-bearing nude mice. As shown in Figure 2B, the tumor uptake of ^{125}I-CL58 was significantly higher than that of mIgG (24.11 ± 4.99 vs 1.13 ± 0.04%ID/g, $P < 0.0001$) on 3 d postinjection, indicating the tumor targeting specificity of ^{125}I-CL58.

Gamma Imaging of ^{125}I-CL58. The representative planar gamma images of LS180 tumor-bearing mice acquired at different time points are shown in Figure 3. The tumors were clearly visualized on 1 d postinjection, and a small amount of radioactivity was also found in blood-rich organs, such as lung and heart, as well as liver. The background activity decreased with time, which was consistent with the ex vivo biodistribution data at the same time points. The images with higher contrast were obtained on 6 d postinjection.

Radioimmunotherapy of ^{131}I-CL58. The RIT efficacy of ^{131}I-CL58 was investigated in BALB/c nude mice bearing CEA-positive LS180 tumors. In all three control groups (saline, mAb CL58, and 150 μCi mIgG), the tumors grew rapidly, and the average tumor size reached >1500 mm^3 on day 12 post-treatment. Lower or moderate dose (150 μCi or 300 μCi) of ^{131}I-CL58 delayed tumor progression significantly compared with the control groups. The tumor size of mice receiving 150 μCi ^{131}I-CL58 was significantly different to that in unlabeled mAb CL58 group on day 12 ($P < 0.001$). Mice receiving 300 μCi ^{131}I-CL58 exhibited significant tumor growth inhibition until day 19 before exponential growth of tumors resumed. For the group treated with the highest dose of 450 μCi, the tumor growth was significantly suppressed, and the average tumor size maintained in a similar level up to day 55 post-treatment. The tumor size in 450 μCi group was smaller than that in other groups from day 9 post-treatment. On day 30, the tumor volume of 450 μCi group was significantly smaller than that in 150 μCi and 300 μCi groups ($p < 0.01$). A dose-dependent effect was observed in this study as the tumor therapeutic efficacy of ^{131}I-CL58 followed the order of 450 μCi > 300 μCi > 150 μCi (Figure 4A).

The CEA-targeted radioimmunotherapy with ^{131}I-CL58 significantly prolonged the survival time of mice. As shown in Figure 4B, all mice in the control groups (saline, mAb CL58, and 150 μCi mIgG) died before day 23, whereas the median survival time for 150 μCi and 300 μCi therapeutic groups was prolonged to be 41 days and 48 days, respectively. All mice in the 450 μCi ^{131}I-CL58 treatment group were still alive on day 55 post-treatment, and the median survival time was 84 days. All mice injected with ^{131}I-CL58 did not show obvious signs of body weight loss (less than 20%), and histopathologic staining results revealed that no renal and hepatic toxicity was observed (Supporting Information Figure S1−S2), indicating the limited toxicity of ^{131}I-CL58 in this therapeutic study.

DISCUSSION

In this study, we evaluated the in vitro and in vivo characteristics of radioiodinated anti-CEA monoclonal antibody CL58 and investigated whether ^{131}I-labeled CL58 could be used for radioimmunotherapy of colon cancers.

RIT can specifically deliver radiation to tumors with minimal toxicity to normal organs. The radiation energy given off by the radionuclides would also kill the adjacent tumor cells, which do not express the target antigen (so-called crossfire). Herein, we have chosen carcinoembryonic antigen (CEA) as the target for RIT of colon cancer xenografts because CEA is expressed at high levels in approximately 95% of colorectal carcinomas but is restrictedly expressed in normal tissues. CEA is located

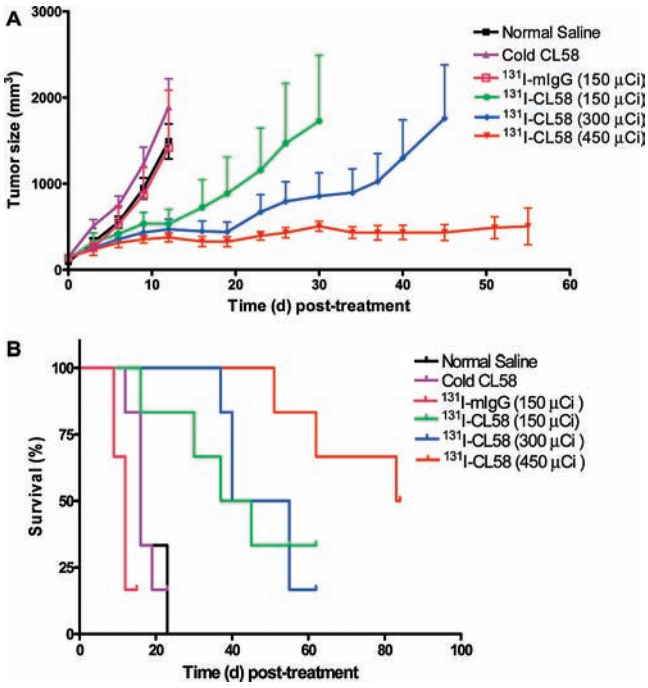

Figure 4. (A) Radioimmunotherapy of established LS180 tumors in nude mice with saline, unlabeled mAb CL58, ^{131}I-mIgG (150 μCi), or different doses (150, 300, and 450 μCi) of ^{131}I-CL58. Volumes of tumors in each treatment group were measured and expressed as a function of time (means ± SD, $n = 6$ per group). (B) Kaplan−Meier plots of individual treatment groups receiving saline, unlabeled CL58, ^{131}I-mIgG (150 μCi), or different doses (150, 300, and 450 μCi) of ^{131}I-CL58.

on the cell surface of tumor cells, and it has been one of the first tumor-associated antigens (TAA) used for RIT. A series of anti-CEA antibodies have been investigated for colon cancer targeted RIT, some of which have been used for clinical trials (see review, ref *21*). In this study, we used a murine anti-CEA monoclonal antibody CL58 as the vehicle for radiation delivery. The mAb CL58, which has been successfully used in clinical trials for tumor imaging and radioimmunoguided surgery (*17, 18*), exhibited a moderate affinity ($K_d = 9.73 \pm 0.84$ nM) to CEA-positive LS180 cells (Figure 1). The low antigen binding affinity of an antibody will certainly affect the in vivo radionuclide delivery in RIT trials; however, it has also been hypothesized that very high affinity interactions between antibodies and tumor antigens may impair efficient tumor penetration of the antibodies and thus diminish effective in vivo targeting (*22*). Consequently, antibodies with moderate affinity may be advantageous, as they can effectively penetrate into tumors and exhibit longer retention on tumor cells (*23*). LS180 cells had an extremely high CEA expression level (Figure 1). In the clinical situation, the CEA expression of other types of colon cancers may not reach such a high level as LS180 tumors, but the highly restrictive expression of CEA in colon cancers as compared with normal organs would still allow the specific delivery of radiation by the anti-CEA mAb CL58.

The in vivo behavior of ^{125}I-CL58 was tested in nude mice bearing CL180 colon cancer xenografts by both biodistribution and gamma imaging studies. ^{125}I-CL58 showed efficient tumor targeting properties, with rapid normal organ clearance and high tumor-to-nontumor ratios (Figures 2 and 3). The longer tumor retention of radioactivity was also found by the biodistribution study, and the tumor uptake of ^{125}I-CL58 was still as high as 11.25 ± 3.82%ID/g on 7 d postinjection. We tested the internalization property of ^{125}I-CL58 by the method reported previously (*20*), and the result demonstrated that ^{125}I-CL58 exhibited an undetectable internalization after binding to CL180 cells (data not shown). The negligible internalization property of ^{125}I-CL58 would effectively avoid the rapid diffusion of iodotyrosine in the target cells after internalization and catabolism of the radioiodinated mAb, leading to the high tumor uptake and long tumor retention of ^{125}I-CL58 in LS180 tumor xenografts. Importantly, the liver and spleen uptake of ^{125}I-CL58 was relatively low compared with that of metal isotope (e.g., ^{64}Cu, ^{111}In) labeled antibodies (*24, 25*), which possibly makes radioiodinated CL58 less toxic. The significantly higher tumor uptake of ^{125}I-CL58 as compared with ^{125}I-mIgG clearly demonstrated the in vivo CEA-targeting specificity of mAb CL58 (Figure 2B).

^{131}I and ^{90}Y are the most commonly used isotopes for radioimmunotherapy. Compared with the pure β emitter ^{90}Y, ^{131}I is much easier for radiolabeling, lower cost, and can also be used for imaging, which makes it possible for monitoring the therapeutic efficacy during the period of RIT. The experimental RIT study using ^{131}I-CL58 showed promising results on the therapy of colon cancer xenografts. In the 450 μCi ^{131}I-CL58 group, the tumor growth was efficaciously inhibited up to the end of therapy study (Figure 4A). The overall body weight loss of mice was <20% (Supporting Information Figure S1), and no signs of liver and kidney damage were found, revealing the limited toxicity of ^{131}I-CL58 at the dose of 450 μCi. In the lower dose groups (150 μCi and 300 μCi), ^{131}I-CL58 could partially inhibit the growth of CL180 tumors with prolonged survival time (Figure 3). The tumor growth inhibition efficacy of ^{131}I-CL58 was obviously superior to that of unlabeled mAb CL58 at the same dose due to the radiation effect of ^{131}I. Compared with ^{131}I-IgG, the same radioactive dose of ^{131}I-CL58 was more effective in slowing tumor growth, demonstrating that mAb CL58 can specifically deliver the radiation to the CEA-positive tumors. Several investigators have reported that dose fractionation could be less toxic and more efficacious than a single dose (*26, 27*). Therefore, further investigation of the direct comparison of a single dose with the fractionated administration of ^{131}I-CL58 may be helpful to optimize the therapeutic dose and select the better regimen for RIT of CEA-positive tumors.

In summary, this study has demonstrated the in vitro and in vivo tumor targeting properties of radioiodinated anti-CEA monoclonal antibody CL58 in CEA-positive colon cancer. ^{131}I-CL58 exhibited obvious therapeutic efficacy of tumor xenografts in the nude mouse model, which guaranteed its further investigation as a promising agent for radioimmunotherapy of CEA-positive tumors.

ACKNOWLEDGMENT

We thank Dr. Zhi Yang for his enthusiastic help with the γ imaging of animals, and also thank Ms. Hong Zhang for preparing mAb CL58. Received September 14, 2009; Revised Manuscript Received November 11, 2009

Novel amino-reactive derivatives of lanthanide-based luminescent labels of enhanced brightness and metal retention were synthesized and used for the detection of cDNA oligonucleotides by molecular beacons. Time-resolved acquisition of the luminescent signal that occurs upon hybridization of the probe to the target enabled the avoidance of short-lived background fluorescence, markedly enhancing the sensitivity of detection, which was less than 1 pM. This value is about 50 to 100 times more sensitive than the level achieved with conventional fluorescence-based molecular beacons, and is 10 to 60 times more sensitive than previously reported for other lanthanide-based hybridization probes. These novel luminescent labels should significantly enhance the sensitivity of all type of nucleic acid hybridization probes, and could dramatically improve the detection limit of other biopolymers and small compounds that are used in a variety of biological applications.

INTRODUCTION

Some lanthanide chelates possess the unique spectral property known as luminescence (*1*−*9*). The principle features of luminescence are long-lived excited states (in the microsecond to millisecond range) and narrow emission spectra. Temporal and spectral gating enables unusually sensitive detection of lanthanide emission, even in samples that exhibit significant, short-lived autofluorescence (e.g., biological specimens or tissues). These compounds are therefore potentially useful in a wide variety of technical and biological tasks, such as tracing analysis, immunoanalysis, tissue-specific imaging, and detection of single molecules in living cells. Despite the benefits offered by this technique, its widespread use is impeded by the limited choice of instrumentation and the extremely high price of commercial probes. Yet, existing lanthanide-based probes could be improved to meet the requirements of new challenging applications.

Due to their very low absorbance ($\varepsilon < 1$ M^{-1} cm^{-1}), lanthanide ions have to be "pumped", which is achieved by tethering the lanthanide ion (through chelation) to an appropriate organic fluorophore (antenna). In such constructs, the energy absorbed by the antenna is transferred radiationlessly to the lanthanide, which finally emits the light. The chelating group also shields the lanthanide ion from the quenching effects of the medium, increasing the quantum yield of the probe. Development of new luminescent probes is challenging, since the transfer of energy from the antenna to the lanthanide is complex (a process not yet well understood) and very sensitive to subtle structural variations in the fluorophore. Another challenge is the necessity of combining three functional units within the same reporting probe: an antenna, a chelated lanthanide, and a cross-linking group (for attachment to the biomolecule of interest). This requires a complex synthetic strategy, eventually leading to compounds whose size often exceeds 1000 Da.

Two commonly used classes of lanthanide chelates are diethylenetriaminepentaacetic acid (DTPA) and tetraethylene-tetraminohexaacetic acid (TTHA). These chelates attached to 7-animo quinolones (*10*−*17*) are known as DTPA and/or TTHA-cs124 derivatives. The advantage of these classes of compounds is their high quantum yield, high solubility in water, and the possibility of introducing chemical modifications in the fluorophore to spectrally optimize the transfer of energy to the lanthanide and to enable the attachment of a cross-linking group. A number of methods for the conjugation of these chelates to biomolecules have been suggested. One of them is to use the dianhydride form of DTPA, in which one of the anhydrides modifies the amino group of the chromophore, while the other anhydride reacts with amino group of the biomolecule (*17*). Even though this approach is technically simple, it raises concerns about the side reactions (modification of other nucleophilic groups) due to the high reactivity of anhydrides. The second approach takes advantage of the conjugation of one of the DTPA anhydride groups with the cs124 moiety, followed by reaction of the remaining anhydride with the diamine. The unmodified amino group of the resulted adduct can then be converted to an amino-reactive isothiocyano or thiol-reactive groups (*12*). This mode of attachment of the cross-linking group weakens the retention of the lanthanide within the chelate by eliminating one ligating carboxylate, and it also reduces the brightness of the lanthanide (*14*) (30% to 1000%) due to the quenching effect of the additional coordinated water molecule. These factors restrict *in vivo* applications where high concentration of metal scavengers is an issue (e.g., intracellular imaging). Analogous derivatives of the fluorophore coumarine have been suggested and used in biophysical studies (*18*). However, compared to their quinolone counterparts, they are less bright and do not support terbium (Tb) luminescence.

To further perfect lanthanide probes, we now report the development of two novel approaches for the introduction of cross-linking groups into DTPA and/or TTHA-cs124 chelates by modification of the chromophore moiety. We demonstrate that the synthesized luminescent probes (Chart 1) are more resistant to EDTA challenge than previously described DTPA-cs124-based probes, and we demonstrate that these new probes are highly luminescent. These compounds were validated as

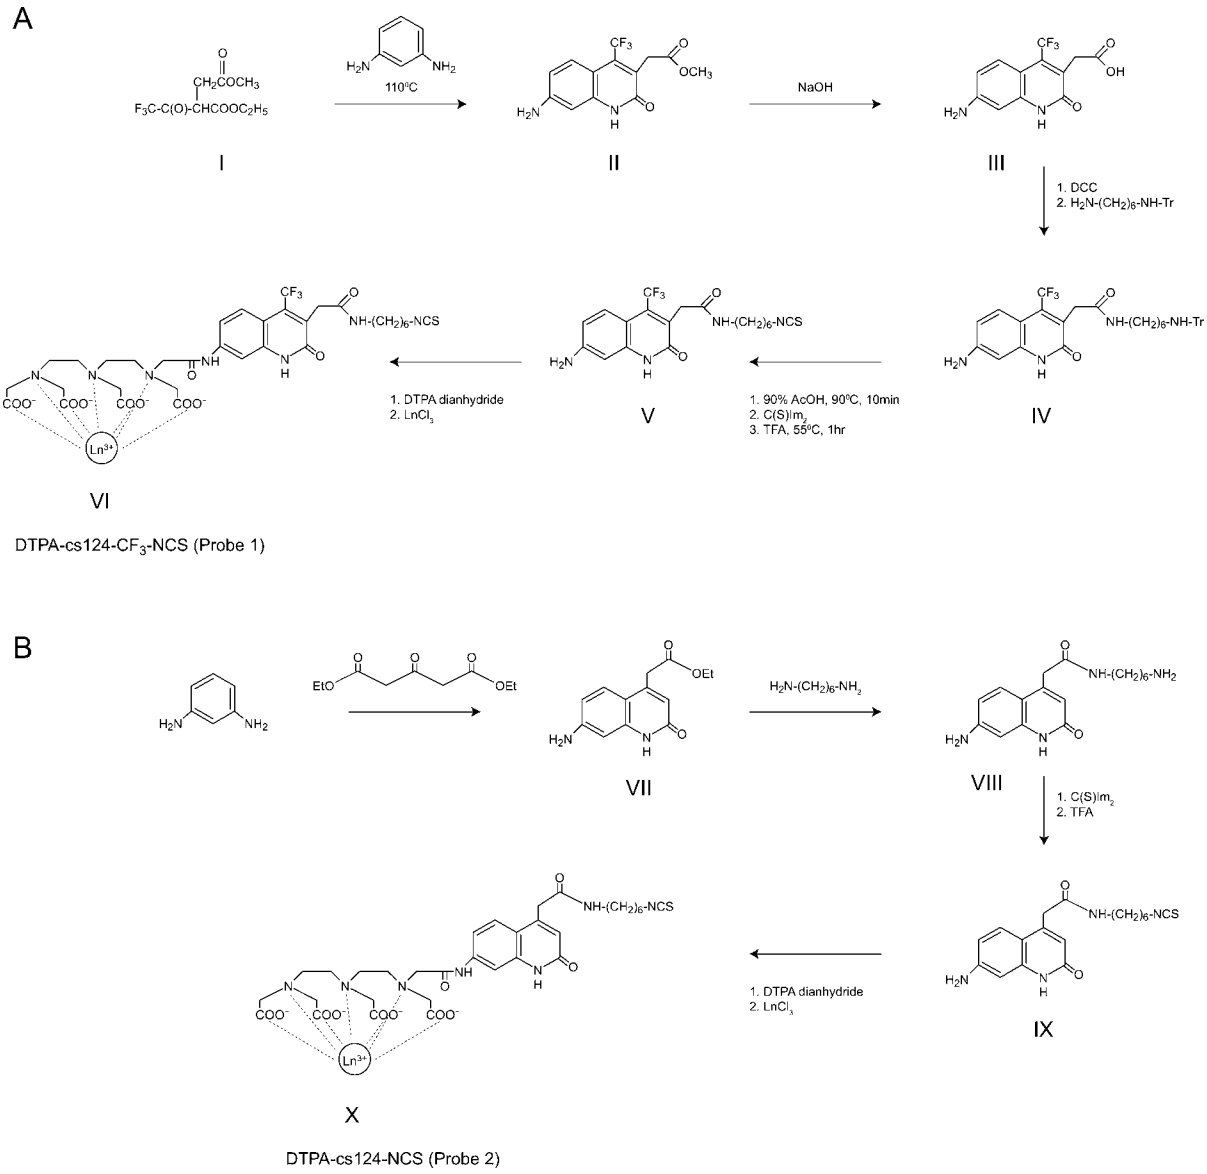
luminescent labels by including them in molecular beacon probes, which are widely used for DNA and RNA detection (*19*). The resulting sensitivity of these molecular beacons was between 0.5 and 1 pM, which is the most sensitive level of detection ever reported for nonamplified DNA detection systems.

EXPERIMENTAL PROCEDURES



Synthesis. The following reagents were purchased from Aldrich: diethylenetriaminepentaacetic acid dianhydride (DTPA), triethylamine, 1,3-phenylenediamine, ethyl 4,4,4-trifluoroacetoacetate, ethylacetoacetate, 1,3-dicyclohexylcarbodiimide (DCC), ethylenedianime, *N*-trityl-1,6-diaminohexane, methylbromacetate, anhydrous dimethylformamide and dimethylsulfoxide, 1-butanol, ethylacetate, chloroform, acetonitrile, ethanol, sodium and potassium hydroxide, $ZnCl_2$, Na_2SO_4, Na_2CO_3, acetic acid, citric acid, thiocarbonyldiimadazole, $TbCl_3$, $EuCl_3$, $SmCl_3$ and $DyCl_3$, silica gel TLC plates on aluminum foil (200 μm layer thick with a fluorescent indicator). Only distilled and deionized water (18 MΩ cm^{-1}) was used. All experiments, including the preparation and use of lanthanide complexes, were performed either in glassware washed with mixed acid solution and rinsed with metal-free water or in metal-free plasticware purchased from Bio-Rad. All chemicals were the purest grade available.

Probe 1 (Scheme 1A). *1. 7-Amino-4-trifluoromethyl-3-carbomethoxymethyl-2(1H) quinolone (**II**) (cs124CF_3−CH_2-$COOCH_3$).* 4,4,4-Trifluoroacetoacetate (2.2 mL, 15 mmol) and KOH (0.86 g, 15 mmol) were mixed in 7 mL of dimethylformamide and stirred at 40 °C until dissolved. To this mixture, 1.5 mL of methylbromoacetate was added and the solution was incubated overnight at room temperature. Three hundred milligrams (5.2 mmol) of KOH was then added, and incubation continued at 60 °C for 1 h. This mixture was diluted by the addition of 20 mL of water and was then extracted with chloroform. The organic layer was collected, dried over anhydrous sodium sulfate, and then evaporated in vacuo, first at 30 °C, and then at 70 °C for 30 min. The residue (1.9 g, product **I**) was dissolved in 3.5 mL of DMSO, and then 0.76 g (7 mmol) of 1,3-phenylenediamine was added, followed by incubation at 110 °C for 6 h. Under these conditions, four fluorescent products were detected by thin layer chromatography in ethyl acetate as developing solvent: $R_f = 0.90$ (green−blue fluorescence); $R_f = 0.45$ (blue fluorescence); $R_f = 0.30$ (blue fluorescence); and $R_f = 0.03$ (green−blue fluorescence). This mixture was diluted with 30 mL of 0.05 M aqueous NaOH and extracted with ether (2 × 40 mL). The aqueous layer was separated and treated as described below (section 2). The organic layer was extracted with 1 vol 0.1 M citric acid, and then collected, dried over anhydrous sodium sulfate, and evaporated in vacuo. The residue was subjected to silica gel chromatography on a 40 mL column, using a hexane/acetone mixture (3:1) as eluent. Fractions corresponding to the products migrating with $R_f = 0.45$ (product **II**) were collected and evaporated to dryness. The residue was then washed with chloroform and dried. Yield ∼ 130 mg. UV: $\lambda_{max} = 365$ nm ($\varepsilon = 14\,300$ M^{-1} cm^{-1}), $\lambda_{min} = 295$ nm ($\varepsilon = 2800$ M^{-1} cm^{-1}). ^{1}H NMR chemical shifts (d) in DMF were as follows: 3.65 (3H, methyl), 3.94 (q, 2H, 3-methylene, $J = 3.6$), 6.24 (broad, 7 amine), 6.72 (m, 1H, 6H), 6.72 (m, 1H, 8H), 7.48 (1H, 5H), and 11.9 (broad, amide).

*2. 7-Amino-4-trifluoromethyl-3-carboxy-2(1H) quinolone (**III**) (cs124CF_3-CH_2COOH).* One milliliter of 1 M aqueous NaOH was added to 100 mg of product **II** dissolved in 2 mL dioxane. After 4 h incubation at 50 °C, the mixture was diluted by the addition of 15 mL water and extracted with ether. The product (**III**) was precipitated from the aqueous phase by the addition of citric acid to pH 3−3.5, collected by centrifugation, washed a few times with water until neutral reaction, and dried in vacuo. Yield ∼ 70 mg.

The aqueous phase obtained after ether extraction (see previous section), containing product **III**, was acidified by the addition of citric acid to pH 3−3.5; the precipitate was collected, washed a few times with water, dried, and then combined with the above. Recrystallization from ethyl acetate resulted in the isolation of pure product **III** (total yield ∼ 200 mg). ^{1}H NMR chemical shifts (*d*) in DMF were as follows: 3.93 (2H, 4

Scheme 1. Schemes for the Synthesis of Probe 1 (A) and Probe 2 (B)

methylene), 6.19 (2H broad, 7 amine), 6.71 (1H, 6H), 6.71 (1H, 8H), 7.48 (1H, 5H), 11.85 (broad, amide), and 12.75 (broad, carboxyl).

3. cs124CF$_3$-CH$_2$C(O)-NH(CH$_2$)$_6$NH-Tr (***IV***). 100 mg (∼0.3 mmol) of product **III** were dissolved in 8 mL of THF and supplemented with 210 mg (1 mmol) of DCC. After 1 h incubation, thin layer chromatographic analysis in ethyl acetate/ethanol (10:1) revealed a single product ($R_f = 0.80$) with intense blue fluorescence. 450 μmol of *N*-trityl-1,6-diaminohexane were added and incubation continued for another 30 min at 20 °C. Thin layer chromatography in ethylacetate/ethanol (10:1) revealed the main reaction product ($R_f = 0.70$). This mixture was diluted with 20 mL of 0.1 M aqueous Na_2CO_3 and extracted with an equal volume of chloroform. The organic phase was then collected and rinsed with 1 volume 0.2 M citric acid, dried over anhydrous sodium sulfate, and the solvent removed by evaporation under reduced pressure. The product was purified by silica gel chromatography, using ethylacetate/ethanol (10:1) mixture as eluent. Yield ∼ 160 mg. ^{1}H NMR chemical shifts (*d*) in DMF were as follows: 1.45 (m, 8H), 1.65 (m, 2H), 1.78 (m, 2H), 2.03 (q, 2H, $J = 7.25$), 2.41 (t, 1H, $J = 7.2$), 3.08 (q, 2H, $J = 7.2$), 3.82 (q, 2H, 4CH$_2$-, $J = 4.0$), 6.14 (s, 2H, broad, 7 amine), 6.7 (1H, 8H), 6.7 (1H, 6H), 7.18 (t, 3H, p-ArH, $J =$ 7.2), 7.30 (t, 6H, m-ArH, $J = 7.4$), 7.48 (d, 6H, o-ArH, $J =$ 7.4), 7.48 (1H, 5H), and 11.75 (1H, broad, amide).

4. cs124CF$_3$-CH$_2$C(O)-NH(CH$_2$)$_6$N═C═S (***V***). 140 mg of compound **IV** were dissolved in 2 mL of 90% acetic acid and incubated at 90 °C for 15 min. After evaporation in vacuo, the resulting residue was suspended in water and extracted with ether to remove triphenylcarbinol. The aqueous phase was then evaporated to dryness. The resulting residue was dissolved in 2 mL of methanol, and 80 mg of thiocarbonyldiimadazole was then slowly added to this solution under rigorous agitation. After 10 min incubation at room temperature, the mixture was supplemented with 100 μL trifluoroacetic acid and kept at 50 °C. Thin layer chromatographic analysis in ethylacetate/ethanol (12:1) revealed nearly quantitative conversion of the original compound ($R_f = 0.05$) to an isothiocyanate ($R_f = 0.40$). This product was purified by column chromatography using the same eluent. Yield ∼ 60 mg. ^{1}H NMR chemical shifts (*d*) in DMF were as follows: 1.35 (m, 4H), 1.46 (m, 2H), 1.65 (m, 2H), 3.13 (m, 2H, $J = 7.25$), 3.69 (t, 1H, $J = 7.2$), 3.08 (q, 2H, $J =$ 7.2), 3.82 (q, 2H, 3CH$_2$-, $J = 3.7$), 6.14 (s, 2H, broad, 7 amine), 6.7 (1H, 8H), 6.7 (1H, 6H), 7.48 (m, 1H, 5H), 7.76 (t, 1H, $J =$ 5.5), and 11.77 (1H, broad, amide).

5. Lanthanide Complexes of DTPA-cs124-CF_3-NCS (probe 1). Thirty milligrams (0.1 mmol) of compound **V** were added to a solution of 80 mg (0.3 mmol) of DTPA dianhydride in 0.8 mL of DMSO. After incubation (45 min at 50 °C), the mixture was supplemented with 10 mL of ether, and the resulting precipitate was spun down, washed with ether, air-dried, dissolved in 1 mL of DMF, and mixed with 0.3 mL of water. After incubation for 10 min at 45 °C, the mixture was diluted with 5 mL of water and extracted with 40 mL of butanol. The organic phase was separated and divided into four equal parts. Each portion was mixed with 0.3 mL of a 0.1 M solution of a lanthanide trichloride (Tb^{3+}, europium (Eu^{3+}), dysprosium (Dy^{3+}), and samarium (Sm^{3+})). After vigorous agitation, the organic phase was collected and concentrated by co-evaporation with water in vacuo at 30 °C. Analytical thin layer chromatography, using an acetonitrile/water system (3:1) as the developing solvent, revealed two main Ln^{3+} products ($R_f = 0.25$ and 0.50). The products with $R_f = 0.50$ (desired compound) were purified using preparative thin layer chromatography under the same conditions. The fluorescent material was eluted with 50% aqueous ethanol and was recovered as a colorless powder after evaporation in vacuo. UV: $\lambda_{max} = 347$ nm ($\varepsilon = 14\,800$ M^{-1} cm^{-1}), $\lambda_{min} = 270$ nm ($\varepsilon = 4700$ M^{-1} cm^{-1}). MS: Eu^{3+}DTPA-cs124-CF_3-CH_2C (O)-NH$(CH_2)_6$N═C═S (-H^+) 950.1 (found), 950.0 (calculated). Ln^{3+} complexes of DTPA-cs124-CF_3 were obtained using the same protocol.

Probe 2 (Scheme 1B). *1. 7-Amino-4-carboethoxymethyl-2(1H) quinolone (**VII**).* A suspension of 1.36 g (10 mmol) of $ZnCl_2$ in 5 mL of DMSO was supplemented with 1.08 g (10 mmol) of 1,3-phelylenediamine and 2.02 g (10 mmol) of diethyl-1,3-acetonedicarboxylate. The mixture was kept at 95 to 100 °C for 24 h. Thin layer chromatography in chloroform/ethanol (10:1) detected one main fluorescent product ($R_f = 0.35$). This mixture was diluted with 8 mL of ethanol, poured into 150 mL of ice-cold 0.1 M citric acid, and left for 3 h at 4 °C. The residue was filtered and successively washed with water (2 × 10 mL), and with hot acetonitrile (2 × 5 mL), and then dried in vacuo. Yield ~ 1.4 g (60%). ^{1}H NMR chemical shifts (*d*) in DMSO were as follows: 1.17 (t, 3H, -OCH_2CH_3, $J = 7.2$), 3.76 (s, 2H, 3-methylene), 4.06 (q, 2H, -OCH_2CH_3, $J = 7.2$), 5.81 (2H, broad, 7 amino), 6.01 (s, 1H, 3H), 6.37 (d, 1H, 8H, $J = 2.4$), 6.43 (dd, 1H, 6H, $J_1 = 7.2$, $J_2 = 2.4$), 7.25 (d, 1H, 5H, $J = 7.2$), and 11.28 (1H, broad, amide).

*2. 7-Amino-4-carboxamido(6-aminohexyl)methyl-2(1H) quinolone (**VIII**).* Premelted 1,6-diaminohexane (2 g, 17 mmol) was mixed with 7-amino-4-carboethoxymethyl-2(1*H*) quinolone (0.5 g, 2 mmol). After incubation (15 h, 90 °C), the mixture was poured into 30 mL of water. The precipitate was washed with water (3 × 30 mL) and ethyl acetate (3 × 20 mL), and then stirred with hot methanol (50 mL), filtered, and the filtrate evaporated to dryness in vacuo. The product appeared as light-brown crystals. Yield ~ 0.5 g. ^{1}H NMR chemical shifts (*d*) in DMSO were as follows: 1.2−1.4 (m, 10H), 3.04 (q, 2H, α-CH_2, $J = 7.2$), 3.49 (s, 2H, 4-methylene), 5.75 (2H, broad, 7 amino), 5.98 (s, 1H, 3H), 6.36 (d, 1H, 8H, $J = 2.4$), 6.43 (dd, 1H, 6H, $J_1 = 7.2$, $J_2 = 2.4$), 7.38 (d, 1H, 5H, $J = 7.2$), 8.07 (t, 1H, amide, $J = 7.2$), and 11.3 (1H, broad, amide quinolone).

*3. 7-Amino-4-carboxamido (6-isothiocyanohexyl) methyl-2 (1H) quinolone (**IX**).* 44 mg (0.22 mmol) of 1,1′-thiocarbonyldiimidazole was added to a solution of 63 mg (0.2 mmol) of product **VIII** dissolved in 4 mL methanol. After 5 min, this mixture was supplemented with 10 μL of TFA and incubated for 40 min at 50 °C. The solvent was removed by evaporation in vacuo, and the product was then washed with water and purified by column chromatography on silica gel using a chloroform/ethanol mixture (4:1) as eluent. Yield ~ 40 mg. ^{1}H NMR chemical shifts (*d*) in DMSO were as follows: 1.2−1.5 (m, 6H), 1.60 (m, 2H, e-CH_2, $J = 7.2$), 3.04 (m, 2H, α-CH_2, $J = 7.2$), 3.49 (s, 2H, 4-methylene), 3.64 (t, 2H, ζ-CH_2, $J = 7.2$), 5.75 (s, 2H, broad, 7 amine), 5.98 (s, 1H, 3H), 6.36 (d, 1H, 8H, $J = 2.4$), 6.43 (dd, 1H, 6H, $J_1 = 7.2$, $J_2 = 2.4$), 7.38 (d, 1H, 5H, $J = 7.2$), 8.07 (t, 1H, amide, $J = 7.2$), and 11.20 (1H, broad, amide quinolone).

4. Lanthanide Complexes of DTPA-cs124 and DTPA-cs124-NCS (probe 2). These products were obtained and purified essentially as described for the synthesis of analogous probe 1 compounds in section 5 above; however, the incubation time of the corresponding isothiocyano compound (**IX**) with DTPA dianhydride was 15 min at 20 °C. UV: $\lambda_{max} = 341$ nm ($\varepsilon = 18\,900$ M^{-1} cm^{-1}), $\lambda_{min} = 308$ nm ($\varepsilon = 10\,000$ M^{-1} cm^{-1}). MS: Tb-DTPA-cs124-NCS (−1) 888.3 (found), 888.0 (calcd); and Eu-DTPA-cs124-NCS (−1) 882.3 (found), 882.0 (calcd).

Synthesis of Luminescent Hybridization Probes. A 10 μL water solution containing 3 to 7 nmol of an oligonucleotide (5′ amino - CTTCGTCCACAAACACAACTCCTGAAG - 3′ Black-hole Quencher 2), prepared according to protocols described previously (*20*), was supplemented with 5 μL of $Na_2B_4O_7$ (pH 10.0), and 15 μL of a 10 to 20 mM aqueous solution of luminescent probe 1 or probe 2. After incubation for 3.5 h at 56 °C, the probe conjugated oligonucleotide was precipitated by the addition of 200 μL of ethanol, and then collected by centrifugation after cooling at −80 °C for 15 min. This procedure was repeated 3 to 4 times. Finally, the residue was dissolved in water and purified by HPLC chromatography, as described in Supporting Information. Yield 40−80%.

Physical Methods. Excitation and emission fluorescence spectra in a steady-state mode were recorded using a QuantaMaster 1 (Photon Technology International) digital fluorometer at ambient temperature. Time-resolved and gated luminescence measurements were performed using a home-built experimental setup (Supporting Information Figure S1). A Suprasil fluorescence cell filled with sample solutions was irradiated by pulsed (ca. 15 ns) UV light from an excimer laser (351 nm, XeF). Before passing through the cell, the laser beam was formed by a rectangular aperture 0.5 cm × 1.0 cm (width × height). Fluorescence from the cell collected at an angle of 90 degrees was focused onto the entrance slit of a grating spectrograph (SpectraPro-300i, Acton Research Corporation, diffraction grating 150 grooves/mm blazed at 500 nm) using a fused silica lens with a focal distance of 2.5 cm. The spectrograph was equipped with a gated intensified CCD Camera (ICCD-MAX, Princeton Instruments) to record transient spectra. A slit width of 0.5 mm was used for time-resolved luminescence measurements, which corresponds to a spectral resolution of 5 nm. Time-gated spectra were recorded with a spectral resolution of 0.3 nm (a slit width of 0.01 mm in combination with a pixel size on the ICCD camera of 0.026 mm). ICCD gating, with a delay after the laser pulse, was used to determine the temporal behavior of the transient fluorescence. For measurements of luminescence lifetimes, the light was diverted to a photomultiplier tube mounted on the exit slit of the spectrograph. The PMT signal was preamplified and averaged, using a digital storage oscilloscope (LeCroy 9310A). High-resolution spectra were recorded with a time delay of 1 μs and a gate width of 1 ms for probe 1 chelated with Eu and Sm and for probe 2 chelated with Tb and Dy.

Steady-State Fluorescence Measurements. Hybridization experiments of the lanthanide-based molecular beacon with its complementary target DNA (5′ TTAGGAGTTGTGTTTGTG-GACTT 3′) were performed in a measuring cell (150 μL) in a hybridization buffer containing 50 mM KCl, 3 mM $MgCl_2$, and 10 mM Tris-HCl (pH 8.0). The concentrations of the molecular beacon and the cDNA oligonucleotide (target) were 300 nM

and 1000 nM, respectively. Water-based or deuterium oxide-based solutions were used.

Time-Resolved Luminescence Measurements. *Protocol A.* Ten microliters of various concentrations (0−100 nM) of target DNA (see previous section) was added to 3 mL of a 1 nM solution of molecular beacons in hybridization buffer (see previous section), and was then transferred to a measuring cell. The luminescence of the sample was measured at different time intervals.

Protocol B. Different concentrations (0−3 nM) of DNA target were added to 3 mL of 10 pM molecular beacon hybridization buffer in a glass tube, and this solution was left for 3 days at room temperature. The solution was then transferred to the measuring cell. The glass tube was washed with 1 mL of the same hybridization buffer containing 30% ethanol, and this solution was also transferred to the measuring cell. The resulting luminescent signal was then measured as described above.

RESULTS

Synthesis and Properties of Cross-Linkable Lanthanide Chelates. The structure of the synthesized luminescent lanthanide probes is shown schematically in Chart 1. These probes are derivatives of previously described cs124 and cs124-CF_3 fluorophores (*10*−*17*). For the synthesis of these compounds, we used an approach based on the condensation of 1,3-phenylenediamine with an ester of an acetoacetic acid derivative. Scheme 1A presents the synthetic strategy developed for probe 1. Alkylation of trifluoroacetoacetate by methylbromoacetate in the presence of a proton acceptor produced trifluoroacetylmethylethylsuccinate (compound **I**). Reaction of the latter with 1,3-phenylenediamine resulted in fluorescent quinolone derivative **II**, which was converted to the corresponding carboxyl derivative **III** by saponification. We intended to introduce the amino function in this compound by treatment with DCC in the presence of 4-nitrophenol and subsequent reaction of nitrophenyl ester with aliphatic diamine. Surprisingly, incubation with DCC and 4-nitrophenol yielded a product that did not contain 4-nitrophenol. The ultraviolet spectrum of this product differed significantly from that of compound **III**. In aqueous medium, this product converted into **III** with a half-time of about 30 min at 20 °C. Incubation of this product with aliphatic amines resulted in acylation of the amino groups. Most likely, this reactive intermediate emerged as a result of intramolecular acylation of the amide oxygen of **III** by activated carboxylate. Incubation of this compound with monotritylated 1,6-diaminohexane yielded the desired compound **IV**. After deprotection, the resulting aminoalkyl derivative was converted to isothiocyanate (compound **V**) by treatment with thiocarbonyldiimidazole and trifluoroacetic acid. Under these conditions, the aromatic amino group of the compound remains intact. Acylation of compound **V** by DTPA anhydride in anhydrous medium, followed by hydrolysis of the second anhydride group, resulted in compound **VI** (probe 1), which was separated from the excess of DTPA by partitioning in butanol/water. Further addition of aqueous lanthanide trichloride to the butanol extract led to complexes between the lanthanides and the probes. The lanthanide complexes were analyzed and purified by thin layer chromatography in acetonitrile:water mixtures that proved to be highly efficient (see Figure 1).

For the synthesis of probe 2, we developed the strategy shown in Scheme 1B. The first step of this synthesis was based on a published protocol (*13*) that includes incubation of *m*-phenylenediamine with diethyl 1,3-acetonedicarboxylate at high temperature to yield quinolone derivative **VII**. Compared to published protocols, a dramatic improvement in the yield of the final product (from <1% to ca. 60%) was achieved by using a mild Lewis acid ($ZnCl_2$) as a catalyst, which allowed lowering

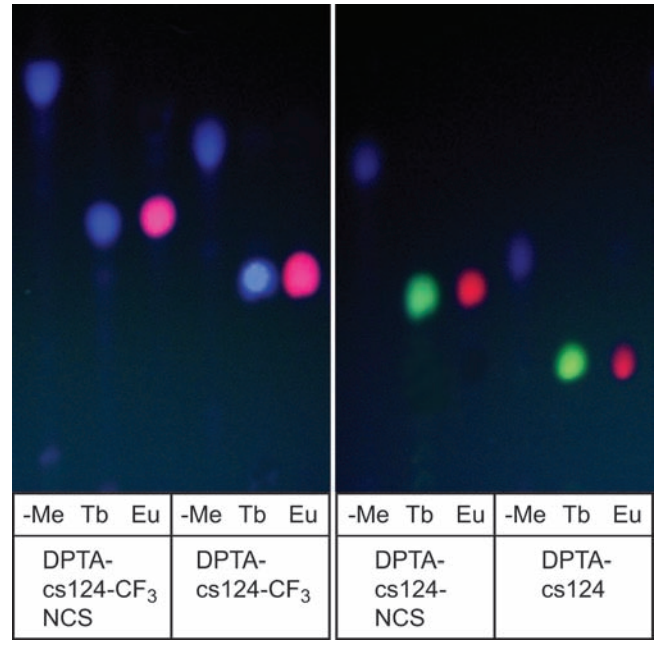


Figure 1. Image recorded by ultraviolet excitation of ligand antenna compounds (−Me) and their lanthanide complexes (Tb and Eu), after separation by thin layer chromatography.

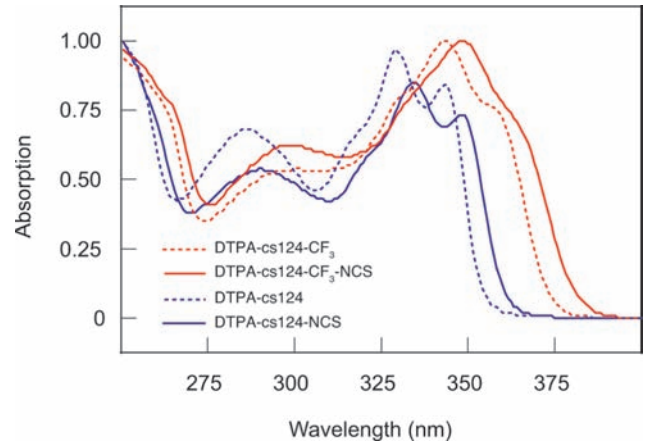

Figure 2. UV absorption spectra of synthesized reactive luminescent probes and reference compounds used in this study.

of the reaction temperature. Reaction of this product with a diamine (added in a few-fold excess to avoid cross-linked products) at high temperature resulted in the formation of aminoalkyl derivative **VIII**, with nearly quantitative yield. Cross-linkable DTPA derivative (**X**, probe 2) was obtained in the same manner as probe 1.

Absorption Spectra. Absorption spectra of the synthesized cs124 and cs124-CF_3 derivatives are shown in Figure 2. They were nearly identical to published spectra for analogous compounds (*10*−*17*). A small red shift of 6 nm was observed for probe 1 (comparing to the reference compound cs124-CF_3) and probe 2 (comparing to the reference compound cs124). The molar extinction coefficients for DTPA-cs124 and DTPA-cs124-CF_3 were determined by direct comparison of the absorption spectra of the original compounds (ε_{max} = 18 900 M^{-1} cm^{-1} at 341 nm for cs124 and ε_{max} = 14 500 M^{-1} cm^{-1} at 360 nm for cs124-CF_3) to their acylated derivatives, which was achieved by monitoring spectral changes in the reaction mixture during the course of the reaction (see Supporting Information Figures S2A and S2B). The presence of isosbestic points in both cases was indicative of the conversion of the original compounds to

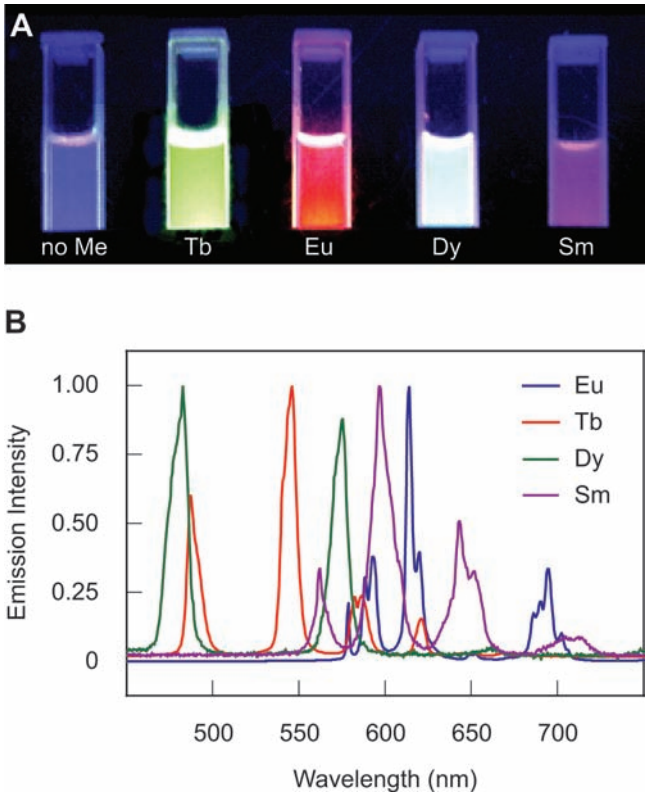

Figure 3. (A) Luminescence of 50 μM solutions of probe 2 (no Me) and its lanthanide complexes: terbium (Tb), europium (Eu), dysprosium (Dy), samarium (Sm); in heavy water, excited at 308 nm. (B) Normalized time-resolved emission of probe 1 Eu and Sm chelates and of probe 2 Tb and Dy chelates.

a single reaction product. Indeed, chromatographic analysis confirmed the formation of single acylation products in both cases. Thus, values of $\varepsilon_{max} = 18\ 200\ M^{-1}\ cm^{-1}$ at 328 nm and $\varepsilon_{max} = 14\ 800\ M^{-1}\ cm^{-1}$ at 341 nm were obtained for DTPA-acylated derivatives of cs124 and cs124-CF_3, respectively. Essentially the same values were obtained for probes 1 and 2 (data not shown). A significant difference in the absorption spectra of probes 1 and 2 (18 nm) allows selective excitation by common sources (at 351 nm by excimer XeF laser for probe 2, and at 365 nm by mercury UV lamp for probe 2). Such selective excitation is important for applications relying on simultaneous monitoring of two independent processes in the same sample.

Emission Spectroscopy of Lanthanide Complexes. The ease of observing the luminescence of these lanthanide complexes is illustrated in Figure 3A for probe 2. All complexes displayed the narrow emission spectrum typical of luminescent lanthanide chelates (Figure 3B). Table 1 shows the luminescence intensities of the synthesized reactive lanthanide chelates, as well as for the intensities obtained for the reference compounds, cs124 and cs124-CF_3 described earlier (*11*, *17*). The process of antenna-mediated lanthanide emission includes the transfer of energy from the antenna fluorophore to the coordinated metal and the subsequent emission of photons by the excited lanthanide. The first step is the most crucial part of the process, because even slight modifications of chromophore-antenna structure dramatically affect lanthanide luminescence (*13*). In this work, we explored a synthetic approach that allows the introduction of a cross-linking group in position 3 (probe 1) or position 4 (probe 2) of quinolone-based antenna fluorophores. Comparison with reference fluorophores (with a non-substituted quinolone at position 3 or a methyl-substituted quinolone at position 4) demonstrates that the structural modification affected the brightness of the lanthanide chelates in different ways. For cs124-CF_3-based antennae, a significant decrease in brightness was observed for Tb^{3+} chelates (ca. 20-fold) and for Dy^{3+} chelates (>30-fold), while the emission of Eu^{3+} and Sm^{3+} chelates was not significantly affected. A similar effect of substitution was previously observed for the analogous Tb-cs124 chelates (*13*). In the case of probe 2, the substitution of a cross-linking group for a methyl group in position 4 did not significantly alter the brightness of all lanthanide complexes. Moreover, a detectable increase in the brightness for Eu (1.5-fold), Dy (1.7-fold), and Sm (1.6-fold) complexes was observed. This is consistent with the results (*13*) previously obtained for the analogous Tb and Eu derivatives of cs124 containing a carboxymethyl group at position 4. Surprisingly, significant luminescence was detected for Tb^{3+}-DTPA-cs124-CF_3 chelates, which were previously reported to be nonluminescent. We do not know the reason for this discrepancy. As seen in Table 1, comparing the emission of probe 1 and probe 2, probe 1 gives brighter complexes with Eu and Sm, while probe 2 is optimal for Tb and Dy. Time-resolved measurements indicated that there is a single-exponential decay mode for the luminescent signal from probe 1 chelates and from probe 2 chelates (not shown), which is indicative of the homogeneity of the complexes.

Effect of Heavy Water on Lanthanide Chelate Emission. The quantum yield of the excited lanthanide ion (defined as the probability of the excited state emitting a photon) in the antenna−chelate complex depends strongly on the number of coordinated water molecules (*21*), due to nonradiative dissipation of the energy of the excited state through the vibration of O−H bonds. This process does not occur with heavy water due to the different frequency of O−D bond vibration. This effect accounts for the enhanced brightness of lanthanide luminescence in heavy water. Indeed, as seen from Table 1 for DTPA ligands in D_2O, the brightness of the Tb^{3+} chelates was 1.3- to 1.5-fold higher than in H_2O-based solutions. As expected, the effect was more pronounced for DTPA-Eu^{3+} chelates (~3- to 3.8-fold), as well as for Dy^{3+} and Sm^{3+} complexes (~ 4- to 6-fold). The number of coordinated water molecules in Tb^{3+} and Eu^{3+} complexes can be calculated from the luminescence lifetime in water and in deuterium oxide-based solutions (*22*). For our probes, the number of coordinated water molecules was close to unity (see Table 1), which is in agreement with the results reported for similar compounds. The same is expected for Dy^{3+} and Sm^{3+} chelates, since they have analogous coordination chemistry.

Effect of EDTA on the Rate of Lanthanide Chelate Decay. The ability to retain the chelated metal ion is an important characteristic of lanthanide probes. This property is especially crucial for intracellular applications, due to the abundance of metal scavengers in living cells (such as free amino acids, amino acid residues in proteins, nucleoside triphosphates, nucleic acids, etc.). To this end, we investigated the decay rates of the lanthanide chelates used in our probes and in those probes described previously (*15*). Reaction of cs124 with excess of DTPA dianhydride yields a primary adduct possessing a preserved acylation function. In previous studies, this function was used to attach the cross-linking group to the chelate construct by subsequent treatment with diamine, which yielded aminoalkylamide derivatives whose amino group was converted to amine reactive isothiocyanates. This modification of the chelating group is likely to weaken the retention of metal. To this end, as a model, we synthesized analogous, but nonreactive, compounds containing a butylamide group. In accordance with expectations, the lanthanide complexes were about 10 times less stable (comparing to those possessing nonmodified chelating groups) when challenged with EDTA (see Supporting Information Figure S3).

Table 1. Emission and Relative Brightness of Lanthanide Chelates under Various Conditions

[a] Determined in ref *13*. [b] Model compounds.

Chemical Reactivity of Synthesized Luminescent Probes. The chemical reactivity of the synthesized probes was evaluated first in reactions with aliphatic diamines and with cysteine, because the resulting reaction products (corresponding thioureas and thiocarbamates) can easily be identified by thin layer chromatography, due to the strong retardation effect. Under the incubation conditions that were used, a nearly quantitative conversion of the probes to the corresponding reaction products was observed, either immediately upon mixing (with 0.1 M cysteine) or after 2 to 3 h at 56 °C (with 10 mM diamine), suggesting that the isothiocyanate groups in the probes survived purification. At the same time, nonreactive control chelates (Ln^{3+}-DTPA-cs124 and Ln^{3+}-DTPA-cs124-CF_3) did not change their mobility after incubation under the same conditions (see Supporting Information).

Synthesis of Luminescent-Based Molecular Beacon Probes. With conventional strategies, the nucleic acids are first coupled with metal-free probe derivatives, followed by the addition of a lanthanide to the probe conjugated products, which is not convenient. To this end, we obtained metal-chelated, ready-to-use luminescent tags. This was especially important for probe 1, since a metal-free compound is not stable.

For the attachment of the luminescent tags to the oligonucleotides, we obtained aliphatic isothiocyanate-reactive probes, as opposed to their more reactive aromatic counterparts that are typically used for modification of biopolymers. Partially, this choice was due to a synthetic strategy that required survival of the reactive cross-linking group during acylation by DTPA dianhydride (see Scheme 1) and during subsequent purification. Also, a closely positioned aromatic moiety of isothiocyanate could affect the energy transferred to the lanthanide by the occurrence of stacking interactions with antenna fluorophores. Under optimized reaction conditions, we were able to achieve a 70% coupling efficiency with amine-containing oligonucleotide constructs. The resulting hybridization probes were purified by ethanol precipitation, followed by size-exclusion chromatography and HPLC. Comparison of the absorption spectra of 3′ BHQ-2 labeled oligonucleotides, with and without probe 2 attached to their 5′ terminal (Figure 4B), revealed additional absorption in the range 300−350 nm due to the presence of the luminescent label. The survival of the lanthanide chelates during all of these operations is indicative of the extraordinarily high chemical stability of these probes.

Steady-State Fluorescence Measurements of Molecular Beacon Probes. Molecular beacon probes are nucleic acid hybridization probes that fluoresce when they bind to a target DNA or RNA sequence (*19*). When they are free in solution and not hybridized to a target nucleic acid, they remain nonfluorescent. Figure 4A illustrates the principle of molecular beacon probes. The probes are single-stranded oligonucleotides that form a stem-and-loop structure. The loop portion of the oligonucleotide is a probe sequence that is complementary to a target sequence in a nucleic acid. The probe sequence is embedded between two "arm" sequences, which are complementary to each other. Under assay conditions, the arms bind to each other to form a double-helical stem hybrid that encloses the probe sequence, forming a hairpin structure. A reporter fluorophore is attached to one end of the oligonucleotide and a nonfluorescent quencher is attached to the other end of the oligonucleotide. The stem hybrid brings the fluorophore and quencher in close proximity, allowing energy from the fluorophore to be transferred directly to the quencher through contact quenching. At assay temperatures, when the probe encounters a target nucleic acid, it forms a relatively rigid probe−target hybrid that is longer and more stable than the stem hybrid. Consequently, the molecular beacon probe undergoes a conformational reorganization that forces the stem hybrid to dissociate, and results in the separation of the fluorophore and the quencher, restoring fluorescence.

Currently, most molecular beacon probes are labeled with organic fluorophore labels (*23*). To increase the sensitivity of detection, we explored the performance of lanthanide-based molecular beacons by using the novel luminescent probes described in this study, instead of probes possessing conventional fluorophores. An example is shown in Figure 4C. In this case, we used a europium complex of probe 1 as the luminophore for molecular beacon. As expected, the addition of a cDNA target resulted in the development of a signal that is distinguished by the narrow emission peaks that occur in lanthanide luminescence. Remarkably, the ratio of the intensity of the luminescence signal to the intensity of the background fluorescence of the molecular beacon (which is due to the fluorescence of the molecular beacon after subtraction of the background fluorescence of the medium) was >400, which is significantly higher than the signal-to-background ratio typically obtained for fluorophore-based hybridization probes, including molecular beacons (*23*). This higher signal-to-background ratio

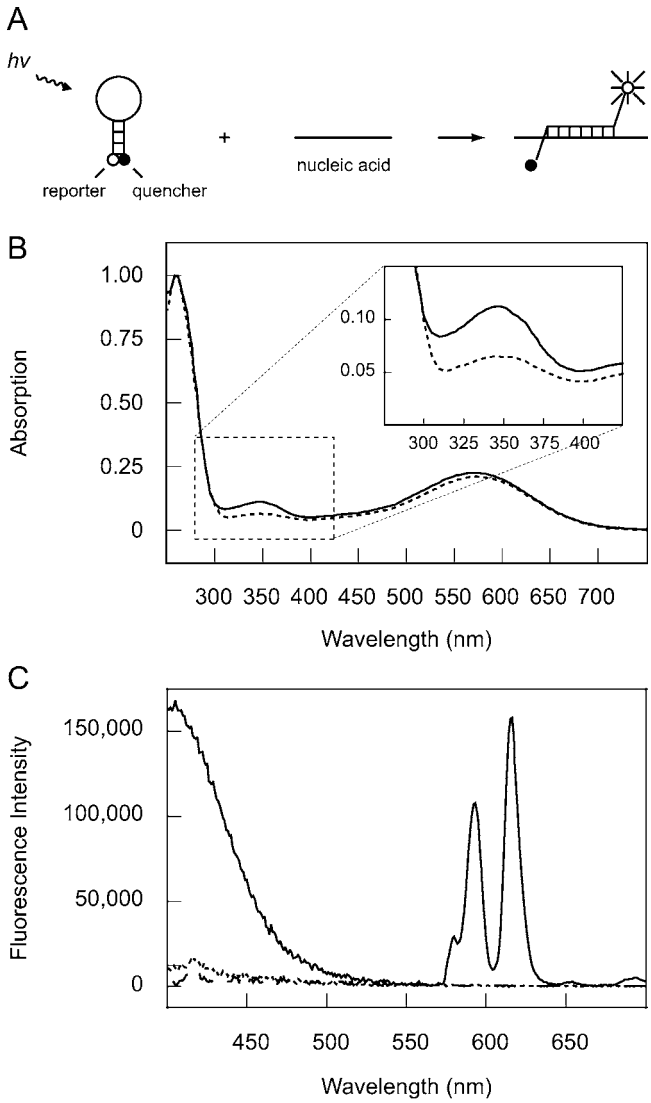

Figure 4. Detection of cDNA oligonucleotide targets using luminescence-based molecular beacons labeled by probe 1 Eu chelate in a steady-state mode. (A) Principle of detection. (B) Normalized absorption spectra of 3′ BHQ-2 labeled oligonucleotides, with (solid line) and without (dotted line) probe 2 conjugated to their 5′ terminal. (C) Luminescence emission spectra of the hybridization buffer (dashed line), the molecular beacon alone (dotted line), and the molecular beacon after hybridization to a complementary oligonucleotide (solid line).

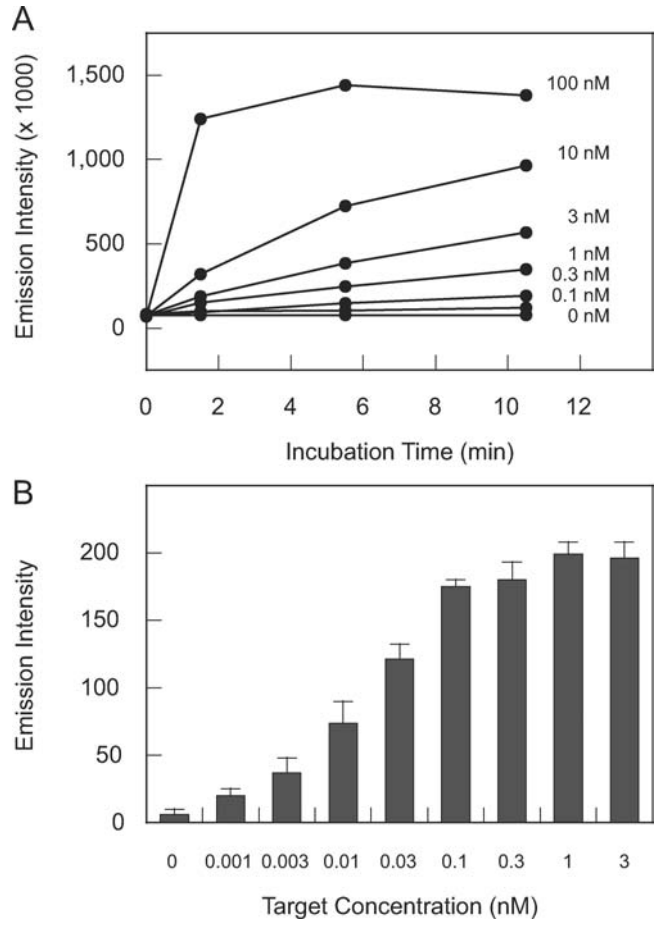

Figure 5. Time-resolved detection of a cDNA oligonucleotide target using a Eu-probe 1-based luminescent molecular beacon. (A) Emission intensity of a molecular beacon (1 nM) in the presence of different concentrations of target. (B) End-point emission detection of an oligonucleotide target at different concentrations in the presence of a 10 pM molecular beacon.

is due to both the suppression of the fluorescence of the antenna and the luminescence of the lanthanide in the "closed" form of the molecular beacon by the quencher. As expected, the signal that occurs upon hybridization of the probe to its target is significantly brighter in heavy water-based solutions.

Time-Resolved Luminescence Measurement of Molecular Beacons Probes. Figure 5A shows the time-course for the development of the luminescence signal that is detected in the time-resolved mode from hybridization mixtures that contain probe 1-based molecular beacons and various concentrations of complementary target DNA. The results demonstrate that, when 1 nM hybridization probe is present, subnanomolar concentrations of the target can be detected after only 10 min of incubation at ambient temperature. As seen from the time-course curves at low concentrations of the target, the hybridization rate decreases significantly, suggesting that the sensitivity of the detection can be improved by increasing the incubation time. Indeed, by lowering the concentration of the hybridization probe to 10 pM (to reduce background emission), and by prolonging the incubation time, we were able to achieve detection limits as low as 0.5−1 pM (Figure 5B), which is about 50- to 100-fold more sensitive than the results that are obtained in the same system using conventional fluorescein-based molecular beacons. Moreover, these detection limits are better than those reported previously for other lanthanide-based hybridization probes.

DISCUSSION

The unique photon emission properties of lanthanide-based probes render them suitable for a wide variety of applications that require ultrasensitive detection of biomolecules. Progress in this field depends on the availability of efficient probes. The mechanism of energy pathways in luminescent lanthanide chelates is not fully understood, leaving much room for improvements in their applications as labels for probes. Even though the first probes of this class were synthesized more than three decades ago and are not very efficient, many of them continue to be used for commercial applications. The development of more efficient probes is highly desirable, because new, more challenging applications have arisen (e.g., for the detection of rare pathogens in environmental samples, and for the detection of single molecules in cells).

In the present studies, we have taken advantage of new synthetic strategies that enable the preparation of highly luminescent probes with high yield. The resulting probes are ready-to-use, since they contain prebound lanthanides, unlike the lanthanide-labeled probes utilized in earlier applications, in

which the biomolecule of interest was first modified with metal-free chelates, followed by the addition of a lanthanide (*10*, *15*). The new compounds that we describe were tested in the form of molecular beacons, which are widely utilized nucleic acid hybridization probes. Our experiments revealed a higher sensitivity of detection than can be achieved with conventional fluorescence-based molecular beacons. Moreover, the detection sensitivity was 10 to 60 times better than previously reported for other lanthanide-based hybridization probes (*24*, *25*). Also, the brightness of the probes is significantly increased in heavy water, suggesting the use of this medium to increase the sensitivity of detection. Because of the superior properties, these new compounds could also be used as luminescent labels in other biopolymers, such as proteins and polysaccharides, as well as labels for small compounds, such as drugs and cellular metabolites.

ACKNOWLEDGMENT

Authors are grateful to Fred Russell Kramer and Sanjay Tyagi for helpful discussion and comments. This program was supported by NIH grant R01 GM-30717-21 for AM and by NIH grant RO1 MH-079197 for SM.

Supporting Information Available: Detailed protocols, including protocols for determining the luminescent and optical properties of the synthesized compounds, studies of their chemical reactivity and stability, as well as a description for purification of the molecular beacon hybridization probes.This material is available free of charge via the Internet at http://pubs.acs.org.

Platinum(II)−Dendrimer Conjugates: Synthesis and Investigations on Cytotoxicity, Cellular Distribution, Platinum Release, DNA, and Protein Binding

Timo Kapp, Anja Dullin, and Ronald Gust*

Institute of Pharmacy, Freie Universität Berlin, Königin Luise Strasse 2 + 4, 14195 Berlin, Germany. Received September 24, 2009; Revised Manuscript Received November 10, 2009

A set of polyamidoamine dendrimers were modified in such a way that they are able to act as carrier and drug delivery systems for cytostatics. The terminal binding of the non-proteinogenic D,L-2,3-diaminopropionic acid allowed the attachment of the cytotoxic PtX_2 moiety (X = Cl, I: **A(PtI$_2$)$_2$**, **A(PtCl$_2$)$_2$**, **B(PtI$_2$)$_2$**, **B(PtCl$_2$)$_2$**), while the 2-carboxypentanedioic acid acted as leaving group for [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]-platinum(II) (**(m-4F-Pt)$_3$C**, **(m-4F-Pt)$_3$D**). Poly(ethylene glycol) chains at **C(PtI$_2$)$_3$** and **C(PtCl$_2$)$_3$** as well as **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** mediated sufficient water solubility. Additional dansyl residues (**B(PtI$_2$)$_2$** and **(m-4F-Pt)$_3$D**) made a simultaneous determination of platinum (graphite furnace atomic absorption spectroscopy (GF-AAS)) and dendrimer (fluorimetry) possible. The ethylenediamine-terminated dendrimers were typically accumulated into MCF-7 cells in clathrin-dependent pathways and targeted the platinum moieties to the nuclear compartment. The highest intracellular platinum concentration and DNA binding caused the dendrimers **A(PtX$_2$)$_2$** and **B(PtX$_2$)$_2$**. A coordinative DNA binding, however, is very unlikely because of low cytotoxic effects. **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** are labile conjugates and liberated the **m-4F-Pt** moiety in biological systems. The effects of these dendrimers were similar to that of the reference compounds **m-4F-PtCl$_2$** and **m-4F-Pt(H$_2$O)$_2$**.

INTRODUCTION

Natural and synthetic macromolecules are attractive and promising drug delivery systems for cytostatics. The advantage of synthetic polymers is the possibility to design them in such a way that they combine drugs, fluorescence markers, and solubilizing groups at their surface (*1*). Furthermore, the renal excretion is reduced if the polymer exceeded a molecular mass of 40 kD and allows a preferred accumulation of the polymers in the tumor tissue by the EPR (enhanced permeability and retention) effect, the property by which macromolecules build up in the tumor due to the special properties of the tissue (for example, poor lymphatic drainage). This tumor selectivity reduced the side effects of the conventional used cytostatics in nontarget tissues (*2*−*5*).

Platinum complexes represent important drugs, which are used in the first-line therapy of several kinds of tumoral diseases (*6*). However, the therapy is not without obstacles. Intolerable side effects such as nephrotoxicity, neurotoxicity, and myelosuppression and development of resistance during the therapy limited the therapeutic use (*7*−*9*).

First attempts to optimize the pharmacological properties of platinum complexes due to the binding to macromolecular carriers started about 10 years ago (*10*−*15*). Despite the pharmacological benefits, there are still problems resulting from their architecture. Linear polymers adopt in solution a coiled structure, which partly buried the bound drugs in the core of the molecule. Further problems result from the heterogeneous and polydisperse structure of the molecules. It is difficult to maintain reproducible polymer properties, drug delivery ability, and therapeutic efficacy (*16*). Thus, dendrimers represent an ideal drug delivery system, because they are characterized by a low polydispersity and a globular structure with good accessible terminal groups as demonstrated by Duncan et al. (*17*).

In a previous study, we synthesized amino-functionalized dendrimers (*18*, *19*) and derived them with the non-proteinogenic D,L-2,3-diaminopropionic acid to yield ethylenediamine-terminated dendrimers of type **A** (see Scheme 1). These dendrimers coordinate the cytotoxic PtX_2 moiety in a very stable five-membered chelate ring (see **A(PtX$_2$)** in Scheme 1) (*11*).

The dendrimers of type **B** combine three fluorescent dansyl moieties with three terminal amide-bound 2,3-diaminopropionic acids and made pharmacological studies in MCF-7 cells possible using fluorescence spectroscopy and graphite furnace atomic absorption spectroscopy (GF-AAS) after coordination of PtX_2.

Poly(ethylene glycol) (PEG) chains of dendrimers **C** and **D** mediate water solubility, and the terminal amino groups were derived with either 2,3-diaminopropionic acid to coordinate PtX_2 (**C**) or with 2-carboxypentanedioic acid to bind [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]platinum(II) (**C** and **D**) (*20, 21*). The G2 generation dendrimer **D** additionally bears a dansyl marker.

Diiodoplatinum(II) complexes **A(PtI$_2$)$_2$**, **B(PtI$_2$)$_2$**, and **C-(PtI$_2$)$_2$** represent hydrolytically stable derivatives of related $PtCl_2$ compounds (**A(PtCl$_2$)$_2$**, **B(PtCl$_2$)$_2$**, **C(PtCl$_2$)$_2$**). In the case of **m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D**, the dendrimers act as leaving groups for the cytotoxic m-4F-Pt moiety. While the [2-carboxyethylenediamine]platinum(II) complexes are relatively stably bonded to the dendrimer via an amide bond, aquation and substitution reactions might cleave m-4F-Pt from the dendrimer.

In this study, we investigated the suitability of dendrimers **A**−**D** to carry cytotoxic moieties into the tumor cells and act as drug delivery systems. Platinum (GF-AAS) and dansyl moieties (fluorescence analysis) were used as analytic probe.

Aldrich. ^{1}H NMR: Advance DPX-400 spectrometer (Bruker, Karlsruhe/Germany) at 400 MHz (internal standard: TMS). Elemental analyses: Microlaboratory of the Freie Universität Berlin. Diaqua[*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]-platinum(II) sulfate (**m-4F-Pt(H$_2$O)$_2$**) and dendrimers **A** to **D** were prepared as already described (*18*−*20*).

General Procedure for Preparation of the Platinum−Dendrimer Complexes. The respective dendrimer (0.01 mmol) was dissolved in water and treated with K_2PtCl_2, K_2PtI_2, or **m-4F-Pt(H$_2$O)$_2$** (0.03 mmol, respectively). Precipitated conjugates were sucked off and dried over P_2O_5. Otherwise, the water-soluble conjugates were extracted at least three times with CH_2Cl_2. The solvent was evaporated and the product was obtained in suitable purity. The purity was determined using capillary electrophoresis. All electropherograms documented the presence of only one species (see Supporting Information).

Platinum Conjugates of Dendrimer Type A. A(PtI$_2$)$_2$. Yield: 9.33 mg (0.006 mmol); 66% brown powder. ^{1}H NMR ([D7]-DMF): δ = 1.88 (m, 6H, CH_2), 2.58 (t, 6H, CH_2Ar), 3.27 (m, 3H, CH_2N), 3.38 (m, 3H, $CHCH_2$), 3.45 (m, 3H, CH_2N), 3.47 (dd, 3H, $CHCH_2$), 4.19 (t, 3H, CH), 4.92 (br, 3H, NH), 5.43 (br, 6H, NH_2), 5.85 (br, 3H, NH), 6.90 (s, 3H, ArH), 8.42 (br, 3H, NH).

A(PtCl$_2$)$_2$. Yield: 8.65 mg (0.008 mmol); 83% yellow powder. ^{1}H NMR ([D7]-DMF): δ = 1.86 (m, 6H, CH_2), 2.55 (t, 6H, CH_2Ar), 3.30 (m, 3H, CH_2N), 3.38 (m, 3H, $CHCH_2$), 3.44 (m, 3H, CH_2N), 3.47 (dd, 3H, $CHCH_2$), 4.19 (t, 3H, CH), 4.92 (br,

3H, NH), 5.44 (br, 6H, NH_2), 5.87 (br, 3H, NH), 6.88 (s, 3H, ArH), 8.45 (br, 3H, NH).

Platinum Conjugates of Dendrimer Type B. $B(PtI_2)_2$. Yield: 14.72 mg (0.006 mmol); 53% brown powder. ^{1}H NMR ([D7]-DMF): δ = 1.28 (m, 6H, H−CH_2), 1.63−1.81 (m, 6H, CH_2), 1.85−1.95 (m, 6H, CH_2), 2.53 (t, 6H, CH_2), 2.66 (m, 12H, CH_2+CH_2), 2.84 (t, 6H, NH−CH_2), 2.96 (s, 18H, CH_3), 3.21 (m, 3H, NH−CH_2), 3.39 (m, 6H, NH−CH_2), 3.41 (m, 3H, NH−CH_2), 3.46 (dd, 3H, NH_2−CH_2), 3.53 (dd, 3H, NH_2−CH_2), 3.80 (t, 3H, CO−CH_2), 4.95 (br, 3H, NH), 5.47 (br, 6H, NH_2), 5.90 (br, 3H, NH), 6.96 (s, 3H, Ar−H), 7.07 (s, 3H, Ar−H), 7.28 (s, 3H, Ar−H), 7.40 (d, 3H, Ar−H), 7.58 (s, 3H, Ar−H), 7.53 (t, 3H, Ar−H), 7.68 (d, 3H, 2 × Ar−H), 8.19 (d, 3H, 2 × Ar−H), 8.21 (d, 3H, 2 × NH_2−CH_2), 8.43 (t, 3H, Ar−H).

$B(PtCl_2)_2$. Yield: 14.90 mg (0.005 mmol); 50% white powder. ^{1}H NMR ([D7]-DMF): δ = 1.28 (m, 6H, CH_2), 1.63−1.81 (m, 6H, CH_2), 1.85−1.95 (m, 6H, CH_2), 2.53 (t, 6H, CH_2), 2.66 (m, 12H, 2 × CH_2), 2.84 (t, 6H, NH−CH_2), 2.96 (s, 18H, CH_3), 3.21 (m, 3H, NH−CH_2), 3.39 (m, 6H, NH−CH_2), 3.41 (m, 3H, NH−CH_2), 3.46 (dd, 3H, NH_2−CH_2), 3.53 (dd, 3H, NH_2−CH_2), 3.80 (t, 3H, CO−CH_2), 4.95 (br, 3H, NH), 5.47 (br, 6H, NH_2), 5.90 (br, 3H, NH), 6.96 (s, 3H, Ar−H), 7.07 (s, 3H, Ar−H), 7.28 (s, 3H, Ar−H), 7.40 (d, 3H, Ar−H), 7.58 (s, 3H, Ar−H), 7.53 (t, 3H, Ar−H), 7.68 (d, 3H, 2 × Ar−H), 8.19 (d, 3H, 2 × Ar−H), 8.21 (d, 3H, 2 × NH_2−CH_2), 8.43 (t, 3H, Ar−H).

Platinum Conjugates of Dendrimer Type C. $C(PtI_2)_2$. Yield: 19.88 mg (0.0042 mmol); 42% colorless oil. ^{1}H NMR ([D7]-DMF): δ = 1.82 (m, 6H, CH_2), 1.84 (m, 6H, CH_2), 2.50 (t, 6H, Ar−CH_2), 3.18 (s, 36H, -OCH_3), 3.25 (t, 6H, NH−CH_2), 3.31−3.54 (2 m, 144H, -OCH_2CH_2O), 3.48 + 3.59 (2 m, 12H, O−CH_2+NH−CH_2), 3.63 (m, 24H, -$OCH(CH_2)_2$), 3.98 + 4.33 + 4.36 (3 m, 9H, −$CHNH_2$ + −CH_2NH_2), 4.58 (quint, 6H, -$OCH(CH_2)_2$), 5.40 (br, 8H, NH_2), 5.78 (br, 4H, NH_2), 6.82 (s, 3H, Ar−H:Core), 7.16 (s, 6H, Ar−H:Gallate).

$C(PtCl_2)_2$. Yield: 17.65 mg (0.004 mmol); 42% colorless oil. ^{1}H NMR ([D7]-DMF): δ = 1.82 (m, 6H, CH_2), 1.84 (m, 6H, CH_2), 2.50 (t, 6H, Ar−CH_2), 3.18 (s, 36H, -OCH_3), 3.25 (t, 6H, γ-CH_2), 3.31−3.54 (2 m, 144H, -OCH_2CH_2O), 3.48 + 3.59 (2 m, 12H, O−CH_2+NH−CH_2), 3.63 (m, 24H, -$OCH(CH_2)_2$), 3.98 + 4.33 + 4.36 (3 m, 9H, −$CHNH_2$ + −CH_2NH_2), 4.58 (quint, 6H, -$OCH(CH_2)_2$), 5.40 (br, 8H, NH_2), 5.78 (br, 4H, NH_2), 6.82 (s, 3H, Ar−H:Core), 7.16 (s, 6H, Ar−H:Gallate).

$(m\text{-}4F\text{-}Pt)_3C$. Yield: 16.52 mg (0.0037 mmol); 37% colorless powder. ^{1}H NMR ([D6]-DMSO): δ = 1.88 (m, 12H, CH_2), 2.10 (t, 6H, CH_2), 2.26 (t, 6H, CO−CH_2), 2.61 (t, 6H, Ar−CH_2), 3.28 (brs, 39H, -OCH_3+COOH−CH), 3.35 (t, 6H, NH−CH_2), 3.41 (t, 6H, NH−CH_2), 3.42−3.64 (2 m, 144H, -OCH_2CH_2O), 3.72 (m, 24H, -$OCH(CH_2)_2$), 4.05 (t, 6H, O−CH_2), 4.60 (quint, 6H, -$OCH(CH_2)_2$), 6.06 (br, 2H, NH), 6.25 (br, 4H, NH), 6.51 (br, 2H, NH), 6.69 (br, 4H, NH), 6.89 (s, 3H, Ar−H:Core), 7.02−7.15 (m, 24H, Ar−H), 7.16−7.28 (m, 12H, Ar−H), 7.23 (s, 6H, Ar−H:Gallate).

Platinum Conjugates of Dendrimer Type D. $(m\text{-}4F\text{-}Pt)_3D$. Yield: 21.22 mg (0.0023 mmol); 23% colorless powder. ^{1}H NMR ([D6]-DMSO): δ = 1.61 (m, 6H, CH_2), 1.74 (m, 24H, CH_2+CH_2), 1.96 (m, 6H, CH_2), 2.13 (m, 6H, CO−CH_2), 2.45 (t, 6H, Ar−CH_2), 2.52 (m, 12H, Ar−CH_2), 3.03 (t, 6H, NH−CH_2), 3.11 (s, 18H, -$N(CH_3)_2$), 3.12 (2s, 72H, -OCH_3), 3.21 (m, 21H, COOH−CH+NH−CH_2), 3.26 (m, 6H, NH−CH_2), 3.27−3.42 (2 m, 288H, -OCH_2CH_2O), 3.45 + 3.56 (2 m, 48H, -$OCH(CH_2)_2$), 3.80 (t, 6H, O−CH_2), 3.92 (t, 6H, O−CH_2), 4.37 (q, 6H, -$OCH(CH_2)_2$), 4.45 (q, 6H, -$OCH(CH_2)_2$), 6.62 (br, 4H, NH), 6.74 (s, 3H, Ar−H:Core), 6.93 (br, 8H, NH), 7.05 (s, 6H, Ar−H:Gallate), 7.09 (s, 3H, Ar−H:Dendron), 7.11 (s, 6H, Ar−H:Gallate), 7.18−7.24 (m, 18H, Ar−H), 7.26−7.32 (m, 18H, Ar−H), 7.33 (m, 6H, Ar−H:Dendron), 7.55 (m, 3H, Ar−H:Dansyl), 7.63 (m, 6H, Ar−H:Dansyl), 8.18 (d, 3H, Ar−H:Dansyl), 8.32 (d, 6H, Ar−H:Dansyl), 8.87 (d, 6H, Ar−H:Dansyl).

Characterization of Fluorophoric Characteristics. Compounds were dissolved in ethanol as stock solutions. If characterization in other solutions was required, the stock solution was diluted with those solutions in such a way that the concentration of ethanol never exceeded 1%. Measurements were done at room temperature with a spectrofluorimeter (F-4500, Hitachi) equipped with a 450 W xenon arc lamp. Because in earlier experiments the excitation wavelength did not alter under the chosen conditions, this was set to 340 nm (bandwidth 5 nm).

BIOLOGICAL METHODS

General. Chemicals were purchased from Sigma and Fluka. Drugs were freshly prepared as stock solutions in dimethylformamide (DMF) or H_2O and diluted with cell culture media or buffer when used for the biochemical experiments (final DMF concentration: 0.1% (v/v)). Platinum amounts were determined by graphite furnace atomic absorption spectroscopy (GF-AAS) with deuterium background correction (AAS vario 6; AnalytikJena AG) using a detection wavelength of 265.9 nm. The program consisted of drying at 105 °C for 30 s (ramp rate = 10 °C/s) and at 120 °C for 20 s (ramp rate = 15 °C/s), ashing at 50 °C for 30 s (ramp rate = 45 °C/s), at 1000 °C for 10 s (ramp rate = 100 °C/s) and at 1700 °C for 10 s (ramp rate = 300 °C/s) as well as atomizing at 2400 °C for 4 s (ramp rate = 1500 °C/s). Purge gas flow rate was 2 L argon/min except at the atomization where it was stopped. Limit of detection was approximately 0.005 mg/L (injection volume: 20 μL).

Binding Behavior to Human Serum Albumine (HSA). Three micromolar quantities of each compound were incubated with HSA (40 mg/mL) in Delbecco's buffer (137.0 mM NaCl, 2.7 mM KCl, 0.9 mM $CaCl_2$, 0.5 mM $MgCl_2$, 1.5 mM KH_2PO_4, 8.0 mM Na_2HPO_4, pH 7.4). Aliquots were taken after appropriate incubation periods and were 2-fold diluted with ice-cold ethanol. The probe was stored after vigorous stirring at −18 °C for at least 4 h. Then, the protein solution was centrifuged (4000 *g*, 4 °C, 10 min), and 300 μL of the supernatant was diluted with 100 μL twice-distilled water and stabilized for GF-AAS determination by addition of 100 μL hydrochloric acid (18% w/v). The recovery rate was calculated from three independent experiments as the ratio of platinum found in the supernatant and the total amount of platinum. Pseudo-first-order kinetic fitting was done using *Origin 7.0* after calculating the platinum found as the percentage of the amount recovered at the beginning of the experiment (n = 2).

Aliquots of 200 μL were transferred immediately after addition of the compounds into centrifugal filter devices (Microcon YM-30 Millipore) to determine the recovery by ultrafiltration. After centrifugation (6000 *g*, 4 °C, 10 min), 50 μL of the ultrafiltrate was stabilized by addition of 350 μL Triton X-100 (1% (w/w)) and 100 μL hydrochloric acid (18% w/v) for GF-AAS determination. The experiments were performed in triplicate. Calculations were done analogously to the ethanol precipitation experiments.

Cell Culture. The human MCF-7 breast cancer cell line was obtained from the American Culture Collection (ATCC, Rockville, Md.). The cells were maintained in Eagle's minimal essential medium (EMEM) containing L-glutamine, supplemented with $NaHCO_3$ (2.2 g/L), sodium pyrovate (110 mg/L), gentamycin (50 mg/L), and 10% fetal calf serum (FCS; Gibco Eggenheim, Germany) using 75 cm^2 culture flasks (Nunc) in a water-saturated atmosphere (5% CO_2) at 37 °C. The cells were serially passaged weekly following trypsinization using 0.05% trypsin/0.02% ethylenediaminetetraacetic acid (EDTA). Myco-

plasma contamination was routinely monitored, and only mycoplasma-free cultures were used.

In Vitro Chemosensitivity Assay. The in vitro testing of the compounds for cytotoxic activity was carried out on exponentially dividing cancer cells according to a previously published microtiter assay (*22*). Briefly, in 96-well microtiter assay plates (Nunc), 100 μL of a cell suspension at 7000 cells/mL culture medium was plated into each well and incubated at 37 °C for 3 days in a water-saturated atmosphere (5% CO_2). By addition of an adequate volume of a stock solution of the respective compound to the medium, the desired test concentration was obtained. For each test concentration and for the control, which contained the corresponding amount of DMF or H_2O (0.1% v/v), respectively, 16 wells were used. The medium was removed after appropriate incubation periods, and the cells were fixed with a glutaraldehyde solution and stored at 4 °C. Cell biomass was determined by a crystal violet staining technique. The influence of the complexes on cell growth is expressed as corrected *T*/*C* value according to the following equations:

$$\text{cytostatic effect:} \quad T/C_{\text{corr}}[\%] = [(T - C_0)/(C - C_0)] \times 100$$

where *T* (test) and *C* (control) are the optical densities at 590 nm of the crystal violet extract of the cell lawn in the wells (i.e., the chromatin-bound crystal violet extracted with ethanol 70%), C_0 is the density of the cell extract immediately before treatment, and

$$\text{cytocidal effect:} \quad \tau[\%] = [(T - C_0)/C_0] \times 100$$

For automatic determination of the optical density of the crystal violet extract in the wells, a microplatereader (Flashscan S19 AnalytikJena AG) was used.

Cellular Uptake Studies. MCF-7 cells were seeded in 6-well plates (Nunc). When the cells had reached 50−60% confluence (approximately after 5 days of incubation) the medium was exchanged by serum-free EMEM containing the drugs. The medium was removed after appropriate incubation periods, and the cells were washed with ice-cold PBS. After trypsination, the cells were harvested, washed two times with ice-cold PBS and centrifuged (2000 *g*, 4 °C, 5 min) for storage at −18 °C until analysis.

For determination of platinum content, the cell pellet was homogenized by sonification in a Triton X-100 solution (1% (w/w)) and was adequately diluted for protein determination (*23*) and for the platinum analysis (GF-AAS). Calibrations were done under identical conditions with K_2PtCl_4 standard solutions. The results were calculated as the average of three experiments. The cellular concentration of the compounds in the MCF-7 cells was determined as previously published (*24*). The accumulation grade was the ratio of cell-associated platinum and compound concentration in the medium.

For the endocytosis inhibitor studies, the medium was exchanged with serum-free EMEM containing the inhibitors (chlorpromazine 10 μg/mL, amiloride 1 mM, nystatin 25 μg/L, genistein 0.4 mM) and preincubated for 15 min. Then, the medium was removed and medium containing platinum compound and inhibitor was added. The control groups were not preincubated, and only platinum compound was added to them. The medium was removed after 2 h, and the cells were washed with ice-cold PBS.

For determination of the content of dansyl fluorophor, the cells were homogenized in TET buffer (0.5% w/v Triton X-100, 0.5% w/v EDTA, 10 mM Tris−Buffer adjusted to pH 8). The protein content was determined as described above. For fluorescence measurement, the samples were diluted with 0.5 aliquot ethanol and 0.5 aliquot TET buffer. Calibrations were done with the respective compound dissolved in ethanol added to blank pellets worked up by the described procedure. Fluorescence was measured using a microtiterplate reader (Victor^2 1420 multilabel counter Perkin-Elmer; filters: Exc. 360 nm; Em. 500 nm).

Platinum Content in the Nuclei. MCF-7 cells were seeded in 175 cm^2 flasks and incubated until 60−70% confluency was reached. Then, the cells were incubated for 24 h with serum-free medium containing the respective drug. The cells were harvested by trypsination, washed with ice-cold PBS, resuspended in ice-cold RSB buffer (0.01 M Tris−HCl, 0.01 M NaCl, 1.5 mM $MgCl_2$, pH 7.4) and incubated on ice for 5 min. Nonidet-P40 was added to the swollen cells to a concentration of 0.25%, and the cells were lysed by vigorous stirring. After 5 min incubation on ice, the raw nuclei were stirred once more and sedimented by centrifugation (1000 *g*) at 4 °C for 5 min. The nuclei pellet was resuspended in 0.25 M sucrose containing 3 mM $CaCl_2$ and layered on a 0.88 M sucrose solution. Nuclei were purified by centrifugation for 10 min at 2500 *g*. The supernatant was removed, and the nuclei were stored at −18 °C until analysis.

For analysis, the nuclei were homogenized in 300 μL Triton X-100 solution (1% (w/w)) by ultrasonification. The homogenate was adequately diluted for protein assay by the method of Bradford (*23*) and for platinum determination by means of GF-AAS. The results were expressed as means of three independent experiments as nanograms of platinum per milligram of nuclear protein.

Platinum Content of Nuclear DNA. MCF-7 cells were treated as described above to yield a raw nuclei pellet, which was incubated with proteinase K and RNase A in a 0.5% (w/v) sodium dodecylsulfonate containing TE-buffer (10 mmol Tris, 1 mmol EDTA, pH 7.8) for 4 h at 55 °C. Purification was performed by using the chloroform phenol extraction method. DNA pellets were obtained by adding 0.1 aliquots of 3 M sodium acetate solution and two aliquots of ice-cold ethanol. For GF-AAS analysis, this pellet was dissolved in 100 μL of water and 50 μL of DNA solution was diluted with 50 μL of 0.01 N HCl containing 0.05% (w/w) Triton X-100. For calibration, equal amounts of salmon sperm DNA were added to the K_2PtCl_4 standards.

DNA content was measured according to Vytasek in a miniaturized assay (*25*). Briefly, the DNA was hydrolyzed by 1 M $HClO_4$. The liberated ribose reacted with 3,5-diaminobenzoic acid under alkaline conditions to a fluorescent chinoline derivative. Reaction was stopped by addition of ice-cold hydrochloric acid. Fluorescence was measured using a microtiterplate reader (Victor^2 1420 multilabel counter Perkin-Elmer; filters: Exc. 405 nm; Em. 500 nm). Calibration was done in the range 0−2.5 μg using salmon sperm DNA.

The purity of the DNA was determined by UV spectroscopy. Each workup showed the ratio E_{260}/E_{280} higher than 1.8 and the ratio E_{260}/E_{230} higher than 2.2. The absorption minimum was always lower than 232 nm (*26*). Results are expressed as means of three independent experiments as picograms of platinum per microgram of nuclear DNA.

RESULTS AND DISCUSSION

Synthesis and Spectroscopic Characterization. The diaminopropionic derived dendrimers of types **A** and **B** should retain at least one free ethylenediamine group to guarantee solubility under physiological conditions. Therefore, K_2PtCl_4 or K_2PtI_4 was reacted with the respective dendrimer (Scheme 1) in a small amount of water (up to 5 mL). Coordination of PtX_2 moieties at two of the three ethylenediamine binding sites reduced the

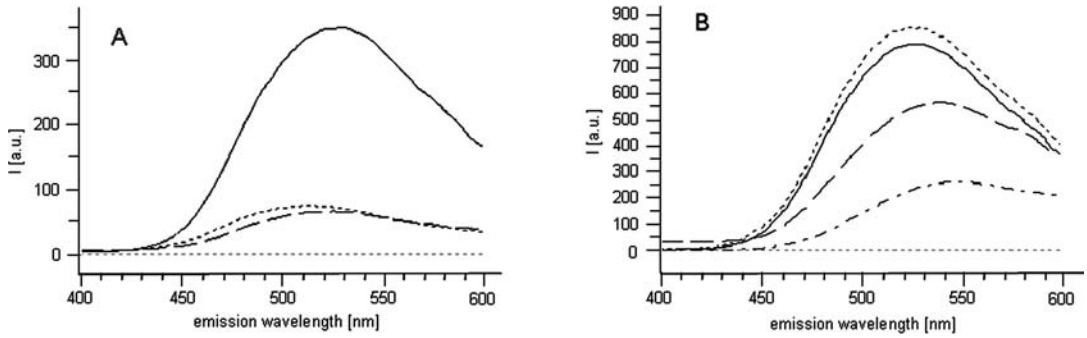

Figure 1. (A) Fluorescence of dendrimer **B** — (0.5 μM), **B(PtI$_2$)$_2$** – – – (2 μM), and **B(PtCl$_2$)$_2$** ------ (2 μM) in ethanol. (B) Fluorescence of dendrimer **D** ------ and compound **(m-4F-Pt)$_3$D** in ethanol —, in TET buffer – – –, and in water – •– (all 0.5 μM).

water solubility of the dendrimers and the conjugates **A(PtI$_2$)$_2$**, **A(PtCl$_2$)$_2$**, **B(PtI$_2$)$_2$**, and **B(PtCl$_2$)$_2$** precipitated, respectively.

The PEG chains of the ethylenediamine-terminated dendrimer **C** mediated a sufficient water solubility so that the molecule can be completely platinated with K_2PtCl_4 or K_2PtI_4 (three [ethylenediamine]platinum moieties per molecules: **C(PtCl$_2$)$_3$** and **C(PtI$_2$)$_3$**.). Repeated extraction with CH_2Cl_2 yielded the analytically pure conjugates.

The carboxyl-terminated polymers were treated with the diaqua[*meso*-1,2-bis(4-fluorophenyl)ethylenediamine-]platinum(II) sulfate (**m-4F-Pt(H$_2$O)$_2$**). The resulting conjugates **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** were soluble in water and were isolated by extraction with CH_2Cl_2.

All dendrimers were characterized by their fully assigned ^{1}H NMR spectra. The diastereomeric splitting of the NH_2 protons resulting in characteristic signals in the region of $\delta = 4.9$ to 5.9 (see Experimental Procedures section) comparable to that of the free [2-carboxyethylenediamine]platinum(II) complexes confirmed the coordination of platinum to the ethylenediamine.

The purity of the dendrimers was verified by capillary electrophoresis (see Supporting Information). Free platinum derivatives were not found. The amount of platinum per molecule was determined by GF-AAS using K_2PtCl_4 as the standard and corresponds to the proposed occupation of the dendrimers (Scheme 1 and Supporting Information).

The dansyl labeled dendrimers B and D showed in their fluorescence spectra emission maxima at 530 nm (Figure 1). Coordination of PtX_2 to the terminal ethylenediamine at dendrimer **B** drastically reduced the fluorescent properties (*19, 27*) as is well-known for other metal ions bound to dansyl-labeled macromolecules (*27, 28*). The fluorescence intensity of the conjugates **B(PtI$_2$)$_2$** and **B(PtCl$_2$)$_2$** is reduced independent of the leaving group to about 5% of **B** accompanied by a hypsochromic shift of the emission maximum from 530 to 514 nm (solvent: ethanol).

The PEG-bearing dendrimer **D** showed in ethanol a higher fluorescence than **B**, which is maintained upon binding of three molecules m-4F-Pt (**(m-4F-Pt)$_3$D**). The use of water, however, reduced the intensity by 70%, and the emission maximum is bathochromically shifted from 530 to 550 nm. This quenching effect is not as pronounced by the addition of TET buffer (*27*) designed for uptake studies. Nevertheless, these compounds confirmed the limitation for the fluorescence microscopic detection in intact cells as already reported for dendrimers **B** and **D** before (*27*).

Biological Properties. The biological properties, e.g., the accumulation in cells and nuclei, the binding to DNA, and the cytotoxicity, were evaluated at the MCF-7 cell line. Furthermore, possible inactivation reactions with human serum albumin (HSA) were of interest.

Cisplatin was used as reference for PtX_2 conjugates, diaqua-[*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]platinum(II) sulfate (**m-4F-Pt(H$_2$O)$_2$**) or [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]dichloroplatinum(II) (**m-4F-PtCl$_2$**) for the dendrimers **(m-4F-Pt)$_3$D** and **(m-4F-Pt)$_3$D**.

Cellular Uptake Studies. MCF-7 cells were incubated for 24 h with the respective derivative. The intracellular platinum content was quantified using GF-AAS and correlated with the extracellular platinum concentration (5 μM) giving the accumulation grade (Figure 2).

The accumulation grade of cisplatin amounted to 3.7-fold compared to extracellular medium at the end of the experiment (24 h; see Figure 2A) and correlated very well with the results of earlier studies (*21, 32*).

The 2,3-diamino-*N*-(3-{3,5-bis[3-(2,3-diaminopropionylamino)-propyl]phenyl}propyl)propionamide represents an excellent carrier for PtX_2 moieties. In contrast to cisplatin, which showed a nearly linear graph, **A(PtI$_2$)$_2$** and **A(PtCl$_2$)$_2$** accumulated very fast and reached their maximum after 8 h (891- and 213-fold, respectively, in relation to the extracellular platinum as well as 445- and 106-fold in relation to the dendrimer-bound Pt atoms; see Figure 2A).

3,5-Bis(3-aminopropyl)-*N*-(3-{3,5-bis[3-{3,5-bis(3-aminopropyl)-benzoylamino}propyl]phenyl}propyl)benzamide bearing three dansyl and two PtX_2 moieties showed a reduced accumulation grade (**B(PtI$_2$)$_2$**, 14.8-fold after 24 h; **B(PtCl$_2$)$_2$**, 18.0-fold after 24 h) and an accumulation kinetic without saturation after 24 h (Figure 2A).

The reduced uptake into the tumor cells might be the consequence of the higher dendrimer generation or the lower numbers of amino groups in relation to the molecular mass. Protonable NH_2 groups might be necessary to attach the dendrimer at the cell surface, the first step of endocytotic transport through the membrane.

The water-soluble **C(PtCl$_2$)$_3$** bearing PEG chains at the 3,5-positions of the terminal aromatic rings showed an accumulation comparable to **B(PtX$_2$)**, while the intracellular platinum concentration obtained with **C(PtI$_2$)$_3$** was as low as determined for cisplatin, however, with a clear indication of saturation after 8 h (Figure 2A).

The carboxyl-terminated dendrimers **C** and **D** bound three [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]platinum(II) moieties (**(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D)**), respectively. The platinum content in cells treated with **(m-4F-Pt)$_3$D** increased with a slightly faster linear kinetic compared to **(m-4F-Pt)$_3$C**. Both did not reach an intracellular saturation after 20−24 h. The accumulation against the media was nearly half of that obtained with the reference compound **m-4F-Pt(H$_2$O)$_2$**. The reason seems to be the long PEG chains, which hinder the transport through the cell membrane.

Therefore, uptake of the dendrimers was quantified in a second experiment by fluorescence measurement. The dansyl label is inert against hydrolytic cleavage as determined by

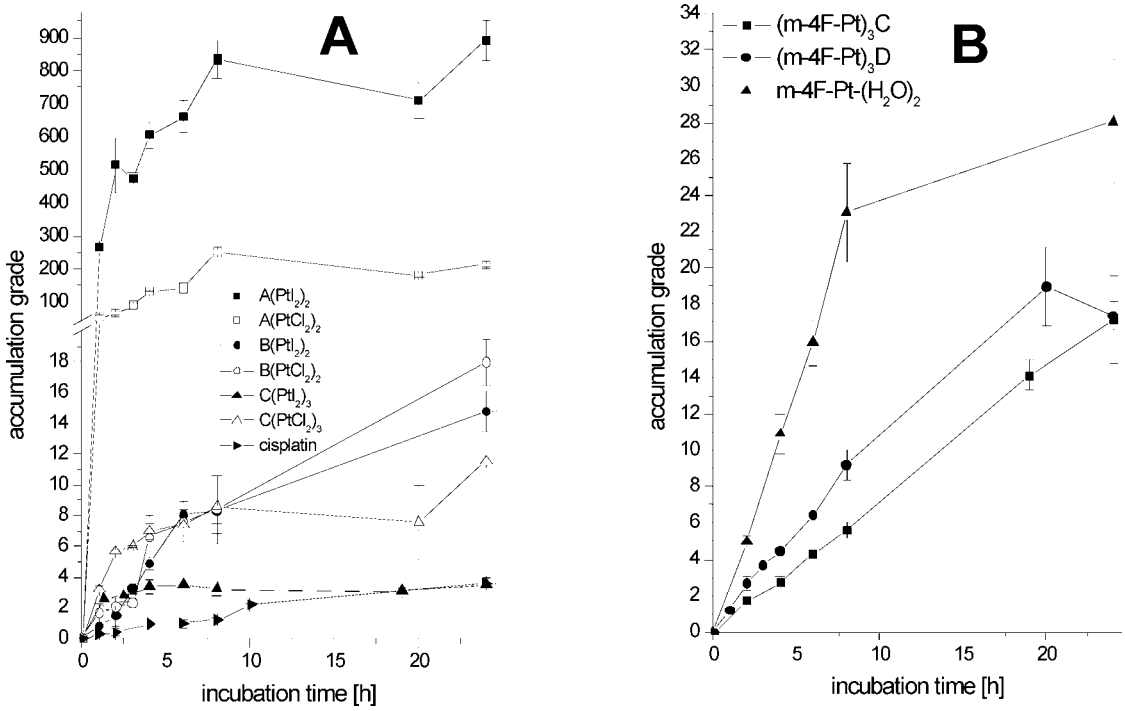

Figure 2. Accumulation of PtX_2−dendrimer conjugates (X = Cl, I) (A) and dendrimer-bound [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]-platinum(II) (B) in MCF-7 cells ($n = 3$).

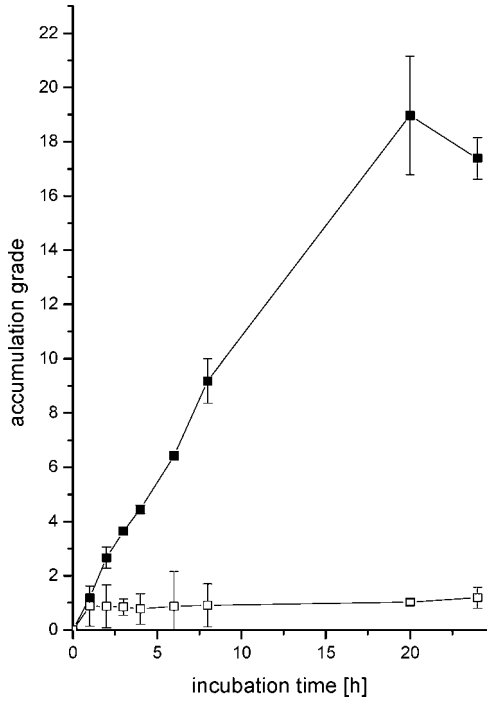

Figure 3. Cellular uptake of **(m-4F-Pt)D** by MCF-7 cells determined by GF-AAS (■) and fluorimetry (□) ($n = 3$).

capillary electrophoretic assays (*29*) so that the cellular content of fluorophor correlates with the cellular content of the dendrimer.

The fluorimetric measurement indicated an accumulation grade of 1 for the platinum-free dendrimer **D** (*27*) and **(m-4F-Pt)$_3$D** (Figure 3). Therefore, the increased platinum content in the tumor cells as depicted in Figures 2 and 3 determined by GF-AAS resulted from a platinum release in cell medium and a transfer into the cells independent of the dendrimer. The graphs of **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** depicted in Figure 2B indicate a slow release (not a burst) of the platinum complexes.

As the **m-4F-Pt** molecules are bound by carboxylic groups to the dendrimer, it is possible to release **m-4F-Pt(H$_2$O)$_2$** complexes in hydrolytic processes or substitution reactions. From studies with carboplatin and related m-4F-Pt derivatives (*30*−*32*), it is well-known that hydrolysis is very slow, but nucleophiles, e.g., chlorine, liberate platinum complexes in a faster kinetic. Therefore, it is very likely that the platinum(II) complexes were taken up as neutral dichloro rather than cationic aqua or diaqua species (*33*). This assumption was confirmed by the results of the same experiment done with the very stable **B(PtI$_2$)$_2$**. The intracellular platinum concentration correlated with the fluorophor content (data not shown) and demonstrated an incorporation of the platinum bound dendrimer into the cells without degradation.

Studies on the Uptake Mechanism. The uptake of polymeric compounds in tumor cells can be achieved in various pathways (*39*). In order to get information about possible pathways for cellular uptake, we selectively block those using specific inhibitors.

In an initial study, the cells were treated with the compounds at 4 and 37 °C. The reduced uptake at 4 °C determined for **A(PtI$_2$)$_2$**, **A(PtCl$_2$)$_2$**, and **C(PtI$_2$)$_3$** (40−50%) and for **(m-4F-Pt)$_3$D** and **m-4F-Pt(H$_2$O)$_2$** (more than 90%) indicated energy-depending pathways including the endosomal routes (e.g., macropinocytosis) and caveolin/clathrin-dependent uptake.

In the next step, the cells were coincubated with inhibitors of endocytosis (Figure 4). Chlorpromazine suppressed the accumulation of **A(PtI$_2$)$_2$**, **A(PtCl$_2$)$_2$**, and **C(PtI$_2$)$_3$** comparable to the temperature lowering experiment (about 40−50%), while other inhibitors such as amiloride and nystatin caused no effect. Therefore, we concluded that these conjugates cross the membrane by clathrin-dependent endocytosis after adsorption to the cell surface.

No inhibitor coincubated with **(m-4F-Pt)$_3$D** or **m-4F-Pt(H$_2$O)$_2$** showed effects as strong as the reduction of the temperature to 4 °C. Chlorpromazine (about 20% for **(m-4F-Pt)$_3$D** and **m-4F-Pt(H$_2$O)$_2$**) and genistein (about 20% for **(m-4F-Pt)$_3$D** and 40% for **m-4F-Pt(H$_2$O)$_2$**) reduced the cellular uptake. Nystatin and amiloride only inhibited the uptake of

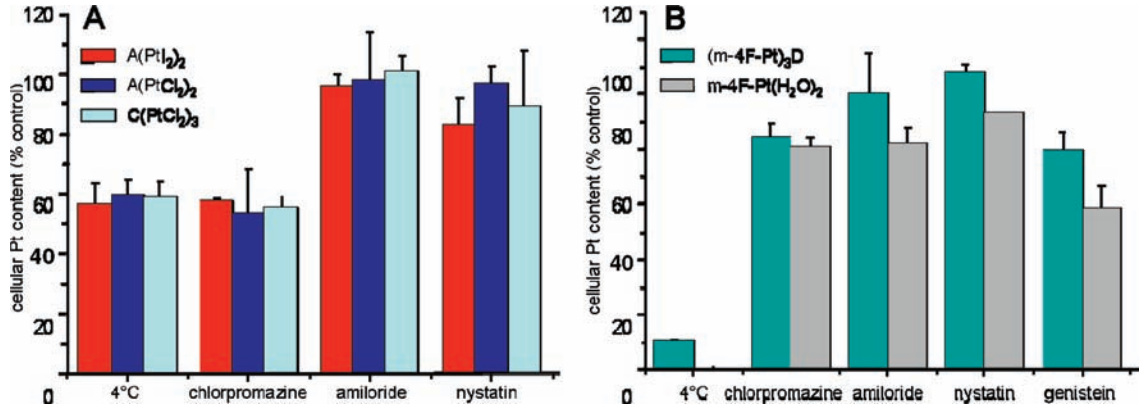

Figure 4. Effect of different endocytosis inhibitors on the cellular uptake of **A(PtI$_2$)$_2$**, **A(PtCl$_2$)$_2$**, and **C(PtCl$_2$)$_3$** (A) and **(m-4F-Pt)$_3$D** and **m-4F-Pt(H$_2$O)$_2$** (B).

Table 1. Quantification of Platinum in the Nuclei and DNA of MCF-7 Cells ($n = 3$)

compound	total amount of platinum in the nuclei [ng Pt/mg protein]	DNA-bound fraction [pg Pt/μg DNA]
cisplatin	10.00 ± 1.12	17.6 ± 1.0
A(PtCl$_2$)$_2$	2107 ± 267	325 ± 34
A(PtI$_2$)$_2$	10594 ± 346	1081 ± 258
B(PtCl$_2$)$_2$	1866 ± 298	122 ± 25
B(PtI$_2$)$_2$	7647 ± 676	44 ± 6
C(PtCl$_2$)$_3$	157 ± 5	19 ± 3
C(PtI$_2$)$_3$	216 ± 25	12.5 ± 2.2
m-4F-PtCl$_2$	165 ± 8	35.0 ± 7.2
(m-4F-Pt)$_3$C	147 ± 7	49 ± 2
(m-4F-Pt)$_3$D	43.7 ± 0.7	14.5 ± 0.4

Table 2. Protein Binding Characteristics with Human Serum Albumin (HSA) ($n = 3$ for the recovery experiments)

compound	free amount of Pt after ultrafiltration [%]	free amount of Pt after ethanol precipitation [%]	reaction rate for the irreversible binding to HAS $k \times 10^3$[min^{-1}]
cisplatin	76 ± 4	100 ± 6	5.35
m-4F-PtCl$_2$	51 ± 6	92 ± 5	6.81
m-4F-Pt(H$_2$O)$_2$	19 ± 1	37 ± 1	6.40

(m-4F-Pt)$_3$D	20 ± 2	47 ± 2	1.88

n.d.: not determinable.

m-4F-Pt(H$_2$O)$_2$ by about 10% and 20%, respectively. Due to the low effects, a clear statement about the accumulation pathway of these compounds is impossible.

Platinum Content in Nuclei and Binding to DNA. After transfer through the membrane, the conjugates can reach various cell compartments. As the DNA represents the main target of platinum complexes in tumor cells, it is of interest to know the platinum content in the nuclei. For this purpose, MCF-7 cells were incubated for 24 h with the respective platinum−dendrimer conjugate (concentration: 5 μM). The nuclei and DNA were isolated, and the platinum content was measured by GF-AAS (Table 1).

The reference cisplatin caused a nuclear platinum content of 10.0 ng Pt/mg protein, efficiently bound to DNA. The recovered platinum amounted to 17.6 pg Pt/μg DNA and correlated with data from the literature (*34*).

The platinum contents in the nuclei of cells treated with **A(PtCl$_2$)$_2$** and **A(PtI$_2$)$_2$** were 210-fold (2107.0 ng Pt/mg protein) and 1060-fold (10 594.0 ng Pt/mg protein), respectively, higher compared to cisplatin, while at the DNA, only 18.5- and 61.5-fold higher platinum contents were determined.

Higher dendrimer generation and dansyl residues did not substantially change the platinum amount in the nuclei (**B(PtCl$_2$)$_2$**, 1866.0 ng Pt/mg protein; **B(PtI$_2$)$_2$**, 7647.0 ng Pt/mg protein) but reduced the DNA-bound fraction to 122.0 pg Pt/μg DNA (**B(PtCl$_2$)$_2$**, 6.9-fold compared to cisplatin) and 44.0 pg Pt/μg DNA (**B(PtI$_2$)$_2$**, 2.5-fold compared to cisplatin). An explanation of these findings might be the precipitation of the dendrimers at the surface of the nuclei as microscopically demonstrated for these dendrimers carrying 6 dansyl labels (*18*). They also showed a nearly linear accumulation kinetic without saturation comparable to **B(PtI$_2$)$_2$** and **B(PtCl$_2$)$_2$** (*27*).

This assumption was supported by the results of the water-soluble derivatives **C(PtI$_2$)$_2$** and **C(PtCl$_2$)$_2$**, which showed lowered nuclear platinum contents (**C(PtI$_2$)$_2$**, 216.0 ng Pt/mg protein; **C(PtCl$_2$)$_2$**, 157.0 ng Pt/mg protein) and DNA binding (**C(PtCl$_2$)$_2$**, 19.0 pg Pt/μg DNA: **C(PtI$_2$)$_2$**, 12.5 pg Pt/μg DNA). An effect of the PEG chain cannot be excluded because **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** showed results in the same range.

The results of **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D**, however, have to be interpreted with caution because of their instability and release of **m-4F-Pt** moieties. Therefore, **m-4F-PtCl$_2$** was used as a reference. This selection is suitable since **m-4F-Pt(H$_2$O)$_2$** if released is quickly converted (less than 1 h) in the presence of chlorine into **m-4F-PtCl$_2$** (*20*).

The nuclei of cells treated with **m-4F-PtCl$_2$** showed a 16.5-fold higher platinum content (165.0 ng Pt/mg protein) than cisplatin, very similar to that obtained with **(m-4F-Pt)$_3$C** (147.0 ng Pt/mg protein). Interestingly, **(m-4F-Pt)$_3$D** (43.7 ng Pt/mg protein) caused only a third of the nuclear platinum content of **m-4F-PtCl$_2$** and **(m-4F-Pt)$_3$C**.

Cells treated with **m-4F-PtCl$_2$** showed a two times higher DNA platination (35.0 pg Pt/μg DNA) than cisplatin despite a 16.5-fold higher nuclear content. For the PEG-bearing conjugates, a clear trend could not be derived. **(m-4F-Pt)$_3$C** caused higher (49.0 pg Pt/μg DNA) and **(m-4F-Pt)$_3$D** lower (14.5 pg Pt/μg DNA) platinum content at the DNA than **m-4F-PtCl$_2$**.

In conclusion, the DNA platination achieved with the conjugates was higher than that obtained with cisplatin. An exception represented **(m-4F-Pt)$_3$D** with a DNA-Pt adduct content comparable to cisplatin.

Binding to Human Serum Albumin. Finally, it is necessary to estimate the binding to human serum albumin (HSA), because it is well-known that the binding to HSA alters the biological activity of platinum complexes. The reactivity of bound complexes is lowered, and they only marginally contribute to the antitumor activity as already reported for a set of polynuclear

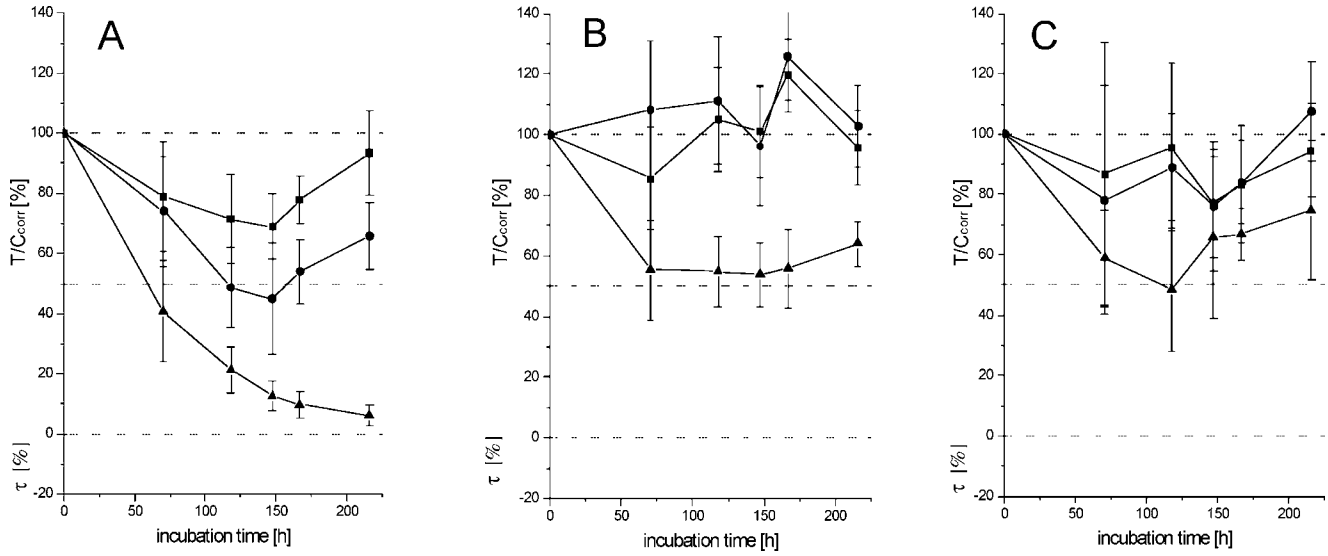

Figure 5. Cytotoxicity of cisplatin (A), **A(PtCl$_2$)$_2$** (B), and **C(PtCl$_2$)$_3$** (C) against MCF-7-cells (■ 0.5 μM, ● 1.0 μM, ▲ 5.0 μM) (n = 16).

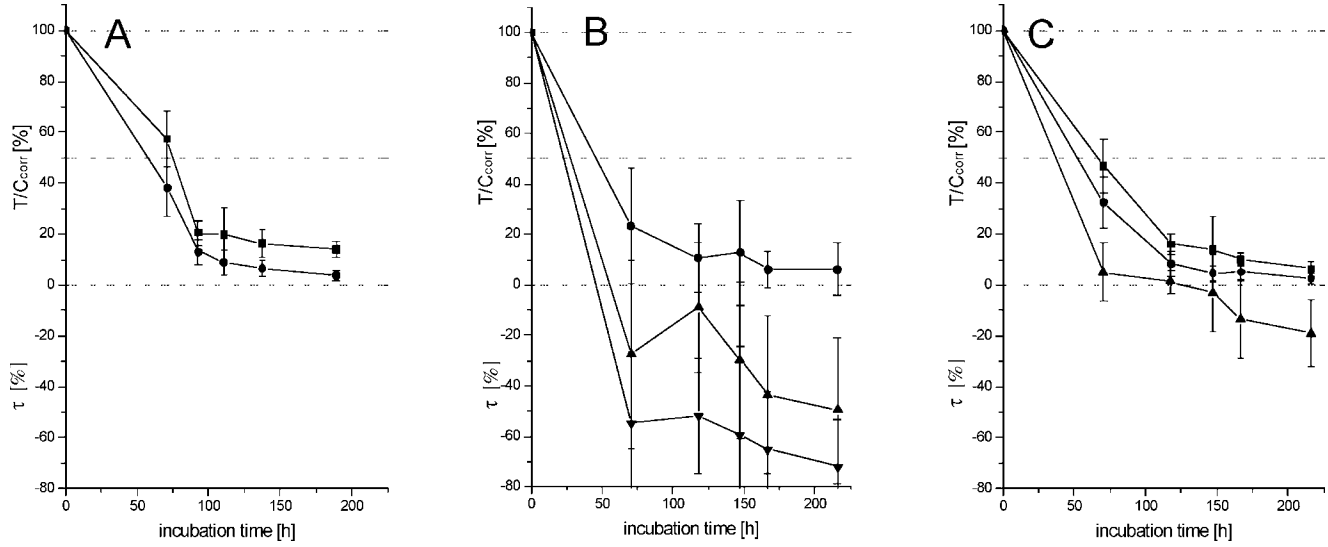

Figure 6. Cytotoxicity of **m-4F-Pt(H$_2$O)$_2$** (A), (**m-4F-Pt)$_3$C** (B), and **(m-4F-Pt)$_3$D** (C) against MCF-7 cells (■ 2.5 μM, ● 5.0 μM, ▲ 10.0 μM, ▼ 20 μM) (n = 16).

drugs (*39*). Therefore, the platinum−dendrimer conjugates were incubated with HSA and the protein-unbound fraction was quantified after ultrafiltration (quantification of unbound drug) and ethanolic precipitation (quantification of reversible lipophilic bound drug) by GF-AAS (Table 2).

Cisplatin, carboplatin, **m-4F-Pt(H$_2$O)$_2$**, and **m-4F-PtCl$_2$** were used as references. After ultrafiltration, they showed recovery rates of 76%, 77%, 19%, and 51%, respectively. The free proportion of platinum increased, except for **m-4F-Pt(H$_2$O)$_2$**, in all cases to 90−100% after ethanol precipitation. This means that **m-4F-Pt(H$_2$O)$_2$** is much more strongly bound to the proteins than the other complexes, very likely by coordination.

All platinum−dendrimer conjugates strongly interact with HSA. For **A(PtI$_2$)$_2$**, **B(PtI$_2$)$_2$**, **B(PtCl$_2$)$_2$**, and **C(PtI$_2$)$_3$**, a very low recovery rate (below 6%) was determined, which increased only for **C(PtI$_2$)$_3$** after ethanol precipitation (49%). **A(PtCl$_2$)$_2$** and **C(PtCl$_2$)$_3$** were much more weakly bound (recovery in the ultrafiltrate, 20% and 32%; after ethanol precipitation, 62% and 95%, respectively). The m-4F derivatives **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** (recovery in the ultrafiltrate of about 22%; after ethanol precipitation about 48%) showed a binding characteristic to HSA similar to that of **m-4F-Pt(H$_2$O)$_2$**. A complete displacement from the protein comparable to **m-4F-PtCl$_2$** was not achieved. This confirmed the release of the [*meso*-1,2-bis(4-fluorophenyl)ethylenediamine]platinum(II) from the polymer.

In order to gain insight into the mode of action, we calculated the reaction rate of irreversible protein binding. The reference compounds **m-4F-PtCl$_2$** and **m-4F-Pt(H$_2$O)$_2$** had a slightly higher reactivity toward HSA (6.81 and 6.4 $\times$ 10^{-3} min^{-1}, respectively) than cisplatin (5.35 $\times$ 10^{-3} min^{-1}).

The dichloroplatinum(II) derivatives **A(PtCl$_2$)$_2$** and **C(PtCl$_2$)$_3$** are somewhat more reactive (10.5 and 16.7 $\times$ 10^{-3} min^{-1}, respectively) than cisplatin or the other reference compounds. Because these compounds possess two (**A(PtCl$_2$)$_2$**) or three (**C(PtCl$_2$)$_3$**) platinum moieties, the optimal orientation to the binding sites seems to be possible, resulting in faster HSA binding.

Carboxyl groups lower the reactivity of platinum(II) complexes. For instance, carboplatin did not hydrolyze in aqueous solution (*30*) but underwent direct substitution reactions with bionucleophils, resulting in a low reaction rate of 0.22 $\times$ 10^{-3} min^{-1} for the irreversible HSA binding.

The Pt−O bond of the dendrimers **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** is not as stable as in carboplatin and is cleaved with a

higher reaction rate (**(m-4F-Pt)$_3$C**, 3.4 × 10^{-3} min^{-1}; **(m-4F−Pt)$_3$D**, 1.88 × 10^{-3} min^{-1}).

For carboplatin and its derivatives, it is suggested that activation by S-containing nucleophils such as methionine (*35*) occurs. A total of five specific binding sites were identified for cisplatin at HSA, including the cysteine residue C34, two methionine sites (M329, M548), and the tyrosine and aspartate O-donor sites Y150 (or Y148) and D375 (or E376) (*36*). So, we assume that the methionine residues were able to replace the dicarboxylate acid in carboplatin (*37*), **(m-4F-Pt)$_3$C**, and **(m-4F-Pt)$_3$D**.

Cytotoxicity against MCF-7 Cells. The platinum−dendrimer conjugates were tested for cytotoxicity against MCF-7 breast cancer cells. Because of the lower water solubility, the concentration of **A(PtX$_2$)$_2$** and **B(PtX$_2$)$_2$** was limited to 5 μM, while the PEG conjugates **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** were tested up to 20 μM.

The obtained results confirmed our assumption of weak interactions between platinum−dendrimer conjugates and the DNA. Although all conjugates caused higher platinum content in the nuclei and at the DNA than cisplatin, the cytotoxic effects are quite low. It is well-known that inactivity of PtI_2 complexes results from the low hydrolysis rate of the Pt−I bond, while the $PtCl_2$ moieties can bind after aquation to nucleobases. If the $PtCl_2$ group is attached at macromolecules, steric effects hinder the binding to nucleobases. This might be the reason for the inactivity of **A(PtI$_2$)$_2$**, **B(PtI$_2$)$_2$**, **B(PtCl$_2$)$_2$**, and **C(PtI$_2$)$_3$**. **A(PtCl$_2$)$_2$** and **C(PtCl$_2$)$_3$** showed at a concentration of 5 μM about 50% inhibition of cell proliferation after 72−96 h (Figure 5B,C).

A(PtCl$_2$)$_2$ seems to be small enough to be coordinated to DNA. It can be interpreted as dinuclear platinum compounds, which were preferentially accumulated in tumor cells by endocytosis (*38*) taken up to a high extent in the nucleus and bound to DNA (*39*). For compounds of similar molecular weights, an inhibitory effect on cell proliferation was observed (*39*−*42*). **C(PtCl$_2$)$_3$** caused a significantly lower platinum concentration in the tumor cells/nuclei compared to **A(PtCl$_2$)$_2$** but showed comparable cytotoxicity. Therefore, another mode of action of action is very likely.

The dendrimers act in **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** as leaving groups. Such dicarboxylic platinum(II) compounds were activated in the tumor cells by hydrolysis reactions or nucleophilic attack. The released m-4F-Pt complex interacted then with the DNA building intrastrand cross-links (*43*, *44*). However, this reaction can occur prior to the transfer into the tumor cells.

m-4F-Pt(H$_2$O)$_2$, **(m-4F-Pt)$_3$C**, and **(m-4F-Pt)$_3$D** reduced at 5 μM the proliferation of MCF-7 cells comparable to cisplatin (compare Figures 5 and 6). Higher concentrations (10 and 20 μM) of **(m-4F-Pt)$_3$D** did not increase the cytotoxicity (Figure 6C), while in the case of **(m-4F-Pt)$_3$C**, strong cytocidal effects were detected (Figure 6B). Like cisplatin, all three compounds showed their maximum effect after 200 h, without recovery of cell proliferation.

In contrast to dendrimer **B**, which reduced the proliferation of MCF-7 cells by 80% (*18*), dendrimers **C** and **D** did not influence the cell growth. The observed cytotoxicity must be the consequence of the release of m-4F-Pt species from the macromolecule. A contamination of nonbound platinum complex resulting from the synthesis can be excluded because of the high purity determined in CE analyses (see Supporting Information).

CONCLUSION

In this structure−activity study, we investigated the pharmacological characteristics of platinum−dendrimer conjugates. The antiproliferative activity, the cellular uptake, the platinum content in cell nuclei, and the binding to DNA and HSA were determined. Conjugates were taken up by adsorptive endocytosis and reached the nuclei. The data pointed to weak binding to DNA not able to cause antiproliferative effects. Only **A(PtCl$_2$)$_2$** and **C(PtCl$_2$)$_2$** were active against MCF-7 cells. M-4F-Pt conjugates were at least as cytotoxic as cisplatin. It is very likely that **(m-4F-Pt)$_3$C** and **(m-4F-Pt)$_3$D** liberate **m-4F-Pt(H$_2$O)$_2$** or **m-4F-PtCl$_2$** as the real antitumor agent unfortunately before entering the cells. Dendrimer **A**, however, was identified as an excellent carrier molecule and caused very high intracellular platinum content (up to 445-fold in relation to dendrimer (**A(PtCl$_2$)$_2$**)-bound Pt molecules). In the next step, we will modify the conjugates (e.g., **A(PtCl$_2$)$_2$**) in such a way that cytostatics are selectively released in tumor cells.

Asymmetric Secondary and Tertiary Streptavidin/DNA Complexes Selectively Formed in a Nanometer-Scale DNA Well

Kentaro Numajiri, Akinori Kuzuya,* and Makoto Komiyama*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro, Tokyo 153-8904, Japan. Received September 26, 2009; Revised Manuscript Received January 7, 2010

Rectangular DNA motifs, which each have a built-in cavity in the middle, were prepared by bundling nine DNA helices into a U-shaped tile first and then assembling two of them together. The cavity was modified with two or three biotin molecules and was used as a nanometer-sized well to capture a single streptavidin (SA) tetramer size-selectively. Selective, one-step formation of asymmetric secondary or tertiary SA/DNA complexes via bidentate or tridentate capture have been shown by analyses of the complexes with denaturing polyacrylamide gel electrophoresis. When biotinylated DNA was simply added to the solution of SA, only symmetric SA/DNA complexes were formed as a mixture of primary to quaternary complexes, depending on the amount of DNA. However, when the DNA motif was preformed prior to SA addition, the asymmetric secondary complex was preferentially formed. The yield of the asymmetric secondary complex was ca. 50% when biotins were tethered to the two-turn well (6.8 nm wide) via 2.3 nm linkers, whereas the yield of the mixture of symmetric and asymmetric secondary complexes was only 7% for the reaction in bulk solution under the corresponding conditions. The larger the size of the well, the lower the yield became. Selective formation of asymmetric tertiary complex was also successful. Treatment of a SA tetramer captured in a well with a biotinylated, long dsDNA has shown that the captured SA still preserves its binding ability to additional biotinylated target.

INTRODUCTION

Protein nanoarrays of regularly ordered and orientated individual molecules should have important roles in future proteome studies. DNA nanotechnology (*1, 2*), which is based on programmed assembly of branched DNA helices, has been attracting great interest as a key technology in preparing scaffolds for nanopatterning of proteins. To date, various DNA nanostructures have been used as a scaffold for protein nanoarrays (*3*−*18*). Recently, we proposed a new strategy for fixation of proteins to a DNA scaffold that leads to robust and regulated protein nanoarrays; this strategy entails making nanometer-scale wells embedded in a DNA sheet and selectively capturing the target protein in these wells in a single-molecule manner, by "anchoring" it with two linkers (bidentate capture strategy, Scheme 1a.) We prepared either a tape-like DNA scaffold, by assembling U-shaped DNA tiles made of nine DNA helices (*19*), or a stick-like DNA origami (*20*), and put regularly arranged nanometer-scale wells in it. By attaching two biotins to the ends of DNA components at the two edges of each well, we have successfully and size-selectively captured just one streptavidin (SA) tetramer in a well and formed regular SA nanoarrays. The SA tetramers captured in a well are quite stable against repetitive AFM-tip scanning, providing a consistently clear image of the individual molecules. Although a significant difference in the stability of SA in a well was observed between the bidentate capture system and the monodentate system (*20*), there has been no direct evidence of the formation of an asymmetric secondary SA/DNA complex, in which two different biotinylated DNA strands are bound to SA. In addition to elucidating the size-selective SA capture, selective formation of such an asymmetric complex should be useful as a key component for nanofabrication of protein−DNA hybrids in other research fields related to protein engineering.

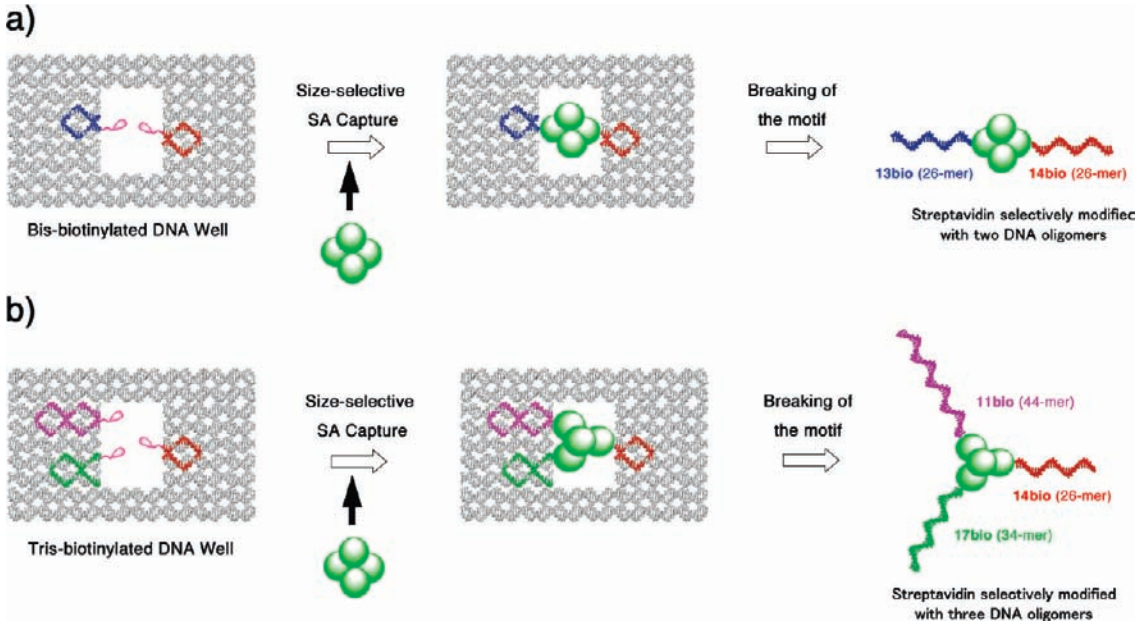
SA is a tetrameric protein (molecular weight ≈ 58 kDa) and is one of the most popular tools in biochemical research along with its related proteins, such as avidin, owing to its enormously high affinity to biotin ($K_a \approx 10^{14}$ M^{-1} for free biotin, or 10^8 M^{-1} for avidin/PEGylated biotin interaction) (*21, 22*). Multiple studies on the formation of SA/DNA complexes and their applications in nanotechnology have been reported by several groups to date (*23*−*26*). However, the DNA portion employed in these studies is rather long (80 bp to 2 kbp) double-stranded (ds) DNA, and the properties of complexes between short single-stranded (ss) DNA and SA have not been well-studied. In addition, previously reported SA/DNA complexes are mostly symmetric complexes, in which the same DNA portion is multiply bound to SA, and as far as we know, there are no reports of simultaneous modification of SA with different strands as expected in the bidentate capture.



In this study, we have prepared new DNA motifs, each of which has a single well of varying size and biotinylated patterns, by assembling two U-shaped DNA bundles. After size-selectively capturing one SA molecule in a well, the motifs were broken down into the ssDNA components again under mild denaturing conditions, and the SA/DNA complexes formed in the well were analyzed in detail by polyacrylamide gel electrophoresis (PAGE).

EXPERIMENTAL PROCEDURES

Materials. Unmodified DNA strands were purchased from Sigma-Genosys (Japan) and used without further purification. Biotin-triethylene glycol (TEG)-modified strands for SA capture were chemically synthesized on an automated DNA synthesizer using biotin-TEG phosphoramidite monomer (Glen Research, VA) for the 5′-end and purified by denaturing PAGE and reverse-phase HPLC. SA was purchased from Sigma, GelStar was from Lonza Rockland (ME), and Quick-CBB was from Wako Pure Chemicals (Japan).

Scheme 1. Schematic Diagram of the Bidentate (a) and Tridentate (b) Capture of SA in a Well

Formation of DNA Tiles. The motifs were first formed as a U-shaped nine-helix bundle with 1 μM DNA (for each strand) in a solution containing 40 mM Tris, 20 mM acetic acid, 2 mM ethylenediaminetetraacetic acid, and 12.5 mM magnesium acetate (1× TAE/Mg buffer, total volume 100 μL). This mixture was cooled from 95 to 25 °C at a rate of −1.0 °C/min using a PCR thermal cycler. Separately annealed solutions of the two U-shaped bundles that correspond to the right and the left portions of the motif were then mixed together to form the desired dimer motif. After being kept at room temperature for 5 min, the mixture was treated with a gel-filtration microspin column (Microspin S-400HR, GE Healthcare, UK), which was equilibrated to 1× TAE/Mg buffer in advance, to remove incomplete fragments that are not precisely annealed. The concentration of the motifs after this process was estimated by measuring the UV absorbance at $\lambda = 260$ nm. Then, excess SA (final concentration, 1 μM) was added to the solution for size-selective capture.

AFM Imaging. AFM imaging of DNA tiles was performed on a SPA-300HV system (SII, Japan). After addition of SA, the DNA tile solution (3 μL) was deposited on a freshly cleaved mica substrate, additional 1× TAE/Mg buffer (200 μL) was added, and imaging was done using the fluid DFM scanning mode with a BL-AC40TS tip (Olympus, Japan).

Denaturing PAGE and Ferguson Analyses. Denaturing PAGE analyses were performed in gels containing 8−14% acrylamide (37.5:1, acrylamide/bisacrylamide), 4 M urea, 45 mM Tris, 45 mM boric acid, and 0.5 mM EDTA (0.5× TBE). Each sample solution was mixed with an equivalent amount of loading buffer containing 0.5× TBE, 7 M urea, 0.03% bromophenol blue, and 0.03% xylene cyanol FF and then loaded onto each gel without heating. For the size markers, a 100 bp DNA duplex ladder was used. It was carefully confirmed that the loading and running conditions without heating did not denature these long DNA duplexes (data not shown). After a 90 min run (37.5 V/cm, constant voltage) at room temperature, the gel was stained with GelStar, and each band was quantified with a FujiFilm FLA-3000G fluorescent imaging analyzer. To calculate the yield of the complexes, the band intensity of GelStar fluorescence was normalized by the expected number of nucleotides in the complex. The migration distances for Ferguson analysis were measured on the digital images. The gel stained by Quick-CBB for staining of SA was scanned on a Canon scanner.

Nondenaturing PAGE. A DNA tile-containing solution was mixed with the appropriate amount of 6× Blue/Orange Loading Dye (Promega) and then loaded onto gels containing 4% acrylamide (37.5:1, acrylamide/bisacrylamide) and 1× TAE/Mg buffer. After a 180 min run (18.6 V/cm, constant voltage) at room temperature, the gel was stained with GelStar and analyzed as above. To test for secondary target binding, a fragment of pBR322 plasmid (nucleotides 1786−3057) was amplified by PCR using a combination of native forward primer and biotinylated reverse primer, and 2 equiv of the resulting 1272 bp dsDNA was added to the solution of SA/**2b** complex, kept at room temperature for 5 min, and analyzed by nondenaturing PAGE as described above.

RESULTS AND DISCUSSION

Design and Construction of the DNA Motifs Bearing a Nanometer-Scale Cavity in the Middle. The structure of the DNA motifs used in this study is shown in Figure 1 (see Supporting Information Figure S1 for the detailed sequence). To assess the effect of the size of the well on size-selective SA capture, three kinds of motifs were prepared by assembling a U-shaped nine-helix bundle (**1**) and its derivatives. The nine-helix bundle **1** consists of four helices that are eight turns long (84 bp) and five helices that are six turns long (63 bp). These helices are connected to the adjacent helices via immobile four-way junctions at two positions, which are two or four helical turns apart. Consequently, a flat, raft-like, nine-helix DNA bundle is formed. The longer helices are placed two by two at the edges of the motif, so **1** has a rectangular concavity that is two turns wide and five helices long at one side. The 5′ ends of the longer helices are sticky ends 5 bases long, and **1** can be further assembled into a dimer motif, which bears a nanometer-scale well with a theoretical dimension of $6.8 \times 10 \times 2.0$ nm^3 in the middle (**2a** and **2b**), by assigning the appropriate sequence to these sticky ends. For the size-selective capture of SA in the well, some of the DNA strands composing the motif were modified with a biotin-TEG residue either at the 5′ end (**13bio**, blue strand; **11bio**, pink strand; **17bio**, green strand) or at the 3′ end (**14bio**, red strand). When **13bio** is used in combination with **14bio**, two biotin molecules are placed in a well via a

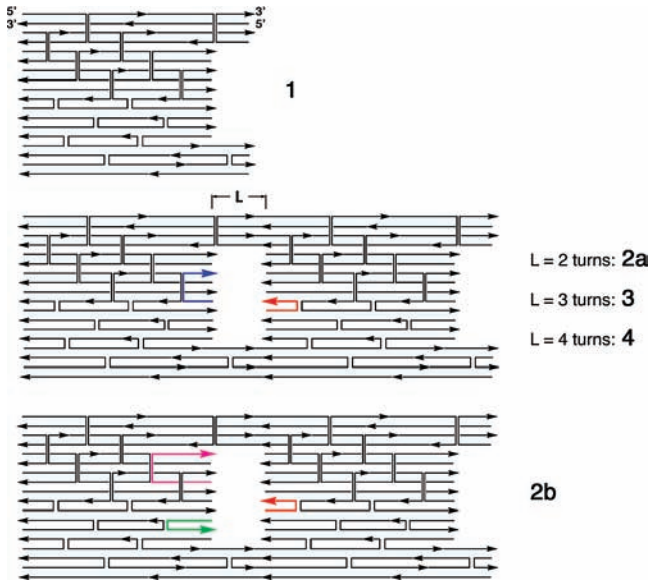

Figure 1. Structures of the DNA motifs used in this study. A U-shaped nine-helix DNA bundle (**1**) and its derivatives were separately annealed and then assembled into rectangular motifs (*2*−*4*) via sticky ends attached to the edges of each bundle (see Supporting Information Figure S1 for the full sequence). By changing the length of the arms of one of the bundles (two helical turns or 6.8 nm for **2**, three turns or 10.2 nm for **3**, and four turns or 13.6 nm for **4**), the width of the well was precisely controlled. For SA capture, biotin-TEG residues were attached to the ends of the strands depicted in colors. Two biotinylated strands (**13bio**, blue; **14bio**, red) were used for bidentate capture (**2a**), and three biotinylated strands (**14bio**, red; **11bio**, pink; **17bio**, green) were used for tridentate capture (**2b**) of SA.

2.3-nm-long linker (*27*), from the opposite two edges 6.8 nm apart (**2a**). Similarly, the combination of three biotinylated strands (**11bio**, **17bio**, and **14bio)** produces a tris-biotinylated well (**2b**). The size of the cavity can also be precisely controlled by changing the length of the arms in **1**. Two additional bis-biotinylated motifs, with a cavity that is three turns wide (10.2 × 10 × 2.0 nm^3, **3**) and one that is four turns wide (13.6 × 10 × 2.0 nm^3, **4**), respectively, were prepared by using the appropriate arm length. Successful formation of the motifs was fully confirmed by analyzing the annealed mixture of the motifs by nondenaturing PAGE and observing a single sharp band for each motif (data not shown).

Size-Selective Capture of a Single SA Molecule in a Well. Size-selective capture of SA in bis-biotinylated wells was first done by adding excess SA to a solution of bis-biotinylated motif **2a** (Scheme 1a). Figure 2a shows an AFM image of SA/**2a** complexes formed in 1× TAE/Mg buffer solution. As clearly seen in the image, exactly one SA tetramer is selectively trapped in a well. This observation is in complete agreement with the findings of previous studies (*19, 20*). In addition to a tape-like DNA scaffold and DNA origami, size-selective capture of SA is also possible with a simple dimer motif. Some SA complexes with incompletely annealed DNA fragments were observed in AFM images at the same time (indicated by the arrow in Figure 2a). The yield of complete SA/**2a** complexes estimated from AFM imaging is ∼70% (Supporting Information Figure S2). Note that such incomplete fragments do not migrate as a band in nondenaturing PAGE analysis, but are visualized only as a smear (vide infra).

Individual SA/DNA complexes formed in a well were then analyzed by denaturing PAGE after breaking down the motif with urea (Figure 2b). An equivalent volume (10 μL) of loading dye containing 1× TBE and 7 M urea was added to the SA/**2a** complex solution (16 nM and 1.25 μM for lanes 2 and 3, respectively), and the resulting mixture was directly loaded onto

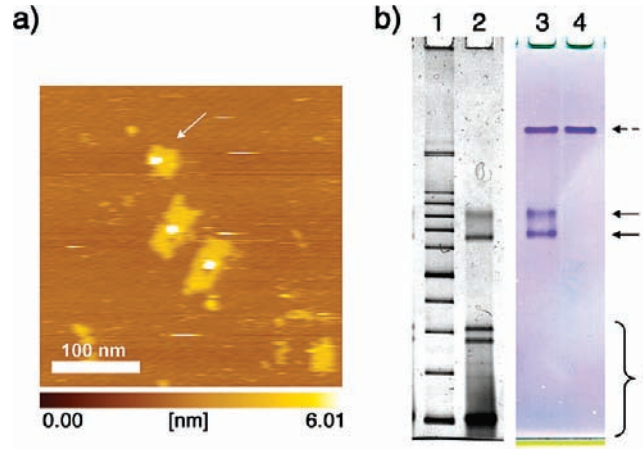

Figure 2. (a) A typical AFM image of **2a** with one SA tetramer in the well. The bright spots are SA. An SA complex with an incomplete fragment (indicated by the arrow) and small flakes of DNA were also observed. (b) A 12% denaturing PAGE analysis of the SA/**2a** complex. The gel was stained with GelStar (stains DNA, lane 2) or Quick-CBB (stains proteins, lanes 3 and 4). Lane 1, 100 bp dsDNA ladder; lanes 2 and 3, the SA/**2a** complex; lane 4, SA only. All sample solutions were mixed with an equivalent volume of loading buffer containing 7 M urea and loaded onto the gel without heating. The bands indicated with an asterisk (*) are unmodified DNA oligomers making up the DNA tile.

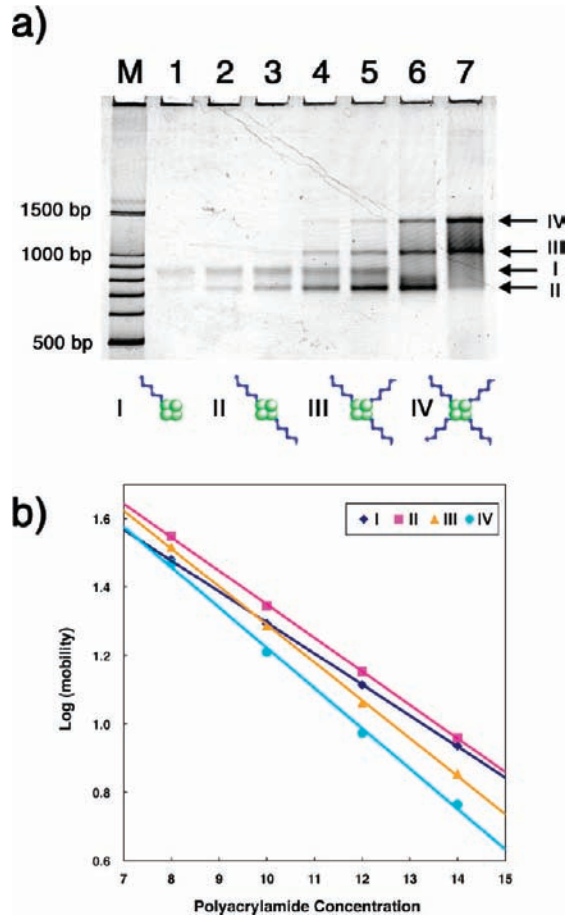

Figure 3. Formation of symmetric SA/DNA complexes in bulk solution. (a) 12% denaturing PAGE analysis of SA/DNA complexes prepared in bulk solution. The gel was stained with GelStar. SA was mixed with various amounts of biotinylated DNA 26-mers (**13bio**). Conditions: [SA] = 1 μM, [**13bio**] = 0.063, 0.13, 0.25, 0.50, 1.0, 2.0, and 4.0 μM (from lanes 1 to 7, respectively). The gel was stained with GelStar. (b) Ferguson plots of the four species observed in (a). The slopes are (I) −0.091, (II) −0.098, (III) −0.111, and (IV) −0.118, and the intercepts are (I) 2.20, (II) 2.32, (III) 2.40, and (IV) 2.40.

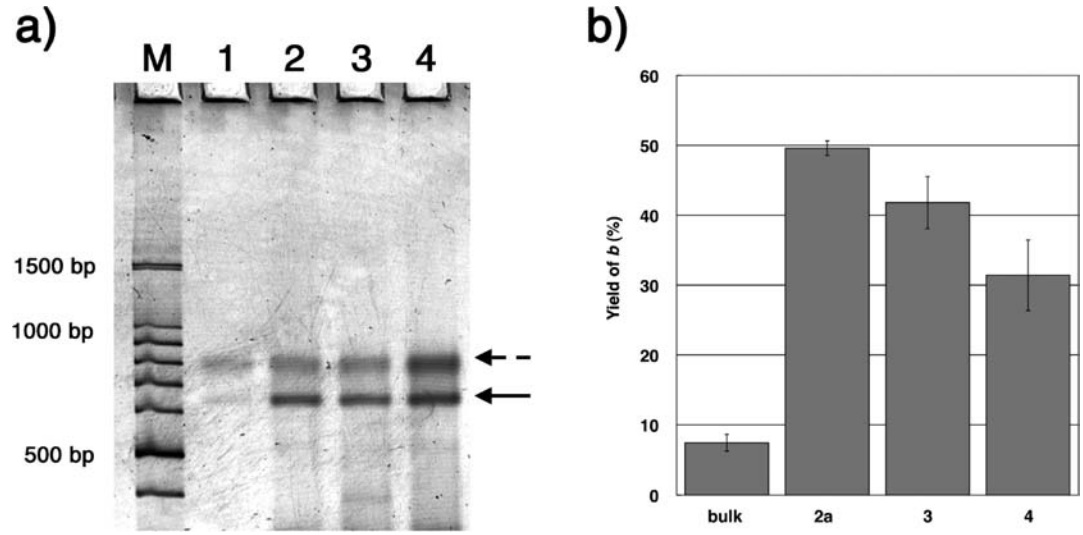

Figure 4. Analyses of SA tetramers captured in motifs with differently sized wells (**2a**, **3**, and **4**). (a) A 12% denaturing PAGE analysis of SA captured in **2a**, **3**, and **4**. The gel was stained with GelStar. Lane 1, SA/DNA complexes prepared in bulk solution; lane 2, SA captured in **2a**; lane 3, SA in **3**; lane 4, SA in **4**. The lower bands indicated by the solid arrow are the asymmetric secondary SA/DNA complex, and the upper bands indicated by the dashed arrow are due to either of the primary SA/DNA complexes (SA/**13bio** or SA/**14bio)**. Conditions: [SA] = 1.1 μM, [**13bio**] = [**14bio**] = 14 nM (lane 1), [DNA motifs] = 14 nM (lanes 2−4). (b) The yield of the secondary complex in (a). Quantified intensities of GelStar fluorescence were normalized by the expected number of nucleotides in the complex.

the gel without heating. The gel was then run at room temperature. When the gel was stained with GelStar, which stains both dsDNA and ssDNA, two significant bands (indicated by the solid arrows) with mobility similar to an 800 bp duplex were observed, along with many other bands with higher mobility (lane 2). These two bands were also stained by Quick-CBB, which stains only proteins (lane 3). Other lower bands in lane 2 were not stained by Quick-CBB. The mobility of the two bands was much greater than that of unmodified SA, which is indicated by the dashed arrow (lane 4). These results suggest that the two bands indicated by the solid arrows are SA/DNA complexes and that two main species are formed when SA is captured in a bis-biotinylated two-turn well. The greater mobility of the SA/DNA complexes than unmodified SA is probably due both to increased total negative charge in the complexes and to conformational changes of SA caused by biotin binding (*28*).

Formation of Symmetric SA/DNA Complexes in Bulk Solution. To characterize the bands in PAGE analyses, SA/DNA conjugates were separately prepared in a bulk solution without forming any DNA motifs. A biotinylated strand (**13bio**, 26-mer) was added to the solution of SA in a variety of ratios to SA (Figure 3a). When the amount of DNA was small enough (0.06 equiv to SA), a faint but reproducible single band (indicated as I) was observed near the 900-bp marker (lane 1). Another sharp band II appeared below I, when the amount of DNA was increased to 0.13 equiv (lane 2). When 0.5 equiv of DNA was added to the solution, the third band (III) appeared above I (lane 4), and finally, the fourth band (IV) above III became obvious after the DNA ratio reached 1 equiv (lane 5). Bands I and II disappeared when SA was treated with excess DNA (lane 7). This order of appearance strongly indicates that bands I, II, III, and IV are the primary, secondary, tertiary, and quaternary SA/DNA complexes, respectively, and that the mobility of the secondary SA/DNA complex is greater than that of the primary complex. Gel electrophoresis depends on both the particle size and surface net charge density. Figure 3b shows the Ferguson plots of the four bands observed in Figure 3a (*29*). The slopes for the primary (I), secondary (II), tertiary (III), and quaternary (IV) complexes are −0.091, −0.098, −0.111, and −0.118, respectively. These plots indicate that the reversed mobility between the primary complex and the secondary complex is observed only when the concentration of polyacrylamide is below ∼16%. The order of the slope is fairly reasonable since it reflects the order of the particle sizes. The intercepts of the plots, which represent the surface net charge densities of the particles, are (I) 2.20, (II) 2.32, (III) 2.40, and (IV) 2.40. Again, these numbers are reasonably ordered.

Biotin binding to SA has been known to drastically enhance the stability of the SA tetramer (*28*). However, the form of SA under denaturing conditions has been a matter of controversy. Sano and Cantor suggested in 1990 that SA saturated with biotin in the presence of 6 M urea dissociates into its dimeric form, based on gel filtration chromatography observations (*28*), and later, González et al. reported partial (60%) dissociation of SA tetramer into its dimeric form in the presence of 8 M urea, based on fast protein liquid chromatography (FPLC) (*30*). By contrast, Kurzban et al. claimed that SA saturated with biotin is intact in its tetrameric form even in the presence of 6 M urea, based on gel filtration chromatography (*31*). At least under the conditions employed in our study (4 M urea), SA seems to stay in its tetrameric form, since sequential formation of all four possible complexes was observed on a gel, and reproducible and fairly proportional plots in the Ferguson analyses were accomplished, although we also observed significant dissociation of the complex if the complex/loading dye mixture was heated at 90 °C for 1 min prior to gel electrophoresis. The binding constant of urea to SA is known to be $K_a \approx 1.3\ M^{-1}$ (*31*), and thus, ligand exchange between biotin and urea during electrophoresis is almost negligible.

Characterization of SA/DNA Complexes Formed in the Well. The complexes formed in the well of **2a** were compared with the products formed in bulk solution (Figure 4). Here, SA (final concentration, 1.1 μM) was added either to a solution of **2a** (lane 2; final concentration, 14 nM) or to a simple mixture of biotinylated strands (lane 1; final concentration, 14 nM). In bulk solution, the primary complex (upper band) is dominantly formed since the number of biotinylated strands is so low compared with that of SA (lane 1). When SA was added to **2a**, a sharp lower band was clearly observed. This band was further analyzed by a Ferguson plot (Supporting Information Figure S3). The slope and the intercept were −0.097 and 2.32, respectively, which are almost the same as those of the secondary complex in Figure 3b. Thus, this lower band can be identified as the desired secondary complex. The yield of this

secondary complex estimated from the quantification of the bands was 50 ± 1%. The yield was also estimated by using a FAM-labeled biotinylated strand, and a similar number was obtained (Supporting Information Figure S4). The rather low yield of the secondary SA/DNA complex in **2a** may be due to the existence of incompletely formed DNA fragments as observed in Figure 2a. Other motifs with a wider three-turn well (**3**) or four-turn well (**4**) were also treated with SA and analyzed by PAGE (lanes 3 and 4). Both of the motifs produced significant amounts of secondary complexes, but more monodentate complexes were formed. The yield of the secondary complex decreased as the size of the well was increased. The yields of the secondary complex were 42 ± 4% in **3** and 31 ± 5% in **4**. Formation of secondary complexes even in wider wells may be attributable to the flexible nature of DNA and DNA nanostructures. A similar pattern but with lower yields of secondary complexes was obtained when the linkers connecting the biotin and DNA were shortened relative to the TEG linker (Supporting Information Figure S5). In any case, the yield of secondary complexes was far higher than that obtained in the bulk system (lane 1, the yield of secondary complexes is 7 ± 1%), showing the importance of the nanometer-scale prepositioning of the strands in the motifs.

Formation of an Asymmetric Tertiary SA/DNA Complex in a Well. Although the aforementioned bidentate capture strategy may be enough to obtain uniformly orientated SA molecules in the future, the possibility of forming a tertiary SA complex in a well was also examined (Scheme 1b). For this purpose, another motif with a tris-biotinylated two-turn well was prepared by using three biotinylated DNA strands (**2b** in Figure 1). Here, the three biotin-TEG residues were attached to the ends of the strands roughly 7 nm apart from each other. Due to the difference in the length of each strand (26-mer for **14bio**, 34-mer for **17bio**, and 44-mer for **11bio**; 104 nucleotides (nt) in total), simple identification of the band corresponding to the tertiary complex using Ferguson analysis is impossible. We thus prepared fluorescently labeled strands corresponding to each of the biotinylated strands. In these three modified strands, a 6-fluorescein amide (6-FAM) residue was inserted between the biotin-TEG residue and the DNA. Figure 5 shows the denaturing PAGE analysis of the FAM-labeled SA/DNA complexes formed in **2b**. Here, excess SA (final concentration, 1 μM) was added to the solution of **2b** (final concentration, 50 nM), in which each of the three biotinylated strands was individually exchanged, one at a time, with the FAM-labeled counterpart (lane 2, **14bio**; lane 3, **17bio**; lane 4, **11bio**). As indicated by the arrow, a common sharp band with the lowest mobility was observed for lanes 2−4. The slope of the Ferguson plot of this common band was −0.117 (Supporting Information Figure S6), which is a fairly reasonable number compared to those for symmetric tertiary SA/DNA complexes separately prepared in bulk solution (−0.111 for SA/**14bio**$_3$ bearing 78 nt, −0.117 for SA/**17bio**$_3$ bearing 102 nt, and −0.149 for SA/**11bio**$_3$ bearing 132 nt). This band was never formed in the mixture of the three FAM-labeled strands and SA in bulk solution (lane 1). Preformation of DNA motif is essential for the efficient formation of these asymmetric tertiary complexes.

We tried to isolate this asymmetric tertiary complex by cutting out the band and eluting the contents into a buffered solution. However, we were unsuccessful since the complex easily equilibrated into a mixture of various complexes with various combinations of strands on SA within a few days at room temperature (reported half-life for the exchange rate of SA/biotin binding is 2.9 days at pH 7.0) (*21*, *32*). This fact conversely emphasizes the stability of the asymmetric tertiary complex in a well, which produced virtually the same PAGE pattern as in Figure 5 even after the solution of SA/**2b** was kept at room temperature for several days. Both cooperativity and the proximity effect, the two essential factors in biomolecular systems, may have key roles in achieving this tremendously high stability. We also attempted MALDI-TOF/MS analysis of SA/DNA complexes before and after purification. However, we could only observe dissociated SA dimer and monomer.

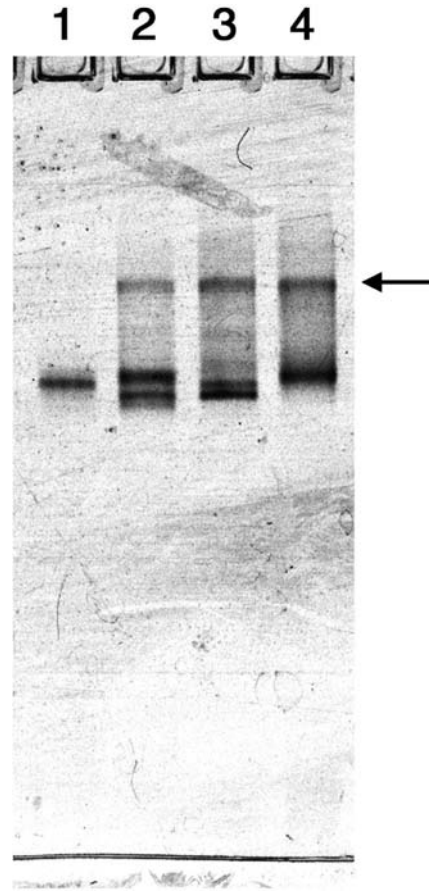

Figure 5. 12% denaturing PAGE analysis of SA captured in the wells of **2b**. The fluorescence of FAM was imaged. In lanes 2−4, one of the three biotinylated strands was exchanged with a FAM-labeled counterpart one by one. Thus, the common band indicated by the arrow contains all three biotinylated strands. Lane 1, SA and the three biotinylated strands (**14bio**, 26-mer; **17bio**, 34-mer; **11bio**, 44-mer) labeled with FAM were mixed in bulk solution; lane 2, SA captured in **2b** containing FAM-labeled **14bio**; lane 3, SA in **2b** containing FAM-labeled **17bio**; lane 4, SA in **2b** containing FAM-labeled **11bio**. Conditions: [SA] = 1 μM, [FAM-labeled **14bio**] = [FAM-labeled **17bio**] = [FAM-labeled **11bio**] = 50 nM (lane 1), [DNA motifs] = 50 nM (lanes 2−4).

Further Modification of SA Captured in a Well with a Long dsDNA. One of the latest topics in DNA nanotechnology is whether proteins attached to DNA scaffolds still preserve their intrinsic structures and functions (*33*, *34*). Although the possibility of tridentate capture of one SA tetramer in a well has been confirmed, it is still unclear whether the empty binding sites in an SA embedded in a well are accessible to the external solvent and retain strong biotin binding activity. To assess the possibility of additional modification of SA embedded in a well with a biotinylated molecule, a 1272 bp biotinylated linear dsDNA was added to a solution of SA/**2b** complexes. In nondenaturing PAGE analysis, the band corresponding to the SA/**2b** complex completely disappeared after the addition of 2 equiv of the biotinylated dsDNA, and a new band with much lower mobility was observed (indicated by the arrow in Figure 6). Similarly, addition of the preformed complex of SA and the 1272 bp biotinylated dsDNA to the solution of **2b** resulted in the disappearance of the band corresponding to **2b** and

Figure 6. Further modification of SA captured in a well. A biotinylated dsDNA (1272 bp) was added to the solution containing SA/**2b** complexes, the mixture was subjected to 4% nondenaturing PAGE, and the fluorescence of FAM was imaged. SA/**2b**/dsDNA ternary complexes were observed as indicated by the arrow. Lane 1, **1** containing FAM-labeled **11bio** and **17bio**; lane 2, **2b** containing FAM-labeled **11bio** and **17bio**; lane 3, **2b** containing FAM-labeled **11bio** and **17bio** mixed with SA; lanes 4 and 5, biotinylated dsDNA added to **2b** containing FAM-labeled **11bio** and **17bio** mixed with SA. Conditions: [DNA motifs] = 33 nM, [SA] = 67 nM (lanes 3−5), [biotinylated dsDNA] = 67 nM (lane 4), or 133 nM (lane 5).

appearance of a similar new band with lower mobility (Supporting Information Figure S7). These results show that the SA captured in a well still preserved its binding ability toward additional targets and that selective preparation of asymmetric quaternary complexes may be also possible in the future.

CONCLUSIONS

Here, we have shown selective formation of asymmetrically modified secondary or tertiary SA/DNA complexes via bidentate or tridentate size-selective capture of SA in a nanometer-sized well formed in DNA motifs. The yield of the secondary complex was ca. 50% for the two-turn well that is 6.8 nm wide when 2.3 nm linkers were used to tether two biotin molecules in a well and capture SA with a diameter of 5 nm. The larger the size of the well, the lower the yield became. The SA captured in a well still preserved its ability to bind additional biotinylated target; thus, it is possible to make protein nanoarrays by additionally conjugating biotinylated proteins to SA captured in wells embedded in various DNA nanostructures such as DNA origami assemblies. Cooperative capture may be feasible also for protein/ligand interactions other than SA/biotin binding such as His-tag/Ni-NTA binding, especially when the protein of interest is a dimer or a multimer (*18, 35*).

Isolation of the asymmetric complex with simple extraction from gels was unsuccessful because SA/biotin binding is still a noncovalent, reversible interaction. A similar process may be possible, however, by using covalent-bond formation for the capture of target proteins in the motif. For example, amide-bond formation between carboxyl or amino groups on the surface of the protein and their activated counterpart on DNA, disulfide-bond formation between thiol groups, or a click reaction between a functionalized protein surface and DNA can be used to capture proteins on the motif and possibly to develop a "molecular operation table", which functionalizes a single protein molecule with multiple DNA strands in the desired geometry, in one pot and one step.

To develop a sterically stable, targeting proteoliposome, a postinsertion method was employed to biofunctionalize the liposome surface with a biocompatible anchor molecule (BAM) linker conjugated with epidermal growth factor (EGF) as a homing molecule. In this method, EGF was first conjugated with BAM that consisted of a hydrophilic reactive group at one end and oleic acid chains at the other end. The EGF-BAM complex was then inserted into the liposomal phospholipid bilayer through lipophilic interaction. When compared with the traditional surface modification method by amine coupling, the modification efficiency with BAM at 25 °C was about 2.5-fold higher, and the 24 h stability of the inserted BAM at 25 °C was also about 2.5-fold higher. The insertion affinity and stability of the BAM to the liposomal bilayer was not influenced by an increase in cholesterol concentration, a component in liposome preparation. Confocal microscopy studies showed that the proteoliposomes biofunctionalized with the BAM-EGF complex encapsulating Cy5 fluorescent dye were selectively bound to the surface of MDA-MB-231 cells overexpressing EGFR (epidermal growth factor receptor), but not to MCF-7 cells, which did not express EGFR. The same proteolipome encapsulating doxorubicin was selectively targeted to MDA-MB-231 cells and killed them. In sum, BAM could be used as a suitable postinsertion linker for biofunctionalization of liposome surface with high modification efficiency and stability. Furthermore, the protein used as a homing molecule maintained its bioactivity after the biofunctionalization.

INTRODUCTION

Among various nanoparticles used as drug delivery systems, liposomes are the most well studied materials because of their amphiphilic and biocompatible characteristics (*1, 2*). A liposome is composed of a vesicular lipid bilayer surrounding a large inner aqueous phase. Their therapeutic advantages include the targeting ability to deliver a large amount of encapsulated drug to specific sites, resulting in improved drug pharmacokinetics and efficacy and reduced drug toxicity (*3*−*5*). One of the drawbacks of a liposomal system is that it can be easily cleared by the reticular endothelial system (RES) resulting in a reduced targeting yield (*6*−*8*). This can be overcome by modifying the liposome surface with flexible hydrophilic polymers such as poly(ethylene glycol) (PEG) to produce so-called "stealth" liposomes (*9*−*13*). This PEGylated liposome was usually prepared by using phosphatidylethanolamine (PE) or PEG-cholesterol derivatives (*12*), and the common method to prepare it (i.e., simple mixing with other phospholipid components) reduced the inner space resulting in lower drug loading capacity (*14*).

Active targeting usually uses guidance ligand molecules called "homing molecules" that have high affinity for cell surface receptors or epitopes (*15*−*17*). Thus, conjugation of a proteineous homing molecule to liposome surface, i.e., targeting proteoliposome, would be interesting for targeted delivery. *N*-Glutaryl phosphatidylethanolamine (NGPE) is a commonly used phospholipid for surface modification, since its carboxyl groups can react with amine groups on proteins (*18*). However, interliposomal aggregation can be problematic especially at high concentrations of both lipids and proteins. Another method of protein conjugation uses thiol-reactive surface of liposome that could couple with sulfhydryl groups of proteins (*19*−*21*). For this type of liposome, 4-(*p*-maleimidophenyl)butyryl phosphatidylethanolamine (MPB-PE) is frequently used as a phospholipid component. However, this sulfhydryl binding method can also cause liposome aggregation at high concentrations of liposome and protein (*22, 23*). One method to avoid or reduce interliposomal aggregation would be to use a relatively inert phospholipid component, e.g., phosphatidylcholine (PC), in liposome formulation. Furthermore, PC is the predominant phospholipid found in natural cell membranes, a lamella-forming lipid, and the most readily available, all of which would render it the ideal phospholipid for liposome formulation.

To prepare targeting liposome composed of relatively inert phospholipid such as PC, a "postinsertion" method for liposome surface modification was employed. It could attach the homing molecule only on the outer surface, maintaining the liposome inner space (*24*−*26*). However, a relatively high temperature (up to 60 °C) was required for postinsertion, which could reduce the activity of the ligand biomolecules, although a thermostable molecule such as affibody was postinserted at 55 °C and still maintained the antigen-binding activity (*26*). Recently, a postinsertion method operating at ambient temperature was reported for stable insertion into various liposomal surfaces (*27*); however, it characterized only the postinsertion linker and did not present surface modification efficiency or liposomal targeting efficiency.

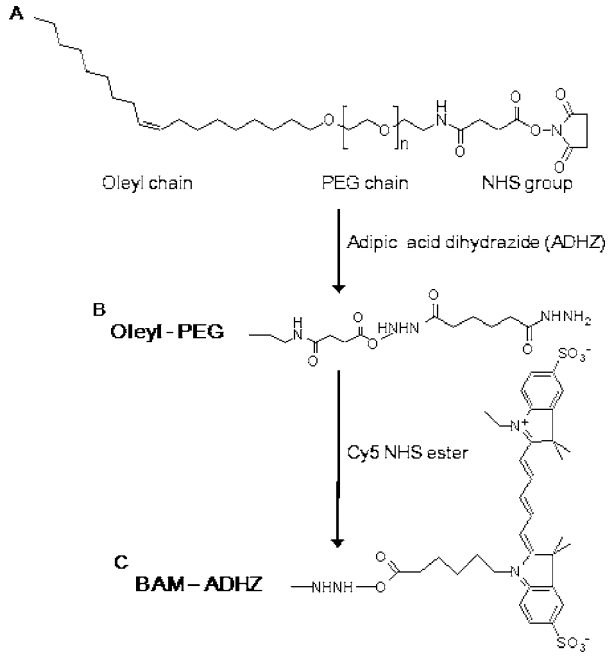

Figure 1. Molecular schematics of (A) BAM, (B) BAM aminated by apidic dihydrazide, and (C) a complex of aminated BAM and Cy5-NHS ester.

In this study, we report the preparation of proteoliposome of which the surface was biofunctionalized by using a commercially available linker, biocompatible anchor molecule (BAM). First, the insertion efficiency and stability of the BAM-protein complex in a relatively inert liposomal bilayer (100% DPPC) was compared with those of the more reactive liposome (90% DPPC with 10% DPPE). Second, the effect of cholesterol content in the phospholipid bilayer on the insertion stability of BAM was investigated. Last, *in vitro* targeting and delivery performance of the proteoliposome to a breast cancer cell line was experimentally demonstrated.

EXPERIMENTAL PROCEDURES

Materials and Liposome Preparation. Both dipalmitoylphosphatidylcholine (DPPC) and dipalmitoylphosphatidylethanolamine (DPPE) was purchased from Avanti Polar Lipid, Inc., USA, and cholesterol (Chol) and dicetylphosphate (DCP) were from Sigma Aldrich, USA. All other chemicals used such as chloroform were of reagent grade. For liposome preparation, DPPC, cholesterol, and DCP were dissolved in a 64:30:6 molar ratio in 5 mL of chloroform and mixed in a 50 mL round-bottom flask. The mixture was evaporated under vacuum in a rotary evaporator to produce a thin lipid film. To thoroughly remove the residual chloroform, the lipid film was stored under vacuum overnight. Six milliliters of 10 mM PBS (pH 7.4) were added to the lipid film, which was then warmed at 45 °C for 10 min and finally peeled off the flask. The mixture was then subjected to 5 cycles of freezing (−70 °C) and thawing (45 °C). Finally, the liposome solution was extruded 15 times through a 200 nm polycarbonate membrane using a mini-extruder (Avanti Polar Lipids, USA).

BAM (Sunbright OE-080CS, NOF, Japan) was used as a postinsertion linker. BAM is commonly used to immobilize floating cells on a solid surface (*28*). Figure 1A shows its molecular schematics: It consists of an oleyl group as a hydrophobic membrane anchor at one end, an *N*-hydroxysuccinimide (NHS) group for protein conjugation at the other end, and they are connected by a linear PEG chain (molecular weight of ca. 3350 Da) for increased solubility and stealth effect. Because of its lipophilic interaction ability, the oleyl chain of BAM is expected to interact with the hydrophobic domains inside the phospholipid bilayers so as to be inserted into the liposomal bilayer.

To quantitatively determine the affinity between liposomal surface and BAM, a surface plasmon resonance system (BIACORE 3000, Biacore AB, Sweden) equipped with lipophilic L1 chip was used. Kinetic values such as the dissociation constant (k_d), association constant (k_a), and affinity constant (K_D) were evaluated.

Temperature Effect on BAM Insertion Efficiency and Stability of Inserted BAM. The BAM insertion efficiency into 100% DPPC liposome was compared with that of a more conventional liposome, i.e., 90% DPPC/10% DPPE. PE was traditionally used as a phospholipid component for the liposomes to be surface-modified by the amine coupling method (*29*). To determine the efficiency of surface modification and the stability of the inserted BAM, a fluorescent dye, Cy5 (Cy5-NHS ester, GE Healthcare, USA), was conjugated to BAM and the conjugate's fluorescence intensity was monitored by a confocal laser scanning microscopy (TCS SL, Leica, Germany). Since Cy5-NHS ester is known to readily react with amine group, the NHS group of the BAM (1 mg/mL) was converted into an amine group by 1.25 mM adipic acid dihydrazide (ADHZ) for 2 h at room temperature as described in Figure 1B. Unreacted ADHZ was removed by centrifugal membrane filtration (MWCO 3 kD, Microgon, USA) at 13 000 rpm for 15 min. Then, the aminated BAM was reacted with Cy5-NHS ester for 1 h at 25 °C in the dark (see Figure 1C). Unreacted Cy5-NHS ester was removed by the same centrifugal membrane filtration.

To identify the temperature effect on the surface modification and to confirm the positive effect of BAM as a postinsertion linker, the BAM-Cy5 conjugate was incubated with 100% DPPC liposome at 22, 32, or 42 °C, and Cy5-NHS ester itself was reacted with 90% DPPC/10% DPPE liposome at the same temperatures. The incubation time was 2 h in both cases. Unassociated BAM-Cy5 conjugate or unreacted Cy5-NHS ester was removed by the centrifugal membrane filtration (MWCO 10 kDa). Two microliters each of the BAM-Cy5 inserted DPPC and Cy5-reacted DPPC/DPPE were spotted on a glass slide and allowed to dry at room temperature. After 0 and 24 h incubation, Cy5 fluorescence intensity was measured by a fluorescence scanner (Genepix, Axon Instrument, Ontario, Canada). The wavelengths for the emission filter and excitation filter was 650 and 668 nm, respectively. The fluorescence intensity was analyzed and quantified by using the *ImageJ* program downloaded from the U.S. National Institutes of Health Web site (http://rsb.info.nih.gov/ij/disclaimer.html). The spot area was designated by determining the spot boundary (or edge), and the average fluorescence intensity was calculated by scanning the spot area by the *ImageJ* program.

Effect of Cholesterol Concentration on Stability of Inserted BAM. To monitor the effect of cholesterol concentration on stability of BAM insertion into the liposomal bilayer, the SPR sensor was used. Liposomes containing various cholesterol concentrations (0%, 10%, 20%, or 30%) were immobilized on L1 chips. The L1 chip contained lipophilic groups on its surface, in which intact liposomes were reported to be stably retained (*30*). PBS (10 mM, pH 7.4) was used as a running buffer. Each liposome solution was injected onto an L1 chip for 5 min at 10 μL/min flow rate. The chip was then washed with 50 mM NaOH for 1 min at 10 μL/min to remove free or weakly bound liposomes. BAM solution (1 mg/mL) in 10 mM PBS (pH 7.4) was injected to the liposome-immobilized chip for 1 min at 5 μL/min. From the sensorgrams, the association and dissociation constants between BAM and

liposome were evaluated by BIA evaluation software, assuming a 1:1 Langmuir binding model. All experiments were performed at 25 °C.

Encapsulation of Cy5 and Biofunctionalization with EGF-BAM Conjugate. To image and trace the liposomal targeting, Cy5-NHS ester was encapsulated inside the liposome. When rehydrating the lipid film, Cy5-NHS ester (2 mg) was added to 6 mL of 10 mM PBS (pH 7.4). The Cy5-encapsulated liposomes were separated from free or unreacted Cy5-NHS ester by gel permeation chromatography (Sephadex G-25, GE Healthcare, USA) using 10 mM PBS (pH 7.4) as an elution buffer.

Preparation of Proteoliposome. For the proteoliposome, epidermal growth factor (EGF) was used as a homing molecule to target the liposome to breast cancer cells since 20−30% of breast cancer cell lines overexpress human epidermal growth factor receptor (EGFR) on their surfaces (*31, 32*). Recombinant human EGF, a stable protein known to undergo receptor-mediated endocytosis (*33, 34*), was gifted from DaeWoong Pharmaceutical Co Ltd., Seoul, Korea. To biofunctionalize the liposome surface with EGF, three sequential steps were performed as follows: (1) BAM was first dissolved in 10 mM PBS (pH 7.4) to yield 1 mg/mL; (2) to form a BAM-EGF complex, 1 mg/mL of EGF solution was incubated with 1 mg/mL of BAM solution for 3 h at room temperature; and (3) for the postinsertion to the liposome surface, the BAM-EGF complex was incubated with the liposome for 2 h at room temperature.

In Vitro Active Targeting of Biofunctionalized Proteoliposomes. MDA-MB-231 mammary gland breast cancer cell line (Korean Cell Line Bank #30026) that overexpresses EGFR on its surface was used as the target cell line. MCF-7 mammary gland breast cancer cell line (Korean Cell Line Bank #30022), which does not express EGFR on its surface, was used as the negative control cell line. Both cell lines were propagated in DMEM supplemented with 10% FBS (fetal bovine serum), 100 IU/mL penicillin, and 100 IU/mL streptomycin (GIBCO, Belgium). The cells were incubated at 37 °C in humidified air containing 5% CO_2. Ca. 5×10^4 of MCF-7 and MDA-MB-231 cells were prepared on a coverslip in a 24 well plate 1 day beforehand. The medium was suctioned, and the cells were washed twice with 2 mL of 10 mM cold PBS for 5 min. Cy5-encapsulated liposomes of which the surface was modified with BAM-EGF complex (100 μg/mL) were incubated with MCF-7 and MDA-MB-231 cells for 1 h at 37 °C. Two milliliters of 3.7% paraformaldehyde were added for fixation and allowed to react for 15 min. The coverslip was washed 5 times with 10 mM PBS (pH 7.4) for 5 min. The interaction between Cy5-encapsulated liposome and the cell was monitored by the confocal laser scanning microscopy. The excitation wavelength was 488 nm, and the emission wavelength was 580−620 nm.

Preparation of Doxorubicin-Encapsulated Liposome. After confirming the targeting performance of the EGF-BAM inserted proteoliposome, its subsequent intracellular delivery performance was investigated by encapsulating doxorubicin inside the proteoliposome. Doxorubicin-HCl (6.5 mg) (Fluka, USA) was dissolved in methanol (11 mL) in a round-bottom flask, and the methanol was evaporated. Then, 21 mg of DPPC and 7.5 mg cholesterol in 5 mL chloroform were added to the dried doxorubicin, and the mixture was stirred to achieve a homogeneous solution, followed by chloroform evaporation. This doxorubicin-HCl concentration was reported to be sufficiently lethal to the cells (*35*). The flask was then placed into a vacuum desiccator for at least 12 h to ensure complete solvent removal. The dried lipid film was resuspended with 6 mL of 10 mM PBS (pH 7.4). The mixture was subjected to 5 freeze−thaw cycles and extruded 15 times through the 200 nm polycarbonate filter using the mini-extruder. The BAM-EGF complex was inserted into a doxorubicin-encapsulated liposome as described above. The free or unencapsulated doxorubicin was removed by the gel permeation chromatography (Sephadex G-25, GE Healthcare, USA) with 10 mM PBS (pH 7.4).

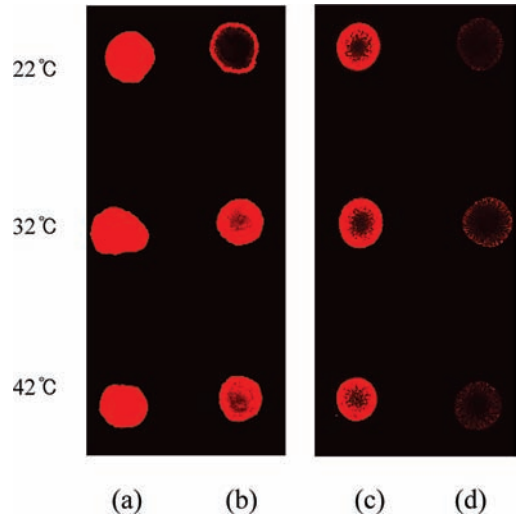

Figure 2. Temperature effect on efficiency and stability of the BAM-mediated liposome surface modification: (a) Cy5 conjugated to the 100% DPPC by the BAM-mediated modification immediately after the modification, (b) Cy5 conjugated to the 90% DPPC/10% DPPE by the conventional amine coupling immediately after the modification at 24 h after the modification, (c) Cy5 conjugated to the 100% DPPC by the BAM-mediated modification at 24 h after the modification, and (d) Cy5 conjugated to the 90% DPPC/10% DPPE by the conventional amine coupling at 24 h after the modification.

SYTOX Green (Invitrogen, USA) was used as a dye to visualize the cytotoxicity. The mixture of 0.1 μg/mL doxorubicin-encapsulated liposomes and 2.5 μM of SYTOX Green were incubated with MCF-7 and MDA-MB-231 cells for 1 h at 37 °C. Two milliliters of 3.7% paraformaldehyde were added and allowed to react for 15 min. The coverslip was washed 5 times with 10 mM PBS (pH 7.4) for 5 min. CLSM was used to check the toxicity of doxorubicin-encapsulated liposomes toward EGFR overexpressing breast cancer cells. The excitation wavelength was 488 nm for both SYTOX green and doxorubicin, and the emission wavelengths were 515−525 nm and 580−600 nm, respectively.

RESULTS

Effects of Temperature and Phospholipid on Efficiency and Stability of BAM Insertion. The effect of incubation temperature on the efficiency of the surface modification was evaluated at various temperatures (22, 32, and 42 °C). As shown in Figure 2a, the fluorescence densities of the Cy5-labeled BAM inserted into 100% DPPC liposomes were nearly the same with respect to the incubation temperature (82.8. 82.9, and 83.0 AU (arbitrary unit)/mm^2 for 22, 32, and 42 °C, respectively). However, the fluorescence intensity of the conventional amine coupling to 10% DPPE/90% DPPC varied with temperatures (27.8, 73.8, and 68.9/mm^2 at 22, 32, and 42 °C, respectively) (see Figure 2b). The result would suggest the superiority of the BAM-mediated surface modification over the amine coupling method.

The stability of the inserted BAM was evaluated by calculating the fluorescence intensity of the conjugated Cy5 at 24 h after the incubation by using the *ImageJ* program. As shown in Figure 2d, the fluorescence intensity by the conventional amine coupling method to 90% DPPC/10% DPPE decreased significantly from the initial intensity (by about 49%, 75%, and 76%

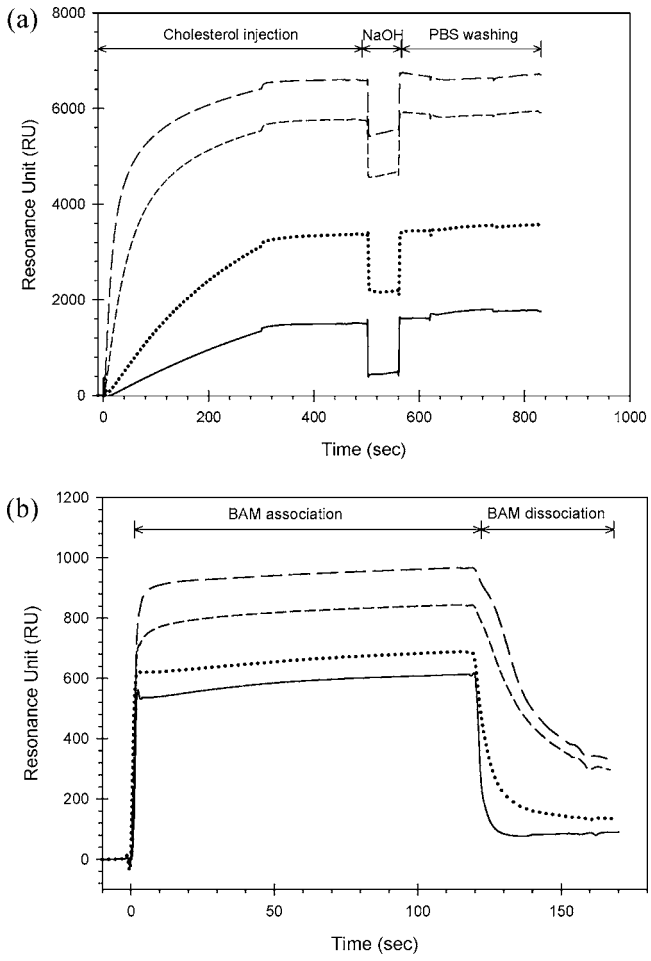

Figure 3. SPR sensorgrams to evaluate the affinity of BAM to liposome. (a) Immobilization of liposome at various cholesterol concentrations on L1 chip, and (b) association and dissociation curves of BAM to liposome containing various cholesterol concentrations. Solid line, 0%; dotted line, 10%; short dashed line, 20%; and long dashed line, 30% cholesterol concentration.

for 22, 32, and 42 °C, respectively). However, as can be seen in Figure 2c, the fluorescence intensity of the BAM-Cy5 conjugate inserted into 100% DPPC decreased much less from the initial density at 24 h after the immobilization (by about 23%, 23%, and 20% for 22, 32, and 42 °C, respectively). These results indicated that the BAM-mediated postinsertion could provide more stable attachment than the conventional amine coupling.

Effect of Cholesterol Concentration on BAM Insertion Stability. The kinetics as well as the amount of BAM insertion into the DPPC liposomes containing various cholesterol concentrations (0%, 10%, 20%, and 30%) was evaluated by using SPR. As shown in Figure 3a, as the cholesterol composition was increased, more liposomes were bound to the lipophilic L1 chip. Figure 3b shows the amount of inserted BAM also increased as the cholesterol concentration was increased. The amount of inserted BAM in liposomes was normalized by dividing the amount of inserted BAM by the amount of immobilized liposome (Table 1). The amount of inserted BAM per unit mass of liposome was similar regardless of the cholesterol concentration. Table 2 shows the kinetic values: K_a, K_d, and K_D. As the cholesterol concentration was increased, the association constant (K_a) increased while the dissociation constant (K_d) decreased. It indicated that at 30% cholesterol composition the BAM was readily inserted with high affinity and stability at even below the T_m of DPPC (41 °C).

Table 1. Effect of Cholesterol Composition in Liposome on BAM Insertion Efficiency

% cholesterol in DPPC	immobilized liposome [RU]	inserted BAM into liposome [RU]	normalized amount of inserted BAM per unit mass of liposome [−]
0	1612	109	0.068
10	3441	155	0.045
20	5910	307	0.052
30	6681	332	0.050

Table 2. Effect of Cholesterol Content in Liposome on BAM Association and Dissociation

% cholesterol in DPPC	K_a (M^{-1} s^{-1})	K_d (s^{-1})	K_D (mM)
0%	8.3	0.050	6.02
10%	490	0.079	1.63
20%	1270	0.036	0.03
30%	1650	0.033	0.02

Targeting Efficiency of Proteoliposome Biofunctionalized with BAM-EGF Complex. Figure 4 shows the schematics of a proteoliposome of which the surface is modified with BAM-EGF complex for targeting and the core is encapsulated with Cy5 dye for fluorescence tracing. For the proteoliposome to have targeting ability, the conjugated EGF should maintain its binding activity toward EGFR after the postinsertion step. To demonstrate the active targeting to EGFR expressed on the cell surface, the proteoliposomes biofunctionalized with BAM-EGF complex were incubated with MDA-MB-231 (EGFR-positive cell) or MCF-7 cells (EGFR-negative cell). As shown in Figure 5, the BAM-EGF inserted liposome was selectively targeted to the MDA-MB-231 cells, but not to the MCF-7 cells. After 1 h incubation, most liposomes were bound to the MDA-MB-231 cell surface on which EGFR was expressed.

To further demonstrate that the proteoliposome could be actually delivered into a cell, cytotoxic doxorubicin was encapsulated inside the same biofunctionalized liposome. Doxorubicin is a DNA interacting drug widely used in cancer chemotherapy. As a cell viability probe, SYTOX Green, a nucleic acid dye, was used. It was used to image only dead cells, since it could easily penetrate plasma membranes of weak or damaged integrity yet could not cross the membranes of healthy live cells. As shown in Figure 6b,e, doxorubicin was taken up and distributed only in the MDA-MB-231 cells and not in MCF-7 cells. The SYTOX green fluorescence was detected also only in the MDA-MB-231 cells, which indicated that most of the MDA-MB-231 cells were not viable (Figure 6f). In contrast, Figure 6c shows no intracellular green fluo-

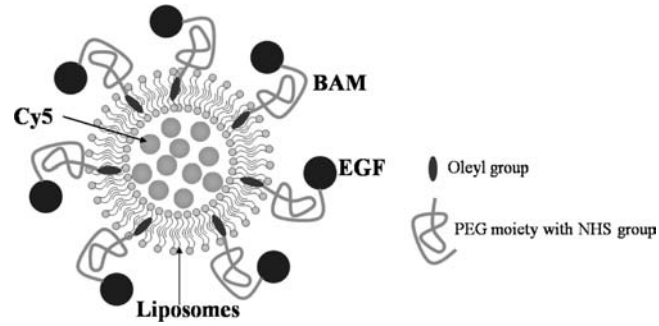

Figure 4. Schematic diagram of proteoliposome biofunctionalized with BAM-EGF complex. Cy5 was encapsulated inside the liposome for fluorescence tracing. EGF was conjugated at the end of the BAM by reacting with NHS group. The PEG moiety connects the EGF and oleyl groups. BAM-EGF conjugate was inserted only into the outside of the liposome by lipophilic interaction between oleyl group and phospholipids.

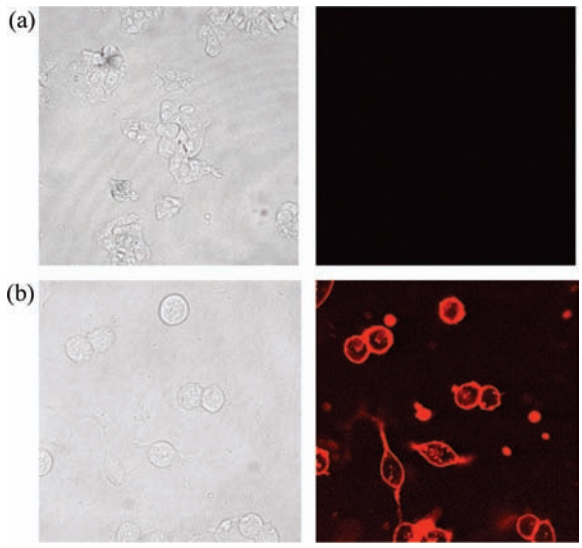

Figure 5. Microscopic images of active cell targeting by the BAM-EGF inserted proteoliposome to breast cancer cells: (a) MCF-7 cells (EGFR-negative), (b) MDA-MB-231 cells (EGFR-positive). Transmitted images are on the left side, and fluorescent images are on the right side. Cy5 was encapsulated inside the liposome. Liposome was incubated with each cell line for 1 h at 37 °C, and a fluorescent image was taken by confocal laser scanning microscopy (λ_{ex} = 488 nm, λ_{em} = 580−620 nm).

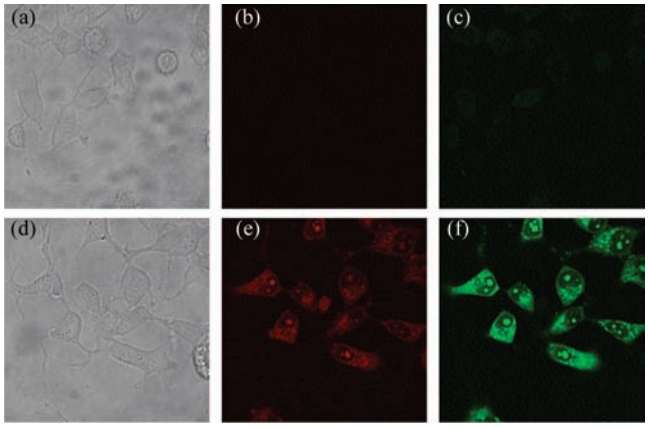

Figure 6. Cytotoxicity evaluation of doxorubicin-loaded, BAM-EGF inserted liposomes by confocal microscopy (λ_{ex} = 488 nm, λ_{em} for doxorubicin = 580−600 nm, λ_{em} for SYTOX green = 515−525 nm). Doxorubicin-loaded proteoliposome was incubated with (a−c) MCF-7 cells, (d−f) MDA-MB-231 cells. (a,d) transmitted image, (b,e) doxorubicin fluorescent image, (c,f) SYTOX green fluorescent image.

rescence, meaning that the EGF-BAM complex liposome was not targeted to MCF-7 cells.

DISCUSSION

The surface modification efficiency and stability of BAM inserted into 100% DPPC liposome were compared with those of a more conventional liposome surface, i.e., 90% DPPC/10% DPPE. PE that contains a primary amine as a reactive group in the amine coupling method was traditionally used as a phospholipid component of liposomes to be surface-modified by the amine coupling method (*29*). In addition, it was reported that the PE composition of 10% was commonly used to prepare the liposomes for surface activation (*27, 36*). Our experimental data clearly indicated that the BAM-mediated modification was superior to the traditional amine coupling to PE. Also, incubation temperature did not influence the BAM insertion into the 100% DPPC. Considering that the T_m (melting point) of DPPC is 41 °C, the result suggested that the BAM's oleyl group was inserted well even below the T_m, which in turn suggested that the insertion was little affected by the fluidity or rigidity of the liposomal bilayer. Dioleylphosphatidylethanolamine (DOPE) with unsaturated chains would have increased the fluidity over DPPE. However, in this study, we used DPPE with saturated chains for the following reasons: First, we intended to focus on the direct comparison between the relatively less reactive choline in DPPC and more reactive ethanolamine in DPPE. Second, DPPE at 10% composition is frequently used to prepare liposomes for surface modification. Furthermore, the T_m of DOPE is 10 °C, so it was not suited as a phospholipid for targeting liposome at the physiological temperature.

The 24 h stability of the inserted BAM was much higher than amine coupling modification. Since the bilayer of 90% DPPC/10% DPPE liposome was supposedly more rigid than 100% DPPC liposome, this result can be compared with a previous report, in which the insertion stability of the tresylated PEG-sterol anchor was dependent on the liposome fluidity (*27*); rigid liposome showed about 40% stability of that of flexible liposome. In addition, while the previous postinsertion methods required incubation at 55−60 °C (*14, 24, 26*), the BAM-mediated postinsertion can be accomplished at room temperature with good stability. Thus, it can serve as a more effective method to biofunctionalize the liposome surface with temperature-sensitive proteins.

Cholesterol has a pronounced effect on the physical properties of membranes, particularly on the structure, fluidity, and permeability of the phospholipid bilayer. Cholesterol has several beneficial effects on liposome rigidity, resulting in increased retention of water-soluble drugs, prevention of lipid phase transitions, and increased resistance against *in vivo* liposomal degradation (*16, 37*). Our data strongly indicated that the higher the cholesterol concentration in the liposomal bilayer, the higher the BAM insertion efficiency and stability. It suggested that the presence of cholesterol would intensify the packing of phospholipids so as to enhance the stability of the inserted BAM. However, the "specific" BAM insertion, i.e.., the amount of BAM inserted into the unit mass of liposome, was little affected by the cholesterol concentration among 0%, 10%, 20%, and 30%.

For the proteoliposome to be targeting, the conjugated homing protein molecule should maintain its binding activity after the postinsertion step. We demonstrated it by monitoring the targeting ability of the postinserted EGF toward the EGFR on the cell surfaces. The fluorescence tracing clearly showed that the proteoliposome biofunctionalized with BAM-EGF complex could be selectively targeted to the EGFR-expressing cells. However, it took a longer time (about 1 h) for the BAM-EGF biofunctionalized liposomes to bind to the MDA-MB-231 cell surface than the liposomes modified with anti-EGFR antibody (about 30 min) (*38*). This is probably because the PEG moiety of the BAM not only induced the protective stealth effect but also decreased the targeting yield.

Since intracellular delivery is another important function of a proteoliposome, we encapsulated DNA interacting doxorubicin inside the proteoliposome and monitored its cytotoxic effect by using a nucleic acid dye, SYTOX Green. The result indicated that the proteoliposome was successfully endocytosed into a cell and released the encapsulated doxorubicin. This result of selective targeting followed by endocytosis is in agreement with the reported observation that the immunoliposomes biofunctionalized with anti-EGFR antibody via maleimide group showed ca. 27-fold higher cytotoxicity toward EGFR expressing cells than those lacking EGFR expression (*38*). We did not determine the degree of cytotoxicity; however, our data clearly

demonstrated the effectiveness of the postinsertion proteoliposome as an intracellular delivery vehicle.

CONCLUSION

Sterically stable, ligand-targeted liposomes were prepared by postinsertion modification using BAM as a linker. By measuring the fluorescence density of Cy5 bound to the liposome surface, we showed that the modification efficiency of BAM-mediated biofunctionalization as well as the stability of the inserted BAM was clearly higher than those of the conventional amine coupling method. The amount of BAM insertion increased with an increase in the cholesterol composition in the liposomal bilayer; however, the "specific" binding affinity of BAM was little affected by the cholesterol composition. By using a fluorescence marker, we confirmed the selective and active targeting of the BAM-EGF-modified liposome to the EGFR overexpressing MDA-MB-231 cells. Furthermore, the doxorubicin-loaded proteoliposome biofunctionalized with EGF showed distinct cytotoxicity only to the MDA-MB-231 cells. It clearly indicated that the EGF maintained its binding bioactivity after the postinsertion. To our knowledge, this is the first report of employing the postinsertion method to obtain a proteoliposome of which the surface was biofunctionalized with both PEG moiety and a protein homing molecule.

Comparing Lipid Photo-Cross-linking Efficacy of Penetratin Analogues Bearing Three Different Photoprobes: Dithienyl Ketone, Benzophenone, and Trifluoromethylaryldiazirine

Chen-Yu Jiao, Isabel D. Alves, Vanessa Point, Solange Lavielle, Sandrine Sagan, and Gérard Chassaing*

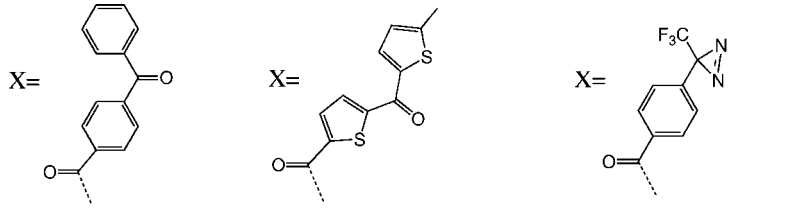
UPMC Paris 06 - ENS - CNRS, UMR 7203, Laboratoire des BioMolécules, FR 2769 Chimie Moléculaire, Université Pierre et Marie Curie, Case courier 182, 4, Place Jussieu, 75252 Paris Cedex 05, France. Received October 26, 2009; Revised Manuscript Received January 4, 2010

Photoactivatable penetratin analogues bearing three different photoprobes, which do not disturb the membranotropic properties of the peptides, have been tested for their photo-cross-linking efficacy in glycerol and lipid media. In the case of glycerol, photo-cross-linking was observed, whereas in the case of SDS (used as a membrane model system), the dynamics of the SDS/penetratin assemblies and the photosensitizer properties of the probes prevented the cross-linking between the peptide and SDS. Bilayers of DMPG were partially photo-cross-linked by the penetratin analogues containing either a benzophenone or a trifluoromethylaryl-diazirine, whereas dithienyl ketone acted exclusively as a photosensitizer. The characterization by MALDI-TOF mass spectrometry of the photoadducts formed after irradiation required basic hydrolysis of DMPG for an efficient capture of the biotinylated peptide analogues with streptavidin-coated magnetic beads. MALDI-TOF analysis of the photoadducts between the photoactivatable penetratin and DMPG allowed an unambiguous identification of the covalent bond formed with the lipids. Altogether, we show herein that the efficacy of the lipid photo-cross-linking depends on the environment, the dynamics of the supramolecular assembly, and the physicochemical properties of the photoprobe.

INTRODUCTION

The formation of a covalent bond, after irradiation of a photoactivatable molecule, is a commonly used strategy for linking ligands to both hard and soft surfaces (*1*−*3*). For that purpose, four types of photoactivatable aryl reagents are mainly used: aryldiazonium salts, diazoaryl, trifluoromethylaryldiazirines, and phenylketone (*4*). To study by photolabeling the interaction topography between a ligand and its protein partner, the specifications are more stringent, since the photoactivatable probe should be located in the immediate vicinity of the binding domain and, upon irradiation, should form promptly a covalent bond with the protein (*5*). The bioconjugated construct possesses different "moieties". A peptide ligand usually includes an adequately positioned photoprobe in its sequence, together with a recognition moiety (e.g., biotin) used to purify the covalent complex from the incubation mixture (*6*). The tricky step is often the correct rational design of a ligand that retains a high and specific affinity for the protein partner.

Upon irradiation, the photoactivatable probe is transformed into a highly reactive radical species that can abstract a hydrogen atom present in its close environment within the protein binding site. Thus, an important aspect to consider is the reactivity of the chosen photoreactive probe, which must lead to molecular species reactive enough within the time scale of the ligand−protein complex half-life time. Generally, the binding affinity of peptide ligands for their receptor is high (in the nanomolar range), corresponding to formation of complexes with a half-life time in the minutes range. This corresponds to a much longer time than what is mostly observed for reactive species ($t_{1/2}$ values around microseconds or shorter). Even in "host−guest" complexes such as benzophenone/cyclodextrin or transmembrane peptide/phospholipids in which the affinity is low ($t_{1/2}$ value around milliseconds), the irradiation-assisted cross-linking was not inhibited (*7*, *8*). The confinement of the reactive species and the "freezing" of internal movements of both the ligand and the receptor (or guest molecule) within these complexes restrain the intrinsic mobility of both molecules. Thus, it is believed that the covalent bond formation likely represents a snapshot of the interaction.



The goal of the present study was to test the feasibility and the limitations of photochemistry in the analysis of the interaction(s) of a cationic peptide with a highly dynamic system, such as plasma membranes constituted of a large range of molecular components and supramolecular assemblies. Plasma membranes are considered a mosaic of coexisting domains: the fluid lipid matrix in disordered phase, lipid ordered domains (rafts), nanodomains associated with different types of proteins (caveolins, clathrin, actin, receptors, protein channels, etc.) and some transient confinement zones (*9*, *10*). The overall dynamic of this mosaic is considered to occur in the nano- to milliseconds time scale (*11*). However, if one considers the rotation around a C−C bond or along the membrane axis and the aliphatic chain wobbling in the disordered phase, the correlation times of phospholipids greatly vary from 10^{-12} to 10^{-7} s. The correlation time for the lateral diffusion is greater than 10^{-5} s and supramolecular assemblages occur starting from very small rafts (diameter <10 nm) to larger ones (from 30 to 230 nm) in time scales of 10^{-3} s (*12*, *13*). Photoactivatable lipids have been used to probe the interaction within lipids (*14*). Modifications of lipids by highly reactive radicals, such as oxygen-derived species, have also been reported (*15*). Herein, we address the question of the photochemistry strategy as a reliable method to study peptide/lipid interaction.

Penetratin, (corresponding to helix-3 of Antennapedia homeodomain: Arg-Gln-Ile-Lys-Ile-Lys-Phe-Gln-Asn-Arg-Arg-Met-Lys-Trp-Lys-Lys), is a cationic membranotropic peptide,

a prototype of cell-penetrating peptide, which is able to enter eukaryotic cells without cytotoxity, and which presents antimicrobial activities in some prokaryotic cells (*16, 17*). Even if parallel orientations of penetratin to bilayer were clearly established by various biophysical methods, a direct translocation has been shown as one of the entry mechanism of penetratin in eukaryotic cells (*18*). As Trp48 was found located in the hydrophobic area of phospholipids (*19, 20*), we have substituted this residue by an acylated lysine on the side-chain with three different photoprobes: phenylketone, dithienylketone, or trifluoromethylaryldiazirine (Scheme 1). As we have already described for other studies (*18, 21*−*23*), these photoactivatable penetratin analogues were also functionalized with biotin, separated from the penetratin sequence by a spacer of four glycines, which allows an easy purification through streptavidin-grafted magnetic beads before MALDI-TOF mass spectrometry analysis. The influence of the different photoprobes on the membranotropic properties of penetratin has been analyzed by monitoring their effect on lipid phase transition using differential scanning calorimetric (DSC). Since electrostatic interactions have been shown to play an important role in lipid interaction with penetratin (*24, 25*) large multilamellar vesicles (MLVs) made of dimyristoylphosphatidylglycerol (DMPG) were used as models of the highly dynamic cell membrane. The photochemical behavior of the different peptide analogues has been analyzed in water, glycerol, and sodium dodecyl sulfate (SDS) as models of aqueous, polar headgroups and lipophilic environment of the membrane, respectively. DMPG MLVs were irradiated with the photoactivatable analogues (above the phase transition temperature) and the resulting photoadducts analyzed by mass spectrometry to compare their cross-linking efficacy.

EXPERIMENTAL PROCEDURES

DMPG was purchased from Genzyme (Switzerland) and was used without further purification. 4-Carboxybenzophenone and 4-(trifluoroacetyl)benzoic acid were purchased from Aldrich and Apollo Scientific Limited, respectively. The 5-carboxy-5′-methyl-2,2′-dithienylketone was a generous gift, from the "Laboratoire d'Ingénierie Moléculaire et Biochimie Pharmacologique", Université Paul Verlaine, Metz, France.

Syntheses of Photoactivatable Probes. *4-[1-(trifluoromethyl)-3H-diazirinin-3-yl]benzoic Acid.* The synthesis of 4-[1-(trifluoromethyl)-3*H*-diazirinin-3-yl]benzoic acid was based on a series of reactions already used for this type of photoprobes (*26, 27*).

4-(trifluoroacetyl)benzoic tert-Butyl Ester **1.** 4-(Trifluoroacetyl) benzoic *tert*-butyl ester **1** was prepared from *tert*-butyl alcohol and 4-(trifluoroacetyl)benzoic acid using anhydrous magnesium sulfate and sulfuric acid. To a suspension of $MgSO_4$ (92 mmol) in CH_2Cl_2 (100 mL), H_2SO_4 (23 mmol) was added dropwise After 15 min of stirring, *tert*-butyl alcohol and 4-(trifluoroacetyl)benzoic acid were added. The mixture was stirred for two days and the reaction was quenched by addition of saturated $NaHCO_3$ (170 mL). The extraction with CH_2Cl_2 led to 10 mmol of pure 4-(trifluoroacetyl)benzoic *tert*-butyl ester. R_F (cyclohexane/ethyl actetate, 8/2) = 0.3. ^{1}H NMR ($CDCl_3$), δ: 1.62 (s, 9H), 8.13 (s, 4H). The unreacted starting material was recovered after acidification of the aqueous phase and extraction with CH_2Cl_2.

4-(2-Trifluoroethanoneoxime)benzoic tert-Butyl Ester **2.** To a stirred mixture of hydroxylamine hydrochloride (8 mmol) and NaOH (8 mmol) in 33 mL of boiling ethanol, compound **1** (8 mmol in EtOH, 4 mL) was added dropwise. After refluxing for 3 days, ether was added, and the organic layers were washed with 0.01 N HCl (3×) and with water (3×). R_F ($CHCl_3$) = 0.25. ^{1}H NMR ($CDCl_3$), δ: 1.6 (s, 9H), 7.59 (d, 2H), 8.10 (q, 2H), 8.38 (s, broad 1H).

4-(2-Trifluoroethanone-O-(p-tolylsulfonyl)oxime)benzoic tert-Butyl Ester **3.** A mixture of compound **2** (19 mmol) and of *p*-sulfonyl chloride (38 mmol) in dry pyridine (30 mL) was refluxed for 3 days. After solvent evaporation, the pure product (yield 73%) was obtained after flash chromatography, (cyclohexane/ethyl acetate, 95/5). R_F ($CHCl_3$) = 0.66. ^{1}H NMR ($CDCl_3$), δ: 1.6 (s, 9H), 2.48 (s, 3H), 7.41 (t, 4H), 7.86 (d, 2H), 8.06 (d, 2H).

4-(Trifluoromethyldiaziridine)benzoic tert-Butyl Ester **4.** Compound **3** (2 mmol) was introduced in a Parr Instrument of 0.3 L capacity, then liquid ammonia (20 g) was condensed after cooling the autoclave in liquid nitrogen for 15 min. The mixture was stirred for two days. After evaporation, the pure product (yield 88%) was obtained after flash chromatography using CH_2Cl_2. R_F ($CHCl_3$) = 0.5. ^{1}H NMR ($CDCl_3$), δ: 1.6 (s, 9H), 2.25 (d, 1H), 2.80 (d, 1H), 7.58 (d, 2H), 8.05 (d, 2H).

4-[1-(Trifluoromethyl)-3H-diazirinin-3-yl]benzoic tert-Butyl Ester **5.** Compound **4** (1 mmol) was mixed with freshly prepared Ag_2O (5 mmol). After stirring for 3 h in the dark, the mixture was filtered on Celite and purified by flash chromatography using cyclohexane. R_F ($CHCl_3$) = 0.75. ^{1}H NMR ($CDCl_3$), δ: 1.59 (s, 9H), 7.24 (d, 2H), 8.01 (d, 2H).

4-[1-(Trifluoromethyl)-3H-diazirinin-3-yl]benzoic Acid **6.** Compound **5** (10 mmol) was stirred with TFA (50 mmol) in CH_2Cl_2 (10 mL). The reaction was completed after two hours stirring, leading after usual workup to compound **6**. R_F ($CHCl_3$) = 0.2. ^{1}H NMR (DMSO), δ: 7.40 (d, 2H), 8.06 (d, 2H), 13.34 (s, 1H).

Synthesis of Penetratin Analogues. The penetratin analogues [Lys^{48}(Bz)]Penetratin, [Lys^{48}(DTK)]Penetratin, and [Lys^{48}(TMD)]-Penetratin abbreviated as Pen(Lys48Bz), Pen(Lys48DTK), and Pen(Lys48TMD), respectively, and modified on Lys48 (number 48 corresponding to the Trp position in the sequence of the *Antennapedia* homeodomain (*28*) were synthesized by solid-phase methodology on a ABI 431 Synthesizer, using either a Rink amide resin or Rink amide MBHA resin by Fmoc or Boc strategies, respectively. Lys48 side chain was protected either by Fmoc or Dde protecting groups for the Boc and Fmoc strategies, respectively. After selective removal of the protecting group, the free amine of Lys48 was acylated either by 4-carboxybenzophenone, 5-carboxy-5′-methyl-2,2′-dithienylketone or 4-[3-(trifluoromethyl)-3*H*-diazirinin-3-yl]benzoic acid, using DCC/HOBt for the activation. The subsequent Ile45 was then introduced manually. The other amino acids were coupled on the synthesizer using standard protocols of Boc and Fmoc chemistries and amino acid activation with DCC/HOBt in NMP. After removal of the last protecting group from the N-terminal glycine, the peptides were biotinylated in NMP, as already described (*18*, *21*−*23*). The resins were washed with NMP, CH_2Cl_2, and MeOH and dried under vacuum. The peptides were cleaved from the resin with TFA/H_2O/TIS (Fmoc strategy) (95/2.5/2.5) or HF/anisole (Boc strategy). The crude peptides were lyophilized and purified by RP-HPLC. The peptides were characterized by MALDI-TOF mass spectrometry leading to *m*/*z* 2864 for Pen(Lys48Bz), 2908 for Pen(Lys48DTK), and 2886 for Pen(Lys48TMD).

Differential Scanning Calorimetry. The calorimetry was performed on a high-sensitivity differential scanning calorimeter (Calorimetry Sciences Corporation). A scan rate of 1 °C/min was used, and there was a delay of 10 min between sequential scans in a series that allow for thermal equilibration. Data analysis was performed with the fitting program *Cpcalc* provided by CSC and plotted with *Igor*. DMPG (1 mg/mL) was used at peptide/lipid ratio of 1/25. Samples containing the peptide alone, dissolved in buffer at similar peptide concentrations, exhibited no thermal events over the temperature range 0−100 °C. This indicates that the peptides do not denature over this temperature range and that the endothermic events observed in this study arise solely from phase transitions of the phospholipid vesicles. A minimum of at least three to four heating and cooling scans were performed for each analysis depending on whether or not the spectra was reproducible.

Photolabeling. The sample of Pen(Lys48Bz), Pen(Lys48DTK), or Pen(Lys48TMD) dissolved at micromolar concentration in water or glycerol (500 μL) was irradiated on ice for 1 h at 365 nm with an UV light (HPR 125-W) located between 6 to 10 cm from the Eppendorf tube corresponding to a surface area of 0.39 cm^2. Then, 1 μL of the irradiated sample was deposited on the sample holder for direct MALDI-TOF mass spectrometry analysis.

DMPG (1 μM in 20 mM ammonium acetate buffer at pH 7.5) was mixed with Pen(Lys48Bz), Pen(Lys48DTK), or Pen(Lys48TMD) at 1/10 peptide/lipid ratio. Theses samples were irradiated on ice for 1 h, under the conditions described above, followed by a basic hydrolysis in MeOH/H_2O (50/50) using NaOH (0.1 M) at 37 °C overnight. After neutralization with acetic acid, the methanol was evaporated before affinity purification.

Purification with Streptavidin-Coated Magnetic Beads. The hydrolyzed sample containing 0.1% of Triton was incubated with streptavidin-coated magnetic beads (100 μg, Dynabeads M280, Dynal) for 30 to 60 min under gentle agitation. The washing steps (5× each) were performed with (1) buffer (Tris pH 7, 50 mM) containing 0.1% SDS, (2) 50 mM Tris pH 7, (3) NaCl 1 M, and (4) H_2O/ACN 50/50. The same procedure was used for the experiments performed in SDS, excepted that no Triton was added during the incubation step.

MALDI-TOF Mass Spectrometry Analysis. The photoadducts were eluted from the magnetic beads with the 2,5-dihydroxybenzoic acid (DHB) matrix, in 1:1 (v/v) CH_3CN/H_2O (1% phosphoric acid) used for MALDI analysis. After 10 min incubation, 1 μL of bead-free supernatant was deposited on the sample holder.

Quantification by MALDI-TOF Mass Spectrometry. After irradiation in glycerol of deuterated Pen(Lys48Bz) (penetratin analogue with four deuterated glycines), a known amount (2 nmol) of hydrogenated Pen(Lys48Bz) (with four 1*H*-glycines) was added to the medium. The photoadduct was then purified by incubating the mixture with streptavidin-coated magnetic beads for 30 to 60 min under gentle agitation. After elution of all biotinylated peptides (photoadduct or free peptide) with the matrix as described above, 1 μL of bead-free supernatant was deposited on the sample holder. The ratio of the ^{1}H/^{2}H MH+ *m*/*z* signals allowed the quantitative determination of the starting peptide that remained intact after irradiation.

RESULTS

Hydrophobic Character of Penetratin Analogues. The modification of the hydrophobic/hydrophilic balance induced by the photoprobes on the behavior of these penetratin analogues can be related to the concentration of acetonitrile required to elute the corresponding peptides by HPLC (in mixture of acetonitrile water 0.1% of TFA). The concentrations required correspond to 32.4% CH_3CN for Pen(Lys48Bz), 21.5% CH_3CN for Pen(Lys48DTK), and 32% CH_3CN for Pen(Lys48TMD), leading to the following hydrophobic scale: Pen(Lys48DTK) > Pen(Lys48Bz) ≈ (Lys48TMD).

Effect of the Medium on the Photochemical Properties of the Different Photoprobes. Ammonium acetate buffer, glycerol, and sodium dodecyl sulfate (SDS) were used as models of the membrane interface. The crude products obtained after irradiation (1 h) at 365 nm of these photoactivatable penetratin analogues within one of the media were analyzed by MALDI-TOF mass spectrometry. As already observed for peptides containing benzophenone, the Pen(Lys48Bz) analogue was mainly unaffected by irradiation in ammonium acetate buffer. Pen(Lys48DTK) was strongly oxidized as a consequence of the irradiation, MALDI-TOF spectra showing the incorporation of one to four oxygen atoms. Pen(Lys48TMD) was nearly totally oxidized but with the incorporation of a single oxygen atom (+16).

The polar heads of phospholipids represent a borderline between two media, with a high dielectric constant (ε = 80, i.e., the aqueous phase) and a low dielectric constant (ε = 3, i.e., the lipid phase). This interface can be mimicked by glycerol (ε = 40). Glycerol adducts were efficiently formed with Pen(Lys48Bz), since a signal with a mass increase of 92 was observed. The signal intensity of the photoadduct was shown to increase as a function of the irradiation time (Figure 2). The disappearance as a function of time of the starting peptide Pen(Lys48Bz) (bearing four deuterated glycines) was quantified by addition after the irradiation of an internal standard (2 pmol) of Pen(Lys48Bz) (bearing four hydrogenated glycines) (*21*). The intact peptide remaining after irradiation was measured by integrating the ^{1}H and ^{2}H *m*/*z* signals (2864.3 and 2872.4, respectively), revealing an almost linear decrease of the starting material (Figure 2) as a function of the irradiation time. In the case of Pen(Lys48TMD), a mass increase of only 90, instead of 92, was observed, which probably resulted from the alcohol oxidation of the glycerol adduct. For Pen(Lys48TMD), the starting peptide and the photoadduct coexisted with the mono- and dioxidized forms. Weak signals were detected for Pen(Lys48DTK)

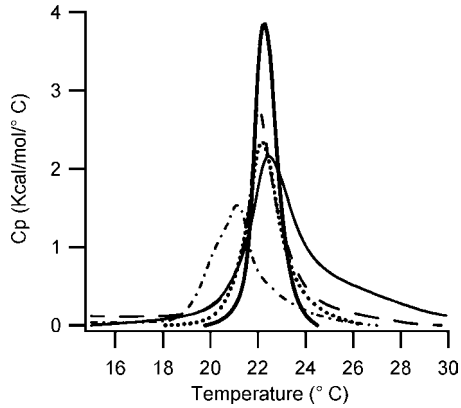

Figure 1. High-sensitivity DSC heating scans. The spectra illustrate the effect of adding penetratin (-•-) and penetratin photoactivatable analogues: Pen(LysBz) (••••), Pen(LysDTK) (- -), and Pen(LysTMD) (—) on the thermotropic phase behavior of DMPG multilamellar vesicles (— bold) at P/L of 1/25. Thermodynamic parameters are given in Table 1.

with a limited number of oxidized states compared to those observed in aqueous solution.

Finally, the reactivity of the photoactivatable penetratin analogues in a lipophilic medium was mimicked by photoirradiation of the peptides in SDS solution. In that environment, very low levels of cross-linking were detected, regardless of the photoprobe used. A small photoadduct signal was only observed for Pen(Lys48TMD). However, a high percentage of peptide oxidation was observed after irradiation under these conditions.

Analysis of the Photoadducts Obtained after Irradiation of Peptides with Phospholipid Bilayers. No photoadduct was observed by mass spectrometry after irradiation of DMPG vesicles in the presence of photoactivatable penetratin analogues, both using a crude preparation and after the purification step with streptavidin-coated magnetic beads. In order to observe photoadducts, the lipid moiety (hydrophobic character) of the adducts had to be removed by basic hydrolysis, which was performed overnight with NaOH (0.1 mol/L) in MeOH/H_2O (50/50) at 37 °C, followed by neutralization with acetic acid. MALDI-TOF mass spectrometry analysis was performed after a subsequent capture with streptavidin-coated magnetic beads in the presence of Triton X-100 (0.1%), followed by the described washing procedure and elution using the 2,5-dihydroxybenzoic acid matrix (*21*).

Photolabeling experiments with Pen(Lys48Bz) (2864.1) and DMPG vesicles led to three pairs of signals: one pair (3092.3 and +16) corresponding to photoadduct with the myristoyl and its oxidized form (+ 228 and + 244, respectively); another pair (2922.1 and +16) that was assigned to the dehydrated form of glycerol adducts formed during the basic treatment, and the third pair corresponding to the starting peptide and its oxidized form. Similar behavior and photoadducts were observed with Pen(Lys48TMD). Besides the oxidized form of Pen(Lys48TMD), previously observed in ammonium acetate buffer, two pairs of signals were detected, corresponding to mass increases of 228 and 72, which were assigned to photoadducts of myristoyl and oxidized/dehydrated glycerol, respectively. Finally, only degraded (low-molecular weights) forms of Pen(Lys48DTK) were detected after irradiation with DMPG vesicles (Figure 3).

Effect on the Organization of the Phospholipid Bilayer. DSC is used to study peptide/lipid interaction by monitoring the ability of peptides to interact and perturb the lipid acyl chain packing (Figure 1). A lipid bilayer composed of a single phospholipid, in the presence of water excess, can undergo two phase transitions upon heating: pretransition and main phase transition occurring at phase transition temperatures T_p and T_m (*29*). The peak area corresponds to the enthalpy of the phase transitions and the $\Delta H/T_m$ ratio to the entropy change. The main phase transition is related to the chain melting during the gel-to-liquid-crystalline phase change, whereas the pretransition reflects changes in headgroup tilting and organization.

In agreement with previous studies, the addition of the cationic peptide, penetratin, to anionic DMPG phospholipids suppressed the pretransition temperature and decreased both the enthalpy and the phase transition temperature (T_m) of the main lipid transition (*30*). One would expect that the introduction of hydrophobic probes in penetratin might promote the insertion of the peptide into the lipid fatty acid chains and so lead to an increased perturbation in the lipid phase transition. This was not the case; indeed, the photoactivatable probes did not significantly change the T_m and overall led to a smaller perturbation in the main phase transition compared to the original penetratin peptide. When comparing the three photoactivatable analogues, Pen(Lys48DTK) perturbed least the pretransition (that was not completly abolished) and main phase transition, leading to a very small reduction in the enthalpy of transition (Table 1). Altogether, the results demonstrate that the introduction of the photoactivatable probes in penetratin did not perturb the overall membranotropic properties of the peptide.

DISCUSSION

All experiments were performed in air-saturated water, in order to mimic the cellular environment. It has to be noted that, in the experiments described herein, 10 nmol of peptide was irradiated in the presence of about 90 nmol of oxygen (air-saturated water). Oxygen or water must be the first source(s), which might prevent the bimolecular photo-cross-linking of the photoactivated probes. The lifetime of the benzophenone triplet is 1.5 μs in air-saturated water, and much longer (20 μs) in degassed water (*31*). Oxygen efficiently quenches the benzophenone triplet by energy transfer, leading to the reactive singlet oxygen species with a short lifetime 4.2 μs in water (*32*), and its deactivation occurs by light emission and electronic-to-vibrational energy transfer and by intermolecular interaction with specific amino acids such as Phe or Trp, which are both present in penetratin (*33*). The benzophenone triplet can also be quenched by intra- or intermolecular interactions, by charge transfer, hydrogen abstraction, or light emission. However, all these reactions are fast and reversible, with the exception of the hydrogen abstraction step. The concentrations of the two active forms, i.e., the ketone triplet and the singlet oxygen, must be low under the irradiation conditions used herein, since the consumption of the starting peptide is slow (total disappearance occurs in over 2 h under permanent irradiation). For the dithienyl ketone triplet in air-saturated water, a large proportion of oxidized forms was observed showing that the singlet oxygen concentration must be much higher than for the benzophenone triplet. The carbene generated from trifluoromethylaryldiazirines has a very short lifetime ($t_{1/2} \approx$ ns) (*34*) because it reacts rapidly and irreversibly with oxygen. However, this competitive reaction with oxygen does not totally prevent the hydrogen abstraction, which can either occur intra- or intermolecularly.

With the benzophenone-substituted penetratin analogue, we have shown that the gradual decrease as a function of time up to the total disappearance of the starting peptide is slow. The intermolecular self-reaction is unlikely since no dimer was observed by MALDI-TOF MS (data not shown). The intramolecular reactions (hydrogen abstraction and radical combination) leading to cyclic peptides cannot be excluded with the techniques used. Photo-cross-linking with other species has already been reported for hydrophobic molecules (peptides, fatty acids,

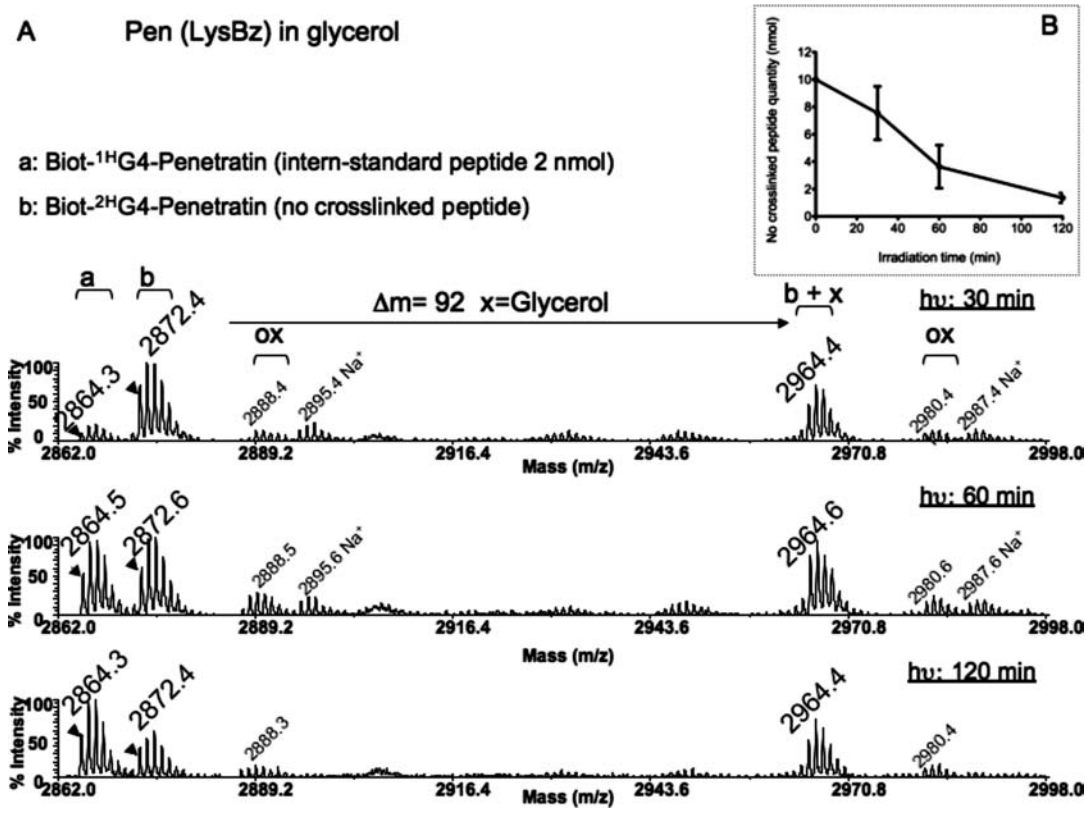

Figure 2. Quantification of remaining Pen(Lys48Bz) by MALDI-TOF mass spectrometry, after different irradiation times (30, 60, and 120 min irradiation) in glycerol. Insert top right, quantification of the areas of B vs A. A corresponds to 2 pmol of the peptide with four hydrogenated glycines added after the irradiation as an internal standard, the irradiation being performed with the same peptide bearing four deuterated glycines; *m*/*z* correspond to peaks B. For the capture by streptavidin-coated magnetic beads and the detection by MALFDI-TOF mass spectrometry as described in the experimental section.

Table 1. Thermodynamic Parameters Obtained by DSC for the Interaction of Penetratin and Its Photoactivatable Analogues with DMPG MLVs at P/L of 1/25

	pretransition		main transition	
	ΔH (kcal/mol)	T_p (° C)	ΔH (kcal/mol)	T_m (° C)
lipid alone	0.4	9.6	6.2	22.3
penetratin	−[a]	−	3.8	22.1
Pen(LysBz)	−	−	4.6	22.3
Pen(LysDTK)	0.2	8.8	6	22.1
Pen(LysTMD)	−	−	8	22.5

[a] − the transition was abolished.

phospholipids, glycolipids) soluble/inserted into a lipophilic phase, such as micelles or vesicles (*8*, *14*, *35*−*38*). A pioneer work has been reported on the labeling of "lipid mimics", i.e., sodium dodecylsulfate (SDS) micelles, with 10 mM benzophenone, using a 1/1 molar ratio (*35*). The very high peptide concentration and peptide/lipid ratio used in this study allowed the observation of the radical combination step, even though SDS exchange between micelles and free components and molecular motion (τ_c between 10^{-10} and 10^{-12} s) is a fast process ($t_{1/2} = 10^{-7}$ s) (*39*). Because the biological effects of membrane active peptides are generally observed at micromolar concentration and P/L ratios of ∼1/50, cross-linking experiments presented here have been performed at micromolar concentrations.

No efficient cross-linking was observed between the three tested photoactivatable peptides, at micromolar concentration in the presence of SDS micelles. These results suggest that a high concentration of photoreactive species is required to compensate the fast dynamics of supramolecular assemblage of SDS in micelles.

However, using DMPG vesicles and also micromolar concentrations of photoactivatable Pen(Lys48Bz) or Pen(Lys48TMD), phospholipid photoadducts were detected, even if the lateral diffusion in the disordered lamellar phase is around $10^{-7} > T_D < 5.10^{-9}$ cm^2.s^{-1} (*40*) with fast phospholipid motion (10^{-12} to 10^{-7} s) and fast exchange between free and bound peptide (with a dissociation constant in the micromolar range). The combination reaction occurs at time scales (10^{-6} s) slower than most phospholipid motion. Thus, the detection of photo-cross-linking with DMPG vesicles indicates the following: (i) cooperative diffusion of the penetratin photoactivatable analogues and the surrounding anionic phospholipids and (ii) restricted motion of the anionic phospholipids.

In a polar microenvironment such as glycerol, the triplet radical state can react by energy transfer like a photosensitizer, which, in the presence of oxygen, leads to the formation of singlet state oxygen. Finally, in a lipophilic medium the triplet radical might react with compounds possessing carbon-bound removable hydrogen atoms, which function as a quencher, as long as the intrinsic movements of the two molecules are slow enough to allow radical combination (DMPG). The cross-linking yield with trifluoromethylaryldiazirines, Pen(Lys48TMD), was also relatively low due to a competitive reaction, the carbene leading to a fast irreversible reaction with oxygen. The oxidation and β-elimination of the polar headgroups by basic hydrolysis prevent the assignment of the exact structures of the photoadducts. Finally, the triplet radical of dithienylketone, Pen(Lys48DTK), must act as a photosensitizer, regardless of the medium, since only oxidized and degraded species (lower molecular mass species) were found.

Thus, among the three photoprobes tested herein, only benzophenone (Bz) and trifluoromethylaryldiazirine (TMD) led to covalent bond formation with lipids, which were identifiable

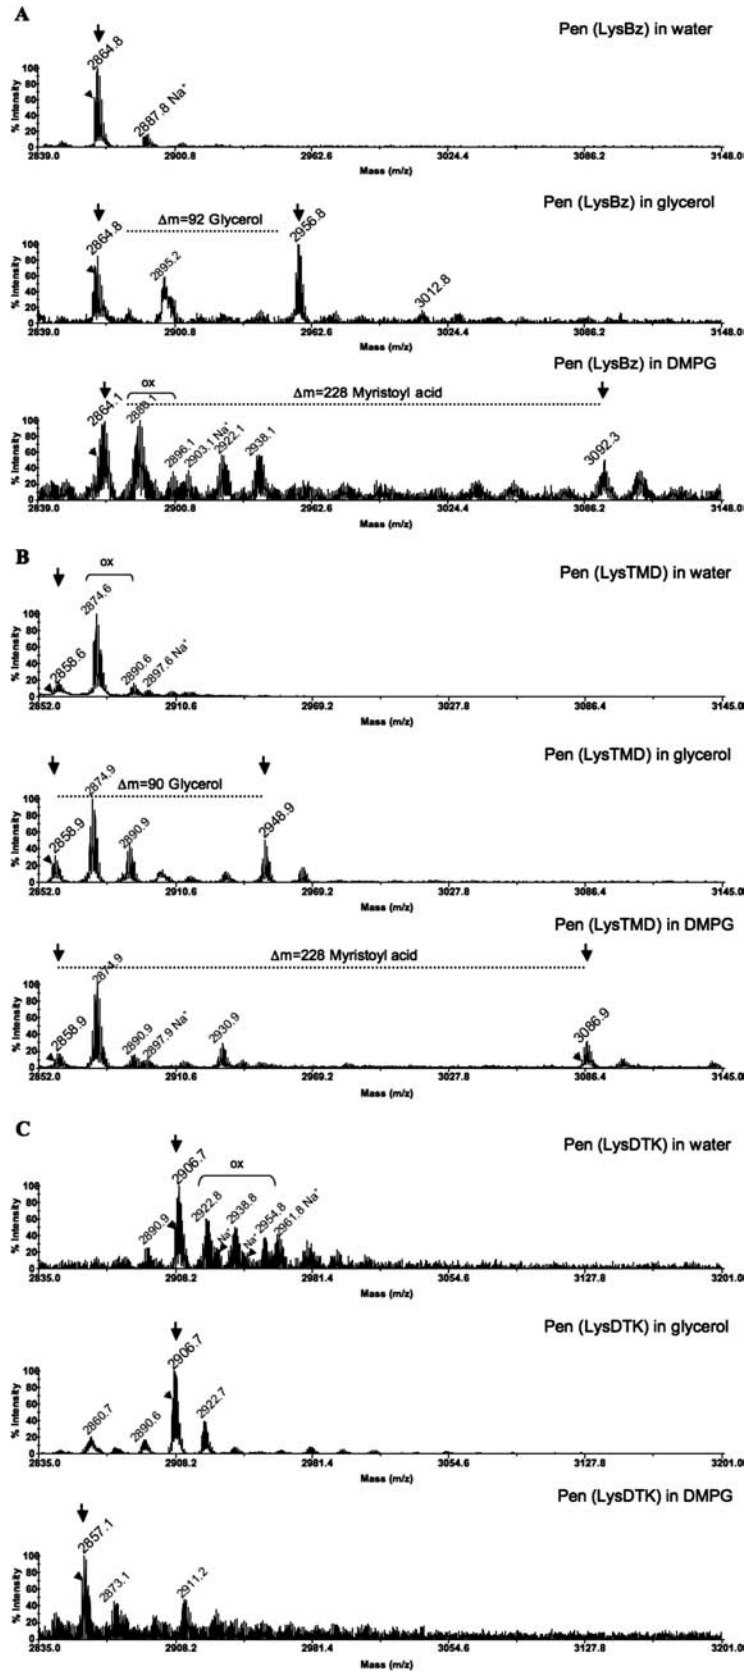

Figure 3. MALDI-TOF mass spectra of Pen(Lys48Bz) (A), Pen(Lys48DTK) (B), and Pen(Lys48TMD) (C) obtained after irradiation in water, glycerol, and DMPG vesicles. Pen(Lys48Bz), Pen(Lys48DTK), or Pen(Lys48TMD) dissolved at micromolar concentration in water or glycerol (500 μL) was irradiated on ice for 1 h at 365 nm. Then, 1 μL of the irradiated sample was deposited on the sample holder for MALDI-TOF mass spectrometry analysis. DMPG (1 mg/mL) was mixed with Pen(Lys48Bz), Pen(Lys48DTK), or Pen(Lys48TMD) at 1/25 peptide/lipid ratio. Theses samples were irradiated on ice for 1 h, at the same conditions as above, followed by an overnight basic hydrolysis. The hydrolyzed sample containing 0.1% of Triton was incubated with streptavidin-coated magnetic beads (100 μg, Dynabeads M280, Dynal). The same procedure was used for the experiments performed in SDS, except that no Triton was added during the incubation step. After different steps of washings, the photoadducts were eluted from the magnetic beads with the 2,5-dihydroxybenzoic acid (DHB) matrix. After 10 min incubation, 1 μL of bead-free supernatant was deposited on the sample holder for MALDI-TOF mass spectrometry analysis.

by MALDI-TOF mass spectrometry. Benzophenone (Bz) appeared to be the most appropriated photoprobe compared to TMD, since Bz leads to similar phase transition effects to those of penetratin, while TMD leads to great changes in the cooperativity of the transition, suggesting that TMD probably inserts deeper into the fatty acid chain region.

CONCLUSION

Herein, the photo-cross-linking of three photoactivatable penetratin peptides in glycerol, SDS, and lipid (DMPG) was evaluated. The dynamics of both SDS and the SDS/penetratin assemblies and the micromolar concentration of photoactivatable penetratin analogues used (in the range of biologically active concentrations) prevented peptide cross-linking to SDS. Regarding glycerol and lipids, even though photo-cross-linking occurred in both cases, the direct MS analysis of the photoadducts formed upon irradiation of the three different photoactivatable penetratin analogues was only achieved in the first one. The characterization of the photoadducts formed after lipid irradiation required basic hydrolysis of the lipid before extraction; otherwise, the capture with streptavidin-coated magnetic beads was ineffective. Bilayers of DMPG were photo-cross-linked with penetratin analogues, containing either benzophenone or trifluoromethylaryl diazirines but not phenylketone. With both photoactivatable penetratin analogues, MALDI-TOF analysis of the photoadducts formed after irradiation of the peptides with DMPG allowed unambiguous identification of the covalent bond formed with this lipid. Therefore, these analogues can be used to analyze the specific lipid(s) recruitment by penetratin, which represents an essential step in the understanding of the translocation mechanism of this cationic cell-penetrating peptide.

ACKNOWLEDGMENT

This work was supported by the Association Nationale pour la Recherche (ANR-Prob DOM). We thank the Pr. Gilbert Kirsch and his co-workers from the "Laboratoire d'Ingénierie Moléculaire et Biochimie Pharmacologique" Metz, France, for the generous gift of 5-carboxy-5′-methyl-2,2′-dithienylketone.

Received October 28, 2009; Revised Manuscript Received January 5, 2010

Although a great number of cationic lipids have been designed and evaluated as gene delivery systems, there is still a need for improvement of nonviral vectors. Recently, cationic lipids incorporating terminal fluoroalkyl segments ("FHP" lipids) have been described to display remarkable transfection potency. Here, we describe the synthesis of a new family of fluorinated triblock cationic lipids in which a fluorous segment lays between the cationic and the lipophilic parts of the molecule ("HFP" lipids). The compounds were designed so their self-assembly would offer enhanced resistance toward the host's degradation mechanisms mediated by lipophilic insertion. Self-assembly properties of these cationic lipids were evaluated at the air−water interface where they collapse in a highly ordered liquid phase. The HFP lipids efficiently condense DNA, and the resulting lipoplexes display enhanced resistance to amphiphilic agents when compared to nonfluorinated or FHP cationic lipids. Transfection properties of the fluorinated vectors, alone or as mixtures with different helper lipids (DOPE and a fluorinated analogue of DOPE), were then investigated on different cell lines (BHK-21, HepG2, and HeLa) and compared to those of the reference cationic lipid DOTAP. Data show that impermeabilization of the lipidic phase by fluorous segments alter significantly the gene transfection activities. Remarkably, incorporation of DOPE within the lipoplexes provides the particles with high gene transfection activity without reducing their resistance to amphiphilic agents.

INTRODUCTION

The delivery of a "medicine" gene in somatic cells involves the use of vectors, the function of which is to help the therapeutic gene cross the biological barriers and reach the nucleus of the target cells where it will be processed into mRNA and, later on, translated into proteins. Due to their high transfection efficiency, viral vectors such as adenoviruses, adeno-associated viruses (AAVs), or retroviruses are the most widespread vectors used in the laboratory or in clinical trials (*1*). However, their performance cannot overcome several major side effects, which include adverse immunogenic reactions, insertional mutagenesis, and sometimes fatal toxicity (*2, 3*). An additional limitation of these vectors lies in the restricted size of the DNA fragments they can introduce into a cell (less than 5 Kbp). The nonviral vectors, including cationic lipids, present interesting activity in vitro, but always appeared rather disappointing when evaluated in vivo. However, these vectors are devoid of some of the limitations of viruses (size restriction of the nucleic acid to be transfected, difficulty of production and purification, immunogenicity, etc.) and allow for specialized delivery options such as time-enhanced circulation, time-dependent release, and targeted delivery (*4*).

Since the first studies were conducted, hundreds of cationic lipids have been synthesized as candidates for nonviral gene delivery (*5*−*7*). Cationic lipids interact with negatively charged DNA through electrostatic interactions leading to condensed nucleic acid particles (lipoplexes). Optimum transfection efficacy invariably requires excess of cationic lipid for full DNA condensation and protection from serum nuclease. On the other hand, the cationic residual charge induces a poor circulation time of lipoplexes in blood, mostly due to their interaction with serum components. Many strategies have been developed to improve gene transfer mediated by cationic lipids. Those aiming at improving lipoplex circulation time are essentially based on the use of a poly(ethylene glycol) (PEG) coating of the cationic particles. However, introduction of PEG at the lipoplex surface unexpectedly does not highly increase the residential time of particles in the blood, which may be related to the drastic increase of the critical micelle concentration (cmc) of a lipid provoked by PEGylation (by a ca. 10^6-fold factor) (*8*). In addition, it may have rather adverse effects by inhibiting gene transfer in some cases (*9, 10*). A related strategy proposed by Mignet and Scherman results from the combination of cationic lipoplexes and PEGylated anionic liposomes (*11*). These pH-sensitive PEGylated anionic particles display interesting DNA delivery properties and are supposed to reverse to non-PEGylated cationic ones in the acidic endosome compartment. Behr and Vierling developed an alternative strategy to improve lipoplex circulation time by introducing a highly hydrophobic fluoroalkyl short segment at the extremity of the fatty acid chains of the cationic lipids (*12*−*17*). Owing to their increased hydrophobic character, these lipids (further named "FHP" fluorinated lipids to indicate that the fluoroalkyl moiety, F, is separated by an alkyl segment, H, from to the polar head, P) condense DNA into lipoplexes with higher stability than conventional cationic lipids. FHP lipid assemblies, however, are not expected to efficiently prevent anchoring/insertion of amphiphilic or lipophilic compounds to/within the bilayer structure, with such an event most often being a prelude to lipoplex destruction (i.e., lipid solubilization, recruitment of amphiphilic proteins triggering particle elimination by the reticuloendothelial system, activation of the complement system and opsonization, etc.). Importantly, FHP helper lipids have been

described to enhance in vitro and in vivo gene delivery by cationic lipids (*18, 19*).

Recently, some of us showed that phospholipids that are fluorinated close to their polar head spread at the air−water interface into monolayers which are stable for several hours in the presence of high concentrations of detergents (*20, 21*). In the same conditions, conventional phospholipid monolayers hardly resist a few seconds. This remarkable property only partly results from the high hydrophobicity of fluorinated species as is the case with FHP lipids. Indeed, displaying the fluoroalkyl segment close to the lipid polar head likely induces a stabilization of higher magnitude, which may be explained by the interactions between adjacent fluorine atoms in the same perfluorinated chain that cause the chain to twist into a rigid, helical conformation (*22*). Consequently, close packing of the rigid fluoroalkyl segments does substantiate a kind of fluorous repelling shield that is highly impermeable to nonfluorinated hydrophilic, lipophilic, as well as amphiphilic compounds (*23*). Thus, by preventing or reducing insertion of surface active compounds within the lipid layer it is possible to efficiently prevent the destruction of the lipid assembly. We made the hypothesis that cationic lipids displaying such characteristics would condense DNA into fluorinated lipoplexes with original capabilities in gene transfer experiments. By resisting serum component adsorption (and subsequent destruction triggered by insertion of hydrophobic anchors of recruited proteins or other destruction mechanisms) (*24*), such lipoplexes are expected to present an extended half-life time, and possibly a higher transfection efficiency, however keeping in mind that intracellular trafficking of the delivery system requires at some points disassembly of the lipid−DNA complexes. Therefore, the immediate goal of this study was to prepare cationic lipids fluorinated close to their polar head (further named "HFP" fluorinated lipids, a terminal alkyl chain, H, being separated by a fluoroalkyl segment, F, from the polar head, P) and to evaluate (i) their capability to form complexes with DNA, (ii) the stability of the resulting lipoplexes, and (iii) the gene delivery efficacy of the latter in vitro. In the following, we describe the design, synthesis, characterization, and evaluation of a series of unprecedented HFP fluorinated triblock cationic lipids.

EXPERIMENTAL PROCEDURES

Chemicals and Materials. Unless otherwise stated, all chemical reagents were purchased from Alfa Aesar (Bischeim, France) and used without purification. α,ω-Diiodoperfluoroalkanes were from Apollo Scientific Ltd. (Bredbury, Cheshire, UK). When required, solvents were dried by standard procedures just before use (*25*). Products were purified by chromatography over silica gel (Silica Gel 60, 40−63 μm, Merck, Darmstadt, Germany). Reverse-phase filtration was carried out with Sep-Pack classic short-body C-18 cartridges (Waters, Division of Millipore, Milford, MA, USA).

N-[1-(2,3-Dioleoyloxy)propyl]-*N,N,N*-trimethylammonium chloride (DOTAP chloride), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), sodium *n*-dodecyl sulfate (SDS), 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), sodium cholate (NaCh), cetyltrimethylammonium bromide (CTAB), Tween 80, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), penicillin, streptomycin, L-glutamine, D-glucose, and tryptose phosphate broth were from Sigma-Aldrich (Saint-Quentin Fallavier, France). Culture media Dulbecco's Modified Eagle Medium Glutamax (DMEM) and Minimum Essential Eagle Medium (MEM) were from GIBCO-BRL (Cergy-Pontoise, France). Fetal calf serum (FCS) was from Perbio (Brebières, France). Lysis and luciferin solutions for monitoring luciferase activity were purchased from Promega (Charbonnières, France). Human hepatocarcinoma cells (HepG2), Syrian hamster kidney cells (BHK-21), and immortalized human epithelial cells (HeLa) were from ATCC-LGC (Molsheim, France). pSMD2-LucΔITR (7.6 kpb) or pEGFP-Luc (6.4 kpb) expression plasmids (BD Biosciences Clontech, Franklin Lakes, NJ, USA) were used as reporter genes to monitor transfection activity. Both plasmids encoded the firefly luciferase gene under the control of a strong promoter. HepG2 cells were transfected with the pSMD2-Luc and the other cell lines with the pEGFP-Luc.

Preparation of Cationic Lipids. *2,3-Bis(3,3,4,4,5,5,6,6,7,7,8,8-dodecafluorotetradecanoyloxy)-propyl-1-trimethylammonium Chloride (**1a**).* The acid **7a** (209 mg, 0.47 mmol) in anhydrous CH_2Cl_2 (2 mL) was stirred at room temperature with oxalyl chloride (0.2 mL, 2.29 mmol) and a catalytic amount of DMF (5 μL) for 4 h. Volatiles were removed under reduced pressure, and the residue was coevaporated twice with anhydrous toluene. The crude acid chloride was dissolved in anhydrous CH_2Cl_2 (2 mL), and the resulting solution was added dropwise to a mixture of anhydrous diol **8** (32 mg, 0.19 mmol) and pyridine (38 μL, 0.47 mmol) in THF/CH_2Cl_2 (2:1 v/v, 3 mL). The resulting suspension was sonicated for 2 h and stirred overnight at room temperature. Solvent was removed under reduced pressure at room temperature, and the residue was purified by flash chromatography over silica gel ($CHCl_3$/MeOH 100:0 to 60:40) to yield compound **1a** (51 mg, 26%; containing 37% of elimination byproduct) as a white wax.

*2,3-Bis(3,3,4,4,5,5,6,6-octafluorohexadecanoyloxy)-propyl-1-trimethylammonium Chloride (**1b**).* Compound **1b** (79 mg, 24%; containing 18% of elimination byproduct) was obtained as a white wax starting from compound **7b** following the same procedure as described for the preparation of **1a**.

*2,3-Bis(3,3,4,4,5,5,6,6,7,7,8,8-dodecafluorooctadecanoyloxy)-propyl-1-trimethylammonium Chloride (**1c**).* Compound **1c** (54 mg, 28%; containing 11% of elimination byproduct) was obtained as a white wax starting from compound **7c** following the same procedure as described for the preparation of **1a**.

*2,3-Bis(3,4,4,5,5,6,6,7,7,8,8-undecafluorotetradecen-2-oyloxy)-propyl-1-trimethylammonium Chloride (**2a**).* Compound **1a** (25 mg, 24.5 μmol) in CH_3CN/CH_2Cl_2 (2:1 v/v, 3 mL) was stirred for 2 h with 2 M triethylamine in THF (36 μL, 62.0 μmol) at room temperature. The reaction mixture was filtered over a pad of finely powdered $NaHCO_3$, and the filtrate was reduced under vacuum to yield **2a** (20 mg, 84%) as a white wax.

*2,3-Bis(3,4,4,5,5,6,6-heptafluorohexadecen-2-oyloxy)-propyl-1-trimethylammonium Chloride (**2b**).* Compound **2b** (6 mg, 88%) was prepared from **1b** following the same procedure as described for **1a**.

*2,3-Bis(3,4,4,5,5,6,6,7,7,8,8-undecafluorooctadecen-2-oyloxy)-propyl-1-trimethylammonium Chloride (**2c**).* Compound **2c** (10 mg, 86%) was prepared from **1c** following the same procedure as described for **1a**.

*1,2-Di[(Z)-3,3,4,4,5,5,6,6,7,7,8,8-dodecafluorohexadec-9-enoyl]-sn-glycero-3-phosphatidylethanolamine (**3**).* Triphenyl phosphine (4.1 mg, 15.7 μmol) and azido compound **15** (6.0 mg, 5.2 μmol) in THF/CH_2Cl_2/CF_3CH_2OH/HCl 2% (3:1:1:0.1 v/v, 3 mL) were stirred for 48 h at room temperature. Volatiles were removed under reduced pressure, and the residue was purified by silica gel chromatography ($CHCl_3$/MeOH/H_2O 10:0:0 to 10:6:1). The fluorinated analogue of DOPE was obtained as a colorless oil (3.0 mg, 51%; mixture of isomers, Z/E = 85:15).

*3,3,4,4,5,5,6,6,7,7,8,8-Dodecafluoro-1,10-diiodotetradecyl Benzoate (**4a**).* Sodium dithionite (3.14 g, 17.8 mmol) was slowly added to a mixture of 1,6-diiodoperfluorohexane (5.00 g, 9.0 mmol), vinyl benzoate (1.25 mL, 9.0 mmol), 1-hexene (1.12 mL, 9.0 mmol), and $NaHCO_3$ (1.91 g, 18.0 mmol) in CH_3CN/H_2O (8:7 v/v, 18.4 mL) at 0 °C. The resulting solution was stirred for 50 min at 0 °C, brought to pH 5−7 with HCl 3N,

and stirred for an additional 20 min period at room temperature. Water was added, and the solution was extracted with CH_2Cl_2. The organic layer was dried over $MgSO_4$, filtered, and reduced under vacuum. The residue was purified by silica gel chromatography (C_6H_{14}/CH_2Cl_2 95:5) to yield benzoate **4a** (2.03 g, 28%) as a slightly yellow waxy solid.
